$[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(ClO_4)(SeCN)$ (**1**). Ethylenediamine (en) (0.12 g, 2 mmol) was added to an aqueous solution (20 cm^3) of $Ni(ClO_4)_2.6H_2O$ (0.36 g, 1 mmol), followed by solid KSeCN (0.15 g, 1 mmol). The mixture was stirred for 15 min afterwards, the blue-violet solution was filtered. Slow evaporation of the clear solution at room temperature afforded, after 1 week, blue-violet crystals suitable for X-ray crystal determination. Yield: 55%. Anal: Calcd for $C_{19}H_{56}ClN_{19}Ni_3O_4Se_5$: C, 18.69; H, 4.62; N, 21.79; Cl, 2.90. Found: C, 18.5; H, 4.6; N, 21.3; Cl, 2.9.

$[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(PF_6)_2$ (**2**). To an aqueous solution (25 cm^3) of $Ni(NO_3)_2.6H_2O$ (0.30 g, 1 mmol), ethylenediamine (en) (0.12 g, 2 mmol) was added, followed by solid KSeCN (0.15 g, 1 mmol). The mixture was stirred for 15 min while solid KPF_6 (0.50 g, 2.7 mmol) was added. The solution was then filtered, and the X-ray quality blue-violet single crystals were obtained by slow evaporation. Yield: 64%. Anal: Calcd for $C_{18}H_{56}F_{12}N_{18}Ni_3P_2Se_4$: C, 16.54; H, 4.29; N, 19.29. Found: C, 16.9; H, 4.3; N, 19.5.

$[Ni(en)_2(NCSe)_2]$ (**3**). This compound was synthesized and crystallized as (**2**) but without adding KPF_6 at the final stage of the synthesis. In this case the yield was poor (20–25%). Anal: Calcd for $C_6H_{16}N_6NiSe_2$: C, 18.53; H, 4.15; N, 21.61. Found: C, 18.7; H, 4.2; N, 21.7.

X-ray data collection and structure determination

Small blue-violet prismatic crystals ($0.1 \times 0.1 \times 0.2$ mm approximately for (**1**), (**2**) and (**3**) respectively) were selected and mounted on an Enraf-Nonius CAD4 four-circle diffractometer, using monochromatic Mo–K_α radiation (0.71069 Å). The crystal system for all three compounds is monoclinic. Unit cell parameters were determined from 25 automatically centered reflections ($12 < \theta < 21°$) and refined by least-squares. Intensity data were collected with the $\omega/2\theta$ scan-technique. Three reflections were measured every 2 h as orientation and intensity control, significant intensity decay was not observed. Lorentz-polarization and empirical absorption corrections (φ-scan method) were performed. The crystallographic data, and some features of the structure, are listed in Table 1. The structure was solved by Patterson synthesis using the SHELXS computer program [10] and refined by full-matrix least-square methods with the SHELX93 computer program [11] using 5153 reflections for (1), 6658 for (2) and 1877 for (3) (the reflections with very negative intensity were not included). The function minimized was $\Sigma w \| F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (kP)^2]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$ and $k = 0.1190$ for (**1**); 0.059 for (**2**) and 0.603 for (**3**). f, f′ and f″ were taken from International Tables of Crystallography [12]. For (**1**) the $NCSe^-$ ion was located in a disordered position, an occupancy factor of 0.5 was assigned according to height of the Fourier synthesis. The disorder of perchlorate ions was not located, showing high U_{eq}. Oxygen atoms of perchlorate ions were refined isotropically. 8H atoms were computed and refined with an overall isotropic temperature factor using a riding model.

Physical measurements

Magnetic susceptibility measurements in the range 300–2 K were carried out on an MPMS Quantum Design instrument (with a SQUID detector). Diamagnetic corrections were estimated from Pascal Tables. IR spectra were recorded on a Nicolet 520 FTIR spectrophotometer.

RESULTS

Starting from $Ni(ClO_4)_2$.aq. and working in a ratio Ni/ethylenediamine/KSeCN = 1,2,1, a dinuclear or a 1-D compound with ClO_4^- as counter anion was expected. However, the reaction followed another route, affording the complex $[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(ClO_4)(SeCN)$ (**1**). The same reaction starting from $Ni(NO_3)_2$.aq, and more than two equivalents of KPF_6, a very similar complex was obtained with only a PF_6^- as a counteranion $[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(PF_6)_2$ (**2**). On the other hand, eliminating the KPF_6 in the reaction, a discrete *trans*-$[Ni(en)_2(NCSe)_2]$ (**3**) mononuclear was synthesized.

The IR spectrum of the three compounds shows the characteristic bands attributable to the amine ligands. Compound (**1**) shows very strong and broad bands centred at 1100 cm^{-1} and 600 cm^{-1}, due to the perchlorate anions. A very strong band centred at 830 cm^{-1} corresponding to PF_6^- anion appears in (**2**). Focusing our interest in the stretching mode of the selenocyanate region, all three compounds show two bands in the 2030–2100 cm^{-1} region. For (**2**) and (**3**) the band at lower frequency is very weak while it is stronger in (**1**): this can be interpreted by the presence of only coordinated selenocyanate bridging ligands in *cis* position for (**2**) and (**3**), according to Curtis [13] but in (**1**) there is two kind of selenocyanate: terminal and bridge. The other frequencies due to selenocyanato ligand are masked by the presence of the bands attributable to ethylenediamine.

The crystal structure determination for (**1**) and (**2**) showed that both complexes have two different discrete mononuclear complexes in the crystal lattice: $[Ni(en)_3]^{2+}$ and *cis*-$[Ni(en)_2(NCSe)_2]$, in the 1:2 relation in each unit cell. Crystal lattice were very

Symmetry transformations used to generate equivalent atoms: #1 $-x, y, -z+1/2$.

(amine) is 2.12 Å). The angles N(amine)—Ni—N(amine) in *cis* arrangement are close to 90°. The N—M—N angles for the chelating *en* ligands are less than 90°, as usual. The N(1)—Ni—N(2), corresponding to the angle between both NCSe ligand is 90.5(2) for (1) and 91.0(2) for (2). The angles corresponding to ligands in *trans* positions are between 174.0 and 177.8°. The tris-chelate moieties are more regular. They have a C_2 axis. The Ni(2)—N(amine) distances moved from 2.140 Å to 2.125 Å. As in the $[Ni(en)_2(NCSe)_2]$ part, the angles N(amine)—Ni—N(amine) in *cis* arrangement are close to 90°. The N—M—N angles for the chelating *en* ligands are less than 90°, as usual. The N(amine)—Ni—N(CSe) angles are 90.09 and 89.91.

The structure of *trans*-$[Ni(en)_2(NCSe)_2]$ (**3**) consists of isolated neutral unities. An ORTEP drawing with the atom-labelling scheme is shown in Fig. 2. The main bond lengths and angles are given in Table 3. The complex has a pseudo-octahedral geometry with an inversion centre in the NiN_6 unit. All Ni—N (amine) distances are 2.104 Å, and both Ni—N(CSe) distances are 2.126 Å. All the N—Ni—N angles in *trans* position are 180°. The angles N(amine)—Ni—N(amine) in *cis* arrangement are close to 90°. As in the structures (**1**) and (**2**), if the two N atoms belong to the same ethylenediamine, this angle, as expected, is lower than for the N atoms not belonging to the same amine. The N(amine)—Ni—N(CSe) angles are 90.09 and 89.91.

The magnetic susceptibility measurements were carried out in the 2–300 K temperature range. The $\chi_M T$ vs T plots for the three complexes are given in Fig. 3. Compounds (**1**) and (**2**) showed the same behaviour. The room temperature $\chi_M T$ values for (**1**) were 3.62 $cm^3\ mol^{-1}\ K$ and 3.48 $cm^3\ mol^{-1}\ K$ for (**2**) (corresponding to a three isolated Ni(II) with $g > 2.00$) and was practically constant in the temperature range analysed.

Symmetry transformations used to generate equivalent atoms: #1 $-x+1, -y+1, -z+2$.

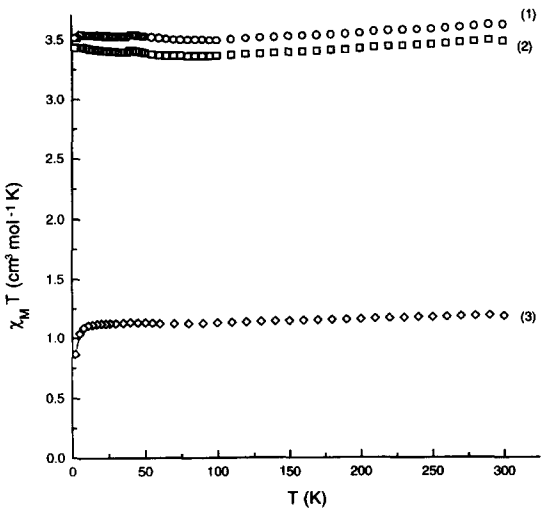

Fig. 3. Plots of the temperature dependence of χ_MT vs T for (**1**), (**2**) and (**3**).

The room temperature χ_MT value for compound (**3**) was 1.18 cm^3 mol^{-1} K which corresponded to an isolated Ni(II), and exhibited a quasi Curie law behaviour with a slight decrease at low temperature as usual in the isolated mononuclears of Ni(II).

As a conclusion, the synthesis of only mononuclear species with selenocyanate anions, could indicate that $NCSe^-$ is a worse bridging ligand than the NCS^- analogue, due to the softer character of the Se atom compared to the S atom, regarding to Ni(II) metallic centre.

New spectrophotometric evidence for the existence of $HCrO_4^-$

J. J. Cruywagen,* J. B. B. Heyns and E. A. Rohwer

Department of Chemistry, University of Stellenbosch, Stellenbosch 7600, Republic of South Africa

(Received 9 June 1997; accepted 27 October 1997)

Abstract—A spectrophotometric study of the protonation and dimerization of CrO_4^{2-} at different concentrations in the pH range 8–2.5 at 25°C in 0.1 M (Na)Cl medium led to the characterization of $HCrO_4^-$ and $Cr_2O_7^{2-}$ in terms of formation constants and absorption spectra. When the pH is varied at constant Cr(VI) concentration the experimental spectra exhibit one real and three accidental isosbestic points. The results of this investigation do not corroborate recent work in which the non-existence of $HCrO_4^-$ was claimed. The spectrophotometric determined equilibrium constants have been verified by potentiometric titrations. The values are: $\log \beta_{11} = 6.09 \pm 0.04$ and $\log \beta_{22} = 13.94 \pm 0.06$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: isosbestic point; chromate solution; spectrophotometry.

In a very recent paper in this journal [1] a seemingly quite convincing case was put forward for the non-existence of $HCrO_4^-$. It was claimed that $HCrO_4^-$ is spectrophotometrically undetectable and that $Cr_2O_7^{2-}$ is the only species to be formed upon acidification of CrO_4^{2-}. The authority of textbooks was questioned on the grounds that early results did not prove the existence of $HCrO_4^-$ but were merely consistent with it. An important consideration was four isosbestic points exhibited by the spectra of chromate solutions measured at various concentrations and pH values. The conclusion was further supported by the results of factor analysis and by application of the method of spectral displacement. This work followed after reports by Michel *et al.* [2,3] that the $HCrO_4^-$ ion could not be detected by Raman spectra. These experiments covered conditions for which relatively high percentage concentrations of $HCrO_4^-$ would be expected, that is if the generally accepted equilibrium constants of $HCrO_4^-$ and $Cr_2O_7^{2-}$ are used to calculate the distribution of species.

The implication of these findings is that the many previous investigators of chromate protonation equilibria determined the formation constant of an imaginary ion. Should this be the case it is really astonishing that such consistent values for the equilibrium constants could have been obtained using a variety of experimental techniques [4]. Also, in a recent ^{17}O-oxygen exchange NMR study of CrO_4^{2-} and $Cr_2O_7^{2-}$ an increase in the line width of the ^{17}O signal of CrO_4^{2-} on adding acid was attributed to a much broader signal of $HCrO_4^-$ [5].

From a theoretical point of view there is no reason to doubt the existence of $HCrO_4^-$. For CrO_4^{2-} to dimerize by elimination of a water molecule, protonation should be the first step in the process. If $HCrO_4^-$ would be too strong an acid to occur at say pH = 2.5 then the tendency for dimerization, especially at low concentration, would be very small at this pH and still smaller at pH > 2.5. In other words, if $Cr_2O_7^{2-}$ is the predominating species at a particular pH appropriate dilution at that pH should yield $HCrO_4^-$ ions.

However, to verify that $HCrO_4^-$ really exists under specified conditions, as has been shown by earlier workers and also presented in authoritative textbooks, new experimental evidence is now needed. This basic knowledge is not only of importance in the general context of oxyacids, but also essential, for example, for the interpretation of the mechanisms of redox reactions of Cr(VI) and for an understanding of the toxic and mutagenic effects of Cr(VI) species; at physiological pH (7.4) the $HCrO_4^-$ ion would be an important species [6].

In earlier spectrophotometric work determinations of equilibrium constants have been based on the change in absorbance at one or only a few suitable wavelengths [7]. With modern sophisticated computer

* Author to whom correspondence should be addressed.

programs large volumes of absorbance data can be treated for model testing and to supply equilibrium constants and spectra of the absorbing species.

In this paper we present spectrophotometric results which verify previously determined equilibrium constants for the protonation and dimerization of CrO_4^{2-} and which also confirm the existence of $HCrO_4^-$. In addition complete individual spectra for the species in question are reported, in particular those of the $HCrO_4^-$ and $Cr_2O_7^{2-}$ ions which cannot be measured directly. These curves show at which wavelengths isosbestic points should occur when the pH of a Cr(VI) solution is varied.

EXPERIMENTAL

Analytical grade chemicals (Merck) were used and solutions were prepared with water purified with a Millipore Milli-Q system. A chromium(VI) stock solution of known concentration was prepared by weighing out an appropriate amount of dried potassium dichromate. Hydrochloric acid was standardized against tris(hydroxymethyl)aminomethane.

A GBC 920 UV-VIS double beam spectrophotometer equipped with a Peltier thermocell was used for the absorption measurements. Absorption spectra of chromium(VI) solutions at four different concentrations, viz. 0.10, 0.20, 1.0 and 1.92 mM (M = mol dm^{-3}) were recorded in the range 220–460 nm at intervals of 2 nm. Each experiment was started with 80 cm^3 solution to which carbonate-free sodium hydroxide was added to convert all chromium(VI) to chromate. This solution was kept in a thermostatted water bath at 25°C and titrated with an acidified chromium(VI) solution of the same concentration covering the pH_c range 8.0–2.1. To exclude carbon dioxide from the system a stream of purified nitrogen was passed through 0.10 M NaCl and then bubbled slowly through the titration solution. Silica cuvettes of path length 1.00 and 0.20 cm were used for the low and high concentrations respectively. For recording the spectrum of a chromate solution at much higher concentration, namely 40 mM, a demountable cuvette of path length 0.01 was used. A potentiometric titration of chromate (10 mM) with hydrochloric acid was carried out as described previously [8]. All solutions were made 0.10 M with respect to chloride ions by adding the appropriate amount of NaCl.

The electrode system was standardized in terms of hydrogen ion concentration. The free hydrogen ion concentration, h, was determined by measuring the potential, E, to ± 0.2 mV using a Ross combination electrode (Orion 8102 SC) with a 3.0 M KCl bridge solution. Equation (1) was used to calculate h from the measured potential:

$$E = E^\circ + 59.16 \log h \qquad (1)$$

E° was determined from a titration of 0.1 M NaCl with 0.1000 M HCl as described by Rossotti [9]. For brevity, $-\log h$ is denoted by pH_c.

RESULTS AND DISCUSSION

The change in absorption as a function of pH_c for solutions at two Cr(VI) concentrations, differing by a factor of 19, is shown in Figs 1 and 2. For both concentrations four isosbestic points are seen, one of which occurs at the same wavelength (339.5 nm) in the two plots. Since isosbestic points are by no means confined to two-component systems [10,11], these results should not be regarded as evidence for the existence of only two absorbing species. For this system, comprising three absorbing species, isosbestic points can be expected to occur if the pH is varied at constant Cr(VI) concentration provided the spectra of the individual species intersect [10,11]. Whether the latter condition would be satisfied can only be decided once spectra for the individual species have been determined.

A reliable test for the number of equilibria, especially when minor species are involved, is to compare experimental absorbance values with calculated values using the whole spectrum and in particular those absorbances where the greatest change with pH and concentration occurs. Obviously such model testing will only yield meaningful results if it is based on data of the highest possible accuracy collected under controlled conditions, e.g. constant ionic medium and constant temperature.

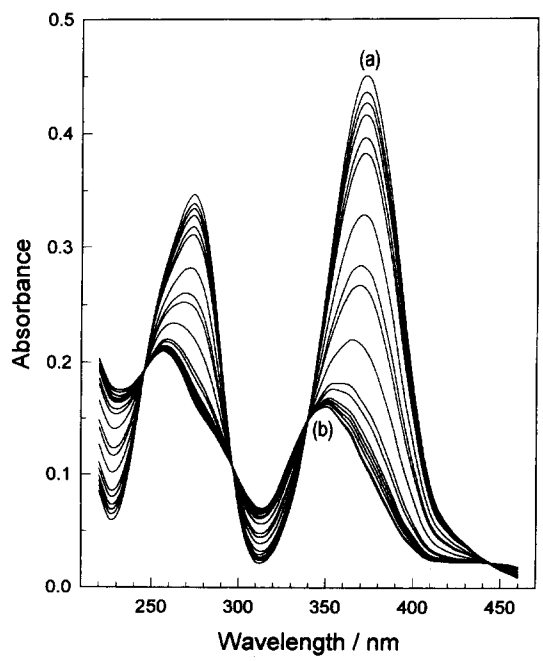

Fig. 1. Change in absorption spectra with change in pH_c from 7 (a) to 2.5 (b) of a 0.1 mM chromium(VI) solution measured in a 1 cm cuvette.

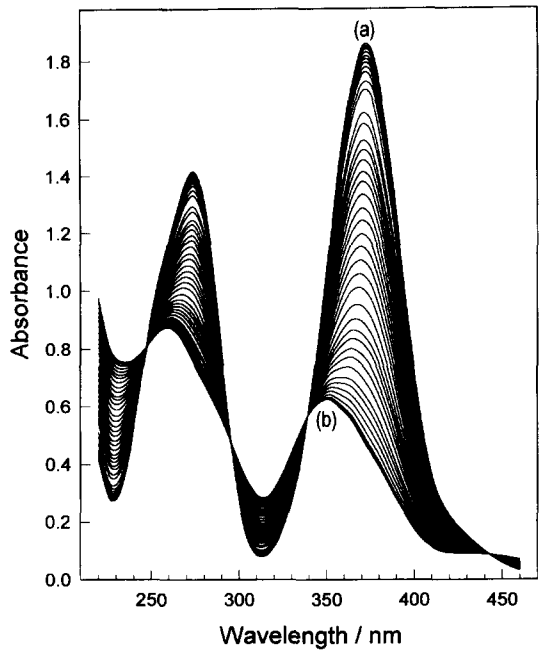

Fig. 2. Change in absorption spectra with change in pH_c from 8 (a) to 2.1 (b) of a 1.92 mM chromium(VI) solution measured in a 0.2 cm cuvette.

The following two reactions were considered in the computer treatment of the data:

$$CrO_4^{2-} + H^+ \rightleftharpoons HCrO_4^- \quad (2)$$

$$2CrO_4^{2-} + 2H^+ \rightleftharpoons Cr_2O_7^{2-} \quad (3)$$

The equilibrium constants are denoted by β_{11} and β_{22} respectively. In this investigation the computer programs PHAB [12] and SPECFIT [13] were employed for model testing. When treating the same data the two programs produced identical values for the equilibrium constants. An advantage of the program PHAB is that it can accommodate more data, accepts known spectra and is faster. The program SPECFIT on the other hand has the facility of factor analysis and also the option of a graphical display of the fit of calculated absorbances on experimental values at any selected wavelength.

After treating the first data set pertaining to Cr(VI) concentration 0.1 mM, it was already clear that $HCrO_4^-$ is the major reaction product at this low concentration. A reaction model assuming the presence of $HCrO_4^-$ resulted in an excellent fit which is significantly better than that for $Cr_2O_7^{2-}$. The results are shown in Table 1. When computations were done with both equilibria then the dichromate ion was rejected. From the constants finally obtained, calculations show that under the conditions of this experiment less than 1% of the Cr(VI) occurs as dichromate. For the data pertaining to a Cr(VI) concentration of 0.2 mM about 2% occurs as dichromate and nearly identical results were obtained. When only the $Cr_2O_7^{2-}$ reaction is considered the absorption/pH plots (at suitable wavelengths) show the expected deviation between calculated and experimental absorbances because in this case the absorption is not dependent on the square of the hydrogen ion concentration.

For the calculations at five-fold higher concentration both equilibria are retained in the model. Although only a relatively small percentage of chromate is converted to dichromate (~8%) a fairly accurate value for β_{22} is acquired and the value of β_{11} is the same as that calculated at the lower concentrations.

For the titration at the highest Cr(VI) concentration (1.92 mM) the best fit again resulted when both $HCrO_4^-$ and $Cr_2O_7^{2-}$ were assumed to be present. For this experiment the maximum percentage of chromate converted to dichromate was about 14%. The equilibrium constants are for practical purposes similar to those obtained from the other sets of data. Results of calculations done with some combinations of data sets are also shown in Table 1. It is reassuring that such consistent results could be obtained despite the relatively low concentration of dichromate in the solutions. At the low ionic strength chosen for the experiments the tendency for hydrogen chromate to dimerize is smaller than at high ionic strength, e.g. 3.0 mol dm^{-3}. The main reason for choosing the low ionic strength was the quest for accuracy. Not only is the background absorption in the UV region much smaller, but the possible introduction of small amounts of protolytic impurities via the high salt concentration is avoided. Ironically, it turned out to be easier to characterize $HCrO_4^-$ than $Cr_2O_7^{2-}$ by spectrophotometry. As an independent check of the accuracy of the spectrophotometric results a potentiometric titration was carried out and the data treated with the program SUPERQUAD [14]. The values of the stability constants thus obtained, log $\beta_{11} = 6.08$ (6.09) and log $\beta_{22} = 13.89$ (13.90) are not only in excellent agreement with the spectrophotometric values but also with literature values (in parentheses) pertaining to the same ionic strength [15].

The individual absorption spectra of the Cr(VI) species obtained from these calculations are shown in Fig. 3; as the experiments were started with chromate the calculated and experimental spectral curves were identical. That the calculated spectra and stability constants give a satisfactory description of the system is also shown by the comparison of a simulated spectrum and an experimental spectrum measured at a much higher concentration namely at 40 mM chromate; at this concentration and $pH_c = 2.3$ about 60% of the chromate is in the form of $Cr_2O_7^{2-}$. The agreement between the two spectral curves (Fig. 4) leaves no doubt about the consistency of the spectrophotometric results. A quite reliable test for the presence of polynuclear species, dinuclear in the present case, and which is based on Beer's Law, is that with a change in total concentration a change in the

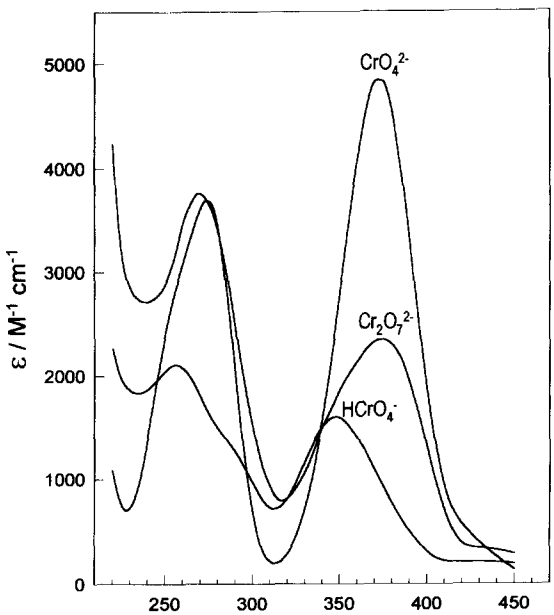

Fig. 3. Calculated absorption spectra of various Cr(VI) species. Molar absorptivities of $Cr_2O_7^{2-}$ have been divided by two in order to present comparable spectra.

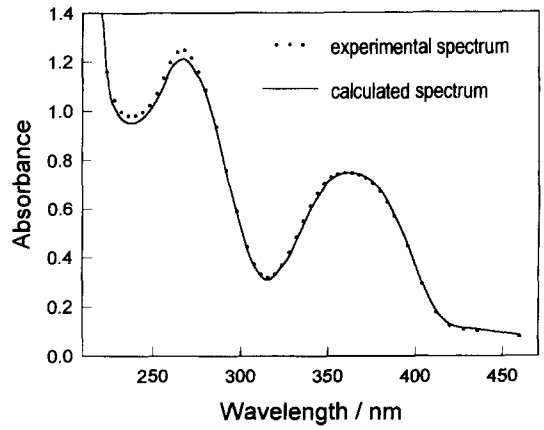

Fig. 4. Experimental and calculated spectra of a solution of 0.04 M Cr(VI) at $pH_c = 2.3$.

molar absorptivity, ε, at a particular wavelength would occur providing nothing else is changed, e.g. constant pH is required. Although Poulopoulou *et al.* [1] compared ε values of solutions over a wide concentration range and at different pH values the focus was mainly on the four observed isosbestic points so that the small changes observed led to the conclusion that $HCrO_4^-$ does not exist. A nice illustration of how the whole spectrum changes due to the presence of both $HCrO_4^-$ and $Cr_2O_7^{2-}$ is shown in Fig. 5 where ε is plotted against wavelength. The spectra of Cr(VI) solutions at low pH_c where all chromate has been converted to $HCrO_4^-$ and $Cr_2O_7^{2-}$ show an increase in ε with increase in concentration at most wavelengths as well as a clear shift of the two absorption peaks to shorter wavelengths. If dichromate were the only species present at low pH_c, as suggested by Poulopoulou *et al.* [1], these curves should have coincided.

Having verified the existence of $HCrO_4^-$ a meaningful discussion of the isosbestic points, whether real or illusory, is now possible because individual spectra of $Cr_2O_7^{2-}$ and $HCrO_4^-$ are available. The experimental spectra shown in Fig. 1 are those of solutions containing only two species in equilibrium, CrO_4^{2-} and $HCrO_4^-$, and the four points of intersection at wavelengths 245.8, 296.5, 339.3 and 443 nm therefore represent the isosbestic points of this two-component system. The same points of intersection are seen in the calculated spectral curves of CrO_4^{2-} and $HCrO_4^-$ (Fig. 3). However, the spectral curve of $Cr_2O_7^{2-}$ intersects at only one of these points namely at 339.3 nm which therefore can be regarded as a real isosbestic point for the three-component system.

For the experimental spectra shown in Fig. 2 about

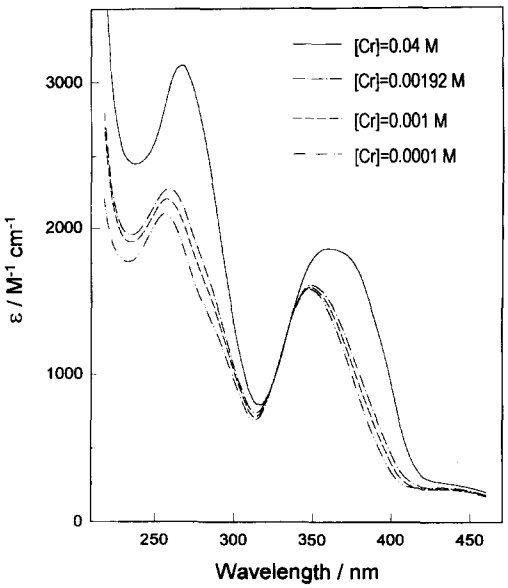

Fig. 5. Change in the molar absorptivity with change in Cr(VI) concentration at $pH_c = 2.3$.

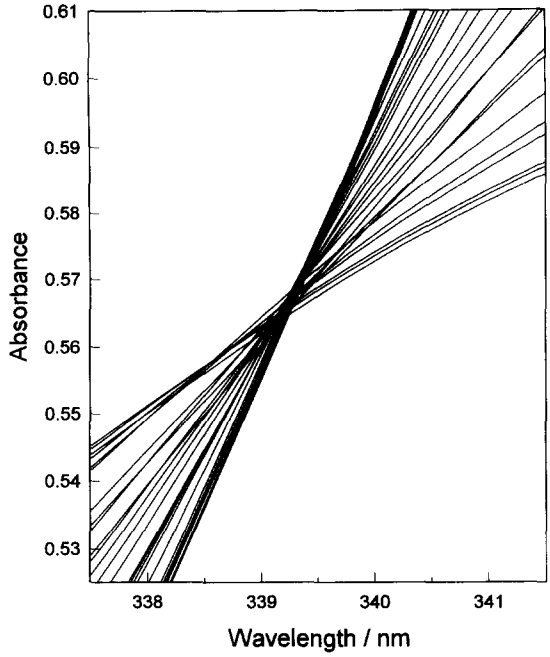

Fig. 7. Small part of Fig. 2 enlarged to show genuine isosbestic point at 339.3 nm.

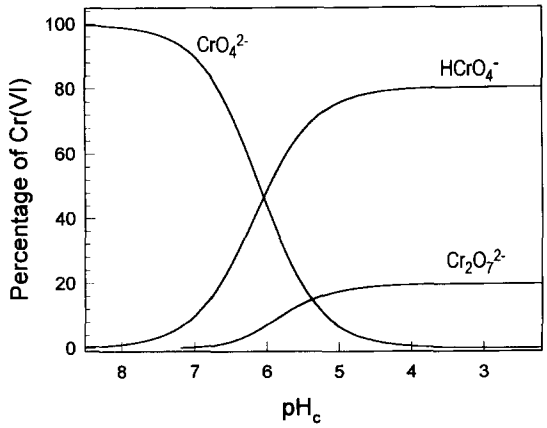

Fig. 6. Distribution of species in a 1.92 mM Cr(VI) solution as a function of pH_c.

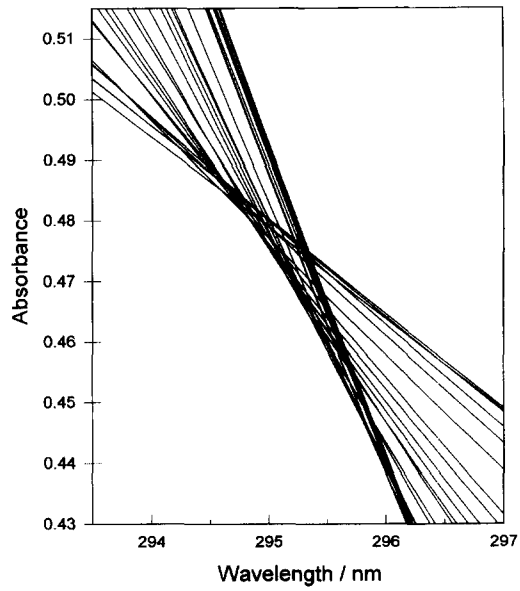

Fig. 8. Small part of Fig. 2 enlarged to show apparent isosbestic point at 295 nm.

14% of the Cr(VI) is converted to dichromate, but four apparently well-defined isosbestic points are still exhibited. However, owing to the very similar shape of the spectra of CrO_4^{2-} and $Cr_2O_7^{2-}$ the changes are hardly discernible as a deviation from the "isosbestic points" of CrO_4^{2-} and $HCrO_4^-$. The isosbestic points at 245.8 and 296.5 nm now occur as points of intersection at approximately 247 and 295 nm while the molar absorbances have increased with about 8% and 15% respectively. The difference between the real isosbestic point at 339.3 nm and an illusory one (e.g. at 295 nm) is illustrated in Figs 7 and 8 where small parts of the experimental spectra of Fig. 2 are "blown up".

These comments also apply to the spectrophotometric results of Poulopoulou *et al.* [1]. For example, using the now-known individual spectra of the three chromate species the five experimental spectra pertaining to 10.0 mM reported by these authors could be simulated to yield four apparently well-defined isosbestic points. However, only the genuine isosbestic point occurred at the same wavelength namely 339.3 nm while the two other points shifted

Table 2. Results of factor analysis of spectrophotometric data showing the decrease in σ_A with increase in the number of factors (1 to 4)

	$\sigma_A \times 10^2$			
$[Cr(VI)]_{Tot}$/mM	1	2	3	4
0.10	3.8	0.056	0.046	0.039
0.20	7.3	0.049	0.043	0.040
1.0	40	0.36	0.14	0.13
1.92	70	1.0	0.3	0.27

from 245.8 to 250 and from 296.5 to 293 nm respectively, owing to the higher percentage concentration of dichromate in the solutions.

Although the interpretation of factor analysis is often ambiguous the result of such analysis of our data using the program SPECFIT [13] gave a clear indication of the number of species at the different concentrations. When the σ_A values for two and three factors are compared (Table 2) the small differences at the lowest Cr(VI) concentration indicate two species, but at the higher concentrations these differences are consistent with three absorbing species.

CONCLUSION

The results of this study have confirmed that $HCrO_4^-$ is an important species in acidified chromate solution and have shown that earlier workers without the benefit of sophisticated instrumentation and high-speed computers gave the correct description of the system. With change in pH the absorption spectra of a solution containing the three absorbing ions, CrO_4^{2-}, $HCrO_4^-$ and $Cr_2O_7^{2-}$ show four apparently well-defined isosbestic points of which only the one occurring at 339.3 nm is real. The small difference in the shape of the spectral curves of CrO_4^{2-} and $Cr_2O_7^{2-}$ as well as the relative changes in absorption with change in pH_c are the main reasons for the occurrence of illusory isosbestic points. For the same reasons it might be difficult to make an unequivocal decision based on the method of spectral displacement [1]. It is also clear now that Raman spectrometry lacks the sensitivity to discriminate between the chromate species in question. The reported spectra [3] do not show any Raman lines other than those corresponding to CrO_4^{2-} and $Cr_2O_7^{2-}$ ions under conditions where more than 60% of the Cr(VI) should exist as $HCrO_4^-$.

With complete spectra for the individual Cr(VI) species now available it is of interest to compare these with the spectra of corresponding vanadium(V) species [16]. The similarities are striking. Protonation of VO_4^{3-}, just like that of CrO_4^{2-}, causes a decrease in absorption and a shift of both bands to shorter wavelengths. Further, dimerization of HVO_4^{2-} to form $V_2O_7^{4-}$ again results in considerably higher absorption together with a shift of the absorption bands to longer wavelengths.

(Received 4 August 1997; accepted 24 October 1997)

Abstract—The mixed [Cu(DANU)(bipy)(H_2O)]$ClO_4 \cdot H_2O$ (**1**) and [Cu(DMV)(bipy)Cl]$\cdot 1/2H_2O$ (**2**) complexes have been isolated from the reaction, in water/EtOH medium, of copper(II) perchlorate and chloride with 6-amino-1,3-dimethyl-5-nitrosouracil (HDANU) and 2,2′-bipyridine (bipy). It is noteworthy that, in the second complex, the uracil ligand is the 1,3-dimethyl-violurato monoanion (DMV), appeared from the hydrolysis of HDANU. In addition to X-ray diffraction studies, these compounds have been characterized from IR and EPR spectra and magnetic measurements (77–290 K). The crystal lattice of **1** is made up of discrete square pyramidal [Cu(DANU)(bipy)(H_2O)]$^+$ cations, a disordered perchlorate group and a water molecule. The coordination geometry about the metal centre is square pyramidal (N_4+O). The basal positions are occupied by a bidentate DANU ligand, coordinated through the N15 and N16 donor positions, and a bipyridine ligand. A water molecule (Cu—O1W 2.193(3) Å) occupies the apical site. The compound **2** presents a similar molecular structure to that of **1** with the copper centre lying in a N_3O+Cl environment. In this case, the basal positions are occupied by a bipy ligand and a DMV ligand coordinated through the N15 and O16 donor positions, instead of the DANU ligand found in the previous compound. The apical position is occupied in this case by a chlorine atom (Cu1—Cl1 2.413(2) and Cu2—Cl2 2.389(2) Å). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; complexes; uracil; violuric acid; copper.

There are many bibliographic data relative to structural features [1–3] and coordination modes [4–23] displayed by violuric acids (4-hydroxy-5-nitroso-1,2,3,6-tetrahydro-pyrimidine-2,6-dione) and 6-amino-5-nitrosouracil (4-amino-5-nitroso-1,2,3,6-tetrahydro-pyrimidine-2,6-dione) derivatives (see Fig. 1).

On binding to metal ions, these compounds exhibit well established patterns, which may be described as follows. At first, there are many examples in which the formation of a N5—O4 five-membered chelate ring (O6 if the IUPAC numbering system for pyrimidine heterocycles is followed) is found [12–17]. How-

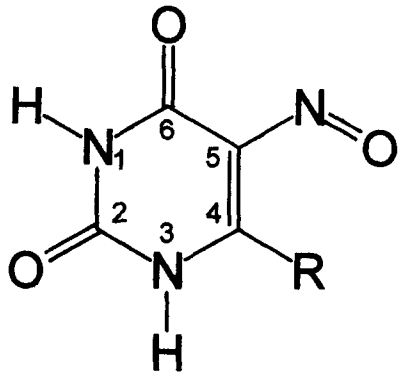

Fig. 1. Molecular structure of 6-amino-5-nitrosouracil (R=NH_2) and violuric acid (R=OH), showing the IUPAC numbering scheme as pyrimidine derivatives.

ever, there are two compounds in which additional coordination schemes are established. In the silver(I)-1,3-dimethylvioluric acid-1,3-dimethyl violurato [18] complex, the metal ion is five-coordinated by two N5,O6 chelates and an O5 atom from a neighbour molecule, resulting in asymmetric chains without metal-metal interactions. The CdL_2 complex with the 6-amino-3-methyl-5-nitrosouracilato anion [19] displays a dodecahedral coordination in which all ligands are equivalents acting as [N5,O4]-[N1,O2] doubly bidentate bridges between two adjacent metal centers.

Moreover, for the 6-amino-5-nitrosouracil derivatives, the bidentate coordination through N5 and N6 atoms has been crystallographically shown [20–23], thus contradicting the authors who pointed out that the primary 6-amino groups are not suitable binding sites due to their low basicity which may be related to the high delocalization of the lone pair of the nitrogen in the heterocyclic ring [24]. These papers describe structures in which there is a N5,N6,N5′,N6′-tetradentate ligand obtained from the condensation of two uracils through the 6-amino group with an alkyl one [21–23] or a roughly planar MN_4 moiety originated by the existence of two N5,N6-bidentate 6-amino-5-nitrosouracil ligands [20].

We have previously reported the structure and properties of 6-amino-1,3-dimethyl-5-nitrosouracilato(N^5,N^6)-2,2′-bipyridine(*N*,*N*′)-ethanol(O)-copper(II) nitrate [25]. Now, as an extension of this work, we report the crystal structure of two new copper(II) mixed bipy complexes with 6-amino-1,3-dimethyl-5-nitrosouracil, $[Cu(DANU)(bipy)(H_2O)]ClO_4 \cdot H_2O$, and 1,3-dimethylvioluric acid, $[Cu(DMV)(bipy)Cl] \cdot \frac{1}{2}H_2O$.

EXPERIMENTAL

Synthesis

All chemicals used in this work were analytical reagent grade. The 6-amino-1,3-dimethyl-5-nitrosouracil (HDANU) was obtained, as monohydrate, by nitrosation of 6-amino-1,3-dimethyluracil (synthesized from condensation of N,N′-dimethylurea and cyanoacetic acid in acetic anhydride) with sodium nitrite and acetic acid.

The synthesis of the complexes was carried out as follows: An aqueous solution (ca 20 ml) containing 0.5 mmol of copper (II) perchlorate (**1**) or copper(II) chloride (**2**) was added, slowly with stirring, to 1 mmol of DANU and 1 mmol of 2,2′-bipyridine, both dissolved in EtOH :water mixture (ca 100 ml). The resulting solutions were stirred for one hour and allowed to stand at room temperature. By evaporation during several days, green crystalline solids were isolated; the yields were ca 85% and 73%, respectively. It must be pointed out that the elemental analysis of the complex **2** clearly indicates the existence of the HDMV (1,3-dimethylvioluric acid) ligand which proceeds from the HDANU hydrolysis; this hydrolysis may be justified by a longer time of crystallisation. However, despite of we have some unpublished results which relate the extent of this reaction with the involvement of the 6-amino group in the hydrogen-bonding in the free ligands, clear conclusions about why and when this process takes place cannot be made. Both solids were filtered off, washed with ethanol and diethylether and air dried. Analytical data were: $[Cu(DANU)(bipy)(H_2O)]ClO_4 \cdot H_2O$. Found: 35.4%C, 3.3%H, 15.1%N, 7.1%H_2O, Calcd 35.7%C, 3.6%H, 15.6%N, 6.7%H_2O; $[Cu(DMV)(bipy)Cl] \cdot \frac{1}{2}H_2O$, Found: 42.5%C, 3.3%H, 15.5%N, 2.2%H_2O, Calcd 42.9%C, 3.4%H, 15.6%N, 2.0%H_2O.

CAUTION! *Perchlorate salts are dangerous and must be handled with care*

Crystallography

Unit cell constants were obtained for crystals of $[Cu(DANU)(bipy)(H_2O)]ClO_4 \cdot H_2O$ (**1**) and $[Cu(DMV)(bipy)Cl] \cdot \frac{1}{2}H_2O$ (**2**) from least squares fits to settings of 25 reflections centred on an Enraf-Nonius CAD-4 diffractometer using graphite-monochromatized Cu-K_α ($\lambda = 1.54056$ Å) and Mo-K_α ($\lambda = 0.71073$ Å) radiations for **1** and **2** respectively. Corrections for absorption were applied: integration (**1**) and Ψ-scans (**2**). The structures were solved by standard Patterson methods and refined by full-matrix least-squares, applying the SHELX-76 [26], SHELXL-93 [27] (**1**) and SDP packages [28] (**2**).

1: $CuClC_{16}H_{19}N_6O_9$, triclinic, space group $P\bar{1}$, $a = 8.049(3)$, $b = 11.946(2)$, $c = 12.024(4)$ Å, $\alpha = 64.71(2)$, $\beta = 86.53(3)$, $\gamma = 88.76(2)^\circ$, $V = 1043.4(5)$ Å^3, $Z = 2$, $F(000) = 550$, $M = 538.36$, $D_c = 1.714$ g cm^{-3}. 3957 independent reflections were collected in the range $2\theta \leqslant 140^\circ$ for a crystal of size $0.53 \times 0.38 \times 0.15$ mm ($\mu = 3.23$ mm^{-1}, max./min. transmission = 0.6252/0.2799). Terminal conventional $R(F_o) = 0.055$ for 3717 reflections with $I > 2\sigma(I)$ and $wR^2(F_o^2, \text{all}) = 0.1647$ ($wR^2 = [\Sigma w(F_o - F_c)^2/\Sigma wF^2]^2$

and $w = [\sigma^2(F_o^2) + (0.1087P)^2 + 0.9972P]^{-1}$ where $P = \frac{1}{3}(F_o^2 + 2F_c^2)$). Max. feature in ΔF map of 0.80 e Å^{-3}. All non-hydrogen atoms were assigned anisotropic temperature factors. The perchlorate group was found to be disordered in three positions with fractional occupation of 0.25, 0.25 and 0.50. Hydrogen atoms of the organic ligands were idealized and those of the water molecules were refined with fixed O—H distances (0.82 Å).

2: $CuClC_{16}H_{15}N_5O_{4.5}$, triclinic, space group $P\bar{1}$, $a = 7.730(9)$, $b = 14.550(6)$, $c = 16.383(8)$ Å, $\alpha = 99.46(4)$, $\beta = 101.55(9)$, $\gamma = 98.43(8)°$, $V = 1750(2)$ Å^3, $Z = 2$, $F(000) = 912$, $M = 448.32$, $D_c = 1.702$ g cm^{-3}. 5889 independent reflections were collected in the range $2\theta \leqslant 50°$ for a crystal of size $0.75 \times 0.35 \times 0.01$ mm ($\mu = 1.49$ mm^{-1}, max./min. transmission 0.993/0.660). Terminal $R(F_o) = 0.067$ for 3825 reflections with $I > 3\sigma(I)$ and $wR(F_o) = 0.084$ ($wR = [\Sigma w(F_o - F_c)^2/\Sigma wF_o^2]^{1/2}$ and $w = 4F_o^2[\sigma^2(I) + (0.1F_o^2)^2]^{-1}$). Max. feature in ΔF map of 0.9 e Å^{-3}. All non-hydrogen atoms were assigned anisotropic temperature factors. Hydrogen atoms of the organic ligands were idealized.

Apparatus

Microanalyses of C, H and N were performed in the Scientific Instrumentation Center of the University of Granada; the water contents of the complexes were determined from the TG plot (Mettler TG-50 thermobalance, air, 10°C min^{-1} heating rate). IR spectra were obtained on a Perkin–Elmer FT-IR 1760x (KBr pellets, 4000–400 cm^{-1}) and Perkin–Elmer 983G spectrophotometer (600–180 cm^{-1}, polyethylene pellets). The EPR spectra were obtained in the X-band at room temperature on a Bruker ESP 300E apparatus, with a microwave frequency of 9.79 GHz and a modulation frequency of 100 kHz. Magnetic measurements were carried out on a Manics DSM-8 system between 77 and 290 K.

RESULTS AND DISCUSSION

Crystal structures

A drawing of molecular units showing the atom numbering is displayed in Fig. 2. Selected bond distances and angles are listed in Table 1.

The crystal lattice of **1** is made up of discrete square pyramidal $[Cu(DANU)(bipy)(H_2O)]^+$ cations, a disordered perchlorate group and a water molecule. The coordination geometry about the metal centre is square pyramidal (N_4+O). The basal positions are occupied by a bidentate DANU ligand, coordinated through the N15 and N16 donor positions and a bipyridine ligand. A water molecule (Cu—O1W 2.193(3) Å) occupies the apical site. The copper centre appears 0.198 Å displaced from the basal plane. The distortion of the polyhedron was calculated by a quantification of the Muetterties and Guggenberger method [29] and the use of trigonal bipyramid (TBP) and square pyramid (SP) as limiting geometries [30], giving an 8% distorted SP (see Table 2).

The structure of **2** is made up of two crystallographically independent square pyramidal [Cu(DMV)(bipy)Cl] entities (I and II) and a crystal lattice water molecule. Compound **2** presents a similar molecular structure to that of **1** with the copper centre laying in a N_3O+Cl environment. In this case, the basal positions are occupied by a bipy ligand and a DMV ligand coordinated through the N15 and O16 donor positions, instead of the DANU ligand found in the previous compound. The apical position is occupied in this case by a chlorine atom (Cu1—Cl1 2.413(2) and Cu2—Cl2 2.389(2) Å). The copper centres are found to be considerably more displaced from the basal plane than in **1**, namely 0.331 and 0.357 Å for Cu1 and Cu2, respectively. This fact may be explained because of considering the covalent radii values of O and Cl, in which it may be deduced a stronger Cu—L axial interaction in compound **2** if it is compared to **1**, which may result in a greater pyramidalization of the coordination polyhedron in **2**. Also, the distortion of the coordination polyhedra in **2** was calculated giving, respectively, 7% and 25% distorted SP for Cu1 and Cu2.

The bond length ratio R(unidentate/bidentate), 1.10 for **1** and 1.20 for **2**, and the normalized bite b (1.29–1.31) of bidentate ligands indicate that these compounds fall into the β class compounds [31]. For those types of molecules nearer the square-pyramid, the structure can be considered to be approaching square-planar four-coordination, with the addition of a fifth more weakly bonded ligand. Both structures are very similar with the related [Cu(DANU)(bipy)(EtOH)]NO_3 [25], in which the ratio R (unidentate/bidentate) is 1.13.

In both cases, the two five-membered chelate rings deviate from planarity, showing an envelope form, and are mutually angled by 11.3° (**1**), and 19.6 (**2**-I) and 23.5° (**2**-II). The uracil moieties are practically planar but are coplanar neither the mean bipy plane (**1**, 5.1°; **2**-I, 12.5°; **2**-II, 18.7°) nor the coordination square-plane [N_4 (**1**) and N_3O (**2**)] (**1**, 4.8°; **2**-I, 4.1°; **2**-II, 11.0°). Also, the mean bipy plane and the coordination plane (**1**, 9.2°; **2**-I, 8.6°; **2**-II, 7.8°) are not coplanar. Finally, both pyridine rings of bipy ligands are slightly angled to each other (**1**, 3.5°; **2**-I, 3.1°; **2**-II, 4.4°).

A very interesting feature is the fact that in **1** the DANU derivative is present whereas in **2** its hydrolysis product DMV appears. However, considered both ligand geometries, it appears difficult to discern which the DANU or the DMV ligand is present in each compound, since there are not statistically significative differences in the C16—N16 (1.242(4) Å) and C16—O16 (1.238(8), 1.263(8) Å) bond distances.

The geometry of pyrimidine moiety in both compounds is very close to those reported for the related

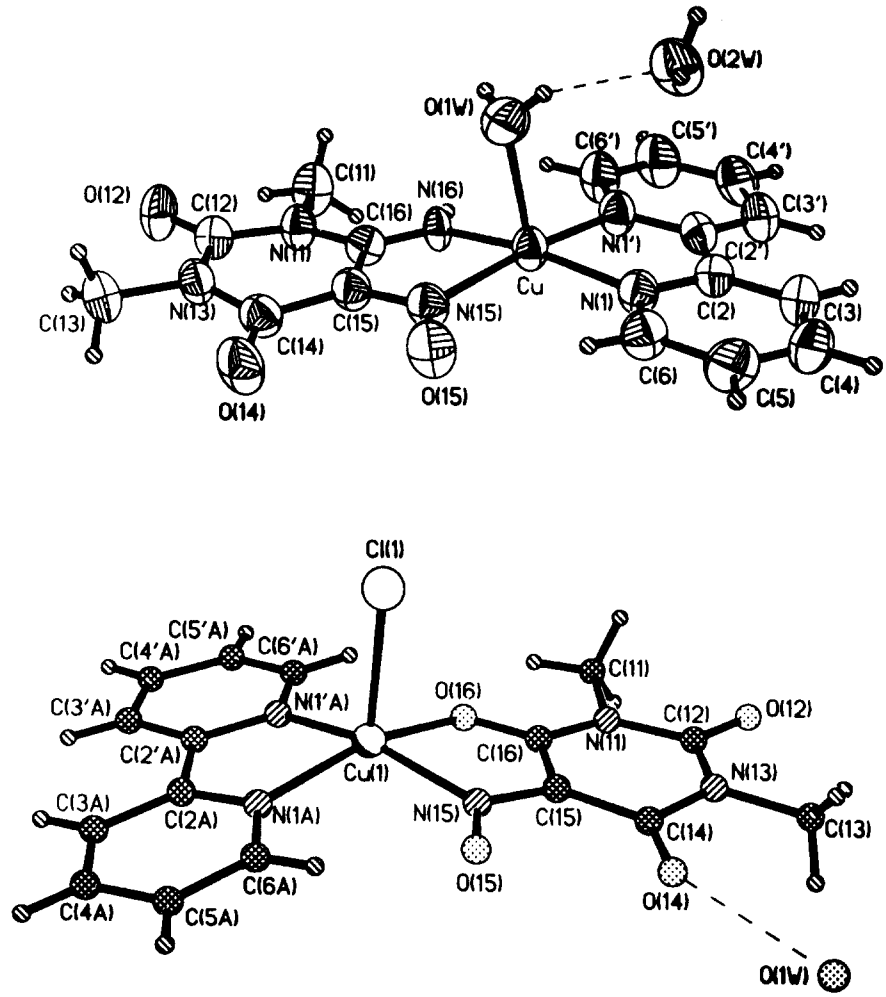

Fig. 2. View of the molecular unit of $[Cu(DANU)(bipy)(H_2O)]ClO_4 \cdot H_2O$ (**1**) (top) and $[Cu(DMV)(bipy)Cl] \cdot \frac{1}{2}H_2O$ (**2**) (bottom). In **1**, disordered perchlorate anions have been omitted for clarity. In **2**, only one unit is displayed; in the other, the DMV atoms are named as X(2*) and the bipy atoms as X(*B).

complexes $[Cu(DANU)_2(H_2O)_2]$ [20], $[Cu(DMV)_2(H_2O)_2]$ [12] and $[Cu(DANU)(bipy)(EtOH)]NO_3$ [25]. The C=O distances correspond to a double bond, the carbonylic character being enhanced on complexation if it is compared with the free ligand [2] although, in the violurato complex, the coordinated C16—O16 and C26—O26 carbonyl groups are significantly longer than the other two ones. In the DANU complex, the C16—N16 distance is shorter (ca 0.06 Å) than the one in the free ligand, showing an increase of the imino character of this group. In all cases, the double N=O bond is also shorter (ca 0.04 Å) in the complex than in the free ligands. On comparing the geometries of all reported data, no significant changes in the bond angles can be detected with the only exception of the angles C14—C15—N15 and N15—C15—C16 which are, on coordinating to the Cu(II) ion, respectively opened and closed (ca 12°) with respect to the free ligand.

The molecules are packed via hydrogen bonding. In **1**, the coordinated water molecule is bonded to the uncoordinated one (O1W···O2W 2.714(4) Å) and to the oxygens of the disordered perchlorate group ($-x$, $-y$, $2-z$) (O1W···O81 2.60(2), O1W···O74 2.86(2) and O1W···O61 2.93(2) Å). Also, the non-coordinated water molecule is involved in hydrogen bonds with the O14 and O15 atoms of uracil moiety ($1-x$, $-y$, $1-z$) (O2W···O14 2.946(4) and O2W···O15 2.935(4) Å) and other perchlorate group ($1+x$, y, z) (O2W···O63 2.87(2), O2W···O71 2.90(2) and O2W···O84 3.07(2) Å). In **2**, there is only a well-established hydrogen bond O1W···O14 (2.952(5) Å) and a weaker contact O1W···Cl1 (3.358(6) Å).

Spectral and magnetic measurements

The IR spectra of these compounds have been compared with those for free HDANU [32] and HDMV [12] and are very similar to those reported for the

related complexes $[Cu(DANU)_2(H_2O)_2]$ [20], $[Cu(DANU)(bipy)(EtOH)]NO_3$ [25] and $[Cu(DMV)_2(H_2O)_2]$ [12]. The main features of the infrared spectra related with the potential donor groups may be described as follows. For DANU complexes, an increase of the imino character of the C6—N6 bond takes place as indicates the shift to upper wavenumber of the band assigned to ν(N—H), which is displaced from 3329 cm^{-1} in the free HDANU [32] to 3466 (**1**), 3473 [25] and 3394 cm^{-1} [20]. This fact may be explained by the behavior of the 6-amino group as a metal binding site. The bands assigned to ν(C=O) carbonyl groups (1729 cm^{-1} in **1** and 1726 in HDANU spectra [32]) remain practically unaffected upon complexation, which is in according with the diffraction results, since the carbonylic oxygen is not involved in the metal-ligand bond. In the other related complexes, this band appears at 1726 [20] and 1729 cm^{-1} [25].

In the IR spectra of DMV complexes, there are no bands around 3300 cm^{-1} assignable to ν(N—H) vibration. This fact was another piece of evidence to the existence of the hydrolysis of DANU to give DMV in the compound **2**. The metal-ligand interaction through the oxygen of one carbonyl group is clearly detected by the changes in the ν(C=O) carbonyl bands, which are all displaced to lower wavenumber with respect to their position in the IR spectrum of the free ligand. In the IR spectrum of **2**, three bands at 1729, 1685 and 1668 cm^{-1} may be assigned to coupled vibrational activity of carbonyl groups. In both title compounds, the band assigned to ν(N=O) of the 5-nitroso group (**1**, 1512 cm^{-1}; **2**, 1510 cm^{-1}) is also shifted to lower wavenumber, as in other related compounds [12,20,25], with respect to its position in the IR spectrum of the free ligands (HDANU, 1518 cm^{-1}; HDMV, 1540 cm^{-1}). Bands corresponding to the main vibrational modes of coordinated 2,2′-bipyridine, clearly distinguished from both HDANU and HDMV bands, appear at 1601, 1585 and 776 cm^{-1} (**1** and **2**) (1579,1558 and 758 cm^{-1} in free bipy), these values being coincident with those found in the spectrum of the related ternary complex $[Cu(DANU)(bipy)(EtOH)]NO_3$ [25]. Also, the infrared spectrum of **1** permits to assign the bands for the

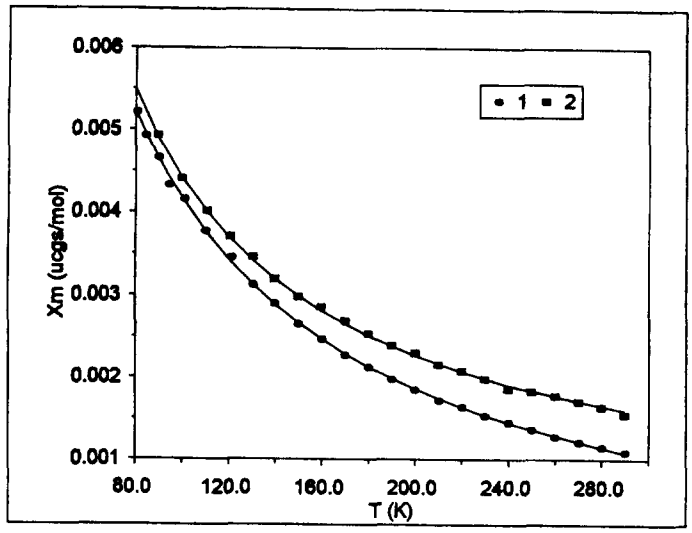

Fig. 3. Magnetic susceptibility values at different temperatures (**1**, circles; **2**, squares).

ν(Cl—O) of perchlorate group [33] (1146, 1117 and 1084 cm^{-1}). The appearance of three bands for this vibration mode in a free tetrahedral anion must be explained by the loss of symmetry that takes place as consequence of the involvement in hydrogen bonds. The analysis of far-IR spectra does not allow us to safely assign any band for metal-ligand vibration modes; only, in the spectrum of **2**, a band at 283 cm^{-1} can be assigned to ν(Cu—Cl) vibration [34].

From the fit of molar susceptibility values at different temperatures (Fig. 3) to the Curie-Weiss' law ($\chi_M = C/[T-\theta]$), the following parameters were obtained: **1**, $C = 0.295(6)$ cgsu K mol^{-1}, $\theta = 33(6)$ K, $r = 0.9950$, $\mu_{eff} = 1.83(4)$ BM and **2**, $C = 0.462(2)$ cgsu K mol^{-1}, $\theta = -3(2)$ K, $r = 0.9998$, $\mu_{eff} = 1.96(6)$ BM. The θ value in the compound **1** indicates that ferromagnetic interactions could be in some extent. However, the confirmation of the apparent trends needs data over a longer temperature range down to 4 K, and that any effects of ferromagnetism must be rather small, particularly in view of the weak intermolecular contacts. In both complexes, the effective magnetic moment for Cu(II) ion, once the diamagnetic corrections were made, is clearly in accord to the existence of magnetically diluted monomeric units [35].

The complexes display axial EPR powder spectra with $g_\perp = 2.03$ and $g_\parallel = 2.25$ (**1**) and $g_\perp = 2.03$ and $g_\parallel = 2.20$ (**2**) and this may be interpreted [36,37] by the existence of a rhombic symmetry with the tetragonal axes parallel, but in which the rhombic component is so small that it is not resolved by the powder technique.

Table 2. Dihedral angles (°) and distortion (Δ) for the coordination polyhedra of **1** and **2**, as proposed by Galy *et al.*, compared to ideal trigonal bipyramid (TBP) and regular tetragonal pyramid (TP) structures[a]

dihedral angles	TBP	1	2 (unit I)	2 (unit II)	TP
δa1	101.5	100.3	97.6	128.8	119.8
δa3	101.5	116.4	113.7	92.2	119.8
δa4	101.5	108.0	104.7	129.7	119.8

Abstract—The potential of photochemistry in cluster synthesis has been demonstrated by the high yield preparation of $(\mu\text{-H})(\mu\text{-X})Ru_3(CO)_{10}$ {X = Cl (**2a**), Br (**2b**), I (**2c**)} from $Ru_3(CO)_{12}$ (**1**) and the molecular structure of $(\mu\text{-H})(\mu Cl)Ru_3(CO)_{10}$ (**2a**) determined by single-crystal X-ray diffraction. As an extension to the work, the halide containing complexes have also been prepared thermally by reaction of the appropriate allyl halide with the novel di-hydrido cluster $H_2Ru_3(CO)_{10}$ (**3**). © 1998 Elsevier Science Ltd. Keywords: photochemistry; ruthenium; carbonyl clusters.

The photochemistry of organometallic compounds is a developing research area, being of importance both in synthesis and catalysis as well as proving fascinating in its own right [1,2]. Research in our group has focused on harnessing the synthetic potential of photochemistry to generate known and novel compounds efficiently and in high yields [3].

The tri-ruthenium cluster $Ru_3(CO)_{12}$ (**1**) can undergo either photofragmentation or photosubstitution reactions [1]. Our studies have shown that it is possible to control the photoprocesses by simply changing the solvent in which the photolysis is performed [3]. Solvents such as dichloromethane and hexane lead, in the majority of cases, to photofragmentation products. Conversely, photolysis in more polar solvents such as acetonitrile, ethyl acetate or diethyl ether leads to photosubstitution products. In this paper we show that, by irradiating an HX {X = Cl, Br, I} saturated diethyl ether solution of $Ru_3(CO)_{12}$, it is possible to generate the trinuclear clusters $(\mu\text{-H})(\mu\text{-X})Ru_3(CO)_{10}$ in high yield.

As an extension to the work, this class of compound was also formed thermally by reaction of the appropriate allyl halide with the novel di-hydrido cluster $H_2Ru_3(CO)_{10}$ (**3**).

EXPERIMENTAL

General

All reactions were performed under an inert atmosphere of dry nitrogen using standard Schlenk techniques and solvents were distilled prior to use. All photochemical reactions were performed in a specially designed glass reaction vessel fitted with a gas bubbler, reflux condenser, solid carbon dioxide cooling finger and a stirrer to ensure that the temperature was even throughout the solution. A 250 W broad-band UV source was used as the light source and reflectors placed around the reaction vessel to maximize efficiency. Solution infrared (IR) spectra were recorded in hexane as solvent using a Perkin–Elmer PE 1710 Fourier-transform infrared spectrometer. ^1H NMR spectra were recorded in $CDCl_3$ as solvent using a Bruker WM250 Fourier-transform NMR spectrometer and data reported using the chemical shift scale in units of ppm relative to the solvent resonance as an internal standard. Ruthenium trichloride was

provided by Johnson Matthey and Co. Ltd and literature methods used to prepare $Ru_3(CO)_{12}$ (**1**) [4] and $H_2Ru_3(CO)_{10}$ (**3**) [5].

Photochemical preparation of $(\mu\text{-H})(\mu\text{-X})Ru_3(CO)_{10}$ {X = Cl (**2a**), Br (**2b**), I (**2c**)}

A diethyl ether solution of **1** (30 mg in 100 ml) was saturated with HX and the reaction mixture then irradiated using the broad-band UV source, the temperature of the solution being maintained around 0°C. The reaction was monitored using IR spectroscopy and deemed complete when there was no further change in the IR spectrum {X = Cl 2 h; Br 3 h; I 5 h}. After evaporating to dryness, the residue was extracted into hexane. After again removing the solvent, the product was recrystallized from pentane yielding pure **2a** (75%) **2b** (60%) or **2c** (50%). Spectroscopic data: **2a** IR(ν_{CO}): 2112 (w), 2077 (s), 2064 (s), 2034 (vs), 2015 (s), 1995 (m) cm^{-1}, ^1H NMR (δ): −13.24 (s, Ru—H); **2b** IR (ν_{CO}): 2116 (w), 2074 (s), 2068 (s), 2027 (vs), 2020 (s), 1994 (m) cm^{-1}, ^1H NMR (δ): −14.42 (s, Ru—H); **2c** IR (ν_{CO}): 2109 (w), 2068 (s), 2062 (s), 2024 (vs), 2007 (s), 1994 (m) cm^{-1}, ^1H NMR (δ): −15.08 (s, Ru—H).

Reaction of $H_2Ru_3(CO)_{10}$ *with allyl halides*

An excess of the appropriate allyl halide was added to a cooled hexane solution of **3** (50 mg in 100 ml). The resultant mixture was stirred for 20 min. After removal of the solvent *in vacuo*, $(\mu\text{-H})(\mu\text{-X})Ru_3(CO)_{10}$ was extracted into cold dichloromethane as the main product (**2a**, 70%; **2b**, 65%; **2c**, 60%), characterised by comparison of IR and ^1H spectral data with that in the literature data [6].

X-ray data collection, structure determination and refinement of $(\mu\text{-H})(\mu\text{-Cl})Ru_3(CO)_{10}$ (**2a**)

Suitable single-crystals of **2a** were grown from a dichloromethane-hexane solution by slow evaporation. Crystal data: $C_{10}HClO_{10}Ru_3$, orange plates, crystal dimensions 0.40 × 0.30 × 0.25 mm, triclinic, $P\bar{1}$ (No. 2), $a = 7.749(5)$ Å, $b = 8.782(6)$ Å, $c = 13.562(8)$ Å, $\alpha = 95.36(3)°$, $\beta = 103.26(3)°$, $\gamma = 110.16(3)°$, $V = 828.1(9)$ Å^3, $D_{calc} = 2.486$ Mg cm^{-3}, $Z = 2$, $F(000) = 580$, Mo–K_α radiation, $\lambda = 0.71073$ Å, μ(Mo–K_α = 2.907 mm^{-1}), $T = 153(2)$ K. Stoe-Siemens AED diffractometer, 2927 reflections collected in the range $3.05 \leqslant \theta \leqslant 25.07$, 2922 unique absorption corrected data ($R_{int} = 0.1159$). The structure was solved by direct methods (Ru atoms) (SHELXTL PLUS [7]) and Fourier difference syntheses and refined with Ru, C and O atoms anisotropic by full-matrix least squares based on F^2 (SHELXL 93 [8]). The bridging hydride was located directly, assigned a fixed thermal displacement parameter and its coordinates refined freely. The refinement converged at $R_1 = 0.0260$ and $wR_2 = 0.0599$ for 2549 observed data [$F > 4\sigma(F)$], and $R_1 = 0.0340$, $wR_2 = 0.0634$ (all data), goodness of fit = 1.059, max, min peak in final difference map = 0.691, −0.604 eÅ^{-3}, max $\Delta/\sigma = 0.001$, weighting scheme $w = 1/[\sigma^2(F_o)^2 + (0.355P)^2 + 0.5868P]$, $P = (F_o^2 + F_c^2)/3$, produced a flat analysis of variance.

RESULTS AND DISCUSSION

Broad-band UV photolysis of a diethyl ether solution of $Ru_3(CO)_{12}$ (**1**) under an atmosphere of HX {X = Cl, Br and I} at 0°C afforded one main product in each case. The reaction products were characterized as the known clusters $(\mu\text{-H})(\mu\text{-X})Ru_3(CO)_{10}$ {X = Cl (**2a**), Br (**2b**), I (**2c**)} (eq. 2) by comparison of spectroscopic data with that in the literature [6].

The photochemical route leads to product yields of approximately 50–75% as compared to about 30% using previous literature methods [6]. This illustrates clearly the advantages of photochemistry as a preparative tool for the synthesis of trinuclear clusters, the reaction here being performed in one stage at room temperature or lower, the yields of the product being high and the reaction time short.

The molecular structure of **2a** was determined by single crystal X-ray analysis (Fig. 1). Selected bond lengths and angles are shown in Table 1. The complex crystallizes in the triclinic space group $P\bar{1}$ (No. 2). The ruthenium and osmium clusters **2a** and $(\mu\text{-H})(\mu\text{-Cl})Os_3(CO)_{10}$ are isomorphous and isostructural, both showing discrete ordered $(\mu\text{-H})(\mu\text{-Cl})M_3(CO)_{10}$ units, separated by normal van der Waals distances [9]. The molecules have approximate C_s symmetry, the doubly-bridged metal–metal bond being slightly longer than the non-bridged bonds. The Ru—Cl—Ru angle in **2a** is relatively acute [71.14(5)°]. By studying the bond lengths in a number of dinuclear ruthenium and osmium complexes containing $(\mu\text{-H})(\mu\text{-Cl})$ bridges it is concluded that there are no clear restraints imposed on the molecule by the [Ru(CO)$_4$] group in **2a** which can, essentially, be considered as a third bridge across the $Ru(\mu\text{-H})(\mu\text{-Cl})Ru$ bond [10].

The molecular structure of $(\mu\text{-H})(\mu\text{-Br})Ru_3(CO)_{10}$ has been reported previously [9]. Unlike **2a, 2b** crystallizes in a monoclinic space group ($P2_1/c$) but both possess the same approximate C_s symmetry in the crystalline state. The di-bridged Ru—Ru bond in **2a** is significantly longer at 2.833(2) Å than that in **2b** {2.819(1) Å} this being interesting since it would be expected that bridging by the larger halogen would lead to a longer metal—metal bond. Also, the Ru—Hal—Ru (Hal = Cl, Br) and Ru—H—Ru angles are larger in the case of **2a** at 70.14(5)° and 96(2)° respectively as compared to **2b** {66.80(5)° and 104.5(1)°}. In both **2a** and **2b** there is a *trans* influence in the Ru—C(O) distances to the carbonyl groups *trans* to the halogen atom {Ru(1)—C(13) = 1.863(5)

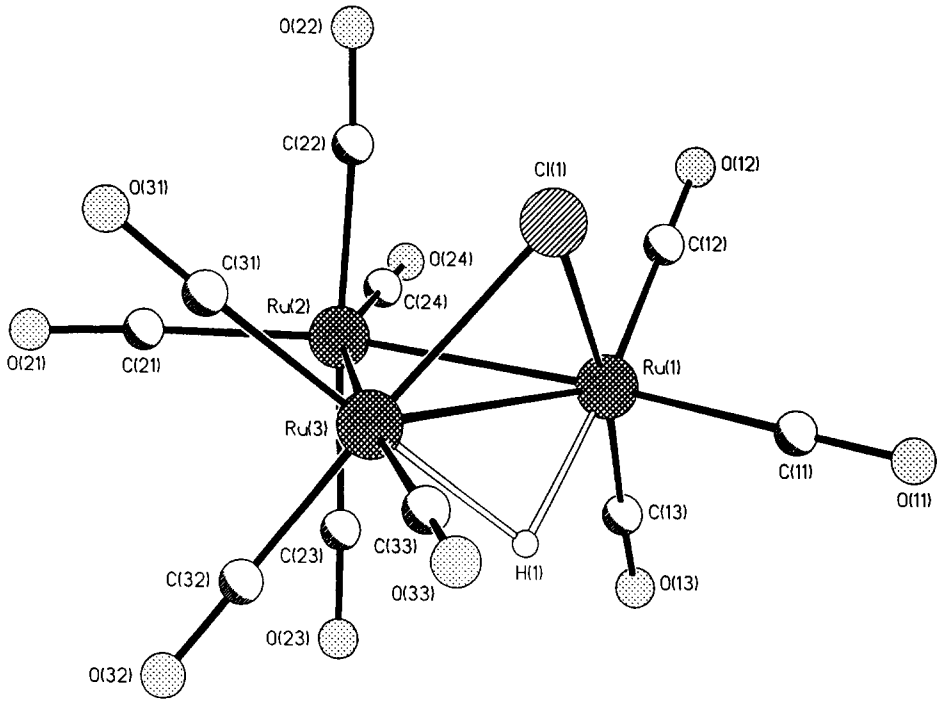

Fig. 1. Molecular structure of **2a**.

Table 1. Selected bond lengths (Å) and angles (°) for **2a**

Ru(1)—Ru(2)	2.810(2)	Ru(3)—Cl(1)	2.433(2)
Ru(1)—Ru(3)	2.833(2)	Ru(1)—H(1)	1.87(5)
Ru(2)—Ru(3)	2.796(2)	Ru(3)—H(1)	1.95(6)
Ru(1)—Cl(1)	2.437(2)		

Ru(1)—Ru(2)—Ru(3)	60.70(5)	Cl(1)—Ru(3)—Ru(1)	54.51(4)
Ru(2)—Ru(3)—Ru(1)	59.88(4)	H(1)—Ru(1)—Ru(3)	43(2)
Ru(3)—Ru(1)—Ru(2)	59.41(3)	H(1)—Ru(3)—Ru(1)	41(2)
Ru(1)—Cl(1)—Ru(3)	71.14(5)	Cl(1)—Ru(1)—H(1)	88(2)
Ru(1)—H(1)—Ru(3)	96(2)	Cl(1)—Ru(3)—H(1)	87(2)
Cl(1)—Ru(1)—Ru(3)	54.35(5)	C(11)—Ru(1)—Ru(3)	113.0(2)

Å, Ru(3)—C(32) = 1.873(5) Å}. This has been observed for similar complexes of general formula $(\mu\text{-H})(\mu\text{-L})Ru_3(CO)_{10}$ {L = COMe [11], $CNMe_2$ [12], NO [13], SCH_2CO_2H [14]}, the *trans* effect in these compounds being even more marked than observed here. Consequently, the differences in these bond lengths are a measure of the donor and π-acceptor properties of L; an increased Ru—X bond strength equating to an increased *trans* Ru—C(O) bond distance. The other Ru—C bond lengths in **2a** range from 1.904(5) to 1.965(5) Å and all the Ru—C—O angles are close to linear, ranging from 175.1(4) to 179.8(4)°.

As well as being synthesised photochemically, **2a**, **2b** and **2c** has been prepared by addition of the appropriate allyl halide to the newly reported di-hydride reagent $H_2Ru_3(CO)_{10}$ (**3**) as in the case of the osmium analogue **4** [15]. This illustrates the potential of **3**, **4** being one of the most versatile tri-osmium clusters known due to its ability to form simple adducts. Of interest is that, even in an excess of allyl halide, the di-halide bridged clusters $(\mu\text{-X})_2Ru_3(CO)_{10}$ are not observed. This is in contrast to **4** where the ratio of $(\mu\text{-H})(\mu\text{-X})Os_3(CO)_{10}$ to $(\mu\text{-X})_2Os_3(CO)_{10}$ is defined by the stoichiometry of reaction [15].

Abstract—18-membered hexadentate N_4O_2 and N_3O_3 Schiff-base polyoxaazamacrocycles derived from 2,6-bis(2-aminophenoxymethyl) pyridine and different organic dicarbonyl compounds are obtained by a template procedure as mononuclear lanthanide(III) complexes. In the absence of the metal salt, macrocycles are not formed. The complexes were characterised by elemental analysis, molar conductivity and mass, UV–V, IR, ^1H NMR and ^{13}C NMR spectroscopy. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: template synthesis; lanthanide(III) complexes; polyoxaazamacrocycle; Schiff-base; ion-selectivity.

The preparation and characterisation of metal complexes with macrocyclic Schiff-base ligands have been the subject of numerous studies in the recent past [1]. This type of ligands have been prepared by cyclo-condensation reaction of appropriate diketo or diformyl and polyamine precursors, often by a template procedure. The presence of a suitable metal ion plays an important role in directing the synthetic pathway of the Schiff base formation and it is now well established that lanthanides can serve as effective templates [2–4].

We are interested in the synthesis and characterisation of new lanthanide coordination compounds with mixed N_xO_y donor set macrocycles. Previously, we have reported the synthesis and spectroscopic properties of lanthanide(III) complexes of N_3O_2, N_3O_3, and N_2O_4 polyoxaaza Schiff-base macrocycles containing aromatic, head and lateral units [5–7]. Herein, we describe the synthesis and characterisation of lanthanide(III) nitrate and perchlorate complexes with the Schiff base polyoxaaza macrocycles L^1 and L^2. Lead(II) complexes with these macrocycles have been previously [8] prepared as intermediates in the preparation of L^3 and L^4, but no further studies were made on them.

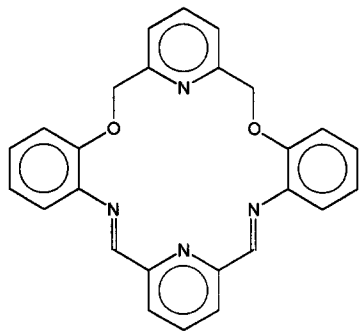
EXPERIMENTAL

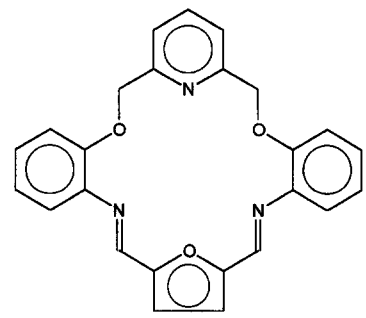
Measurements

Elemental analyses, proton and carbon NMR and mass spectra were carried out by Servicios Generales de Apoyo a la Investigación of the Universidad de La Coruña: elemental analyses were carried out on a Carlo Erba 1108 elemental analyser; proton and carbon NMR spectra were run on a Bruker AC 200 F spectrometer and FAB mass spectra were recorded using a FISONS QUATRO mass spectrometer with a Cs ion-gun and using a thioglycerol matrix. The IR spectra were recorded, as KBr discs and/or fluorolube mull, using a Perkin–Elmer 1330 spectrophotometer and the electronic absorption spectra of complexes in acetone solution were recorded at 25°C using a Uvikon 941 Plus spectrophotometer.

Conductivity measurements were carried out in 10^{-3} mol dm^{-3} dimethylformamide or acetonitrile



L1



L2

solutions at 25°C using a Crison Micro CM 2201 conductivimeter.

Chemicals and starting materials

2,6-Diformylpyridine and 2,5-diformylfuran were prepared according to literature methods [9–11]. 2,6-bis(2-aminophenoxymethyl)pyridine monohydrate was prepared by reduction of the corresponding dinitro precursor [8]. Lanthanide(III) nitrates and perchlorates were commercial reagents from Aldrich and Alfa laboratories, used without further purification. Solvents were of reagent grade purified by the usual methods. **CAUTION:** perchlorates are potentially explosive!

Condensation between 2,6-diformylpyridine and 2,6-bis(2-aminophenoxymethyl)pyridine monohydrate in the absence of metal ions

Procedure 1. An ethanolic solution of 2,6-diformylpyridine (1 mmol in 25 cm^3) was added dropwise to an ethanolic solution of the diamine (1 mmol in 25 cm^3) with stirring and heating. The solution was refluxed with magnetic stirring for 4 h. The colour changed to yellow and a yellow powder precipitated.

Procedure 2. To a 225 cm^3 of refluxing methanol were simultaneously added, dropwise, two methanolic solutions: 2,6-bis(2-aminomethoxymethyl)pyridine (0.3 mmol in 50 cm^3) and 2,6-diformylpyridine (0.3 mmol in 50 cm^3) over a period of 8 h. The resultant yellow solution was heated for 9 h. No identifiable product could be isolated.

Reaction of 2,6-bis(2-aminophenoxymethyl)pyridine and 2,6-diformylpyridine in the presence of lanthanide(III) ions

General procedure for $[LnL^1][ClO_4]_3$. 2,6-Bis(2-aminophenoxymethyl)pyridine monohydrate (0.3 mmol) and $Ln(ClO_4)_3 \cdot xH_2O$ (Ln = La, Pr, Nd, Sm, Eu, Dy, Ho) were dissolved in hot absolute ethanol (35 cm^3). 2,6-Diformylpyridine (0.3 mmol) dissolved in absolute ethanol (20 cm^3) was slowly added. Stirring and heating of the solution was maintained during the addition and the solution was then refluxed for 2 or 3 h. The yellow powder precipitated was filtered off, washed with diethyl ether and air dried. In some cases, a second portion of the same product was isolated by concentration of the mother liquor.

Ce, Gd, Tb and Er complexes were synthesised by the same procedure using acetonitrile as solvent and the products were isolated from the solution after evaporation until 20 cm^3 and addition of diethyl ether (20 cm^3).

The complexes are air stable in the solid state,

soluble in acetone, acetonitrile, dimethyl sulfoxide and dimethylformamide, moderately soluble in methanol and ethanol and insoluble in chloroform, water and carbon tetrachloride.

General procedure for $[LnL^1][NO_3]_3$. To a solution of 2,6-bis(2-aminophenoxymethyl)pyridine monohydrate (0.3 mmol) in methanol (20 cm^3) was added a solution of the hydrated lanthanide nitrate (0.3 mmol) (Ln = La–Lu, except Pm) in methanol (10 cm^3). The solution was vigorously stirred and heated while a methanolic solution of 2,6-diformylpyridine (0.3 mmol) was dropwise added. Within 5–10 min a yellow precipitate began to appear. Refluxing was maintained for ca 2 h. The product was filtered off, washed with acetone and diethyl ether and dried under vacuum.

The complexes are air stable in the solid state, soluble in dimethyl sulfoxide and insoluble in all other common solvents.

Condensation between 2,5-diformylfurane and 2,6-bis(2-aminophenoxymethyl)pyridine monohydrate in the absence of metal ions

To a 225 cm^3 of refluxing absolute ethanol were simultaneously added, dropwise, two ethanolic solutions of 2,6-bis(2-aminomethoxymethyl)pyridine (0.3 mmol in 50 cm^3) and 2,5-diformylfurane (0.3 mmol in 50 cm^3) over a period of 6 h. The resultant orange solution was heated for 4 h. No identifiable product could be isolated.

Reaction of 2,6-bis(2-aminophenoxymethyl)pyridine and 2,5-diformylfurane in the presence of lanthanide(III) perchlorate ions

General procedure for $[LnL^2][ClO_4]_3$. 2,6-bis(2-aminophenoxymethyl)pyridine monohydrate (0.3 mmol) and $Ln(ClO_4)_3 \cdot xH_2O$ (Ln = La, Pr, Nd, Eu, Gd, Tb, Dy, Ho, Er) were dissolved in hot absolute ethanol (35 cm^3). 2,5-Diformylfurane (0.3 mmol) solved in absolute ethanol (20 cm^3) was slowly added to the former solution. Stirring and heating was maintained during the addition and the solution was then refluxed for 10 min. The powdery precipitate was filtered off, washed and stirred with diethyl ether and dried under vacuum. A second portion of the same product was isolated by concentration of the mother liquor. Cerium and samarium complexes were obtained by the same procedure using acetonitrile as solvent and the product was isolated from the solution after evaporation until 20 cm^3 and addition of diethyl ether (20 cm^3).

The complexes are air stable in solid state, soluble in acetone, acetonitrile, dimethyl sulfoxide and dimethylformamide; moderately soluble in methanol and ethanol and insoluble in chloroform, water and carbon tetrachloride.

RESULTS AND DISCUSSION

Lanthanide(III) complexes of L^1

The template reactions of 2,6-bis(2-aminophenoxymethyl)pyridine and 2,6-diformylpyridine in the presence of hydrated lanthanide perchlorates or nitrates in refluxing absolute ethanol or acetonitrile gave complexes with formula $[LnL^1][ClO_4]_3 \cdot xH_2O$ (Ln = La–Er, except Pm) and $[LnL^1][NO_3]_3$ (Ln = La–Lu, except Pm) in good yields. In general, the yield of the reaction decreases with decreasing ionic radii of the metal ions. The microanalytical data and yields are given in Tables 1 and 2. The conductivity data in dimethylformamide (dmf) for the $[LnL^1][ClO_4]_3 \cdot xH_2O$ are in the range reported for 2 : 1 electrolytes in this solvent (Table 1) [12] and suggest that one perchlorate ion is coordinated, at least in dmf. As we have previously found in other similar compounds [5], the nitrate complexes are less soluble than the corresponding perchlorate ones and their sparing solubility in common solvents has made difficult studies in solution and prevented the measurement of conductivity.

The TG-DTA shows the very high thermal stability of the lanthanide nitrate complexes and supports the proposed formulation. The macrocycle remains intact with the metal ions up to 350°C and no mass loss is observed under this temperature.

All the perchlorate complexes have similar IR spectra indicating that they have similar structures. The absence of carbonyl and amine bands, together with the appearance of an imine band at 1607–1628 cm^{-1}, indicates that condensation and cyclisation has occurred [13]. Medium-to-strong bands at 1580 and 1495 cm^{-1} for the two highest-energy pyridine-ring vibrations are also present. Nitate lanthanide complexes have similar IR spectra exhibiting ν(C=N) as a moderately strong band in the region 1607–1618 cm^{-1}. Information regarding the possible bonding modes of the nitrate and perchlorate anions may also be obtained from the IR spectra. The absorption bands at 1120 cm^{-1} (ν_3) and 627 cm^{-1} (ν_4) present in the perchlorate compounds are assignable to the asymmetric Cl—O stretching and Cl—O bending modes respectively [14–16]. The higher energy band shows considerable splitting, and is actually three maxima at 1144, 1121 and 1088 cm^{-1}, suggesting some interaction of at least one of the ClO_4^- anions with the metal. The greater intensity of the peak at 1121 cm^{-1} compared to those of the side peaks suggests the coexistence of ionic perchlorate [17]. All of the nitrate complexes present bands at 1460, 1280 and 1030 cm^{-1} assignable to the ν(N=O), $\nu_a(NO_2)$ and $\nu_s(NO_2)$ vibrations [18] and clearly identify these species as containing coordinated nitrate groups. The two highest frequency bands are separated 163–185 cm^{-1}, indicating strong interaction between the oxygen atoms from the nitrate with the lanthanide ions and it is typical of bidentate coordination [19,20]. When the

[a] Required values are given in parentheses.

IR spectra are recorded as KBr discs, a band at 1385 cm^{-1} can be observed; nevertheless, this band, which might be attributed to ionic nitrate, disappears when the spectra is run as fluorolube mulls indicating that there is no ionic nitrate in these compounds [21].

The FAB mass spectra were recorded using thioglycerol as matrix and all of them show the peak at 421 corresponding to $[L^1+1]^+$, confirming the monomeric [1+1] nature of the macrocycle. Likewise, it is possible to observe peaks due to the species $[LnL^1(ClO_4)_2]^+$ (Ln = La, Pr, Nd, Sm, Tb); $[LnL^1(ClO_4)]^+$ (Ln = La, Pr, Nd, Sm, Ho) and $[LnL^1]^+$ (Ln = La, Pr, Nd, Sm, Eu, Ho, Er) in the case of perchlorate complexes and peaks due to the species $[LnL^1(NO_3)_2]^+$ (Ln = Eu, Gd, Tb, Er, Tm, Lu); $[LnL^1(NO_3)]^+$ (Ln = Eu, Gd, Tb, Er, Tm, Lu) and $[LnL^1]^+$ (Ln = Eu, Gd, Tb, Er, Tm, Yb, Lu) for the nitrates.

The electronic absorption spectra of the perchlorate complexes in acetone solutions are virtually identical and present medium to intense bands with maxima at ca 380 nm and a shoulder at ca 350 nm which can be assigned to a transition either on the ligand or to a charge-transfer transition.

The ^1H NMR spectra of lanthanum, cerium, praseodymium, neodymium and samarium perchlorate complexes (Table 3) and the carbon NMR spectrum of lanthanum complex were run in $(CD_3)_2CO$ solution and they are consistent with the proposed formulations. The proton NMR spectrum of the La(III) complex gave the spected simple spectrum, indicating the integrity of the macrocycle in that medium. The spectra obtained after 12 h, 24 h and even some days were similar to the initial one, which indicates the stability of the complex in acetone solution. For the spectrum of the Sm(III) complex with its very small isotropic shifts and sharp signals, assignments could be made by simple comparison with the diamagnetic La(III) complex. For Ce(III), Pr(III) and Nd(III) complexes, resonance assignments were made on the basis of signal integrations and line width analyses. When the spectra of the paramagnetic complexes are compared with that of the lanthanum complex, significant changes in the chemical shifts, in particular for praseodymium and neodymium, are observed: one of the most important occurs for the imine proton signal which is shifted downfield by 6.95 ppm for Pr, 14.92 ppm for Nd and 2.15 ppm for Ce, and upfield by ca 0.5 ppm for Sm. The assignments for the ^{13}C NMR spectrum of the lanthanum complex

[a] The signals are overlapped.

were achieved with the aid of heteronuclear correlation spectroscopy (^1H-^{13}C COSY), distortionless enhancements by polarisation transfer (DEPT) spectroscopy, and substituent shift calculations: δ_C 164.89 (C_k); 156.24 (C_l); 153.32, 153.01 (C_e, C_j); 143.63 (C_a); 141.54 (C_n); 137.63 (C_c); 132.71 (C_m); 132.35, 125.59 (C_g, C_h), 123.40 (C_b), 121.33 (C_f), 115.74 (C_i); 74.19 (C_d).

It was not possible to run the ^1H NMR spectra of most of the nitrate complexes, because of their poor solubility. The ^1H NMR of lanthanum and samarium complexes were obtained using deuterium dimethyl sulfoxide as solvent. The ^1H NMR spectrum of lanthanum was recorded after different time intervals (3 min, 30 min and 4 h after solution). It becomes more complicated with passage of time and changes in intensity of the signals as well as the appearance of new ones are observed. So, the singlet at 9.24 ppm corresponding to the imine proton is going down in intensity meanwhile other at 9.03 ppm is going up. After four hours, a third signal at 8.67 ppm is also observed. Something similar happens with the signals corresponding to the ethylenic and aromatic protons. The behaviour of perchlorate complexes in this solvent is similar to this one and in either event it is apparent that these compounds are not very stable in this medium. It is possible that this behaviour may be due to the formation of carbinolamines through partial hydrolysis of imine bonds [22], or has been noted previously that there is a loss of metal from the complex on dissolution of polyoxaazamacrocyclic Schiff base complexes in DMSO [23]. In order to understand the real situation, FAB mass spectra of a solution of the $[LaL^1](NO_3)_3$ complex in DMSO were also recorded after different time intervals (immediately after dissolution, and after 1, 3 and 4 h) and all of them show the peak at m/z 421 corresponding to L^1 but no peak corresponding to the complex or to carbinolamines was observed what seems to indicate that the Schiff-base macrocycle L^1 remains intact in the DMSO solution with passage of time and the formation of carbinolamines could be rejected.

The reaction of 2,6-diformylpyridine and 2,6-bis(2-aminophenoxymethyl)pyridine in absolute ethanol or methanol in the absence of metal salt yields a pale yellow solid whose FAB mass spectrum shows a peak at m/z 421, which can be attributable to the Schiff-base diimine macrocycle L^1, nevertheless, the IR spectrum shows a band at 1626 cm^{-1} attributable to $\nu(C{=}N)_{imine}$ together with a carbonyl band at 1721 cm^{-1} indicating formation of acyclic as well as cyclic products. A number of attempts were made to purify the solid but no analytically pure material was obtained. This confirms the importance of the metal ion in directing the steric course of the condensation process; nevertheless, it must be stated that the complexing properties of counterions must be also taking into account in the planning of the template synthesis of macrocyclic

compounds with particular geometries around the metal ion.

Lanthanide(III) complexes of L^2

The reaction of 2,6-diformylfuran and 2,6-bis(2-aminophenoxymethyl)pyridine in absolute ethanol gave a solid whose IR spectrum shows a band at 1620 cm^{-1} attributable to ν(C=N) together with a carbonyl band at 1735 cm^{-1} indicating formation of acyclic as well as cyclic products. ^1H NMR confirms this situation and shows peaks at δ 9.80 and 8.55 corresponding to the aldehyde and imine protons, respectively. After many attempts to purify the solid, no analytically pure material was obtained.

Condensation between 2,6-bis(2-aminophenoxymethyl)pyridine and 2,5-diformylfuran in the presence of hydrated lanthanide perchlorates in absolute ethanol or acetonitrile gave complexes that agree with formula $[LnL^2][ClO_4]_3 \cdot xEt_2O$ (Ln = La–Er, except Pm) in high yields. The yields of the reactions, analytical and conductivity data are given in Table 4. The molar conductance values of the complexes measured in acetonitrile lie in the range reported for 2:1 electrolytes in this solvent, with the exception of Pr and Ho complexes whose values are in the range reported for 1:1 electrolytes [12].

All the IR spectra show a medium intense band at 1614 cm^{-1} attributable to the azomethine groups. None showed any absorption attributable to ν(C—O) of unchanged carbonyl groups or to ν(NH) of amine groups. The ν_3 and ν_4 bands of the ClO_4^- group occurring at 1121 and 627 cm^{-1} are again split, suggesting some interaction of at least one of the perchlorate anions with the metal [14–16]. Likewise, the greater intensity of the peak at 1121 cm^{-1} compared with the side peaks at 1143 and 1090 cm^{-1} suggests the coexistence of ionic perchlorate [17]. The FAB mass spectra of the complexes in thioglycerol show the peak corresponding to the free macrocycle L^2 at m/z 411, what confirms the monomeric [1+1] nature of the ligand.

The electronic absorption spectra were recorded for freshly prepared solutions in acetone and contain intense and medium bands with maxima at 406–408, 426–430 and 454–458 nm which can be assigned to a transition localised either on the ligand or to a charge-transfer transition.

The ^1H and ^{13}C NMR spectra of the diamagnetic $[LaL^2][ClO_4]_3$ complex was run in $(CD_3)_2SO$ and CD_3CN. The proton spectrum in deuterium dimethyl sulfoxide is complicated, indicating that different types of products are present and it is consistent with the behaviour reported for $[LaL^1]^{3+}$. On dissolution in CD_3CN, however, the expected simple spectra was obtained: δ_H 8.91 (s, 2 H, CH=N), 8.15 (t, 1H pyr H), 7.2–7.8 (m, 12 H, furan H and aryl H) and 5.80 (s, 4 H, CH_2—O) and δ_C 155.35, 153.91, 152.99, 150.42, 141.39, 137.72, 131.99, 126.21, 122.79, 122.64, 120.61, 116.77 and 75.76; this remains unchanged over a period of some days indicating its stability in CD_3CN.

(Received 6 August 1997; accepted 20 October 1997)

Abstract—The crystal and molecular structure of the tetrakis(flufenamato)(caffeine)(aqua)dicopper(II) $Cu_2(fluf)_4(caf)(H_2O)$, was determined by direct methods and Fourier techniques. The two copper(II) atoms are bridged by four carboxylate group, with the apical ligand of a water molecule around Cu(1), and a caffeine molecule around Cu(2). The spectral and magnetic properties are also discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper; structure; flufenamate.

Dimeric copper(II) acetate-type complexes constitute a class of compounds with a long history. The earliest reference to copper acetate is from the year 1597 [1]. In these complexes two copper(II) atoms are bridged by four carboxylate groups in a syn-syn arrangement [2]. The apical positions are usually occupied either by oxygen or nitrogen containing ligands. Each copper displays a distorted square pyramidal geometry. The dimeric complex usually show marked antiferromagnetism [3–5].

Fenamates (mefanamic, niflumic and flufenamic acids) constitute an important group of analgetics which are believed to act through inhibition of prostaglandin biosystems, like other anti-inflammatory analgeties [6]. It is known that some drugs act via chelation [7] or via the inhibition of metalloenzymes [8], but little is known about the modification of activity of most drugs when their ligating potential is utilized. The interaction of the copper(II) atom which plays a vital role in a number of quite different biological processes, with therapeutically administered drugs is a subject of considerable interest.

On the basis of spectral and magnetic properties of copper(II) flufenamate monohydrate a dimeric structure was proposed [9] similar to that of copper(II) acetate monohydrate [10].

In order to better understand some aspects of metal ion-drug interactions, we have studied here the complexation of flufenamic acid [flu, or *N*-(α,α,α-trifluoro-*m*-tolyl)anthranilic acid] in the presence of caffeine (caf). The derivative $Cu_2(fluf)_4(caf)(H_2O)$ was prepared, studied by spectral and magnetic methods and also characterized by X-ray crystallography.

EXPERIMENTAL

Preparation

$Cu(fluf)_2H_2O$ was prepared as described by Melník *et al.* [9]. The green $Cu_2(fluf)_4(caf)(H_2O)$ was prepared by treating caffeine with $Cu(fluf)_2H_2O$ in an equimolar ratio in hot methanol. The resulting solution was fil-

* Author to whom correspondence should be addressed.

tered and the filtrate left to stand at room temperature, allowing fine green crystals to precipitate out. These were filtered off, washed with cold methanol and dried at room temperature. Calc.: for $Cu_2(fluf)_4(caf)(H_2O)$: Cu, 7.59%; C, 51.71%; N, 10.05%; H, 3.62%. Found: Cu, 7.82%; C, 51.4%; N, 8.95%; H, 3.21%.

Spectral studies

Electronic spectrum in the region 10–28 kK was measured with a Perkin–Elmer 450 spectrophotometer. IR spectrum in region 400–3600 cm^{-1} was measured with an IR 10 spectrometer. In both cases, Nujol suspension techniques were used. The EPR spectrum of powdered sample was obtained using a Varian E4 spectrometer at room temperature.

Magnetic susceptibility measurements

Magnetic susceptibility of polycrystaline sample was measured by Faraday method over the temperature range of 77–300 K using a sensitive Cahn RG–HV electrobalance. $Hg[Co(NCS)_4]$ was used as calibrant [11], the value of 16.44 10^{-6} cm^3 g^{-1} was taken as its magnetic susceptibility [12]. Magnetism of sample was found to be field-independent. The effective magnetic moments were calculated from the equation $\mu_{eff} = 2.83\ (X_M \cdot T)^{1/2}$.

Crystallography

Data collection and cell refinement was carried out using Kuma (1991) KM4 diffractometer software [13]. Intensity data were corrected to Lorenz and polarization factors. The structure was solved by the heavy atom method with SHELX86 [14], and subsequent Fourier synthesis using SHELXL93 [15]. Anisotropic thermal parameters were refined for all nonhydrogen atoms. Geometrical analyses was performed using SHELXL93 [15]. The structures were drawn using ORTEP [15]. The final parameters after refinement are summarized in Table 1. Select bond distances and angles are in Table 2.

Supplementary material including non-hydrogen and hydrogen atomic coordinates ($\times 10^4$), anisotropic displacement parameters for nonhydrogen atoms [$Å^2 \times 10^3$] have been deposited at the Cambridge Crystallographic Data Centre. Observed and calculated structural factors are available on request from the correspondence author.

RESULTS AND DISCUSSION

The IR spectrum of the complex is very complex. The spectrum of $Cu_2(fluf)_4(caf)(H_2O)$ shows an absorption band at 3250 cm^{-1}. This frequency corresponds to the antisymmetric and symmetric OH stretch and confirms presence of water in the compound. The carboxylate stretching frequencies $\nu_{as}(COO^-)$ at 1625 cm^{-1} and $\nu_s(COO^-)$ at 1390 cm^{-1} are characteristic of copper(II) carboxylate compounds [17]. The stretching vibration of the C=N of heterocyclic ring appears at around 1590 cm^{-1} and on complexation a shift to higher frequencies is observed [18,19]. In the present complex this shift to about 1605 cm^{-1} may suggest bond formation by the metal atom to the nitrogen atom of caffeine, thereby increasing the dipolar contribution of $C{=}N^+$ in the heterocyclic ring.

The electronic spectrum of the complex shows band at 14.2×1000 cm^{-1} (band I) which was identified as *d-d* transition of the copper(II), and a shoulder at 27×1000 cm^{-1} (band II). The shoulder (band II) is characteristic of the bridging system with antiferromagnetic interaction [20].

The EPR spectrum obtained for the powdered sample of $Cu_2(fluf)_4(caf)(H_2O)$ at room temperature contained the typical absorption bands of an axially

Symmetry transformations used to generate equivalent atoms: #1 $x, -y+1/2, z$

symmetric binuclear species [21]. The spectral feature of the powder at room temperature shows absorptions at low and high fields (Hz_1 and Hz_2, respectively), with an asymmetrical absorption near 4500 G (H_T2). One absorption is missing because $|D| > h.\nu$ at the X-band frequency used. The spectrum can be interpreted using a spin Hamiltonian for axial symmetry

$$H = g_{II}\beta H_z S_z + g_\perp (H_X S_X + H_Y S_Y) + D(S_Z^2 + 2/3)$$

where $S = 1$ for the thermally accessible triple state and the other symbols have their usual meaning. The value obtained for the spin Hamiltonian parameters are: $g_\perp = 2.065$; $g_{II} = 2.356$; $\langle g \rangle = 2.169$ and $|D| = 0.326\ cm^{-1}$. The $|D|$ value of $0.326\ cm^{-1}$ is large compared to the magnetic quantities (approximately 3.00 G), but is smaller compared to vibrational frequencies. The values are comparable to those found in binuclear copper(II) carboxylates [17].

The molar susceptibilities corrected for diamagnetism and magnetic moments for $Cu_2(fluf)_4(caf)(H_2O)$ are reported at various temperature in Table 3 and graph μ_{eff} (B.M.) against T on Fig. 1.

The temperature susceptibility data can be described by the equation

Table 3. Magnetic data for $Cu_2(fluf)_4(caf)(H_2O)$ (-diamagnetic corr. $\times 10^6 = 347$)

symbols have the usual meaning. The spectroscopic splitting factor g_{av} was obtained from the EPR spectrum and used as constants in the least-square fitting process. The least-squares fitting was performed using a Fortran V program on an Univac 1108 computer. The energy separation ($-2J$) between the triplet and singlet states of 275(10) cm^{-1} which was obtained is similar to those of related copper(II) carboxylates [5,17].

Crystal structure of $Cu_2(fluf)_4(caf)(H_2O)$ with labeling of atoms is shown in Fig. 2. The compound exists as a dimer consisting of two non-equivalent distorted square-based pyramidal copper(II) polyhedra, joined by four carboxilic groups of flufenamato ions formed a square-based around each copper(II) atom. While the apex around Cu(1) is occupied by a water molecule at a distance of 2.141(5) Å, around Cu(2) by a caffeine at a distance of 2.239(5) Å. To our knowledge, this is the first example in this series of dimer copper(II) carboxylates, which the apex position are occupied by two different donor ligands. The Cu—Cu distance is 2.633(1) Å. The displacement of the copper(II) atoms from the basal plane toward the apical ligands also differ, Cu(1) by 0.189 Å and Cu(2) by 0.223 Å.

This molecule follows the trends already noted for this type of dimer. The Cu—Cu separation (2.633(1) Å) as well as Cu—L bond distances are similar to those observed in other Cu(II) carboxylates [2,22].

The bio-test of the compound is in progress and will be published elsewhere.

Abstract—In this paper the kinetics of the reaction of $[IrCl_5(H_2O)]^{2-}$ with CH_3CN has been studied. The reaction product was isolated and identified as $K_2[IrCl_5(CH_3CN)]\cdot 2H_2O$. The experimental rate constants show no constant order with respect to the acetonitrile concentration. A preferential solvation of $[IrCl_5(H_2O)]^{2-}$ by acetonitrile in water-acetonitrile mixtures is suggested to explain the data. The obtained optical absorption spectra of $[IrCl_5(CH_3CN)]^{2-}$ are in good agreement with data already published, but another interpretation is given for the observed *d–d* transitions. The low energy transition at about 24,000 cm^{-1} is predicted to be a singlet–singlet transition ($^1A_2 \leftarrow {}^1A_1$), and not a singlet–triplet transition as proposed in other work. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: kinetics; optical absorption spectra; singlet–singlet transition.

Recently transition metal complexes of rhodium and iridium gained renewed interest because of their applications in photographic industry where these compounds are important as doping agents for manufacturing of AgX photographic emulsions [3]. In this context different authors emphasised the importance of mono-substituted transition metal complexes [4–6].

Up to now, little has been reported on substitution reactions of transition metal complexes in mixed solvents, with one or both of these solvents acting as potential ligands. In some cases a preferential solvation of transition metal ions by organic solvents is observed. Some transition metal complexes discriminate in favour of the organic solvent over water with respect to their first shell coordination. Earlier studies on the thermal solvolysis of $[Cr(NCS)_6]^{3-}$ in acetonitrile-water mixtures revealed the strong preference of $[Cr(NCS)_6]^{3-}$ for CH_3CN in CH_3CN–H_2O mixtures [1]. Also *trans*-$[Cr(NH_3)_2(NCS)_4]^-$ in water-acetone mixtures shows a strong preference for acetone in its solvation sphere [2].

In our work on the synthesis and study of the chemical behaviour of complexes with the general formula $[MCl_5X]^{2-}$, M = Rh(III) and Ir(III), X = neutral ligand, we investigated the reaction of $[IrCl_5(H_2O)]^{2-}$ with acetonitrile in mixtures of H_2O—CH_3CN:

$$[IrCl_5(H_2O)]^{2-} + CH_3CN \xrightarrow{k} [IrCl_5(CH_3CN)]^{2-} + H_2O \quad (1)$$

The unusual dependence of the formation rate on the concentration of acetonitrile urged us to examine the kinetics of the reaction in more detail. In order to explain the observed kinetics we suggest a preferential solvation of $[IrCl_5(H_2O)]^{2-}$ by CH_3CN in water-acetonitrile mixtures.

An interpretation of the optical absorption spectrum of $[IrCl_5(CH_3CN)]^{2-}$ is reported, which differs from the one presented earlier [7]. This interpretation is compared with the data for other iridium compounds [8,9].

EXPERIMENTAL

Materials

As a starting product $K_2[IrCl_5(H_2O)]$ is used. This complex was obtained by aquation of $K_3[IrCl_6]$ dissolved in H_2O according to the reaction (eqn (2)) [10].

* Author to whom correspondence should be addressed.

$$[IrCl_6]^{3-} + H_2O \rightarrow [IrCl_5(H_2O)]^{2-} + Cl^- \quad (2)$$

The synthesis of $K_2[IrCl_5(CH_3CN)] \cdot 2H_2O$ was reported earlier by Lebedinskii and Fedorov [11] and by Catsikis and Good [7]. An aqueous solution of $K_3[IrCl_6]$ (5×10^{-2} M) was heated for three hours at 50°C. Under these circumstances, the main complex in the solution is $[IrCl_5(H_2O)]^{2-}$ (>95%) [10]. A 10-fold excess of acetonitrile was added, and the solution was boiled for one min. After cooling, the desired compound precipitated immediately. Addition of absolute ethanol to the filtrate increased the yield. The salt was washed first with absolute ethanol and then with ether. It was dried under vacuum over P_2O_5.

An elemental analysis was performed. The amount of H_2O was determined by a Karl-Fisher titration, K^+, Ir^{3+} were respectively determined by AAS and ICP. Cl^- was determined by Ion Chromatography, after the complex was decomposed by boiling it for 1 h in a solution of Na_2CO_3 (10^{-2} M). The Cl^--ligands are released and the solution turns blue according to the formation of $IrO_2 \cdot 2H_2O$ [12]. Anal: $H_2O = (7.3 \pm 0.3)\%$, $K = (15.0 \pm 0.4)\%$, Cl^- $(36.0 \pm 0.7)\%$, $Ir = (35.5 \pm 0.4)\%$ Calcd for $K_2IrCl_5(CH_3CN) \cdot 2H_2O$: $H_2O = 6.86\%$, $K = 14.8\%$, $Cl^- = 33.6\%$, $Ir = 36.3\%$.

RESULTS

UV-visible absorption spectrum

The UV-visible absorption spectrum of $[IrCl_5(CH_3CN)]^{2-}$ in an aqueous solution is given in Fig. 1. Comparison of our spectrum with the data reported in reference [7] indicate some differences in the position of the absorption peaks as well as in the values of the molar extinction coefficients (see Discussion).

Infrared spectrum

The infrared spectrum in the region 4000–600 cm^{-1} of $K_2[IrCl_5(CH_3CN)] \cdot 2H_2O$, obtained in a KBr pellet, corresponds well with the one reported in literature [7], except for the value of the ν(CN) stretching vibration (Table 1).

Kinetics

When the reaction given in eqn (1) is investigated at a temperature range of 22°C to 42°C, its rate is slowed down sufficiently, to allow a kinetic investigation. Since we observed $[IrCl_5(CH_3CN)]^{2-}$ to be photochemical labile, all experiments were carried out in the absence of light. We checked the stability of $[IrCl_5(CH_3CN)]^{2-}$ spectrophotometrically. The spectral observations indicate that further no secondary reactions occur below 60°C.

The reaction rate was studied spectrophotometrically. The solutions were ca 5 mM respect to the aquapentachloro-iridate(III) complex. The concentration of acetonitrile varied from 0.5 M–7.0 M. $NaClO_4$ was used to keep the ionic strength at a constant value of 0.1 M or 1.0 M. $HClO_4$ was used to adjust the pH of the solution. The solutions were placed in 1 cm quartz cells housed in a thermostated cell holder in the spectrophotometer.

The spectral progress of the reaction of the aquapentachloro-iridate(III) complex with acetonitrile exhibits three isosbestic points at 526 nm, 500 nm and 402 nm. With the reaction order of eqn (1), being first order to the concentration of $[IrCl_5(H_2O)]^{2-}$ in the presence of excess acetonitrile, the system is described by the rate law (eqn (3)):

$$-\frac{d[\{IrCl_5(H_2O)\}^{2-}]}{dt} = k_{exp} \cdot [\{IrCl_5(H_2O)\}^{2-}] \quad (3)$$

The apparent concentration of $[IrCl_5(H_2O)]^{2-}$ is calculated from (eqn (4)):

$$[\{IrCl_5(H_2O)]^{2-}]_t = [\{IrCl_5(H_2O)\}^{2-}]_0 - [\{IrCl_5(CH_3CN)\}^{2-}]_t \quad (4)$$

$[\{IrCl_5(CH_3CN)\}^{2-}]_t$ is measured from the spectral changes at 368 nm, corresponding to the absorption maximum of $[IrCl_5(CH_3CN)]^{2-}$. The experimental rate constants k_{exp} are presented in Table 2. For acetonitrile concentrations below 1.0 M, a deviation of linearity is observed near the end of the reaction. The final spectrum is slightly different from the one in Fig. 1.

Earlier studies by Chang and Garner [13] show that $[IrCl_5(H_2O)]^{2-}$ can undergo a further aquation according to the reaction given in eqn (5). The reaction is first order with respect to the aquapentachloro-iridate(III) ion. The aquation rate constant does not depend on the pH of the solution and it decreases as the ionic strength is increased.

$$[IrCl_5(H_2O)]^{2-} + H_2O \xrightarrow{k_{aq}} [IrCl_4(H_2O)_2]^- + Cl^- \quad (5)$$

Since they measured the values of k_{aq} at an ionic strength of 2.2 M–3.7 M, we repeated their experiments in pure aqueous solutions at 42°C and an ionic strength of 0.1 and 1.0 M corresponding to our reaction conditions. Values of 1.5×10^{-5} s^{-1} and 1.0×10^{-5} s^{-1} are respectively obtained for those reaction conditions.

DISCUSSION

Spectral data (infrared and UV-visible)

Catsikis and Good reported only on the position of the absorption maxima and the corresponding extinc-

with our spectrum is found (see Table 1). Comparison literature data of other transition metal complexes of the form $[MX_5(CH_3CN)]$ (Table 4) shows that coordinated acetonitrile exhibits a sharp absorption peak in the region of 2320 cm^{-1} to 2330 cm^{-1}. For $Cs_2[RhCl_5(CH_3CN)] \cdot 2H_2O$, a slightly different value is reported by Catsikis and Good [14]. From earlier studies in this laboratory, $Cs_2[RhCl_5(CH_3CN)] \cdot 2H_2O$ is available and we recorded the IR-spectrum. A splitted band with energies of 2304cm^{-1} and 2325 cm^{-1} is observed. The shift of about 60 cm^{-1} for $K_2[IrCl_5(CH_3CN)] \cdot 2H_2O$ is very unlikely, which makes the identity of the product of Catsikis and Good questionable.

Concerning the identification of the optical absorption spectrum we have to point out the difference between the spin-allowed and the spin-forbidden transitions on one hand, and secondly we have to draw the attention to the influence of the introduction of the hetero ligand on the descent in symmetry, causing a split of the degenerate excited states.

The here considered transition metal complex has a t_{2g}^6 ground state configuration ($^1A_{1g}$) and its low lying excited states belong to a $t_{2g}\,{}^5e_g^1$ configuration. For the corresponding hexa-chloro complex, i.e. $[IrCl_6]^{3-}$, the $t_{2g}\,{}^5e_g^1$ configuration gives rise to the $^3T_{1g}$, $^3T_{2g}$, $^1T_{1g}$ and $^1T_{2g}$ representations. From the optical absorption spectrum of $[IrCl_6]^{3-}$ (dotted curve in Fig. 1) the following *d-d* transitions can be identified; $^3T_{1g} \leftarrow {}^1A_{1g}$ at 16,300 cm^{-1}, $^3T_{2g} \leftarrow {}^1A_{1g}$ at 17,900 cm^{-1}, $^1T_{1g} \leftarrow {}^1A_{1g}$ at 24,100 cm^{-1} and $^1T_{2g} \leftarrow {}^1A_{1g}$ at 28,100 cm^{-1} [8]. Although it is hard to interpret and to identify the singlet–triplet transitions (dotted curve in Fig. 1), it is nevertheless obvious that an energy gap of a few 1000 cm^{-1} between the triplet and singlet states is characteristic for such transition metal complexes. As such the singlet–triplet transitions for $[IrCl_5(CH_3CN)]^{2-}$ should be expected at much lower energy than given by Catsikis and Good [7]. Moreover, singlet–triplet *d-d* transitions for octahedrally bound complexes of this kind of compounds are characterised by much smaller intensities than those given by Catsikis and Good (Table 3). It seems then also evident to us to assign the low intensity band at 18,500 cm^{-1} in Fig. 1 as a singlet–triplet transition.

Tetragonal distortion ($O_h \rightarrow C_{4v}$), implied by the substitution of a Cl^- ligand by a CH_3CN ligand causes the T_{1g} and T_{2g} states (in an octahedral parentage scheme) to split in a A_2 and E state for T_{1g}, and in B_2 and E state for T_{2g}. So, for mono-substituted transition metal complexes of this kind, four *d-d* transitions should be observed, but the $^1A_2 \rightarrow {}^1A_1$ and $^1B_2 \rightarrow {}^1A_1$ transitions are allowed only when vibronic coupling is considered. In general the effect of vibronic coupling is not large enough for mono-substituted rhodium and iridium compounds, and rarely a split-

ting of the 2 spin-allowed singlet–singlet transitions is observed [13–15,17–22]. For some complexes the splitting of the first spin-allowed transition is observed, but never a splitting of the second spin-allowed transition [18–20]. This can be explained by looking at the C_4-symmetry representations; here the transitions to the ^1A state are allowed, but those to the ^1B states are forbidden.

We interpret the other transitions observed in Fig. 1 as the $^1A_2 \leftarrow {}^1A_1$ transition at 23,700 cm^{-1}, the $^1E \leftarrow {}^1A_1$ transition at 27,100 cm^{-1} and the $^1E \leftarrow {}^1A_1$ transition at 31,100 cm^{-1}.

A ligand field calculation for $[IrCl_5(CH_3CN)]^{2-}$ was made, using the STATED computer program. Details for the application of this program are given elsewhere [24,25]. We predicted the $^1A_2 \leftarrow {}^1A_1$ transition at approximately 24,000 cm^{-1}; the first $^1E \leftarrow {}^1A_1$ transition at 26,500 cm^{-1}, the second $^1E \leftarrow {}^1A_1$ transition at 31,800 cm^{-1}, and the $^1B_2 \leftarrow {}^1A_1$ transition at 34,300 cm^{-1}. The energies predicted for these transitions correspond pretty well with the experimental results. An even more important conclusion is that the low energy transition at 23,700 cm^{-1} is predicted to be a singlet–singlet transition, and not a triplet–singlet transition as proposed by Catsikis and Good [7]. So $[IrCl_5(CH_3CN)]^{2-}$ can be considered as an example were vibronic coupling is large enough to cause a splitting of the first transition ($^1T_1 \leftarrow {}^1A_1$) and to have two distinguishable transitions to $^1A_2$ respectively to ^1E. The same effect is also observed for some other $[M(NH_3)_5X]^{n+}$ transition metal complexes [18–20] as explained above.

Kinetics

Comparison of our values of k_{aq} with the data presented in Table 2 shows that at high concentrations of CH_3CN (>1 M), the aquation reaction (eqn (5)) is negligible. This is in agreement with the observation that the final spectrum of the reaction progress equals Fig. 1 at high concentrations of CH_3CN. The values of k_{aq} in an aqueous solution indicate that at 0.5 M CH_3CN the aquation reaction starts to contribute to the total reaction, which explains the small deviation of linearity of $\ln([\{IrCl_5(H_2O)\}^{2-}])$ in function of time at 0.5 M CH_3CN.

The data show that k_{exp} does not depend on the pH. This is expected, since $[IrCl_5(H_2O)]^{2-}$ shows only very weak acid properties, the pK_a being 8.8 [10]; 10.1 [26]. A small effect is noted when the ionic strength is raised from 0.1 M to 1.0 M: k_{exp} decreases by about 17%. The Arrhenius activation energy, obtained from a plot of $\ln(k_{exp})$ versus 1/T at a concentration of CH_3CN of 4.5 M and $\mu = 0.1$ M is (30.0±0.5) kcal/mole.

The dependence of k_{exp} on the concentration of acetonitrile is rather unusual. There is no linear relationship between k_{exp} and the concentration of acetonitrile. This implies that the reaction kinetics can not be described by a simple pseudo first order reaction, for which the experimental rate constant is given by $k_{exp} = k \cdot [CH_3CN]^n$, with n expected to be equal to one. A calculation of the order n from a plot of $\ln(k_{exp})$ in function of $\ln([CH_3CN])$ shows that n varies from 1.2 to 1.9 when the acetonitrile concentration varies from 0.5 M to 7.0 M, as shown in Table 5.

Table 5. Formal reaction order n as a function of the bulk acetonitrile concentration

$[CH_3CN]$ (mol/l)	n
0.5–1.5	1.2
1.5–2.5	1.4
2.5–4.5	1.6
4.5–7.0	1.9

To explain this behaviour, one must be aware of the fact that different interactions have to be taken into account in mixed solvents. Evidence exists for short distance ion–solvent interactions, which lead to immediate reagent surrounding, significantly different of the composition of the bulk medium. More specific, it is shown that some transition metal complexes show preferential solvation by an organic solvent in binary mixtures with water. Behrendt *et al.* [1] studied the aquation of $[Cr(NCS)_6]^{3-}$ in CH_3CN–H_2O mixtures. There kinetic results show that the experimental solvolysis rate constant decreases with increasing mole fraction of CH_3CN. The NMR method for determining the composition of the solvation shell of a paramagnetic solute [27] has been applied to reveal a strong preference of $[Cr(NCS)_6]^{3-}$ for CH_3CN in CH_3CN–H_2O mixtures. Similar results are obtained for *trans*-$[Cr(NH_3)_2(NCS)_4]^-$ in acetone-water mixtures [2]. A similar preference of the complex ion for acetone is demonstrated. Our kinetic results point also in the direction of a preferential solvation of $[IrCl_5(H_2O)]^{2-}$ by acetonitrile. If this indeed occurs, the concentration of CH_3CN in the solvation sphere will be higher then the bulk concentration. This would explain why the experimental rate constant shows no constant order with respect to the bulk acetonitrile concentration.

CONCLUSION

In this paper an optical absorption investigation of $[IrCl_5(CH_3CN)]^{2-}$ in an aqueous solution is presented. The obtained spectra are in rather good agreement with data published before, but another interpretation is given for the observed *d-d* transitions. The low energy transition at about 24,000 cm^{-1} is predicted to be a singlet–singlet transition ($^1A_2 \leftarrow {}^1A_1$), and not a singlet–triplet transition as proposed in other work. As such the $[IrCl_5(CH_3CN)]^{2-}$ compound

can be considered as an example were vibronic coupling is large enough to cause a splitting of the (in an octahedral parentage scheme) first $^1T_{1g} \leftarrow {}^1A_{1g}$ transition of the corresponding hexa-compound.

Our kinetic results suggest a preferential solvation of $[IrCl_5(H_2O)]^{2-}$ by acetonitrile in water-acetonitrile mixtures.

The effect of chelate rings on the structure of copper(II) compounds with triamine derivatives. The crystal structure of [Cu(dptSS)Cl_2]

A. Hatzidimitriou and C. A. Bolos*

Department of General and Inorganic Chemistry, Lab. of Inorganic Chemistry, Aristotle University, Thessaloniki 54006, Greece

(Received May 27 1997; accepted 20 October 1997)

Abstract—The reaction of Schiff bases of dipropylenetriamine (dpt) with 2-thiophenecarboxaldehyde, 2-furaldehyde and pyrrol-2-carboxaldehyde with copper(II) salts in 1 : 2 : 1 molecular ratios, gave compounds of general formula [$CuLX_2$]; [L = Schiff base of dipropylenetriamine with 2-thiophenecarboxaldehyde (dptSS), 2-furaldehyde (dptOO) and pyrrol-2-carboxaldehyde (dptNN) and X = Cl, Br]. The compounds have been characterised by elemental analyses, molar conductance, magnetic, electronic and IR spectral studies. The X-ray crystal structure of the blue-green [Cu(dptSS)Cl_2] has also been solved. Copper(II) is five coordinated with three Cu—N contacts [2.025(3) Å, 2.064(3) Å and 2.004(3) Å] from the tridentate dptSS and two contacts from chlorine atoms at distances 2.545(1) Å and 2.290(1) Å. The five donors form a distorted square pyramid which contains the N(1), N(2), N(3) and Cl(2) on the basal plane and Cl(1) on the apical position. The IR and the electronic spectra are in accordance with the established features of the structure. The molar conductivity indicates that the complexes are 1 :1 electrolytes, while the magnetic moments are consistent with monomeric copper(II) units. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper complexes; dipropylentriamine Schiff bases; crystal structure.

The relationship between structure and the chelate ring size of multidentate ligands (i.e. polyamines, Schiff base derivatives etc.) in coordination compounds is a subject of considerable importance, because this relation provides information on physical and chemical properties, biological activities etc. The first takes into account the geometry, the magnetism and spectroscopy coming from the mode of the ligand's coordination and its conformation [1–6]. The second view is related with the variation in biological activity and cytotoxicity depending on the chain length of the ligands and the oxidation state of the metal atom [7,8].

Among the metal atoms, copper(II) readily forms complexes with polyamines and their Schiff bases [9–12]. The geometry of the copper(II) complexes is related to the size of the polyamine ligand and the additional moieties. A recent detailed study [9] has shown that the reaction of Schiff base ligand 1,7-dithenylidine-1,4,7-triazaheptane (dienSS) with $CuCl_2 \cdot 2H_2O$ yields a polymeric compound with extended linear chain structure. The $[Cu_3(dienSS)_2Cl_6]_x$ repeating units occur via a double $CuCl_2Cu$ bridge that connects highly elongated octahedra and a single CuClCu bridge that connects the octahedra with $[CuCl_4]^{2-}$ units. The factors they may rationalise the observed geometry are: (a) vibronic forces; (b) the increased acceptor abilities of the $[Cu(dienSS)]^{2+}$ units, and (c) the inability of Cl^- to afford higher coordination numbers to Cu(II).

Continuing our studies on similar systems, we have prepared and studied a series of Cu(II) complexes with Schiff bases of dipropylenetriamine with heterocyclic aldehydes and we therefore report in this paper the X-ray crystal structure of the [Cu(dptSS)Cl_2] complex. A comparison between the polymeric $[Cu_3(dienSS)_2Cl_6]_x$ and the monomeric [Cu(dptSS)Cl_2] complex is also discussed. The different heterocyclic aldehydes were used to prepare the dipropylenetriamine Schiff bases due to their ability to change the charge on the Cu(II)

atom [2], transforming thus the complexes to bioactive reagents.

EXPERIMENTAL SECTION

Materials

$CuCl_2 \cdot 2H_2O$, $CuBr_2$, pyrrol-2-carboxaldehyde, 2-furaldehyde and 4-azaheptamethylenediamine were purchased from Merck and used as received. 2-Thiophenecarboxaldehyde were purchased from Aldrich Chemical Company. The solvents used were reagent grade and were used without any further purification.

Preparation of the complexes

The complexes I–V (Table 1) were prepared from the product of the condensation reaction of dipropylenetriamine with the heterocyclic aldehydes and its further reaction with $CuCl_2 \cdot 2H_2O$ or $CuBr_2$.

[Cu(dptSS)Cl_2]. (I) was prepared as follows: 1.31 g (10 mmol) of dipropylenetriamine was stirred for 20 min with 2.24 g (20 mmol) of 2-thiophenecarboxaldehyde and the oily product was diluted with 20 ml of methanol. A solution of $CuCl_2 \cdot 2H_2O$ (1.71 g, 10 mmol) in 10 ml of methanol was added. The resulting blue-green mixture was then allowed to evaporate slowly kept at 4°C. After 5 days blue-green crystals of the compound (I) were isolated by filtration. Yield: 62%.

[Cu(dptSS)Br_2]. (II) was prepared in a similar manner using $CuBr_2$ and was obtained as bluish-green microcrystalline powder in 80% yield.

[Cu(dptOO)Cl_2]. (III)-Dipropylenetriamine 1.31 g (10 mmol) was mixed with 2.62 g (20 mmol) of 2-furaldehyde and the oily product was diluted with 20 ml of methanol. A solution of $CuCl_2 \cdot 2H_2O$ (1.71 g, 10 mmol) in 10 ml of methanol was added. The resulting green mixture was concentrated to 15 ml volume by rotary evaporation. The solution was allowed further to evaporate in low temperature (4°C). After 48 h green crystals of compound III were isolated in 67% yield.

[Cu(dptOO)Br_2]. (IV) was prepared by an almost similar manner. 1.31 g (10 mmol) of dipropylenetriamine was mixed with 2.62 g (20 mmol) of 2-furaldehyde and the oily product was diluted with 20 ml of methanol. A solution of $CuBr_2$ (2.23 g, 10 mmol) in 20 ml of MeOH was added. The resulting solution was then allowed slowly to evaporate in the air. After 2 weeks bluish-green microcrystalline powder was isolated by filtration, washed with ether, and dried *in vacuo*. Yield: 80%.

[Cu(dptNN)Cl_2]. (V) 1.31 g (10 mmol) of dipropylenetriamine and 1.94 g (20 mmol) pyrrol-2-carboxaldehyde were mixed in methanol (15 ml). To the resulting mixture, a solution of $CuCl_2 \cdot 2H_2O$ (1.71 g, 10 mmol) in methanol was added. The resulting brown solution was concentrated to 10 ml volume by rotary evaporation. Then, the brownish precipitate was filtered off, washed with ether and dried *in vacuo*. Yield: 60%.

The complexes were recrystallised from hot methanol and they are soluble in methanol, water, DMSO and DMF but insoluble in $CHCl_3$, CCl_4 and ether.

Methods

C, H and N were analysed with a Perkin–Elmer elemental analyser and copper was determined by

atomic absorption spectroscopy. IR spectra were recorded with a Perkin–Elmer 1650 FT-IR spectrophotometer in the 400–4000 cm^{-1} region using KBr pellets and in the 200–400 cm^{-1} region using polyethylene disks. Electronic spectra were obtained in methanolic solution on a Shimadzu UV-160A spectrophotometer in the 200–1100 nm region. Molar conductivities were measured with a WTW conductivity bridge and a calibrated dip type cell. Magnetic susceptibilities of powdered samples were recorded by the Faraday method with a home-made balance against Hg[Co(SCN)$_4$] as calibrant. Diamagnetic corrections were estimated from Pascal constants.

Theoretical treatments

Molecular mechanics calculations were carried out using the PCMODEL version 6.0 package [13] implemented on an IBM RISK 6000 computer. The MMX force field parameters used were those standard in the program. The coordinates used were those obtained from the crystal structure analysis.

Collection of X-ray data

A crystal suitable for X-ray diffraction was mounted on an Enraf-Nonius CAD4 diffractometer using graphite-monochromatised Mo–K_α radiation ($\lambda = 0.71069$ Å). Unit cell parameters and orientation matrix were obtained from the setting angles of 25 reflections ($12^\circ < \theta < 15^\circ$) and refined by least-squares. Data were collected at room temperature using an $\omega/2\theta$ motion. No significant decay of the standard intensities, collected 27 times during the data acquisition, was observed. Crystallographic data and other pertinent information are in Table 2. All data were corrected for Lorenz and polarisation as well as for absorption using the DIFABS method. The position of the copper atom and the two chlorine atoms were found by direct methods using SHELXS86 [14] and all subsequent calculations were performed using CRYSTALS [15]. All hydrogen atoms were found but only the positions of those belonging to the methylene and amino groups of dipropylenetriamine were refined. The rest of them were positioned geometrically with recalculation after each refinement cycle. All non-hydrogen atoms were refined anisotropically. In the final stage of the refinement, an overall isotropic extinction parameter was introduced. Final refinement was continued until the sum of the shift/esd (estimated standard deviation) ratio was less than 0.01. Selected bonds and angles are in Tables 4 and 5. Illustrations were drawn using ORTEP II [16]. Further experimental details are deposited with the Editor.

RESULTS AND DISCUSSION

The reaction between Schiff bases, dptSS or dptOO or dptNN and copper salts in methanol yielded solid, air stable, coloured microcrystalline or crystalline compounds of the general formula [Cu(dptYY)X$_2$] (Table 1). Their elemental analyses confirm the proposed stoichiometry. The d^9 electronic configuration of copper(II) is confirmed by room temperature magnetic measurements.

Spectral studies

In IR spectra of the ligands (Table 3), the characteristic bands of N—H and C—H stretching vibrations of polyamines were observed at the regions of 3289–3380 and 2900–3000 cm^{-1} respectively [17,18]. The band at the region 3289–3380 cm^{-1}, which could be assigned to secondary amine group of the Schiff bases, is shifted upon coordination to lower wave numbers. This shift is strong evidence that the nitrogen atom of the secondary amino group is binding to copper atom. The band at 1660 cm^{-1} is assigned to the stretching vibration of C=N and shows the formation of the Schiff bases [19]. This band in the complexes spectra is displaced 20–30 cm^{-1} lower, evidence which supports the binding between copper and the nitrogen atoms of —CH=N— moieties. According to the above observations, we may conclude that the ligands are coordinated in a tridentate mode. The formation of the Cu—N bond is further confirmed [18] from the band at 500–520 cm^{-1}. Lastly, the peaks at 310–325 cm^{-1} and 245–247 regions are due to the stretching vibration [20] of the Cu—Cl and Cu—Br bonds, respectively.

The vis spectra (Table 1) of the complexes I, II and III, in MeOH, show a broad band centered at 633–646 nm, while the IV and V complexes show a shoulder at 585 and 500 nm respectively. These bands are of low intensity and are assigned to a Cu(II) *d-d* transitions [21]. The UV spectra, of all complexes, show very strong bands at 263–290 nm which may be assigned to intraligand transitions, whereas the bands at 321 and 339 nm of IV and V complexes respectively may be tentatively assigned to charge transfer transitions.

The combination of the elemental analysis, the IR and UV-vis spectra shows that the Schiff bases bind with copper in a tridentate fashion through the three nitrogen atoms. X-ray crystallography was used to confirm the molecular geometry (see below).

The values of the magnetic moment for the I–V complexes (Table 1) are in the range of 1.73–1.80 BM, which is consistent with monomeric copper(II) units. Finally the molar conductivity values (Table 1) of the compounds, in methanol, show that they behave as 1 : 1 electrolytes [22].

[Cu(dptSS)Cl_2] molecule with the atomic numbering scheme is shown in Fig. 1. The geometry around the metal ion can be described as distorted tetragonal pyramidal with the N(1), N(2), N(3) and Cl(2) atoms forming the square base and Cl(1) on the apical position, at distances from the copper atom 2.025(3) Å, 2.064(3) Å, 2.004(3) Å, 2.290(1) Å, and 2.545(1) Å respectively. All distances are similar to those found in previously reported copper complexes with analogous ligands [9,12]. The equation of the best basal plane is $1.616x-6.573y-8.218z = -5.266$ and the N(1), N(2), N(3), Cl(2) atoms forming it can be considered as lying on it, as their deviations are smaller than the error (0.05 Å). The copper atom was found 0.34(5) Å above this mean plane while the Cl(1) atom was lying in the same direction as copper and at a distance of 2.84(5) Å above the plane.

The carbon atoms C(6), C(7) and C(8) of the dipro-

pylenetriamine ligand lie below the previous best basal plane with a maximum deviation of 2.036(6) Å for C(7), while the atoms C(9), C(10) and C(11) lie above the plane with a maximum deviation of 0.78(6) Å for C(11).

The six member coordination rings adopt the first one the *chair* and the second the *boat* conformation. The atoms N(3), C(11), C(9) and N(2) from the *chair* like ring form a plane with equation $0.452x+9.352y+6.013z=6.873$ and a maximum deviation of 0.07 Å (equal with the error) for C(11). The atoms C(10) and Cu lie at the opposite sides of this plane with deviations 0.72(6) Å and 0.93(6) Å, respectively. The mean plane passing through the atoms N(1), C(6), C(8) and N(2) from the *boat* like ring follows the equation $6.478x+4.905y+11.516z=4.280$. The atoms C(7) and Cu lie at the same side of this plane with deviations 0.65(6) Å and 1.19(7) Å, respectively. The deviations of the atoms forming the best plane have a mean value of 0.15(5) Å, evidence that this ring is slightly distorted.

The ability of the two six membered coordination ring to adopt either the *boat* or the *chair* conformation gives rise to three possible conformations for the complex, that is *chair/chair*, *boat/boat* and *chair/boat*. The relative energies of these conformations have been calculated by means of molecular mechanics calculations. The starting geometry was this found from the X-ray structure. In each calculation the X-ray geometry has been distorted and a full optimisation has been performed including both the heavy and the hydrogen atoms.

All the above conformation have been found as minima in the potential energy surface of the complex. The optimised *chair/boat* conformation, which is almost identical with the geometry found from the X-ray structure, is not the global minimum in the potential energy surface. Instead the *chair/chair* conformation is the global with the *chair/boat* and *boat/boat* ones found as local minima located 0.6 and 1.4 kcal mol^{-1} higher in energy, respectively. The preference of the complex to adopt the second most stable conformation must be due to crystal packing effects. This is also supported by the very small energy difference between the *chair/boat* and *chair/chair* structure (0.6 kcal mol^{-1}).

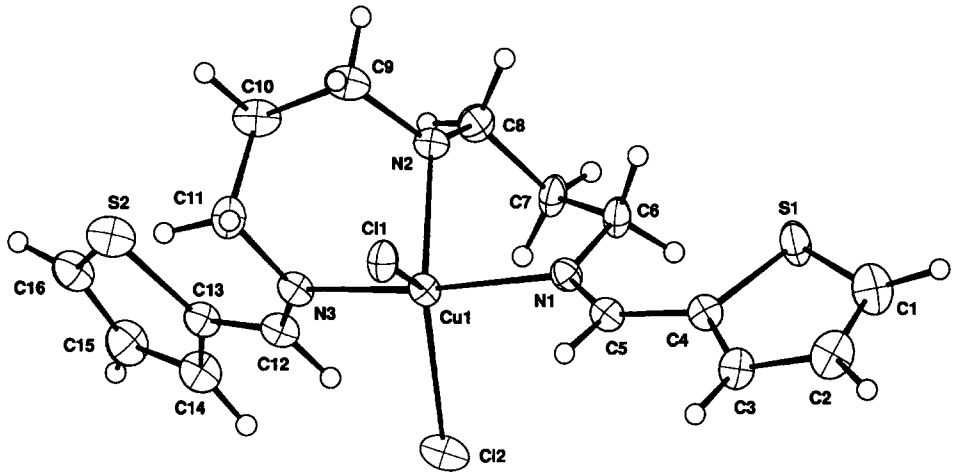

Fig. 1. ORTEP plot showing the molecular structure of the [Cu(dptSS)Cl_2] with the atomic numbering scheme. Atomic thermal ellipsoids are presented at the 50% probability level.

A comparable study of the molecular structures of the complexes [Cu_3(dienSS)$_2Cl_6$]$_x$ [9] and [Cu(dptSS)Cl_2] reveals the reasons leading the first complex being a polymer and forcing the second to remain a monomer.

As far as the polymeric complex [Cu_3(dienSS)$_2Cl_6$]$_x$ is concerned the [Cu(dienSS)] coordination rings are five membered. The size of these two five-membered rings and especially their arrangement (both rings atoms are almost coplanar) gives no protection to the copper ion, allowing chlorine atom from a neighbouring [Cu(dienSS)Cl_2] unit to coordinate the copper atom, forming thus a polymer of coordination octahedra.

In the case of the [Cu(dptSS)Cl_2] complex the existence of one more methylene group in each coordination ring, results in the transformation of the five-member rings of the complex [Cu_3(dienSS)$_2Cl_6$]$_x$ to six-member ones. These formed rings consequently are forced to retain either the *boat* or the *chair* like conformation. The orientation of these *chair* and *boat* like rings above and below the coordination plane, forces the complex [Cu(dptSS)Cl_2] to remain five coordinated, giving no room of approaching to any other bridging atoms to form polymers. As a consequence of the formed chelate rings sizes and their orientation, the complex [Cu(dptSS)Cl_2] is forced to remain a five coordinated monomer, adopting the optimum geometry of the distorted tetragonal pyramid.

Synthesis and magnetic properties of a new oxalato-bridged heterotrinuclear complex, $[NiCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]\cdot H_2O$. A rare case of antiferromagnetic coupling between Cr(III) and Ni(II) ions

(Received 28 July 1997; accepted 6 November 1997)

Abstract—A new heterotrinuclear complex, $[NiCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]\cdot H_2O$, has been synthesized by self-assembling $[Cr(bipy)(C_2O_4)_2]^-$ building blocks with Ni(II) ions. The synthesis way consists of the reaction of a barium(II) precursor, $[BaCr_2(bipy)_2(C_2O_4)_4(H_2O)]\cdot H_2O$, with nickel(II) sulfate. Variable-temperature magnetic susceptibility measurements indicate an antiferromagnetic coupling between Ni(II) and Cr(III) ions ($J = -0.6$ cm^{-1}, $\mathbf{D}_{Ni} = 0.4$ cm^{-1}, $\boldsymbol{H} = -J(\mathbf{S}_{Cr1}\mathbf{S}_{Ni} + \mathbf{S}_{Cr2}\mathbf{S}_{Ni}) + \mathbf{S}_{Ni}\mathbf{D}_{Ni}\mathbf{S}_{Ni})$. © 1998 Elsevier Science Ltd. Keywords: chromium complexes; nickel complexes; oxalato complexes; 2,2′-bipyridine; magnetic properties.

A successful strategy for the design of heteropolymetallic complexes consists in the ingenious use of versatile building blocks, which are usually relatively stable coordination compounds with potential bridging ligands. A particular emphasis has been brought to 2D and 3D multimetallic complexes, with the perspective to design molecular-based magnets [1,2]. On the other hand, oligonuclear systems are useful models for the experimental and theoretical investigation of the factors governing the sign and the magnitude of the exchange interactions between adjacent metal ions [2–4].

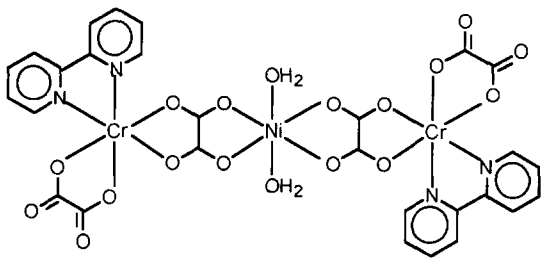
Recently, we have reported on the ability of a new molecular brick, $[Cr(bipy)(C_2O_4)_2]^-$, to generate heteropolymetallic complexes with novel topologies of the metallic centers and, consequently, with interesting magnetic properties [5,6]. We have shown that the self-assembly process is strongly influenced by: (i) the coordination algorithm of the assembling cation (Ba^{2+}, Mn^{2+}, Cu^{2+}, Co^{2+}, Zn^{2+}); (ii) the oxidation state of the assembling cation (Ag^+). Divalent cations which prefer a coordination number of six (Co^{2+}, Cu^{2+}, Zn^{2+}) have been found to generate discrete linear {Cr(III)-μ-C_2O_4-M(II)-μ-C_2O_4-Cr(III)} trinuclear species [5–7]. The synthetic route is straightforward and consists in the reaction of a barium-chromium precursor, $[BaCr_2(bipy)_2(C_2O_4)_4(H_2O)]$ H_2O, with the appropriate transition metal sulfate [5]:

$$Ba\{Cr(bipy)(C_2O_4)_2\}_2 + MSO_4 \rightarrow M\{Cr(bipy)(C_2O_4)_2\}_2 + BaSO_4$$

In this note we report on the synthesis and magnetic properties of the nickel derivative, $[NiCr_2(bipy)_2$

* Author to whom correspondence should be addressed.

$(C_2O_4)_4(H_2O)_2]\cdot H_2O$*. The divalent nickel ion has a marked preference for the octahedral stereochemistry. Therefore, the structure of the $\{NiCr_2\}$ complex is quite predictable, namely it should be isostructural with other $\{M^{II}Cr_2\}$ derivatives ($M^{II} = Co^{II}$, Cu^{II}, Zn^{II}). The solid state electronic spectrum exhibits the characteristic features of both octahedral Cr(III) and Ni(II) chromophores, namely *cis*-$[Cr(III)N_2O_4]$ and $[Ni(II)O_6]$ [8]. The first two bands, located at 395 nm and 550 nm, are assigned to the spin-allowed transitions for the Cr(III)-moiety: $^4A_2 \rightarrow {}^4T_1$ and $^4A_2 \rightarrow {}^4T_2$, respectively (assuming the O site symmetry). The shoulder at ~ 700 nm and the band at 1180 nm are assigned to the $^3A_{2g} \rightarrow {}^3T_{1g}$ and $^3A_{2g} \rightarrow {}^3T_{2g}$ transitions for the pseudo-octahedral $[Ni(II)O_6]$ chromophore.



The most intriguing properties of the heteropolymetallic complexes concern the exchange interactions between the paramagnetic centers. The particular pairs Cr(III)—Ni(II) and Cr(III)—Cu(II) mixed-metal ions are among the classical examples illustrating the ferromagnetic coupling due to the strict orthogonality of the magnetic orbitals, $< t_{2g}|e_g > = 0$, $(t_{2g})^3(Cr)$-$(e_g)^{1,2}$ (Cu, Ni) (considering only the unpaired electrons) [2–4]. The crystal structures of the isomorphous compounds, $[MCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]$, M = Co(II), Cu(II) and Zn(II) [5–7], allow for reliable predictions of the magnetic properties for the whole series. The divalent cation, lying on an inversion center, exhibits a tetragonally distorted octahedral stereochemistry. The elongated bonds involve one oxygen atom arising from each oxalato bridging ligands. In the C_i group symmetry of the trinuclear complex, the magnetic orbitals transform as the a_g irreducible representation and are no more orthogonal. Consequently, the Cr(III)—Ni(II) exchange interaction, as the Cr(III)—Cu(II) one [6], should be antiferromagnetic. Indeed, the results of the cryomagnetic investigation of $[NiCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]\cdot H_2O$, shown in the form of $\chi_M T$ versus T plot, clearly indicate the expected antiferromagnetic coupling (Fig. 1). The magnetic susceptibiliy was measured with a SQUID magnetometer (Quantum Design, San Diego, CA) in the temperature range 1.7–300 K. At room temperature, $\chi_M T$ is equal to 4.89 cm^3 mol^{-1} K, which corresponds to the three uncoupled metal ions ($\chi_M T = 4.75$ cm^3 mol^{-1} K if $g_{Ni} = g_{Cr} = 2$). By lowering the temperature, $\chi_M T$ remains constant down to ca 80 K, then decreases more and more, reaching a value of 3.06 cm^3 mol^{-1} K at 1.70 K.

The expression for the magnetic susceptibility has been based on the full-matrix diagonalization of the following phenomenological Hamiltonian:

$$H = -J(\mathbf{S}_{Cr1}\mathbf{S}_{Ni} + \mathbf{S}_{Cr2}\mathbf{S}_{Ni}) + \mathbf{S}_{Ni}\mathbf{D}_{Ni}\mathbf{S}_{Ni}$$

The local anisotropy tensor, $\mathbf{D}_{Ni}$, was taken into account because, in axial symmetry, nickel(II) can have a significant zero-field splitting. The best least-squares fit gives: $g_{av} = 2.03$, $J = -0.6$ cm^{-1}, and $\mathbf{D}_{Ni} = 0.4$ cm^{-1}. The discrepancy factor, defined as $R = \Sigma[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma[(\chi_M T)_{obs}]^2$, is then equal to 1.5×10^{-5}. For the analogous compound, $\{CuCr_2\}$, the Cu(II)—Cr(III) interaction is also antiferromagnetic ($J = -18.8$ cm^{-1}) [6]. Several other Ni(II)—Cr(III) oligomeric complexes have been synthesized and their magnetic properties investigated. Three of them are oxalato-bridged species and the Cr(III)—Ni(II) coupling was found always ferromagnetic [9,10]. A tetranuclear $\{NiCr_3\}$ dithiooxalato bridged complex has been structurally characterized [11]. The magnitude of the ferromagnetic coupling through the dithiooxalato bridges was found more than twice as large as in the oxalato derivatives. In one Cr(III)—Ni(II) cyanide-bridged heptanuclear

*A suspension of $[BaCr_2(bipy)_2(C_2O_4)_4(H_2O)]H_2O$ (0.5 mmol) in 50 ml of water reacted with the stoichiometric amount of $NiSO_4\cdot 7H_2O$ dissolved in 10 ml of water. The resulting mixture was stirred for 4 h to promote complete precipitation of barium sulfate, which has been removed by filtration. $[NiCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]\cdot H_2O$ was obtained as a red violet microcrystalline powder by slow concentration of the aqueous solution. The heterotrinuclear complex was purified by recrystallization from water. Yield: 84%. FTIR data (KBr, cm^{-1}): 3440 br, 1720 vs, 1690 vs, 1620 m, 1500 w, 1480 w, 1450 m, 1375 s, 1320 w, 1290 w, 1250 w, 1185 w, 1170 w, 1080 w, 1065 w, 1040 w, 900 w, 850 w, 810 m, 780 m, 730 m, 670 w, 560 m, 460 w, 420 w. Correct elemental chemical analyses. The water content was determined by means of thermogravimetric analysis. Any attempt to obtain single crystals failed.

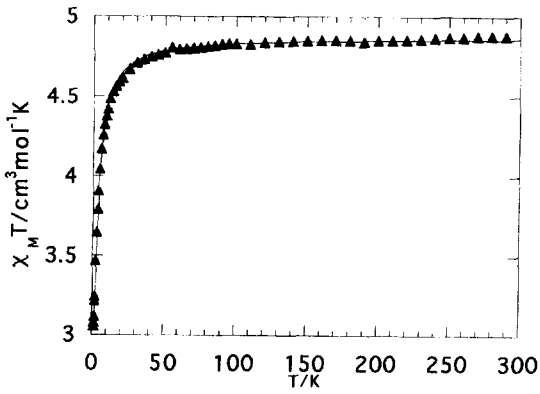


Fig. 1. $\chi_M T$ vs T plot for $[NiCr_2(bipy)_2(C_2O_4)_4(H_2O)_2]\cdot H_2O$.

complex the interaction is ferromagnetic too, as expected from the orthogonality of the magnetic orbitals [12]. An antiferromagnetic coupling was found only in a few Cr(III)—Ni(II) hydroxo-bridged tri- and tetranuclear complexes [13,14].

X-ray structure and solid state ^{29}Si NMR spectroscopy of the octahalocyclotetrasilanes, Si_4Cl_8 and Si_4Br_8

Julian R. Koe,* Douglas R. Powell, Jarrod J. Buffy and Robert West

Department of Chemistry, University of Wisconsin, Madison, WI 53706 U.S.A.

(Received 16 June 1997: accepted 2 September 1997)

Abstract—The crystallographic and solid state ^{29}Si NMR characterisation of octachlorocyclotetrasilane, **1**, and octabromocyclotetrasilane, **2**, are described. In the solid state, **1** and **2** exist as centrosymmetric square planar molecules. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: octachlorocyclotetrasilane; octabromocyclotetrasilane; cyclotetrasilane; X-ray structure; solid state ^{29}Si NMR spectroscopy.

Small strained silicon rings [1,2] have attracted considerable attention due to their reactivity towards ring-opening, extrusion of silylenes and disilenes, polymerisation, substitution and insertion chemistry. Whereas X-ray structures have been reported for a number of alkyl- and aryl-substituted cyclotetrasilanes [3–5], the structure of the unusually coloured octahalocyclotetrasilanes [6,7], Si_4X_8, has been a matter of debate for the last 20 years and a full structural characterisation is required for a deeper understanding of the nature of these species.

In our work on the chemistry of cyclotetrasilanes and their polymerisation, we synthesised the air- and moisture-sensitive compounds octachlorocyclotetrasilane Si_4Cl_8, **1** and octabromocyclotetrasilane, Si_4Br_8, **2**, according to the reported procedure [6], although our purification method (recrystallisation) differed from that in the literature (sublimation). Crystals suitable for single crystal X-ray diffraction analysis were prepared by recrystallisation from toluene at −20°C, coated with Krytox and mounted on a glass fibre. The structures were obtained using a diffractometer equipped with a CCD area detector, the use of which permitted the rapid collection of data, critical in the analysis due to the extreme moisture-sensitivity of the compounds.

The structures of **1** and **2** with selected bond distances and angles are shown in Figs 1 and 2, respectively. The molecules have similar structures and will therefore be discussed together, except where specified. The compounds possess crystallographic centres of inversion and have very slightly rhomboidally compressed square-planar structures, in qualitative agreement with the planar D_{4h} minimum energy structure obtained for Si_4Cl_8 by semi-empirical (PM3) calculations [8], though in contrast to conclusions based on vibrational spectroscopy [6,7]. Similarly apparently contradictory data were obtained for octamethylcyclotetrasilane, for which X-ray analysis indicated a planar structure [3] while both vibrational [9] and gas electron diffraction [10] data indicated folding (the latter gave a value of 29.4(40)°). The planar structures of Si_4Cl_8 and Si_4Br_8 contrast also with the structures of nearly all other cyclotetrasilanes for which X-ray diffraction analyses have been obtained [2,11,12] (dihedral angles of 12–40° are typical), although octakis(trimethylsilyl)cyclotetrasilane is also planar [13], presumably due to minimisation of interactions between the bulky substituents. It is interesting to compare the structure of Si_4Cl_8 with that of its carbon analogue, C_4Cl_8, for which vibrational spectroscopy [14] indicated a puckered D_{2d} structure. This was borne out in the crystal structure [15] which showed a folded cyclic structure with a dihedral angle of 19°.

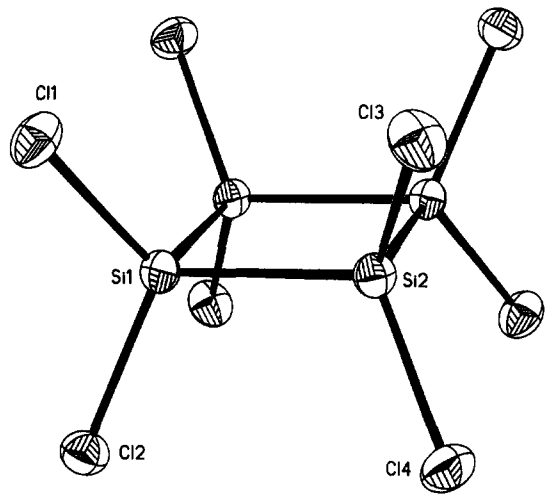

Fig. 1. Molecular structure of Si_4Cl_8 (**1**) with 50% probability thermal ellipsoids. Selected interatomic distances (Å): Si(1)—Cl(1) 2.039(2), Si(1)—Cl(2) 2.049(2), Si(1)—Si(2) 2.372(2), Si(1)—Si(2)$^{\#1}$ 2.372(2). Selected bond angles (°): Si(1)—Si(2)—Si(1)$^{\#1}$ 90.12(5), Si(2)—Si(1)—Si(2)$^{\#1}$ 89.88(5), Cl(1)—Si(1)—Cl(2) 112.17(7), Cl(4)—Si(2)—Cl(3) 111.84(7). $^{\#1}$symmetry transformation used to generate equivalent atoms: $-x+1, -y+1, -z+1$.

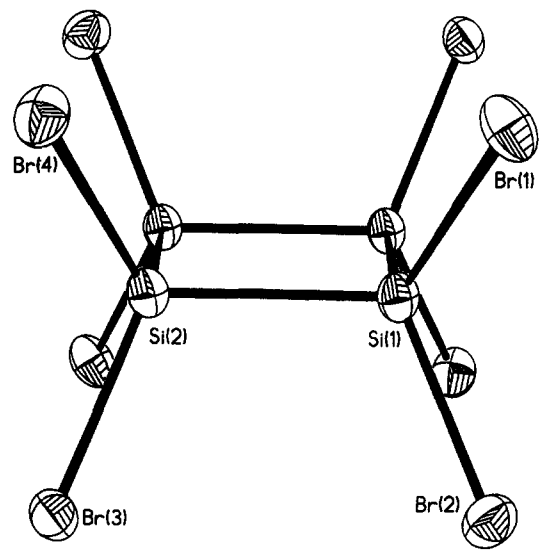

Fig. 2. Molecular structure of Si_4Br_8 (**2**) with 50% probability thermal ellipsoids. Selected interactomic distances (Å): Si(1)—Br(1) 2.203(3), Si(1)—Br(2) 2.202(3), Si(1)—Si(2) 2.370(4), Si(1)—Si(2)$^{\#1}$ 2.372(4). Selected bond angles (°): Si(1)—Si(2)—Si(1)$^{\#1}$ 89.86(12), Si(2)—Si(1)—Si(2)$^{\#1}$ 90.14(12), Br(1)—Si(1)—Br(2) 112.43(11), Br(4)—Si(2)—Br(3) 113.07(11). symmetry transformation used to generate equivalent atoms: $-x+1, -y+1, -z+1$.

The Si—Si bond lengths in **1** (2.372(2)Å) are somewhat longer than in dodecamethylcyclohexasilane [16] (2.338(4)Å) and Si_4Me_8 (mean value: 2.363 Å) [3]. The Si—Si distances in **2** are essentially the same as for **1** within the standard deviational errors. The distances in **1** are also larger than the Si—Si distances in Si_4Me_8 (mean value: 2.363 Å) [3]. The bond lengths are, however, considerably shorter than those reported in the PM3 calculation [8] (2.454 Å) for Si_4Cl_8. Restriction of the Si—Si—Si bond angles to almost 90° permits the opening of the Cl—Si—Cl angles to around 112° and very slightly larger in the case of the bulkier bromo-derivative.

^{29}Si NMR data were also obtained for **1** and **2**. The solid state ^{29}Si MAS-NMR spectrum comprised a single resonance at 7.1 ppm and the solution state ^{29}Si NMR spectrum of **1** gave a signal at 5.44 ppm, which is in reasonable agreement with the published [17] (5.86 ppm) and solid state values. For **2**, a broader peak was observed in the solid state ^{29}Si MAS-NMR spectrum at −8.3 ppm (cf −15.97 for the published [17] solution state spectrum).

We are continuing our endeavours in this area and are currently investigating the cause of the discrepancy between the crystallographic and vibrational data concerning the planarity of the Si_4 ring.

EXPERIMENTAL

Crystallographic data for **1**

Cl_8Si_4: $M = 395.96$; monoclinic, $P2_1/n$; $a = 7.3255(2)$, $b = 7.1815(2)$, $c = 13.2844(4)$Å; $\beta = 104.6800(10)°$; $V = 676.05(3)$Å^3; $Z = 2$; $D_{calc} = 1.945$ g cm^3; Mo-K_α radiation, $\lambda = 0.71073$ Å; absorption coefficient = 1.971 mm^{-1}; $F(000) = 384$; $T = 133(2)$K; yellow transparent prisms. Crystal dimensions: $0.42 \times 0.36 \times 0.25$ mm. 6839 intensity data were collected on a Siemens P4/CCD diffractometer using graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation (range $2.91 \leqslant \theta \leqslant 28.01°$; $-9 \leqslant h \leqslant 9$, $0 \leqslant k \leqslant 9$, $0 \leqslant l \leqslant 17$), 1528 independent reflections ($R_{int} = 0.0330$) and 1356 observed [$I > 2\sigma(I)$]. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL V.5 (1994). Neutral atom scattering factors were taken from ref. 18. $R_1 = 0.0492$ [$I > 2\sigma(I)$], $wR_2 = 0.1337$ (all data); GOF(F^2) = 1.192.

Crystallographic data for **2**: Br_8Si_4: $M = 751.64$; monoclinic, $P2_1/n$; $a = 7.5961(7)$, $b = 7.4198(7)$, $c = 14.0201(13)$Å; $\beta = 103.995(2)°$; $V = 766.74(12)$Å^3; $Z = 2$; $D_{calc} = 3.256$ g cm^3; Mo-K_α radiation, $\lambda = 0.71073$ Å; absorption coefficient = 1.971 mm^{-1}; $F(000) = 672$; $T = 133(2)$K; yellow transparent prisms. Crystal dimensions: $0.44 \times 0.38 \times 0.32$ mm. 3494 intensity data were collected on a Siemens P4/CCD diffractometer using graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation (range $2.81 \leqslant \theta \leqslant 28.82°$; $-10 \leqslant h \leqslant 10$, $-7 \leqslant k \leqslant 9$, $-18 \leqslant l \leqslant 10$), 1837 independent reflections ($R_{int} = 0.0325$) and 1462 observed [$I > 2\sigma(I)$]. The

structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL V.5 (1994). Neutral atom scattering factors were taken from ref. 18. $R_1 = 0.0643$ [$I > 2\sigma(I)$], $wR_2 = 0.19747$ (all data); GOF(F^2) = 1.051.

Full details of the structure determinations have been deposited at the Cambridge Crystallographic Data Centre.

^{29}*Si NMR data for* **1** *and* **2**

Solution state ^{29}Si NMR experiments were referenced to internal tetramethysilane and recorded in C_6D_6 using a Bruker AM-500 instrument operating at 99.36 MHz. Solid state ^{29}Si MAS-NMR spectra were obtained using zirconia rotors in a Varian Unity-300 spectrometer operating at 59.591 MHz and referenced to external tetrakis(trimethylsilyl)silane.

(Received 29 October 1997; accepted 18 December 1997)

Abstract – The ferrocenyl diketone $[(C_5H_5)Fe(C_5H_4)COCH_2COCH_3]$ has been used to form neutral metal complexes of the 1-ferrocenyl-1,3-butanedionate ligand $[(C_5H_5)Fe(C_5H_4)COCHCOCH_3]^-$: the aluminium complex of this ligand, $[Al\{(C_5H_5)Fe(C_5H_4)COCHCOCH_3\}_3]$, has been characterised by ^1H and ^{13}C NMR as a 2:3 mixture of *fac* and *mer* isomers, having C_3 and C_1 molecular symmetry respectively. Electrochemical studies show that each peripheral 1-ferrocenyl-1,3-butanedionate ligand L of both $M^{II}L_2$ (M = Co, Ni, Cu) and $M^{III}L_3$ (M = Al, Cr, Mn, Fe) complexes undergoes reversible one-electron oxidation at potential values essentially overlapping each other. This means that the central metal ions prevent any electronic communication between the two or three ferrocene fragments. In addition to these reversible ferrocene-centred oxidations, there are reversible one-electron reductions centred at M for ML_3 and FeL_3 (but not for CrL_3 or AlL_3), but the metal-centre reductions of $M^{II}L_2$ are irreversible owing to further reactions following reduction. © 1998 Elsevier Science Ltd. Keywords: ferrocenes; ferrocenyl diketone; metal complexes; electrochemistry.

We have recently reported practical routes to a number of 1,3-diketones containing a ferrocene nucleus, of general types $FcCOCH_2COR$ and $FcCH_2CH(COR)_2$ [Fc = $(C_5H_5)Fe(C_5H_4)$] and to some of the corresponding bis(1,3-diketones) $Fe(C_5H_4COCH_2COR)_2$ and $Fe[C_5H_4CH_2CH(COR)_2]_2$ [1]. The crystal and molecular structures have been reported for two representative examples, $FcCOCH_2COMe$ which exists [2] in the solid state solely in the enol form FcCOCHC(OH)Me, and $FcCH_2CH(COCMe_3)_2$ which exists [3] in the solid state solely in the keto form, although ferrocenyl diketones of both types exist as keto/enol mixtures in solution. Despite the fact that ferrocenyl 1,3-diketones were first described more than thirty years ago [4], there have been remarkably few reports of their application as ligands towards metal ions: Imai and Óta reported the characterisation by electronic spectroscopy of some M(II) complexes derived from the ligand $FcCOCH_2COMe$ **1**, for M = Mn, Co, Ni, Cu and Zn [5], although the preparations were not described. For any asymmetric bidentate ligand of general type L—L′, both square planar $M(L—L')_2$ and octahedral $M(L—L')_3$ complexes have the potential to exhibit geometric isomerism, of *cis/trans* and *mer/fac* types respectively, although this possibility was not addressed by Imai and Óta [5]. We have now synthesised a range of M(II) and M(II) complexes of $(FcCOCHCOMe)^-$ **2** and **3** respectively, including the diamagnetic complex $[(FcCOCHCOMe)_3Al]$, and we report here details of the synthesis, the full structural characterisation of $[(FcCOCHCOMe)_3Al]$ by ^1H and ^{13}C NMR spectroscopy, and an electrochemical study of selected examples.

interactions. In this connection interest is rapidly growing around metalla-ferrocene derivatives and most aspects of their chemistry have been recently reviewed [6]. Our emphasis in the present work is on structural (particularly isomerism) and electrochemical aspects.

EXPERIMENTAL

Synthesis of 1-ferrocenyl-3-hydroxybut-2-en-1-one, **1**

A solution of *n*-butyl lithium (128 cm^3 of a 1.6 mol dm^{-3} solution in hexanes, 205 mmol) was added, under N_2 and at 0°C, to a solution of di-isopropylamine (21–5 g, 223 mmol) in sodium-dried THF (200 cm^3). After stirring for 1 h, acetylferrocene (20.4 g, 89.4 mmol) was added portionwise during 1 h. This mixture was stirred overnight at ambient temperature: after cooling to 0°C, ethyl acetate (18.1 g, 205 mmol) was added during 30 min, and the resulting solution was stirred overnight at ambient temperature. Dry ether (100 cm^3) was then added, and the resulting orange precipitate (the lithium salt of the keto-enolate) was filtered off; this solid was hydrolysed with 10% aqueous HCl (50 cm^3). The filtrate meanwhile, was evaporated to dryness, and the resulting oil was diluted with CH_2Cl_2 (30 cm^3) and chromatographed on alumina, with elution by 10% aqueous HCl. The combined aqueous HCl fractions were extracted with ether: the ether extract was washed with sodium hydrogencarbonate solution and then dried over magnesium sulfate. The ether was evaporated and the resulting solid was recrystallised from hexane to give the product **1** in 51% yield, with spectral data identical to those reported earlier [1,2].

Synthesis of M(III) *complexes*, **2** *of* 1-ferrocenyl-1,3-butanedionate

(*a*) Al(III) *complex*, **2a**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in concentrated aqueous ammonia (19 cm^3) and methanol (66 cm^3) was added in portions to a solution of aluminium sulfate octadecahydrate (0.32 g, 0.48 mmol) in water (3 cm^3). After 30 min, a red solid was filtered off and washed well with water. This solid was then dissolved in the minimum volume of CH_2Cl_2, and the resulting solution was washed with water (3×30 cm^3): the organic layer was dried and evaporated to yield tris(1-ferrocenyl-1,3-butanedionato-*O*,*O*′)aluminium (0.38 g, 0.45 mmol, 94%). Anal.: Found: C, 60.0, H, 4.6%. $C_{45}H_{39}AlFe_3O_6$ requires C, 60.5, H, 4.7%.

(*b*) Cr(III) *complex*, **2b**. Chromium(III) hexahydrate (0.10 g, 0.37 mmol) was dissolved in water (4 cm^3) and urea (0.36 g, 6.0 mmol) was added in small portions: diketone **1** (0.44 g, 1.62 mmol) was then added and the mixture was heated to 80°C for 2 h. After cooling, the mixture was filtered to give a red-brown solid, which was twice recrystallised from cyclohexane to yield **2b** (0.04 g, 0.047 mmol, 13%). Anal.: Found: C, 58.1, H, 4.9%. $C_{42}H_{39}CrFe_3O_6$ requires C, 58.7, H, 4.6%.

(*c*) Mn(III) *complex*, **2c**. Diketone **1** (0.50 g, 1.85 mmol) was added to an aqueous solution (2 cm^3) containing manganese(II) chloride tetrahydrate (0.08 g, 0.40 mmol) and sodium acetate trihydrate (0.13 g, 0.96 mmol). To this solution was then added, dropwise with stirring, a solution of potassium permanganate (0.015 g, 0.095 mmol) in water (10 cm^3), followed by a further solution of acetate trihydrate (0.13 g) in water (10 cm^3). After 10 min, the deep red-brown product was filtered off, and washed with water followed by methanol to give **2c** (0.13 g, 0.15 mmol, 30%). Anal.: Found: C, 58.5, H, 4.5%. $C_{42}H_{39}Fe_3MnO_6$ requires C, 58.5, H, 4.5%.

(*d*) Fe(III) *complex*, **2d**. A solution of diketone **1** (0.40 g, 1.48 mmol) in methanol (40 cm^3) was added in portions to a solution of iron(II) chloride hexahydrate (0.13 g, 0.49 mmol) in water (2 cm^3), followed by a solution of sodium acetate trihydrate (0.21 g, 1.54 mmol) in water (1 cm^3). The entire mixture was stirred at 70 C until all the solvent had evaporated: the residue was slurried with a mixture of water (6 cm^3) and methanol (40 cm^3), and then filtered. The solid product was well washed with water and then dried to provide deep red-purple **2d** (0.32 g, 0.37 mmol, 75%). Anal.: Found: C, 58.4, H, 4.8%. $C_{42}H_{39}Fe_4O_6$ requires C, 58.4, H, 4.6%.

Synthesis of M(II) *complexes*, **3**, *of* 1-ferrocenyl-1,3-butanedionate

(*a*) *Vanadyl complex*, **3a**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in methanol (20 cm^3) was added to a solution of vanadyl sulfate monohydrate (0.12 g, 0.66 mmol) in water (0.5 cm^3): to this mixture was then added an excess of an aqueous solution of sodium carbonate. The resulting solid was filtered off, dried and recrystallised from CH_2Cl_2 to give red-brown **3a** (0.20 g, 0.32 mmol, 48%). Anal.: Found: C, 57.3, H, 4.1%. $C_{28}H_{26}Fe_2O_5V$ requires C, 55.6, H, 4.3%.

(*b*) Mn(II) *complex*, **3b**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in methanol (20 cm^3) was added to a solution of manganese(II) chloride tetrahydrate (0.15 g, 0.76 mmol) in water (0.75 cm^3). To this mixture was added dropwise with stirring an excess of an aqueous solution of sodium acetate trihydrate (0.20 g, 1.40 mmol) in water (0.5 cm^3), followed by three drops of concentrated aqueous ammonia. After stirring for 10 min at ambient temperature the mixture was held at 0°C for 4 h. The resulting precipitate was filtered off and washed with water to yield dark brown **3b** (0.30 g, 0.51 mmol, 69%). Anal.: Found: C, 56.0, H, 4.5%. $C_{28}H_{26}Fe_2MnO_4$ requires C, 56.7, H, 4.4%.

(*c*) Co(II) *complex*, **3c**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in methanol (20 cm^3) was added slowly with stirring to a solution of sodium hydroxide (0.06 g, 1.50 mmol) in water (1 cm^3). This mixture

was added dropwise with stirring to a solution of cobalt(II) chloride hexahydrate (0.18 g, 0.76 mmol) in water (10 cm^3). The resulting solid was filtered off and washed with water; recrystallisation from CH_2Cl_2 gave dark brown **3c** (0.15 g, 0.25 mmol, 34%). Anal.: Found: C, 57.0, H, 4.7%. $C_{28}H_{26}CoFe_2O_4$ requires C, 56.3, H, 4.4%.

(*d*) Ni(II) *complex*, **3d**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in methanol (20 cm^3) was added slowly with stirring to a solution of sodium hydroxide (0.06 g, 1.50 mmol) in water (1 cm^3). To this mixture was added dropwise with stirring a solution of nickel(II) chloride hexahydrate (0.18 g, 0.76 mmol) in water (2 cm^3). The mixture was boiled for 2 min, cooled and exhaustively extracted with CH_2Cl_2: the combined extracts were washed with water, dried, and evaporated to yield purple-brown **3d** (0.24 g, 0.40 mmol, 54%). Anal.: Found: C, 56.7, H, 4.4%. $C_{28}H_{26}Fe_2NiO_4$ requires C, 56.3, H, 4.4%.

(*e*) Cu(II) *complex*, **3e**. A solution of the diketone **1** (0.40 g, 1.48 mmol) in methanol (40 cm^3) was added to a solution of copper(II) acetate monohydrate (0.15 g, 0.75 mmol) in water (3 cm^3): the mixture was shaken vigorously and then heated to 60 °C for 5 min. After cooling to ambient temperature, the resulting solid was filtered off and washed with water, followed by a little cold methanol to give orange-red **3e** (0.27 g, 0.45 mmol, 61%). Anal.: Found: C, 55.8, H, 4.4%. $C_{28}H_{26}CuFe_2O_4$ requires C, 55.9, H, 4.4%.

NMR spectra for Al(FcCOCHCOMe)$_3$, **2a**

Spectra were measured in $CDCl_3$ solution at ambient temperature using Bruker AM-300 spectrometer: the ^{13}C spectrum was assigned by use of appropriate DEPT sequences.

(*a*) fac *isomer*. δ(H) 2.08 (s, 3H, CH_3), 4.21 (s, 5H, C_5H_5), 4.39 (m, 2H) and 4.75 (m, 2H) (C_5H_4), 5.81 (s, 1H, COCHCO); δ(C) 27.2 (q, CH_3), 70.0 (d, C_5H_5), 80.2 (s, ipso of C_5H_4), 96.8$_9$ (d, CH), 188.0 (s) and 188.7 (s) (2 × CO).

Electrochemistry

Materials and apparatus for electrochemistry have all been described elsewhere [7]. All potential values are referred to the Standard Calomel Electrode (SCE). Ferrocene can not be used as an internal standard here as its oxidation wave almost overlaps the oxidation waves of the complexes under study: consequently, the formal electrode potential of the couple $[Fe(C_5H_5)_2]/[Fe(C_5H_5)_2]^+$ was determined by cyclic voltammetric experiments performed under precisely the same experimental conditions (solvent, electrode material, supporting electrolyte, scan rate and temperature) as used for the complexes.

RESULTS AND DISCUSSION

The synthesis of the ferrocenyl diketone **1** described in the Experimental section is an improvement of the method described earlier [2], in that the modified work-up procedure provides a rather higher yield.

In the formation of neutral metal complexes from metal ions and neutral 1,3-diketones, protons are liberated [eqn (1)]:

$$M^{x+} + xRCOCH_2COR' \rightarrow [M(RCOCHCCOR')_x] + xH^+ \quad (1)$$

Effective preparative routes therefore require addition of a basic reagent to remove these liberated protons, to ensure efficient complexation of M^{x+}, which do not concurrently effect precipitation of, for example, metal hydroxides; the choice of the bases used in the present work has been guided by experience gained in the synthesis of metal complexes of simple 1,3-diketones. Although the complexes **3b–3e** have been described before [5], the preparative details were not given, and for this reason we report here detailed procedures for their preparations. We have been unable to isolate a zinc complex, although this was described by Imai and Óta. For formation of the Mn(II) and Fe(III) complexes, **3b** and **2d,** the reactions were buffered with sodium acetate, while formation of the Al(III) complex **2a** was promoted by the addition of aqueous ammonia: the formation of the Cr(III) complex **2b** was assisted by addition of urea, which hydrolyses during the course of the reaction to liberate ammonia. Sodium carbonate was employed as the base in the preparation of the vanadyl complex **3a,** while the preparation of both the Co(II) and Ni(II) complexes, **3c** and **3d,** employed preformed ligands generated *in situ* by reaction of the diketone **1** with aqueous sodium hydroxide. The synthesis of the Cu(II) complex **3e** employed the self-buffering copper(II) acetate. The only preparation which did not follow the simple pattern described by eqn (1) is that of the Mn(III) complex **2c**: for this, the Mn(II) complex is synthesised in the presence of an excess of the diketone **1** and, without isolation, converted to the Mn(III) complex in a comproportionation reaction with a stoichiometric quantity of permanganate [eqn (2)]:

$$4[Mn(FcCOCHCOMe)_2]+[MnO_4]^-+ 7FcCOCH_2COMe+H^+ \rightarrow 5[Mn(FcCOCHCOMe)_3]+4H_2O \quad (2)$$

The stoichiometries of all the complexes were established by elemental analysis: although complexes **2** may all be expected to exhibit *fac*/*mer* isomerism (see below), in no case could any chromatography conditions be found which allowed these isomers to be distinguished by means of their R_f values. In consequence no isomer separations were possible and hence, in turn, no structural characterisation by means of single-crystal X-ray diffraction has been possible. For the characterisation of the isomerism in **2**, we have turned instead to the NMR properties of the diamagnetic aluminium complex **2a**.

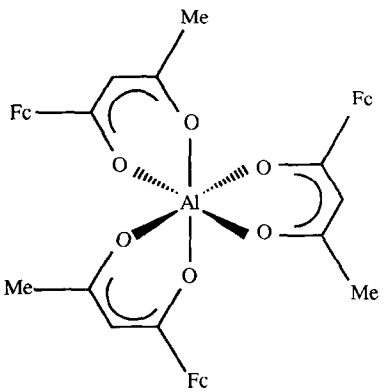
NMR spectra of complex **2a**

Metal complexes of the pentane-1,3-dionate ligand, of type $[(MeCOCHCOMe)_3M]$ are octahedral with idealised molecular symmetry D_3 [8], except for the Mn(III) complex which shows clear evidence of a Jahn-Teller elongation [9]; hence all can occur in enantiomeric Λ and Δ forms. Despite the enforced absence of structural data from X-ray crystallography, it is a reasonable inference that the complexes **2** will adopt octahedral geometries similar to those of the pentanedionate complexes, and the discussion of the NMR spectra of **2** will proceed on that basis.

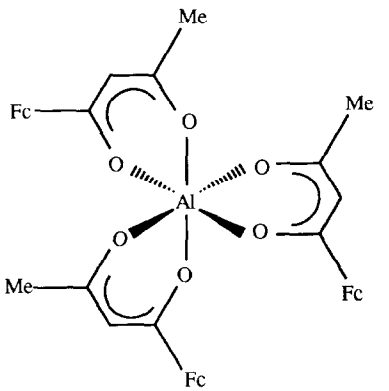
In the ^1H NMR spectrum of compound **2a**, those resonances expected to appear as singlets (CH_3, COCHCO, and C_5H_5) all appear as a set of four resonances, three of which have equal intensity. These data indicate the presence of both *fac* and *mer* isomers: the *fac* isomer has idealised C_3 molecular symmetry, with all three ligands equivalent by symmetry, while in the *mer* isomer, of molecular symmetry C_1, the three ligands are all in different environments.

Hence the three equally-intense resonances in each region arise from the three distinct ligands of the *mer* isomer, while the fourth resonance in each group is attributable to the *fac* isomer. Integration of each group of resonances indicates a *fac*:*mer* ratio of 1:1.6, i.e. approximately 2:3. Precisely the same pattern of (3+1) individual resonances is readily identifiable in each of the regions of the ^{13}C NMR spectrum where the number of separate resonances does not cause problems of coincidental overlap, namely the CH_3, CH, C_5H_5 and CO regions; in addition, the *ipso*-carbon resonances of the C_5H_4 groups conform to this pattern. However, the pattern of the CH resonances arising from the C_5H_4 groups is more complex, in both the ^1H and ^{13}C NMR spectrum.

It is generally observed that whenever there is a stereogenic centre adjacent to the *ipso*-carbon in a monosubstituted ferrocene, then the four CH groups of the C_5H_4 fragment are magnetically inequivalent and it is often possible to distinguish four different chemical shifts in both the ^1H and ^{13}C spectra. In both isomers of complex **2a**, the aluminium ion provides a stereogenic centre: although this is three bonds away from the C_5H_4 unit, nonetheless the NMR spectra show clear evidence of magnetically inequivalent CH groups. A similar effect, over three covalent bonds, has been observed for the C_5H_4 unit in the compound $FcCH_2NH(CHMePh)$ [10]. In the ^1H spectrum, two resonances can be assigned to the C_5H_4 unit of the *fac* isomer, each corresponding to two hydrogens per ligand; for the *mer* isomer six chemical shifts can be distinguished, one of which corresponds in intensity to four hydrogens, three others each correspond to two hydrogens, and the final two to one hydrogen each. It is the observation of resonances in the C_5H_4 region whose integrals corresponding to one hydrogen per molecule which provides clear evidence for the



fac isomer



mer isomer

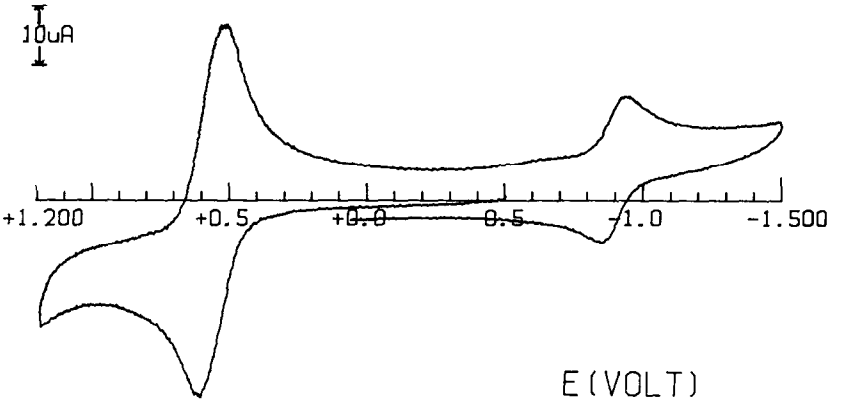


Fig. 1. Cyclic voltammetric response recorded at a platinum electrode on a CH_2Cl_2 solution containing **2d** (0.8×10^{-3} mol dm^{-3}) and $[NBu_4][PF_6]$ (0.2 mol dm^{-3}). Scan rate 0.2 V s^{-1}.

magnetic inequivalence of the CH units in the *mer* isomer C_5H_4 groups. If all such CH units had distinguishable chemical shifts, there would be twelve in all for the *mer* isomer, and four for the *fac* isomer: In the ^{13}C spectrum, a total of twelve resonances assignable to CH units in C_5H_4 groups can be resolved, although assignment of these to individual isomers has not been made: without the stereogenic effect of the metal ion the maximum number expected, for the two isomers together, would be eight. The *fac* and *mer* isomers of a complex $ML_3L'_3$ containing only monodentate ligands L and L′ and having molecular symmetries C_{3v} and C_{2v} respectively, are simple geometric isomers; in the presence of an asymmetric bidentate ligand of type L—L′, as here, giving molecular symmetries C_3 and C_1, the *fac* and *mer* isomers are also diastereoisomers.

Electrochemistry

Cyclic voltammetry and controlled potential coulometry proved that the ligand precursor 1-ferrocenyl-1,3-butanedione (**1**) undergoes in dichloromethane solution a chemically and essentially electrochemically reversible one-electron oxidation. As a matter of fact, controlled potential exhaustive oxidation ($Ew = +0.8$ V) consumes one electron/molecule. Cyclic voltammetry on the resulting solution affords a profile quite complementary to the original one. As a consequence of the electron removal the starting orange solution assumes the green colour ($\lambda_{max} = 640$ nm) typical of the iron-centred ferrocene oxidations. Furthermore, analysis [1] of the cyclic voltammograms exhibited by ligand **1** with scan rate varying from 0.02 V s^{-1} to 1.00 V s^{-1} shows that: (i) the current function $i_{pa}/v^{1/2}$ remains constant; (ii) the peaks-current ratio i_{pc}/i_{pa} is constantly equal to 1; (iii) peak-to-peak separation ΔE_p slightly departs from the theoretical value of 60 mV.

Without exception, members of both the series $M^{III}L_3$ and $M^{II}L_2$ exhibit a single oxidation process having features of chemical reversibility and involving three and two electrons respectively. In some cases reduction processes centred on the central M ions have been also observed, which, but for complexes **2c** and **2d,** are usually complicated by decomposition reactions. As a typical example, Fig. 1 shows the cyclic voltammetric response given by the iron complex **2d**.

As indicated above for all complexes **2,** a single oxidation process is observed for complex **2d,** which consumes three electrons/molecule in controlled potential coulometry ($Ew = +0.8$ V). Upon exhaustive oxidation the original red solution turns green-brown and exhibits a cyclic voltammogram complementary to the starting one. In turn, as far as the chemical reversibility of the Fe(III)/Fe(II) reduction of the central metal ion is concerned it has been also verified by exhaustive cathodic electrolysis ($Ew = -1.1$ V).

Table 1 summarises the formal electrode potentials of the redox changes exhibited by the complexes under study. Without exception, members of the series **2** and **3** exhibit a single oxidation process and consume in controlled potential coulometry three and two electrons respectively.

A comparison of the oxidation potential of **1** with unsubstituted ferrocene points out the electron-withdrawing ability of the diketone group. In addition, it is clearly evident that independent of the nature of the different central metal ions, their complexation to 1-ferrocenyl-1,3-butanedionate somewhat compensates for the inductive effects of the diketonate group.

In none of the complexes studied is there any evidence of electronic communication between the several iron atoms of the ferrocene ligands. Despite the

delocalised nature of the π-electrons in each metal diketonate fragment, the individual ferrocene units are effectively insulated from one another. A number of bis-ferrocenyl compounds, in which the two ferrocene fragments are separated by insulating groups, have been found to exhibit two well-separated and reversible one-electron oxidations, indicative of electronic communication between the two fragments. However, in all cases involving such electronic communication the ferrocene fragments are separated by no more than two covalent bonds, as in Fc_2 [12], and in Fc_2CO, Fc_2CH_2, Fc_2CHOH and Fc_2CPhOH [13]. On the other hand, when the insulating spacer is such that the individual ferrocene fragments are separated by more than two covalent bonds, as in $FcCH_2CH_2Fc$ [14], FcCHROCHRFc [13,15], or $(FcCH_2)_2C(COR)_2$ [13], only a single two-electron oxidation is observed. In the complexes **2** and **3** described here, the shortest pathway between ferrocene units requires six bonds. The related Co(II) complex formed by the conjugate base of formylferrocenethiosemicarbazone, in which the two ferrocene groups are also separated by six bonds, similarly shows a single two-electron oxidation consistent with there being no electronic communication between the ferrocenes [16]. This pattern is rather common for metal complexes of simple ferrocenyl ligands [17], and hence it seems unlikely that coordination polymers based upon ferrocene-1,1′-diylbis(1,3-diketone), or similar, ligands will be effective electrical conductors.

(Received 20 October 1997; accepted 18 December 1997)

Abstract—Copper(II) complexes of general formula, $[Cu(NNS)(H_2O)_xX]\cdot nH_2O$ (NNS^- = uninegatively charged tridentate thiosemicarbazone ligand formed from 6-methyl-2-formylpyridine; $X = NCS^-$, CH_3COO^-, N_3^-; $x = 0,1$; $n = 0.5, 1$) and $[Cu(HNNS)(H_2O)(SO_4)]\cdot H_2O$ have been synthesized and characterized by a variety of physico-chemical techniques. Magnetic and spectroscopic evidence support a square-planar structure for the [Cu(NNS)X] ($X = NCS^-$, N_3^-) complexes and a five-coordinate structure for the $[Cu(HNNS)(H_2O)(SO_4)]\cdot H_2O$ complex. The crystal structures of the $[Cu(NNS)(CH_3COO)(H_2O)]$ and $[Cu(HNNS)(H_2O)(SO_4)]\cdot H_2O$ complexes have been determined by X-ray diffraction. The acetato complex has a distorted square-pyramidal geometry with the thiosemicarbazone ligand acting as a uninegatively charged tridentate NNS chelating agent and the fourth and fifth coordination positions of the copper(II) ion are occupied by a unidentate acetate and water ligand, respectively. The sulphato-complex is also five-coordinate with the thiosemicarbazone coordinated as a neutral NNS ligand and the fourth and fifth coordination sites are occupied by a water molecule and a unidentate sulphate ligand, respectively. © 1998 Elsevier Science Ltd. Keywords: copper(II) complexes; 6-methyl-2-formylpyridinethiosemicarbazone; four- and five-coordinate copper(II) complexes; crystal structures of copper(II) complexes.

Transition metal complexes of thiosemicarbazones have generated considerable interest due to their wide-ranging biological activities [1–3]. Of all the thiosemicarbazones studied so far, the 2-formylpyridinethiosemicarbazone (HPATS) probably got the most attention due to its marked antitumour properties [4]. Its copper(II) complex, Cu(PATS) has been shown to be more active than the free ligand [5]. Structural studies on copper-PATS complexes by X-ray diffraction [6–9] have shown that these complexes are dimeric in the solid state. Since the active antitumour species *in vivo* has been thought to be the monomeric $[Cu(PATS)H_2O]^+$ ion and as HPATS appears to react with copper(II) salts to yield only dimers, we thought it worthwhile to synthesize and

characterize some monomeric copper(II) complexes with the same NNS chelate but using a slightly modified HPATS ligand. In a previous paper [10], we reported that the 6-methyl-2-formylpyridinethiosemicarbazone, which is very similar to HPATS, except that it has a methyl group at the sixth position of the pyridine ring, is capable of forming monomeric four-coordinate square-planar copper(II) complexes, in contrast with HPATS which forms dimeric copper(II) chelates. In this paper, we report the preparation and characterization of some new copper(II) complexes of this ligand together with the X-ray crystal structures of the [Cu(NNS)(CHCOO)(H_2O)] and [Cu(HNNS)(H_2O)(SO_4)] · H_2O complexes.

EXPERIMENTAL

The details of physical measurements have been reported previously [10].

Compound preparation

The method of preparation of the ligand is given in our previous paper [10]. The [Cu(NNS)(CH_3COO)(H_2O)] complex was prepared as described previously [10].

Preparation of [Cu(NNS)X](X = NCS^-, N_3^-)

The [Cu(NNS)(CH_3COO)(H_2O)] complex (1 mmol) was dissolved in water (100 ml) to which excess sodium thiocyanate or sodium azide (5 mmol) was added. The product formed was collected by filtration and washed with water followed by methanol and dried in a desiccator over silica gel. Yield: 80–90%.

Preparation of [Cu(HNNS)(H_2O)(SO_4)] · H_2O

Copper(II) sulphate pentahydrate (1 mmol) was dissolved in a minimum amount of water. The solution was mixed with a boiling solution of the ligand (1 mmol) in methanol (100 ml). On heating on a water bath for ca 5 min, the complex crystallized out of the reaction mixture. Recrystallization from water gave beautiful green x-ray diffraction quality crystals. Yield: 85%.

Determination of the crystal structure of the [Cu(HNNS)(H_2O)(SO_4)] · H_2O *complex*

The intensity data were obtained by using an Enraf-Nonius CAD4 diffractometer at 163 K. Intensities were corrected for Lorentz and polarization effects and empirical absorption corrections were applied based on a set of ψ scans. Calculations were carried out using XCAD49 (data reduction), SHELXTL (absorption correction, structure solution/refinement and molecular graphics). All hydrogen atoms were placed in calculated positions, refined using a riding model, and given an isotropic displacement parameter equal to 1.2 (CH, CH2) or 1.5 (CH3, OH) times the equivalent isotropic displacement parameter of the atom to which it is attached. When warranted, methyl hydrogen atomic positions were allowed to rotate about the C—C bond. Full-matrix least-squares refinement of all data against F^2 of the quantity $w(F_o^2 - F_c^2)$ was used to adjust the position and anisotropic thermal parameters of all non-hydrogen atoms. Unit cell dimensions were refined by use of the settings of 25 accurately determined reflections widely separated in reciprocal space. Intensities were measured by ω scans. The structure was solved by direct methods [11] and subsequent Fourier syntheses were used to determine remaining non-hydrogen atomic positions. A summary of the crystallographic data, experimental details and refinement results is given in Table 1.

Determination of the crystal structure of [Cu(NNS)(H_2O)(CH_3COO)]

The intensity data were collected at 296 K by a Rigaku AFC6S diffractometer. Cell constants and orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from reflections in the range 30.03–36.45°. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in structure factor calculations in their calculated positions. The final cycle of full-matrix least-squares refinement was based on 1301 observed reflections. Neutral atom scattering factors were taken from Cromer and Waber [12]. All calculations were performed using the TEXSAN crystallographic software package of molecular structure [13]. A summary of crystal data, experimental details and refinement results are listed in Table 1. The data were corrected for Lorentz and polarization effects. No absorption correction was made.

RESULTS AND DISCUSSION

The 6-methyl-2-pyridinecarboxaldehydethiosemicarbazone (Fig. 1) has a thioamide function, —HN—C(S)NH_2 and consequently, it can exhibit thione-thiol tautomerism.

However, its IR spectrum as Nujol mull does not display any ν(S—H) band at ca 2600 cm^{-1} indicating that, in the solid state, it remains as the thione form (1a). However, in solution and in the presence of copper(II) salts, it can quickly convert to the thiol form (1b) with the concomitant formation of copper(II) complexes of the deprotonated mercaptide form of the ligand. It is only with the copper(II) sulphate salt that the Schiff base yields a copper(II) com-

Fig. 1. (a) Thione from (**1a**) and (b) thiol form (**1b**).

plex containing the neutral form of the ligand. The related pyridine-2-carboxaldehydethiosemicarbazone (HPATS) has also been found to coordinate with copper(II) ions in both protonated and deprotonated forms. Recently, a bis-chelated copper(II) complex of 2-acetylpyridinethiosemicarbazone ligand has been reported [14] which is unique in that it has a neutral as well as a deprotonated tridentate NNS ligand coordinated to the copper(II) ion in the same complex.

The complexes isolated in the present study have the empirical formulae, $[Cu(NNS)(X)(H_2O)_x] \cdot nH_2O$ (NNS^- = anionic form of the 6-methylpyridine-2-carboxaldehydethiosemicarbazone ligand; X = NCS^-, N_3^-, CH_3COO^-; $n = 0.5, 1$ $x = 0,1$) and $[Cu(HNNS)(SO_4)(H_2O)] \cdot H_2O$. The characterization data for these complexes are shown in Table 2. The molar conductivities of these complexes in DMSO are well below the range (50–70 ohm^{-1} cm^2 mol^{-1}) found for 1:1 electrolytes, indicating that the anions are coordinated to the copper(II) ion. Coordination of the anions to the copper(II) ion is further supported by the IR spectra of the thiocyanato-, sulphato- and the azido complexes (Table 3).

The IR data (Table 3) also support coordination of the Schiff base via the azomethine nitrogen atom {lowering of the azomethine ν(C=N) band and shift of the hydrazine ν(N—N) band of the free ligand to higher frequencies), the pyridine nitrogen atom (shift of the pyridine ring deformation mode from 562 cm^{-1} to about 595 cm^{-1}) and the sulphur atom (lowering of the ν(C=S) band from 830 cm^{-1} to 720 cm^{-1}).

The room-temperature magnetic moments of the present copper(II) complexes (Table 1) indicate that they are magnetically dilute in nature. Their electronic spectra show bands in the regions 210–345, 380–470 and 660–690 nm, corresponding to the intraligand,

charge transfer and *d-d* transitions, respectively. The sulphur to copper charge transfer band, which is characteristic of copper(II)-thiosemicarbazone complexes [7,8] is observed at ca 410 nm.

The x-ray crystal structures of the [Cu(HNNS)(SO_4)(H_2O)]·H_2O *and* [Cu(NNS)(CH_3COO)(H_2O)] *complexes*

The structures of the sulfato- and the acetato complexes, together with the atom numbering schemes adopted, are shown in Figs 2 and 3, respectively. Tables 4 and 5 list the selected bond lengths and bond angles for the sulfato- and acetato-complexes, respectively. The crystal structures of both complexes contain discrete five-coordinate copper(II) ions. The coordination environment around the copper(II) ion in each complex is five-coordinate with the copper atom lying in an approximate plane of four coordinating atoms, three of which are supplied by the 6-methyl-2-formylpyridinethiosemicarbazone, the fourth coordination position is occupied by an oxygen atom of the sulfate or acetate ligand and the fifth

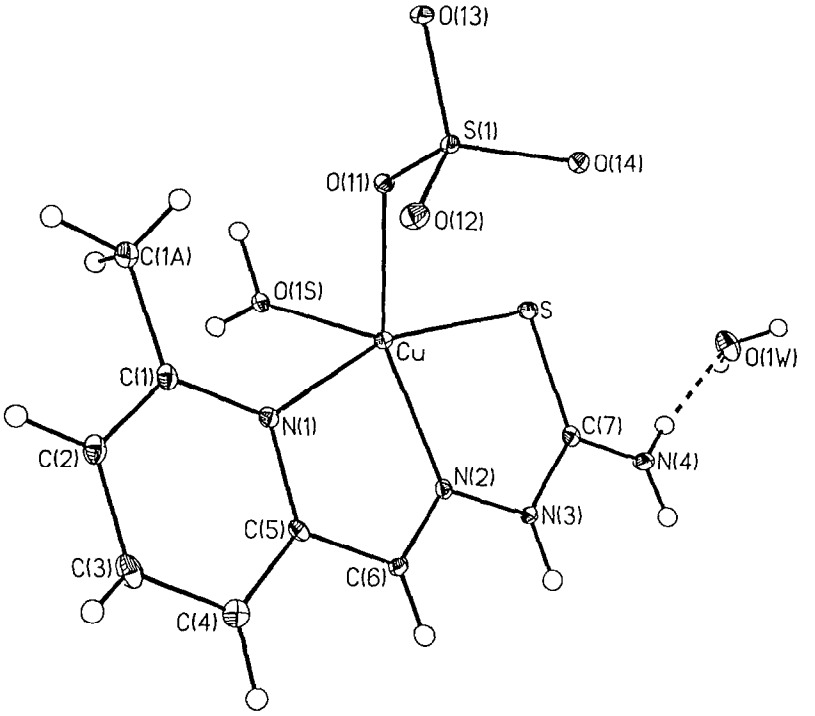

Fig. 2. The structure of [Cu(HNNS)(SO$_4$)(H$_2$O)] · H$_2$O.

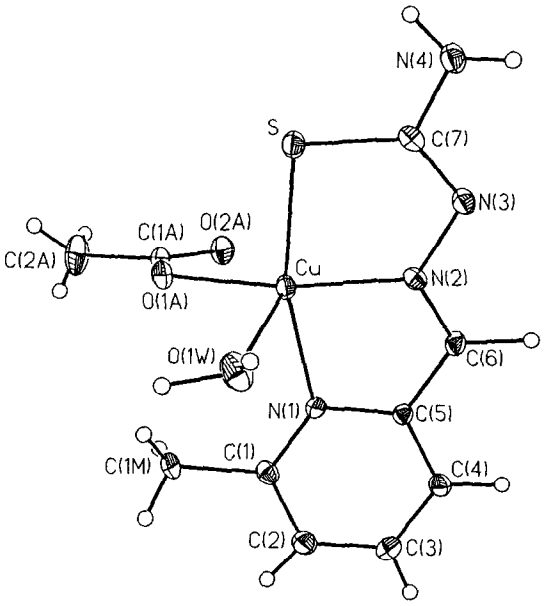

Fig. 3. The molecular structure of [Cu(NNS)(CH$_3$COO)(H$_2$O)] with the atom numbering scheme.

coordination position is completed by an oxygen of the coordinated water molecule. In the [Cu(HNNS)(SO$_4$)(H$_2$O)] · H$_2$O complex, the C(7)—S bond distance (1.710(3) Å) is nearer to that expected of a double bond than a single bond and compares well with that of other thiosemicarbazone-copper(II) complexes containing thione sulfur [7]. Both the sulfato- and acetato-copper(II) complexes of the parent 2-formylpyridinethiosemicarbazone have a dimeric structure with one-atom acetate of sulfate oxygen-bridging [7]. This shows that substitution of a hydrogen atom by a methyl group at the sixth position of the pyridine ring of the ligand prevents formation of a dimer. In spite of the similarity of the coordination sphere around the copper(II) ion in both sulfate and acetate complexes, the crystal structures show that the 6-methyl-2-pyridinecarboxaldehydethiosemicarbazone exists in the deprotonated mercaptide form in the acetate complex, whereas it is present as undeprotonated thione form in the sulfato complex. The deprotonation of the ligand in the [Cu(NNS)(CH$_3$COO)(H$_2$O)] complex is accompanied by tautomerization to the iminothiolate form. While coordinating in the iminothiolate form, the negative charge on the sulfur atom (generated by deprotonation) is delocalized in the C—N—N—C system as indicated by their intermediate bond distances [C(6)—N(2) = 1.273(8) Å, N(2)—N(3) = 1.739(7) Å and N(3)—C(7) = 1.305 Å]. The C(7)—S bond distance (1.728(7) Å) in the acetato-complex, is shorter than that found in the analogous copper(II) complexes containing thiolato sulfur atoms, but the bond orders of the two C—N bonds are closer to two than one. The Cu—S, Cu—N(imine) and Cu—N(py) bond lengths in both complexes (Tables 3 and 4) compare well with those found in other related five-coordinate

copper(II) complexes of thiosemicarbazone ligands [7,8]. The stereochemistry around the copper(II) atom in both complexes is intermediate between a square-pyramidal (SPY) and a trigonal-bipyramidal (TBPY) geometry. Illustration of this point can be made by considering the distortion from idealized TBPY geometry. Taking O(11) and N(2) as the axial donors in the $[Cu(HNNS)(SO_4)(H_2O)]\cdot H_2O$ complex, an angle of 151.45(9)° is subtended at the copper(II) ion [*viz.* the O(11)—Cu—N(2) angle] which is much smaller than the theoretical value of 180°. The angles between the two axial donors and the three equatorial donors O(1S), N(1) and S in the sulfato complex range from 102.02(9)° for the O(11)—Cu—N(1) angle to 117.02(9)° for the N(2)—Cu—O(1S) angle. The three equatorial angles range from 162.47(7)° for N(1)—Cu—S, 96.32(7)° for O(1S)—Cu—S and 93.91(9)° for O(1S)—Cu—N(1) showing marked differences from the ideal value of 120°. A similar comparison can be made for an idealized SPY geometry taking O(11) as the apical donor and N(1), N(2) and O(1S) to form the basal plane.

Similarly, taking 01A and N2 as the axial donors for the acetato complex, an angle of 162.2(2)° is subtended at the copper(II) ion, which is smaller than the theoretical value of 180°. The angles between the two axial donors and the three equatorial donors S, N1 and O1W range from 80.7(2) to 102.4(2)°, showing marked differences from the expected value of 120°. In a similar manner, a comparison can be made for an idealized square-pyramidal geometry for the acetato-complex by taking O1W as the apical donor and S, N2, N1 and O1A as the axial donors. The distortion from idealized stereochemistry for both complexes is attributed to the restricted bite angles imposed by the Schiff base.

The molecular packing study for the sulfato-complex confirms the presence of extensive hydrogen

bonding interactions involving the uncoordinated sulfate oxygens, the coordinated and uncoordinated water molecules and the hydrogen atoms attached to N(4). These hydrogen bonding interactions between the hydrogen atom on N(3) and a sulfato ligand are probably responsible for stabilizing the neutral form of the ligand.

The molecular packing study for the [Cu(NNS)(CH_3COO)(H_2O)] complex shows that one of the two NH_2 protons is involved in hydrogen bonding to the coordinated acetate oxygen of an adjoining molecule. The two water protons are both involved in hydrogen bonding interaction to N3 and O2A in other molecules.

CONCLUSION

Although the parent 2-formylpyridine thiosemicarbazone (HPATS) ligand almost invariably forms dimeric copper(II) complexes with copper(II) salts, the present ligand, which is similar to HPATS expect that it has a methyl group attached to the sixth position of the pyridine ring, yields monomeric copper(II) complexes. The sulfato- and acetato-copper(II) complexes of the present ligand, like those of the HPATS ligand, are also five-coordinate but they are not dimeric with oxygen-bridging.

Synthesis of bis(diphenylphosphino) ethanenickel(II) organodichalcogenide complexes and cyclotrimerisation reaction of dimethylacetylenedicarboxylate: structure of Ni(dppe)(SC_6H_4O)

Mary S. Thomas and J. Darkwa*†

Department of Chemistry, University of the North, Private Bag X1106, Sovenga 0727, South Africa

(Received 21 July 1997; accepted 16 December 1997)

Abstract—Reaction of Ni(dppe)Cl_2 (dppe = bis(diphenylphosphino)ethane) with organodichalcogenide ligands of the type 1,2-HSC_6H_4EH (E = CO_2, O, NH) in the presence of triethylamine to give the products Ni(dppe)($SC_6H_4CO_2$) (**1**), Ni(dppe)(SC_6H_4O) (**2**), and Ni(dppe)(SC_6H_4NH) (**3**). Complex **2** was characterised by single crystal X-ray diffraction, which shows a distorted geometry. Complexes **1–3** and the dithiolato analogues of 1,2-benzenedithiol, Ni(dppe)(SC_6H_4S) (**4**), and 3,4-toluendithiol, Ni(dppe)(SC_6H_3MeS) (**5**), upon reflux with dimethylacetylenedicarboxylate (DMAD) formed the cyclotrimeric product hexamethylbenzene hexacarboxylate (HMBC). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel(II) complexes; crystal structure; cyclotrimerisation; hexamethylbenzene hexacarboxylate.

Since the discovery of the cyclotetramerisation of acetylene by Reppe [1], a number of transition metal complexes have been found to homogeneously catalyse the cyclisation of acetylenes. Much of this work has centred around the group 10 metals, with the cheaper nickel playing quite a prominent role in these studies. Two oxidation states are predominant in the use of nickel as a catalyst for acetylene cyclisation. These are Ni(II) and Ni(0). Early literature reports considered Ni(II) complexes as the active catalysts in the formation of cyclooctatetraenes [2], whereas Ni(0) complexes trimerise acetylenes to benzenoid derivatives [3,4]. In general, studies involving Ni(0) are more abundant than those of Ni(II) mainly because the former readily dissolve in organic solvents whilst Ni(II) salts, that are normally used, are insoluble in such solvents. With the aid of phosphine ancillary ligands the solubility of Ni(II) complexes in organic solvents could be achieved. Such compounds are known to trimerise acetylenes [5]. Recently, Bennet and Wenger [6] have utilised bis(phosphino)nickel(0) complexes to catalytically cyclise a number of alkynes in solution, demonstrating the importance of phosphines in these reactions.

With dithiolato as coligands, phosphinonickel complexes can behave as nucleophilic agents towards acetylenes. Dimethylacetylenedicarboxylate reacts with (triphos)Ni(η^2-S_2CS) (triphos = 1,1,1-tris-(diphenylphosphinomethyl)ethane) to form a heterocyclic five-membered metallo-ring adduct, in which a dimerised DMAD moiety is attached to the C and S ends of the η^2-S_2CS ligand [7]. Adduct formation, through the attachment of dienes to sulfur atoms of bis(1,2-ethylenedithiolato)Ni [8] and of quadricyclane to one sulfur atom of (η^5-C_5H_5)(1,2-BDT)Co(III) (1,2-BDT = 1,2-benzenedithiolato) [9], are known. In an effort to investigate the nucleophilic properties of bis(diphenylphosphino)ethanenickel(II) organodichalcogenide complexes, we reacted the three compounds synthesised in this paper as well as Ni(dppe)(SC_6H_4S) (**4**) and Ni(dppe)(SC_6H_3MeS) (**5**), the synthesis of which has been reported elsewhere

[10], with DMAD. Our investigations showed that DMAD readily trimerises to HMBC.

RESULTS AND DISCUSSION

Syntheses of mixed aryldichalcogenide complexes (**1–3**) were performed in good yields, by adding the appropriate chalcogen containing ligand to a solution of $Ni(dppe)Cl_2$ and excess Et_3N (eqn (1)).

$$Ni(dppe)Cl_2 + 1,2\text{-}HSC_6H_4EH \xrightarrow{2Et_3N} Ni(dppe)(SC_6H_4E) + 2Et_3NHCl (E = CO_2\ (\mathbf{1}),\ O\ (\mathbf{2}),\ NH\ (\mathbf{3})) \quad (1)$$

All reactions were complete within 2 h and products could be isolated in analytically pure form. The ^1H NMR of complexes **1–3** displays a pattern which is consistent with the different environment of all four protons of the phenyl group of the chalcogen containing ligands. Compound **3** has an additional broad peak at 4.35 pm, corresponding to the NH group of the aminothiophenolate ligand. The non-equivalence of the two phosphorus atoms of the dppe is clearly indicated by different electronic properties between the S and E of the thiolate ligands. This results in a set of multiplets for the ethane moiety in the dppe. For **1** and **3** there are two sets of multiplets, with each set associated with one P atom; but the multiplets for **2** are not well resolved. The $^{31}P\{^1H\}$ spectra show doublets corresponding to the expected AX (**1, 2**) or AB (**3**) spin system. The latter is similar to the peaks pattern for $[Ni(dippe)(SR)(CNBu^t)]^+$ (dippe = 1,2-bis(diisopropylphosphino)ethane, R = C_6F_5, C_6F_4H, C_6H_4F, Ph) [11].

Compounds **1–5** are stable indefinitely in the solid state in air at room temperature; but on exposure to air, blue solutions of **3** gradually turn purple in 2 days at room temperature. This is accompanied by the disappearance of the NH peak in the ^1H NMR spectrum. Other phenyl peaks of the aminothiophenolate ligand lose their fine structure gradually and broaden over a period of 12 days.

Structure of $Ni(dppe)(SC_6H_4O)$

The co-ordination around the nickel is a distorted square-planar, with a maximum deviation from the least-square of $NiOSP_2$ being 0.19 Å. This deviation from planarity is more pronounced than that found for **4** [10]. The molecular structure of **2** is shown in Fig. 1 and selected bond distances and angles are given in Table 1 and atomic co-ordinates in Table 2. Apart from the Ni—O and the C(1)—O bonds in **2** which do not exist in **4** [10], all other bond distances and angles in the two compounds are comparable. The bond lengths and angles are in the expected ranges for Ni—S [12] and Ni—P [13] distances. In particular the Ni—S and Ni—O distances are similar to those found

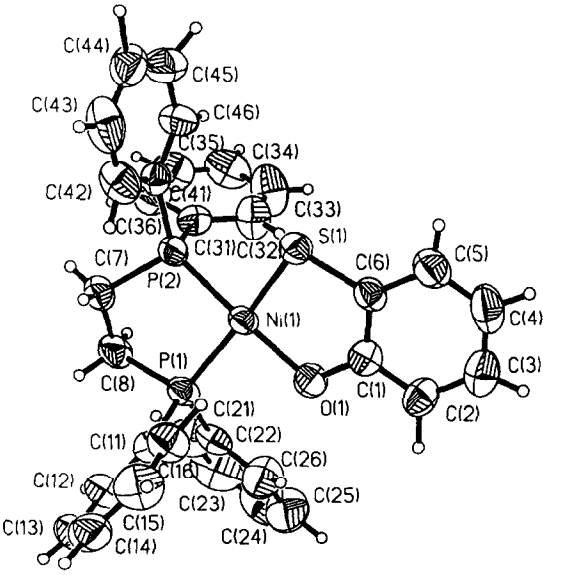

Fig. 1. ORTEP drawing of $Ni(dppe)(SC_6H_4O)$.

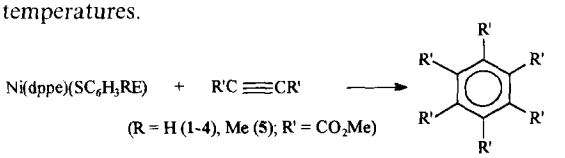
in $[^nBuNH]_2[Ni(SC_6H_4O)_2]$, which are 2.153(2) Å and 1.875(3) Å respectively [14].

Reactions with DMAD

When solutions of compounds **2–5** and DMAD in toluene/CH_2Cl_2 (1 : 1) were refluxed, typically for 48 h, HMBC could be isolated (eqn (2)). The reaction is very slow at room temperature and could take up to 1 week to complete, but it is much faster at elevated temperatures.



(2)

The product was identified as HMBC by its melting point, IR, ^1H, ^{13}C NMR and mass spectroscopy (see Experimental section). The efficiency of these complexes to effect the cyclotrimerisation ranges from 4% for **3** to 42% for **5**; with the ratio of DMAD to the nickel complexes being about 48 : 1. Nevertheless the yields for all are better than expected from a stoichiometric reaction except for **3**; implying some catalytic activity.

However under similar conditions and work-up procedure, HMBC could not be isolated when **1** reacted with DMAD. A brown precipitate was obtained when solutions, after reflux, were allowed to stand at room temperature for several days. The dominant peak in the ^1H NMR spectrum of this brown solid is 3.88 ppm, with some weak and broad peaks in the phenyl region. ^{13}C NMR spectrum gave

peaks assignable to HMBC as the only significant peaks. The parent peak in EIMS of the solid is m/z = 395 and a molecular peak at m/z = 427 (5.7%), which were also observed as the parent and molecular peaks for HMBC. The 395 peak corresponds to a loss of OMe from HMBC. Other peaks in the spectrum were m/z 683, 825, and 967; which we have not been able to assign to any definitive molecular formula. But the difference between peaks show loss of DMAD (m/z = 142). Based on this data it is evident that **1** also cyclotrimerises DMAD, but the HMBC formed could be adsorbed by some reminant nickel complex, thus making it difficult to separate by column chromatography.

NMR tube reaction of **5** and DMAD allowed the progress of the trimerisation to be monitored by ^{1}H NMR spectroscopy. There were not significant changes in the spectrum of **5** during the first 30 min. After 4 h new peaks appeared at 7.08 (d), 7.33 and 7.67, all were weak in intensities, in addition to 7.26 (d), 7.21 (s) and 6.63 (m) for **5**. Peaks of **5** were significantly weaker after 24 h, and the 7.08 peak observed after 24 h had become quite broad. A distinct HMBC peak at 3.88 had begun to emerge at this stage in the reaction. When the spectrum of the mixture was run after 3 days, the peaks found were the same as those of 24 h but better resolved. The ^{31}P NMR after 24 h gave two peaks at 58.62 and 48.22 (intensity ratio 2:1); the 58.62 peak is assignable to **5** but the latter is new. However after 7 days of reaction the peak intensities were equal. Finally, ^{13}C spectrum of this mixture showed the following chemical shifts: 165.2, 152.2, 133.9, 74.5 and 43.4; three of which are the peaks of HMBC (165.8, 133.9 and 53.5). When phenylacetylene and diphenylacetylene were used in place of DMAD, no reaction was observed and the acetylenes could be recovered in near quantitative amounts. This clearly implies that the bulkier and less electrophilic alkynes, could not be activated by the nickel complexes. These observations suggest that the trimerisation process might involve attack of the nickel complex by the alkyne as proposed by Tyler *et al.* [16]. The least efficient of the five complexes in effecting trimerisation was found to be **3** which could be explained by the gradual decomposition of the complex in solution (*vide supra*).

CONCLUSION

With bidentate phosphines as ancillary ligand, homo and mixed aryldichalcogenide nickel(II) complexes could convert the electrophilic acetylene, DMAD, to HMBC catalytically. However bulky acetylenes are unreactive, most likely due to their inability to be activated by the catalysts. The lack of reactivity by the bulkier acetylenes might mean that the initial step in the cyclisation of DMAD is coordination of the acetylene.

EXPERIMENTAL

Materials and instrumentation

All solvents were of analytical grade and were used without further purification. The thiols and 1,2-bis(diphenylphosphino)ethane were purchased from Aldrich and were used as received. Ni(dppe)Cl_2 [16], Ni(dppe)(1,2-BDT) (**4**) and Ni(dppe)(TDT) (**5**) (TDT = 3,4-toluenedithiolato), were prepared by the literature procedure [10].

IR spectra were recorded on a Mattson Polaris or a Nicolet 205 FT-IR. ^{1}H, ^{13}C and ^{31}P NMR were recorded on a Varian Gemini 2000 or a Gemini 300 and referenced to residual $CHCl_3$ for ^{1}H (7.26), ^{13}C (77.0) and externally to 85% H_3PO_4 for ^{31}P. Mass spectra data were collected on a Finnigan MAT SSQ 700 in the electron impact mode and elemental analyses were performed by the microanalytical laboratory

Syntheses of Ni(dppe)organodichalcogenide complexes

All three complexes were prepared and worked-up in a similar manner and typical procedure is described for Ni(dppe)($SC_6H_4CO_2$).

Ni(dppe)($SC_6H_4CO_2$) (**1**). A mixture of Ni(dppe)Cl_2 (1.0 g, 1.89 mmol) and thiosalicylic acid (0.29 g, 1.89 mmol) was degassed and nitrogen saturated CH_2Cl_2 (30 cm^3) added. To the resultant solution was added Et_3N (1.00 cm^3), changing the orange solution to dark red. After stirring the solution for 2 h, hexane (50 cm^3) was added to give an orange brown precipitate. The solid was washed with copious amount of water and recrystallised from CH_2Cl_2/hexane. Yield = 0.88 g, 76%, m.p. = 258–260°C. Anal. Calc. for $C_{33}H_{28}O_2P_2SNi$: C, 65.05; H, 4.63; S, 5.26. Found: C, 63.93; H, 4.70; S, 4.70%. ^1H NMR ($CDCl_3$): 8.11 (q, 1H), 7.30 (q, 1H), 7.01 (m, 2H) ($SC_6H_4CO_2$); 8.03 (m, 8H), 7.51 (m, 12H) (dppe), 2.38 (m, 2H), 2.10 (m, 2H) (dppe). $^{13}C\{^1H\}$ NMR: 168.9 (s) ($SC_6H_4CO_2$), 142.4 (s), 133.5 (d, J_{CP} = 10.20 Hz), 133.1 (d, J_{CP} = 10.30 Hz), 129.2 (d, J_{CP} = 8.30 Hz), 128.7 (s), 123.1 (s) (dppe), 131.9 (s), 131.4 (s), 128.4 (s), 127.4 (s), 126.8 (s) ($SC_6H_4CO_2$), 29.7 (d, J_{CP} = 15.0 Hz), 21.9 (d, J_{CP} = 15.0 Hz) (dppe). $^{31}P\{^1H\}$ NMR: 57.19 (d, J_{PP} = 59.82 Hz), 41.72 (d, J_{PP} = 59.82 Hz). IR (KBr pellet, cm^{-1}): 3043 w, 1592 vs, 1575 vs, 1543 m, 1433 s, 1348 s, 1100 s, 821 s, 752 s, 703 s, 689 s, 528 vs, 488 m.

Ni(dppe)(SC_6H_4O) (**2**). Yield = 0.76 g, 69%; m.p. = 294–296°C. Anal. Calc. for $C_{32}H_{28}OP_2SNi$: C, 66.12; H, 4.86; S, 5.52. Found: C, 65.56; H, 4.83; S, 4.96%. ^1H NMR ($CDCl_3$): 8.08 (t, J_{HH} = 9.0 Hz, 4H), 7.88 (t, J_{HH} = 9.0 Hz, 4H), 7.46 (m, 12H) (dppe), 7.30 (d, J_{HH} = 7.41 Hz, 1H), 6.82 (t, J_{HH} = 8.19 Hz, 1H), 6.72 (d, J_{HH} = 7.98 Hz), 6.50 (t, J_{HH} = 7.41 Hz) (SC_6H_4O), 2.60 (m, 4H) (dppe), $^{13}C\{^1H\}$ NMR: 133.3 (dd, J_{CP} = 9.3 Hz), 131.2 (d, J_{CP} = 22.6 Hz), 128.9 (t, J_{CP} = 10.3 Hz) 115.3 (d, J_{CP} = 33.2 Hz) (dppe), 130.9 (s), 130.3 (s), 129.7 (s), 127.6 (s), 122.5 (s) (SC_6H_4O), 29.5 (d, J_{CP} = 16.0 Hz), 22.7 (d, J_{CP} = 16.0 Hz) (dppe). $^{31}P\{^1H\}$ NMR: 58.88 (d, J_{PP} = 55.46 Hz, 1P), 44.97 (d, J_{PP} = 55.46 Hz, 1P). Ni(dppe)(SC_6H_4NH) (**3**). Yield = 0.82 g, 75%; decompositon = 249.1°C. Anal. Calc. for $C_{32}H_{29}NP_2SNi$: C, 66.23; H, 5.04; N, 2.41; S, 5.53. Found: C, 65.31; H, 5.03; N, 1.94; S, 5.23. ^1H NMR ($CDCl_3$): 7.85 (t, J_{HH} = 7.80 Hz, 8H), 7.46 (m, 12H) (dppe), 6.71 (t, J_{HH} = 6.80 Hz, 1H), 6.43 (dd, J_{HH} = 13.00, 7.20 Hz 2H), 4.38 (s, br, 1H) (SC_6H_4NH), 2.32 (d, 17.60 Hz, 4H) (dppe). $^{13}C\{^1H\}$ NMR: 133.5 (d, J_{CP} = 11.1 Hz), 131.3 (d, J_{CP} = 17.6 Hz), 129.2 (d, J_{CP} = 9.9 Hz), 128.7 (d, J_{CP} = 10.3 Hz) (dppe), 130.0 (s), 127.6 (s), 121.8 (s), 112.9.5 (s) (SC_6H_4NH), 27.9 (t, J_{CP} = 20.1 Hz) (dppe). $^{31}P\{^1H\}$ NMR: 60.44 (d, J_{PP} = 47.56 Hz, 1P), 59.77 (d, J_{PP} = 47.56 Hz, 1P). IR (KBr pellet, cm^{-1}): 3020 m, 1559 s, 1480 w, 1463 s, 1434 vs, 1310 s, 1188 w, 1100 s, 1026 m, 876 m, 851 w, 820 s, 737 s, 689 vs, 528 vs, 480 vs, 432 w, 395 w, 372 m.

Reaction of Ni(dppe) organodichalocogenide *complexes with* DMAD. In a typical reaction excess DMAD (2 cm^3, 16.27 mmol) and Ni(dppe)(SC_6H_4O) (0.20 g, 0.34 mmol) solution in toluene/CH_2Cl_2 (1 : 1) (50 cm^3) was refluxed for 24 h. The dark orange solution obtained was concentrated to about 5 cm^3 and chromatographed (silica gel, CH_2Cl_2/ether 1 : 4) to yield 0.40 g (0.94 mmol) of hexamethylbenzene hexacarboxylate, $C_6(CO_2Me)_6$. ^1H NMR ($CDCl_3$): 3.88

(s, 18H). ^{13}C NMR: 165.2 (s), 133.9 (s), 53.5 (s). IR (KBr pellet cm^{-1}): 3012 m, 2958 s, 1738 vs, 1576 w, 1445 vs, 1413 s, 1363 s, 1332 s, 1235 vs, 1182 vs, 1160 s, 1122 m, 985 vs, 906 w, 872 s, 860 vs, 849 vs, 828 s, 805 w, 787 w, 757 m, 618 s, 603 m, 471 w. MS (EI): *m/z* (relative intensity) 426 (2) (M^+), 395 (100) ($M^+ - OMe$). The other complexes were reacted with DMAD using the same number of moles of nickel complex (0.34 mmol) and DMAD (16.27 mmol). The number of moles of HMBC isolated were **3** (0.23 mmol), **4** (0.52 mmol) and **5** (2.26 mmol).

Crystal structure determination of **2**

Single crystals of **2** suitable for crystal structural determination were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **2** at room temperature. A dark rectangular plate crystal of size $0.70 \times 0.22 \times 0.11$ mm was mounted in a sealed capillary tube for data collection. All geometric and intensity data were collected on a Siemens SMART diffractometer with a CCD detector. Crystal data for $C_{32}H_{28}OP_2SNi$ ($Mr = 581.25$): orthorhombic, Pbca; $a = 12.5385(6)$ Å, $b = 15.1818(2)$ Å, $c = 29.496(2)$ Å, $V = 5614.7(5)$ Å^3; $Z = 8$; $D_{calc} = 1.375$ Mg m^{-3}; Mo-K_α radiation ($\lambda = 0.71073$ Å); $T = 298$; $\theta = 1.38$–28.29 , 10 s/frame exposure; 0.3 /frame; 6563 independent reflections collected, 4970 unique. Full matrix least-squares refinement [17] of 446 parameters on F^2 gave $R_1 = 0.0698$. $wR_2 = 0.1746$, GoF = 1.253. Max ΔF 0.42 eÅ^{-3}, min -0.25 eÅ^{-3}. An absorption correction based on multiple redundant data analysis was applied [18].

Supplementary material. Further crystallographic details can be obtained on request from the Director of the Cambridge Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Acknowledgement—Financial support for this work by the University of the North and the Foundation for Research Development (South Africa) for the purchase of a regional NMR are gratefully acknowledged. We are also grateful to Dr E. Y. Osei-Twum, King Fahd University of Petroleum and Minerals, Saudi Arabia and Dr M. M. Nindi, University of Botswana, for the mass spectral data. We thank Prof. J. C. A. Boeyens and Ms Leanne Cook, University of the Witwatersrand, South Africa, for the X-ray structure determination, which was done as a service.

Note: After we submitted our paper a report on the synthesis of Ni(dppe)($SC_6H_4CO_2$) appeared in the literature [19].

(Received 14 October 1997; accepted 12 December 1997)

Abstract—The preparation and characterization of new hybrid donor-type phosphine-thioether ligands, a linear tetradentate $Me_2P(CH_2)_2S(CH_2)_3S(CH_2)_2PMe_2$ (dmdtn) and a didentate $Me_2P(CH_2)_2SR$ [R = Me (mtdmp) or Et (etdmp)], and their cobalt(III) complexes are described. The reaction of *trans*-$[CoCl_2(py)_4]Cl$ (py = pyridine) with dmdtn, followed by anion metathesis with $NaPF_6$, afforded green crystals of *trans*(*Cl*,*Cl*)-$[CoCl_2\{meso(S)\text{-dmdtn}\}]PF_6$ (**1**), whose geometrical structure and configuration around S atoms were determined by X-ray analysis. Further reaction of **1** with Li(acac) (acac = pentane-2,4-dionate) and crystallization with $LiBF_4$ gave red crystals of the acac complex **2**. The X-ray analysis of **2** confirmed the structure and configuration of *cis*β-$[Co(acac)\{racemic(S)\text{-dmdtn}\}](BF_4)_2$, indicating the configurational inversion at one sulfur during the derivation of complex **2**. An analogous *N*,*N*-dimethyldithiocarbamate (dtc) complex **3** was also prepared, and the electrochemical properties of complexes **1**–**3** were discussed. For analogous mtdmp and etdmp (P—S) complexes, *trans*(*Cl*,*Cl*)*cis*(*P*,*P*)-$[CoCl_2(P—S)_2]PF_6$ reacted with Li(acac) to give not only *trans*(*P*,*S*)-$[Co(acac)(P—S)_2](PF_6)_2$ but also $[Co(acac)_2(P—S)]PF_6$. Similar reactions with Na(dtc) yielded *cis*-$[Co(dtc)_2(P—S\text{-}\kappa P)_2]$ (**14** for P—S = mtdmp), together with *trans*(*P*,*S*)-$[Co(dtc)(P—S)_2](PF_6)_2$ and $[Co(dtc)_2(P—S)]PF_6$. The structures of these complexes were characterized by NMR and UV-visible spectroscopy and X-ray analysis of **14**. These results suggested that the didentate ligands were hemilabile as similar to previously described SPPS-type tetradentate ligands, but the tetradentate dmdtn ligand was not. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: hybrid donor-type ligand; dimethylphosphino group; thioether; tetradentate ligand; cobalt(III); hemilabile.

Because of the soft base characters of phosphines and thioethers, their complexation behaviours and bonding natures to cobalt(III) of a typical Lewis hard acid are expected to be quite different from those of well-examined hard bases of the analogous amines. In line with this view, we have continued to study cobalt(III) complexes with linear hybrid donor-type tetradentate ligands bearing phosphine and amine groups [1–7] or phosphine and thioether groups [8,9]. In previous reports [8,9], we have prepared a large number of cobalt(III) complexes containing $MeS(CH_2)_2$-$PPh(CH_2)_nPPh(CH_2)_2SMe$ (SPPS; $n = 2$ or 3), in order to compare their properties with those of the complexes containing analogous phosphine-amine (NPPN) ligands. In the SPPS complexes, many complicated stereo and geometrical isomers were possible, because the ligands have two chiral phosphorus atoms in the central part and two prochiral sulfur atoms in the terminal of their skeletons. Further, the thioether moieties often did not coordinate to cobalt(III), the weak donor ability of thioethers toward cobalt(III)

* Authors to whom correspondence should be addressed.

being suggested [10]. In order to examine further the coordination abilities and complexation behaviours of the phosphine-thioether ligands, we have extended the study to the PSSP-type linear tetradentate ligand, which has no chiral phosphorus atoms in its skeleton.

The crystal structures of nickel(II) and palladium(II) complexes containing $Ph_2P(CH_2)_2S(CH_2)_3S(CH_2)_2PPh_2$ (dpdtn) have been reported previously [11–13], and several transition metal(II) complexes containing the related PSSP-type tetradentate ligands, $Ph_2P(CH_2)_nS(CH_2)_nS(CH_2)_nPPh_2$ ($n = 2$ [14] or 3 [15]), have been synthesized. We have tried to synthesize the cobalt(III) complexes of dpdtn, but only *cis*β-[Co(dtc)(dpdtn)]$(BF_4)_2$ could be isolated in very low yield (ca 10%); all the other attempts were unsuccessful [16]. The difficulty in syntheses of such complexes may be caused by the steric bulkiness of the diphenylphosphino groups. Thus, we have prepared a new tetradentate ligand $Me_2P(CH_2)_2S(CH_2)_3S(CH_2)_2PMe_2$ (dmdtn; Scheme 1) and its cobalt(III) complexes, because the dimethylphosphino group has a smaller steric requirement and a stronger donor ability than the diphenylphosphino group. The related didentate phosphine-thioether ligands $Me_2P(CH_2)_2SR$ [R = Me (mtdmp) and Et (etdmp)] and their cobalt(III) complexes were also prepared to examine the effect of sulfur position (central or terminal) in the skeleton.

EXPERIMENTAL

All reactions were handled under a dinitrogen atmosphere using Schlenk techniques until such time that air-stable cobalt(III) complexes were formed. All of the solvents used in the preparation of the phosphines and their complexes were deaerated with dinitrogen for 20 min immediately before use. The $^{13}C\{^1H\}$ NMR spectra were recorded on a Hitachi R-90H spectrometer and referenced to tetramethylsilane. The absorption spectra were measured on a Hitachi U3400 spectrophotometer at room temperature. Cyclic voltammograms were measured on a BAS 100B electrochemical analyzer at a scan rate 100 mV s^{-1} in acetonitrile solutions at 25.0 ± 0.1 ([complex] = 1.0×10^{-3} mol dm^{-3}; 0.1 mol dm^{-3} Bu_4NBF_4). A platinum disk, a platinum wire and a Ag/Ag^+ electrode (Ag/0.01 mol dm^{-3} $AgNO_3$) were used as the working, auxiliary and reference electrodes, respectively, the redox potential of ferrocene/ferrocenium ion being observed at +0.15 V vs Ag/Ag^+.

2,12-*Dimethyl*-2,12-*diphospha*-5,9-*dithiatridecane* (**dmdtn**)

To a liquid ammonia solution (200 cm^3) of sodium metal (2.7 g, 0.12 mol), which was cooled in a dry ice-acetone bath, was added tetramethyldiphosphane [17] (6.3 g, 0.052 mmol) dropwise with stirring. The resulting orange solution was stirred for 1 h, and ethylenesulfide (6.3 g, 0.11 mol) was added dropwise with stirring. After stirring for an additional 1 h, 1,3-dibromopropane (10.5 g, 0.052 mmol) was added and the resulting colourless mixture was stirred further for 1 h. From the mixture liquid ammonia was carefully evaporated by removal of the dry ice-acetone bath, affording pale yellow oily residue with a precipitate of NaBr. The residue was mixed with diethyl ether (100 cm^3) and filtered. The ethereal solution was evaporated under reduced pressure to leave a pale yellow oily product of dmdtn (11.3 g, 74% yield). ^{13}C NMR ($CDCl_3$): δ 13.8 (d, $^1J_{PC}$ = 13.1 Hz, PCH_3), 28.6 (d, $^2J_{PC}$ = 17.6 Hz, SCH_2CH_2P), 29.2 (d, $^4J_{PC}$ = 1.7 Hz, $CH_2CH_2CH_2$), 31.0 (s, $CH_2CH_2CH_2$), 32.2 (d, $^1J_{PC}$ = 12.8 Hz, PCH_2). This is soluble in common organic solvents and was used for the preparation of cobalt(III) complexes without further purification.

2-(*Methylthio*)*dimethylphosphinoethane* (**mtdmp**) *and* 2-(*ethylthio*)*dimethylphosphinoethane* (**etdmp**)

The preparation of mtdmp was described previously [19]. The etdmp was prepared by a method similar to that for mtdmp using (2-chloroethyl)ethylsulfide instead of (2-chloroethyl)methylsulfide (90% yield). ^{13}C NMR ($CDCl_3$): δ 13.8 (d, $^1J_{PC}$ = 12.8 Hz, PCH_3), 14.7 (s, SCH_2CH_3), 25.9 (s, SCH_2CH_3), 28.0 (d, $^2J_{PC}$ = 17.6 Hz, SCH_2CH_2P), 32.1 (d, $^1J_{PC}$ = 12.4 Hz, PCH_2).

Scheme 1. The hybrid donor-type phosphine-thioether ligands used in this study.

trans-[$CoCl_2$(dmdtn)]PF_6 (**1**)

To a methanol solution (30 cm^3) of *trans*-[$CoCl_2(py)_4$]Cl·$6H_2O$ [19] (0.59 g, 1.0 mmol) was added dmdtn (0.30 g, 1.1 mmol) with stirring. The mixture was stirred at room temperature for 2 h and then concentrated to ca 5 cm^3 under reduced pressure. The concentrate was applied to a column (ϕ 3.0 × 45 cm) of Sephadex LH-20. The adsorbed products were eluted with methanol, affording faster developing minor green and red bands and then a slowly developing major blue-green band. The major band was collected and concentrated to a small volume. To the concentrate was added a methanol solution of excess $NaPF_6$, giving green precipitate. The crude product obtained was recrystallized by diffusion of diethyl ether vapour into an acetonitrile solution to deposit blue-green crystals of **1** (0.22 g, 40% yield). Found: C, 23.60; H, 4.72. Calc.: for $C_{11}H_{26}Cl_2CoF_6P_3S_2$: C, 23.63; H, 4.69%. ^{13}C NMR (CD_3CN): δ 12.1 (virtual t, J_{PC} = 16.1 Hz, PCH_3), 12.9 (virtual t, J_{PC} = 16.4 Hz, PCH_3), 26.3 (s, $CH_2CH_2CH_2$), 31.5 (s, SCH_2-CH_2P), 33.2 (virtual t, J_{PC} = 16.6 Hz, PCH_2), 34.6 (s, $SCH_2CH_2CH_2S$). This complex is soluble in methanol and acetonitrile, but insoluble in water and diethyl ether.

cisβ-[Co(acac)(dmdtn)]$(BF_4)_2$ (**2**)

A mixture of **1** (0.33 g, 0.59 mmol) and Li(acac) (0.094 g, 0.89 mmol) in methanol (40 cm^3) was stirred for 2 h, and then concentrated to ca 10 cm^3 under reduced pressure. The concentrate was diluted with water (100 cm^3) and applied on a column (ϕ 3.0 × 45 cm) of SP-Sephadex C-25 (Na^+ form). The adsorbed products were eluted with 0.05 mol dm^{-3} aqueous Na_2SO_4 solution, giving a minor yellow band. After the elution of the yellow band, a major red band was eluted with 0.3 mol dm^{-3} aqueous Na_2SO_4 solution. The collected eluate of the red band was evaporated to dryness under reduced pressure, and the residue was extracted with methanol. To the concentrated methanol extract was added a saturated methanol solution of $LiBF_4$ to give a red precipitate. The crude product was recrystallized by diffusion of diethyl ether vapour into an acetonitrile solution to deposit red crystals of **2** (0.23 g, 63% yield). Found: C, 31.07; H, 5.37. Calc: for $C_{16}H_{33}B_2CoF_8O_2P_2S_2$: C, 31.19; H, 5.40%. ^{13}C NMR (CD_3CN): δ 10.4–11.9 (overlapped peaks due to four kinds of PCH_3), 20–35 (overlapped peaks due to SCH_2CH_2P and $SCH_2CH_2CH_2S$), 26.6 (s, CCH_3), 27.8 (d, $^4J_{PC}$ = 4.5 Hz, CCH_3), 102.2 (s, *C*H), 191.5 (s, *C*O), 192.2 (s, *C*O). The complex is soluble in water, methanol and acetonitrile, but not in diethyl ether.

cisβ-[Co(dtc)(dmdtn)]$(PF_6)_2$ (**3**)

To a methanol solution (100 cm^3) of **1** (0.37 g, 0.66 mmol) was added a methanol solution (100 cm^3) of Na(dtc)·$2H_2O$ (0.14 g, 0.78 mmol) dropwise with stirring in an ice bath. The mixture was stirred for 2 h at room temperature, concentrated to ca 10 cm^3, and then diluted with water (100 cm^3). The aqueous solution was applied on a column (ϕ 5.0 × 60 cm) of SP-Sephadex C-25 (Na^+ form), and the adsorbed products were eluted with 0.05 mol dm^{-3} aqueous NaCl solution. After elution of a minor brown band, a major red band was eluted with 0.5 mol dm^{-3} aqueous NaCl solution. The eluate of the red band was evaporated to dryness under reduced pressure, and the residue extracted with a small amount of ethanol. The filtered red extract was concentrated to ca 1 cm^3 under reduced pressure and mixed with a saturated ethanol solution of $NaPF_6$ to afford red precipitate. The crude product obtained was recrystallized by diffusion of diethyl ether vapour into an acetonitrile solution to deposit red crystals of **3** (0.40 g, 80% yield). Found: C, 22.19; H, 4.28; N, 1.98. Calc.: for $C_{14}H_{32}CoF_{12}NP_4S_4$: C, 22.32; H, 4.28; N, 1.86%. ^{13}C NMR (CD_3CN): δ 9.8–12.3 (m, PCH_3), 15.5 (dd, $^1J_{PC}$ = 31.4 Hz, $^3J_{PC}$ = 4.2 Hz, PCH_3), 23.5 (s, $CH_2CH_2CH_2$), 28–37 (overlapped peaks due to SCH_2-CH_2P and $SCH_2CH_2CH_2S$), 30.1 (d, $^1J_{PC}$ = 31.8 Hz, PCH_2), 34.4 (dd, $^1J_{PC}$ = 31.8 Hz, $^3J_{PC}$ = 4.5 Hz, PCH_2), 39.7 (s, NCH_3), 40.3 (s, NCH_3), 199.1 (br, NCS_2). This complex is soluble in water, methanol and acetonitrile, but not in diethyl ether.

trans-[$CoCl_2$(mtdmp)$_2$]PF_6 (**4**)

To a methanol solution (30 cm^3) of *trans*-[$CoCl_2(py)_4$]Cl·$6H_2O$ (3.0 g, 6.0 mmol) was added mtdmp (2.0 g, 15 mmol). The mixture was stirred at room temperature for 2 h and then evaporated to dryness under reduced pressure. The residue was washed with diethyl ether to remove unreacted mtdmp and dissolved in a small amount of water. To the filtered solution was added an aqueous solution of excess $NaPF_6$, affording green precipitate. The crude product obtained was recrystallized by diffusion of diethyl ether vapour into a dichloromethane solution to deposit green crystals of **4** (2.5 g, 70% yield). Found: C, 22.00; 4.44. Calc.: for $C_{10}H_{26}Cl_2CoF_6P_3S_2$: C, 21.95; H, 4.79%. ^{13}C NMR (CD_3CN): δ 11–12 (overlapped peaks due to two kinds of PCH_3), 17.7 (s, SCH_3), 33.8 (s, SCH_2), 35.9 (virtual t, J_{PC} = 18.1 Hz, PCH_2). This complex is soluble in methanol, acetonitrile and dichloromethane, but insoluble in water and diethyl ether.

trans-[$CoCl_2$(etdmp)$_2$]PF_6 (**5**)

This complex was prepared by a method similar to that for **4** using etdmp instead of mtdmp (80% yield). Found: C, 25.22; H, 5.24. Calc.: for $C_{12}H_{30}Cl_2CoF_6P_3S_2$: C, 25.06; H, 5.26%. ^{13}C NMR (CD_3CN): δ 12.0 (virtual t, J_{PC} = 17.4 Hz, PCH_3), 12.2 (virtual t, J_{PC} = 16.8 Hz, PCH_3), 13.0 (s,

SCH_2CH_3), 29.5 (s, SCH_2CH_3), 31.6 (s, SCH_2CH_2P), 36.4 (virtual t, J_{PC} = 18.3 Hz, PCH_2). The solubility of this complex is similar to that of **4**.

trans(*P*,*S*)-[Co(acac)(mtdmp)$_2$](PF$_6$)$_2$ (**6**) *and* [Co(acac)$_2$(mtdmp)]PF$_6$ (**8**)

To a methanol solution (50 cm^3) of **4** (1.0 g, 1.8 mmol) was added a methanol solution (20 cm^3) of Li(acac) (0.40 g, 3.8 mmol) with stirring. The mixture was stirred overnight, then concentrated to ca 5 cm^3 under reduced pressure and diluted with water (2 dm^3). The aqueous solution was applied on a column (ϕ 5.0 × 50 cm) of SP-Sephadex C-25 (Na^+ form), and the adsorbed products were washed thoroughly with water and then eluted with 0.05 mol dm^{-3} aqueous Na_2SO_4 solution to develop violet and orange bands in this order. After the violet band was collected, the eluent was changed to 0.2 mol dm^{-3} aqueous Na_2SO_4 solution. Each eluate was evaporated to dryness under reduced pressure, and the residue was mixed with methanol to extract the violet or orange complex. The methanol extract was concentrated to ca 1 cm^3, and a saturated methanol solution of $NaPF_6$ added until the precipitation of violet or orange complex was completed. The orange crude product was recrystallized from methanol to deposit orange crystals of **6** (0.22 g, 18% yield). Found: C, 25.01; H, 4.62. Calc.: for $C_{15}H_{33}CoF_{12}O_2P_4S_2$: C, 25.10; H, 4.62%. ^{13}C NMR (CD_3CN): δ 7.5–13.3 (overlapped peaks due to four kinds of PCH_3), 16.3 (d, $^3J_{PC}$ = 1.7 Hz, SCH_3), 17.7 (s, SCH_3), 25–40 (overlapped peaks due to CCH_3, PCH_2 and SCH_2), 101.6 (s, *C*H), 191.4 (s, *C*O), 193.0 (d, $^3J_{PC}$ = 2.4 Hz, *C*O). The violet complex was similarly recrystallized to deposit violet crystals of **8** (0.21 g, 21% yield). Found: C, 33.43; H, 4.95. Calc.: for $C_{15}H_{27}CoF_6O_4P_2S$: C, 33.47; H, 5.06%. ^{13}C NMR (CD_3CN): δ 7.5 (d, $^1J_{PC}$ = 30.4 Hz, PCH_3), 8.6 (d, $^1J_{PC}$ = 31.3 Hz, PCH_3), 14.9 (s, SCH_3), 26.1 (s, CCH_3), 26.4 (s, CCH_3), 26.8 (s, CCH_3), 28.0 (d, $^4J_{PC}$ = 7.0 Hz, CCH_3), 30.5 (d, $^1J_{PC}$ = 32.2 Hz, PCH_2), 34.7 (s, SCH_2), 99.1 (s, *C*H), 99.6 (s, *C*H), 188.0 (s, *C*O), 189.7 (s, *C*O), 191.6 (s, *C*O), 192.9 (d, $^3J_{PC}$ = 2.5 Hz, *C*O). The complex **6** is soluble in water, methanol and acetonitrile, while complex **8** is soluble in methanol and acetonitrile but not in water.

trans(*P*,*S*)-[Co(acac)(etdmp)$_2$](PF$_6$)$_2$ (**7**) *and* [Co(acac)$_2$(etdmp)]PF$_6$ (**9**)

These complexes were prepared by methods similar to those for **6** and **8**, using complex **5** as a starting material. The crude orange product was recrystallized by diffusion of diethyl ether vapour into an acetonitrile solution to deposit orange crystals of **7** (16% yield). Found: C, 28.04; H, 4.76. Calc. for $C_{17}H_{27}CoF_{12}O_2P_4S_2$: C, 27.18; H, 4.98%. ^{13}C NMR (CD_3CN): δ 7–20 (overlapped peaks due to PCH_3 and SCH_2CH_3), 25–40 (overlapped peaks due to CCH_3, PCH_2 and CH_2SCH_2), 101.8 (s, *C*H), 192.7 (s, *C*O), 193.3 (d, $^3J_{PC}$ = 2.1 Hz, *C*O). The violet complex was recrystallized from a mixture of methanol and water to deposit violet crystals of **9** (43% yield). Found: C, 35.19; H, 5.45. Calc. for $C_{16}H_{29}CoF_6O_4P_2S$: C, 34.79; H, 5.29%. ^{13}C NMR (CD_3CN): δ 7.5 (d, $^1J_{PC}$ = 30.4 Hz, PCH_3), 8.4 (d, $^1J_{PC}$ = 28.0 Hz, PCH_3), 11.6 (s, SCH_2CH_3), 26.3 (d, $^4J_{PC}$ = 1.0 Hz, CCH_3), 26.8 (s, CCH_3), 27.1 (s, CCH_3), 28.2 (d, $^4J_{PC}$ = 6.9 Hz, CCH_3), 30.6 (d, $^1J_{PC}$ = 32.5 Hz, PCH_2), 31.9 (br, SCH_2CH_3), 32.8 (d, $^2J_{PC}$ = 3.1 Hz, SCH_2CH_2P), 99.0 (s, *C*H), 99.5 (s, *C*H), 187.9 (d, $^3J_{PC}$ = 0.7 Hz, *C*O), 189.6 (s, *C*O), 191.5 (s, *C*O), 192.9 (d, $^3J_{PC}$ = 3.1 Hz, *C*O). The solubilities of these complexes **7** and **9** are similar to those of the corresponding mtdmp complexes **6** and **8**, respectively.

trans(*P*,*S*)-[Co(dtc)(mtdmp)$_2$](PF$_6$)$_2$ (**10**), [Co(dtc)$_2$(mtdmp)]PF$_6$ (**12**) *and cis*-[Co(dtc)$_2$(mtdmp-κP)$_2$]PF$_6$ (**14**)

To a methanol solution (100 cm^3) of **4** (0.55 g, 1.0 mmol) was added a methanol solution (100 cm^3) of Na(dtc)·2H$_2$O (0.18 g, 1.0 mmol) dropwise with stirring in an ice bath. The mixture was stirred for 2 h at room temperature and concentrated to ca 10 cm^3. The concentrate was diluted with water (100 cm^3) and then applied on a column (ϕ 5.0 × 60 cm) of SP-Sephadex C-25 (Na^+ form). The adsorbed products were eluted with 0.01 mol dm^{-3} aqueous NaCl solution, violet (**V1**), violet (**V2**) and red (**R**) bands being eluted in this order. After elution of the violet bands (**V1** and **V2**), a major red band (**R**) was eluted with 0.3 mol dm^{-3} aqueous NaCl solution. The eluate of each band was evaporated to dryness under reduced pressure, and the residue was extracted with a small amount of ethanol. The filtered extract was concentrated to ca 1 cm^3 under reduced pressure and mixed with a saturated ethanol solution of $NaPF_6$ to afford a violet or red precipitate. The crude product obtained from **V1** was recrystallized by diffusion of diethyl ether vapour into a dichloromethane solution to deposit violet crystals of **14** (0.10 g, 14% yield), and those from **V2** and **R** were recrystallized from an aqueous acetone solution to deposit violet crystals of **12** (0.05 g, 9% yield) and red crystals of **10** (0.35 g, 47% yield), respectively. For complex **10**; Found: C, 21.28; H, 4.46; N, 1.86. Calc.: for $C_{13}H_{32}CoF_{12}NP_4S_4$: C, 21.06; H, 4.35; N, 1.89%. ^{13}C NMR (CD_3CN): δ 5.8–16.4 (overlapped peaks due to four kinds of PCH_3), 17.9 (s, SCH_3), 18.7 (d, $^3J_{PC}$ = 4.1 Hz, SCH_3), 25–35 (overlapped peaks due to PCH_2CH_2S), 39.9 (s, NCH_3), 40.9 (s, NCH_3), 196.3 (br, NCS_2). This complex is soluble in methanol, acetone and acetonitrile, but not in water, dichloromethane or diethyl ether. For complex **12**; Found: C, 22.67; H, 4.36; N, 4.79. Calc.: for $C_{11}H_{25}CoF_6N_2P_2S_5$: C, 22.76; H, 4.34; N, 4.83%. ^{13}C NMR (CD_3CN): δ 6.7 (d, $^1J_{PC}$ = 34.9 Hz, PCH_3), 10.6 (d, $^1J_{PC}$ = 30. 4 Hz, PCH_3), 20.2 (s, SCH_3), 30.7

(d, $^2J_{PC}$ = 6.9 Hz, PCH_2CH_2S), 32.9 (d, $^1J_{PC}$ = 30 Hz, PCH_2), 38.8 (br, NCH_3), 39.3 (s, NCH_3), 201.4 (br, NCS_2), 203.4 (s, NCS_2). This complex is soluble in methanol and acetonitrile, but not in water or diethyl ether. For complex **14**; Found: C, 26.92; H, 5.16; N, 3.81. Calc. for $C_{16}H_{38}CoF_6N_2P_3S_6$: C, 26.81; H, 5.34; N, 3.91%. ^{13}C NMR (CD_3CN): δ 2.5 (virtual t, J_{PC} = 14.7 Hz, PCH_3), 13.0 (virtual t, J_{PC} = 16.0 Hz, PCH_3), 20.2 (s, SCH_3), 28.8 (virtual t, J_{PC} = 3.5 Hz, PCH_2CH_2S), 29.2 (virtual t, J_{PC} = 5.7 Hz, PCH_2), 38.5 (s, NCH_3), 38.9 (s, NCH_3), 201.6 (s, NCS_2). This complex is soluble in methanol, dichloromethane and acetonitrile, but not in water or diethyl ether.

trans(*P*,*S*)-[Co(dtc)(etdmp)$_2$](PF$_6$)$_2$ (**11**), [Co(dtc)$_2$-(etdmp)]PF$_6$ (**13**) *and cis*-[Co(dtc)$_2$(etdmp-κP)$_2$]PF$_6$ (**15**)

These complexes were obtained by a method similar to the corresponding mtdmp complexes using complex **5** as a starting material. Complex **11** was obtained as red crystals (67% yield). Found: C, 23.47; H, 4.79; N, 1.96. Calc.: for $C_{15}H_{34}CoF_{12}NP_4S_4$: C, 23.42; H, 4.72; N, 1.82%. ^{13}C NMR (CD_3CN): δ 9.4–11.9 (overlapped peaks due to four kinds of PCH_3), 13.3 (d, $^4J_{PC}$ = 2.1 Hz, SCH_2CH_3), 13.5 (s, SCH_2CH_3), 15–35 (overlapped peaks due to PCH_2CH_2S and SCH_2CH_3), 39.9 (s, NCH_3), 40.5 (s, NCH_3), 199.8 (br, NCS_2). Complex **13** was obtained as violet crystals (9% yield). Found: C, 24.52; H, 4.60; N, 4.70. Calc. for $C_{12}H_{27}CoF_6N_2P_2S_5$: C, 24.24; H, 4.58; N, 4.71%. ^{13}C NMR (CD_3CN): δ 6.7 (d, $^1J_{PC}$ = 34.9 Hz, PCH_3), 10.6 (d, $^1J_{PC}$ = 30.8 Hz, PCH_3), 13.3 (s, SCH_2CH_3), 26.3 (s, SCH_2CH_3), 33.1 (d, $^1J_{PC}$ = 30 Hz, PCH_2), 34.4 (d, $^2J_{PC}$ = 7.1 Hz, PCH_2CH_2S), 38.7 (s, NCH_3), 38.8 (s, NCH_3), 39.2 (s, NCH_3), 201.6 (d, $^3J_{PC}$ = 0.7 Hz, NCS_2), 203.3 (s, NCS_2). Complex **15** was obtained as violet crystalline solid (11% yield). Although the elemental analysis of this product gave no satisfactory result probably due to bad crystallinity of this compound, the ^{13}C NMR and electronic absorption spectra suggested that the product was pure enough for our structural characterization and measurements. ^{13}C NMR (CD_3CN): δ 12.6 (virtual t, J_{PC} = 14.5 Hz, PCH_3), 13.0 (virtual t, J_{PC} = 16.0 Hz, PCH_3), 15.4 (s, SCH_2CH_3), 25–35 (overlapped peaks due to SCH_2-CH_2P and SCH_2CH_3), 29.7 (virtual t, J_{PC} = 11.2 Hz, PCH_2), 38.5 (s, NCH_3), 38.9 (s, NCH_3), 201.6 (s, NCS_2). The solubilities of complexes **11**, **13** and **15** are similar to those of the corresponding mtdmp complexes **10**, **12** and **14**, respectively.

X-ray data collection, structure determination and refinement

A single crystal of each complex **1**, **2** and **14** were glued on top of a glass fibre with epoxy resin. The X-ray intensities were measured at 23°C with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Rigaku four-circle diffractometer AFC-5. Final lattice constants were determined by least-squares refinements of the orientation angles of 25 centred reflections in the range $20 \leqslant 2\theta \leqslant 30°$. Three standard reflections were monitored every 150 and showed no serious decomposition. The intensities were collected for $(+h, +k, \pm l)$ octants at $2\theta \leqslant 60°$ using 2θ-ω scan method. The structures were solved by the usual heavy-atom method using the SHELXS-86 program [20] and refined on F by full-matrix least-squares using anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms of **1** and **2** were located in calculated positions and fixed during refinement cycles, and those of **14** were located on the positions given by Fourier-difference syntheses, or by calculation, and refined isotropically. Complex neutral atom scattering factors [21] were used. All calculations were carried out using the XTAL 3.2 software [22].

Crystal data are summarized in Table 1. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

We have attempted preparing cobalt(III) complexes of dpdtn which is a linear tetradentate phosphine-thioether ligand bearing terminal diphenylphosphino groups. A reaction of a mixture of Co(BF$_4$)$_2$·6H$_2$O and dpdtn in methanol with a dichloromethane solution of tetramethylthiuramdisulfide gave a red complex of *cis*β-[Co(dtc)(dpdtn)](BF$_4$)$_2$ in a poor yield (ca 10%), while all the other attempts were fruitless [16]. The difficulty for preparation of the cobalt(III)-dpdtn complexes would result from the steric bulkiness of diphenylphosphino group. Therefore, we have prepared a new tetradentate ligand dmdtn which is a dimethylphosphino analogue of dpdtn, because the dimethylphosphino group would have a smaller steric requirement and a stronger donor ability to a cobalt(III) centre than diphenylphosphino group. The ligand dmdtn could be prepared in a good yield from sodium dimethylphosphide, ethylenesulfide and 1,3-dibromopropane in liquid ammonia by a one-pot reaction. Owing to its high boiling point, the crude product obtained was used for preparation of cobalt(III) complexes without further purification, and no serious problem was observed in the course of complex preparation.

In order to elucidate the characteristics of dmdtn complexes, analogous didentate phosphine-thioether ligands, mtdmp and etdmp, and their cobalt(III) complexes were also prepared. The preparation of mtdmp and etdmp from sodium dimethylphosphide and (2-chloroethyl)-methylsulfide or -ethylsulfide in liquid ammonia always contained 1,2-bis(dimethylphosphino)ethane (dmpe) as a by-product in ca 5–10%, which was hardly separated because of similar boiling points among mtdmp, etdmp and dmpe. The

contamination of dmpe has no significant influence for preparation of cobalt(III) complexes.

Dichloro complexes

The reaction of *trans*-$[CoCl_2(py)_4]Cl \cdot 6H_2O$ with dmdtn, followed by anion metathesis with $NaPF_6$, afforded a green complex of $[CoCl_2(dmdtn)]PF_6$ (**1**). The yield of complex **1** is relatively low (40%) as compared with the corresponding mtdmp or etdmp complex; a green complex of $[CoCl_2(mtdmp)_2]PF_6$ (**4**) or $[CoCl_2(etdmp)_2]PF_6$ (**5**) was prepared in 70–80% yield by a method similar to that for complex **1**. In contrast to the case of complex **4** or **5**, the preparation of complex **1** was always accompanied by the formation of red and green by-products. The by-products, however, could not be characterized, because they were unseparable from each other by means of fractional recrystallization or column chromatography and unstable in water. Complex **1** is stable in solution even in water, while complexes **4** and **5** are slowly hydrolyzed in aqueous acetone.

The crystal structure of **1** was determined by X-ray diffraction. A perspective view of the complex cation is shown in Fig. 1, and selected bond lengths and angles are listed in Table 2. The Co, Cl(1), Cl(2) and C(6) atoms are located on the crystallographic plane of symmetry, and the geometry around the central Co atom is almost octahedral. Two Cl atoms occupy *trans* positions, and two *cis* sulfur atoms have opposite absolute configurations, i.e., *meso*(S). The five-membered $CoPC_2S$ chelate rings take an envelope conformation and the six-membered $CoSC_3S$ chelate has a chair conformation. Thus, the total geometrical structure of the complex cation is assigned as *trans*(*Cl*,*Cl*)-chair-$[CoCl_2\{meso(S)\text{-dmdtn}\}]^+$ [23].

The Co—P(1) bond length in complex **1** is similar to the Co—P bond lengths in *trans*(*Cl*,*Cl*)-$[CoCl_2\{meso(P)\text{-SPPS}\}]BF_4$ (2.223(3) and 2.230(3) Å; SPPS = $MeS(CH_2)_2PPh(CH_2)_3PPh(CH_2)_2SMe$) [9]. These bond lengths indicate that the *trans* influence of the thioether group is intermediate between those of an amino group and a dimethylphosphino group, because the corresponding Co—P bond lengths in *trans*(*Cl*,*Cl*)*cis*(*P*,*P*)-$[CoCl_2(edmp)_2]^+$ (edmp = $Me_2P(CH_2)_2NH_2$) are 2.190(3) and 2.201(3) Å and those in *trans*-$[CoCl_2(dmpe)_2]^+$ (dmpe = $Me_2P(CH_2)_2PMe_2$) are 2.256(1) and 2.262(1) Å [24]. The Co—Cl bond lengths in complex **1** are also intermediate between those of the edmp complex (2.238(3) and 2.244(3) Å) and the dmpe complex (2.260(1) Å) [24], although the differences among them are rather small. This order is consistent with that of steric congestion due to alkyl groups on P or S atoms which decreases in the order bis(dmpe) > dmdtn > *cis*(*P*,*P*)-bis(edmp). The Co—S bond length in complex **1** is slightly shorter than those in the SPPS complex (2.325(3) and 2.329(3) Å) [9]. The small deviation of the bond lengths probably results from the different relative positions of the S atoms in the ligand skeleton: central positions in dmdtn while terminal in SPPS. The five- and six-membered chelate bite angles are close to a right angle, whereas the P(1)—Co—P(1′) angle is appreciably wider 96.19(3)°. The P—Co—P bond angle is almost equal to that in the edmp complex (96.9(1)°) [24], but relatively larger than the S—Co—S angle in *trans* (*Cl*,*Cl*)-$[CoCl_2\{meso(P)\text{-SPPS}\}]BF_4$ (90.7(1)°) [9]. Therefore, the widening of

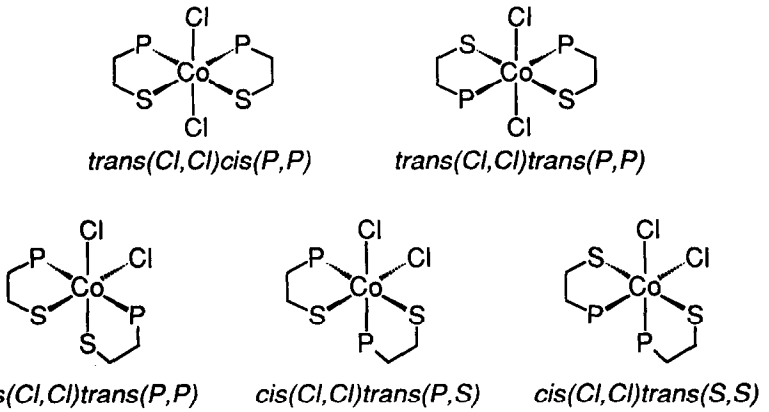
S(1)—Co—S(1')	88.20(3)	P(1)—Co—P(1')	96.19(3)

P—Co—P angle in the dmdtn and edmp complexes can be interpreted by steric repulsion between the mutually *cis*-positioned dimethylphosphino groups.

For the SPPS complexes both green *trans*-[$CoCl_2${*meso*(P)-SPPS}]$^+$ and red *cis*α-[$CoCl_2${*racemic*(P)-SPPS}]$^+$ isomers were obtained [9], but in this study the corresponding *cis*α-isomer could not be isolated. While molecular models indicate that *cis*α-skew-[$CoCl_2${*racemic*(S)-dmdtn}]$^+$ has the least non-bonded steric interaction among the possible isomers (with conformers), the mutual *trans* arrangement of dimethylphosphino groups will be unfavourable because of their strong *trans* influences. The ^{13}C-{^1H} NMR spectrum of a green CD_3CN solution of complex **1**, this green colour suggesting that the *trans* geometrical structure retains in solution as well, shows two kinds of resonances for P—CH_3 and a single resonance for the other carbons. Both conformers of *trans*(*Cl,Cl*)-chair-[$CoCl_2${*meso*(S)-dmdtn}]$^+$ with molecular C_s symmetry (the crystal structure of **1**) and *trans*(*Cl,Cl*)-skew-[$CoCl_2${*racemic*(S)-dmdtn}]$^+$ with molecular C_2 symmetry should give the observed spectral pattern. The former chair conformer is more stable than the latter skew with respect to the $CoSC_3S$ six-membered ring conformation [23], while the steric congestion due to mutually *cis*-positioned PMe_2 groups favour the latter conformer. Although we have no evidence for either conformer, it is more probable for the *trans*(*Cl,Cl*)-chair-[$CoCl_2${*meso*(S)-dmdtn}]$^+$ structure to be maintained in solution as well, since the inversion of absolute configuration at the sulfur in complex **1** will be restricted by chelate rings with stable chair conformation.

For complexes **4** and **5**, there are five possible geometrical isomers (Scheme 2). The absorption spectra of complexes **4** and **5** were quite similar to that of complex **1** (Fig. 2), and the absorption peak positions of the I_a component of the first d-d transition band which appeared at the lowest energy region were almost identical among the three complexes (Table 3). Therefore, the geometrical structures (the donor atoms arrangement) were assigned as *trans*-(*Cl,Cl*)*cis*(*P,P*). Interestingly, the peak positions of the I_a component of the first d-d transition band also coincide with that of *trans*(*Cl,Cl*)*cis*(*P,P*)-[$CoCl_2$(edmp)$_2$]$^+$ (16,600 cm^{-1}, log $\varepsilon = 2.14$) [25].



Scheme 2. Five possible geometrical isomers for $[CoCl_2(P—S)_2]^+$ (P—S = mtdmp or etdmp) complexes.

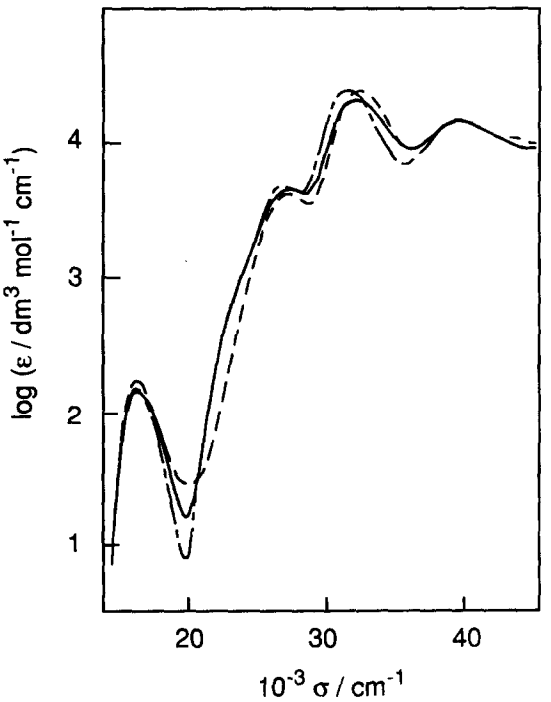


Fig. 2. Absorption spectra of complex **1** in acetonitrile (– –), **4** in methanol (——) and **5** in acetonitrile (– · –) at room temperature.

This indicates that the ligand field strengths of the thioether groups in complexes **1**, **4** and **5** are apparently similar to those of amino group of the corresponding edmp complex, while the ligand field parameters of $\langle—CH_2NH_2\rangle$[5] and $\langle—CH_2SMe\rangle$[5] are previously reported as 21,400 and 17,700 cm^{-1}, respectively [26].

The ^{13}C-$\{^1H\}$ NMR spectra of **4** and **5** in CD_3CN exhibit a spectral pattern similar to that of **1**, i.e., two kinds of resonances for P—CH_3 and a single resonance for the other carbons (except for the overlapped multiplet for P—CH_3 of **4**). This pattern is in contrast to that of the corresponding edmp complex, where only one kind of resonance for P—CH_3 is observed [^{13}C NMR (CD_3CN): δ 11.2 (virtual t, J_{PC} = 16.9 Hz, PCH_3), 34.5 (virtual t, J_{PC} = 15.7 Hz, PCH_2), 41.1 (s, NCH_2)] [16]. The two kinds of P—CH_3 signals observed for complexes **4** and **5** indicate that the configurational inversion at each sulfur is restricted in the complexes. By combination of absolute configuration at two sulfur centres, *meso*(S) and *racemic*(S) diastereomers are possible for the complexes. In these cases, in contrast to complex **1**, the steric factor seems to be dominant. Therefore, the *racemic*(S) isomer is more probable due to steric congestion of mutually *cis*-positioned SR groups, although, again, we have no evidence for this.

As mentioned above, complexes **4** and **5** were prepared in high yields, in contrast to the analogous edmp complex. The reaction of *trans*-$[CoCl_2(py)_4]Cl \cdot 6H_2O$ with edmp in a molar ratio of 1:2 gave *trans*-(*Cl,Cl*)*cis*(*P,P*)-$[CoCl_2(edmp)_2]PF_6$ in only 13% yield together with a large amount of *fac*-$[Co(edmp)_3](PF_6)_3$ (63% yield based on edmp), and the other methods for preparing *trans*(*Cl,Cl*)*cis*(*P,P*)-$[CoCl_2(edmp)_2]^+$ gave similarly low yields (7–10%) due to preferential formation of *fac*-$[Co(edmp)_3]^{3+}$. On the other hand, we could prepare neither [Co(mtdmp or etdmp)$_3$]$^{3+}$ nor [Co(mtdmp or etdmp)(dmdtn)]$^{3+}$ complexes by the reaction of **1**, **4** or **5** with excess mtdmp or etdmp. The steric factor of alkyl substituents on S atoms would result in difficulty in the formation of these $[Co(P)_3(S)_3]^{3+}$-type complexes.

Pentane-2,4-dionate or N,N-dimethyldithiocarbamate complexes

The red complexes of $[Co(acac)(dmdtn)](BF_4)_2$ (**2**) and $[Co(dtc)(dmdtn)](BF_4)_2$ (**3**) were derived from complex **1** in high yields (63–80%), only one isomer

for each being isolated in this study. For each reaction a by-product was detected in column chromatography as a yellow (for acac) or brown (for dtc) band, but the relative yield was very low and we could not isolate it as a pure form. Complexes **2** and **3** were assigned as a *cisβ*-isomer by their ^{13}C-{^1H} NMR spectra. While the ^{13}C resonances due to the dmdtn moiety exhibit very complicated patterns with many overlapped peaks, those due to acac or dtc ligand gave their structural information. The methyl groups of acac moiety in complex **2** exhibit two kinds of resonances at δ 26.6 (s) and 27.8 (d, $J = 4.5$ Hz), and those of dtc in complex **3** at δ 39.7 (s) and 40.3 (s); these indicate that the symmetry around the central Co atom is lower than C_2 of *cisα* configuration, that is, C_1 of *cisβ*. The assignment was confirmed by X-ray analysis for complex **2**.

A perspective view of the complex cation in **2** is shown in Fig. 3, and selected bond lengths and angles are listed in Table 4. The complex has a distorted octahedral geometry with *cisβ* configuration of the linear tetradentate dmdtn ligand. The two coordinated sulfur atoms have the same absolute configuration as each other, i.e., *racemic*(S) (*RR*/*SS*). This fact indicates that the configurational inversion at one sulfur atom occurred during the derivation of complex **2** from complex **1**. The central six-membered chelate ring of dmdtn takes a chair conformation, and the total configuration of the dmdtn ligand is *cisβ*-chair-*racemic*(S). A molecular modeling study suggests that this conformer will be more stable than the other possible isomers, *cisβ*-chair-*meso*(S), *cisβ*-skew-*meso*(S) and *cisα*-skew-*racemic*(S), as discussed by Bosnich *et al.* for the analogous linear tetradentate amine-thioether ligand of $NH_2(CH_2)_2S$-$(CH_2)_3S(CH_2)_2NH_2$ (ete) [23].

The Co—P(1) and Co—P(2) bond lengths in complex **2** are similar to each other, although their *trans*-positioned donor atoms are different: O of acac for P(1) and S of dmdtn for P(2). In contrast, the Co—S(1) and Co—S(2) bond lengths are quite different from each other, which results from the stronger *trans* influence of dimethylphosphino group compared to that of acac. The Co—S(1) bond length is nearly equal to that in complex **1**, both of which are *trans* to the dimethylphosphino group of dmdtn. On the other hand, the Co—S(2) bond length is similar to the Co—S bonds in *cisβ*,*trans*(*Cl*,*S*)-[CoCl(NO_2)(ete)]Cl (2.22(1) and 2.24(1) Å) [27]. The small deviation of Co—O bond lengths would also be affected by the *trans* influence of the dimethylphosphino group. Although the five-membered P—Co—S chelate angles and the P(1)—Co—P(2) bond angle in complex **2** are similar to the corresponding angles in complex **1**, the S(1)—Co—S(2) angle in the six-membered chelate ring in **2** is appreciably larger than in **1**. The reason for the widening of S—Co—S angle is not clear.

Although the lack of X-ray analysis for complex **3** prohibits our discussion of the absolute configuration of sulfur atoms and the configuration of chelate rings in detail, the absorption spectrum of complex **3** was similar to that of **2** except for an additional band observed around 25,300 cm^{-1} (Fig. 4), and a *cisβ*-chair-*racemic*(S) form is expected as the most stable isomer.

The reaction of complex **4** or **5** with Li(acac) in methanol afforded an orange complex of [Co(acac)(mtdmp or etdmp)$_2$](PF_6)$_2$ (**6** or **7**) and a violet one of [Co(acac)$_2$(mtdmp or etdmp)]PF_6 (**8** or **9**). For the former there are three possible geometrical isomers with *trans*(*P*,*P*), *trans*(*P*,*S*) and *trans*(*S*,*S*) configurations (Scheme 3). The ^{13}C-{^1H} NMR spectra of the orange complexes exhibit two kinds of signals for carbonyl carbons: δ 191.4 (s) and 193.0 (d, $J = 2.4$ Hz) for complex **6** and 192.7 (s) and 193.3 (d, $J = 2.1$ Hz) for complex **7**. The lower field doublet signal for each complex is assigned to the carbonyl carbon *trans* to the dimethylphosphino group of mtdmp or etdmp [28]. Thus, the orange complexes **6** and **7** are definitely assigned as the *trans*(*P*,*S*)-isomer, which is corresponding to the *cisβ*-isomer of complex **2** in regard to the donor atom arrangements. The absorption spectra of complexes **2** and **6** showed a similar pattern except for the appearance of a shoulder peak at the

lower energy side of the first absorption band of complex **6** (Fig. 4(a)).

For $[Co(acac)_2(mtdmp \text{ or } etdmp)]^+$ complexes (**8** or **9**), there are two possible diastereomers, Δ-*R*(S)/Λ-*S*(S) and Δ-*S*(S)/Λ-*R*(S). The $^{13}C\text{-}\{^1H\}$ NMR spectra of these complexes in CD_3CN show a singlet signal for the S—R group, which indicates a rapid configurational inversion at the S atom [*R*(S) ↔ *S*(S)] or a preferential formation of either diastereomer. Since there are no steric factors to prevent the inversion at the sulfur, the observed singlet for the S—R group seems to result from a rapid configurational inversion at the sulfur atom. The inversion of the selenium atom, which seems to be much slower than that of the sulfur in the analogous bis(acac) complexes, is detectable by NMR methods [29].

The reaction of **4** with Na(dtc)·$2H_2O$ afforded two violet complexes **12** and **14** as well as a major orange complex **10**, and a similar reaction of **5** gave the corresponding complexes **11**, **13** and **15**. The three complexes formed in each reaction can be separated by means of column chromatography using SP-Sephadex C-25 resin; the first and the second developing violet complexes are found to have the compositions of $[Co(dtc)_2(mtdmp \text{ or } etdmp)_2]PF_6$ (**14** or **15**) and $[Co(dtc)_2(mtdmp \text{ or } etdmp)]PF_6$ (**12** or **13**), respec-

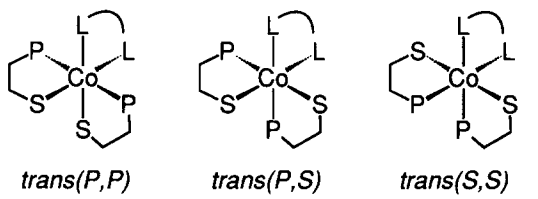

Scheme 3. Three possible geometrical isomers for $[Co(L—L)(P—S)_2]^{2+}$ (L—L = acac or dtc; P—S = mtdmp or etdmp) complexes.

tively, by elemental analyses. The complexes **12** and **13** are assigned as the bis(dtc) analogues of **8** and **9**, respectively, by $^{13}C-\{^1H\}$ NMR spectroscopy.

The structure of complex **14** was determined by X-ray analysis to be *cis*-$[Co(dtc)_2(mtdmp-\kappa P)_2]PF_6$. A perspective view of the complex cation is shown in Fig. 5, and selected bond lengths and angles are listed in Table 5. The Co atom is located on a crystallographic C_2 axis which bisects the P(1)—Co—P(1′) and S(2)—Co—S(2′) angles. The coordination geometry is slightly distorted octahedral with four sulfur and two phosphorus atoms. The two mtdmp ligands function as a monodentate ligand through the coordination of only phosphorus atom and are sited in mutual *cis*-positions. The Co—P bond length in complex **14** was slightly longer than those in complexes **1** and **2**, and the P—Co—P bond angle also wider than a right angle; both of these structural deviations would result from steric repulsion between the mutually *cis*-positioned monodentate phosphines. The corresponding etdmp complex **15** was also characterized as *cis*-$[Co(dtc)_2(etdmp-\kappa P)_2]PF_6$ based on the $^{13}C-\{^1H\}$ NMR spectrum.

The geometrical structures of complexes **10** and **11** are assigned as *trans*(*P*,*S*) isomer based on the $^{13}C-\{^1H\}$ NMR spectra, which are comparable to those of complexes **3**, **7** and **8**. Two kinds of N—CH_3 resonances for dtc moiety and of SR (R = Me for **10** or Et for **11**) for mtdmp or etdmp were exhibited. The absorption spectra of complexes **3** and **10** are also compared in Fig. 4(b). The spectral patterns are similar to each other and to those of the corresponding acac complexes. For each complex two absorption peaks or shoulders appeared in the region 20,000–25,000 cm^{-1}, which are assigned to the first and second d-d transition bands as discussed previously for $[Co(dtc)(dmpe)_2]^{2+}$ (dmpe = $Me_2P(CH_2)_2PMe_2$) [30]. The energy difference between the first and second d-d bands is quite small for mixed donor-type cobalt(III) complexes having both sulfur and phosphorus as donor atoms.

Electrochemistry

The cyclic voltammograms of dmdtn complexes **1**, **2** and **3** are shown in Fig. 6. The latter two *cisβ* complexes exhibited reversible redox waves of Co^{3+}/Co^{2+} at $E_{1/2} = -0.64$ V for the acac complex **2** and -0.82 V for the dtc complex **3**, respectively. On the other hand, the *trans*-dichloro complex **1** gave irreversible reduction waves at -0.52 and -0.82 V, and all of the mtdmp and etdmp complexes also exhibited irreversible reduction waves at -0.5 to -0.8 V; these observations indicated that all complexes other than **2** or **3** are unstable in their Co^{2+} states. The tetradentate ligand with *cisβ* configuration may stabilize their structures even in the Co^{2+} oxidation state. Compared to the reduction potentials of the mono(dtc)-type cobalt(III) complexes, the $E_{1/2}$ value of complex **3** is similar to those of $[Co(dtc)(en)_2]^{2+}$ (-0.75 V) [31] and $[Co(dtc)\{P(OMe)_3\}_4]^{2+}$ (-0.75 V) [32], but fairly shifted to the positive side from those of $[Co(dtc)\{Me_2P(CH_2)_nPMe_2\}_2]^{2+}$ ($n = 1$, 2 or 3; -0.95 to -1.11 V) [31,32]. These redox potentials indicate that the thioether groups are weaker ligands than the dimethylphosphino group in both Co^{3+} and Co^{2+} states.

CONCLUDING REMARKS

In this study three kinds of cobalt(III) complexes containing dmdtn and either dichloro (**1**), acac (**2**) or

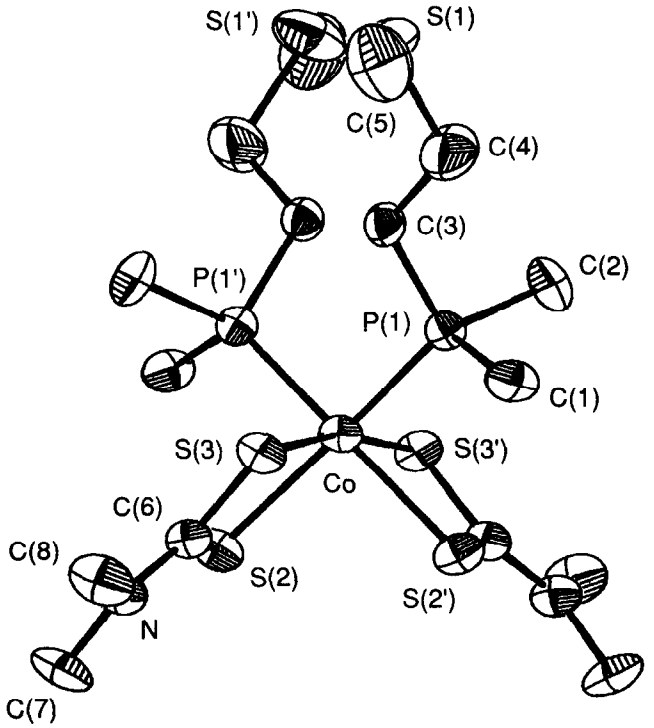

Fig. 5. Perspective drawing of the complex cation in *cis*-[Co(dtc)$_2$(mtdmp-κP)$_2$]PF$_6$, **14** (hydrogen atoms are omitted for clarity).

Table 5. Selected bond lengths (Å) and angles (°) for complex **14**

Co—S(2)	2.312(3)	Co—S(3)	2.275(2)
Co—P(1)	2.241(3)		
S(2)—Co—S(3)	75.6(1)	S(2)—Co—S(3′)	95.1(1)
S(2)—Co—S(2′)	89.0(1)	S(3)—Co—S(3′)	167.1(1)
S(2)—Co—P(1)	162.93(9)	S(2)—Co—P(1′)	89.0(1)
S(3)—Co—P(1)	87.74(9)	S(3)—Co—P(1′)	100.78(9)
P(1)—Co—P(1′)	97.6(1)		

dtc (**3**) ligands are synthesized. For each complex only one isomer can be isolated and the dmdtn acts as a tetradentate ligand. These results are in contrast to the previously described SPPS-type tetradentate ligands, because the SPPS ligands often give more than one isomer due to the relative configurations of the central phosphorus atoms and in some cases act as a didentate diphosphine ligand [8,9]. Several cobalt(III) complexes containing didentate mtdmp or etdmp are also synthesized and compared the properties with those of the analogous dmdtn complexes. The reaction of dichlorobis(mtdmp or etdmp) complex (**4** or **5**) with Li(acac) or Na(dtc) gives not only mono(acac or dtc)-type complexes (**6**, **7**, **10** or **11**) but also bis(acac or dtc)-type complexes (**8**, **9**, **12**, **13**, **14** or **15**). Therefore, it is suggested that the didentate ligands are more labile for substitution than the tetradentate dmdtn and can act as a hemilabile ligand as well as SPPS-type tetradentate ligands.

(Received 1 October 1997; accepted 12 December 1997)

Abstract—Stabilities of the mixed-ligand complexes of Cu^{2+} ion with diethylenetriamine [bis(2-aminoethyl) amine, dien)] as a primary ligand and α-alaninehydroxamic acid [2-amino-N-hydroxypropanamid, α-Alaha] or β-alaninehydroxamic acid [3-amino-N-hydroxypropanamid, β-Alaha] as a secondary ligand L and their absorption and EPR spectra at various pH values are reported. The visible spectra exhibit a characteristic red shift and a shoulder at lower energies indicating a five-coordinate structure of the formed complexes. The change of the EPR spectral parameters as a function of pH reflects two modes of an equatorial-axial chelation by aminohydroxamic acid ligand L in $[Cu(dien)(HL)]^{2+}$ and $[Cu(dien)(L)]^{+}$ species, while the diethylenetriamine nitrogens are coordinated at three equatorial positions in each case. α-Alaha is a more effective chelating ligand than β-Alaha in the Cu^{2+}-dien-L ternary system. This is reflected in the much higher basicity-adjusted stability constants, $\log K_{Cu(dien)(\alpha\text{-Alaha})(\beta\text{-Alaha})} - \Sigma pK^{H}$. © 1998 Elsevier Science Ltd. Keywords: copper(II) complexes; mixed-ligands complexes; five-coordinate; aminohydroxamic acids; diethylenetriamine; e.s.r. spectra; vis spectra.

The importance of ternary complexes in biochemical systems has provided a strong impetus to the study of mixed ligand metal(II) complexes [1–5]. The total ligand concentration greatly exceeds the metal content in the mammalian body leading to competition between various complexing species and metal ions present in the living tissues and fluids. Ternary complexes have been implicated in the storage and transport of metal ions and of active substances through membranes [6]. As the mixed-ligand complexes play such a central role it is worthwhile to assemble information on their formation, stability and structure and on the mutual influence of two ligands bound to the same metal ion [2,7–10].

Copper is a bioessential element with truly unique chemical characteristics. It is also toxic with low legal concentration limits, for example, for drinking water or sewage sludge [11]. In view of the increasingly realistic expectations of therapy aimed at the biological cause of genetic disorders, two hereditary diseases concerning copper metabolism, Wilson's disease and Menke's syndrome, have attracted special attention [11,12]. The therapy consists of administration of copper-specific chelating agents, in particular D-penicillamine or—in cases of the not uncommon intolerance to it—of triethylenetetramine [11,13].

Polyamines play an important role in the processes in living organisms. These compounds are found at a significant concentration in young cells and, particularly, in cancer tumor tissues [14,15]. Polyamines are very effective ligands.

The importance of hydroxamic and aminohydroxamic acids in biology, medicine, pharmacology and agriculture is well known [16–19].

The literature on ternary metal complexes involving aminohydroxamic acids is not rich, however some ternary systems involving aminohydroxamic acid and amino acid [20,21], amine [22,23], or other bioligand as the secondary one [24–27], were investigated.

The aim of the present work was to obtain information on the complex formation ability of α-Alaha or β-Alaha towards $[Cu(dien)(H_2O)_3]^{2+}$ complex, and to characterize the structures of the ternary complexes

formed using potentiometric titration and spectroscopic (EPR and visible) techniques.

EXPERIMENTAL

Materials

α-Alaha and β-Alaha were prepared via the methyl ester of the respective amino acid as described in Ref. 28. Dien was from Aldrich (Germany) used without further purification and its purity was greater than 99%. The fully protonated forms of the ligands are shown in Scheme 1.

The purity of the hydroxamic acids and diethylenetriamine and the exact concentrations of the stock solutions were determined by Gran's method [29]. Copper(II) chloride solution was purchased from Merck. For clarity, the charges of the complexes are omitted in the tables. It has to be mentioned, however, that the fully deprotonated forms of aminohydroxamic acids are L^- while the diethylenetriamine is L.

Potentiometric measurements

Protonation constants of the ligands and the stability constants of the binary and ternary complexes were determined by pH-metric titration of 5 cm^3 samples in water solutions in the pH range of 2–11. The stability constants of the complexes formed, together with derived equilibrium constants characteristic of

some stepwise processes of complex formation, are listed in Table 1.

The data for the Cu^{2+}-α-Alaha and Cu^{2+}-β-Alaha binary systems can be found in the our early papers [30–32], but for the sake of comparison these data are included in Table 2. Data for Cu^{2+}-dien binary system can be found in the literature [33], but we had to determine the stability constants under identical conditions to those of ternary systems, i.e. at 298 K and ionic strength of 0.2 mol dm^{-3} (KCl). Refined values (Table 2) are in good agreement with the literature data, after allowing for changes in experimental conditions and calculation methods [33,34]. For the binary system 1 : 1, 1 : 2 and 1 : 4 metal to ligand ratios were used. The concentration of the ligand in the experimental solution was $4 \cdot 10^{-3}$ mol dm^{-3}. For the determination of the stability constants of the mixed ligand complexes the metal(II) concentration in samples were $2 \cdot 10^{-3}$ mol dm^{-3} and $4 \cdot 10^{-3}$ mol dm^{-3} and concentration ratios of metal : dien : α-Alaha/β-Alaha were 1 : 1 : 1, 1 : 1 : 2, 1 : 2 : 1, 1 : 2 : 2 and 1 : 1 : 4. All the pH-metric titrations were carried out with carbonate-free KOH solution of known concentration (ca 0.2 mol dm^{-3}). The pH-metric titrations were performed with a Radelkis OP-208/1 instrument equipped with a micro combination pH electrode (Mettler-Toledo, Type 2) using a ABU-80 titration unit (Radiometer). The electrodes system was calibrated by periodic titrations of an HCl solution ($5 \cdot 10^{-2}$ mol dm^{-3} KCl) against standard KOH solution. Titration EMF data were used to calculate the hydrogen ion concentration, $[H^+]$. Stability constants $\beta_{pqrs} = [M_p(dien)_qL_rH_s]/[M]^p[dien]^q[L]^r[H]^s$ were calculated with the aid of the SUPERQUAD computer program [35]. The reported standard deviations were calculated by assuming random errors.

Spectroscopic studies

The absorption spectra were recorded on a Beckman DU650 spectrophotometer at room temperature. The EPR spectra were performed using a Bruker 300E X-band spectrometer at 77 K in water/ethyleneglycol (80 : 20 v/v) solution. The spectra were analysed by computer simulation program [36] based on resonance fields calculated according to method of Sakaguchi *et al.* [37]. The concentrations were the same as

Table 2. used in the potentiometric titrations (the metal ion concentration was $4 \cdot 10^{-3}$ mol dm^{-3} and metal to ligands molar ratio were 1 : 1 : 2 for Cu^{2+}-dien-α-Alaha system and 1 : 1 : 4 for Cu^{2+}-dien-β-Alaha system).

RESULTS AND DISCUSSION

The fully protonated form (Scheme 1) of the dien can release three protons in the whole pH range, i.e. one from the NH_2^+ group and two from the NH_3^+ amino groups. The dissociation processes of the two ammonium groups overlap one another, and thus the two higher *pK* values given in Table 2 cannot be ascribed unambiguously. This means that the dissociation constants calculated from the pH-metric data are macroconstants. In this case the dissociation microconstants are not available up to now but this is beyond the scope of the present work.

The dissociation constants found for the fully protonated form of the α-Alaha and β-Alaha in this work are macroconstants. For these ligands both macro- and microconstants are available [38].

Titration

Binary systems. The constants determined by us for the binary Cu^{2+}-dien system agree well with the earlier results [33]. The low stability of $[Cu(dien)_2]^{2+}$ compared with that of $[Cu(dien)]^{2+}$ (Table 2) reflects the fact that only one of the four equatorial coordination positions at Cu^{2+} remains available for the coordination of the second dien and that the expected coordination tendency of the apical positions is low. Formation of $[Cu(dien)_2]^{2+}$ from $[Cu(dien)]^{2+}$ is reflected also by EPR parameters between pH 5.3 and 10 (Table 3). These parameters suggest of 3N,O donor set around Cu^{2+} plane for the latter complex. The apparent decrease in $g_\parallel$ and increase in $A_\parallel$ values confirms that an additional nitrogen atom is involved 4N in-plane coordination in $[Cu(dien)_2]^{2+}$. The change of the parameters is smaller than that expected for the complexes where four nitrogen atoms form strictly planar environment around Cu^{2+} (as in Cu^{2+} complexes with dioxocyclam characterized by $A_\parallel = 215 \cdot 10^{-4}$ cm^{-1} $g_\parallel = 2.171$) [39].

Ternary systems. In spite of the large amount of data which have been collected for mixed chelate systems, it is often not possible to discuss the results

The anisotropic and isotropic parameters are estimated on the basis of computer simulation of the experimental spectra measured at 77 K and 295 K, respectively.

Parameters *A* are given in [10^{-4} cm^{-1}].

The parameters in the parentheses corresponds to the species existing in an apparently smaller contribution.

[a] The parameters relevant to Cu_{aq}^{2+}.

very deeply, because a number of parameters such as kind and ionic charge of donor atoms, density, configuration of metal ions and ligands etc. are involved. Also, the discussion of mixed species has to be based on experimentally determined values of stability constants and intensive factors, all of which have been calculated with due allowance for the contribution of simple species [1]. The general four-component equilibria can be written as:

$$pM + q(\text{dien}) + r(L) + sH \rightleftharpoons M_p(\text{dien})_q(L)_rH_s$$

where p, q, r and s are the stoichiometric coefficients corresponding to the metal ion, M, dien, L (L = α-Alaha or β-Alaha), and H, respectively; charges are omitted for simplicity. The overall formation constants are defined as:

$$\beta_{pqrs} = [M_p(\text{dien})_q(L)_rH_s]/[M]^p[(\text{dien})]^q[(L)]^r[H]^s$$

The β_{pqrs} constant expresses the stability of the [Cu(dien)L]$^+$ ternary species but does not represent directly the binding strength between the L and copper(II) ions. The equilibrium constant, $K_{Cu(dien)L}$, evaluated from the computed values of the related β_{pqrs} values according to equation: $\log K_{Cu(dien)L} = \log\beta_{Cu(dien)L} - \log\beta_{Cu(dien)}$, shows how tightly L (aminohydroxamic anion) is bound to the binary [Cu(dien)]$^{2+}$ complex. Thus, the binding strength of α-Alaha or β-Alaha in the ternary complexes depends on the stability of the binary complex [Cu(dien)]$^{2+}$; in other words, it depends mainly on the basicity of the coligand (dien).

Different methods are known for the estimation of the formation of mixed ligand complexes [1]. In this respect, Sigel's $\log X_{MAB}$ value (the constant due to the equilibrium $[MA_2] + [MB_2] \rightleftharpoons 2[MAB]$) cannot be calculated for the Cu^{2+}-dien-β-Alaha ternary species, since the complex with 1 : 2 ratio is not formed in the Cu^{2+}-β-Alaha binary system (see Table 2). For the Cu^{2+}-dien-α-Alaha system the $\log X_{Cu(dien)(\alpha\text{-Alaha})}$ value (1.35) is larger than that expected on a statistical basis (0.6), which means that the formation of mixed complexes is favoured in this system (Table 1).

Since statistical effects are important for mixed ligand complex stabilization, we have calculated statistical stability constants:

$$\log\beta_{MAB}^{stat.} = \log 2 + \frac{1}{2}(\log\beta_{MA_2} + \log\beta_{MB_2})$$

$\Delta\log\beta_{MAB}$ value given by the following equation:

$$\Delta\log\beta_{MAB} = \log\beta_{MAB}^{calc.} - \log\beta_{MAB}^{stat.}$$

is a measure of additional influences, other than the statistical one, of ligands on the stability of mixed complexes. Positive $\Delta\log\beta_{Cu(dien)(\alpha\text{-Alaha})}$ value (0.37) exhibits higher stability for the 1 : 1 : 1 : 0 mixed ligand species compared to binary ones. It is interesting to compare the stability of the binary complex $M + B \rightleftharpoons [MB]$ with that of the ternary one $[MA] + B \rightleftharpoons [MAB]$. The difference between the stabilities of those complexes, $\Delta\log K$, given by expression

$$\Delta\log K = \log K_{MAB}^{MA} - \log K_{MB}^{M} = \log K_{MBA}^{MB} - \log K_{MA}^{M}$$

is a way to characterize the tendency to form ternary complex. This relation may be expressed in other terms by

$$\Delta\log K = \log\beta_{MAB} - (\log\beta_{MA} + \log\beta_{MB})$$

The $\Delta\log K$ parameter expresses, as is well known, the effect of the bonded primary ligand (dien) towards an incoming secondary ligand (α-Alaha or β-Alaha anion). Since the aminohydroxamic acid coordinates more easily with the free Cu^{2+} ion than with the complexed metal ion, [Cu(dien)]$^{2+}$, $\Delta\log K$ should be negative. It can be seen, by viewing the $\Delta\log K$ values for different systems, that values of this factor for the Cu^{2+}-dien-α-Alaha and Cu^{2+}-dien-β-Alaha systems are very low (−5.75 and −8.91, respectively). This effect of the ternary complex is due to Cu^{2+} lower (than six) coordination number [40].

Cu^{2+}-dien-α-Alaha system. In the Cu^{2+}-dien-α-Alaha system, the titration data fit satisfactorily to the assumption of the presence of the binary ([Cu(dien)]$^+$, [Cu(α-Alaha)$_2$], [Cu(dien)(H-dien)]$^{3+}$, [Cu(dien)$_2$]$^{2+}$, [Cu(α-Alaha)$_2$H$_{-1}$]$^-$) and the ternary [Cu(dien)(H-α-Alaha)]$^{2+}$ and [Cu(dien)(α-Alaha)]$^+$ complexes. The stability constants obtained for the complexes in the binary and ternary systems are given in Tables 1 and 2. Concentration distribution curves are presented in Fig. 1.

The Cu^{2+}-dien 1 : 1 and 1 : 2 complexes are formed at high concentrations at copper(II) : dien : α-Alaha ratio of 1 : 2 : 2. Under these conditions the ternary complexes are of ca 30% of the total copper content, but at 1 : 1 : 2 ratio the ternary complex reaches of ca 60% (Fig. 1(c)). The latter system was studied in the vis spectroscopy (see below). Additionally, Fig. 1(c) shows that the presence of dien supresses the formation of dimeric [Cu$_2$(α-Alaha)$_2$H$_{-1}$]$^+$ species in the ternary system.

The calculated concentrations of these eight copper(II) complex species, as a function of pH, Cu^{2+}-dien-α-Alaha 1 : 1 : 2 ratio system (shown in Fig. 1(c)) indicate that under these conditions the [Cu(dien)]$^{2+}$ species is present in ca 95%. The next complex, [Cu(α-Alaha)$_2$], observed from 4 to 11 pH range, reaches a maximum concentration (70%) at pH 7.4. The [Cu(dien)(H-dien)]$^{3+}$ complex, from pH 7 to 9, is a minor species (ca 2%), so it can be regarded as negligible. The first ternary species, [Cu(dien)(H-α-Alaha)]$^{2+}$, is seen above pH 4 whereas above pH 6.5 [Cu(dien)(α-Alaha)]$^+$ appears and reaches maximum concentration of ca 60% at pH 9.6. At higher pH the [Cu(α-Alaha)$_2$H$_{-1}$]$^-$ and [Cu(dien)$_2$]$^{2+}$ species become also important. The deprotonation process of [Cu(dien)(H-α-Alaha)]$^{2+}$ leading to the formation of [Cu(dien)(α-Alaha)]$^+$ above pH 7 corresponds to the liberation of the proton from the —NH$_3^+$ group,

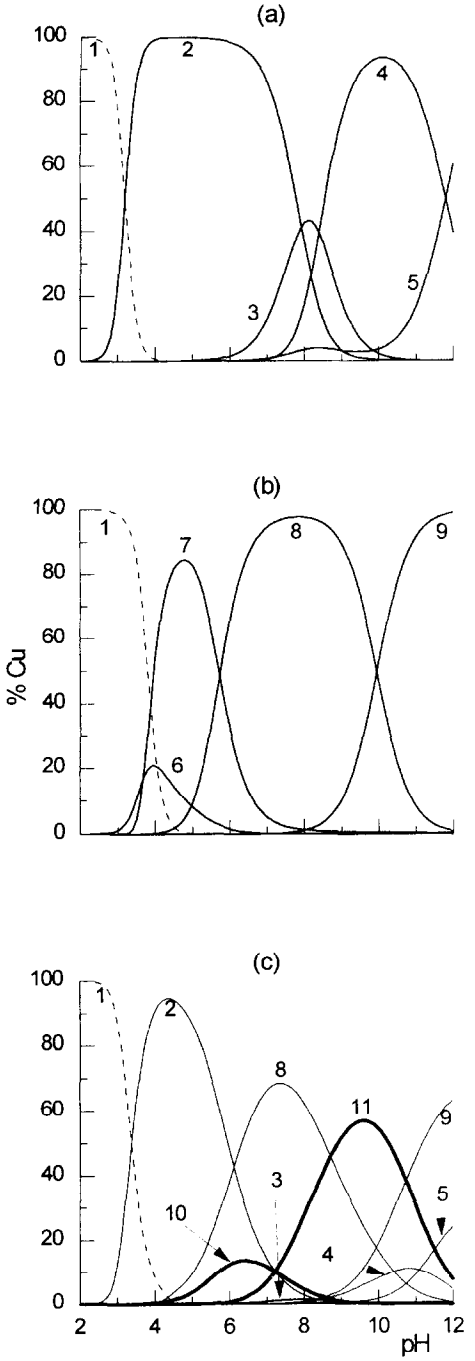

Fig. 1. Species distribution patterns for Cu^{2+} complexes of dien (a) and α-Alaha (b) at 1 : 2 ratio, and dien-α-Alaha (c) at 1 : 1 : 2 ratio; $c_{Cu^{2+}} = 4 \cdot 10^{-3}$ mol dm^{-3}: **1**-Cu^{2+}, **2**-$[Cu(dien)]^{2+}$, **3**-$[Cu(dien)_2H]^{3+}$, **4**-$[Cu(dien)_2]^{2+}$, **5**-$[Cu(dien)H_{-1}]^{+}$, **6**-$[Cu(\alpha\text{-Alaha})]^{+}$, **7**-$[Cu_2(\alpha\text{-Alaha})_2H_{-1}]^{+}$, **8**-$[Cu(\alpha\text{-Alaha})_2]$, **9**-$[Cu(\alpha\text{-Alaha})_2H_{-1}]^{-}$, **10**-$[Cu(dien)(H\text{-}\alpha\text{-Alaha})]^{2+}$, **11**-$[Cu(dien)(\alpha\text{-Alaha})]^{+}$.

which is hardly likely, since the $pK_{Cu(dien)(H\text{-}\alpha\text{-}Alaha)}$ value equal to 7.22 (Table 1 no. 3) is characteristic for the $pK^{micro}_{\alpha\text{-}Alaha}(NH_3^+)$ microconstant. The same effect is observed in the Cu^{2+}-dien-β-Alaha system above pH 8.5; $pK_{Cu(dien)(H\text{-}\beta\text{-}Alaha)} = 8.78$ is characteristic for the $pK^{micro}_{\beta\text{-}Alaha}(NH_3^+)$ microconstant (see Table 2). Taking into account these protonation constants, hydroxamate type (*O*,*O*) coordination of H-α-Alaha and H-β-Alaha ligand can be supposed for the $[Cu(dien)(HL)]^{2+}$ species. The relatively rigid structure of a bound dien molecule enforces deviation of the complex geometry from tetragonal of $[Cu(dien)(H_2O)_3]^{2+}$ to a square pyramidal geometry of $[Cu(dien)(HL)]^{2+}$ as EPR spectra suggest (see below).

The protonated ternary species $[Cu(dien)(H\text{-}\alpha\text{-}Alaha)]^{2+}$ has a maximum concentration at pH 6.5. For the evaluation of the coordinating properties of $H\text{-}\alpha\text{-}Alaha^{+}$ towards $[Cu(dien)]^{2+}$ a comparison of the stabilities of $[Cu(dien)(H\text{-}\alpha\text{-}Alaha)]^{2+}$ and $[Cu(dien)(NH_3)]^{2+}$ is reasonable. This may be done by the corresponding equilibria. For the $Cu(dien)^{2+}$—H—NH_3 system

$$[Cu(dien)]^{2+} + H\text{—}NH_3^+ \rightleftharpoons [Cu(dien)(NH_3)]^{2+} + H^+$$

obtains $\log K_{Cu(dien)(H\text{-}NH3)} = -6.28$ [33]. For the Cu^{2+}-dien-H-α-Alaha system (equilibrium no. 4 in Table 1) $\log K_{Cu(dien)(H\text{-}\alpha\text{-}Alaha)} = -4.22$. It is evident that the coordination tendency of H-α-Alaha towards $[Cu(dien)]^{2+}$ is, by a factor of about 2.06, larger than that of ammonia giving a first hint for an additional apical interaction of H-α-Alaha in $[Cu(dien)(H\text{-}\alpha\text{-}Alaha)]^{2+}$.

Cu^{2+}-dien-β-Alaha system. In the Cu^{2+}-dien-β-Alaha system, the titration data fit satisfactorily to the assumption of the presence of the binary ($[Cu(dien)]^{2+}$, $[Cu(\beta\text{-Alaha})]^{+}$, $[Cu(dien)(H\text{-dien})]^{3+}$, $[Cu(dien)_2]^{2+}$, $[Cu(\beta\text{-Alaha})_2H_{-1}]^{-}$) and the ternary $[Cu(dien)(H\text{-}\beta\text{-Alaha})]^{2+}$ and $[Cu(dien)(\beta\text{-Alaha})]^{+}$ complexes. The stability constants obtained for the complexes in the binary and ternary systems are given in Tables 1 and 2. Concentration distribution curves are presented in Fig. 2.

The Cu^{2+}-dien 1 : 1 and 1 : 2 complexes are formed in high concentrations at copper(II) : dien : β-Alaha ratio of 1 : 2 : 2. Under these conditions the ternary complexes constitute of ca 30% of the total copper content, but at 1 : 1 : 4 ratio they reach of ca 65% (Fig. 2(c)). The latter system was studied in the vis and EPR spectroscopy (see below). Additionally, Figs 2(c) and 7 show that the presence of dien supresses the formation of the polymeric $[Cu_5(\beta\text{-Alaha})_4H_{-4}]^{2+}$ species in the ternary system.

The calculated concentrations of these seven copper(II) complex species, as a function of pH (shown in Fig. 2(c)) indicate that under these conditions the $[Cu(\beta\text{-Alaha})]^{+}$ species constitutes of ca 20%. The next complex, $[Cu(dien)]^{2+}$, observed from 3 to 8 pH range, reaches a maximum concentration (87%) at pH 5. The $[Cu(dien)(H\text{-dien})]^{3+}$ species, from pH 7 to 9, is a minor one (ca 2%), so it can be regarded as negligible. The first ternary species, $[Cu(dien)(H\text{-}\beta\text{-Alaha})]^{2+}$, is seen above pH 6. Above pH 8 $[Cu(dien)(\beta\text{-Alaha})]^{+}$ appears and reaches a

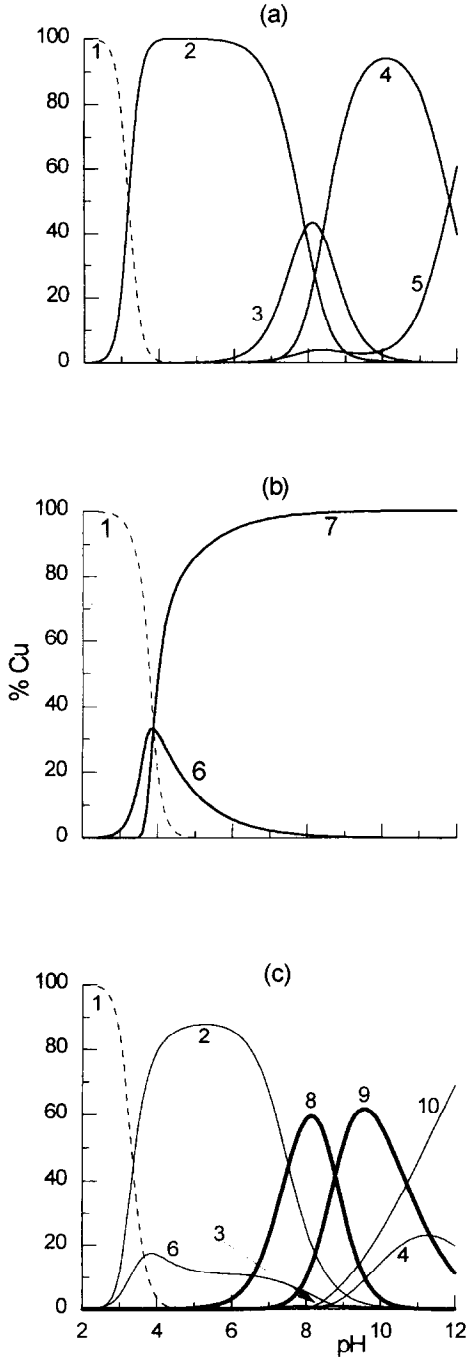

Fig. 2. Species distribution patterns for Cu^{2+} complexes of dien (a) and β-Alaha (b) at 1 : 2 ratio, and dien-β-Alaha (c) at 1 : 1 : 4 ratio; $c_{Cu^{2+}} = 4 \cdot 10^{-3}$ mol dm^{-3}: **1**-Cu^{2+}, **2**-$[Cu(dien)]^{2+}$, **3**-$[Cu(dien)_2H]^{3+}$, **4**-$[Cu(dien)_2]^{2+}$, **5**-$[Cu(dien)H_{-1}]^{+}$, **6**-$[Cu(\beta\text{-Alaha})]^{+}$, **7**-$[Cu_5(\beta\text{-Alaha})_4H_{-4}]^{2+}$, **8**-$[Cu(dien)(H\text{-}\beta\text{-Alaha})]^{2+}$, **9**-$[Cu(dien)(\beta\text{-Alaha})]^{+}$, **10**-$[Cu(\beta\text{-Alaha})_2H_{-1}]^{-}$.

maximum concentration of ca 60% at pH 9.5. Under these conditions at higher pH the $[Cu(\beta\text{-Alaha})_2H_{-1}]^{-}$ and $[Cu(dien)_2]^{2+}$ species become also important (Fig. 2(c)) as a consequence of the "disproportionation" of the ternary species, what can be shown by the following reaction:

$$2[Cu(dien)(\beta\text{-Alaha})]^{+} \rightleftharpoons [Cu(dien)_2]^{2+} + [Cu(\beta\text{-Alaha})_2H_{-1}]^{-} + H^{+}$$

The deprotonation process of the $[Cu(dien)(H\text{-}\beta\text{-Alaha})]^{2+}$ species leading to the formation of the $[Cu(dien)(\beta\text{-Alaha})]^{+}$ complex above pH 8.5 corresponds to the liberation of proton from the $-NH_3^+$ group. This species has a maximum concentration at pH 8. For the evaluation of the coordinating properties of H-β-$Alaha^{+}$ towards $[Cu(dien)]^{2+}$ a comparison of the stabilities of $[Cu(dien)(H\text{-}\beta\text{-Alaha})]^{2+}$ and $[Cu(dien)(NH_3)]^{2+}$ may be done (see above for Cu^{2+}-dien-α-Alaha system). For the Cu^{2+}-dien-β-Alaha system $\log K_{Cu(dien)(H\text{-}\beta\text{-Alaha})} = -5.62$ (Table 1), what means that the coordination tendency of H-β-$Alaha^{+}$ towards $[Cu(dien)]^{2+}$ is, by a factor of about 0.66, larger than that of ammonia.

α-Alaha is more effective chelating ligand than β-Alaha in the Cu^{2+}-dien-L ternary system. This is reflected in the much higher basicity-adjusted stability constants, $\log K_{Cu(dien)(\alpha\text{-Alaha})/(\beta\text{-Alaha})} - \Sigma pK^{H}$. These values are −11.44 and −14.40 for $[Cu(dien)(\alpha\text{-Alaha})]^{+}$ and $[Cu(dien)(\beta\text{-Alaha})]^{+}$, respectively (Table 1). It seems that basicity of the coordinating donor groups is over-compensated by chelating effect which is clearly seen in the case when (N_{amino}, N_{hydrox}) donor set (provided by L ligands) is involved in Cu^{2+} chelation. Thus, due to the preference of Cu^{2+} for five- rather than six-membered chelation [39], the complex with L = α-Alaha is found to be more stable.

Spectroscopy studies

Additional information on the structure of the binary and ternary complexes may be gained from their absorption spectral data. Even at the pH level where the distribution of the ternary $[Cu(dien)(\alpha\text{-Alaha})]^{+}$ species has a maximum, the binary: $[Cu(dien)]^{2+}$, $[Cu(\alpha\text{-Alaha})_2]$, $[Cu(dien)_2H]^{3+}$, $[Cu(dien)_2]^{2+}$, $[Cu(dien)H_{-1}]^{+}$ and $[Cu(\alpha\text{-Alaha})_2H_{-1}]^{-}$ complexes coexist in a greater or smaller extent, as can be seen in Fig. 1(c). Therefore, in the absorption spectra measured even at this pH level would be included the contributions from the binary species. The same problem exists in the Cu^{2+}-dien-β-Alaha system (Fig. 2(c)).

Figure 3 shows the pH-varied absorption spectra of the Cu^{2+}-dien-α-Alaha system (Fig. 3(a)) and Cu^{2+}-dien-β-Alaha one (Fig. 3(b)).

As the pH of the solution increases, the absorbance in the longer wavelength region is greatly enhanced. Such a spectral change, that is the red shift of *d-d* absorption band and the intensity rise, indicates the structural change around the copper(II) ion (from a

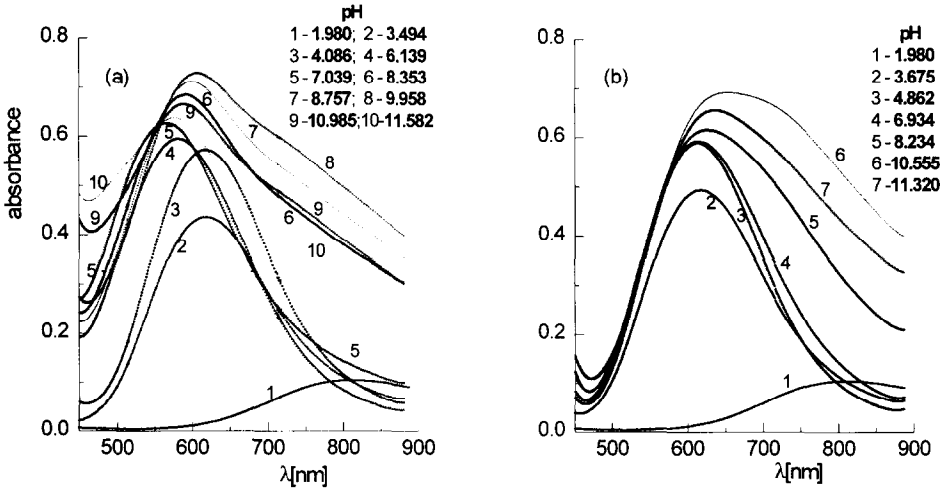

Fig. 3. pH-varied absorption spectra of Cu^{2+}-dien-α-Alaha system at 1 : 1 : 2 ratio (a) and Cu^{2+}-dien-β-Alaha system at 1 : 1 : 4 ratio (b); $c_{Cu^{2+}} = 4 \cdot 10^{-3}$ mol dm^{-3}.

square-planar or tetragonal to a type five-coordination geometry, as is well known) [9,41]. This fact suggests transition from a six to a five-coordination geometry while going from the binary to ternary species.

To extract the net ligand-field absorption band of each ternary species, the spectrum measured at a pH value where each mixed-ligand species exhibits maximal contribution was resolved into the components corresponding to the individual species existing at that pH (as described in Ref. 10). The dotted curves in Fig. 4 show the absorption spectra resolved in this way for the ternary systems.

The molecular absorptivity for the mixed-ligand species was then calculated taking into account their distribution. The distribution-corrected curves are shown in Fig. 5.

The absorption curve for the [Cu(dien)(H-β-Alaha)]$^{2+}$ species (Fig. 5) exhibits a maximum at about 611 nm with ε (molar absorptivity) ~76, a value which almost coincides with that of [Cu(dien)$(H_2O)_3$]$^{2+}$ ($\lambda_{max} = 614$ nm, $\varepsilon = 78$). Titration experiments predict that the amino group of β-Alaha should be protonated in this system. On the other hand, this result is consistent with the expectation of much smaller energy shift upon involvement of oxy-

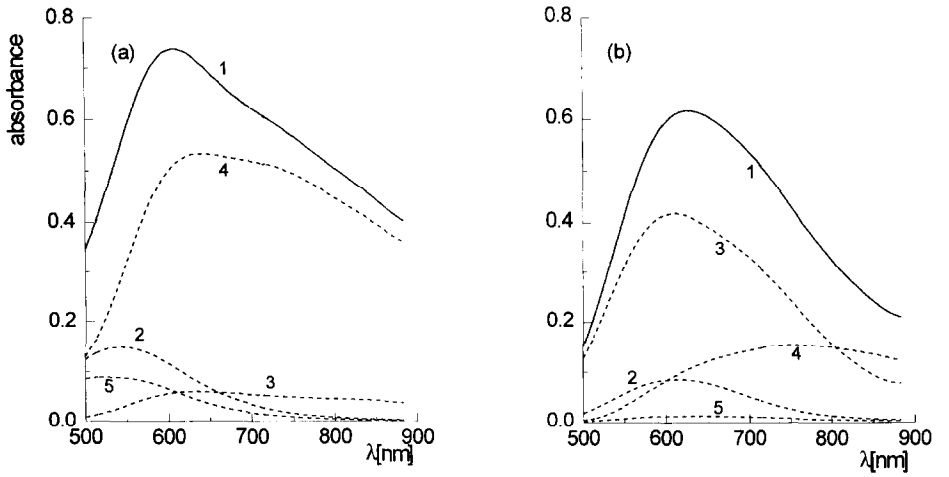

Fig. 4. Species resolutions of the observed spectra of Cu^{2+}-dien-α-Alaha system at pH 9.70 (a) (species and distribution percentages: **2**-[Cu(α-Alaha)$_2$] −22.38%; **3**-[Cu(dien)$_2$]$^{2+}$ −7.00%; **4**-[Cu(dien)(α-Alaha)]$^+$ −56.79%; **5**-[Cu(α-Alaha)$_2$ H_{-1}]$^-$ −12.59%) and Cu^{2+}-dien-β-Alaha at pH 8.23 (b) (**2**-[Cu(dien)]$^{2+}$ −13.79%; **3**-[Cu(dien)(H-β-Alaha)]$^{2+}$ −68.38%; **4**-[Cu(dien)(β-Alaha)]$^+$ −12.73%; **5**-[Cu(β-Alaha)]$^+$ −3.36%).

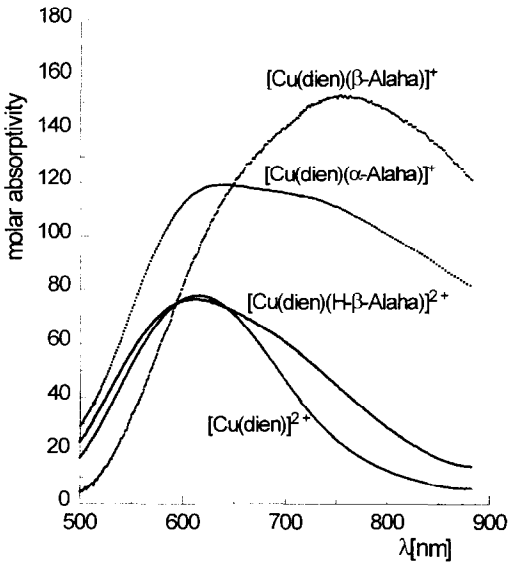

Fig. 5. Distribution-corrected absorption spectra for the $[Cu(dien)]^{2+}$, $[Cu(dien)\text{-}\alpha\text{-}Alaha]^{2+}$, $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ and $[Cu(dien)\text{-}\beta\text{-}Alaha]^{+}$ species.

gen than nitrogen donor atom. Therefore, $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ is expected to have a square-based pyramidal geometry in which dien occupies three equatorial positions and the hydroxamic group forms (*O,O*) type chelate ring involving equatorial and apical positions.

Formation of the $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ complex is reflected by a distinct change in EPR spectra of mixed ligand Cu^{2+}-dien-β-Alaha system in comparison with those manifested by Cu^{2+}-dien and Cu^{2+}-β-Alaha systems separately, starting from pH 6 (Fig. 7). The variation of the $g_{\parallel}$ and $A_{\parallel}$ parameters is well known and widely used criterion for structural identification of the coordination sphere of Cu^{2+} ion provided by the polyfunctional ligands [31,39,42,43,]. The apparent increase of $g_{\parallel}$ and decrease of $A_{\parallel}$ values in comparison with those relevant to $[Cu(dien)]^{2+}$ should be assigned to the effect of electron donation of hydroxamate oxygen bound at an axial position (Table 3). This effect is pronounced in EPR parameters only when relatively small change occurs in equatorial coordination. It is observed when water at the fourth equatorial position in $[Cu(dien)]^{2+}$ is replaced by the oxygen atom of the hydroxamate group.

The absorption curves for the $[Cu(dien)(\alpha\text{-}Alaha)]^{+}$ and $[Cu(dien)(\beta\text{-}Alaha)]^{+}$ species which exhibit a peaks at 651 nm (119) (and shoulder at ~750 nm) and 755 nm (152), respectively, are drastically different from that for binary $[Cu(dien)]^{2+}$ species. This spectral behaviour reveals the structural transformation around the copper(II) ion strongly suggesting [9,41] the formation of a five-coordinate mixed-ligand complex. A comparison between the species distribution curves (Figs 1(c) and 2(c)) and

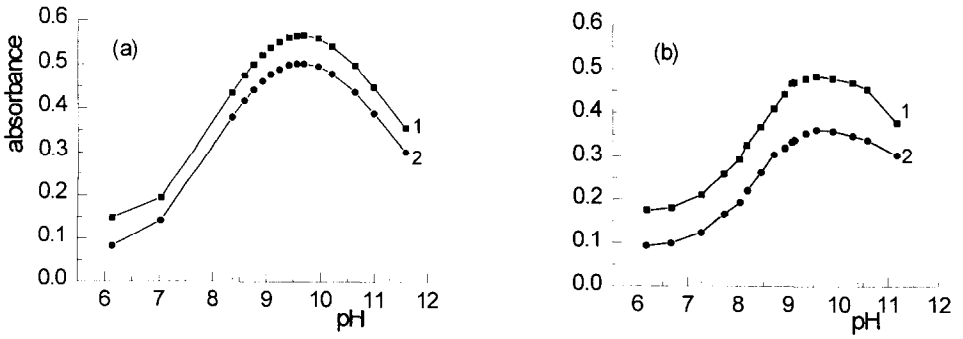

Fig. 6. Plots of absorbance vs pH for the pH-varied spectra of (a) Cu^{2+}-dien-α-Alaha system at 1 : 1 : 2 ratio (**1**—750 nm, **2**—800 nm) and (b) Cu^{2+}-dien-β-Alaha system at 1 : 1 : 4 ratio (**1**—755 nm, **2**—814 nm).

the pH-dependent curves of the absorption (Fig. 3(a) and (b)) clearly indicate that the spectral change shown in Fig. 6(a) and (b) is attributable to the formation and decay of the 1110 species.

EPR spectra allow to detect the formation process of the 1110 species within pH range 8.4–10. An equilibrium between the $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ and $[Cu(dien)(\beta\text{-}Alaha)]^{+}$ species, of increasing contribution, is demonstrated by Fig. 7.

Replacement oxygen by nitrogen atoms into copper(II) coordination sphere is characterized by substantial increase in $A_{\parallel}$ and decrease of $g_{\parallel}$ in comparison to the $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ ternary complex (Table 3). Thus, the EPR spectral data unambigously support the coordination of aminohydroxamic acid ligands through (N_{amino}, N_{hydrox}) donor set. The parameters do not reach the values expected for the complex with an exactly planar 4N coordination around copper(II) [39], in agreement with the suspection that electron donating nitrogen atom is coordinated along z axis. This is remarkable that isotropic hyperfine parameter A_{iso}, determined by the analysis of liquid solution EPR spectra is substantially smaller for the complex formed at pH about 10 than for that existing at pH 7. Because the g_{iso} parameters are almost identical, a decrease A_{iso} values is consistent with reduction in the Fermi contact term. This trend is usually treated as an indication of a stronger electron donation imposed by the donor atoms bound at an axial position. It seems to be probable that upon freezing this effect is partly diminished [44].

CONCLUSION

In the copper(II)-dien-α- (or β-) alaninehydroxamic acid system, the potentiometric, vis and EPR results strongly suggest the formation of five-coordination ternary 1111 and 1110 species. A comparison of the absorption spectra with the results of EPR method shows that formation of the (*O*,*O*) hydroxamate chelate occurs at a lower pH (for $[Cu(dien)(HL)]^{2+}$ species) and (N_{amino}, N_{hydrox}) chelate occurs at a higher pH (for $[Cu(dien)L]^{+}$ species).

(Received 7 November 1997; accepted 11 December 1997)

Abstract—The new polymeric compound $Fe(thiazole)_2Cl_2$ (**1**) has been synthesised by the addition of thiazole to an ethanolic solution of anhydrous $FeCl_2$. The structure of $Cu(tz)_2Br_2$ (**2**) has also been determined. The structures of both polymers consist of pseudo-octahedral units, doubly linked by halide-bridges to form infinite linear chains. Slight variation in the bonding of the two are observed, relating to the Jahn-Teller nature of Cu^{2+}. Room temperature magnetic susceptibility measurements of **1** give an effective moment of 5.51(2) B.M., indicating high-spin Fe(II). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dichlorobis(thiazole)iron(II); dibromobis(thiazole)copper(II).

Polymeric systems of Cu and Co containing thiazole (tz) and di-bridging chloro ligands have been known for some time; however, only the structure of dichlorobis(thiazole)copper(II) has previously been reported [1]. Prior studies of the reaction between thiazole and iron(II) chloride have indicated an analogous compound is formed [2], however thus far no structural data have been reported. This paper details the synthesis and structural characterisation of the iron analogue $Fe(tz)_2Cl_2$ (**1**) by single crystal techniques, as well as the structural characterisation of the previously prepared $Cu(tz)_2Br_2$ (**2**). Room temperature magnetic properties of **1** are presented.

EXPERIMENTAL

Anhydrous $CuBr_2$ (99% purity), anhydrous $FeCl_2$ (98% purity) and thiazole (99% purity) were obtained from Aldrich Chemical Co. Inc. and used as obtained. Ethanol and methylene chloride (A.R. grade) were used when freshly distilled. The synthesis of **1** was carried out under dry Ar using Schlenk techniques, while **2** was prepared in air. Elemental analyses were carried out on a LECO CHNS-900 elemental analyser. Infrared spectra were recorded (Nujol mull) in the 350–5200 cm^{-1} range on a Perkin–Elmer FT-IR 2000 spectrophotometer. Magnetic susceptibility measurements were carried out at room temperature using a Sherwood Scientific Gouy balance.

$Fe(tz)_2Cl$ (1)

Thiazole (12 mmol, 2 ml) was added to an ethanolic solution of anhydrous $FeCl_2$ (6 mmol, 16 ml) with constant stirring. A pale yellow precipitate was immediately formed. The sample was stirred for a further 10 min before being centrifuged. The supernatant was reduced to ~10 ml under vacuum and stored in a sealed vessel under dry Ar. Yellow crystals suitable for X-ray diffraction were obtained after 8 weeks. The microcrystalline precipitate was washed with benzene and diethyl ether. Found: C, 24.6; H, 2.0; N, 9.4; S, 21.6%. Calcd for **1**: C, 24.7; H, 2.0; N, 9.1; S, 21.2%. IR (nujol): ν(ligand) 608 (m), 737 (m), 808 (m), 879 (w), 912 (w), 1060 (w), 1112 (w), 1231 (w) cm^{-1}.

$Cu(tz)_2Br_2$ (**2**)

Thiazole (12 mmol, 2 ml) was added to an ethanolic solution of anhydrous $CuBr_2$ (6 mmol, 16 ml) with constant stirring. A green precipitate was immediately formed. The sample was stirred for 20 min, collected, washed with ether and benzene and allowed to dry under suction. The product was recrystallised from dimethylformanide by addition of an equal volume of methylene chloride followed by cooling in the freezer compartment of a refrigerator. Dark green needle-like crystals suitable for X-ray diffraction were obtained after 3 weeks. Found: C, 18.5; H, 1.6; N, 6.9; S, 16.6%. Calcd for **2**: C, 18.3; H, 1.5; N, 7.1; S, 16.3%. IR (Nujol): ν(ligand) 612 (s), 635 (w), 738 (s), 810 (s), 882 (m), 920 (m), 1065 (m), 1113 (m), 1237 (m) cm^{-1}.

X-ray crystallography

Measurements were made on a Rigaku AFC7R diffractometer an ambient temperature using monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Crystals were mounted on the top of glass fibers. Cell constants were obtained by least-squares analysis of 16 strong reflections in the range $5.53° < 2\theta < 14.33°$ for **1**, and 25 reflections ($29.35° < 2\theta < 29.79°$) for **2**. Details of crystal data, data collection and structure refinement for **1** and **2** are summarised in Table 1. The intensity data were corrected for Lorentz and polarisation effects and an empirical absorption correction based on azimuthal scans of several reflections was also applied.

The structures were solved by direct methods and developed by alternating cycles of difference Fourier syntheses and full matrix least-squares refinements. The positions of the non-hydrogen atoms were determined unequivocally, with the exception of the thiazole ligands in **1**, which displayed static disorder between adjacent carbon and sulfur sites, due to a 180° rotation about its Fe—N bonds. In this case the disorder was modeled by refinement of jointly occupied S/C sites. The minority components of these jointly occupied sites are indicated by a primed label, such that the site S/C′ contains a majority of sulfur, while the adjacent C/S′ site is constrained so as to give an equal proportion of carbon. The occupation factors of sulfur atoms were refined only at the S/C′ sites, while the C′ and S′ occupation factors were constrained so as to give fully occupied sites. The non-hydrogen atoms were refined anisotropically, with the exception of the atoms at the disordered sites which were refined isotropically. Hydrogen atoms were placed at calculated positions. Neutral atom scattering factors were taken from [3], and anomalous dispersion corrections were taken from [4]. Crystallographic calculations were carried ut with a teXsan crystallographic software package of Molecular Structure Corporation (1985 & 1992).

RESULTS AND DISCUSSION

The chemical reactivity of iron(II) chloride with thiazole does not appear to be substantially different

to that observed for copper(II) halides [1]. While compounds of M(II)-thiazole-halides (M = Co, Ni, Cu, Zn and Pd) have been known for some time [5,6], thiazole containing complexes of Fe(II) have only recently been reported [2,7].

Crystal structure of $Fe(tz)_2Cl_2$ (**1**)

The structure of $Fe(tz)_2Cl_2$ (**1**) consists of tetragonally elongated octahedral units, with *N*-donor thiazole ligands in the axial positions. These units are equatorially linked along the *b*-axis by double chloride bridges to form infinite linear chains (Fig. 1). The packing of these chains in the unit cell of **1** is shown in Fig. 2. Selected bond lengths and bond angles for **1** are given in Table 2.

Four distinct Fe—Cl bonds are formed in **1** with roughly equivalent bond lengths ranging between 2.521(2) Å and 2.560(2) Å, which bridge a Fe—Fe distance of 3.717(5) Å. Fe—N bond lengths of 2.196(6) Å (Fe—N1) and 2.150(7) Å (Fe—N2) are typical of those found for the Fe(II)—N bonds (2.21(1) Å) in the complex salt $[Fe(tz)_6][Fe_2OCl_6]$ [7]. The bond angles about Fe in **1** give rise to a pseudo-octahedrally coordinated centre that shows deviations away from regular angles (Table 2). Angles between equivalent chlorine atoms such as Cl1—Fe—Cl1* were found to be ~94°, while those between inequivalent chlorine atoms such as Cl1*—Fe—Cl2 were found to be ~86°. The axial N1—Fe—N2 bond angle (177.4(3)°) also shows a deviation away from regular symmetry.

Constrained refinement of occupation factors for the disordered thiazole ring (N2—C4—C5—S2—C6) revealed that the S2 and C5 sites (as shown in Figs 1 and 2) were approximately 87% occupied with the designated atoms. The C5′ and S2′ atoms that were generated by the 180° rotation about the Fe—N2 bond occupied the remaining 13% of these sites. Orientational static disorder of this type has been previously reported for *trans*-$Mo(tz)_3Br_3$ [23] and $Fe_2O(tz)_4Cl_4$ [2].

The dimensions of the non-disordered thiazole ligand in **1** are typical of those found in other metal thiazole complexes [1,2,7,23]. The axial thiazole ligands of **1** show rotations about their Fe—N bonds with respect to one another (Fig. 1). The thiazole rings N1—C1—C2—S1—C3 (i.e. those labeled A, B, D and F in Fig. 2) are rotated approximately 15° away from the *ac* plane, while the rings N2—C4—C5—S2—C6 (C, E, G and H) are rotated approximately 25° in the opposite direction. The sense of tilting of the thiazole rings in Fig. 2 is indicated such that atoms labeled "+" are positioned above the *ac* plane, while "−" atoms are positioned below.

The crystal structures of a number of polymeric iron(II) compounds have been documented. Of these, the majority are comprised of *O*- [8–15] or *N*-donor

[16–21] bridging ligands. Polymeric iron(II) complexes based on 1-dimensional di-bridging halide chains are almost unknown. A notable example is that of $[FeCl_2(OPMe_3)]_\infty$ [22], where each iron centre is linked by 2 axial and 2 equatorial bridging chlorine atoms to adjacent iron atoms. The $-OPMe_3$ group adopts a third equatorial position about the Fe atom, leading to a distorted trigonal bipyramidal coordination geometry. Thus, while $[FeCl_2(OPMe_3)]_\infty$ is also a dichloride bridged iron(II) polymer, the bonding relationship between adjacent molecular units is substantially different to that observed in **1**.

A much wider range of Fe—Cl bond lengths (2.350 Å–2.603 Å) are observed in the more highly distorted Fe_2Cl_4 chains of $[FeCl_2(OPMe_3)]_\infty$ [22]. The Fe—Fe bond lengths for this complex (3.688(1) Å and 3.560(1) Å) are also slightly shorter than that found in **1**. The axial Cl—Fe—Cl bond angles of $[FeCl_2(OPMe_3)]_\infty$ are similar (174.14(3)°) to those in **1**, however, by virtue of the trigonal bipyramidal coordination, the equatorial Cl—Fe—Cl bond angle (123.49(3)°) is substantially different.

Crystal structure of $Cu(tz)_2Br_2$ (**2**)

The polymeric compound $Cu(tz)_2Br_2$ (**2**) consists of the same dihalide bridged linear structure as **1** and has been found to be isostructural with $Cu(tz)_2Cl_2$ [1]. The chain structure of **2** is shown in Fig. 3 and the packing of chains in the unit cell is displayed in Fig. 4. Selected bond lengths and bond angles are given in Table 3. The Cu_2Br_2 structural motif based-on di-bridging bromide ligands has been observed in numerous Cu(I) and Cu(II) polymeric complexes [24–32]. In particular the complexes $Cu(3,5\text{-dimethylpyridine})_2Br_2$ [24],

$Cu(pyridine)_2$-Br_2 [25] and $Cu(N\text{-methylimidazole})_2Br_2$ [26] show essentially isostructural features to **2** with a *trans*-arrangement of Cu—N bonds and di-bridging Br—Cu—Br* bonds. The Cu—N distance in **2** of 1.988(3) Å is essentially identical to that found in the chloro- analogue (1.990(2) Å), while the disparate Cu—Br distances of 2.472(1) Å and 3.120(1) Å are also consistent with those observed for $Cu(tz)_2Cl_2$ (2.322(1) Å and 2.998(1) Å). The essentially regular Br—Cu—Br* angles of 90.2(1)° are in agreement with those observed for other dibromo-bridged copper complexes [24–26].

The structure of **1** is analogous to these $Cu(tz)_2X_2$ (X = Cl and Br) polymers in that it contains a similar di-bridging linear chain structure along the *b*-axis. Closer examination of Figs 1 and 3 however, indicate slightly different structural behaviour, suggesting dissimilar bonding mechanisms in **1** and **2**. In contrast to the opposed rotational behaviour of the thiazole rings in **1**, the rings in **2** show synchronised rotations about their Cu—N bonds of approximately 21° relative to the *ac* plane (Figs 3 and 4). These distinct rotational behaviours are clearly linked to the different transition metal–halide bonding modes in these complexes. Estes and coworkers [1] described the polymer structure of $Cu(tz)_2Cl_2$ as a square-planar array consisting of two thiazole ligands and two short in-plane chloride bonds linked by the two longer out-of-plane Cu—Cl bonds. The bonding arrangement in **2** can also be described in this matter and is reflective of the Jahn-Teller nature of d^9 Cu^{2+}. Given the in-plane nature of the strongest bonds about the Cu centre, it is likely that the single-ion ground state is essentially $d_{x^2-y^2}$ in character.

Examination of the bonding picture about the Fe centre of **1** indicates a much more regular arrangement in terms of the Fe—N and Fe—Cl bond lengths. The square-planar-like arrangement of two halide and two nitrogen bonds, along with the two longer out-of-plane halide bonds that is observed in **2** is inappropriate for describing **1**, where very little variation is shown between each of the four of the Fe—Cl bonds. The pseudo-octahedral arrangement described above provides a more suitable description, given that Jahn-Teller effects do not contribute significantly to the high-spin d^6 ground state configuration of Fe^{2+}.

Comparison of the tilting of the thiazole rings across the iron and copper transition metal centres (Figs 2 and 4) clearly shows the dissimilar nature of these polymer chains within their crystals. This feature leads to the lowering of crystal symmetry and thus the effective doubling of the unit cell volume of **1** as compared to **2**. Despite these different rotation mechanisms however, the packing arrangements in their respective cells are such that nearest-neighbour interactions between thiazole ligands on adjacent

* An asterisk denotes a translation of the molecule along the *b* axis.

chains are similar. Equivalent interchain relationships are observed along the ⟨−101⟩ direction in **1** (Fig. 2) and the ⟨10–2⟩ direction in **2** (Fig. 4). With respect to the orientation of the thiazole rings, the interchain relationships in **1** between rings C, F and H (Fig. 2) are analogous to those relationships between rings I, J and M in **2** (Fig. 4). The interchain distances between rings in these structures are comparable, although those for **1** tend to be slightly shorter than found in **2** (Table 4).

Although interchain distances are similar for these two complexes, the position of chains along the *b* axis are different in each. Cu centres in **2** occupy high symmetry 2*d* sites (1/2, 1/2, 0 and 1/2, 0, 1/2) in $P2_1/c$, while Fe centres in **1** occupy general 4*a* sites (*x*, *y*, *z*) in *Cc*. The relative positions of adjacent polymer chains along the *c* axis of **1** are therefore shifted in *b* with respect to one another, leading to a modulation throughout the crystal.

Magnetic susceptibility

The molar magnetic susceptibility (χ_{mol}) of $Fe(tz)_2Cl_2$ was measured at room temperature (298 K). Upon correcting for diamagnetism an effective moment (μ_{eff}) was determined as 5.51(2) μ_B; this value being consistent with high-spin Fe^{2+} containing 4 unpaired electrons (S = 2). Cotton *et al.* report a smaller effective moment of 4.90 μ_B for the di-chloro-bridged polymer $[FeCl_2(OPMe_3)]_\infty$ [22], the reduction in magnitude possibly being a reflection of the trigonal bipyramidal coordination geometry. Due to the scarcity of pseudo-octahedral di-halide-bridged Fe(II) 1-dimensional systems, very little has been studied of the magnetic response of these materials to changes in temperature.

The magnetic behaviour of **2,** has previously been characterised [1,5]. Room temperature susceptibility measurements were carried out by Hughes and Rutt [5] who found an effective moment consistent with the 1 unpaired spin of d^9 Cu^{2+} ions (μ_{eff} = 1.77 μ_B). Variable temperature susceptibility data were collected by Estes *et al.* [1] and were able to be fitted by an isotropic Heisenberg model using the relations of Bonner and Fisher [33], giving $J = -10.4$ cm^{-1} and $g = 2.12$. Interestingly, a good fit to the data for $Cu(tz)_2Cl_2$ was found using a model for a two dimensional Heisenberg antiferromagnetic layer, however attempts to fit the $Cu(tz)_2Br_2$ data to this model were unsuccessful. The authors proposed that additional superexchange pathways via sulfur–sulfur contacts played an important role in the dimensionality increase of the chloride system.

The M—M distances observed in **1** and **2** of 3.717 Å and 3.987 Å respectively preclude extensive metal–metal bonding occurring in these complexes, however the possibility of intrachain magnetic superexchange

pathways occurring via the di-halide bridges has been clearly demonstrated in other studies [1,24–26,34–37].

Studies on the synthesis of Pb-Ti-oxo-alkoxo-carboxylato complexes

L. Spiccia, B. O. West* and Q. Zhang

Centre for Chemical Synthesis and Department of Chemistry, Monash University, Clayton, Victoria, Australia, 3168

(Received 6 October 1997; accepted 11 December 1997)

Abstract—Reactions between lead carboxylates $Pb(O_2CR)_2$ and $Ti(OPr^i)_4$ produce complexes of empirical formulae $Pb_2Ti_2(O)(O_2CR)_2(OPr^i)_8$ (R = C_3F_7 **1**; $C(CH_3)_3$ **2**) in toluene and $Pb_2Ti_4(O)_2(O_2CR)_2(OPr^i)_{14}$ (R = $CH(CH_3)_2$ **3**) in Pr^iOH solution. ^{207}Pb NMR evidence indicates that both types of complex form in alcoholic solution. The compound **4** having a Pb_3Ti_3 core is produced when $Pb(O_2CCH(CH_3)_2)_2$ reacts with $Ti(OPr^i)_4$ in toluene. Attempts to prepare acetylacetonate derivatives of compounds having 1 : 1 or 1 : 2 Pb : Ti stoichiometries by direct substitution of the compounds gave poorly soluble Pb containing products but direct reaction of $Pb(O_2CCH_3)_2$ or PbO with Ti-acetylacetonate-alkoxide species gave compounds of empirical formulae $Pb_3Ti_3(O)_4(O_2CCH_3)_2(OPr^i)_7(acac)$ **5** and $Pb_2Ti_2(O)(OEt)_8(acac)_2$ **6**. Reaction of $Ti(OR)_4$ (R = OPr^i, Et) with acetic acid yields products which further react with PbO to form the previously characterised Pb—Ti compounds $Pb_2Ti_2(O)(O_2CCH_3)_2(OPr^i)_8$ **7** and $Pb_2Ti_4(O)_2(O_2CCH_3)_2(OEt)_{14}$ **8**. Molecular weight measurements, ^{207}Pb, ^{19}F, ^1H and ^{13}C NMR and IR spectral data have been used to derive empirical formulae for the various complexes isolated. © 1998 Elsevier Science Ltd. Keywords: lead–titanium; alkoxide; carboxylate; ^{207}Pb; NMR; acetylacetone.

Mixtures of hydrated lead acetate and a titanium alkoxide in alcoholic solution have been used as precursors to the formation of the piezoelectric material $PbTiO_3$ by sol-gel processes. [1–4]. It was recognised that some form of Pb—Ti complex would be formed in such solutions [1] and various empirical formulae were proposed (e.g. $Pb(O_2CCH_3)(O)Ti(OR)_3$, $Pb(O)_2Ti_2(OR)_6$). Subsequent attempts at direct synthesis involving reaction between anhydrous $Pb(O_2CCH_3)_2$ and $Ti(OPr^i)_4$ and $Ti(OEt)_4$ led to the isolation of two compounds each having a different Pb : Ti ratio depending on the alkoxide substituent. The 1 : 1 Pb : Ti ratio complex formed using $Ti(OPr^i)_4$ as reagent [5–7], was shown to be $Pb_2Ti_2(\mu_4\text{-}O)(O_2CCH_3)_2(OPr^i)_8$ **7** by single crystal X-ray analysis [6]. This complex has also been formed by direct reaction of acetic acid on the mixed metal alkoxide $Pb_2Ti_2(\mu\text{-}O)(OPr^i)_{10}$ [8].

The formula of the 1 : 2 complex formed using $Ti(OEt)_4$ has been established as $Pb_2Ti_4(\mu_4\text{-}O)_2(O_2CCH_3)_2(OEt)_{14}$ **8** by two independent X-ray studies [7,9]. The latter complex was the only compound to be isolated whether the Pb : Ti ratio of initial reagents was 1 : 1 or 1 : 2. Each compound has a Pb : acetate ratio of 1 : 1 instead of the 1 : 2 ratio of the starting reagent i.e. acetate has been "lost" in the reaction as had previously been found [10] using various spectroscopic techniques. Moreover an acetate group bridges each of the Pb—Pb and Ti—Ti atom pairs in the 1 : 1 compound while in the 1 : 2 complex, only the pairs of Ti atoms have bridging acetate groups attached i.e. there has been acetate exchange between Pb and Ti as part of the overall reaction. Group exchange between the labile Group 4/14 precursor reagents is not unexpected although the mechanism for the exchange process is unclear. Another extreme case of such an exchange reaction has been observed in the reaction between Zn acetate and a Sn methoxide compound in an attempt to prepare a Sn—Zn heterometallic [11]. Solubility considerations presumably determined that the most readily isolated product was the polymeric homonuclear Zn-acetate-alkoxide $[Zn_2(O_2CCH_3)_3(OCH_3)]_n$.

The isolation of complexes of differing Pb—Ti stoichiometry using the same Pb carboxylate reagent but

* Author to whom correspondence should be addressed.

different Ti alkoxides raises the question as to whether this results from a fortuitous combination of solubility considerations or is due more fundamentally to steric or electronic differences between the alkoxy compounds of Ti, varying bridging capacities of the alkoxide groups or abilities to form oxo groups by ester elimination. Similarly the exchange of acetate groups between Pb and Ti suggests that the alkanoate group could also play a role in determining the final stoichiometry of Pb—Ti compound.

We report here the isolation and empirical formulae of complexes formed by the reactions of $Ti(OPr^i)_4$ with several other lead alkanoates ($Pb(O_2CR)_2$) where R is either strongly electronegative (C_3F_7) or large and capable of exerting steric resistance to bridge formation, ($C(CH_3)_3$, $CH(CH_3)_2$). Also, in view of the addition of acetylacetone to mixtures of a titanium alkoxide and $Pb(O_2CCH_3)_2$ to improve the thickness [12] and electrical properties [13] of $PbTiO_3$ films produced by sol-gel processes we have endeavoured to identify the acetylacetone complexes formed by its reaction with Pb—Ti alkoxide precursors.

A further feature of the two Pb—Ti complexes previously isolated has been the presence of tetrahedrally coordinated oxo groups as key structural features of each complex. In recent years, oxo groups have been found to be common structural units in many other homo- and heteronuclear alkoxides [14] and carboxylato-alkoxides compounds [15,16] even when the compounds have been prepared under scrupulously anhydrous conditions. Although such groups might still result from hydrolytic processes due to the adventitious entry of traces of water, other processes including ether elimination in alkoxides (i)

$$M—OR + RO—M \rightarrow M—O—M + R_2O \qquad (i)$$

and ester elimination in carboxylate-alkoxide reactions (ii)

$$M—OR + R'COO—M \rightarrow M—O—M' + R'COOR \qquad (ii)$$

are more likely to be the routes by which oxo groups are formed. There have been reports of the formation of esters in previous studies of Pb acetate–Ti alkoxide reactions [17–19]. Hubert-Pfalzgraf *et al.* [6] however did not observe ester formation in the room temperature reaction which yielded the 1 : 1 Pb : Ti compound **7** but only when the reactants were initially heated in toluene thus suggesting ether elimination leads to oxo group formation. Extensive ester formation has been reported to occur when mixtures of Zn or other transition metal acetates are heated to high temperatures in decalin with $Al(OR)_3$ [20]. Zn—O—Al and other M—O—Al alkoxy complexes have been proposed to form although their structures are not precisely known. The generality of the formation of oxo groups in reactions leading to alkoxo-carboxylato mixed metal species and indeed polynuclear alkoxides suggests that the fundamental reactions require further study.

The use of PbO as a reagent to produce "basic" lead acetate [21] suggested it be examined as a direct source of oxo groups in the synthesis of Pb—Ti complexes and as part of the present study we have successfully prepared the known 1 : 1 and 1 : 2 Pb : Ti oxo-acetato-alkoxide complexes using the products of reaction of $Ti(OR)_4$ (R = Pr^i, Et) and acetic acid as the titanium reagent. Although strenuous efforts have been made to prepare crystals of suitable quality for X-ray analysis of the new species formed in these studies so far they have been uniformly unsuccessful. Hence the empirical formulae suggested, although supported by spectroscopic and vapour phase osmometric molecular weight measurements, rely greatly on comparisons with other structurally characterised species, where available and on chemically plausible assumptions, particularly with regard to the presence and number of oxo groups in the molecules.

EXPERIMENTAL

All reactions were carried out using dry solvents and manipulations used Schlenk techniques under dry nitrogen. Alcohols were predried over molecular sieves then distilled after the formation of the appropriate Mg alkoxide or in the presence of CaH_2 then stored over molecular sieves. All other solvents were dried by standard procedures.

Molecular weights were measured by vapour phase osmometry (VPO) at 60°K using a Knauer Type II osmometer contained in a dry box facility with benzil as standard. ^{207}Pb NMR spectra were obtained using a Bruker AM-300 spectrometer. Chemical shifts were measured in ppm using $Pb(Me)_4$ as external standard with high field from the standard considered negative. These values were converted to values relative to $Pb(NO_3)_2$ by adding 2961 [22]. ^1H, ^{13}C and ^{19}F spectra were measured at 300 K (unless otherwise stated) on a Varian EM-360A or the Bruker instrument. Tetramethylsilane was used as standard for ^1H and ^{13}C spectra and $CFCl_3$ for ^{19}F spectra. Mass spectra were recorded on VG Micromass 7070F or VG Trio-1 quadrupolar spectrometers. Electron microprobe analyses (EMA) were made with a Cambridge S410 SEM linked through an NEC X-ray detector and pulse processing system to a Packard multichannel analyser. A commercial sample of $PbTiO_3$ (Aldrich) was used as standard. Elemental analyses were by CMAS, Melbourne. $Ti(OPr^i)_4$ (Aldrich) was used as received.

Lead carboxylates

Anhydrous lead acetate. The preparation of 10–20 g quantities, free from evidence for O—H stretching frequencies in the 3000–4000 cm^{-1} region was accomplished by either heating lead acetate trihydrate at 100°C under reduced pressure (10^{-3} Torr) for 5 h or

stirring the hydrate at room temperature with excess acetic anhydride for several hours then removing all volatile materials by pumping at 10^{-3} Torr and 50°C. The product is insoluble in toluene, THF and chloroform, readily soluble in methanol and 2-methoxyethanol and sparingly soluble in ethanol. A typical analysis gave; Found: C, 14.8; H, 1.85. Calc. for $C_4H_6O_4Pb$: C, 14.8; H, 1.85%.

Basic lead acetate $3[Pb(O_2CCH_3)_2]\cdot PbO\cdot H_2O$. The method was based on that of Kwestroo *et al.* [21]. PbO was added to a solution of the trihydrate in water in the mole ratio 1 : 3, oxide to acetate (a slight excess of oxide was used giving a practical mole ratio of 1.05 : 3. The mixture was stirred at room temperature for some hours as the bulk of the oxide slowly dissolved. The solution was finally filtered and evaporated at 40°C under reduced pressure. The powder X-ray pattern of the product was identical with the compound reported [21]. Found: C, 12.0; H, 1.50. Calc. for $C_{12}H_{20}O_{14}Pb_4$: C, 11.8; H, 1.60%.

Lead heptafluorobutyrate trihydrate $Pb(O_2CC_3F_7)_2\cdot 3H_2O$. An aqueous solution of the acid was refluxed with PbO, the solution filtered and allowed to evaporate to crystallisation. Found: C, 13.7; H, 0.2; F, 38.3. Calc. for $C_8H_6F_{14}O_7Pb$: C, 14.0; H, 0.09; F, 38.7%.

Lead pivalate $Pb(O_2CC(CH_3)_3)_2$. PbO was added to a methanol solution containing two equivalents of pivalic acid and the mixture stirred at room temperature until most of the oxide had dissolved. The solution was filtered and on further standing deposited a white solid which was filtered and dried. M.pt. 172–174°C. Found: C, 29.2; H, 4.63. Calc. for $C_{10}H_{18}O_4Pb$: C, 29.3; H, 4.40%.

Lead dimethylacetate $[Pb(O_2CCH(CH_3)_2)_2]_6\cdot 4H_2O$. This compound was prepared by the reported method [23].

1 : 1 *Pb* : *Ti ratio compounds*

$Pb_2Ti_2(O)(O_2CR)_2(OPr^i)_8$. $Ti(OPr^i)_4$ (usually 3.5 mmol) was added dropwise to an equimolar quantity of the carboxylate as a slurry in isopropanol (anhydrous lead acetate [7]) or toluene (lead heptafluorobutyrate) or a solution in toluene (lead pivalate). Volumes of solvent ca 30 cm^3 were found appropriate. The mixtures were refluxed for 2–3 h, filtered, then cooled to 0°C or a lower temperature to induce crystallisation. In the case of the pivalate product the solvent was eventually removed under reduced pressure, the waxy solid remaining redissolved in the minimum of warm toluene and cooled to −20°C until crystals formed. The yields in terms of the amounts of crystalline product recovered were at least 55% in each preparation.

$Pb_2Ti_2(O)(O_2CC_3F_7)_2(OPr^i)_8$ **1**. EMA: Pb : Ti, 1 : 1. Found: C, 26.9; H, 4.10; F, 18.3. Calc. for $C_{32}H_{56}F_{14}O_{13}Pb_2Ti_2$: C, 26.9; H, 3.90; F, 18.6%. Mol. wt. $Pb_2Ti_4(O)_2(O_2CCH(CH_3)_2)_2(OPr^i)_{14}$ **3**. $Ti(OPr^i)_4$ (2.83 g, 10 mmol) was added dropwise to a suspension of $Pb(O_2CCH(CH_3)_2)_2$ (3.81 g, 10 mmol) in Pr^iOH (30 cm^3) and the mixture refluxed for 20 min. The resulting solution was filtered hot and crystals grew as it cooled to room temperature. Yield: 91%. M.pt. 72–72°C. EMA: Pb: Ti, 1: 2. found: C, 36.7; H, 6.85. Calc. for $C_{50}H_{112}O_{20}Pb_2Ti_4$: C, 36.6; H, 6.84%. Mol. wt. (toluene): 1620 ± 50 (theor. for $C_{50}H_{112}O_{20}Pb_2Ti_4$, 1639). NMR: ^1H (d^8-toluene): $\delta = 1.19$ (d, $O_2CCH(C\underline{H}_3)_2$, 12H, $J = 7.0$ Hz); 1.25, 1.35, 1.52, 1.55 (d $OCH(C\underline{H}_3)_2$, 84H, $J = 6.1$ Hz); 2.46 (sp $O_2CC\underline{H}(CH_3)_2$ 2H, $J = 6.1$ Hz) ppm.

$Pb_2Ti_4(O)_2(O_2CCH_3)_2(OEt)_{14}$ **8** *from "basic" lead acetate*. $Ti(OPr^i)_4$ (2.86 g, 10 mmol) was dissolved in ethanol (30 cm^3) and the solution stirred at room temperature for 30 min before evaporating under reduced pressure until an oily "waxy" solid remained. This was redissolved in ethanol (30 cm^3) and the solution added dropwise to a suspension of "basic" lead acetate (3.04 g, 2.50 mmol) in EtOH (50 cm^3). The resulting mixture was refluxed for 1 h then allowed to cool to room temperature and colourless crystals separated. The complex is readily soluble in hexane, benzene and toluene. Yield: 70%. EMA: Pb: Ti, 1: 2. Found: C, 27.8; H, 5.40. Calc. for $C_{32}H_{76}O_{20}Pb_2Ti_4$: C, 27.7; H, 5.48%. Mol. wt. (benzene): 1350 ± 50 (theor. for $C_{32}H_{76}O_{20}Pb_2Ti_4$, 1387). NMR: ^1H ($CDCl_3$) 300 K: $\delta = 1.22$, 1.24, 1.26 (t, $OCH_2C\underline{H}_3$); 1.98 (s, $O_2CC\underline{H}_3$); 3.72–4.56 (broad band of poorly resolved quartets, $OC\underline{H}_2CH_3$): 217 K: $\delta = 1.20$, 1.23, 1.25 (t, $OCH_2C\underline{H}_3$); 1.98 (s, $O_2CC\underline{H}_3$); 3.70, 4.09, 4.44, 4.51, 5.14 (q, $OC\underline{H}_2CH_3$) ppm; (C_6D_6) 300 K: $\delta = 1.30$, 1.35, 1.54 (t, $OCH_2C\underline{H}_3$); 2.01 s, $O_2CC\underline{H}_3$); 4.53, 4.68, 4.90 (q, $OC\underline{H}_2CH_3$) ppm. ^{13}C ($CDCl_3$): $\delta = 17.8$, 18.4, 19.2 ($OCH_2\underline{C}H_3$); 26.2 ($O_2C\underline{C}H_3$); 68.5, 69.2, 71.0, 72.2 ($O\underline{C}H_2CH_3$); 183.0 ($O_2\underline{C}CH_3$) ppm. IR (Nujol): 1564 (vs), 1434 (vs), 1372 (s), 1131 (s), 1094 (s), 1052 (s), 925 (m), 895 (m), 663 (m) cm^{-1}.

Reaction with $Ti(OPr^n)_4$-"$[Pb_2(O_2CCH_3)_3(OPr^n)]$"

$Ti(OPr^n)_4$ (2.84 g, 10 mmol) was dissolved in Pr^nOH (50 cm^3) and $Pb(O_2CCH_3)_2$ (3.25 g, 10 mmol) added. The mixture was refluxed for 1 h as the acetate dissolved. The resulting clear yellow solution was cooled to room temperature and a white solid precipitated. It recrystallised from Pr^nOH. EMA: Pb only. Found: C, 16.7; H, 2.66. Calc. for $C_9H_{16}O_7Pb_2$: C, 16.6; H, 2.46%. NMR: $^1H(CDCl_3)$: $\delta = 0.94$ (t, $OCH_2CH_2C\underline{H}_3$, 3H); 1.60 (sex, $OCH_2C\underline{H}_2CH_3$, 2H); 2.04 ($O_2CC\underline{H}_3$, 9H); 3.61 (t, $OC\underline{H}_2CH_2CH_3$, 2H). IR (Nujol): 1159 (s), 1423 (s), 1227 (m), 1105 (m), 1070 (s), 1017 (s), 888 (w), 721 (s), 665 (s) cm^{-1}. MS: $m/z = 593$ ($Pb_2(O_2CCH_3)_3^+$, 5%); 489 ($Pb_2O(O_2CCH_3)^+$, 3%); 267 ($Pb(O_2CH_3)^+$ 100%).

Reactions with PbO

$Pb_2Ti_4(\mu\text{-}O)_2(O_2CCH_3)_2(OEt)_{14}$ **8**. $Ti(OEt)_4$ (0.82 g, 3.60 mmol) was dissolved in ethanol (30 cm^3) and glacial acetic acid (0.22 g, 3.60 mmol) added. The mixture was heated under reflux for 30 min, cooled, then PbO (0.8 g, 3.6 mmol) added and the mixture returned to reflux for 3 h. The solution was filtered and left until crystallisation occurred. Found: C, 27.8; H, 5.40. Calc. for $C_{32}H_{76}O_{22}Pb_2Ti_4$: C, 27.7: H, 5.48%. EMA: Pb: Ti, 1: 2. ^{207}Pb NMR (toluene): sharp peak at 2868 ppm.

$Pb_2Ti_2(\mu\text{-}O)(OEt)_8(acac)_2$ **6**. Acetylacetone (1 g, 10 mmol) was added to a solution of $Ti(OEt)_4$ (2.29 g, 10 mmol) in EtOH (50 cm^3), the mixture refluxed for 30 min then cooled to room temperature. PbO (2.23 g, 10 mmol) was then added and the mixture heated at reflux for a further 3 h. The solution was filtered, reduced to half its volume under reduced pressure and allowed to stand whereupon a white solid slowly precipitated. It was recovered by filtration, washed with EtOH and dried under reduced pressure. EMA: Pb: Ti = 1: 1. Found: C, 26.3; H, 4.45. Calc. for $C_{26}H_{54}O_{13}Pb_2Ti_2$: C, 28.7; H, 5.02%. Mol. wt. (benzene): 900 ± 50 (theor. for $C_{26}H_{54}O_{13}Pb_2Ti_2$, 1085). NMR: ^1H ($CDCl_3$): $\delta = 1.19$, 1.22, 1.24 (t, $OCH_2C\underline{H}_3$, 24H); 1.94, 2.05 (s, $C\underline{H}_3$ acac, 12H); 4.42, 4.46 (q, $OC\underline{H}_2CH_3$, 16H); 5.55 (s, $C\underline{H}$ acac, 2H) ppm. ^{13}C ($CDCl_3$): $\delta = 18.3$, 20.2, 20.8, 26.8 ($\underline{C}H_3$ (acac and OEt); 68.7, 72.2 ($O\underline{C}H_2CH_3$); 102.9 (CH acac); 188.0 (CO acac) ppm. IR (Nujol): 1594 (bvs), 1521 (vs), 1442 (vs), 1372 (vs), 1271 (vs), 1146 (vs), 1099 (vs), 1057 (vs), 897 (s) cm^{-1}.

RESULTS AND DISCUSSION

The lead carboxylates

The various lead carboxylates were conveniently prepared by the reactions of PbO, suspended in an organic solvent or water, with the appropriate acid. The heptafluorobutyrate was isolated as a trihydrate similar to the acetate whose structure has been shown to be based on chelated acetate groups bridging Pb atoms [24–26] while the anhydrous trimethylacetate was isolated from methanol solution. The dime-

thylacetate, containing 2/3 of a mole of water per Pb, has been shown [23] to exist in the solid state as the cyclic hexamer $[Pb_6(O_2CCH(CH_3)_2)_{12}] \cdot 4H_2O$ soluble in solvents such as toluene. ^{207}Pb NMR data on the compounds are given in Table 1 together with that for the acetate and "basic" acetate. Single resonances were observed for the C_3F_7, $C(CH_3)_3$ and acetate compounds in water. The 4 resonances found in toluene for the sparingly water insoluble dimethylacetate have been previously discussed in terms of its hexanuclear structure [23]. Harrison *et al.* [27] have previously measured the ^{207}Pb chemical shifts of a number of lead(II) compounds PbX_2 in water, including lead acetate, and concluded that the single resonances observed were due to very rapid equilibration between cation anion complexes as in eqn. (iii). They showed that in consequence the shift values varied quite markedly with concentration unless the salt is completely ionised at all concentrations as is the perchlorate.

$$PbX_2(H_2O)_x \leftrightarrow [PbX(H_2O)_y]^+ + X^- \qquad \text{(iii)}$$

No study of the variation with concentration was made for any of the compounds examined in the present work but as far as permitted by solubility considerations, NMR measurements were made at concentrations close to 0.3 mol dm^{-3}. Allowing for conversion to chemical shifts relative to $Pb(NO_3)_2$ the value of 1552 ppm found in the present work for the acetate at 0.3 M is in good agreement with that of 1557 ppm previously reported [27].

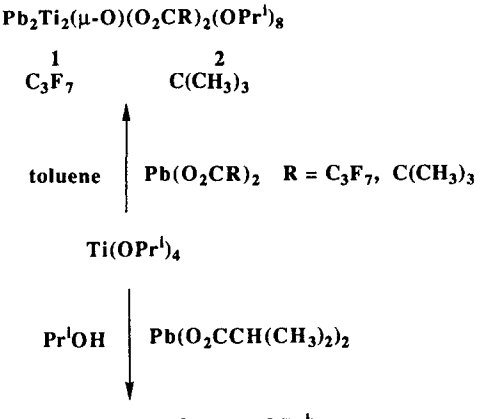
Single ^{207}Pb resonances were also observed for the acetate and heptafluorobutyrate in several ionising coordinating solvents at 300 K and at 226 K in methanol. This implies rapid exchange between the various possible solvated species $[Pb(O_2CR)_2(solv)_x]$ and $[Pb(O_2CR)(solv)_y]^+$, the variation of chemical shift with alkanoate group indicating a difference in equilibrium constants between the complexes of the various alkanoate complexes. The presence of the highly electronegative fluorocarbon group results in a considerable shift to higher field of the observed resonances in each solvent compared to the hydrated acetate.

The "basic" acetate fails to display any resonances in MeOH at 300 K, but multiple resonances were observed at 250 K suggesting either that the compound dissociates in solution giving species that can exchange with each other sufficiently rapidly to prevent NMR detection except at low temperatures or that a single species exists with differently coordinated lead atoms which undergoes such rapid fluxional behaviour at room temperature that single atom resonances are not detected. The crystal structure of the compound has not yet been reported but the tetranuclear empirical formula of the compound, $3Pb(O_2CCH_3)_2 \cdot PbO \cdot H_2O$ [21] may suggest some structural relationship with other tetranuclear, "basic" carboxylates $M_4(\mu_4\text{-}O)(O_2CR)_6$ [28] of Zn, Be and Co which have been structurally characterised and found to have four tetrahedrally arranged metal ions coordinated to a central oxo group with carboxylate ions coordinated in O—O bridging mode to pairs of metal ions. The additional water molecule associated with the empirical formula of the Pb compound could be

coordinated at a single Pb site leading to an overall trigonal pyramidal configuration for the four Pb atoms. Ready displacement of coordinated water from one site and reattachment of MeOH solvent at other Pb sites or the changing of coordination partners of each Pb atom by "opening" and "shutting" of the acetate bridges provides plausible mechanisms of fluxional exchange for such a labile system and even for distinguishing individual Pb atoms when the exchange processes are slowed at low temperatures. The empirical formulation of an oxo group and discrete water molecule however may alternatively represent two OH groups. The only "basic" Pb unit so far structurally defined is the hexanuclear cationic species $[Pb_6O(OH)_6]^{4+}$ found in the "basic" perchlorate salt [29]. It contains one oxo group coordinated to four tetrahedrally arranged Pb atoms with the remaining two Pb atoms linked to two faces of the tetrahedron each by three triply bridging OH groups. This array leads to the presence of three differently coordinated types of Pb atoms in the solid state structure.

Reactions of lead carboxylates with $Ti(OPr^i)_4$

1 : 1 Pb : Ti *ratio complexes.* New complexes having a 1 : 1 Pb : Ti ratio have been obtained from reactions between $Pb(O_2CC_3F_7)_2$ or $Pb(O_2CC(CH_3)_3)_2$ and $Ti(OPr^i)_4$ in hot toluene solution. The solution molecular weights measured for the complexes indicate that they are of comparable stoichiometries to the structurally characterised acetate-isopropoxide complex **7** [6,7] and suggest they have the empirical formulae $Pb_2Ti_2(\mu\text{-}O)(O_2CC_3F_7)_2(OPr^i)_8$ **1** and $Pb_2Ti_2(\mu\text{-}O)(O_2CC(CH_3)_3)_2(OPr^i)_8$ **2**. The ^{207}Pb NMR spectrum of each complex **1**, **2**, **7**, in toluene (and **7** in Pr^iOH) shows two sharp resonances (Table 2), those for the heptafluorobutyrate compound being at notably higher field than for the pivalate or acetate in line with the high field shift shown by the Pb fluoroalkanoate compared to other alkanoates. The structure of complex **7** determined by Hubert-Pfalzgraf *et al.* [5,6] showed a central μ_4-O-(Pb_2-Ti_2) unit with one Pb atom (Pb(1)) 4 coordinate and the other, (Pb(2)), **5** coordinate in the solid state. The pairs of Pb and Ti atoms are each bridged by acetate groups so that there are two differently coordinated carboxylate groups in the crystal structure. The ^{207}Pb NMR spectra are in agreement with the presence of two differently coordinated Pb atoms in each of the Pb—Ti complexes. The 4-coordinate site (Pb(1)) will have a relatively lower electron density than the 5-coordinate (Pb(2)), is therefore less shielded, suggesting that the lower field (2824 ppm) resonance be tentatively assigned to Pb(1) and that at 2447 ppm to Pb(2).



Scheme 1.

Table 2. Empirical formulae of Pb—Ti compounds and ^{207}Pb NMR spectra

Pb : Ti ratio	Complex	^{207}Pb chemical shifts[a] (ppm)
1 : 1	**1** $Pb_2Ti_2(O)(O_2CC_3F_7)_2(OPr^i)_8$	1822, 1717 (1876, 1682, 224 K)

	6 $Pb_2Ti_2(\mu\text{-}O)(OEt)_8(acac)_2$	2688
	7 $Pb_2Ti_2(O)(O_2CCH_3)_2(OPr^i)_4$	2824, 2447 2750, 2438 (Pr^iOH)
1 : 2	**3** $Pb_2Ti_4(O)_2(O_2CCH(CH_3)_2)_2(OPr^i)_{14}$	2599, 2374, 2176 (2556 Pr^iOH)
	8 $Pb_2Ti_4(O)_2(O_2CCH_3)_2(OEt)_{14}$	2868 (2430, 2110, 1780, EtOH)

[a] Spectra measured at 300 K in toluene solution unless otherwise indicated.

Compounds **1** and **7** show ^{19}F and ^{13}C (**1**) and ^{1}H (**7**) NMR resonances indicative of two separate carboxylate groups at room temperature (see Experimental). However only one ^{1}H resonance was clearly observed for the pivalate in compound **2**. The 7 differing isopropoxide ligands seen in the solid state structure of the acetate (**7**) are not individually distinguishable in the clusters of overlapping doublets ($OCH(C\underline{H}_3)_2$ and septets ($OC\underline{H}(CH_3)_2$) due to these groups in the acetate complex or either of compounds **1** or **2**. While the NMR data reported here were obtained using a spectrometer working at 300 MHz, Hubert-Pfalzgraf *et al.* [6] only detected one ^{207}Pb resonance and one CH_3 acetate ^{1}H resonance for compound **7** at 200 MHz. They have moreover presented evidence for the existence of two fluxional species in solution based on the ^{1}H NMR detection of additional acetate resonances at $-50°C$. In support of this we have observed an increase in the number of resonances ascribable to isopropyl CH groups for compound **7** at 217 K. The molecular weights of the compounds in benzene measured in the present work indicates that little or no dissociation occurs in solution.

The ^{1}H spectrum of the heptafluorobutyrate compound also showed groups of overlapping isopropoxide CH_3 and CH signals but neither showed any marked increase in separation or increase in number at 217 K indicating a lower degree of fluxional behaviour for this complex.

1 : 2 Pb : Ti *ratio complexes*

The structural studies [7,9] of the 1 : 2 Pb—Ti complex containing acetate and ethoxide groups have established its formula to be $Pb_2Ti_4(\mu_4\text{-}O)_2(O_2CCH_3)_2(OEt)_{14}$ **8** with equivalently sited 5 coordinate Pb atoms. The molecular weight measured in toluene is in agreement with such an empirical formula while the observation of a single ^{207}Pb NMR resonance [7,9] (Table 2) indicates that it does not dissociate rapidly in that solvent. The ^{1}H NMR spectrum in $CDCl_3$ at 300 K shows three broad, partially overlapping triplets in the region expected for ethoxide CH_3 resonances. A single broad band of unresolved quartets is observed in the region expected to show methylene protons. At 217 K five peaks can be clearly seen in the methylene region but no resolution of the methyl protons was observed. The spectrum in C_6D_6 shows sets of overlapping resonances in each of the methyl and methylene regions. A single resonance due to the acetate methyl is however clearly recognised in both solvents. At lower temperatures the resonances broaden and the acetate methyl resonance shifts until it merges with the residual toluene methyl resonance at 2.1 ppm. These observations indicate a degree of fluxional behaviour for the molecule in solution probably involving interconversion of bridging and terminal alkoxide groups.

When $Pb(O_2CCH(CH_3)_2)_2$ reacts with $Ti(OPr^i)_4$ in isopropanol even in a 1 : 1 mole ratio a high yield of complex **3** having a 1 : 2 ratio of Pb : Ti is obtained. Its ^{1}H NMR spectrum shows a cluster of resonances that may be assigned to the methyl and methylene groups respectively of the isopropoxide groups together with peaks having chemical shifts representative of the dimethylacetate CH and CH_3 protons. Integration of these regions provides a ratio of OPr^i to $O_2CCH(CH_3)_2$ groups of 7 : 1. The molecular weight for the compound in toluene solution indicated the empirical formula $Pb_2Ti_4(\mu\text{-}O)_2(O_2CCH(CH_3)_2)_2(OPr^i)_{14}$ **3**, similar to that of the 1 : 2 Pb : Ti acetate/ethoxide product **8**. However three ^{207}Pb resonances were observed for the compound in toluene solution and a single resonance in Pr^iOH (Table 2). This contrasts with the single resonance shown by the 1 : 2 acetate-ethoxide compound **8**. The reaction between equimolar quantities of $Pb(O_2CCH(CH_3)_2)_2$ and $Ti(OPr^i)_4$ in toluene allowed isolation of a very small quantity of a complex **4** having a Pb : Ti ratio of 1 : 1. In contrast to the other 1 : 1 ratio compounds isolated which have a Pb_2Ti_2 composition the molecular weight of this product in toluene indicated that it contains a Pb_3Ti_3 core. Insufficient quantity of the product was isolated to allow the full range of NMR measurements to be made but the compound shows two ^{207}Pb NMR resonances in toluene solution and three in Pr^iOH (Table 2) one of the latter (2534 ppm) having close to the same chemical shift as given by the 1 : 2 complex (2556 ppm) prepared and measured in that solvent.

The influence of solvent on the formation of mixtures of Pb—Ti complexes

The reaction of $Pb(O_2CCH(CH_3)_2)_2$ and $Ti(OPr^i)_4$ in both isopropanol and toluene was further examined by removing samples from reaction mixtures containing equimolar amounts of the reagents after some hours of reflux and measuring their ^{207}Pb NMR spectra. In the case of the toluene reaction, three strong peaks at 2599, 2374 and 2176 ppm were observed in the ratio 1 : 2 : 2 together with some far less intense peaks. The sample from the isopropanol reaction similarly showed three strong resonances with almost the same chemical shifts 2529, 2343, and 2195 ppm together with several weaker peaks at lower field. Comparison with the spectra of the isolated compounds measured in each solvent thus indicates that both types of compounds with Pb_2Ti_4 and Pb_3Ti_3 cores are formed whether the reaction solvent is isopropanol or toluene. Each type of complex appears stable in one solvent but undergoes some degree of rearrangement in the other to form the second type of complex, possibly reaching an equilibrium condition. A plausible empirical formula for the 1 : 1 species formed with this combination of reagents in agreement with the

various data is $Pb_3Ti_3(O)_4(O_2CCH(CH_3)_2)_2(OPr^i)_8$ **4**. The ^{207}Pb NMR examination of the reaction mixtures shows the presence of other Pb containing species which were not identified. None of these peaks could be ascribed to the unreacted carboxylate.

X-ray structural data on the two different products is necessary if a detailed understanding of their apparent interconvertability is to be obtained. The structural features so far defined by the acetate/ethoxide 1 : 2 Pb : Ti compound **8** may not be found for the dimethylacetate/isopropoxide complex despite their similar metal ratios and ^{207}Pb NMR features while the Pb_3Ti_3 compound represents a new structural type.

The ^{207}Pb NMR spectral examination of several other reaction mixtures has also disclosed the coincident formation of other Pb : Ti ratio complexes to those which were most readily isolated. Thus a freshly prepared equimolar mixture of anhydrous $Pb(O_2CCH_3)_2$ and $Ti(OPr^i)_4$ in Pr^iOH showed not only two peaks representative of the 1 : 1 Pb : Ti compound **7** isolated but also an additional strong peak at 2987 ppm which may well be due to the parallel formation of a 1 : 2 complex similar to **8** formed by reaction between $Pb(O_2CCH_3)_2$ and $Ti(OEt)_4$. The relatively easy isolation of the 1 : 1 species 7 could be due to its lower solubility and formation in greater amount under the reaction conditions employed. The detection of only two peaks in the ^{207}Pb NMR spectrum of the pure complex dissolved in isopropanol, the solvent used in the reaction, indicates that the 1 : 1 compound retains its stoichiometry and possibly its solid state structure in the alcohol, and does not rearrange to give some 1 : 2 product. However the ^{207}Pb spectrum of the 1 : 2 Pb : Ti acetate/ethoxide complex **8** which displays only one resonance in toluene solution, shows three resonances when measured in ethanol solution indicating some form of decomposition or rearrangement of the 1 : 2 Pb : Ti compound occurs in that solvent. Samples removed at various time intervals from a refluxing equimolar mixture of $Pb(O_2CCH_3)_2$ and $Ti(OEt)_4$ in ethanol, from which can be isolated the 1 : 2 compound **8** show the same three resonances and may well indicate the parallel formation of both 1 : 2 and 1 : 1 ratio acetate-ethoxide species.

Similarly, the reaction between $Ti(OPr^i)_4$ and $Pb(O_2CC(CH_3)_3)_2$, which favoured the isolation of the 1 : 1 ratio Pb : Ti complex **2** in toluene, was also studied in refluxing isopropanol by measuring the ^{207}Pb spectra of samples of the reaction mixture withdrawn at intervals. After 30 min reaction time 5 peaks of equal intensity were observed at 2261, 2336, 2682, 2814 and 3069 ppm. These resonances occur downfield of the resonance shown by the carboxylate alone and indicate that the carboxylate had already reacted to form new species. Further refluxing for up to 3 h, showed an increase in intensity of the peaks at 2336 and 2814 ppm had become the dominant features of the spectrum. These were comparable to the chemical shifts measured in toluene for the 1 : 1 complex **2** subsequently isolated. The other peaks initially observed, although much reduced in intensity, were still detectable.

Such qualitative experiments indicate that a variety of compounds can form from reactions between Pb carboxylates and Ti alkoxides in a given solvent. The complex most readily isolated must depend on its solubility in that solvent and the concentration which it can attain because of the solvent influence on the reaction pathway. The different Pb : Ti ratio complexes may or may not be formed in equilibrium with each other.

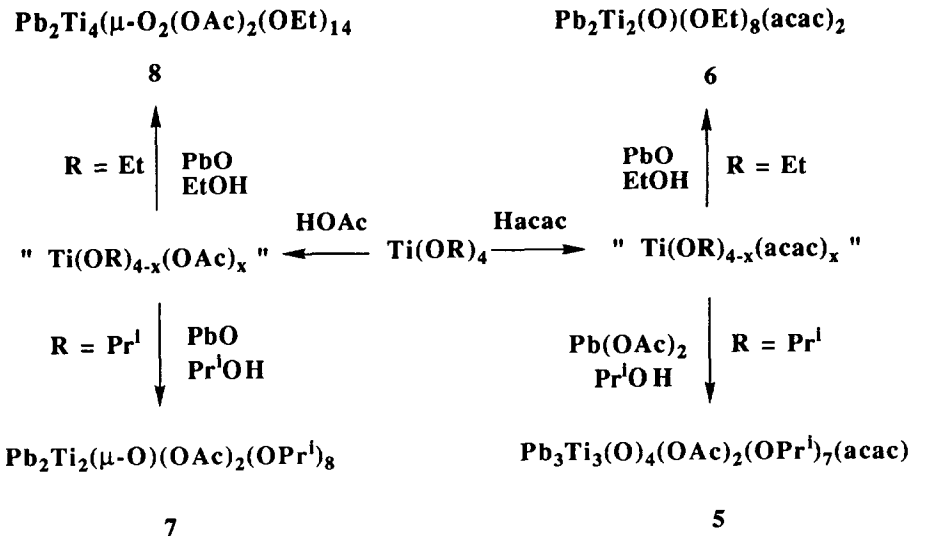
Reactions with other Ti alkoxides

Solubility considerations appeared to dominate several other reactions attempted with $Ti(OMe)_4$, $Ti(OBu^n)_4$ or $Ti(OPr^n)_4$. Reaction between $Pb(O_2CCH_3)_2$ and either of the first two alkoxides resulted in solids shown by EMA to be mixtures of Pb and Pb—Ti products which could not be separated. $Ti(OPr^n)_4$ formed a sparingly soluble product containing only Pb whose mass spectrum showed an ion of mass 593 possibly $[Pb_2(O_2CCH_3)_3]^+$ or $[Pb_2(O_2CCH_3))_{3-x}(OPr^n)_x]^+$. Its ^1H NMR spectrum indicated the presence of acetate and alkoxide groups in the ratio 3 : 1. It appears to be $\{Pb_2(O_2CCH_3)_3(OPr^n)\}_n$ a similar type of compound to $\{Zn_2(O_2CCH_3)_3(OMe)\}_n$ [11].

Action of acetylacetone

Only one Pb—Ti complex containing acetylacetone $Pb_2Ti_2(O)(acac)_2(OPr^i)_8$ has previously been reported [8] resulting from the direct reaction of acetylacetone with the "single source" compound $Pb_2Ti_2(O)(OPr^i)_{10}$ in hexane solution. We have attempted the direct substitution of acetylacetone for other coordinated groups by reaction with $Pb_2Ti_2(O)(O_2CCH_3)_2(OPr^i)_8$ **7** in Pr^iOH and $Pb_2Ti_4(O)_2(O_2CCH_3)_2(OEt)_{14}$ **8** in EtOH. In each reaction a precipitate formed which only contained Pb together with acetate, alkoxide and acetylacetonate groups as indicated by IR spectral examination. Hubert-Pfalzgraf *et al.* [6] have reported that $Pb(O_2CCH_3)_2$ is precipitated following reaction of acetylacetone with **7** in toluene. The pretreatment of a slurry of $Pb(O_2CCH_3)_2$ in isopropanol with a solution of the ligand produced a similar insoluble Pb containing product which did not dissolve in the presence of $Ti(OPr^i)_4$ even under reflux.

A successful procedure involved the dissolution of solid $Pb(O_2CCH_3)_2$ in a Pr^iOH solution of $Ti(OPr^i)_4$ containing acac in the ratio acacH : Ti, 0.5 : 1 allowing isolation of a product having a 1 : 1 Pb : Ti ratio. The molecular weight of the complex in Pr^iOH indicated a Pb_3Ti_3 core was present. The ^{13}C NMR spectrum of the product contained peaks that could be assigned



Scheme 2.

to isopropoxide, acetate and acetylacetonate groups. The shifts assigned to the acetylacetonate group were similar to those reported for that ligand in $Ti(OPr^i)_3(acac)$ [30] and $Pb_2Ti_2(O)(acac)_2(OPr^i)_8$ [8] with 2 separate CO resonances being identified suggesting unsymmetrical binding of the acetylacetonate ligand. Non-symmetric bonding of acac has been observed in the dimeric $[Al(OPr^i)_2(acac)]_2$ [31]. Two intense IR spectral bands shown by the Pb—Ti compound at 1567 cm^{-1} and 1419 cm^{-1} are assigned as $\nu_{as}(CO_2)$ and $\nu_{sym}(CO_2)$ respectively, characteristic of an acetate group symmetrically attached to a metal while the difference $\Delta\nu = 148$ cm^{-1} between these frequencies indicates a bridging mode of coordination [32]. Strong metal alkoxide vibrations are observed in the 1000–1200 cm^{-1} region. The ^1H NMR spectrum showed three septets assigned to CH protons of isopropyl groups which integrated to give a ratio of 4 : 2 : 1 from higher to lower field suggesting the presence of non-equivalent isopropyl groups. The splitting of the isopropyl methyl doublets confirms this inequivalence. The methyl resonances of the acac and acetate groups are likely to have similar chemical shifts [33] around 2 ppm. Three peaks are shown by the complex in that region. One sharp (1.95 ppm), the other two broad (2.03 and 2.09 ppm) with integration giving a 2 : 1 : 1 ratio of intensities. Since the IR spectral evidence suggests equivalent acetate coordination, the sharp NMR peak at 1.95 ppm is assigned to an acetate CH_3 resonance with the remaining broader peaks due to dissimilarly placed acac methyl groups. The sharp peak at 5.51 ppm is then assigned to the acac CH proton, the value being similar to that reported for $Ti(OPr^i)_3(acac)$ [30]. The ^{207}Pb NMR spectrum of the complex in toluene showed two broad diffuse peaks at 2561 and 2161 ppm in the ratio 2 : 1 according to the peak width at half height. This would accord with a 2 : 1 ratio of three Pb atoms in the molecule dispersed over two different types of coordination sites but the broad nature of the peaks does not preclude the existence of more separate Pb sites in the molecule with fluxional properties. These data taken in conjunction with its elemental analysis suggest the empirical formula $Pb_3Ti_3(O)_4(O_2CCH_3)_2(OPr^i)_7(acac)$ **5** with acac coordinated to Ti in an unsymmetrical mode.

Reactions involving PbO

Initial experiments showed that no reaction occurred between PbO and $Ti(OPr^i)_4$ or $Ti(OEt)_4$ when the components were refluxed in the parent alcohols but prior reaction of the alkoxide with one equivalent of either acetic acid or acetylacetone gave products which readily dissolved the oxide. Thus a Pr^iOH solution of $Ti(OPr^i)_4$, previously treated with one equivalent of acetic acid, reacted with an equimolar quantity of PbO to give a solution displaying the same ^{207}Pb NMR spectrum as a solution of $Pb(O_2CCH_3)_2$ and $Ti(OPr^i)_4$ refluxed in Pr^iOH. This was considered above to indicate a mixture of the known 1 : 1 Pb : Ti complex $Pb_2Ti_2(\mu\text{-}O)(O_2CCH_3)_2(OPr^i)_8$ **7** together with the as yet uncharacterised 1 : 2 compound $Pb_2Ti_4(\mu\text{-}O)_2(O_2CCH_3)_2(OPr^i)_{14}$. Reaction of PbO with a similarly formed Ti-acetate-ethoxide species in ethanol allowed the isolation of the known compound $Pb_2Ti_4(\mu\text{-}O)_2(O_2CCH_3)_2(OEt)_{14}$, **8** identified by its IR, ^{207}Pb and ^1H NMR spectra and elemental analysis. Similarly, a solution containing the product formed by reaction of equimolar amounts of $Ti(OEt)_4$ and acetylacetone in ethanol was refluxed with sufficient PbO to give a

1 : 1 Pb : Ti mole ratio. A product isolated from the mixture had a Pb : Ti ratio of 1 : 1 and showed only a single ^{207}Pb resonance in toluene solution (Table 2). Its ^{1}H and ^{13}C NMR spectra showed peaks assignable to ethoxide and coordinated acetylacetonate ions. Its integrated ^{1}H NMR spectrum and molecular weight suggest it is the ethoxy analogue of the isopropoxy-acetylacetonate compound previously reported by Hubert-Pfalzgraf *et al.* [8] with empirical formula $Pb_2Ti_2(O)(OEt)_8(acac)_2$ **6**. PbO failed to dissolve in a solution in which $Ti(OPr^i)_4$ had been first reacted with one mole equivalent or acetylacetone.

Although simple stoichiometric formulae $Ti(OR)_{4-n}(O_2CR)_n$ ($n = 1, 2$) have been assigned [34] earlier to the products formed when $Ti(OR)_4$ react with carboxylic acids, recent structural studies have shown that more complex species are formed. Although the specific product formed on reaction of acetic acid with $Ti(OEt)_4$ has not yet been structurally characterised, the compounds formed in other related reactions have been found to be hexanuclear oxo Ti species of the form $Ti_6(\mu\text{-}O)_4(O_2CR)_8(OR')_8$ ($R = CH_3$, $R' = Bu^n$ [35], $R = CH_3$, $R' = Et$ [36], $R = C_6H_5$, $R' = Pr^n$ [37]). The oxo groups have been suggested to derive from hydrolysis by water produced by the esterification reaction between the acid and liberated alcohol [36]. Polynuclear species have also been detected by various spectroscopic techniques in solutions of $Ti(OEt)_4$ which have reacted with acetylacetone [30]. Such considerations make it impossible to conclude from synthetic experiments alone that oxo groups derived from PbO are found in the final Pb—Ti complexes but the experiments at least show that the oxide can be a useful reagent in the synthesis of mixed Pb—Ti derivatives as an alternative to the use of preformed lead carboxylates.

TCB bridged binuclear and polynuclear copper(II) complexes: a novel three dimension-network structure complex $[(Cudien)_2(Cudien \cdot H_2O)TCB\ (ClO_4)_2 \cdot H_2O]_n$ (TCB = tetracarboxylatobenzene, dien = 3-azapentane-1,5-diamine)

(Received 6 August 1997; accepted 11 December 1997)

Abstract—The binuclear copper(II) complexes $[(Cudipn \cdot H_2O)_2\ TCB] \cdot 8H_2O$ and the three-dimensional network complex $[(Cudien)_2(Cudien \cdot H_2O)TCB\ (ClO_4)_2 \cdot H_2O]_n$, where TCB stands for tetracarboxylatobenzene, dipn is *N*-(3-aminopropyl)-1,3-propanediamine, dien is 3-azapentane-1,5-diamine, were synthesized and characterized by IR, ESR and magnetic susceptibility. The compound $[(Cudipn \cdot H_2O)_2TCB] \cdot 8H_2O$ is a TCB bridging binuclear Cu(II) complex. The complex $[(Cudien)_2\ (Cudien \cdot H_2O)TCB\ (ClO_4)_2 \cdot H_2O]_n$ crystallizes in the monoclinic system, space group C2/c, with $a = 26.257(9)$, $b = 8.087(2)$, $c = 19.301(7)$ Å, $\beta = 116.41(3)^\circ$ and $Z = 4$. The copper atoms have two kinds of coordination environment. Cu(2) atom is coordinated in an elongated octahedral arrangement by three nitrogen atoms from dien, two oxygen atoms from two carboxyl groups of two adjacent TCB molecules and one oxygen atom from the water molecule. The other kind of copper atoms Cu(1) and Cu(1c) are coordinated in a square pyramidal environment by three nitrogen atoms from dien and two oxygen atoms from two adjacent TCB molecules, one of which lays above or below the 2-D network plane. These form a three-dimensional network structure. Moreover four carboxyl groups of TCB^{4-} are divided to two types by their different coordination mode: (1) two *para*-carboxyl groups C(14)O(1)O(2) bridge the copper atom Cu(2) with one oxygen atom O(1) in monodentate fashion, (2) other two-carboxyl groups C(15)O(3)O(4) coordinate to Cu(1) and Cu(1d) in a bridging bidentate fashion. The magnetic susceptibility shows the weak antiferromagnetic interaction in two compounds because of the longer distances between two paramagnetic centers. © 1998 Elsevier Science Ltd. Keywords: crystal structure; polynuclear copper(II) complexes; tetracarboxylatobenzene bridged; magnetic properties.

Owing to its fundamental importance, the study of polynuclear complexes has been an active field of coordination chemistry in recent years [1]. Particular attention is now being paid to synthesis extended transition metal complexes with increasing dimensionally in order to provide efficient exchange pathways between metal ions. Different bridging ligand systems such as cyanide [2], oxalate [3] and oxalate-type ligands [4], end-to-end azide [5], croconate (4,5-dihydroxycyclopent-4-ene-1,2,3-trionate [6], 2,5-dihydroxy-1,4-benzoquinone and its derivatives [7], squa-

rate (3,4-dihydroxycyclobut-3-ene-1,2-dionate) [8], 4,4-bipyridine [9], terephthlate [13–19] have successfully been used to construct polymeric coordination compounds as chains or two or three dimensional infinite networks. Similar to the terephthlate anion, the tetracarboxylatobenzene anion appears to be an ideal ligand with which polynuclear copper(II) compounds are obtained [20], since four carboxyl group, eight O-donor atoms are available for coordination. Furthermore, carboxyl ligand has shown a good capable of bridging and providing exchange pathways when paramagnetic metals are involved. For example [21], they form binuclear or polynuclear complexes with transition metal ions via two oxygen atoms coordinating to two metal atoms, separately, forming a three-atom bridge or even via a single oxygen atom coordinating to two metals forming a one atom bridge.

Continuing our interest in the synthesis of terephthlate anion bridging polynuclear complexes [22], we report a novel three dimension net-work structure of polynuclear copper(II) complex $[(Cudien)_2(Cudien \cdot H_2O)TCB(ClO_4)_2 \cdot H_2O]_n$. To our knowledge, this is the first report about tetracarboxylatobenzene bridging three-dimension polynuclear copper(II) complex.

EXPERIMENTAL

Materials

Dien (3-azapentane-1,5-diamine), dipn (*N*-(3-aminopropyl)-1,3-propane-diamine) and copper(II) perchlorate hexahydrate were used as purchased. Piperidimium tetracarboxylatobenzene was prepared by the literature method [22]. Element analyses (C, H, N) were determined on a Perkin–Elmer 240C microanalysis instrument. IR absorption spectra, as KBr pellets, were recorded on a Nicolet FTIR 170X spectrophotometer. The EPR spectra were recorded on a Bruker ER 200D-SRC. Variable-temperature magnetic susceptibilities were determined on a CF-1 ESM magnetic balance (1.5–300 K) and a CAHN-2000 magnetic balance (75–300 K).

Preparation of $[(Cudien)_2(Cudien \cdot H_2O)TCB(ClO_4)_2 \cdot H_2O]_n$ (**1**)

A methanol solution (50 ml) of copper(II) perchlorate hexahydrate (1.48 g, 4 mmol) was slowly added to the same solution (10 cm^3) of dien (0.43 cm^3, 4 mmol) with stirring. Then the methanol solution (20 cm^3) of piperidimium tetracarboxylatobenzene (594 mg, 1 mmol) was added dropwise. The blue precipitate appeared very soon. The mixture was cooled under refluxing for 1 h, then filtered, washed with methanol and dried. The blue solid was redissolved in hot water (50 cm^3), filtered and the filtrate set aside for one month at room temperature, the blue single crystals were obtained. Calc. (Found) for $C_{22}H_{45}N_9O_{18}Cl_2Cu_3$, C, 26.56 (26.82); H, 4.76 (4.60); N, 12.80 (12.58); Cu, 19.35 (19.00). IR spectrum: 3347 cm^{-1} (s), 3317 (vs), 3248 (s), 3136 (s), 2972 (m), 2933 (s), 2874 (m), 1610 (vs), 1569 (sh), 1564 (vs), 1455 (m), 1409 (s), 1366 (s), 1140 (m), 1100 (vs), 1080 (vs), 1025 (s), 816 (m), 625 (m).

Preparation of $[(Cudipn \cdot H_2O)_2TCB] \cdot 8H_2O$ (**2**)

The same method was followed as for the preparation of the compound (**1**). The blue solid of compound (**2**) was obtained, then redissolved in water. A few days later, the blue crystals were obtained. Calc. (Found) for $C_{22}H_{56}N_6Cu_2O_{18}$: C, 32.03 (32.23), H, 6.62 (6.83), N, 9.62 (10.25). IR spectrum: 3459 cm^{-1} (s), 3378 (s), 3279 (vs), 3136 (s), 2939 (s), 2875 (s), 1690 (sh), 1611 (s), 1572 (vs), 1481 (m), 1412 (m), 1367 (vs), 1322 (s), 1136 (m), 1041 (m), 864 (m), 819 (m).

X-ray structure determination of $[(Cudien)_2(Cudien \cdot H_2O)TCB(ClO_4)_2 \cdot H_2O]_n$

A blue prism crystal with dimensions of $0.65 \times 0.35 \times 0.25$ mm was mounted on an Enraf–Nonius CAD4 diffractometer for data collection using graphite-monochromatic Mo-K_α radiation ($\lambda = 0.71069$ Å) at 296 K. 3445 reflections were collected, of which 3371 were independent and 2399 observed with $I > 3\sigma(I)$. Data were corrected for Lorentz and polarization effects and empirical absorption. The structure was solved by Patterson method, followed by Fourier syntheses and refined by full matrix least squares methods with anisotropic thermal parameters for all non-hydrogen atoms. During the refining, the atoms Cu(2), N(5) and O(5) lie on the C_2 axis, however, in order to reduce the R factor and the remaining peak, let the Cu(2) and N(5) atoms deviate a little from the special site (0, y, 1/4). All hydrogen atoms were found from the difference Fourier map and were refined with isotropic thermal parameters. All calculations were performed on MICRO VAX3100 computer using the MSC TEXSAN V.2.1 programs. The final R value is 0.049 and refinement with the complete data set yielded $\omega R = 0.061$. The crystallographic data are summarized in Table 1.

RESULTS AND DISCUSSION

Crystal structure

Selected bond lengths and angles are shown in Table 2. Figure 1 presents the structure of the cation $[(Cudien)_2(Cudien \cdot H_2O)TCB]^{2+}$ with the atomic-numbering scheme. The unit possesses a center symmetry. Four carboxyl groups of the tetracarboxylatobenzene (TCB^{4-}) anion coordinated to six copper(II) ions with

two kinds of coordination environment. Two copper(II) ions Cu(2), Cu(2c) have octahedral geometry, of which the equatorial plane consisted of N(4), N(5) and N(4a) from dien and oxygen atom O(5) of the water molecular and the apical positions are occupied by two oxygen atoms O(1) and O(1b) from the carboxyl groups of two TCB^{4-} anions in monodentate fashion, which forms a linear chain. Each of other four copper(II) ions Cu(1), Cu(1c), Cu(1d) and Cu(1e) are located in a square pyramidal environment, as for the Cu(1), the basal plane consists of N(1), N(2) and N(3) of dien and O(3) from carboxyl group of TCB^{4-} anion, the axial is occupied by O(4a) from the carboxyl group of TCB^{4-} anion located on the next layer below the 2-D network plane. All these form a three dimension structure. The coordination environments of these copper atoms are analogous to those in compound (**2**). The molecular structure of the complex $[(Cudipn\cdot H_2O)_2TCB]\cdot 8H_2O$ [22] had been reported (Fig. 2). In the complex (**2**), two copper atoms locate in a square pyramidal environment. The basal plane consists of three nitrogen atoms of dipn and oxygen atom of carboxyl group of TCB^{4-} anion, but the axial

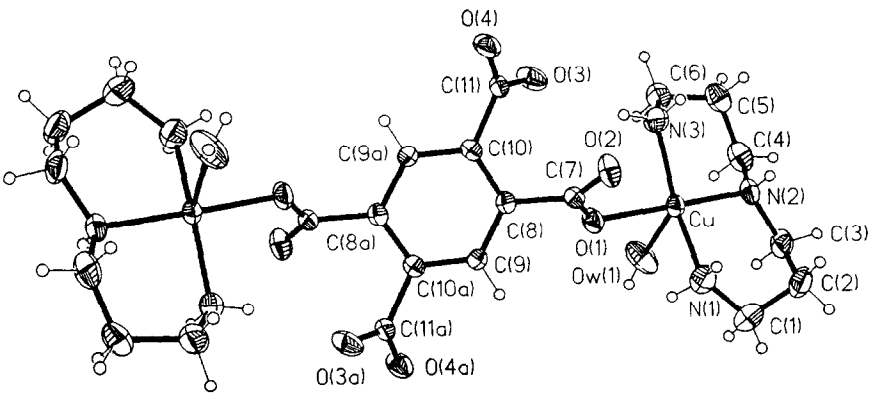

Fig. 2. The molecular structure of the complex $[(Cudipn \cdot H_2O)_2TCB] \cdot 8H_2O$.

position is occupied by the oxygen atom of water molecule. In the complex (**1**), the bond angles of O(4a)—Cu(1)—N(1), O(4a)—Cu(1)—N(2), O(4a)—Cu(1)—N(3) and O(4a)—Cu(1)—O(3) are 88.4 (2)°, 100.4 (2)°, 84.2 (2)° and 98.1 (1)°, respectively. The Cu(1) atom deviates 0.0139 Å from the least square plane consisting of O(3)N(1)N(2)N(3). But in the complex (**2**), the Cu atom lies in the square plane very well, which consists of four atoms: O(1), N(1), N(2) and N(3). It is possible that dipn is more flexible than dien, which produces two quite different results: the complex (**1**) has an infinite structure and the complex (**2**) has a binuclear structure with molecularity.

Four carboxyl groups of TCB^{4-} are divided into two kinds by different coordination modes in complex (**1**). Two *para*-carboxyl groups C(14)O(1)O(2) coordinate to Cu(2) with one oxygen atom O(1) in monodentate fashion. The distance of Cu(2)—O(1) is 2.350(5) Å, which is longer than that of the normal Cu—O (carboxylate) (1.927–2.010 Å) [24]. The distance between the two copper ions Cu(2) and Cu(2c) which were bridged by TCB unit is 10.949(2) Å which is shorter than that in complex (2) (11.194 Å). The other two *para*-carboxyl groups C(15)O(3)O(4) are bound to the Cu(1) and Cu(1d) in a bridging bidentate fashion with a short bond Cu(1)—O(3) (1.957(3) Å) and a long bond Cu(1d)—O(4) (2.407(4) Å). The distance between Cu(1) and Cu(1d) atoms is 4.230(1) Å, this value is the shortest intramolecular distance in complex (**1**).

A carboxylate ion can coordinate to a metal atom in a number of ways [25]. Up to date, five coordination types of carboxyl group have been found, as shown in

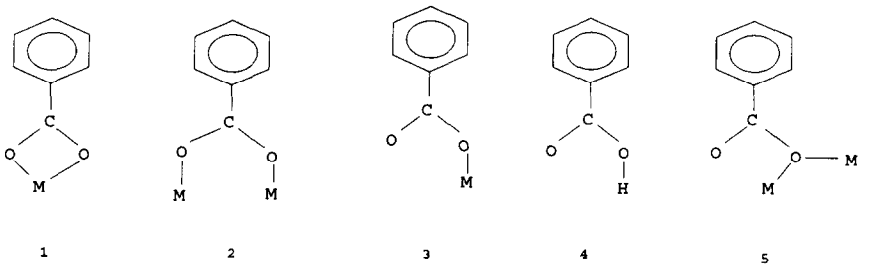

Fig. 3. The coordinating fashion of carboxyl group.

Fig. 3. Their coordination fashions are different: (1) as a bidentate ligand to coordinate with one metal ion; (2) as a bidentate ligand to bridge two metal centers; (3) as a monodentate ligand to bind a metal ion; (4) free COO^- group forming a hydrogen bond with crystal water or coordination water; and (5) as a monoatomic bridge, binding two metal ions. The coordination models of (3) and (4) are present in some carboxyl complexes [13–18]. The mode (5) appears in a few examples [26]. Usually, if the carboxyl group coordinated with mode (2), a layered or three dimensional structure could be formed, such as in a layered structure manganese(II) mellitate $[Mn_2(C_6(COO)_6(H_2O)_6]\,[Mn(H_2O)_6]\cdot 2H_2O]$ [25], the carboxyl groups coordinated to manganese(II) with the model (2). In the complex (**1**), the four carboxyl groups exist in two modes: (2) and (3), a 3-D network structure is obtained. But the other coordinating modes often form molecular complexes. Two *para*-carboxyl groups acted as the model (3) and the other two carboxyl groups are free COO^- (as the model (4)) in the complex (**2**) [22], the complex is a TCB bridging molecular complex.

The crystal packing diagram of the complex $[(Cudien)_2(Cudien\cdot H_2O)\ TCB(ClO_4)_2\cdot H_2O]_n$ is shown in Fig. 4. The noncoordinated perchlorate anions (ClO_4^-) and water molecules fill in the space of an infinite three-dimensional network structure. There are three linear chains in the crystal, one along the diagonal of the cell unit, Cu(2) ions are linked together through the TCB^{4-} unit, in which the carboxyl groups act as in mode (3). The other one along the *c* axis, the carboxyl groups act as the mode (2). Along the *b* axis through the crystal lattice, there is a zigzag chain, in which Cu(1) ions are linked together by carboxyl groups acting as mode (2) from the adjacent layer.

There are six copper atoms around the TCB^{4-} ion and each copper(II) atom is coordinated by the two adjacent TCB^{4-} unit, so, there are three copper(II) ions in each unit.

IR spectrum

The strong broad band at 1569 cm^{-1}, 1564 cm^{-1} and 1366 cm^{-1} for the $\nu_{as}(COO)$ and $\nu_s(COO)$ stretching modes of carboxyl group and ν_s–ν_{as}: 203 cm^{-1} and 198 cm^{-1} respectively in complex (**1**) suggest that there exist two kinds of coordination mode for all carboxyl groups of the TCB^{4-} ligand: an amphimonodentate (end to end) and an anisobidentate (*syn-anti*) coordination models [27] which is proved by the X-ray crystal structure analysis. But for complex (**2**), the shoulder peak at 1690 cm^{-1} belongs to the stretching vibration of the carboxyl free group COO^-. The strong broad bands at 1572, 1367 cm^{-1} are the $\nu_{as}(COO)$ and $\nu_s(COO)$ stretching modes of the monodentate coordinating carboxyl group of TCB [28]. This structure has been proved in our previous work [22].

EPR and magnetic properties

The EPR spectra recorded at room temperature show an isotropic spectrum with $g_{av} = 2.11$ for compound (**1**) and $g_\perp = 2.056$ for compound (**2**). In both the complexes, the half-field peaks are not found which means that the exchange interaction between copper(II) atoms in two compounds are very weak. Variable temperature (1.5–300 K) magnetic susceptibility data were collected for a crystal sample of the complex (**1**). The temperature dependence of the reciprocal magnetic susceptibility $1/\chi_M$ is a linear relationship in the range of 6–300 K with the Weiss constant $\theta = -1.5$, suggesting a very weak antiferromagnetic interaction. In compound (**1**) there are two possible exchange pathways: (i) through the extended terephthalate in two linear chains: along the *c* axis and diagonal of the cell unit with the metal–metal separation 10.949(2) Å. According to the relation proposed by Coffmann and Buetter [30], the separation between the magnetic centers in the range 10–11 Å corresponds to the smallest $|J|$ value of about 0.1 cm^{-1} so the magnetic interactions at these two linear chains could be neglected. (ii) Through the bidentate carboxyl group with the *syn-anti* configuration in the zigzag chain along the *b* axis, the metal–metal separation is 4.230(1) Å which could be responsible for a weak antiferromagentic exchange of the compound (**1**). It is quite similar with the bidentate carboxylate bridged polymeric complex $[Cu(NH_3)_2](CH_3COO)_2]$ ($J/k = -4.3$ K) [27]. This exchange interaction involving overlap between the

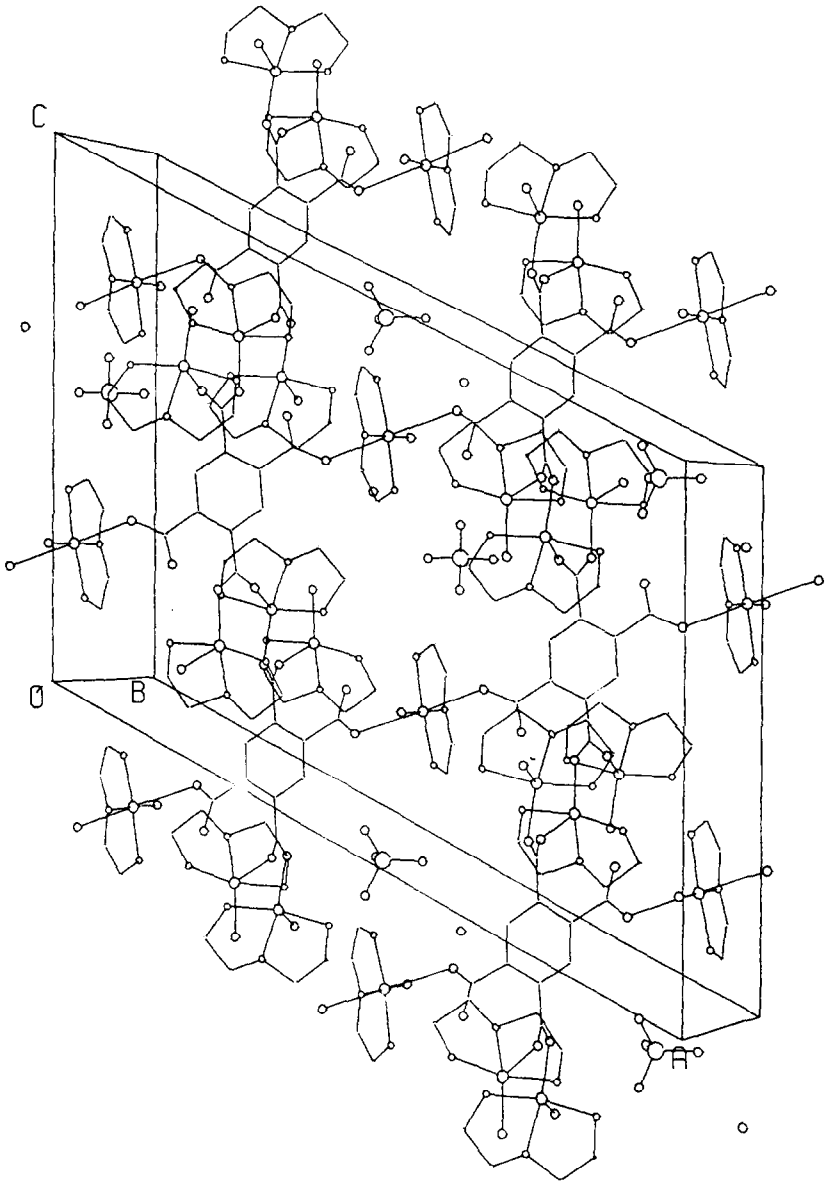

Fig. 4. The crystal packing diagram of the complex $[(Cudien)_2(Cudien \cdot H_2O)TCB(ClO_4)_2 \cdot H_2O]_n$.

two magnetic orbitals of $d_{x^2-y^2}$-type through *syn-anti* carboxyl bridge is very weak.

The thermal dependence of the molar magnetic susceptibility χ_M of complex (**2**) is characterized to an antiferromagnetic interaction between the two copper ions. The susceptibility of the compound was successfully analyzed in the terms of an isotropic exchange interaction for a binuclear species with $H = -JS_1S_2$ and $S_1 = S_2 = 1/2$. The least square analysis for compound (**2**) yields $J = -9.03\ cm^{-1}$ and $g = 2.17$ with $R = 1.81 \times 10^{-4}$ (R is the agreement factor defined as $\Sigma(X_m^{obsd} - X_m^{calc})^2/\Sigma(X_m^{obsd})^2$. The best fit curve is shown in Fig. 5. The J value is much larger than that proposed by Coffmann and Buetter (0.1 cm^{-1}) [30] and shows that the possible magnetic inter-

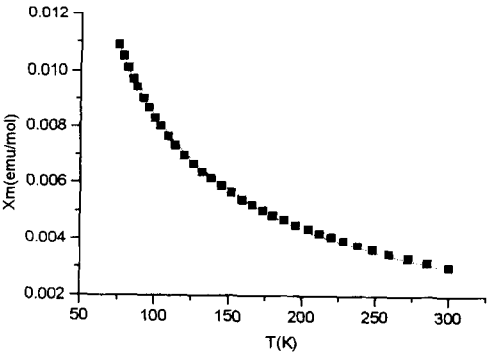

Fig. 5. The best fit curve of the magnetic behavior of the complex (**2**) in the form of χ_M (experiment value: ■ ■ ■; theory value: —) vs T plot.

action pathways of two magnetic centers in complex (**2**) could not go through the TCB^{4-} anion. According to other analogous complexes [19], the intermolecule interaction may be responsible for the magnetic behavior.

The conclusion can be drawn from the two TCB bridged Cu(II) complexes. TCB^{4-} anion has four carboxyl groups which can coordinate with metal atoms in a number of ways, therefore the TCB^{4-} anion is an ideal ligand to synthesize the new structure polynuclear complex. We used two analogous copper complexes Cudien$(ClO_4)_2$ and Cudipn$(ClO_4)_2$ to react with TCB piperidimium salt and two quite different structure complexes were obtained. One is a new three-dimensional infinite structure polynuclear copper complex $[(Cudien)_2(Cudien \cdot H_2O)TCB(ClO_4)_2 \cdot H_2O]_n$ and the other is a binuclear copper complex $[(Cudipn \cdot H_2O)_2\ TCB] \cdot 8H_2O$ with molecularity. The magnetic interaction is very weak, because of the longer distance between two magnetic centers.

(Received 16 October 1997; accepted 10 December 1997)

Abstract—Condensation of *m*-$C_6H_4(SCl)_2$ with $Me_3SiNSNSiMe_3$ in a 1:2 mole ratio produced quantitatively the difunctional chain *m*-$C_6H_4(SNSNSiMe_3)_2$ (**I**) which could be capped with ArSCl [Ar = *p*-$O_2NC_6H_4$, *o*-$O_2NC_6H_4$ and *o,p*-$(O_2N)_2C_6H_3$] to yield the bis(trithiadiazene) chains *m*-$C_6H_4(SNSNSAr)_2$ (**II**–**IV** respectively) or condensed with a further equivalent of *m*-$C_6H_4(SCl)_2$ to give the polymer [*m*-$C_6H_4SNSNS]_n$ (**V**). © 1998 Elsevier Science Ltd. Keywords: thiazyl; sulfur-nitrogen; polymer.

We have recently become interested [1] in the preparation of novel materials in which redox-active functional groups are linked via a π-delocalised backbone which will facilitate through-bond communication between redox active centres. Our synthetic strategy [1] has been to utilise small fragments of conducting poly(sulfurnitride) [2] to provide the delocalised π-framework. As a first step in this research programme we have examined the possibility of forming oligo-functional thiazyl chains, in which two (or more) sulfur-nitrogen chains are linked together through a phenylene spacer unit [3].

Synthetic strategies for the preparation of simple thiazyl chains with up to nine heteroatoms in the chain, e.g. ArS_5N_4Ar, have been developed by a number of research groups [1]. However, the exploitation of these methodologies to yield oligo-functional materials (Scheme 1) has not been fully investigated. Previously, Rees and co-workers have shown [4] that ring closure is the preferred reaction for the condensation of *ortho*-$C_6H_4(SCl)_2$ with $Me_3SiNSNSiMe_3$ (Scheme 1). However, the analogous reaction of *para*-$C_6H_4(SCl)_2$ with $Me_3SiNSNSiMe_3$ has been shown to yield a mixture of difunctional and polymeric material dependent on the reaction conditions [5,6]. Herein we report the high yielding syntheses of a series of difunctional thiazyl chains derived from *meta*-dimercaptobenzene.

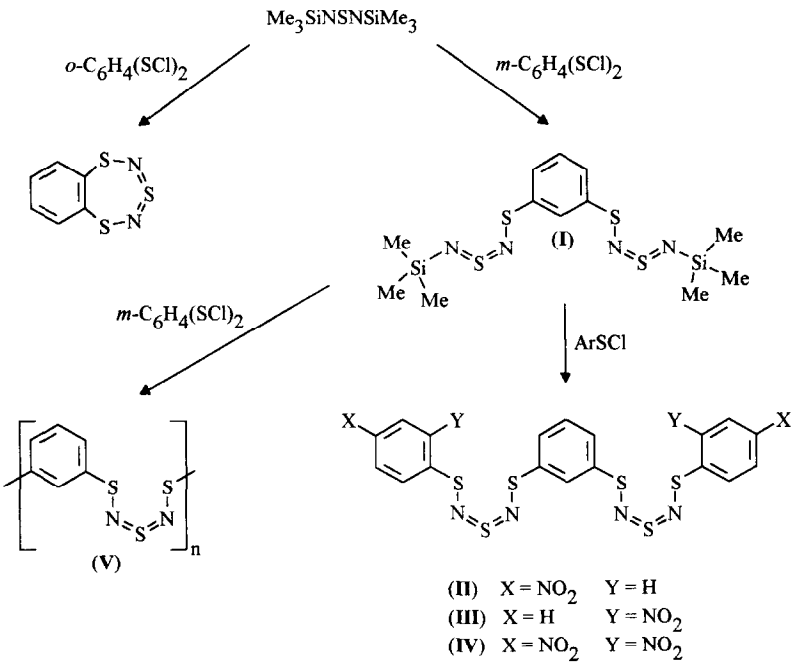
RESULTS AND DISCUSSION

Dropwise addition of *m*-$C_6H_4(SCl)_2$ [prepared by chlorination of *m*-$C_6H_4(SH)_2$ with SO_2Cl_2] to $Me_3SiNSNSiMe_3$ in a 1:2 mole ratio at ambient temperature yielded the difunctional thiazyl chain, *m*-$C_6H_4(SNSNSiMe_3)_2$ (**I**). Spectroscopic studies on the reaction mixture indicated that **I** was prepared quantitatively and there was no evidence for either the ring-closure or the potential polymer-forming reactions (*vide infra*) which might have been anticipated. Evaporation of the reaction mixture yielded crude **I** which was typically contaminated with traces of Me_3SiCl. Analytically pure **I** could be recovered in *ca* 70% yield by recrystallisation from hexane and was characterised by ^1H and ^{13}C NMR and microanalytical data. The ^1H NMR (Fig. 1) consists of a multiplet in the aromatic region and a singlet ($\delta = +0.35$) for the $SiMe_3$ functional group in the relative ratio 2:9. The ^{13}C NMR spectrum exhibits a single resonance ($\delta = 1.8$) for the trimethylsilyl C and four magnetically distinct aromatic C nuclei (in the region $\delta = +121$ to $+139$) of which the $\delta = +139$ resonance



Scheme 1. Condensation pathways between dimercaptobenzenes and bis(trimethylsilyl)sulfurdiimide.

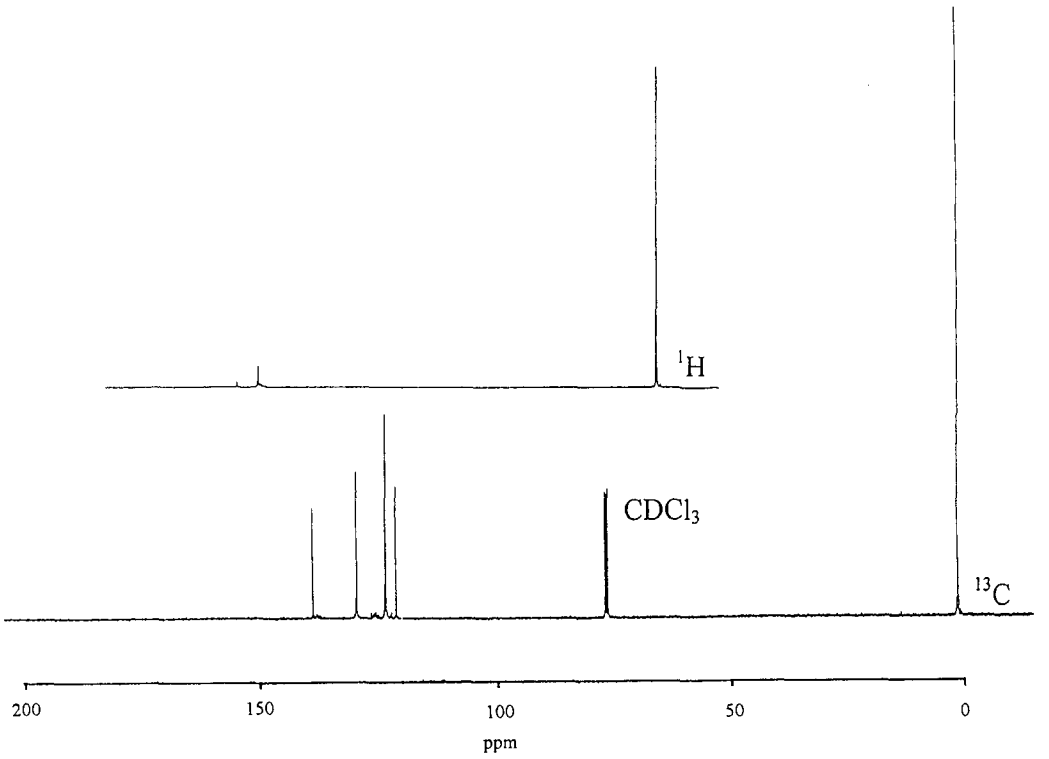


Fig. 1. ^{13}C and ^{1}H (inset) NMR spectra of **I**.

was unambiguously assigned (by APT) as the S-bonded C. The UV–vis spectrum of **I** in $CHCl_3$ exhibited an absorption maxima at 387 nm ($\varepsilon = 2.6 \times 10^4$ mol dm^{-3} cm^{-1}) (Fig. 2) which we attribute to the dithiadiazene chromophore [1]. **I** was found to be soluble in a wide range of solvents including toluene,

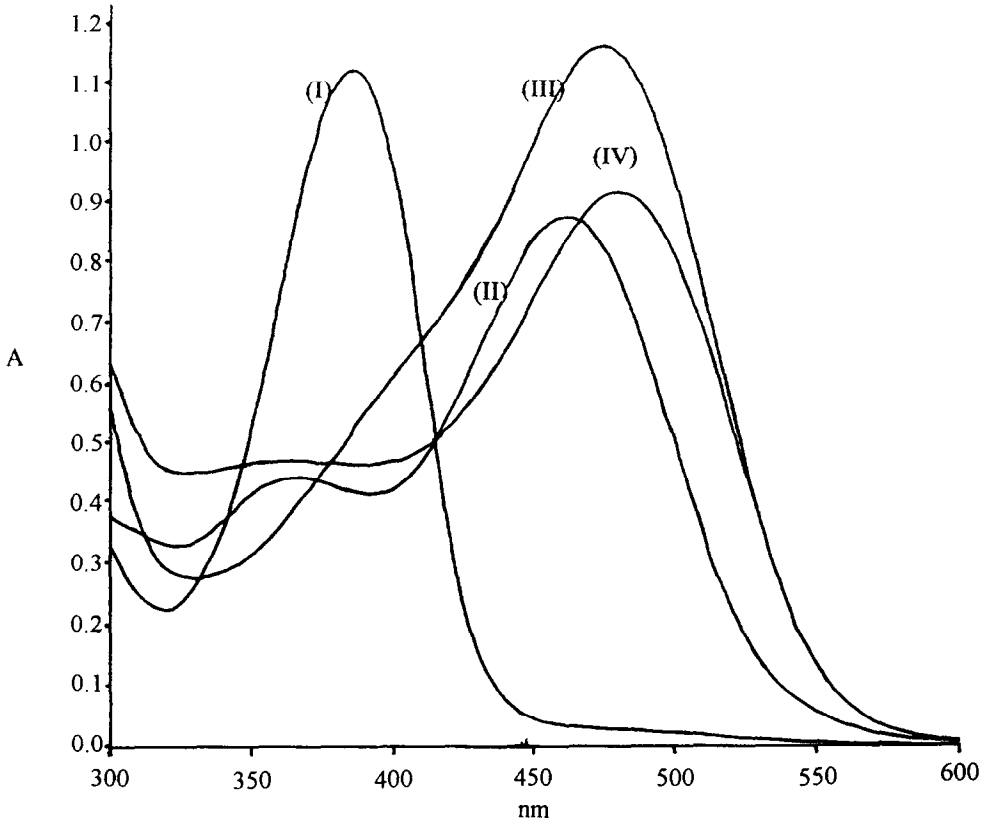

Fig. 2. UV–visible spectra of compounds **I–IV**.

dichloromethane, chloroform and diethyl ether. It is sparingly soluble in hexane.

The quantitative formation of **I**, in preference to polymer-formation, indicated that the trimethylsilyl groups on **I** are significantly less reactive towards *m*-$C_6H_4(SCl)_2$ than those on the sulfurdiimide, Me_3Si NSNSiMe_3. This is in agreement with a report by Kuyper and Street [7] who found that the rate of condensation of the first trimethylsilyl group on Me_3Si-NSNSiMe_3 was significantly greater than the second and this facilitated the isolation of mono-substituted compounds. Nevertheless, the trimethylsilyl groups on **I** are sufficiently reactive to allow **I** to be a useful intermediate for the preparation of longer thiazyl chains. We have found that chain-capping can be achieved via condensation with two equivalents of ArSCl to form the new difunctional chains, *m*-$C_6H_4(SNSNSAr)_2$ [Ar = *p*-$O_2NC_6H_4$ (**II**), *o*-$O_2NC_6H_4$ (**III**) or *o*,*p*-$(O_2N)_2C_6H_3$ (**IV**)] in quantitative yield (by NMR), with recovered yields typically in the range 86–89%. The solubilities of compounds **II–IV** were found to be considerably less than those observed for **I**, although they provided sufficient solubility in chloroform for spectroscopic characterisation. Compounds **II–IV** were characterised by multinuclear NMR and microanalysis. Solution UV–visible studies on compounds **II–IV** exhibited broad absorption maxima (462, 475 and 481 nm respectively, $\varepsilon = 1.3$ to 3.2×10^4 mol dm^{-3} cm^{-1}) "red-shifted" in comparison to **I** (Fig. 2). This "red-shift" is associated with the increased delocalisation, and the absorption maxima for compounds **II–IV** are typical of those observed for simple monofunctional trithiadiazene chains [1]. In addition the relative positions of the three absorption maxima for **II–IV** are entirely consistent with previous observations [1] in which the *ortho*-nitro group produces a shift to higher wavelength of some 15–20 nm, in comparison to the related *para*-nitro substituents.

In Scheme 1, compounds **I–IV** have been represented in the conformations observed for the related crystallographically characterised monofunctional thiazyl chains [1]. However, a variety of geometric isomers are possible for these compounds and the energetic differences between different conformations is small (25–30 kJ mol^{-1}) [8]. This may account for the lack of crystallinity in these difunctional systems. Our attempts to prepare suitable crystals of **I–IV** for X-ray diffraction studies, by slow evaporation, solvent diffusion and cooling saturated solutions, were unsuccessful and produced only microcrystalline precipitates. Attempted vacuum sublimation led only to decomposition at elevated temperatures.

Whereas the longer thiazyl chain compounds exhi-

bit a tendancy to decompose to shorter thiazyl chains via extrusion [1] of S_4N_4, the shorter chains do not undergo similar reactions, although scrambling of thiazyl chains has been reported [9] in the presence of sodium or potassium. In our studies, we have seen no indication of the formation of S_4N_4 by spectroscopic techniques (IR, *m/e*). Furthermore, the effect of the thiazyl-chain on the ^{13}C chemical shift of the aromatic C atoms is sufficiently large that compounds of differing chain-lengths can be clearly identified by ^{13}C NMR and we have seen no indication of chain-scrambling or S_4N_4 extrusion.

Although condensation of *m*-$C_6H_4(SCl)_2$ with $Me_3SiNSNSiMe_3$ in a 1 : 2 mole ratio yielded exclusively **I**, condensation of **I** with a further equivalent of *m*-$C_6H_4(SCl)_2$ at room temperature yielded an insoluble red material of composition $(C_6H_4S_3N_2)_n$ which was characterised as the polymer $(m\text{-}C_6H_4S_3N_2)_n$ (**V**) on the basis of microanalytical data. The analogous polymer $(p\text{-}C_6H_4S_3N_2)_n$, which is also red in colour, has been previously isolated [6] from the reaction of *p*-$C_6H_4(SCl)_2$ with $Me_3SiNSNSiMe_3$.

CONCLUSIONS

This work highlights the use of oligo-functional thiols as suitable precursors for the controlled syntheses of multifunctional thiazyl chains. We are now exploiting similar methodologies to prepare new di- and tri-functional derivatives which possess multiple metal-binding sites and redox-active centres.

EXPERIMENTAL

General procedures

All reactions and manipulations were carried out under an atmosphere of dry nitrogen, using standard double-manifold techniques and a glove box (Saffron Scientific Instruments). Solvents were distilled prior to use. C, H, and N analyses were carried out using an Exeter CE-440 elemental analyser. NMR data was collected on Bruker AM-400 and AC/DPX-250 Fourier transform NMR spectrometers. UV–visible spectra were recorded on a Perkin–Elmer lambda-12 UV–visible spectrophotometer. *m*-dimercaptobenzene (Aldrich) and SO_2Cl_2 (BDH) were used without further purification. $Me_3SiNSNSiMe_3$ was prepared according to the literature method [10].

Synthesis of *m*-$C_6H_4(SNSNSiMe_3)_2$ (**I**). *m*-$C_6H_4(SH)_2$ (1.000 g, 7.03 mmol) in CH_2Cl_2 (20 ml) was added dropwise to a stirred solution of SO_2Cl_2 (3.795 g, 2.3 ml, 28mmol) in CH_2Cl_2 (5 ml) at room temperature. The yellow solution was then refluxed for 1 h, cooled to room temperature and the solvent and excess SO_2Cl_2 removed *in vacuo*, yielding a red oil, *m*-$C_6H_4(SCl)_2$. The oil was redissolved in CH_2Cl_2 (20 ml) and added dropwise to a stirred solution of $Me_3SiNSNSiMe_3$ (2.90 g, 3.4 ml, 14 mmol) in CH_2Cl_2 (5 ml) at room temperature to yield a dark red solution of **I**. After 12 h, the CH_2Cl_2 was removed *in vacuo* yielding crude *m*-$C_6H_4(SNSNSiMe_3)_2$ (**I**) as a pale red solid which was recrystallised (1.9940 g, 70%) from hexane. (Found: C, 35.1; H, 5.2; N, 13.4. Calc.: C, 35.4; H, 5.4; N, 13.8%). ^1H NMR ($CDCl_3$, 250 MHz): δ 0.32, 7.35–7.38, 7.75. ^{13}C NMR ($CDCl_3$, 400 MHz): δ 1.75, 121.3, 123.5, 130.0, 138.9. UV–Visible ($CHCl_3$) λ_{max}/nm 387 ($\varepsilon = 2.6 \times 10^4$ mol dm^{-3} cm^{-1}).

Syntheses of *m*-$C_6H_4(SNSNSAr)_2$ (**II–IV**). A solution of **I** (0.500 g, 1.23 mmol) in CH_2Cl_2 (20 ml) was added dropwise to a stirred solution of ArSCl (2.46 mmol) in CH_2Cl_2 (10 ml) at room temperature, resulting in a dark red solution which was stirred for a further 2 h, prior to removal of solvent *in vacuo*. The crude red solid, *m*-$C_6H_4(SNSNSAr)_2$, was washed with hexane (4 × 5 ml) and dried *in vacuo*. Compound **II**, [Ar = *p*-$O_2NC_6H_4$]: Yield: 0.6140 g, 88%. (Found: C, 38.3; H, 2.3; N, 14.5. Calc.: C, 38.0; H, 2.1; 14.8%). ^1H NMR ($CDCl_3$, 250 MHz): δ 7.31–7.64, 7.81, 7.82, 8.16–8.40. ^{13}C NMR ($CDCl_3$, 400 MHz): δ 122.6, 122.8, 124.5, 124.6, 126.4, 128.7, 137.1, 144.1. UV–Visible ($CHCl_3$) λ_{max}/nm 462 ($\varepsilon = 3.2 \times 10^4$ mol dm^{-3} cm^{-1}). Compound **III**, [Ar = *o*-$O_2NC_6H_4$]: Yield: 0.6220 g, 89%. (Found: C, 38.2; H, 2.1; N, 14.6. Calc.: C, 38.0; H, 2.1; 14.8%). ^1H NMR ($CDCl_3$, 250 MHz): δ 7.31–7.44, 7.67–7.78, 8.03–8.06, 8.14–8.17, 8.33–8.37. ^{13}C NMR ($CDCl_3$, 400 MHz): δ 122.9, 125.1, 125.3, 125.5, 125.8, 126.1, 126.4, 129.9, 134.5, 139.7, 140.8, 141.2. UV–Visible ($CHCl_3$) λ_{max}/nm 475 ($\varepsilon = 2.1 \times 10^4$ mol dm^{-3} cm^{-1}). Compound **IV**, [Ar = *o,p*-$(O_2N)_2C_6H_3$]: Yield: 0.7560g, 86%. (Found: C, 32.8; H, 1.8; N, 17.2. Calc.: C, 32.8; H, 1.5; N, 17.0%). ^1H NMR ($CDCl_3$, 250 MHz): δ 7.31–7.53, 7.68–7.71, 8.20–8.31, 8.48–8.60, 9.15–9.18. UV–Visible ($CHCl_3$) λ_{max}/nm 481 (δ— = 1.8×10^4 mol dm^{-3} cm^{-1}).

Synthesis of $(m\text{-}C_6H_4S_3N_2)_n$ (**V**). A solution of **I** (0.400 g, 0.98 mmol) and *m*-$C_6H_4(SCl)_2$ [prepared as for **I**, from *m*-$C_6H_4(SH)_2$ (0.140 g, 0.98 mmol)] each dissolved in CH_2Cl_2 (25 ml) were simultaneously added dropwise to a stirred reservoir of CH_2Cl_2 (100 ml) over the course of 3 h, yielding a red precipitate. The solution was stirred for a further 1 h and the solid collected by filtration, washing with CH_2Cl_2 (3 × 10 ml) and dried *in vacuo* yielding a red solid of composition $(m\text{-}C_6H_4S_3N_2)_n$ (**V**), (0.1390 g, 35%) which was insoluble in common organic solvents. (Found: C, 35.6; H, 2.3; N, 13.8; Calc.: C, 36.0; H, 2.0; N, 14.0). The filtrate contained a mixture of several uncharacterised soluble products.

Abstract—The title compound has been separated in ca 13% yield from the reaction of *closo*-$[B_{10}H_{10}]^{2-}$, $[(PPh_3)_3RuCl_2]$ and C_6H_5COSH in CH_2Cl_2 solution, and characterized by elemental analysis, infrared spectroscopy, ^1H NMR and ^{31}P NMR spectroscopy and single-crystal X-ray diffraction analysis. The molecular structure is based on an eleven-vertex *closo*-type C_{2v} $\{RuB_{10}\}$ cluster-geometry with the ruthenium atom occupying the unique six-connected apical position. The metal center has three exopolyhedral ligands, one triphenylphosphine and two dative thiobenzoate sulfur atoms. The carbonyl oxygen atoms of two thiobenzoxy are additionally bonded to B2 and B3 atoms respectively, resulting in two exocyclic five-membered Ru—S—C—O—B rings. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: synthesis; molecular structure; metallaborane; ruthenaborane; exopolyhedral cyclic; *closo*-type $\{RuB_{10}\}$.

The exopolyhedral heterocyclic metallaborane and metallacarborane compounds with metal-to-cluster linkages have been the interesting subjects recently. Previous work in this area has been confined to four types of linkage. The *ortho*-cycloboronation processes that lead to the formation of the metal-to-boron *ortho*-P-phenyl linkage have been extensively studied in metallaborane chemistry [1–7]. Most of the known *exo*-cyclic metallaborane compounds which exhibited exopolyhedral metal-to-boron acetate linkage were generally obtained by the reactions in the presence of acetic acid [8–9], but the first example of metallacarborane compound with an acetate linkage on a *closo* ten-vertex $\{IrCB_8H_7\}$ system obtained in an obscure reaction process [4]. A series of compounds which exhibit a metal-to-boron dithioformate linkage have been obtained by the reactions between CS_2 and related metallaheteroborane or metallaborane species under reflux conditions [10–15]. The exopolyhedral heterocyclic platinaundecaborane [7-(PMe_2Ph)-2,7-$(\mu$-$S_2CNEt_2)$-*nido*-7-$PtB_{10}H_{11}$] with an exopolyhedral metal-to-boron *N*,*N*-diethyldithio-carbamate linkage is obtained from the reaction of [7,7-(PMe_2Ph)-*nido*-7-$PtB_{10}H_{12}$] with $[AuBr_2(S_2CNEt_2)]$ [16]. All of these facts indicate that the cyclic exopolyhedral metal-to-cluster linkage in polyhedral metallaborane and metallacarborane compounds may be formed in a quite different way. We are interested in the synthesis of exopolyhedral cyclic metallaborane by the reaction of $MCl_2(PPh_3)_x$ (M = Ru, Ni and Pt; $x = 2$ or 3) with $B_{10}H_{10}^{2-}$ in the presence of carboxylic and thiocarboxylic acid in refluxing CH_2Cl_2 solution. We have reported a series of stable metallaboranes containing from one to three five-membered rings [17–20]. Here we report the synthesis and structure of an exopolyhedral cyclic *closo*-$\{RuB_{10}\}$ cluster compound with two five-membered Ru—S—C—O—B rings.

EXPERIMENTAL

The starting compounds $[(PPh_3)_3RuCl_2]$ [21], $[NEt_4]_2[B_{10}H_{10}]$ [22] and C_6H_5COSH [23] were prepared by previously published methods. Dichloromethane, n-pentane and petroleum ether (b.p. 60–

* Author to whom correspondence should be addressed.

90°C) were purified by repeated distillation. Reactions were carried out under dry nitrogen in oxygen-free solvent, but subsequent manipulation and separation were carried out in air. Chromatography was carried out by preparative thin-layer using Kieselgel 60G (Merck) on plates of dimension 20 cm × 20 cm × ca 1mm, made in the laboratory as required.

Synthesis of compound **1**

$[(PPh_3)_3RuCl_2]$ (0.38 g, 0.4 mmol), $[NEt_4]_2[B_{10}H_{10}]$ (0.15 g, 0.4 mmol) and C_6H_5COSH (0.11 g, 0.8 mmol) were stirred together in a refluxing CH_2Cl_2 (70 cm^3) solution under dry nitrogen for 112.5 h. The resulting bright-red solution was reduced (rotary evaporator, 30°C, water pump) to ca 5 cm^3, and chromatographed (t.l.c.) using CH_2Cl_2-light petroleum (b.p. 60–90°C) (5:3) as eluant to give an orange-red compound at $Rf = 0.81$, in ca 13% yield. The product was recrystallized from CH_2Cl_2/*n*-pentane to give air-stable orange-red crystals. Found: C, 48.71; H, 4.30; S, 7.31. $C_{33}H_{35}RuPB_{10}S_2O_2Cl_2$ requires C, 47.25; H, 4.21; S, 7.65%. FTIR(cm^{-1}): 3050 (w), 2516 (vs), 2461 (s), 1786 (w), 1762 (m), 1733 (m), 1685 (vs), 1640 (vs), 1505 (vs), 1453 (s), 1419 (m), 1334 (m), 1303 (s), 1230 (vs), 1164 (m), 1095 (vs), 1025 (w), 974 (s), 763 (m), 731 (s), 680 (s), 554 (w). ^1H NMR ($CDCl_3$): δ ppm 0.87 (q, 2H, BH), δ ppm 1.28 (t, 4H, BH), δ ppm 1.58 (s, 2H, BH), δ ppm 6.81–8.39 (25H, Ph); ^{31}P NMR ($CDCl_3$) δ 21.868 ppm.

Physical measurements

Elemental analyses were performed on a Carlo Erba 1106 elemental analyser.

IR spectra of the complex in the range 400–4000 cm^{-1} as KBr pellets was measured on a NICOLET 5SXC-FTIR spectrometer.

^1H NMR spectra was collected on a BRUCKER spectrometer and using TMS as the internal reference. ^{31}P NMR spectra was collected on a DRX400 spectrometer and using 85% H_3PO_4 as the external reference.

X-ray crystallography

A crystal with dimensions of 0.30 × 0.30 × 0.27 mm was mounted on an Enraf-Nonius CAD4 diffractometer. Unit cell parameters were determined by a least-squares refinement of 25 reflections with $20.8° < 2\theta < 26.4°$ and the data were collected using graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) with $\omega/2\theta$ scan mode ($0 \leqslant 2\theta \leqslant 50$) at 21 ± 1°C. The structure was determined by Direct methods (MULTAN-82). All non-hydrogen atoms were located successfully and all hydrogen atoms were treated as riding on their attached atoms. The refinement of positional and anisotropic thermal parameters was carried out by full-matrix least-squares method. All calculations were carried out on a Micro VAX-II computer with SDP-*Plus* software package. Experimental data are summarized in Table 1.

RESULTS AND DISCUSSION

In addition to the strong B—H stretch bonds [24,25] at 2516 and 2461 cm^{-1}, the infrared spectra of the compound also exhibits a strong absorption at 1095 cm^{-1} due to PPh_3 aromatic vibration involving some P—C stretching, which has a slight shift than the reported data of PPh_3 (1090 cm^{-1}) [26,27]. Three strong absorption bands at 1685, 1230, and 963 cm^{-1} which are assigned to ν(C—O), ν(C—phenyl) and ν(C—S) of thiobenzoxy ligands respectively, are in correspondence with the reported data (1690, 1210, 950 cm^{-1}) [28,29]. We can deduce that compound **1** contains both PPh_3 and thiobenzoxy as ligands.

A drawing of the molecular structure of compound **1** is shown in Fig. 1. The selected bond lengths and bond angles are listed in Table 2 and Table 3 respectively. Both X-ray diffraction analysis and ^1H NMR spectrum have showed that the cluster has an eleven-vertex cluster structure of idealized C_{2v} symmetry. The borane-to-metal bonding mode is boat-hexaphto. The ruthenium center has three exopolyhedral ligands, one triphenylphosphine and two dative S atoms of thiobenzoxy groups. The exopolyhedral ruthenium-bound ligand phosphorus atom is almost in the reflection plane which bisects the two B4—B5 and B6—B7 vectors. The two thiobenzoxy groups behave as bridging ligands between the ruthenium center and two prow boron atoms, in which their two sulfur atoms coordinate to Ru1 and two carbonyl oxygen atoms are bound to B2 and B3 respectively. This results in two nearly symmetric exopolyhedral five-membered Ru—S—C—O—B rings. From Table 2, the interatomic distance of Ru—B and B—B within the $\{RuB_{10}\}$ cage are similar to those observed in reported 11-vertex *closo*-ruthenaundecaborane clusters as shown in literatures 8 and 30–32. The average values of interatomic distances of C7—O1 and C14—O2 is 1.311 Å, which are between those of C—O single-bond (1.43 Å) and C=O double-bond (1.22 Å). This fact indicates that the carbon–oxygen bonds of two thiocarboxyl groups have some double-bond character and is supported by the infrared spectroscopic observation as shown above.

The idealized C_{2v} closed eleven-vertex metallaborane structural type is to be of interest because of its contravention of the simple Wade-Williams cluster-geometry and electron-counting rules. According to the Wade-Williams' electron-counting rules, there are two possible electron structures for this C_{2v} $\{RuB_{10}\}$ cage. The first would be that the [Ru(1-1)PPh_3(SCPh)$_2$] moiety contributes three orbitals and two electrons to cluster bonding, so that the closed structure has two electron less than that required for

a formal *closo* electron count, and it would be regarded as "electron hyper-deficient" [33,34]. This situation is based on the assumption that the metal center is electronically saturated. If the metal center is allowed to be electronically unsaturated, the second possible electron structure would be that the [Ru(II) $PPh_3(SCPh)_2$] moiety contributes three obitals and four electrons to cluster bonding, so that the cluster has sufficient electrons for a formal *closo* electron count, in this case the compound would have a formally unsaturated 16-electron Ru(II) center. However, there is also a possible electron structure called *isocloso* structure with the metal center having a four-orbital four-electron contribution [30,35]. All of these views are short of sufficient experimental evidences.

Although the reaction mechanism is complex, overall reaction is stoicheiometric and can easily be expressed by a simple equation [eqn (2)],

$$[(PPh_3)_3RuCl_2] + [B_{10}H_{10}]^{2-} + 2C_6H_5COSH \rightarrow [(PPh_3)(C_6H_5COS)_2RuB_{10}H_8] + 2H_2 + 2Cl^- + 2PPh_3 \quad (2)$$

Two interesting facts show that the reaction mechanism is not simple. The first one is that the ruthenium(II) vertex is coordinated by the sulfur atoms of two thiobenzoxy. This gives an evidence that the elimination of two molecules of hydrogen must involve a series of process, not a simple reaction between the terminal-hydrogen of $[B_{10}H_{10}]^{2-}$ anion and the -SH group of thiobenzoic acid. The second fact is that the carbon-oxygen bond of thiobenzoxy in compound **1** keeps its carbonyl character. It implies that the carbonyl group of thiobenzoic acid plays the role as a Lewis base. As we know that $B_{10}H_{12}L_2$ can react with a strong Lewis base R_3N to give the *closo*-$B_{10}H_{10}^{2-}$:

$$B_{10}H_{12}L_2 + 2R_3N = 2R_3NH^+ + B_{10}H_{10}^{2-} + 2L$$

It is reasonable that the presence of a weak Lewis base species, such as the carbonyl group of carboxy or thiocaboxy ligands, would be favorable for the reverse process which leads to the opening of the $B_{10}H_{10}^{2-}$ cage. Because of the great complexity, the mechanism of this type of reaction needs to be further studied in the future.

(Received 11 September 1997; accepted 9 December 1997)

Abstract—Triboluminescent phenomenon of 1,4-dimethylpyridinium tetrakis(thenoyltrifluoroacetonato) europate (**1**) was firstly observed. Its crystal structure and the triboluminescent spectrum were successfully determined. The crystal is centrosymmetric and the Eu atom exhibits an eight-coordinate tetragonal antiprismatic geometry. The triboluminescent spectrum of **1** is basically similar to that of photoluminescent spectrum and the observed triboluminescent emission correlates with the disorders of the S atoms and F atoms.

Keywords: europate complex; HTTA; 1,4-dimethylpyridinium; triboluminescence; photoluminescence; disorder.

Triboluminescence is the emission of light produced during mechanical action on solids. Although it is an old phenomenon, its mechanism is not well understood. In recent years, the complexes of the lanthanide elements exhibiting brilliantly triboluminescent properties have been under extensive research [1,2]. In particular, triboluminescent compounds have received more and more attention due in part to a growing need for optical-pressure sensor device [3]. Furthermore, extensive searching for a clear pattern of triboluminescent activity as a function of crystal structure that would permit the construction of a predictive theory of triboluminescence have been under way [4]. Zink [5] estimated that the correlation of triboluminescence activity with noncentrosymmetric space groups was greater than 95%. Sweeting [1] and Rheingold [2] respectively determined the crystal structures of triethylammonium tetrakis (dibenzoylmethanato)europate and piperidinium tetrakis(benzoylacetonato)europate which all display centrosymmetric space groups. They suggested that disorder and ionic compounds play important roles in triboluminescent activity of centrosymmetric materials. In this paper, we report the crystal structure and the triboluminescent spectrum of the firstly observed triboluminescent lanthanide complex **1**. We believe the disorders of the S atoms and F atoms may provide a sufficient condition for the triboluminescence of centrosymmetric crystals of **1**. This result confirms the discovery of Sweeting [1].

EXPERIMENTAL

Preparations

All the chemicals were analytical grade and used without further purification. Iodine 1,4-dimethyl-

* Author to whom correspondence should be addressed.

pyridinium was prepared according to the literature method.

Synthesis of **1**. 1.04 g (4.68 mmol) HTTA (2-thenoyltrifluoroacetone) and 0.275 g (1.17 mmol) Iodine 1,4-dimethylpyridinium was dissolved in 20 ml of ethanol, by heated to boiling, then 0.187 g (4.68 mmol) NaOH in 10 ml water was added. Under vigorous stirring, $Eu(NO_3)_3$ (1.17 mmol) solution was added dropwise and the resultant mixture was refluxed for 3 h with stirring. After hot filtration, the filtrate was allowed to cool slowly at room temperature for several days. Orange single crystals suitable for X-ray analysis were obtained. Found: C, 40.69; H, 2.43; N, 1.24. Calc.: for $EuC_{39}H_{26}F_{12}NO_8S_4$: C, 40.77; H, 2.61; N, 1.22%. The medium-IR of **1** showed peaks at 3089 (w), 3055 (w), 1607 (s), 1537 (s), 1503 (s), 1467 (m), 1411 (s), 1355 (s), 1300 (s), 1246 (m), 1299 (m), 1185 (s), 1137 (s), 1082 (m), 1059 (m), 1032 (w), 1012 (w), 931 (w), 858 (w), 828 (w), 784 (m), 766 (w), 750 (w), 717 (m), 694 (w), 680 (w), 642 (m), 605 (w), 579 (m), 493 (w), 460 (w). Mp: 190–192°C.

Physical measurements

Elemental analysis were performed on a Perkin–Elmer 240C analysical instrument. The IR spectrum was recorded on a Nicolet FT-IR 170sx spectrophotometer with KBr pellet in the range of 4000–400 cm^{-1}. Triboluminescence spectrum was obtained using an Acton Research Corporation (ARC) SpectraPro-750, Santa Barbara Instruments Group (SBIG) CCD Detection System. The grating chosen was blazed for 500 nm with 1200 grooves per mm. The 10 μm slit used gave a resolution of 0.023 nm. Wavelength accuracy is ± 0.1 nm with the 1200 g mm grating. A curve was acquired with no crushing sample, no triboluminescence. It was set as background. The curve that has been set as the background will be subtracted from each new curve input from the camera. The sample was placed as close as possible to the slit in the quartz colorimetric tube and was ground by hand, drawing up a small portion with a glass rod, crushing it against the side of the tube. Photoluminescence spectrum was obtained on ARC SpectraPro-750, (SBIG) CCD and Nd: YAG laser. 355 nm laser line of Nd: YAG with 20 ns pulse width was used to pump the sample.

X-ray crystal structure determination

A crystal having dimensions of $0.48 \times 0.42 \times 0.36$ mm was mounted on a glass fibre. The intensities were collected on a Siemens P4 four-circle diffractometer with monochromated Mo-Kα ($\lambda = 0.71073$ Å) radiation at room temperature. All computation were carried out on a Pc-586 computer using the SHELXTL-Pc Program Package [7]. Compound **1** crystallizes in the monoclinic space group $P2_1/n$ with $a = 14.333(2)$, $b = 17.640(3)$, $c = 18.169(3)$ Å; $\beta = 103.503(14)°$; $V = 4466.6(11)$ Å^3; $Z = 4$; $D_{calc} = 1.702$ g cm^{-3}. A total of 8463 reflections, of which 4229 reflections were unique ($R_{int} = 0.096$), were collected in the range $3.5 \leqslant 2\theta \leqslant 50°$ using $\omega/2\theta$ scan mode with a variable scan speed 5.0–50.0° min^{-1} in ω. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS [6] and the linear absorption coefficient was 1.692 mm^{-1}. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares methods using SHELXTL version 5.0 [7]. The S(1), S(3) and S(4) atoms (site occupancy factor (sof) for S(1) and S(1′), S(3) and S(3′), S(4) and S(4′) fixed at 0.5 respectively) and F(1), F(2), F(3), F(4), F(5), F(6), F(10), F(11) and F(12) (sof = 0.5) were found disordered. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions (C—H, 0.96 Å) assigned fixed isotropic thermal parameters at 1.2 times the equivalent isotropic U of the atoms to which they are attached (1.5 times for methyl groups) and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factors calculations. The final cycle of refinement included 578 parameters and converged with unweighted and weighted agreement factors of $R = 0.0593$ and $R_w = 0.1560$; GOF = 1.046 (on F^2) (The weighting scheme was $w^{-1} = \sigma^2 (F_o^2) + (0.06P)^2$, $P = (F_o^2 + 2F_c^2)/3$). The maximum and minimum peaks on the final difference Fourier map corresponded to 0.419 and -0.526 eÅ^{-3}.

RESULTS AND DISCUSSION

The structure and labeling schemes of **1** is shown in Fig. 1. Selected bond distances and angles are listed in Table 1. It is tetra-bidentate, eight-coordinate Eu(III) complex containing four HTTA anionic ligands. Many aspects of the eight-coordinated geometry structural europium complexes have been previously discussed. The Eu atom in **1** also has an eight-coordinate tetragonal antiprismatic geometry. The tetragonal planes are defined as [O(1)O(2)O(5)O(7)] and [O(3)O(4)O(6)O(8)] (Fig. 2). The complex **1** possesses an approximate 2-fold rotational axis C (2) (Fig. 3). The average Eu—O distance of **1** (2.385(3) Å) is somewhat shorter than those of 4-methylpyridium tetrakis (thenoyltrifluoroacetonato)europate (**2**) (2.391(7) Å) [8] and N-ethylpyridinium tetrakis(thenoyltrifluoroacetonato)europate (**3**) (2.391 Å) [9] and is longer than that of 3,6-di(dimethylamine)-diphenyliodonium tetrakis(thenoyltrifluoroacetonato)europate (**4**) (2.381 Å) [10]. The average of C—O bond in **1** (1.241 Å) is shorter than those of in **2** (1.261 Å), in **3** (1.259 Å) and in **4** (1.258 Å). It reflects the lower π atom delocalization of C—O double bond in **1**. The O—Eu—O angles within a chelate ring have the following similar averages: **1**, 72.60°; **2**, 71.25°; **4**, 71.0°. 1,4-dimethylpyridinium is a cation and does not coordinate with Eu(III). The C—N bond distance

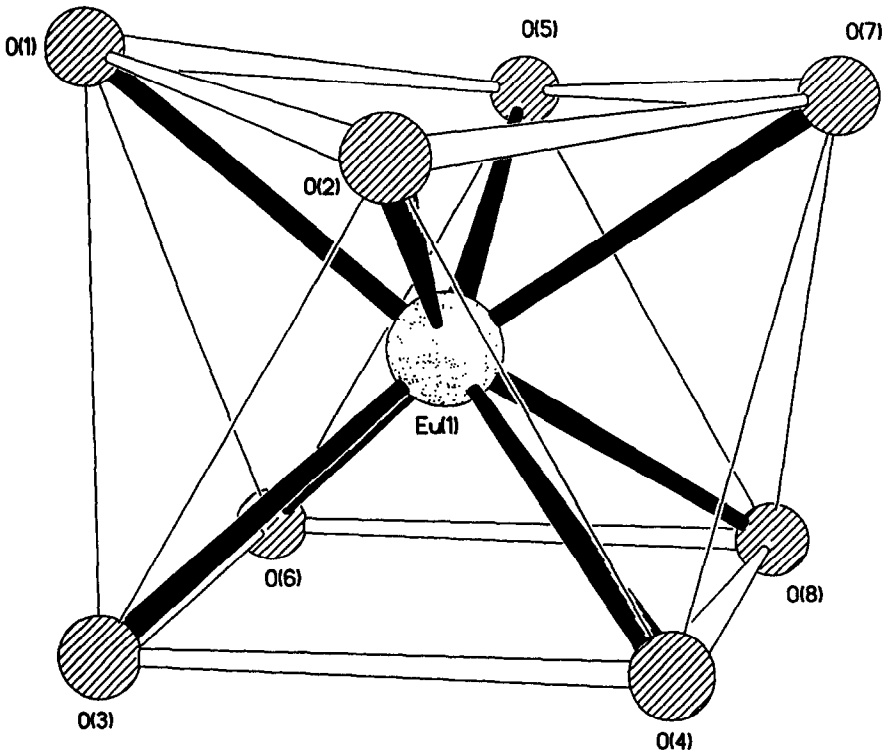

Fig. 2. The antiprismatic coordination geometry for **1**.

(1.529 Å) between the methyl C and N atom is longer than σ typical C—N single bond (1.479 Å). It was the result that *N*-methyl was absorbed by F(4), F(5) and F(6) atoms. So the F(4)—C(9), F(5)—C(9) and F(6)—C(9) bond distances were longer than other F—C bond distances. Two C—N bond distances in the pyridine ring were 1.377(8) Å and 1.447(6) Å respectively. It was the result of π atom delocalization. It is noted that three S atoms of the four crystallographically thienyl rings and three of the four CF_3 in **1** display equally occupied alternative positions.

Complex **1** is highly luminescent in the solid state. Its photoluminescence spectrum at room temperature is shown in Fig. 4. This luminescence is typical of the europium centered transitions from $^5D_0$ levels to the lower $^7F_{0\text{-}4}$ levels of the ground multiplet and has been assigned in Table 2. The transition from $^5D_0$ to $^7F_0$ hasn't been observed. The complex **1** belongs to monoclinic system, the partial symmetry of Eu^{3+} may be C_{2h} after it was excited [11]. Complex **1** which was obtained from the saturated solution was strongly triboluminescent in darkness. When **1** was recrystallized from CH_3CN or CH_3CN-C_2H_5OH, it was triboluminescent with red light emission in daylight. The triboluminescence of **1** is independent of time, but smaller crystals appear to emit less light. The triboluminescence spectrum of **1** is given in Fig. 5. There is no detectable dinitrogen emission. The triboluminescence emission is weaker than that of photoluminescence. So we only observed a part of the emission in the range 550–720 nm which corresponded the most intense emission of the photoluminescence. Other Eu^{3+} ion characteristic emission is much weaker than that of the most intense emission, they haven't been observed in the triboluminescence spectrum. Rheigold [2] stated that the most visible component of their triboluminescent emission of lanthanide complexes is the characteristic photoluminescence of the metallic element. It is apparent that the triboluminescence maximum of complex **1** is similar to that of photoluminescence. Therefore we think that the part of the triboluminescence spectrum does prove that this is europium emission. The emissions observed in triboluminescence is centered transition of the europium from $^5D_0$ level to $^7F_2$ level. The signal to noise ratios which were not very well didn't affect the assignment of the emission [1b,12].

Several mechanism have been proposed for triboluminescence. There is substantial evidence that charge separation created during fracture is the immediate precursor of the triboluminescence emission [13]. It is generally accepted that the primary event in the triboluminescence is the recombination of charges separated during fracture. It has been asserted that only piezoelectric (noncentrosymmetric) crystals may be triboluminescent because only such crystals can develop opposite charges on the opposing faces of a developing crack. The crystal structures of tri-

boluminescent materials show that a noncentrosymmetric space group is neither necessary nor sufficient for triboluminescence. There are many centrosymmetric crystals which are triboluminescent and many noncentrosymmetric crystals which are not. The present study again demonstrates that materials which are centrosymmetric can be triboluminescent: **1** crystallizes in $P2_1/n$. In the discussion of relation of structure and triboluminescence activity, Sweeting [1] suggested that the phenyl-ring and cation disorder in triethylammonium tetrakis(dibenzoylmethanato) europate which is one of the most brilliantly triboluminescent compounds known provided a sufficient source of localized polarity to produce the observed activity. We are now faced with the similar example. A similar effect is also evident in **1**. The disorders of S atoms and F atoms in **1** may provide a structural basis for charge separation by creating randomly distributed sites of slightly different ionization potentials and electron affinities at the faces of developing cracks. It is not clear which disorder is more important to the triboluminescence between S atoms and F atoms. It is interesting to note that **2** and **3** crystallize in the centric space group $P\bar{1}$ and **4** crystallizes in the centric space group $P2_1/n$. They all appear to exhibit no disorder of S atoms and F atoms and exhibit no triboluminescent activity from the parameters. Therefore, we think the disorder of **1** may play an important role in centrosymmetric **1** for triboluminescence. The disorder in the fluorescent europate ion provides the local dissymmetry needed to support charge separation. In conclusion the Sweeting theory, i.e. the disorder provides sufficient condition for the triboluminescent activity of the centrosymmetric crystals, and appears to be correct for the complexes. We are currently searching for other materials to confirm the discovery of Sweeting.

Effects of the benzosubstitution of cryptands for the complex formation between protons, alkali and alkaline earth cations in water

D. A. Dantz, H.-J. Buschmann* and E. Schollmeyer

Deutsches Textilforschungszentrum Nord-West e.V., Frankenring 2, D-47798 Krefeld, Germany

(Received 10 October 1997; accepted 5 December 1997)

Abstract—The protonation reactions of the cryptand (222), benzocryptand (222B) and dibenzocryptand (222BB) and the complexation of alkali and alkaline earth cations in aqueous solution have been studied using pH-metric and calorimetric titrations. The results show that the first proton of all protonated ligands is located inside, and the second proton outside, the cavity. The benzo substituents have no influence upon the enthalpy of the protonation. The entropy of the protonation decreases slightly with the number of benzo substituents due to the lower flexibility of the cryptands. The increasing number of benzo groups leads to lower stability constants for the alkali and alkaline earth cations. These cryptands shield the complexed cations more efficiently from the solvent. Comparing the complexation entropies of the cryptands of barium ion with those of potassium ion it is shown that in the case of the barium ion one more water molecule is released compared with the potassium ion during the complex formation with all three cryptands examined. © 1998 Elsevier Science Ltd. INTRODUCTION

The first stability constants for the complexation of alkali and alkaline earth cations with cryptands were reported more than 25 years ago [1]. The authors of that article show the dependence of the complex stability on the ionic radius of the complexed ion, the cavity size and the nature of the donor atoms in the cryptand. In the meantime, a large number of articles has been published reporting the complexation of cryptands with a variety of cations in different solvents [2–7]. However, concerning the complexation reaction of benzo or dibenzo substituted cryptands in aqueous solution only few thermodynamic data have been published because of the low solubility of the benzo and the dibenzo cryptands in water [12]. More data are available for the complexation reaction in other solvents as methanol or propylene carbonate [9–12]. The hydrophobic benzo groups of the cryptands (222B) and (222BB) influence the complexation behaviour of these ligands. The flexibility and the basicity of the oxygen atoms next to the benzene rings are reduced. Thus, the benzo groups can directly influence the complex formation and indirectly the interactions between the complexed cation and solvent molecules.

EXPERIMENTAL

The cryptands 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosan (Kryptofix 222, Merck) and 5,6–14,15-dibenzo-4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosan (Kryptofix 222BB, Merck) were used without further purification. The cryptand 5,6-benzo-4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosan (Kryptofix 222B, Merck) is available as solution in toluene. After evaporation of the solvent the cryptand is dissolved in water. The concentration of the ligand in aqueous solution was determined by potentiometric titration. The chemical structures of the ligands used are given in Fig. 1.

The salts $LiNO_3$, NaCl, KCl, RbCl, CsCl, $Ca(NO_3)_2$, $Sr(NO_3)_2$, $BaCl_2$, $Cu(NO_3)_2$, $Pb(NO_3)_2$,

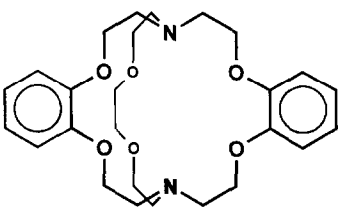
Benzocryptand (222B)



Dibenzocryptand (222BB)

Fig. 1. Chemical structure of the cryptands used.

$Cd(NO_3)_2$, $(CH_3)_4NClO_4$ and $(CH_3)_4NOH$ were of the highest commercially available purity. All solutions were prepared with bidistilled water.

The protonation constants of the cryptand (222B) and the stability constants of the cation cryptand (222B) complex with a log K value higher than 3 were determined by potentiometric titrations [13]. A solution of tetramethyl ammonium hydroxide (0.06 mol/l) was titrated into 20 ml aqueous solution containing the cryptand (0.01 mol/l) and hydrochloric acid (0.04 mol/l). During the titrations the ionic strength was kept constant using tetraethyl ammonium perchlorate (0.05 mol/l) as supporting electrolyte. The titration was performed automatically using a Metrohm Dosimat 665 and a pH-electrode (Metrohm 6.0203.100).

The determinations of the thermodynamic values of the complexation reactions with the cryptands (222B) and (222BB) were performed by calorimetric titrations. The reaction enthalpies were determined using a Tronac Model 450 calorimeter. The measured heat Q produced during the titration is related to the reaction enthalpy ΔH after correction of all non-chemical heat effects by the following equation:

$$Q = \Delta H \cdot \Delta n \qquad (1)$$

where Δn is the number of moles of the complex formed during the titration. The evalution of the data has been described in detail [14–16].

The reaction enthalpy of the monoprotonation reaction K_1 was measured by titrating continuously a solution (0.15 ml) of hydrochloric acid (0.02–0.05 mol/l) into 40 ml solution of the ligands (0.0008–0.003 mol/l) during 30 s. Under these experimental conditions the actual proton concentration in the reaction vessel is much lower than the ligand concentration so only monoprotonation of the ligand takes place. The reaction enthalpy of the second protonation step K_2 is determined by titrating a solution of the ligand (0.00082–0.003 mol/l) into 40 ml hydrochloric acid (0.05 mol/l). Thus, the proton concentration is much higher compared with the ligand concentration. As a result, both nitrogen atoms are protonated. According to the prior measured value of the reaction enthalpy for the monoprotonation, the reaction enthalpy for the second protonation step can be calculated.

The reaction enthalpy of the complexation reaction with the alkali and alkaline earth cations were measured by titrating a solution of the salt (0.03 mol/l) into a solution of the cryptand. The concentration of the cryptand (222B) and (222BB) was 0.003 mol/l and 0.00082 mol/l, respectively. In the case of the cryptand (222BB) a saturated aqueous solution was used. The concentration of the cryptand (222BB) in this solution is known from the literature [8].

RESULTS AND DISCUSSION

The results of the protonation and the complexation of alkali and alkaline earth cations with the different cryptands in aqueous solution are summarized in Table 1. The enthalpies for the complex formation of the cryptands (222B) and (222BB) with alkaline earth cations reported in the literature [17] have been calculated from kinetic measurements at different temperatures. Thus, the accuracy of these values is expected not to be as high as from calorimetric measurements.

The protonated cryptands can exist in three different conformations as shown in Fig. 2. The first protonation K_1 of the cryptand (222) has to be compared with the protonation reaction of trimethylamine due to the decreasing basicity of the nitrogen atoms from primary to secondary and tertiary amines. The first protonation enthalpy of the cryptand (222) ($\Delta H_1 = -47.9$ kJ/mol) is higher than that for the protonation of trimethylamine ($\Delta H = -36.9$ kJ/mol). This indicates that the proton of the protonated cryptand (222) is located inside the cavity where additional interactions with the hetero atoms especially with the second nitrogen atom are possible [13]. The value of the enthalpy for the second protonation K_2 is $\Delta H_2 = -24.5$ kJ/mol. This value is about 12 kJ/mol lower than that for the protonation of trimethylamine. The free electron pair of the second nitrogen atom has to turn from inside the cavity to outside. The addition of the first and the second protonation enthalpy of the cryptand (222) is -72.4 kJ/mol which is twice as much as the enthalpy for the

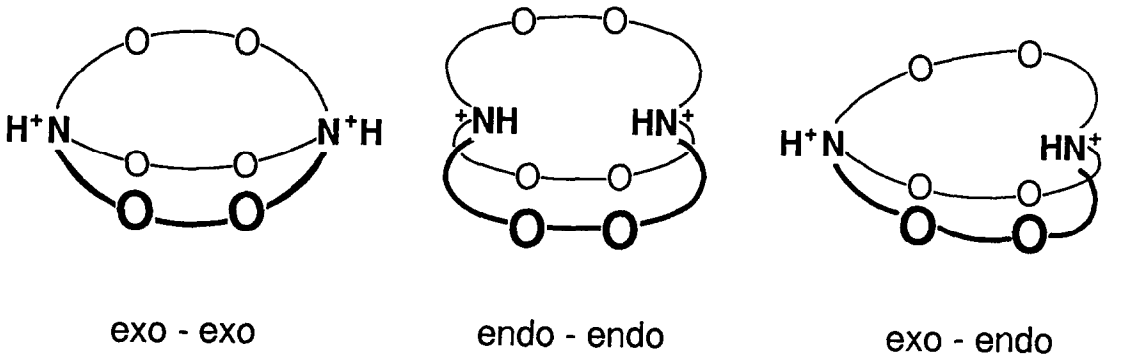

Fig. 2. Possible conformations of the diprotonated cryptands.

protonation of trimethylamine ($2\Delta H = -73.8$ kJ/mol). This shows that both protons mainly interact with the nitrogen atoms in aqueous solution. In the case of the noncyclic analogues of the cryptand (222) no intramolecular interactions of the protonated amine with the oxygen atoms have been observed [18].

The enthalpies of the first protonation step K_1 of the cryptands (222), (222B) and (222BB) are nearly constant. Thus, the decreasing basicity of the oxygen atoms due to the benzo substitution has no effect on the enthalpy of the first protonation. This indicates that generally both nitrogen atoms participate in the first protonation reaction in aqueous solution.

The enthalpy of the second protonation K_2 is almost

constant for all three cryptands used. This is not surprising, because if the second proton is located outside the cavity, the number of benzo substituents should have no influence on the second enthalpy. The entropy of the second protonation decreases slightly which can be explained by the more rigid structure of the benzo-substituted cryptands. In turning the free electron pair of one nitrogen atom from inside to outside, the side chains of the cryptands also have to change their conformation.

Recently crystal structures of the diprotonated cryptand (222) have been published where both protons are located inside the cavity (endo-endo conformation) of the cryptand [20,21]. This structure is in accordance with the molecular dynamic simulation of the protonated cryptand (222) [22]. In this case, both protonated amines are stabilized by the nearest three oxygen atoms. The crystal structure of the diprotonated cryptand (211) is also known from the literature [23]. In contrast to the endo-endo conformation of the crystal structure of the diprotonated cryptand exists in solution the endo-exo conformation. Our results clearly demonstrate that the solvent plays an important role during the formation of the diprotonated cryptand (222).

In the case of the complex formation with alkali and alkaline earth cations the benzo substitution of the cryptand may lead to the following effects:

(a) the cavity size decreases due to the shorter bond of the benzene ring compared with a carbon-carbon single bond;
(b) the rigidity of the cryptand increases;
(c) the benzo ring lowers the basicity of the oxygen donor atoms next to the benzene rings;
(d) the cryptand thickness increases with the number of the benzo substituents. Thicker ligands like the benzosubstituted cryptands shield the cations from the solvent which decreases the stability of the complex. This effect increases with an increasing dielectric constant of the solvent [24].

The potassium (r = 1.38 Å) [25] and barium ion (r = 1.36 Å) [25] fit best into the cavity of the cryptand (222) (r = 1.4 Å) [24] which is shown by the highest stability constant compared with the other alkali and alkaline earth cations, respectively. These stability constants decrease drastically with an increasing number of benzo substituents.

On the other hand, the complex stabilities of the smaller sodium ion (r = 1.02 Å) [25] remains nearly constant with an increasing number of benzo substituents. The decreasing cavity size from the cryptand (222) to (222BB) allows the interaction of the sodium ion with more donor atoms. Thus, the effect of the lower basicity of the oxygen atoms is compensated by the additional interactions with the oxygen atoms. The calcium ion has the same size as the sodium ion (r = 1.00 Å) [25]. In contrast to the stability constants of the sodium ion cryptand complexes the stability constants of the calcium ion cryptand complexes decrease with an increasing number of benzo substituents. The explanation for this result is the increasing ligand thickness which has an effect four times higher for alkaline earth than for alkali ions caused by the charge of the cation [24].

The lithium ion (r = 0.73 Å) [25] is much smaller than the cavity size of the cryptand (222) and therefore the lithium ion interacts only with some donor atoms of the ligand. The decreasing cavity size from the cryptand (222) to (222B) also allows no additional interactions of the lithium ion with other donor atoms in the cryptands. Thus, no changes of the stabilities or enthalpies of the complexation reaction comparing the cryptands (222) and (222B) could be observed. The rubidium (r = 1.49 Å) [25] and caesium ion (r = 1.70 Å) [25] are too big to fit into the cavity of the cryptand (222). These ions are located at one side of the cavity and do not interact with all of the donor atoms of the cryptands. Therefore, the enthalpy of the complexation reaction decreases for these cations. Also the lower basicity of the oxygen atoms next to the benzo groups of the cryptand has an influence upon the enthalpy.

The benzo substitution has also an effect on the solvation sphere of the cryptand cation complex. The ionic radii of the potassium and the barium ion are nearly identical. During complex formation with both cations all contributions e.g., cryptand deformation, cryptand solvation and changes in the structual freedom of the cryptand, are nearly the same. Thus, the observed differences in the entropies which are 9.7, 8.3 and 9.7 kJ/mol for the cryptands (222), (222B) and (222BB), respectively, can only be caused by changes in the number of solvent molecules liberated during the reaction. Dividing these differences of molar entropy for barium as against potassium by the molar entropy for the melting of ice (7.6 kJ/mol) [26] shows that in the case of the reaction of the barium ion with the cryptands are additional water molecule set free compared with the potassium ion. Due to the constant differences between the reaction entropies for barium and potassium ion complexation, it is obvious that the benzo groups of the cryptands have no influence upon the solvation of the complexes. These results are different from those in the solvent methanol, where the substitution of the side chains of the cryptand with benzo groups influences significantly the solvation sphere [12].

(Received 15 July 1997; accepted 4 December 1997)

Abstract—A number of ruthenium(II) complexes containing an NNS chelating thioether ligand (L) have been synthesized and characterized by elemental analysis, UV-visible, IR and ^1H NMR spectroscopy and cyclic voltammetry. Ru(L)(PPh_3)Cl_2 (**1**) has been characterized by X-ray diffraction. Structural features of (**1**) indicate a distorted octahedral coordination environment around the ruthenium(II) centre. The two chlorides are *cis* to each other with the Ru—Cl(1) bond *trans* to PPh_3 longer than the Ru—Cl(2) bond. Several mixed-ligand complexes containing bipyridine, phenanthroline, 2-picolinate and oxalate were also isolated and the structure of one of the heterochelates has been solved. [Ru(L)(PPh_3)(bpy)]$(ClO_4)_2$ (**2**) has also been structurally characterized. The structure and properties of (**2**) correspond to the predictions based on the structure of (**1**).

Keywords: ruthenium(II) complexes; NNS donor ligand; mixed ligand complexes; crystal structures; electrochemical study.

Ruthenium(II) complexes of nitrogen and thioether-sulfur chelating ligands received little attention [1–4] over the last few decades even though one such complex was reported way back in 1960 [5]. The N—S chelated ruthenium complexes reported so far, the sulfur donor centres are confined mainly to thiolato sulfur. The lower reactivity [6] of the thioether complexes of the first row transition metals, probably arising out of the steric hindrance at the sulfur atom offered by the alkyl group attached to it and consequent lowering of the nucleophilicity, may have been the discouraging factor. In contrast, thioether complexes of the second row transition metals are quite reactive towards oxidation [7]. Despite some reports [3,7–8] of the synthesis of some ruthenium(II) thioether complexes as a part of the exploration of the reactivity of thiolato complexes towards CH_3I, interest in structural characterization of the resultant thioether complexes was singularly lacking. It has been observed that use of ruthenium substituted metalloproteins where ruthenium is linked to methionine-sulfur of proteins sometimes provide valuable information for the purpose of exploring the local protein structure and their influence on electron transfer reactions [21]. To date, only three structure determinations of thioether complexes of ruthenium(II) are reported by Sheldrick *et al.* [10,11]. These are

L

ruthenium(II) complexes of an amino acidate ligand, one of which is an organometalic complex [(nbd)Ru(D,L-metme)Cl_2] [10]. [nbd = norbornadiene; metme = methionine methyl ester] and the other two complexes are [RuCl(L-metme)$_2$(PPh_3)]Cl and [RuCl(L-metme)$_2$(PPh_3)] [11]. In this paper we report the synthesis and structure determination of a ruthenium(II) complex of the NNS-chelating thioether ligand 2-pyridyl-N-(2′-methylthiophenyl)methyleneimine(L). The structure of the complex Ru(L)(PPh_3)Cl_2 (**1**) has been determined and the *cis* disposition of the two chloro ligands suggests that substitution by a bidentate chelating ligand is quite feasible and may lead to facile synthesis of mixed chelates. The structure of [Ru(L)(PPh_3)(bpy)](ClO_4)$_2$ one of the derivatives of (**1**), is also determined and discussed.

EXPERIMENTAL

$RuCl_3$ was obtained from Arora-Matthey Limited. Ru(PPh_3)$_3Cl_2$ was prepared by a published procedure [12]. The ligand 2-pyridyl-*N*-(2′-methylthiophenyl)methyleneimine (L) was prepared according to the literature [13]. All other common chemicals were of reagent grade and were used as received. Reagent grade solvents were dried and distilled by usual methods and the solvents were stored over molecular sieves (4 Å). Tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium bromide (Fluka AG) by a standard procedure [7] and was recrystallized twice from water and then dried at 110°C for 24 h. Dinitrogen gas was purified by bubbling it successively through alkaline dithionite solution and concentrated sulfuric acid.

Physical measurements

Electronic spectra were recorded with a Shimadzu Model UV-2100 spectrophotometer. Electrochemical data were collected with a Bioanalytical system CV-27 Electrochemicalanalyser and a BAS model X-Y recorder at 298 K. Cyclic voltammetric experiments were carried out with platinum working and counter electrode and a Ag/AgCl reference electrode which was separated from the working compartment by a medium glass frit. Potentials were referenced internally to the ferricenium/ferrocene couple (Fc^+/Fc, 0.46 V vs Ag/AgCl). ^{1}H NMR data were obtained with a Varian XL 100 FT-NMR spectrometer using TMS as the internal reference. Magnetic data were obtained with help of a Princeton Applied Research Model 155 vibrating sample magnetometer using Hg[Co(SCN)$_4$] as the calibrant. Infrared spectra were recorded with a Perkin–Elmer 783 Spectrophotometer as KBr or CsBr pellets. Microanalysis were carried out using a Perkin–Elmer 240 C,H,N analyser. Solution electrical conductivity was measured with a Philips PR-9500 conductivity bridge fitted with a dip-type cell calibrated with 0.02 M KCl solution.

Preparation of the complexes

cis-Ru(L)(PPh_3)Cl_2 (**1**). 960 mg (1 mmol) of Ru(PPh_3)$_3Cl_2$ was dissolved in 40 ml benzene and the solid ligand (470 mg, 2 mmol) was added to it followed by 30 ml of benzene. The colour changed to red-violet immediately. The mixture was refluxed for ca 5 h. The compound separated out within 30 min. The reaction mixture was cooled and filtered. The dark violet residue was washed thoroughly with benzene and dried *in vacuo* over fused $CaCl_2$. Yield: 570 mg, 86% (Found: C, 56.3; H, 4.2; N, 4.3. Calcd for $RuC_{31}H_{27}N_2SPCl_2$: C, 56.2; H, 4.1; N, 4.2%). Conductance in CH_3CN (Λ_M): 52 (ohm^{-1} cm^2 mol^{-1}).

[Ru(L)(PPh_3)(bpy)](ClO_4)$_2$ (**2**) *and* [Ru(L)(P-Ph_3)(bpy)](PF_6)$_2$ (**3**). **Warning**: Perchlorate salts of metal complexes are potentially explosive [14].

About 330 mg (~0.5 mmol) of compound **1** was dissolved in 50 ml of MeOH. 80 mg (~0.5 mmol) of 2,2′-bipyridine was added to it followed by 10 ml MeOH and the mixture was refluxed in a nitrogen atmosphere for about 24 h. After cooling, it was filtered and the volume of the filtrate was reduced to one third of its original volume in a rotary evaporator. It was then divided into two parts. In one part excess aqueous $LiClO_4$ solution was added and the precipitate was allowed to stand in a refrigerator for 1/2 h. It was filtered and washed thoroughly with water. The compound was dried over fused $CaCl_2$ and recrystallized from MeOH/Et_2O. Yield: 187 mg, 79% (Found for **2**: C, 52.2; H, 3.8; N, 5.8. Calcd for $RuC_{41}H_{35}N_4SPCl_2O_8$: C, 52.0; H, 3.7; N, 5.9%). Conductance for **2** in CH_3CN (Λ_M): 219 (ohm^{-1} cm^2 mol^{-1}).

To the other part excess aqueous NH_4PF_6 was added and the compound was isolated and purified similarly as above. Yield: 215 mg 83% (Found for **3**: C, 47.5; H, 3.5; N, 5.2. Calcd for $RuC_{41}H_{35}N_4SP_3F_{12}$: C, 47.4; H, 3.4; N, 5.4%). Conductance for **3** in CH_3CN (Λ_M): 248 (ohm^{-1} cm^2 mol^{-1}).

[Ru(L)(PPh_3)(phen)](ClO_4)$_2$ (**4**), [Ru(L)(PPh_3)(phen)](PF_6)$_2$ (**5**) *and* [Ru(L)(PPh_3)(2-Picolinate)](PF_6) (**6**). These compounds were prepared and purified by a method similar to that used for

preparing the compounds **2** and **3** except the fact that *o*-phenanthroline for **4** and **5** and 2-picolinic acid for **6** was used in place of 2,2′-bipyridine. Yields: 725 mg (75%) for **4**, 775 mg (73%) for **5** and 600 mg (70%) for **6**. [(Found for **4**: C, 53.0; H, 3.6; N, 5.6. Calcd for $RuC_{43}H_{35}N_4SPCl_2O_8$: C, 53.2; H, 3.6; N, 5.8%). Conductance for **4** in CH_3CN (Λ_M): 281 (ohm^{-1} cm^2 mol^{-1})]. [(Found for **5**: C, 48.8, H, 3.1; N, 5.1. Calcd for $RuC_{43}H_{35}N_4SP_3F_{12}$: C, 48.6; H, 3.3; N, 5.3%). Conductance for **5** in CH_3CN (Λ_M): 285 (ohm^{-1} cm^2 mol^{-1})]. [(Found for **6**: C, 51.6; H, 3.8; N, 4.8. Calcd for $RuC_{37}H_{31}N_3SO_2P_2F_6$: C, 51.7; H, 3.6; N, 4.9%). Conductance for **6** in CH_3CN (Λ_M): 136 (ohm^{-1} cm^2 mol^{-1})].

[Ru(L)(PPh$_3$)(C$_2$O$_4$)]·2H$_2$O (**7**). About 330 mg (~0.5 mmol) of **1** was dissolved in 50 ml of MeOH followed by 208 mg (~1 mmol) of $AgClO_4$. The mixture was refluxed for 1 h under nitrogen atmosphere. It was cooled and filtered to remove the precipitated AgCl. Excess aqueous solution of sodium oxalate was added to it, when a red precipitate separated out. It was filtered and washed thoroughly with water. The dried compound was recrystallized from MeOH/Et$_2$O. Yield: 235 mg, 66% (Found: C, 55.3; H, 3.8; N, 4.2. Calcd for $RuC_{33}N_2H_{31}SO_6P$: C, 55.4; H, 3.9; N, 4.3%). Conductance in CH_3CN (Λ_M): 33 (ohm^{-1} cm^2 mol^{-1}).

Crystallographic structure determinations

Single crystals of *cis*-Ru(L)(PPh$_3$)Cl$_2$] (**1**) and [Ru(L)(PPh$_3$)(bpy)](ClO$_4$)$_2$] (**2**) were grown by slow diffusion of *n*-Hexane into CH_2Cl_2 solutions of the complexes at room temperature. Dark red crystal of dimension $0.58 \times 0.19 \times 0.08$ mm for **1** and $0.60 \times 0.31 \times 0.14$ mm for **2** were selected for diffraction studies. The crystals were flash-cooled in a mineral oil film by placing it in the cold nitrogen stream of an Oxford Cryosystems low-temperature device [15] mounted on a Stöe Städi-4 four circle diffractometer. The reflection widths were derived from on-line profile fitting whose parameters were updated continuously [16]. The intensities of three standard reflections monitored every 60 min showed no significant variation. The lattice parameters were refined from 2θ values (30°–38°) for complex **1** of 35 reflections and (24°–26°) for complex **2** of 19 reflections measured at $\pm\omega$. The structure was solved by using the PATTY routine of DIRDIF [7] and refined on F^2 using SHELXL-93 [18]. All non-hydrogen atoms were allowed anisotropic thermal motion and phenyl rings were constrained to be rigid groups. Hydrogen atoms were included in calculated positions and thereafter allowed to ride on their parent atoms with $U_{iso}(H) = 1.2\ U_{aq}$ (C). Table 1 summarizes the data and information relating to data collection and structure refinement; the fractional atomic coordinates of the compound **1** are given in Table 2 and those of **2** are included in Table 3. The relevant bond distance and bond angle data of compound **1** and **2** are presented in Tables 4 and 5 respectively. The angle between the planes were calculated using a standard program [19].

RESULTS AND DISCUSSION

The ruthenium compounds reported in this study are sufficiently pure and gave satisfactory analytical results. The formula of the neutral, monocationic and dicationic compounds are supported by their respected conductance values. All the complexes are dimagnetic and hence the formal oxidation state of ruthenium in them is +2. ^{1}H NMR spectra of the ligand and metal complexes were recorded in $CDCl_3$. The methyl signal of the ligand (L) at 2.37 ppm is shifted to 3.09 ppm on complexation indicating M—S bond formation. The ill-resolved ^{1}H NMR spectra at 7.00 ppm region is due to the overlapping bands of the phenyl ring protons and the pyridine ring protons. Theoretically two isomers are possible for 6, but only one could be detected by the TLC technique.

Description of the crystal structures

Figure 1 and Fig. 2 (complex cation only) show the ORTEP diagrams of the complexes **1** and **2** respectively along with their atom numbering scheme. The coordination geometry around ruthenium is distorted octahedral and the NNS ligand occupies a meridional plane. The other meridional plane is occupied by the

PPh_3 and two chlorides in **1** and two nitrogen atoms of bipyridyl moiety in **2**. Both the Ru—Cl distances in **1** are somewhat long, but the Ru—Cl(1) bond *trans* to PPh_3 is slightly longer than Ru—Cl(2), due to the greater *trans* effect of phosphorus donor centre over nitrogen. It has been reported [21] that the highest occupied molecular orbital in a thioether is essentially a sulphur 3p orbital which is perpendicular to the SC_2 plane defined by S(2), C(1) and C(3). Thus the Ru—S sigma bond is derived from overlap of a vacant ruthenium $d\sigma$ orbital with the S(3p) HOMO. Hence the strength of Ru—S bond is expected to be maximum when SC_2 plane is perpendicular to the Ru—S bond. One may define [21] X as the mid-point

between C(1)···C(3) vector and the Ru—S—X angle is expected to be 90° for maximum strength of the Ru—S bond. In compound **1** this angle is found to be 87.26° and in compound **2** the corresponding angle is 87.15°. Thus the Ruthenium-thioether bond is expected to be very strong. This is amply reflected in the Ru—S bond length (2.309 in **1** and 2.340 in **2**), which are among the shortest reported for ruthenium-thioether complexes. Compared to that of compound **1** the slight lengthening of the Ru—S bond in **2** may be due to steric repulsion of the bypyridyl ring with the alkyl groups of the thioether ligand. The Ru—P bond lengths are also quite short, indicating pronounced "soft" character of the Ru(II) core, which results in strong back bonding between the metal centre and the phosphine moiety. Again, the slightly longer Ru—P bond in **2** probably arises due to steric effect as well as competition for back bonding between triphenyl phosphine and bipyridyl moiety. For the same reason the Ru—N9 (imine) bond length in **1** (1.988) is shorter than that in **2** (2.025).

IR spectra

Selected IR bands and their assignments are listed in Table 6. A fairly strong band at 1620 cm^{-1}, assigned to ν(CN) vibration of the ligand underwent blue shift due to M—N bond formation in complexes [22]. The ν(CS) bands present at 790 and 760 cm^{-1} in the ligand are lowered by 10–15 cm^{-1} on complexation and point to the formation of M—S bond [23]. The shift of the pyridine ring vibration at 630 and 430 cm^{-1} in all the complexes also indicates that coordination takes place from the pyridine ring nitrogen. In addition, the presence of the broad and strong bands at 1100 cm^{-1} and 850 cm^{-1} in the complexes containing perchlorate and hexafluorophosphate respectively is symptomatic of the ionic nature of these two anions. The strong bands of the free oxalate ion at 1690 cm^{-1} and 1710 cm^{-1} are considerably modified in the corresponding complex **6** pointing to the coordination of the oxalate moiety to the ruthenium(II) centre. The medium intensity ν(Ru—Cl) bands at 315 and 360 cm^{-1} in complex **1** are indicative of the *cis*-disposition of the two coordinated chloride ligands [24].

Electrochemistry

The results of the cyclic voltametric experiments for various Ru(II) complexes are listed in Table 7. Cyclic voltammograms of complex **1** and **2** in acetonitrile and **1** in dichloromethane is shown in Fig. 3. Potential

separations between anodic and cathodic waves, ΔE_p vary between 60 and 90 mV. The peak separations are generally larger than the ideal Nernstian value of 59 mV, but are commonly observed for complexes of this type [2,25], apparently due to uncompensated solution resistance [25]. Plot of peak currents vs the square root of the scan rates are linear, indicating that diffusion-controlled redox processes are occurring at the electrode. The reversible nature of Ru(III)/Ru(II) electron transfer processes is evident from their i_{pc}/i_{pa} ratio of ~1.0. The oxidative response is dominated by a single reversible redox wave corresponding to a Ru(III)/Ru(II) couple. The effect of various parameters on the Ru(III)/Ru(II) couple can be summarized as follows:

(a) $E_{1/2}$(Ru(III)/Ru(II)) values of the neutral complexes $Ru(L)(PPh_3)Cl_2$ (**1**) (0.81 V) and $Ru(L)(PPh_3)(C_2O_4)$(**7**)(E_{pa} = 1.0 V) are lower than that of the monocationic complex **6** (1.19 V) and the dicationic complexes **2, 3, 4** and **5** (~1.50 V) presumably because of their lower formal charge. Similar results were previously observed for other thioether, thiolato [2] and phosphine complexes [26]. It may be noted that redox potential differences between $M^{+1/0}$, $M^{+2/+1}$ and $M^{+3/+2}$ couples are expected simply because the different charge-types lead to different changes in solvation energy for the redox process. The same effect of formal charge is evident if we compare $E_{1/2}$ values of the dicationic thioether complexes $[Ru(L)(PPh_3)(bpy)]^{+2}$ (1.51 V) and $[Ru(L)(PPh_3)(phen)]^{+2}$ (~1.51 V) which are about 0.5 to 0.6 V higher than the corresponding monocationic complexes $[Ru(pabt)(PPh_3)(bpy)]^{+}$ (1.01 V) and $[Ru(pabt)(PPh_3)(Phen)]^{+}$ (1.03 V) (Pabt = demethylated form of L) [27].

(b) On replacing the two chlorides of [Ru(L)(P-

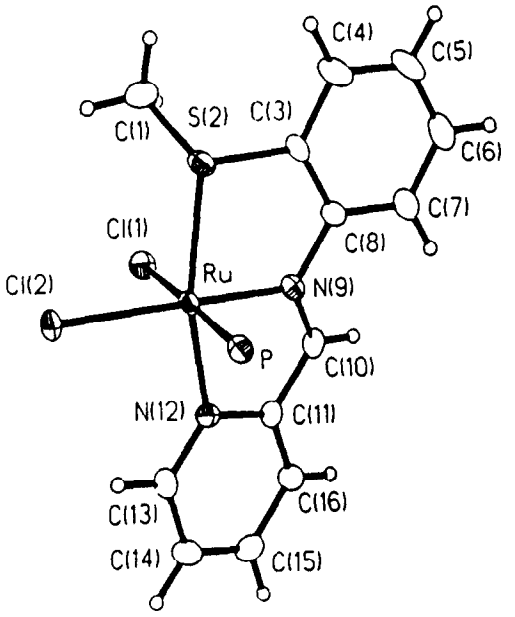

Fig. 1. ORTEP diagram and atom numbering scheme of *cis*-Ru(L)(PPh$_3$)Cl$_2$ (**1**) (the phenyls of the triphenylphosphine ligand have been omitted).

compared to the chloride donors and this is responsible for increase in the $E_{1/2}$ value.

(c) It is interesting to note that the dicationic monothioether complex *cis*-[(bpy)$_2$Ru(PPh$_3$)(S-(CH$_2$CH$_3$)$_2$)]$^{2+}$ exhibits Ru(III)/(II) oxidation [2] at 1.55 V (vs Ag/AgCl) which is almost identical to those of compounds **3** and **5**. This is quite expected, if one assumes that the pyridine-2-aldimino part of the tridentate Schiff base used in this work behaves like a bpy ligand and thus the coordination environment of ruthenium(II) in **3** and **5** is identical to that of [(bpy)$_2$Ru(PPh$_3$)(S(CH$_2$CH$_3$)$_2$)]$^{2+}$ consisting of two bipyridine, one triphenylphosphine and one thioether moiety.

(d) A peak of appreciable current height at 1.11 V present in MeCN solution of **1** disappears in CH$_2$Cl$_2$. This peak is assigned to a solvolysed product of **1** whereby one of the two chlorides is replaced by a MeCN moiety and the resultant species undergoes oxidation at a higher positive potential than the parent complex [28]. It is quite possible that Cl(1) is preferentially replaced by a MeCN molecule due to the greater *trans* effect of PPh$_3$ lying opposite to it. (Λ_M in MeCN of **1** after 12 h standing (R.T.) = 122 ohm^{-1} cm^2 mol^{-1}).

Ph$_3$)Cl$_2$] (**1**) by more electronegative O—O donor to form [Ru(L)(PPh$_3$)(C$_2$O$_4$)] (**7**) the $E_{1/2}$ increases from 0.79 to 1.0 V. The more electronegative oxygen atom increases the effective nuclear charge on the metal

region of the spectra is dominated by strong charge transfer bands responsible for the intense colour of the complexes in the solid state as well as in solution. In the ligand L there are several low lying acceptor orbitals e.g. pyridine π^*, aldimine π^* and low lying vacant *d* orbitals of thioether sulfur. So there may be up to three expected MLCT transitions in the ruthenium complexes of the ligand. Moreover, since all the complexes contain some additional π accepting ligands like triphenylphosphine, bpy or *o*-phen, which themselves contain vacant π^* acceptor orbitals, the actual number of MLCT transitions observed may be much more. Extensive overlapping between these transitions as well as those of the intraligand transitions which, for the free ligand was observed at 363, 251 and 210 nm, make the actual assignment extremely difficult, particularly for the transitions in the UV region. However, the first high intensity band in complex **1** may be reasonably assigned to a $Ru(d\pi) \rightarrow \pi^*(L)$ transition. On substituting the two

CONCLUSION

Apart from the synthesis, characterization and structure determination of two ruthenium(II) complexes of a new NNS chelating thioether ligand, this work clearly demonstrates how determination of structure of a new compound can help to predict its reactivity and to frame synthetic strategies for the preparation of a host of interesting mixed ligand complexes. The *cis* disposition of the two coordinated chloride ion in Ru(L)(PPh$_3$)Cl$_2$ (**1**) pointed to the possible synthesis of heterochelates with different types of bidentate chelating ligands which is realized in this work. It is also demonstrated here that Ru(II) complexes of the thioether ligand 2-pyridyl-N-(2′-methylthiophenyl)-methyleneimine are quite reactive chemically as well as electrochemically.

chlorides by bipyridyl or *o*-phen the first charge transfer band in the visible region exhibits appreciable blue shift, as anticipated. The bands at 280–300 nm are probably due to π–π^* transitions of the ligand and of bipyridyl or *o*-phen moieties [29]. Other bands in the higher energy region may also be assigned to π–π^* and n–π^* transitions of the phenyl, pyridine or bpy/*o*-phen moieties [3].

Additional reactions of inorganic condensed phosphate oligomers during their degradation reactions in the presence of aluminum(III) ions

Genichiro Kura,* Yoshinobu Miyazaki and Jun Sakamoto

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-4192, Japan

(Received 13 October 1997; accepted 2 December 1997)

Abstract—When linear di-, tri-, or tetraphosphate was degraded in the presence of Al^{3+}, in addition to the usual degradation products, phosphates formed which possessed one more PO_4 group than the parent phosphates. This was confirmed by using HPLC. Tetraphosphate produced from the hydrolysis of triphosphate in the presence of Al^{3+} was isolated with the use of an anion-exchange column, and its structure was ascertained by ^{31}P-NMR measurement. Moreover, linear tetra-, penta- and hexaphosphates resulted from the six-membered *cyclo*-triphosphate in the presence of Al^{3+} ions. The yield of the unusual hydrolysis products of the phosphates became maximum when an equimolar amount of Al^{3+} ion was used. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: condensed phosphates; hydrolysis; aluminum(III) ion; HPLC; ^{31}P NMR.

Condensed phosphate oligomers are very interesting polyvalent electrolytes which carry a high charge within their relatively compact molecules [1]. In this group, *cyclo*-polyphosphate anions are relatively weak Brønsted bases in aqueous solutions, and they can exist as high-valent anions [2]. However, they form complexes or ion-pairs with many cations other than tetra-alkylammonium ions [3], and these complexes or ion-pair formations must be considered when their reactions in aqueous solutions are investigated. Linear polyphosphate anions have terminal PO^- groups which are very strong as Brønsted bases [4], and it is necessary to have accurate knowledge of their acid dissociation constants to predict their effect in aqueous solutions. Generally, linear polyphosphate oligomers have a stronger complexibility than cyclic oligomers [5] with the same polymerization degree, though, unlike their cyclic counterpart are highly dependent upon the pH of the aqueous solutions. Moreover, the degradation reactions of P—O—P bonds in the condensed phosphate oligomers must be kept in mind when these entities are used in aqueous solutions. If degradation reactions occur, the chemical properties, especially the complexibilities, of these oligomers vary considerably. It then becomes important to fully understand the nature of the degradation process and the products that result from it.

Both *cyclo*- and linear-polyphosphate oligomers finally decompose to monophosphate [6]. For the last decade the hydrolysis reactions of *cyclo*- and linear-polyphosphate oligomers have been investigated using liquid chromatography. It has been found that in acidic solutions linear oligomers are hydrolyzed faster than cyclic oliogomers, except for *cyclo*-triphosphate [7], and in basic solutions cyclic ones degrade faster [8]; however, the differences in the rate constants of both oligomers in states of the polymerization higher than 6 become smaller, and the degradation rates are also highly dependent upon the cations present [9–12]. When the effect of aluminum(III) ions on the rate of degradation of the oligomers was investigated, it was found that unusual reactions occurred during the degradation reactions [13]. When linear diphosphate was hydrolyzed in the presence of Al^{3+} ions, triphosphate, which has a higher polymerization degree than

* Author to whom correspondence should be addressed.

the parent diphosphate, was found in addition to monophosphate, which is the usual hydrolysis product. Similarly, when tri- and tetraphosphate were degraded in the presence of Al^{3+} ion, tetra- and pentaphosphate, respectively, were found among the hydrolysis products.

In this study, these "unusual reactions" were investigated using HPLC, and the degradation products of triphosphate were separated by the use of an anion-exchange column; tetraphosphate was then isolated from the other degradation products, and its structure was ascertained not only by HPLC but also by ^{31}P NMR spectra measurements. Furthermore, linear tetra-, penta-, and hexaphosphate were found in the degradation products of pure *cyclo*-triphosphate in the presence of Al^{3+} ion. In order to elucidate the mechanism of the new reactions, the ratio of the initial concentration of the condensed phosphate oligomers to that of the Al^{3+} ions was changed, and the relative yields of "degradation products" having an increased degree of polymerization were determined. The yields were consequently highest when the ratio of the concentration of phosphate oligomers to that of Al^{3+} ion was nearly 1 : 1.

These reactions were not observed in the presence of Cu^{2+}, Ni^{2+}, Mg^{2+}, or La^{3+} ions. The reaction mechanism seemed related to the slow exchange of coordinated molecules of the Al^{3+} ion. Since phosphate moieties formed by the cleavage of the P—O—P bond and the parent phosphate are coordinated around the same Al^{3+} ion having relatively long residence times, they can recombine with each other, resulting in the formation of phosphates possessing one more PO_4 group than the parent entity. When *cyclo*-triphosphate is degraded, linear triphosphate as a first degradation product may recombine with linear mono-, di-, and triphosphate, which are the usual degradation products of *cyclo*-triphosphate, thereby producing linear tetra-, penta- and hexaphosphate.

In this paper, *cyclo*- and linear polyphosphates are abbreviated as P_{nm} and P_n, respectively, where n is the number of phosphorus atoms per molecule.

EXPERIMENTAL

Chemicals

Linear di- and triphosphate were of commercial origin and they were recrystallized repeatedly until their purity became satisfactory. Linear tetraphosphate was prepared by the alkaline hydrolysis of sodium *cyclo*-tetraphosphate with NaOH and crystallized as a guanidium salt [14]. Sodium salt of *cyclo*-tri- and *cyclo*-tetraphosphate were prepared following the method described in the literature [15]. The purity of these phosphates was checked by HPLC [16].

Hydrolysis

The initial concentration of diphosphate to be degraded was 2.5×10^{-4} mol/l and the concentration of Al^{3+} ion added was adjusted to 2.5×10^{-4} mol/l. When the concentration of both phosphate and Al^{3+} ion were increased to greater than 2.5×10^{-4} mol/l, a precipitate formed. The initial concentrations of triphosphate samples were 5×10^{-4} mol/l and 2.5×10^{-3} mol/l. The concentration of Al^{3+} ion was varied to achieve a molar ratio ($[Al^{3+}] : [P_3]$) of 1 : 1 or 2 : 1, under which conditions the yield of tetraphosphate formed was measured. The initial concentrations of *cyclo*-triphosphate were 2.5×10^{-4} mol/l or 2.5×10^{-3} mol/l, and the concentration of Al^{3+} to be added were also varied to achieve molar ratios ($[Al^{3+}]$: of 1 : 2, 1 : 1, 2 : 1, 3 : 1, and 5 : 1. The hydrolysis temperature was maintained at 70°C using a thermostat. The hydrolysis samples were then analyzed with an HPLC system devised earlier [16].

Isolation of tetraphosphate in the hydrolysis sample of triphosphate

Tetraphosphate formed from hydrolysis of an equimolar mixture of triphosphate and Al^{3+} ion was isolated with an anion-exchange resin colum. The initial solution contained 3.0×10^{-3} mol/l of triphosphate and Al^{3+} ion, and was hydrolyzed for 5 h at 70°C, after which 10 ml of the sample was passed through the anion-exchange column (ϕ 10 mm × 400 mm) containing Dowex 1-X4 resin (100–200 mesh).

The tetraphosphate was separated with a gradient elution system. The volume of the mixing chamber was 1000 ml, the concentration of KCl solution originally in the mixing chamber was 0.22 mol/l, and the concentration of KCl in the upper reservoir was 0.5 mol/l. The pH of the eluent solution was adjusted to 10.5. The effluent was fractionated with a fraction collector. The fractions which contained tetraphosphate were combined and the tetraphosphate was concentrated to about one-fifth volume with the use of a small amount (0.5 g) of anion-exchange resin. The sample thus isolated was used for HPLC analysis and for NMR measurement, after which the sample was hydrolyzed again at pH 3, 60°C, for 3 h and analyzed with HPLC.

NMR measurement

The ^{31}P NMR spectra were recorded on a JEOL JNM-GSX 500 with a 10 mm multinuclear probe tuned to 202.5 MHz. The NMR parameters were chosen as follows: the flip angle was ca 45° (10 μs), the pulse repetition time was 3 s, and the spectral width was 36 kHz. The chemical shifts were reported with respect to 85% H_3PO_4 as an external reference. A field/frequency lock was achieved with the ^2H resonance of D_2O contained in a 2 mm tube.

RESULTS AND DISCUSSION

In this study triphosphate in the presence of equimolar Al^{3+} ion, 2.5×10^{-3} mol/l, was hydrolyzed at 70°C and pH 3. The chromatograms of its hydrolysis samples are shown in Fig. 1(a). At time 0, trace amounts of mono- and diphosphate were found, though a large portion of the sample remained as triphosphate. After 5 h a significant amount of linear tetraphosphate, never before observed as a hydrolysis product of triphosphate, was found (Fig. 1(b)). This was confirmed by HPLC. Upon isolating this tetraphosphate from the hydrolysis products of triphosphate, it was further examined to reconfirm its identity. A preliminary experiment revealed that linear mono-, di-, tri-, and tetraphosphate can be successively separated from each other by the gradient elution described in the Experimental section. Under these elution conditions, the hydrolysis products of triphosphate which contained tetraphosphate were analyzed, and the chromatograms obtained are shown in Fig. 2. The fractions from 350 to 400 ml were collected, and tetraphosphate as a "hydrolysis product" was isolated. The tetraphosphate thus isolated was chromatographed again, as represented in Fig. 3, and its peak volume agreed with that of standard tetraphosphate synthesized separately. Moreover the tetraphosphate sample was hydrolyzed at pH 3 and at 60°C for 5 h in the absence of Al^{3+} ion. The chromatogram of the hydrolysis products is shown in Fig. 4. The presence of tri-, di-, and monophosphate, the expected hydrolysis products of tetraphosphate, confirmed the identity of the sample.

These facts demonstrate the tetraphosphate was undoubtedly contained in the hydrolysis sample of triphosphate in the presence of Al^{3+} ion. The isolated

tetraphosphate initially contained a large amount of KCl. It was therefore diluted greatly with water and wholly adsorbed with 0.5 g of anion-exchange resin, and eluted with 5 ml of 2 M $(CH_3)_4NCl$. The ^{31}P NMR spectra of the sample solution of tetraphosphate thus concentrated and desalted was measured, as shown in Fig. 5. At -6.53 ppm, a peak due to the end PO^- groups of typical linear polyphosphate, and a peak attributed to the middle PO^- groups at -22.42 ppm were observed. The areas under the two peaks above are almost same, indicating the tetraphosphate structure, which has two end PO^- and two middle PO^- groups.

The experimental results cited above therefore show that when linear triphosphate is degraded under the presence of equimolar Al^{3+} ion, it produces tetraphosphate, even though this product has one more PO_4 unit than its parent.

Next, the chromatograms of the products of *cyclo*-triphosphate hydrolyzed in the presence of equimolar Al^{3+} ion are shown in Fig. 6. Other than the usual hydrolysis products of *cyclo*-triphosphate, appreciable amount of linear tetra-, penta- and hexaphosphate were observed. This may be explained by the degradation of *cyclo*-triphosphate into "active" triphosphate, which would attack mono-, di-, or triphosphate, the usual hydrolysis products of *cyclo*-triphosphate, to form linear tetra-, penta-, or hexaphosphate, respectively.

To consider the mechanism of these unusual reactions, the molar ratio of Al^{3+} ion to be added to the linear phosphates or *cyclo*-triphosphate was varied, and the yield of the polyphosphates which were of polymerization degrees higher than that of parent phosphates was determined. As shown in Table 1, when the molar ratio of Al^{3+} ion to triphosphate or *cyclo*-triphosphate was 1 : 1, the yield became maximum. Moreover, as shown in Tables 1 and 2, the yield increased with the increase in the initial concentration of parent phosphates. If the concentration of Al^{3+} is high compared to that of condensed phosphate oligomers (parent phosphates), the phosphate moieties formed by the degradation are coordinated with the different Al^{3+} ions and thus the probabilities of the recombination reactions between parent phosphates and degradation products may decrease. On the other hand, when the concentration of Al^{3+} ion is lower than that of the parent phosphate, the rate of degradation of the parent phosphates becomes slower, and the probability of the addition reactions might likewise become lower.

(Received 25 August 1997; accepted 2 December 1997)

Abstract—A group of seven complexes of the type *ctc*-$Ru^{II}L_2Cl_2$ (**2a** **2g**) (L = NC_5H_4-N=N-$C_6H_5(R)$, R = H, *o*-Me/Cl, *m*-Me/Cl, *p*-Me/Cl and *ctc* = *cic-trans-cis* with respect to chlorides, pyridine and azo nitrogens, respectively) have been synthesized and characterized. The complexes are diamagnetic (Ru^{II}, t_{2g}^6, S = 0) and electrically neutral. The molecular geometry of the complexes (**2**) in solution has been established by ^1H NMR spectroscopy. They exhibit a strong metal to ligand charge-transfer band in the range 582–603 nm and intra ligand π–π^* transition near 320 nm. In acetonitrile solution the complexes display reversible ruthenium(II) $\rightleftharpoons$ ruthenium(III) oxidation couples in the range 1.02 → 1.36 V vs SCE. Two successive quasi-reversible ligand reductions are observed for each complex in the ranges −0.42 → −0.60 V and −0.68 → −0.85 V vs SCE, respectively. The complexes **2a** and **2e** have been oxidized to the corresponding trivalent species (**3a** and **3e**) by using HNO_3 as oxidizing agent and isolated in solid state as perchlorate salts. Complexes are one-electron paramagnets (Ru^{III}, t_{2g}^5, S = 1/2) and show 1 : 1 conductivity in acetonitrile solution. The presence of perchlorate counter ion in the complexes has been evidenced by the strong infrared bands near 1100 and 600 cm^{-1}. Complexes exhibit a strong ligand to metal charge-transfer band near 530 nm and intra ligand π–π^* transition near 370 nm. In glassy condition (77 K) complexes display rhombic EPR spectra corresponding to the distorted octahedral geometry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; synthesis; spectra; redox.

Selectivity in chemical reactions is one of the primary objectives particularly where the reactions prefer to form multiple products. One example of such kind of reactions is the interaction of ruthenium trichloride salt with the unsymmetrical 2-(arylzao)pyridine (NC_5H_4-N=N-$C_6H_5(R)$, L) ligand. The unsymmetrical nature of L leads to the formation of isomeric dichloro complexes, $[Ru(L)_2Cl_2]$. Out of the expected five isomers of $[Ru(L)_2Cl_2]$ (*ctc*, *ccc*, *ttt*, *cct* and *tcc* with respect to chlorides pyridine and azo nitrogens, respectively) a mixture of three isomeric complexes, *ctc*, *ccc* and *ttt*-$Ru(L)_2Cl_2$ have been obtained from the reaction of ruthenium trichloride with the ligand, L [1]. Extensive chromatographic purifications and further chemical processes are required to get the individual isomeric species from the reaction mixture. In fact almost a week is needed to prepare the thermodynamically end product pure *ctc* isomer [1]. Although *ctc* isomer is found to be an attractive precursor to synthesize various interesting other complexes [2] and itself has shown important reactivities such as oxo-transfer [3], catalysis [4], electrocatalysis [4], electropolymerization [4], aromatic thiolation [5], cleavage of C—S bond of organic molecules [5], there is no direct and convenient method to synthesize this particular *ctc*-isomer. Therefore, there is an obvious need to develop a direct and convenient procedure for the synthesis of the important *ctc*-$Ru(L)_2Cl_2$ isomer.

In this article we would like to report a facile one-pot synthesis of a group of selective *ctc*-$[Ru^{II}(L)_2Cl_2]$ complexes. The complexes have been prepared by

* Author to whom correspondence should be addressed.

reacting the azopyridine ligand, L with the μ-dichloro diruthenium starting complex, $[Cl(CS)(PPh_3)_2Ru^{II}\mu\text{-}(Cl)]_2$, **1**. Their spectroscopic characterization, electron-transfer properties and spectroelectrochemical correlation have been described.

EXPERIMENTAL

Materials

Commercial ruthenium trichloride (S.D. Fine Chemicals, Bombay, India) was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. The starting complex **1** was prepared according to the reported procedure [6]. Other chemicals and solvents were reagent grade and used as received. Silica gel (60–120 mesh) used for chromatography was purchased from S.D. Fine Chemicals, Bombay, India. For spectroscopic and electrochemical studies HPLC grade solvents were used. Tetrabutyl ammonium perchlorate (TBAP) used for electrochemical works was purchased from Aldrich, USA.

Physical measurements

Solution electrical conductivity was checked using Systronic conductivity bridge-305. Electronic spectra (1100–200 nm) were recorded using a Shimadzu UV 160 spectrophotometer. Infrared (4000–300 cm^{-1}) spectra were taken on a Perkin-Elmer 783 spectrophotometer. Magnetic moments were measured with the help of a PAR vibrating—sample magnetometer. ^1H NMR spectra were obtained with the use of a 300 MHz Varian FT-NMR spectrometer. Cyclic voltammetric measurements were carried out using a PAR model 362 scanning potentiostat electrochemistry system. A platinum wire working electrode, a platinum wire auxiliary electrode, and an aqueous saturated calomel reference electrode (SCE) were used in a three electrode configuration. TBAP was the supporting electrolyte and the solute concentration was $\sim 10^{-3}$ M. The half wave potential E^0_{298} was set equal to 0.5 $(E_{pa}+E_{pc})$, where E_{pa} and E_{pc} are anodic and cathodic cyclic voltammetric peak potentials, respectively [7]. The scan rate used was 50 mV s^{-1}. The coulometric experiments were done with a PAR model 370-4 electrochemistry apparatus incorporating 179, digital coulometer. A platinum wire gauze working electrode was used in coulometric experiments. All experiments were carried out under dinitrogen atmosphere and are uncorrected for junction potentials. EPR measurements were made with a Varian model 109 E-line X-band spectrometer fitted with a quartz dewar for measurements at 77 K (liquid nitrogen). The spectra were calibrated by using tetracyanoethylene (TCNE) ($g = 2.0037$). The elemental analyses were carried out with a Carlo Eraba (Italy) elemental analyzer.

Caution! Perchlorate salts of metal complexes are generally explosive. Care should be taken while handling such complexes.

Synthesis of ligands and complexes. The ligands L^1–L^7 were prepared by condensing 2-aminopyridine with the appropriate nitrosobenzene by following the available procedure [8].

The complexes (**2a**–**2g**) were prepared by using a general procedure. Yield varies in the range 65–70%. Specific details are given for one representative complex.

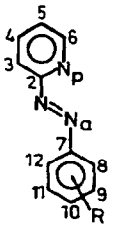
ctc - Bis[2 - (*p-chlorophenylazo*)*pyridine*]*dichloro ruthenium*(*II*), $[Ru(L^7)_2Cl_2]$ (**2g**). The precursor diruthenium complex $[Ru^{II}(CS)(PPh_3)_2Cl_2]_2$, **1** (200 mg, 0.135 mmol) and the ligand 2-(*p*-chlorophenylazo) pyridine, L^7 (118 mg, 0.54 mmol) were dissolved in 15 ml of methanol. The resulting mixture was heated to reflux for a period of 2 h. The initial red brown solution was gradually turned to blue-violet color. The progress of the reaction was monitored periodically by TLC. The solvent was removed under reduced pressure. The crude product was then purified by column chromatography on a silica gel (60–120 mesh) column. Unreacted excess ligand was eluted first with benzene and was rejected. The pure blue colored complex was eluted with 50 : 1 ratio of chloroform and acetonitrile solvents leaving behind a dark band at the top of the column. On removal of the solvent mixture under reduced pressure fine dark crystalline complex $[Ru(L^7)_2Cl_2]$ was obtained. Yield: 102 mg, 70%.

ctc-Bis[2 - (*m-chlorophenylazo*)*pyridine*]*dichloro-ruthenium*(*III*) *perchlorate, monohydrate*, *ctc*-$[Ru(L^5)_2Cl_2]ClO_4 . H_2O$, (**3e**). Finely powdered *ctc*-$[Ru(L^5)_2Cl_2]$ (100 mg) was dissolved in nitric acid. A deep red solution was immediately developed with the evolution of nitrous fumes. The solution was cooled to 273 K and a saturated aqueous solution of sodium perchlorate was added. The deposited dark red solid was filtered off and washed with dilute nitric acid and a small amount of ice-cold water. The oxidized product was then dried in vacuo over P_4O_{10} (yield: 81 mg, 70%).

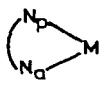
RESULTS AND DISCUSSION

Seven substituted 2-(arylazo) pyridine ligands used are abbreviated as L^1–L^7. The azopyridine ligand binds to the metal ions in a bidentate N_p, N_a manner forming a five membered chelate ring, ML.

During our recent reactivity studies of the dichloro bridged diruthenium complex, $[Ru^{II}Cl_2(CS)(PPh_3)_2]_2$, **1** we had the occasion to conduct the reaction of azopyridine ligands (L) with the **1**. The reaction of L with the metal complex **1** unexpectedly leads to the formation of selective *ctc*-$Ru(L)_2Cl_2$, **2** isomer as a sole product eqn (1). Although the isolation of pure *ctc* isomer **2** by the conventional method takes nearly one week, the pure complex **2** is achieved here within 2 h.



L



ML

$L^1 \rightarrow R = H$

$L^2 \rightarrow R = 8Me$

$L^3 \rightarrow R = 8Cl$

$L^4 \rightarrow R = 9Me$

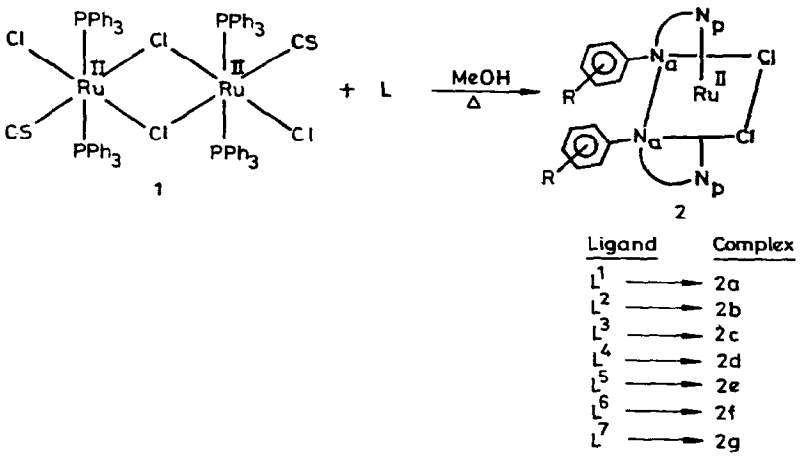
$L^5 \rightarrow R = 9Cl$

$L^6 \rightarrow R = 10Me$

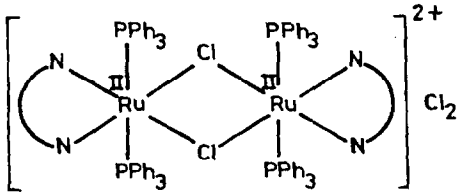
$L^7 \rightarrow R = 10Cl$

The conversion of the complex **1** to **2** involves the cleavage of μ-chloro bonds and the replacement of two phosphines and one thiocarbonyl (CS) group from each of the ruthenium centers by the two azopyridine ligands, L. Under identical reaction conditions the reaction of **1** with the similar strong π-acidic but symmetric N,N donor ligands such as 2,2′-bipyridine and 1,10-phenanthroline result in the dimeric and monomeric complexes, **3** and **4**, respectively [6]. In both the complexes (**3** and **4**) phosphine ligands remain unaffected. Thus the replacement of terminal thiocarbonyl (CS) and chloride groups from each of the ruthenium centers of **1** by the bipyridine molecule facilitates the formation of **3**. In case of incoming phenanthroline ligand dimeric structure of **1** has been lost via the cleavage of μ-Cl bonds. In the present case the situation is more complex, here the complete removal of phosphine from the metal center is an additional step. The removal of bulkier *trans* triphenylphosphines from the $Ru(PPh_3)_2$ core is not a common situation [9]. The driving force of the facile conversion of **1** to **2** is not clear.

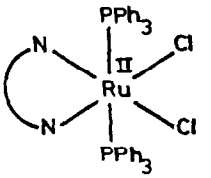
To generalize the reaction we have used a group of seven azopyridine ligands, L^1–L^7 which are varying depending on the nature and the position of the substituents present in the phenyl ring. The complexes **2a** and **2d** were prepared earlier by following the conventional routes and the stereochemistry of the com-



(1)



3



4

plex **2a** was established by single crystal X-ray structure. The ligands L^2, L^3, L^5, L^6, L^7 and their corresponding complexes **2b, 2c, 2e, 2f, 2g** have been prepared first time.

The microanalytical data of the complexes **2** (Table 1) are in good agreement with the calculated values and thus confirming the composition of the complexes, $Ru(L)_2Cl_2$ (**2**). Solid state magnetic moment measurements at 298 K indicate that the complexes are uniformly diamagnetic (t_{2g}^6, S = 0). In acetonitrile, dimethyl formamide and methanol solvents the complexes are non-conducting. Since the spectral properties of the complexes (**2a–2g**) are akin to those of the earlier reported two complexes **2a** and **2d**, it is therefore inferred that all the complexes (**2a–2g**) have very similar isomeric configuration.

Spectral study

I.R. spectra. I.R. spectra of the complexes **2** display several intense bands in the region 4000–300 cm^{-1}. No attempt was made to assign all the bands, however, there are two notable figures: (i) A strong band near 1300 cm^{-1} due to ν(N=N) stretching frequency of the coordinated azopyridine ligand has been observed for all the complexes (Table 1). The N=N stretching frequency of the free L appears near 1425 cm^{-1} [1].

This appreciable lowering of the N=N frequency while moving from the free ligand (L) to the complexes (**2**) is attributed to the presence of strong $d\pi(Ru^{II}) \rightarrow \pi^*(L)$ back bonding in the ground state of ruthenium (II), where $\pi^*(L)$ is the LUMO of the azoimine chromophore [2]. (ii) All the complexes exhibit systematically two bands near 300 cm^{-1} (Table 1) in accordance with the *cis* configuration of the coordinated two chlorides.

^1H NMR spectra. All the complexes display well resolved ^1H NMR spectra in $CDCl_3$ solvent. Chemical shift and spin–spin splitting (among nearest neighbor protons) values are depicted in Table 2. Two representative spectra and schematic representation of inter spectral correlations are shown in Fig. 1. The presence of C_2 symmetry in the *ctc* isomer makes each half of the molecule equivalent. Thus one methyl signal has been observed for the complexes **2b, 2d** and **2f**. Similarly aromatic region of the spectra exhibit calculated number of protons correspond to one particular ligand in accord with the C_2 symmetry of the *ctc* isomer. The individual aromatic proton resonances were assigned (Table 2) on the basis of their relative intensities, spin-spin structure and substituent-induced change in splitting patterns [10]. Chemical shifts are also considered as additional indicators such as 8-H and 12-H are coincident doublets in complex **2a** whereas 8-H signal appears as a separate singlet for the *meta* substituted complexes, **2d** and **2e**. Further, the 8-H singlet is significantly shifted to higher and lower fields in the complexes **2d** and **2e**, respectively, compared to **2a** (Table 2) based on the electron releasing and withdrawing properties of the methyl and chloride substituents, respectively. *Ortho* substituted (**2b, 2c**) and *para* substituted (**2f, 2g**) complexes also show the expected changes in the distributions of the phenyl ring proton signals with respect to the unsubstituted complex (**2a**).

The effect of the specific position of methyl group in the phenyl ring of the complexes **2b, 2d, 2f** has been clearly reflected in the corresponding chemical shifts of the methyl groups (Table 2). The chemical shift of the methyl group follows the order: *o*-Me (**2b**), 2.40 ppm > *p*-Me (**2f**), 2.24 ppm > *m*-Me (**2d**), 2.13 ppm, indicating the effect of nearby electron withdrawing azo group on the *ortho* and *para* methyl groups is more compared to the *meta* methyl group as expected.

Electronic spectra. Solution electronic spectra of the ligands (L^1–L^7) and the complexes (**2a–2g**) were studied in dichloromethane solvent in the range 200–1100 nm. The spectral data are listed in Table 1 and representative spectra are shown in Fig. 2. The azopyridine ligands (L) are exhibiting two bands near 450 nm ($\varepsilon \rightarrow$ in the range of 500–1000) and near 320 nm

($\varepsilon \sim 20{,}000$) (Table 1), these are possibly due to $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions, respectively, centered primarily on the azo group [11]. All the complexes display two major intense bands near 600 nm and 320 nm (Table 1). The lower energy band near 600 nm is associated with a shoulder at the higher energy part near 470 nm. The band near 600 nm is assigned to $d\pi(Ru^{II}) \rightarrow L(\pi^*)$ [where $L(\pi^*)$ is dominated by the LUMO of the azoimine chromophore] MLCT (metal-to-ligand-charge-transfer) transition. Transition of this type are well documented in ruthenium(II) complexes of unsaturated ligands [12]. The band near 320 nm may be due to intra ligand $\pi \rightarrow \pi^*$ transition.

Electron-transfer properties

Metal redox and ligand reductions. All the complexes are electroactive with respect to metal as well as ligand centers. Redox properties of the complexes have been studied in dichloromethane solution by cyclic voltammetry (CV) using a platinum working electrode. All the complexes display the same three redox processes in the potential range ± 1.5 V vs saturated calomel electrode (SCE) (tetrabutyl ammonium perchlorate used as electrolyte, 298 K). Representative voltammograms are shown in Fig. 3. The peak-to-peak separations of the couples lie in the range 80–

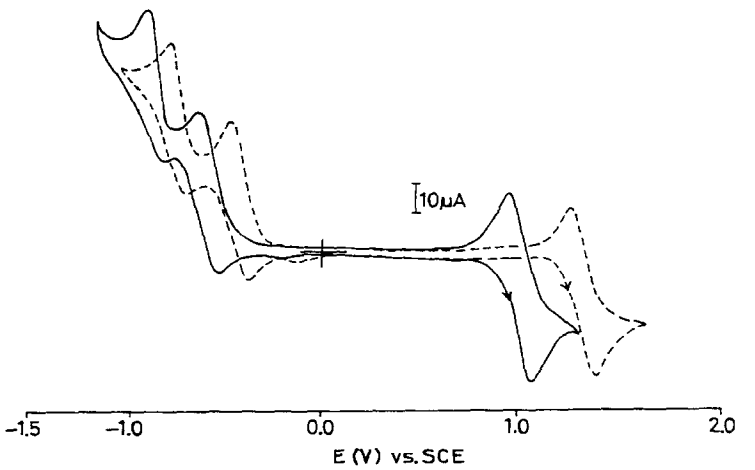

Fig. 3. Cyclic voltammograms of $\sim 10^{-3}$ M solution of the complexes *cis*-$Ru^{II}(L^2)_2Cl_2$, **2b** (—) and *cis*-$Ru^{II}(L^3)_2Cl_2$, **2c** (- - -) in dichloromethane.

110 mV. Reduction potentials data are listed in Table 3.

All the complexes display one reversible oxidative response near 1 V which is assigned to ruthenium(II) to ruthenium(III) oxidation eqn (2). The one-electron nature of the couple eqn (2) was confirmed by constant potential

$$[Ru^{III}(L)_2Cl_2]^+ + e^- \rightleftharpoons Ru^{II}(L)_2Cl_2 \qquad (2)$$

coulometry (Table 3). Here metal oxidation potential varies depending on the nature and the specific location of the substituents present in the phenyl ring of the ligands. The presence of electron donating methyl group in the complexes **2b, 2d, 2f** decreases the metal oxidation potential as compared to the complex **2a** (Table 3). Furthermore, the effect of the position of the methyl group in the ligands has been reflected directly on the metal redox and it follows the order: 1.09 V, *m*-Me (**2d**) > 1.04 V, *p*-Me (**2f**) > 1.02 V, *o*-Me (**2b**). Similarly electron withdrawing chloride group in the complexes **2c, 2e, 2g** increases the metal oxidation potential and depending on the specific position of chloride group in the ligands the metal oxidation potential follows the order: 1.36 V, *o*-Cl (**2c**) > 1.30 V, *p*-Cl (**2g**) > 1.25 V, *m*-Cl (**2e**). Hence, metal oxidation potential can be tuned in the desired direction by introducing specific group in the selective position of the ligand.

All the complexes exhibit two successive quasi-reversible one-electron reductions in the ranges $-0.48 \rightarrow -0.59$ V and $-0.69 \rightarrow -0.85$ V vs SEC, respectively (Fig. 3, Table 3). Azopyridine ligand is a well known potential electron-transfer center and can accept two electrons in one electrochemically accessible LUMO (lowest unoccupied molecular orbital) which is primarily azo in character [13]. Since two electroactive azo groups are present in the complexes **2**, four successive one-electron reductions are therefore expected for each complex. However, in practice we have observed two one-electron reductions cor-

responding to eqns (3) and (4) within the ±1.5 V potential range. The other expected two reductions could not be seen presumably due to solvent cut-off.

$$[Ru^{II}(L)_2Cl_2] + e^- \rightleftharpoons [Ru^{II}(L)(L^{\cdot-})Cl_2]^- \quad (3)$$

$$[Ru^{II}(L)(L^{\cdot-})Cl_2]^- + e^- \rightleftharpoons [Ru^{II}(L^{\cdot-})(L^{\cdot-})Cl_2]^{2-} \quad (4)$$

The reduction potentials of the coordinated ligands systematically vary based on the nature and the position of the substituents present in the ligands (Table 3).

Spectroelectrochemical correlation. The lowest energy metal to ligand charge-transfer (MLCT) bands of the complexes (**2a–2g**) are observed in the range 582–603 nm (Table 1). The reduction potentials of the reversible ruthenium(III)–ruthenium(II) couple and the first ligand reduction (reduction of the azo function) of the complexes have been observed in the ranges 1.02 → 1.36 V and −0.42 → −0.60 V vs SCE, respectively. The lowest energy MLCT transition involves excitation of the electron from the field t_{2g} orbital of ruthenium(II) to the lowest π^* orbital of the azopyridine ligand (dominated by the azoimune, -N=N-C=N- fragment). The energy of the MLCT band for each complex (**2a–2g**) can be predicted from the experimentally observed electrochemical data by considering the following eqns (5)–(6) [14]. Here E^0_{298} (Ru^{II}/Ru^{II}) and E^0_{298} (L) are the formal potentials (in V) of the ruthenium(III)–ruthenium(II) couple and the first

$$\nu_{MLCT} = 8065(\Delta E^0) + 3000 \quad (5)$$

$$\Delta E^0 = E^0_{298}(Ru^{III}/Ru^{II}) - E^0_{298}(L) \quad (6)$$

ligand reduction, respectively. The ν_{MLCT} is the frequency of the lowest energy MLCT transition (in cm^{-1}). The factor 8065 in eqn (5) is used to convert potential difference ΔE from volt to cm^{-1} and the term 3000 cm^{-1} is of empirical origin. The calculated and experimentally observed ν_{MLCT} transition frequencies for all the complexes are listed in Table 3 and there is a linear relationship between the ν_{MLCT} and ΔE (Fig. 4). Here, the calculated values for all the complexes lie within the 900 cm^{-1} of the experimentally observed MLCT energies which are in very good agreement with the previously observed correlations in the other ruthenium complexes [15].

Trivalent ruthenium congener, ctc-$[Ru^{III}(L)_2Cl_2]^+$, **3** *and distortion parameters.* Common oxidizing agents such as ceric ammonium sulfate in $HClO_4$, chlorine gas and hydrogen peroxide cannot oxidize the $[Ru^{II}(L)_2Cl_2]$ (**2**) complexes. However, the strong oxidizing agent, HNO_3 can easily generate the red colored oxidized complexes $[Ru^{III}(L)_2Cl_2]^+$ (**3**) eqn (7).

$$ctc\text{-}[Ru^{II}(L)_2Cl_2] + HNO_3 \rightarrow ctc\text{-}[Ru^{III}(L)_2Cl_2]^+ \quad (7)$$
2 **3**

Oxidized complexes are not stable enough, slowly undergo reductions to the corresponding parent bivalent complexes, $[Ru^{II}(L)_2Cl_2]$ (**2**) both in the solid

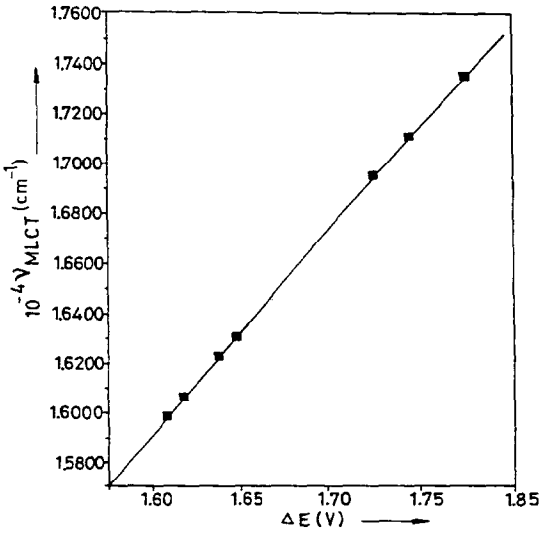

Fig. 4. Least squares plot of the lowest energy metal-to-ligand charge-transfer band (γ_{MLCT}, cm^{-1}) vs the difference in potential (ΔE, V) between the $Ru^{II/III}$ couple and the first ligand reduction.

and solution states. Coulometric oxidations of the complexes (**2**) at a potential 100 mV positive to the corresponding E_{pa} of Ru^{II}/Ru^{III} couple in acetonitrile solution at 273 K produced red-colored oxidized species (**3**). Oxidized complexes (**3**) can be quantitatively reduced to the corresponding bivalent species (**2**) electrochemically or chemically by using ascorbic acid as reducing agent. The presence of trivalent ruthenium in the oxidized solutions has been established by the characteristic rhombic EPR spectra of the oxidized complexes in chloroform solvent at 77 K (liquid nitrogen) [16]. Although all the complexes (**2**) behave equally on oxidation, two particular oxidized complexes **3a** and **3e** have been isolated in pure solid state as monohydrated perchlorate salts and characterized. Microanalytical data of the complexes (**3**) are in good agreement with the calculated values (Table 1). Both the complexes show 1 : 1 conductivity in acetonitrile solvent (Table 4). Solid state magnetic moment measurements indicate that the complexes are one-electron paramagnates (low-spin Ru^{III}, t_{2g}^5, $S = 1/2$) (Table 4). There is 1 : 1 correspondence in the IR bands of the oxidized complexes, $[Ru^{III}(L)_2Cl_2]ClO_4 \cdot H_2O$ and their corresponding bivalent analogues, $[Ru^{II}(L)_2Cl_2]$ except the former show additional bands due to the lattice water (3400 cm^{-1}) and ionic perchlorate (1100 and 630 cm^{-1}). The azo stretching frequency and the Ru–Cl stretching frequencies are found to be shifted to higher energy in the trivalent complexes (Table 1) [17]. Electronic spectra of the complexes were recorded in dichloromethane solvent and the values are shown in Table 1. In the visible region the complexes exhibit one intense band near 530 nm with a shoulder at the lower energy part. The intense visible band near 530 nm is assigned to ligand to metal charge-transfer (LMCT) transition [18]. In the UV region the complexes show ligand based transition near 370 nm. One-electron paramagnetic trivalent ruthenium complexes (**3**) exhibit rhombic EPR spectra in glassy condition (77 K) (Fig. 5) due to the molecular distortion (EPR g values are listed in Table 4).

CONCLUSIONS

We have thus observed an unusual but facile synthetic method for the preferential formation of *ctc*-$Ru(L)_2Cl_2$ isomer, which is conveniently a multistep and cumbersome procedure. Systematic variation of the substituents in the ligand has been directly reflected in the spectral and redox properties of the complexes. It shows that both the nature and the respective location of the substituents in the ligand frame play the crucial role to tune the redox stability of the metal ion in the complexes.

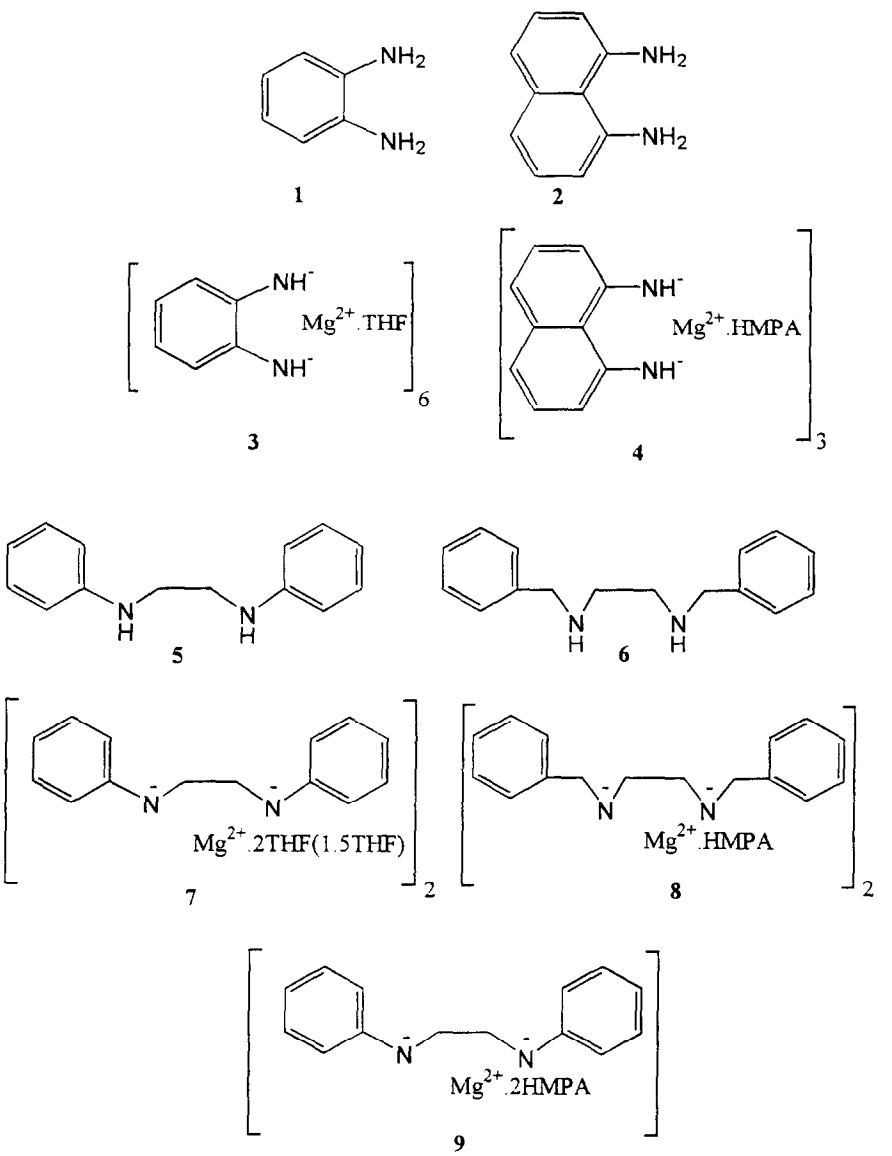
(Received 10 October 1997; accepted 28 November 1997)

Abstract—Three new magnesium diamide complexes have been prepared by treating the diamine precursors *N,N'*-diphenylethylenediamine or *N,N'*-dibenzylethylenediamine with the commercial reagent dibutylmagnesium in the presence of a donor solvent (THF or HMPA). Their crystal structures have been determined. Both $[\{MgN(Ph)CH_2CH_2N(Ph)\cdot 2THF(1.5\ THF)\}_2]$ and $[\{MgN(CH_2Ph)CH_2CH_2N(CH_2Ph)\cdot HMPA\}_2]$ adopt dimeric arrangements based on *trans*-5.4.5-fused ring systems. The former structure is distinctive and noteworthy for exhibiting a five-coordinate, distorted trigonal bipyramidal Mg centre, instead of the more usual four-coordinate, distorted tetrahedral geometry found in the latter structure. Replacing the two THF ligands of the former structure by two HMPA molecules leads to deaggregation, in the form of the monomeric complex $[MgN(Ph)CH_2CH_2N(Ph)\cdot 2HMPA]$, which also displays an unremarkable distorted tetrahedral Mg coordination. Comparisons are made with other dimeric and monomeric, magnesium amide and related complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: chelates; crystal structure; diamides; magnesium.

Recently we have shown that it is possible to construct unusual three-dimensional magnesium–nitrogen bonded cage architectures by doubly deprotonating the primary diamine precursors **1** and **2**. Thus, THF solvate **3** is hexameric with an interpenetrated Mg_6/N_{12} octahedral/cuboctahedral arrangement [1], and HMPA solvate **4** is trimeric with a Mg_3 equilateral triangle encapsulated within a N_6 trigonal prism [2]. A key condition for such cage construction is that the steric bulk of the metal binding sites of these bifunctional dianions must be small; hence, the presence of the hydrogen atom in the "$[RN(H)^-]$" moieties is thought to be critical. Even methyl substituents appear to be too sterically demanding to permit cage formation. Methyl analogues of **3** and **4** are not available for direct comparison, but a close analogy exists in the alkylamide $[\{MeMgN(Me)CH_2CH_2NMe_2\}_2]$, one of the earliest reported magnesium amide crystal structures [3], which adopts a (non-cage) dimeric structure based on a planar $(MgN)_2$ ring with additional Mg—N and Mg—C terminal bonds that complete the distorted tetrahedral metal geometry. We therefore expected to form structures of this more conventional type, either dimeric or monomeric depending on the degree of solvation, when extending our magnesiation studies to *N,N'*-diphenylethylenediamine, **5** and *N,N'*-dibenzylethylenediamine, **6**, i.e. secondary diamine precursors with greater steric requirements than the aforementioned primary systems. As reported herein, whilst our expectations have been realised through the synthesis and crystallographic characterisations of the dimers **7** and **8**, and monomer **9**, surprising features have nevertheless emerged. Most significantly, the Mg centres in dimeric **7**, depart from the normal four-coordination [4]: unusually, the four-membered $(MgN)_2$ ring is tetrasolvated by tetrahydrofuran (THF) ligands, thus lead-

* Author to whom correspondence should be addressed.



ing to a higher five-coordinate Mg geometry. Also, although structures **7** and **9** involve the same dianion and have equal numbers of solvent molecules attached to their Mg centres, they differ in terms of aggregation number *n* (i.e. 2 and 1 respectively). This provides an interesting contrast with the recently reported THF and hexamethylphosphoramide (HMPA) 1 : 1 solvates of magnesium bis(dibenzylamide), $[\{Mg[N(CH_2Ph)_2]_2 \cdot THF\}_2]$ and $[\{Mg[N(CH_2Ph)_2]_2 \cdot HMPA\}_2]$, both of which are dimeric [5].

RESULTS AND DISCUSSION

Synthesis and characterisation

Double deprotonation of the precursor diamines was achieved using the commercial reagent dibutylmagnesium (which contains a statistical mixture of Bu^n and Bu^s groups), by the general reaction shown in eqn (1). The reactions were facile, and complete by the time the chilled solutions reached room temperature.

$$Bu_2Mg + RN(H)CH_2CH_2N(H)R \rightarrow \text{“}[Mg(RNCH_2CH_2NR)]\text{”} + 2BuH \quad (1)$$

In each case an excess of donor solvent was needed to completely dissolve the precipitate initially formed by this magnesium-hydrogen exchange process. Approximately three and five-molar equivalents of HMPA proved sufficient in the preparation of **8** and **9**, respectively. However, it required nearly seventy molar equivalents of the weaker donor THF to accomplish the same task in the case of **7**. This there-

fore denied the opportunity for any stoichiometric control of the degree of solvation [cf, the aforementioned magnesium bis(dibenzylamide) system [5], where, in contrast, mono- and bis-solvates are isolable]. The crystalline solids isolated from solution are each solvated to a different extent. Benzyl-substituted **8** contains one HMPA ligand per metal centre, while phenyl analogue **9** contains two. In the THF solvate **7**, two solvent molecules directly bind to the Mg centre, but there are also additional THF molecules of crystallisation (three for every dimeric molecule) throughout the lattice. The empirical formula of each new compound was confirmed by running ^{1}H NMR spectra in DMSO solution (see Experimental section). A full spectroscopic investigation is planned for a future study. Note that the compounds possess extremely limited solubility in arene solvents.

Attempts to make a THF analogue of **8** to complete the series of solvates proved unsuccessful. As in the preparation of **7**, the precipitate formed initially upon magnesiation of the diamine could only be dissolved (with difficulty) in a large volume of THF. No solid product could then be coaxed from the resulting solution despite prolonged cooling at low temperature. Repeating the attempted preparation in an alternative THF/HMPA solvent mixture afforded, as expected, only the THF-free crystalline HMPA solvate **8**.

X-ray crystallographic studies

The molecular structures of dimers **7** and **8** (Figs 1 and 2, respectively) share similar characteristics. Both

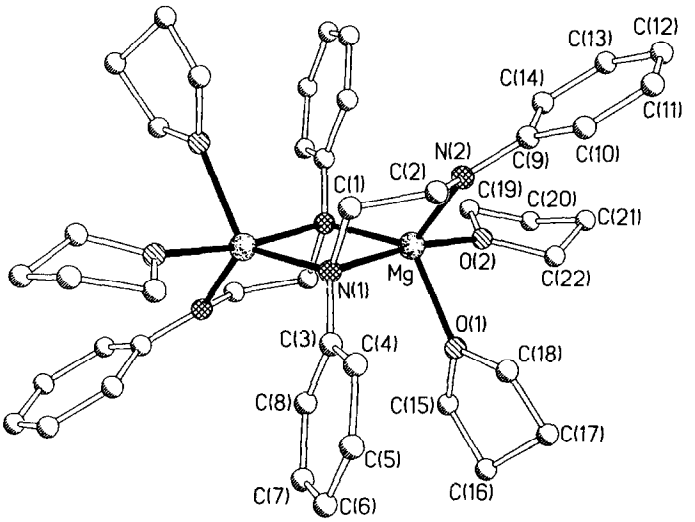


Fig. 1. Molecular structure of **7** showing atom-labelling scheme. Hydrogen atoms, minor disorder components, and THF molecules of crystallisation are omitted.

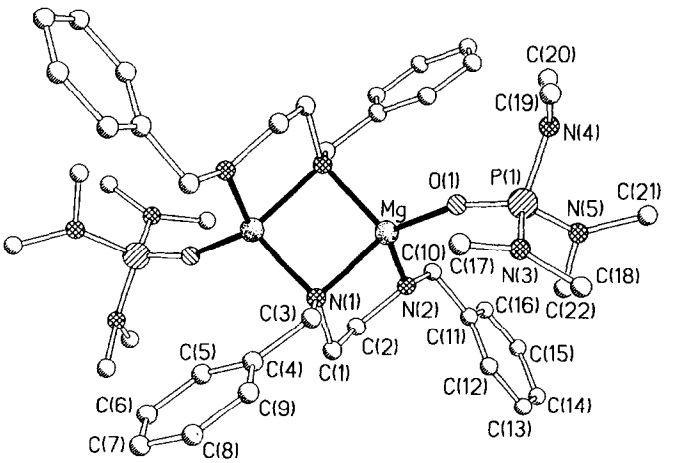

Fig. 2. Molecular structure of **8** showing atom-labelling scheme. Hydrogen atoms are omitted.

are centrosymmetric, with a planar rhomboidal $(MgN)_2$ cyclic ring. Two five-membered MgNCCN chelate rings, arising from the ligation of the second N anion of the diamide [N(2)], lie on opposite sides of this central ring to complete a *trans*-5.4.5-fused ring system. The ladder-like frameworks fashioned by the fusing of the three rings are subtly different: the non-planar MgNCCN chelate rings have an envelope-type appearance with the flap at the C(2) apex; with respect to the central ring, this flap is positioned *exo* in **7** (Fig. 3), but *endo* in **8** (Fig. 4). Steric interferences of the additional atoms (i.e. of a methylene group) within the amido substituent of **8** are minimised by the switch to an *endo* conformation. A more conspicious distinction exists between the two structures: each Mg centre is bis-solvated (by THF) in **7**, and mono-solvated (by HMPA) in **8**. Concomitantly, the metal coordination geometry is distorted trigonal bipyramidal [axial atoms, N(1) and O(2)] in **7**, and distorted tetrahedral in **8**. Five-coordination is rare for Mg in amide crystal structures. At the time of writing, there is no other magnesium amide dimer in the Cambridge Crystallographic Database [6] which exhibits this high coordination number. Commonly, such structures have a steric preference for four-coordinate Mg geometries as illustrated by the alkyl (amide) $[\{Bu^nMgN(CH_2CH_2NMe_2)CH_2Ph\}_2]$ [7], which also features a *trans*-5.4.5-fused ring system with *endo* C flaps (note the presence of the benzyl substituent) like that in **8**. The architectures of the cage structures of **3** and **4**, discussed in the Introduction, do allow for the higher coordination state; however, in contrast to that in **7**, the five ligating atoms are arranged in a distorted square-based pyramidal geometry.

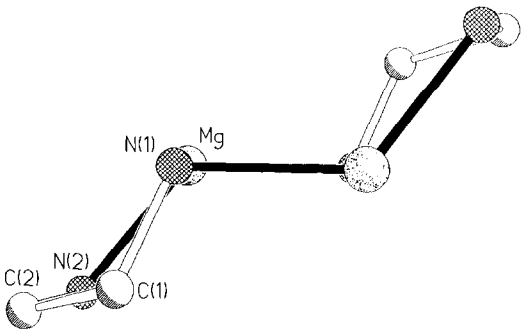

Fig. 3. *trans*-5.4.5-fused ring system of **7** showing *exo* orientation of C(2) atom.

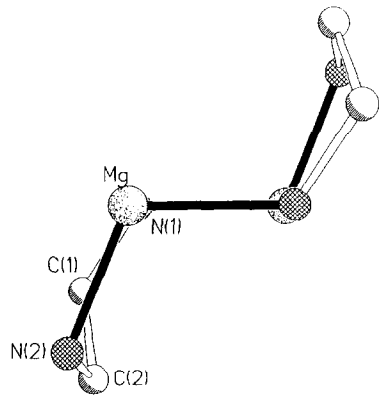

Fig. 4. *trans*-5.4.5-fused ring system of **8** showing *endo* orientation of C(2) atom.

Tables 1 and 2 give individual bond lengths and bond angles for **7** and **8** respectively, while Table 3 compares a selection of them with those in related 5.4.5-fused ring systems. It is immediately obvious from this comparative data that the steric constraints placed on the structures by the fusing of the three rings causes dimensions, in general, to be similar. Illustrating this point, the two sets of Mg—N bonds in the central $(MgN)_2$ rings tend to be non-equivalent, and their lengths show little variation throughout the series (range, 2.077–2.290 Å). Also, the bite angles of the diamine ligands [N(1)MgN(2)] cover a narrow range (84.22–87.83°). In four of the structures the endocyclic bond angles within the central $(MgN)_2$ rings follow the same pattern: acute at N and obtuse at Mg, but close to 90° (mean values, 87.06 and 92.94°). Out of line is structure **7** which displays sharper Mg corners [value, 87.64(8)° cf 92.36(8)° at N]. This anomaly is an effect of the unique five-coor-

N—Mg—N bite angle	84.22	87.83	87.8	83.36/83.97	84.6

10 = $[\{MeMgN(Me)CH_2CH_2NMe_2\}_2]$; **11** = $[\{Mg[N(SiMe_3)C_6H_4N(SiMe_3)\text{-}o](OEt_2)\}_2]$; **12** = $[\{Bu^nMgN(CH_2CH_2NMe_2)CH_2Ph\}_2]$.

dination at this atom, with these corners representing axial-equatorial bond angles. Turning to the chelate outer-rings, where the N centres of the rings are anionic (in **7**, **8**, and $[\{Mg[N(SiMe_3)C_6H_4N(SiMe_3)\text{-}o](OEt_2)\}_2]$ [8]), their bonds to Mg are significantly shorter than those in the central rings, reflecting their terminal, sp^2 nature (cf sp^3 nature of the bridging N centres). The reverse is true in the other two structures (i.e. the terminal Mg—N bonds are longer), as these are dative bonds involving neutral, sp^3 N centres. A further point of interest, pertaining to **7** only, is that the two Mg—O (THF) bonds have different lengths in keeping with the asymmetrical character of the $(MgN)_2$ cyclic core: the equatorial one involving O(1) is 0.084 Å shorter than the axial one involving O(2). The stronger oxygen-donor HMPA found in **8** forms the shortest Mg—O bond (by 0.145 Å) of the dimer series.

Two crystallographically independent monomers of nearly identical molecular structure were found in the unit cell of **9**. For brevity, only one monomer is shown in Fig. 5; but dimensions for both are listed in Table 4. Comparing this data with that of **7** which involves the same dianion reveals that the metal-diamide attachment is shorter (mean Mg—N bond length, 2.023 Å) and more symmetrical in the monomer. The bite angle of the chelating ligand is also slightly wider in **9** (mean value, 87.02°). To prevent eclipsing of the methylene units in **9** there is a twist in the NC $(H)_2C(H)_2N$ bridge (e.g. N—C—C—N torsion angles 46.1° and 44.5° in the two molecules), which forces the attached Ph rings out of co-planarity (dihedral angles 36.9° and 35.8°). The distorted tetrahedral coordination of the Mg centre is completed by two HMPA ligands, which engage in Mg—O bonds of nearly equivalent length, the mean value of which (1.943 Å) is within the error limits of the corresponding bond in the mono-solvated dimer **8**. In **9** the two HMPA molecules are separated by a mean OMgO angle of 100.12°; the mean NMgO angle is considerably larger at 117.75°. Similar dimensions (mean Mg—O bond length, 1.973 Å; O—Mg—O bond angle, 102.9°) to those in **9** are found in the previously reported bis-HMPA-solvated magnesium amide monomer $[Mg\{N(H)Mes\}_2\cdot(HMPA)_2]$ (Mes = 2,4,6-$Me_3C_6H_2$-), as the steric influence of the bulky aryl group is moderated by the fact that the second substituent is a hydrogen atom [9].

A number of other monomeric, magnesium amide and related complexes have been reported. Most exhibit distorted tetrahedral Mg coordination [10–15]. The structure of $[Mg\{N(SiMe_3)_2\}_2\cdot 2THF]$ [16], which has a mean Mg—N bond length of 2.021 Å, is representative of this four-coordinate type. There are, however, particularly interesting examples where the metal centre has a lower or higher coordination

number. In the former category is the two-coordinate silylamide $[Mg\{N(SiMePh_2)_2\}_2]$ [17], notable for its lack of donor ligands, which has a near-linear N—Mg—N geometry (angle, 162.8°) with short bonds (mean length, 1.966 Å). At the opposite extreme is the hypercoordinated iminoaminosulfinate $[Mg\{(Me_3SiN)_2SPh\}_2 \cdot (THF)]$ which possesses four long Mg—N bonds (mean length, 2.142 Å) and one Mg—O(THF) bond [18]: note that five-coordination is made possible here, as in the aforementioned cage complexes **3** and **4**, by the bidentate (*N,N'*) nature of the ligand, though in this case the ligand is monoanionic, not dianionic.

Finally, for completeness, it should be pointed out that the lithium analogue of **9** is available for comparison [19]. An earlier X-ray crystallographic study revealed it to be the monomeric, dinuclear sesqui-HMPA solvate ($PhLiNCH_2CH_2NLiPh \cdot 3HMPA$). Its salient feature is an N_2Li_2 double bridge, reminiscent of the C_2Li_2 "ion-triplet" structures encountered in many dilithiated hydrocarbons [20,21]. The double bridging of two Li^+ cations and one $(N \cdots N)^{2-}$ dianion is electrostatically favoured as it sets up four attractive contacts at the expense of only two repulsive ones. In this diamide system, there can be no equivalent Mg structure on account of the formal 2+ charge on the alkaline-earth metal cation; hence, **9** adopts the simpler single ion-pair arrangement.

EXPERIMENTAL

Syntheses

All reactions were performed in conventional Schlenk apparatus under a protective atmosphere of dry, oxygen-free argon gas.

Compound **7**. A commercial solution of dibutylmagnesium (10 mmol in heptane: purchased from Aldrich) was added via syringe to a chilled solution of *N,N'*-diphenylethylenediamine (10 mmol) in THF (20 ml). Warming the mixture to room temperature gave a cream-coloured precipitate, which was dissolved by the introduction of further THF (40 ml) and on heating to 50°C. Only microcrystalline solid was deposited on cooling this solution, so more THF

(20 ml) was added and the mixture was rewarmed. Allowing the solution to cool to room temperature over twenty-four hours produced colourless needle crystals of **7**. These crystals quickly turn green on the surface when isolated. Yield: 2.01g (20.7%). M.p. 102–104°C. Elemental analyses; Found: C, 69.0; H, 8.2; N, 6.1; Mg, 4.3. Calc. for $C_{56}H_{84}N_4Mg_2O_7$; C, 69.2; H, 8.7; N, 5.8; Mg, 4.9; O, 11.5%. ^{1}H NMR (400 MHz, DMSO-d_6, 25°C) δ 1.77 (t, CH_2 of THF), 3.20 (s, CH_2), 3.61 (t, OCH_2 of THF), 6.53 (m, *p*Ph), 6.58 (m, *o*Ph), 7.07 (m, *m*Ph).

Compound **8**. Dibutylmagnesium (10 mmol in heptane) was added dropwise to neat *N,N'*-dibenzylethylenediamine (10 mmol) which had been cooled beforehand. An off-white precipitate formed on stirring. The heptane solvent was removed *in vacuo* and replaced by toluene (10 ml). Despite vigorous heating complete dissolution could not be achieved, so HMPA was added in small aliquots until this occurred (total amount added, 30 mmol). Hexane (2 ml) was also added since it was found to aid the crystallisation process. Cooling of the solution to −5°C afforded a large crop of colourless crystals of **8**. These crystals turn brown and become sticky on isolation, and thus their melting point could not be obtained. Yield: 0.57g (36.5%). Elemental analyses; Found C, 58.7; H, 8.5; N, 15.3; Mg, 5.1. Calc. for $C_{22}H_{36}N_5Mg_1O_1P_1$; C, 59.8; H, 8.2; N, 15.9; Mg, 5.5; O, 3.6; P, 7.0%. ^{1}H NMR (400 MHz, DMSO-d_6, 25°C) δ 2.52 (d, HMPA), 2.57 (s, CH_2CH_2), 3.65 (s, CH_2), 7.21 (m, *p*Ph), 7.28 (m, *o*/*m*Ph).

Compound **9**. Dibutylmagnesium (10 mmol in heptane) was added dropwise to a chilled hexane suspension of *N,N'*-diphenylethylenediamine (10 mmol). A mildly exothermic reaction ensued producing an amorphous solid. Neither the addition of THF (10 ml) or of pyridine (10 ml) could dissolve this solid. To the pyridine mixture was added HMPA (8 ml). This gave a brown solution initially, before rapidly precipitating a solid. Pale brown/colourless needle crystals of **9** were obtained on recrystallising this solid by adding a toluene/HMPA (5 ml/1 ml) mixture. Yield: 2.55g (43.0%). M.p. 195°C (decomp.) Elemental analyses; Found C, 52.2; H, 7.5; N, 19.3; Mg, 3.4. Calc. for $C_{26}H_{50}N_8Mg_1O_2P_2$; C, 52.7; H, 8.4; N, 18.9; Mg, 4.1; O, 5.4; P, 10.5%. ^{1}H NMR (400 MHz, DMSO-d_6, 25°C) δ 2.49 (d, HMPA), 3.17 (s, CH_2CH_2), 6.50 (t, *p*Ph), 6.55 (d, *o*Ph), 7.04 (t, *m*Ph).

Elemental analysis was carried out using a Perkin-Elmer 2400 elemental analyser and magnesium analysis was performed by atomic absorption using a PU9100 Philips spectrometer.

X-ray crystallography

Crystal data for **7, 8** and **9,** are shown in Table 5, together with information on data collection and structure determination procedures. Measurements for 7 and **8** were at 160 K on a Siemens SMART CCD diffractometer. Cell parameters were refined from the observed ω angles of all strong reflections in each complete data set, which was recorded with frames of 0.3° in ω. Measurements for **9** were made at 160 K on a Stoe-Siemens four-circle diffractometer. Cell parameters were refined from 2θ values of 31 reflections (20–23°) measured at $\pm\omega$ to minimise systematic errors. Intensities were measured with profile-fitted ω/θ scans [22]. No absorption corrections were applied.

The structures were solved by direct methods, and refined by full-matrix least squares on F^2, with weighting $W^{-1} = \sigma^2(F_o^2) + (aP)^2 + (bP)$, where $P = (F_o^2 + 2F_c^2)/3$ [23]. An isotropic extinction coefficient x was refined, whereby $F_c' = F_c/(1 + 0.001xFc^2\lambda^3/\sin 2\theta)^{1/4}$.

Anisotropic displacement parameters were refined for all non-hydrogen atoms while hydrogen atoms were included with riding model constraints. For **7** two-fold disorder was resolved for one coordinated THF and for an uncoordinated THF molecule across a two-fold rotation axis, and was refined with the assistance of geometrical restraints. For the uncoordinated THF molecules, oxygen and carbon atoms could not be distinguished, and hydrogen atoms were not included. The residuals are defined as $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)]/\Sigma[w(F_o^2)^2]\}^{1/2}$ for all data, conventional $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ for reflections having $F_o^2 > 2\sigma(F_o^2)$; the goodness of fit is calculated on F^2 for all data. Programs: standard Siemens SMART and Stoe DIF4 control software. Siemens SAINT area-detector frame integration, SHELXTL [23], and local programs.

Complete bond lengths and angles, coordinates and displacement parameters have been deposited at the Cambridge Crystallographic Data Centre. (See Information for Authors, Issue No. 1).

(Received 4 August 1997; accepted 26 November 1997)

Abstract—1,2-Propanediamine monohydroperchlorate reacts with acetone to give the dihydroperchlorate salt of 3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetra-azacyclotetradeca-4,11-diene, $Me_8[14]dieneN_4$. The reaction is stereospecific giving only the 3,10-C-*meso* diastereoisomer (L_I). Reduction of L_I with $NaBH_4$ in methanol–water solution gives three isomeric $Me_8[14]aneN_4$ ligands (L_A, L_B and L_C). These saturated macrocycles give green *trans*-$[CrLCl_2]^+$ complexes which have been characterised by infrared and visible spectra. The red chloroaqua complexes *trans*-$[CrL(OH_2)Cl]Cl_2 \cdot H_2O \cdot H_2SO_4$ have also been prepared and characterised. The aquation of the dichloro-complexes to the chloro–aqua derivatives has been studied kinetically over a temperature range and rate constants (k_{aq}) and activation parameters are reported. The substantial negative values of $\Delta S^{\ddagger}$ observed are consistent with an associative I_a mechanism. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tetraaza macrocycle; alkyl substitution; chromium(III); aquation kinetics.

Reduction of $Me_8[14]dieneN_4$ (L_I) with sodium borohydride in methanol–water gives three diastereoisomeric $Me_8[14]aneN_4$ macrocycles (L_A, L_B and L_C) [1], Scheme. The 3,10-C-*meso* configuration of the parent diene has been established on the basis of ^1H NMR spectra [2,3] and confirmed by X-ray crystallography on the nickel(II) complex [2]. The three diastereoisomeric $Me_8[14]aneN_4$ macrocycles can be separated by fractional crystallisation from xylene [1]. Structures have been assigned on the basis of ^1H and ^{13}C NMR spectra and the configuration of L_B confirmed by X-ray crystallography [1]. The preparation of the *trans*-$[Co(Me_8[14]aneN_4)Cl_2]ClO_4$ complexes and the crystal structure of *trans*-$[CoL_ACl_2]ClO_4$ have been described [4]. The present paper deals with the preparation of the $[CrLCl_2]^+$ complexes and the determination of their aquation rates.

EXPERIMENTAL

Synthesis

3,10-C-*meso*-3,5,7,7,10,12,14,14-Octamethyl-1,4,8,11-tetra-azacyclotetradeca-4,11-diene dihydroperchlorate ($Me_8[14]dieneN_4 \cdot 2HClO_4$) was prepared as follows. 1,2-Diaminopropane (74 cm^3, 1 mol) was dissolved in acetone (500 cm^3) and cooled in an ice-salt bath. Perchloric acid (99 cm^3, 70%, 1 mol) was added dropwise with continuous stirring. An orange colour developed in the solution. After the addition of the perchloric acid was completed the mixture was stirred at room temperature for ca 4 h until precipitation began. After standing overnight at room temperature, the fine white crystalline product was removed by filtration, washed with ethanol, then ether and dried *in vacuo*.

CAUTION! perchlorate salts of amines are hazardous materials and should not be heated. They can detonate with great violence.

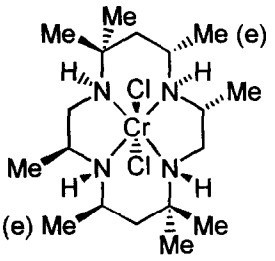
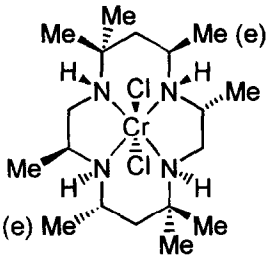
(3) L_A complex



(4) L_B complex



(5) L_C complex

Reduction of 3,10-C-*meso*-Me_8[14]dieneN$_4$·$2HClO_4$ with $NaBH_4$ in 1 : 1 water–methanol was carried out essentially as previously described and the diastereoisomers L_A, L_B and L_C separated by crystallisation from xylene [1]. The ligand L_A is insoluble in hot xylene and has m.p. 350°C (decomp.). L_B the first fraction from xylene was recrystallised from ether, m.p. 122°C. L_C was obtained as cubic crystals as the last fraction from xylene and was also recrystallised from ether, m.p. 85°C.

The complex *trans*-$[CrL_ACl_2]Cl \cdot 2H_2O \cdot HCl$ was prepared as follows. A suspension of L_A (0.20 g, 0.64 mmol) in DMF (3 cm^3) was added to a solution of $CrCl_3 \cdot 6H_2O$ (0.17 g, 0.64 mmol) in DMF (3 cm^3) which had been previously boiled for 10 min. for dehydration. The reaction mixture was refluxed for 30 min. before being filtered warm. The DMF was then removed by gentle boiling to give a green solid, which was dissolved in hot dilute HCl (5 cm^3). The solution was filtered and conc. HCl (3 cm^3) added. On standing at 4°C for several days green crystals formed, which were filtered off, washed with a 1 : 1 ethanol/diethyl ether mixture and dried *in vacuo*. Yield 0.11 g (39%). (Found: C, 40.3; H, 8.6; N, 10.4. Calc. for $C_{18}H_{45}Cl_4CrN_4O_2$: C, 39.8; N, 8.4; N, 10.3%). IR ν H_2O 3369; ν NH 3202 cm^{-1}.

The ligands L_B and L_C are much more soluble in DMF than L_A. As a result, on mixing DMF solutions of the ligands (0.20 g, 0.64 mmol) and $CrCl_3 \cdot 6H_2O$ (0.17 g, 0.64 mmol) the reaction was complete after 15 min. at a reaction temperature of 100°C. The macrocyclic chromium(III) complexes were isolated and recrystallised as described above for *trans*-$[CrL_ACl_2]^+$. Yields 0.21 g (75%) for *trans*-

The red *trans*-$[CrLCl(OH_2)]Cl_2 \cdot H_2O \cdot H_2SO_4$ complexes (L = L_A, L_B or L_C) were prepared by dissolving the dichloro-complexes in 0.05 mol dm^{-3} H_2SO_4. On standing at room temperature for several weeks, red crystalline solids deposited. These solids were filtered off, washed with ethanol then diethyl ether and dried *in vacuo*. (Found (L_A): C, 35.3; H, 7.2; N, 10.2. Found (L_B): C, 35.2; N, 7.4; N, 8.8. Found (L_C): C, 35.1; N, 7.25; N, 8.85. Calc. for $C_{18}H_{46}Cl_3CrN_4O_6S$: C, 35.7; H, 7.7; N, 9.26. IR for L_A ν H_2O 3455; ν NH 3202; ν SO_4^{2-} 1162, 1132, 600 cm^{-1}. For L_B ν H_2O 3400; ν NH 3205, 3125; ν SO_4^{2-} 1170, 1140. For L_C ν H_2O 3479; ν NH 3208, 3104; ν SO_4^{2-} 1158, 1134, 603 cm^{-1}.

The dihydroxo complexes were prepared by dissolving the dichloro complexes in 0.1 mol dm^{-3} sodium hydroxide solution. The diaqua complexes were prepared by acidification of the dihydroxo complexes with 1 mol dm^{-3} nitric acid (one drop was normally sufficient). The UV-visible spectra of the complexes are summarised in Table 1.

Measurements

Infrared spectra were recorded as KBr discs on a Shimadzu IR-435 instrument. Electronic absorption spectra were obtained using a Perkin–Elmer Lambda 5 spectrophotometer.

Kinetics

Loss of the first chloro ligand was monitored spectrophotometrically. Measurements were made using 0.05 mol dm^{-3} solutions of sulphuric acid ($I = 0.05$ mol dm^{-3} as $pK_1 = -3$ and $pK_2 = 2$ for sulphuric acid). The dichloro complexes have very limited solubility in HNO_3 and $HClO_4$. The kinetics were monitored at 510 nm (absorption increase) using a Gilford SP 500 spectrophotometer interfaced with a PC. Rate constants were obtained from the slope of the linear plots of $\ln(A_\infty - A_t)$ vs time t, where A_∞ is the final absorbance at 510 nm and A_t is the absorbance at time t. Absorbance changes were monitored over 4–9 half lives.

RESULTS AND DISCUSSION

The reaction of $[CrCl_3(DMF)_3]$ prepared *in situ* by dehydration of $CrCl_3 \cdot 6H_2O$ in DMF solution with

L_A, L_B and L_C gives the green *trans*-$[CrLCl_2]^+$ complexes. The reaction of cyclam (1,4,8,11-tetra-azacyclotetradecane) [5] and 5,12-dimethyl-cyclam [6] with $[CrCl_3(DMF)_3]$ gives predominantly the violet-purple *cis*-isomer with only ca 10% of the green *trans*-isomer. The ligand tet *a* (1) gives *trans* complexes with Cr(III), while tet *b* (2) gives *cis* complexes [7]. The ligand tet *b* is known to readily fold to give *cis*-octahedral complexes with the (RRRR, SSSS) *sec*-NH chiral nitrogen configuration and two equatorial methyls and one axial methyl substituent on each six-membered chelate ring. The ligand tet *a* only folds with difficulty because of the unfavourable interaction of axial methyl substituents in the six-membered chelate rings with ligands in the axial positions of the octahedral coordination sphere of the metal. The additional steric interactions in the octamethyl ligands would obviously be expected to favour the formation of the *trans* isomer and this was found to be the case.

The reaction of L_A with $[CrCl_3(DMF)_3]$ in DMF solution requires some 30 min. for completion in refluxing DMF. However, due to the greater solubility of L_B and L_C in DMF solution these reactions are complete in 15 min. The green *trans* complexes analyse as $[CrLCl_2]Cl \cdot 2H_2O \cdot HCl$ and presumably contain the species $[H_5O_2]^+Cl^-$ as previously observed [7] in *trans*-$[Cr(tet\ a)Cl_2 \cdot 2H_2O \cdot HCl$.

Electronic spectra

The electronic spectra of the various complexes prepared are summarised in Table 1. In O_h symmetry three ligand field bands are expected for a d^3 ion $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}(F)$ and the two electron transition $^4A_{2g} \rightarrow {}^4T_{1g}(P)$. The electronic spectra are very similar to those previously reported for chromium(III) complexes of macrocyclic tetra-aza ligands [6]. The more symmetrical *trans*-isomers (D_{4h}) normally have absorption coefficients < 30 and the lowest energy *d–d* band occurs in the region 510–570 nm. The less symmetrical *cis*-isomers (C_{2v}) have much higher absorption coefficients ($> 100\ dm^3\ mol^{-1}\ cm^{-1}$) for the lowest energy *d–d* band which occurs in the region 500–560 nm. The spectra of all of the complexes prepared are fully consistent with the *trans* stereochemistry. Bembi and coworkers [4] have recently characterised the diastereoisomeric *trans*-$[Co(Me_8[14]aneN_4)Cl_2]^+$ complexes. Significantly only green *trans*-complexes were characterised and no evidence for *cis*-complexes was obtained. Cobalt(III) gives both *cis*- and *trans*-$[Co(cyclam)Cl_2]^+$ with 1,4,8,11-tetra-azacyclotetradecane [8] and folded *cis*-complexes can

readily be obtained with chelating bidentate ligands such as oxalate, 1,2-diaminoethane and acetylacetonate [9]. The presence of the eight methyl substituents in the 14-membered ring favours the formation of *trans*-isomers.

Aquation studies

All three dichloro-complexes aquate in 0.05 mol dm^{-3} sulphuric acid to give pink solutions of *trans*-$[CrL(OH_2)Cl]^{2+}$. Tight isosbestic points are observed on spectrophotometric monitoring of the reactions. Interval scan spectra for the hydrolysis of *trans*-$[CrL_ACl_2]^+$ at 30 °C are shown in Fig. 1. The products of aquation *trans*-$[CrL(OH_2)Cl]^{2+}$ are stable in aqueous sulphuric acid for several weeks at room temperature. On slow evaporation, red crystalline solids *trans*-$[CrL(OH_2)Cl]Cl_2 \cdot H_2O \cdot H_2SO_4$ were obtained. The presence of sulphate is indicated by the infrared spectra which exhibit ν (SO_4^{2-}) at ca 1600, 1130 and 600 cm^{-1}.

The kinetics of aquation to the chloro–aqua complexes was monitored spectrophotometrically over a temperature range. Values of k_{aq} are listed in Table 2. Activation parameters and values of k_{aq} at 25 °C are summarised in Table 3. The quite substantial negative values of $\Delta S^\ddagger$ observed for the aquation of chromium(III) complexes has been attributed to an associative mechanism and typical values for some *trans*-$[Cr(N_4)Cl_2]^+$ complexes (N_4 = a series of four nitrogen donors) are summarised in Table 4. Most of these reactions exhibit quite negative entropies of activation consistent with an I_a mechanism. The low enthalpy of activation for the complex *trans*-$[CrL_ACl_2]^+$ is compensated by a large negative value of $\Delta S^\ddagger$ and aquation at 25 °C is only some 3–4 times faster than that of the corresponding L_B and L_C complexes which have very similar activation parameters to those obtained for the aquation of *trans*-$[Cr(tet\ a)Cl_2]^+$ [10]. Somewhat similar results have been obtained by Bembi *et al.* [11] for the analogous cobalt(III) derivatives where all of the complexes have aquation rates in the range 4.7×10^{-4}–8.7×10^{-4} s^{-1} at 25 °C.

Stereochemistry

The crystal structure of *trans*-$[CoL_ACl_2]ClO_4$ (α-isomer) has recently been determined [4]. In these complexes a variety of diastereoisomers are possible

Table 4. Rate constants and activation parameters for the aquation of *trans*-$[Cr(N_4)Cl_2]^+$ complexes at 25 °C

Complex	k_{aq} (s^{-1})	$\Delta H^\ddagger$ (kJ mol^{-1})	$\Delta S^\ddagger$ (JK^{-1} mol^{-1})	Ref.
trans-$[Cr(2,3,2\text{-tet})Cl_2]^+$	3.23×10^{-6}	107	0	[13]
trans-$[Cr(3,2,3\text{-tet})Cl_2]^+$	1.06×10^{-6}	95	−50	[14]
trans-$[Cr(cyclam)Cl_2]^+$	2×10^{-8}	116	−8	[15]
trans-$[Cr(tet\ a)Cl_2]^+$	1.26×10^{-5}	93	−37	[10]
trans-$[CrL_ACl_2]^+$	1.8×10^{-4}	23	−238	This work
trans-$[CrL_BCl_2]^+$	4.7×10^{-5}	87	−36	This work
trans-$[CrL_CCl_2]^+$	6.5×10^{-5}	85	−40	This work

due to the presence of the four chiral *sec*-NH centres although normally it is only possible to isolate the most stable of these. The α-isomer of *trans*-$[CoL_A Cl_2]ClO_4$ has the stereochemistry shown in (3). The complex has the trans III arrangement of the *sec*-NH centres. The two single methyl groups in the six-membered rings are axial so that steric crowding around both chloride ligands is identical.

If the ligands L_B and L_C also adopt the most thermodynamically stable trans III configuration in the chromium(III) complexes the configurations of $[CrL_BCl_2]^+$ and $[CrL_CCl_2]^+$ will be as shown in (4) and (5) respectively. In both the L_B and L_C complexes the two single methyl groups in the six-membered rings are diequatorial. These configurations are those defined by the ^1H NMR results in the diamagnetic cobalt(III) complexes. Confirmatory evidence is provided by the crystal structure of the α-isomer of $[NiL_C](ClO_4)_2$ which is found to have the ligand conformation shown in (5) [12].

Synthesis, NMR (^{13}C, ^{111}Cd, ^{199}Hg) spectra and structures of $(Ph_4As)_2[Hg_2Cl_4(SC(O)Ph)_2]$ and $(Ph_4As)_2[CdCl_4Hg(SC(O)Ph)_2]$

Jagadese J. Vittal‡ and Philip A. W. Dean*

Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7, Canada

(Received 15 September 1997; accepted 25 November 1997)

Abstract—Combination of $Ph_4AsCl \cdot H_2O$, $Hg(SC(O)Ph)_2$ and $HgCl_2$ or $CdCl_2 \cdot 2.5H_2O$ in the required stoichiometric ratio gives $(Ph_4As)_2[MCl_4Hg(SC(O)Ph)_2]$, M = Hg (**1**) or Cd (**2**). Crystals of **1** were also isolated in an unsuccessful attempt to prepare the complex $(Ph_4As)[Na\{Hg(SC(O)Ph)_3\}_2]$. X-ray crystallographic analyses of **1** and **2** show both to contain a Hg(II) bonded to two thiobenzoate ligands with a near-linear S—Hg—S skeleton. The S—Hg—S angle is 174.9(2)° in **1** and 175.4(1)° in **2**. In each, the $Hg(SC(O)Ph)_2$ moiety is involved in weak interactions with two chlorine atoms from $[MCl_4]^{2-}$. Mercury-199 and ^{111}Cd NMR spectral studies indicate that the $Hg(SC(O)Ph)_2$ remains intact in solution, and that scrambling or transfer of ligands between the linear and tetrahedral metal centres does not occur. Carbon-13 and ^{199}Hg NMR data are reported for $Hg(SC(O)Ph)_2$. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: cadmium; chloride; mercury; NMR; thiobenzoate; X-ray analysis.

We have been interested in metal complexes of the thiobenzoate anion, thb^- [1–5]. Recently, we reported the synthesis and the structures of $[M(thb)_3]^-$ (M = Zn, Cd and Hg) [4]. Earlier, we had shown [1] that in the presence of the sodium cation Cd(II) forms the $[Na\{Cd(thb)_3\}_2]^-$ anion in which each Cd(II) is bound strongly to three sulfur atoms and Na^+ to six oxygen atoms, three from each $Cd(thb)_3$ moiety. Thus $[Cd(thb)_3]^-$ exhibits monoanionic tridentate ligand behaviour towards Na^+. In an attempt to demonstrate analogous ligand behaviour by $[Hg(thb)_3]^-$, we tried to isolate the $[Na\{Hg(thb)_3\}_2]^-$ anion. From this synthesis we isolated, in crystalline form, an unexpected product that still contained chloride. Thereafter, starting with $Hg(thb)_2$, we were able to prepare this product, $(Ph_4As)_2[Hg_2(thb)_2Cl_4]$, **1**, more directly, as well as to extend the synthesis to the related compound $(Ph_4As)_2[Hg(thb)_2CdCl_4]$, **2**. Both **1** and **2** have been characterized in the solid state by single-crystal X-ray diffraction techniques. In solution they, and $Hg(thb)_2$, have been characterized by multi-NMR (^{13}C, $^{111/113}Cd$, ^{199}Hg).

EXPERIMENTAL

General procedures

All starting materials were obtained commercially and used as received. All solvents were dried by allowing them to stand over 3A molecular sieves. All syntheses and preparations of NMR samples were carried out under an atmosphere of Ar(g). However, neither

solid $Hg(thb)_2$ nor solid **1** or **2** appear to be very air-sensitive. NMR spectra were recorded at ambient probe tempearture using either a Varian Gemini 200 (for ^{13}C or ^{199}Hg) or a Varian XL-300 spectrometer system (for ^{13}C, ^{23}Na, ^{111}Cd or ^{199}Hg), in unlocked mode. Field drift was negligible. (Cadmium-111, rather than the slightly more sensitive ^{113}Cd, was observed because there was interference for ^{113}Cd in the region of interest; no measurable primary isotope effect is expected between ^{111}Cd and ^{113}Cd.) Samples were prepared in CH_2Cl_2 in 10 mm o.d. standard NMR tubes on the basis of mass/volume of solvent. Carbon-13 NMR spectra were referenced to internal TMS using the solvent signal as secondary, internal reference, while ^{23}Na, ^{111}Cd and ^{199}Hg NMR spectra were referenced to external 0.1 M $NaBPh_4$ in Me_2CO, 0.1 M $Cd(ClO_4)_2$(aq) and pure $HgMe_2$ (**Caution!** Highly toxic! [6]) by sample interchange.

$Hg(SC(O)Ph)_2$

This was prepared by Dr Yang Wu, of these laboratories, following Ref. 7 [8]. PhC(O)SH (2.76 g, 20.0 mmol) was added dropwise to a solution of $Hg(CN)_2$ (2.53 g, 10.0 mmol) in EtOH (50 ml). White crystals formed immediately. The mixture was cooled in ice for 1 h, then the product was separated by filtration, washed with ice-cold EtOH, and dried *in vacuo*. Yield: 4.6 g, 86%. Anal. Calc. for $C_{14}H_{10}HgO_2S_2$: C, 35.41, H, 2.12; Found: C, 35.64, 35.48, H, 2.00, 2.03. Carbon-13 NMR (CH_2Cl_2, 293 K): 197.3 (Ph*C*(O)S), 138.4 (C_1), 134.1 (C_4), 129.2 ($C_{2/6 \text{ or } 3/5}$), 128.9 ($C_{3/5 \text{ or } 2/6}$).

$(Ph_4As)_2[Hg_2Cl_4(SC(O)Ph)_2]$ (**1**)

The solids $Hg(SC(O)Ph)_2$ (0.475 g, 1.0 mmol), $HgCl_2$ (0.271 g, 1.0 mmol) and $Ph_4AsCl \cdot H_2O$ (0.844 g, 2 mmol) were added to 15 ml MeOH with stirring. After 5 min Me_2CO (15 ml) was added to get a clear solution, which was was filtered and left at room temperature for crystallization. Long flat crystals were separated by decantation, washed with Et_2O and dried in air. Yield: 1.1 g (69.5%). Anal. Calc. for $C_{62}H_{50}As_2Cl_4Hg_2O_2S_2$: C, 45.20; H, 3.06; Found: C, 46.76, 46.93; H, 3.16, 3.08. Carbon-13 NMR (CH_2Cl_2, 293 K, concentration 0.05 mol/l): 196.9 (Ph*C*(O)S), 139.8 (C_1, PhC(O)S), 135.3 (C_4, Ph_4As^+), 133.4 ($C_{2,6}$, Ph_4As^+), 132.7 (C_4, PhC(O)S), 131.7 ($C_{3,5}$, Ph_4As^+), 128.9 ($C_{2/6 \text{ or } 3/5}$, PhC(O)S), 128.4 ($C_{3/5 \text{ or } 2/6}$, PhC(O)S), 120.9 (C_1, Ph_4As^+); with full relaxation, integration of the $C_{2/6}$ and $C_{3/5}$ signals gives Ph(of Ph_4As^+)/Ph(of PhC(O)S) = 4.0. The product isolated from an attempted preparation of $(Ph_4As)[\{Hg(SC(O)Ph)_2\}_2HgCl_4]$ gave the same ratio of intensities and was, therefore, **1**.

Single crystals that proved, by X-ray diffraction, to be **1** were isolated during an attempted synthesis of $(Ph_4As)[Na\{Hg(SC(O)Ph)_3\}_2]$. In this attempted synthesis, a methanolic solution of NaSC(O)Ph was prepared by the addition of PhC(O)SH (2.02 g, 14.6 mmol) in MeOH (10 ml) to a solution of NaOMe prepared *in situ* by dissolution of Na metal (0.30 g, 13.2 mmol) in MeOH (10 ml). To the resultant yellow solution, $HgCl_2$ (1.19 g, 4.4 mmol) in MeOH (20 ml) was added with stirring to get a white precipitate. Stirring was continued for 5 min, then a solution containing $Ph_4AsCl \cdot H_2O$ (1.92 g, 4.4 mmol) in MeOH (20 ml) was added. This mixture was stirred for a further 30 min, when CH_2Cl_2 (10 ml) and Me_2CO (20 ml) were added to give a clear supernatant liquid over a precipitate that was presumed to be NaCl. The precipitate was removed by filtration. Volatiles were removed from the filtrate *in vacuo* to get a white solid. This was dissolved in CH_2Cl_2 (25 ml), layered with Et_2O and left at room temperature for crystallization. The crystals were washed with Et_2O and dried in air. Yield: 4.57 g. The data crystals used for X-ray analysis were picked from this batch. No resonance was observed in the ^{23}Na NMR spectrum of the bulk material, and the signals observed in the ^{13}C NMR spectrum were those of neither **1** (see above) nor $(Ph_4As)[Hg(SC(O)Ph)_3]$ [4].

$(Ph_4As)_2[CdCl_4Hg(SC(O)Ph)_2]$ (**2**)

The synthesis was carried out following the method used for the direct synthesis of **1** (see above), except that $CdCl_2 \cdot 2.5H_2O$ replaced $HgCl_2$ as starting material. The crude product was crystallized from a mixture of CH_2Cl_2 and Et_2O. Yield: 1.06 g (73.5%). Anal. Calc. for $C_{62}H_{50}As_2CdCl_4HgO_2S_2$: C, 49.78, H, 3.37; Found C, 48.60, 48.43, H, 3.12, 3.17 Carbon-13 NMR (CH_2Cl_2, 296 K, concentration 0.025 mol/l): 197.1 (Ph*C*(O)S), 139.4 (C_1, PhC(O)S), 135.2 (C_4, Ph_4As^+), 133.4 ($C_{2,6}$, Ph_4As^+), 133.1 (C_4, PhC(O)S), 131.7 ($C_{3,5}$, Ph_4As^+,), 129.0 ($C_{2/6 \text{ or } 3/5}$, PhC(O)S), 128.5 ($C_{3/5 \text{ or } 2/6}$, PhC(O)S,), 120.8 (C_1, Ph_4As^+); with full relaxation, integration of the $C_{2/6}$ and $C_{3/5}$ signals gives Ph(of Ph_4As^+)/Ph(of PhC(O)S) = 3.9.

Crystallographic studies

Crystals of **1**, $(Ph_4As)_2[Hg_2Cl_4(SC(O)Ph)_2]$, that were suitable for X-ray analysis were obtained during the attempted synthesis of $(Ph_4As)[Na\{Hg(thb)_3\}_2]$ (see above) while those of **2**, $(Ph_4As)_2$ $[CdCl_4Hg(SC(O)Ph)_2]$, were obtained during the direct synthesis and recrystallization of this compound. For diffraction experiments, the data crystals were mounted at the end of a glass fibre using expoxy glue.

For both **1** and **2** the diffraction experiments were carried out on a Siemens P4 diffractometer with the XSCANS software package [9], using graphite monochromated Mo-K_α radiation at 25°C. *SHELXTL* [10] programs were used for data processing, solution and the least-squares refinements on F^2. The cell constants were obtained by centering 26 high angle reflections

($24.8 \leqslant 2\theta \leqslant 25.1°$) for **1** and 38 high angle reflections ($10.2 \leqslant 2\theta \leqslant 25.1°$) for **2**. During the data collection four standard reflections were monitored at the end of every 296 reflections. At the end of the data collection, face-indexed absorption correction was applied to the data.

The non-hydrogen atoms of the $[Hg(SC(O)Ph)_2MCl_4]^{2-}$ anions, and the arsenic atoms, were refined anisotropically. In the cations, isotropic thermal parameters were refined for the carbon atoms of the phenyl rings and two-fold symmetry constraints were applied to the phenyl rings. Riding models were used to place all the hydrogen atoms in the calculated ideal positions for the purpose of structure factor calculations only. There were no shifts in the final least-squares cycles. The crystal data and the experimental details are given in Table 1.

RESULTS AND DISCUSSION

The compounds **1** and **2** are isolated readily from mixtures of $Ph_4AsCl \cdot H_2O$, $Hg(SC(O)Ph)_2$ and $HgCl_2$ or $CdCl_2 \cdot 2.5H_2O$ in the correct stoichiometric ratio in $MeOH : Me_2CO$. An attempt to prepare $(Ph_4As)[Na\{Hg(SC(O)Ph)_3\}_2]$ from the correct stoichiometric ratio of $Ph_4AsCl \cdot H_2O$, $HgCl_2$ and $Na^+PhC(O)S^-$ in $MeOH : Me_2CO : CH_2Cl_2$ gave, as a minor product, crystalline **1**.

Structures of **1** *and* **2**

The structures of **1** and **2** were determined by single crystal X-ray diffraction analysis. The compounds were found to be isotypical in the solid state. Within the structures, the cations are unexceptional and will not be discussed further. Perspective views of the anions in **1** and **2** are shown in Figs 1 and 2, which also show the numbering scheme. Selected bond distances and angles for the anions in **1** and **2** are in Table 2.

In both the anions, there are recognizable $Hg(thb)_2$ molecules. The Hg—S distances and S—Hg—S bond

angle are 2.345(5) and 2.360(5) Å and 174.9(2)° in **1**, and 2.345(4) and 2.348(4) Å and 175.4(1)° in **2**. The near linearity of the HgS_2 skeleton in the anions of **1** and **2** suggests that these anions may be thought of as weak MCl_4^{2-} : $Hg(thb)_2$ donor : acceptor complexes. Consistent with the presence of a very weak donor : acceptor interaction are the Hg(1)—Cl(1) and Hg(1)—Cl(2) distances, 2.985(4) and 3.065(4) Å in **1**, and 2.990(3) and 3.103(3) Å in **2**, which approach the sum of the van der Waals radii, 3.2–3.4 Å [11,12]. Such long interactions are a common feature of mercury chemistry [13]. A CSD search [14] reveals that in discrete $HgCl_4^{2-}$ anions Hg—Cl distances range from 2.386–2.643 Å and Cl—Hg—Cl angles from 92.018–141.061°. It is difficult therefore to conclude that the $HgCl_4^{2-}$ in **1**, with Hg(2)—Cl distances 2.444(4)–

Cl(1)—Hg(1)—Cl(2)	78.66(10)	78.28(8)
C(1)—S(1)—Hg(1)	103.2(6)	103.1(5)
C(2)—S(2)—Hg(1)	100.8(6)	101.5(5)
Cl(1)—M—Cl(2)	99.34(12)	101.34(10)
Cl(3)—M—Cl(1)	108.88(14)	108.99(11)
Cl(3)—M—Cl(2)	112.93(13)	112.93(13)
Cl(3)—M—Cl(4)	111.43(13)	109.62(11)
Cl(4)—M—Cl(1)	118.18(14)	116.42(11)
Cl(4)—M—Cl(2)	105.53(13)	106.75(10)
M—Cl(1)—Hg(1)	92.54(11)	91.76(9)
M—Cl(2)—Hg(1)	89.40(11)	88.57(9)

2.548(3) Å and Cl—Hg(2)—Cl angles 99.34(12)–118.18(14)°, has been significantly distorted by its interaction with the $Hg(thb)_2$ moiety. However, the bonds Hg(2)—Cl(1) and Hg(2)—Cl(2) in **1**, which involve bridging Cl, are longer than the terminal Hg—Cl distances, as is commonly found for mercury [13].

Similarly, a CSD search [14] shows that bond distances and angles for discrete $CdCl_4^{2-}$ fall in the ranges 2.412–2.565 Å and 94.980–135.794°. Hence, the $CdCl_4^{2-}$ in **2**, with Cd(1)—Cl in the range 2.438(3)–2.502(3) Å and Cl—Cd(1)—Cl angles in the range 101.34(10)–116.42(11)°, is not unusually distorted by its interaction with $Hg(thb)_2$. The mean Hg(1)—Cl_{br} distance for **2** is marginally larger than that for **1** (3.05 Å vs 3.03 Å), and consistent with this the M—Cl_{br} and M—Cl_t distances in **2** are less well differentiated for **2** than for **1**, although we note that the longest and shortest Cd(1)—Cl distances in **2** are associated with bridging and terminal Cd(1)—Cl bonds.

The compound **2** appears to be only the second structurally-characterized compound containing Cd and Hg bridged by halogen atoms. In $I_2Cd(\mu\text{-}I)_2Hg(PPr_3)_2$, as in **2**, there is a tendency of the Hg(II) towards linear co-ordination as evidenced by the P—Hg—P angle of 152.8(1)° [15].

NMR spectra

Mercury thiobenzoate, $Hg(thb)_2$, has a concentration-independent ^{199}Hg chemical shift: $\delta_{Hg}(\Delta\nu_{1/2}) = -1265(\sim 20$ Hz) in CH_2Cl_2. The resonance is shielded relative to that of $Hg(SPh)_2$, e.g. $\delta_{Hg}(Hg(SPh)_2) = -1065$ for a saturated solution in $CHCl_3$ [16]. Shielding of the metal resonances of complexes of $PhC(O)S^-$ relative to those of the corresponding PhS^- complexes appears to be a general phenomenon [1–4].

At ambient probe temperature, $\delta_{Hg}(\Delta\nu_{1/2}) = -1143(\sim 85$ Hz) for a solution containing 0.025 mol of **2**/L of CH_2Cl_2. In the general context of ^{199}Hg NMR chemical shifts [17], the change in δ_{Hg} relative to that of $Hg(thb)_2$ is a minor one, showing that the $Hg(thb)_2$ in **2** has remained intact. The ^{111}Cd NMR chemical shift is ≈ 425 ppm for the very broad ^{111}Cd resonance ($\Delta\nu_{1/2} \approx 2500$ Hz) of the same solution. This signal is in the region expected for $CdCl_4^{2-}$ [18,19]. Apparently no interchange or transfer of ligands has occurred between Cd and Hg in the solution of **2**. On reduction of the concentration, δ_{Hg} moves towards that of free $Hg(thb)_2$, e.g. $\delta_{Hg}(\Delta\nu_{1/2}) = -1157(95$ Hz) for a solution with 0.0125 mol of **2**/L of CH_2Cl_2. Evidently **2** dissociates to $Hg(thb)_2$ and $CdCl_4^{2-}$ in solution, but not completely. In this case, the broadness of the ^{111}Cd resonance for **2** can be attributed to an intermediate rate of exchange (on the timescale of $\Delta\delta_{Cd}$) between free and bound $CdCl_4^{2-}$.

A single ^{199}Hg NMR signal is observed for a solution containing 0.05 mol of **1** l of CH_2Cl_2, with $\delta_{Hg}(\Delta\nu_{1/2}) = \sim -1040(\sim 400$ Hz). This signal does not shift significantly on modest dilution. The resonance is assigned to a $Hg(thb)_2$ moiety. The increase of ~ 225 ppm in δ_{Hg} that accompanies the change from $Hg(thb)_2$ to **1**, and the lack of a change in δ_{Hg} for **1** upon dilution, suggests that the anion of **1** is not extensively dissociated in CH_2Cl_2. However, no ^{199}Hg NMR signal was observed for $HgCl_4^{2-}$. This resonance must be exceedingly broad. By analogy with the results for **2**, we attribute this result to exchange of $HgCl_4^{2-}$ between free and bound sites, indicating the presence of *some* (apparently slight) dissociation of **1**.

CONCLUSIONS

The compounds $(Ph_4As)_2[Hg(SC(O)Ph)_2MCl_4]$ (M = Hg or Cd) can be synthesized readily from $Ph_4AsCl \cdot H_2O$, $Hg(SC(O)Ph)_2$ and $HgCl_2$ or $CdCl_2 \cdot H_2O$. X-ray analysis shows that in the new anions $Hg(SC(O)Ph)_2$, acting as a weak acceptor, is linked to MCl_4^{2-} through two chlorines. Metal NMR suggests that no ligand exchange or transfer occurs between $Hg(SC(O)Ph)_2$ and MCl_4^{2-}, and that when M = Hg, the complex dissociation dissociates only slightly in CH_2Cl_2, while the complex with M = Cd is

more extensively dissociated to $Hg(SC(O)Ph)_2$ and $CdCl_4^{2-}$.

Supplementary material

Tables of bond distances and angles, close nonbonded contacts, positional and thermal parameters, anisotropic thermal parameters, calculated hydrogen atom coordinates, selected torsion angles and selected weighted least-squares planes for **1** and **2** have been deposited with the Cambridge Crystallographic Data Centre.

(Received 24 September 1997; accepted 19 November 1997)

Abstract—Novel two acyclic hexadentate ligands, 1,4-bis[*o*-(pyridine-2-carboxamidophenyl)]-1,4-dithiobutane (H_2bpctb) and 1,4-bis[*o*-(pyridine-2-carboxamidophenyl)]-1,5-dithiopentane (H_2bpctp), containing thioether functions were synthesized and their copper(II) and nickel(II) complexes [(Cu(bpctb)], **1**; [Cu(bpctp)], **2**; [Ni(bpctb)], **3** and [Ni(bpctp)], **4**) were prepared. The structures of **1**–**4** were determined by X-ray crystallography. The coordination geometries of **3** and **4** are octahedral with two amido and two pyridyl nitrogen atoms and two thioether sulfur atoms of hexadentate ligand. However, the coordination geometry of **2** is a flattened tetrahedron combining two amido nitrogen atoms and two pyridyl nitrogen atoms of hexadentate ligand without thioether coordination. X-ray crystallography and ESR spectroscopic studies revealed that the coordination geometry of **1** is an uncommon equatorially elongated octahedron in solid state. However, this coordination geometry changes to an axially elongated one in solution. The copper(II/I) redox processes for **1** and **2** are around −1.2 V and the nickel(II/III) processes for **3** and **4** at around 0.3 V vs ferrocene/ferrocenium couple were observed in DMSO. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: hexadentate thioether ligand; crystal structure; ESR spectra; redox potential; equatorially elongated octahedral copper(II) complex.

The coordination chemistry of thioether sulfur is of great interest in bioinorganic chemistry [1]. Usually, a sulfur atom in a free thioether has a poor coordinating ability to metal ions. However, the thioether sulfur in macrocyclic ligands can coordinate to transition metals, and a number of these type of complexes have been synthesized and characterized [2]. The thioether sulfur can also coordinate to metal ions by using acyclic multidentate ligands containing the thioether function on the internal position [3,4].

In this connection, we designed new acyclic hexadentate ligands containing thioether-amido-pyridyl donor set; 1,4-bis[*o*-(pyridine-2-carboxamidophenyl)]-1,4-dithiobutane (H_2bpctb) and 1,4-bis[*o*-(pyridine-2-carboxamidophenyl)]-1,5-dithiopentane (H_2bpctp). Herein, we describe the synthesis, structure and electrochemical property of the copper(II) and nickel(II) complexes derived from these ligands.

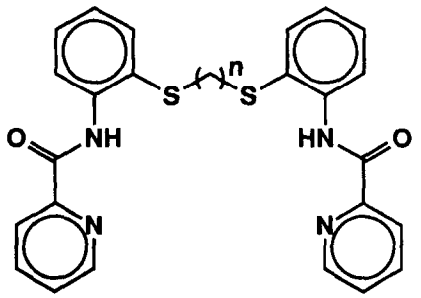
EXPERIMENTAL

Materials

All chemicals used for synthetic work were of reagent grade and used without further purification. All solvents used for physical measurements were purified according to the literature methods [5] and stored under nitrogen atmosphere.

The diamines as precursors of thioether-system ligands, 1,2-bis(2-aminophenylthio)ethane (bape) and 1,3-bis(2-aminophenylthio)propane (bapp), were prepared according to the literature [6].

Two ligands, H_2bpctb and H_2hpctp, were prepared by the procedure in the literature [7]. As an example,



n = 2; H_2bpctb
n = 3; H_2bpctp

the synthesis of 1,4-bis[*o*-(pyridine-2-carboxamidephenyl)]-1,4-dithiobutane (H_2bpctb, Scheme 1) is described here. To a solution of 2-pyridinecarboxylic acid (0.6 mol) in pyridine (240 ml) was added bape (0.3 mol) in pyridine (60 ml). After an addition of triphenylphosphite (0.6 mol) in this mixture, the reaction solution was heated on a steam bath for 4 h and allowed to stand at room temperature overnight. Colorless needles were collected and washed with methanol. Anal. Calcd for $C_{26}H_{22}N_4O_2S_2$: C, 64.17; H, 4.56; N, 11.52%. Found: C, 64.26; H, 4.58; N, 11.39%. Preparation of complexes

The general procedure was followed for all complexes. Details are given for **1** as an example. Methanol solution of copper(II) acetate monohydrate (1.0 mmol) was added to a hot methanol solution of H_2bpctb (1.0 mmol). The mixture was then heated on a water bath for 0.5 h, then deep green microcrystals were separated, and were washed with methanol. Crude product was recrystallized from DMSO/CH_2Cl_2 mixed solution. Deep green prisms were obtained. Anal. Calcd for $C_{26}H_{20}N_4O_2S_2Cu$: C, 56.97; H, 3.68; N, 10.22%. Found: C, 56.68; H, 3.70; N, 10.10%. IR 1617 cm^{-1}, ν_{CO}(amido). Physical measurements

Elemental analyses for C, H, and N were performed at the Elemental Analysis Service Center of Kyushu University. Electrical conductivity measurements were carried out on a Horiba DS-14 conductivity meter in 10^{-3} mol dm^{-3} solution at room temperature. Infrared spectra were measured on KBr disks with JASCO A-102 spectrophotometer. ^1H NMR spectra were recorded in $CDCl_3$ on a JEOL EX 90 spectrometer. Electronic spectra were measured on a Hitachi U-4000 spectrophotometer by the use of the 10^{-3} mol dm^{-3} solutions. Electrochemical measurements were carried out on a Yanagimoto P-1100 polarographic analyzer equipped with three electrodes of a glassy carbon working electrode, a platinum wire auxiliary electrode, and a saturated calomel electrode (SCE) as the reference, in which tetra-*n*-butylammonium perchlorate was employed as the supporting electrolyte. The concentration of the supporting electrolyte in sample solution was adjusted to 0.1 mol dm^{-3}. The sample solutions were deoxidized by nitrogen bubbling for 15 min before measurements. All the observed potentials were corrected by the Fc^+/Fc couple of ferrocene as an internal standard. ESR spectra were recorded on a JEOL TE200 spectrometer at liquid nitrogen temperature. Magnetic susceptibilities at room temperature were measured on a Faraday balance, where the calibration was made with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine) [8]. Corrections were applied for diamagnetism calculated from Pascal's constants [9]. Effective magnetic moments were calculated by the equation $\mu_{eff} = 2.828(\chi_A T)^{1/2}$, where χ_A is the magnetic susceptibility per metal ion.

X-ray data collection, reduction, and structure determination

All measurements were made on a Rigaku AFC7R diffractometer with graphite monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å) and a 12 kW rotating anode generator. The data were collected at a temperature of 20 ± 1°C using ω-2θ scan technique at a scan speed of 16.0° min^{-1} (in omega). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of 3 scans) and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2 : 1. The intensities of three representative reflections were measured after every 150 reflections, showing a good stability of the intensities. An empirical absorption correction based on azimuthal scans of several reflections was applied. The data were corrected for Lorentz and polarization effects.

The structures were solved by direct methods [10] and expanded using Fourier techniques [11]. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the structure factor calculation. Full-matrix least-squares refinements based on the observed reflections ($I > 3.00\sigma(I)$) were employed, where the unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ are used. The weighting scheme was based on counting statistics. Neutral atomic scattering factors were taken from Cromer and Waber [12b]. Anomalous dispersion effects were included in F_{calc}; the values $\Delta f'$ and $\Delta f''$ where those of Creagh and McAuley [12a]. All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation [13].

Crystal data and details of the structure determination for **1–4** are summarized in Table 1.

RESULTS AND DISCUSSIONS

Synthesis and characterization

Two ligands, H_2bpctb and H_2bpctp, were prepared by the same procedure for 1,2-bis(2-pyridinecarboxamido)benzene [7] with high yield (ca 80%). For all complexes, ν_{NH} band was not observed and ν_{CO} bands were shifted to a lower wavenumber in the IR spectra compared with those of ligands. These results indicate that deprotonated amido nitrogen atoms are coordinating to a metal ion in all complexes [14]. The electronic absorption band observed at 317–345 nm in CH_2Cl_2 was assigned to $\pi \rightarrow \pi^*$ transition and the others were assigned to *d-d* transition of the metal ion. Electronic spectra show that the coordination geometry of **1**, **3** and **4** is the octahedron. For compound **1**, however, *d-d* band at 708 nm is splitting in two at 622 nm (shoulder) and 726 nm. It is expected that the transformation occurs between structure of **1** in solid state and in solution. It was obvious that compound **2** had a flattened tetrahedral coordination geometry as described below.

Structural description of compound **1**, [Cu(bpctb)]

An ORTEP view of **1** with the atom numbering scheme is shown in Fig. 1. Selected bond distances and angles are reported in Table 2(a). This complex has a 2-fold axis passing through Cu(1) and the midpoint of C(13) and C(13)*. A copper(II) ion assumes an octahedral coordination geometry with two amido

and two pyridyl nitrogen atoms and two thioether sulfur atoms of hexadentate ligand. The bond distance of Cu(1)—S(1) is 2.503(1) Å. This bond distance lies in the middle of the axial Cu(1)—S distances (2.59–2.64 Å) and the equatorial one (2.32–2.48 Å) for the copper(II) complex with thioether ligands [4,15]. The copper(II) to pyridyl nitrogen bond distance of Cu(1)—N(1) and the copper(II) to amido nitrogen bond distance of Cu(1)—N(2) are 2.155(4) Å and 1.977(3) Å, respectively. This Cu(1)—N(1) bond distance is longer than the normal value of 1.96–2.08 Å for the copper(II) to pyridyl nitrogen equatorial bond distances [16]. On the other hand, Cu(1)—N(2) bond distance lies in the range of normal values for copper(II) to deprotonated amido nitrogen bond distances [16(f),17]. Thus, coordination geometry of this complex is described as an equatorially elongated octahedron which is occupied by N(1), S(1), N(1)*, and S(1)* on the equatorial site and N(2) and N(2)* on the axial site (see ESR spectroscopic study).

Structural description of compound **2**·DMSO, [Cu(bpctp)]·DMSO

An ORTEP view of **2**·DMSO with the atom numbering scheme is shown in Fig. 2. Selected bond distances and angles are listed in Table 2(b). This complex has a 2-fold axis passing through Cu(1) and C(14). Figure 2 shows that the structure of **2** is essentially different from that of **1**. A copper(II) ion assumes a flattened tetrahedral coordination geometry with two amido nitrogen atoms and two pyridyl nitrogen atoms of hexafunctionalized ligand with the bond angles of N(1)—Cu(1)—N(1)* and N(2)—Cu(1)—N(2)* are 134.9° and 172.3°, respectively. The bond distances of Cu(1)—N(1) and Cu(1)—N(2) are 2.056(3) Å and 1.952(3) Å, respectively. These distances are shorter than the corresponding distances of **1**. Neither of the thioether sulfur atoms coordinate to the copper center. A six membered chelate ring containing two thioether sulfur atoms as coordination atom may be unsuitable for the ligation between the thioether sulfur and the copper(II) ion. However, two sulfur atoms, S(1) and S(1)*, sit on two *cis* sites for Cu(1) with the distance of 3.006(1) Å. This value of the distance suggests that the weak interaction exists between Cu and S. On account of this fact, the coordination geometry of Cu(1) can also be described as a distorted octahedral with *cis*-open sites and two S atoms interact weakly on the open sites.

Structural description of compound **3**, [Ni(bpctb)]

An ORTEP view of **3** with the atom numbering scheme is shown in Fig. 3. Selected bond distances and angles are listed in Table 3(a). A nickel(II) ion assumes an octahedral coordination geometry with two amido and two pyridine nitrogen atoms and two thioether sulfur atoms of hexadentate ligand. The average bond distances of Ni(1)—S, Ni(1)—N_{amido}, and Ni(1)—$N_{pyridyl}$ are 2.4058 Å, 2.026 Å, and 2.067 Å,

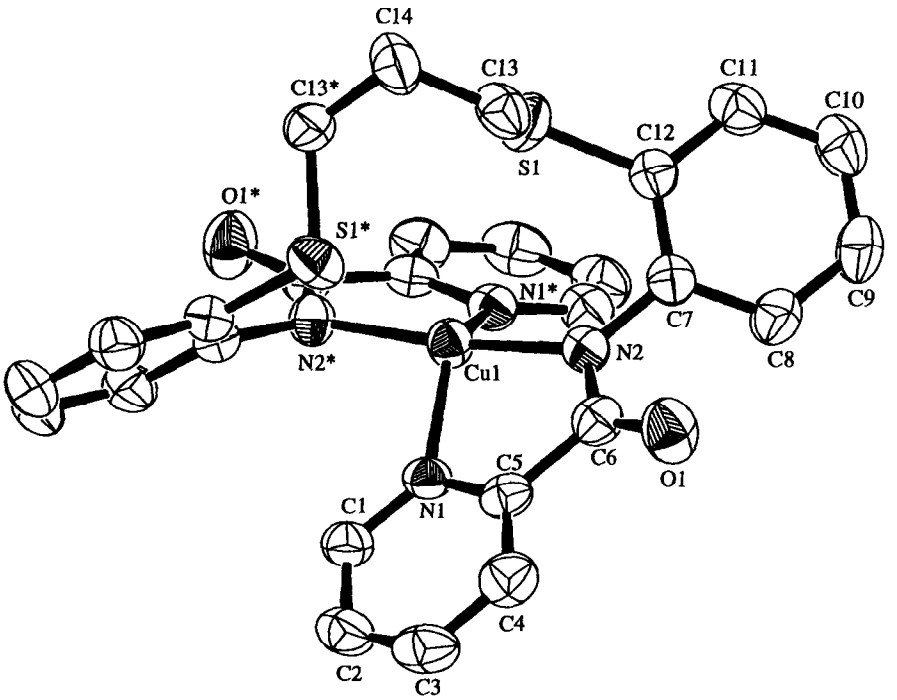

Fig. 2. An ORTEP drawing of compound **2**·DMSO with atom numbering scheme, showing 50% probability ellipsoids.

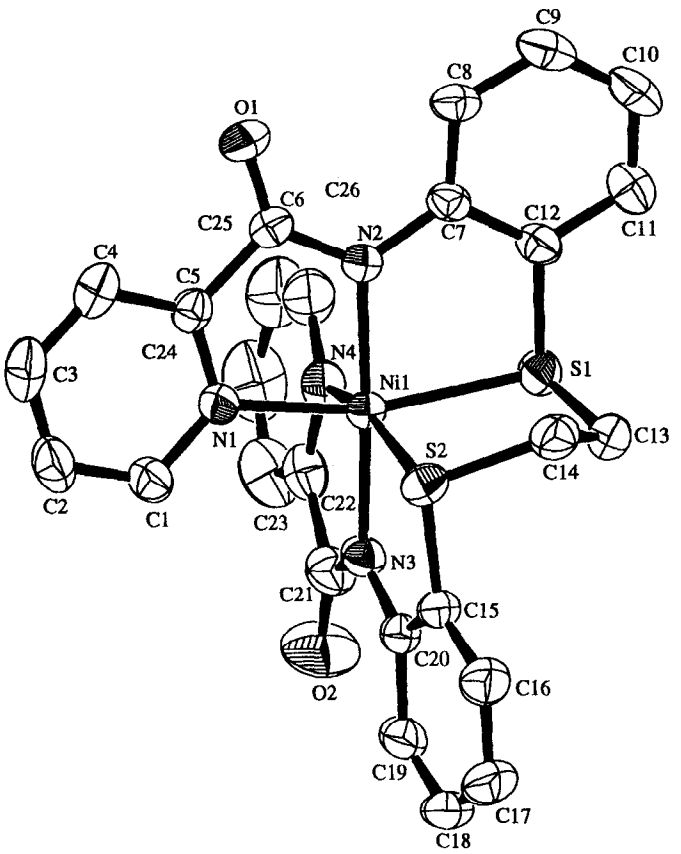

Fig. 3. An ORTEP drawing of compound **3** with atom numbering scheme, showing 50% probability ellipsoids.

respectively. This nickel(II) to thioether sulfur bond distance is within the range of the normal values of 2.39–2.55 Å for octahedral Ni^{II} complexes [1a,3]. These Ni—N bond distances lie in the general value of Ni—N bond distances for octahedral complexes [1a]. Especially, the Ni—N_{amido} bond distance is close to the normal values of ca 2.01 Å for octahedral complexes[18]. Bond angles around the Ni^{II} are close to the corresponding angles of **1**.

Structural description of compound **4**, [Ni(bpctp)]

An ORTEP view of **4** with the atom numbering scheme is shown in Fig. 4. Selected bond distances and angles are listed in Table 3(b). This complex has a 2-fold axis passing through Cu(1) and the midpoint of C(14) and C(14)*, and shows disorder in the propylene bridge (C(14), C(14)*). A nickel(II) ion assumes an octahedral coordination geometry with two amido and two pyridyl nitrogen atoms and two thioether sulfur atoms of hexadentate ligand. The bond distances of Ni(1)—S(1), Ni(1)—N(1), and Ni(1)—N(2) are 2.418(1) Å, 2.063(3) Å, and 2.020(3) Å, respectively. This complex resembles **3** in the structure. However, Ni(1)—S(1) bond distance is longer and S(1)—Ni(1)—S(1)* bond angle is larger than those of **3** with increase the number of carbon atom of alkyl bridge between two sulfur atoms.

ESR spectroscopic study for Cu^{II} *complexes*

The ESR spectra for powder samples of compounds **1** and **2** at the liquid nitrogen temperature are shown in Fig. 5. The powder spectrum of **1** (Fig. 5(a)) is typical of an axial pattern with $g_\perp > g_\parallel$. This spectrum shows that the unpaired electron lies on the d_{z^2} orbital and the coordination geometry of **1** is the uncommon equatorially elongated octahedron in solid state. The result is consistent with the X-ray crystallographic structure of **1**. However, the $CHCl_3$ glass spectrum of **1** (Fig. 5(b)) is of an axial pattern with $g_\parallel > g_\perp$ ($g_\parallel = 2.20$, $g_\perp = 2.07$, $A_\parallel = 12.5$ mT), contrary to the powder spectrum. This fact indicates that the structure of **1** in solid state changes in the $CHCl_3$ solution from an equatorially elongated octahedron to an axially elongated one. In other words, bond distances of Cu^{II} to amido nitrogen atoms are longer and the distances of Cu^{II} to sulfur atoms and Cu^{II} to pyridyl nitrogen atoms are shorter in solution, compared with those in solid state. The same change in a spectrum was also observed in frozen DMF solution.

The powder spectrum of **2** (Fig. 5(c)) shows a rhom-

bic pattern with $g_1 = 2.22$, $g_2 = 2.10$ and $g_3 = 2.03$, and reflects the crystal structure of this compound. The glass spectrum of **2** is essentially the same pattern with the hyperfine structure due to the Cu nucleus, regardless of the solvent. No structural change like compound **1** was observed.

Electrochemical property

Electrochemical measurements for the complexes were carried out in the DMSO solutions; the potentials are summarized in Table 4. The quasi-reversible process of the copper(II) complexes observed at

Table 4. Electrochemical data for compounds **1–4**

Compound	E_{pc}/V	E_{pa}/V	ΔE_p/mV	$E'_{1/2}$/V[a]	$E_{1/2}$/V
1	−1.303	−1.183	120	−1.243	−1.224
2	−1.139	−1.073	66	−1.106	−1.108
3	0.205	0.271	66	0.238	0.246
4	0.365	0.429	64	0.397	0.391

[a] $E'_{1/2} = (E_{pc} + E_{pa})/2$.

All the observed potentials were corrected by the Fc^+/Fc couple of ferrocene which was employed as the internal standard. Tetra-*n*-butylammonium perchlorate was employed as supporting electrolyte. All measurements were carried out in DMSO.

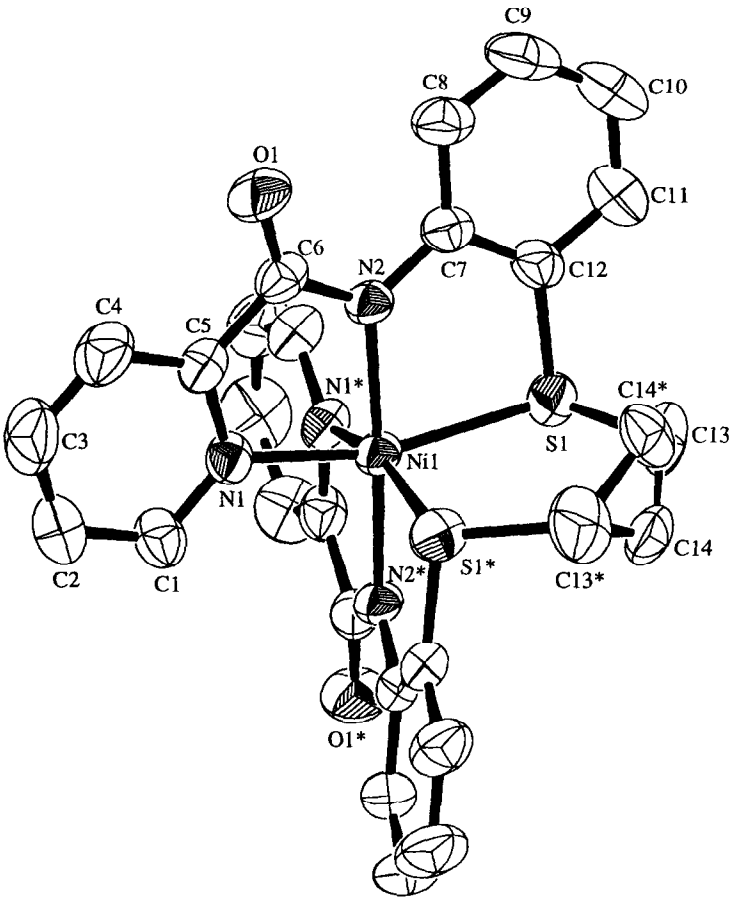

Fig. 4. An ORTEP drawing of compound **4** with atom numbering scheme, showing 50% probability ellipsoids.

-1.224 V for **1** and at -1.108 V for **2** vs the ferrocene/ferrocenium couple is assigned to Cu^{II} to Cu^{I} process. The deprotonated amido nitrogen is known as a strong donor atom and can stabilize the high oxidation state of metal ions [19]. However, Cu^{II} to Cu^{III} process of those complexes was not observed in DMSO. Shukla *et al.* had reported that the copper(II/III) redox process was observed at near $+0.53$ V vs SCE (ca $+0.08$ V vs Fc/Fc^{+}) for Cu^{II} complexes using N_2S_4 ligands which have the thiophenolate groups instead of pyridyl one of our ligands [20]. Thiophenolate sulfur is known as a coordinating atom which has an ability to stabilize the high oxidation state of metal ion [21]. Thus, our ligands have a weaker ability to stabilize the high oxidation state of metal ions, compared with Shukla's ligand system. In addition, the ESR study revealed that the Cu^{II}—N_{amido} bond of **1** is elongated by the solvation and **2** has the tetrahedral coordination geometry. Both of them are disadvantageous to stabilize the high oxidation state of metal ions. Therefore, Cu(II/III) redox process was not observed in the present copper(II) complexes.

The quasi-reversible process of the nickel(II) complexes observed at 0.246 V for **3** and at 0.391 V for **4** vs the ferrocene/ferrocenium couple is assigned to Ni^{II} to Ni^{III} process of them. Contrary to the Cu^{II} complexes, this process is not observed for Shukla's ligand system [20]. As described in crystallographic section, Ni—S bond distance of **4** is longer than that of **3** with increase of the number of carbon atom of alkyl bridge between two sulfur atoms. Owing to this difference, the redox potential of **4** is ca 0.15 V higher than that of **3**.

(Received 18 September 1997; accepted 19 November 1997)

Abstract—A one-dimensional 4,4′-bipy-bridged compound $[Mn(hfac)_2(4,4'\text{-bipy})]_n$ (hfac = hexafluoroacetetylacetonato; 4,4′-bipy = 4,4′-bipyridine) has been prepared and its structure has been determined. The structure consists of a zigzag-one-dimensional chain in which Mn(II) ion is bridged by 4,4′-bipy. The coordination environment is distorted octahedral for Mn(II), and $Mn(hfac)_2(4,4'\text{-bipy})$ has a *cis* coordination. Magnetic investigation shows that this compound presents a very weak antiferromagnetic interaction ($J = -0.196\ cm^{-1}$, $g_{Mn} = 2.02$, $F = 2.24 \times 10^{-3}$). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: one-dimensional compound; 4,4′-bipy-bridged compound; crystal structure; magnetic properties.

High-dimensional compounds are of interest in the field of molecular based magnets because on one side they should help researchers gain a better understanding of the correlation between the magnetism and structure, and on the other side high-dimensional antiferro- or ferromagnets are attractive for possible technical applications. Our interest is to obtain high-dimensional compounds to study magneto-structure correlation. 4,4′-bipyridine and $NaNO_2$ are both good bridging ligand to mediate magnetic interaction between metal ions [1–7]. $Mn(hfac)_2$ is a widely used precursor compound which has two vacant or two substitutable coordination sites to form high dimensional compounds with suitable bridging ligand.

In order to prepare high dimensional compound, we used 4,4′-bipyridine and $NaNO_2$ and $Mn(hfac)_2$ as reaction masses. Unexpectedly $NaNO_2$ did not react in this system; we only got a one-dimensional chain compound $Mn(hfac)_2(4,4'\text{-bipy})$. Although the present compound has a same mononuclear fragment $[Mn(hfac)_2]$ as that of $[Mn(hfac)_2L]$ (L = *trans*-1,2-bis(4-pyridyl)ethylene) which is previously reported by Okawa *et al.* [5], the bridging ligands of the two compounds are different.

In this paper, we report a new one-dimensional 4,4′-bipy bridged compound $Mn(hfac)_2(4,4'\text{-bipy})$ and its magnetic properties.

EXPERIMENTAL

Synthesis

To 10 ml ethanol solution of $Mn(hfac)_2$ (103.5 mg, 0.5 mmol) was added 4,4′-bipy (96.11 mg, 0.5 mmol) dissolved in 10 ml methane alcohol. This mixture solution was added to aqueous $NaNO_2$ (34.5 mg, 0.5 mmol). The clear yellow solution was left to stand undisturbed at room temperature. Several days later, X-ray quality brown-red single crystals were obtained by slow evaporation, which were filtered, washed with water, methane alcohol, ether, and air dried. Yield: 72%. Elemental analysis: Found: C, 44.78; H, 3.28;

N, 34.55. Calc. for $[MnC_{20}H_{10}F_{12}N_2O_4]$: C, 44.59; H, 3.74; N, 34.67%. m.p. 260°C (decomp.).

Physical measurements

Elemental analyses of carbon, hydrogen and nitrogen were carried out with a Perkin–Elmer analyzer model 240. The electronic spectrum was measured with a Perkin–Elmer Hitachi-240 spectrophotometer. The infrared spectroscopy on KBr pellets was performed on a Nicolet 5DX FT-IR spectrophotometer in the 4000–400 cm^{-1} region. Magnetic susceptibility measurement of a crystalline sample was carried out in the temperature range 1.3–300 K on a vibrating sample magnetometer, model CF-1.

Crystallographic data collection and structure determination

A brown-red monoclinic crystal with dimensions $0.2 \times 0.3 \times 0.3$ mm^3 was mounted on a computer-controlled Enraf-Nonius CAD4 diffractometer equipped with a graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å). Crystal data for [Mn(hfac)(4,4′-bipy)], $MnC_{20}H_{10}F_{12}N_2O_4$: Space group C_2/c, $a = 9.852(2)$ Å, $b = 17.026(3)$ Å, $c = 14.208(3)$ Å, $\alpha = \gamma = 90.00(0)°$, $\beta = 94.68(3)°$, $V = 2375(1)$ $Å^3$, $\rho_{calcd} = 1.748$ g cm^{-3}, $Z = 4$, $\mu = 0.6541$ mm^{-1}, $F(000) = 1236$.

The cell parameters were determined by a least-squares calculations based on the setting angles and 25 reflections with 2θ angles ranging from 8.35 to 12.14° at 299(1) K. The intensities of the $\pm hkl$ reflections were measured up to $\theta_{max} = 23°$, the ω-2θ scan technique was employed, the ω-scan width equal to $(0.6 \pm 0.35 \tan\theta)°$, and the scan speed 0.92–5.49° min^{-1}. A total of 1616 independent reflections was measured giving 1309 observed reflections ($I > 3\sigma(I)$) used in the refinement. Three standard reflections monitored every 60 min showed no intensity variation during the data collection. No absorption correction was made during processing.

The structure was solved by direct method (SHELXS-86) using SDP-PLUS program [8,9] and refined by the full-matrix least-squares method with use of the SHELXL-93 package of program. Atomic scattering factors were taken from Ref. 10. The final R and wR values were 0.047 and 0.053 respectively ($R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$. $wR = [\Sigma(w|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/(\sigma^2(F) + 99.0000\ F^2$; $[\Sigma w(|F_o| - F_c|)^2/(N_{obs} - N_{para})]^{1/2}$), and goodness of fit 2.14 for all observed reflections.

RESULTS AND DISCUSSION

Description of the crystal structure

Selected interatomic bond distances and bond angles are given in Table 1. The molecular structure is shown in Fig. 1.

The structure consists of chains in which *cis*-$Mn(hfac)_2$ are bridged by 4,4′-bipy. the chains are generated in the unit cell with *cis*-$Mn(hfac)_2$(4,4′-bipy), as shown in Fig. 1.

The Mn(II) ion assumes a distorted octahedral coordination geometry. The deviation from octahedral coordination geometry is probably due to the large steric hindrance between hfac molecules and 4,4′-bipy. Mn(II) is coordinated with four oxygen atoms from two hfac ligands [Mn(1)—O(1) = Mn(1)—O(1a) = 2.134(4) Å, Mn(1)—O(2) = Mn(1)—O(2) = 2.186(4) Å], and two nitrogen atoms from two 4,4′-bipy ligands [Mn(1)—N(11) = Mn(1)—N(11a) = 2.257(5) Å]. The other nitrogen atoms of the two 4,4′-bipy ligands are coordinated to two adjacent manganese ions. In the crystal lattice, the Mn ion lies on a two-fold rotation axis. From Fig. 2, we can see complex $Mn(hfac)_2$(4,4′-bipy) had a zigzag-chain structure. The two pyridine rings of a 4,4′-bipyridine is in a plane. The dihedral angle is 0.03°. The metal–metal separation across the bridging 4,4′-bipy is 11.674 Å for Mn(1)···Mn(1c).

IR spectrum

The IR spectrum of the compound exhibits two characteristic strong bonds at 1650–1660 and 1490 cm^{-1} attributed to the $\nu_{C=O}$ and $\nu_{C=C}$ stretching vibrations of the hfac respectively, suggesting an enol coordination mode for hfac ligands [11]. Because of the strong absorption of hfac in IR, most absorption bands of 4,4′-bipy were screened by the absorption of hfac, but some characteristic absorption can also be observed: a sharp band at 1610 cm^{-1} attributed to the ν_{ring} and another sharp one at 1410 cm^{-1} attributed to the $\nu_{C=C}$ stretching vibrations, also two sharp unsymmetric bands at 800 cm^{-1} attributed to the ν_{C-H} stretching vibrations [12].

Magnetic properties

The magnetic behavior of the compound is represented in Fig. 3, in the forms of $\chi_m T$ vs T. The observed $\chi_m T$ value is 4.65 cm^3 K mol^{-1} at 295 K, which is slightly higher than the spin-only value of 4.34 cm^3 K mol^{-1} for Mn(II) ($S = 5/2$) and $g_{Mn} = 2$. When the temperature is lowered, $\chi_m T$ remains almost constantly until 6.5 K and then decreases sharply to 0.8 cm^3 K mol^{-1} at 1.5 K, indicating the presence of a weak antiferromagnetic exchange interaction within the chain.

On the base of magneto-structural data on the complex, an antiferromagnetic exchange coupling within 1-D 4,4′-bipy-bridged chain is expected. In principle, the magnetic data for complex can be analyzed with the Hamiltonian $\hat{H} = -2J\Sigma\hat{S}_{2i} \cdot \hat{S}_{2i+1}$, where J is the exchange coupling parameter associated with a particular manganese(II) ion [13]. Since such a Hamiltonian cannot presently be used for an exact

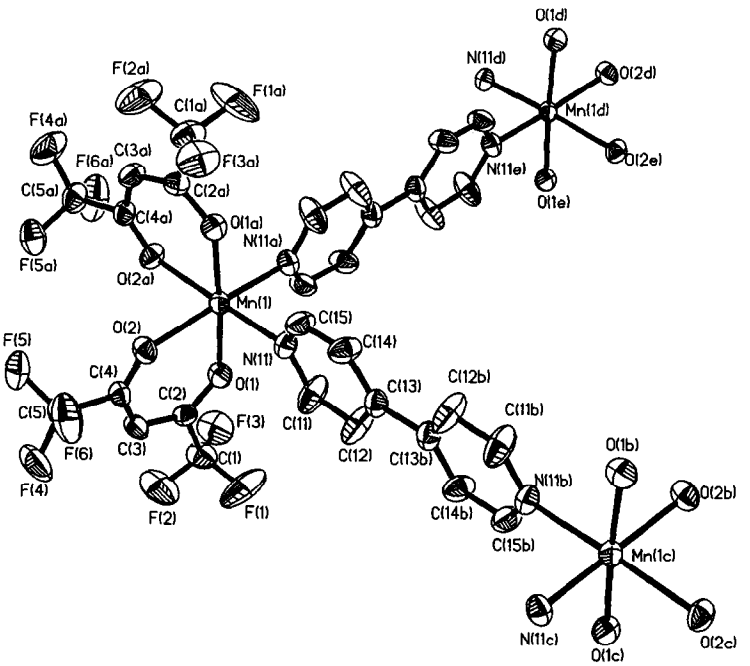

Fig. 1. The ORTEP drawing of $Mn(hfac)_2(4,4'\text{-bipy})$.

solution in the $S = 5/2$ case, we can only treat the present complex by using approximate model. It was found that the polynomial expression (eqn (1)) of Hatfield and co-workers [14] gives a fairly good fit to the data of complex.

$$\chi = \frac{Ng_{Mn}^2\beta^2}{KT}[A + Bx^2]/[1 + Cx + Dx^3] \qquad (1)$$

where $A = 2.9167$, $B = 208.04$, $C = 15.543$, $D = 2707.2$, and $x = |J|/KT$.

The least-squares fit from eqn (1) to the data was found with $J = -0.196(1)$ cm^{-1}, $g_{Mn} = 2.02$, where a very weak antiferromagnetic intrachain interaction between the nearest Mn(II) ions is present. The agreement factor, defined as $F = \Sigma_i(\chi_i^{obs} - \chi_i^{calcd})^2/\Sigma_i(\chi_i^{obs})^2$, was 2.24×10^{-3} for all of the 96 observations.

If we compare this J value with those previously reported for other complexes with 4,4′-bipy bridging ligands, we see that the coupling constant is similar to all the others [1–4,6]. The low value of J might be due to the following reasons: (1) the existence of Mn^{II}-(4,4′-bipy)-Mn^{II} pathway is not a sufficient condition for superexchange; (2) the Mn^{II}—Mn^{II} separation of 11.674 Å is clearly too large to permit larger overlap between magnetic orbitals.

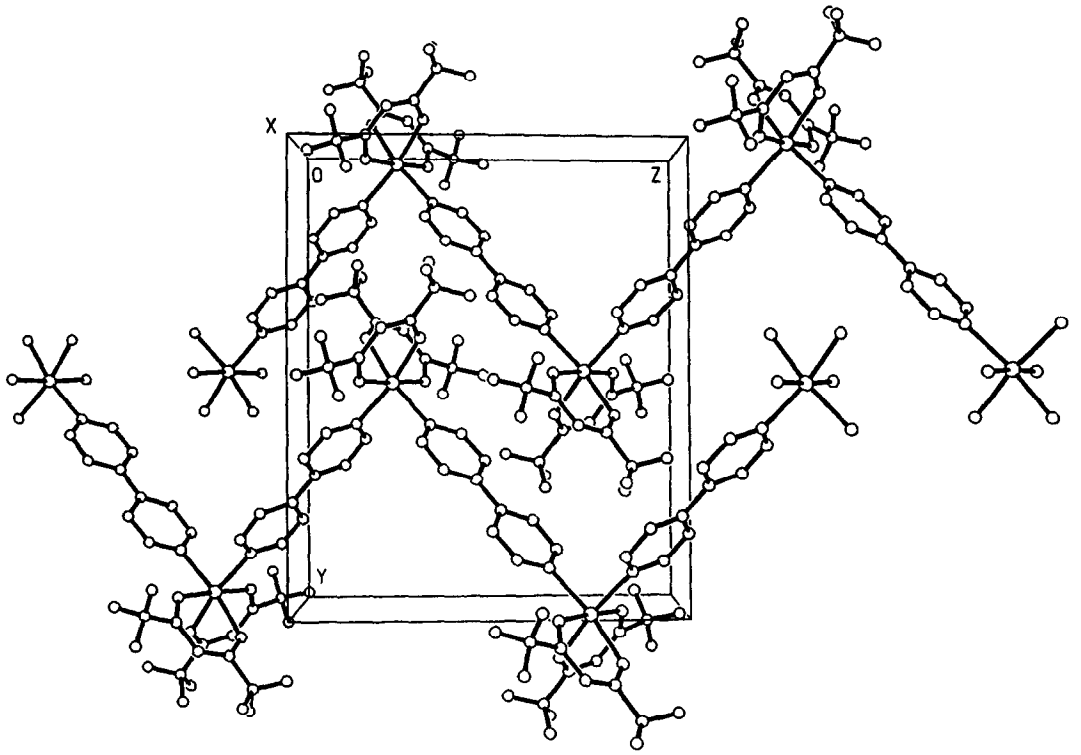

Fig. 2. View of the crystal cell of the compound.

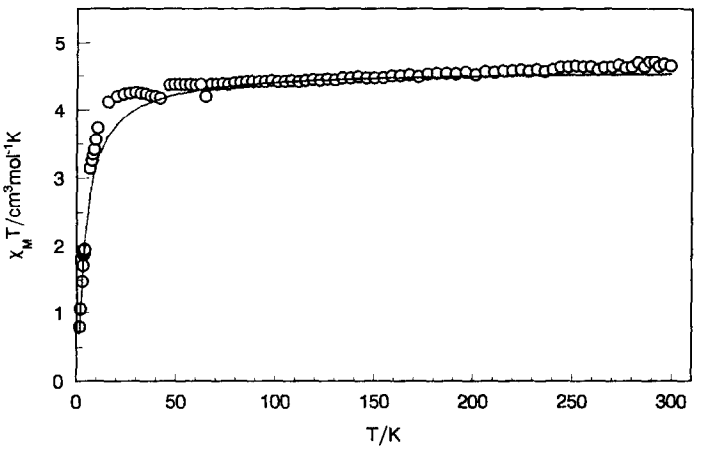

Fig. 3. Plots of the products $\chi_m T$ vs temperature for $Mn(hfac)_2(4,4'\text{-bipy})$. The solid line represents the best fitting (see text for the fitted parameters).

(Received 12 August 1997; accepted 19 November 1997)

Abstract—We have isolated and structurally characterized several novel bismuth coordination compounds. Dissolution of $Bi(NO_3)_3 \cdot 5H_2O$ in concentrated HCl, followed by crystallization from THF lead to the isolation of $[Bi(Cl)(\mu\text{-}Cl)_2(THF)_2]_\infty$, **1**. Each bismuth metal center of **1** adopts a 7-coordinated pentagonal bipyramidal geometry. One THF solvent molecule and one terminal chloride ligand are located in each of the axial positions. A terminal THF solvent molecule and four bridging chlorides reside in the equatorial positions. Dissolution of $Bi(O_2CMe)_3$ in pyridine (py) or N-methylimidazole (MeIm) results in the isolation of the appropriate amine adduct, either $Bi(O_2CMe)_3(py)_2$, **2** or $Bi(O_2CMe)_3(MeIm)_3 \cdot (MeIm)$, **3**. Compound **2** uses two py molecules to adopt an unusual (for bismuth acetate species) 8-coordinated triangular dodecahedral geometry. In contrast, **3** incorporates three MeIm molecules to adopt the 9-coordinated tricapped trigonal prismatic geometry typically observed for bismuth acetate compounds (a "free" MeIm molecule is located in the lattice). The reaction of $Bi[N(SiMe_3)_2]_3$ with $HOCH_2CMe_3$ (HONp) yields $[Bi(\mu\text{-}ONp)(ONp)_2(HONp)]_2$, **4**. An alternative synthetic route to **4** is the metathical exchange between $BiCl_3$ and 3 equivalents of NaONp in the presence of HONp. The bismuth atoms of **4** are 5-coordinated and adopt an apical-shared, square base pyramidal (SP) arrangement. Recrystallization of **4** from py yields the dinuclear complex $[Bi(\mu\text{-}ONp)(ONp)_2(py)]_2$, **5**. The Bi atoms of **5** also adopt a 5-coordinated SP geometry; however, the two metal centers are linked through a basal-shared arrangement. The apical ONp ligands are in an up-down relationship to each other. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: bismuth; halide; acetate; alkoxide; neopentoxide.

Coordination compounds of bismuth are of interest for such varied applications as oxidation catalysts [2–5], medicinal and biomedical practices [6–11], superconductors [7,12,13], and other oxide based materials [1,2,7,14]. Thus, much attention has focused on identification of new bismuth compounds that are suitable for these applications. We are interested in highly soluble Bi compounds for use in precursor solutions to produce ferroelectric thin films. Ferroelectric materials are those ceramics that possess a spontaneous polarization that can be reoriented with an

* Author to whom correspondence should be addressed.

applied electric field [15]. This leads to a hysteresis in the polarization-voltage response and is the basis of computer memory applications. A wide range of ferroelectric materials that contain bismuth and may potentially be used as memory, piezoelectric, or electro-optic devices would include: $Bi_4Ti_3O_{12}$, $SrBi_2Nb_2O_9$, $BiCaNb_2O_9$, $BiCaTa_2O_9$, $Bi_4Ba_2Ti_5O_{18}$, $Bi_4BaTi_4O_{15}$, $BiNaTi_2O_6$, and $BiKTi_2O_6$ [15]. Currently, the most research activity surrounding bismuth ceramics involves the layered-perovskite ferroelectric material $SrBi_2Ta_2O_9$ (SBT) [1,16–19]. SBT materials are of great interest for non-volatile memory applications due to their promise of non-fatigue with extended electrical cycling.

Since the preparation of these bismuth oxide materials requires extremely pure and well-characterized compounds, it is important to know the solid and solution state characteristics of these precursors in order to exploit their properties to the fullest extent. Even though a wide number of bismuth compounds have been crystallographically characterized. [1–3,6,8,10,12–14,20–52], few of these compounds are suitable for the solution processes used to generate films [53]. Recently, we reported the use of pyridine (py) to dissolve $[Bi(O_2CMe)_3]_\infty$ as a key component in the production of low temperature SBT thin films [1,15]. From this investigation, two amine solvated $Bi(O_2CMe)_3$ complexes were isolated [1]. In looking for further alternative precursors, we have investigated ONp derivatives of bismuth. We become interested in the *neo*-pentoxide (OCH_2CMe_3 = ONp) ligand for materials applications due to the combination of favorable characteristics of the hydrocarbon chain [54]. The β-hydrogens of the ONp ligand are easily eliminated upon hydrolysis, allowing for rapid organic decomposition which is vital for production of uniform materials at low temperature. The OBu^t moiety of the ONp ligand greatly increases the solubility of the resulting metal alkoxide by introducing steric bulk around the metal center, inhibiting oligomerization. The combination of these two attributes makes the ONp ligand an ideal candidate to produce well-characterized highly soluble bismuth alkoxides.

This report details the synthesis, characterization, and X-ray structural information of a number of bismuth coordination compounds: (i) the halide precursor, $[Bi(Cl)(\mu\text{-}Cl)_2(THF)_2]_\infty$ **1**, (ii) two solvated acetates, $Bi(O_2CMe)_3(py)_2$, **2** [1,19], and $Bi(O_2CMe)_3(MeIm)_3 \cdot (MeIm)$, **3** [1,19], and (iii) two new solvated bismuth alkoxides, $[Bi(\mu\text{-}ONp)(ONp)_2(HONp)]_2$, **4** and $[Bi(\mu\text{-}ONp)(ONp)_2(py)]_2$, **5**. The solution behaviors of these compounds, based on NMR and molecular weight studies are also discussed.

EXPERIMENTAL

All compounds were handled under an inert atmosphere using standard Schlenk and glove box techniques, unless otherwise noted, as previously described [55]. FT-IR data were obtained on a Nicolet, Magna System Spectrometer-550. Thermal gravimetric analysis/differential thermal analysis (TGA/DTA) experiments were performed on a Polymer Laboratories STA 1500 Instrument. Elemental Analysis was performed on a Perkin–Elmer 2400 CHN-S/O Elemental Analyzer. NMR spectral data were collected on an AC-250 or Brucker 400 MHz spectrometer. All spectra were referenced against the residual proton impurity in the appropriate pre-dried deuterated solvent. The following compounds were used as received (Aldrich): concentrated HCl, $Bi(NO_3)_3 \cdot 5H_2O$, $HOCH_2CMe_3$ (HONp), N-methylimidazole (MeIm), $LiN(SiMe_3)_2$, $BiCl_3$ and $Bi(O_2CMe)_3$ (Alpha). Immediately prior to use, toluene and tetrahydrofuran (THF) were dried over and distilled from Na/benzophenone, whereas pyridine (py, Fisher) was dried over and distilled from CaO. $Bi[N(SiMe_3)_2]_3$ was synthesized according to literature reports [$BiCl_3$ (Aldrich) and 3 $LiN(SiMe_3)_2$ (Aldrich) in THF] [26]. NaONp, synthesized by either the reaction between Na° or NaH with HONp, was purified by sublimation.

$[Bi(Cl)(\mu\text{-}Cl)_2(THF)_2]_\infty$, 1

To a Schlenk flask charged with $Bi(NO_3)_3 \cdot 5H_2O$ (10.0 g, 20.6 mmol), concentrated HCl (20 ml) was slowly added by addition funnel. The reaction mixture, evolves as gas (bubbles) and turns yellow. The reaction mixture was allowed to stir at 60°C under an argon atmosphere. Periodically, excess pressure was removed by introduction of a slight vacuum. After 12 h, the reaction mixture was cooled to room temperature and all of the volatile materials were removed *in vacuo*. The resulting pale yellow powder was dissolved in THF and allowed to sit at glovebox temperatures for several days. The resulting X-ray quality crystals proved to be $[Bi(Cl)(\mu\text{-}Cl)_2(THF)_2]_\infty$, **1**. Yield first crop 4.3 g (47.5%). Repetition of concentration and sitting of the mother liquor leads to a quantitative yield of **1**. TGA/DTA (oxygen) [weight loss up to T°C (total weight loss (%))/thermal event, T°C]: 160°C (30.0)/endo (sm), 70.0°C; 103°C (73.6)/exo (m), 278°C; 395°C (74.0)/exo (m), 360°C. Elem. Anal. Calcd for $C_8H_{16}BiO_2Cl_3$ (two THF): 20.90, C; 3.51, H; for $C_4H_8BiOCl_3$ (one THF): 12.40, C; 2.08, H. Found: 12.46, C; 2.13, H.

$Bi(O_2CMe)_3(py)_2$, 2

$Bi(O_2CMe)_3$ (1.00 g, 2.59 mmol) was dissolved in a minimum amount of py (~1.53 ml), stirred for 12 h, centrifuged to remove any undissolved powder, and then concentrated by rotary evaporation. After sitting at circumjacent glovebox temperatures for 2–3 days, X-ray quality crystals were isolated and proved to be $Bi(O_2CMe)_3(py)_2$, **2**. Repetition of the concentration

and sitting of the mother liquor leads to a quantitative yield of **2**. ^{1}H NMR (400.1 MHz, $CDCl_3$) δ 8.60 (4.5H, bs, NC(*H*)C(H)C(H)C(H)C(H)), 7.71 (2H, mult., NC(H)C(H)C(*H*)C(H)C(H), 7.33 (4.3H, mult., NC(H)C(*H*)C(H)C(H)C(H)), 2.05 (9H, mult., O_2CMe). $Bi(\mu\text{-}OCH_2CMe_3)(OCH_2CMe_3)_2(HOCH_2CMe_3)]_2$, 4

Method A. To a solution of $Bi[N(SiMe_3)_2]_3$ (15.0 g, 218 mmol) in toluene (100 ml), $HOCH_2CMe_3$ (8.62 g, 9.80 mmol) was added via an additional funnel. The bright yellow solution was heated to 65°C until the reaction mixture turns pale yellow (~2.5 h). The volatile components were removed *in vacuo*, the resulting powder was washed with hexanes and extracted with toluene (*note*: extraction of the dried material with THF leads to a higher yield of a white powder with identical analytical data as noted for the crystalline material of **4**). The toluene soluble fraction was cooled to −35°C yields crystals which proved to be $[Bi(\mu\text{-}OCH_2CMe_3)(OCH_2CMe_3)_2(HOCH_2CMe_3)]_2$, **4**. Yield 6.14 g (50.5%). ^{1}H NMR (250.1 MHz, toluene-d_8) 4.22 (2H, s, OCH_2CMe_3), 1.04 (12H, s, OCH_2CMe). ^{13}C NMR (100.6 MHz, toluene-d_8) 74.9 (OCH_2CMe), 34.8(OCH_2CMe), 27.3 (OCH_2CMe). FT-IR (KBr, cm^{-1}) 3477 (w), 2953 (s), 2903 (w), 2863 (m), 2813 (w), 2743 (w), 2696 (m), 1477 (m), 1462 (w), 1391 (m), 1357 (m), 1302 (w), 1260 (m), 1215 (w), 1048 (s), 1006 (s), 930 (w), 897 (m), 622 (m), 584 (m), 564 (m), 534 (m).

Method B. To a solution of NaONp (0.67 g, 6.12 mmol) and HONp (0.27 g, 0.31 mmol) in toluene (30 ml), $BiCl_3$ (0.50 g, 2.04 mmol) was slowly added. The reaction mixture immediately turned cloudy. After stirring for 24 h, the reaction mixture was separated by centrifugation and the volatile materials of the soluble fraction were removed by rotary evaporation. The analytical data of the bulk powder proved consistent with **4** generated by method A. Crystalline yield 0.601 g (52.7%)

$[Bi(\mu\text{-}OCH_2CMe_3)(OCH_2CMe_3)_2(py)]_2$, 5

In a vial, **4** (0.50 g, 0.45 mmol) was dissolved in py (7.5 ml), stirred for 12 h, the solution concentrated, and cooled to −35°C. The resulting crystals proved to be $[Bi(\mu\text{-}OCH_2CMe_3)(OCH_2CMe_3)_2(py)]_2$, **5**. Yield 44.6% (0.22 g). ^{1}H NMR (400.1 MHz, pyridine-d_5, partial coordinated py not differentiated from solvent) δ 4.43 (OCH_2CMe_3), 1.08 (OCH_2CMe_3). ^{13}C NMR (100.6 MHz, pyridine-d_5) δ 73.7 (OCH_2CMe_3), 26.7 (OCH_2CMe_3), 25.9 (OCH_2CMe_3). FT-IR (KBr, cm^{-1}) 2953 (s), 2853 (m), 2793 (w), 2694 (w), 1574 (m), 1474 (m), 1461 (sh), 1401 (m), 1348 (m), 1262 (m), 1063 (s), 1010 (m), 798 (m), 751 (sh), 639 (bw), 553 (w).

X-ray collection, structure determination and refinement

Table 1 lists the data collection parameters for **1**–**5**. All compounds were handled using standard inert atmosphere oil coating techniques. For all of the crystals, the determination of the Laue symmetry, crystal class, unit cell parameters and the orientation matrix were carried out according to standard procedures [56]. Intensity data were collected using a $2\theta/\omega$ scan technique with Mo-K_α radiation and monitored after 97 reflections. The raw data were processed with either: (a) a local version of CARESS [57] which employs a modified version of the Lehman-Larsen algorithm to obtain intensities and standard deviations from the measured 96-step profiles or (b) the SHELXTL PC Version 4.2/360 software using SHELX 93 software for structure refinement corrected for absorption using the ellipsoidal option in the XEMP facility of SHLXTL PC. All data were corrected for Lorentz and polarization effects and were placed on approximately absolute scale. Structures were solved in the proper space group using

Patterson and difference Fourier techniques. Compounds **1, 2,** and **5** were solved by direct methods and refined on F^2 by full-matrix least-squares technique. The analytical factors for neutral atoms were used throughout the analysis.

For **1,** all 3265 data were corrected for decay (20%), absorption, Lorentz, and polarization effects, and placed on an approximately absolute scale. The diffraction symmetry was $2/m$ with systematic absences $0k0$ for $k = 2n+1$ and $h0l$ for $h+l = 2n+1$. The centrosymmetric monoclinic space group $P2_1/n$ space group was therefore uniquely defined. Compound **1** is polymeric with repeating $BiCl_3(THF)_2$ unit and is disordered. To account for this disorder, two components were included for atoms Bi(1), Cl(3), O(2), C(5), and C(8) (see Fig. 1). Hydrogen atoms were not included in the refinement due to the disorder. At convergence, $wR_2 = 0.1065$ and GOF = 1.057 for 175 variables refined against all 3051 unique data (for comparison, refinement on F, $R_1 = 0.0397$ for those 2065 data with $F > 4.0\sigma(F)$).

For compound **2** all 3267 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was $2/m$ with systematic absences $0k0$ for $k = 2n+1$ and $h0l$ for $l = 2n+1$. The centrosymmetric monoclinic space group $P2_1/c$[C_{2h}^5; No. 14] is therefore uniquely defined. Hydrogen atoms were included using a riding model in the solution of the structure of **2**. At convergence, $wR_2 = 0.0593$ and GOF = 1.082 for 227 variables refined against all 3124 unique data (for comparison, refinement on F, $R_1 = 0.0271$ for those 2454 data with $F > 4.0\sigma(F)$).

Compound **3** was successfully solved in the $P\bar{1}$ space group. This solution yielded the Bi atom position and the majority of the carbon, nitrogen and oxygen atom positions. Subsequent Fourier synthesis gave the remaining atomic positions of **3**. At this time a methyl imidazole was found in the lattice. The hydrogen atoms were fixed in positions of ideal geometry, with a C—H distance of 0.93 Å for phenyl hydrogens and 0.96 Å for methyl hydrogens and refined using the riding model in the SFIX facility in SHELXL 93. These idealized hydrogen atoms had their isotropic temperature factors fixed at 1.2 times (phenyl) or 1.5 times (methyl) the equivalent isotropic U of the C

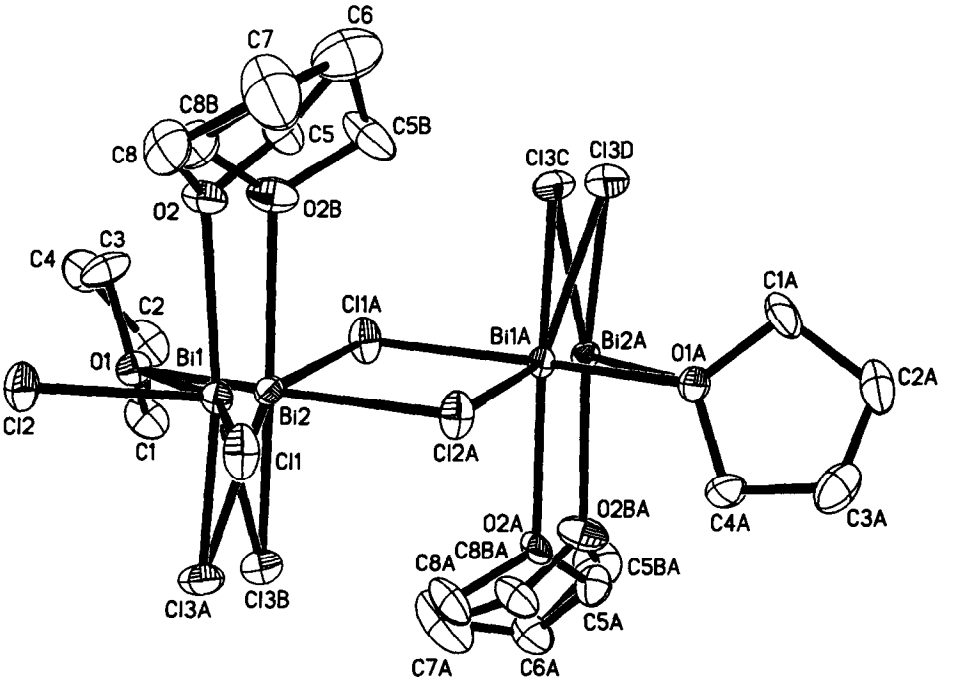

Fig. 1. Thermal ellipsoid plot of $[Bi(Cl)(\mu\text{-}Cl)_2(THF)_2]_\infty$, **1**. Thermal ellipsoids are drawn at the 50% level.

atoms they were bonded to. The final refinement included anisotropic thermal parameters on all non-hydrogen atoms and converged to $R_1 = 0.0488$ and $R2_w = 0.1272$. Another unit cell and space group were also solved for a similar $Bi(O_2CMe)_3(MeIm)_3$ complex but only $\frac{1}{2}$MeIm was located in the unit cell lattice. This compound is referred to as $Bi(O_2CMe)_3(MeIm)_3 \cdot \frac{1}{2}MeIm$, **3a** [58]. A full listing, detailing the collection parameters for this molecule can be found in the supplementary information.

Compound **4** was successfully solved in the $P\bar{1}$ space group. This solution yielded the bismuth atom and the majority of all other atoms. Subsequent Fourier synthesis gave all remaining carbon and oxygen atom positions. All hydrogen atoms were fixed in positions of ideal geometry, with a C—H distance of 0.97 Å for ethyl hydrogens and 0.96 Å for methyl hydrogens and refined using the riding model in the SFIX facility in SHELXL 93. These idealized hydrogen atoms had their isotropic temperature factors fixed at 1.2 times (ethyl) or 1.5 times (methyl) the equivalent isotropic U of the carbon atom they were bonded to. The final refinement included anisotropic thermal parameters on all non-hydrogen atoms and converged to $R_1 = 0.0590$ and $R2_w = 0.1122$ for $I < 2\sigma < (I)$.

For **5**, all 576 data were corrected for decay (15%), absorption, Lorentz and polarization effects, and were placed on an approximately absolute scale. The diffraction symmetry was $2/m$ with systematic absences $0k0$ for $k = 2n+1$ and $h0l$ for $l = 2n+1$. The centrosymmetric monoclinic space group $P2_1/c$ [C_{2h}^5; No. 14] is therefore uniquely defined. Hydrogen atoms were included using a riding model for solving of the structure. The molecule is dinuclear and located about an inversion center. At convergence, $wR_2 = 0.0834$ and GOF = 1.033 for 226 variables refined against all 5468 unique data (for comparison, refinement on F, $R_1 = 0.0318$ for those 4205 data with $F > 4.0\sigma(F)$).

RESULTS AND DISCUSSION

Due to the interest in bismuth containing species, we isolated and characterized a series of bismuth coordination compounds: (a) a THF adduct of $BiCl_3$, (b) two amine adducts of $Bi(O_2CMe)_3$, and (c) two, solvent modified bismuth alkoxide compounds. The solid state structures and solution state behavior were determined.

Synthesis

$BiCl_3$ was generated by the dissolution of $Bi(NO_3)_3 \cdot 5H_2O$ in THF, followed by addition of (concentrated) HCl, and stirring for over 12 h at room temperature (eqn (1)).

$$Bi(NO_3)\cdot 5H_2O + (xs)HCl \xrightarrow[THF]{-5H_2O,\ -3HNO_3} [Bi(\mu\text{-}Cl)_2(Cl)(THF)_2]_\infty \quad (1)$$

After this time, all of the volatile materials were removed *in vacuo*. The resulting powder was re-dissolved in a minimum amount of THF and allowed to

sit at glove box temperature for several days. Large crystals formed which proved to be $[BiCl_3(THF)_2]_\infty$, **1** (see Fig. 1). TGA/DTA analyses indicated that 2 molecules of THF for every Bi atom were present which is consistent with the NMR data (*vide infra*); however, the elemental analysis revealed only one molecule of THF per molecule. As was noted for $BiCl_3(THF)_3$ [35], the THF ligands are volatile and the degree of coordination of THF for **1** is influenced by the time/temperature of drying. $BiCl_3(THF)_3$ was formed at low temperature (−20°C), whereas, **1** was grown at glovebox temperature and this may explain the structure difference (losing one of the labile THF ligands from $BiCl_3(THF)_3$ to form **1** is easily envisioned).

$[Bi(O_2CMe)_3]_\infty$ compounds are reportedly soluble in amine solutions resulting in coordination of the solvent; however, no structural studies on the solvated compounds have been reported [44]. Pyridine (py) and N-methylimidazole (MeIm) were chosen to solubilize $[Bi(O_2CMe)_3]_\infty$ since these amines are highly coordinating Lewis bases and would disrupt the polymer. Using a minimum of amount of the appropriate amine, $[Bi(O_2CMe)_3]_\infty$ was dissolved and allowed to sit at glovebox temperature for 2–3 days. A quantitative yield of crystalline material was isolated from the synthetic route shown in eqn (2).

$$Bi(O_2CMe)_3 + Solv \rightarrow Bi(O_2CMe)_3(Solv)_x \cdot (Solv)_y \quad (2)$$

Solv = pyridine, $x = 2, y = 0$, **2**.
= 1-methyl imidazole, $x = 3, y = 1$, **3**,
$x = 3, y = 1/2$, **3a**.

These solvents have resulted in unusual transition metal and the lanthanide [59–66] complexes necessitating structural determination of the resulting amine coordinated products. The use of py results in the formation of the clear crystalline material of $Bi(O_2CMe)_3(py)_2$, **2**; whereas, using MeIm as a solvent results in the isolation of a slightly yellow colored crystalline material $Bi(O_2CMe)_3(MeIm)_3 \cdot (MeIm)$, **3**. Thermal ellipsoid plots of **2** and **3** are shown in Figs 2 and 3, respectively. NMR data reveal two molecules of py are coordinated to the metal center (*vide infra*) but elemental analyses indicate only one molecule of py is associated with **2**. As was noted for the coordinated THF molecules of **1**, the coordinated py molecules of **2** are labile and the temperature and/or time of drying can influence the number of associated solvent molecules. For the elemental analysis of **3**, the data is consistent with a slight excess of MeIm (a reflection of the low volatility of MeIm upon drying). Due to the additional coordination of the amines, the solubility of **2** and **3** is slightly enhanced in toluene. This simple recrystallization step also turns out to be an excellent method for further purification of these compounds [the starting material (sold as 99.999% pure) had several impurities present by ICP-MS].

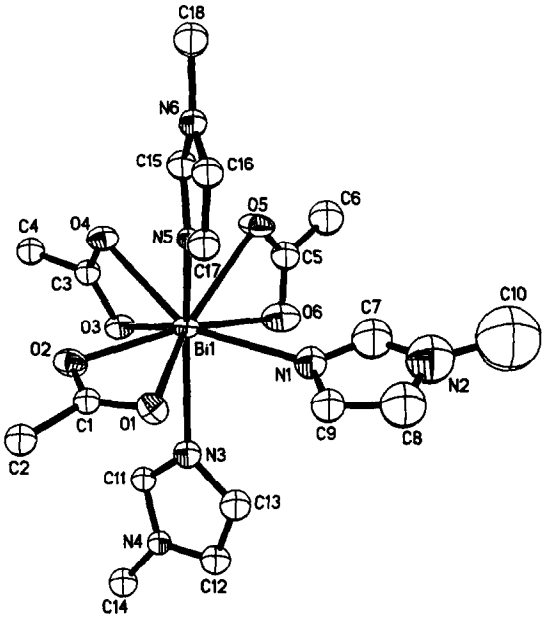

Fig. 2. Thermal ellipsoid plot of $Bi(O_2CMe)_3(py)_2$, **2** Thermal ellipsoids are drawn at the 50% level.

Alcoholysis exchange of $Bi(N(SiMe_3)_2)_3$ with HONp produces $[Bi(ONp)_3(HONp)]_2$, **4**, eqn (3a) (see Fig. 4).

$$2Bi[N(SiMe_3)_2]_3 + 9HONp \xrightarrow[-6HN(SiMe_3)_2]{\text{toluene}} [Bi(\mu\text{-}ONp)(ONp)_2(HONp)]_2 \quad (3a)$$

$$3BiCl_3 + 6NaONp + (xs)HONp \xrightarrow[-6NaCl]{\text{toluene}} [Bi(\mu\text{-}ONp)(ONp)_2(HONp)]_2 \quad (3b)$$

The loss of yellow color of the initial solution was used as an indication that the reaction was finished. At room temperature, this reaction can take one week to reach completion; however, careful heating reduces the reaction time to 2–3 h (*note*: uncontrolled and unmonitored heating, results in decomposition of **4** producing a black precipitate proven by XRF to be Bi/BiO). Removal of the solvent, followed by redissolution in toluene and cooling to −35°C yields X-ray quality crystals of **4**. Extraction of **4** with THF yields a powder with identical analytical data as noted for the crystalline material. As was observed for other amide alcohol exchange reactions, the parent amine is often noted as a minor impurity [67]. Historically, these impurities are removed by heating a toluene solution of the product at reflux temperatures; however, in solution, **4** decomposes at relatively low temperatures (<60°C). An alternative synthesis that produces **4** is the metathical exchange of $BiCl_3$ with NaONp/HONp in toluene (eqn (3b)). Elemental analysis of **4** has proven inconsistent due to its extreme sensitivity to relative humidity and the volatility of

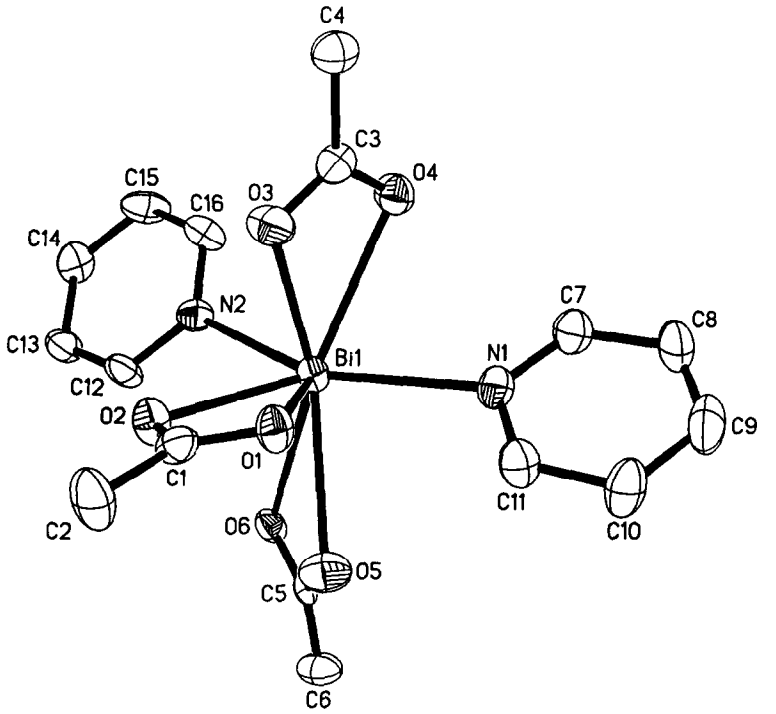

Fig. 3. Thermal ellipsoid plot of $Bi(O_2CMe)_3(MeIm)_3 \cdot MeIm$, **3**. Thermal ellipsoids are drawn at the 50% level. The lattice MeIm is not shown.

this compound. This bismuth alkoxide is stable in a sealed solution (toluene or THF) for extended period of times at room temperature. Attempts to sublime this material have been successful at temperatures < 100 °C ($@ 10^{-3}$ Torr); however, there is a significant amount of decomposition accompanied by this process.

In an attempt to replace the coordinated HONp alcohol of **4**, several Lewis basic solvents were investigated. As observed for the acetate system, amine solvents readily bind to the bismuth metal center. Redissolution of **4** in py resulted in replacement of the coordinated HONp, eqn (4).

$$[Bi(\mu\text{-ONp})(ONp)_2(HONp)]_2 + py \xrightarrow[-2HONp]{py} [Bi(\mu\text{-ONp})(ONp)_2(py)]_2 \quad (4)$$

Crystals were grown by cooling (−35 C) a concentrated solution of **4** in py and crystallographically characterized as $[Bi(\mu\text{-ONp})(ONp)_2(py)]_2$, **5**, verifying that the dinuclear structure is retained in the presence of py. The thermal ellipsoid plot of **5** is shown in Fig. 5. Elemental analysis of **5** has also proven to be inconsistent due to its sensitivity to the atmospheric water as well as its volatility.

Bismuth halides. Typically bismuth(III) halides are mononuclear species of general formula $BiX_3(cmplx)_n$ (X = Cl, Br, or I; cmplx = macrocylces [27,33,43,50], solvent [35,38,41,45,48], and other complexing agents [10,20,49,68] with coordination numbers ranging from 6 to 9). Whitmire and co-workers have shown by crystallographic investigations that $BiCl_3$ is easily complexed using oxygen donor ligands to produce $[BiCl_3(Solv)_3]_n$ (Solv = THF, $n = 1$; diglyme, $n = 2$; and diethylcarbitol, $n = 2$) complexes [35]. The THF

[a] OR = OCH_2CMe_3.

complex in this investigation was found to be a mononuclear species.

In contrast, the product from eqn (1) proved to be the polynuclear complex, $[Bi(\mu\text{-}Cl)_2Cl(THF)_2]_\infty$, **1** (see Fig. 1). The Bi metal centers of **1** are 7-coordinated in a slightly distorted pentagonal bipyramidal arrangement. The equatorial positions are filled by one THF molecule and two bridging chloride atoms. The remaining equatorial positions consist of the two bridging chlorides associated with the next metal center. The axial positions are filled by a terminal chloride ligand and a solvent molecule of THF. Several crystals were investigated and all proved to be the polymeric structure of **1**. This structure is consistent with the hypervalencey normally associated with Bi compounds [35]. Several of the atoms of compound **1** are disordered and due to the proximity of these atoms, several anomalous short distances and angles are noted in Table 7. If these are not included in the discussion of the metrical data for **1**, the Bi—Cl and Bi—O distances and angles of **1** are in agreement with those previously reported [35]. As expected, the μ-Cl distances are slightly longer than those noted for the terminal ligands.

Bismuth acetates. An excellent review of bismuth carboxylates, alkoxides and β-diketonates has been published by Pisarevskii and Martynenko [42]. The polymeric structure of $[Bi(O_2CH)_3]_\infty$ was solved in 1969 [46]. Since then only two other structures containing the tri-acetate arrangement have been reported: the polymeric $[Bi(O_2CMe)_3]_\infty$ [47] and the tetranuclear pivalate adduct, $[Bi(O_2CC(CH_3)_3)_3]_4$ [12]. Each of these compounds has a bismuth center that is 9-coordinated due to oligomerization through bridging oxygen atoms. The increased steric repulsion of the pivalate results in a tetranuclear species, not infinite chains. There is a report on the crystal structure of bismuth(III) trifluoroacetate trifluoroacetic acid $[Bi(O_2CCF_3)_3 \cdot HO_2CCF_3]_\infty$ which maintains a polymeric structure even with the coordination of HO_2CCF_3 [52]. Interestingly, there are two mondentate acetate ligands noted for this compound [52]. Other solvated $Bi(O_2CMe)_3$ compounds have been reported. These include the thiourea solvated species which were characterized as the molecular 9-coordinated species $[Bi_2(O_2CMe)_6 \cdot 3SC(NH_2)_2$ and $Bi(O_2CMe)_3(SC(NH_2)_2)_3]$ [29]. The latter complex has the oxygen atoms on one side of the Bi atom and the S atoms on the other.

While it is known that $[Bi(O_2CMe)_3]_\infty$ will dissolve in amine solvents [44], no amine solvated structures of this compound have been reported to date. Due to

the dearth of structurally characterized amine adducts and the unique characteristics imparted by coordination of imidazole molecules [59–66], the crystal structures of the $Bi(O_2CMe)_3$ amine compounds were solved. Figure 2 is the thermal ellipsoid plot of $Bi(O_2CMe)_3py_2$, **2**. Compound **2** is an unusual 8-coordinated bismuth acetate wherein 6 of the sites are filled by the acetate ligands. The remaining two sites are filled by two molecules of py. Eight-coordinated molecules are found to adopt either a cube, a square antiprism or a triangulated dodecahedron (TD) arrangement [69]. On the basis of the observed angles, **2** adopts a distorted TD geometry with N(1) as the lone capping atom and O(2) and N(2) as the shared capping atoms of the dodecahedron (see Fig. 2). Due to the lability of the py molecules associated with **2**, it is not unreasonable to suggest that several different structures of $Bi(O_2CMe)py_x$ ($x = 1$ or 3) are isolable as well.

In contrast to the 8-coordinated structure of **2**, $Bi(O_2CMe)_3(MeIm)_3 \cdot MeIm$, **3**, (see Fig. 3) is a typical 9-coordinated tricapped trigonal prism complex with 3 molecules of MeIm coordinated on the same side of the bismuth atom. Another MeIm is observed co-crystallizing within the defined unit cell, well away from the bismuth metal center (the three closest contacts to the Bi atom are 4.98, 5.67, and 5.75 Å from the C(22), C(21), and N(7) atoms, respectively). A crystal that has an identical structural arrangement of the $Bi(O_2CMe)_3(MeIm)_3$ core was solved in an alternative space group [58]; however, only $\frac{1}{2}$ of a MeIm was located in the unit cell lattice to form $Bi(O_2CMe)_3(MeIm)_3 \cdot \frac{1}{2}MeIm$, **3a**. Structural information concerning both crystal structure solutions has been deposited in the supplementary information section. The metrical data listed in Table 7 and discussed in this paper were chosen due to the slightly improved R values for **3** versus **3a**.

An average Bi—O distance of 2.53 Å was observed for both **2** and **3** (standard values range from 2.18–2.94 Å; $[Bi(O_2CMe)_3]_\infty = 2.44$ Å). The average Bi—N distance recorded for both **2** and **3** is ~2.58 Å. Typical values for the O—Bi—O angles of a single carboxylate ligand range from 40 to 57 and the angles for **2** and **3** fall within this range as well.

Bismuth alkoxides. Typically bismuth alkoxides are polymeric unless sterically demanding ligands are utilized [24–26,34,39,42]. For example, the first structurally characterized bismuth alkoxide by Evans *et al.* used aryl oxide ligands to form the mononuclear complex $Bi(OC_6H_3Me_2\text{-}2,6)_3$ [34]. The Buhro group [26], and independently Hubert-Pfalzgraf and co-workers [24,25], found that using the less sterically demanding methoxyethanol (OC_2H_4OMe or OEtOMe) yielded the polymeric $[Bi(\mu\text{-}OEtOMe)(OEtOMe)_2]_\infty$. Herrmann *et al.* have isolated a mononuclear β-methoxy alcohol [i.e., $Bi(OCHMe_2CH_2OMe)_3$] derivative but no structure was reported [70]. The majority of other monodentate alkoxide compounds of bismuth (i.e., $Bi(OR)_3$ where R = Me, Et, and Pr^i) are poorly characterized, display low solubility and sublime in low yield [24,25]. The Hubert-Pfalzgraf group also reports the synthesis of the monomeric $Bi(OBu^t)_3$ (nuclearity based on partial X-ray crystallographic results) [24,25]. Whitmire and co-workers have reported a series of fluorinated alkoxides, $Bi(\mu\text{-}OCH(CF_3)_2)(OCH(CF_3)_2)_2(THF)]_2$, $[Bi(\mu\text{-}OC_6F_5)(OC_6F_5)_2 \cdot Solv]_2 \cdot Solv$ (Solv = toluene, THF, cyclohexane) with intermediate ligands that produce dinuclear species [39]. The reported long F···Bi interactions along with increased size of F versus H atoms help reduce oligomerization, creating soluble and volatile precursors.

The structure of $[Bi(\mu\text{-}ONp)(ONp)_2(HONp)]_2$, **4**, (see Fig. 4) proved to be a dinuclear species with each 5-coordinated bismuth adopting a distorted square pyramidal (SP) arrangement of ONp ligands. Table 8 lists the bond distances and angles for **4**. One of the alkoxides of **4** must be considered a coordinated alcohol to maintain charge balance. The O(3) atom was assigned as the oxygen of the coordinated HONp based on the Bi—O(3) bond length being ~0.5 Å longer than the rest of the terminal alkoxides. The C—O—Bi bond angle is not significantly varied from the other ligands but this may be due to steric constraints. Unfortunately, no peaks corresponding to hydrogen atoms could be located on any of the oxygens. Further evidence of this coordinated alcohol was found in the FT-IR spectral data, bond distances (*vide infra*) and the replacement of this ligand by recrystallization from py (see compound **5**). The HONp solvent ligand is located *trans* to the longest Bi—O distance in **4**. It is assumed the 6th coordination site is filled by the lone pair of electrons. Compound **4** has both apical ONp ligands bridge to the basal site of the other metal center (apical shared). The geometry around the metal centers of **4** is distorted from an ideal SP geometry to accommodate the apical bridging ligand [O(1)—Bi(1)—O(basal), 80.5° (av.) for **4**] and the lone pair of electrons [O(basal)—Bi—O(basal), 156° (av.) for **4**] of the Bi metal center. The internal core has acute angles of 72.1(3)° which are slightly greater than those observed for the fluorinated $OCH(CF_3)_2$ complex [70.9(3)] but smaller than that of the OEtOMe [73.0(3) and 72.7(3)] complex [24,25]. The central Bi_2O_2 core of **4** consists of one long and one short Bi—(μ-O) bond distance as was noted for the other compounds [24,25]. The asymmetric core leads to a Bi···Bi bond distance of 3.74 Å for **4**. This distance is consistent with the other bismuth alkoxides (3.64 Å for OEtOMe derivatives within the dinuclear unit (3.96 Å between each moiety) and 3.98 Å for the $OCH(CF_3)_2$ derivative). *Trans* to the shortest ligand (the apical ligand) is the lone pair of electrons of the bismuth metal center. The Bi—OR [2.17 Å (av.) for **4**] and Bi—-(μ-OR) [2.31 Å (av.) for **4**] distances are in agreement with other bismuth alkoxide compounds in the literature [24,25,34,39].

Compound **5** was characterized as [Bi(μ-

ONp)(ONp)$_2$py]$_2$ (see Fig. 5) with bond distances and angles tabulated in Table 8. Compound **5** is derived from the replacement of the coordinated HONp ligands in **4** with py molecules. **5** consists of two SP Bi metal centers linked through basal ONp ligands with the apical ONp ligands pointed in opposite directions. The arrangement observed for **5** is similar to that observed for the [Bi(OCH(CF$_3$)$_2$)$_3$(THF)]$_2$ [39] and the central moiety of [(Bi(OEtOMe)$_3$)$_2$]$_x$ [24,25]. The O(2)—Bi(1)—O(basal) and O(2)—Bi(1)—N(1) angles are 87.0° (av.). The average O(basal)—Bi—O(basal) angle is 167.0°. The asymmetric internal O—Bi—O core (71.55°) leads to a Bi···Bi bond distance of 3.88 Å for **5**. This value and the Bi—OR and Bi—(μ—OR) distances (2.08 Å (av.) and 2.39 Å (av.), respectively) are consistent with literature values [24–26,34,39,42]. Once again the apical ligand has the shortest recorded Bi—O distance in the molecule and is located *trans* to the lone pair of electrons. The more idealized SP geometry of **5** can be accounted for by reduction of steric bulk around the metal center through the replacement of the HONp ligands for the relatively flat py molecules. The coordinated py is 2.79 Å from the Bi metal center and is *trans* to the longest Bi—O distance recorded for **5**.

The reduced oligomerization of **4** and **5** in comparison to the [Bi(OEtOMe)$_3$)$_2$]$_x$ or the fluorinated alkoxides must be due to the steric bulk of the ONp ligand since there is no obvious H bonding to aid in reducing the hypervalencey. Extended F···Bi interactions were noted for the fluorinated compounds [39].

FT-IR *spectroscopy*

The FT-IR carbonyl stretches of Bi carboxylate compounds fall within the range of 1565 to 1525 cm^{-1} and 1410 to 1400 cm^{-1} for the asymmetric and symmetric stretches of the carboxylate ligands, respectively [42]. Furthermore it has been noted that the carboxylate stretches that are split or broadened into several lines may be due to inequivalent carboxylic ligands [42]. This would explain the number of bands observed for the asymmetric structures of compounds **2** (1555, 1493, 1419 cm^{-1}) and **3** (1563, 1553, 1415 cm^{-1}).

The IR spectrum of **4** shows a broad stretch around 3200 cm^{-1} consistent with the coordinated alcohol. For **5**, this stretch is no longer present due to the coordination of the amine solvent. The three standard ONp bands [54] for **4** and **5** appear around 2900 cm^{-1}; however, the amine solvent stretches of **5** make this region more complicated. For **4** and **5** the methyl stretches of the ONp ligands are consistent with other ONp [54,71] and Bi(OR)$_3$ complexes [24,25,34,39,42]. For **5**, three other broad peaks associated with the py are present at 1580, 1262, and 797 cm^{-1}. Consistent with literature reports, the Bi—O stretching peaks of **4** and **5** appear around 550 cm^{-1}.

TGA/DTA

Since **2**–**5** are potentially precursors for bismuth oxide materials, determination of their thermal decomposition characteristics was necessary; therefore, TGA/DTA spectra (under oxygen) were obtained for these compounds. The TGA weight losses associated with volatilization of solvent molecules for **2** and **3** are accompanied by endotherms in the DTA. The remaining thermal events in the DTA are exothermic, consistent with the loss of acetate ligands recorded in the TGA/DTA spectra for [Bi(O$_2$CMe)$_3$]$_x$. Hence, the coordinated solvents of **2** and **3** do not appear to effect the decomposition route of the Bi(O$_2$CMe)$_3$ moiety. The theoretical conversion of **2** to Bi$_2$O$_3$ would involve a weight loss of ~57%. The recorded weight loss of 52.1% for **2** is more consistent with one pyridine coordinated (~50%). This again shows the lability of the pyridine molecules as was evidenced by the elemental analysis. The theoretical weight loss for **3** (67.6%) is consistent with the experimentally recorded weight loss (65.5%). True TGA/DTA spectra were not obtainable for compounds **4** and **5** due to the sensitivity of these compounds to ambient atmospheric conditions and their volatility upon heating.

TGA/DTA spectra were also obtained on BiCl$_3$ and **1** to further investigate solvent effects on decomposition pathways. The resulting TGA spectrum of **1** is not fully understood due to the large weight loss recorded (75.3% versus 51.0% for theoretical conversion to Bi$_2$O$_3$). However, the unsolvated BiCl$_3$ DTA spectrum revealed two medium sized endotherms in the DTA; whereas, **1** had a combination of small endotherms and medium sized exotherms. Unlike what was observed for **2** and **3**, the coordinated solvent of **1** appears to alter the thermal decomposition pathway in comparison to the unsolvated parent halide.

SOLUTION STATE

Typically coordination compounds of bismuth display poor solubility due to increased oligomerization induced by the high coordination numbers achieved with the large Bi cation (calculated radii of 1.10, 1.17, and 1.31 Å for C.N. = V, VI and VIII, respectively) [72]. Due to the coordinating solvents and increased steric bulk of the ONp ligands, we have substantially reduced the oligomerization and increased the solubility of these Bi compounds. Molecular weight and NMR data were obtained to elucidate their solution behavior. All samples were investigated by redissolving the dried crystalline material in the appropriate solvent.

Molecular weight determinations

All molecular weight determinations were performed by the Singer method [73]. The molecular

weight of **1** in THF was found to be 840 ± 84. This is consistent with an average nuclearity of 3.6 or a complex larger than a trinuclear species. The molecular weight of **2** in py was found to be 589 ± 59, consistent with the crystallographically isolated mononuclear complex (MW = 544.31). Compound **3** is assumed to be mononuclear as well due to the structural similarities of **2** and **3** and the greater Lewis basicity of MeIm vs py. Molecular weight determinations of **4** in toluene were found on average to be 1080 ± 108. This appears to be in agreement with the solid state molecular weight (1115.06), indicating a dinuclear species exists in solution. This is consistent with previous reports of sterically hindered bismuth alkoxides [24,25]. Once again, due to the structural similarities of **4** and **5**, the py adduct is also thought to retain its dinuclear complexation in solution.

NMR spectroscopy

Crystalline materials of **2** and **3** were redissolved in $CDCl_3$. Based upon the integration of the appropriate peaks, for a free flowing powder there are two molecules of py per bismuth center for **2** and four MeIm molecules per Bi atom for **3**. Both of these observations are in agreement with the solid state structure (the lattice solvent molecule of **3** does not appear to be more labile than the bound solvent molecules). The acetate resonance of **3** appears ~ 0.1 ppm upfield from that of **2**. Samples of **2** and **3**, redissolved in pyridine-d_5, display methyl acetate resonances at ~ 2.00 ppm. The downfield shift of the acetate resonance for **3** in py is a reflection of the MeIm being replaced by the excess py ultimately forming **2**.

The ^{1}H NMR spectrum of **4** reveals two resonances at δ 4.22 (2H) for the methylene and δ 1.04 (9H) for the methyl groups. This indicates either rapid exchange of the bridging and terminal ligands or adoption of a mononuclear structure in solution. The ^{13}C NMR displays three resonances consistent with the carbons of ONp ligands and does not aid in distinguishing between the two possible interactions. Low temperature variable temperature NMR spectroscopy reveals significant broadening of the ONp peaks and the ingrowth of more than 6 methylene resonances (213 K). The large number of resonances must be due to either the formation of an asymmetric dinuclear complex or the freezing out of dinuclear rotomers. While we cannot distinguish between these two species, both proposed explanations invoke dinuclear compounds. Therefore, the NMR experiments coupled with the results from the molecular weight studies indicate that for **4** a dinuclear species must be present in solution.

The ^{1}H and ^{13}C NMR spectra of **5** in py also reveal only one set of resonances associated with the ONp alkoxide ligands. As was noted for **4**, the terminal and bridging ligands of compound **5** are in rapid exchange. The py resonances of **5** cannot be distinguished from the py solvent; however, in $CDCl_3$, py resonances can be observed with an integration of one py per bismuth metal center. If a sample of **4** is redissolved in pyridine-d_5 the previously coordinated alcohol can be observed in the ^{1}H NMR spectrum as free alcohol.

CONCLUSIONS

We have synthesized and crystallographically characterized a wide variety of bismuth containing complexes: $[BiCl_3(THF)_2]_\infty$ **1**, $Bi(O_2CMe)_3(py)_2$, **2**, $Bi(O_2CMe)_3(MeIm)_3 \cdot MeIm$, **3**, $[Bi(ONp)_3(HONp)]_2$, **4**, and $[Bi(ONp)_3(py)]_2$, **5**. Compound **1** proved to be polynuclear in solution and solid state. The structures of **2** and **3** add to the family of solvated $Bi(O_2CMe)_3$ compounds as the first structurally characterized amine solvated bismuth acetates. There appears to be little change observed in the metrical data for these complexes species vs that of the unsolvated $[Bi(O_2CMe)_3]_\infty$; however, a change in solubility of these compounds in other organic solvents when crystallized from an amine solution has been noted. The first crystallographically characterized monodentate bismuth alkoxide, **4**, is easily modified by addition of Lewis bases, as evidenced in the characterization of **5**. Due to the hypervalencey and increased acidity of the bismuth metal center, these compounds adopt dinuclear structures and possess coordinated Lewis basic solvents.

Acknowledgments—This work was supported by the United States Department of Energy under contract number DE-ACO4-94AL85000. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockeed Martin Company, for the United States Department of Energy.

The authors would also like to thank C. D. Buchheit, C. J. Tafoya and B. A. Hernandez for their technical assistance and Dr Todd M. Alam for NMR investigations.

Supporting information—A complete listing of crystal data collection, positional and thermal parameters, and bond distances and angles for **1–5** (64 pages) are available.

Synthesis and structural characterization of zinc(II) complexes of 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane

Ki-Young Choi

Department of Chemistry, Mokwon University, Taejon 301-729, Korea

(Received 21 October 1997; accepted 19 November 1997)

Abstract—The synthesis and structural characterization of $ZnLX_2$ (X = H_2O(**1**), N_3^-(**2**), and NCS^-(**3**); L = 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane) complexes are reported. The crystal structure analysis was employed to determine solid state structures. The crystal structures of these complexes have an axially elongated octahedral geometry with two axial ligands and adopt the *trans*-III conformation. The long Zn—O bond distance of 2.343(5) Å in complex **1** has a high pK_a value of 11.2. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: characterization of zinc(II) complexes with tetramethyl tetraaza macrocycle.

Recently, there has been great interest for the role of metal ions in the active centers of hydrolytic metalloenzymes such as carbonic anhydrases, carboxypepdidase, and phosphatase [1]. As one of the approaches, various types of zinc(II) complexes have been designed to account for or mimic the functions played by the central Zn(II) ions [2–4]. In carbonic anhydrases the active site of the enzyme consists of a zinc center coordinated to three histidine imidazole groups and a water molecule in which the pK_a value (H_2O) lies ca 7.5 [5,6]. Furthermore, Zn(II) complexes of macrocyclic triamines [7–10] and tetraamines [11–13] have been the most widely studied models due to their similar structural, thermodynamic and kinetic properties with carbonic anhydrases. In these complexes the Zn(II) ion is coordinated to three or four secondary amine groups and a water molecule, which can dissociate giving a Zn—OH species with pK_a values of 7.3–9.8 [7–12]. The nuclephilicity of the zinc hydroxide unit is related to the pK_a of the coordinated water, and among the macrocyclic triamine systems, the less stable complexes yield lower pK_a values. On the other hand, the well-recognized inhibition of carbonic anhydrases by a variety of simple anions has been repeatedly exploited as a probe of its catalytic activity [14]. Recently, X-ray crystal analysis of the SCN^- binding to carbonic anhydrases [15], 1,5,9-triazacyclododecane (L^1) [16] and 3,14-dimethyl-2, 6, 13, 17-tetraazatricyclo(14.4.$0^{1,18}$,$0^{7,12}$)docosane (DTAD) [17] complexes of Zn(II) showed a five-coordinate complexes with SCN^- and water bound.

In this study, we report the synthesis and characterization of $ZnLX_2$ (X = H_2O(**1**), N_3^-(**2**) and NCS^-(**3**); L = 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane) complexes. To understand the nature of the axial ligands, the solid state X-ray crystal structures of $ZnLX_2$ are determined. We have also investigated the acidity of the bound water of complex **1**.

EXPERIMENTAL

Materials and analytical methods

All solvents were reagent grade and purified according to the literature [18]. Reagents such as $ZnCl_2$, methyl vinyl ketone, 1,2-diaminopropane, perchloric acid and $NaBH_4$ were purchased from Aldrich and were used without further purification. All other reagents were reagent grade. Distilled water was used for all reactions. The ligand 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane was prepared according to literature methods [19]. Infrared spectra of solid complexes were recorded on a Perkin–Elmer Paragon 1000 FT-IR spectrophotometer. High-resolution fast atom bombardment spectrometry (FAB mass) were performed by using a Jeol JMS-HA 100A/100A instrument. Elemental analyses were car-

ried out by the Korea Research Institute of Chemical Technology Taejon, Korea.

Preparation of $[ZnL(H_2O)_2]Cl_2$ (**1**)

A methanol solution (20 cm^3) of L (513 mg, 2 mmol) and $ZnCl_2$ (273 mg, 2 mmol) was heated at reflux for 2 h. The solution was allowed to cool at room temperature and was then filtered. The filtrate was evaporated to dryness. The product was redissolved in a minimum amount of water. After the solution was allowed to stand at room temperature over a several day period, colorless crystals formed. Recrystallization from water/acetonitrile (1 : 1, 10 cm^3), filtration, washing with diethyl ether, and drying *in vacuo* produced a white solid (583 mg, 68% yield). Found : C, 39.4 : H, 8.5 : N, 13.2. Calc. For $ZnC_{14}H_{36}N_4O_2Cl_2$: C, 39.2 : H, 8.5 : N, 13.1%. IR (KBr, cm^{-1}) : 3336 (ν_{OH}), 3246 (ν_{OH}), 3172 (ν_{NH}), 3101 (ν_{NH}), 1647 (ν_{HOH}). FAB mass (CH_2Cl_2, *m/z*) : 428.7$(M)^+$.

Preparation of $[ZnL(N_3)_2]$ (**2**)

To a methanol solution (20 cm^3) of **1** (214 mg, 0.5 mmol) was added NaN_3 (65 mg, 1 mmol) and the mixture refluxed for 1 h. The solution was filtered and the filtrate was evaporated to dryness. The product was dissolved in water/acetonitrile (1 : 1, 10 cm^3). When this mixture was allowed to stand for a few days, colorless crystals were obtained. These were filtered off, washed with diethyl ether and dried *in vacuo* (154 mg, 76% yield). Found : C, 41.4 : H, 8.0 : N, 34.7. Calc. For $ZnC_{14}H_{32}N_{10}$: C, 41.4 : H, 8.0 : N, 34.5%. IR (KBr, cm^{-1}) : 3164 (ν_{NH}), 2036 ($\nu_{N=N}$). FAB mass (CH_2Cl_2, *m/z*) : 405.8$(M)^+$.

Preparation of $[ZnL(NCS)_2]$ (**3**)

This compound was synthesized from **1** (214 mg, 0.5 mmol) and KSCN (97 mg, 1 mmol) following the procedure reported for **2**, obtaining **3**, as colorless crystals (171 mg, 78% yield). Found : C, 44.0 : H, 7.4 : N, 19.1. Calc. For $ZnC_{16}H_{32}N_6S_2$: C, 43.9 : H, 7.4 : N, 19.2%. IR (KBr, cm^{-1}) : 3218 (ν_{NH}), 2049 ($\nu_{C=N}$). FAB mass (CH_2Cl_2, *m/z*) : 437.9$(M)^+$.

Potentiometric titrations

Potentiometric titrations were carried out on a Radiometer TIM 900 Titration Manager fitted with

a Radiometer combination electrode. The electrode response was standardized with buffer solution at pH 4.00 and 7.00 (25.0 ± 0.1°C). An aqueous solution (10 cm^3) of 1 : 1 ($C_L = 1.0 \times 10^{-2}$ M, $C_M = 1.0 \times 10^{-2}$ M) ratio for the mixture was titrated with a carbonate-free 0.0982 M KOH at 25.0 ± 0.1°C and $I = 0.2$ ($NaClO_4$). Humidified nitrogen gas free carbon dioxide (through 1N NaOH solution) was passed over the solution during the potentiometric measurements. The hydrogen ion concentrations were obtained from the measured pH values by the method of Martell *et al.* ($pK_w = 13.78$) [20]. Since Zn(II) complexation equilibrium was very slow, the pH values were read after sufficient time (1 h) at each titration point. The complexation constants were obtained by fitting the potentiometric data and the protonation constants [21] to the BEST program [20].

X-ray crystallographic analysis

A summary of crystal data, data collection and refinement for all crystallographically characterized compounds are given in Table 1. Colorless crystals of dimensions $0.2 \times 0.2 \times 0.2$ for **1**, $0.2 \times 0.1 \times 0.2$ for **2** and $0.3 \times 0.2 \times 0.2$ for **3** were mounted on an Enraf-Nonius CAD4 diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$). Accurate cell parameters and an orientation matrix were determined from the least-squares fit of 25 reflections. Intensity data were collected in the $\omega - 2\theta$ scan mode. For all crystals three standard reflections were measured every 240 min. Data were corrected for Lorentz and polarization effects. No absorption correction was applied. The structures were solved by use of heavy-atom methods. All remaining non-hydrogen atoms were found by iterative cycles of full-matrix least squares refinement and difference-Fourier synthesis using NRCVAX [22]. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were included at calculated positions ($d_{C-H} = 1.08$ Å) and refined isotropically at the final cycle. Full crystallographic details, atomic coordinates, interatomic distances and angles, hydrogen atom coordinates, anisotropic displacement parameters and structure factor tables for **1**, **2** and **3** have been deposited with the editor as supplementary material.

RESULTS AND DISCUSSION

Description of structures

In the present compounds, two alternating five- and six-membered chelate rings are in the gauche and chair form with most stable *trans*-III conformations. An inversion center of these complexes exits on the central Zn(II) ion. The N—Zn—N angles of the six-membered chelate rings are larger than those of the five-membered chelate rings.

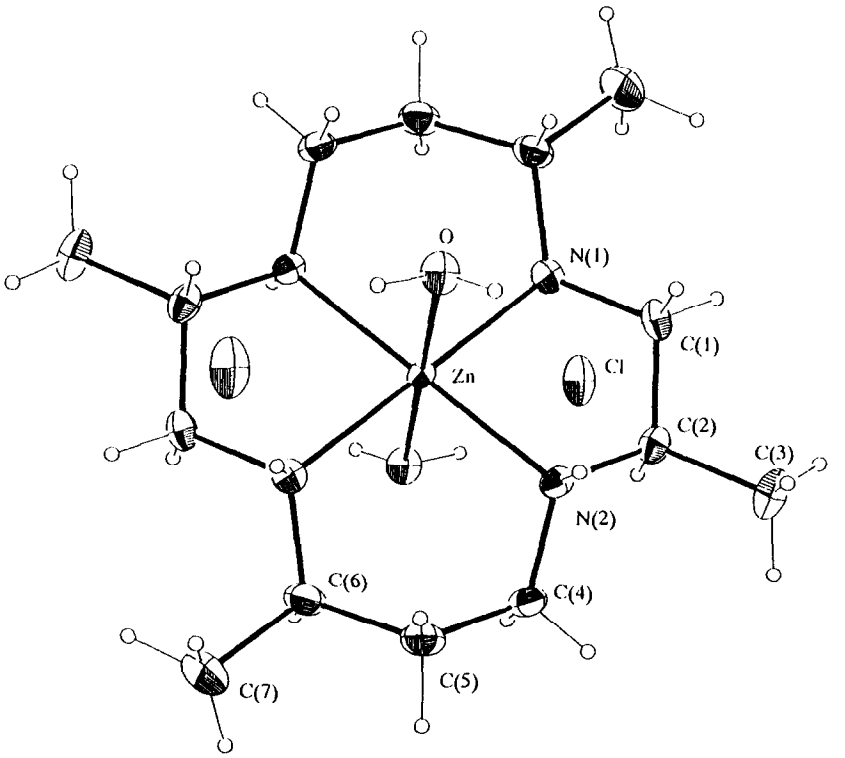

Fig. 1. ORTEP drawing of **1** with the atom-numbering scheme.

Figure 1 shows an ORTEP drawing of **1** with the atomic numbering scheme. Selected interatomic bond distances and angles are listed in Table 2. The crystal structure of **1** consists of $[ZnL(H_2O)_2]^{2+}$ cation and two Cl^- anions. The coordination environment around Zn(II) ion shows an axially elongated octahedron with two oxygen atoms of water molecules and four nitrogen atoms of the macrocyclic ligand. The average Zn—N bond distance of 2.094(5) Å is similar to those found in $[Zn(DTAD)(H_2O)_2]Cl_2$ (2.099(2) Å) [13] and $Zn(O_2COCH_3)$ ([14]aneN_4) (2.099(2) Å) [11] which have the tetragonal six-coordinate complexes. Zn—OH_2 bond distance in five-coordinate complexes with square-pyramidal geometry, [Zn(N,N′)-*bis*(salicylidene)(ethylenediamine)(H_2O)] [23] is reported to be ca 2.0 Å, whereas those in a tetragonal six-coordinate complexes, [Zn(8)-hydroxyquinoline$(H_2O)_2$] [24] and [Zn(DTAD)$(OH_2)_2$] Cl_2 [13], lengthens to 2.263(5) Å and 2.338(3) Å. The Zn—O bond distance of **1** was found to be 2.343(5) Å. The elongation of Zn—O distance in complex **1** may be attributed to the detrimental

effect by the steric hinderance of the four methyl groups on the ligand. Figure 2 shows that the water molecule coordinates to the central Zn(II) ion, accompanied by chlorides and secondary amines of macrocycle which are located close to the coordinated water through the four hydrogen-bonding chelate rings (Table 3).

Figure 3 shows an ORTEP drawing of **2** with the atomic numbering scheme. Selected interatomic bond distances and angles are listed in Table 2. The structure of **2** reveals a six-coordinated octahedral geometry with bonds to the four secondary amines of the macrocycle and to the two axial azide ligands. The average Zn—N (secondary amines) distance of 2.105(3) Å is longer than those observed in the four-coordinated complex $[Zn(L^5)]^{2+}$ (L^5 = 1,4,8,11-tetraazacyclotetradecane) (2.088(2) Å) [25], but are similar to those reported for the six-coordinated complex $[Zn(DTTD)](ClO_4)_2 \cdot H_2O$ (DTTD = 6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine) (2.100(5) Å) [26]. The axial Zn—N(3) bond distances of 2.308(3) Å are equivalent, but both are ca 0.2 Å longer than equatorial Zn—N (secondary amines) bonds which indicate an axially elongated octahedral geometry. The axial Zn—N(3) linkage is bent slightly off the perpendicular to the ZnN_4 plane by 0.71–5.44°. The azido group is slightly asymmetric [N(3)—N(4) = 1.180(4) and N(4)—N(5) = 1.164(4) Å] and linear within the experimental error [N(3)—N(4)—N(5) angle = 179.0(3)°].

Figure 4 shows an ORTEP drawing of **3** with the atomic numbering scheme. Selected interatomic bond distances and angles are listed in Table 2. The structure of **3** shows that the Zn(II) is coordinated by the secondary amines of the macrocycle and that the axial positions are weakly bonded by two nitrogen atoms of the thiocyanate ligands. The average Zn—N (secondary amines) distance of 2.093(5) Å is shorter than those reported for the complex $[Zn(L^5)(NCS)_2]$ (2.104(11) Å) [27], while the axial Zn—N (thiocyanate) distance of 2.461(4) Å is longer than that to the thiocyanate ligands in $[Zn(L^5)(NCS)_2]$ (2.371(13) Å) [27], giving an axially elongated octahedral geometry. Also, the axial Zn—N bond is not perpendicular to ZnN_4 plane with N(1)—Zn—N and N(2)—Zn—N angles of 87.9(2) and 90.2(2)°. The Zn—N—C and N—C—S angles related to the thiocyanate ligand are 115.1(5) and 178.9(7)°, respectively.

Complexation constants

The titration data as shown in Fig. 5 were treated for the 1 : 1 H_4L and $ZnCl_2$ in aqueous solution of 0.20 ($NaClO_4$) at 25.0±0.1 C. The Zn(II) complexation constants K_{ZnL} and K_a are defined as follows:

$$Zn(II) + L \rightleftarrows ZnL \quad K_{ZnL} \tag{1}$$

$$ZnL \rightleftarrows ZnH_{-1}L + H^+ \quad K_a \tag{2}$$

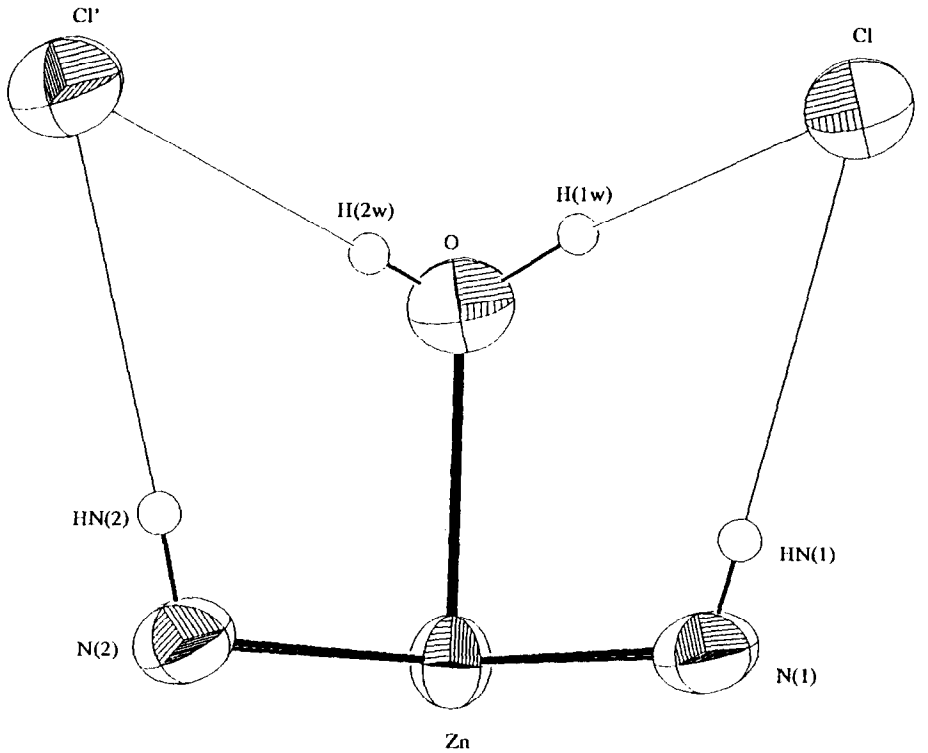

Fig. 2. Hydrogen-bond system of **1**.

[a] $I = 0.10$ ($NaClO_4$), [b] $I = 0.1$ (KNO_3), [c] $I = 0.2$ ($NaClO_4$), [d] $I = 0.1$ ($NaNO_3$), [e] $I = 0.1$ ($NaClO_4$). Abbreviations: L^1 = 1,5,9-triazacyclododecane, L^2 = 1,4,10-triazacyclododecane, L^3 = 1,4,8-triazacycloundecane, L^4 = 1,4,7,10-tetrazacyclododecane, L^5 = 1,4,8,11-tetraazacyclotetradecane, L^6 = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, L^7 = 2-(2-hydroxyphenyl)-1,5,9-triazacyclododecane.

Table 4 summarizes the obtained $\log K_{ZnL}$ and pK_a values in comparison with the reported values of macrocyclic polyamines. The pK_a value of 11.2 with **1** is considerably high compared with those of other Zn(II)—OH_2 macrocyclic tetraamines. It is generally understood that the acidity of Zn(II)—OH_2 moiety is greatly influenced by the nature of macrocyclic polyamines and coordination environments at Zn(II). For instance, the Zn(II) complexes of macrocyclic triamines having larger cavities such as L^1 and L^2 show the most acidic in nature with pK_a values of 7.3 [7], while the Zn(II) complexes of macrocyclic tetraamines show less acidic with pK_a values of 9.77 and 8.36, respectively [7,10]. The high pK_a of H_2O bound to Zn(II) in the hexacoordinate environment is expected with the longer Zn—O bond distances seen in the octahedral geometries. With a longer bond distance the water ligand should be less polarized and result in a decreased acidity. It is also anticipated that an increasing coordination number at Zn(II) decreases the acidity of bound water. Kimura *et al.* reported, on the Zn(II) complex with a [2-(2-hydroxyphenyl)-1,5,9-triazacyclododecane] (L^7), that the H_2O bound

to Zn(II) (distance 2.22 Å) has a pK_a value of 10.7 [9], indicating a greatly reduced (from 7.3 of L^1) acidity of Zn(II) due to the phenolate ($pK_a = 6.8$) coordination. The much low acidity of **1** may be due to the long Zn—O bond distance of 2.388(3) Å in the octahedral geometry.

The reaction of P_4 with $[Cp'Mo(CO)_3]_2$ ($Cp' = \eta^5$-C_5H_4tBu)—the structure of $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4(H)\rangle]$

(Received 1 October 1997; accepted 17 November 1997)

Abstract—The photochemical reaction of $[Cp'Mo(CO)_3]_2$ ($Cp' = \eta^5$-C_5H_4tBu) with white phosphorus in the presence of $[Cr(CO)_5thf]$ leads to the P_n ligand complexes $[Cr(CO)_4\langle(\eta^4\text{-}P_4)\{Cr(CO)_5\}_4\rangle]$ (**1**), $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4(H)\rangle]$ (**2**) and $[\{Cp'Mo(CO)_2\}_2\langle(\mu,\eta^2\text{-}P_2)\{Cr(CO)_5\}_2\rangle]$ (**3**). The products were characterized by NMR, IR and partially by X-ray structure analysis. The reaction proceeds via a P—P bond cleavage leading to the bent *cyclo*-P_4 complex $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4\{Cp'Mo(CO)_3\}\rangle]$ (**2a**), which hydrolysis during the chromatographic work-up to give the more stable compound **2**. Furthermore, a P_3/P_1 fragmentation of **2a** occurs to form the phosphido complex intermediate $[Cp'(CO)_2Mo{\equiv}P \rightarrow Cr(CO)_5]$. The latter dimerises resulting in the formation of the tetrahedral compound **3**, containing a Mo_2P_2 moiety.

Keywords: P_n-ligands; molybdenum complexes; bent *cyclo*-P_4-ligand; Mo_2P_2-tetrahedral complex; phosphido complex intermediate.

Reactions of white phosphorus with transition metal complexes afford co-ordination compounds containing P_n-ligands without organic substituents [1]. While numerous publications exist discussing the structural variety of such compounds, only a few investigations of the reaction pathway have been done so far [2]. In order to study the transformation pathway of the P_4 tetrahedron in the co-ordination sphere of transition metals we developed the concept of the three-component-reaction [3,4]. These reactions are carried out starting from white phosphorus and the corresponding metal carbonyl complex ML_n, e.g. $[Cp''Rh(CO)_2]$ ($Cp'' = \eta^5$-$C_5H_3tBu_2$) as shown in Scheme 1, in the presence of a Lewis-acidic compound like $[Cr(CO)_5thf]$. The lone pairs of the initially formed P_n-ligands are thus able to co-ordinate to the chromium pentacarbonyl units. Therefore, it becomes possible to stabilise intermediates along the reaction pathway. A second function of the $[Cr(CO)_5]$ moieties is the activation of the metal carbonyl complex ML_n by promoting the loss of CO based on the formation of the very stable $[Cr(CO)_6]$ [3]. Due to the steric influence of the $[Cr(CO)_5]$ groups, the reaction pathway of a three-component-reaction may differ from the corresponding two-component-reaction without $[Cr(CO)_5thf]$ [3b,5a].

The reaction pathway of three-component-reactions depends on the nature of the metal complexes used, i.e. they have to be subdivided into those forming fragments with an even or an odd number of valence electrons. In the case of complex fragments with an even number of valence electrons, such as $[Cp^xM(CO)]$ ($Cp^x = \eta^5$-C_5H_4tBu (Cp'), η^5-$C_5H_3tBu_2$ (Cp''), η^5-C_5Me_5 (Cp*); M = Co [5], Rh [3] (Scheme 1), Ir [6]), a stepwise P—P bond cleavage under formation of a bicyclotetraphosphine intermediate is observed. These reactions yield products containing *cyclo*-P_4 moieties. The use of co-ordination compounds forming fragments with an odd number of valence electrons, e.g. $[Cp^*Ni(\mu\text{-}CO)]_2$, however lead to a bent *cyclo*-P_4 ligand complex and a Ni_2P_4 pris-

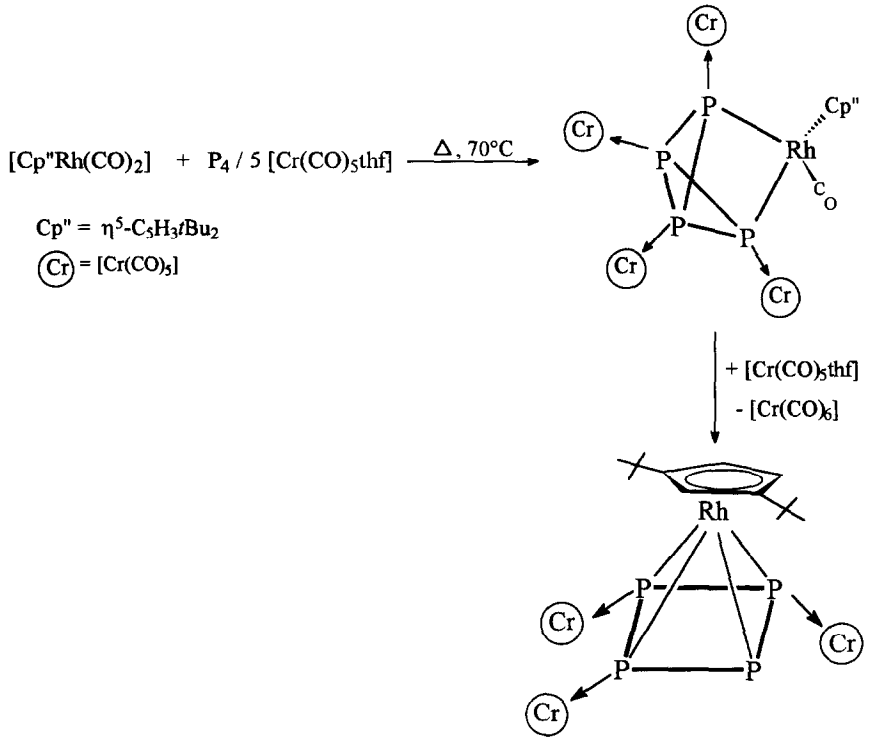

Scheme 1. Three-component-reaction starting from $[Cp''Rh(CO)_2]$ and P_4 in the presence of $[Cr(CO)_5thf]$.

mane, respectively [7]. A P_1/P_3 fragmentation is only observed in a small extent (5%). $[Cp'Mo(CO)_n]_2$ ($n = 2, 3$) also forms fragments with an odd number of valence electrons. Scherer *et al.* showed that the two-component-reaction of $[Cp^*Mo(CO)_2]_2$ with P_4 affords the tetrahedral complexes $[Cp^*Mo(CO)_2(\eta^3\text{-}P_3)]$ and $[\{Cp^*Mo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$, as well as $[(Cp^*Mo)_2(\mu,\eta^6\text{-}P_6)]$, containing a hexaphosphabenzene-ligand, and $[\{Cp^*Mo(CO)\}_2(\mu,\eta^2\text{-}P_2)_2]$ bearing two separated P_2 units [8].

Herein we report our results of the corresponding three-component-reaction starting from $[Cp'Mo(CO)_3]_2$ ($Cp' = \eta^5\text{-}C_5H_4tBu$) and the proposed transformation pathway of the tetrahedral P_4 phosphorus.

RESULTS AND DISCUSSION

Synthesis, properties and spectroscopic data of the complexes 1–3

The thermal reaction of $[Cp'Mo(CO)_3]_2$ with P_4 in the presence of $[Cr(CO)_5thf]$ exclusively affords the complex $[Cr(CO)_4\langle(\eta^4\text{-}P_4)\{Cr(CO)_5\}_4\rangle]$ (**1**). The molybdenum starting compound is not involved in the reaction [eqn (1)].

Under UV conditions, however, $[Cp'Mo(CO)_3]_2$ participates in the three-component-reaction (2).

The $^{31}P\{^1H\}$ NMR spectrum of the crude reaction mixture (2) reveals signals for the compounds **1–3** as the main products. Chromatographic work-up of the reaction mixture results in the isolation of the orange crystalline compound **2** and the reddish brown product **3**, besides some unreacted starting material. The products are slightly soluble in hexane and readily soluble in toluene, CH_2Cl_2 or THF.

Table 1 shows the spectroscopic data for **1–3**. The spectroscopic data of **1** and **3** correspond to those of the compounds we obtained by the cothermolysis of P_4 with $[Cr(CO)_5thf]$ [9] and by the reaction of $[\{Cr(CO)_5\}_2PCl]$ with $[Cp'Mo(CO)_3]K$ [10], respectively.

The IR spectrum of **2** shows five bands in the region of the CO stretching frequencies (Table 1) corresponding to the $2A_1 + E$ bands of the distorted C_{4v} symmetry of the $[Cr(CO)_5]$ units and the coupled CO vibrations of the $[Cp'Mo(CO)_2]$ group.

For $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4(H)\rangle]$ (**2**) a proton decoupled and a coupled ^{31}P NMR spectrum was recorded. In the decoupled spectrum an AMX_2 spin system is observed [$\delta(P_A) = 184.8$ ppm, $\delta(P_M) = 63.7$ ppm, $\delta(P_X) = 25.4$ ppm; $P_A = P(3)$, $P_M = P(1)$, $P_X = P(2)$, P(4), Fig. 2]. The P_A nucleus reveals a triplet at 185.0 ppm. Each of the three lines of the triplet additionally shows a fine splitting [$^2J(P_AP_M)$: 24 Hz; Fig. 1a]. In the proton coupled ^{31}P spectrum (AM_2XH spin system) a pseudo quintet for the P_A phosphorus atom is observed due to the additional coupling with the proton attached to it

^{a} In $CDCl_3$; ^{b} in CD_2Cl_2; ^{c} in KBr; ^{d} in CH_2Cl_2.

(Fig. 1b). Since the $J(P_AH)$ coupling at 277 Hz is almost double that of the $J(P_AP_X)$ coupling of 147 Hz, the outermost lines of the both triplets appear only as one line which results in the pattern shown in Fig. 1b ($w_{1/2} \approx 40$ Hz). The P_X nuclei P(2) and P(4) appear as a doublet of doublets at $\delta(P_X) = 25.4$ ppm with the two coupling constants $J(P_AP_X) = 147$ Hz and $J(P_MP_X) = 310$ Hz. The smaller coupling $J(P_AP_X)$ is in accordance with the longer P(2)—P(3) and P(3)—P(4) bonds [2.247(2) and 2.234(3) Å]. The considerably larger $J(P_MP_X)$ corresponds to the shorter P—P distances of the P(1)—P(4) and P(1)—P(2) bonds [2.173(2) and 2.180(2) Å] (Table 2).

Molecular structure of **2**

An ORTEP drawing of the molecular structure of **2** is given in Fig. 2. Selected bond distances and angles are given in Table 2.

The X-ray structure analysis of **2** reveals a $[Cp'Mo(CO)_2]$ moiety capping an allylic P_3 subunit of

a *cyclo*-P_4 ligand. Additionally all P atoms co-ordinate to $[Cr(CO)_5]$ moieties. The Mo atom is located at a distance of 2.139 Å above the P_3 plane. The P—P bond distances to the P(3) atom, which does not co-ordinate to the Mo atom, are found to be 2.247(2) and 2.234(3) Å, respectively. They are in the range of P—P single bonds [11], whereas the other P—P bond lengths [$\bar{d}$(P(1)—P(2)/(4)) = 2.1765(2) Å] are shorter. Such a P_3/P_1 distortion is also observed in the complexes $[Cp^*Ni(\eta^3\text{-}P_4)\{Cr(CO)_5\}_3\{Cp^*Ni(CO)\}]$ (**4**) [7] and $[\{(CH_3CN)_2(CO)_2WCl\}(\eta^3\text{-}P_4)\{W(CO)_5\}_3(OH)]$ **5** [12]. The P—P bond lengths in **4** and **5** are slightly shorter than in **2** (**4**: $\bar{d}$(P(2)—P(1)/(3)) = 2.166(2) Å, $\bar{d}$(P(4)—P(1)/(3)) 2.217(2) Å; **5**: $\bar{d}$(P(1)—P(2)/(3)) = 2.165(5) Å, $\bar{d}$(P(4)—P(2)/(3)) = 2.207(5) Å). The P(3) atom in **2** lies 42.8° out of the plane defined by the other P atoms. In **5** this angle is almost identical (42°), but the Ni complex **4** shows a considerably smaller angle (28.2°).

We already described the X-ray structure of the Mo_2P_2 tetrahedral complex **3** in [10]. A discussion of the structure of the analogous tungsten complex of **1** can be found in [9].

Discussion of the reaction pathway

The structures of the isolated products give some evidence concerning the transformation pathway of the P_4 tetrahedron in reaction (2). It appears probably that in the first step a P—P bond cleavage in the P_4 tetrahedron occurs and the Mo—Mo bond in $[Cp'Mo(CO)_3]_2$ is split. The formed bicy-

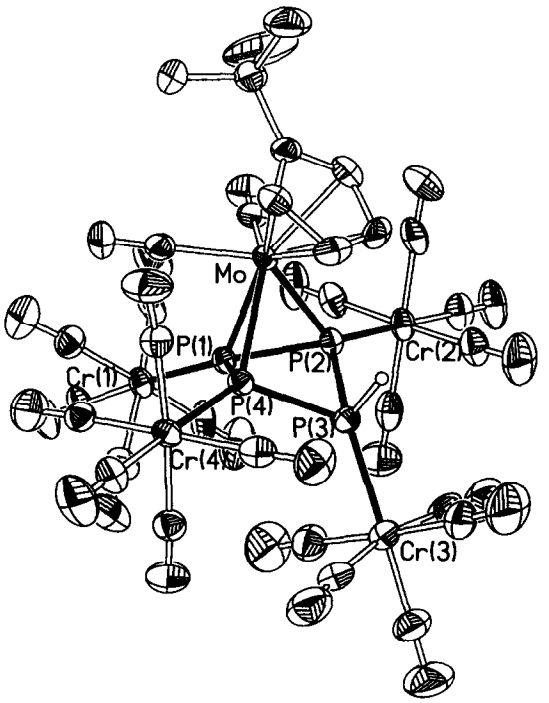

Fig. 2. ORTEP view of the $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4(H)\rangle]$ (**2**) molecule giving the atom number scheme used in Table 2. Thermal ellipsoids are of 50% probability.

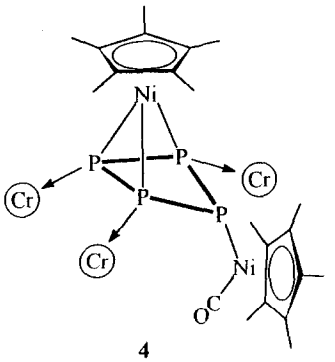
clotetraphosphine complex with two σ bound $[Cp'Mo(CO)_3]$ units reacts under CO elimination. Afterwards the formed $[Cp'Mo(CO)_2]$ complex fragment shifts into a capping position in order to yield a η^3-co-ordinating bent *cyclo*-P_4-ligand complex $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4\{Cp'Mo(CO)_3\}\rangle]$ (**2a**). This compound cannot be isolated after chromatographic work-up. The formation of **2** could be caused by a hydrolysis of the σ bound $[Cp'Mo(CO)_3]$ moiety. The further P_3/P_1 fragmentation of **2a** seems to be the main reaction pathway of reaction (2). It should lead to a P_3 ligand complex with all lone pairs of the P atoms co-ordinating to $[Cr(CO)_5]$ groups. It was not possible, to assign signals in the $^{31}P\{^1H\}$ NMR spectrum unambiguously to such a compound due to the possible existence of several products of $[Cp'Mo(CO)_2(\eta^3\text{-}P_3)\{Cr(CO)_5\}_n]$ with a different number of $[Cr(CO)_5]$ units. The P_1 species, formed at the same time, could be a phosphido complex [13] with the formula $[Cp'(CO)_2Mo{\equiv}P \rightarrow Cr(CO)_5]$. Such species with metals in a low oxidation state are not stable as monomers and a dimerisation to the tetrahedral Mo_2P_2 complex **3** readily occurs [14].

The comparison of the discussed pathway of reaction (2) with the three-component-reaction starting from $[Cp^*Ni(\mu\text{-}CO)]_2$ shows an analogy in the two reactions [7]. In both cases the first step seems to be the appearance of an unstable bicyclotetraphosphine complex followed by the formation of a complex with a η^3-co-ordinating, bent P_4 ligand. $[Cp^*Ni(\eta^3\text{-}P_4)\{Cr(CO)_5\}_3\{Cp^*Ni(CO)\}]$ (**4**) is the starting point of two different reaction pathways [7]; (i) the formation of the prismane $[Cp^*_2Ni_2P_4\{Cr(CO)_5\}_2]$ as the main reaction mode and (ii) a P_3/P_1 fragmentation to form the tetrahedral complexes $[Cp^*Ni(\eta^3\text{-}P_3)\{Cr(CO)_5\}_3]$ and $[(Cp^*Ni)_2\{(\mu,\eta^2\text{-}P_4)\{Cr(CO)_5\}_2\}]$, respectively. However, **2a** seems to react exclusively under P_3/P_1 fragmentation to the tetrahedron **3** and a P_3-ligand complex.

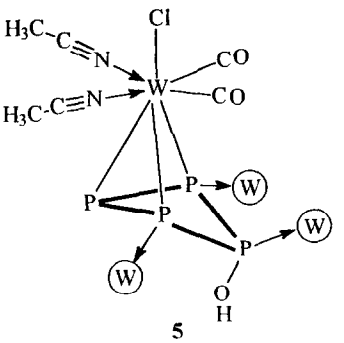
EXPERIMENTAL

General

All experiments were performed under a purified N_2 atmosphere using Schlenk techniques. The solvents were dried, degassed and stored under N_2. The molybdenum starting complex $[Cp'Mo(CO)_3]_2$ was pre-



4



5

(M) = $M(CO)_5$

M = Cr, W

Scheme 3.

pared as previously described [15]. Infrared (IR) spectra were recorded on a Perkin-Elmer PE 883 IR spectrometer, the ^1H and ^{31}P NMR spectra on a Bruker AC 250 [^1H: 250.13 MHz; ^{31}P: 101.256 MHz, Standard: Me_4Si (^1H); 85% H_3PO_4 (^{31}P)].

Reaction of $[Cp'Mo(CO)_3]_2$ *with* P_4 *in the presence of* $[Cr(CO)_5thf]$, *the preparation of* $[Cp'Mo(CO)_2\langle(\eta^3\text{-}P_4)\{Cr(CO)_5\}_4(H)\rangle]$ **(2)** *and* $[\{Cp'Mo(CO)_2\}_2\langle(\mu,\eta^2\text{-}P_2)\{Cr(CO)_5\}_2\rangle]$ **(3)**

(*a*) *Under thermal conditions.* 602 mg (1 mmol) $[Cp'Mo(CO)_3]_2$, 124 mg P_4 (1 mmol) and a solution of 6 mmol $[Cr(CO)_5thf]$ in 20 ml THF, prepared by irradiation of 1.4 g $[Cr(CO)_6]$ in THF, were refluxed for 2 h. The ^{31}P NMR spectrum of the crude reaction mixture shows the exclusive formation of $[Cr(CO)_4\langle(\eta^4\text{-}P_4)\{Cr(CO)_5\}_4\rangle]$ **(1)** [9], which decomposes during chromatographic work-up and unreacted P_4.

(*b*) *Under photochemical conditions.* 602 mg (1 mmol) $[Cp'Mo(CO)_3]_2$, 124 mg P_4 (1 mmol) and a solution of 6 mmol $[Cr(CO)_5thf]$ in 20 ml of THF, prepared by irradiation of 1.4 g $[Cr(CO)_6]$ in THF, were irradiated for 2 h in 250 ml of THF in a UV apparatus (low pressure mercury lamp, TQ 150, Hanau) under internal water cooling to 15°C. All the solvent was removed in vacuum. Unreacted P_4 and $[Cr(CO)_6]$ were removed by sublimation (10^{-3} Torr) at 50–60°C. The brown residue was dissolved in 5 ml CH_2Cl_2, 5 g silicagel was added and subsequently the solvent was removed to dryness. The chromatographic separation on a silicagel column (30 × 1.5 cm; Merck 230–400 mesh) packed with hexane yielded red starting compound $[Cp'Mo(CO)_3]_2$ (240 mg, 40% yield), eluted with hexane, followed by the orange product **2** (90 mg, 8% yield after recrystallization from CH_2Cl_2) eluted with 5:1 hexane/toluene. The reddish brown compound **3** was eluted with 1:2 hexane/toluene (70 mg, 7% yield after recrystallization from CH_2Cl_2).

Crystal structure analysis of **2**

The crystal structure analysis was performed on a STOE STADI IV (ω-scan mode) diffractometer with Mo-K_α radiation ($\lambda = 0.71073$ Å) with empirical absorption corrections (5 Psi-scans). $F(000) = 2296$, $D_{calc} = 1.763$ mg/m^{-3}, 566 parameters, crystal size $0.25 \times 0.20 \times 0.08$ mm, $T = 203(1)$ K, $3 < 2\theta < 50°$. Number of reflections measured 7238, 6635 independent reflections [R(int) = 0.0508] of which 4075 were assigned observed [$I > 2\sigma(I)$], absorption coefficient 1.460 mm^{-1}. The refinement converged at residuals $wR_2 = 0.0966$ for all reflections, corresponding to a conventional $R = 0.0457$ for the observed F_o data. The proton H(3) attached to the P(3) atom was freely refined. Further crystal data and data collection parameters are summarized in Table 3. The structures were solved by direct methods using SHELXS-86 [16a], full-matrix-least-squares refinement on F^2 in SHELXL-93 [16b] with anisotropic displacement for non-H atoms, hydrogen atoms, except H(3), located in idealized positions and refined isotropically according to the riding model. Atomic co-ordinates have been deposited with the Cambridge Crystallographic Data Centre.

(Received 18 September 1997; accepted 17 November 1997)

Abstract—Recently [1] it was claimed that (i) the reaction of $ThCl_4$ with HN_3 in slightly acidic aqueous solution produces the aqueous ion of Th(III) according to the thermodynamically allowed reaction: $Th^{4+} + HN_3 \rightarrow Th^{3+} + 1.5N_2 + H^+$; (ii) Th(III) was identified by its absorption (UV–vis. 200–1300 nm) and ESR spectra. This paper is aimed to prove that the aqueous ion Th^{3+}(aq) is thermodynamically unstable and that the identification of Th(III) in the considered solutions ask for new experiments. © 1998 Elsevier Science Ltd. Keywords: actinides; thorium; electronic configuration; crystal field effect.

Among the chemical properties of the lanthanides, Ln, and actinides, An, the stabilities of aqueous ions in "unusual" oxidation states involving a *d*-electron in the electronic configuration of the ground state of Ln and An is of particular interest [2,3]. The ground electronic configuration of an ion is not always the same in the gaseous state, for instance for Ln and An it could be f^q or $f^{q-1}d$, $f^{q-1}s$ or $f^{q-1}p$ [4,6]. For a gaseous ion, these two configurations are separated by the promotion energy, ΔE. For Th^{3+} gaseous ion, it is known from 50 years ago [4a] that the energies of the configurations $6d^1$ ($^2D_{3/2}$), $7s^1$ ($^2S_{1/2}$) and $7p^1$ ($^2P_{1/2}$) relative to $5f^1$ ($^2F_{5/2}$) are respectively: 1.13856 eV, 2.869 eV and 7.482 eV. Thus for Th^{3+} gaseous ion ΔE, between $5f^1$ and $6d^1$ configurations, is equal to 1.14 eV. This ion belongs to the same category as Np^{2+} ($\Delta E = 0.51$ eV), Pu^{2+} ($\Delta E = 1.61$ eV), Cm^{2+} ($\Delta E = 0.88$ eV) and Pa^{3+} ($\Delta E = 2.07$ eV) [4].

The crystal field effect of ligands, i.e. water molecules, measured by $\Delta(d)$, stabilizes the electronic configurations $6d^1$ by an energy D ($D > 0$, $D > \Delta E$). That is the reason why the old, -3.7 V, [6] recommended redox potential for the pair Th^{4+} (aq)/Th^{3+} (aq) was increased to -3.0 V [5]. It was recently claimed that such potential, -3 V, allows the reduction of Th^{4+} aqueous ion to a Th^{3+} ion, using hydrazoic acid HN_3 [1].

* Author to whom correspondence should be addressed.

The first part of this paper is devoted to a short analysis of the potentials $E^0(3/2)$ with $f^{q-1}d$ electronic configuration for the reduced specie, to the comparison between $E^0(4/3)$ for Th and Pa and a discussion of the recommended potentials $E^0(4/3)$ for Th given in [5] and [6] in the frame of the crystal field stabilization, D, of a $6d$ electron. In the second part the possibility of the reduction of Th^{4+} ion by HN_3 is considered. Finally, in the last part absorption and ESR spectra, assigned in [1] to a trivalent thorium species, are discussed.

CONSIDERATION ABOUT THORIUM IV/III REDOX POTENTIAL

The stabilization of *d* electrons by crystal field effect was taken into account for the first time in [6] and then in [5], to estimate the redox potentials $E^0(3/2)$ and $E^0(4/3)$ of Ln and An. Unfortunately in [5] the crystal field stabilization was taken twice resulting in an increase of the redox potentials $E^0(3/2)$ (more positive than -3 V) for some dipositive Ln (La^{2+}, Ce^{2+}, Gd^{2+}) and An (Pa^{2+}, U^{2+}, Np^{2+}) ions. Therefore it was emphasized that the ions Ac^{2+}, Th^{2+}, Pa^{2+}, U^{2+}, Np^{2+}, La^{2+}, Ce^{2+} and Gd^{2+} could be stable in aqueous solution.

On the other hand, it was proposed that for the two cations Pa^{3+} (aq) and Th^{3+} (aq) the electronic

configurations are respectively, fd and f [5]. Regarding the crystal field stabilization effect, D, two limiting cases have to be considered, the weak, $D < \Delta E$, and the strong one, $D > \Delta E$ (Fig. 1). In the former case the electronic configurations f^1 and f^2 should be realized in Th^{3+}(aq) and Pa^{3+}(aq) respectively. The value for the $E^0(4/3)$ (in short for $M^{4+}(aq)/M^{3+}(aq)$) of An with the f^q electron configuration for An^{3+} is given according to [6] by:

$$E^0(4/3)(V) = -4.00 + 1.37\,(q-1) + F_{q-1} \quad (1)$$

From the eqn (1) and with F_{q-1} values from [6] one has: $q = 1$, $F_{q-1} = 0.18$ V and $E^0_{Th}(4/3) = -3.82$ V for Th; $q = 2$, $F_{q-1} = 0.53$ V and $E^0_{Pa}(4/3) = -2.1$ V for Pa if $D(Th^{3+}(aq)) < 1.14$ eV and $D(Pa^{3+}(aq)) < 2.07$ eV, which correspond to the case of a weak crystal field effect.

In order to realize respectively the fd and d electronic configurations in Pa^{3+}(aq) and Th^{3+}(aq) ΔE should be higher than 1.4 eV in the case of Th^{3+}(aq) and higher than 2.07 eV for Pa^{3+}(aq). In this case the eqn (1) is rewritten:

$$E^0(4/3) = -4.00 + 1.37\,(q-1) + F_{q+1} - D - \Delta E \quad (2)$$

or

$$E^0_{Th}(4/3) = -4.96 + D \quad (3)$$

$$E^0_{Pa}(4/3) = -4.17 + D \quad (4)$$

For the Ln and An complexes there are no experimental data concerning the crystal field effects $\Delta(d)$ and the stabilization energy D. From calculations for U(IV) complexes with ligands L = F, O, Cl, Br and I in octahedral ($CN = 6$) and cubic ($CN = 8$) crystal fields by relativistic Xα SW method, the values of $\Delta(d)$ have been calculated [7]. In the case of cluster complexes $U(IV)O_6^{8-}$, which are the closer to the Th(IV) aqueous ion, the calculated values $\Delta(d)$ are 3.15 and 2.80 eV respectively. The $6d$ electron stabilizations D are 1.26 eV ($CN = 6$) and 1.68 eV ($CN = 8$). For a given element the value of D decreases with the decrease of the oxidation state. Thus, in the case U^{3+} (and Th^{3+}) the stabilization energy, D, should be less than 1.3 eV ($CN = 6$) and 1.70 eV ($CN = 8$). From spectral data (d-d transitions) for fluoride complexes of $5d$ metals, even in the oxidation states IV–VI, the values of D do not exceed 1.7 eV. Consequently the electronic configuration of Pa^{3+}(aq) is rather f^2 with a small energy gap f^2–fd and $E^0_{Pa}(4/3) = -2.1$ V according to eqn (1). The small excitation energy f^2–fd is one of the reasons of the instability of Pa^{3+}(aq).

The same situation (but with d-f electronic transition or $E(fd) < 0$) occurs for the Th^{3+} species with $D < 1.7$ eV for Th^{3+}(aq) ($CN = 8$–9). The value of $E^0_{Th}(4/3)$ may follow both the eqn (1) or (2) since

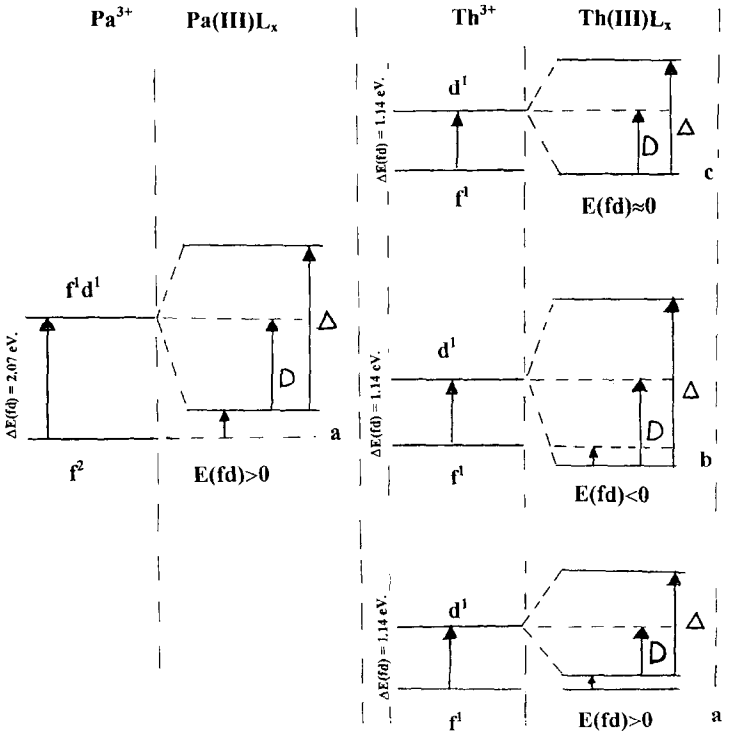

Fig. 1. Stabilization of a $6d$ electron of Th^{3+} and Pa^{3+} by crystal field effect; a: $D < \Delta E(fd)$; b: $D > \Delta E(fd)$; c: D around $\Delta E(fd)$.

$\Delta E(\mathrm{Th}) = 1.14$ eV $< \Delta E(\mathrm{Pa}) = 2.07$ eV. The probability that d^1 configuration is the lowest in energy is larger for $Th^{3+}(aq)$ than for $Pa^{3+}(aq)$. In [5] and [6] the values of D are 1.96 and 1.26 eV respectively. The first one seems too large and the second one rather small. Thus, with an average value of 1.16 eV (Fig. 1b) and accordingly to the eqn (2) corresponding to a $6d$ lowest configuration, the redox potential $E^0_{\mathrm{Th}}(4/3) = -3.35$ V.

For these reasons the instability of $Th^{3+}(aq)$ like $Pa^{3+}(aq)$ ion seems clear. Thus, with a good probability we may accept that $E^0_{\mathrm{Th}}(4/3) = -3.35$ V (d electronic configuration) (Fig. 1b) $> E^0_{\mathrm{Th}}(4/3) > -3.82$ V (f electronic configuration) (Fig. 1a), considering that for $Th^{3+}(aq)$ a pseudo-degenerated f and d configuration can not be completely ruled out (Fig. 1c).

The reducing ability of HN_3

The dissolution of HN_3 in water gives a weakly acidic solution [9] and its redox behaviour in acidic solutions is quite complex, as the following reactions show:

$$HN_3 = H^+(aq) + N^{3-}(aq) \quad pK_a = 4.77 \qquad (5)$$

$$3NH_4^+ = HN_3 + 11H^+ + 8e^- \quad E^0_{298} = +0.66\ V \qquad (6)$$

$$NH_4^+ + N_2 = HN_3 + 3H^+ + 2e^- \quad E^0_{298} = +1.82\ V \qquad (7)$$

$$HN_3 = 3/2\,N_2 + H^+ + e^- \quad E^0_{298} = -2.80\ V \qquad (8)$$

In [1] the value of the redox potential for the reaction (8), $E^0(8)$, used for the discussion was fixed at -3.54 V but not at -2.80 V and for the reaction:

$$Th^{4+} + HN_3 = Th^{3+} + 1.5\,N_2 + H^+ \qquad (9)$$

the potential ΔE^0 was estimated as

$$\Delta E^0 = E^0_{\mathrm{Th}}(4/3) - E^0(8) = -3.0 + 3.54 = +0.54\ V \qquad (10)$$

which was the basis to conclude that the reaction (9) is thermodynamically allowed. With the potential $E^0_{\mathrm{Th}}(4/3) = -3.35$ V or -3.82 (and even with -3.0 V) and $E^0(8) = -2.8$ V, ΔE^0 has a negative value, which indicates that, in fact, the reaction (9) is not thermodynamically allowed.

But there are other reasons. The potential $E^0(UO_2^{2+}/U^{4+})$ in acid solution is $+0.27$ V [10]. Using the eqns (9) and (10) to forecast the reduction of U(VI) by HN_3, led to the conclusion that this reduction is thermodynamically allowed, but it was established that HN_3 does not reduce U(VI) or U(IV) [21]. The matter is that in acid solution the scheme of potentials for HN_3 follows the step reactions (6) to (8). In analytical chemistry, the reaction of formation of ferric azide, FeN_3^{2+}, when hydrazoic acid reacts with ferric chloride is used for the qualitative test of the presence of Fe(III) [11]. However the hydrazoic acid does not reduce Fe(III) to Fe(II) although the potential $E^0(3/2)$ for Fe is $+0.77$ V [12]. Finally in neutral solution of thorium salt, the azide anion promotes thorium hydroxide formation and does not form thorium azide:

$$Th(NO_3)_4 + 4KN_3 + 4H_2O = Th(OH)_4 + 4KNO_3 + 4HN_3 \qquad (11)$$

The reaction (11) is used both in qualitative and quantitative determination of Th in the presence of lanthanides. Under the same circumstances, U and Zr are also precipitated as hydroxides [13].

In conclusion there is no firm basis to consider the reaction (9) as thermodynamically allowed.

About the identification of Th^{3+} *in* HN_3 *solutions*

In the resultant solutions of the reduction of $ThCl_4$ with HN_3 the complexes of Th(III), $[Th(H_2O)_x(N_3)_yCl_z]^{3-y-z}$, are supposed to involve N_3, Cl and H_2O ligands. In the tetravalent azido-chloro-complexes of tetravalent Ti, Zr and Hf both terminal, $[(MCl_4(N_3)_2]^{2-}$, and 1, 1μ-N, $[(M_2Cl_8(N_3)_2]^{2-}$, bonding was found for N_3 [14]. If Th(III) or Th(IV) azides exist within the conditions of the considered experiments, the absorption spectra must be explained.

In [1] room temperature optical spectra of proposed Th(III) solution were measured and discussed for a Th concentration of 0.3 mol l^{-1} at pH around 3.5. The quoted concentration is not the result of measurements but is based on the assumption of a 100% yield for the reaction (9) starting with HN_3 2 mol l^{-1} and Th 0.3 mol l^{-1}. The broad band with a maximum at 460 nm = 21.7 kK (which could correspond also to the absorption of ferric azide FeN_3^{2+} [11]), and the peaks at 332 nm = 30.1 kK, 190 mm = 52.6 kK and 185 nm = 54.1 kK were assigned to the $f \Rightarrow d$ and metal $\Rightarrow$ ligand allowed transitions.

Since reaction (9) is not thermodynamically allowed, let us accept for the discussion that the measured spectrum corresponds to an azide complex of Th(IV) involving also chlorine ligands. The linear azide anion belongs to $D_{\infty h}$ point group. In the $^1\Sigma_g^+$ ground state the 16 valent electrons occupy the 6 MO: $1\sigma_g^2\ 1\sigma_u^2\ 2\sigma_g^2\ 2\sigma_u^2\ 1\pi_u^4\ D_{\infty h} 1\pi_g^4$. The highest occupied molecular orbital is the non bonding π_g. Complexes of Th(IV) with ligands having mobile π electron system (most often azo-group) like the azide anion with the non-bonding π electrons have absorption bands within 320–680 nm [15]. For example the dissolution of $Th(C_9H_6ON)_4$, which is the precipitate of Th by 8-hydroxyquinoline, in 0.1 mol l^{-1} HCl shows absorption at 320–330 nm [15]. In contrast with that on the spectrum reported in [1] at below 650 nm the broad

band until 420 nm (centred at 460 nm) was interpreted as the $f \Rightarrow d$ transition for a trivalent Th complex.

Two kinds of charge transfer bands in the considered complex can be proposed: $N_3^- \Rightarrow Th^{4+}$ and $Cl^- \Rightarrow Th^{4+}$. The intensive absorption at 332, 190 and below 185 nm were interpreted as charge transfer transitions. In fact, the first one (at 332 and 460 nm) could be assigned to $N_3^- \Rightarrow Th^{4+}$ transition and the second and third (at 190 and below 185 nm) could be assigned to the charge transfer $Cl^- \Rightarrow Th^{4+}$.

The equation connecting the charge transfer bands $E(Cl^- \Rightarrow An^{3+})$ and $E(Cl^- \Rightarrow An^{4+})$ for the tetravalent and trivalent actinide chlorine complexes is:

$$E(Cl^- \Rightarrow An^{4+}) = E(Cl^- \Rightarrow An^{3+}) + V_q + \Delta F_q \quad (12)$$

with $V_q = -33.28$ kK and ΔF_q being evaluated using the approach given in [6]. The correlation between $E(Cl^- \Rightarrow An^{4+})$ and $E(Cl^- \Rightarrow An^{3+})$ can be established (Table 1). For simplicity octahedral complexes MCl_6^{3-} and MCl_6^{2-} are only considered, although the charge transfer energies can be easily recalculated for any symmetry and any CN.

The agreement between the experimental and calculated values $E(Cl^- \Rightarrow An^{4+})$ for An = Pa, U, Np and Pu shows the good validity of eqn (12). It means that values of the charge transfer energies for the considered thorium complexes are satisfactory. The charge transfer energies $E(Cl^- \Rightarrow An^{3+})$ and $E(Cl^- \Rightarrow An^{4+})$ differ approximately on 30 kK. Thus, the intensive absorption "below 185 nm = 54 kK" [1] corresponds to the chlorine-Th(IV) charge transfer (in $ThCl_6^{2-}$ one is at 156 nm ≈ 64.2 kK). In the case of non-octahedral symmetry and higher CN the charge transfer energy would be a little changed. In the part of spectra at about 100 nm (eqn (12) and Table 1) where the charge transfer $Cl^- \Rightarrow Th^{3+}$ is expected, any absorption is measured in [1]. With other hand, the $f \Rightarrow d$ transition in Th(III) complex is waited to be about 1200–1300 nm. These transitions are not observed in [1].

Optical spectra do not confirm firmly the existence of trivalent thorium but rather those of Th(IV) complexes.

Finally, the ESR spectrum of a frozen solution was given in [1]. The very broad signal is seen very similar in shape to that of UCl_5SOCl_2. The average value of g tensor was measured as $g = 2.19$.

For $[Th(III)\{\eta^5\text{-}C_5H_3(SiMe_3)_2\}]$ the average experimental value of g, $g = 1.91 \pm 0.001$, is interpreted with the assumption of a $6d$ electron configuration [18]. One can see that g values in [1] and [18] differ significantly for a $6d$ electron configuration, which exist in the former case and is assumed in the later. To go further in the discussion let us propose a $5f^1$ configuration for Th, it is to say let assume the existence of Th(III). The g values for the $5f^1$ electron configuration, for example, in UCl_5SOCl_2, UCl_5, $PaCl_5$, $RbUCl_6$ and other compounds is about 1.1 with the sign undetermined (+ or −) [19]. In [20] the value of g for UCl_5SOCl_2 is negative, $g = -1.18$. Thus, it is difficult to understand why the authors of [1] consider an ESR spectrum with $g = 2.19$ as "very similar" to the spectra of UCl_5SOCl_2 with $g = -1.18$.

It seems that the measured ESR spectrum is not connected with Th(III). Without the measurement of the concentration of spins, it is impossible to discuss ESR spectra. Besides, it is known that the decomposition of HN_3 can go through a variety of ways involving the formation of various radicals like nitrogen and imine radical [9,16].

CONCLUSION

In conclusion thermodynamic considerations, room temperature absorption spectra as well as ESR investigations do not support the first observation of Th(III) species in aqueous solution.

Synthesis and structures of ruthenium(II) mono[1,2-phenylenebis(dimethylarsine)] complexes: precursors to *trans* metal-to-ligand charge-transfer chromophoric assemblies

Benjamin J. Coe,* Christopher I. McDonald and Roy L. Beddoes

Department of Chemistry, University of Manchester, Oxford Road, Manchester M13 9PL, U.K.

(Received 30 September 1997; accepted 14 November 1997)

Abstract—The complex *fac*-[$RuCl_3$(pdma)(NO)] [pdma = 1,2-phenylenebis(dimethylarsine)] reacts with silver(I) salts, AgX, at room temperature in acetonitrile to afford disubstituted derivatives *cis*-[$RuClX_2$(pdma)(NO)] (X^- = trifluoroacetate **1**, *p*-toluenesulphonate **2** or nitrate **3**). Reflux of *fac*-[$RuCl_3$(pdma)(NO)] in 1 : 4 pyridine/methanol containing an excess of AgO_2CCF_3 causes conversion into *cis*-[Ru(OMe)(pdma)$(py)_2$(NO)][PF_6]$_2$ **4** (py = pyridine). Reaction of *fac*-[$RuCl_3$(pdma)(NO)] in refluxing 1 : 7 pyridine/acetonitrile containing 2 equivalents of AgO_2CCF_3 affords *cis*-[RuCl(pdma)$(py)_2$(NO)][PF_6]$_2$ (**5**). **5** is also prepared by reaction of **1** in refluxing pyridine/acetonitrile. The mixed-chelate salts *trans*-[RuCl(pdma)(L—L)(NO)][PF_6]$_n$ [n = 2, L—L = 2,2′-bipyridine **6**, 1,10-phenanthroline **7**, 4,4′-dimethyl-2,2′-bipyridine **8** or 1,2-bis(diphenylphosphino)ethane **9**; n = 1, L—L = picolinate **10**] are produced by reaction of *fac*-[$RuCl_3$(pdma)(NO)] with an excess of L—L in refluxing methanol. The yields of the reactions to produce **5–10** vary according to the ligating ability of the incoming ligand(s). Single-crystal structures of *fac*-[$RuCl_3$(pdma)(NO)], **2**·Me_2CO, **3** and **6** have been determined. **3** is the first ruthenium complex containing monodentate nitrato ligand(s) to be structurally characterized. © 1998 Elsevier Science Ltd. Keywords: ruthenium complexes; ligands; synthesis.

Photoactive ruthenium(II) complexes containing α-diimmine ligands such as 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen) are of particular current interest for potential applications in "photochemical molecular devices" (PMDs) [1]. A metal-based PMD exploits metal-to-ligand charge-transfer (MLCT) excitations to trigger electron or energy-transfers which result in potentially useful phenomena, e.g. long-lived photoinduced charge-separations. A combination of electronic and stereochemical factors determine the utility of an MLCT chromophore in a PMD, and recent studies in this field have featured an increasing emphasis on stereochemical aspects [2–4]. We are developing strategies for controlled ligand substitutions at octahedral metal centres as a means to create functionalized chromophoric *trans* complexes. Work with complexes based on *trans*-$\{Ru(bipy)_2\}^{2+}$ centres was synthetically successful [5], but the products suffer from poor photostability and tend to isomerize to their more stable *cis* forms. Related complexes containing only a single bipy or other α-diimmine ligand are expected to feature potentially useful photoexcitation properties, combined with greatly improved stability.

We have recently begun to explore the derivative chemistry of the complex *trans*-[$RuCl(pdma)_2(NO)]^{2+}$ [pdma = 1,2-phenylenebis(dimethylarsine)] [6]. The *trans*-$\{Ru(pdma)_2\}^{2+}$ core provides a highly stable platform for stepwise axial substitutions of the chloride and nitrosyl ligands, without any isomerization. We have incorporated this non-chromophoric centre into ligand-bridged dinuclear complexes which are of interest for the study of intervalence transfer properties [7]. The complex *fac*-[$RuCl_3$(pdma)(NO)] was first reported in 1966 [8], together with a series of related complexes *fac*-[$RuCl_3L_2$(NO)] (L = triphenylphosphine, etc.). The only one of these to be subjected to attempts at chloride substitutions, *fac*-

$[RuCl_3py_2(NO)]$ (py = pyridine) was reportedly inert, even drastic reaction conditions leading only to decomposition. However, *fac*-$[RuCl_3(pdma)(NO)]$ is known to be an intermediate in the synthesis of *trans*-$[RuCl(pdma)_2(NO)]Cl_2$ [9], demonstrating that the former is amenable to chloride substitutions. We hence sought to investigate the derivative chemistry of *fac*-$[RuCl_3(pdma)(NO)]$, with the primary objective of preparing mixed-chelate *trans*-NO/Cl complexes of α-diimmine ligands which will serve as precursors to stable MLCT chromophoric assemblies.

EXPERIMENTAL

Materials and procedures

The compound $RuCl_3 \cdot 2H_2O$ was supplied by Johnson Matthey plc and pdma was obtained from Dr P. G. Edwards, University of Wales College of Cardiff. The complex *fac*-$[RuCl_3(pdma)(NO)]$ was prepared according to a published procedure [8]. All other reagents were obtained commercially and used as supplied. All reactions were conducted under an argon atmosphere. Products were dried overnight at room temperature in a vacuum desiccator ($CaSO_4$) prior to characterization.

Instrumentation

^{1}H NMR spectra were recorded on a Varian Gemini 200 spectrometer and all shifts are referenced to $SiMe_4$. The complex fine splitting of the pyridine or 2,2′-bipyridine proton resonances is ignored and the signals are reported as simple doublets or triplets. The ^{19}F NMR spectrum of **1** was recorded on a Varian Unity 500 spectrometer with $CFCl_3$ as reference. Elemental analyses were performed by the Microanalytical Laboratory, University of Manchester. Infrared spectra were obtained as KBr discs with an ATI Mattson Genesis Series FTIR instrument. FAB mass spectra were recorded using a Kratos Concept spectrometer with a 6–8 keV Xe atom beam and 3-nitrobenzyl alcohol as matrix.

Cyclic voltammetric measurements were carried out using an EG&G PAR model 173 potentiostat/galvanostat with a model 175 universal programmer. A single-compartment cell was used with the saturated calomel reference electrode (SCE) separated by a salt bridge from the platinum-bead working electrode and platinum-wire auxiliary electrode. Acetonitrile (HPLC grade) was used as received and tetra-*n*-butylammonium hexafluorophosphate, twice recrystallized from ethanol and dried *in vacuo*, was used as supporting electrolyte. Solutions containing ca 10^{-3} mol dm^{-3} analyte (0.1 mol dm^{-3} electrolyte) were deaerated by purging with N_2. All $E_{1/2}$ values were calculated from $(E_{pa}+E_{pc})/2$ at a scan rate of 200 mV s^{-1}.

Preparations

cis-$[RuCl(CF_3CO_2)_2(pdma)(NO)]$ (**1**). To a solution of *fac*-$[RuCl_3(pdma)(NO)]$ (100 mg, 0.191 mmol) in acetonitrile (30 cm^3) was added AgO_2CCF_3 (136 mg, 0.616 mmol) in acetonitrile (5 cm^3). Immediate precipitation of AgCl was observed, and the reaction was stirred at room temperature for 24 h. The solvent was reduced to a small volume *in vacuo*, and the AgCl was removed by filtration through celite. Addition of water to the golden filtrate solution caused precipitation of the product which was filtered off and washed with water. The product was precipitated once more from acetone-water and dried to yield a pale golden solid. Yield: 85 mg, 66%. Found: C, 25.2; H, 2.35; N, 2.55. Calc. for $C_{14}H_{16}As_2ClF_6NO_5Ru$: C, 24.8; H, 2.40; N, 2.05%. ^{1}H NMR data (200 MHz, CD_3COCD_3): δ 8.22 (2 H, m, C_6H_2), 7.83 (2 H, m, C_6H_2), 2.18 (6 H, s, 2AsMe), 2.15 (6 H, s, 2AsMe). ^{19}F NMR data (500 MHz, CD_3COCD_3): δ −75.38 (s). ν(N≡O) 1882 vs, ν(C=O) 1688 vs, ν(C—O) 1195 vs and 1141 s cm^{-1}. *m/z*: 566 ($[M-CF_3CO_2^-]^+$) and 453 ($[M-2CF_3CO_2^-]^+$).

cis-$[RuCl(C_7H_7SO_3)_2(pdma)(NO)]$ (**2**). This complex was prepared in similar manner to **1** by using $AgO_3SC_7H_7$ (174 mg, 0.624 mmol) in place of AgO_2CCF_3. After evaporation to a small volume, dichloromethane was added and the AgCl and excess $AgO_3SC_7H_7$ were removed by filtration through celite. The solution was evaporated to dryness and dichloromethane was added. Further $AgO_3SC_7H_7$ was removed by filtration through celite and acetone was added to the filtrate. Slow evaporation of the dichloromethane *in vacuo* caused precipitation of the product. This was filtered off, washed with acetone then water, and dried to yield a golden microcrystalline solid. Yield: 106 mg, 65%. Found: C, 37.95; H, 4.05; N, 1.55; S, 7.35. Calc. for $C_{24}H_{30}As_2ClNO_7RuS_2 \cdot C_3H_6O$: C, 38.0; H, 4.25; N, 1.65; S, 7.50%. ^{1}H NMR data (200 MHz, $CDCl_3$): δ 7.86 (4 H, d, J = 8.1 Hz, Me-C_6H_4-SO_3), 7.77 (4 H, m, C_6H_4), 7.17 (4 H, d, J = 8.1 Hz, Me-C_6H_4-SO_3), 2.49 (6 H, s, 2AsMe), 2.38 (6 H, s, 2Me), 2.06 (6 H, s, 2AsMe). ν(N≡O) 1881 vs, ν(S=O) 1256 s, 1153 s and 1102 s cm^{-1}. *m/z*: 625 ($[M-C_7H_7SO_3^-]^+$) and 453 ($[M-2C_7H_7SO_3^-]^+$).

cis-$[RuCl(NO_3)_2(pdma)(NO)]$ (**3**). This complex was prepared in similar manner to **1** by using $AgNO_3$ (83 mg, 0.489 mmol) in place of AgO_2CCF_3. The AgCl was removed by filtration through celite and the yellow filtrate was evaporated almost to dryness. This caused precipitation of the orange product which was filtered off and washed with acetonitrile. The product was washed with aqueous $Na_2S_2O_3$ to remove residual AgCl, then washed with water and dried. Yield: 70 mg, 64%. Found: C, 20.5; H, 3.10; N, 7.25. Calc. for $C_{10}H_{16}As_2ClN_3O_7Ru$: C, 20.85; H, 2.80; N, 7.30%. ν(N≡O) 1865 vs, $\nu_{as}(NO_2)$ 1477 vs, $\nu_s(NO_2)$ 1262 vs, ν (N—O) 1000 m cm^{-1}.

cis-$[Ru(OMe)(pdma)(py)_2(NO)]PF_6]_2$ (**4**). A solu-

tion of *fac*-[$RuCl_3$(pdma)(NO)] (100 mg, 0.191 mmol) and AgO_2CCF_3 (215 mg, 0.973 mmol) in methanol (40 cm^3) and pyridine (10 cm^3) was heated at reflux for 14 h. The solvent was reduced to a small volume *in vacuo*, acetone was added and the AgCl was removed by filtration through celite. Aqueous NH_4PF_6 was added to the filtrate and the acetone was evaporated slowly *in vacuo*, causing formation of a yellow precipitate which was filtered off and washed with water. The crude product was reprecipitated from acetone-aqueous NH_4PF_6 and dried (130 mg). Purification was effected by three precipitations from acetone-diethyl ether to afford a gold solid. Yield: 73 mg, 43%. Found: C, 28.3; H, 3.70; N, 4.80. Calc. for $C_{21}H_{29}As_2F_{12}N_3O_2P_2Ru$: C, 28.15; H, 3.25; N, 4.70%. ^1H NMR data (200 MHz, CD_3COCD_3): δ 9.03 (4 H, d, $2H^{2,6}$), 8.38 (2 H, m, C_6H_2), 8.31 (2 H, t, H^4), 8.00 (2 H, m, C_6H_2), 7.85 (4 H, t, $2H^{3,5}$), 3.77 (3 H, s, OMe), 2.34 (6 H, s, 2AsMe), 2.22 (6 H, s, 2AsMe). ν(C—H) 2934 m and 2807 m, ν(N≡O) 1848 vs cm^{-1}. *m/z*: 752 ($[M-PF_6^-]^+$).

cis-[RuCl(pdma)$(py)_2$(NO)][PF_6]$_2$ (**5**). A solution of *fac*-[$RuCl_3$(pdma)(NO)] (100 mg, 0.191 mmol) and AgO_2CCF_3 (85 mg, 0.385 mmol) in acetonitrile (35 cm^3) and pyridine (5 cm^3) was heated at reflux for 30 min. The solvent was reduced to a small volume *in vacuo*, aqueous NH_4PF_6 was added and the precipitate was filtered off and washed with water. The crude product was dissolved through the frit in acetone to leave most of the AgCl, the remainder of which was removed by filtration through celite. The product was then precipitated by addition of aqueous NH_4PF_6, filtered off, washed with water and dried. Purification was effected by two precipitations from acetone-diethyl ether to afford a pale yellow solid. Yield: 67 mg, 39%. Found: C, 27.05; H, 2.85; N, 4.50. Calc. for $C_{20}H_{26}As_2ClF_{12}N_3OP_2Ru$: C, 26.65; H, 2.90; N, 4.65%. ^1H NMR data (200 MHz, CD_3COCD_3): δ 9.02 (4 H, d, $2H^{2,6}$), 8.41–8.32 (4 H, m, $2H^4$ and C_6H_2), 7.97 (2 H, m, C_6H_2), 7.89 (4 H, t, $2H^{3,5}$), 2.41 (6 H, s, AsMe), 2.30 (6 H, s, AsMe). ν(N≡O) 1893 vs cm^{-1}. *m/z*: 755 ($[M-PF_6^-]^+$), 612 ($[M-2PF_6^-]^+$), 531 ($[M-2PF_6^- - py]^+$) and 452 ($[M-2PF_6^- - 2py]^+$).

trans-[RuCl(pdma)(bipy)(NO)][PF_6]$_2$ (**6**). A solution of *fac*-[$RuCl_3$(pdma)(NO)] (100 mg, 0.191 mmol) and 2,2′-bipyridine (305 mg, 1.95 mmol) in methanol (40 cm^3) was heated at reflux for 3 h. The solvent was reduced to a small volume *in vacuo*, diethyl ether was added and the precipitate was filtered off and washed with diethyl ether. The crude product was dissolved through the frit in water to leave a small amount of insoluble material. The product was precipitated by addition of aqueous NH_4PF_6, filtered off, washed with water and dried to yield a pink solid (128 mg). Purification was effected by three precipitations from acetonitrile-diethyl ether to afford a pale yellow solid. Yield: 87 mg, 51%. Found: C, 26.9; H, 2.50; N, 4.35. Calc. for $C_{20}H_{24}As_2ClF_{12}N_3OP_2Ru$: C, 26.75; H, 2.70; N, 4.70%. ^1H NMR data (200 MHz, CD_3CN): δ 8.93 (2 H, d, $H^{6,6'}$), 8.72 (2 H, d, $H^{3,3'}$), 8.53 (2 H, t, $H^{4,4'}$), 8.15 (2 H, m, C_6H_2), 8.01 (2 H, t, $H^{5,5'}$), 7.93 (2 H, m, C_6H_2), 2.36 (6 H, s, AsMe), 2.27 (6 H, s, 2AsMe). ν(N≡O) 1878 vs cm^{-1}. *m/z*: 754 ($[M-PF_6^-]^+$), 609 ($[M-2PF_6^-]^+$) and 579 ($[M-2PF_6^- - NO]^+$).

trans-[RuCl(pdma)(phen)(NO)][PF_6]$_2$ (**7**). This was prepared and purified in identical fashion to **6** by using 1,10-phenanthroline (346 mg, 1.92 mmol) in place of bipy. From 160 mg of crude pale orange product, a pale yellow solid was obtained. Yield: 101 mg, 57%. Found: C, 28.6; H, 2.65; N, 4.50. Calc. for $C_{22}H_{24}As_2ClF_{12}N_3OP_2Ru$: C, 28.65; H, 2.60; N, 4.55%. ^1H NMR data (200 MHz, CD_3CN): δ 9.33 (2 H, dd, J = 1.2, 5.3 Hz, $H^{2,9}$), 9.11 (2 H, dd, J = 1.2, 8.3 Hz, $H^{4,7}$), 8.41 (2 H, s, $H^{5,6}$), 8.31 (2 H, dd, J = 5.3, 8.3 Hz, $H^{3,8}$), 8.20 (2 H, m, C_6H_2), 7.96 (2 H, m, C_6H_2), 2.44 (6 H, s, 2AsMe), 2.37 (6 H, s, 2AsMe). ν(N≡O) 1874 vs cm^{-1}. *m/z*: 733 ($[M-2PF_6^-]^+$) and 603 ($[M-2PF_6^- - NO]^+$).

trans-[RuCl(pdma)(4,4′-Me_2bipy)(NO)][PF_6]$_2$ (**8**). This was prepared and purified in identical fashion to **6** by using 4,4′-dimethyl-2,2′-bipyridine (354 mg, 1.92 mmol) in place of bipy. A pale yellow solid was obtained. Yield: 91 mg, 51%. Found: C, 28.45; H, 3.05; N, 4.80. Calc. for $C_{22}H_{28}As_2ClF_{12}N_3OP_2Ru$: C, 28.5; H, 3.05; N, 4.55%. ^1H NMR data (200 MHz, CD_3CN): δ 8.73 (2 H, d, J = 5.8 Hz, $H^{6,6'}$), 8.56 (2 H, d, J = 1.5 Hz, $H^{3,3'}$), 8.14 (2 H, m, C_6H_2), 7.92 (2 H, m, C_6H_2), 7.80 (2 H, dd, J = 5.9, 1.5 Hz, $H^{5,5'}$), 2.71 (6 H, s, 2Me), 2.33 (6 H, s, 2AsMe), 2.24 (6 H, s, 2AsMe). ν(N≡O) 1875 vs cm^{-1}. *m/z*: 637 ($[M-2PF_6^-]^+$) and 607 ($[M-2PF_6^- - NO]^+$).

trans-[RuCl(pdma)(dppe)(NO)][PF_6]$_2$ (**9**). This was prepared in similar fashion to **6** by using 1,2-bis(diphenylphosphino)ethane (764 mg, 1.92 mmol) in place of bipy. Some of the dppe remained undissolved throughout the reaction. After refrigeration this was filtered off and washed with methanol. The pale golden filtrate was reduced to a small volume *in vacuo* and water was added to precipitate the remaining dppe. This was removed by extraction with dichloromethane (4 × 5 cm^3) and then aqueous NH_4PF_6 was added to the aqueous layer. The crude product was filtered off, washed with water and dried (67 mg). This material was shown by proton NMR to contain ca 5% *trans*-[RuCl(pdma)$_2$(NO)][PF_6]$_2$. The latter was removed by reprecipitation from acetone/NBu^n_4Cl followed by precipitation from water/aqueous NH_4PF_6; *trans*-[RuCl(pdma)$_2$(NO)]Cl_2 is less soluble in acetone than is *trans*-[RuCl(pdma)(dppe)(NO)]Cl_2 and so precipitates first upon addition of NBu^n_4Cl, despite being the minor component. This process was repeated to afford the pure product as a pale yellow solid. Yield: 28 mg, 13%. Found: C, 38.0; H, 3.60; N, 1.55; P, 10.60. Calc. for $C_{36}H_{40}As_2ClF_{12}NOP_4Ru$: C, 37.9; H, 3.55; N, 1.25; P, 10.85%. ^1H NMR data (200 MHz, CD_3COCD_3): δ 8.19 (2 H, m, C_6H_2), 7.98–7.67 (22 H, c m, C_6H_2 and $4C_6H_5$), 4.18 (2 H, c m, CH_2), 3.77 (2 H, c m, CH_2), 2.51 and 2.50 (6 H, s, s, 2AsMe), 1.03 and 1.02 (6 H, s, s, 2AsMe). ν(N≡O) 1873 s cm^{-1}. *m/z*: 996 ($[M-PF_6^-]^+$), 851 ([M–

$2PF_6^-]^+$), 821 ($[M-2PF_6^- -NO]^+$) and 785 ($[M-2PF_6^- -NO-Cl]^+$).

trans-[RuCl(pica)(pdma)(NO)]PF_6 (**10**). A solution of *fac*-[$RuCl_3$(pdma)(NO)] (100 mg, 0.191 mmol) and picolinic acid (236 mg, 1.92 mmol) in methanol (40 cm^3) was heated at reflux for 30 min. The solvent was reduced to a small volume *in vacuo*, water was added and the precipitate was filtered off and washed with water to leave a small amount of insoluble material. The addition of aqueous NH_4PF_6 to the filtrate precipitated the product which was filtered off, washed with water and dried to yield a pale golden solid (83 mg). This material was shown by proton NMR to contain ca 15% *trans*-[RuCl(pdma)$_2$(NO)][PF_6]$_2$. The latter was precipitated by the slow addition of NBu^n_4Cl to an acetone solution of the product mixture. After filtration, the slow addition of aqueous NH_4PF_6 caused precipitation of $NBu^n_4PF_6$ which was filtered off and washed with water. The addition of further aqueous NH_4PF_6 to the filtrate caused precipitation of the product which was filtered off, washed with water and dried. Remaining traces of $NBu^n_4PF_6$ were removed by precipitation from acetonitrile-diethyl ether to afford **10** as a pale yellow solid. Yield: 40 mg, 29%. Found: C, 26.8; H, 2.60; N, 4.00. Calc. for $C_{16}H_{20}As_2ClF_6N_2O_3PRu$: C, 26.7; H, 2.80; N, 3.90%. ^1H NMR data (200 MHz, CD_3COCD_3): δ 9.20 (1 H, d, H^6), 8.52 (1 H, td, J = 1.4, 7.6 Hz, H^4), 8.39–8.32 (3 H, m, H^3 and C_6H_2), 8.05 (1 H, m, H^5), 7.92 (2 H, m, C_6H_2), 2.47 (3 H, s, AsMe), 2.39 (3 H, s, AsMe), 2.37 (6 H, s, 2AsMe). ν(N≡O) 1872 s cm^{-1}, ν(C=O) 1671 s cm^{-1}. m/z: 574 ($[M-PF_6^-]^+$).

X-ray crystallography

Crystals of *fac*-[$RuCl_3$(pdma)(NO)] were obtained by slow cooling of a boiling methanolic solution to room temperature. Those of the other compounds were grown by slow evaporation at room temperature; **2**·Me_2CO from acetone/dichloromethane, **3** from an acetonitrile reaction solution and **6** from acetonitrile/toluene.

A prismatic crystal of each compound was selected for diffraction study, having the following colours and dimensions: *fac*-[$RuCl_3$(pdma)(NO)] (red; 0.15 × 0.25 × 0.45 mm), **2**·Me_2CO (orange; 0.10 × 0.10 × 0.17 mm), **3** (yellow; 0.05 × 0.15 × 0.30 mm) and **6** (yellow; 0.05 × 0.15 × 0.35 mm). The crystals were mounted on glass fibres and data were collected on a Rigaku AFC5R diffractometer at ambient temperature. The structures of *fac*-[$RuCl_3$(pdma)(NO)], **2**·Me_2CO and **3** were solved by standard direct methods using SHELXS86 [10] for *fac*-[$RuCl_3$(pdma)(NO)] and SIR92 [11] for **2**·Me_2CO and **3**. In the case of **6**, heavy-atom Patterson methods [12] were employed. For **2**·Me_2CO, **3** and **6** the structures were expanded using Fourier techniques with DIRDIF94 [13]. In all cases refinement was by full-matrix least-squares on F_o for all unique reflections.

Data were corrected for Lorentz-polarization effects and for absorption with maximum and minimum transmission factors of 1.00 and 0.74 for *fac*-[$RuCl_3$(pdma)(NO)], 1.00 and 0.94 for **2**·Me_2CO, 1.00 and 0.72 for **3** and 1.00 and 0.78 for **6**. All non-hydrogen atoms, including those of the acetone of crystallization in **2**·Me_2CO, were refined anisotropically and hydrogen atoms were included in idealized positions. All calculations were performed using the TEXSAN crystallographic software package [14]. The complexes *fac*-[$RuCl_3$(pdma)(NO)] and **2**·Me_2CO lie on crystallographic mirror planes. Complex **3** has approximate mirror symmetry, but no ambiguity exists with respect to an alternative centrosymmetric space group. Salt **6** is prone to form laminates, which caused some problems with structure solution due to reflection twinning. There is still some distortion present in the final model, mainly in the bipy ligand, which is presumably due to the superposition of a small proportion of the twin in the lattice.

ORTEP [15] diagrams showing views of the complexes are given in Figs 1–4. Crystallographic data and refinement details are presented in Table 2, and selected bond lengths and angles in Tables 3–6. Fractional atomic coordinates, anisotropic thermal parameters, and full listings of bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and characterization

The complex *fac*-[$RuCl_3$(pdma)(NO)] reacts with silver(I) salts, AgX, at room temperature in acetonitrile to afford disubstituted derivatives *cis*-[$RuClX_2$(pdma)(NO)] [X^- = trifluoroacetate, CF_3CO_2 (**1**), *p*-toluenesulphonate, $C_7H_7SO_3$ (**2**) or nitrate (**3**)] in reasonable yield. Yields are independent of the nature of X^- and are unaffected by using an excess of AgX. Selective substitution of the equatorial chlorides in *fac*-]$RuCl_3$(pdma)(NO)] is possible because the linearly bonded nitrosyl ligand delabilizes the axial chloride, as manifested in the Ru—Cl bond lengths (see later). The insoluble product **3** was identified by infrared spectroscopy and by X-ray crystallography (see later) as the neutral complex containing two monodentate nitrato ligands, rather than the isomeric chelate salt, *trans*-[RuCl(*O*,*O*-NO_3)(pdma)(NO)]NO_3.

Fac-[$RuCl_3$(pdma)(NO)] reacts very slowly in refluxing pyridine to afford *cis*-[RuCl(pdma)$(py)_2$(NO)]$^{2+}$ in low yield, accompanied by decomposition to give an insoluble black material. This reaction is predictably much faster in a protic medium, the initial chloride substitution being complete after 30 min at reflux in 1:4 pyridine-methanol,

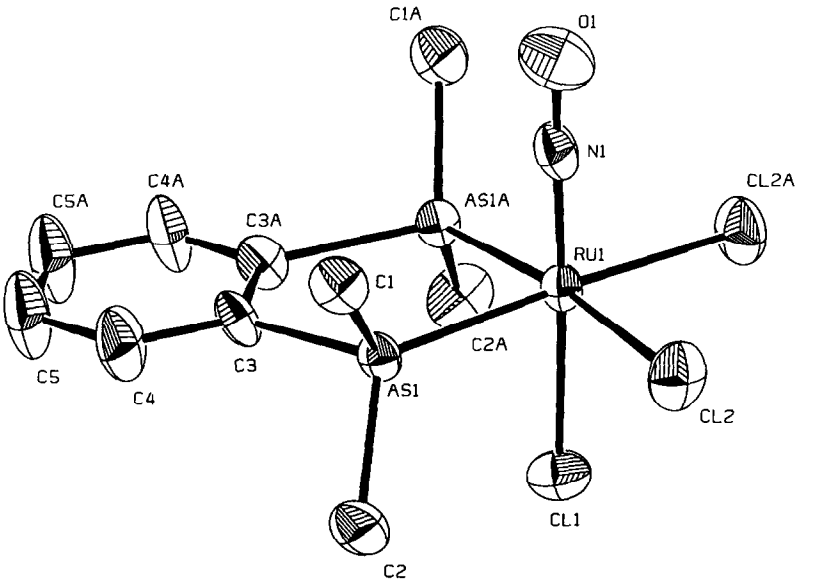

Fig. 1. Structural representation of the complex *fac*-[$RuCl_3$(pdma)(NO)], with hydrogen atoms omitted (50% probability ellipsoids).

as evidenced by an absence of water-insoluble starting material. However, it is not possible to obtain a good yield of *cis*-[RuCl(pdma)$(py)_2$(NO)]$^{2+}$ via this method, and extended reflux times produce an intractable product mixture. Proton NMR spectra indicate that this is due to the participation of methoxide ion as a ligand. In the presence of 3 equivalents of AgO_2CCF_3 the major product of this reaction is the trisubstituted derivative *cis*-[Ru(OMe)(pdma)$(py)_2$(NO)]$^{2+}$, isolated as its PF_6^- salt **4** in reasonable yield.

Reaction of *fac*-[$RuCl_3$(pdma)(NO)] with 2 equivalents of AgO_2CCF_3 in refluxing acetonitrile produces the known [9] complex *trans*-[RuCl(pdma)$_2$(NO)]$^{2+}$ in low yield via scrambling of the pdma ligands.* The most efficient method for the synthesis of *cis*-[RuCl(pdma)$(py)_2$(NO)]$(PF_6)_2$ (**5**) is via the reaction of *fac*-[$RuCl_3$(pdma)(NO)] in 1:7 pyridine-acetonitrile in the presence of 2 equivalents of AgO_2CCF_3. Yields are modest and decrease with extended reflux times, as the production of *trans*-[RuCl(pdma)$_2$(NO)]$^{2+}$ and also of another complex, believed to be *cis*-[Ru(OH)(pdma)$(py)_2$(NO)]$^{2+}$, increases.† **5** can also be prepared by reaction of the trifluoroacetate complex **1** with pyridine in acetonitrile, but this gives slightly poorer yields than the direct reaction.

The mixed-chelate salt *trans*-[RuCl(pdma)(bipy)(NO)]$[PF_6]_2$ (**6**, bipy = 2,2′-bipyridine) is produced in reasonable yield by reaction of *fac*-[$RuCl_3$(pdma)(NO)] with an excess of bipy in refluxing methanol. This reaction is considerably more efficient than that with pyridine due to the superior ligating ability of the chelating bipy. The salts **7**, **8** and **9** are produced in analogous fashion to **6** by using 1,10-phenanthroline, 4,4′-dimethyl-2,2′-bipyridine or 1,2-bis(diphenylphosphino)ethane in place of bipy. The poor yield of **9** is ascribed to diminished ligating ability due to the steric bulk of the dppe ligand. Several attempts at preparing **9** via **1** gave similarly low yields. In the case of **10** a shorter reaction time is necessary in order to minimize the production of *trans*-[RuCl(pdma)$_2$(NO)]$^{2+}$, demonstrating the inferior ligating ability of the picolinate ligand with respect to bipy or phen. We have found that the reaction of

* A partial solution of *fac*-[$RuCl_3$(pdma)(NO)] (100 mg, 0.191 mmol) and AgO_2CCF_3 (96 mg, 0.435 mmol) in acetonitrile (40 cm^3) was heated at reflux for 3 h. After cooling, the solvent was evaporated *in vacuo* to ca 3 cm^3, and the AgCl was removed by filtration through celite. Addition of aqueous NH_4PF_6 gave a sticky golden precipitate which was collected by filtration and washed with water. This was purified by precipitation, first from acetone-aqueous NH_4PF_6 and then from acetone-diethyl ether to afford a yellow solid. Yield: 16 mg, 16%. Found: C, 23.1; H, 3.20; N, 1.40. Calc. for $C_{20}H_{32}As_4ClF_{12}NOP_2Ru$: C, 23.35; H, 3.15; N, 1.35. ^1H NMR data (200 MHz, CD_3COCD_3): δ 8.46 (4 H, m, $2C_6H_2$), 7.99 (4 H, m, $2C_6H_2$), 2.56 (6 H, s, 2AsMe), 2.38 (6 H, s, 2AsMe). ν(N≡O) 1881 vs cm^{-1}.

† The complex *cis*-[Ru(OH)(pdma)$(py)_2$(NO)]$^{2+}$ is identified by the presence of a clearly resolved, minor set of signals attributable to a *cis*-{Ru(X)(pdma)$(py)_2$}$^+$ moiety in the proton NMR spectrum; in particular, a singlet at 6.30 ppm integrating for 1 proton is assigned to the OH resonance. Small amounts of *trans*-[RuCl(pdma)$_2$(NO)]$[PF_6]_2$ or *cis*-[Ru(OH)(pdma)$(py)_2$(NO)]$[PF_6]_2$ can be separated from **5** by precipitation from acetone-diethyl ether or from acetone-aqueous NH_4PF_6, respectively.

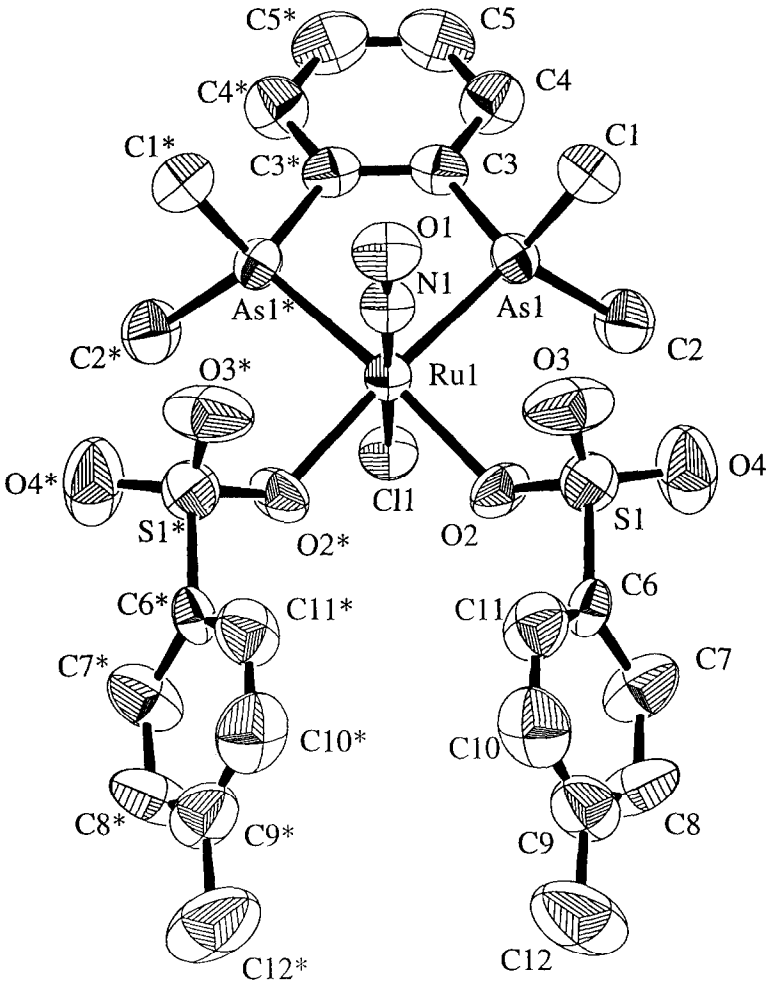

Fig. 2. Structural representation of the complex in *cis*-[RuCl($C_7H_7SO_3$)$_2$(pdma)(NO)]·Me_2CO (**2**·Me_2CO), details as in Fig. 1.

fac-[$RuCl_3$(pdma)(NO)] with α-diimines in refluxing methanol is surprisingly sensitive to the nature of the ligand. Following the synthetic procedure for **6–8**, but using 2,2′-bipyrimidine, 4,5-diazafluoren-9-one, 2,2′-biquinoline or 2,9-dimethyl-1,10-phenanthroline, the only isolable product is *trans*-[RuCl(pdma)$_2$(NO)]$^{2+}$. Investigations are ongoing in order to explain these seemingly anomalous results. The syntheses of **1–10** are shown in Scheme 1.

All of the new complexes display ν(N≡O) bands in the region 1900–1840 cm^{-1}, consistent with the presence of linearly bonded nitrosyl ligands, and confirmed by crystallographic studies (see later). The ν(N≡O) frequencies of **1–3** and **5–10** vary predictably with the nature of the equatorial ligand(s). Replacement of the *trans* chloride in **5** by the more basic methoxide in **4** produces a low-energy shift of 45 cm^{-1} in the ν(N≡O) band. The nitrato ligands in **3** give rise to bands at 1477, 1262 and 1000 cm^{-1} ($\Delta\nu$ = 215 cm^{-1}) consistent with monodentate coordination [16]. Absorptions at similar energies have been assigned to monodentate nitrato ligands in complexes of Ru(IV) [17]. Intense bands characteristic of the other ligands, particularly the CF_3CO_2 and $C_7H_7SO_3$ anions, are also observed.

For **1**, **2** and **4–8** the *trans*-NO/Cl geometry and resulting C_s symmetry is confirmed by the presence of a single 1,2-disubstituted benzene AA′BB′ pattern and two methyl singlets due to the pdma ligands in the ^1H NMR spectrum, accompanied by signals characteristic of the other ligands. Loss of the symmetry plane in **9** and **10** causes splitting of the $AsMe_2$ signals, but only a single AA′BB′ pattern is observed in each case.

Electrochemical studies

The electrochemical properties of the complexes in **4–10** were studied by cyclic voltammetry in acetonitrile, and results are presented in Table 1, together with data for *trans*-[RuCl(pdma)$_2$(NO)][PF_6]$_2$, *trans*-

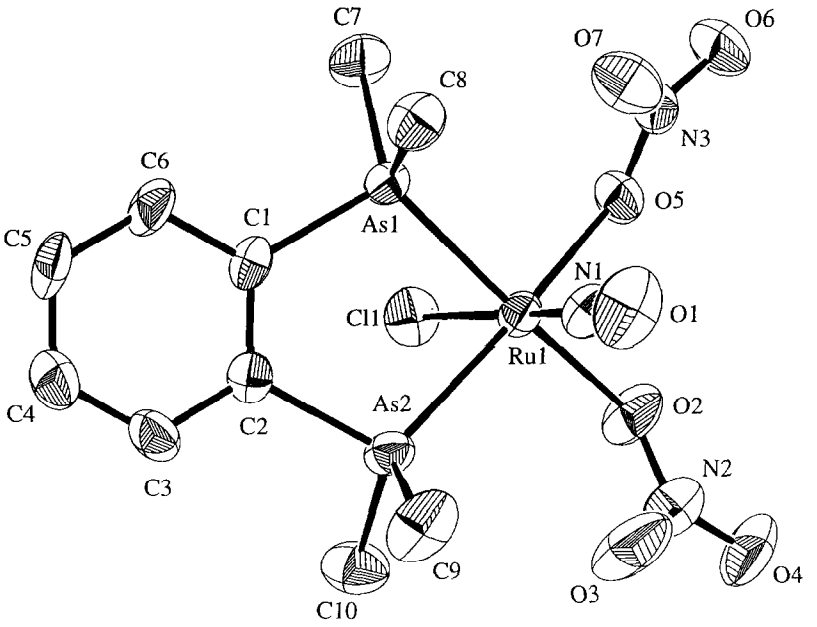

Fig. 3. Structural representation of the complex *cis*-[RuCl(NO_3)$_2$(pdma)(NO)] (**3**), details as in Fig. 1.

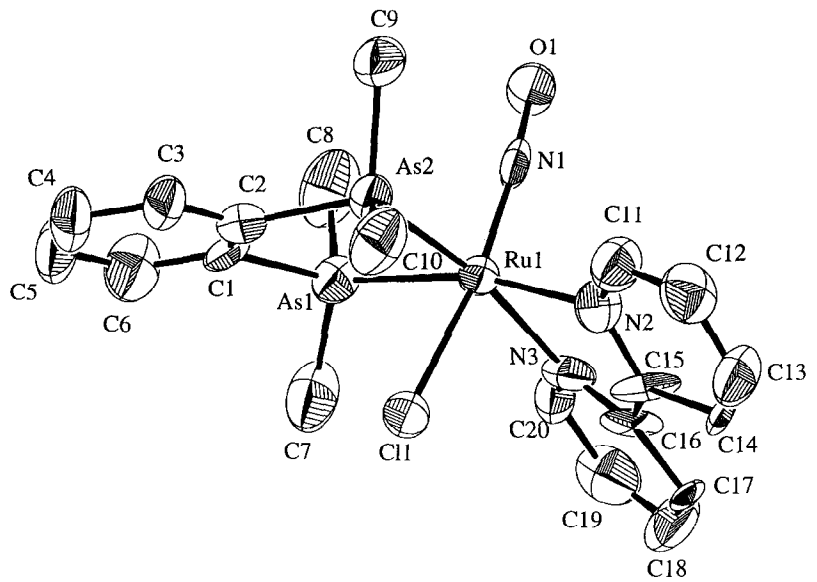

Fig. 4. Structural representation of the cation in salt **6**, *trans*-[RuCl(pdma)(bipy)(NO)]$^{2+}$, details as in Fig. 1.

[RuCl(py)$_4$(NO)][PF_6]$_2$ and *trans*-[RuCl(bipy)$_2$(NO)][PF_6]$_2$ for purposes of comparison [6,18, 19].

With the exception of **4**, all of the new complexes show reversible waves between 0.14 and −0.16 V vs SCE, assigned to one-electron reductions of the {Ru(NO)}$_6$ moieties [20]. Although the potentials of these processes are influenced by the nature of the co-ligands, they cannot generally be correlated with ligand basicity. The only clear trend is that the most negative potentials are observed for the complexes containing the strongly basic anions methoxide or picolinate (in **4** and **10**). Either one or two further reduction waves are observed on cathodic scanning which are irreversible in all cases except for the third reduction of **9**. The redox behaviour of **6–8** and *trans*-[RuCl(bipy)$_2$(NO)][PF_6]$_2$ contrasts with that of *trans*-[RuCl(pdma)$_2$(NO)][PF_6]$_2$, for which quasi-reversible second and third reductions indicate increased stability of the two and three-electron reduced forms [6].

Structural studies

Single-crystal structures were determined for *fac*-[$RuCl_3$(pdma)(NO)], **2**·Me_2CO, **3** and **6**. Representations of the complexes are shown in Figs 1, 2, 3 and 4, respectively.

All of the complexes show the expected *trans*-NO/Cl arrangement, with typical values for Ru—As bond lengths and As—Ru—As chelate angles [6,7]. In each case the Ru—NO unit is essentially linear, consistent with the infrared data (see earlier). The cation in **6** shows a small deviation from ideal octahedral geometry with a N(1)—Ru—Cl(1) angle of 170.5(4)°, the bipy bending away from the nitrosyl ligand.

In *fac*-[$RuCl_3$(pdma)(NO)] the equatorial Ru—Cl

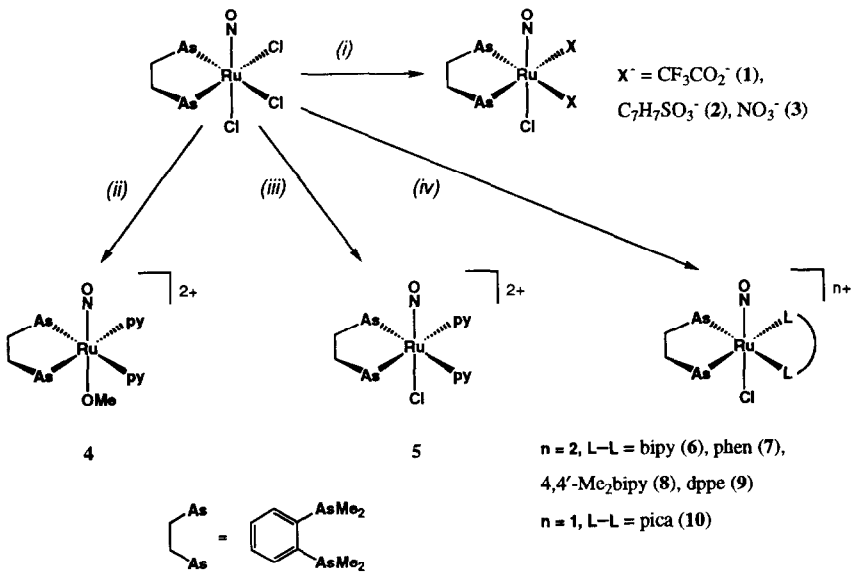

Scheme 1. Synthesis of the complexes **1**–**3** and the cations in the salts **4**–**10**: (*i*) excess AgX, MeCN, r.t.; (*ii*) AgO_2CCF_3 (3 equivalents), MeOH/pyridine, reflux; (*iii*) AgO_2CCF_3 (2 equivalents), MeCN/pyridine, reflux; (*iv*) excess L—L, MeOH, reflux.

bond lengths are longer than the axial one by 0.07 Å, consistent with the observed preferential labilization of the equatorial chlorides. In the related complex *fac*-[$RuCl_3$(bipy)(NO)], the extension of the equatorial vs the axial Ru—Cl bond lengths is only ca 0.03 Å [Ru—Cl_{eq} = 2.383(2)/2.390(1) Å; Ru—Cl_{ax} = 2.354(2) Å] [21]. The pdma ligand hence exerts a greater *trans* labilizing influence on chloride than does bipy in *fac*-[$RuCl_3$(L—L)(NO)] complexes.

To our knowledge, **3** is the first ruthenium complex containing monodentate nitrato ligands to be crystallographically characterized. The Ru(IV) 2,7-dimethylocta-2,6-diene-1,8-diyl complex [Ru(η^3:η^3-$C_{10}H_{16}$)(NO_3)$_2$] features two "semi-chelating" nitrato ligands with Ru—O bond lengths of 2.091(5) and 2.548(8) Å [17], the former being similar to that found in **3**. The free nitrate N—O bonds in **3** are shorter than the coordinated bonds, the average bond lengths of 1.23(1) Å and 1.30(1) Å, respectively, being consistent with partial double bond character in the uncoordinated bonds. **2**·Me_2CO and **3** adopt similar conformations, with the uncoordinated O atoms of the oxoanion ligands directed away from the chlorides. The geometric parameters of the *p*-toluenesulphonate ligands in **2**·Me_2CO are similar to those found in *cis,cis*-[Ru($C_7H_7SO_3$)$_2$(PPh_3)$_2$(CO)(H_2O) [22].

CONCLUSION

Due to the *trans* influence of the pdma ligand, the complex *fac*-[$RuCl_3$(pdma)(NO)] serves as a con-

venient precursor to a variety of derivatives. The mixed-chelates *trans*-[RuCl(pdma)(L—L)(NO)]$^{2+}$ (L—L = bipy or phen) will act as precursors to stable, functionalized *trans* derivatives containing visible MLCT chromophores.* The results of these studies will form the basis of a forthcoming report.

(Received 15 September 1997; accepted 14 November 1997)

Abstract—The reaction of divalent $(ArO)_2Sm(THF)_3\cdot THF$ with phenyl isocyanate directly gives a bimetallic complex $[(ArO)_2(DME)Sm]_2[\mu\text{-}\eta^4\text{-}(PhN)OCCO(NPh)]\cdot 4THF$ (ArO = 2,6-di-tertbutyl-4-methylphenoxo) via one-electron reduction and coupling reactions. In this complex, the deprotonated *N,N'*-diphenyloxamide ligand bridges two units of $(ArO)_2(DME)Sm$ with C(5)—C(5*), Sm—N and Sm—O(1) bonds of 1.43(2), 2.549(8) and 2.318(7) Å, respectively. © 1998 Elsevier Science Ltd. Keywords: coupling reaction; samarium; oxamide; crystal structure.

The reactivity of divalent lanthanide complexes as strong reducing agents has been widely studied [1]. They are reported to react with a variety of unsaturated substrates such as $C_6H_{11}NC$ [2], PhC≡CPh [3], PhC≡CC≡CPh [4], PhN=NPh [5], PyCH=CHPy [6], CO [7], ^{t}BuC≡P [8], PhC≡CH [9], etc., and to show plentiful reaction patterns. For example, $(C_5Me_5)_2Sm(THF)]_2$ reacts with CO at 90 psi to give the ketenecarboxylate of lanthanocene $[(C_5Me_5)_4Sm_2(O_2CCCO)(THF)_2$ [7]. The CO molecules undergo one-electron reduction reactions plus the appropriate coupling. The reaction of $(C_5Me_5)_2Sm$ with PhC≡CH leads to coupling of two phenylethynyl ligands into $(C_5Me_5)_4Sm_2(Ph_2C_4)$ [9].

Isocyanates, as their own structural features, have been widely used in both polymer synthesis [10] and organic synthesis [11]. Study on the reaction of lanthanide complexes with isocyanates should be interesting. Although SmI_2 together with HMPA has been reported to make aromatic isocyanates couple into aromatic oxamides [11a,b], no details about the reaction itself were reported. We are interested in exploring the reactivity of divalent $(ArO)_2Sm(THF)_3\cdot THF$ (ArO = 2,6-di-tertbutyl-4-methylphenoxo) and have studied its reaction with phenyl isocyanate. Here we report the results.

EXPERIMENTAL

Materials and measurements

All operations were performed under pure argon by Schlenk techniques. Pre-dried THF, toluene and DME were distilled from sodium benzophenone ketyl. $(ArO)_2Sm(THF)_3\cdot THF$ was prepared from $SmI_2(THF)_x$ and ArONa in THF and crystallized in toluene [12]. PhNCO was stirred over P_2O_5 for 24 h and then distilled under vacuum. Melting point was determined in a sealed argon-filled capillary and uncorrected. Infrared spectra were recorded on a Magna

* Author to whom correspondence should be addressed.

550 spectrometer (KBr pellet). Proton NMR spectra were recorded on a DRX-400 spectrometer with positive fields being downfield from the external standard $SiMe_4$.

Preparation

To a solution of $(ArO)_2Sm(THF)_3 \cdot THF$ (1.77 g, 2.02 mmol) in 30 ml of toluene was added 0.22 ml of PhNCO (0.24 g, 2.02 mmol) with a syringe. The color of the solution changed from dark brown to yellow-green immediately. The reaction was kept for 24 h with stirring. After the toluene was removed by vacuum and a yellow-green viscose solid was obtained. The residue was dissolved in DME with small amount of hexane. Yellow-green crystals of $[(ArO)_2(DME)Sm]_2[\mu\text{-}\eta^4(PhN)OCCO(NPh)] \cdot 4THF$ (1.14 g, 58.8%) was obtained at -20°C. Crystals suitable for X-ray analysis were grown in THF-DME at 5 C. m.p. 105–110°C. Found: C, 62.3; H, 7.9; N, 1.6; Sm, 15.7. Calc. for $C_{98}H_{154}N_2O_{14}Sm_2$: C, 62.4; H, 8.2; N, 1.5; Sm, 15.9%. IR (cm^{-1}): 2956 s, 1667 s, 1605 m, 1528 m, 1435 s, 1397 m, 1312 w, 1234 m, 1158 m, 1119 w, 1026 w, 864 w, 756 w. ^1H NMR (C_6D_6, 300 K), δ (ppm): 0.96 and 3.34 (THF), 1.42 (aromatic tert-butyl), 2.29 (aromatic methyl), 2.93 and 3.00 (DME), 7.09 (aromatic CH), 7.20 (phenyl ring).

X-ray crystallography

A yellow-green prismatic crystal of approximate dimensions $0.20 \times 0.20 \times 0.30$ mm was sealed in a thin-walled glass capillary under pure argon. Measurements were made on a Rigaku AFC7R diffractometer with graphite monochromated Mo–K_α radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 20 carefully centered reflections in the range $18.37 \leqslant 2\theta \leqslant 21.65$°. The data were collected at a temperature of 20 ± 1°C using the ω-2θ scan technique to a maximum 2θ value of 45.0°. The data were corrected for Lorentz and polarization effects. The structure was solved by heavy-atom Patterson method and expanded using Fourier techniques. Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. all calculations were performed using the TEXSAN crystallographic software package [13].

Crystal data and experimental conditions: $C_{98}H_{154}N_2O_{14}Sm_2$, triclinic, $P\bar{1}$(#2), $a = 14.32(1)$, $b = 14.603(7)$, $c = 13.577(8)$ Å, $\alpha = 97.94(4)$, $\beta = 114.00(5)$, $\gamma = 74.28(5)$°, $V = 2495(2)$ Å^3, $Z = 1$, total reflections 6532, unique 6037 ($R_{int} = 0.136$), observed 4532 ($I > 3\sigma(I)$), $R = 0.063$, $Rw = 0.075$, transmission factors 0.90–1.03. Selected bond distances and bond angles are given in Table 1.

RESULTS AND DISCUSSION

Reductive coupling reactions of some substances mediated by divalent bis(pentamethyl cyclopentadienyl) samarium complex have been reported including the reactions of $^tBuC{\equiv}P$ [8], $PhC{\equiv}CH$ [9], pyridazine [14], benzaldehyde azine [14] and 1,2-di-2-pyridylethene [15]. These reactions all afford the corresponding bimetallic products, characterized by X-ray crystallography. When PhNCO was added into a dark brown solution of $(ArO)_2Sm(THF)_3 \cdot THF$ in toluene at room temperature, the solution color changed immediately to yellow-green indicating the oxidation of Sm^{2+} into Sm^{3+}. After work up, yellow-green air-sensitive crystals of $[(ArO)_2(DME)Sm]_2[\mu\text{-}\eta^4\text{-}(PhN)OCCO(NPh)] \cdot 4THF$ (**1**) were isolated from the THF-DME solution in good yield.

$$(ArO)_2Sm(THF)_3 \cdot THF + PhNCO \xrightarrow{(1)\text{toluene (2)THF-DME}} [(ArO)_2(DME)Sm]_2[\mu\text{-}\eta^4\text{-}(PhN)OCCO(NPh)] \cdot 4THF$$

In the reaction, two phenyl isocyanate molecules undergo reductive dimerization and the resulting new ligand keeps coordinating to samarium atoms to form a bimetallic complex. Figure 1 shows the molecular

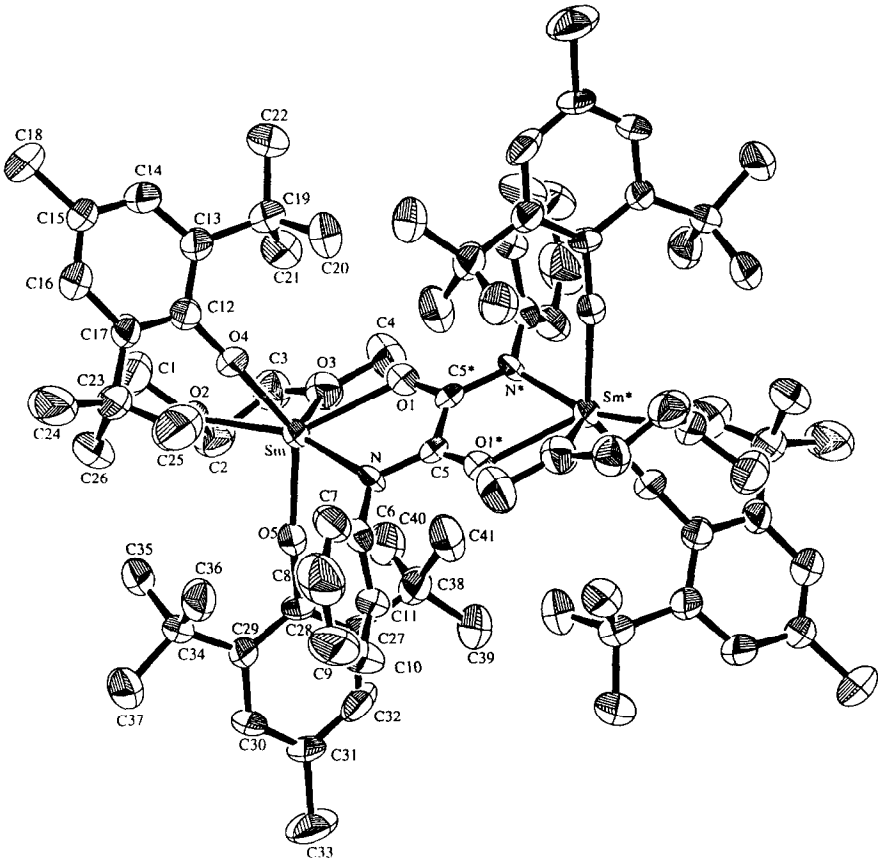

Fig. 1. Molecular structure of **1**.

structure of **1**. Two phenoxo ligands are asymmetrically located on the plane consisting of Sm, N, C(5), C(5*) and O(1) atoms. Sm atom is surrounded by five oxygen atoms and a nitrogen atom to form six-coordinate. The dianionic oxamide ligand [(PhN)OCCO(NPh)]$^{2-}$ connects two samarium atoms. The geometry of **1** is similar to that of $[(C_5Me_5)_2Sm]_2[\mu$-η^4-(PhN)OCCO(NPh)]$\cdot 2C_7H_8$ (**2**) which was formed by the reaction of $(C_5Me_5)_2Sm(\mu$-$\eta^1:\eta^1$-$PhN_2Ph)$ with CO [5]. The Sm—O(Ar) distances are normal. The Sm—O(1) bond is a little longer than Sm—O(Ar) bond, but much shorter than Sm—O(DME) bond. So it is a single bond. The Sm—N distance of 2.549(8) Å in **1** is in agreement with a donor bond, for the donor bond distance for a six-coordinated Sm^{3+} is expected to be 2.41–2.65 Å [5,16]. The distances of N—C bond (1.32(1) Å) and C—O bond (1.29(1) Å) are intermediate between a double bond distance (N=C, 1.29 Å; C=O, 1.20–1.22 Å) and a single bond distance (N—C, 1.47 Å; C—O, 1.43 Å), which are comparable with 1.31(1) and 1.26(1) Å, respectively, in **2**. These distances are consistent with one multiple bond delocalized over the —N—C—O— unit. The C(5)—C(5*) distance of 1.43(2) Å in **1** is shorter than 1.57(2) Å in **2**. The latter is more typically close to a single bond than the former. These bond parameters indicate that [(PhN)OCCO(NPh)]$^{2-}$ dianion in complex **1** highly delocalizes its electrons as well as that in **2**. Figure 2 shows the bond fashion. Although the difference in bond distances between **1** and **2** is small, the bond angles in the two complexes are not fully comparable. For example, the Sm—N—C(5) angle and N—C(5)—O(1*) angle, 114.5(6)° and 123.8(8)° respectively, in **1** are smaller than the corresponding angles, 118.7(6)° and 130.4(10)° respectively, in **2**. It is not clear now whether these differences come from the different metal ionic radii due to their different coordinate numbers.

These results confirm that both C_5Me_5 ligands and ArO ligands here can lead to the same type of complex, which contains a tetradentate oxamide ligand.

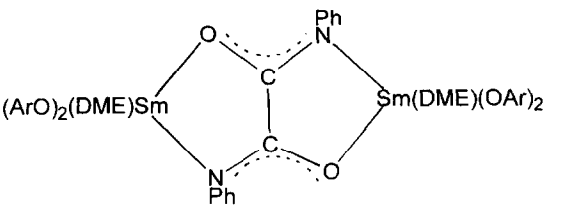

Fig. 2. Bond fashion of dianionic ligand in **1**.

(Received 5 July 1997; accepted 13 November 1997)

Abstract—Fourteen complexes in the series $[RuCl_2(CO)(L)(PPh_3)_2]$ (where L = N-heterocycles) have been prepared and characterized by IR and NMR spectroscopies, and cyclic voltammetry. A good correlation is found between observed and calculated electrochemical potentials; $E_{1/2}$ vs pK_a or (G_p, σ_m for a series of similar ligands. It is now reported that the carbonyl stretching frequency, ν_{CO}, and the ^{13}C and ^{31}P NMR signals do not correlate well with any of the physico-chemical parameters used ($E_{1/2}$, Taft's and Hammett's parameters). This behaviour is probably due to the characteristics of the Ru(II) species, which does not transmit the steric and electron donor/acceptor properties of the ligands to the carbonyl group, or because the measurements are not able to detect the effect induced by the changes in the ligand L. Indeed, good correlations are obtained when the measurements directly involve the metal centre, as is the case in the $E_{1/2}$ measurements. Crystals of $[RuCl_2(CO)(4\text{-pic})(PPh_3)_2]$ are monoclinic, space group $P2_1/n$, a = 12.019(2), b = 13.825(3) and c = 22.253(3) Å. The structure was solved by the Patterson method and was refined by full-matrix least-squares procedure to R = 0.054 and R_w = 0.055, for 2114 reflections with $I > 3\sigma(I)$.

For L = 2-acetylpyridine and 2-methylimidazole, complexes with formulae $[RuCl_2(CO)(L)(PPh_3)] \cdot L$ and $[RuCl_2(CO)(L)_2(PPh_3)]$, respectively, were obtained. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; Lever's parameters; X-ray structure.

Different physico-chemical measurements, such as carbonyl stretching or its force constants [1–9] and chemical shifts [2,4,7,10–12] have been used to study the structural and electronic properties of transition metal carbonyl complexes through correlations with empirical substituent parameters, such as Taft's σ_I [13,14], Hammett's σ parameters [15], Kabachnik's parameters σ^{PH} [16] and pK_a of ligands [17]. Although for certain types of carbonyl complexes it is possible to relate the σ-donor and π-acceptor ability of ligands with ν(CO) frequencies, for other types of ligands there is little correlation [5]. In the complexes *cis*-$[Pt(\eta^1\text{-}C_6H_4X\text{-}p)_2(PPh_3)_2]$ and *cis*-$[Pt(\eta^1\text{-}C_6H_4X\text{-}p)_2(Ph_2PC_2H_4PPh_2)]$ the coupling constant ^1J(Pt—P) increases as X becomes more electron withdrawing and they show a good correlation with σ_I but not σ_p or σ_p^o [18]. Such a correlation is in accord with the *trans*-influence theory and with the notion that the magnitude of s-electron density in the Pt—P bonds increases with decreasing s-electron density on the bonded carbon of the *trans*-ligand [18]. It is interesting to note, however, that the ^{31}P chemical shifts are insensitive to the nature of X. Similar observations were reported [19] for *trans*-$[Pt(CH_3)(XC_5H_4N)(Ph_2PC_2H_4PPh_2)]$ (X = 4-$N(CH_3)_2$, 4-CH_3, H, 4-

* Author to whom correspondence should be addressed: Tel.: 55-16-274-8285. Fax: 55-16-274-8350. E-mail: daab@.power.ufscar.br

CO_2CH_3, 4-$COCH_3$, or 4-CN) for which ^1J(Pt—P) shows a correlation with σ but the ^{31}P chemical shift for the P atom *trans* to the substituted pyridine does not. The nature of the metal may play a role in determining whether a successful correlation is observed, since a linear correlation exists between the ^{31}P chemical shifts and σ or the analogous palladium complexes, *trans*-[$Pd(CH_3)(XC_5H_4N)(Ph_2PC_2H_4PPh_2)$] [19].

The lack of good correlation of the electron density around the molybdenum atom, as indicated by $\delta(^{95}Mo)$ in a series of [$Mo(CO)_3$(bipy){$P(p\text{-}C_6H_4X)_3$}] [X = Cl,F,H,CH_3,OCH_3,$N(CH_3)_2$] complexes with the pK_a of the ligands supported the argument that pK_a values are not an appropriate measure of the interaction between phosphines and soft acid species such as low-valent transition metal centres. This can be attributed to the fact that pK_a values are dependent on the interaction between the phosphine and the hard acid, H^{+2}.

Cyclic voltammetry in acetonitrile has been used to study the reversible one electron reduction in the complex [$RuCl(bipy)_2(4\text{-}XC_6H_4NO)]^{2+}$. Hammett plots of $E_{1/2}$ versus σ_R, σ_R^o and $\sigma_p - \sigma_m$ were linear, a reaction constant, $\rho = 1.05$ was noted in the correlation with σ_R indicating that the redox potential is very sensitive to the nature of X [20]. Since these correlations involve parameters which measure pure resonance effects, the effect of X is presumably transmitted to the metal centre via the π-electron system of the nitrosoarene. Recently, a ligand electrochemical parameter, $E_L(L)$, based upon the Ru^{III}/Ru^{II} reduction potential as an electrochemical standard was introduced [21] and developed [22,23]. This allows one to predict the metal-centered redox potential of a variety of complexes on the basis of the additivity of the $E_L(L)$ parameters. The prediction is made using the linear relationship

$$E_{calc} = S_M[\Sigma E_L(L_i)] + I_M \quad (1)$$

where the slope, S_M, and the intercept, I_M, are constant for all derivatives of a given coordination number, stereochemistry, and spin state undergoing a defined redox process.

This report deals with physico-chemical data for [$RuCl_2(CO)(L)(PPh_3)_2$] complexes. By systematically changing L, we hoped to probe the nature of the bonding between a d^6 metal centre in a low valence oxidation state, and carbon monoxide, triphenylphosphine and various nitrogen donor ligands, especially *N*-heterocycles ones. Our aim in this work is to test the validity of the above equation for the series of complexes with the general formula [$RuCl_2(CO)(L)(PPh_3)_2$] and to evaluate the role of the Ru(II) ion nature in correlations between some physico-chemical parameters.

EXPERIMENTAL

All reactions and manipulations were carried out under a dry, oxygen-free argon or dinitrogen atmosphere. The chemicals employed in this work were of reagent grade quality (Aldrich). Tetrabutylammonium perchlorate (Fluka purum) was recrystallized from ethanol/water and dried overnight, under vacuum, at 100°C. Reagent grade solvents (Merck) were appropriately distilled, dried and stored over Linde 4 Å molecular sieves. Infrared spectra were recorded as CsI pellets on a Bomem–Michelson 102 instrument, and UV-Vis spectra in CH_2Cl_2 on a HP 8452A spectrophotometer and are given as λ_{max} (nm) (ε in $M^{-1}\,cm^{-1}$). ^{1}H, ^{13}C and $^{31}P\{^1H\}$ NMR spectra were obtained in $CDCl_3$ (Aldrich) or CH_2Cl_2 solutions at room temperature with a Bruker 200 MHz spectrometer. All ^{31}P spectra were proton decoupled and an internal 85% phosphoric acid reference was used. Cyclic and differential pulse voltammetries were carried out at room temperature in freshly distilled dichloromethane containing 0.1 M $Bu_4N^+ClO_4^-$ (TBAP), using an EG&G/PARC electrochemical system consisting of a 273A potentiostat. A three electrode system with resistance compensation was used throughout. The working and auxiliary electrodes were a stationary platinum foil and a platinum wire, respectively. The reference electrode was Ag/AgCl in a Luggin capillary, 0.1 mol/L TBAP in CH_2Cl_2, a medium in which ferrocene is oxidized at 0.42 V (Fc^+/Fc). The measured potentials were converted to the standard hydrogen scale by adding 0.222 V. The scans were recorded at different scanning speeds in the range 50–500 mV s^{-1}. Conductivity was measured using 10^{-3} M solutions of the complexes at 25°C under N_2, using a Micronal conductivity bridge, and are quoted in units of $\Omega^{-1}\,cm^2\,mol^{-1}$. Elemental analyses were performed at the Institute of Chemistry of the University of São Paulo, São Paulo.

ttt-[$RuCl_2(CO)_2(PPh_3)_2$] and [$RuCl_2(CO)$(DMF)$(PPh_3)_2$] (DMF = *N*,*N*-dimethylformamide) were prepared according to literature methods [24,25]. In the present work, a series of complexes of composition [$RuCl_2(CO)(L)(PPh_3)_2$] was obtained in the solid state for L = pyridine (py), pyrazine (pz), 2-cyanopyridine (2-pyCN), 3-cyanopyridine (3-pyCN), 4-cyanopyridine (4-pyCN), 2-picoline (2-pic), 3-picoline (3-pic), 4-picoline (4-pic), isonicotinamide (iso), 4-aminopyridine (4-pyam), 4-dimethylaminopyridine (4-pydiam), 2-aminoethylpyridine (2-pyame), imidazole (im) and 1-methylimidazole (1-Meim), where all ligands are coordinated by the nitrogen atom of the pyridine ring. For L = 2-acetylpyridine (2-pyac) and 2-methylimidazole (2-Meim), compounds of composition [$RuCl_2(CO)$(2-pyac)(PPh_3)·2-pyac and [$RuCl_2(CO)$(2-Meim)$_2(PPh_3)$], were obtained. In a typical synthesis the ligand in excess was added to 4 ml of dichloromethane contained in a 15 ml two neck flask and the mixture was deoxygenated with argon, subsequently 0.1 g of *ttt*-[$RuCl_2(CO)_2(PPh_3)_2$] or [$RuCl_2(CO)$(DMF)$(PPh_3)_2$] was added. After 25 min of stirring at room temperature, the solution volume was reduced to approximately 2 ml and ether was added to precipitate a yellow solid, which was filtered

off, washed well with ether and vacuum dried. Yield: ca 80%. For the synthesis of complexes with sterically hindered ligands, such as 2-cyanopyridine or 2-methylpyridine, the procedure was conducted with neat ligand as solvent. The microanalyses data are reported in Table 1.

Crystals of $[RuCl_2(CO)(4\text{-pic})(PPh_3)_2]$ suitable for X-ray crystallography were grown by slow evaporation of a chloroform/ether solution. A single crystal was used for data collection and cell parameter determination on an Enraf–Nonius CAD-4 diffractometer, using graphite monochromatized Mo–K_α radiation at room temperature ($T = 292$ K). Unit cell parameters were obtained by least-squares from the setting angle of 25 reflections. Intensity data were collected in the $\omega/2\theta$ scan mode up to $\theta_{max} = 25$°, with scan rates between 1.4–6.7° min^{-1}. The intensities of 2 standard reflections were essentially constant during the measurement. Data were corrected for Lorentz polarization (correction factors 0.66, 1.00) and absorption effects, following the procedure of Walker and Stuart [26]. The structure determination and refinement were performed with the SHELX76 system of programs [27], Fig. 1 was drawn with ORTEP [28]. In the final cycles of least-squares refinement, all non-hydrogen atoms were treated anisotropically. All hydrogen atoms were assumed in their calculated position by the geometry of the ligand atom and included in the least-squares calculation with fixed isotropic temperature factor (6.0 $Å^2$). The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w^{-1} = \sigma^2(F_o) + 0.0003 F_o^2$, and the refinement converged to final $R = 0.054$, $R_w = 0.056$, $R_{all} = 0.099$ and $S = 1.38$. In the final refinement cycle, the maximum shift/e.s.d. ratio was 0.001 and the maximum and minimum electron densities in the difference map were 0.65 and −0.50 e $Å^{-3}$, respectively. Scattering factors for non-hydrogen atoms were taken from Cromer and Mann [29] with corrections for anomalous dispersion from Cromer and Liberman [30], and for hydrogen atoms from Stewart *et al.* [31].

The data collection and experimental details are summarized in Table 2. The relevant interatomic bond lengths and angles are listed in Table 3. Figure 1 shows the ORTEP drawing of the molecule with the atom numbering scheme.

RESULTS AND DISCUSSION

It is a well known fact that in a complex such as *ttt*-$[RuCl_2(CO)_2(PPh_3)_2]$ with two *trans* carbon monoxide ligands, one of these CO ligands is labile [32]. This property has been used in our laboratory [33] for the synthesis of mononuclear and binuclear complexes, where the labilized CO ligand is substituted by *N*-heterocycle ligands.

The crystal structure of $[RuCl_2(CO)(4\text{-pic})(PPh_3)_2]$ in Fig. 1 shows that the 4-pic ligand is *trans* to CO, the two chlorides are *trans* and the two phosphine groups are *trans*. A similar structure was found previously for the complex *ttt*-$[RuCl_2(CO)_2(PPh_3)_2]$ [34]. Three coordination planes are well defined and their angles

are of a slightly distorted octahedron, attributed to the absence of significant steric effects between the ligands. The Ru—P, Ru—Cl and Ru—C bond distances are similar to those found in analogous system [34–36], as can be seen in Table 4.

All the complexes show single, strong IR absorptions in the range 1930–1960 cm^{-1} (attributed to the symmetric stretching frequency of the carbonyl ligand) and also single weak absorptions in the range 320–335 cm^{-1} ($\nu_{Ru\ Cl}$). The absorption frequencies involving the carbonyl groups and the Ru—Cl bonding are summarized in Table 5.

The $^{31}P\{^1H\}$ NMR data for the series of complexes $[RuCl_2(CO)(L)(PPh_3)_2]$, shown in Table 5, present only singlets around $\delta = 30$, indicating that in all complexes the two phosphorus atoms of the two triphenylphosphine ligands are equivalents. This fact is consistent with the two phosphines being *trans* to each other, which allows us to assume a structure similar to the one found in the solid state for the 4-pic ligand complex. When L = 2-Meim the microanalysis data for the complex with this ligand (Table 1) suggest the formulation $[RuCl_2(CO)(2\text{-Meim})_2(PPh_3)]$. The fact that the ^{31}P NMR signal for this complex is found at a lower frequency compared with the other members in the series, suggests that the phosphine is *trans* to a good acceptor ligand. Thus the IR and ^{31}P NMR data for this complex allow us to propose a structure where the CO is *trans* to the phosphine and the imidazoles are *trans* to each other, which is in agreement with chlorides being mutually *trans*. The ^{31}P NMR of the 2-acetylpyridine complex is essentially identical to the other complexes where the phosphine is *trans* to a substituted pyridine. Considering the ^{31}P NMR data, the microanalysis data, which is consistent with the presence of two molecules of the ligand, and the fact that the IR spectrum of this compound shows only a single ν_{Ru-Cl} at 331cm^{-1}, we suggest that this complex incorporates two monocoordinated 2-acetylpyridines, one of which is *trans* to the phosphine and the other of which *trans* to the carbon monoxide.

The ^{13}C NMR data for the series of complexes $[RuCl_2(CO)(L)(PPh_3)_2]$, show three triplets and one singlet in the region between $\delta = 140$ and $\delta = 120$, attributed to the carbon atoms of PPh_3 ligands, peaks between $\delta = 155$ and $\delta = 110$, attributed to the aromatic carbon atoms of the coordinated *N*-heterocyclic ligands, and triplets around $\delta = 205$. The data for the

ttt-$[RuCl_2(CO)_2(PPh_3)_2]$	2.39	2.43	1.96	1.10	34
ttt-$[RuCl_2(CO)_2(PBz_3)_2]$	2.398	2.418	1.948	1.122	35
cct-$[RuCl_2(CO)_2(PPh_3)_2]$	2.424	2.439	1.859	1.130	36

latter region, shown in Table 5, are of special interest, since they correspond to the signal of the carbon atom of the CO group, being consistent with the carbon atom interacting with two equivalent phosphorus atoms which are mutually *trans*. For L = py, besides the expected triplet in $\delta = 205.08$, two additional singlets around $\delta = 204$ were also observed. These singlets are tentatively attributed to the presence of two nonequivalent CO groups in the binuclear species $[Ru_2Cl_4(CO)_2(py)_2(PPh_3)_2]$ formed in solution and having two bridging Cl groups. Additional evidence for the existence of the equilibrium between mono- and binuclear complexes proposed comes from the ^{31}P NMR spectra where, besides the expected intense signal of the mononuclear complex at $\delta = 30.53$, signals are found at $\delta = -5.0$, 22.26 and 49.17. The negative chemical shift signal is characteristic of the presence of free phosphine in solution, possibly liberated during the process of binuclear complex formation. The signals at $\delta = 22.26$ and 49.17 can be attributed to the coordinated phosphines *trans* to pyridine and CO, respectively, in agreement with the previous discussion about the 2-methylimidazole complex.

When L = 2-pyac, the ^{13}C NMR spectrum is more complicated in the region close to $\delta = 205$, indicating the presence of more than one type of CO. When L = 2-Meim, no ^{13}C signal was observed in this region, probably due to the low solubility of this complex in the chloroform solvent.

The electronic spectra of the complexes $[RuCl_2(CO)(L)(PPh_3)_2]$ show two intense absorptions in the UV-region ($\varepsilon_{max} \cong 10^4\ M^{-1}\ cm^{-1}$) below 350 nm due to internal transitions of the ligands. These bands can be attributed to internal $\pi \rightarrow \pi^*$ transitions in the coordinated aromatic ligands [37]. In the visible

[a] Except for L = 2-pyac and 2-Meim, where compositions $[RuCl_2(CO)(2\text{-pyac})(PPh_3)]$ and $[RuCl_2(CO)(2\text{-Meim})_2(PPh_3)]$ were found.

[b] Absorption maxima and intensity determined by Gaussian deconvolution of the spectra.

region all the complexes, except when L = 2-pyCN and 2-pyac, show two absorption bands (λ_1 and λ_2) of low intensity ($\varepsilon_{max} \cong 10^2\ M^{-1}\ cm^{-1}$), attributed to *d–d* transitions. The position and intensity of the *d–d* bands of all the complexes studied, after deconvolution to correct the strong effect of the intense UV bands, are shown in Table 5.

Experimental data of ν_{CO}, ν_2, δ ^{13}C and δ ^{31}P (Table 5), when correlated with Taft's and Hammett's substituent parameters listed in Table 6, showed very poor agreements. Apparently the effect of the substituent in the *N*-heterocycle ligands is not transmitted to the other ligands through the Ru(II) central atom, or the effect is too small to be detected by the techniques employed in these measurements.

If this is so, better correlations are expected when the measurements are related to properties involving the central metal atom, as in $E_{1/2}$ measurements. The cyclic voltammograms of all the complexes prepared consist of a pair of reversible peaks ($i_a/i_c \cong 1$), attributed to the one electron Ru^{III}/Ru^{II} couple, and the $E_{1/2}$ values are shown in Table 7.

Indeed, for the series of substituted pyridine ligands lacking significant steric effects (L = 3-pyCN, 4-pyCN, iso, py, 3-pic, 4-pic, 4-pyam, 4-pydiam), a reasonable linear plot of $E_{1/2}$ vs pK_a (Fig. 2), correlation coefficient $R = -0.99$ and slope -0.02 was observed. Similar results were obtained when the Hammett parameters ($E_{1/2}$ vs σ_M, σ_P; $R = 0.98$) or Taft parameters ($E_{1/2}$ vs σ^o_M, σ^o_P; $R = 0.97$) were used. As suggested by the decrease of the $E_{1/2}$ values with increasing values of pK_a of L ligands, more effective back-bonding ligands increase $E_{1/2}$ by stabilizing Ru(II) mainly due to this effect.

The experimental and calculated electrochemical data for the series of complexes of general formula $[RuCl_2(CO)(L)(PPh_3)_2]$ by using Lever's equation [1] and the $E_L(L)$ values taken from the literature [21] (for $Ru^{(III/II)}$ couples in organic solvent, $E_{calc} = 0.97[\Sigma_i E_L(L_i)] + 0.04$]) are shown in Table 7. For the same set of substituted pyridinic ligands used before in Fig. 2, a correlation coefficient $R = 0.99$ and a slope equal to 1.02 were obtained for the plot E_{calc} vs $E_{1/2}$ (Fig. 3). Ideally, the best straight line that correlates the observed and calculated values should have a slope of unity, but in view of the small set of data available for our correlation the result obtained can be considered good enough. Similar results were obtained recently in substituted-polypyridyl complexes of ruthenium containing II-acceptor ligands [44], where a slope of 1.2 was observed. If we had included the ligands im, 1-Meim, 2-pyame and pz, the *R* value would decrease to 0.78 and the slope to 0.88. These data together show the utility of the electrochemical parameters proposed by Lever [21], considering the variety of ligands and substrates used in this work.

CONCLUSION

The results obtained in this work suggest that to consider correlations of ligand substituent parameters with physico-chemical properties of coordination

[a] Ref. 15; [b] Refs 13 and 15; [c] Ref. 38; [d] Ref. 39.

The parameter σ is defined through the famous Hammett equation ($\sigma = \log k_X - \log k_H$) where k_H is the ionization constant for benzoic acid in water at 25°C and k_X is the ionization constant for a *meta* (σ_m) or *para* (σ_p) derivative under the same experimental conditions. Positive values of (represent electron withdrawal by the substituent from the aromatic ring; negative σ values indicate electron release to the ring. The parameters σ_p^+ and σ_m^+ were defined for systems where a positive charge is delocalized between substituent and reaction centre via "through resonance"; the σ_p^- served for groups with loosely held lone pair electrons conjugated with a substituent capable of accepting a pair of electrons via resonance. The normalized (σ_p^o, σ_m^o) constants were formulated the ionization of phenylacetic acids from other systems which all through resonance would be eliminated, preventing resonance interaction. σ_I^o, σ_R^o constants have been developed by Taft to separete the inductive and resonance contributions of substituents [13–15].

compounds, the nature of the central metal atom and the technique to be used for measurements are fundamental. In our study, the effect of the ligand substituents reflects in the properties directly related to the "soft" central metal atom, which does not strongly transmit the steric and donor/acceptor properties of the substituents in the *N*-heterocycle species to the remaining ligands.

(Received 19 September 1997; accepted 12 November 1997)

Abstract—Three bis(amide) derivatives of H_5dtpa [(carboxymethyl)iminobis(ethylenenitrilo)tetraacetic acid], H_3L^1 = bis(adamantanamide), H_3L^2 = bis(2-methoxybenzylamide), and H_3L^3 = bis(2-methoxyphenethylamide) were synthesized. Their protonation constants were determined by potentiometric titration in 0.10 mol dm^{-3} KCl and by NMR pH titration at 25.0±0.1 °C. Stability and selectivity constants are measured to evaluate the possibility of using the corresponding gadolinium(III) complexes for magnetic resonance imaging contrast agents. Low stability or selectivity constants indicate higher possibility for releasing free Gd^{3+} ion and free ligand as well from gadolinium(III) complexes. The formations of gadolinium(III), copper(II), zinc(II), and calcium(II) complexes were investigated quantitatively by the potentiometry. The stability constant for gadolinium(III) complex is larger than those for Ca(II), Zn(II), and Cu(II) complexes for these three octadentate ligands. The selectivity constants and modified selectivity constants of the amides for Gd^{3+} over endogenously available metal ions were calculated. Effectiveness of all three ligands in binding divalent and trivalent metal ions in biological media is assessed by comparing pM values at physiological pH 7.4. Spin-lattice relaxivity R_1 for Gd(III) complexes was also determined. The observed relaxivity were found to decrease with increasing pH in the acid range below pH 3 and relaxivity values were become invariant with respect to pH changes over the range of 3–10. © 1998 Elsevier Science Ltd. Keywords: gadolinium complexes; contrast agents; relaxivity; MRI; thermodynamics; paramagnetic complexes.

This report describes the synthesis of three *N,N″*-bis(amide) derivatives of H_5dtpa ((carboxymethyl) iminobis(ethylenenitrilo)tetraacetic acid) i.e. H_3L^1 = bis(adamantanamide), H_3L^2 = bis(2-methoxybenzylamide), and H_3L^3 = bis(2-methoxyphenethylamide). Their protonation constants, thermodynamic, and conditional stability constants of complexes with Gd^{3+}, Cu^{2+}, Zn^{2+}, and Ca^{2+} and their selectivity for Gd^{3+} over endogenously available metal ions are discussed. The spin-lattice relaxivity R_1 of the [GdL^1], [GdL^2], and [GdL^3] are also described.

EXPERIMENTAL

Materials

Gadolinium chloride (>99.9%) was obtained from Aldrich Chemical Co. and oven dried at 110 °C for at least 24 h before use. All other reagents used for the synthesis of the amides were purchased from commercial sources unless otherwise noted. Proton NMR spectra and elemental analyses were used to confirm the composition of the products.

Preparations

Diethylenetriamine-N,N′,N″-*triacetic*-N,N″-*dianhydride*. The anhydride was prepared according to the method of Eckelman *et al.* [1]. White solid (33.23 g, 93%); m.p. 183–185 °C; δ_H [200 MHz, solvent $(CD_3)_2SO$; standard $SiMe_4$] 3.71 (8 H, s, terminal NCH_2CO_2), 3.31 (2 H, s, central NCH_2CO_2), 2.75 (4 H, t, NCH_2), and 2.60 (4 H, t, NCH_2).

N,N″-*Bis*(*amides*) *of* H_5dtpa: H_3L^1, H_3L^2, *and* H_3L^3. The compounds H_3L^1, H_3L^2, and H_3L^3 were synthesized by a modification of the procedure of Konings *et al.* [2]. The dianhydride (5.0 g, 13.99 mmol) was added in portions over 1 h to ice-cold stirred 99% alkylamine (140 mmol). After 30 min, the ice bath was removed and the reaction mixture was stirred at room temperature for 20 h. It was concentrated under reduced pressure to an oil, diluted with water (30 cm^3), and adjusted to pH 1.5 with concentrated HCl. The colourless solid formed was collected and recrystallized from water–acetone to give colourless crystals.

N,N″-*Bis*(*adamantanamide*) H_3L^1. White crystals (3.9 g, 57%), m.p. 192–193 °C (Found: C, 48.8; H, 7.8; N, 14.05. $C_{20}H_{37}N_5O_8 \cdot H_2O$ requires C, 48.65; H, 7.95; N, 14.2%); δ_H (200 MHz; solvent D_2O/NaOD standard $SiMe_4$) 1.65 (6 H, s, $NCCH_2CHCH_2$), 1.94 (6 H, s, $NCCH_2CH_2$), 2.03 (3 H, s, $NCCH_2CHCH_2$), 3.15 (4 H, s, NCH_2CON), 3.16 (4H, s, terminal NCH_2CO_2), 3.52 (2 H, s, central NCH_2CO_2), and 3.1, 2.89 (8 H, s, NCH_2CH_2N).

N,N″-*Bis*(2-*methoxybenzylamide*) H_3L^2. White crystals (6.35 g, 72%), m.p. 152–154 °C (Found: C, 57.1; H, 6.65; N, 11.1. $C_{30}H_{41}N_5O_{10} \cdot H_2O$ requires C, 57.1; H, 6.55; N, 11.1%); δ_H 7.18, 6.93 (8 H, m, C_6H_4) 4.32 (4 H, s, $ArCH_2N$), 3.79 (6 H, s, OCH_3), 3.15 (4 H, s, NCH_2CON), 3.07 (4 H, s, terminal NCH_2CO_2), 3.01 (2 H, s, central NCH_2CO_2), and 2.53 (8 H, m, NCH_2CH_2N).

N,N″-*Bis*(2-*methoxylphenethylamide*) H_3L^3. White crystals (6.19 g, 67%), m.p. 105–107 °C (Found: C, 55.1; H, 7.1; N, 10.1. $C_{32}H_{45}N_5O_{10} \cdot 2H_2O$ requires C, 55.25; H, 7.1; N, 10.1%); δ_H 7.09, 6.92 (8 H, m, C_6H_4), 3.77 (6H, s, OCH_3), 3.41 (4 H, t, $NHCH_2CH_2Ar$), 2.99 (4 H, s, terminal NCH_2CO_2), 3.30 (2 H, s, central NCH_2CO_2), 3.01 (4 H, s, NCH_2CON), and 2.73 (8 H, s, NCH_2CH_2N).

General techniques

Solutions of amides (0.1 mol dm^{-3}) for NMR pH titration were made up in D_2O, and pD was adjusted with DCl or CO_2-free NaOD. Proton NMR spectra were measured in D_2O solution on a Varian XL-200E spectrometer. The final pD of the amide solutions were determined with a microelectrode. The final pD was obtained from the equation pD = pH + 0.40 [3]. The hydrogen electrode used in the present study allows a reliable and accurate determination of the proton activity over an extended pH range.

Solution preparations

Stock solutions of Ca^{2+}, Zn^{2+}, Cu^{2+}, and Gd^{3+} were prepared between 0.015 and 0.02 mol dm^{-3} from the nitrate salts with demineralized water (obtained by a Millipore/Milli-Q system) and standardized by titration with Na_2H_2edta (disodium salt of ethylenedinitrilotetraacetic acid) [4] or atomic absorption spectrophotometry.

Potentiometric measurements

Potentiometric titrations were performed with an automatic titrator system to determine the protonation constants of the amides and the stability constants of the metal complexes. The autotitrating system consists of a 702 SM Titroprocessor, a 728 stirrer, and a PT-100 combination pH electrode (Metrohm). Each titration was performed at least three times. Since the Gd^{3+} chelate is completely or almost completely formed at low pH, their stability constant could not be determined from the normal potentiometric titration method. Therefore, these stability constants were evaluated by a ligand–ligand competition potentiometric titration in this study [5–7]. A 1:1:1 molar ratio of Gd^{3+}, amide, and a reference ligand with a known metal chelate stability was titrated. A good reference ligand for the Gd^{3+} systems was found to be H_4edta. H_4edta forms a complex with Gd^{3+} whose stability constant is accurately known.

Computational method

The protonation constants of the amides were calculated using a FORTRAN computer program PKAS [8] written for polyprotonic weak acid equilibria. The stability constants of normal chelates and the protonated metal chelates were determined from the titration data with the FORTRAN computer program BEST [8]. The average difference between observed and calculated $-\log[H^+]$ was <0.04 throughout all titration. A value of 13.78 was employed for the pK_w at 25 C. The species distribution diagrams were calculated with the FORTRAN program SPE and SPEPLOT [8].

Relaxation time measurement

The Gd^{III} chelate solution was prepared by combining equal molar amounts of the stock $GdCl_3$ and the amides solution. A slight excess (3%) of the amide was used and the solution was allowed to react for at least 2 h at room temperature to ensure completion of the complexation. The Gd^{III} chelate solutions under various pH values were prepared by combining the buffer solution with an appropriately diluted Gd^{III} complex solution in a 1:1 (*v/v*) ratio. The following buffer systems (all 0.10 mol dm^{-3}, except those at pH 7–8) were used: chloroacetic acid/NaOH (pH 2 and 3), acetic acid/NaOH (pH 4 and 5), Tris (=tris(hydroxymethyl)aminomethane)/HCl (pH 7 and 8), and ammonia/HCl (pH 9 and 10) [9]. These buffer solutions were used to maintain constant ionic strength (i.e. 0.10 mol dm^{-3}). The 0.10 mol dm^{-3} buffers were sufficient to keep the solution pH within the desired range in most cases. However, the 0.10 mol dm^{-3} Tris buffer was too weak to maintain Gd^{III} complex solution at pH 7, and a 1.0 mol dm^{-3} Tris buffer solution was used instead. The buffered Gd^{III} chelate solutions were all allowed to equilibrate for at least 2 h. The pH of these solutions was determined immediately before relaxation time T_1 measurements.

Relaxation times T_1 of aqueous solutions of gadolinium(III) complexes of linear bis(amide) derivatives of H_5dtpa were measured to determine relaxivity R_1. All measurements were made using an NMR spectrometer operating at 20 MHz and 37.0 ± 0.1 C (NMS 120 Minispec, Bruker). Before each measurement the spectrometer was tuned and calibrated. The value of T_1 was measured from eight data points generated by an inversion-recovery pulse sequence. The slopes of plots of $1/T_1$ vs concentration give R_1 in dm^3 $mmol^{-1}$ s^{-1}.

RESULTS AND DISCUSSION

Protonation constants

The amide protonation constants are expressed as in eqn (1).

$$K_n = [H_nL]/([H_{n-1}L][H^+]) \quad (1)$$

Table 1 summarizes the protonation constants of the bis(amides) measured in the range pH 3–10. The titration curves of H_3L^1, H_3L^2, and H_3L^3 all show a very sharp increase between pH 9.0 and 4.0 (moles of base per mol amide present = 2). This is due to the large difference between the first ($\log K_1$) and second protonation constant ($\log K_2$), i.e. 9.35 and 4.85, 9.33 and 4.64, and 9.12 and 4.61, respectively. The $\log K_3$ (third protonation constant) values are 3.73, 3.78, and 3.46, respectively. The carboxylates have $\log K_4$ and $\log K_5$ values below 2 (not observed in this study). The protonation constants are very similar to those of the H_3dmdtta ($\log K_1 = 9.37$, $\log K_2 = 4.38$, $\log K_3 = 3.31$ in 0.1 mol dm^{-3} $NaClO_4$) [10].

The replacement of the two carboxylate groups in H_5dtpa by the two *N*-adamantane-, *N*-2-methoxybenzyl-, and *N*-2-methoxyphenethyl-amide groups results in a decrease in $\log K_1$ (i.e. 1.14, 1.16, 1.37 units), $\log K_2$ (i.e. 3.75, 3.96, 3.99 units), $\log K_3$ (i.e. 0.55, 0.50, 0.82 units), and ΣpK_a values (i.e. 8.08, 8.26, 8.82 units). These significant differences in basicity of the amine groups (ΣpK_a) are presumably due to hydrogen bonding from the terminal nitrogen atom and carboxylate to amide protons in the bis(amides) [11–13].

[a] Data were obtained from Ref. 10.
[b] Ref. 18.

NMR pH titration

The macroscopic protonation constants of the amides in Table 1 are determined by the potentiometric titration technique. However, the microscopic protonation scheme is obtained by NMR spectroscopy coupled with pH titration [14]. The proton NMR spectra of H_3L^1 as a function of pH are shown in Fig. 1. These show that the central nitrogen atom is the most basic. Coalescence of the triplets corresponding to the ethylenic group occurs about pH > 9.5 for the H_3L^1, H_3L^2, and H_3L^3. Plots of the chemical shift values (δ) of the methylenic resonance of H_3L^1 as a function of pH was given in Fig. 2. There are three inflections centred at pH about 9.5, 4.5, and 3.5 for the H_3L^1, H_3L^2, and H_3L^3. Only one inflection centred at pH about 9.5 was determined for H_3L^3 because the ligand precipitated below pH 5. The downfield shift of δ in the region pH 4.5–9.5 indicate that the first observed protonation occurred on the central nitrogen atom, which is common to all these *N*-substituted carboxylic systems. At about pH 4.5 a downfield δ shift was also observed for one of the terminal nitrogen atoms which is the second protonation site. These values correlate quite well with the protonation constants of the amides in Table 1 and reflect stepwise protonation of the amino groups of the bis(amides) of H_5dtpa with the formation of the species HL^{2-}, H_2L^-, and H_3L. The species distribution curves for H_3L^1, H_3L^2, and H_3L^3 are shown that the dominant species is the monoprotonated ligand between pH 6.0 and 8.5.

Thermodynamic stability constants

The normal chelate thermodynamic stability constants [$K_{ML(therm)}$] are expressed as in eqn (2) where M represents

$$K_{ML(therm)} = [ML]/([M][L]) \quad (2)$$

the free, unhydrolysed aquametal ion, L the uncomplexed, total deprotonated form of the ligand and ML is the normal unprotonated and unhydrolysed complex. The potentiometric titration curves for the complexes of Gd^{3+}, Cu^{2+}, Ca^{2+}, and Zn^{2+} with H_3L^1 have an inflection point at 3 mol base added per mol amide. Titration curves corresponding to other mixtures, like 2:1 or 1:2, were not significantly different from those of ratio 1:1. Thus, no 2:1 and 1:2 metal:ligand species were observed in these complexes. The $[CaL^1]^-$, $[CaL^2]^-$, and $[CaL^3]^-$ curves increase rapidly from pH 6 to 10. The titration curves for the complexes of Cu^{2+}, and Zn^{2+} with H_3L^1, H_3L^2, and H_3L^3 increase from pH 3.5 to 10. The Gd^{3+} reacts strongly with the amides and at considerably lower pH than do the divalent metals. The stability constants of the complexes of Gd^{3+} with H_3L^1, H_3L^2, and H_3L^3 were derived from the competition reaction H_4edta. In Table 2, the thermodynamic stability constants are presented for the linear poly(aminocarboxylates) H_3L^1, H_3L^2, H_3L^3, H_3dmdtta, and H_5dtpa [10,13]. The similar stability constants of the complexes of Gd^{3+}, Cu^{2+}, Ca^{2+}, and Zn^{2+} with the bis(amides) throughout the series (i.e. H_3L^1, H_3L^2, H_3L^3, H_3dmdtta, H_3dipdtta (dipdtta = di(iso-propylcarbamoyl methyl)diethylenetrinitrilo triacetic acid), H_3dtbdtta (dtbdtta = di(tert-butylcarbamoylmethyl)diethylenetrinitrilo triacetic acid), and H_3dbdtta (dbdtta = di(benzylcarbamoylmethyl)diethylenetrinitrilo triacetic acid)) may indicate similar ligand basicities [10,15,16]. Since the basicity of H_3L^1 (ΣpK_a = 17.93), H_3L^2 (17.75), and H_3L^3 (17.19) is very similar to those of H_3dmdtta (17.06), H_3dipdtta (17.59), H_3dtbdtta (18.01), and H_3dbdtta (17.50) the contribution of the enthalpy term to the thermodynamic stability should be similar in the complexes of Gd^{3+}, Ca^{2+}, Cu^{2+}, and Zn^{2+}. Thus, the lower stability of the bis(amide) of H_5dtpa chelates when compared to the H_5dtpa chelates is assigned to the weaker donor ability of the amide group and the lower basicity of the terminal nitrogen atoms.

Conditional stability constants and selectivity constants

For biological studies the conditional stability constants ($K_{ML(cond)}$) of a metal chelate under physiological conditions (pH 7.4) is more important than the thermodynamic stability constant [14,17]. In Table

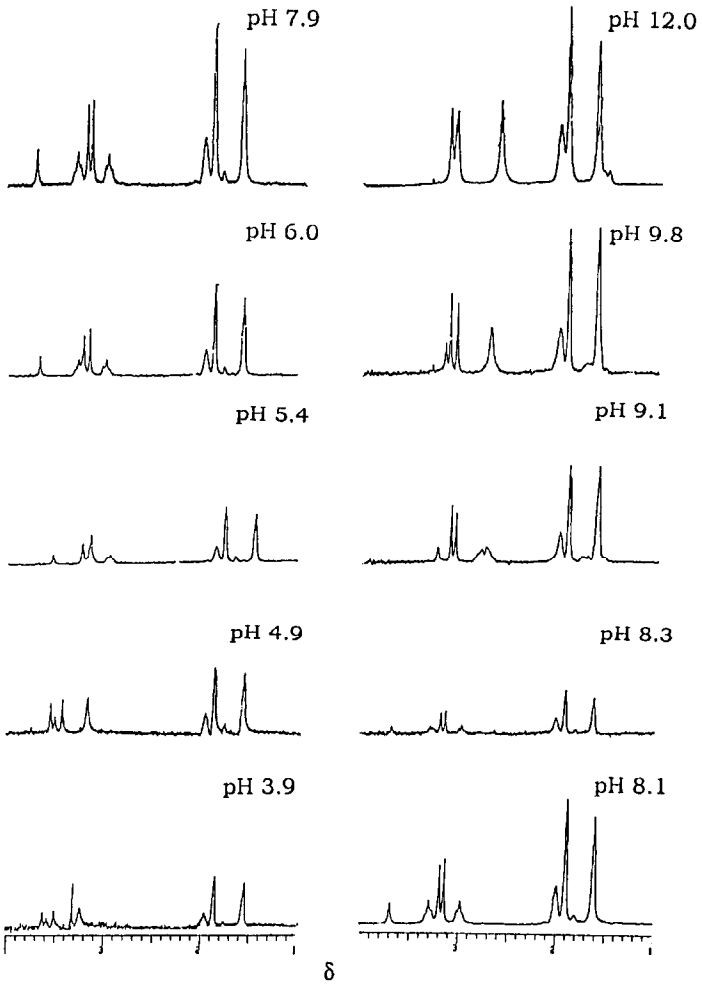

Fig. 1. Proton NMR spectra of H_3L^1 as a function of pH.

2, the conditional stability constants at pH 7.4 are presented for the five poly(aminocarboxylates) H_3L^1, H_3L^2, H_3L^3, H_5dmdtta, and H_5dtpa. Their order is $[Gd(dtpa)]^{2-} > [GdL^1] \approx [GdL^2] \approx [GdL^3] \approx [Gd(dmdtta)]$. This suggests the conditional stability constants of the gadolinium(III) complexes are dependent on the ligand basicity. The thermodynamic stability constants at pH > 11 for $[Gd(dtpa)]^{2-}$ and the gadolinium(III) complexes of the bis(amide) derivatives differ by a factor of the $10^{5.5}$–$10^{6.0}$ that is higher than that at pH 7.4 ($10^{3.0}$–$10^{3.5}$). This indicates that the stability of $[Gd(dtpa)]^{2-}$ is only slightly higher than those of $[GdI^1]$, $[GdL^2]$, and $[GdL^3]$ at pH 7.4.

Stability constants do not provide directly comparable basis for the measuring total ion sequestering abilities of the ligands at physiological conditions (pH 7.4), and therefore they were used to calculate pM values [20]. The advantage of comparing pM values rather than stability constants of the complexes is that the pM values reflect the influence of ligand basicity and metal chelate protonation. The larger the pM value, the higher is the affinity of that ligand for the metal ion under the specified conditions. The relative order of the stability constants may change if a different set of conditions (concentration and pH) is used to calculate the pM values. The results given in Table 3 indicate that the H_5dtpa is much stronger gadolinium(III) chelating agents than are those of the H_3L^1, H_3L^2, and H_3L^3. The pM values of $[GdL^1]$, $[GdL^2]$, and $[GdL^3]$ are larger than those of $[CaL^1]^-$, $[CaL^2]^-$, and $[CaL^3]^-$, $[CuL^1]^-$, $[CuL^2]^-$, and $[CuL^3]^-$ and $[ZnL^1]^-$, $[ZnL^2]^-$, and $[ZnL^3]^-$, respectively. Therefore, the competition among Gd^{3+}, Ca^{2+}, Cu^{2+}, and Zn^{2+} with H_3L^1, H_3L^2 and H_3L^3 is seem to favour Gd^{3+} at pH 7.4, indicating that the complexes should be stable enough to avoid interference by Ca^{2+}, Cu^{2+}, and Zn^{2+}. Even though the stability constants for H_5dtpa chelates are larger than those of the corresponding amides chelates, the pGd values for GdL^1, GdL^2 and GdL^3 are about 3 log unit less than those of $[Gd(dtpa)]^{2-}$, because H_5dtpa has high protonation constants, and therefore formations of its complexes are subject to stronger hydrogen ion competition. Species distribution curves of $[GdL^1]$, $[GdL^2]$, and

[a] $pM = -\log[M]_{free}$ at pH 7.4, $[\text{metal ion}]_{total} = 1$ μmol dm^{-3}, and $[\text{ligand}]_{total} = 1.1$ μmol dm^{-3}.

$\log K_{sel}$(Gd/Cu). The selectivity constants are also given in Table 2. Since the basicity of H_3L^1, H_3L^2, and H_3L^3 is very similar to those of H_3dmdtta, H_3dipdtta, H_3dtbdtta, and H_3dbdtta [15], the contribution of the stability constant to the selectivity constant should be similar for the complexes of Gd^{3+}, Cu^{2+}, Ca^{2+}, and Zn^{2+}. From the selectivity constants, H_3L^1, H_3L^2, and H_3L^3 show a slightly more favourable selectivity toward Gd^{3+} over Zn^{2+} than does H_5dtpa.

The consequences of the modified selectivity constants (K_{sel}) for Gd^{3+} over other endogenous metal ions (Cu^{2+}, Ca^{2+}, and Zn^{2+}) and H^+ for a ligand can be calculated [14]. Table 2 shows the modified selectivity constants of H_3L^1, H_3L^2, H_3L^3, H_3dmdtta, and H_5dtpa at pH 7.4. The concentrations of Ca^{2+}, Cu^{2+}, and Zn^{2+} used were 2.5, 1.0×10^{-3} and 5.0×10^{-2} mmol dm^{-3}, respectively [15]. The $\log K_{sel}$ of H_3L^1 (9.18), H_3L^2 (8.57), and H_3L^3 (8.40) are very similar to that of H_3dmdtta (9.03), but slightly higher than that of H_5dtpa (7.04). Thus, H_3L^1, H_3L^2, and H_3L^3 form the gadolinium(III) complexes that are more stable than $[Gd(dtpa)]^{2-}$ toward transmetallation with endogenous metal ions at pH 7.4.

Relaxometry studies

The spin-lattice relaxivities R_1 of $[GdL^1]$, $[GdL^2]$, and $[GdL^3]$ are given in Table 4. The R_1 values are similar to the 3.90 and 4.08 dm^3 mmol^{-1} s^{-1} determined for the gadolinium(III) complex of H_3dmdtta and H_3dbdtta [15,16,21] under the same experimental conditions, respectively. Since the complexes of gadolinium(III) with H_3L^2 and H_3L^3 studied consist of gadolinium(III) bound to similar amides for the current study. The relaxivity R_1 of a paramagnetic metal chelate is governed by an exchange between coordinated water molecule and surrounding water molecules in solution [22,23]. With everything else being equal the exchange process is only dependent on the hydration number of the metal complex. However, hydration number of the complexes of gadolinium(III) with H_3L^1, H_3L^2, and H_3L^3 may be the same with [Gd(dmdtta)] and [Gd(dbdtta)] [10,15,21,24] leading to almost identical R_1 values. The relaxivity of $[GdL^1]$ is 4.99 dm^3 mmol^{-1} s^{-1} higher than those of $[GdL^2]$ and $[GdL^3]$, and this is undoubtedly due in part to the larger molecular size, which lead to a longer rotational correlation time.

The relaxivities R_1 for the complexes $[GdL^1]$, $[GdL^2]$, and $[GdL^3]$ at various pH values are given in Fig. 3. The relaxivity R_1 curve exhibits no pH dependence over the pH range 3–10. Therefore, no ligand dissociation for gadolinium(III) complexes occurred with varying pH of the solution. It is concluded that

Table 4. Relaxivities R_1 gadolinium(III) complexes

Complex	pH	R_1 relaxivity[a] /dm^3 mmol^{-1} s^{-1}
$[GdL^1]$	7.5±0.1	4.99±0.05
	limiting[a]	5.75±0.03
$[GdL^2]$	7.6±0.1	4.01±0.05
	limiting[a]	4.75±0.07
$[GdL^3]$	7.6±0.1	3.89±0.03
	limiting[a]	4.65±0.05

[a] Average of relaxivity values over the pH range 3–10.

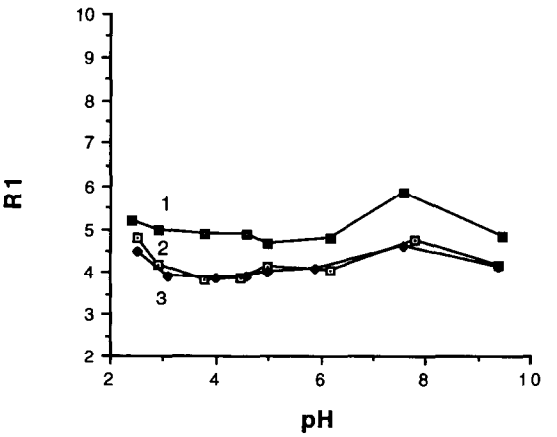

Fig. 3. pH dependence of the relaxivity for the complexes GdL^1, GdL^2, and GdL^3, all in 0.10 mol dm^{-3} buffers (pH 7 data excluded) at 20 MHz and T = 37.0±0.1 C.

the hydration number remains constant in this pH range.

The water solubility of [GdL^2] and [GdL^3] (6.79 g and 7.19 g in 100 g of water at 25°C, respectively) are considerably higher than that of [Gd(dbdtta)] (1.15 g in 100 g of water) [15]. Introducing hydrophilic methoxyl moiety covalently linked to ligand H_3dbdtta exhibits lower lipophicity than that of [Gd(dbdtta)]. High stability and high relaxivity R_1 of the gadolinium(III) chelates are important prerequisites for potential use as magnetopharmaceuticals. The amides, H_3L^1, H_3L^2, and H_3L^3 produce nonionic complexes when they chelate with gadolinium(III). Such nonionic complexes may have good membrane permeability. The fact that the complexes of gadolinium(III) with H_3L^1, H_3L^2, and H_3L^3 are quite stable in the aqueous solution, does not dissociate under physiological conditions (pH 7.4) and do not exchange with Ca^{2+}, Cu^{2+}, and Zn^{2+} to an appreciable extent show that they may be effective MRI contrast agents.

(Received 18 September 1997; accepted 12 November 1997)

Abstract—The reaction between the chalcogenide derivatives $[Au(C_6F_5)_3(PPh_2CH_2PPh_2E)]$ (E = S, O) and [Au(acac)PPh_3] or [Au(TfO)PPh_3] leads to the dinuclear compounds $[Au(C_6F_5)_3\{PPh_2CH(AuPPh_3)PPh_2E\}]$ (E = S, O) or $[Au(C_6F_5)_3\{PPh_2CH_2PPh_2(SAuPPh_3)\}]$, respectively. When the phosphine disulphide complex $[Au(C_6F_5)_3(SPPh_2CH_2PPh_2S)]$ is employed, the reaction with [Au(acac)PPh_3] promotes the double substitution of the methylenic protons. The reaction of [Au(acac)L] (L = PPh_3, $AsPh_3$) with the six-membered auracycle $[Au(C_6F_5)_2\{(SPPh_2)_2CH_2\}]ClO_4$ leads to the double substitution of both methylenic protons by $[AuL]^+$ fragments, keeping the auracycle intact. The crystal structure of one such product, $[Au(C_6F_5)_2\{(SPPh_2)_2C(AuAsPh_3)_2\}]ClO_4$ has been established by X-ray diffraction studies. Starting from the methanide derivative $[Au(C_6F_5)_2(SPPh_2CHPPh_2S)]$, the reaction with [Au(acac)PPh_3] leads to the synthesis of the four-membered ring methanide $[Au(C_6F_5)_2\{SPPh_2C(AuPPh_3)PPh_2S\}]$ © 1998 Elsevier Science Ltd. All rights reserved

Keywords: gold; diphosphinedichalcogenide; diphosphinemonochalcogenide; methanide; crystal structure.

In the last few years there has been a renewed interest in the chemistry of diphosphine chalcogenide ligands and their methanide derivatives [1–5], which can be attributed to the tendency of the diphosphine chalcogenides to charge delocalization, thus enhancing the acidity of the methylenic protons as well as the lability of the chalcogen–metal bonds [6]. This lability can give rise to dynamic processes and thus renders these ligands appropiate for catalytic applications [7–10].

The introduction of oxygen or sulfur atoms at one or both phosphorus centres in bis(diphenylphosphino)methane after or prior to metal complexation can change the character of the donor atom or lead to metallacycle ring expansion, depending on the starting complex employed. This may have a significant influence on the coordination properties or on the reactivity of these products.

The present paper reports the synthesis of some gold(III) derivatives containing mono- or di-chalcogenides of bis(diphenylphosphino)methane and their reactivity towards reagents of the type [Au(acac)L] (acac = acetylacetonate) forming methanide complexes. We employed tris(pentafluorophenyl)gold(III) derivatives, which afford non-cyclic methanides in a different way from that recently described [11] or $[Au(C_6F_5)_2(SPPh_2CH_2PPh_2S)]ClO_4$ [12], from which we have synthesized methanediide species containing a six-membered metallacycle. These last products are not accessible through other

* Author to whom correspondence should be addressed.

classical methods, which lead instead to the formation of four-membered rings.

RESULTS AND DISCUSSION

The reaction of $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$ and equimolecular amounts of sulfur leads to the sulfuration of the free phosphorus to give $[Au(C_6F_5)_3(PPh_2CH_2PPh_2S)]$ (**1**) (see Scheme 1).

Compound **1** is stable to air and moisture, soluble in most common organic solvents and insoluble in hexane. The IR spectrum of this compound shows the characteristic pattern of tris(pentafluorophenyl) gold(III) groups [13]. Besides, a weak band at 611 cm^{-1} corresponding to the ν(P—S) vibration appears [14]. The $^{31}P\{^1H\}$ and ^{19}F NMR spectra of this compound are also in accordance with the proposed structure (see Experimental section).

The presence of the chalcogenide atom near the phosphorus increases the acidity of the methylenic protons of the phosphine and this increase is greater for the sulfur than for the oxygen derivative. Thus, the resonance of the methylene group in complex **1** appears at $\delta = 3.66$ (t), shifted downfield compared to the starting material ($\delta = 3.2$) and making it appropriate for further deprotonations.

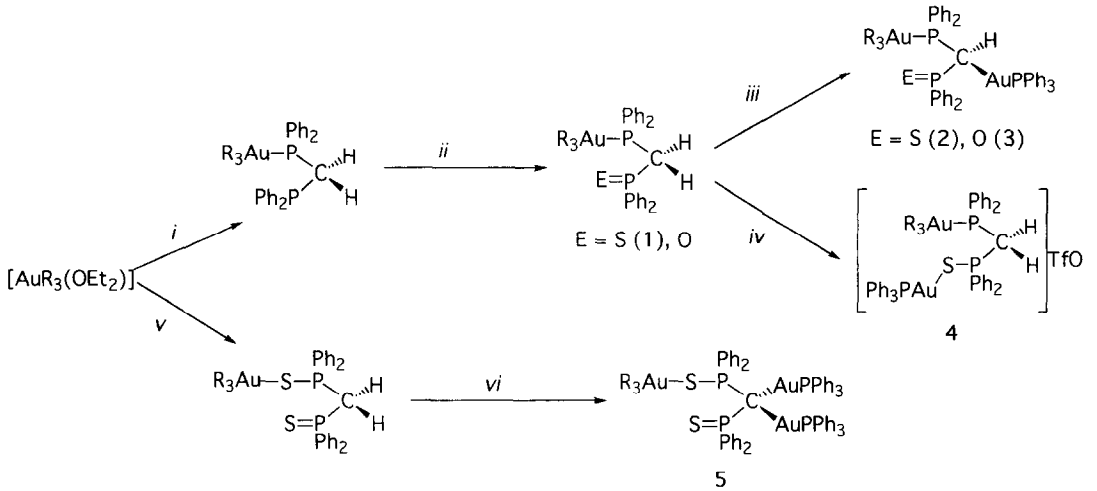
When complex **1** or the corresponding oxygen derivative $[Au(C_6F_5)_3(PPh_2CH_2PPh_2O)]$ [15] are treated with equimolecular amounts of [Au(acac)PPh_3] in dichloromethane, a methylenic proton is substituted by an $[AuPPh_3]^+$ group, affording the dinuclear species $[Au(C_6F_5)_3\{PPh_2CH(AuPPh_3)PPh_2E\}]$ (E = S (**2**), O (**3**)) (Scheme 1). As we already observed in previous studies [16], the substitution of a methylenic proton by an $[AuL]^+$ fragment (L = tertiary phosphine) also increases the acidity of the second methylenic H atom. However, in this case an excess of [Au(acac)PPh_3] does not produce the double substitution.

Complexes **2** and **3** are air and moisture-stable solids, soluble in chlorinated solvents, acetone and diethyl ether and insoluble in hexane. Their analytical and spectroscopic data are in accordance with the proposed formulation; e.g. they display three resonances with relative intensities 1:1:1 in their $^{31}P\{^1H\}$ spectra.

The reaction of complex **1** with the aurating agent [Au(TfO)PPh_3] (TfO = trifluoromethanesulfonate), prepared *in situ* by reaction of [AuClPPh_3] and AgTfO in dichloromethane, leads to the dinuclear complex $[Au(C_6F_5)_3\{PPh_2CH_2PPh_2(SAuPPh_3)\}]TfO$ (**4**), in which the coordination of the new $[AuPPh_3]^+$ fragment takes place at the sulfur atom.

When the phosphine disulphide derivative $[Au(C_6F_5)_3(SPPh_2CH_2PPh_2S)]$ [12] is employed instead of the monosulphide, its reaction with [Au(acac)PPh_3] leads to the synthesis of the di-substituted product $[Au(C_6F_5)_3\{SPPh_2C(AuPPh_3)_2PPh_2S\}]$ (**5**), whatever the molar ratio of the gold(I) derivative and without formation of the monosubstituted species $[Au(C_6F_5)_3\{SPPh_2CH(AuPPh_3)PPh_2S\}]$ (Scheme 1). This result is probably attributable to two factors: (i) the increase of the acidity that the second sulfur atom produces in the methylenic protons and (ii) the increase of the length of the phosphine ligand, reducing the steric restrictions that prevented the synthesis of disubstituted non-cyclic methanides as reported in a previous paper [11].

Complex **5** is obtained as a pale yellow stable solid soluble in acetone, ether and chlorinated solvents and insoluble in hexane. Its $^{31}P\{^1H\}$ NMR spectrum dis-



Scheme 1. $R = C_6F_5$; (i) $PPh_2CH_2PPh_2$; (ii) 1/8 S_8 or H_2O_2; (iii) [Au(acac)PPh_3]; (iv) [Au(PPh_3)]TfO; (v) $SPPh_2CH_2PPh_2S$; (vi) **1** or **2** equiv. [Au(acac)PPh_3].

plays two different resonances for the diphosphine phosphorus and a pseudo-triplet at $\delta = 35.2$ from both phosphorus atoms of the PPh_3 groups.

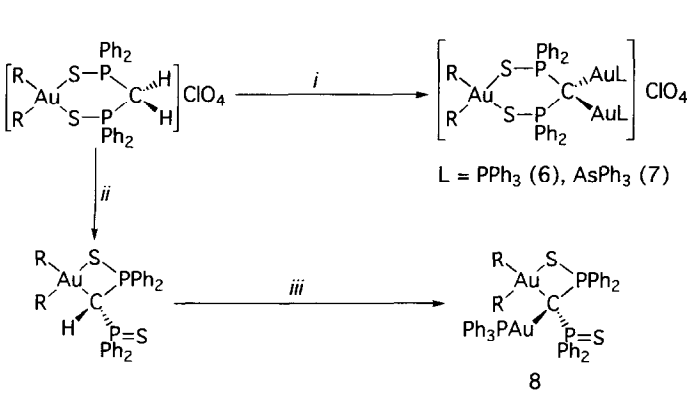
In the case of the diaryl complex $[Au(C_6F_5)_2(SPPh_2CH_2PPh_2S)]ClO_4$ [12], which contains the phosphine disulphide as a chelate, the increase of acidity produced by the sulfur centres is also demonstrated by its reaction with [Au(acac)L] (L = PPh_3, $AsPh_3$). Treatment of one equivalent of the starting complex with two equivalents of [Au(acac)L] results in the substitution of both methylenic protons by two $[AuL]^+$ groups with formation of $[Au(C_6F_5)_2\{(SPPh_2)_2C(AuL)_2\}]ClO_4$ (L = PPh_3 (**6**), $AsPh_3$ (**7**)) (Scheme 2). This is a surprising result in view of our previous studies with the same starting complex, because the employment of stronger deprotonating agents, such as NaH, led to the formation of four membered rings [12].

Complexes **6** and **7** are pale yellow solids, moisture and air stable. They are soluble in chlorinated solvents and acetone and they behave as 1 : 1 electrolytes in this solvent. Their analytical and spectroscopic data are in accordance with their formulation. The resonance from the phosphorus of the diphosphine sulphide appears as a triplet at $\delta = 43.9$ (**6**) or as a singlet at $\delta = 42.6$ (**7**) in their $^{31}P\{^1H\}$ NMR spectra. In the spectrum of the triphenylphosphine derivative **6** the signal corresponding to the PPh_3 groups is located at $\delta = 36.3$ and appears as a triplet because of the coupling with both phosphorus of the chelating ligand.

The crystal structure of complex **7** has been determined. The cation is shown in Fig. 1, with selected bond lengths and angles in Table 1. The complex crystallizes with two independent formula units; the overall distances and angles are very similar and consequently we will comment on only one of them. The precision is not very good for reasons discussed below. The coordination around the gold(III) center is slightly distorted from square planar, whereby the wide bite of the diphosphine disulphide ligand represents the major deviation from ideal geometry, S(2)—Au(1)—S(1) 102.0(2)°. This bite angle is unusually high for a chelating ligand in gold(III) complexes, compared with other examples such as $[Au(C_6F_5)_2(SPPh_2CHPPh_2)]$ (S—Au—P 89.6(1)°) [17] or $[Au(C_6F_5)_2\{(PPh_2)_2C(AuPPh_3)_2\}]ClO_4$ (P—Au—P 70.5(3)°) [16]. The gold(III) atom is coplanar with the C(11), C(21), S(1) and S(2) atoms. The Au—S distances, 2.390(7) and 2.357(8) Å, are longer than those found in $[Au(C_6F_5)_2(SPPh_2CHPPh_2)]$ (2.345(2) Å). The P—S bond lengths are 2.029(11) and 2.050(10) Å corresponding to a slightly shortened single bond. The gold(I) atoms exhibit essentially linear geometry and lie only 2.873(2) Å from each other. These short gold–gold contacts are very frequent in this type of polynuclear methanide complexes e.g., $[Au(C_6F_5)_2\{(PPh_2)_2C(AuPPh_3)_2\}]ClO_4$ (Au···Au 2.826(2) Å) or $[Au_2\{(PPh_2)_2C(AuPPh_3)_2\}_2](ClO_4)_2$ [18] (Au···Au 2.920(2)–2.987(2) Å). The Au—As bond lengths 2.365(3) and 2.370(3) Å are similar to those in the complexes $[Au(CH_3)(AsPh_3)]$ (2.3800(11) Å) [19] or $[Au(CH_2CH_3\text{-}closo\text{-}C_2B_{10}H_{10})(AsPh_3)]$ [19] (2.3740(8) Å) which also have a carbon donor ligand *trans* to the Au—As bond.

Using the same starting complex we have synthesized another methanide featuring a four-membered ring instead a six-membered one. This is made possible by treating it first with NaH, which causes a change in the coordination of the chelating ligand: one sulfur atom is replaced by the new methanide carbon atom at the gold(III) centre. If this product is now treated with one equivalent of $[Au(acac)PPh_3]$, the second methylenic proton is then removed and the $[AuPPh_3]^+$ takes its place (see Scheme 2).

Complex **8** is a yellow solid stable to air and moisture. It is soluble in chlorinated solvents and insoluble in diethyl ether or hexane. The IR spectrum shows two bands at 575 (w) and 625 (m) cm^{-1} due to the ν(P—S) vibration, in accordance with the presence of a free and a coordinated sulfur atom [20]. In the $^{31}P\{^1H\}$ NMR spectrum the signals corresponding to the three non equivalent phosphorus appear at $\delta = 46.9$, 37.5 and 34.8 with 1 : 1 : 1 relative intensity and no coupling between the different phosphorus is observed.



Scheme 2. $R = C_6F_5$; (i) **2** [Au(acac)L]; (ii) NaH; (iii) $[Au(acac)PPh_3]$.

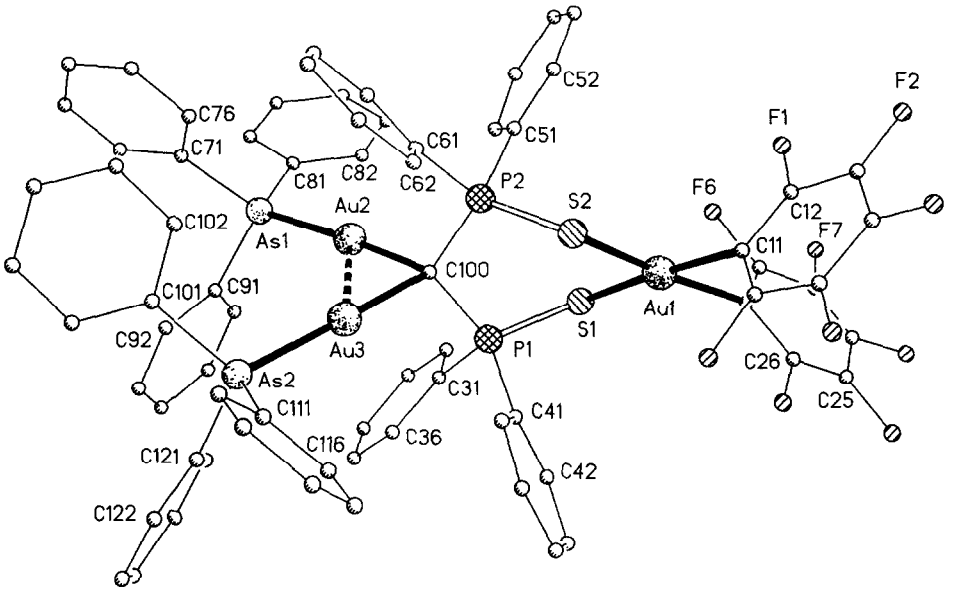


Fig. 1. The cation of complex **7** in the crystal with the atom labelling scheme. H atoms are omitted for clarity, radii are arbitrary.

EXPERIMENTAL

General

NMR spectra were recorded on a Bruker ARX 300 spectrometer in $CDCl_3$ solutions. Chemical shifts are quoted relative to $SiMe_4$ (^1H, external), $CFCl_3$ (^{19}F, external) and H_3PO_4 (85%) (^{31}P, external). All experiments were carried out at room temperature and under nitrogen except for **1**.

$[Au(C_6F_5)_3(PPh_2CH_2PPh_2S)]$ (**1**)

To a toluene solution of $(Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$ [13] (0.27 g, 0.25 mmol) was added S (0.009 g, 0.3 mmol). The mixture was refluxed for 24 h and the solvent was evaporated to dryness. The dry solid was then treated with diethyl ether and insoluble material was filtered off over celite. The solution was concentrated to ca 5 cm^3 and hexane was added to give complex **1** as a white solid. Yield: 77%. m.p. 123°C. $C_{43}H_{22}AuF_{10}P_2S$ (1114.583). Calc: C, 46.3; H, 2.0; S, 2.9. Found: C, 46.9; H, 2.15; S, 2.4. $^{31}P\{^1H\}$ NMR: $\delta = 8.5$ (m, 1P, Au(III)-PPh_2) and 33.2 (d, 1P, SPPh_2, [^2J(P—P) = 17.2 Hz]); ^1H NMR: $\delta = 3.6$ ("t", 2H, CH_2, $N = 11.3$ Hz); ^{19}F NMR: $\delta = -118.9$ (m, 4F, *o*-F), −119 (m, 2F, *o*-F), −156.4 (t, 2F, *p*-F, [^3J(FF) = 20.1 Hz]), −157.2 (t, 1F, *p*-F, [^3J(FF) = 19.9 Hz]), −160.5 (m, 4F, *m*-F) and −160.6 (m, 2F, *m*-F).

$[Au(C_6F_5)_3\{PPh_2CH(AuPPh_3)PPh_2E\}]$ (E = S (**2**), O (**3**))

To a dichloromethane solution of $[Au(C_6F_5)_3(PPh_2CH_2PPh_2E]$ (0.278 g, 0.25 mmol, $E = S$ (**1**)) or (0.274 g, 0.25 mmol, $E = O$ [11]) was added [Au(acac)PPh_3] (0.139 g, 0.25 mmol). After stirring for 2 h the mixture was filtered through a layer of celite and the solvent was evaporated to ca 5 cm^3. Addition of 20 ml of hexane led to the precipitation of **2** or **3** as a pale yellow solids. Yield: 60% **2**, 66% **3**. m.p. 113°C, **2**, 78°C, **3**. $C_{61}H_{36}Au_2F_{10}SP_3$ (1572.833) **2**. Calc: C, 46.6; H, 2.3; S, 2.03. Found: C, 46.8; H, 2.6; S, 2.15. $C_{61}H_{36}Au_2F_{10}OP_3$ (1556.768) **3**. Calc: C, 47.1; H, 2.3. Found: C, 47.2; H, 2.9. NMR **2**: $^{31}P\{^1H\}$: $\delta = 21.8$ (m, 1P, Au(III)-PPh_2) 41.3 (dd, 1P, SPPh_2, [^2J(P-P) = 37.8 Hz], [^3J(P-P) = 12.8 Hz]) and 38.6 ("t", 1P, PPh_3, $N = 11$ Hz). ^1H: $\delta = 3.75$ ("c", 1H, CH, $N = 7.33$ Hz). ^{19}F: $\delta = -118.4$ (m, 4F, *o*-F), −121.2 (m, 2F, *o*-F), −157.8 (t, 1F, *p*-F, [^3J(FF) = 19.9 Hz]), −158.1 (t, 2F, *p*-F, [^3J(FF) = 19.9 Hz]), −160.9 (m, 4F, *m*-F) and −161 (m, 2F, *m*-F). NMR **3**: $^{31}P\{^1H\}$: $\delta = 21.6$ (m, 1P, Au(III)-PPh_2), 29.4 (dd, 1P, SPPh_2, [^2J(P−P) = 33.9 Hz], [^3J(P-P) = 11.3 Hz]) and 38.6 ("t", 1P, PPh_3, $N = 11.3$ Hz). ^1H: $\delta = 3.79$ ("q", 1H, CH, [N(HP) = 8.57 Hz]). ^{19}F: $\delta = -119.4$ (m, 4F, *o*-F), −121.1 (m, 2F, *o*-F), −157.8 (t, 1F, *p*-F, [^3J(FF) = 20.1 Hz]), −158.1 (t, 2F, *p*-F, [^3J(FF) = 19.9 Hz]), −161.5 (m, 4F, *m*-F) and −161.6 (m, 2F, *m*-F).

$[Au(C_6F_5)_3\{PPh_2CH_2PPh_2(SAuPPh_3)\}]$ TfO (**4**)

To a freshly prepared dichloromethane solution of [Au(TfO)PPh_3] (0.25 mmol) was added $[Au(C_6F_5)_3(PPh_2CH_2PPh_2S)]$ (0.278 g, 0.25 mmol) and the mixture was stirred for 2 h. Evaporation of the solvent to

ca 5 cm^3 and addition of 20 cm^3 of hexane led to the precipitation of **4** as a microcrystalline white solid. Yield: 55%. m.p. 114°C. $C_{62}H_{37}Au_2F_{13}O_3P_3S_2$ (1722.909). Calc: C, 43.2; H, 2.15; S, 3.7. Found: C, 43.6; H, 2.2; S, 3.6. Λ_m (5×10^{-4} M) = 133 ($ohm^{-1}\cdot cm^2\cdot mol^{-1}$). $^{31}P\{^1H\}$ NMR: δ = 5.1 (m, 1P, Au(III)-*P*Ph_2), 36.4 (m, 1P, S*P*Ph_2) and 43.6 (m, 1P, *P*Ph_3). ^1H NMR: δ = 4.55 ("t", 2H, CH_2, N = 10.4 Hz). ^{19}F NMR: δ = −117.6 (m, 4F, *o*-F), −120.5 (m, 2F, *o*-F), −155.5 (t, 2F, *p*-F, [^3J(FF) = 19.9 Hz]), −156.5 (t, 1F, *p*-F, [^3J(FF) = 19.9 Hz]), −160.0 (m, 4F, *m*-F), −161.0 (m, 2F, *m*-F) and −120.4 (CF_3SO_3).

$[Au(C_6F_5)_3\{SPPh_2C(AuPPh_3)_2PPh_2S\}]$ (**5**)

To a dichloromethane solution of $[Au(C_6F_5)_3(SPPh_2CH_2PPh_2S)]$ (0.286 g, 0.25 mmol) was added [Au(acac)PPh_3] (0.279 g, 0.50 mmol). After stirring for 1 h the mixture was filtered through a layer of celite and the solvent was evaporated to ca 5 cm^3.

Addition of 20 cm^3 of hexane led to the precipitation of **5** as a pale yellow solid. Yield: 71%. m.p. 110°C. $C_{79}H_{50}Au_3F_{10}S_2P_4$ (2063.147). Calc: C, 46.0; H, 2.4; S, 3.1. Found: C, 46.4; H, 2.1; S, 2.9. $^{31}P\{^1H\}$ NMR: δ = 47.0 (m, 1P, Au(III)-PPh_2), 50.6 (m, 1P, $SPPh_2$) and 35.2 ("t", 1P, PPh_3, N = 7.3 Hz). ^{19}F NMR: δ = −121.2 (m, 4F, *o*-F), −122.2 (m, 2F, *o*-F), −158.6 (t, 1F, *p*-F, [^3J(FF) = 19.9 Hz]), −158.8 (t, 2F, *p*-F, [^3J(FF) = 19.9 Hz]), −162 (m, 4F, *m*-F) and −163.4 (m, 2F, *m*-F).

$[Au(C_6F_5)_2\{(SPPh_2)_2C(AuL)_2\}]ClO_4$ (L = PPh_3 (**6**), $AsPh_3$ (**7**))

A solution of $[Au(C_6F_5)_2(SPPh_2CH_2PPh_2S)]ClO_4$ (0.27 g, 0.25 mmol) in 25 cm^3 of dichloromethane was treated with [Au(acac)PPh_3] (0.279 g, 0.50 mmol (**6**)) or [Au(acac)$AsPh_3$] (0.30 g, 0.50 mmol (**7**)). After stirring for 2 h the mixture was filtered through a layer of celite and the solvent was evaporated to ca 5 cm^3. Addition of 20 cm^3 of diethyl ether led to the precipitation of **6** or **7** as a pale yellow solids. Yield: 80% **6**, 74% **7**. $C_{73}H_{50}Au_3ClF_{10}O_4P_4S_2$ (1995.56) **6**. Calc: C, 43.95; H, 2.5. Found: C, 43.65; H, 2.35. $C_{73}H_{50}Au_3As_2ClF_{10}O_4P_2S_2$ (2083.457) **7**. Calc. C, 42.1; H, 2.4; S, 3.1. Found: C, 42.5; H, 2.1; S, 3.4. Λ_m ($5 \cdot 10^{-4}$ M): 143 (**6**), 140 (**7**) (ohm $^{-1} \cdot cm^2 \cdot mol^{-1}$). NMR **6**: $^{31}P\{^1H\}$: δ = 43.9 (t, 2P, Au(III)-$SPPh_2$, [^{3}J(P-P) = 5.6 Hz]) and 36.3 (t, 2P, PPh_3, [^3J(P-P) = 5.6 Hz]). NMR **7**: $^{31}P\{^1H\}$: δ = 42.6 (s, 2P, Au(III)-PPh_2); ^{19}F: δ = −121.8 (m, 4F, *o*-F), −155.7 (t, 2F, *p*-F, [^3J(FF) = 19.9 Hz]) and −160.5 (m, 4F, *m*-F).

$[Au(C_6F_5)_2\{SPPh_2C(AuPPh_3)PPh_2S\}]$ (**8**)

To a dichloromethane solution of $[Au(C_6F_5)_2(SPPh_2CHPPh_2S)]$ (0.195 g, 0.20 mmol) was added [Au(acac)PPh_3] (0.112 g, 0.20 mmol). After stirring for 1 h the mixture was filtered through a layer of celite and the solvent was evaporated to ca 5 cm^3. Addition of 20 cm^3 of hexane led to the precipitation of **8** as a yellow solid. Yield: 53%. $C_{55}H_{35}Au_2F_{10}P_3S_2$ (1436.85). Calc: C, 45.95; H, 2.45. Found: C, 45.65; H, 2.8. $^{31}P\{^1H\}$ NMR: δ = 46.9 (m, 1P, Au(III)-PPh_2), 34.8 (m, 1P, $SPPh_2$) and 37.5 (s, 1P, PPh_3).

Crystal structure determination of $7 \cdot 2CH_2Cl_2$

Crystal data. $C_{74}H_{52}As_2Au_3Cl_3F_{10}O_4P_2S_2$, M_r = 2168.31, monoclinic, space group $P2_1/n$, a = 18.134(4), b = 15.805(3), c = 51.489(9) Å, β = 95.52(2)°, V = 14689(9) $Å^3$, Z = 8, D_c = 1.961 Mg m^{-3}, μ = 7.156 mm^{-1}, $F(000)$ = 8272, T = −100°C. Colourless prism 0.40 × 0.30 × 0.20 mm.

Data collection and reduction. The crystal was mounted in inert oil on a glass fibre. Data were collected using monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Siemens P4 diffractometer with an LT-2 low temperature attachment to $2\theta_{max}$ = 45°. 19,516 intensities were collected of which 18,818 (R_{int} = 0.070) were independent. An absorption correction based on Ψ-scans gave transmissions factors 0.693–0.904. Cell constants were refined from setting angles of 55 reflection in the 2θ range 6–23°.

The structure was solved by direct methods and subjected to full-matrix least-squares refinement on F^2 (program SHELXL-93) [21]. Au, P, As, S and F atoms were refined anisotropically, others isotropically. Hydrogen atoms were included using a riding model. The final $\omega R(F^2)$ was 0.211 for 18,789 reflections, 751 parameters and 358 restraints, conventional $R(F)$ 0.0812. S = 1.028, maximum $\Delta\rho$ 1.94 e $Å^{-3}$. The poor R value is caused by two factors: (i) the disorder of an perchlorate with very badly defined O atoms (the dichloromethane molecules also display high U values) and, more seriously, (ii) the reflection overlap caused by the long axis (despite narrow reflections and the use of ω scans). A systems of restraints to P, S and F atom displacement-factor components and local ring symmetry was used. CCDC reference number 100612.

(Received 15 September 1997; accepted 12 November 1997)

Abstract—Reaction of $[PdCl\{S_2P(OR)_2\}(PR'_3)]$ with sodium sulfide or selenide in acetone afforded neutral trinuclear palladium(II) complexes of the type $[Pd_3(\mu_3\text{-}E)_2\{S_2P(OR)_2\}_2(PR'_3)_2]$ (E = S or Se; R = Et, Pr^n, Pr^i, Bu^s, R′ = Et or Ph) in 24–42% yield. These complexes were characterized by elemental analysis, NMR (^1H, ^{31}P, ^{77}Se) and FAB mass spectral data. The molecular structure of $[Pd_3(\mu_3\text{-}S)_2\{S_2P(OEt)_2\}_2(PPh_3)_2]$ (**1**) was determined by X-ray diffraction. The molecule consists of three distorted square-planar palladium atoms sharing two μ_3-S ligands. One of the palladium atoms is linked with two triphenylphosphine ligands while each of the remaining two palladium atoms is coordinated with chelating dithiophosphate group. © 1998 Elsevier Science Ltd. Keywords: palladium; chalcogen; dithiophosphate; ^{77}Se NMR; X-ray.

Interest in the chemistry of metal chalcogenide complexes continues to grow [1–4] due to their applications in metal catalyzed hydrodesulfurization [5,6] and in materials science [4,7]. Substitution reactions in palladium(II) dithiolate complexes are quite facile and give a variety of products [8]. The reactions of $[PdCl(S_2CNMe_2)(PEt_3)]$ with thiols in the presence of base have been reported recently to give monomeric palladium thiolate, $[Pd(SR)(S_2CNMe_2)(PEt_3)]$ [9]. We carried out a reaction of $[PdCl\{S_2P(OR)_2\}(PR'_3)]$ with Na_2S/Na_2Se with the hope of isolating binuclear chalcogenido-bridged complexes, similar to Cp*M-Te-MCp* (M = Ti, Zr and Hf) [10]. However, neutral chalcogenido-bridged trinuclear palladium complexes were isolated.

EXPERIMENTAL SECTION

All reactions were carried out in anhydrous solvents under N_2 atmosphere. $[PdCl\{S_2P(OR)_2\}(PR'_3)]$ (R = Et, Pr^n, Pr^i, Bu^s; and R′ = Ph, Et) [11] and Na_2S [12], Na_2Se [12] were prepared by the literature methods. Analysis were performed by the Analytical Chemistry Division of this research centre. The ^1H, $^{31}P\{^1H\}$ and $^{77}Se\{^1H\}$ NMR were recorded in 5 mm NMR tubes as $CDCl_3$ solution on a Varian VXR-300 instrument. Chemical shifts are referenced with internal chloroform peak (δ 7.26 ppm) for ^1H, external 85% H_3PO_4 for $^{31}P\{^1H\}$, Me_2Se for $^{77}Se\{^1H\}$. FAB Mass spectra were recorded on a JEOL SX 102/DA-6000 Mass spectrometer using Argon/Xenon (6 KV, 10 mA) as the FAB gas. m-Nitrobenzyl alcohol was used as the matrix.

Synthesis

$[Pd_3(\mu_3\text{-}S)_2\{S_2P(OEt)_2\}_2(PPh_3)_2]$ (**1**). To an acetone solution (25 ml) of $[PdCl\{S_2P(OEt)_2\}(PPh_3)]$ (150 mg, 0.255 mmol), solid Na_2S (15 mg, 0.192 mmol) was added and the reaction mixture was stirred at room temperature under N_2 for 48 h. The solvent was

* Author to whom correspondence should be addressed.

removed *in vacuo*. The residue was extracted with diethylether and filtered. The filtrate was concentrated to 5 ml and hexane (5 ml) was added. This solution on cooling in a freezer for a week gave orange crystals, which were separated by decanting the solvent and recrystallized again from acetone-hexane (Yield: 31 mg, 29%), m.p. 171–173°C (dec.). Anal. Calcd for $C_{44}H_{50}O_4S_6P_4Pd_3$: C, 41.4; H, 4.0. Found: C, 41.0; H, 3.8. ^{1}H NMR in $CDCl_3$: 1.38, 1.47 (each t, 7.1 Hz, 6H each, OCH_2Me); 4.26, 4.34 (each dq, J_{PH} 9.6 Hz (d), J_{HH} 7.1 Hz (q), 4H each, OCH_2-); 7.18–7.54 (m, 30H, *Ph*). $^{31}P\{^1H\}$ in $CDCl_3$: 22.8 (s, *P*Ph$_3$); 103.7 [s, $S_2P(OEt)_2$]. The supernatant on drying *in vacuo* gave a brown paste. The ^{1}H and $^{31}P\{^1H\}$ NMR spectra showed the existence of a mixture of products together with **1**.

$[Pd_3(\mu_3\text{-}S)_2\{S_2P(OPr^n)_2\}_2(PPh_3)_2]$ (**2**). This complex was prepared in an analogous manner to **1** and was recrystallized from acetone-hexane in 41% yield, m.p. 195–197°C (dec.). Anal. Calcd for $C_{48}H_{58}O_4S_6P_4Pd_3$: C, 43.2; H, 4.4. Found: C, 43.1; H, 4.1. ^{1}H in $CDCl_3$: 0.98, 1.04 (each t, 7.1 Hz, 6H, OCH_2CH_2Me); 1.76, 1.84 (each sextet, 7.1 Hz, 4H each, OCH_2CH_2-); 4.15, 4.23 (each dt, J_{PH} 9.0 Hz (d), J_{HH} 7.1 Hz (t), 4H each, OCH_2-); 7.18–7.55 (m, 30H, P*Ph*$_3$). $^{31}P\{^1H\}$ in $CDCl_3$: 21.6 (s, *P*Ph$_3$); 103.2 [s, $S_2P(OPr^n)_2$].

$[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}_2(PPh_3)_2]$ (**3**). To an acetone solution of $[PdCl\{S_2P(OPr^n)_2\}(PPh_3)]$ (2.147 g, 3.48 mmol) solid Na_2Se (449 mg, 3.59 mmol) was added. The reaction mixture was stirred at room temperature under a nitrogen atmosphere for 36 h. The solvent was evaporated *in vacuo*. The residue was washed thoroughly with hexane (5 × 10 ml), dried *in vacuo*, dissolved in acetone (20 ml) and passed through a Florisil column. To the solution, hexane (15 ml) was added to give brown crystals which were separated and again recrystallized from a cold acetone-hexane mixture. The yield of maroon crystals thus obtained was 35% (580 mg, based on Pd contents); m.p. 198–202°C (dec.). Anal. Calcd for $C_{48}H_{58}O_4S_4Se_2P_4Pd_3$: C, 40.4; H, 4.4. Found: C, 40.5; H, 3.9. ^{1}H NMR in $CDCl_3$: 0.97, 1.04 (each t, 7.4 Hz, 6H each, $POCH_2CH_2Me$); 1.75, 1.84 (each q, 7.1 Hz, 4H each, $POCH_2CH_2$-); 4.13, 4.21 (each m, 4H each, $POCH_2$–); 7.16–7.54 (m, 30H, P*Ph*$_3$). $^{31}P\{^1H\}$ in $CDCl_3$: 13.7 (s, *P*Ph$_3$) 103.2 [s, $S_2P(OPr^n)_2$]. $^{77}Se\{^1H\}$ NMR in $CDCl_3$: −98.7 (d, $^2J(^{77}Se\text{-}^{31}P) = 48$ Hz). FAB mass: *m/e* 1428 (molecular ion); 1215 $[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}(PPh_3)_2]$; 1166 $[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}_2(PPh_3)]$; 1089 $[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}_2(PPh_2)]$; 953 $[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}(PPh_3)]$.

$[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OEt)_2\}_2(PPh_3)_2]$ (**4**). This complex was prepared in an anologous manner to compound **3** and was recrystallized from acetone-hexane mixture in 24% yield, m.p.: 197–198°C (dec.). Anal. Calcd For $C_{44}H_{50}O_4S_4Se_2P_4Pd_3$: C, 38.5; H, 3.7. Found: C, 38.7; H, 3.2. ^{1}H NMR in $CDCl_3$: 1.37, 1.46 (each t, 7.0 Hz, 6H each, $POCH_2Me$); 4.24, 4.33 (each dq, J_{HH} 7 Hz (q), J_{PH} 9.5 Hz (d), 4H each, $POCH_2$-); 7.15–7.54 (m, 30 H, P*Ph*$_3$). $^{31}P\{^1H\}$ in $CDCl_3$: 12.1 (s, *P*Ph$_3$), 101.0 [s, $S_2P(OEt)_2$].

$[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^i)_2\}_2(PPh_3)_2]$ (**5**). This complex was prepared in an analogous manner to **3** and was recrystallized from acetone-hexane in 25% yield, m.p. 224–225°C (dec.). Anal. Calcd for $C_{48}H_{58}O_4S_4Se_2P_4Pd_3$: C, 40.4; H, 4.4. Found: C, 39.5; H, 3.9. ^{1}H NMR in $CDCl_3$: 1.37, 1.47 (each d, 6.2 Hz, 12H each, $POCHMe_2$); 4.98 (m, 4H, $POCH$-); 7.18–7.52 (m, 30H, P*Ph*$_3$). $^{31}P\{^1H\}$ in $CDCl_3$: 15.0 (s, *P*Ph$_3$), 101.1 [s, $S_2P(OPr^i)_2$].

$[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OBu^s)_2\}_2(PPh_3)_2]$ (**6**). This was prepared in an analogous manner to **3**. The complex was recrystallized from diethylether-hexane in 36% yield, m.p. 173–175°C (dec.). Anal. Calcd for $C_{52}H_{66}O_4S_4Se_2P_4Pd_3$: C, 42.1; H, 4.5. Found: C, 42.0; H, 3.7. ^{1}H NMR in $CDCl_3$: 0.95, 1.01 (each t, 7.5 Hz, 6H each, $POCHCH_2Me$); 1.36, 1.47 (each d, 6.2 Hz, 6H each, $POCHMe$); 1.74 (m, 8H, $POCHCH_2$-); 4.76 (m, 4H, $POCH$-); 7.17–7.57 (m, 30H, P*Ph*$_3$). $^{31}P\{^1H\}$ in $CDCl_3$: 12.0 (s, *P*Ph$_3$), 99.0 [s, $S_2P(OBu^s)_2$].

$[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}_2(PEt_3)_2]$ (**7**). This complex was prepared in an analogous manner to **3**, and was recrystallized by cooling a diethylether-hexane mixture in a freezer for a week (yield 42%) m.p. 163–165 C. Anal. Calcd for $C_{24}H_{58}O_4S_4Se_2P_4Pd_3$: C, 25.3; H, 5.1. Found: C, 24.5; H, 4.9. ^{1}H NMR in $CDCl_3$: 0.94 (dt, J_{HH} 7.5 Hz (t), J_{PH} 22 Hz (d), 18H, PCH_2Me); 1.22, 1.28 (each t, 7.5 Hz, 6H each, $POCH_2CH_2Me$); 1.71 (m, 12H, PCH_2-); 1.92 (m, 8H, $POCH_2CH_2$-); 3.97, 4.13 (each dt, J_{HH} 7 Hz (t), J_{PH} 9 Hz (d), 4H each, $POCH_2$-); $^{31}P\{^1H\}$ in $CDCl_3$: 11.4 (s, *P*Et$_3$), 101.7 [s, $S_2P(OPr^n)_2$]. FAB mass: *m/e* 1140 (molecular ion).

X-ray crystallography

All measurements were made at 20 ± 2°C on a Rigaku AFC 6S diffractomer using graphite monochromated Mo–K_α radiations ($\lambda = 0.71073$ Å). Crystal data and data collection details are given in Table 1. The data were corrected for Lorentz and polarization effects. Semi-empirical absorptions correction was based on Ψ scan of several reflections (maximum and minimum transmission factors: 0.57 and 0.26, respectively). The structure was solved by a combination of the Patterson and direct methods and refined by full-matrix least-squares on F^2. Neutral atom factors were taken from Cromer and Waber [14]. Anamolous dispersion effects were included in F_{calc} [15]. All calculations were performed using the TEXSAN [16] crystallographic software package of the Molecular Structure Corporation. The ORTEP [17] plot of the molecule is shown in Fig. 1.

RESULTS AND DISCUSSION

Treatment of $[PdCl\{S_2P(OR)_2\}(PR'_3)]$ with sodium sulfide or selenide in acetone gave neutral chal-

Scheme 1.

ophosphate ligand. The $^{31}P\{^1H\}$ NMR spectra showed singlets for the triphenylphosphine and dialkyldithiophosphate moiety. The ^{31}P resonance for triphenylphosphine is more shielded for the selenido-bridged complexes than the corresponding sulfido-bridged derivatives. The $^{77}Se\{^1H\}$ NMR spectrum (^{77}Se $I = 1/2$, natural abundance 7.58%) of **3** showed a doublet at -98.7 ppm with $^2J(^{77}Se\text{-}^{31}P)_{trans}$ of 48 Hz. FAB mass spectra of $[Pd_3(\mu_3\text{-}Se)_2\{S_2P(OPr^n)_2\}_2(PR'_3)_2]$ (R′ = Et, Ph) showed molecular ion peaks. Other prominent ions observed in the spectra are due to the species formed either by loss of a dithiophosphate ligand or triphenylphosphine ligand. The isotopic patterns for these species are in accord with the pattern calculated for $Pd_3Se_2S_4$ fragment.

The structure of **1**, established by X-ray study, shows that this is a sulfido-bridged trinuclear palladium(II) complex (Fig. 1). Molecule consists of three distorted square-planar palladium atoms sharing two μ_3-S ligands. The molecular geometry may alternatively be viewed of a trigonal bipyramidal Pd_3S_2 core with one palladium atom linked with two triphenylphosphine and each of the remaining two palladium atoms is coordinated with chelating dithiophosphate group. The central palladium atoms in the triangle are not equilateral, the two Pd—Pd distances (av. 3.0446(14) Å) are shorter than the third one (3.217(2) Å). Although **1** is the first neutral trinuclear sulfido-bridged complex, the Pd—Pd distances are in accord with the Pd—Pd bond lengths reported in $[Pd_3(\mu\text{-}S)_2(PMe_3)_6][BPh_4]_2$ [18]. However, the metal–metal distances in other ionic chalcogenido-bridged trinuclear complexes, $[Pt_3(\mu_3\text{-}Te)_2(PEt_3)_6][PF_6]_2$ [19], $[Pt_3(\mu_3\text{-}Te)_2(dppe)_3][BPh_4]_2$ [20], $[Ni_3(\mu_3\text{-}E)_3(PR_3)_6]^{2+}$ (E = S, Se) [21], are equidistant.

The dithiophosphate ligands are symmetrically chelated to the palladium atoms, the Pd—$S_{(dithio)}$ distances are essentially the same (i.e. av. 2.383 Å) and are in good agreement with the values reported for chelated dithio palladium complexes [22,23]. The P—S bond lengths (av. 1.982(5) Å) are intermediate between the double bond (1.94 Å) and single bond (2.09 Å) values confirming the partial double bond character, as expected from symmetrically chelated dithiophosphate ligand. The angles S(21)—Pd(2)—S(22) (84.16(11)°), S(31)—Pd(3)—S(32) (83.64(11)°), S(1)—Pd(2)—S(2) (78.96(9)°), S(1)—Pd(3)—S(2) (78.50(9)°) and S(1)—Pd(1)—S(2) (76.87(9)°) are

compressed owing to the formation of four-membered chelate rings. Consequently other angles have opened. The Pd—P [9,23,24], Pd—$S_{(sulfido)}$ [18] are in good agreement with the reported values. It may be noted that the two of the palladium-sulfido bonds for the palladium linked to triphenylphosphines are longer (0.04 Å) than the other Pd—S bonds where palladium atoms are bound to the dialkyldithiophosphate groups. Selected bond lengths and angles are given in Table 2.

(Received 10 September 1997; accepted 3 November 1997)

Abstract—The first structural characterization of an organolead phosphinodithioate is reported. According to an X-ray diffraction study, the title compound triphenyllead(IV) dimethylphosphinodithioate, $^{1}_{x}[Ph_3PbS_2PMe_2]$, forms a linear polymer in the solid state. Supramolecular association through secondary bonds of the type P=S···Pb leads to a polymeric chain formed by –Pb–S–P=S···Pb– units. The inorganic backbone is wrapped in a lipophilic "hose" made up of methyl and phenyl groups. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: lead; organolead compounds; phosphinodithioates; supramolecular association; secondary bonds.

Supramolecular chemistry is defined as "the chemistry of molecular assemblies and of intermolecular bonds" and deals with "organised entities that result from the association of two or more chemical species held together by intermolecular forces" [1]. The formation of supramolecular structures is the result of a spontaneous association of a large number of components (self-assembly) and can involve various types of interactions, such as metal ion coordination, secondary bonding, hydrogen bonding, electrostatic forces and others.

Metal and organometal derivatives of phosphorodithioato [2a] and phosphinodithioato [2b] ligands display a remarkable diversity of coordination patterns. The ability of these ligands to function as bridging groups in Main Group metal compounds via secondary bonds, M—S—P=S···M, often leads to supramolecular self-assembly [3].

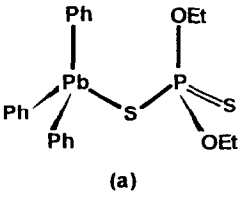
Crystal structure investigations of a number of lead(II) phosphorodithioates, $Pb[S_2P(OR)_2]_2$, with R = Et [4], Pr^i [5], Bu^i [4b], and Ph [4b] and phosphinodithioates, $Pb(S_2PR_2)_2$, with R = Me [6], Et [7] and Ph [8], revealed in all cases supramolecular self-assembly involving P=S···Pb secondary bonds. Moreover, each compound displayed a different structure and there were no two identical modes of association of the $Pb(S_2PR_2)_2$ building blocks.

In spite of the often fascinating structures produced by the two types of phosphoro- and phosphinodithioato ligands, they have been little used in organolead chemistry, and only two organolead(IV) com-

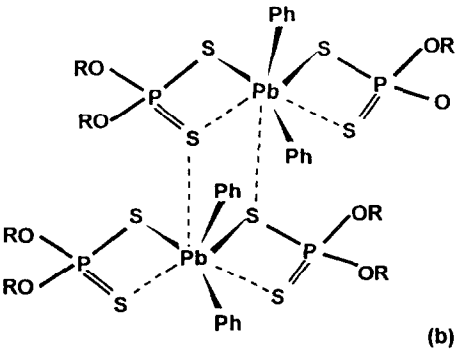
* Author to whom correspondence should be addressed.

pounds have been structurally characterised. Triphenyllead(IV) diethylphosphorodithioate, $Ph_3PbS_2P(OEt)_2$, contains discrete tetrahedral molecules and the ligand is monodentate, (a) with the second sulfur atom pointing away from the metal [9]. Diphenyllead(IV) dibenzylphosphorodithioate, $Ph_2Pb[S_2P(O\text{-}CH_2Ph)_2]_2$, is a dimer, in which the molecules are connected in pair by weak Pb···S secondary bonds, as shown in (b) [9a].

The only organolead phosphinodithioate investigated by X-ray diffraction is the diphenyllead derivative $Ph_2Pb(S_2PPh_2)_2$ [9b].



(a)



(b)

Reported here is the crystal structure of triphenyllead(IV) dimethylphosphinodithioate, $Ph_3PbS_2PMe_2$, the preparation of which has been previously reported [10]. Unlike the diethylphosphorodithioate (a), our compound is a linear polymer, containing a 1–Pb—S—P=S···Pb– chain, wrapped in a lipophilic "hose" made up of methyl groups (on phosphorus) and phenyl groups (on lead).

EXPERIMENTAL

The compound investigated has been obtained in a previously reported work [10].

Crystallographic data for $^1_\infty[Ph_3PbS_2PMe_2]$

$C_{20}H_{21}PPbS_2$. M = 563.65, orthorhombic, space group *Pbca*; a = 1149.6(2) pm, b = 1197.8(2) pm, c = 2.997.3(6) pm, $\alpha = \beta = \gamma = 90°$, V = 4.1273(13) nm^3; $Z = 8$; D_{calc} = 1.814 Mg/m^3, absorption coefficient 8.454 mm^{-1}, $F(000)$ 2160. Data were collected on a Siemens-Stoe AED2 diffractometer, at 153(2) K for 7572 reflections of which 1907 independent reflections (R_{int} = 0.1372) were used in the full-matrix least-squares refinement on F^2 with the SHELXS-90 Program System [11]. The final R indices [$I > 2\sigma(I)$] are R_1 = 0.0519, wR_2 = 0.1343, with R indices (all data) R_1 = 0.0719, wR_2 = 0.1662. Goodness-of-fit on F^2 1.081. The largest difference peak and hole 1786 and −1680 e nm^{-3}.

RESULTS AND DISCUSSION

The structure of triphenyllead(IV) dimethylphosphinodithioate, $^1_\infty[Ph_3PbS_2PMe_2]$, consists of molecules connected into infinite chains. An ORTEP drawing of the unit with the atom numbering scheme is shown in Fig. 1 and the packing of polymeric chains is shown in Fig. 2. Selected interatomic distances and bond angles are given in Table 1.

In the monomeric building block the lead atom is five-coordinate in a trigonal bipyramidal geometry, with the phenyl groups in equatorial positions and two sulfur atoms in axial positions. The two lead-sulfur bonds are not identical, with the shortest Pb(1)—S(1) bond [270.8(4) pm] connected to the sulfur atom single-bonded to phosphorus [P(1a)—S(1) 204.3(5) pm] as primary bond, and the longest Pb(1)—S(2) bond [302.8(4) pm] to the sulfur atom doubly bonded to phosphorus [P(1)=S(2) 197.9(6) pm]. This longer lead–sulfur distance corresponds to a Pb···S secondary bond, and is larger than the sum of covalent radii for lead and sulfur (estimated 250 pm) but significantly shorter than the sum of van der Waals radii (estimated 380 pm).

The phosphinodithioato ligand is bridging, as evident from Fig. 2, and this explains the lengthening of the P=S double bond involved, compared with pure P=S double bonds. The resulting polymeric chain consists of nearly linear S—Pb···S segments [bond angle 165.4(1)°]; bending of the chains occurs at the sulfur sites, with P(1)—S(2)—Pb(1) 126.1(2)° and P(1a)—S(1)—Pb(1) 101.4(2)°. The bending is more pronounced at the primary bonded sulfur atom than at the sulfur atom involved in the secondary bond.

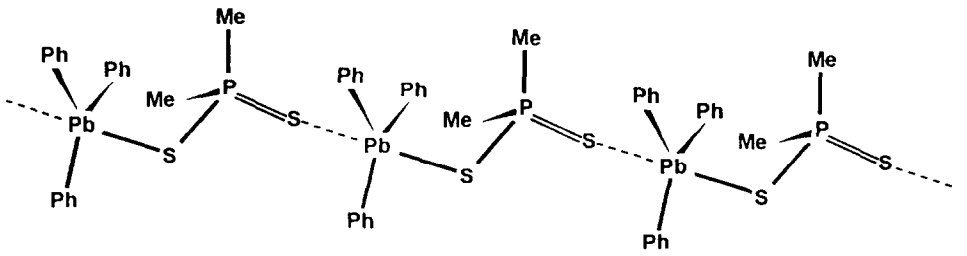
Symmetry transformations used to generate equivalent atoms: [a] $-x+1/2, y+1/2, z$; [b] $-x+1/2, y-1/2, z$.



The Pb—S primary bond lengths (270.8 pm) are comparable with the Pb—S interatomic distances measured in lead(II) phosphinodithioates [2b] and lead(II) phosphorodithioates [2a] (range 275–298 pm). The Pb···S secondary bonds in $^1_\infty$[$Ph_3PbS_2PMe_2$] (302.8 pm) are comparable, even somewhat shorter than other intermolecular lead–sulfur secondary bonds observed in lead(II) phosphoro- and phosphinodithioates [2].

The peripheral organic groups at phosphorus and lead wrap the inorganic chain in a lipophilic "hose" and the intermolecular contacts between chains are determined by the mutual orientation and packing of these groups, interacting through van der Waals forces only. This is obvious from the space filling illustration of the polymeric chains, shown in Fig. 3. It can be seen that alternating phenyl groups at lead and methyl groups at phosphorus are intercalated in the space around the inorganic inner core in such a way as to minimise the exposure of the Pb—S—P chain backbone.

Triphenyllead(IV) dimethylphosphinodithioate is the first self-assembled organo–lead compound displaying a chain structure similar to those found in other Main Group organometal phosphinodithioates, e.g. $^1_\infty$[$PhHgS(S)PEt_2$], [12], $^1_\infty$[$Me_2SbS(S)PMe_2$] [13], or $^1_\infty$[$PhTeS(S)PPh_2$] [14]. There are, however, differences in the coordination mode of the phosphinodithioato ligand, which forms chelate rings in the building blocks of the PhHg and Me_2Sb compounds but participates with only one sulfur atom in the PhTe compound. In the lead derivative, the bridging ligand participates with both sulfur atoms, but no intra-unit chelate rings are formed.

Pd(II) and Pt(II) complexes with mixed phosphorus–oxygen donor ligands

Jui-Sui Sun, Calvin E. Uzelmeier, Donald L. Ward and Kim R. Dunbar*

Department of Chemistry, Michigan State University, East Lansing, MI 48824–1322, U.S.A.

(Received 29 September 1997; accepted 31 October 1997)

Abstract A series of new complexes have been synthesized from reactions of $[M(NCCH_3)_4][BF_4]_2$ (M = Pd, Pt) with the mixed donor ligand tris(2,4,6-trimethoxyphenyl) phosphine (TMPP). Reaction of $[Pd(NCCH_3)_4][BF_4]_2$ with two equivalents of TMPP in acetone produces the ether-phosphine complex $[Pd(TMPP)_2][BF_4]_2$, **1**. In this molecule the Pd atom is situated at the center of a pseudo-octahedron, with the phosphorus atoms in a *cis* orientation. The complex was also characterized by infrared, electronic, and NMR spectroscopies as well as by cyclic voltammetry. Reaction of $[Pd(NCCH_3)_4][BF_4]_2$ with four equivalents of TMPP in acetone yields the neutral phosphino-phenoxide compound Pd(TMPP-*O*)$_2$, **2**, where TMPP-*O* is the demethylated form of TMPP. ^1H and $^{31}P\{^1H\}$ NMR studies of **2** support the assignment of a solution structure that involves free rotation of the uncoordinated phenyl rings of the TMPP ligands. Reaction of $[Pt(NCCH_3)_4][BF_4]_2$ with two equivalents of TMPP in acetonitrile yields $[PT(NCCH_3)_2(TMPP)_2][BF_4]_2$, **3**. Structural and spectroscopic data for **3** indicate that free rotation of the arene rings in solution is restricted due to steric influences of the two CH_3CN co-ligands. Reaction of $PtCl_2(NCCH_3)_2$ with two equivalents of TMPP in acetone or reaction of $[Pt(NCCH_3)_4][BF_4]_2$ with four equivalents of TMPP in acetone gives Pt(TMPP-*O*)$_2$, **4**. Reaction of $PtCl_2(NCCH_3)_2$ with two equivalents of TMPP in tetrahydrofuran yields the neutral compound PtCl(TMPP)(TMPP-*O*), **5**. Although suitable single crystals were not obtained, the structure of compound **5** was deduced from infrared and NMR spectroscopies to be a square planar molecule with one neutral TMPP ligand coordinated in an η^1 fashion and a demethylated TMPP group bound as an η^2-P,O ligand where the phosphorus atoms are *trans* and the other two coordination sites are occupied by a phenoxide oxygen and a Cl atom. © 1998 Elsevier Science Ltd. Keywords: Pd(II) complex; Pt(II) complex; donor ligands.

Transition metal complexes with ether-functionalized phosphine ligands have been found to exhibit enhanced reactivity due to the presence of weak metal-ether interactions that are often labile in the solid-state as well as in solution [1–4]. As a result of this behavior, ether-phosphine ligands have been referred to as "hemi-labile", a term coined specifically for such ligands with the complexes themselves being referred to as "incipiently coordinatively unsaturated" [1d,5,6].

In view of the interest in such molecules, our group has been investigating the unusual ether phosphine tris(2,4,6-trimethoxyphenyl)phosphine (TMPP). Special characteristics of this ligand are high basicity, a large cone angle of 184°, and the presence of *ortho*-methoxy substituents that can act as "built-in" solvent molecules in the chemistry. Among the unusual complexes that have been isolated with this ligand are mononuclear Rh(II) d^7 radicals, molecules that are ordinarily very unstable but which are indefinitely stable towards air and moisture in the presence of TMPP [3a].

One of our goals in this project has been to design homologous series of d^6, d^7 and d^8 TMPP complexes that differ only in the coordination mode adopted by the TMPP [3]. These related compounds are of general interest for probing the structural and reactivity differences exhibited by compounds that possess the same ligand set but a different metal electron count. Earlier work from our laboratories had shown that homoleptic TMPP compounds of Rh^I, Rh^{II} and Rh^{III} exhibit interesting redox chemistry and that they undergo reversible small molecule reactions based on the ability of the ether groups to dissociate [3a–c,e,n]. Given these promising results, it was logical to extend

* Author to whom correspondence should be addressed.

these studies to Pd(II) and Pt(II) which are known to be useful in catalytic applications when weakly bonded ligands are involved [5j,k,7 9]. In addition, polydentate ligands such as TMPP with steric requirements that favor octahedral coordination may enforce this geometry on metals for which six coordination is rarely observed [10,11]. In spite of the considerable interest, a fairly limited number of such compounds have been studied [5]. During the course of preparing this manuscript, a paper by Lindner and coworkers appeared which describes the reactivity of $[Pd(P \cap O)_2]^{2+}$ complexes as CO/ethene copolymerization catalysts, where P ∩ O is an η^2-coordinated polysiloxane-bound ether-phosphine [5k]. Herein we report the syntheses, X-ray structures, and spectroscopic data for a series of Pd(II) and Pt(II) complexes supported by TMPP or phenoxide derivatives of TMPP. In the new compounds, the ligands are shown to adopt η^1, η^2 and η^3 binding modes in square planar or six-coordinate environments. Some of these results have appeared in communication form [3j].

EXPERIMENTAL

Physical measurements

Infrared spectra were recorded on a Nicolet 740 FT-IR spectrophotometer. ^{1}H NMR spectra were measured on Varian 300 or 500 MHz spectrometers; chemical shifts were referenced relative to the residual proton impurities of acetone-d_6 (2.04 ppm with respect to TMS), acetonitrile-d_3 (1.93 ppm with respect to TMS) or chloroform-d_1 (7.24 ppm with respect to TMS). ^{31}P $\{^1$H$\}$ NMR spectra were obtained on Varian 300 or 500 MHz spectrometers operating at 121.4 MHz and 203.6 MHz respectively, and were referenced relative to an external standard of 85% phosphoric acid. Spin-simulation experiments were carried out by using the LAME program which is included in the VNMR software package. Elemental analyses were performed at Galbraith Laboratories, Inc., Knoxville, TN, or Desert Analytics, Tucson, AZ. Electrochemical measurements were carried out by using an EG&G Applied Research Model 362 scanning potentiostat in conjunction with a BAS Model RXY recorder. Cyclic voltammetric experiments were carried out at 22 ± 2°C using 0.1 M tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$) as the supporting electrolyte. $E_{p,a}$ and $E_{p,c}$ were referenced to a Ag/AgCl electrode and are uncorrected for junction potentials.

Starting materials

The starting materials $PtCl_2(NCC_6H_5)_2$ and Pd sponge were purchased from Strem Chemicals, Inc. and were used as received. Tris(2,4,6-trimethoxyphenyl)phosphine (TMPP) was prepared according to published methods [3m] or purchased from Aldrich and used without further purification [12]. $[M(NCCH_3)_4][BF_4]_2$ (M = Pd [13a], Pt [13b]), and $[Cp_2Fe][BF_4]$ [13c] salts were prepared as described in the literature. Acetone was distilled over 3 Å molecular sieves, methanol was distilled over $Mg(OMe)_2$ under a nitrogen atmosphere, and methylene chloride was distilled over P_2O_5 under a nitrogen atmosphere. Benzene, diethyl ether, THF, and toluene were distilled over sodium-potassium/benzophenone. Unless otherwise specified, all reactions were carried out under an argon atmosphere by using standard Schlenk-line techniques.

$[Pd(TMPP)_2][BF_4]_2$ (**1**). An acetone solution (10 ml) containing two equivalents of TMPP (0.476 g, 0.900 mmol) was added dropwise to an acetone solution (10 ml) of $[Pd(NCCH_3)_4][BF_4]_2$ (0.200 g, 0.450 mmol) at −44°C which effected an immediate color change from pale yellow to red. The resulting solution was stirred for 40 min at −44°C and evaporated to dryness *in vacuo*. The compound was recrystallized from acetone and diethyl ether to give a brick-red solid in 82% yield (0.993 g). ^{1}H NMR in acetone-d_6 at −80°C (δ ppm): -OMe 3.32 (s, 6H); 3.34 (s, 6H); 3.47 (s, 6H); 3.52 (s, 6H); 3.83 (br, 18H); 4.03 (s, 6H); 4.25 (s, 6H); *meta*-H: 5.70 (br, 2H), 5.92 (br, 2H), 6.19 (br, 2H), 6.30 (br, 2H), 6.43 (br, 2H), 6.78 (br, 2H). ^{31}P$\{^1$H$\}$ NMR in acetone-d_6 (300 MHz, δ ppm): +1.67. Anal. Calcd for **1**, $PdP_2C_{54}O_{18}H_{66}B_2F_8$: C, 48.22; H, 4.95. Found: C, 48.29; H, 5.05. UV–Vis (CH_2Cl_2): λ_{max} (nm) (ε in M^{-1}, cm^{-1}) 485 (2.3×10^4), 373 (3.7×10^4), 260 (1.7×10^5).

Pd(TMPP-*O*)$_2$ (**2**). An acetone solution (15 ml) containing four equivalents of TMPP (0.719 g, 1.352 mmol) was added dropwise to an acetone solution (10 ml) of $[Pd(NCCH_3)_4][BF_4]_2$ (0.150 g, 0.338 mmol) at 0°C which effected an immediate color change from pale yellow to orange. The resulting solution was stirred for 2 h at 0°C, then warmed to room temperature and stirred for an additional 12 h. The solvent was removed by evaporation to yield an orange solid. This solid was recrystallized from THF and diethyl ether, then washed with a mixture of hexanes and acetone (v/v 2/3) to remove trace amounts of [CH_3-TMPP][BF_4]. The orange product is obtained in 78% yield (0.301 g). ^{1}H NMR (δ ppm in $CDCl_3$): -OMe: 3.10 (s, 6H), 3.12 (s, 24H), 3.66 (s, 6H), 3.75 (s, 12H); *meta*-H: 5.34 (br, 2H), 5.80 (br, 8H), 6.13 (br, 2H). ^{31}P$\{^1$H$\}$ NMR (300 MHz, δ ppm in $CDCl_3$), −3.07.

$[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**). A solution of CH_3CN (10 ml) and two equivalents of TMPP (0.240 g, 0.450 mmol) was added dropwise to 5 ml of a CH_3CN solution of $[Pt(NCCH_3)_4][BF_4]_2$ (0.120 g, 0.225 mmol) at 0°C. The resulting solution was stirred for 40 min at 0°C and the solvent was removed *in vacuo* to give a pale yellow solid. The solid was recrystallized from CH_2Cl_2 and Et_2O; 73% yield (0.250 g). ^{1}H NMR (δ ppm in CD_3CN): 3.33 (s, 6H, CH_3CN); -OMe: 3.42 (br, 12H), 3.61 (br, 24H), 3.78 (s, 6H), 4.82 (s, 12H); *meta*-H: 6.11 (t, 4H), 6.15 (d, 8H). ^{31}P$\{^1$H$\}$

NMR (300 MHz, δ ppm in CD_3CN), −44.5 (d, $^1J_{PtP}$ = 2422 Hz).

Pt(TMPP-*O*)$_2$ (**4**). An acetone solution (20 ml) containing four equivalents of TMPP (0.600 g, 1.13 mmol) was added dropwise to an acetone solution (10 ml) of $[Pt(NCCH_3)_4][BF_4]_2$ (0.150 g, 0.281 mmol) at 0°C. The resulting solution was stirred for 12 h after which time the solvent was removed by evaporation to give a pale yellow residue. The solid was recrystallized from THF and Et_2O to give a pale yellow solid, which was dissolved in a mixture of THF and Et_2O and filtered through Celite to remove the insoluble methylphosphonium salt, $[CH_3\text{-TMPP}][BF_4]$. The volume of the filtrate was reduced under vacuum and the resulting yellow product was washed with Et_2O and dried *in vacuo*, 58% yield (0.201 g). X-ray quality single crystals of Pt(TMPP-*O*)$_2$ were obtained from a solution of the compound in EtCN and Et_2O at 0°C. ^{1}H NMR (δ ppm in CD_3CN), -OMe: 3.40 (s, 6H), 3.58 (s, 24H), 3.69 (s, 6H), 3.82 (s, 12H); *meta*-H: 5.58 (d-d, 2H), 5.81 (d-d, 2H), 6.15 (d, 8H). $^{31}P\{^1H\}$ NMR (300 MHz, δ ppm in CD_3CN), 24.9 (d, $^1J_{PtP}$ = 1950 Hz). Anal. Calcd for $PtP_2C_{54}O_{18}H_{66}B_2F_8$: C, 50.61; H, 4.90. Found: C, 49.57; H, 5.05.

PtCl(TMPP)(TMPP-*O*) (**5**). A mixture of $PtCl_2(NCC_6H_5)_2$ (0.150 g, 0.318 mmol) and TMPP (0.33 g, 0.636 mmol) were loaded in a Schlenk flask, dissolved in 30 ml of THF and stirred for 2 days under reduced pressure to remove the CH_3Cl(g) by-product. A pale yellow precipitate and a yellow solution were obtained. The precipitate was discarded, the yellow solution was filtered into a second flask, and the volume of the filtrate was reduced under vacuum. Et_2O was then added to precipitate a pale yellow solid, which was washed with a mixture of acetone and Et_2O to remove trace quantities of $[CH_3\text{-TMPP}]^+$, washed with Et_2O and finally dried under vacuum to yield a pale yellow compound in 40% yield (0.163 g). IR (Nujol, cm^{-1}) ν(Pt-Cl) 326. ^{1}H NMR (δ ppm in CD_3CN), -OMe: 3.28 (s, 3H), 3.38 (s, 30H), 3.58 (s, 3H), 3.75 (s, 9H), 3.77 (br, 6H); *meta*-H: 5.29 (m, 1H), 5.38 (m, 1H), 5.99 (d, 6H), 6.04 (d, 4H). $^{31}P\{^1H\}$ NMR (500 MHz, δ ppm in CD_3CN), −20.47 (dd, $^1J_{PtP}$ = 3212 Hz, $^2J_{PP}$ = 561 Hz), −26.85 (dd, $^1J_{PtP}$ = 2993 Hz, $^2J_{PP}$ = 561 Hz).

X-ray crystallographic studies

Crystallographic data for compounds **1**–**4** were collected on a Rigaku AFC6S diffractometer equipped with monochromated Mo–K_α radiation produced by a 2 kW sealed tube generator. Crystallographic computing for **1**, **3**, and **4** was performed on a VAXSTATION 4000 by using the Texsan crystallographic software package [14]. Computing for **2** was performed on a Silicon Graphics Indigo II workstation using the Texsan and SHELXTL [15] software system. Crystal parameters and basic information pertaining to data collection and structure refinement are summarized in Table 1.

$[Pd(TMPP)_2][BF_4]_2$ (**1**). Single crystals of **1** were grown by slow diffusion of diethyl ether into a CH_2Cl_2 solution of compound **1**. A red crystal of dimensions 0.50 × 0.40 × 0.36 mm was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a cold N_2(g) stream. Least-squares refinement using 21 well-centered reflections in the range $25 \leqslant 2\theta \leqslant 35°$ indicated an orthorhombic crystal system. The data were collected at −110 ± 1°C using the ω-2θ scan technique to a maximum 2θ value of 47°. A total of 4837 reflections was collected, of which 4181 data with $I > 0.01\sigma(I)$ were used for F^2 refinement, and 3298 data with $I > 3.00\sigma(I)$ were used for F refinement. An empirical absorption correction based on azimuthal scans of three reflections near $\chi = 90°$ was applied which resulted in transmission factors ranging from 0.92 to 1.00. The data were corrected for Lorentz and polarization effects. The space group was determined to be $Pna2_1$ based on the observed systematic absences. The structure was solved by the MITHRIL [16] program, and subsequent cycles of DIRDIF [17] were used to locate the atom positions for full-matrix least-squares refinement. The phenyl rings of the TMPP ligands were refined isotropically for the F^2 refinement and treated as rigid groups for the F refinement to reduce the number of parameters. F^2 refinement of 585 parameters resulted in residuals of $R = 0.075$ and $R_w = 0.101$, while refinement on F of 433 parameters resulted in residuals of $R = 0.057$ and $R_w = 0.074$. Attempts to solve the structure in the higher symmetry space group *Pnma* (#62) were unsuccessful. Both enantiomorphs of the noncentrosymmetric space group $Pna2_1$ (#33) were refined, but no statistically significant difference in the residuals R and R_w (0.0751, 0.1009 for #62 and 0.0750, 0.1009 for #33) were observed.

Pd(TMPP-*O*)$_2$·3.73CH_2Cl_2·H_2O (**2**)·3.73CH_2Cl_2·H_2O. Single crystals of **2** were grown by a slow diffusion of diethyl ether into a CH_2Cl_2 solution of compound **2**. An orange crystal of dimensions 0.98 × 0.40 × 0.22 mm was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a cold N_2(g) stream. Least-squares refinement using 25 well-centered reflections in the range $15.0 \leqslant 2\theta \leqslant 22.3°$ indicated that the crystal is consistent with an orthorhomic crystal system. The data were collected at −85 ± 1°C using the ω-2θ scan technique to a maximum 2θ value of 47°. Of the 10,169 reflections that were collected, 815 were systematically absent. An empirical absorption correction based on azimuthal scans of three reflections with χ near 90° was applied which resulted in transmission factors ranging from 0.55–1.00. The data were corrected for Lorentz and polarization effects. The structure was solved in the space group *Pbcn* using the MITHRIL [16] and DIRDIF [17] structure solution programs and refined by full-matrix least-squares refinement on F [15]. Methoxy methyl groups centered about atoms

[a] $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$.
[b] $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/s^2(|F_o|)$.
[c] $wR2 = [S[w(F_o^2 - F_c^2)^2]/S[w(F_o^2)^2]]^{1/2}$.
[d] Goodness-of-fit = $[Sw(|F_o| - |F_c|)^2/(N_{obs} - N_{parameter})]^{1/2}$.

C39, C47, and C48 were found to be disordered, and each was refined isotropically as twin methyl groups, A and B, with a combined occupancy of 1.0 and with restraints on C—O and C···C. All other non-hydrogen atoms were refined anisotropically, except for solvent molecules. Treatment of the dichloromethane molecules is described in the following section. The final full-matrix least-squares refinement was based on 9199 reflections that were used to fit 774 parameters with 540 restraints to give $R_1 = 0.1065$ and $wR_2 = 0.2598$. The goodness-of-fit index was 1.030, and the maximum shift in the final difference map was 0.002 $Å^3$ associated with C173. After convergence, the mean shift/ESD was 0.006 and the highest peak in the difference Fourier map was 1.16 e $Å^{-3}$ which is associated with the solvent molecule containing C172.

Dichloromethane molecules were located using electron density difference maps generated using the SHELXTL software package [15]. The disordered CH_2Cl_2 molecules were modeled with restraints on the C—Cl and C···Cl distances. All C—Cl bond distances were constrained to 1.79 Å. Occupancies were also refined, resulting in a total of 3.73 dichloromethane molecules per Pd atom. An additional isolated atom was added as the oxygen of a water molecule and refined isotropically.

$[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**). Single crystals of **3** were grown by slow diffusion of diethyl ether into a solution of **3** in acetone and CH_2Cl_2. A pale yellow crystal of dimensions $0.30\times0.44\times0.30$ mm^3 was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a cold N_2(g) stream. Least-squares refinement using 21 well-centered reflections in the range $20 \leqslant 2\theta \leqslant 26°$ indicated a triclinic crystal system. The data were collected at -100 ± 1°C using the ω-2θ scan technique to a maximum 2θ value of 47°. Of the 9951 reflections that were collected, 9519 were unique. An empirical absorption correction based on azimuthal scans of three reflections with χ near 90° was applied which resulted in transmission factors ranging from 0.84 to 1.00. The data were corrected for Lorentz and polarization effects. The structure was solved in the space group $P\bar{1}$ with the program PHASE [18] followed by DIRDIF [17] structure solution programs and refined by full-matrix least-squares refinement. All non-hydrogen atoms were refined anisotropically. The final full-matrix least-squares refinement was based on 7081 observed reflections with $F_o^2 > 3\sigma(F_o^2)$ that were used to fit 820 parameters to give $R = 0.036$ and $R_w = 0.045$. The goodness-of-fit index was 1.64, and the highest peak in the final difference map was 1.59 e $Å^{-3}$ which is associated with the $[BF_4]^-$ counterion.

Pt(TMPP-*O*)$_2$·3EtCN (**4**)·3EtCN. A pale yellow crystal of dimensions $0.36\times0.36\times0.27$ mm^3 was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a cold N_2(g) stream. Least-squares refinement using 21 well-centered reflections in the range $20 \leqslant 2\theta \leqslant 24°$ indicated that the crystal belonged to a monoclinic crystal system.

The data were collected at -100 ± 1°C using the ω-scan technique to a maximum 2θ value of 47°. Of the 9900 reflections that were collected, 9420 were unique and were corrected for Lorentz and polarization effects. The space group was determined to be $P2_1/c$ based on the observed systematic absences. An empirical absorption correction based on azimuthal scans of three reflections with χ near 90° was applied which resulted in transmission factors ranging from 0.95 to 1.00. The structure was solved and developed with the use of the MITHRIL [16] and DIRDIF [17] structure solution programs and refined by full-matrix least-squares refinement. All non-hydrogen atoms were refined anisotropically, with the final cycle being based on 6082 observed reflections with $F_o^2 > 3\sigma(F_o^2)$ that were used to fit 766 parameters to give $R = 0.042$ and $R_w = 0.047$. The goodness-of-fit index was 1.39 and the highest peak in the final difference map was 0.85 e Å^{-3}.

RESULTS AND DISCUSSION

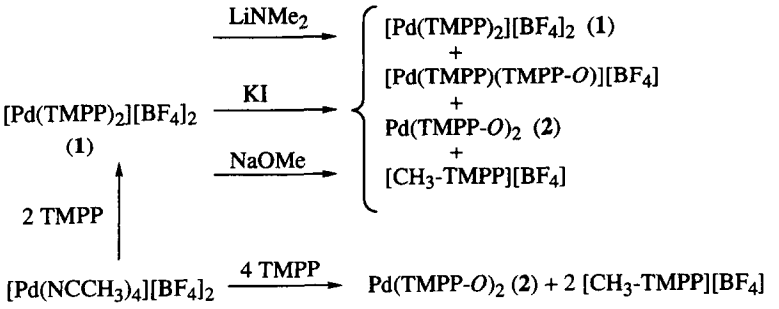
Preparation of Pd^{II} TMPP complexes

The unusual brick-red compound $[Pd(TMPP)_2][BF_4]_2$ (**1**) is readily prepared from $[Pd(NCCH_3)_4][BF_4]_2$ and two equivalents of TMPP in acetone. This compound is thermally unstable in solution, however, and readily converts to the phenoxide derivative Pd(TMPP-*O*)$_2$ (**2**) where TMPP-*O* refers to the mono-demethylated derivative of TMPP. The demethylation reaction is accelerated in the presence of excess TMPP which acts as a nucleophile to react with the electrophilic methoxy groups associated with the metal. This type of decomposition reaction has been previously documented in the analogous Rh, Co and Ni compounds [3b,g,i,l], as well as in the chemistry of TMPP with Rh and Ir olefins [3k]. In an effort to avoid sacrificing TMPP in a rational synthesis of Pd(TMPP-*O*)$_2$, $[Pd(TMPP)_2][BF_4]_2$ was combined with other nucleophiles such as KI, $LiNMe_2$, and NaOMe. Unfortunately, these reactions led to complex mixtures of $[CH_3\text{-TMPP}][BF_4]$, **1** and **2**, as evidenced by ^1H and $^{31}P\{^1H\}$ NMR spectroscopies. Ultimately, compound **2** was obtained in the best yield and in the purest form from the reaction of $[Pd(NCCH_3)_4][BF_4]_2$ with four equivalents of TMPP (75% yield). The reaction of Pd(II) with TMPP are summarized in Scheme 1.

Preparation of Pt^{II} TMPP complexes

The compound $[Pt(TMPP)_2][BF_4]_2$ is obtained from acetone solutions of $[Pt(NCCH_3)_4][BF_4]_2$ that have been treated with two equivalents of TMPP. The product of the same reaction performed in CH_3CN is $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**) as verified by X-ray crystallography. In $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ only two of the original CH_3CN ligands have been replaced with monodentate TMPP molecules; obviously the ether interactions are prevented due to the presence of the more basic CH_3CN ligands.

$PtCl_2(NCC_6H_5)_2$ was found to react with TMPP in the presence of two equivalents of $NaBPh_4$ to yield Pt(TMPP-*O*)$_2$ (**4**), PtCl(TMPP)(TMPP-*O*) (**5**), NaCl, and $[CH_3\text{-TMPP}][BPh_4]$. These reactions are designed to make use of the chloride ligands for dealkylation of the *ortho*-substituted methoxy-phosphines with the liberation of MeX [1a,b,d,f]. Single crystals of Pt(TMPP-*O*)$_2$ (**4**) were obtained by chilling a CH_3CH_2CN/Et_2O solution of the products to 0°C. The presence of **5** suggests that the second *O*-metalation at the remaining chloride ligand is slow and that more forcing conditions are required to drive the reaction to completion. A similar observation was reported by Shaw and co-workers [1a,b,f]. A much higher yield route to Pt(TMPP-*O*)$_2$ is the slow addition of an acetone solution of four equivalents of TMPP to an acetone solution of $[Pt(NCCH_3)_4][BF_4]_2$. The reactions of Pt(II) with TMPP are summarized in Scheme 2.



TMPP = P{$C_6H_2(OCH_3)_3$}$_3$ tris(2,4,6-trimethoxy)phenylphosphine

TMPP-*O* = [P{$OC_6H_2(OCH_3)_2$}{$C_6H_2(OCH_3)_3$}$_2$]$^-$

bis(2,4,6-trimethoxy)phenyl 4,6-trimethoxy-2-phenoxide phosphine

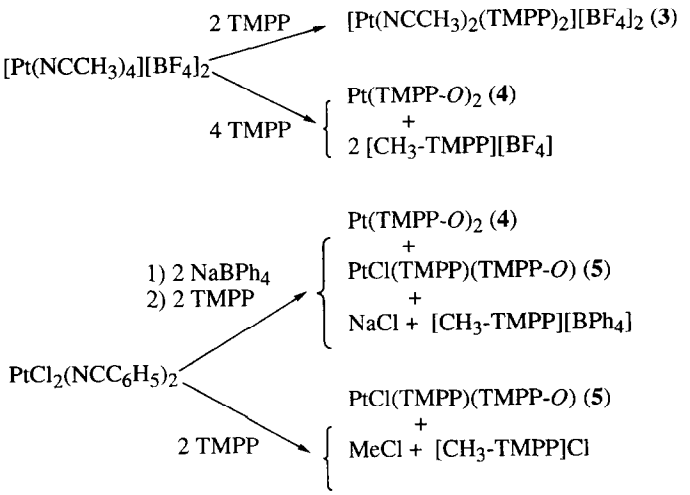

Scheme 2. Reactions of Pt(II) starting materials with TMPP.

Molecular structures of **1** *and* **2**.

ORTEP drawings of the molecular cation of **1** and **2** are displayed in Figs 1 and 2, with selected bond distances and angles provided in Tables 2 and 3. The Pd atom of **1** resides at the center of a pseudo-octahedron defined by P1, P2 and the two ether-oxygen atoms O1 and O10 in an equatorial arrangement; two ether oxygen atoms O4 and O13 occupy axial positions. The deviation of the geometry around the Pd atom from square-planar is evident from the acute angles defined by the five-membered metallacycles Pd1—P1—C1—C2—O1 for which P1—Pd1—O1 = 78.3(2)° and Pd1—P2—C19—C20—O10 for which P2—Pd1—P10 = 78.1(2)°. The average Pd—O_{axial} distance of 2.651 Å is the shortest axial contact reported to data for a Pd(II) compound [19–22]. In comparison, the corresponding distances in $Pd^{II}L_6$

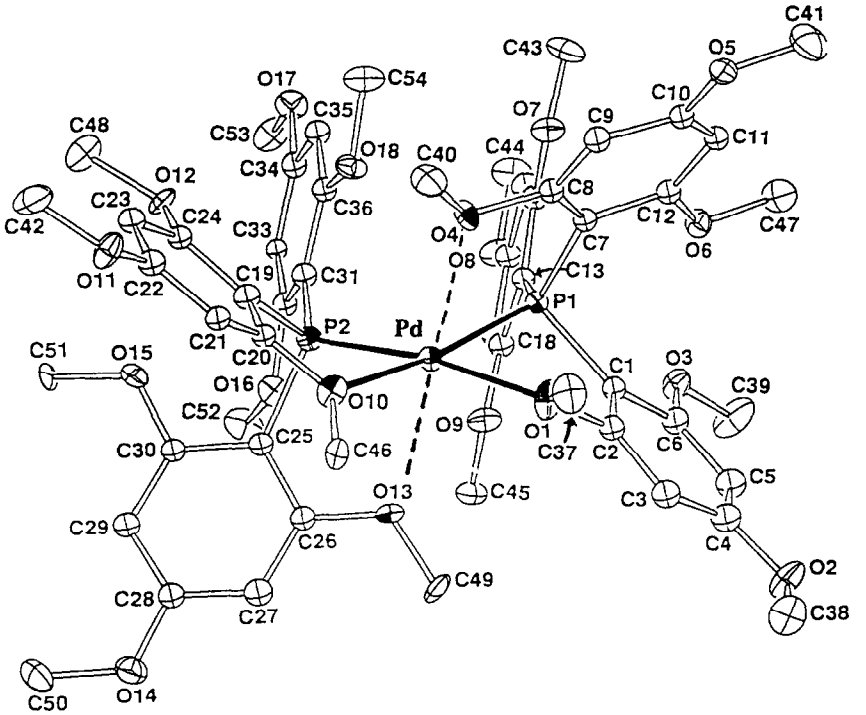

Fig. 1. ORTEP drawing of $[Pd(TMPP)_2][BF_4]_2$ (**1**). Thermal ellipsoids are drawn at the 25% probability level. Hydrogen atoms have been removed for clarity. Selected distances (Å) and angles (°) for **1** can be found in Table 3.

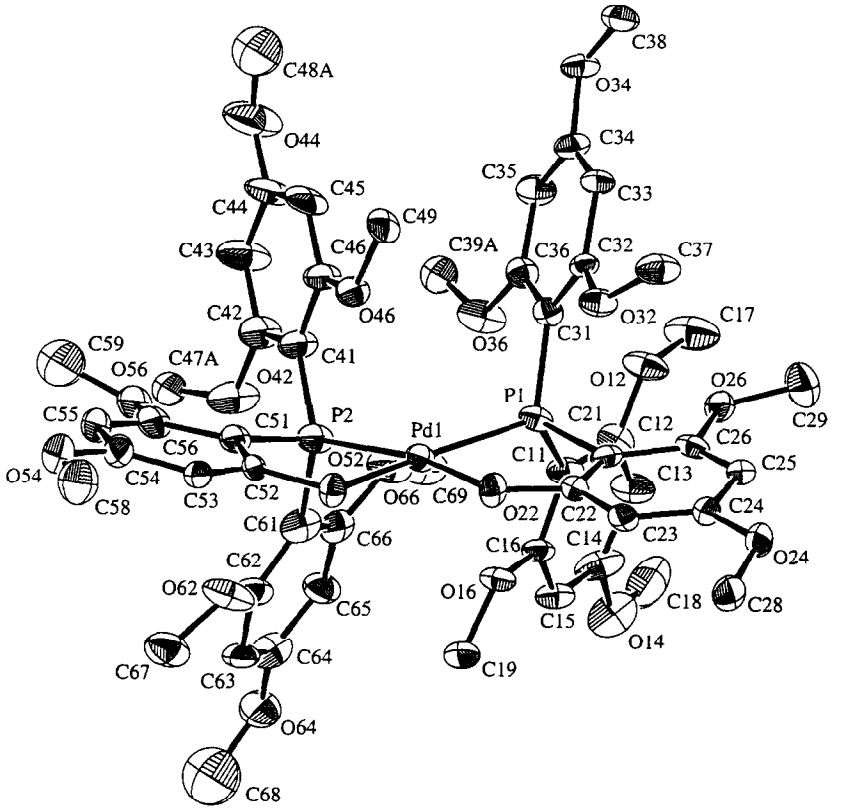

Fig. 2. ORTEP drawing of Pd(TMPP-*O*)$_2$ (**2**). Thermal ellipsoids are drawn at the 25% probability level. Hydrogen atoms have been removed for clarity. Selected distances (Å) and angles (°) for **2** can be found in Table 2.

complexes supported by trigonal (*S,S,S*) or (*S,S,N*) ligands fall in the range 2.95–3.27 Å [21–23]. The geometry about the Pd atom of **2** is square planar, consisting of a *cis* arrangement defined by P1, P2 and the phenoxide oxygen atoms O22 and O52. Ring strain in **2** is evidenced by angles of O22—Pd1—O52 = 81.4(3)°, O52—Pd1—P2 = 84.6(2)°, and P2—Pd1—P1 = 109.4(2)°. Axial ether-oxygen atoms O16 and O46 are at distances of 2.887 and 3.025 Å which are much longer than the analogous interactions in **1**.

Molecular structures of **3** *and* **4**

ORTEP drawings of the compounds $[Pt(NCCH_3)_2(TMPP_2)][BF_4]_2$ (**3**) and Pt(TMPP-*O*)$_2$ (**4**) are presented in Figs 3 and 4, while selected bond distances and angles are provided in Tables 4 and 5, respectively. The coordination number of $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ is four with mutually *trans* monodentate TMPP and CH_3CN ligands. The ⟨P1—Pt1—N1 and ⟨P2—Pt1—N2 angles are 87.0(2)° and 90.3(2)°, respectively, leading to a nearly perfect square planar geometry around the metal center. The *trans* atoms define angles of ⟨P1—Pt1—P2 = 175.67(7)° and ⟨N1—Pt1—N2 = 177.0(3)°. The molecular geometry of Pt(TMPP-*O*)$_2$ consists of a *cis* arrangement of phosphorus and methoxy-oxygen atoms about the metal center and long axial interactions to ether-oxygen atoms. The distortion observed in Pt(TMPP-*O*)$_2$ involves ring strain of the five-membered metallacycles (Pt1—P1—C1—C2—O1 and Pt1—P2—C19—C20—O10) for which the angles are ⟨C2—Pt1—P1 = 84.1(2)° and ⟨O10—Pt1—P2 = 84.2(2)° compared to the η^1-TMPP ligands observed in compound $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**). Free rotation of arene rings on the η^1-TMPP ligands in **3** is effectively blocked by the CH_3CN ligands, which are in the rotational pathway of pendant methoxy groups of TMPP. This is evident in the space filing diagram of the compound depicted in Fig. 5. The solid-state structure is evidently retained in solution as judged by the results of NMR spectroscopy (*vide infra*).

The average Pt—P bond distances in $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ and Pt(TMPP-*O*)$_2$ of 2.356(2) and 2.255(2) Å respectively are similar to those observed in phosphine and phosphite complexes of Pt(II) (2.2 to 2.4 Å) [23]. The η^1-Pt—P bond distances in $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ are longer than those found in Pt(TMPP-*O*)$_2$ which may be due to the chelate effect of the η^2-TMPP ligands in the latter compound and also to the *trans* effect of the TMPP vs the phenoxide ligand. The average Pt—O bond distance of 2.047(5) Å in Pt(TMPP-*O*)$_2$ is longer than the corresponding bond distance reported in the platinum-alkoxide complex, *cis*-$[Pt(PPh_2CH_2CMe_2O)_2]$

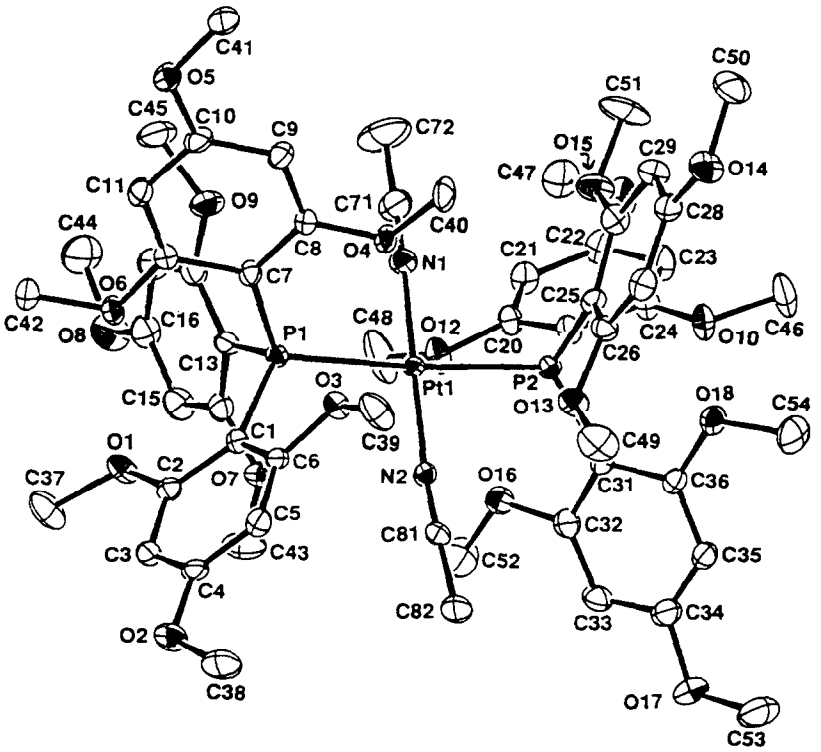

Fig. 3. ORTEP drawing of $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**). Hydrogen atoms have been removed for clarity. Thermal ellipsoids are drawn at the 25% probability level. Selected distances (Å) and angles (°) for **3** can be found in Table 4.

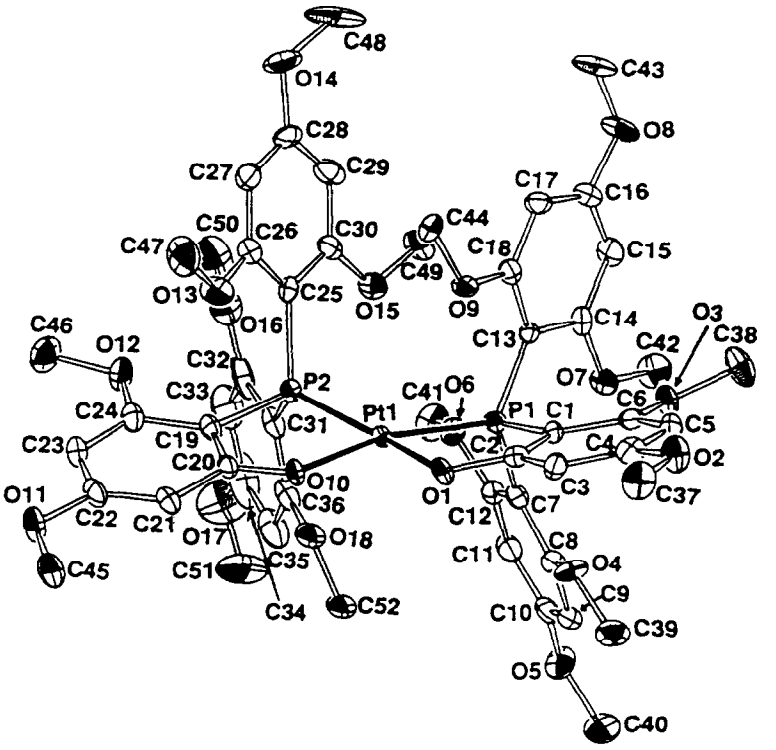

Fig. 4. ORTEP drawing of Pt(TMPP-*O*)$_2$ (**4**). Hydrogen atoms have been removed for clarity. Thermal ellipsoids are drawn at the 25% probability level. Selected distances (Å) and angles (°) for **4** can be found in Table 5.

(2.013(4) Å) [25a] and *cis*-[Pt($Ph_2PCH_2CH_2O$)$_2$]·H_2O (2.039(5) Å) [25b], but shorter than those found in two platinum-ether complexes (2.144(9) Å and 2.192(7) Å) [5f,g]. Axial interactions in the molecule Pt(TMPP-*O*)$_2$ that involve the Pt center and pendant methoxy groups are longer than the sum of the covalent radii of the two atoms (Pt1—O9 = 3.110(5) Å and Pt1—O18 = 3.130(7) Å).

^1H *and* $^{31}P\{^1H\}$ NMR *studies*

Compounds (**1**) *and* (**2**). Variable-temperature ^1H NMR studies of [Pd(TMPP)$_2$][BF_4]$_2$ (**1**) in acetone-d_6 from +20 to −80°C indicate that the TMPP ligands are involved in a fluxional process which is not unusual for these types of complexes [9]. The ^1H NMR spectrum at 20°C contains a broad resonance at 6.3 ppm due to the *m*-protons of the phenyl rings, a sharp resonance at 3.8 ppm assigned to the equivalent *para*-methoxy substituents and a broad signal at 3.6 ppm due to the *ortho*-methoxy substituents. The ^1H NMR spectrum at −80°C contains three resonances between δ = 3.5–6.5 ppm, six distinct resonances in the range δ = 5.60–6.80 ppm assigned to inequivalent *meta* protons, six resonances between δ = 3.30–4.25 ppm due to inequivalent *ortho*-methoxy groups, and one broad resonance at δ = 3.83 ppm due to three *para*-methoxy substituents. This spectrum is consistent with free rotation of the unmetalated aryl groups. A room temperature $^{31}P\{^1H\}$ NMR spectrum of **1** in acetone-d_6 exhibits a single resonance at δ = +1.67 ppm. These data are in accord with the presence of only one type of coordinated phosphine

ligand and support a close relationship between the solution and solid-state structures of the cation. A fluxional process such as this indicates that, for a given phosphine ligand, there are six *ortho*-methoxy oxygen atoms competing for a total of two coordination sites. Such exchange within the coordination sphere is a potentially valuable characteristic for the design of catalytically active complexes.

The ^{1}H NMR spectrum of Pd(TMPP-*O*)$_2$ (**2**) reveals only four distinct features in the methoxy region of the TMPP-*O* ligands between 3.0 and 3.8 ppm, which indicates that the unbound rings on the TMPP ligands are involved in free rotation on the NMR time scale. The Ni(II) analog also behaves in this manner [3i,26]. Two of these four resonances are due to the inequivalent *para* (a) and *ortho* (b) methyl groups of the bonded ring while the other two are due to four equivalent *ortho* (c) and two equivalent *para* (d) methyl groups of the free rings, as depicted in Fig. 6. Three distinct resonances appear in the *meta* proton region of TMPP-*O* ligands between 5.3 and 6.2 ppm. Two of these three resonances are assigned to two inequivalent *meta* protons (1 and 2) of the bonded ring and the third one is attributed to four equivalent *meta* protons (3) of the free rings as indicated on the spectrum. A ^{31}P$\{^1$H$\}$ NMR spectrum of Pd(TMPP-*O*)$_2$ (**2**) in chloroform-d$_1$ at room temperature exhibits a single resonance at $\delta = -3.07$ ppm.

Compounds **3**–**5**. The room temperature ^{1}H NMR spectrum of [Pt(NCCH$_3$)$_2$(TMPP)$_2$][BF$_4$]$_2$ (**3**) (Fig. 7) reveals six distinct resonances in the methoxy region between 3.3 and 3.9 ppm and two resonances in the *meta* proton region between 6.1 and 6.2 ppm due to the TMPP ligands. This pattern indicates that the solution structure of **3** possesses two magnetically inequivalent methoxyphenyl rings which is consistent with the solid-state structure as mentioned earlier. An assignment of the resonances in [Pt(NCCH$_3$)$_2$(TMPP)$_2$][BF$_4$]$_2$ is provided in the inset on the NMR spectrum in Fig. 7. Two rings above and below the plane defined by the three atom sequence P—Pt—P are symmetry related by a mirror plane bisecting the third ring and containing the two phosphorus atoms and the metal center. One singlet at 3.33 ppm is assigned to two CH$_3$CN ligands (a), while the res-

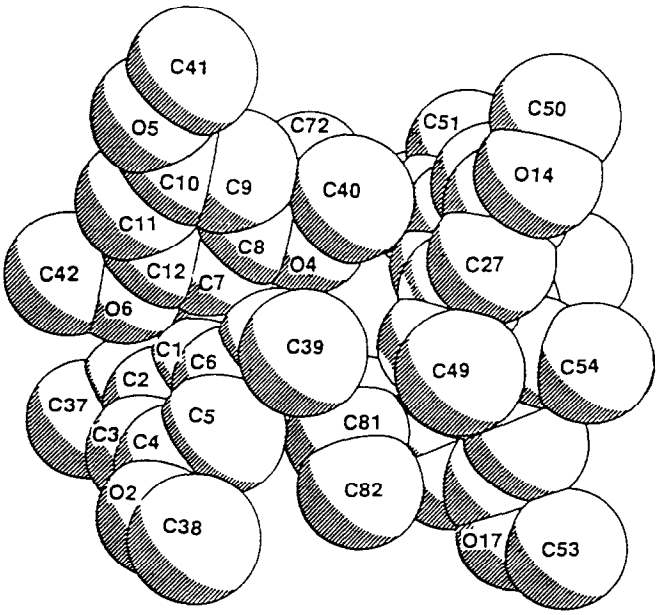

Fig. 5. Space filling diagram of [Pt(NCCH$_3$)$_2$(TMPP)$_2$][BF$_4$]$_2$ (**3**). Hydrogen atoms have been removed for clarity.

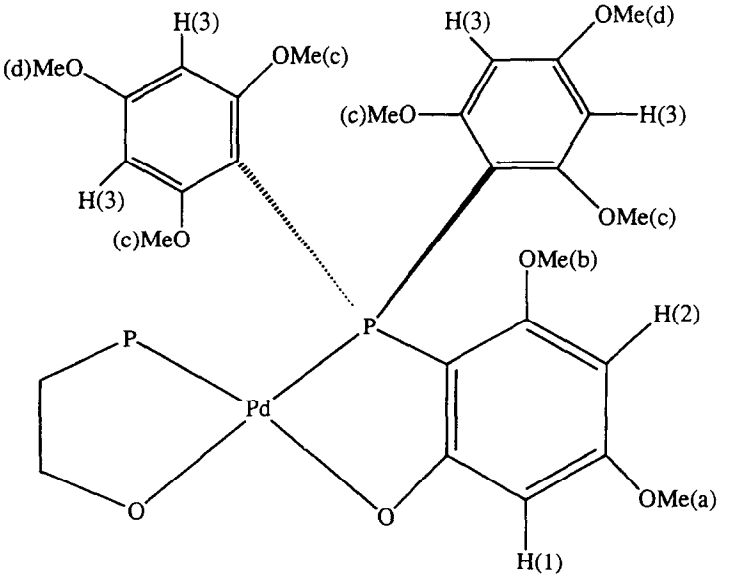

Fig. 6. Illustration of Pd(TMPP-*O*)$_2$ (**2**) with hydrogen atoms labeled. The other half of the molecule is omitted for clarity.

onances at 3.41 and 3.78 ppm are assigned to be the *ortho* (b) and *para* (c) methyl groups on the rings of the TMPP ligands distal from the CH_3CN groups. The two resonances at 3.61 and 3.82 ppm are assigned to the *ortho* (d) and *para* (e) methyl groups on the rings of TMPP ligands proximal to CH_3CN. The triplet and the doublet are attributable to four equivalent *meta* (1) protons on the two distal rings and eight protons (2) on the four proximal phenyl groups rings. The virtual triplet observed in the *meta* proton region of the TMPP ligand is indicative of a *trans* geometry for the two phosphorus atoms, which is supported by the X-ray structure.

The room temperature ^{1}H NMR spectrum of Pt(TMPP-*O*)$_2$ (**4**), shown in Fig. 8, resembles that of Pd(TMPP-*O*)$_2$ and contains four distinct resonances in the methoxy region of the TMPP-phenoxide ligands between 3.3 and 3.9 ppm. This indicates that the unbound rings of the TMPP ligand are free to rotate which has also been observed in the Ni(II) [3i,26] and

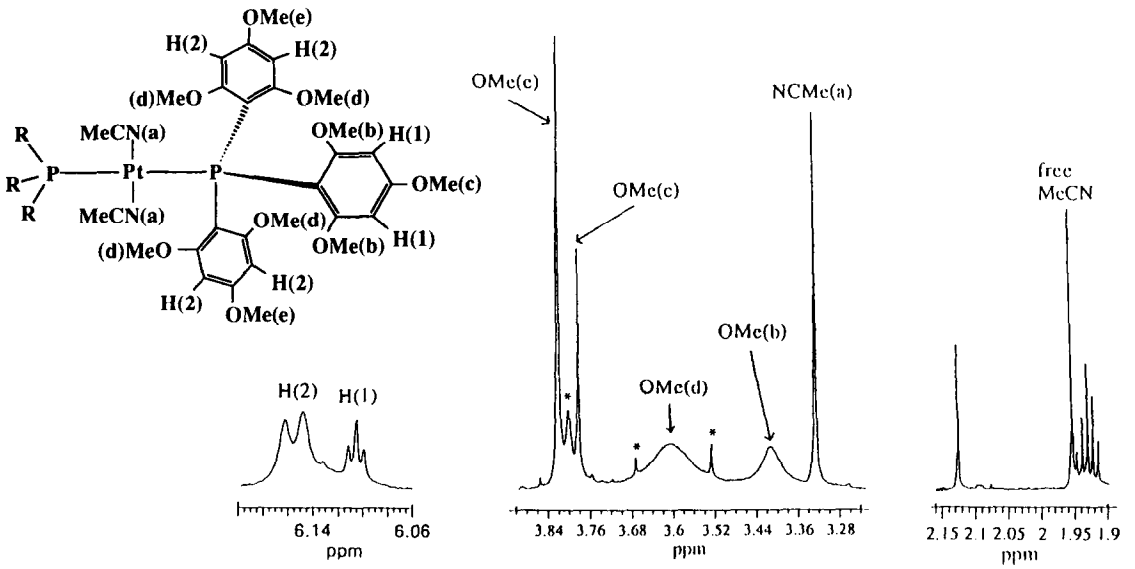

Fig. 7. Room temperature ^{1}H NMR spectrum of [Pt(NCCH$_3$)$_2$(TMPP)$_2$][BF$_4$]$_2$ (**3**). (*) Signals due to demethylation products that are always present in small quantities.

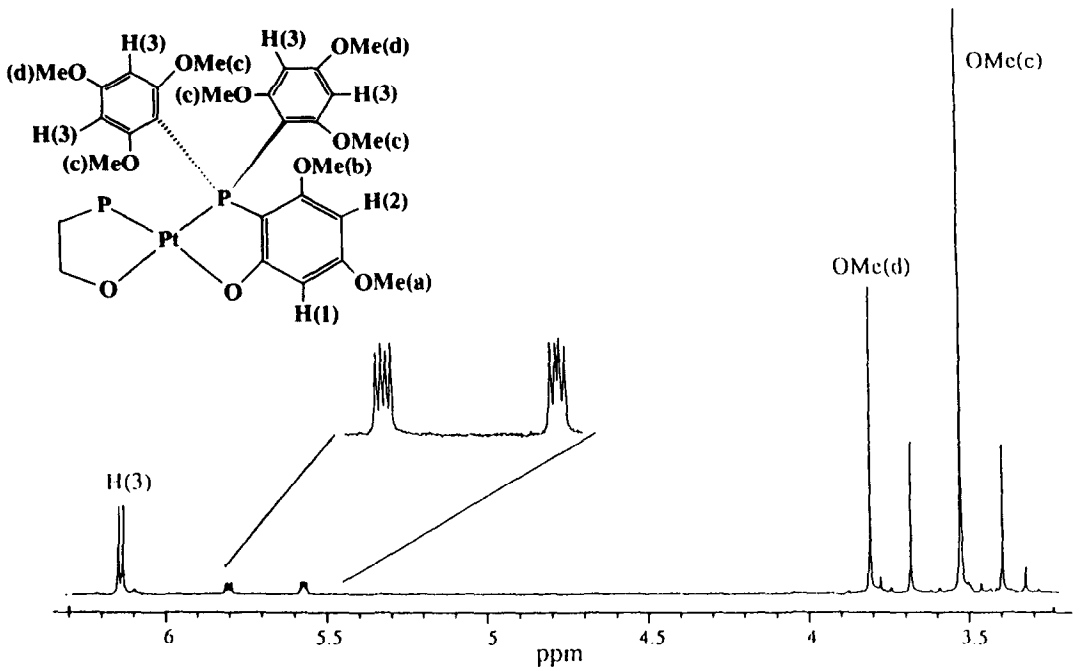

Fig. 8. Room temperature ^{1}H NMR spectrum of Pt(TMPP-*O*)$_2$ (**4**) in acetonitrile-d$_3$.

Pd(II) analogues [3j]. Two of these four resonances are due to the inequivalent *ortho* and *para* methyl groups of the bonded ring and the other two are due to four equivalent *ortho* and two equivalent *para* methyl groups of the free rings. Three distinct resonances occur in the *meta* proton region between 5.5 and 6.2 ppm. Two of these three resonances are due to two inequivalent *meta* protons of the bonded ring and the last one is due to four equivalent *meta* protons of the free rings. A ^{31}P{^{1}H} NMR spectrum of Pt(TMPP-*O*)$_2$ in acetonitrile-d$_3$ at room temperature exhibits a single resonance at $\delta = -24.97$ ppm with a coupling constant $^1J_{Pt\text{-}P}$ of 1950 Hz, which is in the range of values reported in the literature for *cis* phosphine ligands [23]. Despite the increased electron density at the metal center in the neutral compound **4**, the ^{31}P spectrum exhibits a downfield shift as compared to $\delta = -44.5$ ppm for the dicationic complex **3**. Such a shift can be explained by ring contributions from the formation of five-membered rings [24]. These NMR data are in accord with the presence of two types of unsymmetrically coordinated rings of the TMPP ligand.

The room temperature ^{1}H NMR spectrum of PtCl(TMPP)(TMPP-*O*) (**5**) (Fig. 9) reveals five resonances in the methoxy region of the TMPP and TMPP-*O* ligands between 3.2 and 3.9 ppm. These data indicate that the unbound rings of the bidentate TMPP ligand are involved in free rotation. Two of these five resonances are due to the inequivalent *ortho* (a) and *para* (b) methoxy groups of the bonded ring of the TMPP-*O* moiety, while a second set are due to the *para* (c and d) methoxy groups on the free rings of the TMPP and TMPP-*O* ligands. Integration requires the fifth resonance to be an overlap of *ortho* (e) methoxy groups on the free rings of both the TMPP and TMPP-*O* ligands. Four distinct features in the *meta* proton region of TMPP and TMPP-*O* ligands appear between 5.3 and 6.1 ppm. Two multiplets at 5.29 and 5.38 pm are due to the two *meta* (H1 and H2) protons of the bonded ring of the TMPP-*O* moiety, while a doublet at 6.04 ppm is attributed to four *meta* (H3) protons of the free rings. The final doublet at 5.99 ppm is assigned to six equivalent *meta* (H4) protons of the η^1-TMPP ligand. A ^{31}P{^{1}H} NMR spectrum of **5** in acetonitrile-d$_3$ at room temperature exhibits an ABX second-order pattern with satellites, indicating the presence of two inequivalent phosphorus atoms coupled to ^{195}Pt ($I = 1/2$, 33% abundance) [1a–c,23]. Successful simulation of this spectrum was obtained by first simulating the ABX splitting pattern which gave the satellite positions, followed by simulation of the AB P_A—P_B coupling. These two simulations were then combined with appropriate weighting of the satellite intensities. The best fit was achieved with chemical shift values of P_A, $\delta = -20.48$ ppm, P_B, $\delta = -26.39$ ppm and coupling constants of ^1J(Pt—P_A) = 3212 Hz, ^1J(Pt—P_B) = 2993 Hz and ^2J(P_A—P_B) = 561 Hz (Fig. 9). These NMR data are in accord with the molecular geometry depicted in Fig. 10 wherein one neutral TMPP ligand is coordinated in an η^1 fashion and a demethylated TMPP group is bound as an η^2-P,O ligand with *trans* P atoms (deduced from the large magnitude of ^2J(P_A—P_B)), a phenoxide O and a Cl$^-$ ion in a square plane.

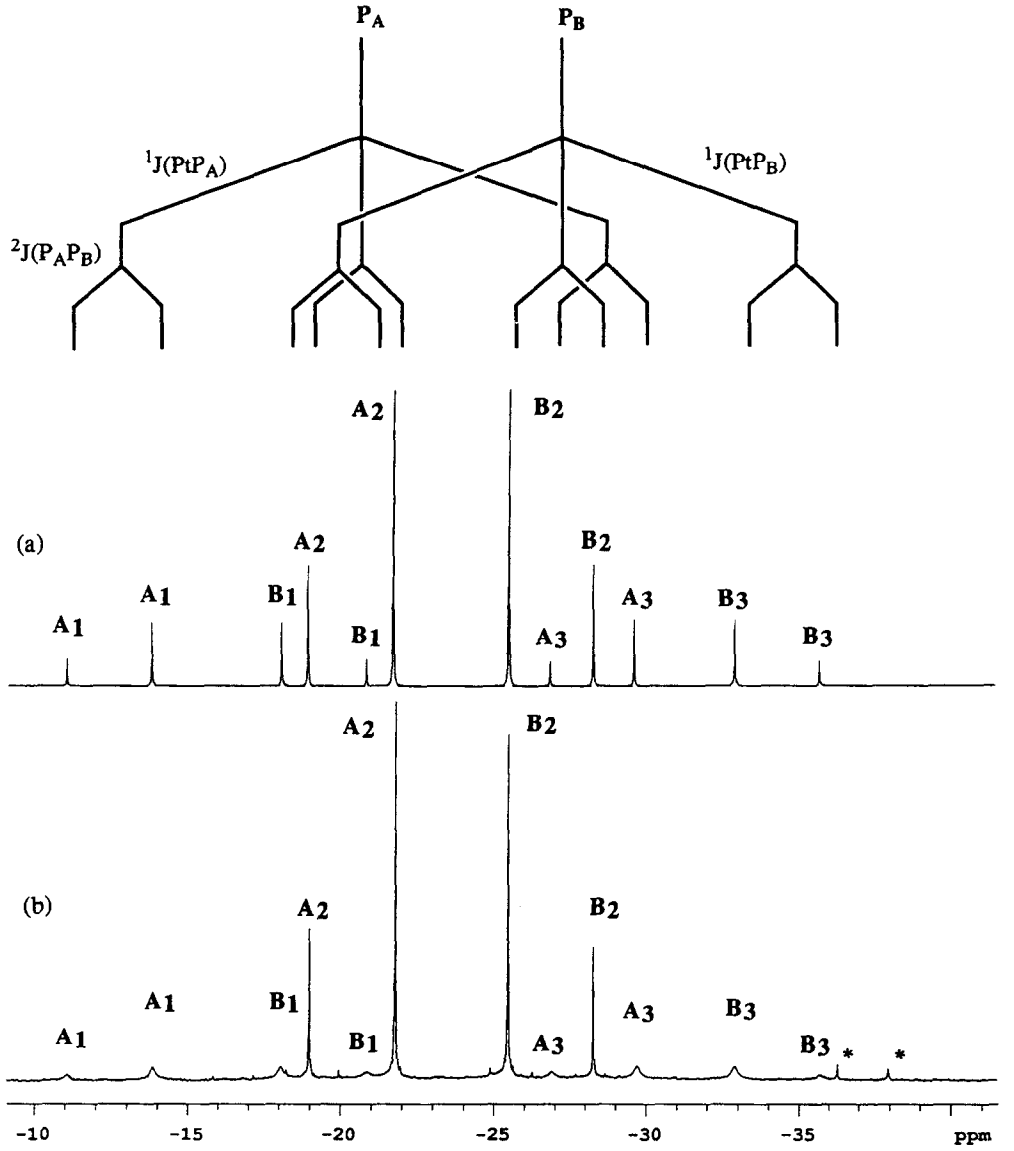

Fig. 9. The splitting diagram for (a), calculated and (b) experimental $^{31}P\{^1H\}$ NMR spectrum of PtCl(TMPP)(TMPP-*O*) (**5**) in acetonitrile-d_3 at room temperature. (*) Signals due to demethylation products that are always present in small quantities.

CONCLUSIONS

Reactions of divalent palladium and platinum complexes with 2,4,6-tris(trimethoxyphenyl)phosphine lead to the formation of new phosphinoether and phosphinophenoxide compounds including a six-coordinate Pd(II) complex possessing the shortest axial contacts reported in the literature to date. Unlike most other P,O chelates reported in the literature, the TMPP ligand appears to be sufficiently flexible to adopt a myriad of bonding modes. This point is well-demonstrated by the observed hapticity changes of TMPP from monodentate in $[Pt(NCCH_3)_2(TMPP)_2][BF_4]_2$ (**3**) to bidentate in Pd(TMPP-*O*)$_2$ (**2**) and Pt(TMPP-*O*)$_2$ (**4**) to tridentate in $[Pd(TMPP)_2][BF_4]_2$ (**1**). The results of this study, taken together with the data obtained in earlier investigations, support the conclusion that homoleptic TMPP complexes of the platinum group metals are fairly unstable due to electrophilic reactions of the coordinated methoxy groups that lead to phenoxide formation. It appears that the TMPP phosphine molecule itself is the most useful demethylation reagent for the high-yield preparation of the demethylated compounds M(TMPP-*O*)$_2$ (M = Pd, Pt), with other nucleophiles being much less specific in their reactions with $[M(TMPP)_2]^{2+}$ species. The fluxional nature of $[Pd(TMPP)_2][BF_4]_2$ allows for the *in situ* formation of open coordination sites which

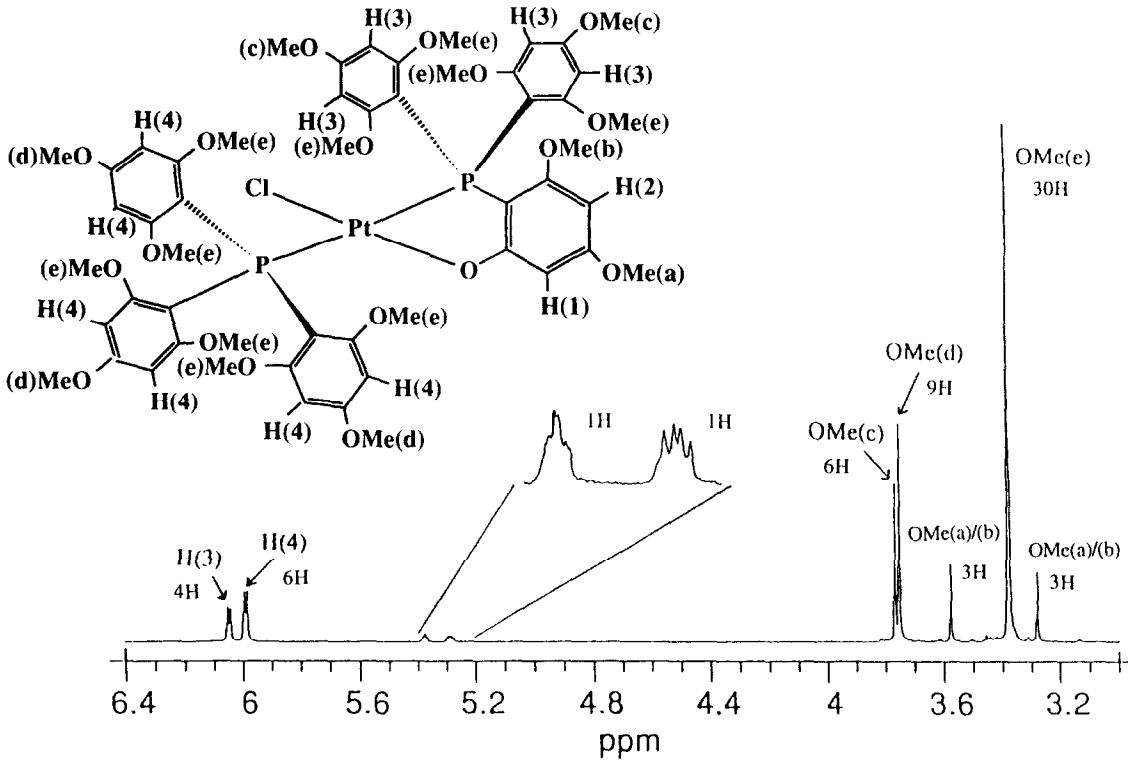

Fig. 10. Room temperature ^{1}H NMR spectrum of PtCl(TMPP)(TMPP-*O*) (**5**) in acetonitrile-d_3.

opens up the potential for small molecule activation or catalytic activity, possibilities that are currently being explored.

(Received 28 July 1997; accepted 21 October 1997)

Abstract—Palladium(II) and platinum(II),(IV) complexes with N^1-acylacetamidrazones (**L1–L5**) and N^1-acyl-2-phenylacetamidrazones (**L6–L9**) are described. The complexes have been prepared by reaction of the corresponding metal chloride with the ligand in the required stoichiometrical ratio and were characterized by chemical analyses and physical measurements. The stereochemistry has been assigned on the basis of IR, far IR spectroscopy, electronic reflectance spectra and molar conductivity values. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: palladium(II) chloride; platinum(II),(IV) chloride; N^1-acylacetamidrazone ligands; complexes; synthesis.

The amidrazones RC(=NH)NHNHR′ (R, R′ = H, alkyl, aryl) have been studied very little as ligands of transition metals [1]. Some published results are available on the structure and catalytic activity of nickel(II) and copper(II) complexes with amidrazones [2], and the structure of cobalt(II) complexes with N^1-aryl-substituted arylamidrazones [3]. Furthermore in the literature were found only the X-ray structure for two novel oxopersulphidoamidrazone tungstate complexes $WO(S_2)_2$[RC(=NH)NHNH] where R = CH_3, C_2H_5 [4]; in the molecular structures the tungsten atom is coordinated by a terminal oxoligand, to two persulphido S_2^{2-} ligands and one bidentate amidrazone ligand. The coordination polyhedron of the tungsten atom is pentagonal bipyramidal, whose two axial ligands are formed by terminal oxoatom and the *N*(H) coordinating atom of the NHNH in amidrazone [4].

The antibacterial activity of first transition metals complexes with picolinamidrazones derivatives [5] and the antibacterial and antitumoral activities of platinum(II) complexes with N^1-phenylsubstituted amidrazones [6] have been also reported.

While, as far as the acetamidrazone complexes are concerned, at the best of our knowledge no references are available. The amidrazones were previously utilized by us in the synthesis of potential biologically active heterocyclic compounds. For example N^1-acetylacetamidrazone **L1**, N^1-ethoxycarbonylacetamidrazone **L2** and N^1-ethoxycarbonyl-2-phenylacetamidrazone **L6** were used as starting materials for the synthesis of imidazole derivatives that have shown a moderate antimicrobial activity [7,8].

EXPERIMENTAL

Solvents and reagents were purified according to standard laboratory techniques.

Microanalysis were carried out with a Fisons EA 1108 elemental analyser.

The IR spectra were recorded in the 4000–180 cm^{-1} range with a Perkin–Elmer mod. 983; the near IR spectra were recorded in KBr pellets, while the far IR spectra were recorded in Nujol mulls (CsI). The electronic reflectance spectra were recorded with a Varian Cary 5 in the 50,000–15,000 cm^{-1} range.

The conductivity measurements were carried out with a WTW, LBR model, conductance bridge at 25°C for 10^{-3} M solution in DMF.

The ^{1}H NMR spectra of ligands and complexes were taken in DMSO-d_6 solution with a Varian Unity

* Author to whom correspondence should be addressed.

300 spectrometer. The chemical shifts are given in ppm relative to TMS as internal standard. The ^{1}H NMR spectra of the complexes, taken in DMSO-d_6 solution showed no signals due to the complexes, probably because the DMSO substituted the ligand in the complexes. It was not possible to register the ^{1}H NMR spectra of the complexes in $CDCl_3$ since they are insoluble in this solvent.

The mass spectra of the complexes were taken via the solid inlet from solid samples in glass capillary sealed on the other end with excitations energies 16–70 eV with a Fisons QMD 1000 spectrometer in EI mode. Unfortunately the molecular peak of all the complexes was not obtained even though the conditions for the mass spectral measurements were varied. Typical by the mass spectra of all complexes were mainly those of the corresponding N^1-acylacetamidrazone ligand.

The N^1-acetyl-,N^1-ethoxycarbonyl- and N^1-benzoylacetamidrazones (**L1, L2, L6**) were prepared according to established procedures [9].

Synthesis of N^1-benzoylacetamidrazones (**L3–L5, L7–L9**)

A mixture of ethyl acetimidate derivative (0.01 mol) and the appropriate acylhydrazine (0.01 mol) in 50 ml of anhydrous ethanol was heated at 70–75 °C for 1–2 min and then kept at room temperature for one night. The precipitate was collected by filtration, throughly washed with ethyl ether and recrystallized from the solvent indicated below.

N^1-benzoylacetamidrazone (**L3**) was obtained from ethylacetimidate and benzoyl hydrazine in 87% yield; M.p. 163–165°C (ethanol); Found: C, 61.0; H, 6.3; N, 23.6%. Calc. for $C_9H_{11}N_3O$: C, 61.0; H, 6.2; N, 23.6%.

^{1}H NMR (DMSO-d_6): δ 1.91 (s, 3H, CH_3), 6.22 (br s, 2H, NH_2), 7.37, 7.88 (m, 5H, Ar), 9.66 (br s, 1H, NH).

N^1-(4-methylbenzoyl)acetamidrazone (**L4**) was obtained from ethylacetimidate and 4-methylbenzoyl hydrazine in 78% yield; M.p. 185 °C (ethanol); Found: C, 62.7; H, 6.9; N, 21.5%. Calc. for $C_{10}H_{13}N_3O$: C, 62.8; H, 6.8; N, 21.5%.

^{1}H NMR (DMSO-d_6): δ 1.92 (s, 3H, CH_3), 2.30 (s, 3H, CH_3), 6.27 (br s, 2H, NH_2), 7.15, 7.77 (m, 4H, Ar), 9.65 (br s, 1H, NH).

N^1-(4-chlorobenzoyl)acetamidrazone (**L5**) was obtained from ethylacetimidate and 4-chlorobenzoyl hydrazine in 86% yield; M.p. 180 °C (ethanol); Found: C, 51.0; H, 4.7; N, 20.0%. Calc. for $C_9H_{10}ClN_3O$: C, 51.1; H, 4.8; N, 20.0%.

^{1}H NMR (DMSO-d_6): δ 1. (s, 3H, CH_3), 6.31 (br s, 2H, NH_2), 7.36, 7.96 (m, 4H, Ar), 9.84 (br s, 1H, NH).

N^1-benzoyl-2-phenylacetamidrazone (**L7**) was obtained from ethyl phenylacetimidate and benzoyl hydrazine in 82% yield; M.p. 175–6 °C (ethanol); Found: C, 71.2; H, 6.0; N, 16.9%. Calc. for $C_{15}H_{15}N_3O$: C, 71.1; H, 6.0; N, 16.6%.

^{1}H NMR (DMSO-d_6): δ 3.49 (s, 2H, CH_2), 6.33 (br s, 2H, NH_2), 7.30, 7.86 (m, 10H, Ar), 9.74 (br s, 1H, NH).

N^1-(4-methylbenzoyl)-2-phenylacetamidrazone (**L8**) was obtained from ethyl phenylacetimidate and 4-methylbenzoyl hydrazine in 70% yield; M.p. 170–72 °C (acetonitrile); Found: C, 71.7; H, 6.4; N, 15.7%. Calc. for $C_{16}H_{17}N_3O$: C, 71.9; H, 6.4; N 15.7%.

^{1}H NMR (DMSO-d_6): δ 2.30 (s, 3H, CH_3), 3.47 (s, 2H, CH_2), 6.38 (br s, 2H, NH_2), 7.30, 7.75 (m, 9H, Ar), 9.68 (br s, 1H, NH).

N^1-(4-chlorobenzoyl)-2-phenylacetamidrazone (**L9**) was obtained from ethyl phenylacetimidate and 4-chlorobenzoyl hydrazine in 70% yield; M.p. 180 °C (ethanol); Found: C, 62.8; H, 5.0; N, 14.7%. Calc. for $C_{15}H_{14}ClN_3O$: C, 62.6; H, 4.9; N, 14.6%.

^{1}H NMR (DMSO-d_6): δ 3.66 (s, 3H, CH_2), 6.40 (br s, 2H, NH_2), 7.30, 7.93 (m, 9H, Ar), 9.93 (br s, 1H, NH).

Synthesis of the palladium(II) complexes

A mixture of the $PdCl_2$ (0.18 g, 1 mmol) and the ligand in the appropriate stoichiometrical ratio was heated for 48 h at reflux in the solvent indicated below. The **A1, A6** complexes were prepared in ethanol using ligand and salt in 3 : 1 ratio. The palladium complexes with amidrazones **L3–L5** and **L7–L9** were prepared in acetone, using ligand and salt in 2 : 1 ratio.

$Pd(L1)_2Cl_2$ (**A1**). To an ethanolic solution (10 ml) of $PdCl_2$ (0.18 g, 1 mmol) N^1-acetylacetamidrazone (**L1**) (0.24 g, ~2 mmol) was added and the resulting mixture was heated at reflux with stirring for 6 h. The formed precipitate was collected by filtration, washed with hot ethanol (5 ml) and dried *in vacuo* over P_4O_{10}. Yield: 0.20 g, 50%.

Synthesis of the platinum(II) complexes

A mixture of the $PtCl_2$ (0.27 g, 1 mmol) and the ligand (3 mmol) was heated for 6 h at reflux in the acetone. The complex **B1** was prepared in ethanol utilizing ligand and salt in 2 : 1 ratio.

$[Pt(L3)_2 \cdot L3 \cdot 2H_2O$ (**B3**). To a Me_2CO solution (20 ml) of $PtCl_2$ (0.27 g, 1 mmol) N^1-benzoylacetamidrazone (**L1**) (0.24 g, ~2 mmol) was added and the resulting mixture was refluxed for 6 h. The formed precipitate was filtered off, washed with hot Me_2CO (10 ml) and dried *in vacuo* over P_4O_{10}. Yield: 0.3 g, 65%.

Synthesis of the platinum(IV) complexes

$Pt(L2)_2Cl_4$ (**B2**). To a Me_2CO solution (20 ml) of $PtCl_4$ (0.34 g, 1 mmol) N^1-ethoxycarbonyl-

acetamidrazone (**L2**) (0.3 g, ~2 mmol) was added and the resulting mixture was refluxed for two days. The formed precipitate was filtered off, washed with hot Me_2CO (10 ml) and dried *in vacuo* over P_4O_{10}. Yield: 0.19 g, 30%.

RESULTS AND DISCUSSION

In this work we describe the preparation of N^1-acylacetamidrazones (**L1–L5**) and N^1-acyl-2-phenylacetamidrazones (**L6–L9**) and their complexes with Pd(II), Pt(II) and Pt(IV) (Scheme and Figure 1).

The synthesis of acetamidrazones was carried out in mild conditions. Short heating of a mixture of acetimidates and acylhydrazines in ethanol gave high yield of **L1–L9** at almost pure state. The ^1H NMR data, recorded in DMSO-d_6 solution, provide evidence for only an amide hydrazone tautomeric species. The complexes were prepared by heating at reflux the salts and an excess of acetamidrazones. A variety of experimental conditions were tested changing the solvent and the ligand/salt ratio. Depending on reaction conditions and on starting compounds, ionic or neutral complexes were obtained.

For **L1, L2** and **L6** we isolated complexes of formula $M(L)_2Cl_2$ where M = Pd(II), Pt(II) and $Pt(L)_nCl_4$; $n = 2, 4$. For **L3–L5, L7–L9** we have obtained complexes of the type $Pt(L)_2 \cdot L \cdot mH_2O$; while for **L3–L5** and **L7** we have isolated $Pd(L)_2 \cdot mH_2O$ complexes and for **L8** and **L9,** also $Pd(L)_2Cl_2 \cdot mH_2O$ type complexes, where $m = 0–2$, were isolated.

For the formation of complexes $Pt(L)_3 \cdot mH_2O$ and $Pd(L)_2 \cdot mH_2O$ without halogens, we can hypothesize that in these reactions HCl is free and that metal ions are coordinated with two anionic ligands.

To establish the coordination behaviour of the ligands and the stereochemistry of the complexes, all the isolated complexes have been studied by infrared, electronic reflectance spectra and by conductivity molar measurements in DMF.

Analytical and physical data of the complexes are reported in Table 1. These compounds are microcrystalline and/or powderlike, coloured from yellow to deep brown, generally soluble in DMF or DMSO and insoluble in other organic solvents. All the attempts made for recrystallize our palladium(II) and platinum(II), (IV) complexes for a X-ray structural investigation were unsuccessful.

The conductivity molar values are typical of non-conductors, except for complexes **B2** and **B6,** that are characteristic respectively of uni-univalent and uni-bivalent electrolites.

The ν(NH) and ν(CO) of the near infrared spectra for the complexes and ligands are reported in Table 2. Generally in the near infrared spectra of the complexes the ν(NH) are shifted to lower energy in the 36–200 cm^{-1} range when compared with the parent ligands. This shift is characteristic for a coordination of a NH_2 or NH group to the metallic ion [10–12]. In some cases **A1,** and **B6** the ν(NH) is either not shifted or moved to higher wavenumbers shifted with respect to the free ligand [13]. Generally the complexes with **L1** show the ν(CO) shifted to lower wavenumbers with respect to that of the free ligand, this fact has confirmed that the oxygen of the CO is involved in the coordination of the metal (Table 2).

In the far infrared spectra of **L1** complexes ν(M—N) [14] and ν(M—O) are present at 380–372 cm^{-1} and 450–429 cm^{-1}respectively, so that the complexes can be described as $[M(L1)_2]Cl_2$, (M = Pd, Pt) (Table 3). The low conductivity values typical for non electrolytes, can be explained by postulating that the complexes are rearranged in solution.

These infrared assignement for $M(L1)_2Cl_2$ complexes could be confirmed by an X-ray investigation [15] on a cobalt(II) complex $Co(L1)_2Cl_2 \cdot H_2O$, which has shown that this complex is ionic and that the

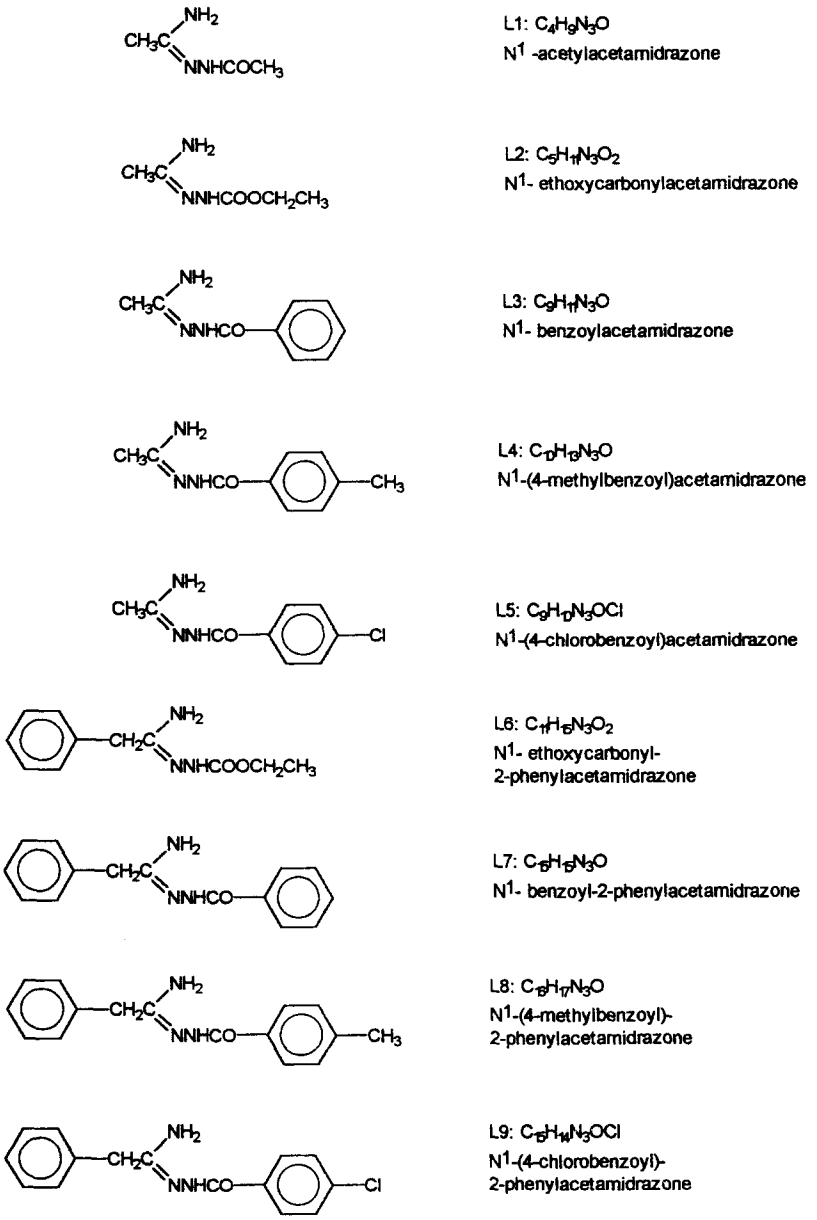

Fig. 1. **L1–L9** ligands.

complex is octahedral with two **L1** chelate coordinated molecules via N^3 and O of CO, two water molecules coordinated to the cobalt ion and two chloride ions out of the coordination sphere.

The reflectance electronic spectra of $[M(L)_2]Cl_2$ complexes where M = Pd(II) and Pt(II) (Table 4) are indicative of a square planar geometry [16,17]. The bands in the 26,180–23,000 cm^{-1} range could be assigned to the ν_1 transition $^1A_{1g} \rightarrow {}^1B_{1g}$. In the UV spectra there are strong absorptions in the 44,400–30,490 cm^{-1} range that may be due to the charge transfer band $L \rightarrow M$. By assuming a value of $F_2 = 10F_4 = 600$ cm^{-1} for the Slater Condon interelectronic repulsion parameters [18] it is possible to derive from the first spin-allowed transition d-d the value $\Delta = \nu_1 + 3.5F_2$. These values lie in the 28,280–25,630 cm^{-1} range.

The complexes of **L2** and **L6** do not show the negative shift of the ν(CO) and there is a negative shift of ν(NH) when compared with the free ligand.

For **A6, B2** and **B6** complexes, the presence of a not shifted or a shifted ν(NH) band to higher wavenumbers respect to the free ligand has been attributed to the presence of the free ligand, so that these compounds can be respectively described as $[Pd(L6)_2Cl_2] \cdot L6$, $[Pt(L2)Cl_4] \cdot L2$ and $[Pt(L6)_2Cl_4] \cdot$

A7	$[Pd(L7)_2]\cdot 2H_2O$	41,670, 26,670, 23,810(25,910)
B7	$[Pt(L7)_2]\cdot L7$	44,440, 36,360, 32,790, 26,320(28,420)
A8	$[Pd(L8)_2]Cl_2$	44,440, 31,250, 23,810(25,910)
B8	$[Pt(L8)_2]\cdot L8\cdot H_2O$	41,670, 36,360, 30,300, 25,640(27,740)
A9	$[Pd(L9)_2]Cl_2\cdot H_2O$	44,440, 40,000, 32,260, 23,530(25,630)
B9	$[Pt(L9)_2]\cdot L9$	42,550, 37,730, 30,300, 25,000

[a] The values of Δ are shown in brackets.

2L6. For the absence of the ν(M—Cl) bands in the expected range, we can conclude that the complexes can be described as $[M(L)_2]Cl_2\cdot mL$.

Some platinum(IV) complexes as **B2** and **B6** show IR absorption bands at 340, 330, 318 and at 333 cm^{-1} respectively, assigned to ν(Pt—Cl) [19,20]. All the complexes with **L2** and **L6** show a band in the 381–359 cm^{-1} range assigned to ν(M—N) [14] (Table 3).

From the infrared spectra and conductivity molar values equal to 149 cm^2 Ω^{-1} mol^{-1}, characteristic for an unibivalent electrolyte, we can describe **B6** as $[Pt(L6)_2Cl_2]Cl_2\cdot 2L6$, while **B2** has a $\Lambda_M = 90$ cm^2 Ω^{-1} mol^{-1} which can be explained by postulating that in DMF is present a partial dissociation of the complex $Pt(L2)_2Cl_4$ described as $[Pt(L2)Cl_4]\cdot L2$.

The shape of the reflectance electronic spectra of the Pt(IV) complexes [21,22] (Table 4) and the far infrared spectra confirm that these compounds are hexacoordinate.

In conclusion the bidentate chelate N^1-acylacetamidrazone derivatives **L** have shown some different patterns of coordination: **L1** coordinates with nitrogen of the N^2 and oxygen of carbonylic group, **L2** and **L6** with the nitrogens of N^3 and N^1. **L3–L5** and **L7–L9** coordinate only two molecules of the anionic species with the nitrogens of N^3 and N^1. Furthermore all the studied compounds are generally non-electrolytes because the complexes are rearranged in solution: we can suggest a square planar stereochemistry for $M(L)_2Cl_2$ (M = Pd(II), Pt(II)) and a distorted octahedral structure for $Pt(L)_nCl_4$ (n = 2, 4) where L = **L1**, **L2** and **L6**. For $M(L)_n\cdot mH_2O$ complexes, where L = **L3–L8**, M = Pd(II), n = 2; M = Pt(II), n = 3, m = 0–2, we can suggest a square planar geometry. For the **L9** $Pd(L9)_2Cl_2\cdot H_2O$ and $Pt(L9)_3$ complexes also square planar structure can be suggested.

(Received 31 October 1996; accepted 17 October 1997)

Abstract—Reactions of C_{60} with iridium cyclo-octadiene dimers containing bridging alkoxide groups, $Ir_2(OR)_2(1,5\text{-}COD)_2$ (R = Me, Et, *n*-Pr, Ph), in a 1 : 1 mole ratio at ambient temperature produced brown solid materials. On the basis of chemical and single crystal X-ray analysis and IR spectra, formulations $Ir_2(OR)_2(1,5\text{-}COD)_2(C_{60})$ are proposed for these compounds. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: fullerene; iridium; alkoxy bridged; cyclo-octadiene; X-ray structure; infrared.

Fullerenes were discovered experimentally in 1985 [1], but they were studied only theoretically until a method of preparation for quantitative amounts of fullerenes was invented in 1990 [2]. Since then fullerenes have been investigated intensively.

Because of their spherical form, fullerenes are unique ligands for organometallic compounds. Several organometallic derivatives of fullerenes have already been synthesized. The first structurally characterized organometallic fullerene derivative was synthesized by Fagan *et al.* [3] in 1991. In this monoadduct $(\eta^2\text{-}C_{60})Pt(PPh_3)_2$ the metal is bound to the fullerene surface in η^2-fashion at the 6-6 ring fusion. In every structurally characterized organometallic fullerene compound the metal is bound to the fullerene surface similarly. In addition to several monoadducts [4], some di- [5] and hexa [6]-adducts have been synthesized.

We have previously synthesized the first ruthenium carbonyl fullerene derivative, $Ru(CO)_4C_{60}$ [7]. This compound was soluble in common organic solvents; and when characterized spectroscopically (IR and ^{13}C NMR spectroscopy), it was found to be similar to the other fullerene compounds.

We have also been able to synthesize and crystallize the compound $C_{60}\{Ir_2Cl_2(1,5\text{-}COD)_2\}_2$ [8], in which the two iridiums bind to two adjacent 6 :6 ring fusions, being the first example of this kind of bonding in fullerenes. It is remarkable because it shows that the neighboring π-bonds of a six-membered ring of C_{60} can also be activated in the formation of a metal complex [8].

Recently the synthesis and crystallographic characterization of two dinuclear derivatives $Cp^*_2Ru_2(\mu\text{-}H)(\mu\text{-}Cl)(C_{60})$ and $Cp^*_2Ru_2(\mu\text{-}Cl)_2(C_{60})$ was reported [9]. These compounds have also two metal centers coordinated to two adjacent 6-6 junctions of C_{60}.

In the present study we have extended the synthesis and characterization of dimeric transition metal derivatives of C_{60} to alkoxy bridged iridium compounds. As starting materials, we have used coordinately unsaturated alkoxy-bridged iridium compounds $Ir_2(OR)_2(1,5\text{-}COD)_2$, where R = CH_3 [10], C_2H_5, *n*-C_3H_7 or C_6H_5 [11]. The influence of the length of the carbon chain (R) attached to the oxygen bridge in $Ir_2(OR)_2(1,5\text{-}COD)_2$ on the reactivity with fullerenes has been also investigated.

EXPERIMENTAL

Materials

All reactions were carried out under either nitrogen or argon, and the solvents used were purged with nitrogen gas and dried over molecular sieves. Commercial fullerenes (purchased from Texas Fullerenes Corporation) were used without further purification. Alkoxy-bridged iridium dimers $Ir_2(OR)_2(1,5\text{-}COD)_2$, where 1,5-COD = 1,5-cyclo-octadiene and R = CH_3 =

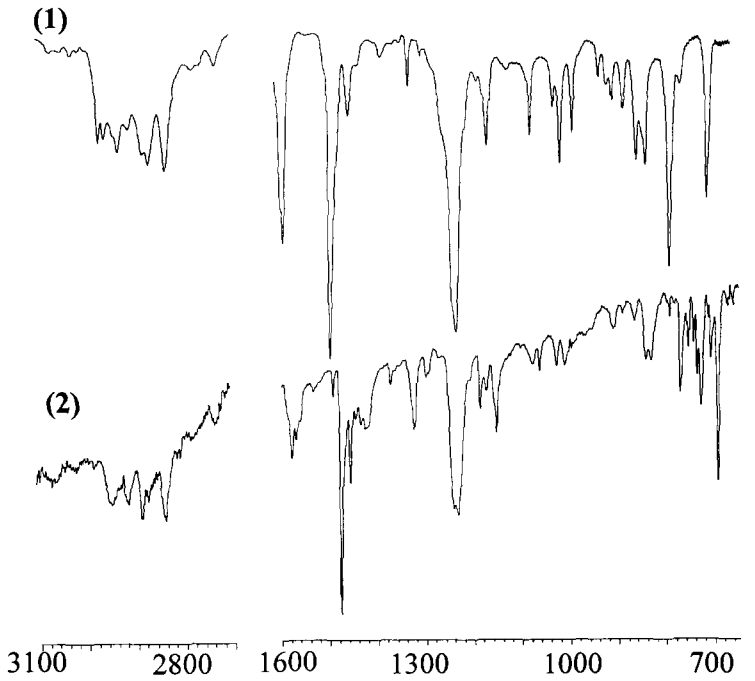

Fig. 1. IR-spectra of the compounds (1) $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2$ and (2) $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2C_{60}$ in KBr.

Me, C_2H_5 = Et, $n\text{-}C_3H_7$ = *n*-Pr or C_6H_5 = Ph (Fig. 2), were synthesized according to procedures described in the literature [10,11] starting from $IrCl_3nH_2O$ or $Ir_2Cl_2(1,5\text{-}COD)_2$ (both purchased from Strem Chemicals).

IR spectra and chemical analyses

The IR spectra were measured with a Nicolet Magna-IR 750 spectrometer. Solid samples were mixed with KBr and pressed into pellets. The pellets were then scanned 100 times in the range 4000–650 cm^{-1} with a resolution of 2 cm^{-1}. The chemical analyses were determined with a Carlo Erba CHN+O/S 1106 analysator. Every observed value is the average of three measurements.

Synthesis of $Ir_2(OR)_2(1,5\text{-}COD)_2C_{60}$. Buckminsterfullerene and iridium compounds, except for $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2$, were dissolved in toluene. Compound $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2$ was insoluble in toluene and was therefore dissolved in dichloromethane. Solutions of fullerene and each iridium dimer were combined in a 1 : 1 mole ratio and stirred at room temperature for 18–24 h except in the case of $Ir_2(OMe)_2(1,5\text{-}COD)_2$ for 2 h. The color of the solutions changed immediately to dark red. During the reaction, a brown precipitate was formed in each reaction. According to TLC, the solutions contained

only unreacted starting materials. The resulting precipitate was separated by decantation, washed several times with small amounts of toluene and dried *in vacuo* at room temperature.

X-ray structure determination of $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2C_{60}\,CH_2Cl_2$

A crystal with approximate dimensions of $0.05\times0.25\times0.45$ mm was measured with a Nicolet R3m diffractometer using an ω-scan data-collection mode and graphite-monochromatized Mo–K_α radiation ($\lambda = 0.71073$ Å). Accurate cell parameters were obtained from 25 automatically centered reflections. Intensities were corrected for background, Lorentz-polarization factors, as well as for absorption from ψ-scan data, the maximum and minimum transmission factors being 0.489 and 0.300, respectively.

The crystal structure was determined by direct methods with SHELX86 [12] and subsequent Fourier synthesis with SHELXL93 [13]. The Ir, Cl and O atoms were refined anisotropically and the C atoms isotropically. The phenyl rings of the phenoxy group was refined as a rigid group (disordered over the mirror plane) with a common isotropic temperature factor. H atoms were placed in calculated positions and not refined, except those attached to the C atom of the methoxy group and those attached to CH_2Cl_2 which were omitted. Details of the crystal data and the structure refinement are given in Table 1.

RESULTS AND DISCUSSION

The dimeric alkoxy-bridged iridium compounds all reacted with C_{60} in a 1 : 1 mole ratio. The reaction was fast for $Ir_2(OMe)_2(1,5\text{-}COD)_2$. The precipitate began to form gradually after the solutions had been combined. The other iridium complexes required a longer time to react with fullerene. In each reaction the color of the solution turned dark red immediately, but with $Ir_2(OR)_2(1,5\text{-}COD)_2$ (R = Et, *n*-Pr, Ph), the precipitate took longer time to form. The longer the alkyl group attached to oxygen was, the longer was the needed reaction time.

The products were insoluble in common organic solvents. Due to the lack of solubility, the products could be characterized primarily by chemical analysis and IR spectroscopy. Based on the results of chemical analysis, all of the new compounds synthesized are 1 : 1 compounds, i.e., in each compound one fullerene molecule is attached to one dimeric iridium molecule. All experimentally observed carbon and hydrogen contents agree with the theoretical values.

The IR spectra of the starting materials and the products were compared and the wavenumbers of the strongest vibrations are given in the experimental section for the products. The observed IR spectra of the starting materials are similar to the IR spectra given in the literature [11] for these compounds. The IR spectra of $Ir_2(OMe)(OPh)(1,5\text{-}COD)_2$ and $C_{60}\{Ir_2(OMe)(OPh)(1,5\text{-}COD)_2\}$ are presented in Fig. 1.

The coordinated cyclo-octadiene ligand in compound $Ir_2Cl_2(1,5\text{-}COD)_2$ has CH-vibrations at wavenumbers 2958, 2914, 2874 and 2830 cm^{-1} [14]. These vibrations can be found in the spectrum of every starting material and product either at exactly the same or slightly different wavenumbers. CH-vibrations due to methyl, ethyl, *n*-propyl or phenyl groups can also be found in the appropriate wavenumber area. Based on the observed CH-vibrations in the IR spectra of the products, some conclusions can be made. Every new compound synthesized in this study contains cyclo-octadiene ligands coordinated to iridium. These complexes have also similar alkyl or aryl groups as the starting materials. Therefore the dimeric structure of the iridium compounds is very likely retained in the new fullerene complexes.

Buckminsterfullerene has only four IR active vibrations at wavenumbers 1429, 1182.5, 576.5 and 527 cm^{-1} [15]. When fullerene reacts with the metal compound, the effect of coordination on the fullerene core is only local. Since the fullerene core remains largely unaffected, IR active vibrations usually remain at the same or nearly the same wavenumbers. This situation can also be seen in the present study. In every spectrum of the product, vibrations due to the fullerene core can be seen at wavenumbers 1439–1407 cm^{-1} and 1189–1183 cm^{-1}.

Attempted crystallizations by the slow diffusion method were accomplished only in the case of $Ir_2(OPh)(OMe)(1,5\text{-}COD)_2C_{60}$ producing thin aggregated plates. The crystal structure determination was successful giving the crystal structure of the compound. The structure refinement was not completed to the standard accuracy due to the data quality (all crystals containing small satellite crystals) and disordered solvent molecules. The coordination geometry (Figs 2 and 3) of the two iridium atoms is similar to that of $C_{60}\{Ir_2Cl_2(1,5\text{-}COD)_2\}_2$, where the metals bind to two adjacent 6 : 6 ring fusions [8]. Selected bond lengths and angles for $Ir_2(OPh)(OMe)(1,5\text{-}COD)_2C_{60}$ are given in Table 2. The bond distances (av. 2.2 Å) between iridium and fullerene carbon atoms in $Ir_2(OPh)(OMe)(1,5\text{-}COD)_2C_{60}$ are similar to those (av. 2.221 Å) found in $C_{60}\{Ir_2Cl_2(1,5\text{-}COD)_2\}_2$. The iridium–oxygen distances in the methoxy and phenoxy bridges are 2.07 and 2.26 Å, respectively.

equivalent positions: $i = x, \frac{1}{2}-y, z$.

Coordinatively unsaturated iridium molecules undergo oxidative-addition reactions rather easily. The formation of these new fullerene complexes with alkoxy-bridged iridium dimers is a new example of this type of reaction. The only change in the dimeric starting materials is the attachment of the new ligand, fullerene. In these reactions the iridium center becomes coordinatively saturated.

CONCLUSIONS

Our results proved that it is possible to prepare fullerene derivatives starting from iridium dimers with different bridging groups. Careful selection of the bridging and terminal group of the starting material is essential.

These investigations open up a new area of fullerene chemistry. The next goal is to investigate different iridium dimers. Because it is possible to activate adjacent 6 : 6 ring bonds, it might be possible to synthesize compounds with more than two metal atoms attached to the fullerene core. The reactivity of other metal compounds with similar structures should be tested.

(Received 15 September 1997; accepted 16 October 1997)

Abstract– The hydrolysis of the phosphate triester 2,4-dinitrophenyl diethyl phosphate to diethyl phosphate is catalysed by $[Cu(tmen)(OH)(OH_2)]^+$ in the pH range 6.5 to 8.0. At pH 7 with a catalyst concentration of 2.5×10^{-3} mol dm^{-3} the rate enhancement is ca 10^4 fold. The pH dependence of the catalysis is consistent with the hydroxoaqua complex being the active species in the hydrolysis. The greater kinetic effectiveness of this weak base, compared with hydroxide ion on a molar basis, indicates a bifunctional mechanism in which bound hydroxide acts as a nucleophile in conjunction with electrophilic catalysis by copper at the phosphoryl oxygen. The copper complex is an excellent catalyst for the hydrolysis of *O*-isopropyl methylphosphonofluoridate (Sarin). At pH 7 and 25°C using a Sarin concentration of 4.5×10^{-2} mol dm^{-3} and a $[Cu(tmen)(OH_2)_2]^{2+}$ concentration of 5×10^{-3} mol dm^{-3}, complete hydrolysis (9 turnovers) occurs in 13 min. © 1998 Elsevier Science Ltd. Keywords: copper(II); tmen; catalysis; phosphotriester; sarin; hydrolysis.

In recent years there has been considerable interest in the metal complex promoted hydrolysis of phosphate esters [1]. Studies have involved kinetically inert cobalt(III) [2] and labile copper(II) [3] and zinc(II) [4] complexes with monoesters, diesters and triesters of phosphoric acid as substrates. A number of phosphate esters and related phosphorus(V) compounds are potent nerve agents and are used in chemical weaponry [5,6]. As a result the development of catalyst systems for the hydrolysis of such compounds is of considerable importance. The present paper discusses the $[Cu(tmen)(OH)(OH_2)]^+$ promoted hydrolysis of 2,4-dinitrophenyl diethyl phosphate. Due to steric effects, *N*-methylation of ethylenediamine leads to the formation of *mono* rather than *bis* complexes with copper(II). A variety of hydroxoaquo complexes of copper(II) and zinc(II) have been found to be active catalysts in the hydrolysis of phosphate esters, and for this reason the present catalyst system was developed. The triester 2,4-dinitrophenyl diethyl phosphate (**1**) is a suitable substrate as it is water soluble and its hydrolysis can readily be monitored by standard spectrophotomeric procedures.

EXPERIMENTAL

Synthesis

2,4-Dinitrophenyl diethyl phosphate was prepared as follows. Diethyl chlorophosphate (63 g, 0.366 mol) was added dropwise to a stirred suspension of dry sodium 2,4-dinitrophenoxide (75.4 g, 0.366 mol) in toluene (450 cm^3). On completion of the addition, the mixture was refluxed for five hours, cooled, washed with ice water (150 cm^3) followed by cold 5% sodium carbonate solution (150 cm^3) then ice water (150 cm^3). The toluene layer was dried over $MgSO_4$ and concentrated *in vacuo* to give the crude 2,4-dinitrophenyl

diethyl phosphate in 60% yield. The crude ester was kept in a deep freeze and aliquots purified immediately before use as described below.

CAUTION: phosphate esters of this type exhibit anticholinersterase activity. Great care should be exercised in their handling and use.

Glassware should be decontaminated with solutions of hypochlorite (bleach).

Immediately prior to use, the ester (1.0 g) was dissolved in ice-cold chloroform, and the solution shaken with ice-cold 5% $NaHCO_3$ (25 cm^3), then ice-water (25 cm^3), followed by ice cold 0.1 mol dm^{-3} HCl (25 cm^3) then finally two aliquots (2×25 cm^3) of ice-cold water. The organic layer was dried over Na_2SO_4 for several hours and finally the solvent was removed at 40°C under vacuum. The phosphate ester residue was used for the kinetic experiments. (Found: C, 37.4; H, 4.1; N, 8.2. $C_{10}H_{13}N_2O_8P$ Calcd C, 37.5; H, 4.1; N, 8.75%.) ^{13}C NMR (reference TMS), 16.3 (doublet, $J = 7.34$ Hz; CH_3); 65.8 (doublet, $J = 7.34$ Hz; $—CH_2—$); 121.6; 129.1 (—C—H); 140.7; 143.8; 148.4 (—C—X). [Cu(tmen)Cl_2]. A solution of *N,N,N′,N′*-tetramethylethylenediamine (1.45 g, 12.5 mmol) in ethanol (40 cm^3) was added dropwise with stirring to a filtered solution of $CuCl_2 \cdot 2H_2O$ (2.55 g, 15 mmol) in methanol (100 cm^3). The mixture was rotary evaporated to half volume. On standing overnight at room temperature, the dark blue complex crystallised and was filtered off and recrystallised from methanol-ether and dried *in vacuo*. (Found: C, 28.4; H, 6.4; N, 10.9. $C_6H_{16}N_2Cl_2Cu$ Calcd C, 28.75; H, 6.4; N, 11.2%.) The complex has λ_{max} 655 nm in water ($\varepsilon = 55$ dm^3 mol^{-1} cm^{-1}) and is a 2:1 electrolyte in water with $\Lambda_M = 202$ S cm^2 mol^{-1} at 25°C.

Kinetics

The kinetics of base hydrolysis of 2,4-dinitrophenyl diethyl phosphate was followed spectrophotometrically using a stopped-flow system, by monitoring the release of the 2,4-dinitrophenoxide ion at 360 nm.

The copper(II) promoted hydrolysis was studied at 35°C using a Gilford 2400 spectrophotometer interfaced with a PC. In order to avoid possible complications due to buffer catalysis the metal complex ($pK_1 = 7.40$ at 35°C) was used as the buffer system. Reactions were initiated by the addition of 50 μl of a ca 5×10^{-3} mol dm^{-3} solution of the ester in acetonitrile to the spectrophotometer cell containing the metal complex previously adjusted to the desired pH. Release of the 2,4-dinitrophenoxide ion was monitored at 400 nm. The reactions were first order in the phosphate ester (ca 8×10^{-5} mol dm^{-3} initial concentration) and excellent first order kinetics were observed. Plots of $\ln(A_\infty - A_t)$ versus time were linear for several half lives.

Measurements with Sarin

Measurements with Sarin (O-isopropyl methylphosphonofluoridate = GB; $LD_{50} = 0.025$ mg/kg) were made at CBD, Porton Down. Hydrolysis in the presence of $[Cu(tmen)(OH_2)_2]^{2+}$ was carried out by monitoring the release of fluoride using a fluoride specific electrode. The measurements were made at 25°C and pH 7 using HEPES buffer (1 mol dm^{-3}). The concentration of copper complex employed was 5×10^{-3} mol dm^{-3} and the concentration of Sarin 4.5×10^{-2} mol dm^{-3}.

Potentiometric titrations

Potentiometric titrations were carried out with a Radiometer Titralab system using G202B glass and K401 calomel electrodes. The electrode system was standardised before and after each titration using Radiometer standard buffer solutions (pH 7.00 and 9.18). The temperature was controlled by circulating water from a Haake FE thermostat. Aqueous solutions of [Cu(tmen)Cl_2] prepared from the solid complex were titrated using standard NaOH (ca 0.1 mol dm^{-3}) under nitrogen. Sufficient KNO_3 was added to maintain the ionic strength at 0.1 mol dm^{-3}. The pK_1 values for $[Cu(tmen)(OH_2)_2]^{2+}$ at 25°C and 35°C were obtained from the relationship, $pH = pK + \log([A^-]/[HA])$ and are thus practical constants involving the hydrogen ion activity and the concentration of the other species.

RESULTS AND DISCUSSION

The complex [Cu(tmen)Cl_2] is readily characterised as dark blue crystals. In the solid state the complex is a chloride bridged dimer. On dissolution in water, the chloride ligands are displaced to give $[Cu(tmen)(OH_2)_2]^{2+}$ according to the reaction,

$$[Cu(tmen)Cl_2] + 2H_2O \rightarrow [Cu(tmen)(OH_2)_2]^{2+} + 2Cl^-$$

In water the complex behaves as a 2:1 electrolyte and has λ_{max} 655 nm consistent with a CuN_2O_4 chromophore. Potentiometric titration of $[Cu(tmen)(OH_2)_2]^{2+}$ with standard sodium hydroxide gives a well defined end point after addition of one equivalent of base, Fig. 1. This end point can be attributed to the ionisation,

$$[Cu(tmen)(OH_2)_2]^{2+} \rightleftharpoons [Cu(tmen)(OH)(OH_2)]^+ + H^+; \quad K_1 \quad (1)$$

to give the hydroxoaqua complex. Analysis of the potentiometric data, Table 1, gives $pK_1 = 7.58 \pm 0.02$ at 25°C and $pK_1 = 7.40$ at 35°C. The *N*-permethylated ethylenediamine sterically hinders the formation of

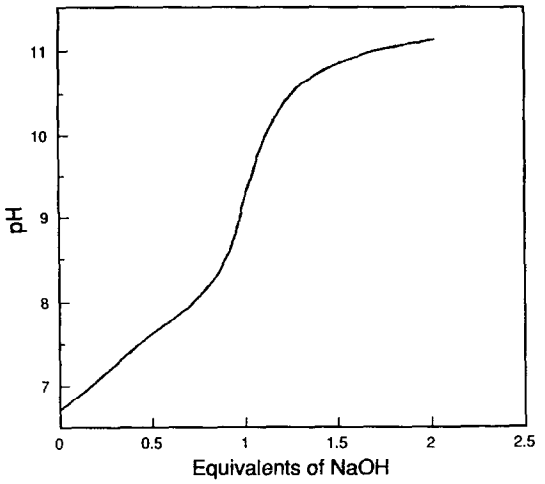

Fig. 1. Potentiometric titration of $[Cu(tmen)(OH_2)_2]^{2+}$ (2.48×10^{-3} mol dm^{-3}) with standard sodium hydroxide (0.10 mol dm^{-3}) at 35 °C and $I = 0.1$ mol dm^{-3} (KNO_3).

The titrating base was 0.985 mol dm^{-3} sodium hydroxide. The end point of the titration was 0.255 cm^3 of base.

bis-complexes in solution, and only the 1 : 1 complex is formed at 1 : 1 ligand to metal ratios. Additional potentiometric work established that dimerisation of the hydroxoaqua complex to the hydroxy-bridged dimer was not significant at concentrations below 10^{-3} mol dm^{-3}.

Kinetic studies

The base hydrolysis of 2,4-dinitrophenyl diethyl phosphate, was studied over the temperature range 9.3 to 42.5 °C giving $\Delta H^{\ddagger} = 50.6$ kJ mol^{-1} and $\Delta S^{\ddagger}_{298} = -79$ J K^{-1} mol^{-1}. At 35 °C and $I = 0.1$ mol dm^{-3}, the value of $k_{OH} = 1.55$ dm^3 mol^{-1} s^{-1}, Table 2.

In the pH range 6.5 to 7.7 the hydrolysis of the ester is markedly catalysed by $[Cu(tmen)(OH)(OH_2)]^+$. The reactions were studied using the copper(II) complex in greater than ten fold excess over the phosphate ester. Values of the observed first order rate constant (k_{obs}) for the disappearance of the ester are listed in Table 3 as a function of the copper complex concentration and the pH. At constant pH the reaction displays a linear dependence on the concentration of the copper(II) complex, Fig. 2. At pH 6.53 no evidence was obtained for the onset of saturation kinetics even when the copper(II) complex was in ca 40 fold excess. Values of the second order rate constant $k_{cat} = k_{obs}/(\text{Complex})_{Total}$ were obtained from the least squares slope of the plots of k_{obs} versus the total concentration of the copper complex, Table 4. Values of k_{cat} increase with the pH in a sigmoidal manner over the pH range 6.5 to 7.9, Fig. 3, consistent with the hydroxoaqua complex being the active species in the reaction. If this is the case values of k_{cat}/α, where α is the fraction of the total complex ionised to the hydroxoaqua complex should be effectively constant. Values of α were calculated from the pH and the experimentally determined ionisation constant at 35 °C. Values of k_{cat}/α are reasonably constant, Table

Table 2. Rate constants for the hydrolysis of 2,4-dinitrophenyl diethyl phosphate at $I = 0.1$ mol dm^{-3} over the temperature range 10–45 °C

Temp. (°C)	$10^6 k_{H_2O}$ (s^{-1})	$10^2 k_{OH}$ (dm^3 mol^{-1} s^{-1})	$10^2 k_{OH}$ (dm^3 mol^{-1} s^{-1})
10.0			11.75
15.0			16.95
20.0			22.2
25.0	1.2	30.5	29.2
30.0	1.7	41.7	39.6

[a] The total catalyst concentration, i.e. ([Cu(tmen)(OH$_2$)$_2$]$^{2+}$ + ([Cu(tmen)(OH)(OH$_2$)]$^+$). The initial 2,4-dinitrophenyl diethyl phosphate concentration was 8×10^{-5} mol dm^{-3}.

The quoted rate constants are the average values obtained in three kinetic runs.

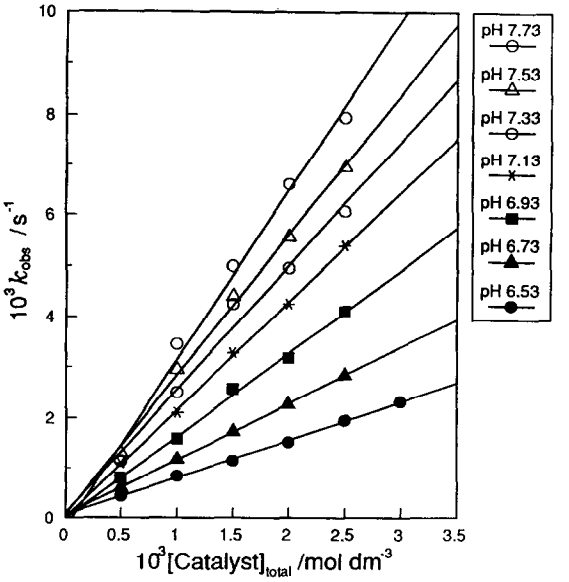

Fig. 2. Plot of k_{obs} versus the total concentration of [Cu(tmen)(OH$_2$)$_2$]$^{2+}$ for the catalysed hydrolysis of 2,4-dinitrophenyl diethyl phosphate at 35°C at various pH values and I = 0.1 mol dm^{-3} (KNO$_3$).

4 giving an average value for $k = k_{cat}/\alpha = 5.7$ dm^3 mol^{-1} s^{-1} at 35°C and I = 0.1 mol dm^{-3}. Some drift in the rate constant is expected as formation of the hydroxoaqua complex is expected to lead to some production of the inactive dihydroxo bridged dimer by the reaction

$$2[Cu(tmen)(OH)(OH_2)]^+ \rightleftharpoons [Cu(tmen)(OH)_2Cu(tmen)]^{2+} + 2H_2O \quad (2)$$

An interesting feature of the reaction is that k is some four fold greater than k_{OH} (1.55 dm^3 mol^{-1} s^{-1} at 35°C) for the base hydrolysis of the ester. Since free hydroxide is at least 10^6 stronger as a base than [Cu(tmen)(OH)(OH$_2$)]$^+$ this observation effectively excludes the copper complex acting as a general base catalyst in the reaction. The present results are consistent with the observations of Gellman, Petter and Breslow [4a] on the [Zn(CR)OH]$^+$ (**2**) catalysed hydrolysis of 2,4-dinitrophenyl diphenyl phosphate. Kinetic studies established that the catalytically active complex is the zinc hydroxo species (pK = 8.7). The second order rate constant for attack of the fully ionised [Zn(CR)OH]$^+$ on the triester is ca 2.8×10^{-1} dm^3 mol^{-1} s^{-1} at 25°C, compared with $k_{OH} = 2.8 \times 10^{-2}$ dm^3 mol^{-1} s^{-1}, which is an order of magnitude *smaller*

Table 4. The pH dependence of the second order rate constants k_{cat} as a function of the fraction of the complex [Cu(tmen)(OH$_2$)$_2$]$^{2+}$ ionised to the hydroxoaqua complex at 35°C and I = 0.1 mol dm^{-3}

pH	k_{cat} (dm^3 mol^{-1} s^{-1})	α	k_{cat}/α (dm^3 mol^{-1} s^{-1})
6.53	0.75	0.12	6.3
6.73	1.10	0.18	6.1
6.93	1.64	0.25	6.6
7.13	2.14	0.35	6.1
7.33	2.45	0.46	5.3
7.53	2.77	0.57	4.9
7.73	3.24	0.68	4.8

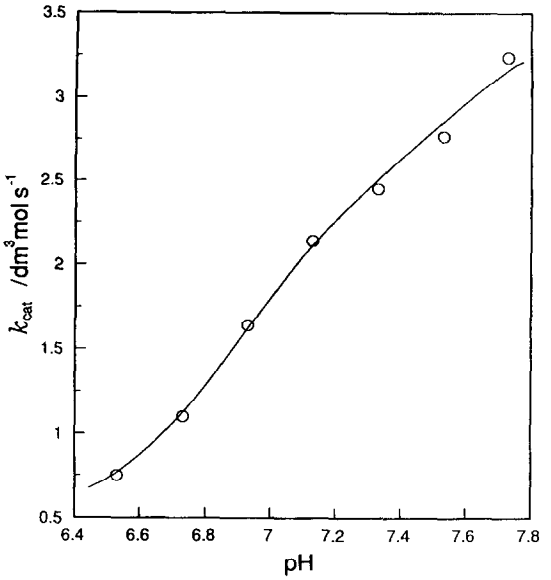

Fig. 3. Plot of k_{cat} versus pH for the $[Cu(tmen)(OH_2)_2]^{2+}$ catalysed hydrolysis of 2,4-dinitrophenyl diethyl phosphate at 35°C and $I = 0.1$ mol dm^{-3} (KNO_3).

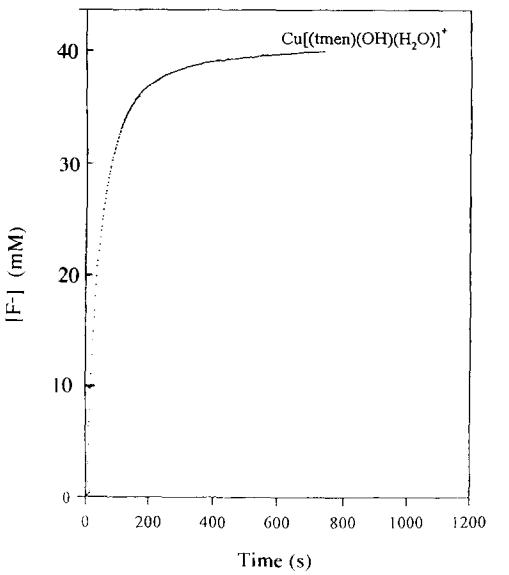

Fig. 4. Hydrolysis of Sarin (O-isopropyl methylfluorophosphonate) at pH 7.0 in 1 mol dm^{-3} HEPES buffer in the presence of the copper(II)-tmen complex. The reaction was monitored using a fluoride specific electrode. The concentration of Sarin was 4×10^{-2} mol dm^{-3} and the total copper(II) complex concentration was 5×10^{-3} mol dm^{-3}.

for the base hydrolysis reaction. To account for such experimental observations it is necessary to invoke a bifunctional "push-pull" mechanism. The metal centre delivers a coordinated hydroxide ion to the triester while simultaneously withdrawing electron density from the phosphorus atom by interacting with the phosphoryl oxygen. This mechanism is illustrated in (**3**). All four atoms of the transient four membered ring have almost normal bond angles and there is little or no strain in the formation of the trigonal-pyramidal phosphorane intermediate. Similar bifunctional mechanisms have been observed in catalytically active cobalt(III) complexes. For example, the hydrolysis of 4-nitrophenyl phosphate in (**4**) has been shown to occur by intramolecular attack by coordinated hydroxide at phosphorus to give initially a five-coordinate phosphorane which decays to $[Co(en)_2PO_4]$ containing bidentate phosphate and 4-nitrophenol [2c]. The effectiveness of Lewis acid catalysis alone in polarising the phosphoryl group can be gauged from the observation that k_{OH} for trimethyl phosphate hydrolysis is increased 400 fold when the phosphoryl group is coordinated to iridium(III) in the complex (**5**) [7].

A true catalytic system should exhibit turnover. Turnover experiments were carried out by pH-stat methods. In a typical run a solution of 7.25×10^{-4} mol dm^{-3} 2,4-dinitrophenyl diethyl phosphate and 5×10^{-5} mol dm^{-3} of the copper(II) complex (ratio 1 : 15) was adjusted to pH 7.6 and the release of H^+ due to ester hydrolysis monitored by the automatic addition of 0.10 mol dm^{-3} sodium hydroxide solution. Measurements were made at 25 and 35°C. At pH 7.6 and 35°C the half life of the ester is 71 hours in the absence of any catalyst. At 25°C there were some 20.6 turnovers per hour using the $[Cu(tmen)(OH)(OH_2)]^+$ catalyst. A few experiments were also carried out by ^{31}P NMR methods. The reaction was run for a period of time and the copper(II) removed by treating with H_2S. The solution was normally analysed before one equivalent of 2,4-dinitrophenolate was produced. The NMR measurements confirmed that only unreacted ester and diethyl phosphate were present in solution.

Measurements were also carried out with *O*-isopropyl methylfluorophosphonate (Sarin) to assess the effectiveness of $[Cu(tmen)(OH)(OH_2)]^+$ as a catalyst for its hydrolysis. The reaction was monitored using a fluoride specific electrode at pH 7.0 controlled by HEPES buffer. The measurements were made at 25°C using a total sarin concentration of 4×10^{-2} mol dm^{-3}. A typical plot for fluoride release versus time is shown in Fig. 4. Complete hydrolysis of the fluorophosphonate occurs in some 700 seconds under these conditions. The copper(II) complex is a very effective catalyst for the hydrolysis of the nerve agent. There was no evidence for product inhibition of the reaction even at quite high Sarin concentrations. However, pH control presents a problem due to the release of HF which lowers the pH so that little of the active hydroxoaqua complex is present in solution.

(Received 1 September 1997; accepted 16 October 1997)

Abstract—The reaction of a diastereomeric mixture of 1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**1**) with $LiAlH_4$, followed by hydrolysis with H_2O, gives a 4:1 mixture of *rac*- and *meso*-1,2-bis(phenylphosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**2a, b**) or 1-phenylphosphino-1,2-dicarba-*closo*-dodecaborane(12) (**3**), depending on the stoichiometry employed. A mixture of **2a, b** reacts with sulfur in undecane at 190°C or without solvent at 105–110°C to give exclusively the cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl(12)-dithiodiphosphinic acid (**6**). **2, 3** and **6** were characterised spectroscopically (^1H, ^{31}P, ^{11}B, ^{13}C NMR, IR, MS) and X-ray structure determinations were carried out on the racemic isomers **2a** and **6**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: secondary carbaboranylbisphosphine; cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl(12)-dithiodiphosphinic acid.

Organic or organo-element derivatives of dicarba-*closo*-dodecaboranes(12) have received increasing attention during the past decade as they exhibit interesting chemical and physical properties. Thus, these compounds have been employed as catalysts [1,2], as doping reagents in semiconductor materials [3], as precursors for ceramic materials [4], and in neutron-capture therapy of tumors (boron neutron capture therapy) [5] and other medical areas [6,7]. Hence applications in medicine can be envisioned for related carbaboranylphosphines and transition metal complexes thereof [8].

While tertiary phosphino derivatives of dicarba-*closo*-dodecaboranes(12), which were first reported in 1963 [9], have been employed as ligands in transition metal chemistry and as starting materials for the preparation of other *closo*-carbaborane(12)-containing organophosphorus compounds [10], their secondary analogues have remained largely unexplored. The only report on the attempted synthesis of secondary phosphinocarbaboranes, by A.V.Kasantsev *et al.* in 1971, claims that the reaction of 2-substituted 1-phenylchlorophosphino-1,2-dicarba-*closo*-dodecaboranes(12) with $LiAlH_4$ yields the corresponding 1-phenylphosphino-1,2-dicarba-*closo*-dodecaboranes (12), which, however, decompose under the reaction conditions with formation of C-substituted 1,2-dicarba-*closo*-dodecaboranes(12) and primary phosphines [11].

We now report the synthesis and spectroscopic properties of the first secondary bisphosphinocarbaboranes, *rac*- and *meso*-1,2-bis(phenylphosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**2a, 2b**) and 1-phenylphosphino-1,2-dicarba-*closo*-dodecaborane(12) (**3**), as well as the separation of the diastereoisomers of **2** and the molecular structure of the *racemic* isomer **2a**. **2a, b** react with sulfur in boiling

undecane or at elevated temperature without solvent to give the cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl (12)-dithiodiphosphinic acid (**6**), which was also structurally characterised.

RESULTS AND DISCUSSION

Synthesis and properties of 2, 3 *and* 6

A mixture (4:1) of *rac*- and *meso*-1,2-bis(phenylphosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**2a, 2b**) was obtained in 91% yield by reacting a diastereomeric mixture of *rac*- and *meso*-1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**1**) [9] (^{31}P: 80.54 and 80.62 ppm) with 1.1 eqv. $LiAlH_4$ in ether and subsequent hydrolysis with 10 eqv. H_2O (Scheme 1). It was observed previously [11] that the P—C bond is cleaved by an excess of $LiAlH_4$ and H_2O. Thus, when a 50% excess of $LiAlH_4$ and 50 eqv. of H_2O are employed, only 1-phenylphosphino-1,2-dicarba-*closo*-dodecaborane (12) (**3**) is obtained, in 42% yield, as well as insoluble boron- and phosphorus-containing products (Scheme 1).

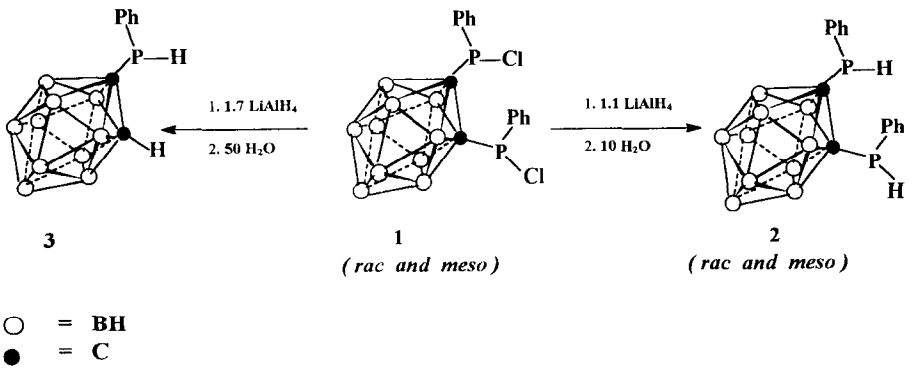
The carbaboranylphosphines **2** and **3** are obtained as air- and water-stable colourless solids, soluble in organic solvents, and purifiable by column chromatography. The better solubility of **2b** in hexane allows the diastereoisomers of **2** to be separated.

In the $^{31}P\{H\}$ NMR spectrum, the two diastereoisomers of **2** exhibit singlets at −15.15 for **2a** and −14.98 ppm for **2b**; for **3**, the resonance is shifted to low field (−2.67 ppm, $^1J_{PH}$ 229 Hz). On proton coupling, the HPC—CPH fragments in **2a** and **2b** show the signals of an AA′XX′ spin system. The coupling constants ($^1J_{PH}$ 244 Hz **2a**, 239 Hz **2b**; $^3J_{PP}$ 84 Hz **2a**, 87 Hz **2b**) were obtained from simulated ^{1}H NMR spectra [12]. However, the two signals of the diastereoisomers of *o*-phenylenebisphosphine, 1,2-$(PhPH)_2C_6H_4$ (−41.8, −42.4 ppm) [13], and 1,2-bis(phenylphosphino)ethane, $PhP(H)CH_2CH_2(H)$-PPh (−45.6, −45.9 ppm) [14], are observed in the same range as those of their corresponding monophosphines, Ph_2PH (−41 ppm) [15] and Ph(Et)PH (−46 ppm) [15]. The observation of no notable chemical shift difference in the ^{31}P NMR spectra indicates only minor magnetic interaction of the P atoms in these bisphosphines. Thus, the low-field shift of the resonance of **3** relative to **2** cannot be attributed to steric or electronic effects of the second PHPh group. Therefore, the observed difference in the chemical shifts of **2** and **3** must be due to the influence of the 1,2-dicarba-*closo*-dodecaborane(12) cluster. This assumption is supported by the observed difference in the ^{31}P chemical shifts of 1-diphenylphosphino-1,2-dicarba-*closo*-dodecaborane(12) (25.6 ppm) [16] and 1,2-bis(diphenylphosphino)-1,2-dicarba-*closo*-dodecaborane(12) (8.2 ppm) [17].

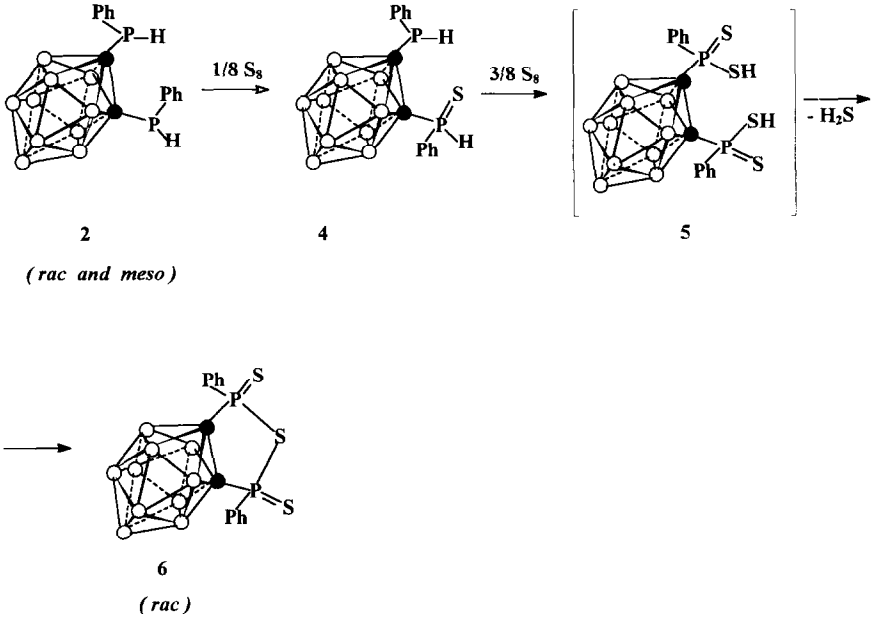
To investigate the chemical reactivity of **2a, b**, its reaction with sulfur was studied (Scheme 2). No reaction was observed on heating a *racemic* mixture of **2a, b** (4:1) and sulfur in THF or toluene under refluxing conditions. However, when the reaction was carried out in undecane at 190°C or without solvent at 105–110°C, the cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl-(12)-dithiodiphosphinic acid (**6**) was obtained in 67 (undecane) or 44% (without solvent) yield.

The course of the reaction, followed by ^{31}P NMR spectroscopy, indicated that the reactivity of **2a, b** is rather different to that of other secondary 1,2-diphosphines [18–20]. **2a, b** were heated with sulfur without solvent and samples were taken after 10 min, 1 h, 2 h, 5 h and 6 h, dissolved in C_6D_6 and studied by ^{31}P NMR spectroscopy.

After 10 *min*. A very intense signal for the starting material **2a, b** is observed at ca −15 ppm and several very weak singlets in the range of +64 to +90 ppm, which could not be assigned. In addition, signals for the two diastereoisomers of **4** [doublets at −13.4 ppm (J_{PP} 59 Hz) and −12.3 ppm (J_{PP} 45 Hz) and doublets at +32.2 ppm (J_{PP} 58 Hz) and +33.4 ppm (J_{PP} 45 Hz)] were observed. On proton coupling, the signals



Scheme 1.



Scheme 2.

at low field show additional P—H coupling [J_{PH} 572 Hz (δ 32.2 ppm) and J_{PH} 513 Hz (δ 33.4 ppm)], indicating the presence of a P(=S)H group [15], while those at high field exhibit coupling constants of 240 and 210 Hz, characteristic of secondary phosphines. The ^{31}P NMR data indicate that this compound is the intermediate 1-phenylphosphino-2-phenylthiophosphoryl-1,2-dicarba-*closo*-dodecaborane(12) (**4**) shown in Scheme 2.

After 1 *h*, 2 *h*, 5 *h and* 6 *h*. Samples taken after 1–6 h show decreased intensity of the signals of **2a, b** and **4**, while a singlet at +75 ppm increases in intensity, indicating the formation of **6**. A crystal structure determination (*vide infra*) showed that **6** consists of the *racemic* isomer only. Surprisingly, no signals for the proposed intermediate, the bis(phosphinesulfide) derivative, are observed. In contrast, the reaction of related 1,2-diphosphines, $H(Ph)P(CH_2)_nP(Ph)H$ (n = 2–6), with sulfur gave the corresponding disulfides, $H(S)(Ph)P(CH_2)_nP(Ph)(S)H$, as the only reaction products [19].

Molecular structure of **2a** *and* **6**

Crystal structure determinations were carried out on the *racemic* isomer **2a** (Fig. 1) and on **6**. The latter proved to be the *racemic* isomer (Fig. 2). To our knowledge, **2a** is the first structurally characterised secondary 1,2-dicarba-*closo*-dodecaboranyl(12)-bisphosphine, and **6** the first structurally characterised cyclic 1,2-bis(thiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl(12)-dithiodiphosphinic acid anhydride.

2a crystallises in the centrosymmetric monoclinic space group $C2/c$, and the molecule is located on a crystallographic C_2 axis which bisects the C(1)—C(1)′ and B(2)—B(2)′ bonds. The cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl(12)-dithiodiphosphinic acid (**6**) crystallises in the centrosymmetric monoclinic space group $P2_1/n$. Of the two possible diastereomers, the *racemic* form is present. Due to the presence of an inversion centre in both space groups, both enantiomeric forms of **2a** and **6** (*R,R*) and (*S,S*), are present in the unit cell. Selected bond lengths and bond angles are given in Tables 1 and 2.

The $B_{10}H_{10}C_2P_2Ph_2$ fragments of **6** and **2a** are similar. A comparison of the P—C and C—C bond lengths of **2a** and **6** with the related phosphino-1,2-dicarba-*closo*-dodecaboranes(12), 1-diphenylphosphino-2-thioisopropyl-1,2-dicarba-*closo*-dodecaborane(12) **7** [21], 1-diphenylphosphino-2-methyl-1,2-dicarba-*closo*-dodecaborane(12) **8** [22], and 1,2 bis(diisopropylphosphino)-1,2-dicarba-*closo*-dodecaborane (12) **9** [23], shows only a small shortening of the $C_{carbaborane}$—$C_{carbaborane}$ bond length in **2a** [1.683(2) Å] and **6** [1.658(3)] compared with **7** [1.747(5) Å], **8** [1.702(6) Å] and **9** [1.719(3) Å]. The P—$C_{carbaborane}$ [1.8727(13) for **2a**, 1.870(2), 1.862(2) for **6**, 1.884(4) for **7**, 1.884(4) for **8** and 1.891(3), 1.894(3) Å for **9**] and P—C_{Ph} bond lengths [1.8244(14) for **2a**, 1.807(3), 1.805(2) for **6**, 1.832(5) Å, 1.822(5) Å for **7**, and 1.829(4) Å, 1.832(4) Å for **8**] remain largely unchanged.

Dithiodiphosphinic acid anhydrides structurally related to **6** are rare. A similar (S)P—S—P(S) frame-

[**6**: 116.42(4), 112.39(4), **10**: 115.68(5), 117.36(5)°] bond angles of **6** and **10** are in the same range, while those of **11** are much smaller [P—S—P 97.21(6), S—P—S 109.90(8), 110.51(8)°] as the P—S—P group is part of two strained fused cyclic systems.

CONCLUSION

The results presented here show that the secondary carbaboranylphosphines **2** and **3** are readily accessible, air- and water-stable solids. The diastereoisomers **2a** and **2b** can be separated by fractional crystallisation. The reaction of **2a, b** with sulfur indicates that the reactivity of secondary carbaboranylphosphines differs significantly from that of secondary alkyl- or arylbisphosphines. Further studies of the reactivity of **2** are under way.

EXPERIMENTAL

All experiments were carried out under purified dry argon. Solvents were dried and freshly distilled under argon. NMR spectra: Avance DRX 400 (Bruker), standards: ^{1}H NMR (400 MHz): trace amounts of protonated solvent, C_6D_6, ^{13}C NMR (100.6 MHz): internal solvent, ^{31}P NMR (162 MHz): external 85% H_3PO_4, ^{11}B NMR: external $BF_3 \cdot Et_2O$. The IR spectra were recorded as KBr mulls on a Perkin–Elmer FT-IR spectrometer System 2000 in the range 350–4000 cm^{-1}. The melting points were determined in sealed

capillaries under argon and are uncorrected. *Rac*- and *meso*-1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**1**) were prepared by literature procedures [9] and obtained in 80% yield.

Synthesis of rac- and meso-1,2-bis(phenylphosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**2a**), (**2b**)

A suspension of $LiAlH_4$ (0.5 g, 13 mmol) in 25 cm^3 ether was added to a solution of **1** (5.1 g, 11.8 mmol) in 125 cm^3 ether at 0 °C over 1.5 h. The reaction was kept at 0 °C for 1 h, then for 1 h at 16 °C; finally, the mixture was refluxed for 1 h. After cooling to r.t., 2.1 cm^3 H_2O was added, the mixture filtered and the solution dried over $NaHSO_4$. The ether was removed *in vacuo* to give 3.9 g (91%) **2**. The diastereoisomers were separated by fractional crystallisation from hexane. After 6 crystallisations, 0.8 g of pure **2a** or, after 10 crystallisations, 0.06 g of **2b** were obtained. M.p. 148–149 °C, **2a**; 120–124 °C, **2b**. Found: C, 46.93; H, 6.01; P, 16.49. Calc.: for $C_{14}H_{22}B_{10}P_2$: C, 46.68; H, 6.10; P, 17.16%. IR for **2a, 2b** (KBr) cm^{-1}: 3072 (C—H); 2626, 2606, 2583, 2561 (B—H); 2323 (P—H); 1957, 1814 (Ph); 1584; 1483; 1436; 1310; 1276; 1113; 1079; 1026; 1000; 941; 919; 876; 813; 741; 728; 689; 483; 407.

Spectroscopic data for **2a** (C_6D_6, 25 °C). ^1H NMR (400 MHz): δ 7.30 (m, 4H, Ph), 7.00 (m, 6H, Ph), 4.78 (dt, 2H, P—H, $^1J_{PH}$ 244 Hz, $^3J_{PP}$ 82 Hz), 3.5–1.6 ppm (br, m, B—H); ^{31}P (161.9 MHz): $\delta -15.15$ ppm (dt, $^1J_{PH}$ 246 Hz, $^3J_{PP}$ 84 Hz); ^{13}C (100.6 MHz): δ 136.8 (m, *ipso*-C, Ph), 131.0, 130.9, 129.0 (Ph), 76.3 ppm (m, $C_2B_{10}H_{10}$); ^{11}B (128.4 MHz): $\delta -0.9$ (2B, $^1J_{BH}$ 142 Hz), -7.2 (4B, $^1J_{BH}$ 144 Hz), -9.4 (2B, $^1J_{BH}$ 225 Hz), -11.3 ppm (2B).

Spectroscopic data for **2b** (C_6D_6, 25 °C). ^1H NMR (400 MHz): δ 7.30 (m, 4H, Ph), 7.00 (m, 6H, Ph), 4.78 (dt, 2H, P—H, $^1J_{PH}$ 239 Hz, $^3J_{PP}$ 87 Hz), 3.5–1.6 ppm (br, m, B—H); ^{31}P (161.9 MHz): $\delta -14.98$ ppm (dt, $^1J_{PH}$ 239 Hz, $^3J_{PP}$ 87 Hz); ^{13}C (100.6 MHz): δ 136.8 (m, *ipso*-C, Ph), 131.0, 130.9, 129.0 (Ph), 77.6 ppm (m, $C_2B_{10}H_{10}$); ^{11}B (128.4 MHz): $\delta -0.9$ (2B, $^1J_{BH}$ 142 Hz), -7.2 (4B, $^1J_{BH}$ 144 Hz), -9.4 (2B, $^1J_{BH}$ 225 Hz), -11.3 ppm (2B).

Synthesis of 1-phenylphosphino-1,2-dicarba-*closo*-dodecaborane(12) (**3**)

3 was prepared analogously to **2** from **1** (5.7 g, 13.3 mmol) in 125 cm^3 ether, 0.8 g (21 mmol) $LiAlH_4$ in 30 cm^3 ether and 10.5 cm^3 H_2O. **3** was purified by column chromatography (hexane/acetone 4:1), yield 1.4 g (42%). M.p. 33–36 °C. ^1H NMR (400 MHz, C_6D_6, 25 °C): δ 7.05, 7.00, 6.92 (m, 5H, Ph), 4.57 (d, 1H, $^1J_{PH}$ 229 Hz, P—H), 3.5–1.6 ppm (br, m, B—H); ^{31}P (161.9 MHz, C_6D_6, 25 °C): $\delta -2.67$ ppm (d, $^1J_{PH}$ 229 Hz); ^{11}B (128.4 MHz, C_6D_6, 25 °C): $\delta -1.2$ (1B, $^1J_{BH}$ 160 Hz), -2.7 (1B, $^1J_{BH}$ 170 Hz), -7.6 (2B, $^1J_{BH}$ 152 Hz), -9.5 (1B, $^1J_{BH}$ 182 Hz), -11.0 (1B, $^1J_{BH}$ 200 Hz), -12.8 ppm (4B); ^{13}C (100.6 MHz, C_6D_6, 25 °C): δ 136.7 (d, $^1J_{CP}$ 18 Hz, *ipso*-C, Ph), 131.8, 130.6, 129.8 (Ph), 69.0 (d, $^1J_{CP}$ 60 Hz, $C_2B_{10}H_{11}$), 63.8 ppm (d, $^1J_{CH}$ 196 Hz, $C_2B_{10}H_{11}$); IR (KBr) cm^{-1}: 3058, 2957, 2927 (C—H); 2586 (B—H); 2320 (P—H); 1957, 1884 (Ph); 1585; 1483; 1437; 1308; 1275; 1172; 1115; 1091; 1072; 1025; 1001; 944; 918; 900; 827; 795; 739; 720; 692; 628; 481; 408. Found: C, 39.07; H, 6.77; P, 11.50. Calc.: for $C_8H_{17}B_{10}P$: C, 38.14; H, 6.75; P, 12.28%.

Synthesis of the cyclic anhydride of 1,2-bis(phenylthiophosphoryl)-1,2-dicarba-*closo*-dodecaboranyl-(12)-dithiodiphosphinic acid (**6**)

In undecane. A racemic mixture of **2a, b** (0.72 g, 2.0 mmol) and sulfur (0.07 g, 9.0 mmol) were heated in undecane (20 cm^3) at 190–200 °C for 5 h. The solvent was distilled off *in vacuo*, the greyish residue was then dissolved in hot hexane and filtered. **6** was obtained on cooling the hexane solution to −5 °C, yield 0.6 g (67%). M.p. 229–232 °C. ^1H NMR (400 MHz, C_6D_6, 25 °C): δ 8.15 (m, Ph), 6.93 (m, Ph), 3.5–1.9 ppm (br, m, B—H); ^{31}P (161.9 MHz, C_6D_6, 25 °C): δ 75.1 ppm; ^{11}B (128.4 MHz, C_6D_6, 25 °C): $\delta -2.7$ (J_{BH} 167 Hz), -4.2 (J_{BH} 166 Hz), -10.3 ppm; ^{13}C (100.6 MHz, C_6D_6, 25 °C): δ 134.3, 133.8, 130.1, 128.9 (Ph), 85.4 (m, $C_2B_{10}H_{10}$). IR (KBr) cm^{-1}: 3059 (C—H); 2664, 2651, 2615, 2583, 2571, 2554 (B—H); 1815 (Ph); 1580; 1480; 1437; 1311; 1187; 1161; 1092; 1078; 1027; 997; 903; 848; 799; 735; 722; 687; 671 ($\nu_s P_2S_2$); 625; 614; 560; 535; 475; 430; 417. Vibrations for P—S—P and $\nu_{as}P_2S_2$ are expected in the range 450–600 cm^{-1} [28]; however, they cannot be unambiguously assigned. Found: C, 37.04; H, 4.89; S, 20.92; P, 13.23. Calc.: for $C_{14}H_{20}B_{10}P_2S_3$: C, 37.00; H, 4.40; S, 21.04; P, 13.59%.

Without solvent. A racemic mixture of **2a, b** (1.0 g, 2.7 mmol) and sulfur (0.35 g, 10.9 mmol) were heated at 105–110 °C for 6 h. After 10 min, 1, 2, 5 and 6 h the reaction mixture was cooled to room temperature and samples were taken for ^{31}P NMR spectroscopic studies. After completion of the reaction, the white mixture was dissolved in hot hexane and worked up as described above giving 0.53 g (44%) of **6**.

Data collection and structural refinement of **2a** *and* **6**

Crystal data for **2a**. $C_{14}H_{22}B_{10}P_2$, $M = 360.36$, white crystals, $0.4 \times 0.3 \times 0.2$ mm, monoclinic, space group $C2/c$ (no. 15), $T = 293(2)$ K, $a = 20.2581(13)$, $b = 8.8653(6)$, $c = 11.8046(9)$ Å, $\beta = 112.374(1)°$, $V = 1960.4(2)$ Å^3, $Z = 4$, $D_c = 1.221$ g cm^{-3}, $F(000) = 744$, μ(Mo-K_α) = 0.216 mm^{-1}, 7114 reflections collected with $2 < \Theta < 26°$; of these 1826 were independent; 162 parameters, refinements converge to $R_1 = 0.0317$, $wR_2 = 0.0816$ (for reflections with $I > 2\sigma(I)$), $R_1 = 0.0359$, $wR_2 = 0.0837$ (all data).

Crystal data for **6**. $C_{14}H_{20}B_{10}P_2S_3$, $M = 454.52$,

white crystals, $0.3 \times 0.2 \times 0.2$ mm, monoclinic, space group $P2_1/n$ (no. 14), $T = 223(2)$ K, $a = 13.5378(9)$, $b = 11.0197(7)$, $c = 15.6155(10)$ Å, $\beta = 104.996(1)^\circ$, $V = 2250.2(3)$ Å^3, $Z = 4$, $D_c = 1.342$ g cm^{-3}, $F(000) = 928$, $\mu(\text{Mo-}K_\alpha) = 0.472$ mm^{-1}, 9685 reflections collected with $1.8 < \theta < 26^\circ$; of these 4015 were independent; 342 parameters, refinements converge to $R_1 = 0.0413$, $wR_2 = 0.0893$ (for reflections with $I > 2\sigma(I)$), $R_1 = 0.0564$, $wR_2 = 0.0975$ (all data).

Data (Mo-K_α, $\lambda = 0.71073$ Å) were collected with a Siemens CCD (SMART). All observed reflections (2θ range: 4–52°) were used for determination of the unit cell parameters. The structures were solved by direct methods (SHELXTL PLUS [26]) and subsequent difference Fourier syntheses and refined by full-matrix least-squares on F^2 (SHELXTL PLUS [26]). Restrictions for **2a**: P, B, and C atoms anisotropic, H atoms located and refined isotropically. Restrictions for **6**: S, P, B, and C atoms anisotropic, H atoms located and refined isotropically. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Fachinformationszentrum [27].

(Received 15 July 1997; accepted 16 October 1997)

Abstract—A μ-Oxo binuclear iron(III) complex $[Fe_2O(bipy)_4Cl_2](ClO_4)_2 \cdot 0.25CH_3CN \cdot 0.25CH_3OH \cdot 0.25H_2O$ with 2,2′-bipyridine and chlorine anion as terminal ligands has been prepared and characterized by X-ray crystallography, Mössbauer and magnetic spectroscopic measurements. The dimeric cation exhibits typical Fe—μ—O bond lengths of 1.786 Å and a bridge angle of 167.0°. The Fe···Fe separations are 3.549 Å. Magnetic susceptibility data have been measured in the temperature range 75–300 K. The μ-Oxo bridge could mediate a strong antiferromagnetic exchange interaction ($J = 115.3\ cm^{-1}$) between the two Fe(III) centers in high spin states. The data of isomer shift and quadrupole splitting obtained from Mössbauer spectrum are in agreement with the distorted octahedral coordination sphere of Fe(III) sites in high spin states. © 1998 Elsevier Science Ltd. Keywords: μ-Oxo iron(III) complexes; dinuclear iron complexes; magnetism; Mössbauer; electronic spectra; infrared spectra.

The (μ-Oxo) diiron(III) complexes bridged by an oxide (or hydroxide, alkoxo, etc) and carboxylates have long been of considerable interest as a result of their distinctive magnetic properties, spectroscopic properties and their relevance to diiron nonheme proteins, such as the invertebrate dioxygen carriers hemerythrin and myohemerythrin, the R2 protein of the ribonucleotide reductase (RNR) from *Escherichia coli*, rubrerythrin and the purple acid phosphatases [1–3]. In the past decade a number of (μ-Oxo) complexes have been reported, of which the (μ-Oxo) diiron(III) complexes bridged by a single oxide is an important category [4,5] and even at present much attention is still paid to this field [6–9]. The crystal structure of μ-Oxo binuclear iron(III) complex using bidentate ligand phenanthroline as terminal ligands ($[Fe_2O(phen)_4(H_2O)]_2(NO_3)_2 \cdot 3.5H_2O$) has been reported [10]. The μ-Oxo binuclear iron(III) complex using bidentate ligand bipyridine as terminal ligands ($[Fe_2O(bipy)_4](SO_4)_2 \cdot 3.5H_2O$) was also synthesized early [11], but the relevant crystal structures have not been obtained until now and the magnetic properties was poorly characterized. In our efforts to synthesize terephthalate-bridged polynuclear iron(III) complex, we obtained the single crystals of the title compound unexpectedly in organic solvent (CH_3OH and CH_3CN). Herein we reported the synthesis, crystal structure, Mössbauer and magnetic spectroscopic properties of the title compound.

EXPERIMENTAL

Preparations

All the chemicals used were of reagent grade and used as received. The piperidinium salt of terephthalic acid was prepared as previously described [12]. The complex $[Fe(bpy)_3](ClO_4)_3 \cdot 3H_2O$ was prepared by the method of Burstall and Nyholm [13]. All operations were carried out under aerobic conditions at ambient temperature.

$[Fe_2O(bipy)_4Cl_2](ClO_4)_2 \cdot 0.25CH_3CN \cdot 0.25CH_3OH \cdot 0.25H_2O$ was prepared as follows: A methanolic solution (15 ml) of bipyridine (2 mmol) and piperidinium isophthalate (0.5 mmol) was added to a solution (15 ml) of iron(III) chloride hexahydrate (1 mmol) in the same solvent with continuously stirring. Then a methanolic solution (10 ml) of sodium perchlorate (2 mmol) was added, whereupon a yellow precipitate formed. The solid was filtered out, washed with methanol and air-dried. Good shaped black single crystals of X-ray quality were obtained in a 54% yield by dispersing ether into CH_3CN solution of the title complex for about two weeks. Anal. Calc.: for $C_{40.75}H_{34.25}Cl_4Fe_2N_{8.25}O_{9.50}$: C, 46.83; H, 3.30; N, 11.06; Fe, 10.69. Found: C, 46.56; H, 3.35; N, 10.92, Fe, 10.98%.

X-ray structure determination

Details of the X-ray diffraction studies of the title compound may be found in Table 1. Diffraction data were collected at 295 ± 2 K on a P4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) by using the ω-$/2\theta$ scan technique. Intensity data were collected in the 2θ range of 3–46°. A total of 6233 reflections were collected and 3124 of them considered as observed [$I > 2\sigma(I)$] and used for the refinement of the structure. The intensities were corrected for Lorentz-polarisation and absorption. Two iron atoms were located by direct method. The positions of all non-hydrogen atoms were created by Fourier syntheses. The C43 in the solvent CH_3OH was found to exhibit locally positional disorder and it has two possible positions (symmetry operation: #1: $-x+1$, y, $-z+5/2$). The hydrogen atoms in C2, C13, C14, C17, C18, C22, C27, C29, C38 were placed in calculated idealized positions (the C—H bond length is 0.930). The hydrogen atoms of crystallization H_2O molecules and solvent H_2O molecules were not disposed. All the other hydrogen atoms were created using difference Fourier syntheses. The final cycle of full-matrix least-squares refinement on F^2 was based on 3124 observed reflections [$I > 2\sigma(I)$] and variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.059$, $wR_2 = [\Sigma[W(F_o^2 - F_c^2)^2]/\Sigma[W(F_o^2)^2]]^{1/2} = 0.1387$. ($W = 1/[\sigma^2(F_o^2) + (0.0920 \times p)^2$, where $p = [\max(F_o^2, 0) + 2F_c^2]/3$). The maximum and minimum peaks on the final difference Fourier map corresponded to 0.645 and 0.356 eÅ^{-3}, respectively. The selected bond lengths and angles are listed in Table 2. Complete listing of atomic coordinates, bond lengths and angles, and thermal parameters are included in the supplementary material.

Physical measurements

UV-Vis spectra were recorded on an Shimadzu UV-visible recording spectra photometer (UV-240) in 1-cm quartz cuvette using H_2O as a solvent. IR spectra were recorded on a Fourier Transform Infrared Spectrometer (170SX) and samples were dispersed in 13-mm diameter KBr pellets. Magnetic susceptibility data on powder-samples were measured over a temperature range of 75–300 K at a measuring 6000 G by using a CAHN-2000 Faraday-type magnetometer. The apparatus was calibrated with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine). Diamagnetic corrections were made using Pascal's constants. Mössbauer spectra were measured with a symmetrical constant acceleration mode at room temperature. Data were collected with an LSI based 256 channel multichannel analyzer using 15 mCi^{57}Co(Pd) as a radiation source. Spectra were fitted with a Lorentzian line shape.

RESULT AND DISCUSSION

Structure description

The labeled molecular structure of the title compound is depicted in Fig. 1. The two ferric atoms are

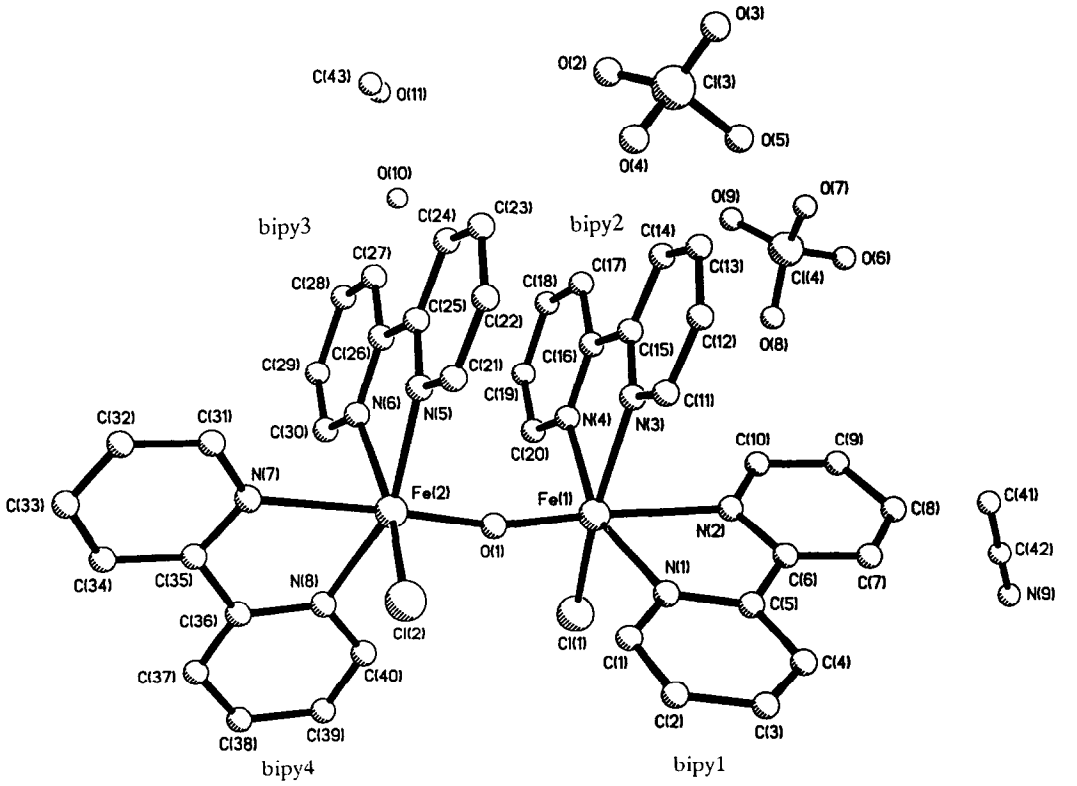

Fig. 1. Plot of the structure of the title compound, together with the numbering scheme used in the structural discussion. Hydrogen atoms are omitted for clarity.

bridged by a single oxo ligand. Each of the two Fe atoms is hexacoordinate and possesses an N_4ClO environment by virtue of four nitrogen atoms [N(1), N(2), N(3), N(4) for Fe(1) and N(5), N(6), N(7), N(8) for Fe(2)] from two chelating bipy groups, a terminal chlorine atom [Cl(1) for Fe(1) and Cl(2) for Fe(2)] and a bridging oxygen atom [O(1)]. The chloride ligand is *cis* to the bridging oxo atom in each case. The Fe(1)—N (bipy) average bond length is 2.193 Å and Fe(1)—Cl(1) bond length is 2.353 Å, while Fe(2)—N (bipy) average bond length is 2.178 Å and Fe(2)—Cl(2) bond length is 2.315 Å. For Fe(1) and Fe(2) the large deviations of bond angle from 90° of the idealized octahedral geometry are found for angles N(1)—Fe(1)—N(2) [73.4(2)°], N(4)—Fe(1)—N(3) [74.1(3)°] and N(8)—Fe(2)—N(7) [73.7(2)°], N(5)—Fe(2)—N(6) [74.5(3)], respectively. So the Fe atoms both have distorted-octahedral coordination sphere. Fe(1) is 0.299(5) Å out of the best equatorial plane which is defined by N(1), N(3), N(4) and Cl(1) (the largest deviation from the mean plane is 0.0325 Å for N(3)), while Fe(2) is 0.271(7) Å out of the best equatorial plane which is defined by N(5), N(6), N(8) and Cl(2) (the largest deviation from the mean plane is 0.0325 Å for N(6)). The Fe—O—Fe linkage is nonlinear, exhibiting an angle (Fe(1)—O—Fe(2)) of 167.0°C. This value is in the range of Fe—O—Fe angles (139–180°) known from previous studies [4,5]. The Fe—μ—O distances (Fe(1)—μ—O = 1.788(4) Å, Fe(2)—μ—O = 1.785(4) Å) are entirely characteristic of such linkages with a known range of 1.755–1.82 Å [4,5]. The combination of the nonlinear bridge and the strong Fe—μ—O bonding produces an intermetallic spacing of 3.54 Å. Because N(2) and N(7) trans to the μ-Oxo ligand are subject to a significant *trans* influence from that strongly bond bridging group, the bond lengths of Fe(1)—N(2) and Fe(2)—N(7) (2.286(6) and 2.242(5)) are apparently longer than those for other Fe—N bond lengths. Two of the chelate rings, bipy2 and bipy3 (Fig. 1) are nearly parallel to one another (dihedral angle 2.114°).

Magnetic properties

The temperature dependence of the molar magnetic susceptibility of the title compound in the form of χ_M versus T is shown in Fig. 2. The effective magnetic moment at 300 K is 2.34μ_B and 0.68μ_B at 75 K. This gradual decrease of μ_{eff} as the temperature is lowered indicated an antiferromagnetic exchange between the two iron(III) centers. The magnetic behavior of the title compound was interpreted by use of the Heisenberg Dirac. Van Vleck $S_1 = S_2 = 5/2$ spin-coupled dimer model ($H = -2JS_1S_2$), where S_1 and S_2 are the spin operators for the two iron(III) centers [14]. The expression of magnetic susceptibility of the title compound is

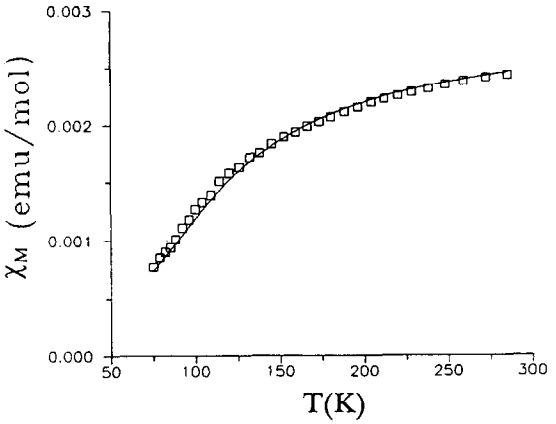

Fig. 2. Experimental (□) and calculated (—) temperature dependent molar magnetic susceptibility.

$$\chi_M = (1-\rho)Ng^2\beta^2/kT\cdot[(2e^{2x}+10e^{6x}+28e^{12x}+60e^{20x}+110e^{30x})/(1+3e^{2x}+5e^{6x}+7e^{12x}+9e^{20x}+11e^{30x})]+35\rho/8T$$

where $x = -J/kT$, ρ = mole fraction of paramagnetic impurities with ($S = 5/2$) spin-only behavior. N, g, β, k and T have their usual meanings.

Using the equation, the least-squares fit to the magnetic susceptibility data gives the parameters: $J = -115.3$ cm^{-1}, $\rho = 4.8\times10^{-3}$ and $R = 2.51\times10^{-3}$ [$R = \Sigma(\chi_{calc}-\chi_{obs})^2/\Sigma(\chi_{obs})$], assuming $g = 2$. The J value indicates a strong antiferromagnetic exchange coupling between the two Fe(III) centers. For complex $[Fe_2O(bipy)_4](SO_4)_2\cdot3.5H_2O$ [11], since the possible small amount of paramagnetic monomer was not considered in the fitting of the magnetic susceptibility data, its magnetic properties was poorly characterized.

The exchange interaction parameters in most of μ-Oxo binuclear iron complexes are from 80 to 130 cm^{-1} [4–9]. The value found here is therefore consistent with the range. Superexchange pathways within a Fe_2O^{4+} unit consist of various orbital overlaps which serve to couple $S = 5/2$ Fe(III) ions via the diamagnetic oxide bridge. For (μ-o) and μ-carboxylates bridged iron(III) complexes Gorun and Lippard have proposed a correlation between J and the shortest superexchanges pathway, but the correlation does not apply to the single μ-Oxo bridged diiron(III) centers [15]. The exchange interaction parameters J values and some structural parameters of a series of single μ-Oxo bridged diiron(III) complexes are listed in Table 3 [16–28]. Although no quantitative correlation between any geometric parameters and the magnitude of the exchange coupling is established from the table, it can be found that J increase with an increased Fe—O—Fe angle and with a decrease in the average. Fe—(μ—O) bond length, approximately.

Mössbauer spectra

The Mössbauer spectrum of the compound at room temperature was measured and the nonlinear least fit gives an isomer shift of 0.3620 mm/s and a quadrupole splitting of 1.364 mm/s. The isomer shift is in the range 0.35–0.60 mm/s which are characteristic of 5- or 6-coordinate high-spin diferric μ-Oxo and μ-hydroxo complexes [4]. The isomer shift reported here supported the high-spin state of iron(III) ($S = 5/2$) determined by magnetism susceptibility fit. The magnitude of the quadrupole splitting is a reflection of the unsymmetrical electric field gradient about each high-spin iron(III) site. The majority of the oxo-bridged diferric complexes gave quadrupole splittings >1 mm/s [4]. The relatively large quadrupole splitting observed here indicate an unsymmetric ligand field about the iron(III) atoms and this result is consistent with the distorted octahedral coordination sphere of Fe(III) centers in the title compound.

Electronic spectra and infrared spectra

The electronic spectrum of an aqueous solution of the title compound show that the well-resolved optical maxima occur at ~230 and ~275 nm with extinction coefficients 31,500 M^{-1} cm^{-1} and 39,500 M^{-1} cm^{-1}. Two shoulders are apparent at ~470 and ~510 nm with $\varepsilon = 550$ M^{-1} cm^{-1} and 450 M^{-1} cm^{-1}, which are assigned to $^6A_1 \rightarrow (^1E, ^4A_1)$ ligand field transition, enhanced by nearby oxo LMCT bands [29]. In addition, a well-resolved optical maxima with an apparent $\lambda_{max} \sim 350$ nm ($\varepsilon \sim 7000$ M^{-1} cm^{-1}) may be noted, which lie in the so-called oxo dimer region and has been assigned to $O^{2-} \rightarrow$ Fe(III) charge-transfer transitions [30].

Infrared spectra of 2,2′-bipyridine, the $[Fe(bipy)_3]^{3+}$ monomer, and the title complex were examined and compared. As observed, the dimer has a strong new absorption at 824 cm^{-1}, which is characteristic of the asymmetric stretch of an Fe—O—Fe moiety [9].

(Received 4 August 1997; accepted 9 October 1997)

Abstract—The structure of $CrBr_2 \cdot 6(py)$ (py = pyridine) consists of a Cr atom at the intersection of three 2-fold axes in the space group *Ccca*. The Cr is coordinated to 4 N atoms of py ligands [CrÅN distances of 2.135(4) and 2.164(5) Å] and interacts weakly with 2 Br ions [Cr—Br distance 2.998(1) Å] giving the CrN_4Br_2 unit D_{2h} symmetry. There are two py molecules per Cr centre trapped in the lattice. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: $[CrBr_2(pyridine)_4] \cdot 2pyridine$; X-ray structure.

Interest in Jahn-Teller distortions, particularly in d^9 and d^4 systems, has remained high over many years. For example, many crystallographic studies have been completed on copper^{II} complexes. Much less has been done with the high-spin d^4 systems Cr^{II} and Mn^{III}. To isolate structural distortions caused by electronic effects from those due to the presence of non-equivalent ligands on a metal centre, monomeric complexes with six equivalent monodentate ligands are of particular importance. Amongst the very few structurally characterized compounds in this category are $[Mn(urea)_6][ClO_4]_3$ [1], $[Cr(CNPh)_6][PF_6]_2$ [2], $[Cr(H_2O)_6][SiF_6]$ [3], CrF_6 units in $CrNbF_6$ [4] and $Cr(H_2O)_6^{2+}$ octahedra in the lattices of Tutton salts [5]. Such compounds are therefore rare relative to those of the type ML_4X_2 and it has recently been shown [6] that even the complex with the empirical formula $Cr(py)_6(PF_6)_2$ (py = pyridine) is an example of the latter type. In this complex, only four of the py molecules are coordinated to the Cr atom and there are weak axial interactions with F atoms of PF_6^- species. It was considered likely at the time of its synthesis that the related complex $CrBr_2 \cdot 6py$, **1**, contains the $[Cr(py)_6]^{2+}$ cation [7]. Thermogravimetric analysis of **1** showed [7] the rapid loss of between 3 and 4 py molecules, with no evidence for even the transitory existence of $CrBr_2 \cdot 4py$, as might perhaps be expected if **1** is analogous to the PF_6 compound. It was therefore of interest to determine the structure of **1**.

EXPERIMENTAL

Crystals of **1** were prepared as previously described [7]. A suitable crystal was sealed in a nitrogen-filled Lindemann capillary and stored in liquid nitrogen to prevent slow decomposition and loss of py.

X-ray crystallographic data collection was carried out on an Enraf-Nonius CAD-4 diffractometer using graphite monochromated Mo–K_α radiation at 173 K. Crystal structure refinement calculations were carried out (at UMD) on a PC Express computer with the SHELX program system [8]. NRCVAX programs were used for scaling and data reduction [9]. Unit cell parameters were obtained by least squares analysis of 25 low angle reflections. The stability of the crystal was measured by monitoring periodically three standard reflections; no systematic intensity variations were observed. Intensity data were corrected for Lorentz and polarization factors. Atomic scattering factors were taken from tabulated values.

The Cr atom was found using direct methods and cycles of Fourier and difference Fourier calculations were used to find the remaining atoms. All atoms were refined with anisotropic thermal displacement

parameters except H atoms whose calculated ideal positions were included but not refined. Relevant data concerning the crystal, data collection and structure solution are recorded in Table 1. (Tables of crystallographic data, including a listing of anisotropic displacement parameters, bond lengths and angles and observed and calculated structure factors for **1** have been deposited with the Cambridge Crystallographic Data Center.)

RESULTS AND DISCUSSION

The problem of py loss, resulting in rapid decomposition of crystals sealed in capillaries at room temperature, was overcome by freezing the sample and collecting the data at low temperatures.

Figure 1 is an ORTEP view of **1** and shows that each Cr atom is surrounded by four py molecules and the two Br atoms. Two py molecules are trapped in the lattice. Compound **1** crystallizes in the space group *Ccca* with 4 molecules in the unit cell and with each Cr atom at the intersection of the three 2-fold axes passing through N1—Cr, N3—Cr and Br—Cr. The relevant bond lengths are Cr—N(1) 2.135(4), Cr—N(3) 2.164(5) and Cr—Br 2.998(1) Å, giving the CrN_4Br_2 unit D_{2h} symmetry. The Cr—N bond lengths are comparable with those found in similar complexes containing $Crpy_4X_2$ units (X = Cl [10], X = FPF_5 [6]) and in other related complexes [11]. The Cr—Br distance of ~3 Å is significantly longer than those found (2.36–2.839 Å) in other Cr(II) complexes [12]. It is also approximately 0.24 Å longer than the sum of the ionic radii of the two ions [13]. At best, therefore, the Br interacts only very weakly with the Cr centre. A similar situation has been found for the Cr—Cl interaction in $Crpy_4Cl_2$ [10]. The C—N, C—C and C—H distances in the py rings are normal.

For clarity, only the unique atoms are labelled in Fig. 1 which also shows the positions of the py molecules trapped in the lattice. Although the molecule contains only two lattice py units per Cr atom, Fig. 1 shows the positions of all the symmetry-related lattice py molecules in the environment of each Cr atom. The view down the N3—Cr axis (Fig. 2) shows this more clearly. Notice that the plane of the py ring of N3 on *one* side of the Cr—N1 py plane is parallel (within 2.8°) with the planes of the two lattice py rings on the *opposite* side of the Cr—N1 py plane. Figure 2 also illustrates that the lattice py molecules are somewhat closer to the N1 py (2.4–2.9 Å) than to the N3 py (2.9–3.3 Å). This crowding of the N1 py may be responsible for the slightly shorter Cr—N1 distance compared to

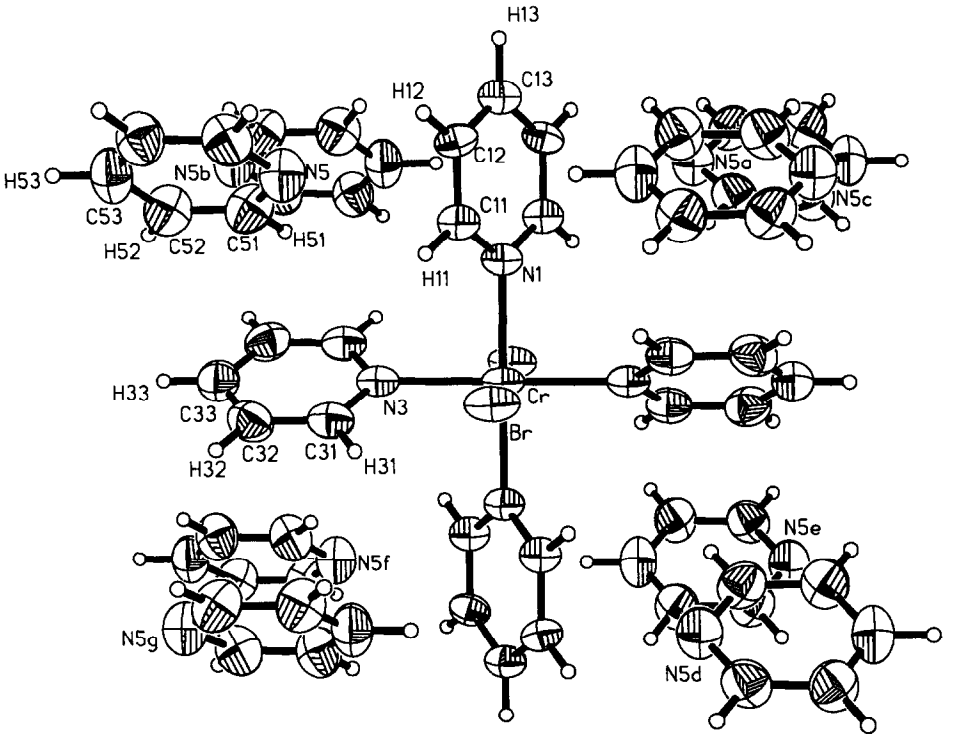

Fig. 1. Diagram of **1** looking down the Cr—N3 axis showing the relationship between coordinated and lattice pyridine molecules.

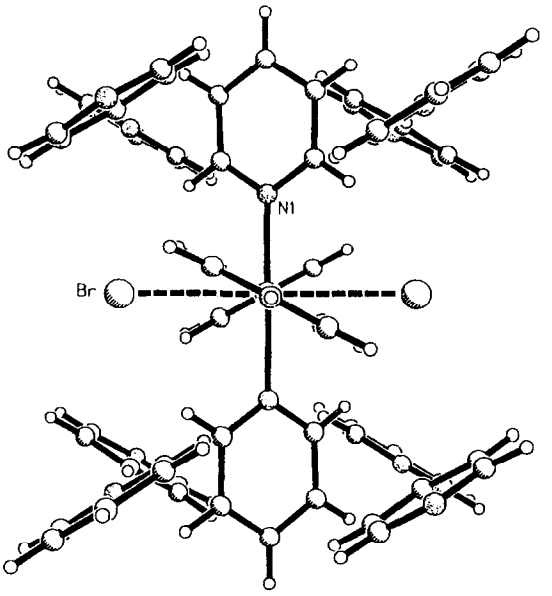

Fig. 2. ORTEP diagram of complex **1** looking down the Cr—Br axis.

the Cr—N3 distance since there is no electronic reason associated with the d^4 configuration of the Cr atom that requires this.

Thus, despite its thermochemical behaviour, **1** does not contain 6 equivalent ligands. It is simply another example of the common ML_4X_2 arrangement about which much has been written in terms of the Jahn-Teller effect.

The syntheses and crystal structures of $[PPh_4][In(SePh)_4]$ and $[PPh_4][In(SePh)_3(SeH)]$

Donna M. Smith and James A. Ibers*

Department of Chemistry, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208-3113, U.S.A.

(Received 15 September 1997; accepted 30 September 1997)

Abstract—The reaction of $InCl_3$ with NaSePh in ethanol followed by addition of PPh_4Cl affords tetraphenylphosphonium tetra(benzeneselenolato)indium(III), $[PPh_4][In(SePh)_4]$ (**1**). Reaction of the $[In(SePh_4)]^-$ reaction mixture with $NaBH_4$ and elemental sulfur followed by the addition of PPh_4Cl yields tetraphenylphosphonium tri(benzeneselenolato)(hydroselenido)indium(III), $[PPh_4][In(SePh)_3(SeH)]$ (**2**). The structures of **1** and **2**, as determined from single-crystal X-ray data, feature well-separated cations and anions with the In(III) centers of the anions tetrahedrally coordinated to four $[SePh]^-$ ligands or three $[SePh]^-$ ligands and one $[SeH]^-$ ligand, respectively. © 1998 Published by Elsevier Science Ltd. Keywords: indium-selenolate complexes; synthesis; X-ray structures.

Many indium thiolates and selenolates have been synthesized [1–3], owing to the potential of such materials as single-source precursors [3,4]. Here we report the syntheses and characterization of the anionic indium selenolates $[In(SePh)_4]^-$ and $[In(SePh)_3(SeH)]^-$ as their PPh_4^+ salts. Apparently, only one other anionic indium selenolate has been reported, namely $[InBr(SePh)_3]^-$ as its $[PPh_4]^+$ salt, although it has not been structurally characterized [2]. Little reaction chemistry of main-group benzeneselenolate compounds has been reported.

EXPERIMENTAL

All manipulations were carried out under N_2 with the use of standard Schlenk techniques. Solvents were purchased from Baxter Scientific Products Inc., McGaw Park, IL and were distilled, dried, and degassed before use. EtOH was dried over MgI_2; CH_3CN was dried over CaH_2. The remaining reagents were purchased from Aldrich Chemical Co., Milwaukee, WI and used as received. The ^{77}Se NMR spectra were obtained with the use of a Varian 400 MHz Unity Plus spectrometer equipped with a 10 mm tunable broad-band probe, a variable temperature apparatus, and a deuterium lock. All ^{77}Se NMR chemical shifts are referenced to the external Ph_2Se_2 standard at 460 ppm, which in turn is referenced to $(CH_3)_2Se$ at 0 ppm.

Preparation of $[PPh_4][In(SePh)_4]$ (1)

NaSePh was prepared *in situ* by the reaction of $NaBH_4$ (0.113 g; 3.0 mmol) in 10 ml EtOH with Ph_2Se_2 (0.468 g; 1.5 mmol) in 10 ml EtOH. A suspension of $InCl_3$ (0.221 g; 1.0 mmol) in 10 ml EtOH was added with stirring to the pale yellow NaSePh solution. After the solution was stirred for several hours, PPh_4Cl (0.430 g; 1.15 mmol) in 10 ml EtOH was added to give a white precipitate. The precipitate was collected by filtration and redissolved in acetonitrile. The solvent was removed under vacuum to afford light yellow crystals of **1**. Yield: 0.50 g; 46% based on In. Found: In, 10.94; C, 51.15; H, 4.39. Calc. for $C_{48}H_{40}InPSe_4$: In, 10.65; C, 53.46; H, 3.74. ^{77}Se NMR (d-DMF, 25°C): $\delta = 69.9$ ppm.

Preparation of $[PPh_4][In(SePh)_3(SeH)]$ (2)

$InCl_3$ (0.110 g; 0.5 mmol) in 15 ml EtOH was reacted with NaSePh (2.0 mmol prepared as described

* Author to whom correspondence should be addressed.

above). The resultant yellow solution was filtered into a flask containing the dry reagents $NaBH_4$ (0.067 g; 1.5 mmol) and elemental sulfur (0.019 g; 0.5 mmol). The solution fizzed and a milky white precipitate formed immediately. The solution was filtered again and PPh_4Cl (0.21 g; 0.5 mmol) in 5.0 ml EtOH was added. Slow evaporation of the solvent afforded white needles (**2**) and a light yellow precipitate. Crystals of **2** were manually separated from the yellow powder. Yield: 0.20 g; 40% based on In. IR: ν(Se—H) 2241 cm^{-1}.

Crystallographic studies

Intensity data were collected at 113(2) K with Mo-K_α radiation on a Picker diffractometer for **1** and with Cu-K_α radiation on an Enraf-Nonius CAD4 diffractometer for **2**. The number of reflections used to obtain unit cell parameters and the 2θ ranges involved were **1**: 25, 30–35°; **2**: 25, 30.1–36.1°. In each study, six standard reflections were monitored and were found to be constant within counting statistics. Continuous scan data were collected for **1** and processed [5] whereas profile data were collected for **2** and processed accordingly. Both data sets were corrected for absorption by means of the analytical method [6]. Additional experimental details are given in Table 1.

The structures were solved by direct methods [7] and were refined by full-matrix least squares methods [8]. Phenyl H atoms were placed in calculated positions and were refined with the use of a riding model. Anisotropic displacement parameters were refined for the heavy atoms and the majority of the C atoms in **1**; the ellipsoids for atoms C(34), C(35), C(52), C(65), C(76), and C(81) were non-positive definite and thus isotropic displacement parameters were refined for these atoms. Anisotropic displacement parameters were refined for all of the non-hydrogen atoms in **2**. No unusual features were observed in the final difference electron-density maps. Lists of final coordinates, displacement parameters, bond distances and angles, hydrogen coordinates, and structure factors have been deposited as supplementary data with the Editor.

[a] The low-temperature system is based on a design by Huffman [16]. The diffractometer was operated with the use of the Indiana University PCPS system [17].

[b] The analytical method as employed in the Northwestern absorption program AGNOST was used for the absorption correction [6].

[c] $R(F_o) = \Sigma||F_o|-|F_c||/|F_o|$; $F_o^2 > 2\sigma(F_o^2)$. $R_w(F_o^2) = \{\Sigma[w(F_o^2-F_c^2)^2]/\Sigma wF_o^4\}^{1/2}$; $w^{-1} = \sigma^2(F_o^2)+(0.04\times F_o^2)^2$ for $F_o^2 \geq 0$ and $w^{-1} = \sigma^2(F_o^2)$ for $F_o^2 < 0$.

RESULTS AND DISCUSSION

The structure of $[PPh_4][In(SePh)_4]$ (**1**) comprises well-separated cations and anions. The In(III) center is tetrahedrally coordinated to four $[SePh]^-$ ligands (Fig. 1). The In—Se bond distances range from 2.570(2) to 2.584(2) Å (Table 2), comparable to the In—$Se_{terminal}$ bond distances in $K_8In_4Se_{10}\cdot 16H_2O$ (average 2.543(2) Å) [9] and in $[MeIn(\mu\text{-}SePh)(SePh)]_\infty$ (2.541(4) and 2.542(3) Å) [3]. The Se—In—Se bond angles in $[PPh_4][In(SePh)_4]$ range from 102.00(7) to 112.58(7)°, slightly distorted from tetrahedral, probably as a result of the steric crowding of the bulky phenyl rings. The structure of $[PPh_4][In(S^tBu)_4]$ also features an In(III) atom in a slightly distorted tetrahedral environment [10].

As expected, the ^{77}Se NMR spectrum of $[PPh_4][In(SePh)_4]$ shows a single resonance (δ = 69.9 ppm). This value falls in the broad range observed for organometallic selenolates [11] and is close to that observed for $In(SePh)_3$ (δ = 38.8 ppm) [12].

The structure of $[PPh_4][In(SePh)_3(SeH)]$ (**2**) also comprises well-separated cations and anions. The In(III) center is tetrahedrally coordinated to three

Table 2. Selected bond distances (Å) and angles (°) for $[PPh_4][In(SePh)_4]$ (**1**) and $[PPh_4][In(SePh)_3(SeH)]$ (**2**)

Distance or Angle	1	2
In(1)—Se(1)	2.584(2)	2.553(1)
In(1)—Se(2)	2.571(2)	2.533(1)
In(1)—Se(3)	2.575(2)	2.555(1)
In(1)—Se(4)	2.570(2)	2.521(2)[a]
Se(2)—In(1)—Se(1)	102.00(7)	117.83(5)
Se(3)—In(1)—Se(1)	110.33(8)	100.20(4)

Se(3)—In(1)—Se(2)	112.34(8)	122.08(5)
Se(4)—In(1)—Se(2)	106.61(8)	99.40(5)
Se(4)—In(1)—Se(3)	112.58(7)	107.18(5)

[a] Se(4) is the Se atom of the SeH group.

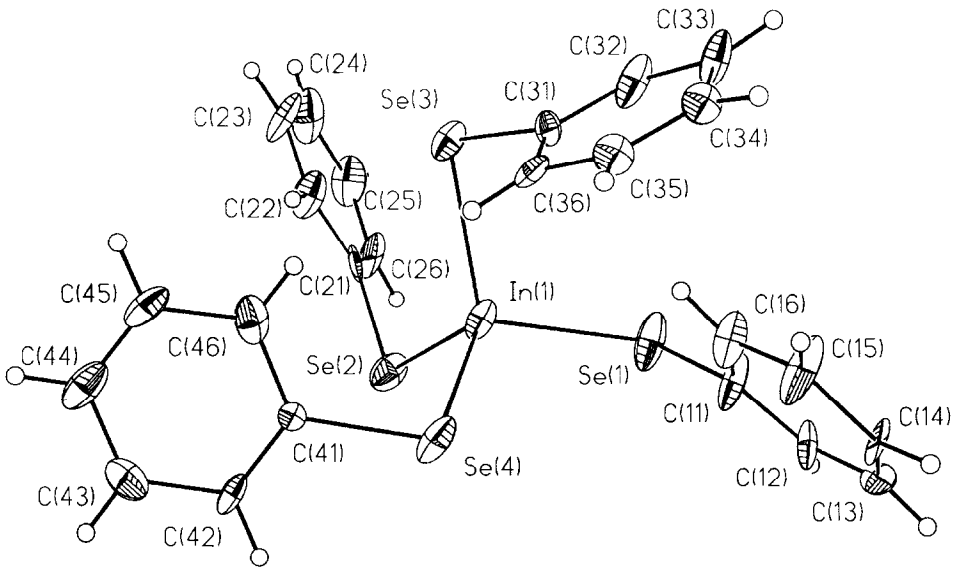

Fig. 1. View of the $[In(SePh)_4]^-$ anion. Here and in the succeeding figure the 50% probability displacement ellipsoids are shown.

$[SePh]^-$ ligands and one $[SeH]^-$ ligand (Fig. 2). The H atom of the $[SeH]^-$ ligand, though not located directly from crystallographic data, was detected spectroscopically (ν(Se—H) = 2241 cm^{-1}). This value may be compared with those of 2260 cm^{-1} in $[(pp_3)RhSeH]$ (pp_3 = tris(2-(diphenylphosphino) ethyl)phosphine) [13] and 2250 cm^{-1} in $[Pd_7Se_6(SeH)Cl(PPh_3)_7]$ [14].

In **2** the In—Se(Ph) bond distances (2.533(1) to 2.555(1) Å) are shorter than those in **1** (2.570(2) to 2.584(2) Å) (Table 2). The In—Se(H) bond distance (2.521(2) Å) is probably shorter than the In—Se(Ph)

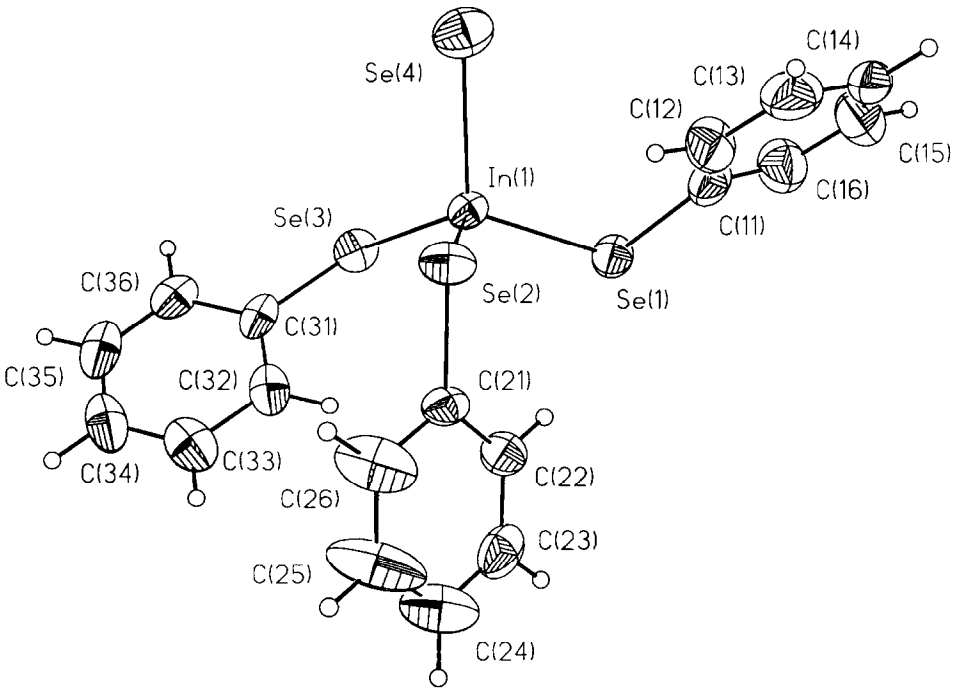

Fig. 2. View of the $[In(SePh)_3(SeH)]^-$ anion.

distances. The In center is again in a distorted tetrahedral environment with the Se—In—Se bond angles ranging from 99.41(5) to 122.10(5)°.

Indium selenolates have been isolated from reactions involving a variety of starting materials. Most often the In source is either In metal [2], $InCl_x$ (x = 1, 3) [4], or InR_3 (R = Me, Mes) [3]. For the synthesis of $[PPh_4][In(SePh)_4]$, $InCl_3$ is reacted with 4 equiv. of NaSePh. Interestingly, if In metal is reacted with 1.5 equiv. of Ph_2Se_2 then $In(SePh)_3$ is isolated [1,2]. $In(SePh)_3$ in turn reacts with PPh_4Br to afford $[PPh_4][InBr(SePh)_3]$ [1,2]. For the synthesis of $[PPh_4][In(SePh)_3(SeH)]$, $InCl_3$ is again reacted with 4 equiv. of NaSePh. The reaction mixture is then added to a flask containing $NaBH_4$ and elemental sulfur to afford **2**. When the reaction is carried out without sulfur or with elemental selenium in place of sulfur crystals of **1** are obtained. In the synthesis of **2** $NaBH_4$ provides a source of hydride and sulfur may act as a phenyl scavenger to afford Ph_2S_2.

Of the few compounds containing $[SeH]^-$ ligands reported, only one was prepared from the reaction of a phenylselenide. Treatment of $Os_6(CO)_{18}$ with $NaBH_4$ followed by the addition of PhSeCl affords the neutral cluster $[Os_6(\mu\text{-H})(CO)_{18}(\mu\text{-SeH})]$ [15]. Here the $[SeH]^-$ unit acts as a bridging ligand.

Voltammetric study of the redox chemistry of 2,3-dihydroxy-quinoxaline and its zinc complexes in non-aqueous medium

Mario E. Bodini,* M. Angélica del Valle, Georgina E. Copia and Cecilia Soto

Departamento de Química Inorgánica, Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 306, Santiago de Chile, Chile

(Received 7 February 1997; accepted 26 September 1997)

Abstract—The electrochemical behaviours of 2,3-dihydroxy-quinoxaline (2,3-DH_2Qx) and the complex species formed with zinc(II) have been studied in non-aqueous media. Using dimethylsulphoxide or *N*,*N*-dimethylformamide as solvents the monoanion of the ligand is obtained quantitatively after reduction of one of the hydroxylic protons. The reduction potential for the hydroxylic proton is −1.93 V *vs* S.C.E. in DMSO and −1.68 V *vs* S.C.E. in DMF, reflecting the different donor number of the solvents. If acetonitrile is used, the simultaneous reduction of both hydroxylic protons is observed. The oxidation to the semiquinone is observed at −0.12 V *vs* S.C.E. in DMSO and DMF whereas it appears at −0.02 V *vs* S.C.E. in acetonitrile.

Neither the protonated ligand nor its quinonic form exhibit the formation of stable complexes with zinc(II) whereas the dianionic species produces two coordination compounds having M : L stoichiometric ratios of 1 : 1 and 1 : 2.

The semiquinone form of the ligand by itself shows the tendency to polymerize on the surface of the electrode and it is not stabilized in the presence of this metal ion. A neutral insoluble compound that passivates the electrode is formed when the semiquinone and this metal ion interact. It was not possible to study this complex in detail but the electrochemical evidence indicates that it has formed on the surface of the electrode. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: zinc; 2,3-dihydroxy-quinoxaline; complexes; aprotic medium; voltammetry.

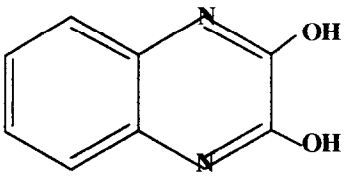
A great deal of information is known concerning biological systems whose functions are facilitated by zinc metal ions. For instance, many enzymes involved in the replication process through DNA and RNA contain zinc in their structure [1] like the RNA-polymerase and the DNA-polymerase enzymes isolated from *Escherichia coli* and the inverse transcriptase isolated from some viruses [2,3]. A totally synthetic model for the photosynthetic process in chlorophyl has been developed in which a tetraphenylporphyrin complex of zinc has been used to capture the visible photons. In this case the electron carriers are ferro- and ferricyanide ions [4,5].

Catechols are bidentate ligands that form a great number of stable metal complexes and that are used by biological systems for the transport and storage of these metal ions [6]. The oxidized form of catechols, quinones, can be reduced reversibly to the semiquinone radical form through one electron transfer. For example, flavins can be reduced through one or two-electron transfer processes to yield the semiquinone or the hydroquinone species [7]. Many other examples of coordination compounds with dioxolenes ligands that are important in biological processes are known [8] as is the case of the stabilization of semiquinone radicals formed by oxidation of dopa by Zn(II) [9]. On the other hand, the extreme reactivity of the Zn(II) dianionic catechol species has been reported [10]. It is clear that these compounds will be the basis for the development of effective catalysts for redox processes.

Trying to develop complexes that can be oxidized at a more positive potential, yielding species with a better reducing power, we have thought of studying the redox chemistry of complexes with a ligand having nitrogen atoms as part of the aromatic ring and two adjacent hydroxyl groups in order to be similar to a catechol and to have a good coordinating capacity.

* Author to whom correspondence should be addressed.

The electron-withdrawing nitrogen atoms caused a deactivation of the ring and the donating ability of the hydroxy groups will be facilitated, making more difficult the release of an electron with the subsequent oxidation of the catecholic residue. Therefore, the oxidation of the dihydroxy species to the corresponding semiquinone will occur at more positive potentials and the coordination compounds will also show this behaviour. We have chosen the compound 2,3-dihydroxy-quinoxaline in which two nitrogen atoms are present in the quinoxaline ring:



2,3 - Dihydroxyquinoxaline (2,3-DH2Qx)

The study of the redox chemistry of this ligand will be done in non-aqueous solvents in order to stabilize any possible radical species that might be formed as the consequence of the electron-transfer processes. The interaction of the different forms of this ligand with the Zn(II) ion will be studied to obtain knowledge of the redox chemistry of the complexes formed with this metal ion.

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Bioanalytical Systems) Model CV-1A 230 and a Linear Model 8036 X-Y recorder were used for the cyclic voltammetric experiments. Controlled-potential electrolysis was accomplished with a Bioanalytical Systems Model SP-2 and a PUC coulometer.

The electrochemical cell was equipped with a Beckman platinum-inlay working electrode (area 0.23 cm^2), a platinum coil auxiliary electrode and an Ag/AgCl reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.00 V vs S.C.E. The latter was contained in a Pyrex tube with a soft-glass cracked tip; this electrode was placed inside a Luggin capillary. For controlled-potential electrolysis a platinum mesh working electrode was employed.

A Milton Roy Model Spectronic 3000 diode array spectrophotometer was used for UV–vis spectrophotometric measurements.

Reagents

The reagents for the investigation and synthesis included $Zn(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), tetrabutylammonium hydroxide (TBAOH, 1.0 M in methanol, Aldrich) and tetramethyl-ammonium chloride (Aldrich). Tetraethylammonium perchlorate (TEAP) was obtained from reaction of a 25% aqueous solution of tetraethylammonium hydroxide (Aldrich) and concentrated perchloric acid (Merck) and recrystallized from anhydrous ethyl alcohol. The ligand 2,3-dihydroxyquinoxaline was obtained from Aldrich Chemical Co.

Aldrich "Gold Label" solvents were used without further purification for all the experiments. High purity argon was used to deaerate solutions.

Since the solvation water of $Zn(ClO_4)_2 \cdot 6H_2O$ interfered with the stoichiometric formation of the complexes under study, $[Zn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea) [11] was used in all the experiments in which the zinc complexes were formed *in situ*.

RESULTS AND DISCUSSION

In order to study the redox chemistry of this ligand the cyclic voltammetric experiments with its solutions in different solvents yielded the voltammograms illustrated in Fig. 1. In dimethylsulphoxide a reduction process is observed at -1.93 V vs S.C.E. if the potential is scanned initially in the negative direction. Upon reversal of the scan direction two anodic peaks show

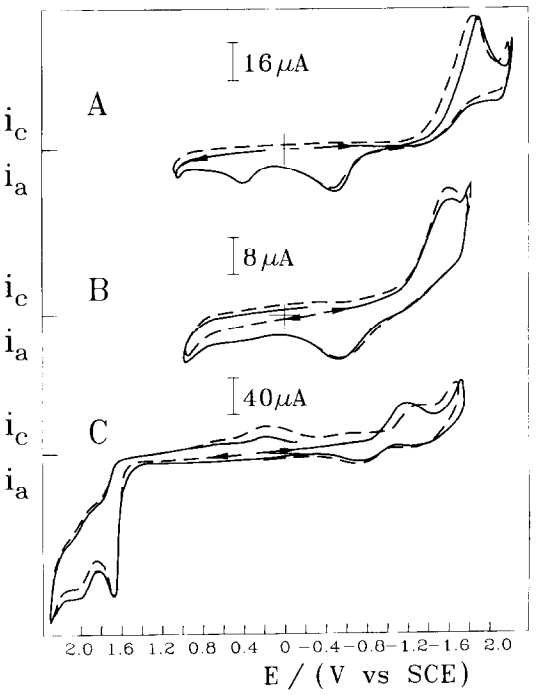


Fig. 1. Cyclic voltammograms of solutions of 2,3-DH_2QX (a) 3 mM in DMSO; (b) 1 mM in DMF and (c) 1 mM in acetonitrile. The scan rate is 100 mV s^{-1}. The supporting electrolyte is 0.1 M TEAP.

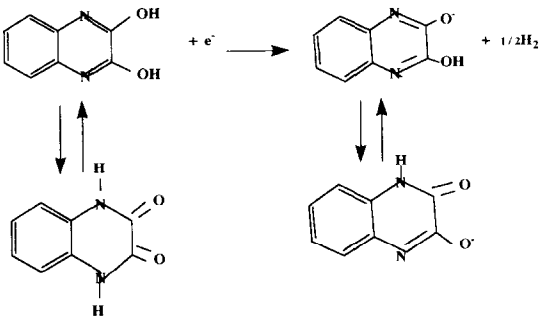
up at −0.52 V vs S.C.E. and at +0.42 V vs S.C.E. The anodic peaks are associated with the former reduction process because an initial potential scan toward positive potentials does not show the presence of these processes. Controlled-potential electrolysis at −2.0 V vs S.C.E. indicated that the residual current was attained after the transfer of one equivalent of charge. The dependence of the peak current with the square root of the scan rate for these voltammetric peaks when DMSO is used as the solvent is illustrated in Fig. 2. We can conclude from these results that we are in the presence of a diffusion-controlled process. However, the dependence of the peak current of the anodic peak at −0.52 V vs S.C.E. with the scan rate is not linear. This is characteristic of the oxidation of hydrogen gas on the surface of the electrode which was generated in the previous reduction process. This phenomenon is observed every time a ligand with acidic protons is studied voltammetrically in non-aqueous solvents [12,13,14] and the activation of molecular hydrogen has been described and analyzed very carefully [15]. An analysis of the dependence of the peak current with the square root of the scan rate for the other anodic peak at +0.42 V vs S.C.E. shows that again a linear dependence is obtained indicating that it corresponds to the oxidation of a species in the solution that remains nearby the surface of the electrode.

The molecular structure of this compound makes possible the existence of two forms in equilibrium in which the protons are located either on the oxygen atoms of the hydroxy groups or on the heterocyclic nitrogen atoms of the quinoxaline residue.

Therefore, the reduction process observed can be represented by:



Consequently, the process observed at −0.42 V vs S.C.E. corresponds to the irreversible oxidation of the monoanionic form of the ligand to the protonated semiquinone.

$$[2,3\text{-DHQx}]^- \xrightarrow{-0.42\,V} [2,3\text{-DHSQx}]\cdot + e^-$$

The cyclic voltammogram of a solution of 2,3-DH_2Qx in dimethylformamide is shown in Fig. 1(b). In this case the reduction of one of the acidic protons is observed at −1.68 V vs S.C.E., the oxidation of hydrogen shows up at −0.58 V vs S.C.E. and the oxidation of the monoanion becomes apparent only at +0.50 V vs S.C.E. If the potential is scanned initially in the positive direction the peak at +0.50 V vs S.C.E. can be observed as a very small signal indicating that the monoanionic species is initially present in the solution. The reason for this behaviour is that dimethylformamide has a more basic character than dimethylsulphoxide. The ligand in this solution partially dissociates forming the corresponding monoanion. If we compare the electrochemical behaviour of this ligand in DMF and in DMSO, namely the results of controlled-potential electrolysis and the dependence of the peak current with the square root of the scan rate, we can see that they are very similar. Therefore, we must conclude that the electrode process is the same in both cases.

If acetonitrile is used as the solvent, the voltammetric behaviour is illustrated in Fig. 1(c). In this case the proton reduction shows up at −1.26 V vs S.C.E. with the corresponding oxidation at −0.56 V vs S.C.E. The most important difference in this case with respect to the other two solvents is that a controlled-potential experiment indicates that two equivalents of charge are being transferred in this process. This is indicative that the two protons are reduced simultaneously in this solvent or, at least, as one proton is being reduced the reduction potential of the

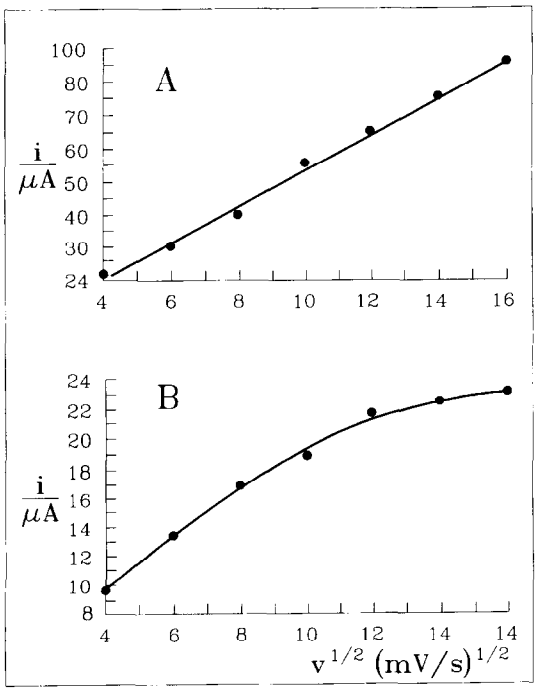


Fig. 2. Dependence of the peak current (a) for the cathodic process at −1.94 V vs S.C.E. and (b) for the anodic process at −0.52 V vs S.C.E. of 2,3-DH_2Qx in DMSO with the square root of the scan rate.

Table 1. Reduction potential for the hydroxylic proton of the ligand and donor numbers of the utilized solvents

Solvent	Ep 2,3-DH_2Qx	Donor effect [16]
DMSO	−1.90 V vs S.C.E.	29.8
DMF	−1.68 V vs S.C.E.	26.6
ACN	−1.26 V vs S.C.E.	14.1

other is shifted so that it is not possible to differentiate them.

$$[2,3\text{-}DH_2Qx]+2e^- \rightarrow [2,3\text{-}DQx]^{2-}+H_2(ads)$$

In this solvent the largest electrochemical window is obtained in the positive side of potentials and two peaks are now observed corresponding to the oxidation of the ligand to yield a radical species which decomposes. Therefore, its reduction is observed only if a very fast scan rate is used. Table 1 illustrates the reduction potentials for the hydroxylic proton of the ligand along with the donor numbers of the solvents used in this work.

If two equivalents of base are added to a solution of 2,3-DH_2Qx to form the dianion no reduction peaks are observed in the solvents studied which is indicative

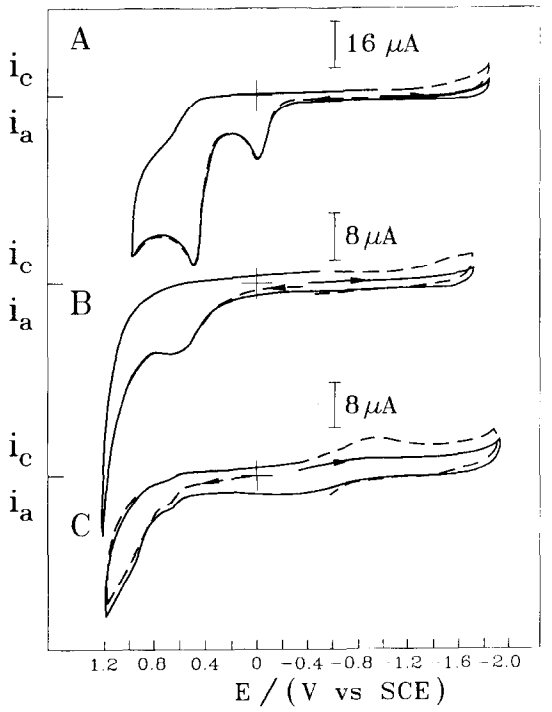

Fig. 3. Cyclic voltammograms of a solution 1 mM in 2,3-DH_2Qx and 2 mM in TBAOH using as solvents (a) DMSO; (b) DMF and (c) acetonitrile. The scan rate is 100 mV s^{-1} and the supporting electrolyte is 0.1 M TEAP.

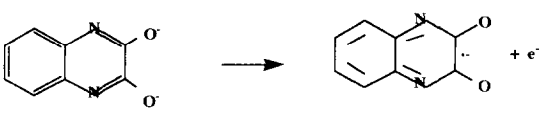
Table 2. Peak potentials for the oxidation of the dianion in the solvents considered

Solvent	Peak	Peak potential (volts vs S.C.E.)
DMSO	a	−0.12
DMF	a	−0.12
ACN	a	−0.02
DMSO	b	+0.46
DMF	b	+0.46
ACN	b	+0.46
DMSO	c	+0.92
DMF	c	+0.84
ACN	c	+1.86

that no reducible protons are present under these conditions. The cyclic voltammograms for this solution are illustrated in Fig. 3. Notice that three anodic peaks are observed (peaks (a), (b) and (c) in the figure) whose peak potentials in the three solvents are summarized in Table 2.

It is interesting to notice that the peak potentials for peaks (a) and (b) are very similar in the three solvents with the only exception of peak (a) in acetonitrile which shows up at a potential slightly more positive. Peak (c) is found very close to peak (b) in DMSO and DMF precluding a good resolution of the voltammogram. In acetonitrile peak (c) appears at a very positive potential so that the three anodic processes are better resolved. Controlled-potential electrolysis at a potential 100 mV more positive than the peak potential for this process in the three solvents studied indicated that one equivalent of charge was transferred in all chases. The dependence of the peak current with the square root of the scan rate corresponded to a diffusion controlled process. At high scan rates the current does not increase accordingly because a high current density causes a very high local concentration of the radical species produced in the charge-transfer process and its polymerization will block the surface of the electrode.

Accordingly, the oxidation process corresponding to peak (a) must correspond to the generation of the semiquinone species and it can be represented by:



The assignment of peak (b) was not possible because the attempt to do controlled-potential electrolysis at a potential 100 mV more positive than its peak potential resulted in the passivation of the

electrode in the three solvents studied. Considering that the area of this voltammetric peak is similar to that of peak (a) we can suggest that this process also involves the transfer of one equivalent of charge leading to the production of the quinone species. Finally, peak (c) would correspond to a further oxidation of the quinone producing some radical species which would originate some polymeric product considering its molecular structure and the positive potential this process takes place at.

The interaction with Zinc(II) was studied using the dianion of the ligand because no change was observed in the UV–vis spectrum of the quinone in the presence of this metal ion leading us to conclude that no complex is formed between these two species. Figure 4 illustrates the UV–vis spectra of a solution of the quinone generated by controlled-potential electrolysis at 0.6 V vs S.C.E. and a solution of the quinone in the presence of an equimolar amount of Zn(II) ion.

The voltammetric behaviour of solutions of the dianion of the ligand in dimethylsulphoxide in the presence of different amounts of Zn(II) are shown in Fig. 5. If the metal-to-dianion of the ligand mole ratio is 1 : 3 no free metal ion is detected as the voltammetric peak corresponding to the reduction of free Zn(II) to Zn(0), which appears at −1.05 V vs S.C.E., is not observed. On the other hand, the anodic peak corresponding to the oxidation of the free dianion to the corresponding semiquinone shows up at −0.12 V vs S.C.E. Therefore, in this case an excess of the dianion of the ligand is detected. If the metal-to-dianion of the ligand mole ratio is made 1 : 2 no excess either of the metal ion or the dianion of the ligand is detected (Fig. 5(b)) indicating that this is the exact stoichiometry of a complex formed. Only one anodic peak is observed in this case, which must correspond to the oxidation of bound ligand.

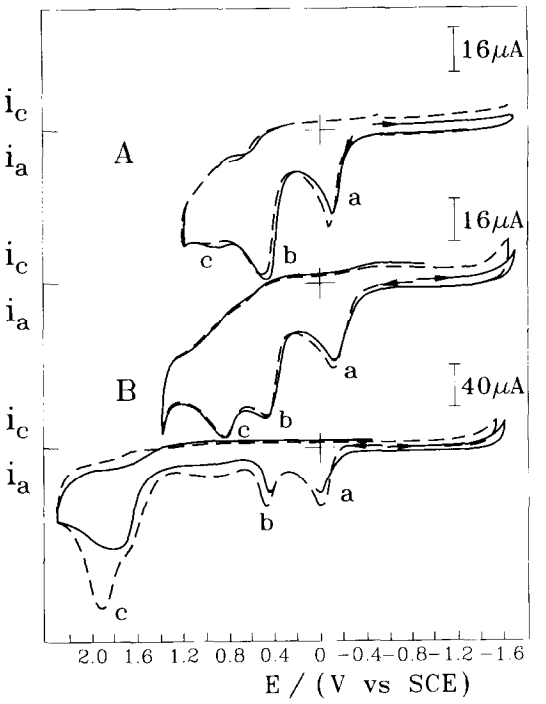


Fig. 5. Cyclic voltammograms of solutions that are 1 mM in 2,3-DQx^{-2} and 2 mM in TBAOH in the presence of (a) 0.33 mM Zn(II). The scan rate is 100 mV s^{-1} and the supporting electrolyte is 0.1 M TEAP.

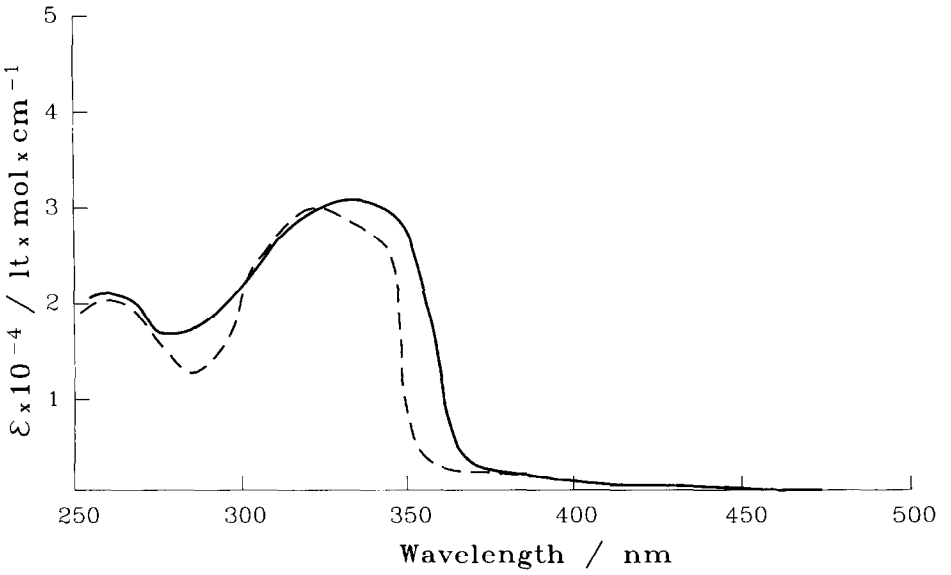

Fig. 4. UV–vis spectra of solutions: (a) 3 mM of the quinone in DMSO generated by controlled-potential electrolysis of the dianion at −0.6 V vs S.C.E. and (b) 3 mM of the quinone and 3 mM of Zn(II) ion.

An attempt to do controlled-potential electrolysis to study this process in detail was not possible because the current dropped to zero very quickly, indicating that in this case the product formed is neutral, it precipitates and blocks the surface of the electrode.

Therefore, we can conclude that a complex with a 1:2 metal-to-dianion of the ligand stoichiometry is formed in solution and that its oxidation can be explained according to the following electrode reaction:

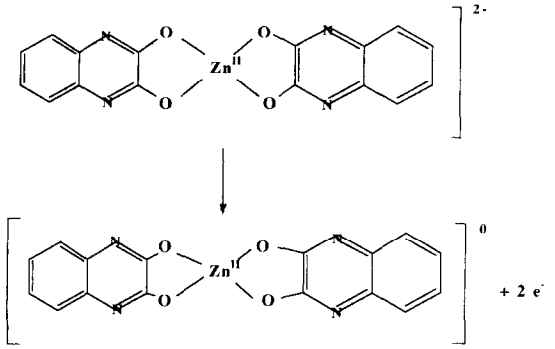

Figure 5(c) shows that in the case of 1:1 metal-to-ligand mole ratio no reduction of the free metal ion is observed if the potential is scanned initially in the negative direction indicating that the metal ion is forming a complex. An anodic peak appears at a potential very close to the solvent discharge. After this oxidation process the presence of free zinc ion becomes evident. In this case, the oxidation of the ligand produces the decomposition of the complex leading to the formation of free quinone and free zinc(II) ion.

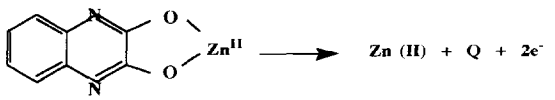

The presence of free quinone after the charge transfer process is inferred by the appearance of free metal ion after the oxidation process and that the UV–vis spectra of a solution of the quinone both in the presence and in the absence of zinc(II) ion look exactly the same. Furthermore, no formation of complexes is observed in the case of 3,5-ditertbutyl-1,2-benzoquinone and Zn(II) ion in dimethylsulphoxide [10].

Therefore, we can finally conclude that the dianion of the ligand 2,3-dihydroxyquinoxaline forms two complexes with Zn(II) having 1:2 and 1:1 metal-to-ligand stoichiometries and that the 1:1 species forms on the surface of the electrode. These complexes probably have a tetrahedral symmetry with two solvent molecules to complete the coordination sphere in the case of the 1:1 complex. The following is a summary of the charge transfer reactions of the different forms of this ligand and the corresponding zinc complexes:

$$[2,3\text{-DHQx}^{=}] \overset{-0.42\,V}{\rightarrow} [2,3\text{-DHSQx}]^{\cdot -} + e^{-}$$

$$[2,3\text{-DHQx}^{=}] \overset{-0.12\,V}{\rightarrow} [2,3\text{-DSQx}^{=}]^{\cdot -} + e^{-}$$

$$Zn[2,3\text{-DQx}]_2 \overset{-0.63\,V}{\rightarrow} Zn[2,3\text{-DSQx}]_2 + 2e^{-}$$

$$Zn[2,3\text{-DQx}] \overset{0.93\,V}{\rightarrow} Zn(II) + Qx + 2e^{-}$$

with the corresponding peak potentials observed. Notice that in this case the oxidation potential for the oxidation of the dianion to the corresponding semiquinone is more positive than in the case of 3,4-ditertbutyl-catechol [10] and in the case of 2,3-dihydroxynaphthalene [17] due to the deactivating effect of the two nitrogen atoms in the quinoxaline residue. In the presence of zinc the oxidation potential of the bound ligands shifts to an even more positive value probably as a consequence of the high stability of the complexes being formed.

These results indicate that this ligand will be very appropriate to stabilize complexes with high oxidation state metal ions considering its high resistance to oxidation.

(Received 4 June 1997; accepted 18 September 1997)

Abstract—The reaction of $[Rh(S_2CNEt_2)(CO)_2]$ and Hpz^{An} (3(5)-*p*-methoxyphenylpyrazole) in acetone at room temperature yields to a mixture of $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (**2**) and $[Rh(S_2CNEt_2)_3]$ (**3**). The same results were obtained from the reaction of $[RhCl(CO)_2(H\text{-}pz^{An})]$ with NaS_2CNEt_2. The first reaction in boiling solvents (acetone, dichloromethane) didn't yield to the binuclear complex (**2**) but an unexpected complex $[Rh(S_2CNEt_2)(CO)]_2$ (**1**) was obtained. Complex (**1**) was proved to be the evolution result of the starting $[Rh(S_2CNEt_2)(CO)_2]$ in boiled solvents. The molecular structure of complex (**3**) has been determined. Crystals of (**3**) are monoclinic, space group C2/c, and is a different form than that previously reported for $[Rh(S_2CNEt_2)_3]$. Subtle differences between the molecular structures are also found. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dithiocarbamate; rhodium; pyrazole.

We have recently described the chemical behaviour of $[Rh(S_2CNEt_2)(CO)_2]$ towards P-donor ligands [1]. In those reactions the substitution of one or both carbonyl groups was induced by the $R_2NCS_2^-$ ligands giving rise to $[Rh(S_2CNR_2)(CO)(P(4\text{-}XC_6H_4)_3)]$ or $[Rh(S_2CNR_2)(P(4\text{-}XC_6H_4)_3)_2]$ (R = Et, Me; X = Cl, F, CH_3, CH_3O) depending on the stoichiometry and reaction conditions [1].

On the other hand, *N*-donor ligands containing the pyrazol functionality have proved to be versatile ligands towards rhodium being attached to the metal either an unidentate neutral (Hpz) or bridging anionic mode (pz) [2,3].

Although the proton loss of the Hpz groups was common by the presence of alkali in the reaction, several other examples indicate that factors like the nature of the other ligands on the metal or the nucleophilicity of the pyrazole group could give rise to the formation of binuclear pyrazolate species [4].

Following our precedents in Rh(I) chemistry we decide to investigate the coordinative ability of the Hpz^{An} (An = 3(5)-*p*-methoxyphenyl) towards $[Rh(S_2CNEt_2)(CO)_2]$. That pyrazol was chosen because in previous works the chemistry of Rh(I) compounds containing this ligand [2,3] had been well established and crystalline structures of $[RhCl(CO)_2(H\text{-}pz^{An})]$ [2] and $[Rh(\mu\text{-}pz^{An})(CO)_2]_2$ [5] solved.

In this work the reactivity of $[RhCl(CO)_2(H\text{-}pz^{An})]$ towards $Et_2NCS_2^-$ ligand has also been analyzed. From that reaction the same $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (**2**) and $[Rh(S_2CNEt_2)_3]$ (**3**) compounds were identified as final products.

The crystalline structure of (**3**) is also described and compared with that previously reported [6]. We also comment on the ligands redistribution process from the starting compound $[Rh(S_2CNEt_2)(CO)_2]$ towards the dimer $[Rh(S_2CNEt_2)(CO)]_2$ (**1**).

RESULTS AND DISCUSSION

The reaction of $[Rh(S_2CNEt_2)(CO)_2]$ and Hpz^{An} (3(5)-*p*-methoxyphenylpyrazole) has been carried out. Different solvents, temperature and reaction times

* Author to whom correspondence should be addressed.

were tried in order to achieve carbonyl derivatives containing $Et_2NCS_2^-$ and pyrazol ligands.

It is interesting to note that in acetone or dichloromethane at reflux temperature, after ca 2 or 6 h of reaction respectively an unexpected product was formed. The new compound was characterized as $[Rh(S_2CNEt_2)(CO)]_2$ (**1**) as will be described below.

The same complex (**1**) was also performed from $[Rh(S_2CNEt_2)(CO)_2]$ both in solid state and in solution.

On the other hand, the complex $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (**2**) was achieved from the above reaction at room temperature after ca 10 days independently of the solvent used.

It was remarkable that in all cases the complex $[Rh(S_2CNEt_2)_3]$ (**3**) was also obtained as by-side product.

In the following points the complexes (**1**), (**2**) and (**3**) will be discussed.

$[Rh(S_2CNEt_2)(CO)]_2$ (1)

$[Rh(S_2CNEt_2)(CO)_2]$ in acetone at room temperature evolves after 9 days to a shine black solid product from which the dinuclear complex $[Rh(S_2CNEt_2)(CO)]_2$ (**1**) was separated after several recrystallizations. $[Rh(S_2CNEt_2)_3]$ (**3**) was also obtained as by-side product and identified by X-ray diffraction. Its crystalline structure which was also solved will be described below. Despite repeated attempts to eliminate (**3**) from the mixture it was not possible as we deduced by ^1H NMR.

If in the above treatment the temperature is increased until reflux of acetone or dichloromethane, the same evolution products were raised after ca 2 or 6 h respectively.

Therefore the observed evolution of $[Rh(S_2CNEt_2)(CO)_2]$ towards $[Rh(S_2CNEt_2)(CO)]_2$ (**1**) appears to be responsible that the reaction of $[Rh(S_2CNEt_2)(CO)_2]$ with Hpz^{An} ligand at reflux temperature doesn't give rise to the desired pyrazolil derivative. The mixture of (**1**), (**3**) and an unidentified product was also obtained after a slow evolution of $[Rh(S_2CNEt_2)(CO)_2]$ in the solid state.

Reaction of $[Rh(S_2CNEt_2)(CO)]_2$ (**1**) with Hpz^{An} was tried, however it didn't work under any conditions.

The complex (**1**) was characterized by elemental analyses, IR and ^1H-NMR spectroscopies, mass spectrometry and magnetic measurements.

IR spectroscopy was used to monitor the course of the evolution (Fig. 1). The complete transformation of the starting complex in solution towards complex (**1**) was observed after 9 days at room temperature.

The IR spectrum (in KBr disc) of the new compound (**1**) (Table 1) shows two ν(CO) bands at 2020 and 1967 cm^{-1} which are shifted to lower frequencies to respect to dicarbonylic precursor. Those values are consistent with an oxidation state + I on the rhodium atom and with a *cis*-$Rh(CO)_2$ distribution [7]. The remaining bands from the dithiocarbamate ligands are similar to those of the related compounds, $[Rh(S_2CNEt_2)_3]$ (**3**) and $[Rh(S_2CNEt_2)(CO)_2]$ [8]. The unique band showing a significant shift is the ν(CN) band which moves 10 cm^{-1} to lower frequencies to respect to the starting monomer. Such a shift has been attributed to the presence of bridging dithiocarbamate ligands [9].

The ^1H NMR spectrum in $CDCl_3$ (Table 1) shows three resonances at δ 3.81, 3.72 and 3.60 ppm as multiplets. The signals at δ 3.72 and 3.60 ppm are assigned to the *N*-methylene protons of two unequivalent ethyl groups of the diethyldithiocarbamate ligands of complex (**1**) and the multiplets at δ 3.81 and 3.60 ppm (as superimposed signal) evidence the presence of $[Rh(S_2CNEt_2)_3]$ (**3**). The multiplet at δ 1.26 ppm includes the signal corresponding to CH_3 groups of both compounds.

The mass spectrum of complex (**1**) does not contain a parent-ion peak being the highest value *m/e* peak at 945.9 corresponding to $[Rh_2(S_2CNEt_2)_3]^+$ ion. Related ion peaks at 797.9 and 649.9 from $[Rh_2(S_2CNEt_2)_4]^+$ and $[Rh_2(S_2CNEt_2)_3]^+$ respectively are also observed. An explanation for that behaviour emerges by considering the interaction of the $[Rh(S_2CNEt_2)_2]^+$ and $[Rh(S_2CNEt_2)_3]^+$ fragments from the mixture of (**1**) and (**3**) derivatives.

The magnetic susceptibility of sample (mixture of (**1**) and (**3**) (as impurity)) was measured showing the diamagnetic character of described complex (**1**).

From the above findings we suggested a structure for (**1**) as depicted in Fig. 2. In that the $[Rh(CO)_2]$ fragment is bonded to the $[Rh(S_2CNEt_2)_2]$ group with the dithiocarbamate ligands acting as chelating to a metal centre and bridging by a S atom to the other rhodium atom. Related structures has also been observed in some dinuclear complexes [9–11].

$[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (2)

Reaction of the compound $[Rh(S_2CNEt_2)(CO)_2]$ with a stoichiometric amount of Hpz^{An} in acetone solution at room temperature leads to the dinuclear $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (**2**) which was isolated after 10 days of reaction as air-stable orange solid, mixed with orange crystal of $[Rh(S_2CNEt_2)_3]$ (**3**). Due to the similar solubility of both products all attempts to obtain pure complex (**2**) were unrewarding as deduced by the analytical data. However the product could be characterized by mass spectrometry, IR and ^1H NMR spectroscopy.

The diamagnetic character of sample was determined suggesting the diamagnetism of complex (**2**).

The dimeric nature of complex (**2**) was evidenced by mass spectrometry. The mass spectrum of (**2**) contains a parent-ion peak at 905 corresponding to the dimer $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ and other peaks at 876.1, 848.1 and 675.0 corresponding to the $[Rh_2(\mu$-

[a] In KBr discs.

[b] In $CDCl_3$ solution. vs = very strong; m = multiplet; t = triplet; q = quartet; d = doublet; br s = broad signal; s = singlet.

$pz^{An})_2(S_2CNEt_2)_2(CO)]^+$ $[Rh_2(\mu\text{-}pz^{An})_2(S_2CNEt_2)_2]^+$ and $[Rh_2(\mu\text{-}pz^{An})(S_2CNEt_2)_2]^+$ fragments respectively. An ion peak at 547 from $[Rh(S_2CNEt_2)_3]^+$ is also present.

On the other hand, some characteristic features were observed in the IR spectrum of the complex (**2**) (Table 1).

1. The two carbonyl bands characteristic of a *cis*-$Rh(CO)_2$ group [7] are moved ca 15 cm^{-1} towards higher energy and the ν(CN) band is also shifted 12 cm^{-1} towards lower energy to respect to the parent dicarbonyl complex. Although those displacements agree with an increase in the oxidation state on the rhodium atom the latter one has also been considered as the result of a decrease in the number of ligands sharing the same positive charge [9].

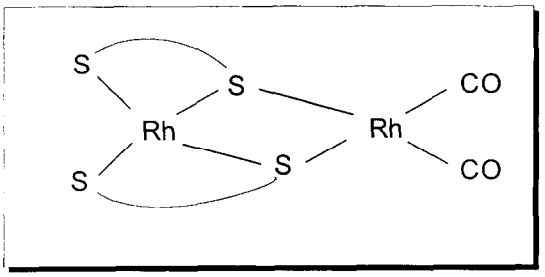

Fig. 2.

2. The compound (**2**) shows the unexpected absence of ν(N—H) of the pyrazole group, which agree with the presence of pyrazolate groups. The derivative (**2**) has been obtained in the absence of alkali, thus providing another example of the formation of a pyrazolate derivative rather than the neutral pyrazole product expected under such conditions. Several other examples of such proton loss exist [4].

From the above results we suggest two types of environment for each Rh in the dinuclear complex (**2**). In that, the $[Rh(S_2CNEt_2)_2]$ fragment should be bonded to a *cis*-$Rh(CO)_2$ group through two pyrazolate bridging ligands.

The ^{1}H NMR data in $CDCl_3$ solution were recorded and listed in Table 1. No signals of H—N protons are observed in agreement with the IR ν(NH) absence confirming the pyrazolate nature of these groups and supporting the suggested formula.

On the other hand, the pattern of signals was more complicated than that expected for one complex containing only one type of $Et_2NCS_2^-$ and pyrazolate groups. So four signals at δ 7.72, 7.56, 7.47 and 7.44 ppm as well as other four signals at 6.50, 6.36, 6.35, and 6.34 ppm are attributed to the H_5 and H_4 protons respectively of four unequivalence pyrazolate rings. In addition four signals at δ 7.97, 7.96, 7.87 and 7.84 ppm corresponding to H(orto) and two signals at δ 7.00 and 6.93 ppm from the related H(meta) of the phenyl substituent are also observed. All of those data imply the presence of a mixture of pyrazolate complexes.

Due to unsymmetrical substitution of the bridging pyrazolate ligands the dinuclear complexes of the type $[Rh(\mu\text{-}pz^R)(L_2)]_2$ [2] may exist as two geometrical isomers, H—H and H—T and indeed both isomers were detected by ^{1}H NMR in the related compound $[Rh(\mu\text{-}pz^{An})(CO)_2]_2$ [2]. Although these types of isomers could also be proposed in complex (**2**), for that the presence of two different metal environments $[Rh(CO)_2]$ and $[Rh(S_2CNEt_2)_2]$ suggests a third new form H—H(B) as depicted in Fig. 3. Therefore the above ^{1}H NMR results could be considered as due to the mixture of the three isomeric forms: H—H(A), H—H(B) and H—T (Fig. 3).

On the other hand, the *N*-methylene proton signals of the $Et_2NCS_2^-$ ligands appear as two multiplets at δ 3.82 and 3.60 ppm of marked different shape and intensity. Both of them are consistent with the presence of $[Rh(S_2CNEt_2)_3]$ (as will be discussed below) but the CH_2 *N*-methylene protons of complex (**2**) should be also included in the broad signal at δ 3.82 ppm. In addition the chemical shifts of the OMe protons of anysol substituent are also observed at δ 3.89 and 3.83 ppm (as superimposed signals to the multiplet at δ 3.82 ppm).

The methyl proton resonance of the $Et_2NCS_2^-$ ligands appears as a broad signal at δ 1.25 ppm in which the characteristic triplet of $[Rh(S_2CNEt_2)_3]$ is also superimposed.

An alternative route to product the complex (**2**) was also found by reaction of the square planar complex $[RhCl(CO)_2(H\text{-}pz^{An})]$ with NaS_2CNEt_2 ligand. The reaction solution colour changed from orange-yellow to dark orange immediately. The course of reaction was monitored by IR spectroscopy. After 9 days a mixture of (**1**) and (**2**) was detected and both complexes mixed with the complex (**3**) were isolated from the solution. It was noteworthy to indicate that the reaction occurs through $[Rh(S_2CNEt_2)(CO)_2]$ as intermediate which was detected after 3 h.

A schematic representation of the reactions is depicted in Scheme 1.

$[Rh(S_2CNEt_2)_3]$ (3)

As we have described above during the study of the reactivity of $[Rh(S_2CNEt_2)(CO)_2]$ with Hpz^{An} we proved the formation of $[Rh(S_2CNEt_2)_3]$ (**3**) as a by-side product in all of the realized treatments.

Complex (**3**) was isolated as orange crystals which were separated from the mixture of products and its crystalline structure solved. The identity of (**3**) as $[Rh(S_2CNEt_2)_3]$ was also evidenced by comparation of its ^{1}H NMR spectrum with that obtained from the product synthetized by reaction of $RhCl_3$ and NaS_2CNEt_2 [12].

Particular results from ^{1}H NMR and X-ray diffraction crystalline structure studies of (**3**) were obtained and reported here.

^{1}H NMR

The ^{1}H NMR studies of diamagnetic *N,N*-dialkildithiocarbamate derivatives of trivalent transition metals have been described in terms of the cobalt(III) behaviour [12]. Therefore for our propose ^{1}H NMR data of $[Co(S_2CNEt_2)_3]$ were used as reference [12].

and temperatures was achieved. $CDCl_3$, $(CD_3)_2CO$, CD_3OD, $(CD_3)_2SO$ and C_6D_6 were used as solvents.

In $CDCl_3$ at room temperature the protons of the *N*-methylene groups appear as a pair of well defined multiplets at δ 3.82 and 3.60 ppm (Fig. 4) in contrast with the multiplet observed for $[Co(S_2CNEt_2)_3]$ in the same solvent and temperature conditions [12]. However, while the former one was performed with a 300 MHz spectrometer the latter one had been registered with a 60 MHz one. Both multiplets characteristic of an ABX_3 system were the result of the magnetic unequivalence of the *N*-methylene protons in agreement with the noncentrosymmetric structure of $[Rh(S_2CNEt_2)_3]$. In all of the other solvents the ^1H NMR spectra of (**3**) show one multiplet for the *N*-methylene protons being the separation of its components increased in the order $C_6D_6 < (CD_3)_2SO < CD_3OD < (CD_3)_2CO$ (Fig. 4).

A strong interaction of the chloroform solvent with $[Rh(S_2CNEt_2)_3]$ (**3**) is proposed as responsible of its ^1H NMR behaviour. The interpretation of this chloroform-dithiocarbamate interaction has been suggested elsewhere that occurs at the nitrogen atom [13], although structural results for dithiocarbamate derivatives indicate that the S···H interactions are the dominant intermolecular forces within the crystal lattices [13].

From our results, chloroform-dithiocarbamate interaction was clearly established but weak similar interactions with *O*-donor solvents should not be excluded. Related with this consideration it was interesting to note that only in C_6D_6 solution in which there was not solvent interaction the ^1H NMR spectrum of (**3**) gave the typical quartet-triplet of symmetric dithiocarbamate complexes.

X-ray crystal structure

The crystal structure of the title compound $[Rh(S_2CNEt_2)_3]$ (**3**) has been determined by X-ray diffraction. In previous studies the crystal structure of $[Rh(S_2CNEt_2)_3]$ has already been reported, the crystal system being monoclinic space group $P2_1/a$ [6]. How-

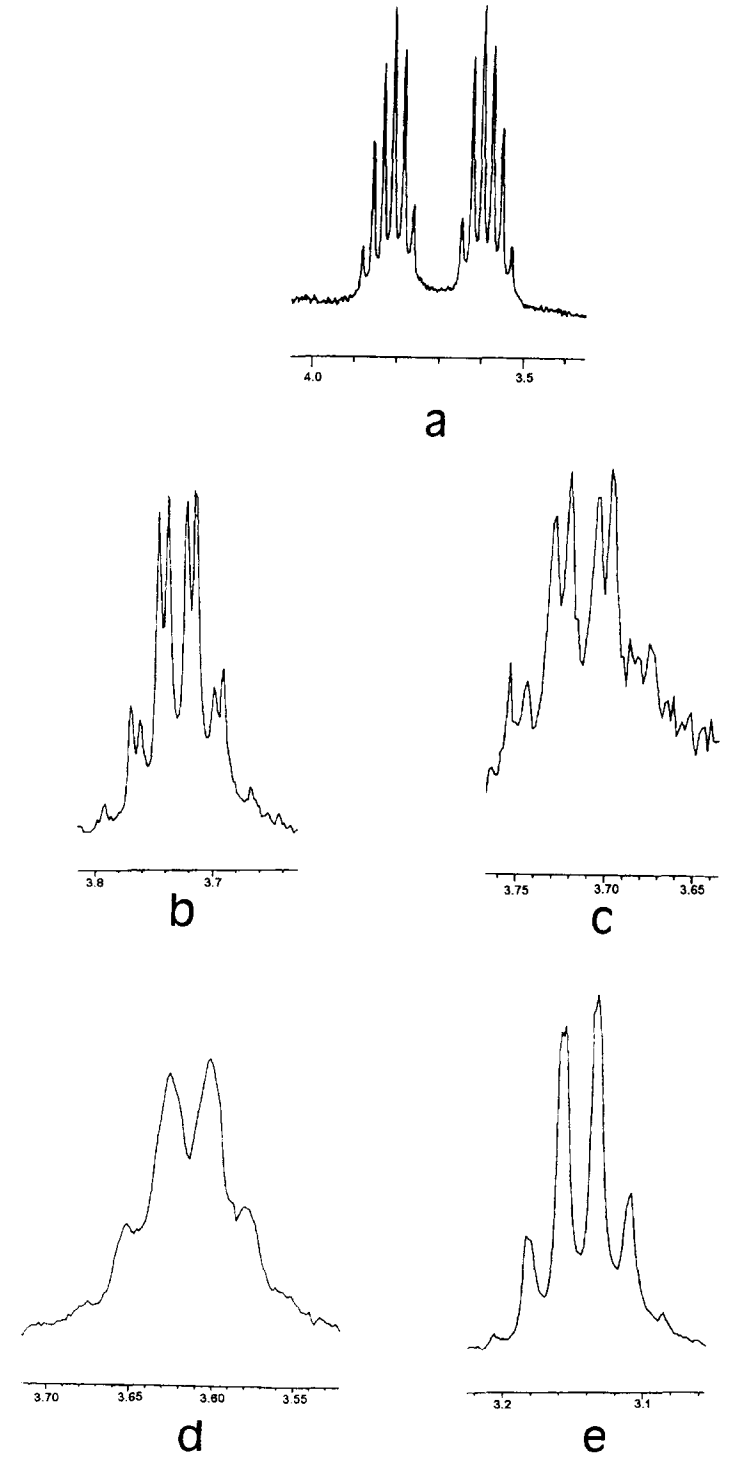

Fig. 4. *N*-methylene proton signals from ^{1}H NMR of (**3**) in different solvents: (a) $CDCl_3$, (b) $(CD_3)_2CO$, (c) CD_3OD, (d) $(CD_3)_2SO$, (e) C_6D_6.

ever, from the structural data of the well formed prismatic crystals of (**3**) we deduced that a new crystalline form had been isolated, cell symmetry *C*2/c. It was elsewhere reported that for complexes of type $[M(S_2CNEt_2)_3]$ subtle differences in the crystalline packing occur as the metal-sulphur distances *r* change. So, the molecular array commons shown a symmetry *C*2/c when $r <$ ca 2.36 Å, a symmetry *A*2/a when

$r >$ ca 2.43 Å and a $P2_1/c$ in the intermediate range [6]. A metal-sulphur distance of 2.352(2) Å (Table 2) was observed in (**3**) in agreement with the space group $C2/c$.

For (**3**), the lattice consists of discrete molecules of $[Rh(S_2CNEt_2)_3]$, which bear a two-fold symmetry axis passing through the rhodium atom and the axis if ligand 1, lying the plane of this ligand approximately parallel to the xy face (Fig. 5). As in the isostructural Co(III) [14] and Ir(III) [15] derivatives each molecule consists of a metal atom coordinated by three bidentate ligands being the MS_6 core geometry a good approximation to D_3.

As usual, the S_2CNC_2 section of the ligands are substantially planar. The best least-squares plane for S_2CNC_2 shows a maximum deviation of 0.0187(7) Å for C2 atom and of 0.046(6) for C7 atom (Fig. 6), of ligand 1 and 2 respectively [16].

The terminal methyl groups on the ligand adopt the usual conformation lying on alternate sides of the ligand plane at the same way that it was observed for $[Rh(S_2CNEt_2)_3]$ $P2_1/a$ [6]. However while the latter one shows almost equivalent distances of the groups to the ligand planes, the former one exhibits marked differences of those distances in two of the ligands (2 and 2′). In addition the methyl-methyl distance in ligands 2 and 2′ was shorter than in ligand 1, in other words the methyl groups of two ligands (2 and 2′) are approached but distanced in other one (1) (Table 3). In Fig. 7 the schematic representation of the two types of molecules founded for $[Rh(S_2CNEt_2)_3]$ were depicted.

Other difference emerges [15] by considering the values of $\theta = 22.03$ and $h = 1.20$ (θ = angle twist about the three-fold axis, h = S—S′ distance divided by M—S distance) following Kepert's ligand repulsion model [17]. From those values a lower distortion from the octahedral geometry than that observed in described crystal $P2_1/c$ was deduced.

EXPERIMENTAL

All reactions were performed under dioxygen-free dry dinitrogen, using freshly distilled, dried and degassed solvents. Syntheses of starting Rh-complex and the ligand have been described previously: $[Rh(S_2CNEt_2)(CO)_2]$ [8], $[RhCl(CO)_2(H\text{-}pz^{An})]$ [2] and Hpz^{An} [18].

Elemental analyses for carbon, hydrogen and nitrogen were carried out by the Microanalytical Service of the Complutense University. IR spectra were recorded on a FT-IR Nicolet magna 550 spectrometer in KBr discs. ^1H NMR spectra were performed on a Varian VXR XL-300 (299.95 MHz). Chemical shifts δ are listed in parts per million relative to tetramethylsilane; coupling constants J are in hertz. The ^1H chemical shifts and coupling constants are accurate to 0.01 ppm and 0.2 Hz respectively. FAB mass spectra were recorded on a VG AutoSpec spectrometer. Magnetic measurements were made using a Faraday type susceptometer equipped with a nitrogen continuous-flow cryostat.

Preparation of $[Rh(S_2CNEt_2)(CO)]_2$ (**1**)

An orange solution of $[Rh(S_2CNEt_2)(CO)_2]$ (0.4 mmol) in acetone (15 ml) was stirred at room tem-

perature for 9 days. The initial orange solution changed to brown with the time. Then, the volume was reduced *in vacuo* to approx. 3 ml. Addition of hexane caused the precipitation of a brown solid, which was filtered off, washed several times with methanol and dried *in vacuo*. The solid was recrystallized from acetone/hexane and identified as complex (**1**). Anal. Found: C, 24.93; H, 3.51; N, 4.68. Calc.: C, 25.80; H, 3.58; N, 5.01. The red-orange crystals obtained from filtrate solution corresponding to the complex $[Rh(S_2CNEt_2)_3]$ (**3**).

This same compound was obtained in a shorter time when the reaction was carried out at reflux temperature in dichloromethane (2 h) or acetone (6 h) as solvents. Also was obtained by evolution of the starting dicarbonyl complex in solid state.

Preparation of $[Rh(\mu\text{-}pz^{An})(S_2CNEt_2)(CO)]_2$ (**2**)

To a solution of $[Rh(S_2CNEt_2)(CO)_2]$ (0.4 mmol) in acetone (15 ml) was added the Hpz^{An} (0.4 mmol) ligand. The orange solution formed was stirred at room temperature for 10 days. The initial orange colour of the solution changed to dark orange. Then, the volume was reduced *in vacuo* to approx. 3 ml; hexane was added to precipitate an orange solid identified as (**2**), which was filtered off, washed several times with diethylether and dried *in vacuo*. Anal. Found: C, 42.38; H, 4.19; N, 9.27. Calc.: C, 41.55; H, 4.08; N, 9.10. Red-orange crystals of $[Rh(S_2CNEt_2)_3]$ (**3**) were obtained from filtrate solution.

On the other hand, complexes (**1**) and (**2**) were also obtained by a different route. To a solution of $[RhCl(CO)_2(H\text{-}pz^{An})]$ (0.163 mmol) in acetone (15 ml) was added the diethyldithiocarbamate ligand as a sodium salt (0.163 mmol). The initial orange-yellow colour of the solution changed to dark orange. The mixture was stirred for 9 days, and then the volume was reduced to approx. 3 ml; hexane was added and a brown-yellow solid precipitated which was filtered off, washed with methanol and dried *in vacuo*. This complex was identified as compound (**1**). The filtrate solution was evaporated to dryness; the orange solid obtained identified as a mixture of (**2**) and (**3**) was washed with diethyl ether and dried *in vacuo*.

X-ray structure determination of $[Rh(S_2CNEt_2)_3]$ (**3**)

Yellow, prismatic single crystal of $[Rh(S_2CNEt_2)_3]$ (**3**) was obtained from acetone-hexane. The data were collected on an Enraf-Nonius CAD4 diffractometer and unit cell constants were refined from least-squares fitting of the θ values of 25 reflections with 2θ range 30–14. A summary of the fundamental crystal data is given in Table 4. The intensities were corrected for Lorentz and polarization effects. Scattering factors for neutral atoms and anomalous dispersion corrections for Rh and S were taken from the International Tables for X-ray Crystallography [19].

The structure was solved by Patterson and Fourier methods. Empirical absorption corrections [20] were applied at the end of the isotropic refinement with unit weights and fixed coordinates and isotropic factors for the hydrogen atoms led to $R = 0.032$ and $Rw = 0.034$. Final difference synthesis showed no significantly electron density. No trend in F versus F_o or $(\sin\theta)/\lambda$ was observed. Most of the calculations were carried out with the X-ray 80 program [21]. Table 5 shows the final atomic parameters.

Ternary complex formation kinetics involving (1,4,7,10-tetraazacyclododecane)nickel(II) and bidentate ligands

Chung-Yu Lai, Wei-Jen Lan, Chi Wang and Chung-Sun Chung*

Department of Chemistry, National Tsing-Hua University, Hsinchu, Taiwan 30043, Republic of China

(Received 5 May 1997; accepted 15 August 1997)

Abstract—The kinetics of reactions of (1,4,7,10-tetraazacyclododecane)nickel(II), NiT^{2+}, with 1,10-phenanthroline, ethylenediamine, and glycine were studied at 25.0°C and $\mu = 0.10$ mol dm^{-3} (NaCl). T is a tetradentate ligand. All reactions were first order in NiT^{2+} and reversible. The reaction with 1,10-phenanthroline was first order in 1,10-phenanthroline with the formation rate constant $k_{NiL}^{phen} = 1.31 \times 10^4$ dm^3 mol^{-1} s^{-1} and the dissociation rate constant $k_d = 19.6$ s^{-1}, followed the Eigen-Tamm mechanism. Ring closure was rate determining. The reaction involving ethylenediamine was resolved into the terms with formation rate constants $k_{NiL}^{en} = 1.61 \times 10^5$ dm^3 mol^{-1} s^{-1}, $k_{NiL}^{Hen} = 4.64 \times 10^3$ dm^3 mol^{-1} s^{-1}, and dissociation rate constants $k^{NiT(en)} = 4.55$ s^{-1} and $k_H^{NiT(en)} = 9.62 \times 10^7$ dm^3 mol^{-1} s^{-1}. Ring closure was rate determining in the en pathway but not in the Hen^+ pathway. The reaction involving glycine varies in order as a function of the glycine concentration, being first order in glycine at low glycine concentration and shifting toward a zero-order dependence a high glycine concentration. The mechanism involves a singly O-bonded LNi—O—N^+ intermediate in rapid equilibrium with reactants, $K_1 = 1.10 \times 10^3$ dm^3 mol^{-1}, followed by a slow ring closure, $k_2 = 5.29 \times 10^2$ s^{-1}. The dissociation rate constant is $k_d = 6.00$ s^{-1}. The important factors affecting the rates and the mechanisms of these reactions are the steric and inductive effects of the coordinated tetradentate ligand, the conformation angle distortion involving the "bite angle" of the two open coordination sites on NiL^{2+}, and the internal conjugate base effect of the attacking bidentate ligand. © 1998 Elsevier Science Ltd. Keywords: kinetics; ternary complex formation; nickel(II) complexes.

The kinetics of reactions of (triethylenetetramine) nickel(II), N(trien)$^{2+}$, with 1,10-phenanthroline (phen), ethylenediamine (en), and glycine (gly) have been reported by Steinhaus *et al.* [1,2]. In the current investigation, we have attempted to gain a more detailed understanding of the effects that a coordinated tetradentate ligand has upon ternary complex formation. To accomplish this, we have studied the kinetics of complexation reactions of (1,4,7,10-tetraazacyclododecane)nickel(II), $[Ni([12]aneN_4)(H_2O)_2]^{2+}$, with phen, en, and glycine as shown in eqn 1, with L representing any bidentate ligand and T representing $[12]aneN_4$.

$$NiT(H_2O)_2^{2+} + L^{n-} \rightleftharpoons NiTL^{(2-n)+} + 2H_2O \quad (1)$$

The X-ray structure of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ has been reported [3] and shown in Fig. 1. The tetradentate $[12]aneN_4$ is folded so that the water molecules can be accommodated in *cis* positions. Thus, $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ is a suitable distorted octahedral nickel(II) substrate, with the $[12]aneN_4$ acting as a non-removable tetradentate ligand and the two *cis*-coordinated aqua groups replaceable by a variety of bidentate ligands as shown in eqn 1.

EXPERIMENTAL

Reagents

$[12]aneN_4$ was prepared by the method of Richman and Atkins [4]. $Ni([12]aneN_4)(NO_3)_2$ was prepared by mixing anhydrous ethanolic solutions of the ligand (0.5 g, 0.0029 mol/50 cm^3) and $NiNO_3 \cdot 6H_2O$ (1 g,

* Author to whom correspondence should be addressed.

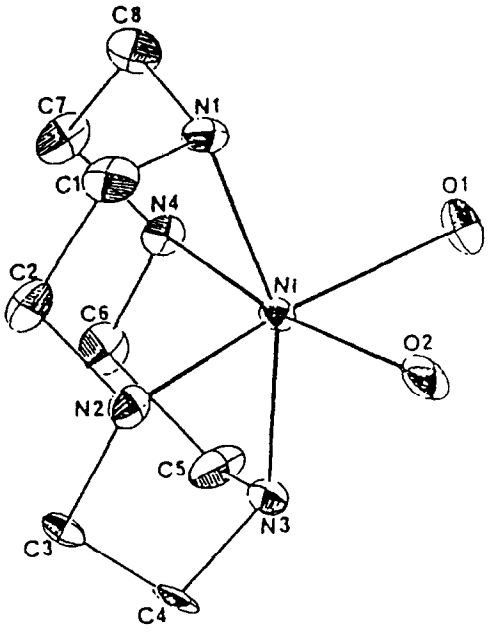

Fig. 1. Crystal structure of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$.

0.0034 mol/100 cm^3) in a water bath with stirring. The mixture turned from green to violet. Reducing the volume to 20 cm^3 by further heating in a water bath, the solution was cooled in a refrigerator for several hours. The violet product was filtered off and recrystallized from methanol (Found: C, 27.1; H, 5.65; N, 23.7. Calc. for $NiC_8H_{20}N_6O_6$: C, 27.0; H, 5.7; N, 23.7%).

All chemicals used were of GR grade (Merck of Fluka). Glycine and 1,10-phenanthroline were recrystallized before use. Ethylenediamine was distilled and standardized by a potentiometric titration against standard HCl solution (Merck). The buffers used were N-(2-hydroxyethyl)piperazine-N′-2-ethanesulfonic acid (HEPES, $pK_a = 7.75$) and {[tris(hydroxymethyl) methyl]amino}-propane (TAPS, $pK_a = 8.4$). NaCl and $NaClO_4$ were used to control the ionic strength.

Kinetic measurements

The kinetics of ternary complex formation between $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and bidentate ligands were followed at 25.0±0.1°C and $\mu = 0.10$ mol dm^{-3} with the use of a Union Giken RA-401 stopped-flow spectrophotometer equipped with a Union RA-415 rapid-scan attachment. The reactions should be carried out with $NaClO_4$ to maintain the ionic strength. Unfortunately, the solubilities of these complexes in 0.1 mol dm^{-3} [$NaClO_4$] is extremely low. Precipitation prevents us from using $NaClO_4$ to maintain the ionic strength. This is the reason why R. K. Steinhaus, B. L. Lee and L. H. Kolopajlo studied the reactions of (triethylenetetraamine)nickel(II) with glycine, 1,10-phenanthroline, ethylenediamine, bipyridine and sarcosine with NaCl being used to maintain the ionic strength [1,2]. In order to compare our results with the reactions of (triethylenetetraamine)nickel(II) with these bidentate ligands, NaCl was used to maintain the ionic strength. Absorbance vs time data were collected at 347, 250, and 248 nm for the reactions of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ with phen, ethylenediamine and glycine, respectively. Pseudo-first-order conditions were maintained by using at least a 10-fold excess of the bidentate ligand to $[Ni([12]aneN_4)]^{2+}$ in each run. Good first-order kinetics were observed in all cases. The rate constants were obtained by linear least-squares fit for the data by using a computer.

RESULTS AND DISCUSSION

$[Ni([12]aneN_4)(H_2O)_2]^{2+}$-1,10-phenanthroline

The kinetics of ternary complex formation between $[Ni(12]aneN_4)(H_2O)_2]^{2+}$ and phen were studied over a pH range from 7.05 to 7.58, covering a phen concentration range of $(1.21–4.39)\times10^{-3}$ mol dm^{-3} at 25.0°C and $\mu = 0.1$ mol dm^{-3} (NaCl). All reactions were carried out with at least a 12-fold excess of phen to $[Ni(12)aneN_4)]^{2+}$ both with and without buffer. The pseudo-first-order constants are listed in Table 1. Under these conditions, $[Ni([12]aneN_4)phen]^{2+}$ is incompletely formed; the reaction is therefore a reversible reaction and follows the rate expression

Table 1. Experimental values of the rate constants for the reaction of $[Ni([12]aneN_4)]^{2+}$ with 1,10-phenanthroline at 25.0±0.1°C and $\mu = 0.1$ mol dm^{-3} (NaCl)

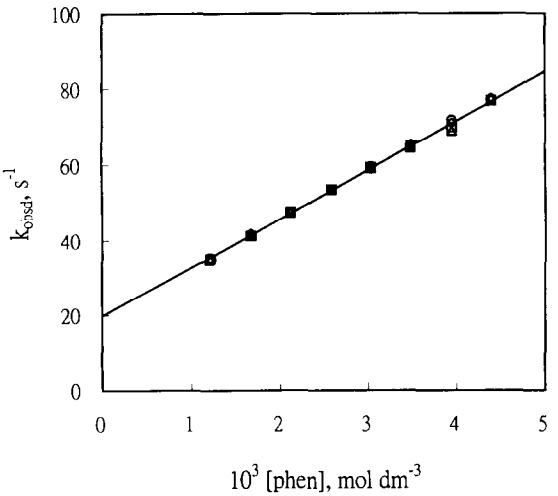
$$-\frac{d[\mathrm{NiT}]}{dt} = k^{\mathrm{L}}_{\mathrm{NiT}}[\mathrm{NiT}][\mathrm{L}] - k_{\mathrm{d}}[\mathrm{NiTL}] \qquad (2)$$

with L = phen and T = [12]aneN$_4$. The observed pseudo-first-order rate constants are plotted vs the concentration of phen and followed eqn (3). This plot is shown in Fig. 2.

$$k_{\mathrm{obsd}} = k^{\mathrm{L}}_{\mathrm{NiT}}[\mathrm{L}] + k_{\mathrm{d}} \qquad (3)$$

Values of $k^{\mathrm{L}}_{\mathrm{NiT}}$ and k_{d} obtained from this plot are given in Table 2 along with corresponding values for the reaction of $[\mathrm{Ni(trien)(H_2O)_2}]^{2+}$ with phen reported by Steinhaus and Lee [1].

In all formation reactions involving nickel(II), the Eigen-Tamm mechanism has been found to hold [5]. As shown in eqns (4), (5) and (6), $\mathrm{NiT(H_2O)_2^{2+}}$ is $[\mathrm{Ni([12]aneN_4)(H_2O)_2}]^{2+}$, L-L is phen, species II is an outer-sphere complex, species III is mono-coordinated, and species IV is chelated.



◇ pH 7.2 ○ pH 7.4 △ pH 7.6 □ pH 7.1

Fig. 2. Dependence of k_{obs} upon [phen] for reaction of $[\mathrm{Ni([12]aneN_4)(H_2O)_2}]^{2+}$ and phen (μ = 0.1 mol dm^{-3}, 25.0 C): runs with buffer (◇, ○, △); runs without buffer (□). Solid line is least-squares best fit of the points.

$$\underset{\mathrm{I}}{\mathrm{NiT(H_2O)_2^{2+}}} + \mathrm{L\text{-}L} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\mathrm{II}}{\mathrm{NiT(H_2O)_2 \cdot L\text{-}L^{2+}}} \qquad (4)$$

$$\underset{\mathrm{II}}{\mathrm{NiT(H_2O)_2 \cdot L\text{-}L^{2+}}} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{\mathrm{III}}{\mathrm{NiT(H_2O)\text{-}L\text{-}L^{2+}}} + \mathrm{H_2O} \qquad (5)$$

$$\underset{\mathrm{III}}{\mathrm{NiT(H_2O)\text{-}L\text{-}L^{2+}}} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \underset{\mathrm{IV}}{\mathrm{TNi}\begin{array}{l}\diagup\ L^{2+}\\ \\ \diagdown\ L\end{array}} + \mathrm{H_2O} \qquad (6)$$

If the usual assumption are made that (1) the outer-sphere reaction is rapid ($K_{\mathrm{os}} = k_1/k_{-1}$), and that (2) the singly bonded species (III) is a steady-state intermediate, then formation rate constant can be written as shown in eqn (7).

$$k^{\mathrm{phen}}_{\mathrm{NiT}} = \frac{K_{\mathrm{os}}k_2k_3}{k_{-2}+k_3} \qquad (7)$$

If ring closure (k_3) were much faster than bond rupture of species III (k_{-2}), then initial complex formation (k_2) were rate limiting and the formation rate constant could be predicted as eqn (8).

$$k^{\mathrm{phen}}_{\mathrm{NiT}} = K_{\mathrm{os}}k^{-\mathrm{H_2O}}\ (2/6) \qquad (8)$$

The value of K_{os} at 25°C was estimated theoretically to be 0.16 dm^3 mol^{-1} (Ref. 6), and the water exchange rate constant for $[\mathrm{Ni([12]aneN_4)(H_2O)_2}]^{2+}$, $k^{-\mathrm{H_2O}}$, is 2.00×10^7 s^{-1} (Ref. 7); the intimate mechanism of this process is probably dissociative (Ref. 8). The statistical factor of 2/6 accounts for the number of available coordination sites of $[\mathrm{Ni([12]aneN_4)(H_2O)_2}]^{2+}$ relative to $[\mathrm{Ni(H_2O)_6}]^{2+}$. The value of $k^{\mathrm{phen}}_{\mathrm{NiT}}$ calculated from eqn (8) is 1.1×10^6 dm^3 mol^{-1} s^{-1}. As listed in Table 2, this value is 84 times larger than the observed value of $k^{\mathrm{phen}}_{\mathrm{NiT}}$. This difference indicates that the coordinated [12]aneN$_4$ exerts a significant decelerating effect on the complexation of the attacking phen and suggests that ring closure contributes to the rate of formation. Thus, the rate-determining step is the formation of the second Ni—N bond. The coordinated [12]aneN$_4$ increases the lability at the remaining coordination sites and increases the monodentate phen dissociation rate constant (k_{-2}). In addition, the steric

Table 2. Rate constant values for $[\mathrm{Ni(trien)(H_2O)_2}]^{2+}$-phen[a] and $[\mathrm{Ni([12]aneN_4(H_2O)_2}]^{2+}$-phen systems at 25.0 C and μ = 0.10 mol dm^{-3} (NaCl)

[a] Values taken from Ref. 1.
[b] Calculated value from eqn 8.

effect of the coordinated [12]aneN$_4$ strongly blocks the formation of the second Ni—N bond so that ring closure contributes to the rate.

The formation rate constant for the reaction of phen with $Ni(H_2O)_6^{2+}$ and the water exchange rate constant of $[Ni(H_2O)_6]^{2+}$ are 1.6×10^{3} dm^3 mol^{-1} s^{-1} and 3.2×10^{4} s^{-1}, respectively [7,9]. [12]aneN$_4$ increases the rate of water loss of nickel(II) by a factor of about 630, but phen reacts only 8 times faster with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ than with $[Ni(H_2O)_6]^{2+}$. The relatively low rate of reaction between $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and phen is further evidence of steric effect coordinated [12]aneN$_4$ has upon the formation reaction.

As shown in Table 2, the rate constants of phen reacting with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and [Ni(trien)$(H_2O)_2]^{2+}$ are similar. These results indicate that the steric effect of coordinated [12]aneN$_4$ upon the formation reaction of its nickel(II) complex with phen is very similar to that of coordinated trien.

$[Ni([12]aneN_4)(H_2O)_2]^{2+}$-*ethylenediamine*

The kinetics of ternary complex formation between $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and ethylenediamine were studied at 25.0°C and $\mu = 0.1$ mol dm^{-3} ($NaClO_4$) over a pH range of 7.35–8.12, covering an ethylenediamine concentration range of $(2.97\text{–}6.93)\times10^{-3}$ mol dm^{-3}. All reactions were carried out with at least a 12-fold excess of en to $[Ni([12]aneN_4)(H_2O)_2]^{2+}$. Under these conditions, the reaction is first order in $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and is reversible. The observed rate constants are listed in Table 3 and followed the expression shown in eqn (9) with L = en and T = [12]aneN$_4$, where $[en]_T$ refers to the total concentration of protonated and unprotonated en.

$$-\frac{d[NiT]}{dt} = k_f[NiT][en]_T - k_d[NiTL] \qquad (9)$$

With the assumption that $[en]_T$ remains constant, eqn (9) can be expressed to eqn (10).

$$k_{obsd} = k_f[en]_T + k_d \qquad (10)$$

Plots of k_{obs} vs $[en]_T$ give straight lines according to eqn (10) (Fig. 3). The values of k_f and k_d as a function of pH are given in Table 4.

In the pH range of this study, the reactive species are the unprotonated and monoprotonated ethylenediamine, en and Hen$^+$. Reactions of these species with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ to produce the ternary complex is then considered to occur as in eqns (11 and 12).

$$NiT(H_2O)_2^{2+} + en \underset{k^{NiT(en)}}{\overset{k^{en}_{NiT}}{\rightleftharpoons}} NiT(en)^{2+} + 2H_2O \qquad (11)$$

$$NiT(H_2O)_2^{2+} + Hen^+ \underset{k^{NiT(en)}_H}{\overset{k^{Hen}_{NiT}}{\rightleftharpoons}} NiT(en)^{2+} + H^+ + 2H_2O \qquad (12)$$

Table 3. Experimental values of the rate constants for the reaction of $Ni([12]aneN_4)^{2+}$ with ethylenediamine at 25.0 ± 0.1°C and $\mu = 0.1$ mol dm^{-3} ($NaClO_4$)

pH	10^4 [Ni([12]aneN$_4$)$^{2+}$], mol dm^{-3}	10^3 [en], mol dm^{-3}	k_{obsd}, s^{-1}
7.35	2.50	2.97	18.73
		3.96	21.92

		4.95	34.62
		5.94	41.50
		6.93	47.12

Table 4. Rate constants for formation (k_f) and dissociation (k_d) reactions of $[Ni([12]aneN_4(en)]^{2+}$ at 25.0 ± 0.1°C and 0.1 mol dm^{-3} ($NaClO_4$)

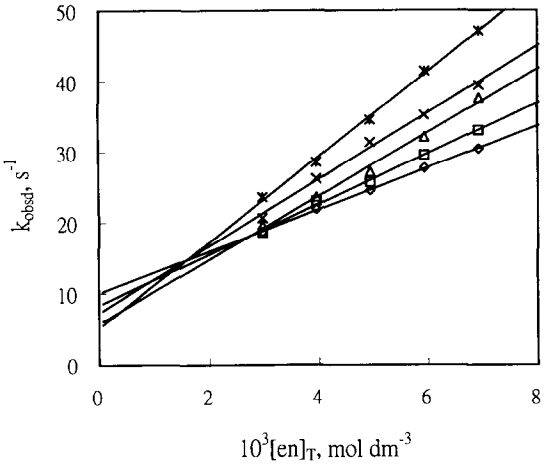
pH	k_f, dm^3 mol^{-1} s^{-1}	k_d, s^{-1}
7.35	2.93×10^3	10.16
7.53	3.57×10^3	8.38
7.73	4.50×10^3	5.79
7.92	4.72×10^3	7.28
8.12	6.05×10^3	5.09

Thus the rate law can be written as two formation terms and two dissociation terms as shown in eqn 13.

$$-\frac{d[NiT(H_2O)_2^{2+}]}{dt} = k^{en}_{NiT}[en][NiT(H_2O)_2^{2+}] + k^{Hen}_{NiT}[Hen^+][NiT(H_2O)_2^{2+}] - k^{NiT(en)}[NiT(en)^{2+}] - k^{NiT(en)}_H[NiT(en)^{2+}][H^+] \qquad (13)$$

Comparing this with eqn 9 yields

$$k_f[en]_T = k^{en}_{NiT}[en] + k^{Hen}_{NiT}[Hen^+] \qquad (14)$$



◇ pH 7.35 □ pH 7.53 △ pH 7.73 × pH 7.92 ✱ pH 8.12

Fig. 3. Plots of k_{obsd} vs $[en]_T$ for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and ethylenediamine (25.0°C, $\mu = 0.1$ mol dm^{-3}).

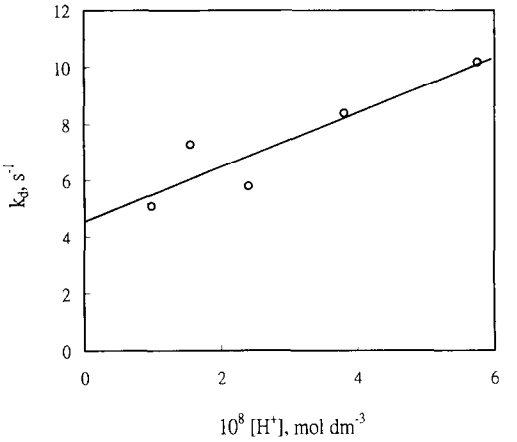


Fig. 5. Dependence of k_d upon $[H^+]$ for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and ethylenediamine (25.0°C, $\mu = 0.1$ mol dm^{-3}).

and

$$k_d = k^{NiT(en)} + k_H^{NiT(en)}[H^+] \quad (15)$$

Equation (14) can be rearranged to eqn (16) and plotted as shown in Fig. 4. A plot of k_d

$$k_f \frac{[\Sigma L]}{[en]} = k_{NiT}^{en} + k_{NiT}^{Hen} K_1^H [H^+] \quad (16)$$

vs $[H^+]$ is shown in Fig. 5. The values of k_{NiT}^{en}, k_{NiT}^{Hen}, k^{NiTen} and $k_H^{NiT(en)}$ obtained from these plots are listed in Table 5 along with corresponding values for the reaction of $[Ni(trien)(H_2O)_2]^{2+}$ with en and Hen^+ reported by Steinhaus and Kolopajlo [2].

The results in this table indicate both reactive unprotonated and monoprotonated terms are found. These results can be explained by modifying the mechanism proposed by Steinhaus and Kolopajlo [2] shown in Fig. 6. Assuming that the outer-sphere reaction is rapid, that the singly bonded species is a steady-state intermediate, and that the protonation equilibrium is rapid leads to the rate expressions in eqns (17 and 18).

$$k_{NiT}^{en} = \frac{2}{6} \frac{K_{os} k_1 k_2}{k_{-1} + k_2} \quad (17)$$

$$k_{NiT}^{Hen} = \frac{2}{6} \frac{K_{os} k'_1 k_2}{k'_{-1} K'_H [H^+] + k_2} \quad (18)$$

For the reaction of Hen^+ with $[Ni([12]aneN_4)(H_2O_2)]^{2+}$, Fig. 4, a plot of eqn (16), shows k_f to be a linear function of $[H^+]$ throughout the pH range studied and thus gives a value of k_{NiT}^{Hen} from the slope that is independent of $[H^+]$. This result indicate that $k'_{-1}K'_H[H^+]$ should be smaller than k_2. Thus eqn (18) simplifies to eqn (19) and the formation of the singly bonded species (II′) may be the rate-determining step.

$$k_{NiT}^{Hen} = \frac{2}{6} K'_{os} k_1 \quad (19)$$

If the steric effect of the coordinated $[12]aneN_4$ upon the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ with Hen^+ were negligibly small, the value of $(k_{NiT}^{HL})'$ can be estimated by eqn (20).

$$(k_{NiT}^{Hen})' = \frac{2}{6} K'_{os} k^{-H_2O} \quad (20)$$

The value of K'_{os} calculated from a modification of the Fuoss equation [6] is 0.044 dm^3 mol^{-1}; the value of k^{-H_2O} is 2.00×10^7 s^{-1} [7]. The predict value of $(k_{NiT}^{Hen})'$, given in Table 5, is 63 times larger than that observed. It has been estimated that an intramolecularly hydrogen bonded form of Hen^+ slows down the reaction of Hen^+ with nickel(II) by a factor of 3 [11]. Thus, the

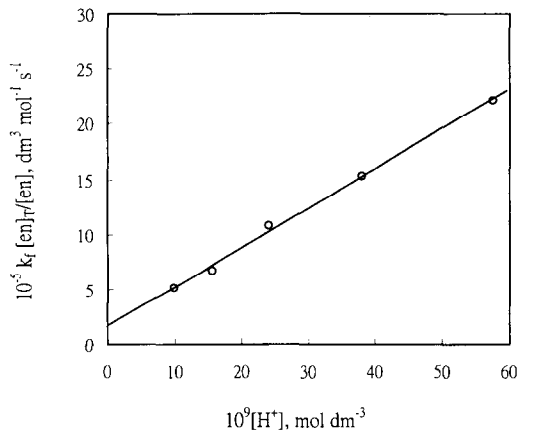

Fig. 4. Dependence of $k_f[en]_T/[en]$ upon $[H^+]$ for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and ethylenediamine (25.0 C, $\mu = 0.1$ mol dm^{-3}).

[a] Values taken from Ref. 2.
[b] Rate constant values for the reactions of unprotonated en with Ni(II) complexes.
[c] Predicted from eqn 21.
[d] Rate constant values for the reactions of monoprotonated Hen with Ni(II) complexes.
[e] Predicted from eqn 20.

actual steric factor of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ reacting with Hen^+ is about 21, which is slightly larger than that of $[Ni(trien)(H_2O)_2]^{2+}$ reacting with Hen^+[2].

If the first Ni—N bond formation is the rate-determining step for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ with en, the value of formation rate constant $(k_{NiT}^{en})'$ can be predicted from eqn (21).

$$(k_{NiT}^{en})' = \frac{2}{6} K_{os} k_1 \qquad (21)$$

The steric factor of the reaction of en with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ is similar to that of the reaction of Hen^+ with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ since the uprotonated end of Hen^+ is the initial reaction site. Equation (21) incorporating an accelerating internal-conjugate-base factor [2] of 190 and a retarding steric factor of 21, predicts a value of $(k_{NiT}^{en})' = 9.7 \times 10^6$ dm^3 mol^{-1} s^{-1}, which is about 50 times larger than the experimentally observed value of $k_{NiT}^{en} = 1.61 \times 10^5$ dm^3 mol^{-1} s^{-1}. The large difference between $(k_{NiT}^{en})'$ and k_{NiT}^{en} indicates the first Ni—N bond formation of en to $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ is not rate determining. The coordinated $[12]aneN_4$ molecule increases the lability at the remaining coordination sites and strongly hinders the formation of the second Ni—N bond. Therefore, the ring closure rate is slower than the

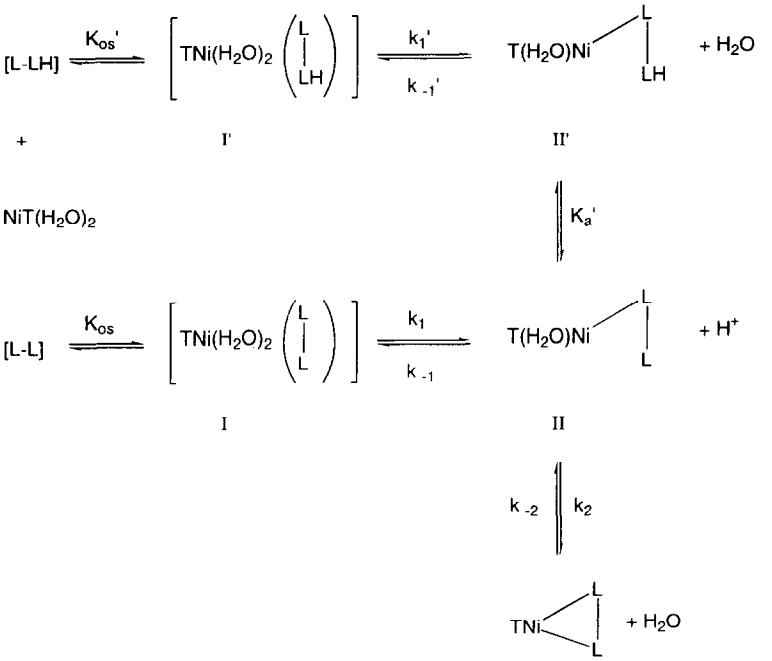

Fig. 6. Proposed mechanism for the reaction of en and Hen^+ with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$.

monodentate en dissociation rate with the result that the second Ni—N bond formation is the rate-determining step.

As pointed out by Steinhaus [2], en requires a bond angle of about 82° when coordinated to nickel(II). The crystal structure of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ (Fig. 1) reveals that the bond angle formed between the two H_2O ligands and nickel(II) is 82.5°. Therefore, the conformation-angle-distortion (CAD) effect should be very small in the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ with en. By contrast, the CAD effect in the reaction of $[Ni(trien)(H_2O)_2]^{2+}$ with en is very large. As shown in Table 5, the formation rate constants k_{NiT}^{en} and k_{NiT}^{Hen} for the reactions of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ are larger than those of $[Ni(trien)(H_2O)_2]^{2+}$; on the other hand, the dissociation rate constant $k^{NiT(en)}$ for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ is smaller than that of $[Ni(trien)(H_2O)_2]^{2+}$. The relatively large formation rate constants for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ is mainly due to the fact that the labilizing effect of the four [12]aneN$_4$ nitrogens is slightly larger than that of the four trien nitrogens. The relatively large k_d value for the reaction of $[Ni(trien)(en)]^{2+}$ may be due to the relatively large CAD effect of $[Ni(trien)(en)]^{2+}$ compared to that of $[Ni([12]aneN_4)(en)]^{2+}$. As pointed out by Steinhaus and Kolopajlo [2], coordination of trien to nickel(II) forces a bite angle of 92.7° on $Ni(trien)^{2+}$ involving the two open coordination sites. On the other hand, coordination of [12]aneN$_4$ to nickel(II) give a bite angle of 82.5° on $[Ni([12]aneN_4)]^{2+}$ involving the two open coordination sites [3]. Therefore, the CAD accelerating effect for the reaction of $[Ni(trien)(en)]^{2+}$ is much larger than that for the reaction of $[Ni([12]aneN_4)(en)]^{2+}$.

$[Ni([12]aneN_4)(H_2O)_2]^{2+}$-*glycine*

The kinetics of ternary complex formation between $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and gly were studied at 25.0°C and $\mu = 0.10$ mol dm^{-3} (NaCl), over a pH range from 6.82 to 7.83, covering a gly concentration of 5.00×10^{-3} mol dm^{-3}–1.50×10^{-2} mol dm^{-3}. Kinetic studies were carried out under pseudo-first-order conditions by using at least a 10-fold excess of gly to $[Ni([12]aneN_4)(H_2O)_2]^{2+}$. The observed pseudo-first-order rate constants are given in Table 6. Under these conditions, $[Ni([12]aneN_4)gly]^{+}$ is incompletely formed; the reaction is therefore a reversible reaction. Plots of the observed pseudo-first-order rate constant, k_{obsd}, against total glycine concentration at a constant pH are shown in Fig. 7. The plots were linear up to pH 7.4. Higher pHs showed a curvature indicative of a shift from first-order to zero-order behaviour in glycine as shown by the pH 7.6 and pH 7.8 curves of Fig. 7. The intercepts of the plots at pHs less than 7.4, listed in Table 7, were constant and gave an average value of 6.00 s^{-1}, which is independent of glycine, hydrogen, or hydroxide ion and buffer anion and protonated buffer. Plots above pH 7.4 appear to intercept at the same point. This value must represent a reaction involving only $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and cannot involve $[Ni([12]aneN_4)(H_2O)(OH)]^{+}$ or $[Ni([12]aneN_4H)(H_2O)_2]^{3+}$ species since these would show a pH dependence. Again, as with the $[Ni([12]aneN_4)(H_2O)_2]^{2+}$-phen system, no biphasic behavior was seen so that the intercepts indicate a reversible reaction with k_{obsd} described by eqn 22.

$$k_{obsd} = k_{NiT}^{gly}[gly] + k_b \quad (22)$$

The average value of 6.00 s^{-1} was subtracted from

k_{obsd} for the glycine reactions. When this corrected value, k'_{obsd}, was plotted against the glycinate ion concentration with $K_a = 2.69 \times 10^{-10}$ for glycine, according to eqn 23, all points covering all pHs and glycine

$$k'_{obsd} = k^{gly}_{NiT}[gly] = k^{gly}_{NiT}\left(\frac{K_a[gly]_T}{K_a + [H^+]}\right) \tag{23}$$

concentrations studied fell on the same line. The plot, shown in Fig. 8 has a definite curvature to it. Behavior such as this is represented by the rate expression shown in eqn (24). Equation 24 can be rearranged to eqn

(25) and plotted as shown in Fig. 9. Values of a and b obtained from this plot

$$\frac{1}{k'_{obsd}} = \frac{1}{ab[gly]} + \frac{1}{b} \tag{25}$$

are $a = 1.10 \times 10^3$ dm^3 mol^{-1} and $b = 5.29 \times 10^2$ s^{-1}. Although all points appear to fit the line (Fig. 9), the standard deviations of K_1 and k_2 of $[Ni\{1,4,7,10\text{-tetraazacyclododecane}\}(H_2O)_2]^{2+}$-gly system shown in Table 7 are very large. We have repeated this experiment, similar results were found. The large deviations are mainly due to the very small intercept of this

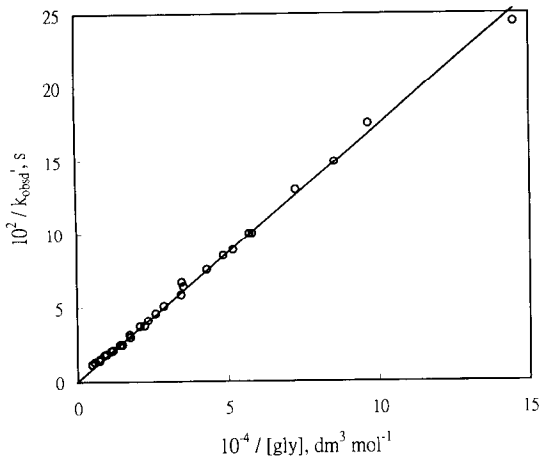

Fig. 9. Resolution of k'_{obsd} for reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ with glycine into terms a and b of eqn 25. Plot covers glycinate ion concentration range of 1.0×10^{-4} to 2.1×10^{-3} mol dm^{-3}. Solid line is least-squares best fit of the data.

plot (Fig. 9). The standard deviations of other rate constants and equilibrium constants are small. Attempts were made to fit the data to other rate laws containing monoprotonated glycine without success. No reactive protonated terms were found.

The mechanism for the reaction of $[Ni(trien)(H_2O)_2]^{2+}$ and gly has been thoroughly studied by Steinhaus and Lee [1]. This mechanism shown in eqn (26) is consistent with the kinetic results of the reaction between $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and gly.

$$[(H_2O)_2Ni(T)] + \begin{matrix} O \\ | \\ N \end{matrix} \overset{K_1}{\rightleftharpoons} \left[H_2O(T)Ni \begin{matrix} O \\ | \\ N \end{matrix} \right] + H_2O$$

$$\downarrow k_2$$

$$\left[(T)Ni \begin{matrix} O \\ | \\ N \end{matrix} \right] + H_2O \quad (26)$$

Assuming that the mono-coordinated intermediate is in equilibrium with $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and gly leads to the kinetic expression given in eqn (27) which is identical with eqn (24) [1]. Thus $a = K_1$ and $b = k_2$. These values are given in Table 7 along with corresponding values for the reaction of $[Ni(trien)(H_2O)_2]^{2+}$ with gly reported by Steinhaus and Lee [1].

$$k'obsd = \frac{K_1 k_2 [gly]}{1 + K_1 [gly]} \quad (27)$$

The equilibrium type of mechanism followed by a slow ring closure of glycine indicates the carboxylate groups bonds first in $[Ni([12]aneN_4)(H_2O)_2]^{2+}$-gly reaction. If the amino group coordinates before the carboxylate group, k_{-1} could not be much larger than k_2 and the equilibrium type of mechanism would not be seen.

Although the basicity of the carboxylato group of gly is weaker than that of acetate, the value of K_1 shown in Table 7 is 220 times larger than the stability constant of Ni(acetate)$^+$ (K = 5.0 dm^3 mol^{-1}) [12]. These results indicate the internal conjugate base (ICB) effect is very important in the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and gly.

The labilizing effect of the four [12]aneN$_4$ nitrogens is 4 times larger than that of the four trien nitrogens. Similarly, the k_2 value for the reaction of $[Ni([12]aneN_4)(H_2O)_2]^{2+}$ and gly is 4 times larger than that of $[Ni(trien)(H_2O)_2]^{2+}$ and gly.

Although the labilizing effect of the four [12]aneN$_4$ nitrogens is larger than that of the four trien nitrogens, it is interesting that the k_d value for the reaction of $[Ni(trien)(gly)]^+$ is larger than that of $[Ni([12]aneN_4)(gly)]^+$. The relatively large k_d value for the reaction of $[Ni(trien)(gly)]^+$ may be due to the relatively large CAD effect of $[Ni(trien)(gly)]^+$ compared to that of $[Ni([12]aneN_4)(gly)]^+$. As pointed out by Steinhaus and Kolopajlo [2], coordination of trien to nickel(II) forces a bite angle of 92.7° on Ni(trien)$^{2+}$ involving the two open coordination sites. On the other hand, coordination of [12]aneN$_4$ to nickel(II) give a bite angle of 82.5° on $[Ni([12]aneN_4)]^{2+}$ involving the two open coordination sites [3]. Therefore, the CAD accelerating effect for the reaction of $[Ni(trien)(gly)]^+$ is much larger than that for the reaction of $[Ni([12]aneN_4)(gly)]^+$.

(Received 25 August 1997; accepted 10 November 1997)

Abstract—The new semi-rigid diimine ligand, $OpyNpy_2$, coordinates the toxic heavy metals ions Cd(II) and Hg(II) in a monohelical fashion, as established, in the former, by X-ray crystallography and, in both, by ^1H NMR spectroscopy; ligand control is attributed to the helical topology of these complexes of stereochemically non-demanding ions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ligand; monohelical; cadmium(II) complex.

Metal-ion coordination chemistry plays a fundamental role in the controlled assembly of novel molecular and supramolecular structures, with particular interest surrounding the topology and intrinsic chirality of helicates [1]. While much attention has focused on double [2,3] and triple [4] helical systems, controlled assembly of single helicates remains limited to only a few examples [5,6]. The relationship between the single/double helices and mononuclear acyclic/macrocyclic ligand complexes can readily be conceptualized as illustrated (Scheme 1). While examples of the former have recently appeared [2], cases of the latter are much less common [5,6]. In this communication, we describe the syntheses and characterization of Cd(II) and Hg(II) complexes that correspond to examples of the monohelical topology.

To produce systems with a propensity for monohelical coordination, we have synthesized the linear diimine ligand, $OpyNpy_2$, attempting to limit free rotation of its multidentate backbone by incorporating unsaturated imine functions and sterically demanding aromatic substituents, together with "hinge" methylene groups in order to generate a conformationally restricted acyclic system for binding in a mononuclear fashion. The complex $[Cd(OpyNpy_2)](NO_3)_2 \cdot 2H_2O$, reported herein is, to the best of our knowledge, the first structurally characterized monohelical Cd(II) complex of an acyclic ligand. The Cd(II) complex similar to the helical Zn(II) complex of $SpyNpy_2$ [5], the sulphur analogue of $OpyNpy_2$.

The complexes $[M(OpyNpy_2)](X)_2$ [where

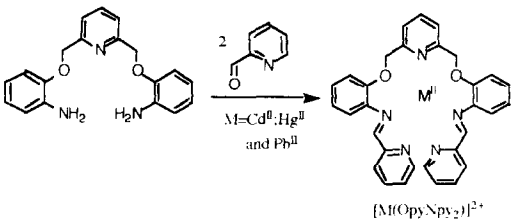

Scheme 2.

M = Cd(II) or Hg(II); X = $(NO_3)^-$ or $(ClO_4)^-$] were obtained from [1 + 2] Schiff-base condensation 2,6-*bis*(2-aminophenoxymethyl) pyridine [7] and 2-pyridinecarboxaldehyde in methanol in the presence of the appropriate metal salt (Scheme 2) and were fully characterized by IR, ^{1}H NMR, fast atom bombartment (FAB) mass spectrometry and elemental analyses.†

Crystals of $[Cd(OpyNpy_2)](NO_3)_2 \cdot 2H_2O$ were obtained by slow diffusion of diethyl ether into acetonitrile : methanol (1 : 2 v/v) solution of the complex. Crystals of one enantiomer only were obtained. The crystal selected for structure determination‡ was found to occur in the chiral space group $P6_122$, giving monohelical *P*(plus) configuration only (Fig. 1). The metal coordinates to all the potential donors of the ligand. However, significantly longer Cd—O than Cd—N bonds are observed which, as indicated in analogous structures [8], presumably result from relatively weak electrostatic metal-ether oxygen interactions common with these d^{10} ions. The 7-coordinate metal sphere is somewhat irregular although is best envisaged as a capped octahedron with N(1A), N(2A), O(1A) and N(2B) describing the equatorial plane and N(3) capping the O(1A), O(1B), N(2B) face. The "crossed" meridional orientation of planar N_2O units within the octahedron [dihedral angle 66.4(4)] underpins the helicity of the complex with the principal twists in the ligand strand occurring across the CH_2O linkages.

^{1}H NMR spectra of $[Cd(OpyNpy_2)](X)_2$ and $[Hg(OpyNpy_2)](X)_2$ in acetonitrile-d_3 (Fig. 2) are broadly similar. The spectra show two key features. Signals arising from the 2-pyridylimine protons in the complexes are flanked by satellites arising from spin-spin coupling to $I = 1/2$ metal nuclei (^{111,113}Cd and ^{199}Hg)§ indicating that the complexes are kinetically inert on the NMR timescale. Observations of this kind are relatively unusual in nitrogen–oxygen donor ligands and have hitherto been limited to macrocyclic [7–9] and cryptate [10] ligands. Notably, this is the second report of mercury(199)–proton coupling through an imine donor; the first corresponding to the thioether analogue of this complex[5]. Furthermore, spectra of both complexes show AB subspectra arising from diastereotopic environments of the methylene protons of the ligand. Such observations are consistent with the assignment of chiral complexes in solution. Consideration of the retention of metal-to-imine (proton) coupling together with the geminal coupling observed in the methylene region suggests that any mechanism of rapid interconversion of helical enantiomers in solution does not involve extensive ligand dissociation. Indeed, the weakly bonding oxygen donors, as evidenced by the X-ray structural data, might facilitate localized dissociation in any such racemization.

These studies show that restricting the degrees of freedom in semi-rigid open-chain ligands can produce monohelical complexes, even with metals that have little geometrical preference. We are currently examining the variation of ligand parameters such as denticity, flexibility and donor type as well as detailed NMR studies.

(Received 8 December 1997; accepted 19 February 1998)

Abstract—Pentacarbonylbromorhenium(I) reacted with 2,6-bis(benzimidazol-2′-yl)pyridine (bbip), 2,6-bis(1′-methylbenzimidazol-2′-yl)pyridine (bmbip), 2,6-bis(5′,6′-dimethylbenzimidazol-2′-yl)pyridine (bdmbip), and 2,6-bis(1′,5′,6′-trimethylbenzimidazol-2′-yl)pyridine (btmbip) to form stable octahedral complexes of type *fac*-[ReBr(CO)$_3$L] (L = bbip, bmbip, bdmbip or btmbip) in which L is acting as a bidentate chelate ligand. At above-ambient temperatures in solution the complexes are fluxional with the nitrogen ligand oscillating between equivalent bidentate bonding modes. Rates and activation energies for these fluxions have been investigated by NMR methods. At low temperatures rotation of the uncoordinated benzimidazolyl unit is restricted and for *fac*-[ReBr(CO)$_3$(btmbip)] in CD_2Cl_2 solution, two preferred rotamers exist in 89:11% relative abundances. A rotational energy barrier has been estimated. The X-ray crystal structure of *fac*-[ReBr(CO)$_3$)(btmbip)] confirms the bidentate chelate bonding of btmbip with a N–Re–N angle of 74.2°. The pendant benzimidazole unit is inclined at an angle of 60.7° to the pyridine ring. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: rhenium; benzimidazolylpyridine; fluxionality; dynamic NMR.

Following the discovery of a 1,4-metallotropic shift in metal complexes of 2,2′:6′,2″-terpyridine (terpy) in which the terpy was bonded as a bidentate chelate ligand to a kinetically inert metal centre [1–5], we have been interested in investigating the generality of this phenomenon. We extended our studies to a series of nitrogen ligands analogous to terpy in which one or both of the outer pyridine rings were replaced by pyrazoles [6, 7, 8, 9].

We now report the results of a study on some rhenium(I) complexes of terpy analogues in which both outer pyridine rings have been replaced by benzimidazole derivatives, namely 2,6-bis(benzimidazol-2′-yl)pyridine (bbip), 2,6-bis(1′-methylbenzimidazol-2′-yl)pyridine (bmbip), 2,6-bis(5′,6′-dimethylbenzimidazol-2′-yl)pyridine (bdmbip), and 2,6-bis-(1′,5′,6′-trimethylbenzimidazol-2′-yl)pyridine (btmbip).

Variable temperature NMR studies of the solution fluxionality of the complexes *fac*-[ReBr(CO)$_3$L] (L = bbip, bmbip, bdmbip and btmbip) and a crystal structure of *fac*-[ReBr(CO)$_3$(btmbip)] are presented.

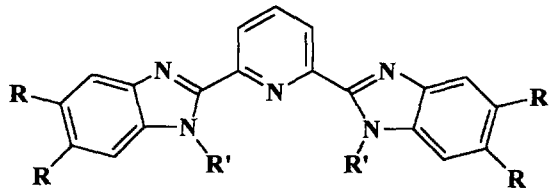
EXPERIMENTAL

Materials

Previously described methods were used to prepare the complex [ReBr(CO)$_5$] [10] and the ligands bbip, bdmbip, bmbip, and btmbip [11, 12].



R	R'	
H	H	bbip
H	Me	bmbip
Me	H	bdmbip

Synthesis of complexes

All preparations were performed by standard Schlenk techniques [13] under purified nitrogen using freshly distilled, dried and degassed solvents. The complexes $[ReBr(CO)_3L]$ (L = bbip, bdmbip, bmbip and btmbip) were all prepared in an analogous manner, synthetic data being given in Table 1. The preparation of $[ReBr(CO)_3(bmbip)]$ is given as a representative example.

2,6-Bis(1'-methylbenzimidazol-2'-yl)pyridinebromotricarbonylrhenium(I)

The compounds $[ReBr(CO)_5]$ (0.1 g, 0.25 mmol) and bmbip (0.1 g, 0.29 mmol) were stirred and heated under reflux in methanol (20 cm^3) for 4 h. The solution was cooled to ambient temperature and the supernatant liquid was decanted off. The orange solid was washed *in situ* with methanol (2 × 10 cm^3), diethylether (10 cm^3) and then dried under vacuum to give orange crystals. Yield 0.16 g (95%). A sample for analysis was dried under vacuum at 50°C for 8 h.

Physical methods

Infrared spectra of dichloromethane solutions of the complexes were recorded on a Perkin–Elmer 881 spectrometer calibrated from the line of polystyrene at 1602 cm^{-1}. Elemental analyses (C, H, N) were carried out by Butterworth Laboratories, Teddington, Middlesex, UK.

^1H NMR spectra were recorded on either a Bruker AC300 FT spectrometer operating at 300.13 MHz or on a Bruker DRX–400 FT spectrometer operating at 400.13 MHz. Chemical shifts are quoted relative to Me_4Si ($\delta = 0$) as an internal standard. Variable temperature NMR spectra were obtained using the Bruker variable temperature units B-VT100 (AC300) and B-VT2000 (DRX-400). Rate data were derived from bandshape analysis of ^1H NMR spectra using a version of the DNMR3 program [14]. Activation parameters based on experimental rate data were calculated using the THERMO program [15].

X-ray crystallography

The crystal used for X-ray work was obtained as described above. All measurements were made on a Delft Instruments FAST area detector diffractometer positioned at the window of a rotating anode generator with Mo-Kα radiation by following procedures described earlier [16]. The crystal data, details of data collection and structure refinement are summarised in Table 2. The cell parameters were determined by least-squares refinement of diffractometer angles for 250 reflections. The data were corrected for Lorentz and polarisation factors and also for absorption effects (DIFABS) [17].

Index ranges	$-12 \le h \le 10$, $-13 \le k \le 8$, $-14 \le l \le 15$
Reflections collected	4926
Independent reflections	3788 [R(int) = 0.0637]
Absorption correction factors	0.865–1.109
Refinement method	Full-matrix least-squares on F^2
Data / restraints / parameters	3788 / 36 / 369
Goodness-of-fit on F^2	0.577
Final R indices (all 3788 data)	$R_1 = 0.0522$, $wR_2 = 0.0762$
R indices [2698 data with $I > 2\sigma(I)$]	$R_1 = 0.0348$, $wR_2 = 0.0716$
Largest diff. peak and hole	0.956 and −0.730 e. Å^{-3}

$R_1 = \Sigma(F_o - F_c)/\Sigma(F_o)$; $wR_2 = [\Sigma\{w(F_o^2 - F_c^2)^2\}/\Sigma\{(wF_o^2)^2\}]^{1/2}$; $w = 1/[\sigma^2(F_o^2)]$

The structure was solved by Patterson methods (SHELXS86) [18] and refined by full-matrix least-squares on F^2 using all unique data with intensities greater than 0 (SHELXL93) [19]. The non-hydrogen atoms were all anisotropic, but it was necessary to use an ISOR = 0.005 restraint for N(2), C(13), C(19), C(22), C(01) and O(01) to prevent these atoms becoming 'non-positive-definite'. The hydrogen atoms were included in calculated positions (riding model) with $U_{iso} = n \times U_{eq}$ ($n = 1.2$ for CH, and 1.5 for OH and CH_3 groups) of the parent atoms. Final R-values are given in Table 2. The diagram was drawn using SNOOPI [20]. Sources of scattering factor data are given in ref. [19]. The calculations were done on a 200 MHz personal computer.

Full details of crystallographic study including the atomic coordinates and displacement coefficients, hydrogen atom parameters, full list of bond lengths and angles have been deposited as supplementary material.

RESULTS

The complexes $[ReBr(CO)_3)L]$ (L = bbip, bmbip, bdmbip and btmbip) were obtained as orange crystalline air-stable solids solvated with methanol from reactions of $[ReBr(CO)_5]$ with the ligand in refluxing methanol. The complexes were not very soluble in the common organic solvents but, as would be expected, the presence of methyl groups in the nitrogen ligand, markedly increased the solubility of the ligand and the complex. In solution all the complexes displayed three strong carbonyl stretching bands in the infrared (Table 1) indicative of a *fac* stereochemistry for the complex and implying that the nitrogen ligands were acting as bidentate chelates. This was confirmed by solution NMR studies.

NMR studies

The ^1H chemical shift data for the four ligand molecules bbip, bmbip, bdmbip and btmbip, are given in Table 3. The structures are shown with a *trans*, *trans* configuration for the pyridine nitrogen and the imidazole nitrogen atoms not bearing an exocyclic group, as this is the structure most likely to be preferred in view of the solid state structure of the protonated form of bmbip [21]. An analogous *trans*, *trans* configuration of nitrogen atoms is also found in the solid

state structures of terpy and 2,6-bis(pyrazol-1-yl) pyridine [22]. The spectra show the expected seven chemical shifts.

At ambient temperatures the four metal complexes show spectra consistent with the N_3 ligand bonding to the rhenium in a bidentate chelate manner. The assignments of the ^{1}H signals due to all thirteen different chemical environments are given in Table 4.

On raising the temperature of the solutions of all four rhenium complexes changes occurred which were consistent with the metal moiety undergoing a metallotropic shift as indicated at the head of Table 4. Such a Re–N bond fluxion will cause exchanges (i) between the aromatic hydrogen or methyl environments, namely A⇌M, B⇌L, C⇌K and D⇌J, (ii) between the pyridyl hydrogens F⇌H and (iii) between the -N-H (or -N-R) environments E⇌I. It is notable that the pyridyl environment H_G will be totally unaffected by this fluxion.

The ^{1}H NMR spectra of the individual complexes will now be described.

[ReBr(CO)$_3$(btmbip)]

This was the most soluble of the four complexes studied, presumably as a result of the heavy methylation of the ligand, and its ^{1}H NMR spectra were easily analysed. Its ambient temperature spectrum, in $(CDCl_2)_2$ solvent, consisted of 13 signals consistent

with a static bidentate chelate complex. Unambiguous assignments of all signals (with the exception of the four closely separated C-methyl signals) were made with the aid of NOE difference experiments. The aromatic region of the spectrum is depicted in Fig. 1. On warming, pairs of signals show mutual exchange broadening consistent with the 1,4-metallotropic shift, with the exception of the triplet signal of H_G ($^3J_{GH} = {}^3J_{GF} = 7.9$ Hz) which remains sharp. At the highest temperature reached (413 K), a broad coalescence of the signals due to H_F, H_H, H_A and H_M can be noted, whereas at this temperature the signals due to H_D and H_J have already coalesced and sharpened to a fairly sharp averaged signal. Changes in the N-methyl region (δ 3.8–4.3) were simpler to follow and total bandshape analysis was performed on the pair of exchanging signals. Experimental and computer simulated spectra are shown in Fig. 2, with the 'best-fit' rate constants for each temperature given. Activation energies were computed in the usual way (Table 5). In

the room temperature spectrum of this complex, the two N-methyl signals Me_E and Me_I were of different widths, with the broader signal due to Me_I having a half-height width of ~5 Hz. This suggested that it might be displaying effects of restricted rotation of the pendant benzimidazolyl portion of the ligand. A low temperature NMR study of this complex in CD_2Cl_2 solvent was therefore performed. On cooling to 213 K (Fig. 3) this signal continued to broaden and eventually split into an unequal intensity pair of signals denoted by I and I′ in Fig. 3 and Table 6. This indi-

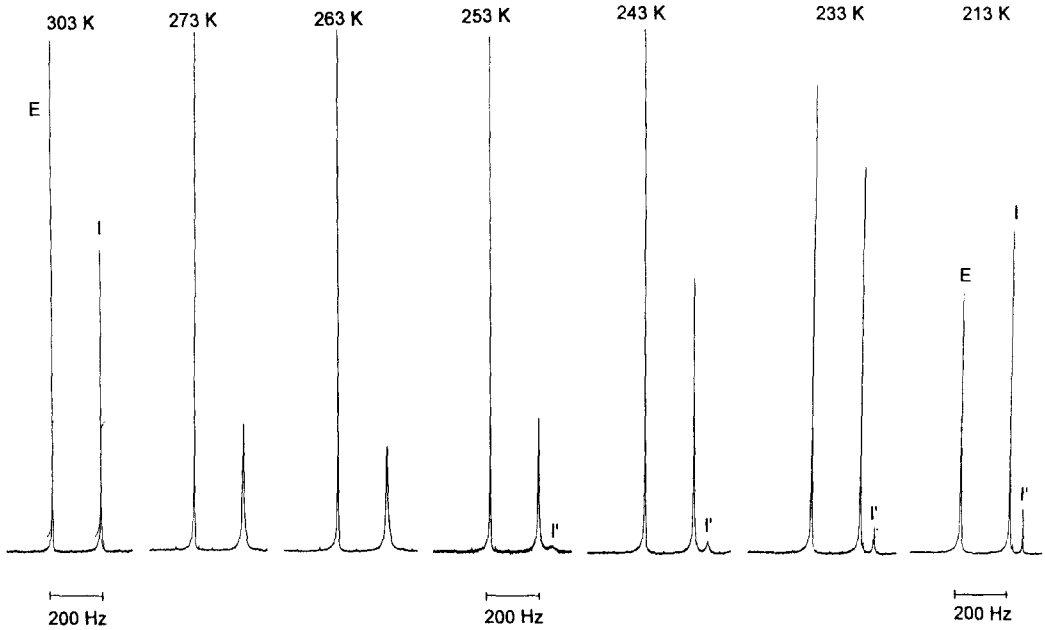

Fig. 3. Low temperature ^{1}H NMR spectra (400 MHz) of the complex [ReBr(CO)$_3$(btmbip)] in CD_2Cl_2 showing the effects of restricted rotation on the N-methyl signal of the pendant benzimidazolyl function.

cated a pair of rotameric species (rel. populations 0.89/0.11) as depicted in Table 6. Cooling of the sample also led to broadening and splitting of some of the ring hydrogen signals, notably H_F, H_H and H_M. The shifts of their minor counterparts $H_{F'}$, $H_{H'}$ and $H_{M'}$ are given in Table 6. An estimate was made of the energy barrier to rotation by fitting the bandshapes for the Me_I and $Me_{I'}$ signals (Fig. 3) at temperatures on either side of the coalescence temperature of 263 K. The activation energy, $\Delta G^{\ddagger}$ (298 K), for the process was calculated (Table 7).

The preferred solution rotamer is presumed to have a geometry similar to that exhibited in the solid state, where, according to the X-ray crystal structure (see

(a) Relative to TMS, $\delta = 0$. Shifts $\delta_A - \delta_E$ were not affected by the restricted rotation and are not quoted.

Table 7. Energy barriers for restricted rotation[a] of the ligand pendant heterocyclic ring in [ReBr(CO)$_3$L] (L = terpy, pbipy, dmpbipy, mpbipy, or btmbip) complexes.

Complex	Pendant ring	Rotamer populations	$\Delta G^{\ddagger b}$/kJ mol^{-1}	Ref.
[ReBr(CO)$_3$(terpy)]	pyridine	~0.5/0.5	not measureable	[3]
[ReBr(CO)$_3$(pbipy)]	pyrazole	0.5/0.5	43.0	[9]
[ReBr(CO)$_3$(dmpbipy)]	3,5-dimethylpyrazole	0.975/0.025	58.4	[9]
[ReBr(CO)$_3$(mpbipy)]	4-methylpyrazole	0.5/0.5	38.5[c]	[9]
[ReBr(CO)$_3$(btmbip)]	1,5,6-trimethylbenzimidazole	0.89/0.11	56.9	This work

a. Major → minor species

b. At 298.15 K

c. Estimated from measurements at the coalescence temperature (≅ 193 K)

terpy = 2,2′:6′,2″-terpyridine, pbipy = 6-(pyrazol-1-yl)-2,2′-bipyridine, dmpbipy = 6-(3,5-dimethylpyrazol-1-yl)-2,2′-bipyridine, mpbipy = 6-(4-methylpyrazol-1-yl)-2,2′-bipyridine.

later), the pendant benzimidazolyl unit is rotated from the plane of the pyridine ring by an amount given by the torsion angle N(2)–C(12)–C(13)–N(4) of 60° and the N-methyl group is in a near *cis*- relationship to Br. The structure of the other solution rotamer is likely to differ from the favoured rotamer by a near 180° rotation of the pendant benzimidazole function, thus causing the N-methyl to be approximately *trans* to Br.

[ReBr(CO)$_3$(bmbip)]

The ^{1}H NMR spectra of this complex showed analogous changes to the btmbip complex (above). The 1,4-metallotropic shift was clearly monitored by the exchanges of the ring pyridyl signals H_F and H_H and the N-methyl signals R_E and R_I. The energy barrier of the fluxion was determined by bandshape analysis of the N-methyl signals in the temperature range 353–413 K. Good agreement between experimental and computer fitted line shapes was achieved for seven temperatures in the above range and reliable activation energy data obtained (Table 5).

[ReBr(CO)$_3$(bdmbip)]

The existence of the 1,4-Re-N fluxion was also displayed in the variable temperature spectra of this complex. At temperatures up to 333 K, the spectra were indicative of a bidentate, chelate complex which was static on the NMR chemical shift timescale. Table 4 lists the chemical shifts of the four aromatic singlets, the three pyridyl signals (H_F, H_H doublets, H_G triplet) and the four C-methyl signals and the 2 N–H signals. On warming, the expected pairs of signals exchanged. The clearest exchanges were between the pyridyl signals H_F and H_H and these were used for bandshape analysis. Five fittings were achieved in the temperature range 373–413 K and an activation energy was calculated (Table 5).

[ReBr(CO)$_3$(bbip)]

This was the least soluble of the complexes and $(CD_3)_2SO$ had to be chosen as solvent.

At room temperature the ^{1}H spectrum was rather complex and the signal assignments (Table 4) are somewhat tentative. However, signals due to the pyridyl hydrogens H_F, H_G and H_H were clearly identified. On warming the solution, the signals H_F and H_H broadened, coalescing around 383 K and then sharpening. Bandshape fittings were made at six temperatures in the range 323–373 K, and activation energy data calculated (Table 5).

Activation energies

The energy data for the Re–N bond fluxions (Table 5) show that magnitudes of $\Delta H^{\ddagger}$ are in the range 72–94 kJ mol^{-1} and magnitudes of $\Delta G^{\ddagger}$ (298.15 K) in the range 74–88 kJ mol^{-1}. $\Delta S^{\ddagger}$ values are small in most cases as expected for purely intramolecular rearrangements, with the exception of the value for the btmbip complex. The positive $\Delta S^{\ddagger}$ value implies a much more weakly bound transition state structure than for the other complexes. This may be a reasonable assumption in view of the high degree of methylation of the benzimidazolyl moiety. This $\Delta S^{\ddagger}$ value causes the trend in $\Delta G^{\ddagger}$ values for the fluxion to differ slightly from that of the $\Delta H^{\ddagger}$ values. It was therefore felt more meaningful to discuss relative activation energies in terms of $\Delta H^{\ddagger}$ data, where the ligand order is btmbip > bdmbip > bmbip > bbip. This implies that methyl substitution on the aromatic ring of the benzimidazole unit causes an increase in the activation energy for the fluxion as does substitution of -N-H

by -N-Me groups. The former effect is quite large ($\Delta\Delta H^{\ddagger} = 15-18$ kJ mol^{-1}) whereas the latter effect is rather smaller ($4-7$ kJ mol^{-1}).

The magnitudes of these 1,4-Re-N fluxion energies are similar to that of the 2,2′:6′,2″-terpyridine complex [ReBr(CO)$_3$(terpy)] ($\Delta H^{\ddagger} = 79.8$ kJ mol^{-1}) [3], but significantly greater than that of the bispyrazolylpyridyl complexes [ReBr(CO)$_3$(bppy)] (bppy = 2,6-bis(pyrazol-1-yl) pyridine, $\Delta H^{\ddagger} = 50.8$ kJ mol^{-1}) and [ReBr(CO)$_3$(tmbppy)] (tmbppy = 2,6-bis(3,5-dimethylpyrazol-1-yl)pyridine, $\Delta H^{\ddagger} = 68.5$ kJ mol^{-1}) [6]. It should be noted that in this pair of complexes introduction of methyl groups to the ligand again causes a significant increase in the energy barrier for the fluxion.

The activation energy ($\Delta G^{\ddagger}$) for the restricted rotation of the unbound 1′,5′,6′-trimethylbenzimidazole function is 56.9 kJ mol^{-1} which is similar in magnitude to that of the pendant 3,5-dimethylpyrazole ring in the complex [ReBr(CO)$_3$(dmpbipy)] [9], (Table 7). When there are no methyl groups on the 3- and 5-positions of the pyrazole ring, as in the corresponding pbipy and mpbipy complexes (Table 7), the rotation barrier falls considerably. Clearly the steric bulk of the rotating unit is the crucial factor in determining the rotation barrier. Also, it would appear that the greater the steric hindrance the greater the population imbalance of the solution rotamers (Table 7).

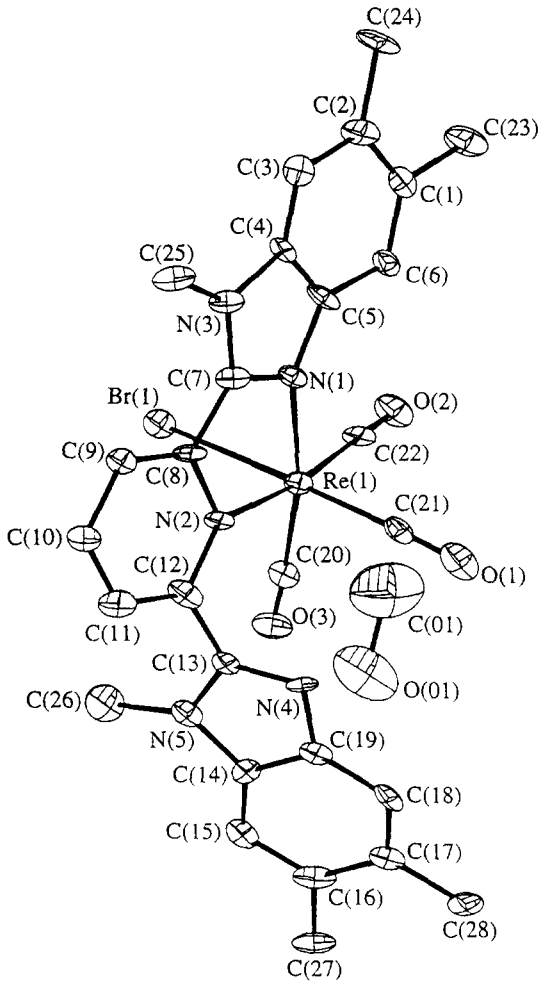

Fig. 4. Structure of [ReBr(CO)$_3$(btmbip)].CH$_3$OH showing the atom numbering scheme. Thermal ellipsoids are drawn at 50% probability level. The hydrogen atoms are omitted for clarity.

Crystal structure of [ReBr(CO)$_3$(btmbip)].CH$_3$OH

In order to confirm the bidentate chelate nature of the N_3 ligand in the complexes in the solid state, to compare the structure with an analogous terpy complex, [ReBr(CO)$_3$(terpy)] [3] and with the structure of the monoprotonated form of bmbip [21] the X-ray crystal structure of [ReBr(CO)$_3$(btmbip)] was determined and found to be a methanol solvate.

A view of the molecule indicating the numbering scheme adopted is shown in Fig. 4. This displays the expected *fac* octahedral coordination for Re and confirms the bidentate chelate nature of the btmbip ligand. As far as we are aware the only other example of a N_3 ligand with the 2,6-bis(benzimidazol-2-yl) pyridine structure acting as a bidentate chelate is in a complex of bmbip with copper [23]. Selected bond lengths and bond angles are given in Table 8.

The Re–N bond distances are unequal with Re–N(1) 2.152(7) and Re–N(2) 2.236(7) Å but they compare with corresponding distances of 2.143 and 2.209 Å in the analogous compound [ReBr(CO)$_3$(terpy)] [3]. Another similarity to the terpy complex is also evident in that the Re–N bond distance to the central N of the N_3 ligand is longer than the bond distance to the terminal N atom.

Inspection of the bond angles at Re shows there to be some distortion from a regular octahedral geometry. The main distortions arise from the small bite angle, N(1)–Re–N(2) 74.2(3)° of the nitrogen ligand, and also the angle C(20)–Re–N(2) of 100.9(4)°. These values are virtually identical to the corresponding values (74.3 and 100.6°) for *fac*-[ReBr(CO)$_3$(terpy)] [3].

The dihedral angles between the ring planes of the N_3 ligand are of interest. The pyridine ring and the coordinated benzimidazolyl unit are inclined to each other at an angle of 7.1(5)°. This compares with values of 30.5 and 45.3° for dihedral angles between adjacent rings in the monoprotonated free ligand bmbip [21], and 12° for the coordinated pyridines in [ReBr(CO)$_3$(terpy)] [3]. The pendant benzimidazolyl unit is rotated from the plane of the pyridine ring, as defined by the torsion angle N(2)-C(12)-C(13)-N(4) of 60.7(12)°. This group is also involved in short hydrogen bonding with the methanol solvate, as exemplified

Table 8. Selected bond lengths (Å) and angles (°) for $[ReBr(CO)_3(C_{25}H_{25}N_5)].CH_3OH$.

(Received 11 November 1997; accepted 17 February 1998)

Abstract—Tellurium tetrachloride and diallyl sulfide react to stereospecifically formed crystals of 1-thia-2-tellura-1(1-allyl-4-chloro)cyclopentane 2,2,2-trichloride. According to single-crystal X-ray determination the structure consists of the (R,R)-(S,S) racemate unit with a centre of symmetry. In the asymmetric units the Te^{IV}-atoms display distorted ψ octahedral coordination. Although the equatorial Te-S bond length is 2.763(1) Å, the Natural Bond Order (NBO) analysis reveals significant electronic interaction. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tellurium heterocycle; stereoselectivity; NBO; crystal structure.

INTRODUCTION

According to Migalina [1–3] compounds of the general structure **1** (Fig. 1) are formed by interaction of (TeO_2 + HCl) in diethyl ether with diallyl derivatives of the general structure [$(CH_2{=}CHCH_2)_2Z$, Z = NH,NCH_3,O,S]. Such compounds would be obvious candidates for couplings to e.g. functionalized pyrrole derivatives, such as **2** and maybe also piperidones **3**, if similar carbonyl insertions observed [4, 5] in the aromatic series could be extended to the aliphatic series. In this connection the reported conversion [6], induced by degassed Raney nickel of e.g. 2,6-diethoxy-3,5-dimethyl-1,4-oxaselenane **4** dichlorides [6, 7] to 3,4-dimethylfurane is of interest.

Attempts to reproduce the synthesis of (**1**, Z = NH,X = Cl) failed and experiments [8] with $(CH_2{=}CHCH_2)_2NAc$ and $TeCl_4$ gave the zwitterionic oxazoline **5** rather than a compound of type **1**.

1,5-Hexadiene and TeX_4 has been claimed to yield the symmetrical tellurophene derivative **6**. This reaction has been reinvestigated [8] and its formation has been confirmed [9]. In addition the C-C coupled products **7** and **8** are produced. Such formation of carbocycles are in line with the previous cyclizations [10–12] of 1,5-hexadiene induced by $Pb(OAc)_4$ and $Hg(OAc)_2$.

Migalina *et al* [1–3], also claimed the preparation of **1** (Z = S,X = Cl). However, attempts to reproduce these experiments gave compounds of type **9**. A related oxygen system, **10** has previously been studied by Detty [13, 14], whereas its sulfur isologue does not seem to have appeared in the literature. Ring systems with S-Te bonds are however rare although *e.g.* compound **11** has been prepared by Irgolic *et al* [15]. Other more or less related compounds [16] have been discussed in four recent reviews [17–20].

Compound **9** can be synthesised in a number of solvents (*e.g.*, benzene and chloroform), but the best yields were obtained in acetonitrile. The nature of the reagent depends on the solvent and evidently $TeCl_4$ exists in acetonitrile as a mononuclear species.

Attempts to synthesise a Se-analogue of **9** with $SeCl_4$ failed and elemental selenium fell out.

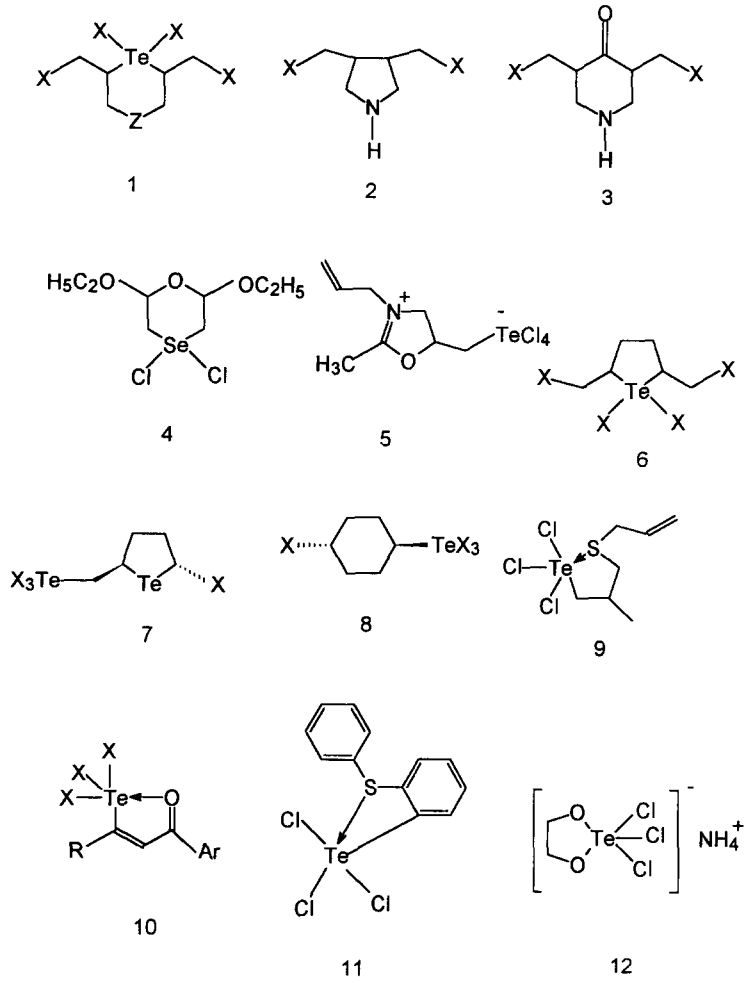

Fig. 1. The tellurium and some related compounds discussed in the present paper.

RESULTS AND DISCUSSION

The synthetic pathway

Unlike the reaction of $TeCl_4$ with diallyl ether, which gives the 1,4-oxatellurane derivative **1** (Z = O,X = Cl) stereoselectively with *cis*-configuration [20], the reaction with diallyl sulfide affords **9** as a racemic mixture of the (R,R) and (S,S) stereoisomers in the solid state (The Scheme). Neither the (R,S)-(S,R) racemate nor any mixed versions were formed. Accordingly, the reaction of $TeCl_4$ with C=C and S-centres takes place by a mechanism, which confers stereochemical control. A relevant question is, whether the crystal (R,R)-(S,S) racemate arises from a stereospecific reaction, or is a result of the crystallisation. Diallyl sulfide has two types of nucleophilic centres, the double bonds and the S-atom. Both paths, (a) and (b), are conceivable. Considering the fact, that the reaction of diallyl ether gives **1**, it is difficult to see, why the regiochemistry would be reversed, if path (a) were followed. It is therefore more likely that Te-S-interaction dominates the initiation of the reaction and the path (b) will dictate the regiochemical result. Then the new chiral centre at the S-atom would react stereospecifically in such a way that (S) would create (S)-configuration at C2 (Fig. 2) and (R) would create (R). Further coordination to give the solid state structure involves the racemate crystallisation and simultaneous expansion of the coordination sphere of the Te-atom. The stability of the chiral centre at the S-atom in solution is not obvious, since the Te-S bond can best be described as a coordinate bond (see *ab initio* calculations) and a decoordination-recoordination sequence is conceivable.

The molecular structure of the racemate of **9** is given in Fig. 2. with selected intermolecular distances. The crystal structure is shown in Fig. 3. The bond lengths and angles are given in Table 1 and contact distances in Table 2.

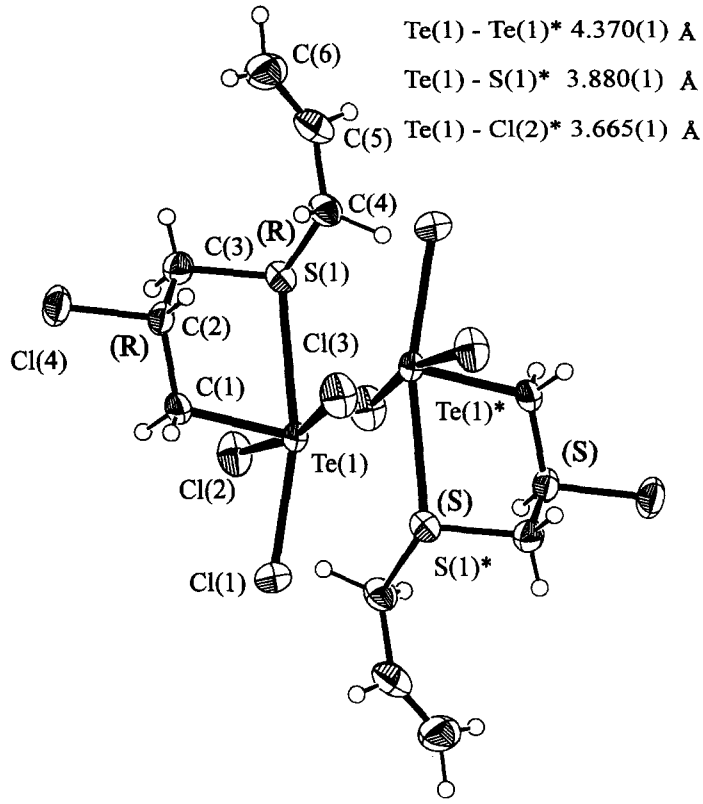

Fig. 2. ORTEP drawing of the racemate of 1-thia-2-tellura-1(1-allyl-4-chloro)cyclopentane 2,2,2-trichloride **9**. The thermal ellipsoids for the non-hydrogen atoms are drawn at 50% level of probability. (S) and (R) denote absolute configuration.

In the solid state the enantiomers of the racemate of **9** are related through a centre of symmetry. The racemic unit forms parallel sheets, which interact through Cl · · · Cl contacts. All Cl-atoms participate in two contacts.

Description of the structure **9**.

The title compound is a new example of tellurium(IV) forming a heterocycle with a C-Te-S bond system (Fig. 2). A previous structure determination of

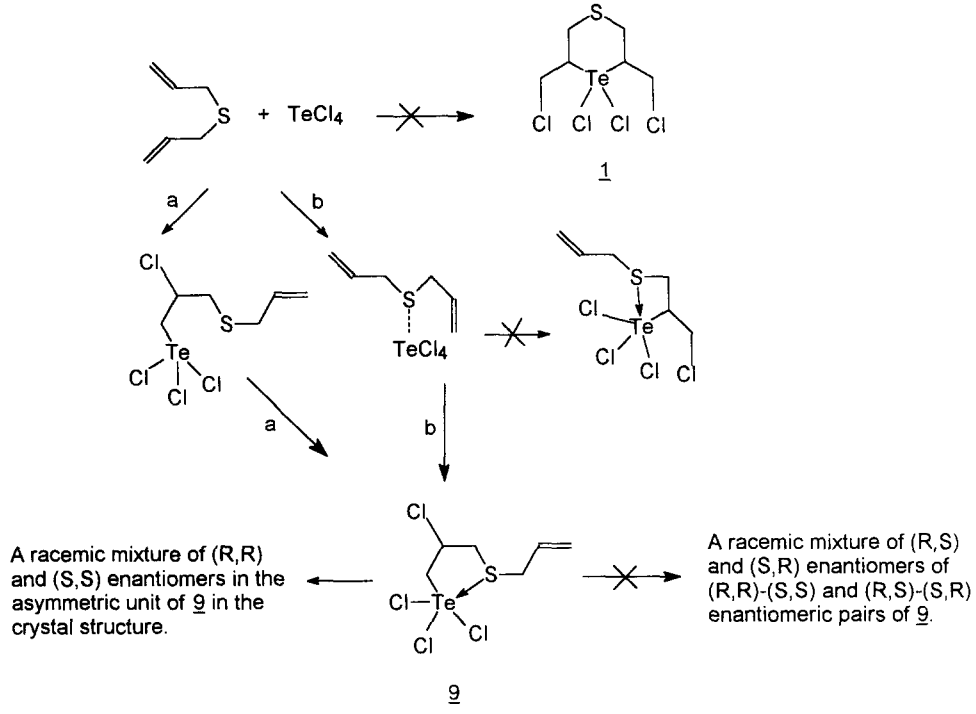
Cl(4)•••Cl(4)^{v}	3.778(1)	$-x+1,-y+2,-z+1$	intralayer



a related Te-compound **11** (Fig. 1) was reported by Irgolic *et al* [15]. The coordination sphere around Te(IV) is distorted ψ octahedron consisting of the above mentioned bonding system and three additional Te-Cl bonds in the equatorial position. The axial positions are occupied by the C(1)-atom and a lone pair of electrons. The average value of the three Te-Cl bonds, 2.477 Å, is shorter than the average value of 2.530 Å found in $[TeCl_6]^{2-}$ anion [22]. The Te-Cl bond lengths appear in the range of 2.34–2.60 with average value of 2.52(3) Å reported for 22 compounds [23]. The Te(1)-Cl(1) bond is shorter than the Te-Cl(2) or Te-Cl(3) bond. It is even shorter than the equivalent Te-Cl(1) bond in trichloro(ethane-1,2-diolato-O,O')tellurate(IV) **12** [2.722(2) Å] [24]. The Te(1)-S(1) bond length [2.763(1) Å] is significantly longer than the average value of 2.541 Å found in bromobis(dimethyldithiocarbamato-*S*,*S*')tellurium(IV) tetrabromo(dimethyldithiocarbamato-*S*,*S*') tellurate(IV)-dioxane(1/1) [25]. The Te(1)-S(1) distance is longer than the sum of the respective covalent radii [2.37 Å] [26]. However, it is shorter than the sum of the van der Waals radii [3.90 Å]. The length of the Te-C(1) bond 2.139(4) Å matches with the average value of 2.139 Å calculated from six Te-C bond containing molecules found from CSD [27].

The racemate of **9** forms layers running along *h*00 planes (Fig. 3). The Te···Cl(2)^{i} distance is significantly shorter than the sum of van der Waals radii [4.00 Å]. These interactions may explain the relatively long Te(1)-Cl(2) bond length of 2.555(1) Å.

Ab initio *calculations for* 9

To elucidate the bonding in **9**, NBO analyses were carried out. Separate calculations were carried out by STO-3G* and LANL1DZ basis sets to evaluate the contribution of the relativistic effect. The atomic coordinates for the racemic unit of **9** (Fig. 2) obtained from X-ray analysis were used as input data.

The results form the population analysis are given in Table 3. The central Te(1)-atom carries a positive charge. The value of 1.121 is less than found in trichloro(ethane-1,2-diolato-O,O')tellurate(IV) **12**, where the value of 1.368 was obtained when calculated at the RHF/STO-3G* level of theory [24]. All the atoms bonded to the Te(1)-atom have negative charges, except the S(1)-atom. The mutually opposite Cl(2)- and Cl(3)-atoms are more negative than the Cl(1)-atom. There seems to be a correlation between the Te-Cl bond lengths and the charge resting on a Cl-atom: the longer the Te-Cl bond is, the more negative charge there will be on a Cl-atom. As expected, the relativistic effect is affecting the Te(1)-atom and its coordination sphere. Especially the positive charge of the Te(1)-atom increases, while the atoms bonded to the Te(1)-atom have received electrons.

Table 3. Summary of Natural Population Analysis (NPA) for the Non-Hydrogen Atoms of 1-Thia-2-tellura-1(1-allyl-4-chloro)cyclopentane 2,2,2-Trichloride **9**.

Atom	Natural Charge	
	STO-3G*	LANL1DZ
Te(1)	1.12111	1.58874
S(1)	0.38445	0.16713
Cl(1)	−0.36436	−0.46503
Cl(2)	−0.51978	−0.62685
Cl(3)	−0.44994	−0.54467
Cl(4)	−0.16568	−0.12205
C(1)	−0.30081	−0.61826
C(2)	0.13503	−0.05490
C(3)	−0.24093	−0.37592
C(4)	−0.19567	−0.41255
C(5)	−0.01665	−0.15607
C(6)	−0.08053	−0.34298

The covalent bonds can be evaluated with the help of NBO analyses (Table S1, Supplementary Material). Although the usual way to interpret the hypervalency is to use the 3c-4e concept, no such bonds were found for the Te(1)-atom. Each Cl-atom has three lone pairs of electrons, the S(1)-atom has two and the central Te(1)-atom one. Although the NBO subprogram does not recognise a covalent Te(1)-S(1) bond, it appears that the lone pair LP2 of the S(1)-atom has 10.7% contribution from Te(1)-atom.

When the relativistic effect is taken into account, the bonding system undergoes a change. The lone pair LP2 of the S(1)-atom gains now 8.7% contribution from Te(1)-atom, and the contribution from C(1)-atom has diminished into 0.6%. Interestingly, there are also interactions across the enantiomeric units. While the lone pair LP2 of the S(1)-atom gains contribution from the Te(1)-atom, the LP1 gets 0.126% of the electron pair from the Te(1)-atom from the neighbouring unit.

The Te(1)-S(1) and Te(1)-Cl(2) bonding can be evaluated with the help of second order perturbation theory analysis of Fock matrix in NBO basis (Table S2, Supplementary Material). When the relativistic effect is not taken into account, the S(1)-atom donates an electron pair partly to the Te(1)-atom and partly to Te(1)-Cl(1) and Te(1)-C(1) bonds. Moreover, the electrons are pushed into the antibonding orbitals of the Te(1)-Cl(1) and Te-C(1) bond. It is relevant to notice that the Te-Cl(2) bond is the longest one among the Te(1)-Cl bonds. This fact may be connected to the participation of the Cl(2)-atom in the shortest intermolecular contacts.

On the basis of the NBO analysis, the Te(1)-S(1) bond can be characterised as a coordinative bond, although it has also features from covalent and charge transfer bonding. When the relativistic effect is included in the calculations, both Te(1)-S(1) and Te(1)-Cl(2) interactions are mostly of charge-transfer type.

EXPERIMENTAL

Spectra

IR spectra were recorded on a Perkin Elmer 1600 FTIR Spectrometer. The NMR spectra were recorded by Bruker AM 400 Instrument.

Synthesis

Tellurium tetrachloride (5.38 g, 2 mmol) was added to a stirred solution of diallyl sulfide (2.58 ml, 2 mmol) in acetonitrile (30 ml) at 35°C. A clear solution was quickly obtained from which soon a white solid was formed. After 2 h at 35°C the mixture was cooled and the solid collected and recrystallised from acetonitrile, yield 6.02 g (75%), mp. 140°C (dec.). IR (KBr): 3018, 2979, 2955, 2941, 1635, 1422, 1404, 1394, 1267, 1235, 1200, 1193, 1168, 1004, 1092, 990, 967, 948, 842, 801, 767, 734, 708 cm^{-1}. ^1H NMR (δ) (CD_3CN): 3.30 (t, 1 H), 3.72(m, 3 H), 3.85 (t, 1 H), 4.45 (m, 1 H), 4.87 (m, 1 H), 5.39 (d, 1 H), 5.50 (d, 1 H) and 5.88 (m, 1 H); ^{13}C NMR (δ) (CD_3CN): 38.54 (CH_2), 40.27 (CH_2), 55.03 (CH), 67.33 (CH_2), 123.14 (CH_2) and 130.3 (CH).

X-ray study

Crystal Data for **9**. $C_6H_{10}Cl_4STe$, $M=383.61$, triclinic, $a=8.2594(11)$, $b=8.8432(11)$, $c=10.469(2)$ Å, $\alpha=96.126(12)$, $\beta=107.610(12)$, $\gamma=117.788(11)°$, $V=616.3(2)$ $Å^3$ (by least-squares refinement of diffractometer angles for 25 independent well-centred reflections, $\lambda=0.71069$ Å), space group $P\bar{1}$ no. 2, $Z=2$, $D_c=2.07$ g cm^{-3}, Crystal dimensions $0.14\times0.21\times0.44$ mm, $\mu=3.47$ mm^{-1}.

Data Collection and Processing. Nicolet P3 diffractometer, ω scan mode, variable scan speed 2.0-20.0°min^{-1}, graphite monochromated Mo-$K\alpha$ radiation, 3604 unique reflections measured ($5°\leq2\Theta\leq60°$), empirical absorption correction based on ι-scans, giving 3241 independent reflections with $F>6\sigma(F_o)$. No decay, but Lorentz and polarization corrections were made.

Structure Analysis and Refinement. Direct methods [28] followed by difference Fourier techniques. The structure was refined by full-matrix least squares techniques with all non-hydrogen atoms having anisotropic and the hydrogen atoms isotropic temperature factors. The function minimised was $\Sigma w(|F_o|-|F_c|)^2$ with $w=1/\sigma^2_F$. The highest peaks in the final difference Fourier maps were near to the Te- and Cl-atoms. Final R and R' ($1/\sigma^2$ weights) values are 0.027 and

0.030, respectively. The neutral atom scattering factors and correction factors for anomalous scattering were those included in the program package. The calculations were carried out with XTAL software [29]. The neutral atom scattering factors were those included in the program. Anisotropic thermal parameters and listings for the observed and calculated structure factors are available as Supplementary Material from the authors on request.

Ab initio *calculations*

The calculations were carried out at the HF/STO-3G* and HF/LANL1DZ levels of theory by the GAUSSIAN92 program package [30] installed on a CRAY-XMP supercomputer. The electronic charges and the bonding properties were analyzed with the NBO program [31], which is a subprogram in GAUSSIAN92. The atomic coordinates for the racemic unit shown in Fig. 2 were used as input data.

A new coordination mode for the tartrato ligand. Synthesis of vanadium(V) oxo peroxo tartrato complexes and the X-ray crystal structure of $K_2[\{VO(O_2)(L\text{-}tartH_2)\}_2(\mu\text{-}H_2O)].5H_2O$

(Received 24 October 1997; accepted 17 February 1998)

Abstract—Vanadium(V) oxo peroxo tartrato complexes $M_2[\{VO(O_2)(L\text{-}tartH_2)\}_2(\mu\text{-}H_2O)].5H_2O$ ($M=K^+$, NH_4^+; $tart^{4-}=C_4O_6H_2^{4-}$) have been prepared from aqueous-ethanolic medium and characterized by elemental analysis and IR spectroscopy. The X-ray crystal structure of $K_2[\{VO(O_2)(L\text{-}tartH_2)\}_2(\mu\text{-}H_2O)].5H_2O$, as the first crystal structure of a vanadium(V) tartrato complex has been determined. The dinuclear anion exhibits two pentagonal bipyramidal polyhedra about vanadium atoms which are joined to each other by sharing two oxygen atoms of hydroxyl groups and oxygen atom from water molecule. The tartrate group is bonded to the vanadium atom in a bidentate way via oxygen atoms of neighbouring carboxylic and hydroxyl groups. The coordinated hydroxyl oxygen atom is bonded also to the second vanadium atom, but in a monodentate way. This type of bonding of tartrate group was not observed so far. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: peroxo tartrato complexes of vanadium; crystal structure.

Since discovery of the insulin mimetic effect of vanadium(V) compounds [1], the structure and reactivity of vanadium(V) complexes with biologically important ligands have been intensively studied [2]. Peroxo complexes constitute a new group of powerful insulin mimics [3–5]. On the other hand vanadium(V) peroxo complexes are probably formed as intermediates in oxidation reactions catalyzed by vanadium bromoperoxidase, an enzyme from marine algae [6]. Anions of α-hydroxycarboxylic acids, which are involved in many biochemical processes, represent an interesting class of biogenic ligands. Vanadium (V) monoperoxo complexes with citrate [7] and malate [8] have been prepared and structurally characterized. Both compounds contain dinuclear complex anion with a double bridge formed by oxygen atoms of hydroxyl groups (Fig. 1).

The tartrato ligand, as another example of this class

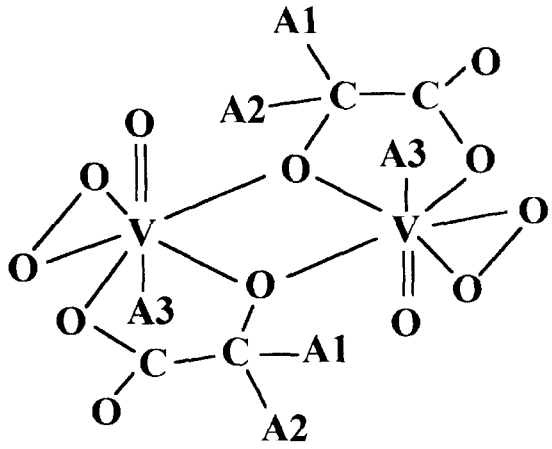

Fig. 1. Schematic structure of α-hydroxycarboxylato monoperoxo complexes of vanadium(V).Malato: A1=H, A2=CH_2–COOH, A3=O (carboxylato, from A_2)Citrato: A1=CH_2–COO(H), A2=CH_2–COO(H), A3=O (carboxylato, from A_2)

*Author to whom correspondence should be addressed.

of ligands, has several alternatives, considering its coordination to central atom. The tartrate anion can act as mono-, bi-, or tridentate ligand with different combinations of donor atoms. Moreover, both hydroxyl and carboxylic groups or the ligand as the whole, can make various bridges between metal atoms, thus forming dimeric or polymeric structures. A number of dimeric tartrato complexes of vanadium(IV) has been structurally characterized e.g. [9, 10], and the synthesis of vanadium(V) complexes e.g. $K_3[HV_2O_5(tart)].H_2O$ and $Na_4[V_4O_8(tart)_2].6H_2O$ [11–14] has been described. The structure reported here represents the first crystal structure of a vanadium(V) tartrato complex. In the dinuclear anion a novel type of tartrato group ligation has been observed.

EXPERIMENTAL

Preparation of complexes

Chemicals. KVO_3 was prepared by thermal decomposition of crystallohydrate obtained by reaction of V_2O_5 with KOH at pH 8. All other chemicals were of analytical grade and used as supplied (Loba Chemie, Lachema).

$$K_2[\{VO(O_2)(L-H_2tart)\}_2\mu-H_2O].5H_2O$$

A solution of KVO_3 (0.69 g, 5 mmol) in 20 cm^3 water was mixed with a solution of L-tartaric acid (0.75 g, 5 mmol) in 5 cm^3 water. After cooling (0°C) of the resulting solution H_2O_2 (30%, 1 cm^3) and ethanol (5 cm^3, dropwise) were added under constant stirring. Light red crystals were isolated after 6 hours standing at 5°C. Found: C 14.67, H 2.71, O_2^{2-} 9.71, V 15.10. Calc. for $C_8H_{20}K_2O_{24}V_2$: C 14.12, H 2.96, O_2^{2-} 9.41, V 14.98%.

The deuterated complex was obtained using D_2O, D_2O_2, and C_2H_5OD instead of H_2O, H_2O_2, and C_2H_5OH.

$$(NH_4)_2[\{VO(O_2)(L-H_2tart)\}_2\mu-H_2O].5H_2O$$

NH_4VO_3 (0.575 g, 5 mmol) and L-tartaric acid (0.75 g, 5 mmol) were dissolved in 10 cm^3 water. After cooling of the solution (0°C) H_2O_2 (30%, 2.5 cm^3) and ethanol (10 cm^3) were added under continuous stirring. The red complex was isolated after 6 hours standing at 5°C. Found: C 15.00, H 4.18, N 4.19, O_2^{2-} 10.09, V 16.04. Calc. for $C_8H_{28}N_2O_{24}V_2$: C 15.06, H 4.42, N 4.39, O_2^{2-} 10.03, V 15.96%.

Both compounds are soluble in water. Solid complexes are stable at −15°C for at least 20 days. The

decomposition at room temperature is accompanied by succesive colour changes from red through brown to black.

Caution: In some cases an explosive decomposition of the ammonium complex occured at room temperature. It is recommended to handle only small amounts of it (up to 20 mg).

Physical measurements and analyses

Infrared spectra were measured on a Nicolet 750 Magna FTIR Spectrometer with the samples as KBr pellets or nujol mulls.

Vanadium(V) was reduced to vanadium(IV) using ascorbic acid. An access of standard EDTA solution was added to the obtained solution and the vanadium content was determined by a back titration with $ZnCl_2$.

Peroxidic oxygen was determined by titration with $KMnO_4$.

Carbon, hydrogen and nitrogen were estimated on a Carlo Erba 1106 C H N analyzer.

X-ray structure determination

Low-temperature X-ray measurements were made on a KUMA KM4 diffractometer with graphite monochromated Mo-Kα radiation using the ω-2θ scan technique. Cell parameters and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 64 reflections in the range $5.82^\circ < \theta < 12.05^\circ$. No significant decay of the intensity of the three standard reflections recorded after every 90 reflections was observed. Data were not corrected for absorption effects. 2319 unique reflections were obtained, of which 2075 with $I > 2\sigma_I$ were classified as observed. The additional crystal data and refinement results are given in Table 1. The structure was solved by a combination of Patterson and difference Fourier methods, and refined by a full-matrix least-squares procedure (SHELLXL-93) [15] on $|F^2|$. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were obtained from a difference Fourier map and were refined isotropically. Not all crystal water hydrogen atoms were found. The final refinement was carried out with a weighting scheme of $w = 1/[\sigma^2(F^2_o) + (0.0975P)^2 + 30000P]$, where $p = (F^2_o + 2F^2_c)/3$ *and* 2310 *reflections. Refinement converged at* $R_1(F) = 0.0433$ and $R_{w2}(F^2) = 0.1240$ for observed reflections and 384 refined parameters. The largest positive and negative peaks in the difference map were 1.023 and $-0.814\,e \cdot Å^{-3}$, respectively. Additional material which comprises the final coordinates of atoms, anisotropic displacement parameters and a list of observed and calculated structure factors is available from the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The red complexes, $M_2[\{VO(O_2)\ (L\text{-}H_2tart)\}_2\ \mu\text{-}H_2O].\ 5\ H_2O$ (M = K, NH_4), were obtained by crystallization from MVO_3 — L-tartaric acid — H_2O_2 — H_2O — ethanol systems. At room temperature, the complexes decompose both in solid state and aqueous solution. The release of peroxidic oxygen is followed by reduction of vanadium (V), which manifests itself by colour change from red, through brown and green to black.

In the infrared spectra (Table 2), the bands corresponding to the OH stretching vibrations of protonated carboxylic and alcoholic groups can be easily assigned, but not mutually distinguished. The bands at 1736 and 1716 cm^{-1} unambiguously prove the presence of protonated and evidently uncoordinated carboxylic group. The bands at 1662, 1636, 1375, and 1359 cm^{-1} can be assigned to stretching vibrations of deprotonated and coordinated carboxylic group. The COO^- group is coordinated in a monodentate way. This is substantiated by the Δ value ($\Delta = \nu_{as}(COO^-) - \nu_s(COO^-) = 248\ cm^{-1}$), which is typical for this mode of bonding [16]. Deprotonation of alcoholic groups is not easily ascertainable from the IR spectra. Nevertheless the stoichiometry of the complex requires the charge of the ligand to be 2−, therefore the simultaneous presence of a protonated and a deprotonated alcoholic groups in the ligand can be assumed. The bands of the $VO(O_2)$ group are in the range characteristic for monoperoxo complexes of vanadium [17, 18].

The conclusions based on the IR studies were confirmed by X-ray structure analysis. The crystals of

$K_2[\{VO(O_2)(L\text{-}H_2tart)\}_2\ \mu\text{-}H_2O].\ 5\ H_2O$ contain eight formula units in the orthorhombic cell. The K^+ cations, $[\{VO(O_2)(L\text{-}H_2tart)\}_2\ \mu\text{-}H_2O]^{2-}$ anions and molecules of crystal water are held together by electrostatic forces and hydrogen bounds. The bond lengths and angles which are in the expected ranges are in Tables 3 and 4.

In the dinuclear anion (Fig. 2), vanadium atoms are bridged by O7 and O7* hydroxyl oxygens from both L-tartrato ligands and by O4 oxygen atom of a water molecule. The coordination about each vanadium atom is that of distorted pentagonal bipyramid which was found, with exception of $[VO(O_2)(glygly)]^-$ [19] in all thirty one structures of monoperoxo complexes of vanadium [20]. The equatorial positions are occupied by peroxo groups (O1, O2 and O1*, O2*), both bridging hydroxyl oxygens (O7, O7*) and oxygen atoms from the monodentate carboxylic groups (O5, O5*). The axial positions are taken by double bonded oxygen atoms O3 and O3*, and the bridging oxygen atom from the water molecule.

The significant differencies between the structure of peroxo- L-tartrato complex presented here and the related structures of malato and citrato complexes (Fig. 1) are summarized in Table 5.

There are fifty structures of tartrato complexes (except complexes with substituted tartrato group, e.g. esters) registered in the Cambridge Structural Database (1996). A monodentate tartrato ligand was found in three structures, bidentate in fourty one, and tridentate only in one structure. In the remaining five structures, tartrato groups with more than one type of bonding (e.g. mono- and bidentate) were found. The coordination mode of the tartrato ligand in complexes with a bidentate tartrato group can be classified, according to the type and number of donor atoms, into five groups (Table 6). As can be seen from this table, the type of tartrate group ligation in $K_2[\{VO(O_2)\ (L\text{-}H_2tart)\}_2\ \mu\text{-}H_2O].\ 5\ H_2O$ differs from the other ones, especially from that found in the related structure of $(N(CH_3)_4)_2\ [MoO_2(L\text{-}H_2tart)_2].\ C_2H_5OH.\ 1.5H_2O$ [21] (type C), thus representing a new type of ligation of the tartrato ligand (type E).

(Received 23 June 1997; accepted 12 February 1998)

Abstract—The ligand 10-methyl-10-amino-1,4,8,12-tetra-azacyclopentadecane has been prepared by the reduction of (10-methyl-10-nitro-1,4,8,12-tetra-azacyclopentadecane)copper(II) nitrate with Zn/HCl. The protonation constants of the ligand at 25°C and $I = 0.1$ mol dm^{-3} are $\log K_{11} = 10.79$, $\log K_{12} = 9.37$, $\log K_{13} = 5.21$, $\log K_{14} = 2.78$ and $\log K_{15} = < 2.0$. The formation constants for the equilibria

$$Cu^{2+} + L + H^{+} \rightleftarrows CuLH^{3+}; \quad \log \beta_{CuLH}$$

$$Cu^{2+} + L \rightleftarrows CuL^{2+}; \quad \log \beta_{CuL}$$

are $\log \beta_{CuLH} = 25.57 \pm 0.03$ and $\log \beta_{CuL} = 21.63 \pm 0.04$. The pK for the ionisation of the protonated 10-amino group in the copper(II) complex, $CuLH^{3+} \rightleftarrows CuL^{2+} + H^{+}$ is 3.94 ± 0.05. The protonated complex is four-coordinate and becomes five-coordinate as the protonated amino group ionises. A new band appears in the visible spectrum of the copper complex at *ca.* 800 nm as the five-coordinate complex is formed. Spectrophotometric titrations using the 800 nm band give a $pK = 3.94 \pm 0.05$. The kinetics of the acid-catalysed dissociation of the copper complex have been studied. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper complex; macrocycle; formation constants; dissociation kinetics.

In a recent paper [1], one of us discussed some aspects of the chemistry of the copper(II) complex of 10-methyl-10-nitro-1,4,8,12-tetra-azacyclopentadecane (1). Reduction of this complex with Zn/HCl to give the amino-substituted macrocycle (2 = L) has recently been reported by Bayada and coworkers [2]. This paper also describes the crystal structure of $H_5L.3Cl^{-}.2ClO^{-}_4.2H_2O$. It has recently been found [3] that a variety of bis-cyclam macrocycles, of the type shown in (3) and (4) are very active against HIV-1 and HIV-2 and have considerable chemotherapeutic potential. Some of these compounds are currently undergoing clinical trials in the United States. The macrocycle (2) can form interesting bis-macrocycles by a [2+1] Schiff base condensation with a suitable dialdehyde 'spacer'. The imine linkages can then be readily reduced with sodium borohydride to give derivatives such as (5) which may have pharmaceutical applications.

The present paper discusses the synthesis of (2) and its coordination chemistry with copper(II).

EXPERIMENTAL

Synthesis

(10-*methyl*-10-*nitro*-1,4,8,12-*tetra-azacyclopentadecane*) *copper(II) nitrate*. The tetra-amine 1,10-diamino-4,7-diazadodecane (3,2,3-tet) (35 g, 0.20 mol) was added to copper(II) nitrate dihydrate (48 g, 0.20 mol) in methanol (1500 cm^3). The resulting dark blue solution was warmed with stirring and triethylamine (22 g, 0.22 mol), nitroethane (37 g, 0.49 mol) and formaldehyde (100 cm^3, 40% aqueous solution, 1.44 mol)

*Author to whom correspondence should be addressed.

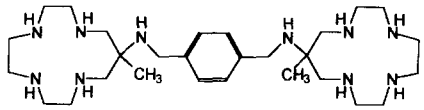
(3) (4)



(5)

added. After heating at 55°C for 30 min. the solution was allowed to cool at room temperature overnight. The beautiful blue-purple crystals obtained were filtered off, washed with methanol then diethyl ether and dried in *vacuo*. Yield 64 g (70%). Found: C, 31.2; H, 6.4; N, 21.3. Calc. for $C_{12}H_{27}CuN_7O_8$: C, 31.3; H, 5.9; N, 21.3%.

10-*methyl*-10-*amino*-1,4,8,12-*tetra-azacyclopentadecane*.5*HCl*. The copper(II) complex prepared above (30 g, 0.065 mol) in distilled water (600 cm^3), were simultaneously added, dropwise, to Zn dust (75 g, 1.15 mol) over a period of 2.5 hr. The solution was heated and stirred during the addition, then filtered and the colourless filtrate diluted to 5 litres. The solution was then added to a cation exchange column in the acid form. The column employed had the dimensions 25 × 7 cm. The zinc(II) was removed from the column by the addition of 1 M HCl (about 1.5 litres), then the macrocycle was eluted by the addition of 5 M HCl (about 2.5 litres are required). Evaporation of the HCl solution gave the pentahydrochloride which was washed with ethanol then diethyl ether. The hydrochloride was recrystallised by dissolving in water, adding HCl and precipitating by the addition of ethanol. The hydrochloride was obtained as a very fine white solid which is quite difficult to filter. The hydrochloride was thoroughly dried in *vacuo* over silica gel. Yield 23 g (84%).

Potentiometric measurements

The titrant was added by a microprocessor controlled (VIT90 video titrator) piston burette (ABU91 Radiometer autoburette). Measurements of pH were made with an Orion Ross combination electrode (Model 8102). The titration data were passed from the VIT90 video titrator to a 386 PC using the program TITRAFILE. Conversion of the data to SUPERQUAD format was made using the Fortran program VITOQUAD. The data was processed using the SUPERQUAD program [4] to give the equilibrium constants.

Solutions of copper(II) nitrate were standardised against standard 0.1 mol dm^{-3} EDTA (Aldrich) in a complexometric titration monitored by a copper(II) selective electrode (Orion 9429). The voltage output from the selective electrode was measured relative to SCE (Orion 900200 reference electrode). Standard sodium hydroxide was prepared by dilution of concentrated sodium hydroxide ampoules (Rhone–Poulenc). The sodium hydroxide solution was standardised by titration against accurately weighed samples of potassium hydrogen phthalate. The standard solution was protected against atmospheric CO_2 by calcium oxide (carbosorb, BDH). Stock solutions of hydrochloric and nitric acid were standardised against standard sodium hydroxide. All aqueous solutions were prepared with boiled out distilled water (kept under a stream of argon during cooling). During the titration, the titration vessel was partially sealed and protected against ingress of atmospheric CO_2 by blowing nitrogen gas over the solution surface. The temperature of the solution was maintained at 25°C using a water jacketed cell and Heto circulator. All measurements were carried out at $I = 0.1$ mol dm^{-3} adjusted with KNO_3 (Aldrich 99.99%). Experimental parameters for the potentiometric measurements are summarised in Table 1.

Spectrophotometric titrations

Approximately the same conditions were used as for the potentiometric titrations. An acidic mixture of

the metal ion (1.9×10^{-3} mol dm^{-3}) and the ligand (2.0×10^{-3} mol dm^{-3}) was titrated with base and at suitable intervals during the titration the UVis spectrum was determined over the wavelength range 1100–350 nm. The measurements were made over the pH range 2.0 to 11.0 at $I = 0.1$ mol dm^{-3} (KNO_3). Absorption spectra were obtained using a Perkin Elmer Lambda 14P instrument controlled by an IBM compatible PC. The cell compartment was thermostated at 25 C.

Kinetics

The kinetics of dissociation of the copper(II) complex were monitored spectrophotometrically at 570 nm which is λ_{max} for the complex. Plots of $\ln(A_t - A_\infty)$ versus time were linear for several half lives and values of k_{obs} (the observed first order rate constant at constant hydrogen ion concentration) were determined from the slope of these plots. The measurements were made at 25 C using nitric acid solutions

RESULTS AND DISCUSSION

Reduction of the nitro group of (1) with Zn/HCl takes place readily and, under the conditions employed, demetalation of the complex occurs to give the ligand pentahydrochloride (2), which was isolated by ion exchange methods.

Potentiometry

The titration curve, Fig. 1, for the protonated ligand shows a buffer region corresponding to the loss of two protons, then a fairly sharp inflexion point after the addition of two equivalents of base. The pK of only one of these acidic protons could be determined, the pK of the other proton being less than 2. A second buffer region corresponds to the titration of a single proton and a third buffer region indicates the removal of two strongly basic protons. The log β values are listed in Table 2. The β values for the protonation of 10-methyl-10-amino-1,4,8,12-tetra-azacyclopentadecane correspond to the following stepwise protonation constants

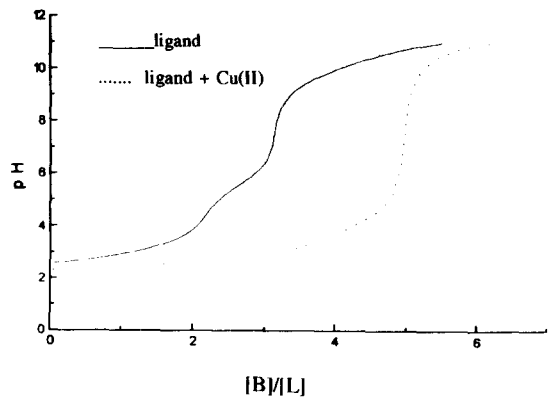

Fig. 1. Titration curves for the ligand pentahydrochloride and for the ligand pentahydrochloride in the presence of one equivalent of copper(II).

Table 2. Protonation constants for L and stability constants for copper(II) complexes.

Protonation constants (ligand = H_4L, errors as σ)		
$\log\beta_{HL}$	$H^+ + L = HL^+$	10.79 ± 0.01
$\log\beta_{H2L}$	$2H^+ + L = H_2L^{2+}$	20.16 ± 0.02
$\log\beta_{H3L}$	$3H^+ + L = H_3L^{3+}$	25.37 ± 0.02
$\log\beta_{H4L}$	$4H^+ + L = H_4L^{4+}$	28.15 ± 0.02
Copper(II) stability constants		
$\log\beta_{CuLH}$	$Cu^{2+} + L + H^+ = CuLH^{3+}$	25.57 ± 0.03
$\log\beta_{CuL}$	$Cu^{2+} + L = CuL^{2+}$	21.63 ± 0.04

$$H^+ + L \rightleftarrows HL^+; \quad \log K_{11} = 10.79 \pm 0.01$$
$$H^+ + HL^+ \rightleftarrows H_2L^{2+}; \quad \log K_{12} = 9.37 \pm 0.02$$
$$H^+ + H_2L^{2+} \rightleftarrows H_3L^{3+}; \quad \log K_{13} = 5.21 \pm 0.03$$
$$H^+ + H_3L^{3+} \rightleftarrows H_4L^{4+}; \quad \log K_{14} = 2.78 \pm 0.03$$
$$H^+ + H_4L^{4+} \rightleftarrows H_5L^{5+}; \quad \log K_{15} < 2$$

Electrostatic repulsion between the protonated amino groups can account for the low values of $\log K_{14}$ and $\log K_{15}$. The high values of $\log K_{11}$ and $\log K_{12}$ may be indicative of intramolecular hydrogen bonding between the protonated and deprotonated amino groups.

Copper complexation

Potentiometric titrations made at a 1:1 metal to ligand ratio were used to calculate the stability constants of the copper(II) complexes using the SUPERQUAD program [4]. A plot of pH *versus* [B]/[L] is shown in Fig. 1, and Fig. 2 shows the speciation curve for the copper(II) complexes formed in the system Cu-L. Hydroxy complexes are not formed as there is a sharp inflexion point after addition of five equivalents of base. This result indicates that the deprotonation and the coordination of the pendant primary amino group occurs. At approximately pH 3–5, the titration curve indicates the formation of a protonated complex $CuLH^{3+}$ which is expected to be four-coordinate with a protonated 10-amino group. For the equilibrium

$$CuLH^{3+} \rightleftarrows CuL^{2+} + H^+; \log K_1$$

$$\log K_1 = (\log \beta_{CuLH} - \log \beta_{CuL}) = 3.94 \pm 0.05$$

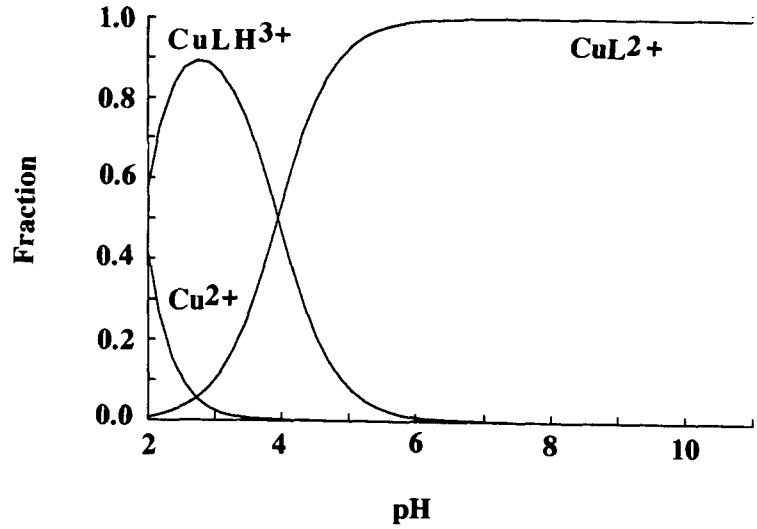

Fig. 2. Speciation curve for the copper(II) complexes. The ligand and copper(II) concentrations are both 1.5×10^{-3} mol dm^{-3}.

Spectrophotometric titrations

Five-coordinate copper(II) complexes normally display two bands in their *d-d* spectrum. Copper(II) complexes of penta-aza macrocycles have the main band near 600 nm and there is an additional band of lower intensity around 800 nm. Exactly analogous behaviour is observed with the copper(II) complex of 10-methyl-10-amino-1,4,8,12-tetra-azacyclopentadecane. At low pH the complex displays a single *d-d* band at 590 nm, Fig. 3. On raising the pH, a new band appears in the spectrum at *ca.* 800 nm. Detailed analysis of the pH-dependence of the intensity of the 800 nm band indicates a $pK = 3.95 \pm 0.05$, fully consistent with the potentiometric measurements.

Kinetics of acid dissociation

A brief investigation of the acid dissociation kinetics of the copper(II) complex was carried out using nitric acid solutions in the concentration range 1.0 to

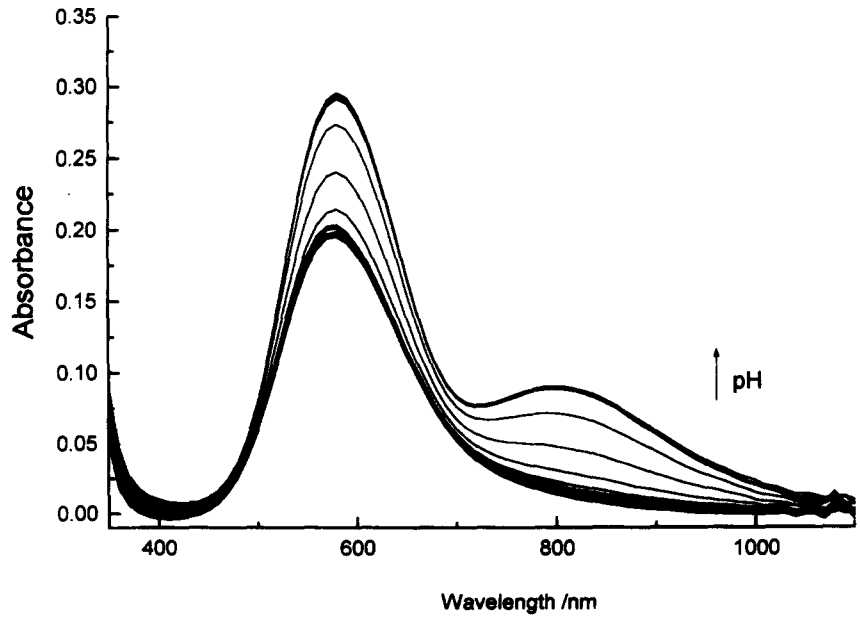

Fig. 3. pH-dependence of the spectrum of $[CuLH]^{3+}$ showing the formation of the five coordinate 'arm on' complex. The measurements cover the pH range 2.0 to 11.0.

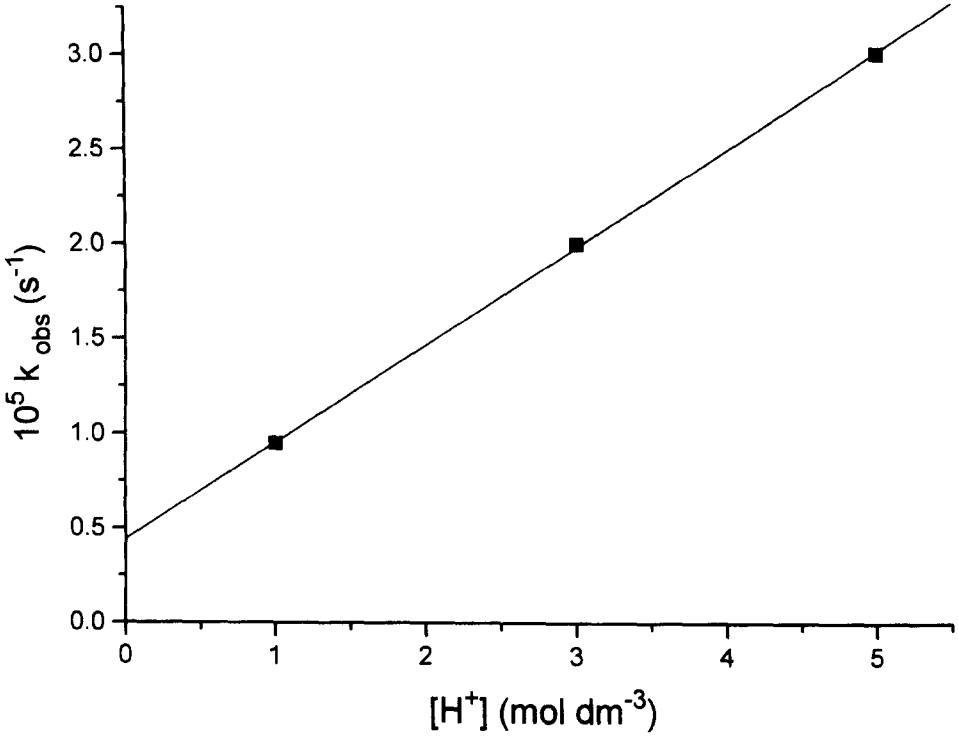

Fig. 4. Plot of k_{obs} *versus* the hydrogen ion concentration for the acid-catalysed dissociation of $[CuLH]^{3+}$ in nitric acid solution at 25°C.

5.0 mol dm^{-3} at 25°C. The plot of k_{obs} (the observed first order rate constant at constant hydrogen ion concentration) *versus* the hydrogen ion concentration is linear, with a small positive intercept, so that $k_{obs} = k_o + k_H[H^+]$, Fig. 4. The rate constant, k_o, relates to the spontaneous dissociation of the complex in water and $k_o = 4.5 \times 10^{-6}\ s^{-1}$ at 25°C. The slope of the plot gives $k_H = 5.1 \times 10^{-6}\ dm^3\ mol^{-1}\ s^{-1}$ at 25°C. The reaction displays kinetic behaviour similar to that observed in the dissociation of the copper(II) complex of [13]aneN$_4$ [5] in a nitric acid solution, where $k_H = 8.0 \times 10^{-4}\ dm^3\ mol^{-1}\ s^{-1}$ at 25°C and I = 5.0 mol dm^{-3}. The dissociation kinetics of the copper(II) complex of [15]aneN$_4$ have previously been studied in some detail [5, 6]. The reaction displays saturation kinetics at high acidities (> 2 mol dm^{-3} H^+) and the hydrolysis can be represented by the equation [5]

$$\text{rate} = k_1[H^+][\text{Complex}]/(1 + k_2[H^+])$$

where $k_1 = 1.4 \times 10^{-2}\ dm^3\ mol^{-1}\ s^{-1}$, $k_2 = 9.91 \times 10^{-1}\ dm^3\ mol^{-1}$ at 25°C and I = 5.0 mol dm^{-3} (HNO_3 + $NaNO_3$). The limiting rate is given by the ratio $k_1/k_2 = 1.4 \times 10^{-3}\ s^{-1}$. The reaction is considerably faster than observed with the present complex and this is probably associated with the difficulty of protonating the species $[CuLH]^{3+}$, which is formed below pH 4.

(Received 21 November 1997; revised 4 February 1998)

Abstract—Molecular dimensions suggest that three crystal forms of the nitric acid adduct of triphenylarsine oxide have the bridging proton more closely associated with the As=O group than with the nitrate moiety, whereas the corresponding phosphorus compound has the proton more closely associated with the nitrate moiety. In all cases, strong hydrogen bonds are formed between the two moieties resulting in X–O bonds (where X=As or P) intermediate in character between single and double bonds. © 1998 Elsevier Science Ltd. Keywords: X-ray structure; triphenylarsine oxide; triphenylphosphine oxide; nitric acid adduct; hydrogen bond.

A series of compounds containing group 15 elements was reported by Tranter [1] as having the constitution $[(C_6H_5)_3XNO_3]_2O$, where X=P, As, Sb. It was suggested that X might have a trigonal bipyramidal coordination with equatorial phenyl groups, apical nitrate groups and the oxygen atom bridging the two halves of the molecule. However, a preliminary crystal structure determination [2], by one of us, of the arsenic compound (hereafter ASNIT) showed it to be the nitric acid adduct of triphenylarsine oxide, (Fig. 1, X=As). Accurate molecular dimensions were not obtained in that determination, so it was decided to seek more accurate nitrate dimensions by replacing As by the lighter P atom. Although X-ray data were obtained for the phosphorus compound (PNIT), judged to be isomorphous from the similarity of cell dimensions, the structure would not refine if coordinates from the As compound were used as a starting point. It was decided, therefore, to collect more accurate X-ray data for the As compound. However, the next few attempts to prepare a new sample resulted in two further crystalline forms of the nitric acid adduct of triphenylarsine oxide (PASNIT1 and PASNIT2) and a material later identified as diphenyl-dihydroxyarsine nitrate. Eventually, a preparation yielded a good sample of ASNIT and an accurate redetermination of the structure was carried out. This paper reports the crystal structures of the three forms of the triphenylarsineoxide adduct and also that of PNIT. The X-ray data for diphenyl-dihydroxyarsine nitrate were too poor to warrant publication of its structural data, though the the structure was reliable enough to establish the molecular formula.

EXPERIMENTAL

The materials were prepared according to the method described by Tranter [1, 3]. All the X-ray data were obtained using a Hilger and Watts computer-controlled, four-circle diffractometer, MoKα radiation ($\lambda=0.71069$ Å) and a $\omega/2\theta$ scan, up to $\theta=25°$. Further data collection and crystal data are in Table 1. The structures of all the materials except PNIT were solved by the heavy-atom Patterson method and all were refined using the CRYSTALS suite of programs

[4]. In view of the refinement problem mentioned above, PNIT was solved by direct methods using SHELX76 [5]. In the later stages of refinement, H atoms were included in calculated positions with fixed isotropic thermal parameters and were not refined, except in the case of PNIT. In that material, H atoms were located in difference maps and their positions and isotropic thermal parameters were refined. Generally, refinement was of the full-matrix type but block diagonal refinement was used for PASNIT1. Weigh-

ting schemes were introduced in the final few cycles of each refinement.

The atomic coordinates, thermal parameters and details of the molecular geometries have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

A summary of the most significant molecular dimensions in all four compounds is shown in Table 2, a line drawing representation is given in Fig. 1, the molecular structures of PNIT and ASNIT are shown in Fig. 2(a) and Fig. 2(b), respectively, and the crystal structure of ASNIT is shown in Fig. 3. In the case of PASNIT1, there are two crystallographically independent molecules (PASNIT1a and PASNIT1b) in the asymmetric unit, providing two sets of dimensions. Since all four dimensions for the three As compounds are so similar, they must represent the same molecule in slightly different environments. They are therefore averaged in the last column of Table 2. Even allowing for an expected increase of about 0.15 Å between equivalent P–O and As–O bonds [6], it is clear that PNIT has significantly different dimensions. These are consistent with the proton in the X–O..H..ONO_2 hydrogen bond being more closely associated with As–O in the As compounds and with N–O in PNIT. In both situations, however, a strong hydrogen bond is formed, so the X–O bonds are all intermediate in character between single and double bonds, and the $(H)ONO_2$ aduct is intermediate between HNO_3 and NO_3^-. Thus, the N–O bond adjacent to the hydrogen bond in PNIT is 1.302(4) Å in length (about 0.10 Å longer than the other two N–O bonds. This compares with lengths 1.24 to 1.26 Å in the arsenic adducts, which are only 0.03 to 0.04 Å longer than the other N–O bonds. (In nitric acid vapour [7], the N–O(H) bond length is 1.406(10) Å and the other two bonds have lengths 1.211(10) and 1.199(10) Å.)

Confirmation of the hydrogen-bonding proton's position from difference Fourier maps was unreliable but a position approximately equidistant between the two moieties was indicated in PNIT, compared with a position about 0.03 Å nearer As–O than N–O in ASNIT. Support from the As–O and P–O lengths for the two different degrees of proton association was also rather weak in view of the intermediate nature of these bonds in the compounds studied. However, an examination of lengths of hydrogen-bonded X–O and X–OH bonds in the Cambridge Crystallographic Database [8, 9] suggests that the cross-over point from X–O..HO to X–OH..O occurs approximately at the X–O distances 1.52-1.53 Å for P and 1.67-1.68 Å for As. The P–O distance in PNIT is 1.499(2) Å, on the P=O side of the cross-over point, and the As–O distances in ASNIT, PASNIT1, and PASNIT2 range from 1.690(5) Å to 1.710(3) Å, all on the As–OH side.

The relationship between the $(C_6H_5)_3XO$ and NO_3 moieties in PNIT and ASNIT is illustrated in Fig. 2; the arrangements in the other structures involving As–O are not appreciably different from ASNIT. In each structure, one nitrate O atom [O(2) in Fig. 2(a) and Fig. 2(b)] approaches a phenyl ring in the same hydrogen-bonded pair more closely than do the other oxygens. However, whereas in PNIT the hydrogen

[a] PASNIT1a and 1b indicate the two crystallographically independent molecules in the the asymmetric unit of PASNIT1.

[b] Mean of all dimensions of this type except for PNIT; The number following each mean dimension is the spread of values, not the standard deviation.

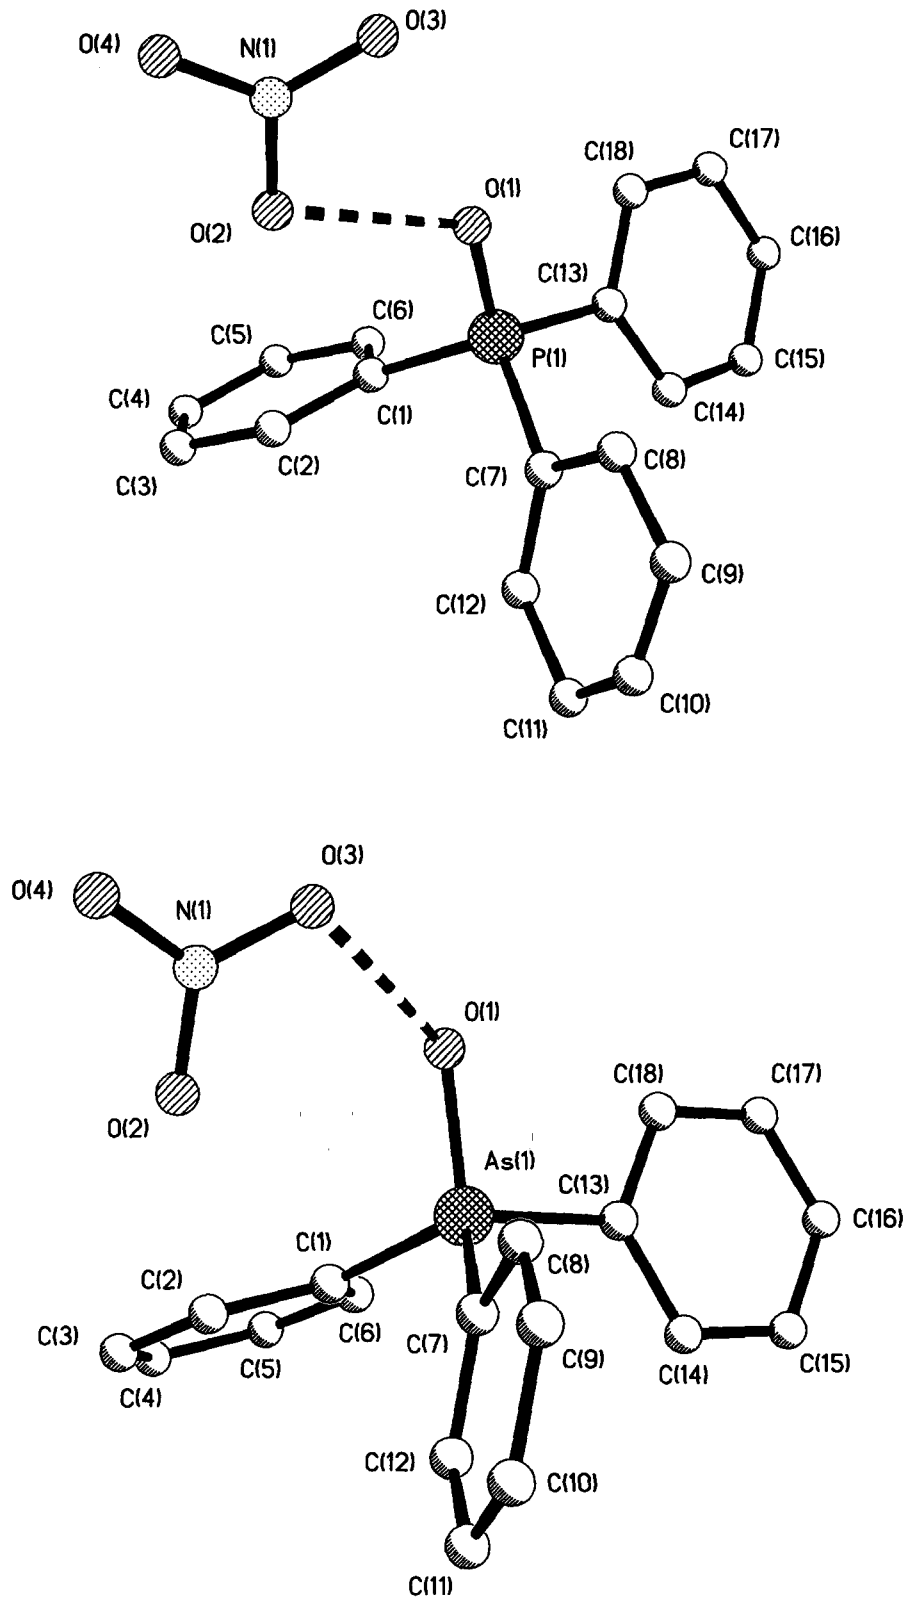

Fig. 2. Molecular structures of (a) PNIT and (b) ASNIT. The broken lines represent hydrogen bonds

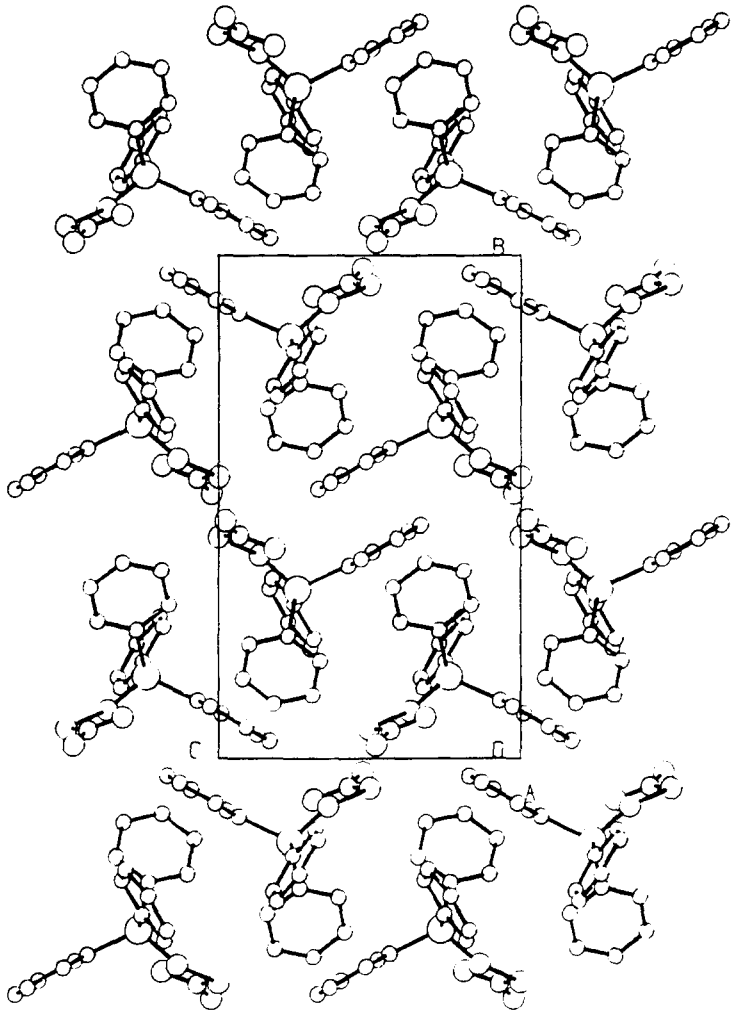

Fig. 3. The crystal structure of ASNIT (a) projected along the a-axis, (b) projected along the c-axis.

bond is formed to this same O atom, in the other structures a hydrogen bond of similar length is formed to a more distant O [O(3) in Fig. 2(b)]. This difference between the P and As structures, and the much greater divergence from planarity of As and the two nearest O atoms of the nitrate group, round the O of the As–O group in all three As structures, compared with the corresponding arrangement round P in PNIT, again indicates a difference in proton location. This difference indicates a greater basicity of As=O compared with P=O in these compounds, consistent with the increasing basicity of Group 15 oxides on descending the group in the periodic table.

The crystal structures may all be thought of in terms of approximately close packed columns of molecules, of van der Waals diameter between 8 and 9 Å. The repeating unit of each column consists of a pair of molecules and varies in length from 11.6 Å in ASNIT to 12.6 Å in PASNIT1. In PNIT and ASNIT, the two molecules comprising each pair are related by a **c**-glide plane, whereas in PASNIT1 and PASNIT2 the two are related by the screw axis parallel to **b**. Figure 3(b), which is a projection of the ASNIT structure along the **c**-axis, shows the view along the columns for this structure and indicates how the columns are arranged in approximately close-packed layers parallel to (010). Figure 3(a), the projection of ASNIT along the **a**-axis, shows how the molecules are arranged within the columns. PNIT is almost identical and PASNIT1 has similar columns extended along the **b**-axis in layers parallel to (001). In PASNIT2, similar columns are again extended along the **b**-axis but the layers are parallel to $(\bar{1}01)$.

Abstract—Nickel(II) bis-complexes of bis(pyrid-2-ylmethyl)amine (bpma) and bis(benzimidazol-2-ylmethyl)amine (bbma) have been isolated. The complexes have been characterised using IR, UV-VIS and ^{1}H NMR spectral techniques. The pink complex $[Ni(bpma)_2](ClO_4)_2$ crystallises in the orthorhombic space group *Fdd*2, with $a=22.12(2)$, $b=28.087(2)$, $c=8.857(3)$ Å, $\alpha=\beta=\gamma=90^\circ$ and $Z=8$. The nickel(II) atom has a slightly distorted octahedral structure in which the ligands are *cis-facially* coordinated. The $M\text{-}N_{py}$ bond length in $[M(bpma)_2]^{2+}$ [M = Mn(II), Fe(II), Ni(II), Cu(II), Zn(II)] complexes decrease and then increase with increase in d-orbital population. The ligand field parameters of the new complexes are compared with those of other complexes with NiN_6 chromophore. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel(II); synthesis; spectra; crystal structure; NiN_6 chromophore; cis-facial coordination.

Linear tridentate triaza ligands have attracted considerable interest [1] because of their ability to coordinate facially. The factors favouring facial or meridional coordination of these ligands have been discussed [1b]. When the terminal coordination sites of these ligands are primary amines with strong σ-donor ability, meridional coordination (a) is preferred in bis complexes. Thus the complexes $[Cu(dien)_2]^{2+}$ [dien = diethylenetriamine] [2], $[Ni(dien)_2]^{2+}$ and $[Ni(dptn)_2]^{2+}$ [dptn = dipropylenetriamine] [3] have been isolated as *mer* isomers. On the other hand, when the two terminal arms are pyridyl groups as in bis(pyrid-2-ylmethyl)amine [1c] (bpma) or bulky benzimidazolyl groups as in bis(benzimidazol-2-ylmethyl)amine [1b] (bbma), facial coordination is facilitated. Thus, the bpma ligand complexes $[M(bpma)_2]^{2+}$ exhibit *trans*-facial coordination [*meso* isomer (b)] when M = Cu(II) [1c], Zn(II)) [1a] and *cis*-facial coordination [*rac* isomer (c)] when M = Mn(II) [1a], Fe(II) [1e] Cd(II) [1a], Zn(II) [1a]. Further, the branched chain tridentate ligand di-2-pyridylmethanamine (dipa) designed to impose facial coordination in $[M(dipa)_2]^{2+}$ complexes display *rac* isomerism when M = Fe(II), Co(II) but *meso* isomerism when M = Cu(II), Ni(II) [4]. In continuing our work with facially coordinating ligands [1b], [1c], [1d]], we report in this paper the isolation and successful X-ray crystal structure determination of $[Ni(bpma)_2]^{2+}$ complex which crystallizes in *rac* rather than *meso* isomeric form. Though this is expected on the basis of the known *rac* structures of $[M(bpma)_2]^{2+}$ [M = Mn(II), Fe(II), Zn(II)], it is unexpected in view of the *meso* structures of $[M(dipa)_2]^{2+}$ [M = Cu(II), Ni(II)] and $[Cu(bpma)_2]^{2+}$ complexes.

EXPERIMENTAL

Materials

Bis(pyrid-2-ylmethyl)amine was a gift from Reilly Industries, USA. Bis(benzimidazol-2-ylmethyl)amine was prepared as described elsewhere [5]. $Ni(ClO_4)_2.6H_2O$ and organic reagents were used as received. Solvents were purified by using established procedures [6].

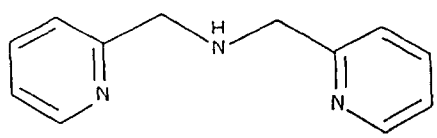
Physical measurements

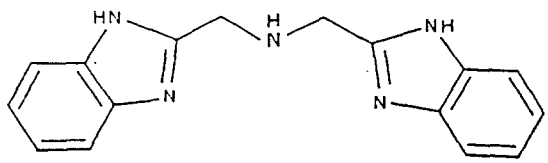
Elemental analyses were performed at CDRI, Lucknow, India. Electronic spectra were measured on a Hitachi U-3410 double beam UV/Vis-NIR spectrophotometer. Infrared spectra were obtained using a Bruker IFS 66 FT-IR instrument. The ^{1}H NMR spectra were obtained on a JEOL GSX-400 spectrometer. Conductivity measurements were done with an Elico Type CM-82 T conductivity bridge (Hyderabad, India) with solute concentrations of *ca* 1.0×10^{-3} mol dm^{-3} at 25°C. The nickel content of the complexes were analysed gravimetrically as its dimethylglyoximate.

Preparation of complexes

$[Ni(bpma)_2](ClO_4)_2$ (**1**). A methanolic solution (20 mL) of $Ni(ClO_4)_2.6H_2O$ (0.36 g, 1.0 mmol) was added to a solution of bis(pyrid-2-ylmethyl)amine (0.4 g, 2.0 mmol) in methanol (10 mL) with constant stirring (5 min). The pink coloured precipitate obtained was filtered off, washed with small amounts of cold methanol and then dried under vacuum (yield 0.60 g, 90%). An acetonitrile solution of the complex on slow evaporation yielded pink needle shaped crystals suitable for X-ray diffraction studies. Anal. Calcd for $C_{24}H_{26}N_6Cl_2O_8Ni$: Ni, 8.95; C, 43.94; H, 3.99; N, 12.81. Found: Ni, 8.90; C, 44.00; H, 4.10; N, 13.00.



bpma



bbma

$[Ni(bbma)_2](ClO_4)_2$ (**2**). This complex was synthesized employing the procedure described above for **1** but by using bis(benzimidazol-2-ylmethyl)amine instead of bpma (yield: 0.7 g, 85%). The crude product was dissolved in acetonitrile and kept for slow evaporation. The pink coloured crystals obtained were not suitable for X-ray diffraction. Anal. Calcd for $C_{32}H_{30}N_{10}Cl_2O_8Ni$: Ni, 7.23; C, 47.32; H, 3.72; N, 17.24. Found: Ni, 7.30; C, 46.98; H, 3.50; N, 17.45.

Structure analysis

A summary of crystal data and experimental parameters for $[Ni(bpma)_2]^{2+}$ are given in Table 1. Diffraction intensities were collected at 293 K on an Enraf-Nonius CAD4 diffractometer employing graphite monochromated Cu-Kα radiation. Unit cell parameters were determined from 25 reflections ($5 < 2\theta < 65$) and refined by least-squares method. The intensities of representative reflections were measured after every 100 reflections. No significant intensity decay was observed. Intensity data were corrected for Lorentz and polarization effects and analytical absorption corrections were applied. The structure was solved by the heavy atom method and refined on F^2 by full-matrix least-squares procedures. The SHELXL-93 of programs was used for structure analysis and refinement.

RESULTS AND DISCUSSION

On the basis of the results of elemental analysis both the complexes **1** and **2** may be formulated as $[ML_2](ClO_4)_2$ where L = bpma or bbma. This is supported by the IR spectra of the complexes, which show an unsplit band around 1150 cm^{-1} characteristic [7] of uncoordinated ClO_4^-. Electrical conductivity data show that both the complexes behave as 1:2 elec-

Crystal structure of $[Ni(bpma)_2](ClO_4)_2$

The ORTEP view of the complex cation $[Ni(bpma)_2]^{2+}$, also showing the atomic numbering scheme is depicted in Fig. 1. The principal bond lengths and angles are given in Table 3. The nickel(II) is surrounded by two ligands, each coordinating in a tridentate manner. The nitrogen atom of the secondary amino group and two pyridyl nitrogens are involved in coordination. Both the ligands are facially coordinated with the two coordinating amino groups being *cis* to each other. Hence the nickel ion is on a site of C_2 symmetry, the two-fold axis relating one ligand to the other. So the isomer isolated is the *cis-facial* isomer represented in (c). This is interesting because the nonlinear ligand dipa coordinates but *trans*-facially in $[Ni(dipa)_2]^{2+}$ eventhough such a coordination is less stable than the *cis*-facial coordination, as predicted by molecular mechanics calculations [4].

The Ni–N_{py} bond lengths, Ni–N(1) [2.093(4) Å] and Ni–N(3) [2.073(4) Å] are shorter than the Ni–N_{amine} bond length Ni–N(2) of 2.106(4) Å, obviously due to

Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, z$

the difference in the state of hybridisation of the amine and pyridine nitrogens. Each of the ligands form two five-membered chelate rings and thus pinches together the three Ni–N bonds leading to intrachelate N–Ni–N bond angles $\sim 10°$ less than the 90° ideal. Thus the octahedral environment around Ni(II) is distorted significantly. When the $M-N_{py}$ bond lengths in $[M(bpma)_2]^{2+}$ [M = Mn(II), Fe(II), Ni(II), Cu(II), Zn(II) (rac)] complexes are plotted as a function of the d-orbital population (Fig. 2) they decrease with the addition of electrons into the t_{2g} orbitals and then increase, as anticipated [8]. On the other hand, the $Cu-N_{amine}$ distance in *meso* $[Cu(bpma)_2]^{2+}$ is higher than the $Zn-N_{amine}$ distance in *meso*-$[Zn(bpma)_2]^{2+}$, which may be due to Jahn-Teller effect and/or hydrogen bonding interaction of coordinated N–H group [1c] in the former. However, it is interesting that the $Zn-N_{amine}$ distance in *meso* isomer is less than that in *rac* isomer.

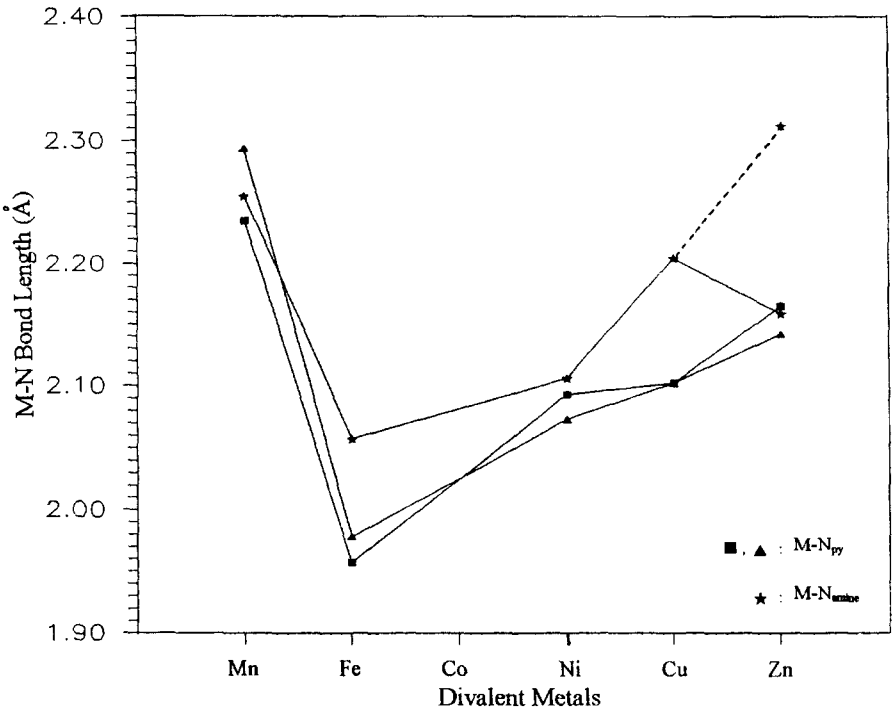

Fig. 2. Plot of M–N bond length versus divalent metals.

The perchlorate anions are apparently ordered, the Cl–O bonds of 1.42(5) Å and associated O–Cl–O angles being normal [109.9(3)°]. This confirms the IR spectral observations that the anion is not involved in coordination.

Electronic absorption spectra

The electronic spectra of both **1** and **2** consist of two principal bands (Fig. 3). In **1** a shoulder occurs on the low-energy side of the lower energy band, whereas in **2** it occurs on the high energy side. Consistency in their assignment [9] and fitment into the equations for the electronic energy levels is achieved by assigning the less intense shoulders to the first spin-forbidden transition $^3A_{2g} \rightarrow {}^1E_g(D)$, and the main bands to the first two spin-allowed transitions $^3A_{2g} \rightarrow {}^3T_{2g}$ (ν_1) and $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ (ν_2) [9]. The third spin-allowed band $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ is predicted to be in the range 29,300–30,540 cm^{-1} (Table 4), but is obviously obscured by the intense ligand bands. The value of the ligand field parameter *Dq* is slightly higher for **1** than for **2**; this illustrates the importance of the strongly π-back bonding pyridine donors in **1** over the strongly σ-donating [10] but sterically demanding bzim nitrogens in **2**. This is consistent with the higher value of the covalency parameter β (Table 5) for the py complex **1**, indicating that the nickel t_{2g} electrons are significantly delocalized over the molecular orbitals of the complex more in **1** than in **2** [11]. It is interesting to note that the $[Ni(dipa)_2]^{2+}$ complex with the same number of pyridine nitrogen donors as for **1** exhibits the same amount of covalency and that the $[Ni(bbp)_2]^{2+}$ [bbp = 2,6-bis(benzimidazol-2-yl)pyridine] [16] complex shows a higher covalency than the bbma complex. The complexes with no pyridine nitrogen as in $[Ni(NH_3)_6]^{2+}$ and $[Ni(dien)_2]^{2+}$ show decreased metal-ligand covalency as expected.

^1H NMR spectra

The ^1H NMR spectroscopy was performed in order to show that the solid state structure of **1** is preserved in solution and to assess the solution structure of its analogue **2**, the crystal structure of which could not be determined for lack of availability of good crystals. Figure 4 shows the ^1H NMR spectrum of **1**, and the chemical shifts for the two complexes are collected in Table 6 along with our proposed assignments. These assignments are based on comparisons with the spectra of Ni(II) complexes [12] of analogous thioether-benzimidazole ligands and Fe(III)-tris(2-pyridylmethyl)amine [13] complex and their relative intensities. The spectral features of **1** and **2** lie in the range 13–50 ppm down field with reference to tetramethylsilane (TMS). The peaks between 40–50 ppm in **1** may be assigned to the pyridine ring protons [H(3) + H(5) and H(6)], with the broad and maximum contact-shifted 50 ppm peak being due to H(6) protons located closest to the nickel(II) center. The broadest peak at 24.9 ppm is assigned to the N–H proton of coordinated secondary amino group. The sharp split

resonance at 13.6 ppm is assigned to the CH_2 proton of the ligand backbone. Further, the splitting (doubling) of the CH_2 proton signal is characteristic of complexes having a C_2 axis of symmetry [14] evident in the X-ray structure. However, no doubling is experienced by the py ring proton resonances probably because all of them experience an equivalent ligand field environment in solution.

47.5		C(6)–H	6.5–7.4	6	C(5)–H
					C(6)–H
					C(7)–H

* Relative intensity

The complex **2** displays the most contact-shifted doublet signal (49.5, 51.8 ppm, Fig. 5) which is assigned to C(4)-H proton of bzim ring, lying closest to Ni(II). The sharpest peaks in the range 6.5–7.4 ppm correspond to other bzim ring protons lying furthest away from Ni(II). The broadest signal located around 34.1 ppm may be assigned to the N-H proton of the coordinated secondary amino group, as in **1**. The similarly broadened resonance around 17.3 ppm is assigned to bzim N-H protons. As for **1** the CH_2 proton (29.1 ppm) signal is split suggesting that the bbma complex also exists as a *rac* isomer in solution.* This is in contrast to the *meso* isomerism shown by $[Cu(bbma)_2](BF_4)_2$ complex [3]. The dipolar broadened isotropically contact-shifted resonances observed for both **1** and **2** in the range 6.5–51.8 ppm are typical [12, 14] of high spin nickel(II). Further, the sign of the shifts is indicative of dominant σ-spin delocalisation mechanism.

CONCLUSION

The ligand bis(pyrid-2-ylmethyl)amine is *cis*-facially coordinated in the Ni(II) bis-complex both in

* The X-ray crystal structure of this complex has been reported [25] after the submission of this manuscript and is consistent with the structure predicted here in solution.

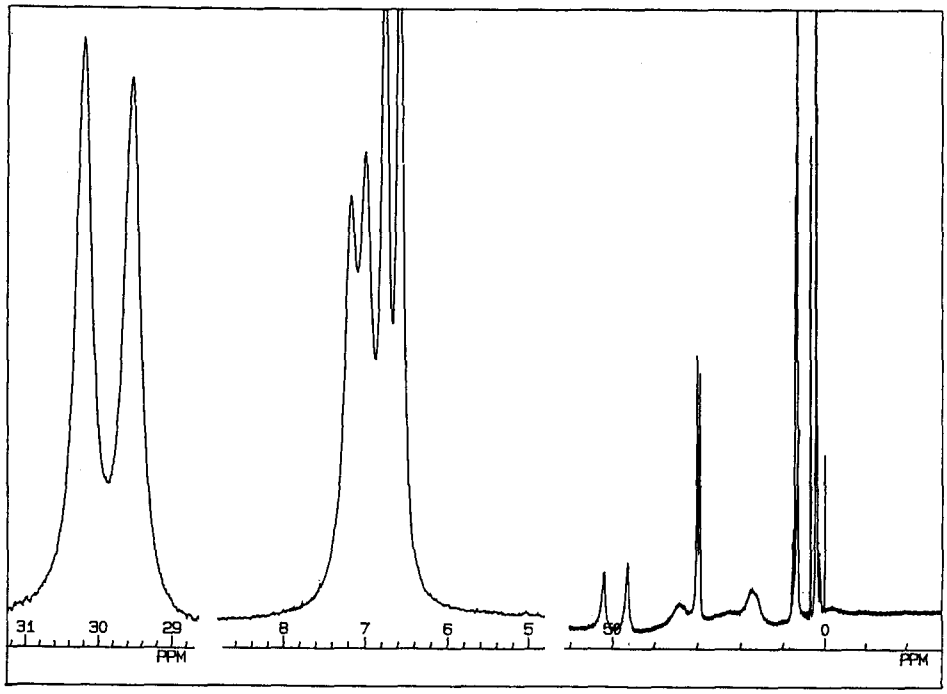

Fig. 5. ^{1}H NMR spectrum of **2** in CD_3CN.

the solid state and in solution. The benzimidazole analogue of this ligand also possesses a similar coordination behaviour in solution.

Abstract—New single-source precursor to tantalum nitride thin films, $(Bu^tN)Ta(NEt_2)_3$, and related complexes, $(RN)Ta(NEt_2)_3$ (R = Pr^i and Pr^n), were prepared by reacting corresponding $(RN)TaCl_3py_2$ complexes (R = Bu^t, Pr^i and Pr^n) with $LiNEt_2$ in hydrocarbon solvents. The structure of $(Bu^tN)TaCl_3py_2$ was determined by X-ray crystallography. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: organoimide complexes; tantalum complexes; CVD precursors.

Imido ligands, =NR, can stabilize early transition metals in high-oxidation states by metal-nitrogen π-bonding [1]. There are many interesting reactions involving these complexes. For example, use of these complexes in homogeneous catalysis, such as olefin metathesis, has been explored [2]. Recently, imido complexes have been employed as precursors to metal nitride and carbonitride thin films by chemical vapor deposition (CVD) [3–6]. For example, cubic phase tantalum nitride thin films can be grown from an ethylimido complex of tantalum, $(EtN)Ta(NEt_2)_3$ [3]. The metal-nitrogen multiple bond of this molecule is speculated to play a major role for the preservation of nitrogen atoms into the solids. However, $(\eta^2\text{-}EtN{=}CHMe)Ta(NEt_2)_3$, a precursor of $(EtN)Ta(NEt_2)_3$, is always in presence with $(EtN)Ta(NEt_2)_3$ [7]. Due to their similar physical properties, complete separation of one from the other is difficult. This makes reaction pathway elucidation complex. The use of other similar organoimido tantalum complexes, such as $(Bu^tN)Ta(NMe_2)_3$, has been considered [8]. The yield of $(Bu^tN)Ta(NMe_2)_3$, however, is low in our hands. Here in we report the systematic syntheses and characterization of $(RN)TaCl_3py_2$ (**1a**, R = Bu^t; **1b**, R = Pr^i; **1c**, R = Pr^n; py = pyridine). These complexes can be converted into $(RN)Ta(NEt_2)_3$ (**2a**, R = Bu^t; **2b**, R = Pr^i; **2c**, R = Pr^n), all of which are volatile liquids at room temperature. These properties make them good candidates for CVD applications; for example, **2a** has been employed successfully as a single-source precursor to grow tantalum nitride thin films by CVD for electronic device applications [9–11].

RESULTS AND DISCUSSION

The air- and moisture-sensitive organoimido complexes $(RN)TaCl_3py_2$ were conveniently prepared in good yields by reacting $TaCl_5$ with the corresponding amines $R(Me_3Si)NH$ and py in hydrocarbon solvents (Scheme 1). The synthetic procedure employed here parallels the methods used to prepare some other organoimido complexes of Ta, for example $(Me_3SiN)TaCl_3L_2$ and $[TaCl(\mu\text{-}Cl)(NBu^t)(NHBu^t)(NH_2Bu^t)]_2$ [12, 13].

Single crystals of **1a** were grown from a toluene solution at −15°C. An ORTEP of **1a**, from an X-ray diffraction study, is shown in Fig. 1. Bond distances and bond angles are listed in Table 1. **1a** has a distorted octahedral geometry. The distance between Ta

Table 1. Selected bond distances and bond angles of **1a**

Bond Distance (Å)		Bond Angle (°)	
Ta-Cl(1)	2.368(2)	Cl(1)-Ta-Cl(2)	92.96(7)
Ta-Cl(2)	2.406(2)	Cl(1)-Ta-Cl(3)	93.77(7)
Ta-Cl(3)	2.382(2)	Cl(1)-Ta-N(1)	99.3(2)
Ta-N(l)	1.745(5)	Cl(l)-Ta-N(2)	168.8(1)
Ta-N(2)	2.273(5)	Cl(1)-Ta-N(3)	86.4(1)
Ta-N(3)	2.452(5)	Cl(2)-Ta-N(3)	160.84(7)
N(1)-C(1)	1.475(1)	Cl(2)-Ta-N(1)	99.6(2)
		Cl(2)-Ta-N(2)	84.6(1)
		Cl(2)-Ta-N(3)	81.5(1)
		Cl(3)-Ta-N(1)	97.0(2)
		Cl(3)-Ta-N(2)	85.4(1)
		Cl(3)-Ta-N(3)	81.1(1)
		N(1)-Ta-N(2)	91.9(2)
		N(1)-Ta-N(3)	174.1(2)
		N(2)-Ta-N(3)	82.4(2)
		Ta-N(1)-C(1)	175.0(5)

and N(1) is short, 1.745(5) Å while the Ta-N(1)-C(1) angle is almost linear, 175.0(5)°. This closely resembles (PhN)TaCl$_3$THF(PEt$_3$), which has a Ta-N distance of 1.765(5) Å and a Ta-N-C angle of 173.3(4)° [14]. The Ta-N(3) distance, 2.452(5) Å, is significantly longer than the Ta-N(2) distance, 2.273(5) Å, reflecting the strong trans influence of the imido ligand. The structure of **1a** derived from solution NMR spectra, which show two sets of non-equivalent py signals, is consistent with the diffraction results. Since **1b** and **1c** showed very similar NMR spectra in the py region, they are thought to be isostructural with **1a**.

The complexes (RN)TaCl$_3$py$_2$ react with LiNEt$_2$ to generate (RN)Ta(NEt$_2$) in good yield (Scheme 1). The three complexes are air- and moisture-sensitive liquids. In a mass spectrometer, they all showed M^+ signals corresponding to the m/z values for the $(RN)Ta(NEt_2)_3^+$ ions. NMR data show resonance signals which can be assigned to the alkyl groups on the imdo and the amido ligands. Based on the data, **2** are proposed to have structures resembling those of tris(dimethylamido)(tertbutylimido)tantalum(V) and tris(dimethylamido)(2,6-diisopropylphenylimido) niobium(V) [8, 15]. Being volatile liquids at 60°C under vacuum is a significant advantage for **2** to be considered as CVD precursors. **2a** has been employed successfully as a single-source precursor to deposit good quality tantalum nitride thin films for electronic device applications [9–11]. Investigations are underway to study the potential applications of **2b** and **2c** as the CVD precursors to TaN thin films.

EXPERIMENTAL

All chemicals and solvents were manipulated under dry and oxygen-free environments. TaCl$_5$ was purchased from Strem and used without further purification. RNH$_2$ and pyridine were supplied by Merck and degassed before use. Me$_3$SiCl was obtained from Janssen and used as received. LiNEt$_2$ was prepared from HNEt$_2$ and Bu^{n}Li (Janssen) in hexane. All ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded at 300 and 75-MHz, respectively, on a Varian Unity-300 spectrometer at +25°C. Mass spectra were measured (Vacuum Generator Trio-2000) by the direct insertion method. Elements were analyzed with a Heraeus CHN-O-Rapid Analyzer.

Preparation of (Bu^{t}N)TaCl$_3$py$_2$ **1a**

To Bu^t(Me$_3$Si)NH (2.3 cm^3, 12 mmol), prepared *in situ* by reacting Me$_3$SiCl (1.5 cm^3, 12 mmol) with Bu^{t}NH$_2$ (2.6 cm^3, 25 mmol) in toluene (100 cm^3), TaCl$_5$ (2.0 g, 5.5 mmol) was added. After the mixture was stirred for 1 h at room temperature, pyridine (1.6 cm^3, 21 mmol) was added. The mixture was stirred overnight then filtered. A yellow solid was separated after the filtrate was concentrated (2.4 g, 85% based on Ta). Recrystallization from toluene at −15°C gave large crystals suitable for X-ray structural analysis. ^{1}H NMR (benzene-d_6): 1.53 (s, 9H, Me_3CN), 6.27 (t, 2H, m-C$_6H_5$N), 6.52 (br, 2H, m-C$_6H_5$N), 6.67 (t, 1H, p-C$_6H_5$N), 6.84 (br, 1H, p-C$_6H_5$N), 8.89 (d, 2H, o-C$_6H_5$N). 9.18 (br, 2H, o-C$_6H_5$N). ^{13}C NMR (chloroform-d): 31.6 (Me_3CN), 66.2 (Me$_3$$C$N), 124.2 (m-

C_6H_5N), 124.5 (m-C_6H_5N), 139.2 (p-C_6H_5N), 140.6 (p-C_6H_5N), 151.6 (o-C_6H_5N), 152.9 (o-C_6H_5N). Mass (EI, m/z, ^{35}Cl, ^{181}Ta): 342 [M-2 py-Me]$^+$. Anal. Calcd. for $TaC_{14}H_{19}N_3Cl_3$: C, 32.54; H, 3.68; N, 8.13. Found: C, 32.50; H, 3.84; N, 8.02.

Preparation of (Pr^iN)$TaCl_3py_2$ **1b** and (Pr^nN)$TaCl_3py_2$ **1c**

By using $Pr^i(Me_3Si)NH$ and $Pr^n(Me_3Si)NH$, **1b** and **1c** were synthesized by a procedure similar to the one used to prepare **1a**.

1b ^1H NMR (benzene-d_6): 1.38 (d, 6H, Me_2CHN), 5.22 (m, 1H, Me_2CHN), 6.28 (t, 2H, m-C_6H_5N), 6.59 (br, 2H, m-C_6H_5N), 6.82 (t, 1H, p-C_6H_5N), 6.92 (br, 1H, p-C_6H_5N), 8.81 (d, 2H, o-C_6H_5N). 9.15 (br, 2H, o-C_6H_5N). ^{13}C NMR (chloroform-*d*): 25.1 (Me_2CHN), 61.9 (Me_2CHN), 124.3 (m-C_6H_5N), 124.7 (m-C_6H_5N), 139.0 (p-C_6H_5N), 140.2 (p-C_6H_5N), 151.6 (o-C_6H_5N), 152.8 (o-C_6H_5N). Mass (EI, m/z, ^{35}Cl, ^{181}Ta): 343 [M-2 py]$^+$. Anal. Calcd. for $TaC_{13}H_{17}N_3Cl_3$: C, 31.06; H, 3.38; N, 8.36. Found: C, 30.95; H, 3.72; N, 8.21.

1c ^1H NMR (benzene-d_6): 1.02 (t, 3H, $MeCH_2CH_2N$), 1.62 (m, 2H, $MeCH_2CH_2N$), 5.02 (t, 2H, $MeCH_2CH_2N$), 7.34 (m, 4H, m-C_6H_5N), 7.81 (t, 1H, p-C_6H_5N), 7.90 (t, 1H, p-C_6H_5N), 8.77 (d, 2H, o-C_6H_5N). 8.88 (br, 2H, o-C_6H_5N). ^{13}C NMR (chloroform-*d*): 12.0 ($MeCH_2CH_2N$), 26.2 ($MeCH_2CH_2N$), 63.1 ($MeCH_2CH_2N$), 124.4 (m-C_6H_5N), 124.8 (m-C_6H_5N), 138.6 (p-C_6H_5N), 140.1 (p-C_6H_5N), 151.5 (o-C_6H_5N), 152.5 (o-C_6H_5N). Mass (EI, m/z, ^{35}Cl, ^{181}Ta): 343 [M-2 py]$^+$. Anal. Calcd. for $TaC_{13}H_{17}N_3Cl_3$: C, 31.06; H, 3.38; N, 8.36. Found: C, 30.71; H, 3.43; N, 8.23.

Preparation of (Bu^tN)$Ta(NEt_2)_3$ **2a**

To **1a** (2.4 g, 4.6 mmol) suspended in hexane (100 cm^3), $LiNEt_2$ (1.8 g, 23 mmol) suspended in hexane (50 cm^3) was added slowly. The mixture turned brown gradually as it was stirred overnight. After filtration, the filtrate was concentrated to a brown liquid. Purification by vacuum distillation (60°C, 10^{-1} mm Hg) gave a yellow liquid (1.4 g, 65% based on Ta). ^1H NMR (benzene-d_6): 1.15 (t, 18H, $MeCH_2N$), 1.43 (s, 9H, Me_3CN), 3.47 (q, 12H, $MeCH_2N$). ^{13}C NMR (benzene-d_6): 17.2 ($MeCH_2N$), 34.5 (Me_3CN), 47.6 ($MeCH_2N$), 66.2 (Me_3CN). Mass (EI, m/z, ^{181}Ta): 468 [M]$^+$. A satisfactory carbon analysis was not obtained. Anal. Calcd. for $TaC_{16}H_{39}N_4$: C, 41.02; H, 8.39; N, 11.96. Found: C, 40.35; H, 8.30; N, 11.93.

Preparation of $Ta(NPr^i)(NEt_2)_3$ **2b** and $Ta(NPr^n)(NEt_2)_3$ **2c**

2b and **2c** were synthesized by a procedure similar to the one used to prepare **2a**.

2b ^1H NMR (benzene-d_6): 1.17 (t, 18H, $MeCH_2N$), 1.32 (d, 6H, Me_2CHN), 3.45 (q, 12H, $MeCH_2N$), 4.38 (m, 1H, Me_2CHN). ^{13}C NMR (benzene-d_6): 17.3 ($MeCH_2N$), 28.1 (Me_2CHN), 47.8 ($MeCH_2N$), 62.2 (Me_2CHN). Mass (EI, m/z, ^{181}Ta): 454 [M]$^+$. Satisfactory C and H analyses were not obtained. Anal. Calcd. for $TaC_{15}H_{37}N_4$: C, 39.65; H, 8.21; N, 12.33. Found: C, 40.35; H, 6.84; N, 12.53.

2c ^1H NMR (benzene-d_6): 1.04 (t, 3H, $MeCH_2CH_2N$), 1.19 (t, 18H, $MeCH_2N$), 1.70 (m, 2H, $MeCH_2CH_2N$), 3.44 (q, 12H, $MeCH_2N$), 4.16 (t, 2H, $MeCH_2CH_2N$). ^{13}C NMR (benzene-d_6): 11.9 ($MeCH_2CH_2N$), 17.3 ($MeCH_2N$), 28.2 ($MeCH_2CH_2N$), 47.8 ($MeCH_2N$), 64.0 ($MeCH_2CH_2N$). Mass (EI, m/z, ^{181}Ta): 454 [M]$^+$. A satisfactory carbon analysis was not obtained. Anal. Calcd. for $TaC_{15}H_{37}N_4$: C, 39.65; H, 8.21; N, 12.33. Found: C, 38.29; H, 7.96; N, 12.64.

Structure determination of **1a**

A single crystal of **1a** was sealed in a glass capillary under an inert atmosphere. Data were collected on a Nonius CAD-4 using graphite-monochromated Mo Kα radiation, and the structure was solved by the heavy-atom method; all data reduction and structural refinements were performed with the NRCC SDP package. Crystal data, details of data collection, and structural analysis are summarized in Table 2. The methyl groups of Bu^t are disorder with half occupancies. They are designated as C(2), C(3), C(4) and C(2)′, C(3)′, C(4)′, and refined isotropically. The other non-hydrogen atoms were refined with anisotropic parameters. Only hydrogen atoms of pyridine were placed in idealized positions and included in the cal-

(Received 25 September 1997; accepted 23 January 1998)

Abstract—The reaction of three phenolic ligands (*viz.* salicylaldehyde, Hsal; 2-hydroxyacetophenone, Hacp and 2-hydroxynaphthaldehyde, Hnap; generally abbreviated as HL, where H stands for the phenolic proton) with $[Os(bpy)_2Br_2]$ has afforded complexes of type $[Os(bpy)_2(L)]^+$, which have been isolated as the perchlorate salts. The complexes are diamagnetic (low-spin d^6, $S=0$) and in acetonitrile solution shows several MLCT transitions in the visible region. Structure of the $[Os^{II}(bpy)_2(sal)]ClO_4$ complex has been determined by X-ray crystallography. The salicylaldehydate anion is coordinated to osmium as a bidentate O,O-donor and the OsN_4O_2 coordination sphere is distorted octahedral. Cyclic voltammetry shows a reversible osmium(II)-osmium(III) oxidation in the range of 0.17–0.25 V *vs* SCE follwed by an irreversible osmium(III)-osmium(IV) oxidation in the range of 1.38–1.48 V *vs* SCE. Three one-electron reductions of the coordinated bpy ligands are also observed on the negative side of SCE (−1.49– −2.08 V). Chemical or electrochemical oxidation of the $[Os^{II}(bpy)_2(L)]ClO_4$ complex affords green $[Os^{III}(bpy)_2(L)]^{2+}$ species, which have been isolated as the perchlorate salts. These complexes are one-electron paramagnetic (low-spin d^5, $S=1/2$) and in acetonitrile solution show LMCT transitions in the visible region. Reduction of the green $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes gives back the respective brown $[Os^{II}(bpy)_2(L)]ClO_4$ complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: osmium; phenolates; synthesis; structure; redox properties.

The chemistry of osmium has been receiving continuous attention [1] largely due to the interesting redox properties exhibited by its complexes. Osmium offers a wide range of chemically accessible oxidation states. The stability and the interconvertibility of these different oxidation states are directed by the coordination environment around the metal ion. Coordination of osmium by ligands of different types is of particular importance in this respect. In the present study, phenolic ligands of type **1** have been used as the principal ligand. The ligands are abbreviated in general as HL, where H stands for the dissociable phenolic proton. The phenolate anions (L^-) bind metal ions as bidentate O,O-coordinator forming six membered chelate ring(**2**). Coordination by phenolate oxygen is known to be very effective in stabilizing the higher oxidation states of osmium [2]. For example, in the tris-catecholato osmium complex, osmium is in +6 oxidation state, which is stabilized by the six coordinated phenolate oxygens [2a, 2b, 2e]. The three phenolic ligands that have been used in the present work are salicylaldehyde (Hsal, **3**), 2-hydroxyacetophenone (Hacp, **4**) and 2-hydroxynaphthaldehyde (Hnap, **5**). It may be noted here that while ruthenium chemistry of these ligands has received considerable attention [3], the analogous osmium chemistry appears to remain unexplored. Herein we have restricted our studies on a group of osmium complexes having only one coordinated L. To satisfy the remaining four coordination sites of osmium in this OsL moiety, 2,2′-bipyridine (bpy) has been used as the

coligand. The synthesis and characterization of three $[Os(bpy)_2(L)]ClO_4$ complexes and their spectroscopic and electron-transfer properties are reported in this paper.

EXPERIMENTAL

Materials

Osmium tetroxide was purchased from Arora Matthey, Calcutta, India and was converted into $[NH_4]_2[OsBr_6]$ by reduction with HBr [4]. $[Os(bpy)_2Br_2]$ was synthesized from $[NH_4]_2[OsBr_6]$ using a literature method [5]. 2,2′-Bipyridine was purchased from Loba Chemie, Mumbai, India. Salicylaldehyde, 2-hydroxyacetophenone and 2-hydroxynaphthaldehyde were obtained respectively from S.D. (Mumbai), Spectrochem(Mumbai) and Aldrich. All other chemicals and solvents were reagent grade commercial materials and were used as received. Purification of acetonitrile and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were performed as reported in the literature [6, 7].

Preparation of complexes

The $[Os^{II}(bpy)_2(L)]ClO_4$ and $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes, reported in this work, were prepared by following two general methods. Specific details are given below for two representative cases.

$[Os^{II}(bpy)_2(sal)]Clo_4$ $[Os(bpy)_2Br_2]$ (100 mg, 0.15 mmol) was taken in 3:1 EtOH-water (40 cm^3) and to the solution was added Hsal (20 mg, 0.16 mmol) followed by NEt_3 (16 mg, 0.16 mmol). The solution was then heated at reflux for 6 h. After being cooled to room temperature, a saturated solution of $NaClO_4$ (1 cm^3) was added to it and the volume of the solution was reduced to about 15 cm^3 under reduced pressure. The solution was then kept in the refrigerator for ~24 h. $[Os(bpy)_2(sal)]ClO_4$ precipitated as a dark brown microcrystalline solid, which was collected by filtration, washed with little ice-cold water and dried *in vacuo* over P_4O_{10}. Purification of the product was done by recrystallization from dichloromethane-benzene solution. The yield was 85 mg (78%).

$[Os^{III}(bpy)_2(sal)](Clo_4)_2$ $[Os^{II}(bpy)_2(sal)]ClO_4$ (100 mg, 0.14 mmol) was dissolved in acetone (20 cm^3) and one drop of bromine was added to it. An instantaneous colour change, from brown to green, took place. The solution was then stirred for 10 min and a saturated aqueous solution of $NaClO_4$ (0.5 cm^3) was added to it. Upon partial evaporation of the solution $[Os(bpy)_2(sal)](ClO_4)_2$ precipitated as a green microcrystalline solid, which was collected by filtration, washed with little ice-cold water and dried *in vacuo* over P_4O_{10}. The yield was 90 mg (79%).

Physical measurements

Microanalyses (C,H,N) were performed using a Perkin-Elmer 240C elemental analyser. Infrared spectra were obtained on a Perkin-Elmer 783 spectrometer with samples prepared as KBr pellets. Electronic spectra were recorded on a Simadzu UV 1601 spectrophotometer. Magnetic susceptibilities were measured using a PAR 155 vibrating sample magnetometer fitted with a Walker Scientific L75FBAL magnet. ^1H NMR spectra were obtained on a Brucker AC-200 NMR spectrometer using TMS as the internal standard. ESR spectra studies were done using a Varian E-109C spectrometer fitted with a quartz Dewar for measurement at 77 K (liquid nitrogen). Solution electrical conductivities were measured using a Philips PR 9500 bridge with a solute concentration of 10^{-3} M. Electrochemical measurements were made using a PAR model 273 potentiostat. A platinum disc or graphite working electrode, a platinum wire auxiliary electrode and an aqueous saturated calomel reference electrode (SCE) were used in a three electrode configuration. A platinum wire gauze working electrode was used in the coulometric experiments. A RE 0074 X–Y recorder was used to trace the voltammograms. Electrochemical measurements were per-

formed under a dinitrogen atmosphere. All electrochemical data were collected at 298 K and are uncorrected for junction potentials.

Crystallography

Single crystals of $[Os(bpy)_2(sal)]ClO_4$ were grown by slow diffusion of benzene into a dichloromethane solution of the complex. Selected crystal data and data collection parameters are given in Table 1. The unit cell dimensions were determined by a least-squares fit of 25 machine-centered reflections ($15.00 < 2\theta < 21.84$°). Data were collected on a Enraf–Nonius CAD-4 diffractometer using graphite monochromated Mo–Kα radiation ($\lambda = 0.7107$ Å) by θ-2θ scans within the angular range 3.0–45.0°. Three standard reflections, measured every 3600 seconds of X-ray exposure, showed no significant intensity variation over the course of data collection. X-ray data reduction, and structure solution and refinement were done using the NRCVAX package. The structure was solved by the Patterson method. Final cycles of refinement converged with discrepancy indices of $R_f = 0.043$ and $R_w = 0.039$.

RESULTS AND DISCUSSION

The three phenolic ligands (HL, **3**–**5**) react smoothly with $[Os(bpy)_2Br_2]$ in 3:1 ethanol-water in the presence of triethylamine to afford complexes of type $[Os(bpy)_2(L)]^+$, which have been isolated subsequently as the perchlorate salts in the solid state. Some characterization data of the complexes are given in Table 2. Elemental (C,H,N) analytical data are in excellent agreement with the compositions of the complexes. ^{1}H NMR spectra of the $[Os(bpy)_2(L)]^+$ complexes have been recorded in $CDCl_3$ solution. The aromatic region of the spectra is rather complex in nature due to overlap of signals and hence assignment of signals in this region to specific protons has not

been attempted. However, intensity measurement of these signals corresponds to the total number of aromatic protons present in the respective complexes. In both $[Os(bpy)_2(sal)]^+$ and $[Os(bpy)_2(nap)]^+$ complexes, the aldehyde proton of the sal and nap ligands shows a distinct resonance at 9.29 ppm. In the $[Os(bpy)_2(acp)]^+$ complex, the methyl signal of the acp ligand appears at 2.31 ppm.

Molecular structure of $[Os(bpy)_2(sal)]ClO_4$ has been determined by X-ray crystallography. A view of the molecule is shown in Fig. 1 and selected bond distances and angles are listed in Table 3. The OsN_4O_2 coordination sphere is distorted octahedral, which is reflected in the three non-linear trans-angles and the twelve cis-angles (non 90°) as well. The salicylaldehyde anion is coordinated to osmium as bidentate O,O-donor with a bite angle of 91.8(3)°.

Infrared spectra of the $[Os(bpy)_2(L)]ClO_4$ complexes shows many vibrations of different intensities below 1700 cm^{-1}. Comparison of these spectra with the spectrum of $[Os(bpy)_2Br_2]$ shows that besides the presence of some similar vibrations, which are prob-

ably due to the common $Os(bpy)_2$ moiety, some additional vibrations are observed in the spectra of the $[Os(bpy)_2(L)]ClO_4$ complexes. Of these additional vibrations, the two intense ones observed near 1100 cm^{-1} and 620 cm^{-1} in all these complexes, are attributed to the perchlorate ion. The other new vibrations are obviously due to the coordinated phenolate ligand L. The $[Os(bpy)_2(L)]ClO_4$ complexes are soluble in common polar organic solvents like ethanol, acetone, dichloromethane, acetonitrile etc., producing solutions in different shades of brown. Conductance measurement in acetonitrile solution shows that these complexes behave as 1:1 electrolytes (Table 2), as expected. Electronic spectra of the $[Os(bpy)_2(L)]ClO_4$ complexes have been recorded in acetonitrile solution. Spectral data are presented in Table 2 and a selected spectrum is displayed in Fig. 2. Each complex shows several intense absorptions in the visible region and a few absorptions of very high intensity in the ultraviolet region. The absorptions in the ultraviolet region are attributed to transitions within the ligand orbitals. The intense absorptions in the visible region are probably due to allowed metal-to-ligand charge-transfer transitions. Multiple charge-transfer transitions in these mixed-ligand complexes may result from lower symmetry splitting of the metal level, the presence of different acceptor orbitals and from the mixing of singlet and triplet configurations in the excited state through spin-orbit coupling [8].

CYCLIC VOLTAMMETRIC STUDIES

Electron-transfer properties of the $[Os(bpy)_2(L)]ClO_4$ complexes have been studied in acetonitrile solution (0.1 M TEAP) by cyclic voltammetry. All the complexes show two oxidative responses on the positive side of SCE and three reductive responses on the negative side. Voltammetric data are presented in Table 2 and a selected voltammogram is displayed in Fig. 3.

The first oxidative response exhibited by each complex in the range of 0.17–0.25 V (all potentials are referenced to SCE) is assigned to the osmium(II)-osmium(III) oxidation [eqn. (1)]. This oxidation

$$[Os(bpy)_2(L)]^+ \rightleftharpoons [Os(bpy)_2(L)]^{2+} + e \qquad (1)$$

is reversible, characterized by a peak-to-peak separation (ΔE_p) of 60 mV which remains unaltered upon changing the scan rate. The anodic peak current (i_{pa}) is almost equal to the cathodic peak current (i_{pc}), as expected for a reversible couple. The one-electron nature of this oxidation has been confirmed by constant potential coulometric experiments (*vide infra*). The osmium(II)-osmium(III) oxidation potential in $[Os(bpy)_3]^{2+}$ is 0.84 V [9]. In the $[Os(bpy)_2(L)]^+$ complexes the same oxidation is taking place near 0.2 V. The negative shift of oxidation potential observed upon replacing one bpy by one L reflects the ability of these phenolate ligands to stabilize the +3 state of osmium. Similar systematic variation in redox potentials by stepwise substitution of pyridine ligands by phenolates in ruthenium complexes is well documented in literature [10]. This further points to the fact that inspite of coordination by the soft carbonyl oxygen, coordination by phenolate oxygen has been very effective in lowering the osmium(II)-osmium(III) oxidation potential. Comparison of the osmium(II)-osmium(III) oxidation potential in $[Os(bpy)_2(sal)]^+$ (0.25 V) with the ruthenium(II)-ruthenium(III) oxidation potential in $[Ru(bpy)_2(sal)]^+$ (0.64 V)[3d] shows that the oxidation is much easier in the osmium complexes, as expected.

A second oxidative response, irreversible in nature, is shown by $[Os(bpy)_2(L)]ClO_4$ complexes in the range of 1.38–1.48 V but its assignment is unclear. The one-electron nature of this oxidation is established by com-

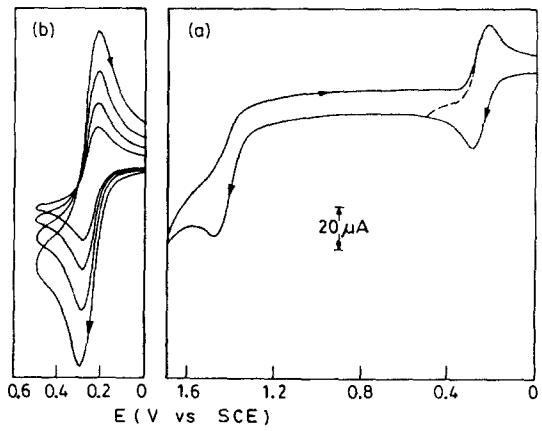

Fig. 3. Cyclic voltammograms of $[Os(bpy)_2(sal)]ClO_4$ in acetonitrile solution (0.1 M TEAP) (a) at a scan rate of 50 mVs^{-1} and (b) at scan rates of 50, 100, 200 and 400 mVs^{-1}.

paring its current height (i_{pa}) with that of osmium(II)-osmium(III) couple.

The three reductive responses, exhibited by the $[Os(bpy)_2(L)]^+$ complexes on the negative side of SCE, are assigned to the reductions of the coordinated bpy ligands as shown in eqs (2)–(4).

$$[Os^{II}(bpy)_2(L)]^+ + e^- \leftrightharpoons [Os^{II}(bpy)(b\dot{p}y)(L)] \quad (2)$$

$$[Os^{II}(bpy)(b\dot{p}y)(L)] + e^- \leftrightharpoons [Os^{II}(b\dot{p}y)_2(L)]^- \quad (3)$$

$$[Os^{II}(b\dot{p}y)_2(L)]^- + e^- \leftrightharpoons [Os^{II}(b\dot{p}y)(b\ddot{p}y)(L)]^{2-} \quad (4)$$

It is well documented in the literature that each bpy ligand can successively accept two electrons in its lowest unoccupied molecular orbital [11]. Hence in these $[Os(bpy)_2(L)]^+$ complexes four successive reductions may be expected, of which three have been experimentally observed. The fourth reduction could not be observed due to solvent cut-off.

$[Os^{III}(bpy)_2(L)]^{2+}$ *complexes*

The reversible nature of the osmium(II)-osmium(III) oxidation in the $[Os(bpy)_2(L)]^+$ complexes shows that the $[Os^{III}(bpy)_2(L)]^{2+}$ species are stable, at least on the cyclic voltammetric time scale. The oxidation potentials are relatively low, which further suggest that the oxidized complexes would be stable much longer time scale. To investigate the stability of the $[Os^{III}(bpy)_2(L)]^{2+}$ complexes, they were electrochemically generated by coulometric oxidation of the $[Os^{II}(bpy)_2(L)]^+$ species at 0.5 V. The oxidations were smooth and quantitative, resulting in a colour change of brown to green. The green solution of the $[Os^{III}(bpy)_2(L)]^{2+}$ complexes shows identical cyclic voltammograms as their respective precursors, except that the osmium(II)-osmium(III) couple now appears as a reductive response. This indicates that no change in the coordination environment around osmium took place during oxidation. Coulometric reduction of the green solutions at 0.0 V gave back brown solutions of the respective $[Os^{II}(bpy)_2(L)]^+$ complexes, which were identified by their characteristic electronic spectra. Chemical oxidation of the $[Os^{II}(bpy)_2(L)]^+$ complexes by bromine in acetone solution also afforded the $[Os^{III}(bpy)_2(L)]^{2+}$ species, which were isolated as the perchlorate salt in the solid state. Characterization data of the $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes are given in Table 4. Composition of these complexes have been confirmed by their microanalitical data. Except small shift in band positions, the IR spectra of these oxidized complexes are almost identical to their respective $[Os^{II}(bpy)_2(L)]ClO_4$ precursors. The $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes are one-electron paramagnetic, which is in accordance with +3 state of osmium (low-spin d^5, $S = 1/2$) in these complexes. However, ESR studies shows that these $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes are ESR-silent. The ESR-inactivity in low-spin d^5 complexes is known to result from extensive mixing of the Kramers doublets by strong spin-orbit coupling which gives rise to short electronic relaxation time [12]. In acetonitrile solution these $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes behave as 1:2 electrolytes, as expected. Electronic spectra of the $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes have been recorded in acetonitrile solution. Each complex shows five absorptions, three intense ones in the visible region and two very intense ones in the UV region (Table 4, Fig. 2). The absorptions in the visible region are attributed to ligand-to-metal charge-transfer transitions and those in the UV region are assigned to transitions within the ligands orbitals. Chemical reduction of the green $[Os^{III}(bpy)_2(L)](ClO_4)_2$ complexes in acetonitrile solution by hydrazine quantitatively affords the respective brown $[Os^{II}(bpy)_2(L)]ClO_4$ complexes. This shows that the osmium(II)-osmium(III) oxidation [eqn (1)] is chemically reversible as well.

CONCLUSION

The present study on the $[Os(bpy)_2(L)]ClO_4$ complexes reveals that coordination by phenolate oxygen is very effective in stabilizing the higher oxidation states of osmium. The observed shift in osmium(II)-osmium(III) oxidation potential in going from $[Os(bpy)_3]^{2+}$ (0.84 V) to $[Os(bpy)_2(sal)]^+$ (0.25 V) indicates that in the osmium complexes having more of these phenolate ligands, this oxidation will be much easier. For example, in the $[Os(bpy)(sal)_2]^{n+}$ and $[Os(sal)_3]^{m+}$ complexes, the same osmium(II)-osmium(III) oxidation may be expected to appear near -0.3 V and -0.9 V respectively. Therefore the air-stable oxidation state of osmium in these two complexes will be $+3$ or higher. Studies on these two and other osmium-phenolate complexes are currently in progress.

(Received 24 September 1997; accepted 23 January 1998)

Abstract—The synthesis, spectral characterisation of the zinc(II) pyrrolecarboxylates, $[Zn(2\text{-Hpyrrc})_2(H_2O)]$ (**1**) and $[Zn(2\text{-Hpyrrc})_2(1\text{-methylimidazole})_2]$ (**2**) ($2\text{-}H_2$pyrrc = 2-pyrrolecarboxylic acid) is reported as well as the X-ray structure determination of the latter compound. The molecular structure of **2** exhibits a distorted tetrahedral geometry around the zinc atom. The pyrrole-2-carboxylic acid acts as a monodentate ligand, *syn*-bound via one carboxylate oxygen atom. In the crystal structure, the discrete molecules of **2** are organised in dimers linked by a complex network of hydrogen bonds. A comparative IR study confirms the existence of different types of hydrogen bonding. © 1998 Elsevier Science Ltd. All rights reserved.

Keywords: crystal structure; zinc carboxylate; imidazole; pyrrole; IR-spectroscopy; self-assembly.

INTRODUCTION

During the course of our studies on new potential carbon dioxide activators, we became interested in systems involving zinc(II) carboxylates since these compounds are known to be effective catalysts for the copolymerisation of CO_2 and epoxides [1, 2]. The most efficient carboxylates are obtained from dicarboxylic acids and display most of the time polymeric frameworks [3–5]. The structural characterisation of such catalysts is poorly documented and the exact nature of the active site remains controversial. Our interest was attracted by carboxylic acids including a pyrrole moiety which might engineer, through hydrogen bonding, new low-molar-weight oligomeric carboxylates. Molecules having self complementary arrays of hydrogen bond donors and acceptors are a topic of main interest in organic chemistry for their ability to build supramolecular assemblies [6–9]. The preparation of hydrogen-bonded aggregates incorporating metal ions is less documented and attracts an ever-growing interest by associating versatile nanoarchitectures and transition metal characteristics [10]. The control of the molecular aggregation should allow, in our case, an easier investigation of the zinc-catalyzed reaction of carbon dioxide with epoxides. Surprisingly, despite a number of extensive studies on the co-ordination of pyrrolecarboxylic acids to metal centres performed with spectroscopic [11, 12] and calorimetric methods [13], no crystallographic data are available, to our knowledge, for the corresponding

* Author to whom correspondence should be addressed.

transition metal carboxylates. We decided to undertake as first part of our study the structural characterisation of such carboxylates. We report here the first X-ray structure of a zinc(II) pyrrolecarboxylate, $[Zn(2\text{-}PyrrcH)_2(1\text{-methylimidazole})_2]$ (**2**).

RESULTS AND DISCUSSION

The reaction of zinc oxide with two equivalents of the 2-pyrrolecarboxylic acid, noted 2-H_2pyrrc, under reflux in aqueous media affords the carboxylato compound, $[Zn(2\text{-}Hpyrrc)_2.H_2O]$, (**1**). This zinc carboxylate reacts with 1-methylimidazole to afford, after recrystallisation from acetonitrile, red parallelepipedic crystals. The analytical and spectral results are consistent with a monomeric compound, $[Zn(2\text{-}Hpyrrc)_2(1\text{-methylimidazole})_2]$ (**2**), presenting a monodentate co-ordination of the carboxylate ligand.

Crystallographic study of 2

The molecular structure of **2** with atomic labelling is given in Fig. 1. Selected distances and angles are given in Table 1. $[Zn(2\text{-}Hpyrrc)_2(1\text{-methylimidazole})_2]$ crystallises in the monoclinic space group $P2_1/c$ with four discrete molecules per unit cell. Each molecule is linked *via* two hydrogen bonds with a centrosymmetrically related counterpart to form a dimer as depicted in Fig. 2. The structural characterisation of such hydrogen-bonded dimeric compounds linked by self complementary donor/acceptor groups is well documented in organic chemistry [14–18] but remains scarce for inorganic compounds. We are aware of only a few transition metal carboxylates of, e.g. zinc [19] and platin [20] displaying such pairs of symmetric C=O . . . H–N bridges.

The zinc atom is tetracoordinated occupying the center of a tetrahedron characterised by a dihedral

C1-O(2)	1.243(3)	O(2)· · N(1a)	2.801(3)
C6-O(3)	1.285(3)	O(4a)· · N(2b)	2.994(3)
C6-O(4)	1.226(3)	O(1a)· · N(2b)	3.114(3)

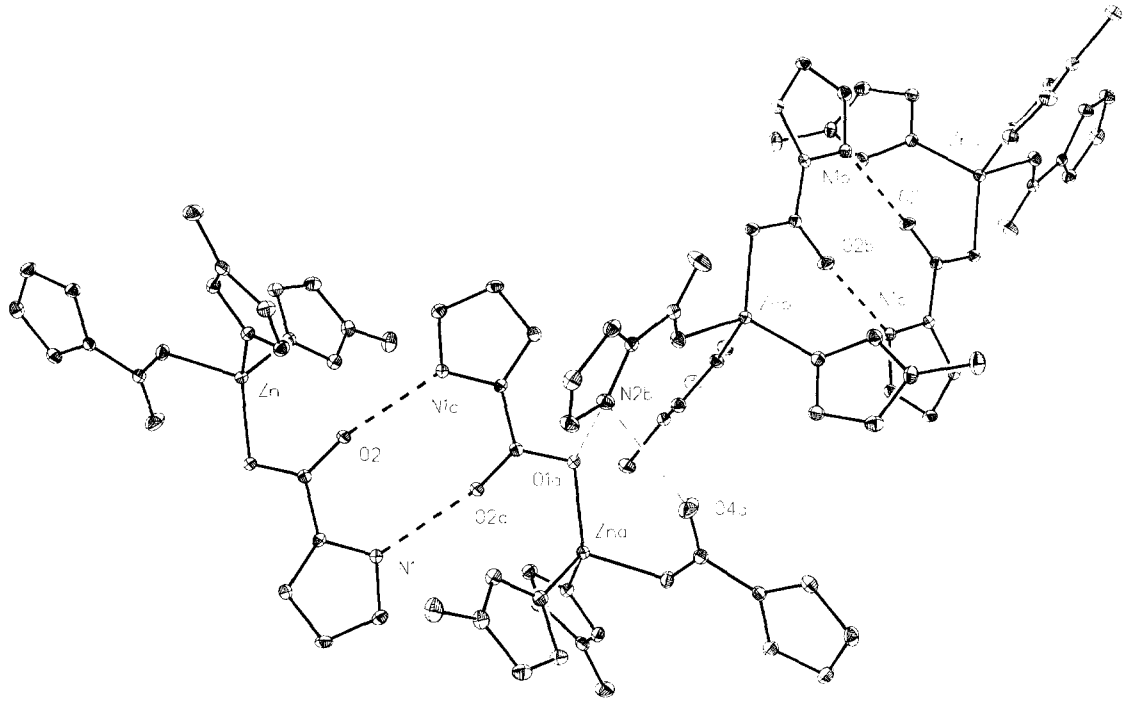

Fig. 2. Representation illustrating the hydrogen bondings within and between the adjacent pairs of **2**. Hydrogen atoms are omitted for clarity. Symmetry transformations used: #a): $-x,1-y,2-z$; #b): $-x,-0.5+y,1.5-z$; #c): $x,0.5-y,-0.5+z$. Intermolecular bond lengths (Å): O(2) . . . N(1a) = 2.801(3), O(4a) . . . N(2b) = 2.994(3), O(1a) . . . N(2b) = 3.114(2) Å.

angle of 90.70(8)° between the planes defined by N(3)-Zn-N(5) and O(3)-Zn-O(1). The angles within the tetrahedron are shifted from the theoretical value and range from 98.62(8)° to 116.44(8)°. The carboxylate groups are bound in a *syn*-monodentate way. This geometry is commonly found in zinc aminocarboxylates and was already described for, e.g. the dichlorobis(L-proline)zinc(II) [21] and bis(L-pyroglutamat)zinc(II) dihydrate. [22]

The ligand-metal distances are 1.969(2) Å and 1.950(2) Å for the Zn-O bonds and 2.002(2) Å and 2.012(2) Å for the Zn-N bonds. The Zn-O bond lengths are within the range reported for tetrahedral environments [21, 22, 23]. The Zn-N bond lengths are similar to those found in other tetrahedral zinc complexes of imidazole (Zn-N: 1.995–2.020 Å) [21, 24] and are shorter than those found in octahedral imidazole complexes [25, 26] (distances ranging from 2.144 to 2.199(4) Å).

The C-O_{sp2} distances measured in the carboxylates groups suggest unequivalent values with 1.226(3) Å and 1.243(3) Å. The latter distance may indicate a weakening of the double bond character and can be compared to those usually found in monodentate zinc

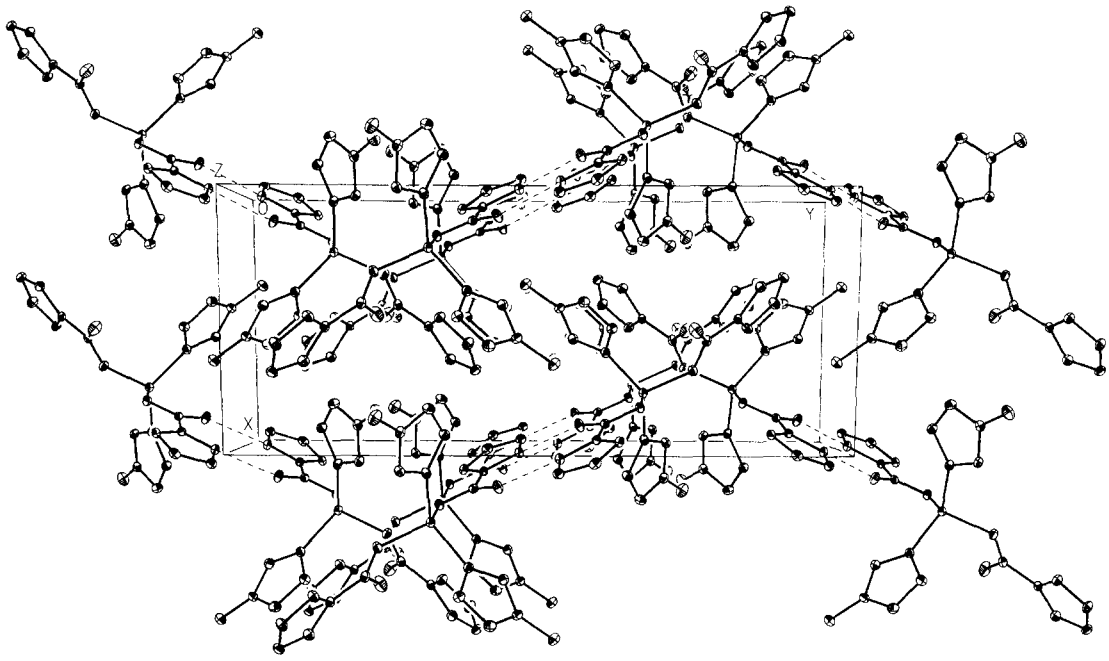

Fig. 3. Unit cell of [Zn(2-pyrrolecarboxylato)$_2$(1-methylimidazole)$_2$] **2**, viewed along the *c* axis.

carboxylates stabilised by hydrogen-bonded networks [19, 22, 27]. As expected, hydrogen bonding plays a significant role in the crystal structure and takes place on two levels, giving rise to interesting structural patterns. Firstly, a "strong"† hydrogen bond is found implicating the pendant oxygens O(2) and the nitrogen atoms N(1a) of pyrrolecarboxylate fragments in two adjacent molecules [O(2)$\cdots$N(1a) = 2.801(2) Å], this interaction accounts for the formation of the above-mentioned dimer. These distant contacts are comparable to hydrogen bond distances found in the crystal structures of many secondary amides involving dimeric arrangements [14]. A second interaction is detected between the oxygen O(4a), the metal-bonded oxygen O(3a) and a pyrazolic nitrogen atom N(2b) belonging to an other adjacent hydrogen-bonded dimer as illustrated in Fig. 2 [O(4a)$\cdots$N(2b) = 2.994(2) Å; O(1a)$\cdots$N(2b) = 3.114(2) Å]. These contacts can be considered as "weak" hydrogen bonds owing to the fact that the carboxylic group O(4a),C(6a),O(3a) is located in the same plane as the pyrazolic nitrogen (deviation ca. 0.025 Å) and directed towards the orbital lobes of the sp^2-hybridised oxygen O(4a) [28]. Likewise, the interaction between O(1a) and N(2b) can be regarded as a weak hydrogen bonding assuming an sp^3 hybridisation for the metal-bonded O(1a) atom [angles within the O(1a)-centred tetrahedron ranging from 105.3(8) to 109.8(8)°] [29]. This kind of secondary "weak" hydrogen bonds may explain some of the features found in the molecular structure such as: i) the different conformations of the pyrrolecarboxylate ligands, whose amino groups display *cis* and *trans* geometries in respect to the pendant carbonyl oxygens and, ii) the distortions observed in the co-ordination geometry of the carboxylato groups to the zinc atom [Zn-O(2): 3.037(2) Å and Zn-O(4): 2.717(2) Å].

The complex hydrogen-bonded network resulting from the combination of these "strong" and "weak" hydrogen bondings links the pseudo-dimers of **2** into staggered sheets which propagate parallel to the [011] plane as depicted in Fig. 3. The methylation at N(4) and N(6) precludes the formation of further hydrogen-bonded networks between the distinct layers.

IR spectroscopic studies

Evidence of hydrogen bonding can also be found in the IR spectra of both zinc carboxylates. Infrared spectra of compounds **1**, **2** and of the ionic sodium pyrrolecarboxylate were run and comparisons were made between the frequencies of the N-H stretching bands in the solid state and the frequency found for the free pyrrolecarboxylic acid in solution ($CHCl_3/CH_3CN$, ν(N-H): 3432 cm^{-1}). Selected IR frequencies are summarised in Table 2.

The spectrum of **1** shows one strong band assigned to the N-H stretching mode at 3350 cm^{-1} comparable

† The terms "strong" and "weak" are used to distinguish the two-centred hydrogen bond (2.801(2)Å) from the three-centred hydrogen bond (2.994(2) and 3.114(2) Å).

Table 2. Selected vibrational frequencies (KBr, $\pm 2\,cm^{-1}$) of compounds **1**, and **2** and of the sodium pyrrole-2-carboxylate. (s = strong, m = medium, w = weak, br = broad, sh = shoulder)

Compound	$\nu(OH_2)$	ν(N-H)	$\delta(OH_2)$	ν_{as}(COO)	ν(C=C), ν(C-N)+ δ(CN-H)	ν(C-C)+ ν_s(COO)

Δ_a shift defined as: ν(N-H) of the free acid in solution $-\nu$(N-H) of the carboxylate in the solid state.
$\Delta\nu_c$ difference defined as: $\nu_{sym}(COO) - \nu_{sym}(COO)$ of the carboxylate in the solid state.

to the vibration found in the solid-state spectrum of the free 2-pyrrolecarboxylic acid. The absence of band shift indicates that the amine of the 2-pyrrolecarboxylic acid is not co-ordinated to the zinc atom [30]. The comparison with the solution spectrum of the free acid reveals a bathochromic shift of $82\,cm^{-1}$ indicating the presence in compound **1**, as in the free carboxylic acid, of a "weak" hydrogen bonding implicating aminogroups and carboxylic oxygens (entry 1, Tab. 2). This bonding might also implicate the water molecule as suggested by the presence of a broad ν(O-H) band at $3418\,cm^{-1}$ [32]. Compound **2** exhibits in the region characteristic of the N-H stretching vibrations two strong well resolved bands at 3338 and $3234\,cm^{-1}$ (bathochromic shift of 94 and $198\,cm^{-1}$, respectively) consistent with the presence of two amino groups engaged in hydrogen bonding of different intensities (entry 2, Tab. 2). In comparison, the spectrum of the ionic sodium pyrrolecarboxylate, **3**, displays only one strong ν(N-H) band at $3262\,cm^{-1}$ (shift of $170\,cm^{-1}$) which would be concordant with a dimeric structure involving strong hydrogen bonds between *cis*-aminogroups and carbonyl oxygens (entry 3, Tab. 2).

Differences in the spectra of **1** and **2** are also observed in the $1700–1350\,cm^{-1}$ range in which the stretching frequencies of the carboxylate group must appear. An unequivocally attribution is arduous owing to the extensive hydrogen bonding and the presence in the same spectral region of stretching vibrations of the pyrrole ring and deformation modes of the amine. However it is possible, according to comprehensive literature studies [30–39], to propose some band attributions. Thus, in compound **1**, the asymmetric ν(COO) vibration can be found at $1562\,cm^{-1}$ whereas the symmetric ones appear, combined with stretching vibrations of the pyrrole rings, at 1442 and $1390\,cm^{-1}$ [34, 35]. The medium bands at 1510 and $1462\,cm^{-1}$ can be attributed, most probably, to the ν(C=C) band and a combination of the ν(C-N) and δ(CN-H) bands [33]. The carboxylate **2** displays a similar pattern with a larger splitting of the different absorption bands due to the presence of both terminal monodentate carboxylate and terminal carboxylate engaged in strong directive hydrogen bonding. The asymmetric ν(COO) bands are located at 1608 and $1574\,cm^{-1}$, confirming the presence of two distinct carboxylate groups [32]. The symmetric ν(COO) bands, associated with stretching modes of both pyrrole and imidazole rings, can be localised, at 1414, 1436 and $1350\,cm^{-1}$. The strong absorption band noticed at $1546\,cm^{-1}$ can be attributed to the stretching mode of the double bonds [33].

The separation $\Delta\nu$, defined as $\nu_{as}(COO)$-$\nu_s(COO)$, provides some useful information on the bonding mode of the carboxylate group [37, 38, 39]. Deacon and Phillips have established, in the case of acetato compounds, some correlations between the $\Delta\nu$ values and the different modes of bonding of the carboxylato moiety found in the molecular structure: i) monodentate complexes display a greater $\Delta\nu$ than the corresponding ionic complexes, ii) chelating complexes exhibit lower $\Delta\nu$ values than the ionic compounds, and iii) bridging carboxylates give raise to $\Delta\nu$ values greater than those of chelating carboxylates and close to those found in ionic compounds. An unambiguous calculation of $\Delta\nu$ is more difficult than usually reported in the literature due to the mixing of the C-C and COO stretching modes which affords more than one symmetric ν(COO) band.[34–39] However, this

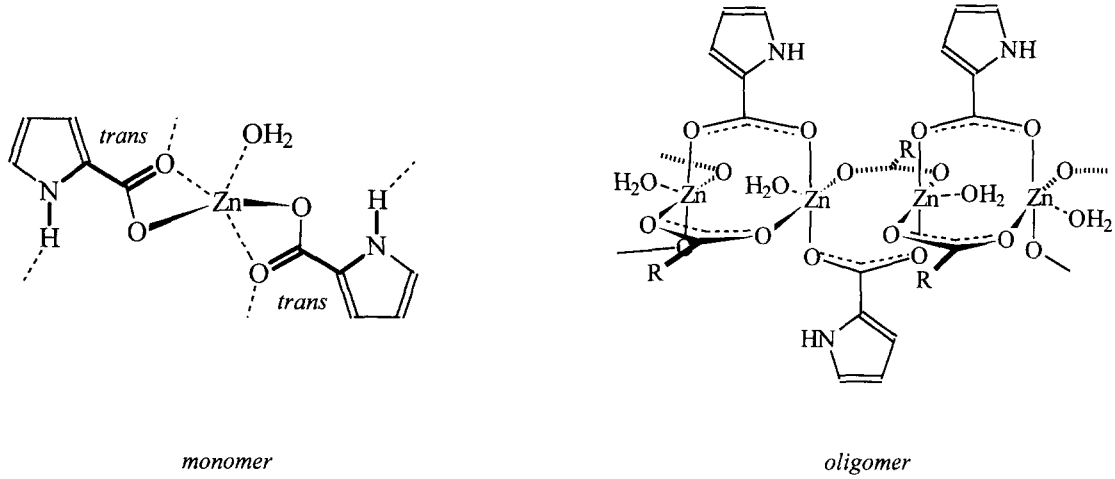

Fig. 4. Potential structures of [Zn(2-pyrrolecarboxylato)$_2$(OH_2)], **1**.

relationship can supply, at least in general terms, some information on the structure of compound **1**. The Δ value found for the compound **1** (120 cm^{-1}) is bigger than that found for the ionic sodium pyrrolecarboxylate **3** (90 cm^{-1}) and is significantly lower than the values found for the monodentate carboxylate **2** (ca. 225 and 260 cm^{-1}). This suggests for compound **1** a near-to-symmetrical bonding of the carboxylate groups to the zinc atom. Two types of solid state structure are therefore conceivable for compound **1** (Fig. 4): on one hand, a mononuclear complexe with carboxylato groups nearly bound in a chelate way such as in [$Zn(O_2CCH_3)(H_2O)_2$] [40] or, on the other hand, an oligomer presenting an O,O′-bridging mode for the carboxylato groups comparable to the bonding described for the anhydrous zinc 2-chlorobenzoate [41] and zinc crotonate [42]. The latter compound was reported to react with an N-donor base to afford low-molar-weighted oligomeric structures such as, e.g.[$Zn_2(CH_3CH=CHCO_2)_4$(quinoline)$_2$] [43]. Such a mechanism might be also conceivable in the case of the pyrrolecarboxylates **1** and **2**, the monomer **2** being the result of the fragmentation of the oligomer **1**. Without an X-ray crystal structure for compound **1** it is not possible to rule out one of these geometries. Such a structural characterisation would also define the nature of the hydrogen bonding in compound **1**, a participation of a further hydrogen bonding occurring between pendant carbonyl oxygens and water molecules cannot be excluded. This interaction can also compensate the asymmetry produced by a monodentate co-ordination of the carboxylate and can consequently decrease the Δν value [40]. More work is planned to elucidate precisely the solid state structure of compound **1** and to rationalise the dependence of the hydrogen-bonded network found in compound **2** on the nature of the present ligands.

EXPERIMENTAL

Reagents and physical measurements

2-pyrrolecarboxylic acid was purchased from Aldrich and used as received. Solvents and reagents were purified by literature methods [44]. 1-methylimidazole was distilled *in vacuo* from calcium hydride (50°C at 0.1 bar). ^1H and ^{13}C NMR data were recorded on a Bruker AC-200 NMR spectrometer. Infrared spectra were measured from KBr pellets in the range of 4000–400 cm^{-1} on a Perkin Elmer PE-16 FT-IR spectrometer. Microanalysis for carbon, hydrogen and nitrogen was carried out by the Institut für Organische und Makromolekulare Chemie of Jena.

Synthesis

Preparation of [Zn(2-Hpyrrc)$_2$.H_2O] (**1**): zinc oxide (0.5 g, 5.1 mmol) was added to a solution of 2-pyrrolecarboxylic acid (1.37 g, 12.3 mmol) in 20 ml of deionized water. The white suspension was refluxed for ca. 12 hours. The reaction mixture was cooled down to room temperature, concentrated (ca. 5 ml), filtered off and washed with acetone. The white precipitate is soluble in MeOH, Acetonitrile, THF and fairly soluble in water.

The solid was recrystallised from hot water (white needles) (1.8 g, 92%) [Zn(2-Hpyrrc)$_2$(H_2O)] Anal. Calc. for $C_{10}H_{10}N_2O_5Zn$: C, 39.55;H, 3.29; N, 9.23. Found: C, 39.37; H, 3.38; N, 9.26. Attempts to isolate singlecrystals of this hydrated carboxylate were not successful.

Spectral characterisation of 1

IR: Table 2; ^1H-NMR in THF d8, δ [ppm] (multiplicity, assignment): 11.01 (s, sharp, N-H); 6.85(s,

pyrrole H3); 6.79 (s, pyrrole H5); 6.10 (s, pyrrole H4); 4.62(s, very broad, H_2O) (The singulets at 11.01 and 4.62 ppm disappear after D_2O addition); ^{13}C-NMR, δ [ppm]: 166.30 (C=O); 126.76, 122.46, 115.30, 109.66, (respectively C2, C5, C3 and C4 of the pyrrole ring).

Preparation of [*zn*(2-*hpyrrc*)$_2$(1-methylimidazole)$_2$] (**2**):

1-methylimidazole (4 ml, 50 mmole) was added to an acetonitrile solution of compound **1** (0.5 g, 1,65 mmole). The colourless solution was refluxed for 10 minutes, filtered and allowed to stand at room temperature. Over a period of ca. 2 weeks, the solution turned slowly to red and deep red crystals suitable for an X-ray structure determination formed (0.2 g, 27%). The crystals are fairly soluble in dmso.[Zn(2-Hpyrrc)$_2$(1-methylimidazole)$_2$] Anal. Calc. for $C_{18}H_{20}N_6O_4Zn$: C, 48.07; H, 4.48; N, 18.68. Found: C, 48.03; H, 4.55; N, 18.79.

Spectral characterisation of 2

IR: Table 2; 1*H-NMR* in dmso d6, δ [ppm] (multiplicity, assignment): 11.12 (s, N-H); 8.16(s, imidazole H2); 7.29 (s, 1-Me-im. H4); 7.23 (s, 1-Me-im. H5); 6.76(s, pyrrole H3); 6.56 (s, pyrrole H5); 6.03 (s, pyrrole H4); 3.72(s, CH3); 13*C-NMR*, δ [ppm]: 166.57(-COO); 121.36, 120.11, 111.97, 108.25, (C2, C5, C3 and C4 of the pyrrole ring);139.43, 127.93, 127.45 (1-Me-im. C2, C4 and C5 sp^2), 30.74 (1-Me-im. C sp^3).

Crystallography of compound 2

X-ray diffraction data: CAD4 diffractometer using graphite-monochromated Mo-Kα radiation. The crystals were mounted in a cold nitrogen stream. Data were corrected for Lorentz and polarisation effects, but not for absorption [45]. The structure was solved by direct methods (SHELXS)[46] and refined by full-matrix least squares techniques against F_0^2 (SHELXL-93)[47]. The hydrogen atoms were located by difference Fourier synthesis and refined isotropically. Finally all non-hydrogen atoms were refined anisotropically. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

(Received 24 October 1997; accepted 21 January 1998)

Abstract—The crystal and molecular structure of a dinuclear copper(II) complex with 3,4,9,10-perylenetetracarboxylic acid (H_4ptca) and ethylenediamine (en) $[Cu_2(en)_4(\mu\text{-ptca})](EtOH)_2(H_2O)_6$ has been determined by X-ray structural analysis. Each copper atom is coordinated by four nitrogen atoms of two en molecules , one oxygen atom of bridging $ptca^{4-}$ and one water molecule in an octahedral arrangement. The resulting dinuclear copper(II) complex forms two-dimensional network through intermolecular hydrogen bonds between carboxylate of $ptca^{4-}$ and the water. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) complex; 3,4,9,10-perylenetetracarboxylic acid; ethylenediamine; hydrogen-bonding network.

A unique network structure of metal complex polymer is designed by covalent bonds, some weaker intermolecular interactions such as hydrogen bonds, π–π stacking and S···S contacts. The hydrogen bonding of the interaction plays an important role in designing and creating a variety of molecular architectures for molecular self-assembly and molecular recognition in chemical, physical, and biological sciences [1]. Etter's work provides useful structural generalizations and predictive guidelines for patterns of solid-state hydrogen-bonded networks [2]. The types of hydrogen bonding in the metal complex polymer with carboxylate group can be classified as Fig. 1 and Table 1 according to their coordination environment: (A) acting as a bidentate ligand to coordinate one metal atom in the formation of four-membered chelate rings; (B) acting as a bidentate ligand to coordinate one metal atom through hydrogen bond (L = H_2O,

In this paper, we report the crystal structure and physical properties of the copper(II) perylenetetracarboxylic acid ($ptca^{4-}$) complex with hydrogen bonding of type C and D. Our interests in two and three-dimensional polymers of metal ions interconnected by aromatic ligands with novel stereochemistry and unique physical properties led to the study of the preparation and structure determination of this complex reported herein.

EXPERIMENTAL

Preparations were performed using the usual Schlenk techniques. All solvents were dried and distilled by standard methods before use. The standard chemicals were obtained from Wako Chemical Co., Japan, and used without further purification. IR spectra were measured as KBr disks on a JASCO FT/IR-8000 spectrometer. ESR spectrum was recorded on a JES-TE200 spectrometer. UV-Vis spectrum was recorded on an Hitachi 150-20 spectrophotometer. ^1H NMR were obtained with a JEOL GSX-270 FT-NMR spectrometer at 23°C. Tetramethylsilane was used as an internal reference.

Synthesis of H_4ptca [8]

A solution of 0.85 g (15.1 mmol) of 85% potassium hydroxide in 150 ml water in a 500 ml beaker is heated to 70–80°C, and 1 g (2.6 mmol) of commercial 3,4,9,10-perylenetetracarboxylic acid dianhydride is stirred in. The pH of the resultant deep-green solution is adjusted to a value of 7 and 6N hydrochloric acid and 3N potassium hydroxide. It is treated with 5 g of decolorizing carbon and filtered. This operation is repeated. The filtrate is heated to 80–90°C and acidified with concentrated hydrochloric acid to pH 1. 3,4,9,10-perylenetetracarboxylic acid precipitates. It is separated from the hot mixture by filtration or centrifugation. It is then suspended in 500 ml of water at 90–95°C, separated by filtration, and washed successively with 300 ml of water, 300 ml of 50% ethanol, and 300 ml of 90% ethanol. After being dried at 80°C/2 mm Hg in a vacuum oven, the 3,4,9,10-perylenetetracarboxylic acid weighs 0.7 g (64%). It does not melt by 300°C.

IR data (KBr, 4000–400 cm^{-1}): 3445 (m broad), 3001 (m, broad), 2658 (m, broad), 1695 (s), 1435 (m), 1396 (w), 1371 (w), 1284 (s).

Preparation of metal complex

Crystals of $[Cu_2(en)_4(\mu\text{-}ptca)](EtOH)_2(H_2O)_6$ suitable for single crystal X-ray analysis were obtained by reaction of $Cu(CH_3COO)_2$ (5 mM) and H_4ptca (10 mM) in an en/water (1/5) aqueous solution (8 ml); the pH of the solution was unadjusted. The mixture was stirred and then filtered. The filtrate and the diffusion solvent, EtOH, were sealed in a glass tube and after standing for one week at room temperature, brown plate crystals were obtained.

IR data (KBr, 4000–400 cm^{-1}): 3304 (s), 3215 (s), 3138 (s), 2964 (m), 1591 (s), 1560 (s), 1412 (m), 1385 (m), 1352 (s), 1043 (m).

X-ray structure determination

Crystal data. $C_{18}H_{32}N_4CuO_8$, M = 496.02, monoclinic, space group $P2_1/c$, $a = 8.538(2)$, $b = 11.361(2)$, $c = 23.019(3)$ Å, $\beta = 97.60(2)°$, $V = 2213.1(6)$ Å^3, $Z = 4$, $D_c = 1.488$ g/cm^3, $\lambda(Mo\text{-}K_\alpha) = 0.71069$ Å, $\mu = 10.34$ cm^{-1}, $F(000) = 1044.00$.

A single crystal of dimensions $0.20 \times 0.20 \times 0.30$ mm was mounted with paraffin on a thin glass fibre. Intensity data were measured on a Rigaku AFC-5R four-circle diffractometer by an ω-2θ scan at 23°C and

were corrected for Lorentz and polarization effects. Empirical absorption corrections were applied. A total of 5697 reflections for which $2\theta_{max} = 55.0°$ were collected. Of these data 5349 were unique.

The structure was solved by the direct method (MITHRIL) [9] and refined anisotropically for non-hydrogen atoms by block diagonal least-squares calculations. Reliability factors are defined as $R = \Sigma(F_o - F_c)\Sigma F_o$ and $R_w = \{\Sigma w(F_o - F_c)^2 \Sigma w F_o^2\}^{1/2}$, where $w = 4F_o^2\sigma(F_o^2)$. Atomic scattering factors and anomalous dispersion terms were taken from the *International Tables for X-ray Crystallography*, Vol. IV [10]. All calculations were performed on a micro VAX computer using the TEXSAN crystallographic software package [11]. The final R and R_w values are 0.063 and 0.076, respectively. The details of the X-ray data collection, structure solution and refinement, a full set of bond lengths and angles, thermal parameters, and complete F_c and F_o tables are available from authors.

RESULTS AND DISCUSSION

The final atomic coordinates for non-hydrogen atoms and equivalent thermal parameters are given in Table 3; selected bond lengths and bond angles in Table 4, respectively. Figure 2 shows the perspective view and atom labeling scheme of a segment of the structure.

The molecule has a distorted octahedral geometry about the central copper atom. The carboxylic oxygen

atom and aqua-oxygen atom occupy the axial positions while the equatorial plane is formed by four nitrogen atoms of two en molecules. The greatest deviations from ideal octahedral geometry are found for the O(2)—Cu—O(5*) angle of 171.7(2)° and Cu—O(2) and Cu—O(5*) distances of 2.461(4), 2.568(4) Å, respectively. The coordination mode of $ptca^{4-}$ is of special interest. Among the four carboxylate groups of $ptca^{4-}$, two form coordination bonds to different copper atoms as a bidentate, respectively (type C, O—H···O 2.760 Å), and the remaining groups form hydrogen bonds to water molecules coordinated with copper atoms, (type D, O—H···O 2.779 Å). All the hydrogen bond distances of O—H···O, Table 5, are as expected [7]. The total result of this hydrogen-bonding gives rise to two-dimensional infinite arrangement. However, the close distances between perylenes is 10.75 Å, indicative of negligible interactions of π–π stacking due to the long separations. The molecular packing of this complex is shown in Fig. 3. Interatomic distances and angles of $ptca^{4-}$ are within the range of values previously

reported for perylene [12]. The benzene ring is planar with the maximum deviation of 0.0207 Å. Each plane of the carboxylate group is twisted out of the plane of the benzene ring ca 50°.

These twists and deviations might be due to the repulsion of the oxygen atoms of the adjacent carboxylate groups, and also to the formation of the hydrogen-bonding network, as was discussed. The C—O distances in the present compound, ranging from 1.246 Å–1.267 Å, are not significantly different compared with those in M_3 (1,3,5-benzenetricarboxylic acid)$_2 \cdot 12H_2O$ (M = Co, Ni, Zn) complex [4].

The IR spectrum of the free H_4ptca molecule shows the C=O stretching band at 1695 cm^{-1}. Upon coordination with copper(II), this frequency shifts to 1591 and 1560 cm^{-1}. This indicates ionic coordination between copper(II) cation and $ptca^{4-}$ anion. Also, the N—H stretching band of en is shown at 3304, 3215, and 3138 cm^{-1}. The O—H broad stretching band is shown in range from 3360–3100 cm^{-1}. These data clearly show the formation of the complex and hydrogen-bonding. The solid state electronic spectrum of the complex has three bands at ca 422 nm, 443 nm, and 485 nm, and in comparison, free H_4ptca molecule shows a maximum at ca 500 nm with a broad slope in visible region. This shift of UV-Vis spectrum of the complex may be attributable to the ionic coordination and the hydrogen bond formation between $ptca^{4-}$ and water molecules. ESR spectrum for the crystal sample was measured at room temperature which shows a typical signal pattern for a monomeric copper(II) complex, indicative of negligible interactions of copper(II)-copper(II) due to the long separations of the metal ions (Cu—Cu distance 7.65 Å).

Electrical resistivity of compacted pellets was measured by the conventional two-probe technique. Although the complex behave as a semiconductor with conductivity of 4.6×10^{-5} S cm^{-1}, electrical resistivity of the complex increased with time and finally changed an insulator. This may mean that conductivity mechanism is ionic mechanism.

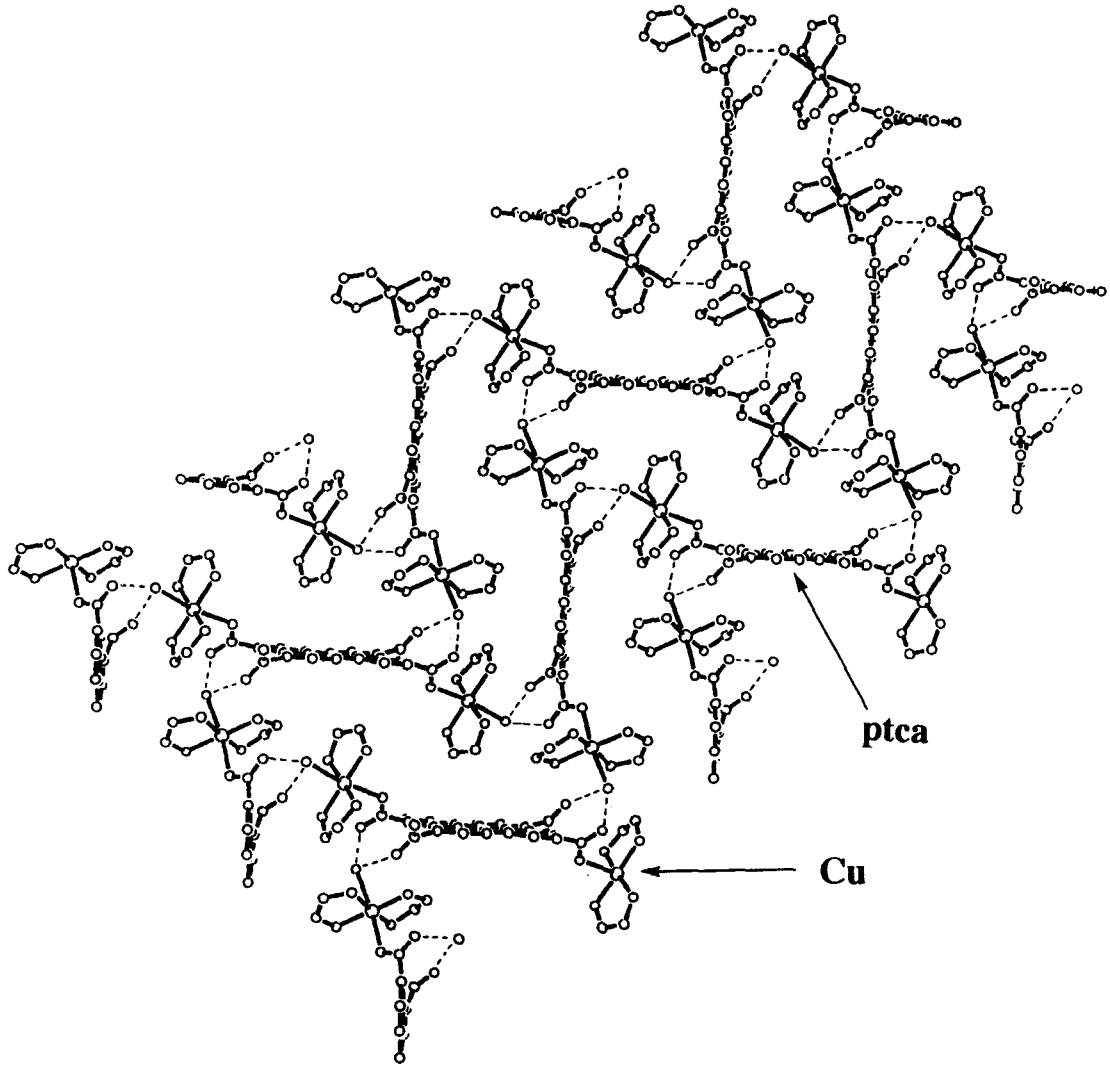

Fig. 3. Molecular structure of $[Cu_2(en)_4(\mu\text{-ptca})](EtOH)_2(H_2O)_6$ assembled by O—H···O hydrogen-bonds.

(Received 15 January 1998; accepted 19 January 1998)

Abstract—5′-Deoxyadenosyl-13-epicobalamin(Ado-13-epiCbl) is a coenzymatically active structural analog of coenzyme B_{12} (5′-deoxyadenosylcobalamin, AdoCbl) in which epimerization at the corrin ring C13 places the *e* propionamide side chain in an "upwardly" axial position. This would seem to bring the *e* side chain into direct steric contact with the adenosyl (Ado) moiety in its normal "southern" conformation (with the purine above the C ring) seen in the solid state for AdoCbl. Molecular mechanics calculations show that this conformation is the global minimum for AdoCbl, but that three other conformations represent local minima, including a "western", a "northern", and an "eastern" conformation, the last of which is known to be populated at room temperature from NMR studies. A structure for Ado-13-epiCbl has been generated by molecular dynamics/simulated annealing calculations starting from the neutron diffraction coordinates for AdoCbl after epimerization at C13. Molecular mechanics calculations on the resulting structure show that a "western" conformation is the global minimum, but that three other conformations, a "northern", an "eastern", and a "northeastern", are of relatively low energy and separated by relatively low energy barriers. The traditional "southern" conformation does not appear as a local energy minimum and is some 6 kcal mol^{-1} destabilized relative to the global minimum due to geometric distortions to relieve steric strain. Two-dimensional homonuclear NMR experiments show extraordinary conformational flexibility in Ado-13-epiCbl with 21 NOE crosspeaks between Ado protons and non-Ado protons, 50% more than in AdoCbl itself. Together with the calculated geometries for the four Ado-13-epiCbl conformers, these data suggest that at least three, and possibly all four of the conformers are populated at room temperature, in contrast to AdoCbl, in which only the "southern" and "eastern" conformers are populated under these conditions. Considering the enzymology of Ado-13-epiCbl, the inaccessibility of its "southern" conformation, and the activity of other AdoCbl analogs structurally modified in the Ado moiety, it is suggested that it may well be the "eastern" conformation, accessible to both AdoCbl and Ado-13-epiCbl, which is enzymatically active. © 1998 Elsevier Science Ltd. Keywords: Vitamin B_{12}; cobalamin; coenzyme B_{12}; conformation; NMR; molecular modeling.

The means by which 5′-deoxyadenosylcobalamin (AdoCbl)[1]-requiring enzymes "activate" this coenzyme (Fig. 1) by catalyzing the homolytic dissociation of its carbon-cobalt bond by as much as 10^{12}-fold (or higher) [2–6] remains an outstanding problem in vitamin B_{12} biochemistry of keen interest to chemists and biochemists alike. One of the most interesting, and potentially informative, aspects of coenzyme B_{12} enzymology is the fact that at least some AdoCbl-requiring enzymes† are quite promiscuous in terms of using structurally modified analogs of AdoCbl as active coenzymes. Thus, a number of AdoCbl analogs modified at the corrin ring side chains [8–12], on the

* Authors to whom correspondence should be addressed.

† It now appears [7] that AdoCbl-requiring enzymes will fall into two classes, one of which (apparently including the enzymes that catalyze carbon-skeleton rearrangements) shows much more stringent structural requirements for the coenzyme than the other.

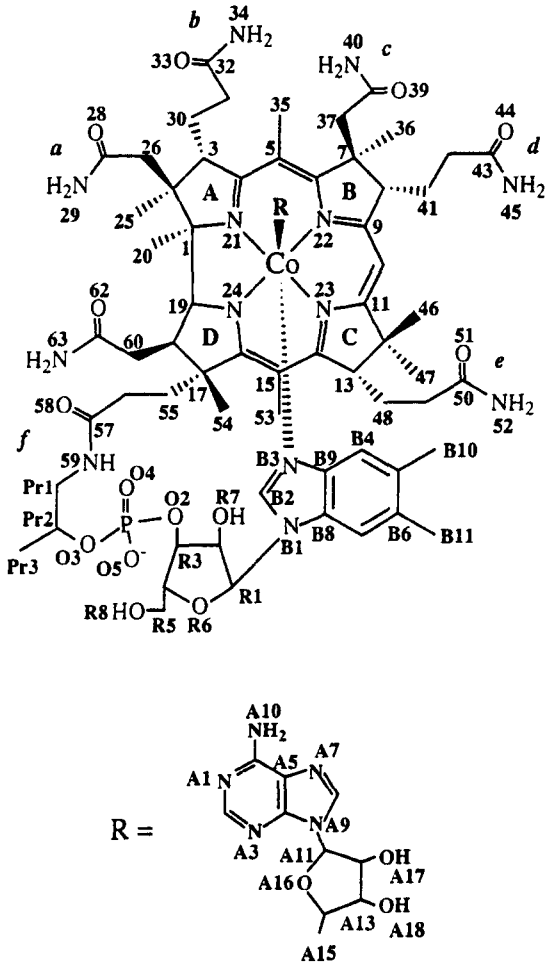

Fig. 1. Structure and numbering scheme of AdoCbl. In Ado-13-epiCbl, epimerization at C13 places the *e* propionamide side chain in an "upwardly" axial position.

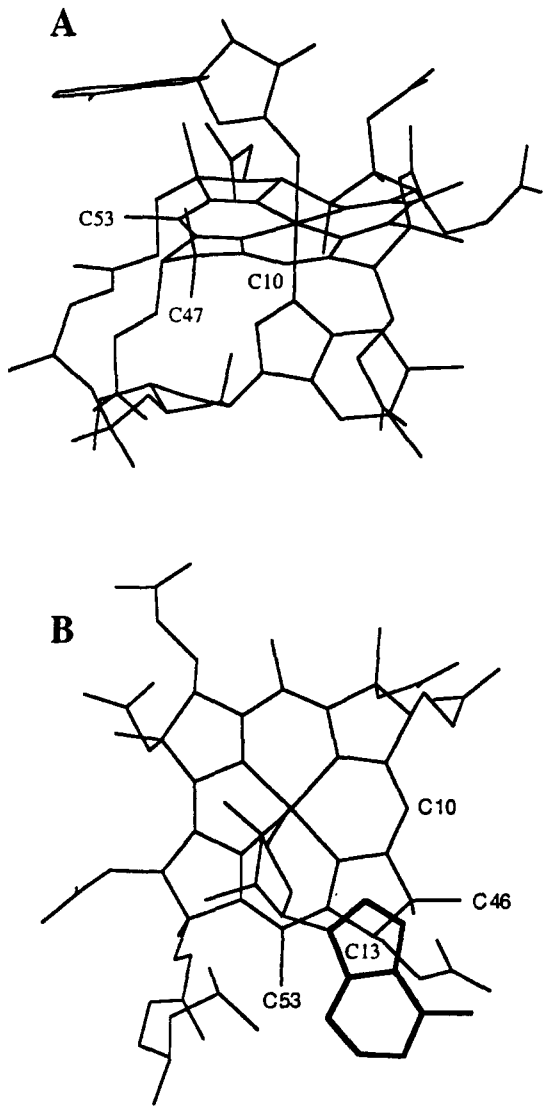

Fig. 2. A. Line drawing of the neutron diffraction structure of AdoCbl (reference 13a) showing the disposition of the adenosine moiety from the "eastern" perspective. B. Top-down view of the same structure of AdoCbl showing the adenine moiety in the "southern" conformation. The axial Bzm ligand has been removed for clarity.

corrin ring itself [13, 14], in the nucleotide loop [8, 15, 16], and in the adenine moiety itself [8, 17–19], are active coenzymes (although others are not), albeit with reduced coenzymic activity. These active analogs potentially have much to tell us about the mechanism(s) by which the B_{12}-requiring enzymes "activate" AdoCbl.

One of the most intriguing of the active AdoCbl analogs is the C13 epimer, Ado-13-epiCbl (Fig. 1), in which the *e* propionamide side chain adopts an "upwardly" axial configuration. This is the case because of certain peculiarities of the structure of AdoCbl. In all of the available crystal structures of AdoCbl [20–25], the conformation of the adenosyl moiety with respect to the remainder of the complex is as shown in Fig. 2. In this universal conformation, the five-membered ribose ring is roughly perpendicular to the corrin macrocycle, pointing towards C15, while the adenine purine is nearly parallel to the corrin ring and deployed over its "southern" quadrant. Molecular mechanics calculations [26–28] have shown, however, that while this "southern" conformation is indeed the global minimum, rotation about the Co–C bond leads to three other reasonably stable local minimum conformations in which the adenine is in the "eastern," "northern," or "western" quadrants. While earlier NMR data [29] had led to the proposal that an "eastern" conformations was, in fact, populated at room temperature, subsequent NMR work [28] showed that the "northern" and "western" conformations could only be populated at elevated temperatures as predicted by the molecular mechanics calculations.

In the 13-epicorrinoids [30, 31], epimerization at

C13 leads to twisting of the C pyrrol ring and an "upwardly" axial disposition of the *e* propionamide side chain, as seen in the X-ray crystal structures of CN-13-epiCbl [32, 33] and in the molecular mechanics calculations of this structure [26]. Since in the global minimum "southern" conformation of AdoCbl, the five-membered ring of the adenine moiety lies directly above the corrin ring C13 (Fig. 2B), it seems highly unlikely that Ado-13-epiCbl can adopt a "southern" conformation. If this is correct, the fact that Ado-13-epiCbl is a partially active coenzyme [14] would seem to suggest that a specific conformation of the Ado moiety relative to the remainder of the cobalamin is not required for catalytic activity. However, studies with AdoCbl analogs modified in the Ado moiety [17–19] suggest that this cannot be correct. This important work shows that the A7 ring nitrogen and the exocyclic primary amino group (A10) of the Ado moiety are essential for catalytic activity in diol dehydrase [18, 19], implying that these groups are specific association points with the enzyme active site, presumably via hydrogen bonding.

The coenzymic activity of Ado-13-epiCbl thus presents a potential dilemma, if it is indeed unable to adopt a normal "southern" conformation. Unfortunately, despite over a year of effort, Ado-13-epiCbl has stubbornly refused to crystallize, preventing an X-ray diffraction study. We have consequently performed the NMR and molecular mechanics study of Ado-13-epiCbl reported below, to address the issue of the conformation of this intriguing AdoCbl analog and confront the question of the importance of Ado conformation and coenzymic activity thus raised.

EXPERIMENTAL

CN-13-epiCbl[30, 31] was prepared from CNCbl and dry trifluoroacetic acid in the presence of 5% (v/v) trifluoroacetic anhydride as previously described [34]. 5′-Deoxy-5′-chloroadenosine was prepared from adenosine by the method of Kikugawa and Ichino [35]. Ado-13-epiCbl was prepared as follows. CN-13-epiCbl (100 mg, 0.074 mmol) was dissolved in 20 mL of 10% NH_4Cl solution. After purging with argon for 60 min, excess Zn wool, freshened by briefly stirring in 1.0 N HCl, was added and the reduction to 13-epicob(II)alamin was allowed to proceed for 60 min. In the dark, an excess of 5′-deoxy-5′-chloroadenosine in deaerated methanol was added, and the alkylation reaction was allowed to proceed overnight. After desalting on Amberlite XAD-2 and purification by HPLC [36–38], Ado-13-epiCbl was obtained in 85% yield (99.1 mg, 0.063 mmol).

NMR spectra were obtained using a Varian Unity Inova 500 MHz NMR spectrometer equipped with pulsed field gradients and operating at 499.899 MHz (^{1}H) and 125.709 MHz (^{13}C). The sample contained 20 mM Ado-13-epiCbl and TSP as an internal reference in 90% H_2O/10% D_2O. All NMR data was collected in the hypercomplex phase-sensitive mode except the HMBC data which were presented in absolute value mode. Data for the TOCSY experiments with watergate solvent suppression were collected into $2K \times 512$ data matrices using 32 scans per t_1 increment, preceded initially by 8 dummy scans. The sweep width was 5400 Hz and the spin-lock field strength was 8.8 kHz. The total spin lock period was 10, 20, or 70 ms. The data matrices were zero filled to $4K \times 4K$ and apodized with a shifted Gaussian function. The data for the watergate ROESY spectra were collected into a $3K \times 512$ data matrix with 64 scans per t_1 increment preceded initially by 64 dummy scans. The sweep width was 5400 Hz, the mixing time was 200 ms, and the spin-lock field strength was 2.5 kHz. The data matrix was zero filled to $4K \times 4K$ and apodized with a shifted Gaussian function. Data for the phase sensitive gradient enhanced HMQC spectrum were collected into a $4K \times 512$ data matrix using 32 scans, preceded initially by 64 dummy scans, over sweep widths of 9115 Hz (^{1}H) and 25,000 Hz (^{13}C). The matrix was zero filled to $4K \times 4K$ and apodized with a shifted Gaussian function. Data for the HMBC experiment were collected into a $2K \times 256$ data matrix using 128 scans, preceded initially by 8 dummy scans, using sweep widths of 5400 Hz (^{1}H) and 37,709 Hz (^{13}C) and a 1.0 s presaturation pulse. A 55 ms transfer delay and an 80 ms homospoil pulse were employed. The matrix was zero filled to $4K \times 4K$ and processed with a shifted Gaussian function.

We have previously described [26] a set of parameters for use with a modified version of the molecular mechanics (MM^1) program MM2(87) [39, 40] for modeling the cobalt corrinoids. We have recently begun to make increasing use of the version of MM2 available in the HYPERCHEM suite of programs and referred to as MM+ [41] because of the visualization graphics capabilities missing from Allinger's original program. The potential energy functions used in MM+ are virtually identical to those used in MM2, but metal ions are handled with a "points on a sphere" model [42]. We have modified [43] our original parameter set [26] to take this into account.

All calculations were performed using MM+ and the force field parameters for the cobalt corrinoids [43] on a 200 MHz PC. Geometry optimizations were carried out using a conjugate-gradient algorithm with a convergence criterion of 0.01 kcal mol^{-1} Å^{-1} r.m.s.d. in the gradient. The steric barriers to rotation of the alkyl ligand in AdoCbl were examined by driving the Co-bound alkyl ligand through 360° in steps of 5° with the starting coordinates those of the neutron diffraction structure of the coenzyme [21]. The dihedral angle, ω_1, chosen for this purpose was the N24-Co-A15-A14 angle, and rotation was performed both in a clockwise and counter-clockwise direction. At each value of ω_1, a full energy minimization was performed, and the structure with the lowest strain energy found at each value of ω_1 was chosen.

To study the possible conformations of Ado-13-

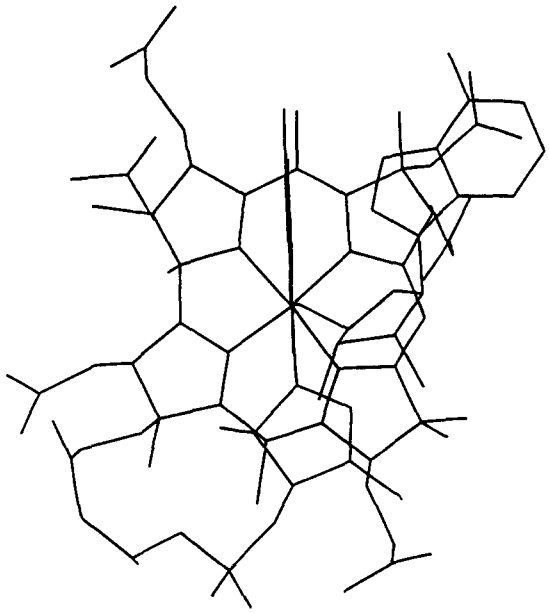

Fig. 3. Line drawing ("top" down perspective) of the structure of Ado-13-epiCbl calculated by the MD/SA procedure described in the text.

epiCbl, in which the *e* side chain at C13 has been epimerized from the lower (α) face to the upper (β) face of the corrin ring, the entire *e* side chain of the neutron diffraction structure of AdoCbl was moved from the lower to the upper face and the C13 proton was moved from the upper to the lower face using the molecular structure editing facilities of HYPERCHEM. The C ring was energy minimized, and the entire structure was then subjected to the following MD/SA procedure: heat from 300 K to 1000 K in 2 ps; run for 20 ps; cool from 1000 K to 300 K over 10 ps; full energy minimization. The annealed structure (Fig. 3) has the Ado ligand over the northeast corner of the corrin ring. This structure was then used as the starting structure for the rotational strain energy profile investigation of the Ado ligand, performed as described above for AdoCbl.

RESULTS

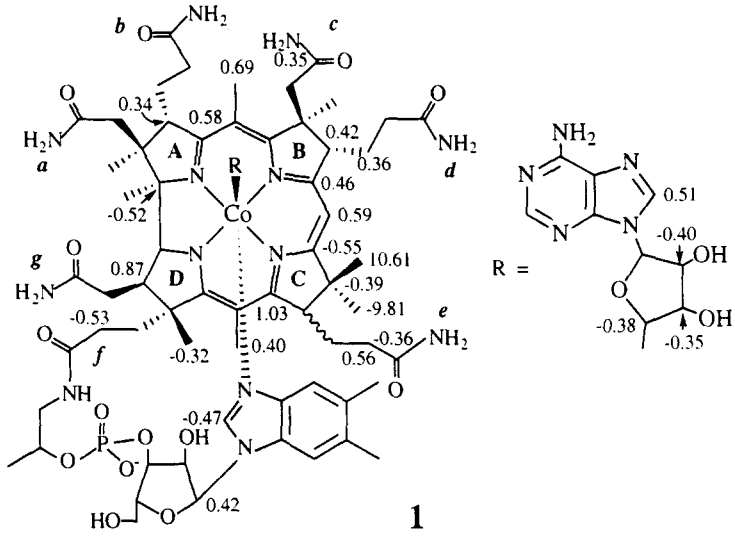
NMR assignments of Ado-13-epiCbl

The ^{1}H and ^{13}C NMR spectra of Ado-13-epiCbl were assigned (Table 1) using the now standard battery of homonuclear and heteronuclear 2D NMR experiments and assignment strategies detailed elsewhere [44, 45], except that the order of resonances in a given spin system was determined using a TOCSY experiment with a decreased spin-lock period (10 or 20 ms instead of 70 ms) rather than a COSY experiment.

The use of pulsed-field gradient solvent suppression in the homonuclear NMR experiments on an aqueous (10% D_2O) sample permits the observation and assignment of the resonances of the exchangeable amide hydrogens. These resonances were assigned from their proximity to ring and side chain hydrogens revealed in the ROESY spectrum using the assignment strategies previously employed for cobalt corrinoids in DMSO-d_6 [46–48]. Absolute assignment of the primary amide *syn* and *anti* protons could be made on the basis of stronger NOE cross peaks from the adjacent methylene protons to the *anti* proton than to the *syn* proton [49, 50]. For each amide except the *d* side chain amide, the *anti* proton was found to be the more downfield member of each pair of coupled amide protons. For the *d* amide, this order was reversed, and the chemical shifts of the *syn* and *anti* protons were much closer together than for the other amides, as is also the case for other Cbls in water [50]. No NOE crosspeaks were found for the *e* amide *syn* proton so it was assigned to the resonance at 6.81 ppm based on a correlation between this signal and that of the *e* amide *anti* proton in the TOCSY spectrum (and an anti-phase Hartmann-Hahn effect cross peak in the ROESY spectrum).

The ^{13}C NMR spectrum of Ado-13-epiCbl is similar to that of AdoCbl [33, 51] but with significant differences around the C pyrrol ring and elsewhere, as shown in **1**, below. By far the largest difference occurs for the C46 and C47 *gem* methyls attached to C12. In AdoCbl, these two resonances occur at 23.9 and 34.2 ppm based on HMQC correlations to ^{1}H signals showing NOE connectivities to C13H [51]. The more downfield ^{13}C resonance has been assigned [51] to the upwardly axial [21–24] C46 methyl group based on its HMBC correlation to C13H which is more strongly coupled to C46 due to their *cis* relationship. The equatorial [21–24] C47 is gauche to C13H and lacks an HMBC correlation to this proton. In addition, the ^{1}H resonance of the group assigned to the equatorial C47 has NOE cross peaks to one of the C48 protons and to the C49 protons, while the ^{1}H resonance of the group assigned to the axially upward C46 methyl lacks these, but has NOE correlations with the Ado protons on A11 and A14. In Ado-13-epiCbl, an HMBC correlation to C13H is seen only for the more downfield methyl at 33.4 ppm. In addition, the protons having an HMQC correlation to this carbon have no NOE correlations to the now upwardly pseudoaxial *e* side chain C48 and C49 methylene protons. However, the protons of an upfield methyl carbon at 23.2 ppm have NOE crosspeaks to both of the C48 methylene protons and to the A2 and A8 Ado protons. Hence, the ^{13}C chemical shifts of the C46 and C47 methyls are interchanged in Ado-13-epiCbl relative to AdoCbl, and the C46 resonance is now shifted upfield due to steric crowding by the C48 methylene.

Surprisingly, there is little difference between the ^{13}C chemical shifts of C13 in AdoCbl and Ado-13-epiCbl; the latter is very close to the chemical shift of C13 in CN-13-epiCbl [33]. Other differences seen in **1**



1

$\delta_{AdoCbl} - \delta_{Ado\text{-}13\text{-}epiCbl}$

include some quite remote from the site of epimerization and extending into the "northern" hemisphere, as was also the case with CN-13-epiCbl [33]. These differences might be associated with a larger corrin ring fold angle in the C13 epimer as seen in the X-ray structures of CN-13-epiCbl [33] and CNCbl [52]. In addition, there are several significant chemical shift differences between Ado-13-epiCbl and AdoCbl in the Ado moiety.

Molecular modeling of ado-13-epicbl

The variation in strain energy with rotation of the Ado ligand in AdoCbl was re-examined using the modified force field parameter set [43]. The results are given in Fig. 4 and are very similar to those obtained previously [26–28] except (i) the eastern (E) conformation is better defined; (ii) the position of the Ado ligand in the northern (N) conformation has been shifted in a clockwise direction by about 30°; and (iii) the western (W) conformation is somewhat higher in energy than before ($\triangle$E, the difference in energy between the western conformation and the global minimum found, the southern (S) conformation, is 3.8 kcal mol^{-1}, previously 1.8 kcal mol^{-1}).

The strain energy profile for rotation of the Ado ligand in Ado-13-epiCbl is shown in Fig. 5. The lowest energy structure has the Ado ligand over the western quadrant of the molecule, nestled above and between the *g* and *a* side chains. A large energy barrier separates this from the eastern conformation, where the Ado ligand's five membered ring is over C10. A small energy barrier separates the eastern from a northeastern conformation (NE) with Ado over C7, and another small barrier leads to the northern conformation in which the Ado is somewhat to the left of C5 when viewed from above.

We have previously shown [27] that there are 32 structures, each with a particular set of orientations of the side chains, which account for $\gtrsim$99.9% of the population of an alkylcobalamin at 300 K. The alkyl ligand in Ado-13-epiCbl was set to, but not constrained to, each of the four lowest energy conformations identified in the strain energy profile (Fig. 5), and the complex was energy-minimized in each of the 32 lowest energy side chain conformations. A Boltzmann distribution was then performed over all such energy-minimized conformations at 300 K. Those conformations with $\gtrsim$0.1% of the population were taken to be significant, and the Co–C bond length and Co–C–C bond angle determined as a population-weighted average; the values found were Co–C = 2.040(17) Å and Co–C–C = 126.8(2.7)°. For comparison, the same technique applied to AdoCbl gave Co–C = 2.039(18) Å and Co–C–C = 123.3(1.0)° (while the solid state values [21] are 2.039 Å and 120.7°, respectively).

The nucleotide loop in the structure of Ado-13-epiCbl obtained from the MD/SA procedure (Fig. 3) is in a different conformation to that in AdoCbl (Fig. 2) [20–24]. We have recently shown in our NOE-restrained MD/SA calculations on the solution structure of CNCbl [53] that a range of conformations is accessible to the nucleotide loop. These range from an "outward" conformation where the *f* side chain orientation is such that the O58 carbonyl oxygen lies beneath C60 and points outward, towards the southwest, the phosphate is beneath and somewhat

between C17 and C53, and the ribose R4 is beneath C14, close to the C ring, to an "inward" conformation in which the O58 carbonyl oxygen points to the southeast, towards C53 and the *e* side chain, the phosphate is tucked in below C57, and the ribose R4 is beneath C53. Although the "outward" nucleotide loop conformation, calculated here for Ado-13-epiCbl, is somewhat unusual as far as the solid state structures of Cbls are concerned, it is not without precedent. Fig. 6 shows two views of the superposition (at the D ring) of 15 Cbl crystal structures. Fourteen of these have the nucleotide loop in the "inward" conformation, but one, the recently reported 10-chloro-aquacobalamin structure [54] (bold line), has the "outward" conformation, demonstrating that Cbls can crystallize in this nucleotide loop conformation. Our calculations [54] show that there is little energy difference between these conformations.

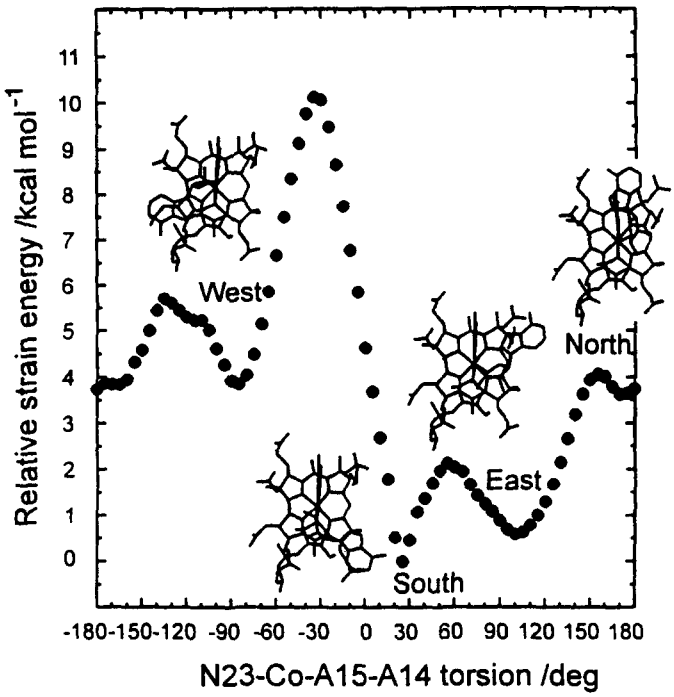

Fig. 4. Strain-energy profile for rotation of the Ado ligand of AdoCbl about the Co–C bond by driving the N24-Co-A15-A14 torsion angle. Line drawings of energy-minimized structures of each of the local minima are also shown.

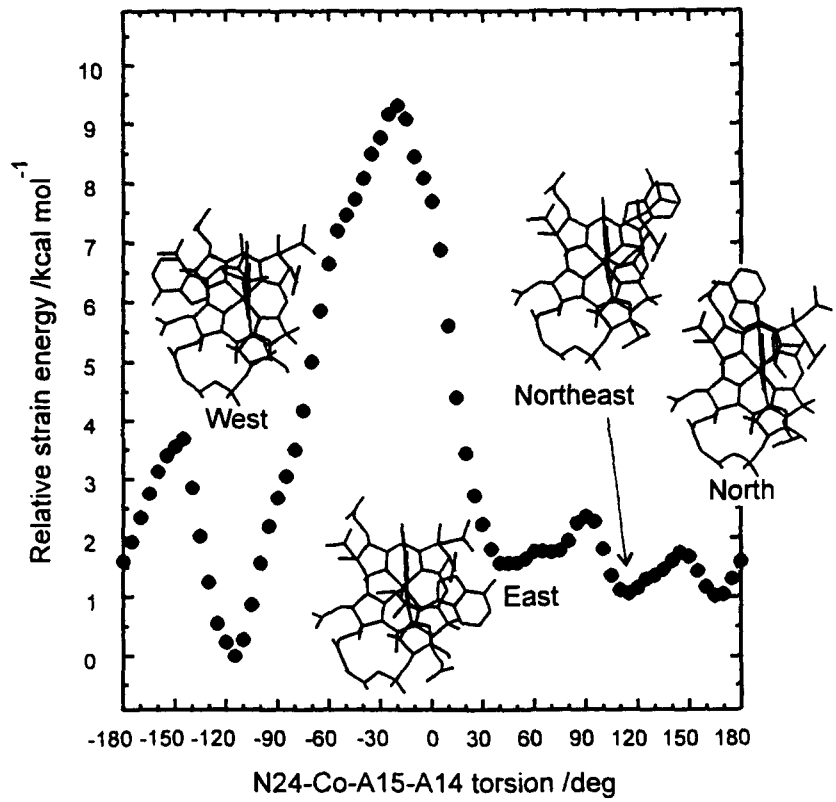

Fig. 5. Strain-energy profile for rotation of the Ado ligand of Ado-13-epiCbl about the Co–C bond by driving the N24-Co-A15-A14 torsion angle. Line drawings of energy-minimized structures of each of the local minima are also shown.

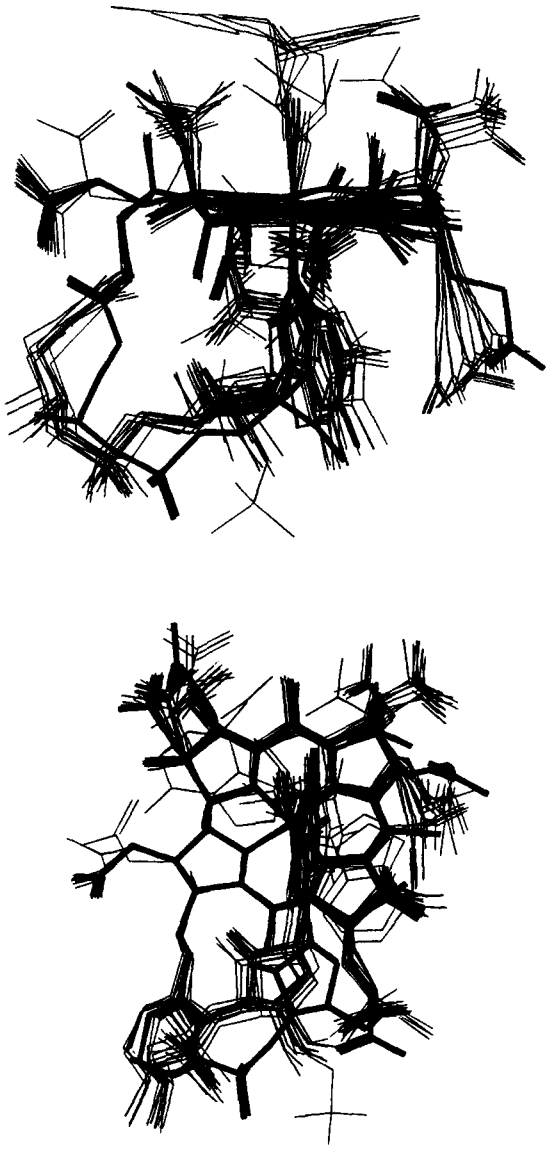

Fig. 6. Superposition (at the D ring) of 15 solid state structures of cobalamins showing that most adopt the "inward" nucleotide loop conformation, but one, 10-chloro-aquacobalamin(bold line) adopts the "outward" nucleotide loop conformation (see text).

[a]Distance between the indicated hydrogen in the energy-minimized molecular mechanics structures. For methyl and methylene protons, the closest distance is given. Distances $\lesssim$4.8 Å are shown in boldface.

NMR analysis of Ado-13-epiCbl conformation

Table 2 shows the NOEs observed at 500 MHz between Ado and non-Ado protons for Ado-13-epiCbl at 25°C, along with the calculated inter-proton distances for each NOE in each of the four stable conformations. These data are extraordinary in that many more such NOEs (21) are observed for Ado-13-epiCbl than could be observed (9 at 500 MHz [29], 12 at 600 MHz [26], for 14 total [28]) for AdoCbl itself. Assuming that at the current field strength, observation of an NOE requires an inter-proton distance of less than about 4.8 Å, only a single NOE, A11-C54, is not accounted for by the current calculations. This NOE is most likely due to the eastern conformation if the inter proton distance for this conformation is slightly shorter than the current calculations suggest. Many of the observed NOEs are compatible with two or more of the calculated conformations. However, importantly, three NOEs (A11-C49′, A8-C46, and A2-C46) are compatible only with the eastern conformation, three (A11-C26′, A8-C54, and A2-C26″) are compatible only with the western conformation, and one (A8-C26″) is compatible only with the northern conformation.

DISCUSSION

The largest differences in ^{13}C chemical shift between Ado-13-epiCbl and AdoCbl occur at the C46 and C47 methyls, which generally appear near 34 and 22 ppm, respectively, in the normal cobalamins. The upfield displacement of the ^{13}C resonance of the equatorial C47 methyl in the normal Cbl's has been attributed [33] to steric crowding [55–58] by the pseudoaxially downward *e* side chain. In the 13-epicorrinoids, these *gem* dimethyl substituents are displaced by the epimerization at C13, so that C46 becomes equatorial

and *gauche* to C13H and C47 becomes downwardly axial and *cis* to C13H [32, 33]. Consequently, it is the equatorial C46 which is sterically crowded by the now pseudoaxially upward *e* side chain, so that its ^{13}C resonance is shifted to high field.

The strain energy profile for rotation of the Ado ligand about the Co–C bond in Ado-13-epiCbl (Fig. 5) predicts four conformations of relatively similar energy, with a western conformation as the global minimum. There is a local minimum at $\omega_1 = 40°$, quite close to the value ($\omega_1 = 25°$) for the global minimum southern conformation for AdoCbl (Fig. 4). However, care must be exercised in comparing Figs 4 and 5. Although the southern conformation of AdoCbl and the eastern conformation of Ado-13-epiCbl appear to be close on the ω_1 axis, the orientations of the Ado ligands are quite different. In AdoCbl, the southern conformation has the Ado ligand over the C ring (as it is in the crystal structures [20–25] while in the eastern conformation of Ado-13-epiCbl, the imidazole ring of the Ado ligand lies over C10 (Fig. 5). Hence, the ω_1 dihedral angle is not necessarily a definitive indicator of the position of the Ado ligand when *different* structures are compared. This is due to flexibility in the Ado ligand itself. Thus, the N24-Co-A15-A14, Co-A15-A14-A16, and A15-A14-A16-A11 torsion angles in the southern conformer of AdoCbl and the eastern conformer of Ado-13-epiCbl are 25° and 40°, 72° and 84°, and 156° and 132°, respectively. This type of internal flexibility in the Ado ligand is responsible for the different disposition of the adenine moiety in the southern conformation of AdoCbl and the eastern conformation of Ado-13-epiCbl, despite the similarity of the ω_1 values for these two conformations. The conformation of Ado-13-epiCbl in which the adenine moiety is in the same position over the C ring as in the southern conformation of AdoCbl occurs at $\omega_1 \approx 10°$, and is consequently some 6 kcal mol^{-1} higher in energy than the global minimum conformation (Fig. 5). In this truly southern conformation of Ado-13-epiCbl, there is considerable distortion to relieve steric contacts with the upwardly-projecting *e* side chain. The Co–C–C bond angle increases to 131.4°, the Co–C bond angle lengthens to 2.084 Å, the C ring becomes planar, and both C46 and the *e* side chain are forced downward into pseudo-equatorial positions. Thus, the conformation of Ado-13-epiCbl in which the adenine has the same spatial orientation as that in AdoCbl is a highly distorted structure due to steric repulsions between the *e* side chain and the adenine.

NOE crosspeaks between Ado protons and protons elsewhere in the molecule in homonuclear 2D NOE spectra have been used to infer conformation in AdoCbl [28, 29]. The original analysis of these NOE's by Bax, *et al* [29], led to the discovery of an eastern conformation for AdoCbl, populated at room temperature, since several NOEs between Ado and non-Ado protons were incompatible with the southern conformation of the neutron diffraction structure [21]. Subsequent NMR studies at elevated temperatures [28] revealed additional NOE's which were incompatible with both the southern and eastern conformations of AdoCbl, and suggested that the northern, and possibly the western conformations could be populated as well at elevated temperatures.

For Ado-13-epiCbl, there are far more NOE's between Ado and non-Ado protons observed at room temperature, and many of these are compatible only with comformations other than the global minimum western conformation (Table 2). We conclude that Ado-13-epiCbl is substantially more conformationally flexible than AdoCbl with respect to the disposition of the Ado ligand. Evidently at least three of the conformations (eastern, western, and northern) are populated at room temperature, and, judging from the rotational strain energy profile (Fig. 5), most likely all four of the conformers contribute significantly at ordinary temperature. These results strongly suggest that while Ado-13-epiCbl is a highly conformationally mobile molecule, it cannot adopt the well-known southern conformation associated with AdoCbl in the solid state [20–25] and in solution [26–28]. Thus, the known catalytic activity of this AdoCbl analog [14] raises important questions regarding the conformation of the catalytically active species at the enzyme active site, and, indeed, even the importance of AdoCbl conformation to activity.

One possible explanation for the coenzymic activity of Ado-13-epiCbl is that the enzyme enforces a catalytically active southern conformation on this analog, using binding energy to overcome the substantial steric strain inherent in this conformation for Ado-13-epiCbl. Studies of vitamin B_{12} binding proteins show that proteins are capable of binding cobalamins extraordinarily tightly, with the release of as much as 23 kcal mol^{-1} of binding free energy [59–63]. However, AdoCbl-requiring enzymes bind AdoCbl many orders of magnitude less tightly.* Consequently, substantial binding energy may well be available for ground state distortion of the coenzyme.

The loss of AdoCbl-enzyme binding energy upon epimerization at C13 can be estimated using Fersht's work on the thermodynamics of the association of substrate analogs with enzymes and of substrates with mutant enzymes [67–69] and Toraya's data [14] for the activity of Ado-13-epiCbl with diol dehydrase. The value of $\triangle\triangle G_b = -RT \ln [(k_{cat}/K_m)_{Ado\text{-}13\text{-}epiCbl}/(k_{cat}/K_m)_{AdoCbl}]$ for diol dehydrase is then 2.7 kcal mol^{-1}. The MM calculations described above suggest

* For instance, the K_m for AdoCbl with the diol dehydrase of *Aerobacter aerogenes* [9] is 0.99 μmM, so that $K_b < 1.0 \times 10^6$ M^{-1} and $-\triangle G^\circ_b < 8.2$ kcal mol^{-1}, and the K_m for AdoCbl with the methylmalonylCoA mutase of *Propionibacterium shermanii* is 3.5×10^{-8} M [64, 65] so that $K_b < 2.9 \times 10^7$ M^{-1} and $-\triangle G^\circ_b < 10.2$ kcal mol^{-1}. For the ribonucleotide reductase of *Lactobacillus leichmanii*, the maximum binding constant for AdoCbl in the presence of the allosteric effector dGTP, is 5×10^3 M^{-1} ($\triangle G^\circ_b = -3.1$ kcal mol^{-1}) [66].

that this binding energy difference is insufficient to overcome the steric energy strain and enforce a traditional southern conformation on Ado13-epiCbl, for which this conformation is about 6 kcal mol^{-1} higher in energy than the global minimum conformation.

It is anticipated that Cbl side chain amide functionalities represent important hydrogen bonding contacts for the association of Cbls with proteins, since it is hard to imagine that the binding of CNCbl to haptocorrin could release nearly 23 kcal of free energy [63] without extensive hydrogen bonding contacts utilizing the side chain amides. The two existing X-ray structure determinations of the binding pockets of Cbl-requiring enzymes [70, 71], both show evidence of extensive hydrogen bonding to side chain amides, including, in one case, multiple H-bonded contacts to the *e* side chain. Unfortunately, in the X-ray structure of the methylmalonylCoA-AdoCbl complex [71], the Ado ligand is missing, so that important questions regarding AdoCbl conformation at an enzyme active site cannot be answered directly from this structure. Nonetheless, displacement of the *e* side chain amide from its normal position in the epimerized Ado-13-epiCbl must be expected to result in the loss of hydrogen bonding contacts. Thus, the 2.7 kcal mol^{-1} loss in binding energy to diol dehydrase upon *e* side chain epimerization, roughly the amount expected for two hydrogen bonds [72], is most likely attributable to the placement of the *e* side chain in an unnatural position in which hydrogen bonding amino acid residues are not available. Consequently, diol dehydrase is unlikely to force Ado-13-epiCbl into a southern conformation and such an enzyme-induced conformational change is unlikely to explain the catalytic activity of this coenzyme analog.

A second possibility to account for the coenzymic activity of Ado-13-epiCbl is that the disposition of the Ado moiety in AdoCbl is not important in enzyme catalysis. However, this would seem to contradict work with coenzyme analogs altered in the Ado moiety [8, 17–19], which suggest that specific interactions of the enzymes with specific structural features of the Ado ligand are essential for activity. Thus, Toraya and coworkers report that A1-deaza-AdoCbl and A3-deaza-AdoCbl (Fig. 1) are partially active coenzymes for diol dehydrase (56% and 46% as active as AdoCbl, respectively), but A7-deaza-AdoCbl and A10-*N*,*N*-dimethyl-AdoCbl are completely inactive competitive inhibitors [18, 19]. Yakusheva and coworkers have reported that A10-*N*-monomethyl-AdoCbl is a partially active coenzyme for the glycerol dehydrase of *Aerobacter aerogenes* with 12% of the activity of AdoCbl [8]. The most straightforward interpretation of these results is that the A7 endocyclic nitrogen and the A10 exocyclic amino group represent essential points of hydrogen bonding contacts with the enzyme and that the latter acts as a donor in two hydrogen bonds. Presumably, the atom substitutions at A1 and A3 in A1-deaza- and A3-deaza-AdoCbl alter the pK_a's at the A7 and A10 sites, lowering the strength of the essential hydrogen bonds, but not abolishing activity. If this interpretation is correct, then a specific conformation of the coenzyme is required at the active site to bring the essential A7 and A10 hydrogen bonding functionalities into juxtaposition with the putative active site amino acid residues which are their hydrogen bonding partners. This line of reasoning argues strongly against the possibility of conformational promiscuity accounting for the coenzymic activity of Ado-13-epiCbl.

It thus may be necessary to conclude that the traditional southern conformation of AdoCbl, always found in the solid state and calculated to be the global minimum, cannot be the coenzymatically active conformation at the enzyme active site. Since both molecular modeling and NMR studies show that an eastern conformation is of reasonably low energy and populated at ordinary temperatures for both AdoCbl and Ado-13-epiCbl, it is possible that it is the eastern conformation of AdoCbl which is the enzymatically active one. It is consequently most unfortunate that the recent X-ray crystal structure determination of methylmalonylCoA mutase [71] failed to reveal the Ado moiety of the bound coenzyme,* as it seems likely that only through such structural studies can this question be definitively answered.

* However, it should be pointed out that methylmalonylCoA mutase belongs to the class of AdoCbl-requiring enzymes that have stringent structural requirements for the coenzyme [7]. The possibility that this enzyme, and the other mutases, has different conformational requirements for AdoCbl conformation and different mechanisms of coenzyme activation than the dehydrases and the AdoCbl-dependent ribonucleotide reductases is quite real.

Redox properties of 17-electron thiolate complexes of cyclopentadienyl iron (III)

C. Díaz,* E. Araya and M. A. Santa Ana

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Casilla 653 Santiago, Chile

(Received 12 January 1998; accepted 15 January 1998)

Abstract—The redox electrochemistry of iron (III) thiolate complexes of the type [CpFe(dppe)-SR]PF_6 R = CH_3, C_3H_7, C_6H_5, p-C_6H_4Br and thiobenzothiazole has been examined by cyclic voltammetry, coulometry and spectroelectrochemistry methods. Four redox waves were observed in the range −1.5 to +1.5 V (S.C.E) in CH_2Cl_2. Around 0.0 V the metal centered reduction Fe (III)→Fe (II) process was observed, while that around +0.5 V the wave observed was attributed to a ligand centered oxidation. Strongly irreversible waves of oxidation near 1.3 V were assigned to the oxidation of RSSR while a reduction wave also strongly irreversible at very high negative potential was attributed to the reduction of the RSSR free ligand, RSSR + 2e→2RS^-. The redox wave observed for the disulphides compounds are discussed in terms of a reductive elimination of RSSR. Chemical and electrochemical reduction of the complexes [CpFe(dppe)-SR]PF_6 was accomplished by the color changes blue → red-brown characteristic of the redox change 17e→18e. © 1998 Elsevier Science Ltd. INTRODUCTION

The chemistry of transition metal thiolates is currently attracting considerable attention, largely as a result of the possible significance of such complexes in metalloenzyme systems [1–3].

Electron transfer processes on metal complexes containing sulfur ligands are very important for the understanding of redox processes occurring at the thiolate-coordinated metal ions in the active sites of several redox-active enzymes [1–3]. Specifically iron-sulfur thiolate bonds are involved in important metalloproteins [3].

Among the known metal-thiolate compounds, those of iron [3] are relatively more abundant than those of other metals [1, 2]. Although there are now several well-demonstrated methods for synthesizing iron (II)-thiolate compounds [2], few iron (III)-thiolate complexes have been reported [4–6]. We have recently reported a general method of obtaining cyclopentadienyl-iron (III) thiolate complexes in a simple step, starting from the organometallic precursor CpFe(dppe)I and the disulfide RSSR [4, 5].

$$2\text{CpFe(dppe)I} + \text{RSSR} \xrightarrow[\text{CH}_3\text{OH}]{\text{NH}_4\text{PF}_6} 2[\text{CpFe(dppe)SR}]\text{PF}_6 \quad (1)$$

As previously suggested[6], the formation of the iron (III)-thiolate complexes from the iron (II) precursor involves an intramolecular electron-transfer reaction in the intermediate disulfide complex

$$2\text{CpFe(dppe)I} + 2\text{RSSR} \xrightarrow[\text{CH}_3\text{OH}]{\text{NH}_4\text{PF}_6} 2[\text{CpFe(dppe)RSSR}]\text{PF}_6 \quad (2)$$

$$2\text{CpFe}^{\text{II}}\text{(dppe)RSSR} \rightarrow 2\text{CpFe}^{\text{III}}\text{(dppe)} - \text{SR}^+ + \text{RSSR} \quad (3)$$

Fe (III)-thiolate complexes have also recently been obtained by oxidative-addition of thiols to CpFe $(dppe)^+$ -fragment.

$$\text{CpFe(dppe)I} + \text{HSR} \xrightarrow[\text{CH}_3\text{OH}]{\text{NH}_4\text{PF}_6} [\text{CpFe(dppe)} - \text{SR}]\text{PF}_6 + [\text{H}] \quad (4)$$

(In this reaction the unidentified product containing the hydrogen thiol is denoted [H] see ref.[6]). It was

*Author to whom correspondence should be addressed.

suggested [4, 6] that this reaction occurs through the intermediate [CpFe(dppe)HSR]PF_6 which after an intramolecular electron transfer leads to the Fe (III)-thiolate product. The oxidative-addition described above for RSSR and RSH has been reported for other organometallic compounds [7].

Because of much of the chemical transformations involved in biological processes involve an electron-transfer process through a bond Fe-S, the redox behaviour of metal-thiolate complexes is essential, for the understanding of the mechanism of such processes.

Although the redox behaviour of molybdenum thiolates and other metal-thiolates have been examined [8, 9], few electrochemical studies on iron (II) and iron (III)-thiolate compounds have been reported [10, 11]. In this paper we describe the electrochemical behaviour of a series of iron (III)-thiolate complexes [CpFe(dppe)SR]PF_6, where R=CH_3, 1; C_3H_7, 2; C_6H_5, 3, C_6H_4Br, 4; thiobenzothiazole, 5.

RESULTS AND DISCUSSION

The electrochemical behaviour of the series of thiolates [CpFe(dppe)-SR]PF_6 was studied by cyclic voltammetry in CH_2Cl_2 solution. Almost all the complexes undergo a reversible (irreversible for 1 and 5) reduction in the range 0.1 V to −0.4 V. (see Fig. 1 and Table 1). The electron transfer associated with this redox process can be assigned to the reduction of the Fe (III)-thiolate complex CpFe(dppe)-$SR^+ + e \rightarrow$ CpFe(dppe)-SR. Thus, the cyclic voltammogram of [CpFe(dppe)-SC_6H_5] exhibits a one electron oxidation wave at −0.25 V corresponding to the Fe (II)→Fe (III) oxidation process [10]. On the other hand, the

complex $CpFe(PMe_3)_2SC_6H_5$ undergoes an oxidation process at -0.20 V [11]. Furthermore, metal thiolates of the type $Ln\ M(SR)^{+z}$ with the metal in an accessible higher oxidation state $Ln\ M\ (SR)^{+(Z+1)}$ in general, exhibit an initial oxidation metal based with $E_{1/2}$ values near 0 V [9]. Its appears to be that the high polarisable and soft thiolate ligand [1] induces a high electron density on the metal atom, which provokes a low facile oxidation of the thiolate complexes. This can be also due to the electron rich nature of the fragment $CpFe(dppe)^+$ [10, 12].

As expected the controlled potential coulometry confirm that the reduction of the complexes [CpFe(dppe)-SR] PF_6 is a one electron process. Data are shown in Table 1. This was also corroborated by UV-visible spectroscopy. The initial blue solution of the thiolate iron (III) complex turned yellow-brown after total electrochemical reduction. The UV-visible changes for $[CpFe(dppe)\text{-}S\text{-}C_3H_7]PF_6$ are shown in Fig. 2. Similar UV-visible spectral changes are observed in the chemical reduction using Red-Al as reducing agent as is shown in Fig. 3.

The second one electron oxidation wave observed in the cyclic voltammogram of the complexes (which is absent in complexes 2–4), can be assigned to a ligand based oxidation (reaction Eq. (6)) according to previous electrochemistry studies on metal-thiolate compounds [8, 9]. Cyclic voltammogram for complex 5 is shown in Fig. 4.

$$2CpFe(dppe)-SR \xrightarrow{solv} 2CpFe(dppe)Solv^+ + RSSR + e \quad (5)$$

In agreement with this suggestion we have detected in the cyclic voltammograms of the complexes 1–5, the typical oxidation of RSSR [9, 13] (peak E_3) in the range 1.1–1.3 V as well as their reduction at very negative potentials (termed peak E_4). Furthermore we have observed similar oxidation and reduction waves in the cyclic voltammetry of the free RSSR ligands as is shown in Table 2.

All these results are consistent with the scheme shown in Fig. 5, for the redox behaviour of the complexes [CpFe(dppe)-SR]PF_6. The absence of the oxidation peak E_2 for the complexes 2–4 can be due to the high stability of the Fe (II) species CpFe(dppe)-SR, which preclude the oxidation of the thiolate ligand. In fact the ip_a/ip_c ratio parameter value near 1 for these complexes, indicates a high chemical reversibility. In complexes 2–4 however in spite of that the peak 2 is not obseved, the peak corresponding to the

[a] Main peaks. For dithiobenzotiazole an oxidation peak was observed at 0.2 V. For C_3H_7-S-S-C_3H_7 a reduction peak at -0.5 V was also observed See ref [9]. and [13].

oxidation of the dithioether appears at ~ 0.5 V which suggest that the chemical equilibrium Eq. (6) could exist.

$$2CpFe(dppe)-SR^{+} \rightleftarrows 2CpFe(dppe)^{+} + RSSR \quad (6)$$

Reductive eliminations of RSSR as the shown in eq. (6) have been previously proposed in the formation of thiolate-bridged dimers of group 6B metals [14, 15]. Thus the 16e specie CpFe(dppe)(solvent)$^{+}$ has been detected by UV-visible spectroscopy [16].

EXPERIMENTAL

All solution manipulations were carried out under purified argon or dinitrogen. Compounds [CpFe(dppe)-SR]PF_6 where R = CH_3, C_3H_7, C_6H_5 and p-C_6H_4Br were synthesized as described previously [1, 6]. The new complex CpFe(dppe)-S-benzo-thiazol was prepared as follow:**[CpFe(dppe)-S-benzothiazol]PF_6**, CpFe(dppe).I 0.15 g (0.23 mmol) and 2,2′-Dithiobis (benzothiazole) 0.076 g (0.23 mmol) in the presence of NH_4 PF_6 1 g (0.69 mmol) where stirred in CH_3 OH (30 ml) for 24 h. After this time, the solvent was removed under reduced pressure until dryness and the solid extracted with dichloromethane, filtered through celite and the solution concentrated to c.a. 10 ml. Upon addition of a 1:1 n-hexane-diethyl ether mixture the precipitate, a dark-blue solid, was washed twice with the same mixture and the solid residue dried under vacuo. Yield. 0.11 g, 57%. Anal.: Found C 53.5 H 3.8 Calcd. Electrochemistry

The cyclic voltrammetry experiments were done with a PARC model 370 electrochemistry system in a specially designed three-electrode glass cell [17, 18]. The working electrode was a carbon glassy disk, the counter was a platinum wire, and the reference electrode an aqueous saturated calomel electrode (S.C.E.) connected to the working cell through a Luggin capillary placed ca. 1 mm from the working electrode. A 0.1 M $[Bu_4N]PF_6$ solution in CH_2Cl_2 was used as supporting electrolyte. Solutions were degassed with nitrogen and a nitrogen atmosphere was maintained

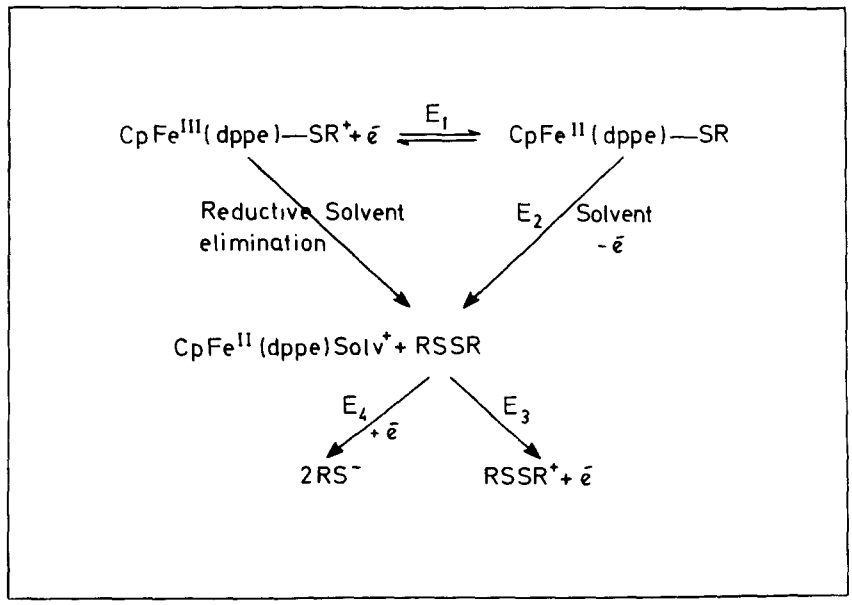

Fig. 5. Redox behavior of [CpFe(dppe)-SR]PF_6 complexes.

over the solution during the experiment. The peak potentials values reported were determined at the first cyclic voltammogram and referenced to the S.C.E.

Controlled potential electrolyses were carried out in the same supporting electrolyte solution using a three electrolysis cell (adapted from Figs 3.14 and 3.16 in ref.[17]) with a platinum gauze as cathode, a platinum wire counter electrode isolated from the working solution by a medium porosity glass frit. The saturated calomel electrode was introduced to the cell through a luggin capillary and placed near the cathode. The charge transfered in the electrolysis was determined with a PARC 179 digital coulometer.

Mononuclear palladium(II) complexes with the phenylselenolato ligand. The crystal and molecular structure of *trans*-[Pd(SePh)$_2$(P(*n*-Bu)$_3$)$_2$].

Elmer C. Alyea,* George Ferguson* and Shanmugaperumal Kannan

Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada, N1G 2W1.

(Received 5 January 1998; accepted 15 January 1998)

Abstract—Mononuclear palladium(II) complexes of the type [Pd(SePh)$_2$L$_2$] [where L = PMe$_3$, PEt$_3$, P(n-Bu)$_3$, PMePh$_2$ or TPA (1,3,5-triaza-7-phosphaadamantane)] have been prepared and characterized by elemental analysis, ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR data and in the case of [Pd(SePh)$_2$(P(n-Bu)$_3$)$_2$] by single-crystal X-ray diffraction methods. Crystals of [Pd(SePh)$_2$(P(n-Bu)$_3$)$_2$] are triclinic, space group $P\bar{1}$, a = 8.4798(7), b = 10.3002(15), c = 12.254(2)Å, α = 77.957(15), β = 85.806(11), γ = 83.550(9)°, Z = 1. The structure was refined by full-matrix least-squares calculations on F^2 to final R values R_{obs} = 0.0267 (for 3187 reflections with $I \geq 2\sigma(I)$) and wR(F^2) = 0.0657 (for all 4549 measured reflections). The structure determination shows that the Pd atom lies on an inversion centre so that the coordination geometry is necessarily *trans* and planar. Main bond lengths are Pd-P 2.3334(7) and Pd-Se 2.4609(4)Å. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: palladium-selenium bonding; phosphine ligands; crystal structure.

Transition metal organochalcogenide complexes are of significant current interest owing to their structural and chemical reactivity [1]. These complexes have attractive potential in material science [2] and in constructing model complexes for catalysis [3]. Pertinent to this work, a large number of mononuclear thiolato complexes of palladium(II), [PdX(SR)L$_2$] and [Pd(SR)$_2$L$_2$] have been prepared and characterized [4]. However the mononuclear complexes of palladium(II) with heavier organochalcogenides (SeR or TeR; R = alkyl or aryl group) have rarely been studied except for a few poorly characterized complexes [5], even though the corresponding platinum complexes are well established [6]. As a part of our work on the complexes of transition metal ions with heavier organochalcogenide ligands, we report here the complexes of palladium(II) with the phenylselenolato ligand and the first structurally characterized mononuclear palladium(II) complex containing an organoselenolato group, viz. *trans*-[Pd(SePh)$_2$(P(*n*-Bu)$_3$)$_2$].

RESULTS AND DISCUSSION

Preparation and characterization

The reaction of *cis*-[PdCl$_2$(L)$_2$] with NaSePh in dichloromethane /methanol yielded orange coloured mononuclear complexes [Pd(SePh)$_2$(L)$_2$] (equation 1).

$$[PdCl_2(L)_2] + 2NaSePh \rightarrow [Pd(SePh)_2(L)_2] + 2NaCl$$

(L = PMe$_3$, PEt$_3$, P(n-Bu)$_3$, PMePh$_2$ or TPA;

TPA = 1,3,5-triaza-7-phosphaadamantane)

The ^{31}P{^{1}H} MR of all the complexes showed a single resonance (Table 1), indicating that the complexes exist exclusively in one isomeric form (*cis* or *trans*). The ^{1}H NMR spectra of all the complexes have the expected peak multiplicities and integrations (Table 1). The phosphines containing a methyl group (PMe$_3$ and PMePh$_2$) show a virtual triplet in these spectra indicating that most likely the complexes exist exclusively in the *trans* isomeric form [6b, 7]. Similarly, the ^{13}C{^{1}H} NMR spectra of all the complexes show a characteristic triplet for the carbon attached to the phosphorus atom. Since the generality of this latter

observation relating the spectral pattern to the identification of *trans* vs. *cis* isomers is currently being explored [8], the $^{13}C\{^{1}H\}$ NMR spectral data will be discussed later together with that for a wide range of palladium-phosphine complexes. The chemical shift of the carbon attached to the 'Se' atom agrees well with the earlier reported values for related platinum complexes [6].

Crystal structure of $[Pd(SePh)_2(P(n\text{-}Bu)_3)_2]$

The molecular structure of the complex *trans*-$[Pd(SePh)_2(P(n\text{-}Bu)_3)_2]$ is shown in Fig. 1 and selected dimensions are given in Table 2. The Pd atom lies at an inversion centre and the coordination geometry is thus required to be *trans* and strictly planar. The planar coordination is not exactly square as the crystalographically unique P-Pd-Se angle is 93.58(2)°. The Pd-P and Pd-Se distances (2.3334(7) and 2.4609(4)Å respectively) agree well with the relevant values (2.323(2) and 2.456(1)Å respectively) reported [9] for *trans*-$[Pd(4\text{-}MeC_6H_4COSe)_2(PEt_3)_2]$. A search of the October 1996 release of the Cambridge Crystallographic Database [10] for further PdP_2Se_2 fragments only revealed two compounds [11], $\{Pd[Ph_2P(CH_2)_nPPh_2](SeCN)_2\}$, n=2 or 3, both with *cis*-stereochemistry and with Pd-P 2.275(2)-2.286(2)Å and Pd-Se 2.458(1)-2.488(1)Å. The Pd1-Se1-C11 angle (104.82(8)°) falls between the Pt-Se-C values (104.2(5), 107.1(5)°) reported [6b] for *trans*-$[Pt(SePh)_2(PPh_3)_2]$.

Reaction of NaSePh with $PdCl_2L_2$ (L = PPh_3 *or 0.5 Diphenylphosphinomethane (DPPM)*)

The reaction of NaSePh with $[PdCl_2L_2]$ (where L = PPh_3 or 0.5 DPPM) yielded brown coloured products, which showed many peaks in their ^{31}P NMR spectra. Either decomposition or polymerization of the mononuclear complexes apparently occurred. However the corresponding platinum complexes are very stable under similar reaction conditions [6a].

Reaction of $[Pd(SePh)_2(L)_2]$ (L = PMe_3, PEt_3, $P(n\text{-}Bu)_3$, $PMePh_2$ *or TPA) with Chloroform*

It was noticed that all the alkylphosphine complexes slowly decompose to give some insoluble brown solids, when solutions in $CDCl_3$ were kept for three to four days after recording the NMR spectrum. This shows clearly that the complexes are unstable in chloroform although they are stable in dichloromethane for several more days.

EXPERIMENTAL

Materials

Diphenyldiselenide and $[PdCl_2(PhCN)_2]$ were obtained from commercial sources (Aldrich). The complexes $[PdCl_2(L)_2]$ [12] and $[PdCl_2(TPA)_2]$ [13] were prepared according to literature methods.

Physical measurements

The ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra were recorded in $CDCl_3$ on a Varian Gemini-200 MHz instrument and the chemical shifts are relative to the internal chloroform resonance (at δ 7.26 ppm for ^{1}H and δ 77.0 ppm for ^{13}C). The $^{31}P\{^{1}H\}$ NMR spectra were

recorded in $CDCl_3$ on a Varian Unity-400 MHz instrument and the chemical shifts are relative to the external 85% H_3PO_4 resonance. C, H and N analyses were performed by M-H-W Laboratories, Arizona, U.S.A. Melting points were recorded in open capillaries and are uncorrected.

X-ray crystallography

Crystallographic data together with data collection and structure solution refinement details are given in Table 3. All non-H atoms were allowed anisotropic displacement parameters. The ORTEP [16] plot of the molecule is shown in Fig. 1.

Atomic coordinates, anisotropic displacement parameters and full details of molecular dimensions have been deposited with the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any requests to the CCDC for this material should quote the full literature citation and the reference number. These data are also available electronically in CIF format from the authors.

Preparation of $[Pd(SePh)_2(P(n\text{-}Bu)_3)_2]$

To a methanolic solution of PhSeSePh (0.538 g, 1.72 mmol), $NaBH_4$ in methanol was added slowly with constant stirring. Addition of $NaBH_4$ was stopped when a colourless solution of PhSeNa formed. To this a solution of $[PdCl_2(P(n\text{-}Bu)_3)_2]$ in dichloromethane (1.08 g, 1.72 mmol) was added and stirred for 5 h. The solvent was evaporated in vacuum, the residue was extracted with dichloromethane (20 mL) and the solution filtered. To the filtrate, 5 mL of methanol was added and the solution was kept for crystallization (yield 1.2 g, 85%). All the other complexes were prepared in an analogous manner and the pertinent data are given in the Supplementary Data as Table 4.

CONCLUSION

The reaction of $PdCl_2(L)_2$ (L = alkylphosphine) with NaSePh yielded the desired mononuclear palladium(II) complexes of the type $[Pd(SePh)_2L_2]$, which are stable in the solid state but decompose in chloroform, whereas the reaction involving L = PPh_3 or 0.5 DPPM gave no products which could be isolated.

Syntheses and reactions of tetrazole-group 13 complexes

Miguel-Angel Muñoz-Hernández, Michael S. Hill and D. A. Atwood*

Center for Main Group Chemistry, Department of Chemistry, North Dakota State University, Fargo, North Dakota, 58105-5516, U.S.A.

(Received 31 October 1997; accepted 15 January 1998)

Abstract—The combination of 5-phenyl-1-H-tetrazole (tet) with AlR_3 in stoichiometries of 1–3 leads to the compounds $[(tet)AlR_2]_n$ R = Me (**1**), Et (**2**), ^{t}Bu (**3**), $[(tet)_2AlMe]_n$ (**4**), and $[(tet)_3Al]_n$ (**5**). The addition of pyridine to **1** leads to a soluble compound with the formulation, $[(tet)AlMe_2\text{-pyridine}]_n$ (**6**). Likewise the addition of $AlMe_3$ to **1** and **4** leads to the products $[(tet)AlMe_2\text{-}AlMe_3]_2$ (**7**) and $[(tet)_2AlMe\text{-}AlMe_3]_n$ (**8**). The compounds were characterized by standard techniques and, in the case of **7** by X-ray crystallography. Compounds **1, 4** and **5** were examined (unsuccessfully) as potential unimolecular precursors to aluminum nitride.

Keywords: aluminum; tetrazole; precursor.

Interesting supramolecular assemblies have been obtained in combinations between tetrazole ligands and tin [1]. Otherwise the tetrazole ligands have had a limited usage with the main group elements. Past work has generally involved the formation, and subsequent reactions of the tetrazoles in the absence of metals [2]. The present work has two goals. The first is an exploration into the various compounds that are possible between this ligand system and alkylaluminum reagents. The second goal involves the use of selected tetrazole-aluminum compounds as unimolecular precursors to aluminum nitride. Recent work into group 13 nitride formation has focused on the use of nitrogen rich ligands to overcome a nitrogen deficiency in the resulting solid state materials [3]. The azide group, for instance, has been used with great efficacy in molecular combinations with alkyl- or amido-group 13 compounds [4]. The tetrazole ligand also contains an excess of nitrogen and should warrant similar consideration. It may be envisioned to decompose to aluminum nitride with the release of dinitrogen and benzonitrile. Unfortunately, the results presented herein will demonstrate that the tetrazole does not undergo this favorable decomposition, although some unique chemistry may yet be accessible.

RESULTS AND DISCUSSION

Synthesis and characterization

The tetrazole (5-phenyl-1-H-tetrazole) is combined with AlR_3 in a 1:1 stoichiometry to form the oligomeric (or polymeric) derivatives **1–3** in high yield. The polymer is formed due to the ability of the tetrazole ligands to form both covalent and (at least one) bridging coordinate covalent bond. This situation is demonstrated in the crystal structures of several supramolecular tin derivatives [1]. The solubilities of **1–3** increase in the order Me < Et < ^{t}Bu such that the ^{1}H NMR of the latter derivative can be taken in C_6D_6. Otherwise they must be dissolved in d_6-DMSO. The DMSO presumably acts to depolymerize the parent compound. The fact that **1, 4** and **5** have the same solubility in DMSO lends support to this supposition. The addition of two and three equivalents of tetrazole to $AlMe_3$ leads to compounds **4** and **5**, respectively. In the NMR the Al-Me resonances of **1** and **4** are similar (δ −1.06 and −1.02 ppm, respectively).

The intermolecular bridge-bonding in **1** can be disrupted by adding either a Lewis base, to coordinate to the aluminum atom, or a Lewis acid, to one of the remaining pairs of electrons on the tetrazole nitrogens. More specifically, the addition of pyridine to **1** leads to a compound having the general formula, $Me_2Al(tet)$-pyridine (**6**). Its Al-Me chemical shift is a singlet at δ -0.31 ppm. When $AlMe_3$ is added to **1** a dimeric compound results (**7**). Three of the tetrazole nitrogens are involved in bonding to an aluminum atom. The ^1H NMR spectrum contains two singlets at high field (δ -1.05 and -0.54 ppm) which can be attributed to the $AlMe_3$ and $AlMe_2$ groups, respectively.

Structural characterization

The molecular structure of **7** is shown in Fig. 1. It is dimeric with bridging tetrazole groups. This creates an Al_2N_4 six-membered ring that adopts a boat conformation. The two aluminum atoms are 0.63 Å (A11) and 0.52 Å (A12) above the plane formed by the four nitrogen atoms. This arrangement is very reminiscent of aluminum [5] and gallium [6] complexes of the pyrazolyl ligands. Indeed the structural parameters of the $[Me_2Al(tet)]_2$ core is isomorphous to that of $[Me_2Al(pyrazolyl)]_2$ [5]. The difference, of course, is that the tetrazole derivative features an additional two equivalent $AlMe_3$ units which are peripherally coordinated to a third tetrazole nitrogen. This interaction is presumably why a molecular species can be isolated from the polymeric parent.

Decomposition studies of compounds **1**, **4** *and* **5**. Thermogravimetric analyses of **1**, **4** and **5** indicated that the compounds decompose to eliminate N_2 in the range of 200–340°C with a weight loss in the range of 48–62%. In order to explore the possibility that these compounds might be suitable precursors for the low temperature deposition of aluminum nitride several experiments were conducted. First, the compounds (150 mg) were (individually) heated at 250°C for 12 h under static vacuum in a closed side arm flask. The IR of the remaining solids showed that organic material was present but not a stretching frequency corresponding to AlN (~ 700 cm^{-1}). Similar experiments to that described above were performed but heating the precursors under a flow of N_2 and H_2 and subsequently washing the remaining material with CH_2Cl_2 and toluene. The IR of the remaining solids using both gases also showed the remnants of organic material and the filtrates contained aryl resonances in the ^1H NMR but which could not be ascribed to benzonitrile. In an effort to completely remove the organic material from any aluminum nitride which might be forming the compounds were heated in a hot-walled pyrolysis unit at 500°C for 12 h under a flow of N_2 and in the same type of experiments, under a flow of H_2. Again, the IR spectra showed organic material remaining in the solid residues. Finally, **1** was heated at 200°C for 4 h in a sublimation apparatus. The solid which remained in the bottom of the flask showed a ^1H NMR spectrum identical to **1**. Conversely the sublimed material showed a completely different ^1H NMR. Full characterization of the sublimed material led to the conclusion that the molecules were indeed decomposing to eliminate N_2 but that the by-product of this decomposition was a stable

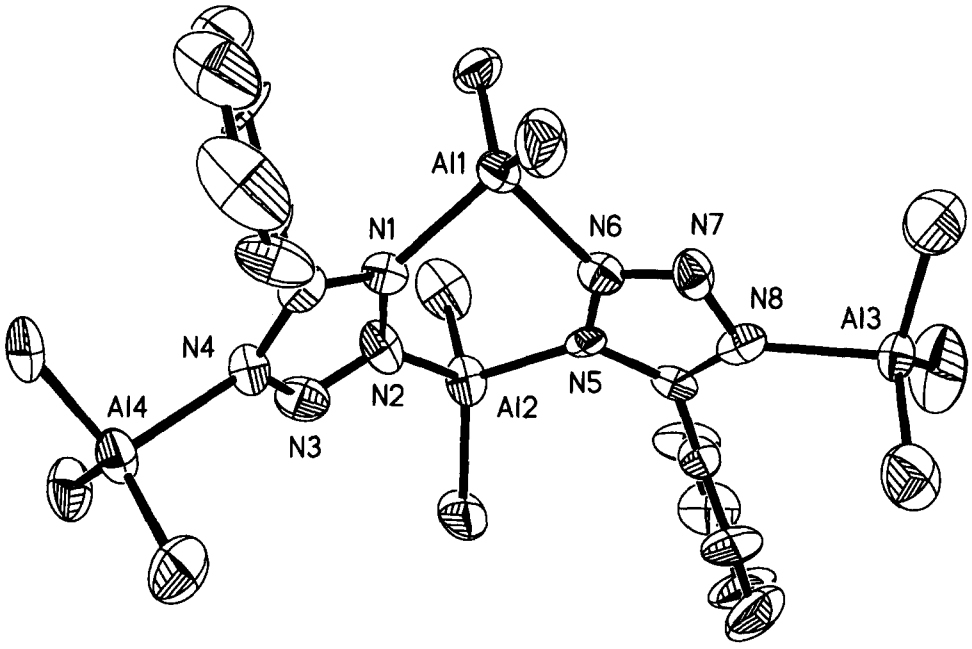

Fig. 1. Molecular structure and atom numbering scheme for compound 7.

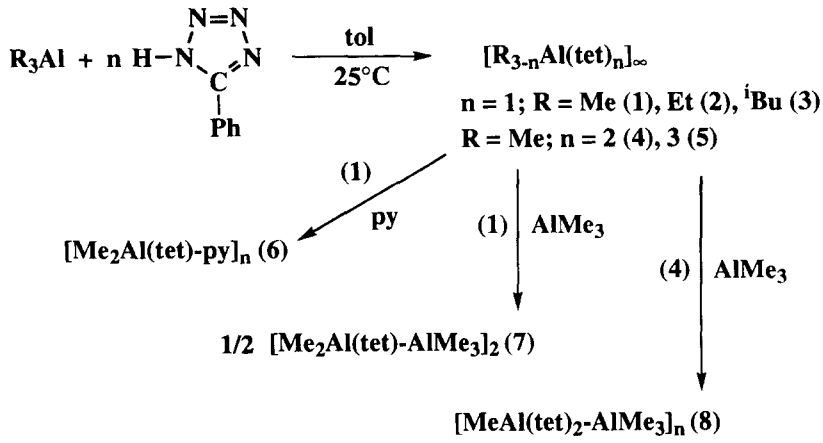

Scheme 1. General syntheses of compounds **1**–**8**.

aluminum containing compound (Scheme 2). Related compounds have been obtained (although not specifically for aluminum) from the decomposition of other tetrazole compounds [2].

CONCLUSIONS

It would thus appear that the tetrazole ligand is a poor choice as a source of nitrogen for aluminum nitride. Stable aluminum containing compounds are produced when either **1**, **4** or **5** are heated to 500 °C. Once a means has been found to prevent polymerization (either with the addition of Lewis bases or acids) tetrazole-aluminum combinations should follow what is known for the related pyrazolyl systems.

EXPERIMENTAL

General considerations

All manipulations were conducted using Schlenk techniques in conjunction to an inert atmosphere glove box. All solvents were rigorously dried prior to use. NMR data were obtained on JEOL-GSX-400 and -270 instruments at 270.17 (^{1}H) MHz in C_6D_6 unless otherwise indicated. Chemical shifts are reported relative to $SiMe_4$ and are in ppm. Elemental analyses were obtained on a Perkin–Elmer 2400 Analyzer. Infrared data were recorded as KBr pellets on a Matheson Instruments 2020 Galaxy Series spectrometer and are reported in cm^{-1}. X-ray data were collected on a Siemens CCD diffractomer using graphite monochromated Mo–K_α (0.71073 Å) radiation. All calculations were performed on a PC using the Siemens software package, SHELXTL-Plus. Selected bond lengths and angles are given in Table 1 while details of the crystal data and a summary of data collection parameters for the complexes are given in Table 2. The data ($\theta = 45°$) for this structure was somewhat weak and there were two molecules of toluene in the lattice. The lowest R value was obtained by narrowing the range to 19.00°. At this point all of the non-hydrogen atoms of the compound were able to be refined with anisotropic parameters but the carbons of the two toluene molecules could only be refined with isotropic parameters.

[$Me_2Al(tet)$]$_n$ (**1**). A solution of trimethyl aluminum (0.25 g, 3.43 mmol) in toluene (10 ml) was added to a stirred suspension of 5-phenyl-1-H-tetrazole (0.5 g, 3.43 mmol) in toluene (20 ml) causing a vigorous gas evolution and the formation of a colorless clear solution, this was stirred for 12 h. Removal of volatiles under reduced pressure produced a white solid which was washed with 10 ml of hexanes, filtration and vacuum dried of the remaining solid afforded **1** in 93% yield as a white toluene insoluble material (mp > 260 °C). ^{1}H NMR (DMSO-d_6): δ −1.06 (s, 6H, $AlCH_3$), 7.52 (m, 3H, C_6H_5), 8.01 (d, 2H, C_6H_5). IR (cm^{-1}): 2962 (m), 1541 (w), 1458 (s), 1400 (m),

$[MeAl(tet)_2]$ (**4**). Prepared as described for **1** from

trimethyl aluminum (0.25 g, 3.43 mmol) and 5-phenyl-1-H-tetrazole (1 g, 6.86 mmol). Yield: 94%; mp > 260 C. ^{1}H NMR (DMSO-d_6): δ −1.02 (s, 3H, AlCH_3), 7.32 (m, 6H, C_6H_5), 8.03 (m, 4H, C_6H_5). IR (cm^{-1}): 3099 (m), 1610 (w), 1525 (w), 1450 (s), 1402 (m), 1282 (w), 1074 (m), 1016 (m), 731 (m), 694 (s), 513 (m). Anal. Calcd for $C_{15}H_{13}AlN_8$: C, 54.22; H, 3.94; N, 33.72. Found: C, 50.31; H, 4.49; N, 28.88.

Synthesis of [Al(tet)$_3$] (**5**). Prepared as described above for **1** from trimethyl aluminum (0.16 g, 2.28 mmol) and 5-phenyl-1-H-tetrazole (1 g, 6.86 mmol). Yield: 96%; mp > 260 C. ^{1}H NMR (DMSO-d_6): δ 7.52 (m, 9H, C_6H_5), 8.03 (d, 6H, C_6H_5). IR (cm^{-1}): 3134 (m), 1450 (s), 1400 (m), 1261 (m), 1097 (s), 1020 (s), 798 (m), 731 (m), 696 (s), 532 (m). Anal. Calcd for $C_{21}H_{15}AlN_{12}$: C, 54.55; H, 3.27; N, 36.35. Found: C, 52.49; H, 3.97; N, 32.23.

[Me$_2$Al(tet)·Py] (**6**). Compound **1** (1.0 g, 4.95 mmol) was suspended in toluene (20 ml). Pyridine (2 ml) was added causing the formation of a colorless solution which was stirred for 2 h. Removal of solvent under reduced pressure produced **6** as a viscous oil which crystallized in stoichiometric yield on standing for 24 h. mp 95 C. ^{1}H NMR ($CDCl_3$): δ −0.31 (s, 6H, AlCH_3), 7.4 (m, 3H, C_6H_5), 7.57 (m, 2H, C_6H_5), 7.06 (m, 3H, C_6H_5), 8.27 (m, 2H, C_6H_5). IR (cm^{-1}): 2357 (w), 1458 (m), 1400 (m), 1261 (s), 1099 (s), 1026 (s), 692 (w).

[Me$_2$Al(tet)-AlMe$_3$]$_2$ (**7**). A solution of trimethyl aluminum (0.25 g, 3.43 mmol) in toluene (10 ml) was added to a stirred suspension of 5-phenyl-1-H-tetrazole (0.5 g, 3.43 mmol) in toluene (20 ml) causing a vigorous gas evolution and the formation of a colorless clear solution. The solution was stirred for 1 h, and then trimethyl aluminum (0.25 g, 3.43 mmol) in toluene (10 ml) was added causing the formation of a colorless crystalline suspension. This was stirred for a further 12 h before **7** was isolated by filtration in 95% yield. Single crystals suitable for X-ray analysis were isolated from the filtrate after several weeks at −30 C. mp 235 C. ^{1}H NMR (DMSO-d_6): δ −1.05 [s, 9H, Al(CH_3)$_3$], −0.54 [s, 6H, Al(CH_3)$_2$], 7.67 (m, 5H, C_6H_5). IR (cm^{-1}): 2933 (m), 2887 (m), 1608 (w), 1527 (w), 1458 (s), 1383 (m), 1288 (w), 1203 (m), 1608 (w), 691 (s). Anal. Calcd for $C_{29}H_{40}Al_4N_8$: C, 52.55; H, 7.35; N, 20.43. Found: C, 47.37; H, 5.97; N, 20.29.

[MeAl(tet)$_2$-AlMe$_3$]$_n$ (**8**). A solution of trimethyl aluminum (0.25 g, 3.43 mmol) in toluene (10 ml) was added to a stirred suspension of 5-phenyl-1-H-tetrazole (1.0 g, 6.86 mmol) in toluene (20 ml) causing a vigorous gas evolution and the formation of a white precipitate. The solution was stirred for 1 h, and then trimethyl aluminum (0.25 g, 3.43 mmol) in toluene (10 ml) was added causing the formation of a colorless crystalline suspension. This was stirred for a further 12 h before **8** was isolated by filtration in 93% yield. mp > 220 C. ^{1}H NMR (DMSO-d_6): δ −0.92 [s, 9H, Al(CH_3)$_3$], −0.54 (s, 3H, AlCH_3), 7.64 (m, 10H, C_6H_5). IR (cm^{-1}): 2936 (m), 2884 (m), 1609 (w), 1528 (m), 1458 (s), 1383 (m), 1289 (w), 1204 (m), 1020 (m), 693 (s). Anal. Calcd for $C_{18}H_{22}N_8Al_2$: C, 53.46; H, 5.48; N, 27.71. Found: C, 52.34; H, 5.01; N, 27.43.

CHEMICAL ABSTRACTS

The combination of 5-phenyl-1-H-tetrazole (tet) with AlR_3 in stoichiometries of 1–3 leads to the compounds [(tet)AlR_2]$_n$ R = Me (**1**), Et (**2**), ^{t}Bu (**3**), [(tet-)$_2$AlMe]$_n$ (**4**), and [(tet)$_3$Al]$_n$ (**5**). The addition of pyridine to **1** leads to a compound with the formulation, [(tet)$AlMe_2$-pyridine]$_n$ (**6**). Likewise the addition of $AlMe_3$ to **1** and **4** leads to the products, [(tet)$AlMe_2$-$AlMe_3$]$_2$ (**7**) and [(tet)$_2$AlMe-$AlMe_3$]$_n$ (**8**). The compounds were characterized by standard techniques and, in the case of **7** by X-ray crystallography (monoclinic, $P2_1/c$, a = 12.576(2) Å, b = 18.358(3) Å, c = 20.262(3) Å, β = 93.272(4)°, V = 4670.6(11) Å^3, Z = 4, with 3714 indp. reflections R_1 = 12.37%).

Compounds **1** and **4** and **5** were examined (unsuccessfully) as potential unimolecular precursors to aluminum nitride.

GRAPHICAL ABSTRACT

The combination of 5-phenyl-1-H-tetrazole (tet) with AlR_3 in stoichiometries of 1–3 leads to a series of poorly soluble compounds having the general formula, $[(tet)_nAlR_{3-m}]_n$ where $m = 1$–3. More soluble compounds can be obtained by the addition of either a strong Lewis base (such as pyridine) or an additional equivalent of $AlMe_3$. This latter reaction results in the formation of a dimeric compound for R = Me (shown). Several of the compounds were examined (unsuccessfully) as potential unimolecular precursors to aluminum nitride.

(Received 4 June 1997; accepted 14 January 1998)

Abstract—Two novel edta-linked 4f-3d heterometallic two-dimensional coordination polymers $Nd_2Mn_3(edta)_3(H_2O)_{11}\cdot 12H_2O$ (**A**) and $Gd_2Co_3(edta)_3(H_2O)_{11}\cdot 12H_2O$ (**B**) were synthesized by reaction of $Ln(OH)_3$ (Ln = Nd, Gd), $MnCO_3$ or $Co(OH)_2$ with H_4edta (edta = ethylenediamine-NNN′N′-tetra-acetate) in water. **A** and **B** crystallize in the monoclinic space group C2 with cell parameters a = 16.003(3), 15.799(5), b = 14.733(3), 14.603(5), c = 14.819(3), 14.690 Å, β = 116.21(2), 116.64(3)°, V = 3135(1), 3029(2) Å^3, and Z = 2. **A** or **B** consists of a two-dimensional heterometallic sheet in which the Ln(III) ion is ten coordinated by six carboxyl oxygen atoms from edta and four oxygen atoms from H_2O molecules, the M(II) ion is seven coordinated by two nitrogen, four oxygen from edta and one oxygen from H_2O molecule. Each Ln(III) ion has three M(II) neighbours, while each M(II) is connected to two Ln(III) ions. The Ln(III) and M(II) ions are linked by tridendate bridging carboxylate oxygen atoms with considerable short Ln-M separations in the range of 4.82 to 4.90 Å, which are shorter than the distances between metal ions in heterometallic 3d complexes of edta. The heterometallic sheets are connected by H_2O molecules through hydrogen bonds. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: edta; 4f-3d heterometallic; crystal structure; two dimensional sheet.

The magnetic properties of heteropolymetallic compounds have attracted considerable interest in the last two decades [1, 2]. Great attention has been paid to extended coordination polymer systems, since they often show long range ferro- or ferri- magnetic ordering in the liquid-helium temperature range. To our knowledge, all of them involve only transition-metal ions except for one series, 'oxamato' bridged compounds $[Ln_2Cu_3]$, which contain both lanthanide and transition metal ions with 1-D or 2-D structures [3–5]. As to edta linked, extended heterometallic 3d compounds, two families are known to date [6–10]. One concerns $MM'(edta)\cdot 6H_2O$ with ferrimagnetic chains ([MM′] = [MnCo], [MnNi], [MnCu], [CoNi], [CoCu], [NiNi]). The other series is a 3-D coordination polymer with general formula $M''M(M'edta)_2\cdot 4H_2O$ ([M″MM′] = [CoCoCo], [CoCoNi], [CoNiNi], [ZnNiNi]). Both series exhibit ferrimagnetic ordering below 1.06 K. In this paper, structures of two novel edta linked 4f-3d heterometallic 2-dimensional coordination polymers were reported, tridentate bridging mode of carboxylate group and seven coordinated Co(II) were observed in the complexes.

EXPERIMENTAL

All starting chemical reagents were commercially available and were of reagent grade. Elemental analysis (C, H, N) was performed by the Carlo Erba 1106. IR spectra were recorded on a Nicolet 750 FTIR spectrometer. The thermogravimetric analysis was made by an LT-1 model thermobalance under atmosphere.

The proportions of Ln(III) and M(II) were determined by Inductively Coupled Plasma (ICP).

Preparation of $Nd_2Mn_3(edta)_3(H_2O)_{11} \cdot 12H_2O$ (**A**)

Nd_2O_3 (99.9%) was dissolved in aqueous HNO_3, from which $Nd(OH)_3$ was precipitated by 6N NaOH. 1 mmol $MnCO_3$ (99.9%), 2 mmol $Nd(OH)_3$ and 2 mmol H_4edta (>99%) were added to 10 ml water. After stirring and heating, the solids were dissolved, yielding an almost transparent solution, which then was filtered. Pink crystals were obtained after a few months. Found: C, 20.80; H, 4.75; N, 4.73%. Anal. Calc. for $C_{30}H_{82}Mn_3N_6Nd_2O_{47}$: C, 20.80; H, 4.73; N, 4.85%.

Preparation of $Gd_2CO_3(edta)_3(H_2O)_{11} \cdot 12H_2O$ (**B**)

$Gd(OH)_3$ and $Co(OH)_2$ were made in a manner similar to $Nd(OH)_3$. 3 mmol $Co(OH)_2$, 2 mmol $Gd(OH)_3$ and 2 mmol H_4edta were mixed in water. After stirring and heating, the mixture became an almost clear solution which was then filtered. Rose-red single crystals were formed after a few weeks. Found: C, 20.30; H, 4.29; N, 4.70%. Anal. Calc. for $C_{30}H_{82}Co_3Gd_2N_6O_{47}$: C, 20.35; H, 4.63; N, 4.75%.

Crystallography of $[Nd_2Mn_3]$ (**A**) and $[Gd_2CO_3]$ (**B**)

The diffraction data of $[Nd_2Mn_3]$ (**A**) and $[Gd_2Co_3]$ (**B**) were collected on an Enraf-Nonius CAD-4 diffractometer using graphite-monochromated Mo Kα radiation in the θ-scan mode ($2\theta_{max} = 50$ and 46°) at room temperature. Cell Parameters of **A** and **B** were determined from 25 reflections in the θ range of 9.32–12.25° (for **A**) and 9.22–12.35° (for **B**) respectively. An empirical absorption correction was applied to the original data set [11]. The crystallographic data of **A** and **B** was summarized in Table 1. The structures were solved using direct methods and refined by a full-matrix, least-squares technique (SDP-PLUS and SHELXL97) [12, 13]. The quantity minimized was $\Sigma w(|F_o|^2 - |F_C|^2)$ with $w = 1/[\sigma^2(F^2_O) + (0.1157*P)^2 + 19.4077*P]$ for **A** and $1/[\sigma^2(F^2_O) + (0.0945*P)^2 +$

The maximum residual hole in the last difference fourier map was $-2.958\,e\text{Å}^{-3}$ (0.97 Å from Nd). The final refinement for **B** was reached with $R_1=0.0368$ and $wR_2=0.1034$ for 2082 observed reflections ($I>2\sigma(I)$). The maximum residual hole in the last different fourier map is $-1.097\,e\text{Å}^{-3}$.

RESULTS AND DISCUSSIONS

Thermal stability of **A**

Thermogravimetric analysis of **A** showed that twenty-three waters were lost during two steps below 162°C, and the cumulative loss was 23.85% (calc. 23.90%). The complex was decomposed and oxidized between 313–412°C and the remaining weight was 27.99%, according to Nd_2O_3 and MnO_2 (calc. 34.47%). The thermal data was confirmed by the crystal structure data.

IR spectra

The IR spectra of H_4edta, complex **A** and **B**, were measured. Compared to the IR spectra of H_4edta, the stretching vibration absorption peak of the carboxylic group of **A** and **B** shifted from a broad band 1674–1704 cm^{-1} to a sharp peak at 1587 cm^{-1} for **A** and 1593 cm^{-1} for **B**. This indicated that the carboxylic group coordinated to the metal ions and the bond length of C–O tends to be unified. This result was also supported by the crystal structure discussed in the next part. Furthermore, the strong ν(O–H) at 3436 cm^{-1} became wider, which anticipated the existence of more hydrogen bonds in the complexes.

Crystal structure of **A** *and* **B**

X-ray crystallography has established that complexes **A** and **B** are isostructural as shown in Fig. 1. The Ln(III) (Ln = Nd, Gd) ion is ten coordinated by six carboxylate oxygen atoms from edta and four oxygen atoms from H_2O molecules, forming a distorted, bicapped tetragonal anti-prismatic coordination polyhedron with the bond lengths of Ln–O in the range of 2.466–2.791 Å (for **A**) and 2.392–2.766 Å (for **B**). In **A**, O5, O10, O21 and O24 form a plane (distance to the plane: O5, 0.21(1); O10, 0.20(1); O21, −0.19(1); O24, −0.22(1)), while O2, O6, O22 and O23 form another plane (distances to the plane: O2,0.13(1); O6, −0.14(1); O22, 0.20(1); O23, −0.19(1)) and the dihedral angle between the two planes is 15.5(2)°. The distances from Nd(III) to the bridged oxygen atoms, O2, O6 and O9 in **A** are a bit longer than those of the other seven non-bridged oxygen atoms. A similar situation was observed in **B**. M(II) ion is seven coordinated by two nitrogen, four oxygen atoms from the carboxylate group of edta and one oxygen atom from the H_2O molecule. **B** is the second seven coordinate cobalt-aqua-edta complex, average bond lengths of Co–O (2.18 Å) and Co–N (2.24 Å) are a little longer than those in the other Co-edta compounds. A similar coordination number and geometry for Co(II) was also found in $[Co(edtaH_2)(H_2O)]\cdot 2H_2O$ [14]. Meanwhile, seven coordinated Mn(II) complexes are not

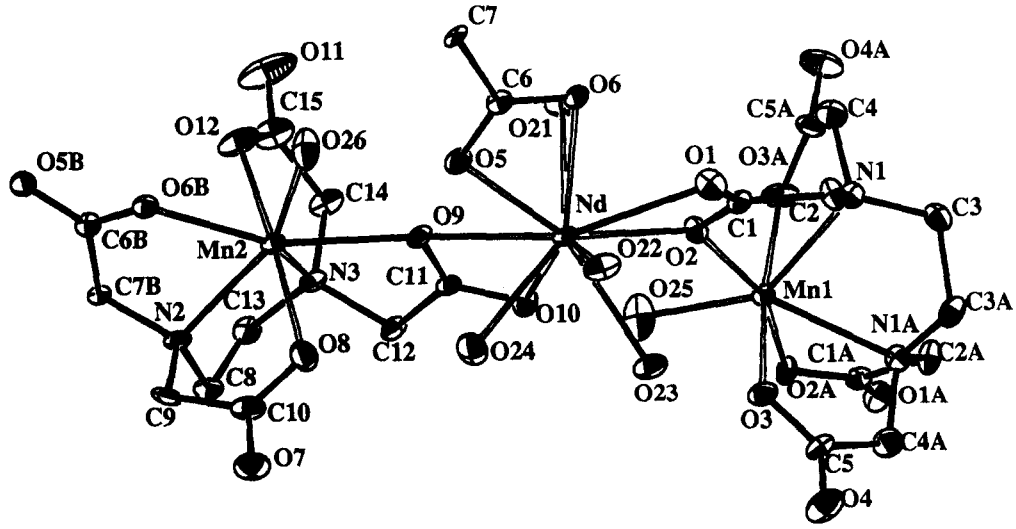

Fig. 1. The ORTEP view of $Nd_2Mn_3(edta)_3(H_2O)_{11}\cdot 12H_2O$ (30% probability displacement ellipsoids). H atoms have been omitted for clarity.

Symmetry transformations used to generate equivalent atoms:
#1 $-x+1/2, y+1/2, -z+2$
#2 $-x, y, -z+1$
#3 $-x+1/2, y-1/2, -z+2$

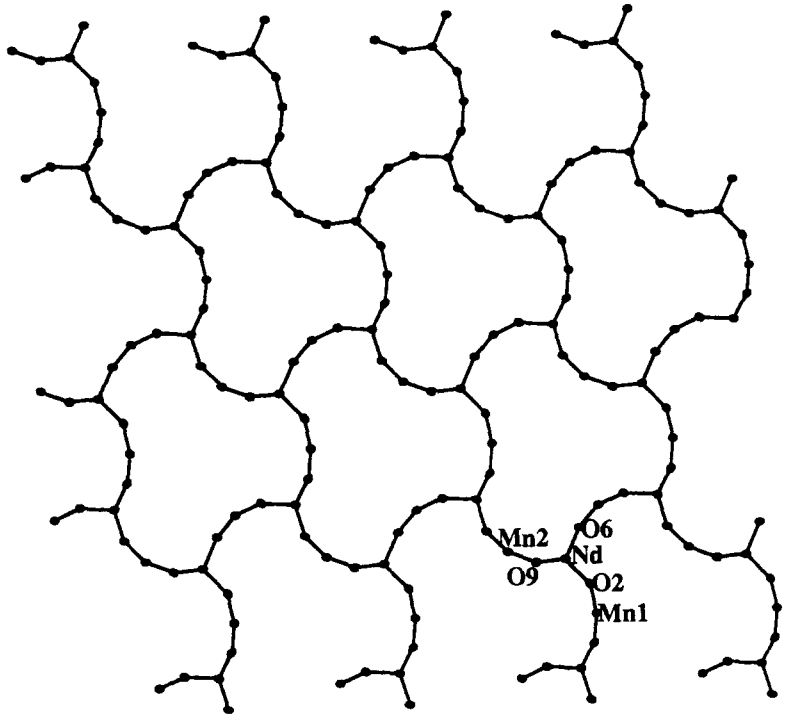

Fig. 2. The connection of metal ions through O atoms in two-dimensional sheet.

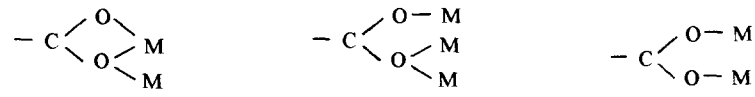
rare, such as $Mn_2edta \cdot 9H_2O$ and $Mn_3(edta)_2 \cdot 10H_2O$ [15].

In the title complex, each Ln(III) ion is connected to three M(II) ions by three tridentate carboxylate-O,O′ bridges, while each M(II) ion has two Ln(III) neighbours. Comparing the structures of the title compounds and other edta linked 3d complexes, the most important and significant structural character is based on the bridging modes of the carboxylate group. In carboxylato-linked 4f-3d heteronuclear complexes, such as $\{[GdMn(dtpa)(H_2O)_5]_2 \cdot H_2O\}_n$ [18] and $[Cu_3Gd_2(O_2CCH_2Cl)_{12}(H_2O)] \cdot 2H_2O$ [19]. It is the special bridging mode of the carboxylate group of edta that makes the distances (4.8-4.9 Å) between bridged metal atoms Ln and M significantly shorter than those in 3d heterometallic edta complexes (> 6 Å) [6–10] and other 4f-3d low-dimensional compounds (5.6–5.8 Å) [3–5].



$[Ln_2M_3]$, the bridging carboxylate-O,O′ group is in a less common situation (a). One of its oxygen atoms is used to link Ln(III) and M(II), the other one is bound to Ln(III). This means that the two atoms of a tridentate carboxylate-O,O′ group are used to coordinate only two metal atoms, which is different from the common tridentate bridging mode (b) in which the two O atoms of a carboxylate group are dentate to three metal centers [16]. Meanwhile, the most conventional bridging mode of carboxylate group is bidentate, type (c) [17], which was also found in edta linked 3d heterometallic compounds [6–10], and some

The complex molecule of $[Ln_2M_3]$ consists of 12-membered metal (6Ln, 6M) circle motifs, which were linked together by twelve oxygen atoms to form a two dimensional sheet, as shown in Fig. 2. In the sheet, the nearest M(II)–M(II) and Ln(III)–Ln(III) distances are larger than 8.1 and 8.4 Å respectively. The sheets are connected by H_2O molecules through hydrogen bonds, as shown in Fig. 3. The structure of title compounds is different from the structure of $MM(edta) \cdot 6H_2O$, which consists of 1-D zigzag chains built up from two alternating octahedral sites, referred to as 'chelated' or 'hydrate' according to their local environ-

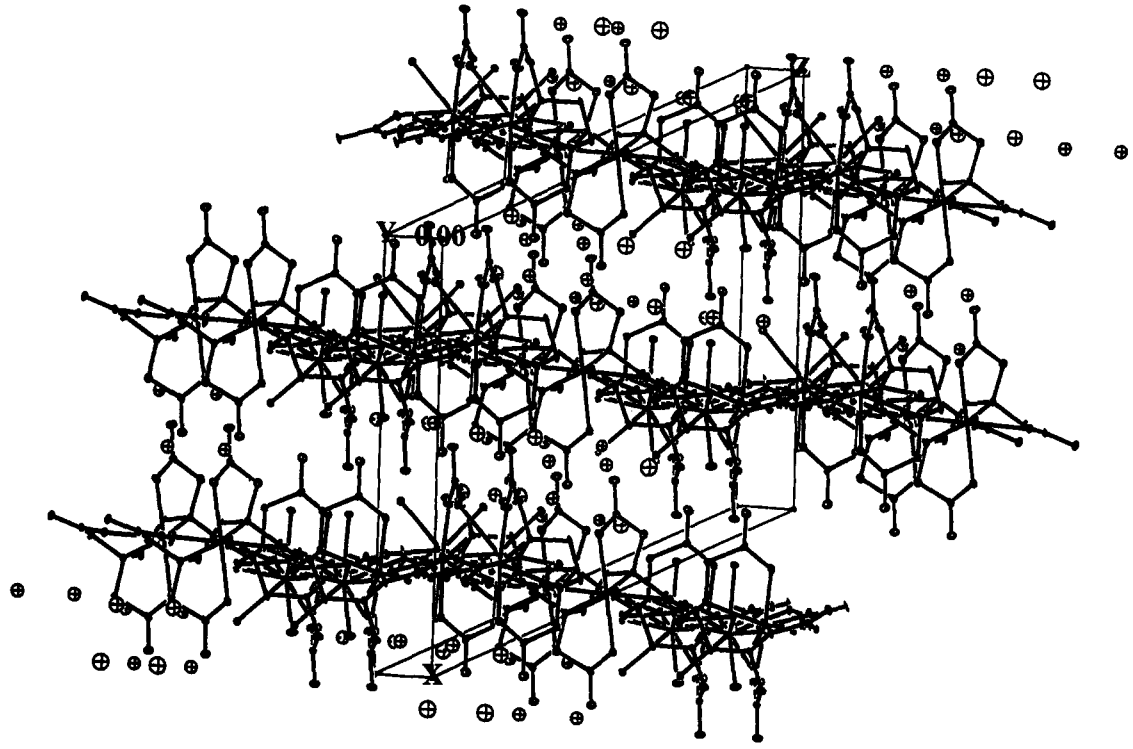


Fig. 3. The packing of 2-D sheets in a unit cell of $[Ln_2M_3]$. H_2O molecules are filled between the layers.

ment and is also different from the layered 3-D $M''M(M'edta)_2 \cdot 4H_2O$. Thus the title complexes may be served as the first 2-D edta coordination polymers, containing both lanthanide and transition metal ions. The investigation of magnetic properties for these complexes is in progress.

(Received 13 November 1997; accepted 12 January 1998)

Abstract—Dimethyl(2,6-diacetyl-pyridine-monothiosemicarbazonato)thallium(III), $[TlMe_2(L)]$, and Diphenyl-(2,6-diacetyl-pyridine-monothiosemicarbazonato)thallium(III) chloroform solvate, $[TlPh_2(L)],CHCl_3$ were prepared by reacting the corresponding diorganothallium(III) hydroxide with 2,6-diacetyl-pyridinemonothiosemicarbazone (HL). $[TlMe_2(L)]$ crystallizes in the triclinic space group $P\bar{1}$ (no. 2) with $a = 7.064(3)$, $b = 9.149(2)$, $c = 12.377(2)$Å, $\alpha = 79.378(11)$, $\beta = 74.92(2)$, $\gamma = 82.75(2)$, $Z = 2$, $R_1 = 0.0305$, $Rw_2 = 0.0673$. $[TlPh_2(L)].CHCl_3$ crystallizes in the monoclinic space group $C2/c$ with $a = 23.559(3)$, $b = 13.582(2)$, $c = 16.808(3)$Å, $\beta = 106.04(1)°$, $Z = 8$, $R_1 = 0.0620$, $Rw_2 = 0.1155$. Both complexes consist of molecules in which the deprotonated ligand is S,N(3),N(4),O-bonded to the thallium atom $[TlMe_2(L)]$, Tl—S = 2.872(2), Tl—N(3) = 2.590(6), Tl—N(4) = 2.686(2), Tl—O = 2.883(6)Å; $[TlPh_2(L)].CHCl_3$, Tl—S = 2.791(6), Tl—N(3) = 2.56(2), Tl—N(4) = 2.579(14), Tl—O = 2.86(1)Å]. A weak bond Tl...O′ $[TlMe_2(L)]$, 3.050(2) Å; $[TlPh_2(L)].CHCl_3$, 3.42(1) Å] between neighbouring molecules give rise to weakly bonded dimers. The ^1H, ^{13}C and ^{205}Tl NMR spectra of both compounds in DMSO indicate that the bonding scheme observed in solid state is only partially retained in solution, where at least two isomers are observed. © 1998 Elsevier Science Ltd. Keywords: crystal structure; thallium complexes; diorganothallium complexes; thiosemicarbazone complexes.

The usefulness of $TlMe_2^+$ cation for isolating, in the solid state, different conformational and tautomeric forms of thiosemicarbazones was pointed out in a preceeding paper [1]. The thiosemicarbazone backbone has several possibilities of coordination to metals, *N*, *S*-coordination **(A)** using the azomethine nitrogen [N(3)] being the most common [2].

This mode of coordination was observed in dimethylthallium(III) cyclopentanone thiosemicarbazonate [3] and in dimethylthallium pyridine-2-carbaldehyde thiosemicarbazonate [4] (although in this last case also the N atom of the pyridine ring contributes to the metal-ligand bond). Nevertheless, other coordinative options exist: (*p*-Anisaldehyde thiosemicarbazonato)-dimethylthallium(III) [5] contains the metal N(2), *S*-coordinated, while the ligand retains the typical structure of free thiosemicarbazones **(B)** and $[TlMe_2(HA)(H_2O)]$ (HA = monoanion of pyridoxal thiosemicarbazone) [1] has the ligand *S*-coordinated (if the very weak interaction of the thallium with the phenolic hydroxyl group of the 3-hydroxy-5-hydroxymethyl-2-methyl-pyridine ring is ignored) **(C)**.

The present study was carried out to explore the coordinative behaviour of the new ligand 2,6-diacetyl-pyridine monothiosemicarbazone (HL), serendipitously isolated in a preceeding work [6]. Its reaction with aqueous TlR_2OH (R = Me, Ph) afforded the complexes $[TlMe_2(L)]$ and $[TlPh_2(L)].CHCl_3$. Although in solid state the thiosemicarbazone chain adopts in both compounds the

(C)

more usual conformation and is N(3), *S*-bonded to the metal, in DMSO solution there are at least two isomers. The structure of these isomers is discussed.

EXPERIMENTAL

Thiosemicarbazide (Merck), 2,6-diacetylpyridine (Aldrich), thallium(I) iodide (Merck), thallium(I) bromide, methyl lithium (Ega-chemie), methyl iodide (Probus), Bromine (Merck) and phenylboronic acid (Aldrich) were used as received. HL, $TlMe_2OH$ and $TlPh_2OH$ were prepared as described elsewhere [6,7].

Elemental analyses were performed with a FISONS Instrument EA 1108 analyser. Melting points were determined with a Gallenkamp Melting Point Apparatus. Mass spectra were obtained using a KRATOS MS50 spectrometer connected to a DS90 data system and operating under FAB conditions (*m*-nitrobenzyl alcohol, Xe, 8 eV). ^1H (300.14 MHz), ^{13}C (62.83 MHz) and ^{205}Tl (173.1287 MHz) NMR spectra in DMSO were recorded at room temperature in a Bruker WM 250 (^{13}C spectra) and AMX 300 (^1H and ^{205}Tl) apparatuses. Chemical shifts in ppm (δ) were referred to TMS using the solvent signal for ^1H and ^{13}C spectra and aqueous $TlClO_4$ after extrapolation to infinite dilution in ^{205}Tl spectra.

Synthesis of $[TlMe_2(L)]$

1.75 ml of an aqueous solution of $TlMe_2OH$ (0.054 g, 0.21 mmol) was added to a suspension containing 0.05 g of HL (0.21 mmol) in 10 ml of hot methanol. The orange solution obtained was refluxed and stirred for 3 h and then left to stand overnight at room temperature. After cooling for one day at 4°C, a crystalline orange solid formed, adequate for X-ray study; it was isolated and dried *in vacuo*. M.p. 175°C (decomposition). Anal. Found: C, 30.7; H, 3.7; N, 11.9; S, 6.5, Calc. for $C_{12}H_{17}N_4OSTl$, C, 30.7; H, 3.6; N, 11.7; S, 6.8%. The main metallated ions in the FAB spectrum were at m/z(%): 470 (M+H, 29), 454 (M−Me, 33), 388 ($C_{11}H_9N_3Tl$, 11), 235 ($TlMe_2$, 25), 205 (^{205}Tl, 100).

Synthesis of $[TlPh_2(L)] \cdot CHCl_3$

0.17 g of HL (0.72 mmol) were suspended in 20 ml of hot methanol and to this suspension was added an aqueous solution (10 ml) of $TlPh_2OH$ (0.27 g, 0.72 mmol). The orange solution obtained was refluxed and stirred affording an orange solid, which was isolated after cooling to room temperature. Single crystals suitable for the X-ray study were obtained by recrystallisation in chloroform. M.p. 170°C. Anal. Found: C, 38.8; H, 2.9; N, 8.1; S, 5.35, Calc. for $C_{23}H_{22}Cl_3N_4OSTl$: C, 38.7; H, 3.1; N, 7.9; S, 4.5%. The main metallated ions in the FAB spectrum were at m/z(%): 595 (M+H, 20), 517 (M−Ph, 63), 440 (M−2Ph, 3), 359 ($TlPh_2$, 100), 205 (^{205}Tl, 49).

Crystal structure determinations

X-ray crystallography was performed using an Enraf–Nonius CAD-4 difractometer with graphite monochromated Mo–Kα radiation ($\lambda = 0.71073$). Crystal data and experimental conditions are listed in Table 1. Numerical absorption corrections were carried out [8].

Structures were solved using the standard heavy atom Patterson method and difference Fourier Techniques. In the final cycles of full-matrix least-squares refinement all non-H atoms were treated anisotropically. In $[TlPh_2(L)].CHCl_3$ the thermal parameter U33 of atom C(5) would refine to a non physical low value, giving rise to a non-definite-positive thermal tensor; it was for that reason, fixed to the value of 0.035, close to the equivalent ones of neighboring atoms. H atoms in $[TlMe_2(L)]$ were included, as fixed contributors, all with a common isotropic displacement parameter that refined to 0.113(11)Å^2. For $[TlPh_2(L)] \cdot CHCl_3$, all H atoms, except those of the two methyl and one amino groups that were not included in the model, were located on stereochemical grounds [U(eq) = 0.065(18) Å^2]. Atomic scattering factors were taken from Ref. [9]. The programs used were SHELX76[10], SHELXL93 [11] and ORTEP [12].

RESULTS AND DISCUSSION

Crystal structures of the complexes

$[TlMe_2(L)]$. Figure 1 shows the molecular structure of this compound with the numbering scheme used. Selected bond distances and bond angles are listed in Table 2. The thallium atom is coordinated to two

′ $-x+2, -y+1, -z+1$.

amidal geometry). The Tl—N and Tl—S distances are within the range observed in other thiosemicarbazone-dimethylthallium(III) complexes [1, 3–5]. The Tl—O distance is clearly shorter than the sum of van der Waals radii (3.48 Å [13]) suggesting a significant bonding interaction. The intermolecular Tl···O′ secondary bond which connects dimers, although shorter than that sum, is weaker than the intramolecular thallium-oxygen bond.

When this coordination sphere is compared with that found in the complex dimethylthallium pyridine-2-carbaldehyde thiosemicarbazonate [4] where the ligand is analogous to L except for the CH_3CO group, it is evident that the incorporation of the Tl—O bond and the replacement of a weak interaction Tl···S for a weak interaction Tl···O in the coordination sphere of the thallium atom lengthens the Tl—S bond (2.825 Å (*av.* value) in the pyridine-2-carbaldehyde-thiosemicarbazone complex [4]) whereas the Tl—N(4) bond is not affected.

The thiosemicarbazone chain C(2)—N(3)—N(2)—C(1)(S)—N(1) adopts an E conformation about the aldimine C(2)—N(3) bond and the thioamide S atom is *cis* respect to the hydrazinic NH–N group, as in the $CdCl_2$ adduct $[CdCl_2(HL)(H_2O)].H_2O$ [6]. The C(1)—S distance is similar in both $CdCl_2$ and $TlMe_2^+$ compounds suggesting that, although in the thallium compound the ligand is deprotonated, the C(1)—S bond retains a close to double bond multiplicity. Nevertheless, although the thione-to-thiol evolution is limited, deprotonation of HL lengthens C(1)—N(1) and shortens C(1)—N(2) as usually occurs in other thiosemicarbazonates.

For the CH_3CO group, the C—O bond distance is that corresponding to a double bond and is also very close to that found in the $CdCl_2$ adduct [6], however in the $TlMe_2^+$ compound this oxygen atom also bridges two thallium atoms which gives rise to a centrosymmetric dimer.

$[TlPh_2(L)] \cdot CHCl_3$. The molecular structure of this complex together with the numbering scheme used is in Fig. 2. Selected bond distances and bond angles are listed in Table 3.

The coordination sphere of the thallium atom is very similar to that described for the dimethylthallium derivative. As in that case, two carbon atoms from the phenyl groups, one S atom, two nitrogens [N(3) and N(4)] and two oxygen atoms give rise to a distorted pentagonal bipyramid coordination sphere, with the carbon atoms occupying the apical positions. Possibly the lower steric hindrance of the phenyl groups relative to the methyl groups (although electronic effects cannot be excluded) allows all the intramolecular metal-ligand bond distances (mainly Tl—S and Tl—N) to be shorter in the diphenyl derivative. Also the angle C—Tl—C is slightly wider.

As a consequence of this stronger intramolecular coordination, the intermolecular interaction Tl···O′ which associates the molecules forming dimers is weaker in the phenyl derivative (Tl···O′ = 3.418 Å).

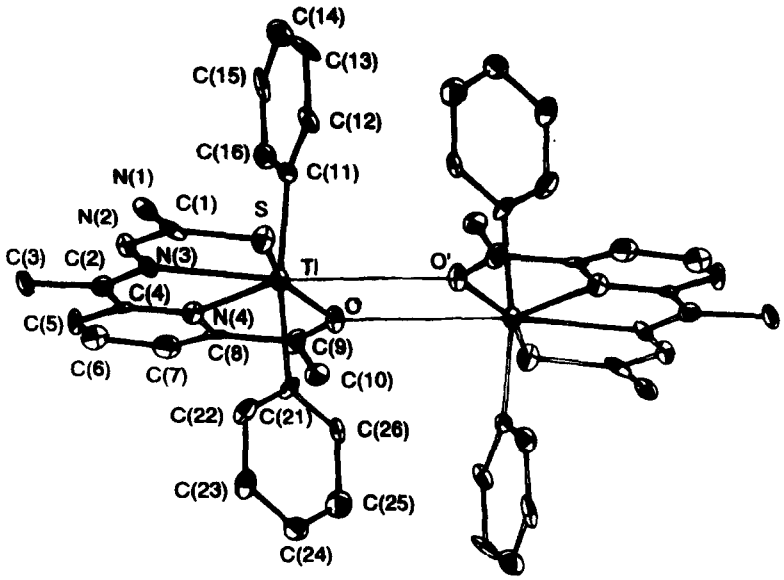

Fig. 2. Crystal structure of $[TlPh_2(L)] \cdot CHCl_3$ showing the atom number scheme used ($CHCl_3$ not shown).

′$1/2-x, 3/2-y, 1-z$.

The ligand, as in the dimethyl derivative, is tetradentate and practically plane. Nevertheless, differences in the Tl-ligand bond distances are accompanied by small differences in the thiosemicarbazone backbone bond distances. Thus, the shorter Tl—S bond corresponds with a larger C(1)—S bond in the diphenylthallium(III) complex.

NMR studies

^1H, ^{13}C and ^{205}Tl NMR data in DMSO-d_6 for HL and its diorganothallium complexes are listed in Table 4. ^1H and ^{13}C NMR spectra of both compounds in DMSO solutions show two different groups of signals for all the protons and carbons of the ligand, sug-

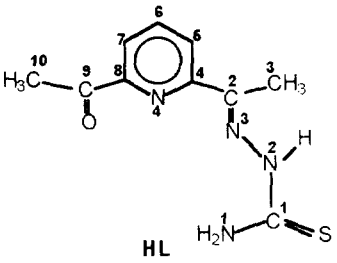
[a] s = singlet, b = broad, d = doublet, m = multiplet.
[b] Major isomer.
[c] $^2J(^1H\text{-}^{205}Tl) = 425.6$ Hz; $^1J(^{13}C-^{205}Tl) = 3032.2$Hz; $\delta(^{205}Tl) = 3734, 3684$ ppm.
[d] $\delta(^{205}Tl) = 3403, 3343$ ppm.
[e] Not observed.



cates that the ratio between both isomers is about 4 : 1. The main changes of the ligand signals in the ^1H NMR spectrum of the major isomer with respect to the free ligand are: (a) the disappearance of the N(2)H signal (at 10.36 ppm in HL) due to deprotonation, (b) the shielding of the NH_2 signal which remains split in two broad bands, (c) the slight shielding of C(5)H, C(6)H and C(7)H (by 0.05–0.1 ppm), (d) the shielding of $C(3)H_3$ (by 0.15 ppm) while $C(10)H_3$ is practically at the same position as that in the free ligand.

In the ^{13}C NMR spectrum the main changes are: (a) C(2), C(3) and C(4) are deshielded by complexation, (b) C(1) and C(7) are shielded while C(5), C(6), C(8), C(9) and C(10) are not affected by deprotonation and metallation. All these changes suggest that, in this tautomeric form, the CH_3CO group and the pyridinic nitrogen probably do not coordinate the metallic center. The shielding of C(1) (about 1 ppm) indicates some evolution of the ligand to the thiol form and the fact that the NH_2 groups still gives two different broad signals may be indicative of either that L retains the typical configuration of the free thiosemicarbazones allowing N(1)H···N(3) hydrogen bonding or that the C(1)—N(1) bond still has enough multiplicity to avoid the free rotation about the $N(1)H_2$ group. These data, together with the chemical shift in the ^{205}Tl NMR spectrum (3734) ppm) suggest that the major tautomeric form may have the structure **(B)** similar to that already described, in solid state, for a dimethylthallium complex with p-anisaldehyde thiosemicarbazone [5].

With regard to the minor isomer, its ^1H and ^{13}C NMR spectra significantly differs from those obtained for the major isomer. The $N(1)H^2$ group gives now just one signal at 6.50 ppm, C(5)H is shielded about 0.6 ppm with respect to the major isomer, while C(6)H and C(7)H are slightly deshielded. In the ^{13}C NMR spectrum significant changes with respect to the major isomer are: (a) a slight shielding of C(9), (b) a slight deshielding of C(1) and (c) a strong deshielding of C(3) and C(4). These results, together with the signal in the ^{205}Tl NMR spectrum (3684 ppm), suggest that the oxygen atom from the CH_3CO group coordinates the thallium atom, together with N(3), N(4) and probably the sulphur, as in solid state. It may therefore be concluded that this isomer has low solubility in the $MeOH/H_2O$ solution used in synthesis, and for that reason this is the one isolated in solid state. $[TlPh_2(L)]\cdot CHCl_3$ behaves similarly to the dimethylthallium derivative in DMSO solution, so the conclusions obtained above can be applied to it.

(Received 27 October 1997; accepted 12 January 1998)

Abstract—The preparations are reported of a range of complexes of Fe^{II}, Co^{II}, Ni^{II}, Cu^{I}, Ag^{I}, Zn and Cd with *N,N'*-1,2-ethylenebis(pyridin-2-thione) (EBPYT) together with relevant spectroscopic data. The compounds $Co(EBPYT)Br_2$ (**1**) and $[Ni(EBPYT)_3](ClO_4)_2 \cdot 2MeOH \cdot MeNO_2$ (**2**) have been studied by X-ray crystallography. Compound **1** has a chain structure in which tetrahedrally coordinated cobalt centres are linked by bridging EBPYT ligands. In compound **2** octahedrally coordinated "NiS_6" centres are connected by EBPYT bridges so as to form a polymeric three-dimensional array of rhomboidal "boxes". © 1998 Elsevier Science Ltd. Keywords: X-ray structures; polymeric complexes; bis(pyridine-2-thione) ligand.

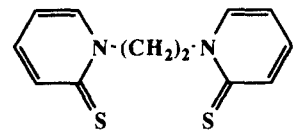
A major component of the very rapidly developing field of supramolecular chemistry is the synthesis of new metal complexes with polymeric sheet or 3D-network structures and in particular those forming cavities or channels capable of taking up guest molecules. The great majority of organic ligands that have been used for this purpose hitherto have involved nitrogen donor groups [1] or, to a somewhat lesser extent, oxygen donors such as carboxylate anions [2] or neutral ligands with O-donor groups [3]. The use of extended reach sulphur donor ligands to form such networks has, surprisingly, received far less attention [4], although a number of dithia-alkanes have been shown to form individual, large metallacyclic rings [5]. In view of the observation [4b] that *N,N'*-ethylenebis(pyridin-2-thione) (**I**, EBPYT) forms chains of 4-, 18- and 36-membered rings in the Cu^{I} compound $\{[Cu_2(EBPYT)_3](PF_6)_2\}_n$ we have extended our studies with EBPYT to a wider range of metal ions and we describe here the results of this work.



I

EXPERIMENTAL

Preparation of compounds

N,N'-ethylenebis(pyridin-2-thione). This was prepared as described previously [4b].

Metal complexes of EBPYT

Analytical data (Microanalytical Laboratory Imperial College), colours and yields of the complexes

of EBPYT are given in Table 1. Preparative details are summarised below.

Caution! Although we did not observe any explosive behaviour with the perchlorate compounds described below, all metal perchlorates must be regarded as potentially explosive and appropriate safety measures taken.

$FeCl_2$(EBPYT). Addition of a solution of hydrated iron(II) chloride (0.31 mmol) in ethanol (5 cm^3), which had been "deoxygenated" by passage of nitrogen, to a solution of EBPYT (0.31 mmol) in deoxygenated nitromethane (6 cm^3) gave an orange precipitate.

$CoCl_2$(EBPYT). A solution of hydrated cobalt(II) chloride (0.11 mmol) in the minimum amount of hot ethanol was added to a hot solution of EBPYT (0.24 mmol) in a mixture of nitromethane (3 cm^3) and ethyl acetate (3 cm^3). The clear green solution quickly deposited a green solid which was filtered off, washed with nitromethane and dried.

$CoBr_2$(EBPYT). This bright green compound separated on mixing hot solutions of hydrated cobalt(II) bromide (0.17 mmol) in ethanol (2 cm^3) and EBPYT (0.24 mmol) in nitromethane (6 cm^3).

CoI_2(EBPYT). This was obtained as for the cobalt(II) bromide complex but using methanol as the solvent for the cobalt iodide.

$Co(NO_3)_2$(EBPYT). A solution of hydrated cobalt(II) nitrate (0.18 mmol) in 0.3 cm^3 of a 1 : 1 mixture of methanol and nitromethane was added to one of EBPYT (0.24 mmol) in nitromethane (6 cm^3). On heating the resulting deep blue-green solution a deep blue-purple solid separated.

$Co(EBPYT)_2(ClO_4)_2 \cdot 2H_2O$. A solution of cobalt(II) perchlorate hexahydrate (0.06 mmol) in ethanol (2 cm^3) was added to a hot solution of EBPYT (0.20 mmol) in nitromethane (3 cm^3). The dark green solution gave a green precipitate on cooling.

$NiBr_2$(EBPYT). This bright green complex precipitated immediately on addition of a solution of hydrated nickel bromide (0.18 mmol) in 0.6 cm^3 of a 1 : 1 mixture of methanol and nitromethane to a hot solution of EBPYT (0.24 mmol) in nitromethane (6 cm^3).

$Ni(EBPYT)_2(BF_4)_2$. Hydrated nickel(II) tetrafluoroborate (0.07 mmol) dissolved in the minimum amount of methanol (0.2 cm^3) was boiled with 2,2-dimethoxypropane (2 cm^3) until the volume was approximately halved. The resulting solution was added to one of EBPYT (0.24 mmol) in nitromethane (8 cm^3) at ca 25°C to give a very finely divided deep blue-green solid. This was collected by centrifugation and washed with nitromethane and then diethylether.

$Ni(EBPYT)_2(ClO_4)_2$ *and* $Ni(EBPYT)_3(ClO_4)_2$. Hydrated nickel perchlorate (0.06 mmol) in warm methanol (2 cm^3) was added to a solution of EBPYT (0.20 mmol) in nitromethane (5 cm^3). The clear brown solution quickly became yellow but, after heating, the

[a] Calculated values are given in parentheses.

brown colour returned and the compound Ni(EBPYT)$_2$(ClO$_4$)$_2$ separated as a dark blue-green solid. This was filtered off, washed with nitromethane, then diethyl ether, and dried. Another reaction mixture, initially prepared as above, was not heated but simply allowed to evaporate slowly in air. The precipitate of Ni(EBPYT)$_2$(ClO$_4$)$_2$ which separated was filtered off and the mother liquor again allowed to evaporate slowly. Small red blocks crystallised, together with some free ligand and a further amount of Ni(EBPYT)$_2$(ClO$_4$)$_2$. The red crystals were separated by hand, carefully washed with a little nitromethane and characterised by X-ray diffraction methods.

Cu$_2$Cl$_2$(EBPYT) *and* Cu$_2$(EBPYT)$_3$(BF$_4$)$_2$. The respective, hydrated copper(II) salt (0.10 mmol) in a 1 : 1 mixture of methanol and nitromethane (total volume 0.3 cm^3) was added to one of EBPYT (0.24 mmol) in nitromethane (6 cm^3). A brown solid which formed initially redissolved on stirring and was replaced by an orange precipitate.

Cu$_2$Br$_2$(EBPYT), Cu$_2$(EBPYT)$_3$(ClO$_4$)$_2$ *and* Ag$_2$(EBPYT)$_3$X$_2$ (X = ClO$_4$, BF$_4$). These compounds precipitated immediately on mixing solutions of the appropriate Cu(II) or Ag(I) salt (0.016 mmol; but 0.011 mmol in the case of copper(II) perchlorate) in a 1 : 1 mixture of methanol and nitromethane with one of EBPYT (0.32 mol) in a 1 : 1 mixture of dichloromethane and nitromethane.

ZnCl$_2$(EBPYT). A solution of anhydrous zinc chloride (0.31 mmol) in warm ethanol (0.3 cm^3) was mixed with a warm solution of EBPYT (0.32 mmol) in a mixture of ethanol (2 cm^3) and nitromethane (4 cm^3). The pale yellow complex which precipitated on heating the solution was collected and then washed with diethyl ether.

Zn(NCS)$_2$(EBPYT). Addition of a solution of zinc thiocyanate (0.32 mmol) in methanol (2.5 cm^3) to a warm solution of EBPYT (0.32 mmol) in nitromethane (6 cm^3) gave an immediate yellow precipitate.

Zn(EBPYT)$_2$(ClO$_4$)$_2$. This was obtained as for the previous complex, but using a 2 : 1 EBPYT : Zn mole ratio, and the product separated more slowly.

Cadmium complexes. These compounds precipitated immediately on adding a solution of the appropriate cadmium salt (0.10 mmol for the halides, 0.16 mmol for the perchlorate, and 0.32 mmol for the nitrate) in the minimum amount (ca 0.4 cm^3) of hot dimethylformamide to a solution of EBPYT (0.32 mmol) in nitromethane (6 cm^3).

Spectroscopy

The electronic spectra of the solid compounds were obtained by the reflectance method using powdered samples and a Beckman DK2 spectrometer. IR spectra were recorded on a Perkin–Elmer 1720 FT spectrometer as Nujol mulls using CsI plates. The Mössbauer spectra of Fe(EBPYT)Cl$_2$ were obtained by Dr Q. A. Pankhurst of the Department of Physics and Astronomy, University College London under the ULIRS service.

Crystallography

Crystal data. For CoBr$_2$(EBPYT), **1**: C$_{12}$H$_{12}$N$_2$S$_2$Br$_2$Co, M = 467.1, monoclinic, space group $P2_1/n$ (no. 14), a = 6.88(2), b = 14.35(2), c = 15.34(2) Å, β = 91.2(1)°, U = 1514(4) Å^3, Z = 4, D_c = 2.05 g cm^{-3}, μ(Mo–K$_\alpha$) = 66.8 cm^{-1}, F(000) = 908. A green needle of dimensions 0.42 × 0.15 × 0.06 mm was used.

For [Ni(EBPYT)$_3$](ClO$_4$)$_2$, **2**: [C$_{36}$H$_{36}$N$_6$S$_6$Ni][ClO$_4$]$_2$ · 2MeOH · MeNO$_2$, M = 1127.8, rhombohedral, space group $R\bar{3}/c$ (no. 167), $a = b$ = 15.914(1), c = 35.966(5) Å, U = 7888(1) Å^3, Z = 6 (the molecule has crystallographic D_3 symmetry), D_c = 1.42 g cm^{-3}, μ(Mo–K$_\alpha$) = 7.7 cm^{-1}, F(000) = 3504. A red block of dimensions 0.30 × 0.21 × 0.18 mm was used.

Data collection and processing

Data for both structures were collected on a Siemens P4/PC diffractometer with graphite monochromated Mo–K$_\alpha$ radiation using ω-scans, 1921 (1546) Independent reflections were measured for **1** (**2**) respectively [$2\theta \leqslant 45$ (50)°] of which 902 (1146) had $|F_o| > 4\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarisation factors, and in the case of **1** an empirical absorption correction was applied; the maximum and minimum transmission factors were 0.67 and 0.20 respectively.

Structure analysis and refinement

Both structures were solved by direct methods. In **1** all of the non-hydrogen atoms were refined anisotropically. In **2**, though the atoms of the complex were ordered and refined anisotropically, both the perchlorate counter ion and the methanol and nitromethane included solvent molecules were found to be disordered. The anion was disordered over a crystallographic mirror plane, and this was modelled by a single one-third occupancy molecule that was refined anisotropically. The methanol molecules were distributed over two reduced occupancy sites, with one of them overlapping one of the partial occupancy nitromethane positions—all of these atoms were refined isotropically. The hydrogen atoms of the ligands in both structures were placed in calculated positions, assigned isotropic thermal parameters, [U(H) = 1.2U_{eq}(C)], and allowed to ride on their parent carbon atoms. The hydrogen atoms of the included solvent molecules in **2** could not be located. Refinements were by full-matrix least-squares based on F^2 to give R_1 = 0.094 (0.066), wR_2 = 0.206 (0.220) for 902 (1146) independent observed reflections and 172 (146) parameters respectively. The maximum and

minimum residual electron densities in the final ΔF maps were 0.66 (0.62) and −0.67 (−0.57) eÅ^{-3} for **1** and **2** respectively. The mean and maximum shift/error ratios in the final refinement cycle were 0.001 (0.000) and −0.005 (0.001) respectively. Computations were performed using the SHELXTL-PC system version 5.03 [6]. Important bond lengths and angles for compounds **1** and **2** are listed in Table 2.

RESULTS AND DISCUSSION

The ligand EBPYT readily forms solid complexes with a range of transition metal ions (Table 1) but only in two cases, Co(EBPYT)Br_2 (**1**) and [Ni(EBPYT)$_3$]$(ClO_4)_2$ (**2**), were we able to obtain crystals of appropriate quality for the single crystal X-ray studies required for elucidation of their extended polymeric structures. These structures are discussed below. Some further, albeit more limited, information about the coordination geometry of the metal ions in the other compounds was obtained by spectroscopic methods.

Metal halide complexes

The metal halide complexes of Fe^{II}, Co^{II}, Ni^{II}, Zn and Cd have stoichiometry M(EBPYT)X_2. The reactions between EBPYT and copper(II) chloride and bromide caused reduction of the copper and the formation of essentially quantitative yields of copper(I) complexes of stoichiometry Cu_2X_2(EBPYT), where X = Cl or Br.

The electronic spectra of the cobalt(II) complexes Co(EBPYT)X_2 (X = Cl, Br, I) in the solid state (Table 3) are typical of an essentially tetrahedral coordination geometry about the Co centre [7], showing strong overlapping bands in the range 5000–8000 cm^{-1} [transitions to components of $^4T_1$(F)] and a strong multicomponent band in the visible region [transitions to components of $^4T_1$(P)]. The electronic spectra of Fe(EBPYT)Cl_2 and Ni(EBPYT)Br_2 (Table 3) are also consistent with a tetrahedral geometry [7–9]. For the compounds M(EBPYT)Cl_2 (M = Fe, Co and Zn) further evidence [10] for tetrahedral coordination geometry is provided by their low frequency IR spectra, which have ν(M—Cl) bands at 296 and 333 cm^{-1} for M = Fe, 300 and 322 cm^{-1} for M = Co, and 291 and 309 cm^{-1} for M = Zn.

The Mössbauer spectrum of Fe(EBPYT)Cl_2 comprises a quadrupole split doublet with Q.S. values of 3.00 mm s^{-1} at 295 K and 3.09 mm s^{-1} at 80 K and with chemical shift (δ) values, relative to α-Fe metal, of 0.74 mm s^{-1} at 295 K and 0.86 mm s^{-1} at 80 K (Fig. 1). Further cooling to 20 K results in little change in these parameters (Q.S. 3.08 mm s^{-1}, δ 0.86 mm s^{-1} at 20 K) but at that temperature the line width increases slightly and with some indication of incipient ordering. The observed parameters, and particularly the δ values, correspond well with other essentially tetrahedral FeL_2Cl_2 complexes where L is a monodentate sulphur donor ligand [11].

Because of the difficulty in growing suitable crystals, X-ray confirmation of these conclusions could be obtained only for Co(EBPYT)Br_2 and even then the crystals were of rather poor quality. They were, however, sufficient to define both the coordination geometry about the metal ion and the long-range structure.

Structure of Co(EBPYT)Br_2 (**1**)

The X-ray study of **1** confirms the essentially tetrahedral coordination at each cobalt centre (Fig. 2) though the S—Co—S angle [92.4(3)°] is significantly distorted from ideal. There are two crystallographically independent EBPYT ligands, each of which has an inversion centre in the middle of the ethylene bridge producing an extended *anti* geometry, the N—CH_2—CH_2—N backbone being inclined by

ca 85° to the plane of the aryl ring. The EBPYT ligands link adjacent cobalt centres to form polymer chains (Fig. 3). Despite the presence of two independent EBPYT ligands, the chains have C_s symmetry with respect to the $CoBr_2$ plane. Each ligand exhibits a 15° torsional twist about the S-aryl bond, thus producing a "winged" geometry for the $CoBr_2$(-S-aryl)$_2$ unit.

Although there is a superficial stacking of the aryl rings along the crystallographic *a* direction, there is only very minimal ring overlap (ring centroid/ring centroid 4.33 Å) and the rings lie more over the coor-

dinated sulphur atoms, which are at 3.62 Å from the ring centroid. Non-stacked chains pack in a "parquet" pattern with their glide-related neighbours.

Complexes with metal perchlorates and tetrafluoroborates

Addition of a hot solution of nickel tetrafluoroborate hexahydrate in 2,2-dimethoxy-propane, containing a small amount of methanol, to a nitromethane solution of EBPYT gave a very dark blue-green complex of stoichiometry $Ni(EBPYT)_2(BF_4)_2$. This compound was found to be diamagnetic, pointing to a planar NiS_4 coordination geometry, and its electronic spectrum in the solid state (Table 3) is also consistent [12] with that geometry.

Reaction of nickel perchlorate hexahydrate with EBPYT in a mixture of methanol and nitromethane gave, on heating, a precipitate of the analogous very dark blue-green, diamagnetic compound $Ni(EBPYT)_2(ClO_4)_2$. However, slow concentration of the reaction mixture at room temperature resulted in the formation of small red block-like crystals of a new compound (**2**) along with $Ni(EBPYT)_2(ClO_4)_2$. Attempts to isolate **2** free from $Ni(EBPYT)_2(ClO_4)_2$ by recrystallisation resulted in crystal decomposition, so the red crystals were hand-selected and characterised by X-ray diffraction methods.

Structure of $[Ni(EBPYT)_3](ClO_4)_2$ (**2**)

The X-ray analysis of **2** established the compound to have the stoichiometry $Ni(EBPYT)_3(ClO_4)_2$. The nickel atoms are six-coordinate being bonded to a sulphur atom from each of six EBPYT ligands in a D_3 symmetric arrangement (Fig. 4). The distortion from O_h symmetry takes the form of a 6° twist of the opposite faces of the octahedron from a perfectly staggered geometry. The *cis* angles at nickel range between 82.84(5) and 100.31(6) ; the *trans* angles are all 175.42(5) . The Ni—S bond lengths are all 2.459(1) Å and are typical for monodentate sulphur donor ligands octahedrally coordinated to nickel(II).

The torsional twist about each S-aryl bond is 31 which results in a significant flattening of the Ni(-S-aryl)$_6$ unit and overlap of pairs of aryl groups from the upper and lower triangular faces. The ring centroid/ring centroid separations are 3.59 Å and overlapping rings are inclined by 18 , thus indicating a degree of π–π stabilisation of the complex conformation.

As in **1**, the EBPYT ligands have a crystallographic inversion centre at the mid-point of the ethylene bridge, with the plane of the N—CH_2—CH_2—N backbone being inclined by 82° to the aryl ring plane. This *anti* geometry for the ligand results in formation of EBPYT bridges to adjacent, symmetry equivalent nickel centres, thus producing a polymeric network structure. The basic component of the network is a rhombohedron with nickel atoms at each vertex and edges formed by the EBPYT ligands; this is depicted schematically in Fig. 5. The Ni···Ni separation is 10.97 Å and the angles subtended by the Ni—Ni vectors are either 87 or 93 .

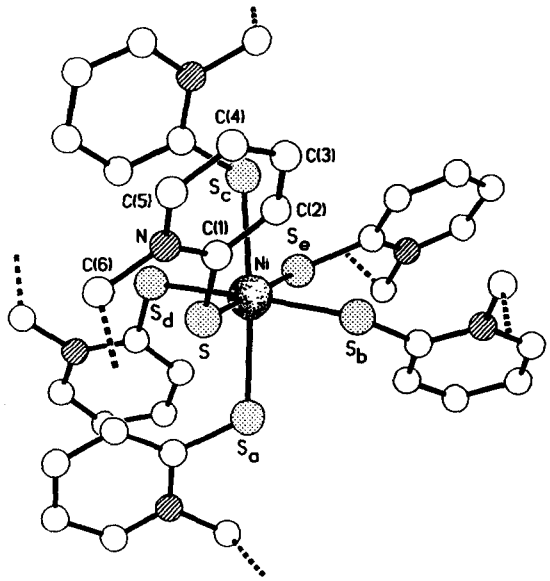

Fig. 4. The coordination geometry about Ni in the structure of **2**: S, S_{a-e} are equivalent by symmetry.

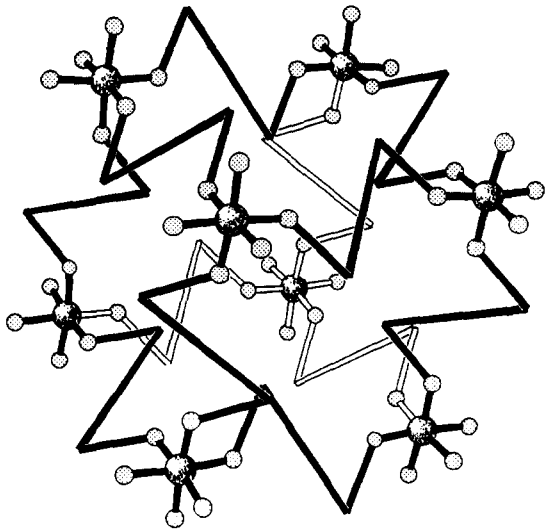

Fig. 5. Schematic representation of one of the contiguous rhomboidal "boxes" forming the polymeric structure of **2**; the long spacer lines link ligand aryl ring centroids.

The network structure we observe here for **2** is similar to those formed by $[Mn\{N,N'$-*p*-phenylenedimethylenebis(4-methylpyridin-2-one)$\}_3](ClO_4)_2$, **3** [3b], and $[Mn(N,N'$-butylenebisimidazole$)_3](ClO_4)_2$, **4** [13]. However in **2** the rhomboid volume (1315 Å^3) is marginally less than that in **3** (1450 Å^3) but is significantly smaller than that in **4** (1950 Å^3). In **4** the free volume is such that rhomboid interpenetration occurs to fill the cavities, whereas in **3** voids are localised along the body diagonals. In **2**, however, the free volume of the central core has a diameter of only ca 5 Å (being restricted by edge-on, inwardly directed aryl rings) and the perchlorate ions are located in the "windows" between adjacent rhomboids (Fig. 6). The smaller central core is populated by disordered molecules of solvation.

Other complexes

The reaction between cobalt(II) perchlorate hexahydrate and EBPYT in a mixture of hot ethanol and nitromethane resulted in the precipitation of a bright green complex of stoichiometry $Co(EBPYT)_2(ClO_4)_2 \cdot 2H_2O$, the solid state electronic spectrum of which (Table 3) is characteristic of an essentially tetrahedral coordination geometry about cobalt(II). The bands arising from the transitions to the components of both $^4T_1(F)$ (in the near IR region) and $^4T_1(P)$ (in the visible region) show pronounced splitting, suggesting that the CoS_4 coordination geometry is somewhat distorted, probably because of steric constraints arising from the form of the bridging action required for the EBPYT ligand to link the tetrahedral metal centres into a polymeric array.

As in the case of the copper(II) halides, reaction

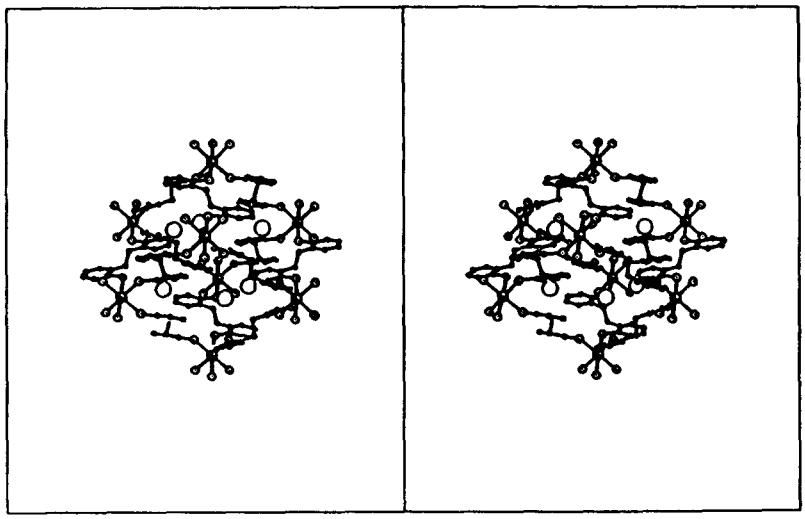

Fig. 6. Stereoscopic view of one of the rhomboidal "boxes" in **2**, with the positions of the perchlorate ions in the "windows" indicated by open circles.

of EBPYT with hydrated copper(II) perchlorate or tetrafluoroborate in mixtures of methanol and nitromethane (and dichloromethane in the case of the perchlorate) resulted in rapid reduction ofthe copper salt and the formation of orange copper(I) complexes of stoichiometry $Cu_2(EBPYT)_3X_2$ ($X = ClO_4$ or BF_4). Analogous complexes $Ag_2(EBPYT)_3X_2$ ($X = ClO_4$ or BF_4) were also formed by silver(I). As the stoichiometry of these complexes is the same as that reported previously [4b] for the complex $\{[Cu_2(EBPYT)_3](PF_6)_2\}_n$, obtained by reaction of $Cu(MeCN)_4(PF_6)$ with EBPYT in acetonitrile, it is quite likely that these new compounds also form sheet polymers in which 4-membered $M_2(\mu\text{-}S)_2$ units are further linked by the EBPYT ligands into arrays of contiguous 18- and 36-membered rings, but single crystals of these compounds were not obtained.

In summary, even though with EBPYT it proved difficult to obtain crystalline samples suitable for full X-ray characterisation, the results of this work, and particularly the structure of **2**, demonstrate that "extended reach" bis-pyridine-2-thione ligands of this type are a potentially fruitful source of new polymeric network complexes. Appropriate ligand modifications, involving substitution on the pyridinthione rings and/or changes in the nature and length of the "spacer" group between the rings, should permit both enhanced crystallinity and a further diversity in the types of arrays that can be formed.

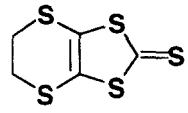
(Received 20 October 1997, accepted 6 January 1998)

Abstract—Two mercury(II) complexes of 4,5-ethylenedithio-1,3-dithiole-2-thione ($C_5H_4S_5$), $[Hg_2(C_5H_4S_5)_2Cl_4]$ (**1**) and $[Hg_2(C_5H_4S_5)_2Br_4]$ (**2**), were synthesized and the structure of complex **1** was characterized crystallographically. Complex **1** has a dimeric structure, in which each mercury atom takes a tetrahedral geometry and is coordinated by two bridging chloride, one terminal chloride and one thiocarbonyl sulfur atom (C=S) of the ligand. These dimers are further packed to form a one dimensional ribbon structure via intermolecular S···S and S···Cl contacts. All of the ligands in the ribbon are co-planar and weakly conjugated. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: mercury(II) complexes; sulfur-rich compounds; crystal structure; intermolecular contacts.

In most conductive sulfur-rich donor-acceptor compounds or radical salts, intermolecular interactions such as S···S contacts have been found to play an important role in the conductivity of these compounds. The molecular packing that influences the S···S interaction is mainly controlled by the identity of the molecule itself, the size of counter ions and co-crystallized solvent molecules [1]. On the other hand, metal ions have properties of special interest as components of supramolecular systems and linkers for self-assembly [2]. Our recent interest was focused on the assembling of sulfur-rich donor compounds via both coordination bonds and S···S interactions [3–5], since the packing and interactions of organic molecules in the coordination compounds have more variety than is observed in pure organic compounds.

To introduce metal ions to these donor-acceptor systems, a sulfur-rich compound of 4,5-ethylenedithio-1,3-dithiole-2-thione ($C_5H_4S_5$), which is known as an electron donor and has available site to coordinate to metal ions [6], was selected as a ligand in this work. The ligand is also a derivative of dmit



$C_5H_4S_5$

(4,5-disulfanyl-1,3-dithio-2-thionate) and has a similar structure to half of BEDT-TTF [bis(ethylenedithio)tetrathiafulvalene]. Recently we have reported four complexes of $C_5H_4S_5$, $[Ag(C_5H_4S_5)_2NO_3]_x$ [3], $[Cu_4I_4(C_5H_4S_5)_4]_x$ [4], $\{[Ag(C_5H_4S_5)_3]ClO_4 \cdot CH_3CN\}_2$ [5] and $[Ag(C_5H_4S_5)CF_3SO_3]_x$ [5]. Each of them has a unique molecular structure and a S···S contact assembled network. In this paper we report two new mercury(II) complexes of $C_5H_4S_5$. One of which was characterized crystallographically, showing a dimer structure with two kind of intermolecular interactions.

EXPERIMENTAL

The reagent $C_5H_4S_5$ was obtained from Tokyo Kasei Co. and used without further purification. Ace-

* Author to whom correspondence should be addressed.

tonitrile was dried and distilled by a standard method before use. Infrared spectra were measured as KBr and CsI discs on a JASCO FT/IR 8000 spectrometer and electronic spectra were recorded with a Hitachi 150-20 spectrophotometer. Electrical resistivity was measured by a conventional two-probe method at room temperature with a compressed pellet.

Preparation of $[Hg_2(C_5H_4S_5)_2Cl_4]$ (**1**)

To an acetone solution (4 cm^3) of $C_5H_4S_5$ (11.5 mg, 0.05 mmol) was added $HgCl_2$ (27.0 mg, 0.1 mmol) in acetone (2 cm^3). The mixture was stirred for 20 min at room temperature under an argon atmosphere. A red precipitate formed and it was filtered and dried in argon. Suitable crystals for X-ray measurement were grown at $-5°C$ from the filtrate which was sealed in a glass tube. Anal: Calc. for $C_5H_4Cl_2HgS_5$: C, 12.11; H, 0.81. Found: C, 12.26; H, 0.76%.

Preparation of $[Hg_2(C_5H_4S_5)_2Br_4]$ (**2**)

The complex **2** was prepared via a similar method as that of **1**. Instead of $HgCl_2$, $Hg(ClO_4)_2 \cdot H_2O$ and $(C_4H_9)_4NBr$ (in 1 : 2 ratio) were used as the starting materials. Anal: Calc. for $C_5H_4Br_2HgS_5$: C, 10.27; H, 0.69. Found: C, 10.65; H, 0.73%.

The iodine-doped compounds of **1** and **2** were prepared by gaseous diffusion. A small amount of powder of the complex and solid I_2 were separately placed in an H-shaped tube which was then sealed under argon and was allowed to stand for one month at ambient temperature. Red-black I_2-doped compounds were obtained.

X-ray structure determination

A red crystal of **1** was mounted on a Rigaku AFC7R four-circle diffractometer equipped with a graphite monochromator utilizing Mo–K_α radiation. The data were collected by using the ω-2θ scan technique to a maximum 2θ value of 54.9°. Of the 2801 reflections collected, 2622 were unique. An empirical correction based on azimuthal scans of several reflections was applied and the data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SAPI91) [7], and expanded using Fourier techniques [8]. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The final cycle of full-matrix least-squares refinement was based on 2435 observed independent reflections [$I > 3\sigma(I)$] and 118 variable parameters. The final R and R_w values were 0.034 and 0.057, respectively. All calculations were performed using the TEXSAN program system [9]. Details of crystal data are summarized in Table 1.

RESULTS AND DISCUSSION

Structural description and discussion

The complex $[Hg_2(C_5H_4S_5)_2Cl_4]$ (**1**) is found to be a halogen-bridged dimer related by an inversion centre. An ORTEP view of the complex together with the atomic labeling scheme is given in Fig. 1. Each mercury atom is four-coordinated with significant distortion from tetrahedral. Two of these bonds are formed by two asymmetric chloride bridges, while the remaining two bonds are formed by a terminal chloride ion and thiocarbonyl sulfur atom of the ligand. The selected bond lengths and angles for the complex are listed in Table 2, in which the data of the dimeric unit are comparable to those reported in the literature for related chloride bridged dimeric Hg(II) complexes [10,11].

Coordination modes of the $C_5H_4S_5$ ligand have been classified into four types by our previous report [5]. They are monodentate coordination by the thiocarbonyl group (type I), bridge formation by the

sulfur of the thiocarbonyl group (type II), bidentate coordination by both thiocarbonyl group and thioether group (type III) and tridentate coordination by the thiocarbonyl sulfur (acting as a bridge) and the thioether sulfur (type IV). Although the coordination of the ligand in type I has been found in complex $[Cu_4I_4(C_5H_4S_5)_4]_\infty$ and $\{[Ag(C_5H_4S_5)_3]ClO_4 \cdot CH_3CN\}_2$ [4,5], other coordination types are co-exist in these complexes. $[Hg_2(C_5H_4S_5)_2Cl_4]$ is the complex found in the coordination of the ligands only in type I. The S(1)—C(1) distance of 1.702 Å in **1** is longer than that for the free ligand 1.633 Å [12] and is the longest found in the complexes of $C_5H_4S_5$. This longer S(1)—C(1) distance attributes to the strong coordination of the thiocarbonyl sulfur to soft mercury(II) ion that weakens the S(1)—C(1) bond.

We are paying significant attention to the S···S contacts in complexes with sulfur-rich ligands, since S···S contact is one of the most important factors by which the compounds exhibit high conductivity [13–16]. We also found that the coordination linkage in metal complexes can be expected to control or change the intra- or inter-molecular interactions in supermolecules [3–5,17]. In the present complex, the S···S contact of 3.583(3) Å between nearby dimeric units is less than the sum 3.70 Å of van der Waals radii of two S atoms. There is another type interaction within the chain, that is strong Cl···S contact. The contact distance of 3.288(3) Å significantly shorter than the sum 3.60 Å of van der Waals radii. Thus, this complex has a one-dimensional supramolecular structure assembled by both S···S and Cl···S contacts. A view of the S···S and Cl···S contacts assembled ribbon structure is given in Fig. 2.

For the head-to-tail S···S contacts (thiocarbonyl to thioether) and the Cl···S contacts, all of the ligands in the ribbon are co-planar and weakly conjugated that indicates an efficient intermolecular π-π orbital interactions and forms a broadened energy band over the whole lattice. Most of the TTF and dmit based superconductors have this character.

Spectroscopic studies and the iodine doped compounds

The IR spectra of **1** and **2** show one broad $\nu_{(C=S)}$ stretching frequency of the heterocyclic ring at 1010 and 1008 cm^{-1} respectively. The C=S stretching frequency of 1477 cm^{-1} for the free ligand [12] is shifted to 1441 cm^{-1} for both of the complexes. These shifts are larger than those of the silver(I) and copper(I) complexes [3–5], attributing to the strong coordination of the mercury(II) with thiocarbonyl sulfur. This result is in accordance with that found in the C=S distances. The infrared frequencies of Hg—X (X = Cl, Br) for complexes **1** and **2** were measured using CsI discs. Comparing with the spectrum of the ligand, the ν(Hg—Cl)$_t$ and ν(Hg—Br)$_t$ (t = terminal)

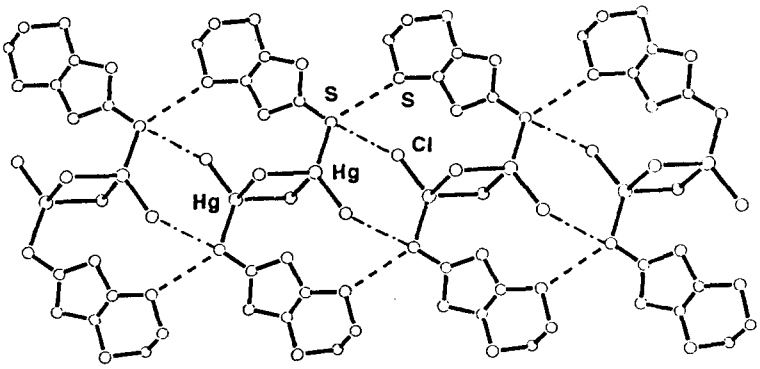

Fig. 2. The one-dimensional ribbon structure assembled by intermolecular S···S and S···Cl contacts.

are 280 and 201 cm^{-1} respectively, and the $\nu(Hg—Cl)_b$ and $\nu(Hg—Br)_b$ (b = bridge) are 226 and 154 cm^{-1} respectively. The dimeric halogen-bridged complexes have been reviewed by P. A. W. Dean in detail [11]. Although only the observation of a bridging Hg—X frequency is probably insufficient to discriminate between halogen-bridged dimers and halogen-bridged polymers with tetrahedral coordination of mercury, considering the other habits of the complex **2**, it should have a dimeric structure as in complex **1**. Both the complexes formed red prismatic crystals and showed high solubility in acetone and acetonitrile. The solid-state electronic spectra of the complexes showed a strong broad peak at about 500 nm assigned to a metal–ligand charge transfer for the red complexes. On the other hand, a weak broad peak at 900 nm can be explained by the intermolecular interactions.

Halogen doping of conjugated electron donors has been shown to be an effective strategy for the synthesis of electrically conductive compounds. Although the iodine doped free $C_5H_4S_5$ ligand is an insulator ($\sigma < 10^{-12}$ S cm^{-1}) the iodine doped complex **1** and **2** exhibit electrical conductivity (σ) of 3.0×10^{-5} S cm^{-1} and 1.5×10^{-5} s cm^{-1} at room temperature. The increase of electronic conductivity is due to the partial oxidation of the ligands and the short S···S contacts within the 1D structure.

Acknowledgments—The financial support from the Ministry of Education, Science, Sports and Culture in Japan and the government of Jiangsu province in China are greatly appreciated.

Hydrolysis of methionine-containing peptides in binuclear and mononuclear palladium(II) complexes

Xiaohua Chen, Xuemei Luo, Yongcheng Song, Shaozhen Zhou and Longgen Zhu*

Coordination Chemistry Institute, State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing, Jiangsu, 210093, P.R. China

(Received 14 October 1997; accepted 5 January 1998)

Abstract—The diaqua complexes of *trans*-$[Pd(py)_2Cl_2]$ (Py-pyridine), *cis*-$[Pd(edta)Cl_2]$ (edta-ethylene diamine tetraacetic acid) (complex A), *cis*-$[Pd(temed)Cl_2]$ (temed-N,N,N′,N′-tetramethylethylene diamine) and *cis*-1,2-bis(2-formylglycinebenzenesulfenyl)ethane Pd(II) dichloride (complex C) react with methionine-containing dipeptides (AcMet-aa) (aa-amino acid) via the thioether group in the methionyl side chain. The *trans*-$Pd(py)_2(H_2O)_2]^{2+}$ and *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ yield binuclear complex $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$, the diaqua complexes of complex A and complex C yield mononuclear complexes, $[PdL(AcMet\text{-aa})(H_2O)]^{2+}$ (L-edta, 1,2-bis(2-formylglycinebenzenesulfenyl)ethane). These reactions and hydrolytic cleavage of the Met-aa amide bond in the coordinated AcMet-aa are conveniently monitored by ^1H NMR spectroscopy. The *trans*-$Pd(py)_2(H_2O)_2]^{2+}$ is a very efficient promoter. The hydrolytic rate promoted by it is almost equal to that promoted by $[Pd(H_2O)_3(OH)]^+$, the fastest one up to now. Although reaction of *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ and *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ with AcMet-aa yield the same binuclear complex, $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$, the kinetic data showed that the hydrolytic rate promoted by *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ was actually controlled by temed release. The new mononuclear complexes, $[PdL(AcMet\text{-aa})(H_2O]^{2+}$, observed for the first time, are also hydrolytically active. It is of interest because they are closely associated with protein cleavage promoted by simple mononuclear Pd(II) complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: palladium; hydrolysis; peptide cleavage; artificial metallopeptidase.

Selective cleavage of peptides and proteins is one of the most common tasks and the most important procedure in analytic biochemistry. Although several proteolytic enzymes are available for this purpose, its number is very limited and only trypsin is highly regioselective [1]. Furthermore, since the requirements for the traditional applications are changing today, new methods for cleavage are needed for many tasks in biochemistry and molecular biology: semisynthesis of proteins; sequencing of large or blocked proteins; structural and functional analysis of protein domain; development of new drugs, and so on. Chemical (non-enzymatic) reagents are well suited for many of these tasks. Although the need for them is growing, only one, cyanogen bromide, is available for routine use [1]. But it has several shortcomings. It is volatile and toxic, requires harsh conditions, and often produces incomplete cleavage.

Transition metal complexes are also suited for cleavage of inactivated amide bonds in peptides [2–22] and proteins [23–31]. In the early studies, complexes of cobalt(III) and copper(II) were studied more than any other. Kinetic and mechanistic studies have been done almost exclusively with amides that variously activated by substituents, by ring strain, by forced non-planarity, or by proximate functional group [2–13]. These complexes are not suitable to a practical use for analytic biochemistry, because only the N-terminal amide bond is cleaved. Practical applications, however, usually require cleavage of internal amide bonds.

In recent studies, a variety of metal complexes have been developed for direct hydrolytic or oxidative cleavage of amide bonds in peptides [14–22] and proteins [23–31]. One of them is simple palladium(II)

* Author to whom correspondence should be addressed

aqua complexes that bind to the side chains of methionine [15–19,22] and histidine [20,21] residues in short peptides followed by selectively hydrolytic cleavage of the adjacent amide group, even with turnover [21,22]. In order to further develop this new method for practical application, it is necessary to synthesize new palladium(II) complexes and investigate the action of cleavage reaction as well as understand the stereochemical requirements for cleavage. In this article, we report some palladium(II) complexes that hydrolyze Met-aa(amino acid) amide bond with different behavior. A monodentate palladium(II) complex, *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$, fast hydrolyzes Met-aa amide bond with a hydrolytic rate comparable with that promoted by $[Pd(H_2O)_3(OH)]^+$. Unlike $[Pd(H_2O)_3OH)]^+$, *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ is more stable and easy to prepare. An N,N-chelated palladium(II) complex, *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ (temed-N,N,N′,N′-tetramethyl ethylene diamine) hydrolyzes Met-aa amide bond with hydrolytic rate controlled by temedH_2^{2+} release. The action of the other two complexes, *cis*-$[Pd(edta)Cl_2]$ (edta-ethylenediaminetetraacetic acid) designated complex A and *cis*-1,2-bis(2-formylglycinebenzenesulfenyl) ethane Pd(II) dichloride designated complex C differs from their similar complexes of *cis*-$[Pd(en)Cl_2]$ (en-ethylenediamine) and *cis*-$[Pd(dtco\text{-}3\text{-}OH)Cl_2]$ (dtco-3-OH-1,5-dithiacyclooctan-3-ol). Although palladium(II) is added to the methionine-containing peptides in the form of mononuclear complexes, the complexes studied so far that actually undergo hydrolysis are binuclear complexes shown as $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$. Both NMR spectra and kinetic experiments support this conclusion. However, when the diaqua complexes of complex A and complex C were used as promoters, a new hydrolytically active mononuclear Pd(II) complex was observed for the first time. This active monomer may closely be relative to hydrolysis reaction proceeded in proteins because its steric bulk prevents formation of active binuclear complexes. This study contributes to our further understanding of the mechanism of hydrolytic cleavage of peptides and brings us a step closer to our ultimate goal, design of palladium(II) complexes as artificial metallopeptidases.

EXPERIMENTAL

Chemicals

Distilled water was demineralized. The deuterium-containing compounds D_2O, DMSO-d_6 and K_2PdCl_4 were obtained from Aldrich Chemical Co. Dipeptides Met-Gly, Met-Ala, and Met-Val were obtained from Sigma Chemical Co. The terminal amino group in each dipeptide was acetylated by a published procedure [15]. All other common chemicals were of reagent grade.

The following dichloro complexes were prepared by published procedures: *cis*-$[Pd(en)Cl_2]$ [32], $[Pd(H_2O)_3(OH)]^+$ [15], *cis*-$[Pd(temed)Cl_2]$ [32], [Pd(dien)I]I (dien-diethylenetriamine) [33].

Trans-$[Pd(py)_2Cl_2]$. 0.5 g of $PdCl_2$ was suspended in 5 ml of pyridine. The mixture was stirred and heated to 80°C. After the solid was almost dissolved, the hot solution was filtered. 50 ml of benzene was poured into the filtrate. The yellow precipitate was collected, washed with benzene and dried *in vacuo*. Yield 90%. Diffusion of methanol into the N,N-dimethyl formamide (DMF) solution of *trans*-$[Pd(py)_2Cl_2]$ in six days produced the yellow single crystals. Its crystal data were reported in literature [34].

Cis-$[Pd(edta)Cl_2]\cdot 5H_2O$. It was prepared by mixing dihydrogen disodium ethylenediaminetetraacetate (Na_2H_2EDTA) with K_2PdCl_4 in water and crystallized from concentrated hydrochloric acid. The bright yellow crystals of *cis*-$[Pd(edta)Cl_2]\cdot 5H_2O$ was obtained. Its crystal data were determined [35].

1,2-bis(2-formylglycinebenzenesulfenyl)ethane Pd(II)dichloride complex designated complex C. It was synthesized according to standard method as described in our previous paper [36]. PhCOOH → 2-HSPh COOH → (2-SPhCOOH)CH_2CH_2(2-SPhCOOH) → (2-SPhCONHCH_2COOH)CH_2CH_2(2-SPhCONH CH_2COOH) → complex C. Molecular structure of the complex C was determined [36].

The corresponding diaqua complexes were obtained by stirring the precursors with 2.0 equivalents of $AgNO_3$ in a solution of pH* 2 for 4 h at 35°C and removal of AgCl by centrifugation, all in the dark. Since the solvent was D_2O the ligand were actually D_2O, but the formulas will be written simply with H_2O. The aqua complexes were always prepared fresh and used as solutions. For complex C, because of low solubility of corresponding diaqua complex, it was treated with DMSO-d_6 instead and designated complex D.

The ^1H NMR spectra of the acetylated dipeptides in D_2O showed the following principal δ values: AcMet-Gly, 2.04, s, CH_3CO; 2.11, s, CH_3S; 3.99, q, GlyCH_2; AcMet-Ala, 2.03, s, CH_3CO; 2.11, s, CH_3S; 1.44, d, AlaCH_3; 4.39, q, AlaCH; AcMet-Val, 2.03, s, CH_3CO; 2.11, s, CH_3S; 4.27, d, ValCH; 0.96, dd, ValCH_3. Stringent control experiments showed that these peptides are stable for long time in solution of pH $\leqslant$ 1.0 and ruled out simple acid catalysis of the peptides hydrolysis [15,16]. Acidic solutions are needed to suppress formation of oligomeric palladium(II) complexes with hydroxo bridges [15,16].

Measurements

Proton NMR spectra at 500 MHz of D_2O solutions, containing sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) as an internal reference, were recorded with an AM500 spectrometer. The sample temperature was kept at 40 ± 0.5°C. The pH was measured with an Orion 901 instrument and a phoenix Ag-AgCl

reference electrode. The uncorrected values in D_2O solutions are designated pH*.

Kinetics of hydrolysis

Stock solutions of all palladium(II) complexes were prepared fresh in D_2O or DMSO-d_6. The concentration of these Pd(II) complexes was 100 mM. Equimolar amounts of AcMet-aa(aa-Gly, Ala, Val) and of the Pd(II) complexes were mixed rapidly in an NMR tube, so that the final concentration of each was 10.0–20.0 mM. The total volume was 600 μl. pH* was adjusted with 1.0 M $HClO_4$ in D_2O solution, and was measured at beginning and the end of the reaction. The difference between two measurements is always less than 0.1 pH*. Acquisition of the ^1H NMR spectra began as soon as possible, and 16 or 32 scans were taken for each time. The hydrolysis products were monitored by enhancements of the ^1H NMR resonance of free amino acids. The concentrations of the hydrolysis products (Ct and C∞) were determined on the basis of resonance area; the estimated error is ±5%. First-order plots of -ln[(C∞-Ct)/C∞] versus time contained 13–20 points and were linear over at least three half-lives, with correlation coefficients of 0.994–0.999. The observed rate constants, k_{obsd}, are the slopes of these plots. The reactions were run for six half-lives.

RESULTS AND DISCUSSION

Hydrolysis of peptides promoted by trans-$[Pd(py)_2(H_2O)_2]^{2+}$

We reasonably assume that the replacement of the two chloride anions in *trans*-$[Pd(py)_2Cl_2]$ by two aqua ligands would not alter the structure. As scheme 1 shows, after mixing the *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ with AcMet-Gly, free pyH^+ can be quickly detected by ^1H NMR. This release is favored by the labilizing *trans* effect of the py (compared to H_2O) and thioether and by the acid in solution. The resonance of SCH_3 of AcMet-Gly at 2.46 ppm shows that the active form is a binuclear complex [15,16,18,22]. Hydrolysis of AcMet-Gly and s-methylglutathione (GSMe) promoted by $[Pd(H_2O)_3(OH)]^+$, *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ is listed in Table 1. for hydrolysis of AcMet-Gly, these three complexes have the same active from, μ_2-s-bridged binuclear complex, that effectively promotes the hydrolysis of peptides in it. However, compared with en, pyridine is a unidentate, weak ligand and more rapidly detached after mixing with the substrate. Therefore, *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ is a more efficient promoter. The hydrolytic rate promoted by it is almost equal to that promoted by $[Pd(H_2O)_3(OH)]^+$, the fastest one up to now. The great advantage of the *trans*-$[Pd(py)_2(H_2O)_2]^{2+}$ is that it is easy to prepare and stable for stocking. As shown from Table 1, the hydrolysis of s-

Table 1. Hydrolysis of AcMet-Gly and GSMe promoted by palladium(II) complexes at 40 C

Promoter	Substrate	pH*	k_{obsd} 10^4, min^{-1}
$[Pd(H_2O)_3(OH)]^+$	AcMet-Gly	1.07	360
trans-$[Pd(py)_2(H_2O)_2]^{2+}$	AcMet-Gly	1.05	330
cis-$[Pd(en)(H_2O)_2]^{2+}$	AcMet-Gly	1.05	199
$[Pd(H_2O)_3(OH)]^+$	GSMe	0.95	8.9

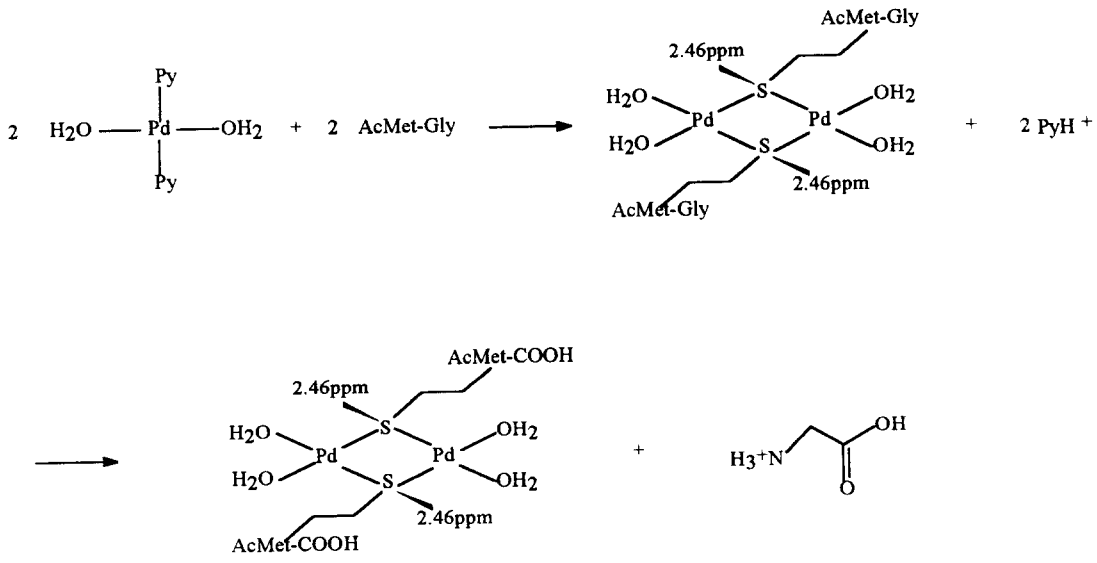
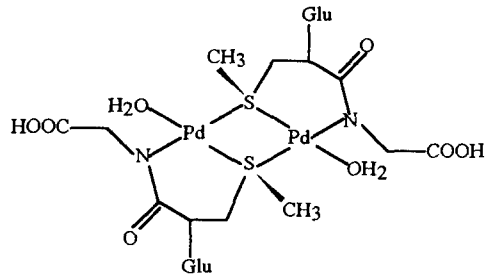


Scheme 1.

methylglutathione is much slower (40–60 times slower) than that of AcMet-Gly. Previous studies showed that s-methylglutathione reacts with Pd(II) complexes to form a binuclear complex as shown below [17].



Palladium(II) can effectively induce deprotonation of the amide nitrogen by binding to it [33]. When palladium(II) is already anchored to the side chain, this process is especially favorable due to six-membered chelating ring formation. The estimated pK_a for this reaction is ca 2, and displacement was observed even in solution with pH < 2.0 [37–42]. The coordination of the amide nitrogen to Pd(II) will stabilize the amide bond [15], and suppress the coordination of the carbonyl oxygen to Pd(II). This type of coordination enables to polarize the carbonyl group and activate it toward external attack by solvent water. Because, in this case, coordination of the amide nitrogen is predominant, the hydrolysis of GSMe is very slow. While, as far as AcMet-Gly is concerned, the longer side chain makes the above two types of coordination less likely because they form a seven-membered chelate ring. The aqua ligands attached to palladium(II) and *cis* to the substrates can be delivered to the carbonyl group internally. Therefore, the hydrolysis of AcMet-Gly is fast.

Dependence of hydrolysis rate constant on ligand substitution reaction

The structures of *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ are similar. They are both N,N-chelated Palladium(II) complexes. Their difference lies in that four hydrogen atoms in en are replaced by four methyl groups in temed. As the two complexes mixed with substrate AcMet-aa (aa-Gly, Ala, Val), the sulfur atom in the side chain of substrate substitutes the coordinated water, and at the same time the chemical shift of CH_3S is downfield from 2.11 ppm to 2.50 ppm. The reaction is very fast, it has completed at the beginning of monitoring. A dimer $[Pd_2(\mu\text{-AcMet-aa})_2L_2]^{4+}$ (aa-Gly, Ala, Val; L-en, temed) is formed. After formation of the dimer, $[Pd_2(\mu\text{-AcMet-Gly-})_2(temed)_2]^{4+}$, the signal of free glycine at 3.90 ppm increased. ^1H NMR also showed another two single peaks appeared at 2.62 ppm and 2.99 ppm that are assigned CH_3 and CH_2 in temed. It is clear that the release of free glycine is accompanied by the detachment of temed ligand. Therefore, we can simultaneously determine the observed rate constant of peptide hydrolysis, designated k^h_{obsd} and observed rate constant of substitution reaction of termed by water, designated k^s_{obsd}. The results are listed in Table 2. The k^s_{obsd} of en release is not given in the Table because enH_2^{2+} release in $[Pd_2(\mu_2\text{-AcMet-aa})_2(en)_2]^{4+}$ was too fast to monitor and completed only in 20 min. To compare the rates of ligand release more carefully, we have done some kinetic study on the reaction of the promoters with AcCysMe(acetyl-s-methylcysteine) at 25°C and pH* 1.52. The k^s_{obsd} values are as follows: $10^3K^s_{obsd}$ of $temedH_2^{2+}$ release is 3.56 min^{-1} and $10^3k^s_{obsd}$ of enH_2^{2+} release is 77.1 min^{-1}, 20-fold faster. Comparing the k^h_{obsd} with the k^s_{obsd} in $[Pd_2(\mu\text{-AcMet-aa})_2(temed)_2]^{4+}$, it revealed for the first time that the hydrolysis rate of dipeptides in the binuclear Pd(II) complex is governed by the temed-substitution reaction. The relationship between k^s_{obsd} and k^h_{obsd} can be explained by a consecutive kinetic equation as follows:

$$[Pd_2(\mu\text{-AcMet-aa})_2L_2]^{4+} + 4H_3^+O \xrightarrow{k^s} [Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+} + 2H_2L^{2+} \quad (1)$$

$$[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+} + 2H_3^+O \xrightarrow{k^h} [Pd_2(\mu\text{-AcMetH})_2(H_2O)_4]^{4+} + 2Haa^+ \quad (2)$$

$$[H^+aa]_t = 2Co[1-(k^h/(k^h-k^s))\exp(-k^st) + (k^s/(k^h-k^s))\exp(-k^ht)]$$

Where Co is the initial concentration of the $[Pd_2(\mu\text{-AcMet-aa})_2L_2]^{4+}$. Because pH* values measured at the beginning and at the end of reaction were always less than 0.1 pH*, we assumed that the concentration of H^+ was unchanged during the reaction. As seen from the equations, the hydrolysis reaction of peptides promoted by palladium(II) complexes proceeds stepwise. First step is detachment of ligand from Pd(II) caused by *trans* effect of thioether and by the acid in solution. Second step is the aqua ligands that *cis*-positioned to the substrate can be delivered to the carbonyl group internally, resulting in scissile of the amide bond. When $k^h \gg k^s$, that means eqn (1) is rate determining step, the hydrolysis rate is governed by detachment of the ligand. If $k^s \gg k^h$, that means eqn (2) is rate determining step, the hydrolysis rate is determined by k^h. When the ligand is temed, as shown in Table 2, the k^s_{obsd} and k^h_{obsd} are well comparable each other. In other words, in this case, the hydrolysis of peptides is governed by detachment of temed ligand and obeys the first order kinetic equation, its k_{obsd} is equal to that of ligand release. When ligand is en or py, because the detachment of en or py is fast, the hydrolysis rate of peptides is mostly governed by eqn (2).

Table 2. The k^{h}_{obsd} of dipeptides hydrolysis and the k^{s}_{obsd} of ligand release in $[Pd_2(\mu_2\text{-Ac-Met-aa})_2L_2]^{4+}$ (L-temed, en) complexes at 40 C and pH* 0.93–1.04

Hydrolysis of peptides in mononuclear palladium(II) *complexes*

The chloride ions in complex A and complex C were removed by $AgNO_3$ in D_2O and DMSO-d_6, respectively. As schemes 2 and 3 show, complex B and complex D were formed as promoters used in hydrolysis reaction. The CH_3S resonance of the free AcMet-aa (aa-amino acid) appears at δ 2.11. The CH_3S resonances of terminal and double-bridging thioether ligands fall in two nonoverlapping intervals, 2.26–2.41 and 2.44–2.65 ppm, respectively [15–18,22]. Initial attachment of the promoter to the substrate amounts to displacement of a solvent ligand by the thioether group in the side chain. The displacement is accompanied by migration of chemical shift of the CH_3S toward downfield. Results of mixing the complex B or complex D with the dipeptides AcMet-aa (aa-Ala, Val) are shown in Table 3. Previous studies, such as *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and *cis*-$[Pd(dtco\text{-}3\text{-}OH)(H_2O)_2]^{2+}$ etc as promoters, contained various kinetic evidences that the hydrolytically active form of substrate-containing complex is binuclear complex in spite of starting promoter is monomer or dimer [15–18,22]. However, when mixing of complex B or complex D with AcMet-aa, as Table 3 shows, only one ^1H NMR resonance of SCH_3 appeared at 2.34 or 2.35 ppm that is characteristic of the mononuclear complexes (2.41 ppm in mononuclear complex $[Pd(dien)(AcMet\text{-}aa)]^{2+}$). Although complex B is a N,N-chelated palladium(II) complex, it differs from *cis*-$[Pd(en)(H_2O)_2]^{2+}$. When *cis*-$[Pd(en)(H_2O)_2]^{2+}$ attached to substrate, the thioether group coordinates to palladium(II) and a μ_2-thioether bridged dimer is formed accompanied by the detachment of the en ligand. However, when complex B reacts with substrate, because of steric bulk and weak protonation of

nitrogen atom of edta, a mononuclear complex that contained edta ligand and one substrate as terminal ligand was formed. The *trans* effect of thioether group in this monomer is not enough to detach two nitrogen atoms in edta without their protonation. Complex D is similar with *cis*-$[Pd(dtco\text{-}3\text{-}OH)(H_2O)_2]^{2+}$ in that they are both s,s-chelated complexes, but complex D is more bulky and prevents the formation of binuclear complex with substrate, and a mononuclear complex is formed instead, with no free glycine detected. The hydrolysis of substrates in the monomers was monitored by ^1H NMR. The observed rate constants, k_{obsd}, are listed in Table 4. As seen from the Table, although complex B and complex D have different coordinated atoms from ligands, their rate of peptide hydrolysis are quite similar. The k_{obsd} values also depend on the leaving group in the mononuclear complexes as they do in the binuclear complexes [16]. The rate of hydrolysis decreased with increase of the volume from analine to valine. In $[Pd(dien)(AcMet\text{-}aa)]^{2+}$ complex, we did not observe the hydrolysis reaction of AcMet-aa. These results confirm our conclusion that at least one aqua ligand is required for palladium(II) to promote peptide hydrolysis no matter in monomer or in

Table 4. Hydrolysis of the Met-aa bond in mononuclear Pd(II) complexes $[PdL(AcMet\text{-}aa)(H_2O)]^{2+}$ (L-edta, 1,2-bis(2-formylglycinebenzene sulfenyl)ethane; aa-Ala, Val) at pH* ≈ 1 and 50°

Promoter	Solvent	Substrate	$10^3 k_{obsd}$, min^{-1}
complex B	H_2O	AcMet-Ala	4.8
		AcMet-Val	2.3
complex D	100% DMSO	AcMet-aa	no reaction

		AcMet-Val	3.4
$[Pd(dien)(H_2O)]^{2+}$	H_2O	AcMet-aa	no reaction

dimer [18]. Comparing the data in Table 1 with that in Table 4, although peptide hydrolysis in mononuclear complexes is much slower than that in binuclear complexes, it is important and of interest. Because this hydrolysis reaction in mononuclear complexes may closely relate to hydrolysis reaction proceeded in horst heart cytochrome *c* [28] and horse heart myoglobin [31] because of the steric bulk of proteins.

CONCLUSION

This study provides new evidences for understanding mechanism of the hydrolytic cleavage of peptides promoted by palladium(II) complexes. The Pd(II) complex with more labile ligand, such as pyridine, is a better promoter. The active species, $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$, was formed by substitution of py with thioether group of AcMet-aa prior to hydrolysis of AcMet-aa. Although reaction of *trans*-$Pd(py)_2(H_2O)_2]^{2+}$, *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and *cis*-$[Pd(temed)(H_2O)_2]^{2+}$ with AcMet-aa yields the same binuclear complex, $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$, the hydrolysis of peptides in $[Pd_2(AcMet\text{-aa})_2(L)_2]^{4+}$ (L-en or temed) proceeds via a consecutive reaction: firstly detachment of the ligand en or temed, followed by cleavage of peptide in $[Pd_2(\mu\text{-AcMet-aa})_2(H_2O)_4]^{4+}$. The new mononuclear complexes reported here, $PdL(AcMet\text{-aa})(H_2O)]^{2+}$ (L-edta etc), are also hydrolytically active. It further confirmed that at least one aqua ligand *cis* to the substrate is required for observation of hydrolysis reaction of peptides promoted by Pd(II) complexes.

On the bonding in π-complexes of borazine

Adam J. Bridgeman

University Chemical Laboratories, Lensfield Road, Cambridge CB2 1EW, UK

(Received 6 October 1997; accepted 5 January 1998)

Abstract—The electronic structure of $[Cr(\eta^6\text{-}B_3N_3H_6))(CO)_3]$ has been investigated in detail using high quality density functional calculations. The bonding is found to be similar to the well established scheme in the arene analogue with the usual ring → metal donation and metal → ring backdonation utilizing the π bonding and anti-bonding orbitals respectively of the ring. The interactions are not localized Cr—N bonds and the ring does not bind as a triamine ligand. The polarization of the π bonding and anti-bonding functions of the free and complexed ligand is however key in determining the adoption of a structure with the CO ligands located *trans* to the nitrogen atoms of the ring in contrast to the structure found for the arene analogue. Puckering of the borazine ring is due to the repulsive interactions between high lying, boron dominated, ring σ-bonding orbitals and the metal's 'lone pairs'. The electronic structure of the unknown diborazine chromium complex is also investigated. Its likely conformation and possible reasons for its instability are suggested. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: borazine; tricarbonyl; arene; chromium; sandwich; DF.

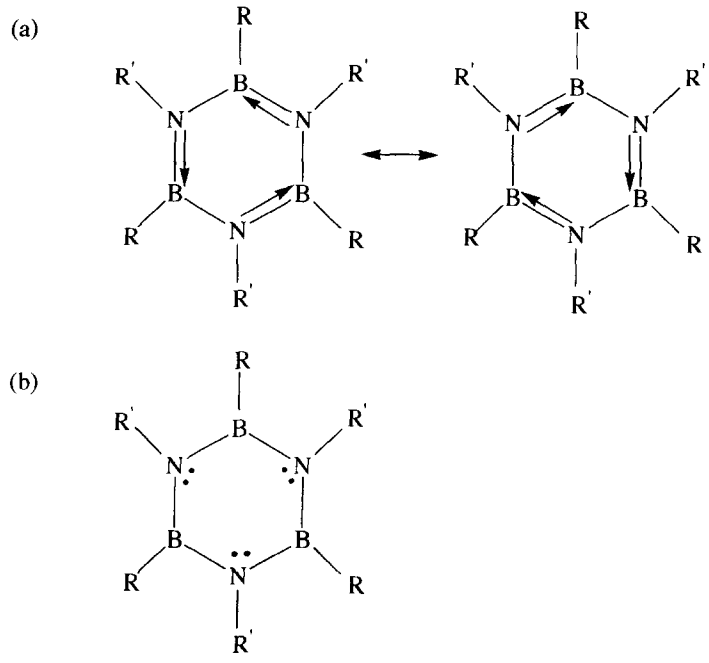
The bonding in the borazine molecule and its derivatives continues to stimulate interest and study. The isoelectronic relationship between benzene and borazine and their similar structural and physical properties has led to borazine being referred to as 'inorganic benzene' These similarities suggest that the bonding in borazine should be represented in an analogous way to that used for benzene. This is illustrated in Scheme 1(a). Chemically though the molecules are known to act rather differently. Lewis acids attack borazine by adding to N whilst Lewis basis add to B. The chemical properties of borazine strongly suggest that the N atom retains some basic character so that the bonding shown in Scheme 1(b) might be a more appropriate formulation. Numerous studies of the bonding and the degree of aromaticity in the borazine molecule and its derivatives have been reported [1].

One of the chemical properties of borazines and arenes that is often used as an illustration in undergraduate courses [2] of the similar behaviour of the two systems is the formation of half-sandwich, η^6 complexes with tricarbonyl chromium. The similarity in the formulation and structures of the complexes of general formula $[Cr(\eta^6\text{-}R_3B_3N_3R'_3)(CO)_3]$ and $[Cr(\eta^6\text{-}R_6C_6)(CO)_3]$ has been taken to infer similar bonding interactions [3,4]. No detailed bonding study of the borazine complex has previously been reported.

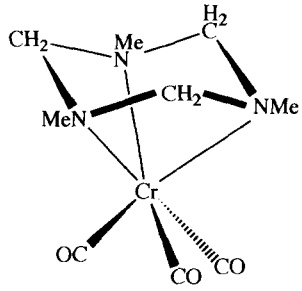
The crystal structure [5] of $[Cr(\eta^6\text{-}Et_3B_3N_3Et_3)(CO)_3]$ however reveals a number of differences between the structure of the borazine and arene complexes. The B_3N_3 ring in the free ligand is planar but upon complexation the ring puckers slightly. This leads to unequal Cr—N and Cr—B distances with the former somewhat shorter.

Lagowski [6] argues that the average Cr—N bond length of 2.2 Å is close to that expected for a tetrahedrally coordinated nitrogen atom. In addition, Lagowski points out the ∠B—N—B angle and the non-planarity of the R—NB_2 group and suggests tetrahedrally bonded nitrogen. The essentially planar geometry around the B atoms and the ∠N—B—N angles are consistent with an sp^2 B and Lagowski suggests that the Cr—B bond length is too long for a bonding interaction between these two elements in the complex. Lagowski proposes that the bonding in $[Cr(\eta^6\text{-}R_3B_3N_3R'_3)(CO)_3]$ species should be compared to that in complexes of a tridentate triamine ligand, such as that shown in Scheme 2, so that the borazine is acting as in formulation (b) in Scheme 1.

Scotti *et al.* [3] and Herberich [4] have reported rather different conclusions about the bonding in η^6-bonded borazine complexes. The CO stretching frequencies in $[Cr(\eta^6\text{-}R_3B_3N_3R'_3)(CO)_3]$ species are approximately the same as those in the arene analogues implying overall similar donor/acceptor properties for the η^6-ligand. In addition, the B—N



Scheme 1.



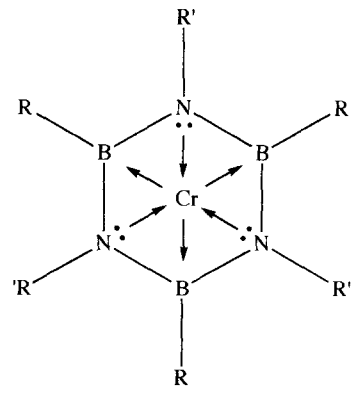
Scheme 2.

bond lengths in the borazine molecule do not increase greatly upon complexation suggesting rather weak Cr-ring interactions and incomplete localization of the nitrogen lone pairs between the chromium and nitrogen atoms. Herberich points out that the difference between the Cr—B and Cr—N bond lengths is similar to the difference in the covalent radii of the main group elements. It is thus argued that the distortion of the ring occurs to accommodate the differing size of the ligand atoms and that the Cr—B bond length is not too long for a bonding interaction.

Herberich also notes that localized Cr—N bonds as argued by Lagowski [6] are inconsistent with the structure of the complex and with the ^{11}B NMR [7]. The puckering of the borazine ring upon complexation is actually rather small. The average torsional angle [5] about the B—N bonds is ca 9°. The torsional angle in truly chair shaped cyclotriborazanes is ca 54.7° whilst the C—N torsional angle [8] in the complex of the triamine shown in Scheme 2 ca 67.2°. Localized Cr—N bonds would result in a low-field shift of the ^{11}B chemical shift upon complexation. A high-field shift is actually observed.

Scotti *et al.* [3] conclude that the ring → Cr σ-donation is more localized between the Cr and N atoms whilst the π-acceptor rôle of the ring is more localized between the Cr and B atoms. This was represented by these workers as in Scheme 3. In a later paper, Scotti *et al.* [9] estimated that the Cr-borazine bond strength is around half that of the Cr-arene bond.

A further structural feature of the borazine complexes is of interest. The CO groups are found [5] to be eclipsed with the B atoms whereas the structure



Scheme 3.

[10] of $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ shows the CO groups to be staggered relative to the carbon atoms of the ring.

The purpose of the present work is to study the nature of the bonding in the η^6-borazine complexes and to compare this with that in the arene analogues. The structural features outlined above, namely the puckering of the ring and the positions of the CO groups in the complex, are addressed.

COMPUTATIONAL DETAILS

All density functional (DF) calculations [11–14] were performed here using the 'DeFT' code written by St-Amant [15] in the linear combination of Gaussian-type orbitals (LCGTO) framework. The calculations set used the Vosko–Wilk–Nusair [16] local spin density approximation of the correlation part of the exchange-correlation potential with non-local corrections using the Becke [17] functional for exchange and the Perdew [18] functional for correlation.

The Gaussian basis sets (GTOs) and the auxiliary basis sets needed for the Coulomb and exchange potential were optimized specifically for LSD calculations by Godbout *et al.* [19] GTO sets of double-ζ quality with the contraction patterns (63321/531*/41+) for chromium, (721/51*/1+) for boron, carbon and nitrogen and (41) for hydrogen were used. All calculations were performed in an all electron treatment.

Bond orders were calculated according to the prescription suggested by Mayer [20]. Calculations were performed using the simplest borazine $B_3N_3H_6$ rather than the alkyl substituted molecules to assist computational efficiency. Calculations were performed using the coordinates determined from crystallographic studies as well as using idealized structures to investigate the structural issues identified above.

RESULTS

(*a*) *Borazine and benzene*

Although many comparative studies of borazine and benzene have been performed [1], it is instructive to report the results at the same level of theory used for the complexed systems. Figure 1 shows a Kohn-Sham eigenvalue diagram for the π-functions of the two molecules and an illustration of the corresponding orbitals. The labels correspond to D_{6h} for benzene, D_{3h} for borazine and to C_{3v} in parentheses. The latter are appropriate to the complex ligands. The occupied borazine orbitals are polarized towards the more electronegative nitrogen whilst the virtual orbitals are more boron in character. Nevertheless, the orbitals show that delocalization is important in both systems.

Table 1 lists Mulliken populations and σ and π bond orders. The π bond order in borazine is approximately a third smaller than in benzene. The B—N bond order in borazine is considerably larger than in the NH_3BH_3 adduct but the breakdown into σ and π contributions shows that this is only partially due to the introduction of a π component. The π-bonding acts to shorten the B—N bond and, as revealed by the Mulliken charges, also acts to make the bond less polar. Both of these act to increase the σ contribution to the bond order.

Distortion to the puckered conformation adopted by the complexed borazine ring requires around 15 kJ mol^{-1} and does not significantly alter the B—N bond order. Similar puckering of benzene requires around 26 kJ mol^{-1}.

(*b*) *$Cr(CO)_3$ fragment*

The valence orbitals of a transition metal $M(CO)_3$ fragment have been discussed [21,22] in detail and only the key aspects are reviewed here. The σ lone pairs (5σ) of the three CO ligands transform as a_1+e. The π* orbitals transform as a_2+e and a_1+e for the sets tangentially and radially orientated respectively relative to the base of the $M(CO)_3$ pyramid. The metal orbitals transform as a_1 (4s, 3_{z^2} and $4p_z$) and $3\times e$ ($\{3d_{x^2-y^2}, 3d_{xy}\}$, $\{3d_{xz}, 3d_{yz}\}$ and $\{4p_x, 4p_y\}$). Calculations were performed using an idealized fragment with dimensions based upon those in $[Cr(\eta^6\text{-}Et_3B_3N_3Et_3)(CO)_3]$. The resulting eigenvalue diagram is shown in Fig. 2.

As shown on Fig. 2, there are three occupied levels, $1a_1+1e$, at low energy corresponding to the Cr—CO σ-bonds. The metal $\{d_{xz}, d_{yz}\}$ e orbitals are orientated to overlap well with the matched σ functions of the ligands. This results in a low lying e level corresponding to Cr—CO σ-bonding and an antibonding level primarily metal d in character. Hybridization of the metal d_{z^2} orbital with the 4s lessens the antibonding interaction with the CO σ-functions. More importantly, it is stabilized by the interaction with the a_1 combination of the CO π* orbitals. The metal $\{d_{x^2-y^2}, d_{xy}\}$ e orbitals are correctly orientated to donate into the matching CO π* functions. The $2a_1+2e$ functions are thus mostly metal d-orbital in character and correspond to metal → CO π-donation.

Mixing of the three pairs of metal orbitals of e symmetry can further increase the bonding in the fragment. Mixing of the $\{d_{xz}, d_{yz}\}$ pair into the $\{d_{x^2-y^2}, d_{xy}\}$ pair tilts [22] the latter so as to maximize the bonding with the CO π* functions. Similarly mixing of the $\{d_{x^2-y^2}, d_{xy}\}$ pair into the $\{d_{xz}, d_{yz}\}$ pair tilts the latter so as to maximize overlap with the CO σ functions. The 2e functions are the M—CO π bonding functions. Figure 3(a) illustrates the π bonding orbital for a single M—CO unit and Fig. 3(b) shows the appropriate combination of these to give the 2e functions for the $M(CO)_3$ unit. The 3e functions are the M—CO σ* orbitals and so maximize diametrically opposite the M—CO vectors. Figure 4(a) illustrates σ* for a single M—CO unit and Fig. 4(b) shows the

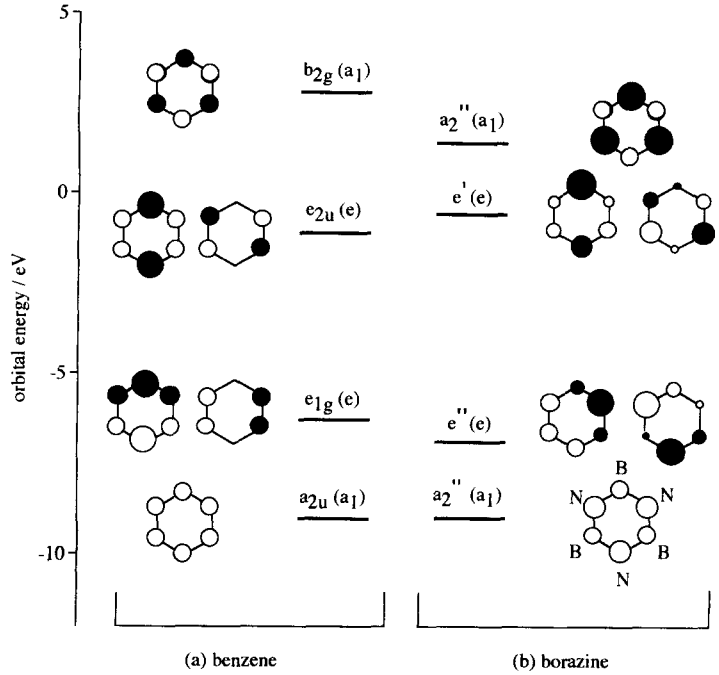


Fig. 1. Kohn-Sham eigenvalue diagram and qualitative representation of the corresponding functions for the π levels of benzene and borazine. The labels correspond to the molecular point groups whilst those in parentheses are appropriate to the functions in the η^6 complexes of $Cr(CO)_3$.

appropriate combination of these for the 2e functions for the $M(CO)_3$ unit. Albright and Hoffmann identify [22] the 2e electrons as 'lone pairs' which orientate themselves in $LM(CO)_3$ complexes to regions of low electron density on the ligand L. Similarly, the empty 3e levels form an acceptor set which seek out regions of high electron density on L.

(*c*) (*Borazine*)*Cr*(*CO*)$_3$

The ring-metal distances were optimized leading to bond lengths of 2.35, 2.39 and 1.52 Å for the Cr—N, Cr—B and B—N bonds respectively. These compare favourably with the observed [5] bond lengths of 2.21, 2.31 and 1.44 Å in $[Cr(\eta^6\text{-}Et_3B_3N_3Et_3)(CO)_3]$. More importantly in the context of the discussion below, the ring is predicted to have the same conformation relative to the carbonyl groups as observed experimentally and to be slightly puckered with a torsional angle about the B—N bonds of ca 6°.

Table 2 lists the Kohn–Sham eigenvalues, their form and an approximate description of their character. The symmetry of the borazine complex is rather

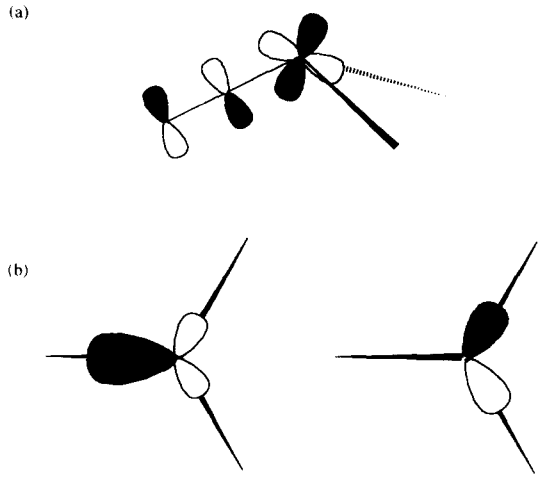

Fig. 3. Representation of (a) a local M—CO π bonding function and (b) the 2e functions of the $M(CO)_3$ fragment.

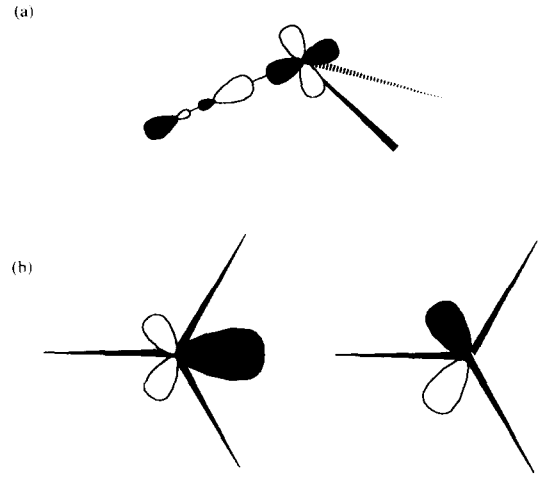

Fig. 4. Representation of (a) a local M—CO σ* function and (b) the 3e functions of the $M(CO)_3$ fragment.

less than the ideal C_{3v} due to unequal bond lengths and angles and this is evident in the splitting of the degenerate functions listed in the table. Table 3 lists Mulliken populations for the complex and for the analogous arene system. The Cr—B, Cr—N, Cr—C, B—N and C—O bond orders in (borazine)$Cr(CO)_3$ are calculated to be 0.30, 0.31, 1.25, 1.24 and 2.32 respectively. The Cr—C_{ring}, Cr—$C_{carbonyl}$, C—C and C—O bond orders in (benzene)$Cr(CO)_3$ are calculated to be 0.40, 1.20, 1.26 and 2.31 respectively. The B—N, C—C and C—O bond orders in the free ligands are 1.31, 1.45 and 2.64 respectively.

The B—N bond order of borazine is slightly reduced upon complexation due to donation from its π system to the metal and acceptance of electron density into the π* functions. This reduction is consistent with the slight increase in the B—N bond length and the small shift in the B—N stretching frequency [3,23]. The size of the reduction however does not suggest complete localization of the π electrons at the nitrogen sites. The Cr—N bond orders are also quite small indicating that the individual interactions are quite weak and are not of the metal-amine type indicated by a formulation such as that shown in Scheme 2. Lagowski proposed [6] that the Cr—B bond length was too long for a bonding interaction. The Cr—B bond order is however of a similar magnitude to that of the Cr—N bond despite the longer bond length. The contributions to the orbitals shown in Table 2 also show that ring → metal donation and metal → ring back donation involve contributions from boron *and* nitrogen. The borazine ring is certainly not bonding as a triamine.

The ring → metal donation is more nitrogen centered due to the polarization of the occupied π orbitals of the ring towards the more electronegative atom. The higher electronegativity of nitrogen, however, also dictates that borazine is a less good donor to the metal than the carbon ring. Similarly, the lower electronegativity of boron ensures that the acceptor functions of the borazine ring are more boron centred and that it is a less good acceptor to the metal than the carbon ring.

The C—C bond order of benzene suffers a rather larger reduction upon complexation indicating that the ring-metal interaction is larger in the arene complex. The C—C bond order quoted above is in fact an average of the values 1.31 and 1.21 for the bonds located *trans* and between the Cr—CO groups respectively. This indicates a small degree of localization of the π bonding in the benzene ring to maximize the donation into the acceptor functions of the $Cr(CO)_3$ unit which are directed at the *trans* C—C bonds, pictured in Fig. 4(b). The carbonyl Cr—C and C—O bond orders and the CO orbital populations are quite similar in the two systems. This is consistent with the similarity in the observed C—O stretching frequencies [3,23]. The Cr—B and Cr—N bond orders are both smaller than that of the ring Cr—C bond in the arene system. The dissociation energies for the processes,

$$\text{(borazine)Cr(CO)}_3 \rightarrow \text{borazine} + \text{Cr(CO)}_3,$$

and

$$\text{(benzene)Cr(CO)}_3 \rightarrow \text{benzene} + \text{Cr(CO)}_3$$

were calculated to be 125 and 241 kJ mol^{-1} respectively. These compare well with the experimental estimates [9] of 105 and 206 kJ mol^{-1}.

(*i*) *Twisting the borazine ring.* The adopted geometry of the complex has the nitrogen atoms *trans* to the three CO ligands. These positions maximize the overlap between the highest lying, nitrogen dominated π function of borazine (the e″ orbital shown in Fig. 1) and the 3e acceptor functions of the $Cr(CO)_3$ fragment, shown in Fig. 4(b). This geometry also max-

imizes the interaction between the high lying donor 2e orbital of the $Cr(CO)_3$ fragment and the boron dominated π acceptor function of borazine (the e′ orbital shown in Fig. 1). The barrier to rotation is calculated to be 22 kJ mol^{-1}; a substantial barrier compared to kT and to the size of the Cr-borazine dissociation energy which has been estimated [9] to be around 105 kJ mol^{-1}.

Figure 5 shows the reduction in the Cr—N and Cr—B bond orders as the ring is twisted from its preferred geometry ($\theta = 0°$) to one with the CO units *trans* to the B atoms ($\theta = 60°$). The high lying 11e orbitals are, as shown in Table 2, M—CO π bonding in character with small, but important, contributions from the acceptor functions on borazine. As the ring is twisted, the overlap between the $Cr(CO)_3$ donor

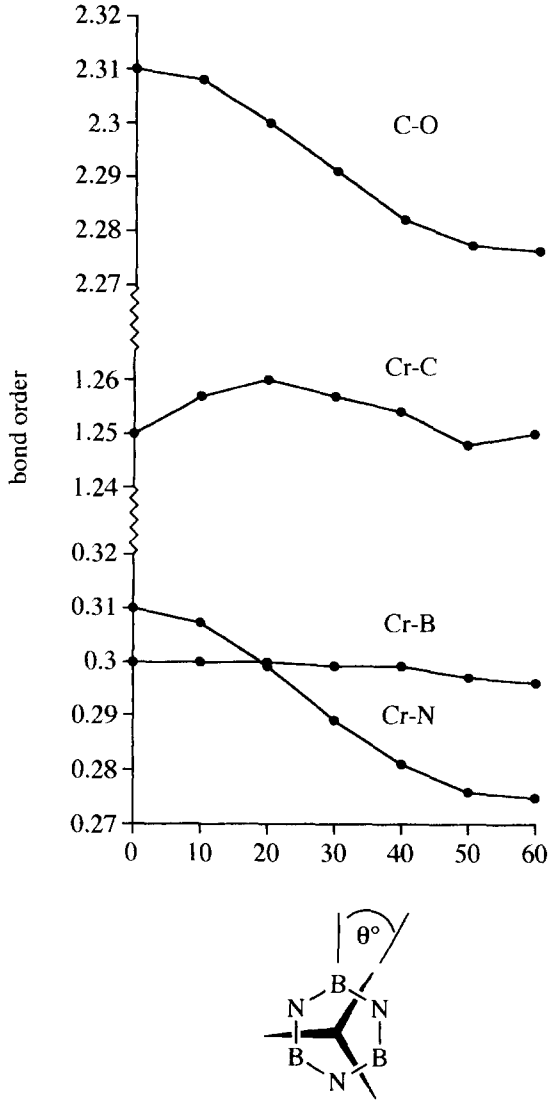

Fig. 5. Bond orders as a function of the twist angle (θ) between borazine and the $Cr(CO)_3$ fragment.

and the borazine acceptor functions decreases. Additionally the $Cr(CO)_3$ donor functions are brought spatially closer to the donor functions of the ring with resulting repulsion. The energy of the orbital increases by 0.12 eV between $\theta = 0$ and 60°.

The 9e orbitals of the complex are, as shown in Table 2, B—N π bonding and ring-Cr bonding in character. They are dominated by the interaction between the ring donor and the $Cr(CO)_3$ acceptor functions. As the ring is twisted, the overlap between the $Cr(CO)_3$ acceptor and the borazine donor functions decreases. As noted directly above, twisting also brings the ring donor functions closer to the donor functions of the $Cr(CO)_3$ fragment. The result is an increase in the energy of the 9e orbital of 0.4 eV between $\theta = 0$ and 60°.

It is interesting to note the character of the B—N π bonding orbital involved in the 9e function of the complex. The ratio of the boron : nitrogen contributions to the e″ orbital of the free ligand is roughly 1 : 2.5. This ratio is approximately maintained in the complex with $\theta = 0°$. When the ring is twisted, however, the boron contribution to this orbital increases whilst that of nitrogen of decreases. The ratio is roughly 1 : 1 when $\theta = 60°$. Thus as the ring is twisted, the B—N π orbital becomes less polarized towards the nitrogen so that donation to the metal is maintained. The increase in the N $p_\pi \rightarrow$ B p_π donation also reduces the repulsion between the donor functions of the ring and those of the $Cr(CO)_3$ fragment. The result is an *increase* in the B—N bond order from 1.24 to 1.30.

The 10e orbital of the complex is predicted to be stabilized by 0.2 eV when the borazine ring is twisted. These orbitals, as shown in Table 2, involve contributions from σ-orbitals of the ring. They are involved in the B—N and B—H σ-bonds and are highly boron in character. The stabilization upon twisting reflects the decease in the repulsive interactions between these high lying orbitals and the spatially and energetically close M—CO σ and π-bonding functions, 8e and 11e respectively. This repulsion acts to destabilize the borazine complex and is also, as discussed below, key in the preference for a puckered ring. Twisting also enables donation from these boron based σ-orbitals into the appropriately aligned acceptor functions on the $Cr(CO)_3$ fragment.

The 10e orbitals in (benzene)$Cr(CO)_3$ are predicted by DF and self consistent field [24] calculations to lie at somewhat lower energy and below that of the ring π function corresponding to the 9e orbital in the borazine system reflecting the intermediate electronegativity of carbon.

As shown in Fig. 5, the C—O bond order also decreases as the ring is twisted from $\theta = 0$ to 60°. This is related for the most part to the increase in the π-back donation from the metal. As outlined above, twisting the ring leads to a decrease in both the ability of the borazine ring to donate and accept electron density. The decrease in the donation by the ring into the M—CO σ* functions (corresponding to the 3e orbitals of the $Cr(CO)_3$ fragment as shown in Fig. 2) leads to an increase in the σ-donation by the CO ligands. Similarly, the decrease in the acceptance by the ring from the M—CO π-bonding orbitals (corresponding to the 2e orbitals of the $Cr(CO)_3$ fragment) leads to an increase in the π-acceptance by the CO ligands. The Cr—C bond order increases as shown in Fig. 5, to a maximum before decreasing as θ approaches 60°. This decrease is related to the repulsive interaction between the ring donor functions and the M—CO π-bonding orbitals.

Whilst borazine is bonding as a π ligand, the polarization of its donor and acceptor functions is key both to the conformation of the ring and the lower stability compared to the arene system.

(*ii*) *Puckering of the borazine ring.* As discussed in

Section (a), puckering of the planar borazine ring to that observed in the η^6 complex requires approximately 15 kJ mol^{-1}. The centre of the coordinated ring was maintained in all of the model calculations and this was chosen to be at the same distance as that of the ring in the observed structure of [Cr(η^6-$Et_3B_3N_3Et_3$)$(CO)_3$]. The ring was then puckered by altering the torsional angles of the B—N bonds. In these calculations, the system was found to be approximately 10 kJ mol^{-1} more stable in the puckered form. The main changes in the orbital energies involve the 9e, 10e and 11e orbitals of the complex. The 9e orbital decreases in energy upon puckering by approximately 0.1 eV because of the increase in the overlap of the acceptor functions of the $Cr(CO)_3$ fragment with the donor functions of the ring as the nitrogen approaches more closely. the Cr—N bond order increases from 0.26 to 0.30. More sizeable stabilizations of 0.25 and 0.21 eV are found for the 10e and 11e levels respectively. Puckering of ring decreases metal → ring donation leading to a reduction in the Cr—B bond order from 0.32 to 0.30. The observed stabilization of the 11e and the 10e functions upon puckering appears to be a result of the decrease in the repulsive interaction between the high lying, boron dominated B—N and B—H σ-orbitals of the ring and the chromium 3d dominated M—CO π bonding functions.

(d) Diborazine chromium

There appear to have been no reports of the preparation of the full sandwich complexes [Cr(η^6-$R_3B_3N_3R'_3)_2$]. Model calculations were performed using averaged structural parameters from the (borazine)$Cr(CO)_3$ system and idealized symmetry. The eigenvalues of the Cr(borazine) fragment are shown in Fig. 6.

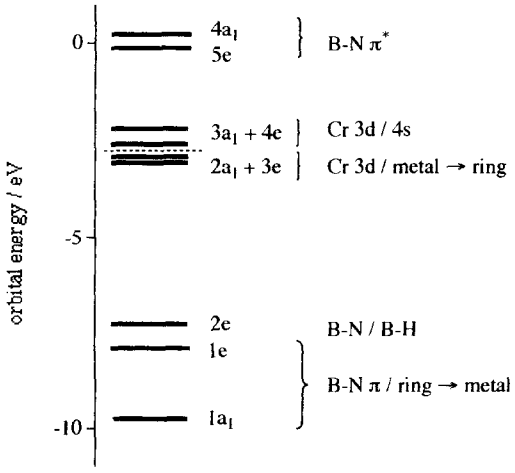

Fig. 6. Kohn–Sham eigenvalue diagram for the Cr(borazine) fragment. An approximate description of the orbitals is given.

The orbitals presented to the incoming ligand by the Cr(borazine) unit are very similar to those of the $Cr(CO)_3$ fragment. The unit presents three 'lone pairs' of $a_1 + e$ symmetry. These are essentially metal → ring donor functions. To maximize interaction with the acceptor functions on the ring, the metal orbitals are tilted towards the boron atoms of the ring to maximize overlap. The resulting 'lone pairs' are thus directed towards the sites diametrically opposite the boron positions of the fragment. There are also three low lying acceptor functions which are essentially the ring → metal antibonding orbitals. As the donor functions of the borazine ring are centred on the nitrogen atoms, the ring → metal bonding functions are tilted to ensure maximum overlap. The resulting antibonding orbitals are thus directed towards the sites diametrically opposite the nitrogen positions of the fragment.

The model calculations predict that the fully staggered geometry is the most stable. This geometry has D_{3d} symmetry and the boron atoms of one ring directly above the nitrogen atoms of the second ring, and *vice versa*. The barrier to rotation of a borazine ring is predicted to require 18 kJ mol^{-1}. In the staggered conformation, the B—N π bonding orbitals then transform as $a_{1g} + a_{2u} + e_g + e_u$ as do the corresponding anti-bonding functions.

Table 4 lists the calculated eigenvalues and a description of the eigenfunctions of the staggered system. Comparison with the results for the tricarbonyl complex listed in Table 2 shows the smaller stabilization of the highest energy, chromium 3d dominated orbitals reflecting the greater acceptor properties of the oxygen dominated carbonyl functions.

Table 5 lists the Mulliken populations and bond orders for the diborazine complex together with those calculated for the dibenzene complex. The increased Cr—C and Cr—B and the decreased C—C and B—N bond orders show increased backdonation to the ring in both cases compared to the tricarbonyl systems. The absence of backdonation to the carbonyl ligands also results in appreciably smaller ring → metal donation. In the diborazine system, this results in a substantial reduction in the Cr—N bond order. Nitrogen is unable to donate effectively to the electron rich metal.

As a borazine ligand is rotated from the fully staggered conformation, the Cr—B and Cr—N bond orders drop and the energies of the $6e_g$ and $4e_g$ orbitals, which correspond to the metal → ring and ring → metal donation respectively, rise. This can be directly related to the discussion above of the donor and acceptor orbitals of the Cr(borazine) fragment which favour the staggered conformation. Just as in the tricarbonyl system, the diborazine complex has high energy, boron dominated, ring σ-bonding orbitals ($5e_g$ and $5e_u$). As the ring is rotated the repulsive interaction between these orbitals and the metal based

"lone pairs" increases—strongly favouring the fully staggered conformation.

The inability of nitrogen to donate to the low valent metal and the poorer acceptor role of boron ensure that the bonding of the borazine ligand is weaker than that of a benzene ring. In the tricarbonyl complexes, the electronically flexible CO ligands are able to tune the metal somewhat to the requirements of the ring. In the diborazine system, however, the electron rich character of the metal is more evident resulting in weaker interaction with the ligands. The repulsive interactions between high lying σ-orbitals on the rings is also important in destabilizing the complex.

(Received 21 July 1997; accepted 30 December 1997)

Abstract—A series of new rhenium(I) complexes of the type [Re(CO)$_3$(3,3′-trimethylene-2,2′-biquinoline)(L)](CF$_3$SO$_3$)$_n$, (L = CF$_3$SO$_3^-$, pyridine (py) or para-substituted pyridine like HO-py, ph-py or NC-py; n = 0 or 1) were prepared and characterized by FTIR, ^{1}H NMR, and UV–vis spectroscopies and by cyclic voltammetry. The pseudo-octahedral facial configuration of these compounds was established by FTIR. The differences found in the spectroscopical and electrochemical results were associated to the effect of the para-position substituent of the L pyridine ligand. © 1998 Elsevier Science Ltd. Keywords: metallic carbonyl complexes; rhenium complexes; heterocyclic nitrogen ligand.

The chemical, photochemical, and photocatalytic properties of rhenium(I) complexes with polypyridine ligands make them potential agents to promote thermal, photochemical and electrochemical catalysis [1]. Examples of this include the electroreduction and photoreduction of CO_2, the latter being a process of interest in the conversion and storage of solar energy [2].

The MLCT and LLCT transitions in this type of compounds have been proposed as key states in some photochemical processes [1c,3]. Thus, the control or modulation of the absorption and/or emission energy can provide a very important tool to modify the catalytic behaviour of these complexes.

In order to evaluate the effect of structural modifications in the polypyridine ligand on the properties of the ground and excited states in these complexes, we have studied complexes of the general structure ReBr(CO)$_3$(L) with L = bidentate polypyridine ligand [4]. In previous works with ReBr(CO)$_3$(3,3′-R,R′-2,2′-biquinoline), (with R = R′ = H, CH$_3$ or R-R′ = dimethylene and trimethylene bridge) we found that the extended conjugation in the biquinoline, as compared to 2,2′-bipyridine, causes a shift towards lower energy both in the MLCT band and in the reduction potential of the polypyridine ligand [4b,d]. Moreover, the distortion degree from the planarity in the polypyridine ligand induces a slight variation of these energies [4d]. We have associated the emissions in these complexes with parallel relaxation processes from an IL and a MLCT state [4e].

The substitution of the bromide atom in these compounds by para-substituted pyridines (L) with electron donating or electron attracting groups can be a good alternative to obtain an electronic state, *[Re(CO)$_3$(3,3′-R,R′-2,2′-biquinoline)(L)]$^+$, closer to the MLCT state [3,4e]. In order to have new rhenium complexes that can help prove the existence of this electronic state, we report here the synthesis and spectroscopical characterization of a new series of complexes of the type [Re(CO)$_3$(3,2N)(L)]$^{+n}$ (3,2N = 3,3′-trimethylene-2,2′-biquinoline, L = CF$_3$SO$_3^-$, pyridine (py), para-substituted pyridine like HO-py, bz-py (bz = benzyl) or NC-py; n = 0 or 1) (Fig. 1).

EXPERIMENTAL

Physical measurements

IR spectra were obtained from solid KBr disk and in $CHCl_3$ solution using a Bruker IFS-66 V FT-IR spectrophotometer. A 0.2 mm KBr cell was used scanning at least 100 times. ^1H NMR spectra were recorded in a 250 MHz Bruker spectrometer. Absorption spectra were recorded on a Shimadzu UV-160 spectrophotometer, using different and previously purified solvents, in quartz cells at ambient temperature. Molar conductivities were determined from 10^{-3} mol dm^{-3} solutions of complex in CH_3CN at 25°C using a Cole-Parmer 01481 conductivity meter. Electrochemical data were acquired in anhydrous acetonitrile solutions of the complexes containing 10^{-1} mol dm^{-3} tetrabutylammonium perchlorate (TBAP) via cyclic voltammetry using a Bank-Wenking POS 73 potentiostat with a Gould OS 4100 oscilloscope, and a Graphtec XY WX 4301 recorder. A three-electrode configuration, a working electrode was a platinum disk, the reference and counter electrodes were an aqueous calomel and a platinum wire, respectively. The test solution was separated from a reference electrode by Vycor bridge filled with corresponding solvent/supporting electrolyte system. A sweep rate of 200 mV s^{-1} was used for all the scans. Potentials were reported as $E_{\frac{1}{2}}^{l} = \frac{1}{2}(Ep_a + Ep_c)$, where Ep_a and Ep_c were the anodic and cathodic peak potentials, respectively. Ferrocene was used as an internal standard to compensate for the junction potential variability among experiments.

Materials

All the operations were carried out under purified nitrogen by standard Schlenk and vacuum-line techniques using freshly distilled, dried and degassed solvents. The solvents used in preparations, recrystallizations, and spectroscopic analysis (Mallinckrodt, grade HPLC) were treated and distilled prior to use. In electrochemical studies, anhydrous acetonitrile was dried using CaH_2 under nitrogen atmosphere at reflux for 2 h, and freshly distilled prior to use. Tetrabutylammonium perchlorate (TBAP) from Fluka was recrystallized twice from HPLC grade ethyl acetate (Mallinckrodt) prior to use. TBAP was stored in a vacuum desiccator over indicating Drierite ($CaSO_4$ anhydrous, Aldrich Chemical Co.) until needed for electrochemical studies. The pyridine ligand, $AgCF_3SO_3$, and $ReBr(CO)_5$, commercially available (Aldrich Chemical Co) were used without further purification. The synthesis of the biquinoline ligand (3,2N) and precursor complex $ReBr(CO)_3$(3,2N) have been previously described [4b,d].

Synthesis of rhenium complexes

The new complexes were obtained at 50°C under an inert atmosphere through stoichiometric precipitation of the corresponding bromide with silver triflate in methylene chloride solutions. Silver bromide was filtered under nitrogen pressure through celite. The filtrate was stirred at 50°C with a stoichiometric amount of the specific pyridine. The resulting orange solution was concentrated and the product purified using a chromatographic column of alumina. The starting material was eluted with methylene chloride and the complexes were eluted with a 5% *v/v* methylene chloride/methanol mixture. The solution was concentrated and the microcrystalline orange product was obtained after dropwise addition of cool hexane.

The $[Re(CO)_3(3,2N)(CF_3SO_3)]$ complex was obtained by concentration of the solution obtained after that the silver bromide was filtered. The product was purified using a chromatographic column of alumina with methylene chloride as eluent and isolated as pure crystals.

$[Re(CO)_3(3,2N)(CF_3SO_3)]$. Yield: 81%. ν_{CO} (in KBr disk) 2014, 1900 (broad) cm^{-1}, (in $CHCl_3$ solution at 25°C) 2013, 1923, 1894 cm^{-1}. Molar conductivity (in acetonitrile) 30 S cm^2 mol^{-1}. Melting point 182°C (d).

$[Re(CO)_3(3,2N)(HO\text{-}py)]^+$. Yield: 58%. ν_{CO} (in KBr disk) 2016, 1895 (broad) cm^{-1}, (in $CHCl_3$ solution at 25°C) 2225, 1917 (broad) cm^{-1}. Molar conductivity (in acetonitrile) 113 S cm^2 mol^{-1}. Melting point 156°C (d).

$[Re(CO)_3(3,2N)(py)]^+$. Yield: 55%. ν_{CO} (in KBr disk) 2015, 1900 (broad) cm^{-1}, (in $CHCl_3$ solution at 25°C) 2019, 1830 (broad) cm^{-1}. Molar conductivity (in acetonitrile) 113 S cm^2 mol^{-1}. Melting point 135°C (d).

$[Re(CO)_3(3,2N)(NC\text{-}py)]^+$. Yield: 52%. ν_{CO} (in KBr disk) 2032, 1911 (broad) cm^{-1}, (in $CHCl_3$ solution at 25°C) 2034, 1930 (broad) cm^{-1}. Molar con-

ductivity (in acetonitrile) 140 S cm^2 mol^{-1}. Melting point 113°C (d).

RESULTS AND DISCUSSION

The prepared complexes are stable in air, either as solid or in solution. They are soluble in several solvents of medium polarity. The formulas proposed of the general type [Re(CO)$_3$(3,3′-trimethylene-2,2′-biquinoline)(L)]$^{+n}$ for the products, are supported by melting points, conductivity measurements and spectroscopical results including FTIR, ^{1}H NMR and UV vis.

The conductivity values indicate a non-electrolyte compound for the [Re(CO)$_3$(3,2N)(CF$_3$SO$_3$)] complex and the existence of a species constituted by two ions for the other complexes.

The IR spectra show no important differences when compared with the characteristic spectra of the co-ordinated and the free pyridine ligands. The spectrum in solution for the [Re(CO)$_3$(3,2N)(CF$_3$SO$_3$)] complex show three strong bands in the carbonyl region which arise from a facial conformation with a local C_s symmetry around a hexacoordinated rhenium. For the other compounds with L = substituted pyridines, the spectra exhibit two intense bands in the typical carbonyl stretching region. This behaviour is consequent with a C_{3v} local symmetry for a facial stereochemistry in these complexes. The lowest energy signal for CO groups appears as a very broad band, which can be attributed to the decreasing of symmetry [5].

The proton NMR spectra of the complexes are summarized in Table 1. The assignments for the complexes were made considering the data and conclusions that we have reported previously for the free ligand and for the precursor complex [4d,6]. For those complexes we found that co-ordination shifts the signal of all the protons of the biquinoline ligand to lower fields. In the new complexes this deshielding increase. The effect is larger for the $H_{4'}$ and $H_{4''}$ protons localized in the para-position to the co-ordinated heterocyclic nitrogens. This behaviour is a good indication that the pyridine ligand induces a lower electronic density over the rhenium atom as compared to bromide ligand in the precursor complex. In the same way, the differences in the $\delta_{complex}-\delta_{precursor}$ values for the series indicate that the substitution in para position of the co-ordinated pyridine also provides an effect that should be considered. Although the pyridine aromatic protons show signals at high field with a characteristic AB pattern in the complexes, in the benzylpyridine complex a multiplet signal is observed due to this proton appears overlapped with the five protons of the phenyl ring. The three-signal pattern (q, m, q) of the aliphatic methylene protons is a consequence of the impossibility of the biquinoline molecule to rotate around of the C_2—$C_{2'}$ bond, but it becomes a two-signal pattern (t, m) in the [Re(CO)$_3$(3,2N)(bz-py)]$^+$ complex. This change suggests, that rotation is allowed in this complex under the working temperature.

The UV–vis spectroscopical data for the complexes are shown in Table 2. Over 400 nm, one or two shoulders of low intensity can be clearly observed. Upon increasing the polarity of the solvent, these shoulders are shifted to the high energy region. This type of band can be assigned as a rhenium-to-biquinoline-charge-transfer (MLCT) transition. Because it is

[b] Ref. 4d.

difficult to unequivocally assign the absorption maximum for this band, we cannot tell if the presence of the pyridine ligand has some influence over the energy of this transition. This difficulty is also related with the position, just under 400 nm, expected for the rhenium-to-p-substituted-pyridine charge transfer band according with the less extensive conjugation of the pyridine compared with the biquinoline [4d]. The latest band appears overlapped by more intense bands corresponding to intraligand transitions ($\pi \rightarrow \pi^*$ biquinoline).

The redox potentials obtained by cyclic voltammetry at 200 mV s^{-1} in acetonitrile solution of the rhenium complexes are collected in Table 3. The complexes showed two successive reversible or quasi-reversible reduction waves between 0.00 to −2.00 volts range (vs SCE). In every case, the first reduction wave could be attributed to the ligand-centered process which involves the addition of an electron to the π^* orbital on the biquinoline ligand. Each of the complexes displayed a reversible or irreversible oxidation in the 0.80 to 1.44 volts range (vs SCE) assigned to a metal-centered process Re(II/I). This processes involves removal of an electron from the $d\pi$ orbital on rhenium(I) [4d,7].

The differences in the redox potential values for the rhenium compounds do not show a relationship with the basicity of the pyridine ligand. Similar behaviour has been reported for analogous complexes [8].

Química Inorgánica, Facultad de Química, C. C.1157, Montevideo, Uruguay

(Received 16 October 1997; accepted 28 December 1997)

Abstract—Nitrite ion competition has been measured for the base hydrolysis reaction of *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ ions (X = Cl^-, Br^-, NO_3^- and SO_4^{2-}) in 1.0 M $NaNO_2$ at 25°C. Both O- and N- bonded $Co(NH_3)_4(NH_2CH_3)NO_2^{2+}$ are formed. Subsequently the $Co(NH_3)_4(NH_2CH_3)ONO^{2+}$ isomer rearranges in OH^- to give the thermodynamically more stable $Co(NH_3)_4(NH_2CH_3)NO_2^{2+}$ ion. The total NO_2^- captured shows a slight dependence on the overall charge of the complex and on the nature of X (R = 2.2, 2.1, 3.6 and 1.2±0.5% for X = Cl^-, Br^-, NO_3^- and SO_4^{2-}, respectively). These results differ from those observed with complexes of the type $Co(NH_3)_5X^{n+}$ and $Co(NH_2CH_3)_5X^{n+}$ where X includes a variety of anions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: base hydrolysis; trans-$[Co(NH_3)_4(NH_2CH_3)X]^{n+}$ complexes.

Competition experiments have provided information on the detailed mechanism of base hydrolysis of pentaamminecobalt(III) ions, $Co(NH_3)_5X^{n+}$. The thrust of these studies has been the close examination of the leaving group (X) dependence of the product distribution for the reaction of $Co(NH_3)_5X^{n+}$ in aqueous OH^- containing competing Y^- [1–9]. There is ample evidence to show that neutral leaving groups (i.e. X = Me_2SO, $(NH_2)_2CO$, $(MeO)_3PO$) result in enhanced Y^- entry, usually reported as $\%Co(NH_3)_5Y^{2+} = 10^2\,[Co(NH_3)_5Y^{2+}]/[Co(NH_3)_5Y^{2+}]+[Co(NH_3)_5(H_2O)^{3+}]$, when compared to uninegative leaving groups, X^-, and SO_4^{2-}. For example, if Y^- = N_3^- ion, $\%Co(NH_3)_5N_3^{2+}$ are 12 for 3+complexes [4], 8.5–10 for 2+complexes [1,3] and 5.8 [4], 7.2 [7] for X = SO_4^{2-}. Among the 2+complexes, there is an increase in the percentage of $Co(NH_3)_5N_3^{2+}$ as the $Co(NH_3)_5X^{2+}$ complex becomes easier to hydrolyze; this trend appears to approach a limiting value of ~10.5% for the most labile complexes [9].

The products of the base hydrolysis of the more strained $Co(NH_2CH_3)_5X^{n+}$ complexes, have also been studied, with azide ion as competitor (X = $OSO_2CF_3^-$, Me_2NCHO, Cl^-). It was found that these complexes, whose enhanced sensitivity to base hydrolysis is well known [10,11] give rise to much higher azide competition than the $Co(NH_3)_5X^{n+}$ complexes ($\%Co(NH_2CH_3)_5N_3^{2+}$ = 36 [8], 52 [12] and 49 [12] respectively).

The present paper explores the competition properties of *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ complexes (X = Cl^-, Br^-, NO_3^- and SO_4^{2-}), using nitrite ion as competitor. The kinetics of the base hydrolysis reaction of these complexes has been recently reported [13], and it was found that methylation of the NH_3 ligand, *trans* to the leaving group, produces a modest increase on the reaction rate. Nitrite ion competition has been measured for the base hydrolysis reaction of a series of $Co(NH_3)_5X^{n+}$ ions in 1.0 M $NaNO_2$ [5]. It was found that both O- and N- bonded $Co(NH_3)_5(NO_2)^{2+}$ ions are formed, along with $Co(NH_3)_5(OH)^{2+}$ complex. It is also known that in aqueous base the $Co(NH_3)_5(ONO)^{2+}$ ion isomerizes completely to the $Co(NH_3)_5NO_2^{2+}$ ion, through a base-catalyzed path [14]. It seemed reasonable that the *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ complexes will show the same behaviour.

We have chosen NO_2^- ion to compete with H_2O for the following reasons: (i) the rate of base hydrolysis for the $Co(NH_3)_4(NH_2CH_3)(NO_2)^{2+}$ complex is con-

* Author to whom correspondence should be addressed.

siderably slower than that for *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ ions [13]; (ii) the synthesis and spectral properties of $Co(NH_3)_4(NH_2CH_3)(NO_2)^{2+}$ and $Co(NH_3)_4(NH_2CH_3)(ONO)^{2+}$ complexes are known [15].

EXPERIMENTAL

C, H, N elemental analysis were carried out with a Carlo Erba EA1108 elemental analyzer. Visible spectra (ε, $M^{-1}cm^{-1}$; λ, nm) were obtained with a Spectronic 3000 diode array spectrophotometer. ^1H NMR spectra were recorded on a Varian Unity spectrometer operating at 100 MHz and 35°C; signals are described in terms of chemical shifts (δ) with tetramethylsilane (tms) as internal reference. Ion-exchange chromatographies were performed with the use of a Dowex (50W × 8, 50–100 mesh; Na^+ form) cation-exchange resin. HPLC experiments were carried out with a Merck Hitachi D2500 apparatus using a cationic-exchange column (PRP-X200-10μ, 4 × 250 mm).

Materials

trans-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)]HSO_4 \cdot H_20$ was prepared as follows. The complex *trans*-$[Co(NH_3)_4(NH_2CH_3)(SO_3)]Cl$ [16] (7.0 mmol) was dissolved in H_2SO_4 (98%; 15 ml) saturated with Li_2SO_4 at ambient temperature. The resultant pink solution was poured carefully into cold methanol (0.4 l) to precipitate the desired compound. This was collected and washed with methanol and ether. Yield: 68%. Anal: Calcd for $CoH_{20}N_5S_2O_9C$: C, 3.25; H, 5.42; N, 18.97. Found: C, 3.37; H, 5.24; N, 18.79. Visible spectrum: ε_{357} 55.1, ε_{520} 65.4 in water. The ^1H NMR spectra confirmed the isomeric purity of the compound (methyl signal δ 1.74, in D_2O). Ion-exchange chromatography was the major tool used to establish the absence of trace impurities, in particular *trans*-$Co(NH_3)_4(NH_2CH_3)(OH_2)^{3+}$. The complex was absorbed onto a cation-exchange resin and was eluted as a single band with 0.4 M $NaClO_4$.

trans-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)Br](ClO_4)_2$ were prepared from the chloride [16] and bromide [17] salts, respectively, by routine treatment with silver perchlorate. *trans*-$[Co(NH_3)_4(NH_2CH_3)(ONO_2)](NO_3)_2$, *trans*-$[Co(NH_3)_4(NH_2CH_3)(OH_2)](ClO_4)_3$, *trans*-$[Co(NH_3)_4(NH_2CH_3)(ONO)]Cl_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)(NO_2)]Cl_2$ complexes were prepared as described previously [15,17].

All the complexes salts analyzed satisfactorily for at least three elements, and their absorption and ^1H NMR spectra agreed with the literature data. None of the ^1H NMR spectra of the complexes in concentrated Me_2SO-d_6 solution (except the aqua complex) showed the characteristic Co—OH_2 signal (δ 5.62) [3]. All other reagents and solvents used were of analytical grade.

Competition experiments

The competition experiments were performed at 25°C by dissolving the complexes (0.5 mmol) in 5 ml of water; immediately, these solutions and solutions 2.0M $NaNO_2$ (5 ml, 0.25 M in NaOH) were mixed. In some experiments, weighed samples of the complexes (0.5 mmol) were dissolved directly in 1.0 M $NaNO_2$ (10 ml, 0.125M NaOH); the results did not differ significantly. After 5 min if $X = Cl^-$, Br^- or SO_4^{2-}, or 2 min for $X = NO_3^-$ (>10 $t_{1/2}$) the reaction mixtures were diluted with cold water to quench the reaction and avoid further decomposition of the products.

The product mixtures were sorbed on a column of Dowex resin and then thoroughly washed with water. The sorbed complexes were eluted with 1 M NaCl (pH 4) to separate first the 2+complexes and then with 3M NaCl to recover the $Co(NH_3)_4(NH_2CH_3)(OH_2)^{3+}$ ion (further called aqua complex). Each band was observed spectrophotometrically and compared with the spectra of the pure complexes. The first one (2+complexes) was a mixture of $Co(NH_3)_4(NH_2CH_3)(ONO)^{2+}$ (further called nitrito complex) and $Co(NH_3)_4(NH_2CH_3)(NO_2)^{2+}$ (further called nitro complex) complexes and the rearrangement of the former into the latter complex could be observed. However, complete separation of the two bands was not achieved, although different experimental conditions were tested (column length, concentration and rate of the eluant). Accordingly, in order to determine the amount of each product, a more efficient and less time consuming analytical method was chosen: HPLC. The complexes (0.2 mmol) were dissolved in water (2 ml) and these solutions were immediately mixed with solutions 2.0 M $NaNO_2$ (2 ml, 0.25 M in NaOH). All the competition experiments were performed at 25°C. After 5 min if $X = Cl^-$, Br^- or SO_4^{2-}, or 2 min for $X = NO_3^-$ (>10 $t_{1/2}$) the reaction mixtures were diluted with cold water and 20 μl of these mixtures were analyzed by HPLC. Nitro and nitrito complexes were separated from the aqua complex by eluting with 0.16 M Na_2SO_4, using a flow (1 ml/min) which provided convenient retention times. Complexes concentrations in the eluate fractions were determined spectrophotometrically at 367 nm (see Results); at this wavelength the molar absorption coefficients are 543 M^{-1} cm^{-1} for nitro and nitrito complexes and 33.5 M^{-1} cm^{-1} for aqua complex. Complete elution was confirmed in all the experiments by washing the column with concentrated solutions of Na_2SO_4. The retention times were compared with those of pure and mixed solutions of nitro, nitrito and aqua complexes separately.

RESULTS AND DISCUSSION

The products of the base hydrolysis reaction of the *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ ions ($X = Cl^-$, Br^-,

NO_3^- and SO_4^{2-}) in the presence of 1.0 M $NaNO_2$ at 25 C, after neutralization, were both O- and N-bonded $Co(NH_3)_4(NH_2CH_3)(NO_2)^{2+}$, and $Co(NH_3)_4(NH_2CH_3)(OH_2)^{3+}$. The presence of both, nitro and nitrito complexes, as reaction products was confirmed by HPLC and cation-exchange experiments.

Attempts at measuring the amounts of nitrito and nitro complexes separately failed because it was not possible to find appropriate experimental conditions to obtain reproducible results. On the other hand, the nitrito complex isomerizes slowly ($t_{1/2}$ = 114 min, 25 C) but completely to the nitro complexes in solution [20]. Therefore, both isomers were measured together at the isosbestic point, ε_{367} 543 $M^{-1}cm^{-1}$.

A representative chromatogram is given in Fig. 1. The chromatogram shows three peaks at 2.2, 4.9 and 6.9 min, corresponding to the excess of NO_2^- present in the solution, the mixture of nitro and nitrito complexes and aqua complex respectively.

The competition was defined as: P (product distribution) = [nitro + nitrito]/[aqua] and %(nitro + nitrito) = 10^2 [nitro + nitrito]/[nitro + nitrito] + [aqua] = $10^2P/1+P$. The conventional [21] competition ratio R was given by $P/[NO_2^-]$.

The product distributions were calculated from the peak areas (A) and the values of the molar absorption coefficients at 367 nm, as follows:

$$P = (\varepsilon_{aqua}/\varepsilon_{nitro\text{-}nitrito})(A_{nitro\text{-}nitrito}/A_{aqua}).$$

There is substantial evidence for a conjugate-base mechanism for hydrolysis of Co (III) amine complexes in basic solutions (Scheme I).

L = amine and L⁻ = deprotonated amine

Scheme I.

It is apparent that if a common intermediate is produced (S_N1CB or D_{CB} mechanism) a constant competition ratio should be found for each species of Y. The results of the competition experiments at 25 C are listed in Table 1. The reported values are averages over at least five independent measurements.

Kinetic and competition data for the base hydrolysis of $Co(NH_3)_5X^{n+}$ and $Co(NH_2CH_3)_5X^{2+}$ ions in the presence of various anions at 25 C, are included in Table 2 and Table 3 for comparison.

These results show, within the experimental error, the following: (i) The *trans*-$Co(NH_3)_4(NH_2CH_3)X^{2+}$ complexes give more nitro complex than the *trans*-$Co(NH_3)_4(NH_2CH3)(OSO_3)^+$ ion. A similar trend has been found for the $Co(NH_3)_5X^{n+}$ complexes; (ii) Among the *trans*-$Co(NH_3)_4(NH_2CH_3)X^{2+}$ complexes there is an increase in the amount of nitro complex found as the complex becomes easier to hydrolyze. The $Co(NH_3)_5X^{2+}$ complexes show a similar behaviour but for the $Co(NH_2CH_3)_5X^{2+}$ this trend is inverted at least for the two complexes already studied ($X = OSO_2CF_3^-$ and Cl^-); (iii) The competition

ratios for the *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ complexes are smaller than those of the $Co(NH_3)_5X^{n+}$ ions and those of the $Co(NH_2CH_3)_5X^{n+}$ are the biggest ones.

Two generalizations can be drawn from these observations:

(i) The three types of reactants, $Co(NH_3)_5X^{n+}$, *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ and $Co(NH_2CH_3)_5X^{n+}$ do not exhibit the same behaviour. The competition ratios are different for each substrate and there is not a correlation between those and the reactions rates;

(ii) For each of the three types of reactants the competition ratios differ on the charge of the leaving group X and for a given charge type of X there is a significant variation of R with the nature of the leaving group.

The dependence of anion competition on the formal charge of the $Co(NH_3)_5X^{n+}$ complexes has been interpreted by Jackson and Sargeson in terms of the conjugate base dissociative (S_N1CB) mechanism "where the short lived intermediate five-coordinated species captures the atmosphere of its immediate precursor" [4–7]. On the other hand, Rotzinger [12,22] has asserted that the base hydrolysis of the $Co(NH_3)_5X^{n+}$ complexes proceeds via hexacoordinated intermediates $Co(NH_3)_4(NH_2)\ldots X^{(n-1)+}$: "these intermediates are hexacoordinated, because the ionic strength dependence of the competition ratios showed unambiguously that the leaving group is present in the first coordination sphere during the product formation step".

The competition properties of the $Co(NH_2CH_3)_5X^{n+}$ complexes have also been studied and compared with the competition ratios of the $Co(NH_3)_5X^{n+}$ ions. Sargenson *et al.* [8] have argued that the competition ratios imply a common intermediate arising from the different leaving groups for each set of the $Co(NH_3)_5X^{n+}$ and $Co(NH_2CH_3)_5X^{n+}$ ions and an increased lifetime for $Co(NH_2CH_3)_4(NHCH_3)^{2+}$ relative to $Co(NH_3)_4(NH_2)^{2+}$. On the contrary, Rotzinger [12] has asserted that the pentacoordinated intermediate $Co(NH_2CH_3)_4(NHCH_3)^{2+}$ exhibits a shorter lifetime than the hexacoordinated intermediates $Co(NH_3)_4(NH_2)\ldots X^{(n-1)+}$. The present (limited) data for the *trans*-$Co(NH_3)_4(NH_2CH_3)X^{n+}$ complexes indicate that no two complexes behave the same. The results do not prohibit the formation of the same five-coordinated species for all substrates in a purely dissociative process, but its lifetime has to be so short that it captures ligating groups from the solvent cage before it has had time to adjust to its changed situation. In summary, we think that the base hydrolysis competition results to date are inconclusive, and that the questions of the competition and lifetime of intermediates have not been finally settled.

(Received 20 October 1997; accepted 18 December 1997)

Abstract—The complex $[(C(NH_2)_3)_3ZrOH(CO_3)_3 \cdot H_2O]_2$ (**A**) has been shown by means of a single crystal X-ray diffraction study to contain $[C(NH_2)_3]^+$ cations and dimeric anions of formulation $[(ZrOH(CO_3)_3)_2]^{6-}$. The anion is centrosymmetric with each metal being bonded to two bridging OH groups and three chelating CO_3^{2-} ions. The Zr atoms are thus eight coordinate with a dodecahedral environment. The Zr—O distances formed by the bridging OH groups are shorter than those formed through zirconium carbonate interactions. The non-bonded Zr···Zr distance is 3.47(2) Å. An infrared spectroscopic investigation of **A** provides data which support the findings of the crystallographic study. Likewise the complex $Na_6(ZrOH(C_2O_4)_3)_2 \cdot 7H_2O$ (**B**) contains the anion $[(ZrOH(C_2O_4)_3)_2]^{6-}$. This anion is structurally related to the anion in **A** as each Zr atom has an eight-coordinate dodecahedral environment being bonded to two bridging OH groups and three chelating oxalate ligands, but has no imposed crystallographic symmetry. The Zr···Zr non-bonded distance is 3.50(1) Å. The O—Zr—O bridge angles are 69.7(4)° in **A** and 67.4(3)° in **B**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: anions; single crystal X-ray diffraction.

Zirconia (ZrO_2) is a material which finds a wide range of industrial applications. These range from use as a light scatterer in ophthalmic glasses [1,2], as a toughener in composite ceramics [3], in X-ray photography [2], as heat shields, in the high temperature filtration of corrosive liquids [4] and in the production of crucibles and furnace cores [4]. Some of these industrial uses require zirconia in a particular phase. For example the cubic phase is often required for optical applications since it has a refractive index of 2.4 and is thus efficient at scattering light [1]. By contrast the tetragonal phase is normally required when zirconia is used to toughen composite ceramics. These phases are only stable at high temperatures (cubic above 2370°C; tetragonal between 1170 and 2370°C) and unfortunately cannot normally be retained by rapid quenching. According these phases are typically stabilised by adding a dopant to the ZrO_2 e.g. the addition of small amounts of yttria (Y_2O_3) to the ZrO_2 may stabilise the cubic or tetragonal forms [3,5]. Adding yttria (or other dopants e.g. CaO) to ZrO_2 also has the effect of increasing the electrical conductivity of the material (pure ZrO_2 is an insulator with a resistivity of about 10^{12} Ωm at room temperature) allowing its use as an electrolyte [6].

In our current investigations one aim is to search for coordination compounds of zirconium, typically containing oxo ligands, which readily yield zirconia upon calcination. Thus we hope to find routes, not

* Author to whom correspondence should be addressed.

only to ZrO_2 itself, but also—by forming complexes which contain alongside Zr other metal ions e.g. Y^{3+} or Ca^{2+}—to doped zirconia. Various complexes have been suggested and used as precursors to zirconia by calcination. Two such classes of compounds are the carbonates and oxalates. Thermal decomposition experiments [7–11] have shown that oxalate complexes of zirconium decompose via carbonates to yield ultimately oxide products.

We have synthesised three closely related zirconium carbonate complexes—$[(C(NH_2)_3)_3ZrOH(CO_3)_3 \cdot H_2O]_2$ (**A**), $[(NH_4)_3ZrOH(CO_3)_3 \cdot 2H_2O]_2$ (**C**) and $[K_3ZrOH(CO_3)_3 \cdot 3H_2O]_2$ (**D**)—during the course of our investigations. **C** [12] and **D** [13] have previously been the subject of single crystal X-ray diffraction studies. Both crystallise in the monoclinic space group $P2_1$. However, it is quite likely that subtle differences in structure may arise between **A** and the other two compounds when it is borne in mind that hydrogen bonding involving the guanidinium cation and water molecules will doubtless play an important role in **A**. We also noted from a preliminary X-ray powder diffraction study that, unlike **C** and **D**, **A** crystallises in the triclinic space group P-1. Previous comments regarding the possible structure **A** [14] have not been based upon any structural data. Indeed in proposing structures for **A**, Dervin *et al.* [14] appeared to be unaware of the earlier X-ray work performed on single crystals of **C** [12] and **D** [13] since no reference is made to these structures. Accordingly we have carried out a single crystal X-ray diffraction study of **A**. We have supported these data by an infrared spectroscopic investigation of the three compounds **A**, **C** and **D**.

Our interest in oxalato complexes of zirconium is driven partly by the scarcity of published work detailing such compounds since the pioneering work of Venables and Baskerville in 1897 [15]. There have been two single crystal X-ray diffraction studies of monomeric zirconium oxalate complexes: $K_4Zr(C_2O_4)_4 \cdot 5H_2O$ [16] and $Na_4Zr(C_2O_4)_4 \cdot 3H_2O$ [17]. Our synthesis of **B** was, however, quite fortuitous. We were attempting to follow the method of Blumental [2] for the preparation of a mixed carbonate/oxalate of zirconium. A small number of crystals were isolated which were shown to be **B** by means of a single crystal X-ray diffraction study.

EXPERIMENTAL

Compound **A** was prepared following the method described by Pospelova and Zaitsev [18]. Saturated aqueous ammonium carbonate solution (9 cm^3) and guanidinium carbonate (4 g, 0.02 mol in 10 cm^3 water) were mixed and solid zicronyl chloride (2 g, 0.01 mol) was added. The mixture was filtered to remove any solid residue and the filtrate was left in a desiccator over H_2SO_4 (conc). After a few days tiny, rod-shaped crystals formed. These were isolated by filtration. The zirconium content of **A** was found by direct calcination. C, H and N analysis was performed using a Perkin–Elmer 240B microanalyser by Medac Ltd at Brunel University. Found: Zr, 19.7%, C, 15.0%, H, 4.2%, N, 26.3%; Calc.: Zr, 19.1%, C, 15.1%, H, 4.4%, N, 26.4%.

A small number of crystals of **B** were prepared during the attempted preparation of a mixed carbonate/oxalate of zirconium following the method of Blumental [2]. "Hydrous carbonated zirconia" [18] was first prepared by adding zirconyl chloride (10 g, 0.04 mol) to sodium carbonate (5 g, 0.05 mol) in aqueous solution. The product (1 g, 0.002 mol) was dissolved in the minium of water and crystals of oxalic acid were added until the solution was saturated. The solution effervesced upon addition of the acid. The residue was filtered and the filtrate set aside. After a few days a micro-crystalline precipitate had formed together which a small quantity of needle-shaped crystals of **B**. The precipitate was found to be multicrystalline and analysis suggested that it consisted of a mixture of compounds which proved impossible to separate. This finding endorses a point made previously by Solovkin and Tsvetkova that "a characteristic feature of (the chemistry of) zirconium is the formation of precipitates of indefinite composition" [19]. The needle-shaped crystals of **B** were studied by single crystal X-ray diffraction. Unfortunately the small quantity of crystals produced did not allow any other form of analysis to be performed.

Crystal data for **A** and **B** are given in Table 1 together with refinement details. For both compounds data were collected with Mo–K_α radiation using the MAR research image plate system. The crystals were positioned at 75 mm from the image plate. Ninety-five frames were measured at 2° intervals, each with a counting time of 2 min. Data analyses were carried out with the XDS program [20]. The structures were solved by the Patterson method using the program Shelx 86 program [21]. In both cases the non-hydrogen atoms were refined anisotropically. Hydrogen atoms on the cations in **A** were included in geometric positions, but those on oxygen could not be located. Hydrogen atoms on the bridging hydroxide in **B** were located in a different Fourier map and refined independently. However, hydrogen atoms in the water molecules could not be located. The structures were then refined on F^2 using SHELXL [22]. Bond lengths and angles in the metal coordination spheres for **A** and **B** are given in Tables 2 and 3. Crystallographic data for **A** and **B** have been deposited at the Cambridge Crystallographic Database. Infrared spectra were recorded on samples of **A** in pressed KBr discs using a Perkin–Elmer model 1720-X Fourier transform spectrometer.

RESULTS AND DISCUSSION

Single crystal X-ray diffraction study of **A**

A is an ionic compound and contains $[C(NH_2)_3]^+$ cations and dimeric anions of formulation

$[(ZrOH(CO_3)_3)_2]^{6-}$. The anion is the most interesting moiety in the structure and it is depicted in Fig. 1 together with the atom numbering scheme. The anion is centrosymmetric with each metal atom being bonded to two bridging OH groups and three chelating CO_3^{2-} ions. Thus the zirconium atoms are eight coordinate. The Zr—O distances formed by the bridging OH groups [2.112(8) Å (Zr—O(1)); 2.119(9) Å (Zr—O(1)*)] are shorter than those formed through zirconium-carbonate interactions. Of these latter the Zr—O bond formed with O(12) [2.162(11) Å] appears shorter than the others that span the range 2.204(9) Å [Zr—O(22)] to 2.252(10) Å [Zr—O(31)]. The structure of the anion found in **A** has been previously reported as part of a study of $(NH_4)_6[Zr(OH)(CO_3)_3]_2$ (**C**) [12]. The data reported in this earlier study are of poorer quality than are those given here. However, the Zr—O bridging distances in **C** were found to be 2.11(1) Å with the Zr—O (carbonate) distances ranging from 2.18(2) Å to 2.25(2) Å. Thus the distances from the two structure determinations are in accord. The angles in **A** subtended by the chelating carbonate groups range from 57.6(3)° [O(32)—Zr—O(31)] to 59.7(4)° [O(12)—Zr—O(11)] and these are the smallest angles subtended at the metal centre. The next smallest angle is that formed by the two bridging OH groups; an angle of 69.7(4)° is found at the metal centre and the dependent Zr—O(1)—Zr* angle is thus 110.3(4)°. The geometry of the metal coordination sphere can best be considered to be a slightly distorted dodecahedron. The Zr···Zr* distance is 3.471(2) Å which is shorter than that previously reported for **C** [3.498(2) Å] [12]. Each of the 18 hydrogen atoms from the amine groups in the three guanidinium cations form a hydrogen bond to a carbonate oxygen atom with distances ranging from 2.67(1) to 3.15(1) Å.

Single crystal X-ray diffraction study of **B**

In the unit cell of **B** there are two $Na_6[Zr(OH)(C_2O_4)_3]_2 \cdot 7H_2O$ moieties which contain the anion $[(Zr(OH)(C_2O_4)_3)_2]^{6-}$ which has no crystallographically imposed symmetry. This anion is depicted in Fig. 2 where the atom numbering scheme is also given. One of the sodium ions (Na(5)) is disordered over two sites (5A and 5B), as is the oxygen atom of one water molecule (2W). The anion, $[(ZrOH(C_2O_4)_3)_2]^{6-}$ is non-centrosymmetric. The two metal centres in the anion have similar but not identical coordination geometries. Each metal atom is eight coordinate being bonded to three chelating oxalate groups and two bridging OH anions. Thus the coordination geometries found here are similar to those seen in **A**. The Zr—O distances formed with the chelate oxalate anions range from 2.178(9) Å to 2.239(9) Å for Zr(1) and 2.185(9) Å to 2.224(8) Å for Zr(2) and cover a similar range to those formed by the

chelating carbonate groups [2.162(11) Å to 2.252(10) Å]. The two metal centres are linked by two OH bridges. The uncertainties in the OH distances are, as expected, large [1.0(2) Å O(1)—H(1); 0.9(2) Å O(2)—H(2)] but the hydrogen atoms were detectable. The Zr(1)—O(1) and Zr(1)—O(2) distances are 2.122(8) Å and 2.098(8) Å respectively while the related distances for Zr(2) are 2.111(8) Å [to O(1)] and 2.110(9) Å [to O(2)]. Thus all the zirconium–oxygen bridging bonds are equal and of equivalent length to the bridging bonds found in **A** [2.112(8) and 2.119(9) Å]. The zirconium–zirconium distance [3.501(1) Å] is longer than the metal–metal distance in **A** [3.471(2) Å].

The angles subtended at the metal centres by the chelating oxalate fragments range from 69.5(3)° to

Table 3.—*Continued*

O(1)—Zr(2)—O(44)	110.3(4)
O(41)—Zr(2)—O(41)	70.1(3)

O(44)—Zr(2)—O(64)	78.7(4)
Zr(2)—O(1)—Zr(1)	111.6(4)
Zr(1)—O(2)—Zr(2)	112.6(4)

71.8(3) for Zr(1) and 70.1(3)° to 71.1(3)° for Zr(2). These angles being part of five-membered rings are, as expected, larger than the angles subtended at the zirconium centres by the chelating carbonate ions in **A** which range from 57.6(3)° to 59.7(4)° and are part of four-membered rings. The geometry of the metal coordination spheres are slightly distorted dodecahedral. The five-membered oxalato chelate ligands are, within experimental error, planar while the uncertainties associated with the C—O distances are such that no significant difference was detected in the bond distances between the bonded and non-bonded C—O groups. The sodium ions are coordinated to oxygen atoms from both the oxalate groups and water molecules. The two bridging OH anions form hydrogen bonds to adjacent dimers $O(1)\cdots O(65)$ $(x-1, y, z)$ 2.75(1) Å and $O(2)\cdots O(35)$ $(x+1, y, z)$ 2.69(1) Å. In addition each water molecule forms at least two hydrogen bonds to oxygen atoms in the oxalate anions or to other water molecules.

Infrared spectroscopic study of **A**

A shows infrared absorptions at the following wavenumbers (ν/cm^{-1}): 1684 (br), 1559 (br), 1361 (s), 1318 (m), 1303 (m), 1051 (w), 1036 (w), 1008 (w), 945 (w), 858 (w), 847 (m), 783 (m), 758 (s), 690 (w), 622 (vw), 554 (br) and 355 (m). Features are also seen in the regions 1680–1720 cm^{-1} [attributable to ν(C—N) vibrations] and 2900–3600 cm^{-1} [attributable to ν(C—H), ν(O—H) and ν(N—H) vibrations]. However, bands in these last two regions were

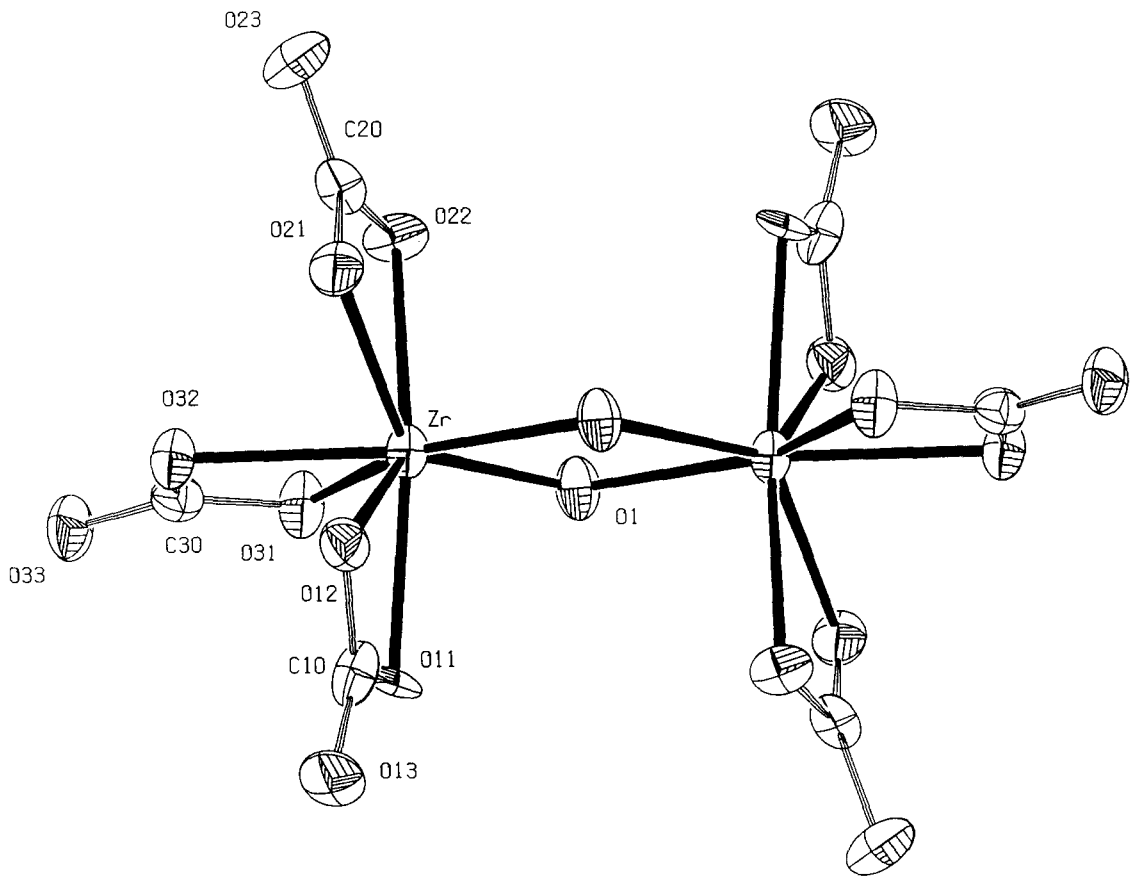

Fig. 1. The $[(ZrOH(CO_3)_3)_2]^{6-}$ anion showing the atomic numbering scheme. Ellipsoids are shown at 50% probability.

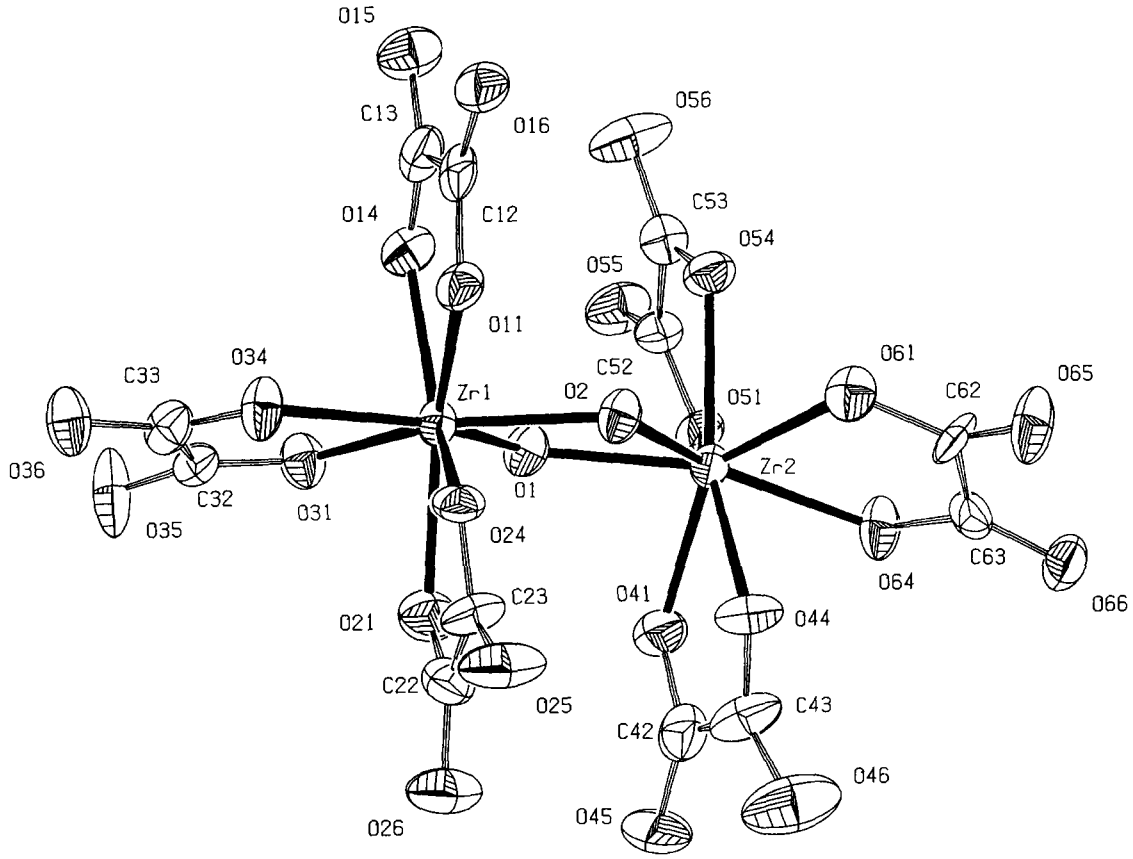

Fig. 2. The $[(ZrOH(C_2O_4)_3)_2]^{6-}$ anion showing the atom numbering scheme. Ellipsoids are shown at 50% probability.

extremely broad and its is difficult to make a detailed analysis or to draw definite conclusions from them. Some points of interest emerge, however, from the infrared data which is listed above, although the situation is necessarily complicated by overlapping of bands and by coupling of vibrations within the molecule. It is possible to distinguish between bands arising from the guanidinium cation or from the anion by a comparison of the spectrum of **A** with spectra of the related compounds **C** and **D** which contain the same anion [12,13]. In order to allow a direct comparison between the infrared spectra of **A, C** and **D** spectra of **C** and **D** were recorded as part of our study under identical conditions used for obtaining the spectrum of **A**. Vibrations which arise from the anion give rise to bands in very similar positions in the spectra of each of the three compounds. The bands of **A** at 1559, 1318 and 1051 cm^{-1} may thus be assigned to stretching vibrations of the coordinated carbonato groups (**C** shows corresponding bands at 1559, 1330 and 1050; **D** at 1560, 1324 and 1048 cm^{-1}). The position of these bands is typical of *chelating* CO_3^{2-} [23,24]. In particular the presence of one higher frequency mode (in **A** at 1559 cm^{-1}) allows an assignment to be made to chelating bidentate as opposed to monodentate CO_3^{2-} [23,24]. The feature at 1008 cm^{-1} most probably arises from the Zr—O(H)—Zr bending mode. **C** and **D** show corresponding features at 997 and 1004 cm^{-1} respectively. This vibration has been found to occur typically in the range ca 950–1000 cm^{-1} for a wide range of complexes [23,25], although Tarte has reported values from 677 to 1000 cm^{-1} for a number of copper compounds [26]. The combination of infrared spectroscopic and single crystal X-ray diffraction data allow us to confirm that compounds **A, C** and **D** have similar structures, although in **A** and **C** (but not **D**) the structure is somewhat complicated by the presence of hydrogen bonding involving the guanidinium (**A**) or ammonium (**C**) cations and water molecules.

A new argument in favor of the ether elimination mechanism: formation of acetals on action of molybdenum alkoxides on carbonyl compounds

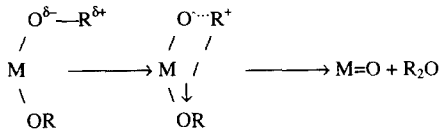
(Received 15 August 1997; accepted 18 December 1997)

Abstract—Molybdenum oxomethoxide and ethoxide are found to react very rapidly with aldehydes and ketones in both alcohol and hydrocarbon media transforming the latter into acetals and ketals respectively. The colloid solution of the molybdenum blue usually formulated as "$MoO_{2.88} \cdot H_2O$" appears to be the major inorganic product of this reaction. The reaction mechanism includes presumably formation of a semiacetal molybdate and its subsequent decomposition with elimination of acetal. Different reaction pathways of metal alkoxides interaction with aldehydes and ketones are discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: acetals; molybdenum alkoxides; carbonyl compounds.

The interest in the mechanistic aspects of metal alkoxides transformation into oxoalkoxides and finally into oxides has risen during the last decade, on one hand, by the prospect of their practical application as precursors of oxide materials in sol-gel and MO CVD processes, and, on the other, by the tremendous increase in both crystallographic and synthetic data available, showing the occurrence of a large variety of transformation pathways beyond hydrolysis or radical pyrolysis, considered traditionally to be the main routes of this conversion [1,2]. The trend to achieve better control over the structure and stoichiometry of the products prepared urged the development of already a series of approaches to non-hydrolytic sol-gel processes, such as cocondensation with metal halides or carboxylic acid salts, accompanied by alkyl halide [3] or ester [4] elimination respectively. In the case of pure metal alkoxides there are two different non-redox transformation pathways evidenced so far, the first of them being the ether elimination reaction that was found to be characteristic of niobium [5,6], and molybdenum and tungsten alkoxides [7,8] and simultaneous elimination of alkene and alcohol observed for the derivatives of zirconium and hafnium [9,10] and also tin and lead alkoxides [10]. The mechanism of the first of these processes was proposed by D. C. Bradley [5]:



and included at the first step the charge redistribution and formation of a carbocation. The analogous mechanism was recently proved experimentally by J. A. Osborn [11] to be true for molybdenum allyloxides structural rearrangements.

In the course of our recent studies of anodic oxidation of molybdenum and tungsten in alcohols [12], we observed formation of mainly oxo-derivatives and found the oxidation of alcohol with formation of aldehyde or ketone to be an important side reaction. However, when the molybdenum dissolution was carried out in ethanol it was not acetaldehyde but its diacetal

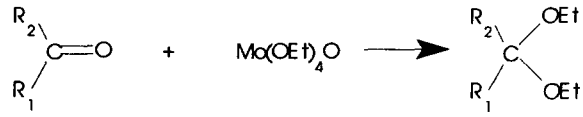
$MoO(OMe)_4$	PhCHO	EtOH	10 min	$PhCH(OEt)_2$, 28 $CH_3CH(OEt)_2$,25 PhCHOEtOH,8 $PhCH_2OEt$, 8

that was isolated. We decided, therefore to study the interaction of molybdenum alkoxides with different aldehydes and ketones to prove if the action of the former is catalytical or it undergoes a quantitative transformation and to determine the nature of the latter.

The choice of the possible molybdenum reagents was limited due to the practical reasons, e.g. the isopropoxides in both homological series—$MoO(OR)_4$ and $MoO_2(OR)_2$ decompose on storage due to redox transformations [13–14], while stable $MoO_2(OR)_2$ (R = Me, Et) have poor solubility; and therefore the prospects of practical application of any kind are open only for methoxide and ethoxide of monooxo series, $MoO(OR)_4$.

The synthesis of molybdenum alkoxides—$MoO(OMe)_4$ and $MoO(OEt)_4$ was carried out in inert atmosphere according to techniques described in literature [3,8]. All the operations connected with investigation of reactivity were carried out in ambient atmosphere but as quickly as possible. Anhydrous solvents (ethanol, toluene, acetone) for reactivity investigations were purchased from Merck (dried, for analysis grade) and used without further purification. For each experiment a measured quantity of molybdenum alkoxide (about 5 mmol in each case) was dissolved in 10 ml of solvent, and then to the solution obtained was added a double quantity of carbonyl compound and the mixture was subjected to vigorous stirring. The reaction speed was monitored following the color changes from yellow, via colorless to dark blue corresponding to transformation of $MoO(OR)_4$ into $MoO_2(OR)_2$ and finally $MoO_{2.88}\cdot H_2O$, which is usually observed in the course of ether elimination reaction [15]. On storage for several weeks the dark blue sediment precipitated, revealing the powder pattern of $MoO_{2.88}\cdot H_2O$ (registered using DRON-3M powder diffractometer). GLC-MS studies of the organic products, separated by vacuum distillation at 50–60°C into a vessel refrigerated by liquid nitrogen, were carried out using a Kratos MS-890 device (source temperature 200°C, SE-30 column).

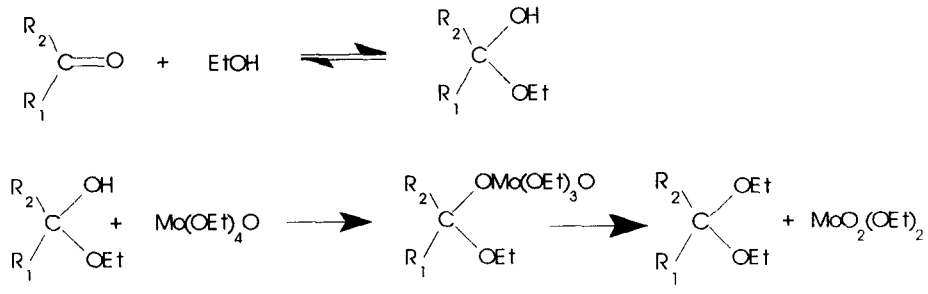
We have found that the action of molybdenum alkoxides, namely $MoO(OMe)_4$ and $MoO(OEt)_4$ transforms the carbonyl compounds into acetals and ketals respectively (Table 1).



Thus acetaldehyde in solution in ethanol gives ethylal in quantitative yields already after 10 min. Reaction of $MoO(OMe)_4$ with trimers of acetaldehyde in hydrocarbons gives mainly dimethylacetal. Titanium ethoxide, which activity was also tested under analogous conditions gives in its turn only 12% of acetal, promoting aldol condensation as a parallel reaction. Acetone reacts much slower with $MoO(OMe)_4$ in EtOH giving semiketal $(CH_3)_2COH(OEt)$ in considerable amounts. Transformation of benzaldehyde is complicated by its reduction into benzyl alcohol with subsequent formation of benzyl acetal.

The reaction mechanism includes, presumably, quick formation of semiacetal and its rapid exchange with the inner co-ordination sphere of the alkoxide molecule. The other possibility of formation of a mixed-ligand derivative is provided by coordination of the molecule of carbonyl compound by the alkoxide, being a Lewis acid, with subsequent transfer of one OR-group to the carbon atom of the carbonyl group (the latter pathway appears to be more probable in the hydrocarbon media). The mixed alkoxide thus formed undergoes acetal elimination analogous to the ether elimination described in literature.

The reaction needs therefore neither basic nor acidic catalysis (which is usually required for the formation of acetals [16]) and proceeds under rather mild conditions. In an alcohol-free media the reaction occurs, presumably, via formation of a semiacetal derivative via addition of aldehyde to the molecule of initial alkoxide; the second step in this case is the same as that in the alcohol. Molybdenum alkoxides are thus undergoing a quantitative transformation into a colloid oxide product.



The condensation of metal alkoxides on action of carbonyl compounds, namely, aceton, has been earlier described in literature for zinc [17] and titanium [18] alkoxides. It was supposed then that the non-hydrolytic condensation proceeded solely due to formation of intermediate enolate compounds and an intermediate oxo-enolate of $Ti_3(\mu_3\text{-}O)_2(O^iPr)_5(OCMe{=}CH_2)_3(^iPrOH)$ really was isolated in the latter case, but the results of the present work permit to suppose that it might not be the only reaction pathway for this kind of transformation.

Electron transfer between nickel(IV) oxime-imine complexes and nitrite: kinetics and mechanism

Amitava Dutta, Santanu Bhattacharya and Pradyot Banerjee*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(Received 1 October 1997; accepted 17 December 1997)

Abstract—The oxidation of nitrite ion by two nickel(IV) oxime-imine complexes, $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ (where H_2L^1 = 3,14-dimethyl-4,7,10,13-tetraazahexadeca-3,13-diene-2,15-dione dioxime and HL^2 = 6-amino-3-methyl-4-azahex-3-en-2-one oxime) has been investigated in aqueous perchlorate medium in the range pH 4.50–7.00 by UV–vis spectrophotometry. The reduction of $[Ni^{IV}(L^2)_2]^{2+}$ involves 2 e^- transfer (one-step) path at pH $\leqslant$ 6.0 and above this, it shows biphasic steps involving Ni^{III} as intermediate. The reduction of $[Ni^{IV}(L^1)]^{2+}$ is, however, biphasic in nature throughout the whole range of pH studied. The reaction rate exhibits a notable dependence on the product Ni^{II} complex added externally. The experimental findings and the low value of the calculated ion-pair constant suggest that the mode of electron transfer is likely to be of outer-sphere type.
© 1998 Elsevier Science Ltd. All rights reserved

Keywords: electron transfer; UV–vis spectrophotometry; nickel(IV) oxime-imine complexes; nitrite.

The interaction of small nitrogen containing species, e.g., nitrite with metal complexes is not only of importance for developing reductase models, but also of interest in a number of other areas. The effective use of nitrite for the contribution of certain types of microbes [1] as well as the prevention of corrosion in iron and steel by nitrite is well documented in literature [2–5]. The electron transfer chemistry of nitrite is thereby worth pursuing. In recent times a number of papers have appeared from our laboratory using nickel(IV) and nickel(III) oxime-imine complexes as oxidants [6–9]. This has been substantiated by a review which encompasses the electron transfer reactions of various types of nickel(III) and nickel(IV) complexes published during the period 1981–1997 [10]. The study of the reaction of nitrite ion with these types of nickel(IV) complexes, $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ (where H_2L^1 = 3,14-dimethyl-4,7,10,13-tetraazahexadeca-3,13-diene-2,15-dione dioxime (**1**) and HL^2 = 6-amino-3-methyl-4-azahex-3-en-2-one oxime (**2**) appears to be a fertile endeavor with regard to mechanistic chemistry. The system may turn out as a possible model for the oxidation of nitrite to nitrate in biological system.

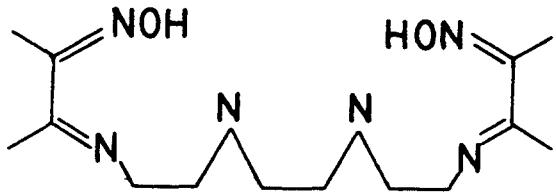
EXPERIMENTAL

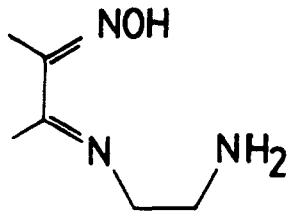
Materials

The complexes $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ (also designated as $[Ni^{IV}(L_y)]^{2+}$) were prepared, characterised and standardised by the method reported earlier [11,12]. Sodium nitrite was purchased from Aldrich and its purity was initially checked by the OCl^- oxidation method as reported earlier [13]. The solutions were prepared by dissolving exact amount of the reagents in doubly distilled water. The solutions were deaerated by bubbling dinitrogen through them. The pH of the solutions was measured in a Systronics digital pH meter (μ-pH system 361, India). High purity perchloric acid, reagent-grade (recrystallised) sodium acetate and sodium dihydrogen phosphate were used as buffers to adjust the pH of the reaction solutions.



H_2L

(1)



HL^2

(2)

Methods

All the kinetic runs were followed spectrophotometrically at 500 nm and 505 nm, λ_{max} for $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ respectively ($\varepsilon^{500}_{max} = 6300$ dm^3 mol^{-1} cm^{-1} and $\varepsilon^{505}_{max} = 6100$ dm^3 mol^{-1} cm^{-1}) maintaining pseudo-first-order conditions with large excess of nitrite ion concentration over the oxidants. The measured pH was calculated in terms of the activity of the hydrogen ion. The hydrogen ion concentration was calculated by using the following relationship [14]

$$[H^+] = 10^-[(pH-0.131)/0.982]$$

where 0.131 is the factor due to ligand junction potential between the glass electrode and the solution, and 0.982 denotes the activity coefficient in the reaction medium. Kinetic measurements were monitored using a Shimadzu (Japan) UV–vis 2100 spectrophotometer. The temperature of the reaction medium was maintained within the limit ± 0.1°C by a Haake F-3 thermostat.

RESULTS

The stoichiometries of the reactions for both the oxidants with nitrite were determined by reacting varied concentrations of nitrite with a measured excess of the oxidants at a constant ionic strength, $I = 0.2$ mol dm^{-3} ($NaClO_4$) and pH 4.75. After the completion of the reaction, the excess unreacted $[Ni^{IV}(L_x)^{2+}]$ were measured spectrophotometrically. The ratio of the moles of Ni^{IV} consumed to moles of nitrite consumed was found to be 1.02 ± 0.02. These results agree with the overall reaction

$$[Ni^{IV}(L_x)]^{2+} + NO_2^- + H_2O \rightarrow [Ni^{II}(L_x)] + NO_3^- + 2H^+ \quad (1)$$

A single step 2 e$^-$ transfer path occurs in the range $4.5 \leqslant pH \leqslant 6.0$ for the reduction of $[Ni^{IV}(L^2)_2]^{2+}$ and then the reduction up to pH 7.0 becomes biphasic in nature. In the case of $[Ni^{IV}(L^1)]^{2+}$ a distinct biphasic 1 e$^-$ transfer reduction occurs throughout the experimental pH range (pH 4.5–7.0). In the biphasic reactions for both the oxidants,the initial faster step corresponds to the conversion of $Ni^{IV} \rightarrow Ni^{III}$ followed by a relatively slower decay of $Ni^{III} \rightarrow Ni^{II}$. In the case of the monophasic reduction for $[Ni(L^2)_2]^{2+}$ in the range $4.5 \leqslant pH \leqslant 6.0$, $Ni^{IV} \rightarrow Ni^{III}$ conversion is rate determining followed by a very fast reduction of $Ni^{III} \rightarrow Ni^{II}$ showing an overall single step 2 e$^-$ transfer process. For $[Ni^{IV}(L^2)_2]^{2+}$, the plots of–log A_t vs t (where A_t is the absorbance at time t) for the single step 2 e$^-$ transfer process were linear up to ca 80% of the total reaction indicating first-order dependence of the reaction rate on $[Ni^{IV}(L^2)_2{}^{2+}]$. In the case of biphasic reaction traces, the first phase accounted for 30–40% of the observed absorbance change and the reactions proceeded to 95–100% yield of the product. For the two consecutive steps, the absorbance vs time curves were successfully treated in terms of two first-order reactions and values of k^I_{obs} ($Ni^{IV} \rightarrow Ni^{III}$) and k^{II}_{obs} ($Ni^{III} \rightarrow Ni^{II}$) were obtained from the initial and the final slopes (clearly distinct) of the plots of $-\log A_t$ vs t.

Dependence on nitrite ion concentration

The dependence of observed rates (k_{obs}) on reductant concentrations were investigated at pH 6.0 for $[Ni^{IV}(L^1)]^{2+}$ and at pH 4.5 and 6.5 for $[Ni^{IV}(L^2)_2]^{2+}$ under the following conditions, $[Ni^{IV}(L_x)^{2+}] = 5.0 \times 10^{-5}$ mol dm^{-3}, $I = 0.20$ mol dm^{-3} ($NaClO_4$), temperature 30°C, [Buffer] = 0.02 mol dm^{-3} (acetate or phosphate as required), [ ] = 0.01–0.09 mol dm^{-3} for $[Ni^{IV}(L^1)]^{2+}$ and 0.001–0.01 mol dm^{-3} and 0.01–0.10 mol dm^{-3} for $[Ni^{IV}(L^2)_2]^{2+}$, pH 4.5 and 6.0 respectively. The plots of k_{obs} vs $[NO_2^-]^2$ were straight lines with positive intercepts indicating a second-order dependence of reaction rate on $[NO_2^-]$. The rate law can thereby be expressed as

$$-d/dt[Ni^{IV}(L_x)^{2+}] = k[Ni^{IV}(L_x)^{2+}][NO_2^-]^2 + k_d[Ni^{IV}(L_x)^{2+}]$$
$$= (k[NO_2^-]^2 + k_d)[Ni^{IV}(L_x)^{2+}] \quad (2)$$

where k_d is the auto redox-decomposition rate constant of the respective oxidant at 30°C and $I = 0.20$ mol dm^{-3} ($NaClO_4$). This auto-decomposition to Ni^{II} complex may occur by the withdrawal of imino-hydrogen atom by OH^- of the medium, thereby causing transference of the electron from $N^- \rightarrow Ni^{IV}$. This auto-decomposition rate constants for both the oxidants are found to be pH dependent [15]. At 30°C and $I = 0.20$ mol dm^{-3} ($NaClO_4$) with $[Ni^{IV}] = 5.0 \times 10^{-5}$ mol dm^{-3} k_d varies from 5.40×10^{-6} s^{-1} to 7.20×10^{-4} s^{-1} in our experimental pH range. While calculating the actual k_{obs} values, the auto-decomposition of the complexes at each pH were taken into account. Subtracting the k_d value from the calculated k_{obs} value, we get the actual k_{obs} value and then the k_{obs} vs $[NO_2^-]^2$ plots for both the oxidants give straight lines passing through the origin (Table 1) leading to Eqn (2a)

$$-d/dt[Ni^{IV}(L_x)^{2+}] = k[Ni^{IV}(L_x)^{2+}][NO_2^-]^2 = k_{obs}[Ni^{IV}(L_x)^{2+}] \quad (2a)$$

Dependence on pH

The effect of acidity on the reaction rate was verified in the range pH 4.5–7.0 at $[NO_2^-] = 0.09$ mol dm^{-3} and 0.08 mol dm^{-3} for $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ respectively. The buffer used up to pH 6.0 was NaOAc–HOAc. Buffering at pH > 6.0 was maintained by Na_2HPO_4–NaH_2PO_4. The pH was adjusted by addition of small amounts of a 0.1 mol dm^{-3} perchloric acid solution. Throughout the experimental pH region, the rate of reaction was found to be independent (within ±4% error) of pH for both the oxidants.

Table 1. Pseudo-first-order rate constants for the oxidation of nitrite by $[Ni^{IV}(L^1)]^{2+}$ and $[Ni^{IV}(L^2)_2]^{2+}$ at two different pHs at 30°C, $I = 0.20$ mol dm^{-3} ($NaClO_4$), $[Ni^{IV}] = 5.0 \times 10^{-5}$ mol dm^{-3}, [buffer] = 0.02 mol dm^{-3} (acetate or phosphate)

[b] For $Ni^{III} \rightarrow Ni^{II}$.
[c] Acetate buffer.
[d] Phosphate buffer.

Effect of buffer

To see the effect of the buffer components on the reaction rate, the kinetics were monitored at pH 5.0 and 6.5 with the varied concentrations of respective buffers (0.005–0.05 mol dm^{-3}) for both the complexes leaving other conditions same as those for pH variation studies. The reaction rates remain unaltered (within ±3% error) indicating that the buffer species do not have any significant interaction with the redox active nickel complexes.

Effect of metal ions

To test for the effect of trace metal ions (Cu^{2+} or Fe^{2+} etc.) on the reaction rate, experiments were conducted by adding phenanthroline (1.0×10^{-4} mol dm^{-3}) externally to the reaction mixture at pH 4.5 leaving other reaction conditions intact. Since no effect was observed, it is concluded that these metal ions are not present in sufficient amounts to effect the reaction rate.

Effect of Ni^{II} (product complex) added externally

A complicated reaction occurs in the presence of $[Ni^{II}(H_2L^1)]^{2+}$ or $[Ni^{II}(HL^2)_2]^{2+}$ (designated as Ni^{II}) added externally. A rapid increase of absorbance takes place initially (Fig. 1) followed by a steady decrease in absorbance with time. With the increase of added $[Ni^{II}]_0$ at a fixed $[NO_2^-]$, the rate of reduction ($Ni^{IV} \rightarrow Ni^{II}$) becomes slower (Fig. 3). Under pseudo-first-order conditions as stated before, in the presence of a large excess Ni^{II} over the Ni^{IV} complexes, a plot of $(A_t)^{-1}$ vs t shows linearity up to ca 80% of the total reactions indicating a second-order dependence of rate on $[Ni^{IV}]$ (Fig. 2). The reaction is also second-order with respect to $[NO_2^-]$. Variation of $[H^+]$ was found to have no effect on the reaction rate. The variation of $[Ni^{II}]_0$ (3.0×10^{-3}–3.0×10^{-4} mol dm^{-3}) added externally shows an inverse first-order dependence in initial $[Ni^{II}]_0$ (Fig. 3). These results point to a different mechanism operative under these conditions.

DISCUSSION

The monophasic ($Ni^{IV} \rightarrow Ni^{II}$) and biphasic ($Ni^{IV} \rightarrow Ni^{III}$, $Ni^{III} \rightarrow Ni^{II}$) nature of reactions in the reduction of the Ni^{IV} complexes concerned at lower and higher pH respectively can be understood on the

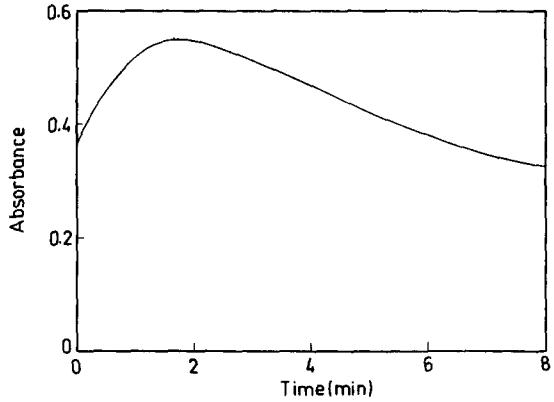

Fig. 1. Change of absorbance with time for the reaction between $[Ni^{IV}(L^1)]^{2+}$ and nitrite in presence of $[Ni^{II}]_0$ at 500 nm. The conditions adopted are: $[Ni^{IV}] = 5.0 \times 10^{-5}$ mol dm^{-3}, $[NO_2^-] = 0.01$ mol dm^{-3}, $[Ni^{II}]_0 = 5.0 \times 10^{-4}$ mol dm^{-3}, $I = 0.20$ mol dm^{-3} ($NaClO_4$), pH = 4.5, [acetate] = 0.02 mol dm^{-3} and temp. = 30°C.

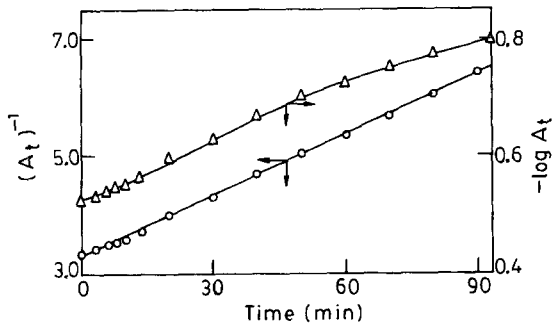

Fig. 2. Plots of (a) $(A_t)^{-1}$ vs time and (b) $-\log A_t$ vs time for the reaction between $[Ni^{IV}(L^2)_2]^{2+}$ and nitrite in presence of $[Ni^{II}]_0$ at 505 nm. Other conditions remain the same as in Fig. 1.

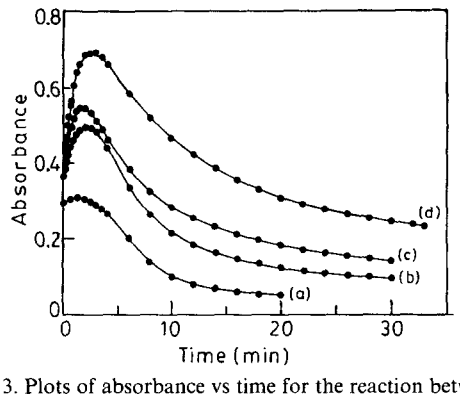

Fig. 3. Plots of absorbance vs time for the reaction between $[Ni^{IV}(L^2)_2]^{2+}$ and nitrite in presence of varying $[Ni^{II}]_0$ at 505 nm (a) $[Ni^{II}]_0 = 1.0 \times 10^{-4}$ mol dm^{-3}; (b) $[Ni^{II}]_0 = 3.0 \times 10^{-4}$ mol dm^{-3}; (c) $[Ni^{II}]_0 = 5.0 \times 10^{-4}$ mol dm^{-3}; (d) $[Ni^{II}]_0 = 7.0 \times 10^{-4}$ mol dm^{-3}. Other conditions are the same as in Fig. 1.

basis of the expected greater proton affinity of Ni^{II} complexes compared to that of Ni^{III} and Ni^{IV} species and also from the E^0 values of the couples present as discussed in our earlier papers [7,8]. Since at low pH E^0_{298} $[Ni^{IV}$–$Ni^{III}] \ll E^0_{298}$ $[Ni^{III}$–$Ni^{II}]$, the reduction of $Ni^{IV} \rightarrow Ni^{III}$ is the rate determining step followed by a very rapid reduction of $Ni^{III} \rightarrow Ni^{II}$. Thus as soon as Ni^{III} is generated from Ni^{IV}, it is reduced to Ni^{II} and hence the single step $2e^-$ transfer process without the involvement of any Ni^{III} intermediate is observed at low pH. However, at higher pH E^0_{298} $[Ni^{IV}$–$Ni^{III}] >$ E^0_{298} $[Ni^{III}$–$Ni^{II}]$ for the proton independent $Ni^{III} \rightarrow Ni^{II}$ transformation but for proton dependent $Ni^{III} \rightarrow Ni^{II}$ transformations have got comparable E^0 values with that of Ni^{III}–Ni^{II} couples. These result in the phase separation at the higher pH.

There are some reports [16–18] where the reactions of nitrite ion have been performed in acidic medium (pH $\leqslant$ 4.25). While preparing nitrite solutions at pH 2.0–4.25, we observed the evolution of small gas bubbles from the solution. Attempted kinetic study shows a strong dependence on $[H^+]$ in this region, and the results are erroneous. This may be due to the presence of kinetically active oxynitrogen species in acidic solutions [19]. Hence the reactions of nitrite would lead to greater complications owing to the rapidly established equilibria:

$$HNO_2 \overset{K_a}{\Leftrightarrow} H^+ + NO_2^- \quad (3)$$

$$H^+ + HNO_2 \Leftrightarrow H_2NO_2^- \quad (\text{or } H_2O + NO^+) \quad (4)$$

$$2HNO_2 \Leftrightarrow N_2O_3 + H_2O \quad (5)$$

$$N_2O_3 \Leftrightarrow NO + NO_2 \quad (6)$$

$$2NO_2 \Leftrightarrow N_2O_4 \quad (7)$$

$$N_2O_4 + H_2O \Leftrightarrow HNO_2 + NO_3^- + H^+ \quad (8)$$

Great care must, therefore, be taken in carrying out such studies in order to determine the proper reactant species. To avoid these, kinetic study has been performed in the range pH $\geqslant$ 4.5. From cyclic voltammetric and spectroscopic studies, it has been reported that the pK_{HS} for $[Ni^{IV}(L_x)]^{2+}$ (involving oxime protons) are less than 1.0 [11,12]. The pK_a of nitrous acid is reported to be 2.95 [eqn (3)] [20]. Hence in the experimental range of pH, only the deprotonated species of both the oxidants and reductant would be expected to exist which could justify the observed lack of $[H^+]$ dependence on the reaction rates (within ±4% deviation). The most characteristic feature of the present reactions is the second-order dependence of rate on $[NO_2^-]$. At first sight this seems rather surprising but it may be relatively simply understood if one considers the involvement of N_2O_4 as an intermediate which may eventually decompose by hydrophylic dismutation. Such an intermediate will also explain the lack of hydrogen ion dependence in the rate-law. The possibility of hydrogen bond formation as encountered in some of the earlier reactions

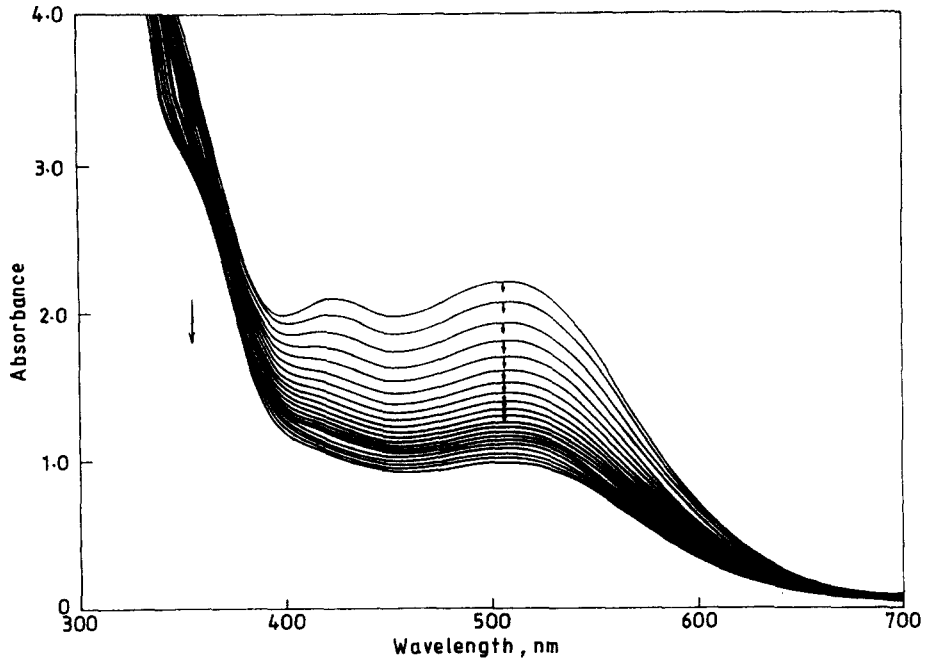

Fig. 4. Spectral scanning for the reaction between $[Ni^{IV}(L^2)_2]^{2+}$ and nitrite at 30°C with $[Ni^{IV}] = 5.0 \times 10^{-5}$ mol dm^{-3}.

[8] is eliminated since the oximato ligand does not find any proton bound on the nitrite reductant. A likely mechanism of the reaction can, thereby, be framed by considering the formation of an outer-sphere associated species between the two oppositely charged reactants [eqn (9)]. A second molecule of nitrite ion then reacts in the rate determining step with the ion-paired species (IP) giving the Ni^{II} product(s) and N_2O_4 [eqn (10)]. The hydrolysis of N_2O_4 takes place rapidly through the k_2 path [eqn (11)].

$$[Ni^{IV}(L_x)]^{2+} + NO_2^- \overset{K_1}{\Leftrightarrow} IP \qquad (9)$$

$$IP + NO_2^- \underset{\text{r.d.s}}{\overset{k_1}{\rightarrow}} [Ni^{II}(L_x)] + N_2O_4 \qquad (10)$$

$$N_2O_4 + H_2O \underset{\text{rapid}}{\overset{k_2}{\rightarrow}} NO_2^- + NO_3^- + 2H^+ \qquad (11)$$

The above scheme leads to a rate-law

$$-d/dt[Ni^{IV}(L_x)^{2+}] = k_1K_1[Ni^{IV}(L_x)^{2+}][NO_2^-]^2 \qquad (12)$$

This is identical to eqn (2a) with $k_1K_1[NO_2^-]^2 = k[NO_2^-]^2 = k_{obs}$, i.e., $k = k_1K_1$. The values of k_1K_1 were evaluated by a least-squares fitting of kinetic data. For monophasic reduction of $[Ni^{IV}(L^2)_2]^{2+}$ at pH 4.5, the value is (5.75 ± 0.07) dm^6 mol^{-2} s^{-1}. For biphasic reduction of both the oxidants at pH 6.0 the values evaluated are: (0.10 ± 0.003) dm^6 mol^{-2} s^{-1} and $(5.04 \pm 0.23) \times 10^{-3}$ dm^6 mol^{-2} s^{-1} for $[Ni^{IV}(L^1)]^{2+}$; (0.532 ± 0.02) dm^6 mol^{-2} s^{-1} and $(7.75 \pm 0.50) \times 10^{-3}$ dm^6 mol^{-2} s^{-1} for $[Ni^{IV}(L^2)_2]^{2+}$ owing to $Ni^{IV} \rightarrow Ni^{III}$ and $Ni^{III} \rightarrow Ni^{II}$ reduction steps respectively. The true comparison between k_1 and k_2 would be possible when one gets an insight into the magnitude of the ion-pair formation constant (K_1) in eqn (9). The value of the ion-pair constant (K_1) can be calculated theoretically using eqns (13)–(15) [21].

$$K_1 = Q_{IP} = \{(4\pi Na^3)/3000\} \exp(-U(a)/KT) \qquad (13)$$

$$U(a) = (Z_1Z_2e^2)/\{Da(1+\kappa a)\} \qquad (14)$$

$$\kappa = \{(8\pi Ne^2\mu)/(1000DKT)\}^{1/2} \qquad (15)$$

where N = Avogadro number, a = distance of closest approach, A = Boltzman constant, T = absolute temperature, Z_1 and Z_2 are the charges on respective ion, e = electronic charge, D = bulk dielectric constant of the medium (water) and μ is the ionic strength. $a = r_1 + r_2$, where r_1 and r_2 are the radii of Ni^{IV} and NO_2^- ions respectively. Values of r_1 and r_2 are considered as 5.1 Å [7] and 1.9 Å [17] respectively. The value of K_1 was calculated to be 2.31 dm^3 mol^{-1}. Dividing k_1K_1 by this value, the rate constant (k_1) was evaluted as: for monophasic reduction of $[Ni^{IV}(L^2)_2]^{2+}$ at pH 4.5 the value is (2.49 ± 0.03) dm^3 mol^{-1} s^{-1}. For biphasic reduction of both the oxidants at pH 6.0, the values evaluated are: (0.04 ± 0.001) dm^3 mol^{-1} s^{-1} and $(2.18 \pm 0.10) \times 10^{-3}$ dm^3 mol^{-1} s^{-1} for $[Ni^{IV}(L^1)]^{2+}$; (0.23 ± 0.01) dm^3 mol^{-1} s^{-1} and $(7.75 \pm 0.50) \times 10^{-3}$ dm^3 mol^{-1} s^{-1} for $[Ni^{IV}(L^2)_2]^{2+}$

for $Ni^{IV} \rightarrow Ni^{III}$ and $Ni^{III} \rightarrow Ni^{II}$ steps respectively. The value of k_2 has been reported to be $1.0 \times 10^3\ s^{-1}$ [22]. Converting it to a second-order parameter with $[H_2O] = 55.5\ mol\ dm^{-3}$, it turns out to $18.0\ dm^3\ mol^{-1}\ s^{-1}$. This shows that the hydrolysis path (k_2) of N_2O_4 is a faster step and not involved in the rate-law.

Nitrite ion can function as both oxidant and reductant [19]. Let us now look into the reactivity features critically when the product Ni^{II} complex is added externally at the onset of the reaction. The nitrite ion may oxidise this Ni^{II} into Ni^{III} or Ni^{IV} due to which there is an initial rise in absorbance and thus loses its initial concentration in the medium. The effective concentration of NO_2^- will go on decreasing as we increase the $[Ni^{II}]_0$ and this clearly justifies the inverse dependence of rate on $[Ni^{II}]_0$ added externally. To explain the second-order dependence on both $[Ni^{IV}]$ and $[NO_2^-]$ and the inverse dependence on $[Ni^{II}]_0$, a possible mechanistic path could be framed as

$$2[Ni^{IV}(L_x)]^{2+} + 2NO_2^- \overset{K_2}{\Leftrightarrow} 2[Ni^{IV}(L_x)\cdots NO_2^-]^+ \quad (16)$$

$$2[Ni^{IV}(L_x)\cdots NO_2^-]^+ \overset{K_3}{\Leftrightarrow} [Ni^{III}(L_x)]^+ + [Ni^{IV}(L_x)\cdots N_2O_4]^+ \quad (17)$$

$$[Ni^{IV}(L_x)\cdots N_2O_4]^+ \underset{k_4}{\overset{k_3}{\Leftrightarrow}} [Ni^{III}(L_x)]^+ + N_2O_4 \quad (18)$$

$$2[Ni^{III}(L_x)]^+ \overset{k_5}{\rightarrow} [Ni^{II}(L_x)] + [Ni^{IV}(L_x)]^{2+} \quad (19)$$

$$N_2O_4 + H_2O \overset{k_6}{\rightarrow} NO_2^- + NO_3^- + 2H^+ \quad (20)$$

The overall stoichiometric reaction can, therefore, be written as

$$[Ni^{IV}(L_x)]^{2+} + NO_2^- + H_2O \rightarrow [Ni^{II}(L_x)] + NO_3^- + 2H^+$$

and this is identical to eqn (1).

Comparison of reactivity of the two Ni^{IV} *complexes*

The reactivity of $[Ni^{IV}(L^2)_2]^{2+}$ towards nitrite ion is found to be greater than that of $[Ni^{IV}(L^1)]^{2+}$. This reflects the ease of rearrangement of tridentate bis-(oxime) ligand (HL^2) having no continuity of the backbone compared to the single-chain hexadentate (continuous) system (H_2L^1) where all sites may be affected equally, although in both the cases there is a change in electronic structure from a low spin t_{2g}^6 to a $t_{2g}^6\ e_g$ configuration.

Conclusion

Preliminary spectral scanning (Fig. 4) shows no indication for the formation of an appreciable amount of thermodynamically stable intermediate species during the reaction. Moreover both the Ni^{IV} and Ni^{III} components of the redox couples have pseudo-octahedral geometry and moderate reduction potential values. These are expected to show low substitution labilities ($< 10^2\ s^{-1}$) [7]. Unfortunately, we could not apply here the Marcus cross-relation equations to test the validity for outer-sphere reactions as the reactions are second-order on $[NO_2^-]$ for both the oxidants. The experimental findings and the low value of the calculated ion-pair constant can best be explained by considering an outer-sphere electron transfer process as above. The present work reveals some interesting aspects: (i) the overall reaction order is three; (ii) the reaction order turns to four in the presence of externally added Ni^{II}-product complex (2–15 times); (iii) presence of kinetically active oxynitrogen species at low pH (< 4.25) renders complicacy and erroneous pH dependency on rate is noted and (iv) low calculated values of ion-pair formation constant are suggestive for the operation of outer-sphere electron transfer route.

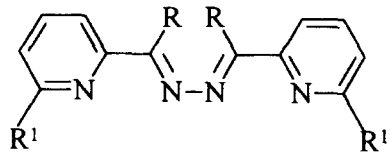
(Received 11 September 1997; accepted 17 December 1997)

Abstract—In the complex *cis*-$[MnCl_2(2\text{-paa})_2]$, (2-paa = 2-pyridinecarbaldehyde azine) each 2-paa behaves as a bidentate chelating ligand using adjacent pyridyl and azine nitrogen donor atoms. Twisting about the N—N bonds removes the remaining two nitrogen donor atoms of each 2-paa away from the vicinity of the metal centre. This complex is the first to be reported containing two bidentate 2-paa ligands. Only one previous example of a metal complex involving a single bidentate 6-methyl-2-paa ligand has been examined structurally. The complexes $[Mn_2Cl_4(2\text{-paa})]$, $[Zn_2(NO_3)_4(2\text{-paa})]\cdot 2H_2O$ and $[Ag_2(NO_3)_2(2\text{-paa})]$ have also been isolated, NMR evidence indicating that in the zinc and silver complexes the 2-paa ligands act in a double bidentate coordination mode. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: 2-pyridinecarbaldehyde azine; 2-pyridinaldazine; manganese(II); structure; zinc; silver.

Potentially tetrafunctional azines have long found use as ligands and as analytical reagents [1]. One such ligand, 2-pyridinecarbaldehyde azine (**I**, R = R¹ = H), also known as 2-pyridinaldazine, was the subject of an extensive study [2] in the late 1950s and 1960s when cationic complexes with stoichiometries $[M(2\text{-paa})_2]^{2+}$ (M = Fe or Ni) and $[M_2(2\text{-paa})_3]^{4+}$ (M = Fe, Ni or Co), as well as the copper(I) and -(II) complexes $[CuCl(2\text{-paa})]Cl$, $[Cu_2Cl_4(2\text{-paa})]$ and $[Cu_2Cl_2(2\text{-paa})]$, were isolated.

Although the locations of the four donor nitrogen atoms of 2-paa are such as to make their coordination to a single metal centre extremely unlikely, 2-paa is a versatile ligand because of three possible geometric isomers arising from the orientation of the pyridyl groups about each azine C=N unit. Thus, in order to act as a double bidentate chelating ligand and so provide a bridge between two metal centres, it will likely be in a *trans*, *trans*-configuration as proposed for $[M_2(2\text{-paa})_3]^{4+}$ (M = Fe or Ni) [2] and $[Mo_2(CO)_8(2\text{-paa})]$ [3]. Alternatively, it will take up



(I)

the *cis*, *trans*-configuration in order to act as a tridentate chelating ligand where both pyridyl and one azine nitrogen atoms are donors, as proposed for $[M(2\text{-paa})_2]^{2+}$ [2]. Coordination to metals in a *cis*, *cis*-configuration has not been confirmed or, indeed, even proposed and is the least likely arrangement for a metal complex involving 2-paa. Some iridium [4] and molybdenum [5] complexes containing 2-paa have been reported. The 2-paa ligands in $[Ir(NO)(PPh_3)_2(2\text{-paa})]^{2+}$ and $[Mo(CO)_3L(2\text{-paa})]$, (L = CO, MeCN or PPh_3) will be bidentate. However, in $[Ir_2(CO)_2(PPh_3)_4(2\text{-paa})]^{2+}$, $[Ir_2H_4(PPh_3)_4(2\text{-paa})]^{2+}$ and in $[Mo_2(CO)_6L_2(2\text{-paa})]$ (L = MeCN, PPh_3 or 1/2

* Author to whom correspondence should be addressed.

μ-dppe) and $[Mo_2(CO)_7(PPh_3)(2\text{-paa})]$ 2-paa is acting as a double bidentate ligand. A variety of lanthanide and actinide complexes of unusual stoichiometries and unknown structures containing this ligand have also been reported recently [6].

Remarkably few crystal structure determinations of complexes containing 2-paa or related ligands have been published. The first [7] showed that five-coordinate $[ZnCl_2(2\text{-paa})]$ contained *cis*, *trans*-tridentate 2-paa. Conversely, the 6-methyl derivative (**I**, R = H, R^1 = Me) is bidentate and in a *trans*, *trans*-configuration in $[IrH_2(PPh_3)_2(6\text{-Me-2-paa})]^+$ [4]. Double bidentate coordination of 2-paa has been confirmed [5] for $[Mo_2(CO)_6(\mu\text{-dppe})(2\text{-paa})]$, the 2-paa not being planar as a result of the short span of the bridging dppe ligand. The 2-paa ligand is, however, closer to being in a *trans*- rather than a *cis*-arrangement. Finally, the structures of two copper(II) complexes containing bis(2-pyridylmethyl)ketazine ligands, (**I**, R = Me, R^1 = H), have been elucidated, the ligand being *trans*, *trans*-double bidentate in $[Cu_2Cl_4(\text{ligand})]$ but *cis*, *trans*-tridentate in $[Cu(NO_3)_2(\text{ligand})]$ [8].

Although, as mentioned, the structure of $[ZnCl_2(2\text{-paa})]$ has been determined, the preparation of this and any other zinc-2-paa complexes have not been reported. Similarly, there are no reports of manganese-2-paa complexes. Therefore, we report here the preparations of zinc nitrate, silver nitrate and two manganese(II) chloride-2-paa complexes, together with the crystal structure of one of the manganese complexes.

EXPERIMENTAL

Infrared spectra (4000–200 cm^{-1}) were recorded as Nujol or hexachlorobutadiene mulls on CsI plates using a Perkin–Elmer 597 spectrophotometer. Proton NMR spectra were recorded on a Jeol GX 270 spectrometer. Room temperature magnetic susceptibilities were measured using a Johnson Matthey magnetic balance. Microanalyses were carried out using a Carlo Erba microanalyser. All solvents were dried over 4A molecular sieves but metal salts were used as received.

Preparation of 2-pyridinecarbaldehyde azine (2-paa)

A solution of hydrazine hydrate (62%; 5.1 cm^3) in ethanol (20 cm^3) was added slowly to a solution of 2-pyridinecarbaldehyde (16 g, 0.15 mol) in a similar volume of ethanol. An exothermic reaction ensued and fine yellow needles of the product appeared. After cooling in ice, the crystals were collected and recrystallised from ethanol. Yield: 8.1 g, 51%. m.p. 148°C (lit. 149°C). (Found: C, 68.4; H, 4.9; N, 26.5. $C_{12}H_{10}N_4$ requires C, 68.5; H, 4.8; N, 26.6%.) ^{1}H NMR ($CDCl_3$), δ 7.35 (m, H^4; $J_{3,4}$ 7.6, $J_{4,5}$ 4.9, $J_{2,4}$ 1.0 Hz), 7.79 (dt, H^3; $J_{2,3}$ 7.6, $J_{3,5}$ 1.8 Hz), 8.13 (ddd, H^2; $J_{2,5}$ 0.9 Hz), 8.70 (s, N=C*H*), 8.73 (ddd, H^5)—assignments relate to protons attached to carbons as numbered in Fig. 1.

Preparation of dinitrato(2-pyridinecarbaldehyde azine)disilver(I)

A solution of 2-paa (0.50 g, 2.4 mmol) in acetone (20 cm^3) was added dropwise with stirring to an aqueous solution of silver nitrate (1.19 g, 7.0 mmol). A yellow precipitate formed immediately and was filtered, washed with water, ethanol and diethyl ether and dried *in vacuo*. Yield: 1.06 g, 81%. (Found: C, 25.9; H, 1.8; N, 15.1. $C_{12}H_{10}Ag_2N_6O_6$ requires C, 26.2; H, 1.8; N, 15.3%.) ^{1}H NMR (CD_3CN) δ 7.77 (m, H^4; $J_{3,4}$ 6.3, $J_{4,5}$ 4.4, $J_{2,4}$ 1.0 Hz), 7.90 (dd, H^2; $J_{2,3}$ 6.3, $J_{2,5}$ 0.9 Hz), 8.15 (dt, H^3; $J_{3,5}$ 1.0 Hz), 8.73 (dd, H^5), 8.88 (s, N=C*H*).

Preparation of tetranitrato(2-pyridinecarbaldehyde azine)dizinc(II) dihydrate

Mixing warm solutions of zinc nitrate hexahydrate (1.20 g, 4.0 mmol) and 2-paa (0.42 g, 2.0 mmol) in acetonitrile followed by cooling gave a yellow precipitate which was filtered, washed with ethanol and diethyl ether and dried *in vacuo*. Yield: 0.97 g, 78%. (Found: C, 22.8; H, 2.4; N, 17.9. $C_{12}H_{14}N_8O_{14}Zn_2$ requires C, 23.0; H, 2.3; N, 17.9%.) ^{1}H NMR (CD_3CN) δ 7.76 (m, H^4), 8.18 (d, H^2 and H^3), 8.82 (d, H^5), 8.88 (s, N=C*H*).

Preparation of tetrachloro(2-pyridinecarbaldehyde azine)dimanganese(II)

A mixture of manganese dichloride tetrahydrate (0.25 g, 1.26 mmol) and 2-paa (0.20 g, 0.95 mmol) were reacted in refluxing ethanol or acetonitrile (30 cm^3) for 1 h. After cooling in ice, the yellow product was filtered, washed with ethanol and diethyl ether and dried *in vacuo*. Yield: 0.24 g, 41%. (Found: C, 31.6; H, 2.3; N, 11.9. $C_{12}H_{10}Cl_4Mn_2N_4$ requires C, 31.2; H, 2.2; N, 12.1%.)

Preparation of cis-dichlorobis(2-pyridinecarbaldehyde azine)manganese(II)

A solution of 2-paa (0.21 g, 1.00 mmol) in ethanol (25 cm^3) was slowly added to a stirred aqueous solution of manganese dichloride tetrahydrate (0.20 g, 1.00 mmol). An aqueous solution of potassium iodide (1.00 g, 6.3 mmol) was then added. No obvious reaction was evident so the solution was allowed to slowly evaporate at room temperature. After two weeks a small crop of wine red crystals began to appear and after a further week these were collected, washed with water and ethanol and dried *in vacuo*. (Found: C, 52.2; H, 3.7; N, 20.9. $C_{24}H_{20}Cl_2MnN_8$ requires C,

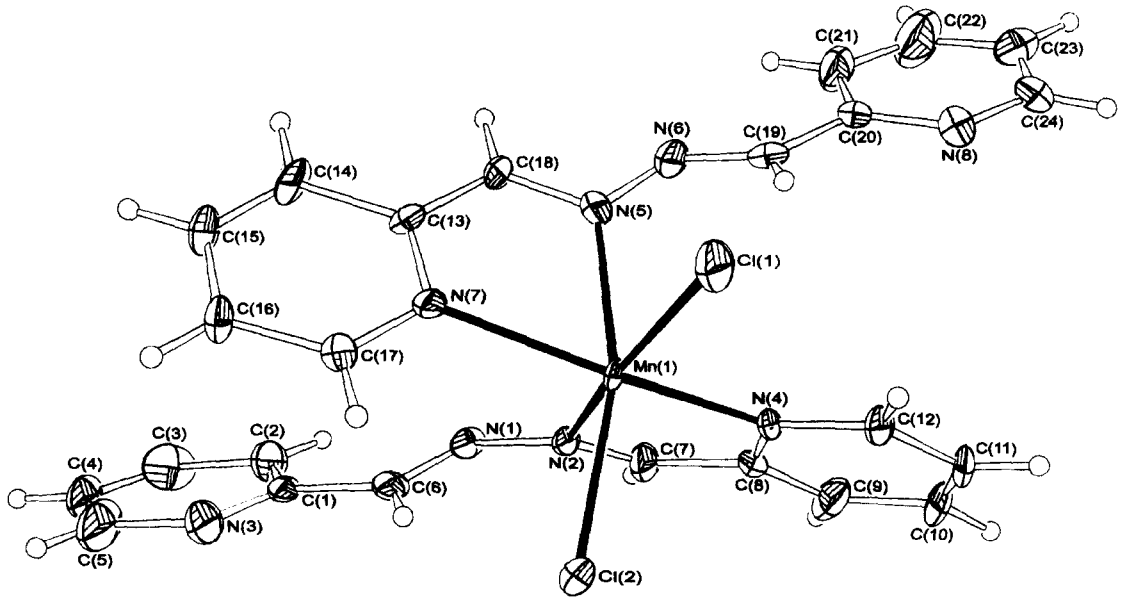


Fig. 1. The asymmetric unit of *cis*-$[MnCl_2(2\text{-paa})_2]$ with atom labelling. Thermal ellipsoids are represented at the 30% probability level.

52.8; H, 3.7; N, 20.5%.) Several preparations carried out as above gave clusters of large crystals but by varying the quantities of solvent smaller crystals were obtained, one of which was selected for a crystal structure determination.

X-ray crystallography

Crystal data: $C_{24}H_{20}Cl_2MnN_8$, M 546.32, triclinic, space group $P\bar{1}$ (No. 2), $a = 8.633(2)$, $b = 9.253(2)$, $c = 16.300(3)$ Å, $\alpha = 100.22(2)$, $\beta = 91.32(2)$, $\gamma = 93.00(3)^\circ$, $V = 1279.0(5)$ Å^3, $Z = 2$, $D_{calc} = 1.419$ g cm^{-3}, $\mu = 0.754$ mm^{-1}, $F(000) = 558$. Data were collected at room temperature, 293(2) K, on a Hilger and Watts Y290 four-circle diffractometer in the range $2.24 < \theta < 22.00^\circ$ using Mo–K_α (0.71069 Å) radiation. A crystal of dimensions $0.4 \times 0.4 \times 0.5$ mm was selected for the structure determination. The index ranges were $0 \leq h \leq 9$; $-9 \leq k \leq 9$; $-16 \leq l \leq 16$. The diffraction intensities were corrected for Lorentz and polarisation effects and for absorption [9]. 3325 Reflections were measured of which 3119 were independent [$R_{int} = 0.0227$]. The structure was solved by Patterson methods. Solution and refinement was achieved using the SHELX suite of programs [10]. Hydrogen atoms were included at calculated positions where relevant throughout. In the final least squares cycles all atoms were allowed to vibrate anisotropically. The large residuals (maximum and minimum 2.904 and -3.133 e Å^{-3} respectively) are a consequence of a very limited batch of crystals, poor crystal quality and several "shadow" peaks close to the heavy atom in the final difference Fourier map despite application of an absorption correction. The goodness-of-fit on F was 1.150 with final R indices [$I > 2\sigma(I)$] of $R_1 = 0.2175$ and $wR_2 = 0.5550$ and R indices (all data) of $R_1 = 0.2415$ and $wR_2 = 0.5864$. The weighting scheme employed was $1/[\sigma^2(F_o^2) + (0.5499P)^2 + 3.8735P]$ where $P = (F_o^2 + 2F_c^2)/3$. Selected bond lengths and angles are given in Table 1. Additional material is available from the Cambridge Crystallographic Data Centre and comprises final fractional atomic coordinates, thermal parameters, hydrogen atom coordinates and a complete listing of bond lengths and angles. The molecular structure, produced using ORTEX [11], is shown, together with the labelling scheme in Fig. 1.

RESULTS AND DISCUSSION

Four previously unreported complexes containing the potentially tetradentate ligand 2-pyridinecarbaldehyde azine (2-paa) have been isolated. The azine itself has prominent IR bands at 1630, ν(C=N), and at 1582, 1570, 1484 and 1437 (pyridine bands) cm^{-1} and its ^{1}H NMR spectrum can be fully assigned (see Experimental section). Two metal nitrate complexes, $\{[Ag(NO_3)]_2(2\text{-paa})\}$ and $\{[Zn(NO_3)_2]_2(2\text{-paa})\} \cdot 2H_2O$ have been prepared and their ^{1}H NMR spectra can be assigned on the basis that a symmetrical ligand arrangement is retained on coordination to the metals. (Proton assignments refer to the related carbon positions shown in Fig. 1.) For the silver complex, only five individual resonances with appropriate multiplicities and couplings are observed for the eight pyridine ring protons and the

two N=CH protons. A comparison with the chemical shifts of 2-paa itself shows that the resonances assigned to H^4, H^3 and the N=CH protons move downfield, that of H^2 moves upfield and that of H^5 is unchanged on coordination to silver. For the zinc complex only four resonances appear in the δ 7.5–9.0 region of relative intensities 1 : 2 : 1 : 1. Although fewer couplings are observed than for the silver complex, the chemical shifts are similar but those of H^2 and H^3 are accidentally identical. The overall simplicity of both spectra shows that the azine is acting as a double bidentate ligand in both complexes, each of the metal centres being bonded to a pyridyl and an azine nitrogen to generate five-membered rings.

Two manganese(II)-2-paa complexes, $[Mn_2Cl_4(2\text{-paa})]$ and *cis*-$[MnCl_2(2\text{-paa})_2]$, have also been isolated. The former was obtained as a yellow precipitate from a reaction between manganese dichloride tetrahydrate and a slight molar deficiency of 2-paa in either refluxing ethanol or acetonitrile. One compound of the type $[M_2Cl_4(2\text{-paa})]$, where M = Cu, has been reported previously [2] and it was suggested that it contains square planar copper(II) with doubly bidentate 2-paa and terminal chloride ligands. A crystal structure of the closely related complex $[Cu_2Cl_4(\text{ligand})]$ where ligand = bis(2-pyridylmethyl)ketazine (**I**, R = Me, R^1 = H) confirmed this arrangement [8]. Although an analogous structure is conceivable for the manganese complex, we cannot advance any evidence in support. A magnetic moment of 5.90 B.M. at 294 K is merely indicative of high spin manganese(II) irrespective of geometry and the IR spectrum shows ν(C=N) at 1635 cm^{-1} and pyridine ring vibrations at 1580 and 1569 sh cm^{-1}. It would seem likely that the two metal ions are in identical environments and this would be achieved by the presence of doubly bidentate 2-paa.

The second manganese complex was obtained from a reaction designed to produce $[MnI_2(2\text{-paa})]$. Thus, aqueous $MnCl_2 \cdot 4H_2O$ was reacted with an equimolar amount of 2-paa in ethanol and a large excess of aqueous potassium iodide added subsequently. No precipitate appeared but slow evaporation at room temperature over a two-week period led to a low yield of wine-red crystals which contained no iodide and were then characterised as *cis*-$[MnCl_2(2\text{-paa})_2]$ with a magnetic moment of 5.92 B.M. at 295 K and IR bands at 1630, 1580 and 1567 cm^{-1}.

The structure of this complex has been elucidated by a single crystal X-ray crystallographic study. Only one other metal halide-2-paa complex, $[ZnCl_2(2\text{-paa})]$, appears to have had its structure confirmed crystallographically [7] and in that complex 2-paa is *cis*, *trans*-tridentate. However, in *cis*-$[MnCl_2(2\text{-paa})_2]$, (Fig. 1), both 2-paa ligands are, rather surprisingly, merely bidentate and as such this is the first metal-azine complex to show this structural feature. The only other compound with a crystallographically confirmed structure involving a bidentate chelating pyridine-azine ligand is $[IrH_2(PPh_3)_2(6\text{-Me-2-paa})]SbF_6$ [4]. The manganese compound consists of distorted octahedral monomeric molecules with two *cis*-chlorides [Mn—Cl 2.391(5) and 2.421(4) Å; Cl—Mn—Cl, 103.6(2)°] and four donor nitrogen atoms comprising a pyridine and an azine nitrogen from each bidentate ligand. The greatest distortion of the octahedral array arises from constraints imposed by the pyridyl and azine moieties which prohibit an N—Mn—N bite of

90°, the actual angles being 70.2(4) and 70.2(5)° in forming MnN_2C_2 five-membered rings.

A recent [5] semi-empirical AM1 electronic structure calculation carried out for 2-paa predicts that the lowest energy conformation of the free ligand is neither *cis*- nor *trans*. An arrangement with an azine CNNC torsion angle of 102° is predicted with the pyridine rings being twisted out of the plane of the central part of the molecule by approximately 50°. This is not supported by the results from a single crystal structure determination* that we have carried out on the free ligand [12]. This shows that 2-paa crystallises in a centrosymmetric space group and is *trans*-planar with the two pyridyl nitrogens on opposite sides of the azine N—N bond and a consequent CNNC torsion angle of 180.0°. In the manganese complex, the uncoordinated nitrogen atoms of each 2-paa ligand are well removed from the metal centre by twisting about the N—N bond so that the strictly *trans*-configuration of the free ligand is destroyed but still leaving the non-coordinated ends of the 2-paa ligands positioned well away from each other. This is illustrated by the C(18)—N(5)—N(6)—C(19) and C(6)—N(1)—N(2)—C(7) torsion angles of 150.8 and 141.3°, respectively. The 2-paa ligands are arranged in such a way that the two coordinated pyridyl nitrogens are *trans* to each other [N(4)—Mn(1)—N(7), 153.6(5)°], whereas the two coordinated azine nitrogens are *cis* to each other [N(2)—Mn(1)—N(5), 76.9(4)°] and *trans* to chlorides [Cl(1)—Mn(1)—N(2), 163.8(4)° and Cl(2)—Mn(1)—N(5), 161.5(3)°]. The octahedral arrangement can therefore be viewed as a plane containing two chlorides and two azine nitrogens with the two pyridine nitrogens positioned axially. The Mn—N(pyridine) bond lengths of 2.262(11) and 2.268(12) Å are significantly shorter than the Mn—N(azine) bond lengths of 2.373(13) and 2.398(13) Å. No significant differences are evident between the lengths of the C=N bonds which are adjacent to or distant from the coordinated pyridine rings. Average C—C and C—N bond lengths within the pyridine rings and C—C bond lengths external to the pyridine rings are in the expected ranges [1.38(3), 1.34(2) and 1.46(2), respectively].

This structure can be compared to those of *cis*-$[MnCl_2(bipy)_2]$ [13] and *cis*-$[MnCl_2(phen)_2]$ [14] (bipy = 2,2′-bipyridyl; phen = 1,10-phenanthroline), significant bond lengths and angles being displayed in Table 2. All three structures involve constrained chelate ring systems with N—Mn—N angles much reduced to around 70°, Cl—Mn—Cl angles around 14° greater than 90° and Mn—N bonds significantly shorter where *trans* to another nitrogen rather than where *trans* to a chloride ligand.

* 2-paa is monoclinic, space group $P2_1/c$, with $a = 10.054(2)$, $b = 4.648(4)$, $c = 11.691(2)$ Å and $\beta = 91.03(2)°$. The poor quality of the crystals grown resulted in large residuals on attempts to solve the structure. Consequently, bond parameters are not discussed here but use is made of the overall structural arrangement in this Discussion section.

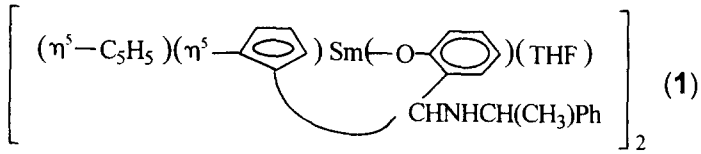
Synthesis and crystal structure of chiral bis(cyclopentadienyl) samarium Schiff base complexes bearing intramolecular C—C bond formation and hydrogen transfer

Qiancai Liu*†, Mengxian Ding, Yonghua Lin and Yan Xing‡

Polymer Chemistry Laboratory, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, 159 Renmin Street, Changchun 130022, People's Republic of China

(Received 11 September 1997; accepted 2 December 1997)

Abstract—$SmCl_3$ reacted with CpNa (Cp = Cyclopentadienyl) in the ratio of 1:3 in THF, which then was reacted with (*S*)-(+)-*N*-1-(phenylethyl)salicylideneamine/toluene to yield the title complex,



(1)

The X-ray crystal structure determination of the title complex reveals that **1** is a dimer with intramolecular C—C bond formation and hydrogen transfer, which leads to the configuration turnover of the carbon atom at the benzyl position of the ligand, while those of the newly formed asymmetric centers may have either *R* or *S* type configurations. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: samarocene complex; chirality; Schiff base; crystal structure; hydrogen transfer; C—C bond formation.

One of the most attractive fields of organolanthanide chemistry is the synthesis and application of optically active lanthanide complexes due to their excellent catalytic properties for polymerization and asymmetric synthesis [1–5]. Moreover, only a few of lanthanide Schiff base complexes synthesized in non-aqueous condition have been determined [6]. Until now, no information of organolanthanocene Schiff base complexes has been available for comparison with these organolanthanocene alkoxides and/or phenoxides [7–8]. In previous communication, we reported on the synthesis and crystal structure of a dimeric organoneodymocene complex with a chiral Schiff base ligand whose structure provided an information of internal C—C bond formation and hydrogen transfer [9]. In order to provide further information about the properties of this type of complex, we report the synthesis and the crystal structure of the title complex.

EXPERIMENTAL

All the procedures were performed using Schlenk techniques. The solvents were dried over NaOH and distilled under argon from sodium benzophenone ketyl. Anhydrous $SmCl_3$ was prepared by Taylor's method [10]. IR spectra was recorded on a Bio-Rad FTS-7 spectrometer as KBr pellets. The Sm analysis was carried out by complexomeric titration.

‡ Y.L. and Y.X. are responsible for crystal structure determination.

Preparation of **1**

A stirred suspension of $SmCl_3$ (2.424 g, 9.442 mmol) in THF (40 cm^3) was added dropwise to a solution of C_5H_5Na (28.0 ml, M = 1.075 mol/l, 30.10 mmol) in THF under argon atmosphere at room temperature. The resulting mixture was stirred for 24 h, then 15 ml toluene solution of (S)-(+)-*N*-1-phenylethylsalicylideneamine (**2**) (2.12 g, 9.430 mmol) [11] was added and the reaction continued for 3 days. After centrifugation and subsequent extraction of the residue with THF (3 × 20 ml), the combined solution was concentrated under reduced pressure. Yellow crystals were obtained several weeks later in 32% yield (1.75 g). M.p. 214–216°C (dec.), $[\alpha]_D^{20} = -2257°$ (c 0.0542, THF). $C_{58}H_{64}N_2O_4Sm_2$ requires: Sm, 26.06. Anal. Found: Sm, 25.74. IR (KBr, cm^{-1}): 3059 (w), 3019 (w), 2961 (w), 2877 (w), 1588 (w), 1568 (w), 1470 (w), 1444 (w), 1366 (w), 1285 (w), 1232 (m), 1092 (w), 1056 (w), 1020 (w), 912 (w), 877 (w), 851 (w), 815 (w), 780 (w), 761 (s), 755 (s), 700 (m), 681 (w), 573 (m), 544 (w), 488 (w).

X-ray crystallography of **1**

A yellow crystal with dimensions of 0.40 × 0.26 × 0.20 mm was sealed under argon in a glass capillary and mounted on a Siemens P4 four-circle diffractometer. Lattice parameters were determined at 293 K from the angular settings of 30 fine reflections measured from $9.88° \leqslant 2\theta \leqslant 25.21°$. Relevant crystal and data parameters are given in Table 1. Corrections for Lorentz polarization and absorption were applied to the reflection data. During the data collection, the intensities of three standard check reflections measured every 100 reflections varied about ±2%. A combination of Patterson and difference Fourier techniques provided the locating positions of all non-hydrogen atoms, which were refined anisotropically using full-matrix least-squares methods. The final difference map contained no recognizable features and its maximum and minimum peaks were of heights 0.913 and −1.904 $eÅ^{-3}$. All calculations were carried out by means of a Siemens Nixdorf PCD 4 computer with the SHELXTL-Plus (Sheldrick, 1993) program. Table 2 lists the selected bond distances and angles.

RESULTS AND DISCUSSION

The reaction of $LnCl_3$ with CpNa in THF led to the formation of $Cp_3Ln(THF)$, which was subsequently treated with the toluene solution of (*S*)-(+)-*N*-1-phenylethyl salicylideneamine resulting in the formation of orange-red suspension. After workup, the concentrated orange solution was set aside for several weeks, deep yellow crystals were isolated in the yield of 32%. IR spectra did not show the feature characteristic peak of C=N double bond. The X-ray determination shows that the C=N double bond was changed to C—N single bond during the reaction process. Furthermore, the configurations of the benzyl carbon centers (C26 and C45) of ligands were both changed from *S* to *R*, while the newly-formed asymmetric carbon centers (C19 and C44) may have either *R* or *S* configurations. Although reactions of organolanthanide metallocenes with phenols have been reported to generate phenoxide complexes, no C—C bond formation or hydrogen transfer occurred in these cases [7–8].

Structure of **1**

The molecule crystallizes in dimeric units. Complex **1** is isostructural to its Nd analogue (**3**) [9]. A line draw view of **1** is shown in Fig. 1. The two samarium centers are each bonded to two Cp rings and three oxygens: one from a THF molecule and the other two from Schiff bases in μ_2-fashion, to form a distorted trigonal bipyrimidal geometry with two oxygen atoms occupying the apical sites, while the centers of cyclopentadienyl rings and a μ_2-oxygen atom are at the triangular plane. The average Sm—C bond lengths for Sm1 are 2.82 and 2.70 Å, while those for Sm2 and 2.66 and 2.76 Å, the average Sm—C distance is 2.74 Å, which is comparable to that in **3** (2.77 Å). The Sm—O distances for Sm1 are 2.399(13) Å, 2.278(12) Å and 2.650(14) Å, and for Sm2 are 2.377(14) Å,

O91)—Sm(2)—O(4)	80.4(5)	O(2)—Sm(1)—O(3)	81.1(4)
O(2)—Sm(2)—O(4)	147.7(5)	O(1)—Sm(1)—O(3)	151.3(5)

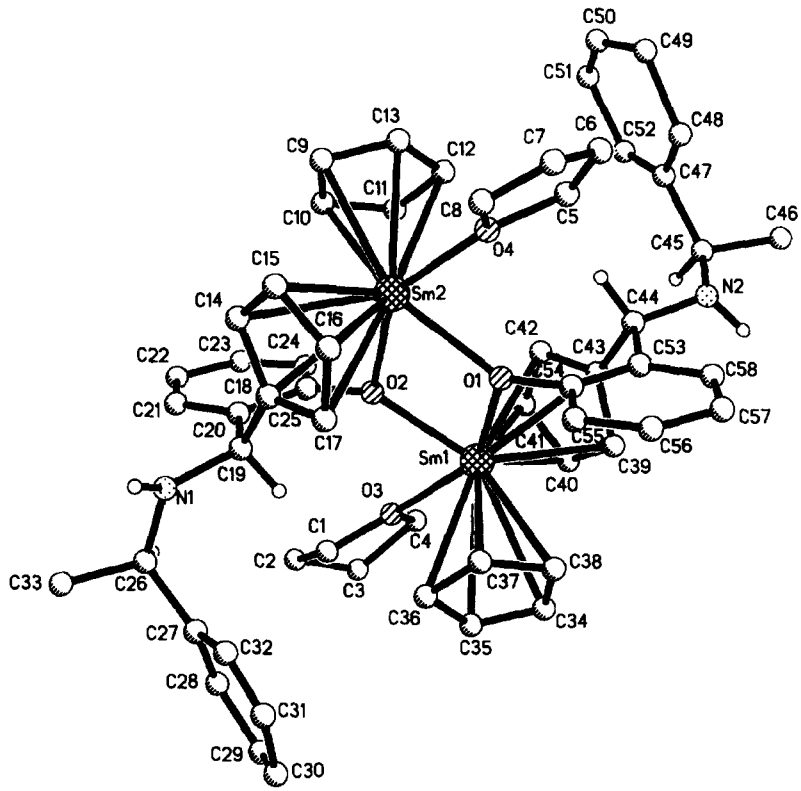

Fig. 1. Molecular structure of **1**. Most hydrogen atoms have been omitted for clarity.

2.484(13) Å and 2.55(2) Å, and the average Sm—O in **1** is 2.60 Å, which is nearly the same as that in **3** (2.602 Å).

Of the greatest interest is the geometry involving the two samarium centers and the Schiff base ligand themselves. The crystal structure of **1** shows that the newly-formed asymmetric carbon centers may bear *R*- or *S*- configuration (e.g. C19 is *S* configuration while

C44 is *R*). The oxygen atoms lie only 0.046 Å from the plane (P1) defined by Sm1, Sm2, O1 and O2 [the sum of the angles in this tetragonal plane = 359.7°]. The dihedral angle between Cp1(C34–C38) and Cp2(C39–C43) is 55.66°, while that of Cp3(C9–C13) and Cp4(C14–C17) is 59.83°, and those of P1 with Cp1, Cp2, Cp3 and Cp4 are 28.34°, 27.34°, 32.67° and 27.30°, respectively. The C19—N1, C26—N1, C44—N2 and C45—N2 bond lengths are 1.51(4), 1.46(3), 1.44(3), 1.41(3) Å, respectively, and are assigned as single bonds by comparison with those in transitional metal complexes and the ligand [9,12]. We think that the formation of **1** can be explained as follows: (1) the reaction of $SmCl_3$ with C_5H_5Na to form tris(cyclopentadienyl)samarium; (2) the protonation of the hydroxy group of Schiff base with one cyclopentadienyl ring omitting CpH; (3) a C—H bond on the cyclopentadienyl ring is activated by the C=N bond of Schiff base which leads to the C—C bond formation; and (4) the hydrogen atom on the Cp ring is transferred onto the nitrogen atom in 1,3-shift fashion and the Cp ring is re-aromatized.

Pd(II) and Pt(II) complexes with chalcogenide derivatized phosphathia ligands

Julie Connolly, Anthony R. J. Genge, Simon J. A. Pope and Gillian Reid*

Department of Chemistry, University of Southampton, Highfield, Southampton SO17 1BJ, U.K.

(Received 24 October 1997; Accepted 24 November 1997)

Abstract—The mixed phosphine sulfide/thioether and phosphine selenide/thioether ligands L^1–L^4 react with $PdCl_2$ or $PtCl_2$ in the presence of $TlPF_6$ in $MeNO_2$ solution to give the distorted square planar complexes $[Pd(L)](PF_6)_2$ or $[Pt(L)](PF_6)_2$ as powdered solids. IR spectroscopy shows ν(P=S) or ν(P=Se) for the complexes are to low frequency of free L^1–L^4, indicating coordination via the sulfide or selenide. $^{31}P\{^1H\}$, $^{77}Se\{^1H\}$ and ^{195}Pt NMR studies confirm η^4-ligation in solution, and the spectra do not alter significantly upon cooling. Also, the ^{195}Pt NMR chemical shifts indicate that the mixed phosphine sulfide/thioether donor set results in a very similar electronic environment at Pt(II) to a homoleptic tetrathioether donor set. $\delta(^{195}Pt)$ for the mixed phosphine selenide/thioether complexes of Pt(II) occur at slightly lower frequency. The crystal structure of L^3 is also reported. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Pd(II); Pt(II); chalcogenide.

We have recently been interested in establishing the coordinating abilities of polydentate and macrocyclic phosphathia ligands to transition metal centres. These ligands are of interest since they combine relatively poor σ-donor thioethers with strong σ-donor phosphines in a single ligand. This combination allows a direct comparison of these donor types and can also lead to structural diversity [1–6] In addition, Rh(I) carbonyl complexes containing phosphino–thiolate and phosphino–thioether ligands have been shown to be very active in catalysing the carbonylation of methanol to ethanoic acid [7].

In our recent work we have shown that the macrocycle Ph_2[14]aneP_2S_2 (8,12-diphenyl-1,5-dithia-8,12-diphosphacyclotetradecane) [1] and the acyclic ligands 1–3, in which the phosphine functions (good σ-donors) are specifically located at the termini, coordinate to a range of metal ions yielding various structural motifs including, for example, $[Au_2(1)_2]Cl_2$ which shows a helical binuclear arrangement with linear P_2 coordination at Au(I) from two bridging phosphathia ligands, and a trapped Cl^- anion within the metallocyclic cavity [2], distorted tetrahedral $[M(L)]^+$ (M = Cu or Ag; L = 1–3) [3] and octahedral *cis*-$[M'Cl_2(L)]^+$ (M' = Co; L = 1, 2; M' = Rh; L = 1–3 or Ph_2[14]aneP_2S_2; M' = Ir; L = 1) [1,4]. With Pd(II) and Pt(II), these ligands also coordinate via both the phosphine and thioether functions, yielding distorted square planar species, $[M(L)]^{2+}$ (M = Pd or Pt; L = 1–3 or Ph_2[14]aneP_2S_2). The resulting Pt(II) species undergo oxidation with halogen (Cl_2 or Br_2) to yield relatively stable octahedral Pt(IV) species $[PtX_2(L)]^{2+}$, demonstrating that the P_2S_2-donor ligands can also support the relatively hard Pt(IV) centre [5]. We have also shown that the sulfide and

$Ph_2[14]aneP_2S_2$

selenide derivatives of 1–3 react readily with the group 11 metals yielding species such as the distorted tetrahedral cations $[M(L)]^+$ (M = Cu or Ag), in which the ligands are bound in an η^4-mode via both the P-bound chalcogen donors and the thioether donors [6]. Introduction of the chalcogen donors results in these species being considerably more labile in solution than the analogous complexes with 1–3. The catalytic potential of phosphine chalcogenide ligands has also been noted [8,9].

In this paper we report the results of our investigations into the synthesis and characterisation of the Pd(II) and Pt(II) complexes incorporating the sulfide and selenide derivatives of 1 and 3, $[M(L)](PF_6)_2$ (M = Pd, Pt; L = L^1, L^2, L^3, L^4). A single crystal X-ray structure determination on L^3 is also reported.

RESULTS AND DISCUSSION

Reaction of MCl_2 (M = Pd or Pt) with one molar equivalents of L^1–L^4 and two molar equivalents of $TlPF_6$ in degassed MeCN or $MeNO_2$ solution affords a white precipitate (TlCl) and a yellow or orange solution. After removing the TlCl, the complexes $[M(L)](PF_6)_2$ were isolated as powdered solids. Using MeCN typically led to rather low yields and more difficulty in purifying the products. This is probably due to the increased coordinating ability of the MeCN over $MeNO_2$, and contrasts with our observations for the preparation of Pd(II) and Pt(II) complexes of the parent diphosphadithia ligands 1–3 which form readily and in high yield in refluxing MeCN [5] IR spectroscopy confirms the presence of the phosphine ligands, ν(P=S) or ν(P=Se) occurring at ca 610 or 520 cm^{-1} respectively, i.e. to low frequency of free L^1–L^4, indicating coordination of the sulfide or selenide donors to Pd(II) or Pt(II). In addition, strong peaks around 840 and 555 cm^{-1} are attributed to $\nu(PF_6^-)$ and $\delta(PF_6^-)$, respectively. The electrospray mass spectra (MeCN) reveal peaks with the correct isotopic distributions for $[M(L)]PF_6^+$ and/or $[M(L)]^+$. These data, together with ^1H NMR spectroscopy and microanalyses, confirm the formulations $[M(L)](PF_6)_2$ (L = L^1–L^4) for the products.

The $^{31}P\{^1H\}$, $^{77}Se\{^1H\}$ and ^{195}Pt NMR data for these complexes are listed in Table 1. The $^{31}P\{^1H\}$ spectra show a singlet (with satellites in the case of the Pt compounds) shifted a few ppm either to higher or lower frequency compared to free L^1–L^4, as well as a septet at ca −145 ppm (PF_6^-). These signal integrate as 1 : 1, indicating one L per metal ion, and cooling to 200 K does not significantly alter the spectra. For the Pt(II) species $^2J_{PtP}$ is ca 100 Hz, considerably smaller than $^1J_{PtP}$ in $[Pt(L)]^{2+}$ (L = 1–3, or $Ph_2[14]aneP_2S_2$) which are typically ca 3000 Hz [1,5]. For the phosphine selenide derivatives (L^2 and L^4), $^{77}Se\{^1H\}$ NMR spectra were also recorded. For the Pd(II) complexes the $^{77}Se\{^1H\}$ NMR spectra each show a doublet ca 100 ppm to high frequency and with $^1J_{PSe}$ reduced substantially compared to the free ligands (ca 540 Hz vs 732 Hz for free L^2 and L^4). For the Pt(II) complexes $\delta(^{77}Se)$ is to higher frequency than for the Pd(II) analogues, with $^1J_{PSe}$ even smaller (ca 515 Hz). These data confirm coordination of L^2 and L^4 to Pd(II) or Pt(II) via the Se donors. The ^{195}Pt NMR spectra for the Pt(II) complexes of the sulfide derivatives each show a triplet at −4238 and −4182 ppm respectively for L^1 and L^2. This is the same region as $\delta(^{195}Pt)$ for Pt(II) complexes of tetrathioether macrocycles which we have previously reported, e.g. $[Pt([16]aneS_4)](PF_6)_2$ ([16]$aneS_4$ = 1,5,9,13-tetrathiacyclohexadecane) −4177 ppm, $[Pt([14]aneS_4)]$

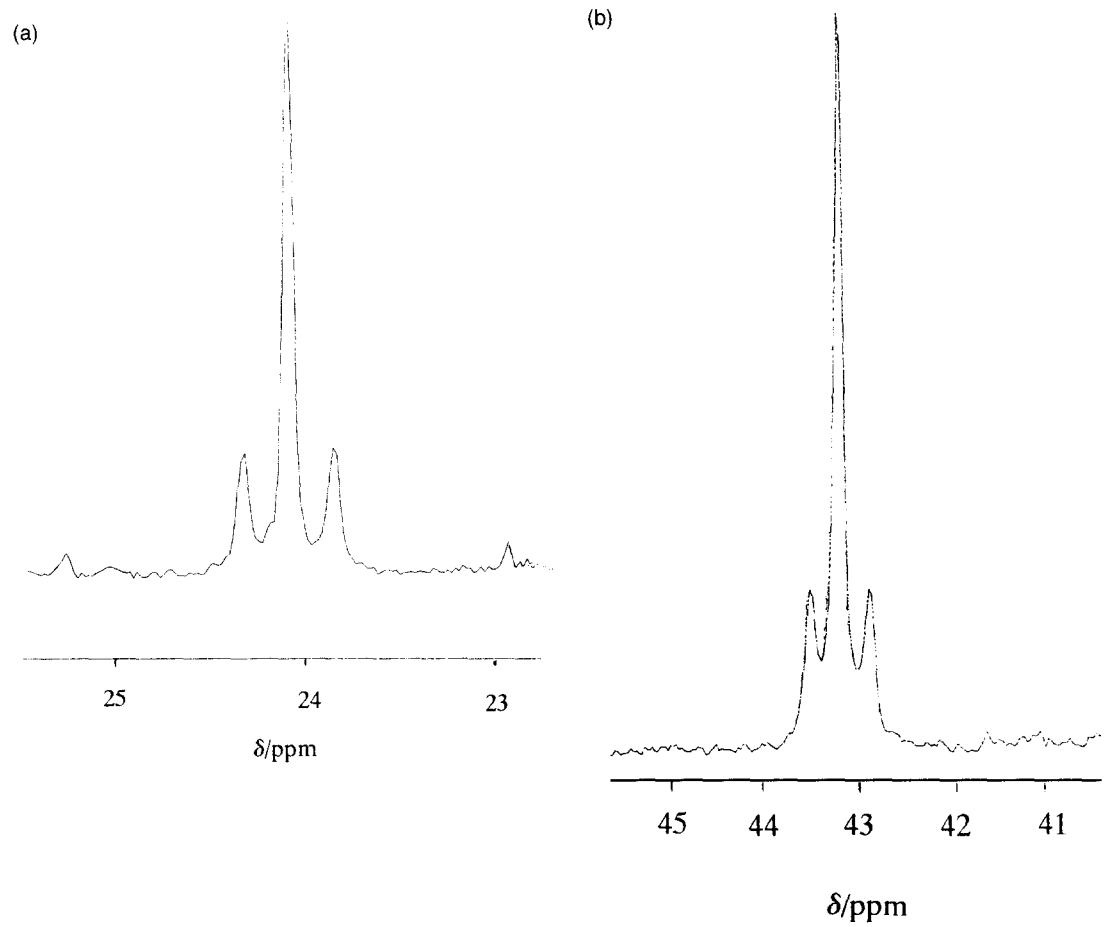

Fig. 1. $^{31}P\{^1H\}$ NMR spectrum of $[Pt(L^2)](PF_6)_2$ (a) and $[Pt(L^3)](PF_6)_2$ (b).

$(PF_6)_2$ ([14]aneS$_4$ = 1,4,8,11-tetrathiacyclotetra-decane) −4645 ppm [10], indicating that the homoleptic S(thioether)-donor set in the macrocyclic complexes generates a similar electronic environment to the mixed thioether/sulfide donor set in the new compounds. In the ^{195}Pt NMR spectra of the selenide species the triplets are centred at approximately −4500 ppm. This compares with −4750 ppm for $[Pt([16]aneSe_4)](PF_6)_2$ ([16]aneSe$_4$ = 1,5,9,13-tetra-selenacyclohexadecane) [11].

$\delta^{77}Se\{^1H\}$: L^3, −352; L^4, −353.
$^1J_{PSe}$: L^3, 732; L^4, 732 Hz.
t = triplet.

Extensive studies have previously been conducted on chalcogenide derivatives of iminobis(diphenylphosphine), $PPh_2P(E)NHP(E)Ph_2$ (E = O, S or Se) [12]. These studies include complexes of Pd(II) and Pt(II), and the NMR properties of the deprotonated neutral species $[M\{Ph_2P(Se)NP(Se)Ph_2\}_2]$ are very similar to those in Table 1. Thus, for M = Pt $\delta(^{195}Pt)$ is −4242 ppm, $^2J_{PPt}$ = 105 Hz and $^1J_{PSe}$ = 543 Hz [13].

Crystals of L^3 suitable for an X-ray crystallographic study were obtained from a solution of L^3 in CH_2Cl_2/hexane. The crystal structure of L^3 shows the expected structure (Fig. 2, Table 2) with P(1)=S(3) = 1.939(1) and P(2)=S(4) = 1.956(1) Å, significantly shorter than *d*(P=Se) in L^4, 2.099(2), 2.111(2) Å [6]. The angles subtended at P lie in the range 103.4(2)–114.5(1)°, indicating approximately tetrahedral phosphorus atoms.

EXPERIMENTAL

Infrared spectra were measured as KBr or CsI discs or as nujol mulls using a Perkin–Elmer 983G spectrometer over the range 200–4000 cm^{-1}. Mass spectra were run by positive electrospray (ES) using a VG Biotech Platform. ^1H NMR spectra were recorded using a Bruker AM300 spectrometer operating at 300 MHz. $^{31}P\{^1H\}$, $^{77}Se\{^1H\}$ and ^{195}Pt NMR spectra were recorded in 10 mm o.d. tubes containing ca 10% deuterated solvent, using a Bruker AM360 spectrometer operating at 145.8, 68.68 and 77.7 MHz respectively and are referenced to external 85% H_3PO_4 [$\delta(^{31}P) = 0$], neat Me_2Se [$\delta(^{77}Se) = 0$] or aqueous $Na_2[PtCl_6]$ [$\delta(^{195}Pt) = 0$]. Microanalyses were performed by the Imperial College microanalytical service. L^1–L^4 were prepared as described previously [6].

Preparations

$[Pd(L^1)](PF_6)_2$. $PdCl_2$ (0.015 g, 0.09 mmol), L^1 (0.050 g, 0.09 mmol) and 2 molar equivalents of $TlPF_6$ (0.063 g, 0.18 mmol) were added to MeCN (20 cm^3). This mixture was then refluxed for 24 h under a N_2 atmosphere during which time a white solid (TlCl) was deposited and a yellow/orange solution formed. After filtering through celite to remove the TlCl, the solution was concentrated and Et_2O added to yield an orange solid. This was collected by filtration, washed with Et_2O and dried *in vacuo* (Yield 0.034 g, 41%). Calc. for $C_{30}H_{32}F_{12}P_4PdS_4 \cdot CH_2Cl_2$: C = 35.0, H = 3.2%. Found: C = 35.0, H = 3.3%. Electrospray mass spectrum (MeCN): found *m/z* = 344; calc. for $0.5[^{106}Pd(L^1)]^{2+}$ *m/z* = 344. ^1H NMR spectrum (300 MHz, $CDCl_3$, 300 K): δ 7.3–8.0 (*m*, Ph), 2.9–3.9 (*m*, CH_2). IR spectrum (CsI disk): 3050 w, 2920 w, 1480 m, 1435 s, 1360 w, 1248 s, 1230 m, 1180 m, 1104 s, 1061 w, 1031 m, 997 w, 840 vs, 748 m, 729 m, 716 m, 690 m, 573 m, 559 s, 522 w, 508 w, 488 w cm^{-1}.

$[Pd(L^2)](PF_6)_2$. Method as for $[Pd(L^1)](PF_6)_2$ above, but using $PdCl_2$ (0.010 g, 0.06 mmol), L^2 (0.038 g, 0.06 mmol) and $TlPF_6$ (0.041 g, 0.12 mmol) giving an orange solid. (Yield 0.032 g, 50%). Calculated for $C_{30}H_{32}F_{12}P_4PdS_2Se_2 \cdot CH_2Cl_2$: C = 30.9, H = 2.9%. Found: C = 30.7, H = 2.6%. Electrospray mass spectrum (MeCN): found *m/z* = 392; calc. for

X-Ray structure determination on L^3

Colourless blocks L^3 in were obtained from a solution of CH_2Cl_2 and hexane. The selected crystal ($0.55 \times 0.50 \times 0.15$ mm) was coated with mineral oil and mounted on a glass fibre under a stream of cold N_2 gas.

Crystal data. $C_{34}H_{32}P_2S_4$, $M = 630.81$, triclinic, space group $P\bar{1}$ (No. 2), $a = 10.291(7)$, $b = 18.819(9)$, $c = 9.012(3)$ Å, $\alpha = 90.30(4)$, $\beta = 114.06(3)$, $\gamma = 95.51(5)^\circ$, $V = 1584(1)$ Å^3 [from 2θ values of 16 reflections measured at $\pm\omega$ ($2\theta = 20.0$–28.2°, $\lambda = 0.71073$ Å)], $Z = 2$, $D_c = 1.322$ g·cm^{-3}, $\mu = 4.09$ cm^{-1}, $F(000) = 660$.

Data collection and processing. Data collection used a Rigaku AFC7S diffractometer equipped with an Oxford Systems cryostream operating at 150 K, using graphite monochromated Mo-K_α radiation, (ω-2θ scan technique), 5927 data collected ($2\theta_{max}$ 50.0°), 5590 unique data ($R_{int} = 0.026$ based on F^2). Preliminary psi-scans showed no significant absorption, and no crystal decay or movement were observed.

Structure solution and refinement. The structure was solved by direct methods [14] and expanded using Fourier techniques to locate all non-H atoms for the one complete molecule in the asymmetric unit [15]. All non-H atoms were refined anisotropically and hydrogen atoms were included in fixed calculated positions [with d(C—H) = 0.96 Å] but not refined. The final cycle of full-matrix least-squares refinement (on F) was based on 3799 observed reflections with ($I > 2.5\sigma(I)$) and 361 variable parameters and converged with $R = 0.039$, R_w 0.040, using the weighting scheme $w^{-1} = \sigma^2(F)$. The maximum residual peak and minimum residual trough corresponded to +0.38 and −0.27 eÅ^{-3}. Selected bond lengths and angles are given in Table 2.

Atomic coordinates, anisotropic thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

Acknowledgements—We thank the EPSRC for support and for provision of the X-ray diffractometer. We also thank Johnson Matthey plc for loans of $PdCl_2$ and $PtCl_2$.

Reactions of platinum(II) anticancer drugs. Kinetics of acid hydrolysis of *cis*-diammine(cyclobutane-1,1-dicarboxylato)platinum(II) "Carboplatin"

Robert W. Hay* and Sian Miller

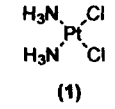
School of Chemistry, University of St Andrews, St Andrews, KY16 9ST, U.K.

(Received 6 November 1996; accepted 21 November 1997)

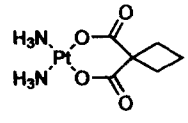
Abstract—The kinetics of acid hydrolysis of "carboplatin" [*cis*-diammine(cyclobutane-1,1-dicarboxylato)platinum(II)] has been studied over a range of acidities at constant ionic strength (I = 1.0 mol dm^{-3}) and various temperatures. Loss of the substituted malonato ligand occurs in a biphasic reaction involving a ring opening step and a slower step in which loss of the monodentate malonato ligand occurs. At low acidities the first step k_{obs} (**1**) is approximately ten times faster than the second step (k_{obs} (**2**)). At higher acidities this ratio falls to *ca* four fold. Plots of k_{obs} (**1**) vs [H$^+$] are linear with a positive intercept and the plots can be adequately described by the relationship k_{obs} (**1**) = $k_0 + k_1$[H$^+$] with $k_0 = 6 \times 10^{-5}$ s^{-1} and $k_1 = 3.3 \times 10^{-4}$ s^{-1} at 25°C and I = 1.0 mol dm^{-3}. The rate constant k_{obs} (**2**) = k_2[H$^+$] with $k_2 = 1.1 \times 10^{-4}$ s^{-1} at 25°C and I = 1.0 mol dm^{-3}. The antitumour activity of carboplatin is discussed in terms of the kinetic results obtained. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: carboplatin; kinetics; acid hydrolysis; ring opening; malonato ring.

"Cisplatin" (*cis*-diamminedichloroplatinum(II)) (**1**) is a well established and effective antitumour agent which is most active against testicular and ovarian cancers [1]. However, the dose-limiting side effect of nephrotoxicity has led to the development of second and third generations of platinum based complexes showing antitumour activity [2]. Of the second generation compounds the complex *cis*-diammine(cyclobutane-1,1-dicarboxylato)platinum(II), [Pt(NH$_3$)$_2$(cbda)] or "carboplatin" (**2**) was found to be an effective antitumour agent [3] with approximately the same spectrum of activity as cisplatin but with reduced toxicity [4].



(1)



(2) = carboplatin

The mechanism of action of cisplatin involving its hydrolysis *in vivo* to the active species *cis*-[PtCl(NH$_3$)$_2$(OH$_2$)]$^+$ [5,6] and its subsequent binding to DNA is relatively well established. However, the mode of action of carboplatin remains uncertain and a number of reaction pathways are possible. For both carboplatin and cisplatin it is known that the *cis*-diammineplatinum(II) species binds to DNA *in vivo* [7]. However, it has not been confirmed that the aqua species derived from carboplatin is the active complex. Aquated platinum(II) species are produced more slowly from carboplatin as opening of the malonato ring is a very slow process compared with the ready hydrolysis of cisplatin. The half life of carboplatin in chloride-free phosphate buffer at pH 7 and 37°C is 268 h compared with 24 h for cisplatin under these conditions [8]. In view of the relative chemical inertness of carboplatin, a variety of suggestions have been

* Author to whom correspondence should be addressed.

made to account for its activity such as enzymatic activation [9,10], reaction with sulphur nucleophiles or direct interaction with DNA itself [11]. The topic has been recently reviewed [12] and an NMR study of the reactions of carboplatin in solution has been published [13].

The kinetics of displacement of cyclobutane-1,1-dicarboxylate from $[Pt(NH_3)_2(cbda)]$ is of considerable interest as it may lead to an understanding of the mode of action of the drug. In addition, the information is also of importance in defining the mechanism of displacement of oxygen donor ligands from four-coordinate Pt(II) complexes [14–18]. Canovese and coworkers [17] have studied the kinetics of ring opening and displacement of the malonato ligand in carboplatin in acidic solution. In the presence of acid it was found that the process was biphasic, resembling the successive displacement of two monodentate carboxylate ligands. The first (ring opening) step followed the rate law $k_{obs} = (k_0 + k_1 K[H^+])/(1 + K[H^+])$ where $k_0 = 8 \times 10^{-5}$ s^{-1}, K = 0.6 dm^3 mol^{-1} s^{-1} and $k_1 = 8.0 \times 10^{-4}$ s^{-1} at 25°C. The second step was found to follow the simple relationship $k_{obs} = k[H^+]$ with $k = 1.61 \times 10^{-4}$ dm^3 mol^{-1} s^{-1} at 25°C. Canovese *et al.* [17] also found that in the absence of acid and other nucleophiles carboplatin was inert. However, in the presence of Cl^- the displacement of the ligand follows a first order dependence on the chloride ion concentration with $k_{obs} = k_{Cl}[Cl^-]$. At 80°C $k_{Cl} = 1.32 \times 10^{-4}$ dm^3 mol^{-1} s^{-1}. In hydrochloric acid solution it was also observed that carboplatin gave yellow crystals of cisplatin as hydrolysis took place.

The present paper describes kinetic studies on the hydrolysis of carboplatin in perchloric acid solution under conditions of constant ionic strength as part of a program to define the mechanism of action of the drug.

EXPERIMENTAL

Diammine(cyclobutane-1,1-dicarboxylato) platinum(II) was purchased from both Strem and Sigma and used without further purification. All other reagents were of AnalaR quality or the best reagent grade available.

Kinetic studies were carried out as follows. Solutions (3.5 cm^3) of perchloric acid (1.0, 0.8, 0.6, 0.4 and 0.2 mol dm^{-3}) and the required amount of $NaClO_4 \cdot H_2O$ to give an ionic strength of 1.0 mol dm^{-3} were allowed to reach thermal equilibrium in a 1 cm quartz spectrophotometer cell placed in the temperature-controlled cell compartment of a Perkin-Elmer Lambda 5 UV-vis spectrophotometer. The reaction was initiated by the addition of solid $[Pt(NH_3)_2(cbda)]$ to the reaction medium. The solid dissolved rapidly on stirring and interval scan or fixed wavelength (245 nm) data collection modes were begun. The reaction was monitored until no further change in absorbance occurred (ca six to eight half lives). The observed first order rate constants k_{obs} (**1**) and k_{obs} (**2**) for the two consecutive reactions were calculated from the absorbance vs time data using standard equations [18].

RESULTS AND DISCUSSION

Canovese *et al.* [17] have found that the UV spectrum of carboplatin in water remains constant for many weeks at 25°C. However, acidification of the solution with dilute perchloric acid leads to an immediate change in the absorbance followed by a slow decrease in the absorbance over the whole range of wavelengths scanned. The final product spectrum closely resembled that of a freshly prepared solution of *cis*-$[Pt(NH_3)_2(OH_2)_2]^{2+}$. Similar observations were made in the present work. At 245 nm the absorbance increased rapidly then slowly decreased with time consistent with a biphasic reaction involving an initial ring opening step followed by a slower loss of the monodentate malonato ligand. No isosbestic points were observed and the final spectrum was consistent with that reported [19,20] for *cis*-$[Pt(NH_3)(OH_2)_2]^{2+}$, Fig. 1. In hydrochloric acid solution, yellow crystals of *cis*-$[Pt(NH_3)_2Cl_2]$ were obtained as the reaction progressed. It is thus quite clear that loss of the malonato ligand occurs under acidic conditions.

The observed first order rate constants k_{obs} (**1**) and k_{obs} (**2**) relating to the first and second steps of the biphasic reaction were calculated from the absorbance-time data for each stage. The infinity absorbance for the first reaction could be estimated from the absorbance-time data and directly measured for the second. As ring opening is faster than the loss of the monodentate malonato ligand, it was necessary to use two different temperature ranges to study the two

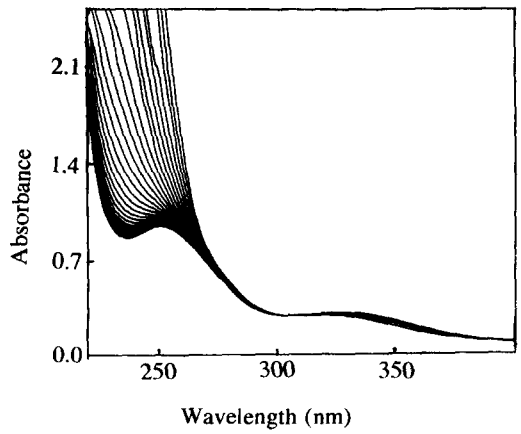


Fig. 1. Spectrophotometric scans for the acid hydrolysis of carboplatin in 0.8 mol dm^{-3} $HClO_4$ (I = 1.0 mol dm^{-3}) at 34.8°C. The scan interval is 10 min. The absorption maximum at 245 nm decreases with time to give a final spectrum with $\lambda_{max} = 252 \pm 1$ nm identical with that of *cis*-$[Pt(NH_3)_2(OH_2)_2]^{2+}$ (see Ref. [20]).

The temperature dependence of k_1 gives $\Delta H^{\ddagger} = 88.4$ kJ mol^{-1} and $\Delta S^{\ddagger}_{298} = -15$ JK^{-1} mol^{-1}. The temperature dependence of k_2 gives $\Delta H^{\ddagger} = 90.0$ kJ mol^{-1} and $\Delta S^{\ddagger}_{298} = -19$ JK^{-1} mol^{-1}.

here k_0 relates to the spontaneous ring opening reaction and k_1 to the acid-catalysed process. Values of k_0 and k_1 at various temperatures are listed in Table 2. The rate constants k_0 are somewhat approximate as they were obtained from the extrapolated intercepts of the plots.

Plots of k_{obs} (**2**) vs the perchloric acid concentration are also linear and have a negligible intercept with k_{obs} (**2**) $= k_2[H^+]$. Values of k_2 are also listed in Table 2. At low acid concentrations the rate constant k_{obs} (**1**) is some ten times greater than k_{obs} (**2**) for the second step. At higher acidities the ratio falls to approximately four.

Cyclobutane-1,1-dicarboxylate is a relatively weak acid and its displacement from Pt(II) would be expected to be subject to acid catalysis. Attempts were made to detect a pre-equilibrium protonation by studying the initial absorbance of solutions of carboplatin in perchloric acid (0.2 to 1.0 mol dm^{-3} at $I = 1.0$ mol dm^{-3} ($NaClO_4$)). No evidence for such an equilibrium could be obtained with the absorbance being essentially constant within experimental error over this acidity range.

The hydrolysis of carboplatin at constant hydrogen ion concentration corresponds to two consecutive reactions

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

the concentrations of A, B and C as a function of time are given by the eqns (1–3)

$$A = A_0 e^{-k_1 t} \quad (1)$$

$$B = A_0 k_1 (e^{-k_1 t} - e^{-k_2 t})/(k_2 - k_1) \quad (2)$$

$$C = A_0[1 + (k_1 - k_2)^{-1}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})] \quad (3)$$

where A_0 is the initial concentration of A. The functions A/A_0, B/A_0 and C/A_0 can readily be computed from these equations [26]. At 25°C in 1 mol dm^{-3} perchloric acid $k_1 = 2.17 \times 10^{-2}$ min^{-1} and $k_2 = 9.66 \times 10^{-3}$ min^{-1}. The relative concentrations

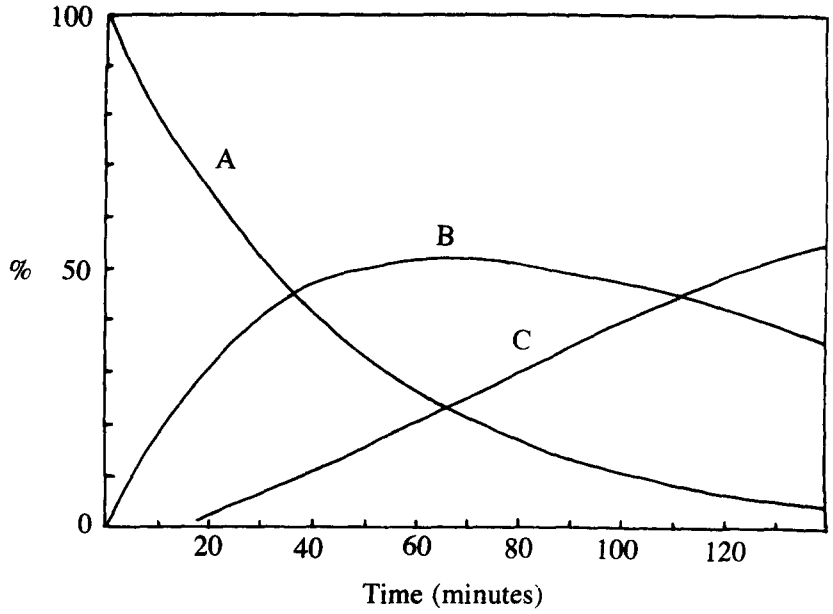

Fig. 3. Concentration vs time curves for the hydrolysis of carboplatin in 1 mol dm^{-3} $HClO_4$ at 25°C and I = 1.0 mol dm^{-3}; A = carboplatin; B = the monodentate carboxylato complex and C = $[Pt(NH_3)_2(OH_2)_2]^{2+}$. The curves are calculated using the equations discussed in the text with $k_1 = 2.17 \times 10^{-2}$ min^{-1} and $k_2 = 9.66 \times 10^{-3}$ min^{-1}. The maximum concentration of B is 50% and is reached at 67.2 min.

of A, B and C are shown in Fig. 3. The maximum concentration of B is 50% and is reached at 67.2 min calculated using the expressions

$$\tau_{max} = \ln Z/(Z-1)$$

$$\beta_{max} = Z^{Z/(1-Z)}$$

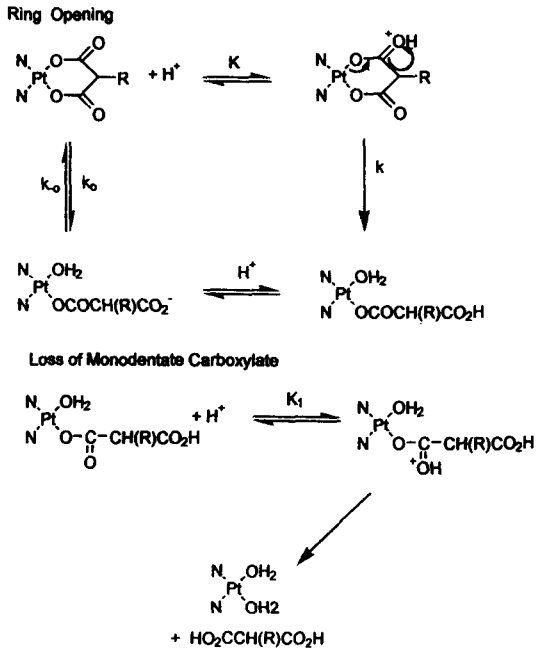
where $Z = k_2/k_1$. Because of the rather similar rates of ring opening and hydrolysis of the monodentate carboxylato complex it is not easy to determine the spectrum of the intermediate.

Mechanistic conclusions

The acid hydrolysis of carboplatin can be represented as shown in the Scheme. Ring opening involves a rapid pre-equilibrium protonation of the carboxylato ligand followed by a slow ring opening step. The kinetic behaviour observed will depend on the degree of protonation of the complex. If A represents carboplatin, the ring opening scheme can be summarised

$$A + H^+ \rightleftharpoons AH^+ ; K$$

$$AH^+ \xrightarrow{k} \text{Products}$$



Scheme 1.

and k_{obs} ($[A]+[AH^+]$) = $k[AH^+] = kK[A][H^+]$, so that $k_{obs} = kK[H^+]/(1+K[H^+])$. In the present work we found that plots of k_{obs} (**1**) vs $[H^+]$ are linear and display no curvature. Canovese *et al.* [17] obtained somewhat similar results but with a considerable degree of scatter in the experimental data. The kinetic results previously obtained [17] are plotted in Fig. 4. Least squares analysis gives $k_0 = 8 \times 10^{-5}$ s^{-1} and $k_1 = 3 \times 10^{-4}$ dm^3 mol^{-1} s^{-1} from the slope which is in good agreement with our values of $k_0 = 6 \times 10^{-5}$

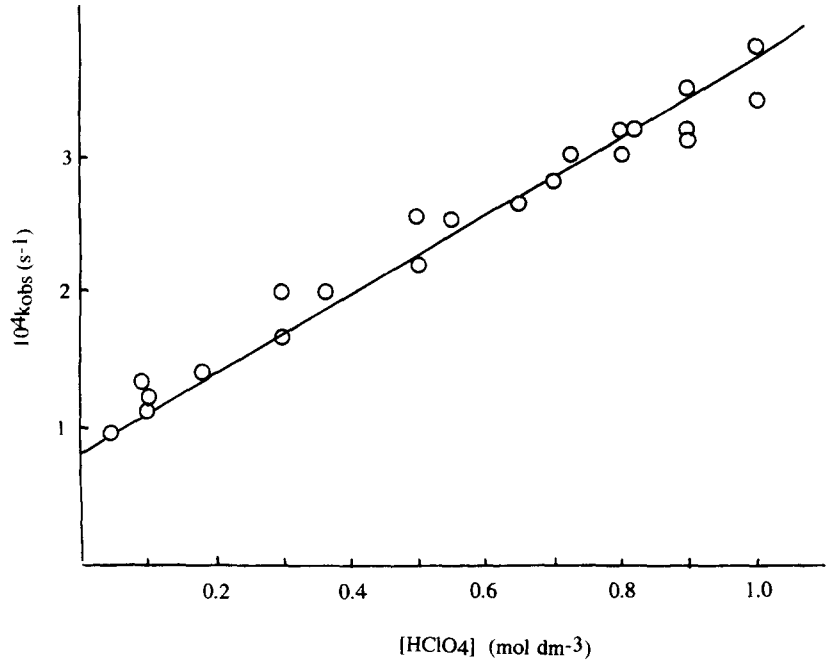


Fig. 4. Plot of k_{obs} vs the concentration of $HClO_4$ for the ring-opening reaction using the data of Canovese *et al.* (Ref. [17]).

s^{-1} and $k_1 = 3.3 \times 10^{-4}$ dm^3 mol^{-1} s^{-1} at 25°C and $I = 1.0$ mol dm^{-3}.

Canovese *et al.* [17] considered that there was curvature in the plot and fitted the data to the eqn $k_{obs} = k_0 + k_1[H^+]/(1 + K[H^+])$ with $K = 0.6$ dm^3 mol^{-1}. This is a remarkably high value for the equilibrium constant and would suggest that the complex is some 35% protonated in 1 mol dm^{-3} $HClO_4$. A carboxylato ligand would be expected to be a very weak base and its protonation behaviour would be predicted to be rather similar to that of a carboxylic acid, $RCO_2H + H^+ \rightleftharpoons RCO_2H_2^+$. The pK_{BH^+} for the protonation of acetic acid is -6 [21], i.e. the acid is 50% protonated at $H_0 = -6$ which occurs in >10 mol dm^{-3} perchloric acid [22]. The previous workers noted very minor absorbance changes (0.02 absorbance units) in the absorbance of carboplatin in the acidity range 0–1.0 mol dm^{-3} $HClO_4$ and attributed these changes to protonation of the complex. We were unable to detect any *systematic* change in the absorbance of the platinum complex as a function of the perchloric acid concentration although random minor variations were observed which we attributed to experimental error in the measurements and/or medium effects.

We conclude that for the ring opening step the kinetics can be adequately described by the eqn k_{obs} (**1**) $= k_0 + k_1[H^+]$. A similar rate expression is observed in the acid-catalysed decarboxylation of cobalt(III) carbonato complexes *cis*-$[CoL(CO_3)]^+ + H^+ \rightarrow [CoL(OH_2)_2]^{3+}$. These reactions have been studied in considerable mechanistic detail [23] and display deuterium solvent isotope effects k_{D_2O}/k_{H_2O} of ca 2.3 consistent with a rapid pre-equilibrium protonation of the complex followed by a slow ring opening step. Deuterium oxide is a weaker base than water and therefore more of the protonated complex occurs in deuterium oxide than in water. These reactions also display a k_0 term attributed to the spontaneous ring-opening step in aqueous solution. These "spontaneous" reactions are observed in acidic solution as the carboxylate group is immediately protonated and this greatly decreases the rate of the reverse ring closure step. Ring closure requires the removal of the carboxylate proton by a base (water) and since water is a much weaker base than the carboxylate group, the reaction is slow

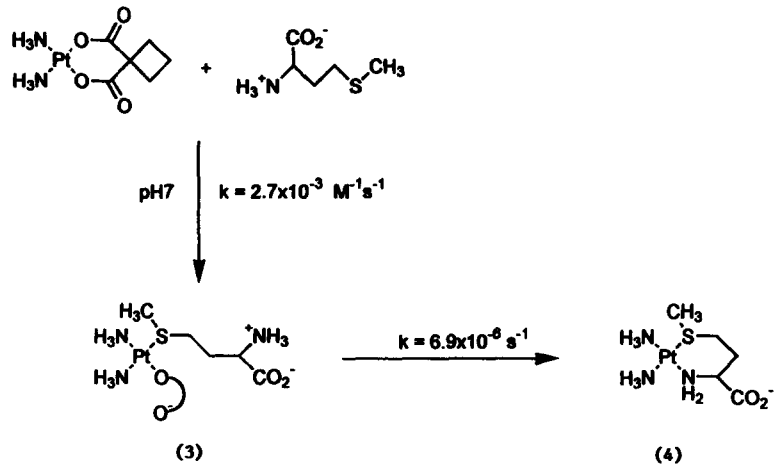
$$RCO_2H + H_2O \rightleftharpoons RCO_2^- + H_3O^+ ; k_f, k_r$$

The equilibrium constant $K = k_f/k_r$ and since K is small $k_f \ll k_r$. Many examples of this effect are seen in the literature [24].

Our results for the second step of the reaction with k_{obs} (**2**) $= k_2[H^+]$ with $k_2 = 1.1 \times 10^{-4}$ s^{-1} at 25°C are in good agreement with the results obtained by Canovese who determined a similar rate law with $k_2 = 1.6 \times 10^{-4}$ s^{-1} at 25°C. It should also be stressed that the reactions described in the present paper were carried out under conditions of constant ionic strength so that medium effects were minimised.

Biological aspects

In the absence of acid and nucleophiles, carboplatin is stable in water for a period of many weeks at 25°C



and it has been suggested [17] that for ring opening in water $k < 10^{-8}$ s^{-1}. A recent NMR study suggests that $k < 5 \times 10^{-9}$ s^{-1} at 37°C [13]. In the presence of chloride there is a first order dependence [17] of ring opening on the chloride concentration with $k_{obs} = k_{Cl}[Cl^-]$ where $k_{Cl} = 1.3 \times 10^{-4}$ dm^3 mol^{-1} s^{-1} at 80°C. The plasma chloride concentration is 104 mM (compared with 4 mM within cells) so that at plasma chloride concentrations $k_{obs} = 1.3 \times 10^{-5}$ s^{-1} at 80°C ($t_{1/2}$ = 14.7 h). At 37°C the half life of the Cl^- reaction is likely to be of the order of 250 h. Such a slow reaction is unlikely to be of biological importance and effectively excludes the idea that carboplatin is simply a prodrug for cisplatin.

We have observed that carboplatin reacts readily with thiol ligands such as glutathione and cysteine, thioethers such as methionine and directly with guanosine in a monophasic reaction. These observations are consistent with recent results reported by Sadler *et al.* [13,25]. Thiols react slowly and sulphur-bridged species containing four-membered Pt_2S_2 rings are the predominant products. Reactions with thioether ligands are much more rapid and a rate constant $k = 2.7 \times 10^{-3}$ dm^3 mol^{-1} s^{-1} at pH 7.0 and 37°C has been reported for the reaction of methionine with carboplatin to give the ring opened complex (**4**) with $k = 6.9 \times 10^{-6}$ s^{-1} at 37°C, Scheme 2.

Carboplatin also reacts with 5′-guanosine monophosphate (5′-GMP) in aqueous solution [13] and the complex *cis*-[Pt(NH$_3$)$_2$(cbda-O)(5′-GMP)] has been detected during the course of the reaction (H$_2$cbda = cyclobutane-1,1-dicarboxylic acid). These results suggest that the direct attack of nucleotides on carboplatin may be of importance in the mechanism of action of the drug.
