Finke *et al.* found that the thermolyzed $Na_8HPW_9O_{34}$ (Δ–PW_9O_{34}) was predominantly a B type tri-vacant heteropolyanion, and also was the key structural requirement for the formation of di-substituted, dimeric heteropolytungstates. These compounds such as $[M_4(H_2O)_2\ (PW_9O_{34})_2]^{10-}$ ($M = M_n^{2+}$, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) could be separated as K^+ salts precipitation from reacting solution with good yields [3, 4]. We therefore reacted Δ–PW_9O_{34} with $FeCl_3$ in 1:2 molar rate, under the same conditions as Finke *et al.* described previously. No expected K^+ salt or Li^+, Na^+, Ca^{2+}, Mg^{2+} salts of $[Fe_4(H_2O)_2(PW_9O_{34})_2]^{6-}$ heteropolyanion was precipated from the orange–red reactive solution; however an orange amorphous material, which was difficult to purify further, precipated immediately from the aqueous solution after adding of Me_4NBr. Only when Me_4NBr was diffused very slowly, did small crystals of title compound appear, together with pale yellow powdery unknown complexes.

The infrared spectrum of the title compound strongly suggested that the framework of this heteropolyanion was structurally similar to the Keggin anion. Four strong absorption bands near 1059, 956, 881 and 775 cm^{-1} are assigned to P–O, W=O, W–O–W (corner-sharing and edge-sharing) vibratory absorptions respectively. Comparing to the Keggin type $[PW_{12}O_{40}]^{3-}$ heteropolyanion, the corresponding four characteristic bands appeared at 1080, 985, 887 and 807 cm^{-1} [6]. A single band appeared at P–O position indicating that the central PO_4 group has a high tetrahedral symmetry. Bands near 3033, 1488 cm^{-1} were ascribed to C–H and C–N stretching vibrations of countercations Me_4N^+. Finally, the broad bands near 3476 cm^{-1} and middle strong band at 1634 cm^{-1} were attributed to the vibratory absorptions of lattice water molecules and bridging hydroxo groups.

The X-ray crystal structure determination revealed that the title compound consisted of one heteropolyanion, ten countercations Me_4N^+ and about nineteen lattice water molecules. The structure of heteropolyanion was shown in Fig. 1, and selected bond distances as well as bond angles were listed in Table 2. The heteropolyanion was centrosymmetric with only half of the molecule crystallographically independent, and thus could be viewed as a dimer of ferric disubstituted Keggin type heteropolyanion. On the basis of charge balance, four protons were associated with each heteropolyanion; furthermore, these protons were confidently located on four bridging oxygen atoms O32, O33, O32A and O33A according to the result of bond valence sum (BVS) calculations. The BVS equation was shown: $BVS = \Sigma BV_i = \Sigma\exp[(r_0 - r_i)/B]$, where $r_0 = 1.917$ Å for $W^{6+}-O^2$; $r_0 = 1.759$ Å for $Fe^{3+}-O_2$; $B = 0.37$ [7, 8].

The bond valence sums of oxygens in heteropolyanion were given in Table 3. For the terminal

oxygen atoms, their BVS values were within the range 1.66–1.75; whereas for the bridging oxygen atoms, their values fall within the range 1.80–2.03 except for O32 and O33. We note that the BVS values were rather high for the bridging oxygen atoms in Fe–O–W and W–O–W bonds, and they were therefore ascribed to the oxo groups. The bridging atoms, O32 and O33, had much lower BVS values (1.31 and 1.13); were presumed to be hydroxo groups [9]. Similar situations were encountered in the manganese di-substituted γ–$[SiW_{10}O_{36}Mn_2(OH)_2(OH_2)_2]^{4-}$ and chromium di-substituted γ–$[SiW_{10}O_{36}Cr_2(OH)(OH_2)_2(OOCCH_3)_2]^{5-}$ heteropolyanions [9, 10]. Moreover, a hydrogen bond was observed between O32 and O40 with O32–O40 distance 2.764 Å, the oxygen O40 belonged to a crystal water molecule.

There were two kinds of bridging hydroxo group in this dimeric structure: one is the bridge hydroxo group (O33 or O33A) in each Fe_2PW_{10} half moiety; the other was the bridge hydroxo group (O32 or O32A) linking two Fe_2PW_{10} half moieties. To our knowledge, a bridging hydroxo group within the framework of an heteropolyanion has not been reported previously. The former bridging hydroxo groups were shared by two FeO_6 octahedra in the same Fe_2PW_{10} half moiety with a Fe–O–Fe angle of 139.2°; while the latter bridging hydroxo groups were shared by two FeO_6 octahedra belonging to different Fe_2PW_{10} half moieties with a Fe–O–Fe angle of 131.4°. The Fe–O bond lengths for the former bridging hydroxo groups were 1.95 Å and 1.99 Å, whereas they were only 1.90 Å and 1.93 Å for the latter bridging hydroxo groups.

Comparing the structure details of $[Fe_4(OH)_4(PW_{10}O_{37})_2]^{10-}$ to that of the Keggin type

$[PW_{12}O_{40}]^{3-}$ [11], the W–O and P–O bond lengths and angles are not substantially affected by the substitution of two Fe^{III} ions. Only slightly shorter W–O bond lengths appeared at oxygen atoms linking to FeO_6 octhedra. The FeO_6 octahedra were obviously distorted with Fe–O bond 2.40 Å linking to the central PO_4 tetrahedron and 1.90(1) 1.99(1) Å to the bridging oxygen atoms linking with WO_6 octahedra.

The hydroxo- or oxo-bridges dimers for the Fe^{III} mono-substituted heteropolyanions have been reported by Tourne *et al*. in 1982, and a series of these compounds including $K_nO[FeXW_{11}O_{39}]_2$ (X = Si, Ge, B) and $K_mO[FEX_2W_{17}O_{61}]_2$ (X = P, As) were prepared [12]. However, these dimer species were only characterized by limited means, such as elemental analysis and UV-vis spectrum; no other unambiguous evidence was provided to confirm their dimeric structure. Our work provided not only a direct view of the of the hydroxo-bridged dimeric structure, but also an ideal model for the future magnetic exchange interaction study in hydroxo-bridged compounds.

Synthesis, reactivity, and X-ray structures of face-sharing Ti(III) complexes; the new trinuclear ion, $[Ti_3Cl_{12}]^{3-}$

Linfeng Chen and F. Albert Cotton*

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, Texas 77843, U.S.A.

(Received 3 December 1997; accepted 18 April 1998)

Abstract—Reduction of $TiCl_4$ with $HSnBu_3$ followed by treatment of the brown solid with a chloride salt produced a precursor (**B**) for synthesis of face-sharing Ti(III) complexes. The precursor, **B**, can be converted into dinuclear complexes, $[Ti_2Cl_7(PEt_3)_2]^-$ (**1′**) and $[Ti_2Cl_9]^3$3-(**3′**) when treated with one equivalent of PEt_3 or Cl^-. When only half an equivalent of Cl^- was used, a trinuclear complex $[Ti_3Cl_{12}]^{3-}$ (**2′**) was isolated. **2′** can be further converted into **3′** by treating with Cl^-. Substitution of the phosphine ligands in **1′** with Cl^- converted **1′** into **3′**. There is no reaction between **3′** and Cl^-. Reaction of **1′** or **3′** with py resulted in the formation of a mononuclear species, [*trans*-$Ti(py)_2Cl_4]^-$ (**4′**). In complexes **1′**, **2′**, and **3′**, the Ti atoms are bridged by three Cl atoms. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: titanium(III); face-sharing complex; chloride; pyridine; crystal structure.

Titanium chlorides tend to form polynuclear complexes with bridging chloride ligands [1]. Two types of structure are dominant in these complexes: a structure with two octahedra fused together by sharing a common edge (**I**), and a face-sharing structure (**II**). In a previous study [2], reduction of $TiCl_4$ with $HSnBu_3$ yielded a brown solid (**A**). When this brown solid was treated with PMe_3, an edge-sharing dinuclear complex, $[(PMe_3)_2Cl_2Ti(\mu\text{–}Cl)_2TiCl_2(PMe_3)_2]$, was formed (Scheme 1). When bidentate formamidinates were used, similar complexes, also with two Cl atoms bridging two Ti atoms, were isolated. Interestingly, when **A** was treated with 0.5 equivalent of Cl^-, the brown solid was converted into a green solid, **B**, a precursor of face-sharing complexes [3]. Reaction of **B** with phosphines resulted in the formation of dinuclear face-sharing complexes, $[(PR_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PR_3)]^-$ [3]. From magnetic susceptibility measurement and *ab initio* calculations with configuration interaction it was concluded that there is essentially no metal-metal bonding between the two Ti atoms, and the Ti(III)–Ti(III) interaction in these face-sharing complexes can be best described as strong antiferromagnetic coupling that leads to a singlet ground state and a thermally accessible triplet first excited state [3]. When a trace of water was present, reaction of **B** with Cl^- yielded a heptanuclear complex, $[Ti_7Cl_{19}O_3]^{3-}$, which contains both edge-sharing and face-sharing components [4].

More face-sharing complexes have now been synthesized from the green solid (**B**) (Scheme 2). These include both dinuclear and trinuclear complexes. The syntheses and reactivity of these compounds as well as their structures are reported here.

EXPERIMENTAL

All manipulations were conducted under an argon atmosphere by using standard vacuum line and Schlenk techniques. Glassware was oven dried at 150°C for 24 hr prior to use. Solvents were predried over molecular sieves and freshly distilled under nitrogen from appropriate drying reagents. $TiCl_4$, $HSnBu_3$, and $[PPh_4]Cl$ were purchased from Aldrich. $TiCl_4$ and $HSnBu_3$ were used as received.$[PPh_4]Cl$ was dried at 150°C under vacuum for 24 hr.$[PPh_4$, $(PEt_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PEt_3)] \cdot 2CH_2Cl_2$ (**1** · $2CH_2Cl_2$) was prepared according to the previously reported method [3]. The magnetic susceptibility measurements were conducted

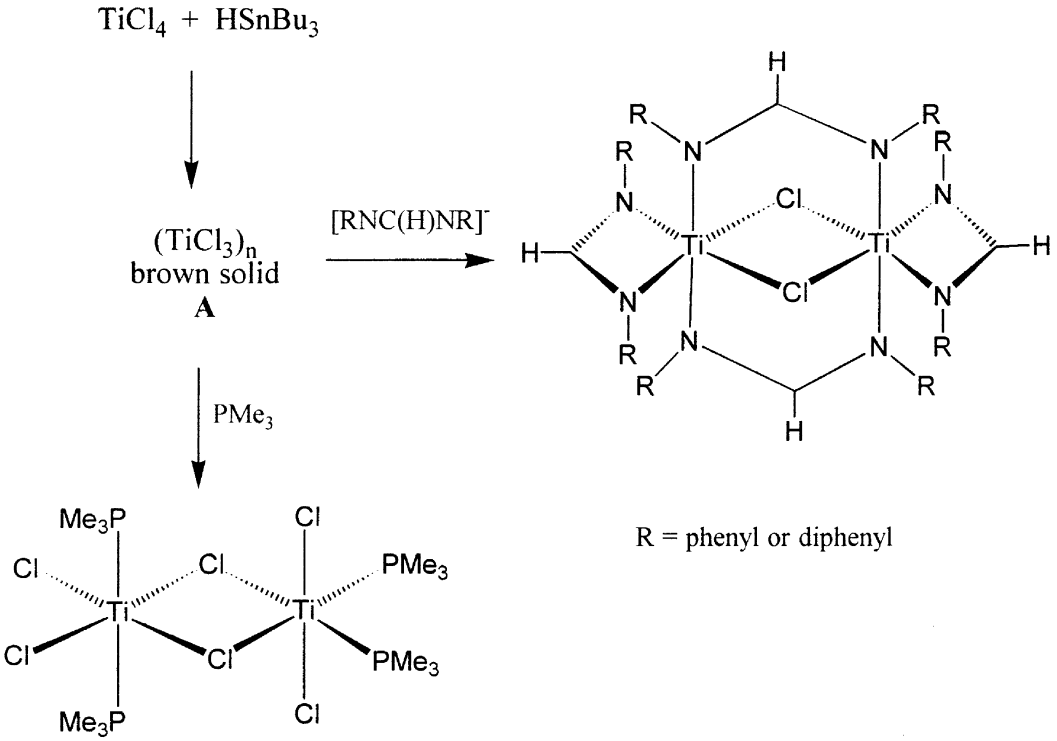


Scheme 1.

at room temperature on a Johnson–Matthey, model MSB-1, balance.

Reduction of $TiCl_4$

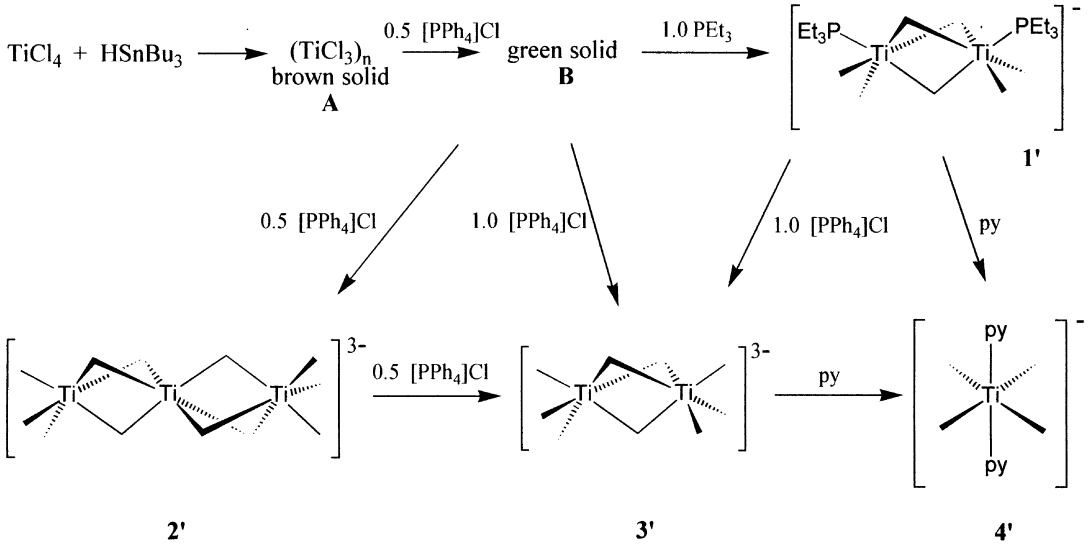
$TiCl_4$ was reduced with one equivalent of $HSnBu_3$ in the previously described way [2, 3]. $TiCl_4$ (0.22 mL, 2.0 mmol) was dissolved in toluene (20 mL). The yellow solution was stirred while $HSnBu_3$ (0.53 mL, 2.0 mmol) was added dropwise by syringe. A brown precipitate formed immediately and the reaction mixture was stirred for 4 hr. The precipitate was separated by decantation, washed with two portions of toluene (20 mL), and then dried in vacuum to give a brown solid (**A**, *ca.* 300 mg).

Reaction of **A** *with* $[PPh_4]Cl$

To the above brown solid (**A**) was added dropwise a solution of $[PPh_4]Cl$ (375 mg, 1.0 mmol) in CH_2Cl_2 (15 mL) with stirring. The brown solid (**A**) became a dark green solid (**B**) immediately.

Synthesis of $[PPh_4]_3[Cl_3Ti(\mu\text{–}Cl)_3Ti(\mu\text{–}Cl)_3TiCl_3]$ (**2**)

A solution of $[PPh_4]Cl$ (375 mg, 1.0 mmol) in CH_2Cl_2 (15 mL) was added slowly to the suspension of green solid (**B**) in CH_2Cl_2 prepared above and placed in a dry ice-acetone bath (*ca.* −78°C). The reaction mixture was warmed up slowly to room temperature by removing the cold bath and stirred at



Scheme 2.

room temperature for 3 hr. A green solution was obtained. It was evaporated under vacuum to *ca.* 20 mL in volume and then layered with hexane (40 mL). After one week, block-shaped green crystals of $\mathbf{2}\cdot 2CH_2Cl_2$ were isolated in 74% yield (865 mg). Magnetic susceptibility of $\mathbf{2}\cdot 2CH_2Cl_2$: $X = 1.79\times10^{-3}$ emu at 298 K after diamagnetic correction; $\mu_{eff} = 2.07$ BM per trinuclear complex anion.

Synthesis of $[PPh_4]_3[Cl_3Ti(\mu\text{–}Cl)_3TiCl_3]$ (**3**)

(1) *From green solid* **b** To the suspension of **B** in CH_2Cl_2 obtained as explained above was added slowly a solution of $[PPh_4]Cl$ (2.0 mmol, 750 mg) in CH_2Cl_2 (30 mL). The resulting greenish-brown solution was layered with toluene. After the diffusion was complete (about two weeks later) large plate-shaped greenish brown crystals of $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ were obtained in 85% yield (1550 mg). Magnetic susceptibility of $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$: $X = 1.21\times10^{-3}$ emu at 298 K after diamagnetic correction; $\mu_{eff} = 1.70$ BM per dinuclear complex anion.

(2) *From* $[PPh_4]_3[Cl_3Ti(\mu\text{–}Cl)_3Ti(\mu\text{–}Cl)_3TiCl_3]$ (**2**) Compound $\mathbf{2}\cdot 2CH_2Cl_2$ (300 mg, 0.171 mmol) was dissolved in CH_2Cl_2 (20 mL). To this green solution was added slowly a solution of $[PPh_4]Cl$ (96 mg, 0.256 mmol) in CH_2Cl_2 (15 mL). The solution turned greenish-brown gradually. After stirring at room temperature for 3 hr, the solution was reduced to *ca.* 15 mL in volume under vacuum and then layered with toluene (30 mL). Crystals of $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ were obtained in 95% yield (440 mg).

(3) *From* $[PPh_4][(PEt_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PEt_3)]$ (**1**) A solution of $[PPh_4]Cl$ (206 mg, 0.550 mmol) in CH_2Cl_2 (10 mL) was added slowly to a green solution of compound $\mathbf{1}\cdot 2CH_2Cl_2$ (300 mg, 0.275 mmol) in CH_2Cl_2 (15 mL). The resulting greenish-brown solution was layered with toluene (40 mL). After two weeks, crystals of $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ were harvested in 87% yield (436 mg).

Treatment of **3** *with* $[PPh_4]Cl$

Compound $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ (200 mg, 0.110 mmol) was dissolved in CH_2Cl_2 (15 mL) to give a greenish-brown solution. To this solution was added a solution of $[PPh_4]Cl$ (0.330 mmol, 124 mg) in CH_2Cl_2 (10 mL). There was no change in the color and the solution was then layered with toluene (35 mL). Two weeks later, compound $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ was recovered in 93% yield (186 mg). No reaction was observed between compound **3** and $[PPh_4]Cl$ even when ten equivalents of $[PPh_4]Cl$ was used.

Synthesis of $[PPh_4][trans\text{-}Ti(py)_2Cl_4]$ (**4**) *and* $[PPh_4]_2[trans\text{-}Ti(py)_2Cl_4]Cl$ (**4a**)

(1) *From* $[PPh_4]_3[Cl_3Ti(\mu\text{–}Cl)_3TiCl_3]$ (**3**) Compound $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ (200 mg, 0.110 mmol) was dissolved in py (20 mL) to give a brown solution. The solution was layered with hexane (40 mL). After 10 days, two products were isolated: prismatic greenish-brown crystals of **4** (47%, 71 mg) and thin plate-shaped, olive-green crystals of **4a** (45%, 105 mg). Magnetic susceptibility for **4**: $X = 1.23\times10^{-3}$ emu at 298 K after diamagnetic correction; $\mu_{eff} = 1.71$ BM per complex anion; for **4a**: $\Omega = 1.25\times10^{-3}$ emu at 298 K after diamagnetic correction; $\mu_{eff} = 1.73$ BM per complex anion.

(2) *From* $[PPh_4][(PEt_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PEt_3)]$ (**1**)

The reaction was carried out as in (1) above to give products **4** and **4a** in 44% and 46% yield, respectively.

X-ray crystallography

Crystals of $\mathbf{2}\cdot 2CH_2Cl_2$, $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$, and **4a** were measured on an Enraf FAST diffractometer with an area detector by placing each crystal on the tip of a quartz fiber under a cold stream of nitrogen at -60°C. The crystal of **4** was measured on an Enraf CAD4 automated diffractometer at 20°C with the crystal sealed in a thin-walled glass capillary. Graphite-monochromated Mo Kα radiation (0.70930 Å) was used for both diffractometers. For the crystal on the CAD4 diffractometer, the unit cell was determined by using search, center, index, and least-squares routines. The Laue class and lattice dimensions were verified by axial oscillation photography. The intensity data were corrected for Lorentz and polarization effects and for anisotropic decay. An empirical absorption correction based on psi scans was also applied. For the crystals on the FAST diffractometer, a preliminary data collection was carried out to establish all parameters and to obtain an orientation matrix. Fifty reflections were used in indexing and about 250 reflections in cell refinement. Axial images were taken to determine the Laue groups and cell dimensions. Neither a decay correction nor an absorption correction was applied [5].

Each structure was solved by a combination of direct methods using the SHELXS-86 program [6] and difference Fourier analyses using the SHELXL-93 program [6]. Crystallographic data and results are listed in Table 1.

Compound $\mathbf{2}\cdot 2CH_2Cl_2$ crystallized in the triclinic crystal system. Space group $P\bar{1}$ (No. 2) was first tried, but the solution gave a chemically unreasonable structure. Space group $P1$ (No. 1) was then chosen and confirmed by the successful solution and refinement of the structure. In the unit cell, there are one $[Ti_3Cl_{12}]^{3-}$ anion, three $[PPh_4]^+$ cations, and two CH_2Cl_2 solvate molecules. One of the two CH_2Cl_2 molecules was disordered over two positions with occupancies of 52% and 48%. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were calculated by assuming idealized geometry and refined with fixed thermal parameters set at 1.2 B_{eq} of the corresponding carbon atoms. Being mindful of the somewhat uncommon occurrence of space group $P1$, an attempt was made to see if $P\bar{1}$ might not, after all, be possible, but it was unequivocally found not to be.

Compound $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ also crystallized in the triclinic system. Space group $P\bar{1}$ (No. 2) was assumed and confirmed by the successful solution and refinement of the structure. In the unit cell, there are two $[Ti_2Cl_9]^{3-}$ anions, six $[PPh_4]^+$ cations, eight CH_2Cl_2 and one $C_6H_5CH_3$ solvate molecules. The toluene molecule is disordered on an inversion center. The non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were treated as mentioned above for compound **2**.

Compound **4** crystallized in the monoclinic crystal system. The absences in the data indicated that the space group is either Cc or C2/c. The centrosymmetric space group C2/c (No. 15) was chosen and confirmed by successful solution of the structure. In the asymmetric unit, there are one $[Ti(py)_2Cl_4]^-$ anion and one $[PPh_4]^+$ cation. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located and refined with isotropic thermal parameters.

Compound **4a** crystallized in the triclinic system. The space group $P\bar{1}$ (No. 2) was determined as in compound $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ and the structure was solved similarly. In the asymmetric unit, there are one $[Ti(py)_2Cl_4]^-$ and one Cl^- anion, as well as two $[PPh_4]^+$ cations.

RESULTS AND DISCUSSION

Treatment of the brown solid (**A**) (from reduction of $TiCl_4$ with $HSnBu_3$) with 0.5 equivalent of $[PPh_4]Cl$ converts **A** into a green solid (**B**), probably a material containing face-sharing units (**II**). A dinuclear face-sharing complex, $[(PEt_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PEt_3)]^-$ (**1′**), was formed from reaction of the green solid (**B**) with one equivalent of PEt_3 [3]. When **B** was treated with 0.5 equivalent of Cl^-, the reaction resulted in the formation of $[Cl_3Ti(\mu\text{–}Cl)_3Ti(\mu\text{–}Cl)_3TiCl_3]^{3-}$ (**2′**) where two face-sharing units are fused to give a linear Ti_3 trimer. In this complex, all three Ti atoms are in the oxidation state 3+, each with one unpaired electron.

Compound $\mathbf{2}\cdot 2CH_2Cl_2$ was characterized by single crystal x-ray diffraction study. The structure of the $[Cl_3Ti(\mu\text{–}Cl)_3Ti(\mu\text{–}Cl)_3TiCl_3]^{3-}$(**2′**) ion in $\mathbf{2}\cdot 2CH_2Cl_2$ is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. The structure of **2′** is similar to those of $[Cr_3Cl_{12}]^{3-}$ [7], $[Ni_3(acac)_6]$ (acac = acetylacetonato) [8], and $[Ru_3Cl_{12}]^{4-}$ as well as its phosphine derivatives [9], all of which contain three atoms bridging two metal atoms. The distances between the central Ti atom and the other two Ti atoms are 3.185(1) and 3.098(4) Å, respectively. These distances are longer than those found in the $[(PR_3)Cl_2Ti(\mu\text{–}Cl)_3TiCl_2(PR_3)]^-$ ions (3.031(2) Å for $PR_3 = PEt_3$ (**1′**); 2.942(1) Å for $PR_3 = PMe_2Ph$) [3]. From the study of variable temperature magnetic susceptibility and *ab initio* CI calculation, it was concluded that the bonding between the two Ti atoms in **1′** is negligible. Accordingly, we expect that there is no strong bonding between the Ti atoms in **2′**. There are two types of bond lengths between a Ti atom and a bridging chlorine atom Cl_b: the one involving the central Ti atom (Ti(2)–Cl_b) is significantly shorter than the one involving a terminal Ti atom (Ti_t–Cl_b), 2.406(4) *vs.* 2.548(4) Å on average, probably due to the different kinds of Cl atoms at the *trans* positions.

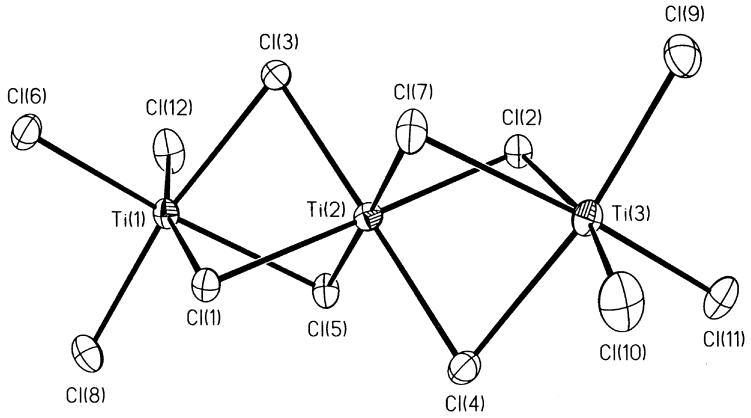

Fig. 1. X-ray structure of the $[Ti_3Cl_{12}]^{3-}$ anion (**2′**) in **2** · $2CH_2Cl_2$ showing 30% probability thermal ellipsoids of Ti and Cl atoms.

They are both longer than the bond length between a Ti atom and a terminal chlorine atom, Ti–Cl_t = 2.329(4) Å. The two terminal Ti atoms are both in a distorted octahedral coordination geometry with Cl_b–Ti_t–Cl_b = 81.1(2)° and Cl_t–Ti_t–Cl_t = 96.7(2)°. The central Ti atom is also in a slightly distorted octahedral geometry with Cl_b(A)–Ti(2)–Cl_b(B) = 87.0(2)° (Cl_b(A) = Cl(1), Cl(3), or Cl(5); Cl_b(B) = Cl(2), Cl(4), or Cl(7)). The average Ti–Cl_b–Ti angle is 78.6(2)°, obviously larger than that in an idealized face-sharing unit (70.53°) [10], indicating there is a repulsion between the Ti(III) atoms.

From the room-temperature magnetic susceptibility of **2**, a magnetic moment of 2.07 BM was calculated. Since this is far less than would be expected for three independent unpaired electrons, while the structure shows that no direct Ti–Ti bonding occurs, it must be concluded that there is strong antiferromagnetic

coupling among the electrons. The value of 2.07 BM could be explained if there is a ground state with $S=1/2$ and a thermally accessible excited state with $S=3/2$.

Reaction of **2′** with 0.5 equivalent of $[PPh_4]Cl$ yielded a dinuclear face-sharing complex, $[Cl_3Ti(\mu\text{–}Cl)_3TiCl_3]^{3-}$ (**3′**). The reaction is:

$$2[Ti_3Cl_{12}]^{3-} + 3Cl^- = 3[Ti_2Cl_9]^{3-}$$

Under the conditions used, the reaction was almost quantitative (95% yield). Complex **2′** can also be synthesized directly from the reaction of the green solid **B** with one equivalent of $[PPh_4]Cl$. Substitution of the phosphine ligands in **1′** also led to the formation of **3′**. Although $[Ti_2Cl_9]^{3-}$ has been extensively studied for its magnetic and spectroscopic properties [11], its full structural characterization was only recently reported [12] for the compound $[NEt_4]_3[Ti_2Cl_9]$. The present results are almost identical; in particular, exactly the same Ti···Ti separation, 3.216 Å, was found in both cases.

The structure of **3′** in $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ is shown in Fig. 2. Selected bond lengths and angles are listed in Table 3. The important structural parameters in **3′** are comparable with those quoted for $Cs_3Ti_2Cl_9$ [11b], Ti···Ti = 3.216(3) *vs.* 3.191, Ti–Cl_b = 2.501(3) *vs.* 2.503, Ti–Cl_t = 2.365(4) *vs.* 2.328 Å, Cl_b–Ti–Cl_b = 83.0(1) *vs.* 83.7, Cl_t–Ti–Cl_t = 95.2(2) *vs.* 95.2°. The distance between two Ti atoms in **3′** is longer than the two in **2′** (3.185(4) and 3.098(4) Å. The Ti–Cl_b–Ti angle is also larger, 80.0(1) *vs.* 78.6(2)°. The Ti–Cl_b bond length is between the values of two sets of such bond lengths in **2′**, 2.501(3) *vs.* 2.406(4) and 2.548(4) Å, while the Ti–Cl_t bond length is just slightly

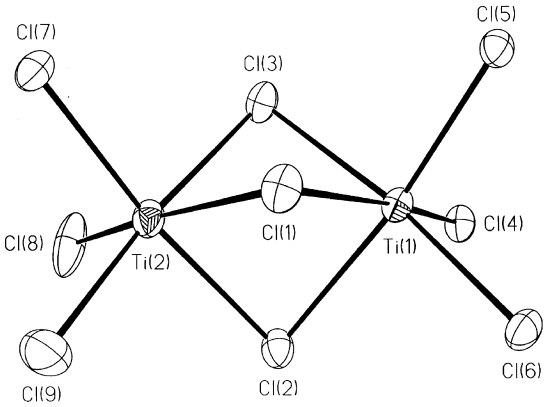

Fig. 2. X-ray structure of the $[Ti_2Cl_9]^{3-}$ anion (**3′**) in $\mathbf{3}\cdot 4CH_2Cl_2\cdot 0.5C_6H_5CH_3$ showing 30% probability thermal ellipsoids of Ti and Cl atoms.

longer, 2.365(3) *vs.* 2.329(4) Å. For the same reason mentioned above, there should be no metal-metal bond between the two Ti atoms in **3′**.

In complex **3′**, each Ti atom is in the oxidation state of 3+ and has one unpaired electron. However, the effective magnetic moment for compound **3** is appreciably lower than the idealized value for a compound with two unpaired electrons, 1.70 *vs.* 2.83 BM. Actually, the magnetic moment is very close to that for compound **1**, 1.72 BM, probably also due to the strong antiferromagnetic coupling between the electrons as in **1**. More extensive magnetic data were reported and discussed in Ref [12].

Even though it is rather easy to break one of the two face-sharing units in **2′** to form **3′**, it is impossible to convert the dinuclear complex **3′** into a mononuclear complex by using $[PPh_4]Cl$. This might be due to the fact that the Ti–Cl_b bond (2.501(3) Å) in **3′** is shorter than the Ti_t–Cl_b bond (2.548(4) Å) in **2′**, indicating a stronger Ti–Cl_b bonding. As a result, the reaction between the green solid **B** and excess of $[PPh_4]Cl$ always ends up with the product **3**.

It appears that in order to break the face-sharing unit in **3′**, stronger ligands are needed. When compound **3** was dissolved in pyridine, it was converted into a mononuclear complex, $[trans\text{-}Ti(py)_2Cl_4]^-$ (**4′**). It is possible that the reaction resulted in the formation of **4′** and $[Ti(py)Cl_5]^{2-}$ in which one Cl atom was then substituted by a pyridine ligand to form **4′**. The Cl^- anion was isolated as $[PPh_4]_2[trans\text{-}Ti(py)_2Cl_4]Cl$ (**4a**). Complex **4′** has been reported before as a pyridinium salt from reaction of $TiCl_2$, py, and CH_2Cl_2 [13].

Both of compounds **4** and **4a** were charaterized crystallographically. The structures of **4′** in **4** and **4a** are similar and they are displayed in Fig. 3 and Fig. 4, respectively. The structure of **4′** in **4** is almost ident-

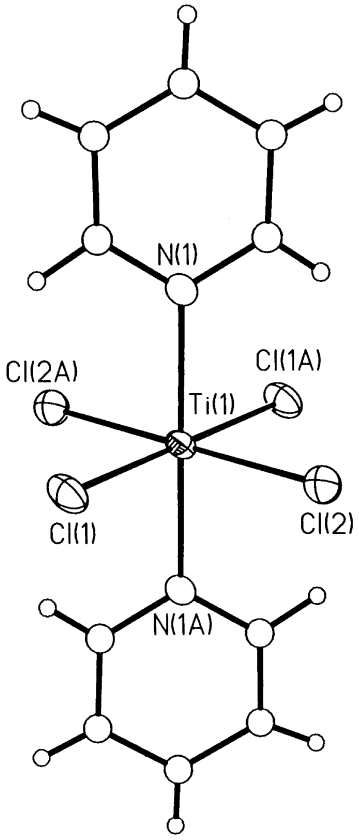

Fig. 3. X-ray structure of the $[Ti(py)_2Cl_4]^-$ anion (**4′**) in **4** showing 30% probability thermal ellipsoids of Ti, Cl, and N atoms. Carbon and hydrogen atoms are represented with arbitrarily small circles for clarity.

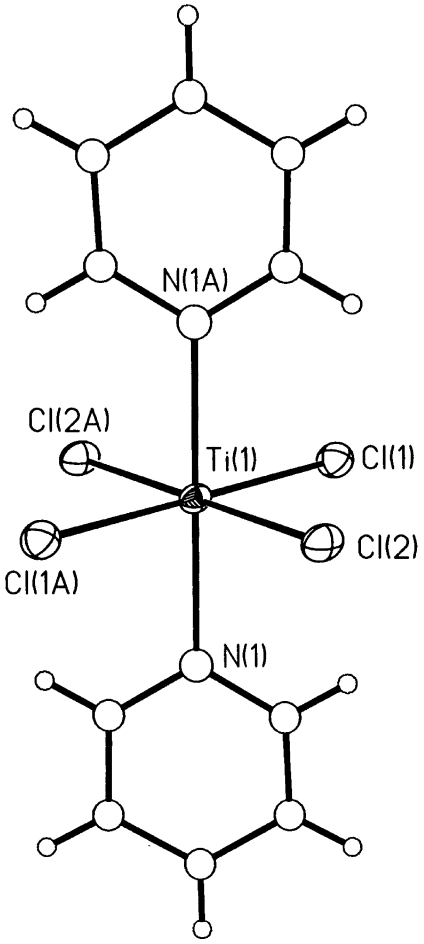

Fig. 4. X-ray structure of the $[Ti(py)_2Cl_4]^-$ anion (**4′**) in **4a** showing 30% probability thermal ellipsoids of Ti, Cl, and N atoms. Carbon and hydrogen atoms are represented with arbitrarily small circles for clarity.

ical to that in $(pyH)[Ti(py)_2Cl_4] \cdot CH_2Cl_2$ [13] with Ti–N = 2.208(2) *vs.* 2.21(1), Ti–Cl = 2.4001(9) *vs.* 2.405(3) Å. However, the corresponding bond lengths of **4′** in **4a** are obviously different. The Ti–N bond is longer, 2.235(4) Å. And there are two sets of Ti–Cl bonds in **4a**, Ti–Cl(1) = 2.365(1) and Ti–Cl(2) = 2.447(1) Å. This might be caused by the presence of the Cl^- anion in the crystal. The distance between the Cl^- anion, Cl(11), and Cl(2) is much shorter than that between Cl(11) and Cl(1), 5.61 *vs.* 7.46 Å. Cl(11) is located between Cl(2) and Cl(2)′ in another [*trans*-$Ti(py)_2Cl_4]^-$ anion. The results from magnetic susceptibility measurements indicated that both compounds, **4** and **4a**, contain one unpaired electron with $\mu_{eff} = 1.71$ and 1.73 BM, respectively.

(Received 16 January 1998; accepted 22 April 1998)

Abstract—Compound $[Ta(Se_2)_2]_2TaBr_6$ was prepared from elements by high temperature (450°C) stoichiometric reaction in high yield. The structure has been determined by single crystal X-ray diffraction. It contains infinite positively charged chains $Ta(Se_2)_2\ldots$ separated by octahedral $TaBr_6^-$ anions. The slightly alternating Ta–Ta distances within the chains [3.182(2)–3.234(2) Å] show a considerable degree of metal–metal interaction along the chain. © 1998 Elsevier Science Ltd. Keywords: crystal structure; tantalum complexes; selenium complexes; bromides; one-dimensional materials.

INTRODUCTION

Chemistry and solid state physics of low-dimensional materials is a well established field of research activity [1, 2]. Chalcogenides and chalcohalides of Group 5 transition elements have so far furnished dozens of one-dimensional materials, the prominent examples being $TaSe_3$ [3] and a remarkable family of "intercalated" selenides $(NbSe_4)_yI$ ($y = 2$–4) [4]. The polymeric NbS_2Cl_2 has a $Nb_2(S_2)_2^{4+}$ core and was one of the first well-characterized transition metal chalcohalides [5]. It has recently been shown to be a convenient lead-in compound into the still largely unexplored area of molecular niobium chalcogen complexes [10, 11]. The corresponding Ta chemistry is far less developed. Well characterized products are $Ta(Te_2)_2I$ [6], $[Ta(Te_2)_2]_4I_2(TaI_6)$ [7], $[Ta(Se_2]_2]_2I$ [12] and $[Ta(Te_2)_2]_6I_4(TaI_6)$ [9]. Here we report synthesis and crystal structure of a novel one-dimensional Ta selenide bromide, $[Ta(Se_2)_2]_2TaBr_6$ (**1**) as a result of our investigations in Ta/Se/X_2 (X = Cl, Br) systems.

[1] Further details of the crystal structure can be ordered from Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen (e-mail: crysdata@fiz-karlsruhe.de) under the depository number CSD-408596.

EXPERIMENTAL

A mixture of Ta powder (1.00 g, 5.53 mmol), gray Se (1.16 g, 14.69 mmol) and Br_2 (0.28 ml, 5.43 mmol) was placed in a quartz tube which then was sealed under vacuum and heated at 450°C for 1 week. A temperature gradient was maintained. The tube was cooled at 20°C h^{-1} rate to promote crystal growth. After cooling down, almost complete transport into the cooler end of the tube was observed. The compound crystallizes in the form of long (up to 1 cm), thin black needles. The yield was 90%. The elemental analysis agreed with the formula $Ta_3Se_8Br_6$ (**1**). The compound can be handled in air for a limited period but must be stored under nitrogen to avoid degradation which releases HBr and H_2Se in moist air.

Small amounts of bronze-colored $TaSe_2$ and red $TaBr_5$ (less than 5%) also form as byproducts but can be easily separated manually from the main product.

The electrical conductivity of crystals of **1** at room temperature was measured by a two-point contact method; $\sigma = 10^{-4}\,\Omega^{-1}\,cm^{-1}$.

Crystal structure determination of 1

The structure was determined by the single crystal X-ray crystallography. X-ray data were measured at 295 K on a Rigaku AFC-5R diffractometer with

graphite-monochromated MoK_α radiation ($\lambda =$ 0.71069 Å) with the ω–2θ scan mode. The DIFABS program was used for absorption correction. A slight decay (5.42% in intensity) was detected during the data collection and the data were corrected accordingly. The structure was solved by direct methods (SHELX-86) [18]. The full-matrix refinements were performed with the teXsan programs [19]. Crystal data and refinement results are given in Table 1. Selected interatomic distances are given in Table 2.

RESULTS AND DISCUSSION

Figure 1 shows the ORTEP drawing of the structure of **1**. The Ta atoms form linear chains running along the *c*-axis with slightly alternating Ta–Ta distances 3.198(2), 3.234(2) and 3.182(2) Å. The sequence is Ta(1)–Ta(1)–Ta(2)–Ta(2)–Ta(1)–Ta(1)..., Ta(1)–Ta(2) being the largest distance. Se(1) and Se(2) are bridging Ta(1) atoms, two Ta(2) atoms are bridged by Se(3) and Se(4) whereas four non-equivalent Se atoms [Se(5), Se(6), Se(7) and Se(5)] connect Ta(1) with Ta(2). The closest analog to **1** is $[Ta(Se_2)_2]_2I$, where all the distances are equal at 3.206(1) Å [12]. Each Ta atom is coordinated to eight Se atoms of four diselenide bridges. The Se–Se distances in the Se_2 ligands vary between 2.35–2.38 Å which can be compared with 2.40 Å in $[Ta(Se_2)_2]_2I$ [12]. It has already been pointed that Se_2 groups are rather flexible and use their π-antibonding orbitals to serve as an electronic pool for adjacent metal chains [1]. The significantly shorter Se–Se distance in **1** than in closely related $[Te(Se_2)_2]_2I$ can thus be explained by stronger electronic demand of metal chains in the bromine compound. The four Se atoms of each bridging pair of the Se_2 ligands lie approximately in planes perpendicular to the chains of Ta atoms, thus forming a

rectangle with two short and two long sides. The dihedral angles between each pair of adjacent Se_4 units are close to 45° to minimize repulsion between Se atoms and to increase the overlap with 5d orbitals of Ta [6]. These restrictions still leave enough room for different modes of stacking of the Se_4 rectangles in the chain [6]. In **1** (Fig. 2) the stacking pattern is the same as found in the structure of $[Nb(Te_2)_2]I$ [6] but differs from those observed for other $Ta(Se_2)_2$ and $Ta(Te_2)_2$ chains [6, 12]. The chains are separated by slightly distorted $TaBr_6^-$ anions (the Ta–Br distances are in the range 2.47–2.52 Å). In a relevant complex $[TaBr_4(diars)_2][TaBr_6]$, this anion forms almost perfect octahedron (Ta–Br 2.49 Å) [14]. The distortions may be due to additional Se...Br contacts (the shortest one, between Se(5) and Br(5), is 3.162(4) Å), which may also favor the observed stacking pattern for the Se_4 rectangles. The contacts of this kind fall well shorter than the corresponding sum of van-der Waals radii and are a well established feature in the chemistry of heavier chalcogens [15].

Since the bond distances in the anion show the oxidation state of the Ta atom in the $TaBr_6^-$ unit to be five, a positive charge +1 should he assigned to the $[Ta(Se_2)_2]_2$ unit. It means that the Ta atoms have the oxidation state +4.5 which leaves 0.5 e per one Ta–Ta bond (if we consider the diselenium bridges as Se_2^{2-}). If we take into account the donation of an extra electron density from the bridging ligands it will give us less negative charge on the Se_2 unit and correspondingly stronger bonding interaction between tantalum atoms. This is in keeping with the observed distances of about 3.20 Å for **1** and $[Ta(Se_2)_2]_2I$ with the same formal oxidation state. It is thus considerably shorter than that in $[Ta(Te_2)_2]I$ (3.33–3.35 Å) where the oxidation state is +5 which implies zero bonding order. Accordingly, preliminary resistivity measurements on the single crystals of **1** gave value which may indicate semiconductive behavior.

The prepared material thus belongs to the by now extensive family of one-dimensional structures, hav-

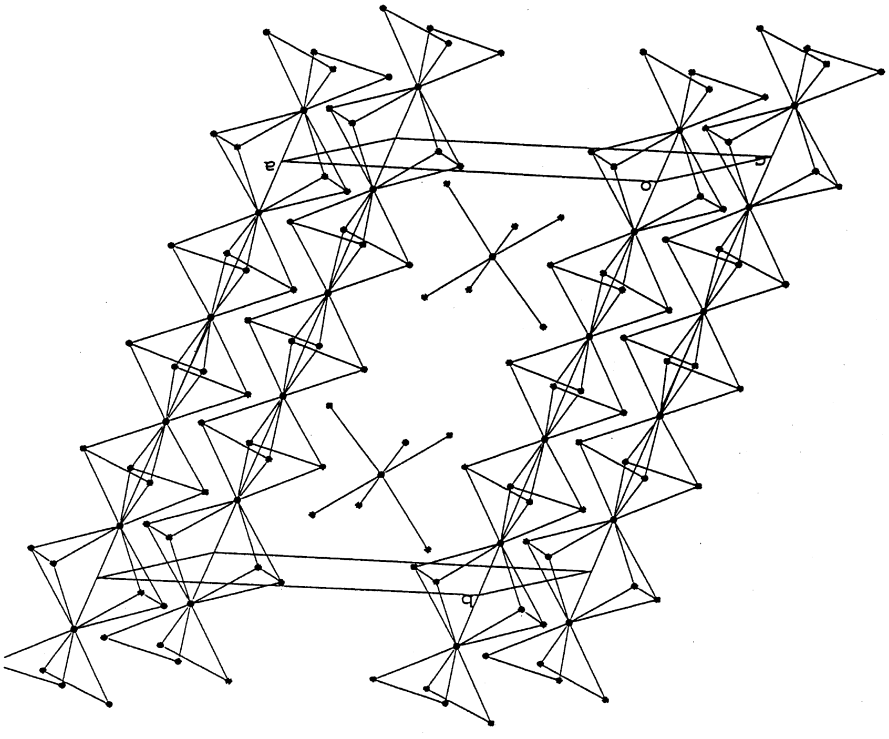

Fig. 3. Unit cell drawing of **1**.

ing positively charged metal–dichalcogen chains separated by counteranions (Fig. 3). As for the latter, both simple small anions (like I^-) and large complex ones (PtI_6^{2-} [8], TaI_6^- [7, 9], $TaBr_6^-$) are effective in the stabilization of this type of structure. It seems possible that other anions of various shape and size may be good candidates as well.

In conclusion it may be mentioned that the synthesis of **1** is one of the rare cases when Nb and Ta do not behave in a similar way. Thus, in the reaction conditions similar to those used in the present study, Nb forms $NbSe_2Br_2$, a coordination polymer where $Nb_2(Se_2)_2$ cluster units are linked by bromine atoms similar to NbS_2Cl_2 [13]. On the other hand it was not possible to prepare the Ta analog of NbS_2Cl_2, only TaS_3 and $TaCl_5$ could be detected [13]. One of the reasons may be the greater reluctance of Ta to form low oxidation states, in keeping with the overall trend in the periodic table.

(Received 15 January 1998; accepted 15 April 1998)

Abstract—Reaction of Li_2PdCl_4 with 2-acetyl- and 2-formylpyridine 3-hexamethyleneiminyl-thiosemicarbazones, HFohexim and HAchexim, respectively, affords the complexes [Pd(Achexim)Cl] and [Pd(Fohexim)Cl]. [Pd(Fohexim)Cl] crystallizes in the triclinic space group $P\bar{1}$ with $a=7.9447(17)$ Å, $b=9.6402(13)$ Å, $c=10.3739(18)$ Å, $\alpha=79.128(12)^\circ$, $\beta=75.104(15)^\circ$ and $\gamma=75.558(14)^\circ$. Crystals of [Pd(Achexim)Cl] are monoclinic, space group $P2(1)/n$, with four formula units in a unit cell of dimensions $a=7.2243(7)$ Å, $b=9.6402(13)$ Å, $c=24.937(3)$ Å, and $\beta=104.048(9)^\circ$. Anions of HFohexim and HAchexim coordinate in a planar conformation to a central palladium(II) via the pyridyl nitrogen, azomethine nitrogen and thiolato sulfur atoms. The complexes have been characterized by spectroscopic techniques (IR and ^{1}H NMR). The protonation constants of HFohexim, $K_{a1}=11.83\pm0.01$ and $K_{a2}=3.70\pm0.02$, were determined spectrophotometrically. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: thiosemicarbazone; hexamethyleneimine; palladium; crystal structure.

INTRODUCTION

Heterocyclic thiosemicarbazones (TSCs) are important because of their possible beneficial biological activity [1]. The 3-hexamethyleneiminyl-thiosemicarbazones of 2-acetyl- and 2-formylpyridine, HAchexim [2] and HFohexim [2, 3], have been screened against HSV-1, HSV-2 and leukemia P388 because of their potential for medicinal use. We have initiated an investigation on complexes of palladium(II) in an effort to correlate structure with biological activity [4–9]. This report includes the crystal structures of the newly prepared [Pd(Fohexim)Cl], and [Pd(Achexim)Cl], which was included in a previous spectral and biological study [9]. This work is an extension of previously studied palladium(II) complexes of 2-acetylpyridine TSC with potentially interesting biological activity [4–9], as well as copper(II) complexes of these TSCs [10].

EXPERIMENTAL

Solvents were purified and dried according to standard procedures. The complexes were analyzed for C, H, and N at the European Environmental Research Institute (Ioannina). The methods of measurement and instrumentation used were as reported previously [4].

*Author to whom correspondence should be addressed.

Preparations

HAchexim and HFohexim were prepared according to the method described by Scovill [11]. The 2-acetyl- and 2-formylpyridine (Aldrich) were mixed with a 3:1 molar excess of hexamethyleneimine (Aldrich) in ethanol with warming. N(4)-methyl-N(4)-phenylthiosemicarbazide, prepared as described [11], was added in small portions to the warmed solution over a period of 1 h after which the mixtures were refluxed for 2 hours. The preparation of [Pd(Achexim)Cl] was described previously [9], and the light yellow crystals were grown by slow evaporation of a DMSO solution. [Pd(Fohexim)Cl] was prepared by mixing 1.5 mmol of Li_2PdCl_4 prepared *in situ* from $PdCl_2$ and LiCl in methanol (15 mL) and 1.3 mmol of HFohexim in methanol (15 mL) and stirred for 24 h. Crystals of the yellow-orange powder of [Pd(Fohexim)Cl] were grown by slow evaporation from a mixture of CH_3CN:DMF (2:1). For [Pd(Fohexim)Cl]: %Found: C = 38.6; H = 4.0; N = 14.0; S = 7.6. %Calcd: C = 38.7; H = 4.2; N = 13.9; S = 7.9.

X-ray data collection and reduction

A yellow prismatic crystal of [Pd(Achexim)Cl] and an orange pyramidal crystal of [Pd(Fohexim)Cl] were mounted on glass fibers and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $8.895^\circ < \theta < 18.142^\circ$ for [Pd(Fohexim)Cl] and $8.822^\circ < \theta < 18.076^\circ$ for [Pd(Achexim)Cl] with an ENRAF-NONIUS MACH3 automatic diffractometer [12]. Data were collected at 291(2) K using MoKα radiation ($\lambda = 0.71073$ Å) and the ω scan technique; the data were corrected for Lorentz and polarization effects [13]. A semi-empirical absorption correction was made [14].

Structure solution and refinement

The structure was solved by direct-methods [15] which revealed the position of all non-hydrogen atoms, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [16]. The majority of the hydrogen atoms in both structures were located from difference Fourier maps and refined isotropically. The exceptions are the hydrogens attached to C9, C10 and C11 of [Pd(Achexim)Cl], which were located in their calculated positions (C–H 0.97 Å) and refined using a riding model. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography* [17]. Molecular graphics are from *PLATON* [14]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

Protonation constants

All solutions were prepared using distilled water obtained from a borosilicate autostill (Jencons Ltd.). A 1×10^{-4} M stock solution of HFohexim was prepared by suspending the appropriate amount of purified, ground thiosemicarbazone in warmed distilled water for some hours until dissolution was achieved, cooling to room temperature, filling the flask to the required volume with distilled water and mixing throughly. Working thiosemicarbazone solutions (1×10^{-5} M) having different hydrogen ion concentrations and constant ionic strength, $\mu = 0.1$, were prepared using standard HCl or KOH and KCl solutions. All absorption spectra and pH measurements (Methrom 691 pH-meter) were made at 25°C. The absorption spectra were collected in the range 250–450 nm with a JASKO V-570 UV/Vis/NIR spectrophotometer guided by a personal computer.

RESULTS AND DISCUSSION

Crystal structures

Interatomic distances and bond angles are compiled in Tables 2 and 3, respectively, for [Pd(Achexim)Cl] and [Pd(Fohexim)Cl]. Atomic coordinates and displacement factor coefficients are included in the Supplementary Material. Figure 1 shows a perspective view of [Pd(Fohexim)Cl] and [Pd(Achexim)Cl] is shown in Fig. 2. The anionic Fohexim and Achexim act as tridentate ligands, which coordinate to palladium(II) centers through the pyridyl nitrogen, N(1), the azomethine nitrogen, N(2) and the thiolato sulfur atoms. The terdentate ligand, Fohexim (and Achexim), show a Z, E, Z configuration about the following bonds: C15–C16 and C35–C36, C16–N12 and C36–N22, N13–C17 and N23–C37 for the two molecules in the asymmetric unit, respectively. The palladium(II)-ligand bond distances for the two complexes are within two to three orders of magnitude of their combined estimated standard deviations although the Pd–N1 (pyridyl nitrogen) and Pd–S bonds are shorter and the Pd–N (azomethine) and Pd–Cl bonds longer for [Pd(Achexim) than for [Pd(Fohexim)Cl]. The thiosemicarbazone moieties' bond distances show even less variation between the two complexes. The coordination spheres (i.e., N1–N2–S–Pd–Cl) deviate from planarity by only 0.0354 and 0.0060 for [Pd(Achexim)Cl] and [Pd(Fohexim)Cl], respectively, and N2 shows the greatest deviation from the plane for both. The dihedral angles formed by the pyridine ring with the coordination plane is 5.10(12)° and 1.15(12)° for [Pd(Achexim)Cl] and [Pd(Fohexim)Cl], respectively.

A comparison of bond distances for the thiosemicarbazone moiety of [Pd(Fohexim)Cl] and [Pd(Achexim)Cl] with previously studied HAchexim [18] and its complexes [19, 20], palladium(II) complexes

with other 2-acetylpyridine thiosemicarbazones [4, 5, 6], and a copper(II) complex of 2-benzoylpyridine 3-hexamethyleneiminylthiosemicarbazone [21] is given in Table 4. The thiosemicarbazone moiety bond distances are independent of both the N(4)-substituent and the metal center. Table 5 lists the palladium(II)-donor bond distances for palladium heterocyclic thiosemicarbazones having a pyridyl nitrogen as the third donor atom. Although the bulkiness of the hexim function would be expected to affect the Pd–S bond distance compared to the other two donor sites, its variation is not signifcantly different from the Pd–N distances.

Spectroscopy

Selected ^{1}H NMR data of the thiosemicarbazones and their palladium(II) complexes are shown in Table

6. The main differences between the spectra of free thiosemicarbazones, HFohexim and HAchexim, and coordinated Fohexim and Achexim are the disappearance of the highest-frequency N(2)H signal and the deshielding of C(1). These changes indicate that deprotonation and metallation occurs, and the structure of the two complexes in the solid state persists in $CDCl_3$ solution. The appearance of the signal N(2)*H*

Table 6. Selected ^{1}H NMR spectra data of the ligands and complexes

Compound	Solvent	(CH_3)C(6)	C(6)*H*	C(1)*H*
HFohexim	$CDCl_3$		7.521*s*	8.579*d*
[Pd(Fohexim)Cl]	$CDCl_3$		7.518*s*	8.705*d*
HAchexim	$CDCl_3$[a]	2.52*s*		8.58*d*
	d^6-DMSO	2.48(75%)[a]		
		2.37(25%)[b]		8.720*d*
[Pd(Achexim)Cl]	$CDCl_3$	1.579*s*		8.776*d*

(a) bifurcated tautomer, designated E′ [18]; (b) E isomer with N(2)H hydrogen bonding to DMSO.

at $\delta = 15.13$ for HFohexim is due to hydrogen bonding and suggests that in $CDCl_3$ the Z isomer is prevalent while previous studies showed three forms, E, Z and the bifurcated E′ tautomer, for HAchexim, with the N(2)H resonances at $\delta = 8.52$, 15.25 and 14.95, respectively [18].

The significant IR bands of the ligands HFohexim and HAchexim and their complexes are similar to those found in other compounds with tridentate coordination [4–9]. Besides these bands the IR spectrum of [Pd(Fohexim)Cl] shows $\nu(PdN_{azo})$, $\nu(PdS)$, $\nu(PdCl)$ and $\nu(PdN_{py})$ at 460, 380, 352 and 330 cm^{-1} respectively.

Protonation constants

Because of the low solubility of HFohexim in water, spectrophotometry was used to determine its protonation constants. In aqueous solutions with pH > 2 there are three independent species ($Fohexim^-$, HFohexim and $H_2Fohexim^+$), and therefore, two distinct steps of protonation, as shown by the absorption spectra in Fig. 3(a,b). The equilibrium between the species is given by the equations (1) and (2)

$$Fohexim^- + H_3O^+ \overset{K_{a1}}{\rightleftharpoons} HFohexim + H_2O \quad (1)$$

$$HFohexim + H_3O^+ \overset{K_{a2}}{\rightleftharpoons} H_2Fohexim^+ + H_2O \quad (2)$$

The concentration protonation constants of HFohexim, K_{a1} and K_{a2}, were determined, and the 95% confidence limits for their logarithms were found to be equal to 10.80 ± 0.01 and 3.73 ± 0.02 ($n = 6$) with relative standard deviations 0.26% and 1.34%, respectively. The pK_{a2} value is lower than that of pyridine (5.0) and 2-acetylpyridine thiosemicarbazone, HAc4DH, (3.98) [4]. Compared to pyridine the lower value can be attributed to the decrease in electron density on the pyridine nitrogen caused by the electron-withdrawing effect of the azomethine function. Also, the p*Ka*1 value is lower than that of thiosemicarbazide (11.45) and 2-acetylpyridine thiose-

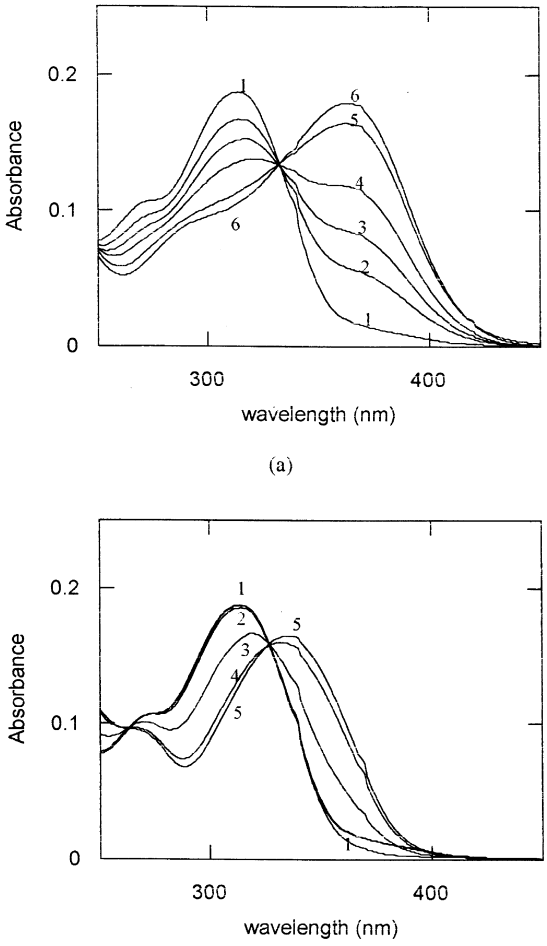

Fig. 3. Plots of absorbance data *versus* wavelength for HFohexim at 25°C in the high pH region, where the species $Fohexim^-$ and HFohexim are present (a) [pH 9.48 (1); pH 10.40 (2); pH 10.79 (3); pH 11.16 (4); pH 11.93 (5); pH = 12.92 (6)], and in the low pH region, where the species HFohexim and $H_2Fohexim^+$ are present (b) [pH 9.48 (1); pH 4.30 (2); pH 4.15 (3); pH 3.49 (4); pH 3.36 (5)].

micarbazone (11.43) and reveals that HFohexim behaves as a weak monoprotic acid. In a recent quantitave analysis of the factor controlling the acidity of N–H bonds in amide compounds, [RC(=X)NH_2], it was found that the field-inductive, polarizability and resonance effects are responsible for this acidity [22]. These three factors combine to make the N(2)*H* (hydrazinic group) more acidic than the corresponding function in HAc4DH; a similar, but smaller, decrease occurs for nitrogen in pyridine rings. When the acetyl group is compared to an aldehyde group, the latter compound is the more acidic. However, solutions of thiosemicarbazones derived from 2-acetylpyridine have been shown by NMR studies to have different mixtures of isomers and tautomers depending on the solvent so that a direct comparison is not always possible.

Abstract—*endo*-8-Camphanylphosphinic acid [(2,2-dimethylbicyclo [2.2.1] hept-3-ylmethyl)phosphinic acid] $camPO_2H_2$ **1** is readily oxidised to the corresponding phosphonic acid $camPO_3H_2$ **2**, the preferred reagent being SO_2 in refluxing isopropanol. Methylation of the phosphonic acid **1** with diazomethane yields the methyl ester $camPO_3Me_2$ **4**. Oxidative chlorination of $camPO_2H_2$ with $SOCl_2$ produces the phosphonic dichloride $camP(O)Cl_2$ **3**, which gives the tertiary phosphine oxide $camP(O)Ph_2$ **5** on reaction with PhMgBr. The phosphonate ester **4** and phosphine oxide **5** readily form complexes **6** and **7** respectively with uranyl nitrate. The phosphonate complex **6** has been subjected to a single-crystal X-ray diffraction study. The structure determination was not straightforward, largely as a result of the combination of a dominant scattering atom (uranium) and substantial disorder of the camphanyl groups. © 1998 Elsevier Science Ltd. Keywords: phosphonate; uranyl nitrate complex; crystal structure; camphene

Compounds containing the phosphoryl (P═O) group are known to possess excellent ligand properties towards a wide range of metal centres, and the coordination chemistry of these ligands has been extensively studied [1]. Additionally, extractants containing P═O groups have also been used for many years in industrial solvent extraction (hydrometallurgical) processes for the recovery and purification of a range of metal ions [2]. Metal extractants are characteristically highly lipophilic in nature, and this property is readily conferred by the use of large, often branched, hydrocarbon moieties, such as the inexpensive 2-ethylhexyl or 2,4,4-trimethylpentyl groups [3]. Branched hydrocarbon substituents are also known to impart selectivity in metal-ion separation processes by increasing steric crowding at the metal centre [3, 4].

Recently we reported the synthesis of (2,2-dimethylbicyclo [2.2.1] hept-3-ylmethyl)phosphinic acid (*endo*-8-camphanylphosphinic acid, $camPO_2H_2$) **1**, by radical-catalysed addition of hypophosphorous acid to camphene [5, 6] and subsequently considered that the bulky, lipophilic camphanyl group might be utilisable in the synthesis of new types of organophosphorus metal extractants. Here we describe the synthesis of a number of new camphene-derived phosphorylic model ligands, together with a preliminary study of their coordination chemistry towards uranyl nitrate. Phosphorylic compounds such as trioctylphosphine oxide and tributyl phosphate are widely utilised in uranium extraction [2]. The structure of one uranyl nitrate complex is also reported.

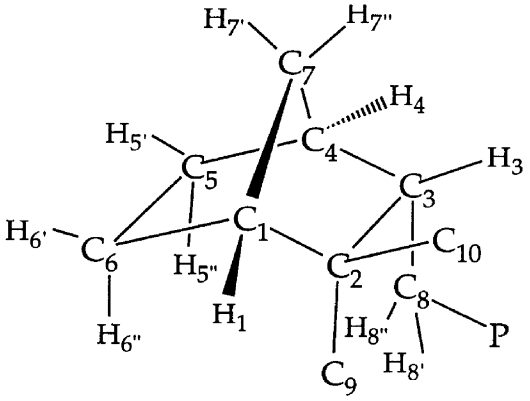
RESULTS AND DISCUSSION

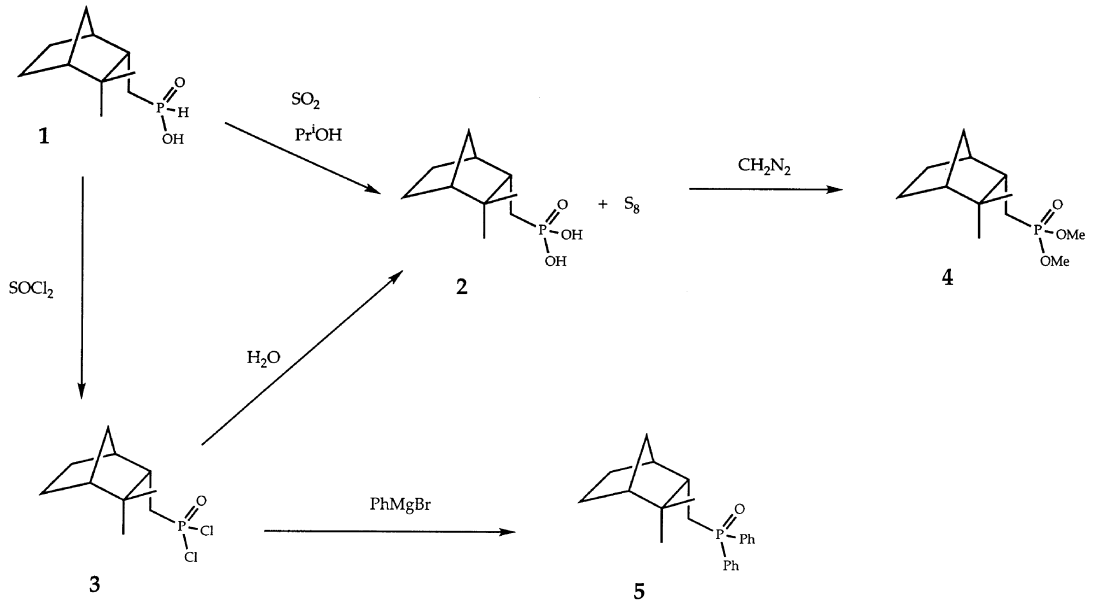
Ligand synthesis and characterisation

As an initial entry into the coordination chemistry of camphene-derived organophosphorus ligands, we have employed the readily-prepared *endo*-8-camphanylphosphinic acid **1** as a starting material. This is very conveniently oxidised to the corresponding phosphonic acid **2** by the use of sulfur dioxide in refluxing isopropanol, Scheme 1 [5]. In this case, the byproduct, elemental sulfur, is readily removed by simple filtration. Copper(II) nitrate in refluxing methanol also oxidises **1** to **2**, producing metallic copper as a byproduct. Alternatively, reaction of **1** with excess thionyl chloride results in oxidative chlorination, giving 8-camphanylphosphonic dichloride camP(O)Cl_2 **3**, which can subsequently be hydrolysed (by refluxing in water) to the phosphonic acid, Scheme 1. Alkaline hydrogen peroxide and concentrated nitric acid were both found to be ineffective for the oxidation of **1**.

The phosphonic acid **2** has been thoroughly characterised by ^{1}H, ^{13}C and ^{31}P NMR spectroscopy. The ^{31}P NMR chemical shift of **2** (D_2O with added NaOH, $\delta = 23.8$) compares well with other phosphonic acids, for example δ 24.8 for $MePO_3H_2$ [7]. The ^{1}H and ^{13}C-$\{^{1}H\}$ NMR spectra have been fully assigned by ^{1}H-^{1}H and ^{1}H-^{13}C COSY and nOe-difference experiments, and by comparison with the spectra of **1**; Scheme 2 shows the atom numbering scheme. The ^{1}H and COSY45 NMR spectra of camphylphosphonic acid **2** are very similar to those of the precursor phosphinic acid **1**. Consequently, resonances H_4, H_3, H_1, $H_{7''}$, $H_{5''}$, $H_{8',8''}$ and $H_{7'}$ are readily identifiable, and a complete assignment of the COSY45 spectrum is straightforward. The positions of the *exo*/*endo* protons $H_{5'}$ and $H_{5''}$ were sufficiently separated to be distinguished. The assignment results from the observation of couplings from H_4 to $H_{5'}$ (but not to $H_{5''}$), H_3 to $H_{5'}$ (but not to $H_{5''}$), and $H_{7''}$ to $H_{5''}$ (but not to $H_{5'}$) and is confirmed by the presence of an nOe from Me″ to $H_{5''}$. The other nOe enhancements are consistent with the structure shown in Scheme 2. nOe enhancements are observed from Me′ to H_3 and $H_{7''}$, and from Me″ to $H_{8',8''}$, $H_{6''}$, and $H_{5''}$, proving that the $-CH_2PO_3H_2$ group is *endo*. The negative-ion electrospray masss spectrum of **2** yielded the $[M\text{-}H]^-$ ion at m/z 217; the electrospray mass spectrometric analysis of organophosphorus acids has been described previously [8].



Scheme 2. Atom numbering scheme for the camphanyl-phosphorus moiety of compounds reported in this paper.



Scheme 1. Synthesis of the camphanyl organophosphorus compounds.

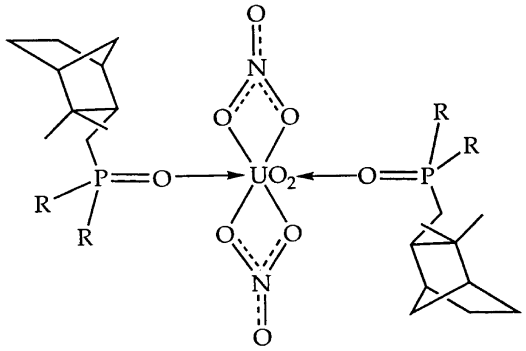
Camphanylphosphonic acid **2** was converted to its dimethyl ester $camPO_3Me_2$ **4** by treatment with excess diazomethane in diethyl ether, Scheme 1. Diazomethane is a convenient and well-known laboratory reagent for conversion of acids to their methyl esters, on a small scale, and was thus employed in this study so that the coordination chemistry of the esters could be investigated. The ester **3**, a colourless oil, was subsequently characterised by NMR spectroscopy and GCMS. The camphene-derived phosphine oxide ligand, $camP(O)Ph_2$ **5** was also synthesised in 75% yield by reaction of **3** with a slight excess of PhMgBr. Compound **5** shows the expected behaviour [9] for a phosphine oxide in the positive-ion electrospray mass spectrum with added KCl, yielding a range of ions of the form $[n(\mathbf{5})+\text{cation}]^+$ ($n = 1$–3, cation = H or K).

Synthesis of uranyl nitrate complexes

A wide range of uranyl(VI) nitrate complexes of the type $UO_2(NO_3)_2L_2$ has been previously prepared by the simple combination of the precursors uranyl(VI) nitrate and the phosphorylic compound (L) in an appropriate solvent, such as ethanol [10]. Similarly, the slow evaporation of a methanolic solution of the phosphonate **4** and uranyl nitrate in a 2:1 molar ratio deposits yellow crystals of the adduct **6**. An analogous complex **7** was obtained from a mixture of the phosphine oxide **5** and uranyl nitrate. Satisfactory microanalytical data were obtained for both complexes. The IR spectrum of **6** showed a U=O stretch at 933 cm^{-1}, similar to the values in other *trans*-uranyl complexes [10, 11] while the Raman spectrum showed a band at 854 cm^{-1}.

X-ray structure determination on the uranyl-phosphonate complex ***6***

A single-crystal X-ray diffraction study was carried out on complex 6. Because of disorder in the camphanyl groups, the presence of a dominant scatterer, and possible space group ambiguity the structure determination was of low quality, but does confirm the *trans* UO_2 isomer of $[UO_2(NO_3)_2(\mathbf{4})_2]$, as expected from the large number of *trans*-uranyl complexes reported in the literature [12]. Figure 1 shows the geometry of the *trans*-isomer of **6**, with some bond parameters included in the caption.



EXPERIMENTAL

^1H and ^{13}C-$\{^1H\}$ NMR spectra were recorded on a Bruker AC300P spectrometer, at 300.13 and 75.47 MHz respectively, in $CDCl_3$ (unless otherwise stated). Chemical shifts are reported relative to $CHCl_3$ (δ ^1H 7.26 and δ ^{13}C 77.06). NMR spectra of the camphene-derived ligands were fully assigned by ^1H-^1H and ^1H-^{13}C COSY and nOe-difference experiments. ^1H-^1H and ^{13}C-^1H COSY spectra were determined in absolute value mode using Bruker-supplied pulse programmes. nOe-difference spectra were obtained by subtracting a reference FID from an irradiated FID, and Fourier transforming the resulting difference-FID. ^{31}P-$\{^1H\}$ NMR spectra were recorded in CH_2Cl_2 solution on a JEOL FX90Q spectrometer at 36.23 MHz, with 85% H_3PO_4 (δ 0.0) as external reference, and a glass capillary containing D_2O used to provide a lock signal. Scheme 2 shows the atom numbering scheme for the camphanyl-phosphorus moiety.

IR spectra were recorded as KBr disks (unless otherwise specified) on a BioRad FTS-40 spectrometer. Raman spectra were recorded on powdered material contained in a glass capillary using a SPEX 1403 Ramalog spectrometer with a He/Ne laser. Melting points were recorded on a Reichert Hotstage apparatus and are uncorrected. Electrospray (ES) mass spectra were recorded on a VG Platform II instrument, with MeCN–H_2O (1:1 v/v) as the mobile phase. Nitrogen was employed as both the nebulising and drying gas, and the source temperature was 60°C. GCMS data were recorded on a HP 5890 GC interfaced to a HP 5970B mass selective detector (MSD) operated in scanning mode. A 25 m HP-1 (methyl silicone) capillary column (o.d. 0.22 mm) was used.

endo-8-Camphanylphosphinic acid **1** [5, 6] and diazomethane [13] were prepared as described previously. Uranyl nitrate hexahydrate and sulfur dioxide (BDH) were used as supplied. All solvents used in this work were of reagent grade.

Synthesis of endo-8-*camphanylphosphonic acid* ***2*** *by direct oxidation using* SO_2

endo-8-camphanylphosphinic acid **1** (77.4 g, 0.38 mol) was dissolved in a mixture of isopropanol (500 mL) and water (100 mL), the solution heated to reflux, and sulfur dioxide bubbled through for 4 hr. The reaction mixture was cooled and purged with nitrogen for 30 min. Sulfur was removed by filtration through a celite bed, and subsequent removal of most of the solvent by rotary evaporation gave *endo*-8-camphanylphosphonic acid **2** as a white crystalline solid

Synthesis of ***2*** *by oxidation with* $Cu(NO_3)_2$

Phosphinic acid **1** (2.0 g, 9.9 mmol) and $Cu(NO_3)_2{\cdot}3H_2O$ (2.39 g, 9.8 mmol) were dissolved in a mixture of methanol (70 mL) and water (10 mL). The reaction mixture was refluxed for 4.5 h, cooled and a brown precipitate (metallic Cu) was removed by filtration. Removal of the solvent by rotary evaporation gave a white solid which was found to be 8-camphanylphosphonic acid **2** (85% yield) by ^{31}P NMR spectroscopy and melting point determination.

Synthesis of $camP(O)Cl_2$ ***3***

Thionyl chloride (40 mL) was added to **1** (1.67 g, 8.2 mmol). Pyridine (10 drops) was added and the resulting yellow solution refluxed for 7.5 h. Removal of the volatiles under reduced pressure gave a light yellow oil (1.88 g, 90%). (Found: C, 47.9; H, 7.0% $C_{10}H_{17}P(O)Cl_2$ requires C, 47.2; H, 6.7%). GCMS *m/z* 254, 256 (M^+, 16% for *m/z* 254 ion). ^{31}P-$\{^1H\}$ NMR, δ 51.6 (*s*). ^1H NMR δ 2.54 (1H, *m*, *br*, $H_{8'}/H_{8''}$), 2.49 (1H, *m*, *br*, $H_{8'}/H_{8''}$), 2.34 (1H, *s*, *br*, H_4), 1.93 (1H, *m*, *br*, H_3), 1.71 (1H, *s*, *br*, H_1), 1.59 (1H, *d*, *J* 10.1, $H_{7''}$), 1.46 (2H, *m*, *br*, $H_{6''}$), 1.36 (1H, *m*, *br*, $H_{5'}$), 1.31 (1H, *m*, *br*, $H_{5''}$), 1.21 (1H, *d*, *J* 4.8, $H_{6'}$), 1.15 (1H, *d*, *J* 10.1, $H_{7'}$), 0.91 (3H, *s*, Me′), and 0.74 (3H, *s*, Me″). ^{13}C-$\{^1H\}$ NMR, δ 48.3 (*s*, C_1), 45.1 (*d*, *J* 6.5, C_3), 41.9 (*d*, *J* 5.2, C_4), 41.85 (*d*, *J* 95.7, C_8), 38.2 (*d*, *J* 17.5, C_2), 37.0 (*s*, C_7), 31.6 (*s*, C_{10}), 24.5 (*s*, C_6), 21.9 (*s*, C_9), and 20.3 (*s*, C_5).

*Synthesis of **2** by hydrolysis of **3***

To camP(O)Cl_2 **3** (0.36 g, 1.41 mmol) was added water (30 mL) and the resulting yellow solution refluxed for 6 h. The white solid which precipitated was filtered off and found to be **2** (0.24 g, 80%) by ^{31}P NMR and melting point.

Synthesis of dimethyl endo-8-*camphanylphosphonate **4***

An excess of a diethyl ether solution of diazomethane was added to **2** (0.29 g, 1.3 mmol) and the resulting solution stoppered. After 24 h the volatiles were removed under vacuum yielding **4** as a colourless oil (0.30 g, 98%). GCMS *m/z* 246 (M^+, 21%). ^{31}P-$\{^1H\}$ NMR, δ 35.8 (*s*). ^{1}H NMR, δ 3.67 [3H, *d*, OMe, J(PH) 12], 2.26 (1H, *br*, *s*, H_4), 1.73 (1H, *br*, *m*, H_3)$_a$, 1.72 (1H, *br*, *s*, H_1)$_a$, 1.72–1.66 (2H, *m*, $H_{8'/8''}$)$_b$, 1.62 (1H, *d*, ^2J 9.7, $H_{7''}$)$_a$, 1.49 (1H, *br*, *m*, $H_{6''}$), 1.31–1.20 (2H, $H_{5''/5'}$)$_b$, 1.23 (1H, *br*, *m*, $H_{6'}$)$_b$, 1.15 (1H, *d*, ^2J 9.7, $H_{7'}$), 0.92 (3H, *s*, Me′); 0.74 (3H, *s*, Me″). [a: partially overlapping signals; b: overlapping signals]

^{13}C-$\{^1H\}$ NMR, δ 52.2 [*d*, ^2J (P,C) 6.8, OMe], 52.1 [*d*, ^2J (P,C) 6.8, OMe], 48.6 (*s*, C_1), 44.3 [*d*, ^2J (P,C) 3.7, C_3], 42.3 [*d*, ^3J (P,C) 3.9, C_4], 37.5 [*d*, ^3J (P,C) 14.3, C_2], 36.9 (*s*, C_7), 31.8 (*s*, C_{10}), 24.6 (*s*, C_6), 22.0 [*d*, ^1J (P,C) 140.1, C_8], 21.9 (*s*, C_9), 20.0 (*s*, C_5). Raman: υ(P═O) 924 cm^{-1} (s).

The phosphonate **4** was found to contain a small amount of **2**, presumably produced by the hydrolysis of **4** in air, since an excess of diazomethane was employed in the synthesis. Despite several attempts to purify this methyl ester by vacuum distillation (140°C at 0.5 mmHg) and vacuum sealing a sample for elemental analysis, satisfactory microanalytical data were not obtainable.

Synthesis of 8-*camphanyldiphenylphosphine oxide **5***

To a solution of PhMgBr (0.022 mol) in dry ether (60 mL) was added, under a nitrogen atmosphere, camP(O)Cl_2 **3** (2.94 g, 0.01 mole), and a brown oil separated. After 24 h the supernatant was removed and the residue dissolved in $CHCl_3$ (200 mL). The organic layer was washed with 10% HCl (100 mL), dried over $MgSO_4$ and evaporated to dryness to give a cream solid. This was recrystallised from hot methanol to give a colourless crystalline solid **5** (2.92 g, 75%), m.p. 171.5–173.0°C. Found: C, 77.8; H, 8.0% $C_{22}H_{27}OP$ requires C, 78.1; H, 8.1%. ESMS (positive-ion, cone voltage 80 V, with added KCl); $[M+H]^+$ (*m/z* 339), $[M+K]^+$ (*m/z* 377), $[2M+H]^+$ (*m/z* 677), $[2M+K]^+$ (*m/z* 715), and $[3M+K]^+$ (*m/z* 1053). ^{31}P-$\{^1H\}$ NMR, δ 31.4 (*s*). ^{1}H NMR, δ 7.77–7.38 (10H, *m*, 2 × Ph)$_b$, 2.22 (2H, *br*, *m*, $H_{8'/8''}$)$_b$, 2.02 (1H, *br*, *s*, H_4), 1.87 (1H, *br*, *m*, H_3), 1.69 (1H, *br*, *s*, H_1), 1.50 [1H, *d*, ^2J 9.8, $H_{7''}$]$_b$, 1.49 (1H, *br*, *m*, $H_{6''}$)$_b$, 1.21 (1H, *m*, $H_{5''}$)$_b$, 1.15 (1H, *m*, $H_{6'}$)$_b$, 1.08 (1H, *m*, $H_{5'}$)$_b$, 1.04 (1H, *d*, ^2J 9.7, $H_{7'}$)$_a$, 0.85 (3H, *s*, Me′), 0.81 (3H, *s*, Me″). ^{13}C-$\{^1H\}$ NMR, δ 131.5-128.4 (*m*, Ph), 48.4 (*s*, C_1), 44.0 [*d*, ^2J (P,C) 4.0, C_3], 42.3 [*d*, ^3J (P,C) 3.1, C_4], 37.8 [*d*, ^3J (P,C) 10.7, C_2], 37.0 (*s*, C_7), 31.6 (*s*, C_{10}), 27.3 [*d*, ^1J (P,C) 62.6, C_8], 24.7 (*s*, C_6), 22.4 (*s*, C_9), and 20.3 (*s*, C_5). [a: partially overlapping signals; b: overlapping signals]

Synthesis of $[UO_2(NO_3)_2(camPO_3Me_2)_2]$ ***6***

Phosphonate **4** (0.50 g, 2.03 mmol) and uranyl nitrate hexahydrate (0.512 g, 1.02 mmol) were dissolved in methanol (20 mL). Spontaneous evaporation to dryness at room temperature gave **6** as a yellow crystalline solid in quantitative yield, m.p. 107–111°C. Found: C, 32.5; H, 5.3; N, 3.3% $C_{24}H_{42}N_2O_{14}P_2U$ requires C, 32.6; H, 4.8; N, 3.2%. ^{31}P-$\{^1H\}$ NMR, δ 42.0 (*s*). ^{1}H NMR, δ 4.12 [*d*, 6H, OMe, $J_{(PH)}$ 11], 4.11 [*d*, 6H, OMe, J(PH) 11], 2.35 (1H, *s*, *br*, H_4)$_b$, 2.04 (1H, *m*, H_3), 2.30 (2H, *m*, $H_{8'}/H_{8''}$)$_b$, 1.75 (1H, *m*, H_1), 1.55 (1H, *d*, ^2J 9.5, $H_{7''}$)$_a$, 1.55 (1H, *m*, $H_{6''}$)$_b$, 1.43–1.20 (3H, *m*, $H_{5''}$, $H_{5'}$, $H_{6'}$)$_b$, 1.14 (1H, *d*, ^2J 9.5, $H_{7'}$), 0.94 (3H, *s*, Me′), and 0.85 (3H, *s*, Me″). [a: partially overlapping signals; b: overlapping signals] IR ν(P═O) 933 cm^{-1}.

Synthesis of $[UO_2(NO_3)_2\{camP(O)Ph_2\}_2]$ *7*

Phosphine oxide **5** (0.10 g, 0.29 mmol) and uranyl nitrate hexahydrate (0.075 g, 0.15 mmol) were dissolved in hot methanol (50 mL) and the resulting solution allowed to spontaneously evaporate at room temperature. After 3 days yellow microcrystalline **7** (0.18 g, 60%) precipitated out of solution, m.p. 226–245°C. Found: C, 49.0; H, 5.1; N, 2.5%. $C_{44}H_{54}N_2O_{10}P_2U$ requires C, 49.3; H, 5.1; N, 2.6%.

*Crystal structure determination of the uranyl nitrate-phosphonate complex **6***

Cell parameters and intensity data were collected by ω-scans on a Siemens P4 diffractometer with Mo-Kα radiation ($\lambda = 0.7107$ Å) at −143°C. The structure was solved by Patterson methods in space group C2/c (although the alternative Cc could not be excluded) and slowly developed. The camphanyl groups were difficult to define accurately because of disorder.

Refinement was full-matrix least-squares based on F^2, with all non-hydrogen atoms anisotropic, using the SHELXS86 [14] and SHELXL93 [15] programs.

Crystal Data: $C_{24}H_{46}N_2O_{14}P_2U$, M 886.60, monoclinic, C2/c, *a* 26.739(2), *b* 8.137(2), *c* 19.782(2) Å, β 127.90(2)°, U 3396.4(9) Å^3, D_c 1.734 g cm^{-3} for $Z=4$, $F(000)$ 1752, μ(Mo-Kα) 4.937 mm^{-1}. Crystal size $0.48\times0.14\times0.08$ mm. A total of 2552 data were collected, 2219 unique (R_{int} 0.0757), 1103 with $I>2\sigma(I)$, corrected for absorption based on ψ-scans.

Refinement converged with R_1 0.0723 (2σ-data), R_1 0.1486, wR_2 0.1621, GoF 0.902 (all data), no final feature $>|1.6|$e Å^{-3}. The low proportion of 'observed' reflections, and the high R_1 figure for all data, can be attributed to the occupation of a special position by the U atom, leading to the $k+l=$ odd class of reflection being systematically weak.

(Received 29 October 1997; accepted 22 April 1998)

Abstract—Reaction of bis(pyridine-2-thiolato-N,S)platinum(II) (**1**) in acetonitrile (obtained from $PtCl_2$ and $Na^+C_5H_4NS^-$) with two equivalents of PPh_3 forms monomeric $Pt(C_5H_4NS)_2(PPh_3)_2$ (**2**) whose X-ray structure has been determined. It crystallises from a acetonitrile–chloroform mixture and exists as a centrosymmetric square planar monomer. Pyridine-2-thiolate binds to Pt via S-atoms in a *trans*-configuration and the other two positions are occupied by P atoms of PPh_3. The interatomic important parameters are: Pt–S = 2.343(2), Pt–P = 2.3147(13), C–S = 1.739(6) Å, bond angles P–Pt–P* and S–Pt–S* each = 180.0°, P–Pt–S, P*–Pt–S = 85.24° (acute) and P–Pt–S*, P*–Pt–S = 94.76° (obtuse). It represents the first example of a structurally characterised S-bonded pyridine-2-thiolato Pt(II) complex. The NMR data (^1H, ^{13}C, ^{31}P) suggest dissociation of **2** in $CDCl_3$ as follows: $Pt(C_5H_4NS)_2(PPh_3)_2$ (**2**)→$Pt(C_5H_4NS)_2(PPh_3)$ (**2a**)+PPh_3. Both N,S- and S-bonded $C_5H_4NS^-$ moieties are confirmed from ^1H and ^{13}C NMR. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

In recent years, there is an upsurge in coordination chemistry of heterocyclic thiones containing chemically active chromophores of the type: –N(H)–C(=S)↔–N=C(–SH), because these ligands provide several possibilities of metal–ligand interactions and have biochemical implications [1–4]. Pyridine-2-thione(C_5H_5NS), the simplest prototype of heterocyclic thiones binds to a metal center in several ways: S-bonding(η^1), S-bridging(η^2), N,S-chelating(η^2), N,S-bridging(η^2), N,S-chelating-cum-S-bridging(η^3) and N,S-bridging-cum-S-bridging(η^3) [4–13]. For structurally characterised Pt(II or III) complexes, N,S-bridging is observed in $[Pt_2(en)_2(\mu\text{-N,S-}C_5H_4NS)_2]Cl_2{\cdot}3H_2O$ [14], $[Pt_2\{\mu\text{-N,S-}C_5H_3(4\text{-}CH_3)NS\}_2]$[15], $[Pt_2Cl_2(\mu\text{-N,S-}C_5H_4NS)_4]{\cdot}2CHCl_3$ [15], and chelation in $[Pt(\eta^2\text{-N,S-}C_5H_4NS)(PPh_3)_2](PF_6)$ [16].

As a part of our interest in coordination chemistry of C_5H_5NS or its derivatives [17–19], we report the crystal structure of $[Pt(C_5H_4NS)_2(PPh_3)_2]$ (**2**) which represents the first example of a platinum(II) complex containing monodentate S-bonded $C_5H_4NS^-$ moiety. The solid state behaviour of **2** is compared with its solution phase behaviour. In literature [20], $C_5H_4NS^-$ ligand scrambling in $Pt(C_5H_4NS)_2(PPh_3)$ has been mentioned. In this investigation, we establish both N,S- and S-bonding modes for the species [**2a**, $Pt(\eta^2\text{-N,S–}C_5H_4NS)(\eta^1\text{-S–}C_5H_4NS)(PPh_3)$] in $CHCl_3$ using multinuclear NMR (^1H, ^{13}C and ^{31}P) spectroscopy and collecting massive scans for ^{13}C NMR spectrum.

EXPERIMENTAL

General materials

Platinum(II) dichloride was procured from M/s Central Drug House Pvt (Bombay) while PPh_3 from Spectrochem. Pvt. (Bombay). 2-Hydroxypyridine was procured from M/s Sisco, Bombay. Pyridine-2-thione-(C_5H_5NS) was prepared as described previously [21, 22]. Sodium salt, $Na^+C_5H_4NS^-$ was prepared as described [17] for $Na^+C_5H_4NOS^-$. Acetonitrile was dried over P_2O_5 and other solvents dried by usual methods.

Preparation of $Pt(C_5H_4NS)_2$ (*I*) *and* $Pt(C_5H_4NS)_2(PPh_3)_2$ (*2*)

$Pt(C_5H_4NS)_2$ (**1**, yellow) was prepared from the stoichiometric reaction of $PtCl_2$ (0.186 g, 0.70 mmol) with C_5H_4NSNa (0.205 g, 1.54 mmol) in CH_3CN (25 cm^3) under reflux for *ca.* 20 h. The concentration of the solution under vacuum formed a yellow coloured solid which was treated with water to remove NaCl, recrystallised from CH_3CN and dried *in vacuo*. Yield, 40%, m.p. (°C) > 250, analytical data (%), found C, 30.4, H, 2.13, N, 6.95; required for $C_{10}H_8N_2S_2Pt$, C, 29.0, H, 1.93, N, 6.75, *IR* data (cm^{-1}), 1137s (νC═S), 426s (νPt–S), 254m (νPt–N).

$Pt(\eta^1\text{-S–}C_5H_4NS)_2(PPh_3)_2$ (**2**, yellow) was prepared by the addition of PPh_3 (0.160 g, 0.613 mmol) to $Pt(C_5H_4NS)_2$ (0.127 g, 0.306 mmol) in CH_3CN (20 cm^3) with magnetic stirring under reflux for 2 h. The excess solvent was removed under vacuum to get a yellow solid which was purified using diethylether and recrystallised from CH_3CN. Yield, 60%, m.p. (°C), 140–45, analytical data found (%), C, 58.2, H, 3.62, N, 3.02, required for $C_{46}H_{38}N_2P_2S_2$ Pt, C, 58.8, H, 4.04, N, 3.00, *IR data* (cm^{-1}), 1110s (νC═S), 430m (νPt–S).

Physical measurements

The elemental analysis for C, H and N were obtained using a Carlo-Erba 1108 microanalyser or from RSIC Chandigarh. The melting points were determined with a Gallenkamp electrically heated apparatus. The NMR spectra were recorded in $CDCl_3$ using, (i) Bruker AMX 300 spectrometer at 300.14 and 75.48 MHz probe frequencies for (^1H and ^{13}C resonances, respectively, with TMS as the internal reference) and (ii) Bruker AMX 500 spectrometer at 202.45 MHz probe frequency for $^{31}P\{^1H\}$ resonance with 85% H_3PO_4 as the external reference (δP, 27.5 ppm).

X-ray data collection and reduction

The crystal of $Pt(C_5H_4NS)_2(PPh_3)_2$ (**2**) was mounted on a glass fiber and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least squares refinement of diffraction data from 25 reflections in the range of $10.60° < \theta < 18.04°$ in a ENRAF-NONIUS MACH3 automatic diffractometer [23]. Data were collected at 293 K using MoK radiation ($\lambda = 0.71073$ Å) and the ω scan technique and corrected for Lorentz and polarisation effects [24]. An empirical absorption correction was made [25]. A summary of crystal data, experimental details and refinement results are listed in Table 1.

Structure-solution and refinement

The structure was solved by direct methods [26] which revealed the position of all non-hydrogen atoms, and refined on F^2 by a full matrix least-squares procedure using anisotropic displacement parameters for all non-hydrogen atoms [27]. The hydrogen atoms were located in their calculated positions (C–H = 0.93–0.96 Å) and were refined using a riding model. After all shift/e.s.d ratios were less than 0.001, the refinement converged to the agreement factors listed in Table 1. The atomic scattering factors taken from International Tables for X-ray Crystallography [28] while molecular graphics were prepared using ZORTEP [29].

RESULTS AND DISCUSSION

Description of the crystal structure of $Pt(C_5H_4NS)_2(PPh_3)_2$ (*2*)

The selected interatomic parameters are given in Table 2 while Fig. 1 shows the molecular structure together with numbering scheme. The basic structural unit is a centrosymmetric monomer $Pt(C_5H_4NS)_2(PPh_3)_2$ (**2**). Two P atoms of PPh_3 molecules and two S atoms of $C_5H_4NS^-$ ligand coordinate to Pt atom in a square planar geometry with *trans* P–Pt–P* and S–Pt–S* angles of 180.0°, two acute (85.24°, P–Pt–S and P*–Pt–S*) and two obtuse (94.76°, P–Pt–S* and S–Pt–P*) angles. Chelation in *cis*-$[Pt(\eta^2\text{-N,S–}C_5H_4NS)(PPh_3)_2](PF_6)$ (**3**) causes more severe distortion as anticipated [e.g. *trans* S–Pt–P = 165.6°; N–Pt–P = 163.8(2)] [16]. It is significant that $C_5H_4NS^-$ can modulate the geometric positions of PPh_3 ligand as in **3** and **2** based on its coordination requirements. The Pt–P distance is normal but marginally longer than in **3** [Pt–P = 2.295, 2.253 Å] [16], while Pt–S distance [Pt–S = 2.348 Å] as well as P–C_{Ph} distance [1.832 Å] are nearly the same. The S–C(2) distance shows partial double bond character in the usual manner. The bite angle of S–C(2)–N(1) [120.7(5)°] is typical of monodentate $C_5H_4NS^-$ [117.6(7)°] as in $Hg(C_5H_4NS)_2$ [30] or is similar to the bridging $C_5H_4NS^-$ derivative [122–124°] in Pt(II) complexes [15]. Finally, the Pt–S–C(2) angle is also similar to the one in dimeric complexes [109.0(8)°]. **2** represents the first structurally characterised Pt(II) 3complex containing monodentate S-bonded $C_5H_4NS^-$ moiety. The steric effect due to

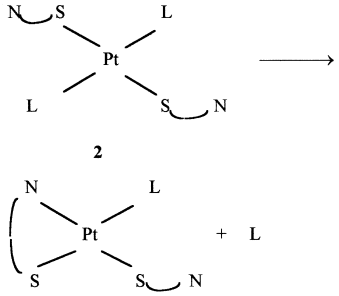
bulky PPh_3 [P–Pt–P, 97.4°] and short bite angle, S–Pt–N of 68.0° in **3** appear to favour *trans*-PPh_3 and S-bonded $C_5H_4NS^-$ in **2**.

NMR spectral studies

Table 3 contains NMR data (^1H, ^{13}C, ^{31}P) for the compounds. The ^{31}P NMR spectrum of **2** (Fig. 2) shows the presence of dissociated PPh_3 in $CDCl_3$ solution according to the equation below.



The NMR spectrum shows that dissociation is not complete, but is considerable. This means that probably **2** and **2a** are in equilibrium, however, there was no evidence for dissociation of both PPh_3 molecules. Since crystals of **2** were grown from CH_3CN, it is possible that this solvent may be acting as a stabiliser of Pt–PPh_3 bonding and as shown by ^{31}P NMR, **2** dissociates in $CHCl_3$ forming **2a** species. The lack of dissociation of **2** in CH_3CN could be attributed to the coordinating properties of CH_3CN presumably along axial sites. Alternatively CH_3CN could interact with the pendant pyridyl group via hydrogen bonding or via delocalised π-electrons on the CN group. This presumably keeps $C_5H_4NS^-$ moiety in S-bonded form with pendant pyridyl group. In contrast, in $CHCl_3$, this stabilisation of the pendant pyridyl group is not available and so it coordinates to Pt(II). It must be emphasised that due to bulky PPh_3 groups with pendant pyridyl groups in *trans* positions, the stereochemical requirements about the Pt(II) center favour dissociation of a PPh_3 group along with chelation by NS-donor set. Low field coordination shift ($\Delta\delta$P, 12.5 ppm) with $^1J_{P-Pt}$ coupling constant of 3866 Hz confirms the coordination of PPh_3 to the Pt metal center.

The absence of ^1H NMR signals due to NH in **1**

and **2** confirms that in these compounds anionic $C_5H_4NS^-$ is coordinating to the Pt(II) center. The H(6) proton shows low-field shift relative to free C_5H_5NS in **1** and **2**. The coordination of PPh_3 to Pt(II) leads to a relative up-field shift in **2**. Further, two sets of H(6) proton (and for other protons) shows evidence for both N,S-chelated and S-bonded $C_5H_4NS^-$ moieties in **2a**. Since H(6), in the vicinity of nitrogen, is most sensitive to the coordination changes, the up-field shifts clearly support de-ligation of M–N bond in **2a**. Further, the fact that H(6) proton of N,S-chelated C_5H_4NS (set I) is still up field relative to that of **1**; it reveals increased Pt–N back-bonding when PPh_3 coordinates. De-ligation of Pt–N bond (set II) leads to increased aromaticity, an usual observation in metal–pyridine thiol chemistry [31].

The H(4) proton remains nearly unaffected (**1**; **2a**, set I) when $C_5H_4NS^-$ is N,S-bonded, but moves up-field when it is S-bonded only (**2**,**2a**; set II). H(3) protons also is significantly up-field when $C_5H_4NS^-$ is S-bonded only but is mildly up-field when it is N,S-bonded and finally H(5) protons are also up-field when $C_5H_4NS^-$ is S-bonded only and down-field for N,S-bonded moiety.

^{13}C NMR spectrum of **2** shows unambiguous evidence for N,S-bonded (**2a**, set I, Table 3) and S-bonded (**2**,**2a**, set II) $C_5H_4NS^-$ moieties. All pyridyl carbons except C(5) show low-field shifts (relative to free C_5H_5NS) for N,S-bonded $C_5H_4NS^-$ moiety (**2a**, set I) [31]. The upfield shift in C(2) signal with reduced shifts in positions of C(6) supports the presence of S-bonded $C_5H_4NS^-$ moiety (**2**,**2a**, set II) [31].

(Received 28 January 1998 ; accepted 24 April 1998)

Abstract—The reaction of Mo═Mo doubly-bonded $(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_2(\mu\text{-}SPh)_2$ (R = MeO_2C, EtO_2C) with elemental selenium in toluene at reflux results in formation of a series of sulfur/selenium quadruply-bridged complexes *trans*/*anti*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$ (**1a**, R = MeO_2C ; **2a**, R = EtO_2C), *trans*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$ (**1b**, R = MeO_2C ; **2b**, R = EtO_2C), and *cis*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu, \eta^2:\eta^2\text{-}Se_2)(\mu\text{-}SPh)_2$ (**1c**, R = MeO_2C ; **2c**, R = EtO_2C) in 58% and 53% overall yields, respectively. The structures of all these new products have been characterized by elemental analysis, IR, ^1H NMR and MS spectroscopies, as well as for **2c** by X-ray crystallography. © 1998 Elsevier Science Ltd. Keywords: Mo═Mo double bond ; selenium ; reaction ; crystal structure.

Although group 6 metal triply-bonded complexes $(\eta^5\text{-}RC_5H_4)_2M_2(CO)_4$ (M = Cr, Mo, W) have been extensively studied [1,2], the corresponding metal–metal doubly-bonded complexes $(\eta^5\text{-}RC_5H_4)_2M_2(CO)_2(\mu\text{-}SR)_2$ are little explored so far [3,4]. On the basis of our recent work concerning this project [5] and in order to further develop the chemistry of the group 6 metal doubly-bonded complexes, we carried out reaction of $(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_2(\mu\text{-}SPh)_2$ (R = MeO_2C, EtO_2C) [6] with selenium powder in refluxing toluene. Herein we report the detailed synthetic procedures and structural characterization of six novel dimolybdenum complexes prepared by the above-mentioned reaction : *trans*/*anti*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$, *trans*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$ and *cis*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu, \eta^2:\eta^2\text{-}Se_2)(\mu\text{-}SPh)_2$ (R = MeO_2C, EtO_2C). Although sulfur/sulfur and selenium/selenium quadruply-bridged transition-metal dinuclear complexes have appeared in the literature [7], such mixed sulfur/selenium quadruply-bridged dimolybdenum complexes, to the best of our knowledge, are the first examples.

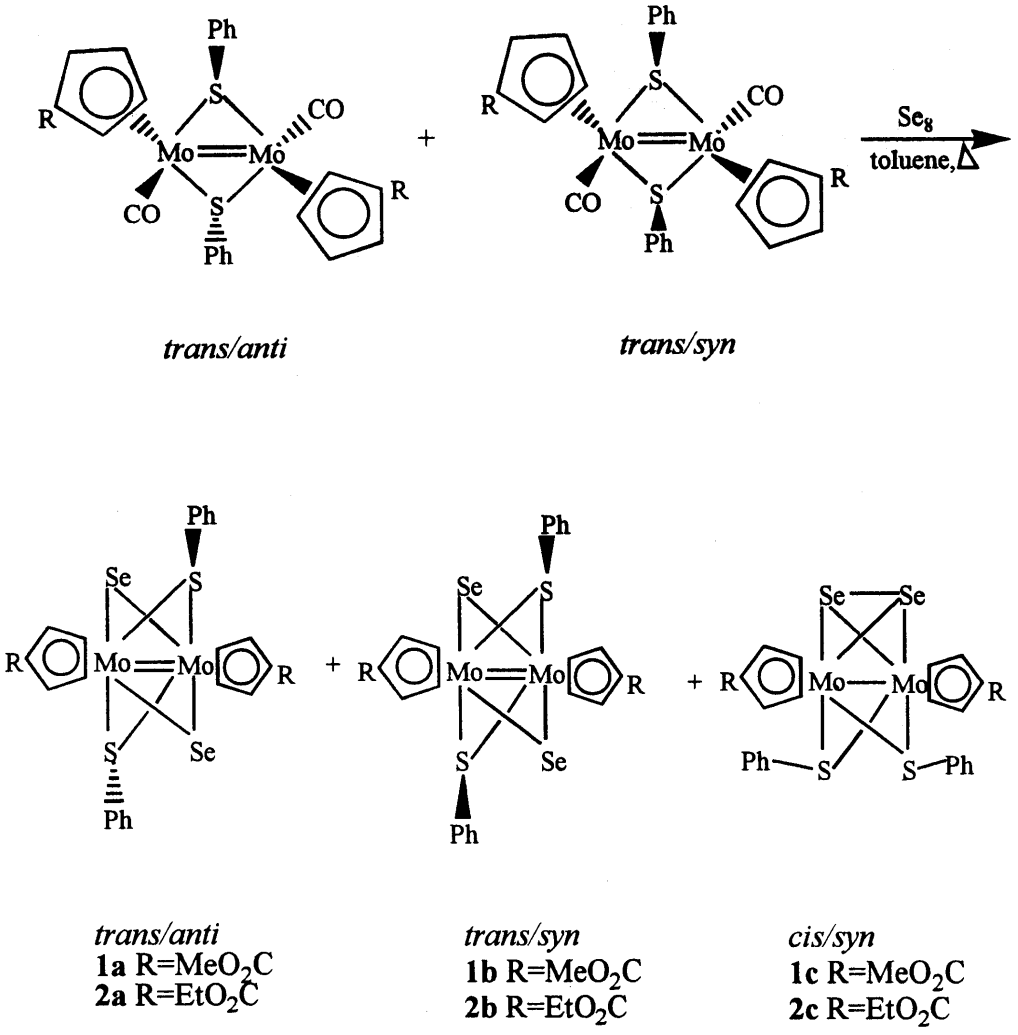
RESULTS AND DISCUSSION

It was found that reaction of Mo═Mo doubly-bonded complexes $(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_2(\mu\text{-}SPh)_2$ (R = MeO_2C, EtO_2C) [6], as a mixture of *trans*/*anti* and *trans*/*syn* isomers, with excess selenium powder in toluene at reflux for 4 h resulted in complete disappearance of the doubly-bonded starting material and in the formation of several products, as evidenced by TLC analysis. After solvent had been removed, the residue was subjected to TLC separation to give three major bands. The first blue band afforded the complexes *trans*/*anti*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$ (**1a**, R = MeO_2C ; **2a**, R = EtO_2C), the second blue band gave the complexes *trans*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu\text{-}Se)_2(\mu\text{-}SPh)_2$ (**1b**, R = MeO_2C ; **2b**, R = EtO_2C), and the third yellow band produced *cis*/*syn*-$(\eta^5\text{-}RC_5H_4)_2Mo_2(\mu, \eta^2:\eta^2\text{-}Se_2)(\mu\text{-}SPh)_2$ (**1c**, R = MeO_2C ;

2c, EtO_2C), as shown in Scheme 1. Note that the terminologies of *trans* and *cis* for complexes **1a**–**c** and **2a**—**c** refer to the relative positions of the two naked Se atoms (or the two S atoms attached to phenyl group) with respect to the Mo—Mo vector, while those of *anti* and *syn* refer to the mutual orientations of the two phenyl groups with respect to their attached planar Mo_2S_2 ring for **1a**, **b** and **2a**, **b**, and to their attached butterfly Mo_2S_2 skeleton for **1c** and **2c**. All these new complexes have been characterized by elemental analysis, IR, ^1H NMR and MS spectroscopies. The ^1H NMR spectra of **1a** and **1b** displayed one singlet at ca 3.74 ppm for their methyl groups, whereas those of **2a** and **2b** exhibited one triplet at ca 1.25 ppm and one quartet at ca 4.25 ppm for their ethyl groups. In addition, they all showed three to four multiplets in the range of 6.24–7.40 ppm for the phenyl groups and the substituted cyclopentadienyl rings. The ^1H NMR spectrum of **1c** showed one singlet at 3.57 ppm for its methyl groups, one singlet at about 7 ppm for its phenyl groups and showed two broad singlets in the range of 5.24–5.52 ppm for its substituted cyclopentadienyl rings, whereas that of **2c** showed one triplet at 1.20 ppm and one quartet at 4.18 ppm for its ethyl groups, one singlet at 7.20 ppm for its phenyl groups and two broad singlets in the range 5.40–5.72 ppm for its substituted cyclopentadienyl rings. The IR spectra of **1a**–**c** and **2a**–**c** are quite similar. Besides the bands for ester carbonyl, their IR spectra all showed weak absorption bands in the range of 200–550 cm^{-1} corresponding to the stretching vibrations of Mo—S and Mo—Se bonds. In addition, the mass spectra of **1a**, **b** and **2a**, **b** demonstrated their respective molecular ion peaks and corresponding fragment ion peaks, which are in good agreement with their formulations. According to the similar reaction of the Mo=Mo doubly bonded complex $Cp_2Mo_2(CO)_2(\mu\text{-}SMe)_2$ with elemental sulfur [8], the formation of **1a**, **b** and **2a**, **b** in this kind of reaction is not unexpected; in addition, some single



Scheme 1.

crystal structures of the compounds similar to **1a**, **b** and **2a**, **b** have been determined (see below for details). However, in this kind of reaction the formation of **1c** and **2c** is unexpected. So, in order to unambiguously confirm their structures, an X-ray diffraction analysis for **2c** was undertaken. Figures 1 and 2 represent its single crystal molecular structure and its molecular projection, respectively. Table 1 shows its selected bond distances and angles.

As seen from Figs 1 and 2 the η^5-$Et_2OCC_5H_4Mo$-$MoC_5H_4CO_2Et$-η^5 moiety is quadruply-bridged by a diselenido and two benzenethiolato ligands, and the two substituted cyclopentadienyl rings are perfectly eclipsed.

The bond distance of Se(1)—Se(2) [2.319(1) Å] in **2c** is close to that in (μ-Se_2)$Fe_2(CO)_6$ [2.293(2) Å] [9] and slightly shorter than the normal Se—Se single bond distances of 2.33(1) to 2.38(1) Å [10]. The four bridged atoms in **2c** form a plane, which is parallel to the two substituted cyclopentadienyl ring planes and

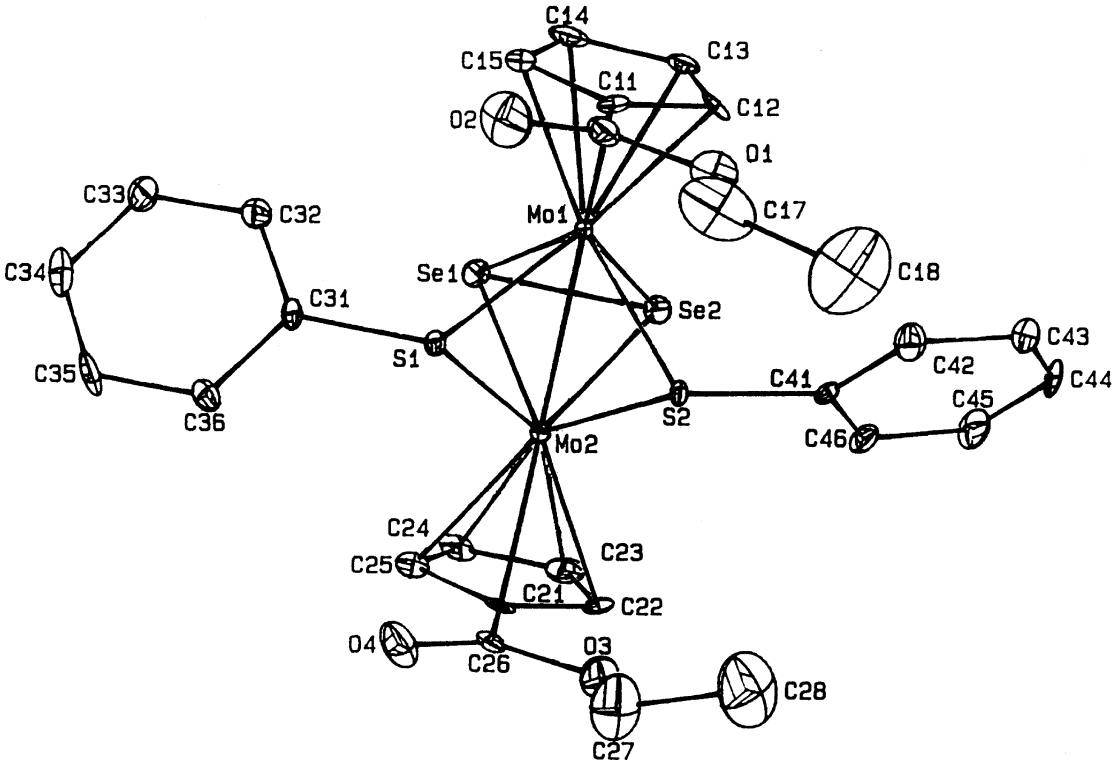


Fig. 1. ORTEP view of **2c**, drawn with 30% probability ellipsoids.

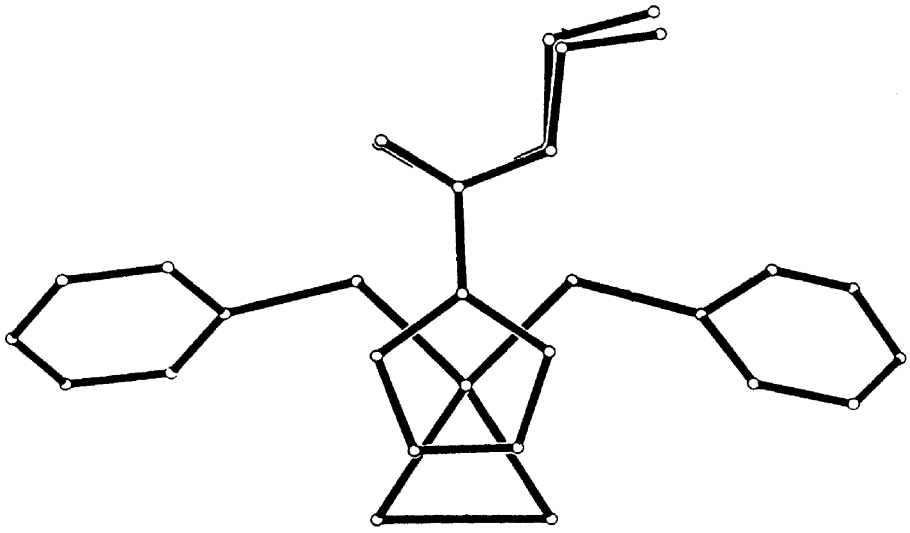

Fig. 2. The molecular projection of **2c** along its Mo—Mo bond.

Table 1. Selected bond distances (Å) and angles (°) for **2c**

Mo(1)—Mo(2)	2.661(1)	Se(1)—Se(2)	2.319(1)

Se(1)—Mo(1)—Se(2)	53.62(3)	Se(1)—Mo(2)—Mo(1)	58.81(3)
Se(1)—Mo(1)—Mo(2)	58.79(3)	Se(2)—Se(1)—Mo(2)	62.89(3)
Se(2)—Mo(1)—Mo(2)	58.50(3)	Se(2)—Se(1)—Mo(1)	62.28(3)
Mo(2)—Se(1)—Mo(1)	62.40(3)	Mo(2)—Se(2)—Mo(1)	62.48(3)
Se(1)—Se(2)—Mo(2)	63.33(3)	Mo(1)—S(1)—Mo(2)	66.47(5)
Se(1)—Se(2)—Mo(1)	63.10(3)	Mo(2)—S(2)—Mo(1)	66.41(5)

bisects the Mo—Mo vector perpendicularly. The non-bonding distances between the bridged atoms are 2.839(2), 3.324(7) and 3.332(2) Å in **2c**. These distances fall in the range of the sum of van der Waals radii of corresponding S/S, S/Se atoms, and indicate a weak interaction between the bridging atoms. Complexes **1a**, **b** and **2a**, **b** are d^2–d^2 dimers and would have a $\sigma^2\delta^2$ electronic configuration [11]. This suggests a double bond present between two Mo(+IV) atoms, which is consistent with the 18-e rule. However, **1c** and **2c** are d^3–d^3 dimers with a $\sigma^2\delta^2\delta^{*2}$ electronic configuration [11], which would suggest a single bond between two Mo(+III) atoms. The single Mo—Mo bond assignment for **1c** and **2c** is also in good agreement with the 18-e rule. It is worth noting that the Mo—Mo bond length of 2.661(1) Å in **2c** is quite short for a normal single bond due to the effect of the four bridging ligands and the oxidation states of two Mo(III) atoms [12]. Some other quadruply-bridged dimolybdenum complexes in which the single Mo—Mo bond length are very close to the Mo—Mo double bond lengths are $Cp_2Mo_2(\mu\text{-SMe})_4$ [2.603(2) Å] [11] and $Cp^*_2Mo_2Br_4$ ($Cp^* = \eta^5$-1-(2,5-dimethoxyphenyl)-2,3,4,5-tetraphenylcyclo-pentadienyl] [2.691 (4) Å] [13]. The other quadruply-bridged dimolybdenum complexes with Mo═Mo double bond are *trans*/*anti*-$(\eta^5\text{-}MeC_5H_4)_2Mo_2(\mu\text{-S})_2(\mu\text{-SMe})_2$ [2.582(1) Å] [14], *trans*/*anti*-$(\eta^5\text{-}Me_5C_5)_2Mo_2(\mu\text{-S})_2(\mu\text{-SMe})_2$ [2.573(1) Å] [15], *trans*/*syn*-$(\eta^5\text{-}^iPrC_5H_4)_2Mo_2(\mu\text{-S})_2(\mu\text{-S}^tBu)_2$ [2.587(1) Å] [16] and *trans*/*syn*-$(\eta^5\text{-}C_5H_5)_2Mo_2(\mu\text{-Se})_2(\mu\text{-SePh})_2$ [2.653(2) Å] [17].

EXPERIMENTAL

All reactions were carried out under prepurified nitrogen using vacuum-line techniques. Toluene was distilled from sodium-benzophenone ketyl. Preparative TLC was carried out on glass plates (26 × 19 cm) coated with silica gel G (10–40 μm). $(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_2(\mu\text{-SPh})_2$ (R = MeO_2C, EtO_2C) were prepared according to published method [6]. IR spectra were recorded on NICOLET MAGNA FT-750 and BIO-RAD FTS-40 infrared spectrophotometers. ^{1}H NMR spectra were recorded on a JEOL FX 90Q NMR spectrometer. C/H analyses and MS determinations were performed by a 240C analyzer and an HP 5988A spectrometer, respectively. Melting points were determined on a YANACO MP-500 micro-melting point apparatus.

Preparation of **1a**, **1b** *and* **1c**

A 100 cm^3 two-necked flask fitted with a magnetic stir-bar, a rubber septum, and a reflux condenser topped with a nitrogen inlet tube was charged with 0.400 g (0.562 mmol) of $(\eta^5\text{-}MeO_2CC_5H_4)_2Mo_2(CO)_2(\mu\text{-SPh})_2$, 0.178 g (2.254 mmol) of selenium powder and 30 cm^3 of toluene. The mixt. was refluxed for 4 h. Solvent was removed at red. pres. and the residue was subjected to preparative TLC separation using CH_2Cl_2 as eluent to give three major bands (Blue, sky-blue and yellow), from which were obtained 0.120 g (26%) of **1a**, 0.070 g (15%) of **1b** and 0.080 g (17%) of **1c**, respectively. **1a**: m.p. 243–244°C. Structure determination of **2c**

Suitable single crystals of **2c** for X-ray diffraction study were obtained by slow evaporation of a CH_2Cl_2/hexane solution. A single crystal with dimensions of $0.40 \times 0.30 \times 0.25$ mm for **2c** was mounted on a glass fibre with epoxy resin. Data collections were performed on a Enraf-Nonius CAD4 diffractometer equipped with a graphite monochromator at room temperature (23 ± 1°C). Details of its crystal parameters, data collections and structure refinements are summarized in Table 2. Lorentz and polarization corrections, and absorption correction were applied to the data. The structure was solved by the direct

(Received 21 January 1998; accepted 24 April 1998)

Abstract—Bis(pyrazolyl)methane can be synthesized by the reaction of pyrazole with dibromomethane in phase transfer catalytic conditions. It reacts with $M(CO)_6$ (M = Mo, W) to give bis(pyrazolyl)methane tetracarbonylmolybdenum(0) and tungsten(0) complexes in good yield. Upon treatment of these complexes with $RSnCl_3$ (R = Ph, Cl), the seven-coordinate Mo(II) and W(II) products were obtained. The molecular structure of $CH_2(3,5\text{-}Me_2Pz)_2W(Cl)(CO)_3(SnCl_3)$ determined by X-ray crystallography showed that the six-membered W–N–N–C–N–N metallacycle was in a boat form. © 1998 Elsevier Science Ltd. Keywords: poly(pyrazolyl)alkanes; bimetallic complexes; X-ray structure

INTRODUCTION

Although heterobimetallic complexes containing M–Sn (M = Mo, W) bonds have been studied for nearly three decades [1, 2], the synthesis and characterization of these complexes is still an active area of organometallic chemistry, because of their catalytic properties [3, 4]. Recently, many complexes containing Mo–Sn bonds have been reported [5–11]. The VIB metals carbonyl complexes bonded with poly(pyrazolyl)alkanes have novel structures and unusual reactivities [12–14], which encourage us to investigate M–Sn bimetallic complexes with poly(pyrazolyl)alkanes. To the best of our knowledge, there have been no reports on these complexes. In this paper, we describe a high yield synthesis of these complexes and the crystal structure of $CH_2(3,5\text{-}Me_2Pz)_2W(Cl)(CO)_3(SnCl_3)$.

EXPERIMENTAL DETAILS

All reactions were carried out under an argon atmosphere. All solvents were dried by standard methods. ^1H NMR spectra were recorded on JEOL FT-90X and BRUKER AC-P-200 spectrometers, IR spectra data were obtained from a Nicolet-FT IR 5DX spectrometer. Elemental analyses were carried out on a Perkin-Elmer 240C analyzer. $CH_2(3,5\text{-}Me_2Pz)_2Mo(CO)_4$ [15], $CH_2(3,5\text{-}Me_2Pz)_2W(CO)_4$ [15], $C_6H_5SnCl_3$ [16] were prepared according to the literature methods. $Mo(CO)_6$ and $W(CO)_6$ were purchased from Fluka.

Synthesis of bis(pyrazolyl)methane(CH_2Pz_2)

Into a mixed solvent of benzene (60 ml) and water (25 ml) pyrazole (0.13 mol), dibromomethane (0.065 mol), tetrabutylammonium bromide (0.75 g), and sodium hydroxide (25 g) were added. The mixture was stirred and refluxed for 48 h. After cooling to the

room temperature, the benzene layer was separated and the water phase was extracted with dichloromethane (3×40 ml). The organic layers were combined and dried by $MgSO_4$. After evaporating the solvent, the residue was washed with cooled petroleum ether (2×20 ml), sublimed *in vacuo* under 100°C. Yield: 67%. m.p 109–111°C (Ref. [17]: m.p 108–111°C).

Preparation of $CH_2Pz_2Mo(CO)_4$ and $CH_2Pz_2W(CO)_4$

A solution of $Mo(CO)_6$ (2 mmol) and CH_2Pz_2 (2 mmol) in dried heptane (40 ml) was stirred and refluxed for 4 h at an argon atmosphere, during this period a yellow precipitate formed. After cooling, the precipitate was filtered off, washed with heptane, and dried *in vacuo*. Yield: 73%.

Compound $CH_2Pz_2W(CO)_4$ was obtained by a similar method described above in octane with a refluxing time of 24 h. Yield: 40%. The analytic data of $CH_2Pz_2Mo(CO)_4$ and $CH_2Pz_2W(CO)_4$ were in accordance with that of the literature [18].

Reaction of $CH_2Pz_2M(CO)_4$ with $RSnCl_3$

Due to the fact that all reactions were similar, a general procedure was described. To a stirred solution of $CH_2Pz_2M(CO)_4$ (1 mmol) suspended in 50 ml of acetonitrile, $RSnCl_3$ (1 mmol) was added by syringe. Stirring continued at room temperature for two hours, the solution became clear. After filtering, the solution was concentrated to dryness *in vacuo*. The residue was recrystallized from dichloromethane/hexane.

$CH_2Pz_2Mo(CO)_3(Cl)SnCl_2Ph$ (**I**): Yield: 74%. Yellow solid. Anal. Found: C, 28.65; H, 2.25; N, 8.38. $C_{16}H_{13}Cl_3MoN_4O_3Sn{\cdot}CH_2Cl_2$ Calcd: C, 28.51; H, 2.10; N, 7.83%. ^{1}H NMR (CD_3COCD_3): δ 8.37(d, 2, 3-H pz); 8.28(d, 2, 5-H pz); 7.98, 7.48(m, m, 2, 3, C_6H_5); 7.28, 6.89(d, d, 1, 1, CH_2); 6.70(t, 2, 4-H pz)ppm. IR (KBr): ν(CO) 2016.0(vs), 1925.8(s), 1893.0(vs); ν(pyrazole ring) 1523.8(m) cm^{-1}.

$CH_2Pz_2W(CO)_3(Cl)SnCl_2Ph$ (**II**): Yield: 68%. Yellow solid. Anal. Found: C, 26.74; H, 1.82; N, 7.87. $C_{16}H_{13}Cl_3N_4O_3SnW$ Calcd: C, 26.74; H, 1.81; N, 7.79%. ^{1}H NMR(CD_3COCD_3): δ 8.35(d, 2, 3-H pz); 8.30(d, 2, 5-H pz); 7.90, 7.47(m, m, 2, 3, C_6H_5); 7.41, 6.85(d, d, 1, 1, CH_2); 6.71(t, 2, 4-H pz)ppm. $CH_2Pz_2Mo(CO)_3(Cl)SnCl_3$ (**III**): Yield: 76%. Red solid. Anal. Found: C, 20.51; H, 1.49; N, 9.24. $C_{10}H_8Cl_4MoN_4O_3Sn$ Calcd: C, 20.37; H, 1.36; N, 9.51%. ^{1}H NMR(CD_3COCD_3): δ 8.33(d, 2, 3-H pz); 8.18(d, 2, 5-H pz); 7.27, 6.87(d, d, 1, 1, CH_2); 6.71(t, 2, 4-H pz)ppm. IR (KBr): ν(CO) 2032.4(vs), 1950.4(sh), 1884.8(vs); ν(pyrazole ring) 1515.6(m) cm^{-1}.

$CH_2Pz_2W(CO)_3(Cl)SnCl_3$ (**IV**): Yield: 54%. Yellow solid. Anal. Found: C, 17.46; H, 1.29; N, 8.56. $C_{10}H_8Cl_4N_4O_3SnW$ Calcd: C, 17.73; H, 1.18; N, 8.67%. ^{1}H NMR (CD_3COCD_3): δ 8.36(d, 2, 3-H pz); 8.15(d, 2, 5-H pz); 7.46, 6.65(d, d, 1, 1, CH_2); 6.72(t, 2, 4-H pz)ppm. IR(KBr): ν(CO) 2024.2(vs), 1948.0(sh), 1904.4(vs); ν(pyrazole ring) 1515.6(m) cm^{-1}.

Reaction of $CH_2(3,5\text{-}Me_2Pz)_2M(CO)_4$ with $RSnCl_3$

$RSnCl_3$(1 mmol) was added to a solution of $CH_2(3,5\text{-}Me_2Pz)_2M(CO)_4$ dissolved in 20 ml of dichloromethane via syringe. The color of the solution became orange–red immediately. After stirring for an hour at room temperature, the solution was concentrated to ca. 10 ml under reduced pressure, and then 10 ml of hexane was slowly added to the solution. After standing overnight, a yellow to red microcrystalline was obtained.

$CH_2(3,5\text{-}Me_2Pz)_2Mo(CO)_3(Cl)SnCl_2Ph$ (**V**): Yield: 92%. Yellow solid. Anal. Found: C, 32.73; H, 2.79; N, 7.69. $C_{20}H_{21}Cl_3MoN_4O_3Sn{\cdot}CH_2Cl_2$ Calcd: C, 32.66; H, 2.98; N, 7.26%. ^{1}H NMR (CD_3COCD_3): δ 8.05, 7.50(m, m, 2, 3, C_6H_5); 6.64, 6.12(d, d, 1, 1, CH_2); 6.20(s, 2, 4-H pz); 2.56, 2.34(s, s, 6, 6, 3 or 5-CH_3)ppm. IR (KBr): ν(CO) 1999.6(vs), 1909.4(vs), 1837.5(sh); ν(pyrazole ring) 1556.6(m) cm^{-1}.

$CH_2(3,5\text{-}Me_2Pz)_2W(CO)_3(Cl)SnCl_2Ph$ (**VI**): Yield: 71%. Yellow solid. Anal. Found: C, 30.26; H, 2.51; N, 7.26. $C_{20}H_{12}Cl_3N_4O_3SnW{\cdot}1/2CH_2Cl_2$ Calcd: C, 30.15; H, 2.70; N, 6.86%. ^{1}H NMR(CD_3COCD_3): δ 7.78, 7.47(m, m, 2, 3, C_6H_5); 6.68, 6.23(d, d, 1, 1, CH_2); 6.26(s, 2, 4-H pz); 2.58, 2.33(s, s, 6, 6, 3 or 5-CH_3)ppm. IR(KBr): ν(CO) 1991.4(vs), 1893.0(vs), 1808.3(sh); ν(pyrazole ring) 1556.6(m) cm^{-1}.

$CH_2(3,5\text{-}Me_2Pz)_2Mo(CO)_3(Cl)SnCl_3$ (**VII**): Yield: 82%. Red solid. Anal. IR(KBr): ν(CO) 2016.0(vs), 1942.2(vs), 1917.6(vs); ν(pyrazole ring) 1556.6(m) cm^{-1}.

$CH_2(3,5\text{-}Me_2Pz)_2W(CO)_3(Cl)SnCl_3$ (**VIII**): Yield: 90%. Red solid. Anal. Found: C, 22.87; H, 2.05; N, 7.48. $C_{14}H_{16}Cl_4N_4O_3SnW$ Calcd: C, 22.92; H, 2.18; N, 7.64%. ^{1}H NMR (CD_3COCD_3): δ 6.81, 6.24(d, d, 1, 1, CH_2); 6.36(s, 2, 4-H pz); 2.63, 2.48(s, s, 6, 6, 3 or 5-CH_3)ppm. IR(KBr): ν(CO) 2032.4(vs), 1958.8(vs), 1925.8(vs); ν(pyrazole ring) 1555.6(m) cm^{-1}.

Structure determination of $CH_2(3,5\text{-}Me_2Pz)_2W(Cl)(CO)_3(SnCl_3)$

Crystals suitable for X-ray analysis were grown from dichloromethane/hexane at 4°C. Crystal data are summarized in Table 1. All intensity data were collected on an Enraf-Nonius CAD4 diffractometer with graphite monochromated Mo-Kα radiation. A total of 2952 independent reflections was collected in the range of $2 \leqslant \theta \leqslant 23°$ by the $\omega/2\theta$ scan mode, of which 2725 reflections with $I \geq 3\sigma(I)$ were considered to be observed and used for subsequent refinement. A correction for empirical absorption was applied to

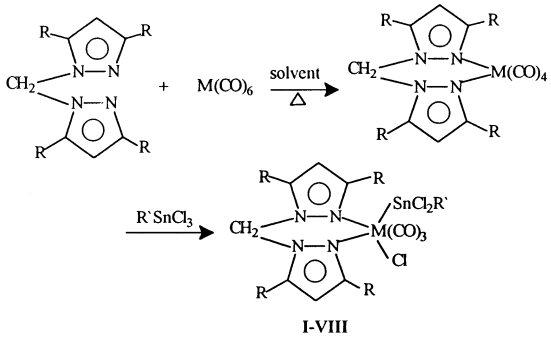
intensity data, and the structure was solved by direct methods. The final refinement by full-matrix least-squares method with anisotropic thermal parameters for non-hydrogen atoms was converged to unweighted and weighted agreement factors of 0.058 and 0.067. All calculations were performed on a PDP11/44 computer using SDP-PLUS program system.

RESULTS AND DISCUSSION

The ligand, CH_2Pz_2, has previously been synthesized by the reaction of pyrazole with dibromomethane [17]. In our work, the ligand was prepared by a similar method used for bis(3,5-dimethylpyrazolyl)methane [19]. $CH_2Pz_2Mo(CO)_4$ and $CH_2Pz_2W(CO)_4$ were synthesized by the reaction of CH_2Pz_2 and $M(CO)_6$ in toluene [18]. These compounds could also be obtained from the reaction between CH_2Pz_2 and $M(CO)_6$ in hydrocarbon solvents. Upon treatment $CH_2Pz_2M(CO)_4$ in acetonitrile, $CH_2(3,5\text{-}Me_2Pz)_2M(CO)_4$ in dichloromethane with $RSnCl_3$, the seven coordinate oxidate-addition products $CH_2Pz_2M(Cl)(CO)_3(SnCl_2R)$ and $CH_2(3,5\text{-}Me_2Pz)_2M(Cl)(CO)_3(SnCl_2R)$ were obtained in good yield, as follows:



I-VIII

(R=H, CH_3; R'=Ph, Cl; M=Mo, W)

These complexes in solid form were stable in air, even in the solution, which could be stored for a period time without obvious decomposition. These complexes were yellow to red crystalline solids, which were moderate soluble in dichloromethane, but very soluble in strong polar solvents such as acetone.

Three typical infrared spectra bands in the carbonyl stretching region were observed in all complexes, which were in agreement with suggested structures. The ν(CO) frequency in the complexes containing $SnCl_3$ group was higher than that of the complexes containing $SnCl_2Ph$ group, which could be easily understood due to $SnCl_3$ group being more electronegative. The IR spectra of heterocyclic ligands at 1500–1560 cm^{-1} were hardly affected by the $SnCl_2Ph$ or $SnCl_3$ group.

The ^{1}H NMR spectra were very interesting. A typical AB system was observed. The ^{1}H NMR spectra of all complexes showed the protons of methylene group were in different environment, which exhibited two sets of resonances. These results were consistent with the boat conformation of complexes (one case shown in Fig. 1), the ^{1}H NMR spectra indicated the boat form was also maintained in solution. The fluxional process expected in these complexes must be present, but cannot give time-averaging singlet at

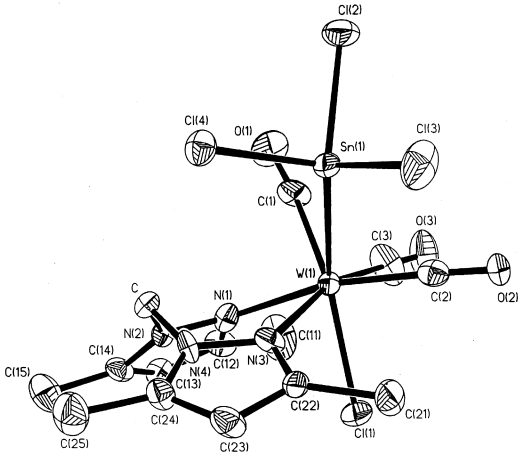


Fig. 1. The molecular structure of VIII.

room temperature on the NMR time scale. We think the presence of Cl and $SnCl_3$ groups, one below and the other above the quadrilateral face, slows the fluxional process of a boat to boat ring flip.

Selected bond lengths and bond angles for $CH_2(3,5\text{-}Me_2Pz)_2W(Cl)(CO)_3(SnCl_3)$ (**VIII**) are listed in Table 2. The crystal structure of **VIII** is presented in Fig. 1. It shows the six membered W–N–N–C–N–N metallacycle adopts the boat conformation, analogous to that in $CH_2(3,4,5\text{-}Me_3Pz)_2W(CO)_2I_2$ [14] (**1**). However, the configurations of tungsten atom are remarkable different, which is a distorted capped octahedron in **1** [14]. In present work, the tungsten atom is seven coordinate with a geometry that is best described as a distorted capped trigonal prism with a chlorine atom, Cl(1), in the unique capping position, and the W–Cl(1) bond length is 2.425 Å. The quadrilateral face consists of two carbonyl groups, C(2)O(2) and C(3)O(3), two nitrogen atoms, N(1) and N(3), which is distorted due to the two W–N bond length [W(1)–N(1) 2.248(10); W(1)–N(3) 2.243(10) Å] longer than the two W–CO distances [W(1)–C(2) 1.986(13); W(1)–C(3) 1.961(17) Å]. Thus, the configuration of tungsten atom is similar to that of $W(Cl)(SnCl_3)(CO)_3(\eta^4\text{-NBD})$ [11] (**2**). The W–Sn distance is 2.741(1) Å and is within the normal range for such bonds [19].

The environment around the tin atom is a distorted tetrahedral geometry. Three Sn–Cl bond lengths are slightly different, Sn(1)–Cl(2) at 2.348(4) Å, Sn(1)–Cl(3) at 2.331(5) Å and Sn(1)–Cl(4) at 2.379(3) Å, respectively. An interesting feature of the structure of **VIII** is that the chlorine bonded to tungsten is in the unique capping position and *trans* to $SnCl_3$ group. The Sn(1)–W–Cl(1) angle is 145.9(1)°, so, there is no chlorine atom bridge between the W–Sn bond. This feature is considerably different from that of the seven coordinated complexes containing W–Sn or Mo–Sn bond such as $W(Cl)(SnCl_3)(CO)_3(L_2)$ ($L = CH_3CN$, PPh_3, dppe, bipy, etc.) [11], $Mo(Cl)(MeSnCl_2)(CO)_3(C_{10}H_8N_2)$ [20], which was described a distorted capped octahedron geometry with a tin atom in the unique capping position and a chlorine atom bridging the W–Sn or Mo–Sn bond, and also different from that of **2** (the $SnCl_3$ group in the apical position).

Received 24 February 1998; accepted 23 April 1998

Abstract—The complex (*R*,*R*/*S*,*S*)-[$PdCl_2\{1,2\text{-}(PPhCl)_2C_2B_{10}H_{10}\}$] (**1**) was prepared by the reaction of (*R*,*R*/*S*,*S*)-1,2-$(PPhCl)_2C_2B_{10}H_{10}$ with [(COD)$PdCl_2$] (COD = cyclooctadiene) in CH_2Cl_2 solution and characterized by NMR spectroscopy (^{31}P, ^{11}B, ^{1}H) and X-ray structure determination (space group P^-). Due to the crystallographic center of inversion, both enantiomeric isomers (*R*,*R*) and (*S*,*S*) are present in the unit cell. The Pd atom is coordinated in a square–planar fashion by two chloro ligands and the 1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: chlorophosphino-substituted carbaborane; palladium dichloride phosphine complex; molecular structure

Transition metal complexes of functionalized phosphine ligands with reactive phosphorus–halogen bonds are rare [1–13], especially those with bidentate chlorophosphine ligands. While complexes containing bidentate tertiary phosphine ligands have been reported for most transition metals, only a limited number of compounds with chelating chlorophosphine ligands are known [6], and so far complexes that contain chlorophosphine derivatives of dicarba-*closo*-dodecaborane(12) have not been reported. Transition metal chlorophosphine complexes are suitable starting materials for the synthesis of coordinated phosphines by substitution of chloro substituents [2, 5, 8–12, 14].

We now report the synthesis of (*R*,*R*/*S*,*S*)-[$PdCl_2\{1,2\text{-}(PPhCl)_2C_2B_{10}H_{10}\}$] (**1**), which, to our knowledge, is the first transition metal complex containing a chlorophosphino-substituted carbaborane ligand and the first structurally characterized chlorophosphine–$PdCl_2$ complex with a *cis* arrangement.

Palladium complexes of general formula L_2PdCl_2 (L = phosphine) have received increasing attention as catalysts in organic syntheses [15]. However, only a limited number of Pd complexes with chlorophosphine [7–13] or dicarba-*closo*-dodecaborane(12) phosphine [16] ligands have been reported, and only two Pd complexes with chlorophosphine ligands have been structurally characterized [7, 13]. While the preparation of a $PdCl_2$ complex of the 1,2-bis(diphenylphosphino)-1,2-dicarba-*closo*-dodecaborane (12) ligand was reported as early as 1965, the product was only poorly characterized [17]. Related Pd [16] and Pt [18] complexes of dicarba-*closo*-dodecaborane(12)-substituted phosphines have only been characterized spectroscopically. For other Pt derivatives, decomposition with formation of a metal–boron bond was observed on recrystallization [19]. Thus, to date the bonding situation in dicarba-*closo*-dodecaborane(12)-phosphino complexes of $PdCl_2$ remains unknown.

Further details of the structure determination may be obtained upon request from the Cambridge Crystallographic Data Centre, giving full literature citation of the paper.

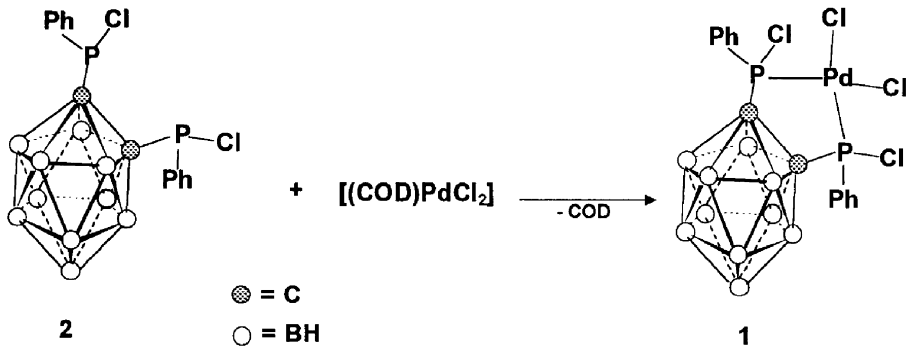
RESULTS AND DISCUSSION

Synthesis and characterization of (R,R/S,S)-[$PdCl_2$\{1,2-$(PPhCl)_2C_2B_{10}H_{10}$\}] (***1***)

When (*R*,*R*/*S*,*S*)-1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (**2**) [20] is treated with [(COD)$PdCl_2$] [21] (COD = cyclooctadiene) in dichloromethane solution at room temperature, (*R*,*R*/*S*,*S*)-[$PdCl_2$\{1,2-$(PPhCl)_2C_2B_{10}H_{10}$\}] (**1**) is obtained (eq. (1)). Complex **1** is air-sensitive as a solid and in THF or toluene solution and slowly decomposes at room temperature in about two hours.



(1)

NMR spectra of ***1***

In the ^{31}P NMR spectrum, **1** exhibits a singlet at 122.7 ppm in THF (122.3 ppm in toluene), which is shifted to low-frequency relative to the free ligand **2** [$\delta(^{31}P)$: 80.54 ppm] by *ca.* 42 ppm. In the $^{11}B\{^1H\}$ NMR spectrum, three broad signals are observed for the 1,2-dicarba-*closo*-dodecaboran(12)yl-cluster at −2.5, −10.7 and −14.1 ppm (cf. **2**: 0.05, −6.4, −10.3, −11.9 ppm). On proton coupling, only the signal at −2.5 ppm splits into a doublet (J_{B-H} = 144.8 Hz), while the other signals are too broad to allow observation of B–H coupling. In the ^1H NMR spectrum, the protons of the Ph groups appear as multiplets at 7.7 and 6.9 ppm. The B–H protons are observed in the range 1.6 to 3.5 ppm as broad signals.

X-ray structural analysis of ***1***

Crystals of **1** were obtained from THF at −30°C. **1** crystallizes with two THF molecules per formula unit. The Pd atom is coordinated in a square planar fashion by two chloro ligands and the 1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (Fig. 1). Due to the crystallographic center of inversion, both enantiomeric isomers (*R*,*R*) and (*S*,*S*) are present in the unit cell. The bond lengths and angles of the 1,2-$(PPh)_2C_2B_{10}H_{10}$ fragment (Table 1) are in agreement with those observed for other phenyl-substituted derivatives of 1,2-dicarba-*closo*-dodecaborane(12) and complexes thereof [23–26]. However, the Pd–P and Pd–Cl bond lengths are much shorter than those of $PdCl_2$ complexes with tertiary phosphine or diphosphine ligands (Table 2) [7, 13, 27–29]. The only exception is [$PdCl_2$\{$Ph_2P(CH_2)_2P(CF_3)_2$\}] [28], which exhibits Pd–$P(CF_3)_2$ and Pd–Cl [trans to $P(CF_3)_2$] bond lengths comparable to those of **1**. The only other structurally characterized Pd complexes with chlorophosphine ligands, (*R*,R_P)-**3** [7] and *trans-meso*-**4** [13] also have longer Pd–P and P–

Cl bonds than **1**. The Pd–Cl bond length in **1** is notably shorter than in (R,R_P)-**3** and comparable with that of the *trans*-complex **4**.

The shortening of the Pd–P and Pd–Cl bond lengths in **1** is indicative of the increased π-acceptor properties [35] of the 1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) ligand (**2**) compared to phenyl-substituted tertiary phosphine or diphosphine ligands (Table 2) caused by the electron-withdrawing properties of the chloro and the 1,2-dicarba-*closo*-dodecaborane(12) groups. Their combined influence is comparable of that of two CF_3 groups.

The electron-withdrawing substituents on phosphorus increase its π-acceptor properties, and this results in a shortening of the P–Cl bond in **1** by 0.04 to 0.1 Å compared with other chlorophosphine complexes or chlorophosphines (Tab. 2) [30–34].

Table 2. Comparison of selected bond lengths in **1** with those of related palladium phosphine complexes, transition metal chlorophosphine complexes, and chlorophosphines

CONCLUSION

$[(COD)PdCl_2]$ reacts with ($R,R/S,S$)-1,2-$(PPhCl)_2C_2B_{10}H_{10}$ to give ($R,R/S,S$)-$[PdCl_2\{1,2\text{-}(PPhCl)_2C_2B_{10}H_{10}\}]$ (**1**). In **1**, the π-acceptor strength of the diphosphine ligand is increased relative to tertiary phosphine ligands.

We are presently investigating the catalytic properties and reactivity of the P–Cl bond of **1**, as well as the coordination properties of **2** towards other transition metals.

EXPERIMENTAL

All experiments were carried out under purified dry argon. Solvents were dried and freshly distilled under argon. The NMR spectra were recorded with an AVANCE DRX 400 spectrometer (Bruker), ^1H NMR: external standard TMS, internal standard solvent; ^{31}P NMR: external standard 85% H_3PO_4; ^{11}B NMR: external standard $BF_3 \cdot Et_2O$. 1,2-Bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) [20] and $[(COD)PdCl_2]$ [21] were prepared according to literature procedures.

Synthesis of (R,R/S,S)-$[PdCl_2\{1,2\text{-}(PPhCl)_2C_2B_{10}H_{10}\}]$ (***1***)

($R,R/S,S$)-1,2-bis(phenylchlorophosphino)-1,2-dicarba-*closo*-dodecaborane(12) (1.25 g, 2.91 mmol) and $[(COD)PdCl_2]$ (0.865 g, 2.97 mmol) were stirred in CH_2Cl_2 (45 ml) for 4.5 h at room temperature. Then the solvent was removed *in vacuo* and the resulting solid was recrystallized from THF. At -30°C crystals of **1**·2 THF are obtained, which rapidly lose THF in vacuum to give **1** (1.53 g, 86% yield). Anal.: Calcd. for $C_{14}H_{20}B_{10}Cl_4P_2Pd$: C, 27.72, H, 3.32. Found: C, 26.73; H, 3.43. At room temperature, **1** slowly decomposes in the solid state and in solution.

*Data collection and structure refinement of **1***

Experimental data (a total of 11980 reflections) were collected at $T = 220 \pm 2$ K on a Siemens CCD (SMART) diffractometer between 3.4 and 52.3° 2Θ with monochromated Mo–Kα ($\lambda = 0.71073$ Å) radiation. This includes a total of 5765 unique reflections ($R_{int} = 0.0269$). All observed reflections (2Θ range: 3.4–52.3°) were used for determination of the unit cell parameters. A studied specimen was a white single crystal having dimensions $0.5 \times 0.4 \times 0.3$ mm. Crystal data for **1**·2 THF are as follows: $C_{14}H_{20}B_{10}Cl_4P_2Pd \cdot 2$ THF, $M = 750.75$, space group P^- (No. 2), triclinic, $a = 11.442(2)$, $b = 12.912(3)$, $c = 13.269(3)$ Å, $\alpha = 106.49(3)$, $\beta = 115.00(3)$, $\gamma = 93.44(3)^\circ$, $V = 1666.7(6)$ Å^3, at $T = 220(2)$ K, $Z = 2$, $D_c = 1.496$ g cm^{-3}, $F(000) = 756$, μ(Mo–Kα) = 0.996 mm^{-1}, no absorption correction.

Positions of Pd, Cl, and P atoms were located by using direct methods (SHELXTL PLUS) [22]. Subsequent least-squares refinement and difference electron density map calculations revealed positions of all C, B, O, and H atoms except hydrogen atoms in the molecules of the solvent (THF), which is probably due to the large thermal displacements found for both THF molecules. Therefore, coordinates of H atoms in both independent THF molecules were calculated geometrically. Final full-matrix least-squares refinement of 451 parameters with a unit weighing scheme (Pd, Cl, P, O, C, and B atoms anisotropic approximation, H atoms in B–H and Ph–H groups isotropic approximation, and H atoms in THF in calculated positions) converged to $R1 = 0.0390$, $wR2 = 0.0867$ (for reflections with $I > 2\sigma(I)$), $R1 = 0.0480$, $wR2 = 0.0924$ (all data). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Fachinformationszentrum (CSD 380169).

(Received 13 March 1998; accepted 4 May 1998)

Abstract—The reaction of the hydrated lanthanide metal β-diketonate complexes $[Ln(tmhd)_3(H_2O)]$ (tmhd = $Bu^tCOCHCOBu^t$) with hexamethyltriethylenetetramine (hmteta = $Me_2N(CH_2CH_2NMe)_2CH_2CH_2NMe_2$) in *n*-hexane at room temperature yields the anhydrous, bridged dimeric complexes, $[\{(tmhd)_3Ln\}_2(hmteta)]$, where Ln = Gd **1** or Y **2**. An X-ray study of **2** shows that only three of the four possible nitrogen atoms of the hmteta ligand are utilised in bonding to the yttrium centres. The complexes are air and moisture stable, and more importantly both have good volatility, thermal stability, and mass transport properties as demonstrated by sublimation, differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA), thus making them potential precursors for MOCVD application. © 1998 Published by Elsevier Science Ltd. INTRODUCTION

Metal alkoxides and β-diketonates have attracted a large amount of interest because they are suitable as precursors for electronic and ceramic materials [1–8]. Metal oxides are of technological importance as solid oxide electrolytes, e.g. $Y_{0.1}Zr_{0.9}O_{1.95}$ (at 800°C) or $Ce_{0.9}Gd_{0.1}O_{1.95}$ (at *ca.* 500°C) [9–11].

Low temperature chemical vapour deposition (LPCVD) routes to a wide range of metal oxide films have been previously studied [12, 13]. Our plan was to use either bulky or chelating alkoxide, or β-diketonate ligands, thereby facilitating simple cleavage pathways and afford a reduction in the carbonaceous content of the films produced. The rational behind this technique is based on studies by Bradley, who demonstrated the dramatic effect of branching in the alkyl chain of a series of Ta and Nb alkoxides [14–17]. Small changes in the molecular architecture of the ligands will alter physical properties such as oligomerisation, volatility, and mass transport [9, 18]. It is an important requirement when designing the molecular precursors that sufficient coordinative saturation is incorporated into both ligand and chelate, such that low molecular mass

† E-mail: d.j.otway@ic.ac.uk

volatile species will result which are air and moisture stable. This approach is highly flexible since L–L may be varied with the use of either O or N functionalised chelates.

Herein we report that the reactions of $[Ln(tmhd)_3(H_2O)]$ (Ln = Gd or Y) with hmteta to yield the dimeric bridged complexes $[\{(tmhd)_3Ln\}_2(hmteta)]$, where Ln is Gd **1** or Y **2**. The results of the crystal structural studies for **2** are also described.

EXPERIMENTAL

General procedures and techniques

The complexes described are air and moisture stable but were routinely prepared under nitrogen using thoroughly degassed and dry solvents. The starting materials $Gd(tmhd)_3{\cdot}H_2O$ and $Y(tmhd)_3{\cdot}H_2O$ were obtained from Inorgtech. Details of procedures and instruments used were the same as described earlier [19].

Synthesis of $[\{(tmhd)_3Gd\}_2(hmteta)]$ ***1***

To a suspension of $Gd(tmhd)_3{\cdot}H_2O$ (0.313 g, 0.5 mmol) in *n*-hexane (20 ml), hmteta (0.18 ml, 1 mmol) was added. The resulting suspension was stirred until all starting material had dissolved over *ca.* 45 min. The resulting solution was then stripped to dryness to yield a colourless oil. The flask was turned to spread the oil all over the surface and then was clamped, and the product crystallized in two days. Yield: 0.34 g, 93%. M.P.: 117–121°C. Anal.: Found C, 57.08; H, 8.63; N, 3.58; $C_{78}H_{144}Gd_2N_4O_{12}$ requires C, 56.96; H, 8.84; N, 3.41%. The complex sublimed intact between 115–150°C at 5×10^{-3} Torr, m.p. of the sublimed product: 125–128°C. IR (Nujol, ν, cm^{-1}): 1589 (ms), 1575 (ms), 1537 (m), 1505 (m), 1412 (m), 1357 (m), 1281 (w), 1244 (w), 1224 (w), 1184 (w), 1137 (w), 1091 (w), 1032 (w), 1017 (w), 957 (w), 931 (w), 868 (w), 792 (w), 758(w), 737 (w), 723 (w), 600 (w), 477 (w). (Hexachlorobutadiene, ν, cm^{-1}): 2961 (s), 2901 (m, sh), 1589 (vs), 1562 (vs), 1538 (s), 1505 (vs), 1470 (m), 1452 (s), 1413 (vs), 1388 (s), 1358 (s), 1281 (w), 1244 (m), 1225 (m), 1131 (ms), 1069 (w), 1017 (w), 760 (m), 737 (w), 600 (mw). UV/visible (*n*-hexane solution, λ in nm): 306, 303, 301, 297, 294 290, 287, 284, 282, 280, 277, 275, 272, 266, 260, 210, 205, 198, 195. Mass spectrum: (EI^+; m/u^+), 706 $[Gd(tmhd)_3]^+$ (8%), 649 $[Gd(tmhd)_2(Bu^tCOCHCOH)]^+$ (51%), 523 $[Gd(tmhd)_2]^+$ (100%), 464 $[Gd(tmhd)(Bu^tCOCHCOH)]^+$ (9%).

Synthesis of $[\{(tmhd)_3Y\}_2(hmteta)]$ ***2***

$Y(tmhd)_3(H_2O)$ (0.72 g, 1.09 mmol) was dissolved in *n*-hexane (10 ml) in a flame dried Schlenk. To the clear colourless solution, hmteta (0.29 ml, 1.09 mmol) was added and stirred for 1 h. The solvent was then removed *in vacuo* and the Schlenk kept under vacuum at 65°C for 30 min. On cooling to room temperature, the Schlenk was turned to spread the oil over its surface and then clamped on its side. Large colourless blocks crystallised over a period of 2 days with the Schlenk being turned every 24 h to spread the oil and induce further crystallization. Yield: 0.76 g, 92%, m.p.: 109–112°C. Anal.: Found, C, 61.53; H, 9.51; $C_{78}H_{144}O_{12}N_4Y_2$ requires C, 62.15; H, 9.56%. The compound sublimes intact between 90–110°C at 5×10^{-3} Torr forming crystals on the cold finger and some microcrystalline powder on the sides of the vessel. The m.p. of the sublimed solid was 110–113°C. IR (Nujol, ν cm^{-1}): 2727 (vw), 1609 (m), 1590 (m), 1576 (vs), 1530 (m), 1506 (s), 1417 (s), 1306 (w), 1245 (w), 1226 (w), 1180 (w), 1141 (w), 1019 (vw), 962 (vw), 793 (vw), 759 (vw), 723 (w), 477 (vw); (hexachlorobutadiene, ν cm^{-1}): 2962 (vs), 2902 (m), 2865 (m), 1609 (s), 1590 (vs), 1539 (s), 1506 (vs), 1479 (m), 1452 (s), 1417 (vs), 1388 (s), 1359 (s), 1286 (vw), 1245 (w), 1226 (m), 1179 (m), 1141 (m), 1026 (w), 605 (vw), 476 (w). ^1H NMR (C_6D_6, 270 MHz, 20°C): δ 1.20 (s, 108H, CH_3), 2.21 (s, 6H, NCH_3), 2.34 (s, 12H, $N(CH_3)_2$), 2.59 (d, 12H, NCH_2), 5.86 (s, 6H, CH). $^{13}C\{^1H\}$ NMR (C_6D_6, 67.94 MHz, 20°C): δ 28.36 (s, CH_3), 40.32 (s, $C(CH_3)_3$), 42.55 (s, NCH_3), 45.50 (s, $N(CH_3)_2$), 54.97, 55.67, 57.49 (s, NCH_2), 90.73 (s, CH), 198.78 (s, CO). Mass spectrum: (EI^+; m/u^+), 638 $[Y(tmhd)_3]^+$ (12%), 581 $[Y(tmhd)_2(Bu^tCOCHCOH)]^+$ (64%), 455 $[Y(tmhd)_2]^+$ (100%), 397 $[Y(tmhd)(Bu^tCOCHCOH)]^+$ (6%), 272 $[Y(tmhd)]^+$ (3%).

X-ray crystallography for $[\{Y(tmhd)_3\}_2(hmteta)]$ ***2***

Crystal data $C_{78}H_{138}N_4O_{12}Y_2$, M_r 1501.74, triclinic, $a=10.274(4)$, $b=21.023(9)$, $c=21.410(9)$ Å, $\alpha=68.58(2)$, $\beta=86.19(3)$, $\gamma=82.93(3)°$, $U=4271(3)$ $Å^3$, space group $P\bar{1}$ (No. 2), $Z=2$, μ(Mo–K_α) = 14.07 cm^{-1}, $\lambda=0.71069$ Å, $T=150$ K, crystal size $0.20\times0.15\times0.13$ mm.

Crystallographic measurements were made using a Delft instruments FAST TV area detector diffractometer equipped with a rotating anode (Mo) generator by following previously described procedures [20]. Total data ($1.97\leqslant\theta\leqslant25.60°$; $-11\leqslant h\leqslant9$, $-23\leqslant k\leqslant23$, $-24\leqslant l\leqslant14$) collected 13962, 12023 unique ($R_{int}=0.0765$). The crystal was weakly diffracting and relatively few data were observed, but the structure was successfully solved by direct methods (SHELXS86) [21] and difference synthesis, and refined on F^2 by full-matrix least-squares (SHELXL93) [22]. Absorption effects were ignored. All nonhydrogen atoms were anisotropic. The hydrogen atoms were included in calculated positions (riding model) with U_{iso} tied to the U_{eq} of the parent atoms. One of the *t*-butyl groups [pivot atom C(12)] was orientationally disordered, and its three methyl groups were refined each with partial occupancies

(0.68 and 0.32). Final R_1 (on F, 1556 data with $F_o > 4\sigma(F_o)] = 0.0614$, wR_2 (on F^2, all 12023 data, 924 parameters) = 0.2789, $w = 1/[\sigma^2(F_o^2)]$. Sources of scattering factors as in Ref. [22]. The diagram was drawn with SNOOPI [23]. The calculations were done on a Pentium 200 MHz personal computer. Full details of crystallographic results have been deposited with Cambridge Crystallographic Data Centre, Ref. No. CCDC-101115.

RESULTS AND DISCUSSION

Synthesis

A range of synthetic routes has been used for the preparation of metal alkoxides or β-diketonates [24–33]. There are several features that may be noted for the synthesis of such materials, i.e. (a) the synthetic strategy of using a preformed metal β-diketonate (either anhydrous or a hydrate) leads to *water free* products [33], (b) the coordinative saturation of the metal centre by the multidentate chelate and β-diketonates leads to *air and moisture stable* precursors of known stoichiometry and is thus highly flexible since L–L may be varied with the use of either O- or N-functionalised chelates, (c) The designed synthesis of volatile molecular metal organics is possible without having to use sterically hindered ligands. The multidendate amine (L–L) forces the complex into a molecular regime, thereby removing the possible interactions between the monomers and increasing the volatility and mass transport properties of the complexes.

Physical properties

Compounds **1** and **2** are both highly soluble in a range of organic solvents. This pronounced solubility even in nonpolar aliphatic hydrocarbon solvents (i.e. *n*-hexane) is most likely to be due to the coordinative saturation of the metal atoms in these complexes. Another important property is their excellent stability to both air and moisture.

Both **1** and **2** show a significant drop (*ca.* 60°C) in their melting points on complexation with the amine ligand. Complex **1** melts at 117–121°C, whereas the parent compound $Gd(tmhd)_3{\cdot}H_2O$ melts at 170–172°C. It sublimes intact between 115–150°C at 5×10^{-3} torr over 1.5 h. The large colourless crystals obtained for compound **2** melt cleanly at 109–112°C compared with 160–165°C for $[Y(tmhd)_3(H_2O)]$ and 77–81°C for $[\{(tmhd)_3Y\}_2(triglyme)]$ (triglyme = $MeOCH_2OCH_2OCH_2OMe$) [33]. Compound **2** sublimes intact between 90–110°C at 5×10^{-3} Torr over 1 h forming crystals on the cold finger and some microcrystalline powder on the sides of the vessel.

Infrared spectra

The infrared bands for **1** and **2** (experimental section) are comparable with those in other hydrated and anhydrous β-diketonates [18, 34]. The only real difference from the spectra of the parent compounds is the presence of the amine ν(C–N) stretch at 1140 cm^{-1}; this is a shift of *ca.* 30 cm^{-1} over the free ligand and indicative of coordinated amine with relatively weak M–N bonding.

NMR spectra

The ^1H and $^{13}C\{^1H\}$ NMR spectra of **2** were run in C_6D_6 but due to large paramagnetic NMR shift of the Gd^{3+} metal nucleus no spectra could be obtained for **1**. The ^1H NMR spectrum of **2** in C_6D_6 shows both the tmhd and hmteta ligands as well resolved peaks. The hmteta protons are split into three groups; singlets for 6H $\{-NCH_3\}$ and 12H $\{-N(CH_3)_2\}$ and a doublet for 12H $\{-NCH_2-\}$. Integration for the complex gives a tmhd:hmteta ratio of 6:1. The $^{13}C\{^1H\}$ NMR spectra reveals only one environment for the tmhd and amine ligand, suggesting that either the complex exists in solution as a symmetrically bonded dimer or a rapid exchange process is occurring.

Mass spectrometry

In the mass spectra for complexes **1** and **2** the highest molecular mass ions observed for these complexes are due to the $[Ln(tmhd)_3]^+$ species at 705 and 638 amu respectively. Other intense peaks are noted in the experimental, in particular $[Ln(tmhd)_2]^+$ at 523 and 455 amu, and below this breakup of the tmhd groups is also seen. The isotope patterns of the metal containing complexes are consistent with those obtained from the natural abundance patterns or by computer simulation. The m/z ratios relate to the isotopes of greatest natural abundance, e.g. ^{157}Gd and ^{89}Y.

The above data suggest that in the vapour phase under high vacuum conditions (10^{-8} Torr) these complexes dissociate to form the oligomeric donor-Lewis base free complexes, $Ln_2(tmhd)_6$. Such behaviour is still an important observation since the materials may be used under atmospheric conditions very effectively or at low vacuum (*ca.* 10^{-3} Torr) conditions as molecular precursors for Ln_2O_3, or other ternary oxides such as $YBa_2Cu_3O_{7-x}$. The fact that the Lewis base (amine) is not coordinated to the metals under the conditions used here has been noted previously for lanthanide complexes [35, 36].

TGA/DSC studies

Both the hydrated starting materials and the amine stabilised products were subjected to thermal analysis. The results show that the addition of an amine ligand

to the hydrated species removes any coordinated water and more importantly it significantly reduces the decomposition point with respect to the parent hydrate compounds. The TGA and DSC plots for **2** are shown in Fig. 1.

The DSC of **1** shows two distinct endotherms over the range 100–300°C. The first, centred at 138.77°C (−8.61 mcal/mg), corresponds to the melting point of the compound. The second, broad peak, centred at 230.68°C (−34.15 mcal/mg), correlates well with its complete, intact sublimation observed in the TGA plot between 180 and 280°C. A very small residue of 2.75% is probably due to a small amount of carbonaceous material left.

The DSC of **2** shows an endotherm between 110–135°C (−7.38 mcal/mg) corresponding to the melting point, and two more endotherms [176–245°C (−4.86 mcal/mg) and 245–280°C] due to sublimation of the complex into the vapour phase. The TGA plot is consistent with these observations; namely a sublimation of 97.4% of the complex over the range 150–280°C leaving a final residue of 2%.

X-ray structure of [{*Y*(*tmhd*)$_3$}$_2$(*hmteta*)] ***2***

A single crystal structural study of complex **2** was undertaken to unambiguously identify its structural composition and to determine whether all of the potential N-donor sites were bound to the yttrium metal centres. The solid state structure of **2** is shown in Fig. 2 and selected bond lengths and angles are given in Table 1.

The structure is a dimer based on two Y(tmhd)$_3$ units linked by a hmteta ligand in an unusual bonding mode. The amine ligand acts simultaneously as a che-

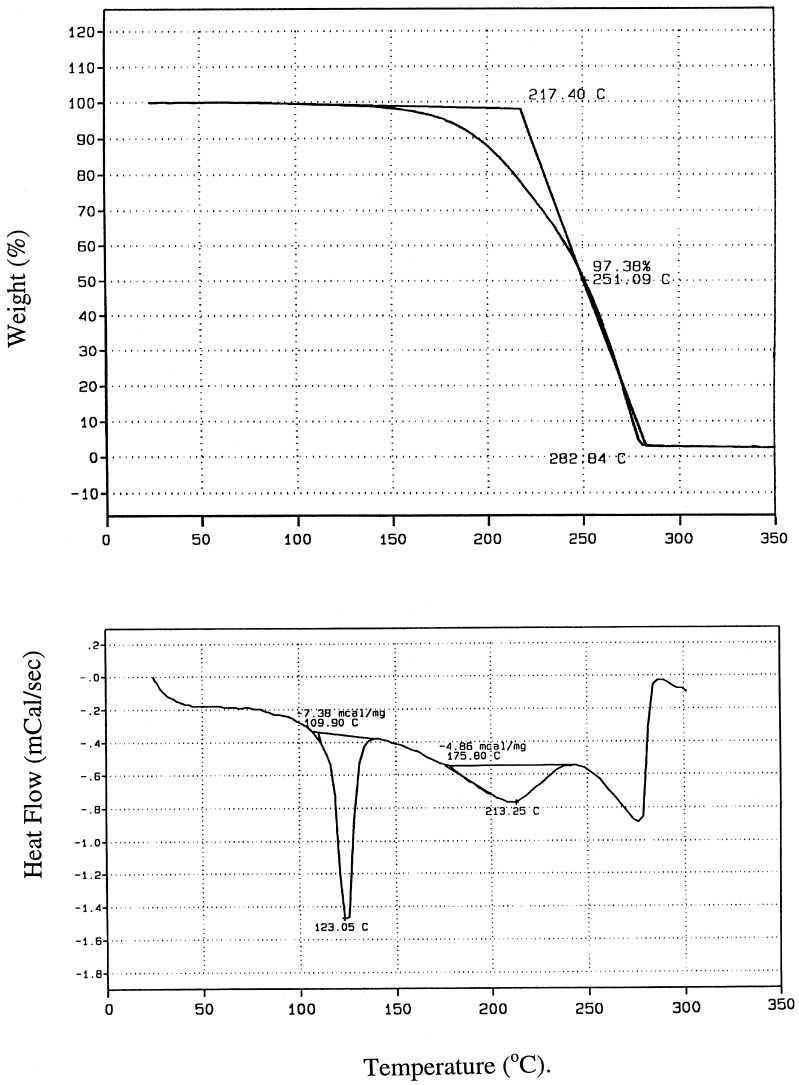

Fig. 1. The DSC and TGA plot for [{(tmhd)$_3$Y}$_2$(hmteta)] (**2**).

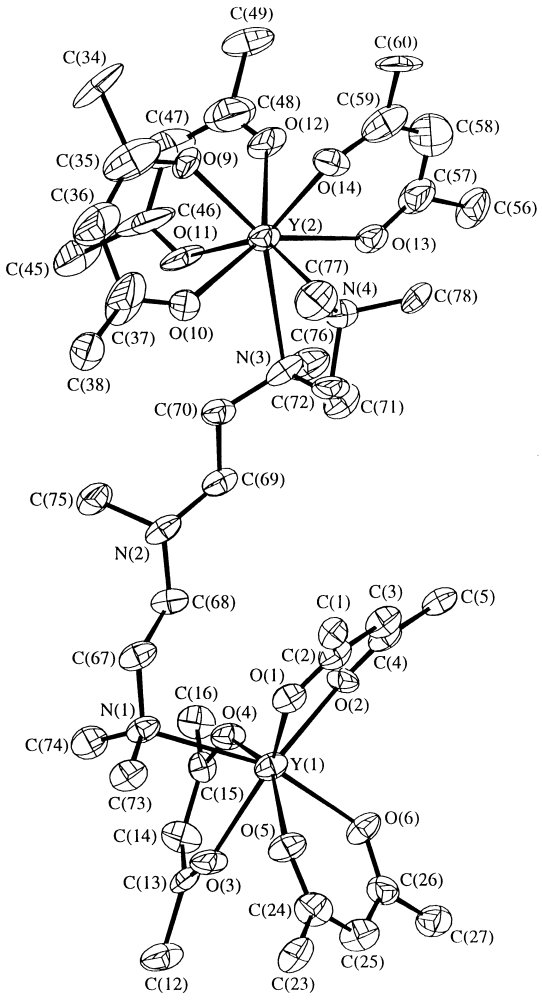

Fig. 2. X-ray structure of $[\{(tmhd)_3Y\}_2(hmteta)]$ **2**; the *tert*-butyl methyl groups are omitted for clarity. Thermal ellipsoids are drawn at 50% probability level.

late [to Y(2)], terminal ligand [to Y(1)] and as a bridging ligand via the central ethylene bridges. This mode of bonding of the potentially tetradentate hmteta ligand appears to be unique; such ligands are normally found to form two chelates involving all the four nitrogen atoms as observed in $[Ba(hfpd)_2(hmteta)]$ (hfpd = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate) [32]. The binuclear structure observed for **2** does not permit utilisation of *all* the four potential nitrogen binding sites and this raises the question why the situation is different from the related triglyme bridged complex $[\{Y(tmhd)_3\}_2(triglyme)]$ [33] in which all the four oxygen atoms are involved in bonding with the metal atoms.

The environments of the two metal centres, Y(1) and Y(2), illustrated in Fig. 3, are significantly different and may be explained by the asymmetric bridging of the amine ligand. Y(1) is bonded to six oxygens from three chelating tmhd ligands and one nitrogen from the bridging hmteta ligand. This atom is seven coordinate with a geometry best described as distorted monocapped trigonal prismatic. Two of the tmhd ligands are chelated along the edges of a square face of the trigonal prism, whereas the third tmhd is chelating from the capping atom to an apex of the prism. The remaining apical site of the prism is occupied by one nitrogen atom from the amine ligand. The coordination around Y(2) consists of six oxygens from three chelating tmhd ligands, as well as two nitrogens from the hmteta ligand forming a 5-membered chelate. Y(2) is thus eight coordinate with a square antiprismatic geometry. The chelation of the ligands around this metal is interesting in that two tmhd ligands are chelating along the edges of square faces whereas the third tmhd and the hmteta ligands chelate between the two square faces. It is to be noted that yttrium resembles the lanthanide elements in most respects and can easily accommodate a high coordination number such as eight. In fact octa-coordination is a common feature observed in different yttrium complexes with β-diketonate and alkoxide ligands, and examples include species with various degrees of oligomerisation, e.g. $[Y(pd)_3(H_2O)_2]\cdot H_2O$ (monomer) (pd = pentane-1,3-dionate) [37], $[\{(tmhd)_3Y\}_2(triglyme)]$ (dimer) [33], $[Y_2(pd)_4(O_2CCH_3)_2(H_2O)_2]$ (dimer) [38] and $[Y_3(pd)_4(OCH_2CH_2OMe)_5]$ (trimer) [39]. The geometry about yttrium in all these complexes is distorted square antiprismatic. There are, however, examples of lower coordination numbers for yttrium, e.g., the hexa-coordinated oxide Y_2O_3 and the hepta-coordinated methoxyethoxide "$Y(OC_2H_4OMe)_3$". The last compound was shown to be a centrosymmetric cyclic decamer $[\{Y(OC_2H_4OMe)_3\}_{10}]$ [40], in which all the five unique yttrium atoms have pentagonal bipyramidal geometry. This compound also appears to be the highest oligomer structurally characterised for homoleptic metal alkoxides.

The Y(2)–N bond lengths are quite asymmetric [2.662(8), 2.716(8) Å], with the terminal NMe_2 group binding closer to the metal centre. In contrast, the Y(1)–N bond length involving only the terminal nitrogen from the other NMe_2 group at 2.608(8) Å is much shorter. These differences in the Y–N bond lengths can be explained by the differing coordination numbers for the two yttrium atoms and also by the steric factors. The bonding of hmteta in the present compound has no immediately accessible comparison in Ln–N chemistry, but may be contrasted with that in the barium compound $[Ba(hfpd)_2(hmteta)]$ [33]. In this compound, which is monomeric, all four nitrogen atoms of hmteta are bonded to barium forming two nearly symmetrical chelate rings [Ba–N distance 2.963(3)–3.022(10) Å], with quite acute N–Ba–N chelate angles, 62.1(3) and 61.4(3)°. The hmteta ligand can bind to barium in this way because the larger radius of Ba^{2+} (1.49 Å) supports the higher coordination number compared with Y^{3+} (1.04 Å) [41].

The Y–O bond lengths involving the β-diketonate ligands lie in the range 2.211(6)–2.338(7), average

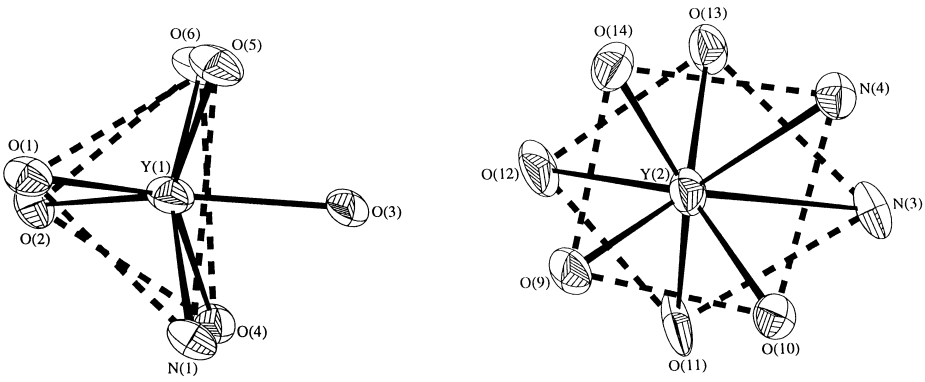

Fig. 3. The coordination sphere around [{(tmhd)$_3$Y}$_2$(hmteta)] **2**.

2.266 Å, and are close to the values in other complexes [33, 37–39, 42]. Close examination of the individual Y–O distances in **2** indicate that only one tmhd ligand [containing O(13) and O(14) and chelated to Y(2)] is nearly symmetric whilst the remaining five tmhd ligands are chelated quite asymmetrically. Not unexpectedly, the Y(2)–O distances [2.235(7)–2.338(7), average 2.28 Å] are in general longer than the Y(1)–O

distances [2.211(6)–2.314(7), average 2.25 Å] reflecting the greater steric crowding around Y(2).

The geometry parameters involving the hmteta and tmhd ligands are as expected. The hmteta chelate is nonplanar with a relative λ conformation. The OC_3O skeletons of one tmhd ligand chelated to Y(2) shows significant deviations from planarity [atomic deviations -0.089–$0.122(2)$ Å] whilst the other tmhd ligands chelated to Y(I) and Y(2) are almost planar [atomic deviations $\leqslant 0.03(2)$ Å]. The six-membered $M(O_2C_3)$ chelates are also nonplanar with fold angles of 7.9–21.7(3)° about the O···O axes. These deformations observed in coordinated tmhd ligands may be attributed to steric factors and reflect the flexible nature of such ligands.

CONCLUSION

Recent developments in organo-lanthanide chemistry have shown that the chemistry of these metals may be controlled by varying the steric environment around the metal. We have applied the above strategy to a range of lanthanides, including Y, Tb, Pr, Eu and Gd, e.g. $[\{(tmhd)_3Y\}_2(triglyme)]$ is a dimeric air stable highly volatile precursor [32]. This technique works because the lanthanide complexes are hard acids which are coordinatively unsaturated, and will react with multidendate Lewis bases which will "plug" vacant coordination sites and even displace water from hydrated species, as for yttrium above. Given that we can use either O or N functionalised chelating ligands, we are now in a position to tailor the coordination environment of the metal quite specifically.

Abstract—A number of chromium(III) complexes with glycine, cysteine, glutamic and nicotinic acids-models for biologically active Cr(III) species have been prepared and characterized with physicochemical methods (UV/Vis, IR spectra, magnetic moments). Four of them have been also tested for their toxicity. On the basis of CF calculation it was found that only the nicotinates were octahedral Cr(III) species. Other complexes exhibited a tetragonal deformations. Based upon 10 Dq values, the sequence of the ligand field strength was found to be: glycine > cysteine ≈ glutamic acid > nicotinic acid. The likely structures were proposed for the isolated compounds. The preliminary toxicity studies showed that all tested complexes appeared to be non-toxic and can be potentially applied as chromium nutrition products. © 1998 Elsevier Science Ltd. Keywords: Cr(III) complexes; glucose tolerance factor; low molecular weight chromium; electronic spectra; toxicity; amino acids.

Chromium has been known to be a micronutrient for almost forty years. The essential nature of this element was recognized in 1959 by Mertz and Schwarz [1]. These authors demonstrated the role of chromium in maintaining normal glucose in rats. Later on, chromium was shown to be important for normal mammalian carbohydrate and lipid metabolism [2–4].

Despite these results very little is known about the composition and structure of the biologically active form(s) of chromium. The most conflicting results have been obtained by studying the problem of the Cr(III) relationship to the so-called glucose tolerance factor (GTF), an organic Cr(III) containing complex responsible for stimulating insulin action. The evidence obtained from the literature suggested that the GTF contained Cr(III) in the form of a complex with nicotinate (pyridine 3-carboxylate) and either glutathione or amino acids: glycine, glutamic acid and cysteine [5, 6]. However, it has also been suggested that Cr(III) may not be a component of the GTF [7–10] or that it does not play any biological role at all [8].

These results prompted many investigators to study synthetic models for the GTF [6, 11–14]. In most models two nicotinate ligands are coordinated as monodentate ligands in *trans* positions via oxygen [13, 15] or nitrogen donor atoms [11, 16, 17]. However, both biological extracts and synthetic GTF models have as yet been poorly characterized.

The other pathway in investigating the biological activity of trivalent chromium was based on Yamamoto *et al*. [18], namely isolation of naturally occurring Cr(III) containing protein of low molecular weight (LMWCr) ~1500 Da. Recently, the isolation of LMWCr in milligram quantities, together with its biochemical and physicochemical analysis, has been reported [19–22]. The composition of ligands in LMWCr is similar to the GTF. One difference is the presence of the aspartate in the former instead of the nicotinate in the latter [19]. It is postulated that in the centre of activity LMWCr contains an assembly composed of four chromium atoms bridged with oxygen, hydroxyl group, chlorine etc [19]. The oligo-

*Author to whom correspondence should be addressed. e-mail: golonka@ichn.ch.pwr.wroc.pl

peptide is probably associated with the kinase active site of the insulin receptor [22].

However, LMWCr of still unknown structure, may not be an alternative for the "old" GTF, since the latter seems to be more a nutrient in an appropriate organic form suitable for chromium deficient organisms [23]. As Cr(III) picolinate used as a dietary chromium supplement has been found to cause chromosome damage [24] other Cr(III) complexes suitable for supplementation of this ion should be investigated [22]. For example, Vincent *et al.* [22] proposed as a nutrient an inexpensive, easy to prepare Cr(III) compound containing a cationic trinuclear $[Cr_3O(O_2CCH_2)_6(H_2O)_3]^+$ species which was found to activate the insulin receptor almost identical to that of LMWCr.

With these facts in mind our studies have been focused on systematic syntheses of mono- and polymeric Cr(III) complexes with "GTF-like" ligands and investigation of their physicochemical properties and biological activity. We have prepared and spectroscopically analyzed seven Cr(III) mono and dimeric complexes with nicotinic (nic) and glutamic (glu) acids, cysteine (cys) and glycine (gly).

To the authors' knowledge, the complexes **I** and **IV** (Table 1) have been obtained for the first time. Additionally, for the previously known compound **II** [6] a new synthetic procedure has been proposed.

EXPERIMENTAL

Chemicals were used as received. Stoichiometries of the complexes were established by microanalysis (C, N, S, H), which gave satisfactory results.

Preparation of the complexes

$[Cr_2nic_2(OH)_4]\,4H_2O$ [***I***]. From the stock solutions: $Cr(NO_3)_3{*}9H_2O$ (10 g in 500 cm^3) and nicotinic acid (6.0155 g in 500 cm^3) equal volumes of 20 ml each were mixed together and warmed to 60°C under continuous stirring. The acidity had been adjusted to pH 6.0 with warm NaOH (2 M). Addition of NaOH caused the changes of colours (from green to blue) and simultaneous precipitation. After 48 h the mixture was filtered off, washed with water and ethanol.

$[Crnic_2OH]\,3H_2O$ [***II***]. $Cr(NO_3)_3\ 9H_2O$ (6 g) and nicotinic acid (3.693 g) were dissolved in a mixture of methanol (70 cm^3) and water (30 cm^3). The reagent mixture was heated to reflux for 6 h. Solid KOH (3.36 g) was added to the solution and the resulting blue precipitate was allowed to remain for 48 h in the mother liquor. The precipitate was filtered, washed with water and ethanol and dried.

$[Cr_2glu_2(OH)_2]glu\ 3H_2O$ [***III***] This compound was prepared as described elsewhere [25].

$[Crcys_2(OH)(H_2O)]\ H_2O$ [***IV***] $CrCl_3\ 6H_2O$ (1.33 g) was dissolved in a mixture of water (10 cm^3) and ethanol (2 cm^3). D,L-Cysteine (1.81 g) dissolved in water

($2\,cm^3$) was added and the reagent mixture was heated and evaporated to half volume. Solid KOH was added until the pH was 8. The pink violet precipitate was filtered and washed with water.

mer-[$Crgly_3$] H_2O [***V***], fac-[$Crgly_3$] H_2O [***VI***] *and* [$Cr_2(OH)_2gly_4$] H_2O [***VII***] Prepared as described in the literature [26].

The analytical results are presented in Table 1.

Physicochemical studies

Infrared spectra were recorded on a Perkin-Elmer FTIR 1600 spectrophotometer (4000–400 cm^{-1}). FIR spectra (400–70 cm^{-1}) were recorded on a Perkin-Elmer 180 spectrophotometer.

The diffuse reflectance spectra (sample in a Li_2CO_3 pressed pellet) and solution spectra (in 2 M HNO_3) were measured in the spectral range 12000–48000 cm^{-1} with a Hitachi 365 UV/Vis spectrophotometer with a IBM/PC computer. The resolution processing of the spectra was performed by applying the variable digital filter method [27–30]. The filtered spectra were used to obtain the band positions precisely and calculate the crystal field parameters, assuming first O_h symmetry and then tetragonality of the Cr(III) environment. The energy matrices were adopted from the paper by Perumareddi [31].

The magnetic measurements were carried out in the temperature range 80–300 K using a Gouy balance with $Co[Hg(SCN)_4]$ as a calibrant.

Preliminary toxicity studies

Four prepared complexes have been checked for their toxicity (**I**, **II**, **V**, **VI**). The suspensions were prepared *ex tempore*. Acute toxicity was investigated on a group of white mice *Balb C*. Mice of both sexes of 20–25 g each were studied. Three doses of the prepared compounds were administrated (in mg/kg): 100, 500 and 2000, respectively. The mice were observed for 24 h.

RESULTS AND DISCUSSION

Thermodynamically, trivalent chromium ion is the most stable oxidation state of chromium; kinetically Cr(III) compounds are inert with the half-filled t_{2g} level (d^3 conf.) in octahedral symmetry (Ref [32], and the references therein).

The prepared complexes together with their physical properties are listed in Table 2. The complexes are blue (**I–II**), violet (**III–IV**) and pinkish-red (**V–VII**). The blue complexes exhibit the presence of CrO_6 and CrO_5N chromophores, respectively. The pinkish-red ones have CrO_3N_3 chromophores with three nitrogen atoms per chromium atom. Additional nitrogen in the coordination sphere of the chromium is consistent with the blue shift of the bands manifested in the spectrochemical series (*vide infra*). In complex **III** ligand molecules are in inert and in outer coordination sphere. It was established through analysis of the infrared spectra, i.e. the presence of the hydroxide ring [25] and bidentate O,N chelation of the ligand (Table 3, vide infra). These results are in line with our findings and those of others [48] and us [49] on the observation that in one compound some organic ligands are directly bound to the central ion and some are situated outside the coordination sphere.

The effective magnetic moments (3.82–4.37 B.M.) for monomers are close to the spin only value for the d^3 system in octahedral and pseudooctahedral symmetry $^4A_2$ ground state). Lower values of the magnetic moments (<3 B.M.) were observed for the dimers.

Infrared spectra

Table 3 presents the major absorption IR frequencies of the prepared compounds. In these complexes the carboxylate groups are involved in the coordination. The values of Δ, i.e. the differences between the two frequencies ν_{as} and ν_s of the carboxyl group (Table 3) pointed to the unidentate coordination of the carboxylate ion in all complexes [33], and is in line with the results found for other Cr(III) complexes

Table 2. Physical properties of the compounds

Symbol	Substrates	Ratio M:L	Formula	Colour	μ (BM) per chromium atom	Refs. (preparation)

with the same or similar ligands [17]. The CrO stretching vibration has been found in the *ca.* 500 cm^{-1} absorption region [53]. All complexes except **II** exhibit bands at 420–470 cm^{-1}, which have been assigned to ν(CrN) vibrations [54, 55]. The proposed structures have been presented in scheme 1. Thus, the nicotinates have been found to be O-bonded (**II**) and both N- and O-bonded in one molecule (**I**). Such bonding is not very unusual in coordination chemistry [34, 35].

Electronic spectra

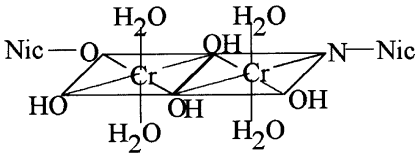
The spectra for the solutions and the solid state are shown in Tables 4–6.

The complexes were found to be practically insoluble in common organic solvents. As HNO_3 was used for dissolution, such spectra usually should be less reliable (i.e. changed under the acid interaction) than the solid state spectra. However, the blue shift of the bands on dissolution is *ca.* 1000 cm^{-1}, consistent with the data found in the literature for water as solvent [29] and consistent with a significant change in the environment of the central atom on dissolution. These effects are connected with a weakening of the strong hydrogen bonding system operating in the rigid solid structure [29, 36]. Thus, assuming only hydrogen bonding effects, the individuality of the complexes appeared to be larger in the solution. The {glu} complex (**III**) was found to be the only one exhibiting a very large (2000 cm^{-1}) hipsochromic shift on dissolution. We relate it to the presence of the glutamic acid molecule in the second coordination sphere (Tables 1–2) which may easily dissociate on solvent influence. This effect makes the first coordination sphere extra strong in solution. *mer*- and *fac*-Cr(III) glycine complexes contain three bidentate ligands. These complexes were the only ones with known crystal structures [36]. The chromium ion in the mono Cr(III) glycinate was found to be octahedrally coordinated with the Cr–O and Cr–N bond length 196 and 206 pm, respectively. Unusual bonding forces were present in these complexes related to the network of hydrogen bonds operating in the solid state.

In the visible absorption region two broad bands associated with the d–d Laporte forbidden quartet–quartet spin allowed transition have been observed (Tables 4–6, Fig. 1). In the near IR absorption region weak but sharp band(s) associated with the doublet–quartet spin forbidden transition(s) can be seen in the {gly} complexes (**V**–**VII**) (Table 4, Fig. 1) [46, 47]. In the rest of the compounds the positions of these bands were found on the filtration analysis (not shown in Tabs. 4–6). As this analysis (i.e. filtration) does not give the intensity values (only the energy of transitions) we were not able to discuss the magnitude of coupling between two chromium(III) nuclei in compounds **I** and **II**.

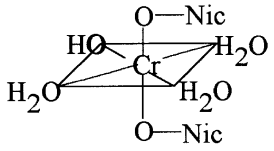
From the crystal structure results available for Cr(III) glycinate, the coordination sphere of the metal

Compound I



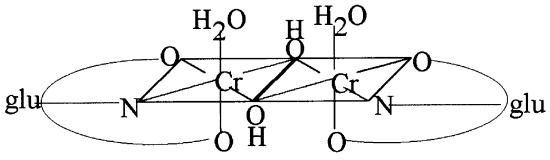
$[Cr_2(nic)_2(OH)_4]\ 4H_2O$

Compound II



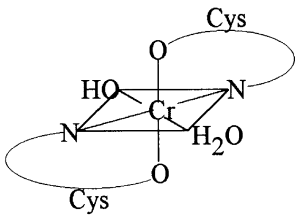
$[Cr(nic)_2OH)]\ 3H_2O]$

Compound III



$[Cr_2(glu)_2(OH)_2(H_2O)_2]*glu*3H_2O$

Compound IV



$[Cr(cys)_2(OH)(H_2O)]*H_2O$

ion is octahedral [36]. Generally, many Cr(III) complexes are octahedrally coordinated [32]. However, the fact that the complexes are dimeric with two OH bridges (**I**, **III** and **VII**), their coordination is via various donor atoms: O, N, S (**I**, **III**–**VII**) and the coordination is via oxygen atoms but from various ligands (**II**), makes the symmetry lowering possible. Thus, we have calculated crystal field parameters assuming (i) O_h symmetry and (ii) tetragonal distortion around Cr(III) ion.

The criterion of proper fitting was the RMS value found on calculation.

The results showed that the complexes belonged to two general groups:

(1) Octahedrally coordinated (the nicotinates **I** and **II**) Table 5.

(2) Tetragonally coordinated (the glutamate (**III**), cysteinate (**IV**) and glycinates (**V**–**VII**) Table 6.

The reasonable explanation for these results may be based on the differences in the M–L interaction between the nicotinates and the other ligands. It is manifested in the crystal field strength calculated for the absorption spectra (Tables 5–6). For the first group of the complexes the Dq values are smaller which is evidence for weaker Cr-nic interaction in comparison to the other ligands studied. However, this effect is not a very strong one. Moreover, the Dt values for complexes (**III**–**VII**) are small indicating only slight tetragonality around the Cr(III) ion. Assuming an octahedral and pseudooctahedral environment, nicotinic acid is evidently the last ligand in the spectrochemical series for the Cr(III) ion: glycine > cysteine ≈ glutamic acid > nicotinic acid.

The electronic spectroscopic data for monomeric Cr(III) species have been rationalised taking into account the 10 Dq value as a criterion (Table 4). The energy of the first spin allowed d–d transition (10 Dq) for Cr(III) monomeric complexes increases in the sequence

$$CrO_6 < CrO_4N_2 < CrO_3N_3 < CrN_6$$

The value for CrN_6 chromophore was taken from the literature [32]. This sequence also reflects the gradually changes of the colour from blue (CrO_6) through violet (CrO_4N_2) to red CrO_3N_3 (VII) and CrN_6 [32].

The grey–green colour of LMWCr concentrated solutions and the energies of two distinct visible d–d bands and UV shoulder [37] resemble water solutions of anionic type binary and ternary complexes of the $[Cr(A)(H_2O)]^{n-}$ and $[Cr(AB)]^{n-}$ type where A, B-non enzymatic cellular reductants: ascorbic acid, cysteine, glutathione [29, 30, 38]. It was found that the S-con-

taining Cr(III) complexes exhibited the absorption in the 260 nm (*ca.* 38000 cm^{-1}) with the Cr←S [50, 51] band intensity of 3000–5000 $dm^3\,mol^{-1}\,cm^{-1}$. The 260 nm band was also found in the LMWCr [19, 37]. However, as this band was also present in the apo (i.e. Cr-free) form of the protein [19, 52] only the detailed analysis of this spectral region might explain the origin of this absorption in the LMWCr.

Toxicity

The literature data on chromium toxicity are incomplete and inconsistent [39]. The toxicity expressed by the lethal dose (LD_{50}) values is dependent on the chromium oxidation state, different species of animals and route of exposure [40–43]. Generally, oral toxicities of Cr(III) compounds appear to be 10–1000 times lower than for the hexavalent chromium compounds [38]. The toxicology of chromium(III) varies greatly among a variety of different chromium compounds [39]. For example, in genotoxical bacterial tests on a series of hexacoordinate Cr(III) complexes, out of 17 complexes 12 were positive [44].

The results of our studies are presented in Table 7. All compounds appeared to be non-toxic in this examination. The completion of the results as well as their extension into other groups of animals are under way.

SUMMARY AND CONCLUSIONS

The interaction between the Cr(III) ion and glycine, cysteine, glutamic and nicotinic acids gives a series of monomeric and dimeric complexes, models for the glucose tolerance factor (GTF). The composition of the species is strongly dependent on the metal–ligand interaction and conditions of the experiment (temperature, time, etc.). The breaking of the strong hydrogen bonding network operating in the solid state may be responsible for the blue shift of the electronic d–d bands in solution. Despite the various types of chromophores and number of the central atoms in the complexes, the coordination sphere for chromium nicotinates was found to be a full octahedron. The rest of the complexes studied can be better described assuming a tetragonally distorted octahedron. The reason for such behaviour was related to the strength of the ligand field around the central metal ion, this being weakest in the nicotinic acid.

The tentative results for the toxicity studies of the complexes are very promising. They are practically non toxic and can be potentially apply as chromium nutrition products.

The kinetics of the acid-catalysed decarboxylation of *cis*-[Co([15]aneN$_4$)CO$_3$]$^+$ ([15]aneN$_4$ = 1,4,8,12-tetra-azapentadecane)

Robert W. Hay* and Andrew M. Danby

School of Chemistry, University of St Andrews, St Andrews KY16 9ST, U.K.

(Received 24 October 1997; accepted 5 May 1998)

Abstract—The decarboxylation of [Co([15]aneN$_4$)CO$_3$]$^+$ in nitric acid solutions has been studied in detail over a temperature range at $I = 1.0\,\text{mol dm}^{-3}$. The reaction is biphasic, the initial reaction is the carbonato ring opening step, which is followed by very rapid decarboxylation of the monodentate carbonato intermediate. The second step is the isomerisation of *cis*-[Co([15]aneN$_4$)CO$_3$]$^+$ to the *trans*-isomer. At constant hydrogen ion concentration, values of k_{obs} for the carbonato ring opening reaction are given by $k_{obs} = k_o + k_H[H^+]$, where k_o relates to the spontaneous water hydrolysis and k_H to the acid-catalysed process. The temperature dependence of k_H gives $\Delta H^{\ddagger} = 71 \pm 2\,\text{J K}^{-1}\,\text{mol}^{-1}$ and $\Delta S^{\ddagger}_{298} = -66 \pm 6\,\text{J K}^{-1}\,\text{mol}^{-1}$. The solvent deuterium isotope effect for the acid-catalysed decarboxylation k_{D_2O}/k_{H_2O} is 2.35, which is consistent with a rapid pre-equilibrium protonation of the carbonato ring, followed by rate-determining ring opening. The mechanisms of these reactions are considered in detail. At 25°C, the rate constant for the isomerisation reaction is $4.9 \times 10^{-6}\,\text{s}^{-1}$ and is independent of the acidity in the range $[H^+] = 0.05$ to $0.5\,\text{mol dm}^{-3}$ at $I = 1.0\,\text{mol dm}^{-3}$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocycle; [15]aneN$_4$; [Co([15]aneN$_4$)CO$_3$]$^+$; decarboxylation; kinetics

There have been a number of studies of the acid-catalysed decarboxylation of cobalt(III) carbonato complexes of macrocyclic tetra-amines [1–3] and many studies [4–6] of the decarboxylation of non-cyclic amine complexes. These investigations have established that the cobalt(III) complexes all undergo acid-catalysed aquation via a common mechanism involving the ring opening of the carbonato ring followed by the rapid decarboxylation of the monodentate carbonato intermediate as shown in eqs. (1–4). The conversion of the monodentate hydrogen carbonate species eq. (3) to the hydroxo-aqua complex is fast and not rate-determining. The ring opening step is catalysed both by water eq. (1) and acid eq. (2) so that k_{obs} (the observed first order rate constant at constant hydrogen ion concentration) is given by the expressions $k_{obs} = k_o + k_H[H^+]$ where k_o is the rate constant for the solvolytic pathway and k_H is the rate constant for the acid-catalysed pathway.

$$cis\text{-}[Co(L)(CO_3)]^+ + H_2O \xrightarrow{k_0} cis\text{-}[Co(L)(OH)(HCO_3)]^+ \quad (1)$$

$$cis\text{-}[Co(L)(CO_3)]^+ + H_3O^+ \xrightarrow{k_H} cis\text{-}[Co(L)(H_2O)(HCO_3)]^{2+} \quad (2)$$

$$cis\text{-}[Co(L)(H_2O)(HCO_3)]^{2+} \xrightarrow{k_1} cis\text{-}[Co(L)(OH)(H_2O)]^{2+} + CO_2 \quad (3)$$

$$cis\text{-}[Co(L)(OH)(H_2O)]^{2+} + H_3O^+ \overset{K_2}{\rightleftharpoons} cis\text{-}[Co(L)(H_2O)_2]^{3+} + H_2O \quad (4)$$

If the macrocycle is 15-membered, stable folded *cis*-complexes are only formed with chelating ligands so that the *cis*-diaqua complex formed on decarboxylation is followed by *cis-trans* isomerisation which can be observed kinetically

$$cis\text{-}[CoL(OH_2)_2]^{3+} \rightarrow trans\text{-}[CoL(OH_2)_2]^{3+}; k_i$$

* Author to whom correspondence should be addressed.

The rate constants k_H which have been reported for the acid-catalysed decarboxylation of cobalt(III) carbonato complexes vary greatly with the structure of the spectator ligand. This variation which extends over six orders of magnitude has been attributed to several factors including sterically induced strain within the carbonato ligand caused by the spectator ligand and the electron donating ability of the N_4 ligand.

Previous studies of the acid-catalysed decarboxylation of cobalt(III) macrocyclic complexes have been primarily concerned with the 14-membered ring system [2, 3, 11, 17]. We have previously studied the acid-catalysed decarboxylation of *cis*-[Co(cyclen)CO_3]$^+$ in detail [1] where cyclen is the 12-membered ring macrocycle 1,4,7,10-tetra-azacyclododecane. We have now extended this work to the 15-membered ring system and the results of this study are reported in the present paper.

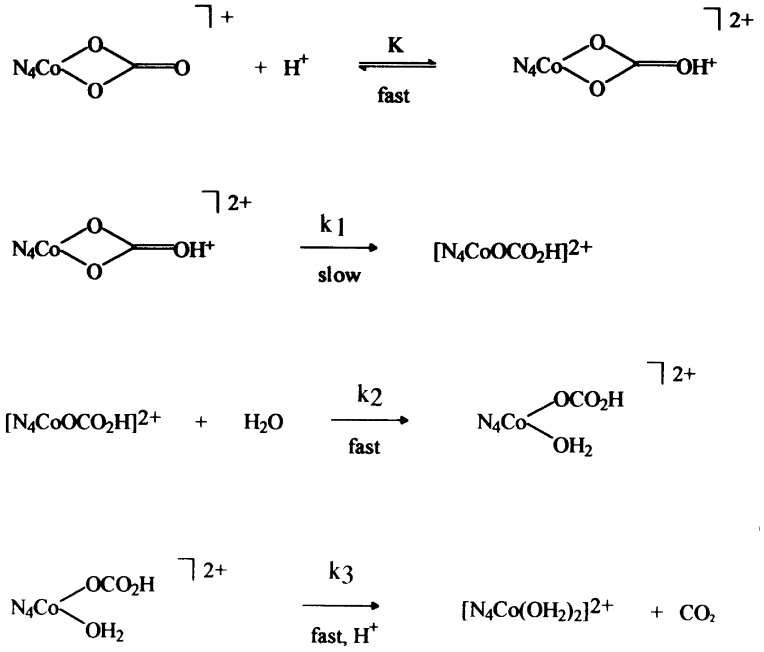
EXPERIMENTAL

Synthesis

The ligand [15]aneN$_4$ (1,4,8,12-tetra-azacyclopentadecane) was prepared by a modification of Barefield's procedure [7]. Nickel(II) chloride hexahydrate (10.2 g, 0.043 mol) was dissolved in water (150 cm^3). To this solution was added 1,11-diamino-4,8-diazundecane (8 g, 0.043 mol) with stirring, followed by 30–40% aqueous glyoxal solution (10 cm^3). The blue solution was heated to 60–80°C for 2–3 hours, during which time the solution changed to a brown–red colour. The solution was then transferred to a hydrogenation bottle along with freshly prepared Raney nickel (20 g). After flushing the vessel with nitrogen, the hydrogenation apparatus was heated to 70°C under 3.5 atmospheres of hydrogen, until hydrogen uptake ceased. The violet solution was filtered to remove the catalyst and cooled in an ice bath. Sodium thiocyanate (5.2 g, 0.065 mol) dissolved in water (25 cm^3) was then added and the purple precipitate obtained filtered off. The thiocyanate complex was dissolved in water (75 cm^3), sodium cyanide (5 g, 0.1 mol) was added and the solution refluxed for 1 hr. The solution was cooled, sodium hydroxide (5 g) was added and the solution extracted several times with dichloromethane. The extracts were combined and dried over anhydrous sodium sulphate. The sodium sulphate was filtered off and the dichloromethane removed on a rotary evaporator to give the product. The ligand was recrystallised from hexane to give white, needle-like crystals and dried *in vacuo*. (Yield 4.85 g, 52%), m.p. 100°C. IR υ(NH) 3242, 3270, 3283 cm^{-1}, ^{1}H NMR ($CDCl_3$), 1.71 (6H, quintet), 1.95 (4H), 2.75 (16H, mult.).

The tetrahydrochloride of the ligand was prepared by adding an excess of concentrated hydrochloric acid to a saturated aqueous solution of the ligand (1.07 g, 5 mmol). The hydrochloride precipitated on addition of the acid and was collected by filtration (Yield 1.64 g, 91%), m.p. 220–222°C (decomp.). IR υ(NH) 3242, 3270 and 3283 cm^{-1})

The complex [Co([15]aneN$_4$)CO_3]ClO_4 was pre-



Scheme

pared as follows. The tetrahydrochloride of the ligand (1 g, 4 mmol) was mixed with an equimolar amount of sodium tris(carbonato)cobaltate(III) trihydrate, $Na_3[Co(CO_3)_3]3H_2O$ (1.45 g, 4 mmol) and the mixture ground to a fine powder in a pestle and mortar. Water (4 cm^3) was added and the resulting green paste slowly changed colour to purple. The purple material was dissolved in ethanol (50 cm^3) and the solution filtered. Sodium perchlorate (0.8 g, 6.5 mmol) was added to the filtrate and the purple perchlorate complex precipitated by the addition of ether. The complex was recrystallised from methanol and dried *in vacuo*.

(Yield 1.54 g, 90%). Found: C, 32.2; H, 5.8; N, 12.8. Calc. for $C_{12}H_{26}N_4ClCoO_7$: C, 32.3; H, 6.0; N, 12.9%). The complex has λ_{max} 528 nm ($\epsilon = 156$) and 369 nm ($\epsilon = 216\ dm^3\ mol^{-1}\ cm^{-1}$) in water.

Physical measurements

UV–vis spectra were determined with a Perkin-Elmer Lambda 5 or Lambda 14P spectrophotometer. The instruments were fitted with a Peltier cell for constant temperature measurements. IR spectra were obtained as KBr discs on a Perkin-Elmer 1710 Fourier transform infrared spectrophotometer. Conductivity measurements were made with an AGB 1000 conductivity meter outputting to a chart recorder. ^1H NMR spectra were determined at 300 MHz with a Varian Gemini instrument. Stopped-flow measurements were made with a Hi-Tech SU 51 stopped-flow spectrophotometer. Solutions of nitric acid were prepared from Volucon reagents and were standardised against sodium hydroxide which had previously been standardised using potassium hydrogen phthalate. The ionic strength in the reactions was maintained at $I = 1.0\ mol\ dm^{-3}$ using KNO_3.

RESULTS AND DISCUSSION

A typical interval scan spectrum for the reaction of *cis*-$[CoLCO_3]^+$ (L = 1,4,8,12-tetra-azacyclopentadecane) in 0.5 $mol\ dm^{-3}$ nitric acid at 35°C and $I = 1.0\ mol\ dm^{-3}$ is shown in Fig. 1. The spectra were taken at 5 minute intervals as the reaction proceeded and confirm that it is not a simple first order process. The decrease in absorbance at 540 nm does not follow a simple first order exponential decay curve. Plots of $\ln(A_t - A_\infty)$ where A_t is the absorbance at time t and A_∞ is the final absorbance against time were not linear over the full time scale and could be fitted to two exponential decays. It was possible to study the spectral changes involved in the two reactions. The complex *cis*-$[CoLCO_3]^+$ has bands at 369 and 528 nm and, as the reaction proceeds, the band at 528 nm decreases in intensity and moves to slightly lower wavelengths (*ca.* 518 nm) and the band at 369 nm disappears. These changes are accompanied by isosbestic points at 397, 477 and 587 nm.

During the second stage of the reaction, the band at 518 nm shifts to ca. 490 nm and decreases slightly in intensity. A new band of lower intensity appears at 610 nm. Good isosbestic points occur at 367, 406, 491 and 598 nm indicating that only two uniquely absorbing species are present in solution. By monitoring the reaction at 485 nm, a wavelength midway between two of the isosbestic points for each reaction, a decrease in absorbance should be observed as the first stage proceeds and should be followed by an absorbance increase as the second reaction occurs. The plot of absorbance *versus* time, Fig. 2 confirms that this is indeed the case. The absorbance *versus* time data at 485 and 540 nm was processed in a manner analogous to the treatment of radiactive decay where a daughter species is produced whose decay half life is longer than that of the parent. Good fits to the experimental results were obtained using this method. Values of $k_{obs}(1)$ and $k_{obs}(2)$ were obtained over the acidity range 0.1 to 1.0 $mol\ dm^{-3}$ $[H^+]$ at 15, 25, 30, 35, 40 and 45°C. The rate constants $k_{obs}(1)$ are summarised in Table 1. The first stage of the reaction is the conversion of *cis*-$[CoLCO_3]^+$ with λ_{max} 369 ($\epsilon = 216$) and 528 nm ($\epsilon = 156\ dm^3\ mol^{-1}\ cm^{-1}$) to the *cis*-diaqua species with λ_{max} 518 nm. Attempts to synthesize the intermediate *cis*-$[CoL(OH_2)_2]^{3+}$ were unsuccessful. However, a comparison of the spectral changes observed in the aquation of the present complex with those observed in the aquation of the analogous complexes *cis*-$[Co(cyclam)CO_3]^+$ and *cis*-$[Co(tet\ a)CO_3]^+$ provides strong confirmatory evidence that the *cis*-diaqua complex is indeed the intermediate (Table 2).

Plots of $k_{obs}(1)$ versus the nitric acid concentration are linear with a small positive intercept, Fig. 3. The rate expression takes the form $k_{obs}(1) = k_o + k_H[H^+]$ where k_o relates to the spontaneous water reaction and k_H to the acid-catalysed process. Values of k_H and k_o over a temperature range are listed in Table 3. The rate constant k_o is subject to quite large errors due to the rather small contribution which it makes to the overall reaction. The activation parameters for the spontaneous water reaction are $\Delta H^\dagger = 161.6 \pm 18.7$ kJ mol^{-1} and $\Delta S^\dagger_{298} = 211 \pm 62$ J K^{-1} mol^{-1}. Values of k_o and the activation parameters previously determined for a range of carbonato complexes are summarised in Table 4. Values of k_o cover a range of four orders of magnitude and there is a good isokinetic relationship between $\Delta H^\dagger$ and $\Delta S^\dagger_{298}$, Fig. 4, indicating that a common mechanism applies.

Activation parameters were also obtained for the acid-catalysed pathway. The values obtained are $\Delta H^\dagger = 71 \pm 1.7$ kJ mol^{-1} and $\Delta S^\dagger_{298} = -60.6 \pm 5.7$ J K^{-1} mol^{-1} and these values are compared with those previously obtained for cobalt(III) carbonato complexes in Table 5. Values of k_H range over approximately six orders of magnitude and the k_H values for the macrocyclic complexes are all some three orders of magnitude smaller than those where $L = (NH_3)_4$, $(en)_2$ or $(pn)_2$. For the macrocyclic complexes the reactivity order is L = *trans*-Me_2[14]diene > *trans*-

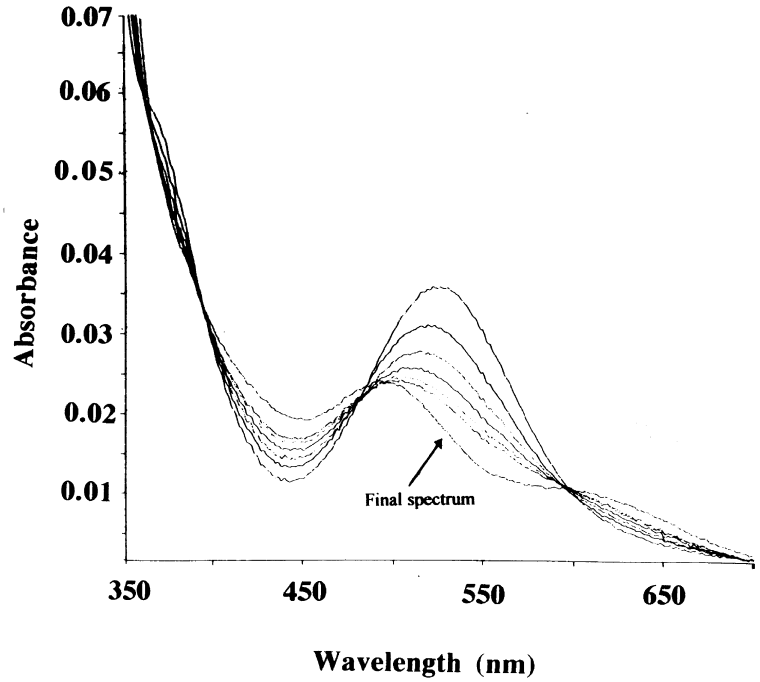


Fig. 1. Interval scan spectrum for the reaction of *cis*-$[CoLCO_3]^+$ in 0.5 mol dm^{-3} nitric acid at 35°C and $I = 1.0$ mol dm^{-3}. The time interval between scans is 5 minutes.

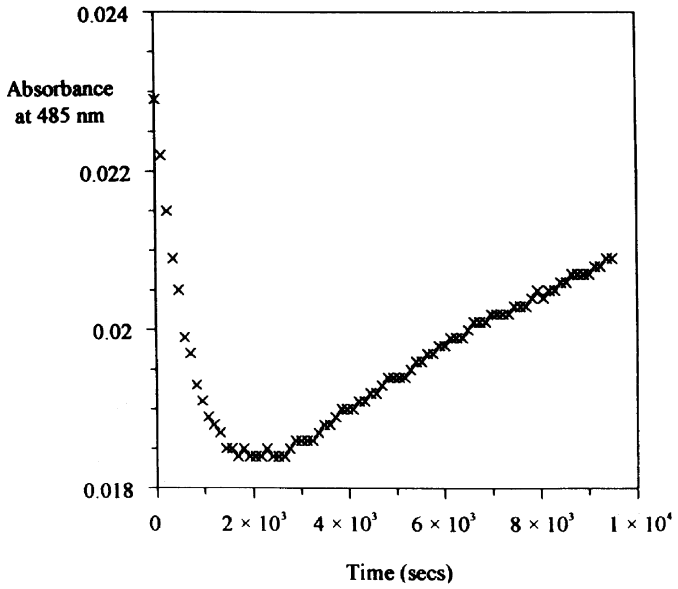

Fig. 2. Absorbance versus time plot at 485 nm for the reaction of *cis*-$[CoLCO_3]^+$ in nitric acid solution.

Me_6[14]diene > [12]aneN_4 > [15]aneN_4 > [14]aneN_4. The complex [Co[15]aneN_4)CO_3]$^+$ undergoes acid-catalysed decarboxylation some four times faster than the analogous cyclam complex at 25°C. The isokinetic plot for the acid-catalysed reactions shows considerable scatter, Fig. 5 and this probably arises in part, because k_H is the product of a rate constant and an equilibrium constant.

Francis and Jordan [8] have suggested that there is a relationship between the rate constant k_H and the average pK_a of the amine ligands in the $[CoN_4CO_3]^+$ complexes. The average pK_a of the amine ligand can

Table 1. Values of $k_{obs}(1)$ for the acid-catalysed decarboxylation of *cis*-$[CoLCO_3]^+$ at $I = 1.0\,mol\,dm^{-3}$ over the temperature range 15–45°C

be used as a rough measure of the basicity and hence the electron donating ability of the nitrogen donors. As the electron donating ability decreases the residual positive charge on cobalt(III) increases and this leads to a stronger Co–O bond. The parameters listed in Table 6 indicate that an approximate relationship of this type does exist.

Mechanisms

A variety of mechanisms can be considered for the acid-catalysed decarboxylation of carbonato

complexes. The most probable mechanism which is supported by the bulk of the experimental evidence is shown in the scheme. The reaction involves a rapid pre-equilibrium protonation of the carbonato complex followed by slow rate-determining ring opening and rapid decarboxylation of the monodentate carbonato intermediate. For this mechanism, it can be readily shown that $k_{obs} = k_1 K[H^+]/(1 + K[H^+])$ and, if $K[H^+] < 1$, the expression simplifies to $k_{obs} = k_1 K[H^+]$. This latter situation applies as plots of k_{obs} *versus* $[H^+]$ are linear and show no curvature. Although some non-linear plots have been observed [4, 9, 10], these effects arise due to an enhanced ring opening reaction which is faster than the rate of decarboxylation. As a result, the decarboxylation step, which is acid independent, becomes rate-limiting at high acidities.

The solvent deuterium isotope effect for the acid-catalysed reaction was studied using $0.50\,mol\,dm^{-3}$

Fig. 4. Isokinetic plot for the spontaneous water reaction in the ring opening of cobalt(III) carbonato complexes.

DCl in D_2O at 25°C giving $k_{obs} = 1.73 \times 10^{-3}\,s^{-1}$ and an approximate value of $k_{D_2O} = 3.39 \times 10^{-3}\,dm^3\,mol^{-1}\,s^{-1}$ if the very small contribution from k_o is ignored. For the equivalent reaction involving 0.50 mol dm^{-3} HCl in H_2O at 25°C, $k_{obs} = 7.20 \times 10^{-4}\,s^{-1}$ and $k_{H_2O} = 1.44 \times 10^{-3}\,dm^3\,mol^{-1}\,s^{-1}$, giving a solvent deuterium isotope effect k_{D_2O}/k_{H_2O} for the acid catalysed reaction = 2.35 at 25°C. This value compares well with previously reported solvent deuterium isotope effects for reactions of this type. For example, 2.3 for *cis*-$[Co(en)_2CO_3]^+$ [10], 2.6 for *cis*-$[Co(Me_2[14]diene)CO_3]^+$ [11] and 2.05 for *cis*-$[Co(cyclen)CO_3]^+$ [1]. All of these values fall within the range 1.9 to 2.6 considered typical for a rapid pre-equilibrium protonation followed by a slow ring-opening reaction. As D_2O is a weaker base than water more of the protonated complex is present in D_2O and a more rapid reaction occurs. Since $k_H = k_1K$, the rate and equilibrium constants may well be affected somewhat differently by steric and electronic effects and this is the probable reason for the large scatter observed in the isokinetic plot.

Isomerisation

The second stage of the reaction involves the conversion of *cis*-$[Co([15]aneN_4)(OH_2)_2]^{3+}$ to a product with λ_{max} *ca.* 490 nm and a second less intense band at 610 nm. This spectrum corresponds to the *trans*-diaqua complex. The rate of isomerisation is independent of the acidity in the range 0.05 to 0.50 mol dm^{-3} nitric acid with $k_{isom} = 4.9 \times 10^{-6}\,s^{-1}$ at 25°C and $I = 1.0$ mol dm^{-3}. Previous studies [3, 8] of the *cis–trans* isomerisation of macrocyclic cobalt(III) complexes have shown that the mechanism is complex and involves the inversion of *sec*–NH centres in an acid or base catalysed process.

(Received 25 March 1998; accepted 13 May 1998)

Abstract—The synthesis and characterisation of copper(II) complexes of Schiff base ligands derived from 2-(2-pyridylmethyl)-1,3-propanediamine and substituted salicylaldehydes are reported together with the crystal structure of $CuL^2 \cdot MeOH$ in which the ligand L^2 is derived from 5-bromosalicylaldehyde is also reported. The pendant arm does not engage in inter- or intramolecular binding and inspection of the packing diagram shows that the molecules coexist as discrete van der Waals dimers. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

The diamine 2-(2-pyridylmethyl)-1,3-propanediamine has been used in the construction of a series of lariat-type B_{12} model complexes [1]. Its reaction with 2,3-butanedione monoxime gave a potentially quinquedentate acyclic ligand (HL) which readily formed mononuclear complexes on reaction with cobalt compounds. The role of the pyridyl moiety as an axial coordinating pendant arm has been confirmed by X-ray structural analysis of $[ClCoL]PF_6$ and $[CH_3CoL]ClO_4/BF_4$. In this work we prepared lariat-type Schiff base ligands by reaction of 2-(2-pyridylmethyl)-1,3-propanediamine and a series of substituted salicylaldehydes in order to determine whether or not there would be an axial pendant arm interaction on reaction of these ligands with copper(II) salts.

EXPERIMENTAL

Physical measurements

Elemental analyses were carried out by the University of Sheffield Microanalytical service. Infrared spectra were recorded as KBr discs using a Perkin Elmer 1600 Fourier Transform spectrometer; NMR spectra were run on a Bruker ACF-250 spectrometer and mass spectra were obtained on a VG PROSPEC spectrometer.

Synthesis of pendant arm Schiff base ligands

2-(2-pyridylmethyl)-1,3-propane diamine was prepared according to the method given in literature [1].

H_2L^1. Salicylaldehyde (4 mmol) in methanol (50 cm^3) was added slowly to a solution of 2-(2-pyridylmethyl)-1,3-propane diamine (2 mmol) in methanol (100 cm^3). The yellow solution was stirred at room temperature for 2 h, then the solvent removed under reduced pressure to yield a viscous yellow oil in quantitative yield. MS (ES^+) 374 a.m.u.; ^1H NMR ($CDCl_3$) δ 13.45 (br), 8.55 (1H, m), 8.35 (2H, s), 7.58 (1H, m), 7.35–7.10 (6H, m), 7.00–6.85 (4H, m), 3.67 (4H, m), 2.95 (2H, d), 2.80 (1H, m); ^{13}C NMR ($CDCl_3$) δ 166.2, 161.1, 159.6, 149.5, 136.5, 132.4, 131.4, 123.9, 121.5, 118.7, 118.7, 117.0, 60.5, 40.6, 39.2

H_2L^2. The procedure for H_2L^1 was followed, using 5-bromosalicylaldehyde. The yellow oil was purified by column chromatography, eluting with dichloromethane–methanol (97:1). Yield 63%; MS. (EI^+) 531 a.m.u.; ^1H NMR ($CDCl_3$) δ 13.40 (2H, s), 8.55 (1H, m), 8.25 (2H, s), 7.60 (1H, m), 7.38 (2H, dd), 7.34 (2H, d), 7.15 (2H, m), 6.85 (2H, d), 3.77–3.58

(4H, 2ddd), 2.92 (2H, dd), 2.82 (1H, m); ^{13}C NMR ($CDCl_3$) δ 165.0, 160.2, 159.3, 149.6, 136.6, 135.1, 133.5, 123.8, 121.6, 120.0, 119.0, 110.14, 60.6, 40.4, 39.1.

H_2L^3. The procedure for H_2L^1 was followed, using 5-chlorosalicylaldehyde, to give the product as a viscous yellow oil in quantitative yield. MS. (EI^+) 441 a.m.u.; ^{1}H NMR ($CDCl_3$) δ 13.35 (br), 8.55 (1H, m), 8.25 (2H, s), 7.60 (1H, m), 7.30–7.20 (4H, m), 7.15 (2H, m), 6.90 (2H, d), 3.70 (4H, m), 2.95 (2H, d), 2.85 (1H, m); ^{13}C NMR ($CDCl_3$) δ 165.1, 159.7, 159.3, 149.6, 136.5, 132.3, 130.5, 123.8, 123.3, 121.6, 119.4, 118.6, 60.6, 40.4, 39.1.

H_2L^4. The procedure for H_2L^1 was followed, using 2-hydroxy-5-nitrobenzaldehyde. The reaction was carried out under nitrogen and protected from light. The product was collected as a pale yellow precipitate in 80% yield. MS (EI+) 464 a.m.u.; microanalysis (%) found (required for $C_{23}H_{21}N_5O_6$): C 59.66 (59.61), H 4.47 (4.57), N 14.93 (15.11); IR (KBr disc) v(C═N) 1637 cm^{-1}, v(NO_2) 1481, 1345 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 14.30 (br), 8.75 (2H, s), 8.55 (1H, m), 8.37 (2H, d), 8.05 (2H, dd), 7.71 (1H, m), 7.29 (1H, d), 7.21 (1H, m), 6.69 (2H, d), 3.75 (4H, d), 2.90 (3H, m); ^{13}C NMR (CDCl3) δ 174.8, 167.9, 158.9, 149.7, 137.2, 135.8, 131.6, 129.2, 124.2, 122.1, 121.7, 115.4, 56.1, 39.3, 38.1.

H_2L^5. The procedure for H_2L^1 was followed, using 2-hydroxy-3-methoxybenzaldehyde, to yield a sticky yellow oil in quantitative yield. MS (EI^+) 434 a.m.u.; ^{1}H NMR ($CDCl_3$) δ 14.01 (br), 8.54 (1H, m), 8.34 (2H, s), 7.59 (1H, m), 7.19 (1H, d), 7.14 (1H, m), 6.94–6.80 (6H, m), 3.90 (6H, s), 3.67 (4H, m), 2.97 (2H, d), 2.77 (1H, m); ^{13}C NMR (CDCl3) δ 166.3, 159.4, 151.9, 149.5, 148.4, 136.5, 124.0, 123.0, 121.5, 118.5, 118.0, 113.9, 59.5, 56.1, 40.5, 38.9.

H_2L^6. A suspension of disodium salicylaldehyde-5-sulphonic acid (4 mmol) in ethanol (140 cm^3) was warmed to 60°C, then water added dropwise until a clear yellow solution formed. An ethanolic solution (15 cm^3) of 2-(2-pyridylmethyl)-1,3-propane diamine (2 mmol) was slowly added and the resulting orange solution stirred at room temperature for 2 h. The solution was left at 0°C overnight and the product precipitated as a pale yellow powder in 47% yield. Microanalysis (%) found (required for $C_{23}H_{27}N_3O_{11}S_2Na_2$): C 43.88 (43.74), H 4.18 (4.31), N 6.78 (6.65); IR(KBr disc) v(C═N) 1636 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 13.70 (br), 8.61 (2H, s), 8.53 (1H, m), 7.77–7.65 (3H, m), 7.57 (2H, dd), 7.28 (1H, d), 7.22 (1H, m), 6.79 (2H, d), 3.62 (4H, d), 2.84 (2H, m), 2.68 (1H, m); co 159.8, 149.7, 139.3, 137.0, 130.4, 129.4, 124.1, 121.9, 117.6, 116.3, 60.0, 38.9, 38.7.

Compounds H_2L^1, H_2L^2, H_2L^3, and H_2L^5 were used in complex formation without further purification.

Synthesis of pendant arm Schiff base complexes

$CuL^1 \cdot 0.5H_2O$, ***1***. A solution of cupric acetate (1 mmol) in methanol (30 cm^3) was added to a solution of ligand H_2L^1 (1 mmol) in methanol (15 cm^3). The mixture was stirred at room temperature for 2 h and the solvent removed under reduced pressure to give a green oil. Ethanol was added and a green precipitate formed, which was collected by filtration and dried to give a green powdery solid in 49% yield. Microanalysis (%) found (required for $C_{46}H_{44}N_6O_5Cu_2$): C 62.64 (62.22), H 4.98 (4.99), N 9.13 (9.46); IR (KBr disc) ν(C = N) 1616 cm^{-1}.

$CuL^2 \cdot MeOH$, ***2***. Cupric acetate (1 mmol) was added to a solution of ligand H_2L^2 (1 mmol) in methanol (25 cm^3) and the mixture stirred at room temperature for 2 h. The resulting green precipitate was collected by filtration and recrystallised from methanol to give dark blue–green crystals in 46% yield. Microanalysis (%) found (required for $C_{24}H_{23}N_3O_3Br_2Cu_1$): C 46.13 (46.14), H 3.54 (3.71), N 6.56 (6.73); IR(KBr disc): v(C═N) 1617 cm^{-1}.

$CuL^3 \cdot MeOH$, ***3***. The method for **2** was used, using ligand H_2L^3, to give a green solid in 50% yield. Microanalysis (%) found (required for $C_{24}H_{23}N_3O_3Cl_2Cu_1$): C 53.89 (53.79), H 4.12 (4.33), N 7.83 (7.84), Cl 13.35 (13.23); IR(KBr disc): v(C═N) 1616 cm^{-1}.

$CuL^4 \cdot H_2O$, ***4***. A solution of cupric acetate (0.7 mmol) in water (10 cm^3) was added to a suspension of ligand H_2L^4 (0.7 mmol) in ethanol (30 cm^3). The mixture was heated at reflux for 1.5 h and the green precipitate collected in 90% yield. Microanalysis (%) found (required for $C_{23}H_{21}N_5O_7Cu_1$): C 50.90 (50.88), H 3.74 (3.90), N 13.28 (12.90); IR(KBr disc) v(C═N) 1628 cm^{-1}, v(NO_2) 1474, 1320 cm^{-1}.

$CuL^5 \cdot 1.5H_2O$, ***5***. The method for **2** was used, using ligand H_2L^5. The resulting solution was concentrated and diethyl ether added to precipitate the product in 45% yield. Microanalysis (%) found (required for $C_{50}H_{56}N_6O_{11}Cu_2$): C 57.44 (57.52), H 5.00 (5.41), N 8.13 (8.05); IR(KBr disc): v(C═N) 1621 cm^{-1}.

$CuL^6 \cdot 5H_2O$, ***6***. 2-(2-pyridylmethyl)-1,3-propane diamine (2 mmol) in ethanol (15 cm^3) was added dropwise to a solution of cupric nitrate (2 mmol) and disodium salicylaldehyde-5-sulphonic acid (4 mmol) in water–ethanol (3:1, 150 cm^3). The solution, which became very dark green, was stirred with warming for 2 h, then ethanol added to precipitate the dark green solid in 82% yield. Microanalysis (%) found (required for $C_{23}H_{21}N_5O_7Cu_1$): C 50.90 (50.88), H 3.74 (3.90), N 13.28 (12.90); IR(KBr disc): v(C═N) 1626 cm^{-1}.

X-ray crystallography

Complex **2**, $C_{24}H_{23}Br_2CuN_3O_3 \cdot CH_3OH$ was crystallised from methanol as blue prisms. The crystallographic data are summarised in Table 1.

Three-dimensional, room temperature X-ray data were collected in the range $3.5 < 2\theta < 45^\circ$ on a Siemens P4 diffractometer by the omega scan method. Of the 3995 reflections measured, all of which were corrected for Lorentz and polarisation effects but not for absorption, 2450 independent reflections exceeded

dant pyridyl arm. The proligands were characterised via ^{1}H and ^{13}C NMR and mass spectrometry.

Synthesis of the copper(II) complexes of H_2L^1–H_2L^5 was achieved by addition of copper(II) acetate to a methanolic solution of the proligand; in the cases where X = Br, Cl and NO_2 the complexes precipitated from solution, otherwise diethylether was added to induce precipitation. The copper(II) complex of the water soluble Schiff base H_2L^6 was prepared by addition of 2-(2-pyridylmethyl)-1,3-propanediamine to a solution containing the sulphonated salicylaldehyde and copper(II) nitrate in a mixture of water and ethanol; ethanol was then added to induce precipitation of the product.

The mass spectral (FAB^+) assignments for the complexes are given in Table 2. In each case the most abundant peak was that corresponding to the parent cation with small peaks attributed to dimeric species, probably arising from aggregation in the matrix, being observed for the complexes containing bromo-, sul-

phonato-, and methoxy substituents. Peaks indicating addition and loss of Na^+ were noted at $m/z = 661$ and 617, respectively, for the sulphonato-complex.

2-(2-Pyridylmethyl)-1,3-propanediamine was employed as a spacer in the Schiff base proligands as it was thought that the pyridine nitrogen atom on the pendant arm might coordinate to the copper atom by occupying a fifth and axial coordination site as had been observed in a cobalt(III) complex of the Schiff base derived from the diamine and 2,3-butanedione monooxime [1]. Recrystallisation of the bromo-complex (**2**) from methanol gave crystals suitable for X-ray structure determination and elucidation of the structure (Fig. 1) revealed that axial ligation had not occurred. The pyridine nitrogen atom was neither coordinated to the central copper atom coordination nor to any other copper atoms in neighbouring molecules. The copper atom interacts with the two imine nitrogen atoms (1.937 and 1.965 Å) and to the two phenolate oxygen atoms (1.896 and 1.918 Å) of the ligand to attain a four-coordinate environment. This is clearly tetrahedrally distorted from a square planar geometry with the mean deviation from the plane including O(1), O(2), N(1), N(2), and Cu(1) being 0.2629 Å. The mean deviations for the planes comprising the two six-membered chelate rings Cu(1), O(1), C(1), C(6), C(7), N(1) and Cu(2), O(2), C(23), C(18), C(17), N(2) are 0.0361 and 0.0189 Å, respectively, and the angle of twist between these two planes is 28.8°. The aromatic rings are each planar (r.m.s deviations 0.008, 0.009 and 0.003 Å with Br(1) −0.015 and Br(2) 0.127 Å out of planarity). The pyridyl ring is approximately perpendicular to the phenyl rings (89° and 111°, respectively). Inspection of the packing diagram (Fig. 2) shows that the molecules coexist as discrete pairs. It has long been known from crystal

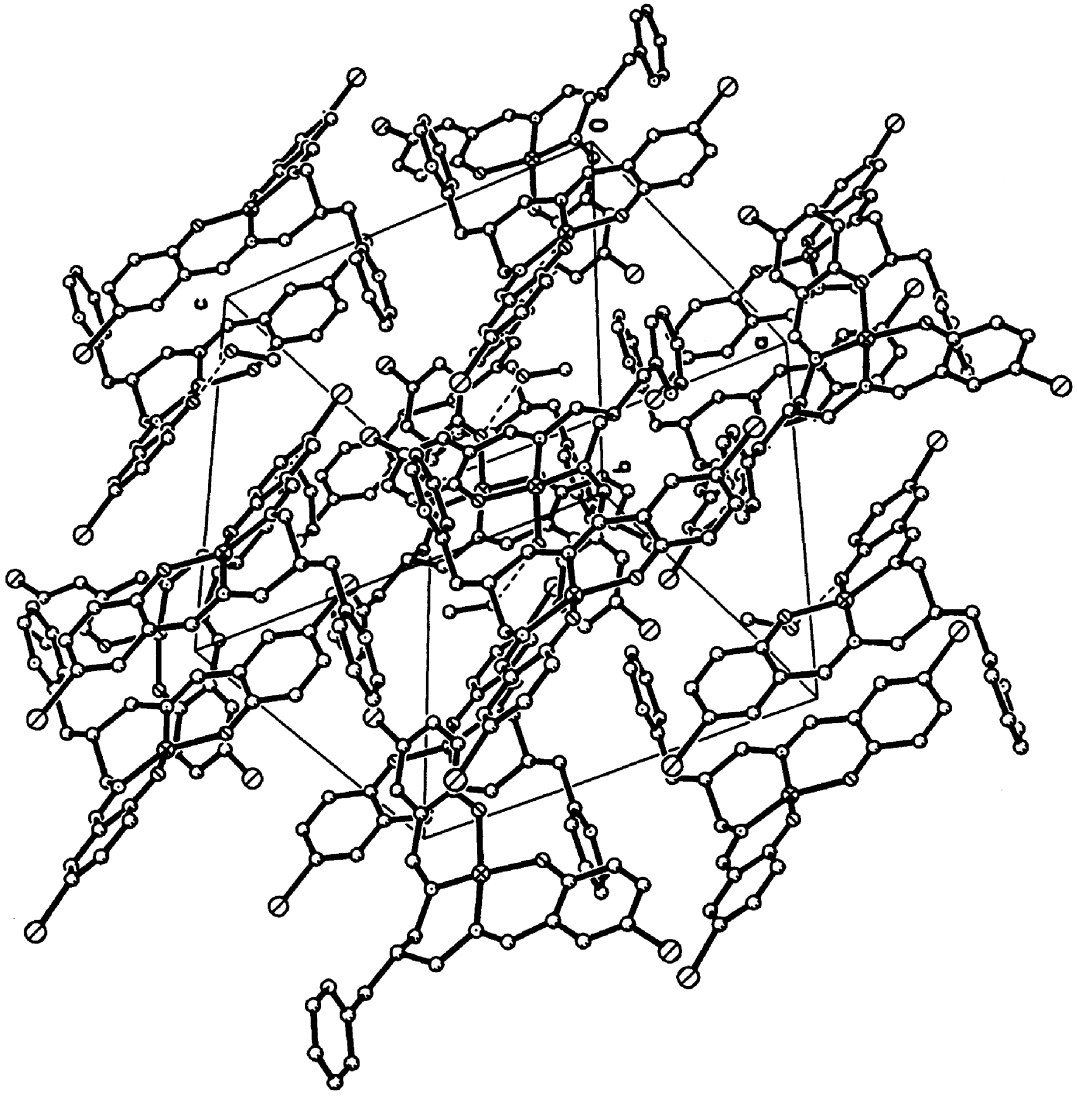

Fig. 2. The crystal packing in complex (**2**) projected along the *a* axis.

structure data that self-association can occur in copper(II) complexes of ligands such as β-diketonates [3]. Such molecules are relatively planar but pack in the crystals such that there is a weak interaction between the copper atom of one molecule and the middle carbon atoms of the chelate rings of neighbouring molecules. This is considered as arising from an interaction of the carbon p_z electrons with the neighbouring copper atom and gives rise to Cu–C separations of 3.0–3.5 Å. More recently bis(tropolonato) copper(II) has been shown to exist as dimers in the crystalline state with the two monomers stacked face to face [4]. The intermolecular nearest neighbour distances lie in the range 3.3–3.8 Å and so the dimer was said to be of the van der Waals type. In complex **2** the molecules align such that the copper atoms lie almost directly under the centroid of a neighbouring benzene ring [Cu-centroid, 3.76 Å; with a distance of 3.69 Å to the nearest edge C atom C(5) or C(19)] suggesting that there is a weak interaction between the copper and the aromatic π-cloud which reinforces, and possibly directs the stereochemical nature of, the van der Waals assisted self-association.

The structure also includes a methanol of solvation which is involved in a strong hydrogen bonding interaction to one phenolic oxygen [O(2)–HO(3) 0.938, HO(3)$\cdots$O(2) 1.903 Å, O(2)$\cdots$O(3) 2.795 Å]. Bond lengths and angles relating to the copper atom are given in the caption of Fig. 1; all other ligand bond lengths and angles were normal.

Abstract—The exchange kinetics of Li^+C221 cryptate in methanol solution was studied by lithium-7 NMR line-shape analysis at a wide range of temperature. Depending on the temperature, two different exchange mechanisms were found to coexist to different extents. A dissociative pathway dominates at high temperatures (from 5 to 25°), while a bimolecular mechanism prevails at lower temperatures (from −30 to −60°C). At the temperature range of −30 to 5°C, both the dissociative and bimolecular mechanisms contribute to the metal exchange. For the dissociative pathway, the activation parameters were calculated as: $E_a = 22 \pm 2\,kJ\,mol^{-1}$; $\Delta H^{\ddagger} = 20 \pm 2\,kJ\,mol^{-1}$; $\Delta S^{\ddagger} = -144 \pm 8\,J\,mol^{-1}\,K^{-1}$. While for the bimolecular mechanism they are: $E_a = 9.9 \pm 0.4\,kJ\,mol^{-1}$; $\Delta H^{\ddagger} = 8.0 \pm 0.4\,kJ\,mol^{-1}$; $\Delta S^{\ddagger} = -146 \pm 2\,J\,mol^{-1}\,K^{-1}$. © 1998 Published by Elsevier Science Ltd. Macrobicyclic polyethers (cryptands), first synthesized by Lehn and co-workers [1], in their endo–endo conformation contain an internal cavity of about spherical shape well suited for the recognition of alkali metal ions [2]. Thus, the thermodynamics of alkali cryptates in various solvent systems have been the subject of extensive research [3, 4]. Investigation of the factors affecting the thermodynamic stability and selectivity of such inclusion complexes in solution have elicited considerable interest. It has been found that the cryptands form complexes with suitable alkali metal ions which are several orders of magnitude higher than those of neutral or synthetic macrocyclic ligands [3–7], a phenomenon called the "cryptate effect" [5–7].

Moreover, a fundamental characteristic of alkali cryptate formation is the rate of cation exchange in and out of the ligand's cavity. Such kinetic studies not only result in important information on the rates and mechanisms of the complexation reactions, but also lead to a better understanding of the high stability and high selectivity of the cryptands toward different alkali cations. A number of such exchange kinetic studies have been carried out using various physico–chemical techniques [3, 4], especially proton and alkali metal NMR spectroscopy [8–17].

We have previously reported the use of line-shape analysis of the ^{7}Li [13], ^{23}Na [18], ^{133}Cs [14, 19, 20] and ^{1}H [21–24] NMR resonance lines in studies of the complexation of Li^+, Na^+, Cs^+, Pb^{2+}, La^{3+} and alkaline earth cations with different crown-ethers and cryptands in a number of different solvent systems. It has been found that the ligand structure, solvent properties, nature of counter ion, concentration of the reactants and temperature have considerable effects on the reaction rates, activation parameters and exchange mechanism of cations and macrocycles between the solvated and complexed sites. Since there was evidence for the change in the exchange mechanism of a number of metal ion–crown ether systems with temperature in methanol solution [18, 20, 23], we were interested in examining the temperature effect on the exchange kinetics of metal cryptates in this solvent. In this paper we used lithium-7 NMR line-shape analysis to determine the kinetic parameters and the mech-

anism for the chemical exchange of Li^+ ion between the solvated and complexed sites with cryptand C221 (I) in methanol solution over a wide range of temperature (i.e. -60 to 25°C). It should be noted that the use of NMR line-shape analysis in monitoring the kinetics and mechanism of reactions involving different lithium compounds has well been documented in the pioneering work of Kaplan and Fraenkel [25].

EXPERIMENTAL

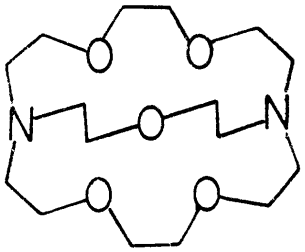
Cryptand C221 (Merck, I) was of the highest purity available and used without further purification except for vacuum drying. Reagent grade lithium perchlorate (Merck) was purified and dried as described before [26]. Spectroscopic grade methanol (Merck) was used as received. The concentration of lithium perchlorate in each solution was kept constant at 0.01 M.

All NMR measurements were done on a JEOL FX90Q FT-NMR spectrometer with a field strength of 21.13 kG. At this field, lithium-7 resonates at 34.77 MHz. The temperature of the probe was adjusted with a temperature control unit using liquid nitrogen at low temperatures and a heating element at high temperatures. To reach the equilibrium temperature, each sample tube was left in the probe for at least 15 min before measurement. At all temperatures used, the accuracy of the temperature measurements was ± 0.1°C.

The line widths of the free and complexed Li^+ ion were measured by fitting a Lorentzian function to their spectra. A complete line-shape analysis technique was used to determine the mean lifetime, τ, for the exchange processes, using the modified Bloch equations [25, 27]. The equations used were of a similar format to those used by Cahen *et al.* [10]. A non-linear least-squares program written based on the Powell technique was used to fit 100–150 points of the spectral data to the exchange equations in order to extract the τ values for the exchange system at several temperatures.

RESULTS AND DISCUSSION

From both the solid crystalline structure [28, 29] and solution studies [10, 30–32], it is well known that the cryptate complexes of alkali ions could exist either in the "inclusive" form or in the "exclusive" form. In an inclusive complex, the metal ion is located in the center of the tridimensional cavity of the cryptand, while in an exclusive structure, the metal ion resides approximately in the center of one of the poly(oxadiazacycloalkane) rings of the cryptand. In the inclusive complexes, the cryptand exists in the endo–endo conformation in which both nitrogen lone electron pairs point toward the cavity center.



I

Lithium ion, due to its suitable size for the cavity of C211, forms a very stable inclusive Li^+C211 complex both in the crystalline state [29] and in solution [10, 31]. Lithium-7 NMR studies [10] revealed two ^{7}Li signals for the free and complexed Li^+ ion with C211, even in solvents of high donicity, the resonance of the ion inside the cryptand cavity being completely independent of the solvents. However, in the case of Li^+C221 and Li^+C222 systems, only one population averaged ^{7}Li signal was observed indicating fast Li^+ exchange between the two sites. In methanol solution, while the stability of Li^+C211 cryptate is very high ($\log K_f = 8.04$) [33], the cation forms much less stable cryptates with cryptands C221 ($\log K_f = 5.38$) [33] and, especially, C222 ($\log K_f = 2.46$) [34].

The exchange kinetics of C221 with Li^+ ion was studied in methanol solution by ^{7}Li NMR line-shape analysis at a wide range of temperature. In all cases, the concentration of lithium perchlorate salt was kept constant at 0.01 M and three solutions with C221 to Li^+ ion mole ratios <1 were prepared, so that each solution contained free and complexed Li^+ ion. The ^{7}Li NMR spectra of the resulting solutions were obtained at several different temperatures (Figure 1). At the same time, and under the same experimental conditions, the ^{7}Li NMR spectra of the solvated and complexed sites (i.e. 0.01 M solutions of $LiClO_4$ with respective ligand-to-metal ion mole ratios of 0.0 and >1) were obtained and the line widths were measured by fitting a Lorentzian function to the spectra. Interestingly, the broadening of the resonance lines of Li^+ in the solvated shell and in the cryptate form, even at very low temperatures, was found to be approximately equal. This observation, which originated from similar symmetry of the electrical field gradients in both sites, implies that the small Li^+ ion should be located in the center of the cavity of the cryptand, as is reported for the crystalline state of the alkaline cryptates [28].

Line-shape analysis to the NMR exchange equations by non-linear regressions of the 100–150 points of the spectra yielded the corresponding mean lifetimes, τ, for the exchange system used at various temperatures. The program requires evaluation of at least four parameters: amplitude, base line, zero-order phase correction and mean life time. A sample computer fit of the ^{7}Li NMR spectra is shown in Fig. 2 and all resulted τ values are collected in Table 1.

As Shchori *et al.* [35] proposed, the lithium ion may exchange between the solvated and cryptate sites by

either a bimolecular mechanism (I) or a dissociative pathway (II).

$$*Li^+ + Li^+C221 \xrightarrow{k_1} *Li^+C221 + Li^+ \quad (I)$$

$$Li^+ + C221 \underset{k_{-2}}{\overset{k_2}{\rightarrow}} Li^+C221 \quad (II)$$

The general expression for τ, in terms of the above mechanisms, is [13, 14, 18–20]:

$$1/\tau = k_1[Li^+]_{tot} + k_{-2}[Li^+]_{tot}/[Li^+]_{free} \quad (1)$$

where $[Li^+]_{tot}$ and $[Li^+]_{free}$ represent the total concentration and the concentration of uncomplexed lithium ion, respectively. According to eq. (1) at a given temperature, a plot of $1/\tau$ $[Li^+]_{tot}$ vs $1/[Li^+]_{free}$ determines the contribution of the two mechanisms to the exchange process. Such plots are shown in Fig. 3.

From Fig. 3, it is immediately obvious that, depending on the temperature, two different exchange mechanisms coexist to different extents. The bimolecular mechanism dominates at low temperatures (below $-30°C$) while the dissociative pathway prevails above $5°C$. However, at the temperature range between -30 to $5°C$, both the dissociative and bimolecular mechanisms contribute the metal exchange; the contributions of the two mechanisms could be obtained graphically. We have previously observed the same kind of temperature dependence of the exchange mechanism for diaza-18-crown-6-NaSCN system in THF [18], dibenzo-30-crown-10-CsSCN system in propylene carbonate and methanol [20] and 18-crown-6-$Pb(NO_3)_2$ in 70% methanol [24].

The first report on the predominance of a bimolecular mechanism was reported by Schmidt and Popov for the K^+-18-crown-6 complex in a number of non-aqueous solvents by ^{39}K NMR [36]. Since then this mechanism has been found to be operative for the chemical exchange of some other complexes of macrocyclic ligands with metal ions including Li^+ [13,

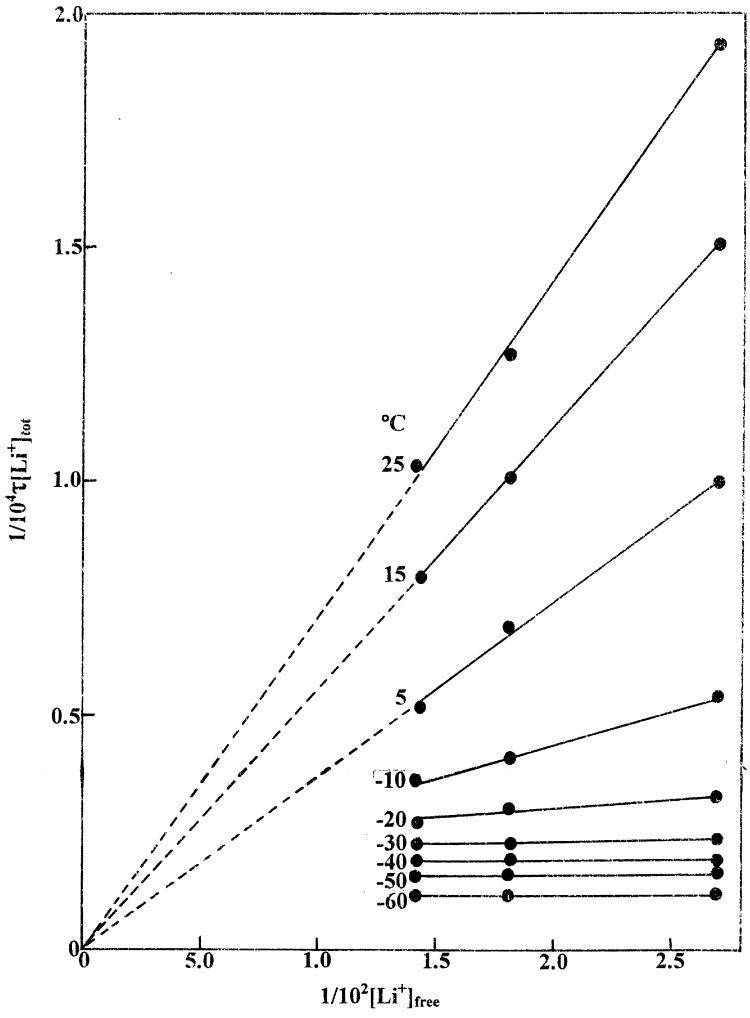

Fig. 3. Plots of $1/\tau$ $[Li^+]_{tot}$ vs $1/[Li^+]_{free}$ for Li^+–C221 system in methanol at different temperatures.

37], Na^+ [18, 38], Cs^+ [14, 19, 20], Ba^{2+} [23] and Pb^{2+} [24] ions, as studied by ^7Li, ^{23}Na, ^{133}Cs and ^1H NMR, respectively. Noteworthy, the competition between the bimolecular and dissociative mechanisms for the exchange not only depends on the temperature [18, 20, 24] but also on other experimental parameters such as the solvent properties [20, 39], nature of counter ion [40] and the concentration range studied [23, 41]. It is interesting to note that, in order for a bimolecular metal exchange to proceed in a metal-macrocycle system, the ligand should have a conformation such that the simultaneous arrival of a free cation and departure of the complexed cation can easily occur [18–20, 36].

Since in the case of both dissociative and bimolecular exchange mechanisms $1/\tau$ is proportional to k_d, it is obvious that the Arrhenius activation plots could also be obtained by plotting $\log(1/\tau)$ vs inverse temperature. Such plots for the two mechanisms, obtained at two different temperature ranges, are given in Fig. 4. Activation energies for the release of Li^+ ion from the C221 cavity were determined from the slopes of these plots and the activation parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ and $\Delta G^{\ddagger}$ were calculated by using Eryring's transition-state theory [42]. The results of these calculations are summarized in Table 2.

From the data given in Table 2, it is immediately obvious that the $\Delta G^{\dagger}$ value for a bimolecular mechanism is smaller than that for a dissociative pathway. A similar behavior has already been reported for other exchange systems [18, 20, 21]. Thus, the observed change in the exchange mechanism seems to be due to the fact that, at low temperature, the system chooses a lower energy pathway for the decomplexation step. It is interesting to note that the predominance of the bimolecular exchange mechanism over the dissociative pathway is mainly of enthalpic origin. While the $\Delta S^{\ddagger}$ values are about the same for the two exchange mechanisms, within the experimental errors, the $\Delta H^{\ddagger}$ value for the bimolecular mechanism is some 12 kJ mol^{-1} smaller than that for the dissociative pathway. The large negative entropy of activation may result from a much higher degree of solvent organization, in going from the initial complex to the transitions state,

Table 2. Activation parameters for the metal exchange in Li^+–C221 system in methanol solution

Exchange mechanism	E_a (kJ mol^{-1})	$\Delta H^\dagger$ (kJ mol^{-1})	$\Delta S^\dagger$ (J mol^{-1} K^{-1})	$\Delta G^\dagger$ [a] (kJ mol^{-1})	k
Bimolecular	9.9 ± 0.4	8.0 ± 0.4	-146 ± 2	51.5 ± 0.2	$(2.3 \pm 0.1) \times 10$ [b]
Dissociative	22 ± 2	20 ± 2	-144 ± 8	62.9 ± 0.4	70 ± 2 [c]

[a] The standard deviation calculated by using the approximate equation $\sigma(\Delta G^\dagger) \approx |\sigma(\Delta H^\dagger) - T\sigma\Delta S^\dagger|$ [44].

[b] Unit: $M^{-1} s^{-1}$ (at $-30°C$).

[c] Unit: s^{-1} (at 25°C).

due to strong solvation of Li^+ ion with methanol [43].

The rate of dissociation of metal ion from the cryptate seems to be primarily dependent on the optimization of fit between the metal ion and the cryptand cavity [13, 16]. The Li^+ ion has just the right size for the cavity of C211 [5, 6] to form a very stable cryptate, while the cation size is too small for the cavity of C221 which results in the formation of a weaker complex, in solution [33]. Thus, it is not unexpected to observe a very low dissociation rate of the Li^+–C211 cryptate in methanol solution (i.e. $k_d = 4.4 \times 10^{-3} s^{-1}$) [33] in comparison with that obtained in this study Table 2.

(Received 20 May 1997; accepted 25 June 1997)

Abstract—Reaction of ferrocenylmethanol, $FcCH_2OH$, with β-cyano-*N*,*N*-diisopropyl chlorophosphoramidite in dichloromethane yields the ferrocenylmethylphosphonate derivative, $FcCH_2P(O)(N(iPr)_2)(OCH_2CH_2CN)$, **2a**. The crystal and molecular structure of **2a** is presented. ^{31}P NMR data suggest that this is formed from $FcCH_2OP(N(iPr)_2)(OCH_2CH_2CN)$ via a Michaelis–Arbusov-type rearrangement. Similar behaviour was also observed for 1,2-phenylene chlorophosphite and diethyl chlorophosphite. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ferrocenyl; phosphonate; Arbusov; cyclic voltammetry; phosphoramidite.

INTRODUCTION

Interest in the chemistry of ferrocenyl-containing phosphines is considerable, particularly so for their co-ordination chemistry (see, for example, Refs. [1–3]). Such compounds have found application in asymmetric catalysis [4a, 4b] and reports have also been made on the biological activity of their metal complexes [5]. By contrast, there are relatively few reports [6a, 6b, 7] on other phosphorus-containing ferrocenyl derivatives, e.g. phosphonates, despite their considerable potential for synthetic applications [8]. Recently, however, the reactivity of ferrocenyl-derived alcohols, specifically 6-ferrocenylhexan-1-ol, has been utilised for the incorporation of the redox-active metallo group into oligonucleotides via reaction with β-cyano-*N*,*N*-diisopropylchlorophosphoramidite, forming initially the ferrocenylphosphoramidite before conversion to the ferrocenyl-modified nucleotide [9].

We have also been interested in the conjugation of the ferrocenyl group with nucleobases and have reported on adenine and thymine-derived examples, along with studies of their interactions with DNA [10]. In this paper we report on the reactions of ferrocenylmethanol, $FcCH_2OH$, with β-cyano-*N*,*N*-diisopropylchlorophosphoramidite and other chlorophosphites in an effort to establish the generality of such reactions.

EXPERIMENTAL

Ferrocenylmethanol was prepared from $FcCH_2NMe_3^+I^-$ as described in the literature [11]. β-cyano-*N*,*N*-diisopropylchlorophosphoramidite (Sigma), 1,2-phenylene chlorophosphite (Avocado) and diethyl chlorophosphite (Avocado) were used as supplied. Diisopropylethylamine (Aldrich) was dried over CaH_2 and distilled prior to use.

Synthesis of $FcCH_2P(O)(N(iPr)_2)(OCH_2CH_2CN)$, **2a**

Ferrocenylmethanol (0.5 g, 2.3 mmol) and dry diisopropylethylamine were dissolved in 20 m^3 of dry dichloromethane. The mixture was cooled on ice, β-cyano-*N*,*N*-diisopropylchlorophosphoramidite (0.81 m^3, 3.5 mmol) was added and the reaction mixture allowed to stand for 30 min at room temperature. Following the addition of methanol, the mixture was evaporated to give a yellow oil, which was loaded onto an alumina column and eluted with chloroform/ethylacetate/triethylamine 45:45:10. Despite evidence for at least two components in the reaction mixture,

*Author to whom correspondence should be addressed.

only the single product was isolated in pure form, **2a**. Yield 63%: m.p. 105°C. Found: C, 57.27; H; 7.15; N, 6.82, $C_{20}H_{29}FeN_2O_2P$ requires: C, 57.70; H, 7.02; N, 6.73. IR: ν(CN) at 2220 cm^{-1}, ν(P=O) at 1250 cm^{-1}.

X-ray crystallography

Crystals suitable for a single crystal X-ray structure determination were grown from a saturated solution in hexanes. Crystal data and other information on structure determination are given in Table 1. Measurements were made with graphite-monochromated Mo-Kα radiation on a Stoe-Siemens four-circle diffractometer. Unit cell parameters were refined from 2θ values (22–25°) of 51 reflections measured at $\pm\omega$ to minimize systematic errors. Intensities were measured by an on-line profile fitting procedure [12]. Absorption corrections were applied semi-empirically from azimuthal scans of sets of symmetry-equivalent reflections [13]; no corrections were required for intensity decay or extinction effects. The data sets consisted of one unique set of reflections, a complete set of Friedal opposites and a few other symmetry-equivalent reflections.

The structure was solved by direct methods and refined by full-matrix least-squares on all F^2 values, with weighting $w^{-1}=\sigma^2(F_o^2)+(0.0494P)^2+(1.2427P)$ where $P=(F_o^2+2F_c^2)/3$. All non-hydrogen atoms were refined with anisotropic displacement parameters, and isotropic H atoms were constrained with a riding model including torsional freedom for methyl groups. Residuals are defined as: $R_w=\{\Sigma[w(F_o^2-F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ for all data, $R=\Sigma\|F_o|-|F_c\|/\Sigma|F_o|$ for reflections with $F_o^2>2\sigma(F_o^2)$. Atomic coordinates, displacement parameters, and complete geometry have been deposited at the Cambridge Crystallographic Data Centre.

NMR spectroscopy

^{1}H, ^{13}C and ^{31}P NMR spectra were measured at 500.16, 125.77 and 202.47 MHz, respectively, on a Joel Lambda 500 and ^{31}P at 36.2 MHz on a Joel FX90Q NMR spectrometers. Phosphorus decoupled proton spectra, ^{1}H–^{1}H TOCSY and ^{1}H–^{13}C HSQC spectra were run using standard Joel pulse sequences. Typical 2D data sets were acquired into 1024×512 data points then zero-filled to 1024×1024 datapoints prior to Fourier transformation using a shifted sine-bell apodization function in both dimensions.

Electrochemistry

A conventional two-compartment glass cell was used with a 1mm diameter platinum disc working electrode. A silver wire was used as a quasi-reference electrode and the potential scale was established by measuring a CV of ferrocene. The electrolyte was $[N(Bu^t)_4, PF_6]$ in dimethylsulfoxide. The potentiostat was an EG&G model 263A.

RESULTS AND DISCUSSION

NMR studies

The reaction of ferrocenylmethanol with β-cyano-*N*,*N*-diisopropylchlorophosphoramidite in dichloromethane was followed at room temperature by ^{31}P NMR and data is presented in Table 2. After mixing, resonances were observed at 180 and 148 ppm. The former signal corresponds to phosphoramidite starting material, while the latter is attributed to $FcCH_2OP(N(iPr)_2)(OCH_2CH_2CN)$, **1a**. This assignment is based on comparison with analogous compounds, *viz*. $Fc(CH_2)_6OP(N(iPr)_2)(OCH_2CH_2CN)$ (^{31}P 147.7 ppm in $CDCl_3$) [9] and other non-ferrocenyl derivatives [14]. At 35 min into the experiment a resonance at 30.0 ppm begins to appear, which is due to the formation of the phosphonate $FcCH_2P(O)(N(iPr)_2)(OCH_2CH_2CN)$, **2a**. Subsequent spectra taken at regular intervals show the steady increase in the signal at 30.0 ppm with a correlated decrease of the signal at 147.7 ppm*. At reaction times greater

*It should be noted that in some reactions a small peak was observed at 13.8 ppm which we interpret as a hydrolysis product of species of type **1**. Hydrolysis of the phosphoramidite gives a product with a signal at 6.5 ppm.

Table 2. ^{31}P NMR data[a] (ppm) for the reaction of ferrocenylmethanol with β-cyano-*N*,*N*-diisopropylchlorophosphoramidite, **a**, 1,2-phenylene chlorophosphite, **b**, and diethyl chlorophosphite, **c**

	Starting material	**1**	**2**

[c]Solvent $CDCl_3$.

than 4 h there remained an approximate 1:1 ratio of **1a**:**2a**.

To put these data into perspective, the reaction of β-cyano-*N*,*N*-diisopropylchlorophosphoramidite with benzylalcohol was also considered. Following the reaction using ^{31}P NMR spectroscopy revealed starting material (^{31}P 149.0 ppm in CH_2Cl_2) and a resonance at 140.1 ppm which corresponds to $PhCH_2OP(N(iPr)_2)(OCH_2CH_2CN)$. Subsequent spectra taken over 12 h showed no evidence for rearrangement.

Confirmation of the nature of product, **2a**, was made based on assignment of the ^1H and ^{13}C spectra using a combination of ^1H–^1H TOCSY and ^{31}Pe decoupling ^1H and ^1H–^{13}C HSQC experiments. The numbering scheme used here is that for the crystal structure (*vide infra*). Chemical shift and coupling constant data are given in Table 3.

The ^1H–^1H TOCSY (Fig. 1) indicated the presence of four spin systems in the ^1H spectrum. These could be assigned to the substituted cyclopentadienyl ring, the CH_2 group bridging the ferrocenyl and the phosphorous, the cyanoethyl chain and the *N*,*N*-diisopropylamido group. This left the singlet at 4.14 ppm which was assigned to the unsubstituted cyclopentadienyl ring of the ferrocenyl. A consequence of the chiral nature of the phosphorus centre is the inequivalence of the pairs of protons and carbons, (7)/(10) and (8)/(9), in the substituted cyclopentadienyl ring. The pattern of coupling indicated by the ^1H–^1H TOCSY spectrum gives the sequential ordering of the protons around the ring, but does not allow the absolute assignment. Similarly the two protons bonded to C(11) are rendered inequivalent by the chiral centre giving a typical ABX pattern, which simplified to an AB upon ^{31}P-proton decoupling. In the cyanoethyl chain the effect of the chiral centre is greatest on the C(12) protons ($\Delta\delta$ $^1H = 0.23$ ppm) which can be distinguished from the cyclopentadienyl signals by their coupling interactions with the C(13) protons at 2.62 ppm; these exhibit no discernible shift difference due to their prochiral nature. Finally the *N*,*N*-diisopropylamido group gives two signals for the methyl groups and one for the methine groups. The chiral phosphorus leads to inequivalence of the methyl pairs C(16)/C(17) and C(19)/C(20). However, the fluxionality about N(2) will lead to rapid exchange of the *N*-isopropyl groups giving rise to only one set of resonances (i.e. one methine and two methyl signals in both the ^1H and ^{13}C spectra). The ^{31}P proton spectrum indicated that only the protons attached to C(11), C(12), C(15) and C(18) had any significant coupling to phosphorus.

Alongside the ^{31}P chemical shift (23.1 ppm in $CDCl_3$) further confirmation of direct P–C bond formation involving the ferrocenylmethyl group was

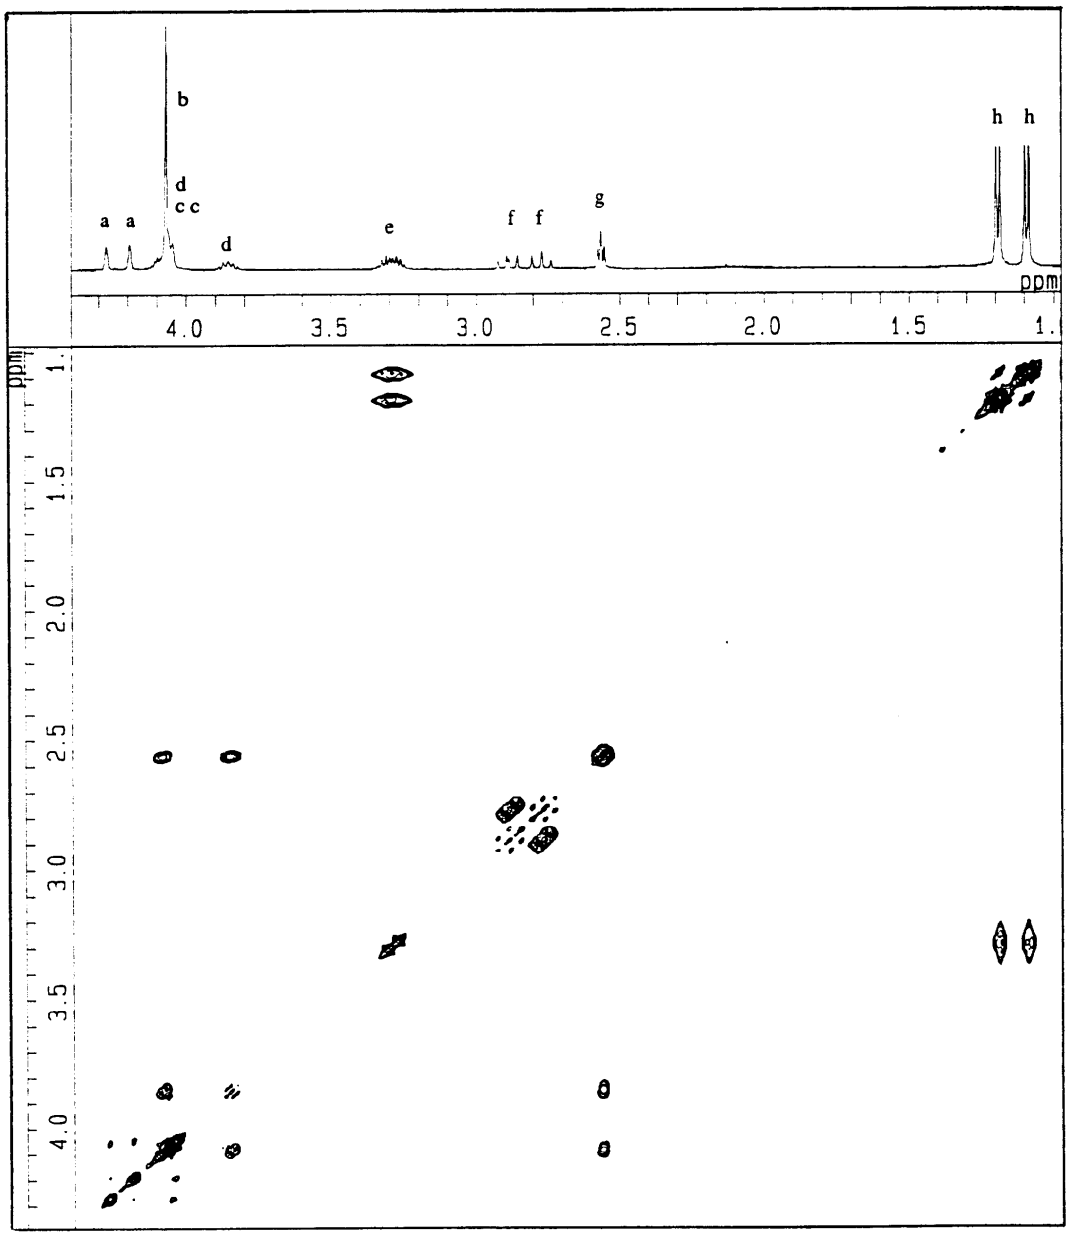

Fig. 1. ^{1}H–^{1}H TOCSY of **2a** in $CDCl_3$ at room temperature. Mixing time 25 ms. Assignments a = H(7),(10), b = H(1)–(5), c = H(8),(9), d = H(12), e = H(15),(18), f = H(11), g = H(13), h = H(16),(17),(19),(20) (see Fig. 2 and Table 3).

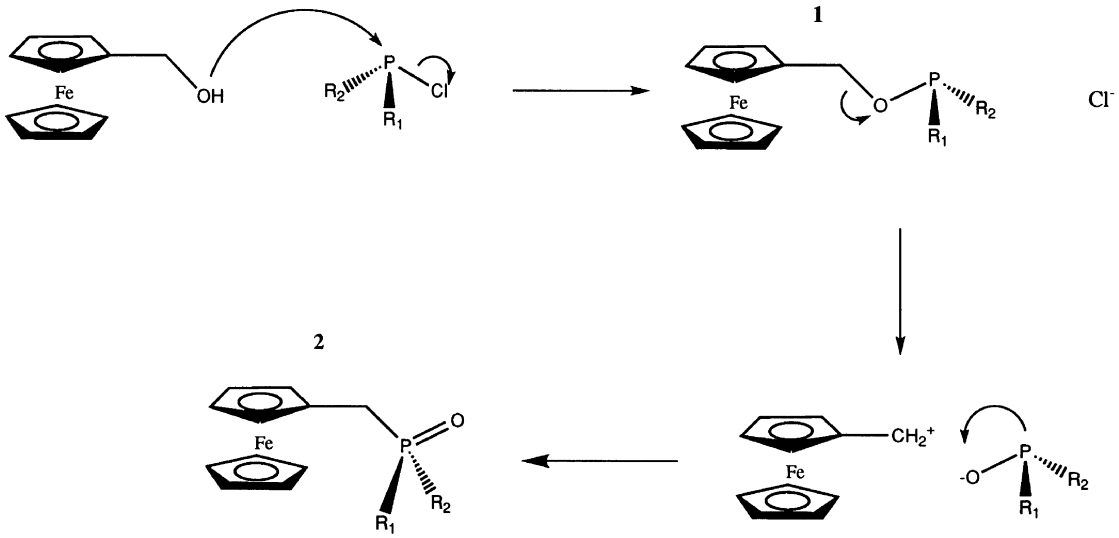
indicated by the magnitude of the $^{13}C(11)$–^{31}P coupling constant [$J(^{31}P$–$^{13}C) = 126$ Hz] [7, 14]. This compares with those of 3–6 Hz for the remaining ^{31}P–^{13}C coupling. These lie in the expected range for ^{2}J and ^{3}J coupling interactions for carbon to phosphorus(V) [14].

Scheme 1 depicts the proposed reaction for the formation of ferrocenylmethyl phosphonates, **2**. Following initial attack to form a ferrocenylphosphite, **1**, a Michaelis–Arbusov type rearrangement occurs to generate the corresponding ferrocenylmethylphosphonate, **2**. The rearrangement proceeds via the relatively stable ferrocenylmethyl cation [15].

In an effort to establish the general nature of this rearrangement the reaction between $FcCH_2OH$ and 1,2-phenylene chlorophosphite and diethyl chlorophosphite, respectively, were studied under the same conditions. The ^{31}P data for these are summarised in Table 2. As in the previous case with phosphoramidite, the reaction proceeds with the initial formation of a species of type **1** (Scheme 1) (^{31}P δ in the range 120–130 ppm), followed by the appearance



Scheme 1. Proposed reaction scheme for compounds of type **2**.

of a signal for the corresponding ferrocenylmethylphosphonate, **2** (^{31}P δ in the range 25–45 ppm). These shifts are in keeping for phosphorus with coordination spheres PO_3 and $O_2CP{=}O$, respectively. However, in both cases at reaction times over 4 h the ratio of products **1**:**2** remained at ~3:1.

In the case of 1,2-phenylene phosphorchloridite the reaction was repeated in $CDCl_3$ to allow monitoring by both ^{1}H and ^{31}P NMR. The ^{31}P showed the same features as in CH_2Cl_2, with slight differences in chemical shift. Formation of the appropriate phophonate, **2b**, based on the ^{31}P NMR was accompanied in the ^{1}H spectra by the formation of a signal at 3.14 ppm with a coupling to ^{31}P of 19 Hz indicating the formation of the $FcCH_2$–P moiety. This was confirmed by performing a selective ^{31}P-decoupling experiment irradiating at the resonant frequency of **2b** in the ^{31}P spectrum.

Crystal and molecular structure of **2a**

Crystals of **2a** suitable for study by X-ray crystallography were grown from a solution in hexane. The compound crystallises in the monoclinic space group $P2_1/c$. The molecular structure is shown in Fig. 2, which also features the atomic numbering scheme, and the selected bond lengths and angles are given in Table 4. The cyclopentadienyl groups are planar with an interplanar angle 3.79(17)° and are effectively eclipsed (7.7° twist about the line joining the ring centroids). The range of Fe–C distances is 2.039(2)–2.058(2), averaging 2.047(2) Å. The iron-ring centroid distances are 1.654(2) Å to the unsubstituted, 1.648(2) Å to the substituted rings, respectively. All of these distances are as expected, based on comparisons with other mono-substituted ferrocenyl derivatives found in the Cambridge Structural Database [16].

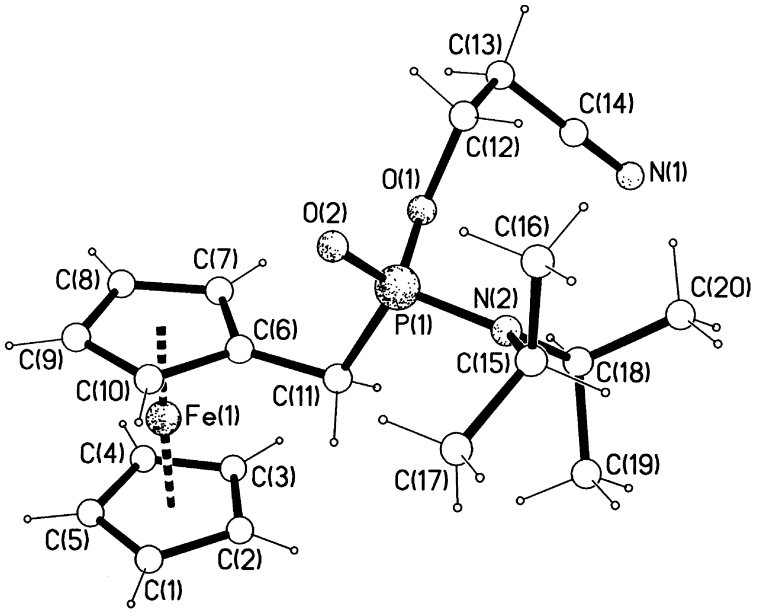

Fig. 2. Molecular structure and numbering scheme for **2a**.

A direct comparison of **2a** can be made with the analogous $FcCH_2P(O)(OPh)_2$ [7]. The Cp–CH_2 distance is 1.508(3) Å in **2a** and compares with 1.521(9) in $FcCH_2P(O)(OPh)_2$ [7]. The bonding distances around P in **2a** are; P(1)–O(1), 1.601(1); P(1)–O(2), 1.473(2); P(1)–N(2), 1.644(2) and P(1)–C(11), 1.814(2) Å. The corresponding bond distances in $FcCH_2P(O)(OPh)_2$ are P=O, 1.461; P–O_{av}, 1.590 and P–C, 1.795 Å [7]. Moreover, the bond lengths found for these ferrocenylmethylphosphonates are comparable with analogous phosphonates, such as diethyl-2-hydroxyl-1,2-diphenylethylphosphonate [17]. The geometry at phosphorus is somewhat distorted from idealised tetrahedral with bond angles around phosphorus in **2a** ranging from 99.29(9)° for O(1)–P(1)–C(11) to 114.24(8)° for O(1)–P(1)–O(2).

Previous structural characterisations of ferrocenylphosphine derivatives containing a methylene spacer attached to phosphorus include the symmetrically substituted bis(η^5-diphenylphosphinomethylcyclopentadienyl)-iron [18], its triphenylphosphinium derivatives [19] and the monosubstituted ferrocenylmethyl(triphenylphosphonium) iodide [19]. Bond lengths for the Cp–CH_2–PR_2 grouping are; C_{Cp}–CH_2, 1.493 and CH_2–P, 1.855 Å, while those for the Cp–CH_2–P+R_3 grouping are in the ranges; C_{Cp}–C, 1.485–1.501 and CH_2–P, 1.813–1.818 Å. The CH_2–P bond length in **2a** lies within the range observed for the phosphonium derivatives and together these are shorter than the equivalent distance for the phosphine.

Electrochemistry

A cyclic voltammogram reveals that **2a** exhibits a reversible one-electron wave with a formal potential, E^0, of $-0.036(5)$ V vs Fc^+/Fc and a peak current ratio of 0.84 in DMSO indicating near chemical reversibility of the redox process (scan rate 0.1 V s^{-1}). This shift in electrode potential indicates slight electron donation by the substituent group on the cyclopentadienyl ring. By contrast, the analogous $FcCH_2P(O)(OPh)_2$ derivative exhibits a slight positive shift ($E^0 = 0.058(6)$ V vs Fc^+/Fc couple) [7].

Further comparison can be made with the oxide of 1,1′-bis(diphenylphosphino)ferrocene which has a reversible ferrocene-based one-electron oxidation at $E^0 = 0.43$ V [20]. As might be expected the insertion of a methylene spacer between the ferrocenyl group and the P=O group, as in **2a** and $FcCH_2P(O)(OPh)_2$, reduces the electron withdrawing effect on the ferrocenyl moiety.

CONCLUSIONS

Reactions between ferrocenylmethanol and β-cyano-*N*,*N*-diisopropylchlorophosphoramidite leads to the formation of $FcCH_2P(O)(N(iPr)_2)(OCH_2CH_2CN)$, **2a**. ^{31}P NMR data suggest that this is formed from $FcCH_2OP(N(iPr)_2)(OCH_2CH_2CN)$ via a Michaelis–Arbusov-type rearrangement. Moreover, NMR data also reveals that this mechanism is quite general for ferrocenylmethanol and chlorophosphites.

Complexation in solution of magnesium(II) and cobalt(II) with purine 5′-monophosphates and pyrimide 5′-monophosphates: a potentiometric and calorimetric study

Luis A. Herrero and Angel Terrón*

Department of Chemistry, Universitat de les Illes Balears, E-07071 Palma de Mallorca, Spain

(Received 29 January 1998; accepted 25 March 1998)

Abstract—The interaction of Mg(II) and Co (II) with purine and pyrimidine nucleoside 5′-monophosphates was studied using potentiometric and calorimetric methods, with 0.1 M tetramethylammonium bromide as the background electrolyte at 25°. The presence in solution of the complexes $[Mg(AMP)_2]^{2-}$, $[Co(AMP)_2]^{2-}$, $[Co(GMP)_2]^{2-}$ $[Co(IMP)_2]^{2-}$ was observed. The relationship between enthalpies and the degree of macrochelation together with the stacking interaction between purine bases in the complexes are discussed. © 1998 Elsevier Science Ltd. Keywords: magnesium; nucleotides; calorimetry.

INTRODUCTION

The bioinorganic chemistry of divalent metallic ions is a topic of great interest [1]. In this respect the role of magnesium(II) in metal-mediated hydrolysis of phosphate esters is known to be a common catalytic pathway in nucleic acid biochemistry. This role has been reviewed recently by Cowan who proposes new stoichiometries for magnesium dependent nuclease activation [[1](b)]. For this reason the knowledge of all the complexation thermodynamic magnitudes for the cellular concentration of Mg(II) (approximately 0.5 mM as free ion) seems to be relevant. It is also known that the influence on the stabilization of DNA by different 3d divalent metallic ions [[1](c)], and the activity as enzymatic cofactor of Mg(II) or Ca(II) complexes with nucleoside triphosphates or monophosphates [[1](d)].

The X-ray structures of metal-nucleotide complexes has been reviewed recently [2]. Solid state structures of the $[Co(NMP)(H_2O)_5].H_2O$ type, where NMP is guanosine 5′-monophosphate and inosine 5′-monophosphate, in which cobalt (II) ion is bound to N(7) and also, via a coordinated water molecule, to the phosphate group have been reported [[3](a)]. Other crystalline structures of the $[Co(NMP)_2]^{2-}$ type in which the metal ion is coordinated to two nucleotides in cis position, have been also described for cobalt (III) complexes with GMP and IMP. The coordination sites are identical to those of the former complex. The latter structures suggest a relevant base stacking stabilization between the purine bases in cis position, despite a butterfly-like arrangement of the two purine residues [[3](b)].

With magnesium only $[Mg(ATPH)_2]^{4-}$ structures, with coordination with the phosphate group, are known [[4](a)]. In the analogous Ca-dAMP complex only coordination of the calcium with the phosphate group are cited [[4](b)].

The interaction of the metal can also alter the hydrogen bond and stacking interactions between the bases in RNA and DNA molecules as it was pointed out by Barton [5]. In a recent publication, Marzilli has also studied by NMR [6] the possible existence of atropisomerism in complexes of the type $Pt(GMP)_2$ in solution.

The interactions of divalent 3d metallic ions with nucleotides in solution have been reviewed recently [7]. Frey and Stuehr [[7](b)] established the formation

*Author to whom correspondence should be addressed.

of the $[Ni(AMP)_2]^{2-}$, with adenosine 5′-monophosphate and adenosine 2′-monophosphate, complexes potentiometrically. Sigel [[7](a,c,d)] studied the relationship between macrochelation and the first stability constants for Co and Mg(II) (and other divalent metals) and purine nucleoside monophosphates compounds. Other studies also measured the self-association of different nucleotides by means of NMR [8].

Very few previous calorimetric studies involving divalent metallic ion and mononucleotides have been published [9] and none, to our knowledge, in which the existence of 1:2 complex has been considered for the Mg(II) and Co(II) metals. The interactions of magnesium with UMP, GMP, and AMP [[9](a,b,c)] and Co(II) with AMP [[9](d)] for the 1:1 complexes were previously published.

As a follow up of the systematic calorimetric studies carried out for the system Ni(II)- nucleoside monophosphate system [10], the aim of our this research is to confirm, by two different techniques, the existence of $[Co(NMP)_2]^{2-}$ (where N is either adenosine, guanosine or inosine) and $[Mg(AMP)_2]^{2-}$ in solution in concentrations of the order of magnitude of magnesium (II) in the cytoplasme, to determine directly their thermodynamic values, and to consider the influence of purine base stacking stabilization on these complexes.

EXPERIMENTAL

Materials

The acids H_2NMP (where N can be either adenosine, guanosine, inosine, cytidine or uridine 5′-monophosphates) used in the potentiometric experiments were purchased from Sigma and the disodium salts of nucleotides (Fig. 1) used in the calorimetric experiments were purchased from Serva.

Magnesium and cobalt (II) nitrate (analytical grade) was purchased from Merck. Tetramethylammonium bromide (analytical grade) was purchased from Aldrich. The concentrations of the nucleotide solutions were determined by weighing and then tested by UV spectrophotometry. All the solutions were prepared with deionized and then destilled water and the ionic strength was adjusted to 0.1 with tetramethylammonium bromide. The titer of the NaOH (Merck) used for the potentiometry titrations was determined with potassium hydrogen phthalate (Merck).

Potentiometric titrations

These were carried out with a potentiometer CRISON micropH 2002 and a glass electrode. The poten-

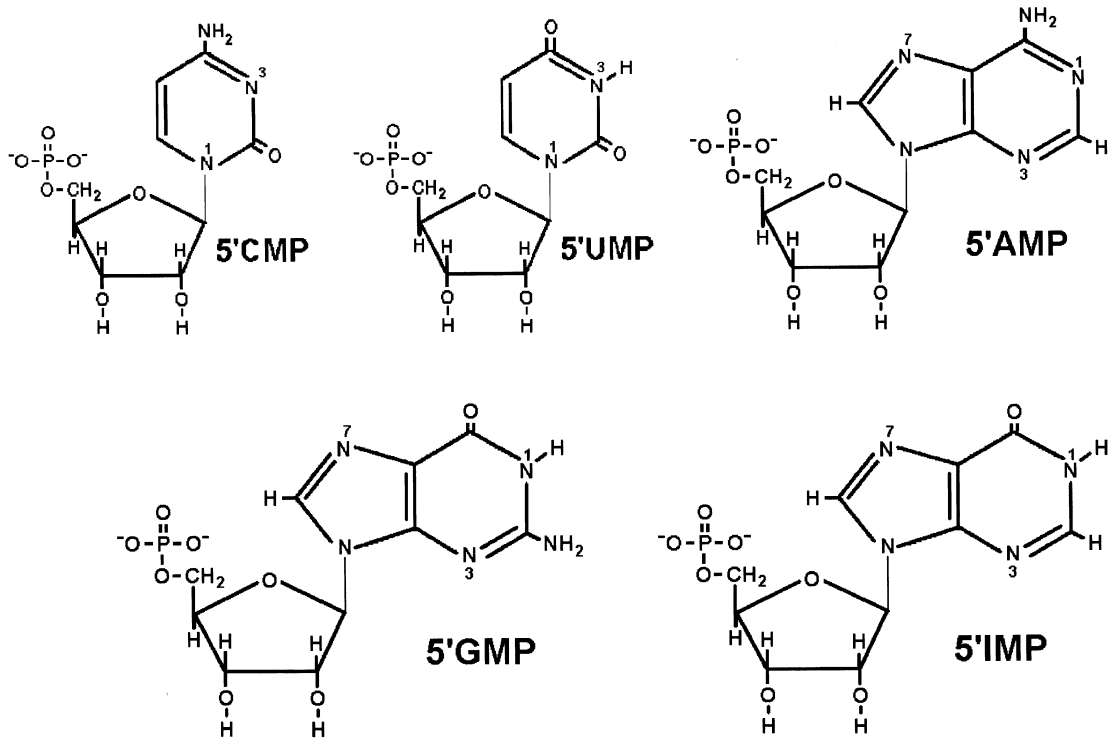

Fig. 1. Formulae and abbreviations of the purine and pyrimidine nucleoside 5′-monophosphates.

tial values were recorded on an IBM PC by means of the VALGRAN program previously described [11]. Additions of the NaOH titrant were made automatically with a CRISON MICRO BU2031 microburet. The titrations were conducted under an atmosphere of N_2 to exclude carbon dioxide in a jacketed titration vessel in which the temperature was maintained by circulating water (25 ± 0.1°C) in the jacket. Magnetic stirring was also used.

(a) Determination of CMP and UMP acidity constants. The constants for the deprotonation of the acid pyrimidine nucleotides were determined previously by titrating a known volume (about 50 ml) of H_2NMP solution with NaOH. The initial concentrations of nucleotide ranged from 6×10^{-4} to 2×10^{-3} M. The acidity constants of the puric nucleotides where determined previously [[10](c)].

(b) The determination of the constants of stability K_{MLH} and K_{ML} of the $[M(NMPH)]^+$ and [M(NMP)] complexes, respectively, was made by titrating a known volume of H_2NMP solution containing Mg(II) or Co(II) nitrate. The initial concentration of nucleotide ranged from 2×10^{-4} M to 6×10^{-4} M. The concentration ratio of metal ion to nucleotide was higher than 25:1 in all cases to avoid formation of $[M(NMP)_2]^{2-}$ complexes.

(c) The constants K_{ML2} for the complexes $[MNMP)_2]^{2-}$ were determined by titrating a known volume of nucleotide solution in the presence of metal(II) nitrate between 2.0×10^{-3} M. and 3.0×10^{-2} M. The initial nucleotide concentrations in solution varied from 1.7×10^{-2} to 2.0×0^{-2} M and the concentration of NaOH titrant was 9.37×10^{-2} M in all cases.

The main equilibria considered for the M-NMP (where M is either Mg(II) or Co(II) and NMP a nucleoside 5′-monophosphate) systems are:

$$NMPH^- + H^+ = H_2NMP\ K^H_{a2} \quad (1)$$

$$NMP^{2-} + H^+ = HNMP^-\ K^H_{a1}(Kpr)\ \text{and}\ \Delta Hpr \quad (2)$$

$$M(II) + NMP^{2-} = [M(NMP)]K_{ML}\ \text{and}\ \Delta H_{ML} \quad (3)$$

$$M(II) + NMPH^- = [M(HNMP)]^+ K_{MLH}\ \text{and}\ \Delta H_{MLH} \quad (4)$$

$$[M(NMP)] + NMP^{2-} = [(M(NMP)_2]^{2-} \quad (5)$$

$$K_{ML2}\ \text{and}\ \Delta H_{ML2}$$

Where H_2NMP is either H_2AMP H_2GMP, H_2IMP, H_2CMP or H_2UMP respectively. For the pyrimidine 5′-mononucleotides the equilibrium (5) does not necessary have to be considered.

The parameters determined and the equilibria considered for each determination are indicated below. The linear equations used to fit the experimental data were deduced from the mass balances in each case in order to establish a relationship between the measured constants with known parameters or parameters obtained during the potentiometric titration [[10](c)].

In the following expressions, A_t is the total concentration of acid hydrogens for each experimental point; K_w the water ionic product (13.72 ± 0.01 under our experimental conditions); c_{nuc} is the total concentration of the nucleotide. The K^H_{z1} values used were those previously determined by Sigel [[8](c)].

Determination of pK_{a1}.

The equilibria considered were 1 and 2. From the mass balance is obtained the following expression:

$$y/[(1-y) \times [H^+]] = K_{a1} + [(2-y) \times [H^+]]/(1-y) \times K_{a1} \times K_{a2}$$

and

$$y = \{At + (Kw/[H^+]) - [H^+]\}/c_{nuc} \quad (6)$$

Determination of K_{ML} and K_{MLH}

The equilibria considered were 1, 2, 3 and 4 and the equation to fit was:

$$(\gamma - \delta)/c_M = K_{ML} \times K_{MLH} \times \gamma \quad (7)$$

Where

$$\gamma = K_{a1} \times \beta \times [H^+]$$
$$\delta = 1 - K_{a1} \times K_{a2} \times [H^+]^2$$
$$\beta = c_{nuc} - \alpha$$
$$\alpha = A_t - [H^+] + (K_w/[H^+])$$

Determination of K_{ML2}

The equilibria considered were 1, 2, 3, 4 and 5 and the equation for the linear correlation between K_{ML2} and the experimental parameters was:

$$z/\{(1-z) \times K_{ML} \times [NMP^{2-}]\} - K_{ML} \times K_{a1} \times [H^+]/K_{ML} - 1 = \{K_{ML2} \times (2-z) \times [NMP^{2-}]\}/(1-z) \quad (8)$$

where

$z = \{c_{nuc}$-$[NMP^{2-}]$-
$K_{a1} \times [NMP^{2-}] \times [H^+] \times (1 + K_{MLH} \times [M^{2+}])\}/M_o$ and M_o is the total metal ion concentration, and $[NMP^{2-}]$ is the free deprotonated nucleotide concentration and $[M^{2+}]$ the free cobalt or magnesium(II) concentration in the equilibrium.

In our conditions, the measured standard potential from the glass electrode follows the equation:

$$E = E'^0 + g \times \log [H^+]$$

$$\text{where} \quad E'^0 = E^0 + g \times \log \gamma_H + + E_j$$

where E^0 is the standard potential (in mV) from the electrode, E_j the liquid junction potential, and γ_{H+} the proton activity coefficient and g is the Nernst constant. E'^0 can be considered constant for one potentiometric titration, and it was determined for each titration.

For calculation purposes, all the experimental results were fitted simultaneously for each system. In the calculation a first approximate value for the glass electrode standard potential in each experiment and the experimental data were used. Optimizing the values of the standard potentials with the program MINIPOT [[11](b)] and the programs POTCAL, POTPK, POTMLH and POTML2 (Adaptations of MINIPOT to our system which allow a simultaneous data treatment for various potentiometric titrations [[11](c)]) and the lineal regression of the equations (eqn (6), eqn (7) or eqn (8) for each system) the constants K_{a1}, K_{ML}, K_{MLH} and K_{ML2} were determined. The final standard potentials minimize the addition of the quadratic differences between the theoretical and experimental potentials ($\Sigma(E_t\text{-}E)^2$). The deviation for the calculated parameters are indicated as 3 σ from the lineal regression equation.

CALORIMETRIC MEASUREMENTS

The calorimetric measurements were carried out in a LKB 20001 batch microcalorimeter connected to an IBM PC for data acquisition by means of the BATCHCAL program described previously [[9](d)]. All the measurements were taken at 25.00 ± 0.01°C. The pH in equilibrium was determined by means of a CRISON micro pH 2002 with an accuracy of 0.001 pH units.

Determination of the protonation heats for CMP^{2-} and UMP^{2-} was performed by addition in independent experiences of 4 ml of 3.27 mM HCl solutions to 2 ml of nucleotide solutions (8.48 mM for CMP and 9.56 mM for UMP). The initial pH of the nucleotide solutions was 7. The determination of the protonation heat for the purine nucleotides was previously carried out [[10](c)].

The formation enthalpies ΔH_{ML} and ΔH_{ML2} for the complexes [M(NMP)] and $[M(NMP)_2]^{2-}$ were determined by mixing in independent experiments 4 ml of nucleotide solutions with 2 ml of cobalt or magnesium nitrate solutions in a calorimetric cell. The magnesium concentrations in the reaction cell at equilibrium had values comprising between 0.35 to 11 mM. The cobalt concentrations in the reaction cell at equilibrium had values comprising between 0.35 to 4.0 mM; higher concentrations were never used to prevent the formation of dimeric hydroxo-cobalt complexes [12]. The nucleotide concentration at equilibrium in the reaction and reference cells varied from 0.5 to 30 mM. Nucleotide solutions were placed in the reference cell to correct the dilution heat in all cases: the metal solution dilution heat was obtained experimentally and then subtracted from that of the reaction cell.

Table 1. Thermodynamic parameters for the purine and pyrimidine nucleoside 5′-monophosphates (at 25°C and I = 0.1 in tetramethyl ammonium bromide, the errors are indicated as 3σ)

NMP	pK_{pr}	ΔH_{pr} kJ/mol	ΔS_{pr} J/(mol × K)
AMP	6.22 ± 0.01[a]	2.0 ± 0.4 [a]	126 ± 1[a]
GMP	6.23 ± 0.01[a]	3.0 ± 0.3 [a]	129 ± 2[a]
IMP	6.22 ± 0.01[a]	2.4 ± 0.4[a]	127 ± 2[a]
CMP	6.22 ± 0.02	3.0 ± 0.3	129 ± 2
UMP	6.16 ± 0.01	3.4 ± 0.4	129 ± 2

pK_{pr}, ΔH_{pr} and ΔS_{pr}: pK_{a2}, enthalpy and entropy of protonation for the equilibrium (2) [a: from reference [10](c)].

Thermodynamic parameters for the complexes

In order to carry out the calorimetric determinations the following values are required: $\log_{KML}$, $\log K_{ML2}$, ΔH_{pr} (protonation heat of the nucleotides) (Table 1), pK_{pr} (pK_{a2}) (Table 1) and the experimental heat values (Q = experimental heat-dilution heat), the initial metal (Mo) and nucleotide (Lo) concentrations, together with the reaction and reference cells pH (pH and pHr respectively). The main equilibria considered for the M(II)-5′GMP and M(II)-5′IMP systems are 2, 3 and 5. Equilibrium 4 can be neglected in the calorimetric experimental conditions owing to the small value of K_{MLH} in comparison with K_{ML} and the low $NMPH^-$ concentration at the pH work. All these parameters either experimental (Table 1) or were determined under in the same conditions as those for the calorimetric measurements.

The total heat is a contribution of the equilibria 2, 3 and 5, and the dilution heats:

$$Q = (C_{ML} + C_{ML2}) \times \Delta H_{ML} + C_{ML2} \times \Delta H_2 + C_H \times \Delta H_p \tag{10}$$

$$Q_R = Q - C_H \times \Delta H_P$$

$$Q_1 = \Delta H_1 + X \times \Delta H_2$$

$$Q_1 = QR/(C_{ML} + C_{ML2})$$

$$X = C_{ML2}/(C_{ML} + C_{ML2})$$

$$Q_R = Q - QP \tag{11}$$

QR is the reaction heat, QP is the heat associated with eqn (2) and C_{ML} and C_{ML2} are the [M(NMP)] and $[M(NMP_2)]^{2-}$ complex amount at equilibrium respectively. The experimental values can be obtained from linear regression from eqn (11)). The values obtained are shown in Table 2. The correlation diagrams are indicated in Fig. 2.

Table 2. Thermodynamic parameters for the Mg(II)and Co(II)-purine and pyrimidine nucleoside 5′-monophosphate complexes (at 25°C and I = 0.1 with tetramnethylammonium bromide). The errors are indicated as 3σ

The values of entropy have been calculated considering

$$\Delta G = \Delta H - T \times \Delta S$$

and $$\Delta G = -2.30 \times R \times T \times \log K.$$

RESULTS AND DISCUSSION

Thermodynamic parameters of the ligands

In the calorimetric measurements, tetramethylammonium bromide has been used as the background electrolyte instead of alkaline salts. The heat of sodium ion (or other alkaline ions) interactions with the phosphate group of nucleotides can mask calorimetric determinations. For this reason, the pK_{a2} (pK_{pr}) for the purine nucleotides [[10](c)] and pyrimidine nucleotides (in the present work) were determined in 0.1 M tetramethyl-ammonium bromide (Table 1). The values are in very good agreement with those obtained by Sigel, with sodium nitrate as background electrolyte, previously published [[7](D)]. The protonation enthalpies of the purine nucleotides [[10]c] and the pyrimidine nucleotides (in the present work) were determined by calorimetry; the calorimetric results point to an endothermic process (Table 1). The value for 5′AMP agrees with the value obtained by Antonelli calorimetrically [13].

Thermodynamic parameters and structural considerations

The constants for the formation of the cobalt and magnesium(II) with purine nucleosides obtained by potentiometry and the corresponding enthalpy and entropy measurements are indicated in Table 2. The values obtained for K_{ML} are in very good agreement with those recently described by Sigel [[7](c,d)]. For instance, for Mg(5′AMP) the constants are log $K_{MgL} = 1.60$ (Sigel at 25°C, $\mu = 0.1$ M $NaNO_3$) and log $K_{MgL} = 1.61$ (our working conditions at 25°C, $\mu = 0.1$ M tetramethyl-ammonium); the values differences are within the deviation error values. This comparison can be carried out for all the remaining metal-purine nucleotide equilibrium constant values. In the case of the pyrimidine nucleotides the constants values used were those reported by Sigel [[7](c,d)].

Sigel studied by potentiometry the degree of macrochelation of different purine nucleotides [[7](c)], discussing the equilibria between complexes where the metal is only bound to the phosphate group (open

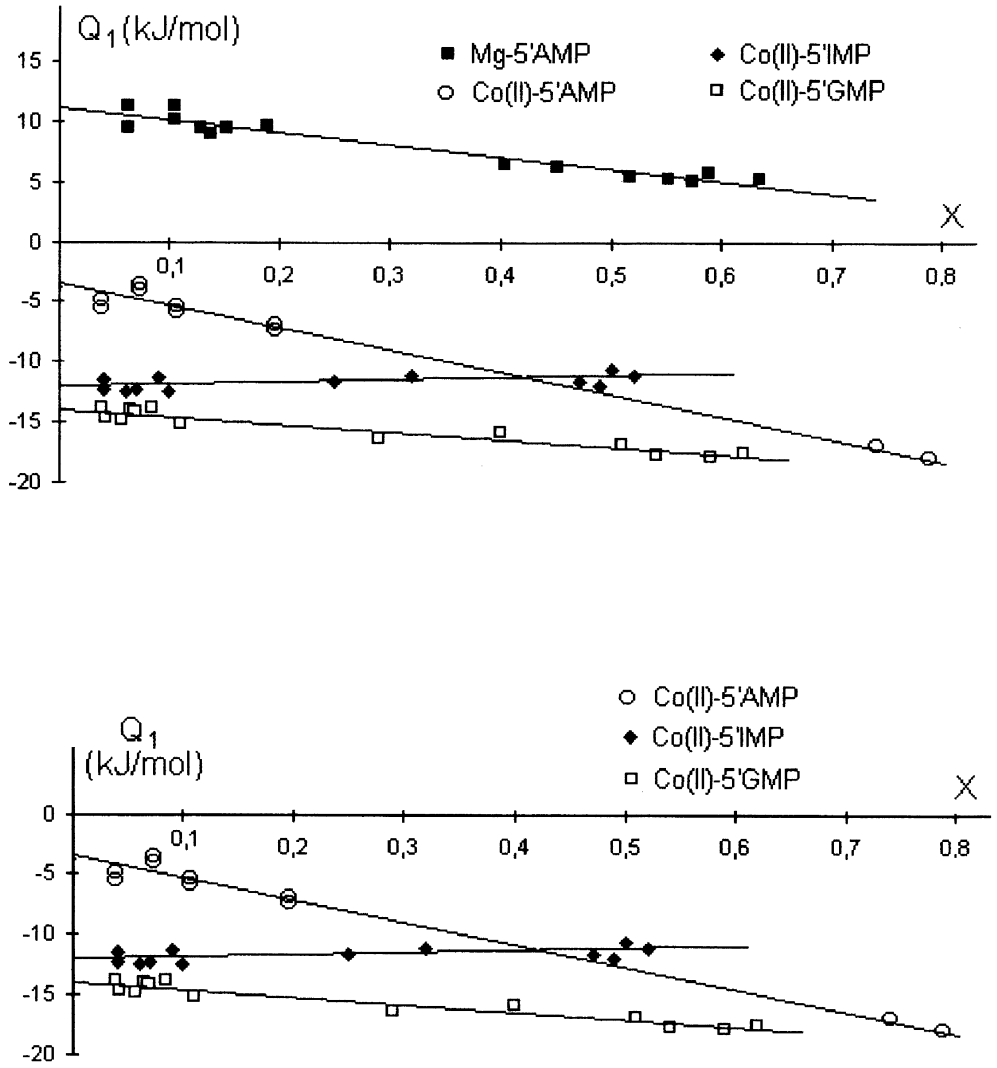

Fig. 2. Correlation diagrams for the M(II)-NMP systems.

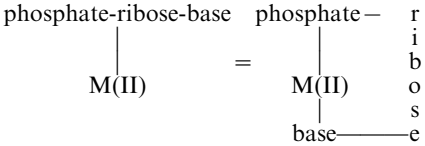
form) and complexes were the metal is bound to the purine ring and the phosphate group (closed form)



(12)

Our representation of ΔH_{ML} or ΔS_{ML} against the degree of macrochelation indicates that the higher the macrochelation the lower the value of the enthalpy and entropy. These relationships show that the macrocyclic formation is, in this case, energetically favorable and entropically unfavorable. Therefore the chelate effect does not take place, probably owing to the large number of bonds in the macrocycle.

In order to study in detail the consequences of the macrochelation on the formation enthalpies of the [M(NMP)] complexes we can consider the global reaction in two steps. In the first process the open complex is formed:

$$M(II) + NMP^{2-} = [(M(NMP)_{op}] \qquad \Delta H_{op} \quad (13)$$

And in a second step, the open complex can partially turn into the closed complex:

$$[(M(NMP)_{op}] = [(M(NMP)_{cl}] \qquad \Delta H_{cl} \quad (12a)$$

The macrochelation degree r is defined as the relation between the concentration of the closed complex [M(NMP)cl] and the total concentration of the complex [M(NMP)] in equilibrium:

$$r = [M(NMP)_{cl}]/\{[M(NMP)_{op}] + [M(NMP)_{cl}]\} \quad (14)$$

Thus the formation enthalpy for the complex can be expressed as the addition of the respective enthalpies corresponding to the two previous reactions, taking into account that the second step takes place only in part:

$$\Delta H_{ML} = \Delta H_{op} + r \times \Delta H_{cl} \quad (15)$$

In this way, it is possible to estimate the enthalpic and entropic contribution for the bonding between the cobalt(II) ion and the purine rings in these complexes, possibly through N(7) as in the solid state. Since ΔH_{ML} has been determined, and the value of ΔH_{op} for the interaction of the cobalt (II)-phosphate group ($+10.2 \pm 1.0$ kJ/mol) has been previously estimated and the values of r have been previously calculated by Sigel [[7](c,d)], the eqn (15)) can be used to obtain the values of ΔH_{cl}. The values obtained for ΔH_{cl} are approximately -28 kJ/mol for the three purine nucleotides (Table 3). Therefore this interaction is energetically favorable in these complexes. This value is of the same order than that previously described for the interaction of cobalt(II) with 9-methylpurine $\Delta H = -20.4$ kJ/mol [14].

In the case of Mg(II) the degree of macrochelation is so low that to compare degrees of macrochelation with enthalpies or entropies is unfeasible.

The same treatment can be carried out on the entropy by means of the following equation:

$$\Delta S_{ML} = \Delta S_{op} + r \times \Delta S_{cl} \quad (16)$$

The entropic values obtained for the interaction cobalt (II)-purine ring in these complexes are also very similar for the three nucleotides and show that this process is entropically unfavorable (Table 3). The rightness of our hypothesis is observed in Fig. 3, a representation of entropies and enthalpies versus r, the degree of macrochelation potentiometrically obtained by Sigel which shows the perfect correlation between the experimental and hypothetical linear parameters. Therefore, calorimetry [[10](c) and this work] supports the previous work by Sigel [[7](d)].

The potentiometric and calorimetric measurements show the existence in solution of complexes of the $[(Co(NMP)_2]^{2-}$ type, similar to those described in the solid state such for the 5′AMP, 5′GMP and 5′IMP ligands.

With the second ligand entrance the stacking phenomena could be important.

Considering the possible geometries for the complexes, four different situations can be found: a) the two nucleotides bound to the metal ion in trans position, b) the two ligands are in cis conformation without any hydrophobic interaction, c) the two nucleotides in cis position with a relevant stacking interaction and d) the second ligand is not directly coordinated to the metal ion hydrophobically interacting only with the other ligand. The known X ray structures point to structures of the type 'b', 'c' or 'd'; and no solid state structure is known, to our knowledge, in the form 'a' for nucleoside monophosphates.

The quantitative evaluation of the differences between the first and second ligand entrance can be performed by means of $\log K_{ML2} - \log K_{ML}$, $\Delta H_{ML2} - \Delta H_{ML}$ and $\Delta S_{ML2} - \Delta S_{ML}$ differences (Table 4). For the Co(II) and Mg(II) 5′AMP derivatives $\log K_{ML2}$ is similar or higher to $\log K_{ML}$, and the differences $\Delta H_{ML2} - \Delta H_{ML}$ and $\Delta S_{ML2} - \Delta S_{ML} < 0$ point to the existence of a structure of type 'c' with a hydrophobic interaction between the purine rings. This interaction could be responsible for these enthalpic and hydrophobic differences, which can be assigned on a first approach to the stacking thermodynamic parameters [[9](a,b,c,d,e,f),[10](c)], in the $[Mg(5'AMP)_2]^{2-}$ complex, the value $\Delta H_{ML2} - \Delta H_{ML}$ is approximately half the autostacking value. These values are lower than the parameters of 5′AMP autostacking ($\Delta H = -42$ kJ/mol and $\Delta S = -134 J/K \times$ mol) [[10](c)].

For the Co(II)-5′GMP and Co(II)-5′IMP the

Table 3. Enthalpies and Entropies related with the degree of macrochelation [**r** from Ref.[7](c)]

Complex	ΔH_{ML} (kJ/mol)	ΔH_{op} (kJ/mol)	r	ΔH_{cl} (kJ/mol)
Co(AMP)	-3.6 ± 0.4	$+10.2 \pm 1.0$	0.49 ± 0.09	-28 ± 8
Co(IMP)	-12.2 ± 1.0	$+10.2 \pm 1.0$	0.78 ± 0.03	-29 ± 4
Co(GMP)	-14.0 ± 0.9	$+10.2 \pm 1.0$	0.83 ± 0.02	-29 ± 3
	ΔS_{ML} (J/(mol × K))	ΔS_{op} (J/(mol × K)	r	ΔS_{cl} (J/mol × K)
Co(AMP)	$+31.0 \pm 2$	$+70 \pm 4$	0.49 ± 0.09	-79 ± 27
Co(IMP)	$+8.0 \pm 3$	$+70 \pm 4$	0.78 ± 0.03	-79 ± 13
Co(GMP)	$+4.0 \pm 3$	$+70 \pm 4$	0.83 ± 0.02	-80 ± 10

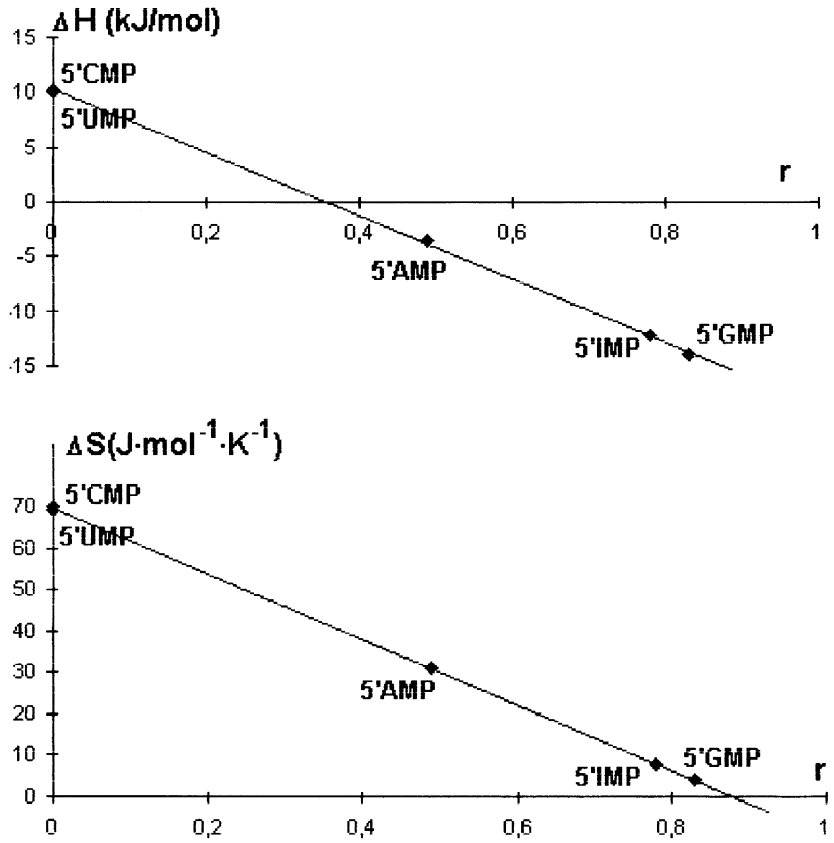


Fig. 3. Graphic representation between the values of enthalpy or entropy ΔH_{ML} and ΔS_{ML} (from this work) and the degree of macrochelation calculated by Sigel [from reference [7](c)].

differences log K_{ML2-} log $K_{ML} < 0$, $\Delta H_{ML2} - \Delta H_{ML} > 0$ and $\Delta S_{ML2} - \Delta S_{ML} > 0$ show clearly that the entrance of the second ligand is unfavorable in relation to the first ligand entrance and the process is energetically unfavorable and entropically favorable. Nevertheless a weak stacking can be masked by the degree of macrochelation, since the two effects are present.

The trend to the autostacking interaction between the purine rings in the nucleotides (5′AMP > 5′GMP > 5′IMP) [[8](a,b,c,d,e), [10](c)] is similar to that of the interaction between the nucleotides in the $[Co(NMP)_2]^{2-}$ complexes ($[Co(5'AMP)_2]^{2-} > [Co(5'GMP)_2]^{2-}$ or $[Co(5'IMP)_2]^{2-}$).

In the case of magnesium, only the $[Mg(5'AMP)_2]^{2-}$ exists due to the important stacking interactions for this nucleoside monophosphate. The latter complex could be biologically relevant to explain the affinity constants between allosteric enzymes and the magnesium-nucleotide cofactors: a) $[Mg(5'ATP)]^{2-}$ complex activates an enzyme interacting with a hydrophobic amino acid (tyrosine, phenylalanine, tryptophan); b) after the enzymatic reaction, the

Table 4. Thermodynamic parameters differences between ML_2 and ML complexes

System	$\log K_{ML2} - \log K_{ML}$	$\Delta H_{ML2} - \Delta H_{ML}$ (kJ/mol)	$\Delta S_{ML} - \Delta S_{ML2}$ (J/mol × K)
Mg(II)–AMP	+0.23	−21.3	−67
Co(II)–AMP	−0.09	−14.6	−51
Co(II)–GMP	−0.56	+7.9	+16
Co(II)–IMP	−0.65	+14.1	+36

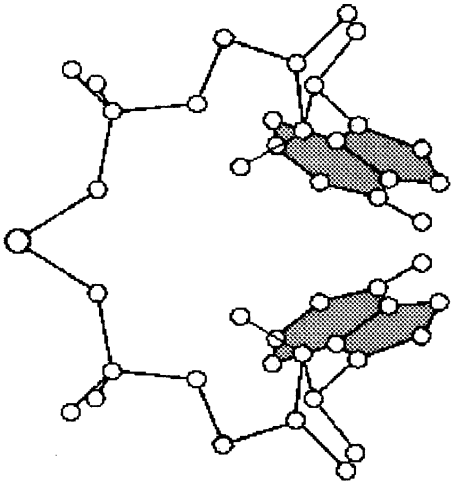

Fig. 4. Possible solution structures for the complexes $[(Mg(AMP)_2]^{2-}$.

[Mg(5′AMP)] complex is obtained, the purine ring being hydrophobically interacting with the amino acid residue has and c) could the $[Mg(5'AMP)_2]^{2-}$ complex be the species liberated from the catalytic site, compensating AMP-protein stacking with the AMP-AMP intramolecular stacking?. In this case, the former interaction in the magnesium complex could be similar to the adenine ring hydrophobic amino acid interaction. This is only a hypothesis, however, energetically balanced, and following previous results by Sigel and Yamauchi [15].

Synthesis, structure and electrochemistry of dinuclear copper(II) complex with dinucleating Schiff-base ligand

Wenxing Zhang*, Shangying Liu, Changqin Ma and Dehua Jiang

College of Chemistry, Shandong University, Jinan 250100, P.R. China

(Received 11 November 1997; accepted 18 March 1998)

Abstract—A new ligand, 1,3-di[*o*-(*o*-vanillideneimino)phenoxo]-2-propanol, H_2L, has been prepared stepwise and identified by elemental analyses (EA), IR and ^1H NMR spectra. The title complex $[Cu_2L_2](py)_2(H_2O)_2$ has been synthesized by reaction of H_2L and $Cu(OAc)_2H_2O$, and characterized by EA and IR. The redox properties of the dinuclear complex have been investigated by cyclic voltammetry. Two successive, one-electron, quasi-reversible processes indicate an interaction between two copper centers. The title complex structure is solved by X-ray diffraction. In the centro-symmetric unit $[Cu_2L_2]$, only phenolic and imino groups bind Cu atoms to form two distortional square coordination geometries, parallel to each other; and the Cu···Cu separation is 9.87 Å. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dinucleating; dinuclear; copper complex; synthesis; structure; cyclic voltammetry.

The dinucleating ligands have been classified as two series in order to study the dinuclear complexes [1]. Being more flexible than the corresponding phenoxo-compartmental ligands, the same series of hydroxo- or alkoxo-comartmental ligands have attracted more attention [2]. Dinuclear copper(II) complexes with these kinds of ligands have been magnetically characterized and structurally determined [3]. In other series of dinucleating ligands, there exist donor sets separated by an organic bridging group. Though the bridges may be non-complete conjugates, the interactions between two copper centers are indicated by the magneto- and/or electrochemical analysis results in the dinuclear complexes with these kinds of ligands [4, 5].

In this paper, the new dinucleating Schiff-base ligand, L^{2-}, belongs formally to compartmental, but in the title complex L^{2-} has selected the other coordination manner (Fig. 1), which is determined by the structural analysis. Although no three oxo atoms, linking the alkyl in the middle of the L^{2-}, coordinate to any atoms, the electro-tranfer action [6] has been confirmed by the cyclic voltammogram results.

EXPERIMENTAL

Materials and measurements

All starting materials were commercial products of chemical or analytic grade purity and were used without further purification. Elemental analysis, IR and ^1H NMR spectra were carried out on a Perkin-Elemer 240C microanalyser, a Nicolet 5DX FT–IR spectrophotometer as KBr disks in the range 4000–400 cm^{-1} and a Joel FX902 spectrometer in $CHCl_3$–d_1 solution, respectively.

Syntheses of H_2L

1,3-*di*-(o-*nitrophenoxy*)-2-*propanol* (*dnpp*). *o*-nitrophenol (25 g, 0.18 mol) in 30 cm^3 hot dimethylformamide (DMF) was treated with potassium carbonate (13.8 g, 0.1 mol) added slowly in ~0.5 g portions to the solution 1,3-dichloro-2-propanol (13 g, 0.1 mol) over 10 min. Gentle reflux was continued for 4 h and the resulting deep red mixture was then poured into 300 cm^3 water. The yellowish-brown granular solid was filtered out, washed with sodium hydroxide diluted anhydrous solution and water, then dried *in vacuo*. The product was recrystallized from ethanol.

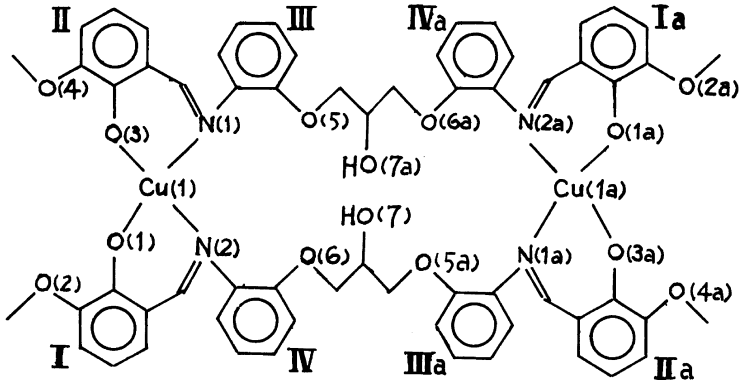

Fig. 1. coordination unit $[Cu_2L_2]$ (Cu, N and O atoms and phenyl rings are numbered).

Yield 55% (16.6 g, 0.050 mol) as yellowish needles. m.p. 127-129°C. Found: C, 53.5; H, 4.1; N, 8.6. Calc. for $C_{15}H_{14}N_2O_7$: C, 54.1; H, 3.9; N, 8.4%. IR (cm^{-1}): 3504 (s, sh, ν(OH)); 1519, 1437 (s, sh, $\nu(NO_2)$); 1254 (s, sh, ν(Ar–O–R)). ^{1}H NMR (δ): 7.80 (s, 1H(OH)); 7.20 (m, 8H(ArH)); 4.38 (s, 4H(CH_2)); 2.44 (br, 1H(CH)).

1,3-*di*(o-*aminophenoxy*)-2-*propanol* (*dapp*). dnpp (6.7 g, 20 mmol) in 100 cm^3 ethanol was refluxed with 5% palladium–carbon (0.6 g), then hydrazine hydrate (85%, 17 cm^3) was added over 30 min and the refluxing was continued until the solution become colorless (>16 h). The filtrate was distilled off *in vacuo* until the volume decreased to ~20 cm^3. The residue was abstracted with chloroform (3×10 cm^3). When the chloroform was evaporated to dryness, an oil with a little red color was obtained from the combined extracts. After several hours, the oil was naturally transformed into granular crystals. The product was recrystallized from ethanol. Yield 44% (2.4 g, 8.8 mmol) as colorless flat hexagonal prism. m.p. 95–97°C. Found: C, 65.8; H, 6.3; N, 10.2. Calc. for $C_{15}H_{18}N_2O_3$: C, 65.9; H, 6.2; N, 10.3%. IR (cm^{-1}): 3454 (s, sh, ν(OH)); 3342, 3195 (s, sh, $\nu(NH_2)$); 1269 (s, sh, ν(Ar–O–)). ^{1}H NMR (δ): 6.75 (m, 8H(ArH)); 4.10 (s, 4H(NH_2)); 3.98 (m, 4H(CH_2)).

H_2L. To a stirred solution of *o*-vanillin (2.64 g, 17.4 mmol) in 20 cm^3 hot ethanol, a solution of dapp (2.38 g, 8.7 mmol) in 20 ml hot ethanol was quickly added dropwise. After several minutes, an orange product was crystallized out. When the temperature of the mixture dropped to ambient, the micro-crystals were filtered out, washed with ethanol and dried in air. The yield (4.2 g, 7.6 mmol) of crude product was 88%, which may be sufficient for use in preparing of the complex described below. Orange colored needle crystals of $H_2L(H_2O)_{0.5}$ were obtained by recrystallization from hot ethanol. m.p. 183–185°C. Found: C, 67.2; H, 5.5; N, 5.4. Calc. for $C_{31}H_{31}N_2O_{7.5}$: C, 67.5; H, 5.6; N, 5.1%. IR (cm^{-1}): 3400 (s, br, ν(OH)); 1620 (s, sh, ν(C=N)); 1254 (s, sh, (Ar–O–R)). ^{1}H NMR (δ): 9.90 (s, 1H (OH)); 8.60 (s, 2H (ArOH)); 6.98 (m, 6H (ArH)); 6.80 (m, 8H (ArH)); 4.46 (m, 1H (CH)); 4.33 (m, 4H (CH_2)); 3.85 (s, 6H (CH_3)).

Preparation and single crystal growth of complex

H_2L (0.55 g, 1 mmol) was added slowly in portions to a stirred solution of $Cu(OAc)_2 H_2O$ (0.20 g, 1 mmol) in 50 ml methanol at room tempreture. After the mixture was refluxed for 5 h, the greater part of the solvent was distilled off. The resulted brown powder was filtered out, washed with methanol and dried *in vacuo*.

The powder was redissolved in a appropriate amount of hot pyridine. The dark red crystals $[Cu_2L_2](py)_2(H_2O)_2$, suitable for X-ray structure determination, were obtained by natural evaporation of the solvent for 1 week. Found: C, 61.2; H, 4.9; N, 6.2. Calc. for $C_{72}H_{70}N_6O_{16}Cu_2$: C, 61.6; H, 5.0; N, 6.0%. IR (cm^{-1}): 3390 (m, sh(OH)); 1639, 1610 (s, sh, ν(C=N)); 1242 (vs, sh, ν(Ar–O–R)).

Cyclic voltammetry

Apparatus and set-up. Cyclic voltammetry (CV) was performed with an MF-1A versatile voltamperemeter. Cyclic voltammograms were recorded with an X-Y recorder (LZ3). An aqueous saturated calomel electrode (SCE) as reference, platinum wire as a counter and platinum plate as a working electrode constituted a three electrode system. The platinum plate and wire electrode were immersed in a dilute solution of nitric acid before each experiment. The SCE was separated from the solution by a double bridge containing the supporting electrolyte adjacent to the SCE. Additionally, the internal resistance inherent in the used set-up, DMF and the carrier adjacent to the solution was regulated in order to minimize liquid–liquid junction potentials.

Compounding of electrolyte. DMF, dried over anhydrous magnesium sulfate and redistilled off under vacuum, was used as the solvent in the experiments. Tetrabutylammonium perchlorate (TBAP) was

employed as the supporting electrolyte in a 0.1 mol dm^{-3} concentration. TBAP was made from equivalent TBA bromide and perchloric acid in water, filtered off, washed, dried and recrystallized from ethyl acetate–*n*-hexane (1:1). The sample of $[Cu_2L_2](py)_2(H_2O)_2$ was quantitatively dissolved in the supporting electrolyte to obtained the electrolyte in 1×10^{-3} mol dm^{-3} concentration used to CV experiments. It was bubbled with nitrogen for 5 min prior to every measurement and all experiments were performed at 20 ± 0.2°C.

X-ray structure determination

Crystal data. $C_{72}H_{70}N_6O_{16}Cu_2$, Mr = 1402.47, triclinic, space group *P*1 (#2). $a = 10.154(4)$, $b = 12.061(5)$, $c = 14.449(7)$ Å, $\alpha = 104.47(3)$, $\beta = 90.57(4)$, $\gamma = 110.65(7)°$, $V = 1595(3)$Å^3, $Z = 1$, $D_c = 1.460$ g cm^{-3}, $F(000) = 730$, $\mu = 7.413$ cm^{-1}.

Data collection and refinement of crystal structure. A single crystal of dimensions $0.25\times0.3\times0.3$ mm was mounted on a glass fibre. The diffraction data were collected on an Enraf–Nonius CAD4 four-circle diffractometer with graphite-monochromated Mo–Kα radiation ($\lambda = 0.71073$ Å) using an $\omega-2\theta$ scan mode with ω scan width $0.8+0.35tg\theta$, scan rate 0.92–5.49° min^{-1}. A total of 4128 independent reflections were collected in the range $2 < \theta < 23°$, of which 2002 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement after *Lp* and empirical absorption corrections. The structure was solved by direct methods (Multan 82). All non-hydrogen atoms were located from an *E*-map and determined with successive difference Fourier syntheses. Hydrogen atoms were introduced in calculated positions but not refined. The final refinement of full matrix least-squares with anisotropic thermal parameters gave $R = 0.072$, $R_w = 0.079$ $(w = 1/\sigma^2(F_o))$, $(\Delta/\sigma)_{max} = 0.34$, $S = 2.64$. The maximum and minimum residuals had heights of 0.74 and -0.49 e Å^{-3}. All calculations were performed using the programs contained in the SDP–PLUS package.

RESULTS AND DISCUSSION

IR spectra

The symmetric and asymmetric stretching frequencies of NH_2 appear in the infrared spectrum of dapp, but none of these reappear in H_2L. As supersedure, a strong sharp peak is represent at 1620 cm^{-1}, designated as the stretching model of C═N, that means to complete the Schiff-base condensation. As contrasted with the ligand H_2L in the spectrum of the title complex $[Cu_2L_2](py)_2(H_2O)_2$, two significant changes occur: the sharpening of one absorption band at ~3400 cm^{-1} and the splitting apart of another band from 1620 cm^{-1} into 1639 and 1610 cm^{-1}. The former indicates that neither coordinated nor associated (*e.g.*, by hydrogen bond) hydroxy groups exist in the complex molecule; the latter shows that the imino group takes part in the coordination with the copper(II) atom.

Cyclic voltammetry

The cyclic voltammograms of $[Cu_2L_2](py)_2(H_2O)_2$ are drawn in Fig. 2. The redox processes of two metal centers, corresponding to two distinct couples, A and B in the curve, can be expressed as

$$\text{A}\quad \text{Cu(II)Cu(II)} \underset{-e}{\overset{+e}{\rightleftarrows}} \text{Cu(II)CuI},$$

$$\text{B}\quad \text{Cu(II)Cu(I)} \underset{-e}{\overset{+e}{\rightleftarrows}} \text{Cu(I)CuI}.$$

Relevant CV data are listed in Table 1. It was tentatively assigned that the processes are one-electron two-step successive and quasi-reversible, judging from the ΔE_p and i_{pa}/i_{pc} (≈1) values of each couple. Cathodic peak E_{pc}, anodic peak E_{pa} and approximate redox

−0.66	−0.43	0.23	−0.55	−0.88	−0.80	0.08	−0.84	0.29	8.0×10^4

*$\Delta E_p = E_{pa}-E_{pc}$, $E^o_{1/2} = (E_{pa}-E_{pc})/2$, $\Delta E^o_{1/2} = E^o_{1/2}(A)-E^o_{1/2}(B)$.
$K_{con} = [Cu(II)Cu(I)]^2/[Cu(II)Cu(II)][Cu(I)Cu(I)] = \exp[nF(\Delta E^o_{1/2})/RT]$.

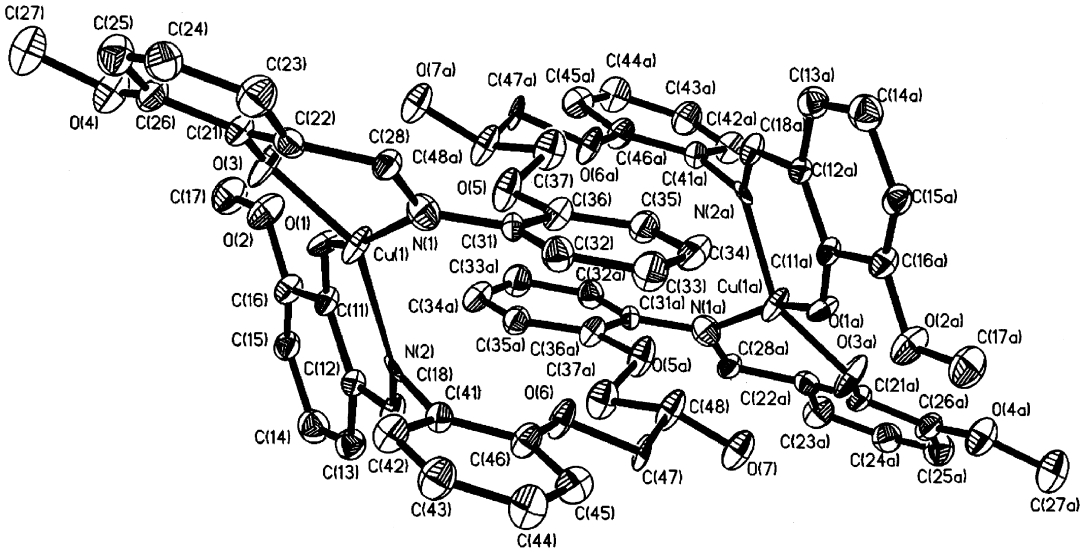

Fig. 3. The crystal structure of the dimer unit $[Cu_2L_2]$.

potential $E_{1/2}$ are all displayed within normal ranges [5, 7]; $E^0_{1/2}$ and K_{con} values, implying stability of the mixed valence state Cu(II)Cu(I), are comparable with those of the literature [7].

It is known that non interacting metal centers in similar environments do not have a $\Delta E^0_{1/2}$ separation larger than 50 mV [8]. The wave splitting magnitude of a few hundred millivolts (here it is 290 mV) should result from the weak Cu···Cu interaction in the present dinuclear complex [6].

Structure

The unit cell contains two congruent pyridine and two water molecules in the crystal, as well as a centrosymmetric dimer unit $[Cu_2L_2]$, which is displayed in Fig. 3. The geometry at each copper(II) center is best described as tetrahedral distorted square planar, being close to D_{2d}. At Cu(1), the *trans* atoms, O(1) and N(1), from two different L^{2-} lie 0.4383 Å and 0.4048 Å, respectively, above the plane, though four donor atoms (see plane V in Table 3), while O(3) and N(2) sit 0.4452 Å and 0.3979 Å, respectively, below this plane; Cu(1) is nearly in the plane, lying 0.0638 Å (Cu(1a), 6.7646 Å away) above. The shortest separation between copper atoms in the crystal lattice is 8.14 Å, but the Cu(1)···Cu(1a) distance in the same dimer is 9.87 Å. The coordinated bond lengths (see Table 2) are approximate to these of an analogous complex [9].

The alkyl group in the middle of L^{2-} are tortured to such a degree that no three oxo atoms bonding to this alkyl, O(5)–O(7), coordinate to any copper. Two phenyl rings separated by one alkyl group, plane III and IVa or IIIa and IV, are inclined at an angle of 9.9°; but two neighboring rings on the same end of one alkyl, plane I and IV or II and III, are at 112.2° or 31.7°. A common consequence of this twisting and the above torturing is that two coordination planes at Cu(1) and Cu(1a), V and Va, are parallel at an interplanar separation of 6.79 Å. It seems that this coordination configuration of the molecule induces the redox behaviors as two couples in the CV curve (*vide supra*). The literature [5] has inferred that face-to-face stacking of coordination planes may stabilize the Cu(II)Cu(I) state in a homodinuclear complex molecule.

In the discussion on CV, the existence of weak

(Received 15 July 1997; accepted 31 March 1998)

Abstract—A series of tris(pyrazoly)hydroborato metal complexes [η^3-HB(3-R^1-5-R^2pz)$_3$]MX (R^1 = Ph, 2′-thienyl, R^2 = CH_3, Ph; M = Ni, Cu, Zn, Cd; X = Cl^-, NO_3^-, CH_3COO^-) and [η^3-HB(3-Ph-5-Mepz)$_3$](3-Me-5-Phpz)Cu(PhCOO), **8**, had been synthesized and characterized. Among them, the complexes [η^3-HB(3,5-Ph_2pz)$_3$]NiCl (**3**), [η^3-HB(3-Ph-5-Mepz)$_3$]Cd(NO_3)(THF) (**4**) and **8** were analyzed by X-ray crystal structure determination, which revealed the bidentate coordination of NO_3^- in complex **4** and isomerized ligands in complex **8**. As model compounds of carbonic anhydrase (CA), the structures of these complexes were contrasted to that of the active site of CA: the derivative chloro may be the closest model compounds among them. The relationship between the coordination modes of X (X = NO_3^-, CH_3COO^-, $PhCOO^-$) in complexes and their IR spectra was also discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tris(pyrazolyl)hydroborato; metal complexes; crystal structure.

INTRODUCTION

The tris(pyrazoly)hydroborato ligand, $[HB(pz)_3]^-$, has played an important role in modeling metalloenzyme active sites since 1980. Its metal complexes have been employed in the carbonic anhydrase (CA), haemocyanin, tyrosinase, non-heme iron proteins and the polymanganese site of the photo-system II oxygen-evolving center [1–5]. The active site structure of CA has two key features: one is four-coordinated distorted tetrahedral of zinc center and the other is unidentate coordination mode of bicarbonate binding to zinc, which often acts as an important intermediate in the reaction [6]: $CO_2 + H_2O \rightarrow HCO_3^- + H^+$. When bulky substituents, e.g. t-Bu, Ph and isopropyl are in the 3-position of the pyrazole ring of $[HB(pz)_3]^-$ these prevent the binding of a second equally hindered tridentate ligand and a four-coordination complex is generally formed with a single axial ligand [1, 7]. Our recent works centered on studying a series of anion X (X = Cl^-, NO_3^-, CH_3COO^-, $PhCOO^-$) derivatives of some metals [HB(pz)$_3$]MX, on the basis that structural changes would indicate the relative tendencies of different metal centers to favour unidentate vs bidentate coordination for X. In this paper, we describe the synthesis and structures of some anion (X) derivatives of certain metals that are supported by tris (pyrazolyl)hydroborato ligation (Scheme 1). In particular, the structural similarity of halide derivatives to the active site of CA, the coordination modes of X (X ≠ Cl) in the complexes will be of central importance. The activity of these model complexes to catalyze reversible hydration reaction of CO_2 is being tested in our laboratory.

EXPERIMENTAL

Materials and physical measurements

All reagents were A.R. grade and used without further purification. ^{1}H NMR spectra (δ, ppm) were rec-

orded on a Bruker AM-400A spectrometer. IR spectra were obtained from KBr disks using a Nicolet-10DX FT-IR instrument. Elemental analyses were obtained by using a Vario EL elemental analyzer.

The tridentate ligands $K[BH(3\text{-}R^1\text{-}5\text{-}R^2\text{-}pz)_3]$ (R^1 = Ph, 2′-thienyl, R^2 = Ph, CH_3) were prepared and characterized as previously described [8].

Preparation of complexes **1**–**7**

To a solution of $K[BH(3\text{-}R^1\text{-}5\text{-}R^2\text{-}pz)_3]$ (2.0 mmol) in THF (10 cm^3) was added a solution of metal salt (2.3 mmol) in THF (20 cm^3), the mixture was stirred at room temperature for 12 h and filtered. The solvent was removed from the filtrate under reduced pressure and the residue obtained was washed with hexane, crystallized from appropriate solvents (see below) and isolated by filtration, washed and dried *in vacuo*.

(**1**) (CH_3COCH_3): IR: 2540(ν_{B-H}), 1365(δ_{CH3}), 759($\gamma_{=CH}$), 692(δ_{ring} of Ph). ^{1}H NMR ($CDCl_3$): 7.65–7.21 (m, 15H, Ph), 6.22 (s, 3H, pz), 2.62 (s, 9H, CH_3).

(**2**) (CH_3Ph/CH_3COCH_3): IR: 2528(ν_{B-H}), 1371(δ_{CH3}), 854,697(thienyl). ^{1}H NMR (CD_3CN): 7.92 (m, 3H, α H of thienyl), 7.50–7.36 (m, 5H, Ph of CH_3Ph), 7.23 (m, 6H, β H of thienyl), 6.26 (s, 3H, pz), 2.66 (s, 9H, 5-CH_3), 2.33 (s, 3H, CH_3 of CH_3Ph).

(**3**) [CH_2Cl_2/CH_3CN (2:1)]: IR: 2612(ν_{B-H}), 758($\gamma_{=CH}$ of Ph), 694(δ_{ring} of Ph). ^{1}H NMR (DMSO): 7.57 (m, 12H, ortho H of Ph), 6.97 (m, 18H, *meta*, *para* H of Ph), 6.48 (s, 3H, pz).

(**4**) (Pentane/THF): IR: 2546(ν_{B-H}), 1495[$\nu_a(NO_2)$], 1265($\nu_{N=O}$), 1028[$\nu_s(NO_2)$]. ^{1}H NMR ($CDCl_3$):7.50 (m, 6H, *ortho* H of Ph), 7.22 (m, 9H, *meta*, *para* H of Ph), 6.21 (s, 3H, pz), 3.64 (m, 4H, α H of THF), 2.56 (s, 9H, CH_3), 1.76 (m, 4H, β H of THF).

(**5**) [CH_3CN/CH_2Cl_2 (3:2)]: IR:2650(ν_{B-H}), 1550($\nu_{C=O}$), 1466(ν_{C-O}), 758($\gamma_{=CH}$ of Ph), 694(δ_{ring} of Ph). ^{1}H NMR ($CDCl_3$): 7.68 (m, 12H, *ortho* H of Ph), 7.01 (m, 18H, *meta*, *para* H of Ph), 6.48 (s, 3H, pz), 1.62 (s, 3H, CH_3COO).

(**6**) [THF/EtOH (1:1)]: IR: 2631(ν_{B-H}), 1486[$\nu_a(NO_2)$], 1281($\nu_{N=O}$), 1010[$\nu_s(NO_2)$]. ^{1}H NMR ($CDCl_3$): 7.62 (m, 6H, *ortho* H of Ph), 7.44–7.09 (m, 12H, *meta*, *para* H of Ph and α H of thienyl), 6.96 (m, 6H, β H of thienyl), 6.43 (s, 3H, pz).

(**7**) [CH_3CN/CH_2Cl_2 (1:1)]: IR: 2630(ν_{B-H}), 1569($\nu_{C=O}$), 1449(ν_{C-O}), 764($\gamma_{=CH}$ of Ph), 696(δ_{ring} of Ph). ^{1}H NMR ($CDCl_3$): 7.68 (m, 6H, *ortho* H of Ph), 7.45–7.11 (m, 12H, *meta*, *para* H of Ph and α H of thienyl), 6.98 (m, 6H, β H of thienyl), 6.44 (s, 3H, pz), 1.62 (s, 3H, CH_3COO).

Preparation of complex **8**

At room temperature, an equal amount (20 mmol) of copper (0.32 g), dibenzoyl peroxide (1.21 g), and tris[3(5)-phenyl-5(3)-methyl pyrazolyl] hydroborato potassium (0.79 g) were mixed with 200 cm^3 of acetone and stirred for 30 h. A green solid was yielded and isolated by filtration, recrystallized from ethanol, filtered, washed with benzene and dried in air. IR data: 2519(ν_{B-H}), 1593($\nu_{C=O}$), 1312(ν_{C-O}), 1389(δ_s of CH_3), 764($\gamma_{=CH}$ of Ph), 694(δ_{ring} of Ph). ^{1}H NMR ($CDCl_3$): 8.42 (m, 5H, PhCOO), 7.91 (m, 8H, *ortho* H of Ph), 7.48 (m, 12H, *meta*, *para* H of Ph), 6.21 (s, 4H, pz), 2.59 (s, 12H, CH_3).

The physical properties and elemental analyses of the complexes **1**–**8** were listed in Table 1.

Crystal structure determination

Data collection was performed with MoKα radiation ($\lambda = 0.71073$ Å) on a Siemens P4 diffractometer with data reduction using the Siemens SHELXTL program system. Experimental details for the structure determination of **3**, **4** and **8** are summarized in Table 2, while Tables 3 and 4 give a listing of selected bond lengths and angles, respectively. A perspective view of **3**, **4** and **8** are presented in Fig. 1(a), Fig. 2(a) and Fig. 3(a). The maps of crystal packing in unit cell of them are given in Fig. 1(b), Fig. 2(b) and Fig. 2(b).

RESULTS AND DISCUSSION

IR spectra

From IR spectra of the complexes, we could find the characteristic vibration peaks of BH, Me, Ph, thienyl and pyrazolyl groups, besides we may also assign certain peaks to the stretching vibration of coordinated NO_3^-, CH_3COO^- and $PhCOO^-$. According to Nakamoto's proposal [9], there is a close relation between the coordination modes of X- and its IR spectra (see Tables 5 and 6). We believe all of complex **4** and **6** conclude the bidentate coordination mode of nitrate and the last has been tested directly by X-ray crystal determination. The results revealed from Table 6, that the value of $[\nu_{(C=O)} - \nu_{(C-O)}]$ of bridged carboxylate was

Origination and isomerization of ligand (3-*methyl*-5-*phenylpyrazole*) *in* **8**

The preparation of complex **8** by a similar method employed to **1**–**7** was unsuccessful and this spurred us on to find a new synthetic method. We inferred that the ligand (3-methyl-5-phenylpyrazole) in **8** may come from the very minor impurity of reactant K[BH(3-Ph-5-Mepz)$_3$].

From bond length data [N(7)–C(32) = 1.344(4) Å, N(8)–C(34) = 1.334(4) Å], we could not distinguish which N atom is 1-position of pyrazole ring formed by N(7), N(8) and other three carbon atoms. However, the structure determination shows that this is much in line with the coordination situation of nitrogen-containing heterocyclic compounds. Therefore, this ligand would be 3-methyl-5-phenyl pyrazole which was an isomer of 3-phenyl-5-methyl pyrazole existing in another ligand [η^3-HB(3-Ph-5-Mepz)$_3$]. Due to a small hindrance of the methyl group, KBH_4 preferentially attacks the NH group of isomer I, instead

of II, H_2 being eliminated and finally formed K[HB(3-Ph-5Mepz)$_3$]. So, the steric effect appears to have great influence on the formation of the complex. We found this phenomenon in our previous work [8].

I **II**

Molecular structure

The molecular structures of complexes [η^3-HB(3,5-$Ph_2pz)_3$]NiCl, [η^3-HB(3-Ph-5-Mepz)$_3$]Cd(NO_3)(THF) and [η^3-HB(3-Ph-5-Mepz)$_3$](3-Me-5-Phpz)Cu(PhCOO) are illustrated in Figs 1–3. Each of the complexes exhibits a slightly different coordination of the tris(pyrazolyl) hydroborato ligands to the metal center, the average M–N bond lengths and N–M–N interbond angles change across the series Ni, Cu, Cd: [2.038 Å, 92.88°], [2.108 Å, 89.26°], [2.299 Å, 86.46°], which is a reflection of different covalent radius of the metal (Ni < Cu < Cd). Moreover the Cd–N bond length is shorter than those in the six-coordinate sandwich complex [η^3-HB(3,5-$Me_2pz)_3$]$_2$Cd [2.36(1) and 2.43(2) Å] [10].

The molecular structure of complex **3** has a C_3 symmetry axis, containing the atoms Cl, Ni, B and H (binding to B). The nickel atom is coordinated by three nitrogen atoms and one chlorine atom, the configuration of the complex is trigonally distorted tetrahedral, as evidenced by three small N–M–N [92.88(9)°] bond angles and three large N–Ni–Cl [123.20(7)°] bond angles. The coordination environ-

ment of **3** also compares reasonably well with a theoretical calculation for the active site of CA, with bond lengths and angles of Zn–O (1.96 Å), Zn–N (2.10 Å) and O–Zn–N (117.6°) [11].

The coordination mode of nitrate in complex **4** is bidentate [2.334(3) and 2.356(3) Å], which is close to that [2.272(6) and 2.295(7) Å] of [η^3-HB(3-Bu^t-5-Mepz)$_3$]Cd(NO_3) [1], but different from our previous observed value in [η^3-HB{3-(2′-thie)-5-Mepz}$_3$]Zn(NO_3) [8], i.e. 1.966(4) and 2.463(4) Å, obviously, the different coordination mode of nitrate results from different metal centers.

As illustrated in Fig. 3, the copper atom in **8** is coordinated by four nitrogen atoms and one oxygen atom, the coordination environment around the copper center being a distorted square pyramid with N(4) at the apical position. The coordination mode of benzoxy in complex **8** is unidentate, with a Cu–O(1) bond length of 1.968(2) Å.

Since the coordination mode of nitrate and acetate in complex **4**–**7** is bidentate, benzoxy exhibits unidentate coordination in complex **8** but has four coordinated N atoms. Therefore, the coordination number of complexes **4**–**8** is five or six.

(Received 17 February 1998; accepted 6 April 1998)

Abstract—The chelating properties of a new series of α-N-heterocyclichydrazones (heterocycle = substituted quinoline, benzothiazole, phthalazine) have been studied. Nickel complexes have been synthesized and structurally characterized in the gas phase by mass spectrometry and tandem mass spectrometry, and in the solid state by x-ray crystallography. Each ligand (LH) acts as tridentate and it undergoes a deprotonation in the complex formation. The complexes are neutral species and they can be formulated as $[ML_2]$. The crystal structure of bis[N-(2-benzothiazolyl)-N′-(methlymethoxycarbonyl)hydrazine]nickel(II) × 0.5 H_2O has been determined. The metal shows a pseudo-octahedral polyhedron and it is coordinated to two nitrogen and to oxygen atoms in the equatorial plane, and to two hydrazone nitrogen atoms in the axial positions. © 1998 Elsevier Science Ltd. Keywords: Ni^{II} complexes; hydrazone complexes; structural characterization; crystal structure; mass spectrometry.

INTRODUCTION

N-acyl- and *N*-arylhydrazones constitute important classes of organic compounds. The interest for these compounds may arise owing to their biological properties as well as for their chelating properties towards metal ions [1, 2]. As an example, 1(2*H*)-phtalazinone causes site-specific DNA damage [3] and mutagenic effects [4], and *N*-acyl- and *N*-arylhydrazones may exhibit pharmacological activities as potential antitumoral agents [5, 6]. It has been also found that complexes with essential metals, particularly first-row transition metals, may be more effective as antitumorals than the free ligands [7, 8]. Several mono and polynuclear metal complexes of hydrazone derivatives have been synthesized and characterized [2, 9–13]. In some cases these complexes are obtained as positive species, having different counter ions, such as chlorine or perchlorate [11, 12]. In other cases, deprotonation of the ligand occurs, so producing neutral metal complexes [9].

Most of these complexes have been characterized by different analytical approaches, such as infrared, UV and visible spectroscopies, nuclear magnetic resonance, magnetic measurements and x-ray crystallography. On the other hand, mass spectrometry, even if constitutes a powerful analytical tool for the characterization of organic and inorganic compounds [14], has been used only in few cases for characterizing metal complexes of hydrazone derivatives. The use of "hard" ionization methods, such as electron ionization, and "soft" desorption techniques, *e.g.* fast

atom bombardment, gives useful complementary information on the behaviour of chemical species in the gas phase.

In the ambit of a general project devoted to the characterization of heterocyclic compounds [15–17], we wish to report here on the coordination properties of new series of α-*N*-benzothiazolyl-, -quinolyl- and -phtalazinylhydrazone ligands (LH) towards Ni(II) (Scheme 1). The complexes have been characterized in the gas phase by mass spectrometry (MS) and tandem mass spectrometry (MS/MS), while x-ray crystallography was applied for the determination of the solid-state structure.

EXPERIMENTAL

Synthesis of the complexes

Metal complexes were obtained by mixing methanolic solutions of nickel acetate (1 mmol) and the appropriate ligand (2 mmol). The reaction mixture was heated under reflux for 1–2 hrs. By cooling the complexes separated as coloured solids which were filtered off, purified and dried in vacuum. Details on synthesis and yields, and other analytical data (NMR, IR) on complexes are given in ref. 6. Single crystals of **3** were obtained by dissolving 100 mg of powder in 50 ml of methanol and allowing to concentrate at room temperature. A dark brown prism of approximate dimensions $0.20 \times 0.25 \times 0.40$ mm was used for data collection.

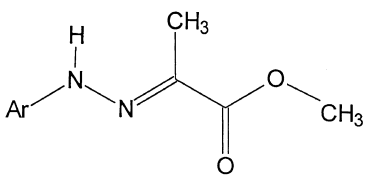
Mass spectrometry

Mass spectra were measured on a double focusing VG 70-250S mass spectrometer (VG Analytical Ltd., Manchester, UK). Electron ionization mass spectra were obtained at electron energy of 70 eV, emission current 0.2 mA, with a source temperature of 180°C. The samples were introduced via the direct inlet system without heating. Liquid secondary ion mass spectrometry (LSIMS) experiments were carried out by bombarding a mixture of the sample and the matrix (glycerol, Fluka) with caesium ions produced by a gun operating at an anode potential and current equal to 35 kV and 2 μA, respectively. The accelerating voltage was 8 kV and the resolution was 1000 M/ΔM (10% valley). Daughter and parent ion spectra were performed to detect metastable decomposition occurring in the first field free region by appropriate linked scans. Data acquisition and analysis of the spectra were performed with a VG 11-250J data system equipped with a Digital PDP 11/83 minicomputer. Electron ionization high resolution mass measurements were performed at resolution 10000 M/ΔM (10% valley) under the data system control against perfluorokerosene standard (Fluka).

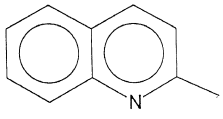
X-ray cystallography

Crystal data. **3**. $C_{22}H_{20}N_6O_5S_2Ni \times 0.51H_2O$, $M = 580.46$, Monoclinic, $a = 10.213(1)$, $b = 16.120(1)$, $c = 15.255(2)$ Å, $\beta = 102.32(1)^\circ$, $V = 2453.6(4)$ Å^3 (by least-squares refinement on diffractometer angles for 50 randomly selected and automatically centered reflections), space group $P2_1/c$ (n. 14), $Z = 4$, $F(000) = 1176$, $D_c = 1.55$ g cm^{-3}, μ(Mo–Kα) = 1.01 mm^{-1}.

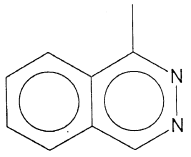
The data were collected on a Siemens P4 four-circle diffractometer with graphite monochromated Mo–Kα radiation ($\lambda = 0.71069$ Å) in the range $-1 \le h \le 12$, $-1 \le k \le 19$, $-18 \le l \le 17$, ω scan mode for $1.9 \le \Theta \le 25^\circ$ scan range, scan width 1.4°, constant scan speed 2.70° min^{-1}. Three standard reflections measured every 60 min. showed no variations. 4323 unique reflections ($R_{int} = 0.028$) were collected at 22°C. Absorption correction obtained by psi scans was applied.



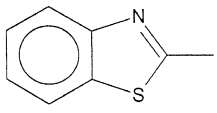
1 Ar =



2 Ar =



3 Ar =



Scheme 1.

The structure was solved by direct methods implemented in SHELX-97 [18]. The refinement was carried out by full-matrix anisotropic least-squares on F^2 for all reflections for all non-H atoms by using SHELX-97 [18]. The hydrogen atoms were located on Fourier difference maps and included in the structure-factor calculations. A thermal parameter fixed at 80×10^{-3} Å^2 was used for the hydrogens of the methyl groups, while a common isotropic temperature factor, refined to 67×10^{-3} Å^2, was assigned to the other hydrogen atoms. The occupancy factor for water molecule was refined to 0.51 while it was 1 for all the other atoms.

Final refinement of 387 parameters gave $R1 = 0.042$ and $wR2 = 0.088$ for $F^2 > 2\sigma(F^2)$. Weighting scheme $w = 1/[\sigma^2(Fo)^2 + 0.0490P^2]$, where $P = (Fo^2 + 2Fc^2)/3$. Min. max height in last $\Delta\rho$ map of -0.218 and 0.450 eÅ^{-3}. Atomic scattering factors including f' and f'' were taken from ref. 18. Geometrical calculations and molecular graphics were performed by using PARST 96 [19] and SHELXTL [20] packages, respectively.

RESULTS AND DISCUSSION

Mass spectrometry

Electron ionization mass spectra of complexes **1** and **2** are reported in Fig. 1. Mass spectra of **3** obtained by electron ionization and liquid secondary ion mass spectrometry are compared in Fig. 2.

The mass spectra allow to determine the stoichiometry of the complexes. Complexes **1**, **2**, and **3** show molecular ions at *m/z* 542, 544 and 554, indicating that each specie can be formulated as $[ML_2]$. This suggests that in their formation one deprotonation for each ligand molecule occurs. It is reasonable that the exocyclic H(–N) proton is removed, as it occurs in the crystal structure of **3** (see below). Deprotonation of hydrazone ligands yielding monoanionic or dianionic species is often observed to occur in metal complex formation [2, 9, 10, 13].

The molecular ions $[ML_2]^+$ show high abundances, their relative intensities being higher than 65% (**1** and **2**) or they constitute the base peak (**3**) (Table 1). The isotopic patterns, mainly due to the five isotopes of Ni, are in good agreement with those theoretically expected. For complexes **1** and **2** the base peaks of the mass spectra are represented by the ions at *m/z* 483 and 485, respectively (Fig. 1). High-resolution data (Table 2), allowing to determine the elemental composition of ions present in the mass spectrum, have shown that these peaks are due to the loss of $^{\bullet}COOCH_3$ radical. When the carboxymethyl radical is lost, the nickel should change its coordination polyhedron, passing from a octahedron to a square pyramid. The high intensity of the ions $[ML_2\text{-}COOCH_3]^+$ suggests that also this complex is very stable in the gas phase. The loss of a further $^{\bullet}COOCH_3$ radical from the other ligand molecule is observed only for **2**, producing ions at *m/z* 426 whose relative intensity is 6.5%.

Another very intense fragment ions common to the three complexes are due to the species $[ML]^+$, producing ions at *m/z* 300 and 301 for **1** and **2**, respectively (Fig. 1; Table 1). Other fragment ions produced in the source are attributed to $[ML\text{-}CH_2O]^+$, $[L]^+$, $[ML\text{-}C_4H_5NO_2]^+$, $[L\text{-}COOCH_3]^+$.

The mass spectra of **3** obtained by electron ionization (Table 1) and LSIMS (Fig. 2) appear to be quite similar to those of **1** and **2**. Under electron ionization conditions the molecular ions $[ML_2]^{+\bullet}$ (*m/z* 554) constitute the base peak of the mass spectrum. Fragmentations occurring in the ion source resemble those described for compounds **1** and **2**. Thus the most intense fragment ions at *m/z* 495, 306, 276, 206 are attributable to the species $[ML_2\text{-}COOCH_3]^+$, $[ML]^+$, $[ML\text{-}C_4H_5NO_2]^+$, $[L]^+$.

In the LSIMS spectrum (Fig. 2, bottom) the pseudomolecular ion $[ML_2 + H]^+$ (*m/z* 555) is the base peak. The fact that the complex must add a proton to assume a positive charge suggests that in the solid state it is a neutral species. Also under *soft* conditions, like it is in LSIMS, a prominent fragmentation occurs in the source. Thus the EI and LSIMS spectra show many common fragment ions with similar abundances in the range *m/z* 300–100. One difference is represented by the ions at *m/z* 495. In fact, while in the EI spectrum of **3** they are very intense (46.2%), in LSIMS conditions their relative intensity is quite poor (10%) (Fig. 2).

Metastable daughter ion spectra, obtained by selecting the molecular ions as main beam, have shown that both the ions $[ML_2\text{-}COOCH_3]^+$ and $[ML]^+$ are produced directly by decompositions of the molecular ions (Fig. 3). It is interesting to evidence that quite different fragmentation pathways are followed by the species $[ML_2]^{+\bullet}$ and $[ML]^+$. In fact, while the elimination of the $^{\bullet}COOCH_3$ radical is highly favored from the molecular ions $[ML_2]^{+\bullet}$, both in the source (Figs 1 and 2) and in metastable processes (Fig. 3), it does not occur from the species $[ML]^+$. On the other hand, for the latter the elimination of 30 u, attributed to CH_2O, occurs and produces abundant ions in the mass spectrum and the most intense daughter ions (Fig. 3). This might be explained by considering that in the specie $[ML]^+$ only three coordination sites are available; the loss of the carbonylic oxygen will reduce them to two only. Other metastable decompositions produced by $[ML]^+$ obtained by **1** yield ions at *m/z* 242, 229, 213, 201 and 186 (Fig. 3). In particular, the ion at *m/z* 242 is attributed to $[L]^+$ due to the extrusion of the metal ion.

Crystal and molecular structure of **3**.

The asymmetric unit is constituted by two ligands N-(2-benzothiazolyl)-N′-(methylmethoxycarbonyl)

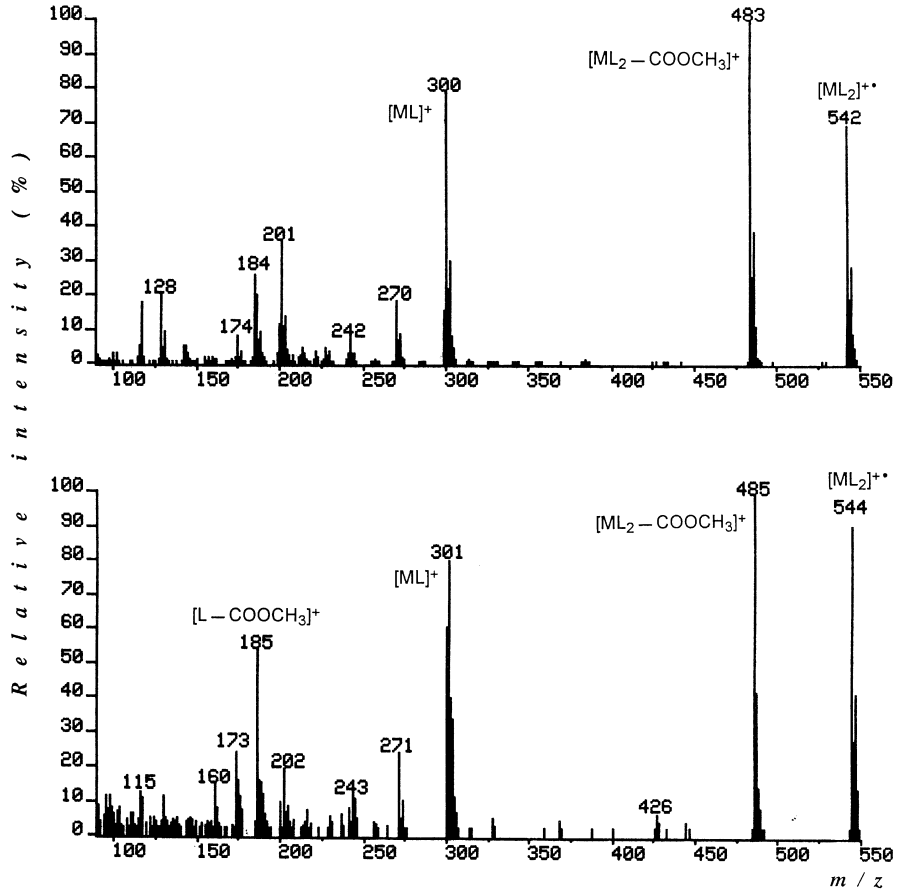


Fig. 1. Electron ionization mass spectra of complexes **1** (top) and **2** (bottom).

hydrazine bound to a nickel atom and 0.51 water molecule. The complex has no imposed crystallographic symmetry.

Each ligand molecule acts as tridentate. The metal ion shows a pseudooctahedral coordination polyhedron and it is coordinated to two oxygen (O(1), O(1A)) and to two nitrogen (N(3), N(3A)) atoms in the equatorial plane and to two hydrazone nitrogen (N(2), N(2A)) atoms in the axial positions (Fig. 4). The Ni–N distances are unequal. The two equatorial Ni–N bond lengths are 2.008(3) and 2.010(3) Å (Table 3), in agreement with Ni–N distances found in other nickel-hydrazino complexes [11, 13, 21]. The axial Ni–N bond lengths are slightly longer (2.061(3) and 2.053(3) Å). The two Ni–O distances are 2.238(3) Å (Ni–O(1)) and 2.198(3) Å (Ni–O(1A)). The octahedron is distorted with major out-of-plane deformations caused by the formation of chelate five membered rings involving both axial and equatorial ligands. As an example, the angles N(2)–Ni–O(1), N(2A)–Ni–O(1A) are equal to 75.8(1) and 76.8(1)°, while the highest in-plane deformation is due to the angles N(3)–Ni–O(1) and N(3A)Ni–O(1A) and equal to 153.9(1) and 153.8(1)°, respectively (Table 3). The nickel atom lies on the equatorial least-squares plane, while the two axial donor atoms, N(2) and N(2A), are −2.000(3) and 2.015(3) Å far from it, respectively.

In the benzothiazole moiety, the S–C bond lengths are in agreement with data previously found in analogous systems. In particular the S(1)–C(2) distance mean 1.747(3) Å in the two ligand molecules (Table 3). A search at the Cambridge Structural Database (CSD) [22] v. 5.14 for a 2-(N–N)-benzothiazolo fragment has produced 11 entries, but only for 9 entries correct geometric data are available. Only one structure is a hydrazone derivative [23], the others being mainly pyrazole and formazane derivatives. The results of the search indicate that the mean of the S(1)–C(2) bond length is equal to 1.737(7) Å, ranging from 1.710 Å in dioxo-methanol-(*β*-hydroxynaphthaldehyde-2-benzothiazolylhydrazonato)-molybdenum(VI)dimethylfor-mamide solvate [23] to 1.768 Å in azobenzene-N-(benzothiazol-2-yl)imide [24].

In the two ligand molecules, the C(2)–N(3) and N(3)–C(4) bond lengths mean 1.325(5) and 1.386(4) Å, respectively (Table 3). The mean values found in the above-cited search are equal to 1.303(8) and 1.393(5) Å, respectively. The two N–N distances in the hydrazone fragment are equal to 1.352(4) and

Table 2. Accurate mass measurements for compound **1**

Ion	Observed mass	Error (ppm)
$[C_{26}H_{24}N_6O_4Ni]^{+\cdot}$	542.1199	2.5
$[C_{24}H_{21}N_6O_2Ni]^{+}$	483.1074	1.0
$[C_{13}H_{12}N_3O_2Ni]^{+}$	300.0292	−2.9
$[C_{12}H_{10}N_3ONi]^{+}$	270.0178	−0.4
$[C_9H_7N_2Ni]^{+}$	200.9960	1.3
$[C_{11}H_{10}N_3]^{+}$	184.0879	−2.5

1.346(4) Å. The endocyclic C–S–C angles are equal to 89.6(2) and 89.4(2)°, respectively (Table 3), in the two ligand molecules, in agreement with the values found in substituted benzothiazoles.

The two benzothiazole moieties are quite planar. In one heterocycle (S(1) ÷ C(9)) the largest deviations from the least squares plane are shown by C(2) and C(6) (0.013(4), 0.009(5) Å), while the other atoms have deviations less than 0.007 Å. The other benzothiazole (S(1A) ÷ C(9A)) shows a less degree of planarity with C(7A), C(2A) and C(4A) having deviations of 0.035(5), 0.030(3), −0.028(3) Å, respectively. The two benzothiazoles are almost perpendicular each other with dihedral angles between their least-squares planes equal to 97.3(1)°. In one ligand molecule (S(1) ÷ C(13)), the pendant group is almost coplanar with the benzothiazole. The largest deviations are due to C(13) (0.133(6) Å) and to O(1) (−0.082(3) Å). On the other hand, the other ligand molecule is quite far from the planarity. In this case, the largest deviations from the weighted least-squares planes defined by the atoms S(1A) ÷ C(13A) are due to C(13A) (0.218(5) Å), C(7A) (0.216(5) Å), while N(1A), N(3A), C(2A), C(6A), C(8A), and O(2A) show deviations larger than 0.1 Å.

Table 3. Selected bond lengths (Å) and angles (°) for bis[N-(2-benzothiazolyl)-N′-(methyl-methoxycarbonyl)hydrazine]nickel(II) × 0.51H_2O (**3**)

(Received 4 November 1997; accepted 17 April 1998)

Abstract—Novel di-μ-oxo dimanganese(IV) complexes, $[Mn^{IV}(N\text{–R–X-sal})_2(\mu\text{-O})]_2$, with bidentate Schiff base ligands, *N*-alkyl-substituted-salicylideneamine, *N*–R–X-salH [R = CH_3 (Me), C_2H_5 (Et), *n*-C_3H_7 (Pr), *n*-C_4H_9 (Bu), *n*-C_6H_{13} (Hx), *n*-C_8H_{17} (Oct), *n*-$C_{10}H_{21}$ (Dec), *n*-$C_{12}H_{25}$ (Dod), or *n*-$C_{18}H_{37}$ (Octd) and X = H or 5,6-benzo], have been prepared by their reaction with potassium permanganate ($KMnO_4$) in MeCN, while stirring at room temperature. These complexes were characterized by spectroscopy, magnetic susceptibility, thermal analysis and X-ray crystallography. The structures consist of a $Mn^{IV}_2(\mu\text{-O})_2$ core with a Mn–Mn separation of 2.731(4) Å for $[Mn^{IV}(N\text{–Me-sal})_2(\mu\text{-O})]_2$, **1**, 2.769(2) Å for $[Mn^{IV}(N\text{-Et-sal})_2(\mu\text{-O})]_2$, **2**, 2.780(2) Å for $[Mn^{IV}(N\text{–Hx-sal})_2(\mu\text{-O})]_2$, **5**, 2.780(2) Å for $Mn^{IV}(N\text{-Dec-sal})_2(\mu\text{-O})]_2$, **7**, and 2.756(3) Å for $[Mn^{IV}(N\text{–Me-5,6-benzo-sal})_2(\mu\text{-O})]_2$, **10**. The complex **1** is the first di-μ-oxo dimanganese(IV) complex having asymmetrical form in which two manganese ions adopt different configurations each other. Moreover, the complexes **5** and **7** are found to exhibit the longest one among all of the Mn–Mn separation observed for the structurally characterized $Mn_2(\mu\text{-O})_2$ complexes prior to this work. The antiferromagnetic exchange interaction has been found to be $J = -83$ and -188 cm^{-1} for **1** and **7**, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: photosystem II; oxygen-evolving complex; di-μ-oxo dimanganese(IV) complexes; bidentate Schiff base ligand; crystal structure, antiferromagnetic interaction.

INTRODUCTION

Manganese plays an important role in biological redox systems, which is exemplified by the oxygen-evolving complex of photosystem II (OEC of PSII) in green plants. The understanding of the structure and mechanism of OEC has grown considerably than two decades ago, however, many questions remain unanswered (i.e. how are the oxygen atoms coupled to form an O–O bond?) [1]. The possibility is that a binuclear or tetranuclear cluster forms the active site in OEC of PSII, although their precise arrangement and oxidation levels have not been determined unambiguously. X-ray absorption experiments have established the existence of at least two 2.7 Å Mn–Mn contacts within the OEC [2, 3]. Therefore, polynuclear high-valent manganese complexes having $Mn_2(\mu\text{-O})_2$ units have been investigated as functional and/or structural models for Mn-cofactor in OEC [4–19]. However, it rapidly became clear that the data from several biophysical measurements of PSII could not be well correlated with the model complexes. The models are too symmetric [20, 21].

Recently, we have reported on the properties and molecular structures of di-μ-oxo dimanganese(IV) complexes, $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]_2$ (salophenH_2 = *N*,*N*′-disalicylidene-1,2-diaminobenzene), **11**, $[Mn^{IV}(\mu\text{-salen})(\mu\text{-O})]_2$ (salenH_2 = *N*,*N*′-disalicylidene-1,2-diaminoethane), **12**, $[Mn^{IV}(salbn)(\mu\text{-O})]_2$ (salbnH_2 = N,N′-disalicylidene-1,4-diaminobutane), **13**, $[Mn^{IV}(salipn)(\mu\text{-O})]_2$ (salipnH_2 =

N,*N*′-disalicylidene-1,2-diaminopropane), **14**, and $[Mn^{IV}(N\text{–Hx-sal})_2(\mu\text{-O})]_2$, **5**, (*N*–Hx-salH = *N*-hexyl-salicylideneamine) obtained by the reaction of $KMnO_4$ with these ligands in MeCN [22–24].

In this paper, we describe the preparation and the detailed properties of novel di-μ-oxo dimanganese(IV) complexes with bidentate Schiff base ligands, $[Mn^{IV}(N\text{–R–X-sal})_2(\mu\text{-O})]_2$ {*N*–R-salH = *N*-alkyl-salicylideneamine [R = CH_3 (Me), **1**, C_2H_5 (Et), **2**, *n*-C_3H_7 (Pr), **3**, *n*-C_4H_9 (Bu), **4**, *n*-C_6H_{13} (Hx), **5**, *n*-C_8H_{17} (Oct), **6**, *n*-$C_{10}H_{21}$ (Dec), **7**, *n*-$C_{12}H_{25}$ (Dod), **8**, or *n*-$C_{18}H_{37}$ (Octd), **9**] and *N*-R-5,6-benzo-salH [CH_3 (Me), **10**, C_2H_5 (Et), *n*-C_3H_7 (Pr), *n*-C_4H_9 (Bu), *n*-C_6H_{13} (Hx), *n*-C_8H_{17} (Oct), *n*-$C_{10}H_{21}$ (Dec), *n*-$C_{12}H_{25}$ (Dod) or *n*-$C_{18}H_{37}$ (Octd)]}. These complexes have been characterized by UV-vis and IR spectra, magnetic susceptibility, thermal analysis, electrochemical analysis and X-ray crystallography.

The di-μ-oxo dimanganese(IV) complex **1** is the first example to overcome the problem that model complexes are too symmetric than OEC of PSII, and the long Mn–Mn distances of **5** and **7** may provide a good model for high oxidized S-states of OEC.

EXPERIMENTAL

Preparation of bidentate Schiff base ligands

The bidentate Schiff base ligands, *N*-alkyl-substituted-salicylideneamine, *N*–R–X-salH where R can be CH_3 (Me), C_2H_5 (Et), *n*-C_3H_7 (Pr), *n*-C_4H_9 (Bu), *n*-C_6H_3 (Hx), *n*-C_8H_{17} (Oct), *n*-$C_{10}H_{21}$ (Dec), *n*-$C_{12}H_{25}$ (Dod) or *n*-$C_{18}H_{37}$ (Octd) and X can be H or 5,6-benzo were prepared according to the method described in the literature [25].

Preparation of di-μ-oxo dimanganese complexes

$[Mn^{IV}(\text{N–}R\text{-}sal)_2(\mu\text{-}O)]_2$ (*R* = *Me*, *Et*, *Pr*, *Bu*, *Oct*, *Dec*, *Dod and Octd*). The manganese(IV) complex **1** was prepared by the reaction of *N*–Me-salH (1.35 g, 10.0 mmol) and $KMnO_4$ (0.79 g, 5.0 mmol) in MeCN (150 ml) with stirring at room temperature. The solution color changed from purple to brown and 6 h after the resulting brown solids, which correspond to manganese oxide, were filtered off. The filtrate was allowed to stand in the dark place at room temperature. Two days later the resulting brownish black crystals, **1**·2MeCN, were collected on a glass filter. They were recrystallized from MeCN (yield 1.33 g, 70%).

Other manganese(IV) complexes, $[Mn^{IV}(N\text{–R-sal})_2(\mu\text{-O})]_2$ (R = Et, Pr, Bu, Hx, Oct, Dec, Dod or Octd) were prepared in the same manner as the following preparation method. The manganese(IV) complex **5** was prepared by the reaction of *N*–Hx-salH (1.03 g, 5.0 mmol) and $KMnO_4$ (0.40 g, 2.5 mmol) in MeCN (150 ml) with stirring at room temperature. The solution color changed from purple to brown and 12 h after the resulting brown solids were collected on a glass filter and dried *in vacuo* (1.10 g). They were extracted with dichloromethane (CH_2Cl_2) (100 ml), and the solution was reprecipitated by the addition of MeCN. The resulting brown micro crystals were collected on a glass filter and dried *in vacuo*. They were recrystallized from a mixed solvent of CH_2Cl_2 and MeCN (yield 0.80 g, 67%).

$[Mn^{IV}(\text{N–}R\text{-5,6-}Benzo\text{-}sal)_2(\mu\text{-}O)]_2$ (*R* = *Me*, *Et*, *Pr*, *Bu*, *Oct*, *Dod and Octd*). The manganese(IV) complexes, $[Mn^{IV}(N\text{-R-5,6-benzo-sal})_2(\mu\text{-O})]_2$ (R = Me, Et, Pr, Bu, Oct, Dec, Dod and Octd) were prepared in the same manner above mentioned for **5**.

Single crystals of **1**·2MeCN, **2**, **5**, **7** and **10**·2MeCN have been used for X-ray crystallographic characterization.

Elemental analyses data for all of the complexes are given in Table 1.

Physical measurements

Elemental analyses were made on a Yanaco Model CHN-CORDER MT-5. UV-vis and IR spectra were recorded on a Shimadzu Model UV-3100 spectrophotometer and a Shimadzu Model IR-470 infrared spectrophotometer, respectively. Electrochemical studies were performed under argon, using a BAS Model CV-27 voltammograph equipped with a Graphtec Model WX 2400 XY recorder and a standard three-electrode assembly (glassy carbon working, Pt wire auxiliary, and Ag/AgCl MeCN 0.1 M *n*-Bu_4NClO_4, TBAP, reference electrode) with 0.1 M TBAP (*n*-Bu_4NClO_4) as the supporting electrolyte. All the redox potentials were corrected to the saturated calomel electrode (SCE). Magnetic susceptibility measurements were carried out by the Gouy method at room temperature. Variable-temperature magnetic susceptibility data were collected between 1.8 and 300 K using a Quantum Design superconducting quantum interference device (SQUID) in an applied magnetic field of 1000 G. A differential scanning calorimetry (DSC) and a thermogravimetric and differential thermal analysis (TG-DTA) were carried out by using a Rigaku TAS-200 thermal analysis system.

X-ray crystallography

Single crystals of **1**·2MeCN were obtained by recrystallization from MeCN and those of **2**, **5**, **7** and **10**·2MeCN were obtained by recrystallization from a mixed solvent of MeCN and CH_2Cl_2. The crystals were then mounted in a glass capillary and coated with silicone oil. All the data were collected on a Rigaku AFC-7R four circle automated diffractometer with graphite monochromated Cu–Kα radiation ($\lambda = 1.54178$ Å) for **1**·2MeCN and **2** or Mo–Kα radiation ($\lambda = 0.71069$ Å) for **5**, **7**, and **10**·2MeCN at room temperature. Unit-cell parameters were obtained from least square fit of 25 reflections, $18.0^\circ < 2\theta < 20.7^\circ$ for **1**, $18.2^\circ < 2\theta < 24.8^\circ$ for **2**, $6.9^\circ < 2\theta < 12.0^\circ$ for **5**,

Table 1. Elemental analyses of [Mn(*N*–R–X-sal)$_2$(μ-O)$_2$]$_2$

R, X	Formula	Analyses[a]

[a]Required values in parentheses.

$6.6^\circ < 2\theta < 10.0^\circ$ for **7** and $6.5^\circ < 2\theta < 12.5^\circ$ for **10**·2MeCN. Three standard reflections were measured every 150 reflections; they showed no systematic decay throughout data collection. The data were corrected for Lorentz and polarization effects. All the calculations were carried out using the TEXSAN [26] crystallographic software package. The structures of the complexes were solved using direct method (SHELX86) [27] and expanded using Fourier techniques [28]. These structures were refined by the full-matrix least-squares technique with anisotropic thermal parameters for all nonhydrogen atoms. Hydrogen atoms were introduced in calculated positions but not refined. Crystallographic data for the complexes are summarized in Table 2.

Reagents

The reagents (salicylaldehyde, 5,6-benzo-salicylaldehyde, and monoamines) were obtained commercially and used without further purification. $KMnO_4$ was of the reagent grade (99.5%). MeCN was purified by distillation over P_4O_{10} twice and then distilled further before use. Other solvents were purified by usual method.

RESULTS AND DISCUSSION

Molecular structures of di-μ-oxo dimanganese complexes

The molecular structures of the di-μ-oxo dimanganese(IV) complexes **1**, **2**, **5** and **7** are shown in Figs 1–4 and these selected bond distances and angles are listed in Tables 3–6, respectively. These structures consist of two Mn(IV) centers bridged by two oxygen atoms to yield a planar Mn_2O_2 core with Mn–Mn separation of 2.731 (4) Å for **1**, 2.769(2) Å for **2**, 2.780(2) Å for **5**, and 2.780(2) Å for **7**.

For complex **1**, the unit cell contains four independent dimers, which have almost the same structure. The complex **1** is the first di-μ-oxo dimanganese(IV) complex having asymmetrical form in which two manganese ions adopt different configuration each other. On the one manganese ion (Mn1) of **1**, two phenolic oxygen atoms are located to *trans* and two imine nitrogen atoms are located to *cis* position toward a bridging μ-oxo group, which is quite similar to the structure of **5**. However, on another manganese ion (Mn2), two imine nitrogen atoms are located to *trans* and two phenolic oxygen atoms are located to *cis* position toward a bridging oxo group. It is conceivable that the formation of the asymmetric complex **1** may be caused by less steric hindrance of $-CH_3$ group of *N*–Me-sal ligand than the other *N*–R-sal ligands. **1** has distinct lengthening of the Mn–O (phenolate oxygen) and Mn–N (imine nitrogen) bond distances *trans* to the Mn–O_{oxo} bonds: Mn–O, 1.91(1) and 1.95(2) Å (*trans*) and 1.90(1) and 1.91(2) Å (*cis*); Mn–N, 2.07(2) and 2.10(2) Å (*trans*) and 2.00(2) and 2.02(2) Å (*cis*).

On the other hand, the other di-μ-oxo dimanganese(IV) complexes, **2**, **5**, and **7**, have symmetrical form. These symmetrical complexes exhibit relatively longer Mn–Mn separation than those of the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff

bases (2.688(1)–2.732(3) Å) [10, 13, 14, 19, 22–24], and the value [2.780(2) Å] observed for **5** and **7** is the longest one among all of the Mn–Mn distances observed for the structurally characterized $Mn_2(\mu\text{-O})_2$ complexes (2.580(1)–2.757(3) Å) prior to this work [5–15] [16–19]. It is considered that the long Mn–Mn distance of these complexes may be caused by the interaction of the alkyl groups of the ligands, because the complex having a longer alkyl group chain in these ligands has a longer Mn–Mn separation. In the structure of these complexes, two *N*–R-sal ligands around each manganese atom bond *via* two phenolic oxygen atoms and two imine nitrogen atoms to complete the roughly octahedral coordination environment. Adoption of this binding model of **2**, **5** and **7** places two phenolic oxygen atoms *trans* and two imine nitrogen atoms of two *N*–R-sal ligands *cis* to a bridging μ-oxo group are similar to the metal center of the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff bases, **11** and **12** [23]. The Mn–O (phenolate oxygen) and Mn–N (imine nitrogen) bond distances of **2** and **5** are almost regular: Mn–O, 1.927(4) and 1.913(4) Å for **2** and 1.950(7), 1.920(7), 1.942(7) and 1.933(7) Å for **5**; Mn–N, 2.028(4) and 2.026(4) Å for **2** and 2.025(9), 2.044(9), 2.022(9) and 2.020(9) Å for **5**. On the other hand, these bond distances of 7 are not so regular: Mn–O, 1.906(6), 1.908(6), 1.947(6) and 1.967(6) Å; Mn–N, 2.059(7), 1.991(6), 2.013(7) and 2.074(7) Å.

The molecular structure of the di-μ-oxo dimanganese(IV) complex having 5,6-benzo substituent groups **10** is shown in Fig. 5 and its selected bond distances and angles are listed in Table 7. For complex **10**, the unit cell contains two independent dimers, which have almost same structure. The complex **10** has symmetrical form, in spite of the complex **1** bearing the same alkyl group, R = Me, has an asymmetrical form. The Mn–Mn separation of **10**, 2.756(3) Å, is longer than the separation of **1**, but slightly shorter than that of **2**. It is conceivable that the symmetric complex **10** may result from the existence of the bulky 5,6-benzo substituent groups; the *N*–Me-5,6-benzo-sal ligand

has much more steric hindrance than the *N*–Me-sal ligand of **1**. The Mn–O (phenolate oxygen) and Mn–N (imine nitrogen) bond distances of **10** are almost regular: Mn–O, 1.928(10), 1.927(9), 1.912(9) and 1.933(10) Å; Mn–N, 2.00(1), 2.00(1), 1.99(1) and 2.01(1) Å.

Scheme 1 shows three types of $N_2O_2(\mu\text{-}O)_2$ ligation sphere for structurally characterized di-μ-oxo dimanganese(IV) complexes with Schiff base ligands. The complexes **2**, **5**, **7** and **10** belong to type I, which has a relatively large Mn–Mn separation. Although the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff base ligands, **11**, **12** and [Mn(μ-dbsalen)(μ-O)]$_2$ (dbsalenH_2 = *N*,*N*′-di-3,5-dibromosalicylidene-1,2-diaminoethane) belong also type I, these complexes exhibit remarkably shorter Mn–Mn separations (2.688–2.718 Å) [18, 22, 23]. The type II is observed for the di-μ-oxo dimanganese(IV) complexes with several tetradentate Schiff base, **13**, **14** and [Mn(salpn)(μ-O)]$_2$ [13, 22, 23]. The Mn–Mn separation of these complexes exhibits around 2.73 Å. On the other hand, **1** is a unique complex of type III,

which is a novel asymmetric di-μ-oxo dimanganese(IV) complex. The bond length and angles of **1** resemble to the complex of type II. These structural differences around Mn ions are strongly correlated to electronic spectra, IR spectra, and electrochemical and magnetic properties (*vide infra*).

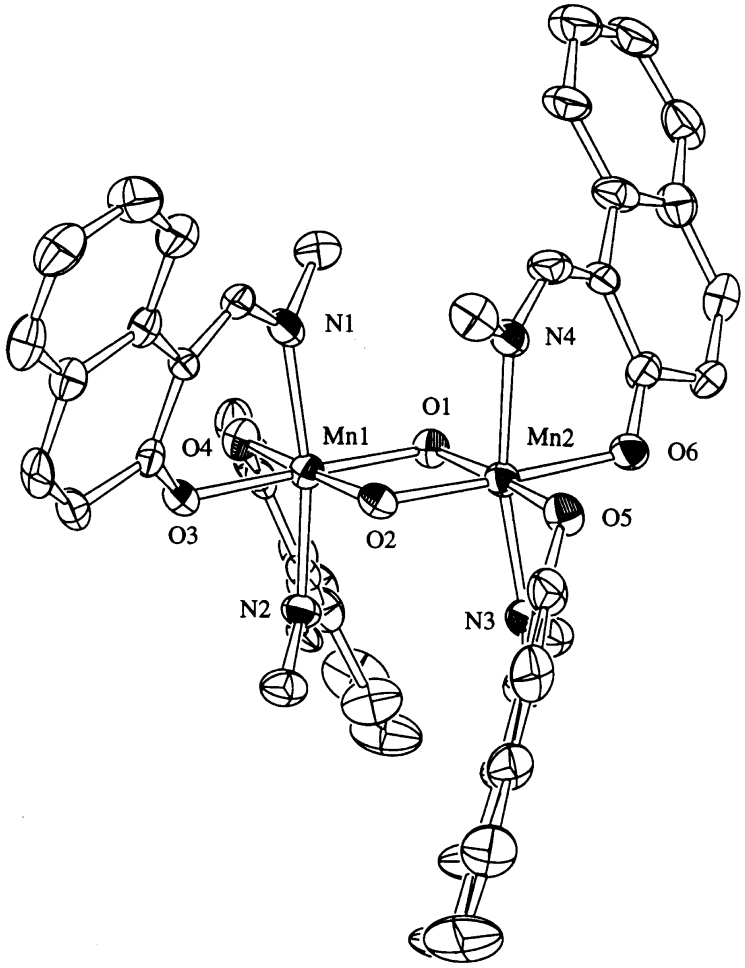

Fig. 5. Molecular structure of $[Mn^{IV}(N\text{-Me-5,6-benzo-sal})_2(\mu\text{-O})]_2$, **10**.

Electronic spectra

The electronic spectrum of the asymmetric di-μ-oxo dimanganese complex, **1**, is different from the other complexes, $[Mn^{IV}(N\text{–R-sal})_2(\mu\text{-O})]_2$ (R = Et-Dod), **2–8**. Further, the spectra of these symmetric complexes are almost the same. Figure 6 shows the electronic spectra of **1** and **8** in dichloromethane (CH_2Cl_2). The absorption bands appearing in the region 400 nm and below are thought to be associated mainly with the ligand transitions. In the visible and near-IR region, the spectra of **1** and **8** exhibit two or four absorption bands around 493 ($\varepsilon = 11100\,M^{-1}\,cm^{-1}$) and 708 nm ($\varepsilon = 477\,M^{-1}\,cm^{-1}$) for **1**, and 402 ($\varepsilon = 13150\,M^{-1}\,cm^{-1}$), 480 nm ($\varepsilon = 8760\,M^{-1}\,cm^{-1}$), 694 ($\varepsilon = 615\,M^{-1}\,cm^{-1}$), and 846 nm ($\varepsilon = 162\,M^{-1}\,cm^{-1}$) for **8**, respectively. Based on the intensities and positions, the absorption bands around 400 and 500 nm can be assigned to the ligand to metal charge-transfer transitions from oxygen atoms of the oxo groups to manganese atoms and the bands around 700 and 850 nm can be assigned to the d–d transitions. The peaks at near-IR region are characteristic to the di-μ-oxo dimanganese(IV) complexes with bidentate Schiff base ligands but not observed for the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff base ligands [24]. Particularly, the intensity and position of the d–d transition band around 850 nm for **8** resemble to the spectra of tris(bidentate ligand) manganese(III) complex, $Mn^{III}(N\text{-Dod-sal})_3$ and of tetranucler manganese(III) complex, Mn^{III}_4-(salmphen)$_6$ (salmphenH_2 = *N*,*N*′-disalicylidene-1,3-diaminobenzene) [29]. Consequently, two types between the di-μ-oxo dimanganese complexes of bidentate and tetradentate Schiff base ligands are found to be discriminative from their electronic spectra. The electronic spectrum of the symmetric complex **10** resembles to those of **2–8**. These results are consistent with those obtained from the structural analyses. On the other hand, the electronic spectrum of **9**

resembles to that of **1** compared with those observed for **2–8**. Numerical data for the electronic spectra of all the complexes are listed in Table 8.

IR spectra

It has been reported that IR spectra of the di-μ-oxo dimanganese(IV) complexes exhibit sharp absorption bands characteristic for a $Mn_2(\mu\text{-}O)_2$ core in the region around 600–700 cm^{-1}, which can be assigned to stretching vibrations of $Mn–O_{oxo}$ bonds [30]. Figure 7 shows the IR spectra of **1**, **2** and **8** in this region which exhibit an intense and two medium bands at 653, 620 and 600 cm^{-1} for **1** and two intense and one medium bands at 641, 620 and 597 cm^{-1} for **2**, and at 633, 620 and 601 cm^{-1} for **8**. The highest energy peak shifts to lower energies along with an increase in the alkyl chain length of these bidentate Schiff bases. These results are consistent with the crystallographic observations: Mn–Mn distances are separated with the same order. With exception for the intense peaks due to *n*-alkyl groups, the spectra of the complexes, **2–9**, are almost same over the region of 4000 to 400 cm^{-1}. On the other hand, in the region of 1300 to 800 cm^{-1} the spectrum of **1** is significantly different from the others. Numerical data for the IR spectra of all the complexes are listed in Table 8.

In the IR spectrum of the product obtained by heating **8** at 137°C for 1 h in vacuo, the intense band (633 cm^{-1}) disappeared without significant changes in other peaks. The resulting spectrum (Figure 7, spec-

trum A) resembled to that of $Mn^{III}(N\text{-Dod-sal})_3$ complex [29]. These results suggest that the bridging oxygen atoms were released from the di-μ-oxo dimanganese(IV) complexes by heating.

Electrochemistry

Cyclic voltammograms (CV) of these complexes were measured in CH_2Cl_2 over the range from +1.30

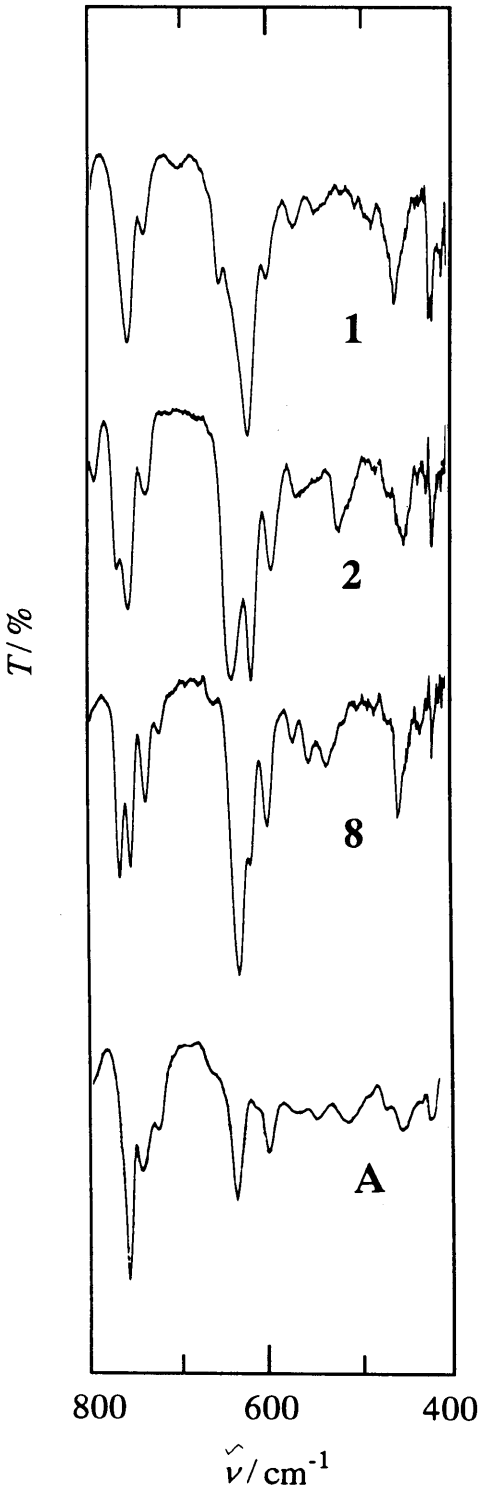

Fig. 7. IR spectra of **1**, **2**, **8** and the product obtained by heating 8 at 137°C for 1 h in *vacuo* (A).

to −1.70 V vs SCE. As shown in Fig. 8, the CVs of **1** and **5** exhibit multistage quasi-reversible redox waves and are relatively indistinct compared with those observed for the complexes with tetradentate Schiff bases [23]. Three reduction peaks are observed at the potentials of −0.24, −0.54 and −0.70 V vs SCE for 1 and −0.17, −0.41 and −0.75 V vs SCE for **5**. The CVs of other complexes, **2–8**, are almost the same feature as that of **5**. On the other hand, the CV of **9** resembles to that of **1**. These results suggest that these complexes are reduced electrochemically stepwise in a CH_2Cl_2 solution: Mn(IV)Mn(IV)→Mn(IV)Mn(III)→Mn(III)Mn(III) or Mn(IV)Mn(II)→Mn(III)Mn(II). The last reduction step may accompany with some decomposition, because this step is electrochemically irreversible.

Magnetic properties

For all the di-μ-oxo dimanganese(IV) complexes, magnetic susceptibility measurements on powdered samples were carried out at room temperature (300 K) and the magnetic moments are listed in Table 8. The temperature dependence of the effective magnetic moments of **1** and **7** are shown in Figs. 9 and 10. The effective magnetic moments (μ_{eff}) of **1** and **7** have been found to decrease from 2.86 μ_B at 300 K to 0.211 μ_B at 1.8 K for **1** and from 1.86 μ_B at 300 K to 0.226 μ_B at 1.8 K for **7**, respectively. In the temperature range 50–300 K, their magnetic moments decrease as a function of temperature. These magnetic behavior indicates that an intramolecular antiferromagnetic interaction between the two manganese(IV) ions (d^3) exists in these complexes. The anomalous magnetic behavior has been observed for the complexes below 50 K, which have arisen from paramagnetic and/or weaker antiferromagnetic impurities. Such magnetic behavior at lower temperatures may also be explained in terms of intermolecular interactions, however, which can be ruled out in the cases of the present complexes because the central manganese ions are effectively separated from other ones by alkyl groups. The magnetic data obtained for **1** and **7** (Figures 9–10) were fitted by employing an expression derived from an isotropic spin-exchange Hamiltonian $H = -2JS_1 \cdot S_2$ ($S_1 = S_2 = 3/2$) and the Van Vleck equation. The curve fitting leads to values of $J = -83\,cm^{-1}$, $g = 1.83$, $TIP = 4.0 \times 10^{-4}$ and $P = 0.16\%$ for **1** and $J = -188\,cm^{-1}$, $g = 1.81$, $TIP = 4.5 \times 10^{-4}$ and $P = 0.18\%$ for **7**, where TIP is the temperature-independence paramagnetism and P is the mole percent of paramagnetic impurities assumed to be a mononuclear manganese(III) complex. The lower J value for the complex **1** is close to those for the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff base ligands [23] and $[Mn(pic)_2(O)]_2$, picH = picolinic acid [6], which fall within the relatively narrow range of −78 to $-88\,cm^{-1}$. On the other hand, the J value for **7** is markedly higher than those reported for several other $Mn^{IV}_2(\mu\text{-}O)_2$ cores, which have J values of $-150\,cm^{-1}$ and below. Furthermore, the curve fittings of the complexes, **2**, **5** and **10** lead to values

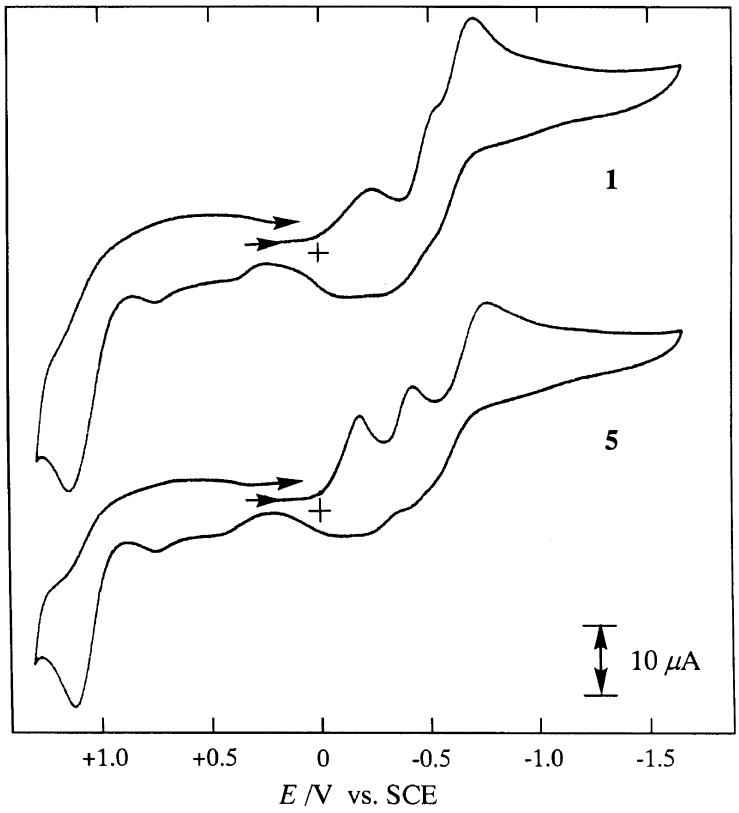

Fig. 8. Cyclic voltammograms (CV) of **1** and **5** in CH_2Cl_2.

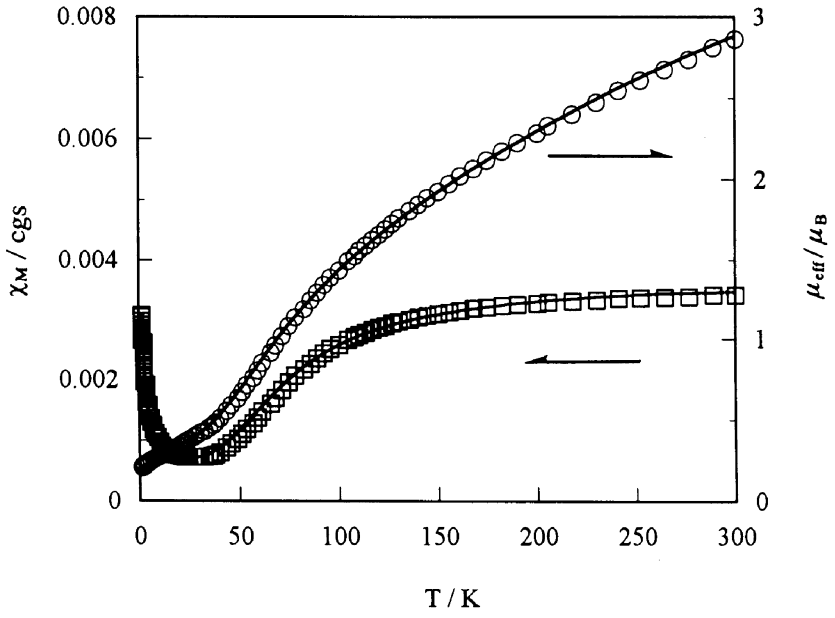

Fig. 9. Plots of χ_M and μ_{eff} of **1** per dimer vs temperature.

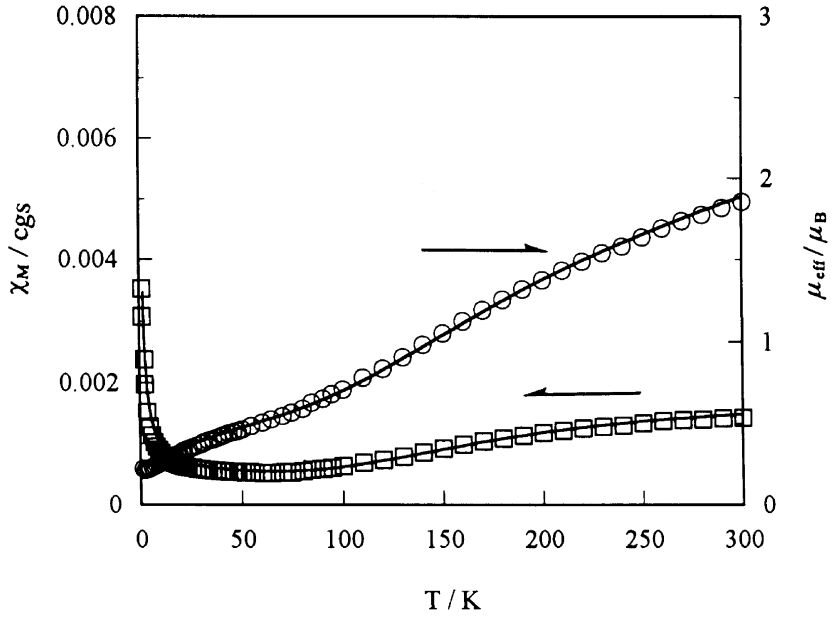

Fig. 10. Plots of χ_M and μ_{eff} of **7** per dimer vs temperature.

$J=-150\,cm^{-1}$, $g=1.90$, $P=3.5\%$ and TIP $=4.8\times10^{-4}$ for **2**, $J=-170\,cm^{-1}$, $g=1.85$, $P=0.08\%$ and TIP $=7.4\times10^{-4}$ for **5**, and $J=-119\,cm^{-1}$, $g=1.80$, $P=0.13\%$ and TIP $=2.5\times10^{-4}$ for **10**, respectively.

In the previous papers, a strong correlation between Mn–Mn distance and a magnetic exchange parameter J value for several $[Mn_2(\mu\text{-}O)_2]^{n+}$ ($n=2$, 3, 4) complexes has been discussed [4, 6, 17, 31]. However, in the case of the $Mn^{IV}{}_2(\mu\text{-}O)_2$ complex, the correlation is poor: for example, although $[Mn^{IV}(phen)_2(\mu\text{-}O)]_2^{4+}$ (phen = 1,10-phenanthroline) [5] and $[Mn^{IV}(pic)_2(\mu\text{-}O)]_2$ [6] have almost the same Mn–Mn distance [2.748(2) and 2.747(2) Å, respectively], their antiferromagnetic exchange parameters are remarkably, different, which are -144 and $-87\,cm^{-1}$, respectively. These complexes have different ligation spheres each other, and there is a limited number of the structurally characterized di-μ-oxo dimanganese(IV) complexes so far.

Table 9 shows structural data and magnetic exchange parameter J for structurally characterized di-μ-oxo dimanganese(IV) complexes with a series of bidentate or tetradentate Schiff base ligands. All of the complexes have a $N_2O_2(\mu\text{-}O)_2$ ligation sphere. The complexes with tetradentate Schiff base ligands and **1** exhibit almost same J values, within the range of -78 to $-88\,cm^{-1}$, their Mn–Mn distance, however, are appreciably different (2.705–2.732 Å). On the other hands, the complexes having large Mn–Mn separation, **2**, **5** and **7** (2.769–2.780 Å), which have strong antiferromagnetic exchange in the range of -150 to $-188\,cm^{-1}$.

From the structural data and the magnetic exchange parameter, shown in Table 8, we could suggest that the di-μ-oxo dimanganese(IV) complexes having larger antiferromagnetic exchange parameter J do have larger Mn–O_{oxo}–Mn angles. The Mn–O_{oxo}–Mn angles for the complex with tetradentate Schiff base ligand and **1** are almost constant (96.2–97.6°), although these complexes have different Mn–Mn separation. The complexes having larger antiferromagnetic exchange, **2**, **5** and **7**, do have larger Mn–O_{oxo}–Mn angles. The angles for **7** [99.7(3) and 100.5(3)°] are larger than **2** [99.1(2) and 99.5(2)°], which is consistent with the difference of J value.

These results suggest that in these compounds dose not rule out a contribution to antiferromagnetic exchange parameter J from Mn–Mn distance (direct d_{xy}–d_{xy} orbital overlap, where the x and y axes are coincident with Mn–(μ-O) bonds), although parameter J has a strong correlation with Mn–O_{oxo}–Mn angles (superexchange coupling via two bonding O atoms). A recent paper has pointed out that in the $Mn_2^{IV/IV}$ system, the longer Mn–Mn separation and the more acute Mn–O_{oxo}–Mn angle will lead to larger exchange parameters, based on the molecular orbital calculations for the di-μ-oxo manganese(IV) complexes, $[Mn(NH_3)_4(\mu\text{-}O)]_2^{n+}$ ($n=2$, 3, 4) [32]. Therefore, a systematic preparation of di-μ-oxo manganese(IV) complexes and their characterization should be needed for much more detailed discussion.

Thermal analysis (differential scanning calorimetry (DSC) and thermogravimetric and differential thermal analysis (TG-DTA))

These dimanganese(IV) complexes having linear-alkyl groups possess good solubility in organic sol-

[a] Based on the spin Hamiltonian $H = -2JS_1 \cdot S_2$.

vents and relatively lower melting points with (without) some decomposition compared to those of the corresponding manganese(IV) complexes with tetradentate Schiff base ligands. Thus, the thermal properties of the present manganese(IV) complexes have been studied. The DSC curve of **9** measured over the temperature range of 25 to 250°C shows both endothermic (110.8°C) and exothermic peaks (118.8°C), which can be assigned to melting and partial decomposition of the complex, respectively. However, the DSC curves of the other symmetric complexes show only exothermic peak at 124.1 (**8**), 126.2 (**7**), 131.2 (**6**), 145.7 (**5**), 149.7 (**4**), 168.8 (**3**), and 169.7°C (**2**). On the other hand, the asymmetric complex **1**·2MeCN exhibits both endothermic (80.8°C) and exothermic peaks (126.8°C) at lower temperature than **3–6**, which can be assigned to dissociation of a crystal solvent (MeCN) and partial decomposition of the complex, respectively. It is conceivable that the lower DSC temperature may arise from its asymmetrical structure. The temperatures of the DSC peaks of all the complexes are listed in Table 8.

The TG-DTA curves of **3** shown in Fig. 11, exhibit a clear weight loss of 4.2% at 174°C) accompanying an exothermic reaction, which corresponds to the calculated value (4.05%) expected for the release of two μ-oxo oxygen atoms from the complex. Similar results were obtained for the complexes of **2** and **4**, but the corresponding weight losses for the other complexes, **5–9**, were slightly less than the calculated values for the release of two oxygen atoms: this may be caused by the difficulty in diffusion of dissociated oxygen atoms from the molten state of the complexes under the thermal analysis conditions in a stream of air. In fact, when these complexes were heated in a vacuum oven for 1 h at higher temperatures by 10°C than those of their exothermic peaks, the weight losses have been

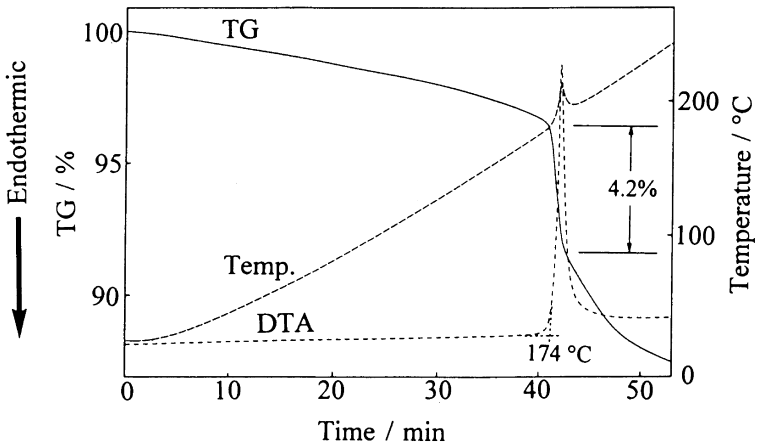

Fig. 11. TG-DTA curves of [Mn^{IV}(N-Pr-sal)$_2$(μ-O)]$_2$, **3**. Heating rate: 5°C/min in flowing air (60 ml/min).

found to correspond to the amount of two oxygen atoms per di-μ-oxo dimanganese complex.

CONCLUSIONS

In the present study, a series of di-μ-oxo dimanganese(IV) complexes with bidentate *N*-alkyl-substituted-salicylideneamine, *N*–R–X-salH, has been prepared and characterized. When R is Me (X = H), the configurations around two manganese ions have been found to be nonsymmetric toward a $Mn_2(\mu\text{-}O)_2$ core, whereas other complexes adopt a symmetric configuration. It is noteworthy that the asymmetric type is the first example, whereas all of the di-μ-oxo dimanganese(IV) complexes reported previously are a symmetrical type.

The results obtained from the X-ray structure analysis and the temperature dependent magnetic susceptibility measurements indicate that intramolecular antiferromagnetic interactions are correlated to both Mn–Mn separation and $Mn–O_{oxo}–Mn$ angles of a di-μ-oxo core. Furthermore, all of the complexes are found to release μ-oxo oxygen atoms by heating.

Received 11 March 1998; accepted 16 April 1998

Abstract—The synthesis, crystal structure, ESR spectra and magnetic properties are reported for the Cu(I-I)/Cu(I) compound $(4\text{-apyH})_4[Cu_3Br_8]$ (4-apyH = $C_5H_7N_2$ = 4-aminopyridinium). Single-crystals of the compound were grown by slow diffusion of *n*-hexane on an ethanolic solution of $(4\text{-apyH})_2[CuBr_4]\cdot H_2O$. The crystal structure is made up of organic cations, isolated $[Cu^{II}Br_4]^{2-}$ anions and infinite $[Cu^{I}Br_2]_n^{n-}$ chains composed of edge-sharing $Cu^{I}Br_4$ tetrahedra. N–H $\cdots$ Br hydrogen bond interactions between organic counter cations and inorganic anionic units are present and contribute to the cohesiveness of the crystal packing. Magnetic susceptibility measurements showed a good isolation of Cu(II) with a normal Curie behaviour in all the temperature range with $C = 0.44\,cm^3\,K\,mol^{-1}$ and $\theta \approx -1\,K$. ESR experiments were made at different temperatures and showed an isotropic signal ($g = 2.154$) operating at the X-band, which was resolved towards an axial-type ($g_{\parallel} = 2.31$, $g_{\perp} = 2.10$, $\langle g \rangle = 2.17$) signal at the Q-band. © 1998 Elsevier Science Ltd. Keywords: bromocuprate; crystal structure; magnetic properties.

Mixed-valence inorganic systems have been of great interest to chemists for a long time because they display intriguing physical and chemical properties, provide valuable information on electron-transfer reactions and serve as possible models in a large range of chemical and biochemical catalytic systems [1]. Cu(II)/Cu(I) systems present an additional interest, because both oxidation states are labile, stereochemically flexible and show a wide range of coordination numbers and geometries. From these reasons, the chemistry of these mixed-valence compounds has been received considerable attention in the last few years and a number of Cu(II)/Cu(I) compounds have been synthesised and their structures determined by X-ray diffraction methods [2–9].

We report here the synthesis, X-ray crystal structure, ESR spectroscopic and magnetic characterisation of a novel Cu(II)/Cu(I) compound $(4\text{-apyH})_4[Cu_3Br_8]$ showing isolated $[Cu^{II}Br_4]^{2-}$ anions and polymeric $[CuBr_2]_n^{n-}$ chains. Crystal structures containing infinite chains of $Cu^{I}X_4$ tetrahedra sharing edges and with $[CuX_2]^-$ stoichiometry have been observed very rarely. An exhaustive search in 1997 update of Version 5.14 of the Cambridge Structural Database (CSD) [10] gave several crystal structures [11–13] with $[Cu^{I}I_2]_n^{n-}$ but no analogous chloro- or bromo-chains were found. The compounds [Cu(cnge)] $[CuBr_2]$ [14] (cnge = 1-cyanoguanidine) and $[Cu_2(\mu\text{-formate})_2(\eta\text{-2-aminoallyl})_2][Cu_2Br_4]$ [15] contain $[Cu^{I}Br_2]_n^{n-}$ chains but in both one of the bridging bromine atoms is coordinated to the cationic copper(I) complex which leads to structural features significantly different than those reported for the title compound. Three compounds containing mixed-valence [Cu^{I}

$Cu^{II}Br_4]_n^{n-}$ chains [7] and one compound with a neutral $[Cu^{II}Br_2]$ chain [16] are known.

RESULTS AND DISCUSSION

Deep violet single-crystals of a compound having the stoichiometry $(4\text{-apyH})_4[Cu_3Br_8]$ have been obtained as unique product during the slow diffusion of *n*-hexane in an ethanolic solution of the compound $(4\text{-apyH})_2[CuBr_4]\cdot H_2O$ [17]. The observed stoichiometry seems to indicate a complicated Cu(II)/Cu(I) system in which two third of the copper ions have to be present in the univalent state and the other third in the bivalent state, but does not indicate whether or not the valences are localised. However, the non-existence of significant couplings in the magnetic behaviour of the compound, as stated below, suggests the absence of direct interactions between the Cu(II) centres.

The formation of Cu(II)/Cu(I) species have been also observed in the reaction of the $CuBr_2$/HBr mixture with tris(1-pyrazolyethyl)amine [18], 6-amino-1,3-dimethyl-5[(2-carboxyphenyl)azo]uracil [6] or 3-aminopyridines [19]. It has been surmised that the Cu(I) ion may be generated by a reaction involving the decomposition of $CuBr_2$ to CuBr and Br_2. Indeed, *para*-bromination of the aromatic ring respect to the amino substituting is produced in the reaction of $CuBr_2$/HBr mixture with 2-amino-*n*-methylpyridine ($n = 3, 6$) [20, 21] and 2-aminopyridine [22], although no copper(I) is present in the final product probably due to the synthesis process takes place in an air open atmosphere which produces the reoxidation of copper(I) to copper(II). Cu(II)/Cu(I) species with brominated pyridine-ring systems have not reported in the literature and, hence, it is no possible to tied the existence of Cu(I) ion to the bromination process. In our work, *para*-bromination is not possible because the *para* position respect to the *exo*-amino group is occupied by the *endo* nitrogen atom. To the rest of our knowledge, the compound $(TEA)[Cu_2Cl_4]$ (TEA = tetraethylammonium) [4] and the compound dealt with here are the only examples so far reported of structurally characterised Cu(II)/Cu(I) species, which were synthesised from a Cu(II) complex precursor. $(TEA)[Cu_2Cl_4]$, containing a Cu(II)/Cu(I) alternative linear-chain, was prepared as a by-product of crystal growth of single crystal of $(TEA)_4[Cu_4Cl_{12}]$ by a simplified temperature gradient technique [23].

In order to determine unambiguously the actual structure and the nature of bonding interactions of the $(4\text{-apyH})_4[Cu_3Br_8]$ compound, a single-crystal X-ray diffraction analysis was undertaken. The results showed that the compound crystallises in the tetragonal system with a crystal structure composed of 4-aminopyridinium cations, discrete $CuBr_4$ tetrahedra and one-dimensional polymeric end-less chains of $CuBr_4$ tetrahedra, running along the *c*-axis of the tetragonal unit cell, in which the metal bromide tetrahedra are joined by two symmetrically equivalent bridging bromine atoms (Fig. 1). Table 1 lists selected bond lengths and angles together with the hydrogen contacts in the crystal structure.

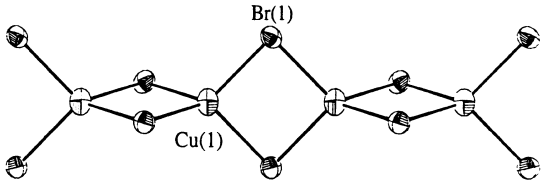

Fig. 1. Thermal ellipsoid plot (50% probability level) of the $[Cu^{I}Br]_n^{n-}$ polymeric anion in $(4\text{-apyH})_4[Cu_3Br_8]$ with the labelling scheme.

The copper atom of the edge-sharing polymeric chain, Cu(1), is located at a site of C_2 symmetry with two Cu–Br distances of 2.507(2) and 2.512(2) Å and Br–Cu–Br angles of 93.32(8), 93.55(8) and 118.04(4)°. These distances and angles are comparable with those determined for bromocomplexes containing tetrahedrically coordinated copper(I) in no-monomeric species [24–26] and are similar than those found for the Cu(I) centres in the mixed-valence $[Cu^{II}Cu^{I}Br_4]_\infty$ chains [7]. Isolated $[Cu^{I}X_4]^{3-}$ anions have not been structurally characterised in the solid state. Table 2 shows the structural parameters for monodimensional chains consisting of edge-sharing $CuBr_4$ tetrahedra. It is interesting to note that, in spite of the lower electrostatic repulsion, the intrachain Cu···Cu distance (3.44 Å) is longer that those observed in chains of edge-shared $CuBr_4$ tetrahedra with alternating and localised Cu(I) and Cu(II) sites (3.30 Å) [7] and significantly longer than that found in the neutral $[Cu^{II}_2Br_4]_\infty$ chain (3.22 Å) [16]. This fact can be explained by the similar Cu–Br–Cu angle in all the chains (84–87°) and the shorter Cu(II)–Br distances. The angle between the two $CuBr_2$ planes bisected by the chain C_2 axis is 90° and Muetterties distortion [27] from the tetrahedron is $\Delta D = 5.4\%$, these values are quite similar to those reported for the $[Cu^{I}Br_4]^{3-}$ centres within the mixed-valence $[Cu^{II}Cu^{I}Br_4]_\infty$ chains and analogous to those reported for the compound $[Cu(cnge)][CuBr_2]$ [14] and $[Cu_2(\mu\text{-formate})_2(\eta\text{-2-aminoallyl})_2][Cu_2Br_4]$ [15]. However in these two last compounds, the coordination of a bridge bromine atom to the copper(I) complex produce the increasing of the Cu–Br bond distances (longest 2.57 Å) and the decreasing of the Br–Cu–Br angles (75–80°) and as a consequence, the strong decreasing of the Cu···Cu distances (3.07–3.13 Å).

The Cu(2) atom in the isolated $CuBr_4$ unit is located on a sit of S_4 symmetry and the chromophore shows a distorted tetrahedral geometry with a Cu–Br distance of 2.371(2) Å and angles of 101.79(5) and 126.26(5)°. The distortion from the tetrahedron ($\Delta D = 15.1\%$) and the observed structural parameters are in good accordance with those usually

[a]dta = diethylammonium, tem = triethylmethylammonium, dem = diethyldimethylammonium, tea = tetraethylammonium, cnge = 1-cyanoguanidine, for = μ-formate, aal = η-2-aminoallyl, 4-apyH = 4-aminopyridinium.

[b]ΔD(%) was calculated according to: $\Delta D(\%) = (1/n)\,\Sigma_j(|\Sigma_i(\delta_i-\delta_{j1})|/|(\delta_{j1}-\delta_{j2})| \times 100$, where δ_i is the experimental dihedral angle and δ_{j1} and δ_{j2} are the theoretical dihedral angles for T_d and D_{4h}, respectively.

[c]φ = Dihedral angle between Br–Cu–Br planes bisected by the chain axis.

[d]There are three inequivalent Cu(I) and Cu(II) ions in the chain. [e]Bromide atom coordinated to the Cu(I) atom of the cationic complex unit.

found for isolated $[Cu^{II}Br_4]^{2-}$ anions [6, 17, 22]. Thus, it is clear structurally that the Cu(I) and Cu(II) ions are localized at sites Cu(1) and Cu(2), respectively, which allows us to formulate the $(4\text{-apyH})_4[Cu_3Br_8]$ compound as $(4\text{-apyH})_4[Cu^{II}Br_4][Cu^{I}Br_2]_2$, a mixed-valence compound containing 4-aminopyridinium cations, isolated $[Cu^{II}Br_4]^{2-}$ anions and an edge-sharing polymeric anionic metal bromide tetrahedra $[Cu^{I}Br_2]_n^{n-}$ chain (Fig. 2).

As far as the 4-aminopyridinium cation is concerned, bond distances and angles are normal [17]. Organic cations are inserted between the anionic units and the observed intermolecular contact distances (see end of Tab. 1) and the geometry supports the assumption of a hydrogen-bond network involving the cations and the anionic entities. One hydrogen atom of the *exo*-amino group is linked to the bromine atoms of the chain, whereas the second hydrogen atom and the *endo*-amino group one are connected to the bromine atoms of two neighbouring $[CuBr_4]^{2-}$ anions which are separated by 11.561 Å (Fig. 3). There are no other important interactions between tetrabromocuprate(II) anions, the nearest non-bonded Cu(II)···Br distance is 6.18 Å and the shortest Br(2)···Br(2) contact in the structure (5.60 Å), established between two neighbouring anions along the *c*-axis, is considerably longer than the sum of the bromine ion van der Waals radii (3.90 Å).

The cohesiveness of the crystal structure is also ensured by a face-to-face non-covalent interaction between π-systems of the pyridinic rings of the two centrosymmetric-related cations which are hydrogen-bonded to two different polymeric chains (see Fig. 2). The dihedral angle between the two adjacent rings, which are staggered in order to avoid steric hindrances, is 0°, the interplanar distance is 3.30 Å, the lateral offset is 1.4 Å and interatomic distances range from 3.3 to 3.5 Å. This structural parameters seems to indicate a significant overlapping degree.

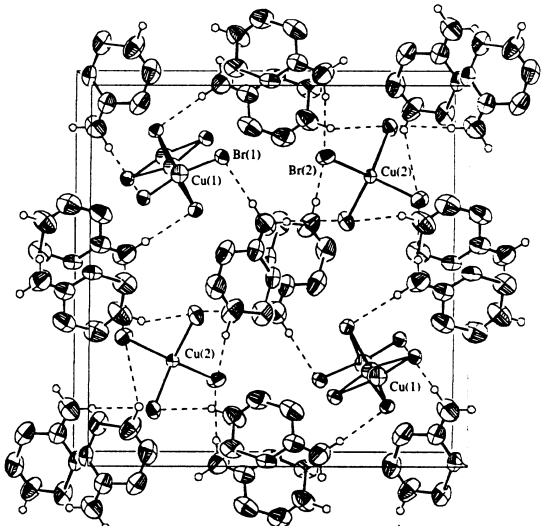

Fig. 2. Crystal packing in the $(4\text{-apyH})_4[Cu_3Br_8]$ compound. Hydrogen atoms attached to carbon were omitted for clarity.

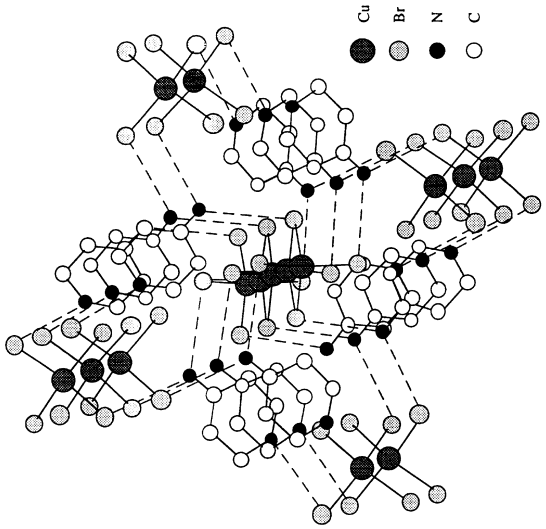

Fig. 3. View of a portion of the crystal structure of $(4\text{-apyH})_4[Cu_3Br_8]$ showing the hydrogen contacts (dashed lines) around a polymeric chain.

In the structure the Cu(II) ions are well separated, with copper–copper distances longer than 6 Å. This fact leads to a good magnetic isolation of Cu(II) as demonstrated by the thermal dependence of the $\chi_m T$ product with a nearly constant value of $\mu_{eff} = 1.88\mu_B$ within the temperature range 4.2–300 K. The susceptibility variation follows a Curie–Weiss law, with $C = 0.44\,cm^3\,K\,mol^{-1}$ and $\theta \approx -1\,K$.

In order to obtain more information about the magnetic environment of the Cu(II) centres, a polycrystalline sample was used to record the X-band ESR spectra of the compound in the range 4.2–300 K. These spectra show a broad and isotropic signal ($g = 2.154$). In attempt to search for the resolution of the spectra, Q-band spectroscopy was used. In these spectra an axial-type signal was obtained with *g*-values of $g_\parallel = 2.31$, $g_\perp = 2.10$ ($\langle g \rangle = 2.17$). Figure 4 shows the X- and Q-band spectra at room-temperature. Spectra remain practically unchanged over the work range of temperature.

EXPERIMENTAL

Reagents and physical measurements

All reagents were purchased from Fluka and Merck and were used without further purification. Microanalyses of carbon, nitrogen and hydrogen were performed on a Perkin-Elmer CHN-2400 analyser. Copper analysis was made on a Perkin-Elmer 360 Atomic Absorption/Flame emission spectrometer. The densities were measured by flotation in $CHBr_3$–CCl_4 mixtures [28]. IR spectra were recorded in the

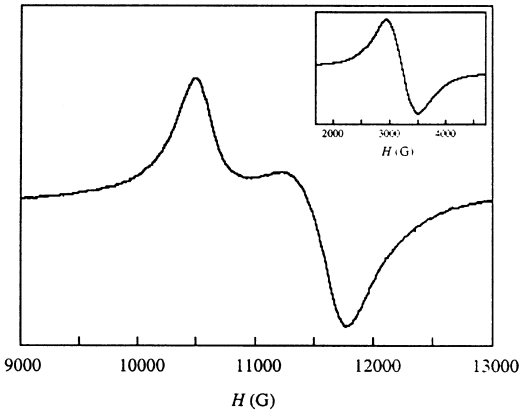

Fig. 4. Q- and X-band (inset) ESR spectra at room temperature.

4000–200 cm^{-1} range on a IR Perkin-Elmer 4200 spectrometer as KBr pellets. A Bruker ESP300 spectrometer, operating at the X- (*ca.* 9.5 GHz) and Q-band (*ca.* 34 GHz) and equipped with a standard Bruker apparatus down to liquid nitrogen and liquid helium temperatures, was used to study the ESR polycrystalline spectra between 4.2 and 300 K. The magnetic susceptibility measurements were carried out on polycrystalline samples in the temperature range 4.2–300 K with a pendulum type susceptometer/magnetometer (Manics DSM8) equipped with a helium continuous flow cryostat. Diamagnetic corrections terms were estimated from Pascal's constants [29] as -565×10^{-6} cm^{-3} mol^{-1}. Experimental magnetic susceptibility data were also corrected for temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1} per Cu^{II}) and magnetisation of the sample holder.

Synthesis of (4-apyH)$_4$[Cu$_3$Br$_8$]

The title compound was obtained as single-crystals during the recrystallization attempts of the monohydrate 4-aminopyridinium salt of the tetrabromocuprate(II) anion. 0.12 g (0.2 mmol) of (4-apyH)$_2$[CuBr$_4$]·H$_2$O [17] was dissolved in 5 ml of ethanol. The resulting solution was transferred to a 15 mm diameter glass tube and then 20 ml of *n*-hexane was dropwise. After 3 days, dark violet prismatic single-crystals of (4-apyH)$_4$[Cu$_3$Br$_8$] were obtained. Crystals were found to be quite stable to light, air exposure and X-ray radiation. All manipulations were carried out in an open-air atmosphere. Thermogravimetric analysis indicated the no presence of water molecules in the compound composition. Yield 0.05 g, 63% based on copper (found: C, 19.88; H, 2.31; N, 9.28; Cu, 15.72. Calc. for C$_{20}$H$_{28}$Br$_8$Cu$_3$N$_8$: C, 19.85; H, 2.33; N, 9.26; Cu, 15.75%); IR data (cm^{-1}): 3480sh, 3390s, 3305s, 3265w, 3205s, 3110m, 2985m, 1645vs, 1605w, 1525vs, 1400w, 1270w, 1195s, 1101w, 995s, 815s, 650w, 580m, 500s, 226w, 218w, 209w and 207w.

The excellent agreement between the proposed stoichiometry and the elemental analysis values seems to preclude the existence of impurities or other compounds. However, the purity and homogeneity of the sample were confirmed by the comparison of the observed X-ray powder diffraction pattern and that generated from the single crystal X-ray data [30].

Crystallographic data collection and structural refinement

C$_{20}$H$_{28}$Br$_8$Cu$_3$N$_8$, $M = 1210.37$ g mol^{-1}, tetragonal, space group P4$_2$/n (No. 86), $a = b = 15.608(3)$, $c = 6.882(2)$ Å, $U = 1676.5(7)$ A^3 (by least-square refinement on diffractometer angles for 25 well-centred reflections, $18 < 2\theta < 32^\circ$), $T = 295(1)$ K, graphite-monochromated Mo–Kα radiation ($\lambda = 0.71069$ Å), $Z = 2$, $D_m = 2.40(1)$ g cm^{-3}, $D_c = 2.40$ g cm^{-3}, $F(000) = 1142$, deep violet, almost opaque, single-crystal with dimensions $0.25\times0.27\times0.30$ mm, μ(Mo–K$_\alpha$) = 114.5 cm^{-1}; Enraf-Nonius CAD4 four-circle diffractometer, ω–2θ scan mode, data collection range $2<2\theta<60^\circ$, h: 0–21, k: $\pm$15, l: 0–9; two standard reflections showed no significant variation in intensity; corrections were made for Lorentz-polarisation and for absorption (empirical correction with minimum and maximum correction coefficients of 0.874 and 1.185) [31]; 2431 reflections were measured, 1105 of which were considered as observed by applying the conditions $I\geq2\sigma(I)$. Crystal structure was solved by direct methods [32] and refined anisotropically by full-matrix least-squares methods on *F* (XRAY 76 System) [33]. Hydrogen atoms were placed at idealised positions and refined as fixed contributors. A conventional weighting scheme was used in the final refinement cycle in order to obtain flat dependence in $\langle w\Delta^2F\rangle$ vs $\langle F_o\rangle$ and vs $\langle\sin\theta/\lambda\rangle$ [34]. After the final refinement cycle, the agreement factors were $R(F_o) = 0.059$ and $wR(F_o) = 0.068$, 90 variables, $S = 1.36$, $(\Delta/\sigma)_{max} = 0.10$, $(\Delta/\sigma)_{av} = 0.01$ and $\Delta\rho_{max} = 0.98$ e Å^{-3} in the cation region. The atomic scattering factors and anomalous dispersion factors were taken from Ref.[35].

Final geometrical calculations were carried out with the PARST [36] and PLATON [37] programs. Graphical manipulations were produced using the ORTEP utility of the XTAL 3.0 system [38]. All calculations were performed on a Digital MicroVAX 4500.

Final atomic positional and thermal parameters, together with the anisotropic thermal parameters for non-hydrogen atoms, a full list of bond distances and angles, dihedral angles and a list of observed and calculated structure factors, have been deposited as supplementary material with the Cambridge Crystallographic Data Centre (CCDC).

(Received 21 October 1997; accepted 8 April 1998)

Abstract—Substitution of H_2 by ligands (L) in either pure *trans*-[Fe(H)(η^2-H_2)(η^2-dppm)$_2$] [BF_4], **1**, or solutions of [Fe(H)$_2$(dppm)$_2$] **2**, L and $HBF_4.Et_2O$ in which **1** is made *in situ*, produce the compounds *trans*-[Fe(H)(L)(η^2-dppm)$_2$] [BF_4] (L=CH_3CN, **3**; succinonitrile, **4**; pyridine, **5**; C_2H_4, **6**; and N_2, **7**). The order of H_2 replacement from **1** appears to be $CH_3CN > N_2 > C_2H_4 \sim$ pyridine. Evidence is presented for the protonation of the hydride ligands of **1** or **2** to produce [Fe(H_2)$_2$(η^2-dppm)$_2$] [BF_4]$_2$, **8**, although **8** could not be fully characterized nor could it be obtained in the solid state. *Trans*-[Fe(CH_3CN)$_2$(η^2-dppm)$_2$] [BF_4]$_2$, **9**, was obtained from solutions of **8** treated with acetonitrile. The coordination geometries of **3**, **9** and **4** (monodentate succinonitrile) have been confirmed by X-ray crystallography (only the gross structural features of **4** were obtained due to a poor data set from a very small crystal). © 1998 Elsevier Science Ltd. Keywords: bis(diphenylphosphino)methane; dihydrogen complexes; dihydrogen displacement reactions; iron complexes; metal hydride complexes; X-ray structures.

There is a body of literature [1–2] on metal-dihydrogen complexes in general and on cations containing Fe^{II}, hydride, dihydrogen and chelating phosphines of the type *trans*-[Fe(H)(H_2)(P-P)$_2$]$^+$ in particular. Most of these complexes have been well characterized and extensively studied by NMR methods and, to a lesser extent, by crystallography. These compounds have also been studied from the point of view of intramolecular exchange of H atoms between H^- and H_2 [1–2], the elimination and ligand substitution of H_2 [1–2], and homolytic and heterolytic splitting of dihydrogen [2]. Relative to some bis-phosphines, dppm has been used less frequently in reactions which produce such complexes although **1** and **2** were briefly reported, but not fully characterized, as being produced from reactions of Fe^{II} with dppm and $NaBH_4$ [3]. In our work on the single-step syntheses of reduced metal-phosphine complexes, we also observed [4] that Fe^{III}- and Fe^{II}-dppm mixtures are not reduced beyond Fe^{II} by $NaBH_4$ in contrast to the behaviour of high-valent Co, Ni, Pd and Pt systems. Even using $LiAlH_4$ as the reducing agent, the main product is the Fe^{II} species **2** from which **1** is derived by protonation. These were both isolated and characterized, **2** by crystallography [4]. This paper describes the substitution reactions of **1**, reactions involving the protonation of **1** and **2** and the molecular structures of three compounds.

EXPERIMENTAL

Reagents and Solvents

Dppm, anhydrous $FeCl_3$, $HBF_4 \cdot Et_2O$, $LiAlH_4$ and $LiAlD_4$ were obtained from Aldrich. The last three reagents were stored under nitrogen. When necessary $FeCl_3$ was dried by heating the hydrated salt under reflux with $SOCl_2$ [5]. Compounds **1**, **2** and **3** were prepared by literature methods [4]. Benzene and THF were both dried before use by distilling from Na wire. All solvents were degassed prior to use by purging with nitrogen.

Physical Measurements

Both samples and reagents were handled under an inert atmosphere during weighing and data collection. Microanalyses for C, H and N were acquired in our laboratories using a Control Equipment Corporation model 240XA analyzer with V_2O_5 used as a combustion aid. Infrared spectra (for Nujol mulls between NaCl plates) were recorded on a Bruker IFS 66 FTIR spectrophotometer. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AC-E 200 spectrometer. Chemical shifts are reported as δ values with positive shifts for ^1H downfield of the signal of Me_4Si (TMS) while those for ^{31}P are downfield of the signal of external 85% H_3PO_4.

Syntheses of the compounds

All the syntheses were performed in a glove box under dry (P_2O_5) nitrogen, argon, ethylene or hydrogen.

Preparation of trans-[*Fe*(*H*)(*CH*$_3$*CN*)(η^2-*dppm*)$_2$] [*BF*$_4$] (**3**)

As an alternative to the published procedure [4] for the preparation of **3**, **2** (0.21 g, 0.26 mmol) was suspended in CH_3CN (10 cm^3) and stirred at -30°C (dry ice and acetone) for 20 min. $HBF_4 \cdot Et_2O$ (200 μl, 1.36 mmol) was added dropwise to the stirred solution to form an orange red solution. Ether (50 cm^3) was added to precipitate the orange yellow solid, which was collected by filtration, dried under reduced pressure, and recrystallized from CH_2Cl_2/hexane. Yield: 86%. The spectroscopic characteristics (^{31}P and ^1H NMR; FTIR) of this product were identical to those previously published [4].

Preparation of trans-[*Fe*(*H*){*NC*(*CH*$_2$)$_2$*CN*}(η^2-*dppm*)$_2$] [*BF*$_4$] (**4**)

(a) A solution of succinonitrile (0.10 g, 1.25 mmol) in THF (4 cm^3) was added to a stirred suspension of **1** (0.13 g, 0.14 mmol) in THF (10 cm^3), and an orange red solution was formed immediately. After 40 min, ether (30 cm^3) was added and the resulting orange solid filtered off, washed twice with ether (10 cm^3 each time) and dried under reduced pressure. Yield: 80%. Recrystallization from CH_2Cl_2/hexane produced thin plates for an X-ray structural determination. Found: C, 65.7; H, 5.2; N, 2.6. Calc. for $FeF_4P_4BN_2C_{54}H_{49}$: C, 65.4; H, 4.9; N, 2.8%. IR: ν(Fe-H) 1881 (w), ν(CN) 2228 (vw), 2239 (w,b) cm^{-1}. $^{31}P\{^1H\}$ NMR (25°C, CD_2Cl_2): δ 30.3 (singlet). ^1H NMR (25°C, CD_2Cl_2): δ -13.1 (Fe-H, quintet, $^2J_{PH} = 47$ Hz); δ 4.34 and 4.81 (PCH^aH^bP, poorly resolved); δ 2.22, 1.93 (Fe-NCC$\underline{H}_2$ C$\underline{H}_2$CN, broad signals, overlapped and poorly resolved). Complex **4** is stable in air. It is soluble and stable in dichloromethane and chloroform.

(b) Alternatively, succinonitrile (0.055 g, 0.69 mmol) dissolved in THF (4 cm^3), was added to a stirred suspension of compound **2** (0.18 g, 0.22 mmol) in THF (10 cm^3). $HBF_4 \cdot Et_2O$ (200 μL, 1.36 mmol) was added dropwise. The clear yellow solution gradually became orange-red. After 20 min, ether (30 cm^3) was added and the resulting orange solid was filtered off, washed twice with ether (10 cm^3 each time) and dried under reduced pressure. Yield: 81%.

Preparation of trans-[*Fe*(*H*)(*pyridine*)(η^2-*dppm*)$_2$] [*BF*$_4$] (**5**)

Pyridine (0.1 mL, 1.24 mmol) was added to a stirred suspension of **2** (0.11 g, 0.12 mmol) in THF (10 cm^3) to produce a clear red solution. Addition of ether (30 cm^3) precipitated a blood-red solid which was washed twice with ether (10 cm^3 each time) and dried under reduced pressure. Yield: 66%. Since the solid smells strongly of pyridine, chemical analyses were unsatisfactory. Found: C, 62.5; H, 5.4; N, 2.0. Calc. for $FeF_4P_4BNC_{55}H_{45}$: C, 67.0; H, 4.6; N, 1.4%. IR: ν(Fe-H) 1853 (w) cm^{-1}. $^{31}P\{^1H\}$ NMR (25°C, deuterated pyridine): δ 22.67 (singlet). ^1H NMR (25°C, deuterated pyridine): δ -17 (Fe-H, quintet, $^2J_{PH} = 46$ Hz). In solution, **5** only has limited stability in pyridine. In acetone or methylene chloride it decomposes quickly and recrystallization attempts were unsuccessful.

Preparation of trans-[*Fe*(*H*)(η^2-*CH*$_2$=*CH*$_2$)(η^2-*dppm*)$_2$] [*BF*$_4$] $\cdot$ 0.5*CH*$_2$*Cl*$_2$(**6**)

(a) Ethylene was passed into a stirred suspension of **1** (0.091 g, 0.10 mmol) in THF (20 cm^3) at a rate of 3 bubbles/s for three h. Addition of ether (20 cm^3) precipitated an orange red product which was filtered off, washed with ether (10 cm^3) and dried under reduced pressure. Yield: 89%. The complex was recrystallized from CH_2Cl_2/hexane under Ar. Found: C, 64.5; H, 5.15. Calc. for $FeC_{52.5}H_{50}P_4BF_4Cl$: C, 64.2; H 5.1%. IR: ν(Fe-H) 1714 (w, sh) cm^{-1}. $^{31}P\{^1H\}$ NMR (25°C, $CDCl_3$): δ 32.8 (singlet). ^1H NMR (25°C, $CDCl_3$): δ -1.78 (Fe-H, quintet, $^2J_{PH} = 50.6$ Hz); δ 5.29

and 4.39 (PCH^aH^bP, poorly resolved); δ 3.18 {Fe-(η^2-$C\underline{H}_2$=$C\underline{H}_2$)}. Complex **6** is very sensitive to moisture. It is stable in dry acetone, chloroform and methylene chloride.

(b) Alternatively, $HBF_4 \cdot Et_2O$ (100 μL, 0.68 mmol) was added dropwise to **2** (0.11 g, 0.137 mmol) in THF (10 cm^3) into which ethylene was passed at a rate of 3 bubbles/s for three h. Addition of ether (20 cm^3) completed the precipitation of an orange-red solid which was filtered off, washed and dried as above. Yield: 72%.

Preparation of trans-[*Fe*(*H*)(N_2)(η^2-*dppm*)$_2$] [BF_4] (**7**)

(a) N_2 was passed at a rate of 3-5 bubbles/s for 5 h into a suspension of **1** (0.12 g, 0.13 mmol) in THF (20 cm^3). Addition of ether (20 cm^3) produced a yellow solid which was filtered off, washed twice with ether (10 cm^3 each time) and dried under reduced pressure. Yield: 77%. Recrystallization was carried out from CH_2Cl_2 under dry N_2. Found: C, 64.0; H, 4.99; N, 2.52. Calc. for $FeF_4P_4BN_2C_{50}H_{45}$: C, 63.9; H, 4.8; N, 3.0%. IR: ν(Fe-H) 1713 (vw) cm^{-1}, ν(NN) 2116 cm^{-1}. $^{31}P\{^1H\}$ NMR (25°C, CD_2Cl_2): δ 24.2 (singlet). ^1H NMR (25°C, CD_2Cl_2): δ -9.38 (Fe-$\underline{H}$, quintet, $^2J_{PH}$ = 43.6 Hz). Complex **7** gradually changes its colour in air. In solution **7** is only stable in dry CH_2Cl_2. It decomposes very quickly in acetone or chloroform.

(b) $HBF_4 \cdot Et_2O$ (100 μL, 0.68 mmol) was added dropwise to a freshly prepared stirred suspension of **2** (0.11 g, 0.13 mmol) in THF (10 cm^3). N_2 was passed into the suspension for 5 h. **7** was isolated as described above for **6** (method b). Yield: >60%.

Preparation of trans-[*Fe*(η^2-H_2)$_2$(η^2-*dppm*)$_2$] [BF_4]$_2$ (**8**)

(a) $HBF_4 \cdot Et_2O$ (15 μL, 0.1 mmol) was added dropwise with shaking to **1** (10 mg, 0.01 mmol) in CD_2Cl_2 (0.6 cm^3) under Ar or N_2 to give a clear yellow solution. $^{31}P\{^1H\}$ NMR (25°C, CD_2Cl_2): δ 3.32 (singlet). Addition of Et_2O produced only pure solid **1**, the identity of which was confirmed by ^1H and ^{31}P NMR and by IR spectroscopic examination. A similar experiment in THF under H_2 produced a solution with the same NMR spectrum (δ 3.32). Addition of Et_2O saturated with H_2 also produced only pure **1**.

(b) $HBF_4 \cdot Et_2O$ (150 μL, 1 mmol) was added dropwise to a stirred suspension of **2** (0.11 g, 0.13 mmol) in THF (10 cm^3) to give a clear yellow solution. $^{31}P\{^1H\}$ NMR (25°C): δ 3.32 (singlet). Addition of Et_2O produced **1** as above.

In spite of repeated attempts under a variety of conditions, no ^1H NMR signals upfield of TMS were observed for any solutions thought to contain **8**.

Preparation of trans-[*Fe*(CH_3CN)$_2$(η^2-*dppm*)$_2$] [BF_4]$_2 \cdot 2CH_2Cl_2$ (**9**)

To a stirred suspension of **2** (0.19 g, 0.22 mmol) in CH_3CN (6 cm^3), $HBF_4 \cdot Et_2O$ (150 μL, 1 mmol) was added to produce a clear deep-red solution. Ether (70 cm^3) was added immediately and the resulting peach-colored solid (0.21 g) was filtered off, washed with ether (10 cm^3) and dried under reduced pressure. $^{31}P\{^1H\}$ NMR (25°C, CD_2Cl_2): δ 29.8 (singlet); δ 14 (singlet); δ 12.3 (triplet) and δ 1.08 (triplet) (see discussion). The mixture of products (0.21 g) was redissolved in CH_3CN (8 cm^3) and stirred overnight. Ether (70 cm^3) was then added to precipitate out a pink solid (0.14 g) which was collected and dried as described above. CH_2Cl_2 (or CH_3CN) (4 cm^3) was added to dissolve the solid and hexane (or ether) (16 cm^3) was carefully layered over the filtrate. The final crystalline product **9**, suitable for the X-ray structure determination, was deposited within 24 h. The crystals were filtered off, washed with ether (10 cm^3) and dried under reduced pressure. Yield: 31%. Found: C, 54.1; H, 4,6; N 2.4. Calc. for $C_{56}H_{54}P_4N_2Cl_4B_2F_8Fe$: C, 53.8; H, 4.4; N, 2.2%. IR: ν(CN) 2249, 2269, 2289, 2317 cm^{-1}. $^{31}P\{^1H\}$ NMR (25°C, CD_2Cl_2): δ 14.2 (singlet). ^1H NMR (25°C, CD_2Cl_2): δ 2.37 [Fe-(NCC$\underline{H}_3$)$_2$]. Complex **9** is stable in air and is soluble and stable in methylene chloride, chloroform and acetonitrile.

The reactivity of **1** *toward propene, cis-2-butene and styrene*

When propene or *cis*-2-butene was used instead of ethylene as outlined above for the synthesis of **6** by procedure (a), or when styrene (1.62 cm^3, 14 mmol) was stirred with **1** (0.13 g, 0.14 mmol) in THF (10 cm^3), under Ar for 3 h, no evidence that **1** had reacted was detected from NMR measurements.

X-Ray Crystallography

Crystallographic data collection for **3** and **9** was carried out on an Enraf-Nonius CAD-4 diffractometer using $\mathbf{Mo}_{K\alpha}$ graphite-monochromatized radiation. Crystal structure refinement calculations were carried out on a PC Express computer with the SHELX program system [6]. NRCVAX computer programs were used for scaling and data reduction [7].

For **3**, an absorption correction was applied. The attenuation coefficient used was 1.0 and the average absorption correction factor was 0.8147. The Fe atom was located by direct methods and all remaining atoms were found by cycles of Fourier and difference Fourier calculations. Calculated ideal positions of the H atoms on the phenyl and methylene C atoms of dppm and on the methyl C of acetonitrile were included but not refined. The hydride ligand was located in the Fourier map and refined along with other atoms. The BF_4^- is disordered, with three rotationally related locations of its four fluorine atoms. All atoms, except H and F, were refined with anisotropic thermal displacement parameters. The four F atoms of each position were refined with equal

B-F distances and equal isotropic thermal displacement parameters.

Crystal data for **9**: monoclinic, $C2/c$, $a=22.5018(5)$, $b=12.3622(2)$, $c=21.6802(5)$ Å, $\beta=106.047(1)^\circ$, $Z=4$. The Fe is on a 2-fold axis so that the asymmetric unit contains the Fe, one dppm, one disordered BF_4 over two independent positions in a 0.79:0.21 ratio, and one CH_2Cl_2 which shows significant thermal motion and therefore contributes to the high residuals. R indices, as defined in ref [4] (all data): $R_1=0.1201$, $wR_2=0.2187$). Relevant bond lengths and angles are: Fe-P(1)=2.2715(14), Fe-P(2)=2.2841(13), Fe-N=1.909(4), N-C=1.1337(7), C-C in CH_3CN=1.466(8) Å; P(1)-Fe-P(2)=73.0° and the internal P-C-P angle in dppm=94.6°. These structural parameters are very similar to those reported [8] for *trans*-$[Fe(CH_3CN)_2(dppm)_2]$ $[FeI_4].2H_2O$ and the published bond lengths for the latter will be used for comparison purposes in this paper.

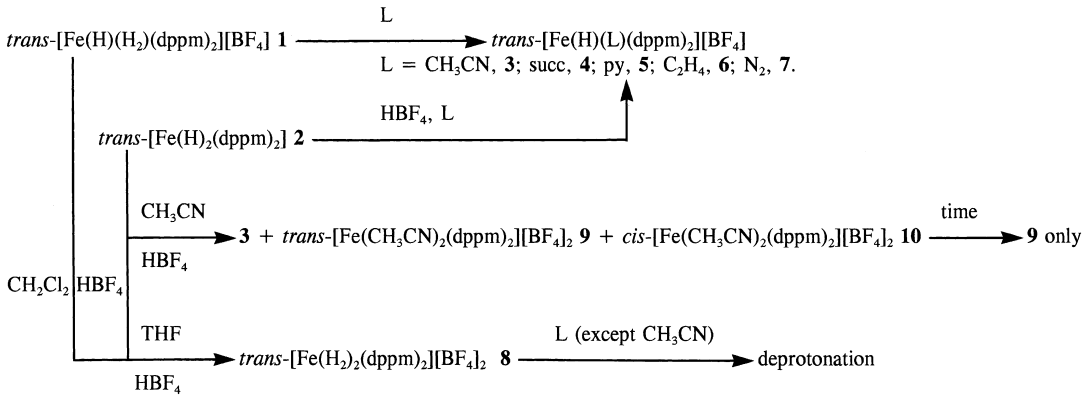
Crystals of **4** were exceptionally thin and consequently a poor data set allowed only confirmation of the overall structural features of **4**, namely that the succinonitrile is indeed *trans* to the H^- and is coordinated to the Fe through one of the nitrile groups [9].

Supplementary X-ray materials for **3**, including atomic coordinates and thermal parameters, have been deposited with the Cambridge Crystallographic Data Center.

RESULTS AND DISCUSSION

The synthesis of derivatives of **1** can be carried out either by the direct replacement of the dihydrogen ligand in pure **1** by several small ligands or from **1** prepared *in situ* by protonating **2** in the presence of the ligands. Care must be taken to ensure anhydrous conditions for reproducibility of the reactions. The ligands selected (CH_3CN, succinonitrile, pyridine, C_2H_4, CO [4] and N_2) have widely varying σ donor-π acceptor properties and can bind to the Fe center in an end on or side on fashion. The fact that ethylene, but not propene, *cis*-2-butene or styrene, can replace the H_2 indicates that the site is sterically constrained. Pyridine replaces the H_2 and although the resulting complex is quite unstable, the complex shows a strong singlet in the ^{31}P NMR spectrum and the expected hydride quintet in the ^1H NMR spectrum. Both pyridine and ethylene are, in turn, displaced from their respective complexes by N_2. Acetonitrile is ideally suited to the site and rapidly replaces, not only H_2, but pyridine, ethylene and N_2. The rates at which the dihydrogen is displaced varies greatly with the acetonitrile and pyridine reactions being virtually instantaneous while those involving ethylene or N_2 take several hours. A combination of infrared spectrophotometry, NMR specroscopy and X-ray crystallography confirms that, in most cases, the final product takes the form *trans*-$[Fe(H)(L)(\eta^2\text{-dppm})_2]$ $[BF_4]$ as summarized in Scheme 1.

In certain cases (Scheme 1), additional reactions occur. For example, the outcome of protonation of **2** by $HBF_4\cdot Et_2O$ (molar ratio 1:5) in acetonitrile is a function of reaction time and temperature. At -30°C, the only product is **3** while at room temperature the main product is **9**, with two *trans* acetonitrile ligands. However, ^{31}P NMR spectra reveal that, initially, three products are present since signals due to **3**, **9** and a third component which shows two triplets centered at δ 12.3 and 1.08 are observed. This third component is believed to be *cis*-$[Fe(CH_3CN)_2(dppm)_2]$ $[BF_4]_2$, **10**. The signals due to this component rapidly disappear from the spectrum as conversion of all components of the mixture into **9** occurs. The largest amounts of the *cis* isomer, **10**, obtainable in these experiments were observed (^{31}P spectrum) to be formed in fresh solutions of **2** and $HBF_4\cdot Et_2O$ (in a 1:5 molar ratio) in CH_3CN. Under these conditions, the two isomers are formed in approximately equal amounts although the relative proportion of the *trans* isomer **9** still grows rapidly with time. The Fe-dppm ring opening and rearrangement apparently required in the formation of the *cis* isomer from **2** or **3** may be facilitated by the reversible interaction of the excess of H^+ present with a P atom of dppm as has been observed [10] in studies



Scheme 1.

of the related reactions of [FeHX(diphosphine)$_2$] (X = Cl, Br) under acid conditions. The fact that **9** is produced from **1** or **2** in the presence of excesses of H^+ and CH_3CN implies that hydride-protonation followed by H_2 displacement is a stepwise process and that after **3** is formed, further protonation of its hydride ligand occurs, as has been observed for the process *trans*-[Os(H)(CH_3CN)(dppe)$_2$]$^+$ → *trans*-[Os(H_2)(CH_3CN)(dppe)$_2$]$^{2+}$ [11]. In the Fe case it seems that there is a second H_2 for CH_3CN exchange. This prompted an investigation of the protonation of **2** with no H_2-displacing ligand present. It was found that protonation of **2** in THF or CH_2Cl_2, or protonation of **1** in CH_2Cl_2 or CD_2Cl_2, under N_2 or argon, or in THF under H_2, produced solutions which exhibited a single ^{31}P NMR signal at δ 3.3. (Fe:HBF_4 molar ratios ranged from 1:1 to greater than 1:10). This signal is believed to be due to the bis(dihydrogen) complex **8** although repeated attempts to detect the dihydrogen signal in the ^{1}H NMR spectrum were unsuccessful due to interference from strong $HBF_4 \cdot Et_2O$ signals. This complex appears to be relatively stable towards H_2-displacing ligands in THF or CH_2Cl_2 in the presence of an excess of acid. For example, with a 10 fold molar excess of HBF_4 present, these solutions react only very slowly with acetonitrile to produce **9**, although again the *cis* isomer is present in the initial stages of the reaction. These observations support the suggestion that in the direct synthesis of **9** from **2**, the most likely intermediate is **3** rather than **8**.

In similar reactions involving protonation of a mixture of *cis*- and *trans*-[Ru(H)$_2$(dppm)$_2$] in CH_3CN using a large excess of HBF_4, only the *cis* isomer of [Ru(CH_3CN)$_2$(dppm)$_2$] [BF_4]$_2$, characterized crystallographically, was obtained [12].

All attempts to isolate solid **8** from solutions exhibiting the δ 3.3 signal in the ^{31}P spectrum resulted in spontaneous deprotonation, even under an atmosphere of H_2, and formation of **1**. This observation, in itself, is good evidence that complex **8** is certainly a symmetrical dihydrogen complex and probably a bis(dihydrogen) complex even though no dihydrogen signals are observable in the ^{1}H NMR spectra under a variety of conditions. The implication is that these signals are displaced from their usual positions and are masked by other solvent signals.

Other than a few species existing in solutions at very low temperatures [13] or in a matrix [14], few complexes containing two dihydrogen ligands are known. Among these are certain complexes of Ru [15, 16], Ir [17] and Re [16], some of which are prepared by protonating polyhydrides [16]. They are labile, the Ir complex, for example, being stable only at -80°C unless kept under an atmosphere of H_2.

Addition of ligands (other than acetonitrile) to solutions exhibiting the δ 3.3 signal in the ^{31}P spectrum resulted in deprotonation to give the corresponding monosubstituted [FeH(L)(dppm)$_2$]$^+$ system and no other bis-substituted complexes analogous to **9** could be obtained. Neither could such complexes be obtained by further protonation of monohydridic complexes such as **5**, **6** and **7** in the presence of an excess of the H_2-displacing ligand. It is possible in these cases that, after H_2 in **1** is displaced by another ligand, a combination of the strong *trans* influence of the H^- and the Lewis basic properties of the ligand leads to proton attack at another site in the molecule.

Considering now X-ray structural data for the complexes reported herein, and related complexes in the literature, *trans*-[Fe(CH_3CN)$_2$(dppm)$_2$] [FeI_4] $\cdot$ $2H_2O$, which contains the same cation as in **9**, has been prepared from FeI_2(dppm)$_2$ and CH_3CN and structurally characterized by crystallography [8]. In addition, recent work [18] has established that related complexes of the type *trans*-[$FeL_2(PP)_2$] [X]$_2$ (L = various nitriles including CH_3CN, PP = $R_2P(CH_2)_2PR_2$ with R = CH_3 or C_2H_5, and X = BF_4 or PF_6) can be synthesized either *via* protonation of $FeH_2(PP)_2$ followed by exchange of the resulting H_2 ligand or from reactions of $FeCl_2(PP)_2$ with nitriles. The structures of several of these analogues of **9** were determined [18] by X-ray crystallography. The structural parameters established by us for **9** itself are very similar to those reported [8] for *trans*-[Fe(CH_3CN)$_2$(dppm)$_2$] [FeI_4] $\cdot$ $2H_2O$ and the published bond lengths for the latter will be used for comparison purposes in this paper.

Structural information has also been acquired for **3** and **4** although due to a very small crystal, only the main structural features of **4** were confirmed (succinonitrile bound through one CN group *trans* to the H^- - see experimental section). For **3**, the crystal, data collection and refinement data are recorded in Table 1 while appropriate bond lengths and angles are summarized in Table 2. An ORTEP drawing showing the Fe coordination geometry is shown in Fig. 1. The BF_4 anion is disordered over three positions (0.40:0.34:0.26 ratio) related by rotation. As in the structures of the other complexes containing chelating dppm, distortions from octahedral geometry are due in large part to the strained 4-membered FePCP rings, with P-Fe-P angles of 73-74° and P-C-P angles of about 18° smaller than that required for a tetrahedral C atom. These, in turn, determine the non-linearity of the *trans* P-Fe-P angles [170.54(6) and 173.12(6)°]. The Fe-H distance of 1.35(6) Å is shorter than the sum of the covalent radii of Fe and H and considerably shorter than Fe-H distances of 1.5-1.6 Å, determined both by X-ray and neutron diffraction methods, found in comparable complexes [4, 19, 20, 21]. This discrepancy is probably due to the difficulties in accurately locating H atoms using X-rays, and also reflects the uncertainty in the N-Fe-H angle of 172(3)° in **3**.

In the acetonitrile ligand, the N≡C and the C-C distances are within the range found for analogous compounds containing coordinated acetonitrile [8, 18]. The most significant observation with respect to the coordinated CH_3CN concerns the Fe-N bond which is longer in **3** [1.927(4) Å] than in

[Fe($CH_3CN)_2$($dppm)_2$] [FeI_4] · $2H_2O$ [1.867(12) Å] due to the strong *trans* influence of the H^- in **3**.

The Fe-P bond lengths decrease significantly, from 2.316(3)-2.290(2) Å in *trans*-[FeCl(CO)($dppm)_2$] [BF_4] to 2.285(4)-2.281(4) Å in [Fe($CH_3CN)_2$($dppm)_2$] [FeI_4] · $2H_2O$ to 2.214(2)-2.203(1) Å in **3** to 2.172(2)-2.153(2) Å in **2**. Since the σ-bonding capabilities of the *trans* ligands increase in this order, it is possible that the corresponding strengthening of the Fe-P bond is associated with a greater involvement of Fe-P π back-

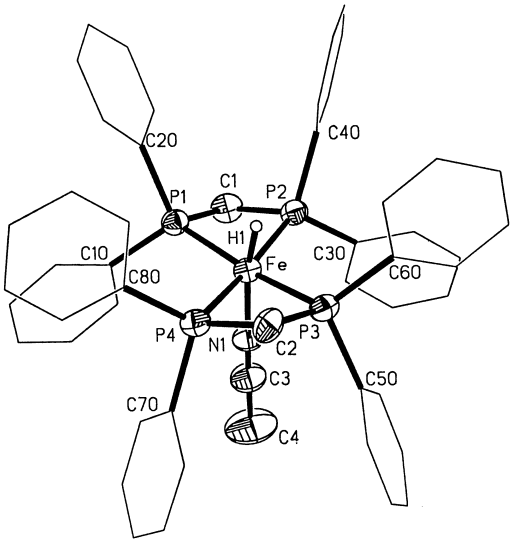

Fig. 1. ORTEP drawing of **3**.

bonding as electron density is redistributed from the Fe. It is also possible that the size of the groups in the axial positions influence the Fe-P bond lengths, with the smallest axial groups resulting in the shortest Fe-P bonds. Since several factors affect the chemical shifts of the P atoms, it is difficult to correlate δ values of 10.3, 14 (in **9**), 30 and 24, respectively, with structural parameters (see also below).

Selected spectroscopic data are summarized in Table 3 for the compounds containing the *trans* L-Fe-H arrangement reported herein together with data for the related structures *trans*-[Fe(H)(Cl)(dppm)$_2$] and *trans*-[Fe(H)(CO)(dppm)$_2$] [BF_4] [4]. There has been considerable discussion in the literature regarding the extent to which metal ions undergo π-back bonding to a dihydrogen ligand. It was hoped that the above series of compounds would allow changes in these spectral parameters to be related to changes in the Fe-ligand bonding pattern. In each case, the singlet in the ^{31}P nmr spectrum, and the upfield quintet in the ^{1}H spectrum are consistent with the *trans* H-Fe-L arrangement. υFe-H varies widely as would be expected from the large differences in the measured Fe-H bond lengths [1.35(6) Å for **3** and 1.56(8), 1.58(8) Å for **2**]. It is apparent that the IR and ^{1}H NMR data fall into two categories. First, when the Fe is coordinated to any of the four predominantly weak σ donor ligands (each with a relatively weak *trans* influence), the *trans* hydride is also strongly bound (highest υFe-H, 1853-1889 cm^{-1}) and highly shielded. In the second group, which contains the strong σ donor H^- and the good π acceptors CO and C_2H_4 (all of which have a strong *trans* influence relative to the corresponding ligands in the first group), υFe-H values indicate a weaker Fe-H bond. The hydride ligands *trans* to the good π acceptors are also the most deshielded. It appears that N_2 behaves in a similar way to C_2H_4 and CO in that there is a significant σ-π interaction as evidenced by the weakening of the N_2 bond (υN_2 reduced from 2331 in N_2 to 2116 cm^{-1} in **7**). The surprising strength of the N_2-Fe interaction is illustrated by the fact that, as mentioned earlier, N_2 displaces pyridine from **5** (rapidly) and C_2H_4 (slowly) from **6**. The Fe-H bond in **1** appears comparable in strength to others in this second group of complexes, also suggesting a σ-π interaction in these complexes consistent with the lengthening of the H-H bond from 0.8 Å in H_2 to, for example, 0.92 Å in **1** as calculated [4] from J_{HD} values. Previous work [4] interpreted the position of υFe-H in **2** as being due to the *trans* influence. It should also be noted that the H_2 ligand in **1** has little effect upon the electronic environment of the *trans* H^- compared to those in **2** and this explains why this remaining H is as susceptible to protonation as are those on the dihydride.

As noted above, there is no discernible relationship between the *trans* ligands in the various complexes and the phosphorus chemical shifts which are generally typical of P in 4-membered rings.

(Received 7 January 1998; accepted 8 April 1998)

Abstract—The novel [η^5:η^1-(2-diphenylphosphinoethyl)cyclopentadienyl]trichlorozirconium (IV) **3** has been prepared *via* (2-diphenylphosphinoethyl)(trimethylsilyl)cyclopentadiene **2**. The structures of an adduct of **3** with tetrahydrofuran (THF) **3b** (two crystal modifications) and of an ionic complex derived from **3** and $ZrCl_4$ $\{[\eta^5{:}\eta^1-(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu-Cl)_3\}^+{}_2[(ZrCl_4)_2(\mu-Cl)_2]^{2-}$ **4** have been determined by an X-ray analysis. The X-ray and NMR data prove the existence of a Zr–P intramolecular coordination in **3** both in solid state and in non-solvating media within a broad range of temperatures. In THF solution the flexible equilibrium between adducts of **3** with one (**3b**) and two (**3c**) molecules of THF has been observed by variable-temperature NMR spectroscopy. The synthetic route to the simplest unsymmetrically ligated zirconocene (η^5-$C_5H_4CH_2CH_2PPh_2$)(η^5-C_5H_5)$ZrCl_2$ **5** derived from **3** has also been elaborated. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: zirconium; substituted cyclopentadienes; crystal structure; NMR spectroscopy.

Transition metal complexes with ω-heteroatomsubstituted alkylcyclopentadienyl type ligands are now under intensive investigation [1]. However, only few examples of diorganophosphino-group side chain functionalized cyclopentadienyl derivatives of the Group 4 metals are known [2–6], with the only representative of monocyclopentadienyl complexes, $[\eta^5-C_5H_3-1,3-(SiMe_2CH_2PPr^i{}_2)_2]ZrCl_3$ and its alkylation products, reported [5, 6]. Meanwhile, compounds of the general type $L_nM(C_5H_4CH_2CH_2PR_2)$ with M=Ga and In [7], Fe [8], Co [4], and Rh and Ir [9] have been described. In connection with this we considered it attractive to prepare and study the structure of [η^5:η^1-(2-diphenylphosphinoethyl)cyclopentadienyl]trichlorozirconium (IV) **3**. Complex **3** was initially supposed to exhibit dynamic behaviour in solutions. To estimate the coordination ability of the diphenylphosphino group towards a Zr(IV) centre we carried out the variable-temperature NMR studies of compound **3** in CD_2Cl_2 and THF-d_8. Since the monocyclopentadienyltrihalozirconiums (IV) are precursors of unsymmetrically ligated dicyclopentadienyl complexes of Zr (IV), we were also interested in elaborating a convenient synthetic route to the simplest

zirconocene of this type derived from **3**, (η^5-$C_5H_4CH_2CH_2PPh_2$)(η^5-C_5H_5)$ZrCl_2$ **5**.

RESULTS AND DISCUSSION

Synthesis of (2-diphenylphosphinoethyl)cyclopentadienyl complexes of zirconium (IV)

The Si–C bond cleavage reaction in silylated cyclopentadienes still remains among the most convenient approaches to monocyclopentadienyltrihalozirconiums (IV) derived from non-hindered cyclopentadienes [10]. Since lithium (2-diphenylphosphinoethyl)cyclopentadienide **1** is readily available [4], preparation of (2-diphenylphosphinoethyl)trimethylsilylcyclopentadiene **2** meets no problems (see Scheme 1).

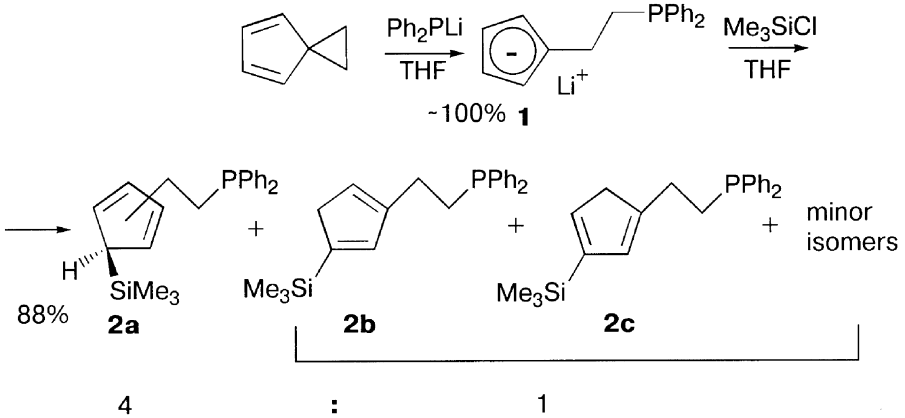
Mixing of equimolar amounts of **2** and $ZrCl_4$ in toluene leads to a complete dissolution of the metal tetrahalide (supposedly caused by initial coordination of $ZrCl_4$ with the PPh_2-groups of **2**), followed by a rapid formation of a thick white precipitate. This precipitate presents crude [η^5:η^1-(2-diphenylphosphinoethyl)cyclopentadienyl]trichlorozirconium (IV) **3**. The crude product **3** can be purified both as an unsolvated form **3a** in a very low yield (fractional recrystallizations from dichloromethane) or, better, as an adduct with one molecule of tetrahydrofuran (THF) **3b** (recrystallization from THF) (see Scheme 2). Contrary to the reported for $C_5H_5ZrCl_3$ [11], adduct **3b** is thermally stable in a THF solution even at 90°C (sealed evacuated NMR-tube, 6 hours).

We suppose that the considerable amount of impurities in crude **3** and the difficulties of its purification in the unsolvated form **3a** are caused by two main factors. First of all, compound **2** presents an equilibrium mixture of isomers with allylic (**2a**) or vinylic (**2b**,**c**...) position of the Me_3Si-group. At room temperature, the ^1H NMR spectroscopically estimated molar ratio of **2a** to **2b**,**c**... is approximately 4:1 (see Scheme 1). There are certain reasons to suppose that only isomer **2a** is cleaved with $ZrCl_4$ and produces the desired complex **3**. Meanwhile, the other isomers **2b,c**.. are able to react in this manner only after their slow conversion into **2a** and may be involved into Lewis acid induced diene polymerisation. Thus, even determining of the initially required molar excess of **2** over $ZrCl_4$ presents a problem and polymeric by-products should be always expected.

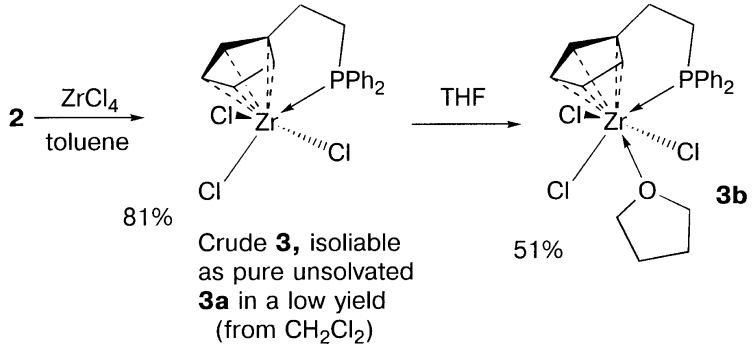
Secondly, if no THF is added, the unreacted $ZrCl_4$ is hardly removable from the reaction mixture. Capturing of $ZrCl_4$ was directly confirmed by the fact, that the combined saturated mother liquors from the fractional recrystallizations of crude **3** gave after standing for 2 months at room temperature a small amount of crystalline solid $\{[\eta^5{:}\eta^1-(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu-Cl)_3\}_2^+[ZrCl_4)_2(\mu-Cl)_2]^{2-}$ **4**. The structure of compound **4** was established by X-ray diffraction analysis (see discussion below).

To prepare the unsymmetrically ligated zirconocene (η^5-$C_5H_4CH_2CH_2PPh_2$)(η^5-C_5H_5)$ZrCl_2$ **5** derived from **3**, we first applied the conventional cyclopentadienylation procedures. However, a reaction between **3b** and sodium cyclopentadienide either in toluene or in THF leads to inseparable mixtures of all the possible cyclopentadienyl ligand exchange products **5**–**7**. In toluene, moreover, zirconocenes **5**–**7** are formed in a statistical ratio (2:1:1, respectively) as white crystalline solids (from ether) (see Scheme 3). In contrast, the application of trimethylcyclopentadienyltin as a gentle cyclopentadienylating agent gives excellent results and pure zirconocene **5** is isolated in a good yield.

It is a well known fact that C_5H_5Na is capable of introducing more than two cyclopentadienyl ligands to Zr (IV) centre [12]. We believe that the observed ligand randomisation is caused by the traces of triscyclopentadienylzirconium (IV) species which are generated when initial **3b** and product **5** compete for $C_5H_5^-$ in the reaction mixture. When the reaction is



Scheme 1.



Scheme 2.

performed in toluene, the initially low solubility of C_5H_5Na increases, due to liberation of THF from **3b**. As far as **3b** is only moderately soluble in toluene, considerable excess of free cyclopentadienide appears in the solution, and, thus, cyclopentadienyl ligand exchange is complete in this case. In contrast to $C_5H_5^-$, $Me_3SnC_5H_5$ does not attack **5** at all, so triscyclopentadienylzirconium (IV) species are not generated and no products of cyclopentadienyl ligand exchange are formed.

X-RAY CRYSTAL STRUCTURE DETERMINATION OF $[\eta^5{:}\eta^1$-$(C_5H_4CH_2CH_2PPh_2)]ZrCl_3 \cdot$ THF 3b AND $\{[\eta^5{:}\eta^1-(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu-Cl)_3\}_2^+[(ZrCl_4)_2(\mu-Cl)_2]^{2-}$ 4

The structures of two different crystalline modifications of **3b** and ionic complex **4** were determined by X-ray analysis.

First modification of **3b** (*crystallised from* CH_2Cl_2)

The unit cell contains two independent molecules with similar geometrical parameters. These molecules seem to be related by the superposition of the rotation around the *b*-axis and 1/4-translation along the same direction. Thus, the correctness of the unit cell dimensions (doubling of axis), possibility of twinning and the space group determination have been specially checked.

The arrangement of molecules in the unit cell is such that the Zr–P directions are approximately parallel to the *b*-axis (7.8 and 5.3°). The orthogonal least-squares fitting of one independent molecule to the other, based on the positions of all non-hydrogen atoms (except carbons of THF) resulted in an r.m.s. deviation 0.07 Å. The greatest differences were observed for the conformations of the coordinated THF molecules, as far as one of them exhibits disorder of the envelope carbon atom C(83). Selected bond lengths and angles are listed in Table 1. The molecular structure of **3b** (first modification) is shown in Fig. 1.

Second modification of **3b** (crystallised from THF)

The unit cell contains only one independent molecule. The coordination environment of the central Zr atom is quite close to that found for the first crystalline modification of **3b**. However, the conformation of phosphino-substituent is completely different from the previous one (different rotations around Ph–P bond). For the first modification of **3b**, all four torsion angles between the planes of phenyl rings and exocyclic P–C bonds lie within a range 43.0–46.0°. As for the second modification, the same angles are equal to 5.7 and 90.1°. Selected bond lengths and angles are listed in Table 1. The molecular structure of **3b** (the second modification) is shown in Fig. 2.

For both modifications of **3b**, the Zr atoms possess a distorted octahedral coordination assuming that Cp-ligands occupy one site. The cyclopentadienyl rings and THF molecules lie in the apical positions while the phosphino-groups occupy equatorial ones. The mean deviation of the Zr atom from the equatorial plane towards Cp-ligand is 0.49 Å. This polyhedron is preferred for monocyclopentadienyl complexes of Zr(IV) [1, 6, 13–18], except for the cases when the latter is prohibited by the steric requirements of the substituted Cp-ligands [10c, 19]. Analysis of the Cambridge Structural Database (Release: October 1996) [20] shows that the Zr–Cl distances (2.4621(11)–2.5138(10) Å) in **3b** are of normal values for terminal Zr(IV)–Cl bonds in monocyclopentadienyl complexes (2.357–2.542 Å). The Zr–O(THF) bonds (2.350(3)–2.3613(12) Å) are noticeably shorter than it was found for the same apical bonds in $(CpR)ZrCl_3 \cdot 2THF$ (R=H, 2.393(3) Å, R=Me, 2.377(2) Å) [13].

Crystal structure of complex **4**

The crystal structure of **4** is shown in Fig. 3. Selected bond lengths and angles are listed in Tables 2 and 3,

* PL(1) and PL(2) mean least-squares planes of the cyclopentadienyl rings.

respectively. The asymmetric unit consists of positively charged dimeric particle $\{[\eta^5{:}\eta^1\text{-}(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu\text{-}Cl)_3\}^+$ and a half of the centrosymmetric $[(ZrCl_4)_2(\mu\text{-}Cl)_2]^{2-}$ dianion. In addition, the crystal lattice contains disordered CH_2Cl_2 molecule. The central $\{[\eta^5{:}\eta^1\text{-}(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu\text{-}Cl)_3\}^+$ unit represents the second example of monocyclopentadienyl zirconium complex containing three bridging chlorine atoms [21]. However, the same $Zr_2(\mu\text{-}Cl)_3$ motif was reported for several neutral complexes of zirconium tetrachloride [22].

Both zirconium atoms have a distorted octahedral coordination. The apical bridging bonds Zr(l)–C1(5) and Zr(2)–C1(3) are significantly longer (2.7365(14) and 2.733(2) Å) than four equatorial non-terminal Zr–Cl bonds (2.5489(14)–2.6254(14) Å). Previously we have observed the same effect for similar complexes $(\eta^5{:}\eta^1\text{-}C_5Me_4CH_2CH_2EMe)ZrCl_3$, (E=S, O) [14]. Of

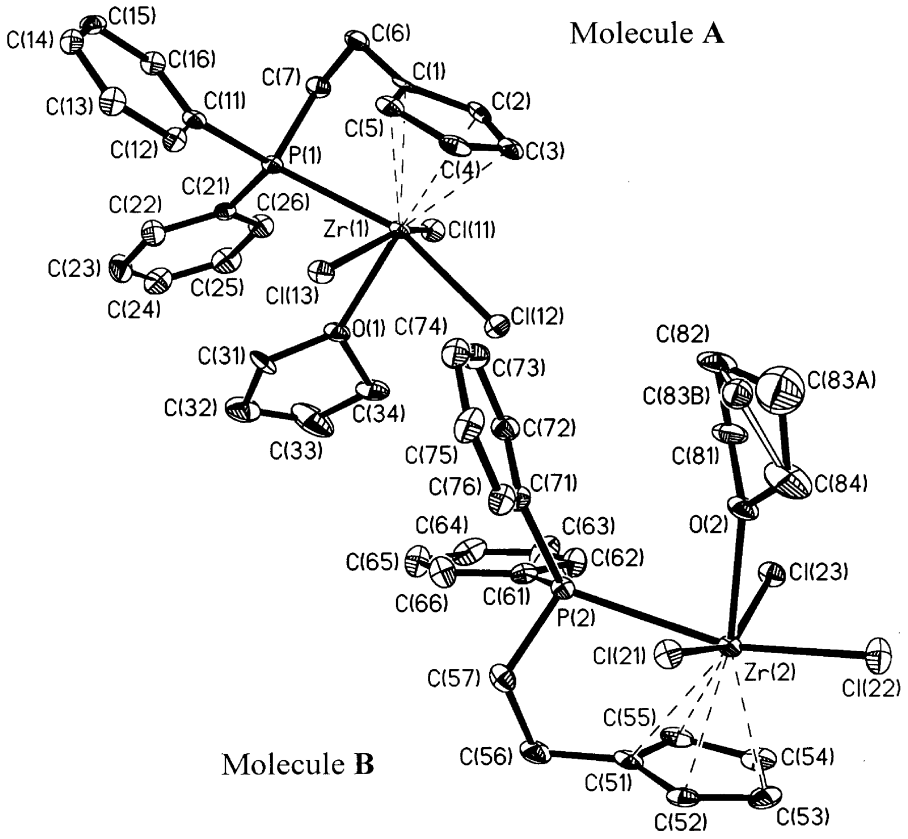

Fig. 1. Molecular structure of **3b** (first modification). Displacement ellipsoids are shown at 50% probability level. Hydrogen atoms are omitted for clarity.

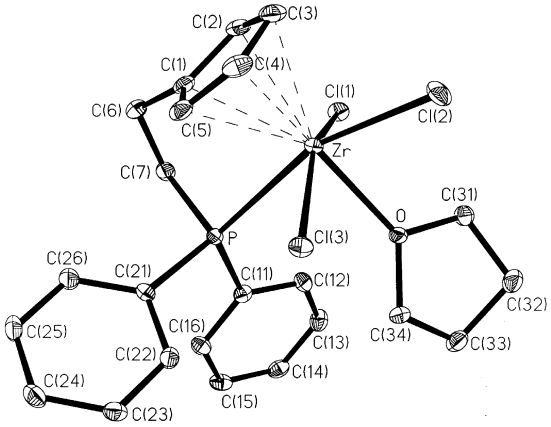

Fig. 2. Molecular structure of **3b** (second modification). Displacement ellipsoids are shown at 50% probability level. Hydrogen atoms are omitted for clarity.

interest, the longer Zr-(μ-Cl) distance (2.794(7) Å) was found in the structure of closely related anionic complex $\{[\eta^5\text{-}(C_5H_4CH_2CH{=}CH_2)ZrCl_2]_2(\mu\text{-}Cl)_3\}^-$ $[Li(DME)]^+$ [21].

The Zr–P distances (2.802(2), 2.817(2) Å) are noticeably shorter than those found in the structure of neutral complex $[\eta^5-C_5H_3-1,3-(SiMe_2CH_2PPr^i_2)_2]ZrCl_3$ (2.897(1), 2.871(1) Å) [6]. The latter can be explained by the influence of the positive charge of the $\{[\eta^5{:}\eta^1\text{-}(C_5H_4CH_2CH_2PPh_2)ZrCl]_2(\mu\text{-}Cl)_3\}^+$ unit.

NMR study of the dynamic behaviour of complex **3** *in solutions*

To determine the coordination ability of the pendant phosphine group in **3a** and **3b** in solvating and non-solvating solvents we performed the variable-temperature NMR spectroscopy investigation of the samples of **3a** in CD_2Cl_2 and **3b** both in THF-d_8 and in CD_2Cl_2. The signals in the ^1H and $^{13}C\text{-}\{^1H\}$ NMR spectra of complexes **3** and **5** (see **Experimental**) were assigned on the basis of the homonuclear Overhauser effect, coupled ^{13}C spectra and selective heteronuclear decoupling experiments.

The value of ^{31}P chemical shift is a good criterion for the presence or absence of the Zr–P coordination bond. Values close to those of free alkyldiphenylphosphines (δ *ca*-15 ppm) are characteristic of a non-coordinated PPh_2-group, while the Zr–P coordination results in the low field shifting of the signal up to δ *ca* 5–8 ppm. The similar differences

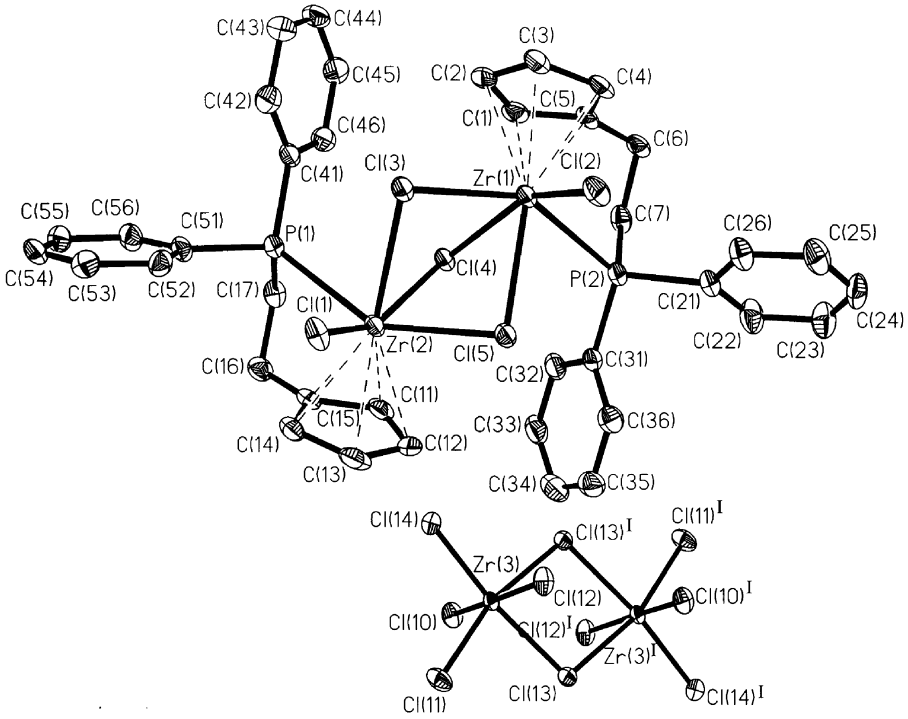

Fig. 3. Molecular structure of **4**. Displacement ellipsoids are shown at 50% probability level. Hydrogen atoms and solvent CH_2Cl_2 molecule are omitted for clarity. Superscript symbol "I" indicates symmetry equivalent atoms.

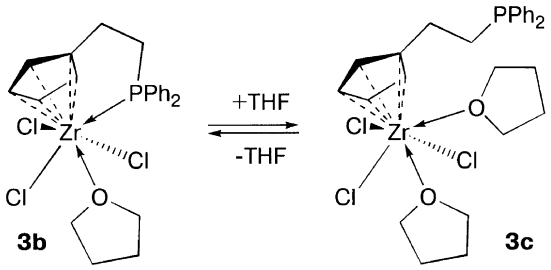
in $\delta(^{31}P)$ shifts of coordinated and non-coordinated phosphino groups ($\Delta\delta$ *ca* 20 ppm) in half-sandwich complexes $[\eta^5-C_5H_3-1,3-(SiMe_2CH_2PPr^i_2)_2]ZrR_3$ (R_3=Cl_3, $Cl_2(CH_2Ph)$ and Me_3) were reported previously [6].

Both non-solvated **3a** and solvated **3b** forms of **3** in CD_2Cl_2 possess coordinated diphenylphosphino groups ($\delta(^{31}P)$ from 6 to 8 ppm, compare with $\delta(^{31}P)-14.3$ ppm for **5**, (see Table 4)). The temperature decrease down to $-70°C$ does not affect considerably the NMR spectra of both **3a** and **3b**, that points to the retention of Zr–P coordination bond over the whole temperature range studied.

Distinct deshielding of both the H^7 and C^7 signals in ^1H and ^{13}C-$\{^1H\}$ NMR spectra of **3** in respect to **5** provides an additional proof that the Zr–P coordination does take place in the half sandwich complex **3**.

All these data on the behaviour of **3** in the non-solvating CD_2Cl_2 media are in a good agreement with those on the structure of the monocyclopentadienyl complex $[\eta^5-C_5H_3-1,3-(SiMe_2CH_2PPr^i_2)_2]ZrCl_3$ in toluene solution, in which the zirconium center is hexacoordinated over a wide temperature range [6].

In a THF solution, the situation is markedly different. In this case compound **3** presents an equilibrium mixture of two forms **3b** and **3c** (see Scheme 4). The variable-temperature ^1H and ^{31}P-$^1\{H\}$ NMR spectra of compound **3** in THF-d_8 are depicted in Figs 4 and 5*. For comparison, the ^1H NMR spectrum of adduct **3b** in CD_2Cl_2 at $-70°C$ is given in Fig. 6. In this equilibrium, the participation of monoadduct **3b**



Scheme 4.

is rather evident due to the close similarity of its NMR parameters to that observed in CD_2Cl_2 (see Table 4). The second component **3c** of the equilibrium mixture exhibits no Zr–P coordination ($\delta(^{31}P)\sim -15$ ppm). As far as the adducts of $(\eta^5$-$C_5H_4R)ZrCl_3\cdot 2THF$, (R=H, Me) are well known [15], a structure of an adduct with two molecules of THF may be assigned to complex **3c** with a high degree of probability. The observed two-site exchange becomes fast on the NMR time scale at the temperatures exceeding 0°C. The content of **3c** increases from ~30% at $-30°C$ up to ~50% at $-70°C$, that may correspond to the greater negative ΔH values (and more strong bonding, respectively) of Zr-OR_2 than Zr-PR_3 coordination bond formation for cyclopentadienyltrichlorozirconiums (IV). So, the NMR spectroscopically observed exchange between **3b** and **3c** appears to be an example of a reversible solvent promoted intramolecular dissociation-coordination of a pendant side chain functionality.

We must admit here that no process of this type was observed in the cases of -OMe and -SMe side chain functionalized complexes $(\eta^5{:}\eta^1$-$C_5Me_4CH_2CH_2EMe)ZrCl_3$, (E=S, O) [14] and $(\eta^5{:}\eta^1$-

* The assignment of the signals in ^1H NMR spectra depicted in **Fig. 4** to **3b** and **3c** was performed on the basis of the homonuclear decoupling experiments and the temperature dependent changes in their relative intensities.

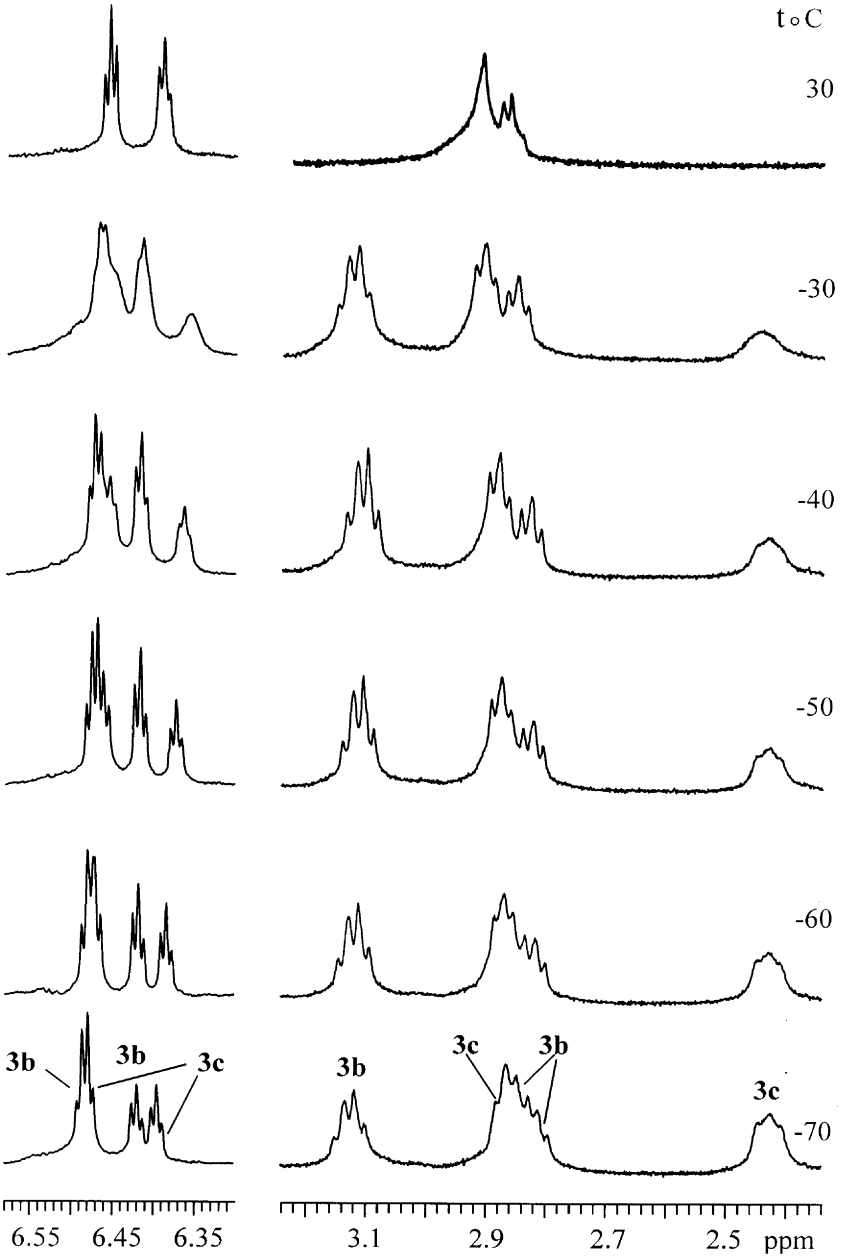


Fig. 4. Variable-temperature ^{1}H NMR spectra of **3b** and **3c** in THF-d_8. C_5H_4 and CH_2CH_2 regions are shown.

$C_5H_4CH_2CH_2OMe)ZrCl_3$ [23] in THF. Thus, the coordination ability of PPh_2-group towards Zr(IV) centre seems to be less than that of methoxy- and methylthio-groups.

EXPERIMENTAL

Initial materials and general techniques

All operations were performed in evacuated sealed glass vessels. The solvents employed (and their perdeuterated analogues) were dried with conventional agents (namely: diethyl ether and THF—with sodium benzophenone ketyl, toluene, heptane and pentane—with Na-K alloy, CH_2Cl_2 - with P_2O_5 and then with CaH_2), degassed by multiple evacuations of the frozen solvent (liq. N_2) and distilled in high vacuum directly into the reaction vessel by trapping into liq. N_2. Spiro[2,4]heptadiene-4,6 [24], trimethylcyclopentadienyltin [25] and lithium (2-diphenylphosphinoethyl)cyclopentadienide [4] **1** were prepared as described previously; lithium diphenylphosphide was prepared as a 0.6 M solution in THF by metallation of diphenylphosphine with *n*-butyl-

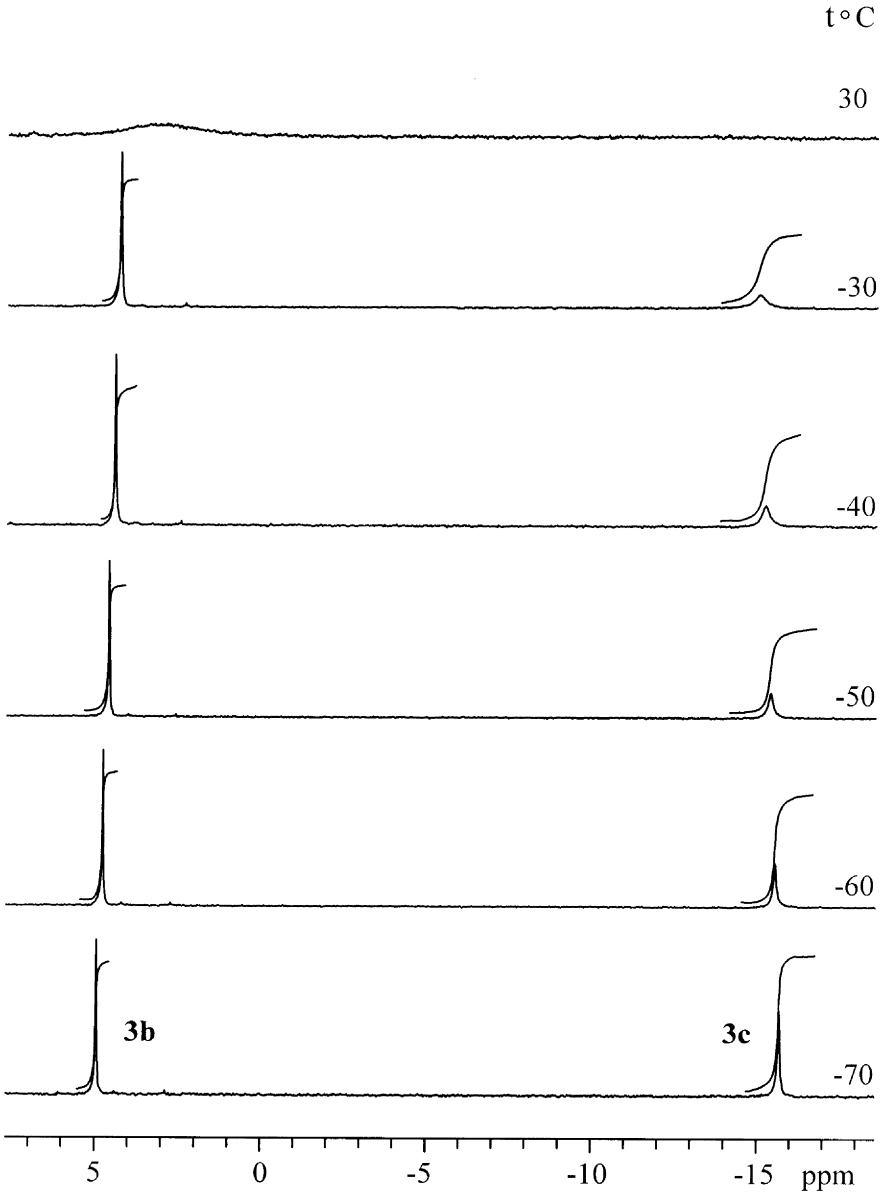

Fig. 5. Variable-temperature ^{31}P-{^{1}H} NMR spectra of **3b** and **3c** in THF-d_8.

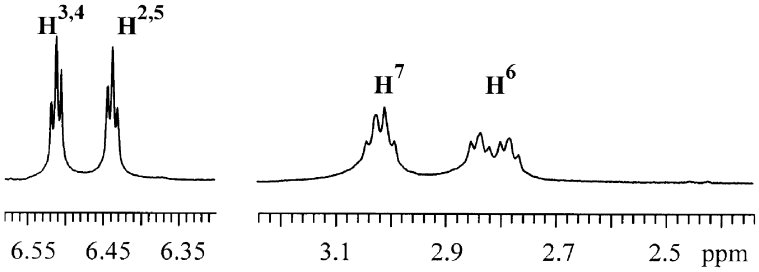

Fig. 6. ^{1}H NMR spectrum of **3b** in CD_2Cl_2 at $-70°C$. C_5H_4 and CH_2CH_2 regions are shown.

lithium in pentane, washing the precipitate with the same solvent and taking it up with THF. Trimethylchlorosilane was refluxed with and distilled from $AlCl_3$ onto aluminium powder, degassed and operated as it was described for the solvents. Commercially available $ZrCl_4$, diphenylphosphine and Me_3SnCl were received from Merck and Aldrich. ^1H, ^{13}C-$\{^1H\}$, and ^{31}P-$\{^1H\}$ NMR spectra were recorded on a Varian VXR-400 spectrometer at 400, 100, and 162 MHz, respectively. For ^1H and ^{13}C-$\{^1H\}$ spectra, solvent resonances [7.15 and 128.0 ppm (C_6D_6), 5.32 and 53.8 ppm (CD_2Cl_2), 1.73 and 25.3 ppm (THF-d_8)] were used as internal reference standards. For ^{31}P-$\{^1H\}$ spectra, 85% H_3PO_4 was employed as an external reference. The temperature of the spectrometer probe was calibrated by measuring the shift difference of the methanol resonance in the ^1H spectrum. The elemental analysis was performed on the Carlo-Erba automated analyzer.

Synthetic procedures

(2 - *Diphenylphosphinoethyl*)(*trimethylsilyl*)*cyclopentadiene* **2** (*a mixture of isomers*)

24.6 ml of 0.60 M solution of lithium (2-diphenylphosphinoethyl)cyclopentadienide **1** in THF (14.7 mmol) was slowly added to a cooled (−20°C) vigorously stirred solution of 1.87 ml (1.60 g, 14.7 mmol) of trimethylchlorosilane in 10 ml of THF. The reaction mixture was allowed to warm up to room temperature and left to stay overnight. On removal of the solvent by trapping it into liq. N_2, the residue was extracted with pentane, the extract evaporated and the crude product purified by distillation, that gave 4.57 g (13.04 mmol, 88.5%) of silane **2**. B.p. 154°C ($3 \cdot 10^{-2}$ torr). Anal. found: C, 75.97; H, 7.82; anal. calc. for $C_{22}H_{27}PSi$: C, 75.39; H, 7.76. NMR (listed for **2a**) (C_6D_6, 303 K) ^1H: −0.10 (*s*, 9H, $SiMe_3$), 2.34 (*m*, 2H, CH_2CH_2P), 2.64 (*q*, $^3J_{HH}=8.0$ Hz, $^3J_{HP}=8.0$ Hz, 2H, CH_2CH_2P), 3.15 (*br. s*, 1H, CH($SiMe_3$)), 6.07 (*br. s*, 1H, =CH–), 6.40 (*br. s*, 1H, =CH–), 6.48 (*br. s*, 1H, =CH–), 7.07 (*m*, 6H, *m*- and *p*-H in PPh_2), 7.46 (*m*, 4H, *o*-H in PPh_2). ^{13}C-$\{^1H\}$: −2.0 ($SiMe_3$), 26.7 (*d*, $^2J_{CP}=17.9$ Hz, CH_2CH_2P), 29.0 (*d*, $^1J_{CP}=13.1$ Hz, CH_2CH_2P), 51.1 (CH($SiMe_3$)), 127.4 (=CH–), 128.6 (*p*-C in PPh_2), 128.7 (*d*, $^3J_{CP}=6.2$ Hz, *m*-C in PPh_2) 132.3 (=CH–), 133.1 (*d*, $^2J_{CP}=18.7$ Hz, *o*-C in PPh_2), 134.2 (=CH–), 139.7 (*d*, $^1J_{CP}=15.3$ Hz, *ipso*-C in PPh_2), 145.9 (*d*, $^3J_{CP}=12.6$ Hz, $=CCH_2CH_2P$); ^{31}P-$\{^1H\}$: −14.2.

[η^5:η^1-(2-*Diphenylphosphinoethyl*)*cyclopentadienyl*] *trichloro*(*tetrahydrofuran*)*zirconium* (*IV*) **3b**

A solution of 6.29 g (17.95 mmol) of silylated cyclopentadiene **2** was added to a stirred suspension of 4.18 g (17.95 mmol) of $ZrCl_4$ in 40 ml of toluene at −20°C. The reaction mixture was allowed to warm up to room temperature, with the solid tetrachloride meanwhile dissolved. In 15 minutes a thick white precipitate formed. The reaction mixture was stirred at 50°C for an additional 2 hours and left to stay overnight. The precipitate was filtered off, washed three times with 50 ml portions of pentane and extracted with CH_2Cl_2. The combined extracts were concentrated, the precipitate filtered off, washed twice with 50 ml portions of pentane and dried in high vacuum, that yielded 6.90 g (14.5 mmol, 81%) of crude complex **3**. Recrystallization from the minimal amount of hot THF, followed by washing with ether and drying in high vacuum yielded 4.55 g (9.59 mmol, 53%) of monoadduct **3b**. Anal. found: C, 50.50; H, 4.79; anal. calc. for $C_{23}H_{26}Cl_3OPZr$ C, 50.53; H, 4.71. NMR (CD_2Cl_2, 30°C) ^1H: 1.59 (*m*, 4H, THF), 2.95 (*dt*, $^3J_{HH}=6.8$ Hz, $^3J_{HP}=21.0$ Hz, 2H, H^6), 3.05 (*q*, $^3J_{HH}=6.8$ Hz, $^2J_{HP}=6.8$ Hz, 2H, H^7), 4.02 (*m*, 4H, THF), 6.48 (virtual *t*, $^{3+4}J_{HH}=5.6$ Hz, 2H, $H^{2,5}$), 6.58 (virtual *t*, $^{3+4}J_{HH}=5.6$ Hz, 2H, $H^{3,4}$), 7.44 (*m*, 6H, *m*- and *p*-H in PPh_2), 7.67 (*m*, 4H, *o*-H in PPh_2); ^{13}C: 23.8 (*dt*, $^1J_{CH}=134$ Hz, $^2J_{CP}=9.5$ Hz, C^6), 25.4 (*t*, $^1J_{CH}=134$ Hz, THF), 32.8 (*dt*, $^1J_{CH}=136$ Hz, $^1J_{CP}=21.3$ Hz, C^7), 72.3 (*t*, $^1J_{CH}=149$ Hz, THF), 117.7 (*d*, $^1J_{CH}=178$ Hz, $C^{3,4}$), 121.7 (*d*, $^1J_{CH}=176$ Hz, $C^{2,5}$), 129.0 (*dd*, $^1J_{CH}=161$ Hz, $^3J_{CP}=8.8$ Hz, *m*-C in PPh_2), 130.8 (*d*, $^1J_{CH}=162$ Hz, *p*-C in PPh_2), 131.6 (*d*, $^1J_{CP}=25.0$ Hz, *ipso*-C in PPh_2), 133.5 (*d*, $^3J_{CP}=6.0$ Hz, C^1), 133.7 (*dd*, $^1J_{CH}=161$ Hz, $^2J_{CP}=9.4$ Hz, *o*-C in PPh_2); ^{31}P-$\{^1H\}$: 6.1.

A sample of unsolvated complex **3a** for NMR

experiments was prepared by fractional recrystallizations of a portion of crude **3** from CH_2Cl_2.

[η^5-(2-*Diphenylphosphinoethyl*)*cyclopentadienyl*](η^5-*cyclopentadienyl*)*dichlorozirconium* (*IV*) **5**

A solution of 0.31 g (1.21 mmol) of trimethylcyclopentadienyltin in 20 ml of toluene and a suspension of 0.66 g (1.21 mmol) of **3b** in 5 ml of toluene were mixed, stirred at room temperature for 3 hours and then heated at 60°C for 2 hours. The volatile components were removed in high vacuum from hot water bath (60°C) by trapping into liq. N_2. The crude product was washed on a glass filter three times with 20 ml portions of heptane, the residue was dried in high vacuum and recrystallized from ether, that gave 0.35 g (0.69 mmol, 57.5%) of zirconocene **5**. Anal. found: C, 57.41; H, 4.62; anal. calc. for $C_{24}H_{23}Cl_2PZr$ C, 57.13; H, 4.59. NMR (THF-d_8, 30°C) ^{1}H: 2.38 (*m*, 2H, H^7), 2.78 (*q*, $^3J_{HH} = 8.2$ Hz, $^3J_{HP} = 8.2$ Hz, 2H, H^6), 6.27 (virtual *t*, $^{3+4}J_{HH} = 5.2$ Hz, 2H, $H^{2,5}$), 6.38 (virtual *t*, $^{3+4}J_{HH} = 5.2$ Hz, 2H, $H^{3,4}$), 6.45 (*s*, 5H, C_5H_5), 7.29 (*m*, 6H, *m*- and *p*-H in PPh_2), 7.43 (*m*, 4H, *o*-H in PPh_2); ^{13}C: 27.4 (*dt*, $^1J_{CH} = 128$ Hz, $^2J_{CP} = 19.7$ Hz, C^6), 29.3 (*dt*, $^1J_{CH} = 128$ Hz, $^1J_{CP} = 12.3$ Hz, C^7), 113.5 (*d*, $^1J_{CH} = 174$ Hz, $C^{3,4}$), 116.5 (*d*, $^1J_{CH} = 174$ Hz, C_5H_5), 117.7 (*d*, $^1J_{CH} = 174$ Hz, $C^{2,5}$), 129.2 (*dd*, $^1J_{CH} = 160$ Hz, $^3J_{CP} = 6.0$ Hz, *m*-C in PPh_2), 129.3 (*d*, $^1J_{CH} = 160$ Hz, *p*-C in PPh_2), 133.6 (*dd*, $^1J_{CH} = 159$ Hz, $^2J_{CP} = 18.7$ Hz, *o*-C in PPh_2), 135.7 (*d*, $^3J_{CP} = 13.7$, C^1), 139.8 (*d*, $^1J_{CP} = 15.0$ Hz, *ipso*-C in PPh_2); ^{31}P-{^{1}H}: −14.3.

X-ray investigation of complexes **3b** *and* **4**

Single crystals were prepared by crystallisation from CH_2Cl_2 (the first modification of **3b**), THF (the second modification of **3b**), and saturated mother liquors from the fractional recrystallizations of crude **3** (complex **4**), mounted in inert oil on a tip of glass fibre and transferred to the cold nitrogen stream inside the diffractometer. Crystal data, data collection, structure solution and refinement parameters for **3b** and **4** are listed in Table 5.

In the case of first modification, the disordered carbon atom C(83) was refined isotropically, all other non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were found from difference Fourier syntheses and refined isotropically, except those attached to disordered carbon atom. They were placed in calculated positions (d(C–H) = 0.96 Å) and refined using a riding model.

In the second case of **3b** all non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were found from difference Fourier syntheses and refined in an isotropic approximation.

As for compound **4**, all non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were placed in calculated positions (d(C–H) = 0.96 Å) and refined using a riding model.

Supplementary material available — Further details of the crystal structure determinations of **3b** and **4**, i.e tables with all atomic coordinates, thermal parameters, interatomic distances, and structure factors, are available from authors.

(Received 11 March 1998; accepted 22 April 1998)

Abstract—Treatment of europium(III) acetylacetonate [$Eu(acac)_3 \cdot nH_2O$] with metal-free porphyrins 5,10,15,20-tetraphenylporphyrin [H_2(TPP)], 5,10,15,20-tetra(4-pyridyl)porphyrin [H_2(TPyP)], 5,10,15,20-tetrakis(4-methoxyphenyl)porphyrin [H_2(TMPP)], 5,10,15,20-tetrakis(4-chlorophenyl)porphyrin [H_2(TCPP)] or 5,10,15,20-tetrakis(4-*tert*-butylphenyl)porphyrin [H_2(TBPP)] gave the half-sandwich complexes Eu(Por)(acac) (Por = TPP, TPyP, TMPP, TCPP, TBPP), which reacted with phthalonitriles $C_6H_2R_2(CN)_2$ (R = H, C_7H_{15}, OC_5H_{11}) in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to give the respective heteroleptic double-decker complexes Eu[Pc*$(R)_8$](Por) (Pc* = 2,3,9,10,16,17,23,24-octasubstituted phthalocyaninate; R = H, C_7H_{15}, OC_5H_{11}) in moderate yields. All of the mixed sandwich compounds were characterized with spectroscopic methods including UV-vis, near IR, IR and mass spectrometry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: phthalocyanines; porphyrins; europium complexes; double-decker complexes.

Owing to their unique optical, electrical and other physical properties associated with the strong $\pi-\pi$ interactions, sandwich-type phthalocyaninato and porphyrinato complexes have been a subject of much current interest [1]. While numerous homoleptic compounds having the same macrocyclic ligands have been reported [[1](b)], the heteroleptic analogs are still relatively rare [[1](a)] which may be attributed to the synthetic barrier. The preparation of mixed phthalocyaninato and porphyrinato lanthanide complexes usually involves the treatment of dilithium phthalocyaninate [Li_2(Pc)] with Ln(Por)(acac) generated *in situ* from $Ln(acac)_3 \cdot nH_2O$ and H_2(Por) [2–4] or the reaction of Li_2(Pc) with $Ln(acac)_3 \cdot nH_2O$ followed by the treatment of H_2(Por) [4, 5]. These reactions normally give mixtures of the heteroleptic double-deckers Ln(Pc)(Por) and the triple-deckers Ln_2(Pc)$(Por)_2$ and $Ln_2(Pc)_2$(Por). It appears that the yields of these products depend on many factors including the nature of the lanthanide metals and the macrocycles, and the ratio of these reactants [[1](a)]. A slight variation of the reaction conditions may lead to different major product. The separation and purification of these products also require very tedious chromatographic procedure. The development of general, convenient, efficient and reproducible synthetic pathways to these mixed sandwich compounds is thus highly desirable. We have recently disclosed a new pathway to unsymmetrical bis(phthalocyaninato) europium(III) [6] and yttrium(III) [7] complexes which involves the base-catalyzed cyclic tetramerization of substituted phthalonitriles using M(Pc)(acac) (M = Eu, Y) as the templates. This synthetic strategy can be extended to give the mixed phthalocyaninato and porphyrinato double-deckers with less amounts of side products compared with the traditional methods. We describe herein the preparation of a series of europium(III)

complexes Eu[Pc*(R)$_8$](Por) using this methodology together with their spectroscopic properties. To our knowledge, heteroleptic phthalocyaninato and porphyrinato double-deckers with a substituted phthalocyaninato ligand have not been reported previously.

EXPERIMENTAL

Experimental details concerning the treatment of reagents and solvents, preparation of starting materials and physical measurements were described elsewhere [[2](c),[6]].

General procedure for the preparation of Eu[Pc(R)$_8$](Por)*

A mixture of Eu(acac)$_3 \cdot$ nH$_2$O (45 mg, 0.09 mmol) and H$_2$(Por) (0.10 mmol) in anhydrous 1,2,4-trichlorobenzene (TCB) (20 cm^3) was refluxed under nitrogen for 6 h. After removing the solvent *in vacuo*, the residue was mixed with phthalonitrile C$_6$H$_2$R$_2$(CN)$_2$ (0.60 mmol), DBU (40 mg, 0.26 mmol) and amyl alcohol (10 cm^3). The mixture was then refluxed for a further 12 h under nitrogen to give a dark green solution. The volatiles were removed under reduced pressure, then the residue was subjected to chromatography over a silica gel column to separate the protonated complex EuH[Pc*(R)$_8$](Por) from the unreacted metal-free porphyrin H$_2$(Por) and side-products including the phthalocyanine H$_2$[Pc*(R)$_8$] and the homoleptic double-decker Eu[Pc*(R)$_8$]$_2$. The protonated complexes were usually eluted out with a certain amount of unprotonated analogs Eu[Pc*(R)$_8$](Por) except for EuH(Pc)(TPyP) of which a pure sample could be isolated. Upon exposure to air for several hours (except for EuH(Pc)(TPyP), which required several days), the green/greenish-brown solutions of EuH[Pc*(R)$_8$](Por) turned to brown gradually and pure Eu[Pc*(R)$_8$](Por) could be obtained by performing column chromatography again under similar conditions and, for unsubstituted phthalocyaninato complexes **1**–**5**, followed by recrystallization from a CHCl$_3$/hexane mixture (or CHCl$_3$/MeOH for **2**). The details are summarized in Table 1.

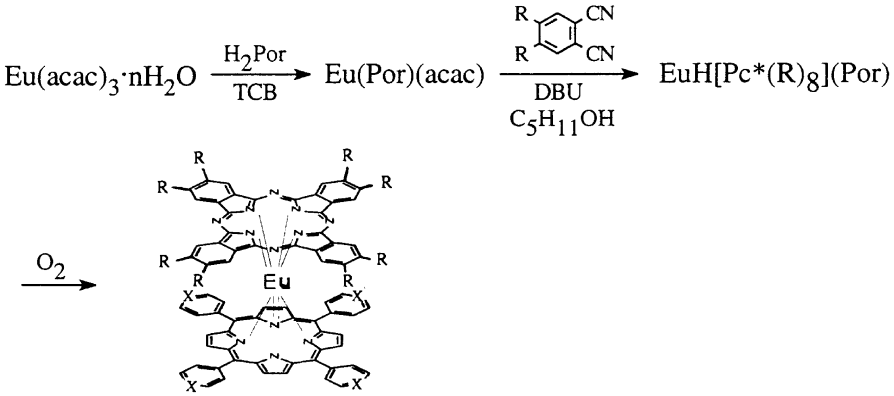
RESULTS AND DISCUSSION

As described previously [2], treatment of Eu(acac)$_3 \cdot$ nH$_2$O with metal-free porphyrins H$_2$(Por) (Por = TPP, TPyP, TMPP, TCPP, TBPP) in refluxing TCB gave the respective half-sandwich compounds Eu(Por)(acac). These complexes prepared *in situ* were then treated with an excess of phthalonitriles C$_6$H$_2$R$_2$(CN)$_2$ (R = H, C$_7$H$_{15}$, OC$_5$H$_{11}$) in the presence of DBU in amyl alcohol to give the protonated double-deckers EuH[Pc*(R)$_8$](Por) as the initial products (Scheme 1). The compound EuH(Pc)(TPyP) was relatively stable to air and could be purified readily by column chromatography [8]. However, by leaving a CHCl$_3$ solution of this compound in air for several days, the green solution turned brown slowly and Eu(Pc)(TPyP) was produced. All other heteroleptic protonated double-deckers were rather air-sensitive. Air-oxidation already occurred during chromatography and the conversion to unprotonated counterparts Eu[Pc*(R)$_8$](Por) was essentially complete within 3 h. This procedure afforded the heteroleptic double-deckers Eu[Pc*(R)$_8$](Por) in moderate yields (Table 1) including those with a substituted phthalocyaninato ligand which, to our knowledge, have not appeared in literature so far. Compounds **1**–**5** were prepared previously by the classical methods described above [2,4]. While compounds **1** [[2](b),[4]] and **2** [[2](a)] were fully characterized, the double-deckers **3**–**5** were only produced in a very small quantity and no detailed spectroscopic data were reported [[2](c)]. For the sandwich compounds **11** and **12**, although their existence was unambiguously confirmed by their mass spectra which showed an intense MH$^+$ cluster (Table 1), their UV-Vis spectra suggested that the samples were impure and attempts to purify them with repeated chromatographic procedure were not successful.

Apart from the desired double-deckers, these reactions also produced small amounts of side products which include the metal-free phthalocyanines H$_2$[Pc*(R)$_8$] and the homoleptic double-deckers Eu[Pc*(R)$_8$]$_2$; both of which were formed by DBU-catalyzed cyclization of phthalonitriles. The former (for R = H) could be removed readily by simple filtration while the other impurities were removed by column chromatography. In contrast to the aforementioned procedures [2–5], the formation of triple-deckers was not detected in these reactions which also simplified the purification process. After the purification by repeated column chromatography, the samples were essentially pure as shown by thin layer chromatography. Satisfactory analytical data, however, could not be obtained as in the case of some other sandwich-type compounds [9].

The mixed double-deckers **3**–**12** were mass-measured using a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. The liquid secondary-ion (LSI) mass spectra of all these compounds showed an intense isotopic cluster assignable to the protonated molecular ion (MH$^+$) and the data are summarized in Table 1. Figs. 1(a) and (b) show the molecular-ion region in the spectra of **5** and **9**, respectively, in which distinct isotopic distribution can be observed. The relative abundance of the isotopic clusters is in good agreement with the corresponding simulated spectra of MH$^+$ as shown in the top-insert.

The UV-Vis and near IR spectra of the sandwich compounds **3**–**10** were also determined and the data are compiled in Table 2. The data for the known compounds **1** [4] and **2** [[2]a] are also included for



1 R = H, X = C-H
2 R = H, X = N
3 R = H, X = C-OMe
4 R = H, X = C-Cl
5 R = H, X = C-^{t}Bu
6 R = C_7H_{15}, X = C-H
7 R = C_7H_{15}, X = N
8 R = C_7H_{15}, X = C-OMe
9 R = C_7H_{15}, X = C-Cl
10 R = C_7H_{15}, X = C-^{t}Bu

comparison. The spectra of **3**–**5** are closely related to those of **1** and **2** and can be assigned in the same manner. By varying the Por ligand, the Pc Soret band (324–326 nm) is virtually unshifted while the Por Soret band (403–412 nm) and the first radical band (467–478 nm) shift slightly by *ca.* 10 nm. In contrast, the remaining two near IR absorptions at 978–1091 nm (another radical band) and 1218–1396 nm (ring-to-ring charge transfer band) are significantly perturbed by such variation. Fig. 2 shows the electronic absorption spectrum of **6**, which is representative for the spectra of complexes **6**–**10** containing a substituted phthalocyaninato ligand. It is worth noting that both the phthalocyanine Soret band and the radical band in the visible region are split for these compounds. The splitting of Soret band of phthalocyanine has also been observed in the spectra of M^{III}[Pc*$(R)_8]_2$ (M = Eu, Gd, Y; R = C_7H_{15}, OC_5H_{11}) [[6],[7],[9](d)]. By introducing eight alkyl chains onto the periphery of Pc, the phthalocyanine Soret band is shifted to the red while the Por Soret band remains essentially unchanged. The lowest-energy near IR band, which can be ascribed to an intramolecular ring-to-ring charge transfer transition [from Por^{2-} to Pc*$(R)_8^{\cdot -}$]

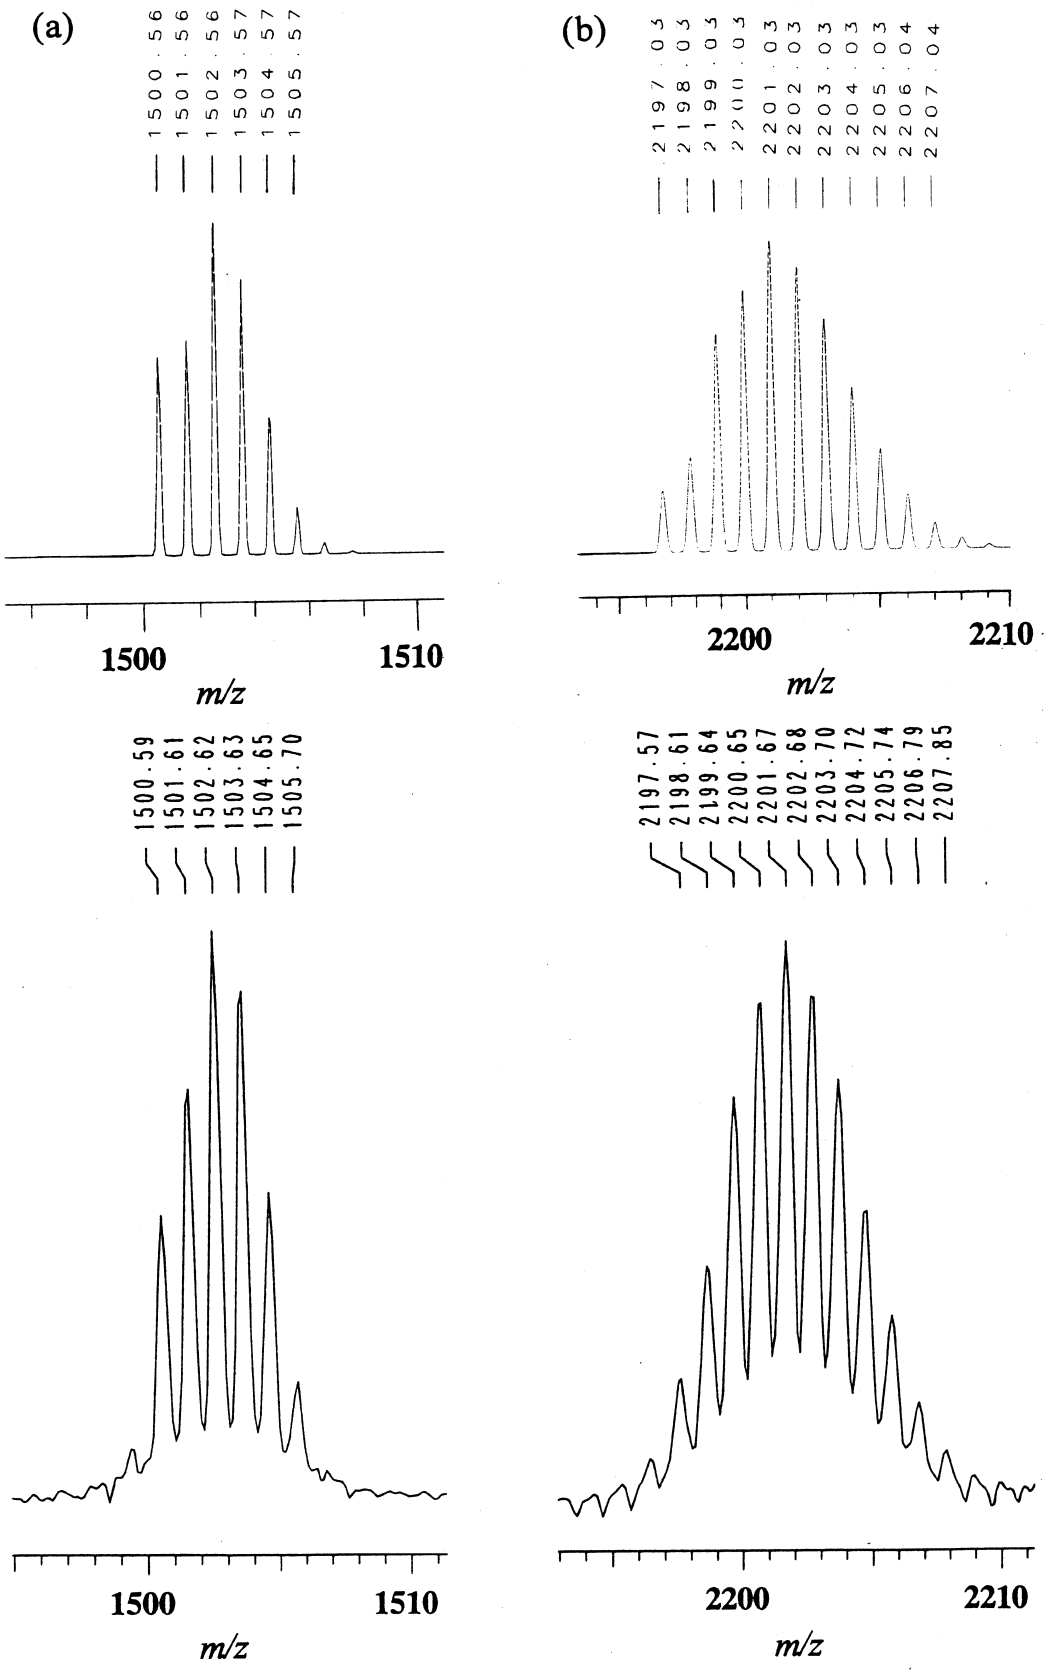

Fig. 1. Observed (bottom) and simulated (top) isotopic distribution for the protonated molecular ions of (a) Eu(Pc)(TBPP) (**5**) and (b) Eu[Pc*$(C_7H_{15})_8$](TCPP) (**9**).

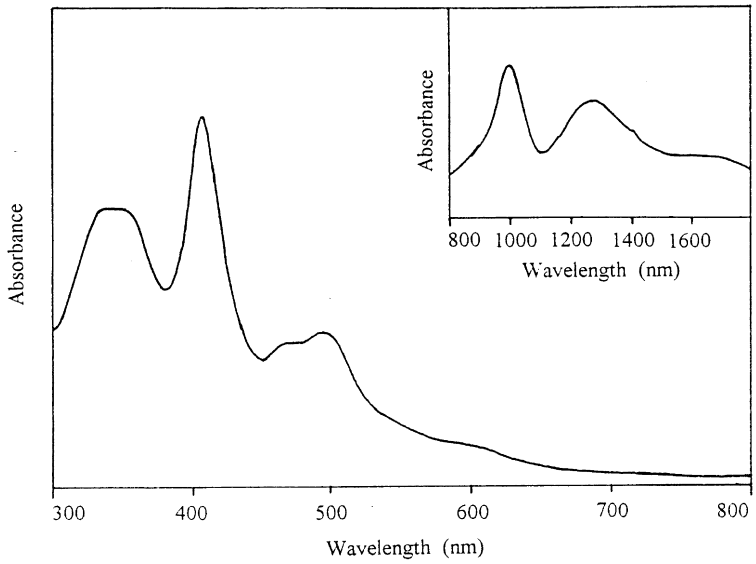

Fig. 2. UV-Vis and near IR (inset) spectra of Eu[Pc*$(C_7H_{15})_8$](TPP) (**6**) in $CHCl_3$.

[[2](a,b),[4],[5],[7]], is significantly blue-shifted. This can be attributed to the electron donating property of C_7H_{15} group which increases the energy of the singly-occupied orbital of Pc*$(C_7H_{15})_8$.

IR spectroscopy has been one of the most versatile techniques used to probe the extent of hole (de)localization in these sandwich-type compounds [[1](a)]. Similar to the double-deckers **1** and **2**, all of the complexes **3**–**10** gave a medium to strong band at 1313–1323 cm^{-1} in their IR spectra which is a diagnostic band for phthalocyanine π radical anion [Pc*$(R)_8^{\cdot -}$] [10]. This band was also observed in the IR spectra of Eu[Pc*$(R)_8]_2$ (R = H, C_7H_{15}) [[9](d)] and Eu(Pc)[Pc*$(C_7H_{15})_8$] [6]. The marker band of TPP π radical anion at 1270–1295 cm^{-1} [11] was not seen for **6**. These results might suggest that the hole in these compounds is preferentially localized on the phthalocyanine ring which is analogous to all known heteroleptic double-deckers M^{III}(Pc)(Por) [[2](a),[4]] and $[M^{IV}(Pc)(TPP)]^+$ [5, 10, 12]. That the introduction of alkyl substituents to Pc did not alter the preference of hole localization can be rationalized by the fact that the macrocycle Pc*$(C_7H_{15})_8$ is significantly easier to oxidize than unsubstituted Pc.

In conclusion, we have developed an effective pathway to heteroleptic phthalocyaninato and porphyrinato double-deckers which involves the cyclic tetramerization of phthalonitriles induced by Eu(Por)(acac). This method affords the desired double-deckers in moderate yields with relatively small amounts of side products. It is envisaged that many other novel double-decker complexes can also be prepared by using this methodology and research work along this direction is under way.

(Received 6 March 1998; accepted 22 April 1998)

Abstract—A pair of seldom seen hydrate isomers with a formula of $LCu_2(CH_3COO)_2(H_2O)_2(ClO_4)_2$, where L is the dinucleating macrocyclic ligand bis-*p*-xytylBISDIEN, have been prepared and characterized by X-ray crystallography, UV/Vis spectra and magnetic measurements. The blue isomer, $[LCu_2(CH_3COO)_2(H_2O)_2](ClO_4)_2$, crystallizes in the triclinic system and the violet isomer, $[LCu_2(CH_3COO)_2](ClO_4)_2 \cdot 2H_2O$, crystallizes in the orthorhombic system. The blue complex consists of one cation $[LCu_2(CH_3COO)_2(H_2O)_2]^{2+}$ and two ClO_4^- anions. The two copper atoms are independent to each other with a separation of 6.781(9) Å. Each has a square pyramidal geometry and is five-coordinated by three N atoms from the macrocycle and two O atoms from the monodentate acetate anion and the coordinated water molecule, respectively. In violet isomer, both central copper atoms are located in an approximately square planar environment and are not coordinated by the water molecules. The isomers have different reflectance spectra due to the different coordination geometry but can rapidly interchange in solution at ambient temperature. Both compounds exhibit quite weak antiferromagnetic couplings verified by the small but negative Weiss constant ($\theta = -5.72$ K for the blue and -25.6 K for the violet isomer). © 1998 Elsevier Science Ltd. Keywords: copper(II) complex; hydrate isomers; hexazamacrocycle; X-ray structure.

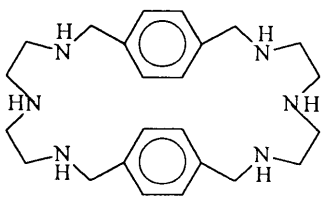
INTRODUCTION

Hydrate isomerism of coordination compounds is a widely known but seldom seen phenomenon. One of the most famous examples is $CrCl_3 \cdot 6H_2O$, which has three hydrate isomers [1]: the green $[Cr(H_2O)_4Cl_2]Cl \cdot 2H_2O$, the blue $[Cr(H_2O)_5Cl]Cl_2 \cdot H_2O$ and the violet $[Cr(H_2O)_6]Cl_3$. No such hydrate isomers as that the metal atoms are accommodated in a macrocycle have been reported. One of the most interesting macrocycles is the macrocyclic polyamine dinucleating ligands, which are discovered to be capable of simultaneously binding two metal ions in close proximity and are further capable of bridging bifunctional donor substrates to provide models of biological dimetallic sites. Some macrocyclic dinuclear complexes containing imidazolato [2, 3], azido [4] and carbonato [5] bridges have been described. In order to synthesize imidazolate- and acetate-bridged dinuclear copper(II)



(L)

complexes, we have employed a 26-membered hexa-

azamacrocycle L (L = bis-*p*-xylylBISDIEN) [6] as a ligand and have succeeded in synthesizing several imidazolate-bridged dicopper(II) complexes [7]. However, we failed to obtain relative acetate-bridged complexes, instead we obtained a pair of quite rarely reported hydrate isomers with formula $LCu_2(CH_3COO)_2(H_2O)_2(ClO_4)_2$. The copper atoms in both of the isomers are independent other than acetate-bridged. The metals in the blue isomer are in square pyramidal geometry with N_3O_2 chromophore and are coordinated by the water molecules; while both of the two copper atoms in the violet isomer have N_3O square planar coordination environment and are not coordinated by water molecules. Reported in this paper are the syntheses, crystal structure and magnetic properties of the two hydrate isomers.

EXPERIMENTAL

Materials

Reagents were used as obtained without further purification. Solvents were purified by standard methods before use.

Synthesis of the ligand L. L·6HBr was prepared as the similar procedure described by Martell [6]. Anal. Calcd. for $C_{24}H_{38}N_6$·6HBr: C, 32.17; H, 4.95; N, 9.38. Found: C, 32.55; H, 5.02; N, 9.11. The relative macrocyclic-polyamine was obtained according to the following method: 4.45 g L·6HBr and 2 g NaOH were dissolved in 5 ml water and cooled and then 50 ml CH_2Cl_2 was added to the mixture to extract the product. The organic phase was evaporated to dryness and was recrystallized from methanol and acetonitrile. 1.70 g white crystals were obtained. The 500 MHz ^1H NMR in D_2O of L gave (ppm from DSS) 3.66, (singlet, 8H, benzene–CH_2), 7.31 (singlet, aromatic H), 2.59 (singlet, 16H, NH–CH_2) in the ratio of 1:1:2.

Synthesis of the blue isomer: $[LCu_2(CH_3COO)_2(H_2O)_2](ClO_4)_2$. To a solution of L (103 mg, 0.25 mmol in 5 ml acetonitrile) was added a solution of $Cu(OAc)_2{\cdot}H_2O$ (100 mg, 0.5 mmol in 2 ml water) with stirring and then was added dropwise five drops of saturated aqueous solution of $NaClO_4$. The resulting solution was stored at -5°C. After 2 days, 140 mg blue prism crystals were obtained, which were filtered off, washed with water and acetonitrile and dried in a desiccator containing silica gel, yield 61%. Anal. calcd. for $C_{28}H_{48}N_6Cu_2Cl_2O_{14}$: C, 37.71; H, 5.43; N, 9.42; Cu, 14.26. Found: C, 37.59; H, 5.57; N, 8.67; Cu, 14.05.

Synthesis of the violet isomer: $[LCu_2(CH_3COO)_2](ClO_4)_2 \cdot 2H_2O$ The same procedure as for the blue isomer except that to the resulting solution was added 5 ml of *n*-butyl alcohol with stirring and was stored in a refrigerator. 2 days later, 210 mg violet crystals were obtained, yield 92%. Anal. calcd. for $C_{28}H_{48}N_6Cu_2C1_2O_{14}$: C, 37.71; H, 5.43; N, 9.42; Cu, 14.26. Found: C, 38.44; H, 5.52; N, 9.35; Cu, 14.26.

Crystallographic data collection and structure determinations

The blue isomer. A suitable crystal of the blue isomer was mounted on an Enraf-Nonius CAD4 diffractometer. Unit cell parameters were determined by a least-squares refinement of 25 reflections with $13.98 < \theta < 16.89^\circ$ using graphite-monochromatized Mo Kα with $\omega/2\theta$ scan mode. Observed reflections with $I > 3\sigma(I)$ were used for structure determination. The data were corrected for LP factors and for empirical absorption. The crystallographic data are summarized in Table 1.

The structure was solved by the Patterson method followed by Fourier syntheses and refined on F by full matrix least squares with anisotropic thermal parameters for the non-hydrogen atoms. All the hydrogen atoms were located on the difference Fourier maps and assigned isotropic thermal parameters. The O(22), O(23) and O(24) atoms of one perchlorate ion were found disordered and the site occupancy factor was fixed at 0.5 for O(22A), O(22B), O(24A), O(24B) and at 0.333 for O(23A), O(23B) and O(23C). Selected distances and angles are listed in Table 2. The calculations were performed on MICRO-VAX 3100 using the TEXSAN plus version 2.01 programs.

The violet isomer. A suitable crystal of the violet isomer was mounted on a Siemens SHELXTL P4 diffractometer equipped with graphite-monochromated Mo Kα radiation. Accurate cell parameters were derived from a least-squares fitting of the setting angles of 25 independent reflections in the range of 6–24°. The relevant crystal data and structural parameters are summarized in Table 1. The intensities were collected with a variable scan speed 5.0 to 50.0° per min in ω. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS [8].

The structure was solved by the direct method and refined on F^2 by full-matrix least-squares methods using SHELXTL version 5.0 [9]. All the non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were placed in calculated positions assigned fixed isotropic thermal parameters at 1.2 times the equivalent isotropic U of the atoms to which they are attached and allowed to ride on their respective parent atoms. The contribution of these hydrogen atoms were included in the structure-factors calculations. All computations were carried out on a PC-586 computer using the SHELXTL-PC Program Package [9]. Analytical expressions of neutral-atom scattering factors employed and anomalous dispersion corrections were incorporated [10]. The atoms O(2) in one water molecule, O(11), O(12), O(13), O(14), O(22), O(23) and O(24) in two perchlorate ions were refined disordered with the site occupancy factor s.o.f. = 1/2. Selected bond lengths and angles are reported in Table 3.

For both isomers, a complete listing of atomic coordinates, bond lengths, bond angles, anisotropic ther-

N(1)–Cu(1)–N(2)	84.6(2)	N(3)#1–Cu(1)–N(2)	164.5(2)

mal parameters and structure factors are included as supplementary materials.

Physical measurements. ^{1}H NMR spectra were obtained at 319 K on a Bruker AM 500 spectrometer using an Aspect-3000 computer data system. Magnetic measurements on powder samples were carried out in the 77–300 K temperature range with a CAHN-2000 Farady-type magnetometer. The molar susceptibilities were corrected for the diamagnetism of the constituent atoms by using Pascal constants. The reflectance and electronic spectra were made on a Shimadzu UV-240 spectrophotometer.

RESULTS AND DISCUSSION

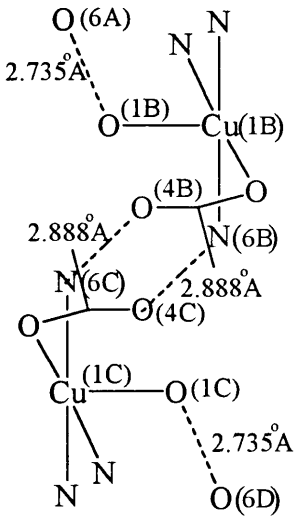
Description of the structure

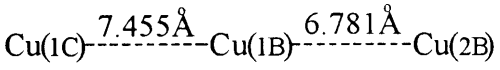
The blue isomer: $[LCu_2(CH_3COO)_2(H_2O)_2](ClO_4)_2$. The crystal structure of the blue isomer consists of one cation, $[LCu_2(CH_3COO)_2(H_2O)_2]^{2+}$, and two perchlorate anions. The cation $[LCu_2(CH_3COO)_2(H_2O)_2]^{2+}$ results from the binding of two $(H_2O)Cu(OOCCH_3)$ units into the macrocyclic ligand L. A view of the molecule structure is given in Fig. 1. Within the macrocycle the two copper atoms are independent at the separation of 6.781 Å. Both copper atoms are in an approximately distorted square-pyramidal geometry, with the basal positions consisting of one oxygen atom [O(3)] from the coordinated acetate and three nitrogen atoms [N(1), N(2) and N(6)] from the macrocycle. The oxygen atom of the water molecule occupies the axial site and is weakly coordinated to copper atom at the distance of 2.496(4) Å [Cu(1)–O(1)] or 2.458(4) Å [Cu(2)–O(2)], which is comparable with the Cu–O(H_2) bond lengths of 2.448(6) Å in $[CuL_2(H_2O)]$ [11] and 2.571(6) Å in $[Cu(en)_2(H_2O)_2]F_2 \cdot 4H_2O$ [12]. The copper atom is at the basal plane with the deviation of 0.034 Å for Cu(1) or 0.008 Å for Cu(2). The Cu–O bond lengths between the copper atoms and the coordinated acetates [Cu(1)–O(3) = 1.911(4) Å] and [Cu(2)–O(5) = 1.916(4) Å] are in general range in copper(II) complexes with carboxylates. The angle between the copper coordination plane and the closest acetate plane is 98.15° for Cu(1) and 61.65° for Cu(2).

The intermolecular hydrogen bonds join the molecules forming a two-dimensional net structure along bc-face (see Scheme 1).

The violet isomer: $[LCu_2(CH_3COO)_2](ClO_4)_2 \cdot 2H_2O$

The crystal structure of the violet complex is presented in Fig. 2. The molecule consists of a cation,





Scheme 1

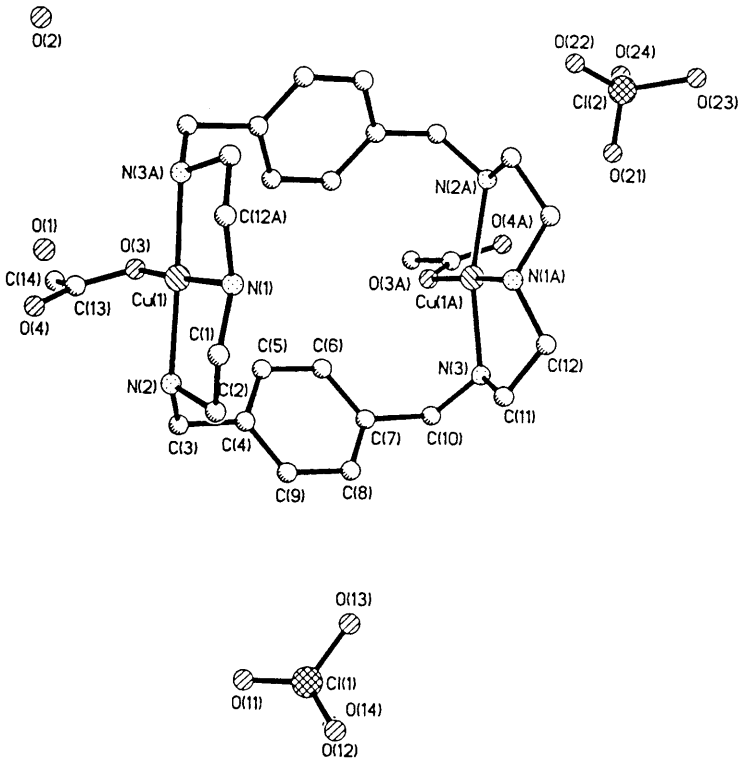

Fig. 2. Molecular structure of the violet isomer with the hydrogen atoms omitted for clarity.

$[LCu_2(CH_3COO)_2]^{2+}$, two perchlorates and two lattice water molecules. A crystallographically required two-fold axis passes through atom Cl(1) along the *z*-axis, which makes the two copper atoms equivalent. Each copper atom is in an approximately square-planar environment with copper deviating by 0.035 Å from the least-square coordination plane and is four-coordinated by three nitrogen atoms from the macrocycle and one oxygen atom from an acetate ligand. The average Cu–N bond length 2.01 Å is consistent with that of Cu(II) complexes with CuN_4 or CuN_3O chromophores. The copper–oxygen distance of 1.886(3) Å is in the general range of Cu–O bond lengths in copper complexes with carboxylates.

The metal coordination plane is nearly perpendicular to the two phenyl rings at 91.8° with one containing C(4) through C(9) and at 95.8° with the other involving C(4A) through C(9A) (symmetry operator: $-x+0.5, -y+1, z$). The angle between the basal plane of copper and the nearest acetate plane is 68.6°.

The intermolecule hydrogen bonds link the molecules along the *b*-axis forming a one-dimensional chain.

Structure comparison of the isomers. Each macrocycle in both isomers adopts a "boat"-type conformation (Figs 3 and 4), which is apparently unstrained, as indicated by the normal bond parameters. The angle between the two phenyl rings of the macrocycle is 57.67° for the blue isomer and 65.4° for the violet isomer. The angle between the two copper coordination planes is 12.9° for the blue isomer and 9.0° for the violet.

The closest intermolecular Cu···Cu separation of 7.455 Å [Cu(1B)···Cu(1C) in Scheme 1 and Fig. 3] for the blue isomer is much longer than that of 5.769 Å [Cu(1)···Cu(1B)] for the violet isomer (Scheme 2 and Fig. 4). The structurally significant difference between the isomers results from the positions of the water molecules in the complexes. For the blue isomer, the strong intermolecular hydrogen bonds (O(1B)–H···O(6A) = 2.735 Å) between the coordinated water molecules and the uncoordinated oxygen atoms of the monodentate-coordinated acetates, together with the hydrogen bonds [N(6)–H···O(4) = 2.888 Å, relative symmetry operators refer to Scheme 1 and Fig. 3], link the complex forming a two-dimensional structure along the bc-face.

Atoms Cl(2) (−0.691, 0.7500, 0.2500), O(21) (0.172, 0.7500, 0.2500), Cl(1) (0.7500, 0.5000, 0.3860) and O(1) (0.2786, 0.2500, 0.2500) of the violet isomer are in the special positions Fig. 2, one of the lattice water molecules is situated between two macrocycles and joins two uncoordinated oxygen atoms from two coordinated acetates of two neighbouring molecules by the strong hydrogen bonds [O(1)–H···O(4) =

2.742 Å], forming a one-dimensional chain (see Scheme 2 and Fig. 4) along the *b*-axis. The distance of 2.886 Å between Cu(1) and O(1) [or Cu(1B) and O(1)] is considered to be weak interaction.

uv/vis spectra

The reflectance spectra (displayed in Fig. 5) of the two isomers in visible region are quite different. There are two absorption maxima observed in the reflectance spectra for the violet complex. The band at 17.12 kK (584 nm) is assigned to $d_{z^2} \rightarrow d_{x^2-y^2}$ transitions and a resolved shoulder band at 20.24 kK (494 nm) to d_{xy}, d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transitions in distorted square-planar symmetry [13], which is consistent with the crystal structure determination.

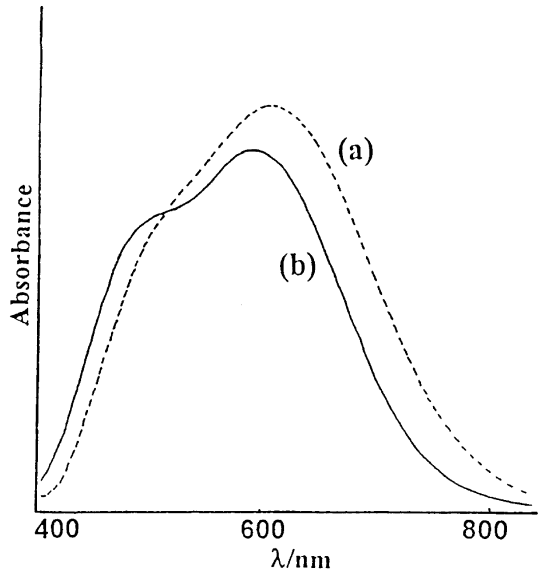

Fig. 5. Electronic reflectance spectra of $LCu_2(CH_3COO)_2(H_2O)_2(ClO_4)_2$: (a) the blue isomer and (b) the violet isomer.

Electronic spectra of copper(II) with square-pyramidal geometry have been studied extensively by Hathaway and coworkers [14, 15] and by reference to this the band at 16.50 kK (606 nm) for the blue complex is assigned to $d_{z^2} \rightarrow d_{x^2-y^2}$ transitions for a square-pyramidal system and the poorly resolved shoulder at about 19 kK (526 nm) indicates that there is some square-planar feature for the chromophore in the blue isomer, which agrees well with the result of the crystal structure determination of the complex where the axial ligation of the water molecule is quite weak (Cu–O bond length $\sim$2.5 Å) and the copper atoms are considered nearly to be with the square-planar configuration.

Magnetic susceptibility

The temperature dependence of the magnetic susceptibilities were measured in the temperature range 300 to 77 K. For the violet isomer, the plot of χ_M^{-1} vs T is linear in the range of 300–160 K (Fig. 6). The Weiss constant determined in this range is negative ($\theta = -25.6$ K), which suggests an antiferromagnetic interaction. For the blue isomer, the magnetic behavior follows the Curie–Weiss law over the measured temperature range. The Weiss constant ($\theta = -5.72$ K) is significantly smaller, indicating a much weaker antiferromagnetic interaction in the blue isomer which can be explained by their structural differences.

For the magnetic coupling between Cu(II) ions, two

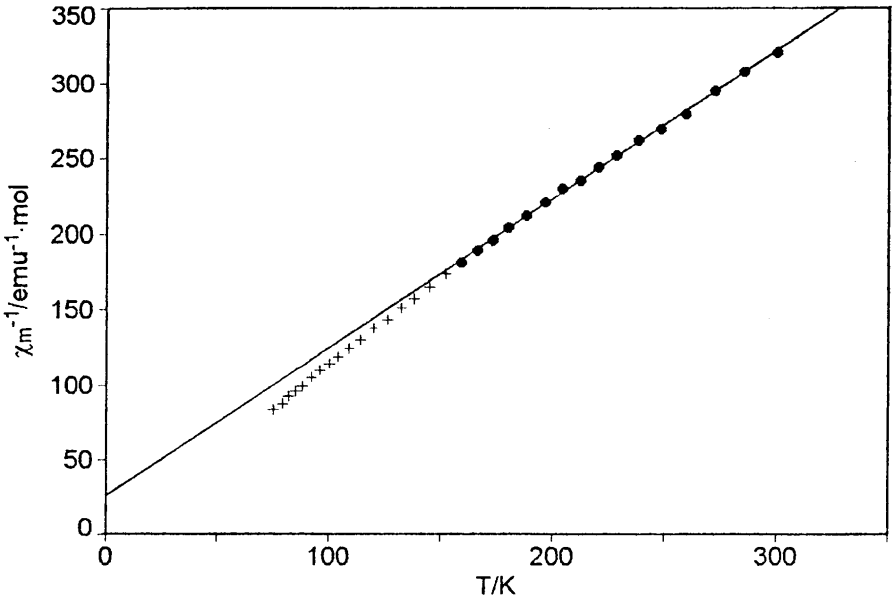

Fig. 6. Plot of χ_M^{-1} vs temperature T for the violet isomer. Dotted intercept $\theta = -25.6$ K.

exchange pathways are possible for both compounds: one is intramolecular through macrocycle ligands and the other is intermolecular through space. In both cases, the intramolecular Cu···Cu separation is very large (6.738 Å for the violet and 6.781 Å for the blue isomer, respectively). The magnetic exchange transmitted by this pathway is expected to be very small. On the other hand, the intermolecular interaction is quite different for the two compounds. In the violet isomer, the intermolecular Cu(1B)···Cu(1) separation is 5.769 Å. Between the neighboring macrocycles, there exist water molecules which "bridge" the two copper ions with Cu(1)···O(1) distance 2.886 Å (Scheme 2). Hence, a weak antiferromagnetic exchange is mediated through Cu(1B)···O(1)···Cu(1) units. The exchange is reduced due to the fact that the orientation of the magnetic orbitals of the copper ions is predominantly perpendicular to the oxygen "bridge" and, therefore, is unfavorable to propagate the interaction along Cu(1B)···O(1)···Cu(1) [16]. The susceptibility data for this compound can be analysed by a dimer model and fitted by a Bleaney–Bowers equation [17]

$$\chi_M = 2N\beta^2 g^2 (kT)^{-1} (3 + \exp(-2J/kT))^{-1}$$

where χ_M is the molar susceptibility and the other parameters have their usual meanings. A best fit, which leads to a solid line in Fig. 7, is obtained with $g = 2.19$ and $J = -1.81\,\mathrm{cm}^{-1}$.

In the blue isomer, the adjacent molecules are connected to each other through extensive hydrogen bondings. The nearest intermolecular Cu···Cu separation is 7.455(9) Å, which is much longer than that in the violet isomer (5.769(9) Å). A possible dipole–dipole or superexchange interaction between the molecules has to be ruled out, thus explains the comparatively much weaker magnetic coupling in the blue isomer.

CONCLUSION

Seldom seen hydrate isomers, the blue and the violet complexes are prepared and characterized. The difference between the isomers are the positions of the water molecules. For the blue isomer, each copper atom is five-coordinated by three N atoms from the macrocycle and by two O atoms, one of which is from the coordinated acetate and the other from the water molecule. However, the central copper atom in the violet isomer is four-coordinated by three N atoms from the macrocycle and by one O atom from the coordinated acetate and is not coordinated by the water molecules. The electronic reflectance spectra of the isomers indicate that the copper atoms are CuN_3O_2 square-pyramidal symmetry for the blue isomer and CuN_3O tetragonal environment for the violet, which is consistent with the result of the crystal structure determination. Both compounds exhibit quite weak antiferromagnetic couplings verified by the small but negative Weiss constant.

Keywords: gold; bis(diphenylphosphino)methane; methanide; methanediide

INTRODUCTION

The chemistry of diphosphines, mainly of bis(diphenylphosphino)methane has been extensively developed in the past [1]. By deprotonation of the methylenic group an anion that can be described by different resonant forms [2] is obtained and its chemistry has been studied by several laboratories producing results that have been included in a recent revision [3]. We have contributed to this topic with the preparation of a great number of methanide or methanediide gold complexes, as for example the structurally characterized $[AuR_2\{(PPh_2)_2CH(AuR)\}]$, [4] $[AuR_2\{(PPh_2)_2C(AuPPh_3)_2\}]ClO_4$, [5] $[(RAu)HC(PPh_2AuPPh_2)_2CH(AuR)]$ [6], or $[(Ph_3PAu)_2C(PPh_2AuPPh_2)_2C(AuPPh_3)_2](ClO_4)_2$ [7] (R = C_6F_5).

However, in these products the diphosphine acts as a chelating or bridging ligand, respectively, and after the deprotonation the only possibility for further coordination is through the methanide carbon atom. Even when the free phosphine is treated with $[Au(acac)(PPh_3)]$ the eight-membered ring methanide $[CH(PPh_2AuPPh_2)_2CH]$, previously prepared by different methods by Schmidbaur [8, 8] and structurally characterized by Mingos, [9] is formed with displacement of triphenylphosphine [10]. The only examples of bridging non-cyclic methanides of gold described to date are obtained from $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$ [11] or its calcogenide derivatives [12].

These results show that the formation of cyclic methanides is more likely than the preparation of open ones, probably due to the additional stabilization produced by the delocalization of the electronic density through the ring. This made up our minds to study the possibility of synthesizing non-cyclic gold methanide complexes and to obtain this we used two different strategies. The first one is the use of the phosphino–phosphonium ligand $PPh_2CH_2PPh_2Me^+$ that features a positive charge on the quaternary phosphorus, which increases the acidity of the methylenic protons, and where the formation of cycles is avoided because of the presence of the quaternary phosphorus. The second strategy is the employment of gold complexes, such as $[Au(C_6F_5)_2X(PPh_2CH_2PPh_2)Au(C_6F_5)]$ (X = Cl, C_6F_5) or $[Au(C_6F_5)(PPh_2CH_2PPh_2)Au(C_6F_5)]$, with a saturated coordination sphere for the metal centers, which also prevents the formation of rings.

This result differs from that previously described in which although the formation of rings is avoided, the coordination was possible through two donor atoms [12].

RESULTS AND DISCUSSION

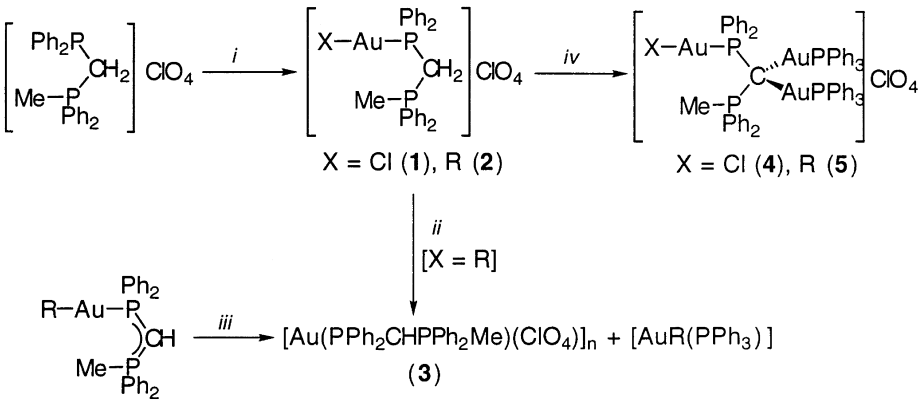
We have mentioned above two different strategies for the synthesis of open phosphino–methanide derivatives. With regard to the use of $PPh_2CH_2PPh_2Me^+$ as ligand we prepared the gold(I) complex $[AuCl(PPh_2CH_2PPh_2Me)]ClO_4$ (**1**) as starting material, by reaction of [AuCl(tht)] (tht = tetrahydrothiophene) with an equimolecular amount of $(PPh_2CH_2PPh_2Me)ClO_4$ (see Scheme 1). Complex **1** is obtained as an air and moisture stable white solid, with similar physical and spectroscopic properties to those observed for the previously described perfluorophenyl derivative **2** [13].

The use of acetylacetonate (acac) complexes has been previously reported in the synthesis of ylide or methanide complexes of gold (Refs. [10, 14, 14] and references therein). When complex **2** is treated with equimolecular amounts of [Au(acac)(PPh_3)] in dichloromethane an initial yellow colour appears, which becomes subsequently discoloured with the simultaneous formation of a white precipitate. After 1 h of reaction the solid is filtered off and $[Au(C_6F_5)(PPh_3)]$ is obtained from the solution. The analytical data for the insoluble product are in accordance with those expected for a complex with an stoichiometry $[Au(PPh_2CHPPh_2Me)]ClO_4$. Its IR spectrum shows two absorptions at 620 (m) and 1100 (vs, br) cm^{-1} [15] due to the perchlorate ion; some bands corresponding to the phosphino–phosphonium ligand at about 500 and 895 cm^{-1}, as well as a band at 586 (m) cm^{-1}, assigned to the ν(Au–C) vibration [16, 16, 16, 16, 17]. Taking these data and its insolubility into account, we propose that a polymeric complex $[Au(PPh_2CHPPh_2Me)(ClO_4)]_n$ (**3**) (probably featuring Au–P and Au–C bonds) is formed, but its low solubility did not allow us to complete its characterization.

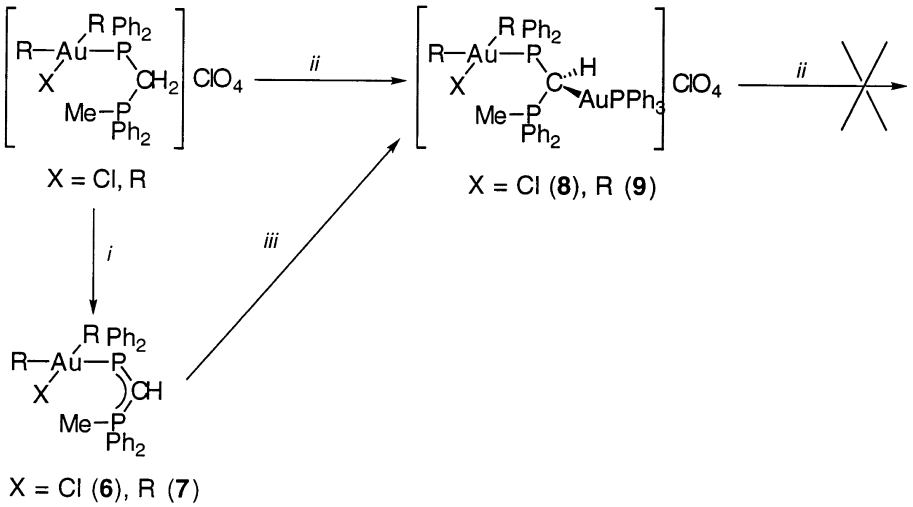
The same result is obtained when the methanide $[Au(C_6F_5)(PPh_2CHPPh_2Me)]$ [13] is treated with $[Au(PPh_3)(tht)]ClO_4$, and no sign of formation of $[Au(C_6F_5)\{PPh_2CH(AuPPh_3)PPh_2Me\}]ClO_4$ is observed.

In contrast, when complexes **1** or **2** are treated with [Au(acac)(PPh_3)] in a 1:2 molar ratio, both methylenic protons are substituted by $[AuPPh_3]^+$ groups, affording the trinuclear species $[AuX\{PPh_2C(AuPPh_3)_2PPh_2Me\}]ClO_4$ [X = Cl (**4**), C_6F_5 (**5**)] Scheme 1. Complexes **4** and **5** are air and moisture stable solids, soluble in chlorinated solvents and acetone and non soluble in diethyl ether and hexane. Their analytical and spectroscopic data are in accordance with the proposed formulation, displaying three resonances with relative intensities 2:1:1 in their $^{31}P\{^1H\}$ NMR spectra.

Non-cyclic methanides are also obtained using phosphino–phosphonium derivatives of gold(III). Thus, reaction of $[Au(C_6F_5)_2X(PPh_2CH_2PPh_2Me)]ClO_4$ (X = Cl, C_6F_5) with $[N(PPh_3)_2](acac)$ in dichloromethane affords the previously described species $[Au(C_6F_5)_2X(PPh_2CHPPh_2Me)]$ [X = Cl (**6**), C_6F_5 (**7**)] through an alternative synthetic pathway. Their analytical and spectroscopic data agree with those previously described. [13] Treatment of the same starting products with one equivalent of [Au(acac)(PPh_3)] leads to different results than the related gold(I) compounds and the monosubstituted species $[Au(C_6F_5)_2X\{PPh_2CH(AuPPh_3)PPh_2Me\}]ClO_4$ [X = Cl (**8**), C_6F_5 (**9**)] are now easily isolated (see Scheme 2). Complexes **8** and **9** can also be prepared from the methanide compounds **6** and **7**, respectively, when reacted with the appropriate amounts of $[Au(PPh_3)(tht)]ClO_4$. Also in contrast with the behavior of the gold(I) species, the disubstituted products $[Au(C_6F_5)_2X\{PPh_2C(AuPPh_3)_2PPh_2Me\}]ClO_4$ can not be prepared even when an excess (1:3) of [Au(acac)(PPh_3)] is employed.



Scheme 1. R = C_6F_5; (i) [AuX(tht)]; (ii) [Au(acac)(PPh_3)]; (iii) $[Au(PPh_3)(tht)]ClO_4$; (iv) 2 [Au(acac)(PPh_3)].



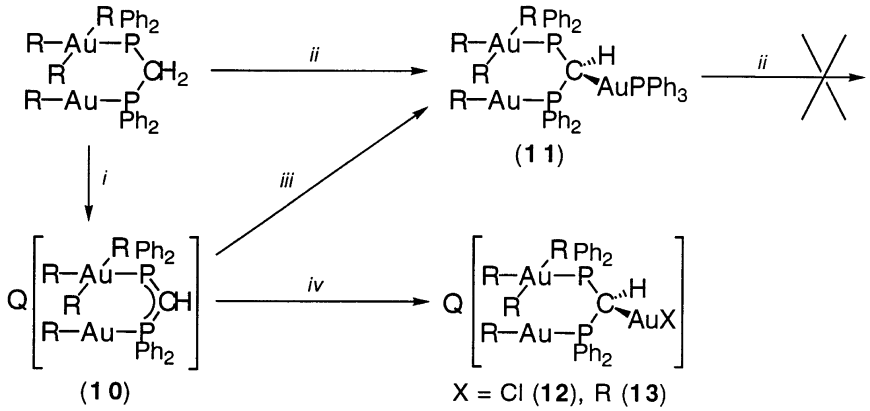
Scheme 2. R = C_6F_5; (i) $[N(PPh_3)_2](acac)$; (ii) $[Au(acac)(PPh_3)]$; (iii) $[Au(PPh_3)(tht)]ClO_4$.

Compounds **8** and **9** are obtained as white, air and moisture stable solids. Their $^{31}P\{^1H\}$ NMR spectra show three resonances with similar relative intensities, in accordance with the substitution of only one methylenic proton. This fact is also confirmed in their ^1H NMR spectra, which display one signal due to the remaining hydrogen atom, as well as a doublet corresponding to the protons of the methyl group. The ^{19}F NMR spectrum is in agreement with the *cis* position of the pentafluorophenyl groups in **8**.

Regarding the second strategy mentioned in Section 1, the use of dinuclear complexes featuring a saturated coordination sphere for the gold atoms, the employment of $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)Au(C_6F_5)]$ [18] leads to the same observations than the gold(III) phosphino–phosphonium species. Thus, the reaction of this dinuclear complex with $[N(PPh_3)_2](acac)$ gives rise to the synthesis of $[N(PPh_3)_2][Au(C_6F_5)_3(PPh_2CHPPh_2)Au(C_6F_5)]$ (**10**), one of the few anionic methanides reported to date (Scheme 3).

Complex **10** is obtained as a yellow air and moisture sensitive oil, which makes its characterization difficult. In its IR spectrum a broad signal located at 1184 (m) cm^{-1}, assigned to the methanide system [3], is present. Its $^{31}P\{^1H\}$ NMR spectrum confirms the presence of the cation, because a sharp singlet at $\delta = 21.7$ ppm appears. It also shows two multiplets with the same intensity, according with the existence of two inequivalent phosphorus of the diphosphino–methanide ligand with a pentafluorophenyl group in *trans* position.

Reaction of **10** with one equivalent of $[Au(PPh_3)(tht)]ClO_4$ or $[AuX(tht)]$ (X = Cl, C_6F_5) leads to the displacement of the sulfur donor ligand and the coordination of the non-saturated methanide carbon to the gold(I) centre affording the trinuclear neutral (**11**) or anionic (**12** and **13**) derivatives, as represented in Scheme 3. Compound **11** can alternatively be synthesized directly from $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)Au(C_6F_5)]$ and $[Au(acac)(PPh_3)]$ in a 1:1 molar ratio.

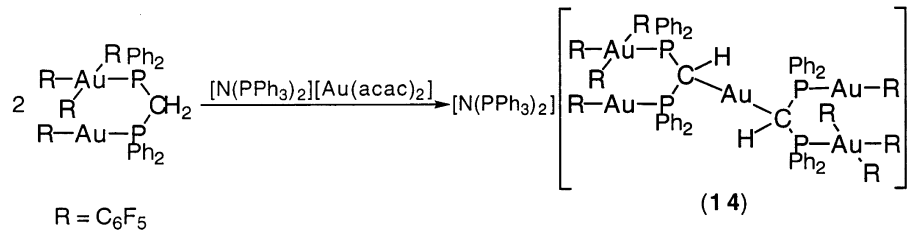


Scheme 3. R = C_6F_5; Q = $[N(PPh_3)_2]$; (i) Q(acac); (ii) $[Au(acac)(PPh_3)]$; (iii) $[Au(PPh_3)(tht)]ClO_4$; (iv) $[AuX(tht)]$.

Besides, as observed for gold(III) derivatives with $PPh_2CH_2PPh_2Me^+$, the use of an excess of [Au(acac)(PPh_3)] does not produce a double deprotonation and the monosubstituted product **11** is formed again.

Complexes **11**, **12** and **13** are obtained as white powders. They are stable in solid state and in solution, except **12**, which rapidly decomposes in solution. They are soluble in most common organic solvents, except in hexane and their analytical and spectroscopic data are in accordance with the proposed formulation (see Section 3).

In order to increase the nuclearity of the products we can use $[N(PPh_3)_2][Au(acac)_2]$, which can at once extract one methylenic proton of two different molecules of $[Au(C_6F_5)_2X(PPh_2CH_2PPh_2)Au(C_6F_5)]$ (X = Cl, C_6F_5) and coordinate both methanide units to the gold(I) center, affording the pentanuclear $[N(PPh_3)_2][\{Au(C_6F_5)_3(PPh_2CHPPh_2)Au(C_6F_5)\}_2Au]$ (**14**) (equation 1).



This complex is obtained as a white solid and it is air and moisture stable in solid state, but its stability decreases in solution. Its $^{31}P\{^1H\}$ NMR spectrum is similar to those registered for **10** and **12**, featuring a singlet at $\delta = 21.7$ ppm, corresponding to the cation, and two multiplets due to both types of phosphorus of the methanide unit. In spite of complex **14** having two chiral carbon atoms and thus two pairs of enantiomers which can be present at the same time (RR, SS and RS, SR), the ^{19}F and ^1H NMR spectra show only one set of signals.

Finally, we have studied the behavior of $[Au(C_6F_5)(PPh_2CH_2PPh_2)Au(C_6F_5)]$ [19]. The reaction with one equivalent of [Au(acac)(PPh_3)] gives rise to the substitution of one methylenic hydrogen, affording $[Au(C_6F_5)\{PPh_2CH(AuPPh_3)PPh_2\}Au(C_6F_5)]$ (**15**), while an excess of the acetylacetonate derivative does not lead to further substitutions, recovering always complex **15** (Scheme 4). This is a white stable solid, soluble in common organic solvents, except in hexane. Its $^{31}P\{^1H\}$ NMR spectrum shows two resonances at $\delta = 40.8$ (t) and 36.8 (d) ppm, with a relative intensity 1:2 and in its ^1H NMR spectrum a pseudotriplet of doublets centered at $\delta = 3.9$ ppm, due to the methylinic proton appears.

EXPERIMENTAL

General

NMR spectra were recorded on a Bruker ARX 300 spectrometer in $CDCl_3$ solutions. Chemical shifts are quoted relative to $SiMe_4$ (^1H, external), $CFCl_3$ (^{19}F, external) and H_3PO_4 (85%) (^{31}P, external). All experiments were carried out at room temperature and under nitrogen.

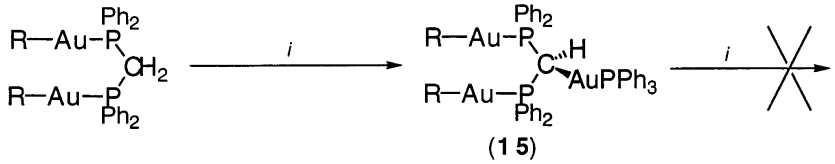
$[AuCl(PPh_2Ch_2PPh_2Me)]ClO_4$ (*1*)

To a dichloromethane solution of [AuCl(tht)] [20] (0.064 g, 0.2 mmol) was added ($PPh_2CH_2PPh_2Me$) ClO_4 (0.098 g, 0.2 mmol). After 30 min of stirring a little amount of precipitate is filtered over celite and the solution was concentrated to *ca.* 5 ml and diethyl ether was added to give complex **1** as a white solid. Yield: 80%. m.p.: 198 (dec). -$C_{26}H_{25}AuCl_2O_4P_2$ (731.30), calcd. C, 42.7; H, 3.45; found C, 42.55; H, 3.3. Λ_m: 115 Ω^{-1} cm^2 mol^{-1}. -$^{31}P\{^1H\}$NMR: δ 22.0 (d, 1P, Au–*P*Ph_2), [$^2J(PP^+) = 4.8$ Hz]) and 18.2 (m, 1P, *P*Ph_2Me); -^1H NMR δ 4.5 (dd, 2H, C*H*$_2$, [$^2J(HP) = 8.4$, $^2J(HP) = 5.4$ Hz]) and 2.4 (d, 3H, *Me*, [$^2J(HP) = 6.7$ Hz]).

$[Au(PPh_2CHPPh_2Me)]ClO_4$ (*3*)

(a) To a dichloromethane solution of **2** [13] (0.086 g, 0.1 mmol) was added [Au(acac)(PPh_3)] [21] (0.055 g, 0.1 mmol) and the solution initially turned yellow, but after a few minutes it became discoloured with the appearance of **3** as a white solid. The mixture was stirred for 1 h and complex **3** (yield: 87%) was then filtered off and [Au(C_6F_5)(PPh_3)] was isolated from the filtrate.

(b) A dichloromethane solution of [Au(C_6F_5)(PPh_2CHPPh_2Me)] [13] (0.076 g, 0.1 mmol) was treated with [Au(PPh_3)(tht)]ClO_4 [22] (0.065 g, 0.1 mmol) and a white precipitate appears. After 1 h the precipitation was complete and filtration of the



Scheme 4. R = C_6F_5; (i) [Au(acac)(PPh_3)].

solid afforded **3** (yield: 82%) while [Au(C_6F_5)(PPh_3)] was recovered from the solution. $C_{26}H_{24}AuClO_4P_2$ (694.84), calcd. C, 44.95; H, 3.5; found C, 44.75; H, 2.9.

$[Au\{PPh_2C(AuPPh_3)_2PPh_2Me\}]ClO_4$ [$X = Cl$ (***4***), C_6F_5 (***5***)]

To a solution of **1** (0.073 g, 0.1 mmol) or **2** (0.086 g, 0.1 mmol) in 20 ml of dichloromethane was added [Au(acac)(PPh_3)] (0.110 g, 0.2 mmol) and after 2 h of stirring a little amount of precipitate is filtered over celite. The solvent was then evaporated in a vacuum and 20 ml of diethyl ether was added to give complexes **4** (yield: 70%) or **5** (yield: 85%) as white solids. 4: m.p.: 130 (dec). $C_{62}H_{53}Au_3Cl_2O_4P_4$ (1647.80), calcd. C, 45.2; H, 3.25; found C, 45.25; H, 3.6. Λ_m: 95 Ω^{-1} cm^2 mol^{-1}. -^{31}P{^{1}H} NMR: δ 37.6 (dd, 2P, *P*Ph_3, [^3J(PP) = 11, ^3J(PP$^+$) = 6.3 Hz]), 32.5 (t, 1P, Au–*P*Ph_2) and 22.6 (t, 1P, *P*Ph_2Me); -^{1}H NMR: δ 2.3 (d, 3H, Me, [^2J(HP) = 13.9 Hz]). 5: m.p.: 142 (dec). -$C_{68}H_{53}Au_3ClF_5O_4P_4$ (1779.37), calcd. C, 45.8; H, 3.0; found C, 45.9; H, 2.95. Λ_m: 104 Ω^{-1} cm^2 mol^{-1}. -^{31}P{^{1}H} NMR: δ 37.6 (m, 2P, *P*Ph_3), 44.9 (m, 1P, Au–*P*Ph_2) and 23.7 (m, 1P, *P*Ph_2Me); ^{1}H NMR: δ 2.4 (d, 3H, Me, [^2J(HP) = 7.8 Hz]); -^{19}F NMR: δ −115.3 (m, 2F, *o*-F), −159.5 (t, 1F, *p*-F, [^3J(FF) = 19.5 Hz]) and −162.8 (m, 2F, *m*-F).

$[Au(C_6F_5)_2X(PPh_2CHPPh_2Me)]$ [$X = Cl$ (***6***), C_6F_5 (***7***)]

To a solution of [Au(C_6F_5)$_2$X($PPh_2CH_2PPh_2$Me)]ClO_4 [13] [0.106 g (Cl) or 0.119 g (C_6F_5), 0.1 mmol] in dichloromethane was added [N(PPh_3)$_2$](acac) (0.076 g, 0.12 mmol). After 2 h of stirring the solvent was evaporated to dryness in a vacuum and 15 ml of diethyl ether was added to precipitate the [N(PPh_3)$_2$]ClO_4 formed in the reaction, which is removed by filtration over celite. Concentration of the filtrate and addition of hexane led to complexes **6** (yield: 95%) or **7** (yield: 98%) as white solids. Their analytical and spectroscopic data agree with those previously described [13].

$[Au(C_6F_5)_2X\{PPh_2CH(AuPPh_3)PPh_2Me\}]ClO_4$ [$X = Cl$ (***8***), C_6F_5 (***9***)]

(a) A dichloromethane solution of [Au(C_6F_5)$_2$X($PPh_2CH_2PPh_2$Me)]ClO_4 [0.106 g (Cl) or 0.119 g (C_6F_5), 0.1 mmol] was treated with [Au(acac)(PPh_3)] (0.055 g, 0.1 mmol). The mixture was stirred for 2 h and the solvent was then evaporated to *ca.* 5 ml. 20 ml of diethyl ether was added to precipitate complexes **8** (yield: 90%) or **9** (yield: 65%) as white solids.

(b) To a solution of [Au(C_6F_5)$_2$X(PPh_2CHPPh_2Me)] [0.096 g (Cl) or 0.110 g (C_6F_5), 0.1 mmol] in 20 ml of dichloromethane was added [Au(PPh_3)(tht)]ClO_4 (0.065 g, 0.1 mmol) and after 30 min of stirring the solution was concentrated in a vacuum. Addition of diethyl ether gave complexes **8** (yield: 83%) or **9** (yield: 62%) as white solids. **8**: m.p.: 95 (dec). -$C_{56}H_{39}Au_2Cl_2F_{10}O_4P_3$ (1523.59), calcd. C, 44.15; H, 2.6; found C, 44.45; H, 2.35. Λ_m: 130 Ω^{-1} cm^2 mol^{-1}. -^{31}P{^{1}H} NMR: δ 39.5 ("t", 1P, *P*Ph_3, [^3N = 9.8 Hz]), 27.4 (dm, 1P, Au–*P*Ph_2) and 21.3 (dd, 1P, *P*Ph_2Me, [^2J(PP$^+$) = 29 Hz]); -^{1}H NMR: δ 5.2 ("td", 1H, C*H*, [^2J(HP) = 14.3, ^3J(HP) = 8.8 Hz]) and 2.6 (d, 3H, Me,

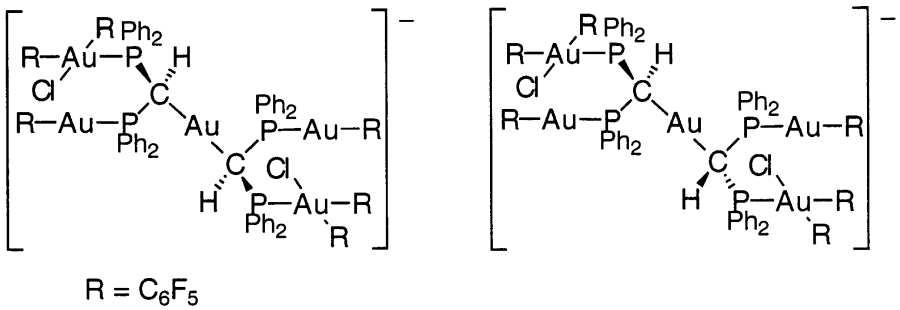


Fig. 1.

[^2J(HP) = 14.1 Hz]); -^{19}F NMR: δ-120.3 (m, 1F, *o*-F), −121.7 (m, 1F, *o*-F), −156.4 (t, 1F, *p*-F, [^3J(FF) = 19.3 Hz]), −159.4 (m, 1F, *m*-F), −160.4 (m, 1F, *m*-F), −121.8 (m, 1F, *o*-F), −122.1 (m, 1F, *o*-F), −156.5 (t, 1F, *p*-F, [^3J(FF) = 19.0 Hz]), −160.6 (m, 1F, *m*-F) and −160.8 (m, 1F, *m*-F). **9**: m.p.: 114 (dec). -$C_{62}H_{39}Au_2ClF_{15}O_4P_3$ (1655.15), calcd.: C, 45.0; H, 2.4; found C, 45.5; H, 2.45. Λ_m: 126 Ω^{-1} cm^2 mol^{-1}. -^{31}P{^{1}H} NMR: δ 38.6 (m, 1P, *P*Ph$_3$), 23.4 (m, 1P, Au–*P*Ph$_2$) and 17.4 (m, 1P, *P*Ph$_2$Me); -^{1}H NMR: δ 3.6 (m, 1H, C*H*) and 2.1 (d, 3H, Me, [^2J(HP) = 13.1 Hz]); -^{19}F NMR: δ −119.1 (m, 2F, *o*-F), −155.7 (t, 1F, *p*-F, [^3J(FF) = 19.9 Hz]), −159.6 (m, 2F, *m*-F), −120.7 (m, 2F, *o*-F), −156.5 (t, 1F, *p*-F, [^3J(FF) = 20.3 Hz]) and −160.8 (m, 2F, *m*-F).

[*N*(*PPh*$_3$)$_2$][*Au*(C$_6$F$_5$)$_3$(*PPh*$_2$*CHPPh*$_2$)*Au*(C$_6$F$_5$)] (***10***)

To a diethyl ether solution of [Au(C$_6$F$_5$)$_3$(PPh$_2$CH$_2$PPh$_2$)Au(C$_6$F$_5$)] [18] (0.144 g, 0.1 mmol) was added [N(PPh$_3$)$_2$](acac) (0.076 g, 0.12 mmol) and the solution turned yellow. After 2 h of stirring the excess of [N(PPh$_3$)$_2$](acac) was removed by filtration and the solution was dried in a vacuum giving complex **10** as a yellow oil. -^{31}P{^{1}H} NMR: δ 31.1 (m, 1P, Au(I)–*P*Ph$_2$), 18.5 (m, 1P, Au(III)–*P*Ph$_2$) and 21.7 (s, 2P, [N(*P*Ph$_3$)$_2$]$^+$).

[*Au*(C$_6$F$_5$)$_3${*PPh*$_2$*CH*(*AuPPh*$_3$)*PPh*$_2$}*Au*(C$_6$F$_5$)] (***11***)

(a) A dichloromethane solution of [Au(C$_6$F$_5$)$_3$(PPh$_2$CH$_2$PPh$_2$)Au(C$_6$F$_5$)] (0.144 g, 0.1 mmol) was treated with [Au(acac)(PPh$_3$)] (0.055 g, 0.1 mmol). The mixture was stirred for 2 h and a little amount of solid was filtered over celite. The solvent was then evaporated to *ca.* 5 ml and hexane was added to precipitate complex **11** as a white solid. Yield: 50%.

(b) To a freshly prepared solution of **10** (0.1 mmol) in dichloromethane was added [Au(PPh$_3$)(tht)]ClO$_4$ (0.065 g, 0.1 mmol) and the solution turned rapidly colourless. The solution was stirred for 30 min and the solvent was then dried in a vacuum. Addition of diethyl ether led to the precipitation of the [N(PPh$_3$)$_2$]ClO$_4$ formed in the reaction, which was removed by filtration over celite. Concentration of the filtrate and addition of hexane gave complex **11** as a white solid. Yield: 40%. m.p.: 140 (dec). -$C_{67}H_{36}Au_3F_{20}P_3$ (1904.65) calcd.: C, 42.2; H, 1.9; found C, 41.5; H, 2.0. Λ_m: 10 Ω^{-1} cm^2 mol^{-1}. -^{31}P{^{1}H} NMR: δ 39.2 ("t", 1P, *P*Ph$_3$, [*N* = 9.8 Hz]), 36.8 (m, 1P, Au(I)–*P*Ph$_2$) and 22.3 (m, 1P, Au(III)–*P*Ph$_2$); -^{1}H NMR: δ 3.6 (m, 1H, C*H*); -^{19}F NMR: δ −118.7 (m, 4F, *o*-F), −158.2 (t, 2F, *p*-F, [^3J(FF) = 20.6 Hz]), −161.1 (m, 4F, *m*-F), −121.5 (m, 2F, *o*-F), −157.9 (t, 1F, *p*-F, [^3J(FF) = 20.6 Hz]), −161.8 (m, 2F, *m*-F), −116.1 (m, 2F, *o*-F), −159.2 (t, 1F, *p*-F, [^3J(FF) = 19.3 Hz]) and −163.1 (m, 2F, *m*-F).

[*N*(*PPh*$_3$)$_2$][*Au*(C$_6$F$_5$)$_3${*PPh*$_2$*Ch*(*AuX*)*PPh*$_2$}*Au*(C$_6$F$_5$)] [*X* = *Cl* (***12***), C$_6$F$_5$ (***13***)]

To a freshly prepared solution of **10** (0.1 mmol) in dichloromethane was added [AuCl(tht)] (0.032 g, 0.1 mmol) or [Au(C$_6$F$_5$)(tht)] [23] (0.045 g, 0.1 mmol) and the solution turned rapidly colourless. After 30 min of stirring the solvent was evaporated in a vacuum and hexane was added to precipitate complexes **12** (yield: 75%) or **13** (yield: 70%) as white solids. **12**: m.p.: 63 (dec). -$C_{85}H_{51}Au_3ClF_{20}NP_4$ (2216.40), calcd. (Received 30 January 1998; accepted 29 April 1998)

Abstract—The reactions of [$Pt_2Me_4(\mu$-$SMe_2)_2$] (**1**) with ligands ArCH═N-(*S*)-CHMePh (Ar═2-BrC_6H_4 (**2a**), 2,6-$Cl_2C_6H_3$ (**2b**), C_6F_5 (**2c**), 2-FC_6H_4 (**2d**), 2-$CF_3C_6H_4$ (**2e**)), give either cyclometallated compounds [$PtMe_2X$(RCH═N-(*S*)-CHMePh)(SMe_2)] (**3**), by intramolecular activation of C–X (X = Br, Cl or F) bonds, or compounds [PtMe(RCH═N-(*S*)-CHMePh)(SMe_2)] (**5**), by orthometallation, followed by methane elimination. The reactions of these compounds with PPh_3 result in the formation of [$PtMe_2X$(RCH═N-(*S*)-CHMePh)(PPh_3)] (**4**), or [PtMe(RCH═N-(*S*)-CHMePh)(PPh_3)] (**6**), respectively. Oxidative addition of methyl iodide to compounds **6** produces the corresponding complexes **4**. The NMR spectra of compounds **3** and **4** indicate that these are formed as two diastereomers. The X-ray structure of [PtMe(2-FC_6H_3CH═N-(*S*)-CHMePh)(PPh_3)] (**6d**) is reported. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cyclometallation; platinum; chiral imines; X-Ray crystal structure

INTRODUCTION

Cyclometallated compounds have been extensively studied because of their potential utility in organic synthesis, catalysis and asymmetric synthesis. Moreover, cyclometallated platinum complexes with N-donor ligands showing interesting photophysical, photochemical or electrochemical properties have been reported [1–5]. While relatively few examples of cycloplatination of chiral N-donor ligands have been described [6, 7], predetermination of helical chirality at the metal center has been achieved for both square–planar platinum(II) and octahedral platinum(IV) cyclometallated compounds, by the use of adequate ligands [8].

Following our interest in cyclometallated platinum complexes containing bidentate (C, N) ligands [9, 10], we now describe new cyclometallated compounds obtained by the reaction of [$Pt_2Me_4(\mu$-$SMe_2)_2$] and imines ArCH═N-(*S*)-CHMePh, derived from (*S*)-α-methylbenzylamine. According to previous results [9, 10], for Ar═2-BrC_6H_4, 2,6-$Cl_2C_6H_3$ and C_6F_5, the formation of octahedral platinum(IV) compounds in which the metal atom becomes a chiral center is expected, arising from activation of C–Br, C–Cl or C–F bonds, respectively. Interestingly, resolution of platinum(II) in a trigonal bipyramidal environment has been achieved by using the enantiomeric imine 2-(CH═N-(*S*)-CH(Me)Ph)-6-MeC_5H_3N [11]. For imines containing the aryl groups 2-$CF_3C_6H_4$ or 2-FC_6H_4, C–H bond activation, followed by CH_4 elimination, is expected to lead to formation of chiral-at-ligand cyclometallated platinum(II) compounds. These complexes may undergo oxidative addition reactions to yield octahedral platinum compounds. Fluorinated substituents were selected for this study because ^{19}F NMR spectroscopy has been reported to be one of the most sensitive techniques for detecting diastereomers [12].

RESULTS AND DISCUSSION

Ligands ArCH═N-(*S*)-CHMePh (Ar═2-BrC_6H_4 (**2a**), 2,6-$Cl_2C_6H_3$ (**2b**), C_6F_5 (**2c**), 2-FC_6H_4 (**2d**), 2-

* Author to whom correspondence should be addressed.

$CF_3C_6H_4$ (**2e**)) were prepared from the condensation reaction of (*S*)-α-methylbenzylamine and the appropriate aldehyde, carried out in refluxing ethanol. The reactions of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with iminic ligands ArCH=N-(*S*)-CHMePh (**2a**–**2e**) were carried out in acetone and the results are shown in Scheme 1.

For imines **2a** and **2b** formation of platinum(IV) cyclometallated compounds $[PtMe_2Br(C_6H_4CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**3a**) and $[PtMe_2Cl(2\text{-}ClC_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**3b**) by activation of a C–Br or a C–Cl bond, respectively, was achieved. Such processes have been reported for analogous ligands derived from benzylamine [9, 10] or *N*,*N*-dimethylethylenediamine [13–15] and, in all cases, a *fac*-PtC_3 stereochemistry is adopted which makes the octahedrally coordinated platinum(IV) a chiral center. As ligands **2** are optically active, platinum (IV) compounds **3a** and **3b** consist of a mixture of two diastereomers (*C*,*S*) and (*A*,*S*), in which *C*/*A* represents the absolute stereochemistry (clockwise and anticlockwise) [16] at the platinum and *S* describes the chirality at carbon. The reaction of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with imine $C_6F_5CH{=}N\text{-}(S)\text{-}CHMePh$ (**2c**) gave a complex mixture which could not be identified.

The reactions of compounds **3a** and **3b** with triphenylphosphine yielded cyclometallated platinum(IV) compounds $[PtMe_2Br(C_6H_4CH{=}N\text{-}(S)\text{-}CHMePh)(PPh_3)]$ (**4a**), and $[PtMe_2Cl(2\text{-}ClC_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(PPh_3)]$ (**4b**).

Although compound $[PtMe_2F(C_6F_4CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**3c**) could not be obtained in a pure form from the reaction of **1** with imine $C_6F_5CH{=}N\text{-}(S)\text{-}CHMePh$ (**2c**), addition of PPh_3 to the reaction mixture gave $[PtMe_2F(C_6F_4CH{=}N\text{-}(S)\text{-}CHMePh)(PPh_3)]$ (**4c**). Activation of a C–F bond has been confirmed by NMR spectroscopy.

Imines **2d** and **2e** yielded cyclometallated platinum (II) compounds $[PtMe(2\text{-}FC_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**5d**) and $[PtMe(2\text{-}CF_3C_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**5e**), respectively, by C–H bond activation with loss of methane. The reaction of compounds **5d** and **5e** with one equivalent of triphenylphosphine in acetone yielded cyclometallated platinum(II) compounds $[PtMe(2\text{-}FC_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(PPh_3)]$ (**6d**) and $[PtMe(2\text{-}CF_3C_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(PPh_3)]$ (**6e**).

The reactions of **6d** and **6e** with methyl iodide were also studied. Oxidative addition of alkyl halides to square–planar platinum(II) complexes is well documented; in particular, studies concerning compounds $[PtMe_2(NN)]$ (where NN is a bidentate nitrogen donor ligand) have been reported and experimental evidence points to *trans* stereochemistry in the resulting platinum compounds [17–20]. Upon addition of an excess of methyl iodide to solutions of compounds **6** in acetone, the color of the solution faded and compounds $[PtMe_2I(2\text{-}FC_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**4d**) and $[PtMe_2I(2\text{-}CF_3C_6H_3CH{=}N\text{-}(S)\text{-}CHMePh)(SMe_2)]$ (**4e**) were isolated as a mixture of two diastereomers (*C*,*S*) and (*A*,*S*). Therefore, analogous results are obtained by intermolecular oxidative addition of methyl iodide to cyclometallated platinum(II) compounds and by intramolecular oxidative addition of C–Br, C–Cl or C–F bonds.

The NMR spectra of compounds **3** and **4** clearly revealed two diastereomers in nearly equal amounts. No epimerization was observed when the solution was left to stand. Attempts to separate the diastereomers by crystallization in several solvents were unsuccessful, which suggests similar solubility properties for both isomers.

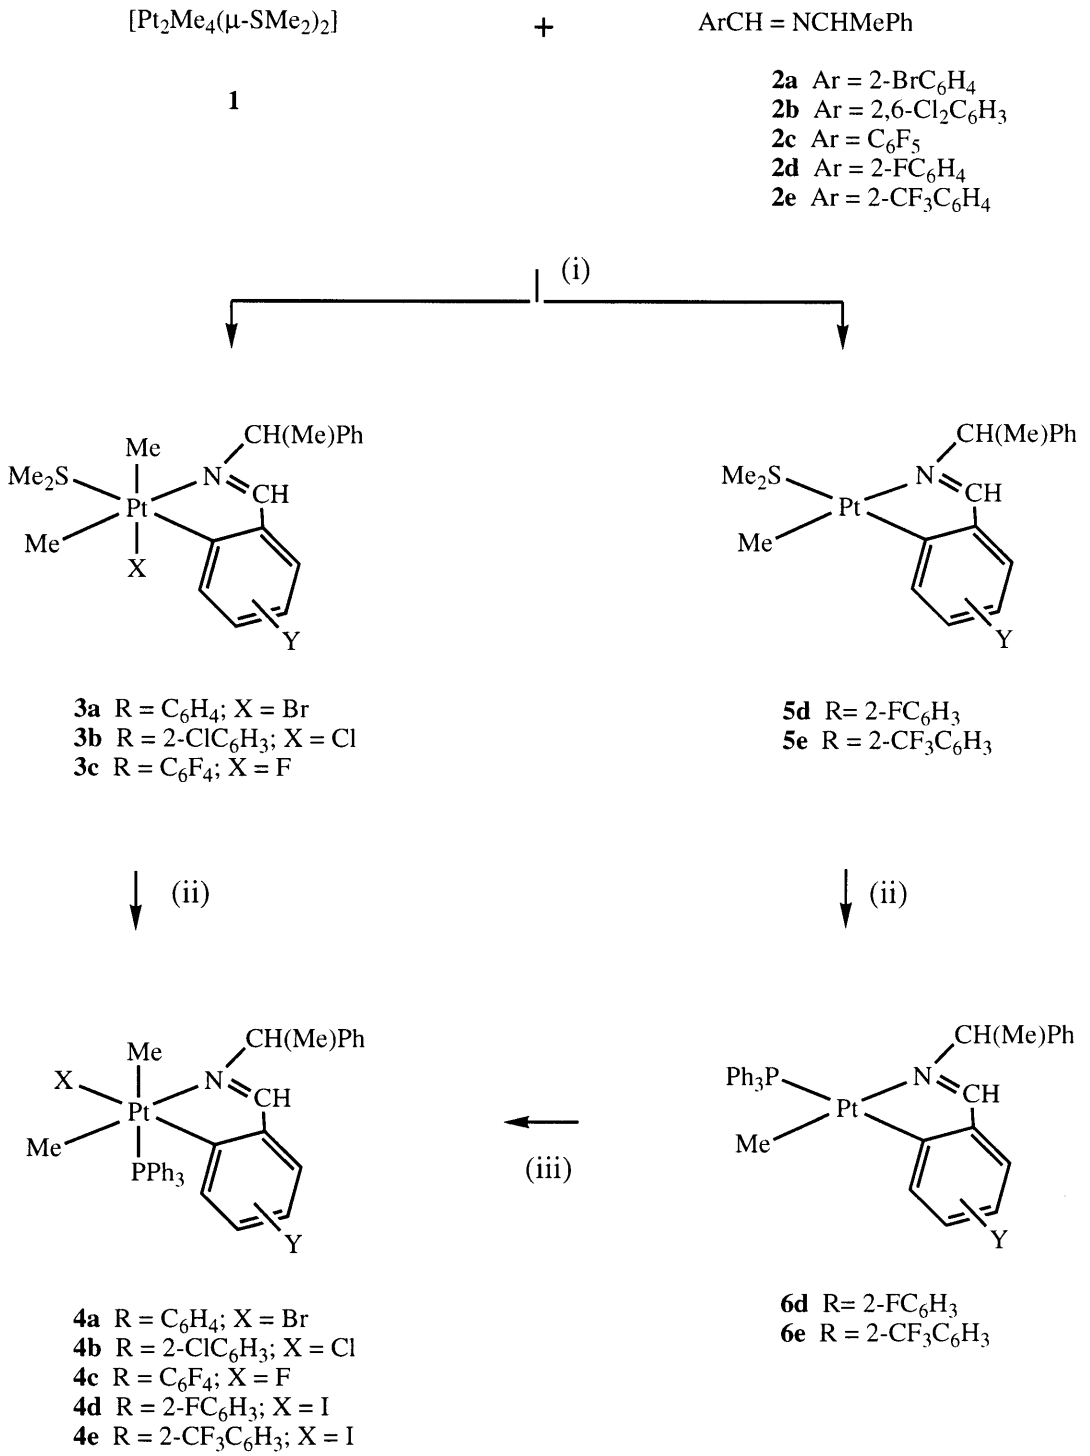
In the ^1H NMR spectra, two methylplatinum resonances, coupled to ^{195}Pt, appear for each isomer, as singlets for compounds **3**, and as doublets, due to coupling with one phosphorus atom, for compounds **4**. The small value for the coupling constant of the axial methyl with platinum suggest a *trans* arrangement of this group and the PPh_3 ligand, as previously reported for analogous compounds [21]. Relative proportions of the isomers, averaged from all the signals, are 1: 0.90 (**4a**), 1: 0.95 (**4b**), 1: 0.85 (**4c**), 1: 0.80 (**4d**) and 1: 0.85 (**4e**).

^{31}P NMR spectra of compounds **4** confirm the presence of two diastereomers since two signals appear, both coupled to ^{195}Pt. Similarly, two fluorine resonances appear in the ^{19}F NMR of compounds **4d** and **4e**. Moreover, in the ^{19}F NMR of **4c**, ten distinct resonances were observed, eight of them in the aromatic region and two at higher field (*ca.* −280 ppm, $J(FPt) = 195$ Hz, $J(FP) = 28$ Hz), which were assigned to platinum bound fluorine atoms, on the basis of previously reported data [10, 14]. A better diastereomeric peak separation (*ca.* 4 ppm) is observed for the F–Pt than for the aromatic fluorine (*ca.* 0.5 ppm) resonances.

In the ^1H NMR spectra of cyclometallated platinum(II) compounds, the resonance for the methylplatinum group appears as a singlet for compounds **5** and as a doublet, due to coupling with one phosphorus atom, for compounds **6**. In both cases, the value of J(Me–Pt) is larger than that obtained for compounds **3** and **4**, which is consistent with the corresponding oxidation states of platinum.

Compound **6d** was also characterized crystallographically. Suitable crystals were grown in acetone solution. The crystal structure is composed of discrete molecules separated by van der Waals interactions. The structure is shown in Fig. 1, and molecular dimensions are listed in Table 1. The platinum atom displays a tetrahedral distorted planar coordination and the following displacements (Å) are observed from the least-squares plane of the coordination sphere: Pt, 0.0338; P, −0.1107; N, 0.1039; C(3), −0.1425; C(16), 0.1155.

In contrast to the results reported for cyclopalladated analogues [22], the PPh_3 ligand and the aryl carbon occupy mutually *trans* positions. Thus, the tendency of phosphines to avoid coordinating *trans* to carbon donor ligands in palladium complexes [23] does not apply to platinum.



Scheme 1. (i) Acetone, room temperature, 16 h; (ii) $+PPh_3$ (1:1), acetone, room temperature; (iii) +MeI, acetone, room temperature, 2 h.

The metallacycle displays an envelope conformation with the N, C(1), C(2), C(3) moiety planar and the platinum atom displaced from the plane by −0.214 Å. The angle between the coordination plane and the planar metallacycle moiety is 11.29°. The angles between adjacent atoms in the coordination sphere of platinum lie in the range 79.9(2)–105.11(13)°, the smallest angles corresponding to the

metallacycle. Bond lengths in the coordination sphere of platinum are in the range reported for analogous cyclometallated platinum compounds [21, 24–27].

In conclusion, the results reported here show that intramolecular activation of C–X bonds of chiral imines at platinum gives either optically active cyclometallated platinum(II) compounds (X = H), or platinum(IV) compounds (X = F, Cl or Br). The latter, and

the products obtained upon oxidative addition to the platinum(II) compounds, as well as their phosphine derivatives, are formed as a pair of diastereomers in nearly equimolecular amounts.

EXPERIMENTAL

^1H, ^{31}P–$\{^1H\}$ and ^{19}F NMR spectra were recorded by using Varian Gemini 200 (^1H, 200 MHz), Bruker DRX-250 (^{31}P, 101.3 MHz), and Varian XL 300FT (^{19}F, 282.2 MHz) spectrometers, and referenced to $SiMe_4$ (^1H), H_3PO_4 (^{31}P), and $CFCl_3$ (^{19}F). δ values are given in ppm and J values in Hz. Microanalyses were performed by the Serveis Científico–Tècnics de la Universitat de Barcelona.

Preparation of the compounds

The complex $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) was prepared by the method reported in the literature [28].

Compounds **2** were prepared by the reaction of 5 mmol of the corresponding aldehyde ArCHO and the equimolar amount of (*S*)-α-methylbenzylamine in 25 mL of ethanol [29]. The mixture was refluxed for two hours and the solvent was removed in a rotary evaporator to yield imines **2a**–**2d** as yellow oils, which were used without any further purification.

2-*$BrC_6H_4CHNCHMePh$* (***2a***) Yield 1.2 g (83%). ^1H NMR ($CDCl_3$), δ = 1.60 [d, ^3J(HMe) = 6, Me], 4.62 [q, ^3J(HMe) = 6, CH*Me*], {7.25–7.57 [m, 8H], 8.11 [d, ^3J(HH) = 7, 1H], aromatics}, 8.74 [s, CH═N].

2,6-*$Cl_2C_6H_3CHNCHMePh$* (***2b***) Yield 1.0 g (72%). ^1H NMR ($CDCl_3$), δ = 1.65 [d, ^3J(HMe) = 7, Me], 4.62 [q, ^3J(HMe) = 7, CH*Me*], 7.10–7.50 [m, aromatics], 8.52 [s, CH═N].

$C_6F_5CHNCHMePh$ (***2c***) Yield 1.2 g (80%). ^1H NMR ($CDCl_3$), δ = 1.63 [d, ^3J(HMe) = 7, Me], 4.57 [q, ^3J(HMe) = 7, CH*Me*], {7.36–7.40 [m], aromatics}, 8.47 [s, CH═N]. ^{19}F NMR ($CDCl_3$), δ = −164.6 [m, F^a], −153.9 [m, F^c], −145.0 [m, F^b].

2-*$FC_6H_4CHNCHMePh$* (***2d***) Yield 1.0 g (89%). ^1H NMR ($CDCl_3$), δ = 1.59 [d, ^3J(HMe) = 7, Me], 4.60 [q, ^3J(HMe) = 7, CH*Me*], {7.05–7.46 [m, 8H], 8.08 [td, J(HH) = 8; 2, 1H], aromatics}, 8.71 [s, CH═N]. ^{19}F NMR ($CDCl_3$), δ = −122.96 [ddd, J(HF) = 13; 8; 5].

2-*$CF_3C_6H_4CHNCHMePh$* (***2e***) Yield 1.1 g (79%). ^1H NMR ($CDCl_3$), δ = 1.60 [d, ^3J(HMe) = 7, Me], 4.62 [q, ^3J(HMe) = 7, CH*Me*], {7.21–7.69 [m], 8.28 [d, 1H], aromatics}, 8.74 [q, J(H–F) = 3, 1H, CH═N]. ^{19}F NMR ($CDCl_3$), δ = −57.9 [s].

Compounds **3a**, **3b**, **5d** and **5e** were prepared by reaction of 100 mg (0.17 mmol) of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with 0.35 mmol of the corresponding imine in acetone (25 mL). The mixture was stirred for 16 h and the solvent was removed in a rotary evaporator. The oily residue was washed with hexane (3 × 5 mL) and dried *in vacuo*.

[*$PtMe_2Br(C_6H_4CHNCHMePh)(SMe_2)$*] (***3a***) Yield 150 mg (75%). ^1H NMR(acetone-d^6), isomer 1 (major): δ = 0.74 [s, ^2J(HPt) = 71, Me–Pt], 1.16 [s, ^2J(HPt) = 69, Me–Pt], 1.66 [s, ^3J(HPt) = 13, SMe_2], 8.61 [s, ^3J(HPt) = 48, CH═N]; isomer 2 (minor): δ = 0.97 [s, ^2J(HPt) = 71, Me], 1.19 [s, ^2J(HPt) = 69, Me], 1.75 [s, ^3J(HPt) = 13, SMe_2], 8.47 [s, ^3J(HPt) = 46, CH═N].

[*$PtMe_2Cl$*(2-*$ClC_6H_3CHNCHMePh$*)(*SMe_2*)] (***3b***) Yield 120 mg (61%). ^1H NMR(acetone-d^6), isomer 1 (major): δ = 0.97 [s, ^2J(HPt) = 70, Me–Pt], 1.19 [s, ^2J(HPt) = 68, Me–Pt], 1.90 [s, ^3J(HPt) = 15, SMe_2], 8.80 [s, ^3J(HPt) = 47, CH═N]; isomer 2 (minor): δ = 0.76 [s, ^2J(HPt) = 71, Me], 1.18 [s, ^2J(HPt) = 68, Me], 1.82 [s, ^3J(HPt) = 15, SMe_2], 8.89 [s, ^3J(HPt) = 48, CH═N].

[*PtMe*(2-*$FC_6H_3CHNCHMePH$*)(*SMe_2*)] (***5d***) Yield 150 mg (87%). ^1H NMR(acetone-d^6), δ = 0.87 [s, ^2J(HPt) = 83, Me–Pt], 1.75 [d, ^3J(H–Me) = 7, Me], 1.94 [s, ^3J(HPt) = 28, SMe_2], 5.54 [q, ^3J(H–Me) = 7, CH*Me*], {6.59 [m], 7.10–7.29 [m], aromatics}, 9.10 [s, ^3J(HPt) = 57, CH═N]. ^{19}F NMR ($CDCl_3$), δ = −113.93 [dd, J(FPt) = 60, J(HF) = 10; 6].

[*PtMe*(2-*$CF_3C_6H_3CHNCHMePh$*)(*SMe_2*)] (***5e***) Yield 160 mg (84%). ^1H NMR(acetone-d^6), δ = 0.90 [s, ^2J(HPt) = 82, Me–Pt], 1.77 [d, ^3J(HMe) = 7, Me], 1.98 [s, ^3J(HPt) = 28, SMe_2], 5.63 [q, ^3J(H–Me) = 7, CH*Me*], {7.35 [m], 7.90 [m], aromatics}, 9.11 [s, ^3J(HPt) = 59, CH═N]. ^{19}F NMR ($CDCl_3$), δ = −58.26 [s].

Compounds **4a** and **4b** were prepared by reaction of 50 mg of the corresponding compounds **3a** (0.064 mmol) and **3b** (0.065 mmol) with 17 mg (0.065 mmol) of PPh_3 in acetone (10 mL). Within one hour, the color of the solution faded and after addition of hexane, the yellow–white solid was collected by filtration, washed with hexane and dried *in vacuo*.

Compound **4c** was prepared by the reaction of 100 mg (0.17 mmol) of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with 104 mg (0.35 mmol) of imine **2c** in acetone (10 mL). The mixture was stirred for 5 h and 90 mg (0.35 mmol) of PPh_3 were added. After one hour, hexane (10 mL) was added and the resulting precipitate was collected by filtration, washed with hexane, and dried *in vacuo*.

[*$PtMe_2Br(C_6H_4CHNCHMePH)(PPh_3)$*] (***4a***) Yield 50 mg (74%). ^1H NMR(acetone-d^6), isomer 1 (major) δ = 0.56 [d, ^2J(HPt) = 60, ^3J(HP) = 8, Me–Pt], 1.32 [d, ^2J(HPt) = 70, ^3J(HP) = 7.5, Me–Pt], 1.08 [d, ^3J(HH) = 7, Me], 6.13 [q, CH*Me*], {6.46 [d, J(HPt) = 40, J(HH) = 7.5], 6.75 [t, J(HH) = 7.5], 6.99 [t, J(HH) = 7.5], aromatics}, 8.96 [s, ^3J(HPt) = 48, CH═N], isomer 2 (minor) δ = 1.10 [d, ^2J(HPt) = 58, ^3J(HP) = 7.5, Me–Pt], 1.42 [d, ^2J(HPt) = 69, ^3J(HP) = 8, Me–Pt], 1.85 [d, ^3J(HH) = 6.5, Me], 5.80 [q, J(HH) = 7, CH*Me*], {6.42 [d, J(HPt) = 40, J(HH) = 8], 6.68 [t, J(HH) = 7.5], 6.85 [t, J(HH) = 7.5], aromatics}, 7.93 [s, ^3J(HPt) = 48, CH═N]. ^{31}P NMR(acetone-d^6), isomer 1 (major) δ = −7.21 [s, ^1J(PPt) = 984], isomer 2 (minor) δ = −7.93 [s, ^1J(PPt) = 1019]. Anal. calc. for $C_{35}H_{35}BrNPPt$: C, 54.20; H, 4.55; N, 1.80. Found, C, 54.4; H, 4.7; N, 1.6%.

[*$PtMe_2Cl$*(2-*$ClC_6H_3CHNCHMePh$*)(*PPh_3*)] (***4b***)

Yield 50 mg (74%). ^{1}H NMR(acetone-d^6), isomer 1 (major) $\delta = 1.02$ [d, ^2J(HPt) = 60, ^3J(HP) = 8, Me–Pt], 1.34 [d, ^2J(HPt) = 69, ^3J(HP) = 8, Me–Pt], 1.90 [d, ^3J(HH) = 7, Me], 5.78 [q, J(HH) = 7, CH*Me*], {6.52 [d, J(HPt) = 40, J(HH) = 8], 6.70 [t, J(HH) = 7], 6.81 [d, J(HH) = 7.5], aromatics}, 9.12 [s, ^3J(HPt) = 50, CH═N], isomer 2 (minor) $\delta = 0.46$ [d, ^2J(HPt) = 60, ^3J(HP) = 8, Me–Pt], 1.25 [d, ^2J(HPt) = 68, ^3J(HP) = 8.5, Me–Pt], 1.17 [d, ^3J(HH) = 7, Me], 6.13 [q, J(HH) = 7, CH*Me*], {6.56 [d, J(HPt) = 40, J(HH) = 8], 6.74 [t, J(HH) = 8], 6.94 [d, J(HH) = 8], aromatics}, 8.26 [s, ^3J(HPt) = 51, CH═N]. ^{31}P NMR(acetone-d^6), isomer 1 (major) $\delta = -6.79$ [s, ^1J(PPt) = 1002], isomer 2 (minor) $\delta = -6.13$ [s, ^1J(PPt) = 978]. Anal. calc. for $C_{35}H_{34}Cl_2NPPt$: C, 54.90; H, 4.48; N, 1.83. Found, C, 54.6; H, 4.1; N, 1.7%.

[$PtMe_2F(C_6F_5CHNCHMePH)(PPh_3)$] (***4c***) Yield 140 mg (51%). ^{1}H NMR(acetone-d^6), isomer 1 (major) $\delta = 0.42$ [dd, ^2J(HPt) = 58, ^3J(HP) = 8, ^3J(HF) = 7, Me–Pt], 1.60 [q, ^2J(HPt) = 65, ^3J(HP) = J(HF^d = J(HF^e) = 8, Me–Pt], 1.21 [d, ^3J(HH) = 7, Me], 5.48 [q, J(HH) = 7, CH*Me*], 8.27 [s, ^3J(HPt) = 49, CH═N], isomer 2 (minor) $\delta = 1.01$ [dd, ^2J(HPt) = 58, ^3J(HP) = 8, ^3J(HF) = 7, Me–Pt], 1.72 [q, ^2J(HPt) = 67, ^3J(HP) = J(HF^d) = J(HF^e) = 8, Me–Pt], 1.86 [d, ^3J(HH) = 7, Me], 5.65 [q, J(HH) = 7, CH*Me*], 9.16 [s, ^3J(HPt) = 50, CH═N]. ^{19}F NMR($CDCl_3$), isomer 1 (major) $\delta = -144.0$ [t, J(F^{a}F^b) = J(F^{a}F^d) = 21, F^a]; −166.5 [t, J(F^{a}F^b) = J(F^{b}F^c) = 20, J(F^{b}Pt) = 15, F^b], −149.9 [t, J(F^{c}F^d) = J(F^{c}F^b) = 21, F^c], −128.7 [m, F^d], −279.8 [d, J(F^{e}P) = 28, J(F^{e}Pt) = 195, F^e], isomer 2 (minor) $\delta = -143.6$ [t, J(F^{a}F^b) = J(F^{a}F^d) = 21, F^a]; −166.1 [t, J(F^{a}F^b) = J(F^{b}F^c) = 20, J(F^{b}Pt) = 15, F^b], −149.4 [t, J(F^{b}F^c) = J(F^{c}F^d) = 21, F^c], −128.3 [m, F^d], −276.0 [d, J(F^{e}P) = 28, J(F^{e}Pt) = 195, F^e]. ^{31}P NMR(acetone-d^6), isomer 1 (major) $\delta = -0.48$ [d, ^1J(PPt) = 950, ^2J (PF) = 30], isomer 2 (minor) $\delta = 1.08$ [d, ^1J(PPt) = 975, ^2J(PF) = 29]. Anal. calc. for $C_{35}H_{31}F_5NPPt$: C, 53.43; H, 3.97; N, 1.78. Found, C, 52.9; H, 3.6; N, 1.6%.

Compounds **6d** and **6e** were prepared by reaction of 50 mg of the corresponding compounds **5d** (0.10 mmol) and **5e** (0.091 mmol) with 26 mg (0.10 mmol) of PPh_3 in acetone (10 mL). The mixture was stirred for two hours and the solvent was removed *in vacuo*. Upon addition of hexane (15 mL), the yellow–white solid was collected by filtration, washed with hexane (3 × 5 mL) and dried *in vacuo*.

[$PtMe$(2-$FC_6H_3CHNCHMePh$)(PPh_3)] (***6d***) Yield 60 mg (86%). ^{1}H NMR(acetone-d^6), $\delta = 0.71$ [d, ^2J(HPt) = 84, ^3J(HP) = 7, Me–Pt], 1.17 [d, ^3J(HH) = 7, Me], 4.55 [m, CH*Me*], {6.88 [m, 2H], 7.19 [m], 7.38 [m], 7.47 [m], 7.77 [m], aromatics}, 8.82 [s, ^3J(HPt) = 58, CH═N]. ^{19}F NMR ($CDCl_3$), $\delta = -114.02$ [ddd, J(FPt) = 46, J(HF) = 14; 5, J(FP) = 8]. ^{31}P NMR (acetone-d^6), $\delta = 32.10$ [s, ^1J(PPt) = 2231, J(FP) = 8]. squares method. Intensities were collected with graphite monochromatized MoKα radiation, using $\omega/2\theta$ scan-technique. 4428 reflections were measured in the range $2.22^\circ \leqslant \theta \leqslant 29.97^\circ$; 3934 were assumed as observed applying the condition $I > 2\sigma(I)$. Three reflections were measured every two hours as orientation and intensity controls; significant intensity decay was not observed. Lorentz polarization and absorption corrections were made. Further details are given in Table 2.

Structure solution and refinement

The structure was solved by Patterson synthesis, using SHELXS Computer Program [30], and refined by the full-matrix least-squares method, with the SHELX93 computer program [31]. The function minimized was $\Sigma w \| F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.1194P)^2]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$. f, f' and f'' were taken from international tables of X-ray crystallography [32]. The extinction coefficient was 0.0000(5). The chirality of the structure was defined from the Flack coefficient [33], which is equal to 0.001(9) for the given results. All hydrogen atoms were computed and refined with an overall isotropic temperature factor using a riding model. Further details are given in Table 2.

Catalysis of esterification reactions by oxo-molybdenum-alkoxides: X-ray structures of $Cl_2(O)Mo(\mu\text{-}^nPr)_2(\mu\text{-}HO^nPr)Mo(O)Cl_2$ and $Cl_2(O)Mo(\mu\text{-}OEt)_2(\mu_2\text{-}\eta^1\eta^1\text{-}HOCH_2CH_2OH)Mo(O)Cl_2$

(Received 19 January 1998; accepted 5 May 1998)

Abstract—The compound $Cl_2(O)Mo(\mu\text{-}OEt)_2(\mu\text{-}HOEt)Mo(O)Cl_2$, **1**, has been shown to catalyse esterification reactions. The reaction rates increase with decreasing acidity of the carboxylic acids employed. The steric effects observed are the same as in catalysis by Brønsted acids, but catalysis by **1** can also be applied in esterifications of protected amino acids. **1** is modified under the catalytic conditions yielding a species which coordinates and thereby activates the carboxylic acids in the rate-determining step. Subsequently an alkoxide ligand, probably originating in the coordination sphere of Mo centres, attacks the carboxylic centre producing the corresponding ester. Other oxo molybdenum(V) compounds do catalyse esterifications, too, but **1** is significantly more efficient as a precatalyst, even in comparison with closely related compounds, like $Cl_2(O)Mo(\mu\text{-}OEt)_2(\mu_2\text{-}\eta^1\eta^1\text{-}HOCH_2CH_2OH)Mo(O)Cl_2$, **4**, in which the labile EtOH bridge had been replaced by $HOCH_2CH_2OH$. The crystal structures of the compounds **4** and $Cl_2(O)Mo(\mu\text{-}O^nPr)_2(\mu\text{-}HO^nPr)Mo(O)Cl_2$, **2**, which possesses a propanol bridge, are discussed. © 1998 Elsevier Science Ltd. Keywords: catalysis; molybdenum oxides; alkoxides; esterification; alcohol bridge; binuclear complexes

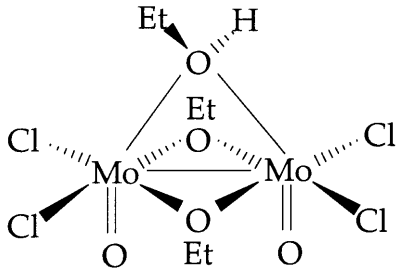
INTRODUCTION

Studies involving transition-metal alkoxides have become an integral part of inorganic and organometallic chemistry [1–8]. Oxo-alkoxides of metals obviously constitute an interesting series of intermediates between alkoxides and oxides of metals [9]. Concerted efforts initiated to elucidate the basic chemistry of the manifold applications of oxo-alkoxides are enhancing the efficacy of such applications [10, 11].

While exploiting the chemistry of the molybdenum-oxo-alkoxide **1** we found that this complex with the unusual ethanol bridge spanning two molybdenum centres catalyses esterification reactions [12].

Usually such reactions are promoted by Brønsted acids catalysing forward and backward reaction by activating the carbonyl group. However, there are cases in which acid catalysis cannot be applied because of the sensitivity of the particular substrates (like protected amino acids, for instance) to protonic attack. Consequently stoichiometric reagents are employed then to achieve esterification [13].



1

* Author to whom correspondence should be addressed.

Bearing these problems in mind we were interested in determining the scope of applicability of **1** in esterifications and the mechanism of action to see whether it can act as a general catalyst for such reactions. The results of this investigation are presented below.

EXPERIMENTAL

All manipulations were carried out with a vacuum line (at a background pressure $< 10^{-4}$ mbar) or else, in a glove-box, or by means of Schlenk-type techniques involving the use of a dry argon atmosphere. Solvents were dried according to standard procedures; microanalyses were performed by the Analytische Laboratorien des Organisch-Chemischen Institutes der Universität Heidelberg. IR spectra were recorded with a Bruker IFS 66 FT IR spectrometer. ^{1}H NMR spectra of solutions were recorded using a Bruker AC 200 instrument operating at 200 MHz. The X-ray diffraction measurements were made on single crystals on a Siemens P4 R3m/V four-circle diffractometer with graphite-monochromated Mo-Kα radiation. **1** was produced by the published procedure [12]. $MgSO_4$ had been dried by heating to 80°C under continuous pumping overnight.

Single crystal structures of $2{\cdot}^n PrOH$ *and* $4{\cdot}(C_2H_5)_2O{\cdot}0.75\ EtOH$

Crystals of **2** and **4** grown by cooling of dichloromethane and diethylether solutions, respectively, were suspended in an oil in the glove box, quickly selected under the microscope, loaded on top of a fibre and frozen to 200 K.

In the case of **2**, 4031 reflections were measured ($\theta_{max} = 50.2°$); all unique. 3069 reflections with $I > 2\sigma(I)$ were used in all calculations. The structure was solved by direct methods and refined by full-matrix least-squares procedures based on F^2, SHELXL-97 [14], with anisotropic thermal parameters for all non-hydrogen atoms apart from the C8 and C9 atoms of the disordered PrOH bridge and the C atoms of the disordered solvent molecule (PrOH) included in the cell. All hydrogen atoms were calculated by the use of a riding model. The final difference synthesis maximum and minimum were 1.094 and -1.014 eÅ^{-3}, respectively.

In the case of **4**, 5552 reflections were measured ($\theta_{max} = 50.1°$); 5207 unique. $R_{int} = 0.0679$, 2907 reflections with $I > 2\sigma(I)$ were used in all calculations. The structure was solved by direct methods and refined by full-matrix least-squares procedures based on F^2, SHELXL-97 [14] with anisotropic thermal parameters for all non-hydrogen atoms apart from those of the solvent molecules. All hydrogen atoms were calculated by the use of a riding model. The final difference synthesis maximum and minimum were 1.357 and -0.829 eÅ^{-3}, respectively. The crystallographic data for $\mathbf{2}{\cdot}^n$PrOH and $4{\cdot}(C_2H_5)_2O{\cdot}0.75$EtOH are given in Table 1.

Catalytic esterifications In general the carboxylic acid (typically 0.02 mol) was dissolved under an argon atmosphere in an excess of freshly distilled alcohol in a Schlenk-tube. Two spatulas of dry $MgSO_4$ were

added and the suspension heated to 80°C for 2 h under stirring (the Schlenk tube was sealed by means of a pressure-relief valve). Subsequently, after cooling of the mixture to room temperature 1 mol.% of **1**, weighted out and loaded into a separate vessel in a glove box, were added in a stream of argon and the mixture heated for another 4 h. After filtering the volatiles were removed under vacuum and the residue investigated ^{1}H NMR spectroscopically. The ratios of the integrals of selected signals of acids and esters gave the yields of the corresponding esterification.

In the cross experiment 1.50 g (0.011 mol) of phenyl acetic acid, 2.35 g (0.011 mol) of diphenyl acetic acid, 1.02 g (0.022 mol) of ethanol and 1.33 g (0.022 mol) of isopropanol were dissolved in toluene and heated to 80°C for 4 h in the presence of $MgSO_4$ and **1** ($2{\cdot}10^{-4}$ mol). After the reaction a 1 N NaOH solution was added and the esters extracted by diethylether. After filtering over basic alox the ester solution was investigated by GC/MS measurements.

The experiments under variation of the ethanol concentration were performed in CH_2Cl_2 solutions in flame-sealed glass tubes. When the ratio of employed phenyl acetic acid and ethanol was increased to 1 the yield with respect to the ester was still 85% (compare the yield of 90% obtained in ethanol as the solvent).

Synthesis of ***2*** 2 g ($4{\cdot}10^{-3}$ mol) of **1** were dissolved in freshly distilled *n*-propanol and heated to 80°C for 4 h. After removal of the volatiles an orange solid was obtained which was crystallised from CH_2Cl_2 and proved to consist of **2**·^{n}PrOH by comparison with the published data [15]. On prolonged pumping the crystals loose their solvent and become amorphous.

Reaction of ***1*** *with acetic acid* 0.59 g ($1.19{\cdot}10^{-3}$ mol) of **1** was dissolved in dry acetic acid [1.44 g (0.024 mol)] and heated to 80°C for 4 h in the presence of $MgSO_4$. Afterwards all volatiles were distilled off the solids and investigated NMR spectroscopically.

Synthesis of ***4*** 1.00 g ($1.9{\cdot}10^{-3}$ mol) of **1** were loaded into a Schlenk tube in a glove box, dissolved in toluene and reacted with freshly distilled ethylene glycol [0.11 ml (0.0019 mol)] introduced into the tube via a syringe. A dark brown viscous oil and an orange solid precipitated which were separated from each other by decanting the suspension from the oil. The solid was filtered off the solution and dried under vacuum. After drying of the solid it is only marginally soluble in pure diethylether, while the solubility of the freshly filtered solid is high enough (because of the EtOH included) to recrystallise it from ether. Yield: 47%; $C_6H_{16}Cl_4Mo_2O_6$ M = 517.89 g/mol; found: C, 13.76; H, 3.06; Cl, 26.21; Mo, 38.17%; calc.: C, 13.91; H, 3.09; Cl, 27.38; Mo, 37.00%; IR ν/cm^{-1}: 3410m, 2974w, 2955w, 1438s, 1362w, 1352s, 1262w, 1000vs, 890vs, 870sh, 540s, 530s (KBr).

IR solution studies A solution of the acid (0.5 mmol) in 15 ml CH_2Cl_2 was prepared in a high pressure tube equipped with a teflon valve, which already contained an excess of $MgSO_4$. After recording of an IR spectrum of the solution in a cell furnished by NaCl windows equimolar amounts of **1** were added. Again a sample was investigated IR spectroscopically and subsequently the whole reaction vessel was heated to 80°C for 1 h. After cooling a further IR spectrum was recorded.

RESULTS AND DISCUSSION

First it was important to employ carboxylic acids with varying acidities and sterical demands in order to compare their yields in the esterification reactions catalysed by **1**. Since each reaction was stopped after 4 h, although the yields could have been improved on further reaction time, accordingly not really yields rather than reaction rates are considered. To guarantee comparability of the results a standard procedure was established being applicable to most of the acids investigated.

Electronic and steric effects

To study the influence of the electronic properties of the acids on the esterification yield, derivatives of acetic acid were reacted with ethanol at 80°C. Acetic acid itself ($K_s = 1.7{\cdot}10^{-5}$) [16] is quantitatively converted into ethyl acetate during the 4 h reaction time while the yield decreases to 90% on substitution of one H atom by phenyl (phenyl acetic acid has a K_s of $4.9{\cdot}10^{-5}$) [16] and to 80% on substitution by 4-nitrophenyl (4-nitro phenyl acetic acid has a K_s of $14.1{\cdot}10^{-5}$) [16]. This makes quite clear that electronic effects do not have a great influence on the reaction rates. However, the effect observed is inverse to the one found for protonic catalysis: the weaker the acid, the faster it can be converted into the corresponding ester. Provided that the catalysis proceeds via activation of the carbonyl groups by coordination to Mo centres this finding must be related to the coordination properties of carboxylic acids or the corresponding carboxylates with respect to hard oxo-molybdenum(V) centres in dependence on their acidity, as discussed later.

In the next step alcohols and carboxylic acids with varying sterical demands were employed. Table 2 shows the yields obtained in esterification reactions of carboxylic acids with varying degrees of substitution at the α-carbon using ethanol as the reagent. From those it can be deduced that, as expected, the reaction rates decrease drastically when the bulk near to the carboxylic group is increased. If in the esterification of phenyl acetic acid ethanol is replaced by *i*-propanol the yield decreases from 90 to 30% while no reaction occurs on employment of *t*-butanol confirming that the sterical demand of the alcohols is relevant to the reaction rates, too.

Surprisingly, no derivative of benzoic acid could be converted into the corresponding ester (no detectable quantities were produced) via catalysis with **1**. Steric reasons for this finding are not obvious since even

adamantanoic acid with its highly branched α-C atom could be esterificated in 39% yield. However, neither electronic effects can be made responsible since all derivatives tried also failed to react, independently of the K_s values (4-nitro-, 3,4-dihydroxy-, 4-methyl-, 4-methoxy-, 4-aminobenzoic acid as well as benzoic acid itself were employed spanning a K_s range of $36 \cdot 10^{-5}$–$1.4 \cdot 10^{-5}$ [16, 18]; compare the K_s values of the acids which had successfully been reacted before). This raised the question of whether such compounds deactivate **1** as a catalyst and suggested a further experiment: an attempt was made to catalyse the esterification of phenylacetic acid by ethanol in the presence of **1** *and* benzoic acid. Indeed the yield decreased from 90 to 54% which means that benzoic acid coordinates strongly (though reversibly) to the catalyst but it cannot be esterificated for unknown reasons thereby deactivating the catalyst. Any explanation probably involves a very special property of benzoic acid derivatives like for instance the hindered rotation of the aryl residue in order not to loose favourable resonance providing such acids with a very special "steric bulk" in comparison to acids like adamantanoic acid. It is not obvious, however, how this should come into play during esterification without knowing the detailed mechanism and the catalytically active species.

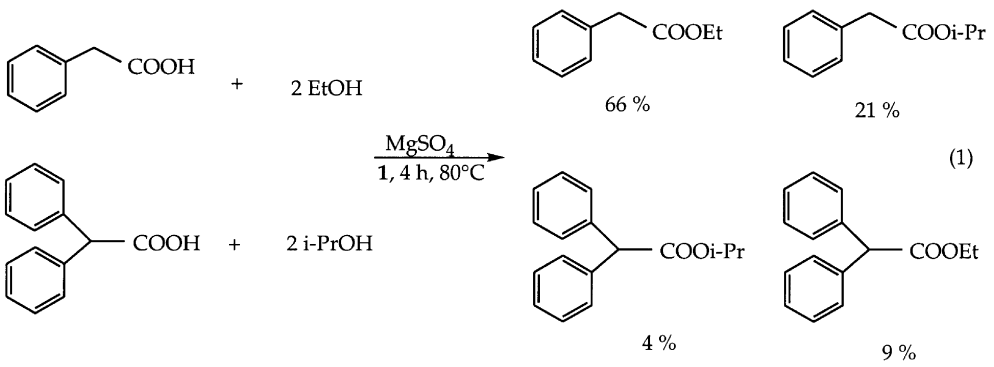
Activation of the carboxylic function

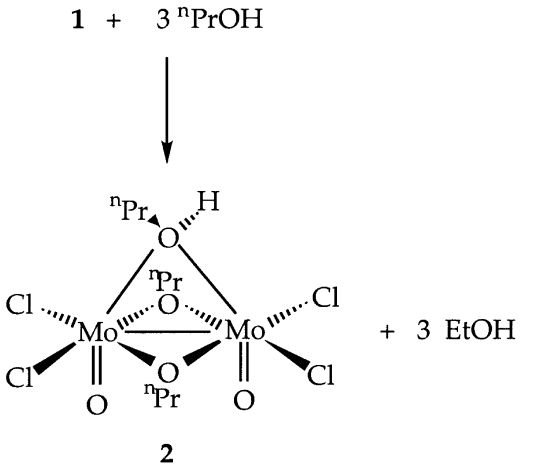
In order to explain some of the peculiarities described above it was important to obtain more detailed information concerning the individual steps of this catalytic esterification. Assumed that the acid or its conjugated base coordinates to the catalyst first and subsequently reacts with the alcohol employed (producing the ester which dissociates subsequently), the question of which step should be assigned as being the rate determining one arises. To decide between the two possibilities an experiment was performed in which two different acids and two different alcohols were present in the reaction mixture. The reagents chosen differed in their sterical demands, the acids additionally in their K_s values.

As a result four different esters were obtained whose relative yields, as shown in eq. (1), were determined by means of GC/MS measurements. They strongly suggest that the coordination of the acid is indeed the rate determining step: $PhCH_2C(O)O^iPr$ and Ph_2CH-C(O)OEt are formed in 21 and 9% yield, respectively, although the ethyl ester should have been formed predominantly in comparison to the *i*-propyl ester according to the results shown in Table 2 and under the assumption that both esters have the same chance to get esterificated by one alcohol or another [19]. Additional support for this conclusion comes from experiments under variation of the ethanol concentration in the esterification of $PhCH_2COOH$: lowering of the alcohol/acid ratio from an alcohol excess to a 1:1 ratio had only a small effect on the esterification rate, consistent with a fast reaction of the alcohol.

Alkoxide transfer and exchange; crystal structure of $Cl_2(O)Mo(\mu\text{-}O^nPr)_2(\mu\text{-}HO^nPr)Mo(O)Cl_2$, ***2***

The question remains, whether the alcohol reacts directly with the activated carboxylic acid or with the catalyst which then acts as an alkoxide transfer mediator. The Mo–OH functions resulting from such a reaction would then be replaced by alcoholate ligands via reaction with the corresponding alcohols and the water produced trapped by the $MgSO_4$ added. A first hint to an intramolecular alkoxide transfer gives the fact that on heating of preparative amounts of **1** with an excess of acetic acid 80% of its alkoxide/alcohol ligands are found in form of ester functions after the reaction. In addition the ethanol and ethoxide ligands in **1** proved to be easily exchangeable by other alcoholate ligands. Heating of **1** in *n*-propanol to 80°C for 4 h exclusively yields the *n*-propoxy derivative of **1**, **2** [15] (compare eq. (2)).





(2)

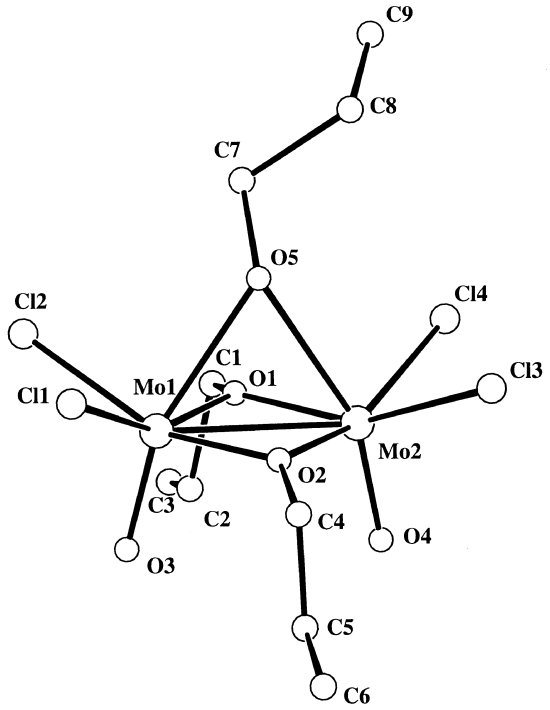


Fig. 1. The molecular structure of **2**; all protons have been omitted in the interest of clarity.

Single crystals of **2** were investigated by X-ray diffraction yielding the structure shown in Fig. 1. The orthorhombic cell contains 8 molecules of **2** each of which forms a hydrogen bond via a hydrogen of the bridging ^{n}PrOH to a solvated PrOH molecule (not shown in Fig. 1). Selected bond distances and angles are listed in Table 3. **2** consists of two O=$MoCl_2$ units bridged by two propoxy groups and one propanol molecule. The Mo(μ-O^{n}Pr)$_2$Mo moiety contains a planar Mo_2O_2 heterocycle. Each Mo atom is therefore placed in a distorted octahedral environment. While the metal atoms are formally in the +5 oxidation state (d^1) the diamagnetism of the complex implies that the two d electrons form a Mo–Mo single bond (d(Mo–Mo) = 2.6760(8) Å). As **1**, **2** contains an unusual bridging alcohol unit. The Mo–O(μ-HO^{n}Pr) bond lengths [2.413(4), 2.435(4) Å] are 0.41 Å larger than the average Mo–O(μ-O^{n}Pr) length [2.006(4) Å] while being only lightly shorter than those found in **1** for Mo–O(μ-EtOH) [2.48(2) Å]. All other bond lengths and angles compare well with those of **1**.

*Applications for **1** as a precatalyst in esterifications*

After the investigations described above had provided an idea of the functioning of the catalyst, attempts were made to employ **1** in esterifications which are more difficult to perform experimentally, i.e. those of substances which are sensitive to Brønsted acids. Protected amino acids of the type S–NR–CH_2COOH (S = protecting group) belong to this class of substances, since the S–N bonds are cleaved in an acidic milieu. Consequently, in order to achieve their esterification, which can be very important to (i) mask acidic protons, (ii) protect the carboxylic group against nucleophilic attack, (iii) vary their solubility and volatility or (iv) protect the carboxylic group with regard to reduction, stoichiometric condensing or alkoxylating reagents have to be used [13]. Dicyclohexylcarbodiimide and BOP–Cl/NEt_3 belong to the first category while $Me_2NCH(OR')_2$ is an effective alkoxide transfer reagent. However, none of these procedures is as simple as the catalysis by protons producing water as the only side product. Accordingly it was attempted to *catalytically* convert such acids into the corresponding esters using **1**. The amino acids

Table 2. Catalytical esterifications of carboxylic acids (RCOOH) with varying degrees of substitution at the α-carbon atoms by alcohols (R′OH). The yields shown have been obtained after 4 h at 80°C in the presence of **1**

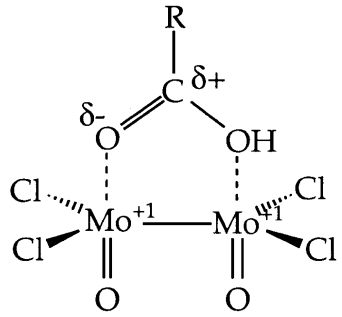
shown in Table 4 were reacted with EtOH in the presence of catalytic amounts of **1** under the usual conditions. As can be seen, these experiments were successful although the yields obtained after 4 h reaction time varied drastically from case to case. Since the K_s values of these carboxylic acids as their steric demands are expected to be quite similar, the reasons for the differing yields are not quite clear. One possibility would be a concurrence of the N-atoms in the complexation reaction of the carboxylic functions to the catalyst in dependence on the electronic conditions of the groups S.

The catalytically active species

In order to obtain more detailed information about the reasons for the substrate selectivity observed and the functioning of the catalyst the next point which had to be addressed was the characterisation of the catalytically active species in solution. Considering the chemical properties of **1** [20, 21] it cannot be expected that this compound is more than a precatalyst being modified in the presence of carboxylic acids under the reaction conditions. In fact it is not possible to isolate **1** back after the catalysis. If not catalytic rather than preparative amounts of **1** are employed in esterifications, after removal of all volatiles brown oils are obtained showing a Mo/Cl ratio of 1/2 according to elemental analysis. This finding rules out the possibility that the observed catalytic activity is merely a result of protonation of **1** by the acids, thereby delivering HCl which is responsible for catalysing the esterification. In addition the latter would also be contradictory to the fact that protected amino acids could and benzoic acid could not be converted into the corresponding ester in the presence of **1**. The observation that no colour change from orange to green can be observed during the esterification suggests (not proves though) that the metal–metal bond remains intact during the reaction [22]. Therefore an intermediate with the metal fragment shown below is imaginable, the carboxylic acid being activated in the rate-determining step by coordination to the two metal centres located in close proximity.

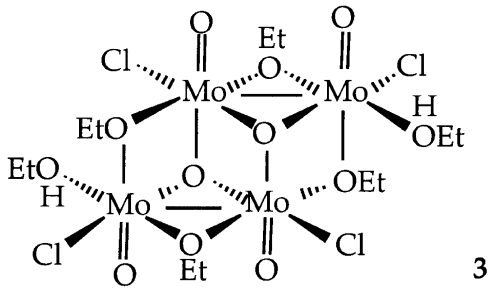


There is a precedent case [23] where such a coordination mode has been proved by X-ray crystallography and if this was relevant to the present case, too, the success of catalysis would be linked to

Table 4. Esterification catalysis of protected amino acids by EtOH in the presence of **1**. The yields shown have been obtained after 4 h at 80°C

S–NR–CH_2–COOH	S–N–R = phthaloyl	25% yield
	S = tosyl; R = H	100% yield
	S = acetyl; R = H	27% yield
	S = *t*-butyl oxycarbonyl; R = H	100% yield

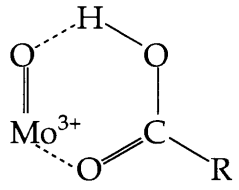
the availability of a binuclear Lewis acidic species with free coordination sites (or labile ligands). To test this hypothesis the reaction of phenylacetic acid with ethanol was performed in the presence of catalytical amounts of the compound $PPN^+NEt_3H^+$ $[Cl_2(O)Mo(\mu_2\text{-}O)_2Mo(O)Cl_2]^{2-}$ [20] whose anion possesses two Mo(V) centres with free coordination sites. However, the esterification yield was only 29%, probably because of the lower lewis acidity of the metal centres as compared to those of the catalyst generated from **1** (note that $[Cl_2(O)Mo(\mu_2\text{-}O)_2Mo(O)Cl_2]^{2-}$ is stable inspite of vacant coordination sites, probably because of electron donation by the O bridges, while it is not possible to remove EtOH from **1** without simultaneously inducing aggregation processes [20, 21]). To further study the modification of **1** under the catalytic conditions several experiments were carried out in which **1** was reacted with equimolar amounts of carboxylic acids under standard conditions (EtOH (exc.), 80°C). By isolation and characterisation of the resulting molybdenum complexes it was hoped to get hints to the catalytically active species in solution. Removal of the volatiles after such experiments, however, yielded in most cases insoluble oils which could naturally not be investigated as thoroughly as necessary to derive definite conclusions. In the case of tosyl glycine a red brown oil was obtained which was soluble in diethyl ether. After cooling of such a solution to −25°C the resulting red solid could be identified as **3**, which had previously been isolated after the reaction of **1** with PMe_3 [20, 21].



3

Since **3** had been produced under the conditions of the catalysis (it is not formed if **1** is just heated to 80°C for 4 h) it was tempting to consider this compound, at least in the case of tosyl glycine, as the catalyst in question being furnished with two labile EtOH ligands suitable to provide free coordination sites. To probe this suggestion **3** itself was tested as a catalyst in esterification reactions under the conditions as described above. The standard reagent, phenylacetic acid, could be converted into the corresponding ethyl ester in 55% yield. From this finding it can be concluded that indeed **3** has the right properties to act as a catalyst in esterification reactions (*vide supra*) but that it is probably not the active species in catalyses with **1** since there the yield was much higher. From the fact that **3** is not capable of coordinating a carboxylic acid as shown above for a binuclear species it follows that a binuclear coordination is not a necessary condition for this type of catalysis and that appropriate electronic conditions on Mo oxo centres in combination with free coordination sites are probably sufficient to provide the corresponding compounds with some catalytic activity.

However, **3** cannot be the sole compound resulting from **1** under catalytic conditions since, as mentioned above, in the raw non-volatile material isolated after such reactions the Mo/Cl ratio still amounts to 1/2. Therefore, if **3** (with a Mo/Cl ratio of 1) is formed, a product with a higher content in Cl must be generated, too. This led us to investigate the catalytic properties of $O{=}MoCl_3(PMe_3)(O{=}PMe_3)$ [21] in the esterification of phenylacetic acid with ethanol, which were yet again less pronounced (50% yield) as compared to those of the species resulting from **1**. In summary, the latter was superior to all model compounds tried with respect to catalytic activity and therefore seems to have special advantageous qualities. Regardless, the above investigation has shown so far that activation of the carboxylic function can be achieved making use of just one Mo=O centre with the right properties (electronically and coordinatively) and that the alkoxy ligands found in the esters after the reactions are probably mediated by such centres, too. Accordingly the rate determining step, the coordination of carboxylic acids to Mo=O centres, might proceed under formation of a favourable 6-membered ring as shown below decomposing again on intra-



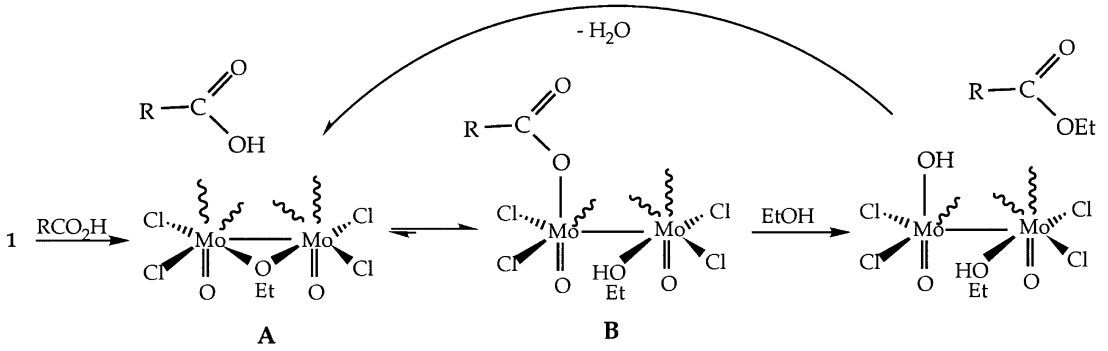
molecular attack of an alkoxy ligand. The ester thereby produced is not able to coordinate in this fashion and therefore leaves the Mo centre making room for a new acid molecule. In an attempt to obtain direct information about the stage *preceeding* this rate determining step, i.e. the interaction of the carboxylic functions with **1** producing the catalytically active species, IR solution studies were performed. Equimolar amounts of **1** and acetic acid/benzoic acid/*p*-nitro-phenylacetic acid were reacted at room temperature in CH_2Cl_2 solution.

Acetic acid Addition of **1** to a CH_2Cl_2 solution of acetic acid causes the ν(C=O) bands of the solution IR spectrum belonging to the free acid to decrease by *ca.* 90%. Apart from new bands belonging to the alkoxide groups of the oxomolybdenum alkoxide species resulting from **1** new features can be noticed

at 1659 and 1630 cm^{-1}. These could have their origins in a η^1-O–C(Me)=O ligand (the corresponding ν_s modes being masked by the bands of alkoxide ligands; a broad band at 1404 cm^{-1} can be observed in form of a shoulder) being formed by addition of the carboxylic OH group to a Mo–μ-OEt bond, the EtOH thereby delivered remaining coordinated. Heating of this mixture to 80°C for 1 h caused no spectral change. However, heating for 0.5 h after addition of two equivalents of EtOH resulted in the formation of free acid (proving that the corresponding complex coexists with free acetic acid in an equilibrium) as well as ethyl acetate. Further heating for 2 h lead to a complete conversion to ethyl acetate. If a 1:1 mixture of **1** and acetic acid is heated in pure EtOH after the removal of all volatiles and redissolution of the residue in dichloromethane an IR spectrum is obtained which is basically identical with the one displayed by **1** at least in the region 900–1900 cm^{-1}. No bands belonging to carboxylate ligands or acids can be detected anymore.

Benzoic acid As in the case of acetic acid on addition of equimolar amounts of **1** to a solution of benzoic acid the ν(C=O) bands of the free acid decrease by *ca.* 90% while a band of medium intensity at 1607 cm^{-1} and a strong complex band centred at 1382 cm^{-1} (with a shoulder at 1410 cm^{-1}) appear. These could be due to ν_s and ν_{as} of a carboxylate ligand and their large separation strongly supports a η^1-O–C(Ph)=O coordination mode [24, 25] of the latter being formed by addition of the OH group of benzoic acid to a Mo–μ-OEt–Mo unit yielding Ph(O)C–O–Mo–Mo–O(H)Et entities (no formation of free EtOH is observed). As above no spectral change is observed upon heating. On isolation of the species a ^{13}C NMR spectrum shows signals for at least four different CH_3CH_2O-groups but for only one benzoate ligand. This is in contrast to the IR spectra which seemed to support the existence of more than one benzoate group. An explanation should be sought in very fast exchange, rearrangement or isomerisation processes which can only be detected on the time scale of the IR spectroscopy. Such processes are not unusual for alkoxide compounds [1–8]. If two equivalents of EtOH are added to a 1:1 mixture of the acid and **1** the bands attributed to the η^1-O–C(Ph)=O ligands decrease somewhat in favour of bands belonging to free acid as well as two new bands which probably have their origin in an η^2-O–C(Ph)=O ligand as indicated by their frequency separation [24, 25] (1525 and 1415 cm^{-1}). In contrast to the acetic acid experiment (*vide supra*) and in agreement with the results of the catalysis experiments the IR spectrum of this mixture remained unchanged after heating to 80°C for 1 h.

p-*Nitrophenylacetic acid* In order to determine the effect of acidity on the observations as outlined above a third acid, *p*-nitrophenylacetic acid, was employed which has a higher K_s value ($14.1 \cdot 10^{-5}$) than both benzoic acid ($6.3 \cdot 10^{-5}$) and acetic acid ($1.75 \cdot 10^{-5}$) but which, in contrast to benzoic acid, can be esterificated in 80% yield under standard conditions. Indeed, also in this case a sharp decrease of the ν(C=O) bands could be observed while, as for benzoic acid, new bands at 1624 (m), 1444 (w), 1410 (sh) and 1383 (s) appeared. The carboxylate regions of the IR spectra are very similar in the cases of *p*-nitrophenylacetic and benzoic acid.



These results have to be interpreted as follows (compare eq. (3)): the IR spectra discussed above belong to the catalytically active species, which can be isolated and probably consists of a complex oxo molybdenum alkoxide **B** (with at least four magnetically different alkoxide groups) containing η^1-O–C(R)=O ligands according to the IR spectra. Addition of a further equivalent of the acid in the cases of benzoic and *p*-nitrophenylacetic acid did not lead to a significant alteration of the IR spectra (the additional equivalent is not consumed) so that the species under discussion is formed via a 1:1 reaction between **1** and the carboxylic acids. All acids react the same way and to the same extent in the first step independently of their acidities, just in the case of acetic acid a species with a further type of carboxylate ligand seems to be present in the equilibrium as indicated by an

additional weak band at 1659 cm^{-1}. Since the reactions between **1** and carboxylic acids are almost quantitative already at r.t. the rate determining step still has to follow. The latter involves either a change in coordination mode of the carboxylate ligands or the intermediate coordination of further acid molecules (possibly of the type as shown above) at higher temperatures being followed by a rapid conversion into the corresponding ester by alkoxide or alcohol ligands in close proximity. The fact that species **B** behaves inert at 80°C in the case of acetic acid but decomposes under formation of the ethylester when EtOH or excess of acid (compare with Section 3.3) had been added previous to heating suggests that its reactivity depends on the presence of donor ligands which can occupy free coordination sites generated by ester formation. The alkoxide transfer step does not seem to be possible in the case of benzoic acid derivatives for one reason or another. Any attempt to give reasons for this finding (compare with Section 3.1), however, would be purely speculative without knowing the constitution of the corresponding Mo-species **B** in solution and is therefore avoided here. **B** had an oily consistence after isolation in all cases and was insoluble when amino acids had been employed as the reagents. In cases where **B** showed sufficient solubility to enable a spectroscopic investigation in solution the available spectroscopic data naturally did not allow to draw conclusions about its constitution (due to its complex nature and constitution).

*Modification of **1**; crystal structure of* $Cl_2(O)Mo(\mu\text{-}OEt)_2(\mu_2\text{-}\eta^1\eta^1\text{-}HOCH_2CH_2OH)Mo(O)Cl_2$, ***4***

Although representing an efficient precatalyst, employment of **1** as such is hampered by its high sensitivity to atmospheric water. Therefore attempts were made to modify this compound with respect to an easier handling. The most labile part of the molecule is the weak ethanol bridge spanning the two Mo centres. Removal of this bridge is the primary step in most of the reactions of **1** [20, 21]. This suggested experiments to stabilise the molecule via replacement of the ethanol by a bifunctional alcohol thereby making use of the chelating effect. The reaction of **1** with ethylene glycol yielded an orange solid which was no longer soluble in solvents like toluene and dichloromethane, making its NMR spectroscopic characterisation difficult. However, IR-spectroscopy and elemental analyses suggested that the initial aim of generating $Cl_2(O)Mo(\mu\text{-}OEt)_2(\mu_2\text{-}\eta^1\eta^1\text{-}HOCH_2CH_2OH)Mo(O)Cl_2$, **4**, had been successful and an X-ray structure analysis of a single crystal obtained from an diethylether solution confirmed the presence of a $\mu_2\text{-}\eta^1\eta^1\text{-}HOCH_2CH_2OH$ bridge in **4**, as shown in Fig. 2 (selected bond lengths and angles are listed in Table 5). The asymmetric unit of the monoclinic cell contains one molecule of **4**, a disordered diethylether molecule and a partially occupied (0.75) disordered EtOH molecule. While the $Cl_2(O)Mo(\mu\text{-}OEt)_2Mo(O)Cl_2$ frame in **4** is in principal the same as in **1** the octahedral environ-

O(3)–C(5)	1.38(2)		
O(4)–C(6)	1.413(14)		

ment of the Mo atoms in **4** is far less distorted than in **1** and **2**. The bond lengths in that core do not differ significantly from those in **1** and **2**. However, the O5–Mo1–Cl1/2 angles [97.2(3), 95.7(4)°] for instance are about 7° smaller than those in **1** approaching 90°. The O6–Mo2–Mo1 and O5–Mo1–Mo2 angles [90.9(3), 91.7(3)°] are even closer to the right angle but the O5–Mo1–O1/2 angles are slightly larger than those in **1** so that the Mo_2O_2 heterocycle is no longer planar (dihedral angles: 156°). At the vacant sites of the core the ethylene glycol bridge coordinates forming O6–Mo2–O4 and O5–Mo1–O3 angles of almost 180° [175.2(4) and 176.7(4)°]. Since each O atom of the bridge coordinates to only one Mo atom naturally the Mo–O bond lengths [2.2844(7), 2.291(7) Å] are much shorter (0.2 Å) than those in **1**.

As hoped in contrast to **1**, **4** can be handled in air for short periods so that in the next step its catalytic properties were investigated. However, the higher resistivity of **4** to air in comparison to **1** goes along with a lower activity as a catalyst (or precatalyst) so that an esterification yield of only 50% was found for the reaction of phenylacetic acid with ethanol. Accordingly the weakly bound EtOH bridge in **1** seems to play a decisive role in the formation of the catalytically active species from **1**.

CONCLUSIONS

In conclusion it appears that certain O═Mo(V) compounds are suitable to catalyse esterification reactions. Our investigation suggests that this process probably proceeds via coordination and activation of the carboxylic acids in the rate determining step followed by intramolecular alkoxide transfer. Compound **1** has unique properties as a precatalyst in this respect, producing species of very high activity in solution under the reaction conditions, which are able to even convert protected amino acids into the corresponding esters. The decreasing reaction rates on employment of the related compound **4** highlights the fine tuning of the properties of these catalytically active species by the nature of the precatalyst. While the usual influence of steric effects on the reaction rates is observed, in contrast to protonic catalysis the rates increase with decreasing acidity of the carboxylic acids. Future research will concern the investigation of the passivating effects of benzoic acid derivatives and the behaviour of other metal oxides.

Abstract—The co-ordination geometry of the monomeric rhenium complexes *mer*-[$Re^{III}Cl_3(L)_3$] (L = py **1**, 3,5-lut **2**, 4-pic **3**) has been determined in the solid state by single X-ray diffraction of the representative complex **2** and in solution by proton NMR spectroscopy. Only a single stable conformation has been found in the solid state and in solution, under the experimental conditions utilised. The NMR spectra of the related complexes *mer*-[$Re^{III}Cl_3(L)_2(PPh_3)$] (L = py **4**, 3,5-lut **5**, 4-vinpy **6**) have also been reported for comparison purposes.

INTRODUCTION

In the past the long established inorganic chemistry of rhenium has provided a useful framework for understanding and expanding the field of technetium co-ordination chemistry [1]. Then, in the eighties, basic inorganic chemistry of the long-lived isotope *i.e.*, ^{99g}Tc has been extensively developed, primarily because of the relevance of the short-lived isotope ^{99m}Tc to diagnostic nuclear medicine [2]. More recently, the advent of ^{186}Re and ^{188}Re therapeutic radiopharmaceuticals [3–5] has made this metal of intrinsic value to nuclear medicine. In this work we have re-visited some rhenium chemistry, including monomeric complexes of the type *mer*-[$Re^{III}Cl_3(L)_3$] (L = py **1**, 3,5-lut **2**, 4-pic **3**) and *mer*-[$Re^{III}Cl_3(L)_2(PPh_3)$] (L = py **4**, 3,5-lut **5**, 4-vinpy **6**) [py = pyridine, 3,5-lut = 3,5-dimethylpyridine, 4-pic = 4-methylpyridine, 4-vinpy = 4-vinylpyridine], previously described by Wilkinson *et al*. [6]. During the synthetic work we have isolated and structurally characterised, for the first time, a monomeric rhenium(III) complex with pyridine-type ligands, namely *mer*-[$ReCl_3(3,5\text{-lut})_3$] **2**. The meridional arrangement of the solid state is retained also in the solution state, as established by proton NMR studies.

RESULTS

Syntheses

Substitution reaction operated by pyridine ligands onto labile [$ReCl_3(MeCN)(PPh_3)_2$] [6], afforded *mer*-[$Re^{III}Cl_3(L)_2(PPh_3)$] derivatives as major product and *mer*-[$Re^{III}Cl_3(L)_3$] in fairly low yields. The crude solid collected from the reaction mixture after 2 h of reflux in the relevant pyridine was loaded onto a silica gel column. Elution with $CHCl_3$ evidenced the existence of three products. The first band contained the par-

tially substituted *mer*-[$Re^{III}Cl_3(L)_2(PPh_3)$] derivative, and the second one *mer*-[$Re^{III}Cl_3(L)_3$], whereas a major impurity (up to 40% of the total rhenium content), then characterised as the oxidised dioxo *trans*-$[ReO_2(L)_4]^+$ complex was retained on silica. The prolonged contact of the crude material with the air and the presence of moisture in the chloroform solution were most likely responsible for the oxidation of Re(III) species to the thermodynamically stable dioxo-Re(V) derivatives.

Structural commentary

The crystal structure of *mer*-[$ReCl_3(3,5\text{-lut})_3$] **2** is built up of two independent molecules [labelled (**A**) and (**B**)] in the asymmetric unit, which also comprises a MeOH hemimolecule solvent. The relative orientation of molecules (**A**) and (**B**) is depicted in Fig. 1, which also shows the thermal vibration ellipsoids of the non-hydrogen atoms. The co-ordination about rhenium is distorted octahedral and the two groups of ligands are arranged in a meridional fashion. The angles between *cis*-ligands vary between 87.8 and 91.7° (Table 1), while the *trans*-angles are between 176.4 and 179.3°, so that the departure from the ideal octahedron, which is usually ascribed to the mutual repulsion of the ligands is very limited, as shown also by the dihedral angle between the N_3 of 3,5-lut_3 and the Cl_3 triangles [90.5 and 88.8° in (**A**) and (**B**), respectively]. The two independent molecules differ slightly, the r.m.s. being of 0.13 Å when the fitting [7] involves 13 atoms (those of the "inner core" plus the two nearest lutidine carbons). The unique differences lie in (i) Cl(2)–Re(1)–Cl(3) angle (91.7°), to compare with Cl(5)–Re(2)–Cl(6) (87.8°) [Cl(5) and Cl(6) atoms interact, in some way, with the solvent molecule, so that Cl(6)––O and Cl(5)––O separations are 3.39 and 3.67 Å, respectively]; (ii) the lutidine rings make, each other, dihedral angles of 115.7, 95.3 and 53.4° in (**A**) to compare with the corresponding values 116.9, 89.5, and 60.6° in (**B**). To our knowledge this structure represents the first example of a mononuclear ReX_3N_3 complex (where X = halide and N is a unidentate pyridine-like N-donor) to be characterised by X-ray crystallography. On the other hand, the X-ray structure of a strictly related technetium compound, namely *mer*-[$TcCl_3(4\text{-pic})_3$], has been recently reported [8]. The Re–N and Re–Cl bond lengths in *mer*-[$ReCl_3(3,5\text{-lut})_3$], compared with those in closely related compounds collected in Table 2, show that: (i) the values of $Re–N_{py}$ distances (in the range 2.06 ÷ 2.17 Å) shorten as the formal oxidation state of the metal is lowered, while the distances become longer when the *trans*-influence is operating, as in

Cis-$[Re(bpy)_2Cl_2]^+$	III	2.095	2.36	[16]
Trans-$[ReCl_4(NO)(py)]^-$	II	2.22	2.35 ÷ 2.38	[17]
$[Re(bpy)_3]^+$	I	2.06		[16]

[a] o.n. = oxidation number; [b] dmap 4-(dimethylamino)py.

$[ReCl_4(NO)(py)]^-$ [17]; (ii) the Re–Cl distances are comprised in the rather narrow range 2.35–2.41 Å and the "abnormal" value of 2.44 Å in $[ReOCl_2(OEt)(py)_2]$ is caused by steric repulsion [12]; (iii) the Re–Cl bond length *trans* to the pyridine ligand is longer than the mutually *trans* Re–Cl distances by 0.04 Å. A similar trend is observed in the above mentioned isostructural *mer*-$[TcCl_3(4\text{-pic})_3]$ complex: the chloride ligand *trans* to the picoline donor is lengthened by 0.13 Å compared to the mutually *trans*-ones, whereas the variation of the Tc–N_{pic} distances is within the experimental error [8].

Proton NMR characterisation

Proton NMR data for synthesised *mer*-Re(III) complexes are summarised in Table 3. In addition, the proton spectrum of the representative complex *mer*-$[ReCl_3(4\text{-vinpy})_2(PPh_3)]$ **6** is depicted in Fig. 2. In spite of the paramagnetism of the low-spin d^4 ion, all of the Re(III) complexes can be conveniently characterised in solution by proton NMR spectroscopy. The two unpaired electrons are responsible for the spreading of the signals over a wide ppm range, but successful observation of proton NMR spectra (with multiplicity retention) is due to the extremely short electron-spin-relaxation time ($T_{1e} < 10^{-11}$ s) of the Re(III) centre [18]. The meridional configuration established in the solid state for *mer*-$[ReCl_3(3,5\text{-lut})_3]$ is retained in solution, as revealed, for example, by the appearance of two A_2B_2C pyridine proton systems, of relative integration 1:2, in $[ReCl_3(py)_3]$. Such a pattern does not undergo detectable modification in the range -50 to $+50\,^{\circ}C$ in chloroform-*d* solutions. Two types of pyridine protons are likewise detected in *mer*-$[ReCl_3(py)_2(PPh_3)]$, along with a further A_2B_2C set arising from the phenyl groups of PPh_3. This pattern is in accordance with two *cis*-positioned pyridine ligands, facing a chloride and a phosphine phosphorus, respectively. Such a distorted octahedral environment with two *cis*-positioned pyridine ligands

has been established recently in the solid state by Beauchamp and coworkers [19].

3 DISCUSSION

The chemistry of low-valent technetium and rhenium species is dominated by the presence in the coordination sphere of moderate to strong π-acid ligands such as alkyl- and aryl-phosphines, isocyanides or carbon monoxide [20–22]. However, the search for a substitution-active low-valent species, which may be of great interest as labile starting material at "carrier free" level, has prompted some synthetic groups to develop complexes with "electron-rich" metal centres surrounded by weak π-acid ligand environments. Among these, polypyridyl ligands have appeared to be suitable substrates for stabilising mononuclear M^{III}, M^{II} and M^{I} complexes (M = Tc, Re) [23, 24]. Moreover, the ability of pyridine to function as both a good σ-donor and a moderate π-acid ligand has provided a rare structural comparison of a transition metal in three different oxidation states contained within a nearly identical ligand field. The peculiar electronic flexibility of pyridine-like ligands turned out to be properly investigated also in the solution state by proton NMR spectroscopy for *mer*-$[ReCl_3(L)_3]$ complexes. In *mer*-$[ReCl_3(py)_3]$ compounds the alternating sign pattern of the ring position chemical shift (the α- and γ-protons are shifted upfield while the β-protons are shifted downfield, see Table 3), and the lack of attenuation of the isotropic shifts with the increasing distance from the metal seems to support that spin delocalisation occurs *via* the aromatic ligand π-system [25]. This behaviour parallels that shown by the second-row congener complex *mer*-$[TcCl_3(py)_3]$ [26]. In this connection the upfield shift experienced by α- and γ-protons is in agreement also with a significant π-back donation operating from the "electron rich" d^4 metal system to the pyridine ligands. Back-bonding to the unique pyridine protons (the unique pyridine is the ligand facing the chloride donor) appears to be stronger; indeed, they receive larger electron density from the metal than do either of the mutually *trans* pyridines, which compete against each other. A greater competition is experienced by the coordinated pyridine facing the more efficient π-acid system PPh_3 in *mer*-$[ReCl_3(py)_2(PPh_3)]$ (Table 3). In this pyridine α- and γ-proton signals move even downfield, whereas the pyridine protons positioned *trans* to the chloride donor retain the usual alternating sign pattern of the ring position chemical shift. Substitution of the γ-proton with a methyl group, as in $[ReCl_3(4\text{-pic})_3]$, determines a downfield shift of the methyl signals (the opposite side than that of the original γ-proton) [27]. Analogously, the methyl groups at the β-positions of the lutidine backbones in *mer*-$[ReCl_3(3,5\text{-lut})_3]$ are upfield shifted, which is again the opposite side than that of the β-protons. The same

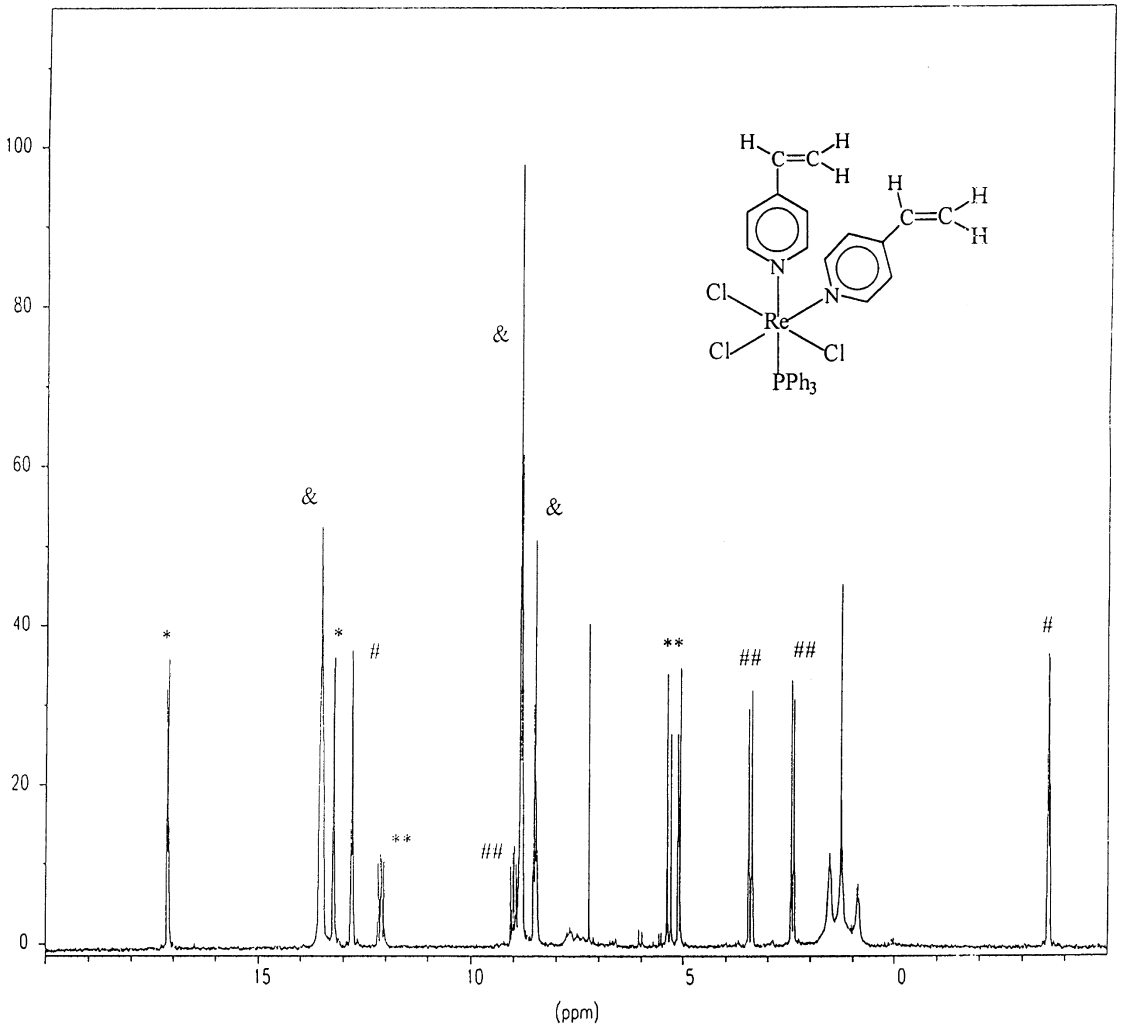

Fig. 2. Proton NMR spectrum of [$ReCl_3$(4-vinpy)$_2$(PPh_3)] **6** over the $+20 \div -5$ ppm region. * Denotes signals arising from the 4-vinyl-pyridine coordinated *trans* to PPh_3 (** protons from the vinyl group), whereas # denotes signals from the 4-vinyl-pyridine coordinated *trans* to Cl (## protons from the vinyl group). & denotes PPh_3 signals.

trend is encountered in the related complex [$ReCl_3$(4-vinpy)$_2$(PPh_3)] **6**, where a vinyl group is incorporated in the *para*-position and a PPh_3 substitutes a pyridine ligand. As above described for *mer*-[$ReCl_3$(py)$_2$(PPh_3)], the two *cis*-positioned vinyl-pyridines face distinct chemical environments, a chloride and a triphenylphosphine donor, which induce different chemical shift values for pyridine protons. However, in both pyridines the vinyl protons at C_α are downfield shifted, whereas those at C_β are upfield shifted (Fig. 2 and Table 3). This recurring behaviour further substantiates the occurrence of π-spin delocalisation through hyperconjugation between the methyl (or vinyl) group and the aromatic ring [9, 10].

In summary, the syntheses and characterisation of *mer*-[$Re^{III}Cl_3(L)_3$] and *mer*-[$ReCl_3(L)_2(PPh_3)$] complexes have provided the first X-ray structure determination of a monomeric polypyridyl Re(III) complex *mer*-[$ReCl_3$(3,5-lut)$_3$]. The meridional configuration found in the solid state originates at least two different types of lutidine ligands. However, the presence of two independent entities in the unit gives rise to significant steric constraints. As a consequence, each one of the three lutidines display a different orientation. The *mer* configuration is retained in solution, where the pyridine protons originate two different set of signals, whose integration ratio is correctly 1:2. No sign of further splitting of pyridine signals is observed in chloroform solutions in the range -50 to $+50\,^{\circ}C$.

EXPERIMENTAL

Apparatus

Microanalyses were carried out with a Fisons EA1108 elemental analyser. The IR spectra were recorded in KBr pellets with a Mattson 3030 Fourier-

transform spectrometer (4000–400 cm^{-1}). Proton NMR spectra were recorded on a Bruker AC-200 spectrometer and were referenced to the resonances of residual protons in the deuterated solvent. Other active NMR nuclei are theoretically detectable in our compounds, including isotopes of ^{187}Re ($I = 5/2$). However, the lack of spherical symmetry in diamagnetic $Re^{V}O_2^{+}$ species make conditions very unfavourable for signal detection [20, 21], whereas solubility problems bar the availability of the potentially useful ^{13}C probe. The proton NMR investigations were performed at 295 K on 10^{-3}–5×10^{-4} M solutions and unambiguous proton assignments were made through relative integration, spin–spin splitting, homo-nuclear decoupling and two-dimensional experiments [28–30]. Fast-atom bombardment mass spectra in the positive mode (FAB^{+}) were recorded by using a 3-nitrobenzyl alcohol matrix on a VG ZAB-2F spectrometer. Xenon was used as the primary beam gas, and the ion gun was operated at 8 keV. Data were collected over the mass range 100–1300 at 0.7 s per scan.

Materials

Unless otherwise stated, all chemicals were of reagent grade. Pyridine and substituted pyridines were purchased from Aldrich Chimica and used as received. $[ReCl_3(MeCN)(PPh_3)_2]$ was obtained according to the published procedure [6].

Syntheses of Re(III) complexes

mer-$[ReCl_3(py)_3]$ **1**. The following modification of the reported preparation was used [6]. In a two-necked flask equipped with a refluxing condenser, solid $[ReCl_3(MeCN)(PPh_3)_2]$ (0.107 g, 0.125 mmol) was dissolved in neat pyridine (11.0 ml) under a dinitrogen atmosphere. The reaction mixture was refluxed for 4 h and then *n*-hexane (200 ml) was added to the cooled solution, which was placed in the refrigerator overnight. A dark precipitate was isolated by filtration, washed with a few drops of Et_2O. Then it was dissolved in 3 ml of $CHCl_3$ and loaded onto a silica-gel chromatography column (20 × 2 cm), which was eluted with $CHCl_3$ yielding the desired product (second band); the solution was then reduced to dryness by rotary evaporation and the solid dried *in vacuo* overnight. Yield 14 mg, 21%. (Found: C, 34.3; H, 3.0; N, 7.7. $C_{15}H_{15}N_3Cl_3Re$ requires C, 34.00; H, 2.85; N, 7.93%). FAB mass spectrum: m/z 530, $[M]^{+}$.

mer-$[ReCl_3(L)_3]$ (L = 3,5-lut **2**, 4-pic **3**). These complexes were prepared as above detailed for **1**. **2**: yield 18%. (Found: C, 41.3; H, 4.6; N, 6.6. $C_{21}H_{27}N_3Cl_3Re$ requires C, 41.08; H, 4.43; N, 6.84%). FAB mass spectrum: m/z 614, $[M]^{+}$. **3**: yield 17%. (Found: C, 38.2; H, 3.7; N, 7.2. $C_{21}H_{27}N_3Cl_3Re$ requires C, 37.80; H, 3.70; N, 7.35%). FAB mass spectrum: m/z 572, $[M]^{+}$.

mer-$[ReCl_3(L)_2(PPh_3)]$ (L = py **4**, 3,5-lut **5**, 4-vinpy **6**) were prepared as reported [6].

Crystallography

$C_{21}H_{27}N_3Cl_3Re \cdot 1/2CH_3OH$, **2**·1/2MeOH, $M = 630.03$, Monoclinic, $a = 13.410(6)$, $b = 20.975(8)$, $c = 17.889(7)$ Å, $\beta = 99.84(5)^{\circ}$, $U = 4958(3)$ $Å^3$, $D_c = 1.688$ g cm^{-3}, $Z = 8$, $F(000) = 2472$, space group $P2_1/n$, Mo–K_α radiation, $\lambda = 0.71073$ Å, μ(Mo–K_α) = 52.4 cm^{-1}. The dark red crystal sample, obtained from a MeOH solution, was an elongated polyhedron of dimensions 0.10 × 0.15 × 0.50 mm. The intensity measurements were carried out on a Nicolet Siemens R3m/V automated four-circle diffractometer; the intensities (up to $2\theta = 45^{\circ}$) were corrected for Lorentz-polarisation effects and absorption, using an empirical method based on the ψ-scans of five reflections at $\chi \cong 90^{\circ}$. Transmission factors were found in the range 0.58–0.81. After removing all the reflections having $I_o < 2\sigma$ (I_o), a final set of 4529 independent data was used in the solution and refinement of the structure performed on F^2. All the non-hydrogen atoms were refined anisotropically, while O and C(8) atoms of MeOH molecule were treated isotropically. The final agreement indices R and $wR2$ $\{ = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma w(F_o^2)^2]^{1/2}\}$ were 0.046 and 0.114, respectively. The atomic scattering factors were taken from *International Tables for X-ray Crystallography* [31] and all calculations were performed with the SHELXTL/PC and SHELXL93 structure analysis packages [32, 33].

(Received 27 January 1998; accepted 5 May 1998)

Abstract—New nickel(II) complexes of general empirical formula, $[Ni(ONS)_2]$ (ONS^- is the anionic form of tridentate ligands formed from methylpyruvate and S-methyl- and S-benzyldithiocarbazates) have been synthesized and characterized by magnetic and spectroscopic techniques. The complexes are six-coordinate and octahedral. The crystal and molecular structure of $[Ni(ONSMe)_2]$ ($ONSMe^-$ is the anionic form of the methylpyruvate Schiff base of S-methyldithiocarbazate) has been determined by X-ray diffraction which shows that the nickel(II) complex has a distorted octahedral structure with the ligands coordinated to the nickel(II) ion as uninegatively charged tridentate chelating agents via the carbonyl oxygen, the azomethine nitrogen and the mercaptide sulphur atoms. The distortion from regular octahedral geometry is attributed to the restricted bite angles of the planar ONS tridentate ligands. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel(II) complexes; Schiff bases; S-alkyldithiocarbazates; crystal structure; methylpyruvate Schiff bases; octahedral nickel(II) complexes

INTRODUCTION

Metal complexes of sulphur–nitrogen chelating agents derived from S-alkyl esters of dithiocarbazic acid have attracted considerable attention over the past few years [1–12] in view of their interesting physico-chemical properties [9, 10] and potentially useful therapeutic properties [13]. Thus, the nickel(II) complex of the 2-acetylpyridine Schiff base of S-methyldithiocarbazate, [Ni(NNS)CI] has been shown to exhibit marked activity in the P388 Lymphocytic Leukaemmia test system [14]. Some Schiff bases of S-alkyl esters of dithiocarbazic acid and their copper(II) complexes have also been shown to display antifungal and antibacterial properties [3, 4, 8]. Although in the past several synthetic and spectral characterization of metal-dithiocarbazate complexes have been reported in the literature, structural work by X-ray crystallography on such complexes are few in number. As part of our ongoing work on metal chelates of dithiocarabazic acid and its derivatives, we report here the preparation and magnetic and spectroscopic characterization of two bis-chelated nickel(II) com-

plexes of the methylpyruvate Schiff bases of S-methyl- and S-benzyldithiocarbazates, together with the X-ray crystal structure determination of the $[Ni(ONSMe)_2]$ complex.

EXPERIMENTAL

All physical measurements and analytical procedures were similar to those described previously [3].

Synthesis of the ligands

The two Schiff bases were prepared by the same general method.

The appropriate S-alkyldithiocarbazate (2 mmol) dissolved in abs. ethanol (100 cm^3) was mixed with a hot solution of methyl pyruvate (2 mmol) in the same solvent (100 cm^3) and the mixture was refluxed for *ca.* 2 h and then left to stand overnight. The volume of the solution was then reduced to about 50 cm^3 whereupon the crystals which had formed were collected by filtration and recrystallized from abs. ethanol to obtain pale yellow needle-shaped crystals. HONSMe (the Schiff base of methylpyruvate with S-methyldithiocarbazate): yield, 80%, m.p. 97°C; found: C, 35.1; H, 4.7; N, 13.7. calc. for $C_6H_{10}N_2S_2$: C, 34.9; H, 4.9; N, 13.6%.

HONSBz (the Schiff base of methylpyruvate with S-benzyldithiocarbazate): yield, 75%. m.p. 109°C; found: C, 51.2; H, 5.1; N, 10.0%; calc. for $C_{12}H_{14}N_2S_2O_2$: C, 5 1.0; H, 5.0; N, 9.9%.

General method of preparation of the complexes

The appropriate Schiff base (2 mmol) was dissolved in a mixture of boiling methanol (50 cm^3) and 2,2-dimethoxypropane (5 cm^3). To the solution, a hot solution of nickel(II) nitrate hexahydrate (1 mmol) in the same mixture of solvents (50 cm^3) was added and the mixture was allowed to stand overnight during which time beautiful brown crystals of the complexes formed. These were filtered off, washed with methanol and dried in a vacuum desiccator over anhydrous silica gel.

Found: C, 30.8; H, 3.7; N, 12.0; calc. for $C_{12}H_{18}N_4O_4S_4Ni$: C, 30.7; H, 3.9; N, 11.9%. Found: C, 46.3; H, 4.0; N, 8.7; calc. for $C_{24}H_{26}N_4S_4O_4Ni$: C, 46.4; H, 4.2 N, 9.0%.

X-ray crystal structure analysis

The intensity data were obtained by means of an Enraf-Nonius CAD4 diffractometer at 293 K. Intensities were corrected for Lorentz and polarization effects and empirical absorption corrections were applied based on a set of ψ scans. Calculations were carried out using XCAD49 (data reduction) SHELXTL (absorption correction, structure solution/refinement and molecular graphics). All hydrogen atoms were placed in calculated positions, refined using a riding model and given an isotropic displacement parameter equal to 1.2(CH, CH_2) or 1.5(CH_3) times the equivalent isotropic displacement parameter of the atom to which it is attached. When warranted, methyl hydrogen atomic positions were allowed to rotate about the C–C bond. Full-matrix least-squares refinement of all data against F^2 of the quantity $w(F_o^2–F_c^2)$ was used to adjust the position and anisotropic thermal parameters of all non-hydrogen atoms. Unit cell dimensions were refined by use of the settings of 25 accurately determined reflections widely separated in reciprocal space. Intensities were measured by ϖ scans. The structure was solved by direct methods [15] and subsequent Fourier syntheses were used to determine remaining non-hydrogen atomic positions. A summary of crystallographic data, experimental details and refinement results is given in Table 1.

RESULTS AND DISCUSSION

The Schiff bases of S-methyldithiocarbazate and S-benzyldithiocarbazate with methylpyruvate (Figure 1), hereinafter abbreviated as HONSMe and HONSBz, respectively, can exhibit thione (1a) and thiol (1b) tautomerism, since they have a thioamide function –NH–C(═S)SR.

The IR spectra of these compounds, however, do not exhibit any ν(S–H) band at *ca.* 2700 cm^{-1}, but display the ν(NH) bands at *ca.* 3200 cm^{-1} indicating that, in the solid state, they remain as the thioketo tautomeric form (**1a**). However, in solution and in the presence of nickel(II) ion, they quickly change to the thiol form with the concomitant formation of nickel(II) complexes of the deprotonated thiolate forms of the ligands. The related thiosemicarbazone ligands have been found to coordinate to metal ions in both protonated [16] and deprotonated [17] forms. However, there are two unique examples of thiosemicarbazone complexes, one of which is a bis-ligand chromium(III) complex [18] and the other is a bis-ligand copper(II) complex [19] where the two tridentate NNS thiosemicarbazone ligands are present as both protonated and deprotonated forms in the same complexes. However, so far as the complexes of Schiff bases of S-alkyldithiocarbazates are concerned, there has not been a single example as yet, where these Schiff bases coordinate to a metal ion as the protonated thione form. Our attempts so far, to obtain nickel(II) complexes of the protonated forms of these ligands have also been unsuccessful.

The present Schiff bases react readily with nickel(II) nitrate to yield the bis-ligand complexes of formula, $[Ni(ONSR)_2]$. Attempts to prepare mono-ligated complexes of the type [Ni(ONS)X] (X = Cl, Br, NCS) have been unsuccessful.

The IR spectra of the free ligands display a very

strong band at 1710 cm^{-1} which is assigned to the ν(C═O) of the carbonyl group. This band is shifted to *ca.* 1655 cm^{-1} in the spectra of the complexes, indicating that the ligands coordinate to the nickel(II) ion via the carbonyl group. The ν(NH) bands of the free ligands at 3220 cm^{-1} completely disappear in the spectra of the complexes indicating that they deprotonate while coordinating with the nickel(II) ion. The azomethine ν(C═N) bands of the ligands at 1610 cm^{-1} undergo a shift to lower frequencies (Table 2) supporting coordination through the azomethine nitrogen atom. The above IR results support that the ligands coordinate to the nickel(II) ion as ONS tridentate chelating agents. This is further supported by the X-ray results discussed later.

The nickel(II) complexes reported here are non-

[a] Log ε ($l\,mol^{-1}\,cm^{-1}$) are in parentheses.

electrolytes in dichloromethane {Λ (Ω^{-1} cm^2 mol^{-1}) <1}, indicating that they coordinate to the nickel(II) ion as uninegatively charged ligands. The brown colours of the complexes may seem to suggest a low-spin configuration for the nickel(II) ion but their room-temperature magnetic moments {2.93BM for $[Ni(ONSMe)_2]$ and 2.94BM for $[Ni(ONSBz)_2]$} indicate that they are of the high-spin type. This is strong evidence that these complexes are six-coordinate and probably octahedral.

Their electronic spectra, in addition to showing intraligand bands at *ca.* 390, 320 and 255 mn, exhibit a ligand to metal charge transfer band at *ca.* 400 nm. The d–d bands were observed at 915 and 550 nm for the $[Ni(ONSMe)_2]$ complex and at 800 and 500 nm for the $[Ni(ONSBz)_2]$ complex. These bands may be assigned to the $^3A_{2g} \Rightarrow {}^3T_{2g}$ and $^3A_{2g} \Rightarrow {}^3T_{1g}$ transitions of octahedral nickel(II), respectively. The third expected band corresponding to the transition, $^3A_{2g} \Rightarrow {}^3T_{1g}(P)$ could not be located probably due to the interference of the intense charge transfer band.

The X-ray crystal and molecular structure of $[Ni(ONSMe)_2]$

The structure of the complex together with the atom numbering scheme used, is shown in Fig. 2. The selected bond lengths and bond angles are listed in Table 3. The complex contains discrete six-coordinate nickel(II) ions with the ligands coordinated to the nickel(II) ion as uninegatively charged ONS tridentate chelating agents via the carbonyl oxygen atom, the azomethine nitrogen atom and the thiolate sulphur atom. The ligand is present as the deprotonated mercaptide form. The deprotonation of the ligand is accompanied by tautomerization to the imino thiolate form. While coordinating in the iminothiolate form, the negative charge on the sulphur atom (generated by deprotonation) is delocalized in the C–N–N–C system as indicated by their intermediate bond distances: C(5A)–N(2A) = 1.315(3) Å, N(2A)–N(1A) = 1.377(3) Å; C(3A)–N(1A) = 1.292(3) Å; C(5B)–N(2B) = 1.312 Å, N(2B)–N(1B) = 1.373(3) Å, C(3B)–N(1B) = 1.295(3) Å. The two Schiff bases are coordinated to the nickel(II) ion in the meridional configurations (the sulfur and carbonyl oxygen atoms *cis* to each other and the azomethine nitrogen *trans*). Bis-chelated nickel(II) complexes of tridentate ligands whose structures are known, have almost always been found to have similar *mer* arrangements of ligands around nickel(II) [11, 20, 21]. The two Ni–N(imine) bond lengths {2.014(2) and 2.013(2) Å} compare well with those of other octahedral nickel(II) complexes of sulphur–nitrogen ligands [11, 20, 21]. The two Ni–S bonds are, however, relatively short compared with other octahedral nickel(II) complexes of related ligands (Table 4). The shorter Ni–S bond lengths in the present complex, compared with those in analogous complexes, are attributed to a stronger nickel–sulphur interaction in this complex. The C–S bond distances in the complexes are longer than those reported for free thiosemicarbazones 1.678 ± 0.002 Å in 4-formylpyridinethiosemicarbazone [22] and 1.684 ± 0.004 Å in 2-keto-3-ethoxybutyraldehydebis(thiosemicarbazone) [23]. The lengthening of the C–S bond can be ascribed to the enethiolization process that occurs prior to coordination of the ligands with the nickel(II) ion. For the purpose of comparison, the nickel(II) donor atom distances in some octahedral nickel(II) complexes of related ligands, whose structures have been determined by diffraction, are shown in Table 4. The data indicate that, bond distances in most octahedral nickel(II) complexes of planar tridentate ligands compare well with each other excepting the Ni–S bond in the present complex, which is much shorter than those in related complexes. In the meridional configuration, the two cis-bonded sulphur atoms are expected to repel each other resulting in longer Ni–S bonds. The electronic effects probably dictate the shorter Ni–S distances in this complex.

The stereochemistry around the nickel(II) ion in the $[Ni(ONSMe)_2]$ complex is a distorted octahedron. The

X(1A)–Ni–S(1A)	156.9(0.2)	159.0(2)	157.6(2)	157.54(5)
X(1A)–Ni–N(1A)	78.1(0.2)	78.2(2)	77.6(3)	76.48(7)

[a] X is carbonyl oxygen or pyridine nitrogen.
[b] pytsc is the pyridine-2-carboxaldehydethiosemicarbazone [20].
[c] isoqtsc is the isoquinoline-2-carboxaldehydethiosemicarbazone [21].
[d] NNSMe is the 6-methyl-2-pyridinecarboxaldehyde Schiff base of S-methyldithiocarbazate [11].
[e] ONSMe is the methyl pyruvate Schiff base of S-methyldithiocarbazate [this work].

S(1A)–Ni–S(1B) angle is 97.78(3)° which is larger than the ideal value of 90°, expected for a perfect octahedron. The twelve angles subtended at the nickel(II) ion by adjacent donor atoms range from 76.22(7)° for the N(1B)–Ni–O(1B) angle to 103.57(7)° for the N(1A)–Ni–O(1B) angle, indicating appreciable distortion from idealized geometry. The distortion from an ideal octahedral geometry is attributed to the restricted bite angles imposed by the planar tridentate ligands. For the purpose of comparison, the bond angles of [Ni(ONSMe)$_2$] and those of other related bis-ligand six-coordinate nickel(II) complexes are listed in Table 5. The data show that none of the bond angles in these complexes are close to the idealized values expected for a regular octahedral structure. From the limited structural data available on octahedral bis-chelated nickel(II) complexes of sulphur–nitrogen chelating agents, it can be safely stated that distortion is a common phenomenon in six-coordinate nickel(II) complexes of planar tridentate SN donor ligands.

(Received 16 March 1998; accepted 7 May 1998)

Abstract—Oligo(digermanylene–phenylene)s and related oligomers were prepared by treatment of di-Grignard reagents of the corresponding aryl dibromides with 1,2-dichlorotetramethyldigermane. Upon ultraviolet irradiation of films of oligo(digermanylene–phenylene) and related oligomer in air, the germanium–germanium bond in the oligomer films changed into a digermoxane chain probed by XPS. The laser flash photolysis of the oligo(digermanylene–phenylene) film showed the formation of an oligogermyl radical as a reactive intermediate during photodegradation. Iodine doping of the oligomers showed the conductivities of the order of 10^{-4} S cm^{-1}.

INTRODUCTION

Considerable interest has been focussed on polymers having a regular alternating arrangement of a group 14 element σ unit and a π-electron system in the backbone in view of their novel properties and potential applications [1, 2, 2–5, 5, 6, 6–9]. These polymers strongly absorb light in the ultraviolet (UV) and near-UV regions, owing to σ–π conjugation. Bleaching of the absorption band is caused by a decomposition of the group 14 element–group 14 element bond under UV irradiation. Therefore, the polymers are quite photosensitive and have an attractive possibility to be used as photoresists. This polymer also shows conducting properties when the polymer is doped with an oxidizing agent such as antimony pentafluoride. While the synthesis and properties of poly(disilanylene-π electron system)s have been amply investigated, there have been few reports on those of poly(digermanylene-π electron system)s [7, 10, 11]. As part of our problem to explore the synthesis and properties of new classes of polygermanes [11–13], we herein describe the synthesis, photochemical and conducting properties of oligo(digermanylene–phenylene)s and related oligomers.

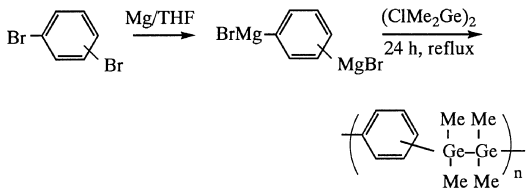
RESULTS AND DISCUSSION

Oligo(digermanylene-π electron system)s were prepared by treatment of di-Grignard reagents obtained from 1,2-, 1,3-, 1,4-dibromobenzene and 2,5-dibromothiophene with 1,2-dichlorotetramethyldigermane. The oligo-(digermanylene-π electron system)s were fractionated by precipitation from toluene with 2-propanol. The molecular weights (M_w) of the oligomers were measured by gel permeation chromatography (GPC) using polystyrene sample for calibration. The oligomers had a narrow molecular weight distribution (M_w/M_n) but were in relatively low yields.

The M_w, M_w/M_n, UV data and ionization potentials (IP's) of the oligomers are summarized in Table 1.

Oligo(digermanylene-1,2-phenylene) (**1**), oligo (digermanylene-1,3-phenylene) (**2**), oligo(digermanylene-1,4-phenylene) (**3**) and oligo(digermanylene-2,5-thienylene) (**4**) have characteristic electronic absorp-

* Author to whom correspondence should be addressed.



tion bands. The oligomers **1**–**4** have a more intense broad absorption from 200 nm ($\varepsilon < 10^4$ at 250 nm), tailing down into the visible region. The very high extinction coefficients of oligomers **1**–**4** may be attributed to an extension of the Ge–Ge σ conjugation effects into π systems. The values of IP's of oligomers **1**–**4** were in the 5.00–5.78 eV range.

The oligomers **1**–**4** are isolated as colorless or pale yellow solids and moderately light-sensitive molecules. The oligomers **1**, **2** and **4** are soluble in common organic solvents such as chloroform, benzene, toluene and THF and show film-forming properties. The oligomer **3** is little soluble.

Thin films of the oligomer **1**, **4** were prepared by spin-coating from a 5–10% THF solution. The film was deposited on a quartz plates and dried under a vacuum at room temperature. The film thickness of the oligomer, which was determined by UV-VIS spectrometry, was 0.4–0.6 μm [14]. As expected, an oligomer film is quite light sensitive. Figure 1 shows the bleaching of a film of oligomer **1**, **4** by irradiation with a 110-W low-pressure Hg arc lamp ($\lambda = 254$ nm) at room temperature in air. The decrease of the absorbance of the oligomer upon irradiation is caused by a Ge–Ge chain scission [13, 15, 16]. After UV irradiation for 5 min, the oligogermane films were dissolved in THF and their M_w's were determined by GPC analysis. GPC spectra showed an almost constant of M_w for the oligomer. Thus, these UV and GPC results show that the Ge–Ge bonds in films of oligogermanes change into a digermoxane chain after UV irradiation.

In addition to UV observation, the process of photodegradation of the oligomer film was observed by X-ray photoelectron spectroscopy (XPS) [17]. The XPS spectra of the Ge 3d region for the oligomer **1**, **4** film were observed both before and after UV irradiated at 254 nm, as shown in Fig. 2. The XPS spectra before UV irradiation shows a peak at 33 eV attributed to the Ge–Ge structure. After UV irradiation in air for 1 h, the peak of Ge–Ge almost disappears and the peak at 38 eV, assigned to the Ge–O–Ge structure, increases. These results of XPS spectra showed that the Ge–Ge bonds in films of oligogermanes changed into Ge–O–Ge chains after UV irradiation.

To obtain information about reactive intermediates in the photodegradation of an oligo(digermanylene-1,2-phenylene) film **1**, the laser flash photolysis ($\lambda = 266$ nm) of the oligomer film **1** was carried out in air [16]. To avoid the thermal and photodegradation of the oligomer film induced by the intense pulsed laser light, measuring spot on the film was shifted after each excitation. The laser flash photolysis of the oligomer film **1** at 293 K gave a transient absorption peak at *ca.* 310 nm, as shown in Fig. 3. The transient peak at *ca.* 310 nm has been assigned to that of the oligogermyl radicals by comparing its spectral characteristics with those for similar previously reported polygermyl radicals in solutions and films [16, 18]. No transient peaks assigned to germylenes (420–450 nm) were observed. Thus, the key intermediate is oligogermyl radicals generated by a Ge–Ge bond scission in the photodegradation of the oligo(digermanylene-1,2-phenylene) film **1** in air.

In general, oligogermanes composed of an alternating digermanylene unit and π electron system are insulators (10^{-9} S cm^{-1}). However, when the oligomers are treated with an oxidizing agent such as SbF_5 and I_2, they become conducting. Thus, when thin films of oligomers **1**–**4** and related compounds were exposed to iodine vapor under reduced pressure (1 mm Hg), the conductivity of the films increased steadily and reached almost constant values after 1 h of doping. The conductivity at this point was determined to be $(1.0–1.3) \times 10^{-4}$ S cm^{-1} by the direct current four-probed method. Germanium-containing polymers and oligomers show similar conductivity as compared with the corresponding silicon analogues [7, 9,

EXPERIMENTAL

^{1}H and ^{13}C NMR spectra were recorded with a Varian Unity-Inova 400 MHz NMR. The GC-MS spectra were recorded using a JEOL JMS-DX 303 mass spectrometer. The UV and UV-VIS spectra were recorded on a Shimadzu UV 2200 spectrometer. Interference spectra were observed with a Hitachi U-3500 UV-VIS spectrometer. Gas chromatography was done on a Shimadzu GC8A with 1 m 20% SE30 and 30% Apiezon L columns. Liquid chromatography

was done on a Twincle with an Asahipak GS 310 column.

Preparation of oligo(digermanylene-1,3-phenylene)

Oligo(digermanylene-1,2-phenylene) and oliogo-(digermanylene-1,3-phenylene) were prepared as described [10]. Oligo(digermanylene-1,4-phenylene) and oligo(digermanylene-2,5-thienylene) were prepared in the same manner by treatment of di-Grignard reagents obtained from *p*-dibromobenzene and 2,5-dibromothiophene, respectively, with 1,2-dichlorotetramethyldigermane as described [7, 10]. As a representative example, the preparation of oliogo (digermanylene-1,3-phenylene) is described. Magnesium (0.97 g, 40 mmol) and *m*-dibromobenzene (4.72 g, 20 mmol) in THF (5 cm^3) were added to a dry Ar inlet, pressure-equalizing dropping funnel and a mechanical stirrer. Distilled 1,2-dichlorotetramethyldigermane (5.52 g, 20 mmol) was added via a funnel to a di-Grignard reagent. The reaction mixture was added and stirred with refluxing for 20 h. After hydrolysis with water, the organic layer was extracted with toluene. The organic layer was washed copiously with water and dried over anhydrous sodium sulfate. The solvent was removed on a rotary evaporator and the residue was recrystallized with ethanol. The solid was dried at 80°C in a vacuum oven for 5 h (20% yield). ^{1}H NMR ($CDCl_3$) δ 0.46 (s, 3 H), 7.30 (m, 4H); ^{13}C NMR ($CDCl_3$) δ −3.51, 127.50, 132.97, 138.39, 140.89; IR (cm^{-1}, KBr) 2970, 827, 787, 780, 596. Photochemical reactions of oligo(digermanylene–phenylene)s film by UV

A thin film of oligo(digermanylene–phenylene) was prepared by spin-coating from a 5–10% THF solution. The film was deposited on quartz plates ($10 \times 30 \times 1$ mm) and dried under a vacuum (10^{-3} mm Hg, 1 mm Hg = 133.322 Pa) at room temperature. The film thickness was determined by UV-VIS spectrometer (0.4–0.6 μm). The film was irradiated with a 110-W low-pressure Hg arc lamp (Sen Tokushu Kogen Co.) at room temperature. The absorption spectrum of the film was recorded by UV and UV-VIS spectrometry.

Time-resolved optical absorption

Laser flash photolysis experiments were performed at room temperature by using the fourth harmonic ($\lambda = 266$ nm) of a Quanta-Ray (GCR-130) Nd:YAG laser as an excitory light source. The sample was a thin film of oligo(digermanylene–phenylene) on a quartz plate. The laser pulse was about 6 ns; details concerning the laser-photolysis apparatus and manipulation have been published elsewhere [16].

Conductivity measurement for oligomer films doped with I_2

A thin film of an oligomer was prepared in the same manner as described above. The film was exposed to saturated I_2 vapor under reduced pressure (1 mm Hg) in a glass vessel. The conductivity of the films increased steadily with increasing time of doping and reached almost constant values after 1 h. The conductivities in vacuum at this point were determined by the direct current four-probe method.

Acknowledgements—The authors thank Dr Koichi Handa of Nissan Auto Co. for measuring the XPS of oligo (digermanylene-π electron system)s. We also thank Mitsubisi Material Co. for providing us with germanium tetrachloride. This work was in part supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 08554024).

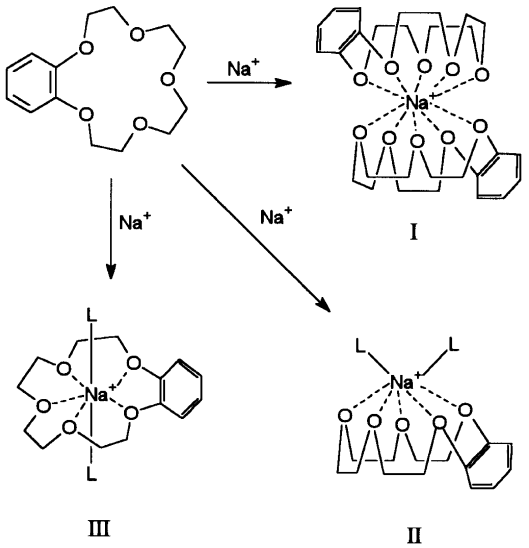
(Received 13 January 1998; accepted 7 May 1998)

Abstract—Reaction of $NiCl_2 \cdot 6H_2O$, Na_2[i-mnt] and benzo-15-crown-5 in CH_3OH/CH_2Cl_2 at room temperature leads to $[\{Na(benzo\text{-}15\text{-}crown\text{-}5)\}_2Ni(i\text{-}mnt)_2]_n \cdot nCH_2Cl_2$ (**1**). The same reaction with Na_2[mnt] instead of Na_2[i-mnt] affords $[\{Na(benzo\text{-}15\text{-}crown\text{-}5)\}_2Ni(mnt)_2]_n$ (**2**). Both complexes were isolated as crystalline products. X-ray diffraction analyses reveal that the main segments of **1** and **2** are infinite "train" structures, in which the building blocks $Ni(i\text{-}mnt)_2$ or $Ni(mnt)_2$ in end-to-end arrangements act as "body frames" and crown cycles standing by the body frames play the role of "cartwheel". They are joined with each other through sodium ions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crown ether; nickel(II) dithiolate; crystal structure; co-ordination polymer.

INTRODUCTION

Crown ether compounds have been well known for their co-ordination ability to alkali, alkaline earth and rare earth metal ions to form various types of structures [1, 2]. Benzo-15-crown-5 with five oxygen atoms on its cycle and suitable diameter of cavity reacting with sodium ions affords very usually the sandwiched structure $[Na(benzo\text{-}15\text{-}crown\text{-}5)_2]^+$ (I, see Scheme 1) [3–7]. In a few cases the mono crown cycle-capped sodium cation $[Na(benzo\text{-}15\text{-}crown\text{-}5)]^+$ (II) with remaining co-ordination positions that can accept other donors were detected. Of this type of structure are examples such as $[Na(benzo\text{-}15\text{-}crown\text{-}5)ClO_4]$ reported by Owen [7] and $[Na(benzo\text{-}15\text{-}crown\text{-}5)C_6H_2N_3O_7]$ by Ward *et al.* [8]. It is possible for one



Scheme 1.

to use $[Na(benzo\text{-}15\text{-}crown\text{-}5)]^+$ as building blocks to construct low dimensional co-ordination polymer. Herrmann *et al.* [9] reported the one-dimensional structure of $[Na(benzo\text{-}15\text{-}crown\text{-}5)(ReO_4)]_n$, which was characterised by sodium ion in a nearly planar crown ether environment (III) and tetrahedral perrhenate. These subunits are joined with each other resulting in helical perrhenate sodium chains of pentagonal bipyramidal configuration around sodium cations. In this paper we present two novel structures that $[Na(benzo\text{-}15\text{-}crown\text{-}5)]^+$ use its two collateral positions (II) to joint complex anions $[Ni(i\text{-}mnt)_2]^{2-}$ and $[Ni(mnt)_2]^{2-}$ to form infinite chain-like co-ordination polymers, where $[i\text{-}mnt]^{2-}$ and $[mnt]^{2-}$ are conjugated ligands isomalenonitriledithiolate and malenonitriledithiolate, respectively.

The ligand $[i\text{-}mnt]^{2-}$ is a versatile and classic ligand in the synthesis of complexes and cluster compounds, about which a number of research reports were raised in the last two decades [10–16]. Metal complexes with $[mnt]^{2-}$ and its analogous, well known for their reversible redox behaviour and extensive ground-state π-electron delocalisation, had been a subject of considerable attention. Investigation in this area had stimulated much interest of synthetic and materials chemists [17–19]. Recently there is much interest in the search for new and improved synthetic molecular metals and many of these are based on Group 10 metals and planar organic donor molecules such as $[mnt]^{2-}$ [20]. It was thought that other metal ions, for example alkali and alkaline earth metal ions or transition metal ions, could connect the complex anions of $[i\text{-}mnt]^{2-}$ and $[mnt]^{2-}$ ligands by bonding to their cyano groups to build new type of conjugated co-ordination polymer [21]. Up to date the case of low dimensional polymer of these ligands in N-coordinated fashion are very rare. The sole example is $[\{Ni(NH_3)_4\}Ni(S_2C{=}C(CN)\}_2]_\infty$ reported by Zhu *et al.* [22]. However only one cyano group of a $[i\text{-}mnt]^{2-}$ ligand in this compound is co-ordinated to nickel cation $[Ni(NH_3)_4]^{2+}$ and in consideration of the hydrogen bondings this compound has in fact a three-dimensional structure.

EXPERIMENTAL

Material and methods

All reagents and solvents purchased were A.R. or C.P. grade and used without further purification. Na_2[i-mnt] [23] and Na_2[mnt] [24] were prepared as described in the literature. Carbon, hydrogen and nitrogen analyses were carried out on a Perkin-Elmer 240C elemental analyser. The infrared spectra (4000–400 cm^{-1}) and far-infrared spectra (650–100 cm^{-1}) were recorded as KBr and CsI pellets on a Nicolet Magna 750 FT-IR spectrometer.

Preparation of complexes

Solid Na_2[*i*-mnt] (0.37 g, 2 mmol) was added to a solution of $NiCl_2{\cdot}6H_2O$ (0.24 g, 1 mmol) in methanol (20 ml) with stirring. The solution colour immediately turned to yellowish-green. After stirring for 30 min, a dichloromethane solution (20 ml) containing benzo-15-crown-5 (0.54 g, 2 mmol) was added dropwisely. The solution was stirred for another hour and its colour gradually changed to slightly reddish brown. The insoluble substance was filtered off and the solvent was removed by distillation to leave about 10 ml solution. Reddish brown crystals of **1** were obtained. Yield 0.72 g. Anal. calc. for $C_{37}H_{42}Cl_2N_4Na_2NiO_{10}S_4$: C, 44.2; H, 4.2; N, 5.6%. Found: C, 43.9; H, 4.1; N, 5.6%. IR (cm^{-1}) 2208vs ($\nu_{C\equiv N}$), 1597w, 1500s, 1454m ($\nu_{C=C}$, Ph), 1400s, 1377vs, ($\nu_{C=C}$, *i*-mnt), 1252s, 1209s, 1122vs ($\nu_{C\text{–}O\text{–}C}$), 1097s, 1047m, 949s, 941s, 897s ($\nu_{C\text{–}S}$), 748m, 740m, 730m, 480m, 380m, 301m, 210m ($\nu_{Ni\text{–}S}$).

$[\{(Benzo\text{-}15\text{-}crown\text{-}5)Na\}_2Ni(mnt)_2]_n$ **2** was prepared using the similar procedure as above with Na_2[mnt] instead of Na_2[i-mnt]. Deep red crystals of **2** were obtained in yield 0.65 g. Anal. calc. for $C_{36}H_{40}N_4Na_2NiO_{10}S_4$: C, 46.9; H, 4.4; N, 6.1%. Found: C, 46.7; H, 4.3; N, 6.0%. IR (cm^{-1}) 2218m, 2195vs, 2152w ($\nu_{C\equiv N}$), 1597w, 1504s, 1456m ($\nu_{C=C}$, Ph), 1481s ($\nu_{C=C}$, mnt), 1357w, 1257s, 1209s, 1124vs ($\nu_{C\text{–}O\text{–}C}$), 1090m, 1045m, 943s ($\nu_{C\text{–}S}$), 906s, 744m, 735m, 515m, 360m, 224m ($\nu_{Ni\text{–}S}$), 206m.

Crystal structure determination

Single crystals for structure determinations were obtained from methanol solution by slow evaporation of the solvent in air.

The crystal data for compound **1** and **2** are summarised in Table 1, together with some experimental details. Intensity data for compound **1** were obtained on a Siemens Smart/CCD area-detector diffractometer with graphite-monochromated Mo–Kα ($\lambda = 0.71073$ Å) radiation. Measurements was made by using an ω scan mode with a scan speed of 10 second/frame and 0.3°/frame in the range of $1.89 < \theta < 23.28$. Data reductions and cell refinements were performed with Smart-CCD software [25]. The cell parameters were obtained by a least-squares fit of 5639 reflections ($1.89 < \theta < 23.28$). Structure solution and refinement were carried out on an Indy workstation of Silicon Graphics using SHELXTL program package [26]. The structure was solved by direct method. All non-hydrogen atoms were located on the E-map or successive difference Fourier syntheses. The structure was refined by full-matrix least-squares techniques on F^2 with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were located theoretically and not refined. The final cycle of full-matrix least-squares refinement converged with $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.040$ and $wR = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2} = 0.099$, $w = 1/[\sigma^2(F_o^2) + (0.0599P)^2]$, where $P = (F_o^2 + 2F_c^2)/3$. Single crystal of **2** was scanned on a Enraf Nonius CAD-4 diffractometer with graphite-monochromated Mo-Kα ($\lambda = 0.71073$ Å) radiation. Intensity data were collected by using $\omega/2\theta$ scan mode with

a scan speed of 5.5°/min in the range of $2\theta < 50°$. The cell parameters were obtained by a least-squares fit of setting angles for 25 reflections ($11 < \theta < 17$). Structure of **2** was solved by direct method and refined by full-matrix least-squares techniques on *F* with anisotropic thermal parameters for all of the non-hydrogen atoms. Hydrogen atoms were located theoretically and not refined. The final full-matrix least-squares refinement converged with unweighted and weight agreement factors $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.060$ and $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.071$, $w = 1/[\sigma^2(F_o) + (0.020F_o)^2 + 1.0]$. All calculations were performed on a COMPAQ 486 computer using MOLEN/PC program package [27].

RESULTS AND DISCUSSION

Synthesis

Benzo-15-crown-5 with suitable cavity for Na^+ ion can form complexes in three fashions I, II and III as demonstrated in Scheme 1. The most probable way is I with the sodium ion sandwiched by two ligand molecules. In the synthesis process of **1** and **2**, the reactant ratios were held carefully. The excessive benzo-15-crown-5 may lead to discrete ionic product characterised as $[Na(benzo\text{-}15\text{-}crown\text{-}5)_2]_2[Ni(i\text{-}mnt)_2]$ and $[Na(benzo\text{-}15\text{-}crown\text{-}5)_2]_2[Ni(mnt)_2]$ [28]. Crystals of complex **1** with CH_2Cl_2 molecules included in are easily effloresced by losing the solvents. Crystals of **2** are very stable when exposed to air. Both the complex polymers are soluble in CH_3OH, CH_3CN, DMF and DMSO and barely dissolved in $CHCl_3$ and water. Complex anion $[Ni(mnt)_2]^{2-}$ in solution is easily oxidised to $[\{Ni(mnt)_2\}_2]^{2-}$ as reported in literature [20]. When the solution of complex **2** was evaporated slowly in air for single crystal growth, a little amount of black crystals was obtained and characterised as $[Na_2(H_2O)_2(benzo\text{-}15\text{-}crown\text{-}5)_3][\{Ni(i\text{-}mnt)_2\}_2]$ by X-ray diffraction, which has nickel(III) dithiolene complex anions and interesting triple-decker crown ether sodium dications [28].

Description of the structure

The labelling scheme and ORTEP diagram of the asymmetric unit for **1** and **2** are shown in Figs 1 and 2. The structures of the moieties [Na(benzo-15-crown-5)] in both **1** and **2** are similar to that of $[Na(benzo\text{-}15\text{-}crown\text{-}5)ClO_4]$ reported by Owen [7] and that of $[Na(benzo\text{-}15\text{-}crown\text{-}5)(C_6H_2N_3O_7)]$ by Ward *et al.* [8]. Each of the sodium ions is half-capped by one benzo-15-crown-5 cycle through co-ordinated oxygen atoms. The Na^+ ions lie about 1.0 Å towards the complex anions from the plane of the five O atoms of associated crown cycles. The oxygen atoms are coplanar to within not larger than 0.5 Å. The Na–O distances in the two structures fall in the range from 2.375(5) to 2.544(4) Å and have a mean value of 2.452(5) Å. Both the lower and upper limits occur at Na(2) in **2**. The selected bond distances and angles are listed in Tables 2 and 3 together with the average Na^+–O bond dis-

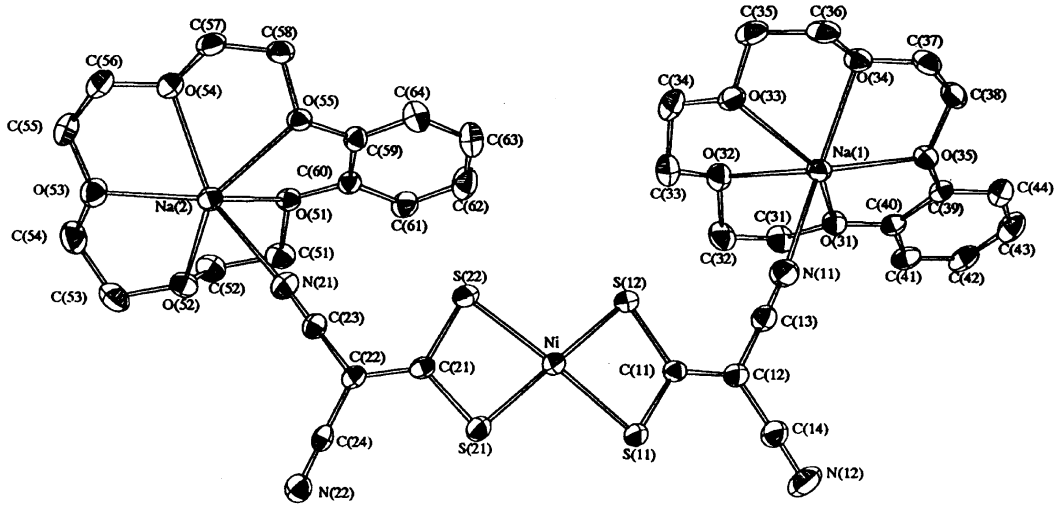

Fig. 1. ORTEP drawing of the molecular structure and labelling scheme for the main segment of **1**. Displacement ellipsoids are shown at the 25% probability level and hydrogen atoms have been omitted for clarity.

tances for individual sodium ions. From the sum of the van der Waals radii [29] 1.40 Å for O and the effective ionic radii 1.02 Å for Na^+, one may expect distance Na^+–O of 2.42 Å. The mean value for the twenty Na^+–O distances in **1** and **2** is in perfect agreement with predicted values and is comparable to 2.399(5) Å (average) observed in [Na(benzo-15-crown-5)ClO_4] [7] and 2.430(3) Å in [Na(benzo-15-crown-5)($C_6H_2N_3O_7$)] [8].

The remarkable structural feature for **1** is the four Na^+–NC bonds and for **2** is the three Na^+–NC bonds and a weak Na^+–S interaction. These contacts link the $[Na(benzo\text{-}15\text{-}crown\text{-}5)]^+$ cations and $[Ni(i\text{-}mnt)_2]^{2-}$ or $[Ni(mnt)_2]^{2-}$ anions to form infinite -Ni-(i-mnt)-$[Na(benzo\text{-}15\text{-}crown\text{-}5)]_2$-(i-mnt)- or -Ni-(mnt)-$[Na(benzo\text{-}15\text{-}crown\text{-}5)]_2$-(mnt)- chains. For the asymmetrical unit, there exist two inversion centres located at the midway between Na(1) and Na(1^i) as well as Na(2) and Na(2^{ii}) (symmetry code for **1**, *i*: $1-x, 1-y, 1-z$; ii: $2-x, -y, -z$ and for **2**, i: $1-x, 1-y, -z$; ii: $2-x, 1-y, 1-z$). From the sum of the van der Waals radii (1.50 Å for N and 1.8 Å for S) [29] and the effective ionic radii for Na^+, the expected distances for Na^+–N and Na^+–S are 2.52 and 2.82 Å, respectively. The Na(1)–N(11), Na(2)–N(21) and Na(2)–N(22^{ii}) in **1** and Na(1)–N(11), Na(2)–N(21) in **2** are all shorter than the predicated value of 2.52 Å, which indicates the genuine bonds between sodium ions and those cyano groups. Na(2)–N(21^{ii}) in **1** and Na(1)–N(12^i), Na(2)–S(22^{ii}) in **2** are slightly longer

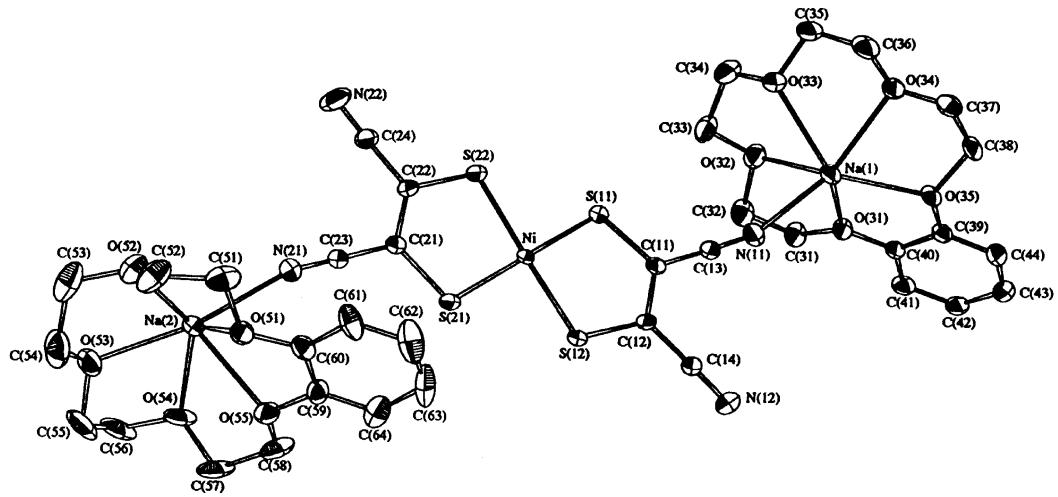

Fig. 2. ORTEP drawing of the molecular structure and labelling scheme for the anion portion of **2**. Displacement ellipsoids are shown at the 25% probability level and hydrogen atoms have been omitted for clarity.

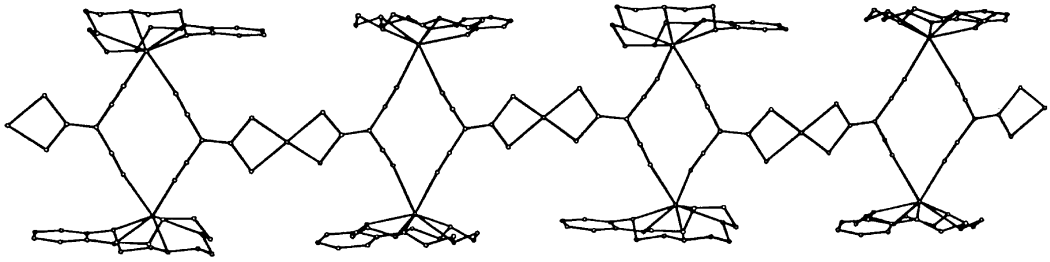

Fig. 3. A drawing of the polymer chain for the main segment of **1**.

than the predicted values showing weaker interactions between these atoms. If all these contacts are taken into consideration, the formation of chain-like polymers are obvious. Typical Na^+–N distances reported are Na^+–$NCCH_3$ 2.523(10) Å in $(NaI)_2(CH_3CN \cdot H_2O)_3$ [30], Na^+–NCS 2.396(2) Å in $Na(C_{12}H_{24}O_5S)(SCN)$ ($C_{12}H_{24}O_5S$ = crown thioether) [31] and Na^+–NC 2.532(15) and 2.568(14) Å in $NaAg(CN)_2$ [32]. A sodium-sulphur co-ordination is primarily found in inorganic compounds with Na^+–S distances in the range 2.8–3.1 Å [33]. The Na^+–N and Na^+–S contacts in Na_2[i-mnt] [34] were found to be 2.616(5) and 2.943(2) Å (average), respectively. The polymer chain structures of **1** and **2** can be described in terms of infinite "train" for the end-to-end arrangements of the complex anions that are considered to be the "body frames". Thus the crown cycles standing by the "body frames" act as "cartwheels" and that joint the body-frame and cartwheels are the sodium ions. Drawings of polymer chain of **1** and **2** are demonstrated in Figs 3 and 4.

For the crystal structures of **1** and **2**, there are two polymer chains in a cell, related to each other through the cell centre (1/2, 1/2, 1/2). One Ni atom was found in the asymmetrical unit co-ordinated by four S atoms of two i-mnt or mnt units. The NiS_4 grouping in both the structures is essentially planar. Notable deviations from planarity are found however when the whole $[Ni(i\text{-}mnt)_2]^{2-}$ and $[Ni(mnt)_2]^{2-}$ units are considered and probably due to the packing force. Na(1) and Na(2) are separately within planes of the nearest ligands with deviations not larger than 0.1 Å. The Ni–S distances in **1** are regularly in the range of 2.201(1) to 2.213(1) Å and are comparable to 2.106(4) Å found in $[\{Ni(NH_3)_4\}Ni(S_2C{=}C(CN)\}_2]_\infty$ [22]. The geometry of the i-mnt ligands in **1** is nearly the same as those detected in this compound. The average C–S bond distance of 1.719(5) shows some double-bond character, which is near the value of 1.713(3) Å observed in Na_2[i-mnt] [34] and is slightly shorter than 1.78(2) Å in the complex $[\{Ag(PPh_3)_2\}_2Ni(i\text{-}mnt)_2]$, in which the sulphur atoms co-ordinate to both Ni and Ag atoms tetrahedrally [35]. For compound **2** the Ni–S separations are slightly shorter than the corresponding values in **1** indicating the difference of cycle intension affecting on bond distances between a five-membered ring and a four-membered one. Structure details with mnt in **2** are similar to those found in $[NBu_4]_2[Ni(mnt)_2]$ [36] and $[\{Ag(PPh_3)_2\}_2Ni(mnt)_2]$ [35]. Compared with the values in free ligand $[i\text{-}mnt]^{2-}$ and $[mnt]^{2-}$ before complexation, no significant changes for the C–C, C=C, C≡N bond distances in both the two structures were found. This indicates that the bondings in the complex polymers are similar to those in free ligands with the delocalization of the π system.

Comments: "pH-Independent decomposition reactions of L-ascorbic acid in aqueous metal solutions—I. Formation and structures of Co(II) and Gd(III) oxalates"

Synthesis and Structure of $[Ln(H_2O)_3]_2(C_2O_4)_3$ with Ln = Eu, Gd, Tb and Dy

D. Trollet, S. Roméro, A. Mosset and J. C. Trombe*

C.E.M.E.S., 29, Rue J. Marvig, F-31055 Toulouse Cedex 4, France

(Received 20 January 1998; accepted 22 February 1998

In their paper *'pH-Independent decomposition reactions of* L-ascorbic acid in aqueous metal solutions—I. Formation and structures of Co(II) and Gd(III) oxalates', C. Ünaleroglu *et al.* claim to have synthesized the gadolinium oxalate 'hexahydrate' and solved its structure by X-ray diffraction on a single crystal [1]. Although the R values were acceptable ($R = 0.055$, $wR = 0.067$) and, moreover, the residuals in the electron map were weak ($\Delta\rho_{max} = 0.11\ eÅ^{-3}$), such a structural determination appears, to us, as being questionable because of its similarity with the well-known gadolinium oxalate 'decahydrate'.

The lanthanide oxalates have been the object of many structural studies. There were two series of lanthanide oxalate hydrate:

—$[Ln(H_2O)_3]_2(C_2O_4)_3.4H_2O$ with Ln = La ... Er (including yttrium), known as 'decahydrate', crystallizing in the monoclinic system, space group $P2_1/c$ or $P2_1/a$ [2–9].

—$[Ln(H_2O)_2]_2(C_2O_4)_3.2H_2O$ with Ln = Ho ... Lu (including yttrium and scandium), known as 'hexahydrate', crystallizing in the triclinic system, space group $P\bar{1}$ [10–12].

Both series have a similar layered structure. Lanthanide elements and oxalate ligands build a layer parallel to (010) for the first series and to $(1\bar{1}0)$ for the second one. The only major difference is the number of water molecules either free or linked to the lanthanide. Three or two water molecules are bounded to the lanthanide for the first or the second series, respectively; that is, the result of the well-known 'lanthanide contraction'. The number of free water molecules also differs, four or two per formula, respectively. Free water molecules are located into the interlayer space and, particularly for the first series, they are disordered. However, they contribute to the cohesion of the lattice through hydrogen bonds.

Usually, gadolinium belongs to the first series. To our knowledge, Ollendorf *et al.* are the first ones to describe gadolinium oxalate 'decahydrate' [5]. The cell constants, reported by these latter authors, are $a = 11.042$ Å, $b = 9.631$ Å, $c = 10.097$ Å, $\beta = 114.14°$; $V = 979.9$ Å^3, and $Z = 2$ (per formula), space group $P2_1/c$. These parameters are very close to those observed by Ünaleroglu, $a = 10.075(1)$ Å, $b = 9.634(1)$ Å, $c = 11.049(1)$ Å, $\beta = 65.8(1)°$; $V = 978.4(1)$ Å^3, space group $P2_1/a$: the parameters a and c are inverted and β must be the supplementary angle $180 - 65.8° = 114.2°$ in order to transform the space groups from $P2_1/a$ to $P2_1/c$.

Thus, it is likely that Ünaleroglu *et al.* have forgotten the free water molecules and, in fact, they are dealing with gadolinium oxalate 'decahydrate'. If the formula stated by these authors were true, the loss of eight free water molecules per unit-cell would result in a very open framework, about 20% in volume (*vide infra*) and, as these last molecules strengthen the framework, their departure would certainly causes a collapse of the lattice.

By contrast, we have clearly shown the existence of

* Author to whom correspondence should be addressed.

such a hexa-aquo di-gadolinium tris-oxalate, $[Gd(H_2O)_3]_2(C_2O_4)_3$ [12–14]. This last complex crystallizes in the monoclinic system, space group $P2_1/c$, with $a = 8.371(1)$ Å, $b = 9.748(4)$ Å, $c = 9.417(4)$ Å, $\beta = 90.26(2)^\circ$; $V = 768.5(4)$ Å^3 and $Z = 2$ (per formula). Indeed, the loss of free water molecules leads to a difference in the cell volume, $979.9 - 768.5 = 211.4$ Å^3, a value which is in agreement with the departure of 8 molecules (2×4) by taking V_{H_2O} as being equal to 26.4 Å^3. The structure is also layered but the frame differs largely from those observed in the 'decahydrate' and the 'hexahydrate'. This structure has been extended from europium to dysprosium.

(Received 20 March 1998; accepted 19 May 1998

In their comment [1], "Synthesis and Structures of $[Ln(H_2O)_3]_2(C_2O_4)_3$ with Ln = Eu, Gd, Tb and Dy", Trollet *et al*. criticize our published paper, "pH-Independent decomposition reactions of L-ascorbic acid in aqueous metal solutions-I. Formation and structures of Co(II) and Gd(III) oxalates" [2]. They claim we have forgotten the free water molecules and in fact have dealt with gadolinium oxalate 'decahydrate' instead of gadolinium oxalate 'hexahydrate' which we reported. They also claim that the absence of free water molecules in this structure, which are assumed to strengthen the framework, would certainly cause a collapse of the lattice.

In our paper, we have reported the crystal structure of gadolinium oxalate 'hexahydrate' obtained by the very slow decomposition of gadolinium ascorbate complex. The crystals were air-dried and stored in a closed vessel for about two months before performing the chemical, thermogravimetrical and X-ray analyses. The crystals were large enough for single crystal work. All analyses were done using samples from the same batch. Chemical analysis results clearly indicate the hexahydrate composition (10.6%C, 1.4%H). As shown by Wendlandt [3], the hydrate water of gadolinium oxalate decahydrate begins to come off at 45°C, at 120°C hexahydrate composition is reached and anhydrous oxalate is obtained at 315°C which then rapidly decomposes beyond 375°C. Our sample starts to dehydrate at 120°C (Fig. 1) and the mass loss of 16% (15.7%, theoretical) in the dehydration step is consistent with the hexahydrate composition. These results undoubtedly indicate the absence of free water. It is also a well known fact that the number of water molecules depends on the preparation conditions [3, 4]. The varying water content obtained for the compounds $M_2(C_2O_4)_3 \cdot nH_2O$ might be explained by the inclusion of different amounts of water in the cavities depending on the conditions such as temperature and the metal ionic radii. It should be noted that our sample has been obtained by the very slow decomposition of gadolinium ascorbate complex rather than by precipitating from aqueous oxalate solutions as for most oxalate hydrates [5, 6] or by heating the decahydrate structure with $Na_2C_2O_4$ at 150°C as reported by Trollet *et al*. [7].

The precise experimental CAD-4 diffractometer measurements of our gadolinium oxalate 'hexahydrate' showed that it crystallized in the monoclinic system, space group $P2_{1/a}$ with $a = 10.075(1)$ Å, $b = 9.634(1)$ Å, $c = 11.049(1)$ Å, $\beta = 65.8(1)°$, $V = 978.4(1)$ Å^3, $Z = 4$, $D_x = 2.33$ Mg·m^{-3}. The final refinement values were $R = 0.055$, $wR = 0.067$, $S = 1.08$ and $\triangle\rho\,(\max) = 0.11$ eÅ^{-3}, which are the most powerful evidence of the correctness of the structure determination. If there were forgotten free water molecules in the structure, then the residual electron density would be higher, and we would expect large values of R, wR and S (goodness of fit).

The structure of $Nd_2(C_2O_4)_3 \cdot 10.5H_2O$ isotypic with $Gd_2(C_2O_4)_3 \cdot 10H_2O$ was studied by Hansson [4] who showed that the two oxalate ligands link the metal atoms in chains running parallel to a-axis and the third oxalate links these chains together to form a network. The cavities were assumed to be occupied by free water molecules. The metal oxalate layers are held together directly by hydrogen bonds formed between the oxygens coordinated to metal atoms of adjacent layers and indirectly *via* the water molecules in the cavities. The following low-temperature work by Hansson [6] on the determination of the previously unlocated free water molecules in $Nd_2(C_2O_4)_3 \cdot 10.5H_2O$, reveals that the main function of these molecules seems to be of filling space and they should be only weakly attached to the surrounding atoms and

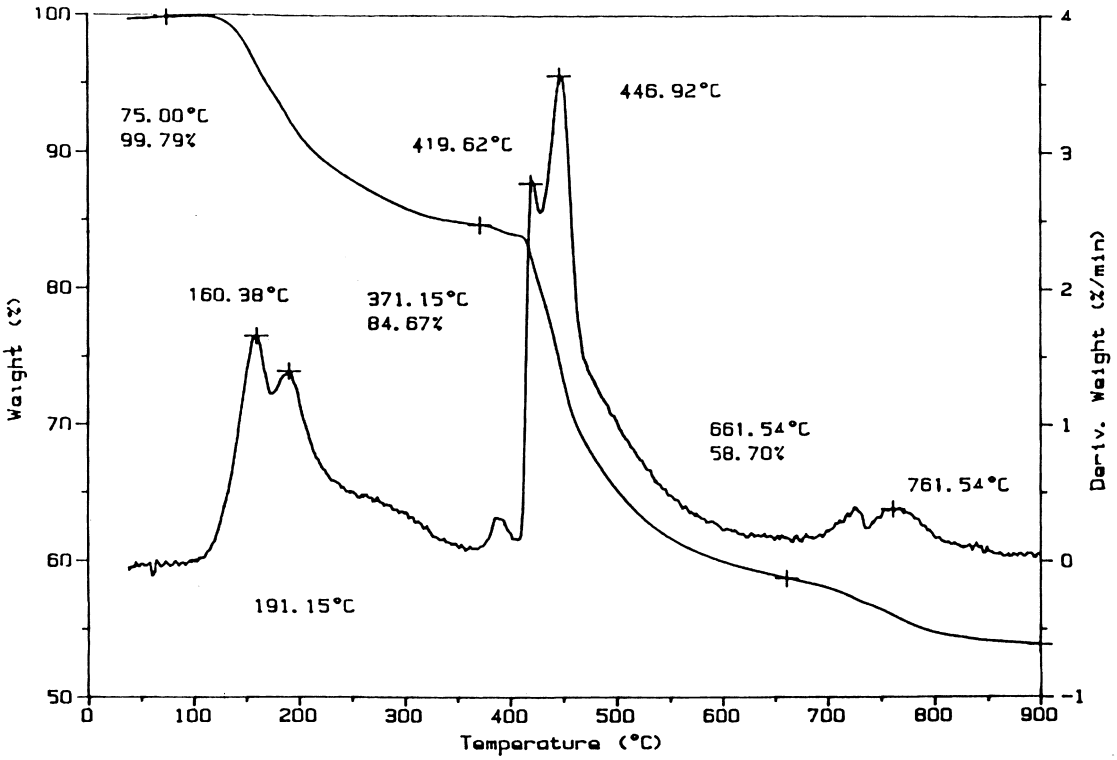

Fig. 1. Thermal decomposition curve of gadolinium oxalate hexahydrate.

each other. The same interaction was reported for the $Sc_2(C_2O_4)_3 \cdot 6H_2O$ structure [8]. It appears that the hydrogen bonds which hold the lattice are those between water molecules coordinated to the metal ion and the carboxylic oxygens in adjacent layers. So, leaving off the free water molecules which can be expected to be thermally labile due to weak hydrogen or Van der Waals bonds from the cavities of such a zeolite-like structure neither causes a collapse of the lattice nor changes the structure and the unit cell volume as determined [9] and reported by us [2].

(Received 3 April 1998; accepted 12 May 1998)

Abstract—The halogenopentacarbonylrhenium(I) compounds react with 2,6-bis(diphenylphosphinosulfide) pyridine (L) under mild conditions to yield ionic complexes of general formulae, *fac*-$[Re(CO)_3L]^+$ $[Re_2(CO)_6(\mu\text{-}X)_3]^-$ (X = Cl, Br or I), in which the ligand adopts a facial terdentate bonding mode. A synthesis of $[Re(CO)_3L]^+$ $[SbF_6]^-$ was carried out to establish the presence of the cation, *fac*-$[Re(CO)_3L]^+$, in the complexes. The character of the anions was confirmed by negative ion MALDI-TOF mass spectrometry. The cation is fluxional; the P–phenyl rings oriented towards the metal moiety exhibit restricted rotation at low temperature. The free energy of activation, $\Delta G^{\dagger}$, for hindered rotation is *ca.* 47 kJ mol^{-1} for all complexes. Solid-state ^{31}P NMR data are reported for the free ligand and for the complexes, $[Re(CO)_3L][SbF_6]$ and $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tricarbonylrhenium(I); solid-state NMR; phosphine ligands.

INTRODUCTION

Metal complexes of ligands that have uncoordinated donor atoms are now well established as fluxional species. The classical example of this type of fluxional behaviour is exhibited by transition metal complexes of 2,2′:6′,2″-terpyridine (terpy), in which terpyridine is restricted to a bidentate bonding mode [1, 2]. Other potentially terdentate ligands, such as 2,6-bis(oxazolinyl)pyridines [3, 4] and 2,6-bis(sulfanyl)pyridines [5, 6], also display fluxional behaviour when coordinated to a metal in a bidentate fashion. As part of our on-going interest in the dynamic stereochemical behaviour exhibited by transition metal complexes of this type, we chose to investigate the tricarbonylrhenium(I) halide complexes of 2,6-bis (diphenylphosphinosulfide)pyridine (L). It was expected that, under mild conditions, the ligand would react with the halogenopentacarbonylrhenium(I) compounds, to form complexes of general formulae *fac*-$[ReX(CO)_3L]$ (X = Cl, Br or I), with the ligand bound in a bidentate fashion via the N donor of the pyridine ring and one of the sulfur donors. However, analytical and spectroscopic data indicate that ionic complexes of the type *fac*-$[Re(CO)_3L]^+$ A^- (where A is the counter ion) are formed, with the ligand adopting a facial terdentate bonding mode. Accordingly, we report here on the synthesis and characterisation of the complexes *fac*-$[Re(CO)_3L]^+$ $[Re_2(CO)_6(\mu\text{-}X)_3]^-$ (X = Cl, Br or I) and *fac*-$[Re(CO)_3L]^+$ $[SbF_6]^-$.

EXPERIMENTAL

Syntheses

All manipulations were carried out under an atmosphere of dry oxygen-free nitrogen, using standard Schlenk techniques [7]. Solvents were dried [8] and degassed before use. The pentacarbonylrhenium(I) halides [9] were prepared using previously published procedures and the ligand, 2,6-bis(diphenylphosphinosulfide)pyridine (L) was prepared by Professor W. McFarlane [10]. The three complexes $[Re(CO)_3L]^+[Re_2(CO)_6(\mu\text{-}X)_3]^-$ (X = Cl, Br or I) were prepared similarly, as illustrated by the procedure for $[Re(CO)_3L]^+[Re_2(CO)_6(\mu\text{-}Br)_3]^-$. The hexafluoroantimonate complex was prepared by treatment of $[Re(CO)_5(thf)]^+$ $[SbF_6]^-$ with 2,6-bis(diphenylphosphinosulfide)pyridine, and from $[Re(CO)_3L]^+$ $[Re_2(CO)_6(\mu\text{-}Br)_3]^-$, by treatment with $AgSbF_6$, as described.

$[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}Br)_3]$

Pentacarbonylrhenium(I) bromide (120 mg, 0.295 mmol) and 2,6-bis(diphenylphosphinosulfide) pyridine (150 mg, 0.293 mmol) were heated under reflux in 20 cm^3 of a 50:50 (v/v) mixture of benzene–petroleum ether (b.p. 60–80°C) for *ca.* 18 h. The resulting orange solid was isolated by filtration, and recrystallised from dichloromethane. Yield: 77 mg, 50%.

$[Re(CO)_3L][SbF_6]$

Method A $[ReBr(CO)_5]$ (50 mg, 0.123 mmol) and $AgSbF_6$ (30 mg, 0.127 mmol) were refluxed in 15 cm^3 of tetrahydrofuran (thf) for *ca.* 2 h. The resulting solution was filtered (to remove AgBr) and then added to a stirred solution of 2,6-bis(diphenylphosphinosulfide)pyridine (70 mg, 0.137 mmol in 5 cm^3 of thf). The reaction mixture was refluxed for *ca.* 18 h, then the solvent removed *in vacuo*, to yield a yellow–orange solid. Recrystallisation from dichloromethane–pentane yielded 60 mg (48%) of yellow $[Re(CO)_3L][SbF_6]$.

Method B $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}Br)_3]$ (100 mg, 0.06 mmol) and $AgSbF_6$ (25 mg, 0.106 mmol) were stirred at ambient temperature for *ca.* 24 h, in 20 cm^3 of CH_2Cl_2. The resulting yellow solution was filtered (to remove AgBr) and evaporated to dryness *in vacuo*. The crude yellow product was crystallised from dichloromethane–pentane. Yield: 64 mg, 98%.

Physical methods

Infrared spectra were recorded in CH_2Cl_2, using matched CaF_2 solution cells on a Nicolet 205 FT-IR spectrometer operating in the region 4000–400 cm^{-1}. Elemental analyses were carried out at University College London. Mass spectra were obtained at the London School of Pharmacy. Fast atom bombardment (FAB) mass spectra were carried out on a VG Analytical ZAB-SE instrument, using Xe^+ ion bombardment at 8 kV energy. Matrix assisted laser desorption/ionisation time of flight (MALDI-TOF) mass spectra were obtained on a Fisons TofSpec instrument, with a linear flight path of 0.9 m, operating in the negative ion mode. The laser was fired fifty times at minimal energy, to produced the averaged spectra. The matrix used was 5-chloro-2-mercaptobenzothioazole. X-Ray powder patterns were obtained by Dr I. P. Parkin, University College London, on a Siemens D5000 X-ray powder diffractometer, using Ge monochromated Cu-K_α radiation ($\lambda = 1.5406$ Å).

Solution-state ^1H, ^{19}F and ^{31}P NMR spectra were recorded in CD_2Cl_2 or $CDCl_3$ on a Bruker AMX400 Fourier transform spectrometer, operating at 400.13, 376.45 and 161.98 MHz, respectively. Chemical shifts are reported relative to tetramethylsilane (^1H), $CFCl_3$ (^{19}F) and 85% aqueous H_3PO_4 (^{31}P). NMR probe temperatures were controlled by a standard B-VT 2000 unit; probe temperatures were periodically checked (100% MeOH) and are considered accurate to within ± 1°C.

High-resolution solid-state ^{31}P NMR spectra were recorded at 121.5 and 242.9 MHz on Bruker MSL300 and AMX600 Fourier transform spectrometers, respectively, equipped with standard Bruker magic angle spinning probes. Spectra were measured at ambient temperature (298 K), on polycrystalline powders in zirconia rotors with a 4 mm external diameter. Chemical shifts are quoted relative to 85% aqueous H_3PO_4. Spectra were recorded using a "single-pulse" sequence with magic angle spinning and high-power ^1H decoupling. The isotropic peaks were identified by varying the MAS frequencies (3–11 kHz) and the principal components of the ^{31}P CSA tensor (δ_{11}, δ_{22} and δ_{33}) were determined using the Herzfeld–Berger method [11] [prior to the spinning side-band analyses, the overlapping resonances were deconvoluted using the NUTS (Acorn NMR) line fitting subroutine]. The chemical shielding anisotropy, $\Delta\sigma$, and the asymmetry parameter, η, are defined as [12]: $\Delta\sigma = [(\delta_{11} + \delta_{22})/2] - \delta_{33}$ and $\eta = (\delta_{11} - \delta_{22})/(\delta_{iso} - \delta_{33})$, where $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$.

RESULTS AND DISCUSSION

Treatment of the halogenopentacarbonylrhenium(I) compounds with a stoichiometric quantity of 2,6-bis(diphenylphoshinosulfide)pyridine (L) (Fig. 1) under moderate conditions was expected to yield complexes of general formulae *fac*-$[ReX(CO)_3L]$ (X = Cl, Br or I), with the ligand bound to the metal in a bidentate fashion [structure (**II**), Fig. 1]. However, microanalytical data indicated the formation of complexes of molecular formulae $Re_3(CO)_9X_3L$. The fast atom bombardment (FAB) mass spectra of all three

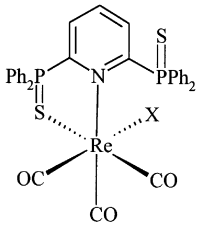
(I)



(II)

Fig. 1. The structures of the free ligand (L), the $[Re(CO)_3L]$ cation (**I**) and the expected complexes, $[ReX(CO)_3L]$ (**II**). The hydrogen atom labelling schemes for the ligand and (**I**) are shown alongside.

complexes displayed a molecular ion at $m/z^+ = 782$, which corresponds to the species $[Re(CO)_3L]^+$ [structure (**I**), Fig. 1] (the observed and calculated isotope patterns are consistent). Since rhenium-halide bonds in halogenotricarbonylrhenium(I) complexes usually remain intact on ionisation [13], FAB mass spectral data indicate the formation of a cationic species, in which the ligand acts in a terdentate bonding mode. As the cation stoichiometry is $Re(CO)_3L$, the counter ions must have the molecular formulae (from the C, H and N analyses) $Re_2(CO)_6X_3$ (X = Cl, Br or I). Complex anions of this stoichiometry are know; namely the triply halide-bridged dirhenium anions, $[Re_2(CO)_6(\mu\text{-}X)_3]^-$ (X = Cl, Br or I) [14, 15]. Negative ion mass spectrometry (using the MALDI-TOF technique) was carried out on the complexes to confirm the nature of the anions; molecular ions were observed for the three complexes at $m/z^- = 645$ (X = Cl), 779 (X = Br) and 920 (X = I), due to the proposed anions. Analytical data are reported in Table 1.

Attempts to prepare the desired complexes, $[ReX(CO)_3L]$, by treatment of the rheniumpentacarbonyl halides with 2,6-bis(diphenylphoshinosulfide)pyridine under milder conditions (CH_2Cl_2; ambient temperature) were unsuccessful; the ionic species, $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I), were again isolated (although reaction times were significantly longer).

To confirm the presence of the $[Re(CO)_3L]^+$ cation in the complexes isolated (see above), an explicit synthesis of the hexafluoroantimonate salt, $[Re(CO)_3L]^+[SbF_6]^-$ was carried out. Reaction of $[ReBr(CO)_5]$ with $AgSbF_6$ in tetrahydrofuran (thf), followed by treatment of the $[Re(CO)_5(thf)]^+$ cation with a stoichiometric quantity of 2,6-bis(diphenylphoshinosulfide)pyridine (L), yielded $[Re(CO)_3L][SbF_6]$ as a yellow solid (see above). Treatment of $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}Br)_3]$ with $AgSbF_6$ also yielded $[Re(CO)_3L][SbF_6]$. Data (FAB-MS, IR and NMR) for the cation in $[Re(CO)_3L][SbF_6]$ were the same as for the proposed cation in the complexes, $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I). Attempts were made to grow single crystals for X-ray crystallographic studies in order to confirm unambiguously the terdentate bonding mode of the ligand; suitable crystals could not be obtained.

All four complexes, $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) and $[Re(CO)_3L][SbF_6]$, are stable in the solid-state under ambient conditions, and are soluble in moderately polar solvents (e.g. CH_2Cl_2). In coordinating solvents, such as acetone and methanol, the complexes quickly decompose; infrared spectroscopy indicates the formation of the $[Re(CO)_3(solvent)_3]^+$ cation and a quantitative yield of the free ligand is recovered.

The infrared spectrum of $[Re(CO)_3L][SbF_6]$ displayed three bands in the carbonyl stretching region, characteristic of a *fac*-octahedral coordination geometry, with local C_s symmetry, for the $Re(CO)_3$ moiety [16]. The free ligand displays a strong band at 647 cm^{-1} due to the P═S stretching mode [10]. Although no band assignable unambiguously to the P═S stretch in the cation, $[Re(CO)_3L]^+$, was observed, the band at 647 cm^{-1} is absent in the IR spectrum of the complex; infrared data therefore clearly indicate that the ligand, 2,6-bis(di-

phenylphoshinosulfide)pyridine, is acting in a *fac*-terdentate bonding mode with the S atoms coordinated to the metal. The IR spectra of the complexes $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) each displayed three bands due to the CO stretching modes of the cation (these were in identical positions to those observed for the SbF_6 salt), plus additional bands due to the counter ions, $[Re_2(CO)_6(\mu\text{-}X)_3]^-$ (X = Cl, Br or I). No band assignable to the free P═S stretching mode (see above) was observed. The isolated $[Re_2(CO)_6(\mu\text{-}X)_3]^-$ anions have local D_{3h} symmetry and are therefore expected to exhibit two IR active carbonyl stretching modes (A_2'' and E′). The sharp A_2'' bands are clearly observed to slightly lower frequency of the A_1 band of the cation. The E′ bands tend to overlap with the cation band at 1920 cm^{-1}; however, the E′ bands of the bromo- and iodo-species are observable. The CO stretching frequencies for the anions are close to those reported previously for the complexes $[Et_4N][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I), in the same solvent (CH_2Cl_2) [14]. Infrared data are reported in Table 1.

NMR studies

The ambient temperature (298 K) $^{31}P\{^1H\}$ NMR spectra of the complexes $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) and $[Re(CO)_3L][SbF_6]$ in CD_2Cl_2 are, as expected, identical. The spectra display a single resonance at $\delta \approx 67.0$ [cf. $\delta = 38.4$ for the free ligand (in $CDCl_3$)], indicating that either (i) both P are equivalent, as a result of the ligand adopting a symmetrical bonding mode or (ii) the ligand is undergoing some rapid fluxional process that leads to the averaging of different P environments. To try to distinguish between these two possibilities spectra were recorded at low temperature (190 K), in an attempt to "freeze-out" any dynamic stereochemical processes. No spectral changes were observed, indicating a stereochemically rigid molecule, with the two P atoms in identical chemical positions. Solution ^{31}P NMR data therefore indicate the formation of complex, in which both S(=PPh_2) atoms of the ligand are bound to the metal centre. This was confirmed by solid-state ^{31}P NMR spectroscopy (see below).

The solid-state ^{31}P spectrum of the free ligand, 2,6-bis(diphenylphoshinosulfide)pyridine, displays two isotropic resonances, with spinning side-bands, in a 1:1 intensity ratio at $\delta = 41$ and 38, as a result of the two P atoms being crystallographically inequivalent. The spectra also indicate the presence of residual dipolar coupling between the nitrogen (^{14}N nuclide) of the pyridine ring and the phosphorus nuclides. We are currently undertaking a full analysis of the solid-state NMR spectra of 2,6-bis(diphenylphoshinosulfide)pyridine and the related oxide and selenide compounds, and will report the results of these studies shortly.

The solid-state ^{31}P NMR spectra of the complexes $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) also display two isotropic resonances (with spinning side-bands), in a 1:1 (integral) intensity ratio at *ca.* $\delta = 65$ and 62. The small chemical shift differences between the signals indicate that they arise as a result of the P

atoms being crystallographically inequivalent, rather than as a result of chemical inequivalence. This clearly supports the hypothesis of the ligand bonding in a symmetrical fashion, with both S atoms coordinated. The hexafluoroantimonate salt, $[Re(CO)_3L][SbF_6]$, displays two isotropic signals, in a 1:1 intensity ratio, at *ca.* $\delta = 71$ and 66. The different chemical shifts of the isotropic resonances of the $[SbF_6]^-$ complex compared to those of the other three complexes (see above) presumably arise because of different packing in the solid-state. This interpretation is supported by the results of X-ray powder diffraction studies on the four complexes. The powder patterns obtained for the complexes $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or Br) are essentially identical, but are different from that obtained for $[Re(CO)_3L][SbF_6]$. The solid-state ^{31}P NMR spectrum of $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}Br)_3]$ is shown in Fig. 2 and ^{31}P NMR data for the ligand, 2,6-bis(diphenylphosphinosulfide)pyridine and the four complexes, $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) and $[Re(CO)_3L][SbF_6]$ are reported in Table 2.

The ambient temperature (298 K) ^1H NMR spectra of the complexes $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}X)_3]$ (X = Cl, Br or I) and $[Re(CO)_3L][SbF_6]$ [L = 2,6-bis(diphenylphosphinosulfide)pyridine] in CD_2Cl_2 are essentially identical. The spectra displayed eight distinct chemical shifts in the region $\delta = 7.2$–8.2 and are indicative of the ligand bonding in a symmetrical fashion. The signals of the pyridine-H nuclides, H_J, H_K and $H_{K'}$ Fig. 1, show the characteristic pattern of an ABB′ sub-set of an ABB′XX′ spin system (the P atoms being the XX′ sub-set). The signal from H_J is readily assigned because the $^4J_{PH}$ coupling (≈ 3.8 Hz) is approximately half that of the $^3J_{HH}$ coupling (≈ 7.8 Hz); thus H_J gives rise to a pseudo septet. The signal from $H_K/H_{K'}$ is then readily identified from a ^1H–^1H COSY experiment (see below).

If rotation about the P–C(phenyl) bonds is assumed to be rapid at ambient temperature (298 K), as appears apparent from the ^1H NMR spectra, the hydrogen nuclides of the P–phenyl rings would be expected to give rise to three resonances, characteristic of an AA′BB′C spin system. Thus the six remaining chemical shifts (see above) must result from inequivalence of pairs of phenyl rings. This inequivalence arises because two phenyl rings point towards the metal moiety and two away from it Fig. 1. If the inequivalence arose as a result of an unsymmetrical mode of co-ordination, then all four P–phenyl rings would be expected to be inequivalent (see Fig. 1) and twelve distinct chemical shifts would result. Ambient temperature ^1H NMR data are therefore consistent with either (i) a symmetrical bonding mode for the ligand or (ii) the presence of rapid fluxional process that leads to a time-averaging of pairs of phenyl rings. The latter possibility can be excluded to the basis of the ^{31}P NMR data (see above) and the results of a low temperature ^1H NMR study (see below). The resonances of the *ortho*-hydrogens of the phenyl rings are readily identified by their couplings to the phosphorus nuclides ($^3J_{PH} \approx 14$–15 Hz). The remaining signals (Table 3) can then be assigned on the basis of a single ^1H–^1H COSY experiment. The assignment of the two sets of phenyl–H signals to the two pairs of phenyl rings was based on the low temperature ^1H NMR spectra (see below). The ^1H NMR spectrum of $[Re(CO)_3L][Re_2(CO)_6(\mu\text{-}Cl)_3]$ at 298 K is shown in Fig. 3 and data are reported in Table 3.

[b] Ambient temperature (298 K) solution NMR data; spectra recorded in $CDCl_3$ or CD_2Cl_2 (see text).

[c] Literature value give in parentheses [see Ref. [10] (solvent not reported)].

A variable temperature ^1H NMR study of the complexes was undertaken, between ambient temperature (298 K) and *ca.* 200 K, to help confirm the stereochemical rigidity of the complexes, and thence the symmetrical bonding mode of the ligand, 2,6-bis(diphenylphosphinosulfide)pyridine. Although the ^1H NMR spectra are temperature dependent (see below), there was no evidence to indicate the slowing of an oscillatory rearrangement, that would be expected if the ligand were bound in a bidentate fashion [1–6]. The low temperature ^1H NMR spectra are therefore consistent with a stereochemically rigid symmetrical bonding mode for the ligand. Band shape changes indicative of restricted rotation about the P–C(phenyl) bonds of *one pair* of phenyl rings were observed on cooling. If it is assumed that the phenyl rings oriented towards the metal moiety have the higher magnitude for the free energy of activation ($\Delta G^{\dagger}$) for the P–C (phenyl) bond rotation, as a consequence of steric interactions with the metal moiety, a full assignment of the phenyl–H resonances to the two pairs of rings can be made. Assignments were made on this basis (Table 3). A full analysis of the variable temperature spectra was not undertaken. Approximate values for the free energies of activation were determined [17] at the temperature of initial line broadening ($T_i \approx 203$ K)

and from band coalescence ($T_c \approx 243$ K); $\Delta G^\dagger \approx 47$ kJ mol^{-1} at both T_i and T_c. The apparent temperature independence of $\Delta G^\dagger$ indicates that the entropy of activation, $\Delta S^\dagger$, is approximately zero, as expected for an intramolecular process. The activation energies measured were the same for all four complexes, consistent with the presence of the same cation in each case.

Although the ^{1}H and ^{31}P NMR data clearly show that the ligand is co-ordinated to the metal centre in a symmetrical fashion, via both S atoms, data do not exclude the possibility that the ligand is bound in a bidentate fashion, with the N donor of the pyridine ring uninvolved in bonding. This is considered highly unlikely on chemical grounds, and is inconsistent with the mass spectral and IR data (see above). The orange/yellow colour of the complexes (which is indicative of tricarbonylrhenium(I)–pyridine complexes [3, 13]) is also consistent with the pyridine ring being bound.

The ^{19}F NMR spectrum of the hexafluoroantimonate complex, $[Re(CO)_3L][SbF_6]$, was obtained to confirm the presence of the $[SbF_6]^-$ anion. The ambient temperature ^{19}F spectrum (in CD_2Cl_2) comprises two overlapping sub-spectra (at $\delta = -123.4$), due to coupling to ^{121}Sb ($I = 5/2$, 57.25%) and ^{123}Sb ($I = 7/2$, 42.75%); $^1J[^{121}Sb\text{–}F] = 1945$ Hz, $^1J[^{123}Sb\text{–}F] = 1050$ Hz. Data are consistent with those reported previously for the $[SbF_6]^-$ anion [18].

Acknowledgements—We are grateful to Birkbeck College for financial support, to Professor W. McFarlane for the synthesis of the ligand and to the University of London for access to the solid-state NMR facilities at University College London and Queen Mary and Westfield College and the 400 MHz solution NMR service at Kings College. Dr B. C. Smith and Dr G. Hogarth are acknowledged for helpful discussions.

(Received 2 April 1998; accepted 7 May 1998)

Abstract—Two 2,2′:6′,2″-terpyridine ligands bearing substituents in the 5 and 5″-positions have been prepared and their iron(II) complexes studied to investigate the influence of substituents in these positions. A synergistic interplay between σ- and π-bonding effects, involving conjugation of the substituents with the central ring, means that, in contrast to 4′-substituted 2,2′:6′,2″-terpyridines, the metal–ligand interactions cannot be simply correlated with the electron-donor or -acceptor properties of the substituents. The crystal structure of the complex $[Fe(\mathbf{3})_2][PF_6]_2 \cdot 2MeCN$ (**3** = 5,5″-bis(propoxy)-2,2′:6′,2″-terpyridine) is reported. In addition, cobalt(II) and ruthenium(II) complexes of 5,5″-bis(propoxy)-2,2′:6′,2″-terpyridine were prepared and characterised.

Keywords: metal complexes; 2,2′:6′,2″-terpyridine; ligand reactions; metallosupramolecular chemistry; oligopyridines.

1. INTRODUCTION

Oligopyridines are widely utilised as metal binding domains for metallosupramolecular chemistry [1–3]. The two earliest members of the series, 2,2′-bipyridine and 2,2′:6′,2″-terpyridine (tpy, **1**) have been most investigated and we have concentrated our attention upon derivatives of **1**. It is synthetically facile to incorporate a wide variety of electron-releasing or withdrawing substituents, in addition to functional components such as redox- or photoactive substituents, into the 4′-position of a 2,2′:6′,2″-terpyridine and we have systematically investigated the effects of such changes upon the coordination chemistry of the ligands and the properties of their metal complexes [4–6]. Surprisingly little is known about the effect of substituents in other positions on the coordination behaviour of derivatives of **1**, although substitution in the 5 and 5″-positions has been shown to lead to topologically novel supramolecular species [7, 8]. In this paper we describe our detailed studies of representative 5,5″-disubstituted 2,2′:6′,2″-terpyridines bearing electron-withdrawing and electron-releasing substituents.

2. EXPERIMENTAL

^{1}H NMR spectra were recorded on Brüker WM250, AM400 and DPX500 spectrometers; positive ion fast atom bombardment (FAB), fast ion bombardment (FIB) and electron impact (EI) mass spectra were recorded on a Kratos MS50 spectrometer using a 3-nitrobenzyl alcohol matrix for the FAB and FIB spectra. IR spectra were recorded on Perkin-Elmer 1710, Perkin-Elmer Paragon 1000 or a Philips PU9624 Fourier Transform spectrophotometers with the samples in compressed KBr disks. Electronic spectra were obtained using Kontron Instruments Uvikon 810P or Perkin-Elmer Lambda 12 spectrophotometers. Electrochemical measurements were carried out using an Autolab PGSTAT20 voltammetric analyser. A conventional three-electrode configuration was used, with platinum bead working and auxiliary electrodes and a silver wire pseudo-reference electrode. All measurements were performed in acetonitrile (distilled from CaH_2 then P_4O_{10}) with a supporting electrolyte of

0.1 M $[NBu^n_4][BF_4]$ (recrystallized from ethanol/water and rigorously dried) with a scan rate of $50\,mV\,s^{-1}$. Potentials are quoted vs ferrocene/ferrocinium ($Fc/Fc^+ = 0.0$ V) couple as measured from ferrocene which was added at the end of each experiment as an internal reference. The compound 5,5″-dinitro-2,2′:6′,2″-terpyridine (**2**) was prepared by the method in Refs [9, 10].

2.1. 5,5″-*Bis*(*propoxy*)-2,2′:6′,2″-*terpyridine*, **3**

Propan-1-ol (0.95 mmol, 57 mg) and **2** (150 mg, 0.464 mmol) were added sequentially to a slurry of powdered KOH (300 mg, 5.4 mmol) in dmso ($8\,cm^3$) and the mixture stirred for 24 h at 50°C. After this period, the reaction mixture was treated with water ($70\,cm^3$) to give an off-white precipitate of **3** (97 mg, 60%). This was recrystallised from $CHCl_3$/MeOH to give **3** as an analytically pure white crystalline material. Yield: 81 mg (50%). Mp. 122–126°C. (Found: C, 71.0; H, 7.2; N, 11.7% $C_{21}H_{23}N_3O_2 \cdot 1/3H_2O$ requires: C, 71.0; H, 6.7; N, 11.8%). IR (KBr): 1565 s, 1561 s, 1472 s, 1446 m, 1493 m, 1286 w, 1262 m, 1219 m, 1133 m, 1020 s, 811 s, 754 w, 719 m, 624 $m\,cm^{-1}$. Mass spectrum (+ve FAB): *m/z* 349 (M), 307 (M-C_3H_7), 265 (M-2(C_3H_7)). ^{1}H NMR ($CDCl_3$): δ 8.52 (d, 2H, H^3), 8.35 (d, 2H, H^6), 8.27 (d, 2H, $H^{3'}$), 7.87 (t, 1H, $H^{4'}$), 7.32 (dd, 2H, H^4), 4.03 (t, 2H, C$\mathbf{H}_2$O), 1.85 (m, 2H, C$\mathbf{H}_2$CH$_3$), 1.06 (d, 3H, C$\mathbf{H}_3$).

2.2. $[Co(\mathbf{2})_2][PF_6]_2$ *and* $[Fe(\mathbf{2})_2][PF_6]_2$

Ligand **2** (100 mg, 0.309 mmol) was added to a solution of $CoCl_2 \cdot 6H_2O$ (37 mg, 0.155 mmol) or $FeCl_2 \cdot 4H_2O$ (31 mg, 0.155 mmol) in methanol ($40\,cm^3$) and the mixture stirred at 50°C for 30 min. After this period, the reaction mixture was cooled to room temperature, filtered and the filtrate treated with an excess of ammonium hexafluorophosphate. The resultant precipitates were dissolved in acetonitrile and recrystallised by the diffusion of ether vapour into the solution to give the desired complexes analytically pure.

2.2.1. $[Co(\mathbf{2})_2][PF_6]_2$*: brown crystals*. Yield: 77 mg (50%). (Found: C, 35.3; H, 1.7; N, 13.5. $C_{30}CoH_{18}N_{10}O_8P_2F_{12}$ requires: C, 36.2; H, 1.8; N, 14.0%). IR (KBr): 1617 s, 582 w, 1540 m, 1452 m, 1356 s, 1292 m, 1257 m, 1129 w, 841 s, 755 m, 559 $s\,cm^{-1}$. Mass spectrum (+ve FAB): *m/z* 851 $\{Co(\mathbf{2})_2(PF_6)\}$, 705 $\{Co(\mathbf{2})_2\}$, 382 $\{Co(\mathbf{2})\}$. ^{1}H NMR (CD_3CN): δ 123, 67.1, 66.0, 25.0, 7.5. UV/VIS (MeCN): λ_{max}/nm ($\varepsilon/10^3\,dm^3\,mol^{-1}\,cm^{-1}$) 520 sh (0.65), 330 (32.2), 282 sh (46.2), 269 (50.3), 208 (46.8).

2.2.2. $[Fe(\mathbf{2})_2][PF_6]_2 \cdot H_2O$*: purple crystals*. Yield: 95 mg (61%). (Found: C, 35.1; H, 1.8; N, 13.3. $C_{30}FeH_{20}N_{10}O_9P_2F_{12}$ requires: C 35.7; H 2.0; N 13.9%). IR (KBr): 1619 m, 1576 w, 1534 s, 1450 m, 1355 s, 1279 m, 842 s, 756 m, 559 $s\,cm^{-1}$. Mass spectrum (+ve FAB): *m/z* 869 $\{Fe(\mathbf{2})_2(PF_6)(H_2O)\}$, 847 $\{Fe(\mathbf{2})_2(PF_6)\}$, 702 $\{Fe(\mathbf{2})_2\}$, 379 $\{Fe(\mathbf{2})\}$. ^{1}H NMR (CD_3CN): δ 8.72 (d, 4H, H^3), 9.23 (d, 4H, $H^{3'}$), 8.61 (dd, 4H, H^4), 8.95 (t, 2H, $H^{4'}$), 7.54 (d, 4H, H^5). UV/VIS (MeCN): λ_{max}/nm ($\varepsilon/10^3\,dm^3\,mol^{-1}\,cm^{-1}$) 582 (5.4), 395 sh (8.9), 334 (64.6), 289 (72.3), 266 (71.4).

2.3. $[Ru(\mathbf{2})_2][PF_6]_2$

Ligand **2** (100 mg, 0.309 mmol) and $RuCl_3 \cdot 3H_2O$ (40 mg, 0.155 mmol) were suspended in ethane-1,2-diol ($15\,cm^3$) and the mixture heated to 150°C for 15 min. After this period, the reaction mixture was cooled to room temperature and treated with methanol ($20\,cm^3$) and treated with an excess of ammonium hexafluorophosphate. The precipitate was dissolved in acetonitrile and recrystallised by the diffusion of ether vapour into the solution to give $[Ru(\mathbf{2})_2][PF_6]_2$ as a dark orange–brown microcrystalline solid. Yield: 72 mg (45%). (Found: C, 33.8; H, 1.6; N, 12.9. $C_{30}H_{18}N_{10}O_8P_2RuF_{12}$ requires: C 34.73; H 1.75; N 13.50%). IR (KBr): 1618 m, 1577 m, 1535 s, 1452 m, 1356 s, 1280 m, 1257 w, 841 s, 755 m, 559 s cm^{-1}. Mass spectrum (+ve FAB): *m/z* 892 $\{Ru(\mathbf{2})_2(PF_6)\}$, 748 $\{Ru(\mathbf{2})_2\}$, 424 $\{Ru(\mathbf{2})\}$. ^{1}H NMR (CD_3CN): δ 8.74 (d, 4H, H^3), 9.04 (d, 4H, $H^{3'}$), 8.65 (dd, 4H, H^4), 8.66 (t, 2H, $H^{4'}$), 7.90 (d, 4H, H^6). UV/VIS (MeCN): λ_{max}/nm ($\varepsilon/10^3\,dm^3\,mol^{-1}\,cm^{-1}$) 499 (6.1), 328 (43.0), 286 (49.9), 265 (41.8), 218 (39.9).

2.4. $[Fe(\mathbf{3})_2][PF_6]_2$

$FeCl_2 \cdot 4H_2O$ (28 mg, 0.141 mmol) was added to a methanolic solution of **3** (98.4 mg, 0.282 mmol) and the mixture was stirred for 30 min at 50°C. The resulting purple solution was filtered and the complex precipitated by the addition of excess methanolic $[NH_4][PF_6]$. Recrystallisation from MeCN/Et_2O gave purple crystals of $[Fe(\mathbf{3})_2][PF_6]_2 \cdot 2H_2O$. Yield: 120 mg (80%). (Found: C, 46.3; H, 4.7; N, 7.65. $FeC_{42}H_{50}N_6O_6P_2F_{12}$ requires: C, 46.7; H, 4.7; N, 7.8%). IR (KBr): 1603 m, 1570 m, 1459 m, 1400 m, 1302 m, 1242 m, 1113 w, 1014 m, 842 s, 802 w, 558 $s\,cm^{-1}$. Mass spectrum (+ve FAB): *m/z* 900 $\{Fe(\mathbf{3})_2(PF_6)\}$, 755 $\{Fe(\mathbf{3})_2\}$. ^{1}H NMR (CD_3CN): δ 8.34 (d, 4H, H^3), 8.64 (d, 4H, $H^{3'}$), 7.38 (dd, 4H, H^4), 8.54 (dd, 2H, $H^{4'}$), 6.57 (d, 4H, H^6), 3.75 (t, 8H, C$\mathbf{H}_2$O), 1.56 (m, 8H, C$\mathbf{H}_2$CH$_3$), 0.83 (d, 12H, C$\mathbf{H}_3$). UV/VIS (MeCN): λ_{max}/nm ($\varepsilon/10^3\,dm^3\,mol^{-1}\,cm^{-1}$) 529 (5.8), 337 (37.8), 273 (76.9), 216 (37.6).

2.5. *Crystal structural determination of* $[Fe(\mathbf{3})_2][PF_6]_2 \cdot 2MeCN$

Red blocks of the compound were obtained by the slow diffusion of diethyl ether vapour into an acetonitrile solution of the complex. A single crystal was mounted in a capillary tube and all geometric and

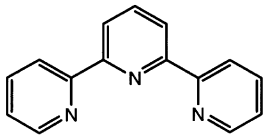
intensity data were taken from this crystal using a AFC7-R diffractometer. Pertinent crystallographic data are given in Table 1. Intensity data, gathered by the ω–2θ method were reduced by routine procedures. Structure solution used SHELXS-86 and the structure was refined using SHELXL-93. Empirical absorption corrections (ψ-scans) were applied.

The structure was solved by direct methods and refined by alternating cycles of least squares refinement and difference-Fourier synthesis. The Fe, C, N and O atoms of the cation and the P atoms of the anions were refined anisotropically. Refinement was carried out on F^2 for all reflections except for two with very negative F^2 values or flagged by the user for potential systematic errors. One of the two hexafluorophosphate counterions is extensively disordered and the propoxy chains show high thermal parameters. Selected bond angles and bond distances are given in Table 2.

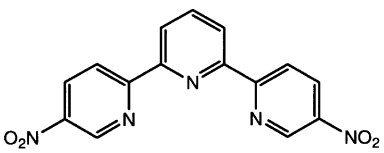
3. RESULTS AND DISCUSSION

3.1. *Ligand synthesis*

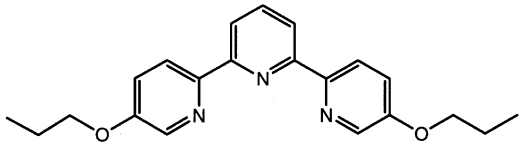
Our aim was to prepare a suite of 2,2′:6′,2″-terpyridine ligands with varying substituents in the 5,5″-positions in order to investigate the effect of electron-releasing and electron-withdrawing groups in these positions. We selected the 5,5″-dinitro compound **2** and the 5,5″-alkoxy derivative **3** as representatives with electron-withdrawing and electron-releasing groups, respectively. The substituted ligand **2** was prepared by the literature method [9, 10] and was obtained as a pale brown microcrystalline solid. All spectroscopic and physical properties were in accord with the structure and with those previously reported. Surprisingly, although **2** has been known for a number of years, the coordination chemistry does not seem to have been systematically investigated.



1



2



3

Although 4-nitropyridines are known to be activated towards attack by) nucleophiles with concomitant displacement of nitrite and the formation of 4-substituted derivatives, such reactions are not well-established for 5-nitropyridines, in which the negative charge which develops on the ring in the associative intermediate cannot be localised onto the more electronegative nitrogen atom of the pyridine ring. However, we have found that **2** reacts smoothly with nucleophiles under forcing conditions to give excellent yields of 5,5″-disubstituted-2,2′:6′,2″-terpyridines. The reaction of **2** with propan-1-ol in dmso containing solid potassium hydroxide resulted in a smooth displacement of nitrite to give **3** in 60% yield. We believe that the ease of displacement represents the availability of resonance-stabilised intermediates in which the charge is localised upon the nitrogen atom of an *adjacent* pyridine ring (Scheme 1.

The new ligand **3** was obtained as a white crystalline solid in 50% yield and was fully characterised by conventional methods. A parent ion is observed in the mass spectrum and the ^{1}H NMR spectrum [Fig. 1(a)] is characteristic of a 5,5″-disubstituted 2,2′:6′,2″-terpyridine. The most obvious feature in the ^{1}NMR spectrum is the observation of H^6 as a doublet ($^3J_{4,6}$ 2.75 Hz). The expected signals assigned to the propoxy groups were observed in the aliphatic region of the spectrum. The electronic effects of the nitro and propoxy substituents may be qualitatively evaluated by a comparison of their ^{1}H NMR spectra. The most remarkable feature is that the chemical shifts of the protons on the central pyridine ring are dramatically affected by the nature of substituents in the 5 and 5″-positions of the two terminal rings. For example, $H^{3'}$ and $H^{4'}$ are found at δ 8.46 and 7.97, respectively, in **1**, whereas they are shifted upfield to δ 8.27 and 7.87 in **3** and markedly downfield to δ 8.66 and 8.09 in **2**. Similar effects are seen for the terminal rings; H^6 shifts upfield from δ 8.63 in **1** to δ 8.52 in **3** and downfield to δ 8.81 in **2**. All of these shifts suggest that the electronic effects of substituents in the 5 and 5″-positions will have a dramatic effect upon the properties of the 2,2′:6′,2″-terpyridine structure and are in marked contrast with the behaviour of 4′-substituted 2,2′:6′,2″-terpyridine where the chemical shifts of the protons on the terminal rings are effectively independent of the nature of the 4′-substituent [4, 5, 6].

3.2. *Iron(II) complexes of* **2** *and* **3**

The reaction of two equivalents of **2** or **3** with iron(II) chloride in methanol yielded deep purple solu-

Scheme 1.

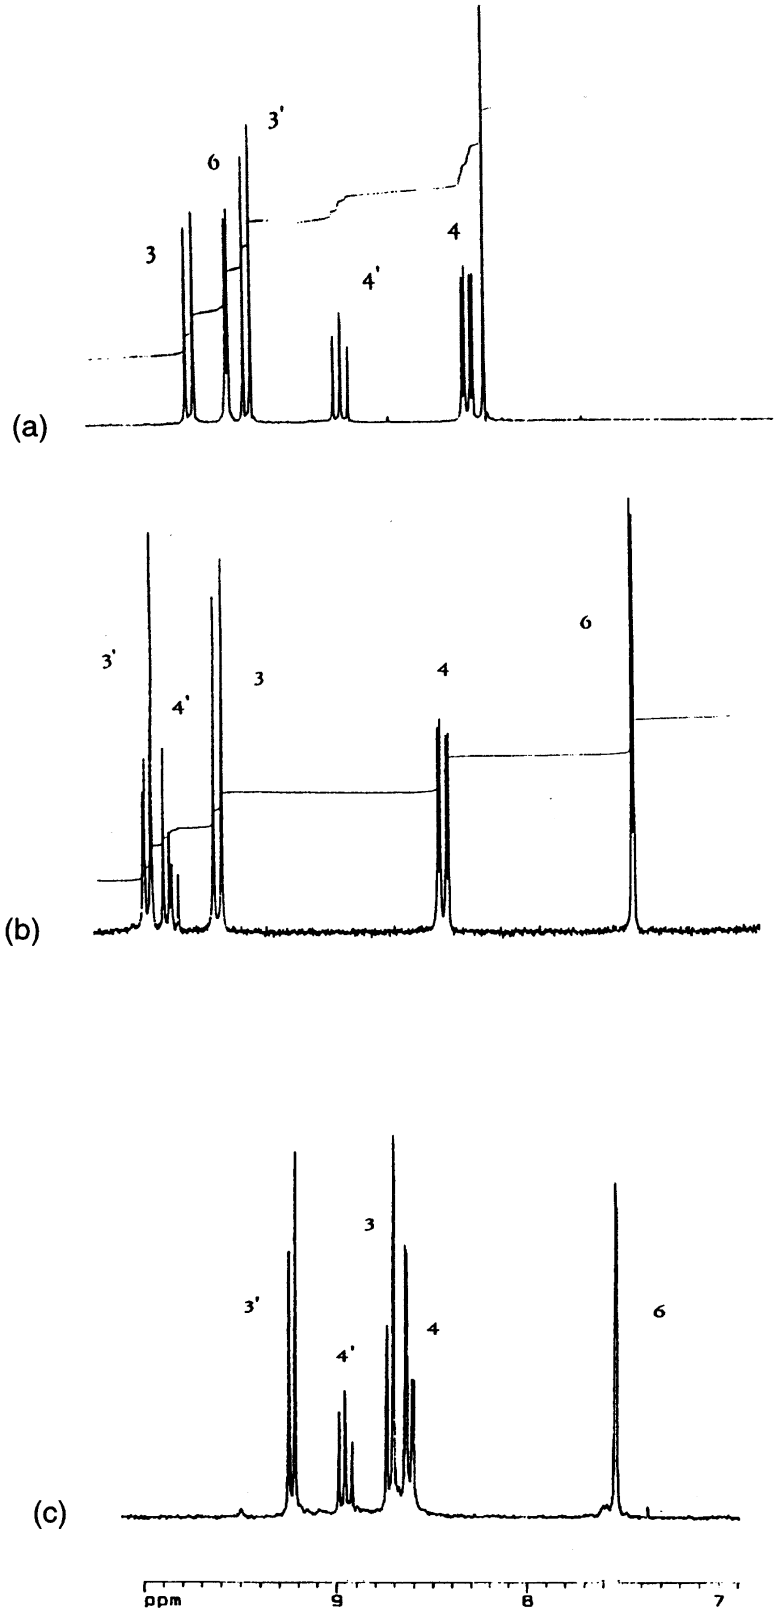

Fig. 1. ^{1}H NMR spectra (250 MHz) of (a) a $CDCl_3$ solution of **3**, (b) a CD_3CN solution of $[Fe(\mathbf{3})_2][PF_6]_2$, and (c) a CD_3CN solution of $[Fe(\mathbf{2})_2][PF_6]_2$.

tions from which the purple salts $[FeL_2][PF_6]_2 \cdot nH_2O$ (L = **2** or **3**) were precipitated with ammonium hexafluorophosphate. In each case, FAB mass spectra of the complexes revealed peaks assigned to $\{[FeL_2, PF_6]\}^+$ and $\{[FeL_2]\}^+$. The differing electronic effects in the two complexes were assessed by a variety of spectroscopic means. We note at this point, that although substituents at the 5 position are not expected to significantly influence the nature of the interaction of the metal ion with the *terminal* rings, the electronic effects may be efficiently transmitted to the *central* ring (Scheme 2).

The electronic spectra of the iron complexes contain a dominant MLCT absorption in the visible region which gives rise to the purple colour (see Section 2). The observed variation in the extinction coefficients represents differing band widths for the various overlapping components of the MLCT processes. The variation in absorption maximum is marked and we have discussed previously the origins of such effects [11]. The nitro substituents in $[Fe(\mathbf{2})_2][PF_6]_2$ result in a shift to lower energy as a result of the lowering of the ligand LUMO energy. Similarly, the electron-releasing substituent in **3** raises the energy of the LUMO and leads to an increase in the energy of the MLCT transition whilst the electron-withdrawing substituent lowers its energy. Semi-empirical calculations (MOPAC, AM1) on the free ligands and the model complexes $[ZnL_2]^{2+}$ (L = **1**, **2** or **3**) fully confirm this model, as do electrochemical studies (see below) which show a reasonable correlation between the MLCT energy and the difference between the metal-centred process and the first ligand reduction.

The electronic effects of the various ligands may be further quantified by a consideration of the redox behaviour of the various complexes. In each case a reversible or quasi-reversible iron(II)/(III) process is observed. In the case of $[Fe(\mathbf{2})_2][PF_6]_2$ these processes are observed at +1.18, −0.90, −1.10, −1.57 and −1.73 V whereas in $[Fe(\mathbf{3})_2][PF_6]_2$ it is found at 0.73, −1.74 and −1.81 V (all potentials quoted vs internal ferrocene/ferrocenium; $[Fe(\mathbf{1})_2][PF_6]_2$ 0.74, −1.64, −1.82 V). We had expected that ligand **2** would destabilise the iron(II) state and shift the iron(II)/(III) couple to more positive potential, as indeed it does. The electron-releasing substituents in **3** play-a multiple role. The raising of the LUMO energy makes **3** a less good π-acceptor than either **1** or **2**. However, this is compensated by a **3** being a better σ-donor. The balance of these two effects is such that the iron(II)/(III) potential for $[Fe(\mathbf{3})_2][PF_6]_2$ is essentially the same as observed for $[Fe(\mathbf{1})_2][PF_6]_2$. These observation stress once again the difficulty in predicting the precise effects of varying ligand structure when synergistic back-bonding is involved [12].

A further measure of the electronic effects within the complexes is found from a study of the ^{1}H NMR spectra of CD_3CN solutions. The ^{1}H NMR spectra of these diamagnetic complexes are sharp and well-resolved and chemical shift data are presented in Table 3 and Fig. 1(b) and (c). Although the individual chemical shifts are quite variable, we have shown previously [4] that $\Delta\delta$ coordination shift values (δ free ligand, $CDCl_3$–δ complex, CD_3CN) are characteristic and, in the 4′-substituted-2,2′:6′,2″-terpyridine series, virtually independent of the substituents. The $\Delta\delta$ values presented in Table 3 indicate that the electronic effects in **1**, **2** and **3** are variable and that they differ in such a way as to give rather different contributions to the coordination shift. The most interesting feature is the relatively large variation in coordination shifts associated with the central ring. This provides further support for our model involving the transmission of electronic effects to the metal through this ring.

We have also determined the crystal structure of the complex $[Fe(\mathbf{3})_2][PF_6]_2 \cdot 2MeCN$ in an attempt to further quantify the electronic interactions between the metal centre and the ligand. The structure of the cation as observed in the solid state is presented in Fig. 2. One of the propoxy groups is disordered with the terminal methyl group occupying two sites. Only one of the conformations is presented in Fig. 2. The

solid state structural determination confirms the presence of the expected cation which adopts approximately D_{2d} symmetry. There are no short contacts between the cations and the anions or the lattice acetonitrile molecules. The tpy domains of the two ligands are approximately planar. Abnormal metal–ligand interactions are expected to be expressed in the Fe–N distances (Table 2). However, the Fe–N distances and bite angles are identical within standard deviations to those of other $[Fe(\mathbf{1})_2]^{2+}$ salts which have been reported [13, 14]. In the crystal lattice the cations form channels with the PF_6^- anions and acetonitrile molecules between them, as indicated in Fig. 3. This appears to confirm our conclusions from the electrochemical studies that the synergism is such that the increased σ-donor and reduced π-acceptor properties of **3** cancel each other out.

3.3. *Cobalt(II) and ruthenium(II) complexes of* 2

For comparison, the complexes $[M(\mathbf{2})_2][PF_6]_2$ (M = Ru or Co) were also prepared, The brown complex $[Co(\mathbf{2})_2][PF_6]_2$ was prepared by the direct reaction of **2** with cobalt acetate in methanol whereas orange $[Ru(\mathbf{2})_2][PF_6]_2$ was obtained by the reaction of **2** with ruthenium trichloride in ethane-1,2-diol. In each case the microanalysis confirmed the formulation of the products and the FAB mass spectrum exhibited ions corresponding to $\{M(\mathbf{2})_2(PF_6)\}^+$, $\{M(\mathbf{2})_2\}^+$ and $\{M(\mathbf{2})\}^+$.

As expected the cobalt(II) complex is paramagnetic and exhibits a typical paramagnetically shifted ^{1}H NMR spectrum with resonances observed at δ 123, 67.1, 66.0, 25.0, 7.5. Although $[Co(\mathbf{1})_2]^{2+}$ complexes show spin crossover behaviour in the solid state, the solution behaviour is better defined. All of the $[Co(Xtpy)_2]^{2+}$ species that we have studied show one of the two ^{1}H NMR spectroscopic behaviours; the lowest field peak is in the range δ 200 to 230 or in the range δ 90 to 130. These values are typical of a low-spin cobalt(II) species, indicating that the introduction of the 5,5″-substituents does not affect the spin state; in solution $[Co(\mathbf{1})_2]^{2+}$ salts are always low spin, whereas the introduction of even a single substituent at the 6-position of the tpy results in high-spin species [15]. The ^{1}H NMR spectrum of the ruthenium complex is typical of a bis(tpy) complex; the resonances of the H^6 and H^4 protons are shifted down-field with respect to $[Ru(\mathbf{1})_2][PF_6]_2$ (0.57 ppm for H^6 and 0.74 ppm for H^4) whilst H^3 experiences only a modest shift of 0.26 ppm. The π-conjugation between the central ring and the nitro substituents is important, and the protons on the central ring also exhibit significant shifts with respect to $[Ru(\mathbf{1})_2][PF_6]_2$ (0.30 ppm for $H^{3'}$ and 0.26 ppm for $H^{4'}$).

The absorption spectrum of the ruthenium complex showed the same trend as the iron analogue with a

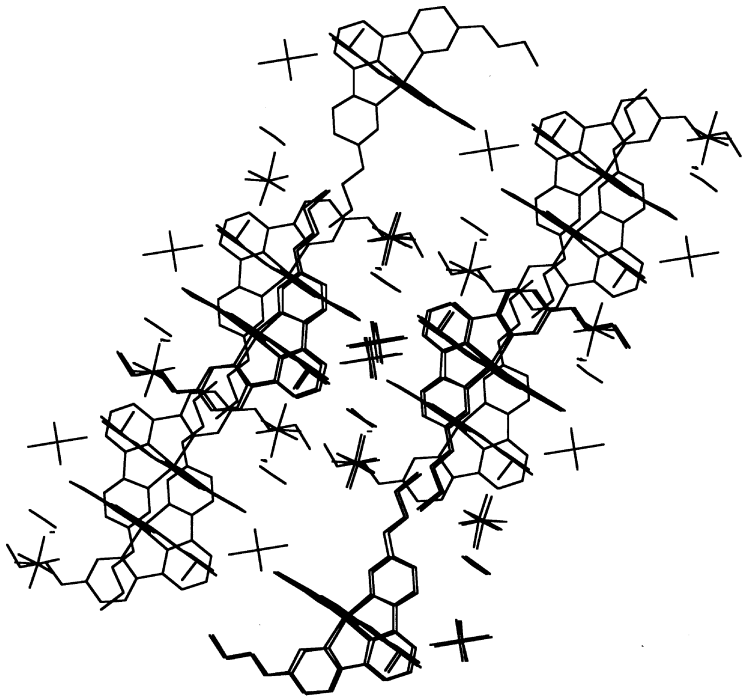

Fig. 3. Packing diagram of $[Fe(\mathbf{3})_2][PF_6]_2 \cdot 2MeCN$ showing the formation of channels between the cations in which the anions and lattice solvent molecules are located.

shift of the MLCT to lower. This behaviour is also paralleled in the electrochemical activity. The complex $[Co(\mathbf{2})_2][PF_6]_2$ exhibited a quasi reversible (ΔE 107 mV) cobalt(II)/(III) process at +0.42 V vs ferrocene/ferrocenium, shifted to more positive potential than that of $[Co(\mathbf{1})_2][PF_6]_2$ (−0.05 V). The ruthenium complex behaves similarly and shows a quasi-reversible ruthenium(II)/(III) process at +1.30 V, shifted 380 mV to more positive potential than $[Ru(\mathbf{1})_2][PF_6]_2$.

4. CONCLUSIONS

The introduction of substituents onto the 5- and 5″-positions of a 2,2′:6′,2″-terpyridine affects the electronic properties of the metal complexes. However, the interactions are complex and cannot be explained simply in terms of the overall electron-releasing or -donating properties of the substituents. The σ- and π-effects act synergistically and conjugation between the substituents on the terminal rings and the central ring is a dominant factor. We are currently extending these observations to other 5,5″-disubstituted ligands.

(Received 19 January 1998; accepted 14 May 1998)

Abstract—Four new polymeric lanthanide(III) complexes of nicotinic acid *N*-oxide and isonicotinic acid *N*-oxide have been synthesized and structurally determined. In the isomorphous compounds $[\{Ln(L^1)_3(H_2O)_2\}_n]\cdot 4nH_2O$ (HL^1 = nicotinic acid *N*-oxide; Ln = Eu, **1**; Ln = Er, **2**) the lanthanide(III) ions form infinite double chains along the *b* direction through the coordination of bridging carboxylate and *N*-oxide groups. The chains are cross-linked through hydrogen bonds between aqua ligands and uncoordinated *N*-oxide groups and between aqua ligands and lattice water molecules, to form a three-dimensional network. $[\{Eu(L^2)_2(H_2O)_4\}_n](NO_3)_n\cdot nH_2O$ (HL^2 = isonicotinic acid *N*-oxide, **3**) has a polymeric structure in which the europium (III) ions are connected into infinite chains by pairs of *syn–syn* carboxylate groups. Adjacent chains are inter-linked by hydrogen bonds between aqua ligands and *N*-oxide groups to form a layer parallel to the (100) plane, and such layers are connected by hydrogen bonds between nitrate anions and aqua ligands, and between oxide groups and lattice water molecules, into a three-dimensional network. In $[\{Er_2(L^2)_4(H_2O)_{10}\}](NO_3)_2\cdot H_2O$, **4**, dinuclear units are inter-linked into a three-dimensional network through hydrogen bonding between aqua ligands and *N*-oxide groups of both bidentate bridging and unidentate L^2 ligands. Factors affecting the formation of coordination chains and dinuclear units are discussed. Luminescence properties of **1** and **3** have also been studied. © 1998 Elsevier Science Ltd. Keywords: lanthanide complex; coordination polymer; crystal structure; luminescence.

INTRODUCTION

Lanthanide complexes of three isomers of pyridine carboxylic acid, namely nicotinic acid, isonicotinic acid and picolinic acid, have been extensively investigated [1–13]. Pyridine carboxylic acid *N*-oxides have an oxygen atom in place of the nitrogen donor site, but studies on ligand behavior toward lanthanides are limited [14–19], as so far only one dimeric lanthanum complex of 6-methyl-picotinic acid *N*-oxide has been structurally determined [19]. *N*-oxide functionalization of nicotinic acid and isonicotinic acid should increase the flexibility of the resulting ligands in addition to enhancement of their capacities for coordination and or hydrogen bonding and, hence, their lanthanide complexes are expected to exhibit different characteristics as compared with the corresponding lanthanide nicotinates and isonicotinates. In this paper, we describe the preparation and structural characterization of four new lanthanide(III) complexes of nicotinic acid *N*-oxide and isonicotinic acid *N*-oxide, namely isomorphous $[\{Ln(L^1)_3(H_2O)_2\}_n]\cdot 4nH_2O$ (HL^1 = nicotinic acid *N*-oxide; Ln = Eu, **1**; Ln = Er, **2**) with a polymeric double-chain structure, $[\{Eu(L^2)_2(H_2O)_4\}_n](NO_3)_n\cdot nH_2O$ (HL^2 = isonicotinic

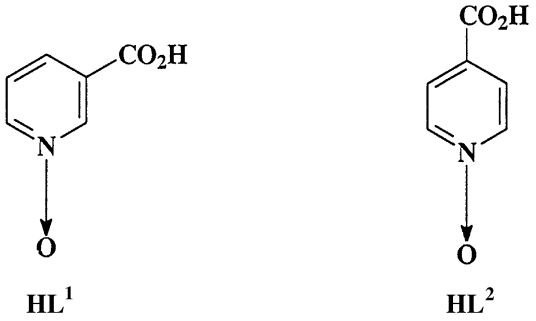
acid *N*-oxide, **3**) whose metal ions are linked into an infinite chain by pairs of bridging carboxylate groups, and a dinuclear complex, $[\{Er_2(L^2)_4(H_2O)_{10}\}](NO_3)_2 \cdot 4H_2O$ (**4**). Luminescence properties of the two europium(III) complexes have also been studied.



EXPERIMENTAL

IR spectra were obtained from KBr pellets with a Nicolet Magna-IR 550 spectrometer. Electronic spetra in the UV-visible range were recorded at room temperature with a Hitachi U-2000 spectrophotometer. Excitation and emission spectral measurements were performed on a Hitachi MPF-4 fluorescence spectrophotometer at room temperature. Luminescence measurements were carried out using solid samples at 298 K and corrections for the lamp response and PMT (type R928 operating in photon counting mode) were applied.

Synthesis of complexes 1–4

Nicotinic acid *N*-oxide (or isonicotinic acid *N*-oxide) (1.0 mmol) was completely dissolved in 10 cm^3 of distilled water by slow addition of aqueous ammonia (2 N) to form a clear solution, to which $Ln(NO_3)_3 \cdot nH_2O$ (0.5 mmol) (Ln = Eu or Er) was added under stirring. The resultant solution was filtered off. Storage of the solution in a desiccator charged with drierite for several days yielded crystals of complexes **1–4**. IR data: of $[\{Eu(L^1)_3(H_2O)_2\}_n] \cdot 4nH_2O$, **1**, 3416s, 3100w, 1656s, 1589s, 1555s, 1387s, 1226s, 1132m, 1085w, 1025w, 944m, 815m, 775m, 669m, 581m cm^{-1}; $[\{Er(L^1)_3(H_2O)_2\}_n] \cdot 4nH_2O$, **2**, 3442s, 3079w, 1670s, 1607s, 1562s, 1418s, 1384s, 1233s, 1139m, 1090w, 1022w, 948m, 818m, 772m, 669m, 601w cm^{-1}; $[\{Eu(L^2)_2(H_2O)_4\}_n](NO_3)_n \cdot nH_2O$, **3**, 3382s, 3098w, 2470w, 2427w, 1664s, 1605s, 1564s, 1480m, 1412s, 1384s, 1300m, 1226s, 1119m, 1025w, 945m, 815s, 772s, 689m, 671m, 584m, 450m cm^{-1}; $[\{Er_2(L^2)_4(H_2O)_{10}\}](NO_3)_2 \cdot 4H_2O$, **4**, 3443s, 3095w, 2426w, 1941w, 1668s, 1635s, 1553s, 1490m, 1409s, 1218s, 1183s, 1151s, 1109m, 1046m, 882m, 868s, 827m, 784s, 682m, 636s, 570m, 472m cm^{-1}.

Crystal structure determination

Information concerning crystallographic data and structure refinement of the four complexes is summarized in Table 1. Raw intensities of complex **1** was collected at 293 K on a MSC/Rigaku RAXIS-IIC imaging plate system with a rotating anode Mo-*K*α X-ray source ($\lambda = 0.71073$ Å, 50 kV, 150 mA) [20, 21] and corrected for absorption using the ABSCOR program [22]. Data collection of complexes **2**, **3** and **4** were performed on a Siemens R3m/V diffractometer in the variable ω-scan mode [23] using Mo-Kα radiation ($\lambda = 0.71073$ Å) at 294 K. Unit-cell parameters were calculated from least-squares fitting of 2θ angles for 25 reflections. Crystal stability was monitored by recording three check reflections at intervals of 197 data measurements, and no significant variation was detected. The raw data were processed with a learnt-profile procedure [24], and empirical absorption corrections based on ψ-scan data were also applied.

All calculations were performed on a PC 486 computer with the SHELXTL-PC program package [25, 26] and SHELXL-93 program package [27]. Each crystal structure was solved with the Patterson superposition method. The non-hydrogen atoms were refined anisotropically. The water O(2w) and nitrate O(21) and O(22) atoms in complex **3** are disordered over the imposed mirror plane and their site occupancy factors are reduced to one-half. All hydrogen atoms were generated geometrically, assigned fixed isotropic thermal parameters and included in the structure factor calculations. Analytical expressions of neutral-atom scattering factors were employed [28], and anomalous dispersion corrections were incorporated.

RESULTS AND DISCUSSION

Crystal structure of $[Ln(L^1)_3(H_2O)_2]_n \cdot 4nH_2O$ (Ln = Eu, ***1***; Ln = Er, ***2***)

These two complexes are isostructural and the structure of the europium(III) complex is shown in Fig. 1(a). The Ln(III) atom is eight-coordinated by six oxygen atoms from four L^1 ligands and two aqua ligands. The carboxylate groups are involved in three different coordination modes: a common bidentate chelating mode [Eu(1)–O(1)–C(6) 91.9(4)° and Eu(1)–O(2)–C(6) 93.5(4)° for **1**; Er(1)–O(1)–C(6) 91.5(2)° and Er(1)–O(2)–C(6) 93.2(2)° for **2**], a bidentate bridging mode in the *syn–syn* configuration [Eu(1)–O(3)–C(12)–C(7) 135.0° and C(7)–C(12)–O(4)–Eu(1a) −140.4° in **1**; Er(1)–O(3)–C(12)–C(7) 134.2° and C(7)–C(12)–O(4)–Er(1a) −141.4° in **2**], as well as a unidentate mode [Ln(1)–O(5)–C(18) = 149.5(5) and 148.7(2)°, respectively, for complexes **1** and **2**]. The mean Ln–O(aqua) distances are 2.426(5) and 2.365(3) Å, respectively, for complexes **1** and **2**. The Ln–O(carboxylate) distances are in the order Ln–O(chelating) > Ln–O(bridging) > Ln–O(unidentate) (Table 2. Most lanthanide complexes of nicotinic acid are dimeric in which the metal ions are bridged by four carboxylate groups and each metal ion is further

coordinated to one bidentate chelating carboxylate group and two aqua ligands [2, 3, 5–8]. Higher coordination numbers for the light lanthanide(III) ions can be achieved with two bridging carboxylate groups adopting the terdentate bridging and chelating coordination mode [4]. Under acidic condition, Ho(III) nicotinate comprises polymer chains made up of lanthanide(III) ions alternately linked by four and two carboxylate groups [4]. The unidentate mode of the carboxylate group is so far only observed in mononuclear europium phenanthroline nicotinate [8]. The significant difference between the structures of lanthanide complexes of nicotinic acid *N*-oxide and those of lanthanide nicotinates is due to the coordination of the *N*-oxide group to the metal ions. In complexes **1** and **2**, one *N*-oxide group bonds to the metal ion [N(2)–O(22)–Eu(1b) 127.1(4)° in **1** and N(2)–O(22)–Er(1b) 127.6(2)° in **2**]; the Ln–O(*N*-oxide) distance is slightly longer than those of Ln–O(carboxylate, bridging) and Ln–O(carboxylate, unidentate), but much shorter than Ln–O(carboxylate, chelating) Table 2. The other two *N*-oxide groups are only involved in hydrogen bonding with both coordinated and lattice water molecules Table 2. Each pair of lanthanide ions are bridged by two bidentate *syn–syn* carboxylate groups with Ln...Ln separation of 5.606(1) and 5.540(1) Å for **1** and **2**, respectively. These dimeric units are linked through Ln–O(*N*-oxide) bonds to form infinite double chains directed along the *b* axis [Fig. 1(b)]. The latter are cross-linked through hydrogen bonds between aqua ligands and uncoordinated oxide groups, and between aqua ligands and cyclic $(H_2O)_4$ units to form a three-dimensional network [Table 2, Fig. 1(b)].

The coordination geometry of the Eu(III) atom is best described as a strongly distorted square-antiprism. The least-squares plane fitted to atoms O(1), O(3), O(4a) and O(2w) has a mean deviation of 0.448 Å, whereas another face defined by O(2), O(22b), O(1w) and O(5) has a mean deviation of 0.416 Å. The dihedral angle between these two least-squares planes is *ca.* 5.5°. The Eu(III) atom is displaced 1.262 and 1.241 Å, respectively, from the above two faces.

Complex **3** contains europium(III) carboxylate chains built of bis(carboxylato-O,O′)-bridged centrosymmetric dimeric subunits. As illustrated in Fig.

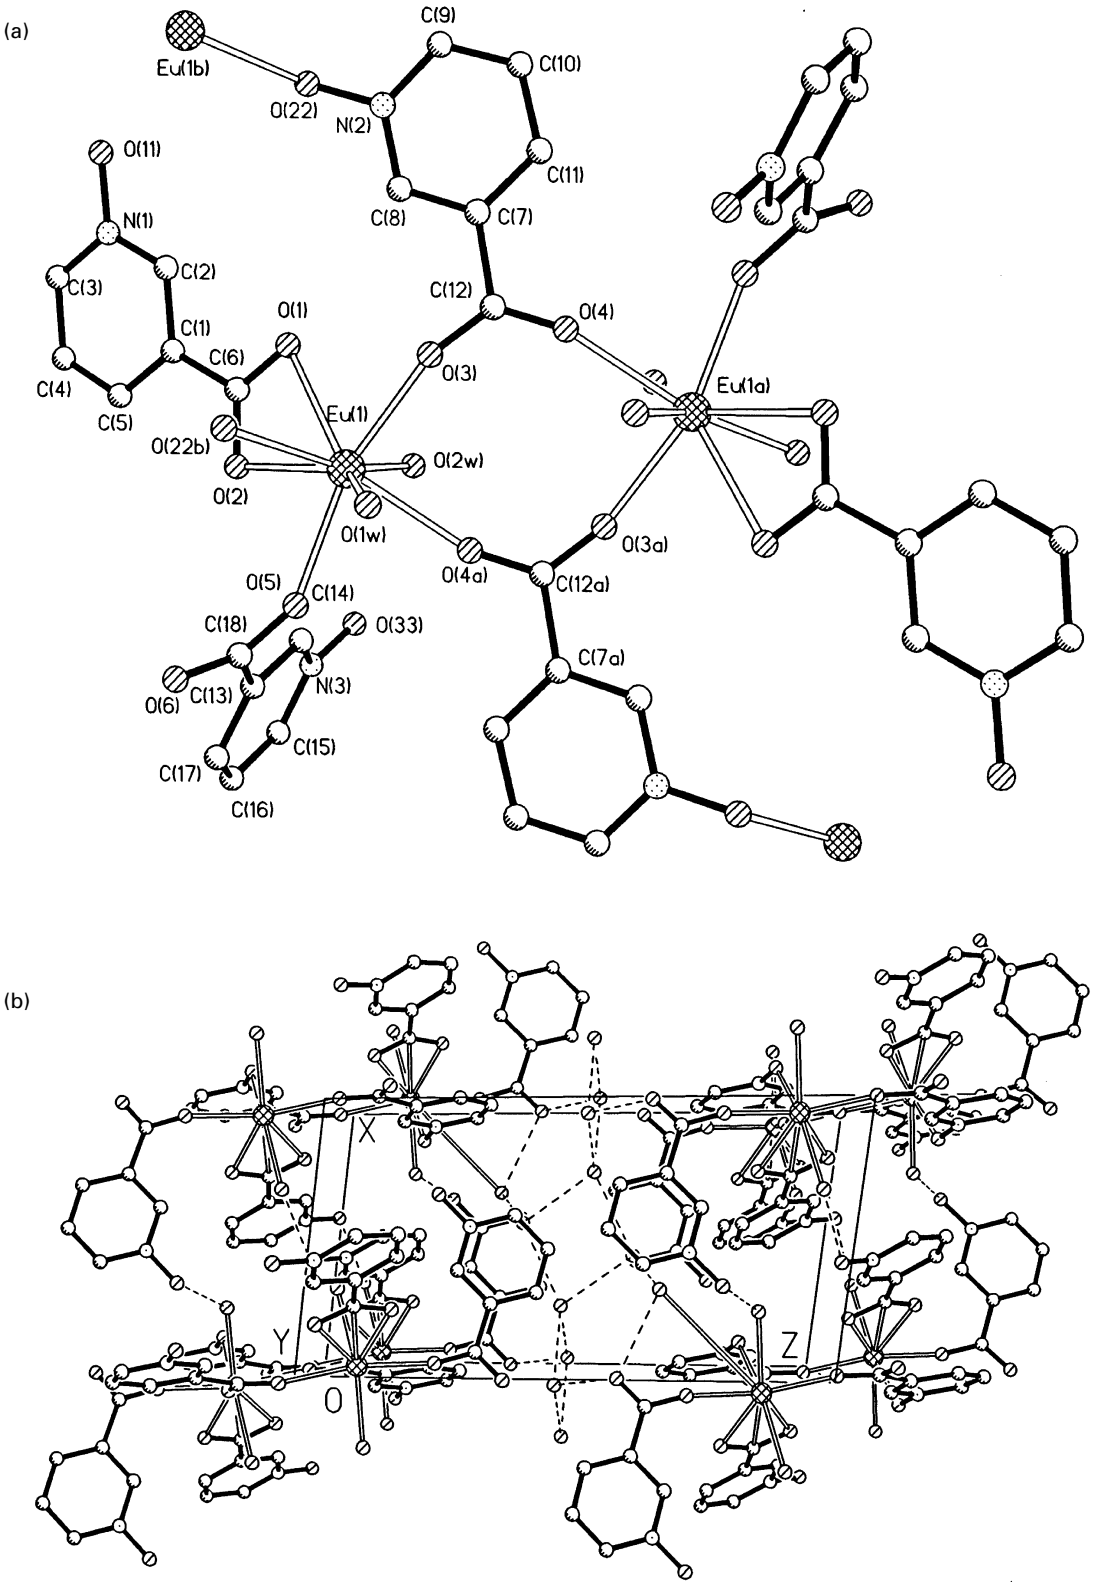

Fig. 1. (a) Perspective view showing the asymmetric unit of complex **1** with the atom labeling scheme (the lattice water molecules have been omitted for clarity). (b) Packing drawing showing the linkage of metal carboxylate double chains through hydrogen bonds between aqua ligands and lattice water molecules.

Symmetry codes: For **1**–**2**: (a) $1-x, 1-y, 1-z$, (b) $1-x, -y, 1-z$, (c) $1+x, y, z$, (d) $x, 1+y, z$, (e) $-x, -y, 1-z$, (f) $2-x, -y, -z$, (g) $1-x, -y, -z$. For **3**: (a) $-x, y, -z+1/2$, (b) $-x, -y, z$, (c) $x, -y, -z+1/2$, (d) $x, y, -z$, (e) $-x+1/2, -y+1/2, z$, (f) $-x, 1-y, -z$. For **4**: (a) $-x, -y, -z$, (b) $x, y-1, z$, (c) $-x, 1-y, -1-z$, (d) $-1-x, 1-y, -z$, (e) $x-1, y+1, z$, (f) $1-x, -1-y, -1-z$.

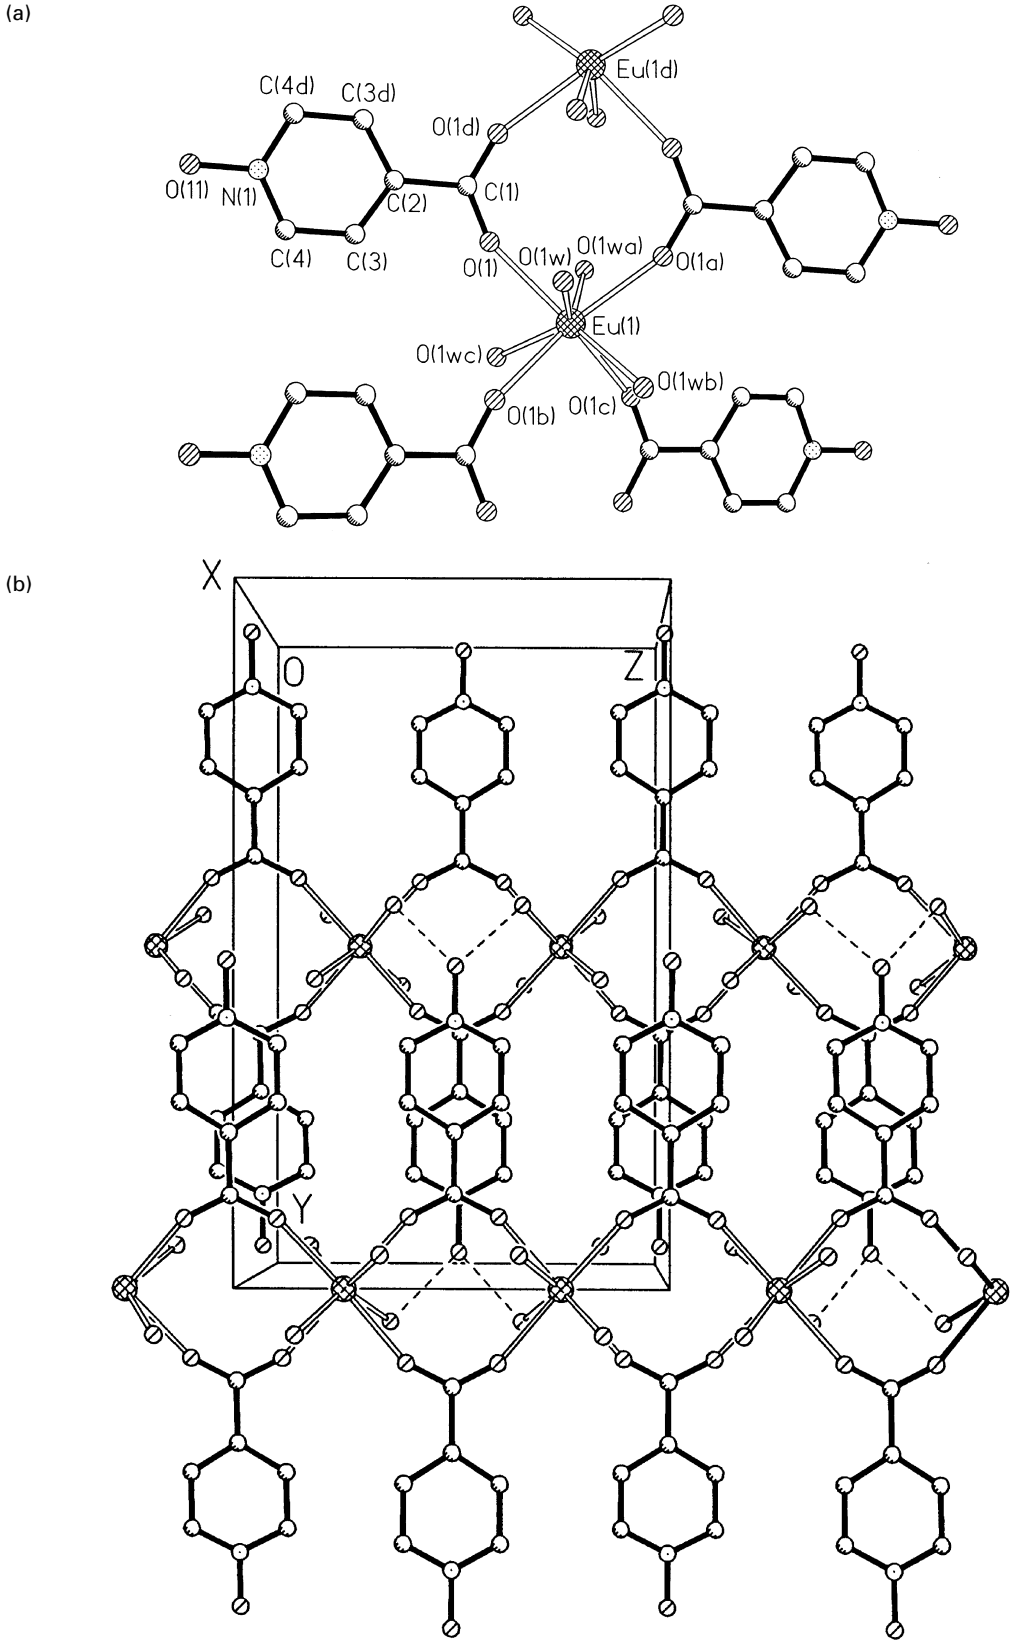

Fig. 2. (a) Perspective view showing the *syn–syn* carboxylato-O,O′ bridged dimeric unit of complex **3** (the lattice water molecules and nitrate anion have been omitted for clarity). (b) Packing drawing showing the three dimensional network of complex **3**.

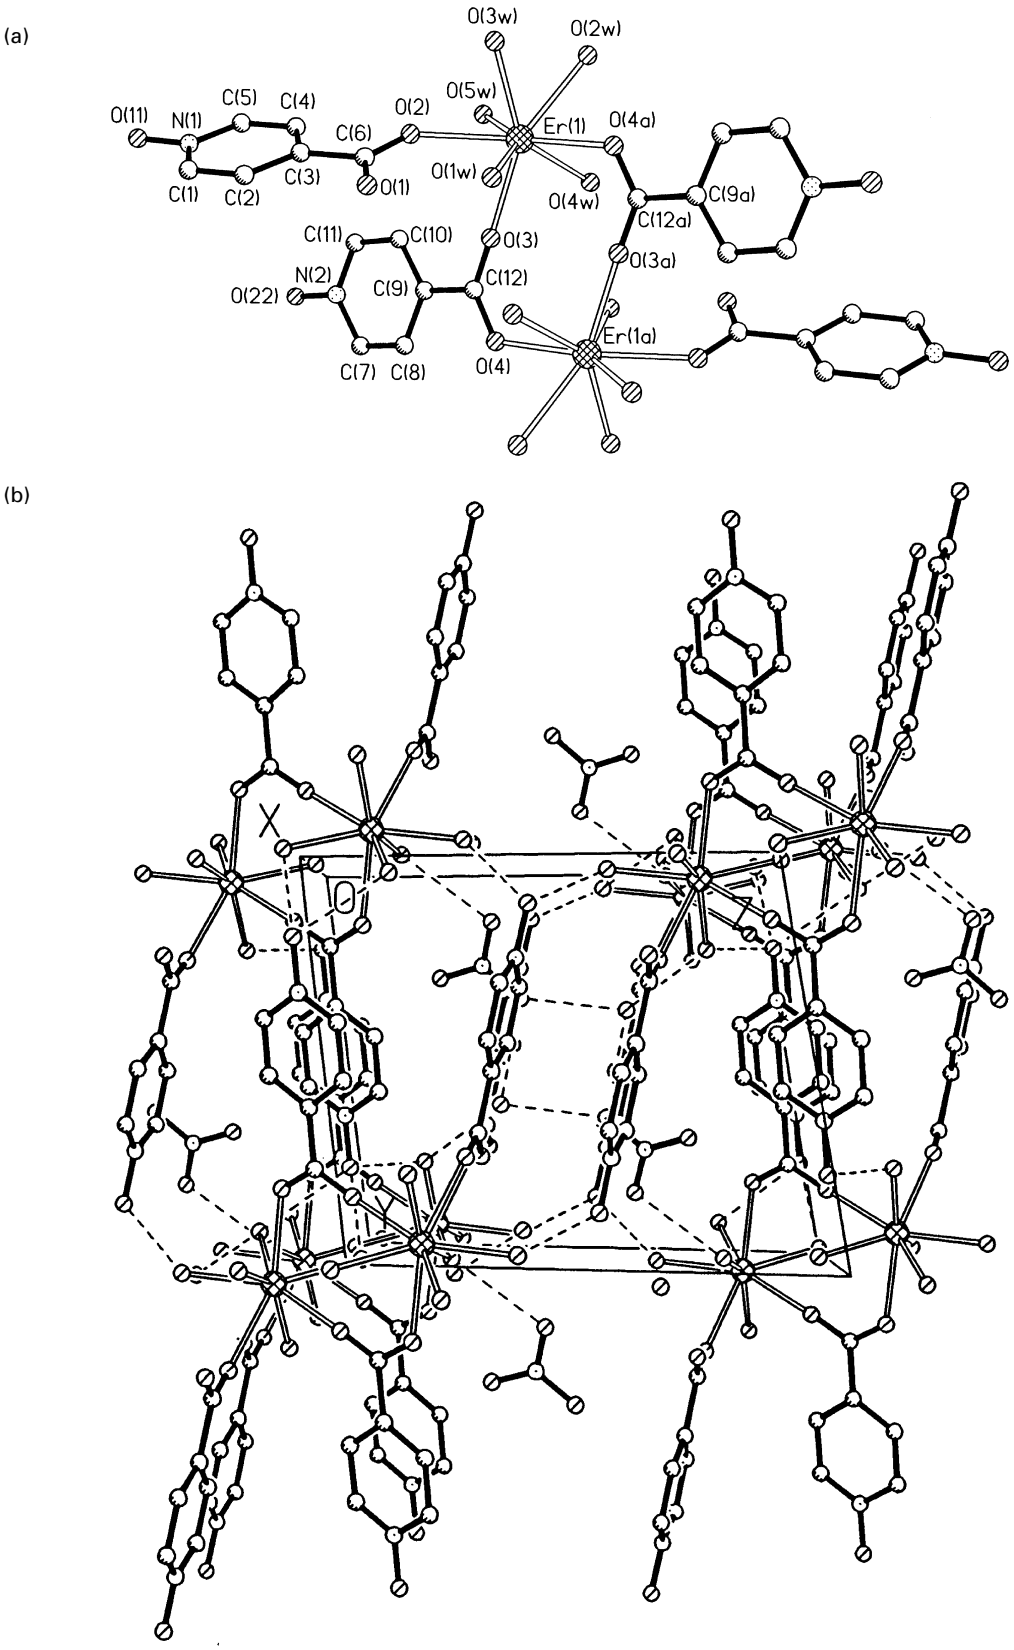

Fig. 3. (a) Perspective view showing the dimeric unit of complex **4** with the atom labeling scheme (the lattice water molecules and discrete nitrate anions have been omitted for clarity). (b) Packing drawing showing the three dimensional network built from dimeric units of complex **4** through hydrogen bonds between aqua ligands and *N*-oxide groups, and between uncoordinated carboxylate groups and aqua ligands.

2(a), the europium(III) ion resides on a site of symmetry 222; it is eight-coordinated by four equivalent oxygen atoms of L^2 ligands and four equivalent aqua ligands with Eu–O(aqua) and Eu–O(carboxylate) bond distances of 2.462(6) and 2.352(6) Å, respectively. The carboxylate group is only involved in the bidentate *syn–syn* bridging mode (C(2)–C(1)–O(1)–Eu(1) −157.4° and C(2)–C(1)–O(1d)–Eu(1d) 157.4°). Each europium(III) ion is linked with its two neighbors through pairs of bridging carboxylate groups with an Eu. . .Eu separation of 5.245(1) Å, forming an infinite chain of symmetry 2 along the *b* direction [Fig. 2(b)]. The *N*-oxide oxygen atoms are not coordinated to the europium(III) ion but form hydrogen bonds with coordinated aqua ligands belonging to neighboring chains Table 2. These hydrogen bonds link the metal carboxylate chains into layers parallel to the *bc* plane [Fig. 2(b)]. The layers are held together by hydrogen bonds between nitrate anions and aqua ligands, and between oxide groups and lattice water molecules, to form a three-dimensional network Table 2. The coordination geometry at the Eu(III) center is a slightly distorted square antiprism. One square face comprises atoms O(1w), O(1wa), O(1) and O(1a) with a mean deviation of 0.269 Å and the other least-squares plane is defined by atoms O(1wb), O(1wc), O(1b)

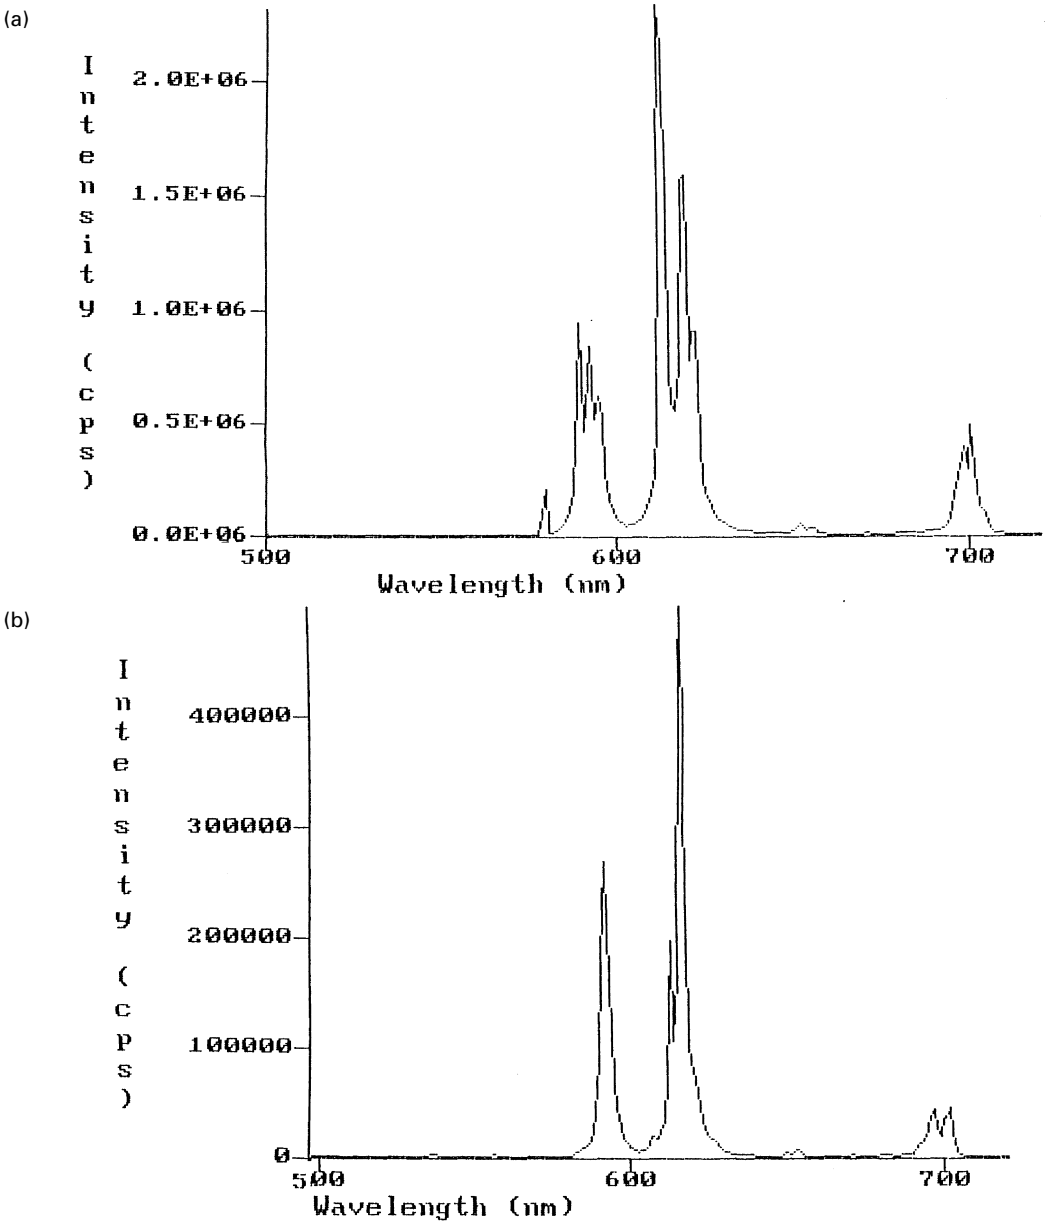

Fig. 4. (a) Emission spectrum of complex **1** for excitation at 333 nm. (b) Emission spectrum of complex **3** for excitation at 337 nm.

and O(1c) with the same deviation. These two faces are parallel to each other. The europium(III) ion resides exactly in the center of the square antiprism, being displaced 1.254 Å from the above two planes.

Due to the smaller ionic radius of the erbium(III) ion as compared to the europium(III) ion, the crystal structure of complex **4** exhibits different features. It comprises a packing of dimeric cations, nitrate anions and lattice water molecules. As shown in Fig. 3(a), the erbium(III) ion is eight-coordinated by three carboxylate oxygen atoms from two L^2 ligands and five aqua ligands with mean Er–O(aqua) and Er–O (carboxylate) distances of 2.363(3) and 2.330(3) Å, respectively. One L^2 ligand acts in the bidentate *syn–anti* carboxylate bridging coordination mode [Er(1)–O(3)–C(12)–C(9) -31.8° and C(9)–C(12)–O(4)–Er(1a) 171.2°], but the carboxylate group of the other L^2 ligand adopts the unidentate coordination mode [Er(1)–O(2)–C(6) 139.1(3)°], leaving the uncoordinated O(1) oxygen atom to form a strong intramolecular hydrogen bond with O(1w) with a separation of 2.613 Å. The distance between the two erbium(III) ions in the dimeric unit is 4.804(1) Å, being much shorter than the Eu...Eu separation in complex **3**. As in the case of complex **3**, the *N*-oxide groups are not directly coordinated to the lanthanide ions, but hydrogen-bonded to both aqua ligands and lattice water molecules Table 2, thereby linking the dimeric units into a three-dimensional network [Fig. 3(b)]. The nitrate anions also participate in hydrogen bonding Table 2.

The reason why complex **4** is dimeric while complex **3** is polymeric arises from the difference of the ionic radii of the relevant lanthanide(III) ions. The heavy Er(III) ion has a smaller ionic radius than the lighter Eu(III) ion and hence is more likely to be hydrated [29]. As the aqua ligands compete with the carboxylate groups for coordination sites of the metal ion, the replacement of one carboxylate oxygen by an aqua ligand in the coordination sphere of the Er(III) ion suffices to breaks up the polymeric chain into dimeric units.

It is notable that hydrogen bonding between coordinated aqua ligands and *N*-oxide groups of L^2 ligands brings the pyridine rings closer and nearly parallel to each other [Fig. 2(b) and Fig. 3(b)], so that the resulting aromatic packing effect further enhances the thermal stability of complexes **3** and **4**.

Luminescence properties of $[\{Eu(L^1)_3(H_2O)_2\}_n]\cdot 4nH_2O$, ***1***, *and* $[\{Eu(L^2)_2(H_2O)_4\}_n](NO_3)_n\cdot nH_2O$, ***3***

The excitation spectrum of **1** ($\lambda_{em} = 617$ nm) exhibits a strong ligand absorption band at 333 nm and the characteristic absorption bands of the europium(III) ion (362, 367, 376, 382, 384, 395(max), 398(shoulder), 417, 465 and 474 nm), whereas the excitation spectrum of **3** ($\lambda_{em} = 614$ nm) shows a relatively weak ligand absorption peak at 337 nm and characteristic absorption peaks of the europium(III) ion (362, 367, 376, 381, 385, 395(max), 417, 465 and 473 nm). The luminescence spectra for ligand excitation are exhibited in Fig. 4(a) and (b), respectively, for complexes **1** and **3**. The luminescence data for the two complexes are summarized in Table 3. From the spectra, it is noticed that the bands originated from the $^5D_0 \rightarrow {}^7F_3$ transition are weak. The appearance of the $^5D_0 \rightarrow {}^7F_0$ transition and presence of three components in the $^5D_0 \rightarrow {}^7F_1$ transition of complex **1** points to the europium(III) ion having a structural environment of low symmetry [Fig. 4(a)] [30, 31]. From structural analysis its site symmetry was assigned to be C_1. For complex **3**, the $^5D_0 \rightarrow {}^7F_0$ transition is not observed and the $^5D_0 \rightarrow {}^7F_j$ ($j = 1, 2$) transition has fewer components [Fig. 4(b)]. Thus the europium(III) ion in complex **3** should reside on a highly symmetric lattice site. This is in good agreement with the results of crystal structure determination. From the results of crystal structural analysis, the chemical and structural environment

Table 3. Luminescence data of complexes **1** and **3**

Complex **1**				Complex **3**			
E (cm^{-1})	λ (nm)	E_0 (cm^{-1})	Assignment	E (cm^{-1})	λ (nm)	E_0 (cm^{-1})*	Assignment

*Calculation based on the $^7F_0$ energy level in complex **1**.

around the europium(III) ion has a symmetry close to D_{2d}. The Eu($^5D_0$) lifetime of complex **3** (0.69 ms for $\lambda_{ex,em} = 338, 617$ nm; 0.73 ms for $\lambda_{ex,em} = 395, 617$ nm) is much shorter than that of complex **1** (1.38 ms for $\lambda_{ex,em} = 333, 614$ nm; 1.44 ms for $\lambda_{ex,em} = 395, 613$ nm). This can be explained by the fact that complex **3** has more aqua ligands in the coordination sphere of the europium(III) ion.

(Received 25 August 1997; accepted 13 May 1998)

Abstract—X-ray crystal structure determination shows that both terminal selenium centres of the Se_4^{2-}-chain in $(TMEDA)_2Li_2Se_4$ (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) are bridging both lithium centres, while the central Se-atoms are loosely coordinated towards the metal centres, resulting in a distorted trigonal prismatic Li_2Se_4 core. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: lithium; selenium; polychalcogenides; nitrogen ligands; X-ray structure.

INTRODUCTION

It is well known that inorganic lithium salts form discrete molecular complexes in the presence of polydentate ligand systems [1]. Lithium polychalcogenides solvated by bi- or tridentate nitrogen chelates exist in the solid state as monomeric complexes of the general composition $L_2Li_2X_n$ (X = S or Se) [2–4]. Scheme 1 illustrates their different structure types. If the tridentate PMDETA (*N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine) is used as in $(PMDETA)_2Li_2S_4$ (**1a**) and $(PMDETA)_2Li_2Se_5$ (**1b**) zig–zag chains with terminally coordinated lithium centres are obtained. In contrast, the presence of the bidentate TMEDA (*N*,*N*,*N*′*N*′-tetramethylethylenediamine) as utilised in $(TMEDA)_2Li_2S_6$ (**2a**) leads to a bridging coordination behaviour of the bent chalcogenide chain [3, 4]. An equal structure pattern is observed in the presence of the more bulky bidentate TEEDA (tetraethylethylenediamin) [2]. Here we report the crystal and molecular structure of the TMEDA solvated selenium derivative $(TMEDA)_2Li_2Se_4$ (**2b**).

EXPERIMENTAL

Preparation of $(TMEDA)_2Li_2Se_4$ (**2b**)

All manipulations were performed under dry argon using Schlenk, vacuum-line and glove-box techniques. $[(CyNH)_2PN]_3$ (1.00 g, 1.38 mmol) was dissolved in 20 ml of THF. To this solution six equivalents of *n*-butyllithium (5.52 ml, 1.5 M in hexane) were added. After stirring this solution for 1 h, selenium powder (654 mg, 8.28 mmol) was added at once. The dark red solution was heated to reflux (5 min) and then stirred for 30 min at room temperature. All solvents were removed *in vacuo* and subsequently the residual dark red oil was dissolved in a mixture of 20 ml diethylether and 1 ml TMEDA. Storage of the filtered solution for 1 day yielded 270 mg of dark red crystals. The physical properties of the obtained crystals correspond with those reported by Tatsumi *et al.* [2].

Side products regarding the phosphazene components, which are formed by the reaction could not be characterised so far. The ^{31}P NMR spectrum of the reaction mixture shows a very complex signal pattern, which cannot be assigned to distinct species.

X-ray structure determination of $(TMEDA)_2Li_2Se_4$ (**2b**)

Data were collected on a STOE four circle diffractometer equipped with MoKα radiation (graphite monochromator, $\lambda = 0.71073$ Å) using an oil-coated crystal, employing the ω–θ scan technique. The data set was corrected for Lorentz, polarisation and absorption (ψ-scans) effects. Crystal data are listed in Table 1. The structure was solved by direct method [5] and refined by full-matrix least-squares procedures using all data on F^2 [6]. All nonhydrogen atoms were

refined anisotropically and hydrogen atoms were set geometrically. $R1 = \Sigma|F_o - F_c|/\Sigma|F_o|$ and $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{0.5}$ with a weighting scheme of the form $w^{-1} = \sigma(F_o^2) + (0.1500P)^2 + 13.7123P$, with $P = (F_o^2 + 2F_c^2)/3$.

RESULTS AND DISCUSSION

In our ongoing studies investigating the reduction properties of multianionic phosphazenates [7, 8], we reacted hexalithiated hexakis(cyclohexylamino)-cyclotriphosphazene, which exists as the THF-solvated dimeric complex $[(THF)_4Li_{12}\{(CyN)_6P_3N_3\}_2]$ (Cy = cyclohexyl) in the solid state [7], with six equivalents of elemental selenium in THF. Recrystallisation of the crude product from Et_2O/TMEDA solution gave dark red crystals of **2b** which were suitable for single crystal X-ray structure analysis. An alternative synthetic route was reported by Tatsumi *et al*. reacting elemental lithium and selenium in liquid ammonia and recrystallising the crude product using a mixture of toluene/TMEDA [2].

The molecular structure of **2b** is illustrated in Fig. 1. Selected interatomic distances and angles are listed in Table 2. The solid state structure of **2b** is composed of monomeric molecular units in which both lithium cations are bridged by the terminally arranged selenium centres of the chelating Se_4^{2-}-chain in a similar way as the lithium centres in the TMEDA-solvated polysulfide **2a**. Li–Se(terminal) bond distances are 2.63 Å on average and in correspondence with those observed in the PMDETA coordinated derivative **1b**. Each lithium centre in **2b** is saturated in a bidentate manner by one TMEDA ligand [Li–N (av.) 2.11 Å] and in addition loosely coordinated by one of the centrally arranged selenium centres Li(1)···Se(2) = 3.09(3) and Li(2)···Se(3) = 3.08(2) Å, resulting in a distorted trigonal prismatic geometry for the central Li_2Se_4 core. The overall geometry of the molecular unit can be described as of non-crystallographic C_2-symmetry. Structural features of the Se_4^{2-}-chain in **2b** are in accordance with those observed in corresponding systems providing highly ionic environments such as [Ba–4en][Se_4] (**3a**) [9], [Ba–222Crypt][Se_4] (**3b**) [10] and $[PPN]_2[Se_4] \cdot 4CH_3CN$ (**3c**) [11]. As in agreement with the structural observations in these systems, the terminal Se–Se-distances in **2b** are slightly shorter [Se1–Se2 2.336(3) and Se3–Se4 2.326(3) Å] than the central one [Se2–Se3 2.376(3) Å]. While the Se_4^{2-}-chains in **3a** and **3c** exist as non-coordinated ion-separated units, **3b** contains a Se_4^{2-}-chain which connects two barium centres in the same fashion as it connets both lithium centres in the PMDETA derivative **1b**. Due to the bridging nature of the terminal Se-centres, the Se1–Se2–Se3–Se4 torsion angle in **2b**, which is 42.5(1)°, is significantly tighter as those observed in **3a**–**c**.

The structural similarities of the TMEDA solvated lithium polychalcogenides **2a** and **2b** on one hand and of the PMDETA solvated derivatives **1a** and **1b** on the other hand show, that the hapticity of the hard nitrogen base directs the overall coordination mode of the resulting complexes. The bidentate TMEDA is leaving two coordination sites at the tetrahedrally complexed lithium centre for the soft polychalcogenide ligands, while the tridentate PMDETA is providing only one coordination site at the metal centre for an additional donor system. Therefore a

bicyclic arrangement with bent X_n^{2-}-chains is favoured in the case of TMEDA, whereas acyclic zig–zag chains with terminally arranged lithium centres are obtained using PMDETA.

Isopropyltetramethylcyclopentadienyl samarium chemistry: structural studies of divalent $(C_5Me_4{}^iPr)_2Sm(THF)$ and mixed valent $[(C_5Me_4{}^iPr)_2Sm]_2(\mu\text{-Cl})$

William J. Evans*, Kevin J. Forrestal and Joseph W. Ziller

Department of Chemistry, University of California, Irvine, CA 92697, U.S.A.

(Received 15 December 1997; accepted 3 May 1998)

Abstract—The isopropyltetramethylcyclopentadienyl samarium complexes $(C_5Me_4{}^iPr)_2Sm(THF)$, **1**, and $[(C_5Me_4{}^iPr)_2Sm]_2(\mu\text{-Cl})$, **2**, have been isolated and structurally characterized. Divalent **1** crystallizes from hot toluene as a monosolvate in space group $P3_121$ with $a=b=15.494(2)$ Å, $c=9.7724(7)$ Å, $\alpha=\beta=90^\circ$, $\gamma=120^\circ$, $V=2031.6(5)$ Å^3 and $D_{calcd}=1.346$ g/cm^3, $Z=3$ and $T=163$ K. **1** has a 141.6° ring centroid–Sm–ring centroid angle and an average Sm–C distance of 2.80(3) Å. **2** crystallizes from hot toluene in space group P1 with $a=9.616(2)$ Å, $b=15.479(2)$ Å, $c=17.844(1)$ Å, $\alpha=111.671(4)^\circ$, $\beta=93.488(8)^\circ$, $\gamma=107.494(9)^\circ$, $V=2309.3(5)$ Å^3 and $D_{calcd}=1.423$ g/cm^3, $Z=2$ and $T=163$ K. The two bent metallocene units in **2** are connected by an asymmetrical chloride bridge which has a 169.88(4)° Sm(1)–Cl–Sm(2) angle and 2.678(1) Å Sm(1)–Cl and 2.891(1) Å Sm(2)–Cl distances. The 2.69(2) Å average Sm(1)–C($C_5Me_4{}^iPr$) distance is characteristic of Sm(III) and the 2.80(2) Å average Sm(2)–C($C_5Me_4{}^iPr$) distance is characteristic of Sm(II). © 1998 Elsevier Science Ltd. INTRODUCTION

The pentamethylcyclopentadienyl ligand has been very effective in providing crystallographically characterizable complexes for the study of organometallic Sm(II) and Sm(III) chemistry and an important body of structural data is available [1–4]. Less symmetrically substituted polyalkylated cyclopentadienyl ligands are also useful in the study of organosamarium chemistry, but only a limited amount of crystallographic data is available on such compounds [5]. As part of a project to make sterically crowded $(C_5Me_4R)_3Sm$ complexes [5, 6], we have prepared and isolated the first example of a structurally characterized isopropyltetramethylcyclopentadienyl samarium complex, $(C_5Me_4{}^iPr)_2Sm(THF)$. In the course of these studies $[(C_5Me_4{}^iPr)_2Sm]_2(\mu\text{-Cl})$ was also isolated. These complexes allow structural comparisons with C_5Me_5 samarium complexes and the chloride complex is a rare example of a mixed valence bimetallic organosamarium compound.

EXPERIMENTAL

The compounds described below are extremely air and moisture sensitive. Therefore, all procedures were conducted using standard inert atmosphere techniques in a nitrogen-filled glovebox and solvents were distilled under nitrogen from sodium or potassium benzophenone ketyl as previously described [7].

Preparation of $C_5Me_4{}^iPrH$

$C_5Me_4{}^iPrH$ was prepared for the first time to our knowledge following the procedure successful for C_5Me_5H [8]. A 250 ml three-neck round bottom flask was equipped with a stir bar, gas inlet adapter and a reflux condenser. The flask was placed under an atmosphere of nitrogen and ^{i}PrMgCl (0.1 mol, 50 ml

of 2.0 M solution in diethyl ether) was added to the flask followed by an additional 100 ml of diethyl ether. The flask was then placed in an ice bath and 2,3,4,5-tetramethyl-2-cyclopentenone (10 g, 0.072 mol) was added dropwise over a 2 h period. The solution was allowed to warm to room temperature and stirred overnight. Any remaining ^{i}PrMgCl was then destroyed by slow dropwise addition of MeOH (5 ml) followed by H_2O (20 ml). The ether solution was washed with an aqueous solution containing NH_4Cl (13 g), concentrated HCl (20 ml) and H_2O (100 ml). This aqueous solution was back-extracted with ether and the ether solutions were combined. The ether solution was stirred for 1 h with 2 ml of 6 N HCl to ensure complete elimination of water. The organic layer was then washed with 5% $NaHCO_3$ and dried over K_2CO_3. Rotary evaporation of the solvent yielded 8.0 g of a pale yellow, viscous liquid which was purified by vacuum distillation at 35–40°C and 0.025 Torr. The ^{1}H NMR spectrum indicated that a mixture of isomers was present.

Preparation of $K(C_5Me_4{}^{i}Pr)$

In the glovebox $C_5Me_4{}^{i}PrH$ (2.0 g, 12.3 mmol) was added dropwise to a slurry of KH (0.40 g, 10.0 mmol) in THF (100 ml) and the reaction was allowed to stir for 24 h. $KC_5Me_4{}^{i}Pr$ is insoluble in THF and was filtered, washed with hexane and isolated as a white, flocculent powder (1.33 g, 65% yield).

Preparation of $(C_5Me_4{}^{i}Pr)_2Sm(THF)$, ***1***

In the glovebox $SmI_2(THF)_2$ (0.67 g, 1.23 mmol), $KC_5Me_4{}^{i}Pr$ (0.50 g, 2.47 mmol) and THF (15 ml) were placed into a vial. The THF solution immediately appeared purple and white insoluble material was present throughout the reaction. The solution was allowed to stir for 12 h at room temperature. Filtration and removal of solvent by rotary evaporation yielded $(C_5Me_4{}^{i}Pr)_2Sm(THF)$ as a purple powder (0.485 g, 72% yield). ^{1}H NMR (C_6D_6, 25°C, 300 MHz) δ 27.6 (6 H, CH_3), 10.3 (6 H, CH_3), 7.32 (4 H, THF), −3.37 (4 H, THF), −9.39(6 H, CH_3). ^{13}C NMR (THF-d_8, 25°C, 500 MHz) δ 95.0 (-*C*H(CH_3)$_2$), 93.0 (CH_3), 81.0 (CH_3), 59.0 (CH_3), −44.0 (C_5R_5), −62.4 (C_5R_5), −66.5 (C_5R_5). Anal. Calcd. for $SmC_{28}H_{46}O$: Sm 27.4. Found: Sm 25.6. Purple crystals suitable for X-ray diffraction were grown from hot toluene.

Preparation of $(C_5Me_4{}^{i}Pr)_2Sm(OEt_2)$

This compound was made in analogy to the preparation of $(C_5Me_5)_2Sm(OEt_2)$ [5, 9]. Diethyl ether (15 ml) was added to desolvated SmI_2 (0.50 g, 1.23 mmol) and $KC_5Me_4{}^{i}Pr$ (0.50 g, 2.47 mmol) in a Schlenk flask. The ether solution immediately appeared very dark green and white insoluble material was present throughout the reaction. The solution was allowed to stir for 12 h at room temperature. Filtration and removal of solvent under vacuum yielded $(C_5Me_4{}^{i}Pr)_2Sm(OEt_2)$ as a dark green powder (0.413 g, 68% yield). ^{1}H NMR (C_6D_6, 25°C, 300 MHz) δ 12.6, 6.53, 3.89, −0.55, −7.85, −8.82.

X-ray data collection, structure determination, and refinement for $(C_5Me_4{}^{i}Pr)_2Sm(THF)$, ***1***

A purple crystal of approximate dimensions $0.20 \times 0.26 \times 0.33$ mm was coated with Paratone oil, mounted on the tip of a glass fiber and transferred to a Siemens P4 diffractometer. The determination of Laue symmetry, crystal class, unit cell parameters and the crystal's orientation matrix were carried out according to standard procedures [10]. Intensity data were collected at 163 K using a 2θ–ω scan technique with MoKα radiation. The raw data were processed with a local version of CARESS [11] which employs a modified version of the Lehman–Larsen algorithm to obtain intensities and standard deviations from the measured 96-step peak profiles. All subsequent calculations were carried out using the SHELXL program [12]. All 3802 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The crystal class is trigonal and the space group is $P3_121$.

The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors for neutral atoms were used throughout the analysis [13]. Hydrogen atoms were included using a riding model. The molecule is located on a two-fold rotation axis ($Z = 3$). At convergence, $wR2 = 0.0733$ and GOF = 1.067 for 143 variables refined against all 2399 unique data. [As a comparison for refinement on F, $R1 = 0.0302$ for those 1961 data with $F > 4.0\sigma(F)$.] Refinement of the Flack parameter [14] was used to determine the absolute structure (i.e. the space group $P3_121$ was chosen over the enantiomeric space group $P3_221$).

X-ray data collection, structure determination, and refinement for $[(C_5Me_4{}^{i}Pr)_2Sm]_2(\mu\text{-Cl})$, ***2***

Dark red crystals of **2** were isolated from a hot toluene solution of the product obtained by treating $(C_5Me_4{}^{i}Pr)_2Sm(OEt_2)$ with a mixture of $Pb(C_5Me_4{}^{i}Pr)_2$ [15] and $PbCl_2$ in toluene (cf. [5]). A red crystal of **2** of approximate dimensions $0.27 \times 0.27 \times 0.33$ mm was handled as described above for **1**. All 10668 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. There were no systematic absences nor any diffraction symmetry other than the Friedel condition. The centrosymmetric triclinic space group $P\bar{1}$ was assigned and later determined to be correct. The structure was solved and refined as described for **1**. At convergence, $wR2 = 0.0821$ and GOF = 1.038 for 460

variables refined against all 10064 unique data. [As a comparison for refinement on F, $R1 = 0.0324$ for those 8422 data with $F > 4.0\sigma(F)$].

RESULTS AND DISCUSSION

Reaction chemistry

$C_5Me_4{}^iPrH$ can be made in a straightforward manner from tetramethylcyclopentenone and ^iPrMgCl following the general route to C_5Me_5H from tetramethylcyclopentenone and MeLi [8]. $C_5Me_4{}^iPrH$ can be deprotonated with KH and the resulting salt reacts with $SmI_2(THF)_2$ to form a purple complex in a manner analogous to the reaction of samarium diiodide with KC_5Me_5 which forms $(C_5Me_5)_2Sm(THF)_2$ [16]. Crystallization of the product of this reaction gives the monosolvate $(C_5Me_4{}^iPr)_2Sm(THF)$, **1** (Fig. 1), which was characterized by analytical, spectroscopic and X-ray diffraction methods (Table 1).

The ^1H NMR spectrum of **1** in C_6D_6 contains a broad resonance at 27.6 ppm ($\nu_{1/2} = 145$ Hz) as well as resonances at 10.3 and -9.39 ppm with line widths ($\nu_{1/2} = 58$ and 46 Hz, respectively) similar to those found in $(C_5Me_5)_2Sm(THF)_2$ [17], which contains the ring methyl resonance between 2.0–3.0 ppm depending on the concentration. A pattern of ring methyl resonances split to high and low field has been observed for the related C_5Me_4R compound $(C_5Me_4Et)_2Sm(THF)_2$ [17], which has ring methyl resonances at 4.54 and 0.10 ppm. Hence, the 10.3 and the -9.39 resonances are attributed to the ring methyl groups and the broad resonance to an unresolved doublet for the isopropyl methyl groups. This assignment is consistent with the 1:1:1 integration ratio for these three resonances. The isopropyl methine proton was not located. The chemical shifts of the remaining two peaks in the spectrum arise from coordinated THF and are highly concentration dependent.

The ^{13}C NMR spectrum of **1** in C_6D_6 has the same type of unusual shifts as observed for $(C_5Me_5)_2Sm(THF)_2$ [16] and other divalent samarocenes. The methyl carbon resonances as well as the isopropyl carbon attached to the ring are shifted downfield of the usual position to 59–95 ppm. The ring carbons are shifted upfield into the -44 to -67 ppm region. This type of ^{13}C NMR spectrum is a hallmark of organosamarium(II) complexes [18].

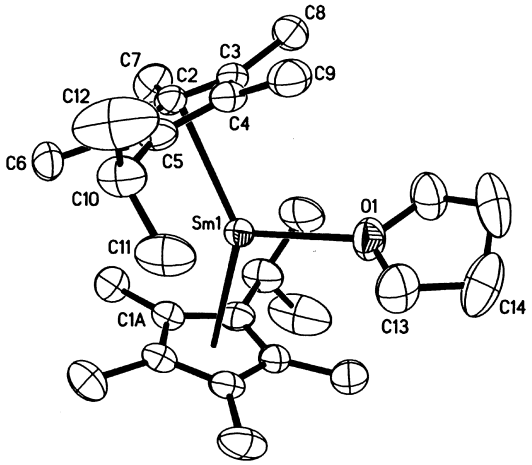

Fig. 1. Thermal ellipsoid plot of $(C_5Me_4{}^iPr)_2Sm(THF)$, **1**, with ellipsoids drawn at the 50% level and hydrogen atoms omitted for clarity.

Crystallographic studies

The structure of **1** is shown in Fig. 1. $(C_5Me_4{}^iPr)_2Sm(THF)$ has a bent metallocene structure with a 141.6° (ring centroid)–Sm–(ring centroid) angle. In comparison, $(C_5Me_5)_2Sm(THF)_2$ [16] has a 136.7° (ring centroid)–samarium–(ring centroid) angle and the analogous monosolvate, $(C_5Me_5)_2Sm(THF)$, **3** [19], has a 138.5° angle. Although the angle is larger in **1**, the 2.80(3) Å average Sm–C distance is equivalent within experimental error to the 2.816(4) Å average in **3**. The 2.540(5) Å Sm–O distance in **1** is also similar to the 2.569(3) Å distance in **3** (Table 2).

Complexes **1** and **3** differ, however, in the position of the THF molecule. In **1**, the THF is positioned symmetrically: the Sm–O bond lies on a two-fold rotation axis. In this central position, it is in the sterically least crowded position. In contrast the THF molecule in **3** is not located symmetrically with respect to the bent metallocene: the Sm–O(THF) vector makes a 37° angle with the plane defined by the samarium and the two ring centroids. In the related complexes $(C_5Me_5)_2Sm(OC_5H_{10})$ [20] and $[C_5H_2(SiMe_3)_3][C_5H_3(SiMe_3)_2]Sm(THF)$ [19] the analogous angles are 30° and 20°. Calculations on the hypothetical d^0 bent metallocene, $[(C_5H_5)_2TiH]^+$, indicated that a 65° angle would be orbitally optimal [21]. The variable 0–37° angles observed in these samarocene complexes are consistent with limited orbital control of this parameter in lanthanide complexes.

One other unusual feature in the structure of **1** is the orientation of the isopropyl methyl carbon C(11) toward Sm. Since the metal center in this monosolvated compound is likely to be sterically unsaturated, it is conceivable that some long range interactions with the isopropyl methyl groups could occur. Agostic interactions involving distant parts of ligands are common in organometallic complexes of the electrophilic lanthanides when they are sterically unsaturated [22–39]. Indeed, the 3.31 Å Sm···C(11) distance is less than the sum of the van der Waals radii of a methyl group and samarium [40]. Although nonbonded Ln–C distances shorter than their van der Waals radii have been observed for divalent lanthanide bis(trimethylsilyl)amide compounds [41–44], e.g. $[(Me_3Si)_2N]_2Sm(THF)_2$ [41] has four non-bonded Sm···C interactions in the 3.32(1)–3.46(1) Å range

and $(C_5Me_5)_2Sm$ has an intermolecular Sm–C(Me) contact of 3.22 Å [45], this appears to be the first intramolecular Ln···C contact of this type for a crystallographically characterized divalent $(C_5R_5)_2Sm$ compound. The agostic interactions observed in lanthanide and yttrium organometallic compounds typically involve distorted angles in the ligand system. In this case the numerical value of the 112.3(5)° C(5)–C(10)–C(11) involving C(11) is more acute than the analogous 114.3(5)° C(5)–C(10)–C(12) angle involving the methyl group away from the samarium, but the values are indistinguishable within the error limits.

The structure of $[(C_5Me_4{}^iPr)_2Sm]_2(\mu\text{-Cl})$, **2**, Fig. 2, allows further evaluation of the metrical parameters of the $C_5Me_4{}^iPr$ ligand since it contains both divalent and trivalent samarium. Crystals of this compound were obtained fortuitously from a hot toluene solution of $(C_5Me_4{}^iPr)_2Sm(OEt_2)$, $(C_5Me_4{}^iPr)_2Pb$ [15] and $PbCl_2$ and the structure is included here since it provides data on the $C_5Me_4{}^iPr$ ligand with samarium in two oxidation states. The mixed valence nature of **2** is shown not only by its composition of five anionic ligands with the two metals, but also by the bond distances which show that this is a class I mixed valence system [46] in which the metals exist in distinct oxidation states. The two distinct $(C_5Me_4{}^iPr)_2Sm$ bent metallocene units have very different Sm–C($C_5Me_4{}^iPr$) bond distance ranges. The Sm(1)–C distances range from 2.650(3)–2.714(4) Å and average 2.69(2) Å, which are typical for a *trivalent*, 7-coordinate, C_5Me_5-ligated Sm complex [18, 47]. The Sm(2)–C distances range from 2.778(4)–2.830(4) Å and average 2.80(2) Å, which is identical to that of divalent **1** above and is slightly shorter than normal for a *divalent*, 7-coordinate, C_5Me_5-ligated Sm complex. The extensive data available on pentamethylcyclopentadienyl samarium

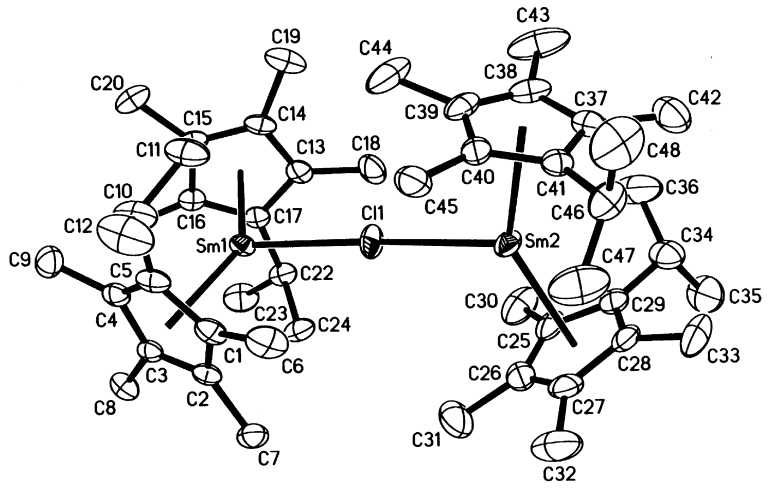

Fig. 2. Thermal ellipsoid plot of $[(C_5Me_4{}^tPr)_2Sm]_2(\mu\text{-Cl})$, **2**, with ellipsoids drawn at the 50% level and hydrogen atoms omitted for clarity.

complexes show that divalent complexes typically have Sm–C average distances 0.1 Å larger than trivalent complexes. In the mixed valence complex, $(C_5Me_5)_2Sm(\mu\text{-}C_5H_5)Sm(C_5Me_5)_2$ [18], the difference in average Sm–C(C_5Me_5) bond distances is 0.048 Å, however.

The Sm–Cl bond distances in **2** are also consistent with the different oxidation states. Hence, the 2.678(1) Å Sm(1)–Cl distance involving the trivalent metal is much smaller than the 2.891(1) Å Sm(2)–Cl distance involving the divalent center. These distances are not as definitive for the mixed valence formulation since bridging halide to lanthanide bond distances vary over a much wider range than Sm–C(C_5Me_5) bond lengths, particularly in asymmetrically bridged complexes. For example, in the complexes $[(C_5Me_5)_2Sm(\mu\text{-Cl})]_3$ and $\{[(C_5Me_5)_2ClSm]_2(\mu\text{-Cl})\}^-$ $\{[(C_5Me_5)_2ClSm](\mu\text{-Cl})[(C_5Me_5)_2Sm](\mu\text{-tetraglyme})[(C_5Me_5)_2Sm]\}^+$, **4**, the trivalent Sm–(μ-Cl) distances vary from 2.76(1)–2.89(1) Å (Table 3) [48].

There are relatively few structurally characterized organometallic samarium compounds of general formula $[(C_5R_5)_2Sm]_2(\mu\text{-X})$. However, the series X = O, S, Se, Te where R is Me and both metals are trivalent has been crystallographically characterized and is available for comparison [49, 50]. The Sm–X–Sm angle for the oxide bridged complex is 180° while the angles in the S, Se, and Te compounds are 170.2(1)°, 169.7(1)° and 170.0(1)°, respectively. The 169.8° angle in $[(C_5Me_4{}^iPr)_2Sm]_2(\mu\text{-Cl})$ closely resembles those of the S, Se and Te compounds. This angle is also similar to the 165.1(4)° and 164.8(4)° Sm–Cl–Sm angles in **4** [48]. Comparison with the ytterbium compounds $[(C_5Me_5)_2Yb]_2(\mu\text{-Se})$, **5** [9], and $[(C_5Me_5)_2Yb]_2(\mu\text{-F})$, **6** [51], can also be made. Complex **5** has a Yb–Se–Yb angle of 171.09(6)° while the smaller bridging fluoride atom in **6** results in a linear 180° Yb–F–Yb angle in order to minimize steric repulsion of the $(C_5Me_5)_2Yb$ units.

Sm(2)–C(28)	2.813(4)	Sm(2)–C(37)	2.817(4)
Sm(2)–C(38)	2.820(4)	Sm(2)–C(27)	2.830(4)
Sm(2)–C1(1)	2.8912(10)	Sm(2)–Cnt3	2.530
Sm(2)–Cnt3	2.528		
Cnt1–Sm(1)–C1(1)	110.8	Cnt2–Sm(1)–C1(1)	108.2
Cnt1–Sm(1)–Cnt2	141.0	Cnt3–Sm(2)–C1(1)	106.3
Cnt4–Sm(2)–C1(1)	109.4	Cnt3–Sm(2)–Cnt4	143.3
Sm(1)–C1(1)–Sm(2)	169.88(4)		

Examination of the positions of the isopropyl methyl carbon atoms with respect to the metals shows that neither methyl group attached to the rings on divalent Sm(2) is within 3.9 Å of Sm(2), but C(11) and C(24) are located 3.26 and 3.18 Å, respectively, from Sm(1). Taking into account a radial difference of about 0.1 Å between divalent and trivalent samarium, these Sm–C distances are in the range of the 3.31 Å Sm···C(11) distance found in **1**. Similarly, the 109.6(3)° C(17)–C(22)–C(24) and 110.9(4)° C(5)–C(10)–C(11) angles are more acute than their analogs involving the other methyl carbons: C(17)–C(22)–C(23) is 115.8(4)° and C(5)–C(10)–C(12) is 114.6(4)°. However, the pairs of C–C–C angles involving the isopropyl groups which are not oriented toward Sm(2) also have this type of angular disparity: C(29)–C(34)–C(35) is 110.9(4)° and

C(29)–C(34)–C(36) is 114.6(5)°; C(41)–C(46)–C(48) is 110.4(4)° and C(41)–C(46)–C(47) is 115.0(4)°.

The 141.6° (ring centroid)–Sm–(ring centroid) angle in **1** and the 141.0° and 143.3° (ring centroid)–Sm–(ring centroid) angles for Sm(1) and Sm(2) in **2** are the largest observed to date in any organometallic samarium complex [47]. This indicates that increased steric bulk on the cyclopentadienyl rings can affect the ring centroid–Sm–ring centroid angles, which could in turn lead to different reactivity patterns when compared to the C_5Me_5 ligand.

CONCLUSION

Complexes **1** and **2** show that samarium metallocenes are accessible with the sterically more demanding $C_5Me_4{}^iPr$ ligand in both divalent and trivalent oxidation states. In comparison to C_5Me_5, the isopropyl-substituted group increases the (ring centroid)–metal–(ring centroid) angles in the complexes, but it does not affect the metal ligand bond distances significantly. The specific orientation of the isopropyl group in **1** suggests that long distance lanthanide hydrocarbon interactions can be studied using appropriately substituted C_5Me_4R moieties.

Abstract—Tris(quinoxaline-2,3-dithiolato)manganese(IV) was synthesised and isolated as two different salts, $(PPh_4)_2[Mn^{IV}(qdt)_3]\cdot 1/2CHCl_3$, **1**, and $(HNEt_3)_2[Mn^{IV}(qdt)_3]\cdot 2H_2O$, **2** (qdt = quinoxaline-2,3-dithiolate). The magnetic behaviour of **1** is the typical of a high spin d^3 system, presenting an effective magnetic moment of 3.85 μ_B at room temperature. The reaction of **2** with copper(II) acetate in DMF (*N*,*N*-dimethylformamide) solution involves redox and ligand exchange processes and produces the new salt $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]_2$, **3**. The crystal structure of compound **3** consists of sequences of two layers of $[Cu^{III}(qdt)_2]^-$ anions and one of $[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cations. Each cation is linked to four anions through O–H···N hydrogen bonds between the water ligand of the cation and one nitrogen atom of qdt ligand in the anion. Magnetic isolation of the Mn(II) centres in **3** is confirmed by magnetic susceptibility measurements. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: quinoxaline-2,3-dithiolate; copper(III) complexes; manganese(IV) complexes; crystal structure; magnetic susceptibility; dimethylformamide

INTRODUCTION

The ligand quinoxaline-2,3-dithiolate (qdt) appears to be particularly interesting and its complexes with several transition metals, Co(III), Cu(II), Cu(III), Fe(III), Fe(IV), Ni(II), Pd(II), Pt(II), Zn(II), have been studied [1–6]. The use of qdt as an analytical reagent [7] and the utilisation of qdt complexes as ion-active substances of membrane electrodes have been reported [8]. Molybdenum complexes have been investigated for modelling of molybdenum hydroxylase enzymes [9–11]. More recently the photophysical properties of the platinum complexes, specially their luminescence, have been studied [12, 13]. Complexes of quinoxaline-2,3-dithiolate are analogous to metal-bisdithiolenes, but although tris(dithiolene)manganese (IV) compounds are known [14, 15], no previous isolation and characterisation of a quinoxaline-2,3-dithiolate complex of manganese has been done.

One or both nitrogen atoms of the qdt ligand in their complexes could be reversible protonated, as observed in the Pt(II) [13], Ni(II) [1, 6] or Mo(IV) complexes [10], for example. To our knowledge, the participation of this group in the direct co-ordination of an "outer" metal has been established only in the binuclear complex, (2,3-dithioquinoxalato)bis(η^5-cyclopentadienyl)titanium(III), $[Cp_2Ti(qdt)TiCp_2]$, where the qdt ligand acts as a bridge [16]. There is some controversy regarding the viability of the pyrazine bridges for mediating electron transfer [17, 18]. Aiming at contributing to establish whether the pyrazine rings may be used to produce magnetically interacting salts M[M′(qdt)2], we used the triethylammonium salts of qdt complexes of Cu(III), Fe(III) and Mn(IV)

combining them with copper(II) salts. Products of these reactions are microcrystalline powders very insoluble in common solvents and were not characterised, except for Mn(IV), from which we have produced monocrystals of a salt, $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]$, with the added/outside metal solvated, with no direct interaction with the nitrogen atoms of the qdt ligand. We present here the preparation of Mn(IV) qdt complexes and the synthesis and crystal structure of this new salt, **3**.

EXPERIMENTAL SECTION

Solvents and reagents were obtained from commercial sources and used without further purification unless otherwise stated. All the reactions were carried out in an open vessel. The ligand H_2qdt was prepared starting from 2,3-dichloroquinoxaline (Aldrich) by the procedure of Theriot *et al.* [2]. Elemental analysis, using a Perkin-Elmer 240 elemental analyser, were made at the analytical service of our laboratory.

Preparation of $(PPh_4)_2[Mn^{IV}(qdt)_3]\cdot 1/2CHCl_3$

H_2qdt (272 mg, 1.40 mmol) was dissolved in a solution of NaOH (112 mg, 2.80 mmol) in methanol (100 ml). A solution of $MnCl_2{\cdot}4H_2O$ (135 mg, 0.68 mmol) in methanol (50 ml) was slowly added with vigorous stirring. After 20 min, a solution of $(PPh_4)Br$ (300 mg, 0.72 mmol) in methanol (70 ml) was added, followed by 50 ml of water. The resultant solution is allowed to stand overnight in an open vessel and the day after green microcrystals appeared which were filtered and washed with water and diethyl ether. The crude compound was recrystallised in chloroform–hexane. Yield, 60%. Found: N, 6.16; C, 63.14; H, 3.45. Calcd. for $C_{72.5}H_{52.5}Cl_{1.5}MnN_6O_6P_2S_6$: N, 6.13; C, 63.55; H, 3.86.

Preparation of $(HNEt_3)_2[Mn^{IV}(qdt)_3]\cdot 2H_2O$

H_2qdt (272 mg, 1.40 mmol), $MnCl_2{\cdot}4H_2O$ (135 mg, 0.68 mmol) and an excess of triethylamine (0.5 ml, 3.6 mmol) were refluxed in methanol during one hour. The mixture obtained was filtered and allowed to stand overnight in an open vessel. The day after green monocrystals were collected by the procedure used for **1**. Yield, 70%. Found: N, 12.87; C, 49.64; H, 5.50. Calcd for $C_{36}H_{48}MnN_8O_2S_6$: N, 12.85; C, 49.58; H, 5.55. The crude compound could be recrystallised in dichloromethane–hexane.

Preparation of $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]_2$

$(HNEt_3)_2[Mn^{IV}(qdt)_3]\cdot 2H_2O$ (50 mg, 0.057 mmol) was dissolved in 10 ml of DMF (dimethylformamide) and a solution of $[Cu(CH_3COO)_2H_2O]_2$ (12 mg, 0.060 mmol Cu) in 10 ml of DMF was added. The dark solution obtained was allowed to stand for a week in an open vessel where dark green monocrystals grew. They were filtered and washed with DMF and diethyl ether. Yield, 20%. Found: N, 12.61; C, 40.53; H, 2.92. Calcd for $C_{44}H_{48}N_{12}O_6S_8MnCu_2$: N, 13.13; C, 41.30; H, 3.78.

X-ray crystallography

A dark-green crystal of approximate dimensions $0.28\times0.08\times0.06\,mm^3$ was mounted in a glass capillary on a goniometer head and transferred to an Enraf-Nonius CAD-4 automatic diffractometer where X-ray data were collected at room temperature with graphite monochromated Mo Kα radiation ($\lambda=0.71069$ Å). Unit cell dimensions and a crystal orientation matrix were obtained from square refinement of the setting angles of 25 reflections in the $10^\circ<\theta<13^\circ$ range. The data set was collected in a ω–2θ scan mode [$\Delta\omega=(0.80+0.35\tan\theta)^\circ$]. The intensities were corrected for Lorentz and polarisation effects and an empirical absorption correction (ψ scan) was made (maximum and minimum transmission factors were 0.9660 and 0.9990). The MoLEN program was used for data reduction. The structure was solved by standard Patterson methods using SHELX86 [19], and subsequently completed by Fourier recycling using SHELX93 [20]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were set in calculated positions. The final refinement on F_o^2 by full-matrix least-square techniques, with anisotropic thermal displacement parameters for the non-hydrogen atoms converged at $R=0.0330$, $R_w=0.0756$ and $S=1.075$. A difference Fourier synthesis revealed residual densities between 0.379 and $-0.350\,e/Å^3$. Scattering factors and anomalous dispersion factors used were those supplied in SHELX93. The drawings were made with ORTEP [29].

Magnetic susceptibility

Magnetic susceptibility measurements were performed in the range 4.2–300 K using a longitudinal Faraday system (Oxford Instruments) with a 7 T superconducting magnet. Polycrystalline samples (8.6 mg for **1** and 9.2 mg for **3**) were placed in a thin-wall Teflon bucket, previously measured. The magnetic fields used were 2 T and force was measured with a microbalance (Sartorius S3D-V) applying forward and reverse gradients of 5 T/m. Paramagnetic susceptibility was calculated from the raw susceptibility data correcting for diamagnetism that was estimated from tabulated Pascal's constants [21] as -727×10^{-6} emu/mol for **1** and -550×10^{-6} emu/mol for **3**.

RESULTS AND DISCUSSION

Manganese(II) chloride reacts with the quinoxaline-2,3-dithiolate ligand, in basic media, giving a green

manganese(IV) complex. Many reasons could explain the change in the oxidation state of the manganese. The qdt ligand favours the stabilisation of transition metal cations in a high oxidation state as observed in many cases. This is a metal centred process, electrochemically observable for instance for the $[Ni^{III}(qdt)_2]^-$–$[Ni^{II}(qdt)_2]^{2-}$ couple in DMF solution [6]. The Cu(III) is air stable; this complex is easily obtained by air oxidation of the Cu(II) complex in solution [2]. The cobalt(II) complex must be prepared under a nitrogen atmosphere [3] but the cobalt(III) one is relatively air stable. Starting from iron(III) chloride, and without any special requirement, an iron(IV) air stable complex is obtained [3]. The molybdenum(IV) complex treated with iodine, a soft oxidant, produces the molybdenum(V) species [11]. In all the reported tris-dithiolene manganese complexes, the Mn is in the +IV oxidation state [14, 15]. These complexes are always green and in some cases are prepared starting from manganese (II) salts in open recipients with no other oxidant addition.

On the other hand, manganese(II) is poorly represented in the chemistry of dithiolenes. Oxidation of the thiol compound of Mn(II) to Mn(III) occurs so readily that Mn(II) compounds have to be prepared anaerobically. In addition, it is well known that the alkaline solutions that contain Mn(II) species are usually not stable in regard to the oxidation to Mn(IV) compounds, the MnO_2 precipitate being formed in many cases.

Although we started from a 2:1 qdt:Mn molar ratio, the elemental analysis of **1** indicates that a 3:1 complex was obtained. This stoichiometry is the observed one for the high oxidation state cation: tris(quinoxaline-2,3-dithiolato) complexes of cobalt(III) and iron(IV) [3], molybdenum(IV) [10, 21] and molybdenum(V) [11] have been characterised. X-ray powder patterns are identical to those of the Fe analogue, suggesting that $(AsPh_4)_2[Mn(mnt)_3]$ has the same octahedral structure defined for the Fe compound [14, 15].

The magnetic behaviour of **1** is typical of a high spin d^3 system (Fig. 1): it presents a μ_{eff} of 3.85 μ_B at room temperature. The isolation of the magnetic centres can also be inferred from the susceptibility data. All the tris(dithiolene)manganese complexes have magnetic moments near 4 μ_B, typical of high spin d^3 systems [14, 15]. Therefore, on the basis of the experimental data and reported values for other Mn compounds in the literature, the assignment of the +IV oxidation state to the two obtained manganese compounds is justified.

In the synthesis of **1** we utilised the much usual route to the qdt complexes, starting from the sodium or potassium salt of the ligand, obtained by the reaction of the slightly acidic H_2qdt with NaOH (or KOH). These salts react with the metal chloride or nitrate to produce a complex. When anionic complexes are obtained, a salt of a bulk cation must be added to precipitate the anionic complex. Basic media must be assured when the complex is still in solution to prevent the protonation of the nitrogen atoms.

$(HNEt_3)_2[Mn^{IV}(qdt)_3]\cdot 2H_2O$ was obtained by a different route based on the addition of an excess of triethylamine to a mixture of H_2qdt and a metallic salt, manganese(II) chloride in this case. The amine acts as a base, to deprotonate the slightly acidic H_2qdt, giving then an ammonium cation suitable to precipitate the anionic complex. Using this method, we have obtained the Mn(IV) complex described here and also salts of other known qdt complexes as $(HNEt_3)_2[Fe^{III}(qdt)_2]_2\cdot 2H_2O$ and $(HNEt_3)[Cu^{III}(qdt)_2]\cdot 2H_2O$. Although the amine can promote the precipitation of metal hydroxide, amine excess helps the formation of soluble species able to react with the qdt ligand to give the desired complex.

These triethylammonium salts, with a cation that

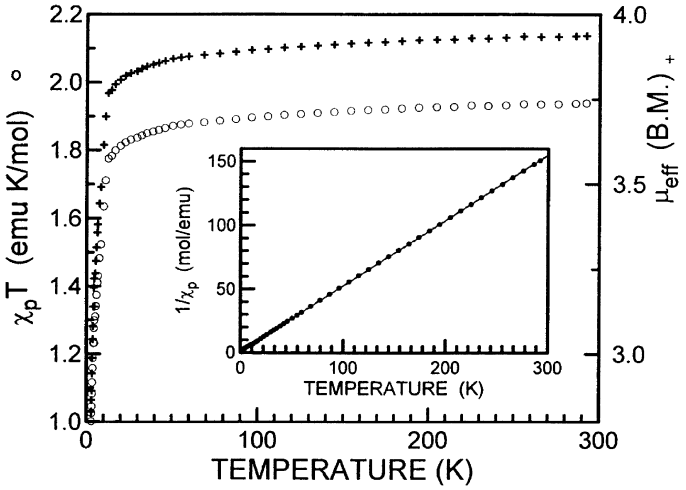

Fig. 1. Experimental χ_pT (crosses, left scale) and effective magnetic moment (open circles, right scale) as a function of temperature for $(PPh_4)_2[Mn^{IV}(qdt)_3]_2$; the inset shows the plot of χ_p^{-1} vs T.

has an acidic nature, are specially appropriate for reacting with other metal compounds in which the ligand has a basic nature (such as the acetates), in order to obtain bimetallic salts of stoichiometry $M^{y}_{(2n-x)/y}[M^{x}(qdt)_n]$. If the ability of solvent co-ordination to M^y is less than the one of the nitrogen atom in the pyrazine rings, both metals may be connected via qdt ligand and the formation of two or three-dimensional networks could be anticipated. These intermetallic contacts could favour interactions between the unpaired electrons of both metals, M^y and M^x, that must originate interesting magnetic properties.

The reaction between $(HNEt_3)_2[Mn^{IV}(qdt)_3]\cdot 2H_2O$ and $[Cu(CH_3COO)_2H_2O]_2$ in DMF produces a monocrystalline compound, $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]$, **3**. X-ray data allowed the identification of the copper and manganese in **3**. This reaction involves a complete reorganisation of the co-ordination sphere of both metals that also change their oxidation states, whose assignment is reinforced by the magnetic susceptibility data. The manganese is not bonded to the dithiolene function, but is solvated by DMF and water. No direct contact between the pyrazine and the manganese is observed, but they are hydrogen-bond connected through the water ligand (a detailed discussion of the structure is given below).

This reaction must be done in an open container; **3** was not obtained when a closed vessel was employed. This indicates that the intervention of the atmospheric oxygen may be a requirement. The synthesis of **3** from the reaction of Mn(II) perchlorate with $(PPh_4)[Cu^{III}(qdt)_2]$ in DMF was not successful (Scheme 1).

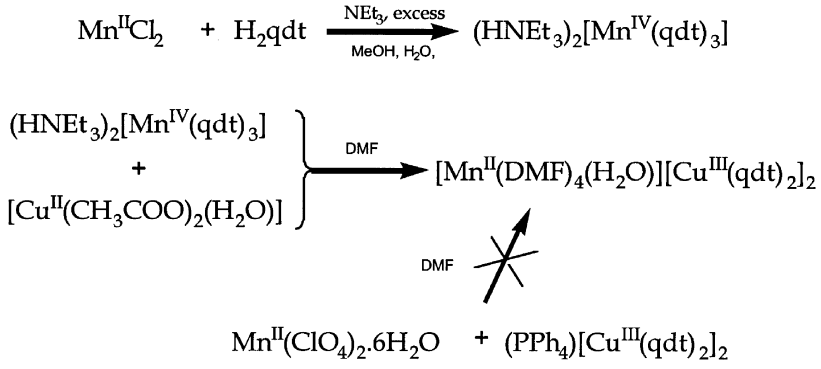
DMF is an aprotic solvent which acts as an oxygen-donor ligand. A number of metal complexes containing DMF, in addition to other different ligands have been synthesised and their structures reported, but the number of homoleptic complexes characterised are reduced. The DMF is *a priori* a weak ligand: anionic ligands with any significant co-ordinating power can compete with amides for co-ordination sites so that the products isolated from reactions of amides with transition metal halides usually contain co-ordinated halide. In all the co-ordination compounds of DMF that have been characterised by X-ray studies, the bonding is through oxygen. Water is also a competitor with them for co-ordination and consequently when dry conditions have not been used, products containing both amide and water are obtained [22].

The magnetic susceptibility measurements for **3** agree with the existence of isolated Mn(II) centres, a classic d^5 system. No contribution to the paramagnetism from the $[Cu^{III}(qdt)_2]^-$ square planar d^8 system must be expected since its tetraphenylphosphonium salt has been reported as diamagnetic [2]. Upon cooling from room temperature, the susceptibility increases, closely following a Curie law until the lowest temperature measured. As shown in Fig. 201, the $\chi_p T$ product curve exhibits a wide plateau (20–300 K) corresponding to an effective magnetic moment of 5.8 μ_B, close to the value due to a $S = 5/2$ spin, which is 5.92 μ_B by the spin-only formula.

CRYSTAL STRUCTURE OF $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]_2$

The crystal structure of $[Mn^{II}(DMF)_4(H_2O)_2][Cu^{III}(qdt)_2]_2$ consists of two sheets of $[Cu^{III}(qdt)_2]^-$ anions alternating with $[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cations (Figs 3 and 4) almost parallel to the *bc* plane. For the $[Cu^{III}(qdt)_2]^-$ anion, the distances and angles are very similar to those found in $(PPh_4)[Cu^{III}(qdt)_2]$ (which contain two independent anions) or $(perylene)_2[Cu^{III}(qdt)_2]$ [23]. In particular, their Cu–S bond distances (2.18 Å average) confirm the charge of the anion (average Cu–S bond distances of 2.26 Å for $[Cu^{II}(qdt)_2]^{2-}$ and 2.18 Å $[Cu^{III}(qdt)_2]^-$ has been measured in their PPh_4 salts [5]).

The qdt ligand is not symmetrically bonded to the copper atom and the two Cu–S bond distances in this compound are quite identical to corresponding ones in similar salts, as indicated in Table 1. In **3**, the two ligands of each $[Cu^{III}(qdt)_2]^-$ anion are also not equivalent as a consequence of the intermolecular



Scheme 1.

interactions: this explains some differences in "symmetrical" bond lengths and angles on the two sides of the molecule. In fact, the $[Cu^{III}(qdt)_2]^-$ deviates from planarity: the angle between the CuS_4 plane and each of the mean planes of the ligands is 5.21(2)° and 4.14(2)° for S1S2...C7C8 and S3S4···C15C16, respectively, and it is 8.31(2)° between the two ligands (Table 2–4).

This is the first characterisation of the $[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cation. A search of the January 1998 release of the Cambridge Structural Database showed no previous determination of this anion, $[Mn^{II}(DMF)_6]^{2+}$ or other manganese related cation.

The $[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cation has two DMF and one water independent molecules. The Mn(II) cation being located on a centre of symmetry, has a pseudo octahedral environment defined by four oxygen atoms of four DMF molecules, located in a plane

(that necessarily contain the manganese atoms), and the two oxygen atoms of the water molecules. The $(H_2)O$–Mn–$O(H_2)$ axis is almost orthogonal to the former equatorial plane (87.90°). This plane defined by the four O atoms of DMF bonded to the Mn atom and the plane defined by the anions, are roughly parallel to the *bc* plane.

The DMF ligand is planar and the intramolecular bond lengths and angles are in good agreement with those found in other DMF metal-bonded complexes: $[Ni(DMF)_6][ClO_4]_2$ [24], $[Fe(DMF)_6][ClO_4]_2$ [25, 26] or $[Fe(DMF)_6][ClO_4]_3$ [27], for instance. The conformation of the two kinds of DMF molecules are different, as denoted by the different angles between their plane and the plane MnO_4 (O = oxygen from DMF) or the different dihedral angles between the carbonyl bond of one DMF ligand and the Mn–O bonds of the remaining ligands. The interaction between the H atoms of the methyl groups of the DMF ligands and the sulphur atoms may play a significant role in the determination of the different conformations. The torsion angles are 150.0(3)° (O3–Mn–O1–C1A) and 1.0(2)° (O3–Mn–O2–C1B).

Interactions between the anionic and cationic species exist, as denoted by several N···H and S···H contacts below or in the range of the sum of the van der Waals radii. Each $[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cation is connected to four neighbouring anions by hydrogen bonding between the water ligand and the nitrogen of the pyrazine ring of the qdt ligand at the distances: O–H···N (O(3)–H···N(3)′, 2.80 Å; O(3)–H·N(2)′, 2.82 Å. On the other hand, each $[Cu^{III}(qdt)_2]^-$ anion interacts with two cations. S···H interactions contact the thiolate function with the one hydrogen of the methylene group (CH_3) of the DMF (S(2)···H(3C)′, 2.92 Å). If we consider this network of hydrogen bonds, the structure can be described as layers of ''sandwiches'' composed by two sheets of $[Cu^{III}(qdt)_2]^-$ anions surrounding one sheet of

$[Mn^{II}(DMF)_4(H_2O)_2]^{2+}$ cations. This situation resembles the $(PPh_4)_2[Mo^{IV}(qdt)_3]$ structure, where the $[Mo^{IV}(qdt)_3]^{2-}$ anions are linked by hydrogen bonding via the quinoxaline nitrogen atoms through water molecules (distances N···O, 3.6 Å) [10] and a similar network is found in $(NEt_4)_2[Ni(qdt)_2]\cdot 2H_2O$ [28].

CONCLUSION

In the present work we showed the possibility of obtaining compounds containing $M(qdt)_2$ complexes and a second metal. However, for getting the latter metal co-ordinated to the outer sphere of the quinoxaline ring further work is necessary in order to eliminate competition from the co-ordinating power of solvents.

Supplementary material available

Complete lists of atomic coordinates, bond parameters and tables of thermal parameters and hydrogen atom coordinates have been deposited at the Cambridge Crystallographic Data Centre (CCDC, deposition number 101599) and are available from the authors on request (21 pages).

Comparative X-ray crystallographic characterization of the mono- and bimetallic complexes of rhenium(I) tricarbonyl chloride with 2,3-bis(2-pyridyl)pyrazine

J.R. Kirchhoff* and K. Kirschbaum

Department of Chemistry, The University of Toledo, Toledo, OH 43606, U.S.A.

(Received 8 February 1998; accepted 3 May 1998)

Abstract—Comparative X-ray crystallographic characterization of $[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$, where dpp is 2,3-bis(2-pyridyl)pyrazine, has been conducted to examine the structural consequences resulting from sequential coordination of two $[Re(CO)_3Cl]$ molecular fragments to dpp. Addition of one metal center results in the coordinating portion of dpp adopting a relatively planar configuration. The dihedral angle between the pyrazine ring and the coordinated N(1)-pyridyl ring is 15.3(4)°, while the dihedral angle between the pyrazine ring and the uncoordinated N(2)-pyridyl ring is 45.8(3)°. The dpp ligand in the bimetallic complex is found to twist to accommodate the second metal center as manifested by a two-fold increase in the N(1)-pyridyl and pyrazine dihedral angle [29.7(4)°] and a decrease for the N(2)-pyridyl and pyrazine dihedral angle [31.6(3)°]. The direct structural consequence is an increase in the distortion of the central pyrazine moiety upon addition of each $[Re(CO)_3Cl]$ fragment. This observation confirms previously reported spectroscopic results that inferred the differences in electronic structure between $[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$ were due to the dpp ligand adopting a nonplanar geometry in the bimetallic complex. © 1998 Elsevier Science Ltd. INTRODUCTION

The photochemical and photophysical properties of metal-to-ligand charge-transfer (MLCT) excited state(s) of complexes of the type $[Re(NN)(CO)_3X]$, where NN is a chelating α,α′-diimine ligand and X is for example a halide, MeCN, PhCN, pyridine, piperidine, $SnPh_3$, $GePh_3$, have attracted significant attention since the initial characterization of the luminescence properties by Wrighton and co-workers [1–3] and the demonstration that $[Re(bpy)(CO)_3X]$ (bpy = 2,2′-bipyridine; X = Cl, Br) complexes acted as combination photosensitizers and electrocatalysts for the reduction of CO_2 to CO [4–11].

A recent aspect of transition metal photochemistry has focused on the characterization of multimetallic or supramolecular complexes as multielectron redox reagents or models for intermolecular electron-transfer [12, 13]. One approach to the design and development of supramolecular complexes utilizes a multidentate bridging ligand as a template to which monometallic molecular fragments are attached to build the multimetallic system. For example in rhenium(I) systems the neutral molecular fragment, $[Re(CO)_3Cl]$, has been exploited to build bimetallic complexes around a variety of α,α′-diimine based bridging ligands (BL) [14–24]. Interestingly, monometallic complexes such as $[Re(BL)(CO)_3Cl]$ with bidentate BL ligands are in general emissive in fluid solution while emission from the bimetallic counterparts, $[Cl(CO)_3Re(BL)Re(CO)_3Cl]$, is rarely observed.[1] In contrast, bimetallic rhenium(I) complexes of the type $[(NN)(CO)_3Re(BL')Re(CO)_3(NN)]$,

[1] Emissive bimetallic complexes of this type have been reported for $[Re(CO)_3Br]_2QP$ (QP = 5,5′,3″,5‴-tetramethyl-2,2′:6′,2″:6″2‴-quaterpyridine) [15], $[Re(CO)_3Cl]_2$Mebpy-Mebpy (Mebpy-Mebpy = 1,2-bis(4′-methyl-2,2′-bipyridyl-4-yl)ethane) [19] and $[Re(CO)_3(CH_3CN)]_2ppz$ (ppz = 4′7′-phenanthrolino-5′6′:5,6-pyrazine) [24].

* Author to whom correspondence should be addressed.

where BL′ links the metal centers by unidentate coordination to each metal center, have been found to be highly emissive in fluid solution [25–30]. The photophysical behavior of these rhenium(I) complexes has been rationalized by a model invoking the energy gap law [20–22, 24–29]. However, it has been recently noted that this model may be oversimplified in some cases and the extent of delocalization of the excited electron and the rigidity of the acceptor ligand should also be considered [31].

For bimetallic complexes of the type $[Cl(CO)_3Re(BL)Re(CO)_3Cl]$, the loss of emission as compared to the monometallic complexes has been described as due to the lowering of the energy of the π^* orbitals on the bridging ligand, which is manifested by the structural changes required to accommodate the addition of a second $[Re(CO)_3Cl]$ fragment [16, 19–22, 24]. In particular, comparative NMR studies of monometallic and bimetallic $[Re(CO)_3Cl]$ complexes with dpp (2,3-bis(2-pyridyl)pyrazine) and ppz (4′7′-phenanthrolino-5′,6′:5,6-pyrazine) as bridging ligands have suggested that the coordinating part of dpp adopts a planar geometry in the monometallic complex while the bimetallic complex requires a puckered or twisted arrangement in order to incorporate the second metal center [19, 24]. In this report, X-ray crystallographic analysis of $[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$ has been used to directly examine the structural consequences that result upon the addition of a second $[Re(CO)_3Cl]$ subunit to $[Re(dpp)(CO)_3Cl]$.

EXPERIMENTAL

Materials

$[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$ were prepared from $Re(CO)_5Cl$ (Aldrich) and dpp (Aldrich) by slight modification of literature procedures [3, 17]. All other reagents were of ACS grade and used without further purification. X-ray quality crystals were obtained by slow evaporation of a methanol solution of each complex.

Crystallographic determination of $[Re(dpp)(CO)_3Cl]$

A pyramidal-shaped orange–red crystal of $[Re(dpp)(CO)_3Cl]$ with approximate dimensions of $0.20 \times 0.20 \times 0.08$ mm was mounted on a fine glass fiber with glue. Preliminary examination and data collection were carried out at room temperature on a Siemens SMART Platform diffractometer. Intensity data were collected using 0.3° ω-scans at three different ϕ-settings corresponding to a nominal hemisphere of data. The cell constants were obtained from the setting angles of 4873 reflections in the range $4^\circ < \theta < 27^\circ$. The intensities of 6317 reflections with $2\theta < 60^\circ$ were corrected for absorption (semi-empirical, ψ-scans). Equivalent reflections were averaged, and the remaining 4352 unique reflections were used for further calculations. The structure was solved by direct methods (SHELXS-86) [32]. All non-hydrogen atoms were refined with anisotropic thermal parameters by full matrix least-squares on F^2 using all unique data (SHELXL-93) [33]. The hydrogen atoms were calculated on idealized positions ($CH_{ar.} = 0.93$ Å, $U_H = 1.2 \times U_C$) and included in the refinements as riding atoms.

Crystallographic determination of $[Re(CO)_3Cl]_2dpp$

A column-shaped red crystal of $[Re(CO)_3Cl]_2dpp$ with approximate dimensions of $0.33 \times 0.20 \times 0.15$ mm was mounted on a glass fiber with glue. Data collection was conducted at room temperature on an Enraf-Nonius CAD4 diffractometer with the ω–2θ scan technique to a maximum 2θ of 52°. The cell constants and an orientation matrix for data collection were obtained from the setting angles of 25 reflections in the range $10^\circ < \theta < 14^\circ$. A total of 5066 reflections were measured and 4809 were found to be unique. Anisotropic decay and semi-empirical absorption (ψ-scan) corrections were applied to the data set; equivalent reflections were averaged. 3906 reflections met the condition $F_o^2 > 3.0\sigma(F_o^2)$ and were used for further calculations. A starting model for the structure was provided by direct methods with MULTAN [34] and further developed to a final structure model with anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. Refinement was accomplished by the full-matrix least-squares technique on F using all observed data [35].

A summary of the crystal data for both complexes is given in Table 1. Selected bond distances, bond angles and torsion angles are given in Tables 2–4, respectively.

RESULTS AND DISCUSSION

The ORTEP diagrams of $[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$ with the atom numbering schemes are shown in Figs. 1 and 2. The local coordination geometry about each rhenium(I) metal center in both complexes can be described as a distorted octahedron. In $[Re(CO)_3Cl]_2dpp$, two $[Re(CO)_3Cl]$ molecular fragments are linked by the dpp bridging ligand through bidentate nitrogen chelation. An approximate C_2 axis bisects the pyrazine ring between C(6) and C(9) with no significant differences between the corresponding bond distances and angles in each half of the molecule. The distortion from octahedral coordination geometry is evident from the significant reduction of the N–Re–N angles from 90° in the idealized polyhedron to $74.5(2)^\circ$ in $[Re(dpp)(CO)_3Cl]$, and $75.1(2)^\circ$ and $75.3(2)^\circ$ in $[Re(CO)_3Cl]_2dpp$, which results from the small bite angles of the dpp ligand. The *trans* angles about rhenium in the monometallic and bimet-

allic complexes range from 171.2(3)° to 179.4(2)° and from 172.1(2)° to 174.8(2)°, respectively. The carbonyl groups assume a *fac* geometry about the metal center in both complexes with an average Re–CO bond distance of 1.914(8) Å ($n = 3$) and 1.915(7) Å ($n = 6$). The average Re–Cl distance is 2.476(2) Å for $[Re(CO)_3Cl]_2dpp$ as compared to 2.478(2) Å for $[Re(dpp)(CO)_3Cl]$. In the monometallic complex the pyridyl and pyrazine Re–N distances are essentially identical with an average distance of 2.177(5) Å ($n = 2$), while in the bimetallic complex the average Re–N distance is 2.164(6) Å ($n = 4$) with the pyridyl Re–N distances slightly longer than the pyrazine Re–N distances. These observed values are in the range for Re-ligand distances and angles in related structurally characterized $[Re(NN)(CO)_3X]$ complexes [29, 30, 36–48].

Sequential addition of $[Re(CO)_3Cl]$ molecular fragments to dpp produces several interesting structural effects. Huang *et al*. have determined the structure of the uncoordinated dpp ligand and found the average deviation from planarity for the pyrazine and pyridine moieties to be only 0.007 and 0.001 Å, respectively [49]. In addition, the pyridyl groups in the free ligand rotate about the C(9)–C(10) and the C(5)–C(6) axes to alleviate a potential steric interaction between H(11) and H(4) [50]. Consequently, dihedral angles of 42.2° between the pyrazine and pyridyl rings are

N(2)–pyridyl–pyrazine	45.8(3)	31.6(3)
N(1)–C(5)–C(6)–N(4)	10.6(9)	−20.5(8)
N(2)–C(10)–C(9)–N(3)		−15.6(8)
Cl(1)–Re(1)–Re(2)–C(18)		−42.3(2)

observed. Addition of one $[Re(CO)_3Cl]$ fragment locks in bidentate coordination through the N(1)-pyridyl and N(4)-pyrazine atoms and reduces the dihedral angle between these two rings to 15.3(4)°. In contrast, the uncoordinated N(2)-pyridyl ring maintains a dihedral angle with respect to the pyrazine ring of 45.8(3)°. Concomitantly, the corresponding torsion angle in $[Re(dpp)(CO)_3Cl]$ is found to be +10.6(9)° as compared to a torsion angle of 136.1° in the free ligand [49]. In related $[Re(NN)(CO)_3X]$ complexes, where NN is 2,2′-bipyridine [29, 30, 39, 41, 43], 2,2′-bipyrimidine [42] and η^2-2,2′:6′,2″-terpyridine [45–47], the analogous torsion angle ranges from −3.3° to +9.83°. In all cases bidentate coordination of a NN-based ligand with one $[Re(CO)_3Cl]$ fragment drives the coordinating part of the NN ligand toward planarity.

Coordination of the second $[Re(CO)_3Cl]$ fragment to $[Re(dpp)(CO)_3Cl]$ reverses this trend. To accommodate both metal centers in a stable complex, the pyridyl rings twist in opposite directions. This causes an increase in the dihedral angle between the N(1)-pyridyl and the pyrazine ring [29.7(4)°] and a decrease

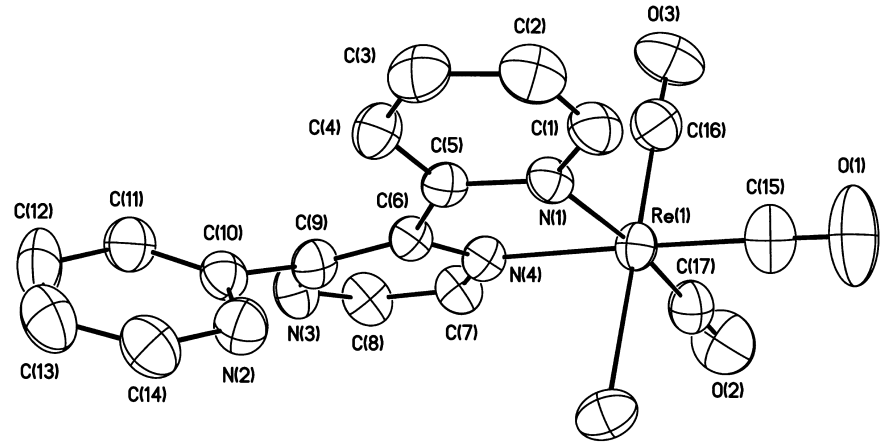

Fig. 1. ORTEP diagram of $[Re(dpp)(CO)_3Cl]$ showing 50% probability ellipsoids.

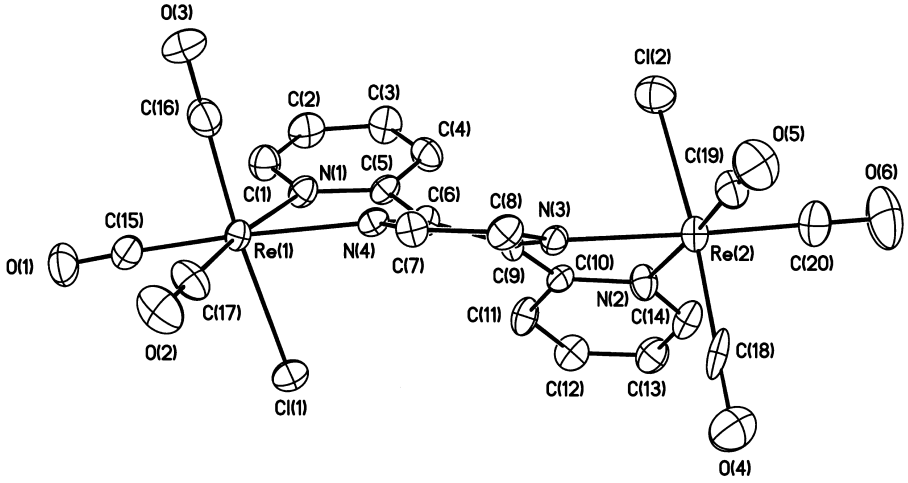

Fig. 2. ORTEP diagram of $[Re(CO)_3Cl]_2dpp$ showing 50% probability ellipsoids.

for the dihedral angle between the N(2)-pyridyl and the pyrazine ring [31.6(3)°]. A further consequence of the increased twist of the dpp ligand in the bimetallic complex is seen in the Cl(1)–Re(1)–Re(2)–C(18) torsion angle [−42.3(2)°]. Thus, looking down the axis defined by the Re(1) and Re(2) atoms, the ligands on the $[Re(CO)_3Cl]$ fragments are arranged in a staggered configuration. The deviation from planar coordination is also demonstrated by the larger torsion angles in $[Re(CO)_3Cl]_2dpp$ in comparison to $[Re(dpp)(CO)_3Cl]$: N(2)–C(10)–C(9)–N(3), −15.6(8)°; N(1)–C(5)–C(6)–N(4), −20.5(8)°. This is further manifested by the shortening of the N(3)- and N(4)-pyrazine to Re bond lengths in the bimetallic complex, and the observation that Re(1) and Re(2) are located −0.462 and 0.376 Å from the best plane defined by the atoms of the central pyrazine ring in comparison to 0.255(9) Å for Re(1) in $[Re(dpp)(CO)_3Cl]$. Bimetallic coordination also brings into play the potential steric interaction of H(11) and H(4) on the pyridyl rings. The X-ray structure for $[Re(CO)_3Cl]_2dpp$ is consistent with the theoretical description necessary to achieve a stable bimetallic complex with a bridging dpp ligand [50]. The calculated H(11) ⋯ H(4) distances are 3.72 Å in $[Re(dpp)(CO)_3Cl]$ and 3.01 Å in $[Re(CO)_3Cl]_2dpp$, which are both well above the minimum theoretical distance of 1.8 Å [50].

Of particular interest are the localized structural distortions that occur within the central pyrazine ring of dpp upon metal coordination. In comparison to the free ligand (0.007 Å) [49], the average deviation from planarity for a single atom in the pyrazine moiety increases to 0.037(5) Å in $[Re(dpp)(CO)_3Cl]$ and to 0.062(6) Å in $[Re(CO)_3Cl]_2dpp$. The largest deviations from planarity within the pyrazine ring occur at C(6) and C(9): $[Re(dpp)(CO)_3Cl]$, C(6) −0.060(4) Å; C(9) 0.053(4) Å and $[Re(CO)_3Cl]_2dpp$, C(6) 0.101(6) Å; C(9) −0.108(6) Å. Coordination of the metal centers clearly requires the dpp ligand to twist, which induces a buckling of the pyrazine ring (Fig. 2). In contrast, the

planarity for the pyridyl rings is only slightly changed upon metal coordination as are the internal bond distances and angles within dpp.

The X-ray structures of $[Re(dpp)(CO)_3Cl]$ and $[Re(CO)_3Cl]_2dpp$ provide direct and quantitative evidence of the degree to which the dpp ligand must twist to accommodate the second $[Re(CO)_3Cl]$ molecular fragment. This result confirms the previous NMR investigations of $[Re(CO)_3Cl]_2BL$ complexes and the resonance Raman study of $[Ru(dpp)(bpy)_2]^{2+}$ and $[(bpy)_2Ru]_2dpp^{4+}$ which inferred the dpp ligand in the bimetallic complexes requires a puckered or non-planar conformation to bind two metal centers [19, 24, 51]. The X-ray structures further reveal the most important structural consequences are borne by the central pyrazine ring as each metal center is added. It is reasonable to believe the structural distortion of the pyrazine ring is a major contributing factor that influences the electronic structure of $[Re(CO)_3Cl]_2dpp$ and results in the corresponding reduction in emission intensity and excited state lifetime relative to $[Re(dpp)(CO)_3Cl]$ [19, 20, 52]. Such structural distortions are most likely absent in bimetallic complexes with the planar ppz bridging ligand. As a result, room temperature emission has been observed in $[Re(CO)_3CH_3CN]_2ppz$ and has been attributed to a decrease in the nonradiative decay rates relative to the dpp bimetallic complex [24].

SUPPLEMENTARY MATERIAL AVAILABLE

Tables of the final values of all refined and calculated atomic coordinates with esd's and a complete listing of bond lengths, bond angles, anisotropic thermal parameters, and the structure factors are available as an X-ray crystallographic file in CIF format from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K. by quoting the complete journal citation.

Crystal structures of the Ba–Cu(I) alkoxides $Ba_4Cu_6(O)(OCEt_3)_{12}$ and $BaCu_6(OCEt_3)_8$

Andrew P. Purdy* and Clifford F. George

Chemistry Division (Code 6120) and Laboratory for the Structure of Matter (Code 6030), Naval Research Laboratory, Washington, DC 20375, U.S.A.

(Received 22 December 1997; accepted 3 May 1998)

Abstract—A single crystal of the Ba–Cu(I) oxo-alkoxide $Ba_4Cu_6(O)(OCEt_3)_{12}$ (**1**) was isolated from the reaction of $Ba_2Cu_4(OCEt_3)_8$ (**2**) with oxygen. Oxo-alkoxide **1** crystallizes in the cubic space group I23 with the four Ba atoms distributed tetrahedrally around the central oxide ion and six $Cu(OCEt_3)_2^-$ units bridging each Ba atom to the three others. The Ba–Cu(I) alkoxides $[BaCu(OCEt_3)_3]_n$ (**3**) and $BaCu_6(OCEt_3)_8$ (**4**) were also synthesized. Crystals were not obtained for **3**, but the easily crystallized **4** has two $Cu_3(OCEt_3)_4^-$ moieties coordinated to a central Ba atom, and disproportionates in solution to many products. © 1998 Elsevier Science Ltd. Keywords: heterometallic alkoxide; barium copper alkoxide; copper (I); oxide; oxo-alkoxide; disproportionation

INTRODUCTION

Heterometallic alkoxides are of interest as precursors to ceramic materials [1–3]. Although many such compounds have been characterized by X-ray crystallography, only a small number of structurally characterized bimetallic Cu(I) alkoxides are known. From the nine examples reported to date, some common structural features are apparent. In all such compounds, the Cu(I) atoms are 2-coordinate and nearly linear. Compounds can have $Cu(OR)_2^-$ ions, which typically bridge two metal atoms. Examples of this configuration include $Li_4Cu_4(OCMe_3)_8$ and $Na_4Cu_4(OCEt_3)_8$, [4] $L_2Ba_2Cu_4(OCRMe_2)_8$ ($L=Me_3PO$, Me_3NO; $R=CH_3$, CF_3) [5–7] and $(THF)_2Ba_2Cu_2(OCMe(CF_3)_2)_6$ [7]. Three examples of Cu_2O_3 moieties bridging two other metal atoms have also been reported, these include $Ba_2Cu_4(OCEt_3)_8$ [4], $Zr_2Cu_2(OCHMe_2)_{10}$ [8] and $Zr_4Cu_4(O)(OCHMe_2)_{18}$ [9]. In the former two compounds, a $Cu_2(OR)_3^-$ ion is the bridging unit and in the latter it is a $^-(RO)_2Cu_2OCu_2(OR)_2^-$ ion. In all except $L_2Ba_2Cu_4(OCRMe_2)_8$, the electropositive metal ($M=Li$, Na, Ba, Zr) is part of a $[M(OR)_n]_2$ ring structure. In this work we report the structures of two new Ba–Cu(I) alkoxides with $OCEt_3$ ligands that exhibit some new structural features. Thus we add to the knowledge base of how stoichiometery and identity of the R group affects the structure of mixed metal alkoxides.

EXPERIMENTAL

General comments

All manipulations were performed under a helium atmosphere in a Vacuum-Atmospheres Dri-Lab, in a Pyrex bulb equipped with a stirbar and a Kontes valve or on the vacuum line. Anhydrous ammonia (Air Products) was used as received. All non-deuterated solvents (Aldrich) were dried by distillation from sodium benzophenone ketyl before use and C_6D_6 was distilled from Na/K. The compounds $CuOCEt_3$ and $Ba(NH_2)_2$ were prepared as described previously [10–12]. NMR spectra were recorded on a Bruker AC-300 instrument. X-ray powder patterns were recorded on a Phillips diffractometer with a graphite crystal monochromator using Cu Kα radiation. Elemental analyses were performed by E+R Microanalytical Laboratories, Corona, NY.

Synthesis of $Ba(OCEt_3)_2$

A mixture of $Ba(NH_2)_2$ (1.63 g, 9.6 mmol), an excess of $HOCEt_3$ (3.1 g, 27 mmol) and pyridine (20 ml) was

* Author to whom correspondence should be addressed.

stirred in a H-tube for 16 h at 80°C. The mixture was filtered and the solids were dried *in vacuo* at 150°C to remove all solvent. A 71% yield of the white solid was isolated (2.52 g). Anal. found (calcd) for $C_{14}H_{30}O_2Ba$: C, 45.74 (45.73); H, 8.17 (8.22); Ba, 37.60 (37.35). ^{13}C NMR: (NMP) δ 9.54 (Me), 33.96 (CH_2), 74.06 (C).

*Isolation of $Ba_4Cu_6(O)(OCEt_3)_{12}$ (**1**) crystal*

In a previously reported experiment, a benzene solution of $Ba_2Cu_4(OCEt_3)_8$ (**2**) was filtered through dry talc and the solvent was stripped from the filtrate to afford **2** [4]. A C_6H_6/THF mixture was then washed through the filter and the second filtrate was oxidized by bubbling with oxygen for a minute, affording a brown, soluble material. The solvents were removed *in vacuo* and the brown solid was redissolved in heptane and allowed to stand in the dri-lab in a stoppered vial for 16 months. Slow evaporation of the solvent deposited a crystal of **1**.

*Attempts to synthesize **1***

(a) A mixture of $Ba(OCEt_3)_2$ (1.40 g, 3.8 mmol) and $CuOCEt_3$ (1.02 g, 5.7 mmol) was stirred in THF (10 ml) at 75°C for 4 h and at room temperature for a week. The mixture was filtered through dry talc and the solvent was removed *in vacuo*, affording 2.4 g of "$Ba_2Cu_3(OCEt_3)_7$". A 236 mg sample of the latter was mixed with 5 mL of toluene in a small H-tube and stirred overnight. The mixture was filtered, the solids were washed twice with re-condensed solvent and all solvents were removed *in vacuo*. A total of 60 mg of the white, toluene insoluble $[BaCu(OCEt_3)_3]_n$ (**3**) was isolated. NMR (D8-THF) ^1H, 0.88 (m, CH_3), 1.30 (br,s, CH_2), 1.42 (q), 1.49 (q); ^{13}C, (δ) 9.42, 9.53 (Me), 34.79, 34.49 (CH_2), 76.98, 76.11, 75.04 (C). Anal found (Calcd) for $C_{21}H_{45}O_3BaCu$: C, 46.19 (46.16); H, 8.51 (8.30); Cu, 11.37 (11.63); Ba, 25.11 (25.13).

(b) A solution of "$Ba_2Cu_3(OCEt_3)_7$" (0.65 g) in THF (8 ml) was prepared in a reaction bulb. A septum cap was put on the bulb and 4.8 μl of H_2O was added with stirring and stirred 3 days. Solvent was removed *in vacuo* and an NMR spectrum of the product in C_6D_6 showed mostly **2** in solution with several other components. All attempts to grow crystals were unsuccessful.

(c) Partially hydrolyzed $Ba(OCEt_3)_2$ was obtained from stirring Et_3COH (1.47 g, 12.6 mmol) and $Ba(NH_2)_2$ (1.07 g, 6.32 mmol) in pyridine (10 ml) for 3 h at 70°C, removal of all volatile materials under vacuum, addition of fresh pyridine, condensation of 1.60 mmol H_2O into the flask at −196°C and 12 h stirring at room temperature. This mixture was added to a four-fold excess of $CuOCEt_3$ (6.81 g, 38.1 mmol) in THF (30 ml), followed by 3 h stirring at 80°C. All solvents were removed *in vacuo*, followed by the addition of warm toluene and filtration. The solvent was stripped off the filtrate *in vacuo* and the resulting solids were recrystallized from heptane. The large, colorless crystals were washed 3 times with heptane and dried *in vacuo* affording $BaCu_6(OCEt_3)_8$ (**4**) [2.66 g (39%)]. Anal. found (calcd) for $C_{56}H_{120}BaCu_6O_8$: C, 46.78 (46.70); H, 8.33 (8.40); Ba, 9.06 (9.54); Cu, 26.14 (26.47). NMR (C_6D_6): ^1H, 0.997 (t), 1.09 (t), 1.49 (q), 1.66 (q); ^{13}C, 8.82, 9.43 (CH_3), 34.73, 34.89 (CH_2), 77.31, 77.34 (C); other peaks from disproportionation, see Fig. 1.

$Ba(OCEt_3)_2 + 3CuOCEt_3$

$Ba(OCEt_3)_2$ (0.30 g, 0.82 mmol) and $CuOCEt_3$ (0.44 g, 2.5 mmol) were stirred in 10 ml THF for 5 h at 70°C and the solvent was removed. The mixture was redissolved in toluene, filtered and the solvent was removed *in vacuo* affording a light tan solid, which was recrystallized by slow evaporation from heptane.

*$BaCu_6(OCEt_3)_8$ (**4**)*

$Ba(OCEt_3)_2$ (0.14 g, 0.38 mmol) and an excess of $CuOCEt_3$ (0.50 g, 2.8 mmol) was stirred in 5 ml THF at 80°C for 4 h, the mixture was filtered and the solvent was removed *in vacuo*. The mixture was redissolved in heptane and the solvent was allowed to evaporate slowly by placing the container into a vessel containing mineral oil. The crystals were washed with heptane and allowed to dry, affording 0.10 g of **4** (19%). Most of the yield was lost during the heptane wash step, and there is little doubt that the synthesis of **4** could be further optimized.

*Hydrolysis of **4***

A sample of **4** (1.0 g, 0.7 mmol) was dissolved in 5 ml THF in an H-tube and frozen at −196°C. Water (0.10 g, 5.5 mmol) was condensed into the H-tube, the mixture was allowed to warm to room temperature and stirred as soon as possible. An initial yellow color quickly turned to deep orange. The mixture was filtered in 30 min, the solids were washed with recondensed solvent and dried *in vacuo* for 16 h affording 369 mg of orange solid. A 136 mg sample of the latter was heated *in vacuo* at 250°C for 1.5 h resulting in 115 mg orange–brown solid.

*Crystal structures of **1** and **4***

Suitable crystals of **1** and **4** were mounted in thin walled glass capillaries under inert gas atmosphere. Data were collected in the $\Theta/2\Theta$ mode on an automated Siemens P4 diffractometer equipped with an incident beam graphite monochromator and the data were corrected for Lorentz and polarization effects. Corrections were made for a linear decay of 9.8% for **4**. In each case the structures were determined by

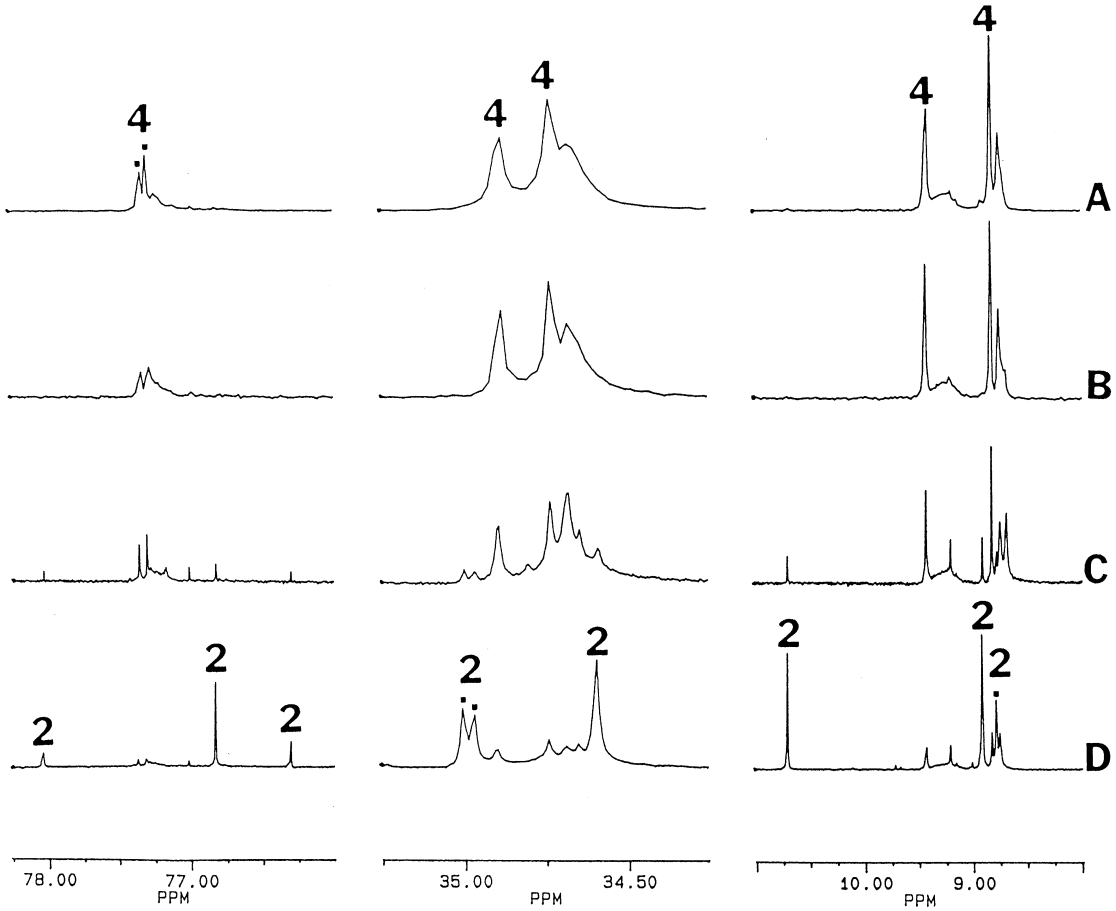

Fig. 1. ^{13}C NMR spectra of $BaCu_6(OCEt_3)_8$ (**4**), $A = 0.40$ M, $B = 0.12$ M, $C = 0.012$ M and D = a 3:1 mixture of $CuOCEt_3$ and $Ba(OCEt_3)_2$.

direct methods and refined using full matrix least-squares methods as implemented by the program SHELXL-PC [13]. For **1** the parameters refined included the coordinates and anisotropic thermal parameters for all but the hydrogen atoms. For **4** only the Ba, Cu and O atoms were refined anisotropically. The carbon atoms in **4** were refined with isotropic thermal parameters and the C–C bonds were constrained to 1.50(1) Å. Hydrogen atoms were placed in idealized positions (C–H = 0.96 Å) and the coordinate shifts for carbon were applied to the bonded hydrogens. The isotropic thermal parameters for the hydrogens were fixed. Additional data collection and refinement parameters are given in Table 1 and selected distances and angles in Table 2. Atom coordinates are available from the Cambridge Crystallographic Database, refcodes 101455 and 101456.

RESULTS AND DISCUSSION

Synthesis and reactivity

Only one crystal of the oxo-alkoxide $Ba_4Cu_6(O)(OCEt_3)_{12}$ (**1**) was isolated from the a mixture obtained from oxidation of impure $Ba_2Cu_4(OCEt_3)_8$ (**2**). The isolation of only one crystal prevented NMR, IR, or elemental analysis from being done on **1**. Some efforts were made to synthesize **1** deliberately, without success. The two binary alkoxides, $CuOCEt_3$ and $Ba(OCEt_3)_2$ were dissolved in a 3:2 ratio in THF. An NMR spectrum of the THF solution (in C_4D_8O) was relatively simple, but showed the presence of **2**. When this THF soluble product was washed with aromatic solvents, the **2** was removed and an insoluble (in PhMe) white solid was left behind. The latter was identified as $[BaCu(OCEt_3)_3]_n$ (**3**) by elemental analysis. However, attempts to obtain crystals of **3** from THF solution were unsuccessful. Since the simple combination of $CuOCEt_3$ and $Ba(OCEt_3)_2$ in a 3:2 ratio did not afford **1**, we thought that a hydrolysis step may be necessary to form the oxide ion in the center of the alkoxide. Addition of a stoichiometric amount of water to a THF solution of "$Ba_2Cu_3(OCEt_3)_7$" afforded a complex mixture from which no crystals were isolated, although one cannot exclude the possibility that **1** was present. In one attempt to prepare **1**, an inadvertent fourfold excess of $CuOCEt_3$ was added. A ternary alkoxide with a Cu:Ba ratio of

6:1 ($BaCu_6(OCEt_3)_8$, **4**) was isolated in good yield from the latter reaction and identified by its crystal structure. This Cu rich Ba–Cu alkoxide disproportionates in C_6D_6 to many products, of which only **2** and $CuOCEt_3$ were positively identified by their NMR spectra. The intensities of the lines are concentration dependent and most of the same products are present in a solution with a Cu:Ba ratio of 3:1. Since **4** should have 2 peaks in a 1:1 ratio for each of its 3 types of carbon atoms and **4** should be present in the greatest amounts in the most concentrated solutions, a tentative peak assignment for **4** can be made. Representative ^{13}C NMR spectra are displayed in Fig. 1 with assignments indicated. Apparently, any combination of $Ba(OCEt_3)_2$ and $CuOCEt_3$ with a Cu:Ba ratio of greater than 2:1 produces a complex equilibrium of products in aromatic solvents. A similar observation was made with $(THF)_2Ba_2Cu_2(OR)_6$ and $(Me_3NO)_2Ba_2Cu_4(OR)_8$ where reaction with additional $[Cu(OR)]_4$ produced mixtures of products [7].

Upon slow evaporation, the 3:1 $CuOCEt_3$:$Ba(OCEt_3)_2$ solution afforded crystals of **2**, whose identity was confirmed by NMR. The crystals were however, a new polymorph with a unit cell volume about half that reported previously [4][1]. The quality of the crystals were too poor to make a full structure solution worthwhile.

An experiment was performed to determine whether **4** would act as a precursor to any new, copper-rich inorganic phases. When **4** was hydrolyzed in THF solution an orange precipitate was formed. That precipitate was converted to a mixture of the known phases Cu_2O and $BaCu_2O_2$ on heating to 250°C as determined by the X-ray powder pattern [14, 15].

[1] Triclinic, $a=12.034(1)$, $b=12.359(1)$, $c=12.914(2)$, $\alpha=77.03(1)$, $\beta=75.59(1)$, $\gamma=78.525(9)$, $V=1791.8(6)$ Å^3.

Crystal structures

The oxo-alkoxide $Ba_4Cu_6(O)(OCEt_3)_{12}$ (**1**) crystallizes in the cubic crystal system with the O^{2-} ion at the origin (Figure 2). All four Ba and all six Cu atoms are, respectively, equivalent by symmetry. The Ba atoms are distributed around the oxide ion in a tetrahedral arrangement with a Ba–O2 distance of 3.167(2) Å, which is very long for a bond between a four-coordinate oxide ion and barium. For example, the complex $Ba_4(O)(O\text{-tamp})_6C{\cdot}3PhMe$ has a similar geometry around a μ_4-oxo atom with Ba–O distances of 2.65(2)–2.675(7) Å [16]. Even the μ-6 oxo atom in $H_4Ba_6(\mu_6\text{-O})(OCH_2CH_2OMe)_{14}$ has shorter Ba–O distances around 2.9 Å [17]. Essentially, O2 is only weakly bonded to the bariums with its interaction being primarily ionic in nature. Each of the Ba atoms is also connected by a nearly linear $Cu(OR)_2^-$ unit [O–Cu–O = 174.7(7)°] to every other Ba, making the barium atoms four-coordinate. Efforts to refine O2 as something heavier than oxygen were unsuccessful. The Cu atoms form the vertices of an octahedron centered on O2 and are 6.0 Å apart. Each Ba atom has an approximately tetrahedral coordination environment [O–Ba–O = 112.5(2) and 106.2(3)°]. Apparently, the Ba–O1–Cu cage prevents the four Ba atoms from making a closer approach to O2.

The heterometallic alkoxide $BaCu_6(OCEt_3)_8$ (**4**) has no molecular symmetry (Figure 3). Two $Cu_3(OCEt_3)_4^-$ units coordinate the barium. Each $Cu_3(OCEt_3)_4^-$ moiety is shaped approximately like a rectangle with a side removed and can be thought of as a $(Cu(OR))_4$ molecule [18] with one copper atom missing. These $Cu_3(OR)_4^-$ ions are almost planar, as the deviations of the O atoms from the Cu1–Cu2–Cu3 and Cu4–Cu5–Cu6 planes range from 0.05 to 0.2 Å. The Cu1–Cu2–Cu3 plane makes a dihedral angle of 20° to the Cu4–Cu5–Cu6 plane. The coordination environment around Ba is tetrahedral to a rough approximation with O–Ba–O angles ranging from 99.4(4) to 127.4(4)° and averaging 108.9°. Some interaction may be present between the Cu atoms in each $Cu_3(OCEt_3)_4^-$ unit, as their average separation is only 2.75 Å. Copper–copper separations range from 2.646(2) to 2.771(3) Å in $[CuOCMe_3]_4$ and are 2.652(2) Å in $Cu_2Zr_2(OCHMe_2)_{10}$.

The Ba–OR distances of both **1** and **4** [2.54(1) to 2.58(1)] are normal for four-coordinate Ba, which for example are 2.414(8) and 2.579(8) Å in $Ba[O\text{-}C_6H_3(CMe_3)_2Me]_2[HMPTA]_2$ [19] and range from 2.51(1) to 2.59(1) Å in **2**. However, the Ba–O distances in the $L_2Ba_2Cu_4(OCRMe_2)_8$ compounds, which have 5-coordinate Ba, are slightly longer, averaging 2.61 Å. The Ba–O–Cu angles in **1** and **4** fall in a fairly narrow range from 104.9(6) to 108.4(6), in which the Ba–O–Cu angles of $Ba_2Cu_4(OCEt_3)_8$ [105.4(4) and 106.4(5)°] also fall. In the *t*-butoxy complexes, $L_2Ba_2Cu_4(OCRMe_2)_8$, the Ba–O–Cu angles range from 103.5 to 110.9° [5–7]. One fluorinated complex, $(THF)_2Ba_2Cu_2(OMe(CF_3)_2)_6$, has smaller Ba–O–Cu angles of 96.9 to 101.7°, however this molecule may be distorted by the extensive Ba–F coordination [7]. A greater range is found for Cu–O–Cu angles (within a Cu_2O_3 or Cu_3O_4 moiety) which vary from 91.7(5)° in $[CuOCMe_3]_4$ to 110.4(3)° in **2** and range from 97.2(7) to 100.5(6) in **4**.

CONCLUSIONS

With seven Ba–Cu(I), two Zr–Cu(I) and two alkali–Cu(I) alkoxides structurally characterized, some gen-

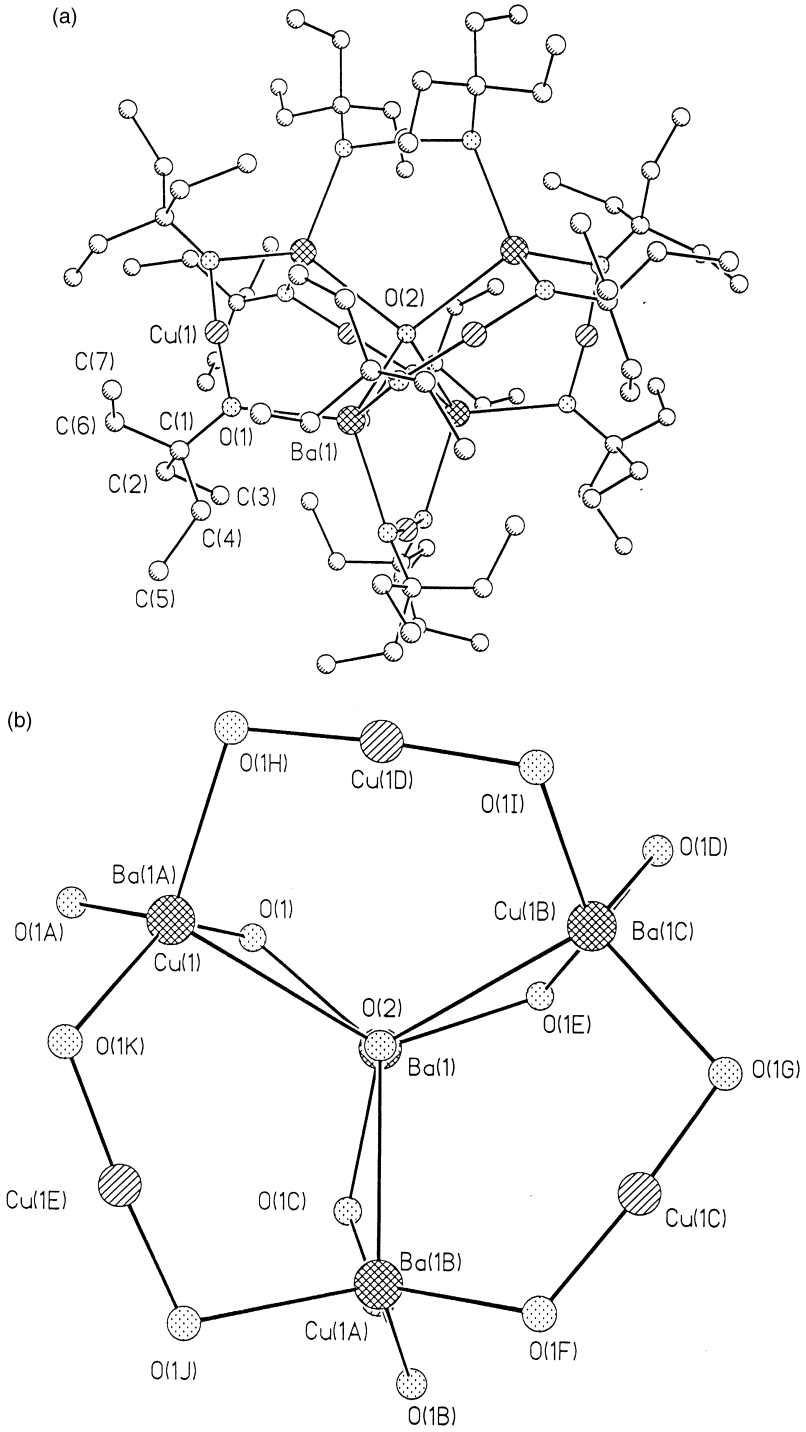

Fig. 2. (a) Structure of $Ba_4Cu_6(O)(OCEt_3)_{12}$ (**1**). (b) A view of the $Ba_4Cu_6O_{13}$ core down a threefold axis. Some Cu atoms are hidden by Ba atoms.

eralizations can be drawn. First, all three examples of Ba–Cu(I) alkoxides with $OCEt_3$ groups have 4-coordinate Ba, whereas the $OCRMe_2$ compounds have at least 5-coordinate Ba and therefore require an extra ligand to afford a soluble molecular compound. Most other Ba alkoxides with $OCMe_3$ groups have at least 6-coordinate Ba (see, for example, Refs. [20, 21]). Second, the Cu–O and Ba–O distances and the O–Cu–O, Cu–O–Cu and Ba–O–Cu angles vary over fairly narrow ranges, with the Cu–O–Cu angle being the most flexible. This means that each $Cu_n(OR)_{n+1}$ moiety has a relatively well defined range of bite sizes

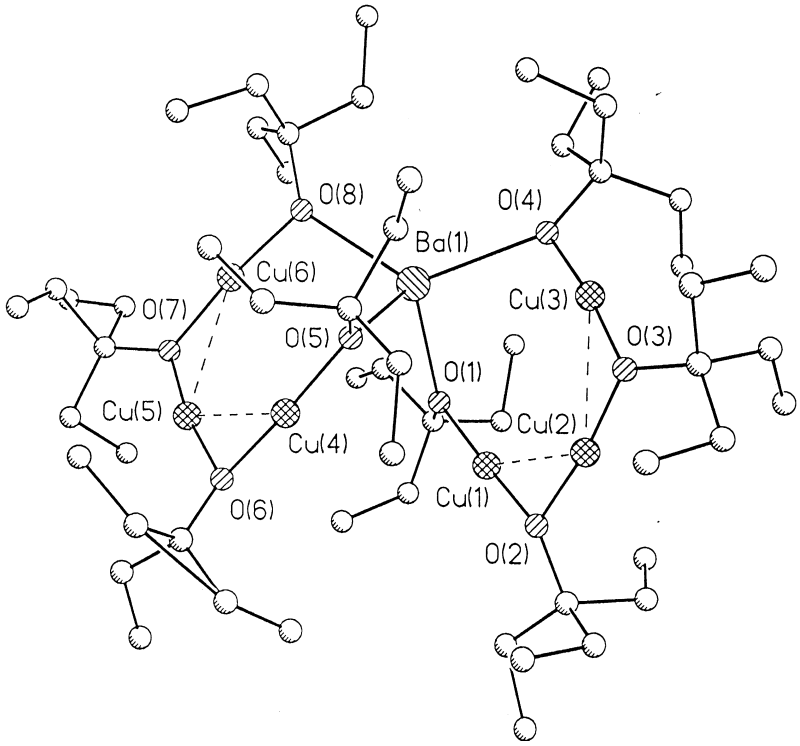

Fig. 3. Structure of $BaCu_6(OCEt_3)_8$ (**4**). Labeling of carbon atoms was omitted for clarity.

and its geometric limits can be readily estimated by calculation, or by using scale molecular models. Thus, a bidentate $Cu(OR)_2^-$ unit can coordinate two Ba atoms separated by 4 to 5.5 Å (Ba···Ba = 5.2 Å in **1**), while $Cu_2(OR)_3^-$ can accommodate Ba–Ba separations from 2.5 to 9 Å and $Cu_3(OR)_4^-$ can coordinate a single Ba atom as it does in **4** or 2 Ba atoms separated by up to 8 Å. Clearly, $Cu(OR)_2^-$ is the most geometrically constrained and $Cu_3(OR)_4^-$ is the most flexible. As observed previously, Ba–Cu(I) alkoxides are highly flexible systems and can have a wide variety of molecular species in solution, especially when copper-rich. The ability to isolate particular solid compounds is probably more related to how lattice energies and packing forces correlate to complex solution equilibria rather than any general preference for a particular stoichiometry.

(Received 7 January 1998; accepted 18 May 1998)

Abstract—The chelating properties of *N*-(*o*-nitrophenyl)-*N*′-(methoxycarbonyl)thiourea (H_2omt) were investigated through the study of the crystal structures of Cd(Homt)$_2$(bpy), **1**, Zn(Homt)$_2$(phen), **2** and H_2omt (bpy = 2,2′-bipyridine, phen = *o*-phenanthroline). The cadmium(II) ion in **1** is in a distorted octahedral geometry contributed by the two N atoms from bipyridine and the two S and the two deprotonated amine N atoms from two Homt groups [Cd–N(bpy) = 2.329(3), Cd–N(amine) = 2.360(3) and Cd–S = 2.690(1) Å]. The Zn(II) ion in complex **2** is four-coordinated by the two N atoms from the *o*-phenanthroline and the two deprotonated amine N atoms from two Homt groups in a distorted tetrahedral fashion, in which the binding of S atom to the metal is not involved [Zn–N(phen) = 2.088(4), Zn–N(amine) = 1.998(3) Å]. © 1998 Elsevier Science Ltd. Keywords: syntheses; crystal structures; cadmium(II) complex; zinc(II) complex; *N*′-(*o*-nitrophenyl)-*N*′-(methoxycarbonyl)thiourea; bipyridine; *o*-phenanthroline.

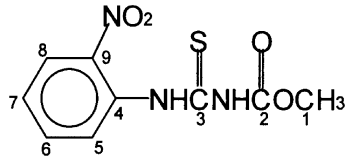
INTRODUCTION

Recently, the derivative *N*-(*o*-nitrophenyl)-*N*′-(ethoxycarbonyl)thiourea (H_2oet) was isolated from the leaves of resistant *Pyricuiria oryzae cav*. rice variety [1] and the preliminary pharmacological tests showed its high antibacterial activity. In our previous work [2], several ligands similar to the basic structure of H_2oet were prepared and their Cu(I) complexes were prepared and crystallographically characterized. It is interesting to find that copper(I) complexes can be obtained from the copper(II) salts by *in situ* reduction in the presence of these thiourea derivatives. In fact, the biological activities of complexes with thiourea derivatives have been well documented and thiourea derivatives have been successfully screened for various biological actions [3–6] and some *N*-substituted-*N*′-alkoxycarbonyl thioureas have been used in commercial fungicides. To date, plenty of transition metal complexes with such thiourea derivatives have been reported and the structures with O,S-binding to the metal ions were well proposed in alkaline media based on a series of physicochemical properties [7–9]. Now, it has been a common knowledge that complexation with metal ions may enhance the biological activity of a wide variety of organic compounds. For example, the copper(II) complex of 2-ace-

* Author to whom correspondence should be addressed.

tyloxybenzoic acid (aspirin), a ligand used as an analgesic since the last century, was reported to be significantly more active as an anti-inflammatory agent than the free ligand (Refs [10,11]. and references cited therein). Complexes of metal ions containing a bidentate organic compound such as 2,2′-bipyridine (bpy) and phenanthrolinine (phen) have been well reported [12,13] and they serve as interesting models for the understanding enzyme–metal ion–substrate relationship, thus playing an important role in metalloenzyme-catalyzed biochemical reactions [14,15]. In our previous work, the chloroform solvated Cd(II) complex with the ligand *N*-(*o*-nitrophenyl)-*N*′-(methoxycarbonyl)thiourea (H_2omt) and *o*-phenanthroline was reported [16] and Zn(II) and other transition metal complexes [e.g. Cu(II), Co(II)] with H_2omt and bipyridine (bpy) were synthesized [17]. To make such work more complete, in this paper we report the crystal structures of Zn(II) and Cd(II) complexes with H_2omt and bpy for Cd(II) and phen for Zn(II).



N-(*o*-nitrophenyl)-N'-(methoxycarbonyl)thiourea (H_2omt) (**m. f.** $C_9H_9O_4N_3S$)
(carbon atoms labelling is for ^{13}C NMR assignments)

EXPERIMENTAL

Chemicals

All reactants were reagent grade and used without further purification.

Physical measurements

C, H and N analyses were carried out on a Carlo Erba 1106 elemental analyzer. IR spectra were recorded on a Magna 750 spectrometer, UV spectral data were collected by a Shimadzu UV-300 spectrometer. NMR (^1H and ^{13}C) spectra were determined with a Bruker AM 500 instrument in DMSO-d_6 solution. Cyclic voltammetry was performed with a HDV-7B Potentiostat and LZ3Q-204 *X*–*Y* recorder with an electrochemical cell containing a Pt wire working electrode, a Pt plate auxiliary electrode and an SCE reference electrode.

X-ray crystallography

Pertinent crystal data, basic information about the data collection and structure refinement of the crystals of **1**, **2** and H_2omt are given in Table 1.

The structures were all solved by direct methods. Refinements were carried out by full-matrix least squares using anisotropic thermal parameters for all the non-hydrogen atoms. The hydrogen atoms were included as fixed contributions in structure factor calculations but not refined. All calculations were performed on a Compaq computer using the TEXSAN program package.

Biological activity

The antibacterial and antifungal activities of the ligand H_2omt and the metal complexes against the standard strains of *B. subtilis* 6633, *S. lutea*, *S. aureus* 209p, *P. diploccus*, *E. coli* and *P. aeruginosa* x313 and *S. Yake Sake* were determined using the plate method [18]. Each of the compounds was prepared at a concentration of 0.55 mM during the tests and the results are listed in Table 6.

Preparations

N-(o-Nitrophenyl)-N′-(methoxycarbonyl)-thiourea (*H_2omt*). The preparation of the ligand H_2omt was according to our previous method [7–9].

General preparation method for Cd(Homt)$_2$(bpy), **1**, *and Zn(Homt)$_2$(phen)*, **2**. A solution of $M(ClO_4)_2 \cdot 6H_2O$ (M = Cd and Zn) (3 mmol) in 20 cm^3 of methanol was added slowly to a methanolic solution of 2,2′-bipyridine or *o*-phenanthroline (3 mmol in 15 cm^3). This was warmed by stirring at 40–45°C for 30 min to give a clear solution which was cooled to room temperature and to it was added the clear methanolic solution (20 cm^3) containing H_2omt (6 mmol) and NaOH (6 mmol). A large amount of yellowish solids were precipitated, this resulting mixture was stirred at room temperature for a further 3 h and the solids were collected by filtration, washed thoroughly with water

and methanol and dried *in vacuo*. Complex **1**, m.p. 243°C (decomp.). Yield, 89%. Found: C, 43.6; H, 4.1; N, 14.6. Calc. for $C_{28}H_{24}N_8O_8CdS_2$: C, 43.2; H, 3.1; N, 14.4%. Complex **2**, m.p. 227°C (decomp). Yield, 91%. Found: C, 47.8; H, 10; N, 14.6. Calc. for $C_{30}H_{22}N_8O_8S_2Zn$: C, 47.9; H, 2.9; N, 14.9%.

Single crystals suitable for X-ray analyses were obtained by slow diffusion of diethyl ether into the solution of **1** or **2** in chloroform over several weeks.

RESULTS AND DISCUSSION

Crystal structures

The structure of complex $Cd(Homt)_2(bpy)$, **1**, is depicted in Fig. 1, which shows that the Cd(II) ion is six-coordinated by two N atoms from bipyridine and two S and two N atoms from two Homt groups. Selected atomic distances and bond angles are listed in Table 2.

The bond lengths Cd–S(1) of 2.690(1) Å and Cd–N(1) of 2.360(3) Å are well within the range of the published results dealing with Cd–S (thiocarbonyl) [19] and Cd–N(amine) [20] and are also comparable to Cd–S (thiocarbonyl) [2.687(2) Å] and Cd–N(amine) [2.326(4), 2.330(4) Å] in our previous work [16]. The structural data within the 2,2′-bypyridine molecule are normal and Cd–N(4) of 2.329(3) Å is comparable to the reported values of Cd–N(bipy) elsewhere [21, 22]. The geometry of the six-coordinated cadmium(II) atom is distorted with the bond angles N(1)–Cd–S(1) = 61.59(7)°, N(1)–Cd–N(4) = 99.2(1)° and N(1)–Cd–N(4a) = 100.2(1)°. The molecule contains two four-membered (from Homt) and one five-membered chelate rings (from phen) and the metal ion deviates by 0.0313(2) Å from the plane N(1)C(2)S(1)Cd. The dihedral angle between the least squares planes N(1)C(2)S(1)Cd and N(4)C(14)C(14a)N(4a)Cd is 100.38(7)°.

The structure of complex $Zn(Homt)_2(phen)$, **2**, is shown in Fig. 2, and selected bond distances and angles are also listed in Table 2. The Zn(II) atom is four-coordinated by the two N atoms from the *o*-phenanthroline molecule and the two deprotonated amine N atoms from two Homt groups in a distorted tetrahedral geometry with N(4)–Zn–N(1) = 115.8°, N(4)–Zn–N(4a) = 79.8(3)° and N(1)–Zn–N(1a) = 128.9(2)°. The Homt ligand is monodentately coordinated to Zn(II) atom with the deprotonated amine nitrogen atom where the S atom does not bind to the metal ion, which is different from that in complex **1**. As Zn(II) ion is a harder acid relative to Cd(II) and

thus less thiophilic, the Homt ligand tends to ligate only through the N atoms with Zn–N(1) 1.998(3) Å like a normal Zn–N(amine) bond [23]. The structural data within the phenanthroline molecule are without much change and the bond Zn–N(4) of 2.088(4) Å is well within the values Zn–N(phen) [24].

The structure of the ligand H_2omt is shown in Fig. 3. The coordination behavior of the Homt group is

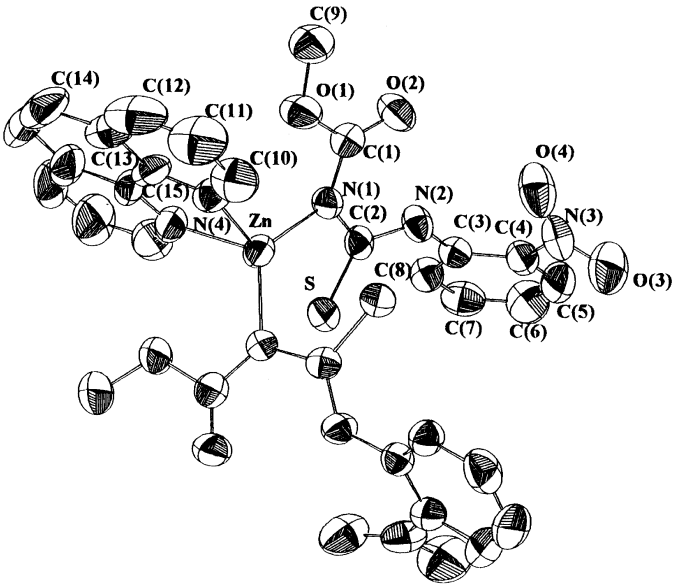

Fig. 2. ORTEP drawing of complex **2** with ellipsoids at 35% probability.

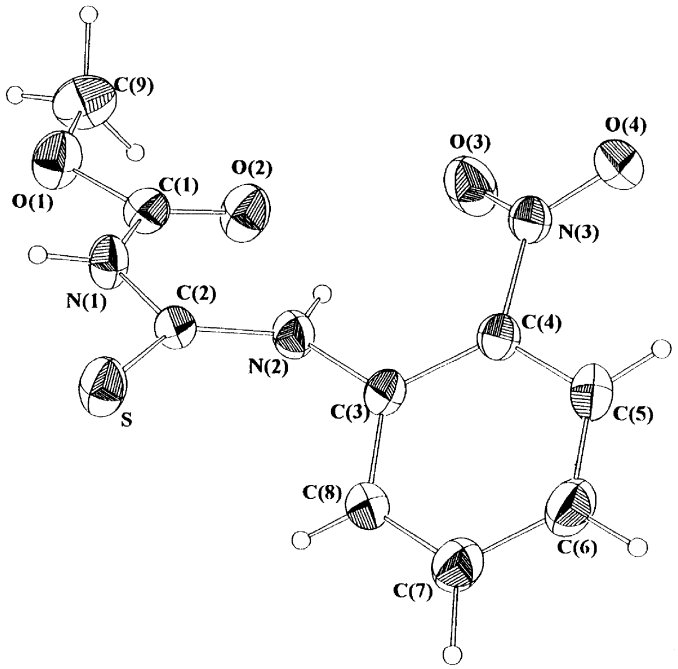

Fig. 3. ORTEP drawing of H_2omt with ellipsoids at 50% probability.

different in each of the complexes, with either mono- or bidentate coordination. In the free ligand H_2omt, the thiourea moiety SO(1)O(2)N(1)N(2)C(1)C(2)C(9) is almost planar and N(3) is in the plane of the phenyl group, these two planes form a dihedral angle of 44.37°. In complex **1**, N(2) is also in the plane of the phenyl group, and the dihedral angle between this plane and the least squares plane SO(1)O(2)N(1)N(2)C(1)C(2) is 70.51°. With respect to complex **2**, the dihedral angle between the plane of N(2) and the phenyl group and the plane O(1)O(2)N(1)C(1)C(2)C(9) is 54.55°. Comparative bond distances and angles involving Homt group for the free ligand H_2omt and complexes **1** and **2** are listed

in Table 3. As shown in Table 3, there is general agreement of the values. The shorter bond N(1)–C(2) for complex **1** can be caused by the formation of S–Cd bond. For the same reason, complex **1** has the longest C(2)–S bond. The different conformation of the compounds arising from the binding of the metal ions to H_2omt gives rise to the following bond angles sequences: (i) O(1)–C(1)–O(2): (H_2omt) > (**1**) ≈ (**2**); (ii) O(2)–C(1)–N(1): (H_2omt) < (**1**) ≈ (**2**); (iii) C(1)–N(1)–C(2): (H_2omt) > (**1**) > (**2**); (iv) N(1)–C(2)–N(2): (H_2omt) < (**2**) < (**1**); (v) S–C(2)–N(2): (H_2omt) > (**2**) > (**1**); (vi) C(2)–N(2)–C(3): (**2**) > (H_2omt) > (**1**).

Spectroscopic properties of the compounds

IR and UV spectra For the compounds of H_2omt, **1** and **2**, the bands at *ca.* 3140 cm^{-1} are usually attributed to the stretching frequency ν(NH), while for complex **3**, the band above 3100 cm^{-1} was not observed, indicating the absence of NH group. The intense band arising from the amide-I stretching vibration at 1732 cm^{-1} for H_2omt is red-shifted when ligation occurs in the Cd(II) (1648 cm^{-1}) and Zn(II) (1661 cm^{-1}) complexes. The C=S band at 867 cm^{-1} for the free ligand H_2omt has shifted to 855 cm^{-1} in complex **1**, indicative of the binding via the thiolato sulfur atom to Cd(II) ion, which is also indicated by the presence of a band of 310 cm^{-1}, assignable to ν(Cd–S) [25]. Therefore, the nearly unchanged ν(C=S) band at 868 cm^{-1} in complex **2** implicates the non-coordination of thiolate sulfur, in agreement with the X-ray crystallographic results. In addition, the coordination of nitrogen atom to Cd(II) or Zn(II) ion in complex **1** or **2** is observed by the presence of bands at *ca.* 320 ~ 335 cm^{-1}, assignable to ν(Cd–N) or ν(Zn–N) [26].

The UV spectra of the ligand H_2omt and complexes **1** and **2** are shown in Fig. 4. For all three compounds, the bands at about 278 nm are ascribed to ^{1}L(b) absorption of the aromatic ring. The signals around

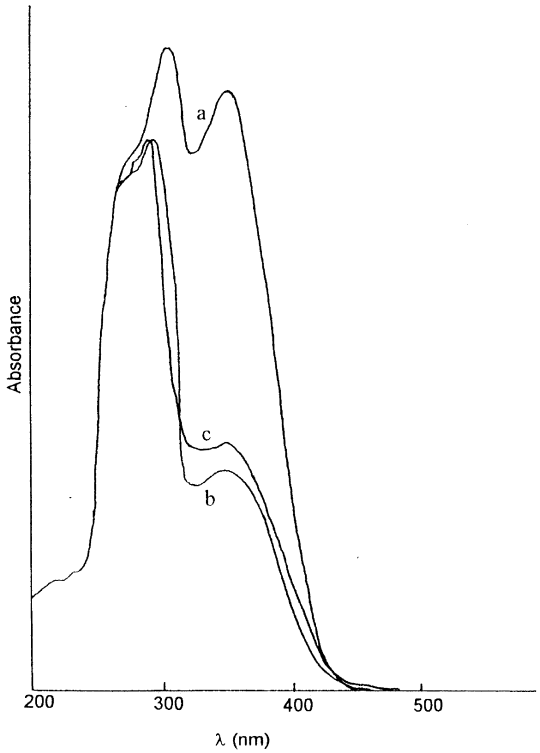

Fig. 4. UV spectra of the compounds in chloroform (a, H_2omt; b, **1**; c, **2**).

Table 4. ^{1}H NMR spectra of compounds H_2omt, **1** and **2** (in ppm)

Compound	Assignment[a]			
	Ar–NHC(S)	HNC(O)	OCH_3	aromatic ring
H_2omt	12.52 (s, 1H)	8.3 (s, 1H)	3.9 (s, 3H)	7.39 ~ 8.47 (m, 4H)
1	12.81 (s, 1H)	–	3.5 (s, 3H)	7.27 ~ 9.06 (m, 12H)
2	12.95 (s, 1H)	–	3.3 (s, 3H)	7.24 ~ 9.58 (m, 12H)

[a] s = single, m = multiple.

300 nm are attributed to the absorption of the NO_2 group. As for the $n\rightarrow\pi^*$ absorptions of C=O, they are near 345 nm. All the absorptions shown a bathochromical shift for the complexes relative to those of the free ligand are caused by the coordination of metal ions to the ligand. The $n\rightarrow\pi^*$ excitation of C=S is not observed in any of the compounds, in agreement with that reported by Barret *et al*. [27].

^{1}H and ^{13}C NMR spectra The ^{1}H and ^{13}C NMR spectra of the ligand H_2omt and complexes **1** and **2** are listed in Tables 4 and 5, respectively.

As shown in Table 4, most of their proton signals are observed to shift to down fields in complexes **1** and **2** relative to those of the free ligand due to the binding of the metal ions. The absence of δ(NH) [s, 1H, HN–C(O)] in the complexes shows the coordination of deprotonated amine to Cd(II) or Zn(II) ion.

In comparison with the ^{13}C NMR spectrum of the ligand H_2omt (Table 5), C_2 has shifted to a lower field at δ 186.34 for **1** and 186.98 for **2**; C_3 to δ 159.31 (**1**) and 159.14 (**2**). However, C_1 is found to have shifted to a higher field at δ 51.85 for **1** and 51.68 for **2**.

Electrochemical studies

The cyclic voltammograms of the compounds H_2omt, **1** and **2** are shown in DMF and CH_3CN solutions at a scan rate of 0.1 V s^{-1} in the scan ranges 0 to +1.8 and −1.8 to 0 V are shown in Figs 5 and 6, respectively. As can be seen from Fig. 5, it is found that each of three compounds exhibit two irreversible cathodic peaks with −0.43 and −1.53 V for H_2omt, −0.30 and −1.40 V for **1** as well as −0.53 and −1.57 V for **2**, and one reversible redox couples at −1.13 and −1.08 V for H_2omt, −0.93 and −0.90 V for **1** and −1.13 and −1.05 V for **2**. Thus, it is tentatively suggested that all these peaks are ascribed to the reduction and oxidation process of the Homt group. In terms of the cyclic voltammograms of the compounds in CH_3CN solution as shown in Fig. 6, each of the compounds display an anodic peak (H_2omt, 1.28 V; **1**, +1.39 V; **2**, +1.39 V) one cathodic peak (H_2omt, −0.83 V; **1**, −0.55 V; **2**, −0.5 V) and one reversible redox couple (H_2omt, −1.15 and −1.13 V; **1**, −0.90 and −0.85 V; **2**, −0.92 and −0.87 V). In addition, it is interesting to find that there is a cathodic peak appearing at −1.50 V for H_2omt, while such a peak is absent for either of the two complexes, suggesting that the cyclic voltammogramms of the compounds are affected by the solvent.

Biological activities

The antibacterial and antifungal activities of the compounds are listed in Table 6, showing that the free

Table 5. ^{13}C NMR spectra of the compounds H_2omt, **1** and **2** (in ppm)

Compound	Assignment[a]								
	C_1[b]	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9

[a] The signals of 2,2′-bipyridinyl ring for **1** appear at δ 150.71, 149.96, 139.37, 121.15 and 120.74, while the ones of *o*-phenanthrolinyl ring for **2** are observed at δ 149.76, 140.98, 138.27, 132.16, 125.07 and 124.60.

[b] The positions of the carbon atoms are denoted in the structure of the free ligand H_2omt.

Table 6. Antibacterial and antifungal activity of the compounds H_2omt, **1** and **2**[a]

Bacterium or fungus	H_2omt	**1**	**2**
B. subtilis 6633	0	5.3	3.8
S. lutea	0	7.5	7.4
S. aureus 209p	0	9.5	11.1
P. diploccus	0	9.2	6.5
E. coli	5.0	7.1	7.7
P. aeruginosa x313	0	9.3	9.3
S. Yake Sake	3.2	6.0	6.9

[a](1) The concentration of each tested compound was given in 0.55 mM. (2) The inhibition zone was given in mm.

ligand H_2omt was inactive against *B. subtilis* 6633, *S. lutea*, *S. aureus* 209p, *P. diploccus* and *P. aeruginosa* x313, but slightly active against *E. coli* and *S. Yake Sake*. Both the metal complexes exhibited inhibition activities against the tested bacteria and fungus, indicating that the enhancement of the biological activities of the complexes is related to the coordination of the metal ion and the bpy or phen molecule.

(Received 30 July 1997; accepted 18 May 1998)

Abstract—The geometrical and conformational isomerism of some β-[alkyl-bridged biferrocenyl]-α,β-unsaturated ketones was discussed on the basis of their IR and ^{1}HNMR spectra. They exist in *s-cis* conformation. The electrochemistry of the title compounds was also studied using cyclic voltammetry. Two distinct consecutive pairs of one-electron reversible redox peaks centered on the two non-equivalent ferrocenyl fragments were observed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: β-[alkyl-bridged biferrocenyl]-α,β-unsaturated ketones; conformational study; electrochemistry.

INTRODUCTION

Binuclear ferrocene derivatives have aroused many researches in recent years as redox active entities with potential application in fields such as materials for molecular electronics and as biologically active compounds [1–3]. Zanello's group has done some work on alkyl-bridged biferrocene compounds [4, 5]. As a continuation of our previous studies on alkyl-bridged biferrocene [6], we now report here the condensation reactions of alkyl-bridged biferrocenyl formaldehyde with aryl ketones, which afford several β-[alkyl-bridged biferrocenyl]-α,β-unsaturated ketones (Scheme 1). Their conformational and electrochemical properties are discussed as well.

EXPERIMENTAL

2,2-Diferrocenyl propane, 2,2-diferrocenyl butane and the corresponding formaldehyde derivatives were prepared as before [6]. Other chemicals were of analytical grade. The instruments used were the same as those described in the literature [6]. Cyclic voltammetric experiments were performed on a BAS-100B electrochemical analyzer equipped with a three electrode assembly with 0.1 mol/l -*n*-Bu_4NPF_6 as support electrolyte and CH_2Cl_2 as solvent. The working electrode was a platinum disk of 1.5 mm in diameter embedded in a cobalt glass seal and was polished consecutively with polishing alumina and diamond suspensions between runs. The reference electrode was a KCl saturated calomel electrode. A platinum filament was used as an auxiliary electrode. The solutions were saturated and blanketed with N_2 before the first scan. Measurements were made at room temperature.

Synthesis of β-[alkyl-bridged biferrocenyl]-α,β-unsaturated ketones

Taking compound **1** as an example: A solution of 2,2-propinyl-bridged biferrocene formaldehyde (4.84 g, 1.1 mmol) and *p*-aminopheylmethylketone (2.97 g, 2.2 mmol) in 95% EtOH (35 cm^3) was stirred at room temperature for 8–12 h in the presence of KOH (0.168 g, 3 mmol). The reaction mixture was then extracted by CH_2Cl_2, washed to neutral by water

1. R^1=CH_3, R_2=*p*-$NH_2C_6H_4$; 2. R^1=CH_3, R_2=C_6H_5; 3. R^1=C_2H_5, R_2=*p*-$NH_2C_6H_4$
4. R^1=C_2H_5, R_2=C_6H_5 ; 5. R^1=C_2H_5, R_2=Fc.

Scheme 1. The preparation of the title compounds.

and dried with anhydrous Na_2SO_4. After removal of the solvent under reduced pressure, the dark red residue was dissolved in a minimum amount of benzene and chromatographed on alumina using C_6H_6 and C_6H_6–Et_2O (2:3) as eluents successively. The resulting product was recrystallized by EtOH–H_2O. **2**–**5** are synthesised analogously. Yield >90%.

RESULTS AND DISCUSSION

All the *β*-[alkyl-bridged biferrocenyl]-*α*,*β*-unsaturated ketones are red solids stable in the air. Their analytical and melting points are listed in Table 1. Their IR, ^{1}H NMR and UV spectra data are listed in Tables 2–4, respectively.

IR spectra

The KBr disk IR spectra of the *β*-[alkyl-bridged biferrocenyl]-*α*,*β*-unsaturated ketones show two strong bands at about 1650 and 1590 cm^{-1}, due to the carbonyl and ethylenic stretching vibration respectively. The two peaks in the region 1000–1077 cm^{-1} were allocated as $\delta_{CH=CH}$ of olefin with a *trans* configuration [7]. While in CCl_4 solution, $\nu_{C=O}$ and $\nu_{C=C}$ bands split, indicating the existence of an equilibrium between *s-cis* and *s-trans* conformation. Their IR spectral data in CCl_4 solution were listed in Table 2.

In compounds **1**–**5**, a conformational equilibrium may occur by the rotation around both C(1′)–C(*β*) and C(*α*)–C(CO) bonds. There are two favored coplanar forms, *s-cis* (**1**) and *s-trans* (**2**), as illustrated in Scheme 2. IR spectra is often used to study the equilibrium between *s-cis* and *s-trans* [8, 9]. Investigation of many substituted monoferrocene analogues have been reported [10, 11].

The *s-cis* form is preferred because there may be strong steric repulsion between H(*β*) and the *ortho*-hydrogens on the phenyl group in *s-trans* conformation. There are sharp carbonyl bands and intensified $\nu_{C=CH}$ bands in the IR spectra of their CCl_4 solutions. On the basis of the empirical rules suggested by Shorter and Hayes *et al.* [8, 9], the existence of the equilibrium and the predominance of the *s-cis* conformation in solution could be inferred. This conclusion is also supported by their ^{1}H NMR spectra.

^{1}H NMR *spectra*

^{1}H NMR spectra of the new compounds are recorded at room temperature. As the cyclopentadienyl protons are in almost the same chemical environment, their signals overlap and form an multiplet. In the ^{1}H NMR spectra of the title compounds, the olefinic protons give a doublet, corresponding to an AB type absorption. The coupling constant is 15 Hz, indicating they exist in *trans*-configuration, in which the biferrocenyl and the carbonyl groups take the opposite

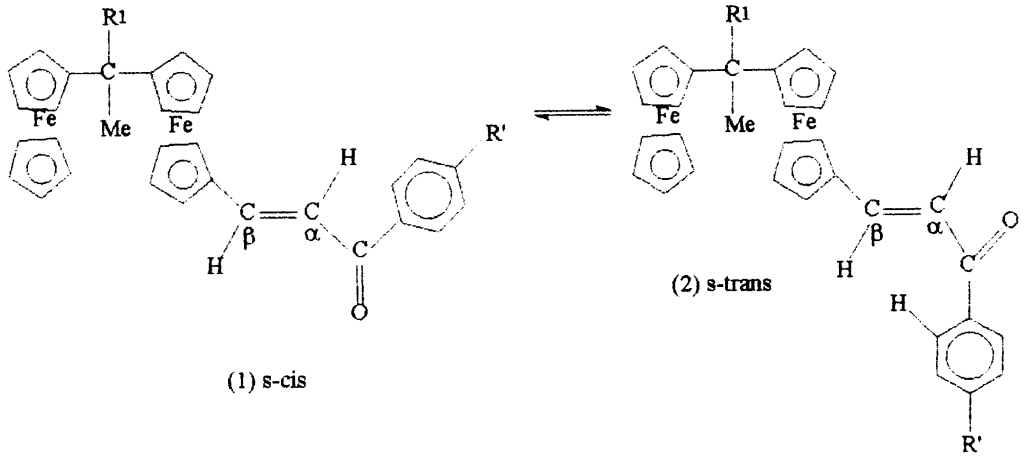
$FcC(Me)_2FcCHO$	204 (130100)		275 (62710)	437–467 (7570–6550)
FcC(Me)(Et)CHO	204 (128900)		282 (59670)	437–472 (7260–6680)

position of the double bond. This is in accordance with their monoferrocenyl analogues reported in the literature [10]. Both H(α) and H(β) signals are shifted upfield. If the *s-trans* rotamer is favored, H(α) is in the shielding area of the carbonyl group and H(β) is closer to the aryl ring, whose anisotropy would increase the shielding about H(β). Their δ values could not be so high. Consequently, the *s-cis* conformation is the favored conformation.

UV spectra

The UV spectra of the title compounds were recorded in 95% EtOH and are summarized in Table 4,



Scheme 2. Conformational equilibrium of the title compounds.

together with some related literature reported ferrocene derivatives. The strongest absorption bands at 322–369 nm can be assigned to the π–π^* transition of the α,β-unsaturated ketone conjugated with the ferrocene nucleus. The d–d transition, appears at a longer wavelength in the region 482–541 nm as a broad peak. The two ferrocenyl groups are indistinguishable by UV spectra. The large bathochromic shifts are ascribed to the extensive conjugation of α,β-unsaturated ketone with the ferrocenyl moiety and the interaction of the nonbonding d-orbital of iron with the substituents on the ferrocenyl group. In addition, such large bathochromic shifts may also involve the bridging alkyl group, which play some role in electronic interactions. This could be inferred from their electrochemical behavior also.

Electrochemical studies

The cyclic voltammetric behaviours of the compounds were studied using CH_2Cl_2 as solvent and 0.1 mol l^{-1} TBAFB(Bu_4NBF_4) as supporting electrolyte. The measurements were carried out at 13°C. The scan rate was 100 mV s^{-1}. The $\overline{E_{p1}}$ [$\overline{E_{p1}} = 1/2(E_{pa1} + E_{pc1})$], $\overline{E_{p2}}$ [$\overline{E_{p2}} = 1/2(E_{pa2} + E_{pc2})$] and their differences $\Delta\overline{E_p} = \overline{E_{p2}} - \overline{E_{p1}}$, together with the K_{con} and Robin–Day classification [12, 13, 14] are given in Table 5. For comparison, ferrocene, 2,2-diferrocenylpropane (DFP), 2,2-diferrocenyl butane (DFB), diferrocenylketone (DFK) [4] and bisferrocene (BF) [4] were also included in the measurements and the results are listed in Table 5. The CV curves of **1** and **5** are illustrated in Figs 1 and 2.

The following could be inferred from Table 5.

1. There are two pairs of redox peaks in the cyclic voltammograms of all the compounds studied.
2. The $\overline{E_{p1}}$ values of the first redox peak are all lower than that of ferrocene. This is attributed to the monosubstituted ferrocenyl group. The bridging alkyl and the other ferrocenyl group exert mainly an electron-donating effect, which makes it easier to be oxidized.

Table 5. Electrochemical characteristics for the oxidation process of the title compounds and related molecules with the Robin–Day classification of the relevant mix-valent species

Compounds	$\overline{E_{p1}}$ (V)	$E_{pc1} - E_{pa1}$ (mV)	$\overline{E_{p2}}$ (V)	$E_{pc2} - E_{pa2}$ (mV)	$\Delta\overline{E_p}$ (V)	K_{con} ($\times 10^4$)	Robin–Day class
1	0.355	89	0.548	75	0.193	0.18	II
2	0.359	103	0.553	71	0.194	0.19	II
3	0.386	72	0.671	78	0.285	6.6	II–III
4	0.389	80	0.676	73	0.281	7.0	II–III
5	0.376	63	0.628	75	0.262	2.7	II–III
DFP	0.355	81	0.551	76	0.196	0.20	II
DFB	0.328	74	0.551	73	0.223	0.59	II
DFK[a]	0.55		0.74		0.19	0.10	II
BF[a]	0.44		0.79		0.35	80	III
Ferrocene	0.44	99					

[a] From Ref.[4].

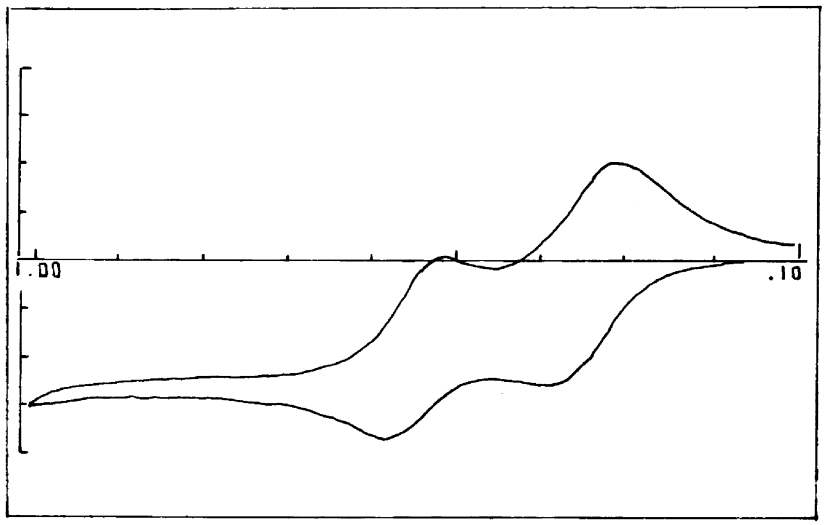


Fig. 1. Cyclic voltammogram obtained in CH_2Cl_2 (0.1 mol/l Bu_4NBF_4) at room temperature at a potential sweep rate of 100 mV s^{-1} for **1**. The initial potential was set at 0.100 V and the switching potential was 1.000 V.

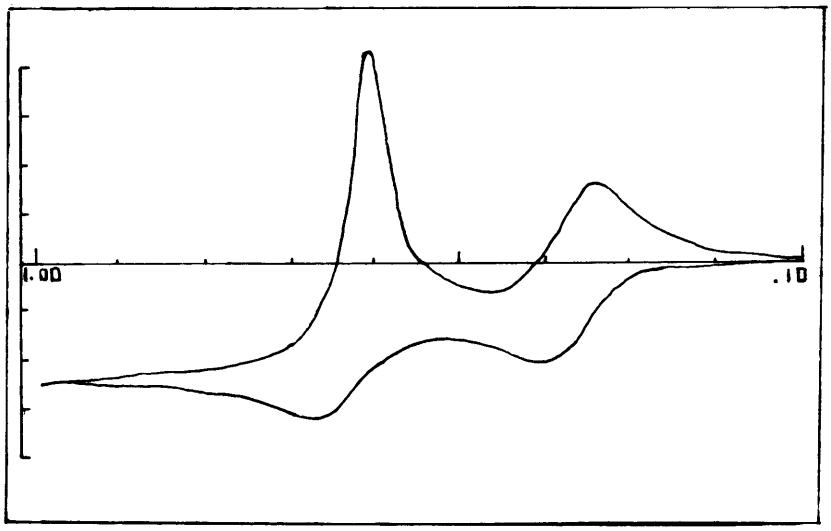

Fig. 2. Cyclic voltammogram obtained in CH_2Cl_2 (0.1 mol/l Bu_4NBF_4) at room temperature at a potential sweep rate of 100 mV s^{-1} for **5**. The initial potential was set at 0.100 V and the switching potential was 1.000 V.

3. The $\overline{E_{p2}}$ value of the second redox peak increases in the order 1→2→5→3→4 and $\Delta\overline{E_p}$ increases in the same order, indicating the more deformation from tetrahedral configuration the parent compounds [15] is, the more non-equivalent the two ferrocenyl groups are. The amino group is an electron-donating group and, as a result, **1** and **3** are oxidized slightly easier than **2** and **4**.
4. The $\Delta\overline{E_p}$ values of **1** and **2** reveal that the interaction between the two Fe sub-units is slight, the monocation is a slightly delocalized, weakly interacting class II mix valent species according to Robin–Day classification [4, 12, 13]. While in **3**–**5**, the two subunits interact more, thus causing extensive delocalization. They are classified between the weakly-interacting class II and strong-interacting class III within the Robin–Day classification.
5. For the redox of compounds with two or more ferrocenyl groups, a number of factors affecting the behavior of the ferrocenyl moieties concur. In the occurrence of two waves, through-space and through-bridge interactions and substituent effects coexist. The through-bridge interactions, however, seemed to be predominant. The more deformation

from regular tetrahedral configuration caused by the bridging group, the larger the difference in the electrochemical behaviors of the ferrocenyl groups.

(Received 20 January 1998; accepted 18 May 1998)

Abstract—The X-ray diffraction study of the Ni^{2+} complex with 1,4-dimethyl-1,4,8,11-tetraazacyclotetradec-8-yl-(2-ethane sulfonic acid) reveals a distorted *cis*-octahedral geometry around the metal ion The four nitrogen atoms of the macrocycle, the sulfonate group of the side chain and a water molecule are the six donor groups. Interesting is that in the crystals we find two relatively unexpected N-configurations of the macrocycle: the *cis*-II and the *cis*-V arrangement. Their relative energies and structures have been calculated using molecular modeling. (density functional theory, DFT). © 1998 Elsevier Science Ltd. All rights reserved. © 1998 Elsevier Science Ltd. 1. INTRODUCTION

The functionalization of polyazamacrocycles has produced a large number of new and interesting compounds [1–3]. On one side the introduction of pendant chains can modify the solubility of the macrocycle, i.e. it can make it more lipophilic and thus one can extract metal ions from aqueous solution into an organic phase [4, 5]. On the other side the pendant chain can be used to covalently attach a macrocycle to a solid support and thus make ion exchangers [6–8] or to a protein such as a monoclonal antibody and thus label it with radioisotopes for nuclear medical applications [9, 10]. Furthermore functional groups, which have donor properties can enhance the complexation properties and selectivity of the macrocyclic moiety. So for example, the introduction of four acetate groups into 1,4,7,10-tetraazacyclododecane has produced an extremely powerful ligand such as DOTA [11], which because of its very high stability constants with Gd^{3+} has applications as contrast agent in magnetic resonance imaging [12].

Especially interesting in this regard are structural studies of metal complexes of such functionalized polyazamacrocycles, since they allow correlation of the molecular structures and coordination geometries [13]. In the case of mono-N-functionalized derivatives of 1,4,8,11-tetraazacyclotetradecane pentacoordination [14, 15] or *trans*-octahedral geometry [16, 17] have been observed depending on whether all nitrogens are tertiary or not. For di-N-functionalized compounds *trans*-octahedral species have been reported [16, 17].

In continuation of such studies we have now introduced a 2-ethanesulfonate group as a side chain into the tetraazamacrocycle **1** to give **2** and studied the structure of its Ni^{2+} complex.

2. EXPERIMENTAL

^{1}H-NMR and ^{13}C-NMR spectra were run on a Gemini 300 using tetramethylsilane as an internal standard.

Compound **1** (1 mM) [18, 19], dissolved in EtOH (30 ml), was added dropwise at 5°C under nitrogen to a mixture of LiOH (4 mM) and sodium-2-chloroethanesulfonate (3 mM) in water (40 ml). The solution was then heated to 60°C for 20 h. After cooling to RT it was filtered and rotatory evaporated. The raw material was taken up in absolute EtOH so that the inorganic salts could be removed by filtration. The solvent was evaporated and the orange–brown oil was dried under high vacuum. ^{1}H-NMR showed that it is a mixture of **1** and **2**. Beside the signals belonging to **1** the following resonances were observed and tentatively assigned to (**2**): ^{1}H- and ^{13}C-NMR (D_6-DMSO) 1.52–1.68 (quint. CH_2–CH_2–CH_2); 2.10, 2.13 (2s, MeN); 2.30–2.43, 2.47–2.52, 2.56–2.72 (3m, CH_2N and CH_2SO_3H); 3.80 (br, NH). ^{13}C-NMR (D_6-DMSO): 24.80 ($CH_2CH_2CH_2$); 45.16, 45.39 (MeN); 47.24, 49.44, 51.25, 52.02, 52.16, 53.46, 54.20, 58.84, 55.15, 55.88 (CH_2N and CH_2SO_3).

A solution of this mixture in EtOH was treated with a slight excess of $Ni(ClO_4)_2 \cdot 6H_2O$, heated to reflux for 30 min and stirred overnight. The precipitated complex was collected by filtration, washed with absolute EtOH and Et_2O and finally dried in the desiccator. The blue complex was characterized by FAB.MS: 393 [complex-ClO_4]$^+$ and X-ray diffraction (see Section 2.1.).

2.1. *X ray crystallography*

[Ni(**2**)]ClO_4 crystallizes in the monoclinic space group P 21/a as cube-shaped, blue crystals (Table 1). A sample was glued on a glass fiber and mounted on the diffractometer.

Unit cell parameters were determined by the carefully centering of 25 independent, strong reflections with $23^\circ \leq \theta \geq 45^\circ$. Data collection has been carried out at 293 K using an Enraf-Nonius CAD4 diffractometer equipped with a Cu Kα fine focus sealed tube and with a graphite monochromator. Three reflections monitored every 2 h showed an intensity loss of 5.97%. The usual corrections were applied. Absorption correction was carried out using psi-scans (minimum and maximum transmission: 0.44/1.00). The structure was solved by direct methods using the program SIR92 [21]. Anisotropic least squares full matrix refinement was carried out on all non-hydrogen atoms using the program CRYSTALS [22]. The hydrogen atoms are in calculated positions. One part of the macrocyclic ligand and the counterion is disordered.

Table 1. Crystal data and parameters of data collection for [Ni(**2**)ClO_4]

Formula	$C_{14}H_{33}ClN_4NiO_8S$ ($C_{14}H_{31}N_4NiO_3 \cdot H_2O \cdot ClO_4$)
Mol. weight	511.66
Crystal system	monoclinic
Spacegroup	P 21/a
a (Å)	13.1296(12)
b (Å)	11.3594(8)
c (Å)	14.1155(13)
α (°)	90.000
β (°)	93.710(7)
γ (°)	90.000
volume (Å^3)	2100.8(3)
Z	4
F(000)	1080
Density (g cm^{-3})	1.62
μ (mm^{-1})	3.87
Crystal size (mm)	$0.18 \times 0.40 \times 0.55$
Temperature (K)	293
Radiation	Cu Kα ($\lambda = 1.54180$)
Scan type	$\Omega/2\theta$
θ max (°)	77.50
No. of measured reflections	4560
No. of independent reflections	4223
No. of reflections in refinement	3911
No. of variables	375
Final R	0.0458
Final R_w	0.0532
Weighting scheme	Chebychev polynomial [20]
Last max/min in diff. map	$0.48/-0.44$

Appropriate restraints have been set up to refine these parts. The refinement of 375 parameters including 3911 reflections with $I > 4.00\sigma(I)$ lead to a residual of 0.0458 ($R_w = 0.0532$). Scattering factors have been taken from the *International Tables* [23]. The fractional coordinates have been deposited at the Cambridge Crystallographic Data Center.

2.2. *Molecular modelling*

All DFT calculations were performed using the DMol program [24]. A double numeric basis set (DND) and a medium integration grid were used. Both structures were geometry optimized using the gradient corrected Vosko–Wilk–Nusair (BVWN) functional to an SCF convergence criteria of 5×10^{-4} a.u. and a maximum geometry gradient < 0.005 a.u.

3. RESULTS AND DISCUSSION

Generally the alkylation of 1,4-dimethyl-1,4,8,11-tetraazacyclotetradecane (**1**) with two ore more equivalents of alkylating agent gives difunctionalized products [18, 19, 25]. In the case of $ClCH_2CH_2SO_3Na$, however, a mixture of the starting compound **1** and the mono derivative **2** resulted. Since attempts to isolate the pure ligand failed, we tried a purification by addition of Ni^{2+} to the raw product. By selective crystallization the Ni^{2+} complex of **2**, besides a small amount of that with **1**, was obtained.

The crystal structure of [Ni(**2**)]ClO_4 (Fig. 1) is disordered in the propylene bridge between N(1) and N(2) and in the ethylene bridge between N(2) and N(3). The structure can be regarded as a superimposition of two N-conformers in the ratio 15:85 one being the *cis*-V the other the *cis*-II form according to the nomenclature of Bosnich *et al.* [26].

In both species the Ni^{2+} is octahedrally coordinated by the four nitrogens of the macrocycle, one oxygen of the sulfonate group and a water molecule. The two oxygens are *cis* to each other and the macrocycle is folded along the N(1)–Ni–N(3) axis. Bonds are in their normal range: 2.11–2.16 Å for Ni–N and 2.09–2.16 Å for Ni–O (Table 2). The angles around the Ni^{2+} ion are somewhat distorted from the ideal octahedral ones (Table 2).

The *cis*-arrangement found here is somewhat unusual for mono-N-functionalized derivatives,

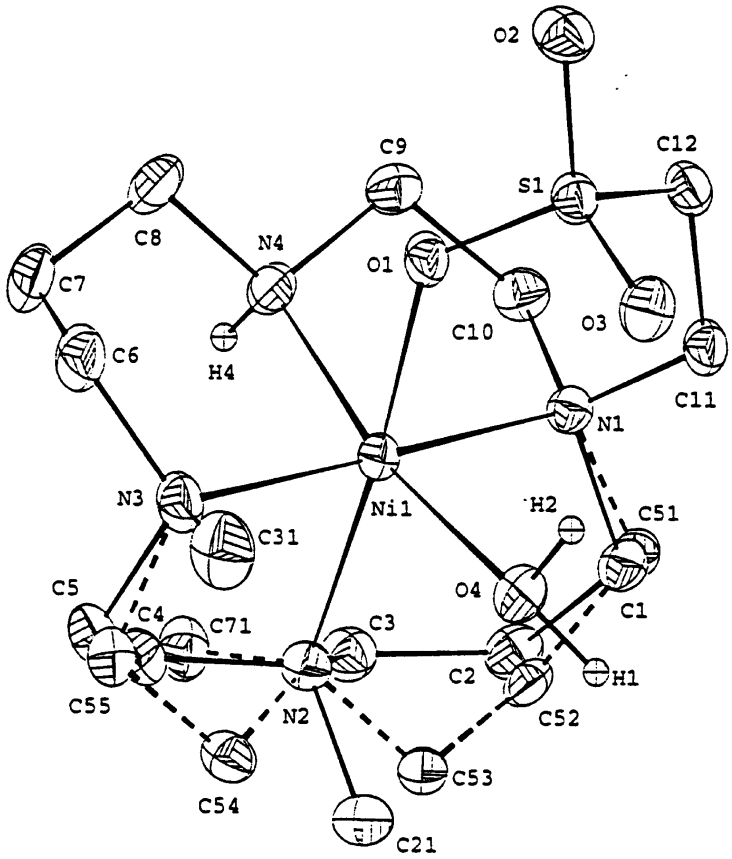

Fig. 1. ORTEP plot of the Ni^{2+} complex with **2**, showing the disorder in the propylene bridge between N(1) and N(2) and in the ethylene bridge between N(2) and N(3).

Table 2. Selected bonds (Å) and angles (°) in the structure of [Ni(**2**)](ClO$_4$) · H$_2$O

Ni(1)–N(1)	2.146(2)
Ni(1)–N(2)	2.134(2)
Ni(1)–N(3)	2.157(2)
Ni(1)–N(4)	2.112(2)
Ni(1)–O(1)	2.089(1)
Ni(1)–O(4)	2.161(2)
N(1)– Ni(1)–N(2)	94.98(6)
N(1)– Ni(1)–N(3)	177.68(7)
N(2)– Ni(1)–N(3)	83.76(7)
N(1)– Ni(1)–N(4)	83.70(7)
N(2)– Ni(1)–N(4)	96.08(7)
N(3)– Ni(1)–N(4)	94.49(8)
N(1)– Ni(1)–O(1)	92.87(6)
N(2)– Ni(1)–O(1)	172.11(6)
N(3)– Ni(1)–O(1)	88.43(6)
N(4)– Ni(1)–O(1)	85.64(7)
N(1)– Ni(1)–O(4)	89.57(6)
N(2)– Ni(1)–O(4)	92.59(6)
N(3)– Ni(1)–O(4)	92.43(7)
N(4)– Ni(1)–O(4)	169.44(7)
O(1)– Ni(1)–O(4)	86.59(6)

which generally give either pentacoordinated [14, 15] or *trans*-octahedral geometries [16, 17].

Also interesting is the fact that two N-configurations (*cis*-II and *cis*-V) are present in the same crystal (Fig. 2). For metal complexes of derivatives of 1,4,8,11-tetraazacyclotetradecane generally the *trans*-I and *trans*-III arrangement are found for square planar, pentacoordinated or *trans*-octahedral coordination geometries, whereas *cis*-V has been observed only in a few cases [27].

Since to our knowledge the *cis*-II arrangement has not been found up to now it was interesting to compare the relative energy of the two species by molecular modeling. The energy difference between *cis*-II and *cis*-V is 2.8 kcal/mol according to the molecular modeling calculation. The difference does not explain the 85:15 ratio found in the crystals, but the coincidence between the calculated and experimentally found structures are good with $R = 0.14$ and $R = 0.13$ for *cis*-II and *cis*-V, respectively (Fig. 2).

In the unit cell there is an extended network of intra [for example O(3) . . . H(2) . . . O(4)] and intermolecular

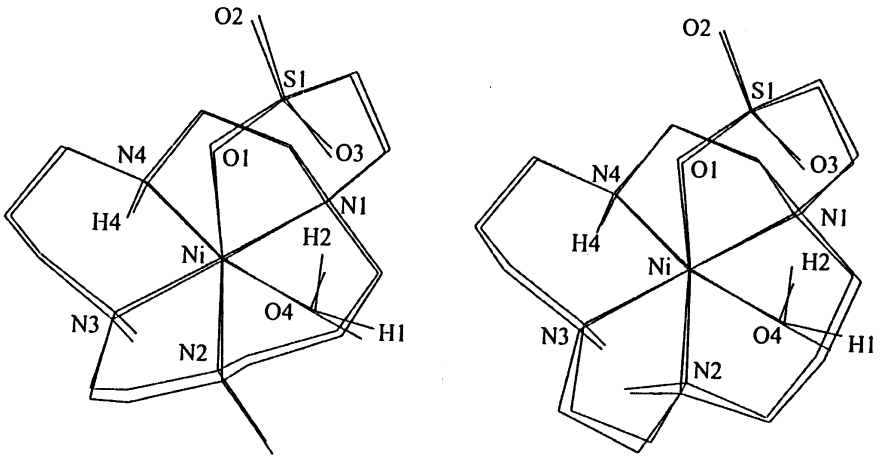

Fig. 2. Superimposition of the experimental and calculated structure of isomer *cis*-II (a) and *cis*-V (b).

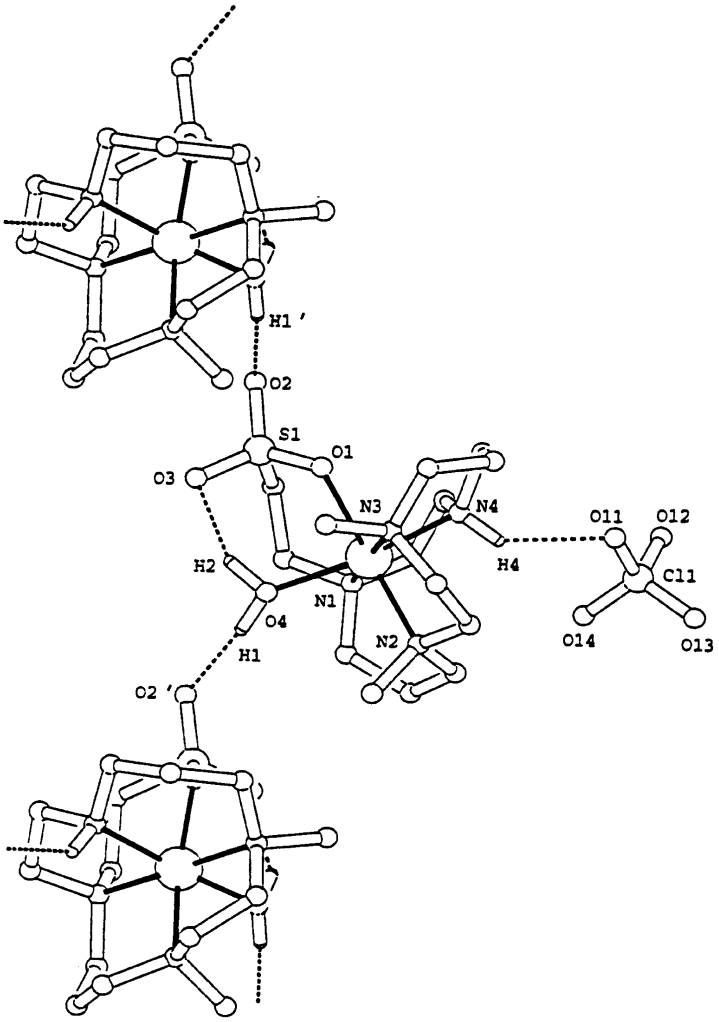

Fig. 3. Inter- and intramolecular hydrogen bonds in the unit cell of $[Ni(\mathbf{2})](ClO_4) \cdot H_2O$.

[O(4)...H(1)...O(2) or N(4)...H(4)...O(11)] hydrogen bonds (Fig. 3).

Whether these are responsible for the stabilization of the two N-configurations in the solid state is difficult to say.

(Received 21 April 1998; accepted 19 May 1998)

Abstract—Platinum(II) and palladium(II) complexes MCl_2L_2 and the gold(I) complex $[AuL_2]Cl$ of the air-stable ferrocene-derived hydroxymethylphosphine $FcCH_2P(CH_2OH)_2$ (L) have been synthesised by ligand substitution reactions, and the η^6-*p*-cymene ruthenium(II) complex $RuCl_2(\eta^6$-$C_{10}H_{14})L$ has been synthesised by a chloride bridge-splitting reaction of the dimer $[RuCl_2(\eta^6$-$C_{10}H_{14})]_2$. The cationic gold complex has been the subject of a single-crystal X-ray diffraction study, which shows the presence of the expected linearly coordinated bis(phosphine)gold cation, hydrogen-bonded to the chloride counterion and a lattice water molecule. © 1998 Elsevier Science Ltd. INTRODUCTION

Hydroxymethylphosphines, containing P–CH_2OH functional groups, together with their metal complexes, have been known for some years [1]. However, in recent years there has been a renewed interest in the chemistry of these ligands ([2], see for example [3, 4]). Transition metal complexes of a variety of monodentate [5, 6], bidentate [7–11] and tridentate [12] hydroxyalkyl-phosphines have been recently reported, including zerovalent complexes of platinum, palladium and nickel [13, 14]. There is general interest in water-soluble phosphines in areas such as catalysis (see for example [15, 16]) and the development of new metal-based drugs [2, 9, 17]. The versatile reactivity of the hydroxymethylphosphine group towards primary and secondary amines (Mannich-type condensation) [18] allows the synthesis of a wide range of aminomethylphosphines [19–22]. Phosphines such as tris(2-cyanoethyl)phosphine [23–26] and phosphatriaza-adamantane (PTA) (for recent references see [27–30]) are synthesised starting from $P(CH_2OH)_3$, and are attracting interest in their own right. Such Mannich-type chemistry of Ph_2PCH_2OH has also been exploited in the synthesis of organophosphine dendrimers and complexes thereof [31–35].

Recently, we reported the high-yield synthesis (from inexpensive and readily-available $(FcCH_2NMe_3)I$ and $P(CH_2OH)_3$) of the air-stable ferrocene-derived hydroxymethylphosphine $FcCH_2P(CH_2OH)_2$ **1** [36]. Full details of the synthesis of this phosphine, together with some derivatives, have been reported [37]. Ferrocene-containing phosphines are being intensively investigated for their coordination chemistry (particularly 1,1′-bis(diphenylphosphino)ferrocene, dppf) [38], and applications to homogeneous catalysis [39–41]. The presence of the redox-active ferrocene centre provides additional interest in such ligands. We have also shown that **1** can be used to synthesise the completely air-stable and crystalline primary alkylphosphine $FcCH_2PH_2$ [42]. In this present paper we report some initial studies on the coordination chemistry of **1**,

towards platinum group metal centres, gold, and ruthenium.

RESULTS AND DISCUSSION

Synthesis, NMR spectroscopy and electrospray mass spectrometry

Platinum(II) *cis*-$PtCl_2[FcCH_2P(CH_2OH)_2]_2$ **3**, palladium(II) $PdCl_2[FcCH_2P(CH_2OH)_2]_2$ **4**, gold(I) $[Au\{FcCH_2P(CH_2OH)_2\}_2]Cl$ **5** and η^6-*p*-cymene ruthenium(II), $RuCl_2(\eta^6\text{-}C_{10}H_{14})[FcCH_2P(CH_2OH)_2]$ **6**, complexes of the bis(hydroxymethyl)phosphine **1** have been prepared. The complexes were synthesised by standard procedures for this type of metal–phosphine–halide complex, involving displacement of the labile 1,5-cyclo-octadiene (COD) ligand from $MCl_2(COD)$ (M = Pd or Pt), by reaction of the *t*-butylisocyanide complex Au(CNBu^t)Cl with two equivalents of phosphine, or by the bridge-splitting reaction of **1** with $[RuCl_2(\eta^6\text{-}C_{10}H_{14})]_2$. The platinum and palladium complexes show relatively low solubilities in dichloromethane, and can be isolated as powders, and washed with dichloromethane to remove any excess ligand and liberated COD. Satisfactory elemental microanalytical data were obtained for all complexes.

NMR data for the complexes **3** and **4** suggest that they both have a *cis* configuration. Evidence for this is seen in the large $^1J(PtP)$ splitting of the ^{31}P NMR signal of **3** at δ 7.8 (3428 Hz) [43]. Also, the multiplets for ^{13}C NMR signals from the CH_2 groups in **3** exhibit a 5-line pattern which has been established as being characteristic of *cis* configuration for compounds of this sort, where there is an $A[X]_2$ spin system with virtual coupling [44, 45]. ^{31}P NMR of **4** indicates this Pd complex exists as only one isomer in solution. The multiplets for the ^{13}C NMR signals of the CH_2 groups in **4** are not as well defined as for **3**, but consist of broad doublets, which have also been identified as indicative of *cis* conformation in this type of compound [44, 45].

The gold complex **5** was initially thought to be the monophosphine complex $[Au\{FcCH_2P(CH_2OH)_2\}]Cl$ (and was reported as such in the initial communication [36]), but after further subsequent characterisation it has been reformulated as the bis(phosphine) complex **5**. Even if the reaction is performed with a 1:1 mole ratio of the reagents, this complex will form in preference to the monophosphine complex. The monophosphine complex can be prepared by reaction of **5** with AuCl(tetrahydrothiophene), but is unstable and degrades in solution.

Electrospray mass spectrometry [46, 47] has been used to provide additional characterisation data for complexes **5** and **6**. The gold complex **5** shows strong peaks for the parent cation $(L)_2Au^+$ (m/z 780.9) (L = **1**), as well as the mono-phosphine complex $(L)Au^+$ (m/z 489.0) (Fig. 1). Gold(I) phosphine complexes have been the subject of a detailed electrospray mass spectrometry study [48], and ions of the type observed in this work were reported previously. The stable carbocation $FcCH_2^+$ was observed at m/z 199.5; this ion is also observed as a fragment ion for the parent phosphine **1** [37], together with other $FcCH_2X$ type compounds [49]. Under the conditions employed for analysis of compound **6**, one peak was observed, arising from the exchange of a chloride ligand for an acetonitrile solvent molecule, i.e. $[M - Cl + MeCN]^+$ at m/z 604.3.

X-ray structure determination of $[Au\{FcCH_2P(CH_2OH)_2\}_2]Cl$ (**5**)

A variety of metal complexes of hydroxymethylphosphines have been structurally characterised previously, all being reported relatively recently. Reported examples [7, 8, 13, 50–52] include *cis*-$PtCl_2(Ph_2PCH_2OH)_2$ [5], the palladium [10], platinum [11] and rhenium complexes [9] of $(HOCH_2)_2PC_6H_4P(CH_2OH)_2$, and the rhenium complex of $(HOCH_2)_2PCH_2CH_2P(CH_2OH)_2$ [9]. Of greater relevance to the present study are the very recently reported compounds $[Au\{(HOCH_2)_2PC_6H_4P(CH_2OH)_2\}_2]Cl_2$ [53], $[Au_2\{(HOCH_2)_2PCH_2CH_2P(CH_2OH)_2\}_2]Cl_2$, $[Au\{P(CH_2OH)_3\}_4]Cl$ [54] and $[Au(Ph_2PCH_2OH)_3]Cl$ [54].

Single crystals of the gold bis(phosphine) complex **5** were obtained by recrystallisation from methanol/diethyl ether and subjected to a single-crystal X-ray diffraction study. The lattice contains the cation $[Au\{FcCH_2P(CH_2OH)_2\}_2]^+$, consisting of the two-coordinate gold(I) centre linearly coordinated by two phosphine ligands **1**, with P(1)–Au(1)–P(2) 176.51(6)°. The structure of the cation of **5** is given in Fig. 2, together with the atom numbering scheme, and selected bond lengths and angles are summarised in Table 1. As well as the cation, the lattice also contains a chloride counterion, and a water molecule of crystallisation. The shortest Au···Cl distance, Au(1)···Cl(1), is 3.436(2) Å, a distance which approximates the sum of the van der Waals radii (3.41 Å); any bonding interaction between the gold and chlorine atoms in the crystal must therefore be very weak. Additionally, the shortest gold–gold distance in the lattice is 5.8587(5) Å, which excludes the possibility of any bonding interactions between gold atoms. Of the gold–hydroxymethylphosphine structures previously reported, the only one displaying linear coordination at the gold atom is $[Au_2\{(HOCH_2)_2PCH_2CH_2P(CH_2OH)_2\}_2]Cl_2$ [53]. However, unlike compound **5** this compound seems to display strong auriophilic interactions. The structure of **5** is disordered at two points: The chloride ion occupies two positions, one on an inversion centre (not the source of disorder), and another position which has 50% occupancy, and the oxygen O(2) shows around 70% occupancy with an alternative position labelled O(2a) around 30% filled.

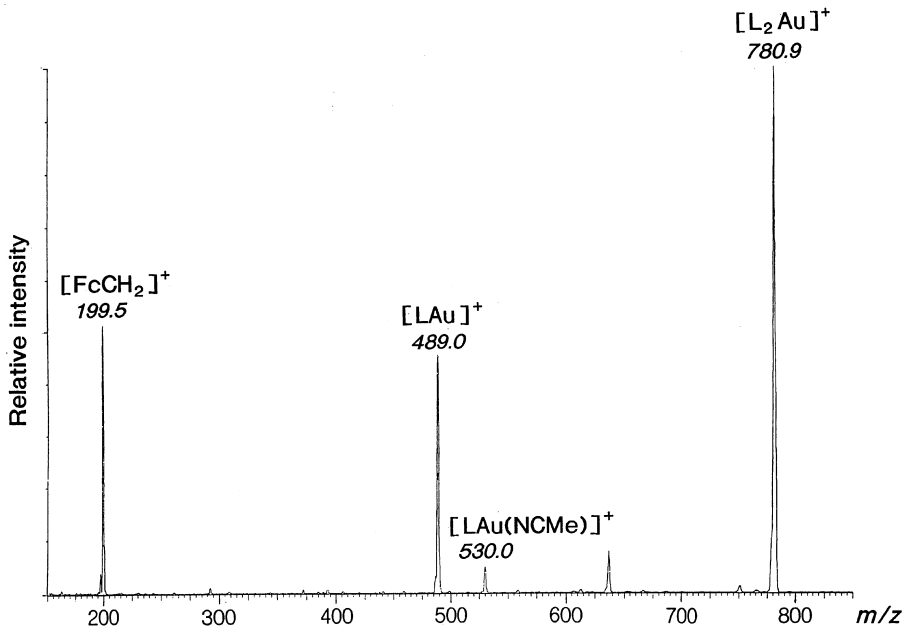

Fig. 1. Positive-ion ESMS spectrum of the gold phosphine complex **5** ($=(L_2Au)^+Cl^-$; L = **1**) in MeCN–H_2O at a cone voltage of 100 V, showing ion assignments.

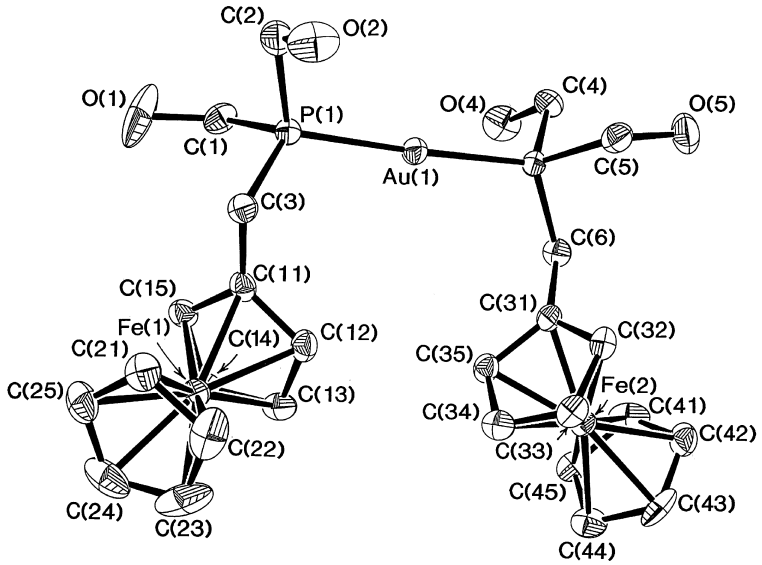

Fig. 2. ORTEP diagram of the $[Au\{FcCH_2P(CH_2OH)_2\}_2]^+$ cation of **5**, showing the atom numbering scheme.

No hydroxyl hydrogen atoms could be located in the final difference map, but consideration of interatomic distances in the structure suggests hydrogen-bonding in the lattice consists of a two-dimensional network in the plane of the *a* and *b* axes. In the direction of the *a* axis, hydrogen-bonding is probable between O(4), O(6) (that is, the water of crystallisation) and O(2) (or O(2a)) of the adjacent molecule ($O(4)\cdots O(6) = 2.707$ Å, $O(6)\cdots O(2a) = 2.748$ Å, $O(6)\cdots O(2) = 3.135$ Å). In the direction of the *b* axis, a hydrogen bond is probable between O(4) and O(5) of adjacent molecules ($O(4)\cdots O(5) = 2.636$ Å). Interatomic distances also suggest some hydrogen-bonding from O–H functions to both Cl(1) and Cl(2) is possible, with a number of $O\cdots Cl$ distances of around 3 Å.

Anti-tumour activity

The platinum, palladium and gold hydroxymethylphosphine complexes **3**–**5** each contain a metal with known anticancer activity [55], as well as phosphine and ferrocene units, which can both also show anti-tumour properties (in the case of ferrocene as the ferricinium ion). Consideration was given to the possibility that in these complexes the combined effect of the sub-units might make them useful anti-tumour agents. However, both **4** and **5** are too insoluble in methanol or water to be tested, while **3** was tested for cytotoxicity and found to be inactive, with an IC_{50} of 250,051 $\mu g\,ml^{-1}$ using the P388 anti-tumour assay.

Conclusion

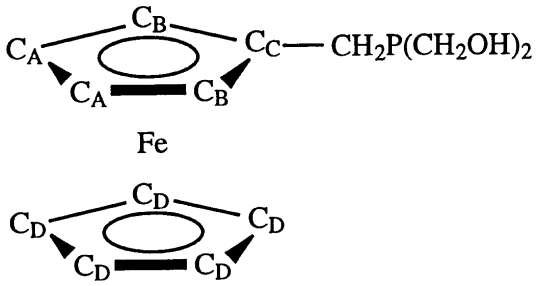
In conclusion, the hydroxymethylphosphine **1** appears to show typical phosphine ligand properties towards precious metal centres. We are currently investigating the synthesis of metal complexes derived from the primary phosphine **2**, together with the electrochemistry of complexes of **1** and **2**; results will be reported in due course.

EXPERIMENTAL

Reactions were carried out in solvents of LR grade or better, in air unless otherwise stated. Light petroleum refers to the fraction boiling in the range 40–60°C.

^1H and ^{13}C–$\{^1H\}$ NMR spectra were recorded in either DMSO-d_6 or $CDCl_3$ solution (as indicated) on a Bruker AC300P spectrometer at 300.13 and 75.47 MHz, respectively, relative to $SiMe_4$ (δ 0.0). Scheme 1 depicts the labelling system employed for assignment of ferrocenyl NMR signals. ^{31}P–$\{^1H\}$ NMR spectra were recorded on the same instrument at 121.51 MHz with 85% H_3PO_4 (δ 0.0) as external reference. IR spectra were recorded as KBr discs on a BioRad FTS40 spectrometer, and melting points were determined using a Reichert Hotstage apparatus, and are uncorrected.

Electrospray mass spectra were obtained in positive-ion mode with a VG Platform II mass spectrometer using a 1:1 v/v acetonitrile–water mobile phase. The compounds were dissolved in the mobile



Scheme 1. Atom labelling used in NMR assignments of the ferrocenyl rings, shown for compound **1**.

phase to give a solution typically of approximate concentration 0.1 mM. The diluted solution was injected into the spectrometer via a Rheodyne injector fitted with a 10 μl sample loop. A Thermo Separation Products SpectraSystem P1000 LC pump delivered the solution to the mass spectrometer source (60 EC) at a flow rate of 0.01 ml min^{-1}, and nitrogen was employed both as a drying and nebulising gas. Cone voltages were typically varied from 10 to 100 V, in order to investigate the effect of higher voltages on fragmentation of the parent ions. Excellent agreement between observed and calculated isotope distribution patterns was observed for all major peaks. Theoretical isotope patterns were calculated using the *Isotope* program [56]. The complexes $PtCl_2$(COD) [57], $PdCl_2$(COD) [58], AuCl(CNBu*t*) [59], AuCl(tetrahydrothiophene) [60] and $[RuCl_2(\eta^6\text{-}C_{10}H_{14})]_2$ [61] and the ligand $FcCH_2P(CH_2OH)_2$ [37] were prepared by literature methods.

Anti-tumour testing of compound **5** was carried out at the Chemistry Department of the University of Canterbury, Christchurch, New Zealand.

Synthesis of cis-$PtCl_2[FcCH_2P(CH_2OH)_2]_2$ (**3**)

Phosphine **1** (0.100 g, 0.343 mmol) and $PtCl_2$(COD) (0.064 g, 0.172 mmol) were dissolved in CH_2Cl_2 (10 ml, LR grade) and stirred for 30 min. The resulting precipitate was removed by vacuum filtration, and dried under vacuum, giving **3** as a yellow powder (0.128 g, 0.151 mmol, 88%), M.P. ca. 210°C (dec). Found: C, 37.1; H, 4.5%. Calcd for $C_{26}H_{34}Cl_2Fe_2O_4P_2Pt$: C, 36.7; H, 4.0%. IR ($cm^{-1}$): 3410 (s), 3093 (w), 2919 (w), 2853 (w), 1462 (w), 1427 (m), 1405 (m), 1386 (m), 1237 (w), 1173 (w), 1105 (m), 1038 (s), 1028 (s), 1002 (m), 924 (w), 878 (m), 832 (m), 747 (w), 501 (m), 484 (m), and 452 (m). $^{31}P\text{–}\{^1H\}$ NMR (DMSO-d_6): δ 7.8 (s, $^1J(PtP) = 3428$ Hz). ^1H NMR (DMSO-d_6): δ 3.25 (FcCH_2P, d, $J = 5.2$ Hz, 2H), 4.04–4.19 (C_A–H, C_D–H, and PCH_2O, m, 11H), and 4.34 (C_B–H, unresolved t, 2H). $^{13}C\text{–}\{^1H\}$ NMR (DMSO-d_6): δ 25.51 (FcCH_2P, m), 58.62 (PCH_2O, m), 71.49 (C_A), 72.57 (C_D), 73.70 (C_B), and 83.65 (C_C).

Synthesis of $PdCl_2[FcCH_2P(CH_2OH)_2]_2$ (**4**)

Phosphine **1** (0.1248 g, 0.427 mmol) and $PdCl_2$(COD) (0.051 g, 0.214 mmol) were dissolved in CH_2Cl_2 (5 ml) and stirred for 15 min. The solution was cooled to 4°C before the precipitate was removed by filtration, washed with CH_2Cl_2, and dried under vacuum. Product **4** was obtained as an orange/brown powder insoluble in most common organic solvents (0.145 g, 0.191 mmol, 89%), M.P. ca. 185°C (dec). Found: C, 41.7; H, 4.4%. Calcd for $C_{26}H_{34}Cl_2Fe_2O_4PdP_2$: C, 41.0; H, 4.5%. IR ($cm^{-1}$): 3389 (s), 3094 (m), 2918 (w), 2852 (w), 1462 (w), 1427 (m), 1405 (m), 1386 (m), 1299 (w), 1237 (w), 1175 (w), 1105 (m), 1139 (s), 1126 (s), 1103 (m), 923 (w), 879 (m), 858 (m), 829 (m), 594 (w), 500 (m), 484 (m), and 444 (m). $^{31}P\text{–}\{^1H\}$ NMR (DMSO-d_6): δ 32.4 (s). ^1H NMR (DMSO-d_6): δ 3.24 (FcCH_2P, d, $J = 7.1$ Hz, 2H), and 4.04–4.44 (C_A–H, C_B–H, C_D–H, and PCH_2O, m, 13H). $^{13}C\text{–}\{^1H\}$ NMR (DMSO-d_6): δ 24.26 (FcCH_2P, m), 57.67 (PCH_2O, m), 69.49 (C_A), 70.48 (C_D), 71.33 (C_B), and 81.64 (C_C).

Synthesis of $[Au\{FcCH_2P(CH_2OH)_2\}_2]Cl$ (**5**)

Phosphine **1** (0.093 g, 0.314 mmol) and AuCl(CNBu′) (0.050 g, 0.159 mmol) were dissolved in CH_2Cl_2 (5 ml) and the solution stirred for 15 min. Petroleum spirits (b.p. 40–60°C) (10 ml) was added and the resulting precipitate removed by vacuum filtration to give **5** as a yellow powder, which was dried under vacuum to give the product **5** (0.105 g, 0.129 mmol, 80.6%). Recrystallisation by cooling a hot MeOH/diethyl ether solution to ca. −30°C yielded golden needles suitable for X-ray structural analysis (0.069 g, 0.084 mmol, 53%). M.P. 127–134°C. Found: C, 37.1; H, 3.9%. Calcd for $C_{26}H_{34}AuClO_4P_2Fe_2 \cdot H_2O$: C, 37.4%; H, 4.3%. IR (cm^{-1}): 3259 (s, br), 1408 (m), 1386 (m), 1298 (w), 1242 (w), 1185 (w), 1106 (m), 1038 (s), 1027 (s), 1002 (m), 926 (w), 887 (m), 804 (m), 595 (w), 504 (m), 483 (m), and 445 (w). ESMS (cone voltage 100 V) *m*/*z*: 780.9 $[L_2Au]^+$, 489.0 $[LAu]^+$, 199.5 $[FcCH_2]^+$ (L = **1**). $^{31}P\text{–}\{^1H\}$ NMR (DMSO-d_6): δ 36.2 (s). ^1H NMR (DMSO-d_6): δ 3.14 (FcCH_2P, s, 2H), 4.05–4.08 (PCH_2O, m, 4H), 4.20 (C_A–H, t, $J = 1.7$ Hz, 2H), 4.24 (C_D–H, s, 5H), and 4.26 (C_B–H, t, $J = 1.7$, 2H). $^{13}C\text{–}\{^1H\}$ NMR ($CDCl_3$): δ 24.90 (FcCH_2P, m), 59.53 (PCH_2O, m), 71.73 (C_A), 72.69 (C_D), 73.15 (C_B), and 84.48 (C_C).

Synthesis of $RuCl_2(\eta^6\text{-}C_{10}H_{14})[FcCH_2P(CH_2OH)_2]$ (**6**)

$[RuCl_2(\eta^6\text{-}C_{10}H_{14})]_2$ (0.070 g, 0.114 mmol) was dissolved in CH_2Cl_2 (10 ml) which was purged and placed under nitrogen before addition of **1** (0.066 g, 0.227 mmol). The mixture was refluxed for 20 min and the solvent removed under vacuum to give the crude product as a dark oil in quantitative yield. Vapour diffusion recrystallisation from CH_2Cl_2/EtOH with pentane yielded the product as a brown powder which was dried under vacuum (0.093 g, 0.155 mmol, 68%). M.P. = 181–188°C. Found: C, 46.2; H, 5.5%. Calc. for $C_{23}H_{31}Cl_2FeO_2PRu$: C, 46.2; H, 5.2%. IR (cm^{-1}): 3398 (s), 3174 (m), 3082 (m), 3043 (s), 2964 (m), 2873 (m), 1498 (w), 1467 (m), 1441 (m), 1384 (m), 1105 (m), 1036 (s), 1023 (s), 1002 (m), 924 (m), 890 (m), 864 (m), 823 (m), 811 (m), 777 (w), 508 (s), 479 (s), 460 (m), 444 (s), 426 (m). ESMS (cone voltage 60 V) *m*/*z*: 604.3 $[M - Cl + CH_3CN]^+$. $^{31}P\text{–}\{^1H\}$ NMR ($CDCl_3$-d_6): δ 25.9 (s). ^1H NMR ($CDCl_3$-d_6): δ 1.23 ($CH(CH_3)_2$, d, $J = 7$ Hz, 6H), 2.05 (CH_3, s, 3H), 2.78 ($CH(CH_3)_2$, hept., $J = 7$ Hz, 1H), 3.24 (FcCH_2P, d, $J = 8$ Hz, 2H), 4.16 (C_D–H, s, 5H), 4.18–4.19 (PCH_2O and C_A–H, m, 6H), 4.29 (C_B–H, s, 2H), 5.44 ($CH_3C(CH)_2$, d,

$J = 6$ Hz, 2H), 5.50 ($Pr^iC(CH)_2$, d, $J = 6$ Hz, 2H). ^{13}C–$\{^1H\}$ NMR ($CDCl_3$): δ 18.36 (CH_3, s), 22.21 ($CH(CH_3)_2$, s), 24.88 ($FcCH_2P$, d, $J = 19$ Hz), 30.75 ($CH(CH_3)_2$, s), 58.34 (PCH_2O, d, $J = 31$ Hz), 68.46 (C_A, s), 69.23 (C_D, s), 69.69 (C_B, s), 80.66 (C_C, s), 85.51 ($CH_3C(CH)_2$, d, $J = 4$ Hz), 87.98 ($Pr^iC(CH)_2$, d, $J = 4$ Hz), 96.41 ($CH_3C(CH)_2$, s), 107.11 ($Pr^iC(CH)_2$, s).

X-ray crystal structure of $[Au\{FcCH_2P(CH_2OH)_2\}_2]Cl \cdot H_2O$

Crystal data: $C_{26}H_{36}AuClFe_2O_5P_2$, $M_r = 834.60$; monoclinic, space group P2/c, $a = 12.3838(2)$ Å, $b = 6.3295(1)$ Å, $c = 36.8279(2)$ Å, $\beta = 92.360(1)^\circ$, $V = 2884.24(7)$ Å^3, $D_c = 1.922$ g cm^{-3} for $Z = 4$. $F(000) = 1640$, μ(Mo Kα) = 1.29 mm^{-1}, λ(Mo Kα) = 0.71073 Å, $T = -70^\circ$C, crystal size = 0.54 × 0.20 × 0.02 mm, yellow plate. A total of 16938 reflections were collected in the range $1.11 < \theta < 26.40^\circ$, corresponding to 6338 unique data ($R_{int} = 0.0409$, $T_{max,min}$ 0.91027, 0.6960).

The unit cell dimensions and intensity data were obtained on a Siemens SMART CCD diffractometer. The data collection nominally covered over a hemisphere of reciprocal space, by a combination of three sets of exposures; each set had a different ϕ angle for the crystal and each exposure covered 0.3° in ω. The crystal to detector distance was 5.0 cm. The data sets were corrected empirically for absorption using SADABS [62].

The structure was solved by Patterson methods and developed routinely. Full-matrix least squares refinement was based on F^2. Oxygen O(2) was disordered over two positions and was refined as O(2) and O(2a), with occupancies refined to 70.8% and 29.2%, respectively while temperature factors for the two atoms were restrained to 0.05. Temperature factors were subsequently allowed to refine without constraint, while occupancy was fixed. Only half the Cl(2) sites were occupied, and so refinement was carried out with occupancy set to 50%. Since Cl(1) occupied an inversion centre between two gold cations, the combined effect of the two chlorine atom positions was to provide one negative charge for each Au(I) atom. Refinement was carried out with all non-hydrogen atoms except O(2a) anisotropic and with hydrogen atoms included in calculated positions with isotropic temperature factors 1.2 times that of the U_{iso} of the atom to which they are bonded. Hydrogen atoms of the OH groups and the water molecule could not be found in the difference map and so were not included in the refinement. Refinement converged at $R_1 = 0.0419$ [for 4910 reflections with $F_o > 4\sigma(F_o)$] and $wR_2 = 0.0912$ (all data) ($w = [\sigma^2(F_o^2) + (0.0295P)^2 + 8.96P]^{-1}$ where $P = (\max(F_o^2, 0) + 2F_c^2)/3$); final GoF = 1.149). The final difference map showed no peak greater than $+1.172$ e Å^{-3} and no hole larger than -1.391 e Å^{-3} [both close to Au(1)]. Programs used for structure solution and refinement were SHELXS-86 [63] and SHELXL-93 [64].

Complete lists of atomic coordinates, bond parameters and tables of thermal parameters and hydrogen atom coordinates have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

Acknowledgements—We thank the University of Waikato and the New Zealand Lottery Grants Board for financial support of this work. We thank Assoc. Professor C. E. F. Rickard and Dr L. J. Baker (University of Auckland) for collection of the X-ray data set, Johnson–Matthey PLC for a generous loan of platinum, and Wendy Jackson for technical assistance. We also thank Professor B. K. Nicholson (University of Waikato) for assistance with the X-ray crystallography. NJG thanks the William Georgetti Trust for a scholarship.

(Received 12 January 1998; accepted 15 May 1998)

Abstract—The syntheses and characterization of five compounds obtained by the reaction of dirhodium(II)tetraacetate with 1,4-dicyanobenzene in different solvent systems are described. The structures of $Rh_2(OAc)_4(NCPhCN)\cdot CH_3COCH_3$ (**1**), $Rh_2(OAc)_4(NCPhCN)\cdot 2CH_3OH$ (**2**), $Rh_2(OAc)_4(NCPhCN)\cdot C_4H_8O$ (**4**) and $Rh_2(OAc)_4(NCPhCN)\cdot C_6H_6$ (**5**) were determined by single crystal X-ray diffraction. All structures contain one dimensional polymeric chain, comprised of dirhodiumtetraacetate units bridged by 1,4-dicyanobenzene molecules. Solvent molecules are located between the chains in each structure and three different packing arrangements of the polymer chains result from the inclusion of these different solvent molecules. Compounds **1**, **2** and **3** crystallize in space group C2/c with similar cell parameters. Compound **4** also crystallizes in the same space group, but its structure is significantly different from those of **1**, **2** and **3**. Compound **5** crystallizes in space group $P\bar{1}$ and contains an unusual polymer chain structure. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: coordination polymer; one dimensional polymer chains; dirhodiumtetraacetate; 1,4-dicyanobenzene; synthesis; crystal structure

INTRODUCTION

The coordination chemistry of dinuclear tetra-carboxylates of the transition metals has been a focus of several previous investigations. Adducts such as $Cr_2(OAc)_4(py)_2$ [1] and several polymers such as: $Cr_2(OAc)_4\cdot(pyz)_2$ [1], $Mo_2(O_2CCH_3)_4\cdot L$ (L = pyrazine, 4,4′-bipyridine, 1,4-diazabicyclo[2.2.2]octane) [2], $[Ru_2(O_2CC_2H_5)_4(phz)]BF_4$ [3] and $Cu_2(OAc)_4(pyz)$ [4] have been studied in detail. Several reactions of the Rh(II) tetra-acetate dimer with organic or organometallic ligands have been reported [5–8]. With some ligands, for example bis(4-pyridinecarbonitrile) [9] and pyridine, $M_2(O_2CR)_4L_2$ [10] metal cluster complexes are formed. One and two dimensional polymers are obtained by reactions with 2-(aminomethyl)pyridine [11], TCNE [12] and 4-amino-5-(aminomethyl)-2-methylpyrimidine [13] and $K_3Co(CN)_6$ [14]. Polymers containing $Rh_2(O_2CR)_4$ dimers with different R groups, for example, $Rh_2(O_2CEt)_4$ [15] or $Rh_2(O_2CCF_3)_4$ [16, 17], bridged by suitable organic ligands have also been reported.

Although extensive studies have focused on the formation of coordination polymers of the $Rh_2(O_2CR)_4$ dimer with linear-bidentate nitrogen ligands, the role of specific solvent molecules in the formation and crystallization of such polymers has not been investigated. In the present work, we report the syntheses and structures of compounds formed by the reaction of $Rh_2(OAc)_4$ with 1,4-dicyanobenzene in different solvents. Five new one dimensional coordination polymers have been obtained: $Rh_2(OAc)_4(NCPhCN)\cdot CH_3COCH_3$ (**1**), $Rh_2(OAc)_4(NCPhCN)\cdot 2CH_3OH$ (**2**), $Rh_2(OAc)_4(NCPhCN)\cdot xC_2H_5OH$ ($x \cong 1$) (**3**), $Rh_2(OAc)_4(NCPhCN)\cdot C_4H_8O$ (**4**) and $Rh_2(OAc)_4(NCPhCN)\cdot C_6H_6$ (**5**).

The structures of **1**, **2**, **4** and **5** were determined by analyses of single crystal X-ray diffraction data. The polymers all consist of one dimensional chains of $Rh_2(OAc)_4$ dimers bridged by 1,4-dicyanobenzene ligands, with the cavities between the chains filled by

* Author to whom correspondence should be addressed.

different solvent molecules. Packing of specific solvent molecules and the chains determines the final crystal structure. For **3**, only the unit cell dimensions and space group were determined and indicate that **3** is isostructural with **1** and **2**.

EXPERIMENTAL

Reagents and apparatus

Rhodium(II)acetate (STREM Chemical) and 1,4-dicyanobenzene (Aldrich) were used as received. Acetone, methanol, ethanol, benzene and tetrahydrofuran (THF) were dried over molecular sieves (4 Å). Infrared data were collected on a Galaxy FTIR 5000 series spectrometer, using the KBr pellet method. X-ray powder diffraction measurements were carried out using a Scintag XDS 2000 automated powder diffractometer (Cu Kα radiation, θ–θ, flat plate geometry). The Cerius 2 program [18] was used to simulate X-ray powder diffraction patterns from the single crystal X-ray data. Thermogravimetric analyses were carried out by using a TA Instruments 2100 thermal analyzer in a flowing nitrogen atmosphere at a heating rate of 1°C/min.

Syntheses

$Rh_2(OAc)_4(NCPhCN)\cdot CH3COCH3$ (***1***). $Rh_2(OAc)_4$ (10 mg, 0.023 mmol) and 1,4-dicyanobenzene (5 mg, 0.039 mmol) were dissolved in 25 ml acetone. The solution was stirred for 30 min and then slowly evaporated. Dark red crystals in the form of long columns or thin plates crystallized from the solution after 6 d. IR bands (cm^{-1}): 3443 (s), 3092 (w), 3046 (w), 2986 (w), 2934 (w), 2396 (w), 2301 (w), 2234 (m), 1588 (s), 1506 (w), 1437 (s), 1417 (s), 1358 (m), 1279 (w), 1051 (w), 924 (w), 845 (m), 702 (s), 629 (w), 561 (m).

$Rh_2(OAc)_4(NCPhCN)\cdot 2CH_3OH$ (***2***). A solution of 1,4-dicyanobenzene (15.2 mg, 0.119 mmol) in THF (30 ml) was added to a suspension of $Rh_2(OAc)_4$ (35 mg, 0.08 mmol) in methanol (40 ml). The mixture was stirred for about 1 h at room temperature. Slow evaporation produced small, red rod-shaped crystals in about 1 week in 95.9% yield. The compound is insoluble in water, but soluble in acetonitrile, THF and methanol. IR bands (cm^{-1}): 3443 (s), 3090 (w), 3044 (w), 2930 (w), 2233 (w), 1591 (s), 1435 (s), 1416 (s), 1385 (m), 1352 (w), 1277 (w), 1219 (w), 1051 (w), 858 (w), 812 (w), 702 (m), 629 (w), 565 (w).

$Rh_2(OAc)_4(NCPhCN)\cdot C_2H_5OH$ (***3***). The same procedure was used as described above for **1**, with ethanol replacing acetone. The dark red crystals were irregular multifaceted prisms. IR bands (cm^{-1}): 3447 (s), 3435 (s), 3098 (w), 3054 (w), 2363 (w), 2234 (m), 1588 (s), 1506 (w), 1437 (s), 1418 (s), 1358 (m), 1277 (w), 1051 (w), 922 (w), 845 (m), 704 (s), 629 (w), 598 (w), 561 (m).

$Rh_2(OAc)_4(NCPhCN)\cdot C_4H_8O$ (***4***). The reaction was carried out as described above for **1**, using THF as the solvent in place of acetone. Dark red diamond-shaped plates formed in 7 days. IR bands (cm^{-1}): 3495 (s), 3422 (s), 3100 (w), 3054 (w), 2971 (w), 2930 (w), 2855 (w), 2361 (w), 2234 (m), 1935 (w), 1588 (s), 1506 (w), 1437 (s), 1416 (s), 1356 (m), 1279 (w), 1057 (m), 845 (s), 799 (w), 698 (s), 629 (w), 596 (w), 561 (s).

$Rh_2(OAc)_4(NCPhCN)\cdot C_6H_6$ (***5***). A solution of 1,4-dicyanobenzene (5 mg, 0.039 mmol) in 10 ml THF was added to a suspension of $Rh_2(OAc)_4$ (10 mg, 0.023 mmol) in 10 ml benzene. The solid dissolved completely after being stirred for 1 h. Two distinct habits of lilac coloured crystals were observed after a week of slow evaporation. The majority of the product consisted of very large multifaceted blocks, while the remainder were square columns. A square column crystal was used for the data collection since the large blocks appeared to be polycrystalline. Subsequently, a small fragment cut from a large block verified that it was indeed the same phase as the crystal used for data collection. IR bands (cm^{-1}): 3449 (s), 3424 (s), 3096 (w), 3054 (w), 3005 (w), 2926 (w), 2390 (w), 2234 (m), 1588 (s), 1437 (s), 1416 (s), 1385 (m), 1356(m), 1279(w), 1045(w), 845(m), 696(s), 629(w), 598(w), 561(m).

All of the compounds show the expected IR stretching frequencies from the $Rh_2(OAc)_4$·dicyanobenzene polymer and the specific solvent molecule. Coordination of the dicyanobenzene is indicated by a CN stretching frequency at 2234 cm^{-1}, which is slightly blue-shifted from the CN stretching frequency (2232 cm^{-1}) of neat 1,4-dicyanobenzene.

Structure determinations

For **1**, **3** and **5**, X-ray data were collected using a Nicolet R3m/V automatic diffractometer (graphite-monochromated Mo-Kα radiation). Data for **2** and **4** were collected using an Enraf-Nonius CAD-4, four circle diffractometer also with Mo-Kα radiation.

A crystal of **1** with dimensions $0.10 \times 0.35 \times 0.45$ mm was mounted on a glass fiber and transferred to the diffractometer. The crystal was cooled to 223 K in a stream of cold nitrogen gas. Lattice parameters were determined from the angles of 25 reflections in the range $16.3° < 2\theta < 30.3°$. Crystal data and details of the data collection and refinement are presented in Table 1. Data were collected in ω–2θ mode. Intensity data for 2386 reflections (2121 unique) were collected in the range $4° < 2\theta < 50°$. Two standard reflections were monitored after every two h or every 100 data collected and these showed a 12% linear decay over the course of the experiment. A normalization factor as a function of X-ray exposure time was applied to account for this. During data reduction, Lorentz and polarization corrections and a semi-empirical absorption correction based on ten

reflections having χ values between 70 and 90° were applied. The structure was solved in space group C2/c by direct methods and standard difference Fourier techniques using SHELXS-96 [19]. Refinement on F^2 was carried out by full-matrix least-squares procedures using SHELXL-96 beta [19]. All nonhydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions riding on their carrier atoms, with fixed isotropic thermal parameters related to the value of the equivalent isotropic thermal parameter of their carrier atoms by a factor of 1.5 for the methyl hydrogen atoms and a factor of 1.2 for the other hydrogen atoms. Weights were optimized in the final refinement cycles.

The data collection and refinement of **5** were carried out in the same way as for **1**. A lilac square column with dimensions $0.08 \times 0.12 \times 0.40$ mm was used. Twenty-five reflections in the range $18° < 2\theta < 42°$ were centered, giving a triclinic cell. Intensity data were collected in the ω–2θ mode with a range of $4 < 2\theta < 50°$. A semi-empirical absorption correction based on ψ scans was applied to the data during data reduction. The structure was determined and refined in space group $P\bar{1}$ using the same programs as **1**.

For **2** and **4**, suitable crystals with dimensions $0.31 \times 0.11 \times 0.10$ and $0.15 \times 0.3 \times 0.3$ mm, respectively, were mounted with epoxy glue on the tip of a glass fiber and transferred to the diffractometer. 25 reflections were used to determine the unit cell and data were collected using the ω–2θ scan method in both cases. Intensities were corrected for Lorentz and polarization effects, as well as for absorption (ψ scans). Intensities of three standard reflections showed no variations greater than those predicted by counting statistics. In both cases, space group C2/c was chosen and confirmed by successful structure refinement. The structure solution and refinement were carried out similarly as the other compounds. For **3**, only the unit cell dimensions and space group were determined (223 K). Selected bond distances and angles for **1**, **2**, **4** and **5** are given in Table 2.

RESULTS AND DISCUSSION

Preparation

The characteristics of the compounds obtained from the reaction of rhodium(II)acetate dimer with 1,4-dicyanobenzene vary with the different solvents used. Two methods were used for the synthesis of the five compounds. **1**, **3** and **4** were synthesized with only one type of solvent. The solvent served to dissolve the starting materials and was subsequently incorporated into the structure within a channel formed by stacking of the polymer chains. For **2** and **5**, two types of solvents were involved in the synthesis. One served to dissolve the starting material and the other one was incorporated into the structure. THF was used as the solvent but was not observed in the final structures. Excess 1,4-dicyanobenzene was used in all of the five reactions. The structure and composition of the final products were insensitive to changes in the stoichiometry of the reactants.

Structures

All of the polymeric structures contain one dimensional chains comprised of rhodiumacetate dimers bridged by 1,4-dicyanobenzene (see Fig. 1 for **1**). Each compound has different solvent molecules located between the polymer chains and each solvent causes significant variations in the crystal structures that are adopted.

Figure 1 shows the local coordination of compound **1** with the atoms labelled. Figures 2 and 3 show different views of the spatial relationship between the linear chains. In Fig. 2, the acetate ligands have been omitted

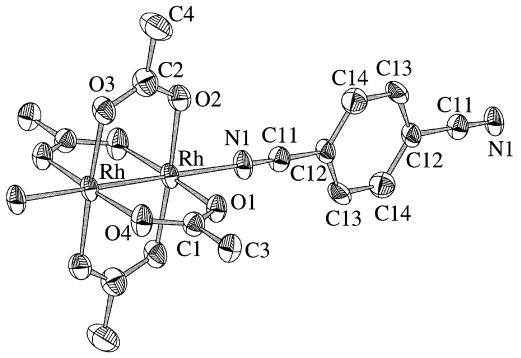

Fig. 1. Ortep drawing of the local coordination of **1** with thermal ellipsoids at the 50% probability level, the solvent acetone is not shown.

for clarity. The dinuclear $Rh^{4+}{}_2$ carboxylate core remains intact, with a Rh–Rh distance of 2.391(1) Å. The Rh–O distances range from 2.029(4) to 2.049(5) Å. The octahedral coordination sphere of Rh is completed by axial coordination to the nitrogen atom of the organic ligand at a distance of 2.239(5) Å. The Rh–N–C linkage is nearly linear, with an angle of 178.1(5)°. The chains stack together with an average separation of 3.8 Å, Fig. 2. The phenylrings from the alternating chains are not parallel to each other and the closest contact between adjacent phenylrings is 3.559 Å (C12 from one ring and C14 from another ring). Adjacent chains are oriented at an angle of 56.3° with respect to each other when projected on the **ab** plane, Fig. 3. Part of the extended structure of **1** is shown in Fig. 3. The intersections of the chains define channels in the structure that are occupied by the solvent molecules.

The acetone molecules in **1** are severely disordered and are difficult to locate in difference maps. One acetone molecule was refined with an occupancy factor of 0.276, while four additional atom sites designated as carbon were also located and refined with fixed occupancies of 0.3. From thermogravimetric analysis data (see Section 3.3), one acetone molecule per dirhodium unit is present.

The arrangement of the polymer chains in the structure of **2** is the same as in **1**. Adjacent chains are oriented at an angle of 56.0° with respect to each other, when projected on the **ab** plane. This angle is essentially the same as observed in **1** (56.3°). The average Rh–O, Rh–N and Rh–Rh bond distances in the two compounds are the same within errors. The methanol solvent molecules in **2** are also disordered. The positions of two methanol molecules could be refined, albeit with high thermal parameters. The exact number of methanol molecules could not be determined from the X-ray data, however thermogravimetric analysis indicates that two methanol molecules per dirhodium unit are present.

In **4**, the THF solvent molecules are ordered and a significant change in the arrangement of the polymeric chains [Fig. 4(a)–(c)] is observed. In **1** and **2** the chains are nearly linear, but in **4** the C–N–Rh angle is reduced to 168.7(3)°. The Rh–Rh–N and N–C–C angles in **4** are still close to 180°. The N–Rh distance [2.226(3) Å]

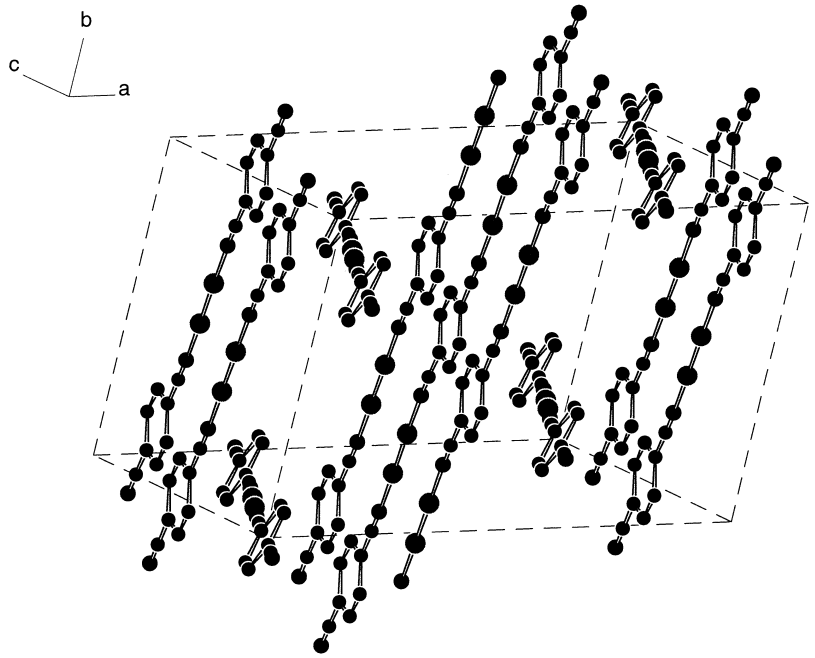

Fig. 2. View of the structure of **1** showing the stacking of the chains. For clarity, the acetate groups of the Rh dimer are not shown.

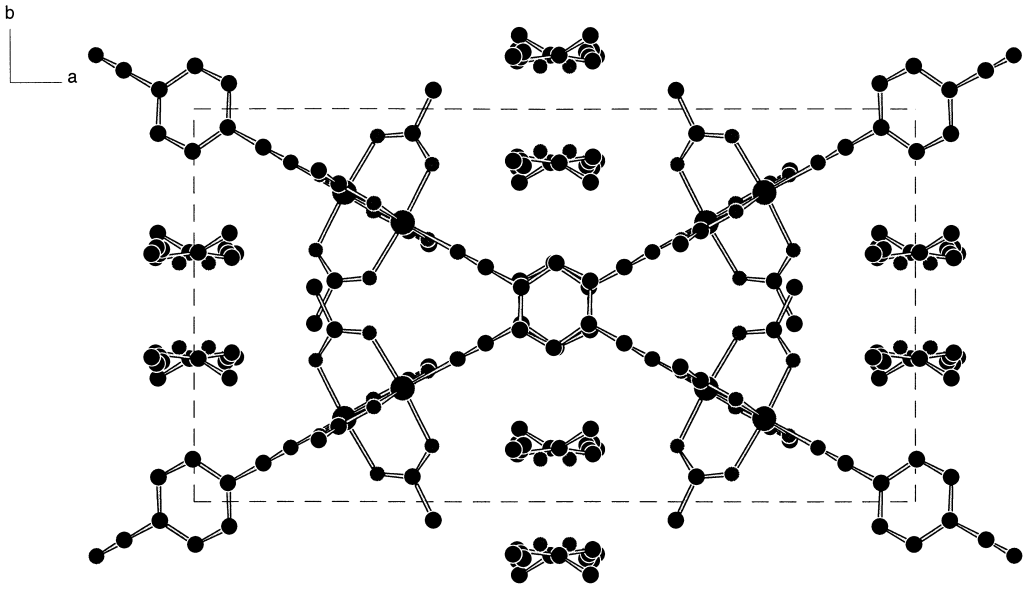

Fig. 3. Projection of the structure of **1** along *c*. Disordered acetone molecules are shown between the chains.

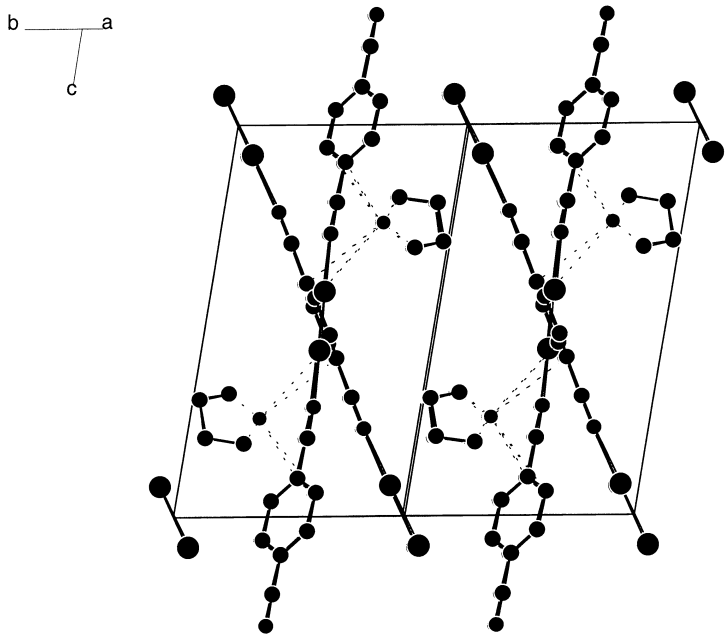

Fig. 4. (a) View of the structure of **4** showing the stacking of the chains and the THF molecules. For clarity, the acetate groups of the Rh dimer are not shown. (b) Local coordination of **4** showing the attraction between oxygen of the THF and the phenylrings in the chains. For clarity, the acetate groups of the Rh dimer are not shown. The dotted lines indicate the closest contact between the THF and phenylrings. (c) View of the structure of **4** showing the attraction between oxygen of the THF and the phenylrings in the chains. For clarity, the acetate groups of the Rh dimer are not shown. The dotted lines indicate the closest contact between the THF and phenylrings.

is similar to the distance in **1** and **2**. The change in angle at the N atom, however, imparts a slight zigzag geometry to the chains as can be seen in Fig. 4. The stacking of the polymer chains in **4** is similar to that observed in **1** and **2**, but the alternating chains make an angle of 39.50° (projected on **ab** plane). The arrangement of THF molecules between adjacent chains suggests a weak interaction through the oxygen lone electron pairs. This interaction may be responsible for reducing the dihedral angle between the

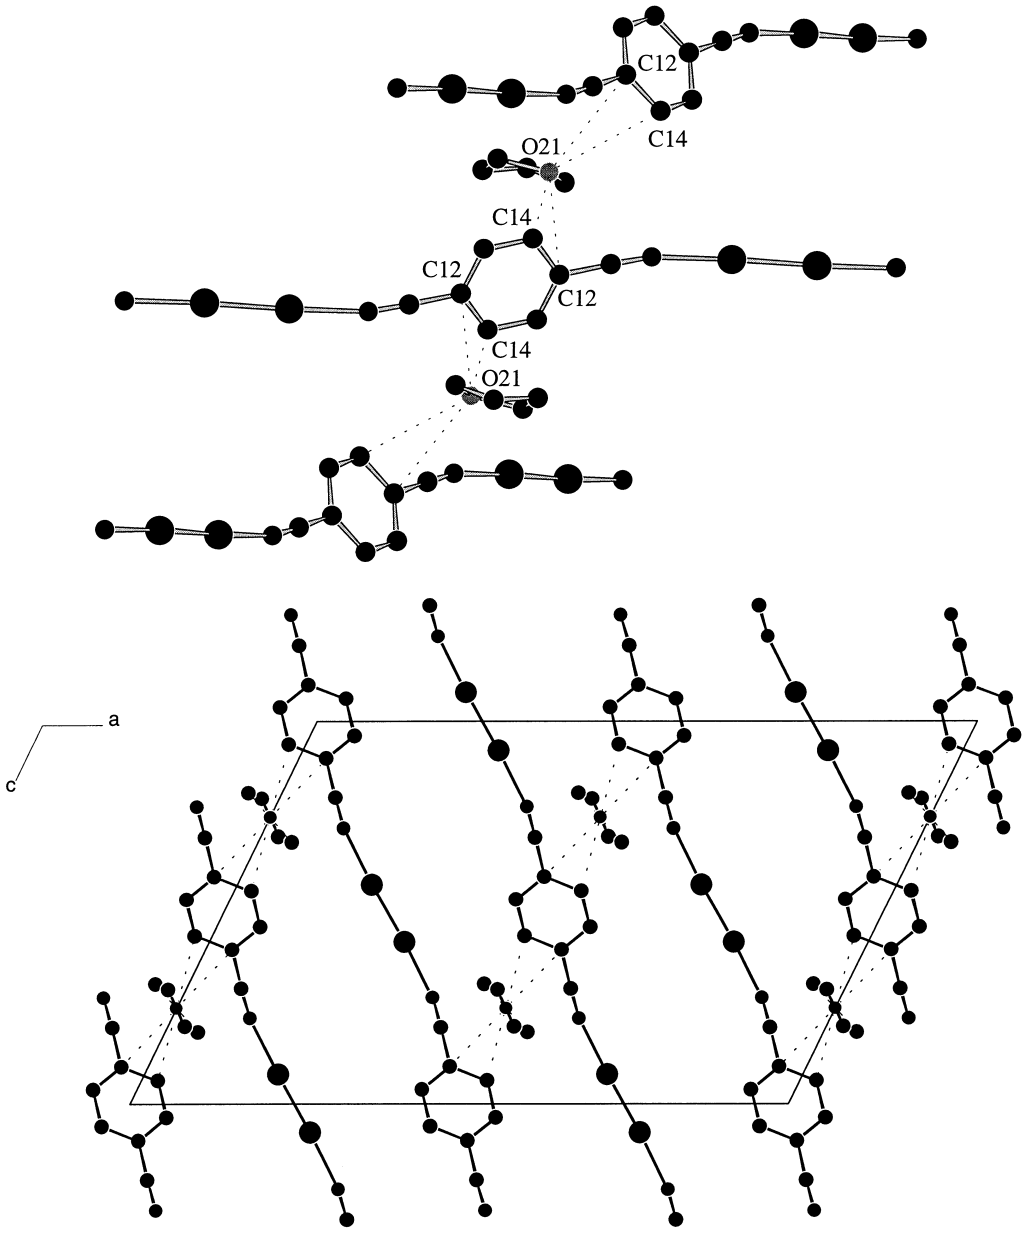

Fig. 4—continued.

chains by ~17°. The distances between the THF oxygen atom and the chains (O21–C14 and O21–C12) are 3.381 and 3.434 Å, respectively. The bridging geometry is symmetric because THF lies on a crystallographic two-fold axis.

A different structure is observed when benzene molecules are trapped between the polymer chains. Crystals of **1**, **2**, **3** and **4** all have the same dark red color, while crystals of **5** are lilac. In **5**, all of the chains in the crystal are parallel to each other (Figure 5). Every polymeric chain zigzags as in **4**, with a C–N–Rh angle of 150.6(2)°, which is much further from linear than the corresponding angle in **4** [168.7(3)°]. The benzene molecules that sandwich each phenylring in the chain are parallel to each other and are separated by a distance of 8.461 Å. The phenylring in the chain and the benzenering are not parallel and the closest contact between them is 3.483 Å (C6–C9), while the distance from C5 of the cyanide group to C9 of the benzenering is 3.352 Å. The spacing between the phenylrings is too large to imply any strong electronic interaction. The benzene molecules are disordered over two different positions, rotated at roughly 30° to each other about a common crystallographic inversion center. Analysis of the isotropic thermal parameters showed a 50% occupancy for each orientation.

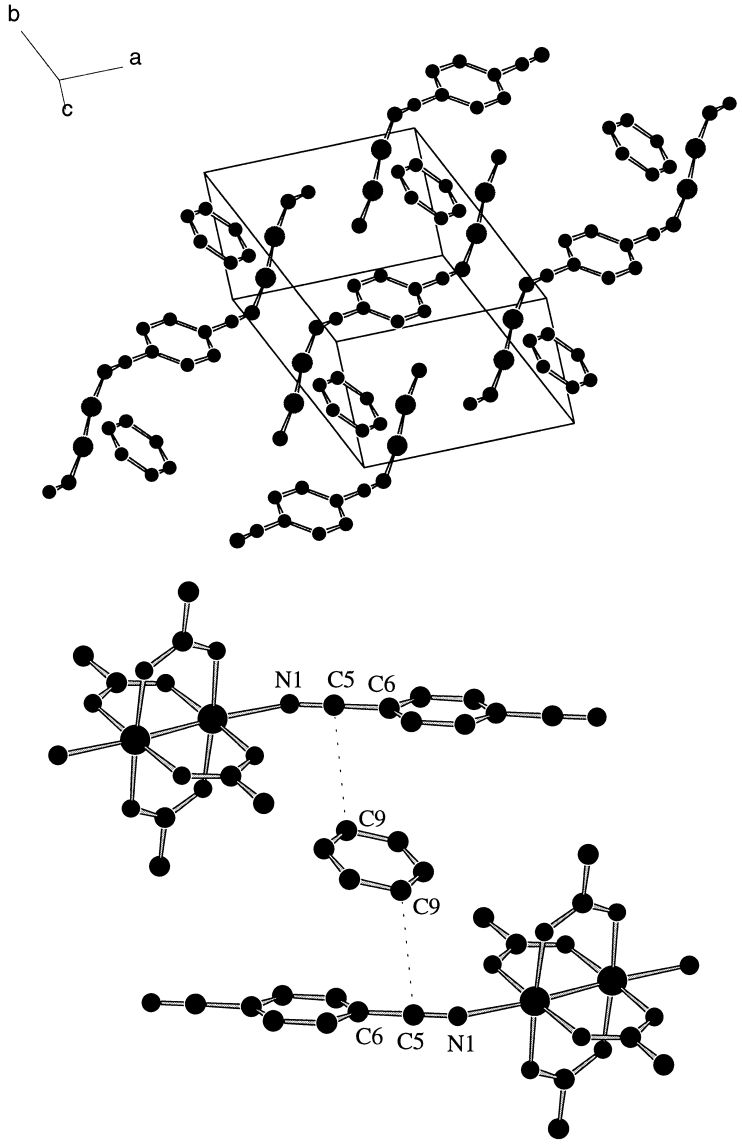

Fig. 5. (a) View of the structure of **5** showing the stacking of the chains and the benzene molecules. For clarity, the acetate groups of the Rh dimer are not shown and only one position of the disordered benzene molecule is shown. (b) Local coordination of **5** showing the attraction between the benzene molecules and the phenylrings in the chains. The dotted lines indicate the closest contact between the benzene molecule with the chains. (c) View of the structure of **5** along *a* showing the stacking of the chains.

All five crystal structures have solvent "channels" leading directly to the surface: **1**, **2**, **3** and **4** have channels along the *c* axis, while **5** has a channel along *a*. In TGA measurements on heating, acetone, methanol and ethanol are all removed near their boiling points. However, THF and benzene are lost at temperatures significantly higher than their boiling points and the removal of the solvent molecules is not well resolved in temperature from the temperature at which the dicyanobenzene molecules are removed. The TGA data suggest some weak interaction between the solvent molecules and the frameworks of **4** and **5**. The structure of **4**, suggests some interaction between the oxygen lone pair electrons in THF and the chains, whereas in **5** the benzene molecules may have some π–π interactions with the phenylrings in the chain.

Thermogravimetric analysis

Each of **1**, **2**, **3**, **4** and **5** was heated to 400°C in nitrogen to determine the solvent contents and thermal stabilities (Figure 6). For **1**, the first two weight losses at $T < 118$°C corresponded to the loss of one

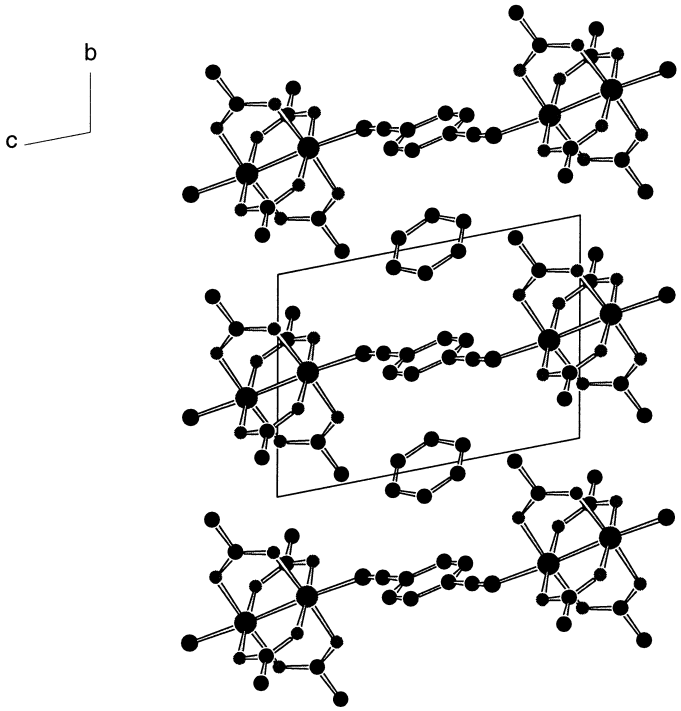

Fig. 5—*continued.*

molecule of acetone (observed 9.67%, calculated 9.25%). From 118 to 175°C, a second weight loss corresponded to removal of one dicyanobenzene molecule (observed 21.99%, calculated 20.40%). The final weight loss occurred between 227 and 246°C and corresponded to the loss of the four acetate groups. No further decomposition was observed above 246°C. X-ray powder diffraction confirmed that the black residue was pure Rh (observed 31.20%, calculated 32.76%). Interestingly the original shape of the crystal was preserved after decomposition.

The thermal decomposition behaviors of **2** and **3** were similar to that of **1**. In both cases, the loss of solvent molecules was completed at relatively low temperature (62°C for **2** and 113°C for **3**). The weight losses corresponding to the loss of dicyanobenzene molecules and the four acetate groups occurred in similar temperature ranges in **2** and **3** and they were not significantly different from those of **1**. The solvent losses indicated a composition of two methanol molecules per dirhodium unit per unit cell in **2** and one ethanol molecule per dirhodium unit per unit cell in **3**.

Compound **4** showed no thermal decomposition until 100°C. This temperature is significantly higher than observed for **1**, **2** and **3**, which lose solvent molecules immediately on heating. The removal of THF and the dicyanobenzene molecules were not well resolved in temperature but the sum of the losses (observed 31.35%, calculated 31.18%) indicated only one THF molecule per formula unit. The weight loss corresponding to the four acetate groups was similar to the value observed for the other compounds. The thermal decomposition of **5** showed three-steps in the weight loss below 178°C, the total weight loss corresponded to the removal of one benzene and one dicyanobenzene molecule (observed 31.81%, calculated 31.82%). The remaining weight losses was similar to other compounds.

4. CONCLUSIONS

Five new one dimensional coordination polymers formed by dirhodium(II)tetraacetate bridged by 1,4-dicyanobenzene have been synthesized and characterized. Each compound has a different solvent molecule filling the cavities between the polymeric chains. The type of solvent apparently plays an important role in the crystallization process and determines the separation and orientation of the polymeric chains. We are currently investigating other solvents that can be introduced between the chains and further work will focus on studying the extensions to 2D and 3D polymers by using multifunctional organic bridging ligands.

(Received 12 February 1998; accepted 21 May 1998)

Abstract—The syntheses of the persulfurated $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$, M = Pd or Pt; $R_F = C_6F_5$ or C_6F_4H-4 compounds allow the separation of two diastereomers and the NMR detection of five conformers (three *anti* and two *syn*) of each compound. ^1H, ^{19}F and ^{195}Pt NMR data have been used to assign each conformer and to obtain their relative populations as well as to follow their equilibrium at high temperatures. The X-ray diffraction molecular and crystalline structure of $[Pt(SC_6F_5)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$ has been determined. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: persulfurated; crystal structure; fluorothiolates; palladium; platinum; sulfur inversion.

1. INTRODUCTION

The chemistry of co-ordination compounds with metal centres surrounded exclusively by sulfur donor ligands has been extensively examined. The interest in this area is due to its relevance to *i.a.* catalysis, bio-inorganics and structural chemistry [1–6].

For complexes containing chiral three co-ordinated sulfur atoms, several structural and kinetic studies have been undertaken with regard to the inter-conversion of isomers that arises from configuration inversion at the sulfur atoms [7,8].

However, for those complexes with three or more possible NMR-observable conformers [9,10], since there is no conclusive evidence to distinguish among spectroscopic signals arising from different conformers, seldom is a precise assignment accomplished [11–13].

Previously [14–16] we were interested in the chemistry of metal centres surrounded exclusively by sulfur atoms and as part of the research done, in this paper we report the syntheses of $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$, M = Pd, $SR_F = SC_6F_5$, **1**; $SR_F = SC_6RH$-4, **2**; M = Pt, $SR_F = SC_6F_5$, **3**; $SR_F = SC_6F_4H$-4, **4**; the separation of two sets of isomers for each complex and the X-ray diffraction crystal structure of a diastereomer of $[Pt(SC_6F_5)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$. The separation of both diastereomers allows, for the first time, a direct identification of the stereoisomers present in solution by ^1H, ^{19}F and ^{195}Pt NMR.

2. EXPERIMENTAL

$[MCl_2\{(meso,rac)\text{-}CH_3SCH(CH_3)CH(CH_3)SCH_3\}]$, M = Pd or Pt [17], $Pb(SC_6F_5)_2$ [18] and $Pb(SC_6F_4H\text{-}4)_2$ [19] were prepared according to published methods.

After $[MCl_2\{(meso,rac)\text{-}CH_3SCH(CH_3)CH(CH_3)SCH_3\}]$, M = Pd or Pt (1.2 mmol) and $Pb(SC_6F_5)_2$ or $Pb(SC_6F_4H\text{-}4)_2$ (1.2 mmol) were dissolved in 60 ml of

* Author to whom correspondence should be addressed.

acetone, the resulting suspensions were magnetically stirred for 2 h at room temperature. $PbCl_2$ was then filtered off and the clear orange or yellow solutions were evaporated to dryness (yields: **1** = 90%, **2** = 84%, **3** = 96% and **4** = 91%).

0.75 g of silica-gel were added to the solids (*ca.* 0.15 g) after they were dissolved in *ca.* 15 ml of acetone. For each compound, the solvent was evaporated and the impregnated silica was placed on top of a chromatographic column and eluted with chloroform:acetone (10:1) to obtain solutions of *cis* [R_f = 3.8, **1**-*cis* (23.5%); R_f = 3.6, **2**-*cis* (47.9%); R_f = 3.1, **3**-*cis* (41.3%); R_f = 3.0, **4**-*cis* (43.2%)] and *trans* [R_f = 4.9, **1**-*trans* (10.9%); R_f = 4.7, **2**-*trans* (25.43%); R_f = 4.4, **3**-*trans* (48.9%); R_f = 4.2, **4**-*trans* (51.8%)] isomers.

Slow evaporation of these solutions at room temperature afforded orange powders or yellow crystals. Analytical data were determined by Galbraith Laboratories, U.S.A.

Infrared spectra were recorded over the 4000–200 cm^{-1} range as CsI pellets on a Perkin-Elmer 1330 instrument equipped with a data station.

^1H, ^{19}F and ^{195}Pt NMR spectra were measured with a SDS-360 MHz and a modified NT-360 spectrometer operating at 360, 282.23 and 77.1 MHz, respectively, by Spectral Data Services (IL, U.S.A.). Chemical shifts are relative to TMS, $\delta = 0$ (^1H); $CFCl_3$, $\delta = 0$ (^{19}F) and $Na_2[PtCl_4]/D_2O$, $\delta = 0$ (^{195}Pt). A standard variable temperature unit was used to control the probe temperature, which was checked periodically by a thermocouple to ensure that temperature readings were kept within ± 1°C. Palladium complexes were studied in $(CD_3)_2CO$ from -37 to 40°C and platinum complexes were studied in $(CD_3)_2CO$ at room temperature and in $(CD_3)_2SO$ at high temperatures.

Crystallographic data for $[Pt(SC_6F_5)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$ **3**-*cis*: $C_{18}H_{14}F_{10}PtS_4$, M = 743.61, a = 7.102(1), b = 19.066(3), c = 16.799(3) Å, β = 94.71(2)°, U = 2267.0(6) $Å^3$, T = 295 K, space group $P2_1/n$, Z = 4, ρ = 2.179 g cm^{-3}, μ = 66.93 cm^{-1}. A crystal of dimensions 0.17 × 0.12 × 0.18 mm was used for indexing and intensity data collection in the scan mode by using graphite monochromatized Mo-Kα radiation in a Siemens AED diffractometer using $\omega/2\theta$ scans ($3 \leq 2\theta \leq 50$°). They were corrected for Lorentz, polarisation and absorption effects. The structure was solved by the Patterson method. All non-hydrogen atoms were anisotropically refined (SHELX-76) [20] and hydrogen atoms were included in the observed positions. Final R and R_w values were 0.024 for 3171 observed reflections [$F \geq 5\sigma(F)$].

3. RESULTS AND DISCUSSION

Methathetical reactions of $[MCl_2\{(meso, rac)\text{-}CH_3SCH(CH_3)CH(CH_3)SCH_3\}]$, M = Pd or Pt with the anionic pseudohalogens $(SC_6F_5)^-$ or $(SC_6F_4H\text{-}4)^-$ in acetone proceeded as expected to give $[M(SR_F)_2\{(meso, rac)\text{-}CH_3SCH(CH_3)CH(CH_3)SCH_3\}]$, M = Pd, $SR_F = SC_6F_5$, **1**; $SR_F = SC_6F_4H$-4, **2**; M = Pt, $SR_F = SC_6F_5$, **3**; $SR_F = SC_6F_4H$-4, **4**; as orange–red (**1** and **2**) or yellow crystalline (**3** and **4**), air stable complexes which are soluble in acetone and dichloromethane. Analytical data consistent with the given formulation have been deposited as supplementary data.

Infrared spectra show characteristic absorption bands of the fluorinated moieties: 1515, 1480, 1085, 975 and 855 cm^{-1} for $SR_F = SC_6F_5$ and 1480, 1430, 1165 and 910 cm^{-1} corresponding to $SR_F = SC_6F_4H$-4 [19]. Other infrared frequencies agree with the dithiolate ligand expected absorptions, but have been omitted since they are of limited value to the following discussion.

From each compound **1** to **4**, two isomers were separated by dry column chromatography on silica-gel by using a chloroform–acetone mixture as eluent as described in Section 2.

Single crystals of the **3**-*cis*, were isolated by slow evaporation of chloroform:acetone solutions at room temperature. The X-ray diffraction structure of **3**-*cis* is shown in Fig. 1 and selected geometric data are collected in Table 1.

The molecules exhibit a slightly distorted square-planar arrangement around the platinum centre, with four co-ordinated sulfur atoms showing a clear sp^3 hybridisation. The racemic mixture of the *cis* isomer crystallise as the conformer with a formal alternate chiral configuration, *RSRS* or *SRSR*, in the chiral atoms of the chelated thioether ligand $CH_3S\text{-}CH(CH_3)CH(CH_3)SCH_3$. The molecular structure of **3**-*cis* corresponds to isomer **A** (see Fig. 4 below).

Sharp *et al.* [21] have found a closely related structure for $[PtCl_2(CH_3SCH(CF_3)CH(CF_3)SCH_3)]$ in which the trifluomethyl groups lie on the opposite side of the chelate ring from the methyl substituents.

The observed mean values for the Pt–S (Pt–SR_F 2.317 and Pt–SC_2 2.291 Å) and S–C [S–C(sp^2) 1.765 and S–C(sp^3) 1.817 Å] bond distances are similar to those found on the related *trans*-$[Pt(SC_6F_5)(SEt_2)_2]$ [16] [Pt–SR_F 2.323, Pt–SC_2 2.302; S–C(sp^2) 1.760, S–C(sp^3) 1.808 Å].

For $[PtCl_2(CH_3SCH(CF_3)CH(CF_3)SCH_3)]$ [21] the platinum–sulfur mean distance is slightly shorter (Pt–SC_2 2.237 Å) probably reflecting a lower *trans*-influence of the chloride ligand as compared with that of the $SC_6F_5^-$ moiety [22]. In general, sulfur–carbon lengths agree satisfactorily with the ranges described for this type of bond distance [23].

The isomers separated from these complexes can be explained simply in terms of the relative orientation of the substituents on methine groups (*cis* and *trans* diastereomers). As shown in Fig. 2, the ring is puckered at the carbon atoms but, as is the case with five membered rings at room temperature, there is fast ring inversion in all species investigated to date. At low temperature, however, few conformers have been previously identified in solution [17].

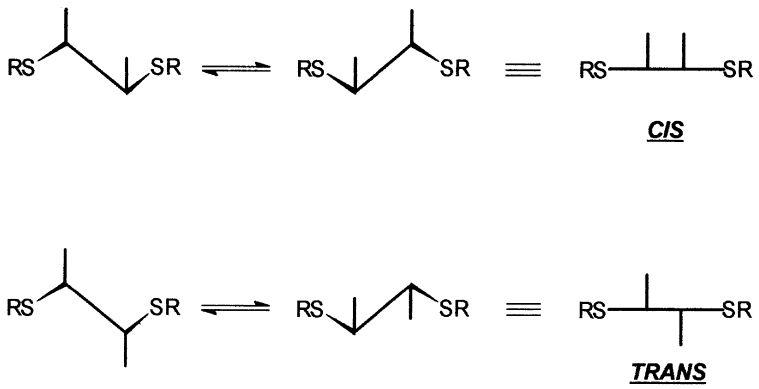

Fig. 2. Diagram representing compounds $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$. The $M(SR_F)_2$ unit lies perpendicular to the paper and in the plane defined by the sulfur atoms.

NMR spectra of compounds *cis* and *trans* revealed the expected presence of further isomeric forms arising from the relative position of the methyl substituents on the sulfur atoms with respect to the plane of the metal co-ordination, giving rise to *anti* and *syn* isomers, as exemplified in Fig. 3.

Anti and *syn* conformers can undergo an interconversion process through inversion of configuration at the sulfur centers. These conformational changes of the sulfur substituents are slow enough as to be detected by NMR experiments.

All together, the relative orientations of both sulfur and carbon substituents can, therefore, generate two different sets of non-interconvertable isomers (*cis* and *trans*) with three NMR-detectable and interconvertable conformers in each set, as shown on Fig. 4.

Therefore, in terms of NMR spectroscopy, both methyl substituents on the sulfur atoms (CH_3–S) are equivalent in isomers **A**, **C**, **D** and **F**, whereas isomers **B** and **E** bear pairs of magnetically non-equivalent CH_3–S moieties. Exactly the same is valid when the CH_3–C and R_F–S fragments are considered.

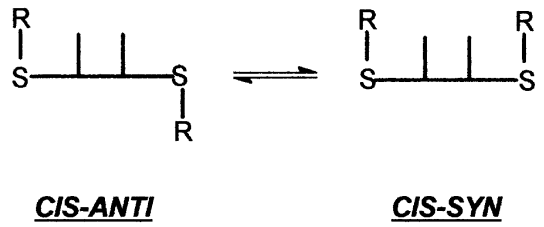

Fig. 3. *Anti* and *syn* isomers of $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$.

3.1. *Cis-diastereomers*

NMR selected parameters for compounds **1**-*cis* to **4**-*cis* are collected in Table 2.

^{1}H NMR spectra of isomers *cis* show three doublets arising from the CH_3–C fragments. In all cases two of these doublets have exactly the same intensity, which suggests that they arise from two non-equivalent methyls attached to the same molecule. These absorptions can, therefore, be assigned unambiguously to isomer **B** in Fig. 4. The third doublet arises from an isomer with magnetically equivalent methyl substituents, which is the case of either **A** or **C**; no definite assignment can be made at this point, however.

Proton NMR spectra also show a complicated overlap of signals due to the -CH–CH- skeleton and, as before, three signals for the CH_3–S substituents which, for compounds **3** and **4**, exhibit satellites characteristic of magnetic coupling with platinum (^{195}Pt, 34% abundance). J_{Pt-H}(**3**-*cis*) = 42.1 Hz and J_{Pt-H}(**4**-*cis*) = 42.1 Hz.

In addition, when $R_F = C_6F_4H$-4 (*cis*-compounds **2** and **4**), three triplets of triplets, characteristic of the X part of two distinct A_2B_2X magnetic systems, are detected.

This fact is of interest and seldom observed since practically all spectroscopic studies on this type of compound focus on the neutral ligand. Very few of the anionic ligands used before are suitable for NMR observation. The fluorothiolates involved in this work thus allow the distinction between magnetic non-equivalence brought up by the molecular asymmetry.

The presence of distinguishable thiolates is also reflected on the ^{19}F NMR spectra, showing three doublets for the *ortho*-fluorine atoms, a complicated multiplet of overlapping signals due to *meta*-fluorine

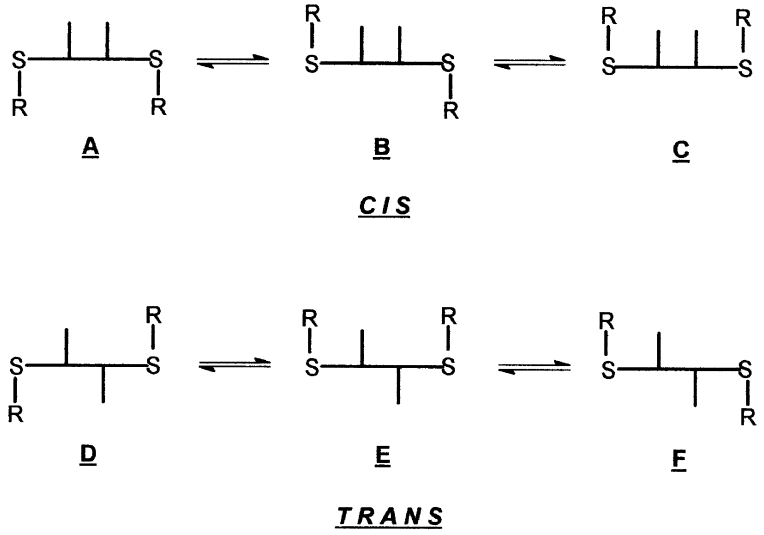

Fig. 4. *Cis* and *trans* isomers of $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$.

atoms and, for complexes **1** and **3**, three triplets arising from the fluorine atoms in the *para* position of the fluorinated ring [Fig. 5(a)].

This spectroscopic information is consistent with the presence of only two out of the three, **A**, **B** and **C** possible isomers. Considering the multiplicity observed on the NMR signals, isomer **B** can be recognised unambiguously, but a distinction between **A** and **C** (Fig. 4) is not evident.

Further evidence for the presence of a single pair of isomers was able to be gained from $^{195}Pt-\{^1H\}$ NMR spectra of compounds **3**-*cis* and **4**-*cis* at room temperature. **3**-*cis* shows two singlets at $\delta_{Pt} = -4253$ and −4251 ppm with a relative proportion of 5.9 to 1. **4**-*cis* shows two absorptions at $\delta_{Pt} = -4340$ and −4339 ppm with 3.5 to 1 relative intensities.

Molecular models indicate extensive steric interactions between the sulfur and carbon substituents and they appear to be in the order **A** < **B** < **C**. In agreement with this order in which the least hindered isomers are predicted to have equivalent methyl–sulfur substituents, it is reasonable to assume that the most abundant isomer is **A**, while **C** has the lowest, unobservable, concentration. Assignment of signals at $\delta_{Pt} = -4253$ (**3**-*cis*) and −4340 (**4**-*cis*) ppm to isomers **A** rather than to isomers **C**, seems further supported by the fact that the structure found in the solid state for $[Pt(SC_6F_5)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$ is in fact that of isomer **A**.

According to that assignment, the relative population of isomers **A** and **B** (Fig. 4), for compounds **1** to **4**, are given in Table 3.

3.2. *Trans-diastereomers*

NMR selected parameters for compounds **1**-*trans* to **4**-*trans* are collected in Table 4.

^1H NMR spectra of complexes *trans* show a complex, ill-defined multiplet on the CH_3–C region. Four signals, however, arising from the CH_3–S fragments, were clearly observed.

For compounds **3** and **4**, these signals exhibit satellites characteristic of $^1H-^{195}Pt$ magnetic coupling with platinum (^{195}Pt, 34% abundance). J_{Pt-H}(**3**-*trans*) = 41.4 Hz and J_{Pt-H}(**4**-*trans*) = 42.5 Hz.

For all compounds **1** to **4**, two of these signals have exactly the same intensity, suggesting that they arise from two non-equivalent methyls attached to the same molecule. These absorptions can, therefore, be assigned unambiguously to isomer **E** in Fig. 4. The remaining two signals are resonances from isomers **D** and **F**, both having magnetically equivalent methyl substituents.

Proton NMR spectra also display a complex multiplet of overlapping signals due to the -CH–CH- skeleton. In addition, when $R_F = C_6F_4H$-4 (*trans*-compounds **2** and **4**), four signals characteristic of the X

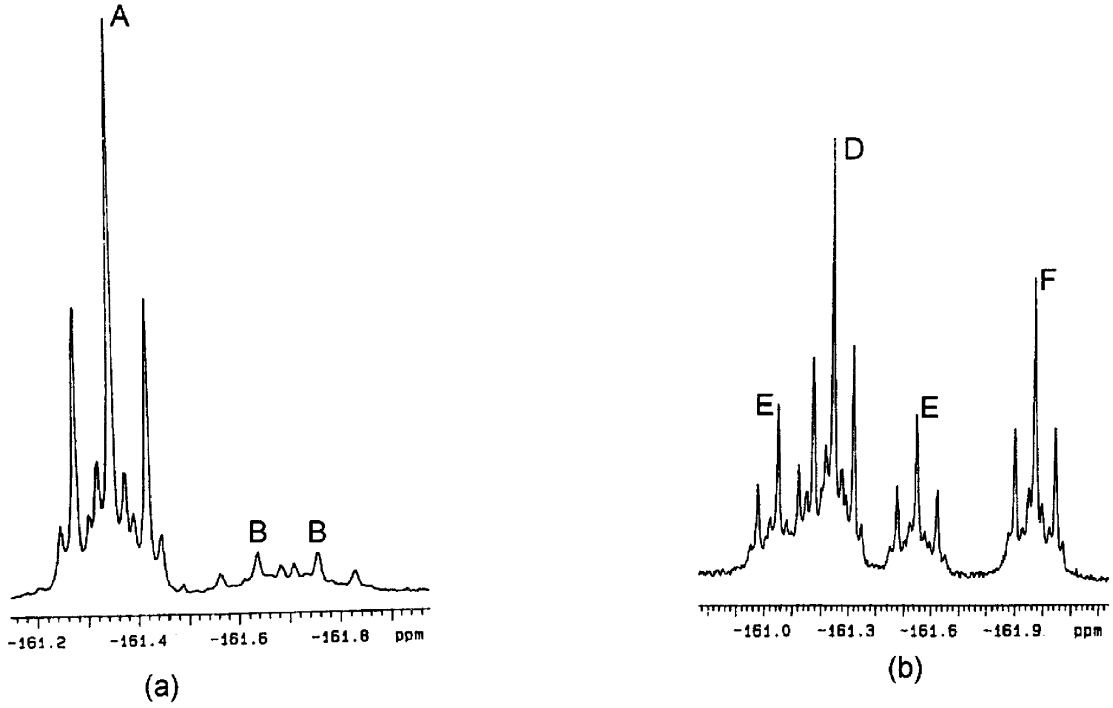

Fig. 5. ^{19}F NMR of *para*-fluorine region of $[Pt(SC_6F_5)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$ **3**-*cis* (a) and **3**-*trans* (b).

Table 3. Relative isomeric populations for $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$, M = Pd (237 K), $R_F = C_6F_5$ **1**; C_6F_4H-4 **2**; M = Pt(298 K), $R_F = C_6F_5$ **3**; C_6F_4H-4 **4**

	Cis			*Trans*		
	A	**B**	**C**	**D**	**E**	**F**
1	6.3	1	–	1.1	1.4	1
2	5.6	1	–	1.1	1.3	1
3	5.9	1	–	1.3	1.1	1
4	3.5	1	–	1.2	1.1	1

part of three different A_2B_2X magnetic systems, are detected.

^{19}F NMR spectra show four doublets for the *ortho*-fluorine atoms, a complicated multiplet of overlapping signals due to *meta*-fluorine atoms and, for complexes **1** and **3**, four triplets of triplets arising from the fluorine atoms in the *para* position of the fluorinated ring [Fig. 5(b)]. No ^{19}F–^{195}Pt magnetic couplings were observed.

The available spectroscopic information is consistent with the presence of isomers **D**, **E** and **F** (Fig. 4) in solution of compounds **1**-*trans* to **4**-*trans*.

Further evidence of such an isomeric distribution is gained from ^{195}Pt–$\{^1H\}$ NMR spectra of compounds **3**-*trans* and **4**-*trans* which show, at room temperature, three singlets at $\delta_{Pt} = -4252$, -4257 and -4261 ppm and $\delta_{Pt} = -4339$, -4342 and -4343 ppm, respectively. The relative intensities of these signals are 1.3:1.1:1 for **3**-*trans* and 1.2:1.1:1 for **4**-*trans*.

As seen before, molecular models indicate considerable steric interactions between the sulfur and carbon substituents, which appear to be in the order **D** < **E** < **F**. In agreement with this order in which the least hindered isomers are predicted to have *anti* and equivalent sulfur substituents, the most abundant isomer is probably **D**, whereas **F** appears to be the least abundant.

The relative populations assigned to *trans*-isomers **D**, **E** and **F** (Fig. 4), for compounds **1** to **4**, are given in Table 3.

Conformers **A** and **B**, on the one hand, as well as **D**, **E** and **F**, on the other, are involved in dynamic equilibria due to a configuration inversion at the thioether sulfur atoms. The pyramidal inversion is a relatively slow process suitable for detection within the NMR time scale as the individual absorptions from each isomer coalesce into a single averaged resonance.

As expected, the thiolate ligands seem to have fast free rotation and, at room temperature and higher, do not participate in the fluxionality of these molecules.

For comparable compounds, palladium derivatives show lower coalescence temperatures than does platinum. This can be attributed to the more effective 3p(S)–4d(Pd) overlap compared with the 3p(S)–5d(Pt)

Table 4. NMR selected parameters for *trans*-diastereomers of $[M(SR_F)_2(CH_3SCH(CH_3)CH(CH_3)SCH_3)]$ **1**–**4**, M = Pd, $(CD_3)_2CO$ at 237 K; M = Pt, $(CD_3)_2CO$ at 298 K

overlap, which allows an easier access to the transition state in the case of palladium complexes [24]. In fact, palladium derivatives show slow sulfur inversion at 237 K while platinum derivatives show it at 298 K in $(CD_3)_2CO$ solutions.

For palladium complexes we have measured coalescence temperatures by observing the ^{19}F NMR spectra of the thiolate moieties. For platinum complexes, coalescence temperatures were determined directly from the variable temperature ^{195}Pt NMR spectra. Coalescence temperatures are collected in Table 5.

Cis-compounds **1** to **4** show a single coalescence of signals in agreement with the fast interconversion **A**⇔**B**. On the other hand, *trans*-compounds **1** to **4** give rise to two consecutive temperatures of coalescence, in agreement with a process involving three species: **D**⇔**E**⇔**F** for which two different energies of inversion are reasonably to be expected (Fig. 6).

In summary, NMR studies of each diastereomer of complexes **1** to **4** show the presence of three conformers of the *trans* isomers but only two of the *cis* isomer. In general, NMR spectra are quite similar and only slight changes in the relative isomeric populations were observed. As expected, relative abundances can be detected regardless of the observed nuclei.

(Received 23 March 1998; accepted 21 May 1998)

Abstract—The known bis(bis(trimethylsilyl)amino)alane $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ (**1**) is obtained from disproportionation of the base-stabilized monomeric bis(trimethylsilyl)aminoalane $[(Me_3Si)_2NAlH_2]\cdot NMe_3$ in refluxing toluene. The single-crystal X-ray structure determination for **1** provides a H-bridged planar dimer with exo-cyclic $N(SiMe_3)_2$ groups. The combination of **1** with $HNMe_2$ in a 1:1 ratio results in competing aminolysis at the Al–H site and transamination at the Al–$N(SiMe_3)_2$ site of **1**, as illustrated by the molecular structure of $(Me_3Si)_2N(Me_2N)Al(\mu\text{-}NMe_2)_2Al(H)N(SiMe_3)_2$ (**2**) which is isolated from this system. The characteristic structural feature of **2** is a puckered {Al–N–Al–N} ring with different ligands on two aluminum atoms.

INTRODUCTION

In the solid state, some alane amine adducts show dimeric connectivities $[H_3Al\cdot L]_2$ (for example, $L=NMe_3$ [1], NMe_2CH_2Ph [2]) with five-coordinated aluminum atoms and somewhat counterintuitive unsymmetrical Al–H–Al bridges while, on the other hand, others seem to favor a monomeric mode with four-coordinated Al in $H_3Al\cdot L$ (for example, $L=N(n\text{-}Bu)_3$ [3], quinuclidine [4]) or five-coordinated Al having a N–$Al(H_3)$–N bond sequence as in trigonal bipyramidal $H_3Al\cdot 2NMe_3$ [5]. This span of bonding preferences in the alane adducts is generally interpreted as a manifestation of the ligand's steric hindrance and is not an exclusive property of amine Lewis bases. The latter is illustrated by examples of the Al–H–Al bridged dimer $[H_3Al\cdot THF]_2$ and trigonal bipyramidal $H_3Al\cdot 2THF$ with an O–$Al(H_3)$–O axis [6]. Even more complex bonding environments are encountered in some polymeric structures containing AlH_3 units [7]. Finally, ionic bonding is displayed by rare species of the type $(H_2AlL)^+(AlH_4)^-$ where L is a tri- or tetradentate amine ligand [8]. The progress in the chemistry of Lewis base adducts of alane and gallane has recently been reviewed [9].

The aminoalanes, $\{H_nAl(NR_2)_{3-n}\}$ ($n=0$, 1, 2), appear to exhibit similar diversity of bonding as outlined above for alane amine adducts but relatively shorter Al–N bond lengths in the former make the steric factor play a more obvious role. For example, the dimethylaminoalane, $(H_2AlNMe_2)_3$, is a N-bridged trimer in solution [10] and in the solid state [11] but both bis(dimethylamino)alane, $[HAl(NMe_2)_2]_2$ [12], and tris(dimethylamino)alane, $[Al(NMe_2)_3]_2$ [13, 14], are N-bridged dimers. Even

larger NR_2 groups may result in N-bridged dimeric cores such as found in 2,6-dimethylpiperidinoalane, $[H_2Al(dmp)]_2$ [15]. A further increase of the bulkiness of the piperidino ligand, in the absence of NMe_3 as in the reaction between $LiAlH_4$ with $(tmpH) \cdot HCl$, yields a postulated H-bridged trimer 2,2,6,6-tetramethylpiperidinoalane, $[H_2Al(tmp)]_3$, or, even in the presence of NMe_3 in the reaction between $H_3Al \cdot NMe_3$ with 2 equivalents of tmpH, gives the authenticated H-bridged dimer bis(2,2,6,6-tetramethylpiperidino)alane, $[HAl(tmp)_2]_2$ [15]. On the other hand, an extreme bulkiness of $N(SiMe_3)_2$ coupled with a latent N-basicity in this group is thought to be responsible for the kinetic stabilization of the unassociated $Al[N(SiMe_3)_2]_3$ [16].

In addition to the formation of the N- or H-bridged aminoalanes, stabilization of the aminoalane unit by an available Lewis base may sometimes also be favorable. In systems utilizing the convenient form of alane, $H_3Al \cdot NMe_3$, trimethylamine as a potent Lewis base is found in a few cases to play that role. It was originally reported that the monomeric aminoalane, stabilized by coordination of NMe_3 at the Al-site, $[H_2AlN(SiMe_3)_2] \cdot NMe_3$, was formed from the reaction between $H_3Al \cdot NMe_3$ and $HN(SiMe_3)_2$ [17, 18]. This finding was later confirmed in a parallel study, which additionally provided a structural proof for the related $[H(Cl)AlN(SiMe_3)_2] \cdot NMe_3$ [19]. Further, a 1:1 ratio reaction between $H_3Al \cdot NMe_3$ and tmpH afforded $[H_2Al(tmp)] \cdot NMe_3$ [20], which can be compared with the previously discussed H-bridged trimer $[H_2Al(tmp)]_3$ [15] obtained in the absence of trimethylamine. One should be aware that this kind of adduct stabilization extends into other group 13–group 15 systems and, for example, is also found in the pnictinoalanes $[H_2AlEMes_2] \cdot NMe_3$ (E = P, As) [21] and $[H_2AlAs(SiMe_3)_2] \cdot NMe_3$ [22].

The original reports by Paine and coworkers on the preparation of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ [17, 18] indicated that thermal decomposition of this compound resulted in the formation of new bis(bis-(trimethylsilyl)amino)alane $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_n$ of an undetermined degree of oligomerization; some analytical evidence, however, supported the presence of Al–H–Al bridges in this product [18]. This was contrary to what the parallel report by Raston and coworkers claimed about the thermal behavior of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ [19], namely, decomposition to elemental aluminum presumably along a reductive coupling pathway with dihydrogen evolution and, here, additionally, with concurrent release of NMe_3. In this regard, one has to be aware that reductive coupling is not the only thermally induced decomposition pathway for aminoalanes and it has long been known that their ligand disproportionation chemistry is of equal importance [12, 23]. Herein, we confirm the originally reported disproportionation of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ and describe the single-crystal X-ray diffraction study for the resulting H-bridged dimer, bis(bis(trimethylsilyl)amino)alane $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ (**1**). We also outline the reaction of **1** with $HNMe_2$ and the isolation of an unsymmetrically substituted product $(Me_3Si)_2N(Me_2N)Al(\mu\text{-}NMe_2)_2Al(H)N(SiMe_3)_2$ (**2**) for which a single-crystal structure is presented.

EXPERIMENTAL

General techniques

All experiments were carried out using standard vacuum/Schlenk techniques. Solvents were dried and distilled from Na benzophenone ketyl or Na/K alloy prior to use. $HNMe_2$ was obtained from Aldrich and used as received. $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ and $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ were prepared by the literature methods [18]; the synthesis and characterization of the latter is also described in more detail below. ^1H and $^{13}C\{^1H\}$ NMR spectra were acquired on a Varian Unity 400 spectrometer at 25°C from toluene-d_8 solutions and referenced vs $SiMe_4$ by generally accepted methods. Mass spectra were collected on a JEOL JMS-SX 102A spectrometer operating in the EI mode at 20 eV. IR spectra of solids and oily products were acquired using KBr pellets and NaCl plates, respectively, on a BOMEM Michelson MB-100 FT-IR spectrometer. A calibrated manifold was used for volume estimations of reaction gases. Melting behavior (uncorrected) was determined with a Thomas-Hoover Uni-melt apparatus for samples flame-sealed in glass capillaries. Single-crystal X-ray diffraction studies for **1** and **2** were performed at the Department of Chemistry and Biochemistry, University of Delaware, Newark, DE, on a Siemens P4/CCD diffractometer, using Mo Kα radiation ($\lambda = 0.71073$ Å). All calculations were carried out with the help of SHELXTL 5.03 programs [24]; the structures were solved by direct methods.

Preparation of $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ (**2**)

A sample of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$, 1.24 g or 5.0 mmol, was dissolved in about 10–15 mL of toluene, stirred and refluxed overnight under nitrogen. Typically, elemental aluminum precipitated on the sides of reaction flask in the form of agglomerates but, sometimes, aluminum would form as a colloidal suspension. The mixture was concentrated by evacuation to about 5–10 mL and refluxed for an additional 24 h. Subsequently, it was filtered, the volatiles evacuated from the filtrate and the resulting residue dissolved in a few mL of hexane. The concentrated hexane solution, after storage at −30°C, afforded abundant colorless crystals of **1**, 0.48 g or 55% yield based on eqn (1) (*vide infra*). More crystalline product could be recovered from the solution by further concentrating and repeating the low temperature crystallization. M.p. 95–97°C. ^1H NMR: δ 0.34 (36H; $SiMe_3$), 4.4 (1H, br; AlH). $^{13}C\{^1H\}$ NMR: δ 6.0 ($SiMe_3$). MS: *m*/*e* (inten-

sity) (ion): peak clusters around: 695 (1) ($\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$–*H* or *M*–*H*), 667 (1) (*M*–2Me + H), 596 (1) (M–$SiMe_3$ + 3H), 552 (2) (M–2$SiMe_3$ + 2H), 536 (2) (M–*N*$(SiMe_3)_2$), 492 (3) (M–*N*$(SiMe_3)_2$–3Me + H), 461 (2) (M–*N*$(SiMe_3)_2$–5Me) 421 (5) (M–*N*$(SiMe_3)_2$–$SiMe_3$–3Me + 3H), 347 (3) ($[(Me_3Si)_2N]_2AlH$–*H* or *M**–*H*), 331 (2) (*M**–Me–2H), 300 (2) (*M**–3Me–3H), 275 (3) (*M**–$SiMe_3$), 202 (3) (*M**–2$SiMe_3$), 161 (20) ($HN(SiMe_3)_2$), 146 (100) ($HN(SiMe_3)_2$–Me), 130 (10) ($HN(SiMe_3)_2$–2Me–H), 74 (9) ($HSiMe_3$). IR (KBr pellet/Nujol mull): *v*(Al–H) range, 1882/1880 cm^{-1}. We note that these Al–H stretching frequencies significantly differ from that of a weak band at 1790 cm^{-1} originally reported for **1** [18]. In the present study, the medium intensity band at about 1880 cm^{-1} was reproducible, but its intensity was decreasing fast in the course of measurements due to deterioration of the sample. At this point, we are inclined to think that the band reported earlier might have been recorded for a significantly decayed sample.

Reactions of $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ *with* $HNMe_2$. *Isolation of* $(Me_3Si)_2N(Me_2N)Al(\mu\text{-}NMe_2)_2Al(H)N(SiMe_3)_2$ (**2**)

0.10 g of **1** (0.14 mmol) was dissolved in about 10 mL of toluene and the reaction flask was freeze-pump-thawed three times. Onto this, using a calibrated vacuum line, 0.29 mmol of $HNMe_2$ was deposited at −78°C. The mixture was stirred at room temperature overnight and non-condensables, H_2, were measured, 0.04 mmol. The solution was then stored for a few days at −30°C. At the end of this period, the volatiles were removed yielding an oil/solid product. IR (neat): weak to medium band in the *v*(N–H) range at 3310 cm^{-1}; medium band in the *v*(Al–H) range at 1833 cm^{-1}. A toluene-d_8 NMR sample of this product was run immediately, 1 day, 2 weeks and 7 weeks after preparation.

Immediately: ^1H NMR (intensity) (group assignment): $SiMe_3$ region: δ 0.08 (9) ($HN(SiMe_3)_2$), 0.27 (23), 0.31 (24), 0.33 (100); NMe_2 region: δ 1.88 (9), 1.89 (9) and several small intensity peaks (<1) in this region at 2.29, 2.32, 2.41, 2.42, 2.51, 2.60, 2.76; AlH region: δ 4.0 (very broad), 4.51. $^{13}C\{^1H\}$ NMR (intensity) (group assignment): $SiMe_3$ region: δ 2.6 (7) ($HN(SiMe_3)_2$), 5.0 (3), 6.2 (100), 6.5 (16), 6.8 (4); NMe_2 region: δ 37.9 (24), 40.4 (1), 41.6 (2), 42.0 (3), 43.2 (2), 43.5 (7).

1 day after: ^1H NMR (intensity) (group assignment): $SiMe_3$ region: δ 0.08 (100) ($HN(SiMe_3)_2$), 0.27 (50), 0.31 (80), 0.33 (35); NMe_2 region: δ 1.88 (1), 1.89 (1), 2.42 (15), 2.51 (1), 2.60 (8), 2.76 (2); no unequivocally measurable broad feature in the AlH region except for the sharp resonance at δ 4.51. $^{13}C\{^1H\}$ NMR (intensity) (group assignment): $SiMe_3$ region: δ 2.6 (90) ($HN(SiMe_3)_2$), 4.9 (55), 6.2 (70), 6.5 (100), 6.8 (14); NMe_2 region: δ 37.9 (13), 40.4 (15), 41.6 (5), 42.0 (10), 43.2 (10), 43.5 (70).

2 weeks after: ^1H NMR (intensity) (group assignment): $SiMe_3$ region: δ 0.08 (100) ($HN(SiMe_3)_2$), 0.27 (55), 0.31 (83), 0.33 (6); NMe_2 region: δ 1.88 (1), 1.89 (1), 2.42 (16), 2.52 (3), 2.60 (8), 2.76 (4); AlH region: δ 4.1 (broad), 4.51. $^{13}C\{^1H\}$ NMR (intensity) (group assignment): $SiMe_3$ region: δ 2.6 (83) ($HN(SiMe_3)_2$), 4.9 (63), 6.2 (35), 6.5 (100), 6.8 (32); NMe_2 region: δ 37.9 (1), 40.4 (20), 41.6 (16), 42.0 (19), 43.2 (17), 43.5 (65).

7 weeks after: The NMR spectra were identical to those obtained after 2 weeks. The oily/solid product was redissolved in a small amount of toluene and, subsequently, volatiles were allowed to evaporate at −30°C in the course of several days. After almost complete removal of volatiles, a small quantity of a colorless crystalline product was isolated. A single-crystal X-ray structure determination provided $(Me_3Si)_2N(Me_2N)Al(\mu\text{-}NMe_2)_2Al(H)N(SiMe_3)_2$ (**2**). ^1H NMR for a freshly prepared sample (intensity) (group assignment): $SiMe_3$ region: 0.281 (85), 0.284 (100), 0.29 (63), 0.30 (77), 0.31 (52), 0.32 (71), 0.33 (58); NMe_2 region: δ 2.42 (14), 2.52 (12), 2.66 (25), 2.77 (19), 2.78 (16); AlH region: no discernible feature between δ 3.0–5.0. This sample was also run two days after preparation and showed an even more complex spectrum indicating continuing changes in the solution. IR (KBr pellet): *v*(Al–H) range, medium to strong band at 1860 cm^{-1}.

Structural determinations for **1** *and* **2**

Specimens of **1** were obtained in the form of thin colorless needles from recrystallization in toluene at −30°C and mounted in capillaries prior to determination. The systematic absences in the diffraction data were consistent with monoclinic space groups $P2_1/m$ and $P2_1$ but only the latter yielded computationally stable results and refinement. The structure was solved using direct methods, completed by subsequent difference Fourier syntheses and refined by full-matrix least-square procedures. All non-hydrogen atoms were refined with anisotropic displacement coefficients. All C-hydrogen atoms were treated as idealized contributions. The Al-hydrogen atoms were located from the difference map and were refined with fixed thermal parameters and fixed Al–H distances, 1.727(1) Å. The geometry of the {Al–H–Al–H} ring was not constrained. There are two symmetry independent, but chemically similar, molecules in the asymmetric unit and the thermal ellipsoid diagram of molecule 1 is shown in Fig. 1. The thermal ellipsoid diagram of molecule 2 is available in the Supporting Information. Specimens of **2** were obtained as blocky colorless crystals from slow evaporation of toluene at −30°C and mounted in capillaries prior to determination. The data were consistent with the monoclinic space group $P2_1/n$. The structure was solved using direct methods, completed by subsequent difference Fourier syntheses and refined by full-matrix

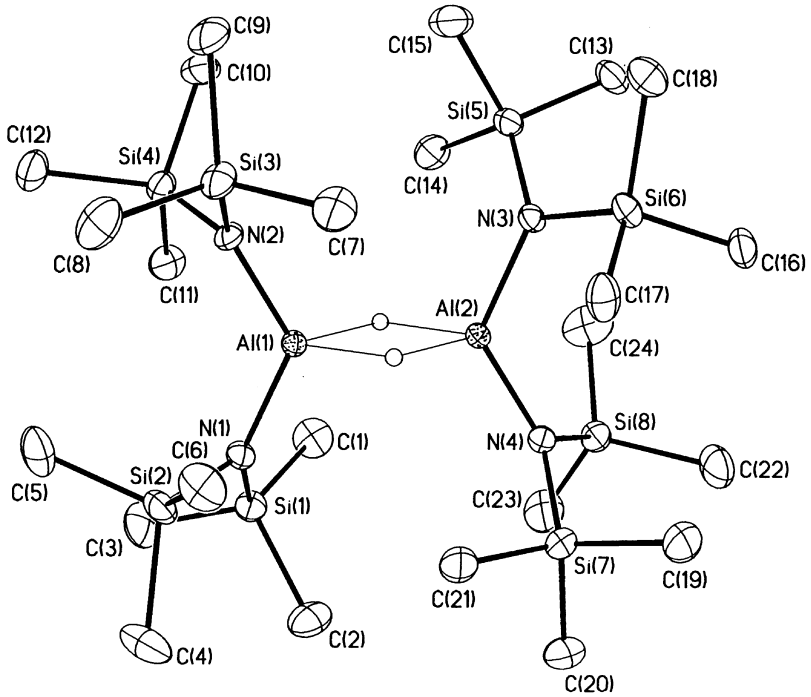

Fig. 1. Thermal ellipsoid diagram (30% probability ellipsoids) showing the molecular structure of **1** (independent molecule 1). All C-hydrogen atoms are omitted for clarity.

least-square procedures. Semi-empirical absorption corrections were not required because there was less than 10% variation in the integrated Ψ-scan intensity data. The Si–N distances were restrained to an average N–Si distance of 1.74 Å. All non-hydrogen atoms were refined with anisotropic displacement coefficients. The hydrogen atom on Al(1) was placed in an idealized position with the fixed Al–H distance of 1.50 Å. All other hydrogen atoms were treated as idealized contributions. The residuals for **2** are rather high due to marginal quality of the specimen. However, the metric parameters and their esd's around aluminum atoms appear to be of acceptable quality. The thermal ellipsoid diagram of **2** is shown in Fig. 2. Details of the

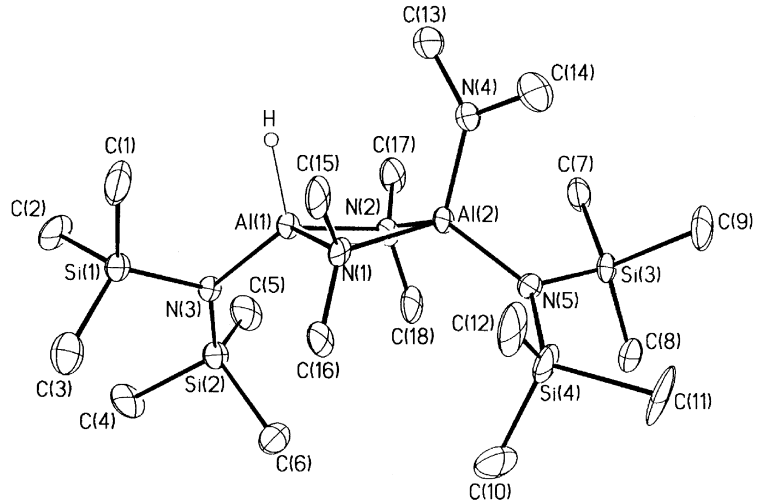

Fig. 2. Thermal ellipsoid diagram (30% probability ellipsoids) showing the molecular structure of **2**. All C-hydrogen atoms are omitted for clarity.

data collection for **1** and **2** are summarized in Table 1, and Table 2 shows selected bond distances and angles.

RESULTS AND DISCUSSION

Bis(bis(trimethylsilyl)amino)alane $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ (**1**) was obtained from disproportionation of the based-stabilized monomeric aminoalane $[H_2AlN(SiMe_3)_2]\cdot NMe_3$ as described by the following idealized equation [18]:

$$2[H_2AlN(SiMe_3)_2]\cdot NMe_3 \xrightarrow[\text{toluene}]{\text{reflux}} H_3Al\cdot NMe_3 + 1/2\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2 \quad (1)$$
$$\downarrow$$
$$Al + 3/2H_2 + NMe_3$$

The anticipated formation of the alane trimethylamine byproduct, $H_3Al\cdot NMe_3$, would have been associated with its decomposition under toluene reflux conditions and precipitation of elemental aluminum [25], which was indeed observed. We found this disproportionation reaction to be crucially dependent on the substrate's concentration. For example, dilute toluene solutions did not show signs of the precipitation of elemental aluminum even after a several day-long reflux. On the other hand, appropriately concentrated solutions appeared to react as above in the course of several hours while intermediate removal of some toluene by evacuation accelerated the reaction's progress and resulted in increased yields. The isolation of **1**, after filtering out aluminum, was accomplished by low temperature recrystallization from hexane in which it was much less soluble than was unreacted $[H_2AlN(SiMe_3)_2]\cdot NMe_3$.

The characterization data acquired for **1** in this study were consistent with its chemical make-up as originally reported [18]. In particular, the mass spectrum showed the parent ion for the dimer and other logically derived fragmentation ions. A few higher than dimer *m/e* fragments of extremely low intensity (<1%) were also detected. This indicated that the dimeric association via H-bridges generally survived the heated probe and electron impact conditions in the MS experiment. The ^1H and $^{13}C\{^1H\}$ NMR spectra were in agreement with the original NMR data for **1** and, based on their simplicity, supported a symmetrical environment for the $N(SiMe_3)_2$ groups while excluding a possible rigid, N-bonded structure.

The crystallographic determination for **1** provided two symmetry independent, but chemically similar, molecules in the asymmetric unit. Fig. 1 shows the structure of one of the molecules. The molecule of **1** is a H-bridged dimer which is structurally very similar although not isomorphous with the H-bridged dimer bis(2,2,6,6-tetramethylpiperidino)alane, $[HAl(tmp)_2]_2$ [15], or related F-bridged dimer $[(tmp)_2AlF]_2$ [26]. For example, the wide average N–Al–N angle in **1**, 124.6°, can be compared with the same angles in $[HAl(tmp)_2]_2$,

126.9(1)° and $[(tmp)_2AlF]_2$, 128.6(1)° and they all may reflect similar steric demands of the amino groups in these compounds. The environment around each N-atom in **1** is planar (2Si, N and Al connected atoms lie in the same plane; sum of relevant angles is close to 360°) and, although it is tempting to associate this property with a mostly dΠ(Si)–pΠ(N) interaction in the $N(SiMe_3)_2$ ligand, a planar environment appears to exist in the similar {2C, N, Al} fragment in $[HAl(tmp)_2]_2$ which is lacking such an interaction.

The average Al–N bond length in **1**, 1.824 Å, belongs to short distances of this type and its magnitude seems to be a consequence of a tetracoordinate Al atom bonded to a sterically congested tricoordinate N atom. This is strikingly supported by comparison with the Al–N distances in the relevant cases of the previously discussed $[HAl(tmp)_2]_2$, 1.835(3) Å, and $[(tmp)_2AlF]_2$, 1.832(2) Å, as well as of $[H(Cl)AlN(SiMe_3)_2]\cdot NMe_3$ [19], 1.823(4) Å [for $Al–N(SiMe_3)_2$]. Shorter Al–N distances are found in tricoordinate Al/tricoordinate N structures, for example, monomeric $Al[N(SiMe_3)_2]_3$, 1.78(2) Å [16], or six-membered planar ring $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$, 1.782(4) Å [27], but in the extremely congested monomeric *t*-$Bu_2AlN(SiPh_3)_2$ this distance is 1.880(4) Å [28]. On the other hand, in tetracoordinate Al/tetracoordinate N ring or cluster structures these lengths typically span the 1.9 to 2.0 Å range, for example, as in cubane $(PhAlNPh)_4$, 1.914(5) Å [29], dimer $[(Me_3Si)_2AlNH_2]_2$, 1.955 Å [30] and trimer $(t\text{-}Bu_2AlNH_2)_3$, 2.008 Å [31], although in the dimer $\{[(Me_3Si)_2N]_2AlNH_2\}_2$ this bond length is much shorter, 1.841 Å (av) [32]. These trends are illustrated by the structure of $(Me_3Si)_2N(Me_2N)Al(\mu\text{-}NMe_2)_2Al(H)N(SiMe_3)_2$ (**2**) (*vide infra*) that contains Al atoms connected to both tricoordinate N atoms (terminal congested $N(SiMe_3)_2$ and noncongested NMe_2) and tetracoordinate N atoms (bridging NMe_2).

The Al–H distance of 1.727(1) Å in **1** is one of the longest among similar symmetrical Al–H bridging distances, possibly indicating a loose association of the monomers in the solid state. However, this can not be reconciled in a straightforward way with the dimer parent ion in the gas phase detected by mass spectrometry. This distance can be compared with the average Al–H lengths in the previously discussed symmetrical dimer $[HAl(tmp)_2]_2$, 1.68 Å or trimer (*t*-$Bu_2AlH)_3$, 1.726(5) Å [33]. For the unsymmetrically H-bridged dimer of the $[H_3Al\cdot L]_2$ type of alane adducts, $[H_3Al\cdot N(Me_2)CH_2CH_2CH_2Cl]_2$, the following Al–H distances are found that span almost the entire range of observable distances of this type, namely, two different ring distances, 1.84(3) and 1.99(5) Å, and two different terminal distances, 1.20(7) and 1.40(6) Å [34]. Of particular interest also is the average Al–Al distance of 2.661 Å. It can be compared with this sep-

aration in other symmetrical dimers such as $(HAlMe_2)_2$, 2.62 Å [35] and $[HAl(tmp)_2]_2$, 2.680(2) Å. More importantly, this distance is in the range of the Al–Al bonding distances in structurally authenticated, neutral, monomeric dialanes $[(Me_3Si)_2CH]_4Al_2$, 2.660(1) Å [36] and $[(i\text{-}Pr_3C_6H_2)]_4Al_2$, 2.647(3) Å [37] or tetrameric cluster $[Al(C_5Me_5)]_4$, 2.769 Å (av) [38]. Based on that, some bonding interaction along the Al–Al axis is thus probable in **1**.

A 1:1 ratio reaction of **1** and $HNMe_2$ was performed to test preferences of the two possibly competing reactions, namely, aminolysis at the Al–H site with the formation of dihydrogen and transamination at the Al–$N(SiMe_3)_2$ site(s) with the formation of $HN(SiMe_3)_2$. These types of reactions were observed to occur simultaneously in the combination of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ and NH_3, and yielded a rare benzene soluble polymeric precursor that was used to make transparent AlN coatings on alumina substrates [18]. Surprisingly, only minute quantities of H_2 were measured several hours past addition indicating very slow aminolysis. This was further supported by an IR spectrum for raw products that showed a N–H stretching band at 3310 cm^{-1} consistent with coordinated $HNMe_2$ by **1** at this stage of reaction. The NMR spectra for the reaction mixture were run in the course of several weeks following addition and showed a multitude of slowly formed products. This was accompanied by increased quantities of evolved H_2 (sharp ^1H NMR resonance at δ 4.51 [39]) and $HN(SiMe_3)_2$ consistent with a relatively slow aminolysis and transamination in the system, respectively.

Compound **2** was isolated in small quantities after several days of a low temperature storage of the reaction mixture accompanied by a slow evaporation of volatiles. The NMR data obtained for a fresh solution of **2** in toluene-d_8 were complex and subject to changes with time. These changes might be indicative of slow equilibration processes and formation of more stable symmetrical products in the solution but, also of some on-going chemical interactions. Interestingly, the IR spectrum for the freshly isolated product showed only a single, well defined but, alas, broad band in the ν(Al–H) range at 1860 cm^{-1}.

The molecular structure of **2** is shown in Fig. 2. It features a puckered {Al–N–Al–N} ring with unsymmetrical (different) ligands on the aluminum atoms, and can be visualized as a Me_2N-bridged, two-site adduct of the different monomeric aminoalanes $Al(NMe_2)_2[N(SiMe_3)_2]$ and $HAl(NMe_2)[N(SiMe_3)_2]$. The $N(SiMe_3)_2$ groups on two different Al ring atoms are in the *cis* position to each other. Potentially increased steric congestion due to the *cis* configuration is apparently counterbalanced by ring puckering, which has the effect of moving apart the $N(SiMe_3)_2$ groups on the congested side of the ring and getting the neighboring small H and NMe_2 ligands closer on the other side of the ring with a concurrent decrease of the Al–Al distance. The latter distance of 2.829(3) Å seems to be, however, outside the range of any significant aluminum–aluminum bonding interaction (*vide supra*). The ring puckering as defined by the angle between the N(1)–Al(1)–N(2) and N(1)–Al(2)–N(2) planes amounts to 25.5°. The N and Al atoms in the ring are four-coordinate; although the hydrogen atom is not resolved on Al(1), its presence is supported by both structural [pyramidal Al(1) atom] and chemical evidence [IR band in the ν(Al–H) range at 1860 cm^{-1}].

Despite the relatively high values of the residuals for **2**, the quality of the numerical data is good enough to address some of the molecule's structural aspects. The aluminum–nitrogen bonds in **2** represent a comprehensive range of bond configurations including ring and different exocyclic bonds, all in one molecule. The average Al–N distance in the ring (Al–*endo*-NMe_2), 1.972 Å, can be compared with the average distances of this type in some of the Me_2N-bridged dimers such as $[Al(NMe_2)_3]_2$, 1.965 Å [14] (or 1.970 Å [13]) and $[HAl(NMe_2)_2]_2$, 1.966 Å [13] or trimer $(H_2AlNMe_2)_3$, 1.950 Å [13]. The Al–*exo*-NMe_2 distance of 1.782(8) Å in **2** belongs, in general, to very short Al–N bond lengths. For example, the following Al–*exo*-NMe_2 distances are found in the dimers $[Al(NMe_2)_3]_2$, 1.800 Å (av) [15] [or 1.814 Å (av) [13]], $[HAl(NMe_2)_2]_2$, 1.804(2) Å [13] and $[(Me_2N)_2Al\{\mu\text{-}N(H)1\text{-adamantanyl}\}]_2$, 1.793 Å [15], while the apparently shortest to-date Al–N bond lengths are reported for monomeric $Al[N(SiMe_3)_2]_3$, 1.78(2) Å [16], and six-membered planar ring $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$, 1.782(4) Å [27]. The other exocyclic AlN distance(s) in **2**, i.e. Al–*exo*-$N(SiMe_3)_2$, 1.839 Å (av), falls well within the range of similar terminal bonds. This is exemplified by comparison of this distance with the respective average lengths in **1**, 1.824 Å, $\{[(Me_3Si)_2N]_2AlNH_2\}_2$, 1.841 Å [32], or $\{[(Me_3Si)_2N]_2Al(NH_2)_2\}_3Al$, 1.850 Å [32]. The Al–*exo*-$N(SiMe_3)_2$ lengths are generally longer than the Al–*exo*-NMe_2 lengths and this may reflect the congestion effect of the bulkier $N(SiMe_3)_2$ group.

In summary, the structure of **2** illustrates the occurrence of both the aminolysis (absence of H on one of the Al atoms) and transamination [singular $N(SiMe_3)_2$ groups on each Al atom] taking place in the reaction between **1** and $HNMe_2$. Similar combinations of $[H_2AlN(SiMe_3)_2] \cdot NMe_3$ and NH_3 were also reported to proceed via concerted ammonolysis and transamination and resulted in a soluble polymeric precursor to aluminum nitride [11]. The data presented here are consistent with complex elimination chemistry in these systems and suggest that the new $\{[(Me_3Si)_2N]_2Al(\mu\text{-}H)\}_2$ may be a valuable precursor for conversion to aluminum nitride materials.

(Received 16 January 1998; accepted 25 May 1998)

Abstract—The synthesis and characterization of new planar mixed chelates of the type [Pd(A)(N,O)] (A = *ortho*-metallated azobenzene or its substituted derivatives, A_1 to A_5, N,O = 2-picolinato (pic), quinaldato (qnd), 8-quinolinolato (q) and 2-methyl-5-sulphonic-8-quinolinolato (msq)) are achieved by splitting the halogeno-bridge in $[Pd_2(A)_2Cl_2]$ by aqueous $AgNO_3$ solution followed by the addition of N,O-chelator. $[Pd(A_2)(N,O)]$ occurs as isomer $[Pd(A_3)(N,O)]$ and the composition have been established using ^1H NMR data. The complex composition is supported by elemental analyses and IR data. Cyclic voltammetric studies suggest two successive redox responses correspond to azo reduction. © 1998 Elsevier Science Ltd. INTRODUCTION

Cyclopalladated compounds of transition metals have attracted a great deal of attention in recent times [1–8]. Many reviews concerning their synthesis and reactivities appear in literature [9–14]. We have extensively studied the cyclopalladation reactions of many substituted azobenzenes and Schiff bases [15–19]. Azobenzene becomes palladated at the azo-nitrogen and *ortho*-carbon atom and produces bridged dimeric species [20–22]. The bridge splitting reactions of the dimer with neutral ligands such as tertiary phosphines [23–25], pyridines [26] and anionic ligands such as acetylacetonate [27], arylazooximate [28] gave large number of planar mixed organopalladium complexes. In the present paper we report a further new type (**2**) of mixed cyclopalladated complexes of azobenzenes with (N,O)-chelators. We have chosen monoanionic N,O-chelator: picolinic acid (Hpic), quinaldic acid (Hqnd), 8-quinolinol (Hq) and its derivative 2-methyl-5-sulphonic-8-quinolinol (Hmsq) (H stands for the phenolic hydrogen) as the capping ligand. They form five membered chelate ring with cyclopalladated Pd(C,N) fragment (**1**).

RESULTS AND DISCUSSION

The complex (**2**) is abbreviated as Pd(A)(N,O) where A represents the azobenzenes. A_1 to A_5 are the specific abbreviations of the ligand A depending on substituents and binding mode as set out in Scheme 1.

The chloro-bridged cyclopalladated azobenzenes $[Pd_2(A)_2Cl_2]$ in acetone were treated with aqueous $AgNO_3$ and refluxed for a few hours. To the filtrate (N,O)-chelators were added in equivalent amount (1:1 mole ratio). The picolinato [Pd(A)(pic)], quinaldato [Pd(A)(qnd)] and 8-quinolinolato [Pd(A)(q)] and [Pd(A)(msq)] derivatives were precipitated as orange solid. The complexes are non-electrolytic in nature and suggest covalent binding of the chelators. The composition of the complexes are supported by elemental analyses data (Table 1).

The complexes display spectral characteristics corresponding to ν(N=N) at 1360–1385 cm^{-1}. The assignment of all bands has not been attempted. However, a comparison of the spectra with those of the respective chloro-bridged dimers and of free (N,O)-chelator affords useful information. Picolinato [Pd(A)(pic)] and quinaldato [Pd(A)(qnd)] derivatives exhibit strong stretching due to ν_{as}(COO) and ν_s(COO) at $\sim$1650 and 1340 cm^{-1} respectively which appears in the free ligand at 1720 cm^{-1}. The difference in stret-

[a] Calculated values are in parentheses.
[b] In $CHCl_3$ except [Pd(A)(msq)] derivatives, those are recorded in DMSO.
[c] Shoulder.

ching frequency ($\Delta\nu = 290\,cm^{-1}$) suggests unidentate carboxylato coordination [29, 30, 31]. Additional bands are observed at 860–840, 720–700 and 680–660 cm^{-1} and support the coordinated picolinate ion. Similarly quinolinolato [Pd(A)(q)] and [Pd(A)(msq)] exhibit two characteristic band at 1560–1580 and 1490–1505 cm^{-1} along with ring deformation at $\sim 400\,cm^{-1}$ supporting the presence of N,O-chelator in the cyclopalladated moiety. All the complexes exhibit stretching at 520–530 and 350–380 cm^{-1} corresponding to ν(Pd–O) and ν(Pd–N), respectively.

The solution electronic spectra of the complexes were recorded in $CHCl_3$ and the transitions are assigned on the basis of reported literature [18–22, 28]. The transition around 500 nm is assigned to charge transfer transition in the metallated fragment [20–22, 28] and the higher energy transitions are referred to intraligand charge transfer transitions.

For asymmetrical azobenzene (A_2/A_3) the cyclopalladated complex occurs as a mixture of isomers but in no case they are separated by chromatography. Because of bad solubility of the chloro-bridged species in common organic solvents direct isomer assessment by ^{1}H NMR is not easily achieved [32]. Different other methods [33, 34] like gas chromatographic analysis of the products obtained by exhaustive carbonylation of the dimer had been used. The ^{1}H NMR spectral technique had been employed in a limited area [28] for the product analysis obtained by bridge splitting reactions using PPh_3, arylazooximes etc. We are also using ^{1}H NMR technique for the assessment of isomer population (Table 2). For symmetrical azobenzenes (A_1, A_4, A_5) no such isomerism is observed. The bridge splitting reaction followed by chelation using N,O-chelator may produce, in principle, two geometric isomers (B and C) for symmetrical and four isomers for asymmetrical azobenzenes, respectively. The isomers could not be isolated by chromatography on silica gel or alumina. There are many bridge splitting reactions [23–27] of cyclopalladated azobenzenes, Schiff bases with pyridines or phosphines where the base occupies *trans*-position to azo/azomethine-N. 2-Picolinic acid is also used as bridge splitter in a cyclopalladated α-naphthylethylamine where heterocyclic-N occupies *trans* to amine nitrogen. This may provide a guide to consider single isomer (B) from the symmetrical azobenzenes and two isomers from asymmetrical azobenzene.

The ^{1}H NMR spectra of free ligands and the cyclopalladated complexes of symmetrical azobenzenes are the guide lines to the signal assignment. In cases, where the metallation of both substituted and unsubstituted rings occurs, the population of the isomer having metallation in the substituted ring is higher, in line with the electrophilic nature of the palladation reaction. Symmetrical azobenzenes yield single mixed chelate complex which is supported by two Me signals of [Pd(A_4)(N,O)] in ^{1}H NMR spectra, in line with the electrophilic nature of the palladation reaction. Asymmetrical ligand in [Pd(A_2)(N,O)] gives closely spaced δ_{Me} signal. Originally cyclopalladated complex exists in two isomeric forms and at least two mixed chelates will appear in the product. The observed ratio of [Pd(A_2)(N,O)]:[Pd(A_3)(N,O)] is 3:2. The results are in agreement with those obtained by the bridge splitting reaction using PPh_3 and pyridine.

[a] Doublet.
[b] Triplet.
[c] Multiplet.
[d] Singlet.
[e] Isomeric δ_{Me}, 2.38 ppm.
[f] δ_{Me} of msq.
[g] Solvent: $CDCl_3$, except [Pd(A)(msq)] where DMSO-d_6 is used.
[h] The concentration of [Pd(A_5)(msq)] is very low to get well defined ^{1}H NMR in DMSO-d_6.

The heterocyclic ring protons appear in general at the downfield region relative to arylazo protons. The proton numbering pattern is shown in Scheme 1. The signals are assigned on the basis of spin–spin interaction and change therein on substitution. In picolinato derivatives the most downfield doublet is 3-H ($\sim$8.6 ppm) followed by 6-H ($\sim$8.2 ppm) signal. The protons 4-H and 5-H appear relatively at upfield position $\sim$8.0 and 7.8 ppm respectively. The quinaldato derivatives [Pd(A)(qnd)] similarly exhibit resonances in downfield region for 3-H to 8-H at 8.7 to 7.8 ppm. 8-Quinolinolato complexes [Pd(A)(q)] exhibit 2-H signal at most downfield region ($\sim$8.9 ppm); the pyridinic ring protons appear in downfield region (2-H to 4-H, 8.9 to 8.4 ppm) and phenolic ring protons appear at relatively upfield region (5-H to 7-H, $\sim$7.6 to 7.8 ppm). Arylazo ring protons appear relatively in upfield position (7.0 to 7.7 ppm) and the signal position is highly sensitive to the substituent in the aryl ring. In A_2/A_3, A_4 and A_5 singlet resonance is due to 9-H proton. Metallated ring protons appear in more downfield region than non-metallated ring ones. Other ring protons appear at usual position and the signal movement is in accordance with the electronic effect of the substituents [35].

Electrochemistry

Cyclic voltammetric data were collected under N_2 environment using glassy carbon working electrode in acetonitrile versus saturated calomel electrode (SCE) in presence of tetrabutylammonium perchlorate (TBAP). The iR compensation was applied internally in the instrument. All the complexes display two redox responses and the data are collected in Table 3. The peak potentials are nearly invariant with scan rate (50–500 mV s^{-1}) and the cathodic peak current (i_{pc}) is proportional to $v^{1/2}$ and i_{pa}/i_{pc} lies at 0.9–1.02 suggesting reversibility of the redox process. The current height measurement shows one-electron redox type and the peak-to-peak separation (ΔE_p) suggests quasireversible character of the couples. Palladium(II) reduction in mixed complexes of cyclopalladated azobenzenes were reported at very high potential and a two-electron quasireversible reduction process followed by chemical reaction [28]. In the present series of complexes the couples are one-electron reduction type at relatively lower value and stable on repetitive cyclic operation. This excludes the metal reduction. Ligand reduction is believed to occur primarily at the azo-function who can accommodate up to two electrons [28] at the LUMO. The coulometric experiment for the first couple confirms one-electron reduction at the azo-centre. The experiment was performed in one case [Pd(A_1)(q)] at -1.4 V vs SCE in MeCN and coulomb count ($\eta = Q/Q' = 0.94$ where Q and Q' are observed and calculated coulomb) suggests just one-electron reduction. On reduction the solution colour has changed from orange red to brown red

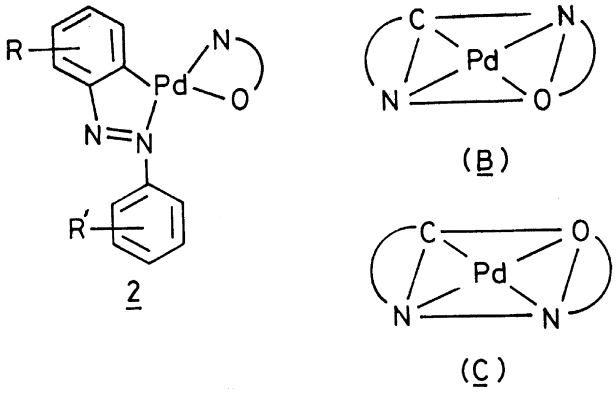

Scheme 1.

and in the UV–VIS spectra the shoulder at 484 nm is eliminated while new band appears at 510 nm. The ESR spectra of the reduced product shows interesting behaviour; at room temperature a broad signal is observed at $g = 2.005$ with peak-to-peak separation 45 G. The spectrum at liquid-nitrogen temperature (77 K) shows hyperfine splitting pattern. Detail investigation is under scrutiny. The observation supports the literature report [36, 37] and suggests that the first reduction is believed to occur at the azo-function of the ligand. The effect of the substitution on reduction potential data again supports the assignment. Change of substituents (*para*-to-azo group in aryl ring) in the metallated ring brings about in increasing cathodic shift of $E_{1/2}$ in the order Cl > H > Me as expected from Hammett relation [38]. The second couple ($E_{1/2}{}^2$) varies irregularly and does not confirm to the second step reduction, of azo-function. The reduction of heterocyclic coligand is not ruled out which may need comparatively higher energy to accommodate electrons at the antibonding orbital. There may be a certain degree of involvement of coligand π^*-orbital in conjunction with azo-antibonding orbital.†

EXPERIMENTAL

The solvents used in the reactions were of reagent grade and were dried by reported procedures [15, 16]. 2-Picolinic acid (Hpic), quinaldic acid (Hqnd) (Fluka), 2-methyl-5-sulfonic-8-quinolinol (Hmsq) (Aldrich) and 8-quinolinol (BDH) were recrystallized before use from ethanol–water (2:1, v/v). Palladium chloride was

† One of the Referees has suggested in this manner.

[a] Meaning of the symbols are as in the text.

[b] Potentials are 0.5 ($E_{pc} + E_{pa}$); E_{pc} and E_{pa} are cathodic and anodic peak potentials respectively, unit in V and ΔE_p in mV (reference to SCE), scan rate 50 mV s^{-1}, solute concentration $\sim 10^{-3}$ M in MeCN, [NBu_4, ClO_4] is supporting electrolyte (0.1 M).

received from Arrora Matthey, Calcutta, India. Disodium tetrachloropalladate was prepared by reported procedure [15, 16]. Azobenzenes were synthesized by condensing nitroaromatics and aromatic amines in hot glacial acetic acid as reported earlier [20–22]. All other chemicals and solvents were reagent grade and were used as received.

IR spectra were recorded on Perkin Elmer 783 and 883 spectrophotometers. ^{1}H NMR data were collected from Bruker 300 MHz FT NMR spectrometer in $CDCl_3$. UV–VIS spectra were obtained using Shimadzu 160A spectrophotometer. Elemental analyses were obtained using Perkin Elmer 2400 CHNS/O analyser.

Synthesis of complexes

Complexes [$Pd_2(A)_2Cl_2$] were prepared according to reported methods [20–22, 28]. The mixed ligand complexes [Pd(A)(N,O)] were synthesized by a general procedure and representative case is detailed below.

2-(*Picolinato*)(7-*phenylazophenyl-C*^{8},*N*)*palladium*(*II*), [*Pd*(*A*)(*pic*)]

To acetone solution (10 cm^3) of [$Pd_2(A_1)_2Cl_2$] (0.2 g, 0.31 mmol) was added aqueous $AgNO_3$ (0.11 g, 0.65 mmol) solution. The mixture was refluxed for 2 h. The precipitated AgCl was filtered at hot condition through G-4 sintered crucible. To this orange solution 2-picolinic acid (0.08 g, 0.65 mmol) in acetone (10 cm^3) was added dropwise with continuous stirring. The colour of the solution turned to orange-red and the precipitate appeared slowly on evaporation in air. The volume of the solution was reduced to half and the precipitate was filtered, washed with water, and recrystallized from chloroform–hexane via diffusion. The product was dried over $CaCl_2$. The yield was 70%.

The yield of other compounds varied between 65 and 80%.

(Received 29 April 1998; accepted 25 May 1998)

Abstract—A major feature of the crystal structure of $K[AsMe_2S_2] \cdot 2H_2O$, which contains two independent formula units, is the presence of infinite sheets formed by edge sharing between two different types of $K(H_2O)_4S_2$ octahedra in which the sulfurs occupy either *cis* or *trans* positions. Although the four independent arsenic–sulfur distances all fall between those for single and double bonds, one sulfur at each arsenic is coordinated to potassium and the As–S distance here is longer [mean 2.140(2) Å] than that to the second sulfur [mean 2.111(5) Å] which is effectively free. The structure also contains a series of weak O–H . . . S hydrogen bonds.

Keywords: arsenic(III); dithioarsinate; dimethyldithioarsinate; crystal structure; sheet structure.

INTRODUCTION

Although the coordination properties of dithiophosphorus based ligands, i.e. dithiophosphates, dithiophosphonates and dithiophosphinates [1, 2], have been extensively studied, there are relatively few reports on the behaviour of the corresponding arsenic based ligands. Both main group and transition metal derivatives are known but few compounds have been investigated by X-ray methods. Such ligands should, and apparently do, show the same coordination versatility that is well established with the phosphorus analogues and examples where the ligands are monodentate [3, 4], chelating [5–7], bridging [8, 9] and tridentate (chelating–bridging) [10] are known. Any discussion of such structures requires information on the As–S separations in simple compounds such as the free acids to define As–S and As=S distances and simple salts to define the separation when the π-component is delocalised. Although free dithioarsinic acids, e.g. $AsR_2S(SH)$, where R = Me or Ph, are not known nor is structural information available on simple dithioarsinate salts, As–S single and double bond distances, ca. 2.25 and 2.07 Å, respectively, have been established from other compounds [4, 11, 12]. During the course of our work on arsenic–sulfur compounds, we prepared $K[AsMe_2S_2] \cdot 2H_2O$ and report here the results of a crystal structure determination.

RESULTS AND DISCUSSION

Alkali metal dimethyldithioarsinates were first prepared from cacodyl disulfide [13] but in the present case hydrogen sulfide was passed through a concentrated equimolar solution of hydrated dimethylarsinic acid and potassium hydroxide in ethanol using a modification of a literature method [14]; the product was isolated as a dihydrate. ^{1}H NMR spectroscopy in dmso-d_6 showed the expected two signals in a 3:2 ratio at 1.64 ppm for the methyl and 3.39 ppm for the water protons and there was a single ^{13}C signal at 31.68 ppm. Signals for the methyl protons varied with solvent and were at 1.85 and 1.96 ppm for solutions in $CDCl_3$ and D_2O, respectively. Symmetric and antisymmetric As–S stretching modes gave strong bands at 428 and 456 cm^{-1} in the IR spectrum of a nujol mull; the As–C stretches were at 616 and 651 cm^{-1} with methyl deformation modes at 913, 1360 and 1406 cm^{-1}. There was also a further broad band

* Author to whom correspondence should be addressed.

between 3300 and 3500 cm^{-1} associated with the hydrate water.

The X-ray determination shows the presence of two independent formula units in the asymmetric unit for this compound. Important bond distances and angles are collected in Table 1 and a diagram showing the asymmetric unit and the atom numbering scheme is in Fig. 1. Each arsenic atom shows distorted tetrahedral coordination with bond angles ranging between 104.8(6) and 114.6(1)° and as expected the smallest angles are those between methyl groups and the largest between two sulfur atoms. Although the As–S distances (mean 2.126 Å) fall between those for single

[b] Symmetry transformation: $x-1, y+1, z$.

[c] Symmetry transformation: $x+1, y-1, z$.

[d] Symmetry transformation: $x, y-1, z$.

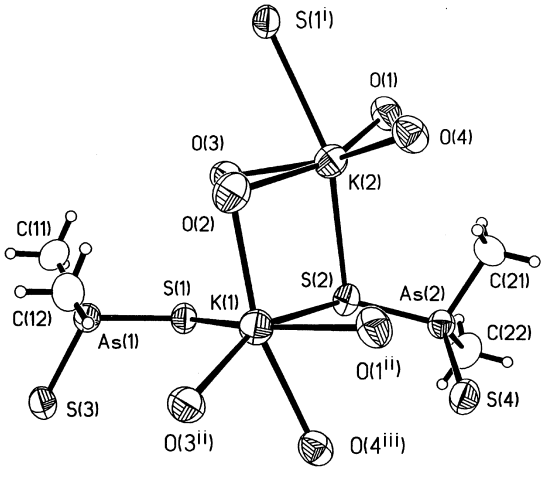

Fig. 1. The asymmetric unit, with completed potassium coordination spheres, for $K[AsMe_2S_2]\cdot 2H_2O$ and the atom numbering scheme. Symmetry operations are: (i) $1+x, 1-y, z$; (ii) $x, 1+y, z$; (iii) $x-1, 1+y, z$.

(*ca.* 2.25 Å) and double (*ca.* 2.07 Å) bonds, implying delocalisation of the π component, one distance at each arsenic is shorter [2.106(3) and 2.116(3) Å to S(3) and S(4), respectively] than the other [2.139(3) and 2.141(3) Å, to S(1) and S(2), respectively)] This is a consequence of the fact that the latter are coordinated to potassium ions while S(3) and S(4) make no other major contacts and are effectively free.

Each potassium ion is in distorted octahedral coordination to two sulfur and four oxygen atoms [*trans* angles range between 151.1(1) and 163.5(3)°] and this unit appears to be the major structure determining factor. Although each potassium coordination sphere contains the same atoms, the sulfurs are *cis* at K(1) [S(1)–K(1)–S(2) 68.0(1)°] but *trans* at K(2) [S(1^{i})–K(2)–S(2) 151.1(1)°]. K–S distances fall between 3.217(4) and 3.262(4) Å [mean 3.24(2) Å] with K–O distances between 2.655(8) and 2.836(9) Å.

For clarity, the overall structure can be considered to arise by sharing O(4)–S(1) and O(2)–S(2) edges between K(1) and K(2) octahedra to give infinite zigzag chains, which are then interlinked into sheets in the *ab* plane by sharing O(1)–O(3) edges. One view of part of the sheet is shown in Fig. 2 while Fig. 3 shows more clearly the edge sharing octahedra. A series of weak hydrogen bonds, all within a given sheet (see Table 2), between hydrogens of the four water molecules and the four sulfur atoms completes the structure.

This crystal structure can be described as a self-organised supramolecular structure, generated by electrostatic interactions and hydrogen bonds. The arrangement of the basic units is dictated by these forces, rather than by the simple packing of ions, and water molecules participate fully in the structure rather than simply occupying interstices or channels. As illustrated in Figs 2 and 3, the structure contains interlinked hexanuclear units, suggesting that under appropriate conditions such units may be isolable as discrete species.

There are strong similarities between this structure and that of $Na[PEt_2S_2] \cdot 2H_2O$ [15] where the asymmetric unit is a single formula unit. Sodium is coordinated by four oxygens and two *cis* sulfurs, as for K(1) in the present structure, and edge sharing between these octahedral NaO_4S_2 units gives related infinite sheets in the *ab* plane. The fact that there are two different coordination arrangements about

[c] Symmetry transformation: $1+x, y-1, z$.

potassium in the present structure, however, leads to no major difference in the sheet structure resulting from edge sharing.

EXPERIMENTAL

Preparation of potassium dimethyldithioarsinate

The compound was obtained by passing hydrogen sulfide for two hours into a solution of hydrated dimethylarsinic acid (500 mg, 3.16 mmol) and potassium hydroxide (170 mg, 3.16 mmol) in ethanol (35 cm^3). On cooling the solution to 0°C, a white precipitate of the required compound as the dihydrate was obtained in almost quantitative yield. Crystallisation from a mixture of dichloromethane and hexane (1/1) gave air stable colourless crystals of the compound, suitable for X-ray crystallography. M.Pt 95°C. Found: C, 9.8; H, 4.1. $C_2H_{10}AsKO_2S_2$ calc.: C, 10.1; H, 4.0%.

Crystal structure determination

Crystal data $C_4H_{20}As_2K_2O_4S_4$, $M=488.5$, triclinic, space group $P\bar{1}$, $a=6.623(3)$, $b=6.694(2)$, $c=24.658(13)$ Å, $\alpha=84.45(4)$, $\beta=87.73(6)$, $\gamma=60.56(2)^\circ$, $V=947.5(7)$ Å^{-3}, $Z=2$, $D_c=1.712$ g cm^{-3}, $F(000)=488$, $\mu=4.402$ mm^{-1}, Mo-Kα radiation, $\lambda=0.71073$ Å, crystal size $=0.47\times0.35\times0.20$ mm.

Data for 3519 reflections ($-7<h<7$, $-7<k<7$, $-18<k<29$) were collected on a Stoe Stadi-4 diffractometer: of these 3295 [$R_{int}=0.133$] were unique and 2678 had $I>2\sigma(I)$. The structure was solved by direct methods (SHELXS-86) [16] and difference Fourier syntheses and refined by least squares on F^2 (SHELXL-93) [17]. Nonhydrogen atoms were assigned anisotropic thermal parameters and hydrogen atoms were placed at calculated positions and refined using a riding model. Refinement converged (3295 data, 146 parameters, GOF 1.248) at R_1 0.0482, wR_2 0.1025 (observed data) and R_1 0.0837, wR_2 0.1657 (all data). Full details of the atomic parameters and bond lengths and angles have been deposited with the Cambridge Crystallographic Data Centre.

(Received 13 March 1998; accepted 29 May 1998)

Abstract—Diphenylphosphinoacetic acid (HA) reacts as a neutral *P*-donor ligand with a variety of transition metal compounds to generate the new complexes [$CuCl(HA)_x$] ($x=1$ or 3), *trans*-[$PdCl_2(HA)_2$], *cis*-[$PtCl_2(HA)_2$], [AuCl(HA)] and *cis*-[$Mo(CO)_4(HA)_2$]. The crystal structure of [AuCl(HA)] involves a linear Cl–Au–P arrangement [179.0(1)°], neighbouring molecules forming hydrogen-bonded dimers in the lattice array. The hydrogen-bonding is of the planar type commonly found in free carboxylic acids with intermolecularly bonded pairs of [AuCl(HA)] molecules being related by an inversion centre. Recrystallisation of *trans*-[$PdCl_2(HA)_2$] from ethanol yields crystals of the solvate *trans*-[$PdCl_2(HA)_2$]$\cdot 0.33H_2O \cdot 0.33C_2H_5OH$. The asymmetric unit contains 1.5[$PdCl_2(HA)_2$] molecules along with water and ethanol molecules exhibiting only half site occupancy. For every three [$PdCl_2(HA)_2$] molecules two are hydrogen-bonded to neighbours using carboxylic acid groups to form chains. The third molecule differs in that hydrogen-bonding occurs between one oxygen of a carboxylic acid group and the lattice water, the oxygen of which further hydrogen-bonds to the lattice ethanol. © 1998 Elsevier Science Ltd. Keywords: diphenylphosphinoacetic acid; gold(I); palladium(II); carboxylic acid; hydrogen bonding.

INTRODUCTION

A vast range of metal complexes containing coordinated acetate anions have been prepared and characterised over many years but complexes containing the parent acetic acid are quite rare. Examples include $[M(CH_3CO_2H)_6]^{2+}$ (M = Mg, Ca, Mn, Co, Ni, Cu and Zn) [1] and a crystal structure determination of the nickel cation as its tetrafluoroborate confirms that the ligands are *O*-unidentate [2, 3]. A similar picture emerges on consideration of substituted acetic acids and their anions as ligands where the substituent contains a group 15 donor atom. The additional group 15 donor atoms may compete with the carboxylic acid donor oxygens for coordination to metal centres, increasing the number of possible coordination modes and providing differentiation between hard and soft metal–ligand interactions. Taking the simplest amino-acid as an example, glycine forms many complexes involving *N*,*O*-chelating glycinate anions but rather few containing glycine itself and these display a range of coordination types. For example, glycine is zwittterionic and *O*,*O*′-bridging in [$Ag_2(O_2CCH_2NH_3)_2](NO_3)_2$ [4], *O*-unidentate in [$(\eta\text{-}C_5H_5)_2Ti(O_2CCH_2NH_3)_2]Cl_2$ [5] and *N*-unidentate in *cis*-[$PtX_2(NH_2CH_2CO_2H)_2$] (X = Cl or Br) [6].

Metal complexes derived from phosphine-substituted acetic acids are less well known. Considering the ligand used in this work, diphenylphosphinoacetic acid $Ph_2CH_2CO_2H$, (abbreviated as HA with the anion as A^-), structure determinations of [$Pd(A)_2$] [7], [PtBr(A)(HA)]$\cdot H_2O$ [8], [Rh(CO)(A)(HA)] [9], [$Rh(A)_3]\cdot PhNO_2\cdot H_2O$ [10], [RhCl(H)(A)$(HA)_2$] [10] and [Et_4N][$W(CO)_4$(A)] [11] confirm that the anion is *O*,*P*-chelating in all cases, although it is tridentate both bridging and chelating through the carboxylate

unit only in [Ca(A)$_2$] [12]. Three of the above complexes also contain HA as a ligand and in each case it is bonded in a *P*-unidentate manner, this coordination mode also having been established for *trans*-[PdBr$_2$(HA)$_2$] [13] and [Hg$_2$Br$_2$(μ-Br)$_2$(HA)$_2$] [14]. Thus the parent acid HA can behave as a ligand in the manner of a diphenylalkylphosphine. We report here the syntheses of a number of new examples and include discussion of two crystal structure determinations.

EXPERIMENTAL

Diphenylphosphinoacetic acid was prepared by a variation of the method of Jarolim and Podlahova [15] (found: C, 68.9; H, 5.39. $C_{14}H_{13}O_2P$ requires C, 68.9; H, 5.36%). NMR ($CDCl_3$), ^{1}H δ 3.11 (s, CH_2, 2H), 7.33–7.48 (m, Ph, 10H), 11.50 (br s, O*H*, 1H); ^{13}C{^{1}H} δ 35.1 (d, $^1J_{CP}$ = 23.2, *C*H$_2$), 128.4 (d, $^3J_{CP}$ = 6.6, C_{meta}), 129.0 (s, C_{para}), 132.4 (d, $^1J_{CP}$ = 19.9, C_{ipso}), 136.7 (d, $^2J_{CP}$ = 14.3, C_{ortho}), 177.2 (d, $^2J_{CP}$ = 8.8, *C*O$_2$H); ^{31}P{^{1}H} δ −15.1. IR (cm^{-1}) 1700 vs $\nu(CO_2)_{asym}$, 1301, 1291 s $\nu(CO_2)_{sym}$.

The starting materials [Mo(CO)$_4$(nbd)], [PdCl$_2$(PhCN)$_2$], [PtCl$_2$(PhCN)$_2$] and [AuCl(tht)] (nbd = norbornadiene, tht = tetrahydrothiophene) were prepared by standard literature methods. Microanalyses were carried out using a Carlo-Erba microanalysis system. Jeol GX 270 and EX 400 spectrometers were used to obtain ^{1}H, ^{13}C and ^{31}P NMR spectra. Infrared spectra were recorded as Nujol or hexachlorobutadiene mulls using Nicolet 510P or Perkin-Elmer 597 spectrophotometers. Positive and negative ion FAB mass spectra were recorded on Vacuum Generators 7070E and Autospec instruments using 3-nitrobenzyl alcohol matrices. The *m*/*z* values reported below are based on ^{35}Cl, ^{63}Cu, ^{98}Mo, ^{106}Pd and ^{197}Au, peak intensities being expressed relative to the strongest metal-containing fragment. Reactions and subsequent manipulations were carried out under an atmosphere of dry nitrogen as required.

Tetracarbonylbis(diphenylphosphinoacetic acid)molybdenum(0)

A solution of [Mo(CO)$_4$(nbd)] (1.00 g, 3.3 mmol) and HA (1.60 g, 6.7 mmol) in dichloromethane (20 cm^3) was stirred at room temperature for 18 h. The resulting colourless precipitate was removed by filtration, washed with dichloromethane and dried *in vacuo*. Yield 2.2 g, 96% (found: C, 55.1; H, 3.72. $C_{32}H_{26}MoO_8P_2$ requires C, 55.2; H, 3.76%). NMR [(CD$_3$)$_2$CO], ^{1}H δ 3.25 (virtual t, CH_2, 4H), 7.39 and 7.51 (m, Ph, 20H); ^{13}C{^{1}H} δ 37.8 (s, *C*H$_2$), 129.0 (d, $^2J_{CP}$ = 17.6, C_{ortho}), 130.4 (s, C_{para}), 133.1 (d, $^3J_{CP}$ = 12.1, C_{meta}), 137.3 (d, $^1J_{CP}$ = 33.1, C_{ipso}), 169.4 (s, *C*O$_2$H), 210.2 (d, $^2J_{CP}$ = 9.9, *C*O), 216.1 (d, $^2J_{CP}$ = 17.6, *C*O); ^{31}P{^{1}H} δ +25.0. IR (cm^{-1}) 2027 vs, 1921 vs, 1910 sh, 1897 vs ν(CO), 1701 s $\nu(CO_2)_{asym}$, 1296 m $\nu(CO_2)_{sym}$. FAB-MS (*m*/*z*), 698 (15% [M]$^+$), 670 (6% [M–CO]$^+$), 642 (40% [M–2CO]$^+$), 614 (3% [M–3CO]$^+$), 586 (21% [M–4CO]$^+$), 454 (100% [M–(HA)]$^+$), 426 (50% [M–(HA)–CO]$^+$).

trans-Dichlorobis(diphenylphosphinoacetic acid)palladium(II)

HA (0.32 g, 1.30 mmol) and [PdCl$_2$(PhCN)$_2$] (0.25 g, 0.65 mmol) were allowed to react for 24 h in stirred dichloromethane (10 cm^3). The resulting yellow–green precipitate was collected, washed with dichloromethane and dried *in vacuo*. Yield, 0.40 g, 92% (found: C, 50.1; H, 3.88. $C_{28}H_{26}Cl_2O_4P_2Pd$ requires C, 50.5; H, 3.94%). NMR (CD_3CN), ^{1}H δ 3.71 (d, CH_2, 4H, $^2J_{PH}$ = 12.5), 7.31, 7.54, 7.83 (m, Ph, 20H); ^{13}C{^{1}H} δ 129.6, 132.1, 133.7, 134.6; ^{31}P{^{1}H} δ +12.4. IR (cm^{-1}) 1732 s, 1707 s $\nu(CO_2)_{asym}$, 1350 m $\nu(CO_2)_{sym}$, 330 m ν(PdCl). FAB-MS (*m*/*z*), 629 (46% [M–Cl]$^+$), 593 (100% [M–2Cl–H]$^+$), 350 (20% [M–2Cl–(HA)]$^+$).

Recrystallisation from ethanol gave yellow cube-like crystals suitable for an X-ray structure determination. The crystals were found to contain one ethanol and one water solvate molecule for every three $PdCl_2(HA)_2$ molecules (found: C, 50.1; H, 4.57. $C_{86}H_{86}Cl_6O_{14}P_6Pd_3$ requires C, 50.6; H, 4.20%).

cis-Dichlorobis(diphenylphosphinoacetic acid)platinum(II)

A solution of HA (0.090 g, 0.37 mmol) in dichloromethane (1.0 cm^3) was added to a solution of [PtCl$_2$(PhCN)$_2$] (0.087 g, 0.18 mmol) in dichloromethane (2.0 cm^3). A further 1.0 cm^3 of dichloromethane was added and the mixture stirred for 10 min. The colourless solution was allowed to stand for 18 h before collecting the precipitated product, washing with dichloromethane and drying *in vacuo*. Yield, 0.103 g, 76% (found: C, 45.2; H, 3.49. $C_{28}H_{26}Cl_2O_4P_2Pt$ requires C, 44.6; H, 3.47%). NMR (CD_3CN), ^{1}H δ 3.63 (d, CH_2, 4H, $^2J_{PH}$ = 11.7), 7.28–7.67 (m, Ph, 20H); ^{13}C{^{1}H} δ 33.2 (s, *C*H$_2$), 129.4, 132.4, 134.7; ^{31}P{^{1}H} δ +3.0 [^1J(^{195}Pt–^{31}P) = 3790]. IR (cm^{-1}), 1734 sh, 1696 s $\nu(CO_2)_{asym}$, 1300 m $\nu(CO_2)_{sym}$, 332 m, 303 m ν(PtCl).

Chloro(diphenylphosphinoacetic acid)copper(I)

Copper(I) chloride (0.20 g, 2.0 mmol) was added to a stirred solution of HA (0.50 g, 2.0 mmol) in dichloromethane (10 cm^3) and any reaction allowed to proceed for 24 h at room temperature. The resulting colourless precipitate was filtered, washed with dichloromethane and dried *in vacuo*. Yield, 0.43 g, 63% (found: C, 49.1; H, 3.80. $C_{14}H_{13}ClCuO_2P$ requires C, 49.0; H, 3.82%). NMR (CD_3CN), ^{1}H δ 3.66 (d, CH_2, 2H, $^2J_{PH}$ = 13.5), 7.46, 7.68, 7.78–7.83 (m, Ph, 10H); ^{13}C{^{1}H} δ 34.7 (d, *C*H$_2$, $^2J_{CP}$ = 12.2), 129.6 (d,

$^3J_{CP}=8.8$, C_{meta}), 131.2 (s, C_{para}), 131.6 (d, $^2J_{CP}=9.9$, C_{ortho}), 133.5 (d, $^1J_{CP}=15.4$, C_{ipso}), 170.1 (s, CO_2H); $^{31}P\{^1H\}$ δ −13.3. IR (cm^{-1}), 1705 vs $\nu(CO_2)_{asym}$, 1294 s $\nu(CO_2)_{sym}$. FAB-MS (m/z), FAB$^+$ 1333 (1% $[M_4–Cl]^+$), 649 (60% $[M_2–Cl]^+$), 551 (100% $[M–Cl+(HA)]^+$), 405 (34% $[M_2–Cl–(HA)]^+$), 342 (10% $[M]^+$); FAB$^-$ 1368 (2% $[M_4]^-$), 1124 (7% $[M_4–(HA)]^-$), 878 (27% $[M_4–2(HA)–2H]^-$), 635 (45% $[M_4–3(HA)–H]^-$), 537 (100% $[M_3–2(HA)–H]^-$), 341 (92% $[M–H]^-$).

Chlorotris(diphenylphosphinoacetic acid)copper(I)

Copper(I) chloride (0.075 g, 0.76 mmol) slowly dissolved when added to a stirred solution of HA (0.563 g, 2.31 mmol) in dichloromethane (10 cm^3). The reaction was allowed to proceed for 24 h at room temperature before removal of some of the solvent *in vacuo* to yield a colourless crystalline product. Yield, 0.33 g, 52% (found: C, 59.9: H, 4.75. $C_{42}H_{39}ClCuO_6P_3$ requires C, 60.7; H, 4.73%). NMR ($CDCl_3$), ^1H δ 3.16 (s, CH_2, 6H), 7.13, 7.32 (m, Ph, 30H), 10.07 (br, CO_2H, 3H); $^{13}C\{^1H\}$ δ 33.5 (s, CH_2), 128.3 (d, $^3J_{CP}=6.6$, C_{meta}), 129.8 (s, C_{para}), 131.5 (d, $^1J_{CP}=23.2$, C_{ipso}), 132.4 (d, $^2J_{CP}=14.4$, C_{ortho}), 171.9 (s, CO_2H); $^{31}P\{^1H\}$ δ −9.5. IR (cm^{-1}), 1725 sh, 1700 vs $\nu(CO_2)_{asym}$, 1290 m $\nu(CO_2)_{sym}$, 247 w ν(CuCl). FAB-MS (m/z) 795 (2% $[M–Cl]^+$), 551 (100% $[M–Cl–(HA)]^+$), 263 (50% $[M–Cl–2(HA)–CO_2]^+$).

Chloro(diphenylphosphinoacetic acid)gold(I)

A solution of HA (0.15 g, 0.60 mmol) in dichloromethane (2.0 cm^3) was added to a solution of chloro (tetrahydrothiophene)gold(I) (0.20 g, 0.60 mmol) in dichloromethane (3.0 cm^3). The mixture was stirred overnight at room temperature giving a yellow solution. Removal of the solvent *in vacuo* gave a yellow crystalline solid which was recrystallised from dichloromethane before drying *in vacuo*. Yield, 0.25 g, 87% (found: C, 35.2; H, 2.70. $C_{14}H_{13}AuClO_2P$ requires C, 35.3; H, 2.75%). NMR ($CDCl_3$), ^1H δ 3.83 (d, CH_2, 2H, $^2J_{PH}=12.5$), 7.62, 7.82 (m, Ph, 10H); $^{13}C\{^1H\}$ δ 35.0 (d, $^1J_{CP}=37.4$, CH_2), 129.9 (d, $^1J_{CP}=61.7$, C_{ipso}), 130.3 (d, $^3J_{CP}=12.1$, C_{meta}), 133.3 (s, C_{para}), 134.2 (d, $^2J_{CP}=14.3$, C_{ortho}), 168.7 (s, CO_2H); $^{31}P\{^1H\}$ δ +25.0. IR (cm^{-1}), 1700 vs $\nu(CO_2)_{asym}$, 1300 s $\nu(CO_2)_{sym}$, 335 vs ν(AuCl). FAB-MS (m/z) 917 (22% $[M_2–Cl]^+$), 685 (3% $[M–Cl+(HA)]^+$), 476 (7% $[M]^+$), 441 (100% $[M–Cl]^+$).

X-ray crystallography

Crystal data, data collection and refinement details are given for *trans*-$[PdCl_2(Ph_2CH_2CO_2H)_2]\cdot 0.33C_2H_5OH\cdot 0.33H_2O$ and for $[AuCl(Ph_2PCH_2CO_2H)]$ in Table 1. Selected bond lengths and angles are reported for each compound in Tables 2 and 3, respectively. Additional information for each structure is available from the Cambridge Crystallographic Data Centre and comprises final fractional atomic coordinates, thermal parameters, hydrogen atom coordinates and complete listings of bond lengths and angles. The contents of the unit cell of the palladium compound, produced using ORTEX [16], is shown in Fig. 1 along with the labelling scheme. Views of the supramolecular structure highlighting the hydrogen-bonding motifs are shown in Figs 2 and 3. The asymmetric unit of the gold compound is given in Fig. 4, also produced using ORTEX [16].

Data were collected at room temperature on a CAD-4 diffractometer using graphite-monochromated Mo-Kα radiation. The diffraction intensities were corrected for Lorentz and polarisation effects. An absorption correction was applied for the gold compound (transmission factor extrema 1.000, 0.230). The structures were solved using SHELX86 [17] and refined using SHELX93 [18]. In the final least squares cycles all atoms were allowed to vibrate anisotropically. For the palladium compound, hydrogen atoms were included at calculated positions on carbon atoms, where relevant. Hydrogens associated with the carboxylic acid moieties, the hydroxyls of the ethanol molecules and the lattice waters could not be located, even by examining a difference Fourier synthesis based on low Bragg data. For the gold compound, hydrogen atoms were included at calculated positions where relevant, except on the carboxylic acid moieties.

RESULTS AND DISCUSSION

Six new complexes all involving diphenylphosphinoacetic acid, abbreviated as HA, as a neutral *P*-donor ligand have been prepared and characterised. In these compounds the ligand is primarily acting as an alkyldiarylphosphine, although additional intermolecular hydrogen-bonding employing the carboxylic acid function is likely to be present in all cases as established by X-ray crystallography for the palladium and gold examples (*vide infra*). The complexes have been prepared either by direct reaction of the acid with a metal chloride as for $[CuCl(HA)_x]$ ($x=1$ or 3), or by displacement of a suitable labile ligand from a metal complex. Thus the syntheses of $[MCl_2(HA)_2]$, (M = Pd or Pt), $[Mo(CO)_4(HA)_2]$ and [AuCl(HA)] have been achieved from $[MCl_2(PhCN)_2]$, $[Mo(CO)_4(nbd)]$ and [AuCl(tht)], respectively (nbd = norbornadiene; tht = tetrahydrothiophene). Characterisation of products has been carried out using ^1H, ^{13}C and ^{31}P NMR, IR and FAB-MS (selected data are given in Section 2) and for the palladium and gold complexes, single crystal X-ray structure determinations.

The ^1H NMR spectra of the six complexes are very

similar to that of diphenylphosphinoacetic acid itself. The methylene resonance appears as a doublet (^{2}J *ca.* 12 Hz) for the palladium, platinum and gold complexes as a result of coupling to phosphorus while that of the molybdenum tetracarbonyl appears as a virtual triplet, with a quite broad central peak, resulting from the two phosphorus nuclei being strongly coupled to each other. Detection of the carboxylic acid proton was only achieved for the ligand itself and for $[CuCl(HA)_3]$.

Apart from the palladium and platinum species the remainder show the expected six ^{13}C resonances (a methylene, a carboxylic acid and four phenyl signals) at quite similar chemical shifts to those of the free ligand. Only partial data were obtained for the palladium and platinum compounds, as a result of low solubilities in non-reacting solvents. Additional carbonyl carbon resonances at 210.2 and 216.1 ppm, with appropriate ^{31}P–^{13}C coupling constants, confirms the anticipated *cis*-octahedral geometry of the molybdenum product. The ^{31}P chemical shift values are invariably downfield relative to the free ligand as a result of bonding by the ligand through phosphorus. However, the coordination shifts, $\Delta\delta$, vary significantly from compound to compound, the molybdenum and gold complexes both showing shifts of 40.1 ppm whereas those of the two copper(I) complexes are much smaller, being only 1.8 and 5.6 ppm for the mono- and tris-ligand complexes, respectively. These coordination shifts are very much of the same magnitude as those of related metal-alkyldiphenylphosphine or -triphenylphosphine complexes e.g. *cis*-$[Mo(CO)_4(PPh_2Bu^n)_2]$, $\Delta\delta=42.9$ ppm [19]; $[AuCl(Ph_2PCH_2CONHMe)]$, $\Delta\delta=41.9$ ppm [20]; $[CuCl(PPh_3)_3]\cdot MeCN$, $\Delta\delta=2.3$ ppm [21]. The coordination shifts for *trans*-$[PdCl_2(HA)_2]$ and *cis*-$[PtCl_2(HA)_2]$ are intermediate in magnitude being 27.5 and 18.1 ppm, respectively. These $\Delta\delta$ values can be compared with those of the analogous *trans*-$[PdCl_2(PPh_2Bu^n)_2]$ [22] and *cis*-$[PtCl_2(PPh_2Bu^n)_2]$ [19] which are 33.4 and 24.1 ppm, respectively. The large $^1J(^{195}Pt–^{31}P)$ coupling constant of 3790 Hz observed for the platinum complex is indicative of *cis*-square planar geometry, a useful comparison [19] being the values for *cis*- and *trans*-$[PtCl_2(PPh_2Bu^n)_2]$ of 3641 and 2531 Hz, respectively. It appears, therefore, from these $\Delta\delta$ and J values that our preparative route leads to the *trans*-isomer for the palladium compound, as has been established by crystallography for $[PdBr_2(HA)_2]$ [13], whereas the platinum compound is isolated as the *cis*-isomer. Further evidence supporting this proposal comes from infrared spectroscopic and, for the palladium complex, crystallographic results (*vide infra*).

The infrared-active asymmetric and symmetric carboxylate stretches are little changed from those of the free acid indicating the lack of coordination to the

Symmetry transformations used to generate O(2′): $1-x$, $1-y$, $2-z$.

metals *via* this part of the ligand but not excluding the likelihood of carboxylic acid hydrogen-bonding which is also present in the free acid [23]. The molybdenum tetracarbonyl complex exhibits four strong ν(CO) stretches as predicted for a *cis*-octahedral species, the frequencies being very similar to those of *cis*-$[Mo(CO)_4(PPh_3)_2]$ [24]. The copper(I) tris-ligand complex shows a ν(CuCl) stretch at 247 cm^{-1} which compares well with that of $[CuCl(PPh_3)_3]\cdot MeCN$ [21] at 249 cm^{-1}. A similar band for the mono-ligand complex has not been detected but would be below the lower limit of our spectrometer (200 cm^{-1}) if it possesses, as we believe on the basis of mass spectrometry evidence, a cubane-type $[CuCl(HA)]_4$ arrangement. The gold complex has ν(AuCl) at 335 cm^{-1}, a similar frequency [25] to that of linear $[AuCl(PPh_3)]$, 325 cm^{-1}. The palladium complex has one band which can be assigned to ν(PdCl) at 330 cm^{-1} whereas the platinum complex has two bands assignable to ν(PtCl) at 332 and 303 cm^{-1}. This is in line with the respective suggestions above of *trans*- and *cis*-square planar geometries and also in agreement with the known structure of *trans*-$[PdBr_2(HA)_2]$ [13] and the stereochemistry of the recrystallised material *trans*-$[PdCl_2(HA)_2]\cdot 0.33EtOH\cdot 0.33H_2O$ produced in this study.

Positive and negative ion FAB mass spectra have been obtained for all except the platinum compound. Generally only the major metal-containing positive ions are given in Section 2. One particularly novel fragmentation involves the decarboxylation of coordinated diphenylphosphinoacetic acid generating methyldiphenylphosphine as the successor ligand. As expected, stepwise loss of four carbonyl ligands is observed for the molybdenum complex. Both positive and negative ion fragments are listed for [CuCl(HA)] only, because significant fragment ions of correct isotopic distribution to be derived from Cu_4Cl_4 units are detected. This strongly suggests that a tetrameric cubane-type structure akin to that of $[CuCl(PPh_3)]_4$ or a step-type stucture as shown by $[CuBr(PPh_3)]_4\cdot 2CHCl_3$ is taken up [26, 27]. The mass spectrum of the gold complex contains few fragments but a dimer parent ion and the dimer less one chloride ligand are both detected in agreement with the solid state structure discussed below.

Recrystallisation of *trans*-$[PdCl_2(HA)_2]$ from ethanol gave crystals of *trans*-$[PdCl_2(HA)_2]\cdot 0.33EtOH\cdot 0.33H_2O$ showing rather different IR band frequencies to those of the unsolvated complex [e.g. $\nu_{asym}(CO_2)$ 1705, 1694 and $\nu_{sym}(CO_2)$ 1302 cm^{-1}]. The crystal stucture is quite involved, the asymmetric unit containing three half molecules of the complex together with one molecule each of water and ethanol, both at half site occupancy, i.e. 1 H_2O and 1 EtOH for every 3 palladiums. Three independent square planar *trans*-$[PdCl_2(HA)_2]$ species are present in the structure, all three metal atoms being located at inversion centres intrinsic to the space group symmetry. Fig. 1 shows a portion of the overall structure with the asymmetric unit delineated by those labelled atoms which are unprimed. Two of the *trans*-$[PdCl_2(HA)_2]$ units, those involving Pd(1) and Pd(2), are similar and are involved in the formation of a one-dimensional polymeric array along the *a* axis *via* two-fold hydrogen bonding to lattice neighbours through carboxylic acid groups (see Fig. 2). This form of hydrogen bonding is directly related to that found in carboxylic acids themselves,

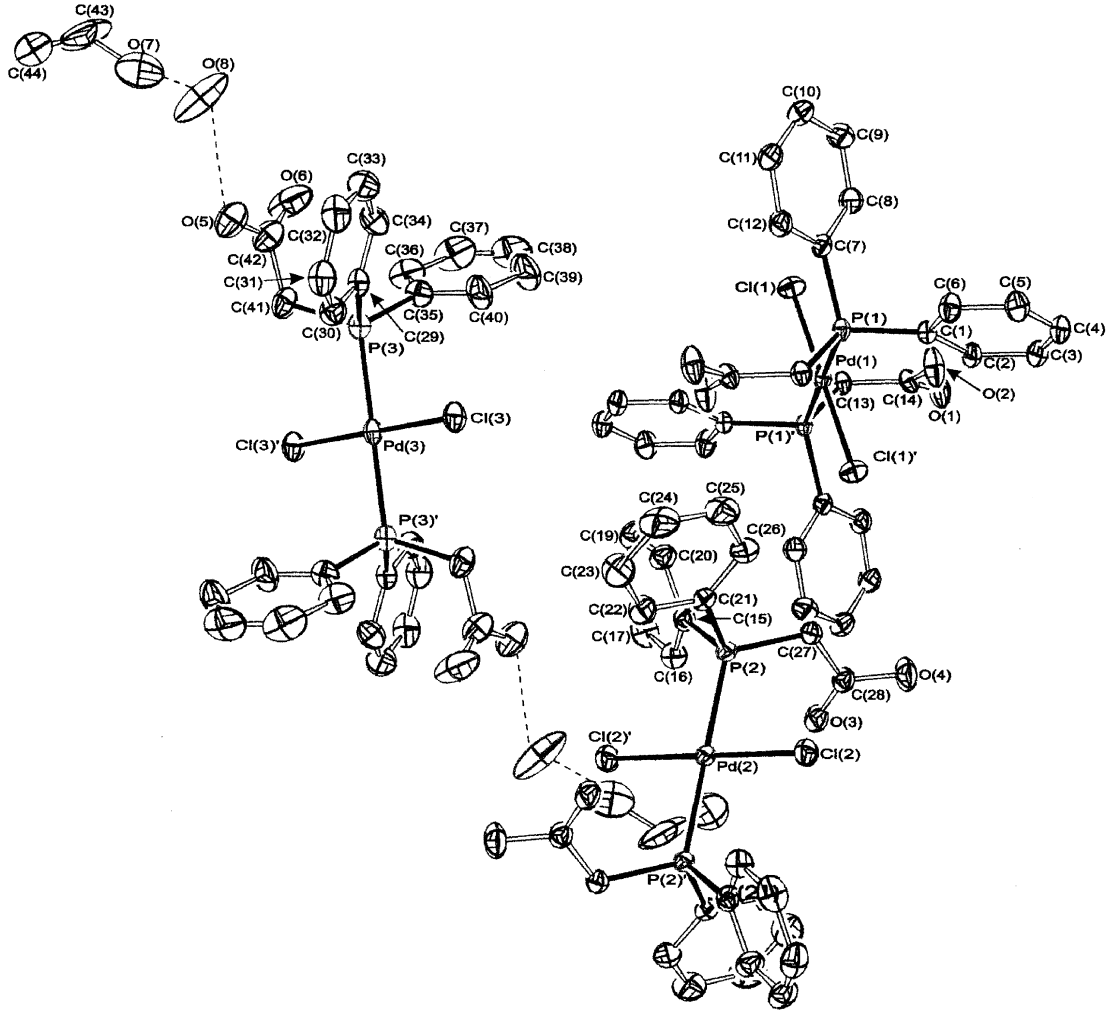

Fig. 1. The unit cell contents of $[PdCl_2(Ph_2PCH_2CO_2H)_2] \cdot 0.33EtOH \cdot 0.33H_2O$ showing the labelling scheme. The asymmetric unit comprises the atoms with unprimed labels. Thermal ellipsoids are at the 30% probability level.

e.g. acetic acid [28]. These polymers are stacked in the *b* direction and alternate between Pd(1)- and Pd(2)-containing molecules at half unit cell intervals. The *trans*-$[PdCl_2(HA)_2]$ moieties containing Pd(3) are different, (see Fig. 3). These molecules are not involved in carboxylic acid derived hydrogen bonding to generate polymeric arrays. Rather, discrete hydrogen-bonded entities are formed by interaction of the -OH of each carboxylic acid unit with the oxygen of each water molecule present. The water molecules are then further hydrogen-bonded to the ethanol solvent molecules. Given that the protons associated with $-CO_2H$, H_2O and ethanol hydroxyl groups could not be located in the crystallographic study, the presence of the various types of hydrogen bonding was inferred from short O . . . O distances.

Despite the fact that all three metal atoms are situated at inversion centres, thus rendering all P–Pd–P and Cl–Pd–Cl angles with a value of 180° where each metal centre is co-planar with its attached donor atoms, the metal centres have, nonetheless, slightly different coordination environments. For example, the three individual Pd–Cl bond lengths are quite consistent [2.295(1), 2.303(1) and 2.305(1) Å] whereas the Pd–P bond lengths vary significantly [2.326(1), 2.309(1) and 2.337(2) Å]. However, the mean of the Pd–P bond lengths exactly matches that determined for *trans*-$[PdBr_2(HA)_2]$, 2.332 Å [13]. Also, whereas the species containing Pd(3) has Cl–Pd–P angles close to the ideal 90° [89.10(5)°], the corresponding angles associated with Pd(1) and Pd(2) show some deviation [86.76(4) and 86.45(5)°, respectively]. Although a Pd . . . O separation of 3.171(6) Å was regarded as evidence of a weak additional interaction in the structure of *trans*-$[PdBr_2(HA)_2]$ [13], the shortest Pd . . . O contact in the present structure is 3.26 Å between Pd(1) and O(2) and we do not feel that this is significant. For all three molecules, the P–CH_2CO_2H bond lengths

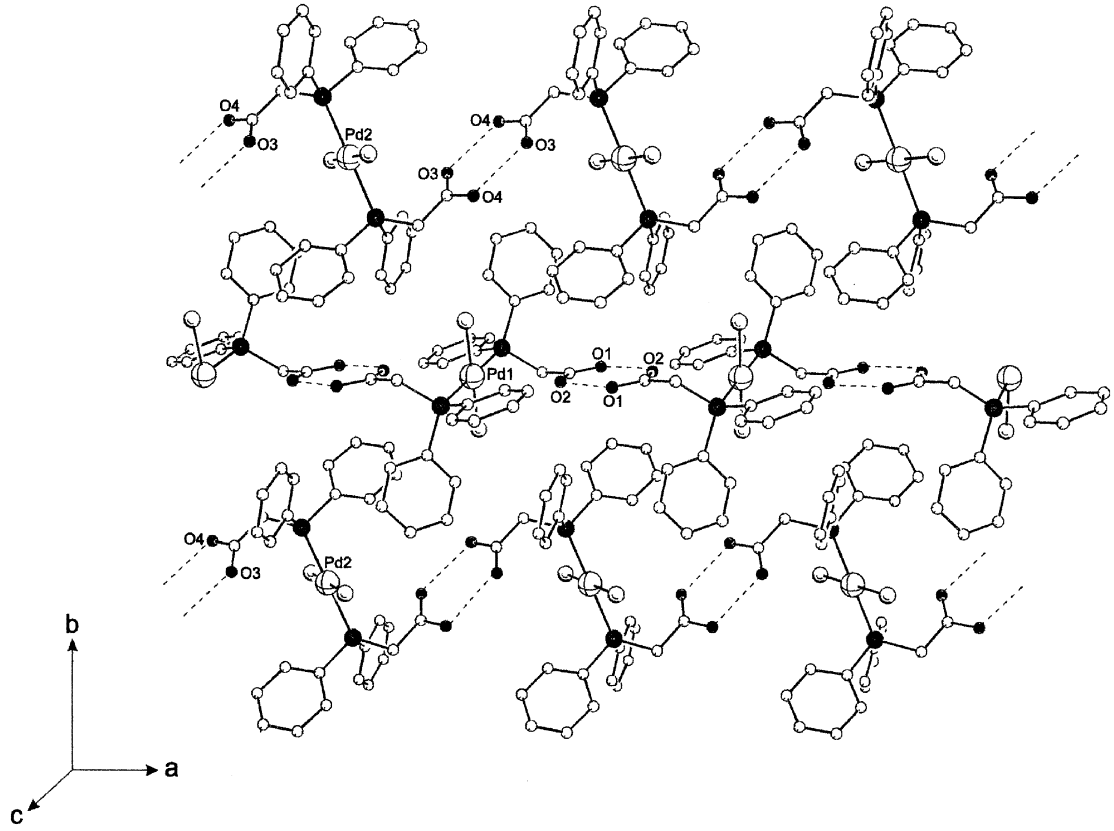

Fig. 2. View down the *c* axis of the palladium compound showing the one-dimensional chains formed by hydrogen bonded carboxylic acid groups.

are noticeably longer than the P–C(aryl) bond lengths, a feature much less apparent in *trans*-[$PdBr_2(HA)_2$]. Conversely, within the -CH_2CO_2H groups, the mean C–C bond length of 1.492 Å is rather shorter than that of *trans*-[$PdBr_2(HA)_2$] at 1.523 Å. The three molecules show quite different carboxylic acid C–O bond lengths, the distinction between the formal C–OH and C=O bonds being most obvious in the molecules containing Pd(2) [difference 0.099(6) Å], which is very similar to that of *trans*-[$PdBr_2(HA)_2$] [difference 0.095(9) Å] [13]. This difference is less significant in the molecules containing Pd(3) [difference 0.052(9) Å] and essentially absent in molecules containing Pd(1) [difference 0.007(6) Å]. This unexpected observation may relate to the type, degree of asymmetry and extent of the hydrogen bonding for each molecular species. Differences between the three molecules are also marked when the various Pd–P–C, P–C–C and C–P–C angles are considered, although details will not be given here. The O–C–O angles in each of the three molecules are slightly greater than 120° [122.4(4), 122.4(5) and 124.4(7)°], the largest angle being associated with molecules containing Pd(3).

The intermolecular hydrogen bonding involving molecules containing Pd(1) and Pd(2) generates two sets of one-dimensional polymeric chains (Fig. 2). The O . . . O distances of molecules involving Pd(2) centres, 2.686(5) Å, are similar to those found in *trans*-[$PdBr_2(HA)_2$] [13], *cis*-[PtBr(A)(HA)] [8], *cis*-[Rh(CO)(A)(HA)] [9] and, indeed, in the free acid [23], being 2.710(7), 2.620(6), 2.67 and 2.660(7) Å, respectively. The hydrogen bonding involved in linking molecules containing Pd(1) is of the same type with a slightly shorter O . . . O interaction of 2.614(6) Å. The hydrogen bonding associated with molecules containing Pd(3) does not generate a polymer as a consequence of only 50% site occupancy of the water and ethanol solvate molecules. The O . . . O contacts between O(5) of the complex containing Pd(3) and O(8) of H_2O and between O(8) of H_2O and O(7) of EtOH are 2.67(2) and 2.91(2) Å, respectively, the latter therefore indicating a much weaker form of hydrogen bonding than that of the carboxylic acid variety in the molecular structure. The final carboxyl oxygen, O(6) is unique among the six carboxylic acid oxygens in not being involved in intermolecular hydrogen bonding, as is evident from the long O(6) . . . O(8) separation of 3.39(2) Å.

In the complex [AuCl(HA)], the gold displays linear coordination [Cl–Au–P 179.0(1)°] with two individual molecules linked into a dimer (Fig. 4) again with two sets of O . . . O interactions of 2.618(9) Å, which are

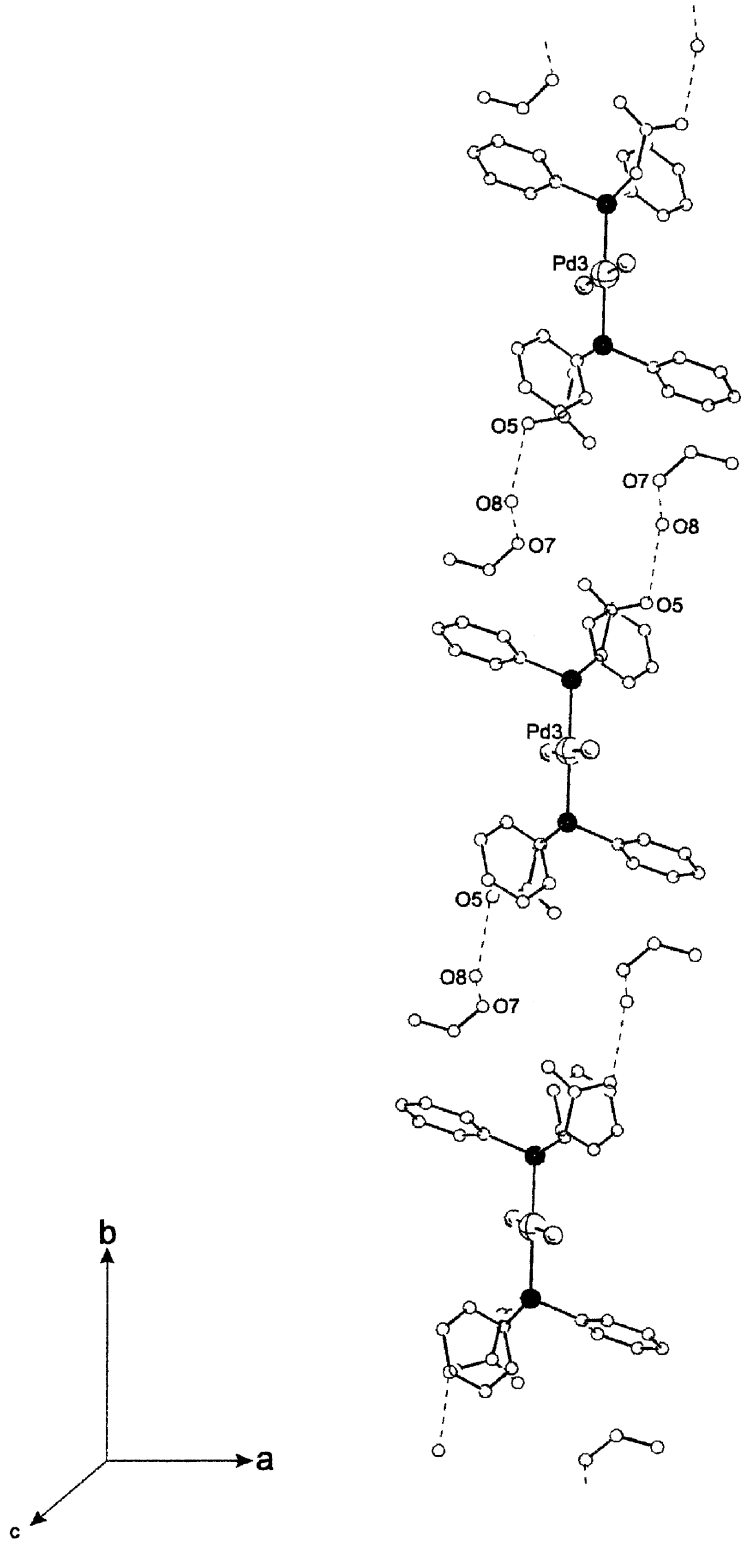

Fig. 3. View down the *c* axis of the palladium compound showing the discrete hydrogen bonding involving carboxylic acid, water and ethanol molecules. Only 50% occupancy of the positions of the solvent molecules is observed.

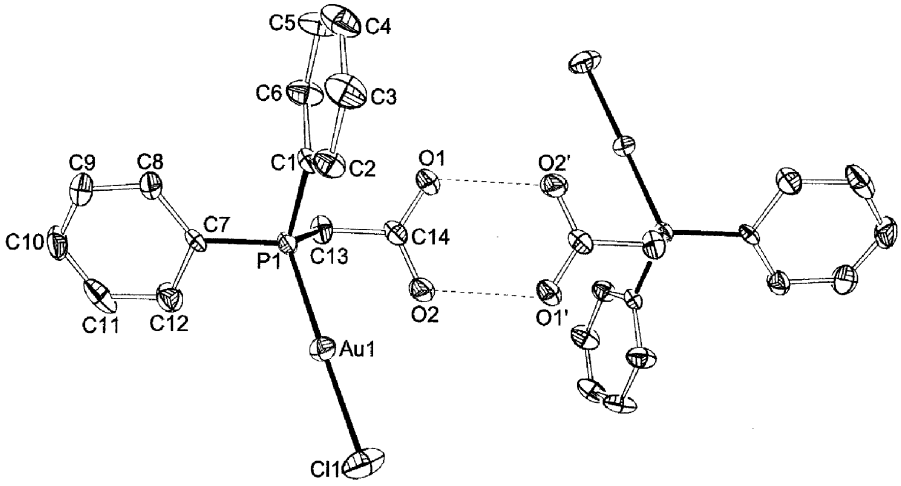

Fig. 4. ORTEX plot of the hydrogen bonded dimer of [AuCl($Ph_2PCH_2CO_2H$)] showing the labelling scheme. Thermal ellipsoids are at the 30% probability level.

slightly shorter than those for the palladium compound noted above. The individual C–O bond lengths of 1.237(10) and 1.265(11) Å suggest that the carboxylic acid protons are not quite symmetrically placed in the hydrogen bonding array, being more closely associated with O(2) rather than O(1). The hydrogen bonded dimers are formed by assembling neighbouring molecules in the lattice which are spatially related by an inversion centre. Typically, O(1) and O(2) of the molecule as presented are hydrogen bonded to O(2′) and O(1′), respectively, of the neighbouring molecule generated *via* the operator $1-x$, $1-y$, $2-z$. The OCO angle of 122.5(8)° compares to that of 122.2(4)° for the free acid [23] which displays a similar hydrogen bonding arrangement. The hydrogen bonding system holds the AuCl units well apart prohibiting intra-dimer aurophilic Au . . . Au contacts which have been identified in the structures of some linear gold(I) compounds [29].

The Au–Cl bond length of 2.270(3) Å is very similar to those of [AuCl(PPh_3)] [30] and [AuCl{$Ph_2PCH_2C(O)NHMe$}] [20] [2.279(3) and 2.275(2) Å, respectively] and the Au–P bond length of 2.220(2) Å also compares well with those of the above two complexes [2.235(3) and 2.221(1) Å, respectively]. The P–CH_2CO_2H bond length is, as found for the palladium complex, slightly longer than the P–C(aryl) bond lengths but the mean P–C bond lengths (1.812 Å) and C–P–Au and C–P–C bond angles (113.8 and 104.8°, respectively) are closely similar to those of [AuCl(PPh_3)] [30] (1.820 Å, 113.5° and 105.1°, respectively) showing that substitution of a phenyl ring for a -CH_2CO_2H group has little effect structurally, apart from the generation of an additional hydrogen bonding array.

(Received 11 November 1997; accepted 30 May 1998)

Abstract—A series of Schiff-base bridged polypyridine ruthenium(II)-quencher [here after abbreviated as Ru-Q] molecules have been prepared and characterized, where the functional groups Q were dimethylamino(-$N(CH_3)_2$, methyloxyl(–OCH_3), hydroxyl(–OH) and nitro group(NO_2). Steady state and time resolved luminescence measurements of these ruthenium complexes show that the luminescence properties of the Ru(II) MLCT excited state of Ru–OCH_3 is only slightly modified from that of $Ru(bpy)_3^{2+}$, whereas the quenchers group Q in the Ru–$N(CH_3)_2$, Ru–OH and Ru–NO_2 complexes can quench the yield and lifetime of the Ru MLCT emission. Electrochemistry measurement suggests that the quenching processes were the long-range intramolecular electron transfer reductive quenching for the Ru–OH and Ru–$N(CH_3)_2$ and oxidative quenching for the Ru–NO_2, respectively. Single crystal structure analysis of the Ru–$N(CH_3)_2$ complex revealed that the coordination geometry of the ruthenium is a slightly distorted octahedron with four nitrogen atoms of the two bipyridine molecule and two nitrogen atoms from the L-$N(CH_3)_2$ ligands, p-dimethylamionbenzaldehyde 4, 5-diazafluorene-9-hydrazone. The Ru–N distances are in agreement with those in the other polybipyridine ruthenium complexes. © 1998 Elsevier Science Ltd. All rights reserved

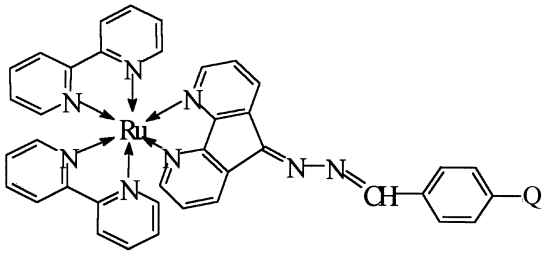
Keywords: Crystal structure; ruthenium(II) complexes; quenching process; electron transfer

Over the last 30 years, a considerable amount of effort has been devoted to probe the mechanism of long range electron transfer, and detailed theoretical treatments have gradually emerged [1–3]. However, experiments have been hampered by the inherent difficulties of designing systems in which each variable can be controlled independently. In comparison to the numerous studies that have focused on the distance dependence of ET rates[4–10], little quantitative information regarding the reaction driving force is available.

In order to gain better understanding of the ET fundamentals in such systems we have designed and synthesized a series of molecules containing an inorganic chromophore and an organic quencher, separated by a long range bridging ligand [11, 12]. In most of these complexes, tris(2, 2′-bipyridine) ruthenium was always chosen as the chromophore, since it can demonstrate the combined attributes of a significantly absorption in the visible spectral region, the relative longevity of the metal-to-ligand charge transfer and capture of the metal center in a variety of oxidation states and the rapidity of the redox reactions involving the excited state (quench). The lowest excited state properties of the complexes of this gene are controlled by the pattern of low-lying electronic levels which are ligand-dependent [13–15]. By changing the ligand around the ruthenium center, it is possible to "fine tune" the redox and photophysical properties of the ground and excited states of these polypyridinyl ruthenium(II) complexes.

†Author to whom correspondence should be addressed.

The Ru-Q systems (see Scheme) described here



possess several features relevant to the study of intramolecular photoinduced electron transfer phenomenon, the most important of which is that the direction and free energy of electron transfer can be controlled simply by changing the redox potential of the functional group Q. This not only allows for the study of electron transfer versus transfer mechanism in fine details, but also offers the opportunity to more fully explore the interplay between the reaction driving force and the electron transfer rate [1, 13].

EXPERIMENTAL

Physical measurements

Elemental analyses were performed on a Perkin–Elmer 240C analytical instrument. IR spectra were recorded on a Nicolet FT-IR-170SX instrument (KBr discs) in the 4000–400 cm^{-1} range. The solution electronic spectra were obtained on a Shimadzu 240 spectrophotometer in CH_3CN solution. ^{1}H-NMR spectra were recorded on a Bruker Aspect AM300 spectrometer at ambient temperature in DMSO-d_6 using TMS as an internal reference.

Preparations

4,5-diazafluorene-9-hydrazine and $[Ru(bpy)_2Cl_2]\cdot {}_2H_2O$ were prepared according to the literature [16, 17]. All other chemicals were reagent grade and used without further purification.

p-Dimethylaminobenzaldehyde 4, 5-*diazafluorene*-9-*hydrazone* (L–$N(CH_3)_2$)

4–5 drops of acetic acid were added to an ethanol solution of 4,5-diazafluorene-9-hydrazine (1.0 mmol, 0.196 g) and p-dimethylaminobenzaldehyde (1.0 mmol, 0.89 g). A red solid formed after refluxing for 3 hours was isolated. Yield 0.31 g (90%). Anal. calcd for $C_{20}H_{17}N_5\cdot H_2O$: C, 69.5; H, 3.5; N, 20.3. Found: C, 69.0. H, 3.2; N, 19.7. IR(cm^{-1}): ν(C═N) 1628, 1564; ν(C═C), 1508, 1397; δ(C–H) 750(diazafluorene), 695(phenyl). ^{1}H-MNR, 8.74(*s*, 1H, N═CH); (4,5-diazafluorne ring): 9.00(*d*, 1H), 8.75(*d*, 1H), 8.73(*d*, 1H), 8.26(*d*, 1H), 7.55(*t*, 1H), 7.53(*t*, 1H); (phenyl ring) 7.90(*d*, 2H), 6.87(*d*, 2H); methyl group: 2.17(*d*, 6H). Uv-vis(nm) (logϵ). 248(2.14), 325(2.19).

p-Methoxylbenzaldehyde 4,5 *diazafluorene*-9-*hydrazone* (L-OCH_3)

The compound was synthesized by similar procedure but by using p-methoxylbenzaldehyde (1.0 mmol, 0.136 g) instead of p-dimethylaminobenzaldehyde, yield 0.24 g(85%) of yellow solid. Anal. calcd for $C_{19}H_{14}N_4O$: C, 68.6. H, 4.8; N, 16.7. Found: C, 69.0; H, 4.6; N, 16.4. IR (cm^{-1}) ν(C═N) 1605, 1565; ν(C═C), 1512, 1395, ν(C–O) 1153, 1060, δ(C–H) 749 (diazafluorene), 693(phenyl). ^{1}H-NMR, 8.69(*s*, 1H, N═CH); (4,5-diazafluorne ring) 8.97(*d*, 1H), 8.71(*d*, 1H), 8.69(*d*, 1H), 8.33(*d*, 1H), 7.53(*t*, 1H), 7.48(*t*, 1H); (phenyl ring) 7.96(*d*, 2H), 7.11(*d*, 2H); methyl group: 2.63(*d*, 3H) Uv-vis(mm) (logϵ) 254(1.69), 377(2.75).

p-Hydroxylbenzaldehyde 4,5-*diazafluorene*-9-*hydrazone* (L-OH)

The compound was synthesized by similar procedure but by using p-hydroxylbenzaldehyde (1.0 mmol, 0.14 g) instead of p-dimethylaminobenzaldehyde. Yield 0.25 g(87%) of orange solid. Anal. calcd for $C_{18}H_{12}N_4O\cdot H_2O$: C, 67.9; H, 4.4; N, 17.6. Found: C, 68.2; H, 4.6; N, 17.1 IR(cm^{-1}) 1615, 1565, ν(C═C), 1504, 1395; ν(C–O), 1020; δ(C–H) 753 (diazafluorene), 705 (phenyl). ^{1}H-NMR: 8.69(*s*, 1H N═CH); (diazafluorne ring) 9,04(*d*, 1H), 8.71(*d*, 1H), 8.68(*d*, 1H), 8.36(*d*, 1H), 7.54(*t*, 1H), 7.47(*t*, 1H), (phenyl ring) 7.90(*d*, 2H), 6.96(*d*, 2H). Uv-vis(nm) (logϵ) 252(1.60), 282(2.80)

p-Nitrobenzaldehyde 4,5-*diazafluorene*-9-*hydrazone* (L–NO_2)

The compound was synthesized by similar procedure but by using p-Nitrobenzaldehyde (1.0 mmol, 0.15 g) instead of p-dimethylaminobenzaldehyde, yield 0.28 g (90%) of yellow product, Anal. calcd for $C_{18}H_{11}N_5O_2\cdot H_2O$: C, 62.2; H, 3.8; N, 20.2. Found: C, 62.5; H, 4.0; N, 19.8. IR (cm^1) ν(C═N) 1598, 1565, ν(C═C), 1508, 1394, ν(N–O), 1394. δ(C–H) 750 (diazafluorene), 695 (phenyl). ^{1}H-NMR: 8.69(*s*, 1H N═CH), (diazafluorne ring) 9,03(*d*, 1H), 8.72(*d*, 1H), 8.67(*d*, 1H), 8.32(*d*, 1H), 7.51(*t*, 1H), 7.47(*t*, 1H); (phenyl ring) 7.80(*d*, 2H), 6.97(*d*, 2H). Uv-vis(nm) (logϵ). 252(2.71), 262(2.48)

Ru–$N(CH_3)_2$)

To an ethanol solution of $[Ru(bpy)_2Cl_2]\cdot {}_2H_2O$ (2 mmol, 1.04 g) was added ligand L-$N(CH_3)_2$ (2.2 mmol, 0.56 g). After refluxing under nitrogen for 8 h in the dark, the mixture was filtered into a methanol solution containing 0.4 g hexafluoro-

phosphate. The dark-brown solid formed was isolated and dried under vacuum. Yield: 1.6 g(75%). Anal. calcd. for $C_{40}H_{33}N_9RuP_2F_{12}$ C, 46.6; H, 3.2; N, 12.2. Found: C, 46.6; H, 3.5: N, 12.0. IR(cm^{-1}): ν(C═N) 1628, 1564; ν(C═C), 1508, 1397; ν(PF), 842; ν(C–H), 750 (diazafluorene), 695 (phenyl); ν(Ru–N), 558. ^{1}H-NMR 8.87(*s*, 1H, N═CH); (bipyridine ring): 8.55(*d*, 2H), 8.40(*d*, 2H), 8.28(*t*, 2H), 8.24(*t*, 2H), 7.97(*t*, 2H), 7.93(*t*, 2H), 7.65(*d*, 2H), 7.62(*d*, 2H); (4.5-diazafluorne ring): 9.08(*d*, 1H), 8.87(*d*, 1H), 8.85(*t*, 1H), 8.45(*d*, 1H), 7.74(*t*, 1H), 7.47(*d*, 1H); (phenyl ring): 8.02(*d*, 2H), 6.91(*d*, 2H); methyl: 2.17(*d*, 6H). Uv-vis(nm) (logϵ). 215(3.00), 234 (3.66), 284(6.26), 440(2.94).

Ru–OCH_3

The compound was prepared according to same procedure using ligand (L-OCH_3) (0.73 g, 2.2 mmol) instead of ligand L-N(CH_3)$_2$. Yield 1.5 g(76%). Anal. calcd for $C_{39}H_{3O}F_{12}N_8OP_2Ru \cdot H_2O$: C, 45.22; H, 3.11; N, 10.82. Found: C, 45.20; H, 2.98; N, 10.47. Electrochemistry

Differential-pulse voltammetry was done with an EG and GPAR model 273 instrument, which has a 50 ms pulse width, with current sampled 40 ms after the pulse was applied. A sweep rate of 2 mV/s was used in all pulse experiments with a drop time of 0.5 s. Cyclic voltammetry were also performed using EG and GPAR model 273 potentiostats in a three-electrodes cell. The cell was fitted with purged N_2 inlet and outlet and comprise of a platinum-wire working electrode, a platinum auxiliary electrode and a Ag/AgCl reference electrode. Current-potential curves were displayed on am IBM computer using model 270 electrochemical analysis software. Data were recorded on a Hewlett-Packard recorder. The voltammograms of the complexes were obtained in dichloromethane with n-Bu_4NClO_4 (0.1 mol dm^{-3}) as the electrolyte.

Caution! Although no problems were encountered in this work, the salt perchlorates are potentially explosive. They should be prepared in small quantities and handled with care.

Luminescence studies

Steady luminescence intensities were measured on Perkin Elmer LS50 spectrofluometer in acetonitrile at room temperature with irradiation at 440 nm. Sample concentrations were $\approx 1 \times 10^5$ M. The Uv-vis absorption spectra of the solutions used in luminescence experiments were measured before and after the collection of steady state and time resolved data. In every case the spectra were identical before and after the experiments, indicating that sample degradation did not occur during data acquisition. Emission intensities for vacuum degassed solution of all the four complexes were measured with respect to Ru(bipy)$_3$(ClO_4)$_2$ in CH_3CN solution (concentration $= 1.0 \times 10^{-5}$ M, $\phi_{em} = 0.062$) [13]. Correction was made for the difference in absorption of the sample at the excited wavelength.

Time-resolved emission decay were measured following excitation by a FL2002 dye laser pumped by an EMG 201 quasimolecular laser. Lasing at 450 nm was achieved by coumarine 460(Excitation). Emission was monitored at right angle to the excitation by using a Hamamastsu R3896 PMT (photo multiplier tube) coupled to a Macpherson 272 scanning mono-

chromator. The output of the PMT was processed by a Lecroy 7200A transient digitizer interfaced to an IBM-PC. Transient decays were fitted to single-exponential functions.

Crystallography

A prismatic crystal with dimensions of $0.34 \times 0.18 \times 0.12$ of Ru–N$(CH_3)_2$ was mounted on a glass fibre and used for data collection. Cell constants were obtained by least-square refinements on the 275 reflections in the range $2\theta_{max} = 55.0^\circ$. The intensities were collected at 294 K on a Rigaku RAXIS-IIC imaging-plate diffractmeter using MoKα radiation ($\lambda = 0.71073$ Å) from a rotating-anode generator operating at 50 kV and 90 mA ($2\theta_{max} = 55.0^\circ$) with 60 oscillation frames and in the range of $0 \sim 180^\circ$, exposure 8 min per frame [18, 19]. Absorption corrections were made using the ABSCOR program based on Fourier-coefficient fitting to the intensities of symmetry-equivalent reflections [20].

The Ru–N$(CH_3)_2$, $C_{40}H_{33}N_9Ru\ P_2F_{12}$ was crystallized in triclinic space group P-1 with cell dimensions of $a = 18.353(1)$, $b = 19.761(1)$, $c = 13.450(1)$ Å, $\alpha = 100.29(1)$, $\beta = 97.43(1)$, $\gamma = 90.44(1)$, $V = 4757(2)$Å, $Z = 4$, $Mr = 1010.8$, $Dc = 1.439\ gcm^{-3}$. The structure was solved by the direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares method. Hydrogen atoms of the ligand and solvent molecule were placed in calculated positions (C–H 0.96 Å), assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were include in the structure-factor calculations. Of 16455 reflection measured, 7662 were unique (Rint = 0.09%) and used in the structure determination and refinement. Final cycles of refinement converged with discrepancy indices of $R = 0.073$ and $R_w = 085$, with the weighting scheme being $[\sigma^2(F) + 0.0003F^2]^{-1}$. The Goodness of Fit is 1.33. The final difference Fourier map revealed only one peak above $1e/Å^3$, lying 0.85 Å from Ru(1). A maximum shift and shift/esd in the final cycles were 0.009 and 0.006, respectively. The atoms in two of the PF_6 anions were disordered and were refined with s.o.f = 0.5 for F(11), F(12), F(13), F(11′), F(12′) and F(13′); P(5), F(52) and F(54); and s.o.f = 0.25 for F(51), F(53), F(55), F(56), F(51′), F(53′), F(55′) and F(56′).

All computation were carried out on a PC-486 computer using the SHELXL-PC program [21] package. Additional materials available from the Cambridge Crystallographic Data Center comprise of the complete lists of atomic coordinates, thermal parameters and bond lengths and angles.

RESULTS AND DISCUSSION

Synthesis and spectral characterization

The ligands (see Scheme) were prepared by treating 4,5-diazafluorene-9-hydrazone with equivalent substituted benzaldehydes in refluxing ethanol solution. On refluxing of the $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ with 1:1 molar equivalent of the ligands in ethanol and with purged nitrogen gas inlet and outlet, the corresponding ruthenium(II) complexes were produced.

IR spectra of the ligand and ruthenium complexes are consistent with their structures, the bands near $1620\ cm^{-1}$ for free ligand and Ru(II) complexes can be assigned to C═N vibration of conjunction π system, the band at *ca* $760\ cm^{-1}$ is safely assigned to the δ(C–H) of the bipyridine and the 4,5-diazaflorene ring. The band at *ca* $560\ cm^{-1}$ which is not present in the IR spectra of the ligand is assigned to the Ru–N (bipy) stretching vibration of *cis*-configuration. The bands due to PF^-_6 and water molecules are present at $840\ cm^{-1}$ and $3400\ cm^{-1}$ respectively.

Proton NMR spectroscopy can play an important role in determining the purity and coordination geometry of ruthenium complexes. For the free ligands, it should be noted that there are six types of protons in the 4,5-diazafluorene ring, indicating the asymmetrical electron density on the two pyridine rings. The two multiplets can be assigned to the protons in the *m*-position of the azonitrogen atoms. Two doublets are assigned to the protons next to the azonitrogen atoms, while other doublets at the lower field should be assigned to the protons near hydrazone moieties. After formula complexes, the chemical shift of azomethine proton shifted to lower field [22, 23]. However, it is very difficult to assign each proton precisely.

The free ligands show two distinctive bands near 250 nm and 270 nm in the Uv-vis spectra, which can be assigned to the transition of $\pi \rightarrow \pi^*$ of the larger π-conjugated system in the these compounds. The π^* levels of bpy and ligand are at different energies. For the ruthenium complexes, new bands at *ca* 450 nm and 243 nm might be assigned to the charge transfer from the filled $d\pi$ (Ru^{II}) levels to low lying π^* (ligand levels) [26, 27] as $d\pi \rightarrow \pi_1^*$ and $d\pi \rightarrow \pi_2^*$, respectively. The broadening of the band at *ca* 450 nm might be contributed to the significant triplet character coupled in single MLCT transition and the mixing of separated MLCT transitions occurring in the Schiff-base ligand and the bipyridine molecules [26, 27].

Steady state and time-resolved luminescence spectra

Table 1 contains a summary of emission maxima and relative quantum yields of the Ru complexes in vacuum degassed CH_3CN solution. It is interesting to note that the emission energy and band shapes (Fig. 1) are nearly identical for each of the complexes indicating that the luminescence is from a $d\pi$ Ru$\rightarrow\pi^*$ bpy MLCT excited state like that of $Ru(bpy)^{2+}_3$ [28–30]. However, a number of distinctive differences between $Ru(bpy)^{2+}_3$ and the complexes are also observed: firstly, the emission maxima of the complexes are found at lower energy than that of $Ru(bpy)^{2+}{}_3$ and

shows one shoulder near 685 nm; secondly the quantum yield became smaller and are dependent on the substitution of the phenyl ring. These differences might be contributed to the quenching of the MLCT excited state of ruthenium moieties by the functional group Q. However, considering the much higher quantum yield of the CH_3O substituted ruthenium complex than the other ruthenium complexes, it can be suggested that the CH_3O functional group does not quench the MLCT excited state. This suggestion is also consistent with the predictions from the electrochemical experiments. The lower quantum yield noted for the $Ru–OCH_3$ relative to $[Ru(bpy)_2(phen)]^{2+}$ [13] is attributed to an effect of the long π-system upon the nonradiative decay rate of MLCT excited state.

Table 1 also listed the lifetimes of the MLCT luminescence for the four ruthenium(II) complexes $Ru(bpy)^{2+}{}_3$. The decay plot of the Ru-OCH_3 [Fig. 2(a)] is described well by a single exponential function with a lifetime of 620 ns. The lowering in quantum yield of the Ru-OCH_3 complex compared to that of $Ru(bpy)^{2+}{}_3$ is likely due to an effect of the OCH_3 group upon the non-radiative decay rate of the Ru MLCT excited state [31]. The experimental emission decays of the other ruthenium complexes are fitted using single-exponential functions, e.g. that for the $RuN(CH_3)_2$ is shown if Fig. 2(b). The emission lifetimes of the three complexes, which range from 350 to 150 ns, are all lower than those of $Ru–OCH_3$. The attenuation in emission lifetimes observed for the three Ru-Q complexes is attributed to quenching of the Ru MLCT excited state by intramolecular electron transfer between the Ru moiety and the functional group Q.

Mechanism of intramolecular electron transfer

Based on the quantum yield and the emission lifetime of these Ru-Q complexes, it is clear that the Ru MLCT excited state are efficiently quenched by the functional group, $-N(CH_3)_2$, –OH and $-NO_2$. Several possible quenching mechanisms must be considered: first, these Ru-Q complexes might undergo intermolecular electron transfer, but this possibility is unlikely, since the experiments are done at very low concentration and the observed quenching rate is too rapid to be ascribed to a bimolecular reaction, second quenching mode of the Ru MLCT excited state may involve energy transfer from ruthenium moieties to the functional group, however, this pathway is also considered unlikely because the spectral overlap between the Ru MLCT emission and absorption of the Schiff-base ligands is so small that energy transfer emission *via* coulombic mechanism can be effectively ruled out [32]; further evidence against an energy transfer mechanism in this system is provided by the sensitivity of the quenching rate to the redox potentials of the functional group Q. For these reasons, we believe that quenching occurs by intramolecular electron transfer.

Cyclic voltammetry and differential-pulse voltammetry of the four ruthenium complexes reveal that the first oxidation and reducation potentials for the Ru center common to each of the complexes are at *ca* 1.30 and -1.15 V(vs AgCl/Ag) on the average (Table 1). According to the emission and Uv-vis spectra of these ruthenium complexes, the MLCT excited state energy of these complexes can be calculated [12] as *ca.* 2.1 eV in an average (Table 1), which is compared to the MLCT excited state energy of $Ru(bpy)^{2+}{}_3$ (2.1 eV) [33] the average excited state potentials might be calculated as $E_{1/2}LRu(III)/*Ru(II)] = -0.80$ V, $E_{1/2}[*Ru(II)/Ru(II)] = 0.95$ V [34]. It follows that the *Ru MLCT is at the same time a good electron acceptor and a good electron donor (eq. 1) Table 2

$$*Ru(II) + Q \rightarrow Ru(III) + Q^{-} \text{ oxidative quenching}$$

$$*Ru(II) + Q \rightarrow Ru(I) + Q^{+} \text{ reductive quenching}$$

These potentials also indicates that an electron acceptor with a reduction potential > -0.80 V or an electron donor with an oxidation potential > 0.95 V will quench the MLCT excited state by electron transfer.

Cyclic voltammetry on the $Ru–OCH_3$ complex reveals that the CH_3O- functional group is not redox active within the potential -1.0 V to $+1.0$ V. This indicates that the CH_3O- functional group cannot quench the Ru MLCT excited state by thermodynamically favorable electron transfer.

Cyclic voltammetry of the $Ru–N(CH_3)_2$ and Ru–OH complexes reveals that in addition to the characteristic waves for the Ru complex, an irreversible cathodic wave is observed at Ep = 0.85 V and 0.76 V for the $–N(CH_3)_2$ and –OH functional group, respectively. The irreversibility indicates that the chemical reactions of the functional group are significant on the tune scale of the electrochemical experiment. Under these conditions the peak potential for the observed wave only approximates the true thermodynamic potential for the electrode process. However, differential pulse voltammetry reveals that the $E_{1/2}$ for the two oxidation reactions are 0.83 and

0.73 V, respectively. From this potential along with the excited state oxidation potentials for the Ru complex described above, the *Ru(II) was quenched through reductive quenching process in the Ru–N$(CH_3)_2$ and Ru–OH complexes. The free energy for *Ru to oxidise the functional groups is estimated to be -0.08 V and -0.28 V for Ru–N$(CH_3)_2$ and Ru-OH complexes respectively.

Cyclic voltammetry of the Ru–NO_2 complex also reveals that in addition to the characteristic waves for the Ru complex, an irreversible cathodic wave is observed at Ep $= -0.65$ V for the NO_2 functional group. Differential-pulse voltammetry reveals that the $E_{1/2}$ for the reduction reaction is -0.59 V. From this potential along with the excited state oxidation potentials for the Ru complex, the *Ru MLCT was quenched through oxidative quenching process in the Ru–NO_2 complex. The free energy for *Ru to reduced the functional group is estimated to be -0.18 eV.

Description of crystal structures

In most references, the mechanism of electron transfer and the relationship between the rate constant and the donor-acceptor separation can not be discussed fully because of the flexibility of the bridging ligand and the uncertainty of the D–A separation. In this case, the crystal structure of the molecular is efficient for a detailed discussion of the photoinduced electron transfer studies. In our earlier studies, the crystal structure of the free ligand L-N$(CH_3)_3$ has been reported [35]. In this paper, we discussed the crystal structure of the Ru–N$(CH_3)_2$ complex.

There are two slightly different Ru(II) moieties in the asymmetric unit (Fig. 3). In each moiety, the coordination geometry of the ruthenium ion is a slightly distorted octahedron with four pyridine nitrogen atoms from the two bipyridine molecules, and two nitrogen atoms from the Schiff-base ligand, *p*-dimethylaminobenzaldehyde 4-5-dizafluorene-9-hydrazone. The Ru–N(bpy) distances of 2.04–2.06 Å are good in agreement with the value of 2.056 Å found in $[Ru(bpy)_3](PF_6)_2$ [36] and similar bis(bipyridyl) ruthenium complexes [37–41].

The bite angles of the two bipyridine ligands are 79.6(2), 79 2(2)° for Ru(1) and 79.5(2), 79.0(2)° for Ru(2), respectively. While the bite angle of the Schiff-base ligand, L-N$(CH_3)_2$, are 83.0(2) for Ru(1) and 82.2 (2) for Ru(2), respectively, these angles are somewhat bigger in keeping with the increased size of the chelating ring, The two *trans* angles associated with the Schiff-base ligand are 171.8(2), 170.9(2) for Ru(1) and 170.0(2), 170.7(2) for Ru(2), respectively. These values are quite different from the *trans* angles associated to the bipyridine nitrogen atoms. (175.2(2) for Ru(1) and 173.9(2) for Ru(2), respectively). The bond lengths and angles of the ligand L-N$(CH_3)_2$ in the complex are in normal range and consistent with those of the free ligand.

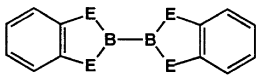
Abstract—The syntheses and structures of the 2,2′-bipyridyl and 1,10-phenanthroline adducts of the diborane(4) compound $B_2(1,2\text{-}S_2C_6H_4)_2$ are described. In both cases, the bidentate nitrogen donor ligands bridge the B–B bond, one nitrogen being bonded to each boron. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: diborane(4); ligand adducts.

INTRODUCTION

Diborane(4) compounds, B_2R_4 (for a recent overview containing key references, see Ref. [1]), have been the focus of renewed interest in recent years, not least because of their importance as reagents in transition metal catalysed diboration reactions [2], and as part of our own interest in such compounds, we have recently reported results relating to the Lewis acidity of the boron centres [3, 4]. Specifically, we noted that the compounds $B_2(cat)_2$ (**1**) (cat = 1,2-$O_2C_6H_4$) and $B_2(thiocat)_2$ (**2**) (thiocat = 1,2-$S_2C_6H_4$) [5, 6] formed both *mono* and *bis*-adducts with 4-picoline [3, 4], whilst **2** also formed *mono* and *bis*-adducts with tertiary phosphines consistent with a greater degree of Lewis acidity for the sulphur substituted boron centres [4]. Herein, we describe the adducts formed between **2** and 2,2′-bipyridyl and 1,10-phenanthroline.



1, E = O; **2**, E = S

4, E = S; **5**, E = O

RESULTS AND DISCUSSION

Reactions between **2** and one equivalent of either 2,2′-bipyridyl (bipy) or 1,10-phenanthroline (phen) in CH_2Cl_2 solution led to the immediate formation of a

* Authors to whom correspondence should be addressed.

coloured (pale red in the case of **3** and red in the case of **4**) solution. After addition of an overlayer of toluene and subsequent solvent diffusion over a period of days at -30°C, dark red (almost black in the case of **4**) crystals were obtained, analytical data for which were in accord with the formulae $[B_2(thiocat)_2(bipy)]$ (**3**) and $[B_2(thiocat)_2(phen)]$ (**4**) (in both cases, with some solvent of crystallisation: see Experimental section).

Single crystals of both **3** and **4**, although of relatively poor quality, were suitable for X-ray crystallography, the results of which are shown in Figs 1 and 2 with selected bond lengths and angles given in Table 1. Compound **3** (Fig. 1) crystallises as a CH_2Cl_2 solvate with two molecules of **3** and two of CH_2Cl_2 in the asymmetric unit. The independent molecules of **3** are essentially identical (they are related by a pseudo-inversion centre; see Experimental section) and consist of units of **2** with the bipy ligand bridging the B–B bond, one nitrogen centre being bonded to each boron. The two B–B distances [B(1)–B(2) 1.65(5) and B(3)–B(4) 1.61(4) Å] are the same within experimental error and similar both to the B–B distance in **2** itself [1.673 Å average for two independent molecules] [6] and to the corresponding bond lengths in the related *bis*-adduct compounds of **2** $[B_2(thiocat)_2(4\text{-picoline})_2]$ [B–B 1.715(10) Å] and $[B_2(thiocat)_2(PMe_2Ph)_2]$ [B–B 1.750(4) Å] [4]. The B–S distances in **3** (average 1.916 Å) are similar to those found in $[B_2(thiocat)_2(4\text{-picoline})_2]$ and $[B_2(thiocat)_2(PMe_2Ph)_2]$ and the B–N bond lengths (average 1.65 Å) are also similar to those found in both the *mono* and *bis*-4-picoline adducts of **1** and **2** described in Refs. [3, 4]. All boron atoms in **3** are tetrahedrally coordinated with angles which do not deviate markedly from ideal values; any deviations which are present are likely to arise from constraints imposed by the five and six-membered rings. The coordination of the bipy ligands does, however, result in a significant twisting about the B–B bond leading to an ethane-like conformation for the $(BS_2N)_2$ unit. Thus the torsion angles defined by taking the coordinates of the mid-point of the S–S vectors in each thiocat group and the two boron atoms are 64.9 and 51.4°. The $B_2N_2C_2$ six-membered rings are markedly non-planar [τ(NBBN) = 50.2 and 50.4°; τ(NCCN) = 14.2 and 29.2°, maximum deviation from $B_2N_2C_2$ plane is 0.32 Å for B(2) and 0.35 Å for B(4)].

Compound **4** crystallises as a CH_2Cl_2 and toluene solvate with molecules of **4** lying on a crystallographic C_2 axis. The molecular structure of **4** (Fig. 2) is similar to that of **3** in that the phen ligand bridges the B–B bond of the $B_2(thiocat)_2$ unit. The B–B [1.707(13) Å], B–S [B(1)–S(1) 1.903(7) and B(1)–S(2) 1.930(7) Å] and B–N [B(1)–N(1) 1.620(8) Å] distances are all in expected ranges when compared with those of **3** and the compounds described in Ref. [4] and the twisting about the B–B bond seen in **3** is also present here [equivalent torsion angles and interplanar angles defined as above are: 38.1° for "S''BB"S"; τ(NBBN) = 35.2°; τ(NCCN) = 7.1°, maximum deviation from $B_2N_2C_2$ plane is 0.22 Å for B(1) and B(1a)].

Perhaps the most unusual feature about **3** and **4** is the observation that the bipy and phen ligands bridge an element–element bond. This type of bridging coordination is extremely rare for these ligands, the only previously known examples being the double quat-

[a] Two crystallographically independent molecules.

ernary, *N*,*N*′-dialkyl species formed by reaction between either bipy or phen and 1,2-dibromoethane [7].

Also interesting is the colour of these two complexes. All of the *mono* and *bis*-picoline adducts of **1** and **2** described in Refs. [3, 4] are colourless or very pale yellow in contrast to the red colours seen here. These are presumably charge-transfer transitions from filled orbitals in the B_2(thiocat)$_2$ unit to empty π*-orbitals of the bipy or phen ligands. That the colours persist in solution indicates that association between **2** and either bipy or phen is present in solution as well as in the solid state although we were not able to confirm this by ^{1}H or ^{11}B NMR studies owing to the very poor solubility of both **3** and **4**.

As a final point, we note that **1** also forms a red solution in $CHCl_3$ when one equivalent of 1,10-phenanthroline is added, with red crystals being isolated after work-up. On the basis of the colour of the solution and solid, a similar structure to **4** is likely but since the crystals were not of X-ray quality, any structural formulation must remain tentative although analytical data were consistent with the formation of a 1:1 adduct albeit as a $CHCl_3$ solvate.

EXPERIMENTAL

General procedures

All reactions were performed using standard Schlenk techniques under an atmosphere of dry, oxygen-free dinitrogen. All solvents were distilled from appropriate drying agents immediately prior to use (sodium for toluene and hexanes and CaH_2 for CH_2Cl_2). Microanalytical data were obtained at the University of Bristol and UV-visible spectra were obtained on a Perkin-Elmer Lambda 2 spectrophotometer.

Compounds **1** and **2** were prepared by the literature methods [5]. 2,2′-bipyridyl and 1,10-phenanthroline were procured commercially but were dried by azeotropic distillation of toluene in a Dean and Stark apparatus before use.

Preparations

[B_2(*thiocat*)$_2$(*phen*)] (***4***) A solution of dried 1,10-phenanthroline (0.029 g, 0.16 mmol) in CH_2Cl_2 (2 cm^3) was added to a stirred solution of **2** (0.050 g, 0.16 mmol) in CH_2Cl_2 (2 cm^3) resulting in the immediate formation of a red solution. Addition of an overlayer of toluene (3 cm^3), cooling to -30°C and subsequent solvent diffusion over a period of two days afforded **4** as dark red (almost black) crystals which were then washed with hexane (2×2 cm^3) (0.089 g, 84%). One of these crystals was used for X-ray crystallography which revealed the presence of one molecule of CH_2Cl_2 and one molecule of toluene per molecule of **4**. $C_{24}H_{16}N_2B_2S_4{\cdot}CH_2Cl_2{\cdot}C_6H_5CH_3$ requires C, 58.30; H, 4.00; N, 4.20%. Found: C, 56.10; H, 3.70; N, 4.80. Some loss of solvent of crystallisation occurred accounting for the poor quality analytical data. UV-VIS (CH_2Cl_2), 509.8 nm, $\varepsilon_0 = 26$.

Compound **3** was prepared in an analogous manner and in similar yield using 2,2′-bipyridyl in place of 1,10-phenanthroline. X-ray crystallography revealed the presence of CH_2Cl_2 of crystallisation. $C_{22}H_{16}N_2B_2S_4{\cdot}CH_2Cl_2$ requires C, 50.90; H, 3.35; N, 5.15%. Found: C, 50.65; H, 3.15; N, 5.05. The pale red colour of solutions of **3** in CH_2Cl_2 were not of a sufficient intensity to obtain satisfactory solution UV-VIS data.

Compound **5** was also prepared similarly but using $CHCl_3$ rather than CH_2Cl_2. Analytical data were consistent with a 1:1 adduct of **1** and 1,10-phenanthroline with one molecule of $CHCl_3$ of crystallisation present. $C_{24}H_{16}N_2B_2O_4{\cdot}CHCl_3$ requires C, 55.90; H 3.20; N, 5.20%. Found: C, 55.05; H, 3.00; N, 4.45. UV-VIS (CH_2Cl_2), $\lambda = 425.0$ nm, $\varepsilon_0 = 540$.

It is important that the 2,2′-bipyridyl and 1,10-phenanthroline used in these reactions is dry and that none of the hydrates are present. Any traces of water lead to extensive decomposition products, one of which, in the reaction which afforded **5**, was identified by X-ray crystallography as the salt [phenH]$^+$[B(cat)$_2$]$^-$ [8].

X-ray crystallography

Crystal data for ***3*** $\cdot CH_2Cl_2$ $C_{23}H_{18}B_2Cl_2N_2S_4$, $M = 543.15$, orthorhombic, $a = 16.828(3)$, $b = 14.553(3)$, $c = 20.069(4)$ Å, $U = 4914.9(17)$ Å^3, $T = 220(1)$ K, space group $Pna2_1$ (No. 33), $Z = 8$, $\mu = 0.62$ mm^{-1}, 3062 reflections measured, 2475 unique ($R_{int} = 0.0970$). Final $R_1 = 0.0830$ for 1849 reflections $I > 2\sigma(I)$.

X-ray diffraction measurements were made on a single crystal mounted on a glass fibre with graphite-monochromated Mo-K$_\alpha$ X-radiation ($\bar{\lambda} = 0.71073$ Å) using a Rigaku AFC7S diffractometer. Unit cell constants and an orientation matrix were obtained from a least-squares refinement using the setting angles of 18 carefully centred reflections in the range $7.31° < \theta < 11.49°$. Intensity data were collected using the ω–2θ scan technique. Azimuthal scans of several reflections indicated no need for an absorption correction. Data were integrated using teXsan [9] and were corrected for Lorentz and polarisation effects. Intensities were weak and collected to only $\theta = 20.26°$. The structure was solved by direct methods and refined by full-matrix least squares against F^2 for all data with $I > -3\sigma(I)$. The structure was solved and refined in the acentric space group $Pna2_1$ with two molecules of **3** and two dichloromethane solvent molecules per asymmetric unit. There appears to be a local pseudo inversion centre between the molecules of **3** although this does not hold for the solvent molecules and is not a true inversion centre. Chlorine, sulphur and nitrogen atoms were refined anisotropically and

hydrogens were assigned fixed isotropic displacement parameters and were constrained to idealised geometries. The aromatic rings of the $BS_2C_6H_4$ groups were restrained to D_{6h} symmetry. The absolute structure parameter [10] was determined by refinement to be $-0.10(40)$.

Crystal data for $\mathbf{4}\cdot 1.0CH_2Cl_2 1.0C_6H_5Me$ $C_{16}H_{13}BClNS_2$, $M=329.65$, monoclinic, $a=12.332(3)$, $b=10.1552(13)$, $c=12.259(2)$ Å, $\beta=90.108(10)^\circ$ $U=1535.1(4)$ Å^3, $T=173(2)$ K, space group $P2/c$ (No. 13), $Z=4$, $\mu=0.51$ mm^{-1}, 9230 reflections measured, 3498 unique ($R_{int}=0.0308$). Final $R_1=0.0898$ for 2974 reflections $I>2\sigma(I)$.

Many of the details of the structure analyses are the same as those for $\mathbf{3}\cdot CH_2Cl_2$. X-ray diffraction measurements on a single crystal coated in a hydrocarbon oil mounted on a glass-fibre under argon were made using a Siemens SMART diffractometer. Intensity data were collected by 0.3° width ω steps accumulating area detector frames spanning a hemisphere of reciprocal space. Data were integrated using the SAINT [11] program and corrected for Lorentz, polarisation and long-term intensity fluctuations. The asymmetric unit contained half a molecule of **4**, CH_2Cl_2 and C_6H_5Me, with molecules of **4** lying over a crystallographic C_2 axis. The toluene and dichloromethane solvates were disordered over an inversion centre. Since the β angle was 90.108° the structure was refined to test the possibility that it may be twinned with a pseudo-orthorhombic cell, using the twin law (1 0 0, 0 −1 0, 0 0 −1). However, the twin component parameter refined to 0.012(2) indicating a marginal amount of twinning and resulted in no significant improvement in the *R*-factor. An extinction parameter, x, of the form $F_c' = F_c/[1+0.001xF_c^2\lambda^3/\sin(2\theta)]^{-0.25}$ was refined to 0.014(2). All calculations were made with programs of the SHELXTL system [12]. Complex neutral-scattering factors were taken from Ref. [13].

(Received 31 March 1998; accepted 1 June 1998)

Abstract—The interaction between bis(4-methylpyrazol-1-yl)methane or bis(3,4,5-trimethylpyrazol-1-yl)methane and several MX_2 salts (M = Mn, Fe, Co, Ni or Cu; X = Cl; M = Mn, Co, Ni or Cu, X = NO_3; M = Zn, X = Br) gives 1:1 and 2:1 adducts depending on counter-ion, molar ratio of reagents and solvent of reaction employed. Structural conclusions are drawn from IR, far-IR, UV, magnetic susceptibility and conductivity data. In the crystal structure of the title compound the zinc atom is found in a strongly distorted tetrahedral coordination [N–Zn–N: 92.2(6); Br–Zn–Br: 119.1(1)°]. The Zn–N [2.075(19) and 2.078(15) Å] and Zn–Br [2.350(3) and 2.372(3) Å] bond distances are longer than those reported for related compounds owing to steric hindrance of the N_2-donor. © 1998 Elsevier Science Ltd. INTRODUCTION

Bis(pyrazol-1-yl)alkanes are a versatile class of neutral N_2-donor ligands which form stable chelates with transition and main group elements [1–7]. They can be prepared readily and contain two pyrazole rings, which are generally very stable toward chemical attack, for example against both oxidizing and reducing agents.

The coordinating behaviour of these molecules is often very different from that shown by the isosteric and isoelectronic anionic poly(pyrazol-1-yl)borates, for which a number of papers [8–13] devoted to their coordination chemistry has been published and also from that shown by 2,2′-bipyridine and 1,10-phenanthroline chelating planar donors, extensively used in the field of the coordination chemistry [14–17]. While 2,2′-bipyridine and 1,10-phenanthroline adducts are likely to contain an approximately planar five membered M–N–C–C–N moiety, upon coordination of bis(pyrazolyl)methanes, six-membered cycle are formed for which a boat conformation is forecast (Fig. 1). It is noteworthy that the bis(pyrazol-1-yl)alkanes, with steric constraints, may impose unusual stoichiometries and geometries on transition metal ions [18–20].

Nevertheless there had been no systematic study on the derivatives of this class of ligands with typical and transition elements, so that an investigation into this area was began, and after working on zinc [21], cadmium [21], mercury [21], tin(IV) and organotin(IV) [22], silver(I) [23] and copper(I) [24] derivatives, we were prompted, by the results obtained, to continue to prepare other new bis(pyrazol-1-yl)alkanes metal derivatives.

It has been previously observed that different substituents on the azole ring can produce reliable chan-

†Author to whom correspondence should be addressed.

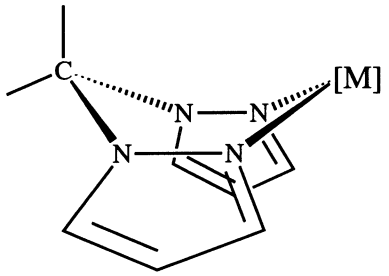

Fig. 1. The six-membered cycle formed by bis(pyrazol-1-yl) alkanes upon complexation.

ges on spectroscopic properties and structures of both transition and post-transition metal derivatives [25, 26], but at this moment the importance of a methyl group in the 4-position of the pyrazole has not been completely realized, so that after the investigation on the coordinating properties of the donor bis(4-methylpyrazol-1-yl)methane (L^M) and bis(3,4,5-trimethylpyrazol-1-yl)methane (L^T) towards group 12 [18, 19, 20, 27] and 14 [22] metal derivatives, it seemed to us opportune to extend the study to interaction between these donors and first-row transition salts.

Here we report the synthesis, analytical (magnetic susceptibility and conductivity) and spectroscopic characterization (IR, UV) of some adducts between L^M or L^T and Mn(II), Fe(II), Co(II), Ni(II) Cu(II) and Zn(II) salts and also the X-ray crystal structure of the zinc(II) bromide adduct of bis(3,4,5-trimethylpyrazol-1-yl)methane.

EXPERIMENTAL

All the chemicals were purchased from Alfa (Karlsruhe) and Aldrich (Milwaukee) and used as received. The samples for microanalysis were dried *in vacuo* to constant weight (20°C, *ca.* 0.1 Torr). Elemental analyses (CHN) were carried out in the house with Fisons Instruments 1108 CHNS-O Elemental analyzer. IR spectra were recorded from 10000 to 100 cm^{-1} with a Perkin-Elmer instrument System 2000 FT-IR. Melting points were taken on an IA 8100 Electrothermal instrument. Electronic spectra were recorded from 800 to 200 nm in CH_3CN solution with an HP 8452 Diode Array Spectrophotometer. The electric resistance of solutions was measured with a Crison CDTM 522 conductimeter at room temperature. The magnetic susceptibilities were measured at room temperature (20°C) by the Gouy method, with a Sherwood Scientific Magnetic Balance MSB-Auto, using $HgCo(NCS)_4$ as calibrant and correcting for diamagnetism with the appropriate Pascal constants. The magnetic moments (in B.M.) were calculated from the equation $\mu_{eff} = 2.84(X_M^{corr} \cdot T)^{1/2}$.

Reagents

Preparation of bis(4-methylpyrazol-1-yl)methane (L^M) and bis(3,4,5-trimethylpyrazol-1-yl)methane. The donors bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) and bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) were prepared according to Claramunt's procedure [28].

Synthesis of the metal derivatives

Bis(4-methylpyrazol-1-yl)methanedichloromanganese(II)(H_2O) **1**. Compound **1** was obtained upon mixing $MnCl_2 \cdot 4H_2O$ (0.099 g, 0.5 mmol) in dichloromethane (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.176 g, 1.0 mmol) in the same solvent (10 ml). The colorless precipitate immediately formed was filtered after 2 h and washed several times with diethyl ether (0.123 g, yield 77%). M.p.: 216–220°C dec. Anal. Calcd for $C_9H_{14}Cl_2MnN_4O$; C, 33.8; H, 4.4; N, 17.5. Found: C, 34.0; H, 4.6; N, 17.9%.

Bis{bis(4-methylpyrazol-1-yl)methane}dichloromanganese(II)(H_2O) **2**. Compound **2** was obtained upon mixing $MnCl_2 \cdot 4H_2O$ (0.195 g, 1.0 mmol) in diethyl ether (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.352 g, 2.0 mmol) in the same solvent (10 ml). The colorless precipitate immediately formed was filtered after 2 h and washed several times with diethyl ether (0.322 g, yield 65%). M.p.: 228°C dec. Anal. Calcd for $C_{18}H_{26}Cl_2MnN_8O$; C, 43.6; H, 5.3; N, 22.6. Found: C, 43.2; H, 5.2; N, 22.3%.

Bis(4-methylpyrazol-1-yl)methanedichloroiron(II)(H_2O) **3**. Compound **3** was obtained upon mixing $FeCl_2 \cdot 4H_2O$ (0.099 g, 0.5 mmol) in ethanol (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.176 g, 1.0 mmol) in the same solvent (10 ml). The brown precipitate immediately formed was filtered after 2 h and washed several times with ethanol (0.131 g, yield 82%). M.p.: 273–276°C dec. Anal. Calcd for $C_9H_{14}Cl_2FeN_4O$; C, 33.7; H, 4.4; N, 17.4. Found: C, 33.6; H, 4.4; N, 17.2%.

Bis{bis(4-methylpyrazol-1-yl)methane}dichloroiron(II)(H_2O)$_2$ **4** Compound **4** was obtained upon mixing $FeCl_2 \cdot 4H_2O$ (0.197 g, 1.0 mmol) in diethyl ether (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.353 g, 2.0 mmol) in the same solvent (10 ml). A pale-brown precipitate was formed immediately, filtered after 2 h and washed several times with diethyl ether (0.464 g, yield 90%). M.p.: 268–270°C dec. Anal. Calcd for $C_{18}H_{28}Cl_2FeN_8O_2$; C, 42.0; H, 5.5; N, 21.7. Found: C, 41.7; H, 5.5; N, 21.7%.

Bis{bis(4-methylpyrazol-1-yl)methane}dichlorocobalt(II)(H_2O)$_2$ **5**. Compound **5** was obtained upon mixing $CoCl_2$ (0.130 g, 1.0 mmol) in diethyl ether (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.354 g, 2.0 mmol) in the same solvent (10 ml). The pale-rose precipitate immediately formed was filtered after 4 h and washed several times with diethyl ether (0.373 g, yield 72%). M.p.: 253–255°C dec. Anal. Calcd for $C_{18}H_{28}Cl_2CoN_8O_2$; C, 41.7; H, 5.5; N, 21.7. Found: C, 41.5; H, 5.7; N, 21.6%.

Bis{*bis*(4-*methylpyrazol*-1-*yl*)*methane*}*dichloronickel*(*II*)(*H*$_2$*O*) **6** Compound **6** was obtained upon mixing $NiCl_2$ (0.130 g, 1.0 mmol) in ethanol (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.423 g, 2.4 mmol) in the same solvent (10 ml). The sky-blue precipitate formed was filtered after 24 h and washed several times with ethanol and diethyl ether (0.390 g, yield 78%). M.p.: 326°C dec. Anal. Calcd for $C_{18}H_{26}Cl_2N_8NiO$; C, 41.8; H, 5.5; N, 21.7. Found: C, 41.5; H, 5.7; N, 21.6%.

Bis(4-*methylpyrazol*-1-*yl*)*methanedichlorocopper* (*II*) **7**. Compound **7** was obtained upon mixing $CuCl_2 \cdot 2H_2O$ (0.138 g, 0.8 mmol) in ethanol (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.405 g, 2.3 mmol) in the same solvent (10 ml). The green precipitate immediately formed was filtered after 2 h and washed several times with ethanol and diethyl ether. (0.191 g, yield 77%). M.p.: 265–268°C dec. Anal. Calcd for $C_9H_{12}Cl_2CuN_4$; C, 34.8; H, 3.9; N, 18.0. Found: C, 35.0; H, 4.0; N, 18.1%.

Bis{*bis*(4-*methylpyrazol*-1-*yl*)*methane*}*dinitromanganese*(*II*)(*H*$_2$*O*)$_2$ **8**. Compound **8** was obtained upon mixing $Mn(NO_3)_2 \cdot 6H_2O$ (0.220 g, 0.76 mmol) in dichloromethane (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.221 g, 1.25 mmol) in the same solvent (10 ml). The colorless precipitate formed was filtered after 4 days and washed several times with dichloromethane and diethyl ether (0.319 g, yield 74%). M.p.: 176–180°C dec. Anal. Calcd for $C_{18}H_{28}MnN_{10}O_8$; C, 38.1; H, 5.0; N, 24.7. Found: C, 37.8; H, 4.8; N, 24.4%.

Bis{*bis*(4-*methylpyrazol*-1-*yl*)*methane*}*dinitrocobalt* (*II*)(*H*$_2$*O*)$_2$ **9**. Compound **9** was obtained upon mixing $Co(NO_3)_2 \cdot 6H_2O$ (0.226 g, 0.77 mmol) in dichloromethane (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.303 g, 1.72 mmol) in the same solvent (10 ml). The pale rose precipitate formed was filtered after 3 days and washed several times with dichloromethane and diethyl ether (0.351 g, yield 80%). M.p.: 157–160°C dec. Anal. Calcd for $C_{18}H_{28}CoN_{10}O_8$; C, 37.8; H, 4.9; N, 24.5. Found: C, 37.6; H, 5.1; N, 24.3%.

Bis{*bis*(4-*methylpyrazol*-1-*yl*)*methane*}*dinitronickel* (*II*)(*EtOH*) **10**. Compound **10** was obtained upon mixing $Ni(NO_3)_2 \cdot 6H_2O$ (0.290 g, 1.0 mmol) in ethanol (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.35 g, 2.0 mmol) in the same solvent (10 ml). The lilac precipitate formed was filtered after 2 days and washed several times with ethanol and diethyl ether (0.511 g, yield 88%). M.p.: 246–249°C dec. Anal. Calcd for $C_{20}H_{30}N_{10}NiO_7$; C, 41.3; H, 5.2; N, 24.1. Found: C, 41.6; H, 5.1; N, 24.3%.

Bis{*bis*(4-*methylpyrazol*-1-*yl*)*methane*}*dinitrocopper* (*II*)(*H*$_2$*O*)$_2$ **11**. Compound **11** was obtained upon mixing $Cu(NO_3)_2 \cdot 2.5H_2O$ (0.186 g, 0.80 mmol) in dichloromethane (20 ml) with bis(4-methylpyrazol-1-yl)methane ($\mathbf{L}^M$) (0.300 g, 1.70 mmol) in the same solvent (10 ml). The dark-blue precipitate formed was filtered after 3 days and washed several times with dichloromethane and diethyl ether (0.433 g, yield 94%). M.p.: 237–238°C dec. Anal. Calcd for $C_{18}H_{28}CuN_{10}O_8$; C, 37.5; H, 4.9; N, 24.3. Found: C, 37.6; H, 5.0; N, 24.2%.

Bis(3,4,5-*trimethylpyrazol*-1-*yl*)*methanedichloro manganese*(*II*)(*H*$_2$*O*) **12**. Compound **12** was obtained upon mixing $MnCl_2 \cdot 4H_2O$ (0.099 g, 0.5 mmol) in diethyl ether (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.23 g, 1.0 mmol) in the same solvent (10 ml). The colorless precipitate formed was filtered after 2 days and washed several times with diethyl ether (0.165 g, yield 88%). M.p.: 334°C dec. Anal. Calcd for $C_{13}H_{22}Cl_2MnN_4O$; C, 41.6; H, 5.9; N, 14.9. Found: C, 41.4; H, 5.7; N, 14.7%.

Bis(3,4,5-*trimethylpyrazol*-1-*yl*)*methanedichloroiron* (*II*)(*H*$_2$*O*) **13**. Compound **13** was obtained upon mixing $FeCl_2 \cdot 4H_2O$ (0.064 g, 0.3 mmol) in dichloromethane (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.23 g, 1.0 mmol) in the same solvent (10 ml). The pale-brown precipitate formed was filtered after 1 day and washed several times with diethyl ether (0.087 g, yield 77%). M.p.: 312–314°C dec. Anal. Calcd for $C_{13}H_{22}Cl_2FeN_4O$; C, 41.4; H, 5.9; N, 14.9. Found: C, 41.7; H, 6.0; N, 14.4%.

Bis(3,4,5-*trimethylpyrazol*-1-*yl*)*methanedichlorocobalt*(*II*) **14**. Compound **14** was obtained upon mixing $CoCl_2$ (0.129 g, 1.0 mmol) in ethanol (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.23 g, 1.0 mmol) in the same solvent (10 ml). The dark-blue precipitate formed was filtered after 1 day and washed several times with diethyl ether (0.225 g, yield 62%). M.p.: >360°C dec. Anal. Calcd for $C_{13}H_{20}Cl_2CoN_4$; C, 43.1; H, 5.6; N, 15.4. Found: C, 43.0; H, 5.8; N, 15.4%.

Bis(3,4,5-*trimethylpyrazol*-1-*yl*)*methanedichlorocopper*(*II*) **15**. Compound **15** was obtained upon mixing $CuCl_2 \cdot 2H_2O$ (0.138 g, 0.8 mmol) in ethanol (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.23 g, 1.0 mmol) in the same solvent (10 ml). After 24 h diethyl ether was added. The light-green precipitate formed was filtered after 2 days and washed several times with diethyl ether (0.243 g, yield 83%). M.p.: 215–220°C dec. Anal. Calcd for $C_{13}H_{20}Cl_2CuN_4$; C, 42.6; H, 5.5; N, 15.3. Found: C, 42.2; H, 5.4; N, 15.1%.

Bis{*bis*(3,4,5-*trimethylpyrazol*-1-*yl*)*methane*}*dinitrocobalt*(*II*)(*H*$_2$*O*) **16**. Compound **16** was obtained upon mixing $Co(NO_3)_2 \cdot 6H_2O$ (0.226 g, 0.77 mmol) in ethanol (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl) methane ($\mathbf{L}^T$) (0.46 g, 2.0 mmol) in the same solvent (10 ml). The violet precipitate was formed, which was filtered after 3 days and washed several times with ethanol and diethyl ether (0.461 g, yield 90%). M.p.: 276–277°C dec. Anal. Calcd for $C_{26}H_{42}CoN_{10}O_7$; C, 46.9; H, 6.4; N, 21.0. Found: C, 47.2; H, 6.5; N, 20.9%.

Bis{*bis*(3,4,5-*trimethylpyrazol*-1-*yl*)*methane*}*dinitronickel*(*II*) **17**. Compound **17** was obtained upon mixing $Ni(NO_3)_2 \cdot 6H_2O$ (0.290 g, 1.0 mmol) in dichloromethane (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.46 g, 2.0 mmol) in the same solvent

(10 ml). The light-blue precipitate formed upon addition of diethyl ether was filtered after 3 days and washed several times with dichloromethane and diethyl ether (0.427 g, yield 66%). M.p.: 320°C dec. Anal. Calcd for $C_{26}H_{40}N_{10}NiO_6$; C, 48.3; H, 6.2; N, 21.7. Found: C, 48.0; H, 6.4; N, 21.5%.

Bis(3,4,5-*trimethylpyrazol*-1-*yl*)*methanedibromozinc*(*II*) **18**. Compound **18** was obtained upon mixing $ZnBr_2$ (0.225 g, 1.0 mmol) in diethyl ether (20 ml) with bis(3,4,5-trimethylpyrazol-1-yl)methane ($\mathbf{L}^T$) (0.23 g, 1.0 mmol) in the same solvent (10 ml). The colorless precipitate immediately formed was filtered after 2 h and washed several times with diethyl ether and recrystallized from dichloromethane/diethyl ether (0.415 g, yield 90%). The spectroscopic and analytical data are in accordance with those reported in literature [27].

X-ray crystallography

Crystal and experimental data are summarized in Table 1. A crystal of $C_{13}H_{20}Br_2N_4Zn$, obtained from a chloroform/diethyl ether solution was mounted on a CS automatic four-circle diffractometer equipped with a Huber goniometer using graphite monochromatized Mo-$K\alpha$ radiation ($\lambda = 0.71069$ Å). The cell parameters were refined by least squares from the angular positions of 32 reflections in the range $5 < 2\theta < 28°$. The data were collected at room temperature for $3 < 2\theta < 60°$ from colorless crystal of approximate $0.1 \times 0.2 \times 0.2$ mm using an ω scan technique. The scan rate was automatically chosen according to the peak intensity in the range 2.0–30.0° min^{-1}. Background counts were taken with stationary crystal with an offset of 0.6° at each end of the scan, and a total background to scan time ratio of 0.5. The intensities of three standard reflections, monitored every 97 reflections during the data collections don't show decay. Data were corrected for Lorentz and polarization effects. A total of 1802 independent reflections having $|F_o| > 6\sigma|F_o|$ were used in all subsequent calculations.

Table 1. Crystal data of compound **18**

Formula	$C_{13}H_{20}Br_2N_4Zn$
Formula weight	457.5
Crystal system	monoclinic
Space group	C 2/c
a (Å)	15.057(5)
b (Å)	16.486(5)
c (Å)	15.973(5)
β (°)	116.390(5)
V (Å^{-3})	3485(2)
Z	8
D_c (g cm^{-3})	1.745
μ (cm^{-1})	5.992
F (000)	1808.0
No. of measured reflections	5044
No. of unique reflections	2290
No. of observed reflections, $\|F_o\| > 6\sigma\|F_o\|$, n	1802
Function minimized	$\Sigma w(\|F_o\| - \|F_c\|)^2$
Variables refined, m	181
a, b and c values in the weighting function[a]	8.387, 0.095, 0.018
R[b]	5.8
R_w[c]	7.5
Goodness of fit, S[d]	1.054

[a] $w = 1.0/(a + b|F_o| + c|F_o|^2)$.
[b] $R = \Sigma(|F_o|^2 - |F_c|^2)/\Sigma F_o^2$.
[c] $R_w = \Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2$.
[d] $S = \Sigma w(|F_o| - |F_c|)^2/(n - m)$.

The structure was solved by direct methods. All non-hydrogen atoms were refined by full matrix least-squares methods with anisotropic thermal parameters. The hydrogen atom was assigned the equivalent isotropic temperature factor of the parent carbon atom and allowed to ride on it. Atomic scattering factors were taken from Ref.[29]. All calculations were done on a PC using the SIR CAOS structure determination package [30].

RESULTS AND DISCUSSION

Derivatives **1**–**18** were synthesized from interaction between the ligands bis(pyrazol-1-yl)alkanes (L in general; in detail: L^M = (bis(4-methylpyrazol-1-yl) methane, L^T = bis(3,4,5-trimethylpyrazol-1-yl) methane) and the appropriate metal salt $MX_2 \cdot xH_2O$ (M = Zn, X = Br, M = Mn, Fe, Co, Ni or Cu, X = Cl; M = Ni, Co or Cu, X = NO_3) in accordance with the following:

$$nL + MX_2 \cdot xH_2O \xrightarrow{S} [(L)_nMX_2] \cdot xH_2O \cdot zS \quad (1)$$

A 2:1 adduct is always the product from metal nitrates also when a different metal to ligand molar ratio was employed, while 1:1 or 2:1 adduct are found with metal halides, depending not only on the donor but also on the solvent and on the molar ratio used in the synthesis.

It is interesting to note that the donor bis(4-methylpyrazol-1-yl)methane L^M gives with $MnCl_2$ and $FeCl_2$ acceptors both 1:1 and 2:1 adducts, whereas the more basic bis(3,4,5-trimethylpyrazol-1-yl)methane, L^T gives only 1:1 adducts. The greater steric hindrance of L^T with respect to L^M causes this different behaviour. No reaction was observed between L^T and $Mn(NO_3)_2 \cdot 6H_2O$ and $Cu(NO_3) \cdot 2.5H_2O$, the starting materials being always recovered.

All the compounds **1**–**18** were identified through elemental analyses (Section 2), solid-state infrared spectra (Table 2), magnetic and conductivity data (Table 3) and electronic spectra (Table 4).

With exception of compounds **2**, **6**, **12** and **17** which melt with decomposition, our adducts have sharp melting points. All the complexes are insoluble in water, diethyl ether, aromatic and aliphatic hydro-

carbons, poorly soluble in chlorinate solvents and acetone, generally soluble in acetonitrile and nitromethane. Derivatives **1**, **2** and **6** were soluble only in the latter solvent. Electronic spectra and conductivity measurements were performed in acetronitrile and nitromethane, respectively.

Several derivatives contain one or two molecules of water of crystallization notwithstanding addition of the dehydrating agent $HC(OEt)_3$ to reactions solutions [31].

The halide adducts **1**, **2**, **5**, **7**, **12** and **13** are non-electrolytes in nitromethane solution, thus ruling out self-ionization or displacement of the anion by the solvent, i.e.

$$2[(L)MX_2] \rightleftharpoons [(L)_2M]^{2+} + [MX_4]^{2-} \quad (2)$$

$$[(L)_nMX_2] + n\ \text{solvent} \rightleftharpoons [(L)_nM(\text{solvent})_n]^{2+} + 2[X]^- \quad (3)$$

Derivatives **3**, **4**, **8**, **14** and **15** seem to be only partially dissociated or not completely electrolytes in nitromethane (Λ_m in the range 24.7–43.3 $\Omega^{-1}\,cm^2\,mol^{-1}$) whereas the derivatives **6**, **9**–**11**, **16** and **17** are 1:1 electrolytes (Λ_m in the range 60–80 $\Omega^{-1}\,cm^2\,mol^{-1}$).

Table 3. Magnetic and conductance data of derivatives **1**–**17**

[a] μ_{eff} are in B.M. (Bohr magnetons).
[b] Concentrations are in mol/l.
[c] $\Omega^{-1}\,cm^2\,mol^{-1}$.

Magnetic moments of the derivatives of manganese(II), iron(II), cobalt(II), nickel(II) and copper(II) are typical of high spin d^5, d^6, d^7, d^8 and d^9 metal complexes, respectively, containing five, four, three, two and one decoupled electrons, respectively.

Derivatives **1**, **3**, and **5** show values of μ_{eff} slightly smaller than appropriate theoretical μ_s, likely due to partial extinction of magnetic moment caused by formation of chloro or nitro-bridged dimers, oligomers or polymers containing weak M···M interactions. In fact, it has been previously observed that many transition metal derivatives containing bis(pyrazol-1-yl)alkane donors adopt binuclear geometries with chloro-bridged metal atoms [2, 4].

In the IR spectra of complexes **1**–**6**, **8**–**13** and **16**, the appearance of broad bands of variable intensity centred at 3200–3400 and 1630–1670 cm^{-1} due to ν(OH) and δ(OH) vibrations, respectively, confirms the presence of water.

The medium band at *ca.* 1570 cm^{-1}, in the derivatives of L^M and those at *ca.* 1570 and 1510 cm^{-1} in the derivatives of L^T, due to breathing of the pyrazole rings [32, 33], do not undergo any notable shift upon coordination. Moreover two strong absorption bands at 640 and 610 cm^{-1} have been assigned to ring deformation modes [34, 35].

In the IR spectra of nitrato derivatives straightforward assignments of the two highest-frequency bands ν_1 and ν_5 of NO_3 groups are not possible due to the presence of nujol and of many overlapped ligand bands in the region 1200–1500 cm^{-1}.

However in the overtone region several weak bands

*The data are from near IR (nujol) spectra.

at 1700–1800 cm^{-1}, due to $\nu_1 + \nu_4$ combination bands, have been detected which can help in distinguishing ionic or coordinate nitrates [36].

Derivatives **9** and **11** exhibit two weak bands and the splitting Δ is 16 and 15 cm^{-1}, respectively, in accordance with an unidentate nitrate group in the solid state, whereas in the spectra of derivatives **8**, **10**, **16** and **17** three weak absorptions have been detected in the same region, indicative of the existence of both ionic and coordinate nitrate. These derivatives likely contain a six-coordinate metal atom surrounded by four nitrogen atoms and two oxygen atoms.

We have assigned some medium-to-strong absorption bands in the 200–400 cm^{-1} range to *ν*(M–Cl), *ν*(M–N) and *ν*(M–O) vibrations modes [37]. In the chloro derivatives **1**, **3** and **5** besides *ν*(M–Cl) stretching frequencies in the region 300–400 cm^{-1}, we have always detected also a strong absorption between 180 and 220 cm^{-1}, likely due to *ν*(M–Cl–M) vibration, in accordance with magnetic results which suggest a dinuclear or polynuclear structure. Only one IR-active *ν*(M–Cl) stretching band is found in the far-IR spectrum of derivatives **2** and **6** in accordance with octahedral N_4Cl_2Mn and N_4Cl_2Ni central cores, respectively, where the Cl atoms occupy *cis* positions. In the spectra of anhydrous derivatives **7**, **13** and **14** two strong *ν*(M–Cl) and two strong *ν*(M–N) vibration modes appeared below 400 cm^{-1} which are indicative of distorted tetrahedral geometries.

The near-IR and visible absorption bands give further support to the hypothesized geometries for our derivatives. The $FeCl_2$ adduct **13** (C_{2v} structure), shows a band at 6670 cm^{-1} with a shoulder at 5860 cm^{-1} assignable to $^5T_{2g} \leftarrow {}^5E_g$ transition with additional fine structure due to the loss of degeneracy of the $^5T_{2g}$ state [38], whereas the likely dinuclear derivative **3** shows only a band at 5770 cm^{-1}.

In the spectrum of compound **4** two absorption at 8930 and 9625 cm^{-1}, respectively, are in accordance with an octahedral distorted geometry (pseudo-D_{4h} symmetry) having a ground state $(t_{2g})^4(e_g)^4$ ($^5T_{2g}$) and the only spin allowed excited state $(t_{2g})^3(e_g)^3$, (^5E_g) being split into $^5A_1 + {}^5B_1$ [39, 40].

In the blue pseudo-tetrahedral cobalt derivative **14** the $^4T_1(F) \leftarrow {}^4A_2$ and $^4T_1(P) \leftarrow {}^4A_2$ transitions appear as multiple absorptions both in the near IR (5970, 7500 and 9350 cm^{-1}) and in the visible (566, 612, 668 nm) regions [31]. Instead the likely dinuclear pink cobalt derivative **5** exhibits a broad band at 9590 cm^{-1} in the near IR and three absorptions at 592, 652 and 678 nm in the visible region as previously observed in high spin five-coordinate Co(II) systems having a structure intermediate between square pyramidal and trigonal bipyramidal [41, 42, 43].

High-spin cobalt nitrate derivatives **9** and **16** are likely six-coordinated with a ionic NO_3 group and the other NO_3 linked to metal in the O_2-bidentate form [31, 44].

Apparent absence of visible absorptions for derivatives **10** and **17** is likely due to their very low energy transitions [45].

The copper nitrato derivative **11** exhibits in the near IR spectrum a band at 9440 cm^{-1} likely due to transitions to z^2 from x^2–y^2 and a band at 690 nm in the visible region which arises from a double degenerate (*xz* and *yz*) level, respectively, in accordance with a *cis*-octahedral geometry [46].

The structure of the compound [bis(3,4,5-trimethylpyrazol-1-yl)methanedibromozinc(II)] **18** with the numbering scheme is given in Fig. 2. Selected bond distances and angles are listed in Table 5. In the unit cell of the adduct **18** there are eight molecules which are monomeric with no short intramolecular contacts and are kept together by van der Waals interactions.

Table 5. Selected crystal data of compound **18**

Bond distances			
Zn–Br(1)	2.372(3)	Zn–Br(2)	2.350(3)
Zn–N(1)	2.078(15)	Zn–N(3)	2.075(19)
Bond angles			
Br(1)–Zn–Br(2)	119.1(1)	Br(1)–Zn–N(1)	107.0(4)
Br(2)–Zn–N(1)	113.7(4)	Br(1)–Zn–N(3)	108.2(4)
Br(2)–Zn–N(3)	113.3(5)	N(1)–Zn–N(3)	92.2(6)
Zn–N(1)–N(2)	116.6(12)	Zn–N(1)–C(3)	136.1(11)
Zn–N(3)–N(4)	118.7(15)	Zn–N(3)–C(10)	133.1(12)

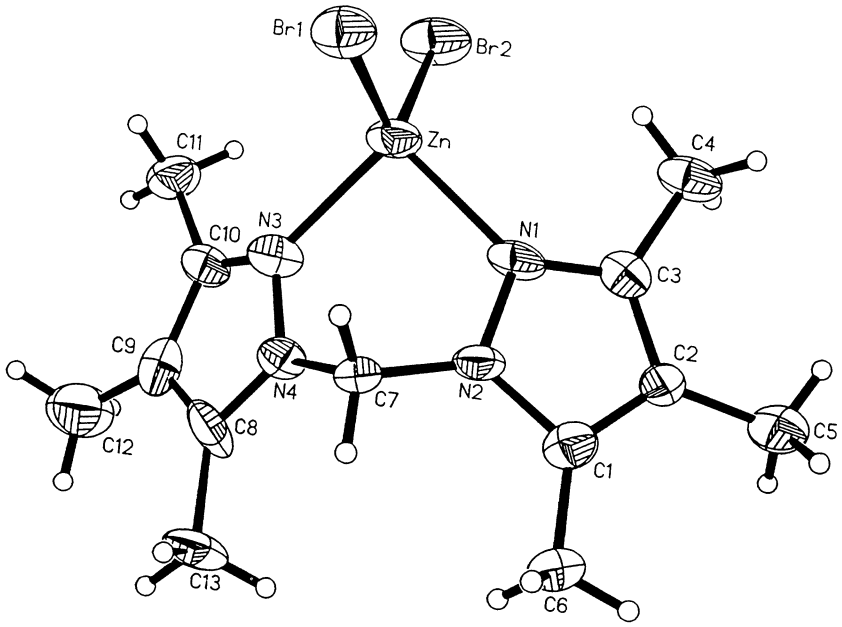

Fig. 2. An ORTEP view of complex $[L^TZnBr_2]$ (**18**).

The two pyridinic nitrogens of the donor L^T and two bromine atoms are arranged around the zinc atom in a strongly distorted environment: the N–Zn–N and Br–Zn–Br angles are 92.2(6) and 119.1(1)°, respectively, whereas the N–Zn–Br angles ranges from 107.0(4) to 113.7(4)°. The six-membered $C(N–N)_2Zn$ ring adopts an inverted boat conformation: the molecule is "butterfly" shaped; in fact the angle formed by the plane passing through each of the pyrazole rings and the plane passing through the central six-membered ring are about 27°. The N–Zn–N angle found in this compound lies out of the upper limit (89°) found for the metal derivatives of bis(pyrazol-1-yl)alkanes [7]. This further confirms the well-known greater flexibility of this family of ligands with respect to 2,2′-bipyridine and 1,10-phenanthroline donors which have a "fixed" bite. The Zn–N distances are longer than those found in similar dibromozinc(II) derivatives [25] and support the steric misfit between the N_2-donor L^T and the tetrahedral zinc ion. On the other hand the Zn–Br distances are in the range found for tetrahedral dibromozinc(II) complexes [25, 47].

CONCLUSIONS

The combined evidence from measurements carried out in solid state and in solution (IR, conductivity, magnetic susceptibility, UV spectra, X-ray crystal structure determination) gives here a picture which is different from that obtained when other poly(pyrazol-1-yl)alkanes were considered [1–7].

The bis(4-methylpyrazol-1-yl)methane seems to be a better donor toward transition metal acceptors with respect to other bis(pyrazol-1-yl)alkanes [1–7]: the ligand/metal ratio *r*, frequently a measure of the donating ability, is 2 not only with good acceptors such as $M(NO_3)_2$ but also with MCl_2 salts; *r* is strongly dependent not only from the solvent but also from the molar ratio employed in the synthesis. We have found a marked difference between the behavior of bis(4-methylpyrazol-1-yl)methane and that of bis(3,4,5-trimethylpyrazol-1-yl)methane.

The donating ability can be easily correlated to basicity and steric hindrance of the heterocyclic ring: the bis(4-methylpyrazol-1-yl)methane also if is less basic than bis(3,4,5-trimethylpyrazol-1-yl)methane, however is less sterically hindered and a better donor ligand.

Polynuclear derivatives are also possible in the case of metal chloride acceptors such as $MnCl_2$, $FeCl_2$ and $NiCl_2$: this behavior is analogous to those previously found [2, 4].

SUPPLEMENTARY MATERIAL

Tables of atomic coordinates and isotropic equivalent thermal parameters, tables of structures factors, a full list of bond lengths and angles and tables of anisotropic displacement parameters are available on request from one of the authors.

(Received 30 March 1998; accepted 1 June 1998)

Abstract—The ferrocenyl 1,2-diketone [$(C_5H_5)Fe(C_5H_4)COCOPh$] when condensed with aromatic 1,2-diamines forms a range of ferrocenyl-substituted quinoxalines: when the diamine is unsymmetrically substituted the quinoxaline is formed as a mixture of two regio-isomers, which can in some cases be separated by careful chromatography. Electrochemical studies show that these present ferrocenylquinoxalines undergo the expected reversible one-electron oxidation centred on the ferrocenyl moiety and a two-electron reduction process centred on the quinoxalyl fragment, which is accompanied by chemical complications. The oxidation of the ferrocenyl group occurs at potentials slightly higher than that of unsubstituted ferrocene (by about 100–150 mV, depending on the substituents) indicating that the quinoxalyl substituent is slightly electron-withdrawing with respect to ferrocene. © 1998 Elsevier Science Ltd. Keywords: cyclic voltammetry; electrochemistry; ferrocene; quinoxaline.

INTRODUCTION

The reaction between 1,2-diketones and 1,2-diamines to form quinoxalines, well-known as a characteristic reaction for both components, has been successfully exploited as a polymer-forming process when applied to combinations of bis(1,2-diketones) and bis(1,2-diamines) [1–3]. For polymer synthesis, the reaction can generally be performed under solvent-free (melt-phase) conditions, when the sole by-product is water which distills from the reaction mixture at the melting temperature of the components. It is the removal of the water by-product, along with the *in situ* formation of new heteroaromatic rings, which drives the process to completion. The effectiveness of this reaction [1–3] makes it an attractive route for the synthesis of organometallic polymers, for example by reaction of 1,1′-ferrocenediylbis(1,2-diketones) with bis(1,2-diamines). We have recently described effective routes to a range of ferrocenyl 1,2-diketones [4, 5] and here we present the results of a study of reactions of a representative ferrocenyl diketone, FcCOCOPh [4, 6] [$Fc = (C_5H_5)Fe(C_5H_4)$] with a range of 1,2-diamines, to form the corresponding ferrocenylquinoxalines, along with an electrochemical study of their redox properties. Monomeric ferrocenylquinoxalines are themselves potentially of interest and importance: a number of quinoxalines are powerful antibiotics and some examples show potential as anti-cancer drugs [7] and their action in this respect is dependent on their binding to DNA by intercalation [8]. At the same time, some rather simple ferricinium salts have been shown to exhibit powerful anti-tumour activity against a range of human tumour types [9]: the introduction of ferrocenyl substituents onto the quinoxaline framework could perhaps provide, in a single molecular species, a powerful combination of these two actions.

RESULTS AND DISCUSSION

Syntheses of ferrocenylquinoxalines

Reaction of 1-ferrocenyl-2-phenylethanedione, FcCOCOPh, **1**, with 1,2-diaminobenzene, **2**, yields the corresponding 2-ferrocenyl-3-phenylquinoxaline, **3**. When the reaction is conducted in the absence of solvent by melting together the two components under

* Author to whom correspondence should be addressed.

an inert atmosphere, the yield of the deep-purple product is generally somewhat less than 50%, after chromatographic purification. However, if the two reactants are first mixed in dioxan solution and then slowly heated first in solution and, subsequently, after all the solvent has evaporated, as a melt, the yield of purified product is consistently around 65%.

The product **3** is readily characterised by its analytical data and its ^{1}H and ^{13}C NMR spectra. The ^{1}H NMR spectrum contains, as well as characteristic signals from the monosubstituted ferrocenyl fragment, well-separated resonances arising from the phenyl and quinoxalyl fragments: the ^{13}C spectrum again shows the characteristic resonances from the ferrocenyl fragment, together with seven CH and five quaternary resonances in the aromatic region. A single-crystal X-ray diffraction analysis of **3**, prepared in this manner, has been published [10]. Because of the significantly enhanced yield obtained when the reactants were first heated in dioxan (b.p. 101°C) prior to the melt-phase condensation, the reactions of **1** with other aromatic 1,2-diamines were all conducted under similar conditions; in all these reactions, the choice of solvent was influenced by a combination of reactant solubility and solvent volatility. As with compound **3**, nearly all the resulting quinoxalines were isolated after chromatography on silica or alumina as hydrates, either monohydrates or hemihydrates.

Thus, when the ferrocenyl diketone **1** was reacted with 3,4-diaminobenzoic acid **4**, initially in chlorobenzene (b.p. 132°C), the quinoxaline **5** was obtained in *ca.* 80% yield after chromatographic purification. However, both the ^{1}H and ^{13}C NMR spectra indicated the presence of the two regio-isomers **5a** and **5b**, arising from the alternative orientations of the reactants in the condensation process: integration of the ^{1}H spectrum in the ferrocenyl region indicated a major:minor isomer ratio of 2:1.

No chromatographic conditions could be found under which the isomers were separable and consequently the assignment of the major and minor isomers as either **5a** or **5b** was not possible. However, it was possible, despite some peak overlap, to analyse completely for each isomer the quinoxalyl region of the ^{1}H NMR spectrum in terms of an ABX pattern having a J_{AX} ($= {}^{5}J_{HH}$) of zero. Similarly, with the 4-nitrodiamine **6**, the two regio-isomers **7a** and **7b** of the corresponding nitroquinoxaline are formed, with in this case a major:minor isomer ratio of 3:1; again, the quinoxalyl region of the ^{1}H NMR spectrum was analysed in terms of two ABX patterns each with a J_{AX} of zero.

From the condensation of the diketone **1** with 2,3-diaminotoluene, again a mixture of two regio-isomers **8a** and **8b** was formed, with a major:minor ratio of 3:2 as judged from the ^{1}H NMR spectrum, but on this occasion the two isomers were separable by careful chromatography on silica. On the other hand, the two regio-isomers **9a** and **9b** obtained using 2,3-diaminopyridine were not separable on silica, but were found to be separable on alumina provided that pure dichloromethane was employed as eluent: even the slightest increase in the polarity of the mobile phase caused the isomers to elute together.

In the quinoxaline-forming condensations involving substituted diamines, the modest regio-selectivity is determined by the relative nucleophilicities of the two amino groups in the diamine component, and the relative electrophilicities of the two carbonyl carbon atoms in the diketone **1**. It is assumed that the more nucleophilic amino group reacts faster with the more electrophilic carbonyl. In diamines **4** and **6**, in which the substituent R is electron-withdrawing, the amino group *meta* to R will be the more nucleophilic, while the carbonyl adjacent to the phenyl ring in **1** will be the more electrophilic, because of the strong electron-donating character of the ferrocenyl fragment. Hence, it is to be expected that **5b** is the more abundant isomer of **5**; similarly for **7**, the ferrocenyl fragment is preferentially *para* to the deactivating substituent. In 2,3-diaminotoluene, the amino group *ortho* to methyl is the more nucleophilic, so that **8b** is expected to predominate, while the strong deactivation of the 2-amino group in 2,3-diaminopyridine leads to the expectation of **9a** as the major isomer.

Use of the bis-1,2-diamine, **10**, under the reaction conditions employed for the formation of quinoxalines **3**, **5**, **7**, **8** and **9** and using dioxan as solvent

9b X = N

gave, as a mixture of regio-isomers, the expected bis-product **11**. However, when the ferrocenyl diketone **1** and the bis-diamine **10** were reacted together in alkaline aqueous solution [11], the predominant product was the monoquinoxaline **12**, accompanied by only a trace of **11**.

Electrochemistry

Figure 1, which refers to compound **3**, shows the typical cyclic voltammogram exhibited by the present compounds in dichloromethane solution. Both an oxidation process possessing features of chemical reversibility and an apparently irreversible reduction process, which is about twice greater in height than the oxidation step, are apparent.

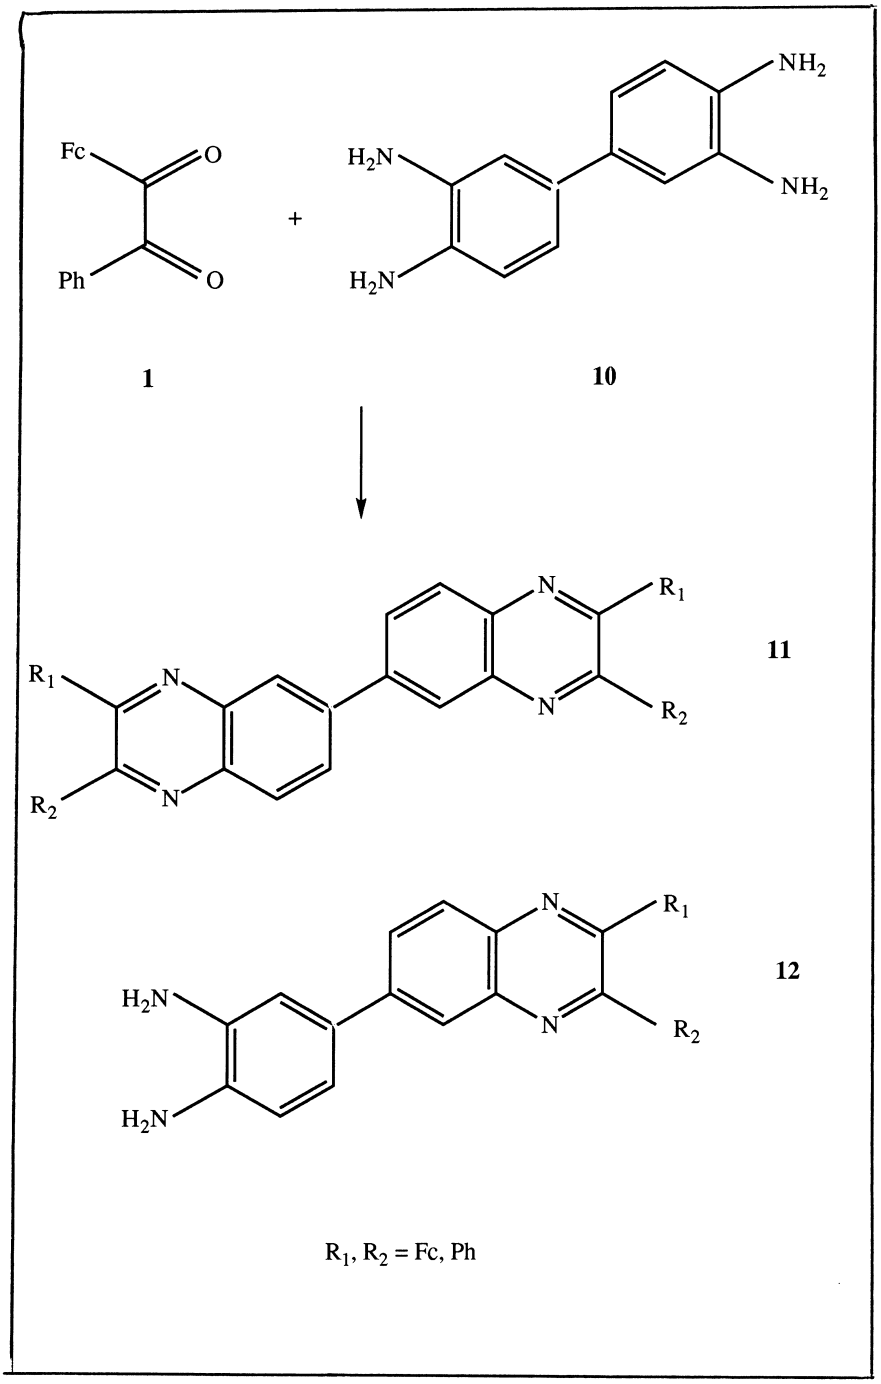
Controlled-potential coulometric investigation of the anodic process ($E_w = +0.7$ V) show the consumption of one electron/molecule. Upon exhaustive one-electron oxidation the original ruby-red solution of **3** turns jade-green and displays an absorption in the visible region at $\lambda_{max} = 692$ nm. In confirmation of the chemical reversibility of the ferrocene/ferricenium oxidation, cyclic-voltammetric tests performed on the oxidised green solution display voltammetric profiles entirely complementary to that shown in Fig. 1.

Analysis [12] of the cyclic-voltammetric anodic responses with scan rates varying from 0.02 to 1.00 V s^{-1} show parameters which are diagnostic of a one-electron removal which is essentially reversible from the electrochemical viewpoint. As a matter of fact, the i_{pc}/i_{pa} ratio is constantly equal to unity, the current function $i_{pa}/v^{1/2}$ remains constant and the peak-to-peak separation progressively increases from 70 to 170 mV. Such a slight departure from the constant value of 59 mV expected for an electrochemically-reversible one-electron process neatly parallels that observed for the one-electron oxidation of unsubstituted ferrocene, so that it may be attributed to uncompensated solution resistances.

So far as the reduction process is concerned, it was not possible to perform macroelectrolysis investigations because of the closeness of the solvent reduction. Based on the relative heights, we assign it to a single two-reduction process, which is however complicated by subsequent reactions, as yet uncharacterised. As the inset of Fig. 1 shows, when the scan rate was increased beyond 2.00 V s^{-1}, a reoxidation appears directly associated to the reduction process. This means that the rate of the chemical complication falls within the cyclic voltammetry time window, allowing estimation of *ca.* 0.05 s as the half-life of the electrogenerable $[\mathbf{3}]^{2-}$ anion [13].

Table 1 presents for all the compounds studied the formal electrode potentials of the redox changes discussed above and, for comparison, the corresponding data for the unsubstituted 2-ferrocenylquinoxaline (**13**) are also reported. The electrogenerated ferricenium species $[\mathbf{5}]^+$, $[\mathbf{9}]^+$ and $[\mathbf{13}]^+$ proved to be not fully stable and to undergo slow decomposition.

In comparison with unsubstituted ferrocene itself, the ferrocenylquinoxalines oxidise at potential values some 100–150 mV higher, thus indicating that the quinoxaline exerts a significant electron-withdrawing



effect. However, the effects of the substituents on the quinoxaline ring are always readily interpreted. Comparison between **13** and **3**, indicates that the 3-phenyl substituent, which might have been expected to make the oxidation more difficult, in fact makes the oxidation slightly easier, suggesting that resonance effects predominate over inductive effects. This could also explain the absence of inductive effects exerted by the methyl group in **8**, or the carboxyl group in **5**, compared with **3**. On the other hand, the strongly electron-withdrawing NO_2 group in **7** generates its expected effect.

The redox behaviour of the biferrocene complex **11** merits comment. It exhibits a single oxidation process, but unfortunately, because of its very low solubility satisfactory controlled-potential coulometry was not possible. However, in view of the absence of further oxidation processes up to $+1.2$ V, it may be specu-

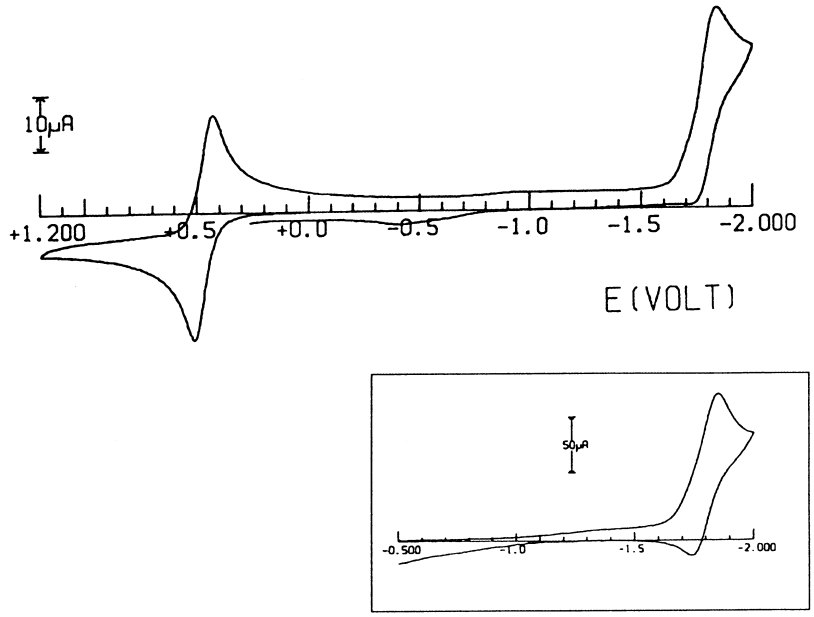


Fig. 1. Cyclic voltammogram recorded at a platinum electrode on a CH_2Cl_2 solution containing **3** (1.3×10^{-3} mol dm^{-3}) and $[NBu_4][PF_6]$ (0.2 mol dm^{-3}). Scan rates: main figure, 0.20 V s^{-1}; inset, 2.00 V s^{-1}.

lated that this is due to a single two-electron step. Were this to be so, it would imply that no electronic communication occurs between the two quinoxalyl units.

Finally, as far as the presence of isomeric species is concerned, as noted above for compounds **5**, **7**, **8**, **9** and **11**, it may be pointed out that only in the case of compound **5** was the presence of two almost overlapping oxidation processes observed, which could account for the somewhat greater peak-to-peak separation in **5** compared with the other species.

EXPERIMENTAL

The diketone FcCOCOPh was prepared as previously described [4]. Aromatic diamines were obtained from commercial sources and were purified using published methods [14]. NMR spectra were recorded at ambient temperatures, in $CDCl_3$ solution unless stated otherwise, on a Bruker AM-300 spectrometer operating at 300.135 MHz for ^{1}H and 75.469 MHz for ^{13}C. Diethyl ether and light petroleum (b.p. 40–60°C) were dried over sodium wire. Elemental analyses were by the Microanalytical Laboratory of this School.

Synthesis of 2-ferrocenyl-3-phenylquinoxaline

Melt-phase reaction Ferrocenylphenylethanedione **1** (0.2 g, 0.63 mmol) and 1,2-diaminobenzene **2** (0.1 g, 0.93 mmol) were taken in a Pyrex glass test tube with a side arm and fitted with a bubbler. The mixture was heated to melting in an oil bath at 140°C under nitrogen for 30 min, water vapours were observed condensing on the walls of tube. After cooling the crude material was dissolved in dichloromethane and checked by TLC; this showed one purplish-red spot almost at the same R_f value as ferrocenylphenylethanedione. This crude product was chromatographed on silica gel using dichloromethane as the eluting solvent, concentrated and crystallised to

give dark purple crystals of 2-ferrocenyl-3-phenylquinoxaline **3** (0.11 g, 45%).

Reaction in dioxan solution Ferrocenylphenylethanedione **1** (0.2 g, 0.63 mmol), 1,2-diaminobenzene **2** (0.1 g, 0.93 mmol) were dissolved in 1,4-dioxan (3 cm^3) in a Pyrex glass test tube with a side arm and fitted with a bubbler. This mixture was heated in an oil bath at 110°C under a gentle stream of nitrogen until dryness. The temperature of the bath was raised to 140°C and held at this temperature for 20 min. The crude product was purified as for the melt-phase reaction. Weight of chromatographed product 0.16 g (65%).

The products from these two processes were found to be identical by TLC and by ^1H and ^{13}C NMR. Anal. found C 72.2, H 4.4, N 6.9; $C_{24}H_{18}FeN_2$ requires C 73.9, H 4.7, N 7.2%; $C_{24}H_{18}FeN_2.0.5H_2O$ requires C 72.2, H 4.8, N 7.0%. M.p. 208–210°C (lit. 208–209°C [4]). NMR δ(H) 4.00. (5H, s, C_5H_5); 4.35 (2H, m) and 4.55 (2H, m) (C_5H_4); 7.50–7.55 (5H, m, Ph); 7.72 (2H, m) and 8.08 (2H, m) (quinoxalyl); δ(C) 69.9 (d, C_5H_5); 70.1 (d), 70.8 (d) and 82.3 (s) (C_5H_4); 128.4 (d), 128.8 (d), 128.9 (d), 129.0 (d), 129.2 (d), 129.3 (d), 129.9 (d), 139.8 (s), 140.3 (s), 141.9 (s), 154.1 (s) and 154.1 (s) (phenyl and quinoxalyl).

Synthesis of ferrocenylphenylquinoxalylcarboxylic acid

In a similar manner, ferrocenylphenylethanedione **1** (0.5 g, 1.57 mmol), 3,4-diaminobenzoic acid **4** (0.26 g, 1.7 mmol) and chlorobenzene (5 cm^3) were heated in a silicone oil bath at 140°C under a gentle stream of nitrogen; after 1 h. TLC showed that no unreacted diketone remained. During the reaction time the colour of the mixture also changed from dark red to dark purple. The mixture was then heated to dryness. After cooling, the solid residue was dissolved in dichloromethane, filtered, washed with water, dried (Na_2SO_4), concentrated and chromatographed over silica gel using diethyl ether as the mobile phase to yield ferrocenylphenylquinoxalylcarboxylic acid **5** (0.55 g, 81%) as a dark purple solid. The ^1H NMR spectrum showed the presence of two regio-isomers. The relative yield of the regio-isomers as calculated from the ^1H NMR integration is 2:1. Anal. found C 66.9, H 4.7, N 5.7; $C_{25}H_{18}FeN_2O_2$ requires C 69.1, H 4.2, N 6.5; $C_{25}H_{18}FeN_2O_2.H_2O$ requires C 66.4, H 4.5, N 6.2%. NMR δ(H) (major isomer) 4.01 (5H, s, C_5H_5); 4.38 (2H, m) and 4.58 (2H, m) (C_5H_4); 7.4–7.7 (5H, m, Ph); 8.15 (1H, d; *J*, 8.8), 8.35 (1H, dd; *J*, 8.8 and 1.6) and 8.92 (1H, d; *J*, 1.6) (quinoxalyl);. (minor isomer) 4.03 (5H, s, C_5H_5); 4.40 (2H, m) and 4.60 (2H, m) (C_5H_4); 7.4–7.7 (5H, m, Ph); 8.15 (1H, d; *J*, 8.8), 8.38 (1H, dd; *J*, 8.8 and 1.6) and 8.91 (1H, d; *J*, 1.6) (quinoxalyl); δ(C) (major isomer) 68.4_7 (d, C_5H_5); 69.0 (d), 69.5 (d) and 80.1 (s) (C_5H_4); (minor isomer) 68.5_3 (d, C_5H_5); 69.3 (d), 69.6 (d) and 80.4 (s) (C_5H_4); (both isomers) 126.9_3 (d), 126.9_6 (d), 127.0_5 (d), 127.1_6 (d), 127.6_3 (d), 127.7_2 (d), 127.7_8 (d), 128.3 (d), 129.6 (d), 129.8 (d), 130.1 (d), 131.1 (d), 137.3 (s), 138.1_7 (s), 138.2_4 (s), 139.4 (s), 140.0 (s), 142.0 (s), 152.4 (s), 153.0 (s), 153.6 (s) and 154.6 (s) (phenyl and quinoxalyl); 166.2 (s) COOH. The resolution of the aromatic resonances requires resolution enhancement. Both the carboxyl carbons appear at the same position, and two of the quaternary carbons of the aromatic/quinoxaline moieties are superimpose on other peaks in that region and hence are not visible in the spectrum.

Synthesis of ferrocenylphenylnitroquinoxaline

Ferrocenylphenylethanedione **1** (0.22 g, 0.69 mmol), 4-nitro-1,2-diaminobenzene **6** (0.12 g, 0.76 mmol) and toluene (5 cm^3) were refluxed, as above, under a gentle stream of nitrogen for 3 h; the reaction was monitored by TLC. The solvent was evaporated after this time. After cooling, the solid residue was redissolved in dichloromethane, filtered, concentrated and chromatographed over silica gel using dichloromethane as the mobile phase to yield ferrocenylphenylnitroquinoxaline **7** (0.22 g, 73%) as a dark purple solid. The compound crystallises as a hemi-hydrate as shown by the elemental analysis and integration of the ^1H NMR spectrum gave an isomer ratio of 3:1. An attempt to separate the two isomers on silica using dichloromethane as eluent yielded a pure fraction of the more abundant isomer, together with a mixture of both the isomers. Anal. found (isomer mixture) C 65.1, H 3.9, N 9.1; $C_{24}H_{17}FeN_3O_2$ requires C 66.2, H 3.9, N 9.6; $C_{24}H_{17}FeN_3O_2.0.5H_2O$ requires C 64.9, H 4.1, N, 9.4%. NMR (major isomer pure, minor isomer from spectrum of mixture) δ(H) (major isomer) 4.01 (5H, s, C_5H_5); 4.40 (2H, m) and 4.57 (2H, m) (C_5H_4); 7.5–7.6 (5H, m, Ph); 8.18 (1H, d; *J*, 9.5), 8.44 (1H, dd; *J*, 9.5 and 2.4) and 8.98 (1H, d; *J*, 2.4) (quinoxalyl); (minor isomer) 4.00 (5H, s, C_5H_5); 4.43 (2H, m) and 4.60 (2H, m) (C_5H_4); 7.5–7.6 (5H, m, Ph); 8.16 (1H, d; *J*, 9.4), 8.48 (1H, dd; *J*, 9.4 and 2.4) and 8.98 (1H, d; *J*, 2.4) (quinoxalyl); δ(C) (major isomer) 69.9 (d, C_5H_5); 70.8 (d), 71.1 (d) and 80.8 (s) (C_5H_4); 121.8 (d), 124.7 (d), 128.4 (d), 128.9_0 (d), 129.5 (d), 130.5 (d), 138.9 (s), 140.4 (s), 142.0 (s), 147.9 (s), 144.8 (s) and 157.1 (s) (phenyl and quinoxalyl); (minor isomer) 70.0 (d, C_5H_5); 71.2_5 (d), 71.2_8 (d) and 80.7 (s) (C_5H_4); 123.2 (d), 125.6 (d), 128.2 (d), 128.8_7 (d), 129.4 (d), 129.6 (d), 138.0 (s), 138.9 (s), 144.1 (s), 146.7 (s), 145.2 (s) and 158.1 (s) (phenyl and quinoxalyl).

Synthesis of ferrocenylphenylmethylquinoxaline

In a similar manner, ferrocenylphenylethanedione **1** (0.5 g, 1.57 mmol), 2,3-diaminotoluene (0.22 g, 1.8 mmol) and chlorobenzene (5 cm^3) were refluxed in an oil bath at 150°C under a gentle stream of nitrogen. The reaction was monitored by TLC and after 4 h the reaction was complete. The two regio-isomers had distinguishable R_f values, but the less polar isomer

had almost the same value as the diketone, so that it was sometimes difficult to differentiate between diketone and this isomer of the product. When the reaction was complete, the solvent was removed and the solid residue was redissolved in dichloromethane, filtered, concentrated and chromatographed over silica gel using dichloromethane/petrol as the mobile phase to yield ferrocenylphenylmethylquinoxaline **8** (0.6 g, 95%) as a dark purple solid. The relative yield of the regioisomers as calculated from the ^{1}H NMR integration is 3:2. Another column was run to separate the two isomers from each other; this yielded first the pure less-polar isomer, then the mixture of two isomers and finally a small portion of the more-polar isomer. Anal. found C 74.0, H 5.0, N 6.7; $C_{25}H_{20}FeN_2$ requires C 74.3, H 5.0, N 6.9%. NMR δ(H) (major isomer) 2.95 (3H, s, CH_3); 4.02 (5H, s, C_5H_5); 4.32 (2H, m) and 4.55 (2H, m) (C_5H_4); 7.4–7.7 (7H, m) and 7.94 (1H, d) (phenyl and quinoxalyl); (minor isomer) 2.82 (3H, s, CH_3); 4.00 (5H, s, C_5H_5); 4.32 (2H, m) and 4.55 (2H, m) (C_5H_4); 7.4–7.7 (7H, m) and 7.94 (1H, d) (phenyl and quinoxalyl); δ(C) (major isomer) 17.1 (q, CH_3); 69.7 (d, C_5H_5); 69.7 (d), 70.8 (d) and 82.9 (s) (C_5H_4); 126.8 (d), 128.1 (d), 128.5_0 (d), 128.5_5 (d), 129.1 (d), 129.5 (d), 136.5 (s), 139.6 (s), 139.8 (s), 140.8 (s), 152.1 (s) and 152.4 (s) (phenyl and quinoxalyl); (minor isomer) 17.0 (q, CH_3); 69.6 (d, C_5H_5); 69.6 (d), 70.7 (d) and 82.7 (s) (C_5H_4); 126.2 (d), 127.9 (d), 128.4 (d), 128.6 (d), 129.2 (d), 129.4 (d), 137.3 (s), 138.8 (s), 140.2 (s), 141.4 (s), 151.4 (s) and 152.9 (s) (phenyl and quinoxalyl).

Synthesis of 2-*ferrocenyl*-3-*phenyl*-5-*azaquinoxaline*

Ferrocenylphenylethanedione **1** (0.32 g, 1.0 mmol), 2,3-diaminopyridine (0.22 g, 2.0 mmol) and 1,4-dioxan (2 cm^3) were heated, as above, in an oil bath at 110°C under a slow stream of nitrogen until dryness. The temperature was then increased to 150°C and held for 30 min. After cooling, the mixture was dissolved in dichloromethane, filtered, concentrated and chromatographed on silica gel to give pure ferrocenylphenylazaquinoxaline **9** (0.26 g, 67%) as a dark purple solid. The product contained both regio-isomers of the azaquinoxaline, confirmed by ^{1}H and ^{13}C NMR. The two isomers which were not separable on silica gel were found to be separable on alumina by very careful elution using dichloromethane as eluting solvent. Any slight increase in the polarity of the mobile phase (e.g. one drop of methanol in 100 cm^3 of dichloromethane) elutes both the isomers at the same time. Integration of the ^{1}H NMR spectrum gave an isomer ratio of *ca.* 3:2. Anal. found C 69.8, H 4.6, N 10.1; $C_{23}H_{17}FeN_3$ requires C 70.6, H 4.4, N 10.7%. NMR δ(H) (major isomer) 4.02 (5H, s, C_5H_5); 4.38 (2H, m) and 4.62 (2H, m) (C_5H_4); 7.4–7.7 (6H, m, phenyl and quinoxalyl), 8.42 (1H, d × d) and 9.10 (1H, d) (quinoxalyl); (minor isomer) 4.06 (5H, s, C_5H_5); 4.40 (2H, m) and 4.68 (2H, m) (C_5H_4); 7.4–7.8 (6H, m, phenyl and quinoxalyl), 8.46 (1H, d × d) and 9.15 (1H, d) (quinoxalyl); δ(C) (major isomer) 69.6 (d, C_5H_5); 70.2 (d), 70.8 (d) and 81.8 (s) (C_5H_4); 124.8 (d), 127.8 (d), 128.9 (d), 129.2 (d), 136.2 (s), 136.8 (d), 138.8 (s), 148.4 (s), 152.5 (d), 155.3 (s) and 155.5 (s) (phenyl and quinoxalyl); (minor isomer) 69.8 (d, C_5H_5); 70.7 (d), 71.0 (d) and 80.5 (s) (C_5H_4); 123.7 (d), 128.2 (d), 128.7 (d), 128.9 (d), 134.2 (s), 137.7 (d), 139.2 (s), 150.0 (s), 153.6 (d), 154.1 (s), 157.8 (s) (phenyl and quinoxalyl).

Synthesis of di(*ferrocenyl*)*diphenylbiquinoxaline*

In a similar manner, ferrocenylphenylethanedione **1** (0.30 g, 0.94 mmol), 3,3′,4,4′-biphenyltetramine **10** (0.40 g, 1.87 mmol) and 1,4-dioxan (2 cm^3) were heated in an oil bath at 110°C under a gentle stream of nitrogen until all the solvent had evaporated. The temperature of the oil bath was then raised to 150°C and the mixture was kept at this temperature for 45 min. After cooling, the solid residue was dissolved in dichloromethane. TLC analysis showed the presence of two purple quinoxaline spots. As three regioisomers of the product **11** could be formed in this reaction, it is possible that the two of these isomers have virtually identical R_f values. As the R_f values of the two distinguishable components are very closely similar, attempts to separate the isomers have not so far been successful.

Synthesis of ferrocenyl-phenyl-6-(3′,4′-*diaminophenyl*)*quinoxaline*

Ferrocenylphenylethanedione **1** (0.10 g, 0.314 mmol), 3,3′,4,4′-biphenyltetramine (0.13 g, 0.61 mmol), sodium sulfite (0.06 g, 0.48 mmol) and potassium carbonate (0.06 g, 0.43 mmol) were dissolved in 50% (v/v) aqueous ethanol (50 cm^3). The mixture was refluxed with stirring for 2 h. After this time, TLC of the organic extract showed two highly polar components of very similar R_f values, in addition to traces of the bis-quinoxaline **11** and unreacted biphenyltetramine. During the course of the reaction some solid product precipitated out; this was filtered off and the filtrate extracted with diethyl ether. The combined solids were purified by chromatography on neutral alumina using 20% (v/v) methanolic diethyl ether as eluent to yield ferrocenylphenyl-6-(3′,4′-diaminophenyl)quinoxaline **12** (0.12 g, 77%). Anal. found C 71.6, H 4.8, N 11.0; $C_{30}H_{24}FeN_4$ requires C 72.6, H 4.9, N 11.3%; $C_{30}H_{24}FeN_4.0.5(H_2O)$ requires C 71.3, H 5.0, N 11.1%.

Electrochemistry

materials and apparatus for electrochemistry have been described elsewhere [13, 15]. All the potential

values are referred to the saturated calomel electrode (S.C.E.).

(Received 16 March 1998; accepted 2 June 1998)

Abstract—Reaction of 1-Li-2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$ with [AuClL] (L = PPh$_3$, PPh$_2$Me, AsPh$_3$) in molar ratio 1:1 affords the organometallic gold complexes [1-AuL-2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$]. The complex PPN[Au{2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$}$_2$] (PPN = N(PPh$_3$)$_2$) has also been synthesised by reaction of PPN[AuCl$_2$] with 1-Li-2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$ in molar ratio 1:2. The crystal structure of [1-{Au(PPh$_3$)}-2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$] has been established by X-ray diffraction. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: gold; carborane

INTRODUCTION

The synthesis of carboranyl derivatives has been extensively studied because in some aspects they resemble organic compounds with electron-accepting groups [1–4]. During the past decade investigations in the field of C-substituted carboranes have involved the creation of new models to be used in theoretical investigations [5], the preparation of organic and organometallic carboranyl compounds for the production of polymeric materials [6–8] (and references cited therein) and biological and medical investigations [9]. These compounds have proved particularly useful in the boron neutron capture therapy (BNCT) for cancer [10–13].

It is known that *o*-carborane derivatives form unusually strong Au–C bonds. Nevertheless, examples of closo-carboranes σ-bonded to gold by 2c–2e σ-bonds are relatively rare (as opposed to the most studied nido-carboranes interacting gold via cluster bonding) [14–18].

The first report was made by Mitchel and Stone [19, 20], who prepared the complexes [Au(2-R-1,2-$C_2B_{10}H_{10}$)(PPh$_3$)] [R = H, Me, Ph]. More recently species of stoichiometry [Au(2-R-1,2-$C_2B_{10}H_{10}$)L] [R = CH$_2$OCH$_3$, Ph; L = PPh$_3$, P(*o*-tol)$_3$, PCy$_3$, PEt$_3$, AsPh$_3$] have been reported by Reid and Welch [21] whereas in the work published by Hawthorne *et al.* [22] dimetallated species of *o*-carborane and bis(*o*-carborane) have been synthesised.

We have reported recently on the synthesis of the first *m*-carborane derivatives bonded to gold by 2c–2e σ-bond [23] as part of our studies with carborane derivatives [24–30]. Our contribution this time is related to some new organometallic gold(I) derivatives with the carboranyl group [1-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$]$^-$. This carboranyl derivative has been described as a good precursor in the synthesis of monosubstituted carborane derivatives [31].

RESULTS AND DISCUSSION

The treatment of 1-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{11}$ with Li^{n}Bu leads to the lithiated derivative 1-Li-2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$ (**1**) which is not isolated; further reaction of **1** with the organochloro complexes [AuClL] affords the organometallic derivatives [1-

* Author to whom correspondence should be addressed. Tel.: +34-976-761-185; Fax: +34-976-761-187; E-mail: alaguna@posta.unizar.es.

(AuL)-2-Si^{t}BuMe$_2$-$C_2B_{10}H_{10}$] [L = PPh_3 (**2**), PPh_2Me (**3**) and $AsPh_3$ (**4**)] (Scheme 1).

Complexes **2**–**4** behave as nonconductors in acetone solutions. In their IR spectra the υ(BH) absorptions appear at 2592 (br, vs), (**2**), 2664 (br, vs) (**3**) and 2566 (br, vs) (**4**) cm^{-1}, respectively.

The positive liquid secondary-ion mass spectra (LSIMS) of complexes **2**–**4** show the molecular peaks at m/z = 716 (**2**, 50%), 597 (**3**, 5%) and 760 (**4**, 40%), although the most intense ones correspond to the fragments $[AuL_2]^+$ [m/z 721 (**2**), 597 (**3**) and 809 (**4**)].

Compounds **2** and **3** exhibit only one signal in their $^{31}P\{^1H\}$ NMR spectra downfield referred to the starting materials ($\Delta\delta$ = 4.8 (**2**) and 5.5 (**3**) ppm).

In the ^{1}H NMR spectra of **2**–**4** a multiplet and a broad signal appear which correspond to the phenylic protons (7–7.8 ppm) and the BH protons (1–3 ppm) respectively. All of them exhibit two resonances due to the Si^{t}BuMe$_2$ fragment at about 1.0 and 0.5 ppm. In addition to this pattern, compound **3** displays one doublet due to the methyl protons of the phosphine ligand.

Complex **2** has been characterised by X-ray diffraction studies and the structure is shown in Fig. 1. Selected bond lengths and angles are collected in Table 1. In the molecule the gold centre exhibits a distorted linear geometry, P–Au–C(1) = 171.3(12)°, although there are no obvious reasons for this distortion, it may be possible that because the bulky nature of the Si^{t}BuMe$_2$ group there is some steric hindrance. This distorted geometry is not observed in [Au(2-CH_2O–CH_3)-1,2-$C_2B_{10}H_{10}$)($AsPh_3$)] [As–Au–C = 177.05(2)°] [21].

The Au–P distance of 2.2718(13) Å is of the same order than those found in another *o*-carboranyl compounds such as [Au(2-H-1,2-$C_2B_{10}H_{10}$)(PPh_3)] (2.271(2) Å) [22] or in the *m*-carboranyl derivative [23] [Au_2(μ-1,7-$C_2B_{10}H_{10}$)(PPh_3)$_2$] (2.265(2), 2.271(2) Å) and can also be compared with those found in complexes of the type [AuR(PPh_3)] (R = C_6F_5, 2.27(1) Å) [32].

The Au–C(1) distance, 2.050(4) Å, is of the same order as those obtained for the complexes commented below (2.054(7), 2.047(7) Å for the *m*-carborane derivative; 2.039(8) and 2.039(8) Å for the mono and disubstituted *o*-carborane derivatives respectively). It has been shown that the Au–C distances depend on the hybridisation state of the carbon atom. The distances found in the commented *o*-carboranyl and *m*-carboranyl complexes are clearly characteristic values of a carbon with sp^2 hybridisation [20], which range from 2.05 to 2.09 Å. These short Au–C distances in carborane derivatives support Stone's observations that the unusual stability of auracarboranes is attributed to the electron withdrawing influence of the cage. The fact that a similar stability is observed in gold-perfluoroalkyl compounds, with the Au–C distances only slightly longer, but in the range of an sp^2 hybridisation, is coherent with such a conclusion.

No organometallic derivative of this ligand has been reported as far as we know, but no appreciably distortion is expected for the Si^{t}BuMe$_2$ group from one compound to another, thus the Si–C(2) distance 1.924(5) Å compares well with those found in 1,2-(1-SiMe$^t{}_2$Bu-1,2-$C_2B_{10}H_{10})_2$-C_6H_4 [1.951(4), 1.956 Å] [33] as well as the C(1)–C(2) distance 1.706(6) Å in complex **2**, 1.714(6), 1.707(7) Å in the related species.

Reaction of **1** with PPN[$AuCl_2$] [PPN = N(PPh_3)$_2$] in molar ratio 2:1 affords a compound which contains two carboranyl groups: PPN[Au{2-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{10}$}$_2$] (**5**) (Figure 1).

Compound **5** behaves as 1:1 electrolyte in acetone solutions. In the IR spectrum of **5** the υ(BH) absorption appears at 2632 cm^{-1}. Its LSIMS (+) spectrum

presents the molecular peak as the most intense at $m/z = 712$. The ^{1}H NMR spectrum of **5** exhibits a similar pattern to those commented above for **2** and **4**.

EXPERIMENTAL

Infrared spectra were recorded in the range from 4000 to 200 cm^{-1} on a Perkin-Elmer 883 spectrophotometer using Nujol mulls between polyethylene sheets. Conductivities were measured in ca. 5×10^{-4} mol dm^{-3} solution with a Philips PW 9509 conductimeter. C and H analyses were carried out with a Perkin–Elmer 2400 microanalyser. Mass spectra were recorded on a VG Autospec, with the liquid secondary ion mass spectrometry (LSIMS +) technique using nitrobenzylalcohol as matrix. NMR spectra were recorded on a Varian Unity 300 and Bruker

ARX 300 spectrometer in $CDCl_3$. Chemical shifts are cited relative to 85% H_3PO_4 (external, ^{31}P) and $SiMe_4$ (external, ^1H).

Starting materials

o-carborane was from Desxil Corporation and Si^{t}BuMe$_2$Cl was from Aldrich, both of them were used as given. Compounds 1-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{11}$ [31], [AuCl(PPh_3)], [AuCl(PPh_2Me)], [AuCl($AsPh_3$)] [34] and PPN[$AuCl_2$] [35] were synthesised according to the literature procedures.

Preparation of [1-(*AuL*)-2-*Si^{t}BuMe$_2$*-1,2-$C_2B_{10}H_{10}$] [*L* = *PPh$_3$* (**2**), *PPh$_2$Me* (**3**), *AsPh$_3$* (**4**)]

To a solution of 1-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{11}$ (77.4 mg, 0.3 mmol) in dried diethyl ether (30 cm^3) at 0°C and under nitrogen atmosphere Li^{n}Bu was added (0.3 mmol, 0.48 ml and 0.62 M). After stirring the mixture for 30 min [AuCIL] was added [0.3 mmol, L = PPh_3, 14.8 mg; L = PPh_2Me, 12.9 mg; L = $AsPh_3$, 15.9 mg]. The suspension was stirred for another 30 min and allowed to warm. After filtration of the suspension over celite and concentration to ca. 5 cm^3 complexes **2** (76%), **3** (48%) and **4** (57%) as white solids are obtained by addition of *n*-hexane (ca. 10 cm^3). **2** Anal. (%) Found: C, 43.05; H, 5.35. Calc. for $C_{26}H_{40}AuB_{10}PSi$: C, 43.55; H, 5.6. $\Lambda_M = 28\,\Omega^{-1}\,cm^2\,mol^{-1}$. ^1H NMR: 0.25 (s, 6H, CH_3), 0.88 (s, 9H, ^{t}Bu), 7–7.6 (m, br, 15H, Ph). $^{31}P\{^1H\}$ NMR: 38.4 (s). **3** Anal. (%) Found: C, 38.35; H, 5.6. Calc. for $C_{21}H_{38}AuB_{10}PSi$: C, 38.55; H, 5.85. $\Lambda_M = 14\,\Omega^{-1}\,cm^2\,mol^{-1}$. ^1H NMR: 0.35 (s, 6H, CH_3), 0.99 (s, 9H, ^{t}Bu), 1.95 (d, J(PH) = 8.4 Hz, 3H, CH_3), 7.2–7.6 (m, br, 10H, Ph). $^{31}P\{^1H\}$ NMR: 22.8 (s). **4** Anal. (%) Found: C, 41.05; H, 5.3. Calc. for $C_{26}H_{40}AsAuB_{10}Si$: C, 41.35; H, 5.4. $\Lambda_M = 9\,\Omega^{-1}\,cm^2\,mol^{-1}$. ^1H NMR: 0.32 (s, 6H, Me), 0.95 (s, 9H, ^{t}Bu), 7.0–7.51 (m, br, 15H, Ph).

Preparation of PPN[*Au*{2-*Si^{t}BuMe$_2$*-1,2-$C_2B_{10}H_{10}$}$_2$] (**5**)

To a solution of 1-Si^{t}BuMe$_2$-1,2-$C_2B_{10}H_{11}$ (77.4 mg, 0.3 mmol) in dry diethyl ether (30 cm^3) at 0°C and under nitrogen atmosphere Li^{n}Bu was added (0.3 mmol, 0.48 ml, 0.62 M). After stirring the mixture for 30 min PPN[$AuCl_2$] was added [0.15 mmol, 12 mg]. The suspension was stirred for another 30 min and allowed to warm. After filtration of the suspension over celite and concentration to ca. 5 cm^3 complex **5** (68%) is afforded by addition of *n*-hexane (ca. 10 cm^3). Anal. (%) Found: C, 50.65; H, 6.5; N, 1.15. Calc. for $C_{52}H_{80}AuB_{20}NP_2Si_2$: C, 49.95; H, 6.45; N, 1.1. $\Lambda_M = 134\,\Omega^{-1}\,cm^2\,mol^{-1}$. ^1H NMR: 0.39 (s, 12H, Me), 1.02 (s, 18H, ^{t}Bu), 7.46–7.65 (m, br, 30H, Ph). $^{31}P\{^1H\}$ NMR: 21.2 (s).

X-ray crystal structure determination of **2**

Crystal Data: **2**, $C_{26}H_{40}AuB_{10}PSi$, Mr = 716.71, triclinic, space group $P\bar{1}$, $a = 10.164(2)$, $b = 12.557(3)$, $c = 14.200(2)$ Å, $\alpha = 115.680(10)$, $\beta = 93.040(10)$, $\gamma = 102.700(10)$, $U = 1570.5(5)$ Å^3, $Z = 2$, $D_c = 1.516$ Mg m^{-3}, λ (Mo-Kα) = 0.71073 Å, $\mu = 4.79$ mm^{-1}, $F(000) = 708$, $T = -100$°C. Single crystals were obtained by a slow diffusion of *n*-hexane into a dichloromethane solution of complex **2**. A colourless prism $0.50 \times 0.40 \times 0.30$ mm was used to collect 5561 intensities to $2\theta_{max} = 50°$ (Siemens P4 diffractometer, monochromated Mo-Kα radiation) of which 5119 were independent ($R_{int} = 0.032$). An absorption correction based on Ψ-scans was applied with transmission factors 0.599–0.863. Cell constants were refined from setting angles of 64 reflections in the range 2θ from 10 to 25°. The structure was solved by the heavy-atom method and subjected to full-matrix least-squares refinement on F^2 (SHELXL-93); all the atoms were refined anisotropically, H atoms were included using a riding model. Refinement proceed to $wR(F^2) = 0.074$ for 5117 reflections and 357 parameters, conventional $R(F) = 0.029$, $S(F^2) = 1.022$, maximum $\Delta\rho$ 2.4 e Å^{-3}.

Received 25 March 1998; accepted 2 June 1998

Abstract—The structures of the copper(II) complexes of two azo-dyes, 1-(2-pyridylazo)-2-naphthol (HPAN) and 2,2′-dihydroxyazobenzene (H_2DAB), Cu(PAN)NO_3 and Cu(DAB)·pyr are reported. In the former the molecules exist as discrete van der Waals pairs whereas in the latter an unusual trimeric unit is found which is held together by long bonding interactions between the copper atom in one molecule and one of the hydroxy oxygen atoms from the adjacent molecule: Cu(2)–O(1B), 2.517; Cu(3)–O(2C), 2.566, Cu(1)– O(2B), 2.622 and Cu(3)–O(1A), 2.768 Å. © 1998 Elsevier Science Ltd. All rights reserved

Keywords:

Although terdentate complexing agents containing an azo-group and a hydroxy group *ortho* to the azo-group have been used as spectrophotometric and titrimetric reagents, in solvent-extraction studies and as dyes, there is a general lack of information about the structures of metal complexes of *o*-hydroxy-*o*-azo-dyes [1]. In the course of a study designed to investigate the factors influencing the solid state assembly of such complexes we have determined the structures of the copper(II) complexes of two azo-dyes, 1-(2-pyridylazo)-2-naphthol (HPAN) and 2,2′-dihydroxyazobenzene (H_2DAB) both of which exist as oligomers.

EXPERIMENTAL

Synthesis

1-(2-pyridylazo)-2-naphthol (HPAN) and 2,2′-dihydroxyazobenzene (H_2DAB) were purchased from Aldrich and used without further purification. Positive ion fast atom bombardment mass spectra (FAB+) were recorded using a VG PROSPEC spectrometer with 4-nitrobenzyl alcohol (NOBA) as the matrix.

Preparation of Cu(PAN)(NO_3)

A solution of copper(II) nitrate (2.04 mmol) in methanol (10 cm^3) was added to a suspension of the red dye, 1-(2-pyridylazo)-2-naphthol, (2.04 mmol) in methanol (50 cm^3). The resulting purple solution was heated at reflux temperature for 30 min, filtered hot and then left to cool overnight. The dark precipitate was collected to yield a purple–brown solid on drying *in vacuo* (76% yield). Recrystallisation from methanol gave crystals suitable for X-ray structure determination. Found: C, 48.4: H, 2.3: N, 15.1%. Calculated for $C_{15}H_{10}CuN_4O_4$: C, 48.2: H, 2.7: N, 15.0%. M.s. (FAB+: NOBA matrix) 311 [Cu(PAN)]; 622 $[Cu(PAN)]_2$.

Preparation of Cu(DAB)·pyr

2,2′-dihydroxyazobenzene (2.3 mmol) was dissolved in methanol (70 cm^3) with warming and the orange solution filtered. To the clear solution was added a solution of copper(II) acetate (2.3 mmol) in methanol (50 cm^3) and a gelatinous precipitate formed. The mixture was heated at reflux temperature for 2 h and the resulting brown solid collected. Vapour phase diffusion of petroleum ether into a solution of the brown solid in pyridine gave shiny green crystals suitable for X-ray structure determination. Found: C,

X-ray crystallography

For both structures three-dimensional, room temperature X-ray data were collected in the range $3.5 < 2\theta < 45^\circ$ on a Siemens P4 diffractometer by the omega scan method. Complex scattering factors were taken from the program package SHELXL93 [2] as implemented on the Viglen 486dx computer. Anisotropic thermal vibrational parameters with e.s.d's, hydrogen atom position parameters and observed structure amplitudes and calculated structure factors are available from the authors by request.

Cu(PAN)NO_3, $C_{15}H_{10}CuN_4O_4$, was crystallised from methanol as blue prisms; the crystallographic data is summarised in Table 1. Of the 4442 reflections measured, all of which were corrected for Lorentz and polarisation effects but not for absorption, 1568 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full matrix least squares on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final $R = 0.0327$ ($wR_2 = 0.0825$, for all 1863 data, 217 parameters, mean and maximum δ/σ 0.000, 0.000), with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density -0.384 and $0.375\,e\,Å^{-3}$. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0309*P)^2 +$

$1.0241*P]$ where $P = (F_o^2 + 2*F_c^2)/3$ was used in the latter stages of refinement.

Cu(DAB)·pyr, $C_{17}H_{13}CuN_3O_2$, was crystallised by vapour diffusion of petroleum ether into a pyridine solution of the complex giving green blocks; the crystallographic data is summarised in Table 1. Of the 9673 reflections measured, all of which were corrected for Lorentz and polarisation effects but not for absorption, 4932 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full matrix least squares on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final $R = 0.0450$ ($wR_2 = 0.1035$, for all 6157 data, 631 parameters, mean and maximum δ/σ 0.000, 0.000), with allowance for the thermal anisotropy of all non-hydrogen atoms with the exception of N(1Ca) and N(2Cb). The atoms N(1Ca), N(2Ca) and N(1Cb), N(2Cb) were refined to an occupancy of 44 and 56%, respectively. Minimum and maximum final electron density -0.338 and $0.838\,e\,\text{Å}^{-3}$. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0485*P)^2 + 0.4503*P]$ where $P = (F_o^2 + 2*F_c^2)/3$ was used in the latter stages of refinement.

RESULTS AND DISCUSSION

[1-(2-*Pyridylazo*)-2-*naphtholato*]*copper*(*II*), [*Cu*(*PAN*)]NO_3

The reaction of HPAN with copper(II) nitrate in methanol yielded a purple–brown solid which analysed as $[Cu(PAN)]NO_3$ [3]; recrystallisation from the same solvent gave crystals suitable for structural analysis. The FAB+ mass spectrum showed a parent peak at m/z 311 attributable to $[Cu(PAN)]^+$ and a further peak at 622 attributable to a dimeric species, $[Cu(PAN)]_2$. In order to determine whether this was due to a genuine molecular association the molecular structure was determined. This shows (Fig. 1) that the azo-nitrogen atom furthest from the pyridine ring coordinates to the copper atom leading to the formation of two five-membered chelate rings; the double

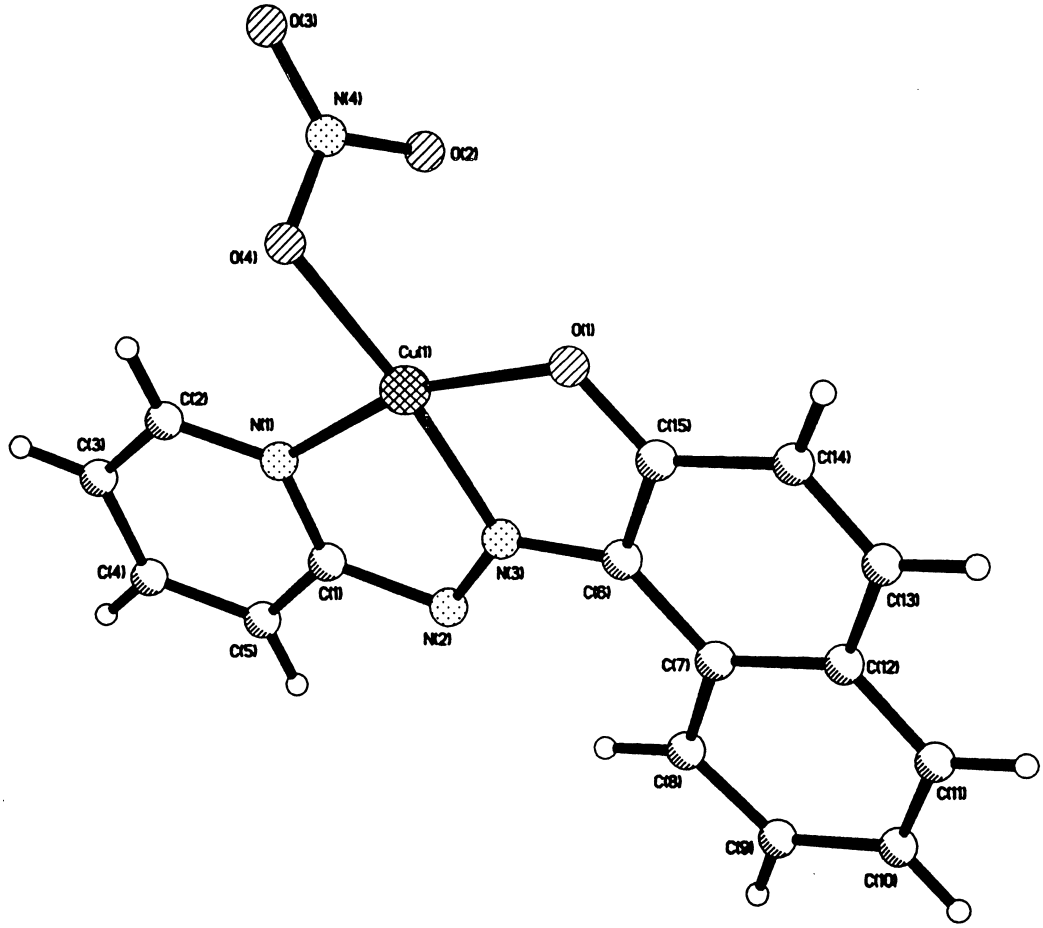

Fig. 1. The molecular structure of $[Cu(PAN)]NO_3$.

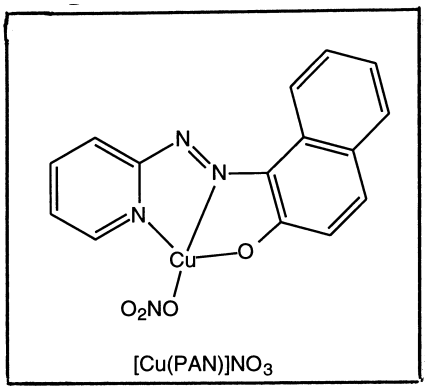
bond character of the azo-group is preserved. The fourth equatorial coordination position is occupied by an oxygen atom from the monodentate nitrate anion. Although the angles around the copper atom deviate from 90° the geometry nevertheless is close to square co-planar [the mean deviation for the plane



including O(1), N(3), N(1) and O(4) is 0.0244 Å and for that including the copper atom, O(1), N(3), N(1), O(4) and Cu is 0.0098 Å. The structure therefore is similar to that previously described for the complex $[Cu(PAN)(H_2O)]ClO_4$ [4]; the significant difference being that there is a water molecule bound to the copper in $[Cu(PAN)(H_2O)]ClO_4$ reflecting the weakly coordinating ability of the perchlorate anion relative to that of the nitrate anion. A comparison of the bond lengths and of the angles at the copper is given in Table 2.

Inspection of the packing diagram (Fig. 2) shows that the molecules exist as discrete pairs and this confirms the dimeric structure implied by the FAB+ mass spectrum. It has long been known from crystal structure data that self-association can occur in copper(II) complexes of ligands such as β-diketonates [5]. Such molecules are relatively planar and pack such that there is a weak interaction between the copper atom of one molecule and the central carbon atoms of the chelate rings of neighbouring molecules. More recently, an investigation concerning bis(tropolonato)copper(II) has clearly shown that this complex forms a sandwich-type van der Waals dimer in the crystalline state [6]. In the present case there is no evidence for interaction involving the copper atom or any π-stacking effects but the interatomic distance between a nitrate oxygen atom, O(2), and the C(5)H group on the adjacent molecule, 2.877 Å, suggests that there a weak hydrogen bonding interaction between these pairs might assist in augmenting the alignment of the present van der Waals dimer.

[2,2′-*Dihydroxyazobenzene*(-2)]*copper*(*II*), *pyridine*, *Cu*(*DAB*)·pyr

A brown gelatinous precipitate was produced when copper(II) acetate was added to a solution of H_2DAB in methanol [3]. Vapour diffusion of diethyl ether into a solution of the precipitate in pyridine gave shiny green crystals of Cu(DAB)·pyr. Unsuccessful attempts were made to record the FAB+ mass spectrum of both the powder and the crystals in NOBA matrices; in each case very protracted ranges of weak intensity peaks were detected and no discrete pattern emerged. It was thought that oligomerisation had occurred and so a crystal structure was determined in order to resolve this problem.

Table 2. A comparison of the bond lengths and bond angles in $[Cu(PAN)]NO_3$ and $[Cu(PAN)(H_2O)ClO_4$

	$[Cu(PAN)]NO_3$	$[Cu(PAN)(H_2O)]ClO_4$[a]
Bond length (Å)

O(1)–Cu(1)–O(4)	100.99(11)	99

[a]This data was taken from Ref. [4].

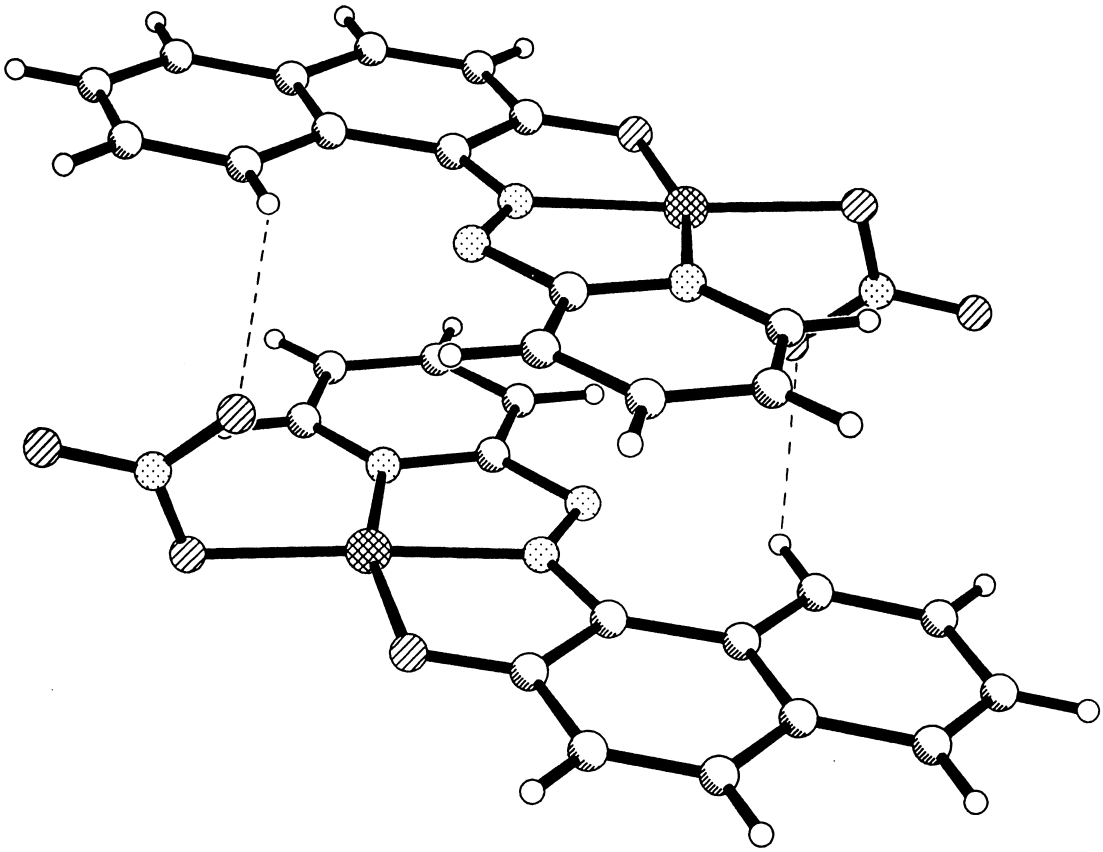

Fig. 2. The dimeric unit found for $[Cu(PAN)]NO_3$.

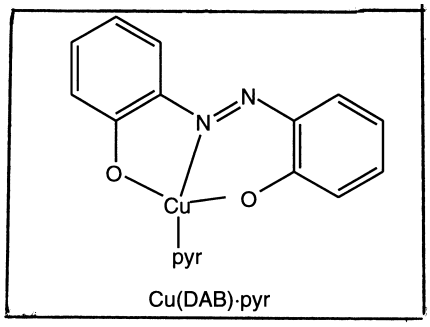

The crystal structure (Figs 3 and 4) revealed that the complex had crystallised in trimeric units, each consisting of three copper-dye molecules. This was unexpected as trinuclear copper(II) complexes are less extensively found than dinuclear complexes and examples of trinuclear complexes arising from self association are rare [7]. The trimers may be described as resembling triple-decker sandwiches in which the outer layers have grown stale and curled back from the central layer. Alternatively they may be viewed as being composed of two dimers with one common unit. Interestingly one pair of molecules lies "head to head", in parallel, with the pyridines adjacent to each other whereas the second set lies "head to tail", or inverted, with the pyridines at opposite ends of the dimer. It is likely that the deviation from planarity of the terminal units, N(3C)–Cu(2)–N(1C), 154.7° and N(3a)–Cu(1)–N(1A), 161.4° as compared with N(3B)–Cu(3)–N(1B), 174.1° for the central unit, leads to the construction of trimers rather than to the formation of stacks as would be anticipated if all three units were planar but it is not obvious why the two terminal units are twisted at 180° to each other.

Copper–ligand bonds have been classified as short interactions [Cu–L, 1.9–2.1 Å], intermediate interactions [Cu–L, 2.1–2.4 Å] and long interactions [Cu–L, 2.4–3.0 Å] [7]. In the present structure the trimer is held together by long bonding interactions between the copper atom in one molecule and one of the hydroxy oxygen atoms from the adjacent molecule: Cu(2)–O(1B), 2.517; Cu(3)–O(2C), 2.566, Cu(1)–O(2B), 2.622 and Cu(3)–O(1A), 2.768 Å. The shorter pair of distances are associated with the "head to tail" dimer and the longer pair with the "head to head" dimer. The copper–copper separations between the copper atoms Cu(2)–Cu(3) and Cu(1)–Cu(3) are 3.361 and 3.473 Å, respectively, with the shorter distance again associated with the "head to tail" dimer.

Although the aromatic rings lie above each other in the "head to head" dimer (Fig. 5) the separations of the centroids are rather long for π–π interactions,

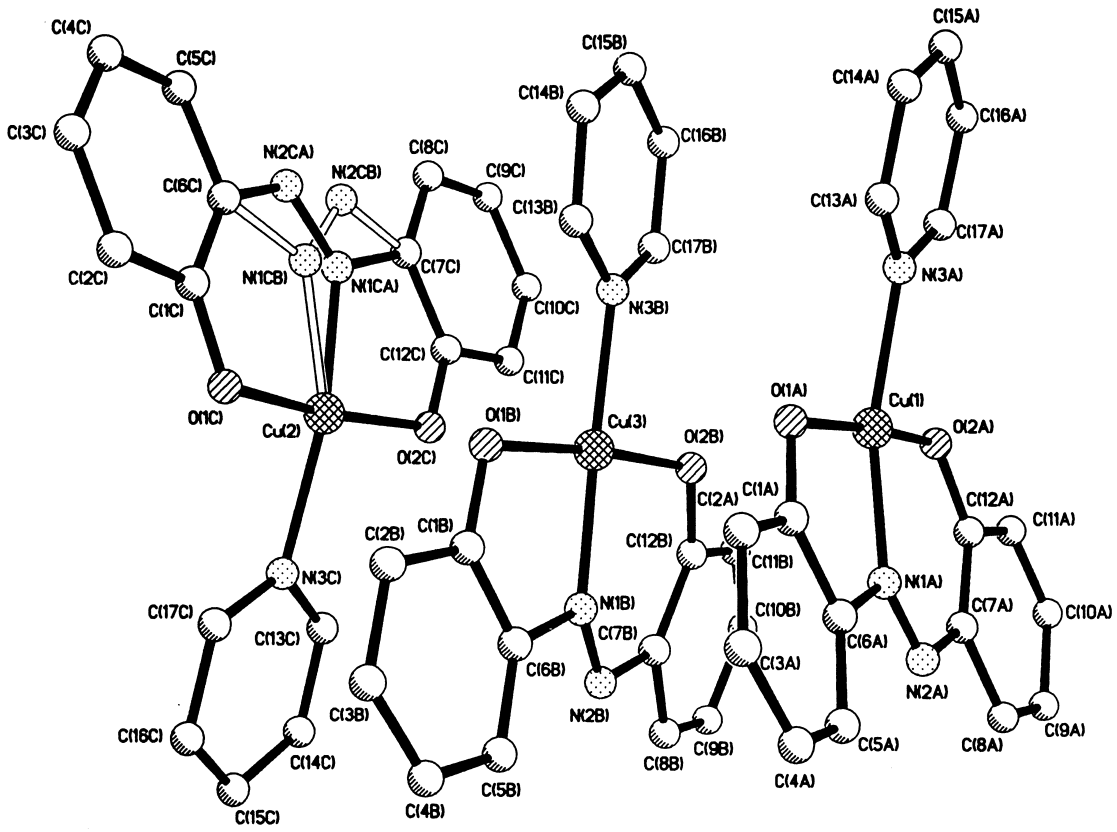

Fig. 3. The trimeric structure of Cu(DAB)·pyr. [Long bonding interactions at the copper atoms are: Cu(2)–O(1B), 2.517; Cu(3)–O(2C), 2.566, Cu(1)– O(2B), 2.622 and Cu(3)–O(1A), 2.768 Å. The intermetallic separations are: Cu(2)–Cu(3), 3.361 and Cu(1)–Cu(3), 3.473 Å].

pyridine[N(3A)–C(17A)]–pyridine[N(3B)–C(17B)], 3.760 A$\mathring{\beta}$; benzene[C(7A)–C(12A)]–benzene[C(7B)–C(12B)], 4.079 Å, and benzene[C(1A)–C(6A)]–benzene[C(1B)–C(6B)], 3.967 Å. Furthermore the benzene rings, which are coplanar having mean deviations from the planes composed of C(1A)–C(6A), C(7A)–C(12A), C(1B)–C(6B) and C(7B)–C(12B) of 0.0034, 0.0084, 0.0147 and 0.0038° respectively, are tilted away from each other, both intramolecularly and intermolecularly. The rings associated with Cu(1), C(1A)–C(6A) and C(7A)–C(12A), have an interplanar angle of 5.1° and those with Cu(3), C(1B)–C(6B) and C(7B)–C(12B), have an interplanar angle of 21.2°. Ring C(7A)–C(12A) and ring C(7B)–C(12B) are tilted away from each other at an angle of 22.6° and rings C(1A)–C(6A) and C(1B)–C(6B) tilt away from each other at an angle of 9.2°.

In the trimer each copper(II) atom is coordinated to the oxygen atoms of both deprotonated hydroxy groups from the dye and to one of the azo-group nitrogen atoms such that five- and six-membered chelate rings were formed. The fourth coordination position at each copper(II) atom was occupied by a molecule of pyridine. Bond lengths and angles at the metal atoms are given in Table 3 and if only these short interactions are considered then as the angles at the copper atoms deviate from 90° the geometry at each copper atom may be regarded as distorted square planar. If consideration is made of the long interactions observed between each copper atom and one of the hydroxy oxygen atoms from an adjacent molecule; Cu(1)–O(2B), Cu(2)–O(1B), Cu(3)–O(1A) and Cu(3)–O(2C) then the central copper atom, Cu(3), can be considered as distorted octahedral with the two terminal copper atoms in square pyramidal environments. Cu(1) has a τ value of 0.215 and Cu(2) a mean τ value of 0.26 where τ is an index of the degree of trigonality within the structural continuum between square pyramidal and trigonal pyramidal geometries [$\tau = (\beta - \})/60$ where β = O(2)–Cu–O(1) and α = N(3)–Cu–N(1)] [8]. For perfect square pyramidal and trigonal pyramidal geometries the values of τ are zero and unity, respectively.

The azo-N atoms binding to Cu(2), N(1C) and N(2C) were found to be disordered and the atoms N(1Ca), N(2Ca) and N(1Cb), N(2Cb) were refined to an occupancy of 44 and 56%, respectively. A similar occurrence has been noted in the structure of the analogous Schiff base complex *N*-(2-hydroxyphenyl)-salicylaldiminato-pyridine-copper(II), Cu(HSP), which

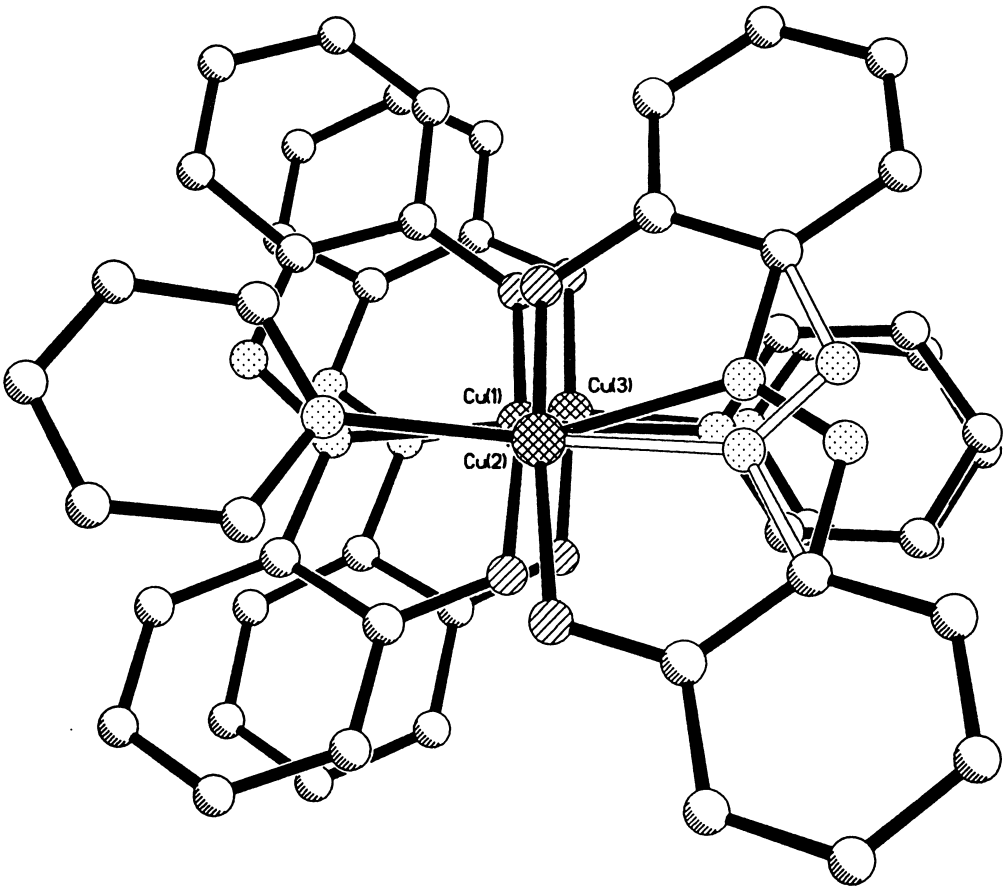

Fig. 5. The trimeric structure of Cu(DAB) · pyr as viewed down the Cu(2)–Cu(1)–Cu(3) axis.

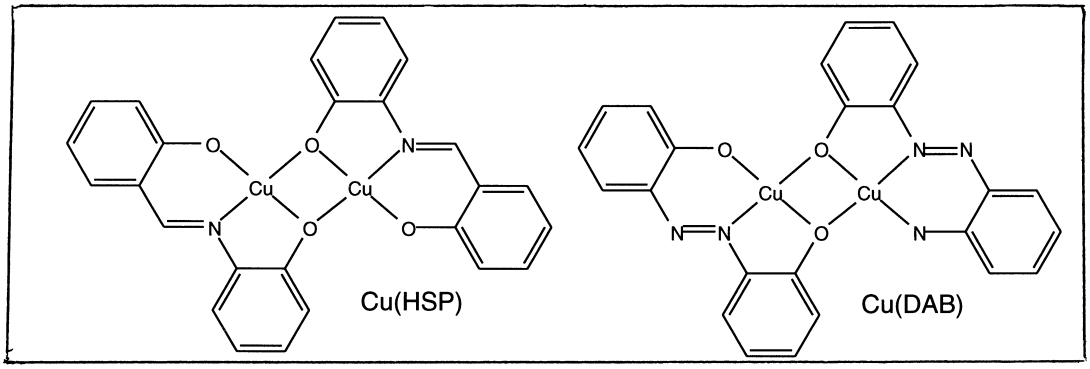
has been reported and shows only discrete molecules of the complex [9]. The bond lengths and angles at the copper in Cu(HSP) are given in Table 3 and show that whereas the copper–nitrogen interactions are slightly longer the copper–oxygen interactions are slightly shorter than for the corresponding distances in Cu (DAB) · pyr.

If Cu(HSP) had been isolated in the absence of pyridine then the copper(II) would have been three-coordinate and coordinatively unsaturated [10]. A



magnetic susceptibility study of *N*-(2-hydroxyphenyl)-salicylaldiminato-copper(II) revealed a subnormal magnetic moment which was attributed to antiferromagnetic coupling arising from dimer formation. Dissolution of this dimer in pyridine led to the formation of Cu(HSP)·pyr. The complex Cu(DAB) was originally isolated as a gelatinous material which dried to an amorphous solid. By analogy with the Schiff base it is proposed that the amorphous material is at least dimeric, but as there are present other donor facilities oligomerisation could occur. Dissolution in protic solvents gives the gelatinous material which could be a mixture of oligomers and of four coordinate species using the solvent as an additional donor.

(Received 20 April 1998; accepted 5 June 1998)

Abstract—Several new complexes of chiral and achiral tetradentate Schiff bases with copper(II), nickel(II) and oxovanadyl(IV) ions have been synthesised and characterised and the structures of [Cu(*R*-salpn)(OH_2)] and [Cu(±-busalcx)] have been elucidated by X-ray analysis. [Cu(*R*-salpn)(OH_2)] is essentially square pyramidal with an unusually long bond [2.494(4) Å] from Cu to the oxygen of the apical water molecule. Molecules are linked by hydrogen bonding between the coordinated water and the salpn oxygens of neighbouring molecules. A long contact between a salpn CH_2 hydrogen and a neighbouring copper atom [H(3B)...Cu = 2.966(1) Å] might be regarded as a CH···Cu hydrogen bond and completes a pseudo-octahedral coordination about copper. [Cu(±-busalcx)] displays tetrahedrally-distorted planar coordination about the copper atom and has no significant intermolecular contacts. The copper, nickel and vanadyl complexes were screened as homogeneous catalysts for the oxidation by Bu^tOOH or H_2O_2 of PhMeS to PhMeSO. All of them are active catalysts but of the chiral complexes only [Cu(*R*,*R*-busalcx)] produced a reasonable enantiomeric excess (14%). Supporting the complexes on silica improved the enantioselectivity of the less sterically hindered [Cu(*R*-salpn)(OH_2)] (from 2 to 10%), but diminished that of the more hindered [Cu(*R*,*R*-busalcx)], probably by slowing the reaction to such an extent that the uncatalysed oxidation could compete effectively. Finally [Cu(salen)], [Cu(*R*-salpn)] and [Ni(*R*-salpn)] were synthesised in the pores of zeolites X and Y. These were shown to be active heterogeneous catalysts for the sulfide to sulfoxide oxidations, but no significant e.e. resulted from the use of the chiral catalysts. © 1998 Elsevier Science Ltd. INTRODUCTION

The favourable ligand properties of tetradentate Schiff bases like salen [ethylenebis(salicylideneiminate); **1**] have ensured continued interest in their complexes for many years. [Ni(salen)] and [Pd(salen)] have recently been investigated as hydrogenation catalysts, both homogeneously and heterogeneously in the cages of zeolites X and Y [1–3]. It has also been claimed that zeolite-encapsulated [Cu(salen)]catalyses the oxidation of cyclohexanol to cyclohexanone [4], the epoxidation of norbornene and the hydroxylation of 1-naphthol [5], all under mild conditions. Of the several chiral examples of complexes of these types, perhaps the most celebrated is the highly sterically crowded Jacobsen's catalyst, [MnCl(busalcx)] (busalcx is ligand **6**), which achieves high enantioselectivity as an alkene epoxidation catalyst [6]. This type of complex, too, has recently been assembled and trapped inside the hypercages of zeolite EMT [7].

We describe here the syntheses and structures of chiral and achiral complexes of copper(II), nickel(II)

and vanadium(IV) with Schiff base ligands **1**–**6** and an examination of their potential as oxidation catalysts for the conversion of sulfides RR'S to sulfoxides.

RESULTS AND DISCUSSION

The copper complexes [Cu(*R*-salpn)(OH_2)], [Cu(*R*,*R*-salcx)], [Cu(busalen)], [Cu(*R*-busalpn)], [Cu(*R*,*R*-busalcx)] and [Cu(±-busalcx)], nickel complexes [Ni(*R*-salpn)], [Ni(*R*,*R*-salcx)], [Ni(busalen)], [Ni(*R*-busalpn)], [Ni(*R*,*R*-busalcx)] and [Ni(±-busalcx)] and vanadyl complexes [VO(*R*-busalpn)] and [VO(*R*,*R*-busalcx)] were prepared by refluxing together the relevant Schiff bases with $Cu(NO_3)_2 \cdot 3H_2O$, $NiCl_2 \cdot 6H_2O$ or $VO(SO_4)$, respectively, and an appropriate base.

The copper *R*-salpn complex was obtained by us as its monohydrate. It has previously been isolated either anhydrous or hydrated [8, 9]. Its structure was confirmed by X-ray crystallographic analysis and is shown in Fig. 1. Salient bond lengths and angles are presented in Table 1 and represent a marked improvement in accuracy over an early two-dimensional X-ray analysis of this material [10]. The compound is essentially square pyramidal in structure with an unusually long bond to the water molecule [2.494(4) Å] in the apical position, located on the opposite side of the square to the propyl CH_3 group. More typical Cu–O bond lengths to apical water molecules in such square pyramidal molecules are the value of 2.355(3) Å found in [Cu(tetraL)(OH_2)] [11] (tetraL is a tetramethylcyclam derivative) and 2.328(3) Å reported in aqua(dimethylpyrazole)(*N*-salicylildeneglycinato)copper(II) [12]. The water molecule in [Cu(salpn)(OH_2)] is hydrogen bonded to both salpn oxygens of a neighbouring molecule [Fig. 2; $O(3)\cdots O(1)' = 2.958(5)$ Å, $O(3)\cdots O(2)' = 2.788(5)$ Å] and a salpn CH_2 hydrogen occupies the pseudo-

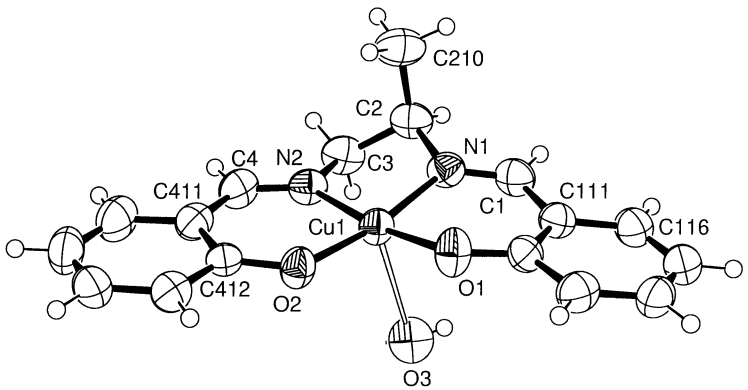

Fig. 1. A view of a molecule of [Cu(*R*-salpn)(OH_2)]. 50% probability ellipsoids are shown, except for hydrogen atoms which are represented by spheres of arbitrary size.

Cu(1)–O(2)	1.916(2)	Cu(1)–O(1)	1.929(2)
Cu(1)–N(1)	1.949(3)	Cu(1)–N(2)	1.952(3)
Cu(1)–O(3)	2.494(4)		
O(2)–Cu(1)–O(1)	91.06(10)	O(2)–Cu(1)–N(1)	169.57(12)
O(1)–Cu(1)–N(1)	91.92(12)	O(2)–Cu(1)–N(2)	92.43(12)
O(1)–Cu(1)–N(2)	171.29(12)	N(1)–Cu(1)–N(2)	83.29(12)
O(2)–Cu(1)–O(3)	99.29(12)	O(1)–Cu(1)–O(3)	87.97(14)
N(1)–Cu(1)–O(3)	90.81(13)	N(2)–Cu(1)–O(3)	99.33(14)

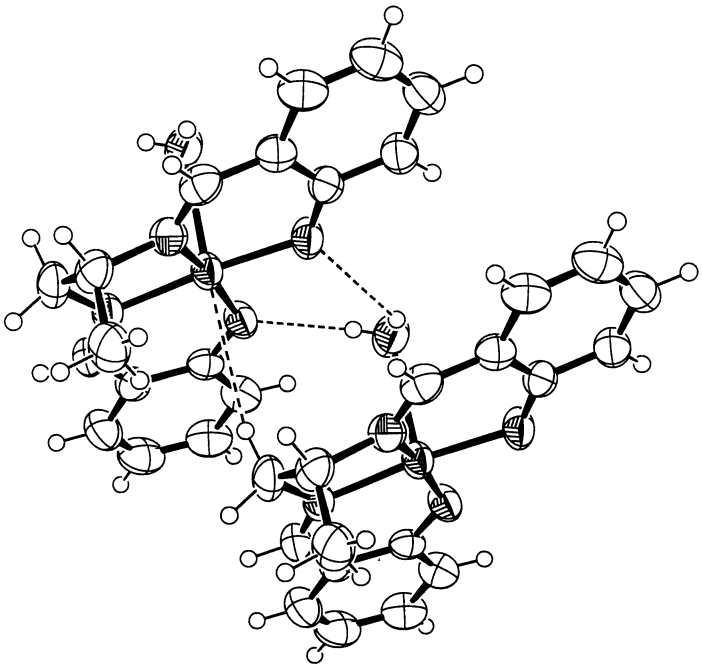

Fig. 2. Intermolecular interactions between molecules of [Cu(*R*-salpn)(OH_2)].

octahedral site of the copper atom of this molecule, with a C–H···Cu distance of 2.966(1) Å. Though extremely long, we note that this arrangement fulfills the criteria proposed for C–H···M hydrogen bonds [13].

Although the slight tendency to form 5-coordinate compounds is also evident in [Cu(salen)], which crystallises in dimeric oxygen-bridged units [14, 15], none of our other copper complexes was obtained as a hydrate. The structure of [Cu(salcx)] has been described previously and is a distorted square plane [16]. The compounds with Bu^t substituents were consistently obtained as feathery needles unsuitable for crystallographic analysis. Using a racemic form of the ligand, however, [Cu(±-busalcx)] was finally obtained as fine needles from which a structure determination was possible using synchrotron radiation. This structure is shown in Fig. 3 with salient bond lengths and angles presented in Table 2. The analysis confirms the *trans*-diamino stereochemistry of the cyclohexyl ring despite the presence of disorder. Each molecular site is occupied with equal probability by *RR* and *SS* diastereomers (only the former is shown in Fig. 3). Although alternative atomic sites are obvious only for C(31), C(33), C(34) and C(36) it is possible that systematic error may affect the positions of other atoms, most notably N(1) and N(2).

Molecules of [Cu(±-busalcx)] have close to C_2 point symmetry, with the two approximately planar O(*n*)N(*n*)C(*n*1)–C(*n*7) units ($n = 1$, 2) defining a dihedral angle of 28.5°. The copper atom displays tetrahedrally distorted square planar coordination characterised by *trans*-O–Cu–N angles of 165°. The Cu–O distances are close to the value (1.893 Å) [16]

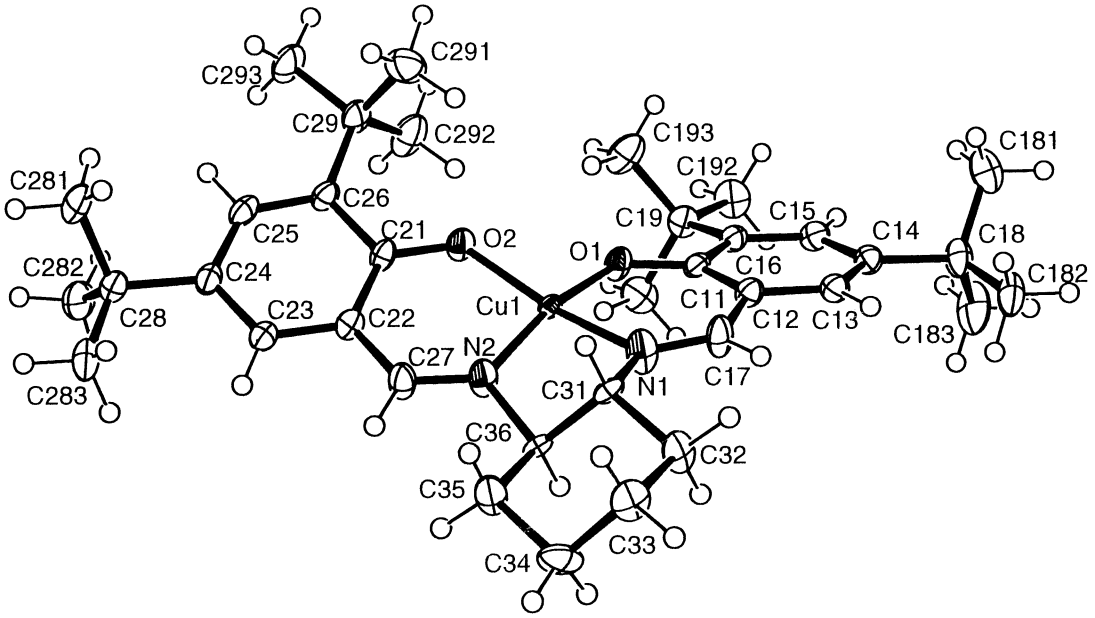

Fig. 3. A view of a molecule of [Cu(±-busalcx)]. 50% probability ellipsoids are shown, except for hydrogen atoms which are represented by spheres of arbitrary size. Only one of the two alternative sites occupied by disordered atoms C(31), C(33), C(34) and C(36) is displayed.

Table 2. Salient bond lengths (Å) and angles (°) for [Cu(±-busalcx)]

Cu(1)–O(1)	1.886(3)	Cu(1)– O(2)	1.887(3)
Cu(1)–N(2)	1.904(4)	Cu(1)–N(1)	1.915(4)
O(1)–Cu(1)–O(2)	91.47(12)	O(1)–Cu(1)–N(2)	165.16(17)
O(2)–Cu(1)–N(2)	94.12(14)	O(1)–Cu(1)–N(1)	94.11(14)
O(2)–Cu(1)–N(1)	165.06(17)	N(2)–Cu(1)–N(1)	83.90(16)

typical of bonds between O and four-coordinate Cu^{II}. The Cu–N bond lengths are on average 0.04 Å shorter than the mean Cu–N distance of 1.954 Å found in related Schiff base complexes [17]. The six-membered chelate rings are nearly flat (Cremer–Pople puckering parameter $Q = 0.123$ and 0.128 Å) [18] whereas the Cu(1)–N(1)–C(31)–C(36)–N(2) ring has $Q = 0.58$ Å and $\varphi = 270.3°$, equal to the ideal half-chair value of 270° to within experimental error. The cyclohexyl ring ($Q = 0.71$ Å and $\theta = 177°$) has a close to ideal chair conformation. The shortest intermolecular contacts involving the metal atom, Cu···H distances of 3.3 Å, are clearly non-bonding.

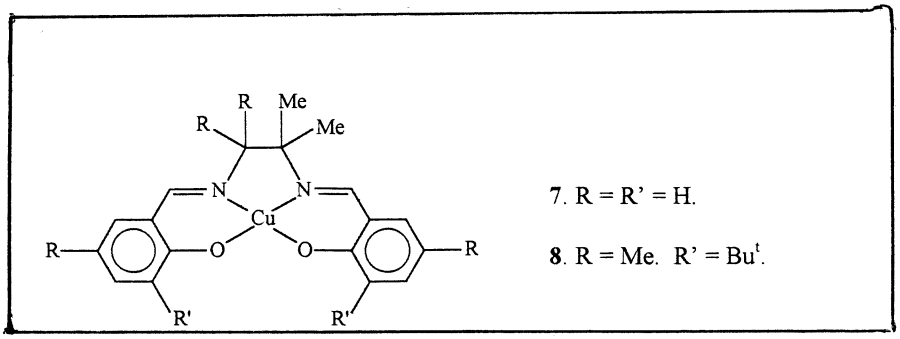
Thus the tetrahedrally-distorted square planar configuration resembles those of the related complexes [Cu(salcx)] [16], **7** [19] and **8** [20]. In all of these 4-coordinate compounds the Cu–O bonds are shorter than Cu–N and both types are shorter than in the 5-coordinated (or pseudo-octahedral; see above) [Cu(salpn)(OH_2)]. The distortions from planar coordination in [Cu(sal-1,3-pn)], with its additional CH_2 bridging unit in the central chelate ring, are noticeably greater than in the others [21].

The nickel compounds are all diamagnetic and hence best described as square planar. Nevertheless an appreciable distortion from planarity is evident in the structure of [Ni(salcx)] [22], although [Ni(salen)] itself, though dimeric, consists of nearly planar molecules [23]. The butyl derivatives again formed fibrous crystals. The vanadyl complexes [VO(*R*-busalpn)] and [VO(*R*,*R*-busalcx)] also formed as feathery crystals unsuitable for X-ray analysis. Their structures are presumably based on the familiar square pyramids, typified by [VO(salen)] [24].

OXIDATION REACTIONS

Homogeneous oxidations

Several copper(II), nickel(II) and vanadium(IV) complexes are known to be effective catalysts for a



7. R = R' = H.

8. R = Me. R' = Bu^t.

number of oxidation reactions. For example, the Baeyer–Villiger oxidation of cyclic ketones to lactams has been successfully catalysed homogeneously by [Cu(OAc)$_2$] or [Ni(OAc)$_2$] [25, 26] and heterogeneously by Cu^{2+} in hydrotalcite clays [27]. The oxidation of prochiral sulfides to sulfoxides has been catalysed by a range of chiral vanadyl complexes [28] including Schiff base complexes [29]. Moderate enantiomeric excesses were also reported from the use of vanadium-containing pillared clays modified by diethyltartrate [30]. Our intention was to probe the effects of sterically hindered complexes as enantioselective catalysts, as our previous experience indicates that greater steric bulk can improve the enantiomeric excess of the products [31]. The oxidation of prochiral PhMeS to its sulfoxide, PhMeSO, by the action of 5% aqueous Bu^{t}OOH in CH_2Cl_2 or acetonitrile at 0° was catalysed by adding 10 mol.% of the molecular complex. It was necessary to maintain the low temperature throughout to suppress the competing, non-catalysed reaction which could only lead to racemic product. In the presence of [Cu(*R*-salpn)] or [Cu(*R*,*R*-salcx)] the reactions proceed smoothly to produce 60% of the sulfoxide in 5 h, but with negligible (<2%) e.e. These observations parallel those previously reported with the use of [VO(salpn)] as catalyst [29]. An explanation advanced for the low e.e.s from that system was that the substrate and/or oxidant could approach the metal from the methyl side or the opposite side of the planar salpn ligand with similar ease. No sulfone was observed from our reactions.

Using the sterically-hindered complexes [Cu(*R*-busalpn)], [Cu(*R*,*R*-busalcx)], [VO(*R*-busalpn)] or [VO(*R*,*R*-busalcx)] as catalysts under the same conditions produced only 10% of products over the same time period. Once again, however, no significant enantiomeric excess was produced. The reactions were repeated using aqueous H_2O_2 as oxidant instead of Bu^{t}OOH in case hindrance between catalyst and oxidant was preventing the reaction from proceeding enantioselectively. These reactions proceeded even more slowly, presumably due to the two-phase solvent system, but [Cu(*R*,*R*-busalcx)] led to a 14% e.e., with [VO(*R*,*R*-busalcx)] producing a 4% e.e.

The nickel complexes [Ni(*R*-salpn)] and [Ni(*R*,*R*-busalcx)] also catalysed the conversion of sulfide to sulfoxide, but without generating any measurable e.e.

Silica supported complexes

The copper complexes [Cu(*R*-salpn)] and [Cu(*R*,*R*-busalcx)] were impregnated onto silica (Gasil 35 M) and the silica-supported complexes tested as catalysts for the H_2O_2 oxidation of PhMeS under conditions similar to above. In both cases the production of coloured solutions testified to some leaching of the complex into solution during the reaction, but the catalytic performance of the [Cu(*R*-salpn)] was improved, producing a 10% e.e. in a 20% reaction over 5 h. This is strongly indicative that despite the leaching problem, the oxidation reaction has taken place predominantly at the surface. The more hindered complex performed less well, reaching only 2% reaction after 5 h with a 4% e.e., indicating that under these conditions at least, restricted access to the chiral centre was not helpful. A possible explanation is that under these extremely slow reaction conditions the non-catalysed process competes more effectively.

Zeolite-encapsulated complexes

In an attempt to utilise the improved performance of the copper catalysts in contact with silica and to overcome the problem of complex leaching, we have synthesised [Cu(salen)], [Cu(*R*-salpn)] and [Ni(*R*-salpn)] in the pores of zeolites X and Y (the pores of these zeolites are not large enough to accommodate our more bulky ligands). These were prepared by standard methods [1–5] by introducing Cu^{2+} or Ni^{2+} into the zeolite by ion exchange, treating this material with salen or salpn (the use of CH_2Cl_2 or CH_3CN solutions for this step proved less efficient than employing molten ligand), then removing excess ligand by prolonged extraction with CH_2Cl_2. Finally, the materials were subjected to further ion exchange with Na^+ to remove any uncomplexed copper ions. (This last stage is of considerable importance, since we established in a control experiment that zeolite-supported copper

ions themselves are excellent catalysts for sulfide oxidations).

Microanalytical results indicated that the zeolites held close to the expected one molecule per cage. The UV/visible spectra of the zeolite materials were similar to those of the copper complexes themselves.

The oxidation of thioanisole to PhMeSO by hydrogen peroxide was indeed catalysed by all three of the zeolite-encapsulated molecules but no significant enantiomeric excess resulted from the use of the chiral materials. Moreover the rate of the reactions was very slow, presumably due to the need for the reactants to diffuse into the zeolite pores. The history of the zeolite encapsulated catalyst could be of importance. It has been reported that Cu(salen)/zeolite-Y is green and inactive towards norbornene or 1-naphthol oxidations after refluxing in CH_2Cl_2, but red and active after MeCN treatment [5]. The differences are assigned to changes in the anchoring of the complex to the cage walls. We note that our Cu(salpn)/zeolites are also colour-sensitive, changing from yellow–green after CH_2Cl_2 reflux to orange after prolonged MeCN treatment, but discerned no change in catalytic ability between the two types.

Overall we conclude that the use of our chiral complexes as homogeneous oxidation catalysts is similar to, but no better than, the less sterically-hindered vanadium(IV) complexes described in the literature [29]. On the other hand there is a real enhancement of selectivity if the catalysts are supported on silica, although catalyst leaching into solution prevents effective exploitation of this method. Encapsulating the smaller compounds in zeolites overcomes the leaching problems under our reaction conditions, but the reactions in the pores are slow and non-selective.

EXPERIMENTAL

1,2-diaminopropane and 1,2-cyclohexyldiamine were resolved by literature methods [32, 33]. Schiff bases were prepared by refluxing the above diamines or 1,2-diaminoethane with salicylaldehyde or 3,5-di-*tert*-butyl salicylaldehyde. Typical syntheses of the copper, nickel and vanadyl complexes are given below. Table 3 lists analytical data on new compounds.

Synthesis of [Cu(R-salpn)(OH_2)]

To a solution of *R*-salpnH_2 (5.9 g, 21 mmol) in ethanol (60 ml) was added $Cu(NO_3)\cdot 3H_2O$ (5.0 g, 21 mmol) in ethanol (30 ml). The mixture was heated and 42 ml of 1 M aqueous NaOH was added. The purple solution was cooled to yield dark purple X-ray-quality crystals of the product [2.9 g, 98%: M.pt. 229–231°. $[\alpha]_D$ +625° (EtOH, $c = 0.66$ mmol·lit^{-1})].

Synthesis of [Ni(R-salpn)]

This was prepared similarly from salpnH_2 and $NiCl_2\cdot 6H_2O$ to yield deep orange crystals of the product [67%: $[\alpha]_D$ 954° (EtOH, 1.0 mmol·lit^{-1}). Found, C, 60.2; H, 4.7; N, 8.45%: req. for $C_{17}H_{16}N_2NiO_2$, C, 60.23; H, 4.75; N, 8.27%].

Synthesis of [Ni(R-*busalpn*)]

$Ni(NO_3)_2\cdot 3H_2O$ (0.861 g; 2.96 mmol) was added to an ethanol (100 ml) solution of *R*-busalpnH_2 (1.5 g; 2.96 mmol) and the mixture refluxed for 1 h. The product was formed as a pale brown precipitate. It was washed with ethanol and recrystallised from acetone (yield, 75%).

Synthesis of [VO(R,R-*busalcx*)]

To a hot solution of [$VO(SO_4)$] (0.163 g; 1 mmol) in methanol (45 ml) was added a slurry of *R*,*R*-busalcxH_2 (0.546 g; 1 mmol) in MeOH (15 ml) and pyridine (2 ml). The green precipitate of product was filtered off and recrystallised from a MeOH/$CHCl_3$ 1:1 mixture.

Homogeneous oxidations

In a typical procedure, thioanisole (0.62 ml; 5.3 mmol) and [Cu(salpn)OH_2] (0.14 g; 0.38 mmol) were dissolved in acetonitrile (25 ml) at 0°. A mixture of Bu^{t}OOH 0.88 ml of 5.5 molar aq. solution (5.3 mmol) in a further 25 ml of acetonitrile at 0° was added and the mixture stirred for 5 h. The clear reaction mixture turned purple. After quenching with aqueous sodium sulfite solution, the organic layer was separated, dried (anhydrous Na_2SO_4) and analysed by HPLC (Chiracel OB column with 10% isopropanol/90% hexane mobile phase, eluted at a flow rate of 0.5 ml/min).

In other variations the Bu^{t}OOH was replaced by aqueous H_2O_2 and the reaction mixture treated in the same way.

Silica-supported complexes

In a typical procedure, 5 g of Gasil 35 M silica was oven dried at 110° for 24 h then added to a solution of [Cu(salpn)(OH_2)] (3.117 g; 8.62 mmol) in $CHCl_3$ (50 ml). After stirring the mixture for 24 h, the solvent was removed by rotary evaporation and pumping under vacuum. The catalyst was kept overnight at 110° prior to use.

0.14 g of this catalyst was placed in a flask with $CHCl_3$ (25 ml) and thioanisole (0.62 ml; 5.3 mmol) and cooled to 0°. To this was added 0.54 ml of 30% aqueous hydrogen peroxide and the mixture stirred for 5 h at this temperature. A purple colour in the solvent indicated that some of the complex had dissolved. The

mixture was treated by aqueous (50 ml) sodium sulfite (0.67 g; 5.3 mmol) and the organic layer extracted into chloroform, filtered and dried (anhydrous $MgSO_4$). After removal of the chloroform under vacuum, the product was diluted by hexane and analysed as above by HPLC.

Zeolite-encapsulated materials

The complexes were prepared as described for [Cu(salen)] in zeolite–Na X and zeolite–Na Y in CH_2Cl_2 solvent [4, 5]. Any non-encapsulated complex was removed by Soxhlet extraction with dichloromethane or acetonitrile for several hours and uncomplexed copper ions were replaced by sodium ions by treatment with NaCl.

In a typical experiment, 0.14 g of Cu(salpn)/zeolite X was placed in a flask with thioanisole (0.62 ml; 5.3 mmol) in CH_2Cl_2 (20 ml) at 0°. To this was added 0.54 ml of 30% aqueous hydrogen peroxide and the mixture stirred for 5 h at this temperature. The mixture was then treated by aqueous (50 ml) sodium sulfite (0.67 g; 5.3 mmol) and the organic layer extracted into chloroform, filtered and dried (anhydrous $MgSO_4$). After removal of the chloroform under vacuum, the product was diluted by hexane and analysed as before by HPLC.

X-ray structure determination of [*Cu*(*salpn*)(*OH*$_2$)]

Details of data collection procedures and structure are given in Table 4. A single crystal of suitable size was attached to a glass fibre using acrylic resin and mounted on a goniometer head in a general position. Data were collected in bisecting mode on an Enraf-Nonius TurboCAD4 diffractometer, running under CAD4-Express software and using graphite monochromated X-radiation. Precise unit cell dimensions were determined by refinement of the setting angles of 25 high-angle reflections which were flagged during data collection. Standard reflections were measured every 2 h during data collection and no significant variation in intensities was noted. Lorentz-polarization corrections were then applied to the reflection data. The ψ-scan data which were collected indicated that no absorption correction was necessary, and none was applied. The structures were solved by direct methods (SHELXS-97) [34]. All non-H atoms were allowed anisotropic thermal motion. Aliphatic CH hydrogen atoms were included at calculated positions, with C–H = 0.96 Å, while the OH protons were found from a difference map and were freely refined. Refinement (SHELXL-97) [35] was by full-matrix least-squares on F^2, using all the unique data and the weighting scheme $w = [\sigma^2(F_o)^2 + (AP)^2 + BP]^{-1}$ where $P = [F^2_o/3 + 2F^2_c/3]$ and $A = 0.0412$, $B = 0.1607$. $\sigma(F_o)^2$ was estimated from counting statistics. Neutral atom scattering factors, coefficients of anomalous dispersion and absorption coefficients were obtained from Ref. [36]. The absolute configuration was confirmed by the refinement of the Flack absolute structure parameter, which refined to zero within error. Calculations using PLATON [37] indicated that there were no voids in the lattice capable of containing any solvent molecules. Thermal ellipsoid plots were obtained using the program ORTEP-3 for Windows [38].

X-ray structure determination of [*Cu*($\pm$-*busalcx*)]

cernable diffraction with a conventional X-ray source. However, it proved possible to make satisfactory measurements on a Siemens SMART CCD diffractometer mounted on the single crystal diffraction station (9.8) at the Daresbury Laboratory Synchrotron Radiation Source, U.K. The intensities of 9775 reflections were averaged to give 6856 unique reflections (85% of those accessible). 5720 unique reflections were deemed observed $[I>2\sigma(I)]$. The data were corrected for Lp and decomposition effects by the standard SAINT software. The structure was solved by Patterson and Fourier methods and refined (SHELXL-97) [35] using all the unique data to convergence on F^2 with $w=[\sigma^2(F^2)+(0.044P)^2+4.5P]^{-1}$ where $P=[F^2_o/3+2F^2_c/3]$. All non-H atoms were allowed anisotropic thermal motion. H atoms rode on their parent C atoms and an orientation parameter was successfully refined for each of the 12 methyl groups. The cyclohexyl ring is disordered so that atoms C(31), C(33), C(34) and C(36) are each distributed over two sites with occupancy 1/2 roughly related by reflection in the CuN_2 plane. The ring C–C bonds were restrained to the value 1.545(6) Å. Mass attenuation coefficients and dispersion corrections (for $\lambda=0.7107$ Å) and atomic scattering factors were those incorporated in SHELXL-97 [35]. The WinGX

package [39] and ORTEP-3 for Windows [38] were used for other calculations.

SUPPORTING INFORMATION AVAILABLE

Tables of atomic parameters, a complete geometry listing and observed and calculated structure factors are available from the authors. The structure will be deposited in the Cambridge Structural Database.

*Acknowledgements*We wish to express our gratitude to Professor William Clegg for making time on the Daresbury SMART-CCD diffractometer available to us. We also thank EPSRC (U.K.) and the University of Glasgow for support.

(Received 30 March 1998; accepted 2 June 1998)

Abstract—The colorless needle-shaped crystals of a new heterometallic 2-methoxyethoxide, $BaMo_2O_5(OC_2H_4OMe)_4(HOC_2H_4OMe)$ (**1**), have been obtained by the saturation of barium 2-methoxyethoxide solution in 2-methoxyethanol with the crystalline $MoO_2(OC_2H_4OMe)_2$. The precipitation started when the Ba:Mo ratio achieved a 1:2 value and the precipitate formed contained $BaMoO_4$ as an admixture thus indicating that the formation of oxo species led partially even to formation of inorganic molybdates. Molecules of **1** involve the metal–oxygen framework quite typical of trinuclear homo- and heterometallic alkoxide species. The rather high coordination number of the barium atom (10) and the lengths of the observed interatomic distances permit to suggest that this atom in **1** forms predominantly ionic bonds and, therefore, complex **1** can be formulated as $[Ba(HOC_2H_4OMe)]^{2+}[Mo_2O_5(OC_2H_4OMe)_4]^{2-}$. © 1998 Elsevier Science Ltd. Keywords: heterometallic oxo-2-methoxyethoxide; barium 2-methoxyethoxide; crystalline $MoO_2(OC_2H_4OMe)_2$

INTRODUCTION

Pursuing our systematic program of investigation of heterometallic alkoxides of molybdenum, we turned to the studies of stabilization of the molybdenum alkoxide derivatives of alkaline earth metals by application of functional alcohols. Such stabilization was needed to avoid the ether elimination reaction that led in the case of the derivatives of aliphatic alcohols to the formation of $M^{II}MoO_4$ on interaction of the corresponding alkoxides. The only compounds isolated so far were bimetallic magnesium–molybdenum methoxides [1], whose stability was presumably due to the reluctance of the methoxy group to form the corresponding R^+ cation, which is considered to be the first step of the ether elimination mechanism. It has also been shown earlier for the sodium derivatives that the use of 2-methoxyethoxide as an alkoxide ligand can lead to stabilization of heterometallic complexes of molybdenum and tungsten. Thus, instead of unstable complexes with a 1:1 composition, involving aliphatic radicals and existing only in solution, the stable crystalline product $NaMoO_2(OC_2H_4OMe)_3$ was obtained. It had reproducible solubility in the parent alcohol even in the presence of excess of NaOR [2].

In the present paper we report the application of this approach for the isolation and structural charac-

terization of a mixed-metal barium–molybdenum compound, $BaMo_2O_5(OC_2H_4OMe)_4(HOC_2H_4OMe)$ (**1**).

EXPERIMENTAL

All compounds described in this work are highly sensitive to moisture and oxygen and therefore all operations with them were carried out in argon atmosphere using a vacuum line or a dry box. Dehydration of 2-methoxyethanol used was performed by boiling it under reflux over magnesium alkoxide with subsequent distillation. Carbon, hydrogen and the incombustible residue content in the samples was determined using conventional combustion technique at the Laboratory of Organic Microanalysis at the Moscow State University.

IR spectra were registered with Specord IR 75 for nujol mulls. Crystalline solids were identified using powder diffractometry (DRON 3M).

Isolation of $BaMo_2O_5(OC_2H_4OMe)_4(HOC_2H_4OMe)$ (**1**)

To the solution prepared by dissolution of 0.496 g (3.6 mmol) of barium metal in 10 ml of 2-methoxyethanol was added on continuous stirring 2.057 g (7.4 mmol) of $MoO_2(OC_2H_4OMe)_2$. The precipitation started immediately and the mixture became non-transparent. It was then warmed to 60°C, but remained turbid in appearance, while no bulky solid precipitate could be observed. It was left for crystallization in a refrigerator at 0°C overnight. The resulting solution did not become clear but from the mixture obtained, 1.216 g of precipitate could be isolated. The latter consisted of regularly shaped transparent crystals and fine particles of a white powder. The attempt to recrystallize the precipitate from 5 ml of pure 2-methoxyethanol at 50°C resulted in the formation of a turbid solution over the unchanged white powder (the transparent crystals were dissolved completely). The insoluble residue was separated by centrifugation and dried *in vacuo* (yield 0.036 g). X-ray powder diffraction study showed it to be a well-formed $BaMoO_4$-phase. The attempt to isolate the other product in a pure form failed as on cooling and storage of the turbid solution, the coprecipitation of the white powder with the regularly shaped transparent crystals occurred constantly. As slow cooling permitted the isolation of quite large crystals (up to approximately $2.0 \times 0.8 \times 0.3$ mm in size), they were separated from the mixture by a needle and analyzed. Found: C, 22.78; H, 4.41; incombustible residue, 56.8. Calc. for $C_{15}H_{36}BaMo_2O_{15}$ (**1**): C, 22.91; H, 4.58; incombustible residue, 56.2. IR, cm^{-1}: 405 w, 468 m, 490 m, 556 s, 575 s, 596 s, 615 s, 812 s, 885 s, 900 s br, 915 s, 925 sh, 3400 s v. br. The exact chemical composition of **1** was established by the X-ray single crystal study. The identity of the single crystal studied and the bulk sample was proved by complete indexing (except for the lines that belonged to $BaMoO_4$) of the X-ray powder pattern of the latter using the X-ray single crystal parameters obtained for **1**.

Crystal data for **1**

$C_{15}H_{36}O_{15}Mo_2Ba$, M = 785.7, monoclinic, space group Cc, at 293 K; $a = 18.353(5)$, $b = 8.947(5)$, $c = 18.236(5)$ Å, $\beta = 116.49(2)^\circ$, $V = 2680(1)$ Å^3, $Z = 4$, $D_c = 1.947$ g cm^{-3}. The X-ray diffraction experiment was carried out with Siemens P3/PC diffractometer ($T = 293$ K, graphite monochromated Mo-Kα radiation, $\lambda = 0.71073$ Å, θ–2θ scan technique, $\theta \leq 33^\circ$). The structure was solved by direct methods using SHELXTL PLUS 5 programs (gamma version) [3]. The positions of all non-hydrogen atoms were refined anisotropically by full-matrix least-squares technique, the H(1) atom position was first determined from the difference Fourier synthesis and then refined isotropically. All other hydrogen atoms were included in the final refinement in calculated positions with the temperature factors $U_{iso} = 1.2U_{eq}(C_i)$, where C_i is the carbon atom to which the correspondent hydrogen atom is bonded). The final discrepancy factors were $R_1 = 0.0354$ [for 4386 observed reflections with $I \geq 2\sigma(I)$], $wR_2 = 0.0970$ (for all 4809 reflections used in refinement; total of 302 refined parameters). No absorption correction was applied. Atomic coordinates, a full list of bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Center.

RESULTS AND DISCUSSION

The interaction of homometallic alkoxides (barium 2-methoxyethoxide prepared by dissolution of barium metal in parent alcohol and $MoO_2(OC_2H_4OMe)_2$ synthesized by the electrochemical method described in Ref.[4]) was studied using the following procedure: the solutions of barium 2-methoxyethoxide in 2-methoxyethanol with approximately 10 wt% concentration were saturated on continuous stirring at room temperature with the solid molybdenum 2-methoxyethoxide. At the beginning no changes could be observed and the solutions remained clear and transparent, but when the metal ratio reached the value of Mo:Ba = 2:1, the precipitation of white powder started immediately. On heating of a portion of the mixture thus obtained it was found that the precipitate could only partially be redissolved in either mother liquor or pure 2-methoxyethanol. The examination of the sediment under the optical microscope has shown it to be a mixture of tiny white non-transparent particles (almost insoluble in alcohol) and regular shaped transparent crystals (long parallelepipeds, nearly needles) that could be extracted with the excess of 2-methoxyethanol. The X-ray powder diffraction showed the first to be a highly disperse powder of

well-formed $BaMoO_4$ phase. The nature of the other product was determined by X-ray single crystal investigation.

The latter has shown that the crystals in question are built up of triangular $BaMo_2O_4(\mu\text{-O})(\mu_3,\eta^2\text{-}OC_2H_4OMe)_2(\mu_2,\eta^2\text{-}OC_2H_4OMe)_2(\eta^2\text{-}HOC_2H_4OMe)$ aggregates (Fig. 1, Table 1), possessing a nearly spherical shape. The aggregates are linked into infinite chains along the *b*-axis of the crystal via hydrogen bonds O–H...O [O(15)...O(5) 2.625(6) Å, H(1)–O(15) 0.55(8) Å, H(1)...O(5) 2.19(8) Å, O(15)H(1)O(5) 137(10)°], formed by the OH group of the alcohol moiety and μ_2-oxo atom that binds the molybdenum atoms together. The coordination polyhedron of the barium atom (coordination number 10) is a severely distorted bicapped tetragonal antiprism (Fig. 2), its coordination sphere including all oxygen atoms of four alkoxogroups and of one solvating alcohol molecule, which means that all OC_2H_4OMe groups in the structure of **1** have η^2 chelate function. The basal planes of the antiprism [O(9)O(13)O(11)O(14) and O(12)O(7)O(10)O(8)] are nearly parallel [they form the dihedral angle 4.5(1)°] and are rotated by 27° relative to each other. The position of the barium atom in relation to the basal planes is considerably asymmetric: it is displaced by 0.993 Å and 1.537 Å from the O(9)O(13)O(11)O(14) plane and O(12)O(7)O(10)O(8) plane, respectively. The O(15) and O(6) atoms are in the capping positions above and below the bases of antiprism, the corresponding bond angle O(15)Ba(1)O(6) being 163.7(2)°. The arrangement of the chelate cycles conforms with the general pattern typical of *cis*-isomers of $[M(L)_5]$ complexes with bidentate L ligand [5], having the geometry of bicapped antiprism, e.g.$[Ba(MeCONHCOMe)_5](ClO_4)_2$ [6]. It is to be mentioned that significant non-systematic variations of the bond lengths within each group of chemically identical Ba–O bonds are observed in the structure of **1**. Thus the Ba–μ_3-OR [Ba(1)–O(6) 2.773(4), Ba(1)–O(7) 2.709(4) Å], Ba–μ_2-OR [Ba(1)–O(10) 2.788(5), Ba(1)–O(12) 2.861(5) Å] and Ba–O(ether) [Ba(1)–O(11) 2.978(6), Ba(1)–O(14) 2.934(6), Ba(1)–O(8) 2.844(5), Ba(1)–O(9) 2.802(5), Ba(1)–O(13) 2.951(7) Å] bonds differ significantly within each group, although in general Ba–O(alkoxo) distances are still noticeably shorter than Ba–O(ether) bond lengths, the corresponding average values being equal to 2.776 and 2.882 Å. Such irregularity in coordination in combination with the high coordination number and long interatomic distances (approximately equal to the sum of the corresponding ionic radii [7]), permits treatment of the bonding of the

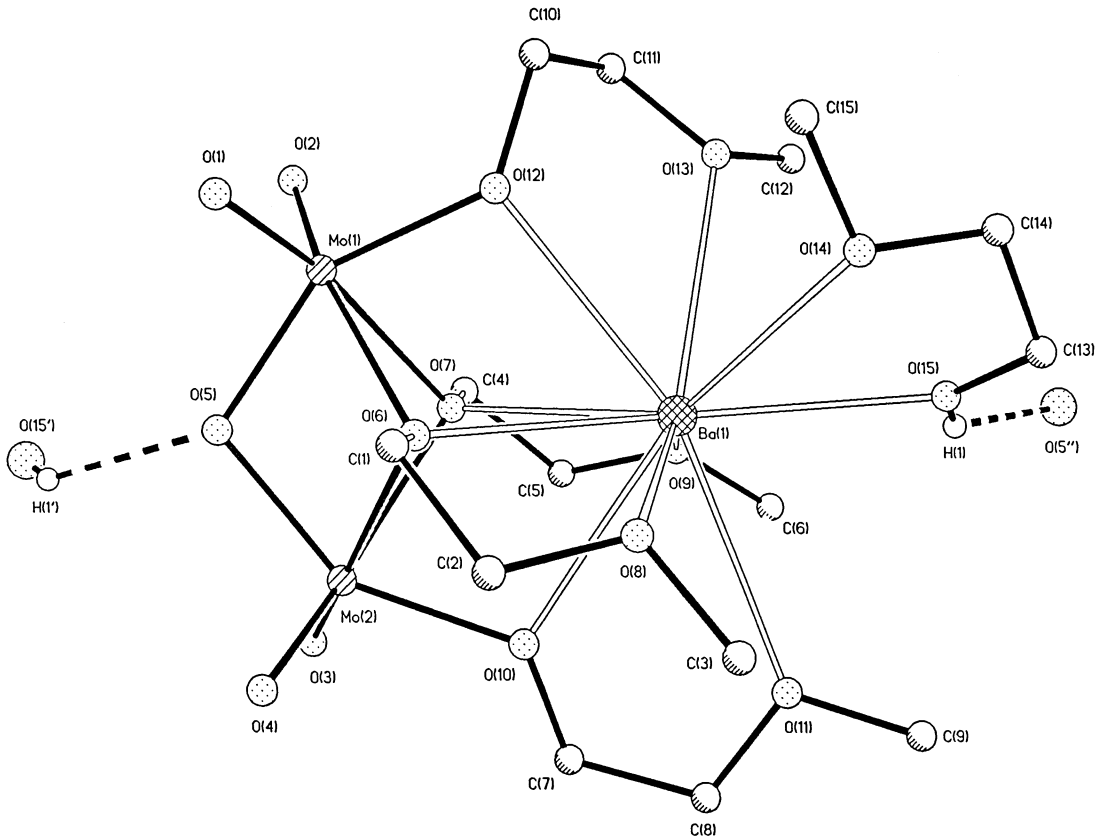

Fig. 1. The structure of the $[Ba(ROH)]^{2+}[Mo_2O_5(OR)_4]^{2-}$ ($R = C_2H_4OMe$) aggregate in the crystal of **1**. Primed and doubly primed atoms are derived from the reference atoms by symmetry operations $x, 1-y, 0.5+z$ and $x, 1-y, z-0.5$, respectively.

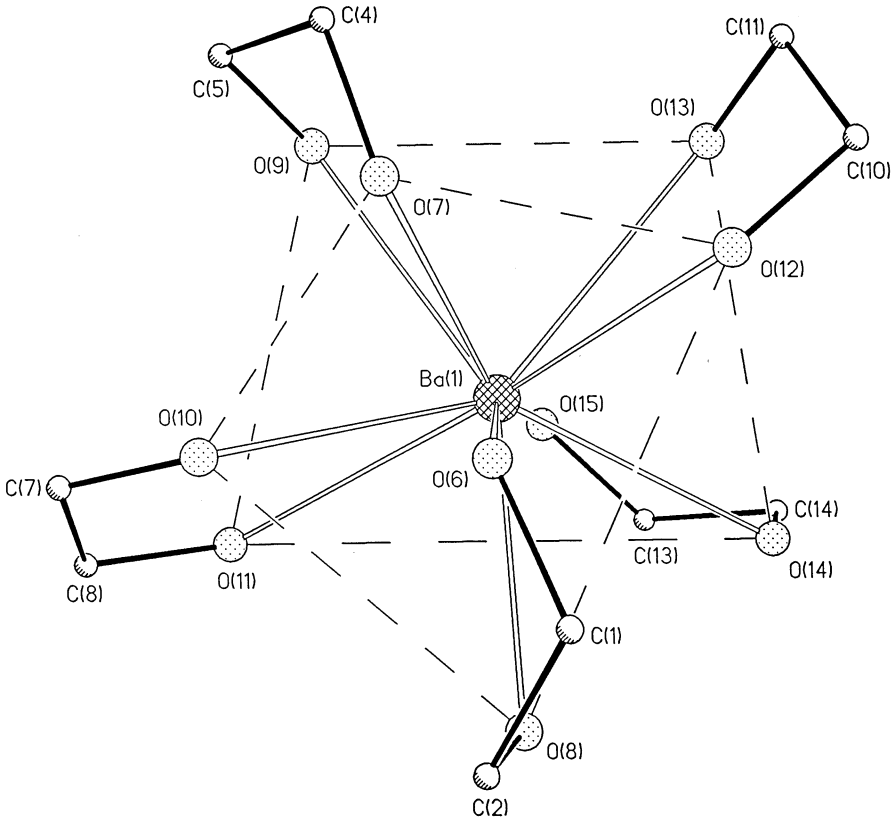

Fig. 2. The coordination polyhedron of Ba atom in the structure of **1** [the projection on O(9)O(13)O(11)O(14) basal plane].

barium atoms as predominantly ionic. The neutral aggregates observed can thus be considered as close ion pairs, consisting of $[Ba(HOR)]^{2+}$ cations and $[Mo_2O_5(OR)_4]^{2-}$ anions ($R = C_2H_4OMe$). It is to be noted that no direct analogy to the described barium coordination can be provided by the structures of known homo- or heterometallic barium oxo-2-methoxyethoxides. All barium atoms in the structure of $H_4Ba_6(\mu_6\text{-}O)(OC_2H_4OMe)_{14}$ [8] have very similar coordination with eight rather than ten neighbours. Their coordination polyhedra are rather irregular, while the values of the corresponding Ba–O distances are very close to those observed for **1** [2.90–2.93 for Ba–O(oxo), 2.67–2.82 for Ba–μ_3-O, 2.71–2.81 for Ba–O(H)R (terminal) and 2.83–2.97 Å for Ba–O(ether)] apparently due to the same nature of bonding in this aggregate. Of the same order of magnitude are also the lengths of corresponding Ba–O distances in the structure of $Ba_4Ti_{13}O_{18}(OC_2H_4OMe)_{24}$ [9] [the average values are: 2.908(9) for Ba–O(ether), 2.693(9) for Ba–O(OR) and 3.07(2) Å for Ba–O(oxo) bonds] while the coordination number of barium atoms in this structure is 12. The same coordination number as in **1** demonstrate the barium atom in the structure of $BaCu_4(thd)_4(OC_2H_4OMe)_6$ [10], however, its coordination environment in this case cannot be attributed to some of the known canonical polyhedra as in **1**. In contrast to **1** only two of eight 2-methoxyethoxide groups surrounding the central atom in this structure are chelating. This peculiarity probably accounts for the rather high variation of bond length within the groups of chemically identical bonds observed in the structure of the Ba–Cu derivative [2.68–3.08 for Ba–μ_3-O(R), 2.73–3.02 for Ba-μ_2-O(R) and 2.85–2.89 Å for Ba–O(ether) functions].

The structure of the dimolybdenum moiety is very close to that described for the $[Mo_2O_5(O_2R)_2]^{2-}$ anion (where O_2R is the pyrocatecholate residue) [11]. The Mo=O [Mo(1)–O(1) 1.714(6), Mo(1)–O(2) 1.705(6), Mo(2)–O(3) 1.703(6), Mo(2)–O(4) 1.695(6) Å], Mo–μ-O [Mo(1)–O(5) 1.955(5), Mo(2)–O(5) 1.958(5) Å], Mo–μ_2-O(R) [Mo(1)–O(12) 1.978(5), Mo(2)–O(10) 1.966(5) Å] and Mo–μ_3-O(R) [Mo(1)–O(6) 2.189(4), Mo(1)–O(7) 2.274(4), Mo(2)–O(6) 2.261(5), Mo(2)–O(7) 2.255(4) Å] bond lengths in **1** lie within the limits usually observed for octahedrally coordinated Mo atoms. The IR spectrum of the complex is in good agreement with the structure of **1** described above.

It is to be noted that this product as well as the bimetallic molybdenum isopropoxides described in the literature [1] belong to those alkoxide systems, which have more oxoligands than the molybdenum species from which they are derived, i.e. $MoO_2(OC_2H_4OMe)_2$. This fact in combination with the inevitable precipitation of $BaMoO_4$ on both synthesis and recrystallization of the product from parent alcohol shows that the application of the functional ligand such as 2-methoxyethanol provides only partial protection from the ether elimination reaction in this particular case.

(Received 20 March 1998; accepted 3 June 1998)

Abstract—The crystal structure of $[Cu(acv)_2(H_2O)_2]$ $(NO_3)_2$ is reported; there is a pseudo-chelate N(7)/O(6) bonding of a purine to the metal and it contains the shortest Cu–O(6) distance [2.698(2) Å] so far reported for a simple copper(II)-nucleoside. This unusual bonding is due to the hydrophobic medium (absolute methanol) used for crystallisation. ^{1}H NMR spectra of the complex recorded both in methanol and in aqueous solution confirm N(7) as the main copper coordination site and that the acyclic chain is not involved in binding. © 1998 Elsevier Science Ltd. Keywords: acyclovir; copper(II) complex; crystal structure; NMR spectroscopy; pseudo-chelate bonding.

INTRODUCTION

For many years the coordination of purines to metal ions has been investigated by several researchers (Refs [1–4]. and references therein). It has been suggested that purines act as chelating ligands to metals through N(7) and the exocyclic atom attached to C(6) [5]. However, in aqueous systems, true chelation has only been observed in 6-thiopurines. The typical bonding pattern in the metal complexes of 6-oxopurines can best be described as indirect chelation where a water molecule in the coordination sphere forms interligand hydrogen bonds to the exocyclic substituent at C(6). In a few cases, when no hydrogen bond donors were available, 6-oxopurines have been found to form weak N(7)/O(6) chelates, though with N(7) remaining as the primary binding site. It has been proposed that such N(7)/O(6) chelation is an intermediate in a critical step of a possible mechanism of action for Pt antitumor drugs and this is the main reason that this topic has been so thoroughly studied [6,7].

It has been calculated that if the M–O(6) and M–N(7) lengths were each of *ca*. 2 Å (normal values for first-row transition metals), the C(5)–N(7)–M angle would be approximately 90°; the maximum overlap of available orbitals on the metal with the hybrid orbitals on N(7), however, occurs when this angle is 135° [8]. This could explain why chelate formation is so rare in this system. On the other hand, a few years ago a semiempirical calculation showed that N(7)/O(6) chelation is possible in the Pt–guanine system [9].

We have previously shown that the antiherpes drug acyclovir (acv = 9-{(2-hydroxyethoxy)methyl}guanine) (Scheme 1) can form various species with Cu(II) ions with bonding occurring typically through N(7) [10,11]. Three copper–acv complexes (including the title compound) have been tested for antiviral efficacy against Herpes Simplex viruses (HSV 1, HSV 2) and were found to exhibit differing activities perhaps due

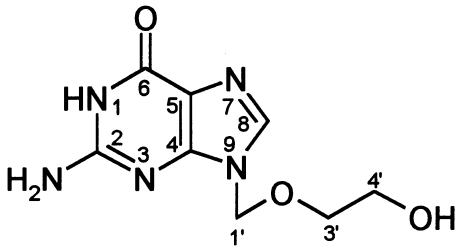

Scheme 1.

to the varying coordination mode of the acv ligands [12].

Here we report an example of N(7)/O(6) copper(II) bonding to 6-oxopurine with the shortest Cu–O(6) distance in a simple copper(II) nucleoside system observed so far. An NMR study of the proton relaxation times (T_1 and T_2) was also performed in the copper(II)–acyclovir system. Our aim was to check for any differences in relaxation times between aqueous and methanolic media which could suggest the presence of different bonding modes.

EXPERIMENTAL

Acyclovir (Sigma) and copper nitrate(V) trihydrate (Merck, p.a. quality, min. 99.5%) were used without further purification. Deuterated solvents were supplied by Fluorochem (D_2O, 99.9% D) and Norell (CH_3OD, 99%). Complex $[Cu(acv)_2(H_2O)_2](NO_3)_2$ (diaquabis[9-{(2-hydroxyethoxy)-methyl}guanine] copper(II) nitrate(V)) was prepared by dissolving $Cu(NO_3)_2 \cdot 3H_2O$ (1.33 mmol) in absolute methanol (30 ml) followed by slow addition of acv (1.33 mmol). After a few days dark green needles were grown from the solution. Found: C, 28.29; H, 3.62; N, 25.01. $C_{16}H_{26}N_{12}O_{14}Cu$ requires C, 28.49; H, 3.90; N, 24.93%. Similar to our previous syntheses [10,11,13] described before, it was necessary to use an excess of metal salt to prevent the precipitation of acv due to its low solubility. It is interesting to note that when a (1:1) methanol–water solvent mixture was used the complex $[Cu(acv)_2(H_2O)_3](NO_3)_2 \cdot H_2O$ was the product [11].

Crystal data for $C_{16}H_{26}N_{12}O_{14}Cu$: $M_r = 674.0$, monoclinic, space group $P2_1/n$ (No. 14), $a = 4.865(1)$, $b = 14.253(1)$, $c = 19.036(1)$ Å, $\beta = 92.48(1)^\circ$, $V = 1318.8(2)$ Å^3, $Z = 2$ (the molecule has crystallographic C_i symmetry), $D_c = 1.697$ g cm^{-3}, μ(Cu-K$_\alpha$) = 20.1 cm^{-1}, $F(000) = 694$. A green platy needle of dimensions $0.37 \times 0.20 \times 0.07$ mm was used. Data were measured on a Siemens P4/PC diffractometer with Cu-K$_\alpha$, radiation (graphite monochromator) using ω-scans. 2176 independent reflections were measured ($2\theta \leq 127^\circ$) of which 1994 had $|F_o| > 4\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarisation factors, but not for absorption. The structure was solved by direct methods and all the non-hydrogen atoms were refined anisotropically. The nitrate anion was found to exhibit slight rotational disorder (*ca.* 35°) about one of the N–O bonds; this was resolved into two alternate partial occupancy orientations (60:40) for two of the oxygen atoms. (The quoted hydrogen bonding geometries refer only to the major occupancy oxygen atoms.) The N–H and O–H hydrogen atoms were located from a ΔF map and refined isotropically subject to a distance constraint (0.90 Å). The positions of the remaining hydrogen atoms were idealised, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent atoms. Refinement was by full-matrix least squares based on F^2 to give $R_1 = 0.036$, $wR_2 = 0.101$ for the observed data and 239 parameters. The maximum and minimum residual electron densities in the final ΔF map were 0.36 and -0.36 eÅ^{-3}, respectively. The mean and maximum shift/error ratios in the final refinement cycle were 0.000 and 0.003, respectively. Computations were carried out using the SHELXTL PC program system [14], CCDC reference number 101706.

^{1}H *NMR spectroscopy*

The ^{1}H NMR experiments were performed on a Bruker DRX spectrometer operating at 600 MHz. All NMR experiments were recorded at 298 K. The solvent peak was suppressed by a 3-9-19 WATERGATE pulse sequence. One-dimensional spectra were recorded into 64K complex points with a 22 ppm spectral width, a 12 μs pulse width and a recycling delay of 2 s. The T_1 measurements were carried out using an inversion recovery sequence, in which the WATERGATE suppression sequence was incorporated. A list of 13 different delays in the range 0.01 to 10 s were used. The NMR data were processed on a PC (Pentium, 133 MHz) using WIN-NMR version 960901.2 (Bruker). The spectra were multiplied by an exponential window function prior to Fourier transformation. Typically, 1 Hz was added to the line width. The 1D spectra were zero filled to 128 K. No base line correction was needed. The proton spectra were referenced to the H_2O/D_2O-resonance in water at 4.76 ppm at 298 K and the methyl resonance in methanol at 3.40 ppm at 298 K.

To a 0.40 mM solution of acv in CH_3OD successive aliquots of *ca.* 4.0 mm $Cu(NO_3)_2$ were added by a micropipette. The analogous titration was also carried out in aqueous solution in order to study the influence of hydration on the coordination geometry. The pH values of the starting solutions were 6.3.

RESULTS AND DISCUSSION

The X-ray analysis of the crystals from the reaction mixture reveals (Fig. 1) a complex in which two acv ligands are bound "monodentately" via N(7) in a *trans*, C_i symmetric arrangement to the copper centre

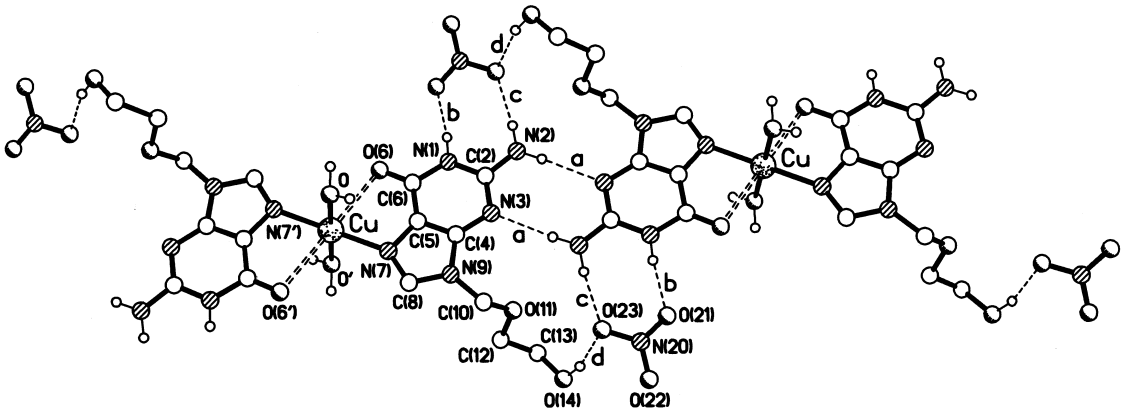

Fig. 1. Perspective drawing of $[Cu(acv)_2(H_2O)_2]$ $(NO_3)_2$ showing the pseudo octahedral geometry at copper. Part of one of the hydrogen-bonded ribbons formed by N–H . . . N "base-pair" links between the purine units and between the terminal hydroxyl and the nitrate anion in the title compound is also shown. Hydrogen bonding geometries [X . . . Y, H . . . Y distances (Å) and X–H . . . Y angles (°)]: (a) 3.04, 2.15, 168; (b) 2.85, 1.96, 172; (c) 2.88, 1.98, 173; (d) 2.78, 1.91, 164 [all X–H distances normalised to 0.90 Å]. Note that the crystallographic numbering scheme is slightly different from the conventional numbering used in Scheme 1 and in Figs 2 and 3.

[2.004(2) Å, Table 1]. The geometry at copper is slightly distorted square planar, the other two coordination sites being occupied by aqua ligands [1.953(2) Å]. This arrangement is in contrast to the square pyramidal geometry observed when the reaction is performed in water alone [11]. The planes of the purine rings are inclined by *ca.* 75° to the copper coordination plane, thus directing the ligand carbonyl oxygen atoms towards the vacant Cu octahedral sites at a distance of 2.698(2) Å. This secondary coordination interaction is clearly significant as evidenced by a severe distortion in the Cu–N(7)–C(8) angle which is enlarged to 143.3(2)°, cf. a normal value of *ca.* 125° [11], and a concomitant contraction of the Cu–N(7)–C(5) angle to 111.5(1)° (cf. *ca.* 130°) [11]. The ligand is thus acting in a pseudo-bidentate fashion with an O–Cu–N bite angle of 77.13(6)°. Precedents for a purine ligand acting in this manner are rare,

there being only a few previously published examples where the metal (platinum [15], titanium [16,17] and rhodium [18])–oxygen distance is shorter than that observed here. There are two other examples of purine acting as a pseudo-bidentate ligand to copper, but in both of these other cases the Cu–O distance is noticeably longer, at 2.83 [19] and 2.92 Å [20], though each exhibit an appreciable enlargement of the external angles at N(7) (142 and 139°, respectively). The hydroxyethoxymethyl side-chain of an acv molecule has an extended geometry with a *gauche* relationship for the two oxygen atoms.

An inspection of the packing of the molecules reveals (Fig. 1) a pattern of C_i symmetric "base-pair" recognition between one of the amino N–H hydrogen atoms of one purine and the N(3) nitrogen of another and vice versa to form ribbons that extend in the crystallographic *b* direction. The other amino hydrogen atom and the imino and hydroxy H-atoms are hydrogen bonded to the nitrate anion. This dihydrogen bond formation between guanine and an oxyanion has been observed in several other X-ray structures of guanine salts of oxyanions [21]. The aqua ligands cross-link these ribbons via O–H . . . O hydrogen bonds to the carbonyl oxygen O(6) (O . . . O 2.68, H . . . O 1.82 Å; O–H . . . O 160°) and the terminal hydroxyl oxygen O(14) (O . . . O 2.62, H . . . O 1.73 Å; O–H . . . 0 170°) creating a series of parallel, corrugated sheets (O–H distances normalised to 0.90 Å). This pattern of hydrogen bonding is in marked contrast to that observed for the complex crystallised from water [11], demonstrating how major changes in the hydrogen bonding preferences can be influenced by changes in the solvent mixture.

It is obvious that the type of solvent is crucial for the mode of acv–metal coordination in the solid state. Whereas in the product isolated from water typical bonding through N(7) was observed, in methanol a rare example of N(7)/O(6) bonding takes place but the isolated compound may not be representative of the main species present in solution. The very elaborate network of hydrogen bonding in the crystal may also influence the coordination pattern. In order to eliminate these possible packing effects the complexation was followed by NMR titrations in both aqueous and methanolic media.

The effect of paramagnetic line broadening of proton signals by adding an aqueous solution of $Cu(NO_3)_2$ to acv dissolved in methanol and the corresponding effect on spin-lattice relaxation rates ($1/T_1$) versus Cu(II) concentration are shown in Fig. 2. It can easily be seen that the H(8) signal (7.91 ppm) is dramatically broadened due to a dipolar interaction between the unpaired electron on Cu(II) coordinated at N(7) and the adjacent H(8) nucleus. There is almost no observable effect on the methylene proton resonances (3.67 and 3.68 ppm) confirming that the Cu(II) ions do not interact with either the ether oxygen or the hydroxy group. The intensity of the residual HOD resonance at 4.76 ppm is seen to increase during the titration due to the addition of aliquots of aqueous $Cu(NO_3)_2$. Since the observed paramagnetic line broadening may be influenced by scalar (non-geometric) factors the spin-lattice relaxation rates were also measured. These data which mainly contain through-space dipolar effects corroborate the conclusion based on line broadening measurements and, furthermore, are in accordance with the crystal structure as far as N(7) binding is concerned.

The NMR measurements (T_1 and T_2) carried out in aqueous solution (Fig. 3) are shown to be comparable to those obtained in methanol regarding the non-exchangeable protons. The signals from the exchangeable protons (N–H and NH_2) show no paramagnetic broadening ruling out any Cu(II)-binding to N(3). Unfortunately, proton NMR spectroscopy was not able to distinguish between a normal hexacoordinated structure and a chelate structure in solution. In conclusion we confirm that both in aqueous and methanolic media N(7) is the dominant binding site and that the atoms of the acyclic chain are not involved in metal ion coordination.

(Received 14 January 1998; accepted 8 June 1998)

Abstract—Two new molybdenum cluster compounds, $Mo_3S_4(DTP)_3(salicylate)(CH_3CN)$ and $[Mo_3S_4(DTP)_3(phthalate)(Py)]_2 \cdot EtOH \cdot CH_2Cl_2$, have been rationally synthesized by the ligand substitutional reaction of $Mo_3S_4(DTP)_4(H_2O)$ with salicylic acid and phthalic acid, respectively. Their crystal structures have been determined. A molecular-design method for Mo_3S_4 cluster compounds was developed. Two incomplete cuboidal molybdenum cluster units can be linked by intramolecular H-bonds. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: synthesis; X-ray structure; H-bond; S–S interaction; aromatic carboxylate; NMR.

INTRODUCTION

Since the trinuclear molybdenum cluster compound $Mo_3S_4(\mu\text{-DTP})(DTP)_3(L)$, where L = loosely-coordinated ligand, DTP = diethyldithiophosphate, (**I**) was reported [1], several new clusters formulated as $Mo_3S_4(\mu\text{-}RCO_2)(DTP)_3(L)$ (**II**) were synthesized by substitution reactions [2]. It is now well established that this Mo_3S_4 precursor **I**, unlike its aqueous analogous cation $[Mo_3S_4(H_2O)_9]^{4+}$, has three different substitutional sites: bridging DTP, terminal DTP [3] and the loosely-coordinated ligand L. By choosing ligands of different chemical properties for the precursor **I**, we can now control the molecular fragmentation to design molybdenum cluster molecules suitable for potential applications, for example, in the exploitation of catalytic reactions promoted at a metal site embedded in metal–sulfur aggregates [4, 5]; in the synthesis of new optical limiting materials [6]. Aromatic carboxylic acids, which can bond with various functional groups, were considered in this paper as the substituting reagents for the bridging DTP ligand.

In our preliminary experiments, the reaction of **I** with benzoic acid yielded a brown powder which was difficult to dissolve in any solvent, making the crystal structure determination impossible. However, we isolated well-formed crystals of $Mo_3S_4(DTP)_3(salicylate)(CH_3CN)$ (**III**) and $[Mo_3S_4(DTP)_3(phthalate)(Py)]_2 \cdot EtOH \cdot CH_2Cl_2$ (**IV**) by the reaction with salicylic acid and phthalic acid, respectively. Compared with the earlier experimental results, this paper provides a further molecular-design method for Mo_3S_4 cluster compounds.

EXPERIMENTAL

General procedure

$Mo_3S_4(DTP)_4(H_2O)$ was obtained by the method of literature [3]. HDTP was purified before used by vacuum distillation [7]. Phthalic acid, salicylic acid, dichloromethane and pyridine are commercially avail-

†Author to whom correspondence should be addressed.

able A.R. grade reagents which are used without further purification. The whole experiments were handled free of water. IR spectra were recorded on Nicolet Magna 750 and FTS-40 spectrometers in KBr pellets. ^{31}P NMR spectra were measured on an Varian Unity-500 NMR spectrometer in deuterated acetone [3] with reference to 85% H_3PO_4. Spectra were first recorded in 100.0 kHz width and then enlarged to a suitable scale.

Preparation of $Mo_3S_4(DTP)_3$(salicylate)(CH_3CN) (**III**): in a flask, 0.3 g $Mo_3S_4(DTP)_4(H_2O)$ was dissolved in 40 cm^3 of mixed solvent of ethanol and acetonitrile (v/v = 3:1). 0.03 g salicylic acid was then added while stirring. When refluxed over an oil bath at 100°C for an hour, the hot dark brown solution was filtered into another flask. Rectangular black crystals precipitated in 10 days. Yield: 0.18 g, 60%. Found: Mo, 25.18; C, 21.76; H, 3.31; N, 1.06; Calc. for $C_{21}H_{38}Mo_3NO_9P_3S_{10}$: Mo, 25.03; C, 21.94; H, 3.33; N, 1.22.

Preparation of $[Mo_3S_4(DTP)_3$(phthalate)(Py)$]_2 \cdot EtOH \cdot CH_2Cl_2$ (**IV**): 0.20 g of $Mo_3S_4(DTP)_4H_2O$ was dissolved in 30 cm^3 dichloromethane and 20 cm^3 ethanol. The solution was then refluxed over an oil bath at 100°C with 0.03 g phthalic acid and 0.2 cm^3 pyridine for an hour. When filtered and cooled to room temperature, this black solution gave well-shaped rectangular black crystals in two weeks. Yield 0.15 g (70%). Found: Mo, 22.30; C, 24.25; H, 3.21; N, 1.06; Calc. for $C_{53}H_{88}Cl_2Mo_6N_2O_{21}P_6S_{20}$: Mo, 22.46; C, 24.84; H, 3.46; N, 1.09.

X-ray structure determinations

The crystal data for compounds **III** and **IV** are summarized in Table 1. The important bond lengths and angles for the complex **III** and **IV** are given in Tables 2 and 3. Single crystals for **III** and **IV** were carefully chosen, coated with epoxy resin and mounted on glass fibers. Data collections and cell dimension measurements were performed on Siemens SMART CCD diffractometer with graphite-monochromatized Mo–Kα radiation ($\lambda = 0.71073$ Å) at 21 ± 2°C. Intensity data for all crystals were obtained in the range $3.08 < 2\theta < 46.6^\circ$ by using an ω scan technique. The data reductions and structural analysis were performed on a silicon computer station with Smart CCD software and the structure were refined on F^2 through the use of the SHELXL-PC programs [8, 9, 10]. Empirical absorption corrections were applied. The positions of the molybdenum atoms were determined by direct methods, and successive difference electron density maps located the remaining nonhydrogen

atoms. All the nonhydrogen atoms except some disordered C atoms of DTP ligand were refined anisotropically. Least-squares refinements were performed by fullmatrix procedures. Crystal structure plots were drawn using ORTEP II [11] software. The positions of all hydrogen atoms were generated geometrically (C–H bond fixed at 0.96 Å), assigned isotropic thermal parameters and allowed to ride on their respective parent C atoms before the final cycle of least-squares refinement. Hydrogen atoms coordinating O were included at idealized positions with an assumed O–H distance of 0.85 Å. Intermolecular S–S distances and dihedral angles were calculated using Molen programs software. The highest peak on the final difference Fourier map in **III** has a height of 1.293 e $Å^{-3}$, which is located at a position 0.738 Å away from Cl2 (chlorine 2).

RESULTS AND DISCUSSION

Crystal structure

$Mo_3S_4(DTP)_3$(salicylate)(CH_3CN) (**III**). The main structural feature of **III** (shown in Fig. 1) is similar to that of the typical incomplete cubane-type Mo_3S_4 clusters with DTP as the ligand [12]. The bond length of Mo1–N 2.269(7) Å is shorter than the corresponding one in $Mo_3OS_3(DTP)_4(CH_3CN)$, 2.274(6) Å [13]. The substitution of salicylate for bridging DTP decreases its bridged Mo2–Mo3 bond from 2.734(1) Å [14] to 2.693(2) Å, which is almost the same as the average Mo–Mo 2.690 Å when bridged by aliphatic carboxylates [2]. However, the average Mo–μ-S bond 2.292(3) Å of **III** (2.293(2) Å of **IV**, see below) is longer than that of the corresponding ali-

phatic carboxylate-substituted clusters(Mo–μ-S, 2.28 Å) [15, 16, 17], showing the effect on the Mo_3S_4 core from the bridging ligand and its substituents.

It is structurally unusual [18, 19] that those atoms in **III**, Mo3, Mo2, O1, O2, C, C1, C2, C3, C4, C5, C6 and O3 share a large plane with good coplanarity, as shown by the data listed in Table 4; the dihedral angle between the plane 2 and the plane 3 is 7(2)°. The bond

lengths Mo2–O2, Mo3–O1 and bond angles O2–C–C1, O1–C–C1 are different, showing higher asymmetry for plane 2 and 3. These structural details result from the intramolecular H-bond formed between O2 and O3 (distance between O1 and O3 is 2.57 Å). The H-bond, which is coplanar to the phenyl group, forces O3 closer to O1, fixing and tilting the phenyl group to O3 side. As a result, the salicylate ligand has more asymmetry and more coplanarity with Mo2 and Mo3. A dihedral angle of 145.77(14)° between the plane 1 and the plane 2 shows the heavily distorted octahedral coordination of Mo in **III**.

$[Mo_3S_4(DTP)_3(Phthalate)(Py)]_2 \cdot EtOH \cdot CH_2Cl_2$ (**IV**). It is interesting to find that the spare –COOH groups in cluster **IV** still have the capability of forming a dimeric carboxylic acid via H-bonding. The cluster **IV**, as shown in Fig. 2, consists of two incomplete cubane-type $[Mo_3S_4(DTP)_3(phthalate)(Py)]$ units

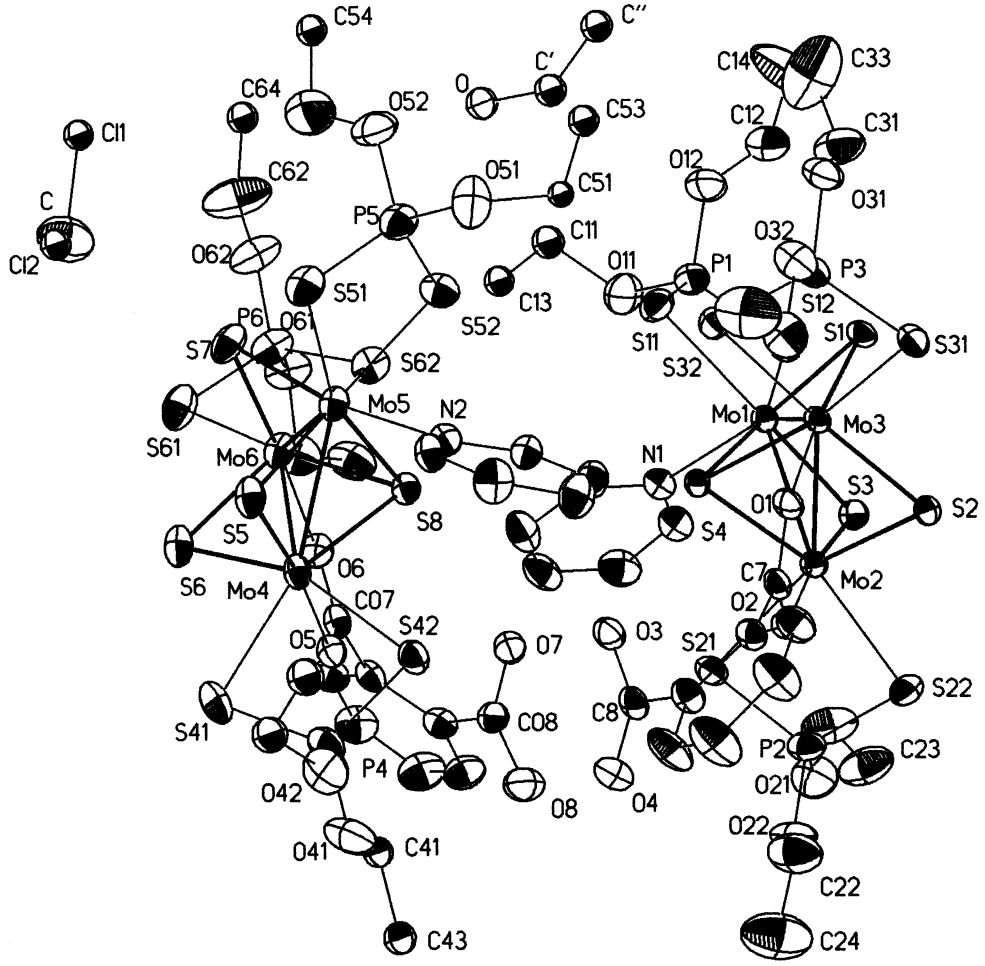

Fig. 2. The ORTEP drawing of compound **IV** with a 30% probability level.

linked together by the intramolecular H-bonds. Two solvent molecules, EtOH and CH_2Cl_2, are situated in the unit cell.

Structural data and dihedrals indicated that two pendant –COOH groups from two phthalate molecules constructed a highly symmetrical rigid plane via intermolecular H-bonding. The structure of this plane was shown in Fig. 3. Although these two H

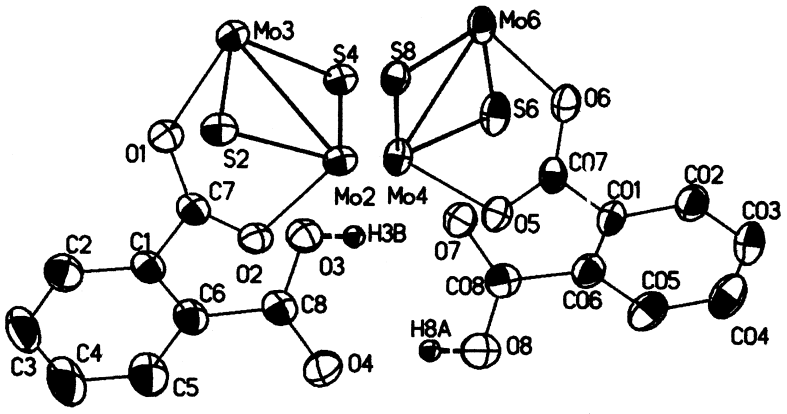

Fig. 3. The ORTEP drawing of two –COOH groups of compound **III** with a 30% probability level.

atoms were theoretically added to the adjacent O atoms (O3–H3B and O4–H8A distances are 0.85 Å, O7–H3B and O4–H8A are 1.84 Å), according to the distance (2.69 Å) of both O3–O7 and O4–O8, we can deduce that the two H atoms H3B and H8A are roughly linear and situated in the same plane with the four O atoms and strong H-bonds are formed. The IR spectra for clusters **III** and **IV** were measured [20] as listed in Table 5. A broad absorption at 3200 cm^{-1} was assigned to ν_{OH} for compound **III** and a sharp absorption at 2978 cm^{-1}, which overlaps with the phenyl absorption, was assigned to the ν_{OH} for **IV**. This is consistent with the crystal structural results that the H-bond in **IV** is linear and much stronger than that in **III**. The dihedral angles calculated between the two phenyl planes (plane 2 and 4) is 92.0(2)° as shown in Table 4, indicate that the two phenyl planes are aligned perpendicularly in the lattice.

The mean Mo–O bond length 2.242(5) Å (to phthalate ligands) in **IV** is longer than that of the similar aliphatic carboxylate cluster compounds [19] and these four Mo–O bonds, listed in Table 3, differ considerably from each other. This difference is even greater than that of the corresponding Mo–O in cluster **III** as shown in Table 2. This distortion of the coordinated –COO groups is caused by crystalline packing effects. The alignment of the bulky Mo_3S_4 core and the neighboring DTP ligand distort Mo2Mo3O1C7O2 and Mo4Mo6O6CO7O5 planes and also twist the H-bonding plane as shown by the following data: O4O8O3 124.5(8)° ≈ O7OO8O8 124.6(9)°, C8–O3 (1.272(10) Å) ≈ C08–O8 (1.267(11) Å) and C8–O4 (1.254(10) Å) ≈ C08–O7 (1.253(10) Å). As reflected by the dihedral angles between plane 1 and 2, 3 and 4 (Table 4), the RCO_2 group is no longer coplanar as opposed to the case in cluster **III**.

S–S interactions

The intramolecular S–S interactions [21, 22] in $[Mo_3S_4]$-type (M = Mo, W) clusters are important in crystal packing along with the ligand substitutional effect discussed above. For both **III** and **IV**, S–S interactions, which are all considerably shorter than the corresponding van der Waals contacts [22, 23], were calculated as shown in Fig. 4 and were listed in Table 6. In cluster **III**, the S–S interactions favor the opposite alignment of the two molecules in the cell. On the other side of the molecule, the phenyl ring sterically hinders μ-S atom to form further superamolecular interaction [14], so the two molecules of **III** are packed into the cell with a symmetric center [24]. Similarly, six S–S interactions are found in **IV**. S1, as well as S6, can form two S–S interactions with another two S atoms.

^{31}P NMR

^{31}P NMR spectra of **III** and **IV**, (Fig. 5), were measured in acetone-d_6. The assignment of the ^{31}P resonances is consistent with the literature [3]. The resonance (T_1) at 110.08 ppm for **III** was assigned to the two coalesced DTP ligands coordinated to Mo2 and Mo3, respectively; the other resonance (T_2) at 111.33 ppm was assigned to the DTP coordinated to Mo1. Similarly, the resonance (T_1) at 110.82 ppm in **IV** was assigned to the four DTP ligands coordinated to Mo2 and Mo3, Mo4 and Mo6; the other resonance (T_2) at 110.20 ppm was assigned to the DTP ligand coordinated to Mo1, Mo5.

Experimentally, the loosely coordinated ligand L affects the NMR spectrum by its dynamic dissociation in the solution and the carboxylate does so by the long-distance electron delocalization. Normally, the pyridine substitution for acetonitrile will broaden NMR linewidths considerably [3], so significant line-broadening in the spectra of compound **IV** is expected.

For this series of trinuclear clusters, the relative position of T_1 and T_2 is determined by the type of the loosely coordinated ligand L. For compound **III**, L = CH_3CN, T_2 is situated at the lower field to T_1; on the contrary, T_2 is situated at the higher field in the spectra of compound **IV**, L = pyridine. Nevertheless, L can only affect the chemical shift of T_2 considerably, it does little to the chemical shift of T_1, so the chemical shift differences between T_1 and T_2 are mainly attributed to aromatic substituents –OH and $-CO_2H$. This leads to the conclusion that the Mo_3S_4 core and the superconjugation translate the electron effect to DTP ligands [25]. A more systematic ^{31}P NMR spectroscopic study on more cluster compounds will soon follow.

(Received 6 March 1998; accepted 6 June 1998)

Abstract—Structures are reported for two anionic antimony(III) bromide chlorides, Hpy[$SbBr_2Cl_2$] and [Hpy]$_4$[$Sb_4Br_{12}Cl_8$], both of which are subject to halogen disorder. The first compound has an infinite chain structure in which antimony coordination is raised to six by the formation of double halogen bridges by atoms with high bromine content. The structure of the second compound is based on a distorted square of antimony atoms, again in distorted octahedral coordination. The antimony atoms are linked together by single bromine bridges and chlorine atoms or atoms with high chlorine content occupy the *trans* positions. The pattern of Sb–Br bridging distances suggests that the structure is derived by interconnection of two singly bridged $[Sb_2Br_5Cl_4]^{3-}$ units by two bridging Br^- ions. © 1998 Elsevier Science Ltd. Keywords: antimony(III) halide anions; mixed halides; crystal structure; halogen disorder.

INTRODUCTION

The well known Lewis acidity of antimony(III) halides leads in the presence of added halide ion to species with the stoichiometries $[SbX_4]^-$, $[SbX_5]^{2-}$, $[SbX_6]^{3-}$ and $[Sb_2X_9]^{3-}$ [1]. Although a monomeric form of the pentahalide is known in $(NH_4)_2[SbCl_5]$ [2] and $K_2[SbCl_5]$ [3], because of coordinative unsaturation at antimony(III) and the availability of lone pair density on the halogens, intermolecular bridging is possible. This leads to both dimeric and chain polymeric forms for the $[SbX_4]^-$ stoichiometry in $(NBu_4)_2[Sb_2Cl_8]$ [4] and $\{(Hpy)[SbCl_4]\}_n$ [5], respectively, and tetrameric and polymeric forms for the $[SbX_5]^{2-}$ stoichiometry in $\{(2,2'\text{-bipyH}_2)[SbCl_5]\}_4$ [6] and $\{(4,4'\text{-bipyH}_2)[SbCl_5]\}_n$, respectively. A dimeric alternative for the latter stoichiometry has been identified in the potassium and ammonium salts of $[Bi_2Br_{10}]^{4-}$ [7]; the corresponding antimony analogue is currently unknown.

We have been interested in the structures of antimony(III) haloanions, both those which are purely inorganic [8] and those also incorporating phenyl groups [9], and now report an extension of this work to species containing both bromine and chlorine. Our interests are in the degree of polymerisation that results and in which of the two halogens occupy any bridging positions. Few compounds containing two of the heavier halides have been investigated but we have previously described the bioctahedral structure of $(NMe_4)_3[Sb_2Br_3Cl_6]$ [8], which contains bridging bromine atoms. In related anionic antimony(III) mixed chloride or bromide fluorides [1], the heavier halogen also occupies the bridging positions. This paper reports the preparation and structures of two further mixed bromide chlorides with the stoichiometries $[SbBr_2Cl_2]^-$ and $[SbBr_3Cl_2]^{2-}$, respectively.

EXPERIMENTAL

Preparation of Hpy[$SbBr_2Cl_2$]

This compound was prepared as described previously [8] by recrystallising [Hpy]$_3$[Sb_2Cl_9] from hot concentrated hydrobromic acid solution and recrystallised from ethanol. (Found: C, 13.8; H, 1.4; N, 3.3; Br, 36.9. Calc for $C_5H_6Br_2Cl_2NSb$: C, 13.9; H, 1.4; N, 3.2; Br, 36.9%).

†Authr to whom correspondence should be addressed.

Preparation of $[Hpy]_8[Sb_4Br_{12}Cl_8]$

A solution of pyridinium chloride (3.2 g, 0.028 mol) in anhydrous ethanol was added to a solution of antimony(III) bromide (5.0 g, 0.014 mol) in the same solvent. The pale yellow precipitate which formed immediately was redissolved by heating and on cooling yellow crystals of $[Hpy]_8[Sb_4Br_{12}Cl_8]$ were obtained. M.p. 160° (dec). (Found: C, 19.9; H, 2.0; N, 4.6; Br, 40.8. Calc for $C_{40}H_{48}Br_{12}Cl_8N_8Sb_4$: C, 20.2; H, 2.0; N, 4.7; Br, 40.5%).

Crystal structure determinations

Crystals of $Hpy[SbBr_2Cl_2]$ and $[Hpy]_8[Sb_4Br_{12}Cl_8]$ suitable for X-ray diffraction were obtained by slow recrystallisation from ethanol.

$Hpy[SbBr_2Cl_2]$. Crystal data: $C_5H_6Br_2Cl_2NSb$, $M=432.6$, monoclinic, space group C2/c, $a=11.631(4)$, $b=12.788(4)$, $c=7.543(2)$ Å, $\beta=92.88(4)°$, $U=1120.5$ Å^3, $Z=4$, $D_c=2.56$ g cm^{-3}, $F(000)=792$, $\mu=10.46$ mm^{-1}, Mo-Kα radiation (graphite monochromated), $\lambda=0.71073$ Å, $T=295$ K, crystal size $0.5\times0.3\times0.3$ mm^3.

Intensity data were collected on a Hilger and Watts four-circle diffractometer for 1040 reflections in the range $0°<\theta<25°$ ($-13<h<13$, $0<k<15$, $0<l<9$) of which 783 unique reflections with $I>3\sigma(I)$ were considered observed. The data were corrected for Lorentz and polarisation effects and for absorption [10]. Crystallographic calculations used the CRYSTALS programs [11] and scattering factors, including anomalous dispersion contributions, were those for neutral atoms [12]. The antimony atom, lying on a two fold axis, was located from a Patterson synthesis and the remaining non-hydrogen atoms were revealed by a series of full-matrix least squares refinements and difference Fourier syntheses. The nitrogen and *para* carbon atoms of the cation lie on the two fold axis. After refinement with anisotropic thermal parameters, the hydrogen atoms were placed at their calculated positions but were not further refined. Because the bromine/chlorine disorder has been observed in related antimony mixed halide species, the occupation factors of the bromine and chlorine atoms were allowed to refine. Final refined values gave the following Br/Cl fractions: Br 0.68 [Cl′ 0.32] and Cl 0.68 [Br′ 0.32]. Application of a four coefficient Chebyshev weighting scheme led to final convergence (54 least squares parameters, maximum shift/esd 0.07) at $R=0.053$ ($R_w=0.064$).

$[Hpy]_8[Sb_4Br_{12}Cl_8]$. Crystal data: $C_{40}H_{48}Br_{12}Cl_8N_8Sb_4$, $M=2370.4$, orthorhombic, space group $Cmc2_1$, $a=14.654(3)$, $b=34.041(2)$, $c=13.681(2)$ Å, $U=6825(2)$ Å^3, $Z=4$, $D_c=2.307$ g cm^{-3}, $F(000)=4416$, $\mu=8.94$ mm^{-1}, Mo-Kα radiation (graphite monochromated), $\lambda=0.71073$ Å, $T=220(2)$ K, crystal size $0.62\times0.28\times0.19$ mm^3.

Diffraction data were collected on a Stoe Stadi four-circle diffractometer at 220 K (ω/θ scan mode and on-line profile fitting [13]). A total of 8380 reflections was collected to θ_{max} 25° and after applying a numerical absorption correction (T range, 0.095–0.224) merging gave 3263 unique data (R_{int}, 0.128) which were used in subsequent calculations. Of these 2833 had $F_o>4\sigma(F_o)$.

Direct methods [14] followed by difference Fourier syntheses located all non-hydrogen atoms and of these, Sb, Br and Cl were refined anisotropically [15]. Hydrogen atoms were placed at their calculated positions and allowed to ride on their parent atoms. The bridging atoms were ordered bromines but there was extensive disorder in the terminal atoms, except for Cl(4). The disorder was modelled as Br and Cl components having coincident positions and identical anisotropic thermal parameters and their linked occupancies were refined. Additional restraints based on the known Br/Cl ratio (3:2) were also employed. As the pyridinium cations were relatively poorly defined, with most disordered about the crystallographic mirror planes, carbon and nitrogen atoms could not be distinguished and geometric restraints were applied to the intramolecular cation geometry. The weighting scheme, $w^{-1}=\sigma^2(F_o^2)+0.127P^2+16.90P$; where $P=1/3[\mathrm{Max}(F_o^2, 0)+2F_c^2]$, led to final convergence at R_1 $[F_o>4\sigma(F_o)]=0.0688$, wR_2 (all data) $=0.1899$,

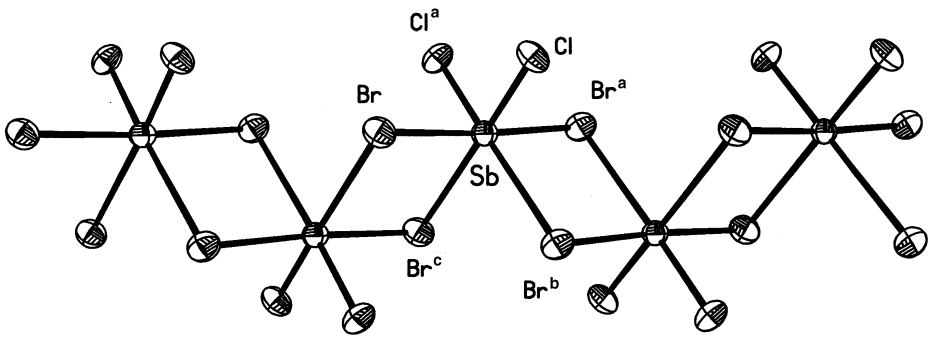

Fig. 1. Structure of $Hpy[SbBr_2Cl_2]$, showing the atom numbering scheme. Both halogen atoms are disordered and the atom label identifies the major component. See text for discussion.

$S=1.05$ for 232 refined parameters and 44 restraints. An extinction correction refined to 0.00018(6) [16], the Flack absolute structure parameter was 0.07(3) and a final difference Fourier synthesis showed no peaks above $+2.61$ or below $-2.75\,e\text{Å}^{-3}$, which were located close to the antimony atoms.

Tables of atomic coordinates, bond distances and angles, anisotropic thermal parameters and hydrogen atom positions for both compounds have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Structure of $Hpy[SbBr_2Cl_2]$

The infinite chain structure of the anion in this compound is shown in Fig. 1 and bond distances and angles are listed in Table 1. In this compound antimony coordination is raised to six by formation of four asymmetric halogen bridges giving distorted octahedral coordination about antimony and stereochemical inactivity for the lone pair of electrons on antimony. From the space group symmetry, only one bromine and one chlorine atom are unique. This chain structure, orientated along the *c* axis, is one of the variants expected for the $[MX_4]^-$ stoichiometry and has been found previously for other Group 15 anions with this stoichiometry, including $Hpy[SbCl_4]$ [5] and $Hpy[SbBr_4]$ [17]; the present compound is, in fact, isostructural with the latter.

We have noted in previous structure determinations on antimony(III) mixed bromide-chlorides that there is a strong possibility of halogen disorder. For example, although the bridging atoms in both $[SbBr_3Cl_6]^{3-}$ [8] and $[Sb_2OBr_4Cl_2]^{2-}$ [18] are truly bromine, those in $[Sb_2OBr_2Cl_4]^{2-}$ have only 0.53 bromine content with the remaining bromine content associated with the four, predominantly chlorine, terminal atoms. Terminal halogens in $[Sb_2OBr_4Cl_2]^{2-}$, formally two bromine and two chlorine atoms, are similarly subject to halogen disorder [18]. On the other hand, in antimony(III) systems containing fluorine and a heavier halogen, e.g. $Na[SbBrF_3(H_2O)]$ [19] and $(NH_4)[SbCl_3F_2]$ [20], etc. such disorder does not occur

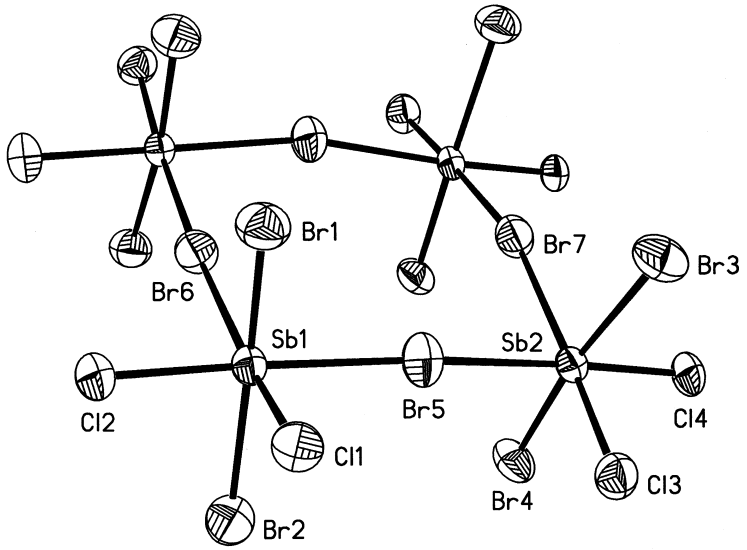

Fig. 2. Structure of $[Hpy]_8[Sb_4Br_{12}Cl_8]$, showing the atom numbering scheme. With the exception of Br(5), Br(6), Br(7) and Cl(4) which are ordered, all other halogen atoms are subject to disorder. The atom label identifies the major component; see text for discussion.

and bridging positions are occupied uniquely by the heavier halogen.

In the present compound, bridging positions are occupied by atoms with 0.68 bromine content and terminal positions by atoms with 0.68 chlorine character and the disorder is reflected in the bond distances. For example, the asymmetric bridge bonds are shorter [2.772(2) and 3.213(2) Å] than those in the corresponding tetrabromide [2.822(3) and 3.234(4) Å] [13] and the terminal atom separation [2.463(2) Å] longer than that for the tetrachloride [2.380(3) Å] [5].

Any anion–cation contacts are expected to involve hydrogen bonding between the pyridinium group and the most electronegative anion site and there are short N...Cl contacts [3.384(7) Å] probably representing a weak, bifurcated hydrogen bond. Such bonding has also been suggested in $Hpy[SbBr_4]$ [17] where the shortest N...Br contact is 3.44 Å, but in the corresponding chloride, the pyridinium cation is disordered with a two-fold axis passing through opposite C–C bonds and the closest contact between a ring atom and the terminal chlorine is 3.56 Å [5].

Structure of $[Hpy]_8[Sb_4Br_{12}Cl_8]$

This compound, with the stoichiometry $[SbBr_3Cl_2]^{2-}$, shows neither the monomeric, square pyramidal structure of $M_2[SbCl_5]$, where $M = NH_4$ [2] or K [3], nor the dimeric, doubly bridged, octahedral structure previously found for $M_4[Bi_2Br_{10}]$ [7]. The observed structure, with a mirror plane passing through Br(4) and Br(5), is shown in Fig. 2 together with the atom numbering scheme and is a tetrameric variant, similar to that of the corresponding 2,2′-bipyridinium salt [6]. Selected distances and angles in the anion are collected in Table 2. As with the compound above, this also showed halogen disorder, but atoms designated as Br(5), Br(6), Br(7) and Cl(4) are ordered. For the remainder, refinement gave the following Br/Cl fractions: Br(1) 0.68(2) [Cl(1′) 0.32(2)], Br(2) 0.80(2) [Cl(2′) 0.20(2)], Br(3) 0.93(2) [Cl(3′) 0.07(2)], Br(4) 0.68(2) [Cl(4′) 0.32(2)], Cl(1) 0.77(2) [Br(1′) 0.23(2)], Cl(2) 0.54(2) [Br(2′) 0.46(2)], Cl(3) 0.74(2) [Br(3′) 0.26(2)].

Antimony atoms are again at the centres of distorted octahedral SbX_6 units with presumed stereochemically inactivity for the lone pair and occupy the corners of a distorted square. They are interlinked by Br(5), Br(6) and Br(7), the latter two lying on a mirror plane. All three bromine bridges are almost linear [Sb–Br–Sb angles of 167.33(11), 176.65(13) and 162.33(11)° at Br(5), Br(6) and Br(7), respectively], with the smallest angle at Br(7) *trans* to the largest angle at Br(6). Ring angles at antimony are also different [94.99(9)° at Sb(1) and 92.95(8) at Sb(2)].

The four independent Sb–Br distances within the eight-membered ring fall into two sets, i.e. those to Br(6) and Br(7), the atoms on the mirror plane, are "long" [3.2277(13) and 3.2303(13) Å] and those to Br(5) which are substantially shorter [3.040(3) and 3.081(3) Å]. The structure could therefore be considered as arising by interconnecting two symmetry related singly bridged $[Br_2Cl_2Sb(1)Br(5)Sb(2)Br_2Cl_2]^{3-}$ units by bromide ions Br(6) and Br(7).

Atoms with high chlorine content, which varies from fully ordered for Cl(4) to 0.54 for Cl(2), occupy positions *trans* to bridging bromines and the observed

Sb1–Br5–Sb2	167.33(11)
Sb1–Br6–Sb1[a]	176.65(13)
Sb2–Br7–Sb2[a]	162.33(11)

Symmetry transformation used to generate equivalent atoms: [a] $-x, y, z$.

"Sb–Cl" distances varying from 2.445(4) to 2.582(3) Å broadly correlate with the halogen content. The remaining *trans* related atoms, occupying the fifth and sixth octahedral positions above and below the Sb_4Br_4 ring plane, have bromine contents ranging between 0.53 and 0.93 and again the Sb–Br separations correlate well with bromine content.

Any discussion of antimony(III)–halogen bond lengths, even in neutral species, is fraught with problems resulting from secondary bond formation [21]. This is a consequence of the Lewis acidity of antimony(III) and occurs with halogens of either neighbouring neutral molecules or, in the case of halogenoanions, with added halide ions. One of the most satisfactory models for describing this type of interaction is to consider it occurring via σ^* orbitals of primary Sb–halogen bonds; this necessarily leads to a correlation between the lengths of the *trans* related bonds so formed [22]. Two extremes can be considered. At the first, one bond will be effectively single and the second a van der Waals contact while at the other, the bond lengths will be equal and equivalent to a "half bond"; any combination between these extremes is theoretically possible. By analysing crystallographic data for compounds where such secondary bonding occurs [23], values of 2.32 and 2.62 Å can be assigned to single and half Sb–Cl bonds and 2.46 and 2.79 Å to single and half Sb–Br bonds. The Sb–Cl and Sb–Br van der Waals contacts are *ca.* 4.0 and 4.2 Å, respectively, and the separation limits are then defined. The compounds currently under consideration, however, present further complications as (a) neither is mononuclear and in some cases one of the atoms of a *trans* related pair is also a bridging atom to a second antimony, inevitably modifying the separations, and (b) there is bromine/chlorine disorder, which again inevitably influences the bond lengths.

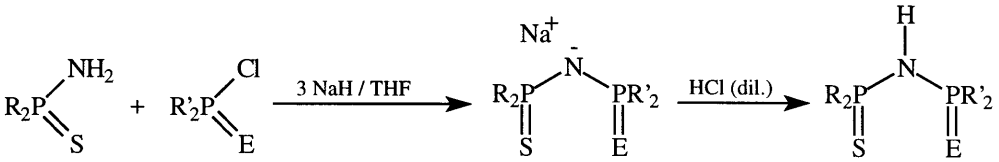
(Received 16 April 1998; accepted 8 June 1998)

Abstract—Reaction of $(EtO)_2P(S)NH_2$ with $ClP(O)Ph_2$ gives $(EtO)_2P(S)NHP(O)Ph_2$ (**1**) similarly reaction of $ClP(S)Ph_2$ yields $(EtO)_2P(O)NHP(S)Ph_2$ (**2**). The X-ray structures of **1** and **2** reveal P═O...H–N hydrogen bonded structures with distinct differences in packing and conformation. Thus **1** exists with the P═S and P═O groups in a *gauche* or *cisoid* orientation with SP...PO torsion angles of 79.5 and −69° for the two independent molecules which form a hydrogen bonded chain whereas **2** is a *transoid* dimer with an SP...PO torsion of 172° in the solid state. ML_2 (M = Zn, Pd, Pt) complexes derived from **1** and **2** are also described and the X-ray structure of $Zn[(EtO)_2P(O)NP(S)Ph_2]_2$ is reported. © 1998 Elsevier Science Ltd. All rights reserved



for R = Ph, R' = EtO. R = EtO, R' = Ph. E = S / O

INTRODUCTION

Mixed donor imidophosphinates can be easily prepared and show interesting structural differences.

There is considerable interest in the co-ordination of metals by monoanionic, bidentate ligands. For example, acetylacetonate, *acac*, and its derivatives form a large class of complexes which have been extensively studied [1]. The dithio- and deseleno-imidodiphosphinate ligands $Ph_2P(E)NHP(E)Ph_2$ may be considered to be main group analogues of *acac*. They are readily prepared and offer the opportunity to vary both the donor atoms and the R-group more easily than is the case of acac, and so are amenable to fine tuning for specific metal complexation [2]. A number of complexes of these types of ligands (including variation of phenyl groups for Me and ^{i}Pr) have been described [2–11] though less work has been reported on alkoxy based systems and mixed systems. There has recently been a report on the preparation of a mixed R, R′ system [12] but little work has been reported on mixed donor systems. Here we describe the preparation of $(EtO)_2P(S)NHP(O)Ph_2$ (**1**) and $(EtO)_2P(O)NHP(S)Ph_2$ (**2**). The X-ray structures and some coordination complexes of **1** and **2** are also reported.

EXPERIMENTAL

General

Unless stated otherwise, all reactions were performed under an atmosphere of oxygen-free nitrogen using standard Schlenk procedures. All glassware was

oven dried at 100°C or flame dried under vacuum before use.

All solvents and reagents were purchased from Aldrich, BDH or Fisons and used as received. In addition toluene, thf, Et_2O and petroleum ether (60–80) were distilled from sodium-benzophenone under nitrogen, and CH_2Cl_2 from CaH_2. $CDCl_3$ (99+ atom% D) was as supplied.

^{31}P (36.2, 101.25 MHz) were recorded on JEOL FX90Q, or Bruker AC250 spectrometers. Chemical shifts are reported relative to 85% H_3PO_4. Infra-red spectra were recorded as KBr discs a Perkin Elmer System 2000 FTIR spectrometer. Raman spectra were recorded on Perkin Elmer System 2000 FT spectrometer with a diode pumped Nd/YAG laser. Microanalyses were carried out by the respective microanalytical services of Loughborough University and Zeneca Specialties Research Centre. FAB +ve mass spectra were recorded by the EPSRC mass spectrometry service at Swansea and the mass spectrometry service at the Zeneca Specialties Research Centre.

Syntheses

$Ph_2P(S)Cl$ $Ph_2P(S)Cl$ was formed by refluxing diphenylchlorophosphine (12.30 g, 10.0 ml, 0.053 mol) with sulphur (1.70 g, 0.053 mol) overnight in toluene (30 ml) under N_2. The solvent was removed *in vacuo* off to give a clear oil (13.31 g; $^{31}P–\{^1H\}$ NMR ($CDCl_3$): δ 79.4 ppm).

$Ph_2P(C)NH_2$ $Ph_2P(S)NH_2$ was formed by bubbling NH_3 through a solution of $Ph_2P(S)Cl$ (4.0 g, 15.84 mmol) in ether (100 ml) for 20 min. After filtering the reaction mixture through celite, the filtrate was evaporated to dryness giving a white solid (3.62 g; $^{31}P–\{^1H\}$ NMR ($CDCl_3$): δ 59.7 ppm).

$(EtO)_2P(S)NH_2$ $(EtO)_2P(S)NH_2$ was formed by bubbling ammonia gas through a solution of diethylchlorothiophosphate (24.0 g, 20.0 ml, 0.127 mol) in ether (100 ml) for 20 min. After filtering the reaction mixture through celite, the filtrate was evaporated to dryness to give a clear oil (21.36 g; $^{31}P–\{^1H\}$ NMR ($CDCl_3$): δ 74.2 ppm).

$(EtO)_2P(S)NHP(S)Ph_2$ ***1*** $(EtO)_2P(S)NH_2$ (1.80 g, 10.6 mmol) was dissolved in thf (50 ml) and 3 molar equivalents of NaH (60% dispersion in paraffin oil 1.26 g, 31.2 mmol) was added slowly at 0°C. The mixture was allowed to warm to room temperature and stirred for 30 min, then $Ph_2P(O)Cl$ (2.50 g, 10.6 mmol) was added dropwise at 0°C. The mixture was stirred overnight at room temperature. Methanol (5 ml) was added dropwise to destroy any excess sodium hydride. The mixture was reduced by half under vacuum before 2 M aqueous HCl (50 ml) was added, producing a white precipitate which was extracted with dichloromethane (3×20 ml). The dichloromethane solution was dried over $MgSO_4$ then evaporated to dryness to give a yellow oil which was recrystallised from the minimum of dichloromethane and petroleum ether (40–60) yielding colourless crystals upon cooling (2.87 g, 7.77 mmol, 73.1% yield, mp 84°C). Microanalysis calculated for $C_{16}H_{21}NO_3P_2S$: C 52.0; H 5.7; N 3.8%. Observed: C 52.5; H 5.7; N 3.6%. $^{31}P–\{^1H\}$ NMR ($CDCl_3$): $\delta(P_1)$ 64.1(d), $\delta(P_2)$ 19.7 ppm. $^2J(^{31}P_1–^{31}P_2)$ 17.6 Hz. FTIR (dichloromethane solution, CsI plates at 100 microns): ν(N–H) 3342 cm^{-1}; (KBr disc): ν(N–H) not observed, δ(N–H) 1344; ν(PNP) 936, 913, 787; ν(PO) 1196, 1128; ν(PS) 607 cm^{-1}.

$(EtO)_2P(O)NHP(S)Ph_2$ ***2*** $Ph_2P(S)NH_2$ (3.62 g, 15.54 mmol) was dissolved in thf (50 ml) and 3 molar equivalents of NaH (60% dispersion in paraffin oil, 1.86 g, 46.61 mmol) was added slowly at 0°C. The mixture was allowed to warm to room temperature and stirred for 30 min, then $(EtO)_2P(O)Cl$ (2.68 g, 2.25 ml, 15.54 mmol) was added dropwise at 0°C. The mixture was stirred overnight to destroy any excess sodium hydride. The mixture was reduced by half under vacuum before 2 M aqueous HCl (50 ml) was added, producing a white precipitate which was extracted with dichloromethane (3×20 ml). The dichloromethane solution was dried over $MgSO_4$ then evaporated to dryness to give a yellow oil which was recrystallised from the minimum of dichloromethane yielding colourless crystals upon cooling (4.62 g, 12.52 mmol, 80.6% yield, mp 174°C). Microanalysis calculated for $C_{16}H_{21}NO_3P_2S$: C 52.0; H 5.7; N 3.8%. Observed: C 51.4; H 5.5; N 3.6%. $^{31}P_1–^{31}P_2$) 13.2 Hz. FTIR (dichloromethane solution, CsI plates at 100 microns): ν(N–H) 3334 cm^{-1}; (KBr disc): δ(N–H) 1315; ν(PNP) 754; ν(PO) 1186; ν(PS) 630 cm^{-1}. FT Raman (capillary sample): ν(PO) 1159; ν(PS) 616 cm^{-1}.

$Zn[(EtO)_2P(S)NP(S)Ph_2]_2$ ***3*** A solution of **1** (0.050 g, 0.135 mmol), KO^tBu (0.015 g, 0.134 mmol) and $ZnCl_2$ (0.010 g, 0.073 mmol) in thf (20 ml) was stirred for 1 hour. The mixture was then evaporated to dryness and dichloromethane added. The resulting mixture was filtered and the filtrate evaporated to dryness yielding a colourless oil. Microanalysis calculated for $C_{32}H_{40}N_2O_6P_4S_2Zn$: C 47.9; H 5.0; N 3.5%. Observed: C 46.9; H 4.9; N 3.3%. $^{31}P–\{^1H\}$ NMR ($CDCl_3$): $\delta(P_1)$ 43.4(d), $\delta(P_2)$ 21.6(d) ppm. $^2J(^{31}P_1–^{31}P_2)$ 24.2 Hz. FTIR (KBr disc): ν(PNP) 1262, 1182, 747; ν(PO) 1161, 1127; ν(PS) 562; δ(NPS) 402 cm^{-1}. FAB +ve MS: m/z 801 corresponds to $\{Zn[(EtO)_2P(S)NP(O)Ph_2]_2\}^+$.

$Zn[(EtO)_2P(O)NP(S)Ph_2]_2$ ***4*** A solution of **2** (0.050 g, 0.135 mmol), KO^tBu (0.015 g, 0.134 mmol) and $ZnCl_2$ (0.010 g, 0.073 mmol) in thf (20 ml) was stirred for 1 hour. The mixture was then evaporated to dryness and dichloromethane added which was filtered and the filtrate evaporated to dryness yielding a colourless oil. Microanalysis calculated for $C_{32}H_{40}N_2O_6S_2Zn$: C 47.9; H 5.0; N 3.5%. Observed: C 47.0; H 4.8; N 3.5%. $^{31}P–\{^1H\}$ NMR ($CDCl_3$): $\delta(P_1)$ 5.4(d), $\delta(P_2)$ 35.6(d) ppm. $^2J(^{31}P_1–^{31}P_2)$ 22.0 Hz. FTIR (KBr disc); ν(PO) 1112; ν(PS) 583; δ(NPS)

421 cm^{-1}. FAB +ve MS: *m/z* 801 corresponds to $\{Zn[(EtO)_2P(O)NP(S)Ph_2]_2\}^+$.

Pd$[(EtO)_2P(S)NP(O)Ph_2]_2$ ***5*** $Pd(cod)Cl_2$ (0.019 g, 0.067 mmol) was added to a solution of **1** (0.0.50 g, 0.136 mmol) and KO^{t}Bu (0.0.15 g, 0.134 mmol) in thf (20 ml) and stirred for 1 hour, changing colour from yellow to red/orange. The mixture was then evaporated to dryness and dichloromethane added. After filtration the filtrate was evaporated to dryness giving a dark red oil. Microanalysis calculated for $C_{32}H_{40}N_2O_6P_4S_2Pd$: C 45.6; H 4.8; N 3.3%. Observed: C 45.4; H 5.0; N 3.1%. $^{31}P-\{^1H\}$ NMR ($CDCl_3$): $\delta(P_1)$ 58.6(d), $\delta(P_2)$ 21.8(d) ppm. $^2J(^{31}P_1-^{31}P_2)$ 13.4 Hz. FTIR (KBr disc): *v*(PNP) 1240; *v*(PO) 1126; *v*(PS) 547 cm^{-1}. FAB +ve MS: *m/z* 843 corresponds to $\{Pd[(EtO)_2P(S)NP(O)Ph_2]_2\}^+$.

Pt$[(EtO)_2P(S)NP(O)Ph_2]_2$ ***6*** $Pt(cod)Cl_2$ (0.020 g, 0.053 mmol) was added to a solution of **1** (0.039 g, 0.106 mmol) and KO^{t}Bu (0.012 g, 0.107 mmol) in thf (20 ml) and refluxed for 1 hour, changing colour from colourless to a yellow solution. The mixture was then evaporated to dryness and dichloromethane added. After filtration the filtrate was evaporated to dryness giving a yellow oil. Microanalysis calculated for $C_{32}H_{40}N_2O_6P_4S_2Pt$: C 41.3; H 4.3; N 3.0%. Observed: C 41.9; H 4.3; N 2.6%. $^{31}P-\{^1H\}$ NMR ($CDCl_3$): $\delta(P_1)$ 65.3(d), $\delta(P_2)$ 19.7(d) ppm. $^2J(^{31}P_1-^{31}P_2)$ 18.7 Hz. No $^2J(^{31}P-^{195}Pt)$ coupling was observed that could confidently be assigned or calculated. FTIR (KBr disc): *v*(PNP) 1259, 1161; *v*(PO) 1125; *v*(PS) 548 cm^{-1}. Crystallography

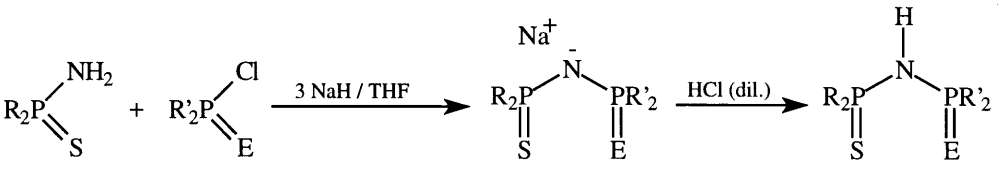
Details of crystallographic parameters are summarised in Table 1. Crystals were mounted on quartz fibres using araldite. Data were collected using Cu–Kα radiation and ω scans at room temperature with a Rigaku AFC7S diffractometer. Intensities were corrected for Lorentz-polarisation and for absorption. In **1** there are two independent molecules, one of which exhibits some slight disorder in the positions of the oxygen and its adjacent carbon atom in one of the ethoxy groups; the disorder was resolved into two sites (occupancies 70/30) and the lower occupancy sites were refined isotropically. The remaining non-H atoms were refined anisotropically. The positions of the C–H hydrogen atoms were idealised whilst the N–H atoms were allowed to refine isotropically. Refinements were by full matrix least squares based on *F* using teXsan [13]. The weighting scheme is as previously reported [3].

RESULTS AND DISCUSSION

The synthesis of **1** and **2** are based upon a literature preparation [14] for compounds with mixed substituent groups. The amine and halide are "clipped"



for R = Ph, R' = EtO. R = EtO, R' = Ph. E = S / O

together with sodium hydride in thf. Silvestru and coworkers recently reported [12] the use of BuLi for this reaction but we have found that NaH is more convenient, less costly and allows for the reactions to be more readily scaled up. It should be noted that (in contrast to S,S systems) the mixed S/O compounds are unstable to heat. Characteristic bands [11] were observed in the FTIR, ν(NH) *ca.* 3300, δ(NH) 1344–1315, ν(PO) 1196–1186, ν(PNP) 976–936, 787–754 and ν(PS) 646–630 cm^{-1}.

The ^{31}P NMR spectra ($CDCl_3$, Table 2) are of the AX type. As expected the δ values of the $R_2P(S)$ part of **1** and **2** are quite close to those of the starting amines. Furthermore changing P═S for P═O results in a shift to lower frequency (as is the case in EPR_3 systems) though this is far more pronounced for the EtO substituted phosphorus than for the Ph substituted phosphorus atom. The larger differences seen in the case of **2** may be due to the greater electron withdrawing effect of the EtO group or it may reflect some difference in the tautomeric form in solution. Another noticeable difference between **1** and **2** is in the magnitude of the $^2J(^{31}P–^{31}P)$ coupling which is considerably less in **2** and this may relate to the P–N–P angle which is smaller (and closer to trigonal) in the crystal structure of **1**.

In the solid state structure of **1** there are two crystallographically independent molecules. In both of these the P═S and P═O groups are in a *gauche* or *cisoid* orientation (Figure 1, Table 3) with SP...PO torsion angles of 79.5 and -69° (i.e. the P═O and P═S groups are rotated in opposite directions in the two crystallographically independent molecules). The molecules form a hydrogen bonded chain similar to that observed in ($^iPR_2P(S)NHP(S)^iPr$ [11]. On electronic grounds the hydrogen bonding is through the oxygen but the factors that favour chain rather than dimer formation (as was the case in $Ph_2P(S)NHP(S)Ph_2$) are not obvious. The P(2)–S(1) bond lengths at 1.895(3)/1.921(2) Å are slightly shorter than previously observed P–S bonds [2] and the P(2)–N(1) bond length average value of 1.66 A is normal for these type of systems. The P(1)–O(1) bond lengths are 1.476(3)/1.484(3) Å and the P–N–P angles are 122.6(2) and 127.2(2)°; the former angle is the smallest P–N–P angle observed by us for any imidodiphosphinate. As mentioned above the molecules pack into chains with the two molecules in the asymmetric unit alternating throughout the chain length; the details of the H-bonding in the chain are given in Table 3.

2 was found to be a typical *trans* dimer (Figure 2, Table 3) with an SP...PO torsion angle of 172.3°. As expected on both steric and electronic grounds the hydrogen bonding contact to form the dimer is thorough the P═O oxygen atoms, with the phenyls substituents on the pendant phosphorus. The P(1)–S(1) bond length is 1.931(1) Å and the P(2)–O(1) bond length is 1.475(2) Å. The P(2)–N(1) bond length of

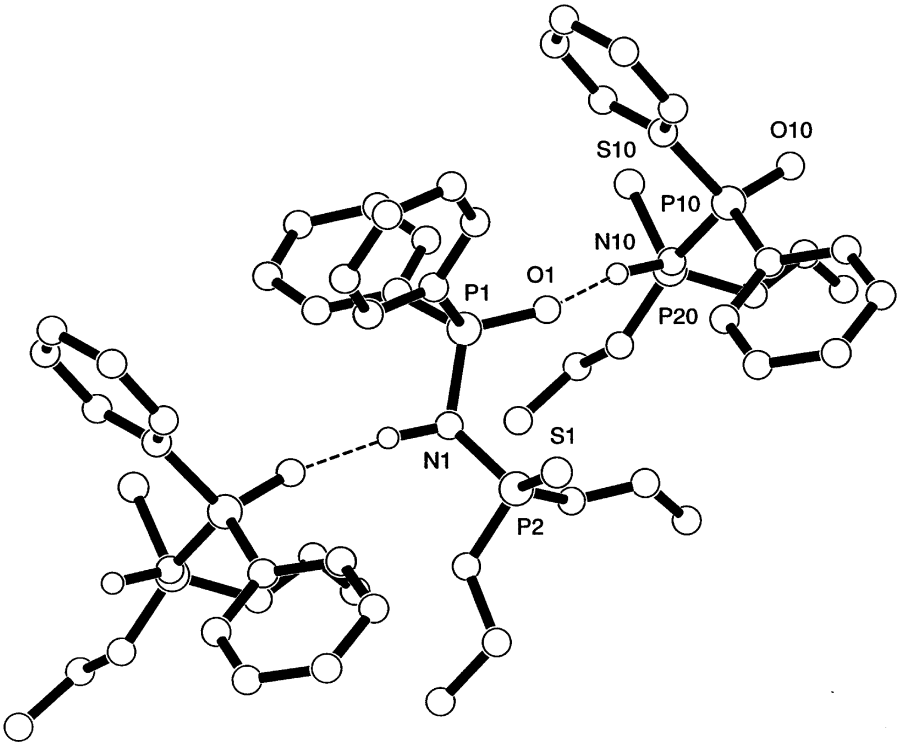

Fig. 1. The solid state structure of $(EtO)_2P(S)NHP(O)Ph_2$ **1** showing the H-bonded chain structure.

1.632(3) Å is short compared to the P(1)–N(1) length of 1.679(3) Å and suggests that there may be some degree of localisation — this would be in accord with the ^{31}P NMR observations mentioned above. As one would expect from the P═O...P═S torsion angle, the molecules in **2** pack into dimer pairs via N–H...O–H-bonds.

It is interesting to note (Table 3) how short the P–S bond length is for **1** (1.90 Å) in comparison to those for the other compounds (*ca.* 1.94 Å) and this can be rationalised as a consequence of the electron withdrawing ethoxy groups. Further support for this argument is that the shortest P–O bonds are observed in **2**. The varying S–P...P–E torsion angles in these types of system cannot be readily explained by steric effects alone, both $(EtO)_2P(S)NHP(S)Ph_2$ and **2** contain phenyl substituted phosphorus with a sulphur donor atom, yet their torsion angles are 87.0 and 172.3° in contrast to the angle of 79.5 and −69° for **1**. Further MO and molecular modelling studies are in progress.

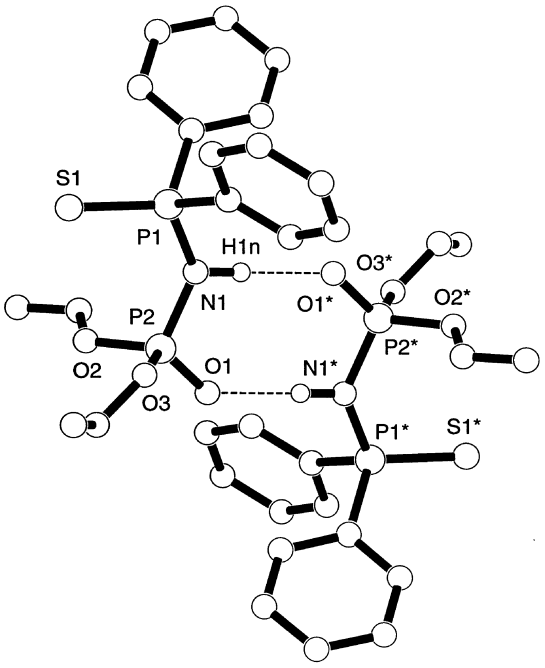

Fig. 2. The solid state structure of $(EtO)_2P(O)NHP(S)Ph_2$ **2** showing the H-bonded dimer.

One mole of zinc chloride and two moles of KO^{t}Bu were stirred at room temperature with two moles of **1** or **2** in thf. The solvent was then evaporated off, dichloromethane added and the mixture was filtered. The filtrate was evaporated to dryness yielding in each case an opaque white oil. For $Zn[(EtO)_2P(O)NP(S)Ph_2]_2$ (**4**) the oil yielded a small amount of crystals from the minimum of dichloromethane at −10°C which were subsequently studied by single crystal analysis. All complexes gave reasonable elemental analyses and the FAB +ve mass spectra revealed the expected parent ions for **3** $Zn[(EtO)_2P(S)NP(O)Ph_2]_2$. Characteristic bands were observed in the FTIR. Again the characteristic shifts in the ν(PNP) vibration from around 950 to 1239–1262 cm^{-1}, the ν(PO) band from around 1190 to 1050 cm^{-1} and the ν(PS) vibration from 640 to 552–583 cm^{-1} all signify the change in bond order within the ligand due to the delocalisation of the negative charge (Table 4).

The ^{31}P NMR Table 2 are of the AX type. The shift of the ethoxy substituted phosphorus of **4** increases by 5 ppm upon coordination/deprotonation. Furthermore the ^{2}J phosphorus coupling in **4** increases by 9 Hz relative to **2**. In contrast the shift of the phenyl substituted phosphorus of **3** has increased by only 1 ppm and the ^{2}J phosphorus coupling increases by 6.5 Hz.

The X-Ray structure of **4** (Figure 3) reveals the expected tetrahedral coordination at zinc (the zinc atom lies on a crystallographic twofold axes and the molecule has crystallographic twofold symmetry). The P–S and P–O bonds lengthen and the P–N bonds shorten upon deprotonation/coordination (as expected from the increase in the frequency of the ν(PNP) vibration in the FTIR). The Zn–S bond is *ca.* 0.025 Å shorter for **4** than for $Zn(^iPr_2P(S)NP(S)iPr_2)_2$ [11] whilst the S–P–N angles compare well. The S–P–N and O–P–N angles for **4** are equal to each other whilst the P–N–P angle increased by 4° upon coordination. The Zn–S–P angle is 98.0(1)°, unexpectedly low for this type of ring in a tetrahedral complex, [9° less than the analogous angle is in $Zn(^iPr_2P(S)NP(S)iPr_2)_2$]. Such a small angle has only previously been observed for square planar complexes with an MS_2P_2N ring in the "chair" conformation. In contrast the Zn–O–P angle at 129.0(2)° is very large. The six-membered ring is folded, with the Zn–P(1)–

Table 4. Selected bond lengths (Å) and angles (°) for $Zn[(EtO)_2P(O)NHP(S)Ph_2]_2$ **4** and $Zn(^iPr_2P(S)NP(S)iPr_2)_2$ [11] (this latter compound is in the space group $I4_1/a$

	4 $Zn[(EtO)_2P(O)NP(S)Ph_2]_2$	$Zn(^iPr_2P(S)NP(S)iPr_2)_2$ [11]

O(1)–Zn–O(1*)	104.7(2)	
S(1)–Zn–S(1*)	117.4(1)	108.0(1)
Zn–S(1)–P(1)	98.0(1)	107.1(1)
Zn–O(1)–P(2)	129.0(2)	

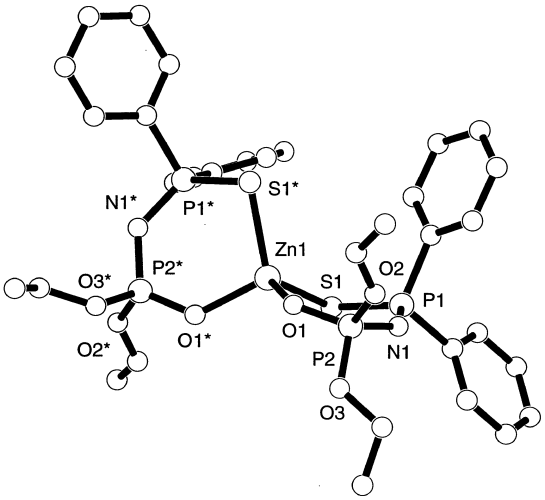

Fig. 3. Solid state structure of $Zn[(EtO)_2P(O)NP(S)Ph_2]_2$ **4**.

S(1) plane being inclined by 33° to the Zn–P(1)–N(1)–P(2)–O(1) plane [max deviation from this plane is 0.05 A for N(1)] and unlike most previous examples is not readily categorised as "chair" or "boat".

One mole of $M(cod)Cl_2$ (M = Pd, Pt) and two moles of KO^tBu were stirred at room temperature with two moles of **1** or **2** in thf. The solvent was then evaporated off and after the addition of dichloromethane the mixture was filtered. The filtrate was evaporated to dryness yielding deep red oils for the palladium complexes and yellow oils for the platinum complexes. Satisfactory elemental analyses were observed for all complexes and expected parent ions in the FAB +ve mass spectra were observed for the palladium complexes $Pd[(EtO)_2P(S)NP(O)Ph_2]_2$ (**5**) and $Pd[(EtO)_2P(O)NP(S)Ph_2]_2$ (**7**) at 843 m/z, and the platinum complexes $Pt[(EtO)_2P(S)NP(O)Ph_2]_2$ (**6**) and $Pt[(EtO)_2P(O)NP(S)Ph_2]_2$ (**8**) at 932 m/z. Bands observed in the FTIR for ν(PNP) were 1206–1259 cm^{-1}, ν(PS) were 539–570 cm^{-1}. The ^{31}P NMR of **5**–**8** are of the simple AX type and the chemical shifts follow the pattern seen in **3** and **4** except in the case of **7** which contains two AX spectra. Possible structures are shown in Fig. 4; the most likely explanation is the presence of *cis* and *trans* isomers of the square planar complex. However we cannot exclude a "chair"/"boat" equilibrium of the PdS_2P_2N rings or the possibility that coordination occurs through the sulphur and nitrogen atoms Fig. 4, similar to the reported palladium complex $Pd[(PhO)_2P(S)NP(O)(OPh)_2]_2$ [15].

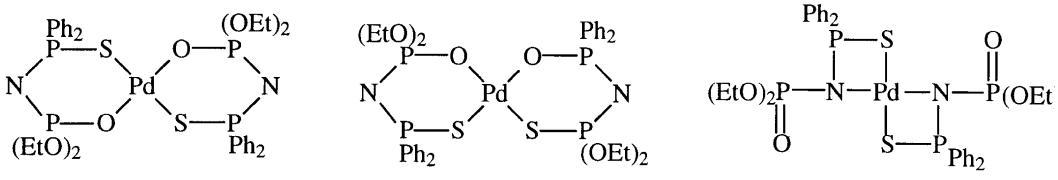

Fig. 4. Possible structures for $Pd[(EtO)_2P(O)NP(S)Ph_2]_2$.

EPR characterisation of nickel(III) complexes with N_2O_2 Schiff base ligands derived from naphthaldehyde and their pyridine adducts

Cristina Freire and Baltazar de Castro*

CEQUP/Departamento de Química, Faculdade de Ciências, Universidade do Porto, 4150 Porto, Portugal

(Received 30 April 1998; accepted 8 June 1998)

Abstract—Nickel(II) complexes with quadridentate N_2O_2 Schiff base ligands derived from naphthaldehyde have been synthesised and their oxidative chemistry was studied in *N*,*N*′-dimethylformamide and in dimethylsulfoxide. Electrochemical and EPR data for the oxidised solutions have revealed that in these strong co-ordinating solvents, only the complexes with aliphatic imine bridges were oxidised to low spin six-coordinate nickel(III) complexes, in a $^2A_1(d_{z^2})$ ground state, formulated as $[Ni(III)(L)\cdot S_2]^+$, where S stands for a solvent molecule. Upon addition of pyridine to fluid solutions of $[Ni(III)(L)\cdot S_2]^+$, new species were formed that on the basis of their EPR spectra can be formulated as $[Ni(III)(L)\cdot py_2]^+$. Extensive electronic characterisation of the Ni(III) compounds was made by coupling EPR and electronic spectroscopic data. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel(II); nickel(III); Schiff base complexes; oxidative chemistry; EPR

INTRODUCTION

High and low valent nickel chemistry has attracted increased attention as it has become clear that these oxidation states are biologically significant [1–3] and their complexes may also be used as catalysts in several redox reactions [4–8]. We have been interested in the study of nickel(I) and (III) complexes with polydentate ligands with mixed co-ordination spheres [9–16], the main purposes of the ongoing work centres on the identification of the factors that control the oxidation/reduction site in these complexes, the determination of their redox potentials and the characterisation of their electronic structure.

Nickel(II) complexes with quadridentate N_2O_2 Schiff base ligands have been know for a long time [17] and our interest in the chemistry and reactivity of their +3 oxidation state has led us to perform a systematic investigation on their oxidative chemistry. In a previous paper we reported the redox properties and electronic characterisation of a series of nickel(II) complexes with salicylaldehyde based ligands [9]. We have now extended this study to a group of nickel(II) complexes with Schiff base ligands derived from naphthaldehyde, in order to assess the contribution of unsaturation in the aldehyde moiety to the strength of equatorial/axial ligand fields, and to the stabilisation of the +3 oxidation state for nickel.

In the present work we report the preparation of nickel(II) complexes with ligands derived from naphthaldehyde with aromatic imine bridges, and on the oxidative chemistry of these and similar complexes with aliphatic amine bridges studies in *N*,*N*′-dimethylformamide and dimethylsulfoxide; the complexes were oxidised by controlled potential electrolysis and their pyridine adducts were also prepared. Extensive electronic characterisation of the Ni(III) species was obtained by coupling EPR and electronic spectroscopic data and the results are compared with those for similar complexes with ligands derived from salicylaldehyde [9] (Scheme 1).

RESULTS AND DISCUSSION

Structural and electronic structure for nickel(II) complexes

The X-ray structure and electronic characterisation, in nujol and Me_2SO, of the complexes [Ni(napen)]

Scheme 1.

[11, 18], [Ni(nappd)] [11, 19] and [Ni(naptMe)] [11] have already been published and the results are included to provide a coherent framework for the overall study reported here. The co-ordination geometry around the metal atom is square planar, with the ligand bound through the nitrogen and oxygen atoms in a N_2O_2 *cis*-configuration. The coordination sphere is unchanged in Me_2SO for [Ni(napen)] and [Ni(naptMe)], but incipient axial co-ordination of solvent molecules occurs for [Ni(nappd)] upon solubilization, as suggested by the bathochromic shift observed for the *d–d* bands [11]. Electronic spectra of [Ni(napen)] and [Ni(naptMe)] in DMF are similar to those in Me_2SO and also suggest the invariance of their structure in this solvent, but for [Ni(nappd)] a similar shift of the band maxima is observed, implying that incipient axial co-ordination also occurs in DMF.

No crystals of diffractometric quality could be obtained for [Ni(napph)] and [Ni(napphCl_2)]; however, we propose a square planar sphere in solid and in solution for these complexes, as for the ones with salicylaldehyde based ligands on the basis of the similar absorption spectra [11, 12, 20].

Spectra of all complexes, in both solvents and in the solid, show several very intense bands at low wavelengths that are assigned to charge transfer transitions [21–23]. Those of complexes with aliphatic bridges show also a weaker band 530–600 nm, that is assigned to the unresolved transitions from the four low-lying d orbitals to the empty d_{xy} orbital [21–23]. This latter band is not observed for complexes with aromatic bridges, as it is masked by the high intensity charge transfer transitions that, due to the larger planar π-system of the ligands, occur at longer wavelengths.

The energy of the *d–d* transitions can provide a rough estimate of ligand field strength, since one of the electronic transitions comprised in the band envelope is $d_{xy} \leftarrow d_{x^2-y^2}$ and the energy associated with this transition is 10 Dq-C [21–23]. Analysis of the energy of *d–d* transitions for complexes with aliphatic bridges, shows that an increase in the number of bridging carbon atoms is associated with a decrease in ligand field. In this context, as [Ni(nappd)] has the largest Ni–N and Ni–O distances of all structures, the weaker equatorial ligand field must be responsible for the axial co-ordination of solvent molecules.

As the energies of *d–d* transitions are similar to those of the homologous complexes with ligands derived from salicylaldehyde [9], the ligand field for both type of complexes is of the same magnitude. However, charge transfer bands occur at longer wavelengths for the complexes reported in this work, a consequence of the replacement of the salicylaldehyde by the naphthaldehyde moiety.

Cyclic voltammetry of nickel(II) complexes

In Table 1 is summarised the electrochemical data for all complexes, including those for [Ni(napen)], [Ni(naptMe)] and [Ni(nappd)] in Me_2SO, which have been published previously [11]. In both solvents, [Ni(napph)] is irreversibly oxidised and [Ni(napphCl_2)] does not show any charge transfer process within the potential range studied; no further studies were pursued with these complexes. The other compounds exhibit in DMF one oxidation process in the potential window studied, with $E_{1/2}$ (vs Ag/AgCl) varying from 0.78 to 0.95 V. With increasing scan rate

Table 1. Cyclic voltammetric results for nickel(II) complexes in DMF and Me_2SO (0.1 mol dm^{-3} TEAP) at 25°C[a]

Complex	In DMF						In Me_2SO					
	Ag/AgCl (1 mol dm^{-3} NaCl)				Fc^+/Fc		Ag/AgCl (1 mol dm^{-3} NaCl)				Fc^+/Fc

[Ni(napophCl_2)]	[e]						[e]					

[a] All potentials in V. Solute concentration $\approx 10^{-3}$ mol dm^{-3}; scan rate = 0.05 V s^{-1}; E_{pa} and E_{pc} are the anodic and the cathodic peak potentials, respectively; $\Delta E = E_{pa} - E_{pc}$; $E_{1/2} = 1/2(E_{pa} + E_{pc})$. Under the conditions used, $E_{1/2}$ (Fc^+/Fc) is 0.50 V in DMF and 0.48 V in Me_2SO.

[b] The ratio i_{pc}/i_{pa} in DMF decreases for scan rates lower than 0.04 V s^{-1}, while in Me_2SO this behavior is observed only for scan rates lower than 0.01 V s^{-1}.

[c] Data in Me_2SO from Ref. [11].

[d] Cyclic voltammograms do not show the corresponding cathodic wave.

[e] No electrochemical processes were detected in the potential range used.

(v) a linear dependence is observed between i_p and $v^{1/2}$ and between E_p and i_p; moreover, the anodic–cathodic peak potential separation [ΔE(DMF) = 0.10–0.12 V] is similar to that observed for the couple Fc^+/Fc, for which a diffusion controlled one electron reversible process is assumed. Furthermore, the ratio i_{pc}/i_{pa} is scan rate dependent and reaches values near 1 only for scan rates faster than 0.04 V s^{-1}.

Electrochemical data in DMF is consistent with the one electron reversible oxidation process Ni(II)→ Ni(III) (see below), which is followed by a chemical decomposition path of the electrogenerated Ni(III) species [24], as has been observed in Me_2SO [11, 13]. However, in DMF the decomposition rates of oxidised species are faster than in Me_2SO, as supported by the observation that the ratio i_{pc}/i_{pa} approaches 1 only for scan rates faster than in Me_2SO.

Dependence of redox potentials on the solvent As has been found for salicylaldehyde related complexes [9, 10], redox potentials show a cathodic shift with an increase in the donor capacity of the solvent, due to the co-ordination of solvent molecules that occurs concomitantly with oxidation of the square planar Ni(II) complexes. The cathodic shift in the redox potentials on going from DMF to Me_2SO is thus attributed to stronger axial bonds that are established between nickel(III) and the molecules of the better donor and this helps to stabilise the high oxidation state of the metal (see below).

Dependence of redox potentials on the ligand For complexes with aliphatic imine bridges no significant differences are observed between $E_{1/2}$ for complexes derived from naphthaldehyde and salicylaldehyde, implying that the change of the aldehyde moiety apparently does not induce great changes in the metal electronic density. However, when the imine bridge is aromatic, the electrochemical behaviour changes significantly: complexes with ligands derived from naphthaldehyde do not show any reversible oxidation process, in contrast with their related *saloph* derivatives [9]. This behaviour can be accounted for by invoking larger π delocalization in the former complexes that would (i) ease electron-density delocalisation from the metal to the ligand and (ii) impart higher rigidity to the planar four-dentate ligand system, thus hindering a contraction of the hole cavity, and making it harder to oxidise the metal ion [25–28].

Introduction of methyl groups in the imine bridge, produces an anodic shift in the redox potential relative to that of [Ni(napen)] as was observed in the homologous compounds derived from salicylaldehyde [9]. Based on X-ray data obtained for [Ni(naptMe)] this observation is consistent with the interpretation that steric hindrance on axial binding sites, imposed by the axially oriented methyl groups of the imine bridge, decreases stabilisation of Ni(III) by co-ordinated solvent molecules [11, 29].

Electronic data for [Ni(nappd)] indicate incipient axial co-ordination of solvent molecules takes place and accordingly the low $E_{1/2}$ values for this complex can be explained by invoking its greater tendency to bind axial solvent molecules in the +2 oxidation state, thus facilitating the oxidation process/formation of six-coordinate Ni(III) complexes.

EPR spectra of electrogenerated nickel species and pyridine adducts

Electrochemical oxidation of the Ni(II) complexes produces a change in solution colour from reddish to dark brown, implying formation of new species. EPR

spectra of fluid electrolysed solutions exhibit a single broad line, with g_{iso} in the range 2.197–2.210 in DMF and 2.182–2.192 in Me_2SO, an indication of a metal-centred oxidation process and consequently of the presence of Ni(III) species in solution. Oxidised complex solutions decay, at room temperature, to EPR silent solutions; the decomposition rates are dependent on the ligand, but are always faster in DMF (half-lives of ≈ 7 min) than in Me_2SO (half-lives up to 30 min). The decay in DMF is significantly reduced at $-20^{\circ}C$, at which temperature half-lives similar to those in dimethylsulfoxide are observed. Samples are stable in both solvents for several days when kept frozen in liquid nitrogen.

Frozen solution EPR spectra of electrolytically generated nickel Ni(III) complexes show rhombic symmetry and large g tensor anisotropy and are typical of low-spin ($S=1/2$) Ni(III) complexes [30–38]. No hyperfine splitting could be detected in any of the three g regions [Figure 1(a)].

In the absence of EPR crystal data for the Ni(III) complexes studied, the observed similarity between their g features and those of analogous nickel(III) and cobalt(II) compounds [9–13, 39] can be extended to support the following orientation scheme for the tensor axes of the nickel complexes: $g_1=g_x, g_2=g_y, g_3=g_z$, where g_1 and g_3 refer to the lowest and highest magnetic field g values, respectively. EPR data for Ni(III) species in DMF and in Me_2SO are summarised in Table 2.

Addition of pyridine to freshly prepared solutions of Ni(III) complexes in Me_2SO, at room temperature and in DMF at temperatures just above the softening point of the frozen glass, originates new species in solution as can be inferred from the rapid colour change of the solutions to yellow red in the first solvent and to yellow brown in the latter solvent.

Frozen solutions of pyridine adducts are EPR silent in Me_2SO, but in DMF they exhibit EPR spectra of rhombic type, although with less rhombicity than the parent complexes, with g_{av} in the range 2.130–2.142, and with hyperfine couplings in all g regions. The existence of one well resolved quintuplet ($a=2.14$–2.27 mT) in the region of higher magnetic field and of

[c] g_{iso} was obtained from fluid solution EPR spectra at 233 K.
[d] ΔQ is the difference between the average energy of the quartet states and the ground state.
[e] g values from Ref. [11].
[f] It was not possible to obtain fluid solution EPR spectra, see text.

two non-resolved quintuplets in the two other g regions, imply the existence in DMF of six-co-ordinate Ni(III) species with two pyridines molecules bound axially [Figure 1(b)]. The similarity between the g patterns of these species with those obtained in the absence of pyridine, supports the same orientation scheme for the tensor axes of the pyridine adducts. EPR parameters for $[Ni(L)\cdot py_2]^+$ are summarised in Tables 2–3.

No EPR signals could be detected in fluid solutions of pyridine/DMF, even at temperatures just above the freezing point of the solution. This result combined with the observation that pyridine adducts in Me_2SO are also EPR silent indicate that Ni(III) pyridine adducts have very short life times in fluid solutions.

Electronic spectra of nickel(III) species

Electronic spectral data for Ni(III) species in Me_2SO are included in Table 4; no data are included for DMF solutions, as decomposition of the Ni(III) species is faster in this solvent and only very weak bands could be observed.

Room temperature electronic spectra of oxidised solutions are very similar to those of Ni(III) complexes with ligands derived from salicylaldehyde [9, 10] and show a very broad band in the near-IR region, $880\,nm < \lambda_{max} < 1040\,nm$, with molar extinction coefficient values in the range 850 to 900 $l\,mol^{-1}\,cm^{-1}$. For some complexes, a band at higher energies could also be observed ($640\,nm < \lambda_{max} < 680\,nm$, $\varepsilon = 790$–

$[Ni(naptMe)(Me_2SO)_2]^+$	960, (900); br	680, (790); s	900	1080	680	393

[a] Band maxima expressed in nm; molar extinction coefficients, in parenthesis, expressed in $mol^{-1}\,dm^3\,cm^{-1}$; br = broad; s = shoulder.

[b] Values obtained by deconvolution of the experimental absorption spectra.

[c] ξ values calculated to get the best fit between the transition energies obtained from electronic spectra and calculated from EPR parameters.

[d] Obscured by high intensity charge transfer bands.

$8201\,mol^{-1}\,cm^{-1}$), but only discernible as a shoulder on a very intense charge transfer absorption band ($380\,nm < \lambda_{max} < 420\,nm$, $\varepsilon = 6800$–$7500\,l\,mol^{-1}\,cm^{-1}$) No electronic spectra for $[Ni(L)\cdot py_2]^+$ could be obtained under the experimental conditions used, since their lifetimes in fluid solution were not long enough to allow the recording of electronic spectra.

Electronic structure of the nickel(III) species

We assume that Ni(III) pyridine adducts have an almost planar equatorial N_2O_2 environment [C_{2v}(x) symmetry], as in the Ni(II) square planar precursor complexes [22, 23]. From the observations that $g_z < g_x$, g_y and that the larger N-hyperfine splittings (Nhfs) are observed in the g_z component, it can be concluded that the unpaired electron must lie in an orbital which is predominantly $d^2{}_z$, implying a $^2A_1$ ground state; since in this symmetry $^2A_1 = a d_{z^2} + b d_{x^2-y^2}$, then $a \gg b$ [40].

This ground state has been observed in the majority of known six-co-ordinate Ni(III) complexes [9–12, 30–38] and the same ground state is assumed for nickel(III) complexes in pure solutions of DMF and Me_2SO, as the patterns of g values are very similar to those of $[Ni(L)\cdot py_2]^+$; nickel(III) complexes in pure solutions are thus formulated as $[Ni(L)\cdot S_2]^+$ [S = DMF, Me_2SO].

None of the Ni(III) species exhibit EPR spectra in which hyperfine splitting due to in-plane nitrogen ligand atoms could be observed. The same is found for analogous Ni(III) and Co(II) complexes and has been interpreted as to imply that these are only weak delocalisation of unpaired spin density to the π system of the equatorial ligand [39–41].

Electronic band assignment was made using the d-orbital ordering $d_{xy} > d_{z^2} > d_{xz}, d_{yz} > d_{x^2-y^2}$ proposed by Hitchman *et al.* for the related Co(II) *salen* complexes [41, 42], which has been used in Ni(III) complexes derived from salicylaldehyde [9, 10] and assuming that: (i) the high intensity bands in the visible region is due to allowed charge transfer transitions from ligand to Ni(III) (superimposed on charge transfer bands to nickel(II), as the electrolysis were not complete; see above) and (ii) the two medium intensity bands in the near infrared region can be assigned to Ni(III) *d–d* transitions. Deconvolution of the broad band yielded two bands at slightly different energies Table 4 that are assigned to the electronic transitions, $d_{xz} \leftarrow d_{z^2}$ ($^2B_1 \leftarrow {}^2A_1$) and $d_{yz} \leftarrow d_{z^2}$; ($^2A_2 \leftarrow {}^2A_1$). The shoulder in the visible region must correspond to the $d_{xy} \leftarrow d_{z^2}$ ($^2B_2 \leftarrow {}^2A_1$) transition.

Analysis of the EPR parameters using the model developed by McGarvey for d^7 systems with a $^2A_1(d_{z^2})$ ground state [40], in conjunction with the approximation suggested by Raynor [43, 44] can provide additional information on the electronic structure of Ni(III) species. The equations for the g tensor are [10]:

$$g_z = 2.0023 + 2C^2{}_3 + 3C_1C_2 - 3C^2{}_2 - 3C^2{}_1 \quad (1a)$$

$$g_x = 2.0023 + 2C^2{}_3 - 3C_1C_2 - 3C^2{}_1 + 6C_2 \quad (1b)$$

$$g_y = 2.0023 + 2C^2{}_3 - 3C_1C_2 - 3C^2{}_2 + 6C_1 \quad (1c)$$

where $C_1 = \xi/\Delta(^2B_1)$, $C_2 = \xi/\Delta(^2A_2)$ and $C_3 = \xi/\Delta(^4B_2)$; $\Delta(^n\Gamma_i)$ is the energy difference between the $^n\Gamma_i$ excited state and the ground state ($^2A_1$) and ξ is the one electron spin orbit coupling constant. C_1 and C_2 yield approximate values for the energies of the excited states $^2B_1$ and $^2A_2$ relative to that of the ground state $^2A_1$.

An estimate for the spin orbit coupling constant can be obtained by finding the value of ξ that minimises the differences between the values of $\Delta(^2B_1)$ and $\Delta(^2A_1)$ obtained by EPR spectra analysis and those from the electronic spectra. In Me_2SO, the values so obtained indicate a reduction of the spin orbit coupling constant of 50% for complexes with *nappd*, and of 55% for the other complexes (Table 4). Values for the latter complexes are comparable with those with ligands derived from salicylaldehyde with aliphatic bridges, whereas ξ for [Ni(nappd)] is similar to those of salicylaldehyde with aromatic bridges [9, 10].

For complexes with axially bound DMF and pyri-

dine, it was not possible to estimate spin orbit coupling constants using the procedure described above, as their electronic spectra could not be recorded and the energy of excited states was calculated using the spin orbital coupling constants in Me_2SO.

A knowledge of ξ and C_3 enables an estimate of the (average) energy of low-lying excited quartet states (ΔQ) and in Table 2 are included the calculated values of $\Delta(^2B_1)$, $\Delta(^2A_1)$ and ΔQ for $[Ni(L)\cdot(DMF)_2]^+$, $[Ni(L)\cdot\{Me_2SO)\}_2]^+$ and $[Ni(L)\cdot(py)_2]^+$. The importance of quartet states to the spin Hamiltonian parameters must be stressed, as their calculated (average) values are non-negligible, typically in the range of 2880–3990 cm^{-1} above the ground state.

As in a previous paper [9], we will use the results of Hitchman [41, 42] to analyse the factors that affect the electronic structure of nickel(III) complexes with ligands derived from naphthaldehyde. Data in Tabs. 2–3 show the energy of the doublets to be more dependent on the axial ligand, whereas that of quartet states on the equatorial ligand, as predicted by Hitchman.

Effect of the axial co-ordination on the energy of excited states No correlation between the energy of excited quartets and axial ligation could be found. The energy of the doublets does not change significantly when the solvent is varied from DMF to Me_2SO, but co-ordination of pyridine increases significantly the energy of the excited doublets, due to stronger interaction of the axial ligands with the d_{z^2} orbital. In fact, raising the energy of d_{z^2} relative to d_{yz} and d_{xz} would decrease C_2 and C_1 and, neglecting second-order terms, eqs. (1a, 1b, 1c) can be expressed as $g_x = 2.0023 + 6C_2$ and $g_y = 2.0023 + 6C_1$, and thus accounts for the observed decrease in g_x and g_y.

Effect of the equatorial ligand on the energy of excited states Data in Table 2 reveal, that for each axial ligand, $[Ni(nappd)\cdot L]^+$ has the lowest energy for both doublet and quartet states, $[Ni(napen)\cdot L]^+$ has the highest energy doublets and $[Ni(naptMe)\cdot L]^+$ exhibits the highest energy quartet states. Furthermore, as the energy of the quartet states are directly related to the in-plane ligand field [41, 42], it is possible to infer that $[Ni(nappd)\cdot L]^+$ and $[Ni(naptMe)\cdot L]^+$ exhibit the weaker and stronger equatorial ligand field, respectively.

To circumvent the lack of structural data for Ni(III) complexes needed to support the aforementioned correlation we will make use of the corresponding data of the Ni(II) precursor complexes. [Ni(naptMe)] has the shortest Ni–N and Ni–O bond distances [11], therefore the smaller cavity, whereas [Ni(nappd)] has the longest bond lengths [19] and the larger cavity. As oxidation of the metal centre induces a decrease in ionic radius, it is to be expected that ligands with large bite will be less prone to adjust the hole cavity to the size of the metal ion, and therefore the same pattern for bond lengths is expected for the Ni(III) complexes. In fact, structural data for the homologous Ni(II) complexes correlate with the observation that $[Ni(naptMe)\cdot L]^+$ and $[Ni(nappd)\cdot L]^+$ have the stronger and weaker equatorial ligand field, respectively. On the other hand, the steric constraint imposed by the methyl groups of the imine bridge on the axially coordinate solvent molecules explain the higher energy for the doublets of $[Ni(napen)\cdot L]^+$, as compared with those of $[Ni(naptMe)\cdot L]^+$.

As the energy of the excited states for the Ni(III) complex with *napen* and *naptMe* are slightly larger than those of the homologous complexes with ligands derived from salicylaldehyde, it can be concluded that the in-plane ligand fields of the naphthaldehyde based complexes are stronger. The excited state energy pattern for *nappd* and the values of ξ are similar to those of salicylaldehyde based complexes with aromatic imine bridges. It is tempting to relate these similarities with structural data from the precursor Ni(II) complexes. In [Ni(nappd)] and in complexes with *saloph*-derived ligands, Ni–N bond lengths (1.871 Å) are longer than Ni–O (1.866 Å), as opposed to what is found in naphthaldehyde- and *salen*-based compounds, for which $d(Ni–N) < d(Ni–O)$ [11, 12, 45–48]. Stronger O-donor in-plane interaction with Ni(III) can thus be invoked for [Ni(nappd)], in contrast to the latter complexes for which the stronger in-plane interaction occur with N-donor atoms.

Nitrogen hyperfine tensor and spin density on nitrogen atoms of axial bound pyridines

The 2s and 2p spin densities, the ratio p:s ($\lambda^2 = C^2_{2p}/C^2_{2s}$) and the total spin density delocalised onto the axially bounded pyridine have been calculated by procedures described elsewhere [9, 10, 49], and are reported in Table 3. The highest values for C^2_{2s}, C^2_{2p} and total spin density are observed for [Ni(napen)], whereas [Ni(nappd)] has the lowest. The values of these parameters for naphthaldehyde-based complexes are slightly higher than those of homologous complexes with *salen*-based ligands, but significantly lower than those with aromatic bridges. We have shown [9] that the total spin density delocalised onto the axial N atoms in complexes with salicylaldehyde is greater for those with aromatic bridges, a consequence of the extensive delocalised π equatorial ligands that act as stronger π donors to nickel(III).

The results reported in this work imply that an increase in ligand unsaturation by the replacement of the salicylaldehyde by the naphthaldehyde moiety does not increase significantly π donation to nickel(III). The influence of aromatic imine bridge in naphthaldehyde based complexes, for which π delocalisation encompasses the aldehyde moieties and the imine bridge as with salicylaldehyde based complexes with aromatic bridges, could not be assessed, as these ligands do not stabilise the +3 oxidation state.

CONCLUSIONS

The oxidation process of nickel(II) complexes with ligands derived from naphthaldehyde in DMF and

Me_2SO is similar to that of their homologous salicylaldehyde based complexes and proceeds through oxidation of the metal centre, originating Ni(III) species with solvent molecules axially co-ordinated, except for complexes with aromatic bridges for which no Ni(III) species could be obtained.

The importance of axial co-ordination in the stabilisation of the +3 oxidation state became evident (i) from the cathodic shift observed for $E_{1/2}$ as the donating ability of the solvent increases; (ii) from the observation that [Ni(naptMe)], which exhibits axial steric hindrance, shows one of the more positive oxidation potentials and finally (iii) by noting that the complex with the lowest $E_{1/2}$, [Ni(nappd)], is the one that exhibits greater tendency to bind solvent molecules in the +2 oxidation state.

Electronic characterisation of nickel(III) naphthaldehyde based complexes has revealed also that the energy of the low lying excited doublets is largely dependent on the axially co-ordinated ligand, whereas that of the excited quartets shows greater dependence on the equatorial ligand. This latter observation allowed us to propose that complexes with *nappd* and *naptMe* have the weaker and stronger in-plane ligand field, respectively; moreover, structural data for the related nickel(II) complexes was used to propose that the strong/weak in-plane ligand strength in Ni(III) complexes is related to small/large ligand bite. Finally, comparison of electrochemical and spectroscopic data of the reported complexes with those of salicylaldehyde based complexes showed that the increase of unsaturation in the aldehyde moiety has only significant changes in the physicochemical properties of Ni(II)/Ni(III) complexes when the ligand has an aromatic imine bridge.

EXPERIMENTAL

The reagents were obtained from commercial sources and used as received, except 2,3-dimethyl-2,3-butanediamine that was prepared by the method of Sayre [50]. Tetraethylammonium perchlorate [51], the ligands and the nickel(II) complexes [17, 52] were prepared by standard methods.

Synthesis and spectroscopic characterisation in Me_2SO of compounds **1**–**3** have been published previously [11]. Electronic spectra (250–1200 nm) of **1**–**3** in DMF are similar to those in Me_2SO. Details on the electrochemical synthesis of nickel(III) complexes and the preparation of their pyridine adducts have been described in Ref. [9].

4: [Ni(napoph)]: $C_{28}H_{20}N_2O_2Ni \times H_2O$: calcd. C 68.5, H 4.0, N 5.7; found C 68.6, H 3.9, N 5.7. ^{1}H NMR ([D_6]DMSO, 297 K): $\delta = 7.05$–8.58 (16 H, aromatic H), 9.70 (2H, =CH). Electronic spectra (250–1200 nm): $\lambda_{max}(\varepsilon) = 495$ (9900), 485 (10500), 435 (30100), 400 nm (21000 $mol^{-1}\,dm^3\,cm^{-1}$) in Me_2SO; $\lambda_{max} = 540$, 505, 440, 410 nm in nujol.

5: [Ni(napophCl_2)]: $C_{28}H_{18}N_2O_2Cl_2Ni$: calcd C 62.0, H 3.0, N 5.2; found: C, 61.6; H, 2.9; N, 5.0. ^{1}H NMR ([D_6]DMSO, 297 K): $\delta = 7.05$–8.60 (14 H, aromatic H), 9.69 (2H, =CH). Electronic spectra (250–1200 nm): $\lambda_{max}(\varepsilon) = 505$ (11100), 490 (13200), 410 (32500), 390 nm (24200 $mol^{-1}\,dm^3\,cm^{-1}$) in Me_2SO; $\lambda_{max} = 530$, 510, 440, 405 nm in nujol.

Physical measurements

Elemental analyses were performed at the Microanalytical Laboratory, University of Manchester. ^{1}H NMR spectra were recorded on a Bruker AC200 spectrometer at 200 MHz (298 K). Chemical shifts are reported in ppm referred to TMS as an internal standard. Electronic spectra of Ni(II)/Ni(III) complexes were recorded with a Cary 17DX spectrophotometer at room temperature. Molar extinction coefficients for the nickel(III) electronic bands were estimated by double integration of EPR spectra, including baseline and Aasa and Vänngard corrections [53], using Me_2SO solutions of copper(II) nitrate as concentration standards. EPR spectra were obtained with an X-band Varian E 109 spectrometer at 77 K. Spectra were calibrated with diphenylpicrylhydrazyl (dpph; $g = 2.0037$) and the magnetic field was calibrated by use of Mn^{2+} in MgO. The reported EPR parameters were obtained by computer simulation [54]; linewidths (x, y, z) were typically 0.3–0.5 mT. The solvents for syntheses were of reagent grade and those for electrochemical measurements of analytical grade; all solvents were used as received.

Electrochemical measurements were made with a VA-Detector E 611, a VA-Scanner E 612 and a Coulometer E 524 (all from Metrohm) using DMF or Me_2SO solutions 1 mmol dm^{-3} in Ni(II) complex and 0.1 mol dm^{-3} Et_4NClO_4. Cyclic voltammetry was performed using a platinum microsphere as working electrode, a platinum wire as counter electrode, and an Ag/AgCl (1 mol dm^{-3} NaCl) reference electrode. All potentials are reported relative to that of the Ag/AgCl (1 mol dm^{-3} NaCl) reference electrode and to $E_{1/2}$ of the Fc^+/Fc couple; under the experimental conditions used (scan rate 0.05 Vs^{-1}) $E_{1/2}$ for the Fc^+/Fc couple: 0.50 V in DMF [$\Delta E(Fc^+/Fc) = 0.10$ V] and 0.48 V in Me_2SO [$\Delta E(Fc^+/Fc) = 0.09$ V]. Measured potentials were not corrected for liquid junction potentials. Scan rates from 0.01 to 0.10 V s^{-1} were used and the low and high potential limits were 0.30 and 1.30 V. Electrolysis were carried out at controlled potential, at a value 0.05 V higher than the anodic peak potential, using a Pt gauze as working electrode, a platinum foil as counter electrode and an Ag/AgCl (1 mol dm^{-3} NaCl) as reference electrode. The time elapsed during electrolysis in either solvent was typically 15 min and this time corresponds roughly to the moment when formation of the oxidised species becomes slower than their decomposition, as can be inferred by following the variation of the intensity of the derivative EPR bands with electrolysis time. Concentration of the

Ni(III) compounds at the end of electrolysis was comprised between 30 and 50% (molar basis) of total nickel in solution.

(Received 7 January 1998; accepted 9 June 1998)

Abstract—Three copper(II) complexes with thiophene-2,5-dicarboxylic acid (H_2Tda) and 1,10-phenanthroline (phen) ligands have been synthesized and structurally characterized: $[Cu(Tda)(phen)(H_2O)_2]\cdot 3H_2O$ (**1**), $[Cu(Tda)(phen)_2]\cdot 1/2H_2Tda\cdot 2H_2O$ (**2**) and $[\{Cu(Tda)(phen)(H_2O)\}_n]$ (**3**). The Cu atom in all of the three complexes is in five coordinate, distorted square pyramidal environments. The thiophene-2,5-dicarboxylate molecule is monodentate in **1** and **2** in which the molecular structure is stabilized by intermolecular aromatic ring stacking interaction between the thiophene ring and the aromatic rings in the 1,10-phenanthroline molecule and hydrogen bondings. In **3** the thiophene-2,5-dicarboxylate ion is bis-monodentate and bridges the $[Cu(phen)(H_2O)]$ units to form a one-dimensional polymer. Complex **2** shows quasi-reversible one-electron redox of Cu^{2+}/Cu^{+} at 0.001 V vs SCE. Coordination environments of copper(II) in the reported complexes and stacking interactions in **1** and **2** are compared with those in the copper(II) site of galactose oxidase (GOase). © 1998 Elsevier Science Ltd. Keywords: crystal structures; copper(II) complexes; thiophene derivatives; stacking interactions

INTRODUCTION

Thiophene derivatives have been known to show biological activities [1]. Yet relatively very few of their metal complexes have so far been reported [2–7]. Thiophene-2,5-dicarboxylic acid (H_2Tda) is reported to be a potential anti-cancer agent [8]. Four lanthanide complexes with formula $Ln_2(Tda)_3\cdot nH_2O$ (Ln = La,Gd,Dy) and $Sm(Tda)OH\cdot H_2O$ have been synthesized, but only their IR data were reported. The coordination modes of thiophene-2,5-dicarboxylate in these complexes are still unknown [9]. Thiophene-2,5-dicarboxylate can potentially be a monodentate, a bidentate and a tridentate ligand; it can also be a bridging or chelating ligand.

Five-coordinate copper(II) complexes are not uncommon; the geometry around the metal ion is trigonal bipyramidal or square pyramidal. Many biologically active copper-containing molecules have five-coordinate metal centres. For example, the active site in the structure of galactose oxidase (GOase, copper-containing enzyme) has been determined [10, 11]. The geometry around the monomeric copper(II) centre is square pyramidal (see Fig. 1) in which the copper(II) ion is coordinated to four amino acid residues from the protein chain and one exogenous acetate anion (pH 4.5) or one water molecule (pH 7.0). One tyrosine oxygen atom, two histidine nitrogen atoms and an acetate oxygen atom (or an oxygen of water) form the square base while the apical position is occupied by a further tyrosine oxygen atom. The structure reveals a novel biological modification of the equatorial tyrosine 272, which is covalently linked by a thioether bond to the sulfur atom of cysteine 228. This thioether linkage very likely contributes to lowering the redox

potential of the Tyr272 free radical. This new observation has stimulated research on synthesising small molecule complexes as models for the copper biosite present in this enzyme [12–16].

Among interactions between nucleic acids and amino acids, hydrogen bonding and aromatic-ring stacking are two of the four possibly important interactions in biological systems [17] and such interactions are known to occur in a number of copper(II) complexes of biological significance [17–32]. The existence of stacking interactions in copper(II) complexes with nucleotides and a second ligand (an aromatic base such as 1,10-phenanthroline and 2,2′-dipyridine), which stabilises the formed complexes, greatly influences the coordination of nucleotides where metal–nucleotide interactions take place predominantly at the phosphate group and the nucleotide base is not bound to the metal ion but stacked with the aromatic ring of the second ligand [19–25]. In the GOase copper site, the unusual thioether bond between Tyr272 and Cys228 is stacked with the indole ring of Trp290 as shown in Fig. 1. These strong interactions seem to stabilize the Tyr272 free radical and are probably involved in the catalytic mechanism [10, 11]. Our selection of 1,10-phenanthroline as the second ligand is based on the consideration that 1,10-phenanthroline is known to be an important aromatic base involved in stacking interactions and may possibly stabilise the formed copper(II) complexes with thiophene-2,5-dicarboxylate by chelate effect and stacking interactions. Here we report the synthesis and crystal structure of three copper(II) complexes with thiophene-2,5-dicarboxylic acid and 1,10-phenanthroline: $[Cu(Tda)(phen)(H_2O)_2]\cdot 3H_2O$ (**1**), $[Cu(Tda)(phen)_2]\cdot 1/2H_2Tda\cdot 2H_2O$ (**2**) and $[\{Cu(Tda)(phen)(H_2O)\}_n]$ (**3**).

EXPERIMENTAL

General

All chemicals were reagent grade and used without further purification.

Elemental analyses were carried out by the Microanalytical Laboratory of the Department of Chemistry, National University of Singapore. Solution pH values of the reaction mixture were measured using a Metrohm 691 pH Meter. IR spectra were recorded as KBr discs using a Perkin Elmer 1600 Fourier-transform IR spectrometer (4400–450 cm^{-1}), UV-Vis spectra were recorded on a Shimadzu UV-240 UV-visible spectrophotometer using Nujol mulls for solid samples and in $EtOH/H_2O$(1:1) for solution samples. Cyclic voltammetry studies of the complexes were performed on a EG&G 273 Potentiostat/Galvanostat using EG&G 270/250 Research Electrochemical Software 4.0. The single-compartment electrochemical cell was equipped with a platinum foil working electrode (0.5 cm^2), a saturated calomel electrode (SCE) and a platinum wire counter electrode. Scans were done at 50 mV s^{-1} in $EtOH/H_2O$(1:1) that contained 0.10 M $(NEt_4)ClO_4$ as the supporting electrolyte. The concentration of the metal complexes were 1×10^{-3} M. Solutions were purged with dry argon prior to data collection. Emf values are reported vs SCE. Thermogravimetric and differential thermoanalysis data were obtained on a Universal V1.5B TA Instrument in air flux with a heating rate of 10°C min^{-1}. Thiophene-2,5-dicarboxylic acid was synthesized by a modified literature method [33].

Synthesis of $[Cu(Tda)(phen)(H_2O)_2]\cdot 3H_2O$ (*1*) *and* $[Cu(Tda)(phen)_2]\cdot 1/2H_2Tda\cdot 2H_2O$ (*2*)

2 cm^3 of 0.1 M $Cu(NO_3)_2$ aqueous solution and 2 cm^3 of 0.1 M H_2Tda–Phen (1:1 molar ratio) ethanol solution were mixed in a 10 cm^3 capped bottle (vial); then 0.6 cm^3 of 0.1 M NaOH aqueous solution was added. The resulting solution with a pH of 3.46 was set aside. Several days later, light green crystals and dark blue crystals were formed. The light green and the dark blue crystals were separated. The light green crystals were complex **1** (15 mg, yield 15% based on Cu). Anal. calcd for $C_{18}H_{20}CuN_2O_9S$: C, 42.90; H, 4.00; N, 5.56; S, 6.36; Cu, 12.61%. Found: C, 42.93; H, 4.22; N, 5.68; S, 6.20; Cu, 12.72%. IR (KBr disc, cm^{-1}): 1571, 1560 (ν_{as} COO^-), 1386, 1356 ($\nu_s COO^-$). UV-Vis [λ_{max} (nm), ε ($dm^3\,mol^{-1}\,cm^{-1}$) in parentheses]: 276, 656 (d–d*) (solid); 204 (5982), 222 (3900), 270 (5380), 735 (226). The dark blue crystals were those of **2** (20 mg, yield 14% based on Cu). Anal. calcd for $C_{33}H_{24}CuN_4O_8S_{1.5}$: C, 55.34; H, 3.38; N, 7.82; S, 6.71; Cu, 8.87%. Found: C, 55.39; H, 3.47; N, 7.89; S, 6.68; Cu, 8.91%. IR (KBr disc, cm^{-1}): 1691 (ν_{as} COOH), 1583 (ν_{as} COO^-), 1353 ($\nu_s COO^-$). UV-Vis [λ_{max} (nm), ε ($dm^3\,mol^{-1}\,cm^{-1}$) in parentheses]: 290, 640 (d–d*) (solid); 204 (9400), 222 (6110), 268 (8460), 728 (250).

Synthesis of $[\{Cu(Tda)(phen)(H_2O)\}_n]$ (**3**)

2 cm^3 of 0.1 M $CuCl_2$ aqueous solution and 2 cm^3 of 0.1 M H_2Tda–Phen (1:1 molar ratio) ethanol solution were mixed in a 10 cm^3 capped bottle (vial); then 0.9 cm^3 of 0.1 M NaOH aqueous solution was added. The resulting solution with a pH of 3.65 was put aside. After several days, green crystals were formed. The green crystals were collected as **3** (28 mg, yield 32% based on Cu). Anal. calcd for $C_{18}H_{12}CuN_2O_5S$: C, 50.05; H, 2.80; N, 6.48; S, 7.42; Cu, 14.71%. Found: C, 49.87; H, 2.67; N, 6.46; S, 7.23; Cu, 14.78%. IR (KBr disc, cm^{-1}): 1590, 1576 (ν_{as} COO^-), 1364 ($\nu_s COO^-$). UV-Vis (λ_{max}/nm): 288, 680 (d–d*) (solid).

X-ray structure determination

X-ray diffraction data for **1** and **3** were collected on a Rigaku AFC5R diffractometer at room temperature with graphite-monochromated Mo-Kα radiation ($\lambda = 0.71069$ Å), using ω–2θ scan mode. Cell dimensions were obtained from 25 reflections in the 2θ range of 20–30° for each compound. Lp and DIFABS corrections were made for all reflections. Data reduction and structure refinement were performed using the TEXSAN packages [34]. The structures of **1** and **3** were solved by the Patterson and direct methods, respectively. All non-hydrogen atoms were refined anisotropically by least-squares methods. Hydrogen atoms for **1** and **3** were located by a combination of difference Fourier map and HYDROGEN program, their positions were not refined. X-ray diffraction data for **2** were collected on a Siemens R3m/V diffractometer using graphite-monochromated Mo-Kα radiation ($\lambda = 0.71073$ Å). Unit cell parameters were determined by a least-squares fit of 25 independent reflections, which were obtained by automatic random search. Semi-empirical absorption corrections were applied. The structure was solved by direct methods on a Digital Equipment Corporation Micro VAX II computer. Refinements by full matrix least-squares were carried out on a PC by using SHELXTL PLUS (PC version) software package [35] and final refinement was run using SHELXL-93 [36]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced at calculated positions (C–H = 0.96 Å). A summary of the crystallographic data is given in Table 1.

RESULTS AND DISCUSSION

Thiophene-2,5-dicarboxylic acid is a dibasic acid with acidity constants of pK_{a1} 3.18 and pK_{a2} 4.28 in

aqueous EtOH (30%) solution and pK_{a1} 4.14 in aq. EtOH (50%) [37, 38]. It exists as an equilibrium mixture of H_2Tda, $HTda^-$ and Tda^{2-} in solutions of different pHs. Hence the complexation reactivity of this ligand depends on its degree of protonation, i.e. the pH of the solution. When the pH of the reaction mixture (pH 3.46) was carefully controlled by addition of 0.6 cm^3 0.1 M NaOH aqueous solution to 4 cm^3 of $Cu(NO_3)_2$ and a H_2Tda–phen mixture, complexes **1** and **2** were obtained simultaneously. Reaction of 2 cm^3 of 0.1 M $CuCl_2$ aqueous solution and 2 cm^3 of 0.1 M H_2Tda–phen ethanol solution, at a pH of 3.65, produced complex **3**. Crystals suitable for X-ray crystallographic determination were obtained directly from the above reaction mixture.

*Structures of **1**, **2** and **3***

The structure of **1** consists of monomeric [Cu(Tda)(Phen)$(H_2O)_2$] units linked by water molecules through hydrogen bonding. The structure of **2** contains discrete neutral units of [Cu(Tda)$(Phen)_2$], thiophene-2,5-dicarboxylic acid molecules and water molecules of crystallization; the uncoordinated H_2Tda molecule is linked to the central complex by hydrogen bonds. In **1** and **2** thiophene-2,5-dicarboxylate is monodentate and the molecular packing is determined mainly by hydrogen bonding and aromatic ring-stacking interactions as depicted in Figs 2 and 3. Selected bond distances and angles are given in Tables 2 and 3. In $[\{Cu(Tda)(phen)(H_2O)\}_n]$ (**3**), [Cu(phen)(H_2O)] units are bridged by thiophene-2,5-dicarboxylate anions which act as bridging bis-monodentate ligands to form one-dimensional polymer chains running in a zig-zag manner. The partial molecular packing is shown in Fig. 4 together with the atomic labelling scheme. Selected bond length and angle are listed in Table 4. Intramolecular Cu···Cu separation along the chain is 10.76 Å, comparable with those bridged by terephathates [39].

The common structural feature of complexes **1**, **2** and **3** is that the copper atom in all of the three com-

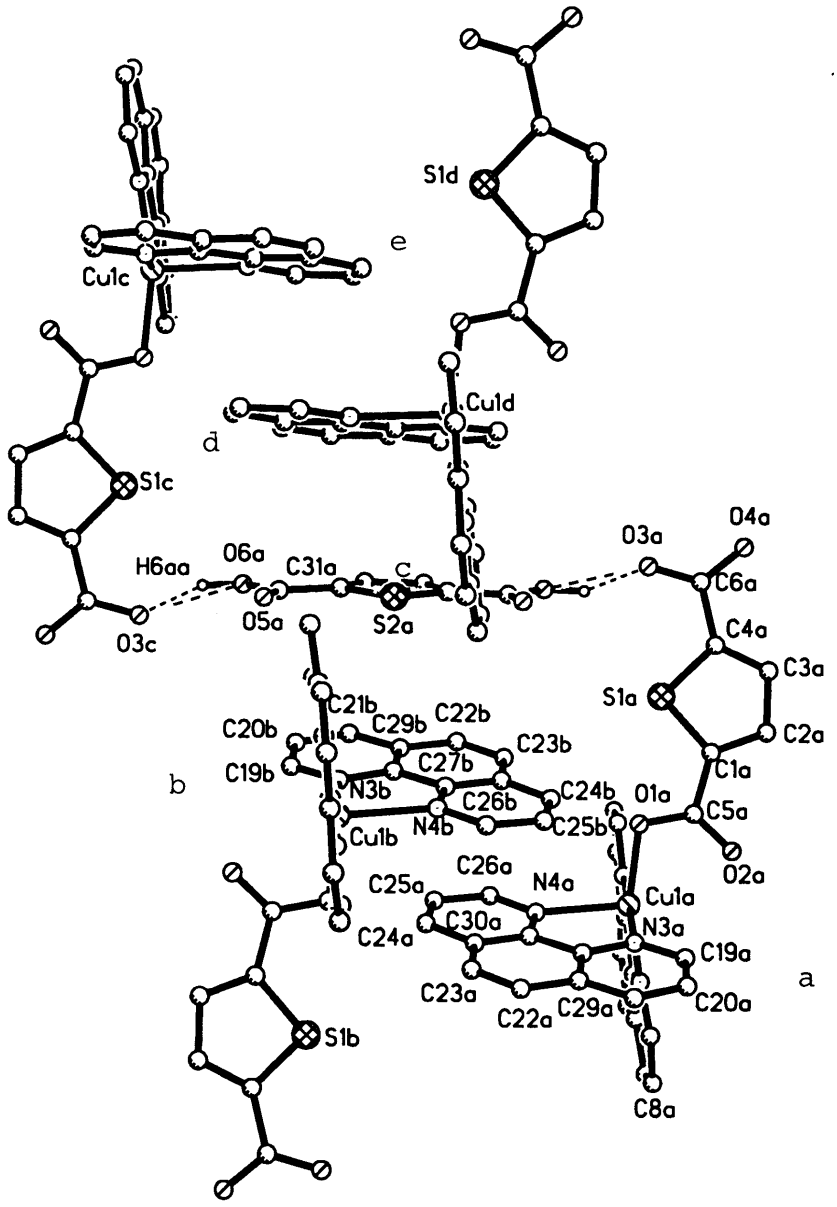

Fig. 3. Partial packing diagram of **2** with atomic labelling scheme showing the stacking interactions and hydrogen bonding.

plexes is in a five coordinate, distorted square pyramidal environment. Figure 5 shows the comparison of copper(II) coordination environments together with the coordination environment of the active GOase site. Some structural parameters of these complexes are listed in Table 5. In the present three complexes the geometries around copper(II) are best described as distorted square pyramidal with small trigonal-bipyramidal component from $\tau = 0.003$ to 0.20 [40].

Observed Cu–N(phen), Cu–O(water) and Cu–O(carboxylate) bond distances are comparable with literature values [27–29, 41–44]. The Cu–O(carboxylate) bond length in **2** [1.993(3) Å] is longer than that in **1** [1.928(3) Å] and 1.932(1) Å in **3** indicating that the coordination of thiophene-2,5-dicarboxylate to copper(II) in **2** is weaker than those in **1** and **3**, possibly due to the steric effects resulting from the presence of two phenanthroline molecules. All the carboxylate coordination to copper is in *syn* mode which is the preferred coordination mode of a carboxylate in small complex molecules [45] and for proteins containing carboxylate–metal ion interactions [46]. The thiophene-2,5-dicarboxylate molecule is nearly planar in all of the three complexes.

A further interesting structural feature which needs to be emphasised is the intermolecular aromatic ring-stacking interactions between the thiophene ring and

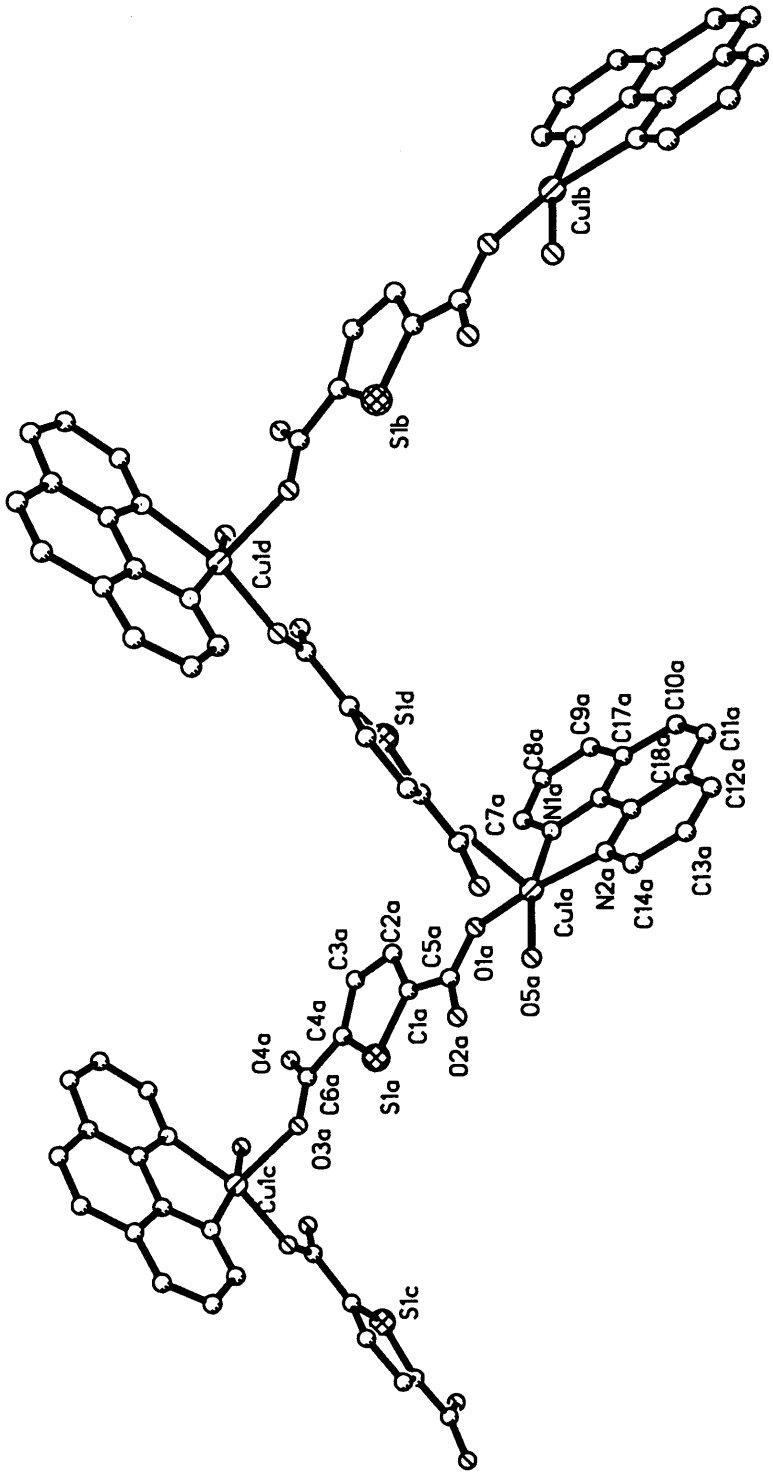

Fig. 4. Partial packing diagram of 3.

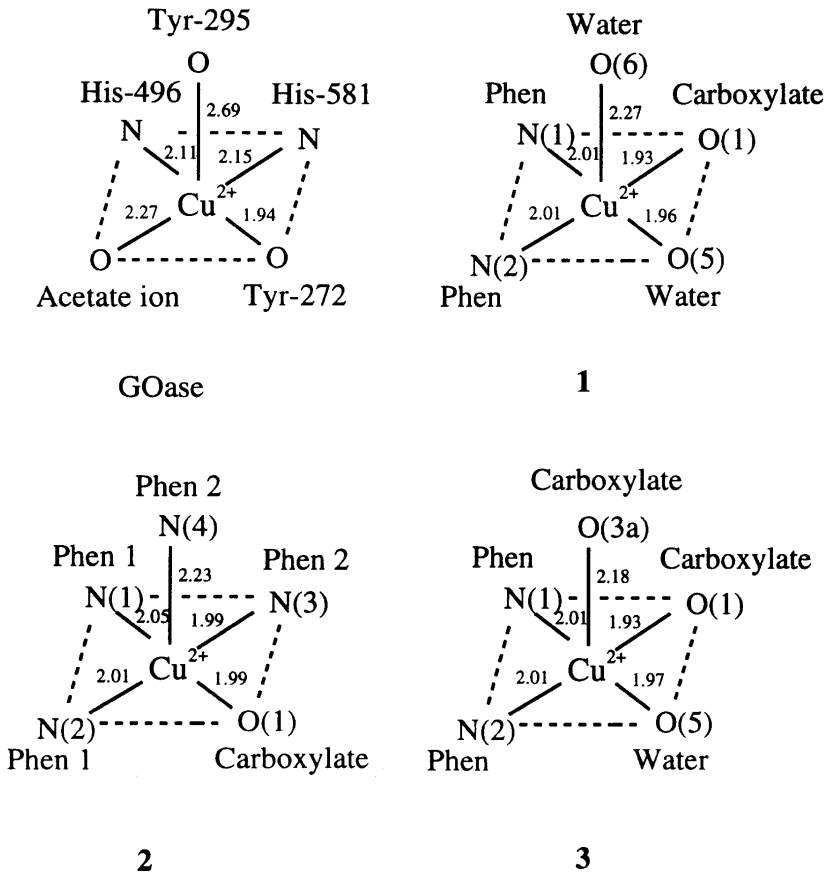

Fig. 5. Comparison of copper(II) coordination environments.

Table 5. Comparison of some structural parameters for copper(II) coordination spheres

Complex	τ^*	R.m.s deviation of basal plane (Å)	Deviation of Cu above plane (Å)	Axial bond length (Å)
1	0.07	0.071	0.20	2.272
2	0.20	0.116	0.11	2.225
3	0.003	0.011	0.21	2.184

*For perfect tetragonal and trigonal-bipyramidal geometries the values of τ are zero and unity, respectively; $\tau = (\beta - \alpha)/60$, being an index of the degree of tetragonality within the structural continuum between square-planar and trigonal-bipyramidal geometries [40].

1,10-phenanthroline rings in **1** and **2** as shown in Figs. 2–3. It has been established that stacking interactions, observed either in solution or in the solid state, are recognized as enhancing the stability of mixed ligand complexes, but more importantly, as creating specific structures [19–25]. The stacking interactions probably also stabilize the structure of **1** and **2**. The dihedral angle between the mean thiophene plane and the mean plane of 1,10-phenanthroline in an adjacent molecule is 9.7° and the average distance between the two planes is about 3.65 Å in **1**. Atom S1c is just below the phenanthroline rings with more overlap with the ring formed by N1a, C7a, C8a, C9a, C17a and C16a. Figure 3 shows the partial packing diagram of the structure of **2**. Planes a, b, d and e are the corresponding phenanthroline molecular planes from four different molecules while plane c is that of the neutral thiophenedicarboxylic acid. Planes b and d (also a and e) are symmetrically displaced with respect to plane c. The dihedral angles between plane b and plane c is 11.2° and separation between the two planes is 3.70 Å. Planes a and b (also d and e) are strictly parallel with

Table 6.Comparison of parameters involved in stacking interactions

Compounds	Dihedral angle (°)	Planes separation (Å)	Distances from sulfur to the atoms at the stacked plane (Å)
1	9.7	3.65	3.46 (N1a), 3.95 (C15a), 3.49 (C16a), 3.82 (C17a) (from S1c)
2	11.2	3.70	3.85 (C21b), 4.04 (C22b) 3.94 (C28b), 3.68(C29b) (from S2a)
GOase	1.8	3.4	3.84 (S to six carbons of Trp290)

a separation of 3.5 Å. S2a is exactly above the centre of the rings formed by N3b, C19b, C20b, C21b, C22b, C30b, C27b, C28b, C29b and C30b. In the GOase copper active site, the thioether bond between Tyr272 and Cys228 is stacked with the indole ring of Trp290 as shown in Fig. 1. The six-membered ring of indole ring of Trp290 located exactly above the sulfur atom [the distances between the sulfur and these six carbons of Trp290 are all 3.84(4) Å]. The "best" plane defined by all the side-chain atoms of Tyr272 and Cys228 makes an angle of 1.8°, nearly perfectly parallel, with the plane of the side-chain atoms of Trp290. The two planes are 3.4 Å apart. A comparison of some of the parameters involved in stacking interactions in **1**, **2** and GOase is listed in Table 6.

Physical, electrochemical and thermal properties

Complexes **1** and **2** can be dissolved in methanol, ethanol, dmf, etc. by ultrasonic shaking and gentle heating, while **3** is insoluble in common solvents.

The infrared spectrum of the free ligand, H_2Tda, shows ν(C═O) of COOH at 1665 cm^{-1} as a strong band indicating that there is intermolecular hydrogen bonding of the type C═O···H–O in the uncoordinated thiophene-2,5-dicarboxylic acid molecules. This is commonly observed in the case of carboxylic acids [47]. After deprotonation and coordination to a copper atom, this band disappears and is replaced by very strong bands in the 1560–1590 and 1350–1390 cm^{-1} regions, which correspond to the asymmetric and symmetric vibrations of the COO^- moiety, respectively. In complex **2**, a strong band at 1690 cm^{-1} indicates that the carbonyl oxygen in H_2Tda is not involved in hydrogen bonding and this is confirmed by the structure determination.

The solid state room-temperature electronic spectra of **1**, **2** and **3** exhibit a broad d–d band with a maximum at 656, 640 and 680 nm, respectively, which is typical for square-pyramidal coordination of copper(II) complexes [12–16, 41, 42]. **1** and **2** exhibit broad absorptions at 735 and 728 nm, respectively, in ethanol–water (1:1) solution. The lower-energy bands suggest that changes have occurred in the geometry around copper(II) and probably indicate the presence of a more trigonal-bipyramidal element in solution [13, 48, 49].

The cyclic voltammogram of **1** and **2** was measured in ethanol–water (1:1) solution contained 0.10 M $(NEt_4)ClO_4$ as the supporting electrolyte. A selected voltammogram is shown in Fig. 6. The complexes are electrochemically active and display irreversible one-electron reduction waves with $E_{1/2}$ −0.126 V ($i_{pa}/i_{pc}=0.85$, $\Delta E_p=162$ mV) for **1** and quasi-reversible one-electron reduction waves with $E_{1/2}$ 0.001 V ($i_{pa}/i_{pc}=1.04$, $\Delta E_p=96$ mV) for **2** vs SCE, which are assigned to Cu^{2+}/Cu^+ one-electron redox. SCE is 0.242 V vs NHE [50], so $E_{1/2}$ is 0.116 V for **1** and 0.243 V for **2** vs NHE, comparable to 0.15 V for Cu^{2+}(aq)/Cu^+(aq) and 0.17 V for $Cu^{2+}(phen)_2$/$Cu^+(phen)_2$ redox potentials (Ref. [44] and references therein).

A water molecule of crystallization can be distinguished from a coordinated water molecule in a complex by means of differential thermoanalysis. The TGA–DTA result shows that **1** first loses water of crystallization between 40–150°C with a total loss of three water molecules (calcd weight lost: 10.7%; found: 10.3%). The complex began losing the two coordinated water molecules at 150°C. In complex **2** the two water molecules of crystallization were lost in the 75–160°C temperature range (calcd weight lost: 5.4%, found: 5.0%). **3** began to lose water at 160°C, a relatively high temperature indicating the absence of water of crystallization; the eventual total weight lost corresponds to the loss of one coordinated water molecule (calcd weight lost: 4.1%, found: 4.2%). In a similar square pyrimidal [Cu(L-glu)(phen)(H_2O)]·$3H_2O$ complex [27], the coordinated water molecule is lost in the 110–150°C temperature range, indicating the bond strength of the coordinated water molecule in this complex is weaker than those in **1** and **3**.

(Received 20 March 1998; accepted 9 June 1998)

Abstract—The reactions between $La_3(OBu^t)_9(HOBu^t)_2$ and $Zn[N(SiMe_3)_2]_2$ have been investigated as a means to access to La–Zn species. A volatile complex $LaZn_3(\mu\text{-}OBu^t)_6[N(SiMe_3)_2]_3$ (**1**) was obtained at room temperature together with $La_4Zn_2O(OBu^t)_{13}[N(SiMe_3)_2]$ (**2**) and $[La_4O(OBu^t)_{10}]_2$ (**3**). The reaction was more selective under reflux although retention of the $Zn–N(SiMe_3)_2$ bond was still observed giving $La_4Zn_2(OBu^t)_{15}[N(SiMe_3)_2]$ (**4**). No La–Zn species were obtained if the La_3 solvate was refluxed with either $Zn(OBu^t)[N(SiMe_3)_2]$ or $[Zn(OBu^t)_2]_m$; $La_5(\mu_5\text{-}O)(OBu^t)_{13}$ was isolated in the latter case. The various compounds were characterized by elemental analysis, FTIR, ^1H NMR. **1** was also characterized by single crystal X-ray diffraction; its molecular structure is based on a central 6-coordinate lanthanum with 3-coordinate zinc atoms. © 1998 Elsevier Science Ltd. Keywords: mixed-metal alkoxides; zinc; lanthanum; sol–gel; MOCVD; amides.

INTRODUCTION

A large variety of electrooptical ceramics are based on lanthanum oxides. Complex oxides such as (Pb, La)(Zn, Nb, Zr, Ti)O_3 (PBLNZT) or $La_2Zn_2SnO_7$ are examples of current formulations and show that lanthanum is associated to zinc [1]. Chemical routes such as sol-gel or MOCVD techniques are crucial for the control of the properties, of the microstructure and for the processing of these materials as films [2, 3]. These techniques depend of the availability of soluble or volatile, homo- or heterometallic oxide precursors. "Single-source" precursors have been shown to improve the properties of high tech materials [3]. Despite the importance of lanthanum in the formulation of advanced materials, mixed-metal oxide precursors involving lanthanum remain scarce. No simple species based on lanthanum and alkaline metals and which could be used as a synthon is available. The mixed-metal species reported so far for lanthanum are isopropoxide derivatives in which the rare earth is associated with niobium [4, 5], with molybdenum [6] or with zirconium [7]. By contrast with most metal alkoxides, zinc derivatives are relatively inert and, as a result, the formation of mixed-metal species requires less classical routes [8]. We recently reported the formation of mixed-metal oxoalkoxides based on zinc and tantalum by metathesis reaction between ZnI_2 and $KTa(OiPr)_6$ or by ultrasonic activation between the homometallic alkoxides [9]. A large number of metal alkoxides are obtained as solvates with alcohol molecules [10, 11]. The enhanced acidity of the coordinated alcohol molecules turns these ligands into functional groups able to react with labile species or even electropositive metals [12–14] allowing the built up of mixed-metal species.

The structurally characterized lanthanum tertiary butoxide solvate $La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(HOBu^t)_2$, appeared as an attractive synthon [15] for this strategy and thus for a convenient route to

La–M species. We report here the results of the investigations between $La_3(OBu^t)_9(HOBu^t)_2$ and zinc bis-trimethylsilylamide $Zn[N(SiMe_3)_2]_2$. By contrast with the reactions between $La_3(OBu^t)_9(HOBu^t)_2$ and other metal bis-trimethylsilylamide derivatives [16], the reaction with $Zn[N(SiMe_3)_2]_2$ is less selective probably as a result of a lower lability of the $Zn–N(SiMe_3)_2$ bond. Mixed-metal La–Zn oxo and nonoxo derivatives displaying $LaZn_3$ and La_4Zn_2 stoichiometries and the lanthanum oxoalkoxide $[La_4O(OBu^t)_{10}]_m$ were obtained depending on the experimental conditions. They were characterized by elemental analysis, FTIR, ^{1}H NMR and by a single crystal X-ray diffraction study for $LaZn_3(\mu\text{-}OBu^t)_6[N(SiMe_3)_2]_3$.

EXPERIMENTAL SECTION

All manipulations were routinely performed under argon using Schlenk tubes and vacuum line techniques with solvents purified by standard methods. $La_3(OBu^t)_9(HOBu^t)_2$ and $Zn[N(SiMe_3)_2]_2$ were obtained according to the literature [15, 17]. NMR(^{1}H, ^{13}C) and IR spectra were run on Bruker AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $LaZn_3(OBu^t)_6[N(SiMe_3)_2]_3$ (**1**), $La_4Zn_2O(OBu^t)_{13}[N(SiMe_3)_2]$ (**2**) and $[La_4O(OBu^t)_{10}]_2$ (**3**)

0.278 cm^3 (0.74 mmol) of $Zn[N(SiMe_3)_2]_2$ in 5 cm^3 of toluene were added to $La_3(OBu^t)_9(HOBu^t)_2$(0.90 g, 0.74 mmol) in 25 cm^3 of toluene. Stirring was maintained for 20 h at room temperature. Evaporation to dryness gave a white solid, which was redissolved in 20 cm^3 of toluene. The solution was concentrated and cooled to 4°C. Crystals of **1** were obtained after 24 h 0.16 g (52%/Zn, 6%/La). Anal. Found: C, 40.8, H, 8.92, N, 3.45; La, 11.02; Zn, 15.42 Calc. for $C_{42}H_{108}O_6N_3LaSi_6Zn_3$, C, 40.2; H, 8.67; N, 3,35; La, 11.09; Zn, 15.65%. IR (cm^{-1}): 1366 s; 1250 sh, 1247 s, ν(Si–C), 1175 s; 972 vs, 925 w, 904 vs, 883 vs, 847 s, 832 vs, 815 s, 756 m, 671 m, 613 w; 559 s, 476 m, 466 m, 408 s, 385 s ν(M–O). ^{1}H NMR ($CDCl_3$, ppm): 1.50 s (9H, μ-OBut), 0.14 s (18H, $SiMe_3$). $^{13}C\{^1H\}$ NMR ($CDCl_3$, ppm): 73.2 (OC), 35.0 (CMe_3), 6.0 (SiMe_3).

Further concentration of the solution gave crystals of **2** (0.18 g, 28%/Zn, 18%/La) after 24 h at 4°C. Anal. Found: C, 38.53, H, 7.62, N 0.80, La, 30.50; Zn, 7.30 Calc. for $C_{58}H_{135}O_{14}NLa_4Si_2Zn_2$ C, 38.42; H, 7.50; N, 0.77, La, 30.67; Zn, 7.22%. IR (cm^{-1}): 1360 s; 1240 s ν(Si–C), 1199 vs; 1021 w, 973 vs, 934 vs, 906 s, 889 sh, 831 m, 766 m; 674 w, 614 w ν(Zn–N); 559 s, 511 s, 481 s, 385 vs ν(M–O). ^{1}H NMR ($CDCl_3$, ppm): 1.66 s, (9H, μ_3-OBut), 1.58 s, (18H, μ_3-OBut), 1.47 s, (9H, μ-OBut), 1.45 s (36H, μ-OBut), 1.21 s (18H, μ-OBut, 1.09 s (18H, LaOBut), 1.06 s (9H, *Z*nOBut), 0.08 s (18H, $SiMe_3$).

The last crop of crystals corresponds to **3** (0.54 g, 56%/La). Anal. Found: C, 36.23, H, 6.77, La, 42.76 Calc. for $C_{40}H_{90}O_{11}La_4$: C, 36.88, H, 6.93, La, 42.59%. IR (cm^{-1}): 1220 m, 1197 s; 976 s, 960 m, 936 s, 905 m, 831 w, 766 w; 564 m, 482 s, 387 s (νLa–OR). ^{1}H NMR ($CDCl_3$, ppm): 1.71 s (54H, μ_3-OBut), 1.51 s (72H, μ-OBut), 1.27 s (18H, OBut), 1.16 s (36H, OBut).

Synthesis of $La_4Zn_2(OBu^t)_{15}[N(SiMe_3)_2]$ (**4**)

A similar procedure but in refluxing conditions applied to 0.263 cm^3 (0.70 mmol) of $Zn[N(SiMe_3)_2]_2$ in 5 cm^3 of toluene and to $La_3(OBu^t)_9(HO^tBu)_2$ (0.85 g, 0.70 mmol) in 25 cm^3 of toluene gave **4** (0.62 g, 91%/Zn, 61%/La). Anal. Found: C, 43.97, H, 8.55, La, 28.42; Zn, 6.36 Calc. for $C_{66}H_{153}O_{15}NLa_4Si_2Zn_2$: C, 43.07, H, 8.38, La, 28.62; Zn, 6.73%. IR (cm^{-1}): 1362 s; 1247 s ν(Si–C); 1219 s, 1197 vs ν(C–O); 1021 w, 992 s, 973 vs, 955 s, 934 vs, 913 m, 905 m, 885 m, 828 m, 798 sh, 767 m; 672 w, 604 w ν(Zn–N); 585 w, 571 w, 508 m, 495 s, 386 vs (νM–OR). ^{1}H NMR ($CDCl_3$, ppm): 1.73 s (18H, μ_3-OtBu), 1.55 s (9H, μ_3-OBut), 1.53 s (9H, μ3), 1.52 s (36H, μ-OtBu), 1.37 s (18H, μ-OBut), 1.27 s (9H, ZnOtBu), 1.16 s (36H, LaOBut), 0.08 s (18H, $SiMe_3$).

All compounds were pale yellow, soluble in toluene and in THF but insoluble in hexane.

Synthesis of $La_5(\mu_5\text{-}O)(OBu^t)_{13}$

0.323 g (0.264 mmol) of $La_3(OBu^t)_9(HOBu^t)_2$ in 15 ml of toluene were added to a suspension of 56 mg (0.264 mmol) of $Zn(OBu^t)^2$ in 10 ml of toluene. The reaction medium was stirred at room temperature for 23 h and refluxed for 6 h. The precipitate isolated by filtration corresponded to Zn ter-butoxide (quantitative amount). The filtrate was evaporated to dryness, the crude solid was recrystallized in THF, colorless crystals were obtained at −25°C (0.145 g, 55%). The same compound was obtained by reflux for 6 h in the absence of the zinc alkoxide. IR (cm^{-1}): 971 vs, 934 vs, 913 m, 827 m, 766 m; 570, 508 m, 484 s, 385 vs (νLa–OR). ^{1}H NMR ($CDCl_3$, ppm): 1.69 s (36H), 1.51 s (36H), 1.15 s (45H).

Crystallography of $LaZn_3(OBu^t)_6[N(SiMe_3)_2]_3$ (**1**)

Suitable crystals of **1** were grown directly from the reaction medium. 3185 data ($4 < 2\theta < 32°$) were collected at −80°C on a CAD-4 diffractometer using the graphite monochromatized Mo-Kα radiation ($\lambda = 0.71070$ Å). The crystals were unstable. The intensities of three standard reflections monitored every hour decayed uniformly to final values about 10% of the initial ones. The data were scaled accordingly. The decay in intensities accounts for the limited range of 2θ, several attempts with various crystals did not improve the data. Basic information is collected in Table 1.

Computations were performed by using CRYS-

TALS adapted on a Micro Vax II [18]. The structure was solved by Patterson methods and subsequent Fourier maps. Of the 3185 unique refections, 2085 with $I > 3\sigma(I)$ were used to solve and refine the structure. All atoms were refined anisotropically. Least squares refinements with approximation in three blocks to the normal matrix were carried out minimizing the function $w(|F_0|-|F_c|)^2$, were F_0 and F_c are the observed and calculated structure factors. Unit weight was used. Models reached convergence with $R=(|F_0|-\Sigma|F_c|)/\Sigma|F_0|$ and $R_w=[\Sigma w(|F_0|-|F_c|^2)/\Sigma(F_0)^2]^{1/2}$ of 0.127 and 0.141 respectively for 246 variables. Criteria for a satisfactory complete analysis were the ratios of rms shift to standard deviation being less than 0.1 and no significant features in the final difference map. Anomalous dispersions terms were applied. Empirical absorption corrections were made [19].

Atomic coordinates, nonessential bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and characterization

The reaction between $La_3(OBu^t)_9(HOBu^t)_2$ and $Zn[N(SiMe_3)_2]_2$ (1:1 stoichiometry) proceeds smoothly in toluene at room temperature (Scheme 1) giving different species which were separated by their solubility properties. While a compound having a La_3Zn stoichiometry was expected with a strategy based on the reactivity of the coordinated alcohol molecules the first compound isolated (in modest yield 6%/La) was actually a species having the opposite stoichiometry, $LaZn_3(OBu^t)_6[N(SiMe_3)_2]_3$ (**1**). Further crystallizations afforded the heterometallic oxoalkoxide $La_4Zn_2O(OBu^t)_{13}[N(SiMe_3)_2]$ (**2**) (yield 18%/la) and, as the last crop and major species (yield 56%/La), the homometallic $[La_4O(OBu^t)_{10}]_2$ oxoalkoxide **3**. Compound **1** is formed at room temperature, independently of the stoichiometry used (molar ratio from 1 to 5). The preceding reaction is more selective if it is achieved in refluxing toluene over 20 h. The nonoxo species $La_4Zn_2(OBu^t)_{15}[N(SiMe_3)_2]$ (**4**) is the only one isolated (yield 61%/La). IR and ^{1}H NMR data confirm the presence of trimethylsilylamide ligands for compounds **1**, **2** and **4**. This is evidenced by ν(Si–C) absorption bands at $\sim 1250\,cm^{-1}$ in the FTIR spectra while resonances at high field (0.14 or 0.08 ppm) are detected in the proton NMR spectra. The poor reactivity of the Zn–$N(SiMe_3)_2$ bond is in agreement with other observations [20]. No evidence for solvating alcohol molecules was found either by FTIR or by NMR (absence of a peak due to hydroxyls by contrast with the solvated La_3 butoxide). The heterometallic character for the various compounds was supported by elemental analyses and by a X-ray structure determination for **1**.

*Molecular structure of $LaZn_3(OBu^t)_6[N(SiMe_3)_2]_3$ (**1**)*

The crystals of **1** are built up by $LaZn_3(\mu\text{-}OBu^t)_6N(SiMe_3)_2]_3$ molecules possessing a pseudo third order symmetry axis. Lanthanum and zinc are 6- and 3-coordinate respectively (Fig. 1). Selected bond lengths and angles are collected in Table 2. The central lanthanum atom is surrounded by six tertiary butoxide ligands [La–μ-OR av. 2.45(2) Å] leading to a trigonal prismatic geometry. The La–OR bond lengths fall in the range commonly observed [2, 3, 15]. The OR ligands act as assembling ligands between lanthanum and trigonal planar zinc atoms still bearing a trimethylsilylamide ligand. The Zn–N bond distances [av. 1.90(3) Å] are comparable to the Zn–OR ones [av. 1.92(3) Å]. The bond lengths and the angles O–Zn–N [av. 135.5(12)°] and O–Zn–O [av. 89.1(10)°] are similar to these observed for $\{Zn(\mu\text{-}OCEt_3)_2[N(SiMe_3)_2]\}_2$ [21]. The framework of **1** is related to that of other tetrametallic lanthanide species namely $[LnAl_3(OPr^i)_{12}]$ [22], $[LaM_3(BINOL)_3]$ (M = Li, Na, BINOL = binaphtol) [23–25], $Ln(\mu\text{-}OtBu)_3(\mu\text{-}Me)_3(AlMe_2)_3$ (Ln = Y, Nd, Pr) [26] or $[Nd(NMe_2)_3(MMe_3)_3]$ (M = Al, Ga) [27].

The ^{1}H NMR spectra give evidence that the structure of **1** is retained in solution. All butoxide and silylamide groups are equivalent. Compound **1** is vol-

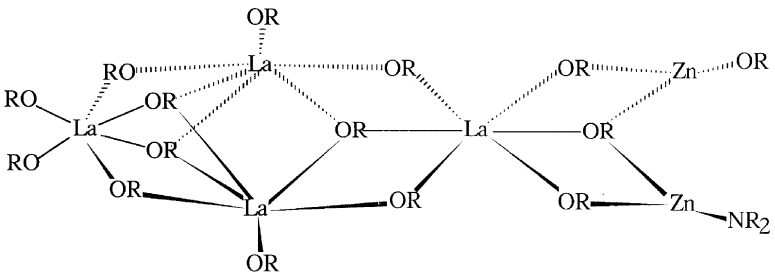
atile (165°C/10^{-3} mm of Hg), it is thus a potential precursor for MOCVD applications. No evolution of the OBu*t*/N(SiMe$_3$)$_2$ ratio is observed by adding three equivalents of tertiary butanol to a solution of **1** in toluene at room temperature. The Zn–N bonds display thus a quite reduced reactivity toward free alcohol.

Although no crystals suitable for X-ray studies were obtained for **2**–**4**, ^{1}H NMR data allow, by comparison with these of La$_3$(OBu*t*)$_9$(HOBu*t*)$_2$, to suggest structures. All compounds displayed chemical shifts of the tertbutoxide groups spreading over the range 1.7–1.0 ppm accounting for magnetically nonequivalent alkoxide ligands namely triply-bridging, doubly-bridging and terminal ones [15]. FTIR and NMR data are in agreement with the retention of the original trinuclear La$_3$(OR)$_9$ core, structures A, B and C which are consistent with the experimental data display the common coordination numbers for the metals, namely 6-coordinated lanthanum and 3-coordinated zinc.

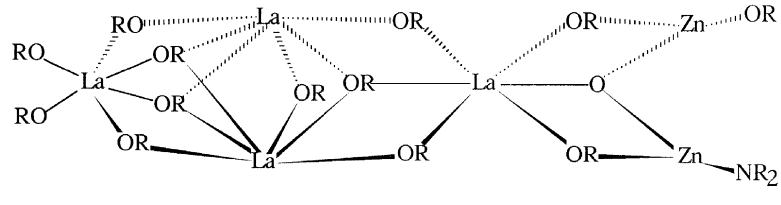
Compound **4** displays seven types of OR signals in a 2:1:1:4:2:1:4 integration ratio. Structure B is in agreement with the experimental data, it can be described as a La$_3$(OR)$_9$ unit associated to LaZn$_2$(OR)$_6$[N(SiMe$_3$)$_2$] which is a fragment of **1**. Seven peaks are observed as well for the proton NMR spectra of compound **2**, they are present in a 1:2:1:4:2:2:1 integration ratio. These data favor a structure of type B.

Zn(OR)$_2$ units. **1** can be seen as the association between La(OR)$_3$ and three Zn(OR)[N(SiMe$_3$)$_2$] species. Alkoxysilylamides seem to have a special stability for zinc, as illustrated by the characterization of {Zn(μ-OCEt$_3$)$_2$[N(SiMe$_3$)$_2$]}$_2$ in the solid state [21].

The tendency to form oxo species is well documented for lanthanide alkoxides. Tetranuclear lanthanide oxoalkoxide units have been stabilized in heterometallic species such as [Y$_4$(μ_3-OBu*t*)$_2$(μ-OBu*t*)$_4$(OBu*t*)$_4$(μ_4-O)(μ-Cl)$_2$Li$_4$(μ-OBu*t*)$_2$] [28] and [Sm$_4$Ti(μ_5-O)(OPr^i)$_{14}$] [29]. Their structures derive from the assembly of two trinuclear Ln$_3$(OR)$_9$ moieties along a face. Praseodymium alkoxides display a tendency to form oxo derivatives based on tetranuclear units namely Pr$_4$O(OR)$_{10}$ or Pr$_4$O$_2$(OR)$_8$ (R = Np) [30]. However, the larger size of praseodymium requires higher coordination numbers and thus frameworks different from these established for the other lanthanides. The hydroxo-oxo cluster Lu$_4$(μ_4-O)(μ_3-OH)(μ_3-OR)(μ-OR)$_4$(OR)$_4$ (R = CMe$_2$CH$_2$OMe) represents another example of a tetranuclear framework [31]. Compound **3** displays a quite simple NMR spectrum with four types of OR ligands which resonate in a 6:8:2:4 integration ratio. These data are compatible with structure C assuming that the signals of all triply-bridging and all doubly-bridging OR are degenerate. **3** can formally be considered as resulting from the assembly of two La$_3$(OR)$_9$ units via two LaO(OR)

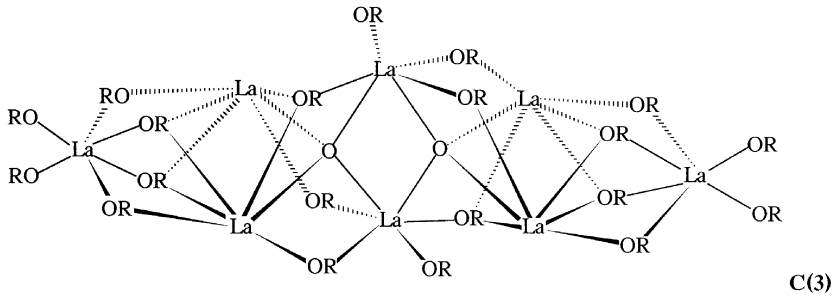


A(4)



B(2)

Compounds **2** and **4** have similar formulaes, formally they differ only by replacement of two OBu*t* ligands by an oxo one. The various LaZn species can actually be formally considered as resulting from the assembly of La(OR)$_3$ and Zn(OR)[N(SiMe$_3$)$_2$] or moieties. The overall structure is thus somehow reminiscent to that of Gd$_6$(μ_4-O)(OR)$_{16}$ (R = C$_2$H$_4$OMe) in which two triangular units are assembled orthogonally via a μ_4-O oxo ligand with a tetrahedral surrounding [32].



The reactivity of the tertiary butanol molecules of $La_3(OBu^t)_9(HOBu^t)_2$ toward metal trimethylsilylamides (M = Pb, Ba) was shown to proceed with retention of the trinuclear lanthanum core thus giving compounds with the anticipated stoichiometry between the metals and complete substitution of the $N(SiMe_3)_2$ ligands [16]. The results reported here show the unique behavior of zinc bis-trimethylsilylamide. The obtaining of several species at room temperature — by contrast to the reaction achieved under reflux — suggests the presence of competing reactions. The reaction at room temperature is characterized by the formation of oxo-species, La–Zn or La ones, the latter being the predominant one.

The poor selectivity and/or control of the LaZn stoichiometry raised the question of whether the reaction proceeded via coordinated or free alcohol molecules (the latter resulting from dissociation reactions of the La_3 solvate). Low temperature ^1H NMR spectra of $La_3(OBu^t)_9(HOBu^t)_2$ were reported to show several types of alkoxide ligands, which were attributed to triply-bridging, doubly-bridging and terminal groups. Additional peaks in the spectra registered at 230 K were attributed to some minor, unidentified species [15]. We observed no reaction between $[Zn(OBu^t)_2]_m$ and $La_3(OBu^t)_9(Bu^tOH)_2$, attempts to induce a reaction by heating afforded $La_5(\mu_5\text{-}O)(O^tBu)_{13}$ having a structure similar to that of the pentanuclear lanthanide oxoisopropoxides as shown by single crystal X-ray diffraction [33] while zinc tertbutoxide was totally recovered. No La–Zn species were formed either at room temperature by mixing $Zn[N(SiMe_3)_2]_2$, terbutanol and $La_3(OBu^t)_9(Bu^tOH)_2$ (only partial alcoholysis of $Zn[N(SiMe_3)_2]_2$ giving $Zn(OR)[N(SiMe_3)_2]$ occurs in such conditions). Heating the reaction medium under reflux ended up with the same homometallic species, namely $La_5(\mu_5\text{-}O)(O^tBu)_{13}$, as for the reaction with $[Zn(OBu^t)_2]_m$ as the reagent. These observations indicate that both $[Zn(OBu^t)_2]_m$ and $Zn(OBu^t)[N(SiMe_3)_2]$ are inert toward the La_3 solvate thus confirming that the building up of LaZn species proceed via the coordinated alcohol molecules. Our findings also account for a limited stability of $La_3(OBu^t)_9(Bu^tOH)_2$ with respect to its evolution into oxoalkoxides such as $La_5(\mu_5\text{-}O)(O^tBu)_{13}$ and $[La_4O(OBu^t)_{10}]_2$ which are inert toward $[Zn(OBu^t)_2]_m$. The La_2Zn stoichiometry of compounds **2** and **4** might be useful for low temperature routes to the La_2ZnO_4 oxide.

(Received 30 March 1998; accepted 9 June 1998)

Abstract—The reactions of ethyl-(*S*)-(−)-lactate with R_3Al in diethyl ether yield the pentacoordinated complexes $[R_2Al((S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(O)OEt))]_2$ (**1**: R = Me; **2**: R = Et; **3**: R = Bu^i). These compounds have been characterized by spectroscopic studies as wells as crystallographic method. These structures show dimeric features containing unusual 5.4.5-fused rings with an Al_2O_2 core and the ester group bonded to Al through the C=O. VT NMR studies of compound **3** suggest that the weak (C=O)→M dative bond may undergo dissociation in solution, giving rise to the equilibrium with a four-coordinate species among two five-coordinate species at ambient temperature. © 1998 Elsevier Science Ltd. Keywords: aluminum; alkoxide; ethyl-(*S*)-lactate; fluxional.

INTRODUCTION

Although compounds containing Al–O bonds have been extensively studied for many years [1, 2], the recognition that aluminum alkoxides may enhance regioselective and stereoselective organic synthesis has recently led researchers to great interest in this area again [3–10]. For example, the first reported highly enantioselective Diels–Alder reaction is the reaction of acrylate ester with 5-benzyloxymethyl-cyclopentadiene in the presence of aluminum trichloride catalyst [11]. *Cis*-dihydropyrone can be obtained in 90% yield with 97% ee by the treatment of a mixture of benzaldehyde and siloxydiene in toluene under the catalysis of a bulky chiral organoaluminum complex prepared from (*R*)-3,3′-bis(tris-arylsilyl)binaphthol and trimethylaluminum [12]. Recently we reported the crystal structure of $[Al\{(S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(Ph)_2OH\}Cl_2]_2$ [13] prepared from the reaction of aluminum trichloride with (*S*)-(−)-1,1-diphenyl-1,2-propane diol that has shown excellent catalytic activities in the Diels–Alder reactions between cyclopentadiene and acrolein or methyl acrylate [14]. In continuation of this study, we present here the preparation and characterization of four aluminum (*S*)-lactate complexes and the variable temperature NMR studies of $[Bu_2^iAl((S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(O)OEt)]_2$. These compounds contain an interesting structure with 5.4.5-fused rings in which two five- and one four-membered rings are coplanar. VT NMR results indicate that $[Bu_2^iAl((S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(O)OEt))]_2$ is dynamic in solution in which slow exchange occurs among two five-coordinate species at ambient temperature.

EXPERIMENTAL SECTION

General

All manipulations were carried out under dry nitrogen atmosphere. Solvents were dried by refluxing at least 24 h over sodium/benzophenone (toluene, hexane, ether) and freshly distilled prior to use. Deuterated solvents (Aldrich) were dried over molecular sieves. $AlMe_3$ (2.0 M in toluene) and ethyl-(*S*)-(−)-lactate were purchased from Aldrich and used without further purification. $AlEt_3$ (15% in hexane), $Al(Bu^i)_3$ (15% in hexane) and Et_2AlCl (15% in hexane) were purchased from TCI and used without further purification. Melting points were determined with a Buchi 535 digital melting point apparatus. ^1H and ^{13}C NMR spectra were recorded on a Varian VXR-300 (300 MHz) or a Gemini-200 (200 MHz) spectrometer with chemical shifts given in ppm from the internal TMS. Mass spectra were recorded on a Jeol Jms-HX 110. Microanalyses were performed using a Heraeus CHN-O-RAPID instrument. Infrared spectra were obtained from a Brucker Equnox 55 spectrometer.

Preparation of complex **1**

To an ice cold (0°C) solution of ethyl-(*S*)-(−)-lactate (0.23 ml, 2.0 mmol) in ether (20 ml), Me_3Al (2.0 M in toluene, 1.2 ml, 2.4 mmol) was added slowly. After all of the later solution was added, the mixture was stirred for 2 hours. Volatile materials were removed under vacuum. The residue was extracted with 20 ml of warm ether, then allowed to cool to 25°C to yield white powder. After filtered, the filtrate was then dried *in vacuo* to give an addition portion of white powder. Both portions of powder exhibited identical ^1H NMR spectra. Yield: 0.32 g (91%). Found: C, 48.28, H, 8.84. Calcd for $C_{14}H_{30}Al_2O_6$: C, 48.27; H, 8.68%. ^1H NMR ($CDCl_3$): δ 4.47 (q, 1H, CH, $J_{H-H}=6.9$ Hz), 4.39 (q, 2H, OCH_2CH_3, $J_{H-H}=7.2$ Hz), 1.45 (d, 3H, CH_3, $J_{H-H}=6.9$ Hz), 1.36 (t, 3H, O–Et, $J_{H-H}=7.2$ Hz), −0.97 (s, 6H, $AlCH_3$). ^{13}C NMR ($CDCl_3$, ppm): 181.84 (COOEt), 66.70 (COOEt), 64.55(OCHMe), 20.37 (COOEt), 13.96 ($OCH(CH_3)$), −9.21 (Al–CH_3). IR (KBr, cm^{-1}): 2997.6, 2942.5, 1699.0, 1471.6, 1384.0, 1345.8, 1278.2, 11.87.1, 1148.6, 1066.5, 1014.4. Mp: 152–154°C.

Preparation of **2**

To an ice cold (0°C) solution of ethyl-(*S*)-(−)-lactate (0.23 ml, 2.0 mmol) in hexane (10 ml), Et_3Al (15% in hexane, 2.6 ml, 2.4 mmol) was added slowly. The mixture was stirred for 2 hours after the addition of Et_3Al and then was dried under vacuum. The residue was extracted with 5 ml of hot hexane and then was cooled to −20°C. Colorless crystals were obtained after 24 h. Yield: 0.18 g (45%). Found: C, 53.03, H, 9.36; Calcd for $C_{18}H_{38}Al_2O_6$: C, 53.45; H, 9.47%. ^1H NMR ($CDCl_3$, ppm): δ 4.50 (q, 2H, $J_{H-H}=7.0$, CH), 4.41 (q, 4H, $J_{H-H}=7.20$ Hz, CH_2 (Et_2O)), 1.48 (d, 6H, $J_{H-H}=7.0$ Hz, CH_3), 1.38 (t, 6H, $J_{H-H}=7.2$ Hz, CH_3), 0.93 (t, 12H, $J_{H-H}=8.2$ Hz, CH_3(AlEt)), −0.28 (q, 8H, $J_{H-H}=8.2$ Hz, CH_2(AlEt)). ^{13}C NMR ($CDCl_3$, ppm): 181.92 (CO), 67.09 (OCH_2CH_3), 64.56 (OCHMe), 20.24 ($OCH(CH_3)$), 14.02 (OCH_2CH_3), 9.77 (CH_2CH_3 (AlEt)), 1.19 (CH_2CH_3(AlEt)). IR (KBr, cm^{-1}): 2995.3, 2941.8, 2861.7, 1687.6, 1455.5, 1388.2, 1346.7, 1315.4, 1272.4, 1139.7. Mp: 93–94°C.

Preparation of **3**

To an ice cold (0°C) solution of ethyl-(*S*)-(−)-lactate (0.46 ml, 4.0 mmol) in ether (20 ml), $(Bu^i)_3Al$ (15% in hexane, 8.0 ml, 4.6 mmol) was added slowly. After all of the later solution was added, the mixture was stirred for 2 more hours. The volatile materials were removed *in vacuo*. The residue was extracted with 30 ml of hexane and then concentrated to *ca.* 5 ml. Colorless crystals were obtained after cooling at 4°C for 24 h. Yield: 0.75 g (73%). Found: C, 59.59; H, 10.61. Calcd for $C_{26}H_{54}Al_2O_6$: C, 60.44; H, 10.53%. ^1H NMR ($CDCl_3$, ppm): δ 4.496 (q, 1H, HCOAl, $J_{H-H}=7.0$ Hz), 4.375 (t, 2H, OCH_2CH_3, $J_{H-H}=7.2$ Hz), 1.687 (m, 1H, CH), 1.488 (d, 3H, CH_3CHOAl, $J_{H-H}=7.0$ Hz), 1.376 (t, 3H, CH_2CH_3, $J_{H-H}=7.2$ Hz), 0.865, 0.854 (dd, 6H, $(CH_3)_2CH$, $J_{H-H}=6.6$ Hz), −0.210, −0.221 (dd, 2H, CH_2Al, $J_{H-H}=6.6$ Hz). ^{13}C NMR ($CDCl_3$, ppm): 182.12 (C=O), 67.01 (HCOAl), 64.68 (OCH_2CH_3), 28.57, 28.21 ($(CH_3)_2CH$), 26.33 (CH), 24.12 (CH_2Al), 20.12 (CH_3COAl), 14.03 (CH_2CH_3). IR (KBr, cm^{-1}): 2943.6, 2859.7, 1687.6, 1457.0, 1408.3, 1347.6, 1264.7, 1142.3, 1066.5, 1014.7, 943.3. Mp: 87–89°C.

Preparation of **4**

To an ice cold (0°C) solution of ethyl-(*S*)-(−)-lactate (0.46 ml, 4.0 mmol) in ether (20 ml), Et_2AlCl (15% in hexane, 5.8 ml, 5.0 mmol) was added slowly. After all of the later solution was added, the mixture was stirred for 2.5 hours and then was dried under vacuum. The residue was extracted with 5 ml of ether and then was cooled to −20°C. Colorless crystals were obtained after 7 days. Yield: 0.40 g (48%). Found: C, 39.81, H, 6.48. Calcd for $C_{14}H_{28}Al_2Cl_2O_3$: C, 40.30; H, 6.76%. ^1H NMR ($CDCl_3$, ppm): 4.95 (q, 2H, $J_{H-H}=7.0$ Hz, CH), 4.56 (q, 4H, $J_{H-H}=7.20$ Hz, CH_2(OEt), 1.64 (d, 6H, $J_{H-H}=7.0$ Hz, CH_3), 1.51 (t, 6H, $J_{H-H}=7.2$ Hz, CH_3), 0.97 (t, 6H, $J_{H-H}=8.2$ Hz, CH_3(AlEt)), −0.08 (q, 4H, $J_{H-H}=8.2$ Hz, CH_2(AlEt)). ^{13}C NMR ($CDCl_3$, ppm): 185.3 (CO), 67.5 (OCH_2CH_3), 67.3 (OCHMe), 19.2 ($OCH(CH_3)$), 13.7 (OCH_2CH_3), 9.1 (CH_2CH_3(AlEt)), 0.8 (CH_2CH_3(AlEt)). IR (KBr, cm^{-1}): 2988.5, 2943.9, 2905.1, 2865.1, 1665.3, 1476.3, 1460.3, 1427.6, 1389.8, 1352.6, 1286.0, 1136.7, 1007.1. Mp: 103–106°C.

(**4**)

X-ray crystallographic studies

Suitable crystals of **1**, **2**, **3** and **4** were sealed in thin-walled glass capillaries under nitrogen atmosphere and mounted on a Siemens P4 diffractometer. The crystallographic data were collected using a θ–2θ scan mode with Mo Kα radiation. The space group determination was based on a check of the Laue symmetry and systematic absences, and was confirmed by the structure solution. The structure was solved by direct methods using Siemens SHELXTL PLUS package [15]. All non-H atoms were located from successive Fourier maps. Anisotropic thermal parameters were used for all non-H atoms and fixed isotropic for H atoms that were refined using riding model† [15]. Crystallographic data of **1**, **2**, **3** and **4** are summarized in Table 1.

RESULTS AND DISCUSSION

Preparation of **1**, **2**, **3** *and* **4**

The reactions of R_3Al with one equivalent of ethyl-(*S*)-(−)-lactate in diethyl ether lead to the formation of five-coordinated complexes $[R_2Al((S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(O)OEt)]_2$ (**1**: R = Me; **2**: R = Et; **3**: R = Bu^i) (eq. 1). Ethyl-(*S*)-(−)-lactate reacts with Et_2AlCl to afford the product $[(Et)(Cl)Al((S)\text{-}(-)\text{-}\mu_2\text{-}OC(H)(Me)C(O)OEt))]_2$ (**4**) (eq. 2). All of these compounds are air and moisture sensitive colorless solid. The ^{1}H NMR spectra of compounds **1**, **2** and **4** taken at 20°C are essentially as expected. There is no OH resonance indicating loss of the hydroxyl proton which is proved by IR spectroscopic studies. Examination of the ^{1}H NMR of these three compounds shows that the alkyl groups bound to the metal atoms in a given complex are equivalent at ambient temperature. This phenomenon is consistent with most five-coordinate aluminum complexes reported by Oliver [17]. However, $[Me_2Al(O\text{-}(R)\text{-}CHC_6H_5((S)\text{-}CH((S)\text{-}NHCH_3)CH_3)]_2$ demonstrate inequivalence in solution at 25°C [18].

Molecular structures of **1**, **2** *and* **3**

Suitable crystals for structure determination of **1** was obtained from an ether solution at 25°C. Compounds **2** and **3** were recrystallized from a hexane solution at 4°C. Their molecular structures have been determined by X-ray crystallography and are shown in Fig. 1. All three structures are similar with the difference only in the alkyl groups bonded to aluminum. The structure of **1** was originally solved in the space group $P4_3$. However, after carefully examining its absolute configuration, the space group $P4_1$ was finally chosen. The structure of **1** shows a dimeric feature which contains 5.4.5-fused rings with an Al_2O_2 core and the ester group bonded to Al through the

† Hydrogen atoms were ride on carbons or oxygens in their idealized positions and held fixed with the C–H distances of 0.96 Å and the O–H distances of 0.85 Å.

C═O in which Al_2O_2 core is essentially coplanar. Similar fused rings have been found in many cases [13, 17, 19]. However, the interesting feature is that each of the mean planes of these two five-member rings are almost coplanar with the Al_2O_2 core with the dihedral angles between 5 and 4-membered rings are only 3.4 and 4.4°, respectively. The coplanarity of these 5.4.5-fused rings is depicted in Fig. 2. The constraints of the fused 5.4.5 ring system result in the rather small O(1)–Al(1)–O(2) and O(1)–Al(1)–O(21) angles of 77.7(2) and 75.7(3)°, respectively. The coordination polyhedron of the central five-coordinated aluminum atom in **1** is somewhat distorted from perfect trigonal bipyramidal geometry with two carbons and one of two bridging oxygen atoms siting on equatorial positions. The aluminum atom, two ligating carbon atoms, and one bridging oxygen atom are almost coplanar. The two equatorial Al–C bonds average 1.959(9) Å that are similar to normal Al–C bonds in four-coordinated complexes. However, the dative O→Al (ester) bonds at 2.154(6) Å are 0.26 Å longer than the longest dative bond from an oxygen to a four-coordinated aluminum for an ester group [20, 21, 22]. The Al–O bonds in Al_2O_2 ring are asymmetric with Al–O distances ranging from 1.837(6) to 1.948(5). The Al–O–Al and O–Al–O bond angles are within the range reported for a Al_2O_2 ring system [23, 24, 25]. Selected bond lengths and bond angles of **1**, **2**, **3** and **4** are given in Table 2. There are five different possible modes of the coordination of ester groups to aluminum centers shown as in Scheme 1 [22, 26]. The average angle of Al–O–C (ester) is 111.4(5)° in **1** and Al(1) is only 0.003 Å above the C(2)C(3)O(2)O(3) plane. Therefore it belongs to type II mode where all atoms of the ester group and aluminum are in the same plane. Ab initio calculations for $H_3Al(O{=}CH_2)$ suggest that type II is the energetically favored geometry [27].

Crystal structure of **4**

Suitable crystals for structure determination of compound **4** were obtained from an ether solution at −20°C. The crystal structure of **4** (shown as in Fig. 3) which is resembling to the structure of **1** also demonstrates dimeric feature with an Al_2O_2 core and an ester group bonded to Al through the C═O group. Both chloride and carbon of ethyl group positions are disordered with respect to chloride/ethyl occupancy, and therefore the least-square refinement was carried out so that for each chloride and ethyl atom site a single set of coordinates and temperature factors was used, but the site occupancy was refined as a fraction of a chlorine atom and a fraction of a ethyl atom such that two fractions summed to unity. This resulted in values of *ca.* 0.75 Cl and 0.25 C for Cl(1)/C(6′) and Cl(2)/C(16′) positions and vice versa 0.75 C and 0.25 Cl for Cl(1′)/C(6) and Cl(2′)/C(16). The average bond distance of Al–O in the Al_2O_2 core of 1.864 Å is within

a normal range for an Al_2O_2 ring. The Al–C and Al–Cl bond distances and C–Al–Cl bond angle are not reliable due to the disordered problem.

VT NMR studies of **3**

It is interesting to note that although the crystal structure of **3** is similar to that of **1** and **2**. However the ^{1}H NMR spectrum of compound **3** taken at room temperature shows two doublets at δ 0.866/0.848 and 0.855/0.833 ppm corresponding to $(CH_3)_2CH$ indicating that these two methyl groups on an iso-butyl group bonded to aluminum are chemically nonequivalent. This phenomenon is in contrast to the results observed for **1** and **2** where only one set of Al–R resonance is found in complexes containing five-coordinate aluminum centers. However in the $[Et_2Al(8\text{-quinolinolato})]_2$ [28] and $[R_2AlOCH_2\text{-}2\text{-}C_5H_4N]_2$ [29] dimer nonequivalence of the methylene groups only appears at low temperature where exchange is slow. In order to probe the structure in solution of **3**, variable-temperature NMR studies in d_8-toluene were performed and the selected spectra are shown in Fig. 4. VT NMR studies demonstrate that the chemical shifts of the various groups on Bu^i group are temperature dependent. At 20°C, two doublets at δ 1.266, 1.243 and 1.255, 1.233 ppm respectively indicating two nonequivalent methyl groups (Me_a and Me_b) of Al–Bu^i. However these two doublet peaks become closer as the temperature was raised. At 92°C these two doublet peaks merge as one set doublet at δ 1.172, and 1.151 ppm indicating that these two methyl groups are chemical equivalent. The above VT NMR studies suggest that the weak (C=O)→M dative bond may undergo dissociation in solution, giving rise to the equilibrium with a four-coordinate species shown in Scheme 2 in which slow exchange occurs among two five-coordinate species at ambient temperature. However a rapid exchange takes place at high temperature above 92°C.

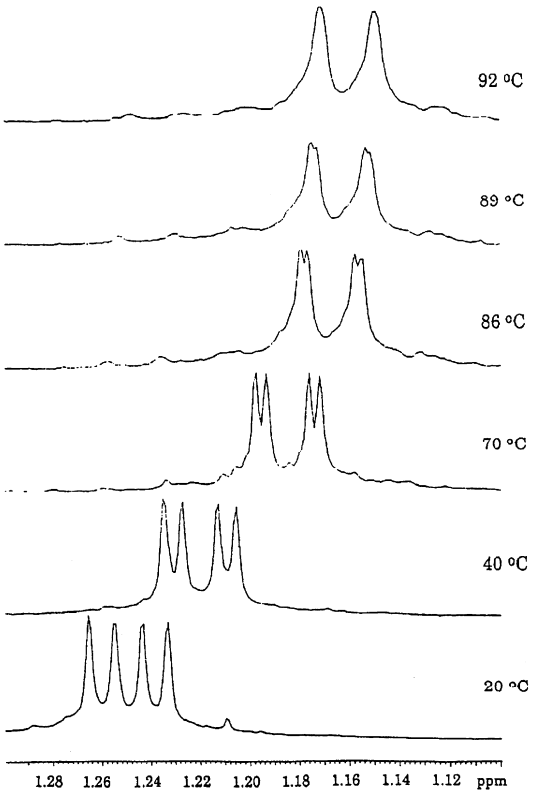

Fig. 4. A variable-temperature ^{1}H NMR spectrum in the methyl region of the Al–Bu^i of **3**.

Infrared spectra studies

The Infrared spectra of free lactate, **1**, **2**, **3**, and **4** in the 1600 to 1700 cm^{-1} range are compared in Table 3. A strong (C=O) absorption due to the lactate was observed at 1687 cm^{-1} for **2** and 1665 cm^{-1} for **4**. There is a decrease in carbonyl stretching frequency in the IR spectrum of the aluminum complexes when compared to the free carbonyls (1738 cm^{-1}). However, its magnitude drop ranges from 39–73 cm^{-1} which is much smaller than those found for four-coordinated aluminum ester complexes (85–125 cm^{-1}) [20, 21, 22]. That the C=O stretching frequency decreases as the substituted group changes from an electron donating group, ethyl group, to the electron withdrawing chloride resulting from a more positive charge on the aluminum center in **4** compared to that in **2** is due to the electronic effect. The result is consistent with the crystal structure data that Al–(O=C) distance of 2.171 Å for **2** is longer than the Al–O distance of 2.027 Å for **4**.

CONCLUSIONS

These structures show dimeric feature containing unusual 5.4.5-fused rings with an Al_2O_2 core and the ester group bonded to Al through C=O. These 5- and 4-membered rings are coplanar. The dative O→Al (ester) bonds at 2.154(6) Å are 0.26 Å longer than the longest dative bond from oxygen to four-coordinate aluminum for an ester group. VT NMR studies of **3** suggest that the weak (C=O)→M dative bond may undergo dissociation in solution, giving rise to the equilibrium with a four-coordinate species in which slow exchange occurs among two five-coordinate species at ambient temperature. However a rapid exchange takes place at high temperature above 92°C. Further studies using these compounds as catalyst in Diels–Alder reactions are proceeding.

(Received 16 February 1998; accepted 10 June 1998)

Abstract—Two new 1:2 polymeric complexes of copper(II) azide with 3-ethylpyridine (**1**) and 4-ethylpyridine (**2**), have been synthesized and characterized by spectroscopic and crystallographic methods. The structure of complex (**1**) contains a dimeric $[Cu(3\text{-Etpy})_2(N_3)_2]_2$ unit and a monomeric $[Cu(3\text{-Etpy})_2(N_3)_2]$ unit. Each copper atom in the dimeric unit attains a five coordination environment, whereas the copper atom in the second unit has an elongated octahedral geometry. In complex (2), each copper atom in the asymmetric unit is coordinated to the end nitrogens of two μ_2-1,3 azido ligands, a pair of *trans* 4-Etpy molecules and a nitrogen atom of a terminal azide group. This same nitrogen atom further links a neighboring copper atom at a long Cu–N distance of 2.920(7) Å, thus connecting the asymmetric units giving rise to a 2D structure. The IR and electronic spectra are reported. Strong absorption bands due to $N_3 \rightarrow Cu^{II}$MLCT transitions are observed in spectra of solids and solutions of both complexes. Magnetic susceptibility and EPR data of both complexes are presented and discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) azide complexes; 3-, and 4-ethylpyridine; X-ray crystal structures; electronic spectra; infrared spectra; magnetic measurements

INTRODUCTION

A substantial array of copper(II) azido complexes of neutral pyridine derivative ligands have been prepared, structurally characterized and shown to have a wide variety of stoichiometries, solid state stereochemistries and varying degrees of oligomerization. Thus neutral complexes of copper(II) azide: ligand ratios of 1:1 [1–9], 1:2 [10–14] and 3:2 [15, 16], in addition to $[CuL_4(N_3)]^+$ cationic complexes [17] have been synthesized and characterized. In these complexes different types of bonding of azido ligands have been demonstrated. Thus, the 1:2 complexes of 4-picoline, which features oligomeric edge-sharing chains of polyhedra, contains terminal and μ_2-1,1 bridging azido ligands, the corresponding complex of 3-picoline contains both μ_2-1,1 and μ_2-1,3 bridging azides, whereas the 1:2 complex of 3-benzoylpyridine [18] possesses only μ_2-1,3 azido ligands. On the other hand, while the polymeric complex $[Cu(N_3)_2(DENA)]$ (DENA = diethylnicotinamide) contains μ_2-1,1 and μ_3-1,1,3 groups, the 3:2 complex of 2-benzoylpyridine possesses μ_2-1,1 and μ_3-1,1,1 bridging azides [16]. These examples demonstrate the versatility of the azide ligand. Moreover, this ver-

satility reflects itself in the variety of magnetic behavior of the metal azido complexes from strong anti-ferromagnetic [19–21] to strong ferromagnetic [22–25] including ferro–antiferromagnetic [26, 27] depending upon the nature of the bridging azido ligand. We now isolated two new complexes of the formula $CuL_2(N_3)_2$, where L = 3-, and 4-ethylpyridine (hereafter abbreviated as 3-, and 4-Etpy), of related structures. The synthesis and characterization of these complexes as elucidated by X-ray crystallography, spectroscopic and magnetic methods are presented in this paper.

EXPERIMENTAL

3-, and 4-ethylpyridine were purchased from Aldrich company and other chemicals were of analytical grade quality.

Preparation of polymeric $[Cu(3\text{-}ethylpyridine)_2(N_3)_2]_n$ *complex* (*I*)

Copper(II) nitrate trihydrate (0.72 g, 3 mmol) dissolved in *ca.* 30 cm^3 acetone and 3-Etpy (0.75 g, 7 mmol) were mixed together, followed by addition of an aqueous solution (*ca.* 5 cm^3) of NaN_3 (0.52 g, 8 mmol). After filtration of the brown solution mixture, several drops of 3-Etpy were added to prevent the co-precipitation of the 1:1 complex. The final mixture was allowed to stand in an open beaker over *ca.* three weeks until black well-shaped crystals of the complex were separated along with a blue crystalline material. Yield, 40% with respect to copper. Anal.; Found; C, 46.3; H, 4.9; N, 30.6; Cu, 17.8. Calc.: C, 46.5; H, 5.0; N, 30.9; Cu, 17.6%.

Preparation of polymeric $[Cu(4\text{-}ethylpyridine)_2(N_3)_2]_n$ *complex* (*2*)

Copper(II) nitrate trihydrate (0.72 g, 3 mmol) and 4-ethylpyridine (1.07 g, 10 mmol) were mixed together in 40 cm^3 acetone. To this mixture, an aqueous solution (*ca.* 5 cm^3) of NaN_3 (0.48 g, 7.5 mmol) was added with continuous stirring. The green precipitate was filtered off and then dissolved in DMF, followed by addition of several drops of 4-Etpy. The final mixture was filtered off and the filtrate allowed to stand in an open beaker over several weeks until dark green crystals of the complex deposited. Yield, 50%. Anal.; Found; C, 46.6; H, 5.0; N, 30.0; Cu, 17.4. Calc.: C, 46.5; H, 5.0; N, 30.9; Cu, 17.6%.

Caution: both compounds are very sensitive to grinding and explode upon heating and friction.

Physical measurements

The experimental procedures and instruments used for different physical measurements are as described previously [18, 26, 27].

X-ray crystal structure analyses

A modified STOE four circle diffractometer was used for single crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 40 (compound **1**) and 65 (compound **2**) reflections in the 2θ range 10–32°. Data were collected at 293(2) K using graphite crystal monochromatized Mo–Kα radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz-polarization effects, for absorption and also for intensity decay (intensities of two standard reflections dropped continuously during data collection by 19% and 9%, respectively). Crystallographic data and processing parameters are given in Table 1.

The structures were solved by direct methods and subsequent Fourier analyses. Anisotropic displacement parameters were applied to non-hydrogen atoms in full-matrix least-squares refinements based on F^2. The hydrogen atoms were assigned with isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. The program DIFABS [28], and the SHELXTL/PC [29] program package were used for computations. Selected bond distances and bond angles are given in Tables 2 and 3. Supplementary data consisting of fractional atomic coordinates, displacement parameters, observed and calculated structure factors and complete lists of bond distances and bond angles have been deposited, CCDC deposition numbers 101853 and 101854.

RESULTS AND DISCUSSION

3-ethylpyridine as well as 4-ethylpyridine interact with the copper(II) ions in presence of azide ions producing complexes of general formula $CuL_2(N_3)_2$. In case of 3-Etpy, crystals of the 1:2 azide complex were co-precipitated with blue crystals of a 1:2 nitrate complex. The sizes of both types of crystals are sufficient to separate them from each other after filtration and dryness. Both azide complexes are insoluble in non-polar solvents, e.g. benzene, carbontetrachloride, etc., and some polar solvents, e.g. methyl alcohol, chloroform and water. They are slightly soluble in acetone and ethanol but soluble in DMF and DMSO, giving non-conducting solutions. The colors of these complexes change to brown immediately in the last two solvents.

Structures

Figures 1 and 2 illustrate the principle structural features of complex (**1**), for which selected bond distances and bond angles are collected in Table 2. The structure contains two different subunits; [Cu(3-

symmetry codes: (a) $-x+1, -y, -z+1$; (b) $-x+3/2, y+1/2, -z+3/2$.

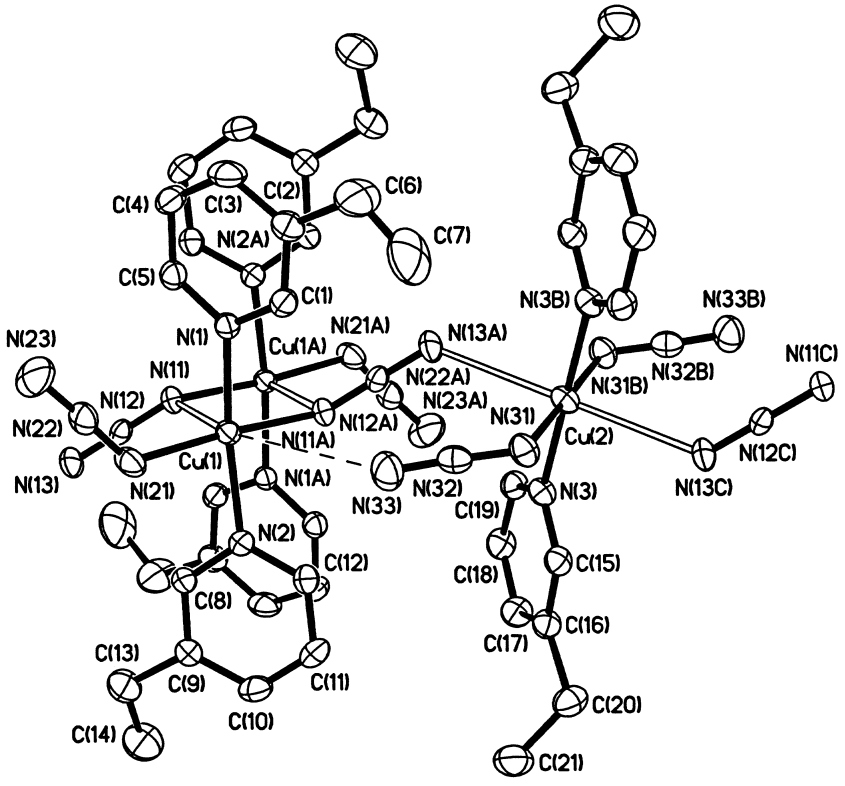

Fig. 1. $[Cu(3\text{-ethylpyridine})_2(N_3)_2]_n$, **1**: Molecular geometry and atom labelling scheme of the trinuclear unit. Hydrogen atoms are omitted. Open stick bonds indicate Cu–N bonds within the range 2.20–2.80 Å; broken lines are Cu–N distances >2.80 Å.

$Etpy)_2(N_3)_2]_2$ (I) and $[Cu(3\text{-}Etpy)_2(N_3)_2]$ (II). Each copper atom in the dimeric unit (I) is coordinated by pairs of trans 3-Etpy molecules, terminal azido groups [N(21)–N(22)–N(23) and N(21a)–N(22a)–N(23a)] and nitrogen atoms of μ_3-1,1,3 bridging azido ligands [N(11)–N(12)–N(13) and N(11a)–N(12a)–N(13a)]. Thus each copper atom is pentacoordinated by four short Cu–N distances [from 1.981(4) to 2.030(3) Å]

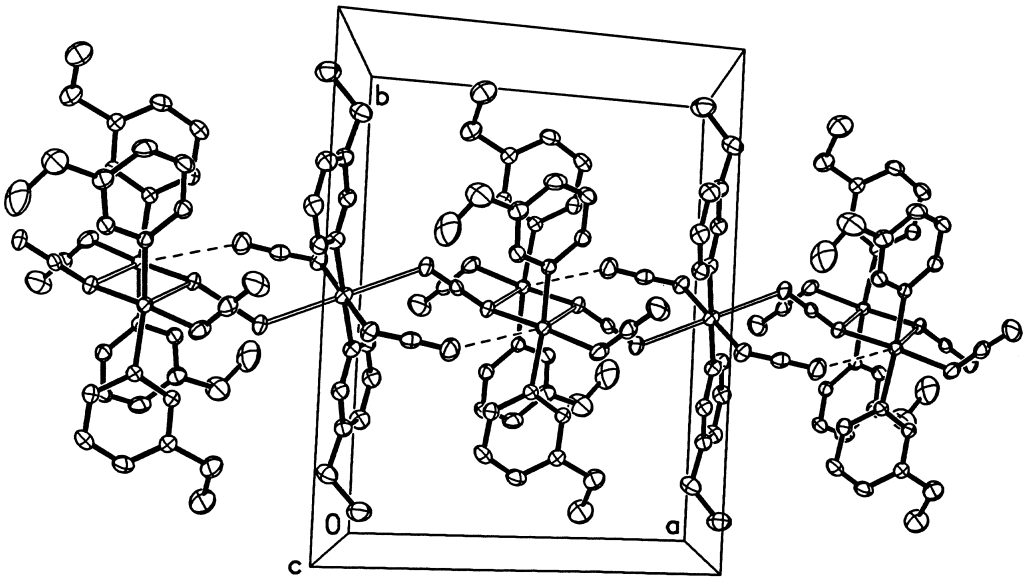

Fig. 2. [Cu(3-ethylpyridine)$_2$(N$_3$)$_2$]$_n$, **1**: One-dimensional chain of copper polyhedra oriented along the *a*-axis of the unit cell.

and a fifth long Cu–N bond length of 2.409(3) Å, adopting a distorted square pyramidal geometry with N(11) at the apical site. The metal center, Cu(2), in unit (II), which is located at an inversion center, binds two azido ligands [N(31)–N(32)–N(33) and N(31b)–N(32b)–N(33b)], two 3-Etpy molecules and the other end nitrogen of the two μ_3-1,1,3 azido ligands at a long Cu–N distances of 2.658(3) Å, giving rise to a (2+2+2) elongated distorted octahedral geometry. The distances between copper atoms of the two units, Cu(2)...Cu(1) and Cu(2)...Cu(1a) are 5.979(2) and 6.459(2) Å, respectively. The terminal azide groups [N(31)–N(32)–N(33) and N(31b)–N(32b)–N(33b)] from unit (II) have very long distances of 3.509(4) Å, between the other end nitrogen atoms and copper atoms of neighboring dimeric units on both sides. The Cu...Cu distance of 3.323(1) Å within the Cu_2N_2 ring of the dimeric unit (I) is longer than corresponding values [3.120(2) and 3.071(2) Å] found in the structure of [Cu(pyridine–N–oxide)(N$_3$)$_2$]$_n$ [14], shorter than that reported for [Cu(3-pic)$_2$(N$_3$)$_2$]$_n$ of 3.546(2) Å [12], but comparable with that found [3.326(2) Å] in the structure of [Cu(3-acetylpyridine)$_2$(N$_3$)$_2$]$_n$ [14].

Figure 3 is a perspective drawing showing the principle structural features of complex (**2**) along with the atom labelling scheme. Selected bond lengths and bond angles are collected in Table 3. The coordination polyhedron around copper atoms may be described as (4+1+1) with four short bonds with N(1) and N(2) from 4-Etpy molecules and N(11) and N(21) from two azido ligands [Cu–N, av = 2.0 Å] and nitrogen atom N(13a) of asymmetric μ_2-1,3 azido group which occupies an apical position at a long Cu–N distance of 2.658(3) Å. Such tetragonal pyramids are connected to zig-zag chains. N(21) further links the former chains of polyhedra at a very long distance, Cu(1)–N(21a) = 2.920(7) Å. Thus azido ligand N(21)–N(22)–N(23) behaves as μ_2-1,1 bridging group and asymmetric di-μ_2-1,1 of such azides form Cu_2N_2 cyclic rings giving rise to sheets of poyhedra (Figure 4). Although the structure of complex (**2**) differs from that of complex (**1**), steric and packing effects are operative and cause the connection of the chains of tetragonal polyhedra through such very long Cu–N distances giving rise to a two-dimensional structure.

The structures of the title complexes (**1**) and (**2**) are closely related to those of diazido-2,2′-bipyridine copper(II) [30] and [(2-aminoethyl)pyridine]copper(II) azide [1]. In the former the copper is described as being square-planar with two additional long bonds [Cu–N: 2.682 and 2.680 Å] leading, through semi-coordination, to polymerization in the *x* direction. In the latter, the coordination geometry around the copper atom is distorted from square planar by a tetrahedral twist of 28°. The copper coordination polyhedron is completed by short interactions, both above and below the mean plane, to the bonded azide nitrogen atoms of adjacent molecules related by the *c*-glide symmetry [Cu–N: 2.88 and 2.66 Å].

Long Cu–N distances are also observed in the linear systems: Cu(4-pic)$_2$(N$_3$)$_2$ [Cu–N: 2.52(2)–2.79(2) Å] [10]; [Cu(DENA)(N$_3$)$_2$] [2.755(5) and 2.841(5) Å] [4, 5]; Cu(3-pic)$_2$(N$_3$)$_2$ [Cu–N: 2.625–2.679 Å] [12]; Cu(3,4-lut)(N$_3$)$_2$ [Cu–N: 2.638(3) Å] [15]; both modifications of Cu(py)$_2$(N$_3$)$_2$ [Cu–N: 2.50–2.76 Å] [31, 32]; Cu(NH$_3$)$_2$(N$_3$)$_2$ [Cu–N: 2.56(1) and 2.67(1) Å] [33]; KCu(picolinato)(N$_3$)$_2$]$_n$ [Cu–N: 2.649(4) Å] [34] and copper azido complex with tridentate ligand 1-(imidazol-4-yl)-2-(2-pyridylmethylene)-amino)-ethane [Cu–N: 2.797 and 2.804 Å] [35]. Sheets of polyhedra are formed in case of copper complexes with the (3-

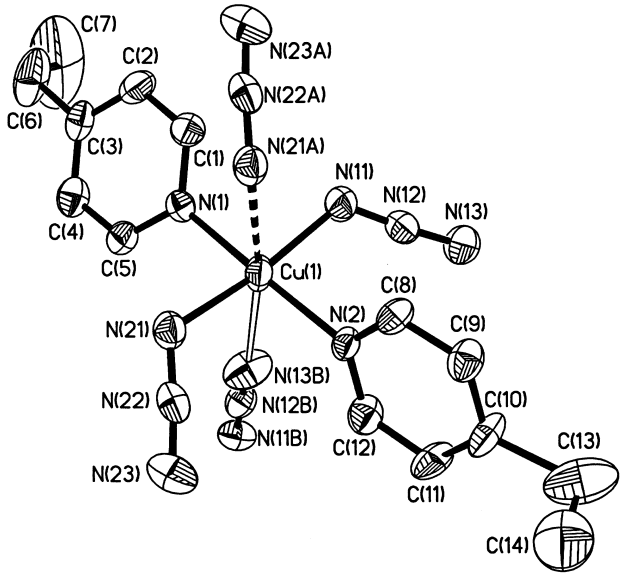

Fig. 3. $[Cu(4\text{-ethylpyridine})_2(N_3)_2]_n$, **2**: Molecular geometry and atom labelling scheme. Hydrogen atoms are omitted. Open stick bonds indicate Cu–N bonds within the range 2.20–2.80 Å; broken lines are Cu–N distances > 2.80 Å.

aminopropyl)oxamidato ligand [Cu–N: 2.564(3) and 2.859(4) Å] [36] and $[Cu_2(bpym)(N_3)_4]$ (bpym = 2,2′-bipyrimidine) [Cu–N: 2.480(2) and 2.743(3) Å] [37], whereas Cu–N distances of 2.60(2) and 2.70(2) Å are observed in $Cu(N_3)_2$ [38] and a long Cu–N distance of 2.627(6) Å in the 3:2 complex with 2-benzoylpyridine [16]. In case of the three copper azido complexes with tridentate ligand 1,4,7-trimethyl-1,4,7-triazacyclononane dimeric units are formed by taking into account Cu–N distances from 2.709 to 2.944 Å [21].

IR spectra

X-ray structure determination showed complex (**1**) to have three asymmetric azides with δd values of 0.047, 0.033 and 0.028 Å, and complex (**2**) to contain two asymmetric azido ligands with δd values of 0.044 and 0.041 Å. While the number of $\nu_{as}N_3$ bands are two (Table 4) as expected in case of complex (**2**), the appearance of only one $\nu_{as}N_3$ sharp band is unexpected for complex (**1**). However, this result is not unusual. For example, the IR spectrum of $Cu(pyridine)_2(N_3)_2$, with two asymmetric azido groups showed only one ν_{as} band at 2040 cm^{-1} [32]. For complex (**2**) the positions of the $\nu_{as}N_3$ absorption bands are not consistent with the δd verses $\nu_{as}N_3$ relationship given earlier [39, 40] which suggests two bands around 2040 cm^{-1}. It is possible that some coincidence of the vibrations related to the azides with such very close δd values leads to some sort of resonance or configuration interactions. It is noteworthy to mention that the markedly strong band usually appeared around 1285 cm^{-1} associated with ν_sN_3 in copper(II) azido complexes containing one ore more di-μ_2-1,1 bridging azido systems [4–7], is not observed in the IR spectra of both complexes (**1**) and (**2**). Instead, a weak to medium band appears around 1284–1289 cm^{-1}.

Electronic spectra

The electronic spectra of the title complexes, **1** and **2**, measured as Nujol mulls are given in Table 5. These spectra exhibit d–d transitions as a broad band centered around 14700 and 15350 cm^{-1}, for **1** and **2**, respectively, suggesting a distorted six-coordinate copper(II) environment [41, 42] for both complexes. The spectra of these complexes also show at least three strong bands in the ranges 33000–22000 cm^{-1} and 31000–18400 cm^{-1}, for **1** and **2**, respectively. These bands are due to $N_3 \rightarrow Cu^{II}$ LMCT transitions. While two and four azide-to-copper charge transfer transitions have been predicted [43] for terminal and μ_2-1,1 or μ_2-1,3 bridging azido ligands in copper(II) complexes, respectively, only one feature is observed for terminal copper(II) azide monomers and two bands are reported for μ_2-1,3 or μ_2-1,1 dimers [36]. The present structure with terminal azides, μ_3-1,1,3 and μ_2-1,1 or μ_2-1,3 azides show at least three $N_3 \rightarrow Cu^{II}$ LMCT bands. In DMF and DMSO both complexes show a very strong band in the range 25250–24000 cm^{-1} due to $N_3 \rightarrow Cu^{II}$ CT transitions, in addition to the d–d absorption around 14000 cm^{-1} for DMF and 13000 cm^{-1} for DMSO. Thus these complexes in DMF and DMSO show only one LMCT absorption band and the d–d transition is shifted to lower wave numbers. The change of color of these complexes in both solvents from green to brown could be associated with a partial reduction of Cu(II) to Cu(I) leading to

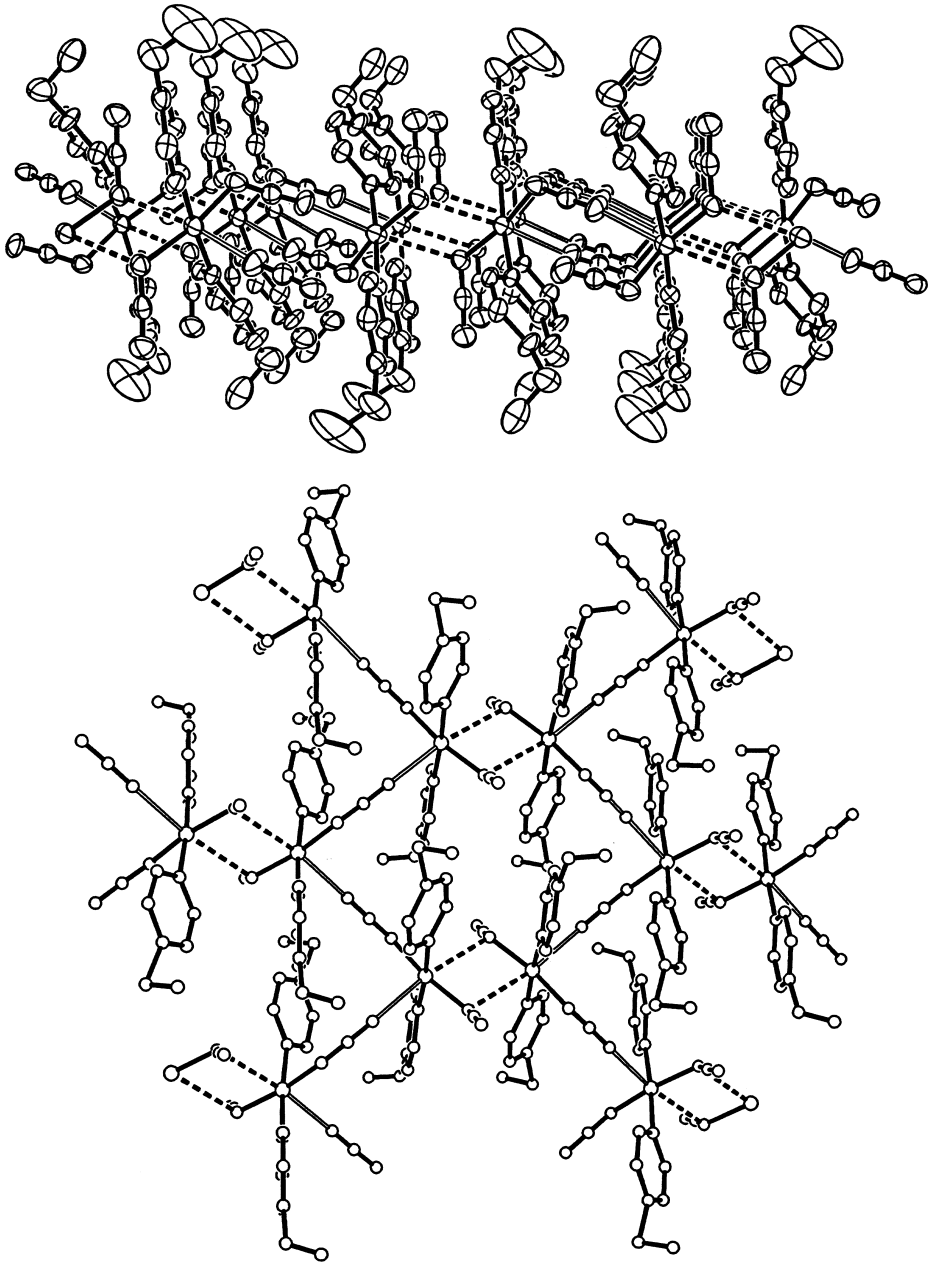

Fig. 4. $[Cu(4\text{-ethylpyridine})_2(N_3)_2]_n$, **2**: Two-dimensional arrangement of the copper polyhedra. Top: front view; bottom: view onto the sheet of copper polyhedra. Bond types as in Fig. 3.

mixed-valence compounds which are well known to exhibit such brownish color. In EtOH, however, complex **2** retains its identity as suggested by its color and the position of the d–d absorption band at $14880\,cm^{-1}$, a little lower value than of the solid sample.

Magnetic properties

$\chi_M T$ verses T plot, (referred to the *three* coppers molecular weight), of compound **1** and the $\chi_M T$ verses T plot (for *two* copper atoms), of compound **2** are shown in Fig. 5. For **1**, the $\chi_M T$ plot shows a practically constant value close to $1.2\,cm^3{\cdot}K{\cdot}mol^{-1}$ in the temperature range 300–25 K, decreasing slightly at low temperature. The 4 K value reaches $0.93\,cm^3{\cdot}K{\cdot}mol^{-1}$. This magnetic behavior indicates a very weak overall antiferromagnetic interaction. Compound **2** shows a room temperature $\chi_M T$ value of $0.86\,cm^3{\cdot}K{\cdot}mol^{-1}$, which increases up to $0.94\,cm^3{\cdot}K{\cdot}mol^{-1}$ at 20 K, decreasing slightly at lower temperatures, indicating a dominating weak fer-

romagnetic interaction in the 300–20 K temperature range and a weak antiferromagnetic coupling at low temperature.

From the structural data, the two compounds show the azide bridges between equatorial-apical sites of square pyramidal or octahedral copper(II) environments. The unpaired electronic density is then largely localized in the *xy* plane, and all interactions involving the non-active $d^2{}_z$ atomic orbital should be very weak or even negligible.

Compound **1** shows the unusual μ_3-1,1,3 azide bridges between each three copper atoms unit, for which two interactions of opposite sign may be expected: the double μ_2-1,1 bridges between Cu(1)–Cu(1a) may afford ferromagnetic coupling, whereas for the end-to-end bridges between Cu(1)/Cu(1a) and Cu(2) antiferromagnetic coupling may be expected. Moreover, all the azide bridges involve at least one axial coordination site of the corresponding copper environments: N(11) acts as a bridge between an equatorial Cu(1) and an axial Cu(1a) sites, as occurs for the Cu(1)–N(11)–N(12)–N(13)···Cu(2), whereas the interaction trough Cu(1a)···N(11)–N(12)–N(13)···Cu(2) involves two large axial sites. From these data, the magnetic behavior of the compound **1** may be reasonably assumed as very weak ferro–antiferro competing interactions which allows to an apparently non-coupled system, with a dominant antiferromagnetic interaction, evidenced at low temperature. Due to the small decay at low temperature, try to evaluate the J values of this system has no sense, and only the qualitative discussion of the observed properties was made.

For compound **2**, the interaction provided by the end-to-end bridge should be quasi-negligible due to the very large Cu(1)–N(13b)–N(12b) bond angle of 172.7(6)°, according to previous MO calculations [26, 27]. Experimental magnetic data have been fitted as a dimeric CuCu ferromagnetic entity including a z"J" parameter to evaluate the weak antiferro–magnetic interactions [44], $S = 1/2$ systems. The best fit parameters, referred to the Hamiltonian $H = -JS_1S_2$ were $J = -12.4(5)\,cm^{-1}$, $g = 2.137$ and $J' = -0.37(3)\,cm^{-1}$.

EPR spectra

The X-band EPR spectra of solid samples of both complexes at room temperature consist of the typical axial copper(II) signals, with $g_{par.} = 2.19$, $g_{perp.} = 2.07$ for **1** and $g_{par.} = 2.17$, $g_{perp.} = 2.09$ for **2**. Absence of half-field signals for the two compounds reinforced the assumption of very weak superexchange interactions.

(Received 25 May 1998; accepted 10 June 1998)

Abstract—A series of potentially dinucleating [2+2] macrocyclic ligands with two *SNS* metal-binding domains separated by a variable polymethylene chain have been prepared. Two examples of these ligands have been structurally characterised. These ligands form polymeric adducts with $[Rh_2(O_2CCMe_3)_4]$ in which the ligands are thought to act as exocyclic *S*-donors to the axial sites of the dinuclear complex. In contrast, reaction with $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ resulted in the formation of dinuclear complexes in which two Rh(CO) units are bound to each macrocyclic ligand. © 1998 Elsevier Science Ltd. Keywords: macrocycles; synthesis; X-ray structure; rhodium complexes.

1. INTRODUCTION

We have been interested in the properties of ligands incorporating both hard and soft donor sites for a number of years and have developed a number of ligand systems incorporating both (hard) nitrogen and (soft) sulfur donors into oligoaromatic [1–8], open chain [9, 10] and macrocyclic [11, 12] ligands. The design of macrocyclic ligands capable of binding two or more metal ions is of current interest and in this paper we show how the inversion of a synthetic strategy allows the formation of [2+2] as opposed to [1+1] macrocyclic ligands. These ligands were designed as they offer the possibility of binding two interacting mononuclear sites or a dinuclear component within a single macrocyclic ligand.

2. EXPERIMENTAL

^{1}H NMR spectra were recorded on Brüker WM250 or AM400 spectrometers; positive ion fast atom bombardment (FAB) and electron impact (EI) mass spectra were recorded on A.E.I. MS12 or Kratos MS50 spectrometers using a 3-nitrobenzyl alcohol matrix for the FAB spectra. IR spectra were recorded on Perkin-Elmer 1483 or 983 spectrophotometers with the samples in compressed KBr disks, as nujol mulls or as liquid films between CsI plates. Melting points were determined using unsealed capillary tubes and are uncorrected. 2,6-Bis(bromomethyl)pyridine **1** [13] and $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ [14] were prepared by the literature methods.

2.1. 2,6-*Bis*(*mercaptomethyl*)*pyridine*, **2**

2,6-Bis(bromomethyl)pyridine (4.0 g, 15.2 mmol) and thiourea (2.3 g, 30.4 mmol) were dissolved in EtOH (50 cm^3) and the mixture heated to reflux for 5 h, after which the solution was evaporated to dryness *in vacuo* to give a white precipitate of solid thiouronium salt which was then treated with a solution of $NaHCO_3$ (2.12 g, 30.4 mmol) in water (100 cm^3) to give a clear solution. This solution was then boiled for 45 min under N_2, cooled to room temperature and extracted with CH_2Cl_2 (3×50 cm^3). The extracts were combined, washed with a saturated aqueous NaCl, dried over $MgSO_4$ and the solvent removed *in vacuo* to give a dark yellow oil. Kugelrohr distillation of this

oil gave **2** as a colourless liquid. Yield: 70–80%. B.p. 96–100°C/0.2 mm Hg. (Found: C, 49.2; H, 5.1; N, 8.2% $C_7H_9NS_2$ requires: C, 49.08; H, 5.30; N, 8.18%). IR (liquid film): 3060 w, 2931 w, 2546 w br, 1598 s, 1572 s, 1452 s, 1219 m, 1160 w, 1088 m, 822 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 171 {**2**}. ^{1}H NMR (CD_3OD): δ 7.60 (t, 1H, H^4), 7.25 (d, 2H, $H^{3,5}$), 3.75 (s, 4H, CH_2).

2.2. 2,3,12,13-*Tetrathia*-[4.4](2,6)-*pyridinophane*, **5**

2.2.1. *Method* 1 As in Section 2.1 to give the thiouronium salt which was then boiled with a saturated aqueous solution of $NaHCO_3$ in air (100 cm^3) for 45 min; the solution was then cooled extracted with CH_2Cl_2 (3 × 50 cm^3), the extracts combined, washed with a saturated aqueous NaCl, dried ($MgSO_4$) and concentrated to give **5** as a cream powder. M.p. 151–152 (lit.[15], 150–152°C). (Found: C, 49.82; H, 4.17; N, 8.36% $C_7H_9NS_2$ requires: C, 49.67; H, 4.17; N, 8.28%). IR (liquid film): 3050 w, 2964 w, 1588 s, 1572 s, 1452 s, 1205 m, 1084 m, 993 w, 815 m, 753 m cm^{-1}. Mass spectrum (EI): *m/z* 338 {**5**}. ^{1}H NMR (CF_3CO_2D): δ 8.30 (t, 2H, H^4), 7.73 (d, 4H, $H^{3,5}$), 4.12 (s, 8H, CH_2).

2.2.2. *Method* 2 A solution of **2** (0.1 g, 0.55 mmol) in MeOH (5 cm^3) was mixed with aqueous NaOH (0.2 g in 5 cm^3) and the mixture left in air for 4 days at 4°C. The white precipitate was collected by filtration and dried to give analytically pure **5**. Yield: 0.04 g (40%).

2.3. [2 + 2] *Macrocycles*

A solution of **2** (100 mg, 0.55 mmol) and the appropriate α,ω-dibromoalkane (0.55 mmol) in EtOH (25 cm^3) was heated to reflux and then treated with solid NaOH (200 mg). The mixture was heated to reflux for 2 h, after which period a white precipitate had formed. The reaction mixture was cooled, the white solid collected by filtration, washed with EtOH (3 × 10 cm^3) and separated by thin layer chromatography on alumina plates using 1:1 PhMe/CH_2Cl_2 as eluent.

2.3.1. 2,8,17,23-*Tetrathia*-[9.9](2,6)-*pyridinophane*, **6** Colourless crystals. Yield: 14 mg (10%). R_f = 0.17. (Found: C, 60.22; H, 7.18; N, 5.92% $C_{24}H_{34}N_2S_4$ requires: C, 60.20; H, 7.16; N, 5.85%). IR (KBr): 2928 m, 2856 w, 1587 s, 1571 s, 1463 s, 1451 m, 1384 w, 1156 w, 1080 w, 993 w, 818 w cm^{-1}. Mass spectrum (EI): *m/z* 478 {**6**}. ^{1}H NMR (CD_2Cl_2): δ 7.60 (t, 2H, H^4), 7.20 (d, 4H, $H^{3,5}$), 3.75 (s, 8H, pyCH_2S), 2.45 (t, 8H, CH_2C**H**$_2$S), 1.50 (m, 8H, C**H**$_2$$CH_2$S), 1.33 (m, 4H, CH_2C**H**$_2$$CH_2$).

2.3.2. 2,9,18,25-*Tetrathia*-[10.10](2,6)-*pyridinophane*, **7** Colourless crystals. Yield: 16 mg (11%). R_f = 0.20. (Found: C, 61.89; H, 7.40; N, 5.81% $C_{26}H_{38}N_2S_4$ requires: C 61.61; H 7.56; N 5.53%). IR (KBr): 2920 m, 2850 w, 1591 s, 1573 s, 1465 s, 1453 m, 1383 w, 1137 w, 1088 w, 993 w, 818 w cm^{-1}. Mass spectrum (EI): *m/z* 506 {**7**}. ^{1}H NMR (CD_2Cl_2): δ 7.60 (t, 2H, H^4), 7.20 (d, 4H, $H^{3,5}$), 3.75 (s, 8H, pyCH_2S), 2.45 (t, 8H, CH_2C**H**$_2$S), 1.50 (m, 8H, C**H**$_2$$CH_2$S), 1.34 (m, 8H, C**H**$_2$$CH_2$$CH_2$S).

2.3.3. 2,10,19,27-*Tetrathia*-[11.11](2,6)-*pyridinophane*, **8** Colourless crystals. Yield: 17 mg (11%). R_f = 0.24. (Found: C, 62.67; H, 7.85; N, 5.52% $C_{28}H_{42}N_2S_4$ requires: C 62.87; H 7.91; N 5.24%). IR (KBr): 2925 s, 2852 m, 1591 s, 1574 s, 1461 s, 1452 m, 1384 w, 1157 w, 1087 w, 993 w, 817 w cm^{-1}. 2.4. *Tetrakis*(μ-*pivalato*)*dirhodium*

Tetrakis(μ-acetato)dirhodium (0.2 g, 0.45 mmol) and pivalic acid (4.0 cm^3) were heated at 130°C for 1 h, after which the solution was allowed to cool and then dried *in vacuo* over P_4O_{10} for 5 days. The solid pale green product was then dried in air at 140°C and used without further purification. Yield: 0.15 g (55%). IR (KBr): 2961 m, 2930 m, 2872 m, 1598 s, 1565 s,

1497 m, 1485 m, 1460 m, 1416 s, 1375 m, 1363 m, 1222 m, 897 w cm^{-1}. Mass spectrum (+ve FAB): *m/z* 610 {**M**}. ^{1}H NMR ($CDCl_3$): δ 0.98 (s).

2.5. $\{[Rh_2(O_2CCMe_3)_4]\}_2(L)$

A solution of *tetrakis*(μ-pivalato)dirhodium (25 mg, 0.041 mmol) in CH_2Cl_2 (5 cm^3) was added to a solution of the [2+2] macrocycle (0.041 mmol) in CH_2Cl_2 (5 cm^3) and the mixture stirred at room temperature for 30 min, after which time the colour had changed from green to purple and a purple oil had separated. The supernatant liquid was decanted and the purple oil was washed with CH_2Cl_2 (3 × 30 cm^3) and the residue dried *in vacuo* to give the $\{[Rh_2(O_2CCMe_3)_4]\}_2$(L) complexes as deep purple powders.

2.5.1. $\{[Rh_2(O_2CCMe_3)_4]\}_2$(**11**) Yield: 17 mg (42%). (Found: C, 48.60; H, 7.03; N, 1.55% $C_{74}H_{126}N_2O_{16}S_4Rh_4$ requires: C, 48.32; H, 6.90; N, 1.50%). IR (KBr): 2958 m, 2926 m, 2855 m, 1584 s, 1548 w, 1484 m, 1455 w, 1415 s, 1376 m, 1362 m, 1223 m, 1164 w, 1137 w, 897 w, 802 w, 780 w, 636 m cm^{-1}. 2.6. $[(CO)Rh(L)Rh(CO)][PF_6]_2$

A suspension of the appropriate [2+2] ligand (0.065 mmol) in methanol (2 cm^3) was added to a solution of freshly sublimed $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ (20 mg, 0.65 mmol) in methanol (2 cm^3) and the mixture stirred at room temperature for 30 min under dinitrogen. The solution was filtered under dinitrogen and the clear yellow filtrate treated with ammonium hexafluorophosphate (100 mg) in methanol (5 cm^3). The coloured precipitates were collected by filtration, washed well with methanol (3 × 10 cm^3) and dried *in vacuo* to give the products in quantitative yield.

2.6.1. $[(CO)Rh$(**11**)$Rh(CO)][PF_6]_2$ Light yellow powder. (Found: C, 36.70; H, 4.65; N, 2.41% $C_{36}H_{54}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 36.93; H, 4.65; N, 2.39%). IR (KBr): 2924 m, 2852 m, 1996 s, 1600 w, 1563 w, 1466 w, 839 vs, 559 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 1026 $\{Rh_2$(**11**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.86 (m, 8H, CH_2CH_2S), 1.25–1.60 (m, 24H, $CH_2CH_2CH_2CH_2CH_2S$).

2.6.2. $[(CO)Rh$(**10**)$Rh(CO)][PF_6]_2$ Light yellow powder. (Found: C, 35.95; H, 4.61; N, 2.55% $C_{34}H_{50}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 35.74; H, 4.41; N, 2.45%). IR (KBr): 2925 m, 2853 w, 1991 s, 1601 w, 1562 w, 1466 w, 839 vs, 559 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 997 $\{Rh_2$(**10**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.86 (m, 8H, CH_2CH_2S), 1.30–1.60 (m, 20H, $CH_2CH_2CH_2CH_2CH_2S$).

2.6.3. $[(CO)Rh$(**9**)$Rh(CO)][PF_6]_2$ Yellow powder. (Found: C, 34.25; H, 4.10; N, 2.30% $C_{32}H_{46}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 34.48; H, 4.16; N, 2.51%). IR (KBr): 2922 m, 2849 w, 1993 s, 1600 w, 1563 w, 1465 w, 839 vs, 559 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 969 $\{Rh_2$(**9**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.86 (m, 8H, CH_2CH_2S), 1.31–1.58 (m, 16H, $CH_2CH_2CH_2CH_2S$).

2.6.4. $[(CO)Rh$(**8**)$Rh(CO)][PF_6]_2$ Burgundy red powder. (Found: C, 33.22; H, 4.11; N, 2.62% $C_{30}H_{42}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 33.16; H, 3.90; N, 2.58%). IR (KBr): 2925 m, 2850 w, 2005 s, 1600 w, 1565 w, 1464 w, 839 vs, 558 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 941 $\{Rh_2$(**8**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.90 (m, 8H, CH_2CH_2S, isochronous with solvent residual resonance), 1.34–1.57 (m, 12H, $CH_2CH_2CH_2CH_2CH_2S$).

2.6.5. $[(CO)Rh$(**7**)$Rh(CO)][PF_6]_2$ Burgundy red powder. (Found: C, 31.98; H, 3.64; N, 2.66% $C_{28}H_{38}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 31.77; H, 3.62; N, 2.65%). IR (KBr): 2925 w, 2852 w, 2006 s, 1600 w, 1566 w, 1467 w, 839 vs, 559 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 913 $\{Rh_2$(**7**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.90 (m, 8H, CH_2CH_2S, isochronous with solvent residual resonance), 1.45–1.68 (m, 8H, $CH_2CH_2CH_2S$).

2.6.6. $[(CO)Rh$(**6**)$Rh(CO)][PF_6]_2$ Orange–red powder. (Found: C, 30.00; H, 3.20; N, 2.79% $C_{26}H_{34}N_2O_2S_4Rh_2P_2F_{12}$ requires: C, 30.30; H, 3.33; N, 2.72%). IR (KBr): 2927 w, 2853 w, 2009 s, 1602 w, 1569 w, 1466 w, 839 vs, 559 m cm^{-1}. Mass spectrum (+ve FAB): *m/z* 885 $\{Rh_2$(**6**)$(CO)_2PF_6\}$. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (AB q, 8H, $pyCH_2S$), 3.04 (t, 8H, CH_2CH_2S), 1.90 (m, 8H, CH_2CH_2S, isochronous with solvent residual resonance), 1.49–1.74 (m, 4H, $CH_2CH_2CH_2S$).

2.7. $[(CO)Rh$(**10**)$Rh(CO)][RhCl_2(CO)_2]_2$

A suspension of the appropriate **10** (20 mg, 0.0338 mmol) in methanol (10 cm^3) was added to a

solution of $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ (26.2 mg, 0.676 mmol) in methanol (5 cm^3) to give a yellow solution. After stirring at room temperature for 15 min the solution had turned orange and a deep orange solid had been precipitated. The mixture was stirred for an additional 30 min and the solid collected by filtration, washed with methanol (3×5 cm^3) and dried *in vacuo* to give [(CO)Rh(**10**)Rh(CO)][$RhCl_2(CO)_2$]$_2$. Yield: 41 mg (92%). (Found: C, 34.48; H, 3.76; N, 2.07% $C_{38}H_{50}N_2O_6Cl_4S_4Rh_4$ requires: C, 34.77; H, 3.84; N, 2.13%). IR (KBr): 2929 m, 2853 w, 2061 s, 1993 vs, 1977 m, 1603 w, 1564 w, 1466 w cm^{-1}. Mass spectrum (+ve FAB): *m/z* 824 {Rh_2(**10**)(CO)}. ^{1}H NMR (CD_3CN): δ 7.96 (t, 2H, H^4), 7.60 (d, 4H, $H^{3,5}$), 4.66 (br d, 8H, $pyCH_2S$), 3.04 (t, 8H, $CH_2C\mathbf{H}_2S$), 1.86 (m, 8H, $C\mathbf{H}_2CH_2S$), 1.30–1.60 (m, 20H, $C\mathbf{H}_2C\mathbf{H}_2C\mathbf{H}_2CH_2CH_2S$).

2.8. *Crystal structural determination of* **6** *and* **10**

Transparent blocks of the compounds were obtained by the slow evaporation of CH_2Cl_2 solutions and were mounted on glass fibres. All geometric and intensity data were taken from these crystals. Pertinent crystallographic data are given in Table 1. Intensity data, gathered were reduced by routine procedures. Structure solution used SHELXTL or SHELXTL PLUS.

The structures were solved by direct methods and refined by alternating cycles of least squares refinement and difference-Fourier synthesis. All non-H atoms were refined anisotropically; in the case of **6** the H-atoms were all given a common isotropic displacement coefficient, whereas for **10** the aromatic and aliphatic H-atoms were given different thermal parameters. Refinement was carried out on F^2 for all reflections. Selected bond angles and bond distances are given in Table 2.

3. RESULTS AND DISCUSSION

3.1. *Ligand synthesis*

Our aim was to prepare a suite of macrocyclic ligands with bridging groups linking two 2,6-bis(thiomethyl)pyridine sub-units in the generic [2 + 2] structure **3** in which L represents the bridging unit. Somewhat to our surprise, examples of such structures in the literature proved to be sparse [11, 12, 16–20]. In contrast, examples of the [1 + 1] congeners **4** are abundant and a large variety of spacer groups have been incorporated [16–18, 21–35]. One feature which struck us forcibly was that with the exception of those systems incorporating diazacrown ether spacers [21] and one thioether exchange reaction [22–24] all of the known [1 + 1] macrocyclic systems were prepared from the action of α,ω-dithiols on the dibromo compound **1** (or its chloro analogue). We were particularly interested in the use of relatively flexible linker groups and decided to adopt an alternate strategy in which 2,6-bis(mercaptomethyl)pyridine **2** was reacted with α,ω-dihalo compounds. The rationale for this strategy came from our eventual hope to use template methods for the synthesis of the macrocycles. A templated reaction seemed to be more likely if the sulfur-containing component had the *SNS* donor set of **2** rather than a flexible, and possibly non-chelating S_2 donor set of an α,ω-dithiol.

The intermediate dibromo compound **1** was prepared in 43% yield as a white crystalline solid using a slight modification of the literature method in which commercially available 2,6-bis(hydroxymethyl) pyridine is treated with concentrated hydrobromic acid [13]. The dithiol **2** was prepared from **1** by reaction with thiourea followed by basic hydrolysis of the intermediate thiouronium salt with $NaHCO_3$ solution in a modified literature procedure [36, 37]. Purification by distillation yielded **2** as a colourless oil with the expected spectroscopic and analytic properties.

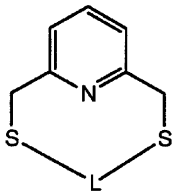
3



4

In the course of our preparative work, we noted that it was critical to add only two molar equivalents of $NaHCO_3$ during the hydrolysis step. If an excess of $NaHCO_3$ were added, we found that smooth conversion to the cyclic disulfide **5** occurred even with exclusion of atmospheric dioxygen. Compound **5** was initially identified by its IR spectrum which generally resembled that of **2** but lacked the S–H stretching mode in the 2500–2600 cm^{-1}; a parent ion was observed at m/z 338 in the mass spectrum. The properties of **5** corresponded to those of a cyclic dimer which had previously been reported [15].

The dithiol **2** was reacted with the α,ω-dibromo compounds $Br(CH_2)nBr$ (n = 5–10) in EtOH in the presence of sodium hydroxide under dinitrogen. In the absence of NaOH, no reaction occurred. When NaOH was added, a white solid precipitated from the reaction mixture over the course of several hours at reflux. This material was indefinitely air-stable in the solid state. The ^1H NMR spectra of $CDCl_3$ solutions of the crude products (after filtration to remove poorly soluble material) showed single aromatic environments consisting of the expected doublets and triplets, but *two* py-CH_2S environments in an approximate ratio of 1:2. Thin layer chromatography over alumina using 1:1 CH_2Cl_2:PhMe as eluent allowed the separation of small amounts (<5%) of a fast running compound and 10–15% of a slower running component in each case. There were also significant amounts of baseline polymeric material.

In each case, the IR spectra of the two isolated components were identical and the most pertinent feature was the absence of any S–H stretching modes. The mass spectra of the products indicated that the faster running components should be formulated as the [1+1] macrocycles and the slower running, more abundant species as the [2+2]. The [1+1] ligands **12**–**15** have been previously reported [17, 30] and as our interest lay in the dinucleating systems, they were not further investigated.

The dinucleating [2+2] compounds were obtained as white crystalline solids with almost identical IR and ^1H NMR spectroscopic properties. The ^1H NMR spectra only differed in the intensity of the aliphatic methylene resonances. In order to fully confirm the formation of the [2+2] ligands and to probe the spatial relationships of the *SNS* donor sets, we have determined the solid state X-ray structures of **6** and **10**.

3.2. *X-ray structures of* **6** *and* **10**

The X-ray structure determination of **6** confirmed the gross structure of the [2+2] macrocycle and revealed the presence of two conformers within the crystal lattice as shown in Fig. 1. In one of the conformers, all four of the sulfur atoms are oriented with exocyclic lone pairs, whereas in the other one sulfur at each *SNS* unit is exocyclic whilst the other is endocyclic. The C–S–C bond angles at the endocyclic sulfur atoms are slightly smaller than those at the exocyclic [98.0(3) vs 101.1(2)–102.7(2)°]. All C–S bond distances are within the usual range and lie between 1.788(6)–1.820(4) Å. The packing of the molecules within the lattice is of some interest. The molecules of **6** form columns in which the two conformations alternate

(Fig. 2). The columns are arranged such that the pyridine rings of adjacent columns are approximately parallel with an interplanar stacking distance of ≈ 3.4 Å.

The structural determination of **10** also confirmed the formation of the [2 + 2] macrocycle and the molecular structure is presented in Fig. 3. In contrast to the structure of **6**, only a single conformer is present in the lattice, with one endocyclic and one exocyclic oriented sulfur at each *SNS* unit. All bond lengths and angles within the molecule are typical. The two pyridine rings of each macrocycle are coplanar and the molecules form a columnar arrangement in which graphitic packing occurs between molecules within the column, as opposed to *between* columns with **6** (Fig. 4). Details of the crystal structure determinations are presented in Table 1 and selected geometrical parameters are given in Table 2.

3.3. *Reactions with Rh–Rh bonded dinuclear rhodium complexes*

One of the principal aims that we had in preparing this series of ligands was to investigate metal–metal interactions in a series of dinuclear complexes in which the distance between the metal-binding domains was varied in a controlled manner. We were encouraged to note that mononuclear rhodium(I) complexes of a related [1 + 1] macrocycle exhibited short (3.32 Å) Rh . . . Rh interactions [22, 23, 24] and considered that the incorporation of two *SNS* donor sets in a ligand would allow these to be maximised. In the first instance, we investigated the behaviour of the representative ligands **6** and **11** with dinuclear metal–metal bonded species to see whether it would be possible for the ligands to fold around a dimetal core.

We chose the complex *tetrakis*(μ-pivalato) dirhodium [$Rh_2(O_2CCMe_3)_4$] with a Rh–Rh single bond as our starting material on the grounds of its good solubility in organic solvents and the characteristic and intense resonance for the *tert*-butyl groups in the ^{1}H NMR spectrum. The reaction of emerald green CH_2Cl_2 solutions of [$Rh_2(O_2CCMe_3)_4$] with CH_2Cl_2 solutions of **6** or **11** at a 1:1 stoichiometry resulted in the deposition of purple oils which gave dark purple solids upon drying. The IR spectra of

these products exhibited absorptions at 1584 and 1425 cm^{-1} characteristic of bridging carboxylate together with absorptions at 1484 and 1455 cm^{-1} typical of the macrocyclic ligands and suggested the formation of adducts in which the dirhodium core remains intact. The FAB mass spectra of the purple products showed highest mass peaks assigned to 1:1 adducts together with a series of fragmentation peaks corresponding to sequential loss of pivalate.

The purple compounds were insoluble in chlorinated solvents and it was only possible to obtain ^1H NMR spectra in CD_3SOCD_3 solution. The complexes are unstable in this solvent and the spectrum corresponds to a superimposition of the spectra of the macrocycle and $[Rh_2(O_2CCMe_3)_4]$ in the same solvent. However, the ratio of the *tert*-butyl singlet to the peaks arising from the macrocycles clearly indicated that products of stoichiometry $\{[Rh_2(O_2CCMe_3)_4]\}_2(L)$ (L = **6** or **11**) had been formed, a fact confirmed by partial microanalysis of the purple solids. The 2:1 stoichiometry argues against the inclusion of the dinuclear units within the macrocyclic cavity, particularly in the case of **6**, and we propose a polymeric structure with an exocyclic bonding mode (Fig. 5). The polymeric formulation is in accord with the insolubility of the product.

The formation of *tetrakis*(carboxylato)dirhodium species with two axial sulfur donor thioether ligands has been previously established [38, 39]. In view of the extreme insolubility of these materials, we have not further investigated their constitution.

3.4. *Reactions with* $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$

As it had not proved possible to directly incorporate a dirhodium unit into the macrocyclic cavity, we decided to try to incorporate two mononuclear fragments with the hope that the imposed proximity would lead to metal–metal interactions. The presence of two *SNS* metal-binding domains suggested that a square-planar rhodium(I) centre bearing one additional ligand would be appropriate. Accordingly, we investigated the interaction of the [2 + 2] macrocycles with $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$.

Suspensions of the [2 + 2] macrocycles in methanol reacted slowly with deep red $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ to give bright yellow solutions. In each case, the addition of ammonium hexafluorophosphate to these yellow solutions resulted in the precipitation of coloured products. Surprisingly, the colour of these microcrystalline precipitates varied considerably, depending upon the macrocycle used. In the case of ligands **9**, **10** and **11** the addition of ammonium hexafluorophosphate yielded yellow solids, but in the case of **6** an orange precipitate was obtained and with **7** and **8**, striking burgundy red solids were obtained. The red and orange solids dissolved in dichloromethane, acetonitrile or acetone to give yellow solutions with identical electronic spectra exhibiting maxima at 221 and 277 nm with a long tail into the visible. The products exhibited a single terminal carbonyl stretching mode in their IR spectra in the range 1996–2009 cm^{-1} together with bands at $\approx$1565 and 1600 cm^{-1} charac-

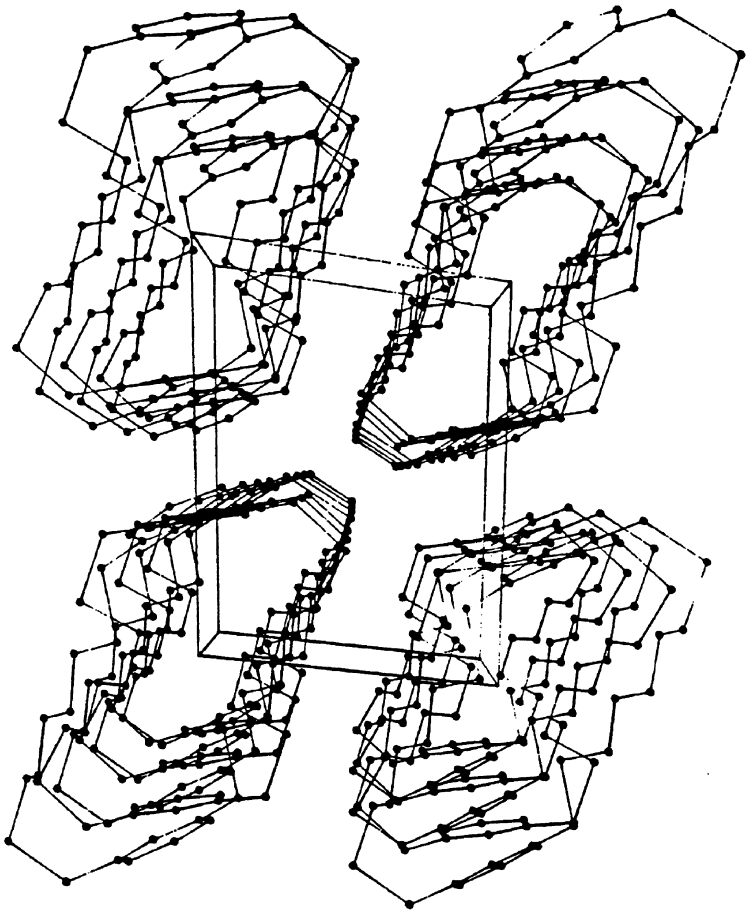

Fig. 2. The packing of the two conformers of **6** in the crystal lattice showing the formation of columns with intercolumnar π-stacking.

teristic of a pyridine coordinated to rhodium(I) [17]. In each case, FAB mass spectrometry gave peaks corresponding to $\{[(CO)Rh(L)Rh(CO)][PF_6]\}^+$ and microanalysis indicated dinuclear formulations $[(CO)Rh(L)Rh(CO)][PF_6]_2$ to be appropriate. These data are all consistent with the formation of dinuclear complexes in which each *SNS* domain is coordinated to a Rh(CO) moiety in a manner similar to that found with related mononucleating [1 + 1] complexes and we propose the structures indicated in Fig. 6.

The variation of colour within these systems is of some interest and is thought to relate to the degree of intermetallic interaction between the square-planar metal centres. The precise origin is somewhat unclear. The observation that the colour differences are only a solid state phenomenon, argues that the interactions are intermolecular and arising by the overlap of metal orbitals directed along the *z* axis (rhodium square plane defining *x* and *y*). However, the variation within the series is more consistent with an intramolecular interaction, in which the macrocyclic ring size controls the interaction of metal centres within the same macrocycle. Of course, conformational changes upon dissolution could also result in the loss of the Rh . . . Rh interactions. Electrochemical studies of solutions of the complexes revealed no oxidative processes and only ligand based reductions.

In an attempt to obtain higher nuclearity complexes, we also investigated the interaction of the representative ligand **10** with two equivalents of $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ in methanol. Upon stirring, the reaction mixture changed from red, to yellow and finally to orange with the simultaneous precipitation of a deep orange solid. The IR spectrum was very similar to those of the products above, but in addition to the expected carbonyl mode at 1993 cm^{-1} also showed two additional carbonyl absorptions at 2061 and 1977 cm^{-1}. The ^1H NMR spectrum of a solution of the orange product was identical to that of $[(CO)Rh(\mathbf{10})Rh(CO)][PF_6]_2$ and the highest mass peak in the FAB mass spectrum was assigned to $\{Rh_2(\mathbf{10})(CO)\}$. Microanalysis indicated a formulation $[(CO)Rh(\mathbf{10})Rh(CO)][RhCl_2(CO)_2]_2$; the $[RhCl_2(CO)_2]^-$ anion is known to be formed from the reaction of $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ with chloride (in this case, released in the formation of the $[(CO)Rh(\mathbf{10})Rh(CO)]^{2+}$

cation) and the IR bands are fully in accord with this species [39–41]. The overall stoichiometry of the reaction is thus:

$$2[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2] + \mathbf{10} \rightarrow [(CO)Rh(\mathbf{10})Rh(CO)][RhCl_2(CO)_2]_2$$

Treatment of methanol suspensions of $[(CO)Rh(\mathbf{10})Rh(CO)][RhCl_2(CO)_2]_2$ with ammonium hexafluorophosphate resulted in the formation of yellow $[(CO)Rh(\mathbf{10})Rh(CO)][PF_6]_2$.

3.5. ^{1}H *NMR studies of* $[(CO)Rh(L)Rh(CO)][PF_6]_2$ *complexes*

In each case, the $[(CO)Rh(L)Rh(CO)][PF_6]_2$ complexes dissolved in acetonitrile to give yellow solutions in CD_2Cl_2 or CD_3CN, the ^{1}H NMR spectra of which resembled those of the free ligands in terms of the number of resonances, but with some peaks broadened and all shifted to lower field. The most significant observation was that the $pyCH_2S$ protons now appeared as broadened doublets rather than as singlets. The appearance of diastereotopic protons for this methylene group is a natural consequence of the coordination of the *SNS* domain to the metal centre and provides evidence for the formulation in Fig. 6. Only in the case of the complex with **6** was the spectrum well resolved and the $pyCH_2S$ protons observed as a sharp AB quartet.

This phenomenon has been observed previously with related [1+1] macrocycles [17, 18, 22, 23, 24] and the dynamic process is assigned to inversion at the sulfur (Fig. 7). The complex $[(CO)Rh(\mathbf{9})Rh(CO)][PF_6]_2$ was taken as representative and variable temperature ^{1}H NMR spectra for CD_3CN solutions over the temperature range 255 to 315 K are presented in Fig. 8. These data may be analysed using a simple two site exchange model and lead to an activation free energy of 64.4 ± 0.2 kJ mol^{-1}, which is comparable to that reported for the related complexes with [1+1] macrocycles.

4. CONCLUSIONS

A range of [2+2] macrocyclic ligands have been prepared from 2,6-bis(mercaptomethyl)pyridine. Reaction with rhodium–rhodium bonded dinuclear complexes resulted only in an exocyclic bonding mode rather than incorporation of the dimer into the macrocyclic cavity. In contrast, reaction with $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ allowed the introduction of two Rh(CO) units into the macrocyclic cavity. We are currently extending these studies to macrocycles derived from 2,6-dimercaptopyridine.

1. INTRODUCTION

Mass spectrometry is one of the oldest instrumental analytical techniques. Since the earliest use for determining the isotopic composition of the elements, it has been extensively developed. In particular, new ionisation

† Author to whom correspondence should be addressed. Fax: +64-7-838-4219; E-mail: w.henderson@waikato.ac.nz

methods have extended the range of samples which can be examined. Electron-impact (EI) ionisation has long been used for converting volatile, neutrally-charged substrates to cations (and less frequently, anions) so that their mass spectra can be examined [1]. This rather harsh method usually induces extensive fragmentation, which can of course be useful in characterising compounds, but which often prevents the detection of the parent ions. The main limitation for this method is the need for the sample to have significant vapour pressure at temperatures below the decomposition point. This has been a handicap in inorganic chemistry for ionic or high-molecular mass samples and for thermally-fragile organometallic (and bio-inorganic) species.

The introduction of fast atom bombardment (FAB) ionisation partially overcame this limitation, so that the use of mass spectrometry could be extended to new areas of inorganic and organometallic chemistry [2, 3]. However, this too is a harsh ionisation technique and only the more robust samples survive the ionisation process intact, and complications arising from recombination of fragments, or interactions with the matrix, are commonplace.

More recently, matrix-assisted laser desorption ionisation (MALDI) has been used to provide gas-phase ions for a range of substrates [4–6], including metal–carbonyl complexes and clusters [7–9] and organogermanium dendrimers [10]. However, this technique is often characterised by aggregation of analytes, giving high molecular mass signals.

A new method of ionisation was introduced in the mid-1980's, largely by Fenn and co-workers [11, 12]. This was termed electrospray mass spectrometry (ESMS) and essentially involves spraying a solution of the sample to be analysed into the source of a mass spectrometer and stripping away the solvent. Solubility rather than volatility then becomes the critical factor and since the ionisation occurs under very mild conditions, as discussed below, molecular ions of fragile molecules can be routinely observed. The method was quickly exploited by researchers working with biomolecules because proteins and other high-mass, thermally-sensitive substrates could be readily analysed; a large number of reviews and compilations have appeared in this area [13–20]. There has also been extensive use of ESMS as the detector for an LC-MS system [21]. The capabilities of the current range of commercial instruments have recently been summarised for those wishing to purchase an instrument [22].

The enormous scope of the ESMS technique in inorganic and organometallic chemistry has only recently become apparent and this is reflected in that to date there has only been one major review of the application of ESMS in inorganic chemistry [23], together with others of more limited scope [13, 24]. This present review describes some of the applications of ESMS in organometallic chemistry, with a particular emphasis on illustrating the types of compounds which can be successfully analysed. We have not attempted to be fully comprehensive in our coverage of the literature, but have tried to present illustrative examples over as wide an area as possible. It is our hope that this account will encourage readers to apply the versatile ESMS technique to their own area(s) of research.

2. THE ELECTROSPRAY IONISATION TECHNIQUE

2.1. *Principles*

Full details of the principles behind the electrospray process fall outside the scope of this review and can be found in the comprehensive reviews in this area [13, 15, 18–21, 23, 25, 26]. However, the basic features are summarised here in order to provide a basic framework for the subsequent discussion.

A diagrammatic representation of an ES mass spectrometer is shown in Fig. 1. Exact details vary with different commercial instruments, but the overall processes are typically similar. The sample, dissolved in the appropriate solvent, is injected as a fine spray at a low flow rate from a capillary held at a high voltage (e.g. 3000–4000 V) into a chamber at atmospheric pressure. This is shown schematically in Fig. 2. The nature of this electrospray, and the mechanism by which it generates ions, has been well debated [28]. Two basic ideas have emerged. The first approach is an electrophoretic one in which it is assumed the charged tip leads to partial separation of positive and negative ions, giving an excess of positive ions (in the positive-ion mode) at the liquid surface as it emerges from the tip [25]. This encourages fine, charged droplets to cleave off. The second approach regards the electrospray process as an unconventional electrochemical cell, with part of the current being carried by the charged droplets [29]. The chamber into which the sample is sprayed is purged with a drying gas (usually nitrogen) which evaporates the solvent from the charged droplets†. As the droplets get smaller the charge density increases and ions are transferred to the gas-phase either by extrusion from the

† Some reports have questioned the importance of evaporation (see Ref. [30]).

surface, or by a "Coulombic explosion" once the charge density exceeds some critical value. The ions formed in this process are then pumped through skimmer cones or similar, each at successively higher vacuum, before transferring to any of the normal mass analysers (i.e. magnetic sector, quadrupole, time-of-flight or to Fourier Transform ion cyclotron resonance (FTICR) [31, 32] or quadrupole [33] ion traps).

Typical flow rates are 0.01 ml min^{-1} and concentrations of a few ppm are ample, so very small samples are required, as with other mass spectral methods. The development of the "nanospray" technique is allowing analysis of even smaller samples [34, 35].

Since the sample is delivered as a solution, the technique allows the direct analysis of reaction solutions. In almost every case where independent evidence for the nature of species present in solution is available (such as NMR spectroscopy or electrochemistry), the information obtained by ESMS is generally in good agreement [23]. For studies of labile systems, ESMS can be particularly effective, since it can typically be used in the analysis of systems inaccessible by techniques such as NMR spectroscopy, due to paramagnetism or lack of a readily observed nucleus. The measurement of ESMS spectra at room temperature is also experimentally more convenient than low temperature NMR.

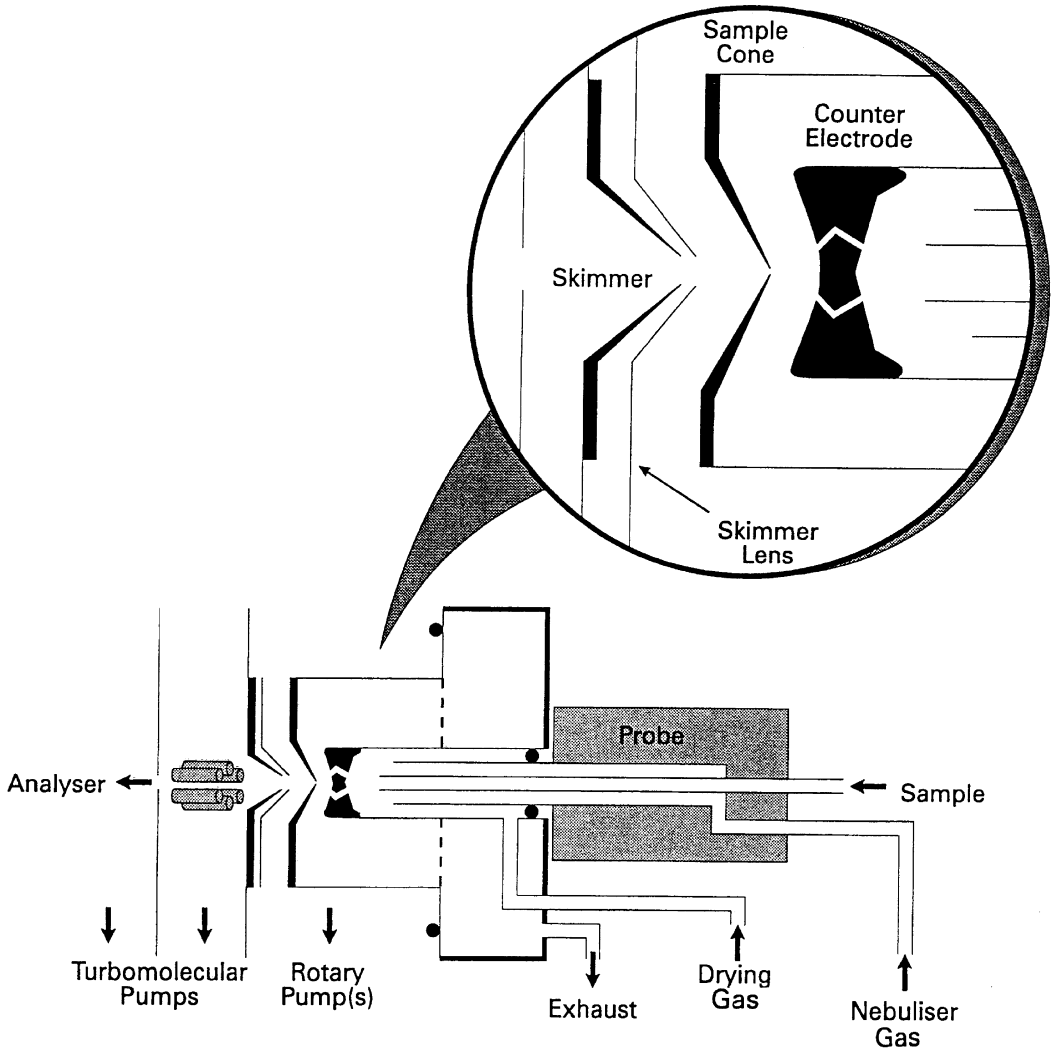

Fig. 1. Schematic diagram of a typical electrospray mass spectrometer. The positioning of the skimmer cone, used in providing fragmentation of the various ions generated in the source, can be clearly seen. (Used with permission from Micromass Australia.)

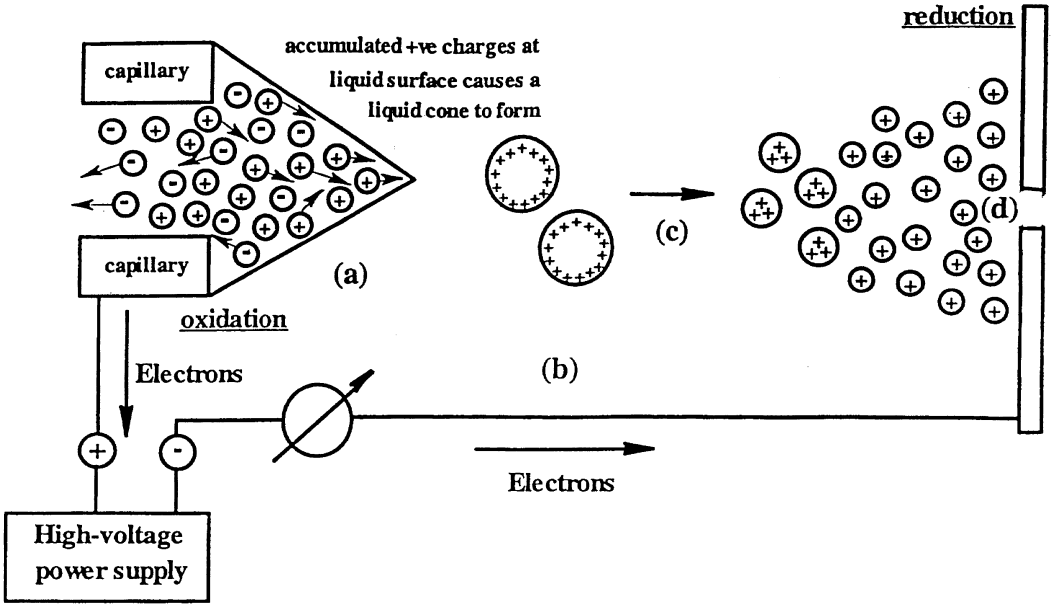

Fig. 2. A schematic representation of the ionisation mechanism in an electrospray mass spectrometer, operating in positive-ion mode. At (a) the high charge drives positive ions to the liquid surface so that the droplets emitted at (b) have a nett charge. Desolvation processes (c) then generate individual ions that pass through an orifice (d) in the negative electrode towards the mass analyser (taken from Ref. [27]).

2.2. *Solvents*

The choice of solvent is largely dictated by the solubility and stability of the compound to be analysed, together with the ionisation mechanism being used (see Section 2.3). A mixture of acetonitrile and water (often 1:1 v/v) is probably the most common mobile phase since it provides sufficient solubility for a wide range of polar and non-polar substrates, and can donate or accept protons. For ionic compounds, non-protic solvents may be used, including tetrahydrofuran, dichloromethane, chloroform, among others. For neutral compounds containing protonatable atoms (see Section 2.3) the use of a protic solvent (e.g. water, alcohols), or solvent combination (e.g. methanol–water, acetonitrile–water) provides sufficient H^+ ions to facilitate protonation, and so allows observation of $[M+H]^+$ parent ions, where M is the parent molecule. Relatively involatile solvents such as ethylene glycol can also be used [30].

For compounds which show either moisture and/or air-sensitivity, then ES analysis is still possible with appropriate precautions for handling the compounds concerned. As an illustration of this, a number of highly moisture-sensitive metal alkoxides typified by $Zr(OR)_4$ have been successfully analysed in rigorously-dried alcohol solvent [36]. Other examples of the ESMS analysis of air-sensitive metal carbonyls are given in Section 4.

2.3. *Ionisation processes*

As with other MS techniques, only ions can be detected, though in ESMS both anions and cations can be analysed equally conveniently. For samples which already contain ions, no further ionisation is needed. The solvated ions in the spray droplets are stripped of the solvent to give gas-phase ions (cations or anions) which are fed directly into the mass analyser. As a typical example, Fig. 3 shows the spectrum obtained for the dianion cluster $[Os_{10}C(CO)_{24}]^{2-}$; signal-to-noise levels of this quality are readily achieved [37].

For highly-charged species, association with counterions is common. For example the anionic cluster $Na_6[Ru_3(CO)_{10}\{P(C_6H_4SO_3)_3\}_2]$ ($\equiv Na_6X$) gives signals in the negative-ion mode which correspond to $[X+Na]^{5-}$, $[X+2Na]^{4-}$, $[X+3Na]^{3-}$ and $[X+4Na]^{2-}$ [38]. Peaks arising from ions with some solvent molecules still attached are also often found. It is charge-density and not total charge *per se* which determines stability; proteins and other large biomolecules typically yield highly-charged ions (but with a low charge density), the resulting relatively low m/z values allowing their analysis by quadrupole analysers with a limited mass range (e.g. 0–3000 Da).

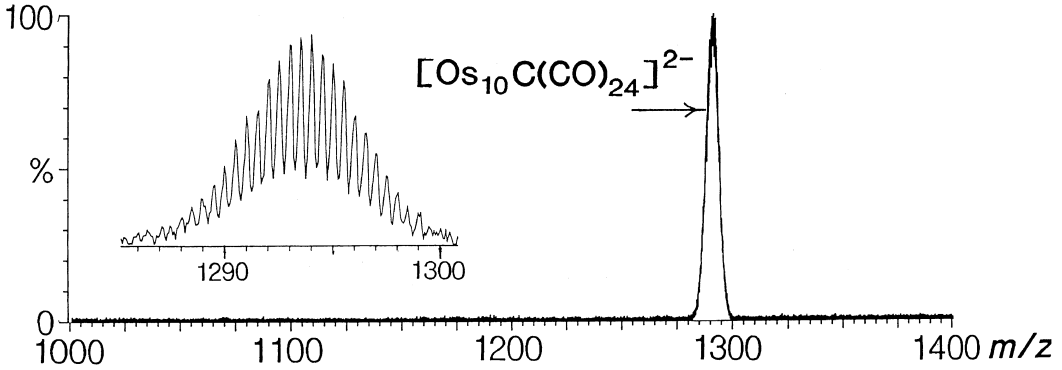

Fig. 3. The negative ion electrospray mass spectrum of $[N(PPh_3)_2]_2[Os_{10}C(CO)_{24}]$, showing the quality of spectra possible for anionic clusters. The inset shows the isotope pattern, with the mass separation of m/z 0.5 confirming the 2- charge (taken from Ref. [37]).

For neutral species some means of ionisation is required for detection and this is where ingenuity is sometimes needed, particularly for organometallic complexes. The commonest process is for the sample to abstract a proton from the solvent to give a $[M+H]^+$ ion, but for this to happen the sample needs to have a site of sufficient basicity to attach the H^+ to. Ionisation takes place with substrates that would normally not be considered strong Brønsted–Lowry bases, so that strong bonds to H^+ are not necessary. Typically, oxygen or nitrogen atoms provide very effective protonation sites, present in functional groups such as ethers, carbonyl compounds (ketones, amides etc), sulfoxides, phosphine oxides, amines and the like. Similarly, species containing -COOH or -OH groups can lose a proton to generate the corresponding negative ion which is detected as $[M–H]^-$. Indeed for many samples both the $[M+H]^+$ and $[M–H]^-$ ions can be detected in positive- or negative-ion modes, respectively, differing by two mass units. To encourage these processes, small quantities of an acid (e.g. HCOOH or CF_3COOH) or base (e.g. NH_3) can be added.

Association of the substrate with other ions is also common and other peaks in the spectrum (which can have variable intensity) in addition to $[M+H]^+$ often include $[M+NH_4]^+$, $[M+Na]^+$ or $[M+K]^+$ from the traces of cations often present in even HPLC-grade solvents. These assignments can be readily confirmed by the deliberate addition of the appropriate ion. Higher aggregates are also common, with some substrates giving $[2M+H]^+$ or even $[4M+NH_4]^+$, for example. The use of metal ions such as Na^+, K^+ or Ag^+ to form ions by association with neutral substrates is sometimes more successful than added H^+ and allows the technique to be extended into non-protic solvents [39, 40]. Silver(I) salts such as $AgClO_4$ are reasonably soluble in aprotic solvents such as benzene, and the Ag^+ ion has a strong propensity for binding to "soft" ligand centres. Accordingly, silver(I) salts have been used in the successful analysis of phosphines [41, 42], arsines [43], thioethers [44], arenes [45] and metal carbonyls [37, 46] by ESMS. Another example of the successful use of an ionisation agent is the addition of methoxide (and other alkoxide ions) to neutral metal carbonyl compounds to allow detection as the $[M+OMe]^-$ species [37, 47]. Further details on this technique are given in Section 4.

In rather rare cases, electrochemical processes occurring in the charged probe tip [29] oxidise electron-rich substrates to generate $[M]^+$ ions rather than protonated $[M+H]^+$ ions [48, 49]. The $[M]^{\ddagger}$ and $[M+H]^+$ ions can be distinguished readily since the instruments have resolution which reliably discriminates between species one mass unit apart. These oxidations are somewhat unpredictable and appear to be instrument- and compound-dependent. For example, analysis of $M[B_3H_8]$ ($M=Me_4N$ and Cs) in methanol solutions resulted in electrochemical conversion to $[B(OMe)_4]^-$ ions [50]. This conversion was not observed in MeCN solvent, or in bulk MeOH solution. Porphyrins also sometimes give $[M]^{\ddagger}$ ions [51].

Among organometallic complexes, the metallocenes are perhaps the most common species to demonstrate this electrochemical behaviour, discussed further in Section 5. Indeed the incorporation of ferrocene moieties into compounds provides a route for ionisation by electrochemical oxidation. Ferroceneboronic acid, $FcB(OH)_2$ [$Fc=(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$] and ferrocenoyl azide, $FcC(O)N_3$ are two reagents which have been used for the derivatisation of alcohols for ESMS analysis [52]. Fullerenes have a high electron affinity and are also relatively easily oxidised, and the direct analysis of the fullerene C_{60} can be carried out, with the radical ions $C_{60}^{\cdot -}$ and $C_{60}^{\cdot +}$ being observed [53, 54].

The addition of a chemical oxidant such as $NOBF_4$ can generate cations from neutral substrates, such as metal–diethyldithiocarbamate complexes [55]. Recently there have been successful attempts to include an electrochemical cell into the electrospray source to induce oxidative ionisation prior to infusion into the source

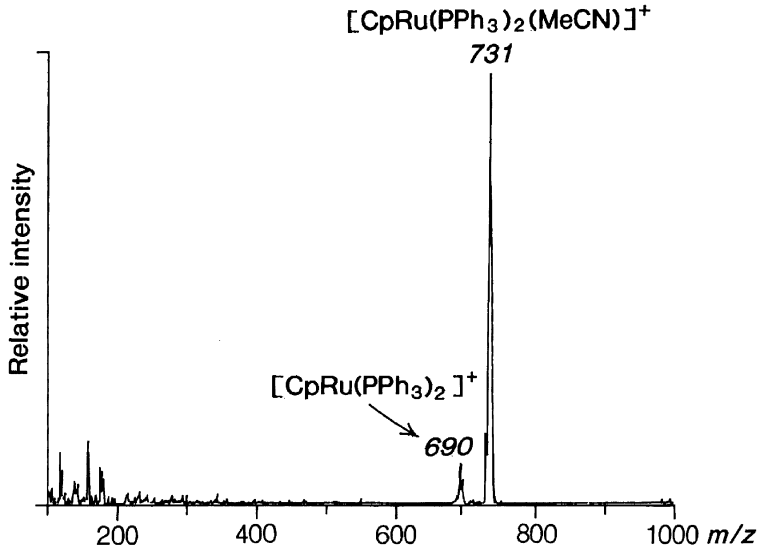

Fig. 4. The positive ion mass spectrum of $CpRuCl(PPh_3)_2$ in $MeCN/H_2O$, showing peaks assigned to $[M–Cl+MeCN]^+$ and $[M–Cl]^+$.

[56, 57]. This is a modification to the basic ES technique which should find many useful applications in organometallic chemistry.

A further ionisation mechanism which can occur for formally neutral substrates is loss of an anionic ligand, typically halide, which may result in the formation of solvated or unsolvated cations. This mechanism appears to be a reasonably general one for coordination and organometallic complexes containing halide ligands. As an illustrative example, Fig. 4 shows the positive-ion spectrum of $[CpRuCl(PPh_3)_2]$ in $MeCN–H_2O$ solution, which gives the ion $[CpRu(PPh_3)_2(MeCN)]^+$ at a low cone voltage and the desolvated ion $[CpRu(PPh_3)_2]^+$ at a higher cone voltage [58]. Other organometallic complexes showing the same general behaviour include *trans*-$[Pt(CH_3)I(PPh_3)_2]$, *trans*-$[IrCl(CO)(PPh_3)_2]$, *cis*-$[PtCl(CH_2COCH_2R)(PPh_3)_2]$ (R = H or Cl) [58] and the organogold(III) halide complexes **1** [59]. The formation of positive ions of this type can generally be enhanced, and the spectra simplified, by adding a volatile donor ligand of better donor ability than the solvent, such as pyridine (py), whereupon ions of the type $[M–halide+py]^+$ ions are readily observed in most cases, at low to moderate cone voltages. The use of pyridine as an ionisation reagent for metal halide complexes is beneficial, since in its absence misleading relative ion intensities may occur. As an illustration, the gold dihalide complex **1a** showed a significant ion at m/z 525 in its positive-ion ESMS spectrum, which is assigned as the bis(cyclometallated) species **2**. Addition of pyridine to the solution however gave the expected $[M–Cl+py]^+$ as the major ion. The species **2** was not observed in the ^1H NMR spectrum and so the strong peak in the absence of pyridine results from a high ionisation efficiency relative to the dichloro complex [59].

2.4. *Fragmentation processes*

The ionisation processes described above are essentially chemical ionisation and are gentle in nature, typically resulting in intact "parent" ions being observed under the normal operating conditions. This is one of the major advantages of the ESMS technique over EI or FAB techniques. However, fragmentation can often be induced by applying a voltage (typically 10–100 V) across the skimmer cones (refer to Fig. 1), the so-called cone voltage. This has the effect of encouraging collisions between ions and between ions and neutral species (such as the gas used), resulting in fragmentation. In general, it is this parameter that has the most dramatic effect on the ions observed in an ES mass spectrum. Other types of mass spectrometer achieve fragmentation in different ways, such as in a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer [31, 32]. Fragmentation can be very useful in determining functional groups, although fragmentation processes are different to those that are found in EI mass spectrometry. Higher values of the cone voltage are also useful for minimising aggregates of ions with solvent molecules. The actual cone voltage required to induce fragmentation is very much dependent on the sample, but the technique can be used in a qualitative sense, for example to determine the most weakly-bonded ligands on a metal centre. It appears that more highly-charged species fragment more extensively under given conditions, presumably because of more energetic collisions induced by the drift voltage between the cones [38, 60]. The effect of varying cone voltage is illustrated for a typical organometallic example in Fig. 5, which shows a series of $[Os_3(CO)_n+OMe]^-$ ions observed from a solution of $[Os_3(CO)_{12}]$ with added methoxide ionisation agent (refer to Section 4) [37, 47].

2.5. *Ion assignment*

Unambiguous assignment of ions observed in ESMS analysis can be achieved by comparing the experimental and calculated isotope distribution patterns. The former can be routinely obtained by recording the spectrum of the ion concerned in high resolution mode, while the latter can be simulated with programs such as the *Isotope* program for the Macintosh, details of which have been published [61]. Many metals, and a number of other elements commonly found in ligands in organometallic systems (e.g. Cl, Br, Se), have several isotopes providing valuable information. The isotope pattern also reveals the charge on the ion, by the m/z separation between adjacent peaks. Using a standard quadrupole mass analyser, we have been able to routinely obtain isotope patterns for ions with up to four charges (in which case adjacent peaks in the isotope pattern are separated by 0.25 Da). As an illustration we refer to Fig. 2, which gives the isotope distribution pattern for the $[Os_{10}C(CO)_{24}]^{2-}$ cluster anion, with peaks separated by 0.5 m/z units.

2.6. *Instrument maintenance*

The commercial instruments now available are remarkably robust. Routine operation is well within the expertise of graduate students, so that continuous specialist technical support is not needed, placing the technique firmly in the instrumental armoury of the practicing synthetic chemist. Since the ionisation chamber is at atmospheric pressure, routine cleaning can be carried out without breaking the vacuum in the rest of the spectrometer, so that a source-clean usually involves less than an hour of down-time.

As a final comment in this section, we note that cross-contamination can occur from some species which have a tendency to linger in the mass spectrometer (specifically, in the capillary systems and injector system). The bis(triphenylphosphine)iminium $[N(PPh_3)_2]^+$, (PPN^+) cation, which is widely used in organometallic chemistry has a marked propensity to linger, giving characteristic m/z 538 signals in subsequent samples. In a similar fashion, the cation $[CpRu(PPh_3)_2]^+$ (m/z 691, refer to Fig. 4) is also remarkably persistent. If silver(I) salts have been used to effect ionisation, they too can linger in the spectrometer for some time, generating unexpected $[M+Ag]^+$ ions in subsequent spectra of compounds with soft donor atoms which favour coordination to Ag^+. Flushing the system with a good donor ligand for silver, for example pyridine, can minimise prolonged contamination. Sodium iodide and caesium iodide are used as mass calibrants in ES spectrometers [62] and can cause problems with halide exchange reactions in metal chloride complexes for example. Polyethers are also used for positive-ion calibration and can be problematical when used in high concentrations. Formic acid, which can be used as a cleaning solution, may linger for some period of time, effecting protonolysis reactions and in some cases the observation of metal–formate complexes. For these reasons, it is useful to maintain a detailed log-book of all samples analysed so that possible sources of contamination from previous samples can be monitored.

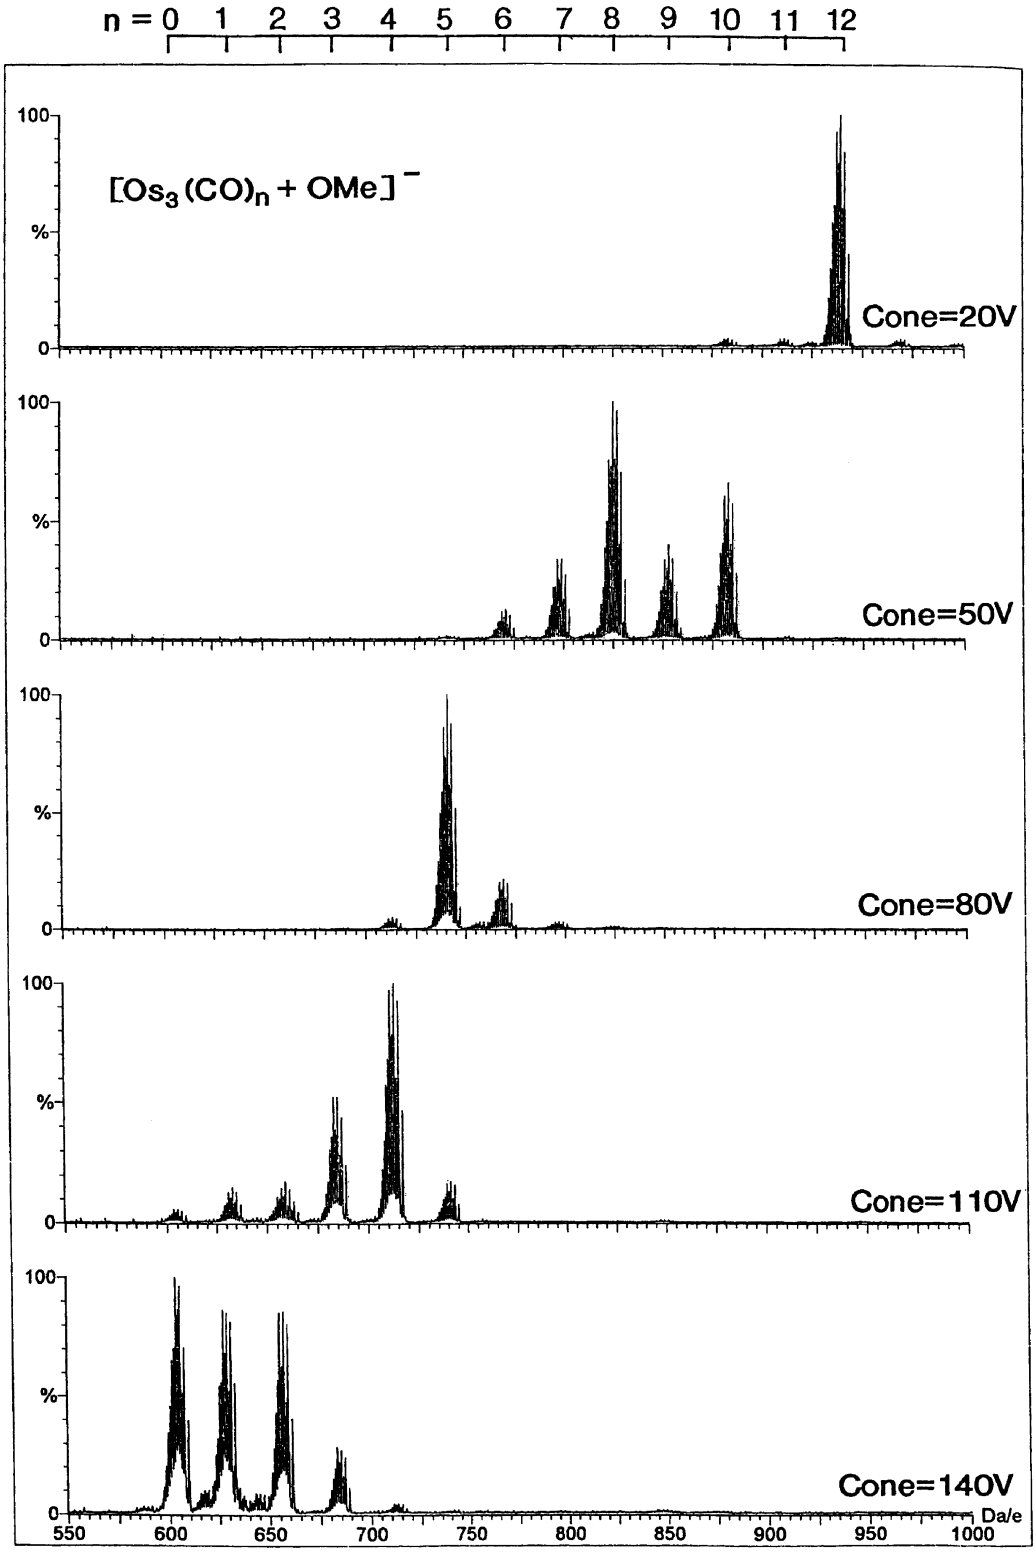

Fig. 5. Cone voltage induced CO fragmentation in the ESMS of the adduct of OMe^- with $Os_3(CO)_{12}$ in MeOH (taken from Ref. [47]).

3. METAL–ALKYL AND –ARYL COMPLEXES

3.1. *Metal–alkyl complexes*

ESMS studies of metal alkyls have to date centred largely on main-group and late transition-metal derivatives, which provide the more stable examples. Reports cover the metal–alkyl complexes of tin, germanium, silicon, arsenic, mercury, platinum, palladium, gold, indium and thallium.

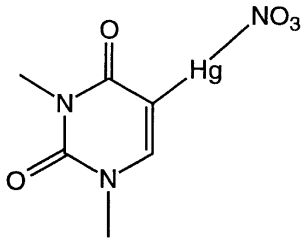
Organotin compounds, especially the organotin halides, have been the subject of several studies. The chemical and toxicological properties exhibited by organotin compounds depend on the speciation of the tin complex and this is conveniently monitored by ESMS. The hydrolysis products of Ph_3SnBr, Ph_3SnCl, Ph_2SnCl_2, Me_3SnCl and $^nBu_3SnCl$ have been investigated by ESMS in both positive- and negative-ion modes, in aqueous acetonitrile solvent [63]. Species observed in positive-ion mode included aggregate ions of the type $[(R_3Sn)_n(OH)_{n-1}]^+$ with intensity decreasing with increased n. The solvated $[R_3Sn(MeCN)_{1\text{ or }2}]^+$ ions were also observed, with the solvating MeCN groups being lost at higher cone voltages. In the negative ion spectra several different types of species could be identified; solutions of Ph_3SnX (X = Cl or Br) yielded $[Ph_3SnX_2]^-$, $[Ph_3SnX(OH)]^-$, $[Ph_3SnO]^-$ and $[Ph_3SnOSnPh_3X]^-$, while Ph_2SnCl_2 yielded primarily $[Ph_2SnCl_3]^-$. The various mixed-halide ions $[^nBu_3SnXY]^-$ (X, Y = halide) were all observed in solutions of $^nBu_3SnCl$ with mixed halides. Other work has been done on organotin compounds to investigate an alternative method (to GC–MS employing EI ionisation) for identification [64]. Mixtures of organotin compounds have also been studied [65]. In this study, carried out in methanol solvent, tin-methoxy species were also detected. Tin has the record number of natural isotopes (10) and the characteristic pattern allows for unambiguous assignment of peaks and clear identification of any dimers which may form. Tributyltin (TBT) species are the most important in the marine environment and have been studied using ionspray mass spectrometry/mass spectrometry (a technique related to ESMS) as part of a trace metal analysis [66]. By means of selected reaction monitoring of a daughter ion pair (m/z 179/291) in the spectrum of TBT, quantitative estimates of the concentration of tin present at low levels were able to be made.

Larger tin aggregates have also been studied by ESMS. The mixed-alkyl distannoxane $[^tBu_2(Cl)SnOSn(Cl)Me_2]$ has been studied by positive-ion ESMS in methanol–water, giving a series of tri-tin species, which presumably arise by reaction with the solvent system [67]. The compound $[(BuSn)_{12}O_{14}(OH)_6]Cl_2$ has been characterised by X-ray crystallography and NMR spectroscopy, and positive-ion ESMS revealed that the cation retained its integrity in dichloromethane–methanol solution, giving a single peak at m/z 1218 [68]. Over time, two hydroxyl groups were replaced by methoxide ions (from methanol in the mobile phase) to give a peak in the spectrum at m/z 1232. Further experiments demonstrated the use of ESMS as a means for monitoring such substitution reactions.

Certain silicon and germanium compounds are also amenable to ESMS analysis. Electrospray tandem mass spectrometry has led to deduction of the structure of a germanium compound, Ge-132 (bis-carboxyethyl germanium sesquioxide) and to some interesting conclusions about its fragmentation pathway [69]. The confirmation of the identity of some silicon-containing heteroboranes was also achieved using electrospray [70]. Moisture-sensitive $H_2N(CH_2)_3Si(OEt)_3$ has been analysed by ESMS in dry ethanol mobile phase [36]. The first three generations of an organo-silatrane-containing dendrimeric wedge have recently been synthesised and characterised by positive-ion ESMS [71]. At low cone voltages, compounds containing a residual tri-alkanolamine moiety predominantly show multiply-charged ions of the type $[M + H + xNH_4]^{(x+1)+}$ ($x = 0$–3), while compounds with residual epoxy groups show strong $[M + xNH_4]^{x+}$ ions, where $x = 1$–4. The observation of such multiply-charged ions for these compounds containing multiple protonation sites is reminiscent of the classical behaviour of larger peptides and proteins in ESMS [19].

ESMS has been employed for the study of various other organoarsenic compounds. Arsenobetaine ($Me_3AsCH_2CO_2$), arsenocholine ($Me_3AsCH_2CH_2OH$), tetramethylarsonium iodide $[Me_4As]I$, methylarsonic acid ($MeAsO_3H_2$) and dimethylarsinic acid (Me_2AsO_2H) were examined by positive-ion ESMS [72]. In a separate study, the quantification of ten organoarsenic compounds (including those listed above, in addition to various arylarsonic acids and trimethylarsine oxide, $Me_3As{=}O$) was described using a reversed-phase microbore HPLC separation coupled with ESMS [73]. Additionally, Ag^+ ions have been used in the analysis of a range of tertiary arsine ligands [43].

The organometallic complex between mercury(II) and the nucleobase dimethyluracil (Hdmura), (1,3-dimethyluracil-5-yl)mercury(II) nitrate **3**, has been analysed as DMSO and H_2O solutions, giving hydrolysed ions of the type $[Hg_6(dmura)_6O_2]^{2+}$, $[Hg_6(dmura)_6O_2(NO_3)]^+$ and $[Hg(dmura)(Me_2SO)]^+$ [74]. A series of methylmercury(II) derivatives (each of which give intact ions in their ESMS spectra) has been investigated for their participation in ligand exchange reactions in solution, and electrospray was found to be a convenient technique by which to follow these reactions [75]. Each compound was a complex of a neutral nitrogen base which was seen to be easily displaced by a variety of other ligands yielding new methylmercury complexes. The methylmercury cation has also been reacted with some amino acids as well as glutathione [76] to give products



3

(observed using ESMS) of the form $[(MeHg)_2(AA–H)]^+$ (AA = amino acid e.g. glycine, histidine) when the reactant was added in 1:1 stoichiometry. The interaction of $MeHg^+$ with a range of proteins and peptides has also been investigated and is discussed in greater detail in Section 8.

Examples of organoplatinum(IV) and -palladium(IV) compounds have been investigated using ESMS [77] to yield results consistent with chemical properties already known about the compounds. The Pt(IV) complexes [78] were more stable towards fragmentation, while the palladium compounds of the type $[Me_2(C_3H_5)Pd(mim\text{-}_2pyCH)]I$ (mim_2pyCH = methylimdazolyl-derived ligand) routinely lost methyl ligands at low cone voltages. A number of ionic Pd(II) compounds have also been analysed and each gave intact cation signals. The platinum(II) acetylide complex $[Pt_2(CC^tBu)_3(\mu\text{-dppm})_2]^+$ (dppm = $Ph_2PCH_2PPh_2$) gives the expected $[M]^+$ ion in its ES spectrum and the fragment ion $[(dppm)Pt(CC^tBu)]^+$ was also observed [79]. The bis-chelate complex $[Pt(CH_2PPh_2CH_2PPh_2)_2]^{2+}$ has been synthesised by reaction of the bis(chloromethyl) complex $[Pt(CH_2Cl)_2(dppm)]$ with one equivalent of dppm and the ESMS spectrum yielded the $[M]^{2+}$ cation [79]. In contrast, the FAB spectrum of the same complex gave both the $[M]^+$ and $[M]^{2+}$ ions, as a result of the FAB ionisation process being more reducing than the ES ionisation process. Fragment ions observed were assigned on the basis of CH_2 expulsions/ring contraction processes.

Gold(III), indium(III) and thallium(III) all form dimethyl derivatives incorporating neutral polydentate nitrogen donor ligands but the indium and thallium compounds tend to have highly variable structures in the solid-state [80]. All the gold complexes exhibited intact cations in their positive mass spectra but this is not always the case for the indium and thallium compounds. The indium compounds are known to be fluxional in solution and reversible ligand dissociation was demonstrated.

Carbon–hydrogen bond activation by transition-metal complexes has been directly observed by ESMS [81, 82]. The cationic complexes $[CpIr(PMe_3)Me]^+$ and $[Cp^*Ir(PMe_3)Me]^+$ undergo C–H bond activation depending on the cone voltage.

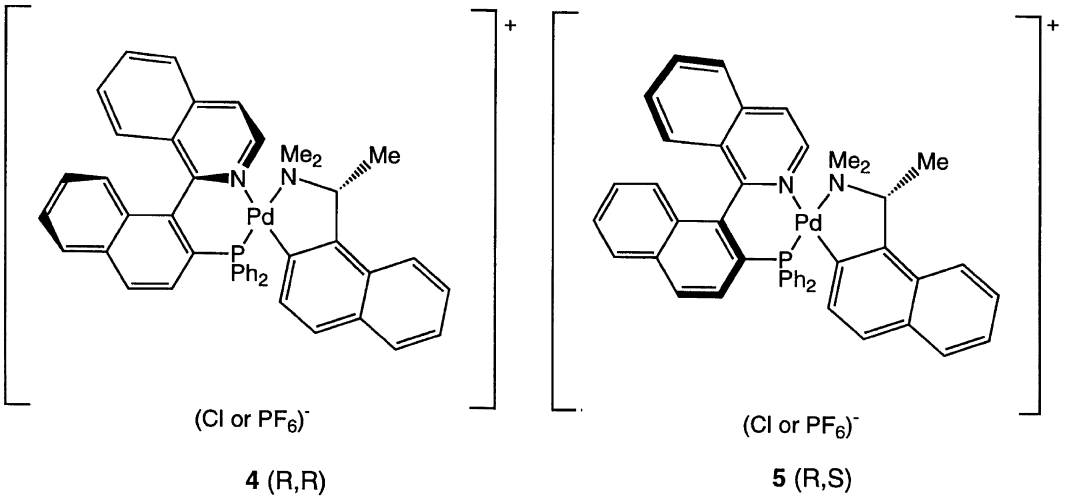
3.2. *Metal–aryl complexes*

Enantioselective fragmentation of palladium–aryl complexes has recently been demonstrated by ESMS [83]. Fragmentation for the (*R*,*R*) enantiomer **4** was more pronounced than that for the (*R*,*S*) enantiomer **5**. A number of metallodendrimers, derived from the palladium–aryl building block **6**, have been synthesised and subsequently characterised by ESMS [84]. The compound **6** yielded the $[M–Cl]^+$ ion in the positive-ion ES spectrum, as found for other metal–halide complexes (*vide infra*).

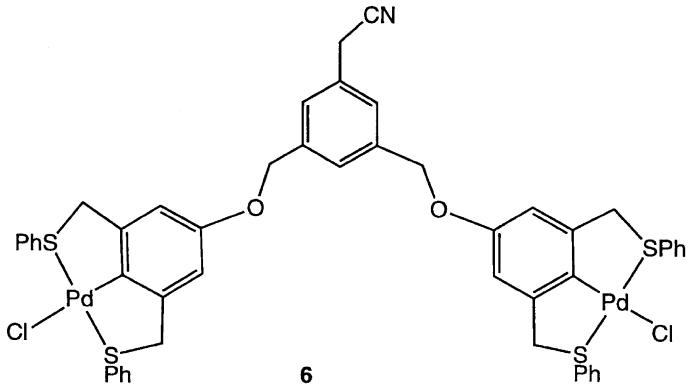
Reactive palladium–aryl intermediates have been detected by ESMS. Catalytic intermediates observed in the palladium(0) catalysed coupling reaction between aryl halides and arylboronic acids (the Suzuki reaction) have been detected by ESMS [85]. In this study, pyridyl halides were used in place of phenyl derivatives so that a protonatable group was present in complexes which otherwise could be invisible to the ES ionisation technique. In another study, intermediates in the palladium catalysed intramolecular arylation of enamines have been observed [86]. These studies suggest the potential of ESMS for the detection of intermediates in other reaction solutions.

Copper(I) salts in conjunction with organolithium reagents are widely used synthetic reagents; ESMS data for mixtures of copper(I) iodide or -cyanide with lithium halides have been reported, and it was indicated that negative ion ESMS data on the organometallic thienyl cuprate 2-ThCu(CN)Li have been obtained, though full details do not yet appear to have been published [87].

Finally, a number of cyclometallated benzylamine gold(III) complexes containing ureylene [88], thiosalicylate [59] and sulfido [89] ligands have been characterised by positive ion ESMS. The gold metallacycles were found



4 (R,R) **5** (R,S)



6

to be generally stable towards cone voltage induced fragmentation. Monocationic sulfido-silver–gold-halide aggregates were the product of a thiourea reaction with **1** in the presence of silver ions [89].

4. METAL CARBONYL COMPLEXES AND METAL CLUSTERS

4.1. *Ionic metal carbonyl species*

The carbonyl ligand is very widespread among organometallic complexes; it may be the sole ligand or may be present in conjunction with other ligands such as phosphines, alkyl groups or π-hydrocarbons. For metal–carbonyl complexes which are charged, the ES process is ideally suited for the analysis of such species, transferring solution ions into the gas phase for direct analysis. The positively-charged chromium(I) species *trans*-$[Cr(CO)_2(dppe)_2]^+$ (dppe = $Ph_2PCH_2CH_2PPh_2$) illustrates this, giving an intact ion in the positive-ion ES spectrum [90, 91]. Cations of the type $[M(CO)_2(P–P)_2X]^+$ (M = Mo, W; P–P = dppe, $Ph_2PCH_2PPh_2$ (dppm); X = F, Cl, Br and I) [92], and *cis*/*mer*-$[Re(CO)_2Br(Ph_2PCH_2PPh_2Me)(dppm)]^+$ [90] have also been successfully observed using ESMS. Related ions $[Re(CO)_2(P_2P')X]^+$ ($P_2P' = Ph_2P(CH_2)_2P(Ph)(CH_2)_2PPh_2$; X = Cl, Br) have been investigated in another study [93]. The amount of deuteration of the complex $[Mo(CO)_2(dppe)_2D]^+$ has been determined by ESMS [94]. Anionic complexes of the types $[M(CO)_5X]^-$ (M = Cr, Mo, W; X = Cl, Br, I) and *cis*-$[M^*(CO)_4X_2]^-$ (M^* = Mn, Re; X = Cl, Br, I) have also been observed [92]. The general feature of all these spectra is the appearance of the intact carbonyl complex ion, which in some cases loses CO ligands when the skimmer (cone) voltage is increased. A comparative study involving ES, FAB and FD (field desorption) mass spectra of a large range of cationic π-hydrocarbon metal carbonyl complexes of the types [(η^5-(dien-

yl)Fe(CO)$_3$]BF$_4$, [CpFe(CO)$_2$(η^2-alkene)]BF$_4$ or [η-(C$_7$H$_7$)M(CO)$_3$]BF$_4$ (M = Cr, Mo, W) concluded that ESMS is the most convenient and informative of the three techniques for compounds of this type [95].

ESMS has been used to identify an unstable rhenium complex which occurs as a reaction intermediate of CO_2-photofixation using the complex [Re(bipy)(CO)$_3$(PPh$_3$)]$^+$ [96, 97]. The parent cation shows the expected strong [M]$^+$ ion at low cone voltages, with loss of a single CO ligand at higher cone voltage (40 V). Upon irradiation in a DMF-triethanolamine (TEOA) solution under a CO_2 atmosphere, the final product was the formate complex [Re(bipy)(CO)$_3$(OCOH)], but two intermediate complexes were identified, by HPLC, one of which was found and confirmed by ESMS to be [Re(bipy)(CO)$_3$(TEOA)]$^+$. The DMF complex was not observed and it was postulated that this is due to the poor donor ability of DMF compared to TEOA.

Polynuclear metal cluster anions can also be characterised by ESMS, though the list is still limited. As expected, charged clusters yield strong and generally simple ES spectra as illustrated earlier for [Os$_{10}$C(CO)$_{24}$]$^{2-}$ (Fig. 2); [Ru$_6$C(CO)$_{16}$]$^{2-}$ also gives pleasing ESMS spectra [37]. Anionic transition-metal clusters of the type (Ph$_4$P)[Fe$_3$(CO)$_{10}$(μ-CO){μ-Hg(M)}] [M = CpMo(CO)$_3$, Co(CO)$_4$, CpFe(CO)$_2$, CpW(CO)$_3$, and Mn(CO)$_5$], having the general structure **7**, have been studied and it was concluded that ESMS was the most appropriate method (when compared to FAB-MS) by which to control ion fragmentation [98]. The most intense peak at a cone voltage of 50 V was the [M–CO]$^-$ species, though the [M]$^-$ ions were also observed. Lower cone voltages than 50 V were not reported, but it would be anticipated that more intense parent ions would be seen at very low (e.g. 10 V) cone voltages. The cluster complex (Et$_4$N)[Fe$_6$C(CO)$_{16}$(AuPPh$_3$)] was also studied by ESMS [98]; the parent anion was the largest peak at a cone voltage of 50 V, and the second-largest was the ion formed by loss of one CO ligand. Related monoanionic complexes [Fe$_4$C(CO)$_{12}${μ-Hg(M)}] formed by reaction of (PPN)$_2$[Fe$_4$C(CO)$_{12}$] [PPN = N(PPh$_3$)$_2^+$] with ClHg(M) [M = as for **7** below] also give the monoanions as the base peaks in the negative-ion ES spectra [99].

Mn(CO)$_5$
Co(CO)$_4$

The ESMS spectrum of the highly air-sensitive platinum carbonyl cluster (Ph$_4$P)$_2$[Pt$_{12}$(CO)$_{24}$] has been described, giving [(Ph$_4$P)(Pt$_{12}$(CO)$_{24}$)]$^-$ (m/z 3351), formed by ion aggregation and [Pt$_{12}$(CO)$_{11}$]$^{2-}$ (m/z 1324) as the two most intense ions [24]. Several Pt$_9$ ions, [(Ph$_4$P)$_2$(Pt$_9$(CO)$_{18}$)]$^-$, [(Ph$_4$P)$_2$(Pt$_9$(CO)$_{13}$)]$^-$ and [Pt$_9$(CO)$_8$]$^{2-}$, are formed by loss of one of the Pt$_3$ triangles. Only preliminary details of this work have so far been reported. Another air-sensitive anionic cluster which has been analysed by ESMS is the species [Ni$_{10}$(BiMe)$_2$(CO)$_{18}$]$^{2-}$; for this species the parent ion was not observed, but instead gave eight peaks corresponding to [M–2Me–nCO]$^{2-}$, as a result of both CO and methyl loss [100]. The related organoantimony species [Ni$_{10}$(SbPr^i)$_2$(CO)$_{18}$]$^{2-}$ showed the parent dianion, together with other fragments formed by CO and propyl loss [101]. These results demonstrated the stability of the Ni$_{10}$Sb$_2$ and Ni$_{10}$Bi$_2$ clusters and the greater strength of the Sb–C versus Bi–C bonds.

The anionic clusters [Ru$_3$(CO)$_{12-n}$L$_n$]$^{3n-}$(n = 1–3), [H$_4$Ru$_4$(CO)$_{11}$L]$^{3-}$ and [Ru$_6$C(CO)$_{16}$L]$^{3-}$ (where L is the water-soluble phosphine [P(m-C$_6$H$_4$SO$_3$)$_3$]$^{3-}$ as the Na$^+$ salt) are readily examined by ESMS in water or

MeOH. They give aggregate peaks containing varying numbers of sodium counter-ions, with the most highly-charged species observed being $[Ru_3(CO)_{10}L_2+Na]^{5-}$ [38].

ESMS has also been used in the identification of the product of CO reduction of Na_2PtCl_6 and $RhCl_3$ on an MgO support [102]. The product cluster anion was extracted from the support and negative-ion ESMS revealed the anion $[PtRh_5(CO)_{15}]^-$ as the major ion, together with the fragment ions $[PtRh_5(CO)_{14}]^-$ and $[PtRh_5(CO)_{13}]^-$.

4.2. *Neutral metal carbonyl complexes*

For neutral metal carbonyl complexes, techniques for study by ESMS have not been available until very recently. Coordinated CO contains a formal lone-pair of electrons on oxygen, but this atom is not readily protonated in solution, although interactions of the CO-oxygen with hydrogen-bond donors in the solid-state occurs [103–106]. This means that "normal" ESMS studies on metal carbonyl complexes are only possible when the co-ligand has suitable functional groups; examples of this type include η^4-(diene)$Fe(CO)_3$ or η^6-(arene)$Cr(CO)_3$ where the organic ligand has $>C{=}O$, $-NH_2$ or ${=}N(R)$ groups that allow ready formation of $[M+H]^+$ ions [107].

More generally, homoleptic metal carbonyls and mixed-ligand complexes which contain only non-protonatable groups must be subjected to alternative ionisation processes. The most successful and general method found to date is to dissolve the metal carbonyl in an alcohol solvent, and to add a small quantity of the corresponding sodium alkoxide (easily generated by adding a small piece of the metal to a separate portion of the alcohol) [37]. Nucleophilic attack of the resulting alkoxide on a coordinated CO ligand then occurs:

$$L_nM\text{–}CO+OR^-\rightarrow[L_nM\text{–}CO_2R]^- \quad (1)$$

The resulting $[M+OR]^-$ ions are readily analysed in negative-ion mode. This derivatisation process is useful since the reactions are general for many metal carbonyls, are rapid and are characterised by large equilibrium constants favouring the charged product. A range of alcohols can be used, but methanol is preferred. A competing ionisation, if hydride ligands are present, may be deprotonation giving $[M\text{–}H]^-$ ions. An illustrative list of the metal carbonyl complexes which have successfully given ions using this ionisation technique is in Table 1, where the generality of the method can be easily seen. It is equally effective for mononuclear complexes and for high molecular mass polynuclear clusters [37, 47, 108, 109].

For direct comparison of techniques there is a recent report of the use of UV laser-desorption mass spectrometry to analyse the hexanuclear ruthenium carbide clusters $[Ru_6C(CO)_{17}]$, $[Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_5Me)]$ and $[Ru_6C(CO)_{12}(\eta^6\text{-}C_6H_4Me_2)(\mu\text{-}C_6H_7Me)]$ and $[Ru_6C(CO)_{14}(C_{16}H_{16})]$ (Fig. 6) [8, 9]. Positive-ion spectra showed abundant singly-charged positive ions, together with CO loss from the parent clusters and a series of high molecular weight clusters formed by aggregation of the intact hexaruthenium carbide cores, observed by a time-of-flight detector. Interpretation of the ESMS spectra is much more straightforward.

Examples discussed so far have been for characterisation of single compounds. ESMS also has valuable application in monitoring reactions. One of the classical routes to high-nuclearity clusters has been the pyrolysis of smaller clusters, but such reactions are typically non-specific. The products isolated and characterised have generally been those which crystallise, often after laborious chromatographic separation. There is no doubt that other clusters remain uncharacterised, especially those that are charged so cannot easily be purified by traditional chromatographic methods. For monitoring cluster reactions ESMS is complementary to, but more sensitive than, IR spectroscopy, since the latter technique can suffer from overlap of bands due to two or more species. As an illustration of the potential of ESMS in this area, Fig. 7 shows the negative-ion ESMS spectrum of pyrolysed (210°C) $Os_3(CO)_{12}$, after extraction with ethyl acetate and derivatisation with NaOMe, yielding osmium carbonyl clusters of a range of metal nuclearities [37].

The addition of OMe^- to derivatise neutral metal carbonyl compounds for ESMS observation involves

Table 1. A representative range of the neutral metal carbonyl compounds that show clean $[M+OMe]^-$ ions in their ESMS spectra when run in MeOH with added NaOMe. For a more complete list see Ref. [37]

$[Fe(CO)_5]$	$[W(CO)_6]$	$[Re_2(CO)_{10}]$
$[Mo(CO)_3Cp]_2$	$[Os_3(CO)_{12}]$	$[Fe_3(CO)_{11}(CNBu^t)]$
$[Ru_3(CO)_{11}(PPh_3)]$	$[Ru_3H(C_2Bu^t)(CO)_9]$	$[Cp(CO)_3Mo\text{–}(C{\equiv}C)_2\text{–}C_6H_5]$
$[Ir_4(CO)_{12}]$	$[Ru_4H_4(CO)_{12}]$	$[NiRu_3H_3(CO)_9Cp]$
$[Ru_5(CO)_9(C_6H_5Me)]$	$[Ru_6C(CO)_{17}]$	$[Ru_6C(CO)_{14}(C_6H_5Me)]$

nucleophilic attack at a coordinated CO. Another example of this type which is less well studied involves corresponding attack by the azide ion, which usually proceeds via the overall process shown in eqn (2) presumably via the initial addition of N_3^- to a coordinated CO followed by loss of N_2:

$$L_nM\text{–}CO + N_3^- \rightarrow [L_nM\text{–}NCO]^- + N_2 \quad (2)$$

ESMS has provided the first direct evidence for an intermediate azide-addition product and serves as a rapid screening technique on a small scale to assess which substrates are most suitable for subsequent preparative-scale reactions [110].

Examples so far discussed have involved formation of negative ions from the neutral metal carbonyl species. An alternative procedure involves attachment of a positively charged species to the substrate. As discussed above, protons do not generally add to give $[M+H]^+$ ions, but in some cases mono-charged ions such as Na^+, Cs^+ or Ag^+ are useful ionisation aids. A series of rhenium–bipyridine complexes of the type *fac*-$[Re(X_2bipy)(CO)_3Y]$ (X_2bipy = 4,4′-X_2-2,2′-bipyridine; X = H, Me, CF_3; Y = CN, Cl, Br, OCHO) yielded no ions of the form $[Re(X_2bipy)(CO)_3]^+$ in methanol solution, but addition of $NaNO_3$ yielded $[Re(X_2bipy)(CO)_3Y+Na]^+$ ions [111]. When X was OH, the methoxy complex $[Re(X_2bipy)(CO)_3OMe+Na]^+$ was observed, but no adduct was observed for $[Re(CO)_5Cl]$ using this method. An $[M+Na]^+$ adduct has also been observed for the complex [*fac*-Re(bipy)$(CO)_3$CN] in the presence of $NaNO_3$ ionisation agent, indicating that it is a general ionisation method for this class of compound [112].

The sodium ionisation method can be applied to other complexes, such as ruthenium–nitrosyl complexes of the type $[Ru(NO)Cl_3(EPh_3)_2]$ (*E* = P, As, Sb), which with added alkali metal cations result in the observation of [M + cation]$^+$ ions [113]. Similarly $[M+Na]^+$ ions are sometimes observed with metal carbonyl clusters that have been treated with NaOMe [37].

For all of these examples it appears that attachment is via an iso-carbonyl (or iso-nitrosyl) link of the type $L_nM\text{–}C{\equiv}O\ldots Na^+$. In support of this, $[M+Na]^+$ ions are usually only found with metal carbonyl clusters that are electron-rich with electron-donating co-ligands. For example $Ru_3(CO)_9(PPh_3)_3$ gives a clean $[M+Na]^+$ signal but the parent $Ru_3(CO)_{12}$ does not [37].

An alternative ionisation technique uses silver(I) ions in a range of solvents and gives $[M+Ag(solvent)_n]^+$ type ions (n = 0 or 1, depending on cone voltage) [37, 46]. Metal carbonyl complexes which give successful ions by this technique include $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$, $Re_2(CO)_{10}$ and $SiFe_4(CO)_{16}$ but overall it is a less general method. Here the ionisation mechanism appears to involve addition of the Ag^+ to a M–M bond rather the isocarbonyl-type interaction assumed for the other metal cations [37]. This method of ionisation is also successful for analysing poly-yne compounds with metal carbonyl end-groups, although here attachment of the Ag^+ via the C≡C bonds seems probable [109].

A more drastic formation of cations from neutral metal carbonyl species comes from a study of the neutral rhenium carbonyl complexes [(ind)$Re(CO)_3$] (ind = η^5-indenyl), and [$CpRe(CO)_3$] in MeCN solution. These give rise to $[Re(CO)_3(MeCN)_3]^+$ ions in the ES analysis, though the original species are stable in bulk solution [114]. It was suggested that oxidation of the parent compound generates seventeen-electron cations, which are labile, resulting in the loss of the cyclopentadienyl or indenyl ligands. In contrast, the complexes [(ind)Re$(CO)_2$(butyne)] and [$CpRe(CO)_2$(butyne)] did not lose the aromatic hydrocarbon ligand on ES analysis and the predominant ions observed were [(ind)Re(CO)(MeCN)(butyne)]$^+$ and [CpRe(CO)(MeCN)(butyne)]$^+$ [114].

Another approach which we are taking in the analysis of metal carbonyl complexes, is to incorporate ancillary protonatable phosphine ligands [115]. Examples of these "electrospray-friendly" analogues of the ubiquitous triphenylphosphine ligand are **8**. These ligands are chemically and electronically similar to triphenylphosphine, yet the methoxy group facilitates ionisation by protonation (Section 2.3). A number of complexes of these ligands have been prepared and examples include $Fe(CO)_3P^*_2$ and $Mo(CO)_4(P^{***})_2$; all complexes of this type yield strong $[M+H]^+$ ions whereas the triphenylphosphine analogues do not.

5. METAL–CYCLOPENTADIENYL COMPLEXES, INCLUDING METALLOCENES

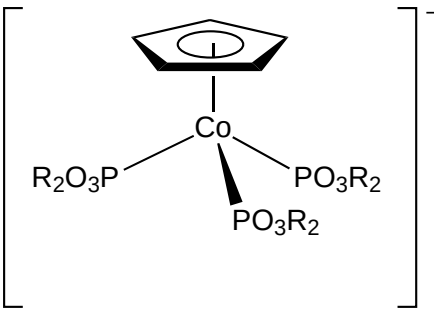
The cyclopentadienyl ligand itself is not protonatable under ES conditions and therefore the behaviour of such complexes is strongly dependent on the nature of the ancillary ligands present.

The archetypal metallocene, ferrocene, Cp_2Fe, is an accepted standard in the measurement of electrode potentials for non-aqueous redox systems and the ease of oxidation of metallocenes results in them being ideal candidates for ESMS study. As described earlier in Section 2, the ES capillary is able to act as an electrochemical cell, resulting in substrate oxidation. The ferricinium ion, in the form of the salt $[Cp_2Fe]BF_4$ generated by oxidation of ferrocene with $NOBF_4$, has been analysed by ESMS and the parent Cp_2Fe^+ ion was observed with high intensity at m/z 186 [90]. A study of collision-induced dissociation (CID) caused by increasing the (skimmer) cone voltage produced two extra peaks corresponding to loss of one and both Cp ligands. These fragments are also the major ions observed upon analysis of ferrocene using EI mass spectrometry.

While chemical oxidation is certainly effective, it is certainly not the only ionisation pathway available for metallocene complexes. Ruthenocene and osmocene have been investigated and each gave the oxidised metallicinium ion $[Cp_2M]^+$ without the addition of an oxidising agent [116]. However, in the case of osmocene, the increased basicity of the metal in this complex resulted in competitive protonation occurring, giving $[Cp_2OsH]^+$. The protonated decamethylosmocene cation $[Cp^*_2OsH]^+$ was observed in the positive ion ESMS spectrum of $[Cp^*_2OsH][Os_2Br_8]$, formed by reaction of H_2OsBr_6 with Cp*H and ethanol [117].

For other metallocene-derived compounds, protonation and oxidation may compete with each other to be the dominant ionisation pathway, the relative amounts of each depending on the redox potential of the metallocene centre, the basicity of the attached substituents, and also on instrumental parameters such as the solvent flow rate. (A slower flow rate results in a greater residence time in the metal capillary and more oxidation). Thus for the ferrocenyl-amine $FcCH_2NMe_2$, only the protonated $[M+H]^+$ ion was observed due to the high basicity of the NMe_2 moiety; the compound $[FcCH_2NMe_3]I$ also gave an intense peak due to the cation [118]. For the phosphonate $FcCH_2P(O)(OPh)_2$, both protonated $[M+H]^+$ and oxidised $[M]^+$ ions were observed, reflecting the lower basicity of the P=O moiety compared to the amine [118]. At higher cone voltages, the unsubstituted ligand was selectively lost and this is interpreted in terms of intramolecular stabilisation of the resulting cation formed. The compounds $FcCH_2OH$ [118], $FcCH_2P(CH_2OH)_2$ [119], and $FcCH_2PH_2$ [120] have also been studied by ESMS (including the addition of silver ions to the phosphines, refer to Section 8). For all of these compounds containing the $FcCH_2E$ moiety (where E is N or P), the ion $[FcCH_2]^+$ is a commonly observed stabilised carbocation, with its ease of formation reflecting the ability of the E moiety to act as a leaving group. The formation of this ion was therefore maximum for $FcCH_2NMe_3^+$, which can readily lose Me_3N. The ferrocene-derived thiolate anion $FcCO_2(CH_2)_{16}S^-$ (together with a number of other thiolate anions) has been studied by negative-ion ESMS, which gives the expected $[M]^-$ ion; the ion $FcCO_2^-$ was also observed as a fragment ion [121].

A number of titanocene(IV) complexes of β-diketonates of the type $[Cp_2Ti(\beta\text{-diketonate})]PF_6$, formed by oxidation of the corresponding titanium(III) complexes with $[Cp_2Fe]PF_6$, gave the expected parent ions in their positive-ion ESMS spectra [122].

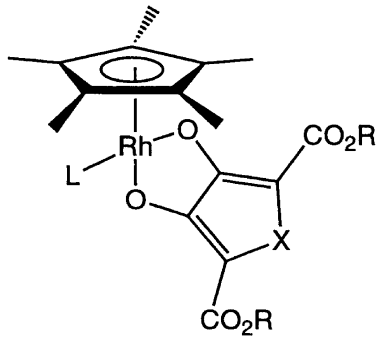


9

Uninegative tripodal oxygen ligands L of the type **9** have attracted much attention for their coordination chemistry, being analogous in many respects to the cyclopentadienyl ligand. Complexes of these ligands (R = Me, Et, ^{i}Pr) with alkali metals have been studied by negative-ion ESMS [123]. Ions of the type $[NaL_2]^-$, $[Na_2L_3]^-$ and $[Na_3L_4]^-$ were observed and related to the known trimeric and polymeric structures of the sodium salts of these ligands. Addition of alkali metal halides (e.g. NaCl) to solutions of these ligands yields

ions of the type $\{[L]^- + n(NaCl)\}$ ($n = 1$–9) and $\{[NaL_2]^- + n(NaCl)\}$ ($n = 1$–8). These results were contrasted with the uninegative tripodal nitrogen ligand $[HB(pz)_3]^-$ (pz = pyrazolyl), which yielded only $[HB(pz)_3]^-$ and $K\{[HB(pz)_3]\}_2^-$ ions, and no adducts with alkali metal halides.

There have been several studies on complexes containing metallocene-derived phosphine ligands. A range of ferrocene-derived phosphine ligands has been surveyed by ESMS, including application of various ionisation reagents for such compounds (refer to Section 7) [42]. ESMS has been used in a study of C–S bond insertion reactions of thiazolium salts with platinum(0) diphosphine complexes containing the ligand $(Ph_2PC_5H_4)_2Fe$ (dppf) [124]. A number of bis(diphenylphosphino)ruthenocene (dppr) complexes of ruthenium, which also contain a coordinated Cp ligand, have been studied by ESMS [125]. The complexes [Ru(Cp)Cl(dppr)] and $[Ru(Cp)(dppr)(MeCN)]PF_6$ both yield the ion $[Ru(Cp)(dppr)(MeCN)]^+$ when analysed by ESMS and the MeCN ligand is lost at relatively low cone voltages. Loss of the CO ligand from $[Ru(Cp)(dppr)(CO)]^+$ required much higher cone voltages, indicating higher stability. The vinylidene complex $[Ru(Cp)(dppr)(=C=CHPh)]^+$ gives the expected molecular ion, together with the dication $[Ru(Cp)(dppr)(=C=CHPh)]^{2+}$, formed by electrochemical oxidation of the ruthenocene moiety in the capillary (refer to Section 2.3).



10
L = pyridine, PPh_3;
X = O, S;
R = Me, Et

A series of pentamethylcyclopentadienyl (Cp*) complexes of rhodium containing dioxolene ligands of the type **10** have been synthesised and characterised by ESMS [126]. The lability of the ancillary PPh_3 ligand was readily ascertained by means of cone voltage-induced fragmentation and by *in situ* reactions with reagents such as hydrogen peroxide and elemental sulfur or selenium, which react with the labilised PPh_3 ligand, generating $Ph_3P{=}E$ ligands (E = O, S or Se), which coordinate to the Rh centre to differing extents. The cyclic trimer $[Cp^*Rh(2'\text{-deoxyadenosine})]_3^{3+}$ has been used in the gas-phase molecular recognition of aromatic acid and aromatic carboxylic acid guests [127]. The supramolecular recognition is believed to occur via non-covalent π–π interactions.

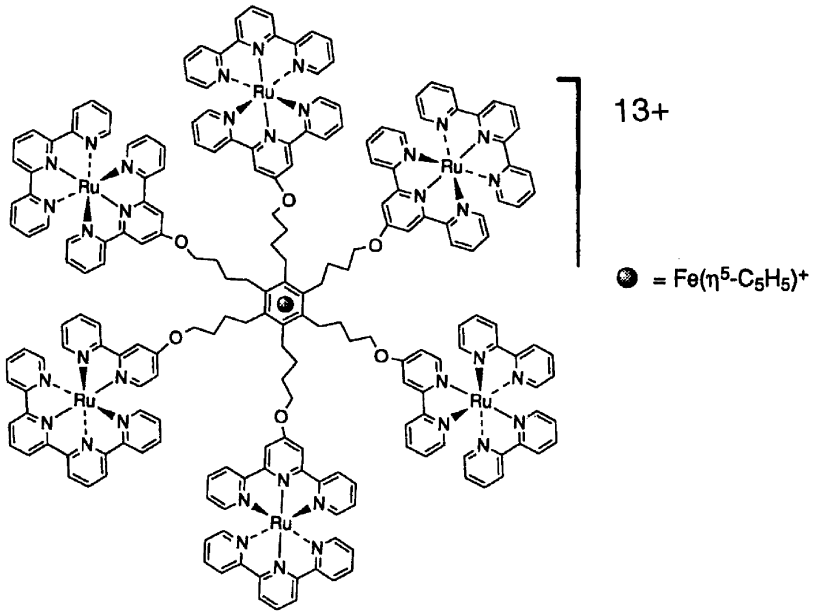
The Cp* tungsten complex $[Cp^*WS_2(SCH_2CH_2Br)]$ has been successfully analysed in THF solution by ESMS, using LiCl as the ionisation reagent [40]. In positive-ion mode, ions of the type $[M + Li]^+$, $[M + Li(THF)]^+$ and $[2M + Li]^+$ were observed, while in negative-ion mode, $[M + Cl]^-$ is seen; these observations illustrate the effective use of a combination of an aprotic solvent and metal salt ionisation reagent in the analysis of sensitive organometallic complexes, as described in Section 2. The cluster $[Cp^*_2Mo_2Fe_2S_4]_3(\mu\text{-}S_4)_3$ has also been analysed in THF solution, to which a small amount of acetic acid was added, giving $[M + H]^+$ and $[M + 2H]^{2+}$ ions, indicating that the species is very readily protonated [128].

Finally in this section, the large star-shaped molecule **11** containing $[Ru(bipy)_3]^{2+}$ type units and a central (arene)$FeCp^+$ moiety has been analysed by positive-ion ESMS, which gave the 4+, 5+ and 6+ ions formed by aggregation with varying numbers of PF_6^- counterions, corresponding to the parent species of mass 5912 Da [129].

6. OTHER COMPLEXES

Silver(I) ions have a propensity to bind with soft electron density donor groups and thus this metal is well-known to form π-complexes with molecules such as alkenes, alkynes and arenes. This can be exploited in the analysis of such compounds by ESMS.

The tungsten tetra-ynyl complex $[CpW(CO)_3\text{-}C_8\text{-}W(CO)_3Cp]$ (M) when analysed at a low cone voltage with



11

added $AgNO_3$ yielded the ions $[M_2Ag]^+$ (*m*/*z* 1631) and $[MAg(MeCN)]^+$ (*m*/*z* 911), while at higher cone voltages, fragmentation by successive loss of CO ligands from the parent ion was observed [109].

A wide range of platinum(II) complexes containing cyclo-octa-1,5-diene (COD) or phosphines, together with various other ligands such as thiosalicylate [130], ureylene [131], β-propiolactam monoanion [132] and thiourea dianion [133] have all been routinely analysed by positive-ion ESMS and all species give strong ions of the type $[M+H]^+$ and $[M+NH_4]^+$. All of these complexes contain ancillary N or O atoms which can act as protonation sites. ESMS was also used to investigate the cone voltage-induced fragmentation pathways of these complexes. Formation of cyclometallated triphenylphosphine species is a common theme for these complexes when subjected to high cone voltages, though complexes containing chelating phosphine ligands [e.g. $Ph_2PCH_2CH_2PPh_2$ (dppe) or $(Ph_2PC_5H_4)_2Fe$ (dppf)] undergo this process much less readily. For the thiourea complexes and the azetidinone complexes, the *in situ* coordination chemistry with Ag^+ ions and with a range of metal cations respectively, was also investigated [133].

Host–guest complexes can also be readily identified by ESMS and there have been extensive studies in this area. A series of calixarenes and paracyclophane molecules, which are conformationally both rigid and defined, have been studied with various metal cations [134]. Complexes of a paracyclophane with Li^+, Na^+ and K^+ were scarcely detectable by either secondary ion mass spectrometry (SIMS), but those with Rb^+ and Cs^+ were very intense and studies suggested that the cavity was optimised for binding of the Cs^+ ion. Although the Ag^+ ion has an affinity for π electron density, it does not bind in the cavity because of its size, which is comparable to K^+.

A number of allyl complexes have been studied by ESMS. The platinum–cyclopentadienyl complex, also containing a π-allyl ligand, $[Pt(C_5H_4Me)(\eta^3\text{-}C_3H_6)]$ has been examined by positive-ion ESMS and found to give an $[M]^+$ ion by oxidation, with a contribution from the protonated ion $[M+H]^+$; the only fragment ion observed was $[M\text{-allyl}]^+$ ([i.e. $(C_5H_4Me)Pt]^+$), though other aggregate ions were observed, including species containing up to six platinums [135]. Complexes of the type $[Pt(\eta^3\text{-}C_3H_6)(PPh_3)X]$ (X = Cl, Br, I) have also been studied and gave the ion $[Pt(C_3H_6)PPh_3]^+$, together with various solvated Pt complexes, including bis(triphenylphosphine) complexes [136].

7. PHOSPHINES, ARSINES AND THEIR ONIUM SALTS

Phosphines (R_3P) and arsines (R_3As) are very widely used as ligands in organometallic chemistry and accordingly they deserve mention in this review. Such compounds, exemplified by PPh_3, are not readily protonated in the absence of other functional groups (such as methoxy substituents, refer to Section 4) and therefore pre-ionisation is necessary. This may be achieved in a number of ways:

(i) Quaternisation to the respective onium salt, for example with methyl iodide. A range of mono-, di- and tri-phosphines have been converted to their methylphosphonium salts in this way and characterised by positive-ion ESMS [137]. In early studies in the ESMS of inorganic species, Colton and Traeger reported that the organic salts $[PhCH_2PPh_3]Cl$ and $[Bu_4N]PF_6$ yield the cations as the base peaks in their positive-ion spectra.

(ii) Conversion to the hydroxymethylphosphonium salt $[R_3P(CH_2OH)]^+$, using a mixture of formaldehyde and hydrochloric acid. A range of phosphines has been analysed by ESMS in this way [41, 42].

(iii) Oxidation to the phosphine oxide (using, for example H_2O_2). The resulting phosphine oxide then yields strong $[M+H]^+$ ions in the positive-ion ESMS spectrum when analysed in a protic solvent [41, 42].

(iv) Addition of silver(I) or copper(I) ions (see Section 2.3). These metal ions form stable complexes with a wide range of phosphine, arsine and stibine (among other) ligands and in the positive-ion ESMS spectra, ions of the type $[n\mathrm{M}+\mathrm{cation}]^+$ (cation = Cu or Ag; M = ligand; $n = 1$–4 depending on metal–ligand combination) are observed [41, 42].

The use of "electrospray-friendly" phosphine ligands **8** has been discussed earlier in this review (Section 4.2) [115]. Additionally, sulfonated aryl phosphines, which are attracting current interest for their applications in transition-metal catalysed biphasic reactions, yield strong negative-ion spectra, and selected examples have been cited earlier [38, 42].

8. MISCELLANEOUS APPLICATIONS

8.1. *Organometallic functionalisation of peptides and proteins for mass spectrometric analysis*

The affinity of organomercury compounds for thiols has been exploited for the derivatisation of cysteine-containing peptides and proteins. Interactions of Hg^{2+}, $MeHg^+$ and $PhHg^+$ cations with the thiol group of cysteine, glutathione and a 27-residue polypeptide containing one cysteinyl sulfur have been studied by positive-ion ESMS [138]. The $MeHg^+$ cation shows a greater affinity for cysteinyl sulfur, whereas $PhHg^+$ also forms isomeric species in which the mercury is bonded to an amino or carboxylic acid group. *p*-Hydroxymercuribenzoic acid has also been used to form derivatives analysed by MALDI-MS. The mass shift before and after derivatisation allows the total number of sulfhydryl groups in the protein to be determined [139]. The ions $MeHg^+$ and $PhHg^+$ have been evaluated (together with a wide range of other metal cations) as ionisation reagents for the proteins myoglobin and ubiquitin [140] while $MeHg^+$ has been investigated with horse heart cytochrome *C* [141]. One practical application of ESMS involves organometallic compounds as an aid in the analysis of peptides [142]. The study used an ionic species, $[(\eta^5\text{-}C_6H_7)Fe(CO)_3]^+$ (Fed^+), to form adducts with various nucleophilic peptides in a 50% methanol solution. These are produced in a similar manner to adducts between such cations and other nucleophilic reagents such as imidazoles or tertiary phosphines. The results showed a high adduction rate with Fed^+ for several peptides including N-acetylhistidine, and glutathione. The pH change was recorded for each peptide solution when the cation was added (*in situ*, in a specific mole ratio) and this yielded valuable information such as possible deprotonation sites in the histidine residues present. In all cases an ion corresponding to $[Fed]^+$ (m/z 219) and $[\mathrm{peptide}+Fed]^+$ was observed at a skimmer cone voltage of 20 V, along with various other protonated species. The only evidence of fragmentation in the ESMS of these organometallic adducts was the presence of weak intensity ions (1% intensity) in the spectra of two of the peptides which were assigned to $[\mathrm{peptide}+\text{Fed-CO}]^+$ in each case. Peptides investigated were *N*-acetylhistidine, *p*-Glu-His-Pro, *p*-Glu-His-Gly-NH_2, glutathione, *p*-Glu-His-Trp-Ser-Try-Gly-Leu-Arg-Pro-Gly and *p*-Glu-His-Trp-Ser-Try-Gly-Leu-Arg-Pro-Gly-Cys. Cysteine and histidine residues show preference for binding. It was concluded that ESMS is a versatile technique for the identification of adducts between peptides and organometallic reagents.

8.2. *Fullerenes*

Fullerenes, typified by the archetypal C_{60}, are of intense current interest in the chemical community, and a wide range of metal derivatives, including organometallic complexes, have been synthesised. Accordingly, development of techniques for their analysis by ESMS is of some interest, particularly since these molecules are characteristically non-polar and have low solubility in many solvents. In addition, the use of the soft-ionisation ESMS is likely to provide more useful information on higher homologues, which may fragment under more vigorous ionisation conditions. A number of indirect approaches have been reported which involve prior derivatisation, including incorporation of crown ether groups [143, 144, 145] and amination [146]. Oxidation or reduction using chemical redox agents has also been studied, using a variety of oxidants and reductants [147, 148, 149]. ESMS analysis of fullerenes is in fact directly achievable, as a result of either electrochemical oxidation or reduction in the ES capillary, which can act as an electrochemical cell. A number of studies have appeared in this area. A mixture of C_{60} and C_{70} ("fullerite") was analysed in dichloromethane

solution and found to yield radical anions ($C_{60}^{\cdot-}$ and $C_{70}^{\cdot-}$) in the negative-ion spectrum. No corresponding radical cations were observed in the positive-ion spectrum in this study. Prior electrochemical reduction of the fullerite sample, followed by ESMS analysis, yielded a more complex and irreproducible spectrum, though the fullerene radical anions were observed [54]. It was concluded that a compound should be directly analysable by ESMS providing its redox potential lies within the range -0.8 and $+1.0$ V vs SCE in CH_2Cl_2 solution. C_{60} and a number of derivatives were subsequently analysed directly in toluene solution, yielding the radical ions $C_{60}^{\cdot+}$ and $C_{60}^{\cdot-}$ in positive- and negative-ion modes, respectively [150]. The spectra were characterised by the presence of strong molecular ions with little or no fragmentation, though minor ions assigned as $C_{60}O^-$ and $C_{60}(PhCH_2)^-$ were also observed.

9. FUTURE SCOPE

The ESMS technique is uniquely suited to the analysis of polar, high molecular weight, involatile, thermally labile and rapidly-exchanging systems, providing they are soluble and stable in some solvent and can be ionised by some appropriate method. The wide variety of examples given in this review demonstrate that the technique has found an important role in the armoury of techniques employed by the organometallic chemist. The vast majority of the references quoted in this review have appeared in the past 4 years, showing applications are multiplying rapidly. There is still great scope for further development of this technique in many areas of chemistry. It is our hope that this review has inspired those organometallic chemists not already *au fait* with the technique to apply it to their own field of research, or to develop new fields, previously inaccessible due to the absence of suitable definitive analytical techniques. Many new and exciting developments in inorganic and organometallic electrospray mass spectrometry are anticipated in the near future.

Acknowledgements—We thank the University of Waikato for supporting our research in electrospray mass spectrometry, together with our co-workers whose names appear in the references cited, in particular Scott McIndoe, Maarten Dinger, Corry Decker and Nick Goodwin. The New Zealand Lottery Grants Board is also acknowledged for a grant-in-aid towards the purchase of our mass spectrometer. We also thank Professor M.I. Bruce for helpful comments.

Abstract—Meridianal- and axial-asymmetrical clathrochelate tris-dioximates of the $FeD_2D'(BF)_2$ and $FeD_3(BX)(Y)$ types (where D,D′ = dioximes dianions, X = C_6H_5, F; Y = BF, B*n*-C_4H_9, $SnCl_3$) have been prepared by a stepwise synthesis from a planar-square macrocyclic precursors in the first case and from a semiclathrochelate compounds immobilized on the sorbent surface in the second one. The composition and structure of the isolated compounds have been established from elemental analysis data, polynuclear NMR, ^{57}Fe Mössbauer and FAB mass spectra. The structure parameters of α-benzyldioximate $FeBd_3(BF)(Bn\text{-}C_4H_9)\cdot C_6H_5CH_3\cdot\frac{1}{2}C_8H_{16}$ (Fe–N distance – 1.89 Å, bite angle – 38.6°, polyhedron distortion angle – 17.9°) were determined by X-ray crystallography. The electrochemical properties of the obtained complexes and their dependence on the nature of a ligand have been determined by cyclic voltammetry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cage compounds; ^{57}Fe Mössbauer spectra; electrochemistry; X-ray structure.

INTRODUCTION

In most cases syntheses of macrobicyclic iron(II) tris-dioximates occur via a one-step procedure enabling one to obtain only complexes with identical dioxime fragments and capping groups [1–7]. It is not expedient to utilize mixtures of dioximes or capping agents with similar properties in these processes to produce asymmetrical compounds because of the formation of a mixture of products that is close to a statistical one. The formation of predominantly symmetrical complexes has been observed even when the dioximes and capping agents used differ significantly in their properties. The former case can be accounted for by the difference of non-macrocyclic tris-dioximates, described in [8–12] as first intermediate, stability constants (in case $\beta^{[Fe(H_2D)_3]^{2+}} \gg \beta^{[Fe(H_2D)(H_2D')]^{2+}}$) predominantly formed symmetrical $[Fe(H_2D)_3]^{2+}$ complex capping for different cross-linking agents due to the symmetrical clathrochelate. Similarly, in the second case, when the capping agents display an essentially different activity, a second intermediate, being of a semiclathrochelate nature, will preferably be formed by the strongest of them and will be presumably capped at a statistic ratio, since the second capping is not a rate-controlling step [8–12]. Additionally, a higher crystal lattice energy for symmetrical compounds as compared to that for asymmetrical ones is observed: in most cases clathrochelates are obtained in a solid state in the course of reaction and, therefore, an increase in the crystal lattice energy leads to a shift in equilibrium in the direction of the symmetrical product formation. When asymmetrical dioximes such as phenylglyoxime or methylglyoxime are employed as the starting ligand, a mixture of *fac*- and *mer*-isomers was obtained. However, in some cases one of them was isolated individually [13]. In spite of the fact that clathrochelates are produced by a multistage mechanism through the formation of semiclathrochelate products, the latter have not been isolated because of their lability. At the same time, a

directed synthesis of clathrochelates containing difference dioximate fragments and capping agents allows one to produce functionally substituted precursors suitable for further functionalization, as well as to vary rather finely the physico-chemical properties of the products obtained. The present study was undertaken to develop new methods for the synthesis of meridianal- and axial-asymmetrical complexes and to determine their physico-chemical properties.

EXPERIMENTAL

The reagents used, $FeCl_2 \cdot 4H_2O$, $Fe(BF_4)_2 \cdot 6H_2O$, $BF_2 \cdot O(C_2H_5)_2$, $SnBr_4$, sorbents, *n*-butyl and phenylboronic acids, dioximes, bases, as well as organic solvents, were obtained commercially. The starting dioximes designations are shown in Table 1.

The analyses for the carbon, hydrogen and nitrogen content were carried out with a Carlo Erba model 1106 microanalyser. Iron and tin were determined spectrophotometrically.

To take FAB spectra, a high-resolution double-focusing MX-1310 mass-spectrometer (electrostatic and magnetic sectors) was used. The substance to be investigated was dissolved in tricyanoethoxypropane. A sample of 5–10 ml of the solution was bombarded by an argon atom beam with an energy of 3.5 keV. The calibration of the mass number scale in the mass-spectrometer under FAB conditions was performed against the peaks of cluster ions. The analyzer peak resolution under FAB conditions was usually 10,000.

The relative intensities of the isotope peaks of molecular and fragment ions were calculated from the data on the abundance of natural isotopes of all the elements forming a part of these ions. The composition of molecular or fragment ions in the experimental mass spectra is confirmed by comparing the

[a] X-ray structure data.

isotope peak series of these ions with the calculated ones.

The IR spectra of solid samples (CsI and KBr tablets) were recorded in the range from 200 to 4000 cm^{-1} on a Specord M-80 spectrophotometer. The bands were assigned using the previous results. The UV–VIS spectra of solutions in chloroform were recorded in the range from 200 to 800 nm on a Lambda 9 Perkin Elmer spectrophotometer. The individual Gauss components of these spectra were calculated using the SPECTRA program. The ^{1}H, ^{13}C, ^{11}B and ^{119}Sn NMR spectra of the solutions in $CDCl_3$ were recorded on a AC-200 Bruker FT-spectrometer.

^{57}Fe Mössbauer spectra were obtained on YGRS-4M spectrometer with a constant acceleration mode. The spectra were collected on 256 multichannel amplitude analyzer. The isomer shift was measured relatively to sodium nitroprusside and α-Fe foil was used for the velocity scale calibration. ^{57}Co in Cr matrix was used as a source, which was always kept at room temperature. The minimum absorption line width in the spectrum of a standard sample of sodium nitroprusside was 0.24 mm/s.

Cyclic voltammograms were recorded in acetonitrile under argon atmosphere using a PI-50-1 potentiostat coupled with a B7-45 tera-ohmic potentiometer as a current–voltage convertor. Tetrabutylammonium tetrafluoroborate (0.1 M) was used as a supporting electrolyte. A platinum microelectrode of 10 μm in diameter, thoroughly polished and rinsed before measurements, was chosen as a working electrode. A platinum wire was applied as an auxiliary electrode. An SCE reference electrode was connected to the cell via a salt bridge. All potentials were referred to the redox potential of the ferrocene (Fc^{+}/Fc) couple as an internal standard. This potential is at +0.400 V vs SCE under the present experimental conditions.

Syntheses of complexes

$[FeDm_2(BF_2)_2(CH_3CN)_2]$, $[FeBd_2(BF_2)_2(CH_3CN)_2]$ and $[Fe(H_2Nx)_3]Cl_2$ complexes were obtained as described previously [14, 15].

$FeDm_2Bd(BF)_2$ $[FeDm_2(BF_2)_2(CH_3CN)_2]$ (4.64 g, 10 mmol) was dissolved/suspended in dry acetonitrile (30 ml) which had been degassed with argon. Then H_2Bd (4.8 g, 20 mmol) and *N*,*N*-diisopropylethyl amine (3.6 ml, 20 mmol) were added to the stirred reaction mixture. The red–violet solution was heated at 40–50°C for 10 min, then $BF_3 \cdot O(C_2H_5)_2$ (2.8 ml, 22 mmol) and *N*,*N*-diisopropylethyl amine (3.6 ml, 20 mmol) were added dropwise. After a reaction time of 30 min, $BF_3 \cdot (C_2H_5)_2O$ (2.8 ml, 22 mmol) was added, the reaction mixture was heated to 80°C, stirred for 20 min and filtered.

The filtrate was treated in a three-fold volume of water and the product was extracted with chloroform (50 ml). The extract was washed with a 5% NaOH aqueous solution, water and dried with anhydrous $CaCl_2$. After evaporation of chloroform to 20 ml, a solid product was precipitated by addition of a four-fold volume of hexane. The solid was dissolved in a benzene–diethyl ether (5:1) mixture. The solution was dried with CaH_2 and precipitated with hexane. The resulting orange product was additionally purified by reprecipitation from a concentrated chloroform solution with methanol, washed with a small amount of methanol, diethyl ether, hexane and dried *in vacuo*; yield 1.16 g, 20%. Found: C, 45.4; H, 4.0; N, 14.3; Fe, 9.6. Calc. for $C_{22}H_{22}N_6O_6B_2F_2Fe$: C, 45.4; H, 3.8; N, 14.4; Fe, 9.6%.

$FeBd_2Dm(BF)_2$ This complex was synthesized like the previous one except $[FeBd_2(BF)_2(CH_3CN)_2]$ (3.68 g, 5 mmol) and H_2Dm (1.16 g, 10 mmol) were used instead of $[FeDm_2(BF)_2(CH_3CN)_2]$ and H_2Bd; yield 0.88 g, 25%. Found: C, 59.2; H, 3.8; N, 12.0; Fe, 7.8. Calc. for $C_{32}H_{26}N_6O_6B_2F_2Fe$: C, 59.4; H, 3.7; N, 12.0; Fe, 7.9%.

$FeDm_2Gm(BF)_2$ This complex was synthesized like the $FeDm_2Bd(BF)_2$ except H_2Gm (1.8 g, 20 mmol) was used instead of H_2Bd; yield 0.43 g, 10%. Found: C, 27.8; H, 3.2; N, 19.3; Fe, 13.2. Calc. for $C_{10}H_{14}N_6O_6B_2F_2Fe$: C, 27.9; H, 3.3; N, 19.5; Fe, 13.0%.

$FeBd_2Gm(BF)_2$ This complex was synthesized like the $FeBd_2Dm(BF)_2$ except H_2Gm (0.88 g, 10 mmol) was used instead of H_2Dm and the reaction was realized at room temperature; yield 0.47 g, 14%. Found: C, 53.2; H, 3.2; N, 12.4; Fe, 8.2. Calc. for $C_{30}H_{22}N_6O_6B_2F_2Fe$: C, 53.1; H, 3.2; N, 12.4; Fe, 8.2%.

$FeBd_2Nx(BF)_2$ This complex was synthesized like the $FeBd_2Dm(BF)_2$ except H_2Nx (0.71 g, 5 mmol) was used instead H_2Dm and the reaction was realized at room temperature; yield 1.17 g, 32%. Found: C, 55.6; H, 3.7; N, 11.4; Fe, 7.6. Calc. for $C_{34}H_{28}N_6O_6B_2F_2Fe$: C, 55.8; H, 3.8; N, 11.5; Fe, 7.6%.

$FeNx_3(BC_6H_5)(BF)_2$ Preliminarily immobilized semiclathrochelate $FeNx_3(BC_6H_5) \cdot (AlO(OH))n$ complex was obtained. Specially prepared aluminium oxide hydroxide was produced by dissolving an aluminium foil (54 g, 2 mol) in 1.5 l absolute *iso*-propanol after activation with $HgCl_2$. The resulted solution was treated with a water–*iso*-propanol mixture (200 and 250 ml, respectively), stirred for 2 h, filtered and the precipitate was dried *in vacuo* at 150°C. 20 g AlO(OH) obtained as described above was placed under argon stream into a solution of $FeCl_2 \cdot 4H_2O$ (2.4 g, 12 mmol) and H_2Nx (8.5 g, 60 mmol) in 200 ml of acetonitrile. The suspension was stirred for 30 min and the solution of phenylboronic acid (2.44 g, 20 mmol) and dicyclohexyl amine (4 ml, 20 mmol) in 50 ml acetonitrile was added dropwise. The reaction mixture was left overnight at 40°C and filtered. The precipitate was washed with acetonitrile (200 ml), chloroform (250 ml), 150 ml of methylene dichloride with phenylboronic acid (1.22 g, 10 mmol) and extracted with methylene dichloride in a Soxhlet extractor for about 60 h to decolored of extragent. The solid after extraction was dried in air; yield ~25 g.

The product obtained (10 g) was suspended in a mixture of ethyl acetate (20 ml) and $BF_3 \cdot O(C_2H_2)_2$ (5 ml), stirred for 1 h, filtered and the filtrate was washed with aqueous sodium carbonate. The solid was washed with ethyl acetate (20 ml) and this filtrate was added to the first one.

The resulted solution was washed with water, dried with Na_2SO_4 and evaporated to dryness. The product obtained was washed with a small amount of diethyl ether, reprecipitated from methylene dichloride with heptane and dried *in vacuo*; yield 0.1 g, 3.5%. Found: C, 48.5; H, 4.8; N, 14.3; Fe, 9.3. Calc. for $C_{24}H_{29}N_6O_6B_2FFe$: C, 48.6; H, 4.9; N, 14.2; Fe, 9.4%.

The $[FeNx_3(BC_6H_5) \cdot Al(OH)]$ complex was also obtained from the above-mentioned immobilized complex by basic decomposition with NaOH and $((n\text{-}C_4H_9)_4N)OH$ followed by extraction with a benzene–THF (1:2) mixture. The resulted solution was precipitated with heptane and reprecipitated from a THF–diethyl ether (1:3) mixture with heptane and dried *in vacuo*.

The $FeNx_3(BC_6H_5)(BF)$ complex can also be obtained from $FeNx_3(BC_6H_5)_2$. This compound (2 g, 3 mmol) and triethyloxonium fluoroborate (1.84 g, 10 mmol) were suspended/dissolved in 15 ml of methylene dichloride and stirred for 50 h at room temperature. The reaction mixture was washed with aqueous $NaHCO_3$, monoethanolamine, water, dried with K_2CO_3, evaporated to ~10 ml and precipitated with heptane. The solid was separated by chromatography on Silasorb C-300 (eluent: chloroform–*iso*-propanol (100:1)) and the products were isolated ($FeNx_3(BC_6H_5)_2$: 0.3 g, $FeNx_3(BC_6H_5)(BF)$: 0.25 g, $FeNx_3(BF)_2$: 0.23 g).

$FeDm_3(BC_6H_5)(BF)$ This complex was synthesized like the previous one except H_2Dm (7.0 g, 60 mmol) was used instead of nioxime; yield 0.12 g, 5%. Found: C, 42.0; H, 4.3; N, 16.2; Fe, 10.7. Calc. for $C_{18}H_{23}N_6O_6B_2FFe$: C, 41.9; H, 4.5; N, 16.3; Fe, 10.8%.

$FeBd_3(BF)(B\text{n-}C_4H_9)$ The starting $Fe(HBd)_2(H_2Bd)$ complex was obtained by reflux of suspension/solution of $FePy_4Cl_2$ (8.86 g, 20 mmol) and H_2Bd (14.4 g, 60 mmol) in 120 ml ethanol. The reaction mixture was filtered and water (400 ml) was added to the filtrate. After precipitation the solid was filtered, washed with water and aqueous ethanol (20%) and dried *in vacuo*; yield 10.5 g, 70%.

Immobilized semiclathrochelate $FeBd_3(Bn\text{-}C_4H_9) \cdot (AlO(OH))n$ was obtained using AlO(OH) sorbent, prepared as described above.

[Fe(HBd)(H_2Bd)] complex (5.0 g, 6.5 mmol) and the above-mentioned sorbent (10 g) were stirred for 30 min in acetonitrile (100 ml) at 40°C and a solution of *n*-butylboronic acid (0.92 g, 10 mmol) in acetonitrile (25 ml) was added dropwise. The reaction mixture was stirred for 4 h at 50°C, filtered and the solid was treated as described for $FeNx_3(BC_6H_5) \cdot (AlO(OH))n$; yield 13.4 g.

The obtained product (2.5 g) was suspended in chloroform (25 ml) and a solution of $BF_3 \cdot O(C_2H_5)_2$ (5 ml) in acetonitrile (5 ml) was added. The reaction mixture was stirred for 20 min, filtered and the solid was washed with chloroform. The filtrate was added to the first one and the solution was washed with aqueous Na_2CO_3, water, dried with $CaCl_2$, evaporated to ~2 ml and precipitated with heptane. The solid was reprecipitated from chloroform with heptane and dried *in vacuo*; yield 0.37 g, 39%. Found: C, 60.5; H, 4.8; N, 10.4; Fe, 6.8. Calc. for $C_{40}H_{39}N_6O_6B_2FFe$: C, 60.4; H, 4.9; N, 10.6; Fe, 7.0%.

$((n\text{-}C_4H_9)_4N)[FeNx_3(BC_6H_5)(SnCl_3)]$ The solution of $[Fe(H_2Nx)_3]Cl_2$ (4.5 g, 8 mmol), nioxime (0.9 g, 6 mmol) and aluminium oxide (neitral, Brockman I, 45 g) in acetonitrile (150 ml) was stirred for 10 h and filtered. The solid was washed with acetonitrile and dried *in vacuo*. Reflux of the obtained product with phenylboronic acid (3.7 g, 30 mmol) and nioxime (0.4 g, 3 mmol) in benzene (200 ml) for 3 h resulted in a solid, which was filtered, washed with benzene (100 ml), chloroform (300 ml) and acetonitrile (250 ml) and dried *in vacuo*; yield 50 g.

The solid was suspended in an acetonitrile–chloroform (1:1) mixture (300 ml) and a solution of $SnCl_4$ (10 ml, 8.6 mmol) in chloroform (50 ml) was added dropwise under vigorous stirring. After a reaction time of 15 min at room temperature the solution was filtered, washed at 0°C with $((n\text{-}C_4H_9)_4N)Cl$ aqueous solution (10%, 50 ml, two times) and water (100 ml, two times) and dried with anhydrous $MgSO_4$. The mixture of solid $((n\text{-}C_4H_9)_4N)_2[FeNx_3(SnCl_3)_2]$ and $((n\text{-}C_4H_9)_4N)[FeNx_3(BC_6H_5)(SnCl_3)]$ complexes was obtained by precipitation from chloroform extract with heptane.

The precipitate was dissolved in THF and the former complex was precipitated with a two-fold volume of diethyl ether. The filtrate, containing the latter one, was treated with a five-fold volume of pentane. The obtained solid product was reprecipitated, washed with a small amount of diethyl ether, pentane and dried *in vacuo*; yield 0.8 g, 10%. Found: C, 46.8; H, 6.2; N, 9.5; Fe, 5.4; Sn, 11.7. Calc. for $C_{40}H_{65}N_7O_6BCl_3FeSn$: C, 46.5; H, 6.3; N, 9.5; Fe, 5.4; Sn, 11.5%.

RESULTS AND DISCUSSION

Meridianal-asymmetrical iron(II) clathrochelates were obtained by the cycloaddition of α-dioximes (H_2D) to preliminarily synthesized planar-square macrocyclic iron(II) bis-dioximates by the following reaction:

$$[FeD_2(BF_2)_2(CH_3CN)_2] + H_2D' \rightarrow FeD_2D'(BF)_2 + 2HF.$$

It is obvious that this reaction is favored by binding the HF acid released during its course, i.e., in the presence of H^+ and F^- ion acceptors. A weakly coordinating sterically hindered *N,N*-diisopropylethyl amine and boron trifluoride etherate were used as H^+ ion acceptor and electrophilic agent to remove F^-

ions, respectively. In addition, $BF_3 \cdot O(C_2H_5)_2$ has prevented the side elimination reactions of capping boronfluoride groups (Scheme 1).

The above reaction proceeds under more rigid conditions and takes more time than a direct template condensation on the iron(II) ion that can be accounted for by the fact that the overall mechanism of clathrochelate synthesis involves, as mentioned above, an intermediate tris-complex formation step [8–12]. It is evident that macrocyclic planar-square iron(II) bis-dioximates are relatively kinetically stable, and the addition of a third dioxime molecule involves not only detachment of an axially coordinated solvate ligand, but also considerable rearrangements in the nearest coordination environment, which is, naturally, accompanied by an appreciable consumption of energy.

In the absence of F^- ion acceptors, a clathrochelate is not formed and the reaction completes at a stage of *cis*-addition of the protonated dioxime to a planar-square macrocycle. In the absence of the base B with certain dioximes (H_2Nx and H_2Dm), the reaction yields a mixture of symmetrical clathrochelates. In other cases, only a mixture of decomposition products has been formed.

A direct synthesis of axial-asymmetrical tris-dioximate iron(II) clathrochelates via the formation of semiclathrochelate complexes of type II, without application of protecting groups, could not be realized even in a great excess of complex I since a compound of type II readily disproportionates to give I and III (Scheme 2).

We have managed to obtain an axial-asymmetrical $FeNx_3(BC_6H_5)(BF)$ complex, along with the symmetrical products, via a "re-boronating" reaction from the preliminarily formed $FeNx_3(BC_6H_5)_2$ attacked by triethyloxonium fluoroborate, the complex was isolated using chromatography (Scheme 3).

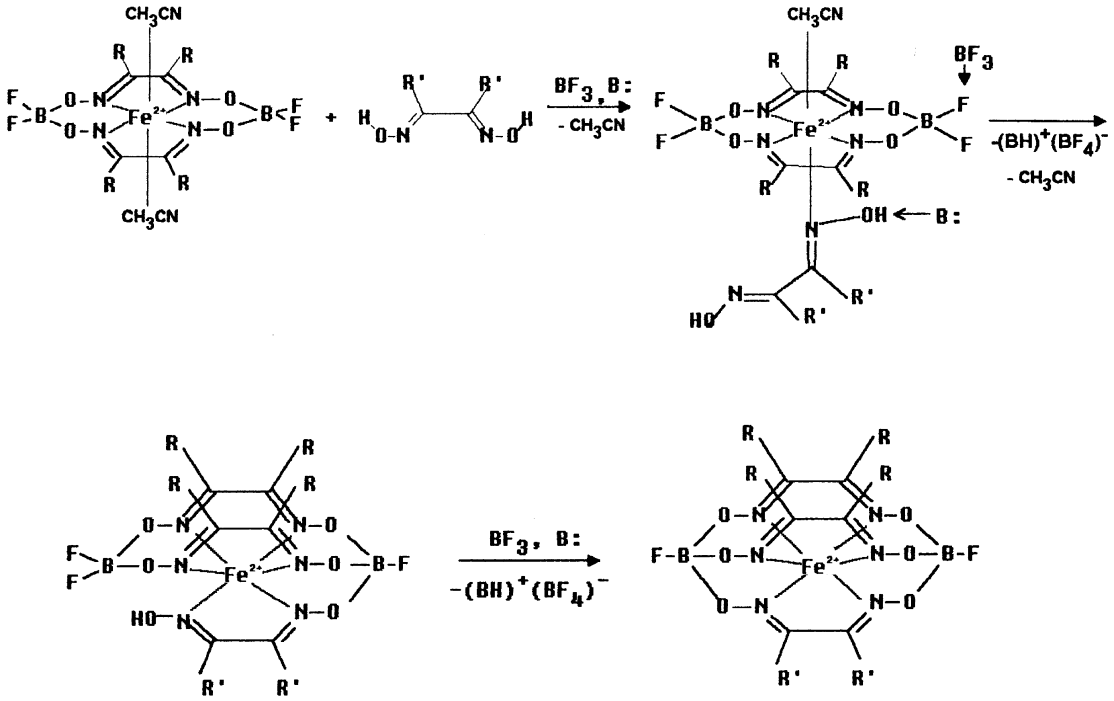
This, however, cannot be a general method. Our attempts to prepare the $FeDm_3(BC_6H_5)(BF)$ complex by an analogous scheme have not been successful: only a symmetrical $FeDm_3(BF)_2$ complex has been formed.

The synthesis of axial-asymmetrical clathrochelate iron(II) dioximates were realized through a stepwise "assembling" on the sorbent surface (Scheme 4).

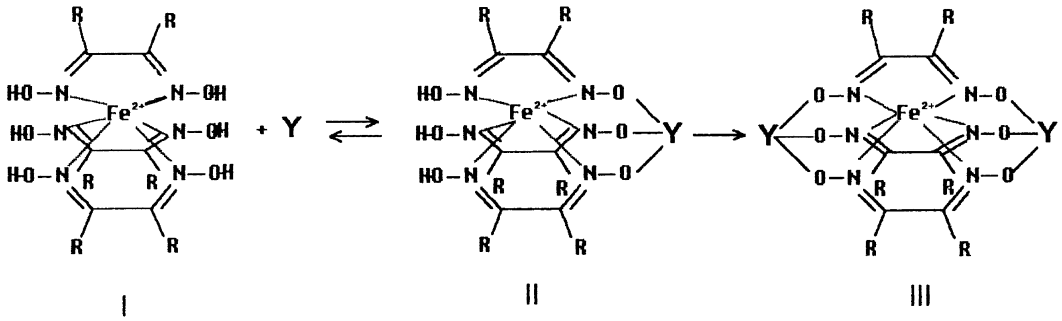
A chemical immobilization of a nonmacrocyclic tris-complex on the matrix surface has enabled us to protect one of its two triangular planes formed by oxime groups (Ia) and to obtain the immobilized semiclathrochelates via capping by Lewis acids. The desorption of these semiclathrochelates (IIa) with the help of another capping agent leads to the formation of asymmetrical clathrochelate (IIIa).

The success of the synthesis carried out by this procedure is governed by a sorbent aptitude for a specific binding of the starting tris-complex (Ia) and the subsequent desorption of a semiclathrochelate (IIa) affected by a capping agents.

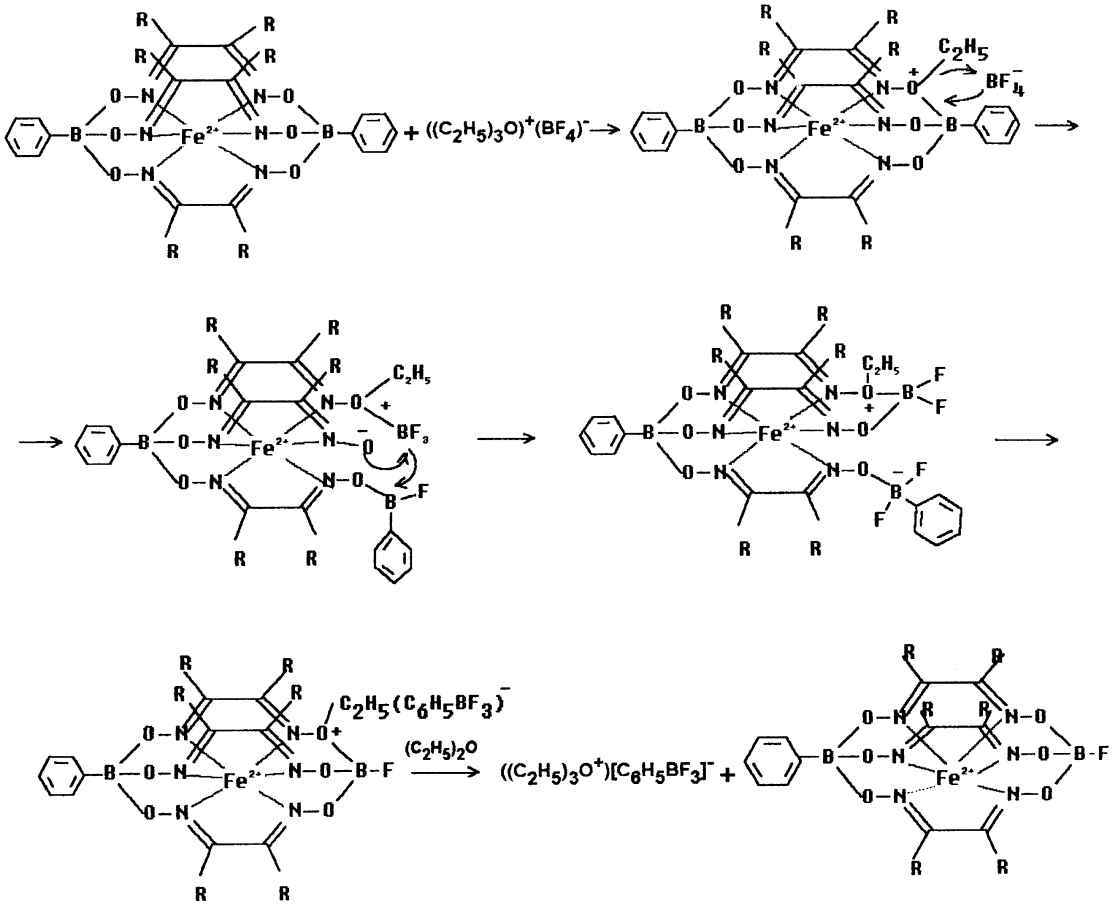
We have examined more than ten sorbents based on aluminium, titanium, silicon oxides and hydroxides. Different sorbents, based on silicon dioxide, adsorb nonmacrocyclic iron(II) tris-dioximates yielding complexes of type Ia which, after the first capping, are



Scheme 1.



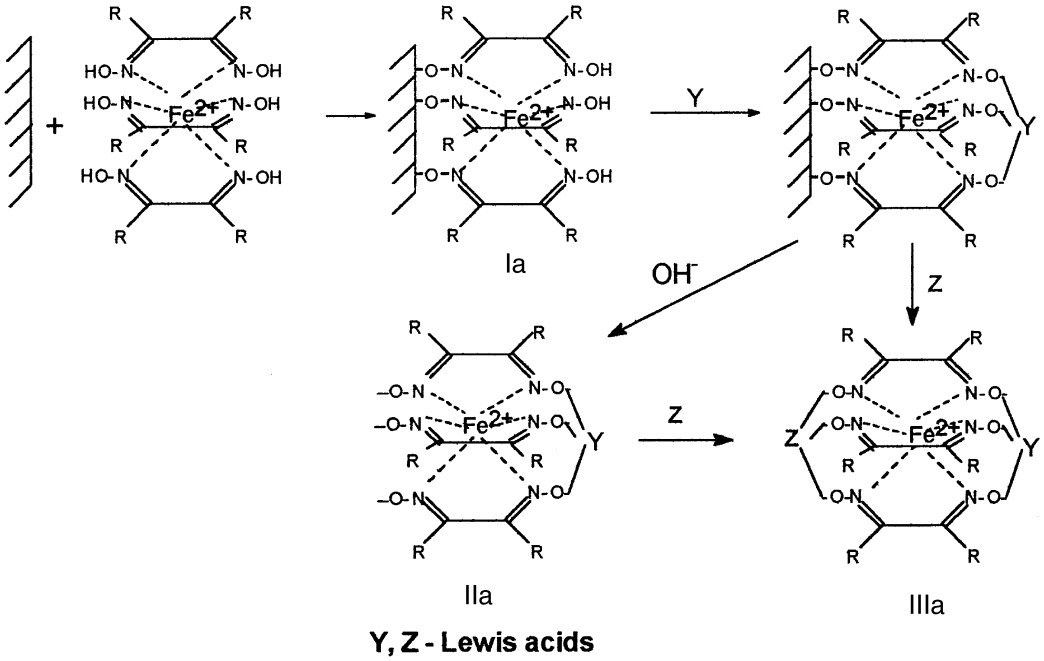
Scheme 2.



Scheme 3.

desorbed by $BF_3 \cdot O(C_2H_5)_2$ to give clathrochelates of type IIIa. However, they display a low sorbtion capacity towards Ia. With silicon(IV) hydroxide, obtained by hydrolysis of silicon(IV) tetraethoxyde, no compounds of type IIa have been formed. The titanium(IV) hydroxide resulted from hydrolysis of titanium(IV) tetrabutoxyde exhibits a very high sorption capacity towards Ia. The latter is, however, apt to desorption to give IIIa, when treated with capping agents.

Aluminium(III) oxides show results depending, to a great extent, on the method of sorbents formation and treatment. As a whole, however, the degrees of both desorption and purity of the formed product IIIa



Scheme 4.

are low. The aluminium(III) hydroxide resulted from corrosion of amalgamated aluminium does not tend to the formation of complexes of type IIa.

The best results were obtained with aluminium hydroxide resulted from hydrolysis of aluminium(III) *iso*-propylate. A high sorption capacity (*ca.* 10%) of compounds Ia, a high degree of desorption of complexes IIa and the purity of clathrochelates IIIa formed make aluminium(III) hydroxide the most suitable agent for the synthesis of targeted compounds.

A hydrolytic decomposition of the immobilized nioximate $FeNx_3(BC_6H_5)\cdot(AlO(OH))n$ semi-clathrochelate by a mixture of aqueous NaOH and $((n\text{-}C_4H_9)_4N)OH$ solutions enables one to isolate the product having a hypothetical composition as $[FeNx_3(BC_6H_5)\cdot(AlOH)]$ detectable in FAB mass spectrum, and to obtain clathrochelates quantitatively by reactions with Lewis acids. Unfortunately, we failed to isolate and characterize this product as a pure one with no admixtures because it readily disproportionates and oxidizes.

For all synthesized compounds (except the mixed borontin-containing one) the most intensive $[M+H^+]^+$ molecular ions were detected in FAB mass spectra.

The main spectral parameters of the synthesized clathrochelates are typical for clathrochelate iron(II) tris-dioximates [4, 5]. The isomer shift (IS) values in ^{57}Fe Mossbauer spectra (Table 1), which is determinated by the s-electron density on the iron nucleus, are characteristic for low-spin iron(II) complexes and markedly lower than those for analogous non-macrocyclic tris-dioximates. This phenomenon reflects a so-called "macrocyclic" effect of ligand field increase upon formation of a clathrochelate structure [4].

A quadrupole splitting (QS) in the ^{57}Fe Mossbauer spectra, which characterize the electric field gradient on the iron nucleus, characterizes a twist angle φ of a coordination polyhedron intermediate between a trigonal prism (TP, $\varphi = 0^\circ$, QS $\sim +1$ mm/s) and a trigonal antiprism (TAP, $\varphi = 60^\circ$, QS ~ -0.3 mm/s). The φ value for each complex may be predicted with the help of a correlation curve "QS vs φ" proposed in [4] or calculated from a new version of the partial quadrupole splitting concept [16].

In the clathrochelate ligand field, binding t_{2g}-level of iron(II) with an electronic d^6 configuration splits into e_1 and a_1 levels. In case of TP geometry, the energy of the e_1 level is higher than that of a_1 and the QS sign is positive. For TAP geometry, e_1 is lower in energy than a_1 and the QS sign is negative. The inversion of these levels takes place at $\varphi \approx 30^\circ$. All boron-containing macrobicyclic tris-dioximates of known structure have a TP geometry [16] and, hence, a positive QS value. There are good reasons to believe that the QS in the synthesized boron-containing complexes has also a positive sign. This fact is confirmed by an appreciable QS absolute value in the majority of the synthesized compounds and allows one to predict the φ values listed in Table 1. The QS values for meridianal-asymmetrical clathrochelates are intermediate between those for the corresponding symmetrical complexes of the known structure.

The introduction of some "new" dioximate frag-

ments into the clathrochelate cage, as a rule, exerts much more on the QS and φ values than in the case when a second such fragment is introduced. The above statements are clearly shown for α-benzydioxime in Table 2.

A similar phenomenon was observed upon introduction of glyoximate and nioximate fragments into the clathrochelate framework instead of α-benzyldioximate and dimethylglyoximate ones.

For axial-asymmetrical complexes, just like for symmetrical boron-containing iron(II) tris-dioximates [4, 16], distinct dependencies of QS and φ values on the nature of a substituent at the boron atom have been obtained.* The QS value in a mixed borontin-containing clathrochelate is equal to zero which is in agreement with the above statements too: the QS value in the corresponding trigonal-prismatic boron-containing $FeNx_3(BC_6H_5)_2$ complex has a positive sign, while the corresponding trigonal-antiprismatic tin-containing clathrochelate, according to the data reported in [5, 18], is characterized by a negative QS value. A superposition of these two contributions gives a twist angle φ close to 30° and, hence, the QS value is zero.

The UV–VIS spectra for synthesized meridianal-asymmetrical compounds in solution indicate a more complex chromophore system than that of symmetrical clathrochelates, while the spectra for boron-containing axial-asymmetrical compounds closely resemble those of the corresponding symmetrical compounds. It should be noted that the UV–VIS spectra for the latter with the same dioxime and different boron-containing capping fragments are practically identical [4, 17]. The spectrum for a mixed borontin-containing $((n\text{-}C_4H_9)_4N)[FeNx_3(BC_6H_5)(SnCl_3)]$ clathrochelate alone essentially differs from that for the $FeNx_3(BC_6H_5)_2$ complex: apart from a singlet band about 460 nm characteristic for boron-containing compounds, a more intense band appears about 500 nm detectable in the UV–VIS spectrum for a tin-chloride tris-dioximate $[FeNx_3(SnCl_3)_2]^{2-}$ dianion. The intensities of these bands are redistributed (Table 3).

An analogous phenomenon was also observed in the spectra of some meridianal-asymmetrical clathrochelates ($FeDm_2Bd(BF)_2$, $FeBd_2Dm_3(BF)_2$ and $FeBd_2Nx_2(BF)_2$). The intense $Md \rightarrow L\pi^*$ charge transfer band in the UV–VIS spectra of these compounds proved to be a superposition of two bands with maxima slightly shifted to the long-wavelength range as compared to the corresponding symmetrical complexes ($(FeDm_3(BF)_2$, $FeBd_3(BF)_2$ and $FeNx_3(BF)_2$), but at an unusual and unexpected ratio of the intensities of these bands takes place.

The UV–VIS spectrum for the $FeBd_2Gm(BF)_2$ complex proved also to be quite unexpected since it contains only one band with the intermediate value of $\lambda_{max} = 464$ nm, rather than two bands at approximately 440 and 480 nm. With this complex, maximal tension in π-systems of different dioxime fragments is presumably observed. Since UV–VIS spectral characteristics of $FeDm_3(BF)_2$ and $FeGm_3(BF)_2$ complexes are identical in the visible part, the charge transfer band in the spectrum for an asymmetrical $FeDm_2Gm(BF)_2$ clathrochelate is nearly the same as that for the first two complexes. In this case the band positions of intraligand π–π^* transitions differ from that for symmetrical compounds.

The asymmetry of the synthesized complexes manifests itself in their IR and NMR spectra (Tables 3 and 4). The C=N and N–O stretching vibrations in the dioxime fragments of meridianal-asymmetrical clathrochelates and in the mixed borontin-containing axial-asymmetrical complex proved to be the most sensitive ones. These vibrations may be assigned to the corresponding dioximate groups or their fragments bound to a certain type of an capping groups. In particular, the stretching vibrations of the C=N band in the spectrum of the $FeDm_2Gm(BF)_2$ complex are a superposition of two signals: one about 1560 cm^{-1}, which may be assigned to a glyoximate fragment (for the $FeGm_3(BF)_2$ clathrochelate, it is detected at 1559 cm^{-1}) and at 1583 cm^{-1}, which may be assigned to dimethylglyoximate fragments (for the $FeDm_3(BF)_2$ clathrochelate, it is detected at 1585 cm^{-1}). The same vibration in the IR spectrum

---

* After sending this paper to the Editor the structure of one axial-asymmetrical complex (Fig. 1) was solved [20]. Single crystals of the $FeBd_3(BF)(Bn\text{-}C_4H_9)\cdot C_6H_5CH_3\cdot\frac{1}{2}C_8H_{16}$ complex were obtained by slow evaporation of the saturated solution in a toluene–cyclooctane (1:3) mixture for several weeks. Due to the partial decay of the sample it turned out to be impossible to get a larger data set. Moreover one of the phenyl rings is disordered, the rest were refined in a "rigid-body" approximation. However, the structure is the first example of asymmetric clathrochelates and the data obtained allow to analyze the coordination environment of the central atom. $C_{57}H_{55}B_2FFeN_6O_6$, crystal size $0.36\times0.28\times0.22$ mm, $M = 1015.74$, triclinic, space group $P\bar{1}$, $a = 10.852(2)$, $b = 14.071(3)$, $c = 17.050(3)$ Å, $\alpha = 87.63(3)^\circ$, $\beta = 87.46(3)^\circ$, $\gamma = 80.20(3)^\circ$, $U = 2561.5(9)$ Å^3, $Z = 2$, $D_c = 1.112$ g cm^{-3}, $\mu = 0.345$ mm^{-1}, $F(000) = 1020.2892$ independent reflections were collected at 293 K on a CAD4 diffractometer using Mo-Kα radiation ($\lambda = 0.71073$ Å) with $\theta/2\theta$ scans ($1.86^\circ < \theta < 19.98^\circ$). The structure was solved by the heavy-atom method, refinement was made by a full-matrix least squares an F^2 for all data with anisotropic displacement parameters for non-hydrogen atoms and isotropic for hydrogen atoms; goodness-of-fit = 1.078, final R indices ($I > 2\sigma(I)$) $R1 = 0.0792$, $wR2 = 0.2114$, $w^{-1} = \sigma^2(F_o^2) + (0.152P)^2 + 16.974P$, $P = (F_o^2 + 2F_c^2)/3$. The main parameters of the iron(II) coordination polyhedron (Fe–N distance is 1.89 Å and N–Fe–N bite (chelate) angle is 39.5°) are characteristic for macrobicyclic iron(II) tris-dioximates. The smaller distortion angle value ($\varphi = 17.9^\circ$) than estimated from ^{57}Fe Mössbauer parameters (Table 1, for analogous $FeBd_3(BF)_2$ complex with similar QS value distortion angle significantly higher, $\varphi = 29.3^\circ$) accounted for the electron–donor effect of *n*-butyl substituent at boron atom rather than an electron-acceptor effect of the fluorine substituent.

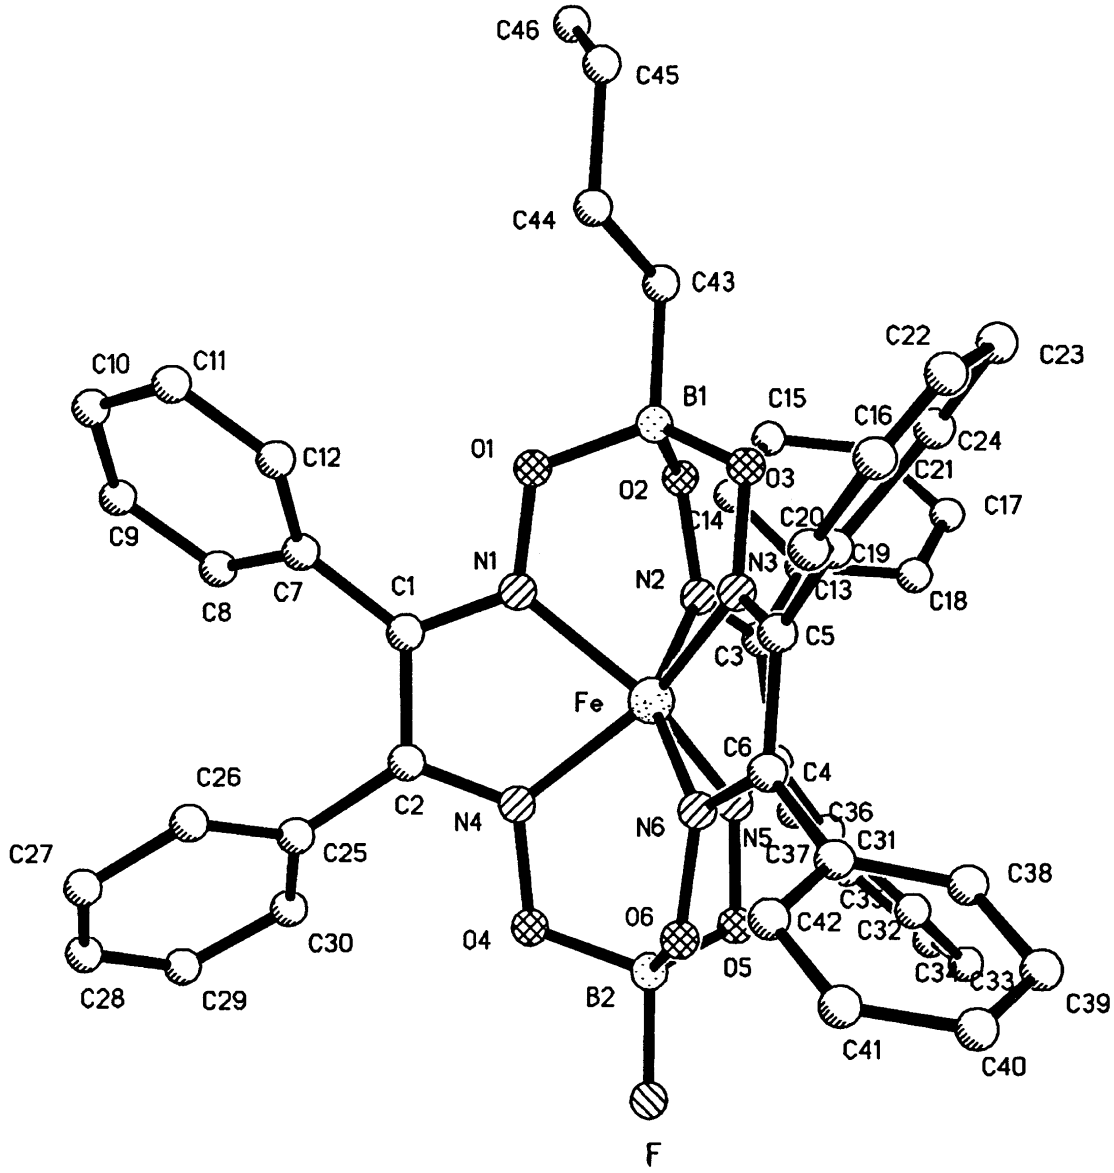


Fig. 1. Molecular structure of the $FeBd_3(BF)(Bn\text{-}C_4H_9)$ complex. Hydrogen atoms are omitted and one of the two disordered phenyl groups C(19)–C(24) are shown.

Table 2.

tin- and boron-containing capping fragments, respectively. The IR spectrum obtained for the later clathrochelate also clearly shows intense characteristic bands of stretching vibrations for both capping fragments (ν(B–O) at approximately 1200 and ν(Sn–Cl) at approximately 320 cm^{-1} [4, 5]). It should also be stressed that for a distorted TAP α-benzyldioximate $FeBd_3(BF)_2$, the ν(B–O) bands have been observed at a higher frequency (1212 cm^{-1}) than for its meridianal-asymmetrical derivatives (for $FeBd_2Dm(BF)_2$ and $FeDm_2Bd(BF)_2$ complexes ν(B–O) = 1197 and 1196 cm^{-1}, respectively) with a geometry close to TP (see above). For the trigonal-prismatic $FeDm_3(BF)_2$ complex this band was detected at 1194 cm^{-1} [4].

The use of the polynuclear NMR spectroscopy has allowed us to confirm the composition of the asymmetrical clathrochelates obtained with the help of the integral intensity ratios of the signals in the ^1H NMR spectra for the protons in the dioxime fragments, substituents at the boron atom and the tetrabutylammonium cation (for the mixed borontin-containing compound). The spectrum for the axial-asymmetrical $FeDm_3(BC_6H_5)(BF)$ dimethylglyoximate also reveals the nonequivalence of methyl substituents. The nonequivalence of dioximate ring fragments in axial-asymmetrical clathrochelates is still more pronounced in the $^{13}C\{^1H\}$ NMR spectra (Table 4). The ^{11}B NMR spectra for these complexes (except for the mixed borontin-containing clathrochelate) reveal signals for the both caps: a broadened singlet of alkyl- or arylborate and a doublet of boronfluoride tetrahedral (judging from the $\delta^{11}B$ value) fragments. The value of a spin–spin coupling constant ($J^{11}B$–^{19}F is approximately 15 Hz) indicates a high symmetry for the BO_3F fragment. The same symmetry of capping boronfluoride fragments was detected in meridianal-asymmetrical clathrochelates (Table 4). In the ^{119}Sn NMR spectrum for the mixed compound in solution, an octahedral SnO_3CI_3 fragment manifests itself as a singlet ($\delta^{119}Sn = -660$ ppm) which is slightly different from the chemical shift value in the case of a symmetrical $[FeNx_3(SnCl_3)_2]^{2-}$ dianion ($\delta^{119}Sn = -640$ ppm).

The above mentioned nonadditivity effect of the introduction of α-benzyldioximate fragments instead of dimethyldioximate ones in the series of ^1H NMR spectral characteristics of meridianal-asymmetrical complexes with α-benzyldioxime and dimethylglyoxime was clearly observed: the introduction of the first fragment increases chemical shifts in the methyl protons by approximately 0.2 ppm, while the appearance of the second diphenyl chelate ring only by 0.06 ppm (Table 4).

The cyclic voltammograms of synthesized iron(II) clathrochelates demonstrate the quasi-reversible waves assigned to Fe^{2+}/Fe^{3+} couple in the anodic range [22]. The position and shape of the waves do not practically depend on the scan rate within the

interval of 5–100 mV s^{-1} but depend on the substituents in the ligand dioxime fragments and capping groups. Table 5 lists the half-wave oxidation potentials for meridianal-asymmetrical mixed dimethylglyoximate–α-benzyldioximate complexes. A decrease in the electron-donating effect of phenyl groups as compared to methyl groups must lead to the reduction in electron density on the iron atom and shift the oxidation potential to the anode range. As can be seen from Table 5, the observed shifts in the oxidation potential really decrease with increasing the number of α-benzyldioximate fragments in the complex, but there appears a nonadditivity of shifts, which correlates with the ^{57}Fe Mössbauer, UV–VIS and NMR spectroscopic evidences indicating the major changes in the complex structure upon introduction of the first α-benzyldioximate fragment.

Table 5 also represents the results of a cyclic voltammetric study of axial-asymmetrical clathrochelates. In this case, a certain rise in $E_{1/2}$ potential was observed with increasing the inductive Taft constant (δ_I) [23] of the substituent at the boron atom in the n-C_4H_9 (−0.06) < C_6H_5 (0.10) < F (0.52) series.

Tin-containing compounds are also worth to be considered: an appreciable effect of negatively charged SnO_3Cl_3 fragments is evident, though it was not determined experimentally. In this case the appearance of the first substituent with +I-effect has a far greater influence on the magnitude of $E_{1/2}$ than the introduction of the second one (Table 5; for nioxime: $(BC_6H_5)_2 \rightarrow (BC_6H_5)(BF)$ (+0.075 V) $\rightarrow (BF)_2$ (+0.035 V); $(SnCl_3)_2 \rightarrow (SnCl_3)(BC_6H_5)$ (+0.145 V) $\rightarrow (BC_6H_5)_2$ (+0.250 V); for α-benzyldioxime: $(Bn\text{-}C_4H_9)_2 \rightarrow (Bn\text{-}C_4H_9)(BF)$ (+0.080 V) $\rightarrow (BF)_2$ (+0.060 V)).

In the case of meridianal-asymmetrical complexes the nonadditivity of the shifts in the iron oxidation potentials has also been observed in passing from

dimethylglyoximates to α-benzyldioximates $Dm_3 \rightarrow Dm_2Bd$ (+0.065 V)→$DmBd_2$ (+0.050 V)→Bd_3 (+0.040 V).*

(Received 11 March 1998; accepted 7 May 1998)

Abstract—Six kinds of benzo-15-crown-5 (L) adducts having the stoichiometric formula $M(Pic)_2 \cdot L \cdot xH_2O$ (M = Mn, Cu, $x = 2$; M = Co, Ni, Zn, Cd, $x = 4$; Pic means picrate anion) have been synthesized and characterized by EA, IR, UV and molar conductance. The X-ray crystal structural analysis of the benzo-15-crown-5 adduct with hydrated copper(II) picrate revealed that the benzo-15-crown-5 molecule virtually acts as a second-sphere ligand, which associates with the copper(II) ion by hydrogen bonding of the coordinating water molecule. By the comparison of the IR, UV spectra and molar conductance of the new adducts prepared, it can be deduced that the other adducts exhibit the similar coordination environment to that of the copper adduct. © 1998 Elsevier Science Ltd. Keywords: copper(II); picrate; crown ether; X-ray; hydrogen bond; crystal structure.

INTRODUCTION

In the process of the chemical extraction of metal ions with crown ether species, picrate is usually used as a hydrophobic counter-anion to carry the host–guest complexes into the organic phase. The extraction mechanism is closely related to the interaction pattern of the picrate complexes of the metal ions with crown ethers. The establishment of the crystal and molecular structures of these complexes indicated that the alkali and alkaline earth metal ions coordinate directly with the crown ether molecules. Nakagawa et al. demonstrated that the solvent extract abilities of aqueous lanthanide picrates with common crown ethers, such as 15-crown-5, 18-crown-6 and their benzo or cyclohexano derivatives, are much lower than those of aqueous alkali- and alkaline-earth–metal picraes, in spite of the apparent matching of the host cavity size and the diameter of the naked lanthanide cation. The low extract abilities are attributed to incomplete dehydration of trivalent lanthanide ions upon extraction [1, 2, 3]. Recently, in the course of our study on the extraction mechanism of hydrated lanthanide picrates with benzo-15-crown-5 (B15C5), a new series of crystalline extracted complexes of hydrated lanthanide picrates with B15C5 have been obtained. X-ray crystal structural analysis revealed that the B15C5 molecules do not coordinate directly with lanthanide ions, but act as a second-sphere ligand which is associated with lanthanide picrates by hydrogen bonding of coordinating water molecules [4, 5, 6]. These interesting results motivated us to extend our study of the second-sphere coordination of metal crown ether chemistry. In the present paper, we report the synthesis and the characterization of the B15C5 adducts with hydrated transition metal (Mn, Co, Ni, Cu, Zn and Cd) picrates and the crystal structure of the B15C5 adduct with hydrated copper(II) picrate.

EXPERIMENTAL

Reagents

All the chemicals used were of reagent grade. B15C5 was recrystallized from *n*-heptane (m.p 79–80°C). Hydrated transition metal (M = Mn, Co, Ni, Cu, Zn and Cd) picrates were prepared by the reaction of picric acid and the corresponding metal carbonates in good yields. Their general formula was determined to be $M(Pic)_2 \cdot 6H_2O$ by elemental analysis.

*Author to whom correspondence should be addressed.

Chemical and physical measurements

Melting points were measured on a WC-1 apparatus and are uncorrected. Transition metal ion contents were determined by EDTA complexometric titration method. Microanalyses (C, H and N) of the adducts were carried out on a Carlo-Erba 1106 elemental analyzer. The IR spectra were recorded on a Shimadzu 435 spectrometer in KBr pellets. UV–VIS spectra were measured with a Shimadzu UV-2100 spectrometer. Conductivity measurements were performed with a DDS-11A conductometer with acetone as solvent at 25°C.

General procedure for the preparation of the adducts

The adducts were prepared by dissolving a 1:2 molar ratio of hydrated metal picrate and B15C5 in a 2:2:1 (v/v/v) mixed solvent of MeCN, EtOH and H_2O, and the resulting solutions were filtered and allowed to stand over several days until the crystalline products of the adducts were separated. A green single crystal of copper(II) adduct suitable for X-ray structural analysis was obtained by recrystallization using the same mixed solvent.

X-ray crystal structure determination of Cu adduct

All measurements were made on a Rigaku AFC7R diffractometer with graphite monochromated MoKα radiation and a 12 kW rotating anode generator. Cell constants and orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 19 carefully centered reflections in the range of $23.23 < 2\theta < 26.73°$. The data were corrected for Lorentz and polarization effects and empirical absorption.

The structure was solved by direct methods and expanded using Fourier techniques. The nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. All calculations were performed on a Micro VAX3100 computer using teXsan crystallographic software package of Molecular Structure Corporation (1985 and 1992). Neutral atom scattering factors were taken from Cromer and Waber. Atomic coordinates and anisotropic temperature factors for all nonhydrogen atoms were refined by full-matrix least-squares.

The crystallographic data and refinement parameters are listed in Table 1. The selected bond distances and angles are given in Table 2

RESULTS AND DISCUSSION

The elemental analysis data as shown in Table 3 indicate that all the adducts prepared have a 1:1 metal picrate–ligand stoichiometry with two or four water molecules, although a mixture of the hydrated transition metal picrate and ligand in a molar ratio of 1:2 was used.

All the adducts possess similar IR spectra, indicating that they have similar coordination pattern. The IR spectra of the adducts revealed that the molecular symmetric vibration absorption of the ligand at *ca.* 980 cm^{-1} disappears and that the ν_{AR-O-C} absorption at 1250 cm^{-1} does not undergo any changes in the adducts. The intensity of the $\nu_{as(C-O-C)}$ absorption at 1120 cm^{-1} for the adducts decreases obviously in comparison with that of the free ligand. These results implied that some interaction between hydrated transition metal picrates and aliphatic ether oxygen atoms rather than the phenolic ether oxygen atoms occurs in the adducts. This conclusion will be further confirmed by the X-ray crystal structure analysis of the copper(II) adduct. The strong absorption bands at 3200–3500 cm^{-1} in the adducts show the presence of the water molecules, which is consistent with that of microanalysis.

The measurements of the UV–VIS spectra of the adducts show that all the adducts possess the similar absorption pattern. The absorption for the picrate anion at 320–330 nm does not show much difference before and after the formation of the adducts. This implies that the coordination pattern of the hydrated transition metal picrates does not undergo a pronounced conformational change after the adducts were formed and as a result the central transition

Table 2. Selected bond lengths and angles for the Cu adduct (estimated standard deviations in parentheses)

$Cd(Pic)_2 \cdot L \cdot 4H_2O$	65	122–124	34.40 (34.34)	3.51 (3.52)	9.31 (9.25)	12.03 (12.37)	33.43 (36.01)

[a]Pic is picrate anion, L is benzo-15-crown-5.

[b]Measured in 10^{-3}M acetone solutions at 25°C; the conductivity values of corresponding hydrated transition metal picrates are shown in parentheses.

metal ions may not take part in the direct interaction with the oxygen atoms of crown ether.

The molar conductivity values (as shown in Table 3) for these adducts in acetone are in the range of 15.3–35.2 $\Omega^{-1}\,cm^2\,mol^{-1}$, which is the indication of nonelectrolytes for the adducts [7]. Therefore, the transition metal ions in the adducts do not coordinate with the B15C5 molecule directly and no free picrate anion was released, which further supports the results obtained by UV–VIS spectral measurements.

The molecular structure of the Cu adduct is shown in Fig. 1. The adduct consists of two parts, $Cu(Pic)_2 \cdot 2H_2O$ and B15C5. In the former part, two phenolic oxygen atoms (O6 and O7) in picrate anions and two oxygen atoms (O8 and O9) in water molecules coordinate with central Cu cation, and as result, the coordination number for Cu(II) is 4. The bond lengths for Cu–O6, Cu–O7, Cu–O8 and Cu–O9 are 1.941(2), 1.916(2), 1.948(2) and 1.937(2) Å, respectively. The bond angles of 91.13(8), 94.13(8), 94.04(8) and 87.40(8)° for O6–Cu–O8, O8–Cu–O7, O7–Cu–O9 and O9–Cu–O6, respectively, are near to 90° and the bond angles of 159.84(8) and 160.11(9)° for O6–Cu–O7 and O8–Cu–O9 are less than 180°. Therefore, the coordination about the Cu atom can be considered as a distorted square planar. It is obvious that the latter part, B15C5, does not take part in the coordination with the Cu cation directly. However, it was included in the adduct by hydrogen bonding between one of the coordinating water molecules and two aliphabic ether oxygen atoms (O1 and O4). Two phenolic oxygen atoms in B15C5 do not participate in the formation of hydrogen bond, which is consistent with the result obtained by IR determination. The distance for O1–H22 and O4–H21 are 1.921 and 1.759 Å, respectively, which is the indication of the formation of typical hydrogen bonds [8]. Therefore, the water molecule in the adduct virtually acts as a bridge to associate the copper(II) picrate with B15C5 molecule through hydrogen bonding. This kind of inclusion phenomenon of B15C5 is similar to the results of our previous studies on the complexation of hydrated lanthanide picrates with B15C5 [4, 5, 6]. However, it is completely different from the complexation patterns

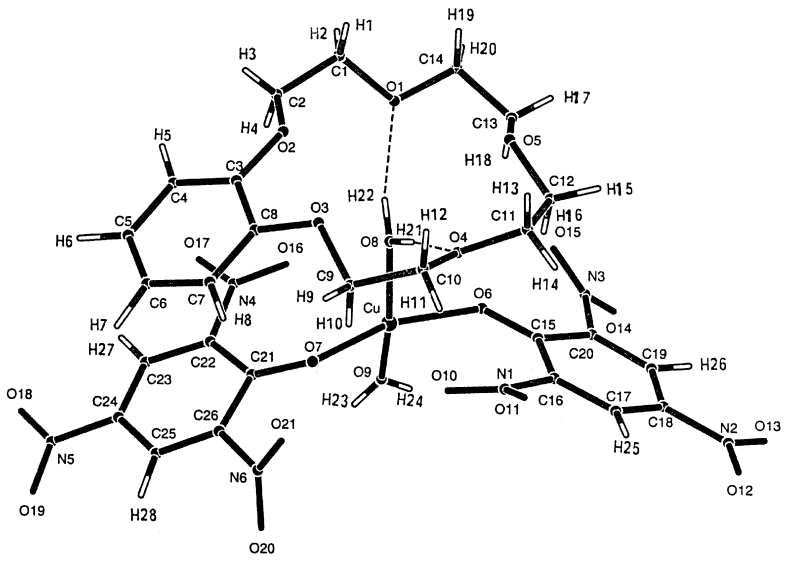

Fig. 1. Molecular structure of $Cu(Pic)_2 \cdot B15C15 \cdot 2H_2O$.

of $CuCl_2$ and hydrated $Cu(ClO_4)_2 \cdot 6H_2O$ with B15C5, where copper(II) cation was included in the cavity of the B15C5 by direct coordination of crown ether oxygen atoms with Cu(II) ion [9, 10].

On the basis of the crystal structure analysis of the copper adduct and the investigation of IR, UV–VIS spectra and molar conductance of the title adducts, it can be concluded that the coordination ability of the water molecules and picrate anion with transition metal ions are stronger than that of B15C5 molecule, and as a result the hydrated transition metal picrate rather than the transition metal crown ether cationic complex is formed predominately. Due in part to the steric hindrance of the bulky picrate anion and coordinating water molecules around the transition metal ion, the cavity of B15C5 molecule can not accommodate the copper(II) or other transition metal ions directly, although the cavity size of the B15C5 molecule is close to the size of these transition metal ions [9, 10]. Consequently, the B15C5 molecule adopts a special association mode in order to combine with them, i.e. the B15C5 molecule virtually acts as a second-sphere ligand which associates with the hydrated transition metal picrates by hydrogen bonding of coordinating water molecule.

Study of kinetics and mechanism of the acid dissociation of copper(II) complex of novel C-functionalized macrocyclic dioxotetraamines[1]

Huakuan Lin*, Shourong Zhu, Appolin Bave Kondiano, Xuncheng Su, Fuping Kou and Yunti Chen

Department of Chemistry, Nankai University, Tianjin, 300071, People's Republic of China

(Received 25 August 1997; accepted 14 May 1998)

Abstract—The kinetics of the acid dissociation of copper(II) complexes of novel C-functionalized macrocyclic dioxotetraamines has been studied by means of a stopped-flow spectrophotometer. The acid dissociation rate follows the law $V_d = C_{com}kK_1K_2H^2/(1+K_1H+K_1K_2H^2)$. From the experimental facts we have obtained, the dissociation kinetics are interpreted by a mechanism involving the negatively charged carbonyl oxygen of the complex being rapidly protonated in a pre-equilibrium step, the rate-determining step being intramolecular hydrogen (enolic tautomer) migration (to imine nitrogen). The dissociation rate reached a plateau in the strongly acidic solution. By means of temperature coefficient method, ΔH^{ϕ}, ΔS^{ϕ} of the pre-equilibrium step and $\Delta H^{\neq}$, $\Delta S^{\neq}$ of the rate-determining step were obtained. The results of 13-membered macrocyclic dioxotetraamines have been discussed. The influence of the substituents to the acid dissociation rates has also been discussed. The Bronsted type linear free energy relationships do also exist in these C-functionalized dioxotetraamine copper(II) complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocyclic dioxotetraamines; acid dissociation; kinetics; mechanism; copper(II) complex.

INTRODUCTION

Acid-assisted dissociation kinetics of open-chain polyamine complexes has been extensively studied [1–12], and many of these works have been reviewed [11]. Recently, there has been considerable interests in the kinetics and mechanism of the acid dissociation of macrocyclic polyamine complexes [13–18]. Most of the previous work concerns mainly the macrocyclic complex without substituents. In general, due to the thermodynamic and kinetic macrocyclic effect, macrocyclic complexes are substantially thermodynamically stable and kinetically inert, the rates of dissociation of metal complexes with tetraazacycloalkanes are relatively slow. In some instances they are so slow that one can study them even under extreme conditions, such as in 10 M $HClO_4$ [13]. Dioxoteraamine macrocycles are unique metal chelators, their structures bear the dual feature of macrocyclic polyamine and oligopeptides [19–25]. Macrocyclic dioxotetraamine complexes display interesting properties from the point of view of the redox activity and stability. Hay *et al*. [26] described the kinetics of the dissociation of copper(II) and nickel(II) complexes with 1,4,8,11-tetraazacyclotetradecane-5,7-dione(dioxocyclam) in the pH region 4–5, in which the analogous complexes with 14-aneN4(cyclam) give no sign of dissociation. Because of electron withdrawing of the carbonyl group, the decrease of electron density on the nitrogen atom of the amido group reduces the strength of the C–N bond and causes the macrocyclic dioxopolyamine complexes to dissociate easier than the corresponding macrocyclic polyamine complexes. The replacement of amino group by amide can greatly increase the acid-dissociation rate of the complexes [26]. In the study of the complex formation of dioxotetraamine, Kimura [25] considered the existence of non-deprotonated or singly deprotonated copper(II) complex unlikely. That is, the dioxotetraamine dissociates both its amide hydrogen atoms simultaneously when coordinated to a 3d metal ion. By

[1] Project 29671020 supported by National Nature Science Foundation of China.

* Author to whom correspondence should be addressed.

means of pH potential titration and spectrum titration Siegfried and Kaden [27] considered, however, that the existence of a non-deprotonated and singly deprotonated complex is possible. Under conditions of non-release of a hydrogen ion on amido nitrogen the metal ion can still coordinate with the amido nitrogen, but there was no definite experimental evidence indicating it to be true. Recently, Siegfried *et al.* [28] obtained the structure of the monocrystal of copper(II) complex with 1,4,8,11-tetraazacyclo-tetradecane-5-one(oxocyclam), and indicated that there were non-released hydrogen ions in these complexes and the positions of protonation were on the carbonyl oxygen atoms. We have obtained the monocrystal of the copper(II) complex of C-functionalized macrocyclic dioxotetraamines [23] which further indicated that singly deprotonated complex MLH_{-1} does exist in the course of formation of the complex MLH_{-2}. Non-deprotonated copper(II) complexes of dioxotetraamine macrocycles had been prepared [21]. From the above mentioned fact, we believe that when the amido-macrocyclic ligands coordinate with the metal ion, the protons on the amide group can transfer to the carbonyl oxygen atoms first and then dissociate stepwise from the complex. Siegfried and Kaden [27] and Hay *et al.* [26] suggested a different acid dissociation tendency, but there is no evidence to support their mechanism. It stimulates us to further investigate the acid dissociation kinetics and mechanism.

We have reported the kinetics and mechanism of the acid dissociation of copper(II) complexes of 6-(2′-hydroxy-3′,5′-substituted benzyl)-1,4,8,11-tetraazatetradecane-5,7-dione previously [29]. In this paper we further investigate the acid dissociation of copper(II) complexes of 12-(2′-hydroxy-3′,5′-substituted benzyl)-1,4,7,10-tetraazacyclo-tridecane-11,13-dione in order to understand how the ring size influenced the rate of acid dissociation of the complex in C-functionalized macrocyclic dioxotetraamines copper(II) complexes.

EXPERIMENTAL

Reagents

All the reagents used were of reagent grade. KNO_3 and chloroacetic acid were recrystallized before use. Redistilled water was used for preparation of all the solutions. The 12-(2′-hydroxy-3′,5′-substituted benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione were prepared according to the methods in Ref. [22] (Scheme 1).

Instructions

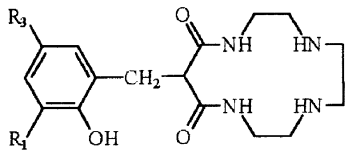
Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer. Stability constants of the macrocyclic dioxotetraamine copper(II) complexes were determined as reported previously [22]. The pH values were measured by means of a Beckman Φ71 pH meter. Kinetic measurement was made by Union Giken RA-401 stopped flow spectrophotometer.

Kinetic measurements

The complex and buffer solutions were prepared and the ion strength of solutions was maintained at $0.1\,mol\,dm^{-3}$, pH values of the solutions were adjusted with $1\,mol\,dm^{-3}$ KOH or HNO_3. Complex solutions were prepared by mixing equimolar quantities of ligand and $Cu(NO_3)_2$, followed by adjustment of pH to 7 with KOH, at which the complex is fully in the form of $[CuH_{-2}L]$. The course of dissociation was followed at their absorption maxima, i.e., 510 nm (L_1), 502 nm (L_2), 498 nm (L_3), 489 nm (L_4), and 520 nm (L_5), respectively. Apparent first order rate constants were obtained with at least 3 half-lives and represent the average of three runs. Reproducibility of the values of k_{obs} was better than $\pm 5\%$.

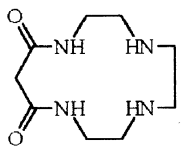
RESULTS AND DISCUSSION

All these complexes have a d–d absorption band at ~ 500 nm, but the free ligands have no absorption in this region. In acid dissociation measurement, the absorption at 500 nm disappeared without any interference, whereas the hydrogen ion concentration was maintained constant by means of buffer solutions, a first-order reaction with respect to the concentration of the copper(II) complex was observed, that is, the kinetics of the acid dissociation of the copper(II) complexes follow the rate law $V_d = k_{obs}C_{com}$, where C_{com} is the total concentration of the complex and k_{obs} is the pseudo-first-order rate constant. The relationship of



L_1:$R_1 = OCH_3$, $R_2 = H$; L_2:$R_1 = R_2 = H$

L_3:$R_1 = H$, $R_2 = Br$; L_4:$R_1 = R_2 = Br$



L_5

Scheme 1. Structure of the ligands.

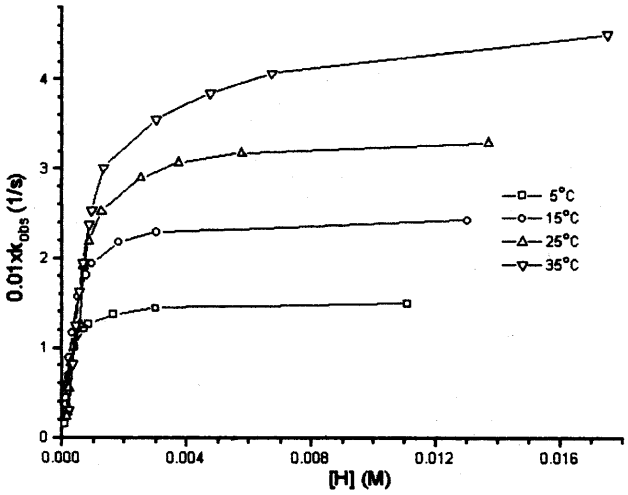


Fig. 1. Plot of acid dissociation apparent constant (k_{obs}) of CuL13(H) complexes; $k_{obs} \sim [H]$.

k_{obs} values vs the hydrogen ion concentration, $[H^+]$, and temperature were plotted in Figs 1 and 2.

From Figs 1 and 2, the same phenomena have been seen with one reported previously [29], we can see that k_{obs} increased rapidly with the increase of $[H^+]$ at low hydrogen concentration, but with further increase of $[H^+]$, k_{obs} increases slowly, until reaching a plateau, i.e., k_{obs} stays unchanged with the increase of $[H^+]$. This work again indicated that the mechanism proposed in a previous paper [29] was reasonable. As yet we have not obtained the crystal structure of the singly-deprotonated 13-membered macrocyclic dioxotetraamine copper(II) complex, but we have reason to believe the protonation of negatively charged amido oxygen atoms of the investigated 13-membered macrocyclic dioxotetraamine copper(II) complex can proceed stepwise. As the rates are very rapid, these processes are considered as pre-equilibrium ones. The third step would be the migration of protons from the amido oxygen to the amido nitrogen with concomitant release of copper(II). This process is the rate-determining step. The fourth step would be very fast protonation of the free ligand obtained in the third step (Scheme 2).

The observed reaction rate is of first-order with respect to the complex concentration C_{com}

$$V_d = k_{obs} C_{com} \tag{1}$$

From the following stoichiometric equation

$$C_{com} = [ML] + [MH_{-1}L] + [MH_{-2}L] \tag{2}$$

we have

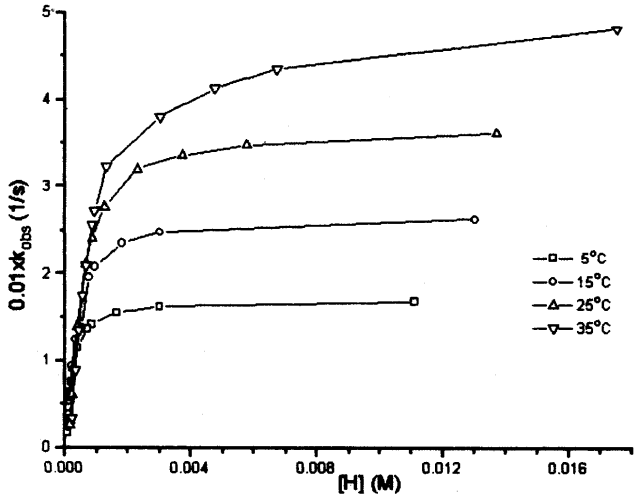

Fig. 2. Plot of acid dissociation apparent constant (k_{obs}) of CuL13(OCH_3) complexes; $k_{obs} \sim [H]$.

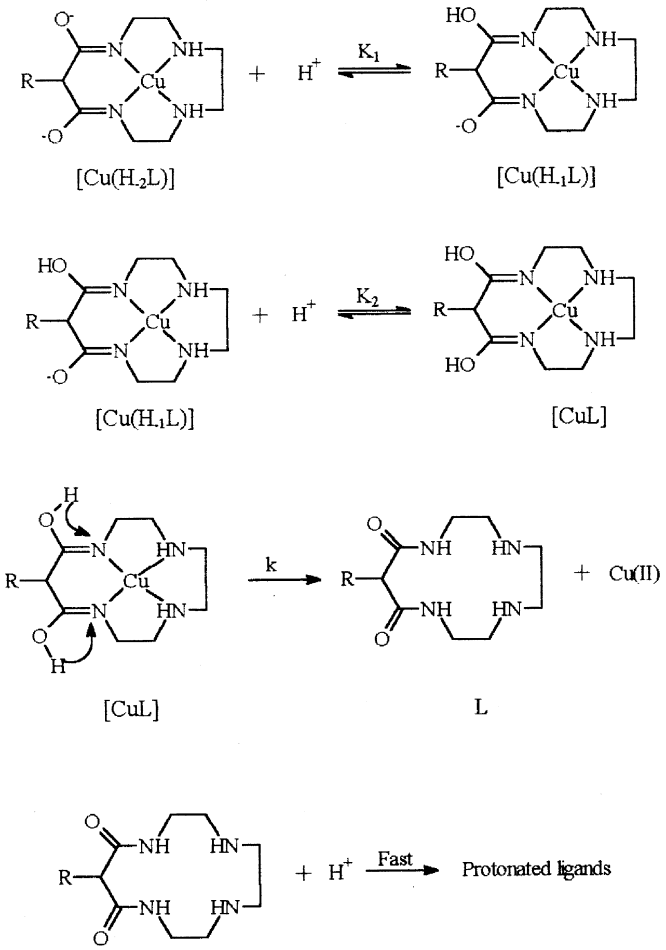

Scheme 2. Proposed acid-dissociation mechanism.

$$C_{com} = [ML](1 + K_1[H] + K_1K_2[H^2])/K_1K_2[H]^2 \quad (3)$$

Accord to the mechanism,

$$V_d = k[ML] = C_{com}kK_1K_2[H]^2/(1 + K_1[H] + K_1K_2[H]^2) \quad (4)$$

therefore

$$k_{obs} = kK_1K_2[H]^2/(1 + K_1[H] + K_1K_2[H]^2) \quad (5)$$

From non-linear least-square fitting of the experimental points using eq. (5), we can obtain the values of κ, K_1 and K_2 which are listed in Tables 1–33, respectively.

From the Eyring equation

$$\ln(k/T) = -\Delta H_m^{\neq}/RT + \Delta S_m^{\neq}/R + \ln(R/N_a h) \quad (6)$$

The activation parameters $\Delta H_m^{\neq}$ and $\Delta S_m^{\neq}$ of the rate-determining step can be obtained.

K_1 and K_2 are equilibrium constants of first and second pre-equilibrium steps, respectively:

$$MH_{-2}L + H = MH_{-1}L, \quad K_1 = [MH_{-1}L]/[MH_{-2}L][H] \quad (7)$$

$$MH_{-1}L + H = ML, \quad K_2 = [ML]/[MH_{-1}L][H] \quad (8)$$

By the following thermodynamic equations:

$$\ln K = -\Delta H_m^{\phi}/RT + \Delta S_m^{\phi}/R \quad (9)$$

The thermodynamic parameters ΔH_m^{ϕ}, ΔS_m^{ϕ} can be obtained.

The activation parameters $\Delta H_m^{\neq}$ and $\Delta S_m^{\neq}$ are listed in Table 1 with the rate-constant k, the thermodynamic parameters ΔH_m^{ϕ} ΔS_m^{ϕ} are also listed in Tables 2–3 with corresponding equilibrium constants, respectively. For comparison, the rate constant k and $\Delta H_m^{\neq}$, $\Delta S_m^{\neq}$ of corresponding 14-membered systems are also listed in Table 1 and the stability constants of binary systems Cu(II)-RTADO-13 [30] and Cu(II)-RTADO-14 [31] are listed in Table 4.

From Table 1 it is seen that the rate constant κ decreases with the change of ligands from $CuH_{-2}L_1$ to $CuH_{-2}L_4$ (the substituents change from CH_3O to

2Br). That is, values of the rate constant κ decrease with the decrease of base-strength of the macrocyclic dioxotetraamine ligands. The larger the electron density on the nitrogen atoms of amido group of the macrocyclic dioxotetraamine ligands, the faster the intramolecular hydrogen migration. The linear regression of the rate constants $\log\kappa$ to the protonation constant $\log\beta_1$ [$L_1(CH_3O)$ 10.26; $L_2(H)$ 10.01; $L_3(Br)$ 9.78; $L_4(2Br)$ 9.39 [30]] gives the following equations:

$$\log\kappa = 1.898 + 0.06364\log\beta_1,$$

$$(25^\circ\text{ C, except for } CuH_{-2}L_1), \quad \gamma = 1.000 \quad (11)$$

The linear regression of the rate constants $\log k$ to the pre-equilibrium constants $\log K_1$ also gives the following equations:

$$\log k = -1.353 + 1.125\log K_1,$$

$$(25^\circ\text{ C, except for } CuH_{-2}L_1), \quad \gamma = 0.9961 \quad (11)$$

In above two linear relationships $CuH_{-2}L_1$ (CH_3O) point deviates the straight line, i.e. the straight line turns the corner at $CuH_{-2}L_2$ (H) point. It is possible due to the different influence of the electron-drawing group and electron-repelling group to this linear relationship. It shows that Bronsted type linear free energy relationships do exist in these C-functionalized dioxotetraamine copper(II) complexes. From Table 1 it is also seen that the rate constants k of 13-membered systems are larger than those of the 14-membered systems, that is, the acid-dissociation of 13-membered complexes is faster than of the 14-membered complexes. This is because the ring size of the 14-membered macrocyclic dioxotetraamine is larger than that of the 13-membered macrocyclic dioxotetraamine and the cavity of the 14-membered ring fits better with the copper(II) ion than that of the 13-membered ring. The stability of Cu(II) complexes of 14-membered systems is higher than 13-membered systems (see Table 4). Therefore, the rate constants k of acid-dissociation of 13-membered Cu(II) complexes is larger than of 14-membered complexes.

From Tabs. 2–3, it is seen that ΔH_1^ϕ, ΔH_2^ϕ, ΔS_1^ϕ and ΔS_2^ϕ have negative values. It implies that the first and second pre-equilibrium steps are exothermic processes with decrease of entropy. This is due to the fact that the first and second pre-equilibrium steps are the protonation of negatively charged carbonyl oxygens (neutralization reaction). It is also seen that the K values, the equilibrium constants of the pro-equilibrium steps which are determined kinetically, agree better with those obtained by pH titration method.

From the above results, we can also understand that the stability of Cu(II) complexes of macrocyclic dioxotetraamine is smaller than that of the corresponding Cu(II) complexes of macrocyclic tetraamines (saturated and analogs) (see Table 4). This is because the electron withdrawing ability of carbonyl oxygen considerably diminishes the density of the electron cloud on the nitrogen atom of amide and thus reduces the stability of the Cu(II) complexes. Therefore, acid-dissociation of Cu(II) complexes of macrocyclic dioxotetraamines takes place much easier than the saturated analogs. In fact, it is very difficult for the Cu(II) complexes of saturated macrocyclic tetraamine to undergo acid dissociation under the investigated conditions reported in this paper.

Abstract—The dppe-bridged Mo–Mo singly-bonded dimers (μ-dppe)(η^5-$RC_5H_4)_2Mo_2(CO)_4$ (dppe $=Ph_2PCH_2CH_2PPh_2$; **1a**, R=H; **1b**, R=MeCO; **1c**, $R=MeO_2C$) prepared by reaction of Mo–Mo triply-bonded dimers (η^5-$RC_5H_4)_2(CO)_2Mo_2(CO)_4$ and dppe, reacted with μ_3-Se cluster $Co_2Fe(\mu_3\text{-}Se)(CO)_9$ to give single clusters η^5-$RC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2a**, R=H; **2b**, R=MeCO; **2c**, $R=MeO_2C$), whereas the disodium salt [(μ-dppe)(η^5-$MeO_2CC_5H_4)_2Mo_2(CO)_4]Na_2$ (**3**) prepared by reaction of **1c** and 1% Na/Hg, reacted with μ_3-S cluster $Co_2Fe(\mu_3\text{-}S)(CO)_9$ to afford single cluster η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}S)(CO)_8$ (**4**) and double cluster (μ-dppe)[(η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}S)(CO)_7]_2$ (**5**). Further treatment of **2b** with $NaBH_4$ gave a single cluster containing hydroxyl group η^5-$MeCH(OH)C_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**6**), which reacted with Et_3OBF_4 to give single cluster η^5-$MeCH(OEt)C_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**7**) and double cluster [η^5-$C_5H_4CH(Me)O(Me)CHC_5H_4$-$\eta^5$][$MoCoFe(\mu_3\text{-}Se)(CO)_8]_2$ (**8**) both containing ether functionality. All the new clusters have been characterized by elemental analysis and spectroscopic methods, as well as by X-ray diffraction analysis for cluster **2b**. © 1998 Elsevier Science Ltd. INTRODUCTION

Since the 1970s heteronuclear transition metal cluster complexes have been attracting considerable attention, largely due to their potential applications such as in catalysis, as well as the novelty and diversity of their reactions and structures [1–4]. Among the reactions studied so far, the isolobal displacement [5, 6] and functional transformation reactions [6] are of great interest and particularly useful for the rational synthesis of such transition metal clusters. As an extension of our project related to those mentioned above [6–9] we wish to report herein: (i) the synthesis of some new single and double tetrahedral MoCoFe(μ_3-E)(E=S, Se) clusters through the isolobal displacement reactions of two new types of dppe-bridged isolobal reagents with parent clusters $Co_2Fe(\mu_3\text{-}E)(CO)_9$. (ii) A series of functional transformation reactions starting from one of the clusters mentioned above to give additional new single and double MoCoFe(μ_3-Se) clusters containing functionally substituted cyclopentadienyl ligands. (iii) The X-ray crystal diffraction analysis for single cluster η^5-$MeCOC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$.

RESULTS AND DISCUSSION

Preparation of **1a–c** *and in situ reaction with* $Co_2Fe(\mu_3\text{-}Se)(CO)_9$; *synthesis and characterization of* **2a–c**

Similar to the preparation of (μ-dppm)$Cp_2Mo_2(CO)_4$ [10], an equimolar amount of triply-bonded dimers $(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_4$ (R = H, COMe, CO_2Me) reacted with dppe ligand in anhydrous THF at 0°C under nitrogen to give a purple solution of (μ-dppe)$(\eta^5\text{-}RC_5H_4)_2Mo_2(CO)_4$ (**1a**, R = H; **1b**, R = MeCO; **1c**, R = MeO_2C); Since dppe-bridged complexes **1a–c** were very air-sensitive and hard to separate, we treated them *in situ* with two molar equivalents of parent cluster $Co_2Fe(\mu_3\text{-}Se)(CO)_9$ at room temperature, affording three new single tetrahedral MoCoFe(μ_3-Se) cluster complexes η^5–$RC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2a**, R = H; **2b**, R = MeCO; **2c**, R = MeO_2C), as shown in Scheme 1.

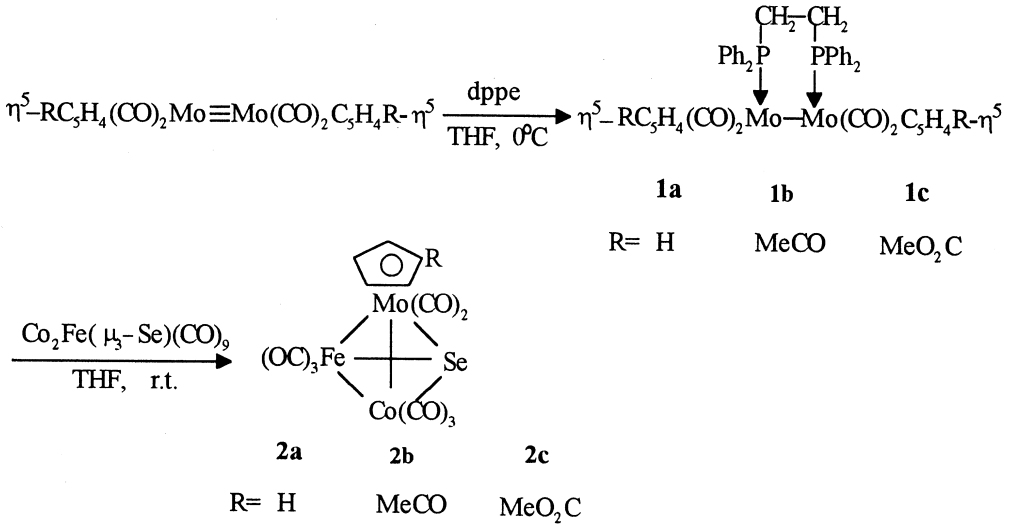
Clusters **2a–c** are deeply colored air-stable solids, which have been characterized by elemental analysis and spectroscopic techniques.

The IR spectra of **2a–c** all showed several absorption bands in the range of 2073–1868 cm^{-1} for their carbonyl ligands attached to transition metals, whereas those of **2b** and **2c** showed one additional absorption band at 1688 and 1721 cm^{-1} for their respective ketonic and ester carbonyls. The ^1H spectrum of **2a** exhibited one singlet at 5.36 ppm for its parent cyclopentadienyl ring, whereas those of **2b** and **2c** exhibited one singlet at 2.44 and 3.92 ppm for their methyl groups of the substituents on cyclopentadienyl ligands, respectively. In addition, the ^1H spectra of **2b** and **2c** showed one multiplet at 5.40–5.72 ppm for H^3 and H^4 protons remote from the substituent and one multiplet at 5.85–6.04 ppm for H^2 and H^5 protons close to the substituent on the substituted cyclopentadienyl rings, since the substituents are electron-withdrawing. Although the mass spectrum of **2a** showed its molecular ion M^+ peak, those of **2b** and **2c** exhibited only a series of reasonable fragment peaks generated from their fragment ions such as M^+-*n*CO (*n* = 1–8).

Crystal structure of **2b**

In order to further confirm the structures of single clusters **2a–c**, a single-crystal structure of **2b** was determined by X-ray diffraction methods. In the unit cell of **2b** there are two independent molecules **A** and **B**, whose structures are shown in Fig. 1. Since the geometric parameters of **A** and **B** are very similar, only the selected bond lengths and angles of **A** are given in Table 1.

As seen from Fig. 1, the molecule of **2b** consists of a distorted tetrahedral MoCoFeSe cluster core, on which there are one acetylcyclopentadienyl and two CO's ligands coordinated to Mo atom as well as two sets of three CO's coordinated to Fe and Co atoms, respectively. Actually, the single tetrahedral cluster **2b** is very similar. to the half of the double tetrahedral cluster $[(\eta^5\text{-}C_5H_4C(O)CH_2]_2[MoCoFe(\mu_3\text{-}S)(CO)_8]_2$ [6] and thus in both clusters the corresponding geometric parameters are comparable. For instance, the bond lengths of Mo–Fe, Mo–Co,Fe–Co are 2.7749(8), 2.8230(9) and 2.570(1) Å in **2b**, whereas the corresponding those are 2.801(1), 2.790(2) and 2.580(2) Å in $[\eta^5\text{-}C_5H_4C(O)CH_2]_2[MoCoFe(\mu_3\text{-}S)(CO)_8]_2$ [6], respectively. The distance of the Mo atom to the substituted Cp centroid is 1.983 Å in **2b**, whereas the corresponding one is 2.001 Å [6]. Among the eight carbonyls of **2b**, seven carbonyls, i.e. C(1)–O(1) through C(7)–O(7), are terminal and one carbonyl,



Scheme 1.

Co(1)–Fe(1)	2.570(1)	Fe(1)–C(5)	1.7931(6)
O(1)–C(1)	1.145(7)	O(8)–C(8)	1.150(7)
O(5)–C(5)	1.142(7)	O(7)–C(7)	1.148(7)
O(9)–C(14)	1.197(8)	C(9)–C(10)	1.399(8)

Se(1)–Mo(1)–Co(1)	51.25(2)	Se(1)–Mo(1)–Fe(1)	51.66(2)
Se(1)–Mo(1)–C(7)	83.3(2)	Se(1)–Mo(1)–C(8)	120.0(2)
Co(1)–Mo(1)–C(7)	79.3(2)	Co(1)–Mo(1)–Fe(1)	54.65(2)
Co(1)–Mo(1)–C(8)	68.8(2)	C(9)–Mo(1)–C(10)	35.0(2)
Mo(1)–Se(1)–Co(1)	71.89(3)	Mo(1)–Se(1)–Fe(1)	70.62(3)
Co(1)–Se(1)–Fe(1)	67.55(3)	Mo(1)–Co(1)–Fe(1)	61.72(3)
Mo(1)–Co(1)–Se(1)	56.86(2)	Mo(1)–Co(1)–C(2)	101.5(2)
Mo(1)–Co(1)–C(1)	108.3(2)	Mo(1)–Fe(1)–Co(1)	63.63(3)
Mo(1)–Fe(1)–Se(1)	57.72(2)	Se(1)–Fe(1)–Co(1)	56.40(3)
Mo(1)–Fe(1)–C(4)	154.0(2)	Mo(1)–C(8)–O(8)	168.9(5)

i.e. C(8)–O(8) attached to Mo atom is semi-bridging. This is due to its asymmetric parameter $\alpha = d_2 - d_1/d_1 = 0.41$ [d_2 = CO(1)...C(8) = 2.80 Å, d_1 = Mo(1)–C(8) = 1.984 Å], which falls well into the range of α value defined for semi-bridging CO's by Curtis [11]. Since the angle of Mo(1)–C(8)–O(8) is 168.9(5)° and the angle of Co(1)–Mo(1)–C(8) is 68.8(2)°, the semi-bridging C(8)–O(8) is bridged across on the Mo(1)–Co(1) bond. The presence of both terminal and semi-bridging carbonyls in **2b** is consistent with its IR spectral data.

Preparation of **3** *and subsequent reaction with* $Co_2Fe(\mu_3\text{-}S)(CO)_9$; *synthesis and characterization of* **4** *and* **5**

More interestingly, we found that reaction of **1c** with an excess amount of 1% amalgam in THF at

0°C, after filtration, gave a yellow solution of another new type of isolobal reagent, [(μ-dppe)(η^5-$MeO_2CC_5H_4)_2Mo_2(CO)_4$]$Na_2$ (**3**). Further treatment of the solution of **3** *in situ* with two molar equivalents of parent cluster $Co_2Fe(\mu_3\text{-}S)(CO)_9$, initially at room temperature and then at reflux, afforded both single cluster η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}S)(CO)_8$ (**4**) and double cluster (μ-dppe)(η^5-$MeO_2CC_5H_4)_2Mo_2Co_2Fe_2(CO)_{14}$ (**5**) (Scheme 2).

While single cluster **4** was previously prepared by another procedure [6], double cluster **5** is new and has been characterized by elemental analysis and spectroscopic methods. In the IR spectrum of **5** there was one ester carbonyl absorption band at 1729 cm^{-1} and four absorption bands in the range of 2049–1877 cm^{-1}, characteristic of its carbonyls attached to transition metals. The ^1H NMR spectrum of **5** indicated the presence of all the organic groups. For example, the multiplet at 2.04–2.52 ppm could be assigned to the ethylene group of dppe ligand, the two singlets at 3.82 and 3.86 ppm might be attributed to methyl groups of the substituted cyclopentadienyl ligands. Similar to **2a**–**c** the four protons on each substituted cyclopentadienyl ring showed two multiplets, one at a higher field ascribed to H^3 and H^4 protons and the other at a lower field assigned to H^2 and H^5 protons. Double cluster **5** is the only example in which two subcluster cores are connected through a dppe bridge, although a series of double clusters containing biscyclopentadienyl bridges such as [η^5-$C_5H_4C(O)CH_2]_2$[$MCoFe(\mu_3\text{-}S)(CO)_8]_2$ (M = Mo, W) [6] are known.

Functional reactions starting from **2b**; *synthesis and characterization of* **6**–**8**

Functional transformation reactions have proved to be a very useful method for preparation of transition metal cluster complexes [6]. For example, treatment of **2b** with an excess amount of $NaBH_4$ in methanol at room temperature gave an acetyl reduced product **6** in 65% yield. Further treatment of **6** with an excessive amount of triethyloxonium tetrafluoroborate in CH_2Cl_2 at room temperature gave both alkylating and condensation products **7** and **8** in 24 and 36% yields, respectively (Scheme 3).

Single and double clusters **6**–**8** are air-stable red–brown oils, which have been characterized by elemental analysis, IR and ^1H NMR spectroscopy. The C/H analysis is consistent with their respective compositions. The IR spectra of **6**–**8** showed their carbonyl absorption bands in the range of 2071–1886 cm^{-1} and hydroxyl and ether group absorption bands at 3441, 1103 and 1119 cm^{-1}, respectively. The ^1H NMR spectra of **6**–**8** showed their respective functionally substituted cyclopentadienyl ligands. For example, the doublet at 1.52 ppm is for the methyl group of **6**, the triplet and quartet at 1.20 and 3.48 ppm is for the ethyl group of **7**. However, the protons on substituted cyclopentadienyl ligands of **6**–**8**, in contrast to those of their starting cluster **2b**, exhibited only one multiplet in the range of 5.04–5.68 ppm, obviously caused by the newly generated chiral α-carbon atoms in clusters **6**–**8** through the functional transformation reactions.

EXPERIMENTAL

All reactions were carried out under highly prepurified tank nitrogen. TLC was performed on 25 × 20 cm glass plates coated with silica gel G (10–40 μm). THF was distilled from Na/benzophenone ketyl. (η^5-$RC_5H_4)_2Mo_2(CO)_4$ (R = H, COMe, MeO_2C)

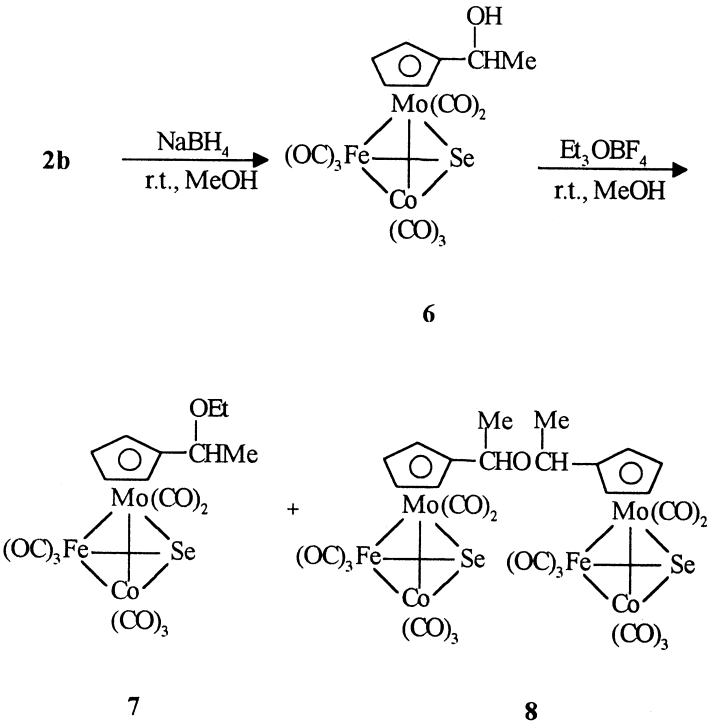
Scheme 2.



Scheme 3.

[12–14], $Co_2Fe(\mu_3\text{-}E)(CO)_9$(E = S, Se) [15] and Et_3OBF_4 [16] were prepared according to the published methods. $Mo(CO)_6$, $Ph_2PCH_2CH_2PPh_2$ (dppe) were purchased from Strem Chemicals. IR and ^1H spectra were recorded on a Nicolet FT-IR 5DX spectrophotometer and a JEOL FX 90Q or Brucker AC-P 200 NMR spectrometer, respectively. Mass spectra and elemental analyses were obtained with an HP 5988A and Perkin-Elmer 240C analyzer, respectively. Melting points were determined on a Yanaco MP-500 apparatus and were uncorrected.

Preparation of η^5-$C_5H_5MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2a**) *via* (μ-dppe)(η^5-$C_5H_5)_2Mo_2(CO)_4$ (**1a**)

To a 100 cm^3 two-necked flask were added (η^5-$C_5H_5)_2Mo_2(CO)_4$(0.283 g, 0.67 mmol) and THF (20 cm^3). The mixture was stirred and cooled to 0°C to give a deep-red THF solution of (η^5-$C_5H_5)_2Mo_2(CO)_4$. To the solution were added dppe (0.267 g, 0.67 mmol) and the mixture was stirred for an additional 10 min to give a purple THF solution of **1a**. $Co_2Fe(\mu_3\text{-}Se)(CO)_9$ (0.676 g, 1.34 mmol) was added to the solution of **1a** and the mixture was stirred for 4 h at room temperature. The solvent was removed under reduced pressure and the residue was extracted with CH_2Cl_2. The extracts were subjected to TLC separation using CH_2Cl_2/petroleum ether (1:3) as eluent. From the main band was obtained **2a** (0.172 g, 22%) as a red–brown solid. **2a**: m.p. 75°C (dec). Found: C, 26.9; H, 0.9. Calc. for $C_{13}H_5CoFeMoO_8Se$; C, 27.0; H, 0.9%. IR (KBr, disc): ν_{CO}, 2073 s, 2024 vs, 1983 vs, 1893 s cm^{-1}. ^1H NMR($CDCl_3$, δ, ppm): 5.36 (s, 5H, C_5H_5). MS(EI): m/z (^{98}Mo) 582 (M^+, 0.5%), 554 (M^+–CO, 0.6), 526 (M^+–2CO, 0.4), 498 (M^+–3CO, 0.8), 470 (M^+–4CO, 0.8), 442 (M^+–5CO, 2.6), 414 (M^+–6CO, 2.4), 386 (M^+–7CO, 1.6), 358 (M^+–8CO, 3.2), 293 (Mo $FeCoSe^+$, 0.8), 219 [$C_5H_5Mo(CO)_2^+$, 1.0], 65 ($C_5H_5^+$, 2.1).

Preparation of η^5-$MeCOC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2b**) *via* (μ-dppe)(η^5-$MeCOC_5H_4Mo_2(CO)_4$ (**1b**)

The same procedure as that for **1a** was followed, but (η^5-$MeCOC_5H_4)_2Mo_2(CO)_4$ (0.347 g, 0.67 mmol) was used instead of (η^5-$C_5H_4)_2Mo_2(CO)_4$ to give a purple THF solution of **1b**. $Co_2Fe(\mu_3\text{-}Se)(CO)_9$ (0.676 g, 1.34 mmol) was added to the solution of **1b** and the mixture was stirred for 4 h at room temperature. The same workup as that for **2a** was followed. From the main band was obtained **2b** (0.126 g, 15%) as a red–brown solid. **2b**: m.p. 95–96°C. Found: C, 29.0; H, 1.2. Calc. for $C_{15}H_7CoFeMoO_9$ Se; C, 29.0; H, 1.1%. Preparation of η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2c**) *via* (μ-dppe)(η^5-$MeO_2CC_5H_4Mo_2(CO)_4$ (**1c**)

The same procedure as that for **1a** was followed, but (η^5-$MeO_2CC_5H_4)_2Mo_2(CO)_4$ (0.367 g, 0.67 mmol) was used instead of (η^5-$C_5H_5)_2Mo_2(CO)_4$ to give a purple THF solution of **1c**. $Co_2Fe(\mu_3\text{-}Se)(CO)_9$ (0.676 g, 1.34 mmol) was added to the solution of **1b** and the mixture was stirred for 4 h at room temperature. The same workup as that for **2a** was followed. From the main band was obtained **2c** (0.122 g, 14%) as a red–brown solid. **2c**: m.p. 55–56°C. Found: C, 28.2; H, 1.1. Calc. for $C_{15}H_7CoFeMoO_{10}Se$; C, 28.3; H, 1.1%. IR (KBr, disc): ν_{CO}, 2073 vs, 2024 vs, 1991 vs, 1893 s; $\nu_{C=O}$ 1721 s cm^{-1}. ^1H NMR($CDCl_3$, δ, ppm): 3.92 (s, 3H, CH_3). 5.40–5.68 (m, 2H, H^3, H^4), 5.90–6.02 (m, 2H, H^2, H^5). MS(EI): *m*/*z* (^{98}Mo) 612 (M^+–CO, 1.0), 584 (M^+–2CO, 3.0), 556 (M^+–3CO, 2.4), 528 (M^+–4CO, 4.6), 500 (M^+–5CO, 9.6), 472 (M^+–6CO, 20.6), 444 (M^+–7CO, 11.6), 416 (M^+–8CO, 11.9), 357 ($C_5H_4MoFeCoSe^+$, 15.1), 293 ($MoFeCoSe^+$, 8.2), 277 ($MeO_2CC_5H_4Mo(CO)_2^+$, 1.7), 221 ($MeO_2CC_5H_4Mo^+$, 3.3), 123 ($MeO_2CC_5H_4^+$, 2.2).

Preparation of η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}S)(CO)_8$ (**4**) *and* (μ-dppe)[(η^5-$MeO_2CC_5H_4MoCoFe(\mu_3\text{-}S)(CO)_7]_2$ (**5**) *via* [(μ-dppe)(η^5-$MeO_2CC_5H_4)_2Mo_2(CO)_4]Na_2$ (**3**)

The above flask was charged with (η^5-$MeO_2CC_5H_4)_2Mo_2(CO)_4$ (0.301 g, 0.55 mmol) and THF (20 cm^3). The stirred mixture was cooled to 0°C to give a deep-red THF solution of (η^5-$MeO_2CC_5H_5)_2Mo_2(CO)_4$. To the solution was added dppe (0.219 g, 0.55 mmol) and the mixture was stirred for additional 10 min to give a purple THF solution of **1c**. To the solution of **1c** at 0°C was added amalgam (1%, 23 g) and the mixture was stirred for an additional 20 min at this temperature, after filtration to give a yellow solution of **3**. To the solution of **3** was added $Co_2Fe(\mu_3\text{-}S)(CO)_9$ (0.504 g, 1.10 mmol) and the mixture was stirred for 1 h at room temperature and then refluxed for 2 h. After removal of the solvent under reduced pressure, the residue was extracted with CH_2Cl_2 and the extracts were subjected to TLC separation using CH_2Cl_2/petroleum ether (1:1) as eluent. From the brown band, **4** was obtained, which was identified by comparison of its IR and ^1H NMR spectra with those of the authentic sample [6]. From the black band, **5** (0.076 g, 9%) was obtained as a black solid. **5**: m.p. 101°C (dec). Found: C, 42.5; H, 2.8. Calc. for $C_{54}H_{38}Co_2Fe_2Mo_2O_{18}P_2S_2$; C, 42.6; H, 2.5%. IR(KBr, disc): ν_{CO}, 2049 s, 1991 vs, 1967 vs, 1877 s; $\nu_{C=O}$ 1729 s cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.04–2.52 (m, 4H, PCH_2CH_2P), 3.82, 3.86 (s, s, 6H, CH_3), 5.50–5.68 (m, 4H, H^3, $H^{3'}$; H^4, $H^{4'}$), 5.80–6.12 (m, 4H, H^2, $H^{2'}$; H^5, $H^{5'}$), 7.04–7.72 (m, 20H, $4C_6H_5$).

Preparation of η^5-$MeCH(OH)C_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**6**)

The above flask was charged with (η^5-$MeCOC_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**2b**) (0.308 g, 0.49 mmol), $NaBH_4$ (0.021 g, 0.55 mmol) and MeOH (10 cm^3). The mixture was stirred overnight at room temperature. The solvent was removed under vacuum and the residue was extracted with CH_2Cl_2. The extracts were subjected to TLC separation using CH_2Cl_2/petroleum ether (1:1) as eluent. From the main brown band was obtained **6** (0.200 g, 65%) as a red–brown oil. Found: C, 29.3; H, 1.3. Calc. for $C_{15}H_9CoFeMoO_9Se$: C, 28.9; H, 1.5%. IR (KBr, disc): ν_{OH}, 3441 m, ν_{CO} 2070 s, 2021 s, 1889 s cm^{-1}. ^1H NMR($CDCl_3$, δ, ppm): 1.52 (d, J = 7.2 Hz, 3H, CH_3), 1.76–2.02 (br, 1H, OH), 4.52–4.80 (m, 1H, CH), 5.10–5.52 (m, 4H, C_5H_4).

Preparation of η^5-$MeCH(OEt)C_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**7**) *and* η^5-$C_5H_4CH(Me)O(Me)CHC_5H_4$-$\eta^5$)[$MoCoFe(\mu\text{-}Se)(CO)_8]_2$ (**8**)

The above flask was charged with η^5-$MeCH(OH)C_5H_4MoCoFe(\mu_3\text{-}Se)(CO)_8$ (**6**) (0.150 g, 0.24 mmol) Et_3OBF_4 (0.185 g, 0.97 mmol) and CH_2Cl_2 (7 cm^3). The mixture was stirred at room temperature for 9 h. After removal of solvent under reduced pressure, the residue was subjected to TLC separation using CH_2Cl_2/petroleum ether (1:1) as eluent. The first band is tiny and thus had not been collected. From the second band **7** (0.038 g, 24%) was obtained as a red oil. **7**: found: C, 31.6; H, 1.7. Calc. for $C_{17}H_{13}CoFeMoO_9Se$: C, 31.4; H, 2.0%. IR (KBr, disc): ν_{CO}, 2071 vs, 2021 vs, 1886 s; ν_{C-O} 1103 m cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 1.20 (t, J = 7.2 Hz, 3H, CH_2CH_3), 1.44 (d, J = 7.2 Hz, 3H, $CHCH_3$), 3.48 (q, J = 7.2 Hz, 2H, CH_2), 4.22 (q, J = 7.2 Hz, 1H, CH), 5.12–5.52 (m, 4H, C_5H_4). From the third band **8** (0.053 g, 36%) was obtained as a red oil. **8**: found: C, 29.6; H, 1.8. Calc. for $C_{30}H_{16}Co_2Fe_2Mo_2O_{17}Se_2$: C, 29.4; H, 1.3%. IR (KBr, disc): ν_{CO}, 2069 vs, 2022 vs, 1893 s; ν_{C-O} 1119 s cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 1.32–1.64 (m, 6H, $2CH_3$), 4.28–4.60 (m, 2H, 2CH), 5.04–5.68 (m, 8H, $2C_5H_4$).

Structure determination of **2b**

The single crystals of **2b** were grown in its CH_2Cl/hexane solution at *ca.* −20°C, from which a single crystal with dimensions 0.20 × 0.20 × 0.30 mm was chosen for X-ray diffraction analysis. Diffraction data were collected on a Rigaku. AFC7R CAD4 diffractometer with Mo-Kα radiation using the $\omega/2\theta$

Transition metal complexes of the tripodal ligand 4-(2′-pyridylmethyl)-4-azaheptane-1,7-diamine. Crystal structures of $[CuLCl]ClO_4$ and $[NiL(MeCN)_2](ClO_4)_2$

Robert W. Hay*, Thomas Clifford and Philip Lightfoot

School of Chemistry, University of St Andrews, St Andrews KY16 9ST, U.K.

(Received 19 January 1998; accepted 18 May 1998)

Abstract—The tripodal ligand 4-(2′-pyridylmthyl)-4-azaheptane-1,7-diamine has been prepared by reaction of 2-aminemethyl pyridine with acrylonitrile, followed by the reduction of the nitrile groups. Copper(II), nickel(II), zinc(II), cobalt(III) and chromium(III) complexes of the ligand have been prepared and characterized and the crystal structures of the complexes $[CuLCl]ClO_4$ and $[NiL(MeCN)_2](ClO_4)_2$ determined. The copper complex is five coordinate with approximate square pyramidal stereochemistry with the apical position occupied by a primary amine donor. The nickel complex is octahedral with the pyridine nitrogen donor lying *trans* to an acetonitrile ligand. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tripodal ligand; copper(II); nickel(II); zinc(II); cobalt(III); chromium(III); crystal structures.

INTRODUCTION

There are a limited number of tripodal amine ligands, important examples are tren $[N(CH_2CH_2NH_2)_3]$ and trpn $[N(CH_2CH_2CH_2NH_2)_3]$. Cobalt(III) complexes of trpn have recently attracted considerable attention as the complex $[Co(trpn)(OH)(OH_2)]^{2+}$ promotes the hydrolysis of unactivated carboxylic esters such as methyl acetate [1a, 1b], the hydrolysis of amides [2] and the hydrolysis of phosphate esters [3a, 3b]. The complex $[Co(tren)(OH)(OH_2)]^{2+}$ is also known to promote the hydrolysis of amino acid esters and peptides [4]. In addition tren and trpn have been used as intermediates in the synthesis of a range of macrocycles and cryptand ligands such as (**1**) in which a variety of dialdehydes can be used as "spacers" [5]. For this reason we have been interested in the chemistry of tripodal amine ligands which may be of value in catalytic studies and as intermediates in the synthesis of macrocyclic ligands. In the present paper we discuss the synthesis and characterization of a variety of transition metal complexes of the tripodal ligand 4-(2′-pyridylmethyl)-4-azaheptane-1,7-diamine (**2**).

EXPERIMENTAL

Physical measurements

Infrared spectra were recorded on a Perkin Elmer 1710 Fourier Transform spectrophotometer as KBr discs or as liquid film. UV–VIS spectra were recorded on a Lambda 14P spectrophotometer. The NMR spectra were obtained at 200 MHZ using a Varian Gemini FT spectrometer.

Synthesis

1,5-Dicyano-3-(2′-pyridyln-ethyl)-3-azapentane was prepared by the Michael addition of 2-ami-

*Author to whom correspondence should be addressed. Tel.: +44-1334-463-827; fax: +44-1334-463-808.

nomethyl pyridine to acrylonitrile, essentially as previously described [17]. It was found that cyanoethylation of 2-aminomethyl pyridine does not require the presence of acetic acid as a catalyst.

4-(2′-*Pyridylmethyl*-4-*azaheptane* (*L*)

The amine was prepared by the reduction of the dinitrile with hydrogen and Raney nickel essentially using the procedure described by Chin *et al*. [3b] for the preparation of the ligand tris(3-aminopropyl)amine.

Moore *et al*. [17] have also described a procedure using Raney nickel and $NaBH_4$ as the reducing agent. The amine was purified by vacuum distillation (b.p. 153–154°C at 0.05 mm Hg). A forerun of the monoalkylated product b.p. 105°C was discarded. Found: C, 64.5; H, 10.2; N, 25.0. Calc. for $C_{12}H_{22}N_4$: C, 64.8; H, 10.0; N, 25.2%. Electron impact mass spectrum [M^+] 222 (calc. 222). ^{1}H NMR ($CDCl_3$) 8.55 (1H,d), 7.70 (1H,t), 7.45 (1H,d), 7.17 (1H,t), 3.72 (2H,s), 2.70 (4H,t), 2.55 (4H,t), 1.75 (4H,br), 1.60 (4H,Pent). The ligand tetrahydrobromide was prepared by the dropwise addition of concentrated HBr to a solution of the amine in ethanol.

[CuLCl]ClO_4

The ligand (0.5 g, 2.25 mmol) was dissolved in ethanol (10 cm^3) and added to copper(II) chloride dihydrate (0.38 g, 2.25 mmol). Addition of isopropanol gave a sticky solid which was dissolved in hot ethanol (*ca*. 10 cm^3). Addition of sodium perchlorate (0.5 g) in ethanol (20 cm^3) gave an immediate pale-blue precipitate. The complex was filtered off washed with ethanol then diethyl ether and recrystallized from boiling acetonitrile (0.42 g, 39%). Found: C, 34.7; H, 5.2; N, 13.5. Calc. for $C_{12}H_{22}N_4O_4Cl_2Cu$: C, 34.25; H, 5.3; N, 13.3%. $\Lambda_M = 116\ S\,cm^2\,mol^{-1}$ in $MeNO_2$. λ_{max}/nm (ε_{max}/$dm^3\,mol^{-1}\,cm^{-1}$) 736 (98), 822 (100) in water, 721 (121), 849sh(108) in acetonitrile.

[ZnL]$(ClO_4)_2$

A boiling solution of the ligand (0.30 g, 1.35 mmol) in ethanol (10 cm^3) was added dropwise to a solution of zinc(II) perchlorate hexahydrate (0.50 g, 1.35 mmol) in boiling ethanol (5 cm^3). On cooling, a small amount of oil was separated from the solution, then colourless blades formed. The complex was filtered off and washed with ethanol, then recrystallized from the minimum volume of boiling ethanol (0.49 g, 74%). Found: C, 29.6; H, 4.0; N, 11.3. Calc. for $C_{12}H_{22}N_4O_8Cl_2Zn$: C, 29.6; H, 4.6; N, 11.5%. $\Lambda_M = 193\ S\,cm^2\,mol^{-1}$ in nitromethane at 25°C.

[NiL$(MeCN)_2$]$(ClO_4)_2$

A boiling solution of the ligand (0.30 g, 1.35 mmol) in ethanol (10 cm^3) was added dropwise to a solution of nickel(II) perchlorate hexahydrate (0.49 g, 1.35 mmol) in boiling ethanol (5 cm^3). The green nickel(II) solution turned blue on addition of the amine and on cooling a blue oil formed. The oil was dissolved in boiling acetonitrile (15 cm^3). On cooling purple blocks formed (0.56 g, 82%). Found: C, 33.9; H, 4.8; N, 14.7. Calc. for $C_{16}H_{28}N_6O_8Cl_2Ni$: C, 34.2; H, 5.0; N, 14.95%. $\Lambda_M = 227\ S\,cm^2\,mol^{-1}$ in nitromethane at 25°C. λ_{max}/nm (ε_{max}/$dm^3\,mol^{-1}\,cm^{-1}$) 524(11) 888(8) in acetonitrile and 569(8) 900sh(7) in water.

[CoLBr_2]Br

The ligand tetrahydrobromide (1 g) was ground together with $Na_3[Co(CO_3)_3]\cdot 3H_2O$ [7] (0.66 g). Water (1 cm^3) was added and after the vigorous effervescence had subsided, the mixture was heated on a hot plate for *ca*. 20 min to give a burgundy red solution. The sticky red solid was dissolved in methanol (10 cm^3) and HBr added with gentle heating until the solution became brown–green. Isopropyl alcohol (25 cm^3) was then added to give a pale green–brown precipitate. The precipitate was dissolved by the addition of methanol (10 cm^3) and gentle heating. Dark brown crystals formed on cooling. The crystals were filtered off and washed with ethanol (1 cm^3) then diethyl ether ($2 \times 2\ cm^3$). Yield 0.5 g. Found: C, 27.5; H, 3.9; N, 10.6. Calc. for $C_{12}H_{22}N_4Br_3Co$: C, 27.7; H, 4.25; N, 10.75%). The complex has $\Lambda_M = 421\ S\,cm^2\,mol^{-1}$ in water at 25°C and $\lambda_{max} = 468$ nm ($\varepsilon = 567\ dm^3\,mol^{-1}\,cm^{-1}$) in methanol.

[CrLCl_2]Cl

The ligand (1 g; 4.5 mmol) and chromium(III) chloride hexahydrate (4.5 mmol) were both dissolve separately in DMF (20 cm^3) and brought to the boil on a hot plate. After boiling for some 20 min the chromium solution became rose–pink due to complete dehydration and was added dropwise to the boiling solution of the ligand. A dark-brown solution formed and the purple complex began to crystallize. Additional product could be obtained by removal of half of the solvent under reduced pressure.

The crude complex was recrystallized from 1 mol dm^{-3} HCl (5 cm^3). Found: C, 37.4; H, 5.8; N, 14.6. Calc. for $C_{12}H_{22}N_4Cl_3Cr$: C, 37.9; H, 5.8; N, 14.7%). The complex has $\Lambda_M = 98\ S\,cm^2\,mol^{-1}$ in water at 25°C. The visible spectrum in aqueous solution has λ_{max} 404 ($\varepsilon = 72$) and 541 nm ($\varepsilon = 59\ dm^3\,mol^{-1}\,cm^{-1}$).

Crystallography

Crystal data. $C_{12}H_{22}N_4CuCl_2O_4$, [CuLCl]ClO_4, M = 420.78, primitive orthorhombic, space group

$P2_12_12_1$ (No.19), $a=9.172(2)$, $b=23.090(2)$, $c=8.270(1)$ Å, $U=1751.4(4)$ Å^3, $F(000)=868$, $Z=4$, $D_c=1.596\,g\,cm^{-3}$, MoKα radiation, $\lambda=0.71069$ Å, $\mu(MoK\alpha)=15.75\,cm^{-1}$, $T=290$ K. Blue block crystal grown by vapour diffusion of diethyl ether into a methanol solution of the complex.

$C_{16}H_{28}N_6NiCl_2O_8$.[NiL(MeCN)$_2$](ClO$_4$)$_2$, $M=562.04$, primitive orthorhombic, space group $Pna2_1$ (No. 33), $a=15.974(3)$, $b=8.054(4)$, $c=19.371(4)$ Å, $U=2491(2)$ Å^3, $F(000)=1168$, $Z=4$, $D_c=1.498$ g cm^{-3}, MoKα radiation, $\lambda=0.71069$ Å, $\mu(MoK\alpha)=10.44\,cm^{-1}$, $T=290$ K. Purple block crystal grown by slow recrystallization from methanol.

Data collection and processing. [CuLCl](ClO$_4$)$_2$. A blue crystal of approximate dimensions $0.20\times0.15\times0.30$ nm was mounted on a glass fibre. The unit cell parameters were obtained by least squares refinement of 25 automatically centred reflections in the range $27.2<2\theta<33.4°$. Rigaku AFC7S diffractometer, ω–2θ scan type with ω scan width $(0.89+0.35\tan\theta)$, ω scan speed $16.0°\,min^{-1}$ (up to 4 scans), 1809 reflections measured (max $2\theta=50.0°$). No decay correction was made, but an absorption correction was required (transmission coefficients 0.8653–1.0000). Corrections were made for Lorentz and polarization effects.

[NiL(MeCN)$_2$](ClO$_4$)$_2$. A purple crystal of approximate dimensions $0.20\times0.10\times0.30$ mm was mounted on a glass fibre. The unit cell parameters were obtained by least squares refinement of 15 automatically centred reflections in the range $6.62<2\theta<11.15°$. Rigaku AFC7S diffractometer, ω–2θ scan type with ω scan width $=(0.84+0.35\tan\theta)$, ω scan speed $16.00°\,min^{-1}$ (up to 4 scans), 2532 reflections measured (max $2\theta=50.0°$). No decay correction was made, but an absorption correction was required (transmission coefficients 0.9057–1.0000). Corrections were made for Lorentz and polarization effects.

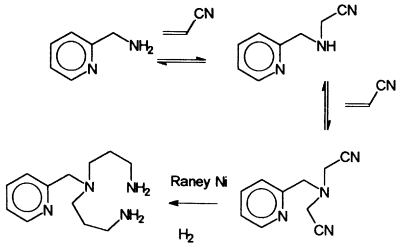
Structure analysis and refinement

[CuLCl](ClO$_4$)$_2$. Direct methods [8] were employed and expanded using Fourier techniques [9]. All nonhydrogen atoms were refined anisotropically. Hydrogens are included but not refined. The final cycle of full-matrix least squares refinement was based on 1528 observed reflections [$I>3.00\sigma(I)$] and 208 variable parameters and converged with unweighed agreement factors of $R=0.045$ and $R'=0.040$ ($R=\Sigma\|F_o|-|F_c\|/\Sigma|F_o|$; $R'=(\Sigma(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. The standard deviation of an observation of unit weight [10] was 2.96. The maximum and minimum peaks in the final difference Fourier map correspond to 0.56 and -0.45 eÅ^{-3}, respectively. The perchlorate anion was refined anisotropically and inspection of the ORTEP thermal ellipsoids indicated considerable disorder of the perchlorate oxygen atem. Attempts to model the disorder on the basis of a number of partially occupied positions around the chlorine atom did not give a significant reduction in the R value. All calculations were performed using the TEXSAN [10] crystallographic software package of the Molecular Structure Corporation.

[NiL(MeCN)$_2$](ClO$_4$)$_2$. As described above, direct methods were employed and expanded using Fourier techniques. All nonhydrogen were refined anisotropically except for the oxygens of one perchlorate group. Hydrogens were included but not refined. The full cycle of least squares refinement was based on 1633 observed reflections [$I>3.00\sigma(I)$] and 277 variable parameters and converged with unweighed agreement factors of $R=0.072$ and $R'=0.061$. The standard deviation of unit weight was 3.94. The weighting scheme was based on counting statistics and included a factor ($p=0.001$) to downweight the intense reflections. Plots of $w(\Sigma|F_o|-|F_c|)^2$ vs. $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$ and various classes of indices showed no unusual trends. The maximum and minimum peaks in the final difference Fourier map corresponded to 0.64 and -0.57 eÅ^{-3} respectively. Attempts to model the disorder of the perchlorate oxygen atoms on the basis of a number of partially occupied positions around the chlorine atom did not produce a significant reduction in the value of R.

RESULTS AND DISCUSSION

The tripodal ligand 4-(2′-pyridylmethyl)-4-azaheptane-1,7-diamine (2 = L) was readily prepared by the reactions outlined in the Scheme. It was found that



cyanoethylation of 2-aminomethyl pyridine does not require the presence of an acid catalyst. Even under the reaction condition employed (a large excess of acrylonitrile) some monoalkylated species are formed. The cyanoethylated product was not purified since distillation led to appreciable decomposition. After reduction the mono- and dialkylated and amines could readily be separated by vacuum distillation.

A variety of metal complexes with copper(II), nickel(II), zinc(II), cobalt(III) and chromium(III) were readily characterized and the crystal structures of the copper and nickel complexes determined.

The $[CuLCl]^+$ cation is five-coordinate with an N_4Cl donor set, Fig. 1. The geometry is best described as distorted square pyramidal, and selected bond lengths and angles are summarized in Table 1. The crystal structure of the analogous complex [Cu(tren)NCS]SCN [11] establishes that with the symmetrical

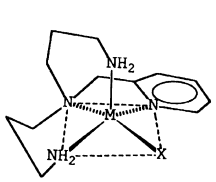
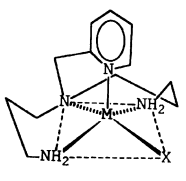
Cu(1)–N(4)	2.033(6)	N(3)–Cu(1)–N(2)	101.4(3)
Cu(1)–CI(1)	2.300(2)	N(1)–Cu(1)–Cl(1)	166.0(2)
		N(3)–Cu(1)–Cl(1)	100.4(2)
		N(2)–Cu(1)–N(4)	151.5(3)
		N(3)–Cu(1)–N(4)	106.3(3)
		N(2)–Cu(1)–Cl(1)	87.6(2)
		N(4)–Cu(1)–Cl(1)	94.2(2)

tripodal tren ligand copper has a trigonal bipyramidal geometry. In the present complex there is a large N4–Cu–N2 bond angle of 151.5° and acute angles of 106.3 and 101.4° for N4–Cu–N3 and N3–Cu–N2, respectively. The donors N1, N2, N4 and Cl may be considered to form the base of the pyramid with copper sitting some 0.5 Å above the plane and N3 occupying the apical position. Two isomers (**3**) and (**4**) are possible in square pyramidal geometry. Isomer



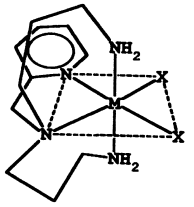
(**3**)



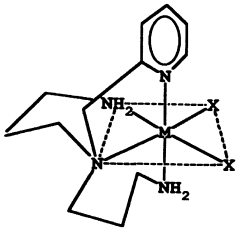
(**4**)

(**3**) is found in this structure with a primary amino group in the apical site. The primary amine in the apical position (N3) has a somewhat longer bond (2.192 Å) to copper than the in-plane amine (2.004 Å). The pyridine nitrogen to copper bond length of 2.033(6) Å is close to that typically observed in pyridine complexes (*ca.* 1.98 Å) and the Cu–Cl bond length also falls within the expected limits for 5-coordinate complexes. The pyridine ring is planar (torsion angles are $0.3 \pm 0.2°$) and the carbon–carbon bond distances in the alkyl chains show no unusual features (1.51 ± 0.02 Å).

The blue cation $[NiL(MeCN)_2]^{2+}$ is as expected six-coordinate and octahedral, Fig. 2, with the two acetonitrile ligands in *cis*-positions. Two isomers (**5**) and (**6**) are possible for an $[MLX_2]$ type complex. Isomer



(**5**)



(**6**)

(**5**) has the pyridine donor *trans* to the group X, while isomer (**6**) has the pyridine *trans* to a primary amino donor. The present complex has the isomer (**5**) geometry with the pyridine donor *trans* to an acetonitrile. Selected bond lengths and angles are summarized in Table 2. The nickel–amine and nickel–pyridine bond distances are all fairly similar with slightly shorter bonds to the tertiary nitrogen donor and the pyridine donor, presumably due to the smaller bite angle of the five-membered chelate ring. The average Ni–N bond length of 2.10(4) Å is quite typical for high spin nickel(II) complexes. The Ni–N bond lengths for the acetonitrile ligands are close to the average values noted in previously published structures [12a, 12b, 12c, 12d, 12e]. The Ni–N–C bond angle (167 and 156°) is distorted from the expected value of 180°. The C–N bond lengths of 1.17 and

		Ni(1)–N(5)–C(13)	167(1)

1.19 Å compare well with the literature values [13] for coordinated acetonitrile and are quite close to the value found in free acetonitrile 1.157 Å. Coordinated acetonitrile is known to hydrolyse quite rapidly in a number of metal complexes to give coordinated acetamide [14]. This result has been attributed to the Lewis acidity of the metal ion leading to polarization of the C=N bond. It is clear from the crystallographic studies that ground state effects are quite small and presumably indicate that the major role of the metal ion in the hydrolytic reaction occurs in stabilising the transition state of the hydrolysis.

The disordered perchlorate anions are located between layers of the complexes and are hydrogen bonded to the primary amino protons as shown in the crystal packing diagram, Fig. 3. The copper(II) complex does not display this type of hydrogen bonding to the perchlorate anions and there are no unusual packing features.

The cobalt(III) and chromium(III) complexes are expected to have the normal octahedral geometry found with complexes of these metal ions. They are also expected to have the isomer (**5**) geometry observed in the nickel(II) complex. Cobalt(III) complexes of trpn of the type $[Co(trpn)X_2]^+$ (X = Cl, Br) are known to aquate very rapidly in aqueous solution to give the $[Co(trpn)(OH_2)_2]^{3+}$ cation [15]. Rapid aquation of the chloride ligands in $[CoLCl_2]^+$ was also observed. The complex is a 3:1 electrolyte in aqueous solution ($\Lambda_M = 421\ S\,cm^3\,mol^{-1}$) indicating rapid loss of the chloride ligands. The much less reactive $[CrLCl_2]Cl$ has $\Lambda_M = 98\ S\,cm^2\,mol^{-1}$ in water consistent with a 1:1 electrolyte. The chromim(III) complex has λ_{max} 404 nm ($\varepsilon = 72$) and 541 nm ($\varepsilon = 59\ dm^3\,mol^{-1}\,cm^{-1}$) values which are quite typical for a *cis*-CrN_4Cl_2 chromophore.

The copper(II) complex $[CuLCl]ClO_4$ has two bands in the visible spectrum in aqueous solution at 736 nm ($\varepsilon = 98$) and 822 nm ($\varepsilon = 100\ dm^3\,mol^{-1}\,cm^{-1}$) consistent with the five-coordinate structure found in the solid state. Hathaway *et al.* [16] have noted two bands in the solid state spectrum of $[Cu(bipy)_2X]X$ complexes which have a trigonal bipyramidal structure in the solid state and in solution.

The $[ZnL](ClO_4)_2$ complex is a 2:1 electrolyte in the noncoordinating solvent nitromethane ($\Lambda_M = 193$ S $cm^2\ mol^{-1}$), suggesting that the complex is 4-coordinate with probably a tetrahedral structure.

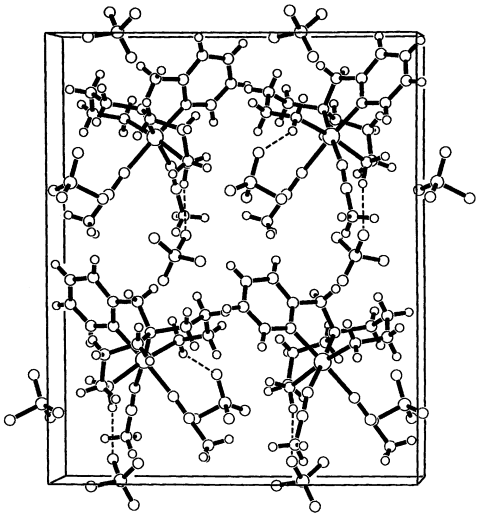

Fig. 3. Packing diagram for the complex $[NiL(MeCN)_2](ClO_4)_2$ showing hydrogen bonding between N3–H...O(3) of the perchlorate anion.

(Received 27 February 1998; accepted 29 May 1998)

Abstract—The extended Hückel molecular orbital (EHMO) calculations have been carried out using cluster approach to polyoxo anions, i.e. calculations have been done for a single octahedron MO_6 of different symmetry and results have been used to analyze ^{183}W and ^{17}O NMR spectra. Using five d→d* energy differences for the individual WO_6 the sum $\Sigma 1/(E_d \rightarrow E_d^*)$ have been calculated and plotted against the ^{183}W chemical shift (from +258 to −670 ppm) for corresponding type of tungsten atom and practically a linear correlation between two parameters have been observed. This points out the electronic nature of the ^{183}W chemical shift. Similar correlation have been found for the ^{17}O NMR chemical shifts (−90 to +800 ppm) when the plotted against product of the R^{-3} $\Sigma 1/(E_p \rightarrow E_p^*)$ where the R^{-3} bond length of the corresponding W–O bond. Increasing the ^{183}W nuclear magnetic shielding with the calculated electron population on tungsten atom for closely related anions has been observed, but no general tendency between δ and the calculated electronic charge if the symmetry of polyhedron is changed is expected. © 1998 Elsevier Science Ltd. Keywords: polyoxometalates; Hückel molecular orbital calculations; ^{183}W and ^{17}O NMR.

INTRODUCTION

NMR is a very important method for determining the structure of polyoxometalates both in solution and sometimes in the solid state [1–6]. It is also valuable for studying the electronic structure of this rather important class of inorganic complexes from the scientific and practical points of view [1–8]. However, in many cases the interpretation of the results lacks understanding the nature of the chemical shifts of the ^{17}O, ^{59}Mo and ^{183}W NMR, the nuclei which constitute a polyoxoanion.

There are various approaches for calculation of the magnetic shielding and *ab initio* is considered as the most reliable method to calculate the paramagnetic and diamagnetic terms, but it is limited to rather small molecules [9]. The ^{95}Mo NMR chemical shifts and charges on atoms have been calculated for simple and mixed tetrahedral anions $MoX^{2-}{}_4$ where $X=O^{2-}$, S^{2-} and Se^{2-}, including *ab initio* approach [9–15] and the gradual increase of the paramagnetic term with increasing number of S has been found. Though the *ab initio* results did not agree with each other, the calculations have shown the importance of the charge transfer transitions from bonding to antibonding MOs involving mainly the d-orbitals of the molybdenum atom [9–11]. However, large discrepancies in the calculated and observed values have also been

* Author to whom correspondence should be addressed. E-mail: leo@surface.phyche.msk.su.

found if the coordination polyhedron MoX_n changes [14]. The use of the *ab initio* method for the calculation of the chemical shifts for large molecules and particularly the ones having a heavy nucleus such as the ^{183}W one in a distorted polyhedron, seems to present a cumbersome problem, especially if the relativistic correction is needed [16].

It is known that the chemical shift of nuclei, other than proton is mainly determined by the change of the paramagnetic contribution which may be estimated by the Jameson–Gutowsky equation involving the mean excitation energy ΔE and the imbalance of the electrons in the valence shell [17]. In a case of d^0 cations ΔE corresponds to the lowest charge transfer (LCT) band.

Importance of the paramagnetic contribution determining the changes in the observed ^{17}O and ^{183}W NMR chemical shifts has been shown by linear correlation between the ^{17}O NMR shifts for polyoxometalates (Ta, Nb, W, Mo, V) [18] and ^{183}W chemical shifts for a number of polyoxotungstates $XW_{12}O_{40}^{x-8}$ with the Keggin structure [19] and the wavelength of LCT band observed in the UV-spectra of solutions for the corresponding polyoxoanion.

Earlier, an analysis of the ^{183}W NMR shifts and geometry parameters [20] of known structures enabled to find the following general tendency: decreasing the averaged bondlength of individual distorted octahedron having one W═O terminal bond and increasing the number of the vertex bridging oxygen atoms result in larger shielding and in decreasing the ^{183}W NMR shifts. But the data for some other geometry do not follow the observed trend and moreover both the ^{17}O and ^{183}W chemical shifts for polyoxotungstates other than Keggin structure do not correlate with the LCT wavelength [18, 19].

Keeping in mind that according to *ab initio* method the ^{95}Mo NMR chemical shift is inversely proportional to the calculated energy separation between the ground and the excited states or between bonding to antibonding MOs ($d \rightarrow d^*$ transitions) [10–12] we have calculated MO energy diagrams with the extended Hückel MO (EHMO) method for MoX^{2-}_4 (where $X = O^{2-}$, S^{2-}, Se^{2-}) and obtained practically linear correlation between the observed ^{95}Mo NMR chemical shifts and the sum $\Sigma 1/E_n$ where E_n is the energy separation between bonding and five antibonding MOs, like it has been found in the *ab initio* calculations [10–12]. We believe it is not surprising at first, because often the step-like substitution of one ligand by other results in the gradual change of the MO energies which will correlate with the observed chemical shifts. Moreover, the observed ^{95}Mo NMR chemical shifts correlates with the averaged M–X bondlengths, as well. Second, the correlation shows that use the energy separation may be good substitute for the actual excited states which are important in the paramagnetic shielding. From this we have assumed that using EHMO calculations for understanding the ^{183}W NMR chemical shifts may be useful. What is more important is to follow the trend in the ^{183}W NMR chemical shifts within range of -700 to 260 ppm, if the geometric configuration is changed with the *same* type of ligand. In the chemical shift pattern there are some peculiarities which are difficult to explain without understanding its nature.

In this paper we would like to show the possibility to find a general trend in the ^{183}W and ^{17}O NMR chemical shifts characteristic for different types of octahedron WO_6 which may be encountered in the polyoxotungstates using the parameters calculated by the extended Hückel MO method. Surprisingly, such an easy approach has given rather fair correspondence between the observed ^{183}W and ^{17}O chemicals shifts and the calculated parameters for the corresponding type of distorted WO_6 octahedra which constitute a large polyoxoanion. Moreover, the calculation may be extended to consideration of the chemical shifts upon reduction when two electrons are introduced into heteropolyanion whose structure rests unchanged.

MO DIAGRAMS FOR THE DISTORTED OCTAHEDRA WO_6

The EHMO calculations have been carried out using the ICON program [21–23]. The parameters for the calculations are presented in Table 1.

In some attempts to understand the electronic structure of polyoxometalates the EHMO method had been applied for a single regular octahedron (or combination of several octahedra) or for large molecules [24–28]. The present MO diagrams have been calculated for isolated *distorted* octahedra using the real bondlengths and angles found from the X-ray diffraction studies and results of calculations are compared with NMR data.

The isolation of a single octahedron may be justified because in many cases polyoxometalates spectroscopically behave as a sum of several octahedra [29].

In all structures of polyoxo anions the octahedra are strongly distorted because of formation of one or two (practically never three in polyoxo anions) multiple bonds $M{=}O_t$ ($R = 1.69$–1.76 Å), where O_t is the terminal oxygen atom, that, by *trans*-effect, substantially weakens a bond ($M–O_i$) ($R = 2.20$–2.45 Å) in *trans*-position (Figure 1I). When an octahedron has the only terminal $W{=}O_t$ bond, its symmetry is close to C_{4v}. Such configuration is characteristic for complexes of the d^1 cations and for the d^0 and d^1 cations in many polyoxoanions, especially in polyoxotungstates.

However, for most of Mo^{6+} and W^{6+} monomeric complexes the symmetry of MO_6 octahedra is close to C_{2v}, (Figure 1II) resulting from the formation of two *cis* O_2M bonds as more stable configuration using all three d_π orbitals [30].

The distances between the tungsten cation and the bridging oxygen atoms O_c (vertex or corner shared)

Table 1. Ionization potentials, exponents and coefficients

Atom	Orbital	Energy, (eV)	Exponent (coefficient)	Exponent (coefficient)
Tungsten	s	−8.260	1.8900 (1.0000)	
	p	−5.170	1.8500 (1.0000)	
	d	−10.370	0.6454 (1.544)	0.5636 (1.0000)
Oxygen	s	−32.300	2.275 (1.000)	
	p	−12.275	2.270 (1.000)	
Hydrogen	s	−13.600	1.300 (1.000)	

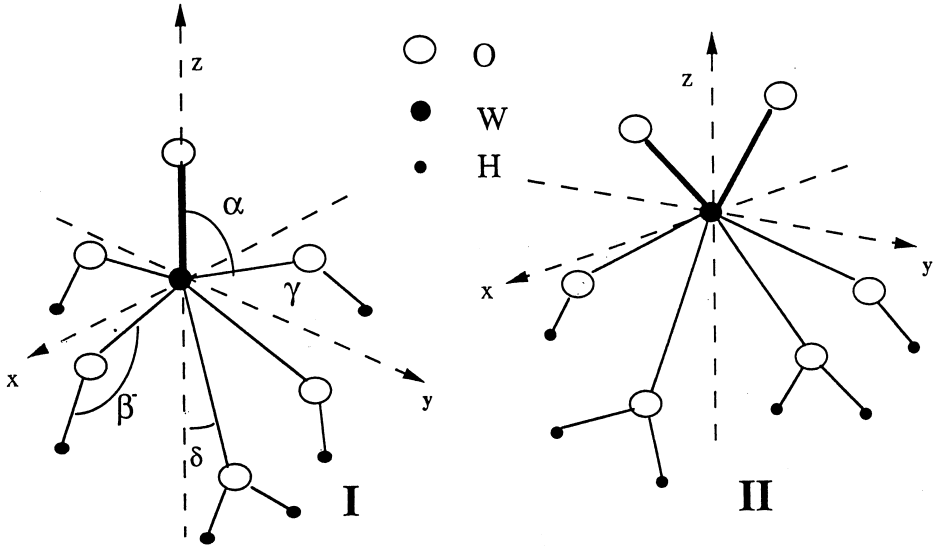

Fig. 1. MO_6 octahedra of C_{4v} (I) and C_{2v} (II) symmetries.

and O_e (edge shared) are in the range of $R = 1.8$–2.0 Å with the angle W–O–W being equal to 150–180° for O_c and 114–125° for O_e, respectively. In the isolated octahedron WO_6 these bridging oxygen atoms are replaced by OH groups ($R_{OH} = 0.94$ Å) to compensate the lack of the adjacent tungsten atoms with the conservation of the angle. The internal oxygen atom O_i is replaced by water molecule. Such presentation may fairly well represent an octahedron in the polyoxometalate frame work. This is confirmed by further EHMO computations using large molecules, though a general gradual stabilization of all antibonding levels has been observed.

The calculation for WO_4^{2-} reveals the expected $d_\pi^* \rightarrow d_\sigma^*$ separation in the MO diagram for tetrahedral configuration. When tetrahedron is converted into a distorted octahedron, its LUMO is stabilized (Figure 2, diagram 0) showing a decrease of HOMO-LUMO separation. Moreover, the calculation for octahedral $OWO(OH)_4OH_2O$ with all bonds (mean for each type) at 90° to each other has showed the difference between the calculated MO diagram with a sequence $d_{xy}^* < d_{xz}^*$, $d_{yz}^* < d_{z^2}^* < d_{x^2-y^2}^*$ and well known and usually accepted MO diagram proposed by Ballhausen and Gray [31] for treating "*yl*" complexes of V, Mo, W (d^1) in the weak ligand field. In their diagram the antibonding orbitals, consisting mostly of metallic *d*-orbitals are found to be in the following order: $d_{xy}^* < d_{xz}^*$, $d_{yz}^* < d_{x^2-y^2}^* < d_{z^2}^*$. Using the geometry adopted in their study, our calculation for $VO(H_2O)_5$ fairly well reproduces the known MO diagram with the coefficient for d_{xy}^* orbital being very close to 1.0. However, in polyoxovanadates as well as in other polyoxometalates, the bond lengths in the bridges M–O–M are much shorter than the V–OH_2 distance as supposed for *penta*aquavanadyl and as a consequence, the position of some MO levels may be changed. The diagram 0 is characteristic for all five cations (V^{5+}, Mo^{6+}, W^{6+}, Nb^{5+}, Ta^{5+}) in the MO_6 octahedron having symmetry close to C_{4v}. The ordering of the energies of the d*-orbitals comes from both the choice of the ligands and the geometry of a polyhedron MO_n.

Actually, the symmetry of each octahedron is deviated from C_{4v}, tungsten atom comes out from the square of the bridging oxygen atoms giving the angle

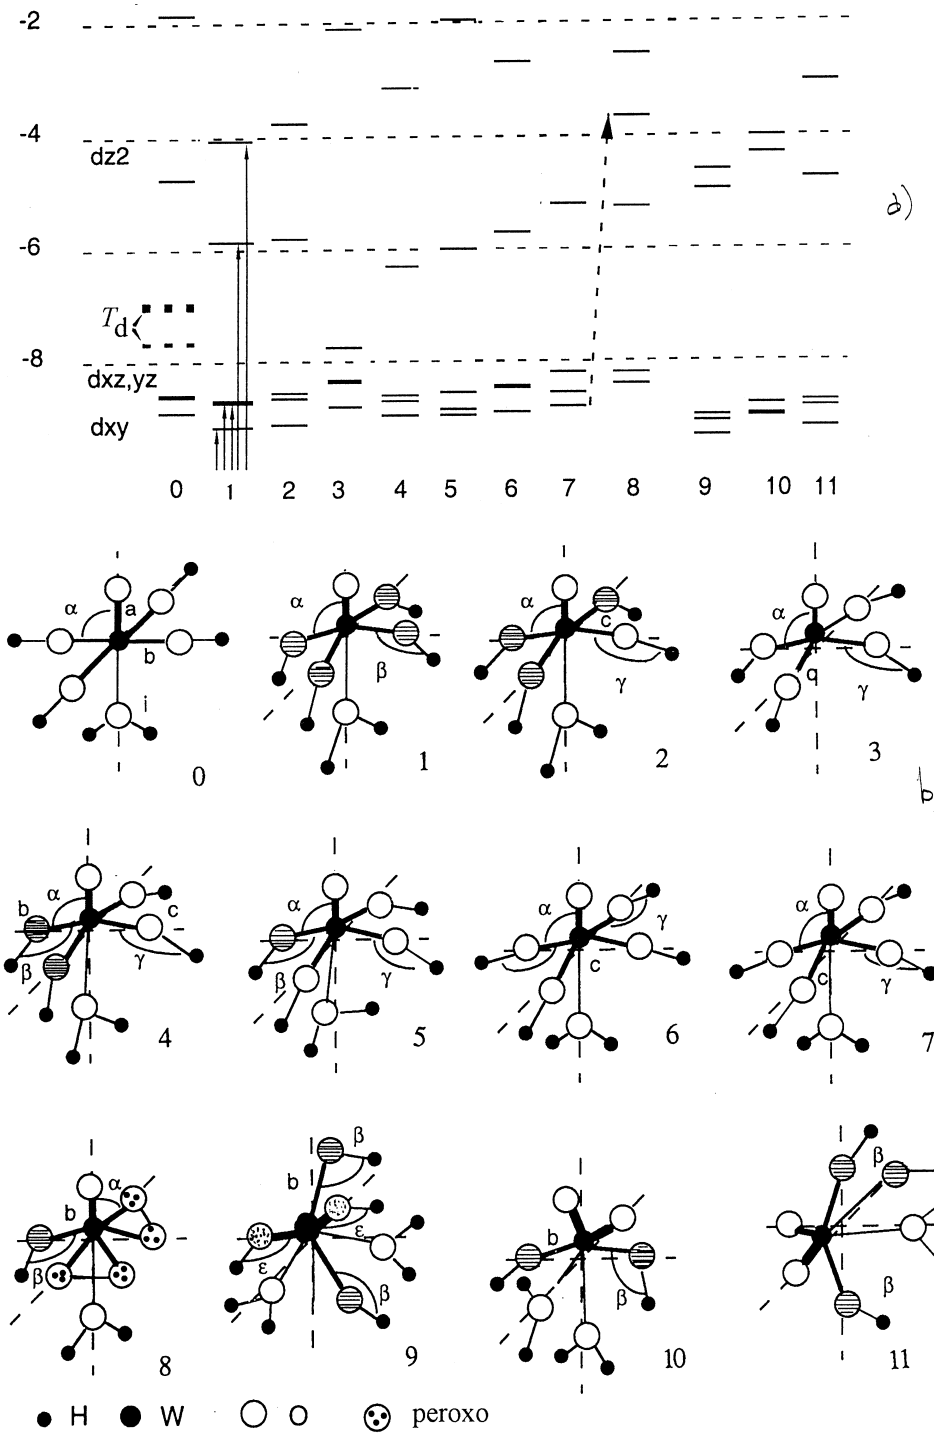

Fig. 2. Calculated MO diagrams (only the virtual antibonding MOs involving mainly the d-orbitals are shown) (a) and distorted polyhedra (b) (α-angle between terminal and bridging (shaded circles for edge-shared and open ones for corner-shared) oxygen atoms, β and γ- angles W–O–W in edge and corner sharing bridges, respectively): (0) for WO_6 – idealized C_{4v} symmetry (broken lines are for WO_4^{2-}); (1) for WO_6 like in $W_6O_{19}^{2-}$ (vertical lines show the transitions from the average bonding to five antibonding levels), (2) for WO_6 in $LnW_{10}O_{36}^{8-}$; (3) for WO_5 like in $P_2W_{21}O_{71}^{6-}$; (4) for WO_6 in $PW_{12}O_{40}^{3-}$, (5) for WO_6 like in the belts of $P_2W_{18}O_{62}^{6-}$, (6) for WOO_4OH_2 in $P_2W_{21}O_{71}^{6-}$; (7) for WO_6 in $P_5W_{30}O_{110}^{14-}$; (8) for WO_7 in peroxotungstates (arrow shows the change of the d_{xy}* position due to substantial interaction with *p*-orbitals of oxygen lying in the plane perpendicular to the *z*-axis; 9, 10, 11) for WO_6 of C_{2v} symmetry $W_7O_{24}^{6-}$-unique W_I with two *pseudo*-terminal bonds (dotted circles) (9), one of four W_{II} (10) and one of two W_{III} (11).

O═W–$O_{c,e}$ larger than 90°. On the other hand, the long bond W–O_i may not be aligned with the axis z, giving the angle ε. Thus the distances W–O and the angles between them are taken from real structures for each type of octahedron with $O_{c,e}$–H direction being aligned with the direction of $O_{c,e}$–W to the neighboring atom, the angles β and γ, respectively.

The change of polyhedron and its symmetry results in the variation of the energies of the antibonding MO levels. The positions of the nonbonding and bonding orbitals are only slightly changing from one case to other with HOMO energy staying fairly constant (Table 2). Therefore, in Fig. 2 only the virtual orbitals, consisting of the metallic d*-orbitals with some admixture of the O2p orbitals and which are more important, are shown.

Without discussing the details of the change in the calculated positions of MOs depending on the geometry we may note that even small deviations from the symmetry close to C_{4v} may change the levels an a result cannot be predicted without calculation. It has been noted as well that the distances noticeably affects the nuclear shieldings calculated by *ab initio* method [14].

Diagram 1 Fig. 2 represents the sequence of MO for an octahedron isolated from highly symmetrical structure $W_6O_{19}^{2-}$ having only edge-shared octahedra [32]. It can be noticed that increasing the angle α between the terminal and bridging oxygen atoms results in decreasing all unoccupied MOs. In the structure of $LnW_{10}O_{36}^{9-}$, there are two types of the tungsten atoms and one which is bound to Ln is taken for calculation (Figure 2, diagram 2) [33]. Each equivalent octahedron WO_6 in the Keggin structure $PW_{12}O_{40}^{3-}$ has two corner and two edge sharing oxygen atoms (Figure 2, diagram 4) [34]. Otherwise, in the Dawson structure $P_2W_{18}O_{62}^{6-}$ two sets (6:12) of WO_6 octahedra [35] one like in the Keggin anion and the other (one of the twelve ones forming two belts) has three corner bridging oxygen atoms. For the latter the MO diagram 5 shows notable change in the position of MOs (Figure 2, diagram 5). The MO diagram 7, calculated for the WO_6 octahedron (all bridging oxygen atoms are used in the corner sharing) which has been found in $NaP_5W_{30}O_{110}^{14-}$ complex, [36] shows large destabilization of MOs.

A peculiar *penta*configuration for one type of tungsten has been found in $As_2W_{21}O_{71}^{6-}$ with rather short W═O_t and four W–O_c bonds [37]. The calculation shows, that such configuration induces the substantial destabilization of all antibonding orbitals, except the $d_{z^2}*$ (Figure 2, diagram 3). As it can be seen, a removal of oxygen from the *trans*-position to O_t stabilizes $d_{z^2}*$ orbital.

In some heteropoly complexes of the types $As_2W_{21}O_{71}^{6-}$, $P_2W_{21}O_{71}^{6-}$ two Keggin fragments may coordinate the tungsten atoms forming WO_6 with four bridging oxygen atoms in the corner positions [37, 38]. A water molecule is really located in *trans*-position to the terminal oxygen atom. This configuration resem-

* Type of polyhedron WO_n in different polyoxotungstates (see text).

bling the idealized one (Figure 2, diagram 0) results in the MO diagram 6.

Finally, the MO diagram 8 is presented for the peroxocomplex of tungsten, where seven coordinations with two peroxogroups located in a plane perpendicular to the W=O$_t$ bond are found [39]. The most noticeable feature is the strong interaction of the W5d$_{xy}$ orbital with the corresponding O2p orbitals, lying in the *xy*-plane. This induces the strong destabilization of the d$_{xy}$* (noted by an arrow).

Thus, changing of a polyhedron geometry results in the variation in energy levels. The calculated data may be compared with the observed chemical shifts.

ENERGY DIFFERENCE BETWEEN OCCUPIES AND UNOCCUPIED MO AND ^{183}W NMR CHEMICAL SHIFTS IN POLYOXOTUNGSTATES

Nuclear magnetic shielding is usually represented as a sum of the diamagnetic, σ^{dia} and paramagnetic, σ^{para} terms [9]. The change in NMR chemical shifts is determined mainly by the paramagnetic term that depends on the excited states of a molecule [9–11]. This is clearly seen in Fig. 3 where ^{193}W chemical shifts for the Keggin anions and ^{17}O chemicals shifts for the terminal and bridging oxygen atoms are plotted against the LCT wavelength (O→M transition) measured in the UV spectra of the Keggin $XM_{12}O_{40}^{x-8}$ anions and isopolyanions $M_6O_{19}^{n-}$. However, if the anions having different structures are compared, no correlation is observed, showing that this optical transition does not contribute much to the observed chemicals shifts.

According to the sum-over-state perturbation theory the paramagnetic term is determined by [10, 11]

$$\sigma_{para} = -\frac{\mu_0 e^2}{8\pi m^2}\sum_n \langle 0|\sum_k r^{-3}{}_k L_{kl}|n\rangle\langle n|\sum_k L_{ku}|0\rangle + \langle 0|\sum_k L_{ku}|n\rangle\langle n|\sum_k r^{-3} L_{kl}|0\rangle/(E_n - E_0),$$

where $|0>$ and $|n>$ denote the ground and excited states wave functions, respectively and E_0 and E_n their energy with r and L being the distance of an electron from the origin and the angular momentum operator around nucleus under study. As Nakatsuji *et al.* [10, 11] have shown, the denominator is the most important in the ^{95}Mo shifts. Thus, σ^{para} is determined by the magnetically dipole-allowed d→d* transitions (the charge transfer from the bonding MO involving d$_\pi$ and d$_\sigma$ metallic orbitals to antibonding MO involving d$_\pi$* and d$_\sigma$*), which usually lie in the far UV-region and do not correspond to HOMO-LUMO separation. For rather distorted MO_6 configuration many transitions are possible, resulting in different contributions to the paramagnetic term and hence to the observed chemical shift. Therefore this should bring about great difficulties in the calculation of the magnetic nuclear shielding. Though EHMO cannot afford the excited states, we believe that the energy separation between the bonding and antibonding levels may fairly represent the excited states of a molecule. So in our case we have simplified the problem and calculated the weight average energy, E_d, of the "effective" bonding MO orbital involving both d$_\pi$ and d$_\sigma$ atomic orbitals using their coefficients and the corresponding calculated energy. As showed calculations, the difference between these bonding *d* orbitals much less then between the antibonding orbitals, so called the ligand field splitting. Then five transitions from this d orbital to five antibonding MO involving W5*d** orbitals (E_d→E(d$_{xy}$), E_d→E(d$_{xz}$), E_d→E(d$_{yz}$), E_d→E(d$_{z^2}$) and E_d→E(d$_{x^2-y^2}$) have been calculated and taken into account.

So in simplified form the paramagnetic term will be proportional [40]

$$\sigma_{para} \propto -r^{-3}\sum \Delta E^{-1}\langle 0|L^2|0\rangle = -r^{-3}\Lambda\langle 0|L^2|0\rangle$$

where $\langle 0|L^2|0\rangle$ is the angular imbalance of the charge and $\Lambda = \Sigma\Delta E^{-1}$ is the sum of five inverse energy separation between the occupied MO (d) orbital and five antibonding MOs involving W5d* Table 2. At present we accept that r^{-3} does not change much throughout a series because the mean bond length R_{W-O} for each octahedron is only slightly changed [20].

Since the antibonding MO's participate both in the magnetic and optical dipole-allowed transitions, for very closely related molecules the chemical shifts may fairly well correlate with the wavelength, λ, or $1/E_{gap}$ (HOMO-LUMO separation). That is why linear correlation between the chemical shifts, δ and λ have been found for MX4n- anions [13, 14] and for polyoxoanions (Fig. 3). But as we have mentioned some points do not fit the correlations because the HOMO-LUMO separation is not important contribution to the paramagnetic term for different symmetries. So for all studied polyhedrons with one terminal bond the Λ values have been calculated and compared with the observed ^{183}W NMR chemical shifts.

The most deshielded tungsten (58 ppm) is observed in $W_6O_{19}^{2-}$ where each WO_6 is linked only by edges. [41] The replacement of one bent W–O–W by W–O–Ln with larger angle in $LnW_{10}O_{36}^{n-}$ results in shielding. [42] Further shielding is observed with increasing the number of the corner sharing oxygen atoms in the Keggin [18, 41], the Dawson [19] and $NaP_5W_{30}O_{110}^{14-}$ anions. [36] The most shielded W is observed in peroxocomplexes with the chemical shift reaching −690 ppm [39]. *Penta*coordinated tungsten atom gives the resonance line in the common range at −40 ppm [37, 39].

Practically linear correlation between the calculated Λ for the individual octahedra, as well as for *penta*- and *hepta*coordinations and the ^{183}W NMR chemical shifts, δ, measured for the corresponding polyoxotungstates is observed [Fig. 4(a)]. It is noteworthy,

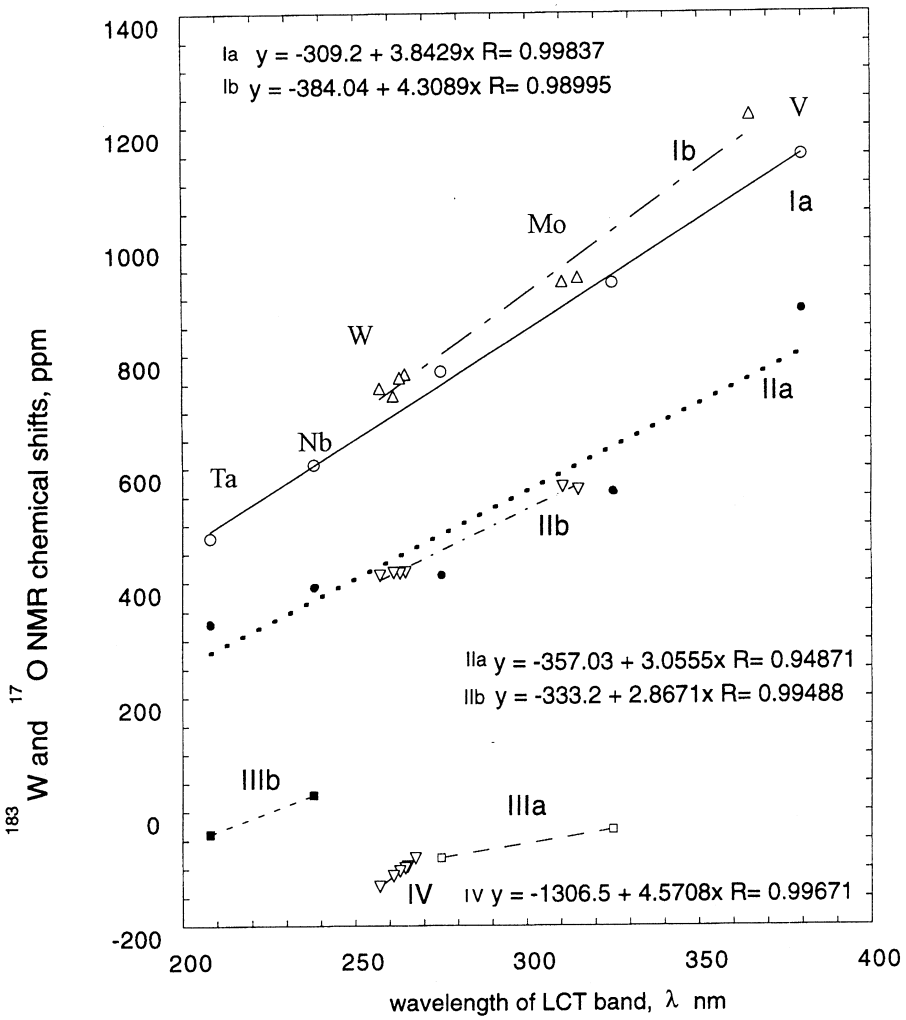

Fig. 3. Correlations between ^{17}O and ^{183}W NMR chemical shifts of different polyoxoanions and the wavelength, λ, of the lowest charge transfer observed in the UV spectra. (Trends Ia and IIa; the chemical shifts for the terminal and bridging oxygen atoms for M6O19*n*-anions, IIIa and IIIb-trends for the internal oxygen atoms in Mo, W and Nb, Ta anions, respectively. Trends Ib and IIb; ^{17}O NMR chemical shifts for the terminal and bridging oxygen atoms of the Keggin anions $XW_{12}O_{40}^{n-}$ and trend IV, ^{183}W NMR in $XW_{12}O_{40}^{n}$ anions, respectively).

that using only the lowest energy separation, for example $d \rightarrow d_{xy}^*$ for any type of octahedron, or the sum of two lowest transitions do not result in the nice correlation. So the paramagnetic term, if we want to compare different symmetries, should include all five transitions and not only the lowest ones, though they certainly dominate.

Additional confirmation of the importance of the $d \rightarrow d^*$ transitions in the chemical shifts has been obtained from MO calculations for the individual octahedra WO_6 with two terminal oxygen atoms (*cis*-MO_2 and symmetry close to C_{2v} as shown in Fig. 2II). Such WO_6 with different degree of distortion are observed in $W_7O_{24}^{6-}$ [43–45], and other polyoxotungstates. The former gives three lines with the 1:4:2 intensity ratio in the ^{183}W NMR spectrum [46, 47]. Corresponding MO diagrams 9–11 Fig. 3 reflect the changes in the coordination sphere with the unique WO_6 (diagram 9) which has two *pseudo*-terminal bonds W=O and reveals the highest chemical shift observed for this type of octahedron (+259 ppm). As we can see, these two points satisfy the correlation except for the unique type of tungsten, whose chemical shift is slightly above, but nevertheless the correlation reasonably explains unusual large shift for this unique tungsten in $W_7O_{24}^{6-}$.

It is encouraging that such a simple approach gives the possibility to assign the observed NMR lines when crystallographic parameters are known and allow to explain some trends in ^{183}W NMR chemical shifts.

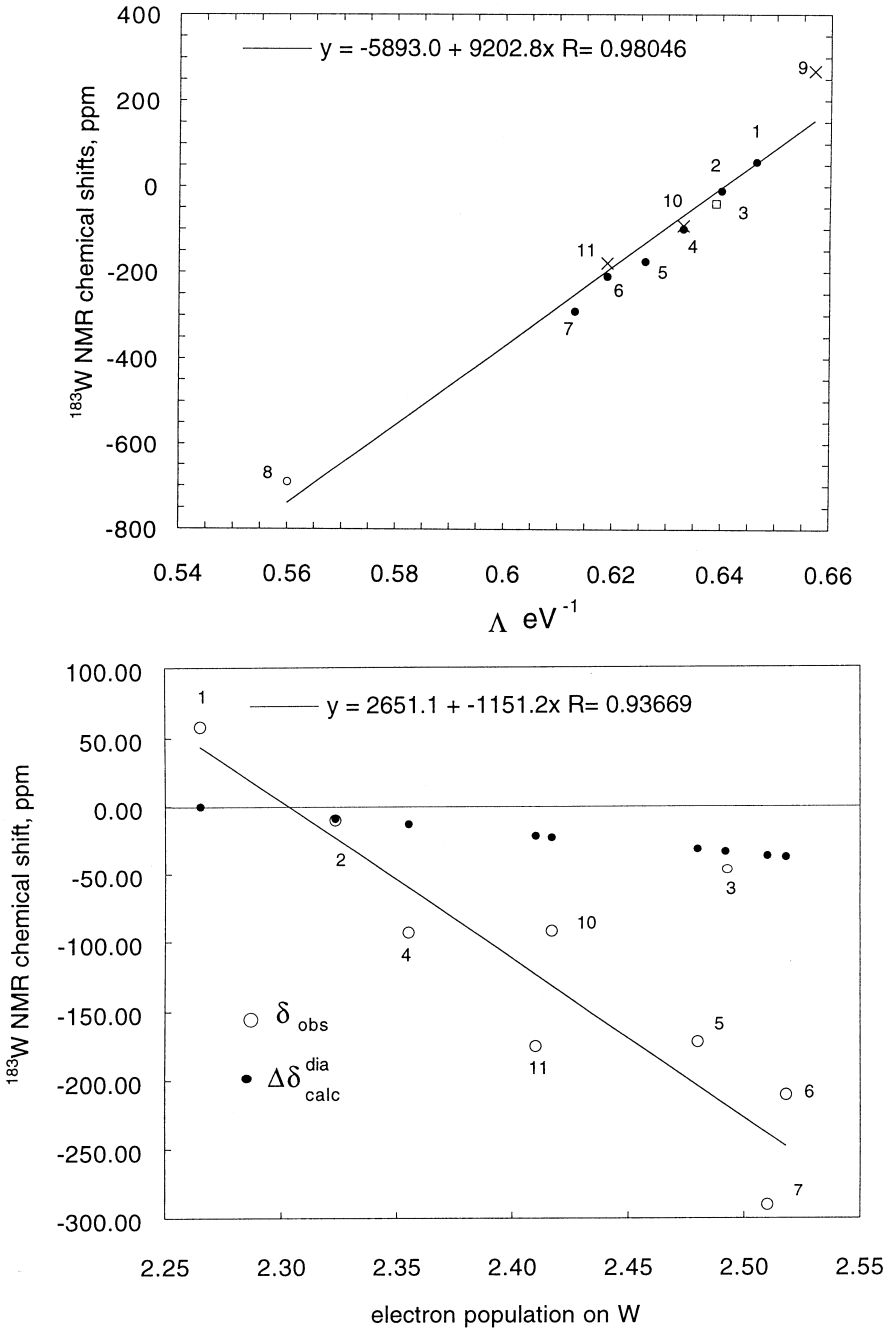

Fig. 4. (a) Correlation of ^{183}W NMR chemical shifts (δ) and the calculated $\Sigma E^{-1}(\Lambda)$ involving separation between occupied and vacant MO (d−d*), involving mainly the W5d and O2p orbitals. (b) Plot between the ^{183}W NMR chemical shifts (δ) and the change of the calculated diamagnetic term, (black circles) against the calculated electron population q, on tungsten atoms.

THE CHEMICAL SHIFTS AND THE CHARGE ON THE TUNGSTEN ATOM

The correlation clearly shows that the excited states contribute considerably to the observed ^{183}W chemical shifts. In some way, the correlation between the ^{183}W shifts, δ and the mean bond length W–O in WO_6 points out a certain dependence of the excited states on the ground state [20]. We may assume that in some extent the ground state determines the excited states and therefore a correlations between δ and a certain ground state property may be observed.

In this connection we have plotted of the measured ^{183}W shifts, δ and the calculated electron population

on tungsten atoms [Fig. 4(b)]. In general, an increase of the negative charge on tungsten results in its shielding that goes parallel to decreasing Λ. Despite some approximations in the calculations of the electron population given by EHMO method, these trends may be used in discussing the chemical shifts of different atoms in complex molecules. For estimation of the effect of the charge we may use the calculated charges and formula given by Malli and Froese [48]. The possible changes in the diamagnetic shielding may be reach 30 ppm. [Fig. 4(b), black points].

Ab initio [10, 11, 14, 15] and EHMO calculations of the charges on molybdenum for $MoO_{4-x}S_x^{2-}$ result in the opposite trend, increasing a gross electron population in the Mo4d orbitals results in the nuclear deshielding. On the contrary, the ^{17}O NMR shifts increase with decrease of the negative charge on oxygen. [13, 14] However, it should be mentioned that the correlation between the chemical shifts and the charges for nuclei other than protons, like presented here and elsewhere [13–15] may be fortuitous and sometimes misleading. The real $\Delta\delta$ depending on the charge may be quite small and may monotonically increases or decreases within a consecutive series adding to or subtracting from much larger values induced by the paramagnetic shielding. The points 3, 11 and 12 in Fig. 4(b) do not fit a general trend found for octahedra of similar symmetry. No general correspondence between ^{77}Se NMR chemical shifts and computed charges has been found in *ab initio* computation of the chemical shifts [49]. Though certain dependence of the ^{55}Mn NMR shifts on the population in d* orbitals had been shown [50].

^{17}O NMR CHEMICAL SHIFTS AND EHMO CALCULATED PARAMETERS

The approach which has been used in analysis of the ^{183}W NMR shifts may be applied for analyzing the ^{17}O NMR chemical shifts, though some limitations should be born in mind because in the calculation we have used an isolated octahedron, whose bridging oxygen atoms are represented by the corresponding OH group. Nevertheless it is appropriate to consider them because the excited states really determine the paramagnetic contribution, as shown by correlation in Fig. 3. Some strengthening of the terminal bond in the Keggin anions compared with hexametalates is clearly seen from the upper position of line IIa in the plot. It shows that the chemical shift is also depended on the metal–oxygen distance. Usually the exponential dependence between the chemical shifts and bondlength for V–O, Mo–O and W–O is usually found [51–53].

For each oxygen atom the weight-averaged energy of the "effective" O2p orbital has been calculated using the appropriate atomic coefficients and the energies. (Table 3) These values do not change much and therefore the values Λ when the separations between this orbital of a given oxygen atom and antibonding MOs are used, are close to each other for the same octahedron. This explains the three dependencies of the chemical shifts on the same wavelength presented in Fig. 3. So in this case we should take into account the bond distances R_{W-O}. In some extent a change in $R_{W-O}{}^{-3}$ is assumed to be proportional to the r^{-3} value of O2p orbital [54]. Therefore for each oxygen atom we multiply the Λ value by the corresponding R^{-3} Table 3 and the observed chemical shifts of three different anions, $W_6O_{19}^{2-}$, $LnW_{10}O_{36}^{9-}$, $PW_{12}O_{40}^{3-}$ and $W_7O_{24}^{6-}$ are plotted against product ΛR^{-3} [Fig. 5(a)]. Once again we have got a fairly linear correlation between two values showing the importance of the electronic origin in the change of the ^{17}O NMR chemical shift. Here we can compare some puzzling results when the shielding of both ^{183}W and ^{17}O nuclei is increasing when passing from $W_6O_{19}^{2-}$ to $LnW_{10}O_{36}^{9-}$ with decreasing Λ, but for $PW_{12}O_{40}^{3-}$ increasing the tungsten shielding (less Λ) corresponds to decreasing oxygen shielding. Namely the term R^{-3} brings about larger values of $R^{-3}\Lambda$ explaining such unexpected trend.

From this position we can come back to Fig. 3 and replot the actual data on the ^{17}O chemical shifts against λR^{-3}, (bondlength W–O and the LCT band with the maximum wavelength, λ, for a number of polyoxotungstates). Linear correlation is observed [Fig. 5(b)] and it validates using this isolated octahedron approach. Extrapolation of the plot $\delta/\lambda R^{-3}$ to zero gives the diamagnetic contribution which is close to the calculated one -350 ppm [48]. It is noteworthy that the point for WO_4^{2-} lies within the observed trend, showing the small influence of the neighboring tungsten atoms of a polymeric structure on the diamagnetic contribution.

As for the charges on the oxygen atoms, their values should be considered when the calculated data for the whole anions are available. It is noteworthy that the internal oxygen atoms reveal some effect on the chemical shifts depending on the overall charge on the polyoxometalates $M_6O_{19}^{n-}$ Fig. 3. Increasing from -2 for W and Mo anions (trend IIIa) to -8 for Ta and Nb anions (trend IIB) results in the positive shift, but it needs special consideration.

CONCLUSIONS

The present calculations of the electronic structure using individual WO_6 octahedra of different symmetries have shown a substantial influence of the local geometry on the position mainly of the antibonding levels. Strong interaction between oxygen and tungsten markedly destabilizes the d_π* and d_σ* orbitals. Despite certain limitations and approximations the practical linear dependence ^{183}W and ^{17}O NMR chemical shifts on the sum of the inverse energies of the five transitions from bonding to antibonding MO points out the electronic nature of the chemical shifts.

[a] Broad shoulder in the UV-spectrum deconvoluted into two components and assigned to different W atoms, with 256 nm being attributed to 8 WO_6 linked to La.

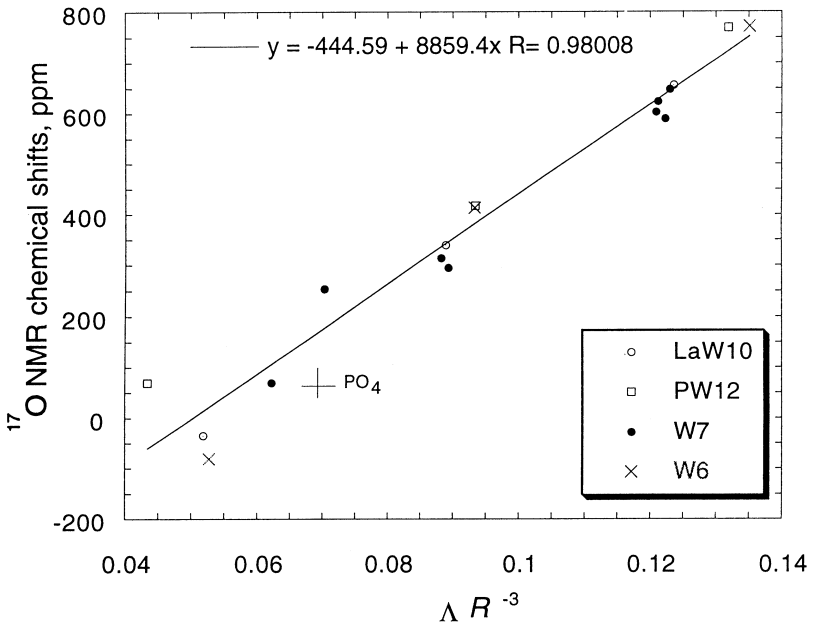

Fig. 5. (a) Correlation between the observed ^{17}O NMR chemical shifts and calculated $R^{-3}\Lambda$ for different types of the oxygen atoms in $W_6O_{19}^{2-}$, $LaW_{10}O_{36}^{9-}$, $PW_{12}O_{40}^{3-}$ and $W_7O_{24}^{6-}$. (b) Plot of the observed ^{17}O chemical shifts and the value $\lambda x R^{-3}$, where λ is the wavelength of the observed lowest charge transfer, O–W (x for WO_4^{2-}) for $W^6O_{19}^{2-}$ (W_6), $PW_{12}O_{40}^{3-}$ and $H_2W_{12}O_{40}^{6-}$ (XW_{12}) and $LaW_{10}O_{36}^{9-}$ (LaW_{10}) anions.

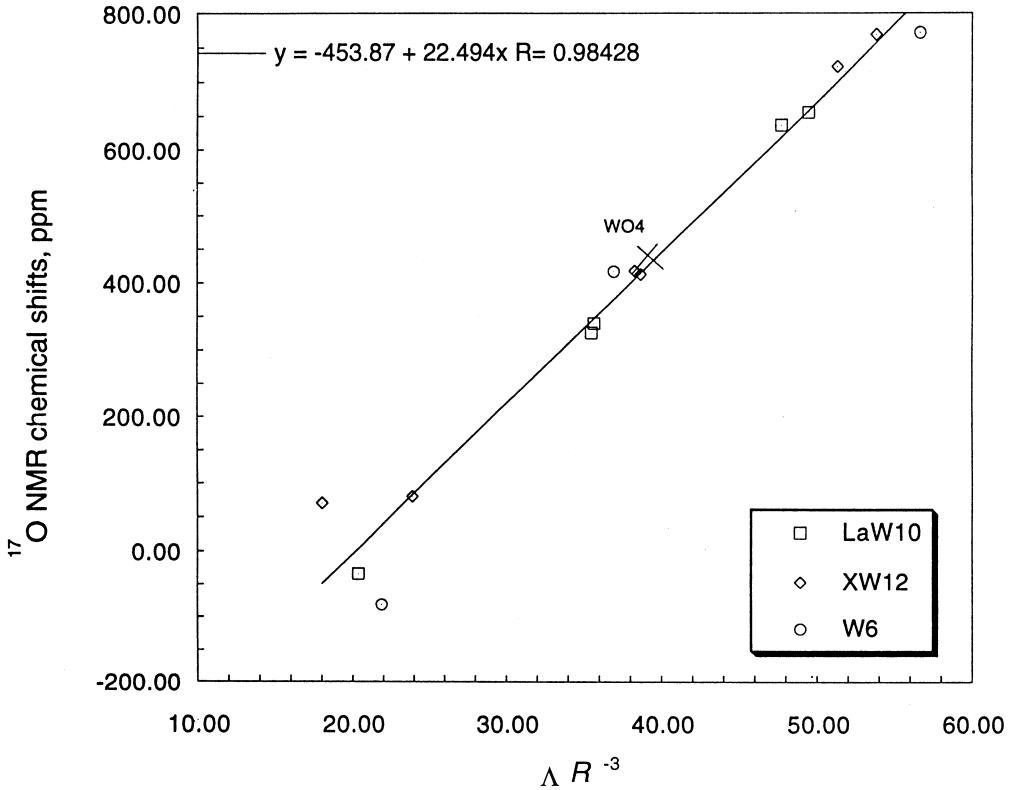

Fig. 5—*continued.*

Even using a distorted polyhedron isolated from a polymeric structure may explain some unexpected chemical shifts. The similar situation has been observed when a cluster approach is used to study the ^{51}V NMR shift in polyoxovanadate with the help of the SOS density functional perturbation theory [55]. We currently try to apply the EHMO for large polyoxoanions to get more insight in the nature of the chemical shifts. Heteropolyanions present an interesting case when one or several addenda cation may be reduced to 5+ or 4+ oxidation states. This reduction may induce large deshielding of the metal nuclei and this case using EHMO approach will be considered elsewhere.

As calculations show, that local geometry of individual in large anions such as $CeW_{10}O_{36}^{8-}$, $W_{10}O_{32}^{4-}$ and $W_7O_{24}^{6-}$ markedly affects the antibonding MO levels, revealing expected trends obtained from the calculations using single octahedron approach. That is why the isolation of one octahedron with its real geometrical characteristics with the linear correlation between the observed chemical shifts and the calculated parameters may be a fairly justifying approach for the qualitative estimation of the chemical shift of a given atom in a molecule. Moreover, using the average energy approach in the calculation made for large polyoxoanions allows to understand some mute points in the chemical shift pattern.

As *ab initio* calculations have shown that the paramagnetic shielding is very critical to the input parameters and by adjusting one may get the full compatibility of the observed and calculated chemicals shielding, especially in a gradual substitution of one ligand atom for other one. So we believe that using "good" input data which may give full correspondence with the observed transitions in the optical spectra, the correlation like we have observed will be much better.

(Received 15 April 1998; accepted 11 June 1998)

Abstract—A group of stable ruthenium(II) and (III) mixed-ligand tris-chelated complexes of the type $[Ru^{n+}(bpy)(L)_2]^{z+}$ (**1**–**8**, $n=2$, $Z=0$; **9**, $n=3$, $Z=1$) have been synthesized and characterized (bpy = 2,2′-bipyridine; L = anionic form of the ligands, ROC(S)SK, (R = Me, Et, ^{n}Pr, ^{i}Pr, ^{n}Bu, ^{i}Bu, $-CH_2-$Ph) or $(EtO)_2P(S)SNH_4$ or $(Et)_2NC(S)SNa$). The complexes **1**–**8** are diamagnetic and electrically neutral and the complex **9** is one-electron paramagnetic and behaves as 1:1 electrolyte in acetonitrile solvent. The complexes **1**–**8** and **9** display two MLCT transitions near 530, 370 nm and 663, 438 nm respectively. Intra-ligand bipyridine based π–π^* transition is observed near 300 nm. The complexes **1**–**8** exhibit room-temperature emission from the highest energy MLCT band (~370 nm). At room temperature the lifetime of the excited states for the complexes **2** and **8** are found to be 90 and 95 ns respectively. In acetonitrile solution the complexes **1**–**9** show a reversible ruthenium(III)–ruthenium(II) couple in the range $-0.08 \rightarrow 0.40$ V and irreversible ruthenium(III)–ruthenium(IV) oxidation in the range 1.19–1.45 V vs Ag/AgCl. One reversible bipyridine reduction is observed for each complex in the range $-1.70 \rightarrow -1.85$ V vs Ag/AgCl. The presence of trivalent ruthenium in the oxidized solution for one complex **1** is evidenced by the axial EPR spectrum at 77 K. The isolated trivalent complex **9** also exhibits an axial EPR spectrum at 77 K. The EPR spectra of the trivalent ruthenium complexes ($\mathbf{1}^+$ and **9**) have been analyzed to furnish values of distortion parameters ($\Delta(cm^{-1}) \rightarrow \mathbf{1}^+$, 3689; **9**, 3699) and energies of the two expected ligand field transitions ($v_1(cm^{-1}) \rightarrow \mathbf{1}^+$, 3489; **9**, 3497 and $v_2(cm^{-1}) \rightarrow \mathbf{1}^+$, 4339; **9**, 4348) within the t_2 shell. One of the ligand field transitions has been experimentally observed at 4673 cm^{-1} for complex **9** and which close to the computed v_2 value (4348 cm^{-1}).© 1998 Elsevier Science Ltd. INTRODUCTION

Since the discovery of important photo-redox properties of ruthenium–bipyridine complexes, there has been continuous research activity in this area [1–12]. Here the main thrust has been primarily focused on the development of newer ruthenium–bipyridine systems with the perspective of interesting physico-chemical properties. Basic strategies behind all these activities are either to incorporate selective groups within the bipyridine moiety itself or use other types of donor sites along with the ruthenium--bipyridine core to generate mixed-ligand mononuclear or polynuclear complexes to modulate the photo-redox activities of this class of complexes [13–28]. The present work originates from our interest in preparing new mixed-ligand ruthenium–bipyridine complexes of type $[Ru(bpy)(L)_2]$, where L is a sulphur donor ligand which can form a four-membered chelate ring on coordination and in studying the effect of sterically hindered S,S donor ligands L on the redox and spectroscopic properties of the Ru–bpy core. As a part of our program here we have chosen dithiocarbonate, $ROC(S)S^-$; dithiophosphate, $(RO)_2P(S)S^-$ and dithiocarbamate $(R)_2NC(S)S^-$ as ligand L. Herein we report the synthesis of three classes of complexes having RuN_2S_4 chromophore, their spectroscopic and

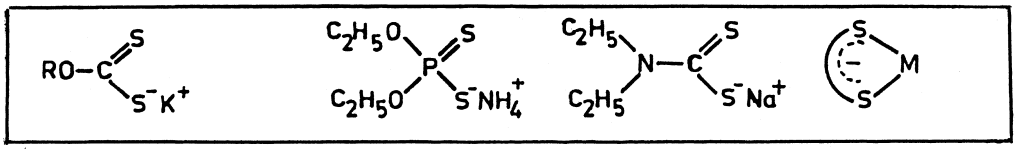
* Author to whom correspondence should be addressed.

electrochemical properties, spectroelectrochemical correlation and preliminary photophysical aspects. To the best of our knowledge this work demonstrates the first example of $[Ru(bpy)(L)_2]$ complexes where L is a sterically hindered four-membered sulphur donor ligand.

RESULTS AND DISCUSSION

Synthesis

Three types of S,S donor ligands, potassium salt of dithiocarbonate (KL^{1-7}), ammonium salt of dithiophosphate (NH_4L^8) and sodium salt of dithiocarbamate (NaL^9) are used for the present study.



The anionic form of the ligands (L^-) bind to the metal ion as bidentate S,S coordinators forming a four-membered chelate ring (ML).

The complexes, $[Ru^{II}(bpy)(L^{1-8})_2]$ (**1**–**8**) and $[Ru^{III}(bpy)(L^9)_2]^+$ (**9**) (bpy = 2,2′-bipyridine) have been synthesized from $[Ru(bpy)Cl_3]$ following the general dechlorination route shown in Scheme 1.

The reactions of potassium salt of dithiocarbonate ligands (KL^{1-7}) with the starting complex $Ru(bpy)Cl_3$ spontaneously result in red colored complexes **1**–**7** at room temperature, whereas the reaction of ammonium salt of dithiophosphate NH_4L^8 with the $Ru(bpy)Cl_3$ requires slight heating to yield the violet colored complex **8**. The crude products **1**–**8** were purified by column chromatography using silica gel column.

The reaction of sodium salt of diethyl dithiocarbamate with the $Ru(bpy)Cl_3$ under stirring condition at room temperature yields green colored cationic complex **9**. The cationic complex **9** has been isolated as perchlorate salt, $[Ru^{III}(bpy)(L^9)_2]ClO_4$.

Although dithiocarbonate (L^{1-7}) and dithiophosphate (L^8) ligands stabilize the ruthenium ion in the complexes **1**–**8** in bivalent Ru(II) state, the corresponding dithiocarbamate complex **9** stabilizes the trivalent Ru(III) state. The chemically and electrochemically generated trivalent Ru(III) congeners of complexes **1**–**8** and bivalent Ru(Il) congener of complex **9** are unstable at room temperature (see later). The bipyridine ligand is known to stabilize the bivalent ruthenium due to its strong π-acidic nature [13–28]. Since all the three types of complexes (**1**–**7**, **8** and **9**) consist of one bipyridine ligand common, the observed metal oxidation state preference in the complexes (**1**–**9**) is therefore naturally originated from the inducted dithio ligands (L^{1-9}).

The stabilization of Ru(III) state in the case of dithiocarbamate complex (**9**) is not clearly under-

stood, however, the inherent electronegativity difference between the N atom of L^9 and oxygen atom of L^{1-7} and the π-acceptor nature of the phosphorus of L^8 might be responsible for the above valence state preference in the complexes **1**–**9**.

The microanalytical data of the complexes are shown in Table 1. The results are in good agreement with the calculated values thus confirming the composition of the mixed-ligand tris-chelates [Ru(bpy)$(L^{1-8})_2$] (**1**–**8**)] and [Ru(bpy)$(L^9)_2$]ClO_4 (**9**). In acetonitrile solution the complexes **1**–**8** do not show any conductivity whereas the complex **9** exhibits 1:1 conductivity (Λ_M, 150 $\Omega^{-1}\,cm^2\,M^{-1}$). Solid state magnetic moment measurements at 298 K indicate that the complexes **1**–**8** are essentially diamagnetic (t_{2g}^6, idealized $S=0$) and complex **9** is one-electron paramagnetic ($\mu_{eff}=1.91\,\mu\beta$) as expected for the 3+ state of ruthenium (low-spin d^5, $S=1/2$).

Spectral study

IR spectra FTIR spectra of the complexes (**1**–**9**) were recorded as KBr discs. Direct comparisons of the IR spectra of **1**–**9** with that of the starting complex [Ru(bpy)Cl_3] indicate that the ν_{Ru-Cl} vibrations near 330 cm^{-1} [29] are absent in the former complexes and new vibrations due to the coordinated ligands L are systematically present in the complexes (**1**–**9**). A very strong and broad vibration at 1098 cm^{-1} and a strong and sharp band at 624 cm^{-1} are observed for the complex **9** due to the presence of ionic perchlorate.

^1H *NMR spectra* In $CDCl_3$ solvent, all the complexes (**1**–**8**) display well resolved ^1H NMR spectra. The spectral data are listed in Table 2 and two representative spectra are shown in Fig. 1. The assignment of the individual proton resonances are made on the basis of their relative intensity and spin–spin structure [30]. All the complexes (**1**–**8**) should have plane of symmetry and this makes each half of the molecule equivalent. In view of the imposed symmetry around the ruthenium center aromatic region of the spectra of complexes (**1**–**6** and **8**) displaying systematically four signals having equal intensities (two doublets and two triplets) (Fig. 1) correspond to one pyridine ring of bipyridine ligand. In the case of complex **7** aromatic region of the spectrum shows additional peaks due to phenyl ring attached to the dithiocarbonate ligand (L^7) (Table 2). The phenyl ring protons are not resolved properly and all the five protons have appeared as one complex signal centered at 7.36 ppm (Table 2), which precluded unequivocal assignment of the signals as doublets or triplets. However, the presence of five phenyl ring protons is clearly observable from the relative intensity of the peaks. Depending on the nature of L aliphatic region of the spectra display distinct signals for O–CH_3, O–CH_2, O–CH, –CH, –CH_2 and –CH_3 protons correspond to one ligand (L) as imposed symmetry makes the two

ligands (L) equivalent in the complexes. In fact the upfield region of the spectra displaying excellent distribution pattern of the aliphatic proton signals (Table 2). In all cases experimentally observed relative ratio of aromatic protons to aliphatic protons matches very well with the calculated values.

Electronic spectra The solution electronic spectra of the complexes (**1**–**9**) were recorded in acetonitrile solvent in the UV–visible region (200–900 nm). The spectral data are listed in Table 1 and the representative spectra are shown in Fig. 2. The absorption spectra of all the complexes **1**–**8** are similar and showing one intense transition in the UV region and two moderately intense transitions in the visible region near 530 and 370 nm. The 370 nm band is associated with a shoulder at the lower energy part near 400 nm (Table 1). The lowest energy bands near 530 and 400 nm can be attributed to $d\pi(Ru) \rightarrow \pi^*(bpy)$ (symmetric) and $d\pi(Ru) \rightarrow \pi^*(bpy)$ (antisymmetric) MLCT transitions [31–36]. The next higher energy band near 370 nm may be due to $d\pi(Ru) \rightarrow L(MLCT)$ transition. The absorption at 300 nm is assigned to π–π^* ligand centered (bpy) transition. It may be noted that the lowest energy MLCT transition of $[Ru(bpy)_3]^{2+}$ appears at 452 nm [37] gets substantially shifted to a lower energy ($\sim$530 nm) on substituting

bpy with dithio ligands, which is in consonance with greater σ-donor and weaker π-acceptor property of L relative to bpy. The electronic spectrum of trivalent ruthenium complex **9** also showing similar three bands but the first two bands are shifted to further lower energy (Table 1). The lowest energy transition at 663 nm is assigned to be the ligand to metal charge-transfer (LMCT) transition as expected for the Ru(III) complexes [38].

Room-temperature emission spectra Emission properties of the complexes (**1**–**8**) were studied in acetonitrile solution at room temperature. The spectral data are listed in Table 1 and the representative spectra are shown in Fig. 3. Excitations of the complexes **1**–**8** near 530 nm (peak position of the lowest energy MLCT band) exhibit very weak emissions, however, excitations near 370 nm (corresponding peak position of the second lowest energy band) result in moderately strong emissions in between 420 to 430 nm (Table 1). The origin of the emissions was further confirmed by the corresponding excitation spectrum of the same solution. It may be noted that the free ligands (KL^{1-7} and NH_4L^8) also showing emissions near 400 nm.

Since both the free ligands (KL^{1-7} and NH_4L^8) and the complexes (**1**–**8**) exhibit emissions around the same positions, the observed emissions for the complexes may therefore be originated from the MLCT band involving primarily the co-ordinated ligands (L).

The lifetime of the excited states of two representative complexes (**2** and **8**) have been determined and are found to be 90 and 95 ns respectively, at room temperature.

Redox properties

All the complexes are electroactive with respect to metal as well as ligand centers. Redox properties of

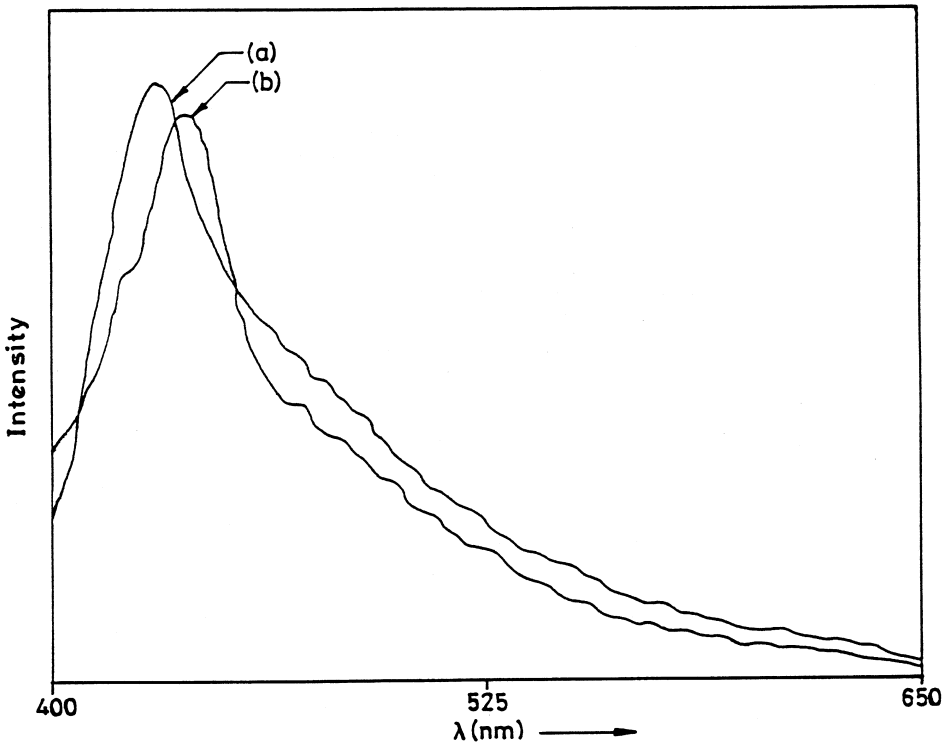

Fig. 3. Emission spectra of (a) $[Ru^{II}(bpy)(L^{8})_2]$, **8** and (b) $[Ru^{II}(bpy)(L^{7})_2]$, **7** in acetonitrile at 298 K.

the complexes have been studied in acetonitrile solvent by cyclic voltammetry (CV) using a platinum working electrode. The complexes (**1**–**9**) display three redox processes in the potential range ± 2.0 V vs Ag/AgCl (tetraethylammonium perchlorate used as an electrolyte, 298 K). Representative voltammograms are shown in Fig. 4. The peak-to-peak separations of the couples lie in the range of 70–90 mV. Reduction potentials data are listed in Table 3.

The ruthenium(III)–ruthenium(II) couple

The complexes **1**–**8** display one reversible oxidation process in the range 0.2–0.4 V and complex **9** exhibits one reversible reduction process at -0.08 V vs Ag/AgCl (Fig. 4) which are assigned to be the ruthenium(III)–ruthenium(II) couple eqn (1) [39].

$$[Ru^{III}(bpy)(L)_2]^{+} + e^{-} \rightleftharpoons [Ru^{II}(bpy)(L)_2] \qquad (1)$$

The one-electron nature of the responses is established by current height and constant potential coulometric data. The presence of trivalent ruthenium in the oxidized solutions of **1**–**8** is confirmed by characteristic EPR spectrum of the ruthenium(III) congener (see later). The formal potential of the couple (eqn (1)) varies depending on the nature of ligands L. Although ruthenium ion in the complexes having dithiocarbonate (**1**–**7**) and dithiophosphate (**8**) ligands stabilizes in 2+ oxidation state, the corresponding dithiocarbamate complex (**9**) stabilizes the trivalent ruthenium ion. The low ruthenium(III)–ruthenium(II) potential ($E_{298}{}^{0} = -0.08$ V) of complex **9** can account for its stabilization in the trivalent state rather than the bivalent state under atmospheric conditions. Thus the electrochemically as well as chemically generated bivalent congener of **9** is unstable in presence of air, spontaneously oxidized to the trivalent complex **9**. Since the reaction takes place particularly under atmospheric conditions the oxygen in air might be responsible for the stabilization of trivalent ruthenium in the complex **9**.

Under identical experimental conditions, the ruthenium(III)–ruthenium(II) reduction potential of $[Ru(bpy)_3]^{2+}$ appears at 1.27 V [31–35]. Thus substitutions of well known π-acidic bpy ligands from the $[Ru(bpy)_3]^{2+}$ core by two dithio ligands, L in the complexes (**1**–**9**) result in decrease of ruthenium(III)–ruthenium(II) potential by 0.9–1.4 V depending on the nature of ligands L. The monoanionic dithio ligands L^{-} decrease the overall charge of the complex cation 2+ in $[Ru(bpy)_3]^{2+}$ to zero in the present complexes (**1**–**9**) and that reduction of overall charge provides further electrostatic stabilization of the oxidized trivalent Ru^{III}–L species. This is possibly developed due to the σ-donor character of the dithio ligands [39]. This substantial decrease in Ru^{III}–Ru^{II} potential while moving from $[Ru(bpy)_3]^{2+}$ to $[Ru(bpy)(L)_2]$ (**1**–**8**) and the reversible nature of the voltammograms (Fig. 4)

indicate the possibility of isolating the trivalent congeners of **1**–**8** under the present mixed-ligand environment.

Although the ruthenium(II)–ruthenium(III) oxidation potentials for the complexes (**1**–**8**) are appreciably low (Table 3), the oxidized trivalent congeners are not stable enough to be isolated (see later).

The complexes (**1**–**9**) exhibit a second irreversible oxidation process in between 1.19–1.45 V vs Ag/AgCl (Fig. 4, Table 3). Although the current height of this

irreversible process is higher than the previous one-electron Ru^{III}–Ru^{II} process, the one-electron nature of the second irreversible oxidation process is established with the help of differential pulse voltammetry (Fig. 4). The second one-electron oxidation process could be due to either Ru^{III}–Ru^{IV} oxidation or oxidation of the thiolato group. Since the potential difference (1.10–1.27 V, Table 3) between the two successive processes ($Ru^{II/III}$–second irreversible oxidation process) in the complexes (**1**–**9**) is comparable well with the reported observed potential difference between the two successive redox processes for the ruthenium center ($Ru^{II/III}$–$Ru^{III/IV}$) in mononuclear systems [40, 41], it may therefore be reasonable to assume the second irreversible oxidation as ruthenium(III)–ruthenium(IV) oxidation. However, the possibility of oxidation of the coordinated thiol group cannot be ruled out. The irreversible nature of the process has precluded its further characterization.

Ligand reduction

All the complexes (**1**–**9**) display one reversible reduction in the range $-1.72 \rightarrow -1.85$ V (Table 3, Fig. 4). The one-electron nature of this couple has been established by the current height and differential pulse voltammetry (Fig. 4). Since the free ligands (KL^{1-7}, NH_4L^8, NaL^9) do not exhibit any ligand reduction within the above mentioned potential range, the observed reduction is therefore considered to be reduction of the coordinated bpy ligand. 2,2′-bipyridine is a well known electron-acceptor center and each bpy can accept two electrons in one electrochemically accessible lowest unoccupied molecular orbital (LUMO) [42–45]. Although two successive one-electron bpy reductions are expected for each of the complexes, in practice one reduction corresponding to eqn (2) has been observed within the experimental potential range (-2 V). The other expected reduction could not be detected presumably due to solvent cut-off.

$$\underset{z=0,\mathbf{1}\text{–}\mathbf{8};\,z=1,\mathbf{9}}{[Ru(bpy)(L)_2]^z} + e^- \rightleftharpoons \underset{z=-1,\mathbf{1}\text{–}\mathbf{8};\,z=0,\mathbf{9}}{[Ru(bpy)(L)_2]^z} \qquad (2)$$

Spectroelectrochemical correlation

Complexes **1**–**8** display lowest energy MLCT transitions of the type $t_2(Ru) \rightarrow$ ligand LUMO (where LUMO is dominated by the diimine function of the bpy ligand) in the range 524–540 nm (Table 1). The reversible ruthenium(III)–ruthenium(II) reduction potentials and the ligand (bpy) reductions are appeared in the ranges $0.23 \rightarrow 0.40$ V and $-1.72 \rightarrow -1.79$ V respectively. Here the MLCT transition involves excitation of the electron from the filled t_{2g}^6 orbital of ruthenium(II) to the lowest π^* orbital of the diimine function. The energy of this band can be predicted from the experimentally observed electrochemical data with the help of eqns (3) and (4) [46, 47].

$$\nu_{MLCT} = 8065(\Delta E^0) + 3000 \qquad (3)$$

$$\Delta E^0 = E_{298}{}^0(Ru^{III} - Ru^{II}) - E_{298}{}^0(L) \qquad (4)$$

Here $E_{298}{}^0$ (Ru^{III}–Ru^{II}) is the formal potential (in V) of the reversible ruthenium(III)–ruthenium(II) couple, $E_{298}{}^0$ (L) that of the ligand reduction and ν_{MLCT} is the frequency or energy of the charge transfer band in cm^{-1}. The factor 8065 is used to convert the potential difference ΔE from V into cm^{-1} unit and the term 3000 cm^{-1} is of empirical origin. The calculated and experimentally observed ν_{MLCT} transitions are listed in Table 3 and there is a linear relationship between the ν_{MLCT} and ΔE (Fig. 5). Here, the calculated values for all the complexes lie within the 900 cm^{-1} of the experimentally observed charge-transfer energies, which are in good agreement with the previously observed correlation in the other mixed-ligand ruthenium–bipyridine and related systems [48–50].

Electrogeneration of trivalent ruthenium congener and distortion parameters

Chemical oxidations of the complexes (**1**–**8**) in acetonitrile solvent by aqueous ceric ammonium sulphate resulted in green solution initially corresponding to the trivalent congeners of the complexes ($\mathbf{1}^+$–$\mathbf{8}^+$). The oxidized complexes are not stable enough to be isolated in the solid state as it get decomposed to an unidentified product.

Coulometric oxidations of the complexes (**1**–**8**) at a potential 200 mV positive to the corresponding E_{pa} of Ru^{II}/Ru^{III} couple in acetonitrile solution at 298 K generated the same green colored trivalent ruthenium-(III) complexes. The observed Coulomb count corresponds to $1e^-$-transfer for all the complexes (Table 3). The resulting oxidized solutions ($\mathbf{1}^+$–$\mathbf{8}^+$) display voltammograms which are superposable on those of the corresponding bivalent complexes (**1**–**8**) which imply that the oxidations here may be stereoretentive in nature. Electrochemically generated oxidized complexes ($\mathbf{1}^+$–$\mathbf{8}^+$) are not stable enough, eventually decomposed to an unidentified product which has precluded their further characterizations. However, in the case of complex $\mathbf{1}^+$ we have been succeeded to record the EPR spectrum by quick freezing the green colored oxidized solution in liquid N_2 (77 K). It exhibits an axial EPR spectrum. The axial nature of the EPR spectrum (Fig. 6) ($g_1 = 2.424$, $g_2 = 2.424$, $g_3 = 1.752$) is characteristic of trivalent ruthenium(III) in axially distorted octahedral environment (low-spin Ru^{III}, $t_{2g}{}^5$, $S = 1/2$) [51, 52].

The green colored isolated trivalent ruthenium-(III)–dithiocarbamate complex **9** also exhibits similar axial EPR spectrum (Fig. 6) ($g_1 = 2.405$, $g_2 = 2.405$, $g_3 = 1.756$). The electrochemical reduction of complex **9** at -0.25 V vs Ag/AgCl resulted in a red-brown colored complex corresponding to the bivalent

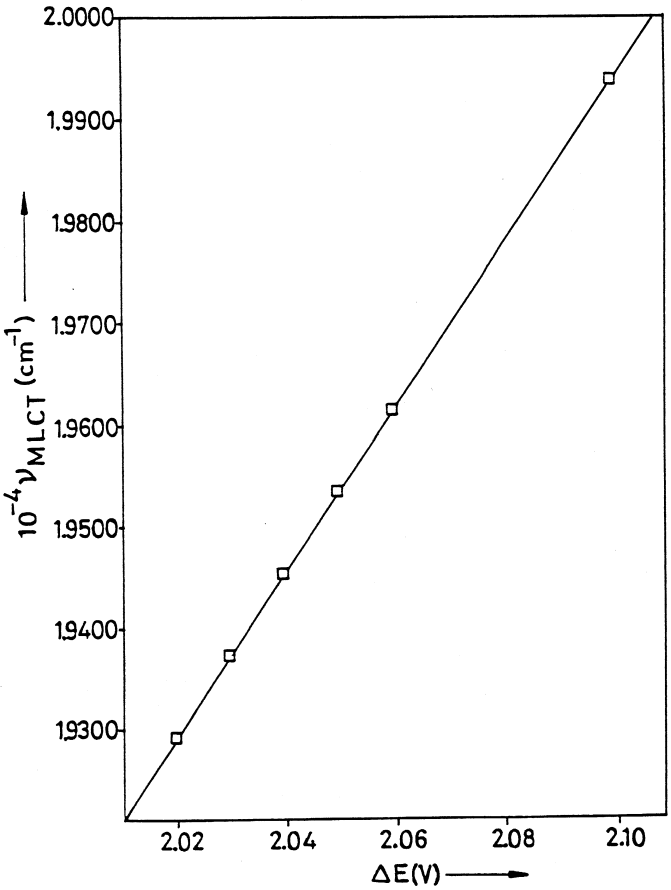

Fig. 5. Least squares plot of the lowest energy metal-to-ligand charge-transfer band (ν_{MLCT}, cm^{-1}) vs the difference in potential (ΔE, V) between $Ru^{II/III}$ couple and the bipyridine reduction.

ruthenium(II) congener ($\mathbf{9}^-$). The reduced species ($\mathbf{9}^-$) shows a voltammogram which is superposable on that of the corresponding trivalent complex **9** which indicates the stereoretentive nature of the reduction process. When the same red-brown reduced solution was coulometrically reoxidized at 0.1 V vs Ag/AgCl, the green colored trivalent complex **9** was formed quantitatively. The chemical reduction of **9** by hydrazine hydrate can also generate the bivalent complex $\mathbf{9}^-$ immediately. The reduced species is unstable under atmospheric conditions, spontaneously oxidizes to trivalent complex **9**.

The theory of EPR spectra of low-spin d^5 complexes are documented in literature [53–57]. The distortion of pseudo octahedral complexes is expressed as the sum of axial (Δ) and rhombic (V) components. The t_2 orbital consists of the components $t_2^0(xy)$, $t_2^+(xz)$, $t_2^-(yz)$. The degeneracy of t_2 orbital is partially removed by axial distortion (Δ), which placed t_2^0 (b) above t_2^+/t_2^- (e). The superimposed (V) then further splits (e) into t_2^+ and t_2^-.

The distortion parameters (Δ and V) and the energies of two optical transitions (ν_1 and ν_2) from ground to upper Kramers doublets can be obtained from the analysis of EPR spectrum using the g tensor theory of low-spin d^5 ions.

The EPR spectrum provides only the absolute g values and so neither their signs nor the correspondence of g_1, g_2 and g_3 to g_x, g_y and g_z are known. There are forty-eight possible combinations based on the labeling (x,y,z) and signs chosen for the experimentally observed g values. For the present case we have chosen the combination $-g_1 = -g_2 > g_3$ (due to axial nature of the spectra g_1 and g_2 are same, Fig. 6) as this particular set gives the orbital reduction factor, $k < 1.0$ The computed values of orbital reduction factor (k), axial distortion (Δ/λ) and the two ligand-field optical transitions (ν_1/λ and ν_2/λ) for the complexes $\mathbf{1}^+$ and **9** are listed in Table 4. The value of spin–orbit coupling constant (λ) of ruthenium(III) is taken as 1000 cm^{-1} [53–57]. In view of the axial nature of the EPR spectra of the complexes, rhombic distortion (V) is found to be zero.

The low energy near-IR spectrum (maximum wavelength scan up to 2500 nm) of the complex **9** (near-IR spectrum of the complex $\mathbf{1}^+$ cannot be checked due to its unstable nature) has been checked and it displays one weak transition at 2140 nm (ε, $M^{-1}\,cm^{-1}$, 60). In

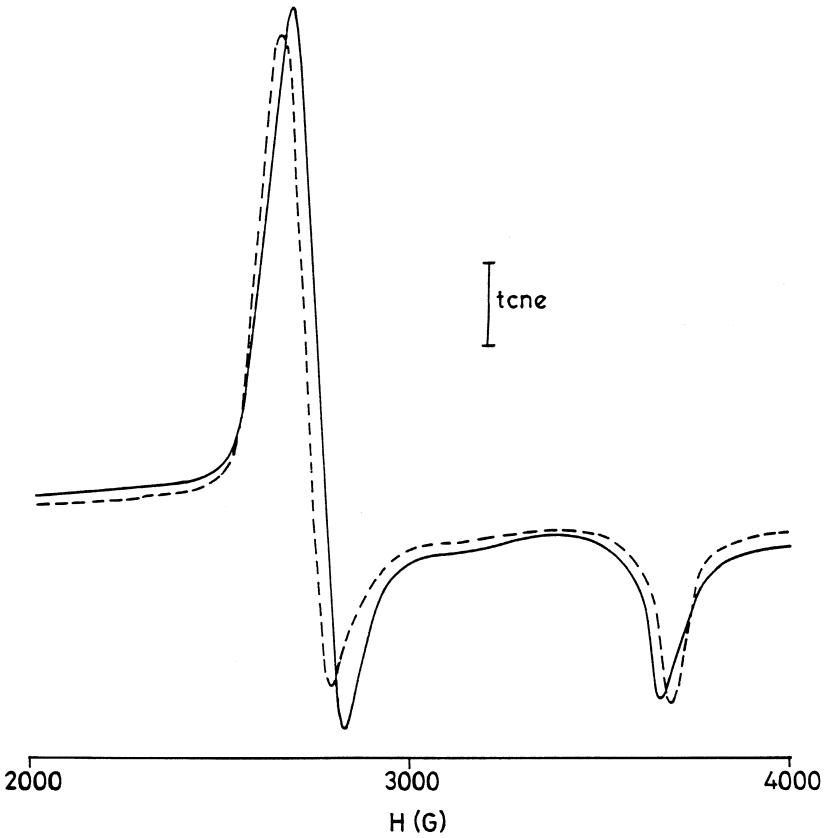

Fig. 6. X-band EPR spectra of coulometrically oxidized complex $[Ru^{III}(bpy)(L^1)_2]^+$, $\mathbf{1}^+$ (- - -) and $[Ru^{III}(bpy)(L^9)_2]\,ClO_4$, **9** (———) in acetonitrile solution at 77 K.

Table 4. The EPR g values[a] and distortion parameters[b]

	Compound

view of the involved approximations in the theory, the agreement between the experimentally observed v_2 and calculated v_2 value is excellent. Due to instrumental limitation (maximum wavelength scan up to 2500 nm) it has not been possible to compare the v_1 band.

CONCLUSIONS

We have thus observed that the dithiocarbamate ligand (L^9) along with bipyridine preferentially stabilizes ruthenium(III) in the complex **9**. However, the similar dithiocarbonate (L^{1-7}) and dithiophosphate (L^8) ligands selectively stabilize ruthenium(II) in the complexes **1**–**7** and **8**. Although the reduced ruthenium(II) congener of the complex **9** and the oxidized ruthenium(III) congeners of the complexes **1**–**8** have been observed in the cyclic voltammetric time scale, the reduced and the oxidized species are not stable enough to be isolated using bulk electrolysis as well as by chemical means. The bivalent complexes **1**–**8** exhibit moderately strong emissions at room temperature which are possibly originated from the dithio ligand based MLCT transitions.

EXPERIMENTAL

Materials

Commercially available ruthenium trichloride (S.D. Fine Chemicals, Bombay, India) was converted to

$RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. The [Ru(bpy)Cl_3] was prepared according to the reported procedure [29]. Other chemicals such as 2,2′-bipyridine, diethyl dithio carbamate and solvents were reagent grade and used as received. Silica gel (60–120 mesh) used for the column chromatography was purchased from S.D. Fine Chemicals, Bombay, India. For Spectroscopic and electrochemical studies HPLC grade solvents were used. Commercial tetraethyl ammonium bromide was converted to pure tetraethyl ammonium perchlorate (TEAP) by following an available procedure [58].

Physical measurements

Solution electrical conductivity was checked using a Systronic conductivity bridge, 305. Electronic spectra (900–200 nm) were recorded using a Shimadzu UV 160 spectrophotometer. Near-IR spectrum was recorded by using a Hitachi 330 spectrophotometer. Infrared spectra were taken on a Nicolet spectrophotometer with samples prepared as KBr pallets. Magnetic susceptibility was checked with a PAR vibrating sample magnetometer. ^{1}H NMR spectra were obtained with the use of 300 MHz Varian FT-NMR Spectrometer. Cyclic voltammetry and coulometric measurements were carried out using a PAR model 273A electrochemistry system. A platinum wire working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode were used in a three-electrode configuration. TEAP was the supporting electrolyte and the solution concentration was $\sim 10^{-3}$ M. The half wave potential $E_{298}{}^0$ was set equal to 0.5 ($E_{pa} + E_{pc}$), where E_{pa} and E_{pc} are anodic and cathodic cyclic voltammetric peak potentials respectively. The scan rate used was 50 mV s^{-1}. A platinum wire gauze working electrode was used in coulometric experiments. All electrochemical experiments were carried out under dinitrogen atmosphere and are uncorrected for junction potentials. EPR measurements were made with a Varian model 109 E-line X-band spectrometer fitted with a quartz dewar for measurements at 77 K (liquid nitrogen). The spectrum was calibrated by using tetracyanoethylene (tcne) ($g = 2.0023$). The elemental analyses were carried out with a Carlo Erba (Italy) elemental analyzer. Solution emission properties were checked using a SPEX-fluorolog spectrofluorometer.

CAUTION! Perchlorate salts of metal complexes are generally explosive. Care should be taken while handling such complexes.

Treatment of EPR data

An outline of the procedure can be found in our recent publications [38, 59]. We would like to note that a second solution also exists that is different from the chosen one, having small Δ, γ_1 and γ_2 values. The experimentally observed near-IR result clearly eliminates this solution as unacceptable.

Synthesis of ligands and complexes

The ligands KL^{1-7} and NH_4L^8 were prepared by following the reported procedures [60, 61].

The complexes **1**–**7** were synthesized using a general method. Yields varied in the range 80–85%. Specific details are given for one representative case.

(2,2′-*bipyridine*) *bis*(*O-ethyl dithiocarbonate*) *ruthenium*(*II*) [Ru(bpy)$(L^2)_2$] (**2**). Ru(bpy)Cl_3 (100 mg, 0.275 mmol) was dissolved in 20 cm^3 of methanol and stirred for 10 min. To this solution, the ligand KL^2 (132 mg, 0.825 mmol) was added. The initial brown solution of Ru(bpy)Cl_3 immediately turned to red color. The progress of the reaction was monitored periodically by TLC. The solvent was then evaporated under reduced pressure and the crude product was then purified by chromatography on a silica gel (60–120 mesh) column. The pure complex (**2**) was eluted with benzene. On removal of the solvent under reduced pressure fine crystalline complex [Ru(bpy)$(L^2)_2$] was obtained. Yield: 82%.

The complex [Ru(bpy)$(L^8)_2$] (**8**) was prepared by following the above procedure except it requires heating for approximately 30 min after the addition of NH_4L^8 ligand in the starting complex. Yield was 85%.

(2,2′-*bipyridine*) *bis*(*diethyldithiocarbamate*) *ruthenium*(*III*) *perchlorate* [Ru(bpy)$(L^9)_2$]ClO_4 (**9**) Ru(bpy)Cl_3 (100 mg, 0.275 mmol) was dissolved in 20 cm^3 of methanol and stirred for 10 min. To this solution, the ligand NaL^9 (180 mg, 0.825 mmol) was added. The resultant mixture was stirred for 30 min. Initial brown solution of Ru(bpy)Cl_3 was gradually changed to green. The progress of the reaction was monitored periodically by TLC. The crude product was then purified by column chromatography on a silica gel (60–120 mesh) column. The pure complex **9** was eluted with a 4:1 ratio of dichloromethane and acetonitrile solvents. On removal of the solvent mixture under reduced pressure a gummy mass was obtained. It was redissolved in minimum volume of acetonitrile and the concentrated solution was treated with an excess of saturated aqueous $NaClO_4$ solution. The resulting mixture was allowed to stand for 30 min at 273 K. The green colored precipitate thus obtained was collected by filtration and washed thoroughly with ice-cold water. The solid mass was then dried in vacuo over P_4O_{10} Yield: 80%.

(Received 23 March 1998; accepted 12 June 1998)

Abstract—We have prepared several new iron(III) complexes with ligands which contain a phenol group; these are tetradentate [(X-phpy)H, X and H(phpy) represent the substituents on the phenol ring and *N*,*N*-bis(2-pyridylmethyl)-*N*-(2-hydroxybenzyl)amine, respectively] and pentadentate ligands [(R-enph-X)H; R = ethyl(Et) or methyl(Me) derivative and H(Me-enph) denotes *N*,*N*-bis(2-pyridylmethyl)-*N*″-methyl-*N*″-(2″-hydroxylbenzylamine)ethylenediamine] and have determined the crystal structures of Fe(phpy)Cl_2, Fe(5-NO_2-phpy)Cl_2, and Fe(Me-enph)ClPF_6, which are of a mononuclear six-coordinate iron(III) complex with coordination of one or two chloride ion(s). These compounds are highly colored (dark violet) due to the coordination of phenol group to an iron(III) atom. When hydrogen peroxide was added to the solution of the iron(III) complex, a color change occurs with bleaching of the violet color, indicating that oxidative degradation of the phenol moiety occurred in the ligand system. The bleaching of the violet color was also observed by the addition of *t*-butylhydroperoxide. The rate of the disappearance of the violet color is highly dependent on the substituent on the phenol ring; introduction of an electron-withdrawing group in the phenol ring decreases the rate of bleaching, suggesting that disappearance of the violet band should be due to a chemical reaction between the phenol group and a peroxide adduct of the iron(III) species with an η^1-coordination mode and that in this reaction the peroxide adduct acts as an electrophile towards phenol ring. The *intramolecular* interaction between the phenol moiety and an iron(III)-peroxide adduct may induce activation of the peroxide ion, and this was supported by several facts that the solution containing an iron(III) complex and hydrogen peroxide exhibits high activities for degradation of nucleosides and albumin. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Iron(III)-peroxide adduct; interaction of peroxide ion and phenol group; activation of peroxide; degradation of nucleoside; degradation of albumin.

INTRODUCTION

Peroxoiron(III) complexes are increasingly being considered as potential intermediates in oxidations catalyzed by both non-heme [1–5] and heme iron centers [6–10]. For example, electrospray mass spectrometry have revealed that an "activated bleomycin" is a monomeric iron(III)-peroxide adduct with an η^1-coordination mode [10]. Although several binuclear iron(III)-peroxide adducts have been characterized by their absorption [11–15], resonance Raman spectra [11, 12, 14], and crystal structure determinations [these are all of (μ-η^1:η^1-peroxo)diiron(III) structure] [16–18], however, evidence for the formation of a monomeric iron(III)-peroxide adduct with an η^1-coordination mode is scarce [19] and their reactivities are unknown [2, 3, 20]. In this study we have prepared several mono-

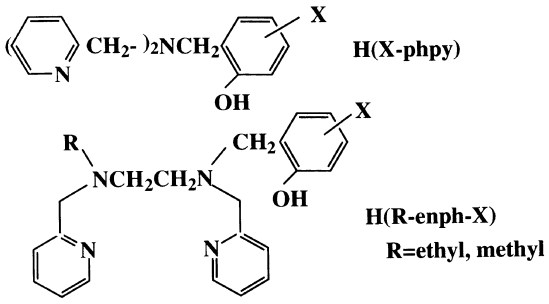
meric iron(III) compounds with ligands containing substituted phenols shown below in order to obtain chemical evidence for formation of a monomeric iron(III)-peroxide adduct and also to obtain information on the reactivity of the peroxide adduct [21].



Structure 1.

EXPERIMENTAL

Materials

Hydrogen peroxide (30%) and *t*-butylhydroperoxide (70%) were obtained commercially.

Synthesis of ligands

By adding $NaBH_4$ into the methanol solution containing salicyclaldehyde and 2-aminomethylpyridine, white solid, *N*-(2-hydroxybenzyl)-2-amino-methylpyridine was obtained. According to the procedure by Toftlund *et al* [22], the ligand, H(phpy), was obtained as oil (illustrated below). For the iron(III) complex preparation, the oil was used without further purification. Other ligands, H(X-phpy), where X = 3-OMe, 5-NO_2, 3-NO_2, 3,5-Br_2, were also obtained as oil according to the same way as described for H(phpy).

In a similar manner, the ligands H(R-enph) were obtained as oil and used for metal complex preparation without further purification (shown below). The substituted forms, H(R-enph-X), were also obtained as oil in a similar manner.

Synthesis of iron(III) complex

The methanol solution of the ligand (0.001 mol) was mixed with a methanol solution of ferric chloride six-hydrate (0.001 mol) and the precipitated violet crystals were filtered and once recrystallized from an acetonitrile/methanol solution. In the case of Fe(III) with

H(R-enph-X) complexes, $NaClO_4$ or NH_4PF_6 was added to the solution. Satisfactory analysis was obtained and analytical data of the new compounds are available on request from the authors.

Crystal structure determinations

Crystals of Fe(phpy)$Cl_2 \cdot CH_3CN$, **I**, and Fe(5-NO_2-phpy)$Cl_2 \cdot CH_3CN$, **II**, were grown from acetonitrile solutions and Fe(Me-enph-H)$ClPF_6 \cdot 2H_2O$, **III**, from aqueous methanol solution. Crystal data are listed in Table 1. X-ray diffraction intensities were measured up to $2\theta = 55°$ using MoKα radiation ($\lambda = 0.71073$ Å) on a Rigaku four-circle diffractometer AFC-5 at Keio University. Structure analysis was carried out using CRYSTAN-GM software version 6.3.3 on a SUN Park-10 workstation. Details of the structure analyses were deposited with the CCDC, Union Road, Cambridge.

Degradation of albumin by iron(III) complex and hydrogen peroxide

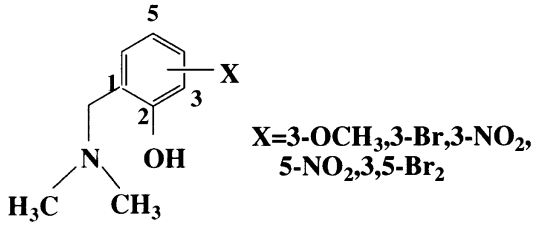
In a typical run, to the solution containing iron(III) complex (5 μl, 0.15–0.6 mmol dm^{-3}), Tris–HCl buffer (5 μl, 0.1 M, pH = 7.8) and hydrogen peroxide (5 μl, 6.25–100 mmol dm^{-3} solution) was added albumin solution (5 μl, 0.11 mmol dm^{-3}) and after 1 h mixing, the reaction solution was mixed with solution containing 2-mercaptoethanol and electrophoresed; denatured samples were analyzed on 12.5% sodium dodecylsulfate-polyacrylamide gel electrophoresis [2]. Products were visualized by Coomasie Blue and the band intensities were quantified on an ATTO Densitograph Model AE-6920-M/W/V (for Mac).

Degradation of nucleosides by iron(III) complex and hydrogen peroxide

To an aqueous solution of iron(III) complex containing nucleic acid or nucleoside, was added hydrogen peroxide solution (10 cm^3, 1/10 M) and the degradation of the nucleic acid or nucleoside were assessed in terms of HPLC according to a similar manner to that reported by Kasai and Nishimura [23]. The nucleosides used are adenine, 2′-deoxyadenosine, 2′-deoxyguanosine, 7-methylguanine, cytosine, deoxycytidine, thymine and deoxythymidine.

Molecular orbital calculations on ligand system

MOPAC calculations (MNDO/AM1) [4] were performed on the substituted 2-(dimethylamino)phenol, illustrated on next page.



Structure 4.

Physical measurements

Absorption spectra were obtained with a Shimazdu UV-2200 at 298 K.

RESULTS AND DISCUSSION

Crystal structure

The ORTEP drawing of the iron(III) compounds, Fe(phpy)Cl_2, Fe(5-NO_2-phpy)Cl_2 and Fe(Me-enph)Cl^+ are illustrated in Figs 1–3 and the selected bond lengths and bond angles are listed in Table 2. The structural features of the first two compounds are essentially the same to each other; both compounds are of a distorted six-coordinate structure. The introduction of nitro-group at 5-position induces the lengthening of the Fe–O (phenolic oxygen) bond by $\sim$0.03 Å.

In the case of Fe(Me-enph)Cl^+ complex, Fe–O (phenol oxygen) is 1.869(5) Å, which are shorter than those observed for the Fe(phpy)Cl_2 compounds, which may be due to higher Lewis acidity of the iron(III) atom in the former complex with positive charge(see Table 3). This is also reflected in the shorter bond length of Fe–Cl atom.

Absorption spectra

In Fig. 4, the absorption spectra of a series of Fe(X-phpy)Cl_2 complexes in acetonitrile are shown; a strong absorption band observed in the range 535–647 nm is attributed to the charge transfer band from phenol to an iron(III) atom [24]. The band positions of the compounds are highly dependent on the substituents on the phenol ring, X; absorption energy is the highest for the compounds containing nitro-group, the compound with 3-OMe exhibits the absorption maximum with the lowest energy (see Table 4). This may also be explained in terms of the energies of the HOMO of the phenol moiety; as shown in the Table 5, energy of HOMO of the compound containing nitro-group is the lowest among the ligands used in this study and the ligand containing 3-OMe group has the highest HOMO. Since the absorption band around 500 nm has been attributed to the charge-transfer from the

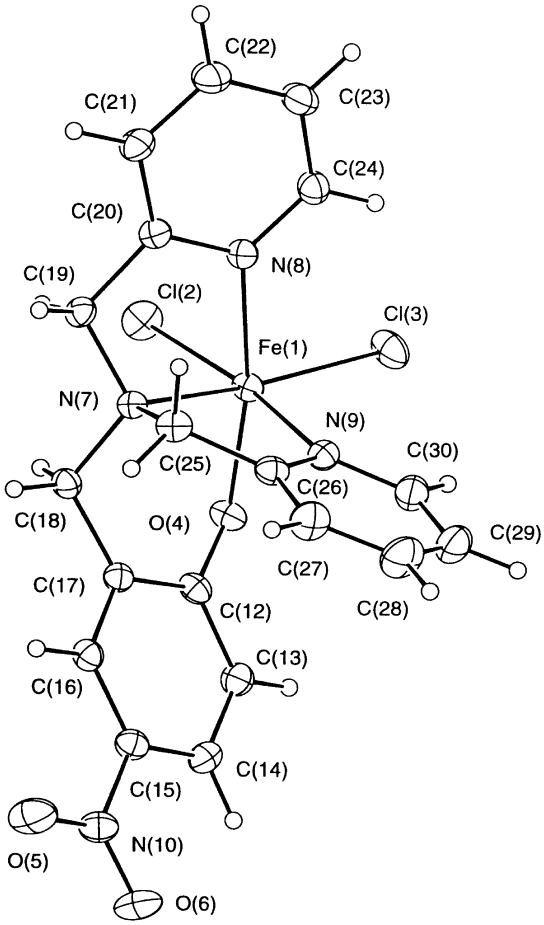

Fig. 2. ORTEP drawing of Fe(5-NO_2-phpy)Cl_2.

HOMO of the phenol to the dπ-orbital of the iron atom, the observed phenomenon can be reasonably explained. A similar shift of the absorption maximum was also observed for the series of Fe(R-enph-X)Cl^+ compounds (see Table 4).

Table 4. Absorption maximum of the CT bands (phenol to iron(III)) of the Iron(III) compounds (in acetonitrile, 298 K)

	Absorption maximum (nm)
Fe(phpy)Cl_2	589.5
Fe(3-OMe-phpy)Cl_2	647.0
Fe(5-Br-phpy)Cl_2	589.0
Fe(3,5-Br_2-phpy)Cl_2	583.0
Fe(3-NO_2-phpy)Cl_2	535.5
Fe(5-NO_2-phpy)Cl_2	541.0
Fe(Et-enph)ClPF_6	616.5
Fe(Et-enph-3-OMe)ClClO_4	688.0
Fe(Et-enph-5-Br)ClPF_6	617.5

Table 5. Energies of HOMO and LUMO of substituted 2-(dimethylamino)phenol

X	HOMO (eV)	LUMO (eV)
3-OMe	−8.59	0.60
H	−8.94	0.37
3-Br	−9.09	0.01
3,5-Br_2	−9.17	−0.23
3-NO_2	−9.68	−0.90
5-NO_2	−9.80	−0.94

The absorption spectra of the compounds are dependent on the solvent used, as shown in Fig. 5; the change of the spectrum in water from that in acetonitrile should be attributed to the displacement of the chloride ion by hydroxide ion in an aqueous solution; this is confirmed by ion spray mass spectroscopy done for the Fe(Et-enph)Cl^+ compound. As shown in Fig. 6, in the acetonitrile solution chloride ion is coordinated to an iron(III) atom ($m/z = 465.8$),

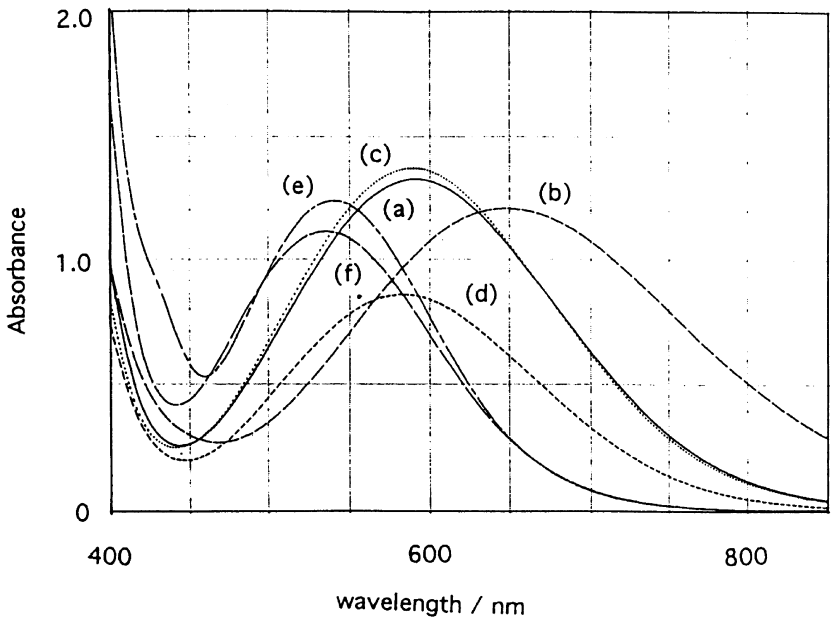

Fig. 4. Absorption spectra of Fe(X-phpy)Cl_2 complexes (in CH_3CN; 5×10^{-4} mol dm^{-3}; 298 K): (a) X = H; (b) X = 3-OMe; (c) X = 5-Br; (d) X = 3,5-Br_2; (e) 3-NO_2 and (f) X = 5-NO_2.

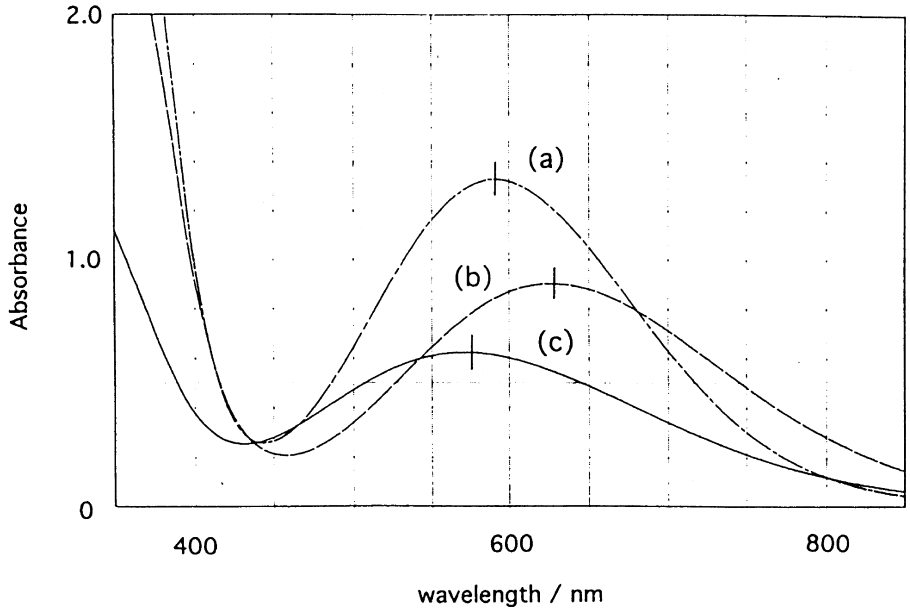

Fig. 5. Absorption spectra of Fe(phpy)Cl_2 in various solvents (5×10^{-4} mol dm^{-3}, 298 K): (a) in CH_3CN; (b) in CH_3OH and (c) in H_2O.

however in the presence of water, OH^- coordinates to an iron(III) instead of chloride ion ($m/z = 448.1$).

When hydrogen peroxide solution was added to the iron(III) compounds, interesting changes were observed in the spectra; one example, the change of the spectrum of the Fe(phpy)Cl_2 system, was shown in Fig. 7. This indicates that disappearance of the absorption band due to phenol to iron(III) charge transfer band occurs during this time, leaving a yellow solution. Similar spectral changes were also observed for other compounds, but the rate of bleaching of the absorption bands are highly dependent on the X on the phenol ring; the order of the bleaching is (see Fig. 8):

$$\text{3-OMe} > \text{H} > \text{5-Br} > \text{3,5-Br}_2 \gg \text{3-NO}_2$$

This order is roughly consistent with the order of energy of HOMO of the ligand system. A similar spectral change was also observed for the Fe(R-enph-X)Cl^+ compounds (data, not shown), the order of the rate of disappearance of the absorption band is also; 3-OMe > H > 5-Br.

It should be noted here that bleaching of the absorption band was also found when *t*-butylhydroperoxide solution was added to a solution of an iron(III) compound, as an example the case of the Fe(phpy)Cl_2 is shown in Fig. 9. It should be noted here that the rate of bleaching by *t*-butylhydroperoxide is much slower than that observed for the case of hydrogen peroxide, although the order of the disappearance of the absorption was the same as that observed for the hydrogen peroxide;

$$\text{3-OMe} > \text{H} > \text{3,5-Br}_2 \approx \text{5-Br} > \text{3-NO}_2.$$

Origin of the change of absorption bands in the visible region

On the addition of hydrogen peroxide to an iron(III) complex solution, a peroxide-adduct formation may occur at the position coordinated by the chloride ion. The rate of disappearance of the absorption band increases with increasing ratio of water vs acetonitrile in the solvents used indicates that formation of hydroxide species is necessary for a facile peroxide adduct formation, as shown in Scheme 1.

There are two reasons to explain the fact that charge transfer bands due to the electronic transition from phenol ring to an iron(III) atom disappeared on the addition of hydrogen peroxide; (1) change of the valence state of the iron(III) ion to Fe(IV) or Fe(V) and (2) change of the electronic structure of the phenol ring through interaction with a peroxide adduct in the Scheme. Since the yellow solution resulting after 1 h does not change anymore for several days, it is undoubtedly true that oxidative degradation of the phenol moiety has proceeded in the reaction course. Formation of Fe(V)=O may be also likely and some researchers have proposed the formation of an iron(IV) or iron(V) state in the reaction cycle in cytochrome P-450 or methane monooxygenase [25, 26]. However, the slower rate of disappearance of the absorption bands in the solution containing *t*-butylhydroperoxide than that in the hydrogen peroxide may suggest that at least the disappearance of the absorption band is not directly related with formation of a high valent iron-oxo species, because it is generally accepted that *t*-butylhydroperoxide exhibits a stronger oxidation power than that of hydrogen per-

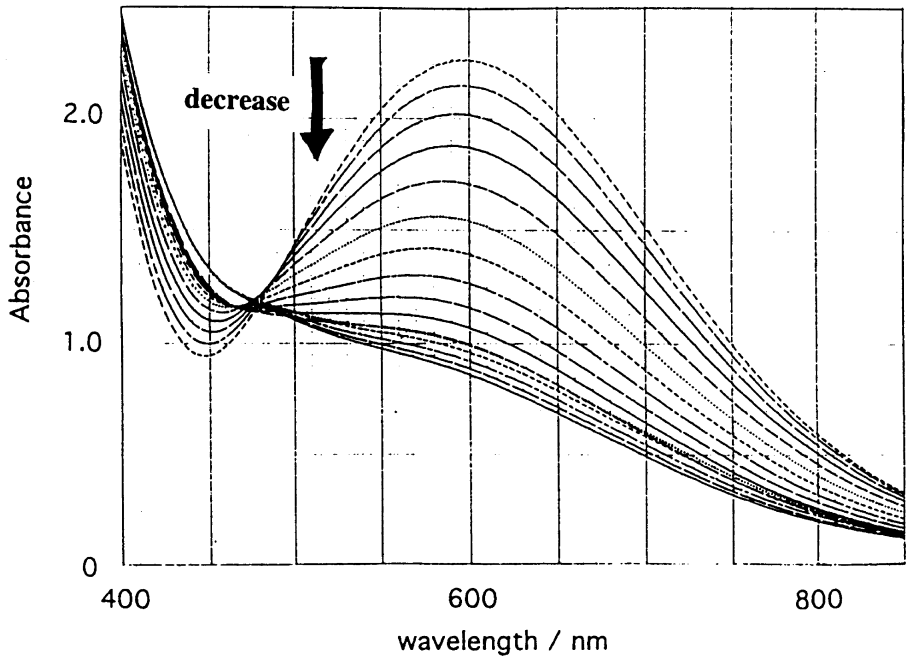

Fig. 7. Time course of absorption spectra of the system containing $Fe(phpy)Cl_2$ and hydrogen peroxide (solvent; $H_2O/CH_3CN = 1/4$, $[Fe^{3+}] = 2 \times 10^{-3}$ mol dm^{-3}, $[H_2O_2] = 2 \times 10^{-2}$ mol dm^{-3}, 298 K. Measurements were performed every 2 min after addition of hydrogen peroxide solution).

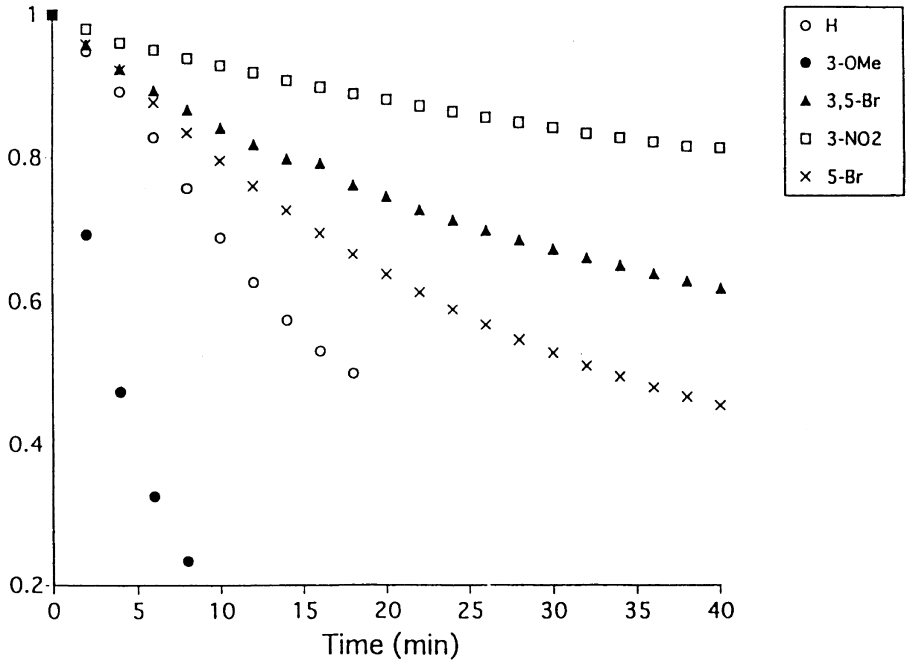

Fig. 8. Time course of absorption maximum of the $Fe(X\text{-}phpy)Cl_2$ complex (in water/acetonitrile = 1/4 solution, 298 K).

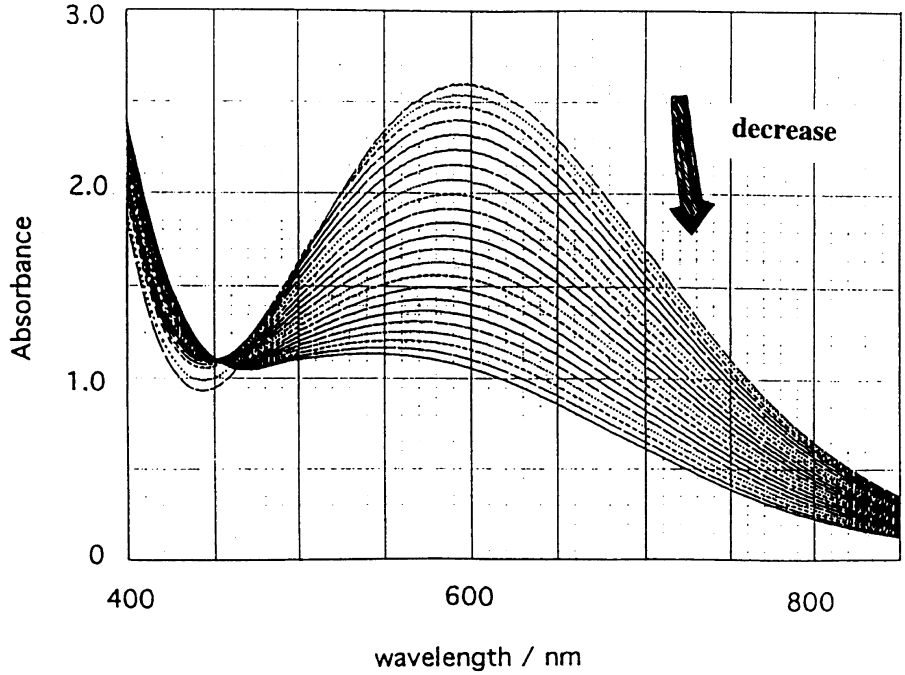

Fig. 9. Time course of absorption spectra of the system containing $Fe(phpy)Cl_2$ and *t*-butylhydroperoxide (solvent; $H_2O/CH_3CN = 4/1$, $[Fe^{3+}] = 2 \times 10^{-3}$ mol dm^{-3}, [*t*-Bu-OOH] $= 4 \times 10^{-2}$ mol dm^{-3}, 298 K. Measurements were performed every 15 min after addition of hydrogen peroxide solution).

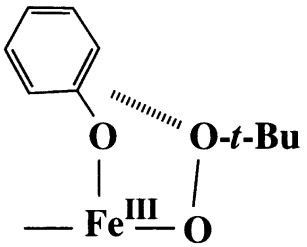
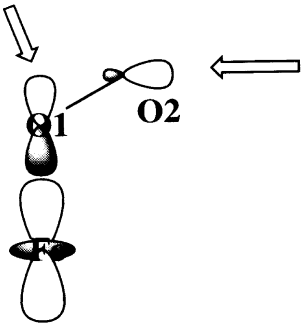
oxide [27, 28]. As the rate of bleaching of the absorption band is not dependent on the concentration of an iron(III) ion, it seems most likely that the degradation of the phenol moiety was induced by the *intramolecular* attack of a terminal oxygen atom of the peroxide adduct with η^1-coordination mode, as shown in the Scheme. The large bulky substituent of the *t*-butylhydroperoxide may prevent the approach of the oxygen atom to the phenol ring (see below), which may reasonably explain the much slower rate of bleaching of the absorption bands observed in this study.



Structure 5.

In our previous papers [3, 4], we have investigated the reactivity of an iron(III)-peroxide adduct with η^1-coordination mode and have reported that this species exhibits electrophilic reactivity at both the O1 and O2 positions, which is confirmed by several examples [4, 21, 29]. In the present case, the reactivity at the O2 position is important.



Structure 6.

Since the peroxide adduct shows electrophilic nature at the O2 position, it is anticipated that the phenol moiety of 3-OMe derivative shows the highest affinity towards the peroxide adduct, because the energy of the HOMO is the highest among the compounds as shown below and this is quite consistent with the experimental results as described before. The *intramolecular* interaction between the peroxide adduct and the phenol moiety may give an oxygenated or oxidized product associated with the disappearance of the absorption band in the visible region, however the details on oxygenation products of the phenol moiety are not clear at present. However, as men-

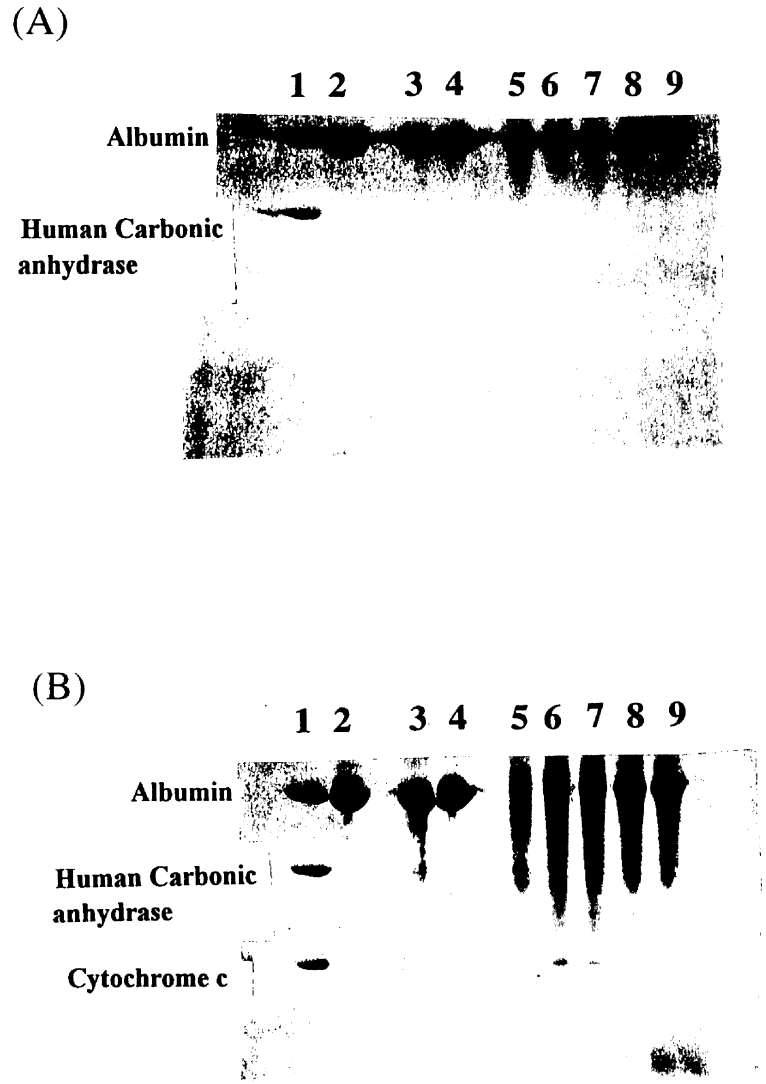


Fig. 10. Degradation of albumin by iron(III) complex in the presence of hydrogen peroxide; concentration of iron(III) complex is 0.5 mmol dm^{-3} (see <secr id=‡2‡>). (A) $Fe(tpa)Cl_2^+$ lane 1, albumin and human carbonic anhydrase I (HCA); lane 2, albumin, only; lane 3, albumin and iron(III) complex; lane 4, albumin and H_2O_2 (100 mmol dm^{-3} solution); lane 5, albumin + iron(III) complex + H_2O_2 (100 mmol dm^{-3} solution); lane 6, albumin + iron(III) complex + H_2O_2 (50 mmol dm^{-3} solution); lane 7, albumin + iron(III) complex + H_2O_2 (25 mmol dm^{-3} solution); lane 8, albumin + iron(III) complex + H_2O_2 (12.5 mmol dm^{-3} solution); lane 9, albumin + iron(III) complex + H_2O_2 (6.25 mmol dm^{-3} solution). (B) $Fe(phpy)Cl_2$: lane 1, albumin, human carbonic anhydrase I (HCA); lane 2, albumin, only; lane 3, albumin and iron(III) complex; lane 4, albumin and H_2O_2 (100 mmol dm^{-3} solution); lane 5, albumin + iron(III) complex + H_2O_2 (100 mmol dm^{-3} solution); lane 6, albumin + iron(III) complex + H_2O_2 (50 mmol dm^{-3} solution); lane 7, albumin + iron(III) complex + H_2O_2 (25 mmol dm^{-3} solution); lane 8, albumin + iron(III) complex + H_2O_2 (12.5 mmol dm^{-3} solution); lane 9, albumin + iron(III) complex + H_2O_2 (6.25 mmol dm^{-3} solution).

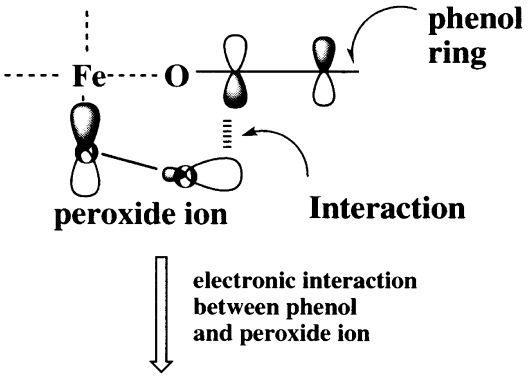
tioned in previous papers [3, 4], the interaction between the phenol ring (π-electron) and the peroxide adduct with η^1-coordination mode in the intermediate (see below) induces more activation of hydrogen peroxide [4], leading to facile heterolytic cleavage of the O–O bond and to formation of an Fe(III)–O (atomic oxygen)–OH^- species. This Fe(III)–O (atomic oxygen), which is alternately written as Fe(V)=O, is assumed to exhibit high activity for oxidation and oxygenation of the organic compounds, which is consistent with several experimental facts as shown below.



Structure 7.

Reactivity of the iron(III)-complexes containing phenol derivatives

In this study we have observed that Fe(phpy)Cl_2 complex exhibits high activity for degradation of deoxyadenosine, but its activity of the (tpa)-complex is negligible. Similar facts were also observed for the other nucleosides and nucleic acids such as cytosine and deoxyguanosine, etc. (data, not shown). Quite high activity of the H(phpy)-complex to that of the (tpa)-complex was also observed for the degradation of albumin in the presence of hydrogen peroxide, as shown in Fig. 10; serious degradation of albumin was detected at low concentration of hydrogen peroxide (6.26 mmol dm^{-3}) in the case of the Fe(phpy)Cl_2 complex, whereas no degradation was found for the (tpa)-complex under the same experimental conditions [see lanes 6–9 of both (A) and (B) in Fig. 10]. The high activity of the H(phpy)-complex also can be attributed to the activated form of the peroxide ion through interaction with the phenol group. Little activity observed for the Fe-(tpa) complex can be explained by the fact that Fe(tpa)Cl_2^+ complex has no phenol moiety and the activation of the peroxide ion by the pyridine ring is negligible (see below) [3, 4].

Abstract—Four trinuclear molybdenum(tungsten)-sulfur carbonyl cluster compounds, $[Et_4N]_2[(OC)_4MoS_2MoS_2Mo(CO)_4]$ (**1**), $[Et_4N]_2[(OC)_4WS_2WS_2W(CO)_4]$ (**2**), $[Et_4N]_2[(OC)_4MoS_2WS_2Mo(CO)_4]$ (**3**), $[Et_4N]_2[(OC)_4WS_2MoS_2W(CO)_4]$ (**4**) have been prepared by both reaction of $[M(CO)_4(S_2CNEt_2)]^-$ with $M'S_4^{2-}$ in MeOH and reaction of MeCN solution of $M(CO)_6$ with $M'S_4^{2-}$ in MeOH (M = Mo, W; M′ = Mo, W). These complexes has been characterized by routine elemental analysis and spectroscopy and the structures of **1** and **3** have been determined by X-ray crystallography. The structure study reveals that the anion of **3** contains a heteronuclear Mo–W–S trimetallic core, $[MoS_2WS_2Mo]^{2-}$, consisting of two perpendicular rhombic MoS_2W units sharing a tungsten atom. The Mo–W bond distances are 3.028(2) and 3.031(2) Å and the Mo–W–Mo angle is 176.04(5)°. The average bond lengths of W–S and Mo–S are 2.21 and 2.54 Å, respectively. The X-ray, structure, IR, CV (cyclic voltammetry) and ^{95}Mo NMR studies on these four cluster complexes indicated that these cluster complexes possess wide separated oxidation states of metal atoms and exhibit the charge transfer, $M^L \rightarrow M^HS_4$ (M^L represents a low-valance metal atom and M^H a high valence metal atom), between the two different valence metallic centers in the cluster complexes. It has been found that the charge transfer, $M^L \rightarrow M^HS_4$, in the complexes are: **1** > **4**, **3** > **2**, **1** > **3**, **4** > **2**, **1** > **2** and **3** ~ **4** implying the electron-donation ability of low-valence metal atoms in the complexes is $Mo^0 > W^0$ and the electron-accepted ability of the high valence metal atoms in the complexes is $Mo^{VI} > W^{VI}$. © 1998 Elsevier Science Ltd. 1. INTRODUCTION

The chemistry of molybdenum–sulfur cluster compounds and mixed-valence-containing metal cluster complexes has increasingly attracted the attention from chemists and bioinorganic chemists because of the existence of molybdenum–sulfur bonding in a variety of Mo-containing enzymes, among them nitrogenase [1–3] and hydrodesulfurization catalysts containing molybdenum and sulfur atoms [4] and also because of the great importance of mixed-valence in biosystems and catalysis systems. As a part of our studies on complexes with low-valence molybdenum atoms [5, 6, 7, 8]. We have found and developed a new Mo(W)S cluster compound family containing low- and mixed-valence metal atoms, $[\{(OC)_4M\}xM'S_4]^{2-}$ (M = Mo, W; M′ = Mo, W; x = 1,2) [9, 10, 11, 12],

* Author to whom correspondence should be addressed.

which corresponds to the linear Mo–Fe–S cluster complexes, $[(FeL_2)xMS_4]^{2-}$ (L = SR, Cl; $x = 1,2$ and M = Mo, W) [13] that have been studied as modeling compounds for the active center of nitrogenase, In our previous publications several dinuclear members and a trinuclear member of this family, the tetraethylammonium salts of $[(OC)_4MoS_2WS_2]^{2-}$ [9], $[(OC)_4MoS_2MoS_2]^{2-}$ [11] $[(OC)_4WS_2WS_2]^{2-}$ [10] and $[(OC)_4MoS_2MoS_2Mo(CO)_4]^{2-}$ (**1**) [12] have been reported. Herein, we present the synthesis of the new trinuclear members including homo- and heteronuclear ones, $[Et_4N]_2[(OC)_4WS_2WS_2W(CO)_4]$ (**2**), $[Et_4N]_2[(OC)_4MoS_2WS_2Mo(CO)_4]$ (**3**) and $[Et_4N]_2[(OC)_4WS_2MoS_2W(CO)_4]$ (**4**), the crystal structure of **3** and the investigation on the charge transfer in this series of compounds including **1** by IR spectra, CV and ^{95}Mo NMR spectra studies.

2. EXPERIMENTAL

2.1. *Materials and methods*

All procedures including synthetic reaction, structure determination, physical and chemical measurements were carried out under nitrogen atmosphere by using standard Schlenk technique and all solvents and reagents were dried and degassed before use. Acetonitrile was distilled from CaH_2. Methanol and isopropanol were dried by distillation with magnesium methoxide. $Mo(CO)_6$, $W(CO)_6$ and NaS_2CNEt_2 were purchased from Alfa (U.S.A.) and the Shanghai Chemical Reagent Company, respectively. The complexes, $[Et_4N][Mo(CO)_4(S_2CNEt_2)]$ [14], $[Et_4N]_2[MS_4]$(M = Mo, W) [15] and $[Et_4N][W(CO)_4(S_2CNEt_2)]$ [10] were prepared by the literature methods.

IR spectra were recorded on a Perkin-Elmer 577 IR spectrometer and Digilab FTS-20E/D-V Foudet IR spectrometer. Elemental analysis were performed on a Carlo Erba instrumentation elemental analyzer MOD 1106; ^{95}Mo NMR spectra of the samples in MeCN were measured on Varin Unit 500 NMR spectrometer (U.S.A.) with a relative solution of 2 M Na_2MoO_4 in D_2O sealed in a capillary.

Cyclic voltammetry (CV) measurements were performed with a three-electrode cell using 0.1 M Bu_4NBF_4 as the supporting electrolyte and MeCN as solvent. The working electrode was glass carbon, the reference electrode was an aqueous SCE separated from the sample solution by a salt bridge and the auxiliary electrode is platinum wire. Solutions were deoxygenated and blanketed with a nitrogen atmosphere and the potentiostat was a CV-B from BAS (Bioanalytical System).

2.2. *Syntheses of complexes*

2.2.1. $[Et_4N]_2[(OC)_4MoS_2MoS_2Mo(CO)_4]$ (**1**) **1** was prepared by reaction of $[Et_4N]_2MoS_4$ with $[Et_4N][Mo(CO)_4(S_2CNEt_2)]$ in MeOH or MeCN according to the literature method [12].

2.2.2. $[Et_4N]_2[(OC)_4WS_2WS_2W(CO)_4]$ (**2**) (i) A mixture of $[Et_4N]_2[WS_4]$ (0.50 g, 0.874 mmol) and $[Et_4N][W(CO)_4(S_2CNEt_2)]$ (1.30 g, 2.26 mmol) in 60 ml of MeCN were stirred at 60–65°C for 3 days resulting in a deep red solution with brown–red precipitate in it. After cooling to room temperature, 0.50 g brown–red product **2** was obtained by filtration, washed with MeOH and dried *in vacuo*, yield: 50%. Analysis: calcd. for $C_{24}H_{40}N_2O_8S_4W_3$, C, 24.74; H, 3.44; N, 2.41; S, 10.99; W, 47.42%. Found: C, 24.47; H, 3.58; N, 2.87; S, 10.98; W, 47.85%. IR (KBr pellet): 2000 s, 1876 s, 1861 s, 1818 s cm^{-1} ($\nu_{WC=O}$); 580 m, 566 m cm^{-1} (δ_{W-C-O}); 465 w, 436 w ($\nu_{W(VI)-Sb}$), ~415 sh ($\nu_{W(O)-Sb}$) and 349 ($\nu_{W(O)-C}$) cm^{-1}. After collecting the **2** product the filtrate was cooled at 4°C. 0.04 g of red microcrystalline product, which was recognized as dinuclear compound $[Et_4N]_2[(OC)_4WS_2WS_2]$ [10] by IR spectrum, was obtained.

(ii) A mixture of $[Et_4N]_2[WS_4]$ (0.572 g, 1 mmol) and $[Et_4N][W(CO)_4(S_2CNEt_2)]$ (0.58 g, 1 mmol) in 50 ml of MeCN were stirred at 55–60°C for 24 h. After treating by the same procedures as in (i), 0.13 g of **2** (yield, 22% based on the amount of $[Et_4N][W(CO)_4(S_2CNEt_2)]$ used) and 0.09 g of red crystalline product of dinuclear compound $[Et_4N]_2[(OC)_4WS_2WS_2]$ [10] (yield: 10%) were obtained.

2.2.3. $[Et_4N]_2[(OC)_4MoS_2WS_2Mo(CO)_4]$ (**3**) (i) A mixture of $[Et_4N]_2WS_4$ (0.572 g, 1 mmol) and $[Et_4N][Mo(CO)_4(S_2CNEt_2)]$ (0.972 g, 2 mmol) in 45 ml of MeOH was stirred at 55°C for 24 h resulting in much deep red microcrystalline precipitate. 0.60 g of **3** were obtained after cooling to room temperature, filtered, washed with MeOH and dried *in vacuo*, yield, 61%. Analysis: calcd. for $C_{24}H_{40}Mo_2N_2O_8S_4W$, C, 29.15; H, 4.05; N, 2.83; Mo, 19.43; S, 12.96; W, 18.62%. Found: C, 28.42; H, 4.17; N, 2.90; Mo, 19.02; S, 12.56. W, 18.89%. IR (KBr pellet): 2004 s, 1895 s, 1865 s, 1815 s cm^{-1} ($\nu_{MoC=O}$); 595 m, 580 m, 570 m cm^{-1} (δ_{M-C-O}); 450 w (ν_{W-Sb}), 428 w (ν_{Mo-Sb}), 340 (ν_{Mo-C}) cm^{-1}. The filtration was cooled at 4°C; a small amount of red crystal product (0.15 g) which is recognized as dinuclear compound $[EtN]_2[(OC)_4MoS_2WS_2]$ [9] by its IR spectrum.

(ii) A mixture of $[Et_4N]_2WS_4$ (0.572 g, 1 mmol) and $Mo(CO)_6$(0.258 g, 2 mmol) in 50 ml of MeCN was stirred at 45–50°C for 3 h and then, at 82°C for 18 h, resulting in a deep red solution. After cooling to room

temperature the reaction mixture was concentrated to the volume of 15 ml by vacuum and 50 ml of EtOH was added leading to a small amount of precipitate. Filtering off the residue, the filtrate was cooled at 4°C resulting in precipitation of a brown solid (~0.23 g) which is an impure mixture judged by its IR spectra. Removing the brown solid, the filtrate was continued to be cooled at 4°C for several days, 0.24 g of red crystalline product, **3**, was collected. Yield: 25%. Crystals suitable for X-ray crystal structure determination of **3** were obtained from a mixed solution of MeOH and MeCN.

2.2.4. $[Et_4N]_2[(OC)_4WS_2MoS_2W(CO)_4]$ (**4**) (i) A mixture of $[Et_4N][W(CO)_4(S_2CNEt_2)]$ (1.15 g, 2 mmol) and $[Et_4N]_2MoS_4$ (0.48 g, 1 mmol) in 50 ml of MeOH was stirred at 45–50°C for 24 h resulting in the precipitation of a brown microcrystalline product. After cooling to room temperature, 0.54 g of microcrystalline **4** were obtained by filtration, washed with MeOH and dried *in vacuo*; yield: 50.2%. Analysis: calcd. for $C_{24}H_{40}MoN_2O_8S_4W_2$, C, 26.77; H, 3.72. N, 2.60; Mo, 8.92. S, 14.90; W, 34.20%. Found: C, 27.09; H, 4.01; N, 3.06; Mo, 8.45; S, 15.02; W, 34.80%. IR (KBr pellet): 2000 s, 1882 s, 1860 s, 1822 s cm^{-1} ($\nu_{WC=O}$); 572 m, 572 m, 562 m cm^{-1} (δ_{W-C-O}), 459 w, 442 w (ν_{Mo-Sb}), 417 w (ν_{W-Sb}), 345 (ν_{W-C}) cm^{-1}.

(ii) A mixture of $[Et_4N][W(CO)_4(S_2CNEt_2)]$ (1.15 g, 2 mmol) and $[Et_4N]_2MoS_4$ (0.48 g, 1 mmol) in 50 ml of MeCN was stirred at 45–50°C for 24 h resulting in a brown–green solution. The resulting reaction mixture was concentrated to a volume of 25 ml and 50 ml of isopropanol was added. A small amount of precipitate was filtered off and the filtrate was cooled at 4°C. 0.33 g of brown crystalline **4** was obtained after filtration, washed with MeOH and dried *in vacuo*. yield: 31%.

2.3. *X-ray crystal structure determination*

A dark plate crystal of **3** with approximate dimensions of $0.20 \times 0.30 \times 0.40$ mm coated with epoxy resin was mounted on a glass fiber in a random orientation. Diffraction measurements were made on an Enraf-Nonius CAD4 computer controlled κ-axis diffractometer equipped with a graphite crystal incident beam monochromator. Unit cell parameters were obtained from a least-squares fit of 25 reflections in the range of $11 < \theta < 13°$ and given in Table 1. The intensity data were recorded using a ω–2θ scan technique to a maximum 2θ of 52.0° with a variable scan speed. A total of 3931 reflections, of which 3688 were unique, were collected. An isotropic decay correction was applied and the correction factors ranged from 0.967 to 1.143. Lorentz and polarization correction were applied to the data. An empirical absorption correction based on a series of psi-scans was applied to the data. Relative transmission coefficients ranged from 0.590 to 1.000. An empirical DIFABS [17] absorption correction was made after structure refinement with isotropic thermal parameters. The maximum and minimum absorption corrections were 1.0204 and 0.9633, respectively. The structure was solved by direct methods with MULTAN-83 program. A total of three atoms were located from the E-map and the remaining atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were not included in the calculations. Only the 2155 reflections with $I > 3.0\,\sigma(I)$ were used in the refinements. The final cycle of refinement included 267 variable parameters and converged (largest parameter shift was 0.53) with unweighted and weighted agreement factors of 0.054 and 0.060, respectively. The e.s.d. of observations of unit weight was 0.59, the highest peak in the final difference Fourier was 1.23 e/Å^3, the minimum negative peak was -0.21 e/Å^3.

All calculations were performed on a VAX computer using MOLEN/PC [18].

A list of atomic coordinates and calculate thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

3. RESULTS AND DISCUSSION

3.1. *Synthesis of* $[Et_4N]_2[(OC)_4MS_2M'S_2M(CO)_4]$ (M = Mo, W; M = Mo, W)

$[M(CO)_4(S_2CNEt_2)]^-$ reacts with $[M'S_4]^{2-}$ (2:1 in mol. ratio) in solvents such as MeOH MeCN, affording trinuclear Mo–W–S cluster complexes, $[Et_4N]_2[(OC)_4MS_2M'S_2M(CO)_4]$ (M = M′ = Mo; (**1**); M = M′ = W, (**2**); M = Mo, M′ = W, (**3**) and M = W, M′ = Mo, (**4**) by the two step synthetic reaction (1) and (2) as reported in our previous paper [12].

$$[M'S_4]^{2-} + [M(CO)_4(S_2CNEt_2)]^- \rightarrow [(OC)_4MS_2MS_2]^{2-} + (S_2CNEt_2)^- \quad (1)$$

$$[(OC)_4MS_2MS_2]^{2-} + [M(CO)_4(S_2CNEt_2)]^- \rightarrow [(OC)_4MS_2M'S_2M(CO)_4]^{2-} + (S_2CNEt_2)^- \quad (2)$$

The reactions in eqns (1) and (2) take place almost simultaneously and because of the small solubility of the trinuclear products in MeOH the trinuclear products precipitated as soon as the reaction in eqn (1) took place, therefore, the yield is higher when the solvent MeOH is used. Nevertheless, in the solution MeCN, besides the reactions in eqns (1) and (2) there is the reaction in eqn (3) [9, 10] between dinuclear and trinuclear products.

$$[(OC)_4MS_2M'S_2M(CO)_4]^{2-} \rightleftarrows [(OC)_4MS_2M'S_2]^{2-} + M(CO)_4(MeCN)_2. \quad (3)$$

This leads to a decrease in the yield of trinuclear products. So, the kind of solvent greatly influences the yield of the trinuclear products. As shown in Table 2,

the yield of trinuclear products are higher in MeOH than in MeCN.

According to the synthetic reaction of this series of trinuclear compounds, it can be predicted that two new members of heterometal compounds $[(OC)_4MoS_2MoS_2W(CO)_4]^{2-}$ and $[(OC)_4WS_2WS_2Mo(CO)_4]^{2-}$, can be synthesized by control of the ratio of M(O) compounds and M(VI) compounds used.

3.2. *Structure of* $[Et_4N]_2[(OC)_4MS_2M'S_2M(CO)_4]$ (**3**) *and the existence of widely separated oxidation states of metal atoms in the compounds*

The selected bond distances and angles of **3** are listed in Table 3 and the structure of the anion of **3** is depicted in Fig. 1. **3** comprised two cations Et_4N^+ and a trinuclear dianion $[(OC)_4MoS_2WS_2Mo(CO)_4]^{2-}$, as shown in Table 3 and Fig. 1, the anion of **3** contained a trinuclear mixed metallic core, $[MoS_2WS_2Mo]^{2-}$ which was composed of two rhombic units, MoS_2W, sharing the high valence tungsten atom in perpendicular arrangement (**A**).

The central tungsten located in the center of a tetrahedron with four bridging sulfur atoms and the geometry of each terminal molybdenum atom in low oxidation state is an octahedron with two bridging sulfur atoms and four carbon atoms from four terminal carbonyls. In another word, the whole geometry

C(13), C(13′), O(13) and O(13′) are statistic distributions.

of the dianion of **3** may be described as **B**, which consists of two terminal octahedrons with low valence molybdenum atom in the center and a medial tetrahedron with central high valence tungsten atom sharing two edges (two perpendicular S . . . S lines). There is a symmetric mirror with Mo1, W, Mo2, S1, S2, C11, C12, C22, C23 O11, O12, O22 and O23 atoms in it and the C13, C13′ and O13, O13′ atoms are statistic distribution. W–Mo bond lengths and MoWMo angles are 3.028, 3.031 Å and 176.04(5)°, respectively, indicating metal–metal interaction. Four W–S bond lengths are basically, equivalent (2.21 Å) and the corresponding Mo–S bond distances are 2.535 (Mo–S1, Mo–S2) and 2.556 Å (Mo–S3) and Mo–C bond lengths are 1.97(Mo1–C) and 1.99 Å (Mo2–C).

Although the formal oxidation states of the two Mo and the W atoms in **3** are zero and VI, respectively, the somewhat longer distance of Mo–C showed that the real oxidation state of the two Mo atoms are higher than zero if comparing with the Mo–C distance (1.965 Å) of Mo(0)complex, $[Mo(CO)_4(S_2CNEt_2)]^-$ [14]. Considering the W–S bond distances, it is obvious that the average W–S bond length of **3** is longer than that of W^{VI} complex, WS_4^{2-} (W–S, 2.17 Å) [19] indicating that the real oxidation state of tungsten atom in **3** is somehow lower than VI. Apparently, the

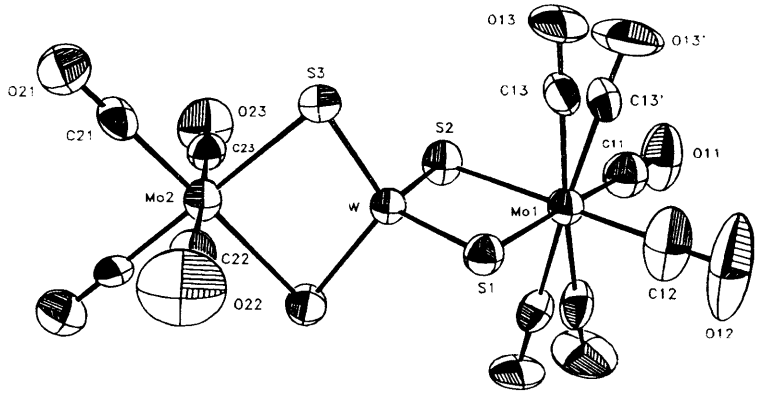

Fig. 1. The structure of the anion of **3**, $[(OC)_4MoS_2WS_2Mo(CO)_4]^{2-}$. The atoms C13, O13 and C13′, O13′ are statistically distributed and the occupancy of each of them is 50%.

existence of mixed valence metal atoms in **3** would lead to the occurrence of charge transfer between the different valence metal centers, $Mo^0 \rightarrow W^{VI}$, resulting in a partial oxidation of Mo^0 and partial reduction of W^{VI} in terms of the suggestion that Fe→M charge transfer is evident in the Fe–M–S (M=Mo or W) complexes when the mean values of the iron–ligand bond lengths and of the M–S bond distances in the MS_4^{2-} ligands are taken into account [13]. However, the electron delocalization takes place only partly, thus, the two kinds of metal atoms (Mo and W) in **3** still exist wide separated oxidation states. Inviting the structural parameters of **1** [12] for comparison (Table 4), it can be found that the Mo–S and Mo–C bond lengths of **1** are shorter and longer than that of **3**, respectively, implying that the oxidation states of the two terminal Mo atoms in **1** are somehow higher than that in **3**. This shows that the charge transfer $Mo^0 \rightarrow W^{VI}$ in **3** is smaller than the transfer $Mo^0 \rightarrow Mo^{VI}$ in **1**. The extent of the charge transfer $M^L \rightarrow M^H$ (M^L and M^H are lower valence and higher valence metal atoms, respectively) should depend on the electron-donation ability of M^L and electron-accepted ability of M^H. The result that the charge transfer $Mo^0 \rightarrow Mo^{VI}$, in **1** is larger than the charge transfer $Mo^0 \rightarrow W^{VI}$ in **3** seems to show that the electron accepted ability of Mo^{VI} is stronger than that of W^{VI}. Of cause, the M^L–M^H–M^L angle, which determines the extent of offset effect [20, 21] between the two $M^L \rightarrow M^H$ charge transfers in opposite direction, also influence on the extent of each $M^L \rightarrow M^H$ charge transfer in complex. The Mo–W–Mo angle of **3** is somewhat bigger than the Mo–Mo–Mo angle in **1** implying the somewhat larger offset effect of charge transfer in **3**. It should be pointed out that the two terminal Mo^0 atoms in **3** are more different than those in **1**. This is, perhaps, due to the statistics distribution of the carbonyl group (C13–O13) in axial position of one Mo atom (Mo1) in **3**. It could be estimated that the structures of the **2** and **4** are similar to that of **1** and **3**. As a matter of fact, the similarity of their IR spectra, cyclic voltammogram and ^{95}Mo NMR spectra support this point (see Sections 3.3–3.5).

3.3. *Infrared spectra*

IR spectra of **1**, **2**, **3** and **4** are very similar. They showed four strong bands in the range of 1600–2010 cm^{-1}, three medium absorption peaks in 500–600 cm^{-1}, two peaks in 430–470 cm^{-1}, one peak at ~350 cm^{-1} and a somewhat weak absorption in 402–417 cm^{-1} (see Table 5). The former four kinds of absorptions are known to be the characteristic vibration frequencies of $\nu_{M(0)C-O}$, $\delta_{M(0)-C-O}$, $\nu_{M(VI)-Sb}$ and $\nu_{M(0)-C}$, respectively [22] and the latter somewhat weak peak should be assigned to the $\nu_{M(0)-Sb}$ because they are observed in the molybdenum(0)compound $[Mo(CO)_4(S_2CNEt_2)]^-$ [14] and $[Mo_2(SPh)_2(CO)_8]^{2-}$ [7].

Referring to the IR data of $[MS_4]^{2-}$(M=Mo, W) [15] and $[M(CO)_4(S_2CNEt_2)]^-$ (M=Mo, W)[10, 14], it can be found that the $\nu_{M(0)C-O}$ and $\nu_{M(0)-Sb}$ in all the four complexes are 13–60 and 9–10 cm^{-1} higher than that of $[M(CO)4(S_2CNEt_2)]^-$, respectively, and the $\nu_{M(VI)-Sb}$ of all the complexes are 5–27 cm^{-1} lower than that of $[MS_4]^{2-}$. This implies that the coordination of

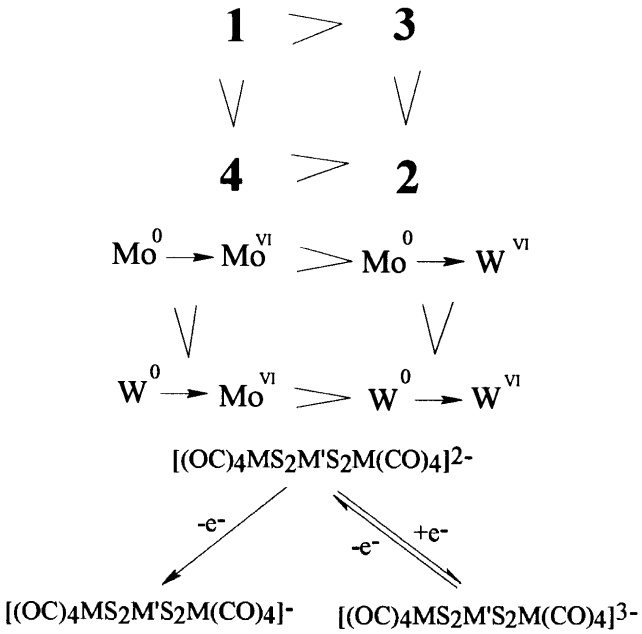
[a]Sb = bridging sulfur atom.

$[M^{VI}S_4]^{2-}$ to $M^0(CO)_4$ moiety leads to increase of the oxidation state of M^0 (partial oxidation of M^0) and decrease of the valence of M^{VI} (partial reduction of M^{VI}) indicating, evidently, the existence of charge transfer of $M^0 \rightarrow M^{VI}$. Carefully inspecting the values of $\nu_{M(0)C-O}$ and $\nu_{M(VI)-Sb}$ listed in Table 5, it is apparent that the $\nu_{M(0)C-O}$ of **1** is larger than that of **3** and the $\nu_{W(0)C-O}$ of **4** is larger than that of **2**; the $\nu_{Mo(VI)-Sb}$ of **4** is higher than that of **1** and the $\nu_{W(VI)-Sb}$ of **2** is larger than that of **3** implying that the real valences of Mo^L atoms in **1** are higher than that in **3**, the real valences of W^L atoms in **4** are higher than that in **2**, the real oxidation state of Mo^H atom in **4** is higher than that in **1** and the real oxidation state of W^H atom in **2** is higher than that in **3**. Thus, the extents of $M^0 \rightarrow M^{VI}$ charge transfers in **1**–**4** can be summarized as following Scheme 1.

Interestingly, a relationship between $Fe^{II} \rightarrow M^{VI}$ charge transfer and $\Delta\nu$ ($\nu_{M(VI)-Sb}$-$\nu_{Fe(II)-Sb}$) found in linear Fe–Mo–S cluster compounds $[(FeL_2)xS_2MS_2]^{2-}$ (L = Cl, SR; M = Mo, W; $x = 1$, 2) [23] also exists in this series Mo–W–S cluster complexes. i.e. the value of $\Delta\nu$ is inversely proportional to that of charge transfer. $\Delta\nu$ ($\nu_{M(VI)-Sb}$-$\nu_{M(0)-Sb}$) of **1**–**4** are 34, 50, 43 and 42, respectively, Obviously, the exact same result of scheme 1 can be obtained based on the $\Delta\nu$ values. It is worth pointing out that employing the $\Delta\nu$ values, the comparison of charge transfers between **1** and **2** and between **3** and **4** can be further made. The $\Delta\nu$ value of **1** is smaller than that of **2** and the $\Delta\nu$ value of **3** is similar to that of **4** indicating the charge transfer of $M^0 \rightarrow M^{VI}$ in **1** is larger than that in **2** and **3** has similar charge transfer as **4**. In general, the existence of charge transfer between two mixed valence metal atoms is dependent on the electron donation ability of the lower valence metal atom and the electron accepted ability of the higher valence metal atom, therefore, the results obtained above should imply that the electron donation ability of Mo^0 is larger than that of W^0 and the electron accepted ability of Mo^{VI} is also larger than that of W^{VI}. In fact, this is consistent with the larger binding energy of W-4f than Mo-3d [24]. If considering the electron configurations between the Mo atom ($3d^5S^1$) and the W atom ($4d^4S^2$) and the fact that W compounds are more inert than Mo compounds, this result is also reasonable.

3.4. *Cyclic voltammetry*

The cyclic voltammograms of **1**–**4** in acetonitrile were shown in Fig. 2 and the cyclic voltammetry data were listed in Table 6. As is shown in Fig. 2 and Table 6, all the four complexes (**1**–**4**) possessed two similar electrochemical events. One is a pseudo reversible redox couple at -1.65–-1.99 V vs SEC (E_1) and one is an irreversible oxidation peak at $+0.19$–$+0.21$ V vs SCE (E_2). The values of E_1 are analogous to the redox potentials of MoS_4^{2-} (-1.08 V vs SCE) [28] and (o-xyl-S_2)$FeMS_4^{2-}$(M = Mo, -1.8 V; M = W, -1.8 V) [29, 30], which was evidenced to be the redox of M(VI)/M(V) by EPR study and the E_2 were very similar to that of $[M(CO)_4(S_2CNEt_2)]^-$ (M = Mo, $+0.14$ [14]; M = W, $+0.15$ V [10]) and $[Mo(CO)_5SR]^-$ ($+0.17$ V) [5]. This apparently indicates that E_1 and E_2 events resulted from the redox of the $M^0(CO)_4$- and $M^{VI}S_4$ centers in the complexes, respectively. In terms of the voltammetric peak current parameters $i_p/v^{1/2}AC$ of E_1 and E_2 similar to that (observed in identical conditions) of Cp_2Fe which was known to be one-



Scheme 1.

electron redox process, both E_1 and E_2 events are one-electron redox processes. Thus the electrochemical behavior of the four complexes can be expressed as shown in Scheme 1.

In comparing the E_1 and E_2 with the redox potentials of related M^{VI} compounds, MoS_4^{2-} and M^0 compounds, $[M(CO)_4(S_2CNEt_2)]^-$ (M = Mo and W), (see Table 6) it is easy to find that E_1 values of all the complexes are more negative than the redox potential of MoS_4^{2-} indicating that the oxidation states of the high valence metal atoms M^H in all the four compounds are lower than VI and the E_2 of all the compounds are more positive than the redox potential of $[M(CO)_4(S_2CNEt_2)]^-$ (M = Mo and W) showing that the oxidation states of the low-valence metal atoms M^L in all the compounds are higher than zero. This implies a partial electron delocalization from M^0 to M^{VI} atoms in the mixed-valence metal cluster compounds. In other words, a charge transfer, $M^0 \rightarrow M^{VI}$, takes place between the mixed-valence metallic centers. Carefully examining the E_1 and E_2 values of **1**–**4**, it could be seen that the E_1 of **3** and **1** are more negative than that of **2** and **4**, respectively, indicating that the oxidation states of the high valence metal atoms M^H in **2** and **4** are higher than that in **3** and **1**, respectively and the E_2 of **1** and **4** are more positive than that of **3** and **2**, respectively, meaning that the low valence metal atoms M^L in **1** (Mo) and in **4** (W) have higher oxidation states than those in **3** (Mo) and **2** (W), respectively. Thus, for the extents of charge transfer $M^0 \rightarrow M^{VI}$ we have the results. **1** > **3**, **4** > **2**, **1** > **4** and **3** > **2**. This result is exactly the same as that shown in Scheme 1 obtained from the IR spectra studies.

3.5. ^{95}Mo *NMR spectra*

The ^{95}Mo NMR spectra of **1**, **3** and **4** are shown in Fig. 3 and the chemical shift data are listed in Table 7. The ^{95}Mo NMR spectra of **1**, **3** and **4** contain two kinds of ^{95}Mo chemical shifts, δ_1 at down field and δ_2 at up field. Referring to the ^{95}Mo chemical shifts of Mo^0 compound, $Mo(CO)_6$ (−1856 ppm [31]) and Mo^{VI} compound, MoS_4^{2-} (2209 ppm), δ_1 and δ_2 are, respectively, related to the MoS_4 and $Mo(CO)_4$ centers, in **1**, **3** and **4**. Obviously, the δ_1 are lower than that of MoS_4^{2-} and the δ_2 are higher than that of $Mo(CO)_6$ showing Mo atom of MoS_4 center in the complexes has somewhat more shielding than that of MoS_4^{2-} and the Mo atoms of $Mo(CO)_4$ centers in the

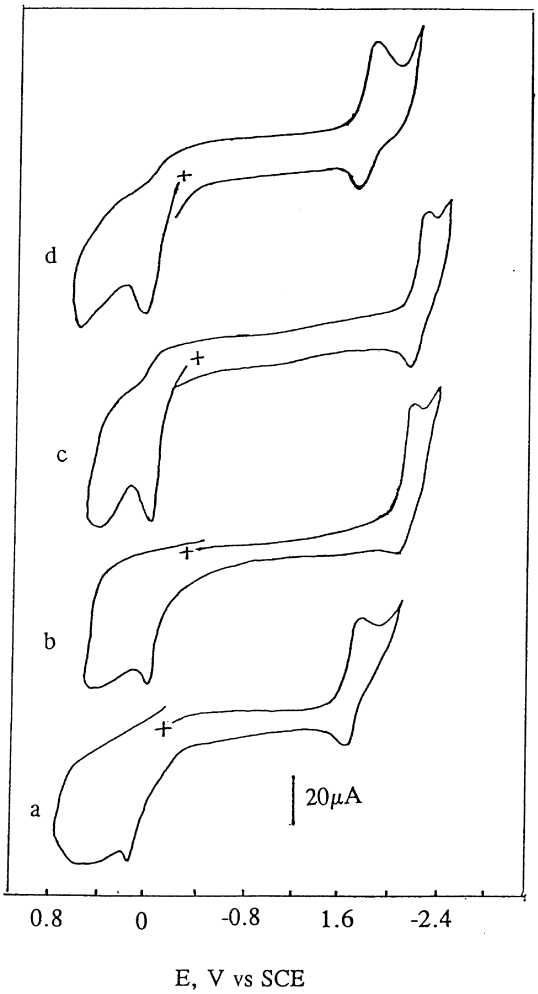

Fig. 2. The cyclic voltammograms of **1**(a), **2**(c), **3**(b) and **4**(d), in MeCN, sample concentration, 0.002 M; scan rate, 100 mV s^{-1}.

complexes have less shielding than that of $Mo(CO)_6$. This is consistent with the results from structure, IR and CV studies that the oxidation states of Mo atom of the MoS_4 center in the complexes are somewhat lower than +6 and the valences of Mo atoms of $Mo(CO)_4$ centers in the complexes are somewhat higher than zero. Such a shift in oxidation state implies the existence of charge transfer between the two different valence metal centers in the complexes. In comparison to the down field δ_1 values of **1** with **4**, it could be found that δ_1 of **1** is larger than the one of **4**. In terms of the "chemical shift-oxidation state relationship" hold in the di- and trinuclear Mo–W– series complexes with an M–M bond: the shielding increases (NMR signal shift to upfield) with an increase in the oxidation state [25, 26], the oxidation state of the Mo atom in a MoS_4-center of **1** would be lower than that of **4**, thus, the larger shift in oxidation state of **1** indicates that the charge transfer in **1** is larger than that in **4**. This is consistent with the results from IR and CV studies mentioned above. Interestingly, according to the X-ray crystallography, IR and CV studies, the oxidation state of the Mo atom in a $Mo(CO)_4$ center of **1** is higher than that in **3**, but the δ_2 of **1** more shifts to downfield than that of **3**. This indicates that, in contrast with δ_1, the δ_2 shows the normal "chemical shift-oxidation state relationship: the shielding increases (NMR signal shift to upfield) with a decrease of oxidation state" as monomeric complexes of molybdenum do [31, 27].

4. SUMMARY

1. Reaction of M^0-carbonyl such as $M(CO)_6$ and $[M(CO)_4(S_2CNEt_2)]^-$ with tetrathiometallate, MS_4^{2-}, results in a series of mixed-valence metal cluster compounds $[(OC)_4MS_2M'S_2M(CO)_4]^{2-}$ (M = Mo or W; M′ = Mo or W) by control of the ratio of reactants and use of different solvents.
2. Trinuclear cluster compounds contain an $MS_2M'S_2M$ skeleton with metal atoms in widely separated formal oxidation states (zero and plus six).
3. X-ray crystal structure, IR, CV and ^{95}Mo NMR studies reveal the existence of mixed valence metal atoms and charge transfer $M^0 \rightarrow M^{VI}$ in all the four cluster complexes.
4. The extent of charge transfer $M^0 \rightarrow M^{VI}$ for all the complexes are: **1** > **4**, **1** > **3**, **4** > **2** and **3** > **2**. This implies the charge transfer extents: $Mo^0 \rightarrow Mo^{VI} > W^0 \rightarrow Mo^{VI}$, $Mo^0 \rightarrow W^{VI} > W^0 \rightarrow W^{VI}$, $Mo^0 \rightarrow Mo^{VI} > Mo^0 \rightarrow W^{VI}$ and $W^0 \rightarrow Mo^{VI} > W^0 \rightarrow W^{VI}$, thus, it appears that the electron-donation ability of Mo^0 is larger than that of W^0 and the electron-accepted ability of Mo^{VI} is also larger than that of W^{VI}. In other words, Mo^0 is more easily oxidized than W^0 and Mo^{VI} is more easily reduced than W^{VI}.

(Received 27 March 1998; accepted 15 June 1998)

Abstract—The stoichiometries and stability constants of the copper(II) complexes with seven aminodiphosphonates [R–N($CH_2PO_3H_2$)$_2$, L] containing iminomethylenephosphonate moieties have been determined pH-metrically at 25°C and at an ionic strength of 0.20 mol dm^{-3} (KCl). The results suggest for L = **1**–**6** only equimolar species: [Cu(H_2L), [Cu(HL), [CuL] and two hydroxo [CuH$_{-1}$L] and [CuH$_{-2}$L], in the pH range of 2–11.5, the only difference is the presence of an additional [Cu(H_3L)] species (~15%) at low pH for N-3-picolyliminodi(methylenephosphonic) acid. For L = **7** the model contains protonated and non-protonated 1:2 species. From the comparative analysis of the stability and the spectroscopic (UV–VIS and EPR) data it has been established that the ligands in [CuHL] and [CuL] are tridentate; the formation of two five-membered chelate rings leads to very stable complexes. The LMCT bands from O$^-$ (PO_3^{2-}) and N_{imino} to Cu^{2+} are at 225–231 and 302–277 nm. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: potentiometry; stability constants; copper(II) complexes; aminopolyphosphonates; EPR spectra; UV–VIS spectra.

INTRODUCTION

The aminopolyphosphonates are analogues of aminopolycarboxylates in which the carboxyl groups (CO_2^-) are substituted by phosphonate moieties (PO_3^{2-}). Among the most widely commercially used of aminoalkylphosphonic acids [1–5] is diethylenetriamine-N,N,N′,N″,N″-pentamethylenephosphonic acid; available under various trade names such as "DEQUEST" and "BRIQUEST". An investigation of the interaction of the phosphonic groups with metal ions may provide useful information on the behaviour of these type of compounds. Studies on the simpler aminomethylenephosphonic acids serve as models for understanding the behaviour of more complex systems [6].

Aminopolyphosphonic acids and their derivatives have also received considerable attention because of their interesting biological activity. For example, N,N′-di(phosphonomethyl)glycine is an active component of Polaris®, known plant growth regulator [7], whereas N-(phosphonomethyl)glycine is an active ingredient of a popular herbicide Roundup® [8, 9].

Metal aminophosphonate (aminopolyphosphonate) chemistry is attracting increasing interest because of the variety of properties than can be introduced via the phosphonate ligand [10, 11]. The complex-formation equilibria have been reported for several kinds of C- or N-substituted derivatives of iminodimethylenebis(phosphonic acid) [12–16]. The

complex formation of N,N-dimethyliminodi(methylenephosphonic) acid and N,N-dimethylaminomethylphosphonic acid with alkaline-earth and divalent transition metals have been investigated by Sawada *et al.* [17]. Thermodynamic parameters for chelate complexes of some aminopolyphosphonates–alkaline-earth metal ions have been studied by calorimetric titrations also by Sawada *et al.* [18]. Kozlowski *et al.* [19] report pH-metric and spectroscopic studies for the proton and copper(II) complexes of a series of ambidentate N-(phosphonomethyl)amino acids containing both iminomethylenecarboxylate and iminomethylenephosphonate moieties. Potentiometric and spectroscopic studies on the coordination ability of biologically important pyridine mono- and bis-phosphonates have shown that, when sterically possible, these compounds undergo tridentate coordination with copper(II) and the complexes are very stable [20].

Thus, although metal complexes of aminophosphonic (aminopolyphosphonic) acids have been studied fairly extensively in solution, their solution chemistry is still not well understood [21, 22]. Moreover, bisphosphonic acid derived herbicides are frequently inactive if applied in natural environment. There are two possible explanations of the lack of their activity: either they may be fast and effectively degraded by soil microflora or strongly bound by soil (most probably as metal ion complexes) and thus inactivated. So, for better understanding and interpretation of the biological findings more detailed knowledge about complexing abilities of this type of compounds is indispensable.

The aim of this work was to study (in aqueous solution) the protonation equilibria, coordination modes and the stability of the complexes of Cu^{II} with a large group of iminodiphosphonic acids which secondary amine moiety substituted by various functional groups (see Scheme 1).

2. EXPERIMENTAL

2.1. *Materials*

Diphosphonic acids used in this paper were obtained according to previously described procedures [23, 24]. The purity and the exact concentrations of the solutions of the ligands used for potentiometric studies were determined by the Gran method [25]. The concentration of copper(II) chloride stock solution was standardized by complexometric ethylenedinitrilotetraacetate (EDTA) titration. Carbonate-free potassium hydroxide (the titrant) was prepared and standardized against a standard potassium hydrogenphthalate solution.

2.2. *Potentiometry*

The stability constants of the proton and copper(II) complexes were determined by pH-metric titration of $2\,cm^3$ samples. The ligand concentration was $2\times10^{-3}\,mol\,dm^{-3}$ and the metal ion:ligand ratio was 0:1; 1:1.5; 1:2 or 1:3. The ionic strength was adjusted to $0.2\,mol\,dm^{-3}$ with KCl in each case. The titrations were performed over the range pH 2.5–11.5 with KOH solution. All titration solutions were thermostated at $25\pm0.1^{\circ}C$ using a constant-temperature waterbath.

The pH was measured with a MOLSPIN automatic titration system using a micro combination pH electrode (Mettler-Toledo, Type 2). The electrode system was calibrated by periodic titrations of HCl solution ($7.5\times10^{-3}\,mol\,dm^{-3}$ in KCl) against standard KOH solution. The resulting titration data were used to calculate the standard electrode potentials, E^0, and the dissociation constant for water ($pK_w=13.74$). These values were then used to calculate the hydrogen-ion concentration $[H^+]$ from emf readings [26]; number of titration, 3; calculations, SUPERQUAD computer program [27].

For clarity, the charges of the complexes are omitted in the text and tables. It has to be mentioned,

however, that the fully deprotonated forms have charges L^{4-}.

2.3. *Spectroscopic measurements* (*UV/VIS and EPR*)

The UV–VIS absorption spectra were obtained at room temperature on a SPECORD M40 spectrophotometer. The spectra were recorded digitally ($20\,cm^{-1}$) over the range 11000–50000 cm^{-1}. The spectral data at selected *ca*. 1000 wavenumbers over the range 28000–50000 cm^{-1} (or 24000–50000 cm^{-1}) were employed for analysis and resolved into Gaussian components. The metal ion concentration was 3×10^{-4} mol dm^{-3} for UV and 3×10^{-3} mol dm^{-3} for VIS. The spectra were fitted with Gaussian bands using the CFP program [28] based on the Slavič [29] numerical algorithm, which for the last a few years has been successfully applied by us to the deconvolution of d–d (ligand field) spectra [30, 31, 32] (and references therein).

Electron paramagnetic resonance (EPR) spectra were performed on a Bruker ESP 300E spectrometer at the X-band frequency (9.45 GHz) at 77 K in ethylene glycol–water (1:1 v/v) solutions. The ligand concentration was 4.0×10^{-3} mol dm^{-3} and the concentration ratio of metal–ligand was 1:2. The spectra were analysed by computer simulation program [33] based on resonance fields calculated according to method of Sakaguchi *et al*. [34].

3. RESULTS AND DISCUSSION

3.1. *Potentiometric and EPR studies*

Protonation constants were calculated first assuming ligand concentrations as calculated from the titration curves and secondly, after allowing ligand and proton concentrations to "float" in SUPERQUAD. It was found that the concentrations never changed by more than 1% and calculated constants remained constant within the calculated errors. These observations confirmed the purity of the aminodiphosphonic acids studied. The list of these compounds is shown in Scheme 1.

The fully protonated forms of the ligands **1**–**5** and **7** contain five dissociable protons (H_5L^+) (two at each phosphonic function and one at the imino nitrogen, N_{imino}), and six protons in the case of ligand **6** (H_6L^{2+}) (due to additional proton at the pyridine nitrogen atom).

The acid–base properties of the aminodiphosphonic acids differ from those of aminomonophosphonates. The latter have three protonation constants with $\log K_{NH_3^+}\approx10$–11, $\log K_{PO_3H^-}\approx5$–6 and $\log K_{PO_3H_2}\approx1$ [35, 36] and give not only equimolar species. The presence of the second phosphonic group ($\log K_{PO_3H^-}\approx5$) in the case of aminodiphosphonates **1**–**6** leads to equimolar species only and to the formation of additional protonated Cu^{II} complexes.

It is evident from Table 1 that the change of pK values calculated for compounds **1**–**7** is consistent with electronic effects of the substituents attached to the imino nitrogen. Thus, substitution of the methyl by more electrodonating izopentyl group increases an electron density on the nitrogen atom; this density is partly transferred to the phosphorous atoms. This effect makes the amino and the PO_3H^- groups more basic and pK values for **2** is higher than this for **4**. On the other hand, the presence of acid strengthening aromatic rings decreases pK(NH^+) values for **5** and **6** as compared to **4**; the highest acidity of the NH^+ group corresponds to stronger electron withdrawing effect of pyridine than that manifested by benzene ring.

The pK values characteristic for the dissociation of the two protons from the two $-PO_3H_2$ groups are $\sim$1.5–2, and thus they are fully deprotonated in the pH range studied and do not take part in metal coordination equilibria. Only the highest pK can be unambiguously assigned (due to proton dissociation from the imino nitrogen, NH^+). The further deprotonation of the phosphonic groups may cause overlapping of each other what means that the $pK_{PO_3H^-}$ macroconstants are not characteristic feature of real acidity of these groups. This means that the microscopic acid dissociation constants must be determined to clarify the acid–base properties of the studied ligands but this was beyond the scope of the present work. The acidic deprotonation site with pK of 2.94 for **6** seems to be localized at the pyridine ring nitrogen.

The ligands **1**–**6** exhibit similar Cu^{II}-coordination pattern (Table 1). The model contains protonated complexes but neither a 1:2 species nor any polynuclear ones. This finding was what is additionally proved by the EPR studies (Table 2). The formation of the bis complexes seems to be generally hindered because studied ligands are generally tridentate yielding two five-membered chelate rings. The electrostatic repulsion of the negatively charged phosphonate groups precludes coordination of the second ligand; the charge of the bis complex would be $6-$. Hence, only 1:1 complexes are formed and data collected in Table 1 indicate high chelating ability of the ligands towards Cu^{II}. The chemical model for system of ligand **7** with copper(II) is different if comparing with all the others studied systems. This model contains protonated and non protonated 1:2 species (Table 1) which result from the presence of the additional coordination site.

The metal complex speciations derived from potentiometric calculations for compounds **1**–**6** do not differ considerably. The Cu^{II}/ligand **5** system presented in Fig. 1 exhibits, in general, approximately the same distribution curves as those observed for the other ones, and thus is representative for all the group. Three complexes: [$Cu(H_2L)$], [Cu(HL)], [CuL] and two hydroxo [$CuLH_{-1}$] and [$CuLH_{-2}$], are formed in the pH range of 2–11.5, with the single difference found

[b]$\log K = \log \beta_{[Cu(HL)]} - pK_{PO_3H^-}$.

for complexes of compound **6**, namely the presence of an additional $[Cu(H_3L)]$ species (~15%) at low pH (Fig. 1).

The deprotonation constant, pK_{CuH_3L}, of the corresponding equilibrium: $[Cu(H_3L)] \rightleftarrows [Cu(H_2L)] + H^+$, is 2.92. This value is almost identical with that obtained for the ligand itself (Table 1) supporting that N_{pyr} is not involved in the coordination. In this case the pyridine nitrogen is unable to coordinate the metal ion due to steric reasons. Thus, for the first species the propose binding mode is (PO_3^{2-}, PO_3H^-) with N_{pyr} and N_{imino} protonated. This may be supported by the d–d transition at around 773 nm. For a species with two monoprotonated phosphonic functions this transition should be around 800 nm [20]. This fact is in good agreement with the EPR spectral properties of the species $[Cu(H_3L)]$ (at pH 2.6). The values of $A_\parallel$ and $g_\parallel$ (Table 2) imply that the coordination sphere around Cu^{II} in plane consists of oxygen atoms as only donors.

Deprotonation of $[Cu(H_2L)]$ leads to the formation of [Cu(HL)]. This process is not accompanied by a significant shift of the d–d band (Table 2). It is interesting that all the first deprotonation constants of $[CuH_2L]$, pK_{CuH_2L}, are of the same order of magnitude and considerably lower than the corresponding deprotonation constants of the free ligands (see Table 1). It seems that in $[Cu(H_2L)]$ the Cu^{II} is coordinated to the N_{imino} and PO_3H^- chelate donor system, whereas the second phosphonic group, PO_3H^-, remains uncoordinated. Taking into account a strong affinity of Cu^{II} to nitrogen donors it is much more likely that a protonation occurs via the phosphonate O^-.

EPR parameters, $g_\parallel$ and $A_\parallel$, of the species formed with ligands **1**–**6** existing at pH 3.6 (Table 2) are apparently different from those found for Cu^{II} ions coordinated by oxygen donors of phosphonic groups as the only ligands [37, 38] (in which $g_\parallel = 2.400$ and $A_\parallel = 143 \times 10^{-4}\,\mathrm{cm^{-1}}$). This fact confirms participation of the imino nitrogen and PO_3H^- group in the chelate ring of $[Cu(H_2L)]$. Furthermore, EPR spectral parameters, for the first $[Cu(H_3L)]$ species for L = **6** at pH about 2.6 are evidently dissimilar in comparison with those observed for the remaining ligand systems and their values are consistent with the smallest strength of metal–ligand interaction.

The deprotonation of the imino group starts above pH 5.0 and may overlap with deprotonation of PO_3H^- groups. Therefore, in [Cu(HL)] the $\{PO_3^{2-}$, N_{imino}, $PO_3H^-\}$ set can be active. The tridentate character of the donor set results in a small but detectable increase in $A_\parallel$ and decrease in $g_\parallel$ (Table 2). Taking into account the difference in acidity of the coordinating donor PO_3H^- group equilibrium constant

[a]**a**: the EPR spectrum of $[Cu(H_2L)]$ for L = **1** and **3** was not found to be in agreement with its smaller contribution than that found for the same complex formed by L = **2** and **5**. It is also difficult to distinguish the spectra at low pH in the case of the systems with L = **1**, **3**, **4** and **6** in accordance with a too small separation between the maxima corresponding to the contribution of $[Cu(H_2L)]$ and [Cu(HL)] species; **b**: the stepwise transition to $[Cu(OH)_4]^{2-}$ is reached after one day, in contrast to the remaining complexes which appeared to be more stable.

[b]The VIS absorption bands presented in the table arise from distribution-corrected absorption spectra and their positions are approximately estimated from experimental spectra. The UV absorption data arise from Gaussian analysis of the experimental spectrum.

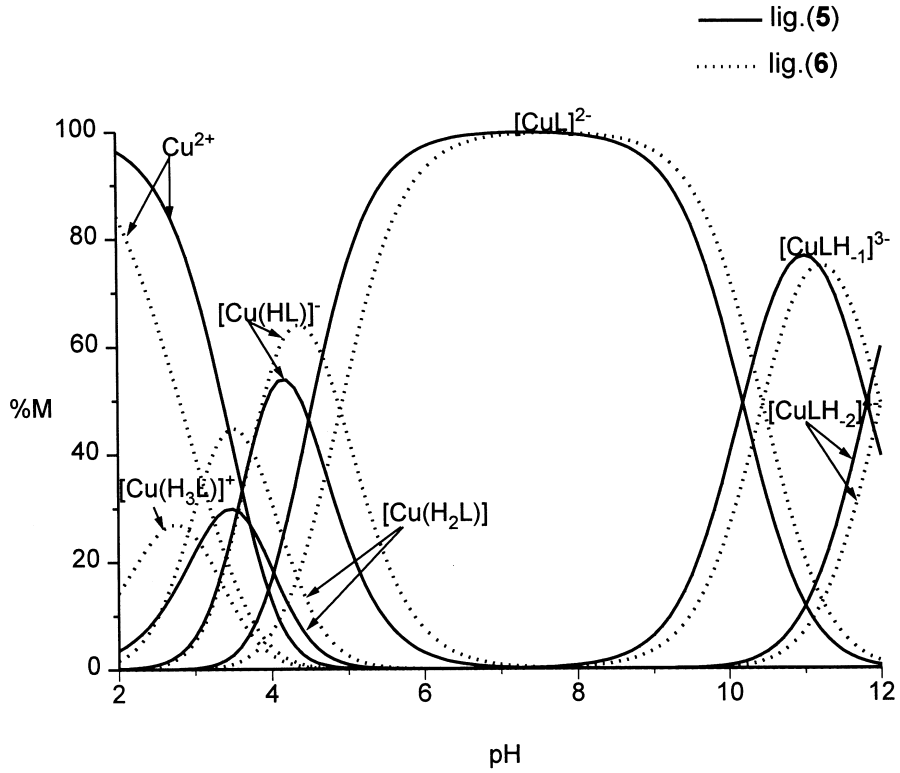

Fig. 1. Species distribution curves for the complexes formed in the Cu^{II}/ligand **5** (full line) and Cu^{II}/ligand **6** (dotted line) systems as a function of pH; $c_{Cu^{2+}} = 3 \times 10^{-3}$ mol dm^{-3}; $c_L = 5 \times 10^{-3}$ mol dm^{-3}.

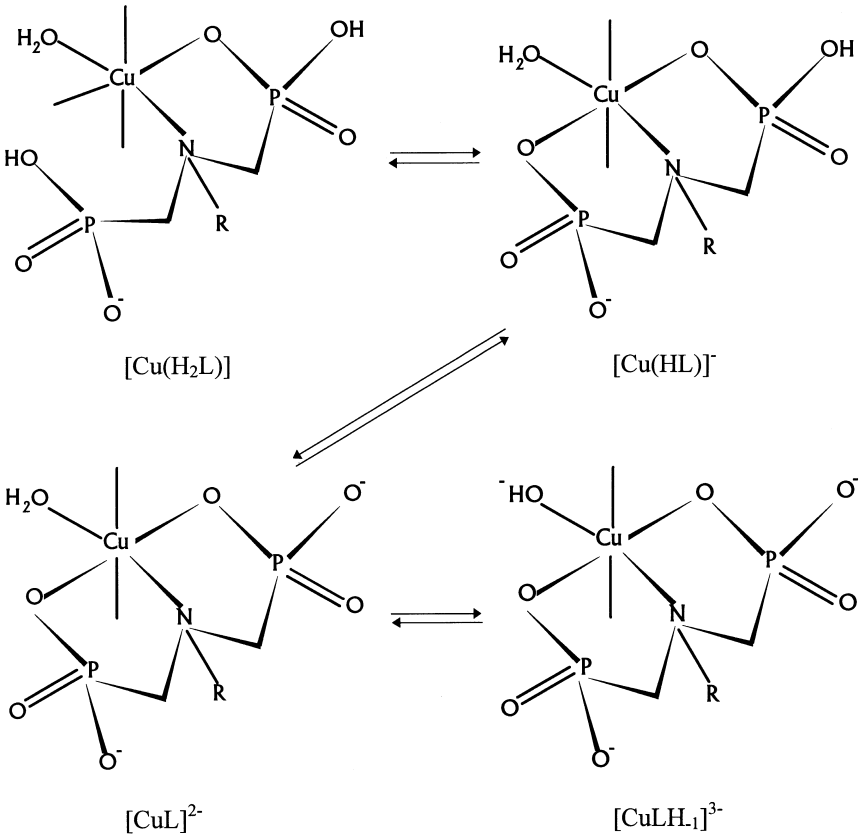
$\log K_{CuHL} = \log \beta_{Cu(HL)} - pK_{PO_3H^-}$, is about of the same order of magnitude as stability constant, $\log K_{CuL}$ (Table 1). This fact suggests the same O,N,O-tridentate binding mode of the ligands in these two species.

The formation of [CuL] follows the liberation of the proton from weakly coordinated $-PO_3H^-$ group, which consequently becomes more strongly bound to Cu^{II}. The proposed bonding mode for [CuHL] and [CuL] (Scheme 2) should be favoured by the stability increase due to the simultaneous presence of two five-membered chelate rings in the molecule. The sterically possible simultaneous binding of the phosphonate–O^- of both phosphonic groups and imino nitrogen [39] of these tridentate ligands to Cu^{II} is reflected in a high stability constant of [CuHL] and [CuL] (Table 1). An evident increase in $A_{\|}$ and decrease in $g_{\|}$ values can be treated as a further indication that Cu^{II} coordination is realized by the $\{PO_3^{2-}, N_{imino}, PO_3^{2-}\}$ donor set. It is noteworthy that the spectrum of [Cu(HL)] for L = **7** is observed at distinctly lower pH than for the remaining ligands. This result is in a good agreement with the calculated species distribution. Ligand **7** is a more effective chelating agent than other ones. This is reflected in the higher basicity-adjusted stability constant, $\log K_{[CuL]} - \Sigma pK$ (Table 1) and also in the pH value of complexation of 20% of Cu^{II}, which is $\sim$5% for other ligands (Figs. 1 and 2). A comparison of the copper complexes of **5** and **7** (these ligands have the same basicity) shows significant differences. Basicity-adjusted stability constants, $\log K_{[CuL]} - \Sigma pK$, are -9.18 and -7.57 for **5** and **7**, respectively. Taking this into account, comparison of [Cu(**5**)] and [Cu(**7**)] complexes still reveals a difference in stabilities of about 1.6 log units, suggesting strong interaction between Cu^{II} and the furyl oxygen atom (Scheme 3). The proposed bonding mode for [CuHL] and [CuL] (L = **7**) should be favoured by the stability increase due to the simultaneous presence of three five-membered chelate rings in the molecule. The sterically possible simultaneous binding of the phosphonate–O^- of both phosphonic groups, imino nitrogen and furyl oxygen to Cu^{II} is reflected in a very high stability constant of [CuHL] and [CuL].

A comparison of the EPR spectra as a function of pH for the Cu^{II}/ligand **7** system with those e.g. for the Cu^{II}/ligand **3** system (Fig. 3) indicates the 2*N* coordination in the former system, which means that 1:2 species are formed. It also results in a distinct shift in the d–d transition to higher energies if comparing spectra of 1:1 and 1:2 species for the former system. Moreover, the EPR spectra show equilibrium between these species in wide pH range (in contrast to lone [CuL] species observed in the case of **1**–**6** ligands) again confirming unique distribution of the species postulated for Cu^{II}/ligand **7** system.



Scheme 2. Proposed structures of complexes formed by ligands **1**–**6** with copper(II).

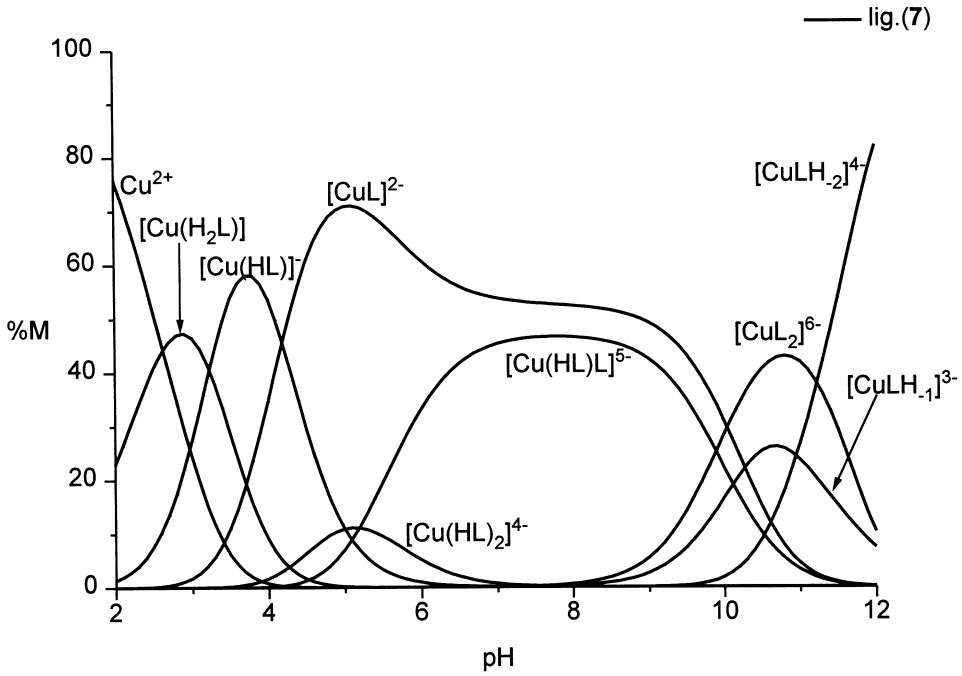


Fig. 2. Species distribution curves for the complexes formed in the Cu^{II}/ligand **7** system as a function of pH; $c_{Cu^{2+}} = 3 \times 10^{-3}$ mol dm^{-3}; $c_L = 5 \times 10^{-3}$ mol dm^{-3}.

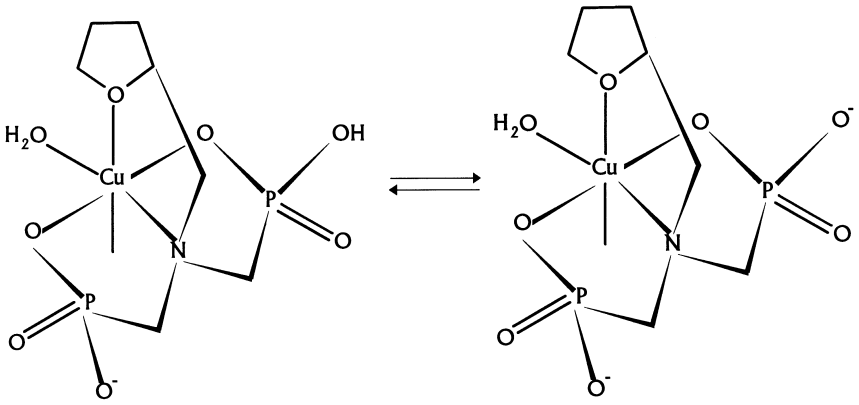

Scheme 3. Proposed structures of the $[Cu(HL)]^{-}$ and $[CuL]^{2-}$ complexes formed by ligand **7**.

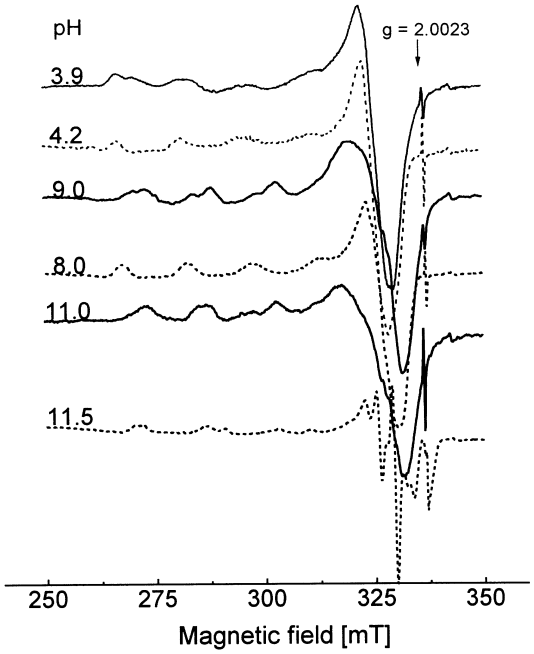

Fig. 3. The comparison between the EPR spectra of the complexes formed by ligand **7** (solid line) and **3** (dashed line) as a function of pH; $c_{Cu^{2+}} = 2 \times 10^{-3}$ mol dm^{-3}; $c_L = 4 \times 10^{-3}$ mol dm^{-3}.

The basicity-adjusted stability constants ($\log K_{[CuL]} - \Sigma pK$) varies in the sequence (Table 1):

$$[Cu(\mathbf{1})] < [Cu(\mathbf{2})] < [Cu(\mathbf{3})] < [Cu(\mathbf{5})] \approx [Cu(\mathbf{6})] < [Cu(\mathbf{4})] < [Cu(\mathbf{7})].$$

This can be explained, in part, by the significant changes of the amine substituent size. It is interesting that the sequence of the basicity-adjusted stability constants of the [Cu(**4**)] and [Cu(**1**)] species is an opposite to the basicity of the free ligands. Probably, in this case the stability increase due to the increase in basicity of the coordinating donor groups is overcompensated by steric (R-group size) and electrostatic effects [40]. This presumably also appears in the spectral parameters of [CuL] (see below).

Two further deprotonation processes of [CuL] leading to the formation of $[CuLH_{-1}]$ and $[CuLH_{-2}]$ are detected in potentiometry and correspond to the subsequent dissociation of the protons from coordinated water molecules. The first $[CuLH_{-1}]$ complex exhibits slightly blue-shifted d–d band and is observed in the EPR spectrum. The characteristic change of the EPR parameters (Table 2) is consistent with replacement of a water molecule by an OH^{-} group in the metal plane.

3.2. *Spectrophotometrical studies*

Absorption spectra of the Cu^{II}/ligand **2** system presented in Fig. 4 exhibit, in general, approximately the same changes vs pH as those observed for the other above-mentioned systems. Even at the pH level where the distribution of the species has a maximum, the other complexes coexist in a greater or smaller extent. Therefore, in the absorption spectra measured even at this pH level the contributions from the other species would be included. To extract the ligand-field absorption spectrum of each species, the experimental spectrum, measured at a pH value where each species exhibits maximal contribution, was resolved into the components spectra corresponding to the individual species existing at that pH. The molecular absorptivity for the individual species was then calculated taking into account their distribution. The distribution-corrected curves for the Cu^{II}/ligand **2** system are shown in Fig. 5. In some cases this method has not given satisfactory results for species which contribution was too small in the system.

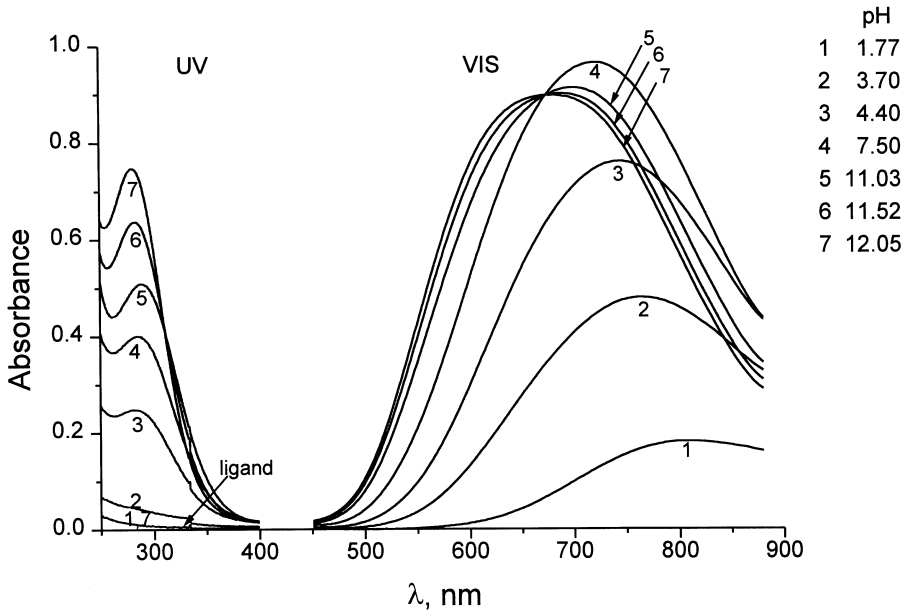

Fig. 4. pH-varied absorption spectra of the Cu^{II}/ligand **2** system: $c_{Cu^{2+}} = 3 \times 10^{-4}$ mol dm^{-3}; $c_L = 5 \times 10^{-4}$ mol dm^{-3} (UV-1 cm cells); $c_{Cu^{2+}} = 3 \times 10^{-3}$ mol dm^{-3}; $c_L = 5 \times 10^{-3}$ mol dm^{-3} (VIS-5 cm cells).

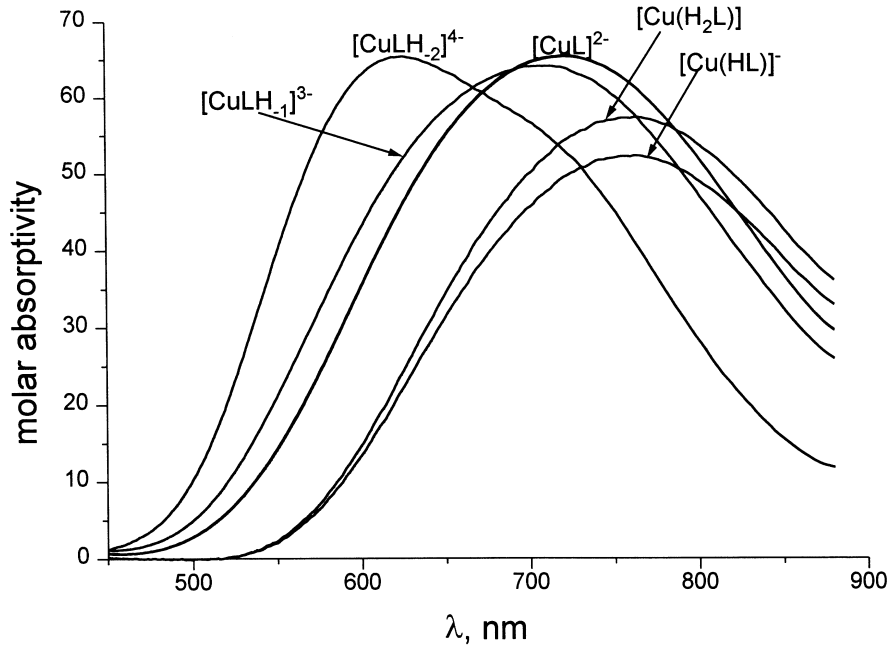

Fig. 5. Distribution-corrected absorption spectra for [Cu(H_2L)], [Cu(HL)], [CuL], [Cu(LH_{-1})] and [Cu(LH_{-2})] in the Cu^{II}/ligand **2** system.

3.3. *Ultraviolet spectroscopic studies*

All the band maxima reported in this work are derived from Gaussian analysis of the experimental curves in the ultraviolet region. In general, the unique procedure (see Section 2) which starts with Gaussian analysis, through assignment of the bands, to calculation of the chemically useful parameters, is based on two assumptions: the symmetry of compound is known, and theoretical model (e.g. ligand field model for the complexes and orbital molecular model for the ligands) is adequate for the calculation of the spectral

parameters. Unfortunately, the systems presented in this work are rather complex. Different structures of the particular ligands are the reason that above mentioned interpretation makes for considerable difficulties. Thus, each system studied should be analysed. separately. Therefore, the Gaussian analysis of the ultraviolet spectra in this work provides the bands which can be really conclusively distinguished from the experimental (observed) spectrum. The numerical spectra $\varepsilon_i = f(\nu_i)$ and full Gaussian analysis results of all spectra are available from the authors on request. Fig. 6(a),(b) presents (as representative example) ultraviolet spectra ($\varepsilon_i = f(\nu_i)$) along with Gaussian components for Cu^{II}/ligand **4** and Cu^{II}/ligand **6** systems.

Because ligands **1**–**4** have not bands in the UV region, observed two bands correspond to the CT transitions (for example: Cu^{II}/ligand **4** system in Fig. 6(a)). Although compounds **5**, **6** and **7** have their own UV absorption spectra, two new bands are easily seen when their spectra are compared with those for the complexes (for example: Cu^{II}/ligand **6** system in Fig. 6(b)). A number of respective bands indicates clearly diversity of the metal-bond donor set. The CT band at 288 nm is not observed for the Cu^{II}/ligand **8** system **8** = 1-hydroxy-3-methylbutylphosphonic acid $(CH_3)_2CHCH_2CH(OH)PO_3H_2$) (Fig. 6(c)). In this case the coordination of phosphonate oxygen atoms to copper(II) is beyond doubt. Thus, the band at 302–277 nm observed for the copper(II)–**1**–**6** and **7** systems corresponds most likely to the $N_{imino} \rightarrow Cu^{II}$ LMCT transition (a similar range of energy was found for the copper(II)-N-iminodi(methylenephosphonic) acid system [20]. The second band are seen in these seven systems at 225–231 nm. This band is similar to this observed for the Cu^{II}/ligand **8** system and $[Cu(H_2O)_6]Cl_2$ complex (212 nm) (Fig. 6(c),(d)) and can be reasonably assigned to the transition from PO_3^{2-} oxygen to copper(II) i.e. LMCT transition.

From the data collected in Table 2 we conclude that the energy order of the lower energetically CT transition displays hipsochromic effect (i.e. increasing energy)

$$[\mathrm{Cu}(\mathbf{1})] < [\mathrm{Cu}(\mathbf{5})] < [\mathrm{Cu}(\mathbf{6})] \approx [\mathrm{Cu}(\mathbf{7})] \approx [\mathrm{Cu}(\mathbf{3})] < [\mathrm{Cu}(\mathbf{2})] \ll [\mathrm{Cu}(\mathbf{4})].$$

This effect depends predominantly on the size of the fragment R (Scheme 1) bonded to the nitrogen donor. These fragments are directly influencing the nitrogen donor–metal bonding. The highest energy is observed when R = methyl group and the lowest when R

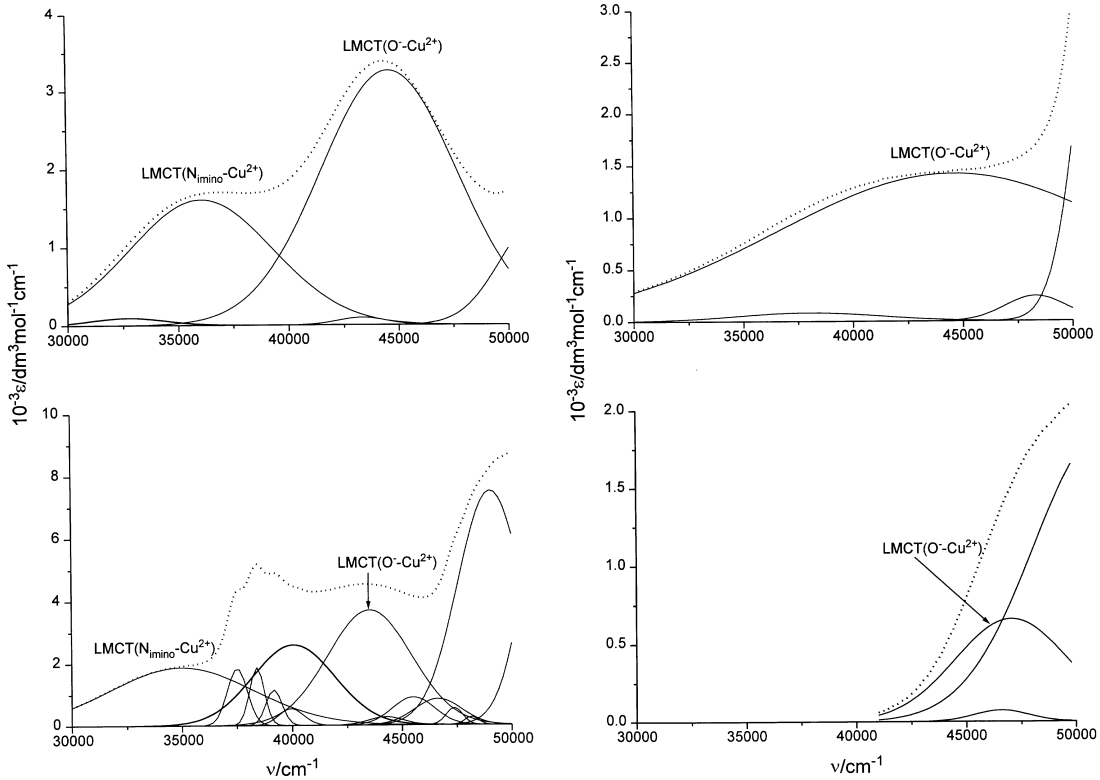

Fig. 6. Ultraviolet spectra and Gaussian line-shape analysis for: [CuL]; L = **4** (a), L = **6** (b); pH 7.5; L = $(CH_3)_2CHCH_2CH(OH)PO_3H_2$ (c); $[Cu(H_2O)]Cl_2$ (d). (· · ·) experimental spectrum, (———) component bands.

involves a cyclohexyl ring. A similar energy relation is observed for the second CT transition.

4. CONCLUSION

The ligands **1**–**6** exhibit the model contains protonated complexes but neither a 1:2 species nor any polynuclear ones. From the comparative analysis of the stability and the spectroscopic (UV–VIS and EPR) data it has been established that the coordination in [CuHL] and [CuL] is realized by the $\{PO_3^{2-}$, N_{imino} $PO_3^{2-}\}$ donor set. Ligand **7** is a more effective chelating agent than other ones. The EPR spectra for the Cu^{II}/ligand **7** system indicate the 2*N* coordination so, 1:2 species are formed. It also results in a distinct shift in the d–d transition to higher energies if comparing spectra of [CuL] and [CuL_2]. A comparison of the basicity-adjusted stability constants, $\log K_{[CuL]} - \Sigma pK$, suggests strong interaction between Cu^{II} and the furyl oxygen atom.

Interaction of nitric oxide with cobalt(II) phthalocyanine: kinetics, equilibria and electrocatalytic studies

Sibulelo L. Vilakazi and Tebello Nyokong†

Department of Chemistry, Rhodes University, Grahamstown 6140, South Africa

(Received 20 April 1998; accepted 16 June 1998)

Abstract—The coordination of nitric oxide (NO) to cobalt(II) phthalocyanine (CoPc) in dimethyl sulphoxide (DMSO) has been studied. CoPc coordinates with NO in a 1:1 ratio, forming a CoPc(NO) species. The IR band observed at 1680 cm^{-1} is assigned to the coordinated NO. In the presence of excess NO, pseudo first order kinetics were followed. The observed rate constant, k_f, was determined to be $15.0 \pm 0.3\ dm^{-3}\ mol^{-1}\ s^{-1}$ and the equilibrium constant was $K = 5.4 \pm 0.4 \times 10^4 dm^3\ mol^{-1}$. Solution or adsorbed CoPc catalyses the reduction of NO. The products of reduction include NH_3 and NH_2OH. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cobalt; phthalocyanine; nitric oxide; catalysis; kinetics; equilibria.

INTRODUCTION

Nitric oxide (NO) has been found to be an essential component of many physiological processes. NO is believed to have a wide range of functions including regulation of blood pressure, neurotransmission and ability to kill intracellular parasites and tumorous cells [1–4]. NO readily forms complexes with transition metal ions, including those found in metalloproteins. Studies into the binding of NO by metalloporphyrins have aided in the understanding of how NO interacts with haem containing biomolecules such as haemoglobin and myoglobin. NO has been shown to have a high affinity for ferrous haem [3]. Both iron(II) and iron(III) porphyrins have been shown to coordinate NO, forming $Fe^{II}P(NO)$ and $Fe^{III}P(NO)$ complexes, respectively [5–7]. Autoreduction of the $Fe^{III}P(NO)$ complex to the $Fe^{II}P(NO^+)$ species has been reported [4, 6]. NO adducts of cobalt substituted myoglobin and haemoglobin have been reported [8], hence the substitution of iron by cobalt in synthetic porphyrins has gained considerable attention. Studies into the coordination of NO to cobalt porphyrin (CoP) complexes are of interest. $Co^{II}P$ readily binds NO forming the $(NO)Co^{II}P$ species. Cobalt(III) tetrakis(*N*-methyl-2-pyridyl)porphine ($[Co^{III}(2\text{-}TMPyP)]^{5+}$) is known to bind with NO through reductive nitrosylation with the formation of the $[(NO)Co^{II}(2\text{-}TMPyP)]^{4+}$ species [9]. Exposure of the $[(NO)Co^{II}(2\text{-}TMPyP)]^{4+}$ species to air rapidly converts it to $[(NO_2^-)Co^{III}(2\text{-}TMPyP)]^{4+}$. Metallophthalocyanine (MPc) complexes have a similar structure to the metalloporphyrins and have been used to mimic the properties of the naturally occurring metalloporphyrin complexes. MPc have an added advantage in that they are more stable to degradation than metalloporphyrin complexes. $Fe^{II}Pc$ has been shown to reversibly bind NO in dimethylsulphoxide (DMSO) according to eq. (1) [10, 11]

$$(DMSO)_2Fe^{II}Pc + NO \rightleftarrows (DMSO)(NO)Fe^{II}Pc + DMSO. \quad (1)$$

Axial coordination of NO to solid MnPc, CoPc and ZnPc has also been reported [12, 13]. Results from X-ray photoelectron spectroscopy showed that coordination of NO to MnPc, FePc and CoPc was accompanied by some electron transfer between the central metal and the NO molecule [13]. We report in this work on the kinetics and equilibria of the coordination of NO to CoPc in solution. It has recently been demonstrated that NO bonds to nickel(II) tetrasulphophthalocyanine ($[Ni^{II}TSPc]^{4-}$) in aqueous solu-

†Author to whom correspondence should be addressed. E-mail: chtn@warthog.ru.ac.za

tion. It was suggested that autooxidation of the $[Ni^{II}TSPc]^{4-}$ occurred following coordination of NO with the formation of a $[Ni^{III}TSPc(NO^{-})]^{4-}$ species [14]. Interestingly, in all the studies on the coordination of NO to metalloporphyrin or MPc complexes, only one mole of NO coordinates to one mole of the metalloporphyrin or MPc complex. However, it has been shown that axial ligand substitutions in MPc complexes occur in a stepwise manner, with the consecutive coordination of the two ligands [15].

Even though there are reports on the binding of NO to CoPc complexes, kinetic or equilibria information on this binding has not been reported. Binding of NO or NO_2^- to CoPc is of importance for analysis of these species, since ring substituted cobalt phthalocyanine complexes have demonstrated an excellent selectivity toward the electroreduction of nitrite ion [16].

There are a number of reports on the use of metalloporphyrin complexes [7, 17–24] and haemoglobin [25] for the electrochemical detection of NO and as electrocatalysts for the reduction of NO to ammonia and other products [9, 26]. Reports on the use of MPc complexes for the detection of NO are limited [27]. Selective reduction of NO to NH_3 has been reported [27] for CoPc adsorbed on a glassy carbon electrode. However, very low yields of NH_3 were observed at pH > 4 [27]. It is important to understand the role played by the MPc complexes during the electrocatalytic reactions. It has been suggested that electron transfer reactions mediate electrochemical detection of NO, using metalloporphyrin complexes [7]. Metal and ring-based reduction and oxidation processes can occur in CoPc complexes. In this work, we study the electrocatalytic ability of CoPc (in solution or adsorbed onto the electrode) for the reduction of NO.

EXPERIMENTAL

Materials

Cobalt(II) and iron(II) phthalocyanine (CoPc and FePc, respectively) were purchased from Aldrich and used without further purification. The solid complex between NO and CoPc was prepared by stirring CoPc in dimethylformamide (DMF) in an NO atmosphere for 4 h, then evaporating the solvent to dryness. NO was prepared by adding saturated sodium nitrite dropwise to a 0.2 mol dm^{-3} H_2SO_4 solution under nitrogen atmosphere. The NO produced was bubbled into nitrogen saturated deionized water or passed through a drying agent into nitrogen saturated, dimethylsulphoxide (DMSO). NO solutions in water or DMSO were prepared freshly before use and kept in a glass flask fitted with a rubber septum. The concentration of NO in DMSO was determined by the method proposed by Ascenzi *et al.* [11], using the reaction of NO with FePc in DMSO. The concentration of NO in DMSO could also be calculated using its solubility of 3.0×10^{-3} mol dm^{-3} [11]. NO concentration in water was calculated using the reported solubility of 2.2×10^{-3} mol dm^{-3} [11].

Electrochemical methods

Electrochemical data were collected with the Bioanalytical Systems (BAS) model CV-50 W voltammetric analyser. For cyclic voltammetry, a glassy carbon electrode (3.0 mm diameter) was used as a working electrode and a platinum wire as an auxiliary electrode. For nonaqueous studies, the reference electrode was the BAS nonaqueous reference electrode containing a silver wire immersed in a 0.01 mol dm^{-3} $AgNO_3$ and containing 0.1 mol dm^{-3} tetraethylammonium perchlorate (TEAP) in DMSO. The electrolyte was TEAP for all electrochemical experiments in nonaqueous solutions. For cyclic voltammetry in aqueous solutions, the reference electrode was the Ag/AgCl(3 mol dm^{-3} KCl). Concentrations of CoPc in DMSO for cyclic voltammetry were in the 10^{-4}–10^{-3} mol dm^{-3} range.

For electrocatalytic reactions, a glassy carbon electrode modified with CoPc (CoPc–GCE) was employed as a working electrode. The GCE was modified by the drop dry method, in which a drop of a saturated ($\sim 1 \times 10^{-3}$ mol dm^{-3}) solution of CoPc in pyridine was placed on the GCE and dried in air. Prior to coating with the CoPc complex, the GCE was polished with alumina on a Buehler felt pad, followed by soaking in dilute nitric acid and rinsing in water, acetone and the solvent of interest. For bulk electrolysis, a two compartment cell was employed, with a platinum plate of area 2.2 cm^2 as counter electrode and a Ag/AgCl (3 mol dm^{-3} KCl) reference electrode. The working electrodes consisted of a carbon rod (area = 0.2 cm^2) coated with CoPc using the drop dry method. Electrical contact with the working electrode was established via a copper wire. Phthalate buffer, pH 4, was used for studies of NO in aqueous solutions. A nitrogen atmosphere was maintained for all electrochemistry experiments. Yields of ammonia were determined by the Nessler method [28] and by monitoring the absorbance at 400 nm. Hydroxylamine was determined spectroscopically using the specific test described in the literature [9].

Kinetics and equilibria

Kinetic and equilibrium studies were run at 20°C and monitored with the Cary 1E UV–VIS spectrophotometer. We monitored the appearance of the spectra due to the product formed following the addition of NO to solutions of the CoPc in DMSO. Typically, a known volume of the DMSO solution of CoPc was added to a 1 cm path length cell and deaerated using nitrogen. Then a known volume of a deaerated solution of NO in DMSO was added to the cell

and the spectra monitored with time. Bubbling of nitrogen into the cell was continued while adding the NO solution. NO is readily oxidized by oxygen, hence the cell was fitted with a stopper to avoid oxygen affecting the reaction. Concentrations of the CoPc were kept constant at 4.5×10^{-6} mol dm $^{-3}$, while NO concentrations were varied from 6.2×10^{-5} to 1.2×10^{-4} mol dm^{-3}. Since the concentration of the NO was larger than that of CoPc by a factor of at least 10, pseudo-first order conditions were assumed for kinetic studies.

Infra red spectra were recorded with the Perkin Elmer Spectrum 2000 IR spectrophotometer, using CaF_2 windows and dichloromethane as the solvent.

RESULTS AND DISCUSSION

Spectral characterization

In DMSO solutions, CoPc is known to be a six coordinate complex [29], hence the starting complex for our studies is expected to be the $(DMSO)_2CoPc$ species. The *Q* band of the $(DMSO)_2CoPc$ species is centred at 660 nm. Figure 1 shows the absorption spectral changes observed when DMSO solutions of NO (1.1×10^{-4} mol dm $^{-3}$) were added to solutions of $(DMSO)_2CoPc$. On addition of NO, the *Q* band of the $(DMSO)_2CoPc$ species shifts isosbestically from 660 to 666 nm. An isosbestic point was observed at 657 nm. The presence of an isosbestic point is a clear indication that only two species are absorbing in the *Q* band region of the spectra. X-ray photoelectron spectroscopy studies [13] have shown that electron transfer from the metal to NO occurs following coordination of NO to CoPc. On the other hand, reductive nitrosylation has been reported for the coordination of NO to Co^{II} porphyrin complexes [9]. We investigated the possibility of the oxidation of $Co^{II}Pc$ to the $Co^{III}Pc$ species, following addition of NO to $(DMSO)_2CoPc$ in solution. When NO was added to solutions of chemically generated $Co^{III}Pc$ species in DMSO, the *Q* band of the resulting complex was observed at 665 nm, a wavelength very close to that obtained in Fig. 1(b) following addition of NO to $Co^{II}Pc$. It is thus likely that the $Co^{III}Pc$ species is formed in Fig. 1. Based on the absorption spectral data and on the X-ray photoelectron spectroscopic data, we represent the complex formed following coordination of NO to $Co^{II}Pc$ as the $Co^{III}Pc(NO)$ species. We used IR spectroscopy to study the interaction between NO and $Co^{II}Pc$. For IR studies, dichloromethane and not DMSO was employed as a solvent due to the strong IR vibrations of the latter in the region of NO vibrations. The IR spectra of $Co^{II}Pc$ in CH_2Cl_2 showed a new IR band at 1680 cm^{-1} in the presence of NO. The IR spectra of free NO was observed at 1847 cm^{-1}. The IR spectra of cobalt(II) porphyrins in CH_2Cl_2 and in the presence of NO, show the ν_{NO} in the 1681–1695 cm^{-1} region [30]. Thus, the IR band observed at 1680 cm^{-1} is assigned to bound NO. Vibrational frequencies of NO greater than 1700 cm^{-1} have been associated [14] with the electron

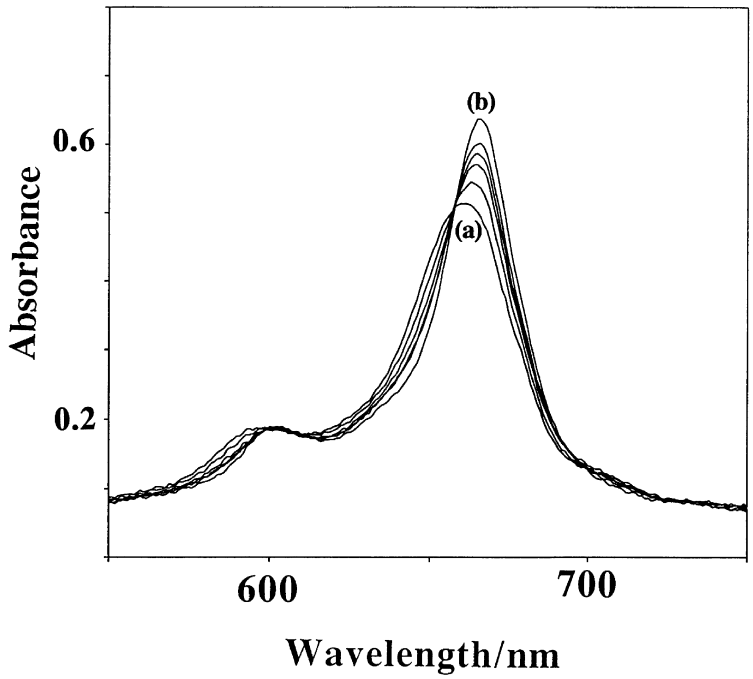

Fig. 1. Absorption spectral changes observed on addition of NO (1.1×10^{-4} mol dm^{-3}) to $(DMSO)_2CoPc$ in DMSO. (a) spectra before addition of NO (b) spectra 18 min after addition of NO.

transfer from NO to the central metal and NO vibrational frequencies less than 1700 cm^{-1}, to the metal to NO electron transfer [14]. Thus, the observation of an NO frequency lower than 1700 cm^{-1} for the complex formed when NO is added to $Co^{II}Pc$, supports the formation of the $(NO)Co^{III}Pc$ species as a result of electron transfer from the central metal to NO. Attempts to synthesize solid (NO)CoPc species by bubbling NO to solutions of CoPc in dimethylformamide, then evaporating off the solvent resulted in the formation of a complex that was more soluble in organic solvents than the original species. Absorption spectral studies of the (NO)CoPc complex showed the presence of a $Co^{III}Pc$ species.

Kinetic and equilibrium studies

Kinetic and equilibria data for the coordination of NO to CoPc were determined by monitoring the formation of the (NO)CoPc species. The increase in the Q band of this species at 666 nm was monitored for kinetic and equilibrium measurements. Equilibrium data were determined by standard spectroscopic techniques using eq. (2)

$$\log[(A_{eq}-A_0)/(A_\infty-A_{eq})]=\log K+n\log[NO]. \quad (2)$$

In eq. (2), A_{eq} is the equilibrium absorbance at 666 nm, A_0 is the absorbance before addition of NO and A_∞, the absorbance after complete formation of the (NO)CoPc complex, was determined from the final absorbance at 666 nm. Figure 2 shows a plot of $\log[(A_{eq}-A_0)/(A_\infty-A_{eq})]$ vs log[NO]. A linear plot with a slope near unity ($n=0.9\pm0.1$) was obtained, showing that only one mole of NO is coordinated to the CoPc species. The linearity of the plot confirms the coordination of NO to the CoPc complex. Least square analysis gave an equilibrium constant of, $K=5.4\pm0.4\times10^4\ dm^3\ mol^{-1}$.

Plots of the observed rate constant, k_{obs}, vs the concentration of NO were linear, Fig. 3, showing that the coordination is first order in NO. Axial ligand substitution reactions in metallophthalocyanines are dissociative with the formation of a highly reactive five-coordinate intermediate [15, 31]. The axial ligand substitution in $(DMSO)_2CoPc$ may thus be represented by the reactions of eqs. (3) and (4)

$$(DMSO)_2CoPc \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (DMSO)CoPc + DMSO \quad (3)$$

$$NO + (DMSO)CoPc \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [(DMSO)(NO)CoPc \quad (4)$$

The rate law for axial ligand exchange reactions in MPc complexes shown by the reactions of eqs. (3) and (4) is generally given by eq. (5)

$$k_{obs}=k_f[NO]+k_r, \quad (5)$$

where k_f, the rate constant for the forward reaction, is given by $k_1k_2/k_{-1}[DMSO]$ and k_r is the rate constant for the reverse reaction. Least square analysis of the data presented in Fig. 3 gave $k_f=15.0\pm0.3\ dm^{-3}\ mol^{-1}\ s^{-1}$ from the slope and from the intercept, $k_r=3.1\pm0.1\times10^{-4}\ s^{-1}$ was obtained. Using these values of rate constants, the value of the equi-

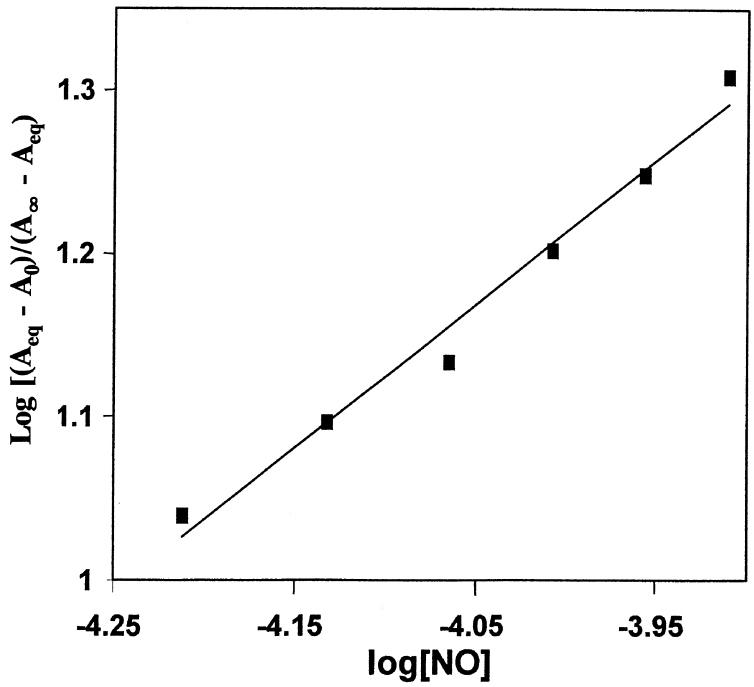

Fig. 2. Plot of $\log[(A_{eq}-A_0)/(A_\infty-A_{eq})]$ vs log[NO] for the formation of the (NO)CoPc species.

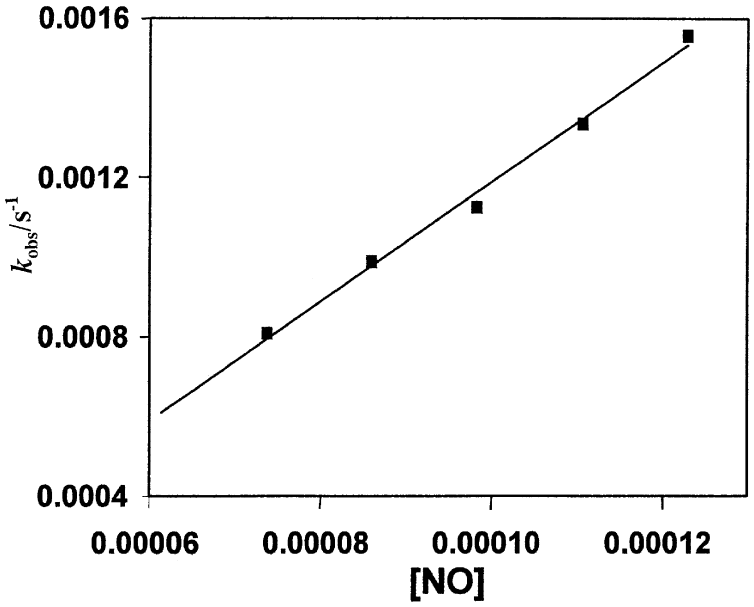

Fig. 3. Plot of the observed rate constant, k_{obs}, vs the concentration of NO for the formation of the (NO)CoPc species.

librium constant for NO coordination to CoPc was estimated to be $K_1 = 4.8 \times 10^4\,dm^3\,mol^{-1}$ from the relationship, $K_1 = k_f/k_r$, in excellent agreement with the value determined above from the equilibrium data.

For the coordination of NO to $(DMSO)_2FePc$, Ascenzi *et al.* [10] obtained an equilibrium constant of $1.1 \times 10^6\ dm^3\ mol^{-1}$ and $k_f = 2.2 \times 10^4\ dm^3\ mol^{-1}\,s^{-1}$. These values are much larger than the values obtained in this work for the coordination of NO to $(DMSO)_2$ CoPc. The coordination of pyridine in $(DMSO)_2$ FePc also occurred [32] with much larger equilibrium and rate constants than the coordination of pyridine in $(DMSO)_2$CoPc. This implies that the five coordinate (DMSO)FePc species are more reactive than the corresponding (DMSO)CoPc. The equilibrium constants observed for coordination of NO to CoPc are of the same order of magnitude as the equilibrium constants reported for the coordination of NO to cytochrome C and metmyoglobin [6]. The rate constant for the coordination of NO to CoPc is similar to the rate constants reported for the coordination of NO to Mn porphyrin complexes [26].

Electrocatalytic reduction of NO

Cyclic voltammetry of CoPc in donor solvents such as DMSO is well documented [33]. Figure 4(a) shows the cyclic voltammogram of CoPc in DMSO in the absence of NO. The first reduction in CoPc is known [33] to occur at the central Co^{II} metal to form the $Co^{I}Pc$ species. Subsequent reductions occur at the phthalocyanine ring. Thus, the reduction labelled I in Fig. 4(a) is assigned to $Co^{II}Pc(-2)/Co^{I}Pc(-2)$. The metal reduction in $Co^{II}Pc$ in dimethylacetamide was observed at -0.2 V vs saturated calomel electrode [33]. The rest of the reductions in Fig. 4(a) are then due to ring-based processes. The half-wave potentials for couples I, II, III and IV were respectively found to be -0.08, -0.36, -0.66 and -0.93 V vs Ag/AgCl.

On addition of NO to solutions of CoPc in DMSO, the cyclic voltammogram shown in Fig. 4(b) was obtained. Following the discussion above, the cyclic voltammogram in Fig. 4(b) should be due to the $(NO)Co^{III}Pc$ species in DMSO. Three quasi-reversible reduction couples were obtained in Fig. 4(b). The reduction couples were enhanced relative to the reduction couples for CoPc in the absence of NO. Also the reduction couples in Fig. 4(b) are observed at slightly different potentials than the potentials for the reduction of $(DMSO)_2Co^{II}Pc$. A considerable enhancement in the cathodic currents was observed for the fourth reduction, labelled IV in Fig. 4(b) on addition of NO to $(DMSO)_2$CoPc. There was no corresponding return peak for IV following addition of NO. The large increase in cathodic current relative to the anodic currents is typical behaviour for catalytic reduction. The catalytic peak was observed at -0.93 V vs Ag/AgCl. The potential for the catalytic peak shifted to more negative potentials, with increase in NO concentration. The catalytic currents for the reduction of NO increased with increase in concentration as shown in Fig. 5, clearly showing that the peak (IV) is due to the reduction of NO. The catalytic peak currents also increased linearly with increase in the square root of scan rate, for scan rates ranging from 50 to $500\,mV/s^{-1}$, confirming a diffusion controlled process for the reduction of NO.

It is expected that the reduction of $Co^{II}Pc$ species

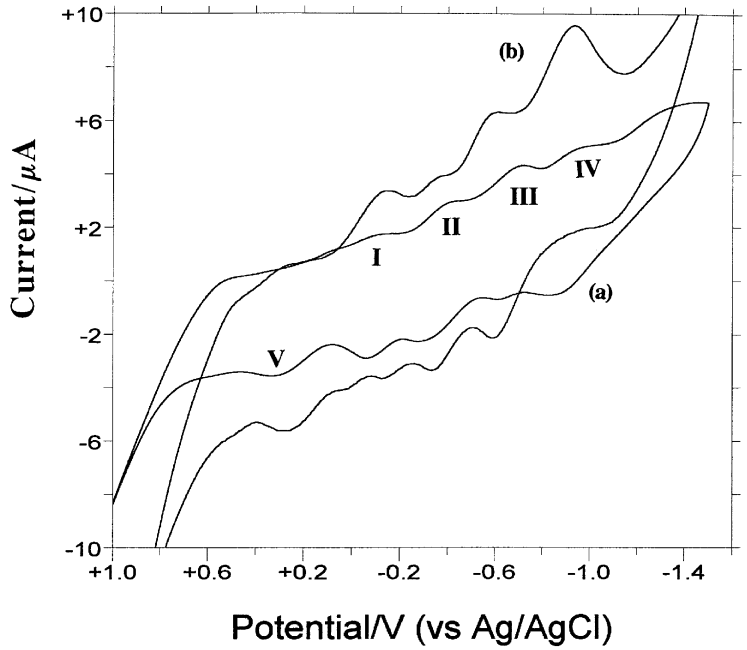

Fig. 4. Cyclic voltammogram of CoPc in DMSO (a) before and (b) after addition of NO (1.1×10^{-4} mol dm^{-3}) to the same concentration of CoPc as in (a). Electrolyte is 0.1 mol dm^{-3} TEAP and the scan rate 100 mV/s.

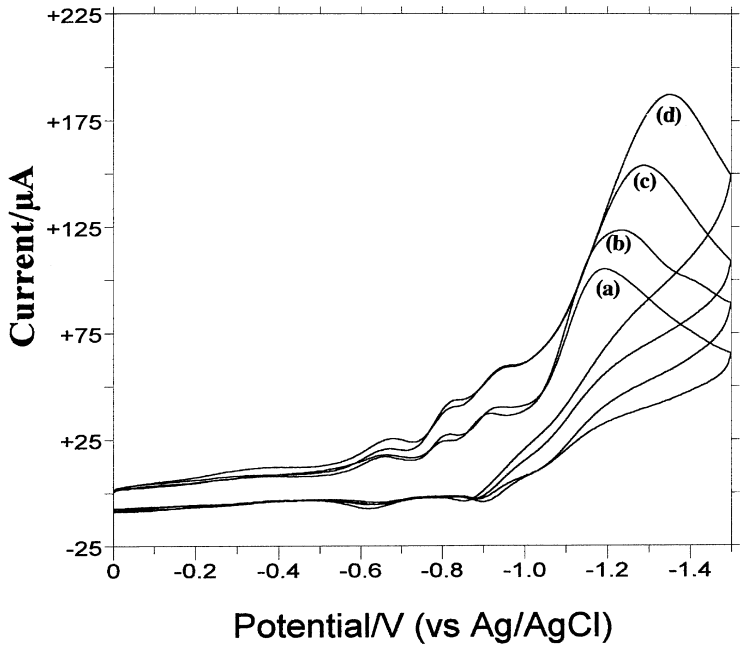

Fig. 5. Cyclic voltammograms of CoPc in DMSO, in the presence of increasing concentrations of NO: (a) 4.6×10^{-4}; (b) 5.7×10^{-4}; (c) 6.7×10^{-4} and (d) 8.3×10^{-4} mol dm^{-3}. Electrolyte is 0.1 mol dm^{-3} TEAP and the scan rate 100 mV/s.

would occur by consecutive one-electron reductions. The reduction occurs first at the central metal to give a $Co^{I}Pc$ species. Subsequent reductions are expected to occur at the phthalocyanine ring. The reduction labelled IV is at the potentials reported [33] for ring reductions of the CoPc species. The fact that we observe an enhancement in the cathodic currents of the peaks associated with phthalocyanine ring-based reductions on addition of NO to CoPc, suggests that it is these reductions that are involved in catalysing the reduction of NO. In many reductions involving CoPc as a catalyst, metal-based reduction processes

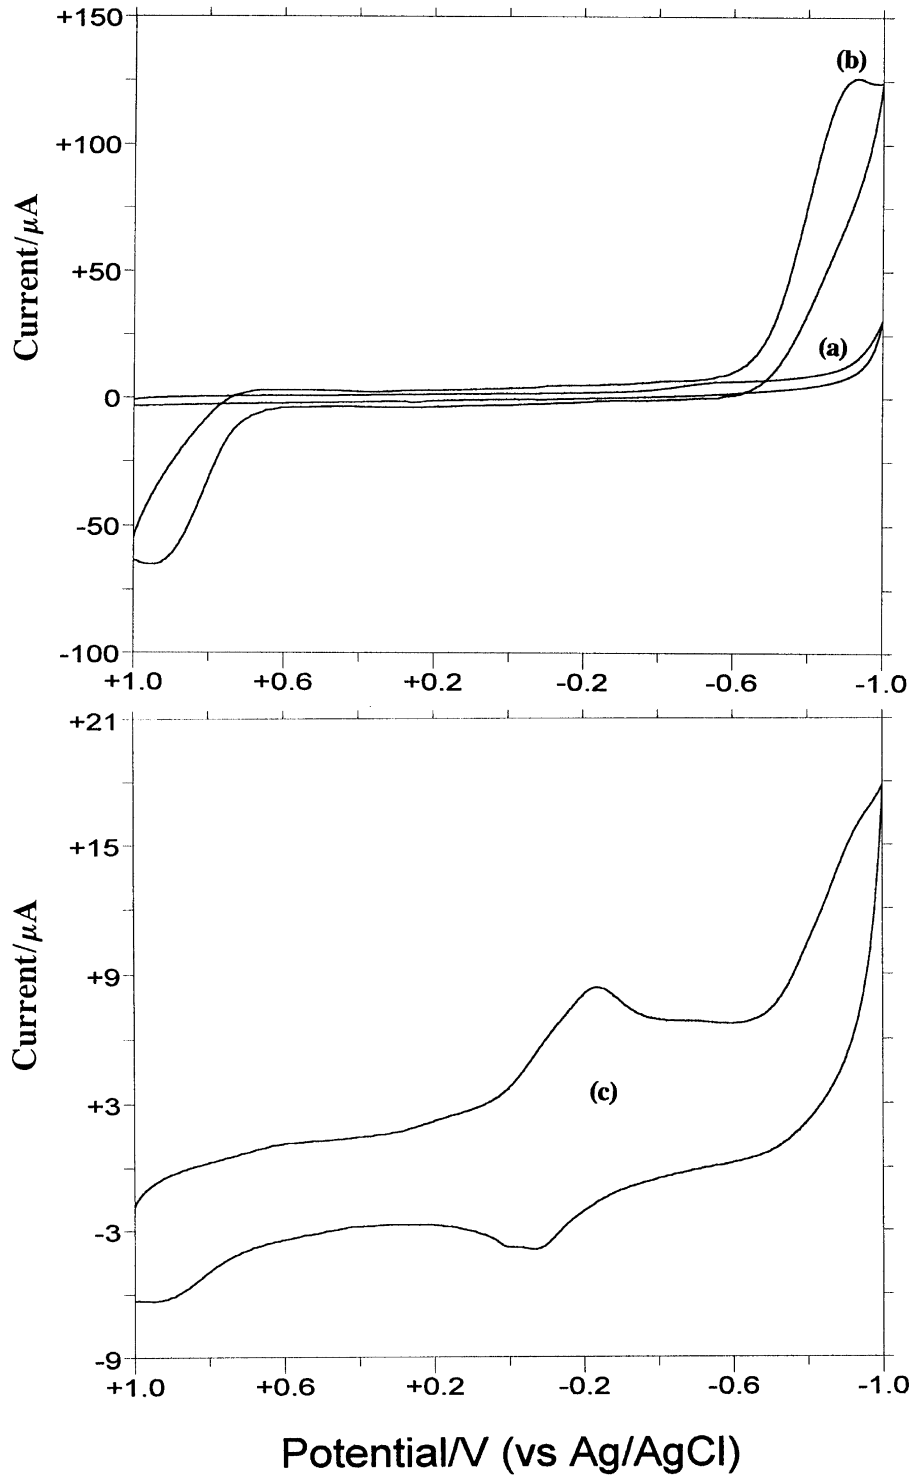

Fig. 6. Cyclic voltammograms of NO (7.0×10^{-4} mol dm^{-3}) on (a) unmodfied glassy carbon electrode and (b) CoPc modified glassy carbon electrode. (c) cyclic voltammogram of CoPc–GCE in buffer alone. Electrolyte pH 4 buffer. The scan rate is 100 mV/s.

have been suggested as playing a major role [12]. This work, however shows that ring-based processes may be involved in the catalytic reduction of NO using CoPc. The following mechanism is thus proposed for the reduction of NO using CoPc in solution:

$$Co^{II}Pc(-2) + NO \rightarrow (NO)Co^{III}Pc(-2) \quad (6)$$

$$(NO)Co^{III}Pc(-2) + e^- \rightarrow (NO)Co^{II}Pc \quad (7)$$

$$(NO)Co^{II}Pc(-2) + e^- \rightarrow (NO)Co^{I}Pc(-2) \quad (8)$$

$$(NO)Co^{I}Pc(-2) + e^- \rightarrow (NO)Co^{I}Pc(-3) \quad (9)$$

$$(NO)Co^{I}Pc(-3) + ne^- \rightarrow NH_3 \text{ and other products.} \quad (10)$$

The DMSO solvent and the overall charge have been left out of the above equations for clarity. Following the formation of the reduction products it is expected that the $Co^{II}Pc$ species would be regenerated.

Figure 6 shows the cyclic voltammograms of NO reduction on unmodified glassy carbon electrode and on a glassy carbon electrode modified with CoPc. In the absence of NO the reduction peaks due to adsorbed CoPc are observed near -0.15 V vs Ag/AgCl, Fig. 6(c). Reduction peaks observed for adsorbed CoPc have been assigned to Co^{III}/Co^{II} and Co^{II}/Co^{I} [12]. In the presence of NO, a catalytic reduction current rose sharply from about -0.6 V and showed a reduction peak at -0.93 V. The catalytic currents did not decrease significantly with subsequent scan on the same CoPc–GCE, indicating that the electrode was not deactivated by the adsorption of the reduction products. The catalytic currents observed in Fig. 6(b) for NO on CoPc–GCE, were much higher than the reduction currents observed for NO on an unmodified glassy carbon electrode, Fig. 6(a). Catalytic currents were also observed for the oxidation of NO on CoPc–GCE, with a peak at 0.94 V vs Ag/AgCl. The reduction currents at -0.93 V increased linearly with increase in the concentration of NO, Fig. 7. The reduction peak for the reduction of NO on a glassy carbon electrode modified with CoPc was observed before at -0.8 V in a citric acid–hydrochloric acid solution [27].

Bulk electrolysis of a solution containing NO in a pH 4 buffer at potentials of the catalytic reduction currents (-0.95 V), gave $n=5$, where $n=$number of moles of electrons involved in the reaction. Since reduction of NO to ammonia requires five electrons, the value of $n=5$ confirms that NH_3 is one of the reduction products of NO, as has been observed before. Analysis of the solution following bulk electrolysis gave a 35% yield of ammonia (with respect to NO) after 2 h of electrolysis of 10 cm^3 solution containing 2.1×10^{-3} mol dm^{-3} NO. Hydroxylamine was also detected as one of the reduction products.

In conclusion, we have shown in this work that NO coordinates to CoPc in DMSO solutions, forming a (NO)CoPc species. The equilibrium and rate constants for this interaction are lower than reported for the interaction of NO with FePc. There was evidence for electron transfer from the central Co ion to NO, with the formation of the $(NO)Co^{III}Pc$ species. Axial ligand exchange reactions in metallophthalocyanine and complexes normally involve the exchange of both ligands in $(L)_2Mpc$ complexes. The coordination of

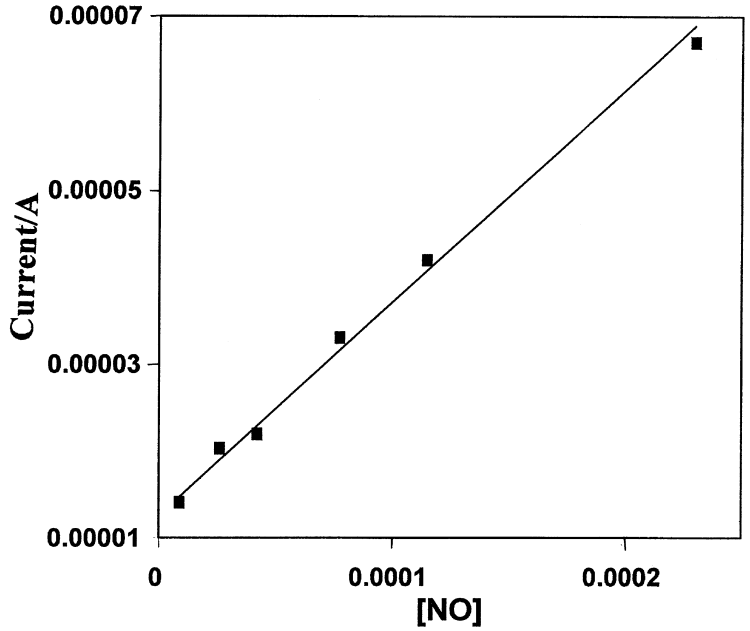

Fig. 7. Plot of [NO] vs catalytic reduction currents for the reduction of NO on CoPc–GCE. Electrolyte is pH 4 buffer and the scan rate 100 mV/s.

the second NO ligand to CoPc was not observed. Cyclic voltammetry studies showed that phthalocyanine ring-based reductions of the CoPc species catalyse the reduction of NO.

Synthesis and X-ray crystal structures of new trirhenium nonachloride chalcogenide clusters

Robert W. McGaff, Randy K. Hayashi, Douglas R. Powell and Paul M. Treichel*

Department of Chemistry, University of Wisconsin-Madison, 1101 University Avenue, Madison, WI 53706, U.S.A.

(Received 21 January 1998; accepted 2 June 1998)

Abstract—The acetone adduct of trirhenium nonachloride, $Re_3Cl_9(acet)_3$, where acet = acetone, reacts in acetone solution at room temperature with tetrabutylammonium chalcogenides $[N(C_4H_9)_4]_2E$, where E = S, Se and Te, producing the tetrabutylammonium salts of the new cluster anions $[Re_3(\mu_3\text{-}E)(\mu_2\text{-}Cl)_3Cl_6]^{2-}$. In the crystallographically determined structures of these compounds, triangles of rhenium atoms are capped by single chalcogen atoms, giving anions of near C_{3v} symmetry. The compound where E = S is also formed in the reaction of Re_3Cl_9 with $[N(C_4H_9)_4]_2[MoS_4]$ by sulfide transfer. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

Our research efforts are centered on finding rational low- or ambient-temperature synthetic routes to Re(III) cluster compounds. To this end, we carried out the reaction of $Re_3Cl_9(acet)_3$ with the tetrathiomolybdate ion, $[MoS_4]^{2-}$, in acetone solution. Rather than isolating a Re–Mo mixed-metal cluster with bridging sulfide ligands, however, a previously unknown cluster dianion, $[Re_3(\mu_3\text{-}S)(\mu_2\text{-}Cl)_3Cl_6]^{2-}$ was obtained. This new species, isolated as a tetrabutylammonium salt, was formed via sulfide transfer from $[MoS_4]^{2-}$, well known behavior for this species.

The same dianion was then synthesized by the more logical direct reaction of $Re_3Cl_9(acet)_3$ with a stoichiometric amount of $[(C_4H_9)_4N]_2S$. Generalizing, this direct reaction was next used to synthesize other members of the homologous series of compounds $[(C_4H_9)_4N]_2$ $[Re_3(\mu_3\text{-}Se)(\mu_2\text{-}Cl)_3Cl_6]$, **2**, and $[(C_4H_9)_4N]_2[Re_3(\mu_3\text{-}Te)(\mu_2\text{-}Cl)_3Cl_6]$, **3**, using $[(C_4H_9)_4N]_2Se$ and $[(C_4H_9)_4N]_2Te$, respectively. This paper describes the synthesis and structural characterization of these three compounds.

EXPERIMENTAL

Materials

Acetone was dried by refluxing over $CaSO_4$. Tetrahydrofuran and diethyl ether were dried by refluxing over Na/benzophenone. These solvents were distilled immediately prior to use. Sodium sulfide, ammonium tetrathiomolybdate (99.97%), selenium powder (100 mesh, 99.5%), trirhenium nonachloride, lithium (3.2 mm wire, 98%), tellurium powder (200 mesh), sodium and anhydrous ethanol were obtained from commercial sources and used as received. Tetra-*n*-butylammonium chloride monohydrate (98%) was obtained from a commercial source; prior to use, it was recrystallized twice from anhydrous ethanol/diethyl ether to remove as much water as possible. All manipulations were carried out under an atmosphere of dry nitrogen using standard Schlenk techniques [1].

Spectroscopic measurements

Electronic spectra were measured on a Cary 4Bio spectrophotometer. Matrix assisted laser desorption/ionization (MALDI) mass spectra were recorded on a Bruker Reflex II spectrometer equipped with a

N_2 laser operating with an accelerating voltage of -20 kV and a reflectron voltage of -21.2 kV. Spectra were obtained in the negative ion mode, using a dithranol matrix and are the sum of 50 shots. Samples for MALDI analysis were dissolved in acetone and then mixed with the matrix in tetrahydrofuran prior to deposition onto the target. Ion signals in the spectra were assigned based both on m/z values and distinctive isotopic patterns which accurately match calculated patterns. The relevant information from these spectra was the presence of a peak whose mass corresponded to the parent anionic mass lacking one Cl^-, $[M–Cl]^-$ (and the lack of any peaks at other masses that could be assigned to other clusters). The observed pattern was predicted based on ongoing MALDI studies in our group on anionic rhenium clusters [2].

Structure determination and refinement

Crystals used in the crystallographic study were mounted on glass fibers. Intensity data were collected at 133 K on a Siemens P4 diffractometer equipped with a CCD detector using phi scan frames with a range of 0.3° in phi. Graphite monochromated Mo-Kα radiation ($\lambda = 0.71069$ Å) was utilized. Absorption corrections were calculated by a semi-empirical method and applied to the data. Hydrogen atom positions were refined by use of a riding model. Data collection [3] and reduction [4] were accomplished on a Silicon Graphics computer using software standard in the crystallography laboratory at the University of Wisconsin-Madison. Structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL Version 5 software [5]. Neutral atom scattering factors were taken from standard tables [6]. Other details regarding the crystallographic experiments are contained in Table 1.

Reaction of $[(C_4H_9)_4N]_2S$ *with* $Re_3Cl_9(acet)_3$

A 50 ml Schlenk flask was charged with 19.2 mg (0.246 mmol) Na_2S and 136.8 mg (0.526 mmol) $[(C_4H_9)_4N]Cl$. Acetone (20 ml) was added and the contents of the flask were stirred at room temperature for 1 h. Another 50 ml Schlenk flask was charged with a solution of $Re_3Cl_9(acet)_3$ (formed *in situ* from 215.9 mg (0.246 mmol) of $[Re_3Cl_9]_x$ and 20 ml of acetone) [7]. This solution was transferred by cannula into the flask containing the sulfide ion. The reaction mixture was stirred overnight (approximately 12 h). The solution was then filtered to separate a dark precipitate (discarded). The dark red–orange filtrate was concentrated to *ca.* 5 ml and then approximately 4 ml of the concentrated solution was filtered into a 22 mm O.D. Schlenk tube. The remaining solution was filtered into a 12 mm O.D. Schlenk tube. Both samples were layered carefully with diethyl ether. Over several days, dark red crystals formed in both tubes. Crystals of $[Bu_4N]_2[Re_3(\mu_3\text{-}S)(\mu_2\text{-}Cl)_3Cl_6]$, **1**, from the larger Schlenk tube were collected and weighed (95.2 mg). The estimated overall yield, correcting to account for the solution used for growing crystals for X-ray analysis was 34%. The MALDI mass spectrum of **1** contained a peak at $m/e = 874.4$ (calc. 874.6), corresponding to the parent ion minus one chloride ligand, $[Re_3Cl_8S]^{1-}$. The electronic spectrum of this sample contained peaks at 343 nm ($\varepsilon = 2800\ M^{-1}\ cm^{-1}$), 372 nm (sh), 470 nm ($\varepsilon = 1900\ M^{-1}\ cm^{-1}$) and 563 nm (sh).

Crystals of **1** from the smaller tube, containing one acetone molecule per formula unit, were used for an X-ray structural determination. Details regarding the crystallography and structure of **1** are contained in Tables 1–3; the structure of the anionic portion of **1** is shown in Fig. 1.

Reaction of $[(C_4H_9)_4N]_2Se$ *with* $Re_3Cl_9(acet)_3$

The same reaction conditions and workup procedures were used to prepare dark red crystalline $[(C_4H_9)_4N]_2[Re_3(\mu_3\text{-}Se)(\mu_2\text{-}Cl)_3Cl_6]$, **2**, from $Re_3Cl_9(acet)_3$ and $[(C_4H_9)_4N]_2Se$. The estimated yield was 20%. A literature method [8] was used to prepare Li_2Se, which was converted to $[(C_4H_9)_4N]_2Se$ by metathesis with $[(C_4H_9)_4N]Cl$. The MALDI mass spectrum of **2** contained a peak at $m/e = 920.8$ (calc. 920.5) corresponding to the parent ion minus one chloride ligand, $[Re_3Cl_8Se]^{1-}$. The electronic spectrum of this sample showed peaks at 329 nm ($\varepsilon = 13000\ M^{-1}\ cm^{-1}$), 372 nm (sh), 456 nm ($\varepsilon = 3400\ M^{-1}\ cm^{-1}$), and 541 nm (sh). Crystals of **2**, which also contain one acetone molecule per formula unit and belong to the same space group as **1**, were isolated. Details regarding the crystallographic experiment and structure of **2** are contained in Tables 1–3; the anionic portion of **2** is isostructural to the anion in **1**.

Reaction of $[(C_4H_9)_4N]_2Te$ *with* $Re_3Cl_9(acet)_3$

Similar reaction conditions and workup procedures were used to prepare **3** from $Re_3Cl_9(acet)_3$ and $[(C_4H_9)_4N]_2Te$. Li_2Te was synthesized by an adaptation of a published procedure [8], substituting lithium wire for potassium, and converted to $[(C_4H_9)_4N]_2Te$ by metathesis with $[(C_4H_9)_4N]Cl$. (A purple color in the reaction mixture indicated that there was some polytelluride in the solution.) Compound **3** did not crystallize as readily as **1** or **2**; most of the sample came out of solution as a thick paste. However, a few dark red crystals of $[(C_4H_9)_4N]_2[Re_3(\mu_3\text{-}Te)(\mu_2\text{-}Cl)_3Cl_6]$, **3**, were isolated. The MALDI mass spectrum of **3** showed a peak at $m/e = 970.6$ (calc. 970.5) corresponding to the parent ion minus one chloride ligand, $[Re_3Cl_8Te]^{1-}$. The electronic spectrum of this sample showed peaks at 338, 351 (sh), 457 and 547 nm (sh). Extinction coefficients were not measured for **3**, due to the small amount of pure sample.

Although the quality of the crystals of **3** was poor, it was possible to determine with certainty the presence of the core structure of three rhenium atoms capped by a tellurium atom in the anion. Crystals of **3** formed in the space group C2/c and did not contain solvent. Details regarding the crystallographic experiment and structure of **3** are contained in Tables 1–3. The anionic portion of **3** is isostructural to the anions in **1** and **2**.

Reaction of $[MoS_4]^{2-}$ *with* $Re_3Cl_9(acet)_3$

A 50 ml Schlenk flask was charged with 41.3 mg (0.159 mmol) $[NH_4]_2MoS_4$ and 54 mg (0.208 mmol) $[(C_4H_9)_4N]Cl$. Acetone (15 ml) was added to the flask and the contents were stirred at room temperature for 2 h, resulting in an orange–red solution and a white solid (presumably ammonium chloride). Another 50 ml Schlenk flask was charged with 140 mg (0.159 mmol) of $[Re_3Cl_9]_x$ and acetone (15 ml). After the solid dissolved, forming $Re_3Cl_9(acet)_3$, this solution was transferred by cannula into the flask containing the MoS_4^{2-}. The combined contents were allowed to stir overnight. A dark solid (discarded) was separated from the red–orange solution by filtration. Approximately 2 ml of this solution was transferred, using a filter-tipped cannula, into a Schlenk tube. Diethyl ether was carefully added in a layer above the solution. Dark red crystals of **1** formed on standing. Identification as compound **1** was verified by a match of unit cell data (space group $P\bar{1}$) with identical unit cell dimensions to the product obtained by the reaction described above). The yield of **1** in this reaction was low.

RESULTS AND DISCUSSION

The syntheses of compounds **1**, **2** and **3** were accomplished by the general reaction shown in eq. (1), where E = S, Se, or Te. These three compounds, dark

red in color, were isolated in crystalline form and characterized by a combination of X-ray crystallography and mass spectrometry. Moderate yields of the first two compounds were obtained; however **3** was only obtained in low yield.

$$Re_3Cl_9(acet)_3 + [(C_4H_9)_4N]_2E \rightarrow [(C_4H_9)_4N]_2[Re_3(\mu_3\text{-}E)(\mu_3\text{-}Cl)_3Cl_6] + 3\text{acetone} \quad (1)$$

The synthetic procedure used here is viewed as well suited to the formation of these species: the chalcogenide ion's preferred mode of coordination is to bridge three metals, while the uncharged rhenium complex contains three weakly bonded and readily displaced acetone ligands.

The rhenium–chalcogen core of the anions in compounds **1**, **2** and **3** is isostructural; the structure of the anionic portion of **1** is shown in Fig. 1. The crystal lattices of both **1** and **2** contained acetone and crystals of both compounds are quite sensitive to solvent loss. Crystals of **3** were of poorer quality than those of **1** and **2**; thus, the *R* value for **3** is quite high. Still, there can be no doubt as to the core structure of the anion; that is, three rhenium atoms capped by a μ_3-Te atom. MALDI mass spectrometric results and the similarity of the electronic structure of **3** to those of **1** and **2** serve to further confirm the identity of **3**.

The anions in **1**, **2** and **3** with a triangle of rhenium atoms capped by the chalcogen atom have approximate C_{3v} symmetry. Similar to all other triangular clusters of rhenium (III), bridging chloride ions lie in the plane of the three metal atoms. Rhenium–rhenium distances are approximately 2.4 Å, typical of Re–Re double bonds (Ref. [9] and references therein). The average Re–chalcogen distance increases from 2.421 Å in **1** to 2.556 Å in **2** and 2.724 Å in **3**, a predictable variation based on atomic radii of the chalcogens. Lists of selected bond distances and angles are given in Tables 2–3, respectively. A complete listing of bond lengths and angles is given as supplementary material.

Rhenium(III) cluster species have been known for more than thirty years. Trirhenium clusters have been widely studied and many derivatives with this core structure have been reported [9, 10]. Thus the existence of a new series of compounds with relatively simple structures and their relatively straightforward synthesis, was surprising. Perhaps this is a consequence of the fact that derivatives of $[Re_3Cl_9]_x$ with sulfur ligands are not very common [9, 10].

Although **1**, **2** and **3** represent the first examples of triangular rhenium(III) halide clusters capped by single chalcogen atoms with halide ligands on all other rhenium positions, there are some interesting structural comparisons to be made with clusters of other nuclearities and with rhenium compounds in which the metals are in an oxidation state other than +3. A number of hexanuclear rhenium species having an octahedron of metal atoms with face bridging sulfide ions are known [10]. The species $Re_3S_7Cl_7$ [11], $Re_3S_7Cl_6AlCl_4$ [12] and $Re_3S_7Br_7$ [12] contain Re_3 triangles capped by sulfur atoms, but in contrast to **1**, **2** and **3**, rhenium atoms are in the +5 oxidation state in these species. In accordance with the higher oxidation state, longer Re–Re bonds in these clusters (about 2.7 Å) match single bond distances. Rhenium triangles capped by sulfur are also seen in the mixed valent, rhenium(III)–rhenium(IV) complex $Re_3S_4Br_3(PEt_3)_4$

[13] and the rhenium(IV) complexes $Re_3S_4Cl_4(PEt_3)_3$ [13], and $Re_3NiS_4Cl_6(PEt_3)_4$ [14]. Capping oxygen atoms on rhenium triangles are observed in the crystallographically determined structures of the organometallic compounds $[NEt_4]_2[Re_3H_3(\mu_3\text{-}O)(CO)_9]$ [15], $[NEt_4][Re_3H_3(\mu_3\text{-}OH)(CO)_9]$ [16] (which exists as a hydrogen-bonded trimethylamine adduct), and $[NEt_4][Re_3H_3(\mu_3\text{-}OEt)(CO)_9]$ [17]. A capping sulfur atom occurs in the structure of the triangular organometallic rhenium compound $[NEt_4][Re_3H_3(\mu_3\text{-}SBu^t)(CO)_9]$ [18]. In these compounds Re–Re distances of 2.7–3 Å are found, corresponding to single bonds between rhenium atoms. Triangular rhenium complexes with capping selenium and tellurium atoms have not been structurally characterized before this report.

As noted in Section 1, compound **1** was also prepared by the reaction of $[(C_4H_9)_4N]_2[MoS_4]$ with

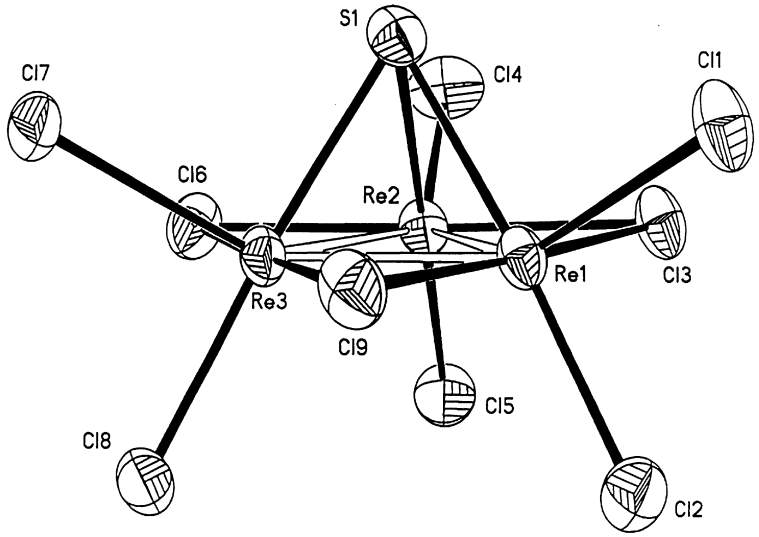

Fig. 1. The crystallographically determined structure of the anion in **1**.

$Re_3Cl_9(acet)_3$ eq. (2). Donation of sulfide ion is one of the general reaction types known for $[MoS_4]^{2-}$.

$$Re_3Cl_9(acet)_3 + [(C_4H_9)_4N]_2[MoS_4] \rightarrow [(C_4H_9)_4N]_2[Re_3(\mu_3\text{-}S)(\mu_2\text{-}Cl)_3Cl_6] + \text{byprod.} \quad (2)$$

Analogous reactions include those of $[NH_4]_2[MoS_4]$ with sulfates of copper, nickel and cobalt to produce mixtures of the corresponding metal sulfides and MoS_3 [19]. Other examples of this reaction type are seen in the hydrolysis of $[NH_4]_2[MoS_4]$ to give MoS_3, NH_4OH and H_2S [20, 21] and in the reaction of $[MoS_4]^{2-}$ with H^+ to give MoS_3 and HS^- as products [21].

Supplementary material available: crystal data, structure refinement description, data collection parameters, complete listing of atomic coordinates, thermal displacement parameters (isotropic and anisotropic), bond lengths and angles and torsion angles for **1**, **2** and **3**.

Complexation of cobalt(II), nickel(II), and zinc(II) ions with mono and binucleating azo compounds: A potentiometric and spectroscopic study in aqueous solution

Gabriela A. Ibañez and Graciela M. Escandar*

Departamento de Química Analítica, Facultad de Ciencias Bioquímicas y Farmacéuticas, Universidad Nacional de Rosario, Suipacha 531 (2000) Rosario, Argentina

(Received 21 January 1998; accepted 2 June 1998)

Abstract—The interaction of Co(II), Ni(II) and Zn(II) ions with a series of aromatic α-hydroxy azo compounds, 1,4-*bis*-*p*-sulfonylazo-2,3-dihydroxy naphthalene, 4-(2-hydroxy-1-phenylazo)-benzenesulfonate, 4-(2-hydroxy-1-naphthylazo)-benzenesulfonate, and 4-(9-hydroxy-10-phenanthrylazo)-benzenesulfonate, has been studied in aqueous solution. While both mono and binuclear chelates were found in the complex systems formed by the first azo compound, the existence of mononuclear chelates with different degrees of protonation was verified in the systems formed by the other ones. The equilibrium constants for all metal complexes were evaluated using a combination of potentiometric and spectrophotometric titration data. Within the mononucleating ligands, the magnitudes of the complexes equilibrium constants were to be found similar, even when their aromaticities are different. Both the metal coordination sites and the tautomeric structures of the ligand in each complex have been inferred through spectroscopic analysis. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: coordination chemistry; spectroscopy and potentiometry; aromatic hydroxy azo compounds

INTRODUCTION

Azo compounds play an important role in analytical chemistry as chromogenic agents [1]. Furthermore, from a biological point of view, the study of the binding properties of organic chelating ligands containing both mono- and binucleanting aromatic α-hydroxy azo groups is significant due to their use as models for certain metal-enzyme interactions and also for the possible transport of metal ions in biological media [2–5]. Specifically, the study of binuclear complexes for developing small model compounds for the active sites of biomolecules may contribute to the better understanding of the original systems [6]. On the other hand, it has been proved that polydentate chelating agents can remove the metal ions from metalloenzymes through the formation of ternary complexes between the metal, the ligand and the apoenzyme. As an example, the inhibition of carbonic anhydrase by acetazolamide which is able to bind Zn(II) ion can be cited [7]. A substantial number of works have been performed, in the solid state and in solvent mixtures, with both Schiff bases and aromatic hydrazones which are structurally related with the presently studied compounds [2, 3]. However, azo compounds have the advantage of being soluble and stable in water solutions, allowing a more suitable understanding of biological processes [7]. We have previously reported a study of the coordination abilities of aromatic α-hydroxy azo compounds towards the copper (II) ion [8, 9]. We have now extended the study to other transition metal ions of interest, such as bivalent Co(II), Ni(II) and Zn(II). Specifically, the ligands analyzed are: 1,4-*bis*-*p*-sulfonylazo-2,3-dihydroxy naphthalene (SADN), 4-(2-hydroxy-1-phenylazo)-benzenesulfonate (HPBS), 4-(2-hydroxy-1-naphthylazo)-benzenesulfonate (HNBS) and 4-(9-hydroxy-10-phenanthrylazo)-benzenesulfonate (HPTBS) (Scheme 1). These compounds show interesting prototropic properties and are represented in Scheme 1 in their more stable tautomeric forms [8, 9].

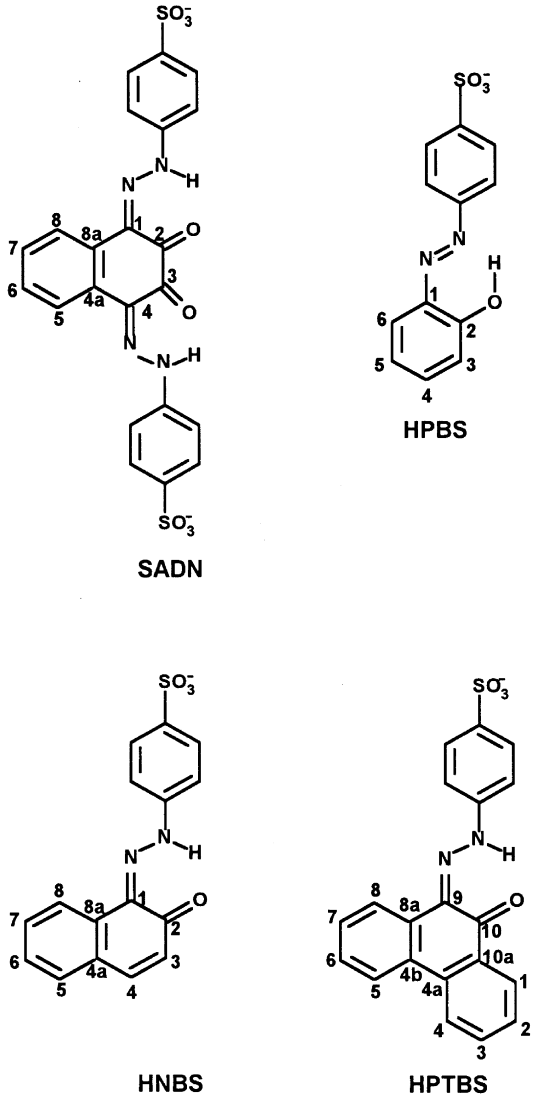

Scheme 1.

The study has been carried out taking into account the tautomeric properties of these ligands and correlating them with their chelating behavior.

EXPERIMENTAL

Reagents

The ligands were prepared as previously described, using standard procedures [8–10]. Their purities were checked by elemental analysis, ^{1}H NMR and potentiometric titrations. Stock solutions of about 0.01 M of Zn(II), Co(II) and Ni(II) were prepared by dissolving the corresponding nitrates (AR) in doubly distilled water. The metal concentrations were determined by titrations with previously standardized ethylenediamine-N,N,N′,N′-tetraacetic acid solution in the presence of appropriate indicators [11]. Solutions of carbonate-free NaOH and HNO_3 were standardized against potassium hydrogenphthalate and sodium carbonate, respectively.

Potentiometric equipment and measurements

Potentiometric titrations were carried out under nitrogen atmosphere at 20.0 ± 0.1°C, with the ionic strength (μ) adjusted to 0.10 M with $NaNO_3$. Prior to each experiment, the Metrohm 713 pH meter used was fitted with glass and reference electrodes and calibrated to read pH directly with freshly prepared solutions of standard HNO_3, standard NaOH and standard acetic acid. Thus, the term pH is in this work defined as $-\log[H^+]$. The initial concentrations of metal and ligand in the 1:1 system were in the range 7×10^{-4}–1×10^{-3} M. In the solutions used to investigate 1:2 and 2:1 metal–ligand ratios the concentrations of ligand or metal were doubled, as required. Equilibrium pH values were determined at every incremental addition of NaOH or HNO_3 to the experimental solutions. For each system three or more replicate measurements were carried out. Since the complexes studied were not fully formed at low pH, their stability constants could be determined by potentiometric titrations without the need of using competitive methods. The computational program for processing the potentiometric data was Best [12]. The selection of the chemical model for each investigated system was done according to previously known similar systems. Refinements were considered satisfactory when the value of σ_{fit} was lower than 0.04 [13]. Standard deviations for the reported constants refer only to random errors [14].

Spectrophotometric determinations

These measurements were performed with a Beckman DU 640 spectrophotometer, using 1.00 cm quartz microcells, at 20.0°C and $\mu = 0.10$ M ($NaNO_3$). The initial concentrations of metal and ligand in the 1:1 system were in the range 1×10^{-5}–6×10^{-5} M. Conformity of Beer's law was verified in all cases. In the experimental solutions employed to investigate 1:2 and 2:1 metal–ligand ratios the concentrations of ligand or metal were doubled, as required. The spectrophotometric titrations were carried out following procedures which are described in detail elsewhere [9]. Briefly, small increments of NaOH *ca.* 0.02 M were added to the nitrogen bubbled solution, which contained the metal and ligand in the corresponding ratio. For each pH point a known aliquot of solution was extracted and the absorption spectrum was read. The obtained profile of absorbances at the wavelength of the absorption maximum vs pH in each run was used to calculate the equilibrium constants of the complexes formed in each system. These calculations were performed with the aid of the program Epsilon

(FTP://WWW.FBIOYF.UNR.EDU.AR/CIENTIFICO/QUIMICA.ZIP) [15]. Standard deviations for the reported constant values refer only to random errors [14].

The hydrolysis constants for the investigated cations were calculated from the data of Baes and Mesmer [16]. The log of the overall metal hydrolysis constants used in both potentiometric and spectrophotometric computations were:

$K_{ZnH_{-1}} = -9.15$, $K_{Zn_2H_{-1}} = -8.89$, $K_{ZnH_{-3}} = -28.4$, $K_{ZnH_{-4}} = -40.7$, $K_{CoH_{-1}} = -9.85$, $K_{Co_2H_{-1}} = -10.95$, $K_{CoH_{-3}} = -31.5$, $K_{CoH_{-4}} = -45.8$, $K_{NiH_{-1}} = -10.06$, $K_{Ni_2H_{-1}} = -10.45$, $K_{NiH_{-3}} = -30.0$, $K_{NiH_{-4}} = -43.5$.

All these values correspond to 25°C and $\mu = 0.10$ M. The log K_w value used throughout this work was -13.87 (20°C, $\mu = 0.10$ M) [16].

RESULTS AND DISCUSSION

The values of both the deprotonation constants and extinction coefficients for the ligands studied in this work were those previously reported [8, 9] and are summarized in Table 1. The equilibrium constant values for the complexes formed in each system are listed in Table 2 and are discussed below. They were evaluated spectrophotometrically at wavelengths which are similar to those in the corresponding deprotonation constant determinations.

SADN systems

While potentiometry may be considered as the most accurate method for the evaluation of complex equilibrium constants, spectrophotometric determinations are useful when the former cannot be employed, for example when insoluble species are formed at the concentrations typical of potentiometric techniques [17]. However, if the spectrophotometric method is applied, certain intrinsic limitations should be taken into account, namely the fact that association reactions are not favored at low concentrations, and therefore that the species found may be different that those detected at higher metal–ligand concentrations. Further, the errors associated with the formation constants calculated from spectrophotometric data are larger than those obtained from potentiometry [15]. On the other hand, there are advantages from a qualitative point of view, since the spectra of the complex systems are informative with respect to the structure of the complexes formed.

Conforming to the position of the binding groups of SADN, both mono- and binuclear species could be formed. The study of mononuclear complexes should be the first step to evaluating binuclear chelates. In general, the experimental data from both potentiometric and spectrophotometric titrations in the mononucleating SADN systems could be described by considering eqns (1)–(3):

$$M^{2+} + H_2L^{2-} = [ML]^{2-} + 2H^+ \quad (1)$$

$$M^{2+} + H_2L^{2-} = [MH_{-1}L]^{3-} + 3H^+ \quad (2)$$

$$M^{2+} + H_2L^{2-} = [MH_{-2}L]^{4-} + 4H^+. \quad (3)$$

Notice that negative charges for the ligand (H_2L^{2-}) correspond to those of sulfonate groups, and that H_{-n} represents the protons released upon complex formation, in addition to those of the ligand. On the other hand, the equilibria implicated in the binuclear complexes formation can be, in general, represented by eqns (4) and (5):

$$2M^{2+} + H_2L^{2-} = [M_2L] + 2H^+ \quad (4)$$

$$2M^{2+} + H_2L^{2-} = [M_2H_{-2}L]^{2-} + 4H^+. \quad (5)$$

In addition to these reactions, deprotonation of $[M_2H_{-2}L]^{2-}$ may occur at very high pH. The presence of these binuclear complexes is not only required by the refinement, but by the fact that hydroxide precipitation is not observed in alkaline media in neither

of the studied metallic systems. It is necessary to point out that the binuclear complexes were only detected in potentiometric concentrations.

Co(II)

The potentiometric equilibrium profile of pH vs *a* (*a*: mol of base added per mol of ligand) for the 1:1 Co(II)–SADN system, shown in Fig. 1, shows one break at $a = 2$, which is followed by a flattening of the curve. The reverse curve displayed a similar behavior. The curve could only be satisfactorily fitted by considering both $[CoL]^{2-}$ and $[CoH_{-1}L]^{3-}$ species formation (Table 2). In the spectrophotometric titration experiments only $[CoL]^{2-}$ was found. According to the species distribution for this system, the latter complex begins to form at pH 8 and reaches a maximum of 95% at pH 11. With the purpose of obtaining structural information, the complex spectrum was analyzed. An absorption corrected spectrum at pH 11 was obtained by subtracting from the latter the spectrum of the ligand at the same pH and at the corresponding free concentration of SADN (Fig. 2). The resulting spectrum resembles that of SADN in the diketo tautomer, with an absorption band at 530 nm [8]. In principle, two different deprotonation schemes may be proposed for the ligand in $[CoL]^{2-}$. If the ligand releases one proton, and a coordinated water molecule the other one, the most probable structure is **f** (Scheme 2). On the other hand, if the ligand loses both protons, the fully deprotonated structure of the chelating agent in the complex would be **k** (Scheme 2). According to these statements, the structures A and B of Scheme 3 represent feasible coordinations for Co(II) in the $[CoL]^{2-}$ species. Because a high metal coordination would involve a strong steric strain, as in other metal systems formed by related compounds, a tetracoordinated metal ion is suggested [3, 8].

The potentiometric curve corresponding to the 2:1 metal–ligand system exhibits two inflections (Fig. 1), the first at $a = 2$ and the second one at $a = 4$. These results could be explained on the basis of the formation of analogous binuclear complexes proposed above for the Cu(II)–SADN system (i.e., $[M_2L]^{2-}$ and $[M_2H_{-2}L]^{4-}$) [8]. The complexes being more stable in the latter case. As previously mentioned, in the 2:1 system and under spectrophotometric conditions, only the 1:1 complex was found.

Ni(II)

In both 1:1 and 2:1 potentiometric systems, the behavior of Ni(II) ion towards SADN is similar to that of Co(II) ion (Fig. 1 and Table 2). The $[NiL]^{2-}$ complex is also detected in the 1:1 system from spectrophotometric data. Its structure was analyzed according to the spectrum at pH 11, in the similar way to the Co(II) complex. In this case, the spectrum (Fig.

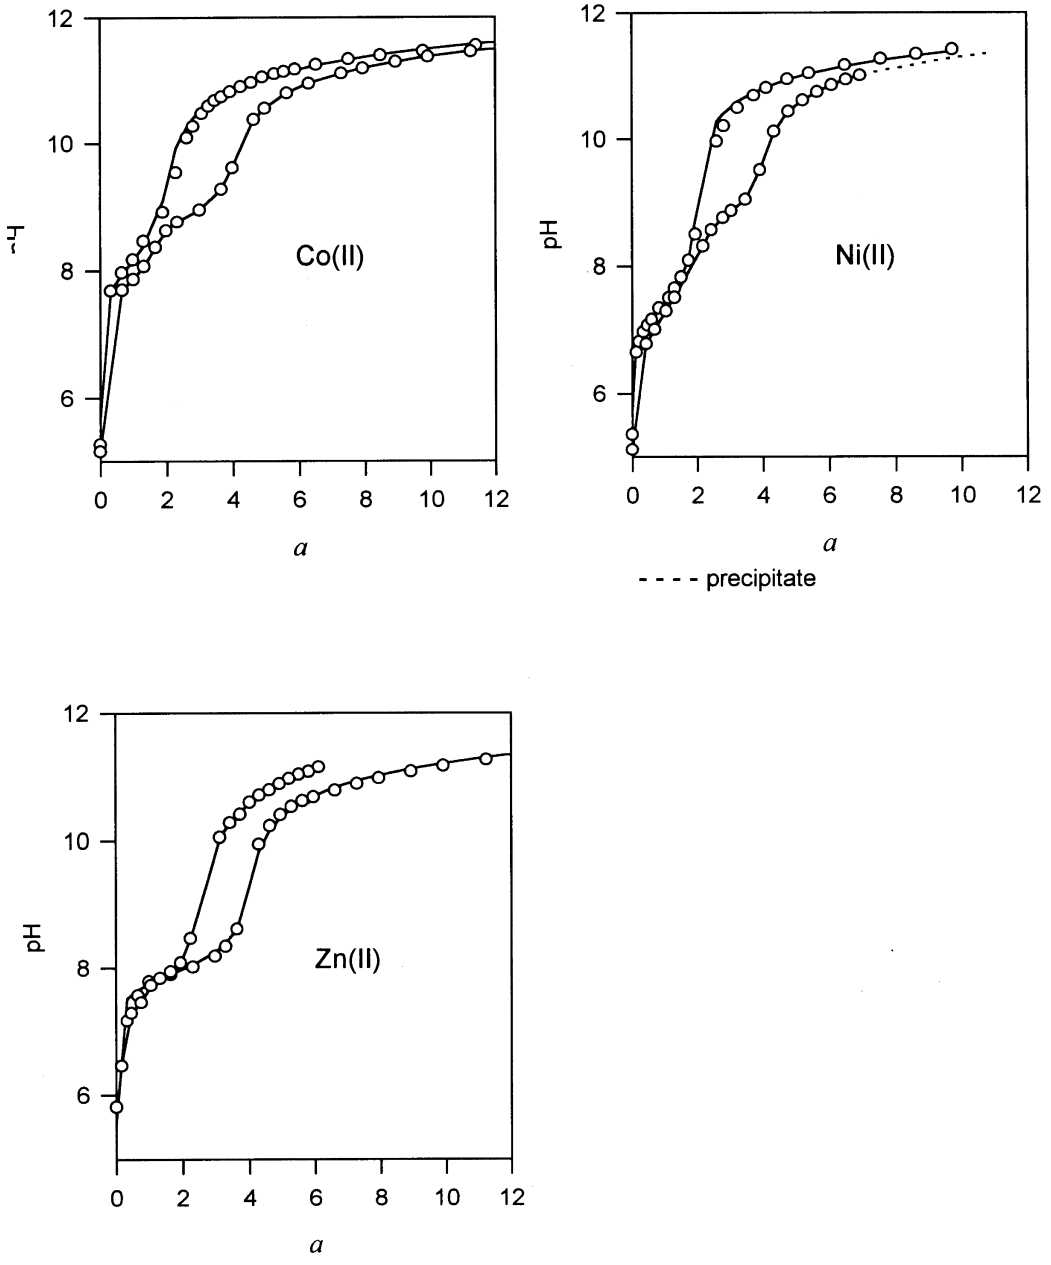

Fig. 1. Comparison of experimental (○) and calculated (———) pH values vs a (moles of base per mol of ligand or cation) in the case of 1:1 and 2:1 metal–SADN systems.

2) displays an absorption band at 548 nm (corresponding to either structure A or B of Scheme 3) and a shoulder at 430 nm. This shoulder could be related with a slight contribution of a dicatecholate-type structure.

Zn(II)

A typical potentiometric profile corresponding to a 1:1 Zn(II)–SADN system is presented in Fig. 1, along with the calculated pH values. In contrast to the Co(II) and Ni(II) systems, this curve presents an inflection at $a=3$, and the flattening beyond this value suggests an additional equilibrium corresponding to the formation of a more deprotonated complex. Therefore, the discrepancies between the measured and calculated pH values were minimized by considering the species $[ZnL]^{-2}$, $[ZnH_{-1}L]^{-3}$ and $[ZnH_{-2}L]^{-4}$. Only the $[ZnL]^{-2}$ complex was spectrophotometrically detected, between pH 8 and 10.5, in concentrations not higher than 67% with respect to the total metal

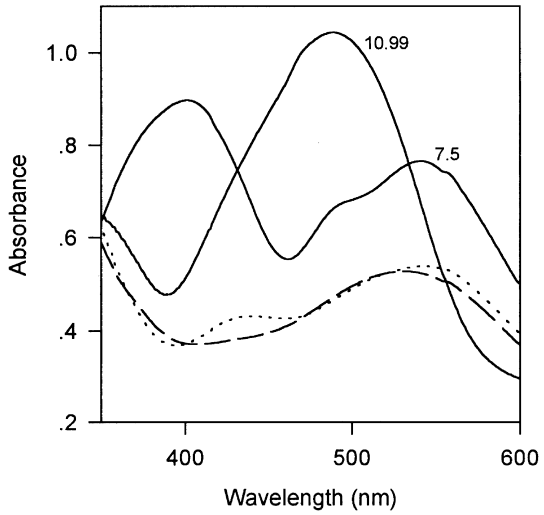

Fig. 2. Absorption spectra of: (———) SADN (H_2L) at indicated pH values ($C = 4.09 \times 10^{-5}$ M), (- - -) $[CoL]^{2-}$ ($C = 3.58 \times 10^{-5}$ M) and (· · ·) $[NiL]^{2-}$ ($C = 3.71 \times 10^{-5}$ M).

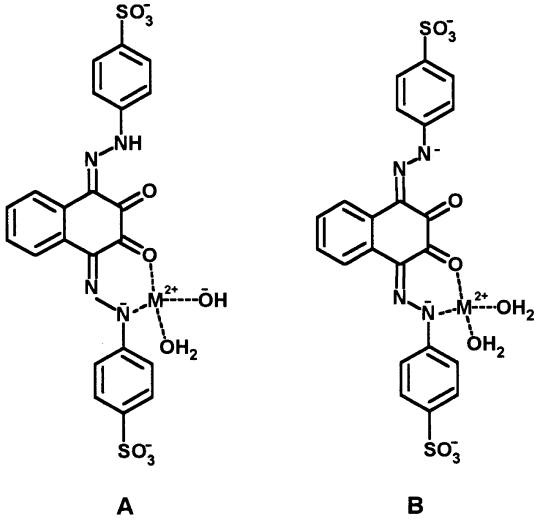
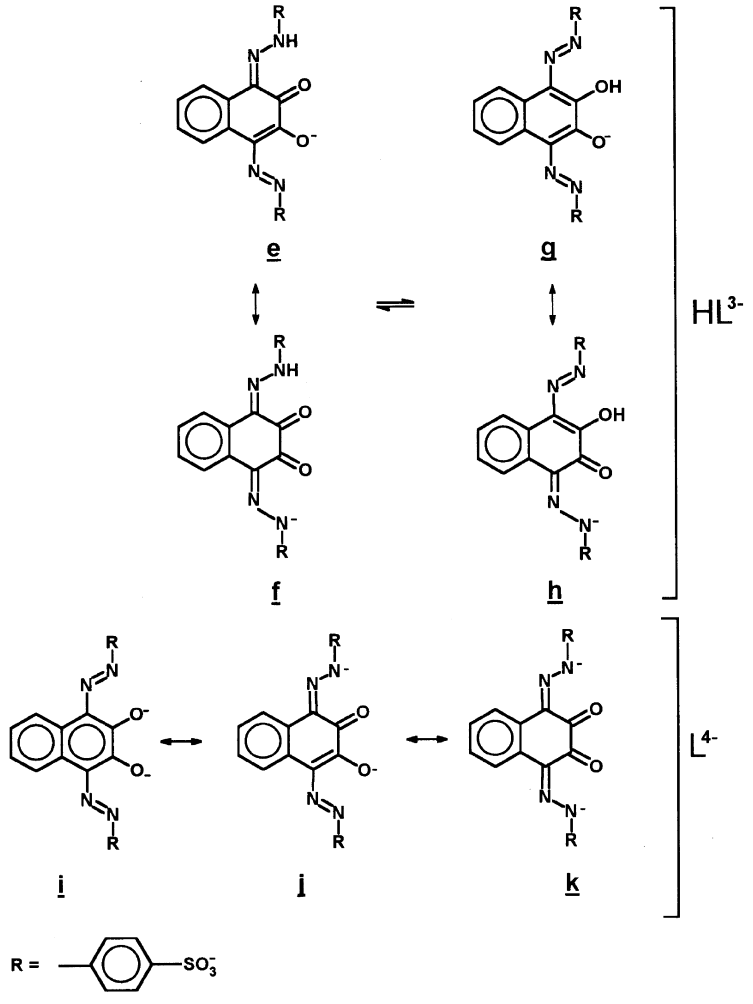


Scheme 3.



Scheme 2.

concentration. At pH higher than 11 the hydrolytic species are dominant, and the spectra correspond to those of free ligand in its monoprotonated keto–enol form (Fig. 2).

The potentiometric profile for a typical 2:1 Zn(II)–SADN solution (Fig. 1), is also different than those in the analogous Co(II) and Ni(II) systems. It only shows a jump at $a=4$. In this case the species found were $[Zn_2H_{-2}L]^{2-}$ and $[Zn_2H_{-3}L]^{3-}$. Although a structural analysis cannot be performed due to the dominance of hydrolytic species at high pH, it is likely that both in mononuclear and binuclear zinc complexes the coordination would take place with N(1) and one of the aromatic oxygen atoms. Because the metal ions here analyzed are "borderline" cations, they should be preferentially complexed by "borderline" bases, such as unsaturated nitrogen donors rather than negatively charged oxygen donors [18]. Furthermore, this type of coordination provides additional stabilization by a six membered ring formation.

HPBS, HNBS and HPTBS systems

The complexes formation in these mononucleating systems would involve the following equilibria:

$$M^{2+}+HL^{-}=[ML]+H^{+} \quad (6)$$

$$M^{2+}+HL^{-}=[MH_{-1}L]^{-}+2H^{+} \quad (7)$$

$$M^{2+}+HL^{-}=[MH_{-2}L]^{2-}+3H^{+}. \quad (8)$$

Again, the negative charge on the ligand represents that of the sulfonate group. The species formed resemble those of the mononuclear complexes of SADN. However, it should be taken into account that the same chelate stoichiometries do not necessarily correspond to the same structures, since SADN has an additional ligand proton.

The first mole of the released proton (eqn (6)) can be attributed to dissociation of the ligand. According to the azocompound analyzed, this H may have more phenolic or hydrazonic character (Scheme 1). The additional protons might be attributed to the deprotonation of water molecules coordinated to the metal. In each system, the presence of either of the above mentioned equilibria should be related with both the hydrolytic tendency of the metal and with the characteristics of the coordinating compound. In neither case was there any indication of the formation of 1:2 metal–ligand complexes.

Co(II)

While no complexation was detected in the Co(II)–HPBS systems in our working conditions, complex formation was found when the ligand was HNBS. The species formed are insoluble at the concentrations used in the 1:1 metal–ligand potentiometric experiments, even at low pH. However, on using higher ligand to metal ratios, and performing reverse titrations, no solid was observed. The solution appears to be stable, yet supersaturated with respect to the insoluble species. Therefore, and according to the suggestion of Martell [19], the data were considered as corresponding to equilibrium and the constant values were determined (Table 2). A precipitate slowly formed after the experiment. As can be appreciated, two complexes were found: [CoL] and $[CoH_{-1}L]^{-}$. The previously mentioned solid phase is ascribed to the latter complex, with the negative charge of the sulfonate group being neutralized with a counter-ion of the supporting electrolyte.

The spectrophotometric curves at different values of pH for the 1:1 Co–HNBS system exhibit isosbestic points (539 and 387 nm) above pH 9. Values of pH higher than 10.5 could not be analyzed because of the presence of a fine precipitate, even at the low concentrations used. From the profile of absorbance vs pH (Fig. 3) $[CoH_{-1}L]^{-}$ was found. The spectra also show that when the complex concentration is increased, the band at 483 nm (previously assigned to the keto form of HNBS) [9] decreases but does not shift. This fact suggests that the complexes formed would display a keto-hydrazonic structure, with the metal ion binding to N(1), to the lone pair electrons of the oxygen atom and to hydroxy groups from coordinated water molecules.

Due to the low solubility of the compound HPTBS, their systems could not be potentiometrically evaluated and therefore results from spectrophotometric determinations were obtained. The refinement of the spectrophotometric titration curves also indicates the presence of $[CoH_{-1}L]^{-}$ as the major species in alkaline

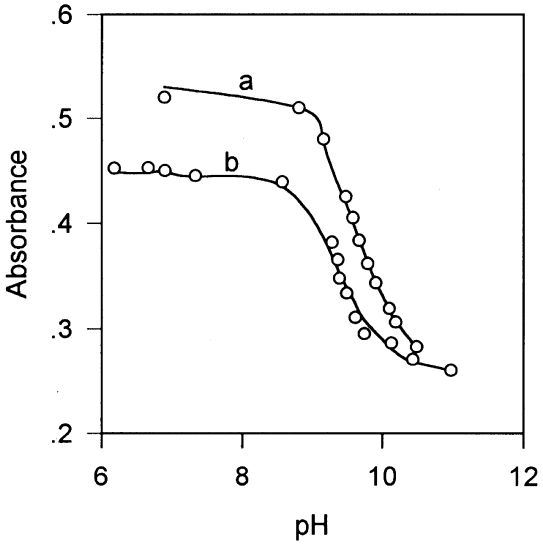


Fig. 3. Experimental (○) and calculated (———) absorbance values vs pH in (a) Co(II)–HNBS system, initial $C_{NHBS}=2.57\times10^{-5}$ M, initial $C_{Co}=2.53\times10^{-5}$ M; (b) Co(II)–HPTBS system, initial $C_{HPTBS}=2.06\times10^{-5}$ M, initial $C_{Co}=2.24\times10^{-5}$ M. $\mu=0.10$ M, $t=20.0$°C.

media. In this case the spectra also suggest a keto tautomer for the ligand in the complex, with a band at 478 nm [9].

Ni(II)

Ni(II) ion forms weak complexes with the phenolic derivative HPBS (Table 2), and $Ni(OH)_2$ precipitation is observed in basic media. No complexes were detected under spectrophotometric conditions.

Due to the insolubility of the systems, the complexes formed with both the naphtholic and phenanthrolic derivatives could not be potentiometrically studied. However, from spectrophotometric titrations, the species $[NiH_{-1}L]^-$ was found in the HNBS system. This species forms a fine precipitate above pH 10. The spectra show an isosbestic point at 528 nm above pH 9. This fact would be in accordance with the simultaneous presence of two absorbing species (protonated ligand and complex). These spectra also suggest a keto-hydrazonic structure for this complex.

In the Ni(II)–HPTBS system, the absorbance curves are modified above pH 8 with respect to that of the free ligand. This fact would be indicative of a complex formation, but a turbidity in the working solution at this point precluded the equilibrium constant determination.

Zn(II)

As in the Co(II) and Ni(II) systems, and according to both electrochemical and spectrophotometric data, the Zn(II) ion shows a weak interaction with HPBS. In the potentiometric experiment only the $[ZnH_{-1}L]^-$ complex was detected, reaching a maximum of 14% with respect to the total analytical metal ion concentration, before precipitation is observed at $pH \approx 7.6$. Since at this pH value the concentration of free Zn(II) ion is enough to form $Zn(OH)_2$, the solid phase is attributed to this latter species. At the low concentrations of reagents used in the spectrophotometric titration, no hydroxide formation was detected and zinc hydrolytic species are predominant at high pH. However, the low concentration of $[ZnH_{-1}L]^-$ complex does not allow us to determine spectrophotometrically its equilibrium constant, without incurring in large errors in the calculated value. For the same reason, the complex structure was not assigned.

The same type of complex was detected in the Zn(II)–HNBS system from potentiometric measurements. In this case the former is more stable with respect to that formed by the phenyl derivative, but this fact does not avoid hydroxide precipitation in alkaline media. Under spectrophotometric conditions, no complex formation was detected.

A stable $[ZnH_{-1}L]^-$ formed with HTPBS was spectrophotometrically found. This complex is the predominant species at alkaline medium and begins to precipitate at pH 10. Its structure, inferred from the spectra, is in agreement with a keto-hydrazonic form.

CONCLUSIONS

By using potentiometric and spectrophotometric methods, the interaction of a series of aromatic α-hydroxy azo compounds with bivalent metal ions of biological interest has been established. Thus, the equilibrium constants were evaluated, confirming the existence of chelates with different degrees of deprotonation. SADN forms mono- and binuclear complexes with the analyzed metal ions. In both types of complexes, the metal center would be bonded to a ligand oxygen, a nitrogen and hydroxyl groups. In the systems containing HPBS, HNBS and HPTBS, the formation of the $[MH_{-1}L]^-$ complex (insoluble at high concentrations) was always detected. The magnitudes of the complexes equilibrium constants are not significantly different within this series of compounds, even when the aromaticity increases in going from HPBS to HPTBS. Within the complexes, these ligands appear to exist in the keto-hydrazonic form, with the metal ion also coordinated to oxygen, nitrogen N(1) and hydroxyl groups. The equilibrium constant values for $[ML]^{2-}$ complexes of SADN are, for most systems, significantly larger than those for analogous $[MH_{-1}L]^-$ complexes of HNBS. This fact could be attributed to the presence of an additional aromatic oxygen in SADN, which favors a negative charge distribution over the other binding oxygen. It can be appreciated that the ligands herein studied form more stable complexes with the bivalent Cu(II) ion.

(Received 13 May 1998; accepted 17 June 1998)

Abstract—Lanthanide orthochromites of general formula $LnCrO_3$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Tb, Lu) and $YCrO_3$ have been made by self-propagating high-temperature synthesis (SHS). Four different SHS reactions were found to form $LnCrO_3$: reaction of Ln_2O_3, Cr and CrO_3 with $NaClO_4$ or $Ba(ClO_4)_2$ in air; reaction of Ln_2O_3, Cr and CrO_3 in oxygen; reaction of $LnCl_3$, $CrCl_3$ and NaO_2 or Na_2O_2 in air and reaction of $Ln(NO_3)_3$, Cr and melamine in air. Reactions were studied by DTA and TGA experiments which showed exotherms and weight losses associated with the initiation temperatures (*ca.* 350°C) of the SHS reactions. Maximum reaction temperature T_c and propagation velocity U_c were measured for selected reactions. X-ray powder diffraction showed a single phase orthorhombic perovskite structure was produced in all reactions. Systematic changes in the lattice parameters, cell volume and pycnometrical densities were seen as a function of lanthanide atomic number. SHS prepared $LnCrO_3$ samples were all shown to be weak antiferromagnets. IR spectra for the $LnCrO_3$ materials showed bands at 635, 480, 440, 350 and 180 cm^{-1}. © 1998 Elsevier Science Ltd. Keywords: lanthanide; orthochromite; SHS

INTRODUCTION

Lanthanide orthochromites have the general formula $LnCrO_3$ and adopt the perovskite crystal structure [1]. These materials have been widely studied as refractory conducting ceramics because of their electrical conductivity, oxidation resistance and high melting points (>2400°C). These properties have lead to applications in high-temperature furnace heating elements and interconnects in solid oxide fuel cells [2–5]. Substituted $LnCrO_3$ also show potential in gas sensing applications [6]. Lanthanide orthochromites have been made in air at 1200°C by combination of the appropriate metal oxides [7–9], however the process also involves multiple heating and regrinding steps to help overcome the solid state diffusion barrier. Alternative synthesis strategies have been employed including nitrate decomposition [10], hydrothermal reaction [11], co-precipitation [12], the hydrazine method [13] and decomposition of molecular precursors such as $La[Cr(CH_2(COO)_2)_3]$ [14]. All of these reactions give some improvement in synthesis time and product quality by allowing mixing of the precursors at the molecular level. These methods often involve multiple stages and the precursor always requires heating in a furnace to *ca.* 1200°C. We have shown that it is possible to form $LnCrO_3$ by a metathesis reaction [15],

$$LnCl_3 + CrCl_3 + 3Li_2O \rightarrow LnCrO_3 + 6LiCl. \quad (1)$$

This reaction is exothermic and is driven by the lattice energy of the coproduced lithium chloride. In this particular case the reaction required heating at 800°C for 2 h to produce $LnCrO_3$ and the reaction did not proceed with a synthesis wave or thermal flash. Solid state metathesis reactions have been utilised for the

* Author to whom correspondence should be addressed.

formation of a range of inorganic materials [16]. When the metathesis reaction is sufficiently exothermic, a powder of the green mixture can be ignited at one end with a heated filament. This produces a solid flame that moves out from the point of initiation through the whole material. Such reactions proceed in a matter of seconds, producing crystalline products which do not require furnace heating or further treatment other than simply washing with water to remove byproduct salt. Solid state metathesis reactions are a subclass of self-propagating high-temperature synthesis (SHS). SHS is a the name given to a general process where an exothermic chemical reaction replaces the requirement to heat the reagents; energy for the transformation primarily comes from the reaction enthalpy. SHS reactions are typically of the oxidation–reduction type, two well known examples are the thermite reaction ($Al+Fe_2O_3$), which produces iron metal and is used in welding, and the Goldsmidt reaction ($Al+Cr_2O_3$), which is used to form chromium metal [16]. Here we report the rapid synthesis of lanthanide and yttrium orthochromites by four different SHS reactions.

EXPERIMENTAL

All reagents were obtained from Aldrich (U.K.) and Saint Gobain (France) and used as supplied. Milling operations were carried out in a FRITSCH 05.102 ball mill (Germany) using Halsedon containers and balls. Combustion temperatures were measured using an optical pyrometer (Promin-M1) and tungsten–rhenium (5% and 20% Re) thermocouples. X-ray powder diffraction was performed on a DRON 3M spectrometer using Ni filtered $CuK_{\alpha 1}$ radiation ($\lambda = 1.54056$ Å). Phases were identified and indexed using the ASTM system. Pycnometrical densities were measured by standard methods using toluene; magnetic measurements were made on an EG&G PARC 4500 (U.S.A.); TGA and DTA experiments were carried out on SETARAM TAG24 (France) using alumina standards. FT-IR spectra were obtained on a Bruker IFS 307 in the reflection mode. SEM/EDAX were determined on a Hitachi S300 instrument. Coefficients of linear expansion were measured by dilatometric techniques.

Preparation of $LnCrO_3$ from reaction of Ln_2O_3, Cr and $NaClO_4$; Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Th, Lu and Y

The same reaction scale and procedure was adopted for all the lanthanides illustrated here for Ln = La.

La_2O_3 (15.00 g, 0.045 mmol), chromium metal (4.67 g, 0.090 mol) and sodium perchlorate (4.13 g, 0.0375 mol) were ground for 1 h in a ball mill. The mixture was pressed (30 kg/cm^3) into a 2 cm by *ca.* 4 cm cylindrical pellet. Small holes were drilled through the pellet and W–Re thermocouples inserted. The pellet was supported on a ceramic boat and the reaction ignited by an electrically heated nicrome wire filament at one end. This produced an orange–yellow propagation wave that proceeded through the solid at *ca.* 2–4 mm s^{-1}. This produced a green solid which was ground in a pestle and mortar, washed with distilled water (3×200 ml) filtered through a Buchner funnel and dried in air at 80°C for 4 h. Yields were essentially quantitative. The solid was analysed by X-ray powder diffraction, VSM, and for selected samples by coefficient of linear expansion (Table 1). FT-IR spectra for all $LnCrO_3$ were identical showing five

Table 1. bands in the region 700–200 cm^{-1}. SEM showed uniform micron sized agglomerates. EDAX showed consistent Ln to Cr (1:1) ratios across all surface spots. Similar reactions were also studied by replacing $NaClO_4$ with $Ba(ClO_4)_2$. This gave comparable samples.

Preparation of $LnCrO_3$ from reaction of Ln_2O_3, Cr and oxygen (Ln = La, Sm, Dy)

The same reaction scale and procedure was adopted for all lanthanides illustrated here for Ln = La.

La_2O_3 (15.00 g, 0.045 mol) and chromium metal (4.67 g, 0.090 mol) were ground for 1 h in a ball mill. The resulting powder was supported on a ceramic boat (15 cm by 3 cm) and placed inside of a 5 cm i.d. quartz tube. Oxygen was admitted through the tube (10 l/min) and the reaction ignited at one end by an electrically heated filament (800°C). This initiated a yellow–white propagation wave that travelled through the solid at *ca.* 4 mm s^{-1}. The resultant yellow–green powder was collected (after *ca.* 15 min) and analysed by X-ray powder diffraction ($a = 5.500$ Å, $b = 5.480$ Å, $c = 7.762$ Å; $\gamma = 89.46°$) and FT-IR which showed single phase $LaCrO_3$ was produced. Yields from the reaction were essentially quantitative.

Preparation of $LnCrO_3$ from the reaction of $LaCl_3$, $CrCl_3$ and Na_2O_2 (Ln = La, Ce, Gd, Ho)

All the manipulations and weighings were performed inside of an inert atmosphere (N_2) glove box, the same procedure was followed for all lanthanides illustrated here for Ln = La.

Anhydrous $LaCl_3$ (8.00 g, 0.0326 mol), $CrCl_3$ (5.17 g, 0.0326 mol) and Na_2O_2 (7.64 g, 0.098 mol) were ground together inside a ball mill for 1 h. The resulting powder was supported on a ceramic boat (15 cm, by 3 cm) and an SHS reaction initiated by a heated filament (800°C) in air. This produced a synthesis wave that travelled through the solid at *ca.* 2 mm s^{-1}. The reaction was left for 10 min and the products were washed with distilled water (2×1 l) and filtered in air using a Buchner funnel. The resultant green powder was analysed by X-ray powder diffraction ($a = 5.501$ Å, $b = 5.481$ Å, $c = 7.760$ Å; $\gamma = 89.44°$) and FT-IR. These techniques showed that the product was single phase $LaCrO_3$. Yields were essentially quantitative.

Reaction of NaO_2 with $LaCl_3$ and $CrCl_3$ proceeded in the same manner as that outlined above except the molar ratios of the starting materials were adjusted to salt balance the sodium and chlorine.

Reaction of lanthanide nitrate, melamine and chromium powder were investigated under the same conditions as previously reported [17].

Caution

Solid state metathesis reactions and self-propagating high-temperature synthesis can eject material from the initiation zone. Some of these reactions have been known to self-initiate on grinding and mixing the reagents (although this was not observed for the reactions studied here), especially when strong oxidising ($NaClO_4$) and reducing agents are present. New systems should be studied on a small scales using suitable safety screens.

RESULTS AND DISCUSSION

Synthesis and characterisation

Four separate types of SHS reaction were studied for the formation of $LnCrO_3$,

$$0.5Ln_2O_3 + Cr + 0.375NaClO_4 \rightarrow LnCrO_3 + 0.375NaCl, \quad (2a)$$

$$0.5Ln_2O_3 + xCr + (1-x)CrO_3 + (0.75x - 0.375)NaClO_4 \rightarrow LnCrO_3 + (0.75x - 0.375)NaCl, \quad (2b)$$

$$0.5Ln_2O_3 + xCr + (1-x)CrO_3 + (0.375x - 0.1875)Ba(ClO_4)_2 \rightarrow LnCrO_3 + (0.375x - 0.1875)BaCl_2, \quad (2c)$$

$$0.5Ln_2O_3 + Cr + 0.75O_2 \rightarrow LnCrO_3, \quad (3)$$

$$LnCl_3 + CrCl_3 + 3Na_2O_2 \rightarrow LnCrO_3 + 6NaCl + 1.5O_2, \quad (4a)$$

$$LnCl_3 + CrCl_3 + 6NaO_2 \rightarrow LnCrO_3 + 6NaCl + 4.5O_2, \quad (4b)$$

$$Ln(NO_3)_3 + Cr + C_3N_6H_6 \rightarrow LnCrO_3 + 2NH_3 + 3CO_2 + 2N_2. \quad (5)$$

The products from all of the reactions (after trituration with water in the case of eqs. (2a, 2b, 2c, 4a, 4b)) were analysed by X-ray powder diffraction Table 1, VSM Table 1 and FT-IR. Selected samples from reaction (2a) and (4a) were analysed by SEM which showed micron sized aggregates, EDAX on these samples gave consistent Ln to Cr ratios over all of the surface spots.

The IR spectra of all the lanthanide orthochromites (Equations (2a, 2b, 2c, 3–4a, 4b, 5)) were measured in the reflection mode. These showed five broad bands at *ca.* 635 480, 440, 350 and 180 cm^{-1}. All of the materials showed similar IR patterns consistent with an isostructural series. Some slight shifts (*ca.* 5–10 cm^{-1}) in frequency were observed between samples dependent on the lanthanide although no clear pattern of shift with lanthanide atomic weight was observed.

The band at 635 cm^{-1} is due to a Cr–O stretching vibration [13]. The IR spectra do not show any evidence for incorporation of starting materials or the $LnCrO_4$ phase (dominant IR bands at 900–700 cm^{-1}). The $LnCrO_4$ phase has been observed as an intermediate and a contaminant in the traditional synthesis of $LnCrO_3$ [13].

X-ray investigations of the SHS prepared lanthanide chromites indicated that they are all isostructural and have an orthorhombic unit cell with the exception of $PrCrO_3$ which was tetragonal. The lattice parameters were consistent between samples prepared by different reactions (2–5), the data reported in Table 1 is for reaction (2a) only. There have been a number of reports concerning the crystal structures of lanthanide chromites. For example $LaCrO_3$ has been reported with both monoclinic and rhomohedral structures [18, 19] and $PrCrO_3$ with a tetragonal space group (as also observed here) [20]. Despite this, most authors agree that the data can be best fitted to an isostructural series of materials with orthorhombic symmetry [17, 21, 22] akin to the structure also adopted by gadolinium ferrite [23]. As noted above all the SHS prepared materials show orthorhombic symmetry. A steady decrease in the *a* and *c* parameters and unit cell volume was observed with increasing lanthanide atomic number. This is consistent with a contraction in size of the lanthanide cation across the series. There is no detectable pattern in the variations of the *b* unit cell parameters with lathanide atomic number. Some variation in angle between the (110) and (−110) planes is observed within each lanthanide subgroup. In the La–Eu subgroup an increase in angle is observed from 89°46′ for $LaCrO_3$ to 93°40′ for $SmCrO_3$ Table 1. The variation in angle is also observed in the Gd–Lu subgroup. A plot of variation in angle and *c*-cell parameter against rare earth atomic radius is shown in Fig. 1. The SHS prepared lanthanides had in most cases (Ln = La, Ce, Pr, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu and Y) indexing within error limits of traditionally prepared materials and literature standards [12–16, 21, 22]. This is shown in Fig. 2 which plots unit cell volume and pycnometrical density against lanthanide ionic radius for SHS and conventionally prepared materials. The unit cell volumes are extremely similar for the lanthanides of large and small radius (within 1 $Å^3$), however a discontinuity was observed for Nd and Sm where the SHS prepared materials had a slightly smaller unit cell volume. Considering the error in the measured lattice

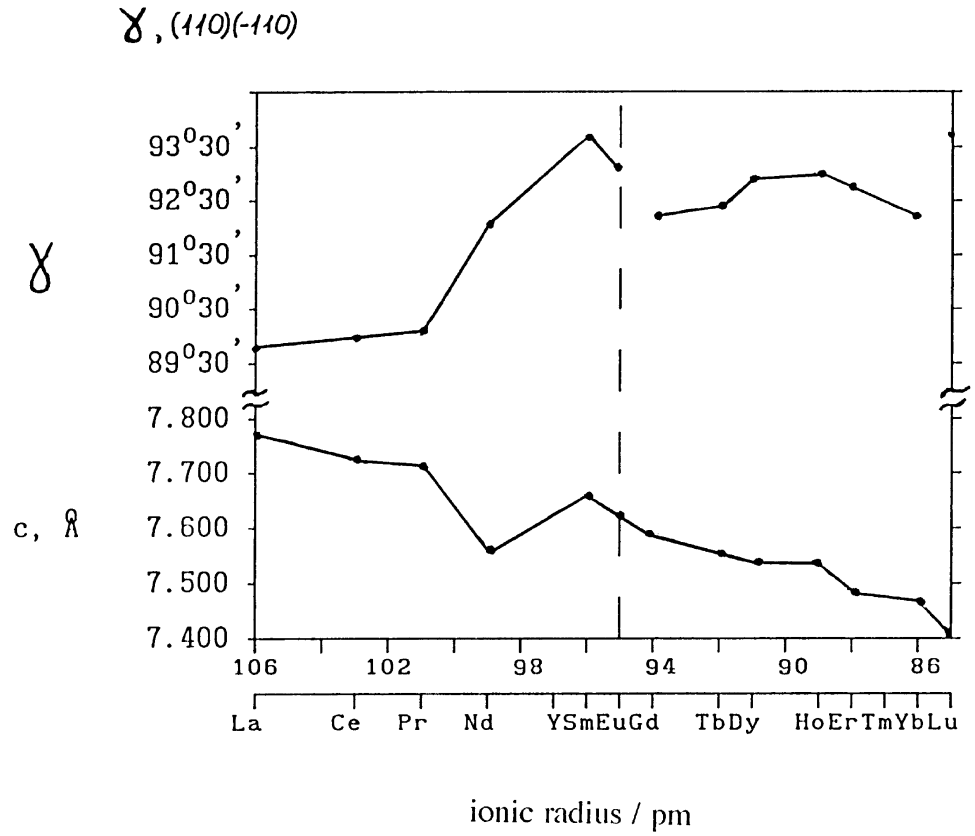

Fig. 1. Changes of orthorhombic parameter *c* and angle of rhombic distortion of lanthanide chromites prepared by self-propagating high-temperature synthesis against lanthanide ionic radius [24].

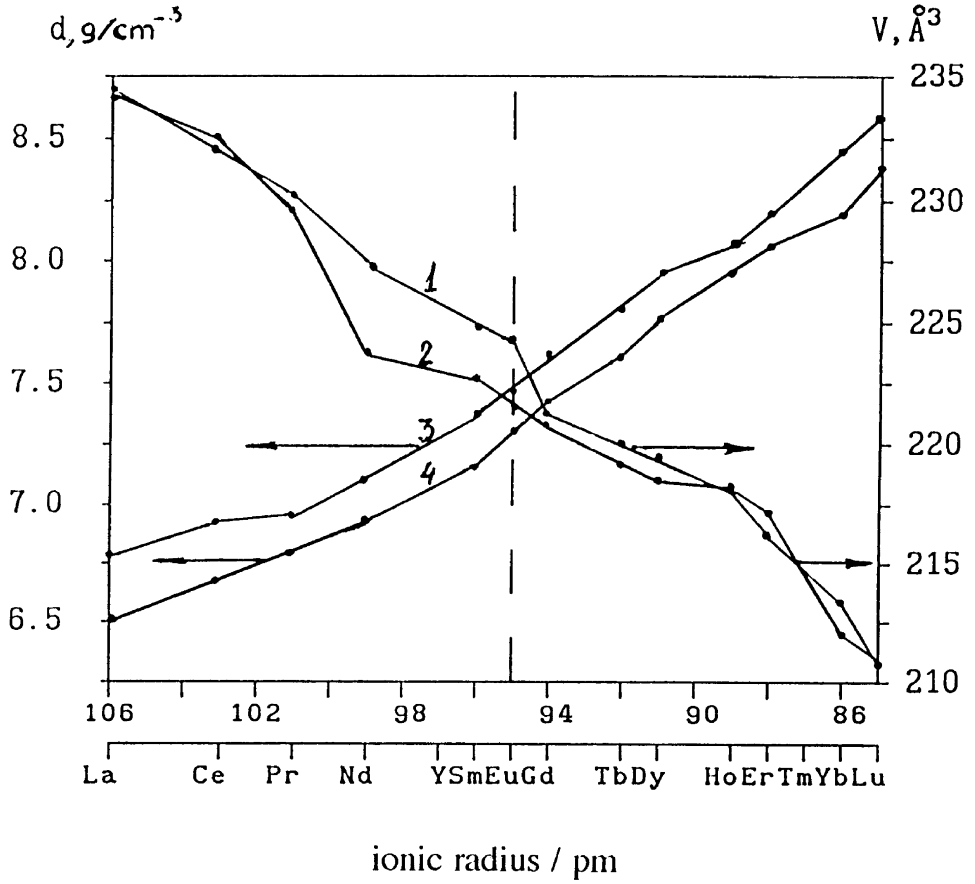

Fig. 2. Plots of unit cell volume (lines 1, 2) and pycnometrical density lines (3, 4) against lanthanide ionic radius [24] for SHS prepared (reaction 2a, lines 2, 4) and conventionally prepared materials (lines 1, 3).

parameters, this difference is significant and not easily accountable. The pycnometrical densities of the SHS prepared lanthanide orthochromites are less than the densities produced by conventional methods [22] Fig. 2. This can be readily accounted as a huge gas evolution occurs during the SHS process, producing a porous materials [23]. It has been shown previously that densification of samples is possible during SHS if a compressive force or controlled constricted environment is used, however this was not investigated for $LnCrO_3$ [25]. For traditionally prepared $LnCrO_3$ materials the maximum rhombohedral distortion (b/a) of the lattice in La–Lu series was 1.059 for $LuCrO_3$ [22]. For the SHS prepared materials the rhombohedral distortion was maximised for both $SmCrO_3$ and $LuCrO_3$ at 1.066.

The magnetic characteristics of the SHS prepared rare-earth chromites were determined Table 1. These indicated that all the materials are antiferromagnets with weak spontaneous magnetic moments. The specific magnetisation values within the La–Eu and Gd–Lu subgroups were different. Measurements at $T = 83$ K and 10 kOe indicated that within both subgroups maxima were observed at the middle of the series Table 1. For the La–Eu group the maximum value is for $PrCrO_3$ – 2.019 and for the Gd–Lu series $HoCrO_3$ – 9.402. These measurements were directly comparable to previous conventionally prepared materials [10–14, 24].

All of the energy (apart from the small amount required to initiate the reaction) for the SHS formation of $LnCrO_3$ comes from an exothermic chemical reaction. In reactions (2a)–(2c) the oxidation of chromium metal provides the driving force for the reaction and the oxygen comes from the solid oxidisers $NaClO_4$ and $Ba(ClO_4)_2$. In reaction (3) the oxidation of chromium metal by gaseous oxygen provides the fuel source for the reaction. In reaction (4a) and (4b) the SHS reaction is promoted by the metathetical exchange of ions and the production of six moles of sodium chloride. In reaction (5) the SHS reaction of $Ln(NO_3)_3$ and Cr is promoted by the exothermic decomposition of melamine $C_3N_6H_6$. Thermochemical data for lanthanide chromites is lacking [26–28]. However one report for $CeCrO_3$ indicates a heat of formation of -1527.2 kJ/mol [29]. Assuming similar heats of formation for all of the lanthanides and using Hesses law this gives heats of reaction for (2a)

of *ca.* $-670\,kJ\,mol^{-1}$; for (3) of $-640\,kJ\,mol^{-1}$ and of (4a) of $-830\,kJ\,mol^{-1}$. These heats of reaction are sufficient to heat up the reactants and drive the transformation. In some cases (2a–2c, 4a, 4b) coproduced NaCl is produced and this in part is vapourised from the reaction. This vapourisation acts as a heat break and limits the reaction temperature to *ca.* 1400°C [16]. It should be noted that the SHS reactions cool relatively quickly and that within 10 min the samples are close to room temperature.

The SHS reaction of Ln_2O_3, xCr, $(1-x)CrO_3$ and $NaClO_4$ proceeded by a steady combustion wave of velocity U_c 2.0 mm/s. The reaction was very sensitive to the ratio of Cr metal to CrO_3. Chromium metal provides the fuel for the reaction and chromium oxide acts in part as a dilutent to absorb some of the reaction energy. Thermocouple measurements indicated that the maximum reaction temperature inside of the reaction was 1900–2300°C. Optical pyrometry measurements indicate a surface reaction temperature in the range of 1000–1150°C. Combustion velocity and temperature seemed largely independent on which lanthanide was used. The maximum reaction temperature and propagation velocity were observed to decrease with x eq. (2b). An SHS reaction proceeded for $x = 1$ to $x = 0.55$ (Table 2). The reaction failed to propagate for values of x below 0.55 as insufficient chromium fuel was present. This meant that the reaction is insufficiently exothermic to allow spread of reaction away from the source of initiation [30, 31]. Combined DTA and TGA data (Figure 3) indicates that for $x = 1$ the reaction initiated at $T = 330$°C and the maximum heat flow from the reaction occurred at 450°C. This corresponds with the decomposition temperature of $NaClO_4$ releasing oxygen which combines with the chromium metal to produce the large exotherm.

The reaction of lanthanide oxide with chromium metal also propagates using oxygen gas instead of an internal intimately mixed solid oxidiser. The propagation velocity and temperature of both reactions are comparable providing sufficient oxygen gas is used in the reaction. At slow flows of oxygen and if the reaction is conducted in air, the propagation velocity is dramatically curtailed and the propagation wave can falter. The limiting step in this reaction is the diffusion of oxygen through the powder. This also explains why the reaction of Ln_2O_3 with Cr and oxygen does not work on a compressed pellet.

Combination of the anhydrous halides and sodium superoxide or peroxide supported an SHS reaction and formed single phase $LnCrO_3$ (Ln = La, Ce, Gd, Ho). One difficulty of this route is that the reagents are hydroscopic and required prior grinding in an inert atmosphere. The driving force for this reaction is the formation of NaCl and $LnCrO_3$. The maximum temperature observed in this reaction was lower than that observed in reactions (2a) and (2c). This is because the coproduced NaCl partly vapourises during the reaction and acts as an internal heat break to soak up some of the reaction enthalpy. The final products were readily obtained after washing off the coproduced NaCl with water.

Lanthanide orthochromites can also be made by combustion of chromium metal and lanthanide nitrate providing an exothermic co-reaction is present within the green mixture. A mixture of the lanthanide nitrate and chromium metal does not ignite in air because the reaction is insufficiently exothermic [30, 31] (*ca.* $300\,kJ\,mol^{-1}$) to propagate between adjacent layers. When a combustion additive is placed in the green mixture two effects occur. Firstly the combustion additive provides heat and dramatically raises the temperature of the starting reagents, in effect it is a form of "chemical oven". Secondly the decomposition of the additive produces large quantities of gas. This gas expansion can be detrimental to the SHS process because it spreads the product and consequently lowers the overall reaction temperature. In the reactions studied here, melamine ($C_3N_6H_6$) was used as a combustion aid (*ca.* $300\,kJ\,mol^{-1}$). Despite producing large quantities of gas on melamine decomposition, the reaction did propagate rapidly. Notably despite addition of the combustion aid no impurities were detected in the product. This indicates that the melamine is completely converted into gaseous products during the reaction (NH_3, CO_2, N_2). The use of a combustion aid does increase the overall cost of the

Table 2. Dependence of combustion temperature on quantity of chromium metal in the system $0.5La_2O_3 + x\text{Cr} + (1-x)CrO_3$.

SHS reaction, indeed the combustion aid is often more expensive than the ingredients of the SHS process.

All of the SHS reactions produced single phase $LnCrO_3$ in minutes without the need to externally heat the reaction. In practical terms the reaction of lanthanide oxide and chromium metal using perchlorate solid oxidisers are the easiest to perform. The SHS reactions are all somewhat easier to perform than conventional synthesis in that they require no prior chemistry and do not require heating in a furnace. In many previously reported SHS reactions a second stage of thermal post treatment of the powders is required because the initial synthesis wave only promotes about 90% conversion [30, 31]. In the SHS reactions studied here only single phase $LnCrO_3$ was obtained despite the very short heating times invoked by the reaction. The large exothermicity of the SHS reactions studied (all $>600\,kJ\,mol^{-1}$), the extremely high reaction temperatures (1400°–2200°C), relatively large reaction scale and the premilling of reagents helped to promote single phase formation. It is also notable that by using solid oxidisers the reactions can be promoted in air, this is relatively unusual for an SHS reaction to form a metal oxides where special reaction containers and an oxygen atmosphere are normally required [32].

CONCLUSIONS

Lanthanide chromites with general formula $LnCrO_3$ were synthesised by four separate self-propagating high-temperature syntheses. All the reactions produced single phase orthorhombic $LnCrO_3$ which were weak antiferromagnets. The SHS prepared $LnCrO_3$ show uniform changes in lattice parameters and unit cell volume with lanthanide atomic number. The SHS materials are equal in quality to traditionally prepared materials and require relatively simple synthesis conditions without recourse to use of a furnace.

(Received 21 April 1998; accepted 18 June 1998)

Abstract—In this study, the sandwich complex of tmtaa, Y(tmtaa)(Htmtaa)·2THF (H_2tmtaa = 6,8,15,17-tetramethyldibenzo[*b*,*i*][1,4,8,11]tetraaza[14]annulene, THF = tetrahydrofuran) was synthesized and characterized by IR, UV, mass and NMR spectra as well as DSC measurement. The crystal structure of the complex was determined by X-ray crystal diffraction. The yttrium(III) is coordinated though 8 nitrogen atoms of a dianionic macrocyclic ligand, tmtaa, and of an anionic macrocyclic ligand, Htmtaa, to form an octacoordinated complex which has a sandwich structure. The average bond lengths of Y–N for tmtaa and Htmtaa are 2.40(2) and 2.47(2) Å, respectively. The distances of the yttrium to the planes of the 4 nitrogen atoms for tmtaa and Htmtaa are 1.44(2) and 1.51(2) Å, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocycles; crystal structures; yttrium(III) complexes; tmtaa complexes; sandwich complexes; NMR spectra

INTRODUCTION

Since 6,8,15,17-tetramethyldibenzo[*b*,*i*][1,4,8,11]-tetraaza[14]annulene, usually abbreviated with H_2tmtaa, was first synthesized by Jaeger [1], there has been considerable research activity concerning the syntheses and structural characterization of metal complexes with H_2tmtaa [2–23]. There are three reasons for this phenomenon: (a) H_2tmtaa has a structure and property similar to porphyrins and phthalocyanines and such systematic research provides a great help to model some biological phenomena [2–10]; (b) metal complexes of tmtaa, electron-rich compounds, have strong functions to stabilize metal–carbon bonds and so some metal complexes with H_2tmtaa, called organic–metal blocks, are prepared as an initial materials for the organic–metal syntheses [11–17]; (c) the 7,16-positions of H_2tmtaa and its metal complexes have been found to act as nucleophilic centres and many electrophilic reagents could react with these positions, which provide an opportunity for preparing more complex compounds employed as models for biologically significant macrocyclic systems [18–23]. However, there are a few papers reporting on rare earth complexes of H_2tmtaa, but the crystal structures of [Li(THF)][Ce(tmtaa)$_2$]·THF [24] and [K(THF)$_3$][Sm$_2$(tmtaa)$_2$]·4THF [25] were determined by Magull and Simon. As a continuation of our research work, an yttrium complex with H_2tmtaa has been synthesized and characterized and its structure has been determined by X-ray diffraction.

EXPERIMENTAL

Materials and methods

All chemicals were reagent grade and were used without further purification except as noted. All solvents were distilled from their sodium–benzophenone blue solution (THF, benzene, hexane and diethylether) or from phosphorus pentoxide (dichloromethane, acetonitrile) under a nitrogen atmosphere. All reaction operations were performed in a dry box

* Author to whom correspondence should be addressed.

under an argon atmosphere. The H_2tmtaa was prepared according to the literature [26, 27]. $YCl_3(THF)_3$ was also prepared according to literature [28] and recrystallized from dichloromethane/hexane.

Infrared spectra in the 400–4000 cm^{-1} region were taken on a Hitachi 260-30 spectrophotometer at room temperature. KBr disk and Nujol mull techniques were employed. Ultraviolet and visible spectra covering the 14000–37000 cm^{-1} range were recorded on a Shimadzu UV-200S double beam spectrophotometer for benzene solutions at room temperature. ^1H NMR measurements were taken on a JEOL JNM-A500 spectrometer operating in a Fourier transform mode. The NMR spectra were run in benzene-d_6 and chemical shifts were given in ppm relative to tetramethylsilane as an internal reference standard. FAB mass spectra were carried out with a JEOL JMS-SX102A gas chromatograph–mass spectrometer in a glycerin matrix. Element analyses were determined with a Yanaco CHN corder MT-3. DSC data were obtained using a Shimadzu DSC-50 differential calorimeter.

Synthesis of Y(tmtaa)(Htmtaa)·2THF complex

H_2tmtaa (0.688 g, 2.0 mmol) and THF (16 cm^3) were added into a 50 cm^3 flask with a rubber cap. The mixture was stirred at 0°C for 30 min. After that, *n*-butyllithium in hexane (2.5 cm^3 of 1.59 M, 3.98 mmol) was added dropwise slowly. When stirred at 0°C for 30 min, a clear red solution was formed. A saturated THF solution (20.4 cm^3) of $YCl_3(THF)_3$ (0.412 g, 1.0 mmol) was added dropwise slowly. After the reaction solution was kept at 0°C for 12 h, yellow crystals were deposited. The crystalline product was collected by filtration and washed three times with cold THF; yield 0.311 g (33.9%). Anal. calc. for $C_{52}H_{61}N_8O_2Y$: C, 68.4; H, 6.6; N, 12.0. Found: C, 67.8; H, 6.6; N, 11.7%. UV-Vis (benzene, nm) 379 ($\log\varepsilon = 4.49$), 410 ($\log\varepsilon = 4.17$). IR (KBr, cm^{-1}) 3000 (w), 2960 (w), 2925 (w), 2810 (w), 1676 (m), 1624 (w), 1551 (s), 1465 (s), 1456 (s), 1420 (s), 1390 (s), 1360 (w), 1272 (s), 1188 (s), 1114 (w), 1040 (m), 1020 (m), 923 (w), 795 (m), 740 (s). FBA-MS: $m/z = 775$ [$(M+1)^+$]. Crystals for X-ray analysis were obtained by dissolving the complex in dry THF solution. After this solution is filtered, the filtrate was cooled to 0°C for 2 h and then hexane was layered carefully. After for 24 h, the yellow and blocklike crystals had formed.

X-ray crystallography

The yellow crystals were selected from the products and were mounted on glass fibres. X-ray data were collected on a Siemens P4 four circle diffractometer by means of an ω–2θ scan and MoK_α radiation at room temperature. The cell parameters and an orientation matrix for data collection were obtained from the least squares method for the diffraction data from 25 reflections. The three check reflections measured with every 100 reflections showed no decay in intensity. The data were corrected by a Lorentz and Polarization factor and an empirical absorption correction. The structure was determined by a standard heavy atomic method and refined by the full-matrix least-squares methods. All nonhydrogen atoms of the complex were refined anisotropically. Since the THF molecules in the structure keep as uncoordinated solvent molecules, the THF molecules have high vibration states and so the second THF molecule was finally treated as a rigid group and was refined as an individual isotropic thermal parameter. A summary of the crystal data, the experimented detail and the refinement results are listed in Table 2.

RESULTS AND DISCUSSION

Syntheses and characterization of Y(tmtaa)(Htmtaa)·2THF

Reaction of the H_2tmtaa in THF solution with 2 equivalent of LiC_4H_9 in hexane gave a clear red solution and so Li_2tmtaa was produced. When the Li_2tmtaa reacted with 1/2 or 1 eq. of $YCl_3(THF)_3$, the yellow crystals, Y(tmtaa)(Htmtaa)·2THF, were crystallized out from the reaction solution. The three reactions may occur in the solution as follows:

$$H_2\text{tmtaa} + n\text{-}LiC_4H_9 \xrightarrow{THF} Li_2\text{tmtaa}$$

$$Li_2\text{tmtaa} + YCl_3 \xrightarrow{THF} LiY(\text{tmtaa})_2$$

$$LiY(\text{tmtaa})_2 \longrightarrow Y(\text{tmtaa})(\text{Htmtaa})$$

Though all reaction operations were performed in a dry box under an argon atmosphere, there were trace amounts of water in the reaction solution and so the water reacted with the $LiY(tmtaa)_2$ to produce the Y(tmtaa)(Htmtaa). Since the coordination number of yttrium(III) in $LiY(tmtaa)_2$ and Y(tmtaa)(Htmtaa) is eight, the solubility of them in the THF solution is different. Y(tmtaa)(Htmtaa) has a lower solubility than that of $LiY(tmtaa)_2$ and is easy to separate from the reaction solution. Consequently, Y(tmtaa)(Htmtaa)·2THF were obtained from the reaction solution.

The complex was characterized by UV, IR, mass and NMR spectra as well as DSC measurement. IR bands of H_2tmtaa at 1620 (s), 1600 (m), 1554 (s) and 1512 (s) cm^{-1} are assigned to C=N and C=C stretching modes [29–31]. After formation of the complex, the IR bands shifted to lower frequency and the bands appeared at 1551 (s), 1465 (s), 1456 (s) and 1390 (s) cm^{-1}. The UV-Vis spectra of the complex was mea-

sured at room temperature in benzene solutions. Two absorption peaks appear at 379 nm ($\log \varepsilon = 4.49$) and 410 nm ($\log \varepsilon = 4.17$). Comparison with a maximum absorption band (348 nm) of H_2tmtaa shows a 31 nm shift to a longer wavelength for complex formation. The crystalline complex is stable in dry air, but decomposes easily in a moist condition. The DSC data under a nitrogen atmosphere show that the complex loses two THF of crystallization at 93°C and then the complex decomposes at 399.5°C. This is in agreement with the TG result (percent mass loss: $W_{\text{calc.}} = 15.67\%$, $W_{\text{found}} = 15.7\%$).

A molecular ion peak of the complex, $[M+1]^+$, appeared at m/z 775 in the FBA mass spectra. The base peak is m/z 431 which corresponds to $[Y(tmtaa)]^+$. Consistent with diamagnetism, Y(tmtaa)(Htmtaa)·2THF gave well-resolved ^{1}H NMR spectra. Chemical shift assignments were made on the basis of comparison with H_2tmtaa. ^{1}H NMR data and its assignments for Y(tmtaa)(Htmtaa)·2THF are compiled in Table 1. The methine proton signals of two kinds appear at about 4.68 ppm because of two different macrocyclic skeletons, namely tmtaa and Htmtaa. The amine proton signal appears at 13.9 ppm and is a singlet, having no proton which couples it. The methine signal and the amine signal in the integrated rate = 2:1 spell out the complex and so the complex has two kinds of the macrocyclic skeletons. The methine proton signal, the methyl proton signal and the aromatic proton signal are little shifted on the formation of the yttrium(III) complex. On the other hand, the amine proton signal is shifted by 0.8 ppm to a lower field. This is mainly attributed to the placement of the methine, methyl and aromatic proton groups further from the positive change of the yttrium(III) ion which offers the inductive effect.

Crystal structure of the complex

The perspective view of the molecular unit is shown in Fig. 1. The selected bond lengths and the selected bond angles are given in Table 3. Though the quality of the crystal data is not very good, the results of crystal structure of the complex are in agreement with those of UV, IR, mass and NMR spectra of the complex. Figure 1 shows that the structure unit of the crystal consists of one complex molecule and two THF molecules. Because of steric interaction between the methyl groups and the benzene rings, H_2tmtaa and its transition metal complexes have a markedly nonplanar saddle shape [6]. In the complex, the Y(III) is coordinated through 8 N atoms from the two saddle shaped ligands, macrocyclic dianion, tmtaa and macrocyclic anion, Htmtaa, to form an octacoordinated sandwich complex.

The dianionic tmtaa coordinates to the central ion as two delocalized conjugated π-electron systems. On the other hand, the anionic Htmtaa coordinates to the central ion as a delocalized conjugated system and as a nonconjugated system. The position of the amine hydrogen (N–H) in the complex seems to be fixed. This may be demonstrated by the markedly longer bond length of Y–N(8) [2.66(2) Å]. The average atomic deviation from the plane of the nonconjugated 2,4-pentanediiminate chelate ring is 0.11 Å and is much larger than that of the conjugated 2,4-pentanediiminate chelate rings. In the complex, the two conjugated 2,4-pentanediiminate chelate rings of tmtaa and one conjugated 2,4-pentanediiminate chelate ring of Htmtaa are coplanar and the average atomic deviations from the planes are 0.05, 0.03 and 0.01 Å, respectively. This is shown in Fig. 2.

The average bond lengths of Y–N for tmtaa and Htmtaa are 2.40(2) and 2.47(2) Å, respectively. The longest bond length of Y–N is 2.66(2) Å and the shortest bond length is 2.34(2) Å. These parameters may be compared with those of the structurally characterized rare earth tmtaa complexes [24, 25], $[Li(THF)][Ce(tmtaa)_2]\cdot THF$ and $[K(THF)_3][Sm_2(tmtaa)_2]\cdot 4THF$, in which average bond lengths of Ce–N (A ring and B ring) and Sm–N are 2.48 Å (A ring), 2.65 Å (B ring) and 2.35 Å, respectively. The four nitrogens of tmtaa and Htmtaa are almost coplanar in the complex. The average atomic deviation from the planes (defined by nonhydrogen atoms) is 0.02 Å for tmtaa and 0.03 Å for Htmtaa, respectively. The two saddle shaped ligands are rotated by nearly 90° relative to one another and two corresponding mean 4 N planes are almost parallel to each other. The dihedral angles are only 2°. In the complex, the central ion lies at 1.44(2) Å away from the 4 N mean plane for tmtaa and at 1.51(2) Å out of the 4 N mean plane of Htmtaa. The distance is shorter than that of $[Li(THF)][Ce(tmtaa)_2]\cdot THF$ [1.53 Å (A ring) and 1.65 Å (B ring)], but is longer than that of $[K(THF)_3][Sm_2(tmtaa)_2]\cdot 4THF$ (1.23 Å).

Table 1. ^{1}H—NMR data for H_2tmtaa and Y(tmtaa)(Htmtaa)·2THF[a]

Complex	Amine (-N–H)	Aromatic	Methine (-CH═)	Methyl (-CH_3)
H_2tmtaa	13.10(s)	6.80(m)	4.69(s)	1.88(s)
Y(tmtaa)(Htmtaa)·2THF	13.90(s)	6.89(m)	4.69(s), 4.68(s)	1.88(s)

[a] Chemical shifts are given in ppm for TMS. Measured in benzene-d_6.Multiplicity of a proton signal is given parentheses after δ-value: s: singlet; m: multiple.

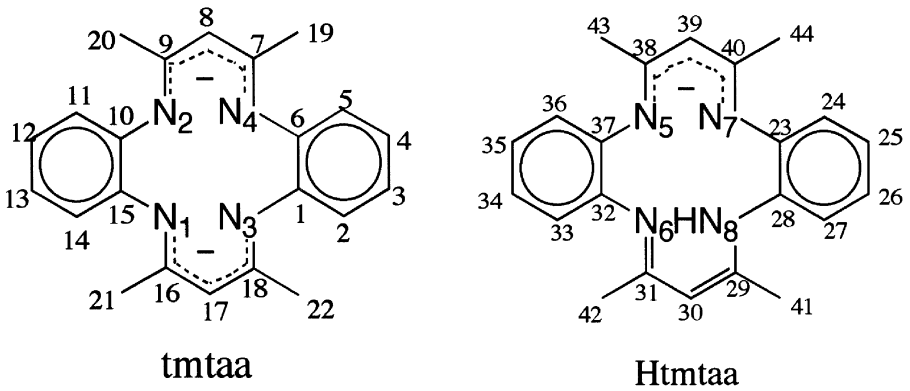

Fig. 2. The coordination models of tmtaa and Htmtaa in the complex.

Since H_2tmtaa has a property similar to phthalocyanine (H_2Pc), Y(tmtaa)(Htmtaa) has a structurally characterization similar to $LuHPc_2$ [32, 33]. Both complexes are coordinated through 8 N atoms from a dianionic ligand and an anionic ligand to form octacoordinated sandwich complexes. The electron-delocalized capability of tmtaa is different from that of Pc. Pc is a delocalized 16-membered ring with a full electron and HPc also is a delocalized system with a full electron and so the position of N–H could not be located in $LuHPc_2$. On the other hand, Htmtaa and tmtaa are nondelocalized 14-membered rings and the position of N–H could be located in the complex. Though the two ligands are rotated by nearly 90° to one another for formation of the complex, the interaction between the methyl groups and the benzene rings of the two ligands is very strong and causes the angles to change largely between the benzene planes and the 4 N atom planes. Some important angles between selected planes are listed in Table 4.

INTRODUCTION

Interest in the coordination chemistry of metal–sulfur complexes arises from their potential relevance to active sites in metallo-enzymes and also from their ability to adopt various nuclearities and significant structural complexity [1–4]. These features are the result of the tendency of thiolate ligands to bridge metal centres to give polymeric species. Such association phenomena can be controlled by introducing coligands. In this context, the synthesis and characterisation of mixed complexes containing both thiolate and additional donors, such as tertiary phosphines, have been objects of extensive studies [5]. However, ligands containing both phosphorus and sulfur as donor atoms have received far less attention. In the last decade, compounds containing arenophosphinothiolate ligands have been reported by Dilworth and Zubieta, mainly with heavier transition metals, such as molybdenum [6], technetium and rhenium [7], rhodium [8] and iridium [9].

As a result of our continuing interest in the chemistry of monomeric and low molecularity thiolate complexes, we now describe the synthesis of cobalt and nickel compounds with aromatic phosphinothiol ligands, using an electrochemical procedure, where the metal is the anode of a cell containing the ligand in an acetonitrile solution. This method has been successfully used for the synthesis of cobalt and nickel thiolate compounds [10]; and also for metallic compounds with other ligands having weak acid groups,

such as heterocyclic thiones [11–14]. Although the compounds [Ni{2-(Ph_2P)C_6H_4S}$_2$] and [Ni{2-(Ph_2PO)-6-($SiMe_3$)C_6H_3S}$_2$] have been previously prepared by nonelectrochemical methods and their structures described [15], the other compounds reported in this article have not been reported previously.

EXPERIMENTAL

All manipulations were carried out under an inert atmosphere of dry nitrogen. Cobalt and nickel (Aldrich Chemie) were used as plates (*ca.* 2×2 cm). Ligands were synthesised using slight modifications of the standard literature procedure [16].

Electrochemical synthesis

The electrochemical method used in the synthesis of the complexes was similar to that described by Tuck [17]. The foil anode was suspended from a platinum wire and the cathode was also a platinum wire. The ligand was dissolved in acetonitrile and about 10 mg of tetramethylammonium perchlorate was added to the solution. Applied voltages of 10–20 V allowed sufficient current flow for smooth dissolution of the metal. During electrolysis, nitrogen was bubbled through the solution to provide an inert atmosphere and to stir the solution phase. The cell can be summarised as $Pt_{(-)}/CH_3CN + RP–SH/M_{(+)}$, where RP–SH represents the ligand and M is either Co or Ni.

[Co{2-(PPh_2)C_6H_4S}$_3$], ***1***. Electrochemical oxidation of a cobalt anode in a solution of 2-diphenylphosphinobenzenethiol, 2-(Ph_2P)C_6H_4SH, (0.230 g, 0.782 mmol) in acetonitrile (50 cm^3), at 16 V and 10 mA for two h caused 21 mg of cobalt to be dissolved, $E_f = 0.48$ mol F^{-1}. During the electrolysis hydrogen was evolved at the cathode and at the end of the electrolysis green crystalline needles appeared at the bottom of the vessel. The solid was filtered, washed with acetonitrile and ether and dried under vacuum, (0.20 g, 83%). Anal. Calc. for $C_{54}H_{42}CoP_3S_3$: C, 69.1; H, 4.5; S, 10.2. Found: C, 68.8; H, 4.6; S, 9.8% IR (KBr, cm^{-1}): 1571(m), 1482(m), 1433(s), 1416(m), 1241(s), 1091(m), 738(s), 692(s), 525(s). FAB (*m*/*z*): 939, $[Co(R–PS)_3]^+$; 645, $[Co(R–PS)_2]^+$; 294, $[RP–S]^+$. ^1H NMR ($CDCl_3$ ppm): δ 8.0–6.1 (m, 42 H). ^{31}P NMR ($CDCl_3$, ppm): δ 40.6, 38.8 and 37.0.

[Ni{2-(PPh_2)C_5H_4S}$_2$], ***2***. A similar experiment (12 V, 10 mA, 2 h) with nickel as anode and 0.220 g (0.748 mmol) of 2-(Ph_2P)C_6H_4SH in 50 cm^3 of acetonitrile, dissolved 23 mg of nickel, $E_f = 0.52$ mol F^{-1}. As the reaction proceeds, the solution colour changed from colourless to dark green. At the end of the electrolysis the green crystals deposited in the cell were recovered, washed with cool acetonitrile and diethyl ether, dried under vacuum and identified as **2** (0.17 g, 70%). Anal. Calc. for $C_{36}H_{28}NiP_2S_2$: C, 67.0; H, 4.3; S, 9.9. Found: C, 66.7; H, 4.3; S, 9.4%. IR (KBr, cm^{-1}): 1568(m), 1481(m), 1437(s), 1423(m), 1244(s), 1096(m), 740(s), 693(s), 530(s). FAB (*m*/*z*): 644, $[Ni(R–PS)_2]^+$; 352, $[Ni(R–PS)]^+$; 294, $[RP–S]^+$. ^1H ($CDCl_3$, ppm): δ 7.9–6.7(m, 28 H). ^{31}P NMR ($CDCl_3$, ppm): δ 54.0.

[Co{2-(Ph_2P)-6-(Me_3Si)C_6H_3S}$_3$], ***3***. A solution of acetonitrile (50 cm^3) containing 2-diphenylphosphino-6-trimethylsilylbenzenethiol (0.307 g, 0.839 mmol) was electrolyzed at 10 mA during 1.5 h and 17 mg of cobalt metal were dissolved from the anode, $E_f = 0.51$ mol F^{-1}. Dark blue crystals of **3**, suitable for X-ray studies, were obtained and the end of the reaction. They were recovered by filtration, washed with acetonitrile and dried (0.42 g, 88%) and identified by elemental analysis. Anal. Calc. for $C_{63}H_{66}CoP_3S_3Si_3$: C, 66.0; H, 5.7; S, 8,3. Found: C, 65.5; H, 5.9; S, 8.0% IR(KBr, cm^{-1}): 1554(m), 1483(m), 1434(m), 1355(s), 1245(m), 1086(m), 852(s), 746(s), 692(s), 530(s). FAB (*m*/*z*): 1153, $[Co(R–PS)_3]^+$; 789, $[Co(R–PS)_2]^+$; 365, $[RP–S]^+$. ^1H NMR ($CDCl_3$, ppm): δ 7.7–5.9 (m, 39H), 0.10(s, 9H), 0.30 (s, 9H), 0.50(s, 9H). ^{31}P NMR ($CDCl_3$, ppm): δ 45.0, 43.0 and 39.0.

[Ni{2-(Ph_2P)-6-(Me_3Si)C_6H_3S}$_2$], ***4***. A similar experiment (6 V, 10 mA, 2.0 h) with 0.29 g (0.792 mmol) of the ligand 2-(Ph_2PO)-6-(Me_3Si)C_6H_3SH in 50 cm^3 of acetonitrile, dissolved 21 mg of nickel, $E_f = 0.48$ mol F^{-1}. Green crystals, suitable for X-ray studies, were obtained directly from the cell. The solid was collected, washed with cool acetonitrile, diethyl ether and dried under vacuum (0.27 g, 86%). Anal. Calc. for $C_{42}H_{44}NiP_2S_2Si_2$: C, 63.9; H, 5.8; S, 8.1. Found: C, 63.7; H, 5.7; S, 7.8%. IR(KBr, cm^{-1}): 1555(m), 1482(m), 1433(m), 1359(s), 1243(m), 1098(m), 852(s), 746(m), 690(m), 540(s).). FAB (*m*/*z*): 789, $[Ni(R–PS)_2]^+$; 424, $[Ni(R–PS)]^+$; 365, $[RP–S]^+$. ^1H RMN ($CDCl_3$, ppm): δ 7.9–6.9(m, 26 H), 0.25(s, 18H). ^{31}P NMR($CDCl_3$, ppm): δ 52.5.

[Co{2-(Ph_2PO)-6-(Me_3Si)C_6H_3S}$_2$], ***5*** *and* [Co{2-(Ph_2PO)-6-(Me_3Si)C_6H_3S}$_3$], ***6***. The electrochemical oxidation of cobalt in a solution of 2-(Ph_2PO)-6-(Me_3Si)C_6H_3SH (0.428 g 1.12 mmol) in acetonitrile (60 ml) for 3 h at 10 V and 10 mA resulted in the loss of 32 mg of cobalt from the anode, $E_f = 0.50$ mol F^{-1}. During the electrolysis a small amount of a red crystalline compound, **5**, was recovered in the cell as a minor product. This compound has been characterised as [Co{2-(Ph_2PO)-6-(Me_3Si)C_6H_3S}$_2$]. Anal. Calc. for $C_{42}H_{44}P_2O_2S_2Si_2Co$: C, 61.4; H, 5.4; S, 7.8. Found: C, 61.0; H, 5.3; S, 7.7%. Concentration of the solution yielded dark blue crystals (0.35 g, 76%) of **6**. (Anal. Calc. for $C_{63}H_{66}P_3O_3S_3Si_3Co$: C, 62.9; H, 5.5; S, 8.0. Found: C, 62.5; H, 5.4; S, 7.9%, IR(KBr, cm^{-1}): 1554(m), 1437(s), 1352(s), 1243(m), 1127(s), 1062(s), 852(s), 750(s), 691(m), 558(s). FAB (*m*/*z*): 1201, $[Co(R–PS)_3]^+$; 821, $[Co(R–PS)_2]^+$; 382, $[RP–S]^+$. ^1H NMR ($CDCl_3$, ppm): δ 8.0–6.5(m, 39H), 0.35(s, 27H). ^{31}P($CDCl_3$, ppm): δ 41.7 ppm.

[Ni{2-(Ph_2PO)-6-(Me_3Si)C_6H_3S}$_2$], ***7***. Electrolysis of an acetonitrile solution (50 cm^3) containing 2-(Ph_2PO)-6-(Me_3Si)C_6H_3SH (0.214 g, 0.56 mmol) using

10 mA electric current for 1.5 h caused the dissolution of 16 mg of nickel ($E_f = 0.49$ mol F^{-1}). Concentration of the final solution produced green crystals (0.17 g, 74%) of **7**. Anal. Calc. for $C_{42}H_{44}P_2O_2S_2Si_2Ni$: C, 61.4; H, 5.4; S, 7.8. Found: C, 61.0; H, 5.3; S, 7.7%. IR(KBr, cm^{-1}): 1556(m), 1437(s), 1352(s), 1244(m), 1129(s), 1067(s), 854(s), 749(s), 692(m), 555(s).). FAB (m/z): 819, $[Ni(R–PS)_2]^+$; 439, $[Ni(R–PS)]^+$; 382, $[RP–S]^+$. ^1H NMR ($CDCl_3$, ppm): δ 8.6–6.4(m, 26H), 0.5 (s, 18H). $^{31}P(CDCl_3$, ppm): δ 58.2 ppm.

Instrumentation

Elemental analysis were performed on a Carlo-Erba EA microanalyser. IR spectra were recorded in KBr mulls on a Bruker IFS 66 V spectrophotometer. FAB mass spectra were recorded on a Kratos-MS-50T connected to a DS90 data system, using 3-nitrobenzyl alcohol (3-NBA) a matrix material. ^1H and ^{31}P NMR spectra were recorded on a Bruker AMX 300 MHz instrument, using in all cases $CDCl_3$ as solvent; ^1H NMR chemical shifts were determined against TMS as internal standard and ^{31}P NMR against 85% H_3PO_4. Solid-state electronic spectra were recorded on a Shimadzu UV 3101 PC.

X-ray crystallography

Compound **3** was studied on a Siemens Smart diffractometer, **4** on a CAD-4 system and **5** on a Rigaku AFC6S diffractometer. Data collection was carried out under ambient conditions, using graphite monocromated Mo Kα for all compounds. The crystal parameters and other experimental details of the data collection are summarized in Table 2. A complete description of the details of the crystallographic methods is given in Table 1. The structures were solved by direct methods and refined by a full matrix least squares procedure. Neutral atom scattering factors were taken from Cromer and Waber [18] and anomalous dispersion were taking from Cromer [19]. All calculation were performed using SHELXTL PLUS (PC version) [20] for **3** and **5** and using DECMicroVAX 3500 computer for **4**. No anomalies were encountered in the refinements of any of the structures. The crystal parameters and other experimental details of data collection and refinement are summarized in Table 1. Atomic positions, a full list of bond lengths, angles and other crystallographic data have been deposited as supplementary publication No. CCDC 102069–102071. Copies can be obtained through Cambridge crystallographic data centre, Union Road, Cambridge.

RESULTS AND DISCUSSION

The analytical data show that the electrochemical procedure described can be satisfactorily used, in good yield, for the synthesis of complexes of cobalt and nickel with phosphinothiol ligands and the method represents a simple alternative to other standard chemical procedures.

The nickel compounds have general formulae $[Ni(RP–S)_2]$ where RP–S stands for the monoanion of the RP–SH ligand. The electrochemical efficiency value, E_f, defined as the amount of metal dissolved per Faraday of charge, was always close to 0.5 mol F^{-1}. This fact and the evolution of hydrogen at the cathode are compatible with the following reaction mechanisms

$$\text{cathode: } 2\,RP-SH + 2e^- \rightarrow 2\,RP-S^- + H_2$$

$$\text{anode: } Ni + 2\,RP-S^- \rightarrow [Ni(RP-S)_2] + 2e^-.$$

Values of E_f close to 0.5 mol F^{-1} were found in the synthesis of cobalt complexes and are indicative of a similar anodic oxidation mechanism. However, the ddformulation of these compounds is $[Co(RP–S)_3]$. This observation suggests an additional oxidation in solution of Co(II) to Co(III). This behaviour has been previously observed in the synthesis of other cobalt complexes via an electrochemical procedure [21]. When the ligand used was 2-(Ph_2PO)-6-($SiMe_3$) C_6H_3SH, in addition to the analogous Co(III) compound, a small amount of crystals of $[Co\{2\text{-}Ph_2P(O)\text{-}6\text{-}(Me_3Si)C_6H_3S\}_2]$ could be isolated as a minor product.

Structure of $[Co\{2\text{-}(Ph_2P)\text{-}6\text{-}(Me_3Si)C_6H_3S\}_3]$, ***3***

Figure 1 shows the molecular structure of **3** together with the atom labelling scheme. Selected bond distances and angles are given in Table 2. The compound consists of discrete molecules with the metal coordinated to three monoanionic bidentate ligands, bonded to the cobalt through their phosphorus and sulfur atoms. The environment around the metal can be described as $[CoP_3S_3]$ slightly distorted octahedral geometry; all the dihedral angles between the coordination planes defined by four donors atoms are close to 90°. Angles defined by two *trans* donor atoms and the metal atom are the range 167.67(7)–177.39(7)° and the angles determined by cobalt atom and two *cis* donor atoms are close to 90°, even those corresponding to five membered chelating rings exhibit values of 86.49(6), 88.37(6) and 81.72(6)°. These values are larger than those found in other trischelate metal complexes containing this ligand.

The arrangement of the three sulfur and phosphorous atoms in **3**, is such that the compound can be described as the *meridional* isomer. This is the disposition found in $[Tc\{2\text{-}(Ph_2P)C_6H_4S\}_3]$, $[Re\{2\text{-}(Ph_2P)C_6H_4S\}_3]$ [7] and $[Ir\{2\text{-}(Ph_2P)C_6H_4S\}_3]$ [9]. ^1H and ^{31}P NMR data (*vide infra*) show that this arrangement is maintained in solution.

The Co–S bond distances are in the range 2.245(2)–2.335(2) Å, with the longer one corresponding to the

cobalt–sulfur bond *trans* to a phosphorous atom, suggesting some *trans* influence of the phosphorus. This effect has been also observed in other complexes, such as [Ir(2-(Ph_2P)C_6H_4S)$_3$]. Nevertheless, the average value for the Co–S bond distances, 2.286(2) Å, is comparable to the value of 2.27 Å reported for Co–S bond distances in [Co(III)–S_6] octahedral complexes [22] or 2.297(4) Å in the octahedral cation [Co(SC_6H_5)$_2$(phen)$_2$]$^+$ [10]. The Co–P bond distances are also different, with longer bond distances associated with atoms *trans* to one another. This may be again due to the *trans* influence of two mutually *trans* positioned phosphine donor atoms. The average value, 2.278(2) Å, is in the range of other octahedral Co(III) complexes containing tertiary phosphine as donors [23] (and references cited therein).

Structure of [Ni{2-(Ph_2P)-6-(Me_3Si)C_6H_3S}$_2$], ***4***

The molecular structure of [Ni{2-(Ph_2P)-6-(Me_3Si)C_6H_3S}$_2$] is shown in Fig. 2, together with the atomic numbering scheme adopted. Selected bond distances and angles are given in Table 3. The structure shows the nickel atom, located at a crystallographic inversion centre and coordinated to two thiolato sulfur atoms and to two phosphorous atoms of two symmetry related moieties. The arrangement is strictly planar to within experimental accuracy, with the sulfur atoms in a *trans* disposition; bond angles between the adjacent atoms are very close to the theoretical 90° limit. The structure of this molecule is similar to that of [Ni{2-(Ph_2P)C_6H_4S}$_2$] which exhibits the same environment for the metal, but distinct from that of [Ni{2-(Ph_2PO)-6-($SiMe_3$)C_6H_3S}$_2$] which possesses planar S_2O_2 environment around the metal, in which the two thiolate sulfur atoms adopt a *cis* disposition [15]. The Ni–S bond distance, 2.151(3) Å, is similar to the value found in [Ni{2-(Ph_2P)C_6H_4S}$_2$], 2.180(1) Å and also in the range 2.149–2.179 Å described for Ni(II) square planar complexes with five ring chelating ligands and sulfur thiolate donor atoms [15]. In addition, the Ni–P bond distance, 2.172(3) Å, is marginally shorter than the value of 2.181(2) Å found

Symmetry transformations used to generate equivalent atoms: $^{\dagger}1-x+1, -y+1, -z+1$.

asymmetric unit. The structure of one, with the atom labelling is given in Fig. 3. Selected bond distances and angles with the estimated standard deviations are given in Table 4. The compound consists of discrete molecules, with the cobalt atom tetracoordinated to two thiolate sulfur atoms and two oxygen atoms of two ligands, such that the environment around the central atom can be described as $[CoO_2S_2]$ distorted tetrahedral, with bond angles, 99.46(9) and 98.80(10)°, significantly distorted with respect to the tetrahedral value.

The average values for the Co–S bond lengths for both molecules, 2.2838(14) Å, are normal and similar to that in Co(II) complexes with the same geometry and coordination number. Thus, these values are comparable to those found for the tetrahedral anion $[Co(SC_6H_5)_4]^{2-}$, average value 2.328 Å [24, 25], or in $[Co(SC_{10}H_{13})_3CH_3CN]^-$, average value 2.28 Å [26]. Similarly, the Co–O bond distances, average 1.974 Å, are in the range for those found in tetrahedral complexes containing triphenylphosfineoxide as ligand, for instance 1.971 Å (average value) in $[CoCl_2(OPMe_3)_2]$ [27] and 1.928 Å (average value) in $[CoCl_2\{OP(CH_2Ph)_3\}_2]$ [28].

Bond distances and angles in the coordinated ligand are similar to those found for the free ligand [29]. Thus the average value for the P–O bond distance in the complex, 1.518(3) Å, is slightly higher than the 1.493(3) Å value found in the free ligand. This lengthening can be attributed to the weakening of the P═O bond, by coordination to the metal.

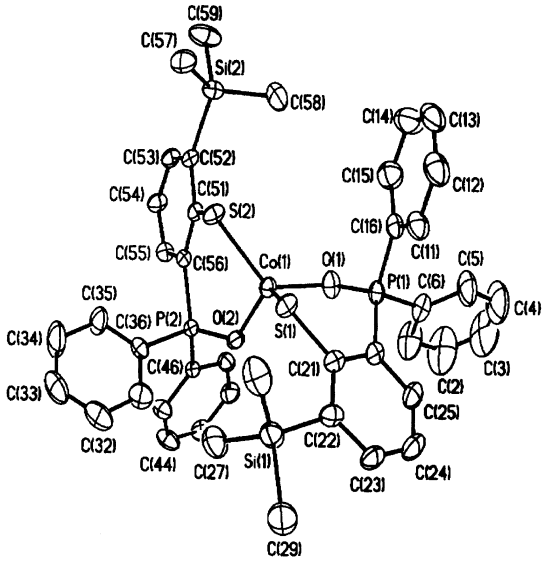

Fig. 3. The molecular structure of $[Co\{2\text{-}(Ph_2PO)\text{-}6\text{-}(Me_3Si)C_6H_3S\}_2]$.

Spectroscopic studies

The IR spectra of the ligands exhibit a band in the 2400–2550 cm^{-1} range attributed to ν(S–H). This band is absent in the spectra of the complexes, indicating that the ligand is in the anionic thiolate form in all complexes. The complexes also show bands in the 1500–1580 cm^{-1} region, characteristic of aromatic ring vibrations, as well as bands in the 1100–1000 cm^{-1} region attributable to ν(P–C). The trimethylsilyl derivatives show in addition a very strong band around 840–850 cm^{-1} assignable to the n(Si–C) mode. Compounds **5**, **6** and **7** show a very strong band at 1130 cm^{-1} characteristic of ν(P–O).

The FAB mass spectra of all compounds show the molecular ion with appropriate isotope distributions. In many cases, ions formed by loss of one ligand from the initial complex are also observed, as well as a peak attributed to the free ligand.

The magnetic moments of the Co(III) complexes show that these complexes are diamagnetic, as

expected for low spin d^6 octahedral complexes. The solid state electronic spectra of these complexes show two bands near 16,000 and 25,000 cm^{-1}. The first band is due to $^1T_{1g} \leftarrow {}^1A_{1g}$ transition and the second to $^1T_{2g} \leftarrow {}^1A_{1g}$ transition [30]. The nickel complexes are also diamagnetic, compatible with the square planar coordination around the metal. The solid-state electronic spectra of these complexes show two bands at *ca*. 16,000–17,000 and 22,000–24,000 cm^{-1}, which can be attributed to the $^1B_{1g} \leftarrow {}^1A_{1g}$ and $^1E_{1g} \leftarrow {}^1A_{1g}$ transitions, characteristic of nickel compounds in a square-planar environment [30].

The diamagnetic nature of these complexes (except compound **5**) allowed their study by in solution. In no instance do the ^1H NMR spectra show the thiol -SH signal of the free ligand around 4.1 ppm, proving that the ligand is in the monoanionic form in all complexes. The spectra also show multiplets over 8.0–6.5 ppm characteristic of the phenyl groups. The ^1H of $[Co\{2\text{-}(Ph_2P)\text{-}6\text{-}(Me_3Si)C_6H_3S\}_3]$ shows the presence of three nonequivalent trimethylsilyl groups, at 0.10, 0.30 and 0.50 ppm, indicating that the *meridional* conformation of the ligands found in the solid state is maintained in solution. This is corroborated by the presence of three signals in the ^{31}P NMR spectra at 39, 43 and 45 ppm corresponding to the nonequivalent phosphorus in the *meridional* conformation. By contrast, the ^1H NMR of $[Co\{2\text{-}(Ph_2PO)\text{-}6\text{-}(Me_3Si)C_6H_3S\}_3]$ shows only a singlet at 0.35 ppm, attributable to the $-SiMe_3$ groups, indicating that the ligands in this complex are equivalent and therefore that the compound has a *facial* arrangement of the ligands in solution. The ^{31}P NMR of this compound shows only one signal at 41.6 ppm, as expected for this ligand arrangement.

Synthesis and conformational studies of palladium(II) complexes containing $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S or Se)

Alexandra M. Z. Slawin, Martin B. Smith and J. Derek Woollins*

Department of Chemistry, Loughborough University, Loughborough, Leics LE11 3TU, U.K.

(Received 29 April 1998; accepted 18 June 1998)

Abstract—The ligands $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S **I**; E = Se **II**) can readily be complexed to a range of palladium(II) starting materials affording new six-membered Pd–O–P–N–P–E palladacycles. Hence ligand substitution reaction of the chloride complexes $[PdCl_2(bipy)]$ (bipy = 2,2′-bipyridine), $[\{Pd(\mu\text{-}Cl)(L–L)\}_2]$ (HL–L = $C_9H_{13}N$ or $C_{12}H_{13}N$), $[\{Pd(\mu\text{-}Cl)Cl(PMe_2Ph)\}_2]$ or $[PdCl_2(PR_3)_2]$ [$PR_3 = PPh_3$; $2PR_3 = Ph_2PCH_2CH_2PPh_2$ or *cis*-$Ph_2PCH=CHPPh_2$] with either **I** (or **II**) in thf or CH_3OH gave $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(bipy)]PF_6$, $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(L–L)]$, $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}Cl(PMe_2Ph)]$ or $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(PR_3)_2]PF_6$ in good yields. All compounds described have been characterised by a combination of multinuclear NMR [$^{31}P\{^1H\}$ and ^1H] and IR spectroscopy and microanalysis. The molecular structures of five complexes containing the selenium ligand **II** have been determined by single-crystal X-ray crystallography. Three different ring conformations were observed, a pseudo-butterfly, hinge and in the case of all three PR_3 complexes, pseudo-boat conformations. Within the Pd–O–P–N–P–Se rings there is evidence for π-electron delocalisation. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

Over the last few years the co-ordination chemistry of the monoanionic ligands $[R_2P(E)NP(E)R_2]^-$ (R = alkyl, aryl, alkoxy, aryloxy; E = O, S, Se) has been the subject of great interest due principally to its close analogy to acetylacetonate (hereafter abbreviated acac) [1–34]. Whereas metal complexes of acac (and its derivatives) have found important applications in diverse areas such as catalysis, in organic synthesis, as medicinal based drugs, CVD precursors and in liquid crystals, metal complexes of $[R_2P(E)NP(E)R_2]^-$ have found only limited use as selective metal extraction agents [30] and NMR shift reagents (Ref [10] and references cited therein). Recently the tetranuclear Ag(I) cluster $[Ag\{Ph_2P(O)NP(O)Ph_2\}]_4.2EtOH$ has been shown to be an olefin epoxidation catalyst [9].

In common with acac, the principal co-ordination mode of $[R_2P(E)NP(E)R_2]^-$ is that of chelation through both E donor atoms although the propensity to adopt a range of other different bonding modes has been reported [6–9, 27, 31, 32, 34]. One particularly interesting feature that has emerged from the extensive studies concerning the co-ordination chemistry of $[R_2P(E)NP(E)R_2]^-$ is the ability of the M–E–P–N–P–E chelate to exist in different ring conformations. An initial report from this laboratory revealed that by modifying the exocyclic substituents (Ph vs OPh) bound to phosphorus in $[R_2P(S)NP(S)R_2]^-$ the Pt–S–P–N–P–S ring conformation in $[Pt\{R_2P(S)NP(S)R_2\text{-}S,S'\}(PR'_3)_2]PF_6$ (R = Ph or OPh; R′ = Me or Et) is significantly altered [24]. Silvestru and co-workers [23] found that in the manganese(I) complex $[Mn(CO)_4\{Ph_2P(S)NP(S)Ph_2\text{-}S,S'\}]$ the unit cell contains two independent monomeric molecules in which both Mn–S–P–N–P–S rings adopt dissimilar geometries. In 1996 we reported [17] an unusual homoleptic complex *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}_2]$ which, from X-ray crystallographic studies, revealed that both six-membered Pd–O–P–N–P–Se metallacycles assume disparate ring conformations (pseudo-boat and chair-like geometries) *within* the co-ordination sphere of the molecule.

Since the mixed ligands $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S or Se) have been very poorly studied [13, 17] we report here the synthesis and characterisation of some new palladium(II) complexes of the type *cis*-$[PdL_2\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}]$. Five crystal structure determinations have been performed on complexes bearing different *trans* ancillary ligands and furthermore reveal that the six-membered Pd–O–P–N–P–Se metallacycles can adopt a range of different ring conformations.

EXPERIMENTAL

General

All reactions were carried out in air using distilled solvents. The potassium salts of $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S or Se) [17] and the metal complexes $[\{Pd(\mu\text{-}Cl)Cl(PMe_2Ph)\}_2]$ [35] and $[\{Pd(\mu\text{-}Cl)(L\text{–}L)\}_2]$ [L–L = dimethylbenzylamine ($C_9H_{12}N$) and *N*,*N*-dimethyl-1-naphthylamine ($C_{12}H_{12}N$)] [36] were prepared according to previous published procedures. The palladium(II) compounds $[PdCl_2(PR_3)_2]$ [$PR_3 = PPh_3$; $2PR_3 = Ph_2PCH_2CH_2PPh_2$ or *cis*-$Ph_2PCH{=}CHPPh_2$] were synthesised by stoichiometric addition of the appropriate PR_3 to [$PdCl_2$(cod)] (cod = cycloocta-1,5-diene) in dichloromethane. [$PdCl_2$(bipy)] was purchased from Aldrich Chemical Co. and used without further purification.

Infrared spectra were recorded as KBr pellets in the range 4000–200 cm^{-1} on a Perkin-Elmer System 2000 Fourier-transform spectrometer. $^{31}P\{^1H\}$ NMR spectra (36.2 MHz) were recorded on a JEOL FX90Q spectrometer with chemical shifts (δ) in ppm (± 0.1) to high frequency of 85% H_3PO_4 and coupling constants (J) in Hz (± 3). All NMR spectra were measured in $CDCl_3$ unless otherwise stated. Elemental analyses (Perkin-Elmer 2400 CHN Elemental Analyzer) were performed by the Loughborough University Analytical Service within the Department of Chemistry.

Palladium salts were provided on loan by Johnson Matthey.

Preparations

$[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(bipy)]PF_6$, **1** To the solids [$PdCl_2$(bipy)] (0.054 g, 0.162 mmol) and $K[Ph_2P(O)NP(S)Ph_2]$ (0.076 g, 0.161 mmol) was added CH_3OH (2 cm^3). The solids dissolved to give an orange solution and after stirring for *ca.* 2 h a yellow suspension formed. To this was added $[NH_4][PF_6]$ (0.067 g, 0.411 mmol, 2.54 equivs.) in CH_3OH (*ca.* 0.5 cm^3) and the mixture stirred for 10 min. The solid **1** was isolated by suction filtration, washed with CH_3OH (*ca.* 1 cm^3) and dried *in vacuo*. Yield: 0.119 g, 87%. Compound **1** could be recrystallised from CH_2Cl_2/Et_2O.

In a similar manner $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(bipy)]PF_6$ **2** was prepared in 88% yield.

$[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(C_9H_{12}N)]$, **3**. To a solution of $[\{Pd(\mu\text{-}Cl)(C_9H_{12}N)\}_2]$ (0.040 g, 0.0724 mmol) in thf (5 cm^3) was added solid $K[Ph_2P(O)NP(S)Ph_2]$ (0.072 g, 0.153 mmol) in one portion. After stirring for *ca.* 30 min, the solvent was evaporated to dryness *in vacuo*. The residue was dissolved in CH_2Cl_2 (2 cm^3), filtered through a small Celite pad and addition of petroleum ether (b.p. 60–80°C, *ca.* 15 cm^3) gave a pale yellow solid **3**. The product was collected by suction filtration and dried *in vacuo*. Yield: 0.084 g, 86%.

Using similar experimental conditions the following compounds were prepared: $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(C_9H_{12}N)]$ **4** (92%), $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(C_{12}H_{12}N)]$ **5** (96%) and $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(C_{12}H_{12}N)]$ **6** (89%). Slow diffusion of petroleum ether (b.p. 60–80°C) into a CH_2Cl_2 solution of **6** over the course of *ca.* 7 d gave crystals suitable for X-ray crystallography.

$[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}Cl(PMe_2Ph)]$, **7**. To a solution of $[\{Pd(\mu\text{-}Cl)Cl(PMe_2Ph)\}_2]$ (0.042 g, 0.067 mmol) in thf (5 cm^3) was added solid $K[Ph_2P(O)NP(S)Ph_2]$ (0.065 g, 0.138 mmol) in one portion. After stirring for *ca.* 30 min, the solvent was evaporated to dryness *in vacuo*. The residue was dissolved in CH_2Cl_2 (2 cm^3), filtered through a small Celite pad and addition of petroleum ether (b.p. 60–80°C, 20 cm^3) gave a yellow solid. The product was collected by suction filtration and dried *in vacuo*. Yield: 0.088 g, 93%.

In a similar manner $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}Cl(PMe_2Ph)]$, **8**, was prepared in 70% yield. Slow diffusion of petroleum ether (b.p. 60–80°C) into a $CDCl_3$ solution of **8** over the course of *ca.* 5 d gave crystals suitable for X-ray crystallography.

$[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(Ph_2PCH_2CH_2PPh_2)][PF_6]$, **12**. The solids $[PdCl_2(Ph_2PCH_2CH_2PPh_2)]$ (0.048 g, 0.0834 mmol) and $K[Ph_2P(O)NP(Se)Ph_2]$ (0.047 g, 0.091 mmol) were suspended in CH_3OH (2 cm^3). After stirring for 2 h the yellow solution was treated with a methanolic solution of $[NH_4][PF_6]$ (0.032 g, 0.196 mmol, 2.35 equivs.) whereupon a yellow precipitate formed immediately. The mixture was stirred for *ca.* 10 min and the product **12** collected by suction filtration and dried *in vacuo*. Yield: 0.082 g, 87%.

The following cationic compounds were synthesised using a similar method: $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(PPh_3)_2][PF_6]$ **9** (94%), $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(PPh_3)_2][PF_6]$ **10** (94%), $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(Ph_2PCH_2CH_2PPh_2)][PF_6]$ **11** (90%), $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(cis\text{-}Ph_2PCH{=}CHPPh_2)][PF_6]$ **13** (79%) and $[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}(cis\text{-}Ph_2PCH{=}CHPPh_2)][PF_6]$ **14** (92%). Slow diffusion of diethyl ether into either $CDCl_3$ (or CH_2Cl_2) solutions of **10**, **12** or **14** over the course of several days gave crystals suitable for X-ray crystallography.

Microanalytical and selected spectroscopic data for compounds **1**–**14** are given in Tables 2 and 3.

Table 1. Details of the X-ray data collections and refinements for compounds **6**, **8**, **10**, **12** and **14**

X-ray crystallography

The crystal structures of complexes **6**, **8**, **10**, **12** and **14** were determined using a Rigaku AFC7S diffractometer with graphite-monochromated (Cu–Kα) radiation and ω-scans. Details of the data collections and refinements are given in Table 1. Empirical absorption corrections (DIFABS [37]) were applied. Psi-scans proved unsatisfactory and DIFABS gave generally superior results. The structures were solved by the heavy-atom method [38]. In **14** poor crystal quality and the presence of an unidentified solvent fragment precluded complete refinement of the structure. The Pd, Se, P, N and O atoms were refined anisotropically whilst the C and F atoms were refined isotropically with the phenyl rings being refined as rigid bodies. All of the non-hydrogen atoms in the other structures were refined anisotropically. The C–H atoms were idealised and fixed (C–H, 0.95 Å). No additional constraints or restraints were applied. Refinement was by full-matrix least-squares methods based on *F*. Calculations were performed using TEXSAN [39].

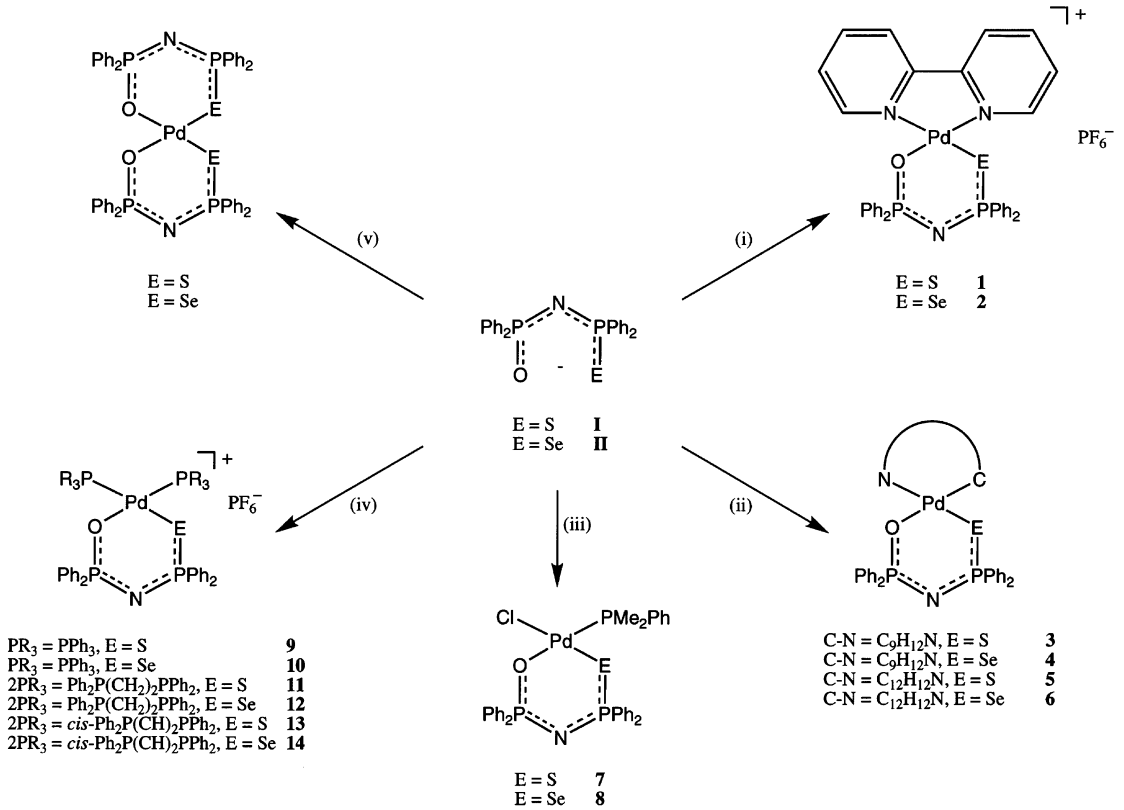
RESULTS AND DISCUSSION

O,E-Chelate complexes of $[Ph_2P(O)NP(E)Ph_2]^-$ (*E = S or Se*)

We previously reported the synthesis of the mixed ligands $K[Ph_2P(O)NP(E)Ph_2]$ (E = S **I**; E = Se **II**) from the monooxidised compound $Ph_2P(O)NHPPh_2$ and elemental sulfur (or selenium) followed by deprotonation with base [17].

The stoichiometric reaction of $[PdCl_2(bipy)]$ (bipy = 2,2′-bipyridine) and one equivalent of either **I** (or **II**) in CH_3OH, followed by addition of a methanolic solution of $[NH_4][PF_6]$, gave the cationic complexes $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(bipy)]PF_6$ (E = S **1**; E = Se **2**) (Scheme 1). Analytical and spectroscopic data are given in Tables 2 and 3 and are broadly as expected. The $^{31}P\{^1H\}$ NMR spectra of **1** and **2** show, in both cases, two singlet resonances [*J*(PP) coupling not resolved] corresponding to P_O and P_E of the chelating $[Ph_2P(O)NP(E)Ph_2]^-$. In addition, the ^1J(PSe) coupling constant of 470 Hz for **2** is of similar magnitude to that reported for *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}_2]$ [^1J(PSe) 492 Hz] [17]. Treatment of **I** (or **II**) with the chloro bridged binuclear compounds $[\{Pd(\mu\text{-}Cl)(L\text{–}L)\}_2]$ (L–L = $C_9H_{12}N$ or $C_{12}H_{12}N$) or $[\{Pd(\mu\text{-}Cl)Cl(PMe_2Ph)\}_2]$ gave the neutral complexes $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(L\text{–}L)]$ (E = S, L–L = $C_9H_{12}N$ **3**; E = Se, L–L = $C_9H_{12}N$ **4**; E = S, L–L = $C_{12}H_{12}N$ **5**; E = Se, L–L = $C_{12}H_{12}N$ **6**) and $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}Cl(PMe_2Ph)]$ (E = S **7**; E = Se **8**) in respectable yields (70–96%). Compounds **3**–**8** were characterised by a combination of $^{31}P\{^1H\}$, ^1H and IR spectroscopy (Table 3) and microanalysis (Table 2). In particular, $\delta(P_O)$ for **3**–**8** is shifted to lower frequency (*ca.* 10–15 ppm) with respect to **1** and **2** and to higher frequency (*ca.* 10–15 ppm) with respect to **I** and **II**. The $^{31}P\{^1H\}$ and ^1H NMR spectra of **3**–**8** (recorded in $CDCl_3$) confirm that, in all cases, only one isomer is present in solution (either the geometric isomer **A** or **B**). X-ray crystallogaphic studies on compounds **6** and **8** (*vide infra*) unambiguously demonstrate that isomer **A** (E *trans* to X where X = N, Cl) is exclusively formed. The formation of one isomer has also been observed in the related cyclopalladated complexes $[Pd\{Ph_2P(O)NPPh_2\text{-}O,P\}(L\text{–}L)]$ (L–L = $C_9H_{12}N$, $C_{10}H_8N$, $C_{12}H_{12}N$) (P *trans* to N) [40] but in contrast, both isomers of $[Pt\{Ph_2P(O)NPPh_2\text{-}O,P\}Cl(PMe_2Ph)]$ have been independently synthesised and fully characterised [41]. Furthermore in the complexes $[Pd\{Ph_2P(S)NP(Se)Ph_2\text{-}S,Se\}(L\text{–}L)]$ (L–L = $C_9H_{12}N$,



Scheme 1. (i) $[PdCl_2(bipy)]$, $[NH_4][PF_6]$, (ii) $[\{Pd(\mu\text{-}Cl)(L\text{-}L)\}_2]$ (L-L = $C_9H_{12}N$ or $C_{12}H_{12}N$), (iii) $[\{Pd(\mu\text{-}Cl)Cl(PMe_2Ph)\}_2]$, (iv) $[PdCl_2(PR_3)_2]$ ($PR_3 = PPh_3$; $2PR_3 = Ph_2PCH_2CH_2PPh_2$, *cis*-$Ph_2PCH{=}CHPPh_2$), $[NH_4][PF_6]$ and (v) $[PdCl_2(cod)]$ (cod = cycloocta-1,5-diene).

A **B**

O-E = $OPPh_2NPPh_2S$, $OPPh_2NPPh_2Se$
X,Y = $C_9H_{12}N$, $C_{12}H_{12}N$, Cl/PMe_2Ph

Isomers A and B

$C_{12}H_{12}N$) containing different "soft" donor centres, both isomers were detected in $CDCl_3$ solution in *ca.* 5:1 ratio ($^{31}P\{^1H\}$ evidence) [42].

We have also prepared several square-planar palladium(II) complexes with one chelating $[Ph_2P(O)NP(E)Ph_2\text{-}O,E]^-$ and several different tertiary phosphine ligands. Hence replacement of both chloride ligands in $[PdCl_2(PR_3)_2]$ [$PR_3 = PPh_3$; $2PR_3 = Ph_2PCH_2CH_2PPh_2$, *cis*-$Ph_2PCH{=}CHPPh_2$] with one equivalent of **I** (or **II**) in CH_3OH presumably affords the cations $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(PR_3)_2]Cl$. The cationic compounds were most conveniently obtained as their hexafluorophosphate salts by metathesis with $[NH_4][PF_6]$ in CH_3OH. In this manner we have isolated $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(PR_3)_2][PF_6]$ (E = S, $PR_3 = PPh_3$ **9**; E = Se, $PR_3 = PPh_3$ **10**; E = S, $2PR_3 = Ph_2PCH_2CH_2PPh_2$ **11**; E = Se, $2PR_3 = Ph_2PCH_2CH_2PPh_2$ **12**; E = S, $2PR_3$ = *cis*-$Ph_2PCH{=}CHPPh_2$ **13**; E = Se, $2PR_3$ = *cis*-$Ph_2PCH{=}CHPPh_2$ **14** (Scheme 1) in good yields. The *in situ* reaction between $[PdCl_2(Ph_2PCH_2CH_2PPh_2)]$ and **I** (1:1 ratio) in CH_3OH gave exclusively $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(Ph_2PCH_2CH_2PPh_2)]Cl$ verified by $^{31}P\{^1H\}$ NMR spectroscopy. We have also been able to liberate $[Ph_2P(O)NP(S)Ph_2]^-$ (^{31}P NMR evidence) by treatment of **11** with concentrated HCl [affording the parent acid $Ph_2P(O)NHP(S)Ph_2$] or by the addition of one equivalent of $Ph_2PCH_2CH_2PPh_2$ [giving $[Ph_2P(O)NP(S)Ph_2]^-$ and the dication $[Pd(Ph_2PCH_2CH_2PPh_2)_2]^{2+}$]. Compounds **9**–**14** were characterised by $^{31}P\{^1H\}$ NMR and IR (Table 3 for data). Typically the $^{31}P\{^1H\}$ NMR data reveal that $\delta(P_S)$ for **9**, **11** and **13** is observed at *ca.* 32 ppm whilst for **10**, **12** and **14** $\delta(P_{Se})$ is around 18 ppm with $^1J(PSe)$ *ca.* 490 Hz. Moreover the two inequivalent phosphorus centres of the co-ordinated tertiary phosphines in **9**–**14** have similar $\delta(P)$ to those observed in $[PdCl_2(PR_3)_2]$. Consistent with $[Ph_2P(O)NP(E)Ph_2\text{-}O,E]^-$ chelate formation was the absence of ν(PdCl) absorptions and the presence of ν(PE) absorptions which in the latter case, could not accurately be assigned with confidence.

Crystal structure determinations of complexes **6**, **8**, **10**, **12** and **14**

The structures of **6**, **8**, **10**, **12** and **14** (Table 4, Figs 1–5) have some common features. Thus all five complexes display the expected square planar geometry (Table 5 gives the maximum deviation from the ML_4 co-ordination plane). The Pd–P bond lengths reflect the nature of the *trans* ligand. Thus in **10**, **12** and **14** Pd(1)–P(4) (*trans* to selenium) is larger than Pd(1)–P(3) (*trans* to oxygen) suggesting that the Se atom is a poorer σ donor/better π acceptor than the O atom. The Pd–Se bond lengths vary [2.406(1)–2.521(1) Å] also as a consequence of the *trans* ligand. The phosphine ligands *trans* to Se give the largest Pd–Se bonds whilst N and Cl give the shortest Pd–Se distances which are not distinguishable from each other. Interestingly the Pd–Se bond lengths in *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph\text{-}O,Se\}_2]$, with *cis* O donors, (Table 4 and Fig. 6) are much shorter than any of those reported here. The Pd–O distances are in the range 2.083(4)–2.129(5) Å [c.f. 2.075(3) and 2.085(3) Å for *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph\text{-}O,Se\}_2]$ [17]] and as anticipated are less sensitive to the identity of the *trans* atom. Within the Pd–O–P–N–P–Se metallacycle the bond lengths are consistent with a fair degree of delocalisation.

The conformation of the Pd–O–P–N–P–Se rings vary somewhat in the various structures. Compound **6** has a unique conformation and the ring is best described as consisting of two planar fragments Pd(1)–Se(1)–P(1)–N(1) and Pd(1)–O(1)–P(2)–N(1) which are inclined by 36° with respect to each other. This difference in geometry is noticeable in the Pd(1)–Se(1)–P(1) angle for **6** [104.68(7)°] which lies well outside the range observed in the other structures including *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph\text{-}O,Se\}_2]$ [93.46(6)–101.5(4)°]. The conformation in **6** can be described as pseudo-butterfly and to the best of our knowledge has not been observed before in ME_2P_2N systems. Compound **8** has a ring conformation which, though rare, is similar to that observed in some previous examples [17,

24] with the six-membered ring being hinged about the O(1)...Se(1) vector (hinge angle 60°) and the O(1)–P(1)–N(1)–P(2)–Se(1) atoms forming an approximate planar array [maximum deviation of this mean plane is 0.27 Å for O(1)]. Compounds **10**, **12** and **14** have quite closely related ring conformations which can be most readily described as pseudo-boat with Se(1) at the prow and P(2) at the stern of the "boat". The Pd(1)...P(1) hinge angle in **10**, **12** and **14** are very similar (*ca.* 40°) but there are some differences in the hinge angle at O(1)...N(1) (Table 5). It appears that the smallest O(1)...N(1) hinge angle is

for the bulkiest phosphine (PPh_3) and this is further reflected in the O(1)–Pd(1)–Se(1) angle which increases in the order **10** < **12** < **14** in parallel with the change in hinge angle.

Overall then, it appears that the $PdSeOP_2N$ ring is able to adopt a range of geometries and the nature of the *trans* ligand does influence the geometry within the metallacycle.

CONCLUDING REMARKS

We have shown that a range of new palladium(II) complexes with a chelating anionic [$Ph_2P(O)NP(E)Ph_2$]$^-$ (E = S or Se) ligand are ammenable and have been fully characterised. Furthermore from X-ray structure studies it is apparent that the Pd–O–P–N–P–Se six-membered chelate ring is flexible and can take up a range of conformations. Further work into the generality of these observations would be useful.

(Received 5 May 1998; accepted 22 June 1998)

Abstract—Ionic compounds, [Q] [$R_2SnX(dmit)$] [dmit = 1,3-dithiole-2-thione-dithiolate; Q = 1,4-dimethylpyridinium or tetraalkylammonium; R = Ph or alkyl; X = Cl, Br, I, NCS, NCSe, or N_3] have been obtained by (a) from R_2SnX_2 and $[Q]_2[Zn(dmit)_2]$ in the presence of excess QX, (b) from halide exchange reactions in acetone solution between [Q] [$R_2SnCl(dmit)$] and a halide or pseudohalide source, or (c) by addition of QX to [$R_2Sn(dmit)$]. Crystal structure determinations of [NEt_4] [$Ph_2SnI(dmit)$] and [1,4-Me_2pyridiniuml [$Ph_2SnBr(dmit)$] as well as of the mixed halides, [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}(dmit)$] ($n = 0.57$, 0.42 or 0.22), indicated that the tin atoms have distorted trigonal bipyramidal geometries in the anions, with the X ligand and a dithiolato atom in the axial sites. The $[R_2SnX(dmit)]^-$ anions remain essentially intact in organic solvents, but lose X^- on extraction with H_2O to give the neutral species, $R_2Sn(dmit)$. © 1998 Elsevier Science Ltd. Keywords: stannates; crystal structures; organotin; dithiolates.

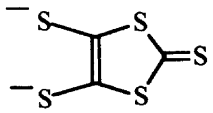
INTRODUCTION

Complexes of the 1,3-dithiole-2-thione-4,5-dithiolato ligand, (**1**, dmit, $C_3S_5^{2-}$) attracted considerable attention in recent years [1]. While much of the interest has centred on transition metal compounds, main group metal complexes have not been neglected and indeed have featured in a number of synthetic and structural studies [2–5].



(1)

While *bis*(1,3-dithiole-2-thione-4,5-dithiolato)zincate salts, $[Q]_2[Zn(dmit)_2]$, as precursors of other metal dmit complexes, are clearly of general importance [2], tin dmit complexes have arguably enticed more structural study than those of any other main group metal [3]. *Mono*-, *bis*- and *tris*-dmit complexes, e.g [$R_2Sn(dmit)$]. (**2**: R = alkyl or aryl) [3], [Q] [$RSn(dmit)_2$] (**3**) [3], $[Q]_2[SnX_2(dmit)_2]$ (**4**: X = I or Br) [3] and $[Q]_2[Sn(dmit)_3]$ (**5**) [3], can be obtained, with the synthesis and

†Author to whom correspondence should be addressed.

structural details for **2–4** being fully reported. Some limited information on the ionic species, [Q] [$R_2SnX(dmit)$] (**6**: Q = onium cation; X = halide), [3] has been provided in earlier communications; we now wish to report more fully on **6**.

RESULTS AND DISCUSSION

Synthesis

The syntheses of [Q] [$R_2SnX(dmit)$] (**6**: R = unfunctionalised alkyl or aryl group) have been achieved in three ways: (a) from a reaction between R_2SnX_2 and [Q] [$Zn(dmit)_2$] in the presence of an excess QX, (b) from halide exchange reactions in acetone solution between [Q] [$R_2SnCl(dmit)$] and either NaX or QX, or (c) by addition of QX to [$R_2Sn(dmit)$], see Scheme 1.

Tables 1 and 2 list the compounds, **6**, with analytical, melting point and selected IR and NMR spectral data. The work-up of all products involved the minimum use of aqueous extractions to reduce the risks of loss of QX from [Q] [$R_2SnX(dmit)$] to give polymeric [$R_2Sn(dmit)$], (reaction d in Scheme 1 [3a]. The use of R_2SnX_2 with functionalised R groups able to complex intramolecularly to tin, such as $R'O_2CCH_2CH_2$, led directly to [$R_2Sn(dmit)$] species on reactions with $[Q]_2[Zn(dmit)_2]$ [3a].

The halide (or pseudohalide) exchange reactions

[b] solid state values.

(reaction b in Scheme) proceeded readily in Me_2CO solution for most [Q] [R_2SnCl(dmit)] complexes, using NaX or QX (X = Br, I, NCS or NCSe) in moderate excess (i.e. 2 to 4 mole equivalents): with these excesses, halide exchanges were generally complete. However, for the NaI/[1,4-Me_2pyridinium] [Ph_2SnCl(dmit)] exchange reaction, a larger excess of NaI was required to drive the exchange to near completion. Products with mixed chloride/iodide contents, [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}$(dmit)], could be isolated from incomplete exchanges. Examples of such mixed halide products had I:Cl mol ratios of 0.43: 0.57; 0.58: 0.42 and 0.78: 0.22, as deduced from X-ray and elemental analyses, e.g. iodine analysis in the three mixed chloride/iodide complexes were 8.2, 11.4 and 14.3%, compared to calculated values of 8.4, 11.1 and 14.5%, for [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}$(dmit)] with $n = 0.43$, 0.57 and 0.78, respectively.

A simple exchange reaction was not obtained between [NEt_4] [Ph_2SnCl(dmit)] and a large excess of NH_4F (mol ratio 1:22) in MeOH; the product isolated analysed for the fluorine bridged dinuclear species, [NEt_4] [Ph_2(dmit)SnFSn(dmit)Ph_2].

Organotin-dmit complexes undergo ready disproportionation reactions in solution, with products showing suitable losses and gains of organic and dmit groups. *Tris*(dmit)stannate salts, $[Q]_2[Sn(dmit)_3]$, are ubiquitous materials, appearing as unwanted coproducts in various tin-dmit preparations and solutions, e.g. crystals of $[NEt_4]_2[Sn(dmit)_3]$ were deposited, albeit in a low yield, from a dilute solution of analytically pure [NEt_4] [Ph_2Sn(NCSe)(dmit)] in MeOH. The isolation of a product bearing a greater number of organic groups than the original organotin compound is a strong indication of a disproportionation reaction; such an example is [NEt_4] [$Ph_3Sn(NCS)_2$], isolated [6] as a minor product, from a reaction mixture containing Na_2(dmit), $Ph_2Sn(NCS)_2$ and [NEt_4]Br. Disproportionations of diorganotin compounds, R_3SnX, to di- and tetra-organotin species, are also well-established processes, especially for compounds with chelating X groups [7].

Holmes *et al*. reported the isolation of $[NEt_4]_2[Sn(o\text{-}SC_6H_4O)_3]$, (**7**), from solutions of [NEt_4, $SnF(o\text{-}SC_6H_4O)_2$] in organic solvents [8]; rather than disproportionation, Holmes *et al*. suspected hydrolysis was responsible for the formation of **7** and suggested the intermediacy of $[NEt_4]_2[Sn(HO)_2(o\text{-}SC_6H_4O)_2]$ [8]. Hydrolysis of carbon–tin bonds was also invoked for the formation of [NEt_4] [Na] $[Sn(mnt)_3]$, from $PhSnCl_3$, Na_2(mnt) and NEt_4Cl in Me_2CO solution (mnt = 1,2-dicyanoethylene-1,2-dithiolate)] [9] and for the preparation of $[Sn(catecholato_3]^{2-}$ in the reaction of [PhSn(O)OH] with catechol in the presence [8] of NEt_3 and $Me_2C(OMe)_2$. However, our experience with the dmit complexes suggests that disproportionations are more probable causes of the unexpected products than are hydrolyses. The mobility of dmit group between tin centres has been additionally shown in exchange reactions between R_2SnX_2 and R'_2Sn(dmit) [3a].

A limited number of other [Q] [R_2SnX(dithiolate)] complexes have been previously reported; these include [NEt_4] [Ph_2SnCl(3,4-toluenedithiolate)], prepared by addition of NEt_4Cl to Ph_2Sn(3,4-toluenedithiolate) [10a, 10b] and [Ph_4As] [Me_2SnX(mnt)], from[11] Me_2SnX_2 (X = Cl, Br or I), Na_2(mnt) and $[Ph_4As]NO_3$ [11].

Crystal structure determinations

In addition to the previously reported structures of [NBu_4] [Me_2SnCl(dmit)] [3f] and [1,4-Me_2pyridinium] [Ph_2Sn(NCS)(dmit)] [3g], the crystal structures of the single halide species, [NEt_4] [Ph_2SnI(dmit)] and [1,4-Me_2pyridinium] [Ph_2SnBr(dmit)] have been determined.

Unfortunately, suitable crystals of the bridged fluoride complex, [NEt_4] [(dmit)Ph_2SnFSnPh_2(dmit)] could not be obtained for an X-ray diffraction study.

As well as those of the single halide species, the structures of the mixed halide species, [1,4-Me_2 pyridinium] [$Ph_2SnCl_nI_{1-n}$(dmit)] ($n = 0.57$, 0.42 and 0.22) have been determined. The structure of [1,4-Me_2pyridinium] [$Ph_2SnC_{0.57}I_{0.43}$(dmit)] was solved with a *R* factor of 0.049; although much less satisfactory *R* values (*ca.* 0.10) were obtained for the other mixed I/Cl species, the data is sufficient to allow useful comparisons to be made with those of the other compounds. The mixed halide species can be considered to be solid solutions, obtained by crystallisation from solutions containing both halides, with structures in which an axial site in the trigonal bipyramidal array is randomly occupied by either of the different halide ligands. In the cases of the [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}$(dmit)] ($n = 0.57$ and 0.42), the positions of both ligands, as well as their occupancy factors, could be resolved. However. only a single site could be determined for the halides in [1,4-Me_2pyridinium] [$Ph_2SnCl_{0.22}I_{0.78}$(dmit)].

Selected bond lengths and angles in these ionic compounds, including data for the previously published [NBu_4] [Me_2SnCl(dmit)] [3f] and [1,4-Me_2pyridinium] [Ph_2Sn(NCS)(dmit)] [3g] are listed in Table 3. Figs 1– provide the atom arrangements in [1,4-Me_2 pyridinium] [Ph_2SnBr(dmit)], [NEt_4] [Ph_2SnI(dmit)], [1,4-Me_2pyridinium] [$Ph_2SnCl_{0.57}I_{0.43}$(dmit)] and [1,4-Me_2pyridinium] [$Ph_2SnCl_{0.42}I_{0.58}$(dMit)], respectively. The atom numbering system used for [1,4-Me_2 pyridinium] [$Ph_2SnCl_{0.22}I_{0.78}$(dmit)] is the same as that used for [1,4-Me_2pyridinium] [$Ph_2SnCl_{0.42}I_{0.58}$(dmit)] although for the latter only a single halide site was determined.

There are no interactions between the cations and anions of the [Q] [R_2SnX(dmit)] species, however, in general there are S–S contacts between anions just within the sum of the van der Waals radii (3.67 Å) [8]. In all cases, the structures of the anions are basically

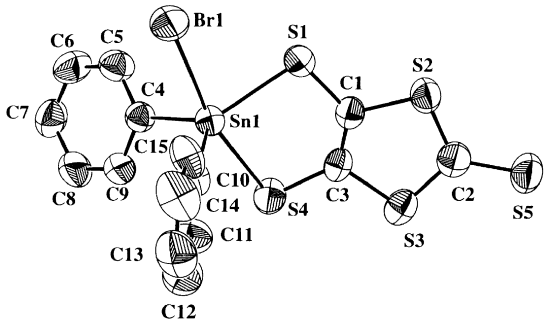

Fig. 1. The atom arrangement in the anion of [1,4-Me_2-pyridinium] [Ph_2SnBr(dmit)]. Displacement ellipsoids are shown at the 50% probability level.

trigonal bipyramidal with some distortions towards rectangular pyramidal structures. In the distorted trigonal bipyramidal anions of each compound, a thiolato sulfur and the halide or thiocyanate ligand occupy the axial sites, with the S_{ax}–Sn–X angle in the narrow range of 162.1(1) to 167.9(7)°; the equatorial atoms in each case being the other thiolato sulfur and the two carbon atoms of the organic groups. There is a particularly narrow range of values for the equatorial Sn–S_{eq} bond lengths [2.439(7) to 2.454(5) Å]; a much greater variation is found for the Sn–S_{ax} bond lengths [2.551(4) to 2.662(3) Å]. The dithiolato bite angles, S_{ax}–Sn–S_{eq}, vary over the range 84.5(1) to 86.37(3)°. The bond angles and lengths within the dmit moiety vary little in the various ionic complexes; the average geometric parameters of the dmit units are provided in Fig. 5.

The Sn–Cl, Sn–Br, Sn–I and Sn–N(CS) bond lengths in [1,4-Me_2pyridinium] [Ph_2Sn(NCS)(dmit)], [NBu_4] [Me_2SnCl(dmit)], [1,4-Me_2pyridinium, Ph_2SnBr(dmit)] and [NEt_4] [Ph_2SnI(dmit)] are 2.261(3), 2.556(3), 2.7139(10) and 2.985(2) Å, respectively; these values are *ca.* 5, 7, 7 and 9% longer, respectively, than the appropriate sums of the covalent bond radii [12] of 2.15, 2.39, 2.54 and 2.73 Å. Very few compounds of a similar nature have been reported. The Sn–Cl bond length in [NBu_4] [Me_2SnCl(dmit)] is similar to that determined of 2.556(3) Å in the trigonal bipyramidal anion of [NEt_4] [Ph_2SnCl(3,4-toluenedithiolate] [10a]. The Sn–I bond length, 3.225(1) Å, in [PPh_4, Me_2SnI(*o*-OC_6H_4S)] is considerably longer than the Sn–I bond length in [NEt_4] [Ph_2SnI(dmit)], however the anions in [PPh_4] [Me_2SnI(*o*-SC_6H_4O)] are linked via Sn–O bridges into centrosymmetric dimers[13] to give six coordinate tin centres [13].

The Sn–Cl and Sn–I bond lengths, determined for the mixed halide complexes, [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}$(dmit)], are 2.62(2) and 2.873(9) Å for

[a]X = I.
[b]X = Cl.

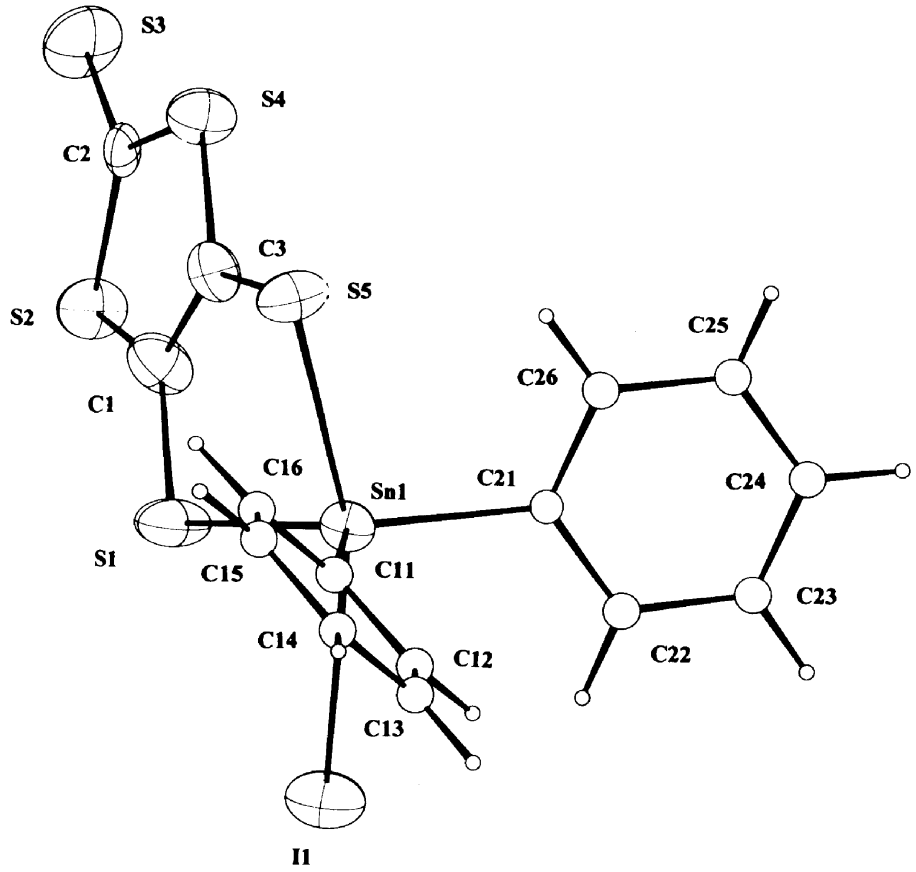

Fig. 2. The atom arrangement in the anion of $[NEt_4]$ $[Ph_2SnI(dmit)]$. Displacement ellipsoids are shown at the 50% probability level.

$n = 0.57$ and 2.724(3) and 2.859(13) Å for $n = 0.42$, i.e. the Sn–Cl and Sn–I bond lengths are longer and shorter respectively, than values determined for single halide complexes. As already indicated, only an average tin–halide bond length [2.926(3) Å] could be extracted from the X-ray data for [1,4-Me_2pyridinium] $[Ph_2SnCl_{0.22}I_{0.78}(dmit)]$. Yoon and Parkin have clearly demonstrated that bond lengths obtained from disordered structures can be incorrect, when judged against values in pure compounds [14]. Our results are in agreement with the conclusion of Yoon and Parkin, that while satisfactory refinement of a disordered structure be taken as evidence for the nature of the disorder and therefore a good indication of the molecular structure, attempts to extract the true bond lengths from such a structure must be treated with caution.

Spectra

All isolated compounds are orange to red–brown in colour: λ_{max} in Me_2CO solution for [Q] $[R_2SnX(dmit)]$ (e.g. Q = NEt_4, NBu_4or PPh_3Et; R = Me or Ph; X = Cl or Br) is 455 ± 5 mμ, compared to values of 433 ± 5 mμ for the corresponding iodides. The asymmetry of the C=C unit in the dmit group, as established by X-ray crystallography, is observed in the solid state ^{13}C NMR spectra, $\delta^{13}C(C{=}C)$ values for [1,4-Me_2 pyridinium] $[Ph_2SnI(dmit)]$ being 127.7 and 136.4 ppm and for $[NBu_4]$ $[Me_2SnCl(dmit)]$ 125.3 and 138.7 ppm. In solution, the ethylenic carbons of each anion are equivalent, with $\delta^{13}C$ values in the range 130.5 ± 0.8 ppm. The $\delta^{13}C(C{=}S)$ values are grouped around 207 ppm; the solid state $\delta^{13}C(C{=}S)$ value for [1,4-Me_2pyridinium] $[Ph_2SnI(dmit)]$ is 205.2 ppm. In the IR spectra in KBr discs, the $\nu(C{=}S)$ values are in the ranges 1055–1065 and 1032–1035 cm^{-1}.

Acetone was generally used as the NMR solvent in order to obtain reasonable concentrations. Such a coordinating solvent could influence the structure of the anions; however, essentially the same $\delta^{119}Sn$ values for $[FcCH_2NMe_3]$ $[Ph_2SnCl(dmit)]$ were obtained in Me_2CO and $CDCl_3$ solutions suggest that this is not the case, at least not for this complex. The $\delta^{119}Sn$ values could also be effected by dissociation, as shown in eq. (1) a process readily realised in aqueous systems (cf. step d in Scheme).

$$[Q]^+[R_2SnX(dmit)]^- = [Q]^+X^- + R_2Sn(dmit). \qquad (1)$$

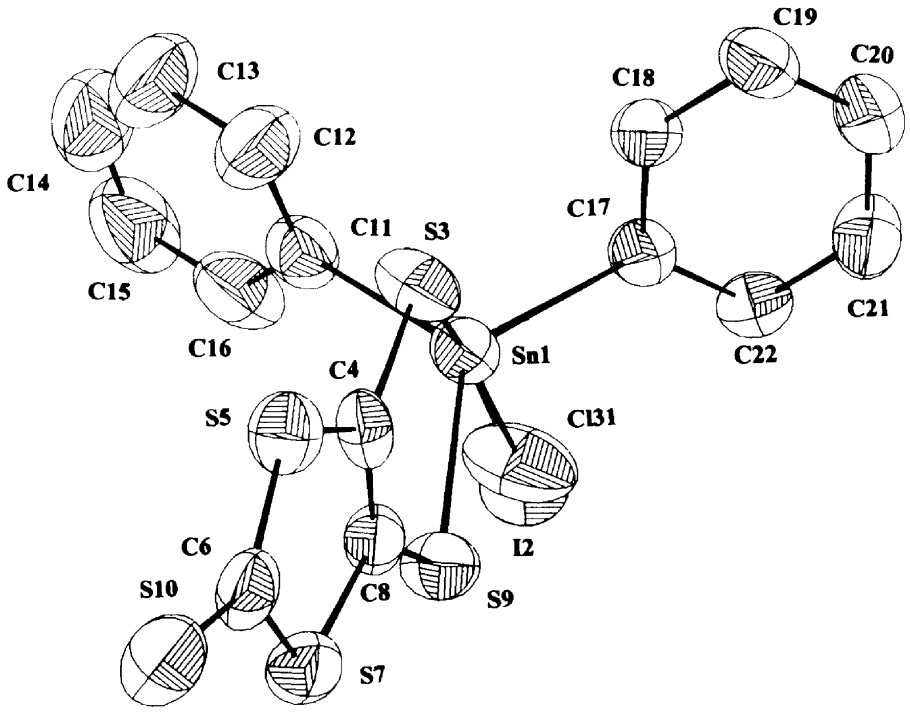

Fig. 3. The atom arrangement in the anion of [1,4-Me_2-pyridinium] [$Ph_2SnCl_{0.57}I_{0.43}$(dmit)]. Displacement ellipsoids are shown at the 50% probability level.

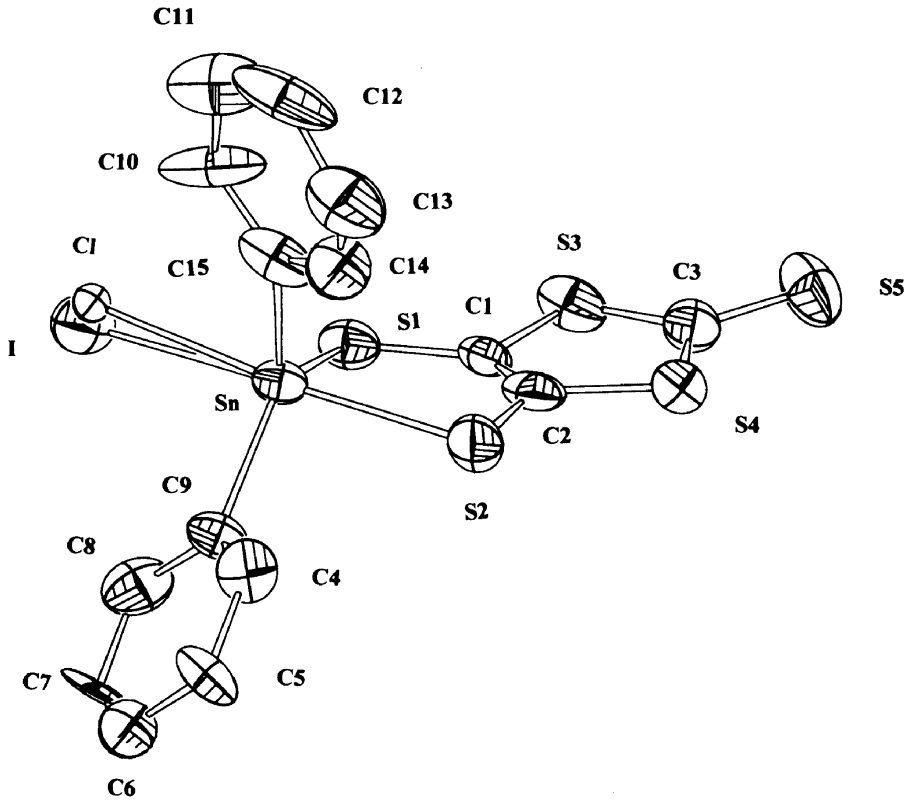

Fig. 4. The atom arrangement in the anion of [1,4-Me_2-pyridinium] [$Ph_2SnCl_{0.42}I_{0.58}$(dmit)]. Displacement ellipsoids are shown at the 40% probability level.

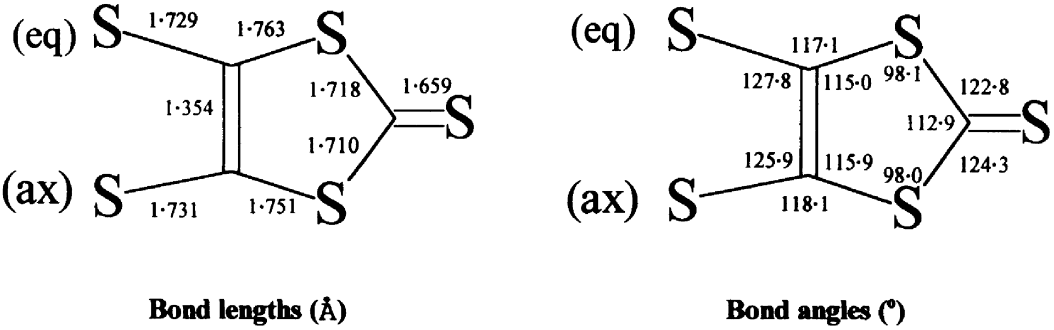

Fig. 5. The average geometric parameters within the dmit units in [Q] [$R_2SnX(dmit)$].

The δ^{119}Sn values in Me_2CO solution for [Q] [$R_2SnX(dmit)$] and $R_2Sn(dmit)$ show considerable differences; e.g. δ^{119}Sn for $Ph_2Sn(dmit)$ is -25 ppm, compared to the values for [Q] [$Ph_2SnCl(dmit)$] of -143.2, -145.1, -146.3, -144.2 and -135.5 for Q = NEt_4, 1,4-Me_2-pyridinium, $FcCH_2NMe_3$, methylviologen (2[Q]) and NBu_4, respectively. Significant differences in δ^{119}Sn values are also realised between the pairs $Me_2Sn(dmit)$/[Q] [$Me_2SnX(dmit)$] and $Bu_2Sn(dmit)$/[Q] [$Bu_2SnX(dmit)$]; δ^{119}Sn for $Me_2Sn(dmit)$ and $Bu_2Sn(dmit)$ Me_2CO-d_6 are 135.2 and 161.5 ppm, respectively [3a].

Only a single δ^{119}Sn value was observed for each solution of [Q] [$R_2SnX(dmit)$] suggesting either a single tin species was present in solution, or a rapid equilibrium process was at hand. The δ^{119}Sn values for [Q] [$R_2SnX(dmit)$] do not vary with changes in concentration or Q. This suggests that dissociations, as shown in eq. (1), can be generally ignored; furthermore, the cations and anions must be essentially independent in solution. Exception could be some NBu_4 salts, e.g. of [$Ph_2SnX(dmit)$]$^-$ (X = Cl or I) which do show lower field values than do salts of other cations, Q^+. Of interest, the mixed halide compounds, [1,4-Me_2pyridinium] [$Ph_2SnCl_nI_{1-n}(dmit)$], exhibit a single δ^{119}Sn value between those expected for the simple chloride and iodide. The similarity in the solid state and $CDCl_3$ solution δ^{119}Sn values for [NBu_4] [$Me_2SnCl(dmit)$], -33.2 and -24.7 ppm, respectively, also points to no change in structure on dissolution.

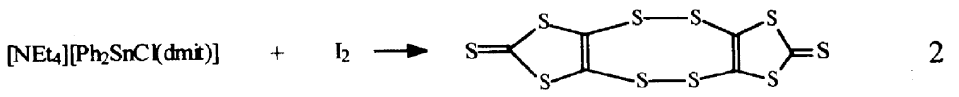
The average δ^{119}Sn values for [$Ph_2SnX(dmit)$]$^-$ vary slightly in the sequence Cl, NCSe, Br, I and NCS; -144.6, -148.3, -149.9, -159.3 and -163.3 ppm, respectively. These values indicate that the X group has little influence on the tin centres in the [$Ph_2SnX(dmit)$]$^-$ anions. The J(^{119,117}Sn–^{13}C) values for the *ipso* aryl carbon in the [$Ph_2SnX(dmit)$]$^-$ anions also show little variation with X, being *ca.* 800 Hz.

Reactions

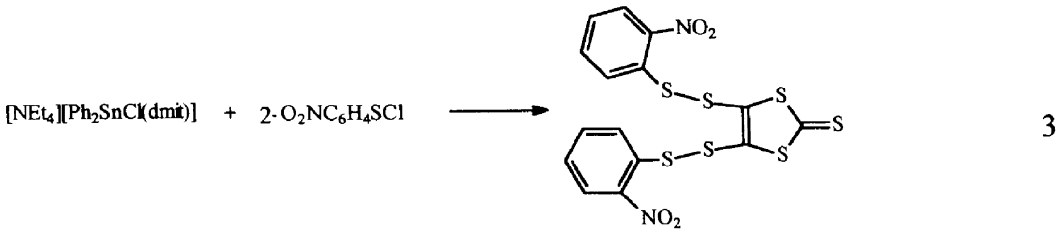
The complexes, [Q, $R_2SnX(dmit)$] can act as dmit sources, as shown by the reactions with iodine, to give the dmit dimer, C_6S_{10} and with 2-$O_2NC_6H_4SCl$ (see equations 2 and 3).

EXPERIMENTAL

Melting points were measured using a Kofler hot-stage microscope and are uncorrected. NMR spectra were obtained on a Bruker 250 MHz instrument. Ten second pulse delays were utilised in the acquisition of



2



3

the ^{13}C NMR spectra of the dmit compounds. IR spectra were recorded on Phillips Analytical PU900 and Nicolet 205 Fourier-transform instruments. Solid state NMR spectra were obtained by the EPSRC service at the University of Durham.

Zincate salts, $[Q]_2[Zn(dmit)_2]$, [Q = NEt_4, NBu_4, 1,4-dimethylpyridinium or ferrocenylmethyl(trimethyl) ammonium] [15] and $R_2Sn(dmit)$ (R = Me or Ph) were prepared by published routes [3a]. Onium salts were commercial samples, except 1,4-dimethylpyridinium iodide, which was obtained from 4-methylpyridine and methyl iodide.

Preparation of [Q] [$R_2SnX(dmit)$] complexes

The [Q] [$R_2SnX(dmit)$] complexes were produced by three reactions: (a) from reaction between R_2SnX_2 and $[Q]_2[Zn(dmit)_2]$ in the presence of excess QX; (b) from halide exchange reactions in acetone solution between [Q, $R_2SnCl(dmit)$] and either NaX, KX or QX; or (c) by addition of QX to [$R_2Sn(dmit)$]. Each of these routes is illustrated below. Melting points, solvents used for recrystallisation, colours, yields, analyses and selected spectral data for [Q] [$R_2SnX(dmit)$] complexes are listed in Tables 1 and 2.

Reaction (*a*); *preparation of* [NEt_4] [$Ph_2SnCl(dmit)$]

A solution of Ph_2SnCl_2 (5.0 g, 14.5 mmol) in MeOH (10 ml) was added to a solution of [NEt_4] $[Zn(dmit)_2]$ (5.22 g, 7.27 mmol) in Me_2CO (50 ml). After stirring the reaction mixture for 30 min, it was filtered and the volume of the filtrate was reduced to *ca*. 25 ml. Orange coloured crystals were formed. These were collected and washed successively with a little water and petrol (40–60°C). The title compound was recrystallised from MeOH.

Reaction (*b*); *preparation of* [1,4-Me_2-pyridinium] [$Ph_2Sn(NCSe)(dmit)$]

A solution of KSeCN (0.72 g, 5.0 mmol) in MeOH (10 ml) was added to a solution of [1,4-Me_2 pyridinium] [$Ph_2SnCl(dmit)$] (1.53 g, 2.5 mmol) in Me_2CO (50 ml). The reaction mixture darkened in colour on reaction and a precipitate of KCl formed. The reaction mixture was filtered and the filtrate was rotary evaporated to leave an orange coloured solid residue. This was washed successively with a little water, propan-2-ol and petrol (40–60°C) and was recrystallised from Me_2CO/petrol (40–60°C).

Reaction (*c*); *preparation of* [NEt_4] [$Ph_2SnNCS(dmit)$]

The compound [$Ph_2Sn(dmit)$] (0.47 g, 1 mmol) was mixed with NEt_4Br (0.21 g, 1 mmol) and an excess of $NaSCN.2H_2O$ (0.46 g, 4 mmol) in MeOH (20 ml) and agitated on an ultrasonic bath for 2 h. The reaction mixture was filtered and the solid recrystallised from MeOH/Me_2CO to give orange needles.

Preparation of [methylviologen, $Ph_2SnCl(dmit)]_2$

A solution of $Ph_2Sn(dmit)$ (0.75 g, 1.6 mmol) and methylviologen dichloridehydrate (0.45 g, 1.8 mmol) in Me_2CO (75 ml) was agitated in an ultrasonic bath for 15 min. The reaction mixture was filtered and the filtrate evaporated under vacuum. The solid residue was recrystallised from CH_2Cl_2/Me_2CO as black crystals.

General NMR spectral data for [Q] [$Ph_2SnX(dmit)$] complexes in Me_2CO-d_6 solutions are as follows:

[NEt_4]$^+$: ^1H NMR (Me_2CO-d_6, 250 MHz): δ: 1.34 ± 0.02 [12H, tt, J 7.3 and 1.9 Hz), 3.40 ± 0.03 [8H, q, J 7.3 Hz] ^{13}C NMR (Me_2CO-d_6, 63 MHz): δ: 7.7 [Me], 52.9 [CH_2, J 6.2 Hz]

[NBu_4]$^+$: ^1H NMR (Me_2CO-d_6, 250 MHz): δ: 0.93 ± 0.02 [12H, t, J 7.3 Hz], 1.31 ± 0.03 [8H, m, CH_2CH_2Sn], 1.56 ± 0.03 [8H, m, $CH_2CH_2CH_2Sn$], 3.16 ± 0.03 [8H, t, J 7.3 Hz, CH_2N] ^{13}C NMR(Me_2CO-d_6, 63 MHz): δ: 13.5, 19.2, 23.1 and 57.5.

[1,4-Me_2pyridinium]$^+$: ^1H NMR (Me_2CO-d_6, 250 MHz): δ: 2.69 ± 0.02 [3H, s, Me–C], 4.51 ± 0.03 [3H, s, Me–N], 7.41 ± 0.03 [2H, d, J 7 Hz] and 8.02 ± 0.055 [2H, d, J 8 Hz] (aryl). ^{13}C NMR (Me_2CO-d_6, 63 MHz): δ: 21.9 [Me–C], 48.3 [Me–N], 129.3 [$C_3 + C_5$], 145.3 [$C_2 + C_6$], 160.2 [C_4].

[$Ph_2SnX(dmit)$]$^-$: ^1H NMR (Me_2CO-d_6, 250 MHz): δ: 7.42 ± 0.04 [6H, m, *m*-+*p*-H], 8.06 ± 0.06 [4H, m, *o*-H] ^{13}C NMR (Me_2CO-d_6, 63 MHz): δ: 129.3 ± 0.03[J ^{119}Sn–^{13}C 83 Hz, C*m*], 130.0 ± 0.3 [$J^{119}Sn$–^{13}C 17 Hz, C_p], 136.9 ± 0.5 $J^{119}Sn$–^{13}C 61 ± 1 Hz, C_o], 148.0 ± 0.5 [$J^{119}Sn$–^{13}C 800 ± 10 Hz, C_i], 130–131 [C=Cl, 208.2 ± 0.5 [C=S].

Reaction between [NEt_4] [$Ph_2SnCl(dmit)$] *and ammonium fluoride*; *formation of* [NEt_4, $\{Ph_2Sn(dmit)\}_2F$]

A solution of [NEt_4, $Ph_2SnCl(dmit)$] (0.634 g, 1.00 mmol) and NH_4F (0.80 g, 22 mmol) in MeOH (75 ml) was stirred for 10 min. The solution was concentrated under vacuum and cooled to yield an orange coloured solid, which was recrystallised from MeOH/Me_2CO; m.p. 195°C (dec.).

IR (KBr, cm^{-1}); 3045, 2984, 2982, 1478, 1431, 1425, 1390, 1061, 1046, 1029, 997, 893, 727, 694.

^1H NMR (250 MHz, Me_2CO-d_6): δ: 1.41 (12H, tt, J 7.2 and 1.9 Hz, Me), 3.51 (8H, q, J 7.2 Hz, CH_2), 7.41 (12H, m, *m*-H + *p*-H), 7.82 (8H, m, *o*-H).

Found: C, 42.0; H, 3.7; N, 1.5. $C_{38}H_{40}FNS_{10}Sn_2$ requires: C, 42.0; H, 3.7; N, 1.3%.

Reaction of [NEt_4] [$Ph_2SnCl(dmit)$] *with o-nitrobenzenesulfenyl chloride*; *preparation of* 4,5-*bis*(*o-nitrobenzenethiolato*)-1,3-*dithiole*-2-*thione*

Solutions of [NEt_4] [$Ph_2SnCl(dmit)$] (0.317 g, 0.500 mmol) in MeOH (10 ml) and *o*-nitro-

benzenesulfenyl chloride (0.190 g, 1.00 mmol) in MeOH (10 ml) were mixed and stirred for 10 min. A yellow precipitate formed, which was collected, washed with MeOH and recrystallised from EtOH; yield 0.097 g, 66%, m.p. 158–160°C.

IR (KBr, cm^{-1}): 3094, 1590, 1568, 1510, 1451, 1334, 1307, 1105, 1065, 1040, 1022, 853, 785, 737.

UV–VIS (Me_2CO, mμ): 367.

Found: C, 35.1; H, 1.7; N, 5.4. $C_{15}H_8N_2O_4S_7$ requires: C, 35.7; H, 1.6; N, 5.6%.

Reaction of [NEt_4] [Ph_2SnCl(dmit)] *with iodine*; *preparation of* $(dmit)_2MeOH$

To a stirred suspension of [NEt_4] [Ph_2SnCl(dmit)] (0.317 g, 0.500 mmol) in MeOH (10 ml) was added a solution of I_2 (0.127 g, 0.500 mmol) in MeOH (10 ml). The solution was filtered and the solid was collected and dried under vacuum; m.p. 155–158°C.

IR (KBr, cm^{-1}): 1061.

Found: C, 19.5; H, 0.6; S, 75.3. $C_7H_4OS_{10}$ requires: C, 19.8; H, 1.0; S, 75.5%.

Treatment of [NEt_4] [Ph_2SnCl(dmit)] *with water*; *preparation of* [Ph_2Sn(dmit)]

A solution of [NEt_4] [Ph_2SnCl(dmit)] (0.513 g, 0.809 mmol) in Me_2CO (10 ml) was shaken with H_2O (30 ml). Addition of petrol (b.p. 40–60°C, 20 ml) led to the formation of an orange solid. This was collected, refluxed for 1 h in H_2O/MeOH (2:1), filtered and dried under vacuum at 100°C; m.p. 204–206°C (Ref.[3a]; value 206–207°C). NMR and IR spectra were identical with those of an authentic sample.

Crystal structure determinations

[1,4-Me_2pyridinium] [Ph_2SnBr(dmit)]. The unit cell and intensity data were collected on a Delft Instruments FAST diffractometer using the routines ENDEX, REFINE and MADONL in the madness programme [16] and processed using ABSMAD [17]; detailed procedures have been described [18]. Absence of crystal decay in the X-ray beam was confirmed by checking equivalent reflections at the beginning and end of data collection, which lasted ca. 8 h. The structure was solved with SIR92 [19] and refined with SHELXL97 [20]. Attempts to solve the structure in the super group $C222_1$ with $a = 15.395$, $b = 34.746$ and $c = 9.479$ Å were unsuccessful. Crystal data and structure refinement details are listed in Table 4. The Sn, Br, S and C atoms were refined with anisotropic thermal displacement parameters. The hydrogen atoms were allowed to ride on their attached atoms with common isotropic temperature factors which converged at 0.010 $Å^2$. Molecular diagrams were obtained by the program ZORTEP [21].

The cation is disordered with an inversion centre in the middle of the ring. The asymmetric unit of the monoclinic cell contains the anion and two half cations, C(16)–C(19) and C(20)–C(23). See Fig. 1; the remaining atom positions in the cation are generated by the inversion centre. The positions 17 and 21 are each shared by a carbon and nitrogen atom constrained to have identical population parameters (0.5) and identical thermal parameters.

[NEt_4] [Ph_2SnI(dmit)]. The data were collected on a CAD-4 instrument. The structure was refined by full matrix least squares. All nonhydrogen atoms, except the phenyl and ethyl carbons, were refined anisotropicially. Restraints were applied to the refinement of the phenyl and tetraethylammonium groups. The hydrogen atoms were placed in calculated positions with C–H = 1.00 Å. The first phasing model was obtained and the structure completed using SIR92 [19]. Structure refinement used CRYSTALS-PC [22]. Computations were performed on a Viglen Genie P590 Pentium PC with CRYSTALS-PC running under the Salford Software Services memory manager DBROS. Crystal data and structure refinement details are listed in Table 4.

[1,4-Me_2pyridinium] [$Ph_2SnCl_{0.57}I_{0.43}$(dmit)]. The structure was solved using direct methods, SIR92 [19], followed by CRYSTALS-PC [22] for Fourier and least squares refinement. A difference Fourier synthesis yielded a peak, which was identified as Cl. This was added to the cell contents and the I and Cl occupancies refined as a limited pair. The hydrogen atoms were placed in calculated positions with C–H = 1.00 Å.

Restraints were applied to the refinement of the cation, which were on two inversion centres and the phenyl groups which were regulised before refinement. Computations were performed on a Viglen Genie P590 Pentium PC with CRYSTALS-PC running under the Salford Software Services memory manager DBROS. Crystal data and structure refinement details are listed in Table 4.

[1,4-Me_2pyridinium] [$Ph_2SnI_{0.78}Cl_{0.22}$(dmit)] *and* [1,4-Me_2pyridinium] [$Ph_2SnI_{0.58}Cl_{0.42}$(dmit)]. Cell dimensions were determined using 14 reflections at 8.5–8.7° in θ for [1,4-Me_2pyridinium] [$Ph_2SnI_{0.78}Cl_{0.22}$(dmit)] and at 8.6–9.1° in θ for [1,4-Me_2 pyridinium] [$Ph_2SnI_{0.58}Cl_{0.42}$(dmit)].

Data collection and cell refinement employed Nicolet P3 software [23]. Data collection used 2θ scan rates of 5.33 ($I_p < 150$) to 58.6 ($I_p > 2500$)°min^{-1}, where I_p was the prescan intensity. Scan widths were 2.4 to 2.7° 2θ. Refinement was by full matrix least squares. The asymmetric unit consists of a single anion in one of the 4*e* general positions of $P2_1/c$ and half of each of the two independent cations in the centrosymmetric 2*b* and 2*c* sites respectively. The cations are therefore disordered in terms of the position of the nitrogen atoms and all their constituent atoms were treated as C. In the final stages of refinement, the site occupancy factors of I and Cl were refined to give the best values of *R*.

The disorder of the cations and the partial occu-

[c] $W = w[1 - \Delta F/6\sigma(F)^2]^2$ where w is calculated using a three term Chebychev series with coefficients: 5.94, −1.39 and 4.57 [28].

pancy of the halide sites, taken with the marginal quality of the crystals as evidenced by the poorly determined unit cells are all considered to be contributory factors to the relatively high R values for both compounds. No attempt was made to position or refine H. All computations were performed on the SUN SpARCserver (UNIX operating system) of the Computing Centre of Aberdeen University, SHELXS86 [24] and SHELX76 [25] were used for structure solution and refinement, respectively. Molecular graphics used are: PLOTAID [26] and ORTEX [27]. Crystal data and structure refinement details are listed in Table 4.

(Received 13 May 1998; accepted 22 June 1998)

Abstract—The reactions of imidazole (L^1), benzimidazole (L^2), 2-phenylimidazole (L^3), 1-acetylimidazole (L^4), imidazoline-2(1,3*H*)-thione (L^5) and 1-methyl-imidazoline-2(3*H*)-thione (L^6) with R_nSnCl_{4-n} (R = Me, Bu^n or Ph; $n = 1$, 2 or 3) were investigated. Twenty-seven novel adducts were obtained and characterized by analytical (elemental analysis, conductivity and vaporimetric molecular weight measurements) and spectral (IR, far IR, ^{1}H and ^{119}Sn NMR) data. The ligands L^1, L^2, L^3 and L^4 behave in the monodentate N-donor fashion, whereas L^5 and L^6 behave as monodentate S-donor molecules. Breaking of the N–CO bonds and protonation of imidazolate moiety occurred when the donor L^4 reacts with organotin acceptors in not rigorously anhydrous conditions. The behavior of the adducts in acetone and chlorinated solvents is also discussed. Comparison was made with related organotin(IV) complexes of imidazoles. © 1998 Elsevier Science Ltd. Keywords: tin(IV) and organotin(IV) complexes; ligands; imidazole; imidazoline-2-thione derivatives

INTRODUCTION

Imidazole-type heterocycles represent an important class of ligands in coordination chemistry: the imidazole ring is an essential component of many biological systems such as proteins, nucleic acids and the vitamin B_{12} coenzyme.

Expanding the earlier studies carried out with mercury(II) [1] and copper(I) [2], we have recently initiated a systematic study of tin(IV) and organotin(IV) compounds of imidazoles, in order to evaluate the bonding ability of imidazoles, which is important for understanding the effect of these N-donor ligands on the physico–chemical properties of metal complexes.

To investigate the influence of the nature of the tin(IV) acceptors and of the substituents on the azole ring, we previously investigated the interaction of 1-benzyl- [3], 4-phenyl- [4], 4-methyl-, 2-methyl-, 2-isopropyl- [5] and 1-methyl-imidazole [6] with R_nSnX_{4-n} acceptors (R = Me, Et, Bu^n and Ph; $n = 1$, 2 or 3; X = Cl, Br, I, NO_3, ClO_4, NCS and BPh_4). The reactivity of these imidazoles towards organotin(IV) acceptors depends not only on the electronic and steric features of the groups bonded to tin, but also on the position of the alkylic or arylic substituent in the imidazole moiety and on the nature of the counterion: the ligand/metal ratio can range from 1:1, as in [(1-methylimidazole)$(C_6H_5)_3$SnCl] and to 4:1, as in [(4-methylimidazole)$_4(CH_3)_2$Sn]$(BPh_4)_2$. NMR data, molecular weight measurements and X-ray crystal and

* Author to whom correspondence should be addressed. E-mail: pettinar@camserv.unicam.it.

molecular structure determinations indicate that the bonding interaction between the imidazole donors and R_nSnX_{4-n} generally increases with the decreasing of *n*.

With the aim to complete our systematic study on tin(IV) and organotin(IV) complexes of imidazoles we report here the synthesis, spectroscopic characterization (IR and ^{1}H NMR data) and behavior in solution (conductivity and molecular weight measurements) of new adducts between organotin(IV) acceptors and the ligands in Fig. 1, i.e. imidazole (L^1), benzimidazole (L^2), 2-phenylimidazole (L^3), 1-acetylimidazole (L^4), imidazoline-2(1,3*H*)-thione (L^5) and 1-methyl-imidazoline-2(3*H*)-thione (L^6).

EXPERIMENTAL

General methods

The organotin(IV) halides were purchased from Alfa (Karlsruhe) and Aldrich (Milwaukee) and used as received. The ligands imidazole (L^1), benzimidazole (L^2), 2-phenylimidazole (L^3), 1-acetylimidazole (L^4), imidazoline-2(1,3*H*)-thione (L^5), 1-methyl-imidazoline-2(3*H*)-thione (L^6) were obtained from Aldrich and were crystallized from diethyl ether/petroleum ether (1:2). Solvent evaporations were always carried out *in vacuo* (water aspirator). The samples for microanalysis were dried *in vacuo* to constant weight (20°C, approx. 0.1 Torr). Elemental analyses (C, H, N, S) were performed in house with a Carlo–Erba model 1106 instrument.

IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin-Elmer System 2000 FT-IR instrument. ^{1}H and ^{119}Sn NMR spectra were recorded on a VXR-300 Varian spectrometer operating at room temperature (300 MHz for ^{1}H and 111.9 MHz for ^{119}Sn). The chemical shifts are reported in ppm from $SiMe_4$ (^{1}H calibration by internal deuterium solvent lock) and $SnMe_4$ (^{119}Sn).

Melting points were taken on an IA 8100 Electrothermal instrument. The electrical conductance of the solutions was measured with a Crison CDTM 522 conductimeter at room temperature. The osmometric measurements were carried out at 40°C, over a range of concentrations, with a Knauer KNA0280 vapor pressure osmometer calibrated with benzil. The solvent was Baker Analyzed Spectrophotometric grade chloroform. The results were reproducible to $\pm 2\%$.

Syntheses

All experiments were carried out under a dinitrogen atmosphere. Hydrocarbon solvents were dried by distillation from sodium–potassium, dichloromethane from calcium hydride and tetrahydrofuran from $LiAlH_4$. All solvents were outgassed with dry dinitrogen prior to use.

[*Trimethylbis*(*imidazole*)*tin*(*IV*)]*chloride* (***I***). To a stirred refrigerated (0°C) petroleum ether/diethyl ether (10/1) solution (100 cm^3) of imidazole (L^1) (272 mg, 4.0 mmol), $(CH_3)_3SnCl$ (398 mg, 2.0 mmol) was added under N_2 stream. The mixture was stored at 0°C and stirred for 12 h. The solution was stored in freezer overnight. A colorless precipitate was formed, which was separated from the solution, washed with diethyl ether (3×20 cm^3), dried *in vacuo* to constant weight (20°C, approx. 0.1 Torr) and shown to be com-

[*Trichlorophenylbis*(*benzimidazole*)*tin*(*IV*)] (***11***). Compound **11** was prepared similarly to compound **8**. Yield: 80%, m.p. 121–124°C (Found: C, 44.5; H, 3.1; N, 10.5. Calc. for $C_{20}H_{17}Cl_3N_4Sn$: C, 44.6; H, 3.2; N, 10.4%). NMR (Acetone-d_6): ^{1}H, δ 12.5 (br, 2H, N–*H*), 8.95 (br, 2H, 2-C*H*), 7.96 (br, 2H, Sn-*o*-C_6H_5), 7.72, 7.26 (br, 7H, Sn-*m*-, Sn-*p*-C_6H_5 and 4-, 5-, 6- and 7-C*H*). IR: 3278 br [ν(N–H)], 3134 w [ν(C–H)], 455 s, 437 s, 420 s, 408 s [δ(Ph)], 285 m [ν(Sn–C)], 266 sh, 257 br, 250 br, 236 s [ν(Sn–Cl)]. Λ (acetone, 25°C, 0.8×10^{-3} M): 30.5 Ω^{-1} cm^2 mol^{-1}.

[*Dichlorodimethylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***12***). To a stirred dichloromethane/diethyl ether (2/1) solution (100 cm^3) of 2-phenylimidazole (L^3) (577 mg, 4.0 mmol), $(CH_3)_2SnCl_2$ (439 mg, 2.0 mmol) was added at room temperature. A colorless precipitate was formed immediately, which was filtered off after 6 h, washed with diethyl ether (3×20 cm^3), dried *in vacuo* to constant weight (20°C, *ca.* 0.1 Torr) and shown to be compound **12**. Yield: 52%, m.p. 130–132°C (Found: C, 47.4; H, 4.4; N, 10.9. Calc. for $C_{20}H_{22}Cl_2N_4Sn$: C, 47.3; H, 4.4; N, 11.0%). NMR ($CDCl_3$): ^{1}H, δ 8.22 (d, 4H, *o*-C_6H_5), 7.41 (t, 2H, *p*-C_6H_5), 7.31 (t, 4H, *m*-C_6H_5), 7.24 (s, 4H, 4- and 5-C*H*), 1.25 [$|^2J(^{119}Sn–H)| = 71.7$ Hz, $|^2J(^{117}Sn–H)| = 69.0$ Hz, s, 6H, SnCH_3]. IR: 3140 br [ν(N–H)], 3110 w, 3048 w [ν(C–H)], 575 m [ν(Sn–C)], 438 s [δ(Ph)], 233 s br [ν(Sn–Cl)]. Λ (acetone, 25°C, 1.1×10^{-3} M): 67.3 Ω^{-1} cm^2 mol^{-1}.

[*Dichlorodibutylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***13***). To a stirred ethanol/diethyl ether (2/1) solution (100 cm^3) of 2-phenylimidazole (L^3) (577 mg, 4.0 mmol), $(C_4H_9)_2SnCl_2$ (304 mg, 1.0 mmol) was added at room temperature. A colorless precipitate was formed immediately, which was filtered off after 6 h, washed with diethyl ether (3×20 cm^3), dried *in vacuo* to constant weight (20°C, *ca.* 0.1 Torr) and shown to be compound **13**. Yield: 93%, m.p. 109–111°C (Found: C, 53.0; H, 6.0; N, 10.0. Calc. for $C_{26}H_{34}Cl_2N_4Sn$: C, 52.7; H, 5.8; N, 9.5%). NMR ($CDCl_3$): ^{1}H, δ 10.6 (br, 2H, N*H*), 7.96 (d, 4H, *o*-C_6H_5), 7.27 (m, 6H, *m*- and *p*-C_6H_5), 7.11 (s, 4H, 4- and 5-C*H*), 1.8 (m, 4H, Sn–C_4H_9), 1.39 (ps, 2H, Sn–C_4H_9), 0.93 (t, 3H, Sn–C_4H_9). IR: 3400 br [ν(N–H)], 3155 w [ν(C–H)] 600 v br [ν(Sn–C)], 445 m, 418 m [δ(Ph)], 230 m [ν(Sn–Cl)]. Λ (acetone, 25°C, 1.3×10^{-3} M): 23.4 Ω^{-1} cm^2 mol^{-1}.

[*Dichlorodiphenylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***14***). To a stirred dichloromethane/methanol (1/1) solution (100 cm^3) of 2-phenylimidazole (L^3) (577 mg, 4.0 mmol), $(C_6H_5)_2SnCl_2$ (688 mg, 2.0 mmol) was added at 40°C. A colorless precipitate was formed immediately, which was filtered off after 6 h, washed with diethyl ether (3×20 cm^3), dried *in vacuo* to constant weight (20°C, *ca.* 0.1 Torr) and shown to be compound **14**. Yield: 54%, m.p. 171–173°C (Found: C, 57.2; H, 4.3; N, 8.7. Calc. for $C_{30}H_{26}Cl_2N_4Sn$: C, 57.0; H, 4.2; N, 8.9%). NMR ($CDCl_3$): ^{1}H, δ 7.0–8.0 (m br, 24H, Sn–C_6H_5, 2-C_6H_5, 4- and 5-C*H*). IR: 3350 br [ν(N–H)], 3061 w, 3039 w [ν(C–H)], 455 s, 444 m [δ(Ph)], 278 m, 269 s [ν(Sn–C)], 226 m [ν(Sn–Cl)]. Λ not available in acetone due to poor solubility.

[*Trichloromethylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***15***). Compound **15** was prepared similarly to compound **12**. Yield: 70%, m.p. 135–138°C dec. (Found: C, 43.0; H, 3.7; N, 10.8. Calc. for $C_{19}H_{19}Cl_3N_4Sn$: C, 43.2; H, 3.6; N, 10.6%). NMR (Acetone-d_6): ^{1}H, δ 8.8 (br, 2H, N–*H*), 8.17 (d, 4H, *o*-C_6H_5), 7.60–7.72 (m, 10H, *m*-C_6H_5, *p*-C_6H_5, 4- and 5-C*H*), 1.41 [$|^2J(^{119}Sn–H)| = 117.5$ Hz, $|^2J(^{117}Sn–H)| = 113.0$ Hz, s, 3H, SnCH_3]. IR: 3150 br [ν(N–H)], 3103 w [ν(C–H)], 527 s [ν(Sn–C)], 442 s [δ(Ph)], 317 s, 300 sh, 288 m [ν(Sn–Cl)]. Λ (acetone, 25°C, 0.8×10^{-3} M): 95.0 Ω^{-1} cm^2 mol^{-1}.

[*Trichlorobutylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***16***). To a stirred dichloromethane solution (100 cm^3) of 2-phenylimidazole (L^3) (577 mg, 4.0 mmol), $(C_4H_9)SnCl_3$ (564 mg, 2.0 mmol) was added at room temperature. The mixture was stirred for 24 h; the solvent was removed with a rotary evaporator and diethyl ether was added. A colorless precipitate was formed immediately, which was filtered off, washed with diethyl ether (3×20 cm^3), dried *in vacuo* to constant weight (20°C, *ca.* 0.1 Torr) and shown to be compound **16**. Yield: 90%, m.p. 109–112°C (Found: C, 47.4; H, 4.2; N, 10.0. Calc. for $C_{22}H_{25}Cl_3N_4Sn$: C, 47.3; H, 4.4; N, 9.8%). NMR ($CDCl_3$): ^{1}H, δ 13.9 (br, 2H, N*H*), 8.11 (d, 4H, *o*-C_6H_5), 7.20–7.50 (m, 10H, *m*-C_6H_5, *p*-C_6H_5, 4- and 5-C*H*), 2.45 (m, 2H, Sn–C_4H_9), 1.96 (m, 2H, Sn–C_4H_9), 1.51 (ps, 2H, Sn–C_4H_9), 0.97 (t, 3H, Sn–C_4H_9); ^{119}Sn, δ −269.1 ppm. IR: 3150 br [ν(N–H)], 3085 w [ν(C–H)], 616 m [ν(Sn–C)], 457 w, 441 w, 422 w [δ(Ph)], 316 s, 303 sh [ν(Sn–

Cl)]. Λ (acetone, 25°C, 1.0×10^{-3} M): 88.9 Ω^{-1} cm^2 mol^{-1}.

[*Trichlorophenylbis*(2-*phenylimidazole*)*tin*(*IV*)] (***17***). Compound **17** was prepared similarly to compound **12**. Yield: 65%, m.p. 128–130°C dec. (Found: C, 48.6; H, 3.4; N, 9.6. Calc. for $C_{24}H_{21}Cl_3N_4Sn$: C, 48.8; H, 3.6; N, 9.5%). NMR (Acetone-d_6): ^{1}H, δ 8.30 (d, 2H, Sn–C_6H_5), 8.19 (d, 4H, 2-C_6H_5) 7.71, 7.61, 7.33 (m, 13H, 2-C_6H_5, Sn–C_6H_5, 4- and 5-C*H*). IR: 3154 w, 3125 w [ν(C–H)], 1133 m, 1096 m [ν(C–S)], 520 s, 512 sh [ν(Sn–C)], 276 s [ν(Sn–Cl)]. Λ (acetone, 25°C, 1.0×10^{-3} M): 4.6 Ω^{-1} cm^2 mol^{-1}.

RESULTS AND DISCUSSION

Synthesis, reactivity and properties of the organotin(IV) complexes

Interaction between R_nSnCl_{4-n} (R = Me, Bu^n or Ph; n = 1, 2 or 3) compounds and an excess of imidazole (L^1), benzimidazole (L^2) and 2-phenylimidazole (L^3) in organic solvents (alcohols, dichloromethane, diethyl ether or petroleum ether) at 0°C or at room temperature gave the compounds **1**–**17** in accordance with eq. (1):

$$x(L) + (R_nSnCl_{4-n}) \xrightarrow{\text{Solvent}} \underset{\mathbf{1–17}}{[(L)_x(R_nSnCl_{4-n})]\cdot zH_2O}. \quad (1)$$

No.	Ligand, L	R	x	n	z

13	L^3	Bu^n	2	2	0
14	L^3	Ph	2	2	0
15	L^3	Me	2	1	0
16	L^3	Bu^n	2	1	0
17	L^3	Ph	2	1	0

In the same conditions no adduct was obtained from the interaction between L^1 and Bu$^n{}_3$SnCl, between L^2 and Me_3SnCl, Bu$^n{}_3$SnCl or Bu$^n{}_2$SnCl$_2$, and finally between L^3 and R_3SnCl (R = Me, Bu^n or Ph) or Me_2SnCl_2. On the other hand, even if different reaction conditions with respect to literature reports [7–10] were employed, from the interaction between L^1 and R_2SnCl_2 analogous 2:1 complexes were afforded.

With the exception of the derivative **6** (for which a ligand to metal ratio of 1:1 was observed) 2:1 adducts were obtained from the interaction between L^1 or L^2 and triorganotin(IV) acceptors. This fact further indicates the possibility of obtaining 2:1 adducts with triorganotin(IV) chlorides when imidazole type donors able to involve the halide group in a hydrogen bonding network were employed [4].

Interaction between R_2SnCl_2 (R = Me or Ph) and excess 1-acetylimidazole L^4 in diethyl ether produces the derivatives $[(L^4)_2(Me_2SnCl_2)]$ **18** and $[(L^4)_2(Ph_2SnCl_2)]\cdot H_2O$ **19**. Whereas L^4 reacts with other organotin acceptors yielding neutral adducts of unsubstituted imidazole L^1 upon hydrolysis of the N(1)–$COCH_3$ bond. The presence of a small quantity of water in the solvent is sufficient for the attack of the N(1)–C bond and formation of the donor L^1 which immediately coordinates the organotin acceptor. If rigorously anhydrous conditions were employed, no product afforded.

The reaction between imidazoline-2(1,3*H*)-thione (L^5) or 1-methyl-imidazoline-2(3*H*)-thione (L^6) and R_nSnCl_{4-n} acceptors (R = Me, Bu^n or Ph; n = 1, 2 or 3) was carried out in diethyl ether or diethyl ether/dichloromethane solutions from which compounds **20**–**27** were isolated as insoluble or sparingly soluble precipitates, in accordance with eq. (2) (see Table):

$$x(L) + (R_nSnCl_{4-n})\cdot zH_2O \xrightarrow{\text{Solvent}} \underset{\mathbf{20–27}}{[(L)_x(R_nSnCl_{4-n})]\cdot zH_2O}. \quad (2)$$

of 1:1 was found), all the derivatives obtained show a ligand to metal ratio of 2:1.

No adduct was obtained from the interaction of L^5 or L^6 and R_3SnCl or $Bu^n_2SnCl_2$.

From the interaction of L^5 with Me_nSnCl_{4-n} ($n=1$ or 2) analogous compounds to those reported in literature afforded [11].

It is interesting to observe that in diethyl ether from the reaction between L^6 and $RSnCl_3$ ($R=Bu^n$ or Me) a 2:1 adduct was obtained, whereas in dichloromethane a 1:1 adduct was previously synthesized [11].

All the diorgano- and triorgano-tin(IV) derivatives are moderately soluble in chlorinated solvents, acetone and DMSO, and generally insoluble in diethyl ether, ethanol and water. The monoorganotin(IV) adducts are generally less soluble in all the solvents commonly used. These compounds are stable also when exposed to moisture for a long time, whereas upon prolonged standing at 120°C, or in acetone and chloroform solutions, organotin(IV) oxides and hydroxides are often recovered.

The triorganotin(IV) adducts **1** and **2** are often unstable not only in solution but also in the solid state and when they exposed to moisture for many hours, they decompose in accordance with the following equation:

$$2[L_2R_3Sn]Cl \rightleftharpoons [(L)_2R_2SnCl_2] + R_4Sn + 2L. \quad (3)$$

The decomposition (3) is established by the presence in the ^{119}Sn NMR spectrum of compounds **1** and **2**, previously exposed to moisture for 2 days, of the signals due to $[(L)_2R_2SnCl_2]$ and R_4Sn species.

IR data

By comparison with the data reported for other organotin(IV) complexes containing N-donor ligands, we suggest the following assignments for adducts **1**–**27**.

Ligand absorptions In the 3200–2950 cm^{-1} region, the ligands exhibit weak bands typical of C–H stretching due to a pseudoaromatic ring, and in the region 1600–1500 cm^{-1} some more intense absorptions due to the ring breathing mode [12]. These bands do not shift markedly upon coordination to tin, suggesting a weak influence of the complexation on the absorptions within the donor.

In the 2800–2600 cm^{-1} region the ligands exhibit a broad band typical of N–H stretching. In the tin(IV) and organotin(IV) adducts this band shifts in the 3400–3100 cm^{-1} region suggesting an important influence of the coordination to tin. The position and the broadening of the N–H stretching band are consistent with the presence of a hydrogen bond between the N–H moiety and the halide groups [4, 13, 14].

Sn–C stretching frequencies. In the trimethyltin(IV) derivative **1** a strong absorption is observed at *ca.* 549 cm^{-1}. It is due to $\nu_{(asym)}$ Sn–C stretching vibration and is consistent with an essentially trigonal pyramidal arrangement of methyl groups (C_{3v}) [15–18]. In the derivatives **2** and **6** the $\nu_{(asym)}$ Sn–C stretching vibration is found at *ca.* 290 cm^{-1}: a trigonal pyramidal arrangement of aryl groups is likely.

Only a single Sn–C stretching vibration was observed in the spectra of the diorganotin(IV) derivatives **7**, **8**, **12**, **13**, **15**, **18**, **19**, **23** and **24** in accordance with a *trans*-octahedral configuration of the two alkyl groups [19, 20]. In the spectrum of derivatives **14** and **20** two medium or strong absorptions in the range 290–270 cm^{-1} were found. In this case the presence of the *cis*–isomer is likely.

Sn-halide stretching frequencies. In the triorganotin(IV) derivative **6**, we observed the tin–chloride stretching frequency as medium absorption at 226 cm^{-1}. This indicates the non-ionic nature of this compound. The absorption is markedly shifted with respect to that indicated for the starting triorganotin(IV) chloride [21].

In the other triorganotin(IV) derivatives **1** and **2** the tin–chloride stretching frequency is absent. On the basis of previous reports [22] on triorganotin(IV) complexes and in accordance with the X-ray crystal structure determination of [bis(4-phenylimidazole)trimethyltin(IV)]chloride [4] we have hypothesized an ionic formulation of the type $[(L)_2R_3Sn]^+[Cl]^-$.

The tin(IV) chloride stretching frequencies in the di- and tri-halidetin(IV) derivatives fall as strong or medium broad bands in the range 220–320 cm^{-1}. These bands are lowered by 90–130 cm^{-1} with respect to those found in the starting tin(IV) reagents [23].

Behavior in solution

The conductivity measurements were carried out in acetone solution for all the soluble compounds whereas the molecular weight determinations were performed in chloroform solution only on selected sufficiently soluble and stable adducts.

The conductivity data show that triorganotin(IV) halide adduct **1**, **2** and **6** are not electrolytes in acetone and dissociate in $CHCl_3$ solution to a large extent (r = ratio between the vaporimetric molecular weight and formula weight lying in the range 0.30–0.55), in accordance with eq. (4), which indicates ligand loss in solution.

$$(L)_xR_3SnCl \rightleftharpoons (L)_{x-1}R_3SnCl + L \rightleftharpoons R_3SnCl + xL. \quad (4)$$

The conductance values for the diorganotin adducts of L^1, L^2, L^4, L^5 and L^6 are in the range 2.0–36 $\Omega^{-1}\,cm^{-2}\,mol^{-1}$ and also suggest a not electrolytic nature in acetone. The vaporimetric molecular weight determinations indicate extensive dissociation in chloroform solution for the soluble adducts. Some of the trichlorotin(IV) adducts and derivatives con-

taining the donor L^3 are partly ionized. The conductivity values for these complexes are in the range 44–95 $\Omega^{-1}\,cm^{-2}\,mol^{-1}$: they are lower with respect to those reported for 1:1 electrolytes in this solvent (the typical 1:1 electrolyte tetra-*n*-butylammonium bromide has a specific conductivity of 137 $\Omega^{-1}\,cm^2\,mol^{-1}$) in accordance with a partial ionic dissociation, but they are also greater with respect to those found in analogous imidazole organotin(IV) adducts [3–6].

^{1}H *NMR data*

The ^{1}H NMR spectra of the donors and of the organotin(IV) complexes **1**–**27** were recorded in $CDCl_3$ or in acetone-d_6 due to poor solubility in the former solvent.

The spectrum of the trimethyltin(IV) complex **1** indicates a nearly complete dissociation into the starting reagents. In fact, the Δ value (difference in chemical shift for the same type of proton in the free base and in its organotin(IV) complexes) is in the range 0.04–0.01 ppm and the tin–proton coupling constants are of the same order of magnitude as those reported for the starting triorganotin(IV) acceptors [24].

Instead, in the spectra of the triphenyltin(IV) complexes **2** and **6**, the signals of the ligand are displaced upfield and the Δ value is in the range (−0.26)–(−0.06) ppm. This peculiarity can be explained by considering the shielding effect exerted on H2, H4 and H5 protons by aromatic protons of the phenyl rings linked to tin(IV).

In the spectra of the mono- and di-organotin(IV) complexes of L^1, L^2, L^3 and L^4, the signals of the ligands are generally displaced to lower field. The deshielding observed is attenuated at a position remote from the metal. The Δ observed is likely due to a σ-charge donation from the N-donor to tin(IV) acceptor and is evidence of the existence of the complexes in solution. The Δ is greater for the trihalo- with respect to for dihalo-tin(IV) adducts in accordance with a stronger Sn–N bonding interaction in the former compounds.

The magnitudes of the tin(IV)–proton coupling constants for these diorganotin(IV) complexes are different from those reported in literature for the starting tetracoordinate diorganotin(IV) halides [25], but they are smaller with respect to that indicated for hexacoordinate undissociated organotin(IV) complexes containing N-donor ligands [26, 27]: this suggests a partial dissociation of our complexes in acetone or in chloroform solution in accordance with the data derived from molecular weight measurements.

The ^{1}H NMR spectra of the diorganotin(IV) adducts of 1-methyl-imidazoline-2(3*H*)thione (L^5) and imidazoline-2(1,3*H*)-thione (L^6) exhibit Δ values in the range 0.001–0.02 suggesting a nearly complete dissociation into starting reagents.

^{119}Sn *NMR data*

The ^{119}Sn NMR data are reported in acetone-d_6 for only some adducts, because the quality of the spectra is sometimes poor owing to the low solubility. The ^{119}Sn NMR chemical shift of compounds is comparable with that of the corresponding organotin(IV) acceptor in the same solvent [24] and clearly indicate that these adducts are extensively dissociated in acetone solution. Whereas the $\delta(^{119}Sn)$ chemical shifts for derivatives of imidazoline-2(1,3*H*)-thione (L^5) and 1-methyl-imidazoline-2(3*H*)thione (L^6) are sensibly different from those reported for the corresponding Lewis acid: also on the basis of literature data [24] and vaporimetric molecular weight determinations we suggest that these complexes are not completely dissociated in acetone solution.

Comparison with other imidazole organotin(IV) adducts

Table 1 shows a summary of the interactions of imidazoles with some organotin(IV) derivatives [3–11, 28–31].

In the adducts reported the ligand to metal ratio *n* goes from 1:1, for example in $[(L^2)Ph_3SnCl]$, to 3:1 in $[(L^{10})_3PhSnCl_3]$. When the ratio is 3:2, as in $[(L^8)_3(BuSnCl_3)_2]$, a dinuclear structure with the bridging chloride group is likely.

The solubility of the adducts reported in Table 1 is limited to a few polar solvent, such as acetone, *N*,*N*-dimethylformamide or DMSO. The adducts of L^7, L^8, L^9 and L^{10} are generally also soluble in chlorinated solvents due to the presence of methyl and aryl substituents in the azole ring. The derivatives of L^5 and L^6 show appreciable solubility also in water.

In no cases was the imidazole ring metallated or did basic salts result, whereas only in the interaction between 1-acetylimidazole (L^4) and organotin(IV) acceptors did breaking of the N(1)–C bond and coordination of the unsubstituted imidazole L^1 formed occur.

In most of cases mono and di-organotin(IV) chlorides adducts containing N-donor imidazole ligands have a perfect octahedral environment with all-*trans* coordination.

The triorganotin adducts prefer a distorted trigonal bipyramid geometry with the organic groups always in equatorial positions. If the imidazole was able to involve a chloride group in a hydrogen bonding network, a 2:1 adduct was obtained, whereas if the imidazole possess an alkyl or an aryl group in the N(1) position only 1:1 adducts were obtained. The reaction between imidazoles and tributyltin(IV)chloride was often unsuccessful, no simple adduct but intractable material being formed with the exception of derivatives $[(L^9)Bu_3SnCl](H_2O)$ and $[(L^{10})_2Bu_3Sn]Cl$, likely obtained owing to the greater basicity of these donors with respect to those so far employed.

The donating ability of this family of ligands can be correlated to the ratio *n* and to the stability of the complexes in solution. On the basis of this systematic study L^1, L^9 and L^{10} seem to be the better donors (L^{10} is the only able to give a 3:1 ligand to metal ratio) also due to the minor dissociation of the organotin(IV) complexes in chloroform and acetone solution. L^3, L^{11} and L^{12} are weaker donors probably due to the steric hindrance of phenyl, methyl and isopropyl group, respectively, in the C(2) position, whereas the lower donating ability of L^5 and L^6 is due to the fact that they coordinate throughout the S-atom, which has a lower affinity for the organotin(IV) acceptors with respect to the N-atom. With the latter donors, it is also possible to obtain a 1:1 adduct not only with triorgano- but also with di- and mono-organotin(IV) acceptors.

1:1 adducts are also obtained if the donor is able to coordinate in a bidentate fashion as 1-methyl-2-(methylsulfinyl)imidazole (L^{14}).

If hydroxideorganotin(IV) acceptors were used, substitution of the OH group and coordination of the deprotonated ligand occurred as in [Ph_3Sn(2-mercapto-1-methylimidazolato)tin(IV) [30].

Various degrees of hydration were found from 1/3 in [(L^{10})Ph_3SnCl]·1/3H_2O to 6 in [(L^{10})$MeSnCl_3$]·6H_2O.

(Received 24 February 1998; accepted 23 June 1998)

Abstract—44 members of the compound series $Ph_{4-n}MR_n$ (M = Si, Ge, Sn, Pb; R = *o*-, *m*-, *p*-Tol; *n* = 0–4) were synthesized (15 new compounds). The crystal structures of $Ph_3Sn(o\text{-Tol})$ and $PhSn(o\text{-Tol})_3$ were determined and compared to 16 known structures. Subject to the distance *d*(M–C), an interplay between through-space π–π repulsion and π–σ attraction leads to either elongated or compressed tetrahedral geometry. ^{29}Si-, ^{119}Sn- and ^{207}Pb-NMR chemical shifts were determined in solution and in the solid state. ^{73}Ge chemical shifts were measured only in solution. An upfield or downfield sagging of the chemical shifts along each series is rationalized in terms of a π–σ* charge transfer which is constrained by torsion of the aromatic groups. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: silicon; germanium; tin; lead; through-space interaction; heteronuclear NMR in solution and solid state; π–σ* charge transfer.

INTRODUCTION

As part of ongoing studies about tetraarylmethane analogues [1–4], the series of compounds $Ph_{4-n}M(p\text{-Tol})_n$ (M = Si, Ge, Sn, Pb; *n* = 0–4) was synthesized and investigated using X-ray diffraction and NMR spectroscopy [1]. The structural finding of elongated tetrahedra for M = Si and Ge and compressed tetrahedra for M = Sn and Pb (see Ref. [5]) was rationalized by means of an interplay between π–σ attractions and π–π repulsions of the aromatic groups [1, 6, 7]. The sagging effect (see Refs. [8–10]) observed in the solution state ^{29}Si-, ^{119}Sn- and ^{207}Pb-NMR chemical shifts was rationalized by means of a π–σ* charge transfer from the aromatic groups into the LUMO associated mostly with the hetero atom M [1].

In this paper the subject is extended synthetically to the groups *o*- and *m*-tolyl [four series of compounds $Ph_{4-n}MR_n$, (**1**–**4**)]. In addition to the 16 crystal structures known previously [1–4], the structures of $Ph_3Sn(o\text{-Tol})$ and $PhSn(o\text{-Tol})_3$ were determined. Heteronuclear NMR chemical shifts in solution and also in the solid state were determined for all compounds of series eq. (1), eq. (3) and eq. (4). In addition, ^{73}Ge-NMR chemical shifts for the five compounds of series eq. (2) in solution are given [11–16]. Semi-empirical MO calculations have been done to support the concept of a π–σ* charge transfer. As will be seen from

RESULTS AND DISCUSSION

Structural results

Figure 1 shows the molecular structures of $Ph_3Sn(o\text{-Tol})$ and of $PhSn(o\text{-Tol})_3$. Relevant bond lengths and angles are listed in Table 1. Both molecules possess crystallographically a S_4 symmetry, i.e. the ortho methyl groups exhibit a statistical disorder. One of the four possible ordered arrangements is given in Fig. 1, respectively.

As outlined for tetraaryls with phenyl and *p*-tolyl substitution [1], the tetrahedra with M = C, Si, Ge are elongated (two bond angles less and four bond angles greater than 109.5°) whereas the tetrahedra with M = Sn, Pb are compressed (two bond angles greater and four bond angles less than 109.5°). This result is valid also for the cases of *o*-tolyl and *m*-tolyl substitution. Figure 2 gives a plot of d(M–C) vs the twofold angle Φ(C–M–C)–[2x] for all 18 cases $Ph_{4-n}MR_n$, which have been investigated by X-ray crystallography. At $d(M\text{–}C) = 2.06$ Å (cubic fit curve) an overall repulsion between the aromatic groups transforms into an overall attraction. For short M–C distances the through-space π–π repulsion predominates; for long M–C distances the through-space π–σ attraction prevails.

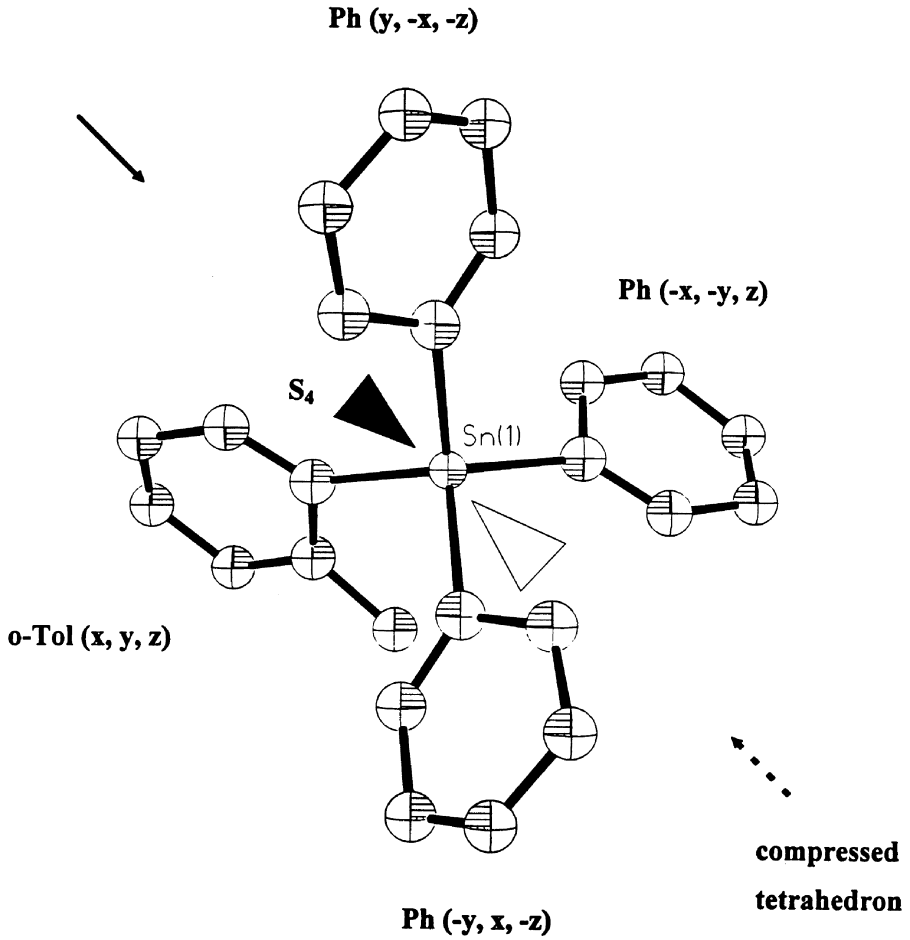

Fig. 1. Ortep drawings of $Ph_3Sn(o\text{-Tol})$ (top) and of $PhSn(o\text{-Tol})_3$ (continued). Only one of the four possible ordered arrangements is given, respectively. Thermal ellipsoids are at the 20% probability level; hydrogen atoms are omitted for better clarity. The molecules are compressed along the outlined pseudo S_4 axes. The group identifications include the symmetry operators of the space group $P\bar{4}2_1c$.

NMR chemical shifts

Table 2 gives the heteronuclear NMR chemical shifts for the homoleptic and heteroleptic tetraaryls $Ph_{4-n}MR_n$ in $CDCl_3$ solution. The series eq. (2) is the first systematic investigation of ^{73}Ge-NMR chemical shifts, which has been described (Figure 3) [11–16]. Table 3 gives the solid state ^{29}Si, ^{119}Sn and ^{207}Pb chemical shifts of the compounds of the series eqs. (1, 3–4). Figure 4 shows exemplarily for M = Sn the six sequences of $\delta(^{119}Sn)$ in the solution (top) and in the solid (bottom) state. The values are connected by cubic fit curves.

With regard to the aliphatic compounds Me_4M,

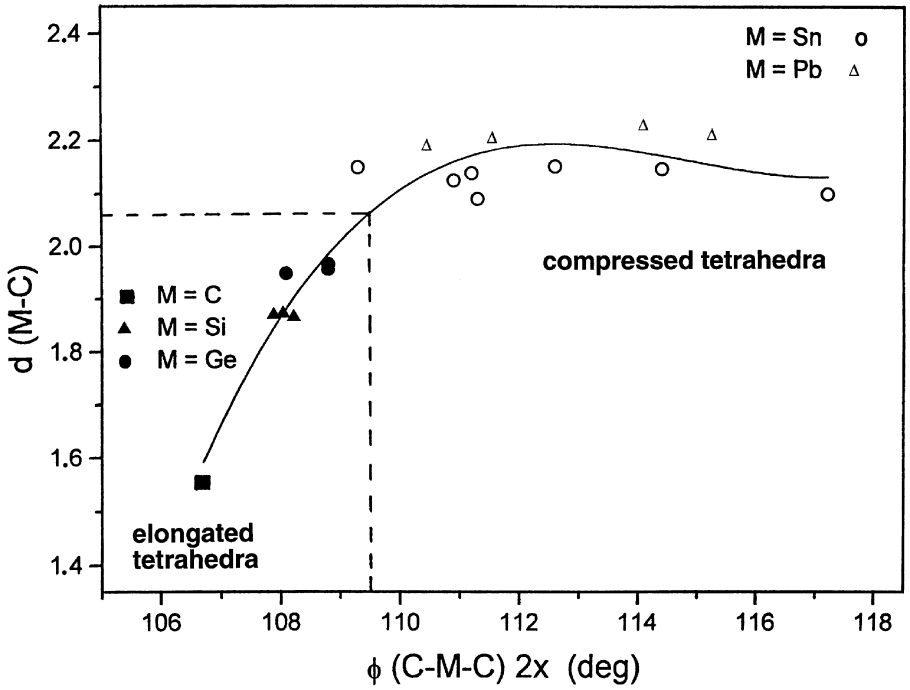

Fig. 2. Plot of the bond distances d(M–C) (Å) vs the two-fold bond angle ⟡(C–M–C)-2× (°) for 18 compounds $Ph_{4-n}MR_n$ (M = C, Si, Ge, Sn, Pb; R = *o*-, *m*-, *p*-Tol; n = 0–4) in relation to the distortion of the tetrahedra around M. Data from Ref. [1–4] and references cited therein. Cubic fit curve (change of distortion at 2.06 Å).

the chemical shifts $\delta(^{29}Si/^{73}Ge/^{119}Sn/^{207}Pb)$ of the homoleptic members Ph_4M and $MTol_4$ are all upfield and this shielding had been explained by a π(aromatic)→σ^*(M) charge transfer[1] [1]. Between the homoleptic end members Ph_4Sn and SnR_4, a sagging pattern [8–10] holds. The sagging effect is different for the solution and for the solid state. Furthermore, the effect changes from the (*o*-Tol) to the (*m*-Tol) to the (*p*-Tol) series. A possible explanation may be that π–σ^* charge transfer depends on the torsion of the aromatic groups about the M–C_{ipso} axis. In solution the torsion angles easily arrange themselves, such as, to optimize the energetic interactions among

[1] A seeming exception is Ph_4C with $\delta(^{13}C) = +65.0$ ppm (Me_4C + 28.0 ppm). The central carbon atom has four short distances (cf. Figure 2) to the deshielding side-on position of the aromatic ring current [1].

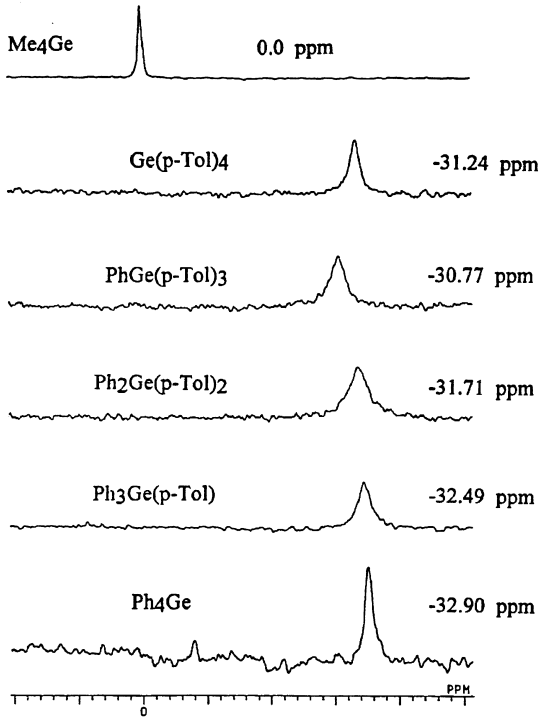

Fig. 3. ^{73}Ge-NMR spectra for the series compounds $Ph_{4-n}Ge(p\text{-Tol})_n$ in $CDCl_3$ solution. Chemical shifts are given with reference to Me_4Ge.

the four aromatic groups whereas in the solid state the torsion angles are constrained by the crystal packing [7]. In solution, the sterically undemanding groups *m*-tolyl and *p*-tolyl lead to an upfield sagging (excess of charge, with regard to a linear course). On the other hand, the sterically crowded *o*-tolyl group leads to a distinct downfield sagging (shortage of charge).

In accordance with the similar molecular forms of the compounds with M = Sn and Pb (see Section structural results), the three solution state $\delta(^{207}Pb)$ sagging curves are nearly identical to those of $\delta(^{119}Sn)$ (Table 2 and Fig. 4). Also the three solid state $\delta(^{207}Pb)$ sagging curves show a close correspondence to those of $\delta(^{119}Sn)$. Similar torsions of the aromatic groups and similar crystal structures can be assumed.

In solution the $\delta(^{73}Ge)$ and $\delta(^{29}Si)$ sagging curves show similar trends to those described for $\delta(^{119}Sn)$ and $\delta(^{207}Pb)$. The shortage of charge (downfield shift) is enhanced for the case of the sterically very demanding *o*-tolyl group at Si. However the known solid state structures of the Si series are different and this fact manifests itself in sagging curves definitely different from those of Fig. 4.

Semi-empirical MO calculations

To support the concept of a π–σ^* charge transfer, semi-empirical MO calculations at the PM3 level (MOPAC 6.0 program package, parameter set: [18, 19] (all 44 compounds $Ph_{4-n}MR_n$, molecular geometries optimized starting from the known crystal structures) and at the Extended Hückel level [20] ($PhSn(o\text{-Tol})_3$, fixed geometry of the structure determination) were performed. The results are similar for all compounds. On the basis of the main coefficients, the energetic sequences of the MO's are in the order eq. (5). With regard to this order, a definite higher transition probability is needed for the assumed π–σ^* charge transfer (high energy gap) than for a π–π^* charge transfer (low energy gap) [21] (A quantitative correspondence between the PM3 energy differences and the energies of the experimental UV bands between 240 and 270 nm does not exist.)

$$(\text{several } \pi - \text{HOMO's}) \rightarrow (\text{several } \pi^* - \text{LUMO's}) \rightarrow (\text{four } \sigma^* - \text{LUMO's}). \quad (5)$$

	m-Tol		−147.8	−146.4	−128.0	−119.3
	p-Tol		−145.9	−142.0	−150.0	−148.8

[a] Conditions as given in Section 3.
[b] Additional trace signal at −14.7 ppm.

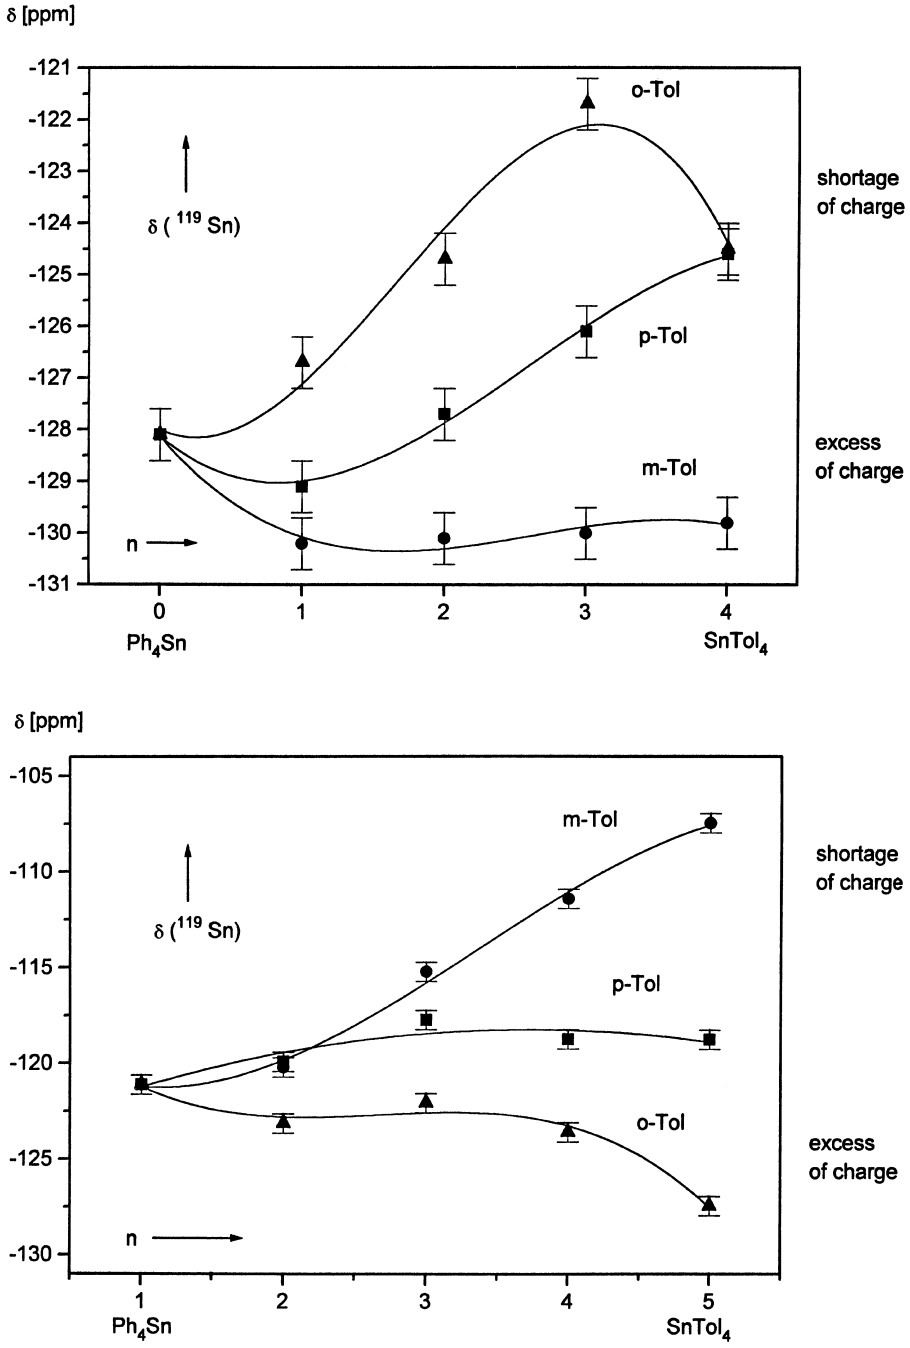

Fig. 4. Course of ^{119}Sn-NMR chemical shifts vs n for the series of compounds $Ph_{4-n}SnR_n$ (R = *o*-, *m*-, *p*-Tol; n = 0–4) in $CDCl_3$ solution (top) and in the solid state (bottom). Cubic fit curves.

In detail, all PM3 calculations result in the energetic σ^*–LUMO sequences eq. (6). With regard to the NMR behavior of eqs. (1–4), no definite order or correlation exist with E(σ^*–LUMO) or with its difference to the π–HOMO, apart from the fact that the MO sequences are most disturbed if the group (*o*-Tol) is involved.

$$E(\mathrm{Si}) > E(\mathrm{Pb}) > E(\mathrm{Sn}) > E(\mathrm{Ge}). \quad (6)$$

In fact, it can be concluded that semi-empirical calculations have to lower a sophistication, to be of any purpose in discussing the postulated π–σ^* charge transfer.

EXPERIMENTAL

Synthesis

The 14 homoleptic compounds and the 12 heteroleptic *p*-tolyl compounds were prepared by literature methods [1–4]. For previous work on the *o*-tolyl substituted silicon compounds, see Ref. [22–25]. The mixed ortho- and meta-substituted tin and lead compounds $Ph_{4-n}M(o\text{-}, m\text{-Tol})_n$ ($n = 1$–3; M = Sn, Pb) were synthesized via a Grignard reaction with the corresponding halides $Ph_{4-n}MX_n$ (X = Cl, Br, I). Compounds of the series $Ph_{4-n}SiM(m\text{-Tol})_n$ ($n = 1$–3) were obtained by reaction of $Ph_{4-n}SiCl_n$ with Li(*m*-Tol). A representative detailed procedure follows for the compound $PhGe(p\text{-Tol})_3$, which had been described in Ref. [1] as contaminated with $Ge_2(p\text{-Tol})_6$. To 15.6 mmol of (*p*-Tol)Li in 50 ml ether is slowly added, at ambient temperature 1.02 g (4 mmol) of freshly distilled $PhGeCl_3$, dissolved in 50 ml ether. After 1 h under reflux, the ether is distilled off and substituted continuously by toluene. After further stirring for 4 h under reflux and for 20 h at ambient temperature, the solution is hydrolyzed by slow addition of 1 M HCl. The organic layer is dried with Na_2SO_4, the solvent distilled off and methanol added. The crude product is separated by filtration, washed with cold methanol and recrystallized from methanol/toluene (3:1). Table 4 summarizes the results obtained in this study.

Melting points were determined in glass capillaries in a Kofler melting block. Elemental analyses (C and H) were obtained from the Institut für Organische Chemie, Universität Mainz, with a Perkin-Elmer CHN-Analyser 240.

Crystal structure determinations

Colorless single crystals of $Ph_3Sn(o\text{-Tol})$ and $PhSn(o\text{-Tol})_3$ were obtained by slow evaporation of a $CDCl_3$ solution. As previously [1–4], the crystals of the heteroleptic compounds were all of a poor quality. An inspection by means of Weissenberg exposures was essential. Both eventually chosen crystals had a low diffraction power. A summary of crystal data, intensity data collections and refinements, is given in Table 5. The crystals were fixed with glue and sealed in thin-walled glass capillaries. The experimental densities were determined by flotation in an aqueous polytungstate solution. Integrated intensities were collected on an Enraf-Nonius CAD4 diffractometer.

Both compounds crystallize in the same tetragonal space group $P\bar{4}2_1c$ as their homoleptic end members (see the first footnote of Table 5). Trials of refinement in a monoclinic setting resulted in distinctly worse geometries and esd's. The space group symmetry requires a S_4 symmetry for both molecules, i.e. the ortho-methyl groups are statistically disordered (site occupations 0.25 and 0.75, respectively). On account of the small number of reflections of significant intensity, only the Sn atom was given anisotropic thermal parameters, the C atoms were handled isotropically. The hydrogen atoms were calculated as riding on their carbon atoms. For calculations and drawings local versions of SHELX-76 and ORTEP were used. Tables listing details of crystal data and structure determinations, full sets of parameters (Sn, C and H), all bond lengths and angles and torsion angles and labelled plots have been deposited at the Cambridge Crystallographic Data Centre as supplementary material.

Solution state NMR

^{29}Si-, ^{119}Sn- and ^{207}Pb-NMR spectra were recorded on a Bruker WP 80/DS instrument (digital resolution 0.5 Hz) at 15.92 MHz (^{29}Si), 29.88 MHz (^{119}Sn) and 16.74 MHz (^{207}Pb). Solution state ^{73}Ge-NMR spectra were recorded on a Jeol JNM-GX 270 spectrometer (frequency 9.3 MHz, sweep width 2000 Hz, acquisition time 2 s, scans 1500). The chemical shifts are relative to the external standards Me_4Si, Me_4Ge, Me_4Sn and Me_4Pb. Solutions of 100–400 mg of compound/3 mL of $CDCl_3$ were used.

Solid state NMR

^{29}Si-, ^{119}Sn- and ^{207}Pb-NMR spectra were measured on a Bruker MSL-300S spectrometer operating at 59.641, 111.922 and 62.55 MHz, respectively. Samples of 300 mg of the organosilicon and lead compounds were packed into 7 mm zirconia rotors and spun at the magic-angle, at speeds of 2.5 kHz. The organotin compounds (*ca.* 100 mg) were measured in 4 mm zirconia rotors at 5 kHz. Spectra were obtained with broad-band double air-bearing cross-polarization Bruker WB–BL probes, at ambient temperature (295 K) from single contact cross-polarization (CP) experiments.

Solid state ^{29}Si-NMR: spectral width, 20 kHz; pulse width, 5.5 μs (90°) ^1H pulse; contact time, 1 ms; recycle time, 20 s; chemical shifts with respect to kaolinite ($\delta(^{29}Si) = -91.5$ ppm (Q^3 connected Si) [26, 27]; set up of the CP conditions and use as an external standard. Solid state ^{119}Sn-NMR: spectral width, 33 kHz; pulse width, 4.0 μs (90°) ^1H pulse; contact time, 10 ms; recycle time, 10 s; chemical shifts with respect to $Sn(c\text{-Hex})_4$ ($\delta(^{119}Sn) = -97.4$ ppm [28]; set up of the CP conditions and use as an external standard. Acquisition of 128 scans was sufficient to obtain spectra with a satisfactory signal to noise ratio. Solid state ^{207}Pb-NMR: spectral width, 62.5 kHz; pulse width, 3.5–4.0 μs (90°) ^1H pulse; contact time, 5–20 ms; recycle time, 30 s; chemical shifts with respect to $Pb(p\text{-Tol})_4$ ($\delta(^{207}Pb) = -148.8$ ppm [29, 30]; set up of the CP conditions and use as an external standard). Acquisition of 64–128 scans was sufficient to obtain spectra with a satisfactory signal to noise ratio.

(Received 25 March 1998; accepted 23 June 1998)

Abstract—In the back-end of the nuclear fuel cycle, liquid–liquid extraction is the selected separation method. For an improved design of new extracting agent, the knowledge of the coordination polyhedra of the metal ions is important. In this paper, we investigated the coordination sphere of a series of uranyl complexes with selected organophosphorus extracting molecules: $UO_2(NO_3)_2L_2$ (with L = tri-*iso*-butylphosphate, tri-*n*-butylphosphate, trimethylphosphate and triphenylphosphate) using X-ray absorption spectroscopy. FEFF7 calculations of the EXAFS spectra corresponding to the model compound $UO_2(NO_3)_2(TiBP)_2$ (with TiBP = tri-*iso*-butylphosphate) for which the crystal structure is known led to a multiple scattering approach of the data fitting. EXAFS results show subtle U–O(P) bond distance differences between the different complexes that are discussed in terms of both electronic and steric effects of L. These results are discussed with regards to the extraction ability of L. In the same time, exploratory work has been attempted in order to evaluate U–O–P bond angle variations as a function of L using multiple photon-scattering paths. Satisfactory values have been obtained compared to the crystallographic data. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

The chemical species involved in the PUREX liquid–liquid extraction process of the back-end of the nuclear fuel cycle are still poorly identified, particularly concerning the coordination polyhedra of the complexes of actinide ions (e.g. U(VI), Pu(IV)) present in the solvent. The molecular processes underlying the macroscopic behavior of extraction must be more clearly understood for a possible improved future control of behavior of the elements to be separated in this industrial process.

The determination of structural data in a liquid medium demands probing the local order of the target element (uranium in this work) in order to determine its radial distribution function (i.e. nature, number and distances of the neighbor atoms). Coupled with other spectroscopic techniques such as infra-red, Raman and NMR spectroscopies, the information obtained by X-ray absorption spectroscopy (XAS), in conjunction with a molecular model, should contribute significantly to progress in the molecular design of new extractants.

In a previous study [1], we described the use of XAS to investigate the local order around the uranium atom within the complex $UO_2(NO_3)_2(TBP)_2$ (TBP = tributylphosphate) in solution in pure liquid TBP. Solid state compound $UO_2(NO_3)_2(TiBP)_2$

(TiBP = tri-*iso*-butylphosphate) of known crystallographic structure was taken as a reference compound by extensive use of *ab initio* XAS calculation code FEFF7 [2]. In the present paper, we continue to investigate the series of homologous extractants of the $PO(OR)_3$ type (where R = *iso*-butyl, butyl, methyl and phenyl groups, respectively) in order to try to understand the variation in the extracting power† of the organophosphate for uranyl nitrate. Oda *et al.* have recently calculated the contribution of the alkyl groups of the phosphate in the extracting ability of $PO(OR)_3$ of the $UO_2(NO_3)_2[PO(OR)_3]_2$ complexes (with $[PO(OR)_3]$ = T*i*BP, TBP and TMP) [3, 4]. According to these authors, and on an electronic point of view, the extracting power which varies in the order T*i*BP ≈ TBP > TMP ≫ TPhP [5] might be partly explained by the differences in the electron donating ability of the alkyl groups of the organophosphate (the TPhP case is however not discussed in these works). In the present work, the coordination sphere of the uranium atom is fully described for the four complexes $UO_2(NO_3)_2[PO(OR)_3]_2$ in order to evaluate the relation, if any, between the extracting power and the complex geometry. This is achieved by means of both single and multiple scattering approaches using code FEFF7. This way, all contributions from oxygen, phosphorus and nitrogen atoms (Fig. 1) are to be identified and used in the fitting procedure using FEFFIT code [6].

EXPERIMENTAL

Synthesis

$UO_2(NO_3)_2$(T*i*BP)$_2$ and $UO_2(NO_3)_2(TBP)_2$ were prepared as described in Ref.[1].

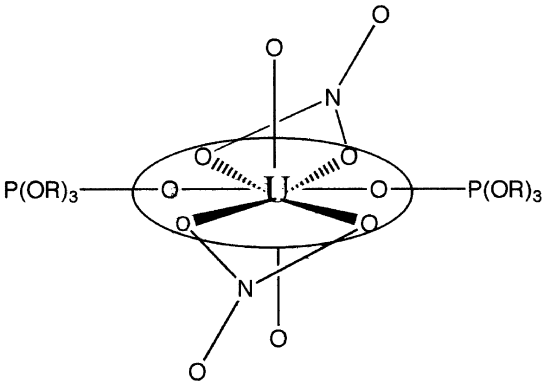

Fig. 1. Schematic representation of the uranyl equatorial plane in $UO_2(NO_3)_2L_2$ complexes where L is an organophosphorus ligand.

†Note that for TMP the U(VI) extracting power is rather low due to the high solubility of TMP in aqueous solutions and not to the peculiar weakness of the interaction between $UO_2(NO_3)_2$ and TMP.

$UO_2(NO_3)_2(TMP)_2$ solvate was prepared in an excess of TMP by dissolving 5.3 g (0.0106 mol) of $UO_2(NO_3)_2 \cdot 6H_2O$ (Prolabo grade) in 25 ml (0.21 mol) of pure TMP (Aldrich grade). Uranium(VI) concentration was determined to be 100 g/l (0.42 mol/l).

$UO_2(NO_3)_2(TPhP)_2$ was prepared from an excess of pure liquid TPhP at 60°C by dissolving 0.5 g of $UO_2(NO_3)_2 \cdot 6H_2O$ (0.0010 mol) in 2.7 g (0.008 mol) of melted TPhP (Aldrich grade). Uranium (VI) concentration was determined to be 71 g/l (0.30 mol/l). The complex remained in the liquid phase even at room temperature when introduced in the EXAFS liquid cell, but slowly crystallized for IR analysis.

IR spectroscopy

IR spectra were recorded for both liquid (on a ZnSe horizontal attenuated transmitted reflectance crystal) and solid phase (in KBr pellets) on a Nicolet Magna 560 spectrometer.

IR spectra all show the characteristic uranyl O–U–O stretching band around 940 cm^{-1} (italicized in the frequency list). Also, a sharp band due to the stretching vibration mode of the P–O–C bond appears around 1030 cm^{-1}, which is in agreement with previous studies on these phosphate ligands [1, 7]. Further structural information can be hardly deduced from these results, but the similarity of all spectra compared with that of solid $UO_2(NO_3)_2$(T*i*BP)$_2$ complex suggests the formation of the uranyl nitrate organophosphate complexes with TBP, TMP and TPhP ligands.

EXAFS spectroscopy

Data recording and data treatment. EXAFS measurements were carried out at LURE at the DCI high energy ring (1.800 GeV, $\lambda_c = 3.7$ keV) on D44 experimental hutch [8]. Transmission detection mode was used with two ionization chambers filled with argon. Spectra were taken at the uranium L_{III} edge (17166 eV) using a double crystal Si 311 monochromator.

Sample quantities were calculated in order to obtain an X-ray absorption jump close to 1 after the edge. Solid state sample (71 mg/mm^2) was dispersed in cellulose and then pressed in order to obtain a solid pellet placed in a sample holder. Liquid samples were measured in an *in house* [9] liquid cell (path length = 3 mm) at room temperature.

Data treatments were carried out using *in house* codes [10]. A straight line was used for background removal and polynomial function of order five was used to simulate the U atomic absorption. Fourier transformed (FT) window (Kaiser window with shape parameter = 2.5) was used between 3.5 and 14.5 Å^{-1}.

Data adjustment. Data adjustments were carried out using the FEFFIT code [6] that is related to the *ab initio* simulation code FEFF. Electronic parameters used to fit the spectra of the unknown compounds (electron mean free path λ, intrinsic losses, phases and amplitudes) were extracted from the simulation of solid state complex $UO_2(NO_3)_2(TiBP)_2$ at 77 K using FEFF7 code.

Adjustments were conducted in two times for each sample: (i) adjustment of the filtered single scattering contributions of the FT between 0.7 and 2.9 Å and (ii) adjustment of the total EXAFS spectrum.

Determination of global parameters, energy threshold e_0 and amplitude losses $S0^2$, was achieved by first fitting the 0.7/2.9 Å range and total spectrum on model compound $UO_2(NO_3)_2(TiBP)_2$, giving $e_0 = 2.96$ eV and $S0^2 = 1.25$. These two parameters were kept constant in all other adjustments of all other complexes.

Fitting of the 0.7/2.9 Å range was achieved by fitting both Debye–Waller factors and bond distances of the five first paths A–E (see details in the text). Debye–Waller factors of paths C and D were linked since these two paths account for the two U–O(N) contributions of the same NO_3^- ligand.

Fitting of the total EXAFS spectrum was achieved as described in details in the text (*vide infra*).

Evaluation of the goodness of the fit is given by the *r* factor (related to the statistical CHI^2 function) as fully described in Ref.[6].

RESULTS AND DISCUSSION

In order to evaluate the modifications of the uranyl nitrate coordination spheres, going from TBP to TPhP ligands, a detailed analysis of the uranium photoelectron scattering paths was undertaken. Based on our previous study of the uranium coordination sphere [1] in solid state compound $UO_2(NO_3)_2(TiBP)_2$, path enumeration was fully accomplished on this complex using FEFF7 code. According to this, quantitative adjustments of the filtered FT were carried out in two times for all four complexes.

In the first time, only single scattering paths were considered in the fit of first and second uranium coordination spheres that include all the first neighbor oxygen atoms as well as the two nitrogen atoms of the nitrate groups. In the second time, eleven single and multiple scattering paths were included to fit the total EXAFS spectra.

Uranium photoelectron scattering path enumeration of compound $UO_2(NO_3)_2(TiBP)_2$

Figure 2 shows the Fourier transform (FT) of the calculated (FEFF7) EXAFS spectrum of solid state $UO_2(NO_3)_2(TiBP)_2$ at 77 K. All the 540 scattering paths that contribute to the total EXAFS spectrum for more than 0.1% were included (path amplitudes are normalized with respect to the amplitude of the most intense path over the entire *k* range, set to 100%). However, only paths that contribute for more than 10% were isolated and presented in Fig. 2 for the seek of clarity. These eleven paths are detailed in Table 1.

Each path contributes constructively or destructively to the total EXAFS spectrum, depending on its phase. Figure 3 presents the EXAFS oscillations of each of these paths, showing the different phasors (i.e. the entity $Fi\sin(2\delta_c + \phi + 2kri)$, where *Fi* is the global path *i* amplitude, δ_c is the central atom phase-shift, ϕ the back-scatter phase-shift and *ri* the total path length) that are characteristic of both path length and atoms involved. For instance, paths C and D that both account for U–O(N) single scattering with almost the same path length are completely constructive. It is also to be noted that multiple scattering paths that involve forward scattering are particularly intense, as for example paths F and I. All multiple paths that do not include forward scattering are less than 10% intense.

The path enumeration also shows that single scattering paths that involve all the oxygen first neighbors as well as the two nitrogen atoms of the two nitrate groups can be isolated within a filter window between 0.7 and 2.9 Å (not phase-shift corrected).

Single scattering path fitting

Taking the filter window (0.7–2.9 Å) and neglecting the small part of multiple scattering paths that is included in it, a pure single scattering approach is a reasonable approximation to fit the contributions that occur in this window. The five first paths were therefore included in the fitting procedure of the filtered EXAFS spectra of compounds $UO_2(NO_3)_2(TiBP)_2$, $UO_2(NO_3)_2(TBP)_2$, $UO_2(NO_3)_2(TMP)_2$ and $UO_2(NO_3)_2(TPhP)_2$. Structural parameters (i.e. U–X (X = O, N atoms) distances and their corresponding Debye–Waller factors) that were obtained are displayed in Table 2. Best fits of the filtered EXAFS oscillations are presented in Fig. 4. In the case of $UO_2(NO_3)_2(TiBP)_2$ at 77 K, bond distances compare satisfactorily within the error of ± 0.02 Å with the U–O structural data given by X-ray diffraction at 77 K for this solid state complex [11]. It is however not surprising that path E is

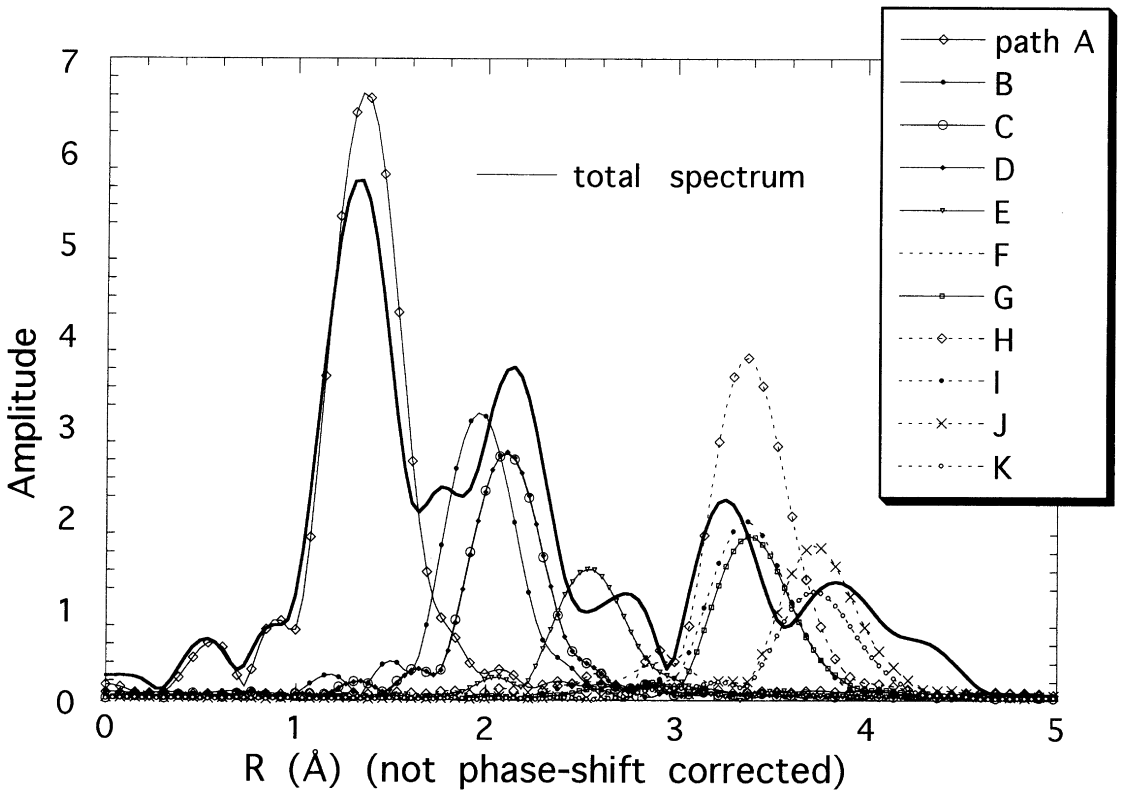

Fig. 2. Modulus of the Fourier transform (FT) of the calculated EXAFS spectrum (FEFF7) of $UO_2(NO_3)_2(T\textit{i}BP)_2$ complex. Moduli of the FTs of the main photoelectron scattering paths are also represented.

less accurately determined (within the error of $+0.04$ Å) since it does not correspond to a chemical bond between the central atom and the backscattering atom. For the solid state complex $UO_2(NO_3)_2(T\textit{i}BP)_2$ at both 77 and 298 K, all bond distances compare well. This differs from previous work results [1] that overestimated the U–O(P) bond distance r_p for this complex at room temperature. We attribute this fluctuation (-0.05 Å) to the new fitting procedure and fitting code that we used in this work, yielding to a better estimation of the energy threshold e_0 that is directly linked to the determination of the bond distances. The e_0 value taken here is equal to 17178.3 eV for all paths, whereas e_0 used in our previous study was allowed to vary for each path, being respectively equal to 17182.4 eV for U–O(UO_2^{2+}), 17194.1 eV for U–O(P) and 17189.8 eV for U–O(N). The very high discrepancy between e_0 for the U–O(P) path and the two other ones may be at the origin of r_p over-estimation in our previous work.

Considering the TBP solution complex, it was previously shown that there is no significant difference in r_p when the *iso*butyl groups in the solid state complex are replaced by the butyl ones in the liquid phase complex, both at 298 K. This result is confirmed here and the lengthening of r_p of $+0.03$ Å lies within the error bars. On the other hand, the significant shortening of r_p from $UO_2(NO_3)_2(TBP)_2$ to $UO_2(NO_3)_2(TMP)_2$ (-0.05 Å), both measured at room temperature in the liquid phase, seems to be caused by the replacement of the butyl groups by the methyl groups. Furthermore, this compares well with the X-ray diffraction measurements carried out on the TMP complex in the solid state [12]. Our assumption is that the steric hindrance of the phosphate ligand plays the main role in the structure modification. In fact, it has been shown using relativistic molecular orbital calculations that a decrease of the electronic donor effect of the alkyl group (in the order TBP > TMP) leads to a decrease of the strength of the covalent U–O(P) bond in the order TBP > TMP and thus must result in a decrease of r_p from TMP to TBP [3]. The opposite phenomenon is observed here. We think that the size of the TMP ligand allows it to approach the UO_2^{2+} coordination plane closer than the TBP ligand does, thus leading to a smaller value of r_p for TMP complex. On the contrary, the small variation of $+0.02$ Å between r_p in $UO_2(NO_3)_2(TMP)_2$ and in $UO_2(NO_3)_2(TPhP)_2$ which stays within the error bars, is not considered significant. However, it is be surprising that r_p does not increase from TMP to TPhP ligand because of the substitution of the methyl by the phenyl groups. To explain this experimental fact, two phenomena may be considered: an electronic effect due to the participation of the phenyl rings that are electron withdrawing and therefore should contribute

to weaken the bond (i.e. lengthen r_p), and a steric effect that should play the same role as TBP does compared to TMP (i.e. lengthen r_p). Our assumption is then that the phenyl groups might be stack together in a way that the steric hindrance is minimized, thus accounting for the relatively low value of r_p.

According to these results and as it might have been expected, r_p seems to be directly related to the nature of the hydrocarbon groups of the organophosphate, mainly because of steric effects of the ligand instead of electronic effects.

Using the multiple scattering paths that are particularly sensitive to bond distortions (i.e. forward scattering paths that are resonant for bond angles of 180° [13]) we further attempted to adjust the total EXAFS spectra of all complexes, allowing the dis-

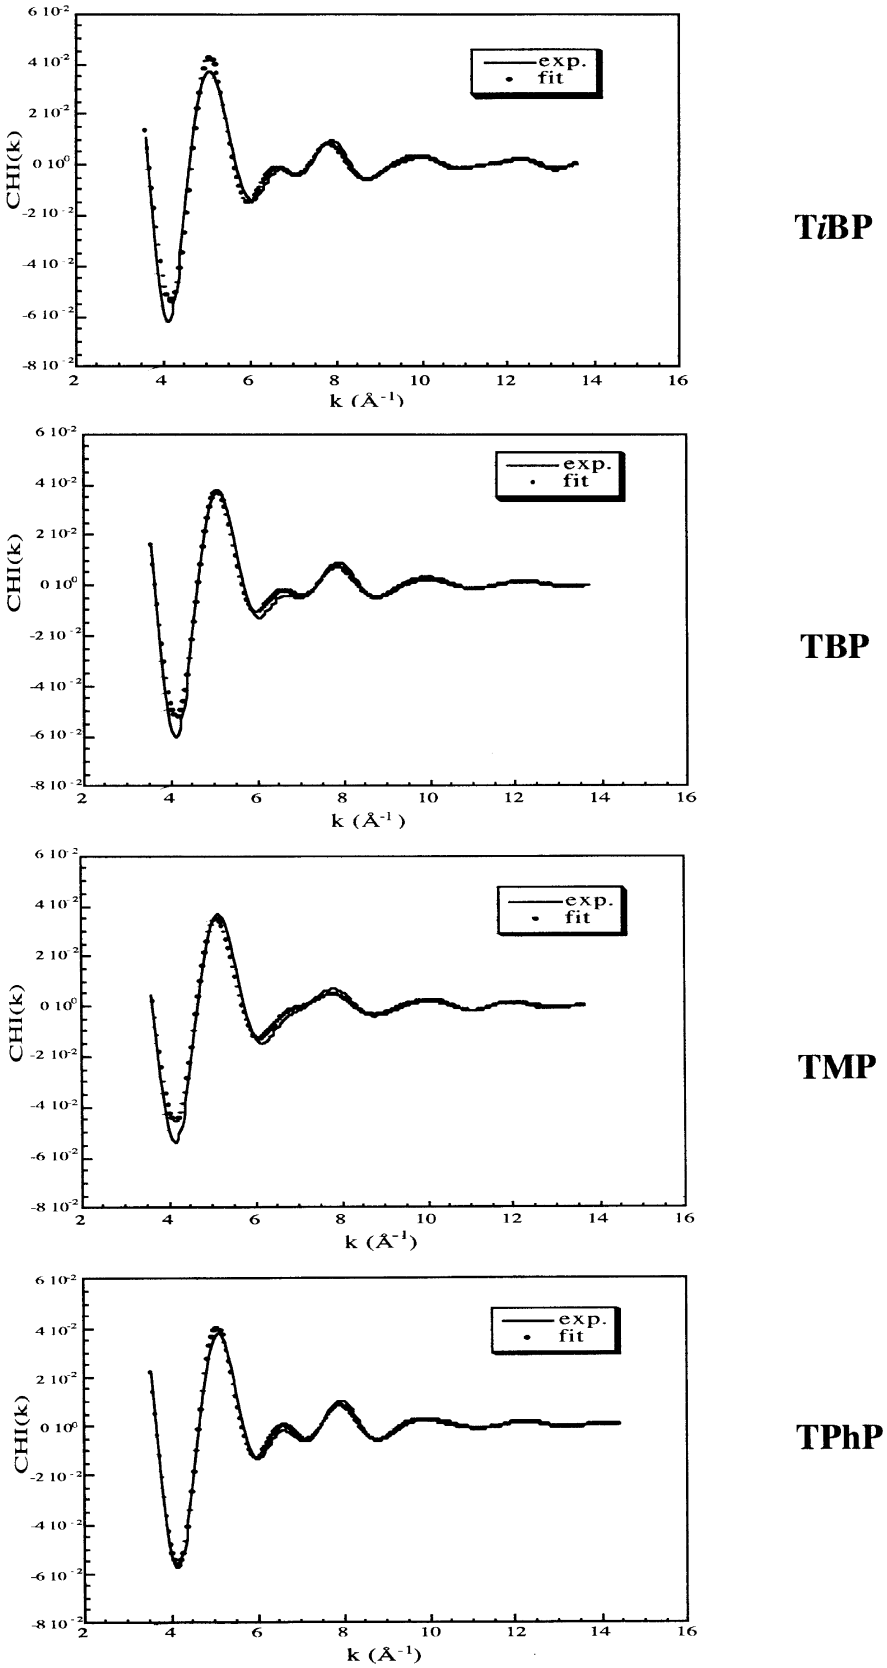

Fig. 4. Adjusted filtered EXAFS oscillations (between 0.7 and 2.9 Å) of $UO_2(NO_3)_2L_2$ complexes (L = T*i*BP, TBP, TMP, TPhP) in the single scattering approximation. All complexes are in the liquid phase (298 K) except for the solid state complex $UO_2(NO_3)_2(Ti BP)_2$ (77 K).

tortion of the U–O–P bond, if any, to vary. This is a first attempt for further bond distortion estimation in series of related compounds.

Multiple scattering approach

Further analysis of the five spectra was carried out by fitting the crude total EXAFS spectra considering the eleven paths A–K that have been defined before. In the fitting procedure, both Debye–Waller factors and bond distances of the first five paths were fixed equal to the values determined in the first adjustment of paths A–E.

In these adjustments, we took into account the distortions of the U–O–P bond that might occur when varying the hydrocarbon parts of the phosphate ligand. Forward scattering paths H and I are then of particular interest since they are the most sensitive of all eleven paths to any modifications of the U–O–P bond geometry.

In order to first test the sensitivity of the total EXAFS spectra of the organophosphate complexes to the U–O–P bond distortions (distortions considered are of two kinds: bond length elongation and bond angle variation), total EXAFS spectrum reconstruction was carried out using the eleven paths calculated from the simulation of model structure of $UO_2(NO_3)_2(TiBP)_2$ with FEFF7. Within two sets of calculations, paths H and I were both modified in order to simulate with calculated EXAFS spectra (i) bond length elongations of r_p and (ii) bond angle modifications of the U–O–P bond characterized by the δ angle, all other parameters being unchanged. The two parameters δ and r_p are identified as shown below and compared to the corresponding crystallographic values: $r_p = 2.37$ Å and $\delta = 164^\circ$ of $UO_2(NO_3)_2(TiBP)_2$ at 77 K.

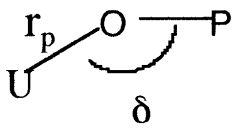

Figure 5 presents the two simulation sets and shows the influence of δ and r_p on the beating at 10 $Å^{-1}$ in the reconstructed EXAFS spectrum. Both parameter values affect the same region of the EXAFS spectrum. However, in the fitting of the experimental spectra, r_p is fixed to the value determined in the fitting of the filtered single scattering contributions (r_p is fixed by the fit of path B).

In the fitting procedure of the five experimental spectra, bond distances of paths F–K were linked and fitted according to the description of Table 3. Modification of δ in paths H and I was also taken into account by scaling the specific amplitudes $f_H(k, \delta)$ and $f_I(k, \delta)$ of these two paths by a constant factor F (all other amplitudes of all other paths being unchanged with regard to FEFF7 calculations). In order to determine the scaling factors $F_H(\delta)$ and $F_I(\delta)$, molecular models of $UO_2(NO_3)_2(TiBP)_2$ with different values of δ were generated using INSIGHT II molecular modeling system from MSI and their EXAFS spectra were simulated by FEFF7. For each δ value, $f_H(k, \delta)$ and $f_I(k, \delta)$ were plotted against k and curve fitted at 8 $Å^{-1}$ in order to get $F_H(\delta)$ and $F_I(\delta)$ for which δ was included in the fit as a free parameter. Debye–Waller factors of paths F–K were found to be highly linked with the value of δ. To avoid this influence of Debye–Waller values on δ, Debye–Waller factors of multiple scattering paths were fitted, given they were all kept equal to each other. While this is a fairly crude approximation, we have found however that adjusting the six different factors leads to unrealistic instabilities on the fit result. In all cases, oscillation amplitude below 5 $Å^{-1}$ (delimited by the vertical line in Fig. 6) is poorly adjusted, mainly because of poor estimation of the amplitude parameters by FEFF7 at low k values. This is however not affecting the fit results since the number of uranium neighbors N is not adjusted here.

Table 4 gives the best fit parameters that were obtained. The value found for $UO_2(NO_3)_2(TiBP)_2$ at 77 K, $\delta = 156^\circ$, agrees within 5% error with the crystallographic value: 164°. This is a very satisfactory agreement showing that both the number of paths considered here and the fitting approximations can account for simulating the experimental EXAFS spectra. Precision on the δ value is however to be taken

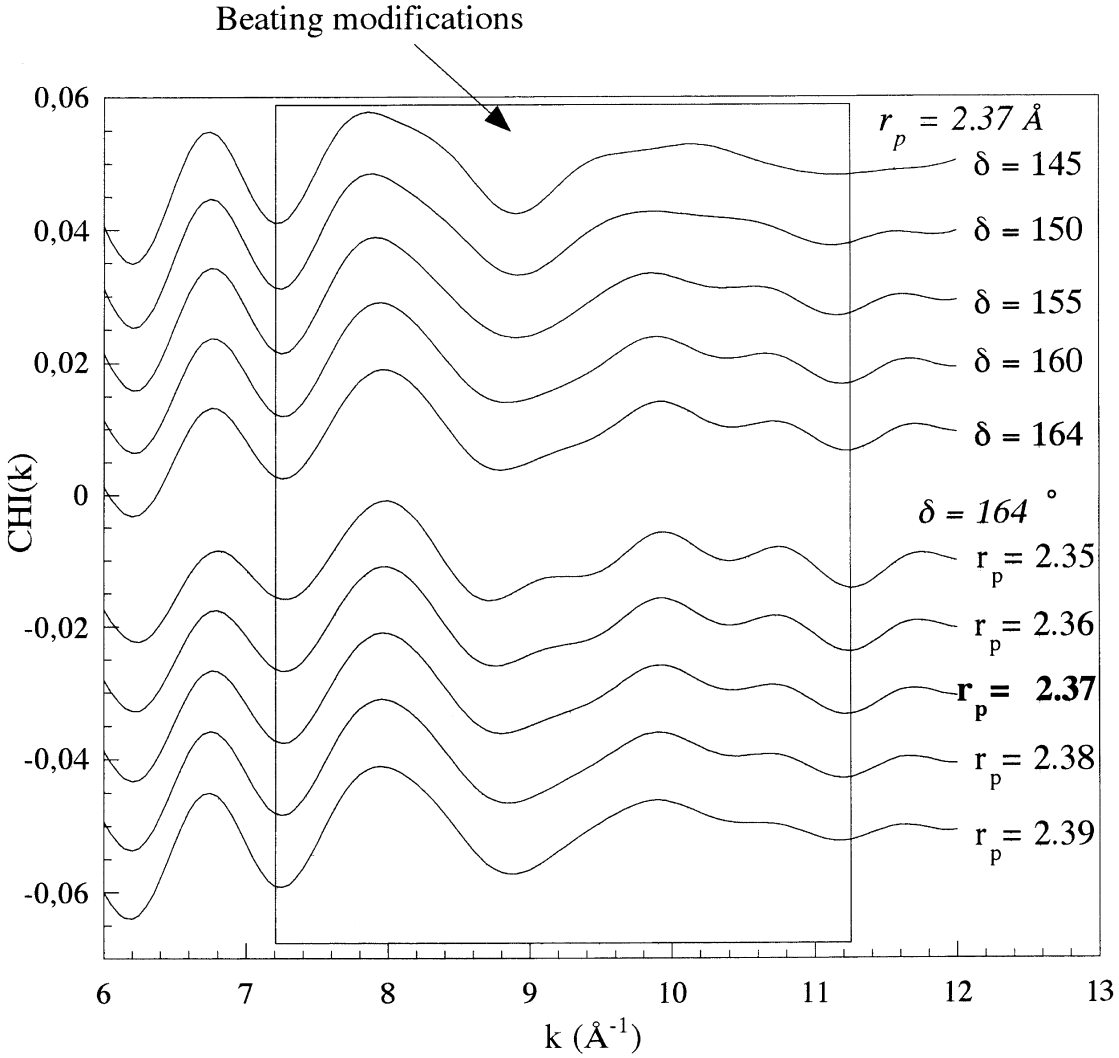

Fig. 5. Simulated EXAFS oscillations (FEFF7) based on solid state model complex $UO_2(NO_3)_2(TiBP)_2$. In the first simulation set, the U–O–P bond angle, δ, is varied and the U–O(P) bond length, r_p, is set to the crystallographic value 2.37 Å. In the second simulation set, the U–O–P bond angle, δ, is set to the crystallographic value (264°) and the U–O(P) bond length, r_p, is varied.

Table 4. Best fit parameters of the total EXAFS spectra adjustment of $UO_2(NO_3)_2(TiBP)_2$, $UO_2(NO_3)_2(TBP)_2$, $UO_2(NO_3)_2(TMP)_2$ and $UO_2(NO_3)_2(TPhP)_2$ complexes (all structural parameters that are not presented here are those given in Table 2)

Complex	δ value (°)	σ (Å)	r factor
$UO_2(NO_3)_2(TiBP)_2$ at 77 K	156 ± 3	0.053	0.06
$UO_2(NO_3)_2(TiBP)_2$ at 298 K	157 ± 3	0.058	0.06
$UO_2(NO_3)_2(TBP)_2$ at 298 K	172 ± 10	0.066	0.04
$UO_2(NO_3)_2(TMP)_2$ at 298 K	161 ± 7	0.089	0.08
$UO_2(NO_3)_2(TPhP)_2$ at 298 K	142 ± 5	0.067	0.06

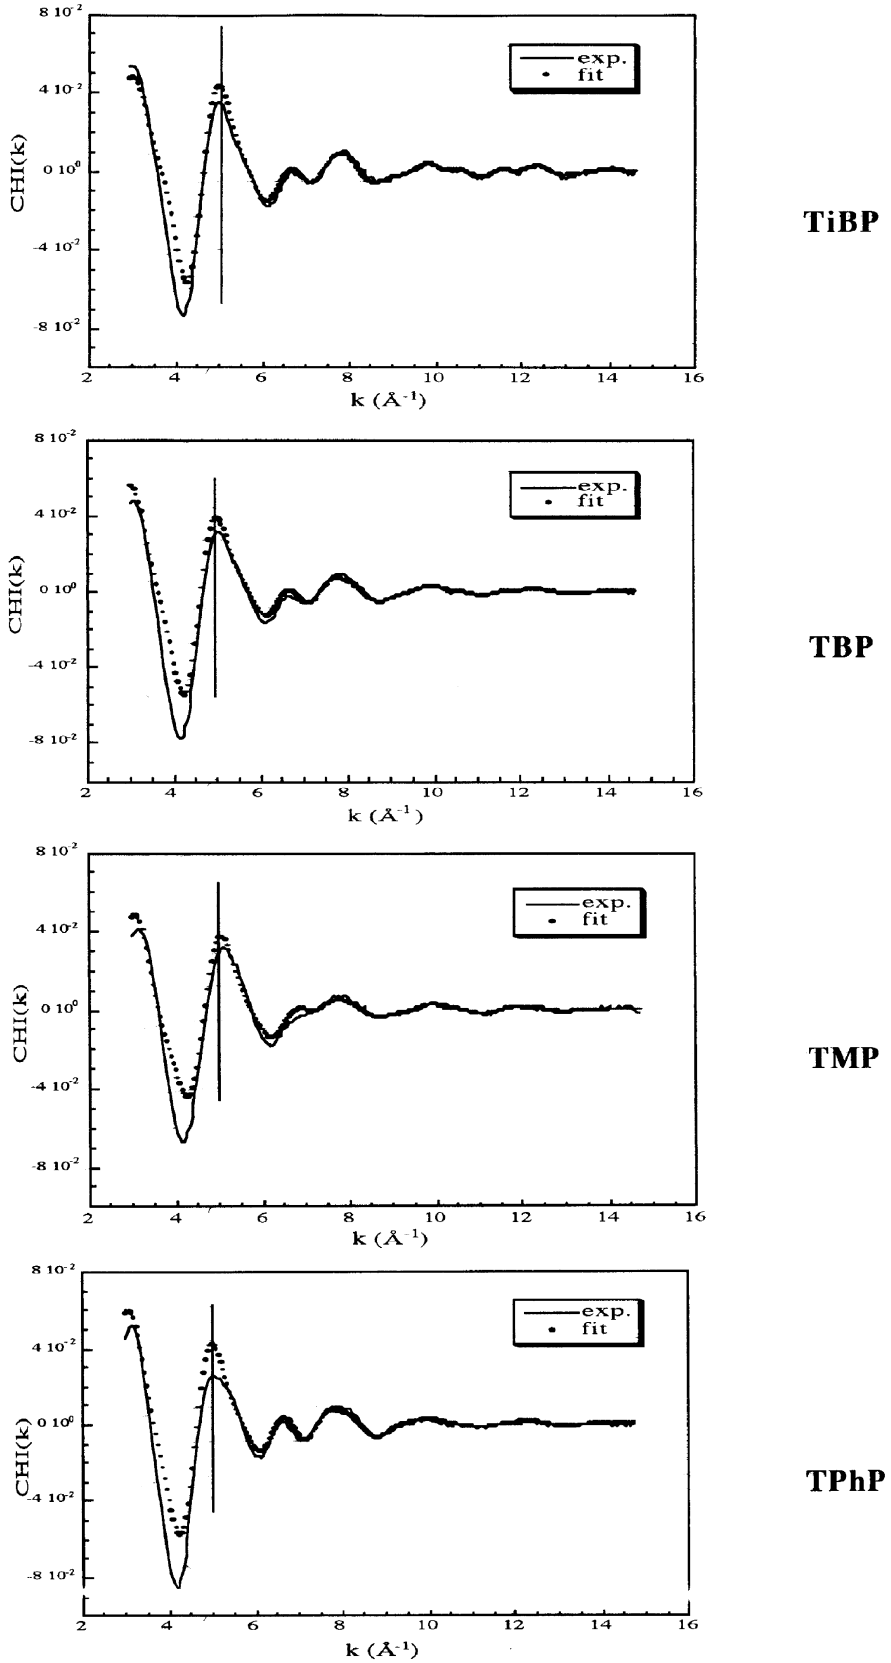

Fig. 6. Adjusted total EXAFS oscillations of $UO_2(NO_3)_2L_2$ complexes (L = T*i*BP, TBP, TMP, TPhP) in the single multiple scattering approximation. All complexes are in the liquid phase (298 K) except for the solid state complex $UO_2(NO_3)_2(Ti BP)_2$ (77 K).

very carefully since the evaluation of many parameters used in the model (as the Debye–Waller factors, the amplitude losses, amplitude of the multiple scattering paths to be taken into account as a function of δ and r_p) have still to be improved.

All δ values, except for the TPhP ligand, agree within 5% with the T*i*BP complex crystallographic value. It is striking that the δ_{TPhP} value is significantly smaller than the other δ values. This might be related to our assumption concerning the peculiar arrangement of the phenyl groups, as described above.

In light of these results (i.e. in the complexes $UO_2(NO_3)_2L_2$, r_p ranks in the order $L = TBP > TMP \approx TPhP$), a simple correlation between the extraction affinities of L for $UO_2(NO_3)_3$ (in the order $L = TBP > TMP \gg TPhP$) and shortest r_p distances is not established. More than electronic interactions between U and O phosphoryl atoms, steric hindrance as well as lipophilicity of L should be taken into account. It is therefore still not clear why L = TPhP is such a poor extractant molecule compared to TBP.

CONCLUSIONS

The results presented here are related to the characterization of uranyl nitrate coordination sphere when complexed by organophosphorus ligands. When varying the nature of the hydrocarbon groups of the organophosphate, a modification of the U–O(P) bond length r_p is observed. Decrease of r_p for the liquid phase complexes at room temperature is in the order $TBP > TMP \approx TPhP$. In all cases, this variation is attributed to a decrease of the steric hindrance of the hydrocarbon groups that allows a better approach of the ligand coordinating atom in the uranyl coordination plane.

Furthermore, tentative work using a multiple scattering approach was undertaken in order to adjust the total EXAFS spectra and accounting for U–O(P) bond distortions. Satisfactory fitting results were obtained, showing the validity of the approximations used. Not only U–O(P) bond distances were determined, but our model was able to evaluate satisfactorily U–O–P bond angles. Improvement of the method should include in the future better estimation of the Debye–Waller factors for multiple scattering paths. We believe that a major part of the uncertainties in bond angle evaluations may be caused by this poor estimation of these factors.

Our study is part of major efforts in understanding the structure–properties relationship in the field of solvent extraction. This type of approach of structure–affinity relationship was recently studied by Rabbe *et al*. [14] in the case of the uranyl nitrate extraction by monoamide extractants.

Abstract—The first metal–dmit polymeric complex, $[(Et_4N)_2\{Ag_4(dmit)_3\}\cdot DMF]_\infty$, has been synthesized and structurally characterized. The crystal of the complex is monoclinic with space group C2/c, $a=32.078(4)$, $b=11.791(2)$, $c=29.409(4)$ Å, $\beta=124.14(1)^\circ$, $V=9206.8$, $Z=8$, $R=0.053$, $R_w=0.061$. In the complex, the S · · · S contacts exist both intra- and inter-molecularly, through the intermolecular S · · · S contacts shorter than 3.7 Å the two-dimensional polymeric anions form a three-dimensional unique supramolecular networks.

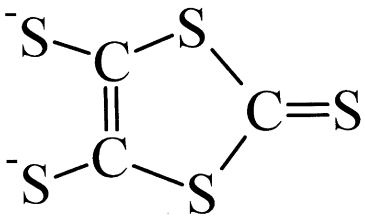
INTRODUCTION

The supramolecular chemistry has been one of the important research fields of chemists [1,2] due to the goals of developing advanced materials. Intermolecular interactions such as hydrogen bonding, S · · · S contacts and π–π stacking are efficient organizing forces in supramolecular architecture and the design of new solid-state materials for a number of applications. Some of the metal–dmit complexes with S · · · S contacts were reported to exhibit conductivities and even superconductivities [3–5]. Recently, it has been shown that intermolecular interactions in transition metal bis(dithiolate) complexes of this type are also important for the assembly of molecular ferromagnets [6]. A large number of metal–dmit complexes have been synthesized and structurally characterized, however, no polymeric compound with dmit has been reported.



We report here the crystal structure and electrical properties of the metal–dmit complex $[(Et_4N)_2\{Ag_4(dmit)_3\}\cdot DMF]_\infty$ **1**, which is the first example of polymeric compounds with dmit.

EXPERIMENTAL

All procedures for preparation of the title complex were carried out under nitrogen atmosphere using standard Schlenk techniques. The chemicals used in the experiment were of A.R. grade and were used without purification. 4,5-Bis(benzoylthio)-1,3-dithiole-2-thione was prepared following the detailed procedure described by Steimecke [7]. Elemental analysis was performed by the Elemental Analysis Laboratory

* Author to whom correspondence should be addressed. E-mail: wxt@ms.fjirsm.ac.cn

in our institute. The UV–VIS spectra and IR spectra of the complex were recorded on a Schimadyzu UV-3000 and a Perkin Elmer 577 spectrometer. Electrical resistivity was measured by a conventional two-probe method with compacted pellets.

Preparation of $[(Et_4N)_2\{Ag_4(dmit)_3 \cdot DMF]_\infty$

0.408 g (1.0 mmol) of 4,5-bis(benzoylthio)-1,3-dithiole-2-thione was dissolved in a methanol (30 ml) solution containing 0.046 g (2 mmol) of sodium metal. To the resulting purple solution of $Na_2[C_3S_5]$ was added under stirring 10 ml of concentrate ammonia solution containing 0.085 g (0.5 mmol) of $AgNO_3$. After being stirred for a while at room temperature, to the reaction mixture was added 25 ml of methanol solution with an excess amount of Et_4NBr (0.53 g, 2.5 mmol), precipitating immediately the red product. The red precipitate was collected by filtration and re-dissolved in 10 ml of DMF, then it was filtered after stirring for several minutes, and the filtrate was diffused by gaseous Et_2O and EtOH solvent at room temperature for several weeks to yield the deep-red crystals of the complex. Yield: 0.06 g (35.5%). The crystals are insoluble in CH_3CN, CH_3COCH_3 or CH_2Cl_2. Its X-ray quality crystals were obtained after many experiments. Anal. calcd. for $C_{28}H_{47}N_3OS_{15}Ag_4$: S, 35.52%; C, 24.84%; H, 3.50%; N, 3.10%. Found: S, 35.26%. C, 25.70%; H, 3.50%; N, 3.12%.

IR (KBr pallet, cm^{-1}): 460(s), 527(s), 661(s), 783(s), 866(s), 903(s), 983(s), 997(s), 1035(vs), 1056(vs), 1099(w), 1171(vs). UV–VIS (DMF, λ_{max}, nm) (ε, $dm^3\,cm^{-1}\,mol^{-1}$): 290 (3.28×10^4), 450 (2.99×10^4).

Crystal structure determination

Crystallographic data for the complex are given in Table 1. The intensity data were collected at room temperature on an Enraf–Nonius CAD4 diffractometer. The radiation used was monochromatized MoKα with graphite. The crystal chosen for data collection had dimensions $0.10 \times 0.15 \times 0.25$ mm. The unit cell parameters were determined by least-squares refined with 25 reflections in the $10.94^\circ \leq \theta \leq 12.52^\circ$. Intensity data were collected in the range $3^\circ \leq 2\theta \leq 50^\circ$ by the ω–2θ scan technique. A total of 8545 reflections were collected, of which 7931 were unique and 4453 observed, $I > 5.0\sigma(I)$. Intensities were corrected for Lorentz and polarization effects, and DIFABS [8] empirical absorption correction was applied. The structure was solved by the direct method using MULTAN [9], from which four Ag atoms were obtained. The rest of non-hydrogen atoms were obtained from subsequent difference Fourier map. The non-hydrogen atoms in the anion were refined anisotropically, and other non-hydrogen atoms were refined isotropically, whereas the positions of the hydrogen atoms calculated in ideal positions and their isotropical thermal parameters were fixed. Non-hydrogen scattering factors were taken from Cromer and Waber [10]. All calculations were performed on a

RESULTS AND DISCUSSION

$[Ag_4(dmit)_3]_n^{2n-}$ is shown in Fig. 1. Selected bond lengths and bond angles for the complex are given in Tables 2 and 3, respectively. It is revealed that **1** consists of $[Ag_4(dmit)_3]$ repeating units and the dmit acts as a bridging and chelating ligand with coordination to silver atoms. In the repeating unit, the four silver atoms are in a distorted tetrahedral arrangement, and the tetrahedral metal frame is held together by three dmit ligands. It is noted that in **1** the sulfur atom of the thiocarbonyl group is able to coordinate and it does so by Ag(1) and Ag(4) atoms to form a two-dimensional structure polymer. In the anion of **1**, Ag(2) and Ag(3) have a distorted trigonal-planar sulfur coordination, with S–Ag–S angles of 89.2(2) to

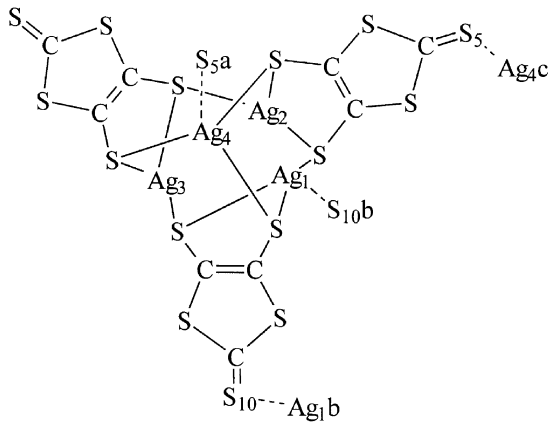

Fig. 1. X-ray structure of **1** with atom numbering scheme (dashed lines indicate S · · · S contacts shorter than 3.7 Å).

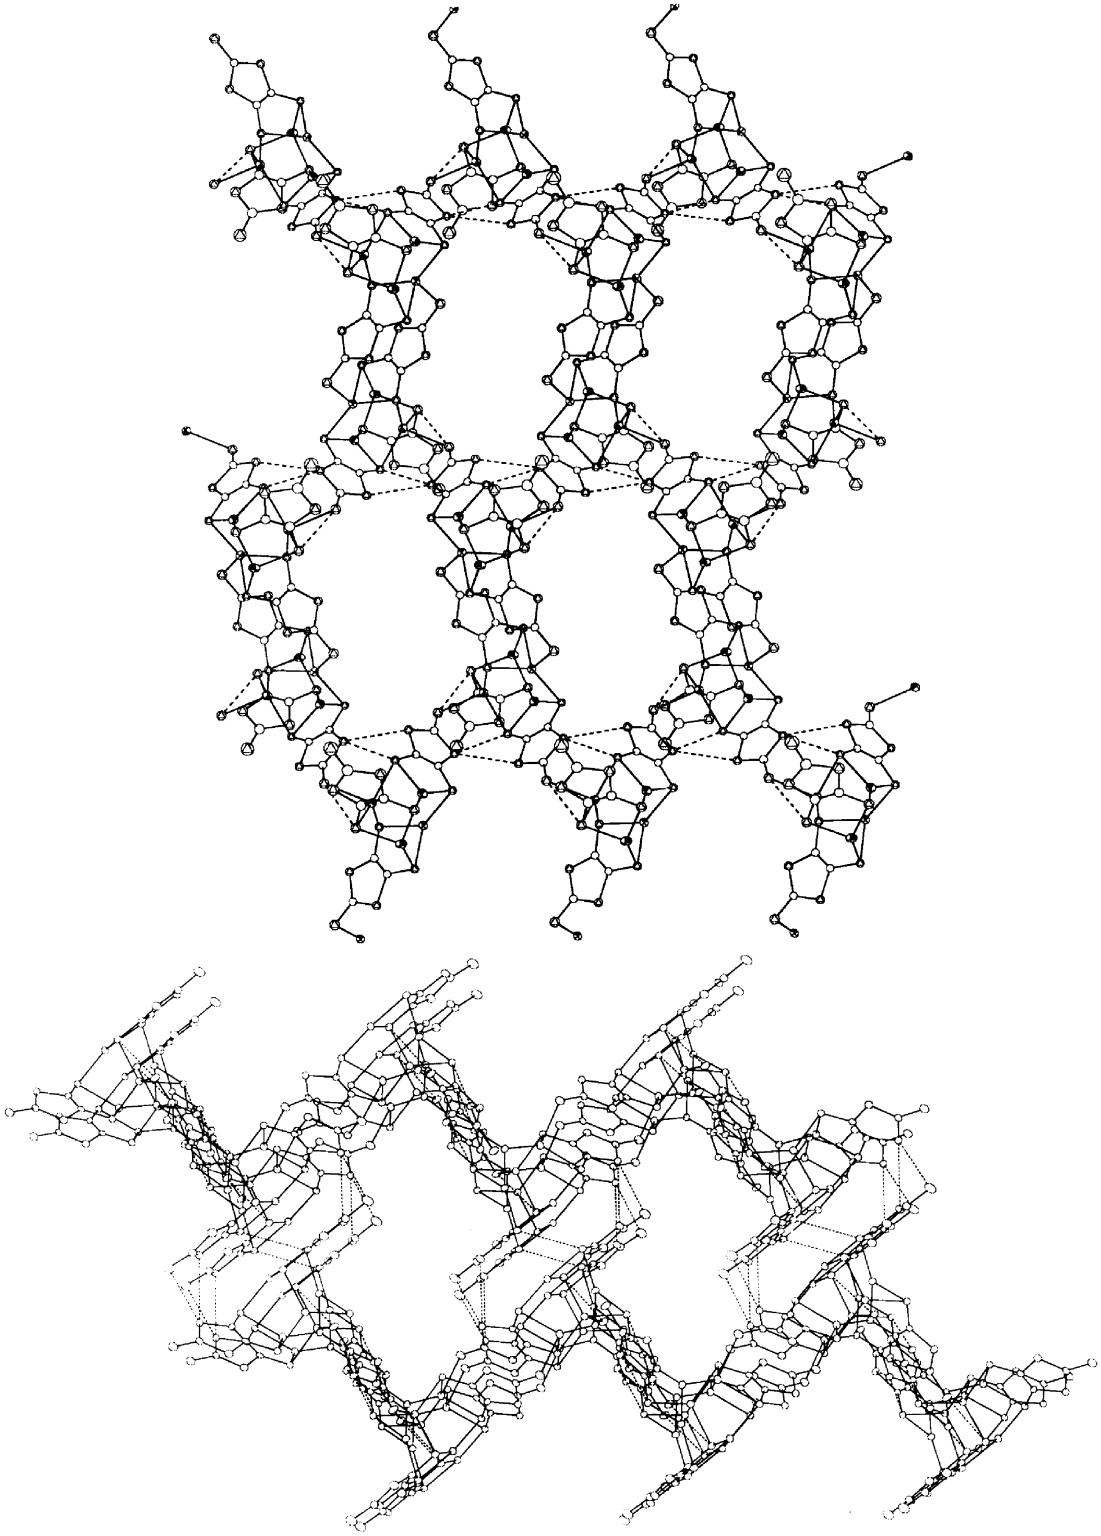

Fig. 2. (a) The two-dimensional sheet structure of **1** viewed down the *a* axis; (b) the crystal packing of **1** viewed down the *b* axis (the Et_4N^+ cations and DMF solvent molecules are omitted for clarity, dashed lines indicate S · · · S contacts shorter than 3.7 Å).

147.2(1)° and 87.4(1) to 146.4(1)°, whereas Ag(1) and Ag(4) have a distorted tetrahedral sulfur coordination, with S–Ag–S angles of 88.1(1) to 133.4(1)° and 86.8(1) to 121.00(9)°, respectively. The Ag–S bond distances in the repeating unit of **1** range from 2.417(3) to 2.600(4) Å, and are comparable to those in $[Ph_4N]_2[Ag_4(SCH_2C_6H_4\ CH_2S)_3]\cdot 6MeOH$ [12], whereas those between the two repeating units (Ag(1)–S(10b), 2.797(1) Å, Ag(4)–S(5a), 2.733(1) Å) are relatively longer, but shorter than the related Ag–S bond length of 2.812(4) and 2.841(1)–2.920(1) Å reported in the literature [13,14]. In the three dmit ligands, the bond-lengths of S–C bonds have an average value of 1.72(2) Å, and the bond lengths of C–C bonds have an average value of 1.34(8) Å, which are similar to those of other dmit complexes.

The S · · · S contacts in **1** exist both intra- and inter-molecularly. The intramolecular S · · · S contacts are 3.605(1), 3.552(1) and 3.656(2) Å, respectively. Also, there are three different intermolecular S · · · S contacts of 3.644(1), 3.653(3) and 3.696(1) Å between the two-dimensional polymeric anions (as shown in Fig. 2), through which the anions form a three-dimensional supramolecular network (as shown in Fig. 3).

Electronic absorption spectra of the complex have been obtained. The UV–visible spectrum of the complex in DMF has a characteristic absorption band at 450 nm ($\varepsilon = 2.99\times10^4\,dm^3\,cm^{-1}\,mol^{-1}$). The absorption band is ascribed to the π–π^* transition of the dmit ligand. The similar absorption bands of the π–π^* transition are also observed in the $[Au(dmit)_2]^-$ complex (468 nm in acetonitrile) [15], while the bands for Na_2dmit (514 nm in methanol), $[Zn(dmit)_2]^{2-}$ (530 nm in acetonitrile) and $[Cu(dmit)_2]^{2-}$ (540 nm in acetonitrile) [16] occur at somewhat longer wavelengths.

(Received 3 March 1998; accepted 24 June 1998)

Abstract—Pyridine-2-carbonitrile (2-CNpy) undergoes Cu(II) or Co(II)-promoted hydrolysis to pyridine-2-carboxamide (piaH) and/or pyridine-2-carboxylic acid (pycH). The pathway of pycH formation depends on the presence of 2-amino-2-hydroxymethyl-1,3-propanediol (AL^1) and on the central atom. In the absence of AL^1, Co(II) or Cu(II) ions mediate piaH formation under mild reaction conditions in the first hydrolytic step. Cu(II) ions assist in piaH transformation to pycH by subsequent reflux. In the presence of AL^1 and Co(II), a Co(II) complex containing pyoxaL^1 (2-(2-pyridinyl)-4,4-bis(hydroxymethyl)-2-oxazoline) is formed in the first stage; subsequent decomposition of pyoxaL^1 under the reflux yields pycH. Under similar conditions, no solid Cu(II) complex with pyoxaL^1 can be isolated, but a Cu(II) complex with coordinated pyc$^-$ anions precipitates from the reaction mixture. The synthesis, spectral and magnetic properties of the complexes [Co(H$_2$O)$_2$(piaH)$_2$]Cl$_2$, [Co(H$_2$O)$_2$(pyc)$_2$]·2H$_2$O, [Cu(H$_2$O)$_2$(piaH)$_2$]Cl$_2$, [Cu(pyc)$_2$] and [Cu(pyc)$_2$]·2H$_2$O, including the structure determination of the latter one, are described. © 1998 Elsevier Science Ltd. Keywords: pyridine-2-carbonitrile; hydrolysis; copper(II) complexes; cobalt(II) complexes; crystal structure.

INTRODUCTION

Organic nitriles can coordinate to transition metal ions via their nitrile group (three bonding modes have been described so far; for a review see [1]) or by another donor atom of the organic moiety. In the chemistry of pyridinecarbonitriles, the former mode is typical for pyridine-2-carbonitrile (further denoted as 2-CNpy) while the latter for pyridine-3-carbonitrile and pyridine-4-carbonitrile. It should be pointed out, however, that the coordination of 2-CNpy through the pyridine nitrogen cannot be excluded, at least for kinetically inert complexes [2].

Either mode of 2-CNpy coordination to electron-withdrawing transition metal ions results in enhanced electrophilicity of the nitrile carbon, thus making it susceptible to nucleophiles such as OH$^-$, H$_2$O, ROH, and R–NH$_2$ [1,3].

As it has previously been observed [4–7], the reaction of 2-CNpy with some metal(II) salts in aqueous or alcoholic solutions leads to formation of solid complexes containing pyridine-2-carboxamide (piaH) and *O*-alkylpyridine-2-carboximidate (*O*-Rpii), respectively. It is worth mentioning that a similar metal(II) promoted hydrolysis of the nitrile group to amide was observed in the systems containing 2-carbonitrile-1,10-phenanthroline instead of 2-CNpy [8] for which, based on a kinetic analysis, the authors showed that its mechanism involved an external attack of a non-coordinated OH$^-$ ion to the nitrile group of coordinated ligand.

In the presence of amino alcohols (AL^1–AL^3 in Scheme 1) and 2-CNpy, Ni(II) salts yield solid complexes containing 2-pyridinyl-2-oxazolines (pyoxaL^1-pyoxaL^3) [9] under mild reaction conditions both in water and alcohols. However, Cu(II) and most Co(II) complexes containing oxazolines could be prepared only from ethanolic solution. For example, solid complexes $[CoX_2(pyoxaL^1)_2]$ (X = Cl, Br or NCS) and $[CuX(pyoxaL^1)_2]X \cdot 0.5H_2O$ (X = Cl or Br) have been prepared by the reaction of 2-CNpy with AL^1 in ethanolic solutions of the corresponding Co(II) and Cu(II) salts. Also, solid complexes containing different hydrolytic products of 2-CNpy [10] have been isolated from aqueous solutions. The complexes were not, however, characterized in more detail.

In this paper the results on the hydrolytic reactions of 2-CNpy in the presence or absence of AL^1 in aqueous solutions of copper(II) and cobalt(II) salts are given. The course of the reactions was monitored by a solution IR study. Moreover, the synthesis and characterization of the solid pyc^- or piaH-containing complexes isolated from the above mentioned aqueous solutions are also described. The X-ray molecular and crystal structure of one of the products, $[Cu(pyc)_2] \cdot 2H_2O$, is presented. The paper summarizes results obtained within the study of metal(II)-facilitated hydrolysis of 2-CNpy and offers general conclusions relating to this field.

2. EXPERIMENTAL

2.1. *Chemical reagents*

All the chemicals used were of reagent grade. Solid pyridine-2-carbonitrile (2-CNpy) was purified by distillation under reduced pressure. 2-Amino-2-hydroxymethyl-1,3-propanediol (AL^1) was used without further purification. Water was double distilled prior to use. The other chemicals were used as received.

2.2. *Analysis and physical measurements*

Copper, cobalt and nickel were determined by EDTA titration; carbon, hydrogen and nitrogen by microanalytical methods (Carlo Erba Instruments EA 1108) with maximum deviations (in %): M, ±0.2; C, ±0.4; H, ±0.3; and N, ±0.2. The water content in hydrates was determined by thermogravimetry. The yields of products are related to the metal contents in reacting mixtures.

Magnetic moments were measured with a Gouy balance for the powdered solid at 293 K. Electronic spectra of the powdered samples in nujol mulls and diffuse reflectance spectra in MgO were recorded at room temperature on a Specord M 40 and a Magna 750 spectrophotometer, respectively. Magnetic moments, electronic and IR spectral data of solid complexes are gathered in Table 1.

Measurements of IR spectra (in solid state and aqueous solution) as well as pH measurements of the aqueous solutions are described elsewhere [9].

2.3. *X-ray structure determination*

Data collection and cell refinement were carried out using KUMA (1991) KM4 diffractometer software [11]. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by standard heavy atom procedures with SHELX86 [12], and subsequent Fourier synthesis using SHELXL93 [13]. Anisotropic thermal parameters were refined for all non-hydrogen atoms. Geometrical analysis was performed using SHELXL93 [13]. The structures were drawn using ORTEP [14]. The final refined parameters are summarized in Table 2. Selected bond lengths and angles are collected in Table 3.

Supplementary material including non-hydrogen and hydrogen atomic coordinates ($\times 10^4$), anisotropic displacement parameters for non-hydrogen atoms ($Å^2 \times 10^3$) have been deposited at the Cambridge Crystallographic Data Centre. Observed and calculated structural factors are available from P. S.

2.4. *Preparation of complexes*

Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, -z$.

above reaction mixture was refluxed for up to 20 h. The crystals were separated from the cool solution by filtration, washed with ethanol and dried *in vacuo* (yield 95%).

In addition to the above method, the complex $[Cu(H_2O)_2(piaH)_2]Cl_2$ was prepared directly from piaH and $CuCl_2$ [15]. No hydrolysis of piaH to pycH was also observed.

$[Cu(pyc)_2] \cdot 2H_2O$ (**III**). Method A. 20 mmol of 2-amino-1,3-propanediol (AL^1) was dissolved in 50 cm^3 of an aqueous solution of $CuCl_2$ (10 mmol). 2-CNpy (20 mmol) was then added to the system and the resulting solution was left to slowly evaporate at room temperature. A mixture of solid complexes containing piaH or pyc^- ligands was deposited after several days. Upon adjusting pH of the above resulting solution to 3.5, complex **I** was precipitated within 15 min. When an aqueous solution of 2-CNpy, AL^1 and $CuCl_2$ was refluxed for 32 h and then cooled down, the only compound, formed in 95% yield, was pure blue violet solid complex **III**. A well-shaped crystal of **III** was used for structure determination.

Method B. An aqueous solution (50 cm^3) of 10 mmol of $[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ [10] was left to slowly evaporate at room temperature. From the concentrated solution, complex **III** deposited upon several days standing (yield 95%).

Cobalt(II) complexes

$[Co(H_2O)_2(piaH)_2]Cl_2$ (**IV**) *and* $[Co(H_2O)_2(pyc)_2] \cdot 2H_2O$ (**V**). When 50 cm^3 of an aqueous solution of cobalt(II) chloride hexahydrate (10 mmol) was mixed with 2-CNpy (20 or 40 mmol), orange complex **IV** started to crystallize after several days. The crystals were filtered off, washed with ethanol and finally dried *in vacuo* (yield 80%). Contrary to its Cu(II) analogue (complex **I**), complex **IV** did not convert to the pyc-ligand containing complex even after 20 h reflux of the above reaction mixture, i.e. pure complex **IV** was isolated again as the only product in 75% yield. Compound **IV** was also prepared directly from $CoCl_2$ and piaH [15, 16] with no piaH hydrolysis observed.

The complex $[Co(H_2O)_2(pyc)_2] \cdot 2H_2O$ (**V**) was formed by 30 h reflux of a 50 cm^3 aqueous solution of 2-CNpy (20 mmol), AL^1 (20 mmol) and $CoCl_2$ (10 mmol). Orange crystals of **V** were filtered off and washed with ethanol (yield 80%). Complex **V** can also be synthesized by 30 h reflux of 10 mmol $[CoCl_2(pyoxaL^1)_2]$ [10] in water in a similar way as complex **III** in about 85% yield.

3. RESULTS AND DISCUSSION

3.1. *Stereochemistry of solid complexes*

The values of magnetic moments, electronic and IR spectral data for the studied complexes are listed in Table 1. The spectral and magnetic properties of complexes $[M(H_2O)_2(piaH)_2]Cl_2$ (**I** and **IV**) are identical to those prepared directly from piaH [15, 16] and consistent with their monomeric, hexacoordinated structure with two *N*,*O*-chelating piaH ligands and two water molecules present in the primary coordination sphere. The mode of piaH coordination has been proved by a single-crystal X-ray analysis of complex **I** [17].

The IR spectra of complex **III** show broad bands located in the region from 3100 to 3600 cm^{-1} attributable to the water molecules. Both copper(II) complexes **II** and **III** exhibit (Table 1) a band of the asymmetric stretch $\nu_a(COO^-)$ at 1637 and 1644 cm^{-1} together with a band of the symmetric stretch $\nu_s(COO^-)$ at 1343 and 1348 cm^{-1}, respectively. The

difference $\nu_a(COO^-)-\nu_s(COO^-)$, being 294 and 296 cm^{-1} for complexes **II** and **III**, respectively, can be taken as a proof of unidentate coordination of the carboxylato group to the central atom [18]. The IR spectra of all complexes **I**–**V** provide an evidence of organic ligands coordination through the 2-pyridinyl ring nitrogen [19].

In general, room temperature magnetic measurements and spectral data do not provide sufficient information for a definite determination of the stereochemistry of Cu(II) complexes [20] and this relates also to complexes **II** and **III** previously prepared from pycH [21, 22, 23]. To eliminate the question on stereochemistry of **II** and **III**, an X-ray single-crystal analysis of complex **III** (the one with better evolved crystals) was performed.

The spectral and magnetic properties of $[Co(pyc)_2(H_2O)_2]\cdot 2H_2O$ (**V**) are identical to those given in [24] for a compound of the same composition synthesized directly with pycH. Moreover, the X-ray crystal study of **V** [25, 26] has revealed that the primary coordination sphere of this monomeric octahedral complex consists of two anions of pyridine-2-carboxylic acid (as *N*,*O*-coordinated chelates) and two molecules of water.

3.2. *Crystal structure description of complex* **III**

The crystal structure of $[Cu(pyc)_2]\cdot 2H_2O$ (**III**) consists of discrete $Cu(pyc)_2$ molecules and water molecules occupying lattice sites (Fig. 1). The $Cu(pyc)_2$ molecule, as a whole, is nearly planar. The Cu(II) atom has centrosymmetric square-planar coordination with *trans* positioned oxygen and nitrogen donor atoms of two *N*,*O*-chelating pyc^- ligands. The interatomic distances Cu–O(1) and Cu–N are 1.941(2) and 1.979(2) Å, respectively, and are consistent with the values reported for other copper(II) complexes [27]. The packing of $Cu(pyc)_2$ moieties in the crystal structure is shown in Fig. 1. The molecules $Cu(pyc)_2$ form parallel planes. There are weak interactions between copper atoms of one plane and O(2) atoms of neighboring planes (Cu · · · O(2aa) = 2.814(4) Å). The molecules of water are not coordinated to the central atom, they are bonded to O(2) atoms of pyc^- ligands by hydrogen bonds (O(2) · · · H(2) = 1.954(5) Å; O(3)–H(2) · · · O(2) = 172.1(6)°).

The similarity of the IR spectra for **II** and **III** (Table 1) led us to the conclusion of the square planar coordination of the central Cu(II) atom just like in **II**.

3.3. *IR spectra of aqueous solutions*

Owing to the known characteristic IR spectral features of 2-CNpy and the products of its transformation, the course of the reactions occurring in the investigated systems at various conditions can cosily be followed. The assignment of solid state and solution IR spectral bands in Fig. 2 to free and coordinated ligands is supported by the literature and our previous data [9,10,18].

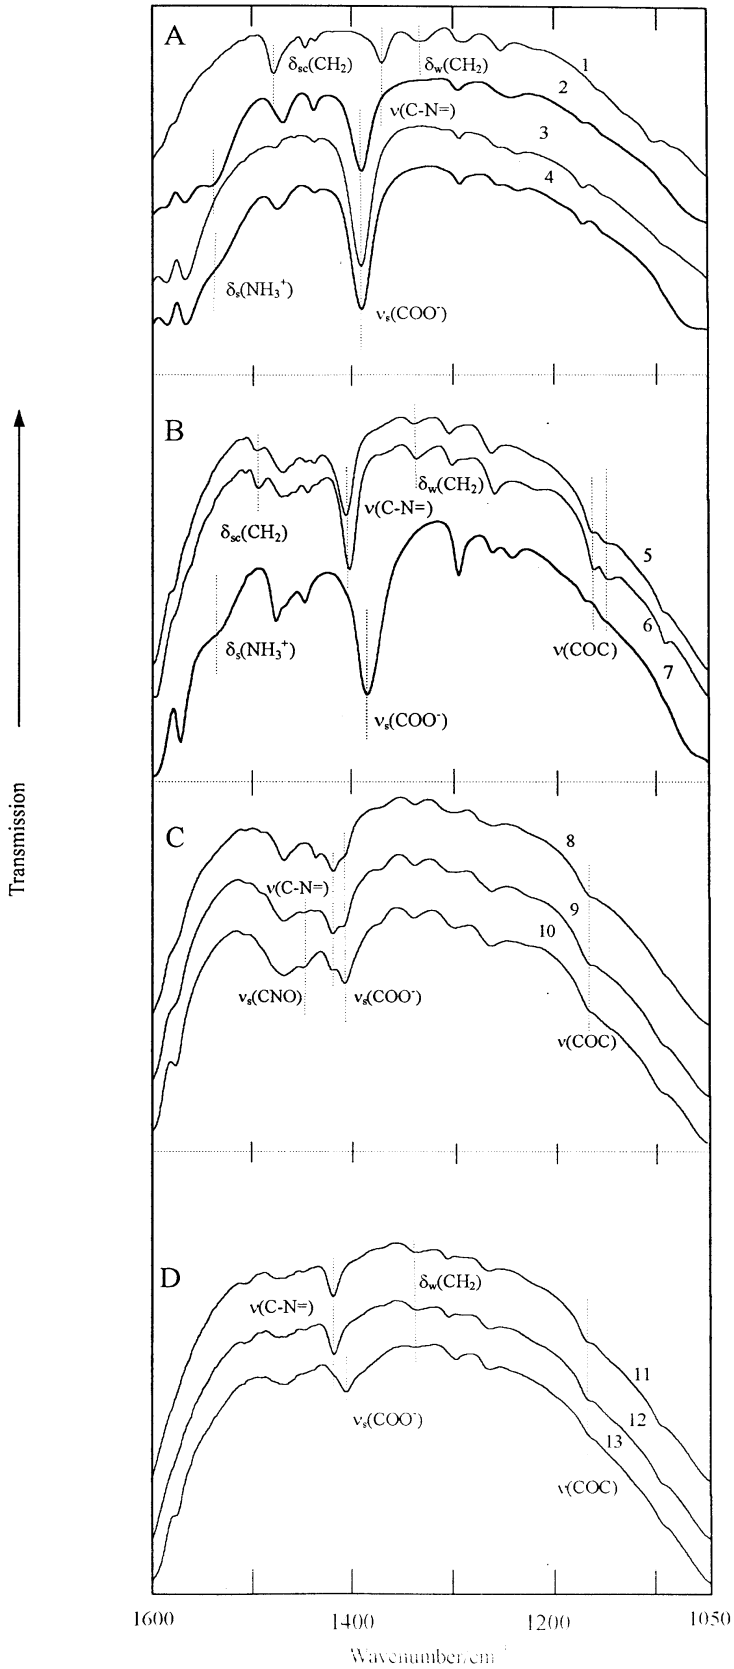

Fig. 2. IR spectra of aqueous solutions. Numbers in the figure represent spectrum numbers in Table 4. For assignment and denotation of vibrations see Table 1 and our papers [9, 10].

A kinetic study of the reaction of 2-CNpy with AL^1 in aqueous solutions of Ni(II) by means of electronic spectroscopy has been presented partly in [28]. Some new mechanistic information of this reaction was obtained from a solution IR study [9]. The IR spectra of pyoxaL^1 and its solid complexes of Ni(II), Co(II) and Cu(II) have been published, too [9, 10].

In this paper the results on the hydrolytic reactions of 2-CNpy in the presence or absence of AL^1 in aqueous solutions of copper(II) and cobalt(II) salts are given. Changes in solution IR spectra in the region from 1050 to 1600 cm^{-1} are for some of the studied systems illustrated in Fig. 2. The curves 1, 3, 5, 6, and 8–13 represent the spectra of solutions prepared at room temperature, thick solid curves 2, 4 and 7 were obtained after several-hours reflux of the solutions. The composition of the starting solutions, the time and temperature used in preparing the measured solutions, as well as the dominant components observed in the IR spectra are given in Table 4.

The spectra of pyoxaL^1 itself and its decomposition products in aqueous solution are illustrated in Fig. 2(A) [9]. Uncoordinated pyoxaL^1 (curve 1) is quite stable at room temperature for a long time. Under reflux it undergoes, however, a gradual hydrolysis to pycH, AL^1 and its protonated form AL^1H (spectrum 2). Curve 3 represents a solution IR spectrum of uncoordinated pycH, curve 4 relates to a aqueous solution of the 1:1 molar mixture of pycH and AL^1.

The room temperature IR spectra of aqueous solutions of 2-CNpy and AL^1 in the absence of metal(II) salts [9] showed that the rate of pyoxaL^1 formation is very low in comparison with that observed in the metal(II) salts containing systems.

Formation of the Co(II) complexes was indicated by significant spectral changes (Fig. 2(B)). Moreover, the IR spectrum of none of the systems related to Fig. 2(B) exhibits the strong band due to $\nu(C{\equiv}N)$ of 2-CNpy at 2246 cm^{-1}. At the same time, the pH values of the measured solutions depend strongly on the reaction time (see Table 4). In agreement with these spectral and pH changes we have concluded that a nucleophilic reaction on 2-CNpy takes place at room temperature yielding a Co(II) complex with pyoxaL^1 (spectrum 6 has not changed during several days). This conclusion is also confirmed by a comparison of the uncoordinated pyoxaL^1 spectrum (curve 1) with those of the Co(II) solutions containing pyoxaL^1 (spectra 5 and 6). However, in the presence of Co(II), pyoxaL^1 gradually hydrolyses when being refluxed for 30 h leading thus to the solution containing mainly pycH, AL^1 and its cationic form AL^1H (spectrum 7).

Unlike the solutions containing Co(II) ions, the presence of Cu(II) gives rise to different spectral changes (Fig. 2(C)). Stemming from the IR spectra evolution we have concluded that a nucleophilic reaction on the nitrile group proceeds in such solutions at room temperature (spectrum 8) and Cu(II) complexes with both pyoxaL^1 and pyc^- ligands are formed. Simultaneously, however, decomposition of pyoxaL^1 to pyc^- proceeds (spectrum 9) and after 24 h Cu(II) complexes with pyc^- ligand become dominant species in solutions (spectrum 10). Moreover, bands at 1445 cm^{-1} in spectra 9 and 10 are assigned to the

[a] Solutions 1–10: the concentrations of organic compounds and MCl_2 were 0.50 and 0.25 M, respectively; solutions 11–13: the concentration of complex $[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ was 0.25 M.

[b] r.t. = room temperature.

[c] Species observed in IR spectra.

symmetric valence vibration of the CNO group of pyridine-2-carboxamide (Table 1) which has appeared in the solution, too. PyoxaL[1] is present in solution after 24 h only in a small amount.

Curve 11 in Fig. 2(D) represents the IR spectrum of an aqueous solution of $[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ [10]. The spectral changes (curves 12 and 13) confirm a gradual room temperature hydrolysis of the coordinated pyoxaL[1] directly to pyc^-. Contrary to the solutions which are represented by spectra 9 and 10, no formation of piaH was observed in the solutions 12 and 13.

3.4. *Reactions of pyridine-2-carbonitrile and formation of pyridine-2-carboxylic acid*

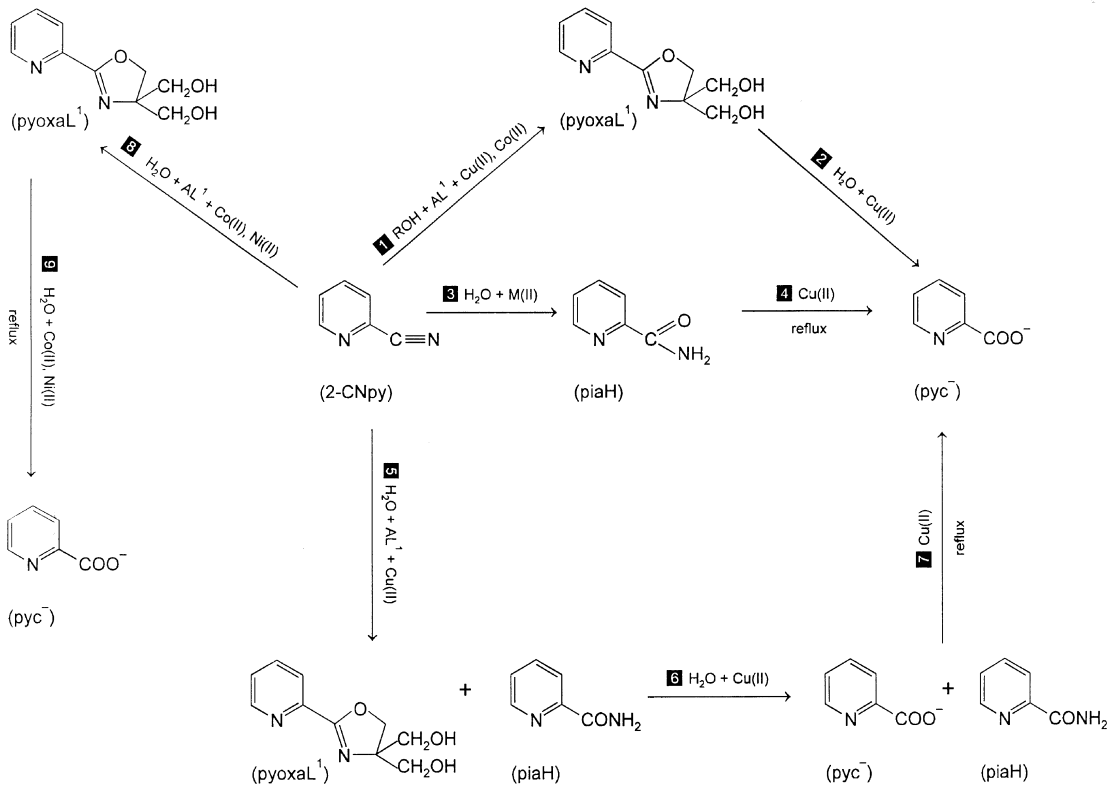
The reactions of 2-CNpy and pyoxaL[1] in aqueous solutions of Co(II) and Cu(II) salts under our experimental conditions are outlined in Scheme 2 (see also Section 2, Fig. 2 and Table 4). Moreover, the solid complexes of Co(II) and Cu(II) containing pyoxaL[1] have been prepared by the reaction of 2-CNpy with AL[1] [10]. For the sake of mutual comparability, Ni(II) complexes are included in Scheme 2, too.

All three transition metals M(II) mediate a pyoxaL[1] formation from 2-CNpy and AL[1]. The process is, however, solvent and starting salt dependent. Solid Ni(II) complexes with pyoxaL[1] are formed both in water (reaction 8) and ethanol [9] regardless the counter anions. Halide complexes of Co(II) with pyoxaL[1] are formed only in ethanol (reaction 1) while pyoxaL[1] formation in water (reaction 8) was observed when starting with $Co(ClO_4)_2$ or $Co(NCS)_2$ [10]. Solid Cu(II)–pyoxaL[1] complexes [10] can be synthesized only in ethanolic solution (reaction 1). Some of these reactions can take place also in the presence of other amino alcohols (denoted in Scheme 1 as AL[2] and AL[3]) but the present paper is focused mainly to the influence of AL[1] on addition reaction products of 2-CNpy. However, in this paper the results on the hydrolytic reactions of 2-CNpy in the presence or absence of AL[1] in aqueous solutions of copper(II) and cobalt(II) salts are described in detail.

4. CONCLUSIONS

The main conclusions of this paper can be summarized as follows.

1. The reaction of 2-CNpy with water or hydroxide ion in aqueous solution of metal(II) salts leads to the solid complexes containing piaH (reaction 3). The hydrolysis of piaH to pycH (reaction 4) was



Scheme 2. Formation of Cu(II), Ni(II) and Co(II) complexes containing different reaction products of pyridine-2-carbonitrile (2-CNpy).

observed only in refluxed solutions containing Cu(II).

2. The reaction of 2-CNpy with AL^1 in aqueous solution of Cu(II) salts at room temperature (reaction 5) leads to the fast formation of Cu(II) complexes containing pyoxaL^1. These complexes behave as intermediates and undergo a gradual decomposition to pyridine-2-carboxylic acid (reaction 6) already at room temperature. Simultaneously the nucleophilic attack of water or hydroxide on the nitrile group of coordinated 2-CNpy leads to the formation of copper complex with pyridine-2-carboxamide which is fully stable at room temperature in solution. This sequence of reaction steps is supported by a kinetic analysis of analogous systems containing 2-carbonitrile-1,10-phenanthroline instead of 2-CNpy, described in [8]. From that solution a mixture of solid complexes containing piaH or pyc^- ligands deposited after several days (see Section 2). When an aqueous reaction mixture of 2-CNpy, AL^1 and $CuCl_2$ is refluxed for a long time, well-shaped crystals of product **III** appeared (reaction 7).
3. Upon a reflux of aqueous solutions of $[CoCl_2(pyoxaL^1)_2]$ (reaction 9) a gradual hydrolysis of the pyoxaL^1 ligand to pycH and AL^1 is observed and complex $[Co(H_2O)_2(pyc)_2]\cdot 2H_2O$ is isolated. That complex can also be prepared by refluxing an aqueous solution of 2-CNpy, AL^1 and $CoCl_2$ for up 30 h.
4. The pure $[Cu(pyc)_2]\cdot 2H_2O$ was also prepared at room temperature directly from $[CuCl(pyoxaL^1)_2]Cl\cdot 0.5H_2O$ [9] via its decomposition in water (reaction 2).
5. Now the crystal and molecular structure of complex **III** fully confirms the conversion of the 2-CNpy to the coordinated pyc^- anions in aqueous solutions of $CuCl_2$. This complex is square-planar with two *N*,*O*-coordinated pyc^- ligands and two uncoordinated molecules of water. The same arrangement of donor atoms bonded to the central atom Cu(II) is supposed for complex **II**.

Electrochemistry of the bis(1,4,7-triazacyclodecane) cobalt(III) complex and its role in the catalytic reduction of hydrogen

Refat Abdel-Hamid,† Hussein M. El-Sagher, A. M. Abdel-Mawgoud and Aywan Nafady

Department of Chemistry, Faculty of Science, Sohag, Egypt

(Received 11 March 1998; accepted 25 June 1998)

Abstract—The electrochemistry of the bis(1,4,7-triazacyclodecane) cobalt(III) complex at a mercury electrode, HMDE, in aqueous Britton–Robinson buffer solutions was investigated using cyclic voltammetry, double-potential-step chronoamperometry and chronocoulometry. The cyclic voltammetric data were analyzed by digital simulation to confirm and to measure the heterogeneous and homogeneous parameters for the suggested electrode mechanism. Generally, the complex is electrochemically reduced giving rise to two cyclic voltammetric waves. The first wave is a diffusion-controlled reversible wave. It is assigned to the stable Co(III)/Co(II) redox couple. The second one is found to be irreversible and corresponding to a reduction of Co(II) to Co(I) species. The monovalent cobalt, highly unstable, is rapidly protonated, and then forms cobalt hydride. The hydride decomposes to hydrogen molecules and regenerates Co(II) species following a disproportionation pathway. The overall reduction mechanism is concluded to be an EECC kinetics. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocycles; cobalt complexes; cyclic voltammetry; chronoamperometry; reduction; simulation; catalytic.

INTRODUCTION

Metal complexes of polyazamacrocyclic ligands have received recently great attention due to their variety of functions [1–7]. Stabilization of unusual oxidation states of coordinated metal ions and catalytic activity are the most interesting. These ligands can form complexes with various transition metals, of which the structures are similar to those of the active sites of enzymes. Electrochemical studies of transition metal complexes of tetraazamacrocylics have appeared in connection with investigations of their catalytic properties [8–13]. However, to date, no detailed studies were reported on the electrochemical behavior of triazamacrocyclic complexes. Therefore, it is important to study the electrochemical reduction behavior of this type of complexes. This has been done to learn more about the properties and electrochemical reactivity of some water soluble triazamacrocyclic complexes.

In the present investigation, the electrochemical reduction mechanism of the bis(1,4,7-triazacyclodecane) cobalt(III) complex, $[Co([10]aneN_3)_2](NO_3)_3$, has been studied on a hanging mercury drop electrode, HMDE, in aqueous Britton–Robinson universal buffer solutions using different electrochemical techniques, *viz*., cyclic voltammetry, chronoamperometry and chronocoulometry, controlled potential coulometry and digital simulation. The mechanism of the electrode reaction is fully characterized and discussed.

EXPERIMENTAL

1,4,7-triazacyclodecane was synthesized according to the Koyama and Yoshino method [14] modified by Richman and Atkins [15]. The required product was extracted as a viscous yellow oil with chloroform. The elemental analytical and ^{1}H NMR spectral data of the final product were consistent with its structure.

The bis(1,4,7-triazacyclodecane) cobalt(III) com-

†Corresponding author. E-mail: science@sohag.jwnet.cun.eg

plex was synthesized on addition of the ligand solution to an air bubbled ethanolic solution of cobalt nitrate. The solution mixture was warmed and allowed to evaporate slowly to give small yellow crystals. The crystals were filtered off, washed with ether and recrystallized from an ethanol–water mixture. The elemental analytical and ^{1}H NMR spectral data of the complex were consistent with its structure.

A stock solution of fresh 5.0 mM bis(1,4,7-triazacyclodecane) cobalt(III) complex in triple-distilled water was prepared, kept in an inert nitrogen atmosphere and diluted as required. Britton–Robinson universal buffer solutions were prepared from analytical grade chemicals.

The cell and the instruments used for cyclic voltammetry and double potential step chronocoulometry were described elsewhere [16]. The electrochemical system was interfaced with an IBM value point 433 DX/DP computer. The data were captured, stored and manipulated with EG&G M270/500 software. Positive feed back was used for compensation of the solution resistance. For all experiments an Ag/Ag^+ electrode was used as reference electrode. The hanging mercury drop electrode, HMDE, in hanging drop mode was used throughout. The electrode area is 1.66×10^{-4} cm^2. All measurements were obtained at 298 K. Solutions were deaerated by purging with pure nitrogen before measurements and a blanket of nitrogen was maintained above the working solution.

The electrode reaction mechanism was confirmed and homogeneous and heterogeneous parameters of the electrode reaction were determined on analyzing the cyclic voltammetric data making use of CVSIM and CVFIT simulation softwares [17].

RESULTS AND DISCUSSION

Cyclic voltammograms of bis(1,4,7-triazacyclodecane) cobalt(III) complex, $[Co([10]aneN_3)_2](NO_3)_3$, are recorded in aqueous Britton–Robinson universal buffer solutions over a pH range from 2.70 to 10.30 using a hanging mercury drop electrode vs Ag/Ag^+. A representative illustration is given in Fig. 1. Generally, on the negative going potential scan, two reduction waves are observed, whereas on the reverse scan, one wave is seen at less negative potentials. On limiting the potential scan to the first reduction wave, switching the potential at -1.05 V, the wave appears to be reversible. At low pH, 2.70, the second cv wave is ill-defined and it is difficult to be evaluated quantitatively due to the incipient hydrogen evolution.

Analysis of the voltammetric data for the first cv wave indicates that the anodic to cathodic peak separation, $\Delta E_p = E_{pa} - E_{pc}$, has a larger value than what would be expected for a reversible one-electron transfer process [18] and varies with scan rate, cf. Table 1. This suggests that the electrode reaction is not perfectly Nernstian. On the other hand, the unit ratio of anodic to cathodic currents, i_{pa}/i_{pc}, constancy of the peak width, $E_{pc} - E_{pc/2}$, and the peak current function, $i_{pc}/v^{1/2}$, with variation of the potential scan rate, v, indicate that the electrode reaction corresponds to a reversible one electron transfer process. Thus, taking into account the electrochemical inactivity of the

ligand, 1,4,7-triazacyclodecane, the electrode reaction is attributed to the Co(III)/Co(II) redox couple. The one electron nature of the couple is confirmed coulometrically at a constant potential of -0.78 V. Furthermore, the peak current, i_{pc}, increases with the potential scan rate and from the log–log relationship, $\log i$–$\log v$, a straight line is obtained with a slope of 0.49 and correlation coefficient of 0.999. This is an indication of the diffusion-controlled nature of the first cv wave [19]. Thus, this wave can be used as internal standard for a reversible one-electron transfer process.

Upon increasing the pH of the solution, the peak potential and the peak current of the first cv wave do not change, while the peak potential of the second one shifts to more negative potential and its peak current decreases. This indicates that the hydrogen ions play a certain role in the electrochemical reduction process along the second cv wave. Comparing the peak current for the second wave at certain pH and scan rate with that for the first cv wave it is evident that it is always higher than what would be expected for a diffusion-controlled one electron-transfer process. Therefore, the second cv wave corresponds to either a multielectronic process or a charge-transfer coupled with a kinetic catalytic process. This leads to an electroactive species which is easily reduced at the same peak potential, thereby producing an increase in the observed current.

For the second cv wave, the peak current, i_{pc}, increases upon increasing the scan rate as shown in Fig. 2. Plotting of $\log i_{pc}$ vs $\log v$ relations gives straight lines with slopes of 0.38 and 0.23 at pH 7.35 and 10.30, respectively. This reveals that the second cv wave is complicated with a kinetic process. Moreover, the current function, $i_{pc}/v^{1/2}$, decreases upon increasing the scan rate. This supports the above suggestion that the electrode reaction is due to a reversible electron-transfer process coupled with a catalytic chemical reaction, i.e., $E_{rev.}C_{cat.}$ mechanism.

Upon scanning the cyclic voltammograms of the subject complex at different initial times, a steadily increase in the peak current for the second cv wave with time is observed until at a certain time of 180 s, it levels off. This implies an adsorption of Co(II) species on the HMDE surface. Furthermore, the peak current depends on the initial adsorption potential, E_i, cf. Fig. 3. Obviously, the peak current increases on increasing the adsorption potential cathodically, revealing an adsorption of the positively charged divalent cobalt complex species, $[Co(II)([10]aneN_3)_2]^{2+}$. Adsorption of the positively charged cobalt(H) species on the mercury electrode has also been proposed earlier [20, 21, 22]. Upon increasing the adsorption potentials to more negative values than -1.0 V, a decrease in the peak current is observed, indicating that the adsorption is inhibited and the divalent cobalt species is reduced once transported from the bulk of the solution to the reaction layer.

It is well known that cobalt macrocyclic complexes catalyze the hydrogen evolution [20–22]. Thus, the second cv wave can be attributed to a catalytic reduction of hydrogen ions. It is interpreted as follows: initially, adsorption of the cobalt(II) species on the electrode surface, then reduction into the monovalent cobalt species on uptaking of an electron occurs. The highly unstable Co(I) reacts with protons to form cobalt hydride, as a result of its powerful nucleophilicity. According to the hydrogen evolution mechanism proposed earlier [20], two possible pathways from the decomposition of the cobalt hydride are suggested. These are the proton attack on/or the disproportionation of the hydride, Eqs (1) and (2) (see below), respectively.

The Co(III) formed in the first pathway will be reduced to Co(II) at the electrode or in solution by the Co(I) species. In the second pathway, the disproportionation of the hydride, the Co(II) species is regenerated,

$$\text{Co(III)–H}^- + \text{H}^+ \longrightarrow \text{H}_2 + \text{Co(III)}, \qquad (1)$$

$$\text{Co(III)–H}^- \longrightarrow \tfrac{1}{2}\text{H}_2 + \text{Co(II)}. \qquad (2)$$

To justify which pathway is favored at the given conditions, the electromotive force and the equilibrium constants of the reactions taking place must

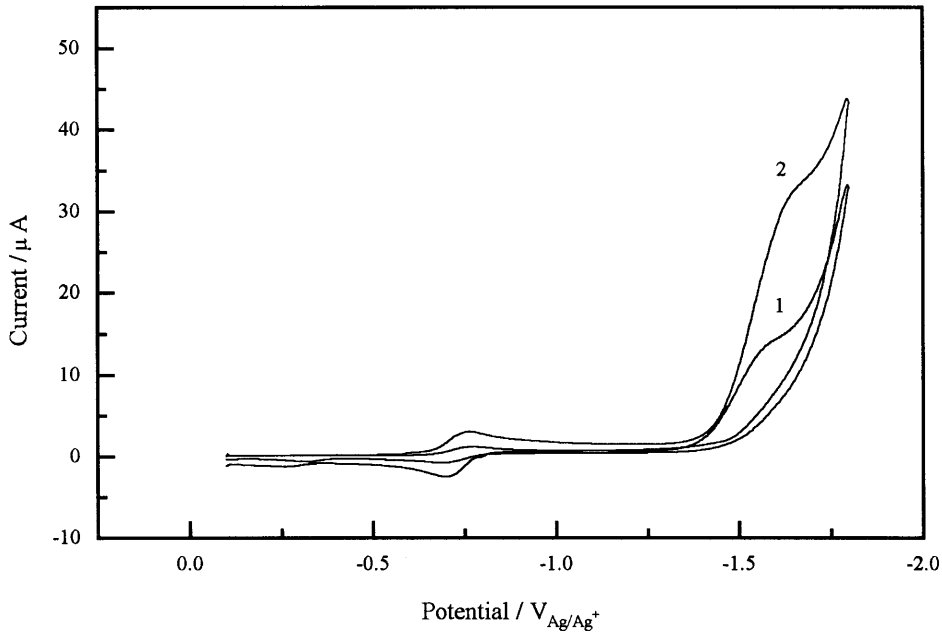

Fig. 2. Cyclic voltammograms of 4×10^{-4} mol dm^{-3} bis(1,4,7-triazacyclodecane) cobalt(III) complex at scan rates of 100 and 1000 mV s^{-1}.

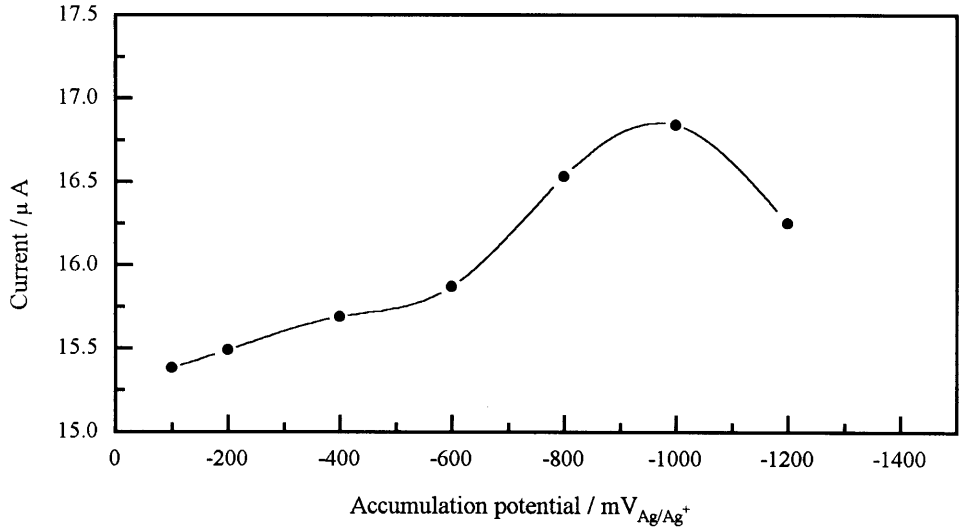

Fig. 3. Dependence of peak current on the accumulation potential of the bis(1,4,7-triazacyclodecane) cobalt(III) complex at pH 7.35.

be computed. For the first pathway, the hydrogen evolution proceeds via the following reactions:

$$\begin{aligned} &\tfrac{1}{2}\mathrm{Co(I)} + \mathrm{H^+} \rightleftarrows \tfrac{1}{2}\mathrm{Co(III)} + \tfrac{1}{2}\mathrm{H_2}, \\ &\tfrac{1}{2}\mathrm{Co(III)} + \tfrac{1}{2}\mathrm{e^-} \rightleftarrows \tfrac{1}{2}\mathrm{Co(II)}, \\ &\tfrac{1}{2}\mathrm{Co(II)} + \tfrac{1}{2}\mathrm{e^-} \rightleftarrows \tfrac{1}{2}\mathrm{dCo(I)}. \end{aligned} \quad (3)$$

The electromotive force for reaction (3) is estimated using

$$E(3) = E(\mathrm{H^+/H_2}) - \tfrac{1}{2}E(\mathrm{Co(III)/Co(II)}) - \tfrac{1}{2}E(\mathrm{Co(II)/Co(I)}). \quad (4)$$

For the second pathway, the following reactions will take place:

$$\mathrm{Co(I)} + \mathrm{H^+} \rightleftarrows \mathrm{CO(II)} + \tfrac{1}{2}\mathrm{H_2}, \quad \mathrm{Co(II)} + \mathrm{e^-} \rightleftarrows \mathrm{CO(I)} \quad (5)$$

and the electromotive force is given by

$$E(5) = E(H^+/H_2) - E(Co(II)/Co(I)). \quad (6)$$

In order to estimate the electromotive forces, $E(3)$ and $E(5)$, and the corresponding equilibrium constants, $K(3)$ and $K(5)$, for reactions (3) and (5), the standard electrode potentials for the Co(III)/Co(II) and Co(II)/Co(I) couples need to be calculated. This is performed by digital simulation analysis of the cyclic voltammograms. Digital simulation analysis is based on the suggestion that the electrode reaction proceeds following an EECC kinetics, according to the Scheme.

To establish the simulated voltammograms, the heterogeneous electron transfer reactions are assumed to be fast with k^s values of 1.0 cm/s, $\alpha = 0.5$ and the diffusion coefficients for all species are identical. Several simulations were performed by varying the input parameters, the rate of heterogeneous and homogeneous reactions, the charge-transfer coefficients and the standard electrode potentials, until a good visual fit between the experimental and simulated cyclic voltammograms is obtained. CVFIT program is used to confirm the obtained digital simulation results, through a quantitative comparison of the experimental and simulated voltammograms. The obtained digitally simulated parameters of the complete voltammogram are used as inputs to be fitted in order to obtain the best correct values. The parameters obtained for the subject triazamacrocyclic cobalt are illustrated in Table 2. A satisfactorily fit between the experimental and simulated cyclic voltammograms is recorded in Fig. 4.

Examination of the simulated E^0 values in Table 2 indicates that E^0 of the couple Co(III)/Co(II), -0.733 V, is more positive than those, -1.541 and -1.563 V, of the two pathways of the couple Co(II)/Co(I), respectively. The electromotive forces, $E(3)$ for the proton-attack pathway and $E(5)$ for the disproportionation pathway, are calculated to be $+0.926$ and $+1.319$ V, respectively. This implies that reaction (5) has a much greater driving force than reaction (3). At low pH, however, reaction (3) may be kinetically favored, it proceeds spontaneously. This condition will be satisfied so long as $E(3) > 0$. From eq. (1), the condition can be represented numerically as follows:

$$E(Co(III)/Co(II)) + E(Co(II)/Co(I)) < 2E(H^+/H_2).$$

Since $E(H^+/H_2) = -0.222$ V on the Ag/Ag^+ scale,

$$E(Co(III)/Co(II)) + E(Co(II)/Co(I)) = -0.733 + (-1.563) = -2.296\ V,$$

which is much lower than $2E(H^+/H_2)$, -0.444 V.

Furthermore, the equilibrium constants of these pathways are computed to be $K(3) = 4.49 \times 10^{15}$ and $K(5) = 1.97 \times 10^{22}$, respectively. Thus, it is evident that the decomposition of cobalt hydride is most likely to follow the disproportionation pathway, reaction (5), since the values of $E(5)$ and $K(5)$ are much higher than the corresponding values for reaction (3). Therefore, the catalytic action of the bis(1,4,7-triazacyclodecane) cobalt(III) complex for hydrogen evolution can be formulated as in the Scheme.

It is worth to mention that the decrease in the catalytic reduction current upon increasing the pH of the medium confirms its catalytic nature. However, the

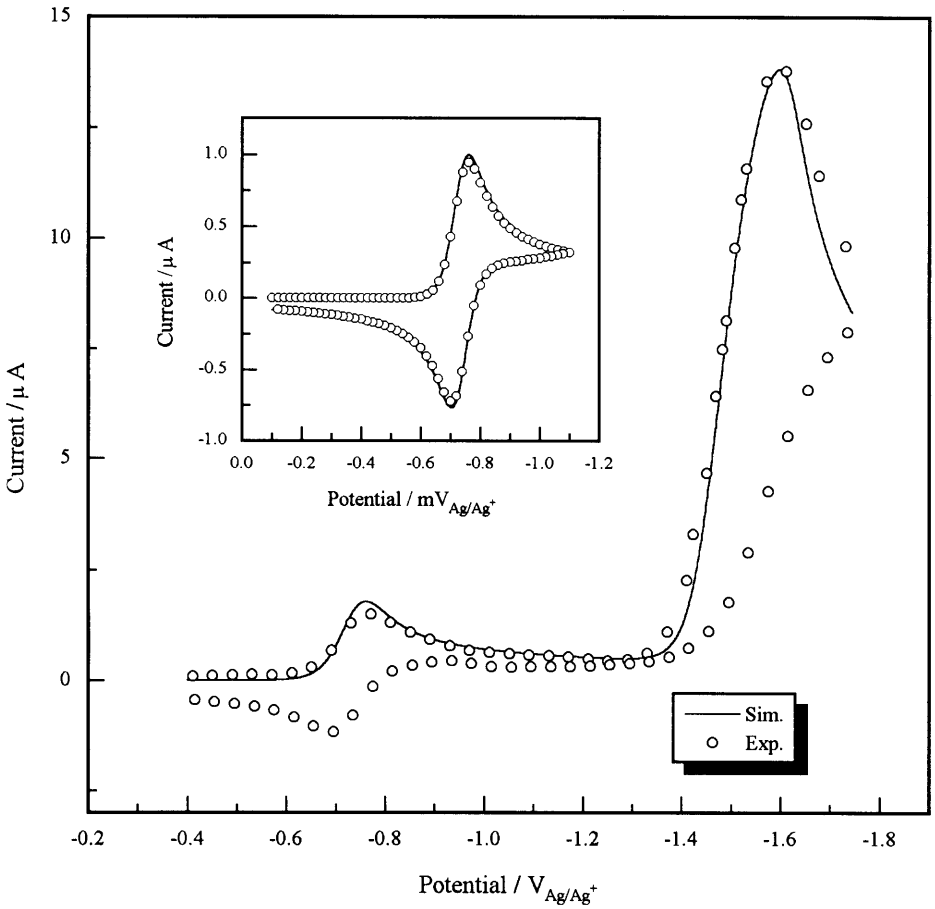

Fig. 4. Simulated/fitted cyclic voltammogram and the experimental one of the bis(1,4,7-triazacyclodecane) cobalt(III) complex for the disproportionation pathway at pH 7.35.

process is not simple. On plotting the logarithm of the catalytic current of the second cv wave as a function of pH, a straight line is obtained with a slope of 0.14, compared to an expected value of unity for the rate-limiting Co(I) protonation or proton attack on cobalt hydride reactions. This shallow response is attributed to the adsorption of the divalent cobalt complex species at the electrode surface.

In Britton–Robinson aqueous buffer solution of pH 7.35 at a hanging mercury drop electrode, chronoamperograms of 4.0×10^{-4} mol dm^{-3} bis(1,4,7-triazacyclodecane) cobalt(III) complex are recorded. The electrode potential was changed from an initial value of -0.30 V, in which the complex is electrochemically inactive, to a final potential of -0.95 V, where the desired electrode reaction takes place and the cathodic current is determined solely by diffusion. Then at switching time, τ, the potential was suddenly

returned back to its initial value. The obtained chronoamperograms were analyzed using the Cottrell equation, eq. (7). Straight lines are obtained upon plotting the cathodic current, $i(t<\tau)$ vs $t^{-1/2}$, with correlation coefficient of 0.999 at different duration times. This reveals that the reduction of the subject complex along the first cv wave is diffusion controlled. From the slopes of these straight lines the mean value of diffusion coefficient of bis(1,4,7-triazacyclodecane) cobalt(III) complex is calculated. It is found to be $(3.944 \pm 0.004) \times 10^{-6}\,\mathrm{cm^2/s}$.

On changing the electrode potential from $-1.0\,\mathrm{V}$ to $-1.60\,\mathrm{V}$ and suddenly returning back to $-1.0\,\mathrm{V}$, after a duration time τ, the chronoamperograms for the second cv wave are obtained. Upon integrating the current response, the corresponding chronocoulograms are obtained and analyzed according to the Anson equations [23], eqs (8) and (9) respectively. Straight lines are obtained for the Q_f vs $t^{1/2}$ and Q_r vs θ plots.

$$i(t<\tau) = \frac{nFAD^{1/2}{}_0C_0^*}{\pi^{1/2}t^{1/2}}, \tag{7}$$

$$Q(t<\tau) = \frac{2nFAD^{1/2}{}_0C_0}{\pi^{1/2}}t^{1/2} + Q_{dl} + nFA\Gamma_0, \tag{8}$$

$$Q_r(t) = \frac{2nFAD^{1/2}{}_0C_0}{\pi^{1/2}}\theta + Q_{dl}, \tag{9}$$

where $Q(t<\tau)$ is the amount of charge passed along the cathodic step at time t since the application of the potential step, C_0 and D_0 are the concentration and diffusion coefficient of the reactants, respectively, A is the surface electrode area, n and F have their usual significance, $Q_r(t) = Q(\tau) - Q(t>\tau)$, Q_{dl} is the charge consumed by the electrode–electrolyte double-layer capacitance, Γ_0 is the excess surface of the adsorbate and $\theta = \tau^{1/2} + (t-\tau)^{1/2} - t^{1/2}$.

The observed intercept of the cathodic step generally has a greater value than the anodic one. This is a strong evidence for the adsorption of the reactant, the divalent cobalt species, along the second cv wave. Furthermore, the amount of the adsorbate expressed as the surface excess, Γ_0, is determined from the difference in the intercepts of the forward and the reverse Anson' plots, eqs (8) and (9), which is simply $nFA\Gamma_0$. This difference cancels Q_{dl} and leaves only the net Faradaic charge due to adsorbate. The charge obtained for $4.0 \times 10^{-4}\,\mathrm{mol\,dm^{-3}}$ subject cobalt complex is found to be $2.25\,\mathrm{nC/cm^2}$. This value is equivalent to surface excess of $1.40 \times 10^{-10}\,\mathrm{mol/cm^2}$.

(Received 6 April 1998; accepted 25 June 1998)

Abstract—The protonation and stability constants of the binary Cu^{2+} complexes with 1,1′-[(1H-pyrazole-3,5-diyl)bis(methylene)]bis(octahydro-1H-1,4-triazonine) were determined by potentiometric titrations at 25° and $I=0.5$ M (KNO_3). The results show that a series of mononuclear [Cu(LHn)] ($n=1, 0, -1, -2$) and dinuclear species [Cu_2(LHm)] ($m=0, -1, -2, -3$) are formed. Structures are proposed for them based on their absorption spectra and results previously obtained from X-ray diffraction studies. Complex $[Cu_2(LH_{-1})]^{3+}$, in which the pyrazole bridging group is deprotonated, is especially interesting since it is able to bind exogenous ligands Z such as N_3^-, pyrazole and 1H,1′H-4,4′-methanediyl-bis-pyrazole (bispyr) to give ternary species $[Cu_2(LH_{-1})Z]$ and $[[Cu_2(LH_{-1})]_2Z]$, the stabilities of which have been measured by spectrophotometric titrations. In the case of bispyr the existence of the tetranuclear complex $[[Cu_2(LH_{-1})]_2(bispyr)]^{2+}$ has been proven by ES–MS. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: binary Cu^{2+} complexes; 1,1′-[(1H-pyrazole-3,5-diyl)bis(methylene)]bis(octahydro-1H-1,4-triazonine)

INTRODUCTION

Bismacrocyclic ligands, in which two macrocyclic rings are connected by a carbon chain, form dinuclear metal complexes [1–15]. The metal–metal interaction can be controlled in these systems by the length of the linking chain, which in this respect has also the function of a spacer. If the distance is short as in the case of an ethylene chain, strong interactions are observed. For example in the case of dinuclear Cu^{2+} complexes strong antiferromagnetic coupling has been determined from the temperature dependence of the magnetic susceptibility [16, 17], or spin–spin coupling can be observed by ESR spectroscopy [17], or the stepwise oxidation–reduction of the metal centres are found by cyclic voltammetry or differential pulse polarography at potentials which differ by more than the statistical value [17, 18]. If the distance between the two metal centers is larger than a few carbon atoms the metal ions do not interact any more and behave as two independent units [17, 19].

In many of the structures determined by X-ray diffraction studies the conformation of these dinuclear complexes is *anti*, which allows to minimize the electrostatic repulsion of the two positively charged metal centers [17, 20]. However, if an exogenous bridging ligand is also present the *syn* (ear-muff) arrangement is found [21]. Another way to induce the *syn* arrangement is to introduce a bridging group into the chain, which connects the two macrocycles [22, 23].

We have previously shown by X-ray studies that ligands of typ **1**–**3** are always found in the *syn*-conformation and that additional exogenous ligands easily can bind to complete the coordination sphere of the metal ions [16]. It was therefore interesting to study

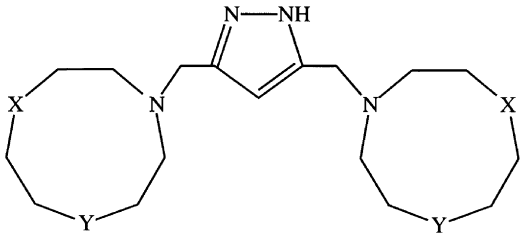
the complexation equilibria of one of these systems consisting of Cu^{2+}, ligand **2** and exogenous donors in order to gain a better understanding of their stability in water.



1 X = Y = NH, **2** X = NH, Y =S, **3** X = Y = S

EXPERIMENTAL

Compounds 4,4′-[(1H-pyrazole-3,5-diyl)bis(methylene)]-bis[octahydro-1,4,7-thiazonine] [16] and 1H,1′H-4,4′-methanediyl-bis-pyrazole [24] have been prepared according to the literature and identified by ^{1}H-NMR and ^{13}C-NMR.

Potentiometric titrations

Automatic titrator, as described previously [25], at $25 \pm 0.1^{\circ}$ and $I = 0.5$ M (KNO_3). Typical concentrations: $[L] = 2.51 \times 10^{-3}$ M with $[Cu^{2+}] = 0$, or 2.27×10^{-3} M, or 4.55×10^{-3} M. The equilibration of the Cu^{2+}/ligand titrations was relatively slow, so that the waiting time between the 0.4 M NaOH additions was kept at 480 s and the pH tolerance at 0.002 pH units. Calibration of the electrode and determination of the proton activity coefficient α_H and of pK_W was performed as described [25]. The evaluation of the protonation and stability constants was done with the program TITFIT [26], in which the global constants β_{mlh} are defined by eqn (1), where a_H is the proton activity.

$$\beta_{mlh} = \frac{[M_m L_l H_h]}{[M]^m [L]^l a^h{}_H} \quad (1)$$

Spectrophotometric titrations

Automatic setup as described in [27], using 1 cm quartz cuvettes and working at $25 \pm 0.1^{\circ}$ and $I = 0.5$ M (KNO_3). To determine the stability constants of the ternary complexes, 2.2–2.4 ml of a 6.0×10^{-4} M buffered solution. (4.0×10^{-2} M lutidine-3-sulfonic acid adjusted with 0.1 M NaOH to pH 5.5) of the dinuclear Cu^{2+} complex was titrated with 1.0×10^{-2}–2.5×10^{-2} M bridging ligand, which was added in 3–10 μl aliquots up to 0.06–0.3 ml. Equilibrium was fast, so that the waiting time between the additions was kept at 60 or 120 s. The calculations were done with the program SPECFIT [28].

Electrospray–ionisation–MS

Pneumatically-assisted electrospray (ES–MS) mass spectra were recorded on an *API III* tandem mass spectrometer (PE Sciex, Concord, Canada) by infusion at 5–10 μl/min. The single MS spectra were recorded under low up-front declustering or collision-induced dissociation (up-front CID) conditions, typically $\Delta V = 0$–30 V between the orifice and the first quadrupole of the mass spectrometer [29, 30]. Determination of the total charge of the complexes (z) was made by using the isotopic pattern. Solutions of the dinuclear Cu^{2+} complex (2.5×10^{-4} M) in CH_3CN (1.0 ml) were treated with different solutions of 1H,1′H-4,4′-methanediyl-bis-pyrazole (bispyr) in CH_3CN (1.0 ml) in decreasing concentrations (2.50×10^{-4}, 1.25×10^{-4}, 0.63×10^{-4}, or 0 M) containing 3 equivalents of N-ethyl-diisopropylamine as base.

UV–VIS spectra were measured on a Perkin Elmer, Lamda 9 Spectrophotometer in 1 cm cuvettes. Solutions of Cu^{2+} (2.3×10^{-3} or 4.6×10^{-3} M) and ligand (2.5×10^{-3} M) were adjusted to pH values at which the 1:1 and 2:1 species are dominant: pH 2.8 for $[Cu(LH)]^{3+}$, pH = 8.8 for $[CuL]^{2+}$, and pH = 10.8 for $[Cu(LH_{-1})]^{+}$, pH = 4.1 for $[Cu_2(LH_{-1})]^{3+}$, and pH = 8.1 for $[Cu_2(LH_{-2})]^{2+}$.

RESULTS AND DISCUSSION

From pH titrations of ligand **2** the pK_H values were determined (Table 1). The highest two pK_H cor-

respond to the protonation of one nitrogen of each N_2S ring and the ΔpK_H of 0.67, very close to the statistical factor, indicates that the protonation sites are relatively independent from each other. The third and low pK_H is due to the strong electrostatic repulsion when a further proton is bound to one of the N_2S rings.

Titrations of **2** in the presence of 0.9 or 1.8 equivalents of Cu^{2+} (Fig. 1) allow in a batch calculation, in which both titration curves are fitted at the same time with one model, to calculate the stability constants of the mononuclear species $[Cu(LH)]^{3+}$, $[Cu(L)]^{2+}$, $[Cu(LH_{-1})]^{+}$ and $[Cu(LH_{-2})]$ as well as of the dinuclear complexes $[Cu_2(L)]^{4+}$, $[Cu_2(LH_{-1})]^{3+}$, $[Cu_2(LH)_{-2})]^{2+}$, and $[Cu_2(LH)_{-3})]^{+}$. The absolute stability of these species could not be determined, since $[Cu(LH)]^{3+}$ is already fully formed at low pH. To describe the system we therefore use the pK_H values (eqn (2)) connecting the protonated species and their conjugate bases (Table 1).

$$Cu(LH_n) \rightleftharpoons Cu(LH_{n-1}) + H^+;$$

$$K_n = [Cu(LH_{n-1})] \cdot [H^+]/[Cu(LH_n)] \qquad (2)$$

The species distribution (Fig. 2) for $[L] = 2.5 \times 10^{-3}$ M and $[Cu^{2+}] = 2.3 \times 10^{-3}$ M shows that $[(CuLH)]^{3+}$

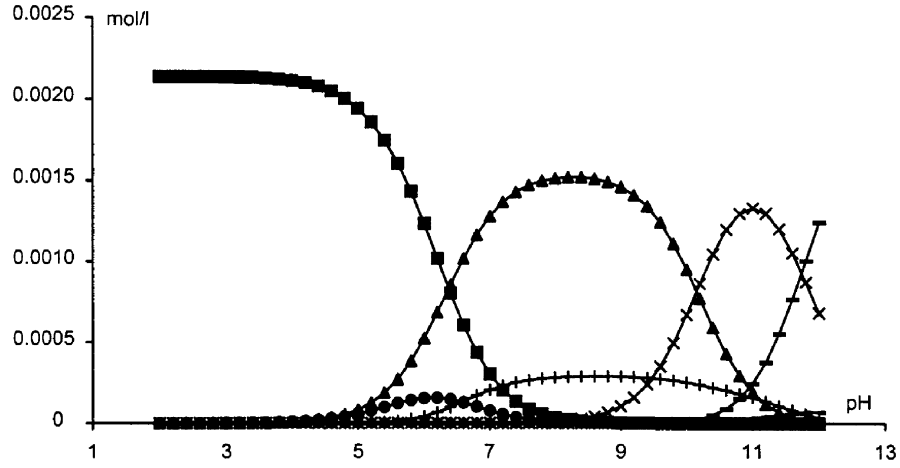

Fig. 2. Species distribution of the complexes of **2** with 0.9 equivalents Cu^{2+} ($[L] = 2.5 \times 10^{-3}$ M, $[M] = 2.3 \times 10^{-3}$ M). ■ $[Cu(LH)]^{3+}$, ▲ $[CuL]^{2+}$, × $[Cu(LH_{-1})]^{+}$, — $[Cu(LH_{-2})]$, ● $[Cu_2(LH_{-1})]^{3+}$, + $[Cu_2(LH_{-2})]^{2+}$.

dominates at pH below 6, whereas the main species between pH 6 and 11 are $[CuL]^{2+}$ and $[Cu(LH_{-1})]^{+}$ $[Cu(LH_{-2})]$. exists in measurable concentrations only above pH 11.

$[Cu(LH)]^{3+}$ (**4**) is the complex in which the Cu^{2+} ion is bound by one of the N_2S-rings, the proton being located on a nitrogen of the second ring not involved in coordination of the metal ion (see Scheme 1).

The subsequent three deprotonation steps to $[CuL]^{2+}$, $[Cu(LH_{-1})]^{+}$ and $[Cu(LH_{-2})]$ stem from the

neutralization and concomitant coordination of the pyrazole group, from the formation of a hydroxo species and from the deprotonation of the ammonium group of the N_2S ring. Whereas the structure of the final product (**7**) is clear, the exact sequence of the proton neutralizations is more difficult to determine. The shift of the absorption maximum from 637 nm for $[Cu(LH)]^{3+}$ to 612 nm for $[CuL]^{2+}$ (Table 1) is a clear indication that it is in this step that the pyrazole becomes deprotonated and through coordination of the pyrazolide group an increase of ligand field strength takes place. So the structure of $[CuL]^{2+}$ must be **5**. The exact sequence of the other two deprotonation steps is even more difficult to determine since they occur very close to each other and the spectrum of the final product cannot be measured and used for comparison purpose (structures **6** and **7**, Scheme 1).

Ligand **2** was specifically designed to form dinuclear complexes and indeed several of them have been isolated and characterized in the solid state by X-ray diffraction [16]. In aqueous solution we also find such species, which differ in their protonation degree. For example in a mixture with $[L]=2.5\times10^{-3}$ M and $[Cu^{2+}]=4.6\times10^{-3}$ M $[Cu_2L]^{4+}$ is formed already at very low pH and deprotonates with $pK_H=2.41$ to give $[Cu_2(LH_{-1})]^{3+}$ (Fig. 3). The structure of $[Cu_2L]^{4+}$ (**8**) can be described by two Cu^{2+} symmetrically coordinated by the two macrocyclic rings, whereas that of $[Cu_2(LH_{-1})]^{3+}$ (**9**) with a maximum at 627 nm contains in addition the pyrazolide bridging group as it was found in the solid state structures [16]. Further deprotonation to $[Cu_2(LH_{-2})]^{2+}$ (**10**) and $[Cu_2(LH_{-3})]^{+}$ (**11**) gives the mono- and dihydroxo moieties.

Since the X-ray studies showed that $[Cu_2(LH_{-1})]^{3+}$ is able to bind exogenous bridging ligands [16], it was interesting to study this reaction in solution. By spectrophotometric titrations (Fig. 4) one can follow the formation of the ternary species as indicated in eqs (3) and (4).

$$[Cu_2(LH_{-1})]^{3+}+Z \rightleftharpoons [Cu_2(LH_{-1})Z];\quad K_1 \quad (3)$$

$$2[Cu_2(LH_{-1})]^{3+}+Z \rightleftharpoons [[Cu_2(LH_{-1})]_2Z];\quad K_2 \quad (4)$$

As bridging ligands N_3^-, pyrazole (pyr), and 1H,1′H-4,4′-methanediyl-bis-pyrazole (bispyr) were used. The results obtained by fitting the titration with the program SPECFIT (Table 2) are interesting since they show that N_3^- and bispyr can form 1:1 and 2:1 species (Fig. 5), whereas pyr is, as expected, only able to give a 1:1 complex. It must be pointed out, that the stability constants for these ternary complexes are conditional constants obtained at pH = 5.5, at which $[Cu_2(LH_{-1})]^{3+}$ is the dominant binary moiety. A change in pH will modify not only the species distribution but in the case of pyr and bispyr, also the concentration of the deprotonated form of the exogenous ligand.

Table 2. Conditional stability constants (pH = 5.5) for the formation of the ternary complexes with N_3^-, pyr and bispyr according to Eqs (2) and (3) at 25° and $I=0.5$ M KNO_3

	N_3^-	pyr	bispyr
$\log K_1$	4.22(5)	3.85(3)	3.85[a]
$\log K_2$	7.27(6)	–	7.65(5)

[a]Kept fixed during the fitting procedure.

To confirm these findings we have studied the ternary system with bispyr also by ES–MS. By mixing $[Cu_2(LH_{-1})]^{3+}$ and bispyr in different ratio in the presence of a base one can see how the dinuclear and tetranuclear species are indeed formed (Fig. 6).

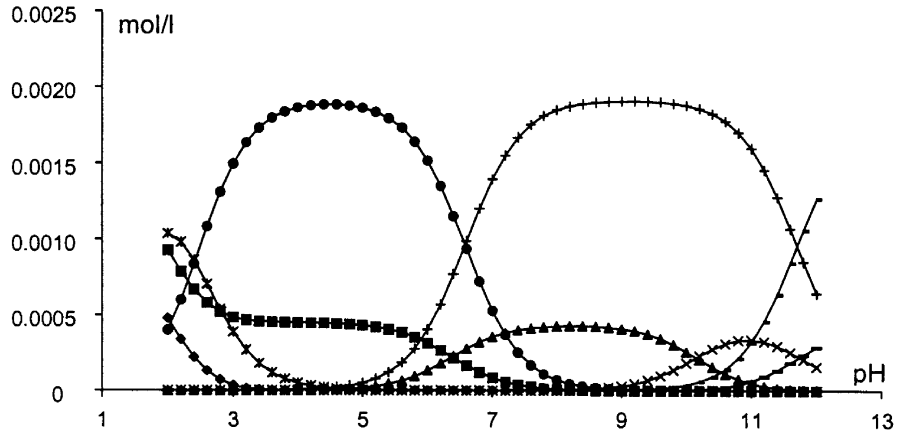

Fig. 3. Species distribution of the complexes of **2** with 1.8 equivalents Cu^{2+} ($[L]=2.5\times10^{-3}$ M, $[M]=4.5\times10^{-3}$ M). ◆ Cu^{2+}, ■ $[Cu(LH)]^{3+}$, ▲ $[CuL]^{2+}$, × $[CuLH_{-1})]^{+}$, — $[Cu(LH_{-2})]$, * $[Cu_2(L)]^{4+}$, ● $[Cu_2(LH_{-1})]^{3+}$, + $[Cu_2(LH_{-2})]^{2+}$.

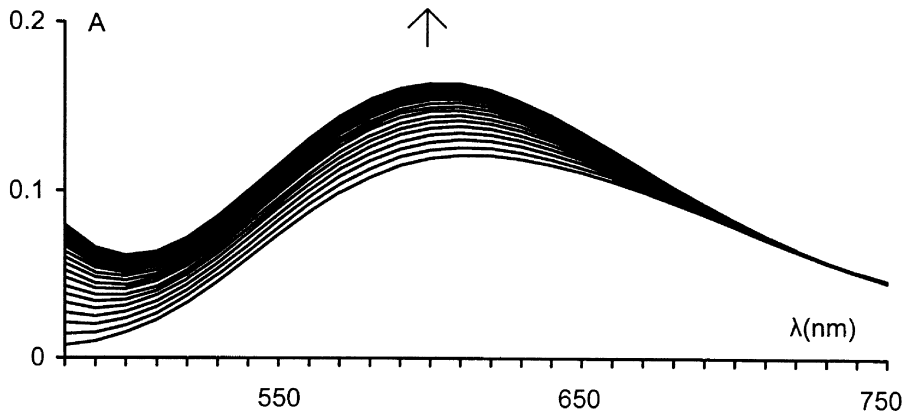

Fig. 4. Spectrophotometric titrations of $[Cu_2(LH_{-1})]^{3+}$ (6×10^{-4} M) with increasing amounts of 1H,1′H-4,4′-methanediyl-bis-pyrazole (bispyr) at pH 5.5.

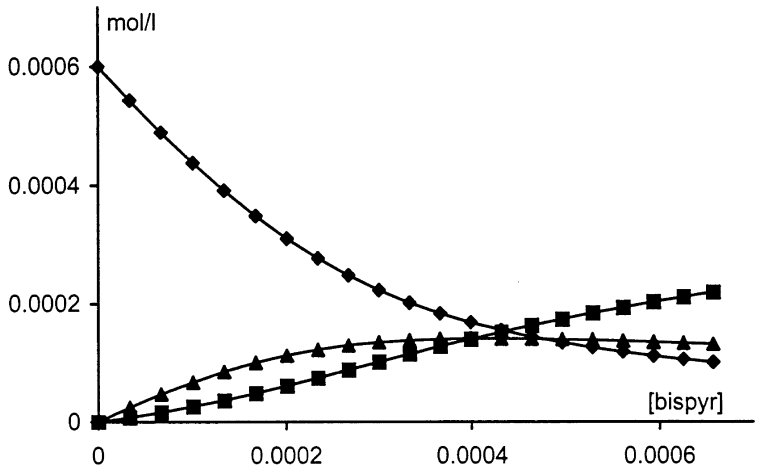

Fig. 5. Concentrations of the ternary species as a function of the 1H,1′H-4,4′-methanediyl-bis-pyrazole (bispyr) concentration. ◆ $[Cu_2(LH_{-1})]^{3+}$, ■ $[Cu_2(LH_{-1})bispyr]^{2+}$, ▲ $[[(Cu_2(LH_{-1})]_2bispyr]^{4+}$.

The ES–MS at a ratio (1:0) shows the presence of several doubly charged ions (m/z 264.1, 277.1), which may correspond to solvent cluster ions of the complex $[Cu_2(LH_{-1})]^{3+}$. The addition of small amounts of bispyr results in the appearance of the ions at m/z 292.2 and 329.0 corresponding to a quadruple and doubly charged species. At a ratio of 2:1 those two ions become predominant. The isotopic distribution of the ion at m/z 292.2 is in good agreement with a complex corresponding to $[[Cu_2(LH_{-1})]_2bispyr]^{4+}$ while the ion at m/z 329.0 fits with the complex $[Cu_2(LH_{-1})bispyr]^{2+}$. Electrospray ionization reflects generally qualitatively the species present in solution [29, 30]. The intensity of the ions observed in the spectra is strongly charge and compound dependent especially when working at such high concentration. Therefore the signal intensities can not be used quantitatively. However, at a 1:1 ratio $[Cu_2(LH_{-1})bispyr]^{2+}$ is almost exclusively observed. For the structures of these two complexes we propose Structures **12** and **13** (Scheme 2).

The species **13** is an interesting moiety which self-assembles from seven species by mixing four equivalents Cu^{2+}, two equivalents **2** and one equivalent bispyr and enough base to deprotonate the pyrazole rings.

In conclusion we can say that ligand **2** consisting of two macrocyclic units bridged by a pyrazole moiety gives a series of mononuclear $[Cu(LHn)]$ ($n = 1, 0, -1$) and dinuclear $[Cu_2(LHm)]$ ($m = 0, -1, -2, -3$) species in solution, which have been characterized. As in the structures previously found in the solid state,

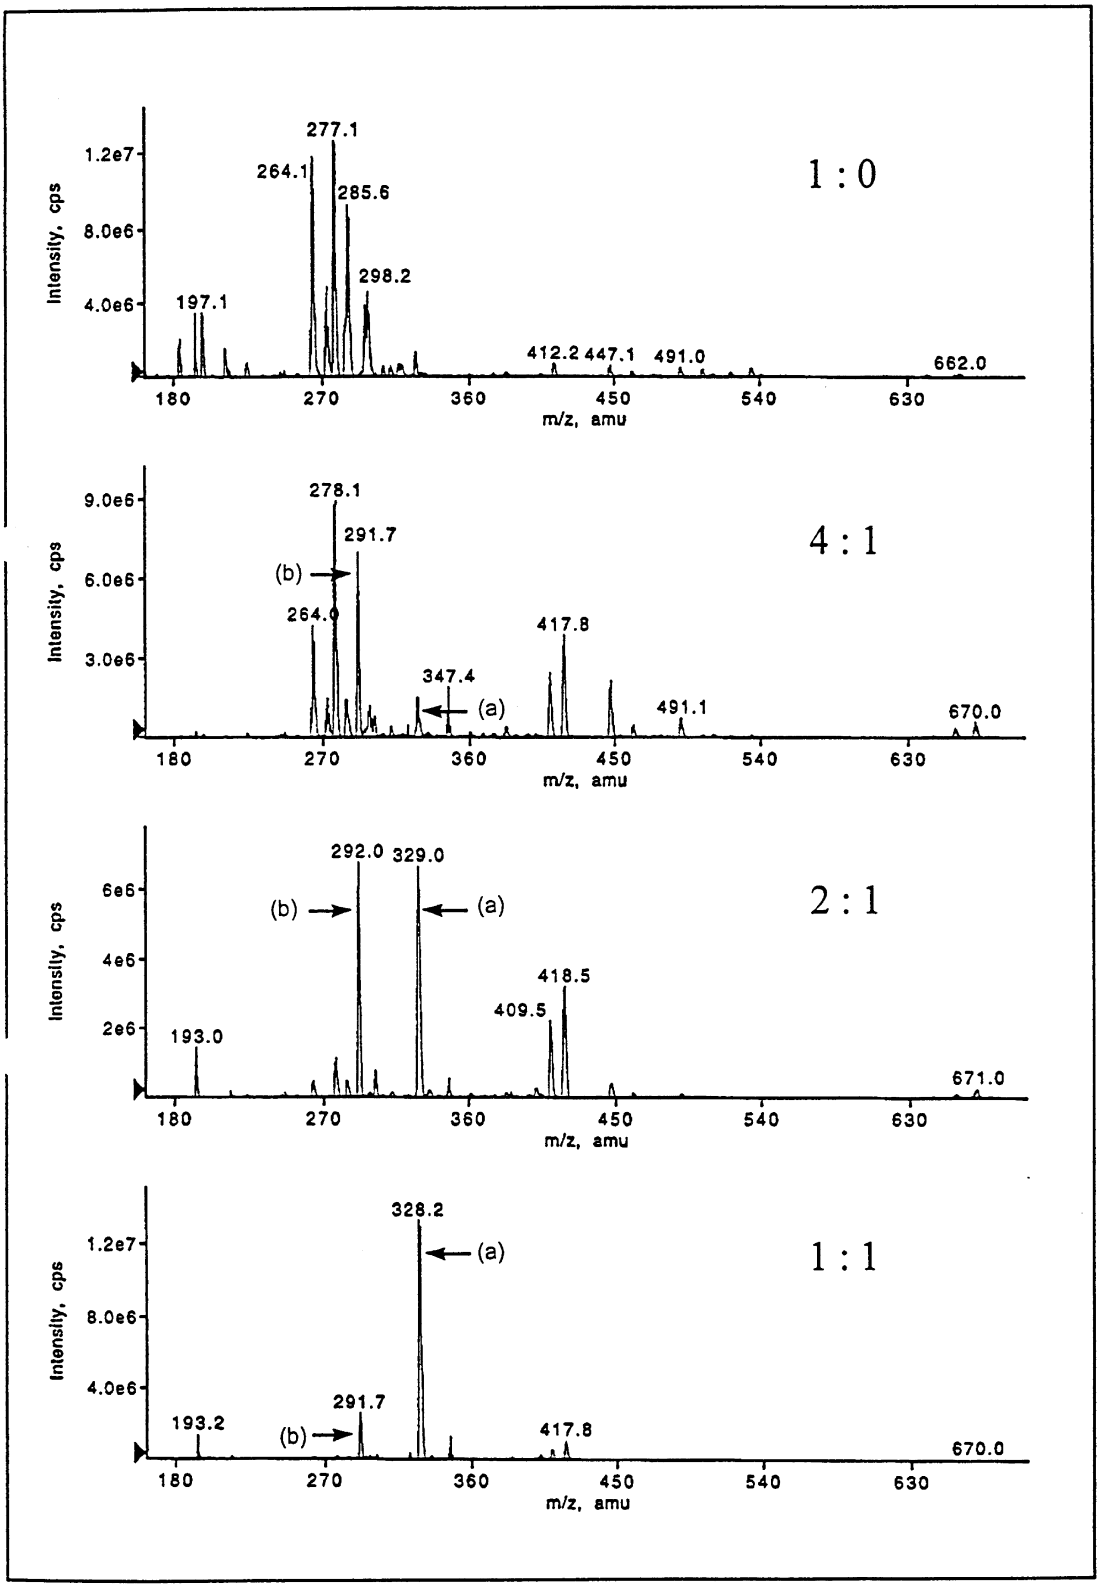

Fig. 6. ES–MS of the complex $[Cu_2(LH_{-1})]^{3+}$ in presence of different amounts of bispyr, showing the formation of $[(Cu_2(LH_{-1})]_2bispyr]^{4+}$ (a) and $[Cu_2(LH_{-1})bispyr]^{2+}$ (b).

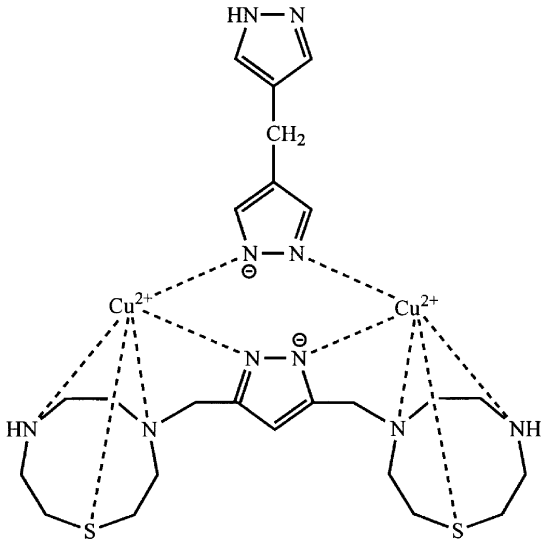
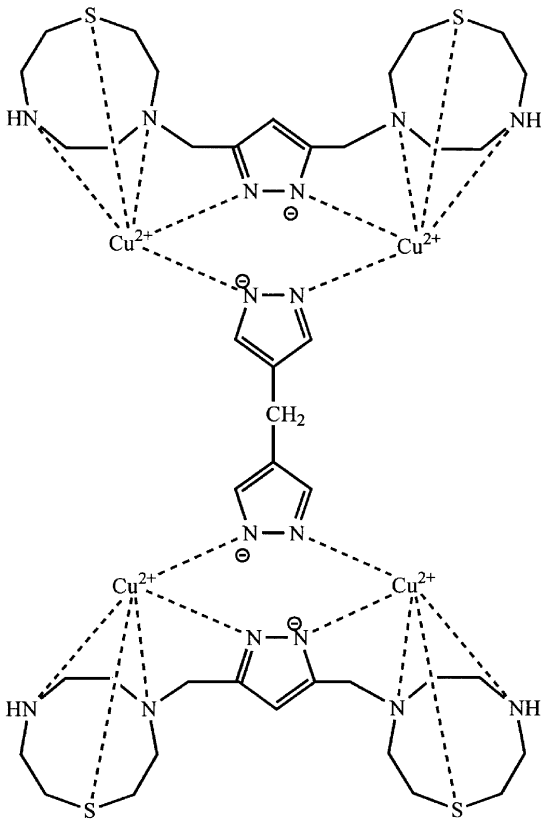


12 $[Cu_2(LH_{-1})bispyr]^{2+}$



13 $[[Cu_2(LH_{-1})]_2bispyr]^{4+}$

Scheme 2.

also in solution $[Cu_2(LH_{-1})]^{3+}$ is able to coordinate exogenous ligands such as N_3^-, pyr and bispyr, the latter one giving an interesting tetranuclear species as confirmed by ES–MS experiments.

Abstract—Thermal and/or photochemical conversion of a series of copper(II) complexes containing mixed dithiocarbamato–alcohol ligands, $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ ($Y = ClO_4^-$, NO_3^-), into $Cu^{II}(Et_2dtc)Cl$ in chloroalkane/alcohol solutions, where chloroalkane = CCl_4, $CHCl_3$ or CH_2Cl_2 and alcohol = MeOH, EtOH or *i*-BuOH, proceeds in chloroalkanes. Both reactions follow a similar pathway which is more effective the stronger the acceptor properties of chloroalkanes and the weaker the coordinating abilities of alcohols are. A detailed reaction mechanism is proposed which well fits the experimental results obtained by EPR and UV–VIS spectra and quantum yields. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: CT photochemistry; copper(II) dithiocarbamate mixed-ligand complexes

INTRODUCTION

In recent communications [1, 2] we have described the photochemical properties of a series of copper(II) diethyldithiocarbamate mixed-ligand complexes, $Cu^{II}(Et_2dtc)X$, where X represents Cl^-, ClO_4^- or NO_3^-, studied in acetone, $CHCl_3$/*i*-PrOH (1:1), and CCl_4/*i*-PrOH (1:1) solutions. The complexes are characterized by their strongly allowed ligand-to-metal charge-transfer (LMCT) transition in the visible region of the spectrum at about 400 nm ($\lg \varepsilon = 3.7$) [1]. The reaction from the LMCT state is reduction of Cu(II) to Cu(I) proceeding via an intramolecular electron transfer from an equatorially bound S atom of the ligand to copper(II). Photo-irradiation of $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ and $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$ in the CT band in chloroalkane/*i*-propanol (1:1) solutions gives rise to $Cu^{II}(Et_2dtc)Cl$ as an intermediate product as seen by the appearance of its characteristic EPR spectrum [1] where the high field copper hyperfine line with $m_I = -3/2$ splits into four shf lines, implying interaction of the Cu(II) unpaired electron with one $^{35,37}Cl$ nucleus and thus proving that one Cl^- ion is covalently bound in the plane of the complex.

In CCl_4/*i*-propanol (1:1) solutions both $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ and $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$ undergo thermal conversion to $Cu^{II}(Et_2dtc)Cl$. The steps involved in this conversion could be better understood if we consider the abilities of CCl_4 and $CHCl_3$ to form adducts with $Cu^{II}(Et_2dtc)X$ complexes [2].

Although our previous studies [1, 2] have shown that both the photolytic and thermal reactions of $Cu^{II}(Et_2dtc)X$ occur by a Cu–S bond cleavage, the details of the reactions occurring before and subsequent to it were unclear. In order to clarify the role of chloroalkanes in the thermal reactions of $Cu^{II}(Et_2dtc)X$ and of its primary photo-products, and to correlate their behavior with the nature of the protic solvent of the mixture, it seemed necessary to perform a systematic study varying the solvents and looking for their effect on product formation and $Cu^{II}(Et_2dtc)X$ disappearance both in the thermal and photolytic pathways.

EXPERIMENTAL

Starting materials

The ligands and the p.a. grade metal salts were obtained from Fluka and used without further purification. To remove crystal water copper salts were treated as described before [1]. The solvents were used after distillation.

†Author to whom correspondence should be addressed.

Preparation of the coordination compounds

Mixed-ligand complexes $Cu^{II}(Et_2dtc)X$ ($X = Cl^-$, ClO_4^-, NO_3^-) are insoluble in neat CH_2Cl_2, $CHCl_3$ or CCl_4, but dissolve in mixtures of chloroalkanes and alcohols. Therefore, they were obtained according to the reactions [1]:

$$Cu(Et_2dtc)_2 + CuCl_2 = 2Cu^{II}(Et_2dtc)Cl, \quad (1)$$

$$Cu(Et_2dtc)_2 + CuY_2 = 2Cu^{II}(Et_2dtc)^+ \ldots Y^- \quad (2)$$

$$(Y = ClO_4^-, NO_3^-),$$

by mixing of chloroalkane solutions of $Cu(Et_2dtc)_2$ with alcohol solutions of the corresponding copper(II) salt as described before [1, 2]. The parent bis(diethyldithiocarbamato) copper(II) complex, used in the preparation, was obtained by a standard literature method [3]. The initial concentrations of its chloroalkane solutions were determined spectrophotometrically from the value of the molar absorptivity coefficient of the visible CT-band. The alcohol solutions of the corresponding copper(II) salts were titrated with EDTA before use. The solutions in this paper were not deaerated since it was found earlier [1] that deaeration was not a significant factor.

Instrumentation

The EPR spectra were taken on an X-band Bruker ER 420 spectrometer using 100 kHz modulation of the magnetic field. The electronic absorption spectra were recorded on a Specord UV–VIS (Carl-Zeiss, Jena) spectrophotometer using quartz cells to record in the 250–750 nm region.

Kinetic study

The thermal conversion of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ ($Y = ClO_4^-, NO_3^-$) to $Cu^{II}(Et_2dtc)Cl$ has been monitored by EPR spectroscopy. For this purpose EPR spectra of CCl_4/alcohol (1:1) solutions were recorded at different time intervals after their preparation on keeping the sample probe at fixed position in the EPR spectrometer cavity and room temperature. Since the time required to obtain a spectrum was small compared to their half-lives, EPR data provided satisfactory results for compounds formed or consumed in the reaction stages. By extrapolation to zero time, the observed changes in the signal intensities of the starting complexes were related to changes in their actual concentrations. The concentration of the product was determined with the use of freshly prepared $Cu^{II}(Et_2dtc)Cl$ reference solutions in the appropriate solvent mixtures. For all reactions CCl_4 and ROH were in pseudo-first-order excess over the Cu(II) complexes (ca. 10^{-4}–10^{-3} mol dm^{-3}).

Irradiation and quantum yields

Photolysis experiments were performed with the full spectrum of a 250 W medium-pressure mercury lamp or through a 406 nm solution filter [4] as previously described [5]. For quantum yield determination the complex concentrations were such as to have essentially complete light absorption. No correction was made for internal filter effects. The incident light intensity was determined before and after each photolysis by a ferrioxalate actinometric method [4]. At least three determinations of quantum yields were made for each complex. Photolyses of all complexes were carried out at 25 ± 1°C. To correct for possible thermal reactions, UV–VIS and EPR spectra were obtained immediately after photolyses and compared with the spectrum of an aliquot kept in the dark. Thermal corrections were not significant for any of the complexes in CH_2Cl_2/ROH or $CHCl_3$/ROH solvent mixtures. UV–VIS photolysis was studied on freshly prepared CCl_4/ROH solutions.

RESULTS AND DISCUSSION

EPR spectra

The EPR measurements were carried out at room temperature under the same conditions as those of the photolytic experiments. The Hamiltonian parameters calculated from the spectra obtained for ligand and metal concentrations of 1×10^{-3} mol dm^{-3} at 293 K are listed in Table 1. Typical EPR spectra are given in Fig. 1.

The results of Table 1 provide a systematic basis for identifying the coordination of alcohol in the *xy* plane of the complex. It is seen from Table 1 that the EPR parameters of all $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complexes obtained in chloroalkane/alcohol solvent mixtures do not vary with the chloroalkane or the anion Y^- and depend on the nature of the alcohol. Therefore, it seems that besides the bi-dentate dtc ligand, the coordination plane of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ is comprised of two alcohol molecules yielding the chromophore $Cu^{II}S_2(solv)_2$ and that of $Cu^{II}(Et_2dtc)Cl$ consists of a chloride ion, and an alcohol molecule in the chromophore $Cu^{II}S_2Cl \cdot solv$ (Table 1).

Only the hyperfine lines of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ are seen in the EPR spectra obtained in all chloroalkane/ROH solutions (spectra 1–3 in Fig. 1(a)) indicating a quantitative ligand exchange between $Cu(Et_2dtc)_2$ and CuY_2 to yield exclusively $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ by reaction (2) and the same is valid for $Cu^{II}(Et_2dtc)Cl$ obtained by reaction (1) in chloroalkane/*i*-BuOH (1:1) (spectrum 3 in Fig. 1(b)) and in chloroalkane/*i*-PrOH (1:1) as seen before [1, 2]. When *i*-BuOH (resp. *i*-PrOH) as solvent is replaced by MeOH (or EtOH) the EPR spectra of $Cu^{II}(Et_2dtc)Cl$ (1 and 2 in Fig. 1(b)) reveal the superposition of a spectrum that is due to the bis-solvated $Cu^{II}(Et_2dtc)^+$ species on that of

*^{35}Cl shfs is not well resolved because of the high polarity of the solvent.

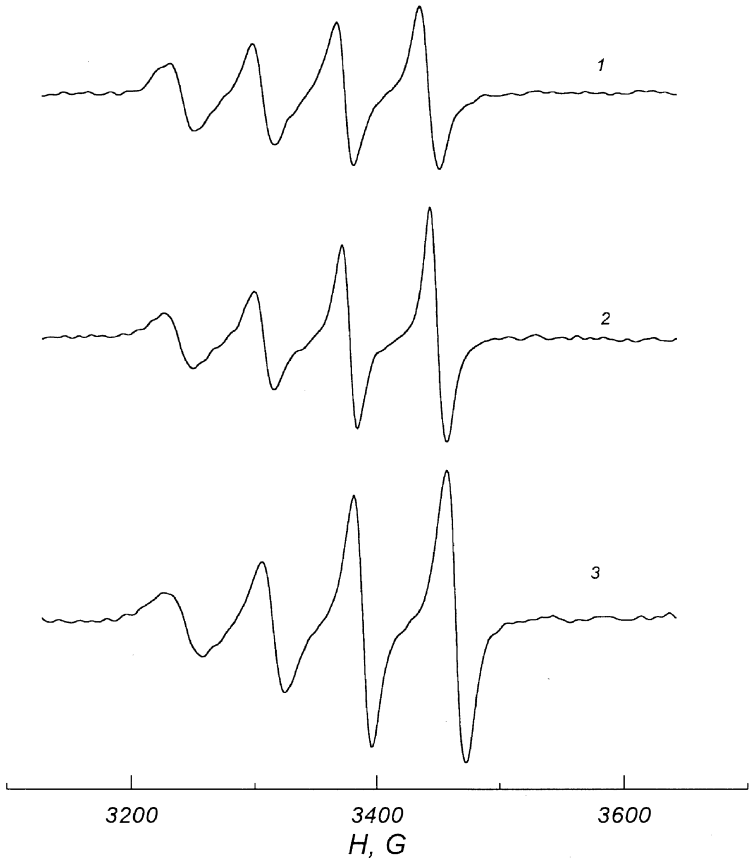

Fig. 1. EPR spectra of equimolar (1×10^{-3} mol dm^{-3}) mixtures of (a) $Cu(Et_2dtc)_2$ in CH_2Cl_2 and $Cu(ClO_4)_2$ in MeOH (1), EtOH (2), *i*-BuOH (3).

$Cu^{II}(Et_2dtc)Cl$ (see Table 1) suggesting the following equilibrium between the mono- and bis-solvated form of the complex in these solvents:

$$Cu^{II}(Et_2dtc)Cl \rightleftharpoons Cu^{II}(Et_2dtc)^+ \ldots Cl^- . \qquad (3)$$

Therefore, in chloroalkane/MeOH (1:1) solutions $Cu^{II}(Et_2dtc)Cl$ is partly converted into a bis-solvated form and MeOH has replaced chloride ion as an equatorial ligand. The same is observed with EtOH, but the relative intensities of the signals of both species in spectrum 2 (Fig. 1(b)) suggests higher amounts of $Cu^{II}(Et_2dtc)Cl$ and lower $Cu^{II}(Et_2dtc)^+$ concentration compared to spectrum 1 (Fig. 1(b)) which is in accordance with the weaker coordinating ability of EtOH compared to MeOH in the following order of nucleophilicity [6]:

$$MeOH > EtOH > i\text{-}PrOH > H_2O > t\text{-}BuOH.$$

UV spectra

In addition to the visible LMCT band, the ultraviolet spectra of the mixed-ligand complexes $Cu^{II}(Et_2dtc)X$ are dominated by two main absorptions in the region 260–300 nm ascribed to intraligand dtc transitions [7], which are not observed in CCl_4 because of the strong absorption of this solvent in UV.

Thermal reactions

The electronic absorption and EPR spectra of all mixed-ligand complexes are quite stable in CH_2Cl_2/ROH or $CHCl_3$/ROH (1:1) solutions and show no decomposition for times < 120 h. Opposite to them, the obtained absorption and EPR spectra reveal thermal decomposition of all mixed-ligand complexes in CCl_4/ROH (1:1) with more complicated changes for $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ than for $Cu^{II}(Et_2dtc)Cl$. Fig. 2 illustrates the absorbance vs time profiles obtained at 25°C at the CT band of the appropriate mixed-ligand complex in CCl_4/MeOH (1:1) solution. The kinetic runs show a slow decrease in the CT absorbances and an increase of the 282 nm absorption at larger reaction times due to the appearance of tetraethylthiuramdisulphide [8, 9] (Et_4tds) as the final product. Because of the UV–VIS spectral similarities of $Cu^{II}(Et_2dtc)Cl$, $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ and $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$, the kinetic curves in Fig. 2 are not very informative and they are additionally

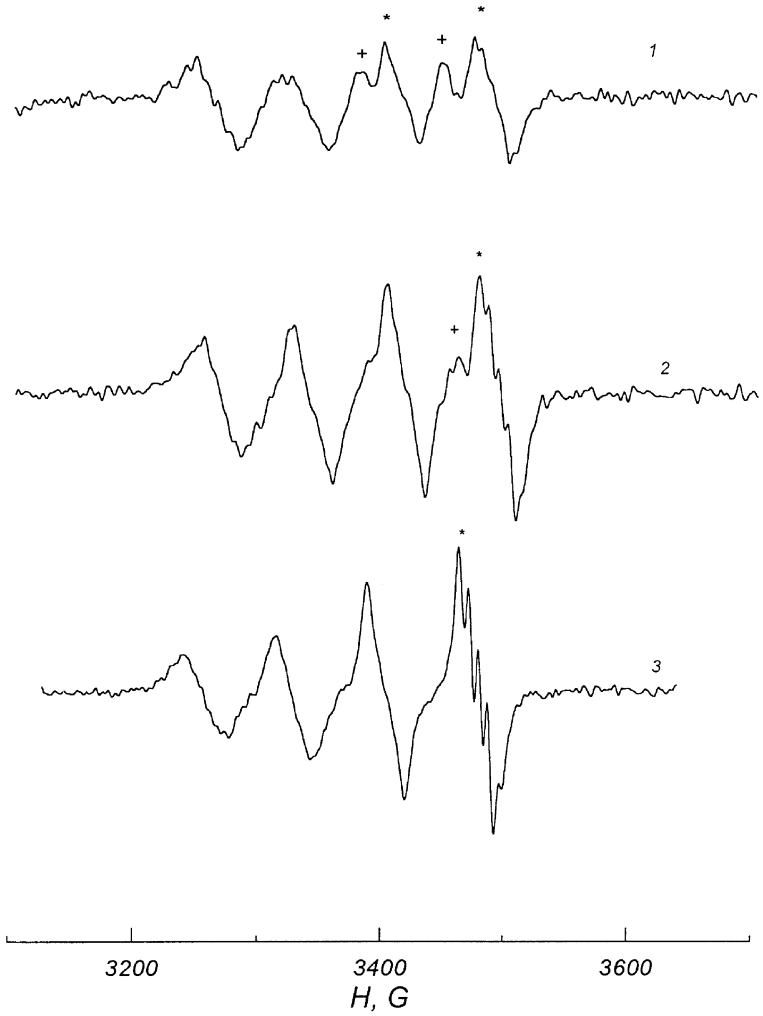

Fig. 1. (b) $Cu(Et_2dtc)_2$ in CH_2Cl_2 and $CuCl_2$ in MeOH (1), EtOH (2), *i*-BuOH (3). EPR lines marked * and + correspond to $Cu^{II}(Et_2dtc)Cl$ and $Cu^{II}(Et_2dtc)^+$ species, respectively.

complicated in CCl_4/MeOH and CCl_4/EtOH (1:1) solutions by the equilibrium reaction (3). For this reason EPR spectra were recorded at different time intervals after preparation of all CCl_4/ROH (1:1) solutions in an attempt to obtain more information about the occurrence of different kinetic steps.

A relevant representation of the EPR spectral changes obtained in the thermal reactions occurring after mixing of equimolar quantities of $Cu(Et_2dtc)_2$ in CCl_4 with *i*-BuOH solution of $Cu(ClO_4)_2$ (a) or MeOH solution of $Cu(NO_3)_2$ (b) is depicted in Fig. 3. The observed EPR spectral changes confirm the conversion of the bis-solvated $Cu^{II}(Et_2dtc)^+$ species into a chloride coordinated monosolvated $Cu^{II}(Et_2dtc)Cl$ form. This conclusion is also supported by the similarities between the values of g and A of the independently obtained (see Section 2) sample of $Cu^{II}(Et_2dtc)Cl$ and the product of $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ thermolysis taking place in CCl_4/ROH solvent systems (Table 1). Once obtained the chromophore $Cu^{II}S_2Cl \cdot solv$ is retained in all CCl_4/alcohol (1:1) solutions and thermal decomposition of $Cu^{II}(Et_2dtc)Cl$ to $CuCl_2$ and Et_4tds proceeds much slower.

Determination of rate constants

The observed EPR behavior was used for a kinetic study. It was easy to follow by this method in CCl_4/MeOH (1:1), CCl_4/EtOH (1:1) and CCl_4/*i*-BuOH (1:1) as the starting $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complexes and the product $Cu^{II}(Et_2dtc)Cl$ had different EPR parameters and the reaction proceeded at a convenient rate at 25°C. Figure 4 shows the concentration vs time profiles derived from the EPR data for the major species detected by EPR on keeping CCl_4/*i*-BuOH (1:1) solution of $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$(a) and CCl_4/MeOH (1:1) solution of $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ (b) for several hours in the dark. A strong decrease

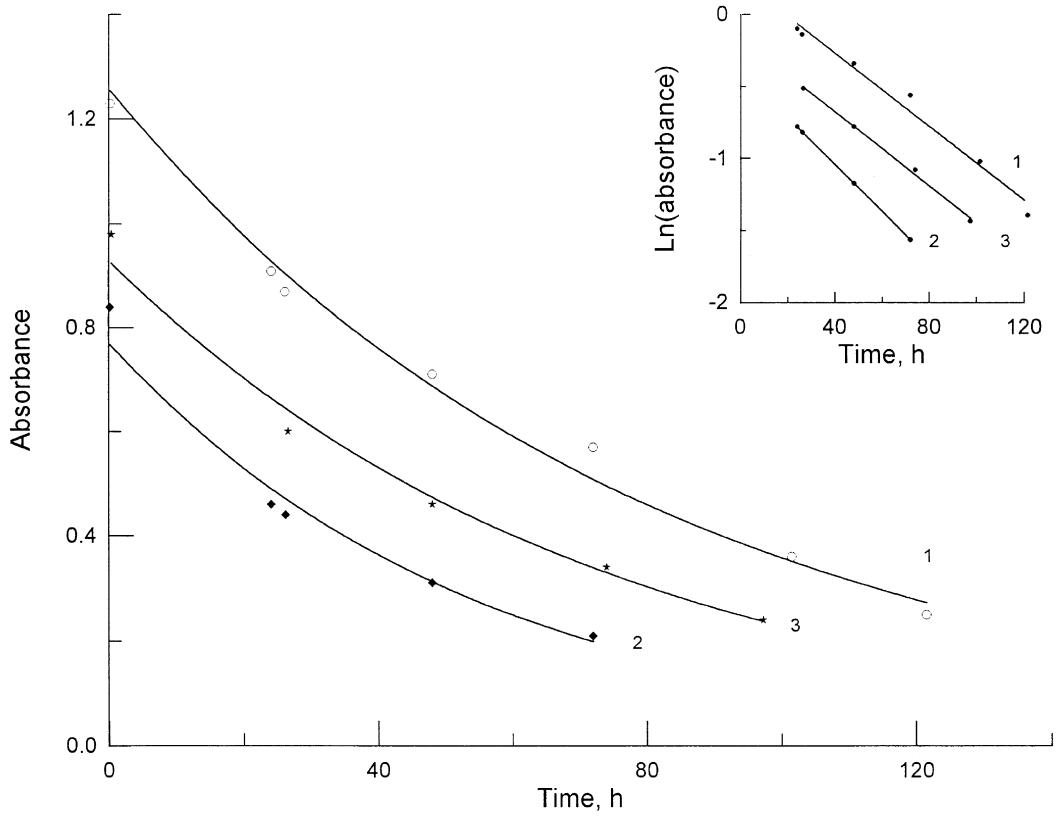

Fig. 2. Absorbance vs time profiles obtained at 25°C at the CT band of $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$ (1), $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ (2) and $Cu^{II}(Et_2dtc)Cl$ (3) in CCl_4/MeOH (1:1). Insets: The corresponding plots of ln(A) vs time.

in EPR intensity is observed during the reaction associated with the disappearance of the original $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complexes at 25°C illustrated by kinetic curves (1) in Fig. 4(a, b). The plots obtained in CCl_4/*i*-BuOH (1:1) showed that practically all $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ had reacted in this solvent yielding $Cu^{II}(Et_2dtc)Cl$ (Fig. 4(a)). In CCl_4/MeOH (1:1) (Fig. 4(b)) and CCl_4/EtOH (1:1) the EPR signal intensity of the original $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complex was decreasing to a definite value corresponding to its equilibrium concentration maintained by reaction (3).

The strongly descending curves (1) of the starting $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complexes were analyzed by the least squares method to give the results of k_1 in Table 2. This step was first order in the concentration of the starting complex as plots of ln(concentration) vs time (insets 1 in Fig. 4(a, b)) were linear to more than 50% reaction completion and the obtained values of k_1 followed the order of the hydrogen donating power of solvents *i*-BuOH > EtOH > MeOH [10].

The kinetic analysis of the changes of $Cu^{II}(Et_2dtc)Cl$ concentration given with curves (2) in Fig. 4(a, b) indicated that in all CCl_4/ROH (1:1) solvent mixtures it appeared after induction periods at different time depending on ROH. It seemed that $Cu^{II}(Et_2dtc)Cl$ was yielded in a reaction of an EPR silent intermediate

Table 2. Rate constants ($k \times 10^4\,s^{-1}$) of the room temperature reaction of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ (Y = ClO_4, NO_3) with CCl_4 under pseudo-first-order conditions in CCl_4/ROH (1:1)

Solvent	$Cu(Et_2dtc)^+ \ldots ClO_4^-$		$Cu(Et_2dtc)^+ \ldots NO_3^-$	
	k_1	k_2	k_1	k_2
CCl_4/MeOH	2.0	1.1	2.0	1.4
CCl_4/EtOH	2.4	1.3	2.1	1.2
CCl_4/*i*-BuOH	5.0	1.5	3.0	1.4

(A) and kinetic curves (2) were complicated by the existence of at least two steps with similar rate constants. The values of the rate constant k_2 with respect to $Cu^{II}(Et_2dtc)Cl$ concentration were calculated by the least squares method from the slope of the linear plots between ln(concentration) and time, obtained after the inflection point of curves (2) and given as insets 2 in Fig. 4(a, b). Although there were few experimental points, satisfactory fits were obtained to give approximate values of the rate constant k_2 corresponding to the formation of $Cu^{II}(Et_2dtc)Cl$ in a first-order reaction of A. The

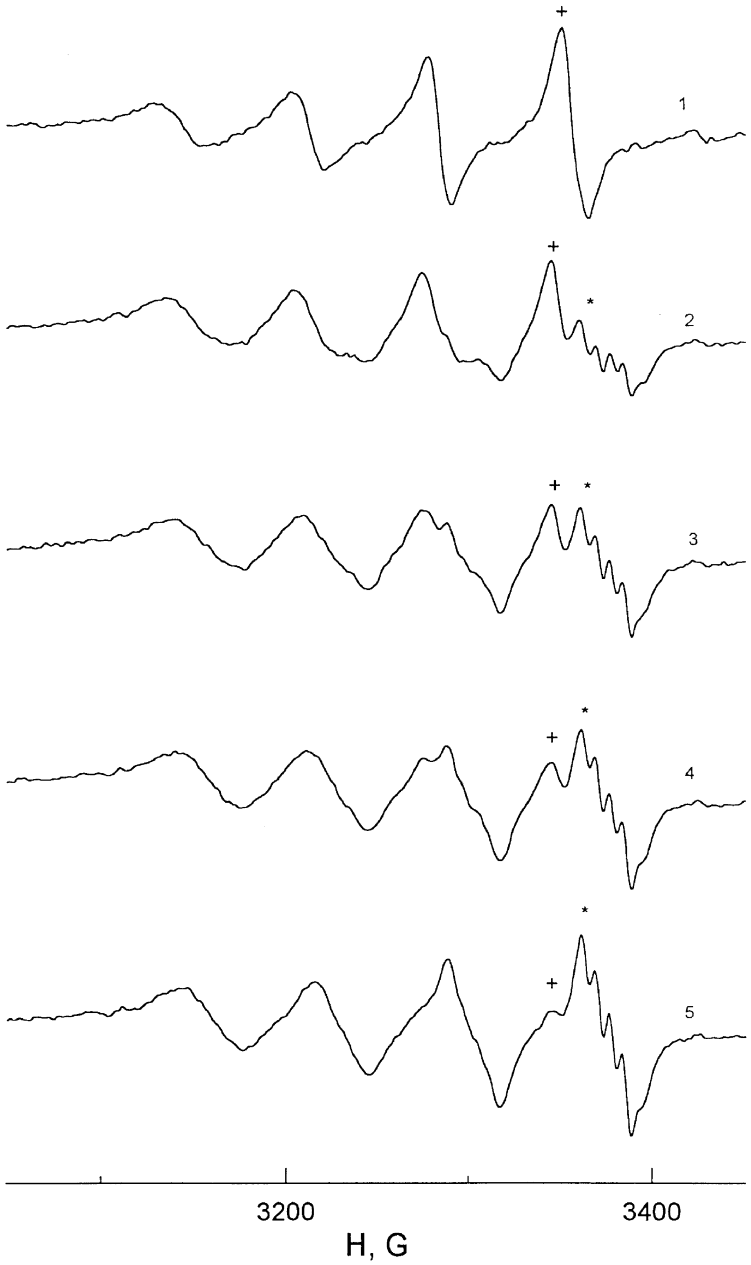

Fig. 3. EPR spectral changes obtained after mixing of equal volumes of $Cu(Et_2dtc)_2$ solution in CCl_4 (1×10^{-3} mol dm^{-3}) with 1×10^{-3} mol dm^{-3} solutions of (a) $Cu(ClO_4)_2$ in *i*-BuOH (spectra taken at 5–110 min) and (b) $Cu(NO_3)_2$ in MeOH (spectra taken 5–220 min), 25°C. EPR lines marked + and * are measured to obtain the respective curves 1 and 2 in Fig. 4.

results obtained in different solvent mixtures did not vary as seen in Table 2. On the ground of the simple rate law for this step (eqn (4)),

$$\frac{d[Cu(Et_2dtc)Cl]}{dt}=k_2[A], \qquad (4)$$

graphical differentiation of the experimental plots (2) in Fig. 4(a, b) gave the kinetic curves (3) of formation and disappearance of A.

Further conversion of $Cu^{II}(Et_2dtc)Cl$ proceeded in a slow step at the end of the reaction with very small changes in EPR occurring during large intervals compared to the scale of the intensity vs time profiles, thus this step was neglected in the EPR study. The value $k_{obs}=4\times10^{-6}$ s^{-1} about the rate constant of $Cu^{II}(Et_2dtc)Cl$ conversion was calculated by the least squares method from the slopes of the linear plots between ln(A) and time (the insets in Fig. 2) at larger reaction times.

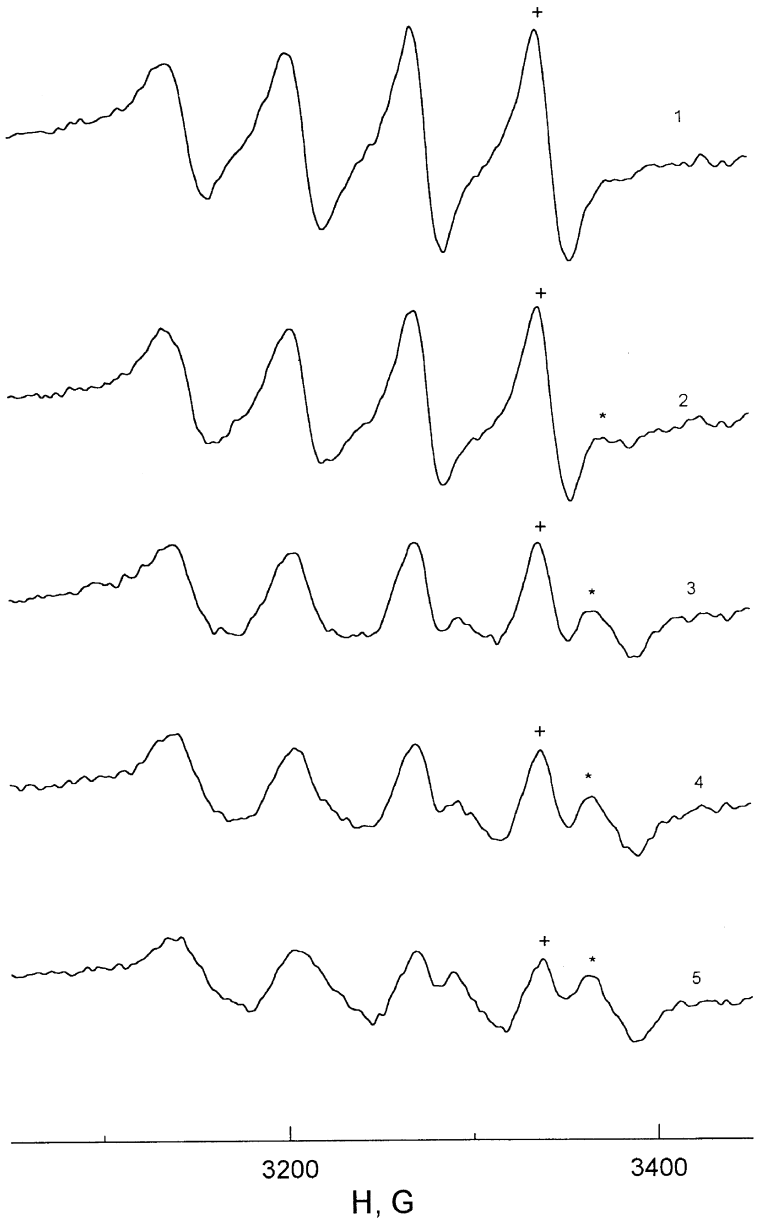

Fig. 3—*continued.*

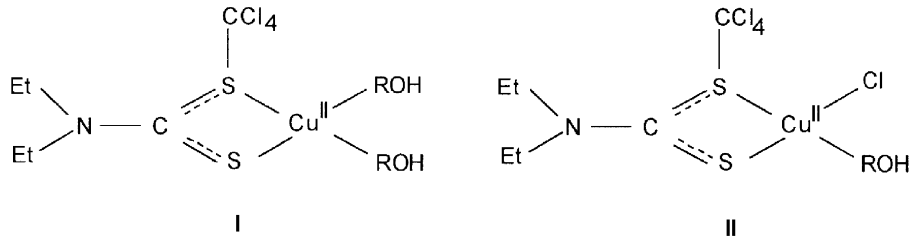
Mechanism of the thermal reaction

Based on the observed EPR behavior the formation of $Cu^{II}(Et_2dtc)Cl$ from $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ can be reasonably assumed to occur in two steps with apparent rate constants, the first involving the formation of an EPR silent intermediate. Since ligand substitution reactions of copper are typically rapid [11], it was likely to suppose that the formation of the mixed-ligand complex $Cu^{II}(Et_2dtc)Cl$ would involve two steps of electron transfer with the rate constants k_1 and k_2 involving consecutive reduction and oxidation of the metal ion. Considering the ability of CCl_4 to form associate **I** with $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ we could accept that a homolytic cleavage of a Cu–S bond in **I** proceeds as the first step initiated by the close approach and coordination of the acceptor CCl_4 molecule to the S atom, which is the donor center of the chromophore $Cu^{II}S_2(solv)_2$.

There are two possible mechanistic routes after this initial step of electron transfer. The first takes into account that the homolytic cleavage of the Cu–S bond in $Cu^{II}(Et_2dtc)^+$ facilitates the breaking of the remaining Cu–S bond to give Cu(I) and the free $Et_2dtc\cdot$ radical of the ligand which may either give Et_4tds (reaction (5)) or abstract a hydrogen atom from the solvent [12] (reaction (6)) to give Et_2dtcH which itself then undergoes reaction (7),



Structure 1.

$$2Et_2dtc^{\cdot} = Et_4tds, \quad (5)$$

$$Et_2dtc^{\cdot} + ROH = Et_2dtcH + RO^{\cdot}, \quad (6)$$

$$Et_2dtcH + Cu(I) = Cu^{I}(Et_2dtc) + H^{+}. \quad (7)$$

The proposed complex of Cu(I) can then be oxidized to Cu(II) in a second step of electron transfer. Several oxidants are present in these solutions that could react with $Cu^{I}(Et_2dtc)$. The oxidant present in highest concentration is CCl_4 reacting spontaneously [13] with Cu(I) compounds to give compounds of Cu(II),

$$Cu^{I}(Et_2dtc) + CCl_4 = Cu^{II}(Et_2dtc)Cl + CCl_3^{\cdot}. \quad (8)$$

The free $CCl_3^{\cdot}$ radical is converted to $CHCl_3$,

$$CCl_3^{\cdot} + ROH = CHCl_3 + RO^{\cdot} \quad (9)$$

and $RO^{\cdot}$ undergoes secondary reactions [14].

Parallel oxidation of Cu(I) by CCl_4,

$$Cu(I) + CCl_4 = Cu^{II}Cl^{+} + CCl_3^{\cdot} \quad (10)$$

would proceed much slower than reactions (6) and (7).

Another potentially oxidizing species in solutions open to the air is dissolved dioxygen and Et_4tds, the latter giving $Cu(Et_2dtc)_2$ with both Cu(I) and Cu(II) according to eqn (11)eqn (12) respectively [8],

$$Et_4tds + Cu(I) \rightarrow Cu(Et_2dtc)_2, \quad (11)$$

$$Et_4tds + Cu(II) \rightarrow Cu(Et_2dtc)_2. \quad (12)$$

However, the effect of these oxidants is minor, because of the low Et_4tds concentration and the previously observed independence of photolysis on aeration [1].

The second possible mechanism also involves an initial step of electron transfer. The close proximity of the chlorine atom from the associated CCl_4 molecule to Cu^{I} in **I** then may result in a rapid Cl atom transfer from CCl_4 to Cu in the transition state to produce $Et_2dtc^{\cdot}$, $Cu^{II}Cl$ and reduced CCl_4. This scheme may play a small part in the conversion but does not adequately explain the induction period of $Cu^{II}(Et_2dtc)Cl$ formation since reaction (13) should also be rapid,

$$Cu^{II}Cl + Et_2dtcH = Cu^{II}(Et_2dtc)Cl + H^{+}. \quad (13)$$

The first scheme appears to be a general mechanism for the thermal conversion involving related chloroalkane associates of $Cu^{II}(Et_2dtc)^{+} \ldots Y^{-}$ and $Cu^{II}(Et_2dtc)Cl$. The reaction of $Cu^{II}(Et_2dtc)^{+} \ldots Y^{-}$ with CCl_4 is much faster than that between $Cu^{II}(Et_2dtc)^{+} \ldots Y^{-}$ and $CHCl_3$ (or CH_2Cl_2). The significantly different acceptor properties of CCl_4 and $CHCl_3$ (or CH_2Cl_2) and their different C–Cl bond dissociation energies [15, 16] are expected to contribute to the observed rate difference through enthalpy terms.

Similar to **I**, the homolytic Cu–S bond cleavage in **II**, initiated by the coordinated CCl_4 molecule, proceeds with the breaking of the remaining Cu–S bond to give the free $Et_2dtc^{\cdot}$ radical of the ligand, as well as Cu(I) and chloride ion connected in the following equilibrium:

$$Cu(I) + Cl^{-} \rightleftharpoons CuCl. \quad (14)$$

Therefore, reactions of CuCl should also be considered,

$$Et_2dtcH + CuCl = Cu^{I}(Et_2dtc) + H^{+} + Cl^{-}, \quad (15)$$

$$CuCl + CCl_4 = CuCl_2 + CCl_3^{\cdot} \quad (16)$$

the first being much faster than the second. Reactions (5) and (16) give the final Et_4tds and $CuCl_2$ products of thermolysis.

Continuous photolysis

All investigated complexes undergo photodecomposition upon irradiation with UV and visible light <420 nm. EPR data in Fig. 5(a) which are typical of all chloroalkane/*i*-BuOH (1:1) solutions show that the initial EPR spectrum of $Cu^{II}(Et_2dtc)^{+} \ldots ClO_4^{-}$ is completely converted into the $Cu^{II}(Et_2dtc)Cl$ EPR spectrum which also fades on further irradiation following the reduction of Cu(II) to Cu(I).

Contrary to chloroalkane/*i*-BuOH (1:1), when CH_2Cl_2/EtOH (1:1) (Fig. 5(b)) or CH_2Cl_2/MeOH (1:1) solutions are used for the irradiation of 1×10^{-3} M $Cu^{II}(Et_2dtc)^{+} \ldots Y^{-}$, the intensity of the initial EPR spectrum is gradually decreasing, but only an extremely low intensity intermediate EPR signal of $Cu^{II}(Et_2dtc)Cl$ appears as a result. The hindered formation of the intermediate $Cu^{II}(Et_2dtc)Cl$ complex in these solvent mixtures could be explained with the low

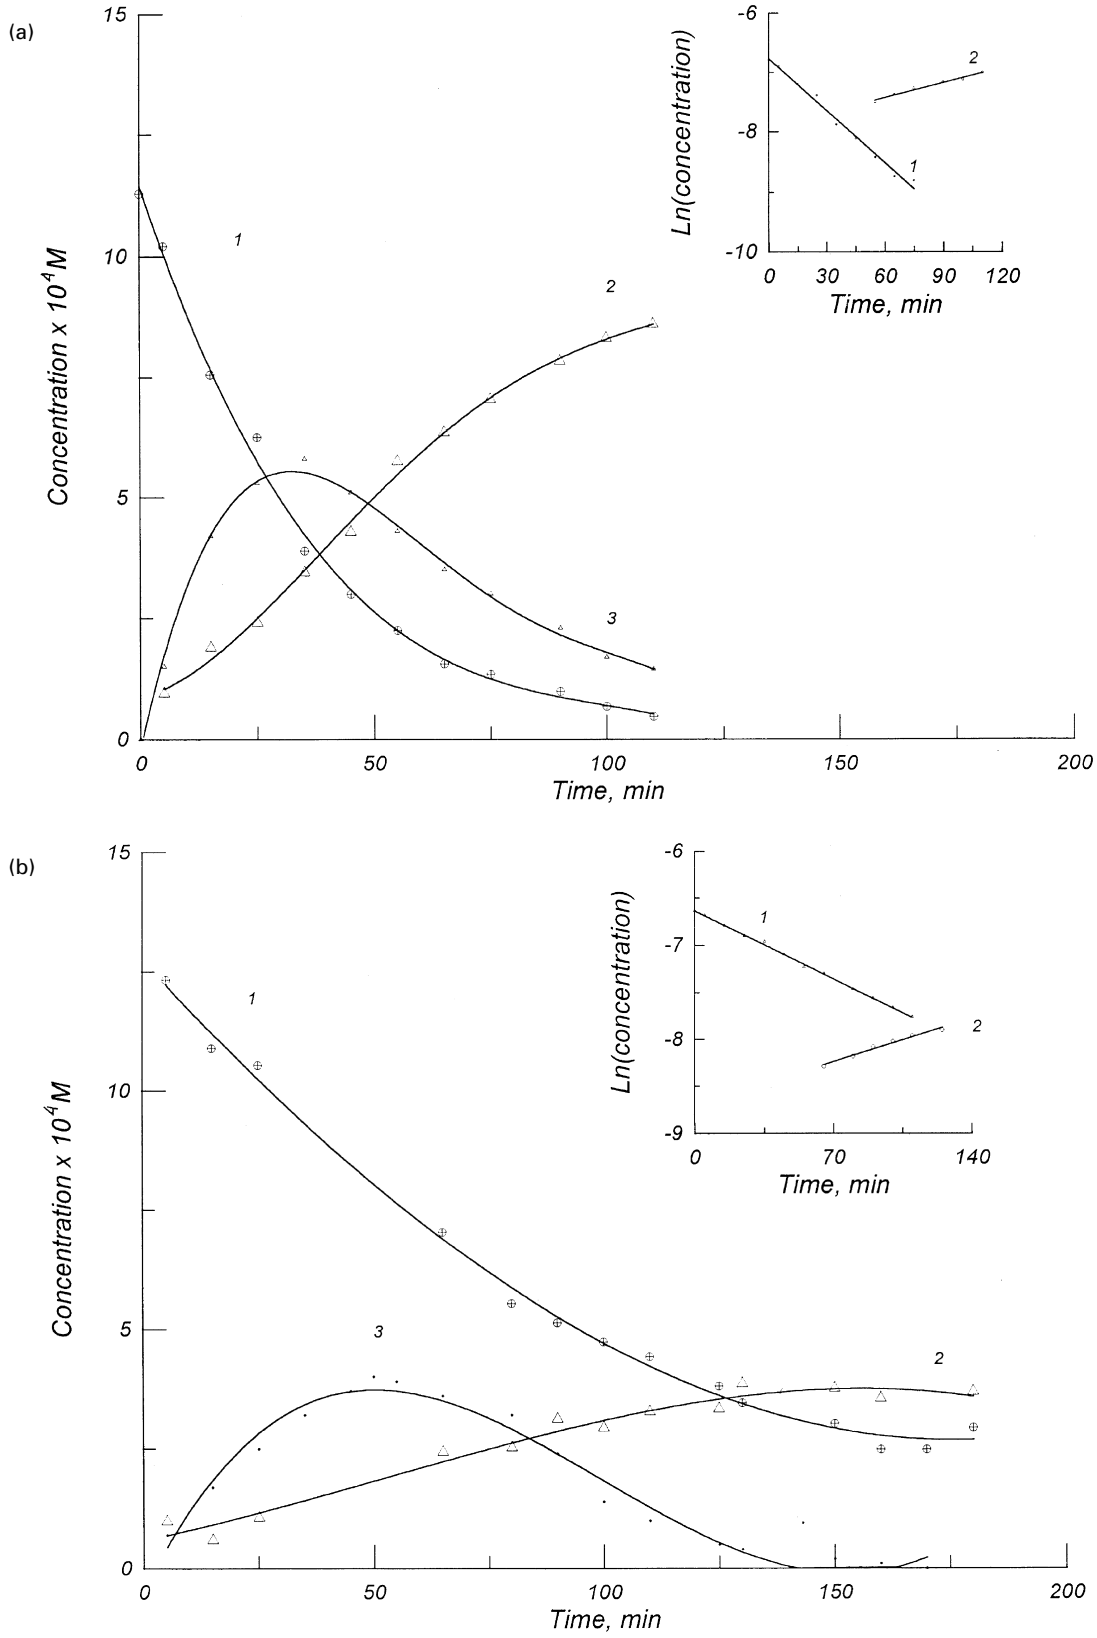


Fig. 4. Concentration vs time profiles derived from the EPR data for the major species detected after mixing of equal volumes of $Cu(Et_2dtc)_2$ solution in CCl_4 (1×10^{-3} mol dm^{-3}) with 1×10^{-3} mol dm^{-3} solutions of $Cu(ClO_4)_2$ in *i*-BuOH (a) and $Cu(NO_3)_2$ in MeOH (b), 25°C. (1) $Cu^{II}(Et_2dtc)^+ \ldots Y^-$; (2) $Cu^{II}(Et_2dtc)Cl$; (3) EPR silent intermediate. Insets: The corresponding plots of ln(conc.) vs time.

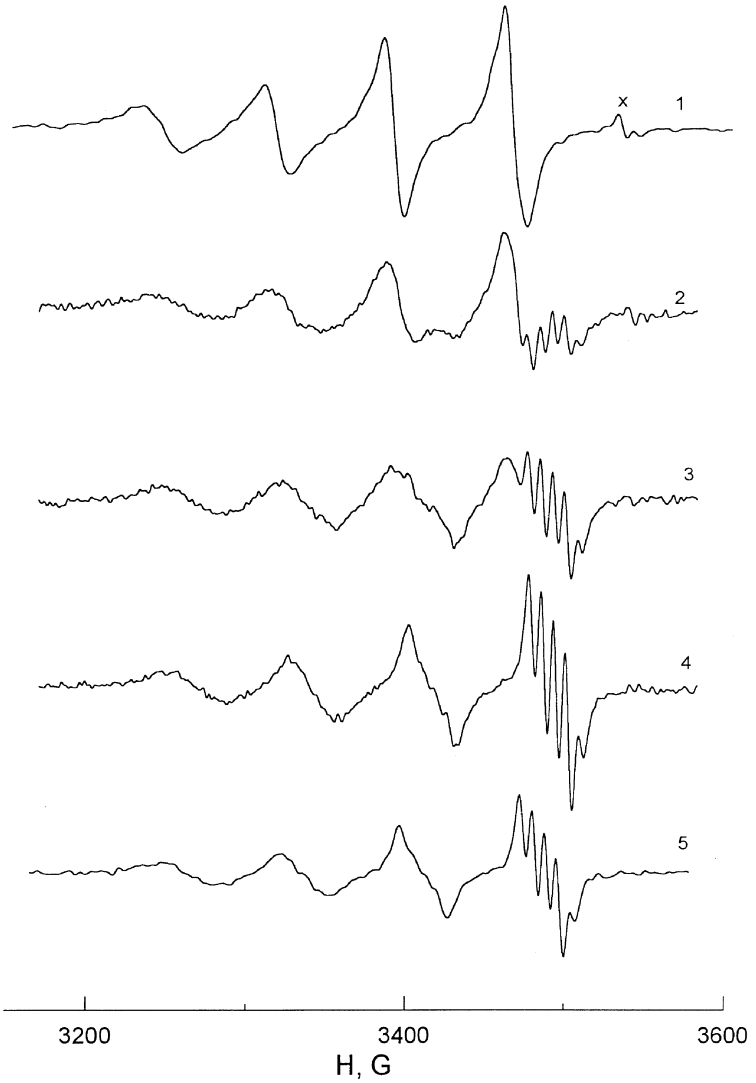

Fig. 5. EPR spectra taken after consecutive UV irradiations of (a) 1×10^{-3} M $CHCl_3$/*i*-BuOH (1:1) solution of $Cu^{II}(Et_2dtc)^+ \ldots ClO_4^-$ for 0 s (1), 15 s (2), 30 s (3), 65 s (4), and 90 s (5); and (b) 1×10^{-3} M CH_2Cl_2/EtOH (1:1) solution of $Cu^{II}(Et_2dtc)^+ \ldots NO_3^-$ for 0 s (1), 20 s (2), 40 s (3) and 50 s (4). Signals marked × are due to the parent $Cu(Et_2dtc)_2$.

concentration of the released chloride taking part in equilibrium (3).

Typical UV–VIS spectral changes (Fig. 6) observed in all chloroalkane/alcohol (1:1) solutions of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ complexes show the decay of their CT band in the time course of photolysis after the first 5–10 s of increasing. Longer irradiation leads to the formation of a new band at 282 nm due to the absorption of Et_4tds, which is the final reaction product. The appearance of Et_4tds is consistent with the formation of the free $Et_2dtc^{\cdot}$ radical as the primary photo-product.

Quantum yields of photolysis

The absorbance of the CT band at about 402 nm was observed to decrease linearly after the first 15–20 min of increasing [1] upon CT-irradiation ($\lambda_{irr} = 406$ nm), indicating that the photolytic process followed zero-order kinetics. This allowed us to calculate the photo-reduction quantum yields (ϕ_{red} = moles of Cu(II) complex per minute per mole of photons absorbed per minute) for all Cu(II) complexes examined.

Table 3 shows the quantum yields for the photolytic reactions studied upon CT irradiation at 406 nm. It seems that the three complexes display essentially the same quantum yields of electron transfer which is the main reaction neglecting the transformations of the primary photoproducts. However, this conclusion appears to be incorrect when we consider the observed conversion of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ to $Cu^{II}(Et_2dtc)Cl$ which replaces the initial 397 nm LMCT band with a similar band at 402 nm and maintains practically the

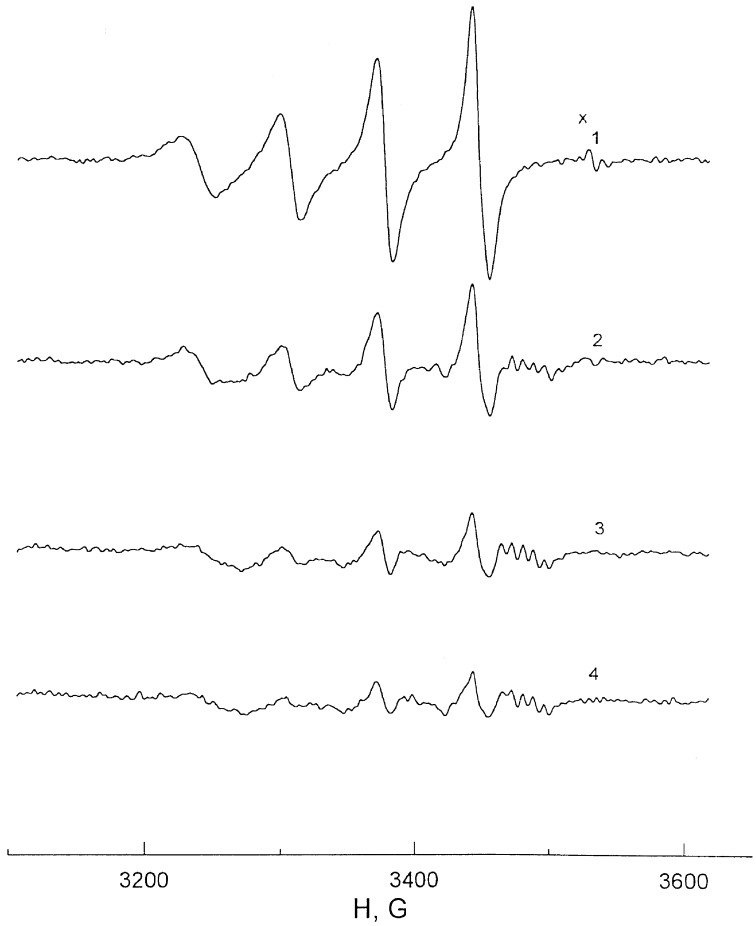

Fig. 5—*continued.*

same measured absorbance values at the early stages of photolysis. Therefore, the equal ϕ_{red} values obtained by the linear decrease of the CT band intensity upon 406 nm irradiation of all solutions correspond to $Cu^{II}(Et_2dtc)Cl$ photolysis proceeding within associate **II**, which is the main reaction at this stage. It is obvious that the primary photochemical act taking place within associate **I** at the early stages of photolysis to give $Cu^{II}(Et_2dtc)Cl$ is more effective.

On the other hand, quantum yields in Table 3 appreciably depend on the solvent composition and the ϕ_{red} values increase with decreasing coordinating abilities of ROH and increasing acceptor properties of chloroalkanes.

Mechanism of photolysis

The reaction from the LMCT excited states of both **I** and **II** is reduction of Cu(II) to Cu(I) proceeding via an intramolecular electron transfer from an equatorially bound S atom of the ligand to copper(II). The homolytic photo-cleavage of Cu–S bond in the LMCT excited state facilitates the breaking of the remaining Cu–S bond to give the same products as the thermal reaction. The primary photochemical act taking place within associate **II** is more effective the stronger the acceptor properties of chloroalkane and the weaker the coordinating abilities of alcohol.

CONCLUSIONS

The conversion of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ ($Y = ClO_4^-$, NO_3^-) to $Cu^{II}(Et_2dtc)Cl$ on photolysis in halocarbon/alcohol solvent mixtures proceeds within its associate with the halocarbon. The photolysis is proposed to occur from the LMCT excited state giving free dtc$^\bullet$ radical and Cu(I). The quantum efficiency of photolysis is attributed to the extent of charge-transfer contribution, acceptor properties of halocarbon and hydrogen atom donating ability of alcohol. Thermal reaction of $Cu^{II}(Et_2dtc)^+ \ldots Y^-$ species in CCl_4/alcohol solvent mixtures to $Cu^{II}(Et_2dtc)Cl$ follows a similar pathway.
