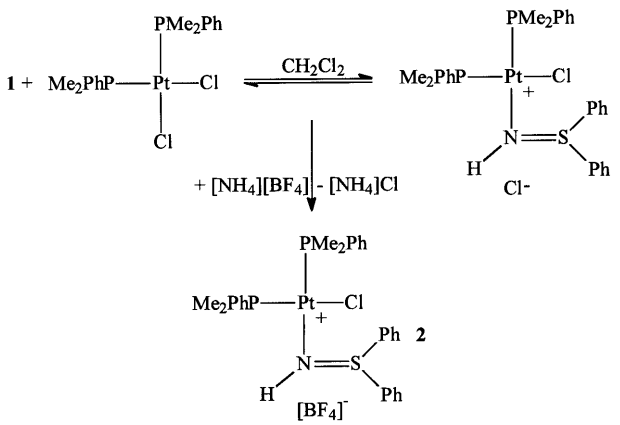
^{31}P NMR reveals that an equimolar mixture of **1** and *cis*-$PtCl_2(PMe_2Ph)_2$ in CH_2Cl_2 at room temperature contains both the platinum starting material and a complex identified by an AX spectrum. Both these features of the spectrum remain, albeit in varying ratios, even when the relative amounts of the reagents are altered; even a large excess of **1** does not remove all *cis*-$PtCl_2(PMe_2Ph)_2$ from the system. This observation suggested the presence of an equilibrium between **1**, *cis*-$PtCl_2(PMe_2Ph)_2$ and a new coordination complex and this was confirmed by removing free chloride from the system. Thus, treatment with $[NH_4][L]$, where L = $[PF_6]^-$ or $[BF_4]^-$, results in the complete conversion of the platinum starting material through to the product. Though both salts may be precipitated by addition of ether, the $[PF_6]^-$ case does not crystallise well via slow diffusion-only an oil is obtained. In the case of the $[BF_4]^-$ salt, however, slow diffusion of ether leads to colourless crystals of the product, which we have characterised as *cis*-$[PtCl(Ph_2SNH)(PMe_2Ph)_2][BF_4]$ (**2**) by a combination of NMR, IR and micro-analysis. The key evidence comes from the fact that an AX pattern is observed in the ^{31}P NMR spectrum; this rules out a

trans structure, while the $^{195}Pt-^{31}P$ coupling constants of the phosphorus atoms are consistent with P *trans* to Cl and to N. Comparison of the latter value (3141 Hz) with that for P *trans* to N(H) in the $[S_2N_2H]^-$ complex $[Pt(S_2N_2H)(PMe_2Ph)_2]^+$ (3240 Hz) serves to confirm that the ligand is *N*-bound (noting that in the aforementioned case the value for P *trans* to S is significantly different: 2595 Hz) [8]. By analogy with the latter case therefore we can be confident therefore that the sulfimide has coordinated through the nitrogen atom.



Attempts to use X-ray crystallography to confirm the structure find problems brought about by the small size and poor quality of the crystals and by disorder within the anions[1]. For this reason we do not formally present the X-ray data here though it should be noted that the solution is accurate enough to confirm the connectivity as shown in the structure in Scheme 1.

Two immediate questions come to mind as an extension to this reaction and the structure of **2**, namely (i) can more than one unit of **1** be coordinated to the platinum and (ii) is it possible to generate the *trans* isomer of **2**? On the first point, there is no evidence that, at ambient temperatures at least, a second molecule of **1** can react with **2** to generate a complex of the type $[Pt(Ph_2SNH)_2(PMe_2Ph)_2]^{2+}$. While it is possible that steric influences play a part in precluding formation of the latter, the isolation of a homoleptic sulfimide complex noted below would make this a less likely explanation. On the second point we have so far produced no evidence for the formation of the other potential isomer of **2**. Heating in toluene — a technique which can be used to generate the *trans* isomer of $[PtCl_2(PMe_2Ph)_2]$ from the *cis* — for example [9] does not appear to induce isomerisation. It may well be that again, steric considerations are paramount and mitigate against formation of the *trans*-phosphine isomer; for example, it could be argued that in the *cis* arrangement the bulky sulfimide unit has close contact with only one of the phosphines whereas it would interact with both in a *trans* structure.

If a solution of **2** in CH_2Cl_2 is treated with one equivalent of $[^nBu_4N]Cl$, ^{31}P NMR reveals the presence of both **1** and **2**. This observation confirms that the initial reaction of **1** with $[PtCl_2(PMe_2Ph)_2]$ must proceed via the kind of equilibrium shown in Scheme 1. It is only through removal of the free chloride as $[NH_4]Cl$ that the reaction can be driven to completion. That the choice of anion should have such a dramatic effect upon the ability of the product to crystallise is somewhat surprising; there would appear no obvious reason why the $[BF_4]^-$ salt should crystallise so readily while the $[PF_6]^-$ analogue generates only an oil.

The above reaction allows us to make some important comparisons between the coordinating ability of **1** and that of species such as S_4N_4. The latter is inert to $PtCl_2(PMe_2Ph)_2$ at ambient temperatures and only reacts upon either thermolysis [10] or photolysis [11]. In both cases the reaction probably proceeds via smaller anions such as $[S_3N_3]^-$; the sodium salt of the latter reacts to give $Pt(S_2N_2)(PMe_2Ph)_2$, a product which also forms when $S_4N_4H_4$ reacts in the presence of the base DBU [12]. Thus in order for underivatised S–N species to react with $PtCl_2(PMe_2Ph)_2$ a driving force such as salt elimination, photochemical disruption or simple brute force of high temperatures has to be employed. Clearly, therefore, **1** has a much stronger affinity for the platinum centre as it reacts, albeit in the equilibrium shown in Scheme 1, at ambient temperatures.

Although the above reaction appears to be limited to addition of one unit of **1** as ligand, we can in the correct circumstances generate a homoleptic platinum complex of **1**. We have previously shown that $[PPh_4]_2[PtCl_4]$ forms when $K_2[PtCl_4]$ reacts with $[PPh_4]Cl$ in water [13]. The presence of the phosphonium cation solublises the $[PtCl_4]^{2-}$ anion in CH_2Cl_2 and addition of four equivalents of **1** results in a slow reaction which eventually deposits $[Pt(Ph_2SNH)_4]Cl_2$ (**3**) as a well-formed pale yellow crystalline product after a few days standing. The product has been characterised by micro-analysis and IR spectroscopy; in the latter case the spectrum is quite distinctly similar to that of the copper analogue $[Cu(Ph_2SNH)_4]Cl_2$ [6]. Thus it shows a very strong and broad N–H stretch at 3056 cm^{-1} (3081 cm^{-1} for the Cu analogue) and a strong S–N stretch at 934 cm^{-1} (which comes at 940 cm^{-1} in the copper case). The N–H stretch is particularly pertinent — we have noted that this stretch is only strong when **1** is present on a cation and there is thus H-bonding to the anion; in neutral species it can often be hard

Scheme 1. The equilibrium present in solutions of **1** and $PtCl_2(PMe_2Ph)_2$ and the formation of **2**.

[1] Triclinic, $a = 15.724(5)$, $b = 17.407(6)$, $c = 14.64(1)$ Å; $\alpha = 112.31(3)$, $\beta = 97.537$, $\gamma = 90.86(3)°$; $V = 3466(3)$ Å^3; space group $P\bar{1}$. Due to the small size and poor quality of the crystal the refinement did not converge well. The $[BF_4]^-$ ions show signs of disorder but this could not be resolved into discrete sites.

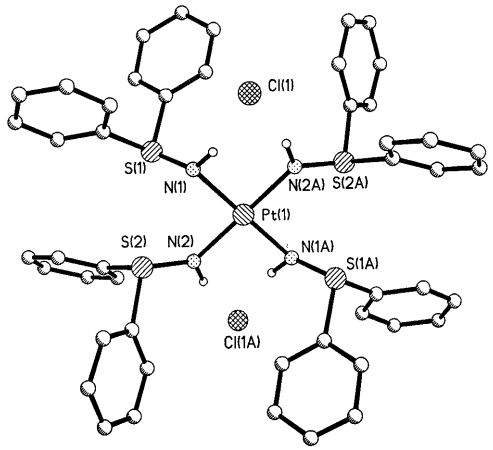


Fig. 1. The molecular structure of $[Pt(Ph_2SNH)_4]Cl_2$ (**3**).

to detect. Ultimate confirmation of the structure of **3** comes through X-ray crystallography. Fig. 1 shows its molecular structure and confirms the expected square-planar geometry; it also confirms that the ligands are all *N*-bound (an important point given the thiophilic nature platinum — note the presence of a Pt–S bound sulfimide-type unit, albeit as part of a metallocycle, in $[Pt(Ph_2SNH)(Ph_2SNC(Me)NH)Cl]Cl$ [5]). Comparison with the structure of $[Cu(Ph_2SNH)_4]Cl_2$ [6] reveals an effectively identical S–N bond distance within the ligands though the average angle at the nitrogens is less (122.6 cf. 125.3°) in **3**. Perhaps the most important observation is that, as in the Cu case, the ligands arrange themselves in such a way that the two pairs of *cis* sulfurs extend on to opposite sides of the MN_4 plane; as a result each pair of N–H groups can co-operate in H-bonding to a chloride. The overall average H–Cl bond distance is thus only 2.25 Å, with N–H–Cl angles of 168°. As mentioned earlier such cooperative H-bonding seems to be a feature of complexes of **1**; in the case of **3** Table 1 it clearly raises the possibility that insertion of the appropriate bridging H-bonding anion could result in the formation of extended structures. Thus one may envisage metathesis reactions to introduce anions such as fumarate or terepthalate into the system which could then link the cations into extended arrays. Work towards this is underway.

Table 1
Selected bond distances (Å) and angles (°) in complex **3**

Pt–N(1)	2.042(5)
Pt–N(2)	2.041(5)
N(1)–S(1)	1.589(5)
N(2)–S(2)	1.580(5)
N(1)–Pt–N(2)	92.2(2)
N(1)–Pt–N(2A)	87.8(2)
Pt–N(1)–S(1)	120.6(3)
Pt–N(2)–S(2)	124.6(3)

This reaction also provides a contrast between the reactivity of **1** and S_4N_4. In the latter case we have observed substitution of one of the chlorides of the $[PtCl_4]^{2-}$ followed by a redox reaction to give a Pt(IV) complex of $[S_4N_4]^{2-}$ [13]. Although a redox reaction is not an obvious option for **1**, the fact that no more than one chloride is substituted by the S_4N_4 (even when in excess) clearly provides further evidence of relative reactivity of the two species.

In conclusion we can say that this work clearly indicates that **1** has a powerful affinity for platinum centres; although the option to bind via sulfur is there, it prefers to coordinate through the nitrogen and is significantly more reactive than 'organo-free' sulfur nitrides such as S_4N_4. The presence of strong, concerted H-bonding interactions within **3** confirms the potential of sulfimide ligands such as **1** to act as a new class of initiator of extended array systems.

4. Supplementary material

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 143910 for compound **3**. Abstract

The stoichiometries and stability constants of the manganese(II), cobalt(II) and nickel(II) complexes with seven aminodiphosphonates [$RN(CH_2PO_3H_2)_2$, L] containing iminomethylenephosphonate moieties have been determined pH-metrically at 25°C and at an ionic strength of 0.20 mol dm^{-3} (KCl). The results suggest for L = **1**–**6** only equimolar species: $[M(H_2L)]$, $[M(HL)]^-$, $[ML]^{2-}$ and hydroxo $[MH_{-1}L]^{3-}$, in the pH range of 3–11.5, the only difference is the presence of an additional $[M(H_3L)]^+$ species at low pH for *N*-3-picolyliminodi(methylenephosphonic) acid. For L = **7** the models contain protonated and non-protonated 1:2 species. From the comparative analysis of the stability and the spectroscopic (UV–VIS) data it has been established that the ligands coordinate to the metal ions only by the phosphonate group(s) in a monodentate or bidentate manner. The LMCT bands from $O^-(PO_3^{2-})$ to Ni^{2+} are at 222–211 nm. © 2000 Elsevier Science Ltd. All rights reserved.

1. Introduction

Beginning in the 1970s, the search for environmentally safer compounds focused on amino acid biosynthesis inhibitors, several of which were successfully developed as herbicides [1]. Aminoalkylphosphonic acids are broadly defined as amino acid analogues in which the carboxylic function is replaced by a phosphonic one or related function. Aminopolyphosphonic acids and their derivatives have also received considerable attention because of their interesting biological activity [2–4]. Metal aminophosphonate (aminopolyphosphonate) chemistry is attracting increasing interest because of the variety of properties that can be introduced via the phosphonate ligand [5–10]. Although metal complexes of aminophosphonic (aminopolyphosphonic) acids have been studied fairly extensively in solution, their solution chemistry is still not well understood [11–13]. Besides, glyphosate (*N*-phosphonomethylglycine, a well known herbicide) acts by inhibiting the sixth step in the initial common route of aromatic amino acid biosynthesis. The first step in aromatic metabolism is the condensation of phospho*enol*pyruvate (PEP) with erythrose-4-phosphate (E4P), a reaction catalysed by 3-deoxy-D-arabinoheptulosonate-7-phosphate (DAHP) synthase. DAHP synthase has been shown to occur in plants as two distinct isoenzymes with different roles and properties. One form, localized in the cytosol, strictly requires the presence of divalent cations (Co^{2+} in the range 0.4–0.7 mM, or Mg^{2+} at higher concentrations) [14,15]; however, the activity of the other plastidial form does not, but is stimulated three- to five-fold by 0.5 mM Mn^{2+} [16]. The activities of these two enzyme forms were

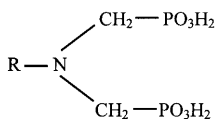
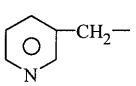
measured in the presence of seven different *N*-substituted aminomethylenebisphosphonic acids by Forlani et al. [17].

The manganese(II) diphosphonic acid systems is an area of Mn^{2+} chemistry in which a significant amount of structural data are not available.



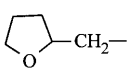
Manganese is one of the twenty-five life elements and participates in the formation of a variety of metalloenzymes: superoxide dismutase, pyruvate carboxylase [18,19], arginase and enolase [20]. Manganese catalases originating from *Thermus thermophilus* and *Lactobacillus plantarum* protect organisms from oxidative damage [21]. To explore the potential possibilities of manganese bonding to proteins, a number of investigations on manganese interactions with simple amino acids have been carried out. Many papers suggest O,O type coordination whereas the amino nitrogen remains rather uncoordinated [22–26]. In some cases the coordination through the nitrogen atom of the amino acid has been postulated [27,18]. This bonding mode is also proposed for some naturally existing enzymes [20].

For a better understanding and interpretation of the biological findings, a more detailed knowledge about complexing abilities of this type of compound with different metal ions is indispensable.



As part of our program on the coordination chemistry of divalent cations with aminopolyphosphonic acids (aminodi- and aminobisphosphonic acids), we have set out to elucidate the molecular structures and reactivities of these types of complex.

We have recently reported results on metal complexes of the same iminodi(methylenephosphonic) acids [28,29]. It has been established that the coordination in all copper(II) complexes is realized by the phosphonic group(s) and imino nitrogen [28]. The tridentate complexes with two joined five-membered chelate rings predominate in solutions at a pH of about 7–11, for the majority of the zinc systems. On the contrary, Ca^{2+} and Mg^{2+} prefer a pure phosphonate coordination [29].



The aim of the present work was to obtain information on the protonation equilibria and the complex-forming ability of those iminodi(methylenephosphonic) acids (see Scheme 1), by establishing the compositions and stabilities of the species formed with Mn^{2+}, Co^{2+} and Ni^{2+} ions in aqueous solution.

2. Experimental

2.1. Materials

Diphosphonic acids used in this paper were obtained according to previously described procedures [30,31]. The exact concentrations of the solutions of the ligands used for potentiometric studies were determined by the Gran method [32]. The concentrations of the metal(II) chloride stock solutions were standarized by complexometric ethylenediaminetetraacetate (EDTA) titration. Carbonate-free potasium hydroxide (the titrant) was prepared and standardized against a standard potassium hydrogenphthalate solution.

2.2. Potentiometry

The stability constants of the proton and metal(II) complexes were determined by pH-metric titration of 2 cm^3 samples. The ligand (L) concentration was 2×10^{-3} mol dm^{-3} and additionally 4×10^{-3} mol dm^{-3} for ligand **6** and 1×10^{-3} mol dm^{-3} for ligand **1**. The metal:ligand molar ratio was 0:1; 1:1.5; 1:2 and the ionic strength adjusted to 0.2 mol dm^{-3} with KCl in each case. The titrations were performed with a carbonate-free KOH solution under argon atmosphere over pH range 2.5–11.5 for ligand and 2.5–10.5 for metal:ligand systems. The exceptions were the Ni^{2+}–**1** and Co^{2+}–**1** systems, where precipitation was observed at pH about 9. All titration solutions were thermostatted at 25 ± 0.1°C using a constant-temperature water-bath.

The pH was measured with a MOLSPIN automatic titration system using a micro combination pH electrode (Mettler–Toledo, Type 2). Small amounts ($\Delta v = 0.001$ cm^3) of titrant were added (total volume = 0.1 cm^3). The electrode system was calibrated by periodic titrations of HCl solution (7.5×10^{-3} mol dm^{-3} in KCl) against standard KOH solution. The resulting titration data were used to calculate the standard elec-

trode potentials, E^0, and the dissociation constant for water ($pK_w = 13.74$). These values were then used to calculate the hydrogen-ion concentration [H^+] from emf readings [33]. Calculations were carried out using the SUPERQUAD computer program [34].

The charges of the complexes have been omitted in the text and tables. However, for clarity, it should be mentioned, that the fully deprotonated forms have negative charges L^{4-}.

2.3. Spectroscopic measurements (UV–VIS)

The UV absorption spectra for systems with nickel(II) were recorded at room temperature on a Specord M40 spectrophotometer, digitally (20 cm^{-1}) over the range 28000–50000 cm^{-1}. The spectral data at selected ca. 1000 wavenumbers over the range 30000–50000 cm^{-1} (or 37000–50000 cm^{-1}) were employed for analysis and resolved into Gaussian components. The metal ion concentration was 5×10^{-4} mol dm^{-3}. The spectra were fitted with Gaussian bands using the CFP program [35] based on the Slavič [36] numerical algorithm, which for the last a few years has been successfully applied by us to the deconvolution of d-d (ligand field) spectra [37] (and refs. therein).

The VIS absorption spectra for systems with cobalt(II) and nickel(II) were recorded at room temperature on a Cary 5 spectrophotometer, digitally (0.5 nm) over the range 270–900 nm. The metal ion concentration was 1×10^{-2} mol dm^{-3}.

3. Results and discussion

3.1. Potentiometry

The values determined in the present work are in good agreement with those published earlier in our former works [28,29] or by others [38,39,7]. The list of these compounds is shown in Scheme 1. Although the fully protonated ligand forms contain five dissociable protons (H_5L^+) for **1**–**5** and **7** and six protons (H_6L^{2+}) for **6** (because of the additional proton on the pyridine nitrogen atom) they release only three protons in the measurable pH range: two protons from each of the phosphonic groups (PO_3H^-) and one imiono nitrogen, NRH^+. An additional proton from NH^+_{pyr} dissociates in **6** (Table 1). The characteristic pK values for dissociation of one proton from each of the PO_3H_2 groups lie in the range 1.5–2. Thus, they do not participate in the metal coordination equilibria.

3.2. Systems with manganese(II), cobalt(II) or nickel(II)

The chemical models for the ligands **1**–**6** with these metal ions contain only equimolar complexes: protonated, deprotonated and hydroxo complexes (Tables 1 and 2). The formation of the bis complexes seems to be generally hindered because of the electrostatic repulsion of the negatively charged phosphonate groups precludes coordination of the second ligand; the charge of the bis complex would be $6-$. Hence, only 1:1 complexes are formed and data collected in Tables 1 and 2 indicate lower chelating ability of the ligands towards Mn^{2+}, Co^{2+} or Ni^{2+} than Cu^{2+} [28]. However, the overall stability constants of the manganese(II) complexes are distinctly lower if compared with that obtained for the cobalt(II) and nickel(II) complexes. The chemical models for systems of ligand **7** with these metal ions are different if compared with all the other systems studied. These models contain protonated and non protonated 1:2 species (Tables 1 and 2).

The metal complex speciations derived from potentiometric calculations for compounds **2**–**6** in the range pH 3–10.5, do not differ considerably. The incipient precipitation, in the Co^{2+}–**1** and Ni^{2+}–**1** systems, caused by the formation of complex(es) and/or hydroxo complex(es) at pH near 9 makes the observation of the next step doubtful, also in the presence of higher ligand-to-metal molar ratio. The Co^{2+}–**5** and Ni^{2+}–**5** systems presented in Figs. 1 and 2 exhibit, in general, approximately the same distribution curves as those observed for the other ones, and thus is representative for all the ligands. Three complexes: $[M(H_2L)]$, $[M(HL)]^-$, $[ML]^{2-}$ and hydroxo $[MLH_{-1}]^{3-}$, are formed in the above-mentioned pH range, with the single difference found for complexes of compound **6**, namely the presence of an additional $[M(H_3L)]^+$ species at low pH. Although the concentration of this complex is very low ($\sim 5\%$), the assumption of this species improved the fit between the experimental and the calculated titration data. Since the agreement of this fit with or without the assumption of the $[MOH]^-$ species

[a] Data presented in this table actually reflect the optical properties of solutions in which the given forms are the major species; sh denotes shoulder. **A**, d–d transition in an octahedral complex; **B**, d–d transition in a tetrahedral complex.

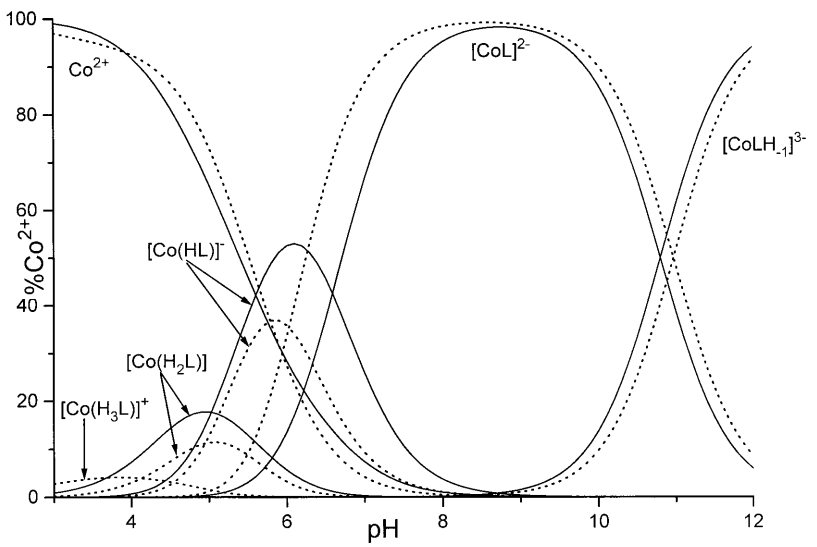

Fig. 1. Species distribution curves for the complexes formed in the Co^{2+}/ligand **5** (full line) and Co^{2+}/ligand **6** (dotted line) systems as a function of pH; $c_{Co^{2+}} = 1 \times 10^{-3}$ mol dm^{-3}; $c_L = 2 \times 10^{-3}$ mol dm^{-3}.

is within experimental error and the value of $\log K_{[M(OH)]}$ differs very much from the values in SC-Database [40], we decided to remove this species from our models.

The deprotonation constant, $pK_{[M(H_3L)]^+}$, for the reaction $[M(H_3L)]^+ \rightleftarrows [M(H_2L)] + H^+$ for the ligand **6** with Mn^{2+}, Co^{2+} or Ni^{2+}, is 3.93, 4.13 and 4.09, respectively. These values are lower than obtained for the PO_3H^{1-} groups of the free ligand (Tables 1 and 2). Thus, for the first species the pyridine nitrogen is involved in the coordination and both PO_3^{2-} and N_{imino} groups remain protonated. In this case the phosphonate O^- is unable to coordinate the metal ion due to steric reasons. This fact is supported by the absorption spectra of the Ni^{2+}–**6** system presented in Fig. 3. These spectra exhibit the changes versus pH. It has to be mentioned that at pH 3 the high-intensity charge-transfer band, being near to the d-d transitions, and is observed and distorts the visible spectra (Table 4). At a higher pH region this band disapeared. From these and the data collected in Table 4 we concluded that at this pH in the $[Ni(H_3L)]^+$ species the pyridine nitrogen is coordinated and the CT band is the consequence of the transition between N_{pyr} and Ni^{2+}.

In the systems presented, only one species, $[M(H_2L)]$, is formed as a minor species in which the protonated ligands coordinate to these metal ions by the phosphonate group(s) in a monodentate(bidentate) manner. Deprotonation of $[M(H_2L)]$ leads to the formation of $[M(HL)]^-$. The $pK_{[M(H_2L)]}$ values characteristic for the next deprotonation step for the $[M(H_2L)]$ complexes are considerably lower than the corresponding deprotona-

[a] The strong overlap between d-d band and that of the dominant high-intensity charge — transfer band.

tion constants of the free ligands (see Tables 1 and 2). It can be assigned to deprotonation of the phosphonic group promoted by the studied metal ions binding, i.e. the protonated ligand coordinates to these metal ions by the phosphonate groups in a bidentate manner. In this case the formation of an eight-membered chelate ring may be assumed [41,42]. The following deprotonation step, has the $pK_{[M(HL)]^-}$ values much lower than the pK_{NH^+} of the free ligands. On the other hand, the deprotonation of $[M(HL)]^-$ in the range pH 6–9.5, which leads to $[ML]^{2-}$, does not generate considerable changes in the spectra of cobalt(II) and nickel(II) systems, so the bonding mode in both species might be the same with O,O coordination. The only CT bands at 222–211 nm, which were observed for the systems with Ni^{2+} (Table 4) are similar to this observed for $[Ni(H_2O)_6](ClO_4)_2$ complex (198 nm) and can be reasonably assigned to the transition from PO_3^{2-} oxygen to Ni^{2+}, i.e. LMCT transition (Fig. 4). Similar studies were made on the copper(II) complexes of these ligands and in those cases two different CT bands were obtained [28].

Ligand **7** bearing the oxygen atom of the tetrahydrofuryl substituent placed in the sterically favourable position which allows it to be an additional effective metal binding site, is a more effective chelating agent than other ones. This is reflected in the higher basicity-adjusted stability constant, $\log K_{[ML]^{2-}} - \Sigma pK$ (Tables 1 and 2).

A comparison of Mn^{2+}, Co^{2+} or Ni^{2+} complexes of **5** and **7** (these ligands have the same basicity) shows significant differences. Basicity-adjusted stability constants, $\log K_{[ML]^{2-}} - \Sigma pK$ are -15.28 and -14.40 for Mn^{2+} with ligand **5** and **7**, respectively; -13.93 and -12.72 for Co^{2+} with **5** and **7**, respectively and -13.97 and -13.03 for Ni^{2+} with **5** and **7**, respectively. Taking this into account, comparison of $[M(\mathbf{5})]^{2-}$ and $[M(\mathbf{7})]^{2-}$ complexes still reveals a difference in stabilities of about 0.88 and 1.2 or 0.94 log units, respectively, suggesting interaction between Mn^{2+}, Co^{2+} or Ni^{2+} and the furyl oxygen atom.

The basicity-adjusted stability constants ($\log K_{[CoL]^{2-}} - \Sigma pK$) varies in the sequence (Table 1):

$$[Co(\mathbf{2})] < [Co(\mathbf{3})] < [Co(\mathbf{5})] < [Co(\mathbf{4})] < [Co(\mathbf{6})] < [Co(\mathbf{7})]$$

The similar sequence is observed for manganese(II) and nickel(II) complexes. This can be explained, in part, by the significant changes of the imino substituent size.

It is interesting to compare the stability of the simple complex $M^{2+} + OH^- \rightleftharpoons [M(OH)]^+$ with that of the mixed one $[ML]^{2-} + OH^- \rightleftharpoons [ML(OH)]^{3-}$. The equilibrium constant, $K_{[ML(OH)]^{3-}}$, evaluated from the computed values of the related β values according to equation: $\log K_{[ML(OH)]^{3-}} = \log \beta_{[MLH_{-1}]^{3-}} - \log \beta_{[ML]^{2-}}$, (equilibrium 3 in Tables 5 and 6 and the $[MLH_{-1}]^{3-}$ species corresponds to $[ML(OH)]^{3-}$ in terms of equilibrium) shows how tightly OH^- is bound to the simple $[ML]^{2-}$ complex. Thus, the binding strength of OH^- in mixed complexes depends on the stability of the simple complex $[ML]^{2-}$ (see Table 2).

When we consider $[ML(OH)]^{3-}$ to be a mixed-ligand complex, the difference in stability, $\Delta\log K$, between the simple and mixed-ligand species is given by:

$$\Delta\log K = \log K^{[ML]}_{[ML(OH)]} - \log K^{M}_{MOH}$$
$$= \log K^{[MOH]}_{[ML(OH)]} - \log K^{M}_{[ML]}$$

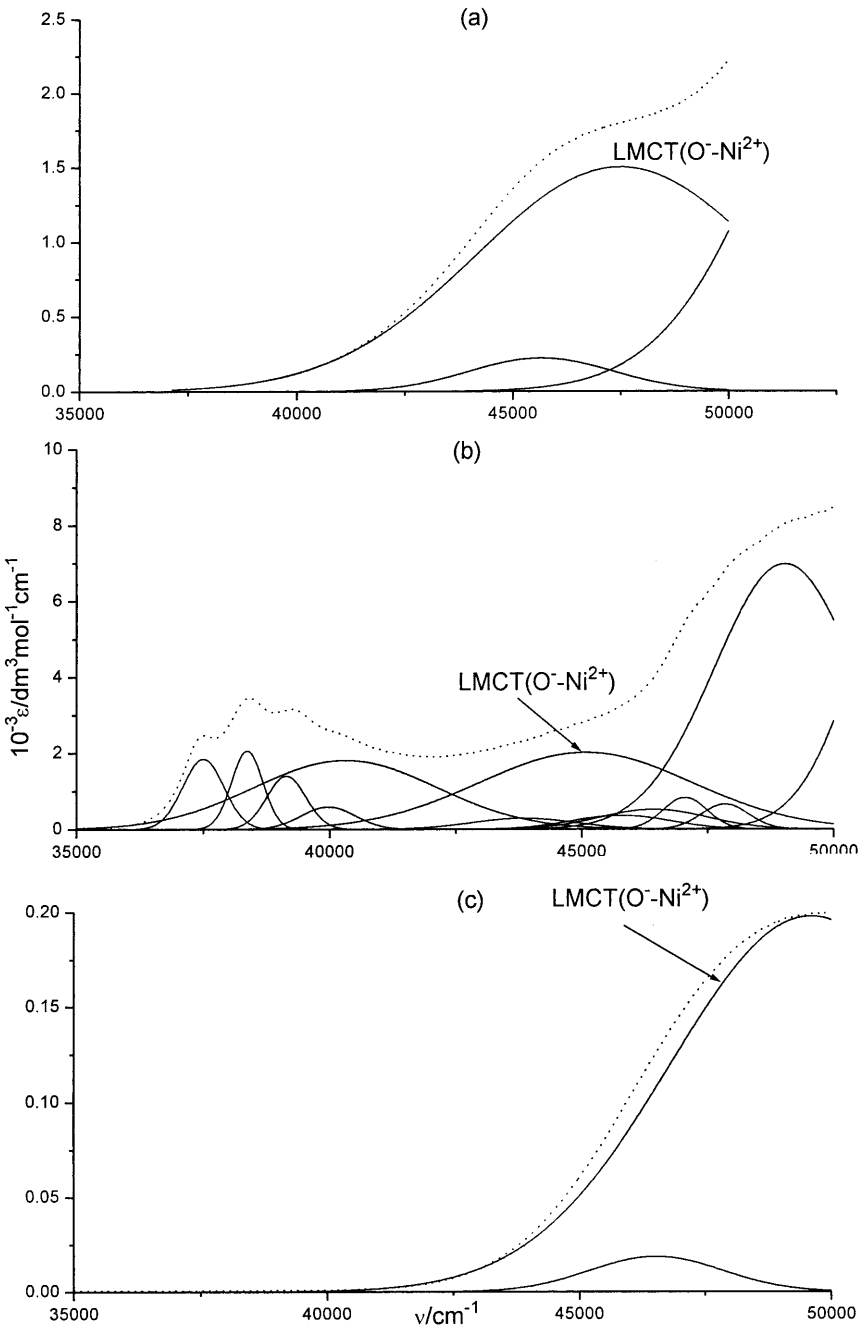

Fig. 4. Ultraviolet spectra and Gaussian line-shape analysis for: $[NiL]^{2-}$; L = **4** (a); L = **6** (b); pH 9; $[Ni(H_2O)](ClO_4)_2$ (c); experimental spectrum (grey line); component bands (black line).

[a] Ref. [44].

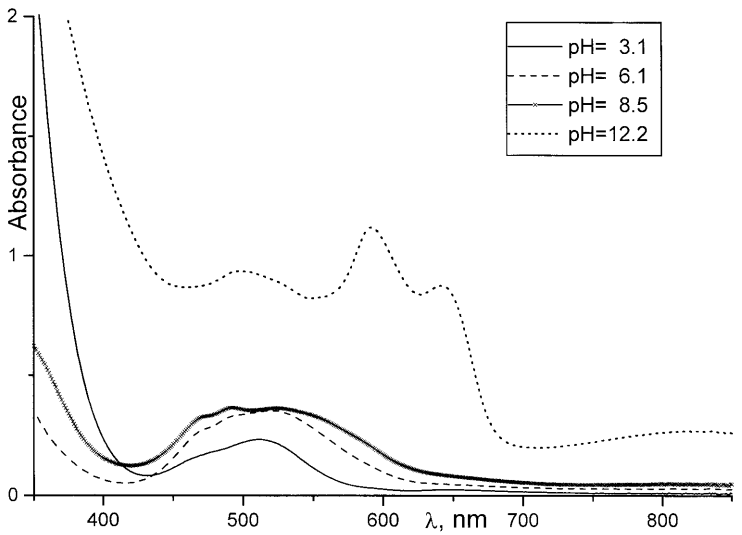

Fig. 5. pH-varied absorption spectra of the Co^{2+}/ligand **6** system: $c_{Co^{2+}} = 1 \times 10^{-2}$ mol dm^{-3}; $c_L = 2 \times 10^{-2}$ mol dm^{-3}; 4 cm cell.

The $\Delta\log K$ parameter (equilibrium 5 in Tables 5 and 6) expresses the effect of the bonded primary ligand (L) towards the incoming secondary ligand (OH^-). For comparison, also the $\log K$ values for the hydrolysis of both M^{2+} [43,44] and $[ML]^{2-}$ ions of cobalt(II)/nickel(II) are included in Tables 5 and 6. Since the OH^- group coordinates more easily with the free cobalt(II)/nickel(II) ion than with the complexed metal ion, $[ML]^{2-}$, $\Delta\log K$ should be negative. The binding strength of OH^- in mixed-ligand complexes depends on the stability of $[ML]^{2-}$ which, in our case, does not necessarily mean that it depends on the basicity of the ligand (compare values in Table 1 and equilibrium 3 in Tables 5 and 6). In a case of bulky L bonded in the Co^{2+} (Ni^{2+}) equimolar complex the coordination of OH^- is more favoured than that of the second ligand of the same kind.

3.3. Spectrophotometrical studies

Absorption spectra of the Co^{2+}-ligand **6** system presented in Fig. 5 exhibit, in general, approximately the same changes versus pH as those observed for the other above-mentioned systems with cobalt(II). Even at the pH value where the distribution of the species has a maximum, the other complexes coexist in a greater or smaller extent. Therefore, in the absorption spectra measured even at this pH value the contributions from

the other species would be included. To extract the ligand-field absorption spectrum of each species, the experimental spectrum, measured at a pH value where each species exhibits maximal contribution, was resolved into the components spectra corresponding to the individual species existing at that pH. The molecular absorptivity for the individual species was then calculated taking into account their distribution. In some cases this method has not given satisfactory results for species which the contribution was too small in the system.

The electronic spectra of cobalt(II) complexes depend on the configuration of these complexes. The difference in the ligand-field bands between various configurations, is so apparent that the electronic spectrum may be regarded as diagnostic of the stereochemistry of the cobalt(II) complexes.

The $[CoL]^{2-}$ complexes are formed from $[Co(HL)]^{-}$ at pH ca. 5.5 and they are predominant species at around pH 7–10.5 in solution. This process involves deprotonation of an imino nitrogen and is accompanied by a deviation of the complex geometry from octahedral or pseudo- octahedral and formation of the $[CoL]^{2-}$ results in distinct changes in absorption spectra. The spectrum in the visible region reveals additional d-d bands (Table 5). The deprotonation of $[CoL]^{2-}$ leads to the formation of $[CoLH_{-1}]^{3-}$ and corresponds to the subsequent dissociation of the proton from coordinated water molecule. This hydroxo species predominated above pH 11 and solutions give a deep blue color. These observations and spectroscopic results shown in Table 3 strongly suggest preorganization at Co^{2+} binding site and indicate changing geometry from octahedral towards tetrahedral. The much higher electron-donating ability of OH^{-} relative to that of H_2O is responsible for the changes in the spectra.

3.4. Ultraviolet spectroscopic studies

All the band maxima reported in this work are derived from Gaussian analysis of the experimental curves in the ultraviolet region. In general, the unique procedure (see experimental section) which starts with Gaussian analysis, through assignment of the bands, to calculation of the chemically useful parameters, is based on two assumptions: the symmetry of compound is known, and theoretical model (e.g. ligand field model for the complexes and orbital molecular model for the ligands) is adequate for the calculation of the spectral parameters. Unfortunately, the systems presented in this work are rather complex. Different structures of the particular ligands are the reason that the above mentioned interpretation makes for considerable difficulties. Thus, each system studied should be analysed separately. Therefore, the Gaussian analysis of the ultraviolet spectra in this work provides the bands which can be conclusively distinguished from the experimental (observed) spectrum. The numerical spectra $\varepsilon_i = f(\nu_i)$ and full Gaussian analysis results of all spectra are available from the authors on request. Fig. 4(a and b) present (as representative example) ultraviolet spectra $\varepsilon_i = f(\nu_i)$) along with Gaussian components for Ni^{2+}-ligand **4** and Ni^{2+}-ligand **6** systems.

Because ligands **2-4** do not have bands in the UV region, one observed band corresponds to the CT transition (for example: Ni^{2+}-ligand **4** system in Fig. 4a). Although compounds **5, 6** and **7** have their own UV absorption spectra, one new band is easily seen when their spectra are compared with those for the complexes (for example: Ni^{2+}-ligand **6** system in Fig. 4b). The CT band at 198 nm is observed for the $[Ni(H_2O)_6](ClO_4)_2$ (Fig. 4c). In this case the coordination of oxygen atoms to nickel(II) is beyond doubt. Thus, the CT band at 222–211 nm observed for the nickel(II)–**2**, –**6** and **7** systems corresponds most likely to the $O–Ni^{2+}$ LMCT transition.

From the data collected in Table 4 we conclude that the energy order of the CT transition displays a hipsochromic effect (i.e. increasing energy):

$$[\text{Ni (6)}] < [\text{Ni (5)}] \approx [\text{Ni (2)}] < [\text{Ni (3)}] \approx [\text{Ni (7)}] < [\text{Ni(4)}]$$

This effect depends predominantly on the size of the fragment R (Scheme 1) bonded to the nitrogen donor. The highest energy is observed when R = methyl group and the lowest when R involves an *N*-3-picolyl ring. A similar energy relation was observed for the systems with copper(II) [28].

4. Conclusion

The ligands **1**–**6** exhibit the model contains equimolar protonated and deprotonated complexes but neither a 1:2 species nor any polynuclear ones. Otherwise, the model for M^{2+}-ligand **7** systems includes 1:2 species. From the comparative analysis of the stability and the spectroscopic (UV–VIS) data it has been established that the coordination in $[ML]^{2-}$ is realized by both phosphonic groups $\{PO_3^{2-}, PO_3^{2-}\}$ with an eight-membered chelate ring. The N-atom is not coordinated. For all systems studied the only LMCT band from O^{-} (PO_3^{2-}) to M^{2+} exists in the UV region. Compound **7**, in which the tetrahydrofuryl oxygen atom is sterically accessible for some interaction with metal ions is a more effective chelating agent than other ones. A comparison of the basicity-adjusted stability constants, $\log K_{[ML]^{2-}} - \Sigma pK$, suggests some interaction between M^{2+} and the furyl oxygen atom. The manganese(II), cobalt(II) and nickel(II) complexes of the aromatic iminodimethylenephosphonic acids are more stable

than those of the aliphatic ones. This is reflected by the relative stability data. It can also be seen from the values of the relative stability constants (Tables 1 and 2) that the lowest affinity for the hard oxygen donor atoms is in the case of manganese(II) complexes.

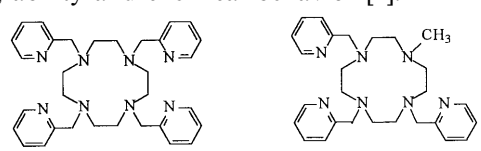
Received 18 May 2000; accepted 11 July 2000

Abstract



Two new Mn^{II} complexes with polydentate macrocyclic polyamine ligands functionalized with pyridyl donor pendants, 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane ($\mathbf{L}^1$) and 1-methly-4,7,10-tris(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane ($\mathbf{L}^2$), have been synthesized and their structures determined by X-ray diffraction analysis. In $[Mn\mathbf{L}^1](ClO_4)_2$ (**I**), the Mn^{II} central ion is eight-coordinated with all the eight donor nitrogens of $\mathbf{L}^1$ (including four pendant pyridyl nitrogens and four tertiary amines of cyclen) to form a distorted square-prism coordination geometry, and in $[Mn\mathbf{L}^2](ClO_4)_2$ (**II**), the M^{II} central ion is seven-coordinated (distorted monocapped octahedral geometry) with all the seven nitrogen donor atoms of $\mathbf{L}^2$ (including three pendant pyridyl nitrogens and four tertiary amines of cyclen) comprising the donor set. The solution chemistry of the two Mn^{II} complexes has been further studied by cyclic voltammetry (CV), UV–Vis and ESR spectral techniques. © 2000 Elsevier Science Ltd. All rights reserved.

Keywords: Crystal structures; Synthesis; Macrocyclic polyamine ligand; Manganese complexes; Octa- and hepta-coordination

1. Introduction

The coordination chemistry of macrocyclic polyamine ligands bearing functional pendant donor groups has attracted much interest in recent years, mainly as the metal complexes of such ligands might be effective models for protein-metal binding sites in metalloproteins in some biological systems, as potential therapeutic reagents or as multi-electron catalysts [1]. 1,4,7,10-Tetraazacyclododecane (cyclen) is a versatile macrocyclic polyamine ligand [2] from which many ligands have been derived by attaching functional groups on its backbone and their metal complexes show interesting properties and functions [3].

We previously reported a potential octadentate ligand, 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane ($\mathbf{L}^1$), by attaching four pyridyl donors to the cyclen backbone [4], which potentially provides four nitrogen donors from the flexible cyclen ring and four N donors from the pendant pyridyl donors. This ligand, in which the cyclen backbone often adopts a well-defined square and its functional arms can offer the topology suitable for effective encapsulation of large metal ions [1g,3–5], has been found to present interesting features both regarding its coordinating ability and chemical behavior [4].

The discovery that Mn^{II} complexes of some macrocyclic polyamines [1h] and polydentate ligands [6,7] were effective superoxide scavengers attracted our interest, and led us to study the Mn^{II} complexes of $\mathbf{L}^1$ and a new heptadentate ligand 1-methyl-4,7,10-tris(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane) ($\mathbf{L}^2$, see Chart 1), which is potentially a heptadentate ligand. The Mn^{II} complexes of the two ligands show that both the two ligands can encapsulate Mn^{II} ion effectively using all their nitrogen donors to form octa- or hepta-coordinated complexes. Both of the complexes show superoxide scavenger activity from our preliminary cyclic voltammetry (CV) studies. We report herein the syntheses, crystal structures and solution properties of the two Mn^{II} complexes with $\mathbf{L}^1$ and $\mathbf{L}^2$.

2. Experimental

2.1. Materials and general methods

Most of the starting materials and solvents for syntheses were obtained commercially and used without further purification. 1,4,7,10-Tetrakis(2-methylpyridyl)-1,4,7,10-tetraazacyclododecane) ($\mathbf{L}^1$) [4], and 1-methyl-4,7,10-teraazacyclododecane [8] were synthesized according to published procedures. ^{1}H NMR was recorded on a Bruker AC-P200 spectrometer (200 MHz, 25°C, in $CDCl_3$, with tetramethylsilane as the internal reference). FT-IR spectra were taken on a 170SX (Nicolet) spectrometer. Elemental analysis was performed on a P-E 240C analyzer. ESR spectra were measured on a Bruker ER-200-D-SRC10 spectrometer at room temperature and 110 K, respectively. Magnetic susceptibilities were measured on a Faraday balance at room temperature and the calibration was made with Mohr's salt. Effective magnetic moment was calculated by the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$, where χ_M is the magnetic susceptibility corrected for diamagnetism of the constituting atoms using Pascal's constants.

2.2. Synthesis

2.2.1. 1-Methyl-4,7,10-tris(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane ($\mathbf{L}^2$)

To a solution of 1-methyl-1,4,7,10-tetraazacyclododecane hydrochloride (540 mg, 1.8 mmol) in water (15 cm^3) was added NaOH (660 mg, 16.5 mmol), and this mixture was stirred for ca. 30 min. Then a solution of 2-(chloromethyl)pyridine hydrochloride (900 mg, 5.5 mmol) in CH_2Cl_2 (50 cm^3) was added dropwise over a period of ca. 2 h. The stirring was continued at 30°C for 1 week under an argon atmosphere. The organic layer was then separated and the aqueous layer was extracted with $CHCl_3$ (50×5 cm^3), and the combined organic layers were evaporated to give a residue which was purified by column chromatography on silica gel (eluent: CH_2Cl_2/CH_3OH 92:8). The product was finally recrystallized from ethanol–ether as colorless needles (Yield: 0.56 g, 60% based on 1-methyl-cyclen). ^{1}H NMR: δ1.90 (s, 3H), 2.62–2.74 (m, 16H), 3.50 (s, 6H), 7.12–7.23 (m, 8H), 7.57–7.67 (m, 4H). IR (KBr pellet, cm^{-1}): 625, 764, 1095, 1148, 1309, 1433, 1474, 1571, 1593, 1625, 2016, 2812, 2969, 3400 (br). *Anal.* Calc. for $C_{27}H_{37}N_7$: C, 70.6; H, 8.06; N, 21.4. Found: C, 70.9; H, 8.14; N, 21.0%.

2.2.2. Preparation of $Mn\mathbf{L}^1(ClO_4)_2$ (I) and $Mn\mathbf{L}^2(ClO_4)_2$ (II)

I was prepared by mixing a 1:1 molar ratio of $Mn(ClO_4)_2 \cdot 6H_2O$ (68 mg, 0.19 mmol) and $\mathbf{L}^1$ (100 mg, 0.19 mmol) in mixing solvents (CH_3CN/CH_3OH 1:1) at ca. 60°C under argon for ca. 30 min. The reaction mixture was then filtered, and crystals suitable for X-ray analysis were obtained by slow evaporation of the solvent. Yield: 88 mg, 60%. IR (KBr pellet, cm^{-1}): 630, 760, 1085, 1118, 1309, 1436, 1480, 1571, 1636, 2026, 2865, 2980, 3405, 3440 (br). *Anal.* Calc. for $C_{32}H_{40}N_8MnO_8Cl_2$: C, 48.6; H, 5.06; N, 14.2. Found: C, 48.3; H, 5.32; N, 14.4%.

II was prepared by a similar procedure to the preparation of **I**. Yield: 74 mg, 48%. IR (KBr pellet, cm^{-1}): 487, 620, 766, 1092, 1435, 1479, 1570, 1603, 2869, 2965, 3430 (br). *Anal.* Calc. for $C_{27}H_{37}MnN_7O_8Cl_2$: C, 44.6; H, 5.09; N, 15.4. Found: C, 44.4; H, 5.31; N, 15.7%.

2.3. Crystallographic studies

The data collections and determination of unit cells were performed with Mo Kα radiation ($\lambda = 0.71073$ Å) on an Enraf-Nonius CAD-4 diffractometer equipped with a graphite crystal monochromator. Unit cell parameters were obtained by least-squares refinement of one setting angle of 25 reflections in the range 9.34–12.2° (for **I**) and 9.10–10.49° (for **II**). The structures were solved by direct methods (SHELXS-86) with empirical absorption corrections. The Mn atoms were located from *E*-maps. The other non-hydrogen atoms were determined by successive difference Fourier syntheses on *F*. Final refinement was done by full matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were added theoretically, refined with riding model position parameters and fixed isotropic thermal parameters. All the calculations were performed on an IBM PC/586 computer, using the Siemens SHELTXTL-PC program package [9]. The crystallographic data and refinement details have been summarized in Table 1.

2.4. Electrochemical studies

Cyclic voltammograms were obtained by a BAS-100B electrochemical apparatus equipped with a glassy-carbon working electrode, a saturated calomel electrode (SCE) reference and a platinum auxiliary electrode. Solutions of **I** or **II** (1.0, 2.0, 3.0 mmol dm^{-3}) were prepared by dissolving appropriate amounts of the complexes in anhydrous acetonitrile with 0.1 mol dm^{-3} (n-butyl)$_4NPF_6$ ($TBAPF_6$) as supporting electrolyte. The tested system was oxygenated by bubbling pure O_2 gas at room temperature through the solution, and the concentration of O_2 was assumed to be 3 mmol dm^{-3} [6]. The cyclic voltammograms at scan rates of 50 or 100 mV s^{-1} were evaluated graphically.

3. Results and discussion

3.1. Synthesis and general characterization

$\mathbf{L}^1$ was synthesized by a method reported in our previous paper [4]. $\mathbf{L}^2$ was synthesized by a similar method. It was obtained as colorless needles in 60% yield. All the analytical and spectral data are in good agreement with the theoretical requirements of $\mathbf{L}^2$.

The syntheses of **I** and **II** were achieved by the reaction of the corresponding ligands with $Mn(ClO_4)_2\cdot6H_2O$ in nearly equimolar ratios in mixed solvent (1:1 CH_3CN–CH_3OH). The results of elemental analysis of the two complexes are consistent with the composition of $[Mn\mathbf{L}](ClO_4)_2$ ($\mathbf{L}=\mathbf{L}^1$ or $\mathbf{L}^2$). The IR spectra of the two complexes show absorption bands due to the pyridine ring skeletal vibrations and bands from the perchlorate counter anions. The electronic spectra of the colorless Mn^{II} complexes in methanol solution are essentially featureless in the range 400–800 nm, and d–d transitions are hardly observable. The effective magnetic moments of both **I** and **II** are 5.65 and 5.56 B.M. (at 293 K), corresponding to $S=5/2$ spin state (high spin) with an appreciable orbital contribution.

3.2. Description of crystal structure

3.2.1. Crystal structure of $[Mn\mathbf{L}^1]ClO_4$ (I)

The structure of **I** consists of $[Mn\mathbf{L}^1]^{2+}$ cations and ClO^{4-} counter anions. A view of the cation of **I** is given in Fig. 1 and the selected bond distances and angels are listed in Table 2.

The Mn^{II} ion in $[MnL^1]^{2+}$ cation is eight-coordinated by four N atoms of the macrocycle and the four nitrogens of the pendant pyridyl groups arranged at the corners of a square prism. Each set of N atoms [nitrogens on cyclen ring, N_{cyclen}: N(1), N(2), N(3), N(4); and nitrogens on pendant pyridine, N_{py}: N(11), N(21), N(31), N(41)] is nearly co-planar, with mean deviation of 0.006 and 0.036 Å from the corresponding least-squares planes. These two planes are essentially parallel to each other and form a 0.6° dihedral angle with each other. The nitrogen atoms thus fully encapsulate the Mn^{II} ion which lies 1.270 and 1.354 Å from the basal planes in the above-mentioned order.

Table 3
Selected bond distance (Å) and angles (°) for **II**

Mn(1)–N(1)	2.316(4)	Mn(1)–N(2)	2.327(4)
Mn(1)–N(3)	2.430(4)	Mn(1)–N(4)	2.371(4)
Mn(1)–N(21)	2.239(4)	Mn(1)–N(31)	2.334(4)
Mn(1)···N(11)	2.732(4)		
N(1)–Mn(1)–N(2)	77.6(1)	N(1)–Mn(1)–N(3)	122.4(1)
N(2)–Mn(1)–N(3)	76.5(1)	N(2)–Mn(1)–N(31)	164.1(2)
N(1)–Mn(1)–N(4)	76.7(1)	N(2)–Mn(1)–N(4)	120.7(2)
N(3)–Mn(1)–N(4)	74.2(1)	N(1)–Mn(1)–N(21)	131.6(1)
N(2)–Mn(1)–N(21)	74.1(2)	N(3)–Mn(1)–N(21)	87.8(2)
N(4)–Mn(1)–N(21)	151.6(2)	N(1)–Mn(1)–N(31)	100.2(2)
N(3)–Mn(1)–N(31)	116.9(2)	N(4)–Mn(1)–N(31)	73.3(2)
N(21)–Mn(1)–N(31	96.8(2)	Mn(1)–N(1)–C(1)	108.6(3)

The $Mn(1)–N_{cyclen}$ distances are normal Mn–N bonds. A pair of $Mn–N_{py}$ bond distances are shorter than those of $Mn(1)–N_{cyclen}$ while other two $Mn(1)–N_{py}$ are longer. The Mn(1)–N(21) and Mn(1)–N(41) bonds can be considered as semi-coordination bonds, similar to the $[Mn–(py)_3tren]^{2+}$ complex [7] which exhibits an Mn–N distance equal to 2.79 Å. The coordination geometry of **I** is similar to that found for the Mn^{II} complex with 1,4,7,10-tetrakis(pyrazol-1-ylmethyl)-1,4,7,10-tetraazacyclodecane) [1h].

The potentially octadentate ligand L^1 yields complexes with coordination numbers from six to eight, according to the stereochemical requirements of the metal ions involved. In the series of the structures, the Ni^{II} [4a], Co^{II}, Fe^{II} [11], and Mn^{II} complexes show the following fundamental features: the metal ions are always bound to the four nitrogen atoms of cyclen, whose bonding cavity is too small to accommodate those cations and completes their coordination sphere with two or four additional N donors from the pendant pyridine groups. All donor atoms of cyclen are forced to lie on the same side of the metal atom while all the donor pendant arms are forced to point to the other side of the metal ion. Analysis of the M–N bond distances and angles for these complexes reveals some regular trends: (1) on going from the complexes of Mn^{II} to Ni^{II}, the distance of the metal ion from the basal cyclen plane decrease from 1.270 to 0.901 Å; (2) the difference between N(1)–M–N(3) and N(2)–M–N(4) angles (N labels as for I) increases from Mn^{II} to Ni^{II}. Cyclen ring folds to yield six-coordinated complexes (for Ni^{II}) or remains planar in the eight-coordinated complexes (Mn^{II} and Fe^{II}); (3) in these complexes, two of the four pyridine donor pendants in non-adjacent positions interact with the central metal to form normal M–N bonds, while the other two pendants remain uncoordinated or semi-coordinated, and the distances from metal to uncoordinated or semi-coordinated donor atom (N) increased from Mn^{II} to Ni^{II}. This indicates that Mn^{II} accepts the strongest coordination from the pendant pyridines in this series of complexes.

3.2.2. Crystal structure of $[MnL^2]ClO_4$ (II)

The structure of **II** consists of a discrete monomer $[MnL^2]^{2+}$ cation and two uncoordinated perchlorate anions. The ORTEP view of **II** is shown in Fig. 2, and the selected bond distances and angles are listed in Table 3.

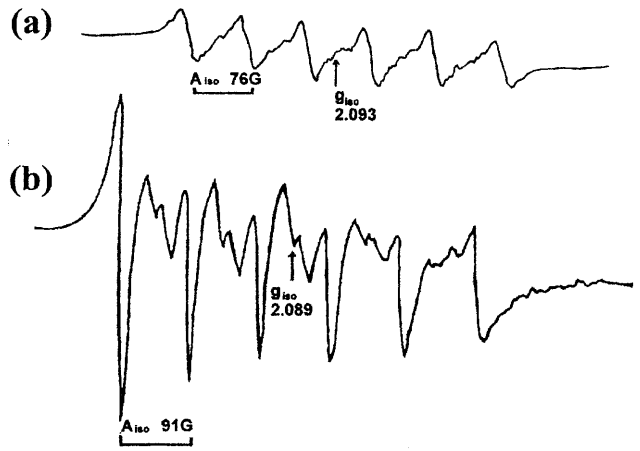

Fig. 3. The X-band ESR spectra of **II** in MeOH at room temperature and 110 K.

The structure indicates that **II** has a hepta-coordinated metal center defined by four nitrogen atoms of cyclen [N(1), N(2), N(3) and N(4)] and three nitrogen atoms of the pendant pyridine groups [N(11), N(21) and N(31)]. The coordination polyhedron may be best described as a square-prism with the basal planes defined by cyclen and the pyridine nitrogens (N_{cyclen} and N_{py}), respectively, and having a vacant donor site on the latter face. A basal least-squares plane from the four nitrogens of cyclen gave a mean deviation of only 0.009 Å while the three pyridine nitrogens form the other basal face. These two planes form a 3.6° dihedral angle and are essentially parallel to each other, and the Mn^{II} ion is displaced by 1.151 and 1.484 Å from that two planes.

In **II**, such a high coordination number is achieved at the expense of a longer Mn–N distance (Mn–N (11)) of 2.732 Å which is much longer than normal Mn–N bonds, but shorter than the sum of van der Waals radii of Mn^{II} and N. The other six normal Mn–N coordination bonds have typical Mn–N distances. The distances of Mn–N_{py} (N (21) and N (31)) are shorter than those of Mn–N_{cyclen}. The average distances from metal to N_{cyclen} or N_{py} (normal or semi-coordinated) in **II** are shorter than those distances in **I**. Thus the coordination of $\mathbf{L}^2$ to Mn^{II} in **II** is stronger than that of $\mathbf{L}^1$ in **I**, and this may be considered as the reduction of the steric hindrance due to fewer pyridyl pendants on $\mathbf{L}^2$ (see Fig. 2).

Table 4
ESR parameters of **I** and **II** in methanol solution

Complex	Room temperature		110 K	
	g	A, G (cm^{-1})	g	A, G (cm^{-1})
I	2.11	91 (8.9×10^{-3})	2.10	89 (8.7×10^{-3})
II	2.09	76 (7.4×10^{-3})	2.09	91 (8.9×10^{-3})

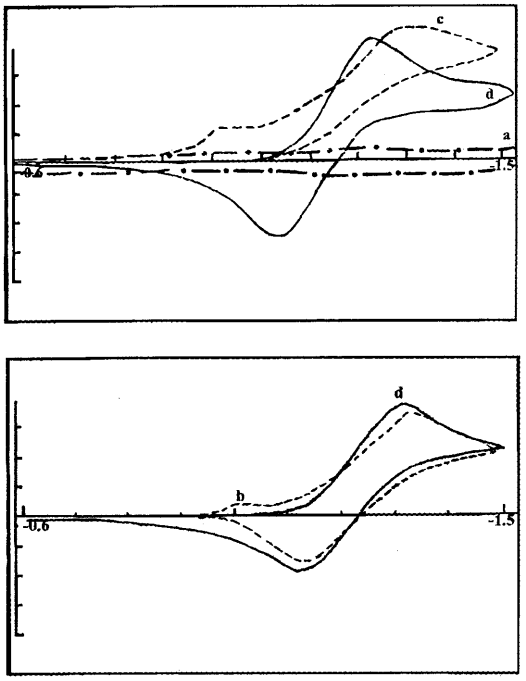

Fig. 4. Cyclic voltammograms in acetonitrile solution containing 0.1 mol dm^{-3} $TBAPF_6$ and various substrates (scan rate 50 mV s^{-1}): (a) 2.0 mmol dm^{-3} **II** only; (b) 1.0 mmol dm^{-3} **II** and 3 mmol dm^{-3} dioxygen; (c) 3.0 mmol dm^{-3} **II** and 3 mmol dm^{-3} dioxygen; (d) 3 mmol dm^{-3} dioxygen only.

3.3. ESR studies

The ESR spectra were obtained in CH_3OH solution at room temperature and 110 K, respectively, and the spectra of **II** is shown in Fig. 3. For **II**, the spectrum with a symmetry center was split into six equally spaced absorption peaks by the interaction with the $^{55}Mn^{II}$ nucleus ($I = 5/2$) at room temperature. When the solution was frozen at 110 K, these six absorption peaks split to give further hyperfine structures, perhaps due to coupling with the N atoms of the ligand. The spectrum of **I** was similar to that of **II** at room temperature, but when the sample of **I** in CH_3OH was frozen at 110 K, no change was observed in the ESR spectrum, indicating a weaker coordination to $\mathbf{L}^1$ than to $\mathbf{L}^2$, which is in agreement with the crystal structural results of the two complexes as have been discussed above and the data have been listed in Table 4.

3.4. Electrochemical studies

The mechanism of SOD (superoxide dismutase) catalyzing the dismutation of O_{2-} is commonly proposed to commence with the coordination of O_{2-} to the metal activity center of SOD and produce the intermediate metal···O_{2-} adduct [12]. Despite SOD mimics having many kinds of structures, the first step in catalyzing O_{2-} dismutation is same: formation of the intermediate

$$O_2 + [LMn^{2+}] \longrightarrow [LMn^{2+}O_2]$$
$$[LMn^{2+}O_2] + e \longrightarrow [LMn^{2+}O_2^-]$$

Scheme 1. The production of the intermediary ($\mathbf{L} = \mathbf{L}^1$ or $\mathbf{L}^2$)

$[LMn^{+}\cdots O_{2-}]$ [6]. So the propensity of the catalyst to form the superoxide adduct is a good guide to whether the model SOD can catalyze O_{2-} dismutation. The superoxide adduct can be detected under anhydrous conditions by electrochemistry.

Fig. 4 shows the cyclic voltammograms recorded with a glassy carbon working electrode and illustrates the behavior of the present system. Curve a is the cyclic voltammogram of **II** in the dehydrated system without oxygen. The cyclic voltammogram of **II** in the presence of oxygen is shown as curve b and c. Curve d shows the cyclic voltammogram of oxygen in the absence of **II**. By comparison of parts b, c and d in the dehydrated system of Fig. 4, it appears a new reduction wave at a more positive potential than that of the oxygen reduction wave. This new wave is chemically irreversible. The anodic wave corresponding to the oxidation of O_{2-} is diminished when the concentration of **II** is increased for a fixed concentration of oxygen. It should be noted that oxygen can be excluded completely from the solution by an argon stream, and the situation observed in curve a is restored. Hence the complex reacts reversibly with oxygen. For a concentration of oxygen larger than that of the metal complex, the current of the irreversible new wave increases with complex concentration. Similar phenomena can be observed in **I**; however, it shows a lower current compared to **II** under the same experimental conditions. The positive shift in the cathodic peak potential is attributable to the more positive formal potential of the $[LMn^{2+}O_2]/[LMn^{2+}O_{2-}]$ couple compared with the O_2/O_{2-} wave [13].

These observations support the interpretation of a complex-assisted O_2 reduction in the presence of **II** is one in which the O_2 and **II** forms an adduct prior to the electron transfer (Scheme 1).

In analogous systems, the precursor complex is formed prior to reduction is the accepted mechanism [14,15]. The intermediate complex product by the first step of the superoxide scavenging reaction also was detected by electrochemistry. This is good evidence of the complexes (**I** and **II**) ability to bind oxygen to produce $[LMn^{+}\cdots O_{2-}]$ which is the essential intermediate in the mechanism of SOD or its models in catalyzing O_{2-} dismutation. Thus these complexes have potential ability for scavenging superoxide.

Abstract

The reaction of $N_3P_3Cl_6$ with the sodium salts of pentachloro- and pentafluorophenol, has been investigated. In contrast to the non-*geminal* substitution typified by other RO^- nucleophiles, the regiochemistry of the reaction of $C_6X_5O^-$ (X = Cl and F) with $N_3P_3Cl_6$ is dominated by *geminal* substitution. The reaction of $C_6Cl_5O^-$ with $N_3P_3Cl_6$ in refluxing tetrahydrofuran yielded *gem*-$N_3P_3Cl_2(OC_6Cl_5)_4$ (**1**) as the major product. The fully substituted derivative $N_3P_3(OC_6Cl_5)_6$ (**2**) was attained in low yield from reaction in refluxing diglyme. In contrast, the reaction of $C_6F_5O^-$ with $N_3P_3Cl_6$ in refluxing tetrahydrofuran yielded the fully substituted product $N_3P_3(OC_6F_5)_6$ (**3**) after approximately 4 h. ^{31}P NMR spectral results suggest the $C_6F_5O^-$ ion may be attacking in a 'random' fashion at low degrees of substitution, which is largely replaced by an electronic *geminal*-directing effect at tetrasubstitution. Single crystal X-ray crystallographic analyses have been carried out on compounds **1** and **3**. Electrospray mass spectrometry has been evaluated as a general technique for characterizing cyclotriphosphazenes, $N_3P_3R_6$. If R = OEt or OPh, good positive ion spectra are observed but, in contrast, if R is more strongly electron withdrawing (Cl, C_6Cl_5O or C_6F_5O) negative ion spectra are obtained. © 2000 Elsevier Science Ltd. 1. Introduction

Phosphazenes have been extensively studied for the last forty years. Although much of the research has focussed on the synthesis of commercially useful phosphazene polymers, it is the investigation of small cyclophosphazenes which have yielded the wealth of information regarding reactivity, mechanism and structure.

While the mechanistic aspects of substitution by amine nucleophiles are well understood, less information is available for RO^- nucleophiles and consequently more uncertainty surrounds their reactivity with $N_3P_3Cl_6$. Almost invariably RO^- ions react non-*geminally*, which is proposed to be via an S_N2 backside attack [1,2]. Since an S_N2 attack favors the most electrophilic site, the observed non-*geminal* regiochemistry implies the non-*geminal* directing alkoxy and aryloxy nucleophiles are electron-releasing relative to Cl (i.e. $\equiv PCl_2$ more electrophilic than $\equiv PCl(OR)$]. This is supported by phosphazene ring-nitrogen basicity studies conducted by Shaw et al. [3], which indicate groups such as OMe, OEt, OPh and OCH_2CF_3 are all electron-donating relative to Cl. Even the latter, which is the least electron-releasing, yields only approximately 2% of *geminal* products [4]. With the possible exception of 2,6-dichlorophenoxide [5], there appears to have been no regiochemical studies conducted on electron-withdrawing RO^- nucleophiles. It is therefore not surpris-

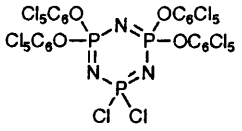
PII: S0277-5387(00)00511-8

ing that *geminal* substitution products are rare and of very low yield for the RO^- ions studied thus far.



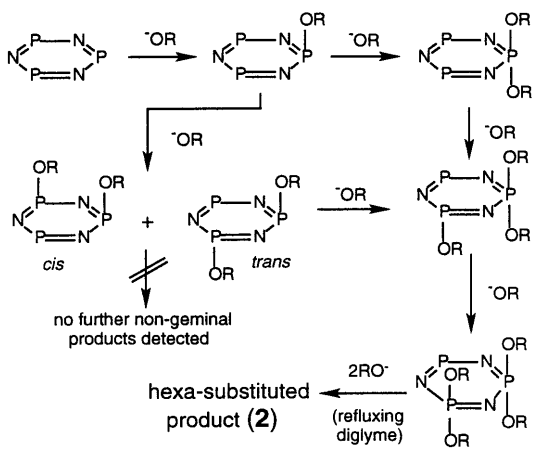
Assuming all RO^- ions react via an S_N2 mechanism, and ignoring any steric effects, one can generalize that relative to Cl, electron-releasing and electron-withdrawing RO^- ions should react non-*geminally* and *geminally*, respectively. Likewise, RO^- ions that have a net electronic effect similar to that of Cl should react via both *geminal* and non-*geminal* routes. Therefore the major intent of this study was to investigate the substitution pattern of electron-withdrawing aryloxy nucleophiles with $N_3P_3Cl_6$, and thereby determine whether the expected *geminal* substitutions occurred.

2. Results and discussion

Based on the pK_a values of the parent phenols [6–8], the sodium salts of C_6Cl_5OH and C_6F_5OH were considered to be suitable examples of strongly electron-withdrawing RO^- ions. The electron-withdrawing effect of progressively adding halogens to phenol is apparent from the following pK_a values [7]: phenol 9.92; 2-chlorophenol 8.52; 2,6-dichlorophenol 6.80; 2,4,6-trichlorophenol 5.99; 2,3,4,6-tetrachlorophenol 5.22 and pentachlorophenol 4.74.

2.1. Reaction of pentachlorophenoxide with $N_3P_3Cl_6$

The reaction of excess $NaOC_6Cl_5$ with $N_3P_3Cl_6$ in refluxing tetrahydrofuran was monitored at regular intervals by ^{31}P NMR spectroscopy. The reaction is very slow and proceeds via a predominantly *geminal* pathway (Scheme 1), with significant quantities of non-*geminal* products observed only at disubstitution. Accurate integration of the ^{31}P spectra was complicated by overlapping peaks, but approximately one-third of the disubstituted products are non-*geminal*. After 10–13 days the major product is the *gem*-tetra[3], and although there are di- and tri-substituted derivatives still present, there are no peaks in the ^{31}P spectra corresponding to higher degrees of substitution. The *gem*-tetra product, *gem*-$N_3P_3Cl_2(OC_6Cl_5)_4$ (**1**), was isolated via slow evaporation of the filtered tetrahydrofuran solution, yielding crystals suitable for single crystal X-ray crystallography.



1

Reaction times in excess of approximately 13 days did not result in the formation penta- or hexasubstituted derivatives, although it is possible that low solubility may preclude their detection by ^{31}P NMR spectroscopy. Similarly, increasing the reaction temperature to 101°C (dioxane) resulted in no penta- or hexa-derivatives being observed, and presumably on account of the lower solubility of the phenoxide salt in dioxane, the reaction is significantly slower. Increasing the temperature further to 162°C (diglyme) yielded a small quantity of $N_3P_3(OC_6Cl_5)_6$ (**2**), which was recrystallized from benzene as the di-solvate. Compound **2** has been reportedly formed from $C_6Cl_5O^-$ and $N_3P_3Cl_6$ in a continuous process at room temperature (r.t.) after 0.5–1 h [9], however, characterization data was not given and our results indicate that under these conditions hexasubstitution would be unlikely.

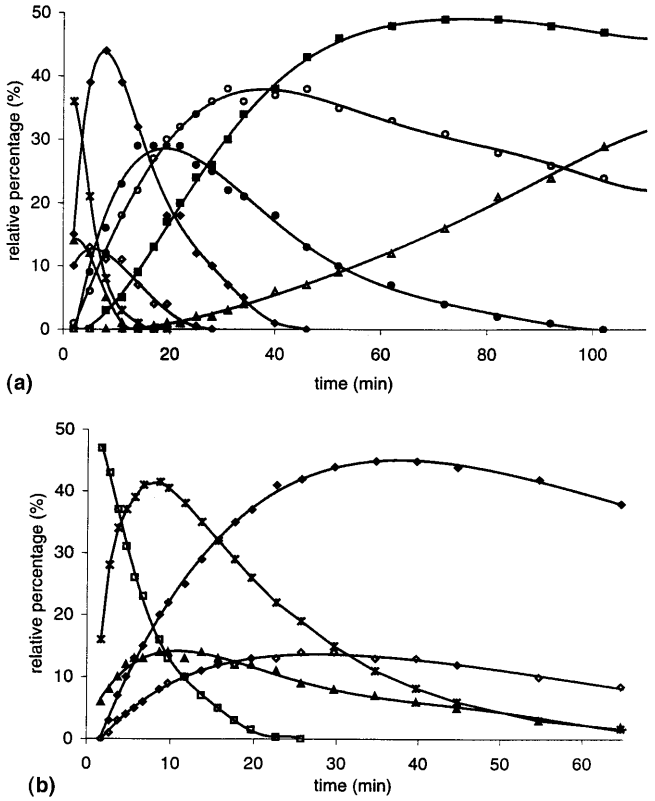
The predominantly *geminal* substitution is consistent with an S_N2 mechanism and pentachlorophenoxide being significantly electron-withdrawing. The electron-withdrawing effect of the $C_6Cl_5O^-$ group is evident from the failure of the ring-nitrogen atoms to protonate under the conditions required for the observation of a positive ion electrospray mass spectrum of **1** (see later). Consequently, ≡PCl(OR) sites are more electrophilic than $\equiv PCl_2$ sites and are thus favored by an S_N2 attacking RO^- ion.

The non-*gem*-di-substituted isomers are most likely formed by a competing S_N2 attack at less electrophilic $\equiv PCl_2$ sites, which although electronically less favorable, are favored both sterically and statistically (i.e. two $\equiv PCl_2$ sites for every one ≡PCl(OR) site) at disubstitution. The non-*geminal* trend is not repeated at tri-substitution since *geminal* substitution is now favored both electronically and statistically with two ≡PCl(OR) sites available.

The reaction of 2,6-$Cl_2C_6H_4O^-$ with $N_3P_3Cl_6$ yields mainly *geminal* products at di- and tri-substitution [5], but in contrast to $C_6Cl_5O^-$, tetrasubstitution is pre-

Scheme 1. S_N2 substitution pathway for the reaction of $NaOC_6Cl_5$ with $N_3P_3Cl_6$.

[3] A *geminal* tetrasubstituted product has been abbreviated to *gem*-tetra, a non-*geminal* trisubstituted product to non-*gem*-tri, etc.



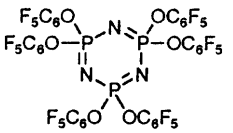


Fig. 1. Relative percentage of the substituted products (derived from ^{31}P NMR integration) from a 7:1 reaction of $C_6F_5O^-$ and $N_3P_3Cl_6$ (a) at 22°C and (b) at −10°C. Key to symbols: □ mono, ▲ *gem*-di, × non-*gem*-di, ◆ *gem*-tri, ◇ non-*gem*-tri, ○ *gem*-tetra, ● non-*gem*-tetra, ■ penta, △ hexa.

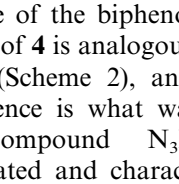
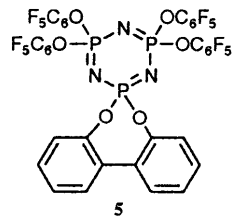
dominately non-*geminal*. The authors proposed an S_N1 mechanism with a subsequent mechanistic 'cross-over' to an S_N2 mechanism at higher degrees of substitution. As outlined for $C_6Cl_5O^-$, the reaction regiochemistry can also be accounted for by competing S_N2 reactions. The non-*geminal* preference at tetra-substitution possibly reflects the inferior electron-withdrawing nature of 2,6-$Cl_2C_6H_4O^-$, and hence a decreased electrophilicity difference between ≡PCl(OR) and ≡PCl_2 sites. Consequently for 2,6-$Cl_2C_6H_4O^-$, when steric demands are small (e.g. disubstitution), electronic effects will favor *geminal* products, whereas at higher degrees of substitution (e.g. tetra-), steric effects may transcend the slight electronic preference for *geminal* substitution-resulting in non-*geminal* products.

2.2. Reaction of pentafluorophenoxide with $N_3P_3Cl_6$



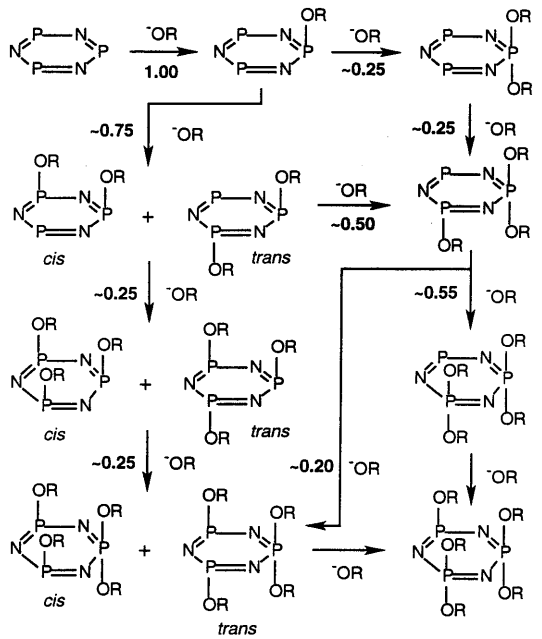
In contrast to $C_6Cl_5O^-$ the reaction of $C_6F_5O^-$ with $N_3P_3Cl_6$ in tetrahydrofuran is much faster, the reasons for which are not understood. The fully substituted derivative $N_3P_3(OC_6F_5)_6$ (**3**) was formed exclusively after approximately 4 h in refluxing tetrahydrofuran, and 30 h at r.t. Compound **3** has been reported previously [10–12], but the regiochemistry of the reaction between $C_6F_5O^-$ and $N_3P_3Cl_6$ has not been examined.



3

^{31}P NMR spectroscopy showed that non-*geminal* and *geminal* pathways appear to alternate during the progress of the reaction, as the major di- and tri-substituted products (approximately 75%) are non-*geminal* and *geminal*, respectively (Fig. 1a, b; the latter, at −10°C, shows the mono- and disubstituted products more clearly). This indicates that $C_6F_5O^-$ is attacking randomly, because at di-substitution there are twice the number of non-*geminal* ≡PCl_2 sites available on the mono-substituted compound. Therefore ignoring steric and electronic effects, two thirds of the mono-substituted product should react non-*geminally*. The observed approximately 75% of non-*gem*-di may reflect a contributing steric preference for non-*geminal* substitution. Similarly at tri-substitution, a random attack on the non-*gem*-di isomers would predict two thirds reacting *geminally* [twice as many ≡PCl(OR) sites] to give the *gem*-tri product, which accounts for the observed 75% of *gem*-tri product. The approximately 11:9 *geminal* preference at tetrasubstitution indicates that attack on the ≡PCl_2 and ≡PCl(OR) sites of the *gem*-tri is no longer random, since approximately three-quarters of the *gem*-tri has to react *geminally* to account for the observed regiochemistry. At higher degrees of substitution, the electrophilicity difference between ≡PCl(OR) and ≡PCl_2 sites must therefore become significant, resulting in the random attack being largely replaced by an electronic *geminal* preference. The proposed pathway is depicted in Scheme 2.

The change over to a *geminal* preference at higher degrees of substitution is supported by the approximately 70% *geminal* preference at disubstitution when $N_3P_3(2,2'\text{-}O_2C_{12}H_8)Cl_4$ (**4**) [13] was reacted with $C_6F_5O^-$. The presence of the biphenoxy group means that the disubstitution of **4** is analogous to the tetrasubstitution of $N_3P_3Cl_6$ (Scheme 2), and hence the observed *geminal* preference is what was expected. The fully substituted compound $N_3P_3(2,2'\text{-}O_2C_{12}H_8)(OC_6F_5)_4$ (**5**) was isolated and characterized from the corresponding 4:1 reaction. The closely related compound, $N_3P_3(2,2'\text{-}O_2C_{12}H_8)(p\text{-}FC_6H_4O)_4$ has been reported previously by Shreeve et al. [14].



4

5

In comparison to $C_6Cl_5O^-$, the increased tendency of $C_6F_5O^-$ ions to initially react non-*geminally* with $N_3P_3Cl_6$ is presumably attributable to the much greater reactivity of the fluoro analogue. Consequently, attack by $C_6F_5O^-$ at a phosphorus center is less discriminating at di- and tri-substitution, despite the electrophilicity of $\equiv PCl(OC_6F_5)$ sites which are conducive to *geminal* substitution.

Although more examples are needed before any general conclusions can be made regarding the reactivity of electron-withdrawing RO^- nucleophiles, it appears that as for the F^- ion [15], *geminal* substitution tends to be favored for electron-withdrawing aryloxides, but is not exclusive (especially for $C_6F_5O^-$) until higher substitution is achieved.

Scheme 2. Proposed substitution pathway for the reaction of $NaOC_6F_5$ with $N_3P_3Cl_6$.

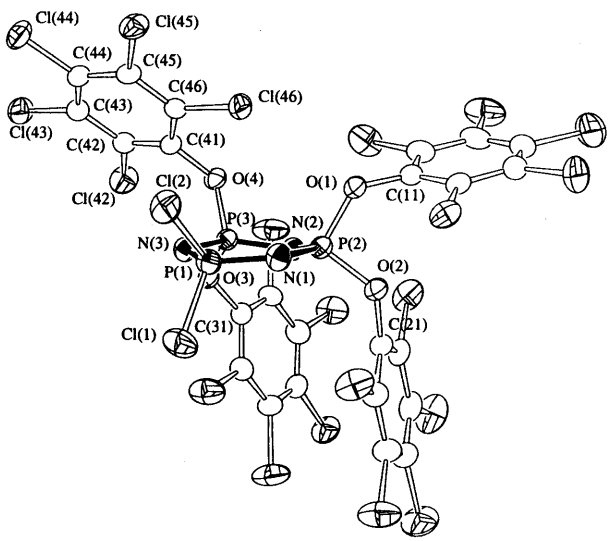


Fig. 2. ORTEP diagram of *gem*-$N_3P_3(OC_6Cl_5)_4Cl_2$ (**1**) (ellipsoids are drawn at 50% probability level); the tetrahydrofuran solvate molecule is omitted.

2.3. Structures of *gem*-$N_3P_3(OC_6Cl_5)_4Cl_2 \cdot C_4H_8O$ (**1**) and $N_3P_3(OC_6F_5)_6$ (**3**)

Compound **1**, which crystallizes with tetrahydrofuran molecules in the lattice, contains a cyclic trimeric phosphazene ring, with P(2) and P(3) each connected to two pentachloro-phenoxy groups via P–O–C linkages, and P(1) connected to two chlorine atoms (Fig. 2). The phosphazene ring is slightly puckered, with a maximum deviation from the mean ring plane of -0.136 Å for N(2). The P–N bond lengths are similar, and range from 1.576(3) to 1.582(3) Å with a mean of 1.580(1) Å. The N–P–N and P–N–P bond angles range from 117.1(2) to 118.5(2)° and 120.3(2) to 121.7(2)°, respectively. The P–O bond distances are between 1.586(2) and 1.607(2) with a mean of 1.595(4) Å. The average P–Cl bond distance is 1.999(1) Å. Selected bond lengths and bond angles of **1** are given in Table 1.

Compound **3** contains a cyclic trimeric phosphazene ring, with each phosphorus atom connected to two pentafluorophenoxy groups via P–O–C linkages (Fig. 3). The phosphazene ring is slightly puckered, with maximum deviations from the mean ring plane of 0.127 and -0.156 Å for N(3) and P(3), respectively. The P–N bond lengths range from 1.564(2) to 1.571(2) Å with a mean of 1.568(1) Å, and the N–P–N and P–N–P bond angles range from 115.90(11) to 119.11(11)° and 119.90(13) to 120.81(13)°, respectively. The P–O bond lengths range from 1.574(2) to 1.590(2), with a mean value of 1.584(3) Å. Selected bond lengths and bond angles for **3** are given in Table 2.

Because of the electron-withdrawing nature of $C_6Cl_5O^-$ and $C_6F_5O^-$, compounds **1** and **3** might be expected to exhibit long P–O bonds and short P–N bonds [15]. However, comparing these bond lengths of compounds **1** and **3** with the starting material ($N_3P_3Cl_6$) [16] and phosphazenes with electron-releasing phenoxy groups (Table 3) [17,18], does not show any significant trends in P–O and P–N bond lengths. The 1.568(1) mean P–N distance of **3** is significantly shorter than that of $P_3N_3Cl_6$ and **1**, although it is unclear whether this is indicative of the electronegativity of the $C_6F_5O^-$ group, since it is not accompanied by a correspondingly

long P–O distance. The mean P–O bond length of **1** approaches the accepted P–O single bond distance [19] of 1.61 Å; however, interpretation of this is limited since all mean P–O bond distances in Table 3 are not significantly different.

2.4. Electrospray mass spectrometry

As far as we are aware, the study of phosphazenes by electrospray mass spectrometry (ESMS) has not been reported previously. This technique has proven to be a useful alternative to EI or FAB mass spectrometry for characterizing inorganic and organometallic compounds because there is often less fragmentation and

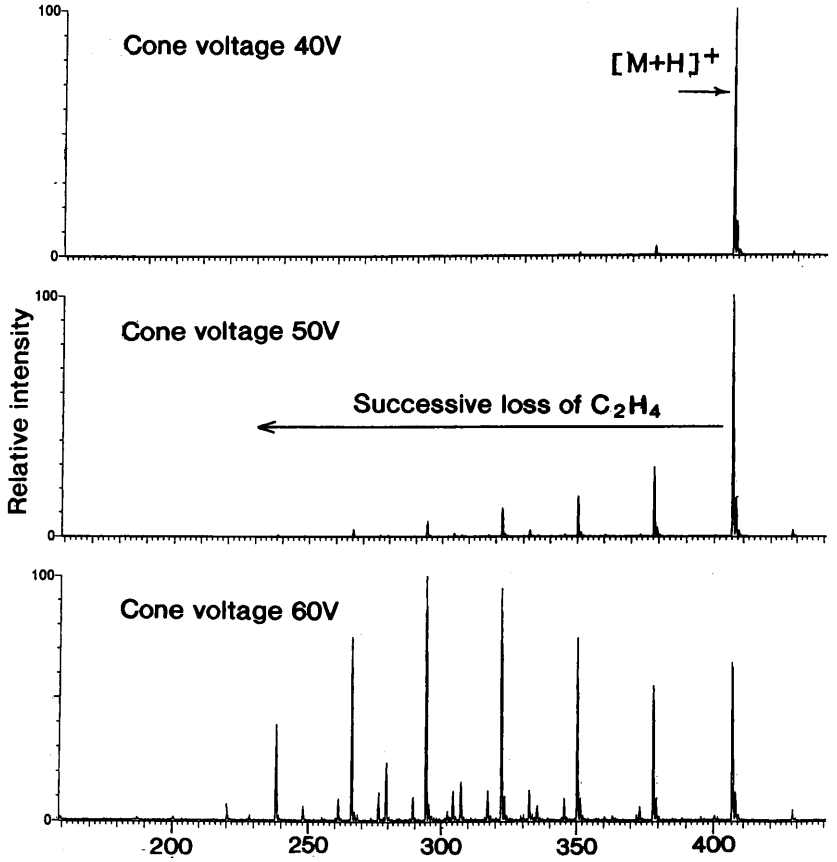

Fig. 4. The electrospray mass spectra of $N_3P_3(OEt)_6$ in $CH_3CN–H_2O$ (1:1) showing the increased net elimination of C_2H_4 (or hydrolysis) with increasing cone voltage; 40 V (a), 50 V (b) and 60 V (c).

low volatility is not a problem since the samples are introduced as solutions [20–22].

The observation of a positive-ion ESMS spectrum requires the formation of a cationic species, e.g. $[M + H]^+$ or $[M + Na]^+$. As mentioned in Section 1, basicity studies on a range of cyclotriphosphazenes have shown that the ring-nitrogen atoms are basic [3] and in fact protonated species can be isolated with metal-containing anions [23]. Hence the most likely cation binding site in the ESMS experiment is the ring-nitrogen atom. However, the basicity of this nitrogen atom is sensitive to the substituents on the phosphorus atoms, with electron-withdrawing substituents decreasing it. We were therefore interested to discover whether or not the basicity of the ring-nitrogen atoms decreased sufficiently when $C_6Cl_5O^-$ or $C_6F_5O^-$ were attached to the phosphorus atoms to preclude the observation of positive-ion ESMS spectra.

2.4.1. $N_3P_3(OEt)_6$

This gave a very clean $[M + H]^+$ peak at m/z 406 when run in $CH_3CN–H_2O$, the ion presumably forming by protonation at one of the ring nitrogen atoms. The spectrum is illustrated in Fig. 4a, which was run under relatively mild conditions (40 V cone voltage). As the cone voltage was increased to 50 and then 60 V (Fig. 4b,c) fragmentation occurred to give a series of peaks differing by 28 mass units, corresponding to successive net loss of C_2H_4 from the ethoxy groups to convert the $P–OC_2H_5$ to P–OH groups. The elimination from all six P–OR bonds presumably yields metaphosphimic acid, $[NHP(O)OH]_3$ (m/z 238), which is the phosphazene formed from tautomerization of $N_3P_3(OH)_6$ [24]. There was also a weak peak corresponding to $[2M + H]^+$ at m/z 811, where two $N_3P_3(OEt)_6$ molecules have aggregated about one proton.

To test the basicity of $N_3P_3(OEt)_6$ towards other cations, a solution in CH_3CN was treated with a drop of an aqueous solution containing all of the Group 1 cations ($Li^+–Cs^+$) at approximately 0.01 mol l^{-1}. This gave the spectrum shown in Fig. 5. One family of peaks in the 400–550 region consists of $[M + \text{cation}]^+$ signals, with H^+ cation dominating and the others in the relative order $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$. A second set around 800–950 consists of $[2M + \text{cation}]^+$, with the H^+ cation now a minor contributor. This can be understood in terms of the relative sizes. H^+ will be the most abundant cation and is a strong acid so forms $[M + H]^+$ very readily. However, it is small so aggregating two $N_3P_3(OEt)_6$ molecules to generate $[2M +$

$H]^+$ will not be favored on steric grounds. The other cations are present in equal concentrations, hence the adducts formed will depend on competition between solvation by H_2O and/or CH_3CN and coordination to the ring-nitrogen atoms. For the larger Cs^+ ion, solvation will be weaker so adducts form more readily than with the more tightly solvated Li^+ (with the other intermediate). All, however, are now large enough to form $[2M + \text{cation}]^+$ species without excessive steric hindrance.

2.4.2. $N_3P_3(OPh)_6$

This compound behaved similarly to $N_3P_3(OEt)_6$, giving strong $[M + H]^+$ ions at m/z 694 and weak $[2M + H]^+$ ions at m/z 1387 in either $CH_3CN–H_2O$ or EtOH. It too formed adducts with other cations. Particularly strong signals were found with added Ag^+, corresponding to $[M + Ag]^+$, $[M + Ag + CH_3CN]^+$ and $[2M + Ag]^+$, and, perhaps more surprisingly, a strong $PhHg^+$ adduct was seen at m/z 972 in a solution of $N_3P_3(OPh)_6$ in EtOH with added PhHgOAc. The fact that a stable, ring-nitrogen coordinated, silver(I) complex can be isolated using hexakis(2-pyridyloxy)cyclotriphosphazene [25], would support a similar interaction in the ESMS experiment, as opposed to arene ring coordination.

2.4.3. $N_3P_3(OPh)_5Cl$

This gave the expected $[M + H]^+$ and $[2M + H]^+$ ions in either $CH_3CN–H_2O$ or MeOH. Added PhHgOAc again produced a clean $PhHg^+$ adduct ion, and with Ag^+ clear $[M + Ag]^+$, $[M + Ag + CH_3CN]^+$ and

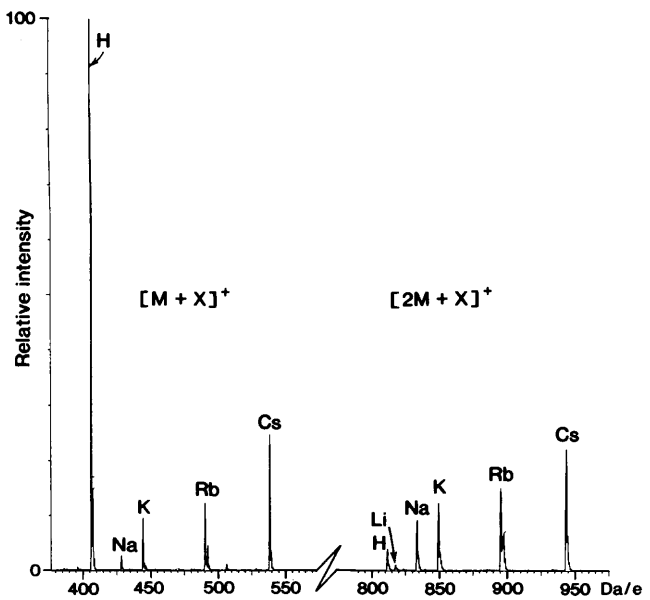

Fig. 5. The electrospray mass spectrum of $N_3P_3(OEt)_6$ in CH_3CN with an added drop of an aqueous solution containing all the Group 1 metal cations in equimolar concentration, showing the relative selectivities for both the $[M + X]^+$ and $[2M + X]^+$ aggregates.

$[2M + Ag]^+$ signals were seen. In the latter case, there was no sign of an ion $[N_3P_3(OPh)_5]^+$, which would have been formed by Cl^- abstraction. Similarly, the negative ion spectrum gave no signals, which shows that Ag^+ induced hydrolysis to give $N_3P_3(OPh)_5(OH)$ has not occurred since this would have given a $[N_3P_3(OPh)_5(O)]^-$ peak.

2.4.4. $N_3P_3(OC_6F_5)_6$ (3)

This compound behaves completely differently from those described above. In the positive ion mode no signals were detected in $CH_3CN–H_2O$ or EtOH (even with added acid), showing the basicity of the ring nitrogen atoms has been reduced through electron withdrawal by the C_6F_5O groups to the point where attachment of a proton does not take place. However, in negative ion mode a strong, clean peak at m/z 1066 corresponding to $[M - C_6F_5]^-$ is seen in $CH_3CN–H_2O$. This presumably arises from hydrolysis to give $N_3P_3(OC_6F_5)_5(OH)$ which then deprotonates to give $[N_3P_3(OC_6F_5)(O)]^-$, an anion which would be stabilized by the plethora of electron withdrawing C_6F_5O groups. This is consistent with the observation that hydrolysis rates of aryloxycyclophosphazenes are greater when the phenoxy groups contain electron-withdrawing substituents. For example, in 25 vol% aqueous diglyme, the rate constants for $R = p\text{-}NO_2$ and $R = p\text{-}Me$ are 5.16×10^{-1} and 6.93×10^{-7} mol^{-1} l s^{-1}, respectively [26]. It is therefore not surprising that similar hydrolysis is not observed for $N_3P_3(OPh)_6$ in the negative ion spectrum. Addition of $AgClO_4$ to a CH_3CN solution of $N_3P_3(OC_6F_5)_6$, gave no signals in the positive ion mode corresponding to an Ag^+ adduct, but in the negative ion showed a strong $[M + ClO_4]^-$ species at m/z 1332. For this phosphazene, aggregation with anions appears to have become more favorable than with cations.

2.4.5. $N_3P_3(OC_6F_5)_4(O_2C_{12}H_8)$ (4)

As expected by comparison with the results for **3**, this compound gave a strong signal at m/z 884 in the negative ion mode in $CH_3CN–H_2O$ or CH_3OH, corresponding to the hydrolysis product $N_3P_3(OC_6F_5)_3(O_2C_{12}H_8)O^-$. However, a weak $[M + H]^+$ peak at m/z 1052 shows that some residual basicity is still retained for **4** (in the positive-ion mode). However, there was no adduct formed with either Rb^+ or Cs^+ ions.

2.4.6. $N_3P_3Cl_6$

This compound gave no signals in positive ion mode in $CH_3CN–H_2O$. However, addition of Ag^+ ions led to a complex set of peaks from which a $[M + Ag]^+$ envelope could be found at m/z 456, but the complicated nature of the spectrum makes it unsuitable for analytical purposes. The negative ion spectrum, in contrast, gave a clean signal of $[N_3P_3Cl_5(O)]^-$, arising from a hydrolysis reaction of the parent species.

2.4.7. gem-$N_3P_3(OC_6Cl_5)_4Cl_2$ (1)

For this compound spectra were difficult to record because of poor solubility in all solvents used. However, a sufficient amount dissolved in CH_3CN to give a weak signal in negative ion mode centered about m/z 1018 corresponding to $[N_3P_3(OC_6Cl_5)_3Cl_2(O)]^-$ from hydrolysis of one of the $C_6Cl_5O^-$ groups (rather than one of the P–Cl bonds), which is consistent with the C_6Cl_5O substituent being more electron withdrawing than the Cl. More unexpectedly was a weak signal at m/z 1267 in positive ion mode under relatively harsh conditions, which corresponds to an M^+ ion (rather than a $[M+H]^+$ ion; the calibration of the instrument can distinguish these). The source of the electrospray mass spectrometer can be regarded as an unconventional cell, and redox processes giving M^+ ions are not unknown [20,27]. However there is no obvious reason why there should be an M^+ ion formed in this case, but not for any of the other samples examined. Possibly for the compounds with more basic ring-nitrogen sites, the formation of $[M+H]^+$ ions swamps a small amount of M^+ arising from oxidation, but for $N_3P_3(OC_6Cl_5)_4Cl_2$ the lack of competing protonation highlights the alternative ion-forming process.

2.4.8. $N_3P_3(OC_6Cl_5)_6$ (2)

For this sample, total insolubility precluded exploration.

In summary, ESMS is a useful technique for characterizing $N_3P_3(OR)_6$ and related species when R is an electron-releasing organic group, since strong $[M+H]^+$ ions are formed via the basic ring-nitrogen sites. Other simple cations also form strong adducts, meaning relative coordinating strengths can be assessed readily from ESMS spectra. For corresponding species with strongly electron-withdrawing R groups, protonation to give positive ions was not observed. In situ hydrolysis of these groups can occur to give –OH, which on deprotonation, allows detection of the corresponding anion. This, however, is a less satisfactory method of characterization. Hydrolysis of a P–Cl bond was also seen for $N_3P_3Cl_6$, but appears less favorable than reaction at P–OR bonds.

3. Experimental

3.1. General

All manipulations were carried out under nitrogen using standard Schlenk techniques. Analytical grade solvents were purchased from standard chemical suppliers, and with the exception of tetrahydrofuran, were used without further purification/drying. Tetrahydrofuran (THF) was distilled from Na–benzophenone and stored over activated molecular sieves. Technical grade (BDH) pentachlorophenol and hexachlorocyclotriphosphazene, $N_3P_3Cl_6$ (Aldrich), were sublimed prior to use. NaH was isolated as a pure powder from a paraffin oil mixture by washing with hexane. $N_3P_3(2,2'\text{-}O_2C_{12}H_8)Cl_4$ (**4**) [13], $N_3P_3(OEt)_6$ [28], $N_3P_3(OPh)_6$ and $N_3P_3(OPh)_5Cl$ [29] were prepared by literature methods. 2,2′-Biphenol (Aldrich) and pentafluorophenol (Aldrich) were used as received. NMR spectra were run on a JEOL GX270W MHz spectrometer and ESMS samples were run on a VG Platform II instrument. For the chlorinated samples, the m/z values quoted are for the most intense peaks in the isotopomer envelope, confirmed by simulation.

3.2. Synthesis of compounds

3.2.1. gem-$N_3P_3(OC_5Cl_5)_4Cl_2$ (1)

Pentachlorophenol (1.838 g, 6.90 mmol) was added whilst stirring to NaH (160 mg, 6.67 mmol) in dry tetrahydrofuran (30 ml). After stirring the mixture for approximately 20 min at r.t., $N_3P_3Cl_6$ (200 mg, 0.575 mmol) was added and the reaction heated to reflux. After approximately 10–13 days ^{31}P NMR showed predominantly the *gem*-tetrasubstituted product, at which time the reaction was stopped. The solvent was removed under vacuum and the solid residue washed with dilute NaOH (0.04 mol l^{-1}). The remaining residue was digested in boiling tetrahydrofuran and filtered whilst hot through kiesulghur. Slow evaporation of the filtrate yielded colorless crystals of monosolvated
gem - tetra(pentachlorophenoxy)dichloro - cyclotriphosphazene (**1**) (150 mg, 21%). m.p. 286–293°C. *Anal.* Found: C, 25.26; H, 0.42; Cl, 58.46; N, 3.12. $C_{24}N_3O_4P_3Cl_{22}\cdot C_4H_8O$ requires C, 25.11; H, 0.60; Cl, 58.24; N, 3.14%. ^{31}P NMR (THF) δ_P 0.1 (d), 26.4 (t), $J_2 = 88$ Hz. ES MS (m/z): positive ion 1267 M^+; negative ion 1018 $[P_3N_3(OC_6Cl_5)_3Cl_2(O)]^-$.

3.2.2. $N_3P_3(OC_6Cl_5)_6\cdot 2C_6H_6$ (2)

Similarly, $N_3P_3Cl_6$ (100 mg, 0.288 mmol) was added to 12 mole equivalents of sodium pentachlorophenoxide (prepared in situ as for **1**) in diglyme (20 ml), and the reaction stirred under reflux for 5 days considerable decomposition was evident from the brown color of the reaction. Once cooled, the reaction mixture was filtered and the precipitate washed ($NaHCO_3$–H_2O) and subsequently extracted with hot benzene. Slow diffusion of pentane into the benzene solution afforded, in low yield, hexa(pentachlorophenoxy)cyclotriphosphazene·$2C_6H_6$ (**2**); a colorless, micro-crystalline solid (45 mg, 8%). m.p. (dec.) >330°C. *Anal.* Found: C, 30.49; H, 0.62; Cl, 56.20; N, 2.19. Calc. for $C_{36}N_3O_6P_3Cl_{30}\cdot 2C_6H_6$: C, 30.62; H, 0.64; Cl, 56.48; N, 2.23%. ^{31}P NMR (benzene:CH_2Cl_2 2:1) δ_P 2.1 (s).

3.2.3. $N_3P_3(OC_6F_5)_6$ (3)

Similarly, $N_3P_3Cl_6$ (200 mg, 0.565 mmol) was added to seven molar equivalents of sodium pentafluorophenoxide (prepared in situ as for **1**) in tetrahydrofuran (30 ml), and the reaction stirred under reflux for 6 h. After removal of the solvent, the residue was washed (H_2O) and subsequently extracted with CH_2Cl_2 and dried with $MgSO_4$. Hexane was added and the solution cooled to 4°C, which yielded colorless crystals of hexakis(pentafluorophenoxy)cyclotriphosphazene (**3**) (490 mg, 70%). m.p. 110–111°C. *Anal.* Found: C, 35.30; N, 3.55; P, 7.51. Calc. for $C_{36}N_3O_6P_3F_{30}$: C, 35.06; N, 3.41; P, 7.53%. ^{31}P NMR (THF) δ_P 10.7 (s). ES MS (m/z): negative ion 1066 $[P_3N_3(OC_6F_5)_5(O)]^-$. Crystals suitable for single crystal X-ray studies were grown via the slow diffusion of pentane into a CH_2Cl_2 solution of **3**.

3.2.4. $N_3P_3(OC_6F_5)_4(2,2'\text{-}O_2C_{12}H_8)$ (5)

Similarly, **4** (100 mg, 0.217 mmol) was added to 4 mole equivalents of sodium pentafluorophenoxide in tetrahydrofuran (30 ml^{-1}), and the reaction stirred under reflux conditions for approximately 24 h. The reaction mixture was worked up as for **3**. Colorless crystals of (2,2′-biphenolate)tetra(pentafluorophenoxy)-cyclotriphosphazene (**5**) (91 mg, 40%) were obtained by slow evaporation from CH_2Cl_2–hexane. m.p. 148–151°C. *Anal.* Found: C, 41.24; H, 0.73; N, 4.05. $C_{36}H_8N_3O_6F_{20}P_3$ requires C, 41.13; H, 0.77; N, 4.00%. ^{31}P NMR (THF) δ_P 13.6 (d, $J_2 = 95$ Hz), 22.4 (dd, $J_2 = 90$ and 100 Hz). ES MS (m/z): positive ion 1052 $[M+H]^+$; negative ion 884 $[N_3P_3(OC_6F_5)_3\text{-}(O_2C_{12}H_8)O]^-$.

3.3. Reaction of $NaOC_6F_5$ with $N_3P_3(2,2'\text{-}O_2C_{12}H_8)Cl_4$ (4)

Similarly, **4** (100 mg, 0.217 mmol) was added to 2 mole equivalents of sodium pentafluorophenoxide in tetrahydrofuran (30 ml), and the reaction stirred under reflux conditions for approximately 18 h. ^{31}P NMR was used to determine the ratio of *geminal* and non-*geminal* disubstituted products — no further work up was performed on the reaction mixture.

3.4. Monitoring the reaction between $NaOC_6F_5$ and $N_3P_3Cl_6$

The general procedure was as follows: a solution of $N_3P_3Cl_6$ (200 mg, 0.575 mmol) in tetrahydrofuran (3 ml) was added quickly to a stirred tetrahydrofuran (7 ml) solution containing seven molar equivalents of in situ prepared $NaOC_6F_5$. After approximately 30 s stirring, 5 ml was transferred to a 10 mm NMR tube and loaded into a JEOL 270 MHz spectrometer. ^{31}P NMR spectra were acquired at routine time intervals. Similarly, the reaction was also monitored at low temperature, with the initial solutions cooled to 0°C prior to mixing and the probe temperature set to −10°C.

Similarly, using ^{31}P NMR, the reaction of pentachlorophenoxide with $N_3P_3Cl_6$ was monitored. However, because of the slow nature of the reaction, monitoring was performed once every 1–3 days.

3.5. Crystal structure determination of compound 1

Single crystals of *gem*-$N_3P_3Cl_2(OC_6Cl_5)_4\cdot C_4H_8O$ (**1**.C_4H_8O) were recrystallized from tetrahydrofuran, mounted in inert oil and transferred into the cold gas stream of a Siemens SMART CCD area-detector diffractometer. Crystal data for $C_{28}H_8N_3O_5P_3Cl_{22}$: $M = 1339.18$, monoclinic, space group; $P2_1/n$, $a = 16.8730(2)$, $b = 15.0169(2)$, $c = 19.2459(2)$ Å, $\beta = 109.60(1)°$, $V = 4593.97(9)$ Å^3, $T = 203(2)$ K, $Z = 4$, $D_{calc} = 1.936$ g cm^{-3}, $F(000) = 2624$, μ(Mo Kα) = 1.45 mm^{-1}, 27 675 reflections were collected ($2.78 < 2\theta < 55.02°$), of which 10 063 were unique ($R_{int} = 0.0376$). Data was corrected for absorption effects (SADABS); $T_{max} = 0.8803$, $T_{min} = 0.7404$. Refinement of 550 parameters converged at $R_1 = 0.0471$ [observed data: 7233 $|F_o| > 4\sigma(F_o)$], $wR_2(F^2) = 0.1025$ (all data).

3.6. Crystal structure determination of compound 3

Single crystals of $N_3P_3(OC_6F_5)_6$ (**3**) were recrystallized via slow CH_2Cl_2–pentane diffusion, mounted in inert oil and transferred into the cold gas stream of a Siemens SMART CCD area-detector diffractometer. Crystal data for $C_{36}N_3O_6P_3F_{30}$: $M = 1233.30$, monoclinic, space group; $P2_1/n$, $a = 7.9946(1)$, $b = 43.4044(2)$, $c = 12.1024(1)$ Å, $\beta = 108.863(1)°$, $V = 3974.00(6)$ Å^3, $T = 203(2)$ K, $Z = 4$, $D_{calc} = 2.061$ g cm^{-3}, $F(000) = 2400$, μ(Mo Kα) = 1.45 mm^{-1}, 14 645 reflections were collected ($5.12 < 2\theta < 50.44°$), of which 6990 were unique. Data were corrected for absorption effects (SADABS); $T_{max} = 0.9308$, $T_{min} = 0.8796$. Refinement of 703 parameters converged at $R_1 = 0.0415$ [observed data: 6097 $|F_o| > 4\sigma(F_o)$], $wR_2(F^2) = 0.0909$ (all data).

Structures of **1** and **3** solved and refined routinely using direct methods (SHELXS-97) [30] and full-matrix least-squares on F^2 (SHELXL-97) [31] respectively. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the molecules were geometrically idealized and refined using a riding model.

4. Supplementary material

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 144167 and 144168. Copies of this information may be obtained free of charge

Tetranuclear manganese carboxylate clusters with imidazole-carboxylate chelating ligands. X-ray crystal structure of the 4-imidazoleacetate complex

Colette Boskovic, Kirsten Folting, George Christou *

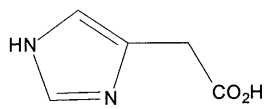
Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405-4001, USA

Received 9 May 2000; accepted 17 July 2000

Abstract

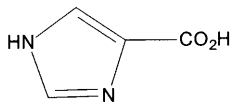
Procedures are described for the synthesis of tetranuclear manganese carboxylate complexes with ligands derived from 4-imidazoleacetic acid (imidacH) and 4-imidazolecarboxylic acid (imidcarbH). Reaction mixtures containing NBu^n_4imidac or $NHex^n_4$imidcarb generated in situ and either $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$ or $Mn(O_2CR)_2$, RCO_2H (R = Me, Ph) and NR'_4MnO_4 ($R' = Bu^n$, Hex^n) give red–brown solutions from which the products $(NBu^n_4)[Mn_4O_2(O_2CR)_7(imidac)_2]$ (R = Me (**1**); R = Ph (**2**)) and $(NHex^n_4)[Mn_4O_2(O_2CR)_7(imidcarb)_2]$ (R = Me (**3**); R = Ph (**4**)) can be obtained. The X-ray crystal structure of **2** reveals that the anion consists of an $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ core with the four Mn atoms disposed in a 'butterfly' arrangement and the O atoms triply bridging each 'wing'. Peripheral ligation is provided by seven bridging O_2CPh^- ligands and two chelating $imidac^-$ groups. All available characterization data are consistent with the same core for complexes **1**, **3** and **4**, with the structures varying only in the peripheral ligation. ^1H NMR spectroscopy of all four complexes indicates that the structure is maintained in solution and the majority of the resonances have been assigned on the basis of T_1 measurements and substitution and exchange experiments. Cyclic voltammetry reveals the presence of a single quasi-reversible oxidation processes for complexes **1** and **2**. © 2000 Elsevier Science Ltd. All rights reserved.

Keywords: Polynuclear manganese-carboxylate clusters; Imidazole-carboxylate chelating ligands; Paramagnetic NMR



1. Introduction

The chemistry of Mn carboxylate clusters is an area of considerable interest, and numerous examples varying widely in both nuclearity and structure have been reported [1]. The interest in these species is in part due to their application to the modeling of Mn-containing proteins and enzymes, in which up to four Mn nuclearities have been identified [2,3]. We have previously described procedures that allow the synthesis of tetranuclear Mn carboxylate compounds possessing the $[Mn_4(\mu_3\text{-}O)_2]$ core and of formulation $[Mn^{III}_4O_2(O_2CR)_7(L)_2]^z$, where L is a pyridine-based N/N or N/O chelate derived from 2,2′-bipyridine (bpy), picolinic acid (picH), 8-hydroxyquinoline (hqnH) or 2-(hydroxymethyl)pyridine (hmpH) [4–6].



As part of a continuing exploration of tetranuclear Mn carboxylate clusters with chelating ligands, we have recently turned our attention to the use of imidazole-containing chelates in order to compare and contrast the products with those already obtained with pyridine-based chelates. We describe herein our initial results comprising the syntheses and characterization of tetranuclear clusters possessing imidazole-based N/O chelating ligands derived from 4-imidazoleacetic acid (imidacH) and 4-imidazolecarboxylic acid (imidcarbH). These species allow informative comparisons with those possessing pyridine-based chelating ligands with which they are isostructural, as well as providing access to compounds that possess either five- or six-membered chelate rings but are otherwise identical. In addition, imidazole ligation to tetranuclear Mn clusters is of interest due to the histidine ligation of the tetranuclear Mn complex responsible for water oxidation in Photosystem II [7].

2. Experimental

2.1. Synthesis

All manipulations were performed under aerobic conditions, using materials as received. Trinuclear $[Mn_3O]$ complexes were available from previous work [8]. $NBu^n_4MnO_4$ and $Mn(O_2CPh)_2{\cdot}2H_2O$ were prepared as described [4,9] and $NHex^n_4OH$ (Hex = hexyl) was prepared according to Giovannellio et al. [10]. WARNING: Appropriate care should be taken in the use of $NR^n_4MnO_4$, and readers are referred to the detailed warning given elsewhere [9].

2.1.1. $NHex^n_4MnO_4$

To a vigorously stirred solution of $KMnO_4$ (5.00 g, 31.6 mmol) in H_2O (100 cm^3) was added a solution of $NHex^n_4Br$ (13.50 g, 31.6 mmol) in H_2O (100 cm^3), resulting in the formation of a purple precipitate. This was filtered, washed copiously with H_2O and Et_2O and dried in vacuo at room temperature. The yield was 13.49 g, 92%.

2.1.2. $(NBu^n_4)[Mn_4O_2(O_2CMe)_7(imidac)_2]$ (**1**)

Method A: to a stirred solution of $Mn(O_2CMe)_2{\cdot}4H_2O$ (0.74 g, 3.0 mmol) and glacial acetic acid (1 cm^3) in MeCN (70 cm^3) was slowly added $NBu^n_4MnO_4$ (0.27 g, 0.75 mmol) in small portions to give a deep brown solution. To this was added a solution resulting from the combination of imidacH·HCl (0.31 g, 1.9 mmol) in MeCN (5 cm^3) and 1.0 M NBu^n_4OH in MeOH (3.8 cm^3, 3.8 mmol). The reaction mixture was stirred overnight and a brown precipitate removed by filtration. The filtrate was reduced in volume to 50 cm^3 and Et_2O (100 cm^3) was added, leading to the formation of a red–brown precipitate which could be recrystallized from MeCN–Et_2O. The yield was 0.60 g (55%). Drying in vacuo leads to the unsolvated form. Elemental analysis, *Anal.* Found: C, 41.09; H, 5.78; N, 6.08. Calc. for $C_{40}H_{67}N_5O_{20}Mn_4$: C, 41.50; H, 5.83; N, 6.05. Selected IR data (cm^{-1}): 1647(m), 1608(s), 1493(m), 1467(w), 1401(s), 1387(s), 1333(s), 1320(s), 1266(w), 1227(w), 1176(w), 1087(w), 1028(m), 943(m), 935(sh), 882(w), 802(w), 737(sh), 721(m), 678(m), 650(s), 635(sh), 613(m), 436(m).

Method B: to a stirred solution of $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$ (0.30 g, 0.34 mmol) in MeCN (20 cm^3) was added a solution resulting from the combination of imidacH·HCl (0.11 g, 0.68 mmol) in MeCN (3 cm^3) and 1.0 M NBu^n_4OH in MeOH (1.4 cm^3, 1.4 mmol). The reaction mixture was stirred overnight and a brown precipitate was removed by filtration. The filtrate was reduced in volume to 10 cm^3 and Et_2O (20 cm^3) was added, leading to the formation of a red–brown precipitate which could be recrystallized from MeCN–Et_2O. The yield was 0.14 g (47%). The product was spectroscopically identical to that obtained by method A.

2.1.3. $(NBu^n_4)[Mn_4O_2(O_2CPh)_7(imidac)_2]$ (**2**)

To a stirred solution of $Mn(O_2CPh)_2{\cdot}2H_2O$ (1.34 g, 4.0 mmol) and $PhCO_2H$ (0.86 g, 7.0 mmol) in MeCN (100 cm^3) was slowly added $NBu^n_4MnO_4$ (0.36 g, 1.0 mmol) in small portions to give a deep brown solution. To this was added a solution resulting from the combination of imidacH·HCl (0.41 g, 2.5 mmol) in MeCN (5 cm^3) and 1.0 M NBu^n_4OH in MeOH (5.0 cm^3, 5.0 mmol). The resulting solution was stirred overnight, filtered through celite, reduced in volume to 40 cm^3, and Et_2O (100 cm^3) added dropwise with vigorous stirring. This led to the formation of a red–brown precipitate, which could be recrystallized from MeCN–Et_2O. The yield was 1.45 g (73%). Crystals suitable for crystallography were grown by layering an MeCN solution of the complex with Et_2O, and they were kept in contact with the mother liquor to prevent interstitial solvent loss. Drying in vacuo leads to the unsolvated form. Elemental analysis. *Anal.* Found: C, 56.77; H, 5.66; N, 4.34. Calc. for $C_{75}H_{81}N_5O_{20}Mn_4$: C, 56.58; H, 5.13; N, 4.40. Selected IR data (cm^{-1}): 1606(s), 1571(s), 1501(w), 1490(m), 1466(w), 1448(m), 1384(s), 1331(s), 1314(m), 1303(m), 1265(m), 1231(w), 1173(m), 1143(w),1089(w), 1068(w), 1026(m), 940(m), 838(m), 720(s), 690(m), 676(m), 650(s), 630(m), 610(m), 468(m), 437(m).

2.1.4. $(NHex^n_4)[Mn_4O_2(O_2CMe)_7(imidcarb)_2]$ (**3**)

Method A: to a stirred solution of $Mn(O_2CMe)_2{\cdot}4H_2O$ (0.74 g, 3.0 mmol) and glacial acetic acid (1 cm^3) in MeCN (70 cm^3) was slowly added $NHex^n_4MnO_4$ (0.35 g, 0.75 mmol) in small portions to give a deep brown solution. To this was added a solution resulting from the combination of imidcarbH (0.21 g, 1.9 mmol) in MeCN (10 cm^3) and 0.2 M $NHex^n_4OH$ in MeOH (9.5 cm^3, 1.9 mmol). The reaction mixture was stirred overnight and a brown precipitate removed by filtration. The filtrate was reduced in volume to 50 cm^3 and Et_2O (100 cm^3) was added, leading to the formation of a red–brown precipitate which could be recrystallized from MeCN–Et_2O. The yield was 0.55 g (47%). Drying in vacuo leads to the unsolvated form. Elemental analysis. *Anal.* Found: C, 44.34; H, 6.28; N, 5.12. Calc. for $C_{46}H_{79}N_5O_{20}Mn_4$: C, 44.49; H, 6.41; N, 5.64. Selected IR data (cm^{-1}): 1681(s), 1615(s), 1579(sh), 1504(w), 1486(w), 1465(w), 1397(s), 1332(s), 1313(s), 1263(w),

1188(m), 1154(w), 1099(w), 1076(w), 1043(w), 1013(m), 933(w), 822(m), 800 (w), 776(w), 679(s), 654(s), 614(m), 569(w), 502 (m).

Method B: to a stirred solution of $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$ (0.50 g, 0.57 mmol) in MeCN (60 cm^3) was added a solution resulting from the combination of imidcarbH (0.097 g, 0.86 mmol) in MeCN (5 cm^3) and 0.2 M $NHex^n_4OH$ in MeOH (4.3 cm^3, 0.86 mmol). The reaction mixture was stirred overnight and a brown precipitate was removed by filtration. The filtrate was reduced in volume to 30 cm^3 and Et_2O (60 cm^3) was added, leading to the formation of a red–brown precipitate which could be recrystallized from MeCN–Et_2O. The yield was 0.27 g (50%). The product was spectroscopically identical to that obtained by method A.

2.1.5. $(NHex^n_4)[Mn_4O_2(O_2CPh)_7(imidcarb)_2]$ (**4**)

To a stirred solution of $Mn(O_2CPh)_2{\cdot}2H_2O$ (0.49 g, 1.5 mmol) and $PhCO_2H$ (0.32 g, 2.6 mmol) in MeCN (80 cm^3) was slowly added $NHex^n_4MnO_4$ (0.17 g, 0.36 mmol) in small portions to give a deep brown solution. To this was added a solution resulting from the combination of imidcarbH (0.10 g, 0.92 mmol) in MeCN (5 cm^3) and 0.2 M $NHex^n_4OH$ in MeOH (4.6 cm^3, 0.92 mmol). The resulting solution was stirred overnight, filtered through celite, reduced in volume to 40 cm^3, and Et_2O (100 cm^3) added dropwise with vigorous stirring. This led to the formation of a red–brown precipitate, which could be recrystallized from MeCN–Et_2O. The yield was 0.12 g (54%). Drying in vacuo leads to the unsolvated form. Elemental analysis. *Anal.* Found: C, 57.50; H, 5.57; N, 4.18. Calc. for $C_{81}H_{93}N_5O_{20}Mn_4$: C, 58.03; H, 5.59; N, 4.18. Selected IR data (cm^{-1}): 1680(s), 1610(s), 1572(s), 1508(w), 1490(w), 1464(w), 1448(m), 1375(s), 1344(sh), 1305(s), 1188(w), 1174(m), 1156(w), 1140(w), 1068(m), 1025(m), 1012(m), 936(w), 827(m), 780(w), 718(s), 688(m), 676(m), 654(s), 617(m), 563(w), 502(m), 468(m).

2.2. X-ray crystallography

Data for complex **2** were collected on a Bruker platform goniometer equipped with a SMART 6000 CCD detector at −163°C; details of the diffractometry, low temperature facilities and computational procedures employed by the Molecular Structure Center are available elsewhere [11]. Data collection parameters are summarized in Table 1.

The initial survey of a limited portion of reciprocal space located a set of reflections with no symmetry or systematic absences. Solution and refinement of the structure confirmed the choice of the centrosymmetric space group $P\bar{1}$. The structure was solved using a combination of Patterson and direct methods (DIRDIF-96 [12]). Most of the atoms in the cation and anion were located from DIRDIF-96. The remaining atoms were located in successive iterations of least-squares refinement followed by generation of a difference Fourier map. In addition to the main anion of interest, the asymmetric unit contained a $NBu^n_4{}^+$ cation and five molecules of MeCN. Many of the hydrogen atoms were visible in a later difference Fourier map. On three of the solvent molecules, at least one hydrogen atom was located on the methyl carbon atom. Hydrogen atoms were then introduced in fixed calculated positions and assigned a thermal parameter of 1.0 plus the isotropic equivalent of the parent atom. In the final cycles of least-squares refinement the non-hydrogen atoms were refined using anisotropic thermal parameters, while the hydrogen atoms were fixed. The final difference map was essentially featureless, the largest peak was 1.42 e Å^{-3} located 1.05 Å from H(55) and 1.92 Å from C(93) (in the cation). The next largest peak was 0.98 e Å^{-3} also in the region of the cation, indicating a possible small disorder.

2.3. Other measurements

IR spectra (KBr pellet) were recorded on a Nicolet model 510P spectrometer. ^{1}H NMR spectra were recorded in CD_3CN at ~20°C with a 300 MHz Varian Gemini 2000 NMR spectrometer. Cyclic voltammetry employed a BAS CV-50W voltammetric analyzer and a standard three-electrode assembly (glassy-carbon work-

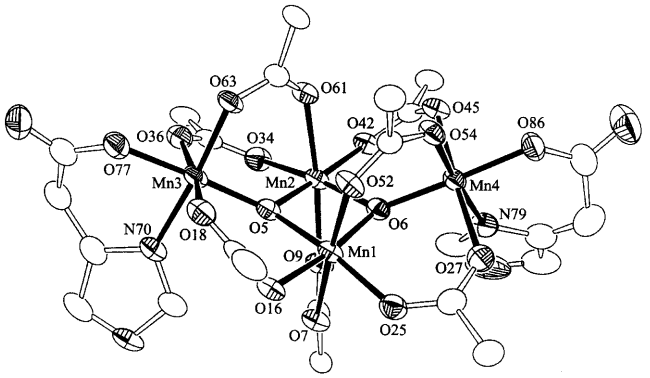

Fig. 1. ORTEP representation for the anion of complex **2** at the 50% probability level. For clarity, only the *ipso* carbon atom of each benzoate ring is included.

ing, Pt-wire auxiliary, $Ag–AgNO_3$ reference) with 0.1 M $NBu^n_4PF_6$ as supporting electrolyte. Potentials are quoted versus the ferrocene–ferrocenium couple under the same conditions. Elemental Analyses were performed by Atlantic Microlab Inc., Norcross, Georgia or in-house with a Perkin–Elmer Series II CHNS/O Analyzer 2000.

3. Results and discussion

3.1. Syntheses

In earlier reports we have described two procedures for the preparation of $[Mn^{III}_4O_2(O_2CR)_7(L)_2]^z$ complexes, where L is derived from 2,2′-bipyridine (bpy), picolinic acid (picH), 8-hydroxyquinoline (hqnH) and 2-(hydroxymethyl)pyridine (hmpH) [4–6] The first procedure involves treatment of trinuclear $[Mn_3O(O_2CR)_6(py)_3]^+$ complexes with salts of the chelating ligand L, or with the acid form of the ligand and an equivalent of base. The second procedure involves a comproportionation reaction between Mn^{II} and MnO^-_4 in the presence of RCO_2H and L. In the present study both procedures have allowed the synthesis of the analogous $imidac^-$ and $imidcarb^-$ complexes with R = Me and Ph. NBu^{n+}_4 salts of the $imidac^-$ species were isolated, while $NHex^{n+}_4$ salts of the $imidcarb^-$ species were preferred in order to obtain soluble materials. Thus, treatment of an MeCN solution of $[Mn_3O(O_2CMe)_6(py)_3]^+$ with NBu^n_4(imidac) or $NHex^n_4$(imidcarb) generated in situ afforded a brown solution from which $NBu^n_4[Mn_4O_2(O_2CMe)_7(imidac)_2]$ (**1**) or $NHex^n_4[Mn_4O_2(O_2CMe)_7(imidcarb)_2]$ (**3**) were obtained with minimal workup in good yield (47 and 50%, respectively). Employment of the second procedure, whereby a reaction mixture containing $Mn(O_2CR)_2$, NR'_4MnO_4 (R′ = Bu^n or Hex^n) and RCO_2H was similarly treated with NBu^n_4(imidac) or $NHex^n_4$(imidcarb) also resulted in brown solutions from which **1**, $NBu^n_4[Mn_4O_2(O_2CPh)_7(imidac)_2]$ (**2**), **3** and $NHex^n_4[Mn_4O_2(O_2CPh)_7(imidcarb)_2]$ (**4**) were obtained with minimal workup in good yield (55, 73, 47 and 54%, respectively). This reaction employed a 4:1 Mn^{II}:Mn^{VII} ratio, as required for preparation of a Mn^{III}_4 product (Eq. (1))

$$4Mn^{2+} + Mn^{7+} \rightarrow 5/4Mn^{3+}_4 \quad (1)$$

Compound **2** was structurally characterized, and all available characterization data for **1** are consistent with it having the same structure as **2**. Crystals of **3** and **4** suitable for X-ray crystallography could not be obtained; however, all of the characterization data are consistent with structures analogous to those of **1** and **2**.

3.2. Description of structure

An ORTEP representation of the anion of complex **2** is given in Fig. 1. Crystallographic data and selected bond distances and angles are listed in Tables 1 and 2, respectively.

Complex **2** crystallizes in the triclinic space group $P\bar{1}$. The asymmetric unit contains the complete anion, the NBu^{n+}_4 cation and five MeCN solvate molecules; the latter two will not be further discussed. The anion of **2** possesses a Mn_4O_2 core with the familiar 'butterfly' structure. Mn(1) and Mn(2) occupy the 'body' positions, while Mn(3) and Mn(4) occupy the 'wingtip' positions and O(5) and O(6) triply bridge each wing. The structure can be considered as two triangular Mn_3O units edge-shared through Mn(1) and Mn(2) with a dihedral angle of 142.2°. Unlike the planar core of the Mn_3O complexes, the μ_3-O atoms of the triangular units of the 'butterfly' structure lie slightly below the plane (Fig. 1). Two distinct Mn···Mn distances are observed, with the 'body' Mn(1)···Mn(2) separation of ca. 2.8 Å significantly shorter than the four 'body' to 'wingtip' separations of 3.3–3.4 Å. These separations are consistent with the presence of two and one bridging oxygen atoms, respectively [13]. Peripheral ligation is by seven bridging benzoate ligands and two $imidac^-$ ligands chelating the 'wingtip' Mn atoms. Each Mn atom is six-coordinate with axially elongated octahedral geometry typical of Jahn–Teller distorted high spin d^4 Mn^{III} ions. The axially elongated sites are all occupied by benzoate oxygen atoms, with both of the oxygen atoms of the unique benzoate ligand (bridging the 'body' Mn atoms) occupying JT elongated positions. The $imidac^-$ oxygen atoms are coordinated *trans* to the μ_3-O atoms at a distance of 1.9 Å, which is comparable to the other (non-JT elongated) Mn-benzoate bonds. The molecule has idealized C_2 point symmetry and, overall, the structure is extremely similar to those of the analogous bpy, pic^-, hqn^- and hmp^- complexes, with the cores of each species essentially superimposable

[4–6]. The structural differences between complex **2** and the previously reported 'butterfly' complexes arise in the vicinity of the chelating ligand. In particular, the imidac$^-$ species possesses a significantly non-planar six-membered chelate ring in contrast to the planar five-membered chelate rings of the bpy, pic$^-$, hqn$^-$ and hmp$^-$ species.

3.3. ^1H NMR spectroscopy

The ^{1}H NMR spectra of complexes **1** and **2** in MeCN-d_3 are shown in Fig. 2 and the resonance positions are listed in Table 3 using the labeling scheme given in Fig. 2. Assignments were made on the basis of: (i) comparison with the spectrum of the O_2CMe-d_3 analog of **1** to distinguish between the resonances of the imidac$^-$ protons and those associated with the carboxylates; (ii) addition of D_2O to the NMR solution to assign the amine resonance of the imidac$^-$ ligand; (iii) T_1 measurements (inversion recovery method) correlated with the relative proton to metal centre distances to assign the remaining resonances associated with the imidac$^-$ protons; and (iv) comparison with the spectra of structurally analogous 'butterfly' complexes with other chelating ligands [5,6]. Both complexes display five resonances due to the protons of the imidac$^-$ ligand in addition to resonances due to the carboxylate protons.

For complex **1** four resonances due to the methyl protons of the four inequivalent acetate ligands are observed with an approximate intensity ratio of 2:2:2:1, indicating that the peak at 16.9 ppm (C′) can be assigned to the unique acetate bridging the 'body' Mn atoms Mn(1) and Mn(2). The resonance positions and T_1 values of these four resonances are similar to those observed for the pic$^-$ and hqn$^-$ 'butterfly' complexes and are consistent with idealized C_2 point symmetry, implying retention of the solid state structure in solution. A more complex spectrum is evident for **2** due to the presence of four inequivalent benzoate ligands. Assignment of the resonances as due to *ortho*, *meta* or *para* protons may be broadly made on the basis of the relative chemical shifts and T_1 values [14], although it is not possible to ascertain which peaks correspond to the unique benzoate ligand bridging the 'body' Mn atoms. Nevertheless, the pattern of benzoate resonances is again similar to that observed for other benzoate 'butterfly' complexes.

Five resonances of approximately equal intensity are observed for the protons of the imidac$^-$ ligands for both complexes **1** and **2**. For complex **1** the most downfield imidac$^-$ resonance at ca. 26.3 ppm is obscured by a resonance due to the protons of the unique acetate ligand and is only evident in the spectrum of the O_2CMe-d_3 analogue. Addition of a small amount of D_2O to the NMR solutions of **1** and **2** leads to the immediate disappearance of the resonances at -2.5 and -4.3 ppm, respectively. This is attributed to exchange broadening and allows assignment of these resonances to the amine proton of the imidac$^-$ ligand, H_B. Assignment of the remaining resonances relies predominantly on the correlation between the line widths, measured T_1 values and the proton to 'wingtip' metal centre [Mn(3) and Mn(4)] separations derived from the crystal

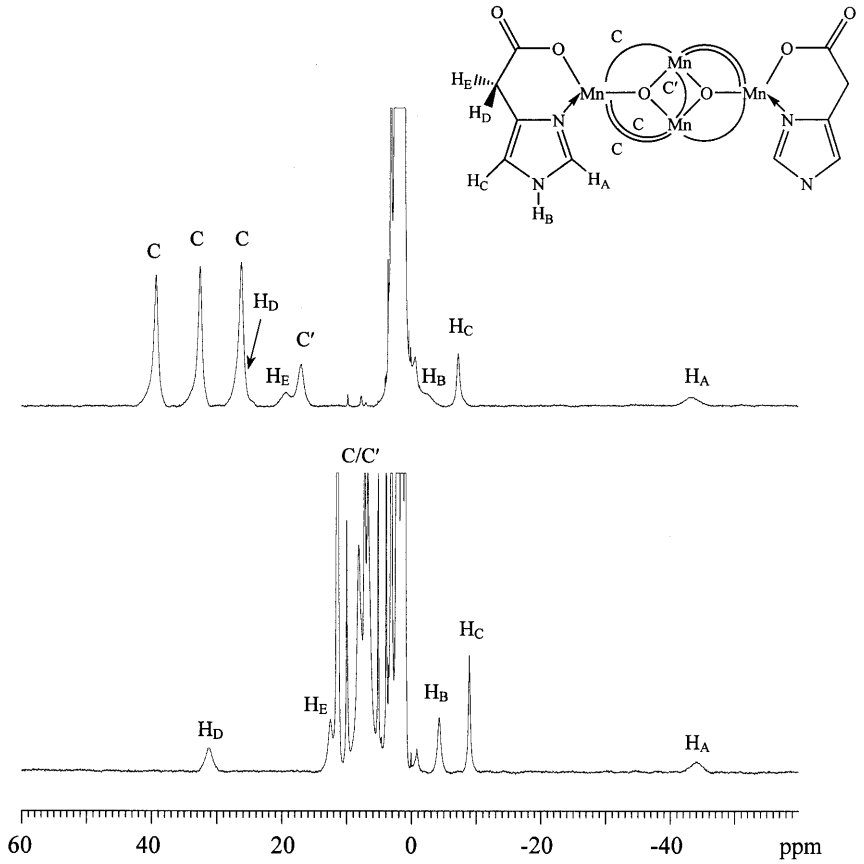

Fig. 2. Proton NMR spectra of complexes **1** (top) and **2** (bottom) in MeCN-d_3. The peaks are labeled according to the scheme shown as an inset. The band of resonances in the -1 to 5 ppm region is from the NBu_4^{n+} protons, residual protio solvent and adventitious water.

structure of **2**. This is on the basis of previous studies that have concluded that the major contibution to the line widths in Mn^{III} complexes is dipolar broadening, which is proportional to r^{-6} [15–18]. The broadest resonance, with the smallest T_1 value, at ca. −40 ppm is assigned to the proton closest to the wingtip Mn atoms, H_A. The significant upfield chemical shift of this resonance is consistent with those observed for the proton at the position adjacent to the Mn-coordinated N atoms in the pic$^-$ and hqn$^-$ 'butterfly' compounds. The sharpest resonance with the largest T_1 value is assigned to the proton most distant from the Mn centre, H_C. Protons H_D and H_E are diastereotopic with H_D significantly closer to the Mn atom (ca. 3.5 versus 4.2 Å), and are assigned accordingly. The marked chemical shift difference between the resonances of these protons indicates the significant contribution of a dipolar mechanism to the observed isotropic shifts. The chemical shifts of resonances H_A, H_B and H_C are relatively consistent between complexes **1** and **2**, with less than 2 ppm difference observed in each case. However, slightly larger chemical shift differences of ca. 5 and 7 ppm are observed for H_D and H_E, respectively. The reason for this is unclear in the absence of a crystal structure of complex **1**.

The ^{1}H NMR spectra of complexes **3** and **4** in MeCN-d_3 are shown in Fig. 3 and the resonance positions are listed in Table 4 using the labeling scheme given in Fig. 3. Assignments were made analogously to those for **1** and **2**. The pattern of resonances due to the carboxylate protons of **3** and **4** are very similar to those observed for **1** and **2**. Three resonances due to the imidcarb$^-$ protons are observed for **4** while only two are evident for **3**. The one missing is that due to H_B, which is presumably because of exchange with adventitious water. The resonances due to H_A and H_C display very similar isotropic shifts to the equivalent resonances in **1** and **2**, while the resonance due to H_B is shifted by ca. 20 ppm, presumably due to exchange effects.

3.4. Electrochemistry

The cyclic voltammograms (CVs) of complexes **1** and **2** (1 mM) have been recorded in MeCN solution (0.1 M $NBu^n_4PF_6$) (Fig. 4). Similar results are observed for both complexes and the CV of **2** is shown in Fig. 3. Both complexes display a quasi-reversible one-electron oxidation at 0.58 and 0.59 V versus ferrocene for **1** and **2**, respectively. The peak separations at a scan rate of 100 mV s^{-1} are 187 and 154 mV, respectively, compared with that for the ferrocene–ferrocenium couple of 116 mV under the same conditions. Plots of i_p versus $v^{1/2}$ are linear in the scan rate (v) range of 10–500 mV s^{-1}, indicating a diffusion-controlled process. Both complexes also display an irreversible oxidation at peak potentials of 1.35 and 1.30 V, respectively at a scan rate of 100 mV s^{-1}. In addition two irreversible reductions are observed at peak potentials of −0.94 and −1.37 for **1** and −0.91 and −1.37 V for **2**.

The quasi-reversible oxidation at 0.59 V for **2** in MeCN is assigned to oxidation to the $Mn^{III}_3Mn^{IV}$ level

as shown in Eq. (2). The oxidation potential can be compared with the

$$[Mn_4O_2(O_2CPh)_7(imidac)_2]^- \overset{0.59\ V}{\rightleftharpoons} [Mn_4O_2(O_2CPh)_7(imidac)_2]^0 \quad (2)$$

value of 0.69 V found for the corresponding couple in $[Mn_4O_2(O_2CPh)_7(pic)_2]^-$ under the same conditions. This is consistent with the greater acidity of picH (pK_a of 5.25 [19]) versus imidacH (pK_a measured as ca. 7.0), as the more electron-donating $imidac^-$ is better able to stabilize higher oxidation states of Mn than pic^-.

Well-defined cyclic voltammograms of complexes **3** and **4** could not be obtained due to their relative insolubility in MeCN in the presence of 0.1 M $NBu^n_4PF_6$ as support electrolyte. However, poorly resolved oxidation processes with peak potentials of ca. 0.60 and 1.2 V and reduction processes at ca. −1.2 and −1.6 V were evident for **4** under these conditions.

The presence of apparently accessible oxidation processes for complexes **1** and **2** suggested the possibility of oxidation of these complexes. Indeed, oxidation of other 'butterfly' complexes has resulted in the formation of new species [20]. An investigation of similar reactivity for **1** and **2** is in progress, with preliminary studies involving electrochemical oxidation of these species resulting in insoluble red–brown solids. Further efforts are required to fully characterize these materials, although their IR spectra do not display bands associated with $NBu^n_4{}^+$, implying that they are uncharged.

4. Conclusions

Tetranuclear Mn clusters possessing imidazole-carboxylate based chelating ligands have been synthesized and found to be essentially isostructural with those possessing pyridine-based chelating ligands. ^{1}H NMR spectroscopy indicates that the species retain their structure in solution and the resonances can be assigned using the methods described in the text. An investigation of the electrochemistry of the species reveals a quasi-reversible oxidation process, similar to those observed for the analogous compounds possessing pyridine-based chelating ligands.

5. Supplementary data

Supplementary structural data for compound **2** have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 141954. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 3 April 2000; accepted 11 July 2000

Abstract

The high-spin cobalt(II) complexes with homoscorpionate hydrotris(3-phenylpyrazolyl)borate (Tp^{Ph}) and heteroscorpionate hydrobis(3-phenylpyrazolyl)(3-*tert*-butylpyrazolyl)borate {$HB(3\text{-}Phpz)_2(3\text{-}t\text{-}Bupz)$} anionic ligands (Tp′) of the general formula Tp′Co(X) were studied. The former tripodal ligand provides intermediate steric hindrance for the central metal ion, which is able to adopt two additional donors from thiocyanate and neutral ligands like pyrazole (pzH) and methanol, or two oxygen donors from the lactate anion. Replacement of one of three 3-phenyl substituents in Tp^{Ph} by the *tert*-butyl one produces a ligand of high steric hindrance which gave tetracoordinate Tp′Co(X) complexes, where X = thiocyanate or monodentate lactate. The complexes were studied by the ^1H NMR spectroscopic method in solution and two of them, $Tp^{Ph}Co(NCS)(pzH)$ and $[HB(3\text{-}Phpz)_2(3\text{-}t\text{-}Bupz)]Co(NCS)$, were characterized structurally by X-ray crystallography. © 2000 Elsevier Science B.V. Keywords: Heteroscorpionate tris(3-*R*-pyrazolyl)borate cobalt(II) complexes; Structures; NMR

1. Introduction

Since Trofimenko's first report on the synthesis of transition metal ion complexes of tris(pyrazolyl)borate anions (Tp), they have been widely used as convenient tripodal ligands mimicking the three nitrogen donor arrangment of histidine residues in metalloenzymes [1,2]. However, in metalloenzymes the *cis*- arranged nitrogen donors are chemically different and thus form the chiral surrounding of the metal centre. Until now homoscorpionate Tp′ ligands were studied almost exclusively containing all the pyrazole residues (pz) modified by introducing variable size substituents into the 3, 4, and/or 5 position of pz [2a,3–13]. The syntheses of the first heteroscorpionate Tp′ ligand and its thallium(I) complex were briefly reported quite recently by Parkin [14]. The synthesis of chiral tris(pyrazolyl)borate anionic ligands, with three different pyrazoles remains a long-standing challenge. The promising catalytic properties of transitions metal ion complexes with homoscorpionate ligands prompted us to study mixed-pyrazole Tp′ ligands with variable steric hindrance placed at the 3- and 5-position of pyrazole to finally construct chiral Tp′ ligands with desirable steric and electronic anisotropy. Its complexes are expected to induce asymmetry in some catalytic reactions. The reported precedence is the successful attempt of enantioselective cyclopropanation of styrene by ethyldiazoacetate, catalyzed by the $Tp^{pm}Cu(I)$ complex, containing chiral substituents fused with 3,4-pz positions [15]. On our way to a chiral Tp′ ligand we have chosen 3-phenylpyrazole as a relatively chemically inert intermediate sterically hindered structural element and prepared mixed-pyrazole Tp′ ligands with 3-*tert*-butylpyrazole and 3,5-di-*tert*-butylpyrazole. Here we present the structural studies on high-spin Tp′Co(X)

complexes (where $X = [NCS]^-$ and lactate $[OOC\text{-}CH(OH)CH_3]^-$) by single-crystal X-ray crystallography and ^1H NMR spectroscopy (in solution).

2. Experimental

2.1. Methods

^1H NMR spectra were obtained with a Bruker AMX300 spectrometer operating in the quadrature mode at 300 MHz. The residual peaks of deuterated solvents were used as internal standards. The magnetic moments of complexes were measured in solution according to the modified Evan's method [16]. The FTIR spectra were recorded on a Perkin–Elmer 1725X instrument. The UV–Vis experiments were performed using a HP 8453 diode-array and a Beckman DU 640 spectrophotometer. Mass spectra were obtained using a Finnigan MAT TSQ 700 spectrometer by the ESI method at 4.5 kV ionization potential and 250°C capillary temperature in acetonitrile and tetrahydrofuran solvents. Crystal data were collected for **1** and **3·pzH** on a Kuma KM4CCD area detector single-crystal X-ray diffractometer with ω scans. Data reduction and structure solutions were carried out with KM4CCD and SHELXS-97 software packages, respectively. Least-square refinements were performed with SHELXL-97. The crystal data of both crystals are given in Table 1, together with refinement details.

2.2. Synthesis of Tp′ ligands and Tp′Co(NCS) complexes

2.2.1. General procedure

All potassium salts of homo- and heteroscorpionate Tp′ ligands were prepared by condensation of KBH_4 with melted pyrazoles and the progress of the reaction was controlled by measurement of hydrogen gas evolved. The KTp′ salts were purified by washing out the excess pyrazoles with appropriate solvents and drying in high vacuum. In case of mixed-pyrazole salts, the stepwise condensation method was applied, the ligands were converted straightforwardly into Tp′Co(NCS) salts by dropwise addition of a tetrahydrofuran (THF) solution of KTp′ into the vigorously stirred aqueous solution of 0.1 M cobalt(II) thiocyanate and 1.0 M potassium thiocyanate. The blue solid complexes were extracted with methylene dichloride solvent, the organic layer was washed twice with water, the solvent was removed on a rotary evaporator and the solid residue was recrystallized from a THF–hexane mixture to give the crystalline material. Details on synthesis and isolation procedures are given below. Potassium hydrotris(3-phenylpyrazolyl)borate (KTp^{Ph}) was prepared by a known method [3] on a scale of 0.01 mol. The $Tp^{Ph}Co(NCS)$ complex was prepared according to the general procedure.

2.2.2. Thiocyanato[hydrobis(3-phenylpyrazolyl)-(3-tert-butylpyrazolyl)borato]cobalt(II) (1)

Potassium hydrobis(3-phenylpyrazolyl)(3-*tert*-butylpyrazolyl)borate $K[HB(3\text{-}Phpz)_2(3\text{-}t\text{-}Bupz)]$ was synthesized by the two-step condensation of 0.908 g KBH_4 (0.015 mol) with 4.32 g 3(5)-*tert*-butylpyrazole (0.03 mol) and 2.79 g 3(5)-phenylpyrazole (0.0255 mol). The excess of pyrazoles was washed out with 150 cm^3 hot hexane and 50 cm^3 pentane. 3.8 g of HTp′ salts were isolated (55% yield). The mixture of Tp′Co(NCS) complexes was obtained by addition of 0.5 g of KTp′ salts in 15 cm^3 THF into a 100 cm^3 stock solution of cobalt(II) thiocyanate. The Tp′Co(NCS) products were

isolated by a general procedure. The [HB(3-Phpz)$_2$(3-*t*-Bupz)]Co(NCS) (**1**) and [HB(3-*t*-Bupz)$_2$(3-Phpz)]Co(NCS) (**2**) complexes were separated from [HB(3-Phpz)$_3$]Co(NCS) (**3**) by repeatable crystallization from a THF–hexane mixture; the first crop gave pure crystals of violet blue **3**·(THF) [3], whereas the second crop of collected blue crystals contained **1** and **2**. The complexes **1** and **2** were separated by selectively dissolving **2** in methanol. The yields were: 51.86% **1** (1.21 g), 19.50% **3** (0.472 g), 3.25% **2**; total yield 74.6%. Using both procedures we were able to get pure blue crystals of **1**, which were grown from THF–hexane and subsequently subjected to X-ray analysis.

Elemental analysis calculated for $C_{26}H_{26}N_7BSCo$ (M.W. 538.34) C, 58.00; H, 4.87; N, 18.21. Found: C, 58.32; H, 5.01; N, 18.32%. Mass spectrum (ESI) *m*/*e*: [**1** + H$^+$] 539 (44%); [**1**–NCS]$^+$ 480 (100%). IR (KBr): $\nu_{(NCS)}$ 2065; $\nu_{(BH)}$ 2495 cm^{-1}. UV–Vis: λ [nm] (ε [mol^{-1} dm^3 cm^{-1}]): 337 (3.26×10^3), 641 (1.01×10^3). Magnetic moment (Evans's method) $\mu = 4.40$ B.M. (in $CDCl_3$ at 296 K). ^{1}H NMR ($CDCl_3$, 293 K): δ [ppm] (intensity, assignment): −6.90 (1H, B–H); 3.02 (9H, $C(CH_3)_3$); 8.98 (4H, *m*-H(3-Phpz)); 9.69 (2H, *p*-H(3-Phpz)); 19.10 (4H, *o*-H(3-Phpz)); 36.52 (2H, 5-H(3-Phpz)); 45.32 (1H, 5-H(3-*t*-Bupz)); 70.13 (2H, 4-H(3-Phpz)); 77.61 (1H, 4-H(3-*t*-Bupz)).

2.2.3. Thiocyanato[hydrobis(3-tert-butylpyrazolyl)-(3-phenylpyrazolyl)borato]cobalt(II) (2)

Potassium hydrobis(3-*tert*-butylpyrazolyl)(3-phenylpyrazolyl)borate K[HB(3-*t*-Bupz)$_2$ (3-Phpz)] was synthesized by similar procedure as above. The optimized conditions to obtain the desired Tp′ ligand required 0.6 equivalents of 3-phenylpyrazole and 2.5 equivalents of 3-*tert*-butylpyrazole. The isolated Tp′Co(NCS) complexes yielded 70% of Tp-*t*-BuCo(NCS) (**4**) and 30% of **2**.

^{1}H NMR ($CDCl_3$, 293 K) δ [ppm] (intensity, assignment): −7.00 (1H, B–H), 4.10 (18H, $C(CH_3)_3$), 9.01 (2H, *m*-H(3-Phpz)), 10.44 (1H, *p*-H(3-Phpz)), 21.60 (2H, *o*-H(3-Phpz)), 31.47 (1H, 5-H(3-Phpz)), 42.01 (2H, 5-H(3-*t*-Bupz)), 67.71 (1H, 4-H(3-Phpz)), 76.35 (2H, 4-H(3-*t*-Bupz)).

2.2.4. Thiocyanato[hydrotris(3-phenylpyrazolyl)borato]-cobalt(II) pyrazole (3·pzH)

This complex was obtained as a side-product during the synthesis of the mixed-pyrazole heteroscorpionate Tp′ ligand containing 3-phenylpyrazole and pyrazole according to general procedure. Pure crystals of **3** were grown from THF–hexane solvents, containing pyrazole. The results on cobalt(II) and thallium(I) complexes of [hydrobis(3-phenylpyrazolyl)(pyrazolyl)]$^-$ ligand will be presented separately.

Elemental analysis calculated for $C_{31}H_{26}N_9BSCo$ (M.W. 626.42): C, 59.44; H, 4.18; N, 20.12. Found: C, 59.39; H, 4.01; N, 20.20%. IR (KBr): $\nu_{(NCS)}$ 2077; $\nu_{(BH)}$ 2502 cm^{-1}. UV–Vis λ [nm] (ε [mol^{-1} dm^3 cm^{-1}]): 640 ($7.89 \cdot 10^2$) for **3**.

2.2.5. [Hydrotris(3-phenylpyrazolyl)borato]-cobalt(II)lactate (5)

The complex was obtained on a 0.005 mol scale according to the general procedure modified by the use of 0.1 M cobalt(II) lactate and 0.5 M sodium lactate instead of the thiocyanate salts as for **3**.

Elemental analysis calculated for $C_{29}H_{27}N_6O_3BCo$ (M.W. 577.32) C, 60.33; H, 4.71; N, 14.56. Found: C, 60.22; H, 4.60; N, 14.42%. ^{1}H NMR (in $CDCl_3$) δ [ppm] (intensity, assignment): −51.67 (6H, *o*-H(3-Phpz)), 2.94 (6H, *m*-H(3-Phpz)), 4.50 (3H, *p*-H(3-Phpz)), 51.07 (3H, CH_3(lactate)), 52.78 (3H, 4-H(3-Phpz)), 62.70 (3H, 5-H(3-Phpz)), 77.02 (1H, CH(lactate)), 90.76 (1H, B–H).

3. Results and discussion

3.1. Synthetic procedures

The synthesis of mixed-pyrazole Tp′ anionic ligands (heteroscorpionates) requires condensation of borohydride with an optimized equivalent number of substituted pyrazoles. The reaction can be performed in one step using appropriate amounts of pyrazole equivalents or in multistep approach used here. The reaction in melted mixtures is controlled by measurements of hydrogen gas evolved. The temperature of every step of stepwise condensation depends on: (i) number of the step; (ii) the steric and electronic properties of the R substituent at the 3, 4, and/or 5 position of the pyrazole used in the condensation; and (iii) the chemical structure of the $[(R\text{–}pz)_nBH_{(4-n)}]^-$ anion used in a given step of the reaction.

$$[BH_4]^- + (R_1\text{–}pzH) \rightarrow [(R_1\text{–}pz)BH_3]^- + H_2 \quad (1)$$

$$[(R_1\text{–}pz)BH_3]^- + (R_2\text{–}pzH) \rightarrow [(R_1\text{–}pz)(R_2\text{–}pz)BH_2]^- + H_2 \quad (2)$$

$$[(R_1\text{–}pz)(R_2\text{–}pz)BH_2]^- + (R_3\text{–}pzH) \rightarrow [(R_1\text{–}pz)(R_2\text{–}pz)(R_3\text{–}pz)BH]^- + H_2 \quad (3)$$

Thus, the optimization of synthesis of $[(R_1\text{–}pz)(R_2\text{–}pz)(R_3\text{–}pz)BH]^-$ chiral ligand requires many attempts to be done in order to drive the reaction towards the desired product with reasonable yield. We have undertaken the systematic studies on the synthesis of mixed-pyrazole Tp′ ligands. As a fixed structural element of these ligands we have chosen 3-phenylpyrazole, the substituent is of intermediate steric hindrance

and is relatively chemically inert in comparison with 3-isopropylpyrazole with similar steric hindrance [2a]. In order to construct the Tp′ ligand of rather high steric demands we have introduced the *tert*-butyl-substituents into the 3- and 5- positions of the third pyrazole instead of the 3-phenyl and synthesized the mixed-pyrazole Tp′ ligand and its high-spin Tp′Co(NCS) complexes. Obviously, the sequence (1–3) of condensations resulted in the formation of a statistic mixture of Tp′ ligands, whenever two or more R–pzH were used. These were converted into Tp′Co(NCS) complexes and separated as such. This approach allowed us first to identify the Tp′ products formed in synthetic step by ^{1}H NMR spectral measurements of paramagnetic Tp′Co(NCS) complexes, and second to isolate and characterize structurally individual Tp′Co(NCS) species. Gathering those data are necessary steps to design and synthesize a chiral Tp′ ligand. Thus, we have found that introducing two pyrazoles of intermediate steric hindrance (3-phenylpyrazole) and only one pyrazole with large steric demands (3-*tert*-butylpyrazole) produced the Tp′ ligand of high steric demands (vide infra). The synthetic route optimized for **1** required the 1:2:1.7 KBH_4:3-*tert*-butylpyrazole:3-phenylpyrazole ratio in stepwise condensation leading to 69.5:4.4:26.1% **1**:**2**:**3** distribution of products. At the second step of the synthetic route the 3-phenylpyrazole condensed with both $[H_3B(3\text{-}t\text{-Bupz})]^-$ and the substituted 3-*t*-Bupz in $[H_2B(3\text{-}t\text{-Bupz})_2]^-$ formed in the first step. The latter reaction was also observed to occur between $K[H_2B(3\text{-}t\text{-Bupz})_2]$, $K[HB(3\text{-}t\text{-Bupz})_3]$ and ten equivalents of 3-phenylpyrazole in toluene-d_9 in an NMR tube at 393 K within a 3 h time interval under ^{1}H NMR spectral examination. The synthetic procedure in dimethylacetamide did not give any superior control over the stoichiometry of the synthesis and the number of side-products was greater than in the case of the reaction between substituted pyrazoles and KBH_4 in the melt. On the other hand, the optimized synthetic route for **2** required a 1:2.5:0.6 KBH_4:3-*tert*-butylpyrazole:3-phenylpyrazole stoichiometry to avoid the formation of **1**, which otherwise could not be easily separated from **2**. Still, separation of **2** from the homoscorpionate complex **4** was not achieved. For our purposes, however, only the ^{1}H NMR spectral identification of **2** was necessary.

3.2. X-ray crystallographic studies of Tp′Co(NCS) complexes

The molecular crystals of **1** and **3·pzH** were grown from the same THF–hexane mixture of solvents. The molecular structure of complexes **1** and **3·pzH** are presented as ORTEP diagrams at Figs. 1 and 2. The geometry around the cobalt(II) ion in **1** is trigonally-elongated tetrahedral, with Co–N(pz) bond lengths of 2.023(5) Å, and a N-bonded thiocyanate inside a hydrophobic pocket formed by two 3-phenyl substituents. The phenyl substituent planes are twisted about 24.9° in relation to the pyrazole planes (Fig. 1). There is a plane of symmetry passing through the central metal ion, boron atom and 3-*tert*-butylpyrazole moiety. The crys-

tal structure of **1** showed no additional ligands present in the coordination sphere, unlike **3**·THF [3] or **3**·**pzH** (Fig. 2). For comparison the geometry around the cobalt(II) ion in **3**·**pzH** is trigonal bipyramidal with additional nitrogen-coordinated pyrazole. All the Co–N bond distances are considerably larger than those in **1**, different for all the pz(Tp^{Ph}) and very close to those found in **3**·THF. The hydrophobic pocket formed by the 3-phenyl substituents is enlarged if compare with that in **1** by an increase in the twist of the Ph/pz planes up to 33–38°.

3.3. Reactivity of complexes

The ^{1}H NMR spectroscopy for high-spin cobalt(II) complexes was proven to be very useful method for elucidation of the structure of Tp′Co(X) complexes [5,7,8,10–13]. We have applied this method to study the series of title complexes and products of their chemical conversion. The ^{1}H NMR spectrum of tetracoordinate **3** in $CDCl_3$ is presented in Fig. 3(A). For this and other tetracoordinate complexes studied till now the B–H resonance is shifted upfield to about −5.0 ppm, and the *o*-H (from the phenyl substituent of 3-phenylpyrazole) resonance is shifted downfield to 17.5 ppm. When **3** in $CDCl_3$ is titrated with CD_3OD, the B–H and *o*-H resonances shift dramatically to 80.7 and −48.2 ppm, respectively. Obviously, the new species **3**·$\mathbf{CD_3OD}$ is formed (Fig. 3(B)). For the unambiguous assignment of 5-H and 4-H resonances both in tetra- and pentacoordinate Tp′Co(XY) complexes we have compared the ^{1}H NMR spectra in a $CDCl_3$–CD_3OD mixed-solvent system for complexes **3** (i.e. Tp^{Ph}Co(NCS)) and $Tp^{Ph,Me}$Co(NCS). The 4-H resonance shifted upfield upon increase of methanol-d_4 concentration in both species, whereas the 5-H in **3** shifted downfield. Consequently, the 5-H and 4-H resonances for **3** in $CDCl_3$ were observed at 40.7 and 71.0 ppm, respectively. In the case the complex **3**·$\mathbf{CD_3OD}$ in CD_3OD they shifted into 65.1 and 53.7 ppm, respectively. A similar spectrum was produced by Tp^{Ph}Co[OOCCH(OH)CH_3] (**5**) in $CDCl_3$ (Fig. 3(C)). We were able to produce **5** in situ by addition of solid sodium lactate into **3** in $CDCl_3$. The ^{1}H NMR spectrum of the pure heteroleptic complex Tp^{Ph}CoTp has been obtained by addition of one equivalent of KTp (in CD_3OD) into the **3**·$\mathbf{CD_3OD}$ (Fig. 3(D)).

The ^{1}H NMR spectrum of the high-spin Co(II) complex **1** in $CDCl_3$, (Fig. 4(A)) consists of two 4-H resonances at 70.1 and 77.6 ppm, two 5-H resonances at 36.5 and 45.3 ppm with an integral intensity ratio of 2:1, respectively, the broad resonance of *o*-H(3-Phpz) at

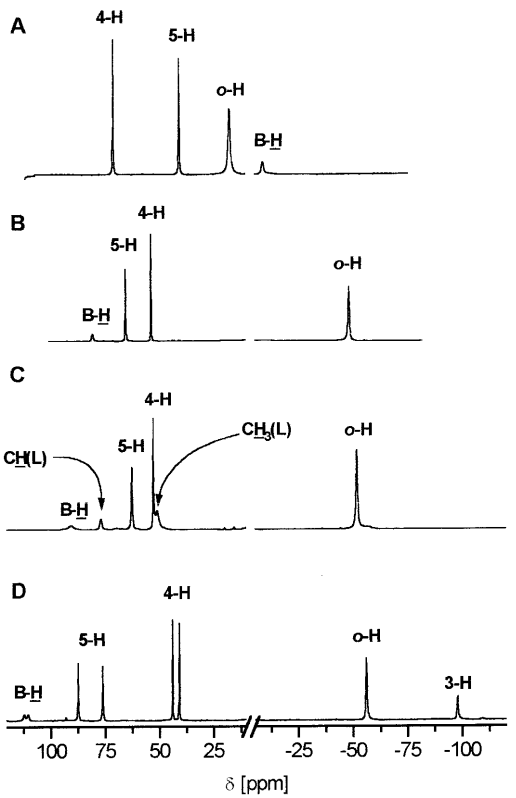

Fig. 3. The ^{1}H NMR spectra of: (A) Tp^{Ph}Co(NCS) in $CDCl_3$; (B) Tp^{Ph}Co(NCS)(CD_3OD) in CD_3OD; (C) Tp^{Ph}Co(OOCCH(OH)CH_3) in $CDCl_3$; (D) Tp^{Ph}CoTp in CD_3OD at 295 K. The 10–0 ppm region of the spectra in this and subsequent figures, containing high intensity, narrow resonances of *m*- and *p*-H (Ph) has been omitted for clarity.

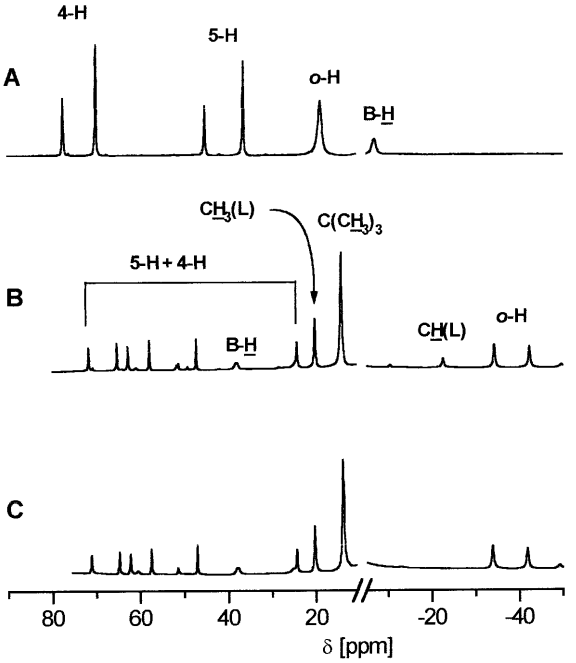

Fig. 4. The ^{1}H NMR spectra of: (A) [HB(3-Phpz)$_2$(3-*t*-Bupz)]Co(NCS) (**1**) in $CDCl_3$; (B) [HB(3-Phpz)$_2$(3-*t*-Bupz)]Co(OOCCH(OH)CH_3) in CD_3OD generated in situ by addition of ten equivalents of sodium lactate dissolved in CD_3OD into **1** dissolved in $CDCl_3$; (C) the spectrum was taken 24 h later from the same solution as B.

19.1 ppm and the broad signal of B–H at −6.9 ppm. The position of the latter is characteristic for tetracoordinate Tp′Co(II)(X) complexes (for comparison see Fig. 3(A and B)). Albeit the cobalt(II) metal centre in **1** is not able to adopt an additional ligand like THF or pzH, methanol does coordinate to the metal ion in **1**; the ^{1}H NMR spectrum of the adduct being complicated, revealing the presence of at least three species of different concentration.

The complexes **1**, **2**, and **3** could not be separated chromatographically in aerobic conditions; our attempts to isolate them on silica gel (even in the presence of [Bu_4N][SCN]) with 5% methylene dichloride in hexane as eluent), led to oxidation of Co(II) to Co(III) in **1** with putative oxidation of the Tp′ ligand, already reported for $(Tp^{iPr})_2M$ complexes (M = Mn(II), Co(II)) [17–19]. Still **3** remained intact under these conditions.

Further comparison of the reactivity of **1** and **3** was achieved at the level of metathesis reactions. The exchange of the thiocyanate anion by Tp or lactate was monitored by means of ^{1}H NMR spectroscopy. We have found that in both cases (**1** and **3**) the quantitative conversion of thiocyanate starting complexes into lactate counterparts occurred. The conversion of **1** into [HB(3-*t*-Bupz)(3-Phpz)$_2$]Co[OOCCH(OH)CH_3] (**6**) (Fig. 4(B)) was achieved by stepwise addition of ten equivalents of sodium lactate stock solution to the NMR tube containing partially dissolved **1** in methanol-d_4. The product **6** dissolves easily in methanol. It was also proven to be a high-spin cobalt(II) complex with 3.90 B.M. magnetic moment measured by Evan's method at 293 K in $CDCl_3$. A characteristic feature of the spectrum of **6** is the presence of two *o*-H(Phpz) resonances separated by 9 ppm (−42.3 and −33.3 ppm) indicating that the [HB(3-*t*-Bupz)(3-Phpz)$_2$] ligand is a very sensitive diastereotopic probe of second face chirality of the cobalt(II) complex brought up by attachment of the chiral auxiliary ligand. Variable-temperature ^{1}H NMR experiments have shown that fluxional behavior in both **5** and **6** is similar. The coalescence point was 230 K in both studied complexes, which gave a value of $\Delta G^{\neq} = 36$ kJ mol^{-1}. Below that temperature the 4-H, 5-H, and *o*-H(Phpz) resonances of **5** split into three sets, while only two sets of resonances of the 95:5 integral intensity ratio (based on *o*-H(Phpz) resonances) are produced in case of **6,** indicating the presence of two rotational isomers around Co–OOC(lactate) at 200 K in methanol-d_4. Another interesting feature of **6** was observed during ^{1}H NMR spectral studies; the lactate C–H resonance at −22.6 ppm decreased its intensity over time and eventually disappeared completely (for comparison see traces B and C in Fig. 4). The selective deuteration of lactate is not surprising in view of the known C–H bond activation properties by Tp′Co(II) and Tp′Rh(I) complexes [17–20] and will deserve further study. The coordination mode of lactate in **6** differs from that in **5**. Most probably the hydroxyl oxygen is coordinated to the metal ion in **5**, giving rise to a substantial downfield shift (76.7 ppm) of the C–H (lactate) resonance (Fig. 3C), whereas large steric hindrance introduced by the *tert*-butyl substituent in **6** hampers this kind of interaction, leading to an upfield shift of the corresponding C–H resonance to −22.6 ppm (Fig. 4(B)). The attempts to isolate **5** in crystalline form suitable for X-ray crystallographic studies failed due to decomposition of **5** into the known (κ^3-Tp^{Ph})Co(κ^2-Tp^{Ph}) [21] complex and cobalt(II) lactate. We were unable to grow crystals of **6**.

Yet another reactivity difference between **1** and **3** was observed by the ^{1}H NMR technique; **1** underwent slow reaction with chloroform-*d* to produce [HB(3-*t*-Bupz)(3-Phpz)$_2$]CoCl at room temperature within several hours, whereas **3** showed no trace of conversion into the chloride form. The replacement of thiocyanate by Tp was monitored spectrally by titration of **1** with KTp in methanol-d_4. In the case of **1** (dissolved in chloroform-*d*) titrated with a methanolic-d_4 solution of KTp no formation of the stable heteroleptic bis-tris(pyrazolyl)borate complex was found and eventually upon addition of one equivalent of KTp all the starting material disappeared. Finally, Tp_2Co and diamagnetic product from the conversion of **1** were found. This again indicates that in aerobic conditions **1** can be readily converted into its oxidized form.

4. Conclusions

The comparison of steric hindrance imposed by 3-R substituents on pyrazole in hydrotris(3-phenylpyrazolyl)borate (Tp^{Ph}) and heteroscorpionate hydrobis(3-phenylpyrazolyl)(3-*tert*-butylpyrazolyl)borate anionic ligands in their high-spin cobalt(II) complexes of the general formula Tp′Co(X,Y) have shown that in the case of the former ligand the pentacoordinate complexes with X = $[NCS]^-$, Y = pyrazole (pzH); X = $[NCS]^-$, Y = methanol; and XY = lactate (with carboxylic and hydroxyl oxygen donors) as well as heteroleptic hexacoordinate (κ^3-Tp^{Ph})Co(κ^3-Tp) (where Tp = trispyrazolylborate anion) form readily, whereas the steric hindrance from only one 3-*tert*-butyl substituent instead of the 3-phenyl one hampers the coordination of any additional ligand to form a stable complex with a cobalt(II) coordination number higher than 4.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic

Data Centre, CCDC Nos. 138237 for compound **1** and 138236 for **3·pzH**. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

POLYHEDRON

A new simple synthetic route to M_3Se_7 (M = Mo or W) core containing complexes: crystal structure and characterisation of $[M_3(\mu_3\text{-}Se)(\mu\text{-}Se_2)_3(dtc)_3]_2Se$

Abstract

The reaction of $M(CO)_6$, (M = Cr, Mo or W), with elemental Se and $(Et_2NCS_2)_2$ in refluxing 1,2-dichlorobenzene has been studied. For M = Mo the previously unknown compound $[Mo_3(\mu_3\text{-}Se)(\mu\text{-}Se_2)_3(dtc)_3]_2Se$ (**1**) (dtc = Et_2NCS_2) was obtained. A single crystal X-ray crystallographic study shows that **1** contains two $[Mo_3(\mu_3\text{-}Se)(\mu\text{-}Se_2)_3(dtc)_3]$ subunits joined by a bridging selenium atom which is coordinated to the three axial Se atoms of the three Se_2 moieties in each subunit. The results of vibrational spectroscopic and mass spectrometric studies back up this crystallographic investigation. Similar reactions where $Cr(CO)_6$ or $W(CO)_6$ replace $Mo(CO)_6$ in the reaction mixture give, with $Cr(CO)_6$, the well-known complex $[Cr(dtc)_3]$ or, with $W(CO)_6$, a mixture of products including **2** which is the tungsten analogue of **1**. © 2000 Elsevier Science B.V. Keywords: Crystallographic; Selenium; Tungsten analogue; Refluxing

1. Introduction

Studies of compounds containing a core consisting of a Group 6 metal, particularly molybdenum, and sulfur have been stimulated by the search for model compounds that may be used to provide an understanding of functioning of iron- and molybdenum-containing nitrogen-fixing enzymes. A large variety of metal–sulfur cores have been identified a number of which are bonded to the dithiocarbamate ligand $[R_2NCS_2]^-$ (dtc) [1–3]. In many such studies it is found that the central metal sulfide core is in the form of the triangular $[M_3S(S_2)_3]^+$ ion. This core generally exists as a single structural unit in a monomeric species e.g. in $[Mo_3S_7(dtc)_3]Cl$ [4] or $[Mo_3S_7(dtc)_3]X$ (X = I or Br) [5].

The majority of the work in this area has been carried out on metal sulfide species. Reports of analogous selenides are rare although the monomeric species $[M_3Se_7(dtc)_4]$ (M = Mo or W) [6] has been prepared. It is also possible that two structural units may be linked together via a central chalcogen atom. Such coordination has been seen in the dimer $[Mo_3S_7(dtc)_3]_2S$ [7]. This interesting species is formed from $(NEt_4)[Mo_3S_7Br_6]$ as a starting material; this is reacted with the bidentate hydroxyquinoline ligands which are then displaced by diethyldithiocarbamate in slight excess. It is presumed that the additional S^{2-} anion is formed by hydrolysis of some of the tetraethylthiuram disulfide. A single crystal X-ray diffraction study of $[Mo_3S_7(dtc)_3]_2$ S (**4**) demonstrates that the S atom between the two clusters is coordinated to six sulfur atoms in total i.e. the three axial sulfur atoms of the three S_2 units in each Mo_3S_7 subunit. The formation of a complex $[Mo_3S(SSe)_3(dtc)_3]SeCN$ has also been reported [8]. In some aspects this complex shows a structural similarity to $[Mo_3S_7(dtc)_3]_2S$ in that the selenium atom of the $SeCN^-$ counter ion is coordinated to sulfur and selenium atoms of the SSe units in the $[Mo_3S(SSe)_3]$ core.

In the current work we report the synthesis and crystallographic and spectroscopic characterisation of the hitherto unknown selenium analogue of **4** i.e. $[Mo_3Se_7(dtc)_3]_2Se$ (**1**). One of the features of this work is the relatively high yield obtained simply by heating a

PII: S0277-5387(00)00515-5

mixture of $Mo(CO)_6$, solid elemental selenium and $(Et_2NCS_2)_2$ in refluxing 1,2-dichlorobenzene. We also report the synthesis (albeit in lower yield) and structural characterisation of the tungsten analogue of **1** i.e. $[W_3Se_7(dtc)_3]_2Se$ **2**. These preparations contrast with chemistry carried out in this laboratory where mixtures of binary carbonyls and elemental selenium are heated under reflux in the absence of any coordinating ligand. In these cases no crystalline products are seen [9,10]. Here the products are the new selenium-rich selenides $CrSe_3$ (from $Cr(CO)_6$) and $MoSe_{\sim 5}$ (from $Mo(CO)_6$) [9]. Although **1** has not previously been observed there are precedents for compounds where $[Mo_3Se_7]^{4+}$ building blocks are linked together via coordinating selenium atoms e.g. in the anions $[Mo_9Se_{40}]^{8-}$ [11] and $[Mo_{12}Se_{56}]^{12-}$ [12] which have been synthesised by hydrothermal methods.

An impetus is given to our research from the recent use of dithiocarbamate complexes as precursors to thin layers of transition metal compounds by Low Pressure Chemical Vapour Deposition processes [13]. Specific examples include the growth of layers of PbS [13,14], CdS [13] and ZnS [15]. Layers of In_2Se_3 have also been generated from the selenocarbamate [In($Se_2CN(CH_3)$*n*-hexyl)] [16]. We anticipate that complexes containing a metal–chalcogenide core surrounded by dithiocarbamate ligands might have sufficient volatility to be used as precursors in Low Pressure Chemical Vapour Deposition and that such compounds might yield layers of unusual composition [17]. The preparation of **1** and **2** by a straightforward synthetic route is thus of some interest in the context of the preparation by CVD growth of metal chalcogenides.

2. Experimental

Infrared spectra were recorded on a Perkin–Elmer FTIR spectrometer (1720-X) with a resolution of ± 1 cm^{-1}. Raman spectra were recorded on a Perkin–Elmer 1700X FT spectrometer, with NIR excitation at 1032 nm and with a typical resolution of ± 1 cm^{-1}. Elemental analysis was performed by Medac Ltd. at Brunel Science Centre, University of Surrey. FAB mass spectrometry was performed by the EPSRC National Mass Spectrometry Centre, University of Swansea.

Crystal data for **1** and **2** are given in Table 1, together with refinement details. Data were collected with Mo Kα radiation using the MARresearch Image Plate System. The crystals were positioned at 70 mm from the Image Plate. 95 frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [18]. The structures were solved using direct methods with the SHELX86 program [19]. In **1**, Mo, Se and S were refined anisotropically and in **2**, W and Se were refined anisotropically with the remaining atoms isotropic. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. The structures were then refined using SHELXL [20]. Empirical absorption corrections were carried out using the difabs program [21]. All calculations were carried out on a Silicon Graphics R4000 Workstation.

3. Preparations

All reactions were carried out under a nitrogen atmosphere. All reagents were purchased from Aldrich and used as supplied.

3.1. $[Mo_3(\mu_3Se)(\mu Se_2)_3(dtc)_3]_2Se$ (1)

1.00 g (3.79 mmol) $Mo(CO)_6$, 1.2 g (15.20 mmol) Se, 1.1 g (3.71 mmol) $(Et_2NCS_2)_2$ were heated under reflux in 50 cm^3 1,2-dichlorobenzene for 1.5 h. The reaction mixture was allowed to cool overnight and filtered under suction to remove unreacted Se. The solution was treated with petroleum ether (100–120°C) producing a heavy orange precipitate (1.36 g) which was filtered under suction and washed with petroleum ether (40–60°C) and allowed to dry in air. The product was recrystallised from dimethylformamide. Red/orange crystals of $[Mo_3(\mu_3Se)(\mu Se_2)_3(dtc)_3]_2Se$ (**2**) were obtained. The mass of the recrystallised product was 0.71 g (52.3% yield).

4. Results and discussion

4.1. Characterisation of 1

The structure of **1** is shown in Figs. 1 and 2; it is isostructural with **4** [7] and consists of two $[Mo_3Se(Se_2)_3(dtc)_3]$ subunits which are linked via a bridging selenium atom Se(10) over a crystallographic twofold axis. The subunit is shown in Fig. 2 with the atomic numbering scheme. The dimensions of the $[Mo_3Se(Se_2)_3(dtc)_3]$ subunit are compared to those found in **4** in Table 2. Allowing for the replacement of sulfur by the larger selenium, it is clear that the main characteristics of the subunit are maintained. The three molybdenum atoms form a triangle and pairs are bridged by three independent μ^2, Se_2 moieties. Distances of the selenium atoms from the plane are highly asymmetric (Se (41) 1.77, Se (42) –0.36, Se (51) 1.81, Se (52) –0.32, Se (61) 1.84, Se (62) –0.22 Å). Clearly the asymmetry is caused by the strongly-bound Se (11) which bridges all three molybdenum atoms with a mean Mo–Se (11) distance of 2.485 Å compared to 2.381 Å for the analogous Mo–S bonds. This capping atom Se (11), unlike Se (10) on the other side of the anion, is bound to the three molybdenum atoms and steric constraints open up the Se_3 face for its inclusion. This capping also leads to a lengthening of the three Mo–Se (n2) ($n = 4, 5, 6$) bonds closest to the bridging Se (11), defined as equatorial, and these are longer (mean 2.612 Å), than the other three Mo–Se(n1) ($n = 4, 5, 6$) defined as axial (mean 2.544 Å) which form the cavity around

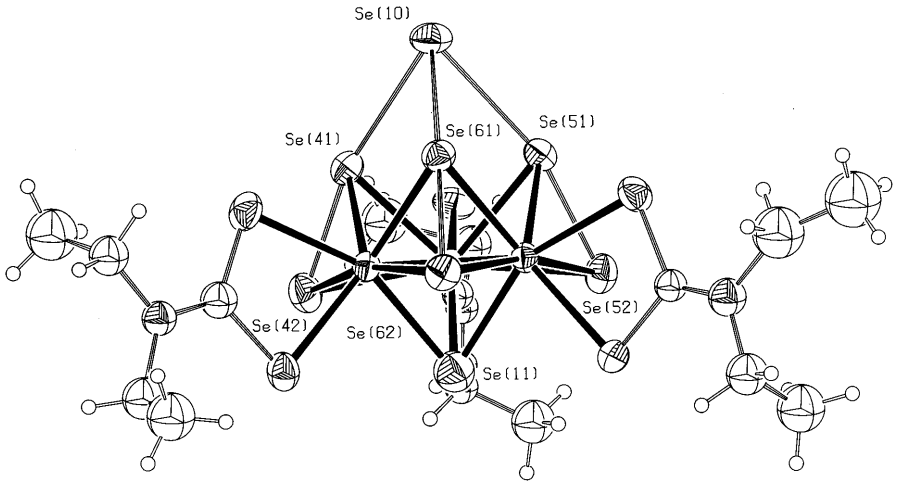

Fig. 1. The structure of the $[Mo_3Se(Se_2)_3(dtc)_3]_2Se$ dimer. Ellipsoids shown at 30% probability. Se(10) is the bridging atom and Se(11) the atom that caps the Se3 face.

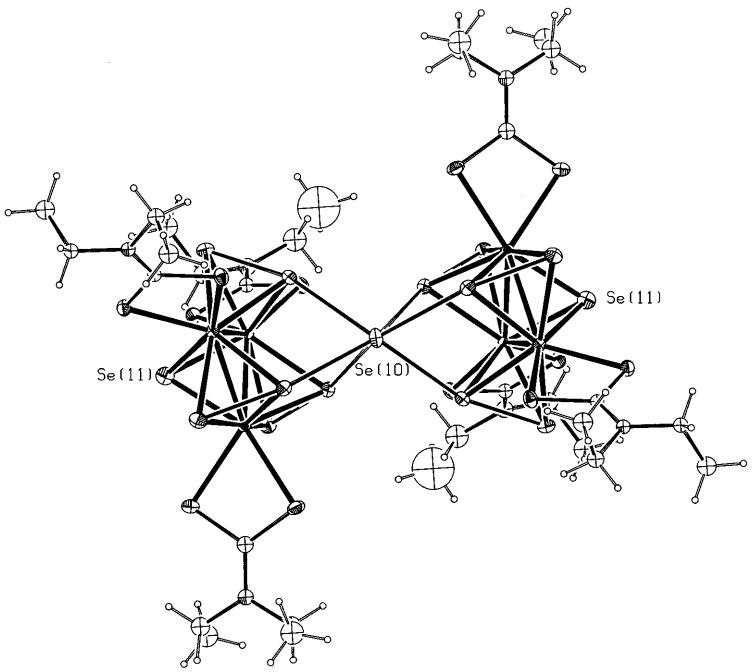

Fig. 2. The structure of the $[Mo_3Se(Se_2)_3(dtc)_3]Se$ subunit together with the atomic numbering scheme. Ellipsoids shown at 30% probability. Se(10) is the bridging atom and Se(11) the atom that caps the Se3 face.

Se(10). A very similar difference is also observed in the analogous Mo–S bonds in **4** (e.g. 2.481, versus 2.415 Å). The bonds to the dtc ligand are asymmetric with the Mo–S(n1) ($n = 1, 2, 3$)(*cis*) bonds shorter at 2.507 Å than the Mo–S(n2) ($n = 1, 2, 3$)(*trans*) bonds at 2.489 Å (comparable distances in **4** are 2.491 and 2.526 Å). Distances of sulfur atoms from the Mo_3 plane are S(11) −1.74, S(12) 1.09, S(21) −1.76, S(22) 1.07, S(31) −1.83, S(32) 0.97 Å. The Mo–Mo bond lengths are increased slightly but significantly in **1** compared to **4** by the larger size of the bridging selenium atoms with a mean Mo–Mo distance of 2.766 Å in **1** compared to 2.716 Å in **4**.

There are many examples of this $Mo_3S(S_2)_3$ core in the literature and the dimensions found in **4** are common to all the structures. However, this is the first example of the selenium analogue. It is of significant interest that in all structures containing this $[Mo_3S(S_2)_3(dtc)_3]$ core, there is found to be an additional anion approaching the three axial sulfur atoms of the complex, so clearly these three atoms form a cavity which forms an anionic binding site. In **4** the anion that is bound in the site is an additional sulfide anion, but many other examples are known, but predominantly halides. A list of 15 examples is given in Ref. [7]. These

[b] Mean value.

additional anions are only weakly bound with distances to S (axial) of between 2.87 and 3.25 Å. However in **4** the sulfide anion forms a significantly shorter contact at 2.71 Å. In **1**, in the present structure, the selenium analogue $[Mo_3Se(Se_2)_3(dtc)_3]$, the anionic binding site remains in situ and is occupied by a selenide anion. The mean distance between this anion and the selenium atoms in the pocket is 2.86 Å. The vast majority of the examples listed in [7] show the anion forming a single unit but in **4** and in **1**, the anion bridges two such subunits. The bridge is significantly asymmetric in that the angle subtended at the anion by the axes of the two subunits (defined as being perpendicular to the Mo_3 triangles is (46, 33° in **4**)).

The spectroscopic findings back up the crystallographic determination. The IR spectrum of **1** shows bands characteristic of coordinated diethyldithiocarbamato ligands [22–26]. Of more interest perhaps is the Raman spectrum where relatively strong bands in the region 200–600 cm^{-1} are seen. These principally arise from the Mo_3Se_7 core or from Mo–S vibrations. A tentative assignment of these bands, see Section 2, has been made by comparison with the vibrational spectra of related compounds [27–30]. The FAB mass spectrum of **1** shows a fragmentation pattern entirely as expected. Although the elemental analysis for **1** does not tally precisely with the calculated values the discrepancy may be accounted for by the presence of a small amount of trapped solvent or by the presence of small quantities of other impurities. Repeated attempts further to purify **1** by recrystallisation were not successful.

4.2. Characterisation of *2*

We have extended this work by repeating the synthesis of 1 under identical conditions but using W $(CO)_6$ or $CrCO)_6$ in place of Mo $(CO)_6$. With W $(CO)_6$ a mixture of products is formed. Crystals of 2 were obtained by treatment of the brown solid obtained from the reaction mixture with diethyl ether. Unfortunately it proved to be impossible to characterise the other components of the mixture. However, a combination of single crystal X-ray diffraction, infrared and Raman spectroscopies and FAB mass spectrometry demonstrate that **2** is the tungsten analogue of **1**.

The structure of **2** is shown in Figs. 3 and 4, it is similar to both **1** and **4** and consists of two $[W_3(\mu_3-Se)(\mu-Se_2)_3(dtc)_3]$ subunits linked by a bridging selenium atom just as the corresponding Mo subunits are linked by a selenium atom in **1**. However, it is not isomorphous as no crystallographic symmetry is present. The dimensions of the Mo subunit of **1** and the W subunit of **2** are compared in Table 2. The triply bridging selenium atom (Se(11)) is strongly bound to three tungsten atoms with an average distance of 2.493 Å (cf. the corresponding Mo–Se distance of 2.485 Å in **1**). In **2** there is a smaller difference between the W–S (eq) and W–Se (ax) bonds than in **1**. As in **1**, however,

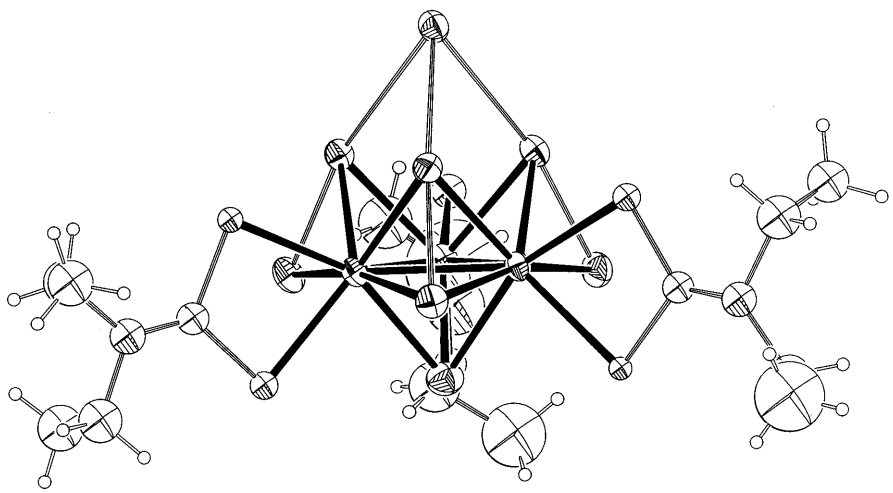

Fig. 3. The structure of the $[W_3Se(Se_2)_3(dtc)_3]Se$ subunit. Ellipsoids shown at 20% probability.

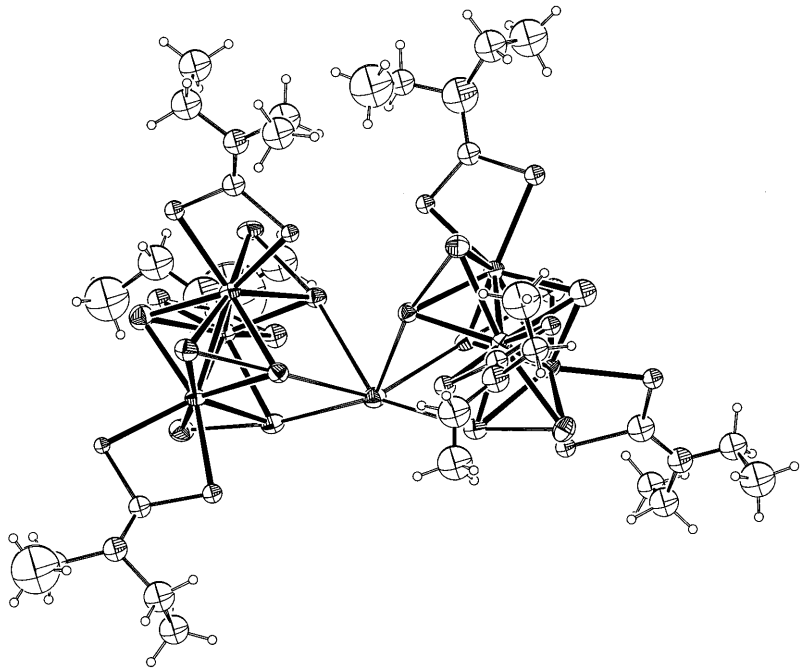

Fig. 4. The structure of the $[W_3Se(Se_2)_3(dtc)_3]_2Se$ dimer. Ellipsoids shown at 20% probability.

the bonds to the dtc ligand are asymmetric with the W–S (*cis*) bonds shorter than the W–S (*trans*) bonds (2.538 cf. 2.565 Å). Again, however, the asymmetry is not so pronounced in **2** as in **1**. The average W–W distance in **2** (2.751 Å) is shorter than the average Mo–Mo distance in 1 (2.766 Å) possibly reflecting somewhat stronger metal–metal bonding, as expected for the heavier transition metal.

The infrared spectrum of **2** is very similar to that of **1**. Most of the Raman spectrum of **2** was masked by strong fluorescence. However, strong Raman scattering was seen at 297, 237 and 202 cm^{-1} and these features were assigned to ν(W–S), ν(W–Se) and ν(W–W) stretches respectively. It may be seen that these features have all shifted to low frequency when compared to the corresponding bands of **1** reflecting the greater mass of tungsten compared to molybdenum. The FAB mass spectrum of **2** shows three distinct clusters of peaks centred around m/e values of 1636, 1588 and 1556. These are assigned to the ions $[W_3(\mu_3Se)(\mu Se_2)_3(S_2CNEt_2)_3]Se^+$, $[W_3(\mu_3Se)(\mu Se_2)_3(S_2CNEt_2)_3]S^+$ and $[W_3(\mu_3Se)(\mu Se_2)_3(S_2CNEt_2)_3]^+$ respectively. A large number of peaks were seen at lower m/e values but these could not be assigned with any degree of certainty.

4.3. Reaction of $Cr(CO)_6$

With $Cr(CO)_6$ there is no hint of any product akin to **1** or **2**. Rather the well-known compound $Cr(S_2CNEt_2)_3$ (**3**) [31] is formed in almost quantitative yield. **3** has been characterised by a combination of single crystal X-ray diffraction, IR and Raman spectroscopies and FAB mass spectrometry. The identical product, **3**, is also formed if the synthesis is repeated with no selenium in the reaction mixture. The FAB mass spectrum of **3** shows a molecular ion peak at $m/e = 496$; together with a number of other peaks including those at $m/e = 348$ and 200 corresponding to the loss of one and two dtc ligands from the parent molecule, respectively. The single crystal study confirms the nature of **3** [31]. It is not unexpected to find that chromium behaves in a different manner to molybdenum and tungsten; as expected the heavier metals readily form clusters incorporating metal-metal bonding whereas such behaviour is not seen for chromium.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC 144857 for compound **1** and CCDC 144858 for compound **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: hhtp://www.ccdc.cam.ac.uk).

Abstract

The combination of $EuCl_3 \cdot 6H_2O$ with the trifunctional ligand 2,6-$[(C_6H_5)_2P(O)CH_2]_2C_5H_3NO$, in a 1:2 ratio, produces the coordination complex $[Eu\{[(C_6H_5)_2P(O)CH_2]_2C_5H_3NO\}_2(H_2O)_2]Cl_3 \cdot 9H_2O$. The molecular structure of the complex has been determined by single-crystal X-ray diffraction methods. The *N*,*P*,*P*′-trioxide ligands each bind to the central Eu(III) ion in a tridentate fashion along with two water molecules. The eight inner sphere oxygen atoms surrounding the Eu(III) ion form a square antiprism. These results are discussed in the context of the structures formed by lanthanide nitrates. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Lanthanide complex; Tridentate chelate; Europium(III) chloride

1. Introduction

The liquid–liquid extraction (LLE) properties of the trifunctional 2,6-bis[(diorganylphosphino)methyl]pyridine *N*,*P*,*P*′-trioxides (NOPOPO's) [1–5] have stimulated interest in the molecular structures adopted in the coordination complexes of these ligands [6–8]. For example, ligand **1** in $CHCl_3$ extracts trivalent lanthanides and americium(III) from concentrated nitric acid solutions (1–6 M HNO_3), and it reversibly releases the extracted metal ions to dilute nitric acid solutions [1,4,5].

1

The magnitudes of the distribution ratio, $K_D = [M]_{org}/[M]_{aq}$, vary from $\sim 10^{-2}$ in 0.01 M HNO_3 to $\sim 10^3$ in 10 M HNO_3 [1,4,5]. Under similar conditions, carbamoylmethyl phosphonates (CMPs) and phosphine oxides (CMPOs) show similar trends in increasing K_D values with increasing $[HNO_3]$ using $CHCl_3$ [5] or aromatic solvents [9–12] as the diluents. These types of behavior are unique since most neutral organic extractants show depressed K_D values with increasing aqueous acid concentration presumably due to increasing competition between protons and metal ions for the extractant donor sites. We have also observed that K_D varies with the concentration of ligand used in the extractions, and the slope of the dependency ($\log K_D$ versus $\log [\mathbf{1}]$) is classically interpreted to indicate the number of ligands participating in the extraction complex [9]. In the case of **1** in $CHCl_3$ solution extracting Am(III) from HNO_3 solutions, the slopes are 2.3 at 0.1 M HNO_3 and 1.8 at 1.0 M HNO_3 [1,4]. Non-integral slopes are typically interpreted to result from formation of: (a) mixtures of complexes having different L/M ratios; (b) ligand aggregates in the organic phase; (c) non-stoichiometric outer-sphere complexes and/or (d) non-ideal organic solutions. In most cases it is difficult to determine which of these features operates especially under conditions directly comparable with a LLE pro-

PII: S0277-5387(00)00519-2

cess, where extractant concentration far exceeds the metal ion concentration. Furthermore, based upon extraction data, it is not possible to conclude how **1** binds to trivalent metal ions in $CHCl_3$ solution.

In support of synthetic efforts aimed at deriving new, improved extractants, it is important to obtain a more detailed molecular view of the complexes formed by **1** and its analogues. Ideally, it would be preferred to directly determine, under LLE conditions, full solution phase structures by using one or more readily available physical methods. With such data and companion molecular modeling, efficient molecular redesign of extractant structures would be possible. Limited success in identifying solution phase inner coordination sphere structures has been achieved for CMP and CMPO complexes by using IR [13], NMR [14–16] and EXAFS [17] techniques. However, additional detail is required. A 'next-best' approach involves full structure determination of isolated, crystalline coordination complexes from single-crystal X-ray diffraction data. This method is quite precise; however, there is no guarantee that the solid-state structure of the isolated complex is the same as the liquid phase solvent extraction complex. Still, crystal structure data provide useful information about how ligands organize about a metal ion. Furthermore, in the current case, it is not practical to isolate and structurally characterize Am(III) extraction complexes or to study the equilibrium speciation of the organic solvent soluble Am(III) complexes by spectroscopic techniques under the strongly ligand-loaded conditions employed in LLE. As a result, we have chosen to use stable lanthanide ions as stand-ins for the radioactive Am(III) ion. In previous studies we have reported on the structural characterization of $Ln(NO_3)_3$ complexes with **1** [6], and report here the isolation of a complex formed from $EuCl_3$ and **1**. The structure determination allows for discussion of the observed extraction behavior of **1** toward Eu(III) in HCl solutions.

2. Experimental

The ligand **1** was prepared according to the published procedure [6,7]. Chloroform and ethanol were purchased from EM Science (Omnisolv) and McCormick Distilling Co., respectively, and they were used without purification. Infrared spectra were recorded from KBr pellet samples by using a Mattson 2020 FT-IR spectrometer. TGA data were obtained on a Perkin–Elmer TGA-7 analyzer using N_2 as the purge gas. NMR spectra were recorded on Bruker 250 MHz and JEOL 400 MHz spectrometers. Elemental analyses were obtained from Galbraith Laboratories.

2.1. Synthesis of the complex

The complex was prepared by addition of **1** (0.4 mmol) in $CHCl_3$ (40 ml) to a vial containing $EuCl_3(6H_2O$ (0.2 mmol) in EtOH (20 ml). The vial was shaken and then allowed to stand for 2 days. The mixture produced a colorless solid. The solid was separated from the mother liquor and washed with Et_2O to remove residual free ligand. The mother liquor was placed in the refrigerator at 10°C and crystals suitable for X-ray analysis slowly formed in the vial. The solid was hydroscopic and vacuum drying resulted in a colorless powder. The vacuum-dried powder was used for spectroscopic and compositional analyses. Infrared spectrum (KBr, cm^{-1}): 3356(m), 3054(w), 1437(m), 1227(m), 1159(s), 1127(s), 862(w), 750(m), 727(m), 696(m), 507(m). Elemental analysis. Found: C, 50.46; H, 4.47; N, 2.09. Calc. for $C_{62}H_{76}Cl_3EuN_2O_{17}P_4$: C, 49.53; H, 5.09; N, 1.86%.

2.2. Crystallographic analysis

A prism-shaped crystal was selected and mounted in a sealed glass capillary. Data collection was performed on a Siemens P4 instrument with a CCD area-detector and low-temperature device operating at 193 K. Mo Kα radiation was used with a graphite single-crystal monochromator. Pertinent data collection and refinement information are summarized in Table 1. Data were recorded in the hemisphere mode (two settings, $\Delta/\phi = 0.3°$) with a measurement rate of 10 s per frame. No extinction correction was applied and the absorption correction employed SADABS. Data reduction was accomplished by use of SAINT (Siemens Analytical In-

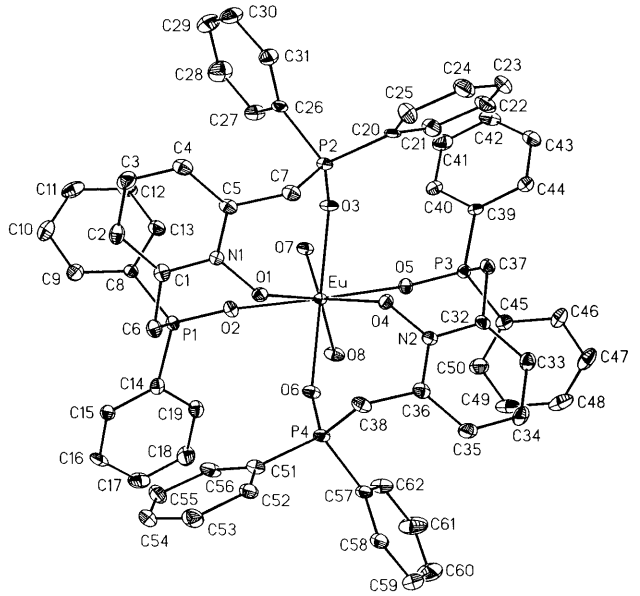

Fig. 1. ORTEP view of $[Eu\{[(C_6H_5)_2P(O)CH_2]_2C_5H_3NO\}_2(H_2O)_2]Cl_3{\cdot}9H_2O$.

struments, Version 4.1). The structure was solved by direct methods and refined by using full-matrix least-squares techniques. All non-hydrogen atoms were refined anisotropically except for one disordered outer sphere water oxygen atom: O(9) and O(10) occupancies 0.57 and 0.43, respectively. All hydrogen atoms were included (riding model) with $U_{iso} = 1.25U_{eq}$ of the parent atom.

3. Results and discussion

As noted in Section 1, previous liquid–liquid extraction studies of Am(III) from HNO_3 solutions with $CHCl_3$ solutions of **1** revealed ligand dependencies of 2.3 at 0.1 M HNO_3 and 1.8 at 1.0 M HNO_3 [1,4]. As noted above, crystallographic studies of solid-state structures do not necessarily accurately reflect all of the structural details of complexes formed in aqueous or organic solutions; however, they do provide some clues on the nature of the possible metal–extractant liquid phase interactions. For example, in prior work [6,8] $Ln(NO_3)_3{\cdot}xH_2O$ salts have been combined with **1** in EtOH or EtOH–$CHCl_3$ solutions, and 1:1 and 2:1 L/M complexes have been isolated and characterized. Single-crystal X-ray diffraction analyses show that the 1:1 complexes of these metal nitrates contain one tridentate ligand **1** and three bidentate nitrate groups bonded to the central Ln(III) ion. The resulting Ln(III) coordination number is nine. Such complexes are not likely to be present in large amounts in LLE systems where the ligand concentration in the organic phase is huge relative to the metal concentration in the acidic aqueous phase. In addition, 2:1 complexes have been isolated, and they have two tridentate coordinated molecules of **1** and one bidentate nitrate in the inner sphere giving rise to a coordination number of eight. The remaining two nitrates, and in some cases several solvent molecules, reside in the outer coordination sphere of the crystalline complexes. The structure of the 2:1 complexes is somewhat unusual since neutral acyclic ligands typically do not displace NO_3^- ions from the inner sphere in Ln(III) complexes. Of course, several macrocyclic ligands displace nitrate ions from the inner coordination sphere of Ln(III) ions [18]. Examination of space filling models of the 2:1 complexes show that the two neutral ligands nearly completely encapsulate the Ln(III) leaving only a narrow slot for one NO_3^- ion to fit in the inner sphere. The exterior of the complex is therefore, dominated by the 'greasy' organic fragments of the ligands and this is consistent with the high $CHCl_3$ solubility of the complex. No doubt this character facilitates the transfer of Ln(III) ions from aqueous acid solutions to the organic phase in extractions. Complexes with more than two ligands bonded to the central Ln(III) ion have not yet been isolated despite attempts to produce them under various conditions. This suggests that a ligand dependency of 2.3 at low nitrate concentration does not arise from a mixture of ML_3 and ML_2 complexes, but instead it may reflect the presence of aggregates or outer sphere complexes containing **1** when the ligand is present in high concentration.

Interestingly, extractions of Am(III) from 1 M HCl solutions by **1** in $CHCl_3$ produce a ligand dependency of 3.1 [2]. Due to the poor coordination ability of Cl^- relative to NO_3^-, it seemed possible that isolated coordination complexes obtained from combination of excess of **1** with $LnCl_3{\cdot}nH_2O$ salts might display a 3:1 L/Ln ratio. In this case the molecular structure might contain, for example, two tridentate ligands **1** and a monodentate ligand **1** in the inner coordination sphere although preliminary molecular modeling suggested an unfavorable 'tight-fit' for a P=O bonded monodentate ligand in the slot left by the two tridentate ligands. The tight-fit would result from steric crowding between substituents on the phosphoryl groups in the tridentate ligands and the phenyl groups on a P=O group in a monodentate ligand.

In the present study, we have examined reactions of $LnCl_3{\cdot}nH_2O$ salts with **1** in various ratios in EtOH, EtOH–$CHCl_3$ and EtOH–H_2O mixtures. Suitable single crystals were obtained in only one case where the ligand–Eu(III) ratio was 2:1 and the solvent mixture was EtOH–$CHCl_3$. The crystal structure determination reveals that the isolated complex has the composition $[Eu\{[(C_6H_5)_2P(O)CH_2]_2C_5H_3NO\}_2(H_2O)_2]Cl_3{\cdot}9H_2O$. A view of the molecular structure is shown in Fig. 1 and the eight-coordinate polyhedron is presented in Fig. 2.

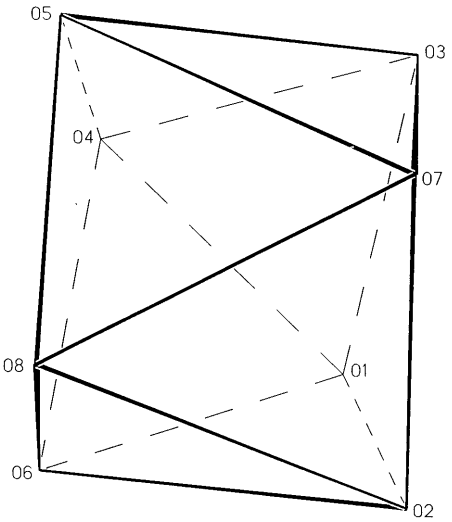

Fig. 2. Coordination polyhedron for $[Eu\{[(C_6H_5)_2P(O)CH_2]_2C_5H_3NO\}_2(H_2O)_2]Cl_3\cdot 9H_2O$.

Two tridentate molecules of **1** are present in the Eu(III) molecular structure, but a third molecule of **1** is absent both from the inner and outer spheres. The weakly binding Cl^- anions are displaced from the Eu(III) inner sphere and replaced by two water molecules. The three Cl^- anions and an additional nine molecules of water are found in the outer sphere in a complex hydrogen bonded array.

The $Eu(\mathbf{1})_2(H_2O)_2$ inner sphere complex has an approximate C2 rotation axis. The average P(O)–Eu distance, 2.355 Å (range: 2.343(3)–2.369(4) Å), is comparable with distances found in lanthanide nitrate complexes of **1** [6–8]. The average N(O)–Eu distance, 2.462 Å (range: 2.467(3)–2.458(3) Å), is longer than the P(O)–Eu distance, and a similar trend is observed in all complexes of **1** [6–8]. As in the lanthanide nitrate complexes of **1** the two tridentate ligands form a large 'mushroom cap-like' enclosure around the Eu(III) ion. Unlike the complexes containing nitrate counter ions, the remaining small coordination 'slot' is occupied by two neutral water molecules instead of one bidentate NO_3^- ion. The average H_2O–Eu distance, 2.464 Å (range: 2.479(4)–2.448(4) Å), is comparable to the N(O)–Eu distance. The fact that one of the water molecules has a significantly longer Eu–OH_2 distance suggests that it is more loosely bound, probably in response to steric crowding in the inner sphere. The average P=O distance, 1.503 Å, and N–O distance, 1.336 Å, are identical to those reported earlier for nitrate complexes [6–8]. The O(7)–Eu–O(8) bond angle is 69.9(2)° which is similar to the value for a bidentate NO_3^- ion [6].

The molecular structures for the corresponding 2:1 complexes $[Eu(\mathbf{1})_2(NO_3)](NO_3)_2$ [3], $[Pr(\mathbf{1})_2(NO_3)](NO_3)_2$, and $[Yb(\mathbf{1})_2(NO_3)](NO_3)_2$ [6,8] have also been obtained. As suggested above, the structures of these nitrate complexes are closely similar with two tridentate ligands **1** and a bidentate nitrate forming the eight-coordinate inner sphere geometry. In these cases the three ligand oxygen donor atoms form nearly isosceles triangular coordination footprints on the central metal with the following non-bonded O···O separations: Eu–ligand **1**: (P)O···O(N), 2.837; (P)O···O(N), 3.009; (P)O···O(P) 3.648 Å. Ligand **2**: (P)O···O(N), 2.848; (P)O···O(N), 2.965, (P)O···O(P) 3.584 Å. Pr–ligand **1**: (P)O···O(N), 2.873; (P)O···O(N), 2.986; (P)O···O(P), 3.488 Å. Pr–ligand **2**: (P)O···O(N), 2.875: (P)O···O(N), 3.029; (P)O···O(P), 3.829 Å. Yb–ligand **1**: (P)O···O(N), 2.929; (P))···O(N), 2.770; (P)O···O(P), 3.462 Å. Yb–ligand **2**: (P)O···O(N), 2.952; (P)O···O(N), 2.791; (P)O···O(P), 3.439 Å. These values can be compared with the non-bonded O···O separations in the $EuCl_3$ complex: ligand **1**: O(1)···O(2), 2.874; O(1)···O(3), 3.049; O(2)···O(3), 3.756 Å. Ligand **2**: O(4)···O(5), 2.887; O(4)···O(6), 3.057; O(5)···O(6), 3.828 Å. As we have noted before [6,7] the ligand **1** is able to accommodate a range of central metal ion radii by adjusting the size of the footprint through small conformational changes in the C(ring)–CH_2–P(O)Ph_2 arms. The largest effect appears in the non-bonded (P)O···O(P) separation which is reduced as the M(III) ionic radius decreases. The Pr(III) ionic radius (1.14 Å, CN = 8) is larger than that of Eu(III) (1.07 Å, CN = 8), hence it would be expected that the ligand footprints in the Eu(III) complexes would be significantly smaller than in the Pr(III) complex. This is the case when comparing the structures of the $[M(\mathbf{1})_2(NO_3)](NO_3)_2$ (M = Pr, Eu) complexes. However, in the present case, it appears that the sizes of the ligand footprints in $[Eu(\mathbf{1})_2(H_2O)_2]Cl_3$ more closely match those in $[Pr(\mathbf{1})_2(NO_3)](NO_3)_2$ rather than those in $[Eu(\mathbf{1})_2(NO_3)](NO_3)_2$. Therefore, the size variation between the Eu(III) nitrate and chloride complexes probably arise in response to the effective space occupied by a single inner-sphere bidentate nitrate ion compared to two inner-sphere water molecules (Table 2).

Returning to the question regarding the identity of the extraction complex, it is informative to compare the structural results with other characterization data for the complex. First, it is noted that in our relatively dry

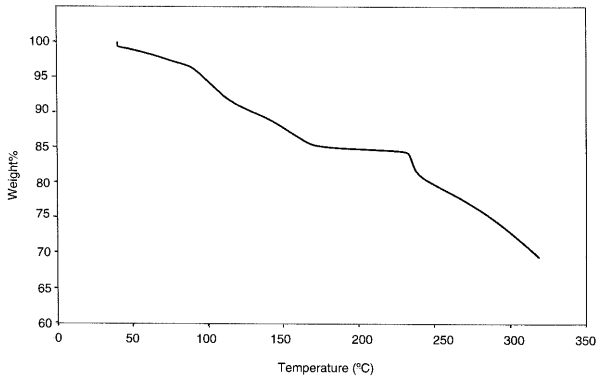

Fig. 3. Thermal gravimetric analysis (TGA) for the vacuum-dried complex.

laboratory atmosphere single crystals and bulk solid samples of the complex lose water and disintegrate into a powder. Depending upon length of exposure, analytical samples show significant variations in CHN content. In an effort to obtain consistent analytical results, samples were vacuum-dried for several hours before submission for analysis or spectroscopic studies. The observed CHN analysis (%) data are C, 50.46; H, 4.47; N, 2.09, while calculated values for $Eu(\mathbf{1})_2(Cl)_3 \cdot nH_2O$ ($n = 9$, 10 and 11) are C, 50.75, 50.14, 49.53; H, 4.95, 5.02, 5.05; N, 1.91, 1.89, 1.86, respectively. Although there is no evidence for it in the crystal structure determination, integrated peak intensities obtained from the ^1H NMR spectra of the complex suggest that one-quarter equivalent of EtOH may be present in powder samples. The calculated CHN composition for a complex $Eu(\mathbf{1})_2(Cl)_3 \cdot 1/4EtOH \cdot 9H_2O$ is C, 50.76; H, 4.97; N, 1.89. Clearly, it is difficult to arrive at a definite composition even for the isolated complex based upon these data alone. In an effort to shed further light on the composition of the vacuum-dried material, a TGA study was completed, and a typical trace is shown in Fig. 3. There appear to be several gradual weight loss events between 40 and 200°C. The total measured weight loss up to 200°C is 15.2%. At $\sim$240°C a more abrupt weight loss occurs. The complex $[Eu(\mathbf{1})_2(H_2O)_2](Cl)_3 \cdot 9H_2O$ would be expected to show a weight loss of 13.2% if all water of hydration were lost with no chemical reaction in the remaining complex. A complex with less water of hydration due to prior vacuum drying should show less weight loss. Further, the complex $Eu(\mathbf{1})_2(Cl)_3 \cdot 1/4EtOH \cdot 9H_2O$ mentioned above would produce a weight loss of 13.3% by removal of the EtOH and H_2O. Unfortunately then, the analytical and TGA data do not provide an unambiguous chemical formula for the complex prior to drying or a complete picture of the compositional changes in the isolated complex as a result of drying. Similar patterns have been found in lanthanide nitrate complexes with **1** [6,8].

Infrared analysis of the dried powdered complex shows a single band at 1227 cm^{-1} that most likely corresponds to the coordinated N–O group of **1** and a band at 1159 cm^{-1} that corresponds to the coordinated P=O groups. There is no evidence for uncoordinated functional groups that would most likely be indicated by a P=O band in the vicinity of 1190 cm^{-1} [6].

Given the data presented here, it remains to speculate over the nature of the solvent extraction complex such as formed by **1** in $CHCl_3$ when exposed to HCl solutions of $EuCl_3$. The simplest interpretation of ligand dependency of the extractions that produce a slope 3.1 is that the very high ligand–metal ratios ($\sim 10^6$) employed in the radioactive tracer analyses drives the addition of a third equivalent of **1** to the complex as it transfers to the ligand rich organic phase. It is possible that this third equivalent displaces the two inner sphere water molecules found in the isolated crystals; however, it is also likely that the extra ligand is simply included in a hydrogen bonded outer sphere structure. Indeed, this ligand may take the place of some or all of the outer sphere water found in the crystals isolated at lower ligand concentrations.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 133406. Copies of this information may be obtained free of charge from The Director CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336033 or e-mail: deposit@ccdc.com.ac.uk or www: http://www.ccdc.com.ac.uk).

Abstract

MoO_2(dipic)(L) (dipic = pyridine 2,6-dicarboxylate (dipicolinate); L = dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), hexamethyl phosphorotriamide (HMPA), triphenylphosphine oxide ($OPPh_3$), triethylamine, tripropylamine, tributylamine, pyridine, 2-methylpyridine, 3-methylpyridine, 4-methylpyridine) have been prepared by reacting equimolar amounts of $MoO_2Cl_2(L)_2$ (L = DMF, DMSO) with Na_2dipic, followed by addition of the appropriate ligand to the resulting solutions. The molecular structures of the DMF, DMSO and HMPA derivatives have been established by X-ray diffraction analysis. The ability of MoO_2(dipic)(L) (L = DMF, DMSO, HMPA, $OPPh_3$) to work as oxotransfer catalysts has been examined and compared with that of the prototypical $MoO_2(Et_2dtc)_2$ (Et_2dtc = diethyl dithiocarbamate). Dipicolinate complexes proved to be more efficient catalysts than dithiocarbamate for the deoxygenation of azoxybenzene with triphenylphosphine in boiling toluene. © 2000 Elsevier Science B.V. Keywords: Dioxomolybdenum dipicolinate; Oxygen-atom transfer; Azoxybenzene deoxygenation

1. Introduction

It has been assumed for years that the presence of sulfur atoms coordinated to molybdenum is a requisite for complexes of this metal to have oxotransfer activity, and many model compounds that mimic oxotransferases have been studied [1–7]. The first oxotransfer reaction involving a molybdenum complex without coordinated sulfur atoms was reported in 1990 [8]. This observation proved that the presence of sulfur atoms coordinated to molybdenum is not essential for oxotransfer activity in mild conditions, and since then a number of complexes of this kind have been reported [9–14]. One of the most relevant is the anionic $[MoO_2(NCS)_4]^{2-}$ species, which contains *N*-coordinated thiocyanate and has a catalytic activity greater than that of the prototypical $MoO_2(Et_2dtc)_2$ in the oxidation of PPh_3 with DMSO [9]. More recently the catalytic activity of $MoO_2(CH_3)_2(L)$ (L = bipyridine, alkyl substituted bipyridine) [15], and that of MoO_2[2,6-bis(mentyl)pyridine)] in oxotransfer processes has been mentioned [16]. In our laboratory we found that simple, air-stable complexes derived from MoO_2Cl_2 and MoO_2Br_2 are also superior to dithiocarbamates in the oxygen atom transfer from DMSO to PPh_3 at room temperature [13,14,17]. This prompted us to search for new dioxomolybdenum(VI) compounds in order to test their potentiality as oxotransfer catalysts. Here we report on the synthesis, characterization and catalytic activity of a number of dipicolinate complexes.

2. Experimental

2.1. General procedures and measurements

All operations were carried out in a dry oxygen-free nitrogen atmosphere using standard Schlenck techniques, except the synthesis of the compounds with DMF, DMSO, HMPA and $OPPh_3$ which were conducted in air. Diethyl ether and toluene were distilled from sodium under nitrogen prior to use. *N*,*N*-Dimethylformamide was dried with barium oxide and distilled under reduced pressure. Acetone and amines for the preparation of amine complexes were distilled immediately before use. Triphenylphosphine was recrystallized prior to use and checked by ^{31}P NMR and melting point for purity. All other reagents were commercial products and were used without further purification. $MoO_2Cl_2(DMSO)_2$ and $MoO_2Cl_2(DMF)_2$ were prepared as reported [13]. Na_2dipic was prepared by reacting equimolar amounts of Na_2CO_3 and H_2dipic in water, crystallizing the resulting solution and heating the solid at 100°C under vacuum for 5 h. Melting points were determined with a Buchi 'Tottoli' with variable warm speed. Elemental analyses (C, H, N) were performed on a Perkin–Elmer 2400 CHN analyzer and molybdenum was determined by titration with lead(II) nitrate [18]. IR spectra were recorded on a Perkin–Elmer 843 spectrometer with Heyden and Son Spectrafile-IR version 2.2 operating software, and UV–Vis spectra on a Milton Roy Spectronic 3000 Arrays spectrometer equipped with a thermostated cell. NMR spectra were recorded on a Bruker AC-300 and a Bruker DPX 300 spectrometer (^1H, 300 MHz; ^{31}P, 121.5 MHz). Chemical shifts are relative to TMS (^1H), or external 85% H_3PO_4 (^{31}P), with downfield values reported as positive. Coupling constants J are given in Hz.

2.2. General procedure for the preparation of MoO_2(dipic)(L) (L = DMF, DMSO, HMPA, $OPPh_3$)

A mixture of Na_2dipic (2.11 g, 10.5 mmol), $MoO_2Cl_2(DMF)_2$ (3.45 g, 10 mmol) and L (12 mmol) in acetone (60 ml) was refluxed with stirring for 1 h. The white precipitate was separated by filtration and washed with acetone (10 ml). The combined filtrate and washing was concentrated to 10 ml and then diethyl ether (50 ml) was added. The resulting light yellow microcrystalline precipitate was filtered, washed with diethyl ether (2 × 10 ml) and dried under vacuum.

2.2.1. MoO_2(dipic)(DMF)

Yield 3.07 g (83.8%). — M.p. (dec.) 200–202°C. — IR (KBr) cm^{-1}: $\nu(MoO_2) = 942$ s, 905 s; $\nu(CO_2) = 1693$ s, 1489 s; ν(C=O, DMF) = 1637 s. — ^1H NMR (300 MHz, acetone-d_6, 25°C, TMS): $\delta = 8.85$ (t, $J = 7.63$, 1H, dipic), 8.46 (d, $J = 7.63$, 2H, dipic), 8.19 (s, 1H, H–CO), 3.06 (s, 3H, CH_3), 2.62 (s, 3H, CH_3). — *Anal.* Calc. for $C_{10}H_{10}MoN_2O_7$ (367.96): Mo 26.20, C 32.81, H 2.75, N 7.65. Found: Mo 26.12, C 31.67, H 2.87, N 7.56%.

2.2.2. MoO_2(dipic)(DMSO)

Yield 3.40 g (91.6%). — M.p. (dec.) 185–187°C. — IR (KBr) cm^{-1}: $\nu(MoO_2) = 942$ s, 909 s; $\nu(CO_2) = 1707$ s, 1470 s; ν(S=O) = 1081 s. — ^1H NMR (300 MHz, acetone-d_6, 25°C, TMS): $\delta = 8.81$ (t, $J = 7.73$, 1H, dipic), 8.45 (d, $J = 7.73$, 2H, dipic), 2.69 (s, 6H, CH_3). — *Anal.* Calc. for $C_9H_9MoNO_7S$ (372.92): Mo 25.85, C 29.12, H 2.44, N 3.77. Found: Mo 25.73, C 29.24, H 2.39, N 3.79%.

2.2.3. MoO_2(dipic)(HMPA)

Yield 3.62 g (76.7%). — M.p. (dec.) 234–236°C. — IR (KBr) cm^{-1}: $\nu(MoO_2) = 934$ s, 912 s; $\nu(CO_2) = 1707$ s, 1466 s; ν(P=O) = 1192 s; ν(HMPA) = 1303, 993 and 756. — ^1H NMR (300 MHz, acetone-d_6, 25°C, TMS): $\delta = 8.76$ (t, $J = 7.76$, 1H, dipic), 8.43 (d, $J = 7.76$, 2H, dipic), 2.46 (d, $J_{HP} = 9.63$, 18H, CH_3). — ^{31}P NMR (121.5 MHz, acetone-d_6, 25°C, H_3PO_4): $\delta = 29.60$. — *Anal.* Calc. for $C_{13}H_{21}MoN_4O_7P$ (474.02): Mo 20.32, C 33.06, H 4.48, N 11.86. Found: Mo 20.22, C 32.18, H 4.30, N 11.68%.

2.2.4. MoO_2(dipic)($OPPh_3$)

Yield 4.20 g (73.5%). — IR (KBr) cm^{-1}: $\nu(MoO_2) = 940$ s, 910 s; $\nu(CO_2) = 1710$ s, 1585 s; ν(P=O) = 1154 s. — ^1H NMR (300 MHz, acetone-d_6, 25°C, TMS): $\delta = 8.71$ (t, $J = 7.76$, 1H, dipic), 8.31 (d, $J = 7.93$, 2H, dipic), 7.7–7.5 (m, 15H, C_6H_5). — ^{31}P NMR (121.5 MHz, acetone-d_6, 25°C, H_3PO_4): δ = 33.07. — *Anal.* Calc. for $C_{25}H_{18}MoNO_7P$ (572.99): Mo 16.79, C 52.56, H 3.27, N 2.45. Found: Mo 16.62, C 52.42, H 3.23, N 2.50%.

2.3. General procedure for the preparation of MoO_2(dipic)(amine) (amine = pyridine (Py), 2-methylpyridine (2-MePy), 3-methylpyridine (3-MePy), 4-methylpyridine (4-MePy), triethylamine (NEt_3), tripropylamine (NPr_3), tributylamine (NBu_3))

To a solution of MoO_2(dipic)(DMF) (1.46 g, 4 mmol) in acetone (20 ml) a solution of amine (4.2 mmol) in acetone (5 ml) is added. After stirring the resulting mixture for 5 min, the white precipitate is filtered, washed with acetone (2 × 5 ml) and diethyl ether (2 × 10 ml), and dried under vacuum.

2.3.1. MoO_2(dipic)(Py)

Yield 1.41 g (95%). — IR (KBr) cm^{-1}: $\nu(MoO_2) =$ 946 s, 919 s; $\nu(CO_2) = 1730$ s, 1484 s. — *Anal.* Calc. for $C_{12}H_8MoN_2O_6$ (372.14): Mo 25.78, C 38.73, H 2.17, N 7.53. Found: Mo 25.35, C 38.52, H 2.32, N 7.25%.

2.3.2. MoO_2(dipic)(2-MePy)

Yield 1.03 g, (67%). — IR(KBr) cm^{-1}: $\nu(MoO_2)$ = 946 s and 918 s; $\nu(CO_2)$ = 1726 s, 1431 s. — *Anal.* Calc. for $C_{13}H_{10}MoN_2O_6$ (386.17): Mo 24.85, C 40.43, H 2.61, N 7.25. Found: Mo 24.85, C 40.13, H 2.38, N 7.07%.

2.3.3. MoO_2(dipic)(3-MePy)

Yield 1.24 g, (80%). — IR(KBr) cm^{-1}: $\nu(MoO_2)$ = 947 s, 914 s; $\nu(CO_2)$ = 1726 s, 1455 s. — *Anal.* Calc. for $C_{13}H_{10}MoN_2O_6$ (386.17): Mo 24.85, C 40.43, H 2.61, N 7.25. Found: Mo 23.96, C 39.62, H 2.57, N 6.95%.

2.3.4. MoO_2(dipic)(4-MePy)

Yield 1.32 g, (85%). — IR(KBr) cm^{-1}: $\nu(MoO_2)$ = 942 s, 908 s; $\nu(CO_2)$ = 1730 s, 1433 s. — *Anal.* Calc. for $C_{13}H_{10}MoN_2O_6$ (386.17): Mo 24.85, C 40.43, H 2.61, N 7.25. Found: Mo 24.98, C 39.86, H 2.77, N 6.96%.

2.3.5. MoO_2(dipic)(NEt_3)

Yield 1.17 g, (74%). — IR(KBr) cm^{-1}: $\nu(MoO_2)$ = 942 s, 912 s; $\nu(CO_2)$ = 1609 s, 1447s. — *Anal.* Calc. for $C_{13}H_{18}MoN_2O_6$ (394.24): Mo 24.34, C 39.61, H 4.60, N 7.11. Found: Mo 24.03, C 39.35, H 4.72, N 7.25%.

2.4. Preparation of Mo_2O_3(dipic)$_2$($OPPh_3$)$_2$

2.4.1. Method A

A mixture of MoO_2(dipic)($OPPh_3$) (0.71 g, 1.25 mmol) and PPh_3 (0.33 g, 1.25 mmol) in toluene (30 ml) was refluxed for 1 h under nitrogen. The dark brown powdered precipitate is filtered, washed with diethyl ether and dried under vacuum (0.61 g, 87%).

2.4.2. Method B

A mixture of MoO_2(dipic)($OPPh_3$) (0.71 g, 1.25 mmol) and PPh_3 (0.33 g, 1.25 mmol) in acetone (30 ml) was refluxed for 2 h under nitrogen. The resulting solution is concentrated to 10 ml and then treated with diethyl ether (30 ml). The dark brown precipitate is filtered, washed with diethyl ether and dried under vacuum (0.63 g, 89.5%).

IR(KBr) cm^{-1}: $\nu(MoO_2)$ = 953 s, 914 s; $\nu(CO_2)$ = 1688 s, 1438 s; $\nu(P{=}O)$ = 1160 s. — ^1H NMR (80 MHz, $CDCl_3$, 25°C, TMS): δ = 8.0–8.4 (m, J = 7.76 Hz, 3H, dipic), 7.4–7.6 (m, 15H, C_6H_5). — *Anal.* Calc. for $C_{50}H_{36}Mo_2N_2O_{13}P_2$ (1129.99): Mo 17.03, C 53.30, H 3.22, N 2.49. Found: Mo 17.23, C 53.12, H 3.06, N 2.32%.

2.5. Catalytic activity

The measurement of the catalytic activity of MoO_2(dipic)(DMSO) in the oxidation of triphenyl phosphine with dimethyl sulfoxide was followed by ^{31}P NMR spectroscopy, and compared with that of $MoO_2(Et_2dtc)_2$, as previously reported [13]. Two 5 ml DMSO (20% v/v in DMSO-d_6) solutions, at [Mo] = 0.02 mol dm^{-3} and [PPh_3] = 0.40 mol dm^{-3}, were used. At 25°C the oxidation of 50% PPh_3 required 175 min in the dipicolinate solution and 85 min in that of the dithiocarbamate. PPh_3 became undetectable with the former after 7 h. Solid PPh_3 (50 mg) was added to the dipicolinate solution that was examined after 4 h showing only the presence of $OPPh_3$. The same result was obtained when this operation was repeated after 2, 4 and 7 days.

2.6. Deoxygenation of azoxybenzene

The deoxygenation of azoxybenzene was followed in toluene at 105°C monitoring the reaction by visible spectroscopy. Samples of 2 ml were collected off by syringe from the reacting system at regular intervals, and immediately transferred to graduated rubber-capped tubes, containing 2 ml of 4 M NaOH, immersed into an ice bath. After vigorous shaking of the tubes to remove the molybdenum complexes from the toluene phase the absorbance was measured at 446 nm, wavelength at which azobenzene is the only absorbing species present in toluene.

2.7. Crystal-structure determinations

Suitable single crystals were grown at room temperature by diffusion of diethyl ether on acetone solutions of the complexes in a dry atmosphere. Crystal data MoO_2(dipic)(DMF) were collected using an Enraf–Nonius MACH3 diffractometer with graphite-monochromated Mo Kα radiation. Crystal data for the complexes MoO_2(dipic)(DMSO) and MoO_2(dipic)($OPPh_3$) were collected using a KappaCCD diffractometer with graphite-monochromated Mo Kα radiation. Hydrogen atom positions were located from difference Fourier maps. All three structures were solved using OPENMOLEN

2.2. Table 1 provides crystallographic details for these compounds.

3. Results and discussion

3.1. Synthesis and characterization of the complexes

To the best of our knowledge only a marginal reference to the synthesis and characterization by melting point and infrared spectroscopy of MoO_2(dipic)-(HMPA) has been reported [19]. More recently, in studies on the reactivity of molybdenaoxaziridine complexes, the formation of Mo_2O_3(dipic)$_2$(HMPA)$_2$ was postulated [20]. MoO_2(dipic)(HMPA) was prepared by reacting MoO_2(acac)$_2$ (acac = acetylacetonate) with dipicolinic acid and HMPA in CH_2Cl_2. In these conditions a green solution was obtained which suggests that a redox process also occurs, probably involving the acacH displaced.

To overcome this difficulty we have used the easily available $MoO_2Cl_2(L)_2$ (L = DMF, DMSO) [17] complexes instead of MoO_2(acac)$_2$. Metathetic reactions between the disodium salt of dipicolinic acid and the corresponding chlorocomplex in acetone proved to be appropriate for preparing MoO_2(dipic)(DMF) and MoO_2(dipic)(DMSO). The reaction requires about 24 h at room temperature for completion, probably because Na_2dipic is scarcely soluble in acetone, but less than 1 h when carried out to reflux. The compounds are recovered in good yield from the resulting solutions by removing most of the solvent under vacuum followed by precipitation with diethyl ether.

MoO_2(dipic)(L) (L = HMPA, $OPPh_3$, tertiary amine) were prepared by treating acetone solutions of MoO_2(dipic)(DMF) or MoO_2(dipic)(DMSO) with the corresponding ligand. MoO_2(dipic)(HMPA) and MoO_2(dipic)($OPPh_3$) are obtained by addition of diethyl ether to the resulting solutions, while the amine derivatives separated as fine white precipitates; further studies for the complete characterization of the latter are in progress. MoO_2(dipic)(HMPA) and MoO_2-(dipic)($OPPh_3$) can also be prepared by reacting $MoO_2Cl_2(L)_2$ (L = DMF, DMSO) with Na_2dipic in presence of the corresponding ligand, followed by filtration of NaCl and addition of diethyl ether to the resulting solution. In this regard the DMF complex is superior to that of DMSO since DMF is miscible with diethyl ether. The presence of minor amounts of water either in Na_2dipic or in the solvent has not significant effect on the preparation of the derivatives with DMF, DMSO, HMPA and $OPPh_3$ since these ligands are able to displace water from the coordination sphere of molybdenum. Also they have a low affinity for protons, thus precluding the formation of polymolybdates. By the contrary, the high proton basicity of tertiary amines requires the use of rigorously anhydrous conditions to obtain pure products.

No relevant features are observed in the IR spectra of the compounds. The presence of two bands in the region 900–950 cm^{-1} indicates that, as usual for dioxomolybdenum(VI) species, all the complexes contain

the *cis*-MoO_2 moiety [21,22]. A relationship between the basicity of the *O*-donor neutral ligand and the separation of the $\nu(MoO_2)$ bands (the higher the basicity the lower the separation) is also appreciated, but a definite explanation for this effect is not attempted since the differences in bond lengths and angles for the group *cis*-MoO_2 are not significant (see Table 2). The stretching bands for O–C, O–S and O–P of the coordinated ligands in complexes with DMF, DMSO, HMPA and $OPPh_3$ occur at 1637, 1081, 1154 and 1192 cm^{-1} respectively; they are shifted 20–25 cm^{-1} to lower wavenumbers with respect to those of the free ligands, which is indicative of coordination through the oxygen atom [23].

The ^1H NMR spectra of MoO_2(dipic)(L) (L = DMF, DMSO, HMPA and $OPPh_3$) are in agreement with those expected for octahedral complexes having a reflection plane and free rotation around the molybdenum-neutral ligand bond. The presence of two singlets for the methyl groups in MoO_2(dipic)(DMF) indicates that no free rotation exists around the C–N bond.

3.2. Molecular structures

Single-crystal X-ray diffraction studies on MoO_2(dipic)(L) (L = DMF, DMSO, $OPPh_3$) revealed that the three complexes have a closely related structure, similar to that of MoO_2(dipic)(DMF) shown in Fig. 1.

The molybdenum atom adopts the expected distorted octahedral geometry, which is determined by the usual way of coordination for the dipicolinate ligand (planar tridentate) to the angular *cis*-MoO_2 moiety.

Selected bond lengths and angles are listed in Table 2. The bond lengths for Mo–O(5) and Mo–O(6) are not identical, the former being shorter. While the Mo–O(6) distance, involving the oxygen *trans* to N(1), is nearly identical for all the complexes, the Mo–O(5) distance increases with the basicity of the *trans* ligand.

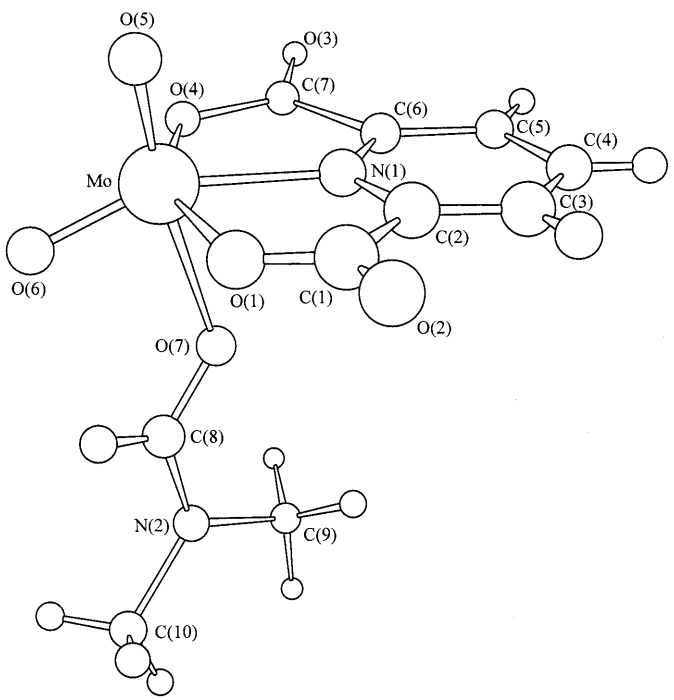

Fig. 1. Molecular structure and atom-labeling for complex MoO_2(dipic)(DMF); the hydrogen atoms are shown with small arbitrary radii.

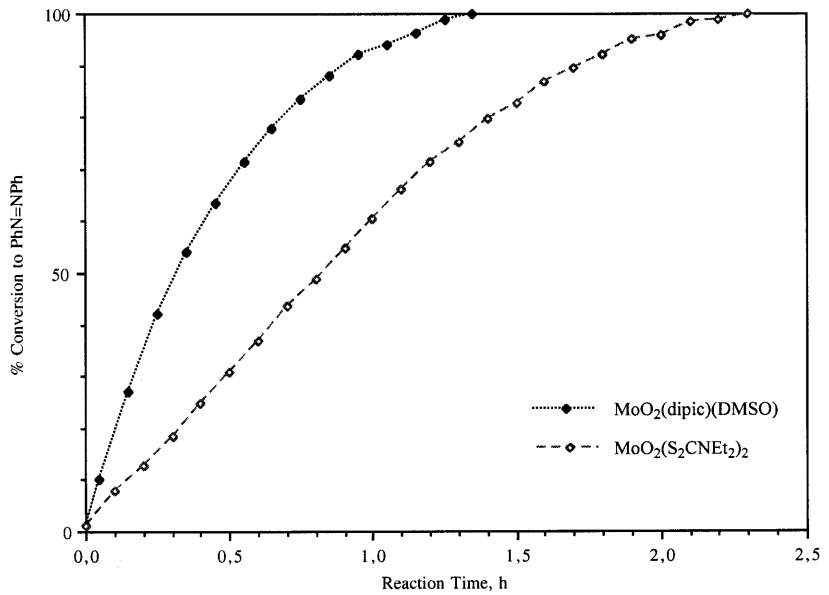

Fig. 2. Reduction of PhN(O)=NPh to PhN=NPh using PPh_3 as a funtion of time at [Mo] = 1.25 10^{-3} mol dm^{-3} and $[PPh_3]_0/[PhN(O)=NPh]_0/[Mo^{VI}]_0 = 10/1/0.05$.

The angles for the *cis*-MoO_2 group, O(5)–Mo–O(6), are very similar in the three compounds (ca. 105°), and in good agreement with those found for analogous complexes with *N*- and *O*-coordinated ligands [1,24].

3.3. Oxotransfer reactions

The oxygen atom transfer from MoO_2(dipic)(L) (L = DMF, DMSO, HMPA, $OPPh_3$) to PPh_3 has been examined. By treating acetone solutions of the complexes with PPh_3 a brown solution results at the same time that $OPPh_3$ forms. No significant difference in the behavior of the complexes MoO_2(dipic)(DMF), MoO_2(dipic)(DMSO) and MoO_2(dipic)($OPPh_3$) was observed, except for the evolution of the foul-smelling dimethyl sulfide (DMS) when the DMSO adduct was used. The only molybdenum product we could characterize, even in a large excess of PPh_3, is $Mo_2^{V}O_3$(dipic)$_2$($OPPh_3$)$_2$. Attempts to grow crystals suitable for X-ray characterization have been unsuccessful to date. Evidence — based on the ^{1}H NMR of the product — about formation of $Mo_2^{V}O_3$(dipic)$_2$(HMPA)$_2$ was found when using MoO_2(dipic)(HMPA), presumably due to the superior coordinating ability of HMPA with respect to $OPPh_3$. These results strongly suggest that: (i) $Mo^{IV}O$(dipic)(L) comproportionates as it forms with the remaining $Mo^{VI}O_2$(dipic)(L), at the same time that the coordinated DMF or DMSO are displaced by the $OPPh_3$ produced, thus leading to the dinuclear complex $Mo_2^{V}O_3$(dipic)$_2$($OPPh_3$)$_2$ which is very resistant to reduction; (ii) $Mo^{IV}O$(dipic)(DMSO) rearranges to $Mo^{VI}O_2$(dipic)(DMS) (PPh_3 is unable to deoxygenate DMSO in absence of MoO_2(dipic)(L) in the same conditions) and the resulting, soft ligand dimethyl sulfide is easily displaced from the coordination sphere of molybdenum. After this, it becomes evident that at least MoO_2(dipic)(DMSO) displays catalytic activity in oxotransfer reactions.

The catalytic activity of MoO_2(dipic)(DMSO) in the oxotransfer from DMSO to PPh_3 has been measured and compared with that of the prototypical $MoO_2(Et_2dtc)_2$ by following the formation of $OPPh_3$ by ^{31}P NMR as previously reported [13]. At 25°C the dithiocarbamate complex showed to be considerably more active than MoO_2(dipic)(DMSO). However, while $MoO_2(Et_2dtc)_2$ decomposes slowly in DMSO at room temperature, MoO_2(dipic)(DMSO) retains its catalytic activity for several days, as shown by addition of new batches of PPh_3 to the original solution.

The oxotransfer from azoxybenzene to PPh_3 has also been examined. Azoxybenzene derivatives are difficult to deoxygenate [25], and because of the low basicity of the azoxy group a weak coordinating solvent is advisable to avoid competition for the molybdenum center.

Fig. 2 shows the transformation of azoxybenzene into azobenzene with a large excess of PPh_3 in hot toluene in presence of $MoO_2(Et_2dtc)_2$ and MoO_2(dipic)(DMSO). The behavior of MoO_2(dipic)(DMF), MoO_2(dipic)(HMPA) and MoO_2(dipic)($OPPh_3$) is closely similar to that of MoO_2(dipic)(DMSO) and the results are omitted for clarity.

After completion of the deoxygenation process, $Mo_2O_3(Et_2dtc)_4$ and $Mo_2^{V}O_3$(dipic)$_2$($OPPh_3$)$_2$ could be isolated. The fact that we were unable to isolate oxomolybdenum(IV) complexes in a large excess of PPh_3 suggests that $Mo_2O_3(Et_2dtc)_4$ and $Mo_2^{V}O_3$(dipic)$_2$($OPPh_3$)$_2$ are the prevalent species in toluene solution, and that the equilibrium represented below — as well

as the analogous for $Mo_2O_3(Et_2dtc)_4$ — is strongly displaced to the left in poor coordinating solvents.

$$Mo_2O_3(dipic)_2(OPPh_3)_2 \leftrightharpoons MoO_2(dipic)(OPPh_3) + MoO(dipic)(OPPh_3)$$

4. Conclusions

(i) A number of air stable dioxomolybdenum(VI) dipicolinates can be easily prepared in good yields by reacting the readily available DMF or DMSO adducts of MoO_2Cl_2 with Na_2dipic, followed by addition of the appropriate ligand. (ii) The compounds, while showing a low catalytic activity in oxotransfer reactions at ambient temperature, display a high activity above 100°C which combined with the thermal stability of the complexes can be exploited in deoxygenation processes otherwise difficult to achieve.

Received 7 February 2000; accepted 21 July 2000

Abstract

The template synthesis of a new open-chain tetra-aza ligand derived from *N*-benzylethylenediamine is reported. X-ray structural analysis of the title compound has been determined. ^{13}C CP-MAS NMR for the $[Ni(benacet)](ClO_4)_2$ complex was made and assignment of the signals was carried out by the use of the open gate decoupling technique and by comparison with the Ni(II) and Zn(II) complexes of the *trans*-[14]diene ligand as well as with the perchlorate salt of the free macrocycle. Based on the type of isolated compound, a hypothesis of the possible mechanism of reaction that explains the formation of the mesityl moiety during the template reaction is discussed. This hypothesis could also be used to explain how in the original reaction made by Curtis, a mixture of *cis*- and *trans*-isomers are formed. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The development of multidentate ligands that form a coordination sphere surrounding a metal ion and particularly the development of synthetic procedures to obtain macrocyclic ligands is of current importance [1]. The relevance of this is due in part, to the interest in preparing simple coordination compounds that could mimic the metallo-biomolecules and their activity [2]. This type of chemistry has been defined as biomimetic chemistry and these new molecules may act as artificial enzymes, artificial oxygen carriers, etc. One of these activities is the oxidative DNA cleavage [3]. In particular, nickel macrocyclic compounds have been found to promote site- and conformation-specific oxidative cleavage of DNA [4]. Muller et al. have demonstrated that reactivity of these macrocyclic nickel complexes, depends upon the in-plane donor strength, flexibility of macrocyclic ligand and to a lesser extent on redox potential [5,6].

Template reactions have been widely studied as a synthetic route for macrocyclic ligands. In particular, the synthesis of tetra-aza macrocycle ligands developed in the 1960s, where the Ni(II) ion was employed as a templating agent, opened a field with great possibilities in preparative chemistry. In this template reaction developed by Curtis [7], the crucial step is a Schiff base condensation between the carbonyl fragment with the primary amine coordinated to the metal ion, and therefore imposing geometric restrictions to the ligand and their reactivity. It has been found that copper(II) can also act as a template agent; however nickel has usually been preferred. The formation of the ligand complexes depends significantly on the dimension of the cavity, the rigidity of the ligand, the nature of the donor atoms and the complexing properties of the anions involved in the reaction. In particular the rigidity of the tetra-aza

ligands will vary extensively depending on whether they are macrocycles, or open chains with or without bulky terminal groups. An example of the first class is the macrocyclic ligand originally prepared by Curtis, [14]diene, (see Fig. 1a); an example for the second group is the analogous ligand with an open chain structure (see Fig. 1b) [7]; however, as far as we know there is no example of direct template synthesis to obtain complexes with ligands of the third class, involving the formation of a mesytil moiety.

In the current investigation, we attempted to gain more insight about the template mechanism in the Curtis-type reaction, as well as the type of structure obtained when the amine employed is a mono-substituted ethylenediamine with a bulky group.

2. Experimental

All reactants and solvents were analytical grade and were used without further purification, with the exception of ethylenediamine which was distilled over NaOH before use.

Infrared spectra were recorded on a Perkin–Elmer 1600 series FTIR on KBr pellets. Electronic spectra were recorded on a Perkin–Elmer model lambda 4B on quartz cuvettes and methanol as solvent. ^{13}C, ^{15}N NMR CP-MAS and solution spectra were recorded on a Varian Unity-Plus spectrometer of 300 MHz equipped with a VT CP-MAS probe and a broad band 5 mm probe for solution. X-ray diffraction data were collected on a Siemens P4/PC diffractometer.

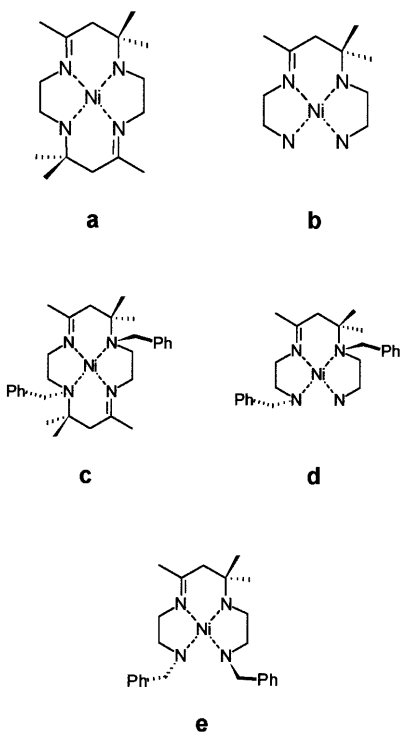

Fig. 1. Products from the Curtis template reaction: (a) the cationic macrocyclic complex: 2,4,4,9,11,11-hexamethyl-1,5,8,12-tetra-aza-tetradecacyclo-1,8-diene nickel(II) ([14]diene); (b) the cationic complex: 5,7,7-trimethyl-1,4,8,11-tetra-aza-undeca-4-ene nickel(II); (c–e) possible isomers obtained from the condensation reaction between $[Ni(ben)_3]^{2+}$ and acetone (see text for explanation).

2.1. Synthesis of products

N-Benzyl-ethylendiamine was prepared according to a previous report [8].

Tris-*N*-benzylethylendiamine nickel(II) perchlorate, $[Ni(ben)_3](ClO_4)_2$, was prepared by adapting a previously reported technique [8–10]. In the original procedure after the precipitate was filtered off, it must be washed with acetone. Instead in this preparation we used a mixture of 2:1 ethanol–ether. The precipitate was collected and dried in vacuum at 80°C. **Caution!** As with all perchlorates this compound is very sensitive and could explode on heating or shaking it. In particular, when this product was recrystallized from a methanol solution, as soon as the solution was concentrated and cooled down a massive precipitation occurred, with the consequent solvent occlusion. At this point the material becomes very sensitive and any movement could produce a violent explosion.

5,7,7,12,14,14-Hexamethyl-1,4,8,11-tetra-azacyclotetradeca-4,11-diene diperchlorate (*trans*-[14]diene perchlorate) and their complexes with Ni(II) and Zn(II) were prepared according to the literature [15].

1,11-Bis-benzyl-5,7,7-trimethyl-1,4,8,11-tetra-aza-undeca-4-ene nickel(II) perchlorate ($[Ni(benacet)](ClO_4)_2$ ($C_{24}H_{36}Cl_2N_4NiO_8$). Formula weight: 638.18, was prepared as follows: 0.830 g of $[Ni(ben)_3](ClO_4)_2$ was dissolved in 50 ml of acetone dried over molecular sieves. The mixture was stirred for 72 h. In the first 3 h the original blue color became reddish–brown and this became darker until it was not possible to appreciate any further change of color. The solution obtained was rota-evaporated until no further condensation of solvent was observed. The oily residue was then dissolved in 25 ml of methanol and stirred for 1 h. After a few minutes a yellow precipitate was formed. This precipitate was filtered off and dried under air-flow. By evaporation of the remaining solution it was possible to obtain even more of the compound. Yield: 0.558 g, 77%. Elemental analysis: Found: C, 44.97; H, 5.65; N, 8.78%. Calc. for $C_{24}H_{36}N_4O_8Cl_2Ni$: C, 45.16; H, 5.64; N, 8.78%.

2.2. Single crystal of 1,11-bis-benzyl-5,7,7-trimethyl-1,4,8,11-tetra-aza-undeca-4-ene nickel(II) perchlorate ($[Ni(benacet)](ClO_4)_2$

Orange prismatic crystals were grown by slow evaporation of a methanol solution, prepared by redissolu-

tion of the obtained product. A specimen of $0.4 \times 0.3 \times 0.3$ mm was selected and mounted on the diffractometer. Unit cell parameters were determined from 50 reflections obtained by incremental (25) and thin shell (25) methods and refined by the least-squares method. Intensities were collected with graphite monochromatized Mo Kα radiation, using the ω-scan technique, with a scan width 0.85° + separation $K\alpha_1$ and $K\alpha_2$ position and variable scan speed 4–60° min^{-1}. 4131 independent reflections were measured in the range. 3687 intensities were collected over the range $2 \leq \theta \leq 28$, 2837 of which were assumed as observed applying the condition $I \geq 2\sigma(I)$. The structure was solved by direct methods and difference Fourier map location using the program SHELXS-86 [11] and refined with SHELXS-97 [12], by full-matrix least-squares. Refinement of F^2 was made against all reflections. The weighted R-factor wR and goodness of fit S are based on F^2, conventional R-factors R are based on F, with F set to zero for negative F^2. The threshold expression of $F^2 > 2\sigma(F^2)$ is used only for calculating R-factors (gt) etc. and is not relevant to the choice of reflections for refinement. R-factors based on F^2 are statistically about twice as large as those based on F, and R-factors based on all data, will be even larger. The quantity minimized was $\Sigma w(F_o - F_c)^2$ where $w = \{\sigma^2(F_o^2) + (0.0649P)^2 + 2.1500P\}^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$. Absorption correction was applied to the data. Hydrogen atoms where calculated geometrically and U-refined isotropically. All other atoms where refined anisotropically. Crystal data, bond distances and bond angles are given in Tables 1–3.

Table 1
Crystal data for the compound $[Ni(benacet)](ClO_4)_2$

Formula	$C_{24}H_{36}Cl_2N_4NiO_8$
Crystal system	Monoclinic
Space group	C_c

Index ranges	$-1<h<27$, $-1<k<13$, $-20<l<17$
Reflections collected	4131
Independent reflections	3687 [$R_{int} = 0.0243$]
Observed reflections	2838 [$F>2\sigma(I)$]
Final R indices (observed data)	0.0472 ($wR = 0.1137$)
Final R indices (all data)	0.0697 ($wR = 0.1283$)
Goodness-of-fit (all)	1.041
Goodness-of-fit (observed)	1.047
Final maximum difference electron density (e Å^{-3})	0.523
Final minimum difference electron density (e Å^{-3})	−0.431
Final average difference electron density (e Å^{-3})	0.066

3. Results and discussion

As stated in the introduction, our interest was focused in gaining insight on the template mechanism involved in Curtis type reactions. The template reaction of tris-*N*-benzylethylenediamine nickel perchlorate with acetone could potentially give several products such as those illustrated in Fig. 1c–e. However we only obtained one product (Fig. 1e).

The orange–yellow product obtained was diamagnetic in the solid state and slightly paramagnetic when dissolved in DMSO or other donor solvents. The infrared spectrum shows the signals due to stretching vibrations ν(N–H) at 3255.1 cm^{-1} and ν(C=N) at 1645.7 cm^{-1}, characteristic for these imino–amino complexes. Electronic spectra in the visible region displayed a symmetric band centered at 456 nm ($\varepsilon = 116$ l mol^{-1} cm^{-1}) when dissolved in acetone, at 454 nm ($\varepsilon = 112$ l mol^{-1} cm^{-1}) in methanol and at 448 nm in water. The maximum blue shift follows almost a linear relationship with the dielectric constant of the solvent (20.7 for acetone, 32.63 for methanol and 78.54 for water). This suggest that axial interaction between the metallic center with the solvent is present and explains the paramagnetic behavior observed in solution.

The molecular structure of $[Ni(benacet)](ClO_4)_2$ is shown in Fig. 2 and bond lengths and bond angles are shown in Tables 2 and 3, respectively. In this compound, the nickel ion displays a square planar coordination surrounded by the ligand with a helical

conformation (see Fig. 2), having only one type of helix present in the crystal. Metal–nitrogen distances in the complex are very similar, however it should be noted that bonds between nickel with N1 and N4, while corresponding to the secondary amines *trans* to each other, are the shortest. The longest one is the Ni–N3 bond, corresponding to the imine group. The sum of the bond angles around nickel is 360.7°, indicative of the high level of planarity in this complex in the solid state.

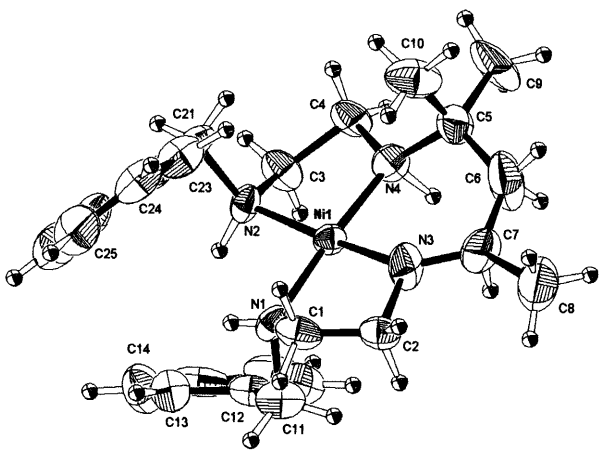

Fig. 2. ORTEP diagram [16], for the $[Ni(benacet)]^{+}$ cationic complex where the square-planar coordination for nickel and the helical structure of the ligand are shown. Observe that one of the benzyl groups is above and the other below the coordination plane.

As stated above, only one helical form of the molecule is present in the crystal. These helical molecules pack in an alternating form, where a self-complementary arrangement between the helixes is observed through a π–π interaction between the aromatic rings of the adjacent molecules. The average distance between the mean plane of one of the phenyl rings to the carbon atoms of the adjacent ring is 3.55(6) Å. The angle formed between the two mean planes is 3.45°. Therefore, the π–π interaction of the phenyl rings and the helical self-complementary arrangement should control packing. A similar type of interaction has been observed in $[Cu(ben)_2(NO_3)_2]$ [9]. This latter complex is differently packed than other *N*-alkyl-ethylenediamine complexes [13,14] supporting the assumption that the π–π interaction between phenyl rings is an important contribution in the driving force for crystal packing.

Because the complex is diamagnetic in the solid state, it was possible to obtain a CP-MAS ^{13}C-NMR spectra. Assignment of the signals was made by a comparative study using the normal spectra and the spectra collected using interrupted decoupling in order to identify the quaternary carbons. The compounds selected for this study were the free macrocycle *trans*-[14]diene (see Fig. 1a) as perchlorate and their metal complexes with Ni(II), and Zn(II). In Fig. 3 are the solid state ^{13}C NMR spectra for these compounds and the assignments made in Table 4. Three different signals for methyl carbons are observed for all compounds, similar to those ^{1}H NMR results previously reported in solution for the [14]-diene complexes. In the imino signal an interesting difference was observed. In the *trans*-[14]diene perchlorate and $[Ni(benacet)]^{2+}$ a single signal was observed, whereas for $[Ni[14]diene]^{2+}$ and $[Zn[14]diene]^{2+}$ complexes two signals were observed (splitting of 117 and 183 Hz for Ni and Zn complexes, respectively).

These observed doublets are due to the dipolar interaction between the imino carbon and ^{14}N. This effect results from the ^{14}N nuclear quadrupole moment interfering with the ability of magic angle spinning and cross polarization to average out carbon–nitrogen dipolar interactions. This splitting is given by [17] (Eq. (1))

$$S_1 = \frac{9\chi D}{20Z}(3\cos^2\beta_{CN} - 1 + \eta\sin^2\beta_{CN}\cos 2\alpha_{CN}) \qquad (1)$$

where D is the dipolar coupling between ^{13}C and ^{14}N ($D = \gamma_C\gamma_N h/4\pi^2 r^3$), Z is the Zeeman energy for ^{14}N, χ is the quadrupole coupling constant, η is the asymmetry in the quadrupole tensor and β_{CN} and α_{CN} are the polar and azimuthal angles between the C–N bond with the principal axis system of the electric field gradient tensor. This coupling is strongly dependent on the inverse

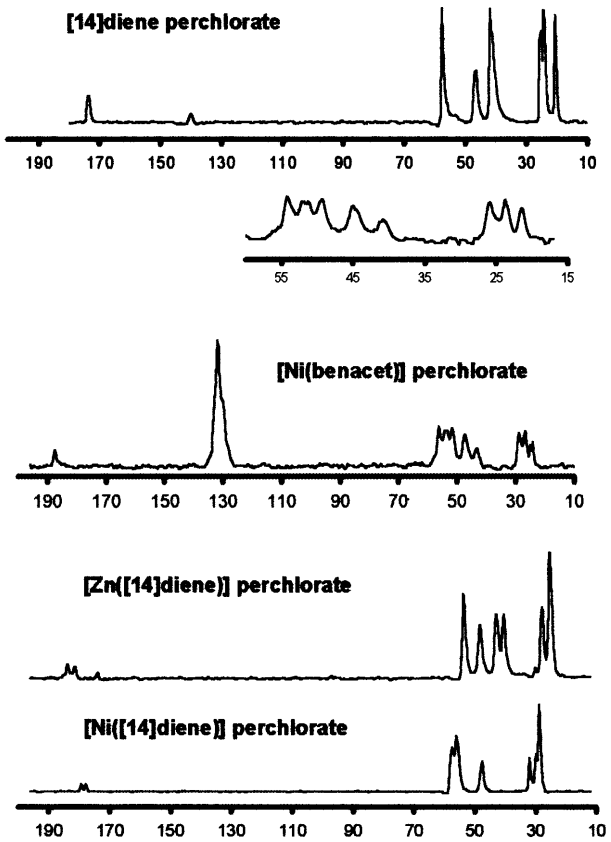

Fig. 3. CP-MAS ^{13}C NMR for the [Ni(benacet)]$(ClO_4)_2$ complex, [14]diene perchlorate and complexes with zinc and nickel.

of the cube of the carbon–nitrogen distance, the field strength, and the asymmetry of the coupling tensor. When the splitting energy is very small then the two peaks are not resolved and only a weighted average peak of the two components is observed. If it is considered that all the parameters in the above equation are similar for all the compounds studied, except in the C–N distance, then for the *trans*-[14]diene and $[Ni(benacet)]^{2+}$ a longer C–N distance than in the nickel and zinc complexes with the [14]diene ligand would be expected.

For the cationic complex $[Ni(benacet)]^{2+}$, a ^{15}N CP-MAS spectra was obtained, with signals at 232.3, −3.4 and −28.6 ppm referred to NH_4Cl (0.0 ppm). These signals were assigned to N3, the imino nitrogen; N4, the nitrogen *cis* to the imino group forming part of the mesityl moiety and N1, N2, the amine nitrogen atoms that have the benzyl groups attached, respectively. This assignment is in agreement with the crystal data described above. In particular, the chemical shift of N4 (−3.4 ppm) could be explained in terms of its geometry. From data in Table 3 it is possible to observe that this nitrogen is distorted from tetrahedral geometry, making that hybridization change from sp^3 to an intermediate between sp^3 and sp^2. This change should affect the shielding on the nitrogen nucleus protecting more than the N1 and N2 that have normal behavior.

In a previous work [9], we reported the crystal structure of $[Cu(ben)_2(NO_3)_2]$, this compound displays a *trans*-arrangement of benzyl residues. Also, similar compounds with *N*-alkyl-ethylenediamine with this arrangement have been reported [13,14]. This difference between $[Cu(ben)_2(NO_3)_2]$ and the $[Ni(benacet)]^{2+}$ where the benzyl residues are in the *cis*-position, suggests that the mechanism of this reaction involves a *cis*-condensation between two adjacent acetoimino groups, and therefore explains why it is required as a starting material to form the tris-*N*-benzylethylenediamine nickel(II) cation. The proposed mechanism is illustrated in Fig. 4.

As a key step, it is required a proton be extracted from one of the methyl groups. This extraction is carried out by free benzylethylenediamine originated from the equilibrium present in solution between the tris-complex and the bis-complex and free base. Then, the quaternary carbon of the neighboring acetoimine is in a good position for a nucleophilic attack carried out

Table 4

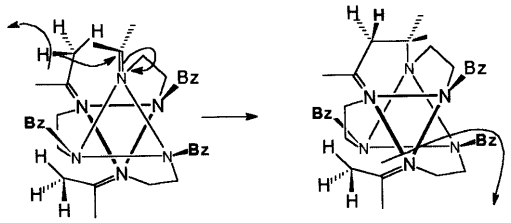

Fig. 4. Scheme illustrating the stereochemical requirements of condensation to form a mesityl residue with two acetoimino groups coordinated to nickel(II) as a possible step in the Curtis-type reaction. A proton extraction is required in the first step in order to obtain nucleophilic attack of the methylene anion to the imino-carbon. After the formation of the mesityl moiety a rearrangement of the new ligand should occur with the consequent elimination of the remaining benzylethylenediamine.

by the methylene anion to form the mesityl moiety. Finally, after this condensation takes place, the tension generated in the system due to the new bond formed is released by rearrangement of the ligand and elimination of the third *N*-benzylethylenediamine, to give the final product, where both benzyl groups are in a *cis*-positions.

This mechanism could also explain the original template reaction between $[Ni(en)_3]^{2+}$, where a mixture of *cis*- and *trans*-$[Ni([14]diene)]^{2+}$ is obtained. The process followed should be the same and once the rearrangement described above takes place, a second mesytil condensation occurs, noting the possibility that proton extraction may occur from any of the acetoimino groups and therefore allowing the formation of a *cis*- or *trans*-complex to take place. Formal kinetic studies are required to validate the proposal of this mechanism for this powerful synthetic reaction.

Finally, the helical structure of the complex reported here opens an interesting field for the development of new, potentially active compounds as oxidative nucleases that could act with more site-specificity. Preliminary studies are currently in progress.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC 139837. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank Dr Sylvain Bernès, USAI, FQ-UNAM, México, D.F., for collecting the diffraction data of the crystal and to Dr S.P. Kasprzyk (Poland) for his valuable suggestions on the synthetic procedure. This work was partially supported by the Dirección de Intercambio Académico of Universidad Nacional Autónoma de México.

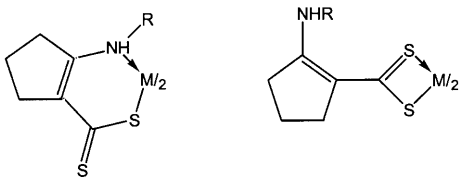
Abstract



Oxovanadium(IV) complexes of the 2-amino-1-cyclopentene-1-dithiocarboxylate (acdc) and 2-methylamino-1-cyclopentene-1-dithiocarboxylate (N–CH_3acdc) anion have been synthesized and characterized by using IR, EPR, magnetic susceptibility and XPS measurements to elucidate the coordination environment of oxovanadium(IV) complexes of the acdc ligand and its derivative. The corresponding spin-Hamiltonian parameters, $\langle g \rangle$ values and hyperfine coupling constants, $\langle A \rangle$ have been examined for the prepared complexes having $VO(IV)N_2S_2$ and $VO(IV)S_4$ chromophore. The EPR data confirm its usefulness in the characterization of the coordination environments of these compounds. The XPS studies have also provided us with valuable information on the binding properties of $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$. The magnetic susceptibility, coupled with the V=O stretching frequency suggest the presence of some degree of magnetic interaction in these compounds. © 2000 Elsevier Science B.V. 1. Introduction

It is becoming increasingly apparent that the chemistry of vanadium is of great importance in many biological systems [1–4]. A more detailed understanding of the nature of vanadium and potentially biologically important ligands such as dithiocarboxylic acid necessitates a detailed knowledge of the coordination environment and oxidation states of the metal within the systems. By studying the molecular structure, electronic structure, and magnetic properties of existing compounds, it is possible to design ligand environments to introduce specific magnetic properties to oxovanadium centers. For example, most dimeric oxovanadium(IV) complexes exhibit an antiferromagnetic exchange interaction [5], and Dutta et al. have observed flexibility and diversity in the electronic and molecular structures of dinuclear vanadium complexes using the tridentate ONS donor ligand system [6]. A number of vanadium complexes having sulfur environments, covering a wide structural variety and oxidation state range, have been synthesized in recent years in order to obtain the above objectives [7–10].

Bereman et al. showed that 2-amino-1-cyclopentene-1-dithiocarboxylate and its derivatives could coordinate to metal ions in bidentate and/or tetradendate coordination modes and form either MN_2S_2 or MS_4 chromophores, depending on the type of metal ions and the geometry of the ligands. A series of M(II) complexes with *N*-alkyl-2-amino-1-cyclopentene-1-dithiocarboxylate have also been prepared and characterized using EPR, electronic absorption spectroscopy and electrochemical methods. Alkyl substituents were found to impose subtle effects on the coordination geometry and physicochemical properties of the central metal ions [11,12].

The 2-amino-1-cyclopentene-1-dithiocarboxylate ligand can coordinate to a metal center in two ways (type I, II). By substitution it should be able to tune the coordination of this ligand from one form to the other. Since the coordination environment around the metal is different, large effects on the electronic and magnetic properties are expected.

In this study we utilize the oxovanadium(IV) ion (d^1 electronic configuration). We show that this metal ion, being harder than copper(II), might prefer the nitrogen donor of the amine unit to the sulfur donor of the dithiocarboxylate unit. The introduction of various alkyl groups on the amino group was carried out to enhance the basicity of the nitrogen donor atom. Previously, the $VO(acdc)_2$ complex was synthesized [13], but the bonding nature of this compound has not been fully characterized. In this paper we report the coordination mode for the complexes $VO(acdc)_2$ and $VO(N–CH_3\text{-}acdc)_2$ and the magnetic interaction on monomeric oxovanadium(IV) complexes in the solid phase via IR, EPR, magnetic susceptibility and XPS.

2. Experimental

2.1. Materials

2 - Amino - 1 - cyclopentene - 1 - dithiocarboxylic acid (Hacdc) and 2-methylamino-1-cyclopentene-1-dithiocarboxylic acid ($N–CH_3$acdc) were prepared by a published method [14]. $VOSO_4·3H_2O$ was purchased from Aldrich Chemical Co. and used without further purification. All solvents were reagent grade and were distilled over 4-A molecular sieves. Spectrophotometric grade acetonitile and methylene chloride (Aldrich) were used for all spectrophotometric measurements. All manipulations were performed under an argon atmosphere using standard Schlenk techniques.

2.2. Preparation of bis(2-amino-1-cyclopentene-1-dithiocarboxylato)oxovanadium(IV), $VO(acdc)_2$

To a solution of $VOSO_4·3H_2O$ (0.217 g, 1.0 mmol) in deaerated 1:1 ethanol–water (20 ml) was added a solution of 2-amino-1-cyclopentene-1-dithiocarboxylic acid (0.319 g, 2.0 mmol) in 25 ml of aqueous sodium hydroxide (2.0 mmol) solution under vigorous stirring. After the addition was completed, the reaction mixture was stirred continuously for 2 h at room temperature under an argon atmosphere. The red–brown solid was filtered, washed successively with deaerated H_2O and EtOH, and dried in vacuo. Yield: 87%. IR (KBr): 3328(m), 3278(w), 3170(m), 3141(w), 1634(s), 1470(s), 1409(m), 1326(w), 1285(w), 946(m), 806(w), 662(w), 568(w), 552(w,br), 430(w) cm^{-1}. Elemental analysis: *Anal*. Found: C, 37.31; H, 4.23; N, 7.66; S, 33.01. Calc. for $C_{12}H_{16}N_2S_4VO$: C, 37.60; H, 4.17; N, 7.31; S, 33.46%.

2.3. Preparation of bis(2-methylamino-1-cyclopentene-1-dithiocarboxylato)oxovanadium(IV), $VO(N–CH_3acdc)_2$

To a solution of 2-methylamino-1-cyclopentene-1-dithiocarboxylic acid (2.0 mmol) in deaerated methanol (50 ml) was slowly added a solution of $VOSO_4·3H_2O$ (0.209 g, 1.0 mmol) in deaerated methanol–water (20 ml), and the mixture was stirred for 2 h at room temperature. The olive-green compound was filtered, washed with warm water, followed by cold methanol, and dried in vacuo. Yield: 63%. IR (KBr): 3412(m), 2928(m), 1610(s), 1492(s), 1381(w), 1346(s), 1281(s), 987(m), 911(w), 759(w), 610(w,br), 434(w) cm^{-1}. Elemental analysis: *Anal*. Found: C, 39.90; H, 4.96; N, 6.84; S, 32.07. Calc. for $C_{14}H_{20}N_2S_4VO$: C, 40.88; H, 4.86; N, 6.81; S, 31.18%.

2.4. Measurements

IR spectra (KBr pellets) were obtained on a Polaris FTIR spectrophotometer over the range 4000–400 cm^{-1}. EPR measurements were carried out with an ESP-300S Bruker spectrometer operating at the X-band frequency (9.45 GHz). The external magnetic field was calibrated with a microwave bridge model ER 032MR Bruker wavemeter and the temperature was controlled with a model ER4111VT Bruker device with accuracy of $\pm 1\%$. Magnetic susceptibility measurements were made on a powered sample over the temperature range 2–300 K using a Foner type100 vibrating sample magnetometer with a field calibrated at 10 000 G using the magnetic susceptibility standard $HgCo(NCS)_4$ [15]. The data were corrected for the diamagnetism of the constituent atoms using Pascal's constants. X-ray photoelectron spectra were recorded on a Perkin–Elmer Physical Electronics model 5400 X-ray photoelectron spectrometer equipped with a magnesium anode X-ray source and a hemispherical analyzer. The residual gas pressure was 5×10^{-9} torr and the binding energies were calibrated using the Au $4f_{7/2}$ peak at 84.9 eV and the Cu $2P_{3/2}$ peak at 932.4 eV. The adventitious C 1S line at 284.6 eV was used for charge referencing. Elemental analyses (C, H, N, and S) were performed at the Korea Research Institute of Standards and Science.

3. Results and discussion

IR spectra of the free ligands are characterized, in part, by prominent bands appearing at approximately 2538 and 1351 cm^{-1} due to $\nu_{N–H}$ and $\nu_{C=S}$ stretching

modes, respectively; these bands disappeared upon complexation to the metal ion (see Table 1). For the $VO(acdc)_2$ complex: (a) the C=S stretching band of the dithiocarboxylate unit is largely shifted to lower frequency at 1326 cm^{-1} upon complexation; (b) the intensity of C–S stretching band is largely reduced; and (c) a new band appears at 662 cm^{-1}. For the $VO(N–CH_3acdc)_2$ complex, the C–N stretching band appearing at 1282 cm^{-1} in the free ligand is shifted to 1288 cm^{-1}. Similar behavior has been observed in the analogous copper and nickel compounds, and is consistent with extensive π-delocalization [13]. In addition, the $VO(N–CH_3acdc)_2$ complex displays a broad band at 3412 cm^{-1}. This band is assigned to the deformation vibration of the amine group of the $NHCH_3$ unit. The intense C=S stretch appearing at 1351 cm^{-1} in the free ligand is shifted to 1385 cm^{-1} upon complexation. The results clearly indicate that the nitrogen of the amine group and the sulfur of the dithiocarboxylate unit of the ligand are coordinated to the oxovanadium(IV) ion. In these two complexes, the frequency of the vanadium–oxygen double bond stretching mode was considered to be directly proportional to the strength of the metal–ligand interaction. However, the shift of $\nu_{V=O}$ has also been found to depend on coordination numbers and the type of donor molecules [16b]. The IR spectrum of $VO(acdc)_2$ shows an intense V=O stretch at 946 cm^{-1}. The relatively low value of $\nu_{V=O}$ is consistent with the rather long V=O bond encountered for most square pyramidal oxovandium(IV) complexes [16a] [17]. The obtained value, $\nu_{V=O}$ for $VO(acdc)_2$ is almost identical to that in $VO(ddc)_2$ (945 cm^{-1}) (ddc = diethyldithiocarbamate) [18], but is substantially lower than those in VO(t-salen) (975 cm^{-1}) (t-salen = *N*,*N*′-ethylenebis(thiosalicylidene-aminato) [19], $VO(mpo)_2$ (984 cm^{-1}) (mpo = 2-mercaptopyridine *N*-oxide) [20], and slightly higher than that in $VO(Hmpp)_2$ (937 cm^{-1}) (H_2mpp = 2-mercapto-3-pyridinol) [21]. On the other hand, a strong V=O terminal stretch appearing at 982 cm^{-1} for $VO(N–CH_3acdc)_2$ is higher in energy than for the $VO(acdc)_2$ complex. In terms of Ballhausen and Gray's molecular orbit Scheme, the π-bonding between the vanadium $3d_{xz}$, $3d_{yz}$ orbitals and the oxygen $2p_x$, $2p_y$ orbitals in V=O bond is largely enhanced when ligand coordination at the sixth axial site (*trans* to the V=O bond axis) is achieved [22]. The frequency for oxovanadium(IV) complexes having $O=V(L)_2$ compositions (L = bidendate ligand) was found to be ca. 985 cm^{-1}. Variation of the frequency of the V=O vibration, due to changes in the environment of the VO^{2+} entity, has been extensively studied [23]. The V=O frequency spread for various oxovanadium (IV) complexes has been reported to be 985 ± 50 cm^{-1}, which approximately corresponds to the force constant spread, $k = 7.0 \pm 0.7$ mdynes $Å^{-1}$. Thus it is tempting to suggest that the shift to lower frequencies of the V=O stretching is due to the transfer of increasing amounts of charge onto the vanadium by ligands of increasing donor strength. Metal to ligand π-bonding is expected to play a significant role in many complexes of this sort. Therefore, the ligand series derived from vibration spectra arises primarily as a result of variations in σ-bonding by the ligands and secondarily as a result of metal-to-ligand π-bonding. However, if the complexes have an intermolecular interaction through the V=O···V=O units [22b], the V=O stretching band will appear at lower frequency. For the $VO(acdc)_2$ complex, the V=O stretching band at 946 cm^{-1} may be due to intermolecular interactions through the inter-chain interaction of V=O···V=O units or a sulfur atom of an equatorial coordinated dithiocarboxylate ligand to vanadium center may simultaneously bond to axial position of another oxovanadium center to form a bridge. These two possibilities do not rule out the intermolecular interaction of the oxovanadium complex. If the reduction of the V=O stretching frequency in the $VO(acdc)_2$ complex is due to intermolecular interactions, the molecular structure must be different in these two complexes. We postulate that the bulky alkyl groups sufficiently alter the vanadium coordination environment and significantly weaken the intermolecular interaction of V=O···V=O chains in $VO(N–CH_3acdc)_2$, leaving the V=O stretching frequency unchanged.

Zelentsov [24] suggested for the magnetic abnormality of oxovanadium(IV) complexes of substituted *N*-(2-hydroxyphenyl)-salicylidenimine which having an oxygen bridged dimeric structure, provides an appropriate symmetry for the 3d orbitals of vanadium(IV) to overlap with each other and form a strong metal–ligand bond. Symal et al. [23], for a series of Schiff base complexes of the type $VO(ONS)_3 \cdot nH_2O$, proposed a binuclear structure on the basis of their subnormal magnetic moment (1.27–1.52 B.M.). Similarly, Poddar [25] and others [26] observed subnormal magnetic moments in the case of oxovanadium(IV) complexes of

bidentate Schiff base and suggested the oxygen bridged dimeric structure independently. Fig. 1 shows the temperature dependence of the magnetic behavior. The complexes exhibit near-straight lines when the inverse value of the susceptibility is plotted against temperature, satisfying the Curie–Weiss equation. At room temperature the observed values of solid-state magnetic moments for $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ complexes are 0.69 and 1.25 B.M., respectively. The moments are slightly lower than the spin-only value ($\mu_{eff} = 1.73$ B.M.) of the expected $3d^1$ configurations. This subnormal magnetic moment may be due to the presence of intra or intermolecular antiferromagnetic coupling, and/or oxidation of V(IV) to diamagnetic V(V). The magnetism of the polycrystalline sample $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ were investigated in the temperature range 2–300 K to confirm whether these complexes are of oxomonomeric- or coupled dimeric-type structure. When the orbital contribution is quenched, the magnetic moment of the complex differs from the spin-only value. This variation results from the two sources: (i) mixing in excited state having some contributions from spin–orbit coupling, and (ii) second-order Zeeman effects (temperature-independent paramagnetism). The temperature dependence of the magnetic moment predicted for a $^2T_{2g}$ ground term in octahedral symmetry is not observed, indicating that the $VO(S_4)$ and $VO(N_2S_2)$ core symmetry for these complexes is lower than octahedral. Therefore, it is expected the $^2T_{2g}(Oh)$ term is split by a near-trigonal field to give an orbital singlet $^2A_1$ as the ground state, consistent with the near-Curie-like $1/\chi_M(T)$ and $\mu_{eff}(T)$ plots, and also with EPR studies. From the variable-temperature magnetic data it should be possible to calculate the spin–orbit coupling constant, λ, for vanadium (IV) by following Figgis's estimation [27]. We obtained the spin–orbit coupling constant, λ as 180 ± 60 cm^{-1}. Thus, the value of the spin–orbit coupling constant is quite large since μ_{eff} values for $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ do not vary much with temperature. The reduction of the spin–orbit coupling constant from its free ion value is indicative of strong delocalization of the metal d-electron to ligand orbitals. The unusually low magnetic moment of the $VO(acdc)_2$ complex at 298 K was calculated from the measured magnetic susceptibility to be $\mu_{eff} = 0.69$ B.M. (vanadium), which may be due to less quenching of orbital contributions than in the mononuclear vanadium(IV) complex ($\mu_{eff} = 1.73$ B.M.), as expected for a simple $S = 1/2$ paramagnet with a d_{xy}-based ground state [28]. Therefore, from the magnetic data together with infrared data, it may be suggested that the $VO(acdc)_2$ complex exhibits a magnetic interaction through the overlap of the d_{xy} magnetic orbital on one monomeric oxovanadim(IV) with intermolecular interaction of V=O units in the solid state.

More compelling evidence could be obtained by conducting single-crystal X-ray studies. However, these complexes are quite unstable and crystal growth has been unsuccessful. Even though we could not determine the molecular crystal structure, we attempted to use EPR measurements and an XPS spectroscopic method to determine the coordination environment of $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$. Fig. 2 shows the X-band EPR spectra of $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ obtained in a CH_2Cl_2 at 77 K, as well as at room temperature. These complexes gave a clear eight-line pattern indicative of ^{51}V hyperfine coupling. The g values ($g_\perp$ and $g_\parallel$) which are well within the characteristic g values for most oxovanadium(IV) compounds having a VOS_4 chromophore [29]. At room temperature, a spectrum of $VO(acdc)_2$ shows to be a typical anisotropic spectrum of a molecule with axial symmetry, and consists of an eight-line hyperfine structure indicative of electron coupling to an $I = 7/2$ ^{51}V species superimposed upon a broad background. The calculated values of $g_o = 1.970$ and $A_o = 1.887 \times 10^{-18}$ erg $= 95 \times 10^{-4}$ cm^{-1} ($a_o = 104$ G) are consistent with those observed for monomeric square-pyramidal oxovanadium(IV) complexes, in which all four coordination sites on the vanadium basal plane are occupied by sulfur atoms. The $VO(N–CH_3acdc)_2$ complex is characterized by a similar spectral pattern, and the corresponding spin-Hamiltonian parameters are $g_\parallel = 1.952$ ($A_\parallel = 182 \times 10^{-4}$ cm^{-1}) and $g_\perp = 1.984$ ($A_\perp = 59 \times$

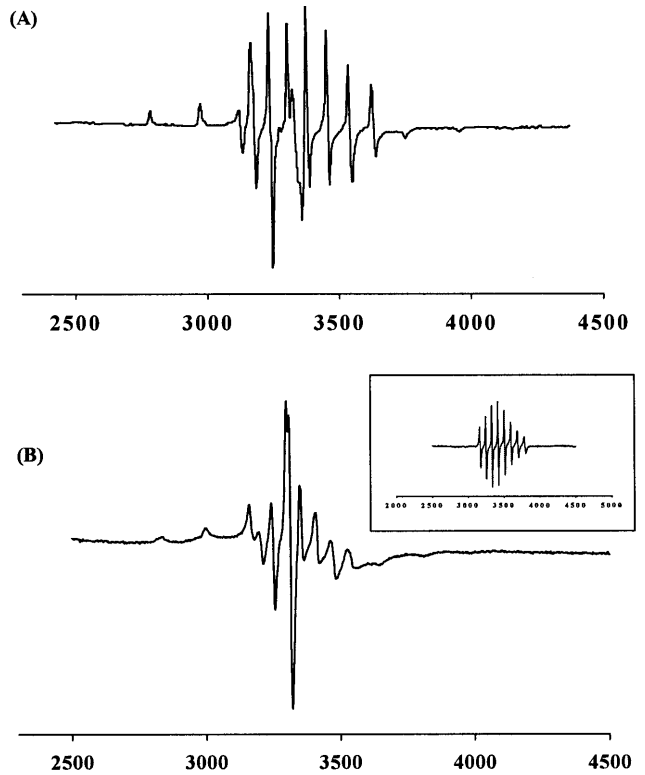

Fig. 2. X-band EPR spectrum of $VO(acdc)_2$ (A) and $VO(N–CH_3acdc)_2$ (B) in CH_2Cl_2 at 77 K; the insert shows the spectrum of $VO(N–CH_3acdc)_2$ at room temperature.

10^{-4} cm^{-1}). The parameters are summarized in Table 2, together with EPR data for complexes with related donor sets. Additional interesting features that deserving mention are the small hyperfine coupling constants and relatively large $g_\perp$ values in comparison to those observed for related complexes featuring N/O donor sets [30,31]. This indicates moderate π-interaction of sulfur in the present ligand system, leading to increased delocalization of the vanadium unpaired electron [32]. Dickson and co-workers have shown that the EPR spectra of various oxovanadium complexes yield hyperfine coupling constants (A_o) and g_o values in reasonable well-defined characteristic ranges for the type of metal–ligand bonds, i.e. g_o values increase and A_o decreases in the series of $VO(O_4)$, $VO(N_2S_2)$, $VO(N_4)$ and $VO(S_4)$ chromophores [33]. In comparison with other square pyramidal VO^{2+} complexes, the $VO(acdc)_2$ complex gives a higher g_o value and a lower A_o value than expected, whereas, the values for $VO(N–CH_3acdc)_2$ are near the average observed for the $VO(S_4)$ and $VO(N_4)$ complex systems. This is consistent with nephelauxetic series, $S > N > O$, suggesting that the sulfur atom is more covalently bound than either nitrogen or oxygen donor ligands, resulting in larger electron delocalization and ultimately a higher g_o value and a smaller A_o value. The difference in $A_\parallel$ values for the $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ complexes reflects the differences in coordination environment of VOS_4 and VON_2S_2 chromophores, respectively, and it reflects well the highly covalent nature of the metal–ligand bonding in VOS_4 chromophores.

X-ray photoelectron spectroscopy (XPS) has been particularly useful in elucidation of the structure of the complexes; it can be used for determining bonding configurations because the technique detects changes in the electronic environment of an atom, as evidenced by shifts in the binding energy of core electrons. Fig. 3 shows the XPS spectrum for the $VO(acdc)_2$ complex, the peak at 516.3 eV corresponds to vanadium $^2P_{3/2}$ in the oxidation state of IV [34]. This shows that the vanadium atoms in the $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ complex are in the same oxidation state, V(IV) and no indication for oxidation of the metal atom in the $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ complex. In general, the core binding energy of N 1s in NH_3 is 398.9 eV, while in the metal complex it shifts to

higher binding energy by ~ 1.0 eV [35]. This binding energy shifts are understandable in terms of the lower electron density on the bonded nitrogen atom as a result of the coordination to a metal ion. If the comparison of the N 1s binding energies of $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ are made, the higher values N 1s binding energies of the $VO(N–CH_3acdc)_2$ reflects the electron-donating properties of the methyl group which, in turn, likely promotes the basicity of nitrogen to participate in chelation with central metal ion. The binding energies of $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ are listed in Table 3. The sulfur ($2p_{1/2,3/2}$) binding energies for $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ are 163.9 and 163.1 eV, respectively. This indicates that the charge on vanadium(IV) within the $VO(acdc)_2$ complex is more delocalized onto the coordinated ligand and resides in large part on the sulfur atoms (equally distributed over the four equivalent sulfur atoms) than in the $VO(N–CH_3acdc)_2$ complex.

4. Conclusions

IR, EPR and XPS studies have provided us with valuable information regarding the coordination environments of the $VO(acdc)_2$ and $VO(N–CH_3acdc)_2$ complexes. Also, magnetic susceptibility data suggest that the magnetic interaction occurring within the two compounds is quite different. Simply introducing a methyl group on the nitrogen of the amine group causes a change in the coordination around the oxovanadium(IV) center. Previously, Choi et al.[36] reported on the basis of EPR studies that copper(II) reacts with 2-methylamino-1-cyclopentene-1-dithiocarboxylate to produce a CuS_4 chromophore and concluded that $Cu(acdc)_2$ and $Cu(N–CH_3acdc)_2$ have the same coordination structure. However, what we have observed in this study shows that both ligands, acdc and $N–CH_3acdc$ are coordinated quite differently to the vanadium(IV) center. Even when enhancement of the basicity of the nitrogen donor of the amine is achieved, copper(II) prefers the sulfur donor of the dithiocarboxylate unit to the nitrogen donor of the amine group. So, the reason why $VO(N–CH_3acdc)_2$ prefers one nitrogen donor of the amine and one sulfur donor of the dithiocarboxylate group is apparently due to the characteristics of the metal center. The copper(II) ion is a d^9 system while VO^{2+} is a d^1 system. The copper(II) ion is softer than vanadium(IV) on the basis of the Hard–Soft Acid–Base model and prefers the more polarizable sulfur donors. The vanadium(IV) center prefers nitrogen and sulfur donors to about the same degree. Therefore, the coordination mode of the 2-amino-1-cyclopenetene-1-dithiocarboxylate and the 2-methylamino-1-cyclopenetene-1-dithiocarboxylate ligand and toward metal ions is not simple to explain. Rather, factors affected by the intrinsic basicity of ligand donors and the hard–soft relationship seem to be intermingled.

Table 3
Binding energies (eV) of oxovanadium(IV) complexes

Compound	Vanadium		N (1s)	S (2p)	O (1s)
	$2p_{3/2}$	$2p_{1/2}$			
$VO(acdc)_2$	516.3	523.5	398.8	163.9	531.3
$VO(N–CH_3acdc)_2$	516.1	523.0	399.7	163.1	531.1

POLYHEDRON

Synthesis, magnetic, spectroscopic and electrochemical studies of mixed pyrimidine-2-thiolate/triphenylphosphine rhenium(V) and rhenium(III) complexes

Abstract

Equimolar amounts of *trans*-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) precursors and potentially bidentate *N*,*S*-donor pyrimidine-2(1*H*)-thione (pymSH) react in refluxing acetone to give mononuclear octahedral paramagnetic *trans*-[$Re^{III}X_2(pymS)(PPh_3)_2$] (X = Cl, Br, I) species. Starting from a metal–ligand molar ratio of 1:3, in the presence of $N(C_2H_5)_3$ as deprotonating agent in refluxing ethanol, the same reaction proceeds stepwise, affording octahedral [$ReO(pymS)_3$] or [$ReO(pymS)_3$] and pentagonal-bipyramidal [$Re(pymS)_3PPh_3$] complexes as a function of the reaction time. The compounds were characterized by elemental analysis, magnetic susceptibility, UV–Vis–NIR, IR and ^1H NMR spectroscopy and by cyclovoltammetric measurements. Reaction pathways and physico-chemical properties of the complexes are discussed. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Thiopyrimidine; Rhenium(V) complexes; Rhenium(III) complexes; Cyclic voltammetry; UV–Vis–NIR, IR, ^1H NMR spectra

1. Introduction

We are particularly interested in sulfur-containing heterocyclic ligands in which the combination of soft (S) and hard (N) donors leads usually to the formation of chelate rings which stabilize rhenium centers in intermediate oxidation states. Recently [1], we have reported that the reaction of 4,6-dimethylpyrimidine-2(1*H*)-thione (Me_2pymSH) with *trans*-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) precursors in 1:1 molar ratio, in refluxing acetone, proceeds step-wise affording rhenium(V), [$ReOX_2(Me_2pymS)(PPh_3)$] (X = Cl, Br, I), or rhenium(V) [$ReOX_2(Me_2pymS)(PPh_3)$] (X = Cl, Br, I), and rhenium(III) *trans*-[$ReX_2(Me_2pymS)(PPh_3)_2$] (X = Cl, Br) mixed octahedral complexes, as a function of the reaction time. In this paper, we report on the reactions of the pyrimidine-2(1*H*)-thione (pymSH), with rhenium(V) *trans*-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) synthons in order to compare the stoichiometry, structure and the chemistry of new rhenium species with related rhenium- Me_2pymS/triphenylphosphine mixed complexes. The pymSH is the simplest and the least sterically demanding 1,3-diazine derivative containing the following group subject to the tautomeric equilibrium:

–NH–C(S)–N=↔=N–C(SH)=N–

The new *trans*-[$ReX_2(pymS)(PPh_3)_2$] (X = Cl, Br, I) complexes and the species [$ReO(pymS)_3$] and [$Re(pymS)_3PPh_3$], whose X-ray crystal molecular structures have been reported by Zubieta et al. [2], were characterized with elemental analysis, electrochemical and magnetic measurements and UV–VIS–NIR, IR and ^1H NMR spectra.

2. Experimental

2.1. Materials

trans-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) synthons [3–5] and pyrimidine-2(1*H*)-thione [6] were prepared by

literature methods. Acetone, ethanol (RPE, C. Erba), dichloromethane (Fluka, over molecular sieves) and deutero-chloroform (100% D, Jansen Chimica) were used as received.

2.1.1. Preparation of the trans-[$ReX_2(pymS)(PPh_3)_2$] (X = Cl, Br, I) complexes

trans-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) precursors (1.0 mmol) and pymSH (1.0 mmol) were suspended in acetone (20 cm^3) and refluxed with stirring for 45 min. On heating, the solutions became clear and dark-brown in color. Upon cooling to 0°C for 12 h, the red–brown crystalline products were filtered off, washed with acetone and dried in vacuo.

2.1.1.1. trans-[$ReCl_2(pymS)(PPh_3)_2$]·0.5C_3H_6O. Found: C, 54.0; H, 3.9; N, 3.0; S, 3.4. Calc. for [$ReCl_2$(pymS)-(PPh_3)$_2$]·0.5C_3H_6O: C, 54.0; H, 3.9; N, 3.0; S, 3.5%. Yield ca. 42%. $\mu_{eff} = 1.72$ BM. Selected IR bands (cm^{-1}), $pymS^-$, ring: 1553m, 1535m; ν(NCN) + ν(NCS) + ν(CS): 1259w, 1185m, 1162ms; ν(Re–Cl): 309vs, 297vs. ^1H NMR ($CDCl_3$), δ(ppm), PPh_3: 13.98(m) [12H], 8.82 (m) [18H]; $pymS^-$: 17.52 (d) [1H, –CH], 13.01(s) [1H, –CH]; 3.65(t) [1H, –C_5H]; acetone: 2.18 (s) [6H, –CH_3].

2.1.1.2. trans-[$ReBr_2(pymS)(PPh_3)_2$. Found: C, 48.8; H, 3.4; N, 2.8; S, 3.2. Calc. for [$ReBr_2$(pymS)(PPh_3)$_2$]: C, 48.9; H, 3.4; N, 2.8; S, 3.3%. Yield ca. 48%. $\mu_{eff} = 1.73$ BM. Selected IR bands (cm^{-1}), $pymS^-$, ring: 1555m, 1538m; ν(NCN) + ν(NCS) + ν(CS): 1258w, 1187s, 1160m; ν(Re − Br): 208m, 189m. ^1H NMR ($CDCl_3$), δ(ppm), PPh_3: 14.23 (m) [12H], 8.81 (m) [18 H]; $pymS^-$: 16.92(s) [1H, –CH]; 12.40(s) [1H, –CH]; 4.21(t) [1H, –C_5H].

2.1.1.3. trans-[$ReI_2(pymS)(PPh_3)_2$]. Found: C, 44.6; H, 3.0; N, 2.6; S, 2.9. Calc. for [ReI_2(pymS)(PPh_3)$_2$]: C, 44.6; H, 3.1; N, 2.6; S, 3.0%. Yield ca. 46%. $\mu_{eff} = 1.76$ BM. Selected IR bands (cm^{-1}), $pymS^-$, ring: 1553m, 1540m; ν(NCN) + ν(NCS) + ν(CS): 1259mw, 1186ms, 1163m; ν(Re–I): 164m, 156m. ^1H NMR ($CDCl_3$), δ(ppm), PPh_3: 14.36(m) [12H], 8.80(m) [18H]; $pymS^-$: 14.62(s) [1H,–CH], 9.91(s) [1H, − CH], 5.28(t) [1H, − C_5H].

2.1.2. Preparation of the [$ReO(pymS)_3$] and [$Re(pymS)_3PPh_3$] complexes

Solid *trans*-[$ReOX_2(OEt)(PPh_3)_2$] precursor (X = Cl or Br or I) (0.6 mmol) was added to a solution of pymSH (1.8 mmol) containing 1.8 mmol of $N(C_2H_5)_3$ in 30 cm^3 of absolute EtOH. The mixture was refluxed under stirring for 2 h. On heating a green microcrystalline solid precipitated immediately and the clear and green solution became red-brown in color. After standing overnight the green compound was filtered off, washed many times with ethanol and dried in vacuum.

2.1.3. [$ReO(pymS)_3$]

Found: C, 26.9; H, 1.6; N, 15.6; S, 17.9. Calc. for [$ReO(pymS)_3$]: C, 26.9; H, 1.7; N, 15.7; S, 17.9%. Yield ca. 80%. Selected IR bands (cm^{-1}), $pymS^-$, ring: 1561vs, 1544vs; ν(NCN) + ν(NCS) + ν(CS): 1260mw, 1179m, 1169ms; ν(Re≡O): 967vs. Upon rotary concentration, the residual brown mother liquor (8–10 cm^3) leads, with time, to the separation of large dark-brown crystals of [$Re(pymS)_3PPh_3$]·EtOH as a minor product of the reaction. The crystals were washed with EtOH, Et_2O and dried in vacuo. Yield ca. 13%.

2.1.4. [$Re(pymS)_3PPh_3$]·EtOH

Found: C, 46.3; H, 3.6; N, 10.0; S, 11.5. Calc. for [$Re(pymS)_3PPh_3$]·EtOH: C, 46.4; H, 3.6; N, 10.1; S, 11.6%. Diamagnetic. Selected IR bands (cm^{-1}), $\nu(OH)_{EtOH}$: 3440mbr; PPh_3,ν(C–C):1582w, 1570w, 1480ms,1432s; ν(P–C): 1090 ms; $pymS^-$, ring: 1550sh, 1544ms; ν(NCN) + ν(NCS) + ν(CS): 1260mw, 1181m, 1155m. The brown [$Re(pymS)_3PPh_3$]·EtOH compound was also obtained with a good yield (ca. 93%), starting from [$ReO(pymS)_3$] and PPh_3 1:4 molar ratio and refluxing the mixture in ethanol for about 3 h.

2.2. Analyses and physical measurements

Elemental analyses (C, H, N, S) were carried out by a C. Erba Elemental Analyzer Model 1110. IR spectra were recorded in KBr pellets (4000–400 cm^{-1}) and in powdered polyethylene pellets (400–50 cm^{-1}) on a Perkin–Elmer 1600 series FTIR and a Bruker-IFS 113 V FTIR spectrophotometers, respectively. Room temperature magnetic susceptibilities were measured by Gouy method and corrected for diamagnetism by Pascal's constants. Conductivity measurements of the complexes, were performed on fresh 10^{-3} mol dm^{-3} solutions in CH_2Cl_2 at 25°C with a Jenway 4020 Conductivity Meter. Diffuse reflectance and solution spectra (in CH_2Cl_2, *C* ca. 10^{-5} and *C* ca. 10^{-3} mol dm^{-3}) between 200–2400nm were recorded on a Perkin–Elmer UV–Vis–NIR spectrometer 19. ^1H NMR spectra of the free ligands pymSH and PPh_3 and their rhenium(III) halide-complexes, were obtained with a Bruker-AMX 400 instrument at 25 ± 0.1°C in $CDCl_3$. The residual signal of $CDCl_3$ at 7.27 ppm was used as internal standard and the chemical shifts were converted to the usual TMS scale. Cyclic voltammetric measurements were performed on 10^{-4}–10^{-5} mol dm^{-3} CH_2Cl_2 (dried over molecular sieves) solutions of the complexes with a PAR Model 273A Potentiostat/Galvanostat under argon at 25°C. Tetrabuthylammonium perchlorate (TBAP) and chloride (TBACl) were used as base electrolytes and the ionic strength of the solutions was kept constant (5×10^{-2} mol dm^{-3}). A three-electrode arrangement was employed with a glassy-carbon working electrode (GC; PAR), a plat-

inum ring (1 cm^2) as a secondary electrode and Hg/Hg_2Cl_2, Cl^-_{sat} in CH_2Cl_2 as reference electrode. Potential scan rate between 0.05 and 0.5 Vs^{-1} were used. All the potential values are referred to the SCE electrode, their accuracy was ± 0.01 V.

3. Results and discussion

3.1. General

At variance with that reported for 4,6-dimethylpyrimidine-2(1*H*)-thione (Me_2pymSH) [1], the reaction of pyrimidine-2(1*H*)-thione (pymSH) with the same synthons, *trans*-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I), carried out with the same procedure (with a molar ratio of 1:1, in refluxing acetone for 10–15 min), does not result initially in the separation of mixed oxo-complexes of the rhenium(V) of the type [$ReOX_2$(pymS)(PPh_3)], but affords directly and exclusively *trans*-[ReX_2(pymS)-(PPh_3)$_2$] (X = Cl, Br, I) rhenium(III) species with yields close to the 50% (trans notation refers to the arrangement of phosphine ligands).

The formation of these paramagnetic, mononuclear, octahedral complexes is undoubtedly the result of a sequence of events (equilibria between isomeric rearrangements, formation of transient intermediate species etc.) that involve as fundamental steps the substitution of trans EtO^- and O^{2-} groups in the precursors and reduction of Re(V) to Re(III) centers. Reduction of Re(V) to Re(III) cannot be due to the oxidation of thiopyrimidine to the corresponding disulfide since under our experimental conditions, the yields in *trans*-[ReX_2(pymS)(PPh_3)$_2$] (X = Cl, Br, I) species are higher than 40% and not close to 33% as it would be expected in the case of oxidation of thiopyrimidine to disulfide. Therefore, it seems probable that the formation of the rhenium(III) pyrimidinethiolate/PPh_3 mixed complexes in acetone can be interpreted in terms of a *trans* → *cis* isomerization of the *trans*-[$ReOX_2(OEt)(PPh_3)_2$] precursors, followed by substitution of pymSH, in thiol form, for EtO^- and an equatorial PPh_3 ligand, with formation of the transient oxo-intermediate of the rhenium(V) species [$ReOX_2$(pymS)(PPh_3)] (X = Cl, Br; I) and the EtOH and PPh_3 compounds. Subsequently, the hypothesized oxo-intermediate reacts rapidly {as reported for the complexes [$ReOX_2(acac)(PPh_3)_2$] (X = Cl, Br, I) [7,8]} with the displaced PPh_3 (2 equiv. of PPh_3 per rhenium(V) are required), evolving to the final mixed pyrimidinethiolate/PPh_3 rhenium(III) (theoretical yield 50%) and $O=PPh_3$ species, according the overall reaction scheme previously reported [1].

In contrast with the behavior of the related *trans*-[$ReX_2(Me_2pymS)(PPh_3)_2$] (X = Cl, Br) complexes [1], the species *trans*-[ReX_2(pymS)(PPh_3)$_2$] (X = Cl, Br, I) in CH_2Cl_2 or $CHCl_3$ solution are stable also in the presence of atmospheric oxygen. In fact, they maintain their color and give electronic and ^{1}H NMR spectra, which are unchanged after 2 days at room temperature. In addition, the pymSH ligand reacts with *trans*-[$ReOX_2(OEt)(PPh_3)_2$] (X = Cl, Br, I) in refluxing ethanol in the presence of $N(C_2H_5)_3$ as deprotonating agent, in 1:3:3 molar ratio, affording mainly the green microcrystalline [$ReO(pymS)_3$] complex (yield ca. 85%), and a brown crystalline [$Re(pymS)_3PPh_3$]·EtOH species as minor product (yield ca. 13%). Despite the different starting materials and preparation methods, the close similarity of the stoichiometry and spectroscopic properties of the present complexes with those structurally characterized reported previously by Zubieta [2], provide strong evidence in favor of identical structures.

3.2. Magnetic moments, vibrational, electronic and ^{1}H NMR spectra

The chloro-, bromo- and iodo-derivatives of the rhenium(III), *trans*-[ReX_2(pymS)(PPh_3)$_2$], show room temperature magnetic moments of 1.73, 1.72 and 1.76 BM, respectively. These values are characteristic of mononuclear complexes with low-spin rhenium(III) (d^4) ions in O_h field [9], and arises because of the large spin-orbit coupling ($\xi = 2500$ cm^{-1} [10]), which gives a diamagnetic ground state.

According with the elemental analyses, the acetone- and ethanol-containing complexes *trans*-[$ReCl_2$(pymS)-(PPh_3)$_2$]·0.5 C_3H_6O and [$Re(pymS)_3PPh_3$]·EtOH, display a medium ν(C=O) and ν(O–H) absorptions centered at 1713 and 3440 cm^{-1}, respectively. The ν(NH) IR bands of pymSH ligand {ν(N–H···S) at 2620 cm^{-1}, for the free ligand in KBr [11]} are absent from the spectra of all the complexes, suggesting deprotonation of the pyrimidine ligand. Confirmation of the presence of the $pymS^-$ anion is given by the absorption bands in the 1600–1500 region, which are attributable to ν(C···C) and ν(C···N) skeletal stretching modes of "aromatic six-membered heterocyclic ring" [12,13]. Furthermore, the lowering in intensity and the shifts to smaller wavenumbers of the strong ligand bands between 1225–1182 cm^{-1} [11,14], assigned to mixed ν(NCN), ν(NCS) and ν(CS) modes, strongly suggest, in accordance with X-ray structural results reported for [$ReO(pymS)_3$], [$Re(pymS)_3PPh_3$] [2] and with related *trans*-[$ReX_2(Me_2pymS)(PPh_3)_2$] (X = Cl, Br) [15] and [$ReCl_2$(pyrS)(PPh_3)$_2$] [16] complexes, an *N*,*S*-chelation of the aromatic $pymS^-$ anion around the rhenium (V) and rhenium(III) ions. Analogously to the complexes having a $[ReO]^{3+}$ core [9], the [$ReO(pymS)_3$] compound shows a very strong IR band at 967 cm^{-1} assignable to ν(Re≡O) mode. In the far-IR region (500–50 cm^{-1}) the [ReX_2(pymS)(PPh_3)$_2$] (X = Cl, Br, I) complexes show, besides the ligand bands and absorptions

due to ν(Re–N), ν(Re–S) and ν(Re–P) modes (whose assignments have not been achieved), two strong or medium bands with a peak-to-peak separation varying from 8 to 12 cm^{-1}, readily assigned to the ν(Re–X) stretching modes of mutually *cis* halides. All the three halide-complexes show similar solid state diffuse reflectance spectra and, when dissolved in CH_2Cl_2 the non-conducting solutions give absorption spectra similar to those of the related solid species (Table 1). From this it follows that the compounds are stable and retain their identity in solution and with time. The solution spectra exhibit intense (ε, 44100–8624 $dm^3\ mol^{-1}\ cm^{-1}$) absorption bands between 230–380 nm that are the result of interligand electronic transitions of $pymS^-$[17] and PPh_3 [18] ligands. In the range 450–850 nm, the spectra show some weaker absorptions (ε, 7805–29 $dm^3\ mol^{-1}\ cm^{-1}$) which fall at higher wavelengths on going from chloro- to the bromo- and iodo-compound. These bands can be assigned to a combination of ligand-to-metal charge transfer and d–d bands. In agreement with that reported previously [1], we tentatively assign the peaks in the range 1800–1833 nm (ε, 132–440 $dm^3\ mol^{-1}\ cm^{-1}$), which are better resolved in the solution spectra, to spin-allowed $^3T_{1g}(\Gamma_3,\Gamma_5) \leftarrow {}^3T_{1g}(\Gamma_1)$ excitations between levels of the ground state $^3T_{1g}(t_{2g}^4)$ split by large spin-orbit coupling. The bands in the regions 1240–1445 nm (ε, 19–38 $dm^3\ mol^{-1}\ cm^{-1}$) and 941–1010 (ε, 4–17 $dm^3\ mol^{-1}\ cm^{-1}$) might be due to the formally spin-forbidden $^1T_{2g}(\Gamma_5) \leftarrow {}^3T_{1g}(\Gamma_1)$ and $^1E_g(\Gamma_3) \leftarrow {}^3T_{g1}(\Gamma_1)$ transitions, respectively.

The ^{1}H NMR spectrum of pymSH ligand in $CDCl_3$ contains a triplet at 7.10 ppm downfield from TMS, assigned to the –C(5)H proton and a peak at 8.60 ppm of intensity 2, assigned to the equivalent –C(4)H and –C(6)H protons. The presence of two unpaired electrons in the *trans*-$[ReX_2(pymS)(PPh_3)_2]$ (X = Cl, Br, I) complexes, affects markedly the resonance signals giving rise to large chemical shifts ($+17$ to $+3$ ppm) and narrow signals due to fast relaxation of the metal center. The sharp doublet of the pymSH free ligand at 8.60 ppm in all the halide-complexes is shifted downfield and split in two singlets, each one of intensity 1, with the –CH proton adjacent to the coordinating nitrogen shifted to higher frequency than the other. The signal of –C(5)H proton of pymSH, is also shifted from 7.10 ppm to 3.65–5.28 ppm range. The *trans*-PPh_3 ligands give rise to a single set of PPh_3 signals and exhibit a pattern which is lightly affected by the nature of the halide: the *ortho* protons appear around 14 ppm (intensity 12) downfield the meta and para protons (8.80–8.84 ppm, intensity 18). The presence of acetone of crystallization in the $[ReCl_2(pymS)(PPh_3)_2]\cdot 0.5C_3H_6O$ complex is confirmed by a singlet around $\delta = 2.18$ ppm, which on integration corresponds to six protons.

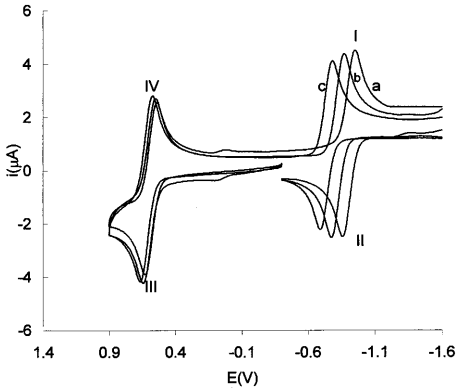

Fig. 1. Cyclic voltammograms for: (a) $[ReCl_2(pymS)(PPh_3)_2]$; (b) $[ReBr_2(pymS)(PPh_3)_2]$. $[ReI_2(pymS)(PPh_3)_2]$ complexes taken in CH_2Cl_2; $C = 4 \times 10^{-4}$ mol dm^{-3}; $v = 0.05$ V s^{-1}.

Both rhenium(V) $[ReO(pymS)_3]$ and rhenium(III) $[Re(pymS)_3PPh_3]$ are air-stable diamagnetic solids. The diamagnetism of the $[ReO(pymS)_3]$ species, according with a structural study [2] (which shows that the rhenium(V) ion adopts a distorted octahedral coordination in which the Re–O bonding of length 1.675 Å is formally a triple bond), is perfectly consistent with that expected from the simple crystal field theory for a d^2 mono-oxo complexes in a roughly C_{4v} symmetry [19]. In fact, taking the z axis as coincident with Re–O bond axis, for a C_{4v} symmetry the lowest energy non-bonding d_{xy} orbital of the rhenium(V) will accommodate the two d-electrons giving a spin-paired complex. The seven-coordinate $[Re(pymS)_3PPh_3]$ complex, contains a Re(III) metal center in a d^4 electronic configuration in an approximate pentagonal-bipyramidal environment [2]. In this geometry (pyramid base in xy plane) two of the three t_{2g} d orbitals (d_{xz}, d_{yz}) are sufficiently lowered in energy [20,21] to contain the two pairs of paired d-electrons to result in a diamagnetic species. The non-conducting CH_2Cl_2 solutions of both $[ReO(pymS)_3]$ and $[Re(pymS)_3PPh_3]$ complexes display electronic spectra (Table 1) showing a good correspondence with solid-state reflectance spectra. This strongly indicates that both species retain their identity in solution with time (after 6 days). A common feature of the absorption spectra of the $[ReO(pymS)_3]$ and $[Re(pymS)_3PPh_3]$ derivatives is the presence of the UV absorption bands (at 230–300 nm) characterizing the chromophore systems of the $pymS^-$ and/or $pymS^-$ and PPh_3 ligands. The most dominant spectral feature of the solution spectra of the green $[ReO(pymS)_3]$ species, are two band envelopes centered at 366 nm ($\varepsilon = 6427$ dm^3 mol^{-1} cm^{-1}) and at 653 nm ($\varepsilon = 250$ dm^3 mol^{-1} cm^{-1}) which contain some components. With reference to previous spectroscopic works on d^2 metal-ligand multiply bonded systems containing a $[ReO]^{3+}$ core [1,22], the relative intensity of the bands between 580–900 nm probably suggests that they are components of a $^3E_g[b_{2g}(xy)^1e_g(xz, yz)^1 \leftarrow b_{2g}(xy)^2]$ excited state that is split by strong spin–orbit coupling interactions [23]. The slightly more intense bands between 366–414nm presumably arise from mixed ligand-to-metal charge transfer and to singlet → singlet $^1E_g[(b_{2g})^1(e_g)^1] \leftarrow {}^1A_g[(b_{2g})^2]$ transitions.

Mononuclear seven-coordinate pentagonal-bipyramidal Re(III) (d^4) species, have not been deeply investigated through electronic spectroscopy. In a D_{5h} field, the five degenerate d orbitals split into three groups, a degenerate $e_1''[(xz), (yz)]$ ground state, a degenerate $e_2'[(x^2-y^2), (xy)]$ excited state and an $a_1'(z^2)$ excited state [24]. The ligand field symmetry in the $[Re(pymS)_3PPh_3]$ compound is lower than D_{5h} owing to distortions due to a $[ReN_3S_3P]$ coordination, which split the e_2' degenerate excited state. If the e_2' state is split by the distortions, then the e_1'' ground state is expected to be split too. Therefore, in accordance with that reported by Drew [25] for a diamagnetic $K_5[Mo(CN)_7]$ complex in which the Mo(II) ($4d^4$) center displays a distorted pentagonal-bipyramidal environment, and considering the energy and intensity of solution ($\varepsilon > 10^3$ dm^3 mol^{-1} cm^{-1}) and solid spectral absorptions, we suggest that the bands between 378 and 730 nm, presumably arise from a combination of d–d and metal–ligand [26] charge transfer transitions.

3.3. Cyclic voltammetry measurements

3.3.1. trans-[$ReX_2(pymS)(PPh_3)_2$] ($X = Cl, Br, I$) complexes

The cyclic voltammetric curves (CV) of these complexes, show two cathodic–anodic coupled peaks (Fig. 1). The corresponding data are reported in Table 2. The analysis of the peak current values, which depend linearly on the concentration of the complexes and on the square root of the potential scan rate, suggests that all the processes are diffusion controlled. The peak to peak separation and the ratio between the currents of the cathodic and anodic peaks also show that both the redox couples are reversible. Finally, the comparison of current values with those of p-NO_2–toluene, whose electrochemical reduction process is monoelectronic and reversible, indicates that all the processes involve one electron. Therefore, the potential peak in the cathodic range corresponds to the reduction process of Re(III) to Re(II) and its anodic counterpart to the oxidation, so the overall process is:

$$[ReX_2(pymS)(PPh_3)_2] + e \leftrightarrows [ReX_2(pymS)(PPh_3)_2]^- \quad (X = Cl, Br, I)$$

The couple in the anodic potential range corresponds to the overall process:

$$[ReX_2(pymS)(PPh_3)_2] \rightleftarrows [ReX_2(pymS)(PPh_3)_2]^+ + e$$

Table 2

[b] $C = 4 \times 10^{-4}$ mol dm^{-3}.

When X = Cl, the complex is more difficult to reduce and is oxidized more easily due to the different coordinating ability of the chloride with respect to bromide or iodide ions. The CV curves of bromo- and iodo-derivatives do not change with time, therefore these complexes are stable. At variance the CV curves of the chloro-complex change with time, in fact it has been demonstrated that this compound loses the ligand molecule (Fig. 2) and completely decomposes in four hours. In the latter case the cyclic voltammetry shows the peaks of the free thiopyrimidine ligand and the solution color changes from yellow–orange to yellow–green first and finally to yellow. This color change suggests a Re(III) → Re(V) oxidative process and it is so remarkable that it can be attributed to a homogeneous reaction involving the bulk complex in solution. This is due to the TBAP used as base electrolyte. In fact this process does not occur in the presence of TBACl. The Re(III) → Re(V) oxidation was confirmed upon electrolytic oxidation of the Re(III) species at $E = 1$ V: indeed the CV curves recorded in TBAP after four hours and in TBACl after anodic electrolysis are identical.

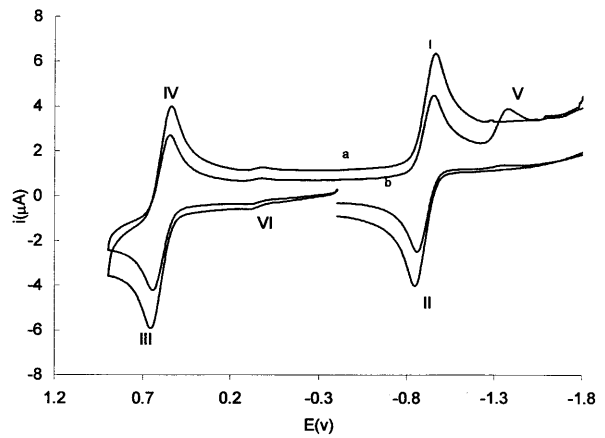

Fig. 2. CV curves of the $[ReCl_2(pymS)(PPh_3)_2]$ complex in CH_2Cl_2 ($C = 4 \times 10^{-4}$ mol dm^{-3}, $v = 0.05$ V s^{-1}): (a) recorded on fresh solution, (b) recorded after 2 h. The cathodic peak V corresponds to the oxidation to the anionic dimeric form $(pymS)_2^-$ due to the partial dimerization of the radical anion. This result agrees with the literature data [27].

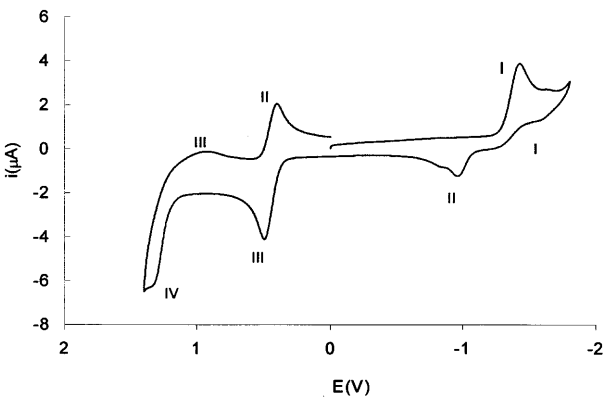

Fig. 3. Cyclic voltammogram of the $[Re(pymS)_3PPh_3]$ complex in CH_2Cl_2. $C = 4 \times 10^{-4}$ mol dm^{-3}, $v = 0.05$ V s^{-1}.

3.3.2. *[Re(pymS)$_3$PPh$_3$] complex*

A typical CV curve of the compound is reported in Fig. 3. The voltammogram shows two cathodic and four anodic peaks. The cathodic peak (I) corresponds to the reduction of Re(III) to Re(II). The process is monoelectronic and diffusion controlled: in fact the i_p values depend linearly on the complex concentration and on the square root of the potential scan rate. Its anodic counterpart shows two peaks (I) and (II): the first is controlled by a homogeneous kinetic process and it can be attributed to a structural modification after the reduction process; the second is diffusion controlled. The sum of the currents of the first and the second anodic peak corresponds to the current value of the cathodic peak and it can be attributed to the oxidation of Re(II) to the Re(III) (reaction 1). The overall process is quasi reversible. In the positive potential range, the Re(III) complex is oxidized in two different monoelectronic steps to Re(IV) (peak III) and Re(V) (peak IV), respectively. These processes are diffusion controlled. The anodic peak (III) shows a cathodic counterpart peak and the process is reversible, while the anodic peak (IV) doesn't show a definite cathodic counterpart and the redox process appears to be quasi reversible (reaction 2 and 3, respectively). The electrochemical data are reported in Table 3. CV curves were repeated several times on the same electrode surface. In all cases the CV curves are reproducible, and this suggests that the electrochemical processes do not cause decomposition of the complex. The overall scheme can be suggested:

$$[Re(pymS)_3(PPh_3)] + e \rightleftarrows [Re(pymS)_3(PPh_3)]^- \quad (1)$$

$$[Re(pymS)_3(PPh_3)] \leftrightarrows [Re(pymS)_3(PPh_3)]^+ + e \quad (2)$$

$$[Re(pymS)_3(PPh_3)]^+ \rightleftarrows [Re(pymS)_3(PPh_3)]^{2+} + e \quad (3)$$

3.3.3. *[ReO(pymS)$_3$] complex*

The CV curve is reported in Fig. 4 The voltammogram shows two cathodic peaks and four anodic peaks. The cathodic peaks I and II and the anodic peaks I and IV are diffusion controlled. The current value of the cathodic peak I is twice with respect to the II and corresponds to the IV anodic peak current. The current value of the cathodic peak II coincides with that of *p*NO_2-toluene, recorded in the same experimental conditions, therefore this peak corresponds to a monoelectronic process. Since the potential value of this peak is similar to that for the reduction of the

Table 4
Comparison of the potential values of $[ReO(pymS)_3]$ and $[Re(pymS)_3(PPh_3)]$complexes. $v = 0.05$ V s, $C = 4 \times 10^{-4}$mol dm^{-3}

Compounds	$-E_{pc}$(I) (V)	E_{pc}(II) (V)	$-E_{pa}$(I) (V)	$-E_{pa}$(II) (V)	E_{pa}(III) (V)	E_{pa}(IV) (V)
$[ReO(pymS)_3]$	0.91	−1.49	1.35	0.81	0.40	1.36
$[Re(pymS)_3(PPh_3)]$	1.47	0.40	1.33	1.03	0.50	1.36

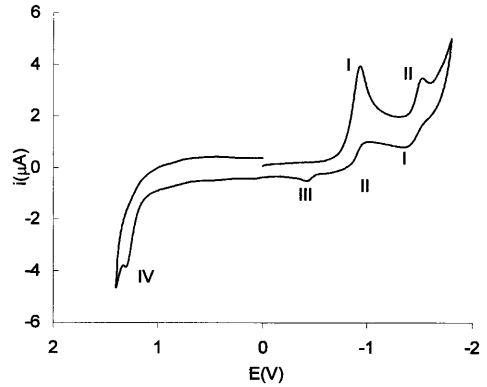

Fig. 4. CV curve of the $[ReO(pymS)_3]$ compound in CH_2Cl_2. $C = 4 \times 10^{-4}$mol dm^{-3}, $v = 0.05$ Vs^{-1}.

$[Re(pymS)_3(PPh_3)]$ complex to Re(II) species, we may attribute it to the same reduction process (Table 4). Also the corresponding oxidation process shows a behavior similar to that shown by the $[Re(pymS)_3(PPh_3)]$ complex, therefore the anodic peaks I and II indicate the oxidation of the Re(II) to Re(III) (reaction 5). The anodic peak III can be attributed to an adsorption process of the electrochemical product. The first cathodic peak corresponds to the reduction of the Re(V) complex to Re(III) species (reaction 4). The potential value of the anodic peak IV corresponds to the oxidation to Re(V) (reaction 6) and the current value indicates that it is a bielectronic process. This peak does not show a clear cathodic counterpart. The CV curves of the complex, repeated on the same electrode surface, do not change, suggesting that this compound is stable in electrochemical processes.

$$[ReO(pymS)_3] + 2e \rightarrow [ReO(pymS)3]^{2-} \quad (4)$$

$$[ReO(pymS)_3]^{2-} + e \rightleftarrows [ReO(pymS)_3]^{3-} \quad (5)$$

$$[ReO(pymS)_3]^{2-} \rightarrow [ReO(pymS)_3] + 2e \quad (6)$$

The electrochemical data are reported in Table 4. The electrochemical behavior of the $[ReO(pymS)_3]$ complex is not modified by the O_2 presence. In fact, degassing the saturated O_2 solution, the voltammogram corresponds to the initial CV curve of the compound.

POLYHEDRON

Alkyne complexes of tungsten(II) containing carboxylate and sulfonate substituted pyridine ligands. Water-soluble alkyne complexes of tungsten(II)

Paul K. Baker *, Alyn E. Jenkins, Margaret M. Meehan

Department of Chemistry, University of Wales, Bangor, Gwynedd, LL57 2UW, UK

Received 14 March 2000; accepted 24 July 2000

Abstract

Reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) with one equivalent of L{L = 3-(CO_2Na)-py, 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} in a mixture of CH_2Cl_2–CH_3OH (1:1 ratio) at room temperature gave the acetonitrile replaced products, $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1**–**10**) in good yield. The 2-butyne complexes are slightly water-soluble, whereas the diphenylacetylene complexes are insoluble in water. Treatment of $[WI_2(CO)_3(NCMe)_2]$ with two equivalents of propiolic acid (HC_2CO_2H) in CH_2Cl_2 at 0°C yields the bis(propiolic acid) complex $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$ (**11**). Reaction of **11** with two equivalents of NaOH in MeOH–CH_2Cl_2 (1:1) affords the completely water-soluble complex, $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2Na)_2]$ (**12**) in 58% yield. All the new complexes **1**–**12** were characterised by elemental analysis (C, H, and N), IR and ^1H NMR spectroscopy. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Tungsten(II); Carboxylate and sulfonate substituted pyridines; Propiolic acid; Water soluble complexes

1. Introduction

The importance of water-soluble organometallic complexes in catalytic processes has become increasingly important in recent years [1,2]. Although a wide range of water-soluble organometallic complexes which have attached water-solubilising phosphine ligands have been described [3], far fewer containing water-solubilising nitrogen donor ligands have been reported. Herrmann et al. [4,5] have described several water-soluble metal-carbonyl complexes containing 2-(2′-pyridyl) pyridine-5-sulfonate as a water solubilising bidentate nitrogen donor ligand. Since our preliminary report in 1995 [6], of the first water soluble seven-coordinate complexes of tungsten(II) containing carboxylate and sulfonate substituted pyridine ligands, we have extended this work to zero-valent tetracarbonyl complexes of molybdenum and tungsten [7], and π-allyl dicarbonyl complexes of molybdenum(II) [8].

In 1986 [9], we described the reaction of the zero-valent complexes *fac*-$[M(CO)_3(NCMe)_3]$ (prepared in situ) with one equivalent of iodine at 0°C to give quantitative yields of the seven-coordinate complexes $[MI_2(CO)_3(NCMe)_2]$. In 1988, [10], we described the reactions of $[WI_2(CO)_3(NCMe)_2]$ with RC_2R (R = Me, Ph) to give the bis(alkyne) complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$, both of which have been structurally characterised. The chemistry of the seven-coordinate complexes $[MI_2(CO)_3(NCMe)_2]$ and the alkyne complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$(R = Me, Ph) has been extensively studied [11,12]. In this paper we describe the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$-(R = Me,Ph) with one equivalent L {L = 3-(CO_2Na)-py, 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} to give the complexes, $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$, and the synthesis of $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$, and its conversion to the completely water soluble complex, $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2Na)_2]$.

2. Experimental

All reactions described in this paper were carried out under an inert atmosphere of dry nitrogen using standard vacuum/Schlenk line techniques. The starting materials used in this research, namely $[WI_2(CO)_3(NCMe)_2]$ [9] and $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ [10] were prepared by literature methods. All chemicals used were purchased from commercial sources.

Elemental analyses (C, H and N) were determined using a Carlo Erba Elemental Analyser MOD 1108 (using helium as a carrier gas). Infrared spectra were recorded as KBr discs. ^{1}H NMR spectra were recorded on a Bruker AC 250 NMR spectrometer in DMSO-d_6 referred to $SiMe_4$.

2.1. Preparations

2.1.1. $[WI_2(CO)\{3\text{-}(CO_2Na)\text{-}py\}(\eta^2\text{-}MeC_2Me)_2]$ (1)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.2 g, 0.325 mmol) dissolved in a 1:1 mixture of $EtOH/CH_2Cl_2$ (30 ml) was added 3-(CO_2Na)-py (0.047 g, 0.325 mmol). The solution was stirred for 3 h, at room temperature (r.t.), and the reaction mixture filtered through Keiselguhr. The solvent was removed in vacuo to give a yellow product. Recrystallisation of this product from $EtOH/CH_2Cl_2$ yielded the pure compound, $[WI_2(CO)\{3\text{-}(CO_2Na)\text{-}py\}(\eta^2\text{-}MeC_2Me)_2]$ (**1**) (Yield = 0.21 g, 88%).

Similar reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with one equivalent of L {L = 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} gave the new complexes $[WI_2(CO)L(\eta^2\text{-}MeC_2Me)_2]$ (**2**–**5**).

2.1.2. $[WI_2(CO)\{3\text{-}(CO_2Na)\text{-}py\}(\eta^2\text{-}PhC_2Ph)_2]$ (6)

To a solution of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (0.25 g, 0.29 mmol) dissolved in a 1:1 mixture of $MeOH–CH_2Cl_2$ (30 ml) was added 3-(CO_2Na)-py (0.042 g, 0.29 mmol). The reaction mixture was stirred for 24 h, at r.t.; the solution was filtered over Keiselguhr and the solvent removed in vacuo giving a black product. The product was recrystallised from $MeOH–CH_2Cl_2$ at −17°C to give the analytically pure product, $[WI_2(CO)\{3\text{-}(CO_2Na)\text{-}py\}(\eta^2\text{-}PhC_2Ph)_2]$ (**6**). (Yield = 0.14 g, 52%).

In similar reactions, $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ was dissolved in a 1:1 mixture of $MeOH–CH_2Cl_2$, and reacted with one equivalent of L {L = 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} to give the products, $[WI_2(CO)L(\eta^2\text{-}PhC_2Ph)_2]$ (**7**–**10**).

2.1.3. $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$ (11)

To $[WI_2(CO)_3(NCMe)_2]$ (0.5 g, 0.832 mmol) dissolved in CH_2Cl_2 (20 cm^3) was added HC_2CO_2H (0.1 g, 1.664 mmol). The solution was allowed to stir for 1 h at 0°C during which a red precipitate formed. The solvent was removed via a syringe and the product dried in vacuo to give the analytically pure product, $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$ (**11**) (Yield = 0.41 g, 76%).

2.1.4. $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2Na)_2]$ (12)

To a solution of $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$ (0.3 g, 0.464 mmol) dissolved in a 1:1 mixture of $MeOH–CH_2Cl_2$ (30 ml) was added NaOH (0.04 g, 0.928 mmol). The reaction mixture was stirred for one hour, after which the solution was filtered over Keiselguhr, and the solvent removed in vacuo giving a yellow product, which was recrystallised from H_2O–hexane at −17°C to give the analytically pure product, $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2Na)_2]$ (**12**) (Yield = 0.19 g, 58%).

3. Results and discussion

The reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with one equivalent of L in a 1:1 mixture of CH_2Cl_2 and CH_3OH at r.t. gave $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ {R = Me, Ph; L = 3-(CO_2Na)-py, 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} (**1**–**10**) with the acetonitrile ligand being replaced by L. The complexes were characterised by elemental analysis (Table 1), IR spectroscopy (Table 2) and ^{1}H NMR spectroscopy (Table 3). The complexes were stable in the solid state when stored under dinitrogen at −17°C, but were very unstable in air when in solution. The complexes were soluble in dimethylsulfoxide, acetone and methanol, sparingly soluble in dichloromethane. The 2-butyne complexes **1**–**5** are slightly soluble in water, whereas the diphenylacetylene complexes **6**–**10** are insoluble in water. The total insolubility in water of the diphenylacetylene complexes **6**–**10** is probably due to the phenyl rings in the diphenylacetylene ligand.

The IR spectra of complexes **1**–**10** showed one strong carbon monoxide stretching band between 2071 and 2012 cm^{-1}. An alkyne absorption was also observed between 1668 and 1602 cm^{-1} for complexes **1**–**10**. These bands are of much lower wavenumber than for the uncoordinated alkyne due to the back donation into empty π* antibonding orbitals of the coordinated alkyne. Carbonyl stretching bands for the carboxylate units were observed for the complexes **1**–**4** and **6**–**9** between 1700 and 1733 cm^{-1}. The complexes $[WI_2(CO)\{3\text{-}(SO_3Na)\text{-}py\}(\eta^2\text{-}RC_2R)_2]$ (**5**) and (**10**) have an S=O stretching band at 1224 cm^{-1}.

The ^{1}H NMR spectra (Table 3) of complexes **1**–**5**, showed two singlets which can be assigned to the protons of the 2-butyne ligands. The proton assignments of the substituted pyridine ligands is shown in Fig. 1. The complex $[WI_2(CO)\{3\text{-}(CO_2Na)\text{-}py\}(\eta^2\text{-}MeC_2Me)_2]$ (**1**) showed resonances at 9.4 (H_a), 9.1 (H_b), 8.7 (H_c) and 7.0 ppm (H_d). The complexes **6**–**10** showed

[a] Calculated values in parentheses.

broad multiplets at around 7.3 ppm in their ^{1}H NMR spectra, which can be attributed to the hydrogens of the diphenylacetylene ligand. The pyridine protons in the complexes **6**–**10** have similar resonances to those observed in complexes **1**–**5** respectively. The structure of the compounds **1**–**10** is very likely to be very similar to those of $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ {L = NCMe, R = Me, Ph [10]; L = NCBu^t, R = Me [13]; L = $NCCH_2(3\text{-}C_4H_3S)$, R = Me [14]; L = CO, R = Me [15]}. The proposed structure for complexes **1**–**10** is shown in Fig. 2.

The reactions are likely to proceed via an associative mechanism with the formation of a seven-coordinate adduct, $[WI_2(CO)(NCMe)L(\eta^2\text{-}RC_2R)_2]$, in which each alkyne ligand donates two electrons to the metal. The loss of the acetonitrile ligand from the intermediate would allow the alkynes to donate an average of three electrons each to the metal as in the acetonitrile complexes, $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$. Associative mechanisms for ligand substitution reactions of molybdenum(II) and tungsten(II) have been previously proposed for this type of reaction [16,17]. Attempts to protonate **1**–**5** with $H[BF_4]$ were unsuccessful. Although reactions occurred in each case, no identifiable products could be isolated from these reactions.

The starting materials $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) were reacted with two equivalents of L {L = 3-(CO_2Na)-py, 4-(CO_2Na)-py, 3,4-$(CO_2Na)_2$-py, 3,5-$(CO_2Na)_2$-py, 3-(SO_3Na)-py} for 24 h in a mixture of dichloromethane and methanol at r.t. did not give the expected cationic complexes $[WI(CO)L_2(\eta^2\text{-}RC_2R)_2]I$ [18]. The elemental analysis results for the products formed did not correspond to the calculated values for $[WI(CO)L_2(\eta^2\text{-}RC_2R)_2]I$, the expected products we have previously observed from the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with simple pyridines [18]. For all of the complexes formed the analytical data were in agreement with the values expected for the reaction of $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ with one equivalent of L. The experiments were repeated by refluxing for 24 h to see if a second substituted pyridine ligand could be coordinated to the tungsten. However, the results were comparable with the reactions carried out at r.t.

Another approach to preparing a water-soluble alkyne complex of tungsten (II) was made by reacting the seven-coordinate complex $[WI_2(CO)_3(NCMe)_2]$ with two equivalents of propiolic acid (HC_2CO_2H) in dichloromethane at 0°C for one hour gives $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$(**11**). The complex was fully characterised (Tables 1–3), but was not water-soluble. In an attempt to make the alkyne complex water-soluble, the complex $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2H)_2]$(**11**) was reacted with two equivalents of NaOH in MeOH–CH_2Cl_2 (1:1) at r.t. for thirty minutes, affording the completely water-soluble complex $[WI_2(CO)(NCMe)(\eta^2\text{-}HC_2CO_2Na)_2]$(**12**). Complex **12** was characterised by elemental analysis (Table 1), IR spectroscopy (Table 2) and ^{1}H NMR spectroscopy (Table 3). Since proton resonances for the terminal alkyne protons (C≡C-*H*) for **11** and **12**, appear at $\delta = 7.1$ and 7.3 ppm, respectively, it is likely [19], the alkynes are donating a total of six-electrons to the

tungsten in these complexes. This enables **11** and **12** to obey the effective atomic number rule.

Although no suitable single crystal was grown for X-ray crystallography, the structure of the complexes **11** and **12** (see Fig. 3) is likely to be similar to the structure of other [WI_2(CO)(L)(η^2-RC_2R)$_2$] complexes which have been characterised crystallographically [10,13–15]. The formal geometry of the complexes is eight-coordinate, but they can be considered to be six-coordinate with each alkyne ligand occupying a single coordination site. The two iodine atoms are mutually *cis*-, and each is *trans*- to an alkyne ligand. The acetonitrile ligand lies *trans*- to the C≡O group. The IR spectra of the complexes **11** and **12** have C≡O stretches at 2018 and 2013 cm^{-1}, respectively, C=O stretches at 1730 and 1728 cm^{-1} and C≡C stretches at 1674 and 1661 cm^{-1}, respectively.

In conclusion, we have described the preparation and characterisation of the first example of a totally water-soluble bis(alkyne) complex of tungsten(II). In view of many complexes derived from [WI_2(CO)(NCMe)(η^2-RC_2R)$_2$] being alkene metathesis catalysts [20], being able to induce water solubility in this type of complex is an important breakthrough.

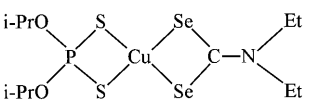
Abstract



Photolysis of the ternary system consisting of diethyldiselenocarbamate (Et_2dsc), diisopropyldithiophosphate (i-Pr_2dtp) and copper(II) (1:1:1) has been studied in toluene, CH_2Cl_2, $CHCl_3$, CCl_4 and chloroalkane–EtOH solutions. The results obtained by EPR techniques and UV–Vis data indicate that a homolytic Cu–S bond cleavage involving dtp ligand appears as the primary photoprocess in Cu(dsc)(dtp) photolysis. Further conversion of the primary photoproduct $Cu^{I}(Et_2dsc)$ is discussed in terms of specific interaction with the solvent. According to quantum yield data solvent efficiencies in photolysis could be related to their oxidizing power. A reaction mechanism is proposed well fitting the experimental results. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: CT photochemistry; Ternary copper(II) complexes; Diselenocarbamate and dithiophosphate ligands

1. Introduction

In recent papers [1,2] we have described the photochemical behaviour of bis(diethyldiselenocarbamato)-Cu(II), $Cu(Et_2dsc)_2$, and bis(diisopropyldithiophosphato)Cu(II), $Cu(i\text{-}Pr_2dtp)_2$, in aprotic solvents. The results obtained show that the primary photochemical act in both complexes is an intramolecular electron transfer from the equatorially bound Se (resp. S) atom of the ligand to copper(II) yielding the corresponding complex of copper(I) and the free radical from the ligand. Further reactions of the primary photoproducts are related to the redox properties of both ligands and solvents. It was also found that upon irradiation in the corresponding charge transfer band the quantum yield of $Cu(dsc)_2$ photolysis is lower than the value obtained for $Cu(dtc)_2$ in the same solvent.

In the present paper we report our data on the photochemical properties of the ternary Cu(dsc)(dtp) complex obtained with ligands of chemically different donor sets as a part of our study on the photochemistry of copper(II) chelate complexes with different chromophores.

2. Experimental

2.1. Starting materials

The complex bis(diethyldiselenocarbamato)Zn(II) was obtained and purified following a literature procedure [3,4]. Diisopropyldithiophoshoric acid and its sodium salt were prepared as previously described [5]. $CuSO_4.5H_2O$ (p.a.) was obtained from Fluka and used without further purification. The solvents were used after distillation.

2.2. Preparation of compounds

The parent complexes $Cu(Et_2dsc)_2$ and $Cu(i\text{-}Pr_2dtp)_2$ were prepared by standard literature methods [1,2,4,5]. The ternary complex Cu(dsc)(dtp) was obtained according to the reaction:

$$Cu(Et_2dsc)_2 + Cu(i\text{-}Pr_2dtp)_2 = 2Cu(dsc)(dtp) \quad (1)$$

by mixing the corresponding equimolar solutions of $Cu(Et_2dsc)_2$ and $Cu(i\text{-}Pr_2dtp)_2$ to obtain Cu:dtc:dtp = 1:1:1. The initial solutions of the parent complexes were prepared by weighing and dissolution of the appropriate amounts.

2.3. Instrumentation

The EPR spectra were taken at room temperature on an X-band Bruker ER 200D-SRC spectrometer. The standard ER4202ST rectangular cavity (TE_{102} mode) was used. The microwave power was 3 mW and 2 G modulation amplitude of the magnetic field (at 100 kHz) during all experiments.

The electronic absorption spectra were recorded on a Specord UV–Vis (Carl Zeiss, Jena) spectrophotometer using quartz cells to record in the 250–750 nm region.

All measurements were performed at room temperature (293 K).

2.4. Irradiation and quantum yields

Photolysis experiments were performed with the full spectrum of a 250 W medium-pressure mercury lamp or through a solution filter to separate the 436 nm mercury line [5] as described previously [1,2]. For quantum yield determination the complex concentrations were such as to have essentially complete light absorption. The total amount of photolysis was limited to less than 5% to measure the quantum yield of the primary photoprocess. No correction was made for internal filter effects. The absorption values at the visible LMCT band were used to determine the concentration change of the complex during the photolysis. The incident light intensity was determined immediately after each photolysis by a ferrioxalate actinometric method [5]. At least three determinations of quantum yields were made for each complex. Photolyses of all complexes were carried out at 20 ± 1°C. The accuracy of the quantum yield measurements was found to be within 20–25%. Photolysis reactions were also monitored by measuring the UV–Vis and EPR spectra directly in the photolysis cell or by removing aliquots at various intervals to record UV–Vis absorption.

3. Results and discussion

3.1. EPR spectrum of Cu(dsc)(dtp)

The isotropic EPR spectra of the ternary complex Cu(dsc)(dtp) in $CHCl_3$, CH_2Cl_2, acetone and toluene are compared in Fig. 1 with the spectra of the parent complexes $Cu(Et_2dsc)_2$ and $Cu(i\text{-}Pr_2dtp)_2$. It is seen from Fig. 1 that the newly obtained spectrum of Cu(dsc)(dtp) exhibits four hyperfine lines due to the interaction of the copper unpaired electron with $^{63,65}Cu$ nucleus ($I = 3/2$) which are additionally split into superhyperfine (shf) lines by one ^{31}P and one ^{77}Se nuclei both with nuclear spins $I = 1/2$. However, since the natural abundance of ^{77}Se is 7.5%, only 15% of the molecules of the ternary complex contain one ^{77}Se nucleus. Thus in fact the recorded spectrum of Cu(dsc)(dtp) is a superposition of two EPR signals, one containing ^{77}Se and the other corresponding to the remaining Se isotopes ($^{74,76,78,80,82}Se$). The estimated EPR parameters of Cu(dsc)(dtp) are: $g_o = 2.034 \pm 0.002$; $A_o(^{63,65}Cu) = 78 \pm 1$ G; $A_o(^{77}Se) = 48 \pm 1$ G; $A_o(^{31}P) = 7.5 \pm 0.5$ G. The obtained g_o and $A_o(^{63,65}Cu)$ values are the average of the corresponding parameters of the parent $Cu(Et_2dsc)_2$ and $Cu(i\text{-}Pr_2dtp)_2$ complexes which are $g_o = 2.020 \pm 0.002$; $A_o(^{63,65}Cu) = 80 \pm 1$ G; $A_o(^{77}Se) = 46 \pm 1$ G about $Cu(Et_2dsc)_2$ and $g_o = 2.046 \pm 0.002$; $A_o(^{63,65}Cu) = 73 \pm 1$ G; $A_o(^{31}P) = 9.5 \pm 0{,}5$ G about $Cu(i\text{-}Pr_2dtp)_2$, respectively. Therefore, the considered EPR parameters indicate an average covalence within the chromophore CuS_2Se_2 of the ternary Cu(dsc)(dtp) complex as compared to the parent bis-chelates with CuS_4 and $CuSe_2$ chromophores according to the 'additive rule' [6,7]. This effect is due to the fact that unpaired electron occupies a 'group' orbital in which Cu and four donor atoms of the chromophore are included and the magnitudes of the EPR parameters g and A are averaged as a result. However, this is not the case with ^{31}P shf split-

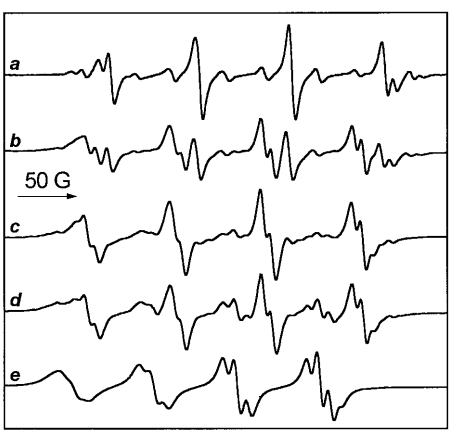

Fig. 1. EPR spectra taken after mixing of $Cu(dsc)_2$ with $Cu(dtp)_2$. The ratio $Cu(dsc)_2/Cu(dtp)_2$ is: (a) 1:0; (b) 2:1; (c) 1:1; (d) 1:2; (e) 0:1. Spectrum (c) corresponds to the Cu(dsc)(dtp) complex. Solvent: $CHCl_3$, $T = 298$ K.

Table 1
Values of λ_{max} (nm) for the complexes $Cu(Et_2dsc)(i\text{-}Pr_2dtp)$, $Cu(Et_2dsc)_2$ and $Cu(i\text{-}Pr_2dtp)_2$ in various solvents

Solvent	$Cu(Et_2dsc)(i\text{-}Pr_2dtp)$	$Cu(Et_2dsc)_2$	$Cu(i\text{-}Pr_2dtp)_2$
CH_2Cl_2	452	495	420
$CHCl_3$	455	495	420
CCl_4	455	495	420
Toluene	450	495	420
Acetone	453	495	417

ting constant which may be used [8] as the probe of precise unpaired electron distribution in mixed-ligand complexes. In the case of Cu(dsc)(dtp) ternary complex the magnitude of ^{31}P shf splitting from dtp ligand is lower than in the parent $Cu(dtp)_2$ complex, suggesting a shift of the unpaired electron density from this ligand to dsc. In the same time, ^{77}Se shf splitting in the mixed-ligand Cu(dsc)(dtp) complex is higher than in the parent $Cu(dsc)_2$. As seen from Fig. 1, equilibrium in reaction (1) is practically shifted to the right.

3.2. UV–Vis spectra of Cu(dsc)(dtp)

The visible absorption of Cu(dsc)(dtp) is due to the strongly allowed ligand to metal charge transfer (LMCT) band which appears near to 455 nm in CH_2Cl_2, $CHCl_3$, CCl_4, toluene and acetone (Table 1). Similar to the corresponding EPR parameters, the obtained λ_{max} values of Cu(dsc)(dtp) are close to the average magnitudes of λ_{max} of the parents LMCT bands which are at 495 nm about $Cu(Et_2dsc)_2$ and 420 nm about $Cu(i\text{-}Pr_2dtp)_2$.

3.3. Continuous photolysis

Solutions of Cu(dsc)(dtp) in toluene, acetone and chloroalkanes could be kept for several days in the dark without any changes in their UV–Vis and EPR spectra. The complex undergoes photolysis when irradiated with UV or visible light of $\lambda < 450$ nm. In general, the irradiation produces a colour change in solution, accompanied by changes in their UV–Vis and EPR absorption.

3.4. Photoreduction of Cu(dsc)(dtp) in toluene

EPR spectral changes obtained upon photo-irradiation of 1×10^{-3} mol dm^{-3} toluene solutions of Cu(dsc)(dtp) with visible light (because of the strong absorption of toluene in UV) are given in Fig. 2. The data show the decreasing intensity of the EPR spectrum of Cu(dsc)(dtp) because of the reduction of Cu(II) to Cu(I).

When 6×10^{-5} mol dm^{-3} toluene solutions of Cu(dsc)(dtp) are photolysed with visible light at 20°C (Fig. 3) the electronic absorption changes reveal only the bleaching of the visible LMCT absorption.

To check whether photoreduction of Cu(II) is reversible the irradiated solutions were kept for 24 h in the dark and the absorption spectra were measured again after that. The obtained spectra clearly showed that photoreduction was partly reversible due to a thermal back reaction, proceeding when photolysis was limited to less than 50%. But they were continuing to bleach when the total amount of photolysis was more than 80%.

3.5. Photoreduction of Cu(dsc)(dtp) in acetone

The LMCT absorption of Cu(dsc)(dtp) in aerated acetone and its EPR intensity gradually decrease following the reduction of Cu(II) to Cu(I) without any intermediate absorption or EPR signal upon irradiation with visible light (because of the strong absorption of acetone in UV). On keeping the irradiated solutions

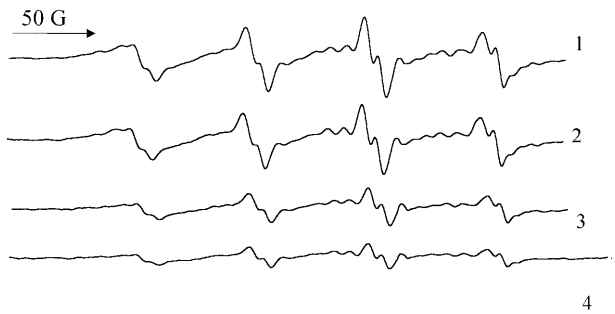

Fig. 2. Set of EPR spectra of Cu(dsc)(dtp) in toluene, 298 K, irradiated for 0 (1), 10 (2), 20 (3) and 40 s (4).

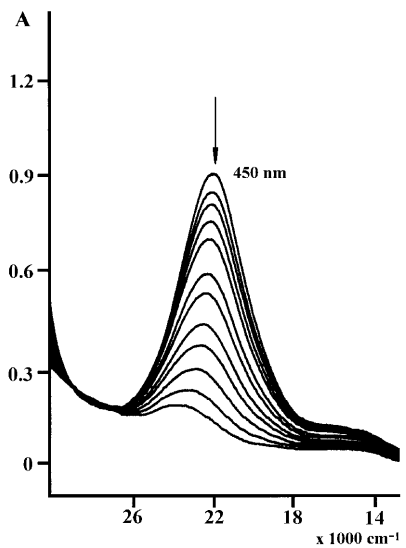

Fig. 3. Absorption spectrum of 7×10^{-5} M Cu(dsc)(dtp), irradiated for 0–285 s in toluene.

within 24 h in the dark the original spectrum is partly restored due to a thermal back reaction, proceeding when the total amount of photolysis is less than 60%.

3.6. Photoreduction of Cu(dsc)(dtp) in chloroalkanes

More complicated UV–Vis spectral changes were observed when photolysis was monitored in chloroalkanes. Fig. 4 shows the UV–Vis spectral changes obtained upon irradiation $\lambda < 450$ nm of 7×10^{-5} mol dm^{-3} Cu(dsc)(dtp) in CH_2Cl_2. It is seen that the LMCT absorption of Cu(dsc)(dtp) at about 450 nm gradually decreases in photolysis with the consecutive increases in absorption at 435 nm (22 990 cm^{-1}) and 350 nm (28 750 cm^{-1}). The new bands attain a maximum absorption and fade upon longer irradiation to give a nearly colourless solution. The observed spectral changes are rather similar to those previously reported about the photolysis of the parent $Cu(Et_2dsc)_2$ in chloroalkanes [1] proceeding with the formation of the mixed-ligand complex $Cu^{II}(Et_2dsc)Cl$ ($\lambda_{max} = 445$ nm) and its chloride-bridged dimeric form $Cu_2(Et_2dsc)_2Cl_2$ ($\lambda_{max} = 350$ nm) as intermediates. Under the same experimental conditions the other parent, $Cu(i\text{-}Pr_2dtp)_2$, exhibits a different photolysis pathway discussed before [2].

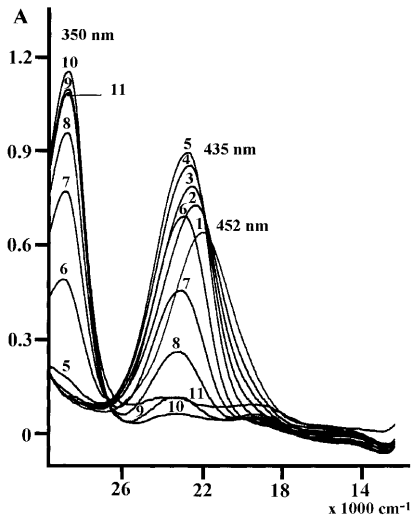

Fig. 4. Absorption spectrum of 8×10^{-5} M Cu(dsc)(dtp), irradiated for 0–94 s in CH_2Cl_2.

The intensity of the EPR spectrum of a 5×10^{-3} mol dm^{-3} Cu(dsc)(dtp) solution in CH_2Cl_2 is gradually decreasing upon photo-irradiation following the reduction of Cu(II) to Cu(I).

Partially photolyzed CH_2Cl_2 solutions of Cu(dsc)(dtp), containing both $Cu^{II}(Et_2dsc)Cl$ and $Cu_2(Et_2dsc)_2Cl_2$, left standing in the dark, undergo thermal back reaction as monitored by UV–Vis spectroscopy. When the total amount of photolysis is more than 80% and $Cu^{II}(Et_2dsc)Cl$ ($\lambda_{max} = 445$ nm, 22 470 cm^{-1}) is completely removed by a secondary photolytic process, the 350 nm band of $Cu_2(Et_2dsc)_2Cl_2$ is continuing to bleach in the dark to give a colourless solution.

Similar UV–Vis and EPR changes are observed during photo-irradiation of Cu(dsc)(dtp) solutions when CH_2Cl_2 is replaced by $CHCl_3$ as the solvent (Fig. 5) indicating that the same reaction mechanism is operative for both chloroalkane solvent systems. However, when irradiation is carried out in CCl_4 only the absorption band at 420 nm (23 800 cm^{-1}) (Fig. 6) appears in the visible part of the spectrum simultaneously with the gradual decrease in intensity of the initial charge transfer band of Cu(dsc)(dtp) at 455 nm (21 980 cm^{-1}).

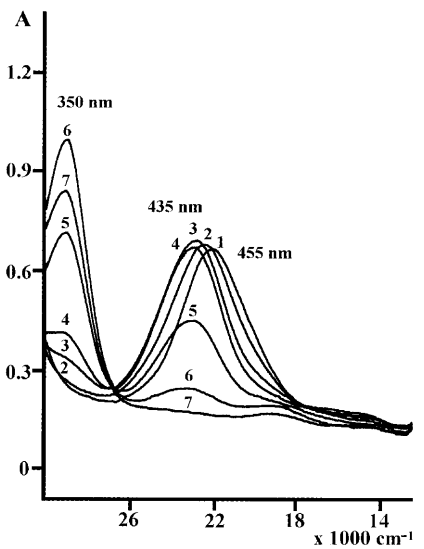

Fig. 5. Absorption spectrum of 5×10^{-5} M Cu(dsc)(dtp), irradiated for 0–55 s in $CHCl_3$.

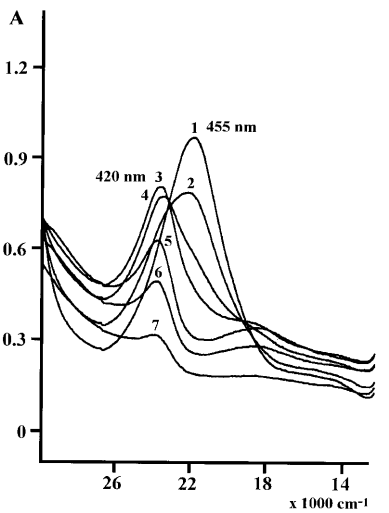

Fig. 6. Absorption spectrum of 6×10^{-5} M Cu(dsc)(dtp), irradiated for 0–50 s in CCl_4.

3.7. Quantum yield

The quantum yield proved to be sensitive to the solvent. For solutions in 20°C CCl_4 the quantum yield of 436 nm irradiation was determined to be 1.5×10^{-3} mol einstein^{-1}. In $CHCl_3$ photolysis the same light irradiation gave about 1.0×10^{-3} mol einstein^{-1}, but it was much smaller in CH_2Cl_2. A photoredox process was also seen in acetone and toluene but it gave immeasurably small quantum yield values. Therefore, the data obtained at 436 nm irradiation decreases in the following order of solvents $CCl_4 > CHCl_3 > CH_2Cl_2 >$ acetone, toluene. Because of their electron acceptor properties [9] chloromethanes act as oxidants and their Cl atom donating power increases with decreasing energy of the C–Cl bond which is 75 kcal mol^{-1} in CH_2Cl_2, 71.9 kcal mol^{-1} in $CHCl_3$ and 68 kcal mol^{-1} in CCl_4 [10,11]. In view of this the observed solvent efficiencies in photolysis could be related to their oxidizing power.

3.8. Mechanism

The evidence about $Cu^{II}(Et_2dsc)Cl$ and $Cu_2(Et_2dsc)_2Cl_2$ formation (Fig. 4) as intermediate products of Cu(dsc)(dtp) photolysis in chloroalkanes is in accordance with a scheme in which the primary photo-electron transfer to Cu(II) would occur with the participation of i-Pr_2dtp ligand to form free i-$Pr_2dtp^{\bullet}$ radical and $Cu^{I}(Et_2dsc)$. The subsequent reactions of $Cu^{I}(Et_2dsc)$ following the primary homolytic Cu-S bond cleavage are strongly solvent dependent as found before [1]. In chloroalkanes the primary photo-process is followed by a rapid $Cu^{I}(Et_2dsc)$ thermal oxidation with the chloroalkane to give $Cu^{II}(Et_2dsc)Cl$ in equilibrium with the dimeric form $Cu_2(Et_2dsc)_2Cl_2$ [1] and by a i-$Pr_2dtp^{\bullet}$ recombination to the stable disulphide (ds) of dithiophosphate. Furthermore, the products $Cu^{II}(Et_2dsc)Cl$ and $Cu_2(Et_2dsc)_2Cl_2$ undergo secondary photo-processes yielding CuCl and a free $Et_2dsc^{\bullet}$ radical as found before [1]. The details of this mechanism account for all of the observations made in this study as well as for the electron-acceptor properties of chloroalkanes and their oxidizing power.

The data of Fig. 2 compare well to those obtained in acetone, suggesting rather similar photochemical pathways of Cu(dsc)(dtp) in acetone and toluene.

4. Conclusions

The primary photo-process appearing upon UV–Vis irradiation with $\lambda < 450$ nm of Cu(dsc)(dtp) in acetone, toluene and chloroalkane (CH_2Cl_2, $CHCl_3$ and CCl_4) solutions involves the homolytic cleavage of the bond between S atom of i-Pr_2dtp and Cu(II) to give $Cu^{I}(Et_2dsc)$ and a free i-$Pr_2dtp^{\bullet}$ radical as the primary photo-products. The solvent appears to play a major role in determining further reactions of the primary photo-products.

Abstract

Octahedral Co^{II} and Ni^{II} complexes with 1-allylimidazole (L), of general formula $[ML_6](NO_3)_2$, have been obtained in the solid state and characterised by single-crystal X-ray analysis, spectroscopic evidence (IR, far-IR, UV–Vis–NIR) and magnetochemical measurements. Effective magnetic moments of the cobalt(II) and nickel(II) complexes are 5.10 and 2.90 BM, respectively. Crystal field parameters for these high-spin, octahedral species are comparable with those of imidazole and 1-alkylimidazoles. Formation processes of successive cobalt(II), nickel(II) and copper(II) complexes with 1-allylimidazole were followed quantitatively by the potentiometric method. As was the case with imidazole and 1-alkylimidazoles, the complexation proceeded according to the Bjerrum's model with retention of the six-coordinate geometry of the central ion. The complexation pattern was also confirmed by absorption spectra taken over the visible range in aqueous solution. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Imidazole derivatives; Transition metal complexes; Crystal structure; Absorption spectra; Stability constants

1. Introduction

Histamine, histidine, pilocarpine and allantoin belong to the class of the most widely known imidazole derivatives occurring in living organisms. A crucial role in elucidation of the interaction of proteins with metal ions has been attributed to the imidazole entity in the molecule of histidine. The imidazole ring of histidine provides a link, tying a protein molecule with Fe^{II} on the histidine molecule. The mechanisms of many enzymatic reactions involve complexation processes of the Co^{2+}, Ni^{2+}, Fe^{2+}, Cu^{2+} and Zn^{2+} ions. Catalytic activity of a metal ion in the active centre of a metalloproteide has been found to depend on its tendency towards complexation and on the structure of the compounds [1]. For this reason structural and physicochemical studies of metal complexes with ligands incorporating the imidazole ring are of cognitive importance.

In the preceding paper [2], physico-chemical characterisation and X-ray structure of the nitrato complexes of copper(II) with 1-allylimidazole were presented. These were tetragonal $[CuL_2(NO_3)_2]$ and dinuclear $[Cu_2L_4(NO_3)_2]$ complexes. Again, in Ref. [3], heptacoordinate isomorphic cobalt(II) and nickel(II) complexes with 1-allylimidazole have been reported. This contribution is a continuation of our studies on coordination compounds of 1-allylimidazole and deals with octahedral Co^{II} and Ni^{II} complexes of the ligand in the solid state and with stability of the Co^{II}, Ni^{II} and Cu^{II} complexes in aqueous solution.

2. Experimental

2.1. Investigation in the solid state

2.1.1. Synthesis

A 2 mmol solution of $Co(NO_3)_2 \cdot 6H_2O$ or $Ni(NO_3)_2 \cdot 6H_2O$ in propan-2-ol containing trimethyl orthoformate was mixed with analogous 12 mmol solution of 1-

PII: S0277-5387(00)00521-0

allylimidazole (Aldrich, Europe). After a few days, precipitated compounds were purified by crystallization from propan-2-ol. The crystals were washed with abs. ethyl ether and dried at room temperature under vacuum. The results of elemental analysis are as follows: cobalt(II) complex: C, 51.8; H, 5.9; N, 23.7. Calc. for $[CoL_6](NO_3)_2$ C, 51.58; H, 5.82; N, 23.57; nickel(II) complex: C, 52.1; H, 6.0; N, 23.6. Calc. for $[NiL_6](NO_3)_2$: C, 51.99; H, 5.82; N, 23.58%.

2.1.2. Physical measurements

Elemental analyses were run on a model 240 Perkin–Elmer CHN analyzer. The IR spectra were recorded on a Perkin–Elmer 180 (spectral range 50–4000 cm^{-1}) spectrophotometer in Nujol and in KBr pellets. The far-IR spectra were obtained in Nujol mulls sandwiched between polyethylene plates. The electronic spectra (5000–30 000 cm^{-1}) were recorded on a Cary 5 UV–Vis–NIR spectrophotometer in Nujol mulls. Magnetic susceptibility data were obtained at room temperature and corrected for diamagnetism by Pascal's constants.

2.1.3. Crystal data

X-ray measurements were performed on a Kuma KM4CCD diffractometer. The structures were solved by direct methods using the SHELX-97 programme [4] and refined by full-matrix least-squares methods using the SHELXL-97 programme [5]. Details of the crystal data and refinement for the cobalt(II) and nickel(II) compounds studied are shown in Table 1.

2.2. Solution studies

2.2.1. Potentiometric measurements

Potentiometric measurements of the metal-ion systems were carried out using a PHM-84 pH meter (radiometer) and a GK 24001 C combination electrode placed in a glass vessel (298 K thermostat) solution of constant ionic strength ($I = 0.5$ mol dm^{-3}) maintained with KNO_3. The electrode was calibrated by means of a HCl solution of known titre with a NaOH solution according to Ref. [6]. The concentration of protonated ligand (HL^+) in stock solutions used in potentiometric titrations was 0.20 mol dm^{-3}.

In the three series of measurements the metal–HL^+ molar ratios were 1:4, 1:8 and 1:10. The titration with the base was conducted in triplicate, over the pH range 2.5–7.5. The dissociation constants of the conjugate acid and stability constants, β_n, of the complexes were refined by the SUPERQUAD program. Standard deviations quoted refer to random errors only.

2.3. Spectroscopic measurements

The visible-range absorption spectra of the Co^{2+}, Ni^{2+} and Cu^{2+} complexes in aqueous solutions were recorded on a Specord M-40 (Carl Zeiss, Jena) spectrophotometer. The solutions were prepared in an analogous manner as were those for the potentiometric titrations. The initial metal concentrations were 0.04 mol dm^{-3}. The highest concentration of the protonated ligand was 0.20 mol dm^{-3}.

3. Results and discussion

3.1. Studies in the solid state

3.1.1. Description of structure

Both the labelling of atoms and molecular structures of the complexes are shown in Fig. 1. Selected bond lengths and bond angles are compiled in Table 2. A similar environment for the central ion in the $[ML_6]^{2+}$ ion is provided by 'pyridynic' nitrogen atoms of six imidazole rings. The shape of the coordination polyhedron fits onto a slightly distorted octahedron. In the nickel(II) complex, the shortest Ni–N distance is 2.046 Å and the longest is 2.133 Å, the difference being 0.087 Å. In the cobalt(II) complex the difference between these bonds is smaller (0.029 Å). The *trans*-angles in the coordination plane formed by atoms labelled N(11), N(21), N(31) and N(41) are 178.5(1) and 177.9(1)° for the cobalt(II) compound and 179.0(1) and 177.2(1)° for the nickel(II) compound.

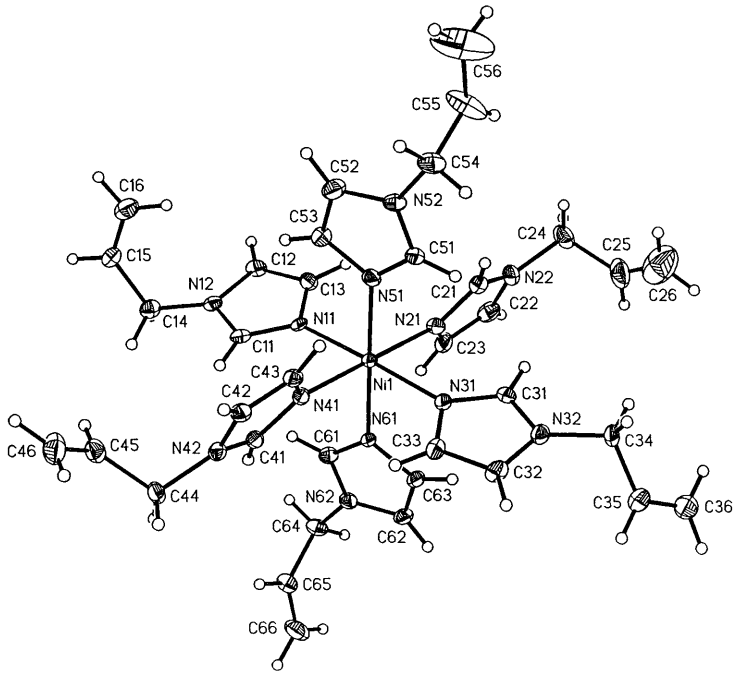

Fig. 1. The structure and numbering scheme for the complexes studied.

The angles between the aforementioned coordination plane and the planes of imidazole rings with pyridynic nitrogen atoms labelled N(11), N(21), N(31), N(41), N(51) and N(61) are respectively, 18.4(1), 67.8(1), 71.5(1), 70.1(1), 69.9(1) and 1.1(2)° in the cobalt(II) complex and 18.2(1), 67.0(1), 71.3(1), 70.0(1), 69.7(1) and 0.9(3)° in the nickel(II) complex. The bond lengths and bond angles in the 1-allylimidazole ligand are similar to those in its complexes with other metals [2,3].

3.1.2. The infrared spectra

The shapes of the IR and far-IR spectra of the complexes support the structures suggested. Coordination of the 1-allylimidazole molecules through 'pyridynic' nitrogen atoms of the imidazole rings manifests in displacement towards higher energies of the ν(C=C) vibrations coupled with those of ν(C=N) of the imidazole ring from 1508 (free 1-allylimidazole) to 1518 cm^{-1} (the cobalt(II) complex) and 1520 cm^{-1} (the nickel(II) complex). The metal–nitrogen linkage emerges in the far-IR region as a rather broad intense band at 228 and 246 cm^{-1}, respectively for cobalt(II) and nickel(II) complexes [2,3,7–9]. The lack of interaction between the nitrate group and the metal ion is indicated by the position of a band characteristic of this group. Thus, broad intense bands at 1376 and 820 cm^{-1} (the cobalt(II) complex) and at 1385 and 822 cm^{-1} (the nickel (II) complex) are assigned, respectively, to symmetric and antisymmetric vibrations of the free nitrate ion [10,11].

3.1.3. Magnetic properties and d-d electronic spectra

Magnetic moments determined for the cobalt(II) and nickel(II) complexes at room temperature are 5.10 and 2.90 BM, respectively. These values are characteristic of high-spin octahedral complexes of metals [12]. The electronic spectrum of the nickel(II) complex is typical for the six coordinate compounds of the metal. Characteristic absorption bands emerge over the visible and near-IR regions. A low-energy absorption appears as a broad band at 11 600 cm^{-1} and can be assigned to the $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ (ν_1) electron transition. The next two bands at 16 800 and 27 500 cm^{-1} are assignable, respectively, to the $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ (ν_2) and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ (ν_3) transitions. The ν_2 and ν_3 frequencies were subsequently utilised to determine Dq values and the Racah parameter [12,13] (Table 3). With octahedral high-spin cobalt(II) complexes, the crystal field theory allows for three spin permissible d-d transitions, namely $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ (ν_1), $^4T_{1g}(F) \rightarrow {}^2A_{2g}$ (ν_2) and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ (ν_3) [11]. With the cobalt(II) complex, the first of these bands appears over the near-IR range at $\nu_1 = 9560$ cm^{-1}. In the visible range of the spectrum, only one asymmetric band appears at 20 600 cm^{-1}. On the low-energy side of the band there are distinct deformations which, in the case of octahedral cobalt(II) complexes, can be explained in terms of overlapping the ν_2 and ν_3 bands as well as a spin forbidden band due to the $^4T_{1g}(F) \rightarrow {}^2T_{1g}(G)$ transition. The components of this absorption region were obtained by means of the Gaussian distribution. The maxima of the three bands

appear at 21 000, 20 000 and 18 900 cm^{-1}.The strongest 21 000 cm^{-1} band can be assigned to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ (ν_3) transition. Unfortunately, interpretation of the remaining bands is not as straightforward a priori. On the basis of the frequencies $\nu_1 = 9560$ and $\nu_3 = 21\ 000\ cm^{-1}$, parameters of the crystal field could be determined [10,12] (Table 3). By utilising the relation $\nu_2 = \nu_1 + 10$ Dq, the position of ν_2 should be around 20 200 cm^{-1}, i.e. in the immediate vicinity of the ν_1 band. The band is likely to emerge at $\nu = 18\ 900$ cm^{-1}. These asignments are supported by parameters Dq and B calculated by using frequencies ν_2 and ν_3 [13]. In this case the calculated values of Dq = 1061 and $B = 855$ are quite compatible with the parameters determined by using ν_1 and ν_3 (Table 3). With both the cobalt(II) and nickel(II) complexes, the crystal field parameters assume magnitudes matching those of imidazole and 1-alkylimidazoles and are consistent with the basicities of the ligands (Table 4). The positions of 1-allylimidazole in the spectrophotometric and nepheloauxetic rank orders closely matches those of imidazole and 1-alkylimidazoles [15].

3.2. Studies in aqueous solution

On the basis of the pH-metric measurements, the acid dissociation constant of protonated 1-allylimidazole was determined to be 9.52×10^{-8} ($pK_a = 7.02$). The dissociation constants of imidazole and selected 1-substituted imidazoles are shown in Table 4.

These data show that the basicity of 1-allylimidazole is just equal to that of imidazole and 1-alkylimidazoles. 1-Allylimidazole is, by an order of magnitude, a stronger Brönsted base than its homologue, 1-vinylimidazole ($pK_a = 5.92$). The weaker basicity of the latter is due to the negative inductive effect of the vinyl substituent. With allyl substituents, the effect is absent, because the π electrons of the double bond are isolated from the lone electron pair of the pyridynic '3' nitrogen atom of the imidazole ring. The complexation of Co^{II}, Ni^{II} and Cu^{II} with 1-allylimidazole was conducted over pH range 2.5–7.5. The equilibrium constants for these systems are summarized in Table 4. On the basis of these constants, curves of percentile molar contributions of successive complexes being formed in solution were plotted in Fig. 2.

The stability of the complexes of the three metals is compatible with the Irwing–Williams series ($Co^{II} < Ni^{II} < Cu^{II}$) as seen in the plots presented in Fig. 2. Successive Cu^{II} complexes are formed in more acidic solutions than those of the remaining metals. The regularity in variation of the successive equilibrium constants, K_n, of the cobalt(II), nickel(II) and copper(II) complexes shows that the complexation reactions in solution proceed according to the Bjerrum's model, with retention of the six coordinate geometry of the central ion, as was the case with analogous complexes of imidazole and 1-alkylimidazoles [18].

A comparison of the constants in Table 4 shows that the stability of the complexes is comparable, in terms of basicity, to that of the corresponding complexes of imidazole and 1-alkylimidazoles. Thus, 1-allylimidazole forms slightly more stable complexes than 1-vinylimidazole, in spite of the fact that the pK_a values of respective ligands suggest larger differences in their stability. As demonstrated previously [19], stability of the 1-vinylimidazole complexes is strengthened by contribution of additional $\pi_{M \rightarrow L}$ back-bonding.

The visible absorption spectra of aqueous solutions of the complexes provide further support in favour of the conclusion that the coordination reactions with 1-allylimidazole proceed without the change of the coordination number of the central ion. Upon raising concentration of free 1-allylimidazole (increasing pH), a

Abstract

The reaction of Se_2 or S^{2-} with the $[MoS_2O_2(S_2C_2H_4)_2]^{2-}/2Cu^+$ yielded two novel dodecanuclear interstitial clusters having the general formula $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}Se_2)]\cdot CH_2Cl_2$ (**1**) and $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}S)]\cdot 3H_2O$ (**2**) (edt = $^-SC_2H_4S^-$), whose crystal structures were determined by X-ray crystallography. The anions in **1** and **2** can be viewed as a cage consisting of three $[MoS_2O_2(S_2C_2H_4)_2]^{2-}/2Cu^+$ fragments, with an Se_2^{2-} or an S^{2-} at the center, respectively. © 2000 Elsevier Science B.V. Keywords: Dodecanuclear; Mo–Cu–S cage cluster; Interstitial group

1. Introduction

Cluster compounds play an important role in bioinorganic chemistry, material science and catalysis etc. Recently, polynuclear metal cluster compounds have become even more interesting owing to their fascinating electronic, structural, chemical, magnetic and optical properties, and potential uses as heterogeneous catalysts as well as synthetic analogs of biological systems [1]. The structure of polynuclear transition metal clusters may often be described as fragments of metal aggregates stabilized by ligand shells. Many cage-like clusters containing an interstitial group have been reported, such as: $Co_6C(CO)_{12}S_2$ [2], $[Rh_9P(CO)_{21}]^{2-}$ [3a] and $[Rh_{10}P(CO)_{22}]^{3-}$ [3b] $[Cp_6Yb_6Cl_{13}]^-$ [4], $[W_6O_{19}]^{2-}$ and $[V_{10}O_{28}]^{6-}$ [5], $Ag_2C_2\cdot 8AgF$ (the interstitial group is $^-C{\equiv}C^-$) [6]. A few heterobimetallic cage-like clusters containing an interstitial group are also known, for example $[Nb_2W_4O_{19}]^{4-}$ and $[(C_5H_5)Ti(W_5O_{18})^{3-}$ [5], $[Mo_6Cu_6S_6O_6(S_2)_6(\mu_6\text{-}S)]^{2-}$ [7], $[\{M_2Cu_2S_2O_2(S_2C_2H_4)_2\}_3(\mu_6\text{-}S_2)]^{2-}$ (M=Mo, W) [8] and $[\{M_2Ag_2S_2O_2(S_2C_2H_4)_2\}_3(\mu_6\text{-}S)]^{2-}$ (M=Mo, W) [9]. In this contribution, we report the syntheses and characterization of two dodecanuclear heterometallic cage clusters $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}Se_2)]\cdot CH_2Cl_2$ (**1**) and $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}S)]\cdot 3H_2O$ (**2**), which contain a μ_6-Se_2 and a μ_6-S ligand, respectively. To our knowledge, **1** is the first cluster compound containing a μ_6-Se_2 group.

2. Experimental

The synthesis of compound **2** and the starting material $[Et_4N]_2[Mo_2S_2O_2edt_2]$ were carried out in air; and the synthesis of compound **1** was carried out in a nitrogen atmosphere. Infrared spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer as KBr pellets for M-IR (4000–400 cm^{-1}) and as CsI pellets for Far-IR (600–100 cm^{-1}). Elemental analyses were performed by the Elemental Analysis Laboratories in our Institute.

2.1. Preparation of $[Et_4N]_2[Mo_2S_2O_2edt_2]$

H_2S gas was bubbled into a 20 ml aqueous solution of Na_2MoO_4 (4.84 g, 20 mmol). Three minutes later, the solution turned to red and was then heated to 85°C, when $Na_2S_2O_4$ (0.469 g, 3.3 mmol) and $H_6S_2C_2$ (1.6 ml, 20 mmol) were added. After stirring for 2 h, 4.2 g of $[Et_4N]Br$ (20 mmol) was added to the solution, which was cooled in air to deposit a red precipitate. The precipitate was collected and washed by C_2H_5OH and Et_2O three times, and 6.5 g of $[Et_4N]_2[Mo_2O_2S_2edt_2]$ was obtained (yield 91.3%). *Anal.* Calc. for $C_{20}H_{48}Mo_2N_2O_2S_6$: C, 32.78; H, 6.60; N, 3.82. Found: C, 32.80; H, 6.7; N, 3.81%. IR (cm^{-1}): 2972.7 (s), 2891.0 (s), 1479.4 (s), 1456.4 (s), 939.2 (vs), 472.5 (m), 443.5 (m), 339.4 (m).

2.2. Preparation of $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}Se_2)]\cdot CH_2Cl_2$ (**1**)

Se powder (0.032 g, 0.4 mmol) was placed in a S tube, and 5 ml DMF solution and metallic Na (0.01 g, 0.43 mmol) was added. The solution was heated to 363 K for 1 h, and then suspension (i) was produced. To a solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.242 g, 1 mmol in 30 ml of MeCN and 30 ml of CH_2Cl_2) was added $NaBH_4$ (0.038 g, 1 mmol) with stirring. After 30 min, $[Et_4N]_2[Mo_2S_2O_2edt_2]$ (0.356 g, 0.5 mmol) was added, and the mixture was stirred for 1 min, whereupon suspension (ii) was produced. Next, suspension (i) was added to suspension (ii) and stirred for 30 min and then the black precipitate was removed by filtration. The dark red filtrate was allowed to stand at room temperature under nitrogen for 15 days, after which 0.07 g of black crystals of **1** were obtained (yield: 18%). Complex **1** is slightly soluble in MeCN and CH_2Cl_2, and easily soluble in DMF. *Anal.* Calc. for $C_{29}H_{66}Cl_2Cu_6Mo_6N_2O_6S_{18}Se_2$: C, 15.13; H, 2.89; N, 1.22; Se, 6.86. Found: C, 15.15; H, 2.92; N, 1.29; Se, 6.82%. IR: (cm^{-1}): 2974.2 (s), 2890.2 (s), 1479.0 (s), 1456.4 (s), 954.6 (vs); 462.8 (m), 432.0 (m), 343.3 (m).

2.3. Synthesis of $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}S)]\cdot 3H_2O$ (**2**)

To a solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.242 g, 1 mmol in 60 ml of MeCN) was added $NaBH_4$ (0.038 g, 1 mmol) with stirring. After 30 min, $[Et_4N]_2[Mo_2S_2O_2edt_2]$ (0.356 g, 0.5 mmol) was added to the suspension, and the mixture was stirred for 0.5 min. Some flocculate appeared in the reaction solution. Then, two drops of $(NH_4)_2S$ aqueous solution (containing 8% S) were added to the reaction solution and stirred for 20 min, the flocculate disappeared and a black precipitate was obtained. The precipitate was filtered off, and the dark red filtrate was allowed to stand at room temperature in air for 5 days, after which 0.08 g of the black crystal of **2** was obtained (yield: 22.3%). Complex **2** is stable in air, slightly soluble in MeCN and CH_2Cl_2, and easily soluble in DMF. *Anal.* Calc. for $C_{28}H_{70}N_2Cu_6Mo_6O_9S_{19}$: C, 15.68; H, 3.29; N, 1.31. Found: C, 15.7; H, 3.32; N, 1.36. %. IR (cm^{-1}): 2973.7 (s), 2890.8 (s), 1479.2 (s), 1456.0 (s), 950.7 (vs), 470.5 (m), 439.7 (m), 352.9 (m).

2.4. Crystallographic structure determination

Crystallographic data for compounds **1** and **2** are listed in Table 1. Data were collected at room temperature on a Siemens SMART-CCD area-detector diffractometer with a graphite monochromator utilizing Mo Kα radiation ($\lambda = 0.71073$ Å). Intensity data were obtained by using an ω scan technique with scan rates of 19 s/frame and 0.3°/frame, in the range $3.26 < 2\theta < 50.32$ for **1** and $3.30 < 2\theta < 46.50°$ for **2**. Data reductions and absorption corrections were performed with SMART and SADABS softwares, respectively.

Structural analyses were performed using a Silicon Graphics in Indy workstation with the program

SHELXTL [10]. The structures were solved by direct methods, and the positions of heavy atoms were obtained from E maps. The remaining non-hydrogen atoms were located from successive difference Fourier maps. The refinement of structures was performed by full-matrix least-squares techniques on F^2 using SHELXL93 [11]. For **1**, all non-hydrogen atoms were treated as anisotropic. For **2**, all non-hydrogen atoms are anisotropic except the O atoms of H_2O molecules and the C, N atoms. No attempt was made to locate hydrogen atoms. The selected bond lengths and angles for **1** and **2** are listed in Tables 2 and 3, respectively.

3. Results and discussion

3.1. Syntheses

For the synthesis of compound **1** or **2**, $[Et_4N]_2[Mo_2O_2S_2edt_2]$ and Na_2Se_2 or $(NH_4)_2S$ were used as starting materials. Cu^+ cations were introduced through the reduction of $Cu(NO_3)_2{\cdot}3H_2O$ by $NaBH_4$. Se_2^{2-} or S^{2-} was added into the reaction solution after the precursor $[Mo_2S_2O_2edt_2]^{2-}/2[Cu(MeCN)_2]^+$ fragment had been formed. Three $[Mo_2S_2O_2edt_2]^{2-}/2[Cu(MeCN)_2]^+$ fragments can be assembled together by Se_2^{2-} or S^{2-}, then compound **1** or **2** was obtained.

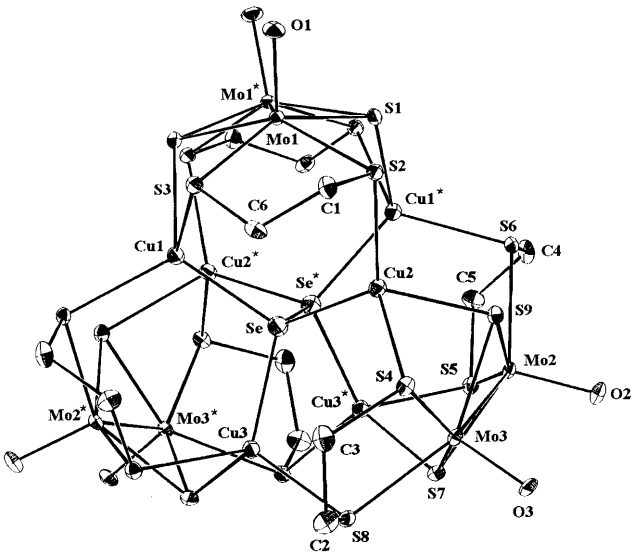

Fig. 1. ORTEP plot of the anion $[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}Se_2)]^{2-}$ in **1** with the ellipsoids drawn at 10% probability level.

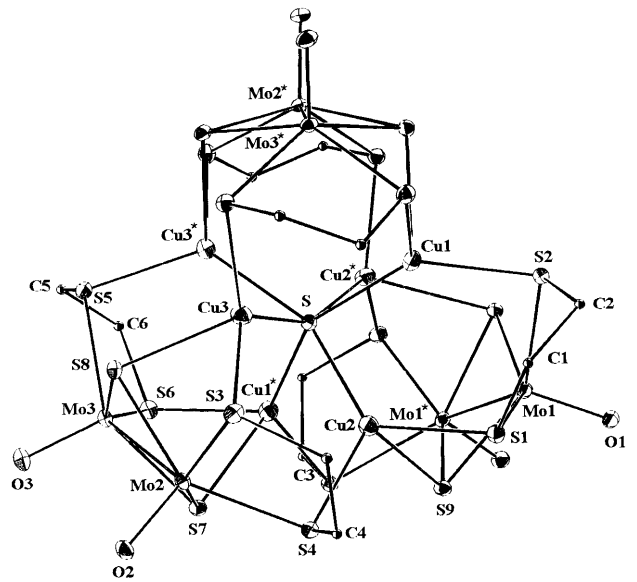

Fig. 2. ORTEP plot of the anion $[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}S)]^{2-}$ in **2** with the ellipsoids drawn at 10% probability level.

3.2. Structure of $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}Se_2)]{\cdot}CH_2Cl_2$ (1)

The structure of the anion in **1** (Fig. 1) may be viewed as a cage which is composed of three $[Mo_2S_2O_2edt_2]^{2-}/2Cu^+$ fragments assembled by an Se_2^{2-} ion at its center and bonded to six Cu atoms in μ_6 fashion. Each Se atom is bound to three Cu atoms with Se–Cu bonds having approximate sp^3 geometry. The Cu–Se–Cu angles range from 109.20 to 113.71° and the Se–Cu distances range from 2.301 to 2.310 Å, average 2.306 Å. The angles Se*–Se–Cu range from 106.59 to 108.62° and the Se–Se* bond is 2.257 Å. Each Mo atom displays tetragonal-pyramid (TPY) coordination geometry, being surrounded by two S atoms of $^-SC_2H_4S^-$ (S_{edt}), two bridging S atoms of binuclear molybdenum (S_{br}) and one terminal oxygen atom. The oxygen atom occupies the axial position of each TPY with an average M–O distance of 1.677 Å, and the four remaining sulfido atoms are equatorial. The average Mo–S_{br}–Mo angle is 75.63°. Each Mo atom is chelated by one $^-SC_2H_4S^-$ forming a five-membered ring, and the average Mo–S_{edt} distance and average S_{edt}-Mo–S_{edt} angle are 2.446 Å and 81.19°, respectively. There are three Mo–Mo metal–metal bonds and the average Mo–Mo distance is 2.886 Å. Each Cu atom is coordinated by three S atoms (two S_{edt}, one S_{br} atom) and one Se atom of the μ_6-Se_2 ligand, to give a distorted tetrahedral geometry [angles S–Cu–S and S–Cu–Se are in the wide range of 81.55(14)–118.80(13)°]. The average S_{br}–Cu and S_{edt}–Cu distances are 2.354 and 2.326 Å, respectively.

The anion of **1** has two big windows each composed of a puckered $Cu_3S_6C_6$ 15-membered ring which consists of three Cu atoms combining three $^-SC_2H_4S^-$ ligands. It has a pseudo-3-fold axis exactly along the –Se bond and approximately perpendicular to the two windows.

3.3. Structure of $[NEt_4]_2[(Mo_2Cu_2S_2O_2edt_2)_3(\mu_6\text{-}S)]{\cdot}3H_2O$ (2)

The structure of the anion in **2** (Fig. 2), which is similar to that in **1**, may be viewed as a cage with a μ_6-S^{2-} ion at the center and bonded to six Cu atoms. The average Cu–μ_6-S distance is 2.383 Å, and the Cu–μ_6-S–Cu angles range from 78.46–155.45°. There are three narrow Cu–μ_6-S–Cu angles with 81.10(8)° of Cu1–S–Cu2*, 81.09(8)° of Cu–S–Cu1*, 78.46(13)° of Cu3–S–Cu3*. Each Cu atom is coordinated by four S atoms (two S_{edt}, one S_{br} and the μ_6-S atom) to give a distorted tetrahedral geometry [angles S–Cu–S are in the wide range of 74.85(11)—132.70(13)°]. The average S_{br}–Cu distance of 2.472 Å is longer than that in anion **1** (2.354 Å), and the average S_{edt}–Cu distance of 2.398 Å is longer than that in anion **1** (2.326 Å). These may

be due to the fact that the interstitial group S^{2-} in anion **2** is small than Se_2^{2-} in anion **1**.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystalographic Data Centre, CCDC Nos. 139119 and 139120, respectively, for compounds **1** and **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The condensation product of pyridinecarboxaldehyde *N*-oxide with *o*-phenylenediamine yields a ligand 2-(2-benzimidazolyl)-pyridine *N*-oxide (poxbim) which has been isolated in a free form. The bidentate ligand gave a series of complexes with Mn(II), Fe(II), Co(II), Ni(II), Cu(II) and Zn(II) with 1:1, 1:2, 1:3, 1:4 and 1:5 metal-to-ligand ratios. The 1:2 cobalt(II) adduct, $[Co(poxbim)_2(H_2O)_2](ClO_4)_2$, has been structurally characterised. Its temperature-dependent magnetic susceptibility shows a behaviour that is characteristic for the octahedral $^4T_{1g}$ term under the axial distortion due to symmetry lowering to D_{4h}. The structure of a 1:4 zinc(II) adduct shows that two ligands remain uncoordinated in $[Zn(poxbim)_2(H_2O)_2](ClO_4)_2 \cdot (poxbim)_2 \cdot 2H_2O$.

1. Introduction

In dealing with the chemistry of the pyridine *N*-oxide ligands a novel ligand Hpoxap — the product of the condensation of 2-pyridinecarboxaldehyde *N*-oxide (poxal) with *o*-aminophenol — and its Cu(II) complexes have been described recently [1]. In the present study, *o*-phenylenediamine was used instead of *o*-aminophenol. The aim was to prepare a corresponding tetradentate Schiff base, as produced by the salicylaldehyde or pyridinecarboxaldehyde upon the 2:1 condensation with *o*-phenylenediamine [2–4]. Contrary to expectations, the aldehyde used (poxal), yielded 2-(2-benzimidazolyl)pyridine *N*-oxide (poxbim) (**1**). A different route of the preparation of such a compound has already been presented: the oxidation of 2-(2-pyridyl)benzimidazol (pybzim) by the peroxoacetic acid (Scheme 1). The product has been tested as an anthelminticum [5]. To our best knowledge it was never used as a ligand in coordination compounds. This prompted us to undertake a systematic study of poxbim complexation reactions with transition metals.

Scheme 1. Possible routes of preparation of poxbim.

2. Experimental

2.1. Ligand and complexes

A solution of 10.0 g (0.0708 mol) of 2-pyridinecarboxaldehyde *N*-oxide, monohydrate (prepared by the method of Jerchel [6]) in 45 cm^3 of EtOH was added to a solution of 7.65 g (0.0708 mol) of freshly recrystallised *o*-phenylenediamine in 50 cm^3 of EtOH under stirring and heating. The resulting dark-red solution was boiled for a few minutes and then cooled to room temperature (r.t.) under stirring. After 1 h an orange solid was filtered off, washed with EtOH and air-dried. Yield 3.9 g (26%). M.p. 234–235°C. *Anal*. Found: C, 68.5; H, 4.23; N, 20.0. Calc. for $C_{12}H_9N_3O$: C, 68.7; H, 4.29; N, 20.0%. Orange prisms (**1**), suitable for X-ray structure determination, were obtained upon the recrystallisation of the crude product from acetone.

2.1.1. $[Co(poxbim)_2(H_2O)_2](ClO_4)_2$ (**2**)

A solution of 0.5 mmol (0.183 g) of the metal salt $Co(ClO_4)_2{\cdot}6H_2O$ in 5 cm^3 of hot EtOH was slowly added to the solution of 1 mmol (0.211 g) of **1** in 25 cm^3 of hot EtOH under rigorous stirring. The mixture was kept boiling until the volume reduced to approximately 5 cm^3 and then cooled to r.t. under stirring. The product was filtered off, washed with EtOH and air-dried. Yield 0.294 g (82%). *Anal*. Found: C, 40.7; H, 3.01; Cl, 9.84; N, 11.7. Calc. for $C_{24}H_{22}N_6O_{12}CoCl_2$: C, 40.2; H, 3.09; Cl, 9.90; N, 11.7%.

A series of other complexes involving poxbim ligand with Mn(II), Fe(II), Co(II), Ni(II), Cu(II) and Zn(II) has been prepared; the metal to ligand stoichiometry was 1:1, 1:2, 1:3, 1:4, and 1:5 (Table 1).

2.1.2. $Cu(poxbim)Cl_2$ (**3**)

A solution of 0.106 g (0.5 mmol) of **1** in 30 cm^3 of hot EtOH was slowly added to the solution of 0.170 g (1.0 mmol) of $CuCl_2{\cdot}2H_2O$ in 13 cm^3 of hot EtOH under rigorous stirring. The dark-green solution was boiled for 5 min and a pale-green solid started to precipitate, which subsequently recrystallised to a brown product. The stirring was continued without heating for another 60 min when the product was filtered, washed with a small amount of EtOH and air-dried. Yield 0.154 g (89%). *Anal*. Found: C, 41.7; H, 2.62; Cl, 22.2; Cu, 19.9; N, 11.9**.** Calc. for $C_{12}H_9N_3OCuCl_2$: C, 41.7; H, 2.62; Cl, 20.5; Cu, 18.4; N, 12.2%.

2.1.3. $Fe(poxbim)_2(ClO_4)_2(H_2O)_4$ (**4**)

In order to eliminate traces of Fe(III) a piece of metallic Fe and three drops of concentrated perchloric acid were added to a solution of 0.181 g (0.5 mmol) of $Fe(ClO_4)_2{\cdot}6H_2O$ in 5 cm^3 of EtOH–water (2:1) mixture. After 5 min of heating the filtered mixture was added to the hot solution of 0.211 g (1.0 mmol) of **1** in 25 cm^3 of hot EtOH under rigorous stirring. The resulting dark Bordeaux solution was boiled 1 min, cooled to r.t. under stirring and let to crystallise overnight. The orange product was filtered, washed with a small amount of EtOH and air-dried. Yield 0.192 g (51%). *Anal*. Found: C, 38.7; H, 3.07; Cl, 9.94; N, 11.1. Calc. for $C_{24}H_{26}N_6O_{14}FeCl_2$: C, 38.5; H, 3.50; Cl, 9.46; N, 11.2%.

2.1.4. $Cu(poxbim)_2Cl_2(H_2O)$ (**5**), $Cu(poxbim)_2(ClO_4)_2(H_2O)$ (**6**)

A solution of 0.5 mmol of the metal salt (0.085 g of $CuCl_2{\cdot}2H_2O$ or 0.185 g of $Cu(ClO_4)_2{\cdot}6H_2O$) in 10 cm^3 of hot EtOH was slowly added to the solution of 1 mmol (0.211 g) of **1** in 50 cm^3 of hot EtOH under rigorous stirring. A green solid crystallised immediately. The mixture was cooled to r.t. under stirring, and then the products were filtered, washed with EtOH and air-dried. Yield for **5**, 0.215 g (75%). *Anal*. Found: C, 50.0; H, 3.52; Cl, 12.9; Cu, 11.6; N, 14.4. Calc. for $C_{24}H_{20}N_6O_3CuCl_2$: C, 50.2; H, 3.51; Cl, 12.3; Cu, 11.0; N, 14.6%. Yield for **6**, 0.206 g (59%). *Anal*. Found: C, 42.2; H, 2.95; Cl, 10.9; Cu, 8.51; N, 11.8. Calc. for $C_{24}H_{20}N_6O_{11}CuCl_2$: C, 41.0; H, 2.87; Cl, 10.1; Cu, 9.04; N, 12.0%.

2.1.5. $Zn(poxbim)_2(ClO_4)_2(H_2O)_3$ (**7**)

A solution of 0.211 g (1.0 mmol) of **1** in 5 cm^3 of hot EtOH was added to the hot filtered solution of 0.372 g (1.0 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 10 cm^3 of EtOH under rigorous stirring. The pale-yellow solution was boiled for 1 min, cooled to r.t. under stirring and then put in a closed beaker into the refrigerator. After 1 month a product was filtered, washed with a small amount of EtOH and air-dried. Yield 0.288 g (78%). *Anal*. Found: C, 39.5; H, 3.32; Cl, 9.58; N, 11.3; Zn, 7.63. Calc. for $C_{24}H_{24}N_6O_{13}ZnCl_2$: C, 38.9; H, 3.27; Cl, 9.57; N, 11.3; Zn, 8.83%.

*2.1.6. $Ni(poxbim)_3(ClO_4)_2(H_2O)_2$ (**8**), $Mn(poxbim)_4(ClO_4)_2(H_2O)_5$ (**9**) and $Zn(poxbim)_4(ClO_4)_2(H_2O)_4$ (**12**)*

A solution of 0.5 mmol of the metal salt (0.183 g of $Ni(ClO_4)_2{\cdot}6H_2O$, 0.181 g of $Mn(ClO_4)_2{\cdot}6H_2O$) and 0.186 g of $Zn(ClO_4)_2{\cdot}6H_2O$) in 5 cm^3 of hot EtOH was slowly added to the solution of 1 mmol (0.211 g) of **1** in 25 cm^3 of hot EtOH under rigorous stirring. The mixture was kept boiling until the volume reduced to approximately 5 cm^3 and then cooled to r.t. under stirring. The products were filtered, washed with EtOH and air-dried. Yield for **8**, 0.124 g (40%). *Anal.* Found: C, 46.6; H, 3.40; Cl, 7.78; N, 13.2; Ni, 6.39. Calc. for $C_{36}H_{31}N_9O_{13}NiCl_2$: C, 46.6; H, 3.37; Cl, 7.65; N, 13.6; Ni, 6.33%. Yield for **9**, 0.237 g (81%). *Anal.* Found: C, 48.5; H, 3.68; Cl, 5.48; N, 14.0. Calc. for $C_{48}H_{46}N_{12}O_{17}MnCl_2$: C, 48.5; H, 3.90; Cl, 5.96; N, 14.1%. Yield for **12**, 0.192 g (65%). *Anal.* Found: C, 48.9; H, 3.70; Cl, 6.32; N, 14.2; Zn, 5.22. Calc. for $C_{48}H_{44}N_{12}O_{16}ZnCl_2$: C, 48.8; H, 3.75; Cl, 6.00; N, 14.2; Zn, 5.54%.

*2.1.7. $Co(poxbim)_4(ClO_4)_2(H_2O)_4$ (**10**) and $Ni(poxbim)_4(ClO_4)_2(H_2O)_4$ (**11**)*

A solution of 0.3 mmol of the metal salt (0.110 g of $Co(ClO_4)_2{\cdot}6H_2O$, 0.110 g of $Ni(ClO_4)_2{\cdot}6H_2O$) in 5 cm^3 of hot EtOH was slowly added to the solution of 1.2 mmol (0.253 g) of **1** in 10 cm^3 of hot EtOH under rigorous stirring. The mixture was boiled and then cooled to r.t. under stirring and let to crystallise. The adducts were filtered, washed with EtOH and air-dried. Yield for **11**, 0.308 g (87%). *Anal.* Found: C, 49.0; H, 3.64; Cl, 5.00; N, 14.0; Ni, 4.53. Calc. for $C_{48}H_{44}N_{12}O_{16}NiCl_2$: C, 49.1; H, 3.78; Cl, 6.04; N, 14.3; Ni, 5.00%. Yield for **10**, 0.267 g (76%). *Anal.* Found: C, 48.9; H, 3.70; Cl, 6.28; N, 14.1. Calc. for $C_{48}H_{44}N_{12}O_{16}CoCl_2$: C, 49.1; H, 3.78; Cl, 6.04; N, 14.3%.

*2.1.8. $Co(poxbim)_5(ClO_4)_2(H_2O)_5$ (**13**)*

A solution of 0.110 g (0.4 mmol) of $Co(ClO_4)_2{\cdot}6H_2O$ in 5 cm^3 of hot EtOH was slowly added to the solution of 1.2 mmol (0.253 g) of **1** in 20 cm^3 of hot EtOH under rigorous stirring. The mixture was boiled and then cooled to r.t. under stirring and let to crystallise slowly. The brown products were filtered, washed with EtOH and air-dried. Yield, 0.284 g (84%). *Anal.* Found: C, 51.4; H, 3.78; Cl, 5.19; N, 15.0. Calc. for $C_{60}H_{55}N_{15}O_{18}CoCl_2$: C, 51.3; H, 3.95; Cl, 4.20; N, 15.0%.

2.2. Instruments

IR spectra (Philips, PU 9800 FT-IR spectrometer) were recorded in the 4000–200 cm^{-1} range in Nujol suspension between CsI windows.

Magnetic susceptibility measurements (alternating current susceptometer, LakeShore, model 7221) were conducted in the temperature range 4–90 K; the field parameters were $f = 222$ Hz, $H_{AC} = 800$ A m^{-1}, $H_{DC} = 800$ A m^{-1}. The correction to the underlying diamagnetism has been calculated on the basis of Pascal constants [7]: -3.94×10^{-9} m^3 mol^{-1}.

2.3. X-ray crystal structure determination

Single-crystal data collection of **1** and **12** was performed at 299 K with an Enraf-Nonius CAD-4 diffractometer [8]. The unit cells were determined by least-squares refinements from θ values of 25 accurately measured reflections. Intensities were recorded with an ω–2θ scan. Corrections to Lorentz, polarisation and absorption (ψ empirical) effects were applied. Diffraction data of **2** were collected at 303 K on a Siemens SMART CCD area detector diffractometer using 0.3° ω-scans. The crystal-to-detector distance was 3.85 cm. Graphite-monochromated Mo Kα radiation, $\lambda =$ 0.71093 Å was used in both cases.

The structures were solved by direct methods [9] and subsequent Fourier differences techniques, and refined anisotropically by common least-squares methods [10]. The hydrogen atoms were refined with fixed distances from the parent carbon atoms. The final R indices [$I > 2\sigma(I)$] were $R_1 = 0.026$, $R_1 = 0.051$, and $R_1 = 0.075$ for **1**, **2**, and **12**, respectively. The crystal data on **1**, **2** and **12** are presented in Table 2.

3. Results and discussion

The condensation of poxal with *o*-phenylenediamine in the molar ratio 2:1 gave **1** (poxbim) in a relatively low yield (25%). The same yield (26%) was obtained upon the condensation using the molar ratio 1:1. It seems to be evident that, after the condensation of one molecule of poxal, the oxidation of the reaction intermediate (either Schiff base or imidazolidine) occurred. This is in contrast to a synthesis based on the salicylaldehyde [2] or pyridinecarboxaldehyde [4]; it illustrates a higher reactivity of pyridine *N*-oxides [11]. The observed oxidation could be a reason for the low yield. However, the yield is a bit higher than that of the direct oxidation of pybzim (19%). IR spectra were used to check the identity of the poxbim products obtained by the two routes.

The molecular structure of **1** with the atom numbering is shown in Fig. 1. The whole molecule is almost planar and bond lengths and angles are within the values typical for such a type of heterocyclic compounds. Only a negligible twist around the C(7)–C(8) bond (the pyridine ring forms the dihedral angle of 4.1° to the benzimidazole fragment) disturbs the ideal pla-

narity. The oxygen atom of the pyridine *N*-oxide fragment lies 0.010 Å above the mean plane of the pyridine ring. The hydrogen atom on the imidazole nitrogen forms one intramolecular hydrogen bond and one intermolecular hydrogen bond with O(1′) of the neighbouring molecule. Via the net of hydrogen bonds molecules are joined into infinite chains along the crystallographic *a*-axis.

To study the coordination ability of the poxbim ligand, perchlorates as poorly coordinating anions were used for reactions of poxbim with selected first row transition metals. The complexes obtained could be divided into three groups according their metal to ligand ratio.

Only one 1:1 adduct (compound **3**) was obtained using the excess of copper(II) chloride (Table 1). Preliminary susceptibility measurements in the temperature range (80–300) K ($\mu_{eff}/\mu_B = 1.6$ at 80 K, and 2.0 at 300 K) indicate a dimeric or higher nuclearity for its molecular structure.

The second group of product with the stoichiometry of $ML_2X_2{\cdot}nH_2O$ (compounds **4**–**7**) is exemplified by the complex $[Co(poxbim)_2(H_2O)_2](ClO_4)_2$, for which the molecular and crystal structure was determined. Fig. 2 presents a view of the $[Co(poxbim)_2(H_2O)_2]^{2+}$ cation along with its atom numbering. The cobalt atom lies in the inversion centre surrounded by two bidentate chelating poxbim molecules: Co(1)–O(2) = 2.0286(2) and Co(1)–N(3) = 2.1117(4) Å. Two oxygen atoms from water molecules complete the hexacoordination: Co(1)–O(1) = 2.1422(3) Å. The ligand poxbim coordinates through the oxygen and imine nitrogen atoms of the imidazole group. This means that the poxbim ligand altered its conformation with respect to the free molecule. The intramolecular hydrogen bond was interrupted due to the rotation of the benzimidazole group around the C(7)–C(8) bond. The oxygen atom lies in the pyridine mean plane without considerable deviations (0.026 Å). The cobalt atom deviates slightly from

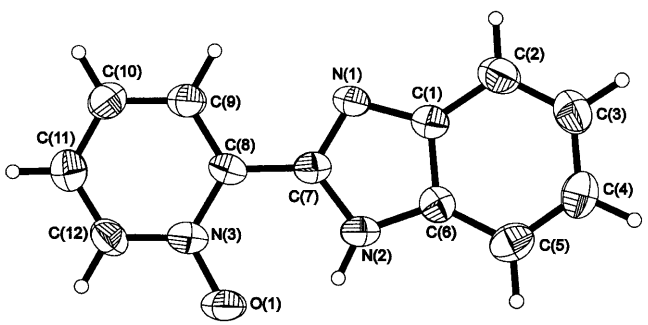

Fig. 1. View of the poxbim molecule, **1**.

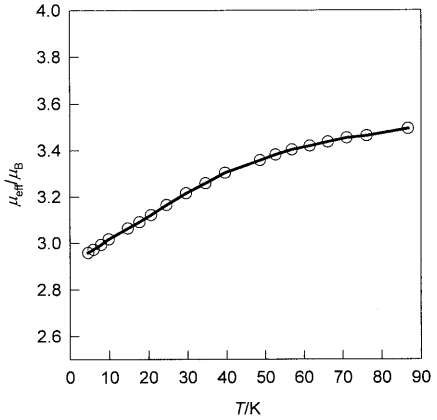

Fig. 4. Temperature dependence of the effective magnetic moment for **2**.

the mean benzimidazole plane (0.122 Å) but essentially from the pyridine plane (− 1.207 Å). A similar coordination mode of the pyridine *N*-oxide group has also been observed for other bidentate ligands: dipyridine *N*,*N*′-dioxide [12,13] or 1,10-phenanthroline *N*-oxide [14]. The Co(1)–O(2)–N(1) angle, 120.9(2)°, is close to those found in Cu(II) complexes [12,13]. It is, however, slightly lower than the angle found in [Cu(poxap)X] complexes [1] in which the central Cu(II) atoms lie in the calculated pyridine planes.

The crystal packing of **2** is determined by three hydrogen bonds involving hydrogens of coordinated water molecules and imidazole group and perchlorate oxygen atoms (Fig. 3).

The molar magnetic susceptibility for **2**, corrected to the underlying diamagnetism, has been converted to the effective magnetic moment and its temperature dependence is shown in Fig. 4.

It can be seen that the effective magnetic moment ranges from the value of $\mu_{eff}/\mu_B = 2.9$ at 4.6 K to $\mu_{eff}/\mu_B = 3.5$ at 87 K. These values are considerably lower relative to the spin-only value for three unpaired electrons ($\mu_{eff}/\mu_B = 3.87$). Such behaviour is typical for the octahedral $^4T_{1g}$ term under the axial distortion due to symmetry lowering to D_{4h} [15]. There exist a number of factors influencing the magnetic properties, namely: (i) the spin Zeeman term; (ii) the orbital Zeeman term; (iii) the spin–orbit interaction; (iv) the orbital reduction factor ($\kappa \leq 1$); (v) the Figgis T_1-term mixing parameter ($1 \leq A \leq 3/2$); and (vi) the axial crystal field splitting (Δ). These parameters enter the spin Hamiltonian of the form [16,17]:

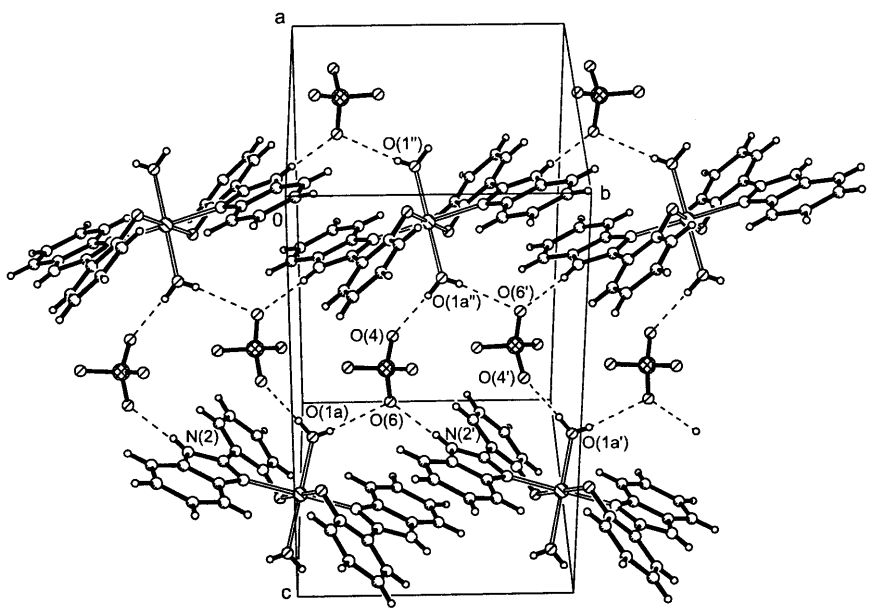

Fig. 3. Crystal packing of the $[Co(poxbim)_2(H_2O)_2](ClO_4)_2$ showing hydrogen bonding.

$$\hat{H}^{\text{spin}} = \mu_B(g_e\vec{S} + \kappa\gamma^{[\text{strong field}]}A\vec{L}) \cdot \vec{B}[\hbar^{-1}] + \kappa v_\xi^{[\text{strong field}]}A\vec{L} \cdot \vec{S}[\hbar^{-2}] + \Delta(\hat{L}_z^2 - \hat{L}^2/3)[\hbar^{-2}]$$

and they interplay in a complicated manner. Therefore it is difficult, if not impossible, to fix all of them reliably from the powder susceptibility data alone. Definitely, 12 magnetically active energy levels are partially populated in the temperature interval concerned.

However, an alternative model of the magnetism comes into consideration; this considers spin-admixed states $^4A_1$–$^2A_1$. When the excited $^2A_1$ state is close to the ground $^4A_1$ state, its thermal population results in some reduction of the magnetic productivity – the fact really observed on the basis of magnetic data for **2**. The adaptation of such a model is not a routine task since the key matrix elements of the type $\langle {}^4A_1|\hat{H}^{so}|{}^2A_1\rangle$ within the point group D_{4h} or D_{2h} have not been derived so far. An analogous model of $^6A_1$–$^4A_1$ is known for Fe(III) complexes and successful in describing the reduced magnetic productivity of iron(III) porphyrins [18,19].

The third group of products (**8**–**13**) is characterised by higher metal to ligand stoichiometry than 1:2. The IR spectra for **8**–**13** are more complex than that for ML_2X_2-type complexes in the fingerprint region. Additional peaks could be assigned to peaks of uncoordinated or differently coordinated (possibly monodentate) poxbim molecules. Parallel occurrence of two different kinds of poxbim in the crystal structure can explain higher ligand-to-metal stoichiometries as well as the IR data. The X-ray structure determination for the $Zn(poxbim)_4(ClO_4)_2{\cdot}4H_2O$ complex (**12**) gives a surprising explanation of the role of poxbim in the complexes of the third group. The structure shows that two ligands remain uncoordinated in $[Zn(poxbim)_2(H_2O)_2]$-$(ClO_4)_2{\cdot}(poxbim)_2{\cdot}2H_2O$. The geometry of the coordination polyhedron $[Zn(poxbim)_2(H_2O)_2]^{2+}$ is analogous to the $[Co(poxbim)_2(H_2O)_2]^{2+}$ in **2**. Some relevant distances are: Zn(1)–O(1) = 2.074(4), Zn(1)–N(3) = 2.094(5) and Zn(1)–O(2) = 2.130(4) Å (Fig. 5).

Two uncoordinated ligands form a pair due to the hydrogen bonds between the imidazole hydrogen and the oxygen of the *N*-oxide group. The positions of pairs $[poxbim]_2$ resemble the positions of the coordinated ligands in the $[Zn(poxbim)_2(H_2O)_2]^{2+}$ complex (Fig. 6). The separation of the best-fit planes of poxbim molecules in the $[Zn(poxbim)_2(H_2O)_2]^{2+}$ complex is 1.50 Å and it equals to 1.64 Å for two uncoordinated ligands in the $[poxbim]_2$ pair. Intermolecular O–O and O–N contacts between two $[Zn(poxbim)_2(H_2O)_2]^{2+}$ units are 2.75 and 3.14 Å. These are not too far from similar contacts between two $[poxbim]_2$ units, which are 3.39 and 3.01 Å, respectively.

Noticeable is the fact that the IR spectra of all M:L = 1:3, 1:4 and 1:5 complexes look very similar. Therefore, we assume that these compounds contain $[ML_2]^{2+}$ and $[L_2]$ units in a different ratio: repetition of $[ML_2]^{2+}$ and $[L_2]$ motifs in crystal packing in the 2:1 ratio will lead to the apparent stoichiometry $[ML_3]^{2+}$ of the nickel complex **8**, and 2:3 ratio yields the $[ML_5]^{2+}$ stoichiometry found for the cobalt complex **13**.

Spectroscopic characterization of lanthanide complexes with *N*,*N*′-tetraethyl-*N*″-benzoylphosphoryltriamide. Crystal structure of tris(*N*,*N*′-tetraethyl-*N*″-benzoylphosphoryltriamide) cerium(III) trinitrate complex

Received 28 April 2000; accepted 2 August 2000

Abstract

A new range of lanthanide compounds of the formula $Ln(HL)_3(NO_3)_3$, where Ln = La, Ce–Nd, Sm–Lu, Y; HL = $C_6H_5C(O)N(H)P(O)[N(CH_2CH_3)_2]_2$–*N*,*N*′–tetraethyl–*N*″-benzoylphosphoryltriamide have been prepared and characterized by means of IR, ^1H, ^{31}P NMR and UV–Vis spectroscopies. The compounds are isomorphous according to X-ray powder diffraction studies. The crystal and molecular structure of $Ce(HL)_3(NO_3)_3$ has been determined by X-ray diffraction studies. The complex has a molecular structure. The monodentate neutral phosphoryltriamide ligands are coordinated to the metal ion via phosphoryl oxygen atom. The coordination polyhedron of Ce is a tricapped trigonal prism, CN = 9 [6O(NO_3^-) + 3O(P=O)]. By UV–Vis spectroscopy it was shown that in acetonitrile solution the neodymium complex with molar ratio 1:3 (Nd^{3+}:HL) exists (stability constant = 2.56). © 2000 Elsevier Science B.V. Keywords: Lanthanide; Carbacylamidophosphate; NMR; X-ray data

1. Introduction

The present work is a continuation of regular studies of lanthanide complexes with carbacylamidophosphate compounds of the general formula $R_1C(O)NHP(O)R_2$, which are also potential *O*,*O*′-donor ligands for metal ions [1]. The presence of a peptide group in the compound causes its diverse biological activity and some of their *N*-ethyleneimine derivatives (at the phosphoryl group) have been proposed as anticancer drugs [2]. Carbacylamidophosphates may be regarded as powerful chelating systems, closely related to β-diketonates.

The first studies of the coordination chemistry of carbacylamidophosphates were devoted to complexes of the lanthanides because of the high affinity of the phosphoryl group for the rare-earth elements [3].

Studies of rare earth coordination compounds with bis(diethylamido)-trichloracetylamidophosphorus acid [4] and *N*,*N*′-tetramethyl-*N*″-benzoylphosphoryltriamide [5] were reported earlier.

Herein, we report the synthesis and studies of the lanthanide coordination compounds with *N*,*N*′-tetraethyl-*N*″-benzoylphosphoryltriamide in the solid state and in non-aqueous solutions and the result of X-ray studies of $Ce(NO_3)_3(HL)_3$.

2. Experimental

2.1. Preparation of $Ln(NO_3)_3(HL)_3$

N,*N*′-Tetraethyl-*N*″-benzoylphosphoryltriamide was prepared and identified according to Ref. [2].

Complex compounds were synthesized through the following reaction:

$$Ln(NO_3)_3 \cdot nH_2O + 3HL \rightarrow Ln(NO_3)_3(HL)_3 + nH_2O$$

where Ln = La–Nd, Sm–Lu and Y.

Hydrated rare earth nitrate (1 mmol) was dissolved in isopropanol (15 ml). The solution was heated to boiling point to dissolve the rare earth salt completely, and the resulting solution was added to the solution of HL (3 mmol) in methanol (15 ml). The obtained solution was allowed to stand in a vacuum desiccator over $CaCl_2$. After a while the crystals precipitated from the solution. They were filtered off, washed with cooled acetone, and dried over $CaCl_2$ (yield 80–90%). A single crystal of $Ce(HL)_3(NO_3)_3$ was prepared by slow crystallization from isopropanol.

According to X-ray diffraction, the prepared complexes are isostructural crystalline compounds. They are stable in air and slightly colored depending on the color of the Ln(III) aqua ion, soluble in methyl and ethyl alcohol, less soluble in acetone, and essentially insoluble in nonpolar aprotic solvents and water.

For all compounds the contents of metals were determined by a complexometric titration method with xylenol orange as indicator:

3. Methods

IR spectra were recorded in KBr pellets on an UR-10 spectrometer (Carl Zeiss, Jena) (400–4000 cm^{-1}). X-ray diffraction patterns were recorded on a DRON-3 diffractometer using Cu Kα radiation. The ^1H (TMS) and ^{31}P (H_3PO_4 in D_2O) NMR spectra were recorded on a Bruker WP 100 SY spectrometer at room temperature in acetone-d_6 solution.

Electroconductivity measurements for $Nd(HL)_3(NO_3)_3$ were made at room temperature in acetone solutions in the concentration range 0.09–0.01 mol^{-1}.

Crystal data for the cerium compound were collected using an Enraf–Nonius CAD4 automated diffractometer. Table 1 lists the cell parameters and details of data acquisition and structure refinement. Selected geometrical parameters of $Ce(HL)_3(NO_3)_3$ are listed in Table 2. The structure was solved by direct methods and refined by the least-square method using the programs SHELXS and SHELXL-93 [6,7]. All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated from the geometry of the molecule. In the final difference map, the highest peak 0.37 e $Å^{-3}$ was near the cerium ion (1.12 Å).

UV–Vis spectra were measured at room temperature in absolute acetonitrile on a KSVU-23, LOMO adapted for an IBM PC.

Systems with a constant concentration of Nd^{3+} and various concentrations of phosphorylic ligand (HL) in acetonitrilic solutions of neodymium perchlorate were studied. The equilibrium concentration values of complexes were determined by means of measurement of integral intensities of $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transitions appropriate to a solvated ion Nd^{3+} and complex. These bonds were divided by GAUSSIAN.

The number of ligands *n* in complex, was determined graphically on the equation [8]: $\log [ML]/[M] = \log \beta_n - n \log [L]$.

The stability constants of the complexes were calculated from values for the equilibrium concentrations of the components.

4. Results and discussion

4.1. IR spectroscopy

The IR spectra of the coordination compounds are very similar. The spectra reveal significantly lower frequencies of ν(PO) compared to the data for the free

ligand ($\Delta\nu$(PO) = 15–55 cm^{-1}), reflecting the coordination via the phosphoryl oxygen atom [9,10]. The ν(CO) values of the complexes (1680–1690 cm^{-1}) do not differ from the parameters for the free ligand (1675 cm^{-1}).

The broad absorption band in the IR spectrum of the free ligand at 3070 cm^{-1} can be assigned to vibrations of the NH group connected by a hydrogen bond to a phosphoryl group of a neighboring molecule [11]. By coordination to the lanthanide ion the intermolecular hydrogen bonds break up and that is why in the spectra of the complexes ν(NH) is detected near 3320–3335 cm^{-1}.

Thereby the main changes in the spectra deal with the ν(NH) and ν(PO) bands. This fact can be explained by the formation of a coordination bonding lanthanide ion with a phosphoryl ligand via a phosphoryl group.

The vibrations of the nitrate groups appear as two absorption bands in the range 1500–1300 cm^{-1}, which is evidence for the bidentate coordination of a nitrate ion [12].

4.2. UV–Vis spectroscopy

The comparison of the diffuse reflectance spectrum of the complexes of $Nd(NO_3)_3(HL)_3$, and absorption spectrum in acetonitrile solution allows one to assume the identity of the structure of the coordination spheres of this compound in the solid state and in acetonitrile.

The ratio of intensities and character of splitting of lines in the hypersensitive transition $^4I_{9/2} \rightarrow {}^4G_{5/2},{}^2G_{7/2}$ region Fig. 1 testifies to the similarity of the environment of the central atom in these compounds [13].

It was shown that the acetonitrile solutions of $Ln(HL)_3(NO_3)_3$ are weak electrolytes ($C = 3.0 \times 10^{-2}$–0.4×10^{-2} mol^{-1}, $\lambda = 23$–$43\ \Omega^{-1}$ cm^2 mol^{-1}), therefore very probably the structure of the coordination unit is preserved in acetonitrile. A decrease in complex concentration results in the values of molecular conductivity growing sharply.

A number of solutions with constant concentration of neodymium perchlorate (0.1 mol^{-1}) and different metal:ligand ratios were studied. Fig. 2 shows the absorption spectra of these solutions in the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition region. The oscillator strength of the f–f transitions for the solutions of neodymium compounds are given in Table 3. Fade-in of f–f transitions in $^4I_{9/2} \rightarrow {}^4G_{5/2},{}^2G_{7/2}$ region up to ratio a metal:ligand ratio equal to 1:4 with an exit at a plateau observed. Data accounting for the composition of the complex and the constant of stability are given in Table 4.

The absorption spectra of neodymium perchlorate contain one band in the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition region (428.1 nm). By addition of the ligand to the solution we can observed a new band (429.84 nm) in the spectrum. The intensity of the above-mentioned band grew with increasing concentration of HL. Apparently, this band corresponds to a complex whose concentration grows by increasing the metal: HL ratio. The ratio of the integrated intensity of these two bands was accepted for the calculation.

Plotted versus $\log[ML]/[M] = f(\log[L])$, Fig. 2, and the linear least-squares approximations for the series solutions give the equation of a straight line $y = 2.56$–$3.28x$ (with the correlation coefficient $K = 0.99$) which evidences complex formation with composition 1:3 (stability constant 2.56).

Thus, in acetonitrile solutions equilibrium takes place:

$$Nd[(Solv)_n]^{3+} + 3HL \leftrightarrows [Nd(Solv)_{n-m}(HL)_3] + mSolv$$

It is interesting to note that investigations of complex formation in solutions of a ligand, close on a structure (*N*,*N*′ - tetramethyl - *N*″ - benzoylphosphoryltriamide),

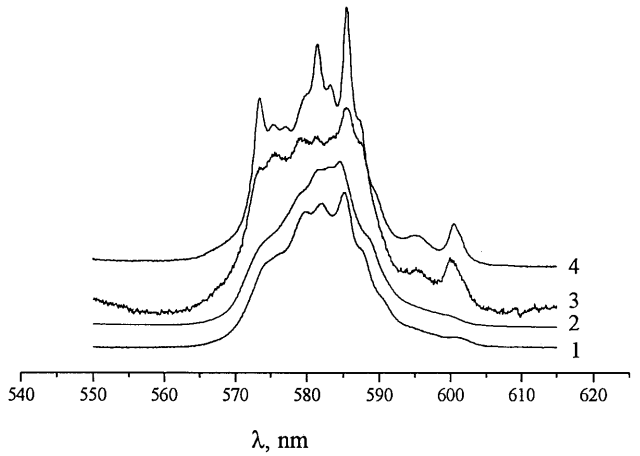

Fig. 1. $^4I_{9/2} \rightarrow {}^4G_{5/2},{}^2G_{7/2}$ in the absorption spectra of neodimium complexes: (1) $Nd(NO_3)_3(CCl_3C(O)NHP(O)[NEt_2]_2)_3$ in acetone solution; (2) $Nd(NO_3)_3(HL)_3$ in acetonitrile solution; (3) $Nd(NO_3)_3(HL)_3$ in the solid state; (4) $Nd(NO_3)_3(CCl_3C(O)NHP(O)[NEt_2]_2)_3$ in the solid state.

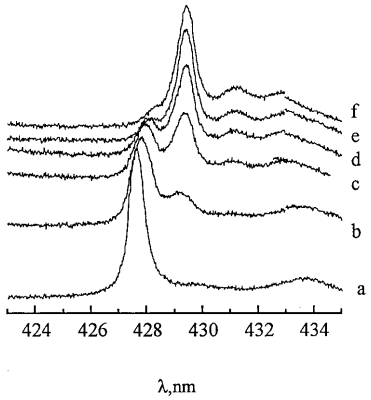

Fig. 2. $^4I_{9/2} \rightarrow {}^2P_{1/2}$ in the absorption spectra of neodimium complexes in acetonitrile solutions $C(Nd^{3+}) = 0.1$ mol l^{-1}. Ratio of metal:ligand is equal: (a) sol. $Nd(ClO_4)_3$; (b) 1:1; (c) 1:2; (d) 1:2.5; (e) 1:3; (f) 1:3.5.

concluded that in simulated conditions a complex of composition 1:2 is formed [14].

4.3. NMR spectroscopy

A rather wide range of chemical shifts in the NMR spectra of the synthesized compounds is due to the paramagnetic properties of rare-earth ions [15]. Table 5 presents the chemical shifts in the ^1H and ^{31}P NMR spectra of solutions of the $Ln(NO_3)_3(HL)_3$ complexes in acetone. The ^1H NMR spectra show the signals from the protons of the methyl and methylene groups. Broad signals of amide protons appear in the NMR spectra of the compounds of La, Ce, Sm, Yb, Lu, Y at 8.88, 12.6, 9.69, 9.55, 8.7, 8.64 ppm, respectively. The ^{31}P NMR spectra of the solutions of the complexes in acetone exhibit one singlet, indicating the magnetic equivalence of all phosphorus atoms in the molecule.

4.4. X-ray

The coordination sphere of Ce in $Ce(NO_3)_3(HL)_3$ is a tricapped trigonal prism (coordination number is nine) (Fig. 3). The O(1a), O(1b), and O(1c) oxygen atoms of the three ligands HL occupy the vertices of one triangu-

lar base of a prism, and the O(4), O(6), O(9) oxygen atoms from the three nitrate groups are located at the vertices of another triangular base. The caps adjacent to the rectangular faces of the prism are occupied by the second oxygen atoms O(3), O(7), O(10) of the coordinated nitrate groups. The symmetry of such an environment is roughly C_3. A similar structure was observed for the complex $Eu(NO_3)_3(CCl_3C(O)NHP(O)[NEt_2]_2)_3$ [4].

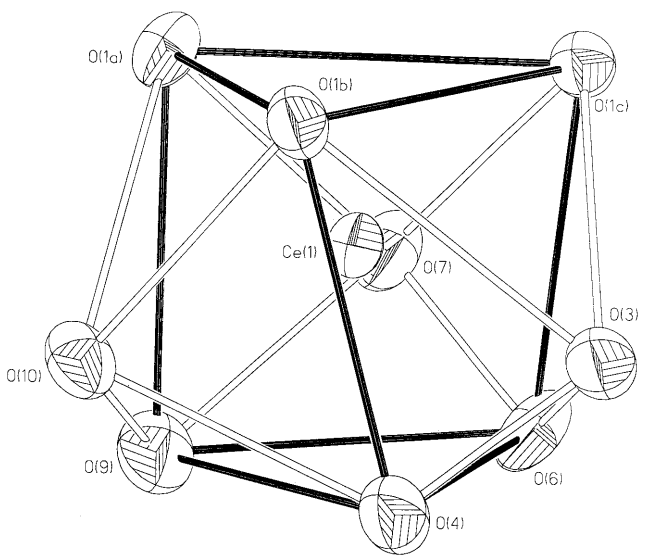

Fig. 3. Polyhedra of complex $Ce(NO_3)_3\{(C_6H_5C(O)NHP(O)[N(CH_2CH_3)_2]_2\}_3$.

The nitrate groups symmetrically coordinate the central atom, therefore the coordination polyhedron of $Ce(NO_3)_3(HL)_3$ can be conventionally considered to be a distorted pseudo-octahedron if every nitrate group is assumed to occupy one site in the coordination polyhedron ($3O(HL) + 3X$), where X is the midpoint of the line connecting the coordinated oxygen atoms of the nitrate group). All of the angles of this coordination polyhedron are close to the octahedral angle (Table 3).

In the planar four-membered CeO_2N chelate rings, the average angle CeON is 96,6°, and the average Ce–O bond length for the nitrate groups is 2.51(12) Å, which agrees well with the literature data on nitrate lanthanide complexes [6]. The coordinated nitrate groups have virtually planar triangular structures. The tightening effect of the coordination center leads to the average ONO angle of the chelate ring (118.1°) being smaller than the other angles (on average, 121.7°). The average N–O distance is 1.229(2) Å, and the bonds adjacent to the Ce–O bonds are the longest (on the average, they are 0.05 Å longer). Therefore, the coordination of the nitrate groups results in their slight distortion. Interestingly, the nitrate groups lie in three mutually perpendicular planes (the angles between these planes are in average 86°).

As in the majority of the complexes based on the phosphoryl ligand [6] the P–O and Ce–O bonds in the $Ce(NO_3)_3(HL)_3$ complex are not collinear. The CeOP angles range within 155.8(6)–159.9(6)°, which is similar for lanthanide complexes with *N*,*N*′-tetraethyl-*N*″-trichloroacetylphosphoryltriamide.

The average cerium phosphoryl oxygen distance in the complex is 2.402 Å, which falls within the bond length range typical of lanthanide complexes with phosphoryltriamide ligands.

The phosphoryl and carbonyl groups are in the *anti* position to each other (Fig. 4), The same configuration is typical of the free ligand HL [11]. However, a different conformation is observed in the structure of the complex $Ln(NO_3)_3\{C_6H_5C(O)NHP(O)[N(CH_3)_2]_2\}_2$, where the ligand is a coordinated bidentate with C=O and P=O groups in the *sin* position [16].

In as much as the structures of the three phosphoryl ligands are similar, hereafter we will consider the average geometry of the neutral ligands.

The phosphoryl group forms the OPN angles of 112.45(6)°, and 104.1(7)° with the nitrogen atoms of the diethylamino groups and benzamide group, respectively. The small value of the latter angle is probably caused by the occurrence of hydrogen bonding $NH\cdots ONO_2$.

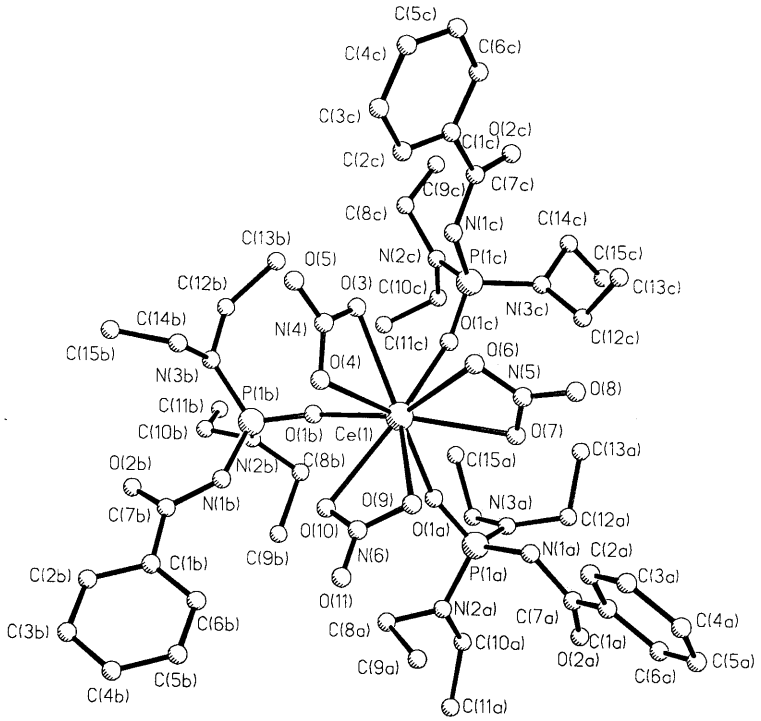

Fig. 4. Molecular structure of the complex $Ce(NO_3)_3\{(C_6H_5C(O)NHP(O)[N(CH_2CH_3)_2]_2\}_3$.

Geometry of hydrogen bond

Donor (D)	Hydrogen atom (H)	Acceptor (A)	*d* (Å)			Angle (°)
			D–H	A–H	D–A	D–H–A
N(1a)	H(1a)	O(7)	0.86	2.044	2.848	155.3
N(1b)	H(1b)	O(10)	0.86	2.09	2.881	1522.8
N(1c)	H(1c)	O(3)	0.86	2.143	2.938	153.5

The sum of the angles about the amide nitrogen atom is close to 360° (sp^2-hybridization), which is caused by delocalization of the lone pair of electrons of the nitrogen. This fact and the decrease in P–N distances in the coordinated ligand compared to the free ligand (1.616 Å in the complex, versus 1.631(2) in the free ligand) can be explain by an increase in the $d_\pi-p_\pi$ conjugation between the phosphorus atom and nitrogen atoms of diethylamide groups upon complex formation.

The carbonyl atom shows sp^2-character.

The angle between the benzene ring plane and the carbamide plane change within 6–23°, showing the presence of π-conjugation between the carbonyl group and the benzene ring. This fact can be confirmed by a decrease in the C–C bond length (1.49 Å) between these groups compared with the bond lengths of other such bonds.

5. Conclusion

The distinctions in the way of coordination by the ligand with dimethylamide substituents (bidentate coordination) from analogous with diethylamide substituents deals with steric factors: more apparent diethylamide substituents near the phosphorus atom lead to monodentate coordination.

Received 15 March 2000; accepted 11 May 2000

Abstract

The title compound, {AuCl[P($C_9H_{11}O_3$)$_3$]}, has three fold symmetry in the solid state. The Au–Cl and Au–P bond lengths are 2.294 and 2.255 Å, respectively, and the Au atom has nearly linear coordination geometry, with P–Au–Cl 176.03(9)°. The extreme bulkiness of the phosphine ligand is shown by the mean cone angle of 188° (based on O atoms defining the cone), though the cone angle is considerably smaller than 214° for trimesitylphosphine in the known analogous complex. The shorter Au–P bond distance than for Ag–P (2.379(1) Å) in the corresponding known silver chloride complex of tris(2,4,6-trimethoxyphenyl)phosphine tentatively supports an earlier conclusion that gold is smaller than silver. © 2000 Elsevier Science B.V. Keywords: Bulky phosphine; X-ray structure; Cone angle; Two-coordinate gold complex.

1. Introduction

Our long-standing interest in the steric effects of bulky phosphine ligands [1,2] led us some years ago to determine the crystal structure of chloro(trimesitylphosphine)gold(I) containing the bulkiest known phosphine [3]. Another related bulky phosphine, tris(2,4,6-trimethoxyphenyl)phosphine, has garnered recent attention [4]. Since several crystallographic studies of mono tertiarylphosphine gold(I) chloride complexes have been reported [5–28] we undertook the structural determination of the title compound to provide a relative steric profile of tris(2,4,6-trimethoxyphenyl)phosphine, particularly as compared with other bulky phosphines.

2. Results and discussion

Chloro{tris(2,4,6 - trimethoxyphenyl)phosphine}gold-(I) (**1**) has approximate threefold symmetry in the solid state (Fig. 1). The dihedral angles between the aryl ring planes and the relevant Au–P–Cln1(n = 1, 2, 3) planes are 50.4(3), 56.7(3)and 15.3(3)° for planes C11–C16, C21–C26 and C31–C36, respectively. The three aryl

rings of the bulky triarylphosphine ligand have very similar geometries. The P atom is displaced 0.18(1), 0.22(1) and 0.09(1) Å from the aromatic plane and the *ortho* methoxy O atoms are displaced in the opposite direction (e.g. O12 −0.04(1), O16 +0.09(1) Å). There are also weak interactions between the Au atom and the three immediately adjacent methoxy oxygens (O32, O12 and O22, Au···O separations 2.922(1), 3.112(1) and 3.122(1) Å. Comparable values for the known analogous Ag complex are: 2.818(3), 3.038(3) and 3.140(3) Å [4]. In the analogous trimesitylphosphine complex the significant Au···H interactions to the *ortho* methyl groups (mean contacts Au···C 3.229 Å and Au···H 2.40 Å) were characterized as 'remote agostic' [29]. Whether the same designation of an attractive interaction is applicable for (**1**) is not as clear from the structural data. All six *ortho* methoxy groups in (**1**) have their methyl groups oriented so that they are remote from the central P atom and are turned away from the Au atom. In the trimesitylphosphine complex the mean P–C*n*1–C*n*6 angle (117.3(6) Å) (where $n = 1$, 2, 3) is 6.7° less than the mean P–C*n*1–C*n*2 angles (124.0(6)°). Comparable angles in the present complex are 118.8(17) and 125.2(17)°, respectively. For the analogous 1:1 silver chloride and bromide complexes studied by Baker et al. [4], these angles follow the same trends. The mean Au–P–C angle and the mean C–P–C angle in (**1**) are 110.5(8) and 108.4(10)°, respectively; comparable values for the corresponding trimesitylphosphine complex are 107.6(2) and 111.2(3)°, attesting to the greater *ortho* interactions due to the larger steric bulk of the $Pmes_3$ ligand (see below). The comparable mean angles in the known silver chloride complex are identical to those found in (**1**) [4].

The Au–Cl bond length (2.294(2) Å) and P–Au–Cl bond angle (176.03(9)°) in (**1**) are comparable with those reported in other structural studies of species containing the R_3P–Au–Cl fragment (R_3P = triaryl- or trialkyl-phosphine). For comparison, relevant Au–Cl and Au–P bond lengths and P–Au–Cl angles for some selected structures of this type, revealed in a search of the Cambridge Structural Database [30], are shown in Table 1. The Au–P bond length of 2.255(2) Å (**1**) is slightly less than the Au–P bond distance in chlorotrimesitylphosphine (2.2634(15) Å), but comparable to those found in Cy_3PAuCl (2.242(4) Å) and $(o\text{-tolyl})_3PAuCl$ (2.243(2) Å). The Ag–P bond distance in previously reported chloro{tris[trimethoxyphenyl)phosphine]}silver(**I**) is 2.379(1) Å and a weak Ag···O interaction of 2.818(3) Å gives rise to a P–Ag–Cl angle of 175.0(1)° [4]. This longer distance for the Ag–P bond compared to the Au–P one in the present complex is in keeping with the recent conclusion that gold is smaller than silver based on a structural comparison of the analogous bis(trimesitylphosphine) cations [31]. However, since our much earlier structural analysis of the $[Ag(Pmes_3)_2]$ cation indicated that significant intramolecular steric distortions occur within that cation [32], the recent conclusion based on comparing the $[M(Pmes_3)_2]$ cations is clearly flawed. Our present comparison of the analogous L–M–Cl complexes provides more valid evidence for the conclusion that gold is indeed smaller than silver. However, the presence of other intramolecular interactions which are still significant in the present complex (such as the Au···O interactions) suggests that caution should still be exercised in making such a conclusion, i.e. a definitive study should involve a smaller phosphine.

In order to quantify the relative bulkiness of the tris(2,4,6-trimethoxyphenyl)phosphine and trimesitylphosphine ligands, we calculated the cone angles of these ligands from the crystallographic data for the two analogous gold complexes. By calculating semi-cone angles ($\theta/2$) using the 'ligand-profile' concept [1] with C–H at 1.08 Å, resultant average cone angles [2] of 188° and 214° were obtained for tris(2,4,6-trimethoxyphenyl)phosphine and trimesitylphosphine, respectively. The smaller estimated steric size of the former ligand is commensurate with the folding back of the methoxy groups and the observed structural data for the title complex.

3. Experimental

3.1. Compound synthesis and NMR spectral data

The compound was synthesized by stirring tris(2,4,6-trimethoxyphenyl)phosphine with (dimethylsulfide)-

gold(I) chloride in dichloromethane at room temperature for about 5 h. The yield of **1** was 90%. The colorless crystals were obtained from chloroform–toluene mixture on slow evaporation. The melting point is 503 K (dec). Spectral data: ^{31}P-NMR ($CDCl_3$): −32.9. ^{1}H-NMR ($CDCl_3$): 3.53 (s, 18H, OCH_3); 3.78 (s, 9H, OCH_3); 6.02 (d, 4 Hz, 6H, phenyl) ppm.

3.2. Crystal data and data collection parameters

$C_{27}H_{33}AuClO_9P$, $M = 764.92$, Tetragonal, $a = 15.3343(9)$, $c = 12.3291(11)$ Å, $U = 2899.1(3)$ Å^3, $T = 294$ K, space group $P4_3$, graphic monochromated Mo Kα radiation, $\lambda = 0.71073$ Å, $Z = 4$, $D_{calc} = 1.753$ Mg m^{-3}, $F(000) = 1512$, colourless crystals with dimensions $0.43 \times 0.25 \times 0.22$ mm, $\mu = 5.275$ mm^{-1}, CAD4 diffractometer, θ range for data collection 2–27°, 3331 unique reflections measured, 2562 with $I > 2\sigma(I)$.

3.3. Structure solution and refinement

The structure was solved by Patterson methods and refined full-matrix least-squares on F_o^2, using the program SHELXL-93 [33]. All data used were corrected for Lorentz-polarization factors, and for absorption (Gaussian integration, NRCVAX [34]). The hydrogen atoms were included in idealized positions as riding atoms. Final R-factors were $R = 0.0291$, $wR = 0.0556$ for observed data and $R = 0.0569$ and $wR = 0.0603$ for all data.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited at the Cambridge Crystallographic Data Centre, CCDC No. 141601 for compound **1**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The new binucleating ligand 3,5-bis(1′-(4′-(2″-pyridyl)-2′-thiabutyl))pyrazole (BLEPH) forms dinuclear Cu^{II} complexes which are able to bind one additional exogenous bridging molecule such as N_3^-, Cl^-, Br^- and OH^-. Three of these complexes $[Cu_2(BLEP)(\mu\text{-}N_3)(N_3)_2]$ (**1**); $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl$ (**2**); and $[Cu_2(BLEP)(\mu\text{-}Br)(Br)(H_2O)]Br$ (**3**) were characterized by X-ray single crystal structure analysis. The two copper centers are bridged by the central pyrazolyl group of the BLEP and one azide (in **1**), one chloro (in **2**) or bromo (in **3**) and the side arm of BLEP coordinates to each of the coppers with one pyridyl N and one thia S. Electrochemical studies of these complexes reveal that the redox waves are -247 and 15 mV for **2**; -215 and 37 mV for **3** corresponding to the $Cu^{II}Cu^{II}/Cu^{I}Cu^{II}$ and $Cu^{I}Cu^{II}/Cu^{I}Cu^{I}$ couples, and -291 mV for **1** corresponding to the $Cu^{II}Cu^{II}/Cu^{I}Cu^{I}$ process, respectively. The intramolecular magnetic exchange coupling ($J = -46.6\ cm^{-1}$) in the bromo-bridged complex shows weaker antiferromagnetic interaction than the N_3-bridged complex. The exchange coupling process through μ_2-N_3 ligand enhances the net antiferromagnetic interaction. Electronic spectra covering the 12 500–50 000 cm^{-1} region are also reported for these complexes. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Dinuclear; Antiferromagnetic interactions; Pyrazolyl groups

1. Introduction

Stimulated by the occurrence of N/S coordinated copper ions in a variety of proteins [1], numerous ligands with N and S donor atoms have been synthesized and investigated in order to model the properties of these metallobio-sites [2–4]. Biological systems like the mononuclear 'blue' type-1 copper sites and the dinuclear Cu_A center in cytochrome *c* oxidase and catalysis of catechol autoxidation are involved in electron transfer processes during enzyme turnover [1,5]. Much effort has been devoted to the study of dinuclear copper model complexes with bridging thiolates and terminal N donor atoms [6,7]. With regard to a general study of the properties of dimeric copper units in a mixed N/S environment it is of interest to also investigate inverse systems, i.e. those incorporating bridging nitrogen moieties and terminal thioether coordination. The ability of the diazole unit of pyrazolates to bridge two metal centers is well documented [8]. However, relatively few studies of pyrazolate-based ligands bearing additional side arms in the 3- and 5-positions of the heterocycle have been reported, and most of these systems possess N-donors in the substituents [9–13]. On the other hand, various mononuclear complexes of chelating ligands containing both azole and thioether moieties have been designed as model complexes for type 1 copper proteins [3,4a,14]. In the present study dinuclear copper complexes of mixed N/S donor systems based on bridging diazole heterocycles are investigated.

Binuclear copper azide systems have been of considerable interest due to the broad range of their structural and magnetic properties. In particular, azide can act as a bridging ligand in an end-on (μ-1,1) and end-to-end (*cis* μ-1,3) fashion. It is now well established that μ-1,1 bridging gives ferro- and μ-1,3 bridging antiferromagnetic coupling between the copper centers. Moreover,

binuclear copper azide systems have been studied as structural models for copper-containing enzymes involved in the reversible binding and activation of dioxygen like hemocyanin (Hc) [15]. However, the vast majority of studies have focused on binuclear copper(II) azide complexes [16].

In recent work we described the synthesis of mononuclear or dinuclear complexes derived from a series of alkoxo or pyrazolate-based ligand with pendant 2-(2′-mercaptoethyl)pyridine side arms [17] and demonstrated the possibility to tune the range of accessible metal–metal separations in these systems selectively by variation of the bridging function group.

In this paper we report a new synthetic strategy to generate a new dinucleating pyrazolate-based ligand providing both S- and N-rich coordination spheres for two metal centers. Four binuclear Cu(II) complexes $[Cu_2(BLEP)(\mu\text{-}N_3)(N_3)_2]$ (**1**), $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl$ (**2**), $[Cu_2(BLEP)(\mu\text{-}Br)(Br)(H_2O)]Br$ (**3**) and $Cu_2(BLEP)(\mu\text{-}OH)(ClO_4)_2\cdot H_2O$ (**4**) where BLEP is deprotonated 3,5-bis(1′-(4′-(2′-pyridyl)-2′-thiabutyl)) pyrazole are prepared and structurally characterized in order to probe the coordination potential of the new ligand system. X-ray structure investigation revealed that the two copper centers are bridged by the central pyrazolyl group of the BLEP and one azide (in **1**), chloro (in **2**) or bromo ligand (in **3**), and the side arm of BLEP coordinates to each of the coppers with one pyridyl N and one thia S.

2. Experimental

2.1. Ligand synthesis

2.1.1. Methyl pyrazole-3,5-dicarboxylate

Pyrazole-3,5-dicarboxylic acid (5.04 g, 0.029 mol) and sulfuric acid (5 ml) were mixed in 250 ml methanol and refluxed for 6 h. The solution was concentrated to about 60 ml by rotary evaporation, followed by saturated sodium carbonate to bring the pH to 8. After standing at 0°C overnight, white needle crystals were obtained in about 86% yield.

2.1.2. 3,5-Bis(hydroxymethyl)pyrazole

A suspension of $LiAlH_4$ (6 g, 0.158 mol) in 400 ml dry ether under N_2 was prepared. Finely ground methyl pyrazole-3,5-dicarboxylate (3.78 g, 0.021 mol) was placed in a paper thimble of a Soxhlet apparatus that was then fitted to the flask. The ether was refluxed for 24 h with a recycle time of 10–15 min. Then, 60 ml H_2O was added dropwise to the cooled suspension over 45 min. The ether was removed under reduced pressure, and the resulting white cake was suspended in 200 ml methanol, treated with CO_2(g) for 10 min, and then refluxed for 6 h. The solid was filtered, and the filtrate was evaporated to give an oily residue (5 ml). Water in this residue was removed azeotropically with ethanol. The residue was redissolved in ethanol and filtered, and the filtrate was evaporated. The product (as the hydrochloride salt) was obtained as white needles by dissolution of this residue in 20 ml ethanolic HCl by the addition of ether; 2.36 g (70%).

2.1.3. 3,5-Bis(chloromethyl)pyrazole hydrochloride

3,5-Bis(hydroxymethyl)pyrazole (2.36 g, 0.0143 mol) in neat $SOCl_2$ (50 ml, distilled from $P(OPh)_3$) was placed in a preheated 95°C oil bath and was refluxed for 0.5 h. The excess $SOCl_2$ was removed by distillation under reduced pressure. The residue was dissolved in 75 ml ethanol and filtered, and ether was added to produce white plates, 2.67 g (92%).

2.1.4. 2-(2′-Mercaptoethyl)pyridine [21]

This compound was synthesized by a literature method.

2.1.5. 3,5-Bis(1′-(4′-(2′-pyridyl)-2′-thiabutyl))pyrazole (BLEPH)

2-(2′-Mercaptoethyl)pyridine (2.78 g, 0.02 mol) was dissolved in 50 ml absolute ethanol and deprotonated by means of one equivalent of sodium metal (0.69 g, 0.03 mol) at 0°C. 3,5-Bis(chloromethyl)pyrazole hydrochloride (2.00 g, 0.01 mol) was then added in one portion and the resulting solution was kept stirring overnight at room temperature. The solution was kept at 0°C and filtered. The filtrate was evaporated to give a white orange oily product in about 80% yield.

2.2. Metal complexes

2.2.1. $[Cu_2(BLEP)(\mu\text{-}N_3)(N_3)_2]\cdot C_3H_7OH$ (1)

Reaction of a 1:2:3 molar ratio of 3,5-bis(1′-(4′-(2″-pyridyl)-2′-thiabutyl))pyrazole, $Cu(NO_3)_2\cdot 3H_2O$ and NaN_3 in absolute ethanol for 30 min afforded dark brown microcrystals of $[Cu_2(BLEP)(\mu\text{-}N_3)(N_3)_2]$ (82%). *Anal.* Calc. for $Cu_2C_{22}S_2N_{13}H_{29}O$: C, 38.70; H, 4.28; N, 26.67. Found: C, 38.47; H, 4.02; N, 26.78%. The crystals suitable for X-ray single-crystal structure analysis were obtained by evaporation from dichrolomethane–isopropyl alcohol (4/1) mix-solvent.

2.2.2. $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl\cdot 2H_2O$ (2)

A solution of sodium metal (0.023 g, 1.0 mmol) and a solution of $CuCl_2\cdot 2H_2O$ (0.341 g, 2.0 mmol) in ethanol (30 ml) were added stepwise to a solution of BLEPH (0.37 g, 1.0 mmol) in CH_3CN (40 ml). Add 30 ml methanol into the deep green solution which was filtrated from the crude mixture, and it was evaporated to dryness. The resulting green powder (80%) was washed several times with small portions of ethanol. *Anal.* Calc. for $Cu_2C_{19}S_2N_4H_{27}Cl_3O_3$: C, 34.73; H, 4.14;

N, 8.53. Found: C, 34.56; H, 4.07; N, 8.47%. The crystals suitable for X-ray single-crystal structure analysis were obtained by diffusion of ether into a dichloromethane solution.

2.2.3. $[Cu_2(BLEP)(\mu\text{-}Br)(Br)(H_2O)]Br\cdot 2H_2O$ (3)

A solution of sodium metal (0.023 g, 1.0 mmol) and a solution of $CuBr_2$ (0.447 g, 2.0 mmol) in ethanol (30 ml) were added stepwise to a solution of BLEPH (0.37 g, 1.0 mmol) in absolute methanol (40 ml). The green reaction mixture was evaporated to dryness, and the resulting green powder (86%) was washed several times with small portions of ethanol. *Anal.* Calc. for $Cu_2C_{19}S_2N_4H_{27}O_3Br_3$: C, 28.87; H, 3.44; N, 7.09. Found: C, 28.62; H, 3.47; N, 6.98%. The crystals suitable for X-ray single-crystal structure analysis were obtained by diffusion of ether into a dichloromethane solution of the product.

2.2.4. $Cu_2(BLEP)(\mu\text{-}OH)(ClO_4)_2\cdot H_2O$ (4)

A solution of sodium metal (0.089 g, 3.9 mmol) and a solution of $Cu(ClO_4)_2\cdot 6H_2O$ (1.44 g, 3.9 mmol) in methanol (30 ml) were added stepwise to a solution of BLEPH (0.72 g, 1.9 mmol) in absolute methanol (40 ml). The solution filtrated from the green crude mixture was evaporated to dryness, and the resulting green powder (82%) was washed several times with small portions of methanol. *Anal.* Calc. for $Cu_2C_{19}S_2N_4H_{24}O_{10}Cl_2$: C, 31.24; H, 3.31; N, 7.67. Found: C, 31.48; H, 3.39; N, 7.70%.

2.3. Physical measurements

Elemental analyses (C, H, N) were performed at National Cheng Kung University on a Heraeus CHN-O-Rapid Analyzer. The ^1H NMR spectrum was recorded on a Varian EM390 spectrometer at National Sun Yat-sen University. Electronic absorption spectra in the visible and ultraviolet regions were recorded on Shimazu UV-210 spectrophotometer. Cyclic voltammetry was measured by using a Bioanalytical Systems instrument (model BAS-100A). The platinum-disk working electrode (1.5-mm diameter) was polished with 1-μm aluminum oxide powder prior to each series of scans. A silver wire in 0.01 M $AgNO_3$ ($Ag/AgNO_3$) served as a reference electrode and was separated from the working electrode. A platinum wire was used as an auxiliary electrode, and all scans were recorded in deoxygenated DMSO solution with N_2 blowing over the top during the scan. Tetraethylammonium perchlorate (0.1 M NEt_4ClO_4; TEAP) was used as the supporting electrolyte. The choice of solvent was based on the solubility and coordination effect of the complexes. Scan rate ranging from 50 to 200 mV s^{-1} were used. The potentials reported for the redox couples were obtained by averaging the anodic and cathodic peak potentials which were referenced to the $Ag/AgNO_3$ electrode and uncorrected for junction potential.

2.4. X-ray crystallography

The crystal data were collected on a R3M/E four-circle diffractiometer with a graphite monochromator using a Mo Kα radiation ($\lambda = 0.71073$). Intensities were measured by a θ–2θ mode. Details of crystal parameters, data collection and structure refinement are summarized in Table 1. The structure was solved by the direct method. Hydrogen atoms were not found. The final refinement (based on F) was by full-matrix least-squares. The highest peak on the final Fourier-difference map had the value of 1.15 (**1**), 0.57 (**2**) and 0.47 (**3**) e A^{-3}. All calculations were performed with the NRC-VAX package [19].

3. Results and discussion

The new binucleating ligand (BLEPH) was synthesized by the methods outlined in Scheme 1. The diol that is produced from the reduction is tenaciously bound to the aluminum and required extraction with carbonated methanol to remove it from the alumina cake. The hydrochloride salt is then readily obtained. We found that the BLEPH ligand is most efficiently produced by the reaction of equivalent amounts of $NaSCH_2CH_2Py$ and 3,5-bis(chloromethyl) pyrazole.

3.1. Synthesis and structural characterization of $[Cu_2(BLEP)(\mu\text{-}N_3)(N_3)_2]\cdot C_3H_7OH$ (1)

The dark brown complex **1** is produced when the ligand BLEPH is first deprotonated by means of sodium metal and subsequently treated with 2 equivalents of $Cu(NO_3)_2\cdot 3H_2O$ and 3 equiv. of NaN_3. Complex **1** shows good solubility in CH_2Cl_2 and proved to be stable in air over prolonged periods.

The structure of complex **1** is shown in Fig. 1. Selected bond lengths and angles are given in Table 2. Both copper ions are pentacoordinate involving a tridentate binucleating ligand, a bridging azide and a terminal azide ligand, resulting in a distorted square planar N_4S coordination sphere, better described as a distored square pyramid with the pyridyl group in the axial position, rather than as a trigonal bipyramid. The azido ligand is linked to both copper centers in an end-on (μ-1,1) fashion, with a Cu···Cu separation of 3.486(2) Å and a Cu–N5–Cu bridge angle of 116.8°, which lies almost at the longest limit of the range reported for μ-1,2-diazine(pyridazine, phthalazine, thiadiazole) [15–18] end-on (μ-1,1) azido dicopper(II) complexes. The end-on azido bridge is roughly symmetrically disposed with respect to the dinuclear

center, with a slightly different copper–nitrogen distances of 2.037(4) and 2.056(4) Å, and the same Cu–N5–N6 angles of 119°. This may be compared with the analogous complex [23] μ-1-3-azido{μ-{1,1′-[(1*H*-pyrazol-1-ido-3,5-diyl)bis[1,4,7-triazacyclo-nonane]]} dicopper(II), another pyrazolate- based ligand with two pendant 1,4,7-triazacyclononane side arms, in which the azide bound to dicopper in a μ-1,3 bridging form and the Cu···Cu distance is 4.15 Å. The Cu–S distance (2.439(2) and 2.444(2) Å) lie within the normal range usually expected for a Cu^{II} thioether bond [4,16]. The Cu···Cu distance is found to be 3.486(2) Å.

3.2. Synthesis and structural characterization of $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl\cdot 2H_2O$ (2)

Treatment of the deprotonated potential ligand with 2 equiv. of $CuCl_2\cdot 2H_2O$ affords the green ionic complex $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl\cdot 2H_2O$ (**2**), which crystallizes upon vapor diffusion of ether into a CH_2Cl_2 solution of the product. A view of the molecular structure of **2** is depicted in Fig. 2; selected distances and angles are listed in Table 3. This structure is analogous to the square pyramidal coordination found in the solid state [18] for $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl$ in which the two coppers are bridged in the equatorial plane by a chloride ion and apical coordination to the two coppers is provided by another chloride ion and a water molecule. The Cu–Cu distance in $[Cu_2(BLEP)(\mu\text{-}Cl)(Cl)(H_2O)]Cl$ is 3.6356(8) Å. The two square pyramidal copper ions have their apical sites located on the same side of the complex. This cofacial arrangement is ideal for apical interaction of the catechol substrate with the two copper ions in the manner suggested by Nishida and co-workers [20]. In contrast to the type of catecholate coordination found by Karlin et al. [21], a phenolate–bridged dicopper(II) complex would appear to be highly strained for **2**. In Karlin's structure the two oxygens of tetrachloro-catecholate span basal positions of the two square pyramidal copper ions [6].

3.3. Synthesis and structural characterization of $[Cu_2(BLEP)(\mu\text{-}Br)(Br)(H_2O)]Br\cdot 2H_2O$ (3)

Treatment of the deprotonated potential ligand with 2 equiv. of $CuBr_2$ affords the green ionic complex $[Cu_2(BLEP)(\mu\text{-}Br)(Br)(H_2O)]Br\cdot 2H_2O$ (**3**), which is isomorphous with **2**. Selected distances and angles are listed in Table 3. This structure is analogous to the square pyramidal coordination found in **2**, in which the two coppers are bridged in the equatorial plane by a bromide ion and apical coordination to the two coppers is provided by another bromide ion and a water molecule. The Cu–Cu distance in **3** is 3.706(2) Å that is observably longer than that in **1** (3.486(2) Å), and is slightly longer than that in **2** (3.6356(8) Å) due to the increased size of the exogenous bridging atom.

the potential range -0.8 to 0.5 V versus the Ag/$AgNO_3$ electrode in DMSO at sweep rates of 50 mV s^{-1}. Two main behaviors can be distinguished in Fig. 3. First, complex **1** exhibits a single two-electron transfer redox wave at -0.291 V with cyclic voltammetric peak separations of 206 mV. Second, complexes **2** and **3** show quasi-reversible redox processes and corresponding to successive one-electron-transfer steps observed for each complex. The redox waves are -0.247 and 0.015 V for **2** and at -0.215 and 0.037 V for **3**, correspond to the $Cu^{II}Cu^{II}/Cu^{I}Cu^{II}$ and $Cu^{I}Cu^{II}/Cu^{I}Cu^{I}$ couples, respectively. The peak potentials and half-wave potential of quasi-reversible process of complex **1** are listed in Table 4 and cyclic voltammogram is shown in Fig. 3. Reductive cyclic voltammograms of this complex show a quasi-reversible two-electron redox wave, and we attribute this to the reduction of $Cu^{II}Cu^{II}/Cu^{I}Cu^{I}$. Because the ability of σ-donation of the azide is much stronger than that of the halides, the values of reduction potentials of E_{pc}(**1**) is more negative than E_{pc}(**2**) and E_{pc}(**3**). Since the σ-donation effect will raise the energy level of the LUMO of these complexes, the half-wave potentials of reductive waves decreases with the increasing σ-donor strength of the azide complex [24,25]. These results also agree with the spectrochemical series $N_3^- > Cl^- > Br^-$ [26,27]. The difference between the two redox potentials of these complexes are about 250 mV, and the phenomenon is due to the

interaction between two copper centers through the bridging ligand and the asymmetric coordination environments of two copper centers in complexes **2** and **3**.

3.5. Electronic spectroscopy

Electronic absorption spectra in the UV–Vis region of these complexes were recorded in methanol solution and collected in Table 5. An analysis of LMCT spectra must necessarily consider the electronic structure of the free ligands and the perturbation, if any, in their absorption spectra by a spectroscopically inactive dipositive ion such as Zn(II), and Mg(II). The absorption bands below 300 nm are due to absorption of the free ligand, and the extinction coefficient corresponds to typical π to π* transition. These four complexes have similar electronic absorption and exhibit two main features (Fig. 4), one band at 320–356 nm, the other band at lower energy ca. 420 nm. In addition to these two bands, the spectrum of azide shows a medium intensity absorption ($\varepsilon = 2500$ dm^3 mol^{-1} cm^{-1}) at 495 nm, which can be assigned to be the LMCT band of N_3^- to Cu charge transfer.

3.6. Magnetic properties

Variable-temperature DC magnetic susceptibility data were collected for complex **1** and **3** at an applied field of 10.0 kG. Magnetic data μ_{eff} versus T plots of complexes **1** and **3** were displayed in Figs. 5 and 6, respectively. Fig. 5 shows plots of the effective magnetic moment (μ_{eff}) per Cu_2 versus temperature for several

different samples of complex **1**. As can be seen in Fig. 5, the values of μ_{eff}/Cu_2 for several different samples of complex **1** are consistent around 1.82 μ_B at 300 K. As the temperature is decreased, the values of μ_{eff}/Cu_2 decrease and reach around 0.2 μ_B at 5.0 K. If there were no exchange interaction between the metal ions in a Cu_2^{II} complex, the spin-only effective magnetic moment would be 2.45 μ_B and it would be independent of temperature. Clearly, there is appreciable antiferromagnetic exchange interaction between the two copper ions in complex **1**. However, the antiferromagnetic property is different from other ferromagnetic μ-1,1 azido dicopper complexes, we think it maybe caused by the coordinated S atoms of ligand. The curve for each sample is slightly different from each other, it indicates there is different intermolecular and/or intramolecular magnetic interactions.

In Fig. 6, the effective magnetic moment (μ_{eff}) per Cu_2 is 2.33 μ_B at 319.5 K. As the temperature is decreased, the value of μ_{eff}/Cu_2 also decreases and reaches 0.35 μ_B at 2.0 K. The value of effective moment at 319.5 K is 2.33 μ_B, slightly lower than the spin only value (2.45 μ_B), indicative of the presence weak to moderate antiferromagnetic exchange interaction between the two copper ions in complex **3**.

In order to assess the nature of exchange interaction in complexes **1** and **3**, the theoretical expression for the magnetic susceptibility per molecule is given by Eq. (1) [22],

$$\chi_m = \frac{N\mu_B^2 g^2}{3k(T-\theta)}\left[1+\left(\frac{1}{3}\right)\exp(-2J/kT)\right]^{-1}(1-\rho) + \frac{\rho N\mu_B^2 g^2}{4kT} + N\alpha \quad (1)$$

where θ is the Weiss constant which correlates to the intermolecular interaction, $N\alpha$ is temperature-independent susceptibility, ρ represents the fraction of possible magnetically impurity, and N, μ_B, and k have their usual meanings. The data for complexes **1** and **3** were fitted to Eq. (1) with g, J, ρ and θ as variables. The

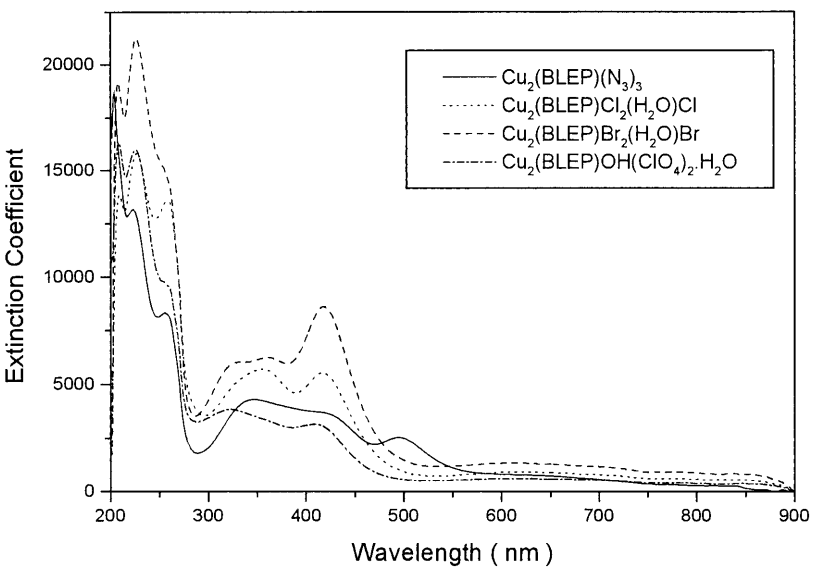

Fig. 4. Electronic absorption spectra of complexes **1**, **2**, **3** and **4** in methanol.

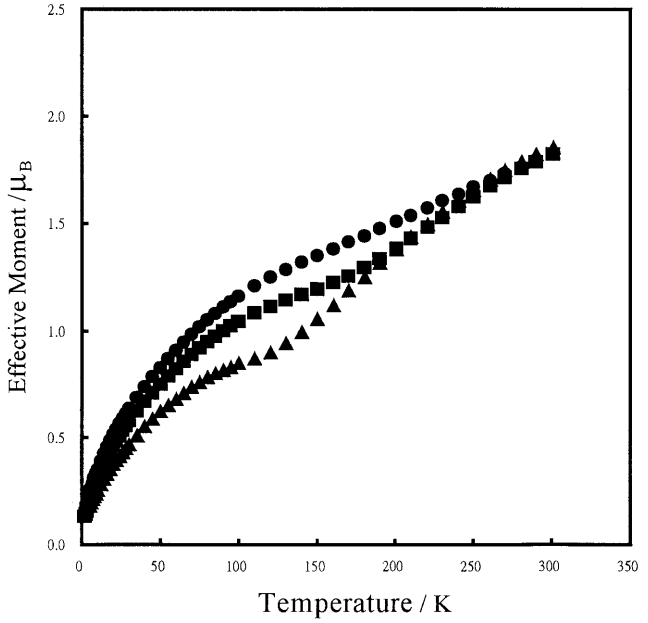

Fig. 5. The experimental data curves of magnetic moments of complex **1**.

agree factor R is defined as $(\Sigma[(\chi_m)^{obs} - (\chi_m)^{calc}]^2/\Sigma[(\chi_m)^{obs}]^2)^{1/2}$. The best fit line for complex **3** (solid line) gives $g = 1.96$, $J = -46.6$ cm^{-1}, $N\alpha = 179 \times 10^{-6}$ emu mol^{-1}, $\theta = -2.2$ K, and $\rho = 0.016$. The agreement of factor ($10^2R = 6.5$) is small, giving a good data fit. The sharp increase in susceptibility at low temperatures is associated with a small amount of paramagnetic impurity ($\rho = 0.016$). The small value of the Weiss constant ($\theta = -2.2$ K) indicates a weak antiferromagnetic intermolecular interaction, which probably results from hydrogen-bonding interaction. The intramolecular magnetic exchange coupling ($J = -46.6$ cm^{-1}) is a weaker antiferromagnetic interaction than that of $[Cu_2(PAP6Me)(\mu_2\text{-}N_3)(\mu_2\text{-}Br)Br_2]$ ($J = -162$ cm^{-1}) [16]. The exchange coupling process through μ_2-N_3 ligand enhances the net antiferromagnetic interaction.

Kinetic evidence of ring closure step in the substitution of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ with $[M(CN)_8]^{4-}$ (M = Mo, W)

Rafał Kania, Barbara Sieklucka *

Received 7 July 2000; accepted 8 August 2000

Abstract

The substitution reaction of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ with $[M(CN)_8]^{4-}$ (M = Mo,W) results in the formation of $\{[(bpy)_2Cr(\mu\text{-}NC)_2M(CN)_6]\}^-$. The new species exhibit intense MMCT transitions and a high degree of electronic coupling revealing a borderline localized-to-delocalized class of behavior. The complex formation reactions were studied as a function of $[M(CN)_8]^{4-}$ concentration, pH and temperature. Two consecutive reaction steps were observed: the first exhibits dependence on the $[M(CN)_8]^{4-}$ concentration and the second is concentration-independent. The mechanism has been rationalized in terms of an ion-pair formation preceding two successive anation steps: initial attachment of the N-end of the cyano ligand of the octacyanometalate moiety followed by slower intramolecular binding of the other N-site leading to ring closure. The large positive $\Delta H^{\neq}$ and large and negative $\Delta S^{\neq}$ values for the second step suggest associative character of the substitution reaction. © 2000 Elsevier Science B.V. 1. Introduction

The good σ-donor ability of the N-end of terminal cyano ligands has been extensively employed to the construction of polymetallic molecular cyano-bridged systems due to their applications in electron-transfer processes, molecular electronics and as molecular magnets [1–3]. The fundamental process linking metal centers through a cyano-bridge is the substitution reaction of cyanometallate at the labile coordination site of a second complex.

Substitution of hexacyanometallates $[M(CN)_6]^{n-}$ on cationic complexes $[M'L_5(H_2O)]^{m+}$ with single available coordination sites have contributed significantly to the understanding of the mechanism of the formation of cyano-bridged species. The numerous studies revealed that substitution proceeds by a step mechanism involving the formation of an ion-pair followed by its conversion to the cyano-bridged product and have generally been interpreted in terms of the activation mode characteristic of an aqua complex [4,5].

Our interest in the possibility of binding $[M(CN)_8]^{n-}$ ions (M = Mo or W) to other metal centers [6–9] has resulted in kinetic studies of the substitution of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ with $[M(CN)_8]^{4-}$ (M = Mo, W) ions. The preliminary investigations, carried out at 25°C, have shown that the reaction generally follows the accepted mechanism with substitution of two aqua ligands in a single step [10]. We have now extended this work over a wide temperature range and have been able to resolve the detailed kinetics of the two subsequent aqua ligand substitution steps. The reactivity of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ with $[M(CN)_8]^{4-}$ ions involves the formation of the $\{[(bpy)_2(H_2O)Cr(\mu\text{-}NC)M(CN)_7]\}^-$ intermediate species followed by the rate-determining ring-closure step into the final $\{[(bpy)_2Cr(\mu\text{-}NC)_2M(CN)_6]\}^-$ complex.

2. Experimental

2.1. Materials

$K_4[Mo(CN)_8]$ and $K_4[W(CN)_8]$ were prepared according to the published procedure [11]. Stock solutions

[a] Ref. [10].

of sodium octacyano-molybdate(IV) and -tungstate(IV) were obtained by a cation-exchange technique (Dowex 50X8). A stock solution of *cis*-$[Cr(bpy)_2(OH_2)_2](ClO_4)_3$ was prepared either by hydrolysis of $[Cr(bpy)_3](ClO_4)_3$ [12,13] or substitution of *cis*-$[Cr(bpy)_2Cl_2](ClO_4)_3$ [14]. The identity and purity of *cis*-$[Cr(bpy)_2(OH_2)_2](ClO_4)_3$ and $Na_4[M(CN)_8]$ (M = Mo, W) solutions were checked by means of electronic spectra [15–17]. Other reagents of analytical grade (Aldrich) were used as received.

2.2. Measurements

Kinetic studies were performed on a Shimadzu 2101 PC spectrophotometer equipped with a thermoelectrically controlled cell holder CPS 60. Stoichiometries, the overall equilibrium constants K_T and molar absorptivity coefficients (ε_{max}) of the final products were calculated from the sets of spectrophotometric data by the application of Job's method. The stoichiometry of the substitution reaction of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ by $[M(CN)_8]^{4-}$ (M = Mo, W) was found to be 1:1 directly from the Job's plots. The values of the overall equilibrium constant K_T and molar absorbance coefficient (ε_{max}) were calculated by using SPECFIT[1] software package; this is a global least-squares fitting routine for equilibrium and kinetic studies which uses a factor-analysis decomposition method [10]. Pseudo-first-order conditions for the excess of octacyanometalates [$(0.349–1.39) \times 10^{-2}$ M] over *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ concentration (6.96×10^{-4} M) were employed. The kinetics of the substitution reaction of the *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ with the $[M(CN)_8]^{4-}$ ions were followed from the build-up of the products, $[(bpy)_2Cr(\mu\text{-}NC)_2M(CN)_6]^-$ ions, monitored at 515 and 562 nm for (CrMo) and (CrW), respectively. The reaction temperature was maintained to within 0.1°C over the range 30–50°C. The $[H^+]$ ion concentration and ionic strength of the reaction solutions were maintained by means of $HClO_4$ and $NaClO_4$. Generally, the kinetic measurements were performed using an acid ($HClO_4$) concentration of 0.1 M. Some kinetic runs were performed at different $[H^+]$ concentrations in the range $0.1–5 \times 10^{-4}$ M. More details on the data-fitting procedure are given in the Section 3. All attempts to isolate pure solid products were unsuccessful.

3. Results and discussion

The addition of each of the $[M(CN)_8]^{4-}$ ions to an aqueous solution of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ results in slow formation of highly colored products. Job's method combined with a least-squares fitting routine was applied to determine stoichiometry, overall equilibrium constants K_T, and molar absorbance coefficients (ε_{max}) of the product [10]. The substitution of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ by $[M(CN)_8]^{4-}$ proceeds according to the stoichiometry of 1:1 and results in the formation of the $[(bpy)_2Cr(\mu\text{-}NC)_2M(CN)_6]^-$ ions with K_T of $(1.0 \pm 0.1) \times 10^4$ and $(2.5 \pm 0.3) \times 10^4$ M^{-1} for Mo and W, respectively, in agreement with (Eq. (1)).

$$[Cr(bpy)_2(OH_2)_2]^{3+} + [M(CN)_8]^{4-} \overset{K_T}{\rightleftharpoons} [(bpy)_2Cr(\text{-}NC)_2M(CN)_6]^- + 2H_2O \quad (1)$$

The characteristic transitions in the visible part of the spectra of 515 nm (CrMo) and 562 nm (CrW) are not present in either the reduced or oxidized form of either complex alone and we assigned it to the optical MMCT (metal–metal charge-transfer) transition from M(IV) to Cr(III). The Hush model [18] (Eqs. (2) and (3)),

$$H_{if} = \nu_{max}\alpha = 2.05 \times 10^{-2}\left(\frac{\nu_{max}}{d}\right)\sqrt{\frac{\varepsilon_{max}\Delta\nu_{1/2}}{\nu_{max}}} \quad (2)$$

$$\alpha^2 = 4.24 \times 10^{-4}\left(\frac{\varepsilon_{max}\Delta\nu_{1/2}}{\nu_{max}d^2}\right) \quad (3)$$

where ν_{max}, $\Delta\nu_{1/2}$ and ε_{max} are the energy (cm^{-1}), bandwidth (cm^{-1}) and molar absorbance coefficient of MMCT band, has been applied to the above spectroscopic data. The intermetallic distance of 5.3 Å between metal centers has been assumed on the basis of the crystallographic data of *cis*-$[Cr(bpy)_2(OH_2)(Cl)]Cl_2$ [19] and $K_4[M(CN)_8]$ [20,21]. The electronic absorption characteristics of the MMCT bands together with the calculated Hush parameters are shown in Table 1. The high degree of electronic coupling characterized by $H_{if} = 1963$ (CrMo) and 2248 cm^{-1} (CrW) suggests that these complexes are similar to the examples of the borderline localized–delocalized class of compounds [22–26]. The H_{if} values and MMCT bandwidths, exhibiting low energy asymmetries, are significantly larger than those obtained for $[(NC)_7M^{IV}(\mu\text{-}CN)Os(NH_3)_5]^-$ (M = Mo, W) localized mixed-valence cyano-bridged complexes with H_{if} of 915 and 1030 cm^{-1} for Mo and W, respectively [27].

The kinetic studies were carried out with $[M(CN)_8^{4-}]$ (M = Mo,W) in excess. At 25°C, the observed dependencies of the pseudo-first-order rate constants k_{obs} on the concentration of the entering ligand $[M(CN)_8^{4-}]$ (M = Mo or W) were linear with small positive intercepts, consistent with an ion-pair ligand substitution mechanism depicted in Eqs. (4) and (5). The corresponding rate law is given in Eq. (6) [10].

$$[Cr(bpy)_2(OH_2)_2]^{3+} + [M(CN)_8]^{4-} \overset{K_{os}}{\rightleftharpoons} \{[Cr(bpy)_2(OH_2)_2]^{3+}, M(CN)_8]^{4-}\} \quad (4)$$

$$\{[Cr(bpy)_2(OH_2)_2]^{3+}, M(CN)_8]^{4-}\} \overset{k'_s}{\underset{k_{aq}}{\rightleftharpoons}} [(bpy)_2Cr(NC)_2M(CN)_6]^{-} \quad (5)$$

$$k_{obs} = k_{aq} + k_f[M(CN)_8^{4-}] \quad (6)$$

where $k_f = k'_sK_{os}$.

The typical kinetic plot at higher temperatures, 30–50°C, is shown in Fig. 1. The kinetic data clearly exhibited two consecutive exponential functions. The biphasic kinetic data have been analyzed in terms of Eq. (7) with the corresponding expression of A_t in Eq. (8).

$$A \overset{k^I_{obs}}{\rightarrow} B \overset{k^{II}_{obs}}{\rightarrow} C \quad (7)$$

$$A_t = A_\infty + a_1 \times \exp(-k^I_{obs} \times t) + a_2 \times \exp(-k^{II}_{obs} \times t) \quad (8)$$

where k^I_{obs} and k^{II}_{obs} are pseudo-first-order rate constants of the first and second step, respectively. The composite parameters a_1 and a_2 are the functions of the initial *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ ion concentration, molar absorbance coefficients and rate constants [28] (Eqs. (9) and (10)):

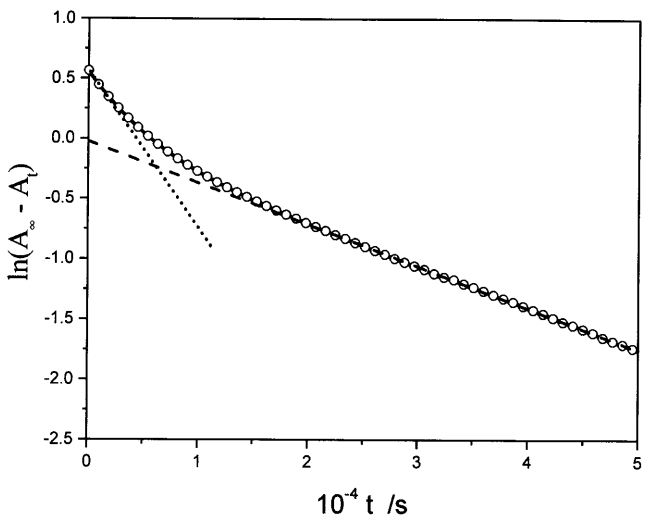

Fig. 1. Typical plot of two-step kinetics of the substitution reaction *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ by $[M(CN)_8]^{4-}$; M = W, $[Cr(bpy)_2(OH_2)_2^{3+}] = 6.96 \times 10^{-4}$ M, $[W(CN)_8^{4-}] = 1.18 \times 10^{-2}$ M, $[H^+] = 0.1$ M, $I =$ 1.0 M ($HClO_4 + NaClO_4$), $T = 40$°C, $\lambda = 560$ nm.

$$a_1 = \frac{[Cr(bpy)_2(OH_2)_2^{3+}]_0\{k^{II}_{obs}(\varepsilon_A - \varepsilon_C) - k^I_{obs}(\varepsilon_A - \varepsilon_B)\}}{k^{II}_{obs} - k^I_{obs}} \quad (9)$$

$$a_2 = \frac{[Cr(bpy)_2(OH_2)_2^{3+}]_0 k^I_{obs}(\varepsilon_C - \varepsilon_B)}{k^{II}_{obs} - k^I_{obs}} \quad (10)$$

The non-linear least-squares fitting procedure of the kinetic data to Eq. (8) yielded the values of A_∞, k^I_{obs}, k^{II}_{obs}, a_1 and a_2. It was not practical to obtain an experimental value of A_∞, since the reactions are characterized by very long half-lives [29]. In cases where A_∞ was experimentally determined, the difference between the calculated and the experimental value of A_∞ was less than 8%. The coupling of the exponential expressions by a_1 and a_2 variables resulted in significant errors in k^I_{obs} and k^{II}_{obs}.

The pseudo-first-order rate constants k^I_{obs} exhibited a dependence on $[M(CN)_8]^{4-}$ concentration. The application of the rate law in the form of Eq. (6) to k^I_{obs} gave inconsistent values for k_{aq}. However, the fitting of the data to the rate law in Eq. (11),

$$k^I_{obs} = k_sK_{os}[M(CN)_8^{4-}]/(1 + K_{os}[M(CN)_8^{4-}]) \quad (11)$$

gave satisfactory fitting and well-behaving values of k_s and K_{os}, the forward reaction rate constant and the ion-pair association constant, respectively. Initially, the presence of the back reaction (k'_{aq}) was expected. Eq. (11) rearranged into a linear expression including k'_{aq} and has the form of Eq. (12) [29].

$$1/(k^I_{obs} - k'_{aq}) = 1/(k_sK_{os}[M(CN)_8^{4-}]) + 1/k_s \quad (12)$$

The attempts to refine a correlation coefficient by varying the value of k_{aq}, according to the rate law in Eq. (12) were unsuccessful, indicating that the values of k_{aq} were too small to be determined. The values of k_s and K_{os} were calculated from the linear plots of $1/k^I_{obs}$ versus $1/[M(CN)_8^{4-}]$ (M = Mo or W) (Figs. 2 and 3) and the rate data along with the corresponding activation parameters are collected in Table 2. The value of the ion-pair association constant K_{os} exhibits no dependence on the temperature, which is in agreement with the temperature independence of K_{os} of $\{[Cr(NH_3)_5(H_2O)]^{3+}\ [Co(CN)_6]^{3-}\}$ and other Cr(III)-based ion-pairs [29]. The mean values of K_{os} are 23 ± 14 M^{-1} for $\{cis\text{-}[Cr(bpy)_2(OH_2)_2]^{3+}, [Mo(CN)_8]^{4-}\}$ and 27 ± 19 M^{-1} for $\{cis\text{-}[Cr(bpy)_2(OH_2)_2]^{3+}, [W(CN)_8]^{4-}\}$. The experimental value of K_{os} is in good agreement with the value of $K_{os} = 33$ M^{-1} calculated from the Eigen–Fuoss expression (assuming the hydrogen bonded ion-pair has a distance of 8.9 Å between the metal centers [19–21]) [10,30,31].

The rate constants k^{II}_{obs} show no dependence on $[M(CN)_8^{4-}]$ concentration. The mean values of k^{II}_{obs} and

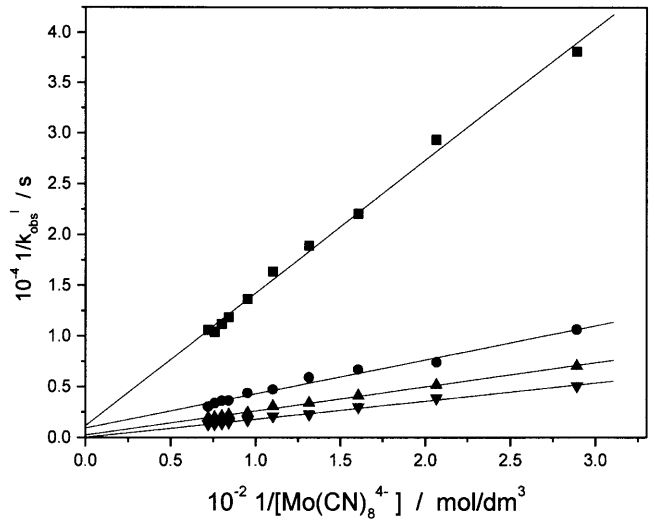

Fig. 2. The plot of $1/k^{I}_{obs}$ versus $1/[Mo(CN)_8^{4-}]$ at 30°C (■), 40°C (●), 45°C (▲) and 50°C (▼); $[Cr(bpy)_2(OH_2)_2^{3+}] = 6.96 \times 10^{-4}$ M, $[H^+] = 0.1$ M, $I = 1.0$ M ($HClO_4 + NaClO_4$).

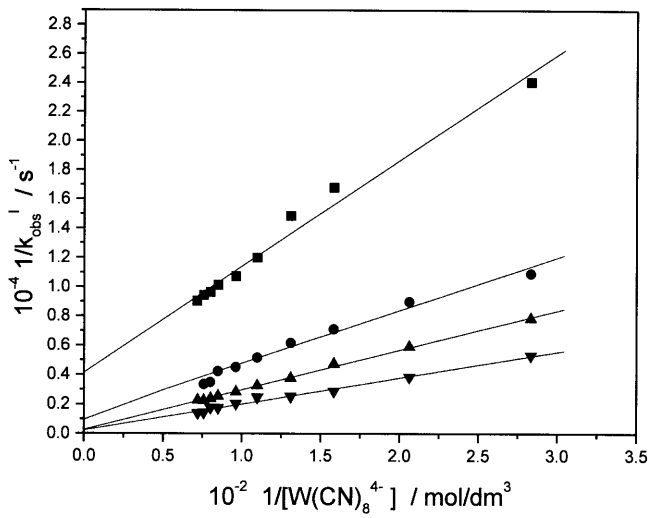

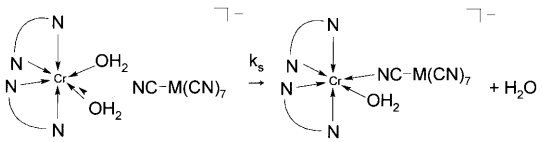

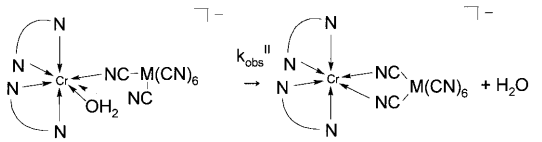

Fig. 3. The plot of $1/k^{I}_{obs}$ versus $1/[W(CN)_8^{4-}]$ at 30°C (■), 40°C (●), 45°C (▲) and 50°C (▼); $[Cr(bpy)_2(OH_2)_2^{3+}] = 6.96 \times 10^{-4}$ M, $[H^+] = 0.1$ M, $I = 1.0$ M ($HClO_4 + NaClO_4$).

corresponding activation parameters are listed in Table 2. The independence of k^{II}_{obs} on $[M(CN)_8^{4-}]$ concentration suggests a ring-closure reaction [32,33]. The substitution of $[M(CN)_8]^{4-}$ on *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ can be rationalized in terms of Eqs. (13) and (14), where the formation of an ion-pair (Eq. (2)) precedes two distinguishable substitution steps:

(13)

(14)

the substitution of aqua ligand within the ion-pair (k_s) followed by the rate-determining ring-closure step (k^{II}_{obs}). These results indicate that the closing of the ring by the substitution of a second aqua ligand is sterically controlled by the large, bulky octacyanide ligand.

The values of k^{I}_{obs} and k^{II}_{obs} at different $[H^+]$ are listed in Table 3. The substitution of $[M(CN)_8]^{4-}$ on *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ is independent of $[H^+]$ in the range 1.15×10^{-3} 0.1 M, despite the first protonation equilibrium of *cis*-$[Cr(bpy)_2(OH_2)_2]^{3+}$ ($pK_a = 3.5$ [15]) and protonation of $[M(CN)_8]^{4-}$ in acidic solution ($K_{a1} > K_{a2} > K_{a3} > 0.1$, $K_{a4} = (2.5 \pm 0.8) \cong 10^{-2}$ M) [34].

The apparent activation parameters do not give unequivocal evidence of the type of mechanism. Both reaction steps are characterized by large positive $\Delta H^{\neq}$ values. While the large positive $\Delta S^{\neq}$ value of the first substitution step is largely charge-controlled for the reaction between unlike charged species, the second ring-closure step is accompanied by large and negative activation entropy, suggesting the associative character of the substitution process [32,35,36]. The substitution

Synthesis, characterisation and study of mercury(II) chloride complexes with triphenylphosphine and heterocyclic thiones. The crystal structures of [(benzothiazole-2-thionato)-(benzothiazole-2-thione)(bis-triphenylphosphine) chloro mercury(II)] and [(μ_2-dichloro){(bis-pyrimidine-2-thionato)-mercury(II)}{(bis-triphenylphosphine)mercury(II)}] at 100 K

Abstract

Direct reaction of mercury(II) chloride with triphenylphosphine (PPh_3) and benzothiazole-2-thione (bzthtH) in the molar ratio of 1:1:2 results in the formation of the [Hg(PPh_3)(bzthztH)(bzthzt)Cl] (**1**) (bzthzt = the anion of benzothiazole-2-thione) while the reaction of mercury(II) chloride with triphenylphosphine (PPh_3) and pyrimidine-2-thione (pmtH) in the molar ratio of 1:1:1 gives [$Hg_2Cl_2(PPh_3)_2(pmt)_2$] (**2**) (pmt = the anion of pyrimidine-2-thione). The complexes have been characterised by their elemental analyses, melting points and their FTIR, far-IR spectroscopic data. The crystal structure of complex **1** which has been determined by single-crystal X-ray crystallography at r.t. reveals that the molecule is monomeric with tetrahedral geometry around the metal ion. A benzothiazole-2-thione molecule and a benzothiazole-2-thionato anion are coordinated, via sulfur atoms, to the mercury(II) ion [Hg–S(2A) = 2.726(2) and Hg–S(2) = 2.419(2) Å]. A triphenylphosphine molecule is also coordinated through a phosphorus atom to the metal ion [Hg–P = 2.453(2) Å] while the tetrahedral geometry around the mercury is completed by a chlorine atom [Hg–Cl = 2.633(2) Å]. The complex is covalent in the solid state. The crystal structure of complex **2** which has also been established by single-crystal X-ray crystallography at 100(1) K shows that the molecule is binuclear and consists of two different moieties with tetrahedral geometry around each mercury(II) ion. One moiety consists of a mercury(II) ion with two phosphorus atoms from phosphine ligands and two bridging chlorine atoms, while the other consists of a mercury(II) ion and two sulfur atoms of pyrimidine-2-thionato ligands. The entire complex is covalent in the solid state. The two Hg(2)–S(42) bond lengths are 2.3513(11) Å while the two Hg(1)–P(1) bond lengths are 2.4826(9) Å. The two parts of the molecule are linked to each other by two chlorine atoms with Hg(1)–Cl(1) and Hg(2)–Cl(1) bond distances of 2.5310(10) and 3.0472(10) Å, respectively. © 2000 Elsevier Science B.V. Keywords: Mercury(II) complexes; Triphenylphosphine; Benzothiazole-2-thione; pyrimidine-2-thione; Crystal structures

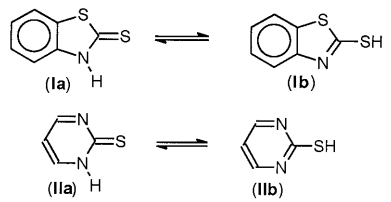
1. Introduction



The study of the coordination and structural chemistry of mercury(II) halide complexes with ligands containing a variety of donor atoms has been a matter of interest over several decades [1–5]. The study of mercury complexes with sulfur-containing ligands has attracted considerable interest due to the relevance of this type of molecule as structural and spectroscopic models of biological systems [6–13]. Among the topics of interest in the study of the chemistry of mercury complexes with ligands containing thiolate or thione groups is the potential of these ligands for use in the detoxification of

mercury from living systems afforded by the binding of mercury ions to the thiolato or thione groups of the ligands rather than to the cystein thiolate groups of proteins [14,15]. In the literature, there are some reports on the interaction of heterocyclic thiones and mercury ions [16–24]. On the other hand, the multiformity of the structural types which have resulted for the mercury(II) complexes with aryl-phosphine ligands provides an area of interest [25–29]. Surprisingly, there are very few reports on the structural characterisation of mixed-ligand mercury(II) complexes with heterocyclic thiones and triaryl-phosphine ligands [30].

Here we report the structural and spectroscopic characterisation of mercury(II) complexes derived from the reaction of mercury(II) chloride with triphenylphosphine and benzothiazole-2-thione (**I**, $C_7H_5NS_2$) or pyrimidine-2-thione (**II**, $C_4H_4N_2S$) in different molar ratios.

2. Experimental

2.1. Materials and instruments

All solvents used were reagent grade, mercury(II) chloride and triphenylphosphine (Merck) as well as benzothiazole-2-thione and pyrimidine-2-thione (Merck or Aldrich) were used with no other purification prior to use. Elemental analyses for C, H, N, and S were carried out with a Carlo Erba EA model 1108. Melting points were measured with a Stuart Scientific apparatus and are uncorrected. IR spectra in the region of 4000–370 cm^{-1} were obtained in KBr discs while far-IR spectra in the region of 400–50 cm^{-1} were obtained in polyethylene discs, with a Perkin–Elmer Spectrum GX FTIR spectrometer.

2.2. Synthesis of [Hg(PPh_3)(bzthztH)(bzthzt)Cl] (*1*)

A mixture of mercury(II) chloride (0.138 g, 0.5 mmol), triphenylphosphine (0.132 g, 0.5 mmol) and benzothiazole-2-thione (0.167 g, 1.0 mmol) in a 20 ml solution of 1:1 methanol–acetonitrile was stirred for 3 h. The suspension was filtered off and the clear solution was kept in darkness. Slow evaporation of the solvent at room temperature (r.t.) yielded orange crystals suitable for single-crystal analysis by crystallography. M.p. 167°C. *Anal.* Found: C: 46.87; H: 2.99; N: 3.76; S: 15.47. Calc. for $C_{32}H_{24}ClHgN_2PS_4$: C: 46.21; H: 2.91; N: 3.37; S:15.42%. IR (cm^{-1}): 1597m, 1496s, 1451s, 1433vs, 1407vs, 1332s, 1097vs, 1071vs, 1022vs, 1008vs, 985vs, 747vs, 687vs, 601vs, 519vs, 501vs, 486vs. Far-IR (cm^{-1}): 310m, 248s, 192s, 165s, 152s, 141m.

2.3. Synthesis of [$Hg_2Cl_2(PPh_3)_2$(pmt)$_2$] (*2*)

A mixture of mercury(II) chloride (0.138 g, 0.5 mmol), triphenylphosphine (0.132 g, 0.5 mmol) and pyrimidine-2-thione (0.056 g, 0.5 mmol) was suspended in a 20 ml solution of 1:1 methanol–acetonitrile and stirred for 3 h. The suspension was filtered off and the clear solution was kept in darkness. Slow evaporation of the solvent at r.t. yielded pale yellow–white crystals suitable for single-crystal analysis by crystallography. M.p. 220°C. *Anal.* Found: C: 43.29; H: 2.95; N: 4.32; S: 5.85. Calc. for $C_{44}H_{36}Cl_2Hg_2N_4P_2S_2$: C: 43.36; H: 2.97; N: 4.60; S: 5.26%. IR (cm^{-1}): 1560s, 1537s, 1481m, 1425s, 1370vs, 1201m, 1172s, 1097s, 803s;743vs, 691vs, 519s, 504vs, 489s. Far-IR (cm^{-1}): 248s, 227m, 177m, 172m, 165m, 151s, 134m.

2.4. X-ray data collection and reduction of the intensity data of the complexes

X-ray diffraction data were collected on a Kuma KM4CCD [31] diffractometer equipped with a CCD area detector. The experiment for **1** was carried out at r.t., while for **2** the temperature was set at 100(1) K, using graphite–monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The frames were record using $\Delta\omega = 0.75°$ rotation scans. A total of 782 frames in six runs were measured for each structure. Each frame was recorded twice in order to eliminate accidental spots. Reflection indexing, Lorentz and polarisation correction, peak integration and background determinations were performed using the Kuma CRYSALIS RED software package [32]. The unit cell dimensions were initially determined from the 15 appropriately chosen frames and were then refined with all recorded images. Empirical absorption corrections were applied for both data sets; $T_{min} = 0.40$ for **1** and 0.491 for **2**, $T_{max} = 0.944$ and 0.972 for **1** and **2**, respectively. Both structures were solved by direct methods using the program SHELXS-86 [33]. For each structure, full-matrix least-squares refinement with all reflections was carried out with the program SHELXL-93 [34]. Scattering factors incorporated in SHELXL-93 were used. The function $\Sigma w(|F_o|^2 - |F_c|^2)^2$ was minimised with $w^{-1} = [\alpha^2(F_o)^2 + 0.0504P^2]$ ($P = [\max(F_o^2, 0) + 2F_c^2]/3$)). Empirical extinction corrections were also applied to compounds **1** and **2**, according to the formula $F_c' = kF_c[1 + 0.001 \times F_c^2\lambda^3/\sin 2\theta]^{1/4}$. The final values for **1** and **2** are listed in Table 1. The non-hydrogen atoms were refined with anisotropic thermal parameters. The coordinates of the other hydrogen

atoms were calculated as 1.2 times U_{eq} for the appropriate carrier carbon atom. Bond lengths and angles for both compounds are listed in Tables 2 and 3. Thermal ellipsoid representations of the molecules together with atomic numbering schemes are shown in Figs. 1 and 2.

2.5. Computational details

Extended Hückel calculations were performed using the program CACAO [35]. The calculations were carried out using crystallographic data of the molecules studied. The EHT parameters for Hg, were those established in the literature.

3. Results and discussion

3.1. General aspects

Crystals of complex **1** were prepared by slow evaporation of the solution remaining after the filtration of the initial product had deposited from the reaction of $HgCl_2$ with triphenylphosphine and benzothiazole-2-thione in a molar ratio of 1:1:2 in methanol–acetonitrile solution. Smaller yields of the same product were obtained using a 1:1:1 molar ratio of reactants. Crystals of complex **2** were similarly obtained from the reaction of $HgCl_2$ with triphenylphosphine and pyrimidine-2-thione in equimolar ratio. The formulas of the complexes were firstly deduced from their elemental analysis, m.p. and their spectroscopic data. The crystals of the complexes are air stable when they are stored in darkness at r.t.

3.2. IR spectroscopy

The IR spectra of complex **1** shows distinct vibrational bands at 1496 and at 1332 cm^{-1} which have been assigned as C–N bond vibrations (thioamide bands I and II) and at 1008 and at 747 cm^{-1} which were attributed to the C–S bond vibrations (thioamide bands III and IV). The corresponding thioamide bands of the free benzothiazole-2-thione ligand are given at 1490, 1320, 1010 and 860 cm^{-1}, respectively [36,37]. The most significant change has been observed in the thioamide band IV, supporting the sulfur donation of the ligand upon its coordination to the metal ion. The

[a] Symmetry transformations used to generate equivalent atoms: $1-x, y, -z+1/2$.

bands at 687, 519, 501 and 486 cm^{-1} have been attributed to the vibrations of the C–P bond. Further information about the complex formation was obtained from the study of far-IR spectra. The new bands at 137, 192 and 248 cm^{-1} have been assigned to the vibrations of Hg–P, Hg–S and Hg–Cl bonds, respectively [22,38,39]. The IR spectra of complex **2** shows bands at 1560 1370, 1172 and 803 cm^{-1} for the thioamide bands I, II, III and IV, respectively, while the bands observed at 690, 508, and 489 cm^{-1} are characteristic for the vibrations of the P–C bond. The corresponding thioamide bands of the free thione ligand are given at 1510, 1320, 982 and 791 cm^{-1}, respectively [40]. The far-IR spectra of complex **2** contains new bands at 141, 165 and 247 cm^{-1} which have been attributed to the Hg–P, Hg–S and Hg–Cl bonds, respectively [22,38,39].

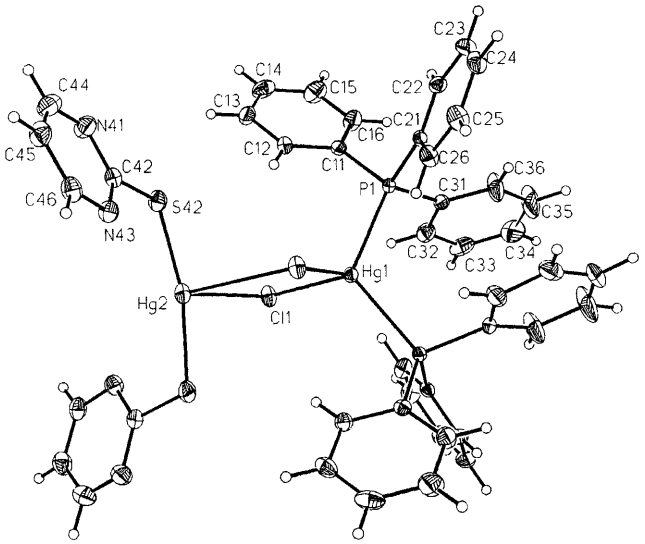

Fig. 2. Thermal ellipsoid representations of molecule **2** together with the atomic numbering scheme.

3.3. Structure of the $[Hg(PPh_3)(bzthztH)(bzthzt)Cl]$ (1)

A view of molecule **1** is shown in Fig. 1, while selected bond lengths and angles are given in Table 2. The molecule is a covalent monomer in the solid state with tetrahedral geometry around the metal ion. Two sulfur atoms, one phosphorus atom and one chlorine atom surround the mercury atom to build a distorted tetrahedron. Thus, one of the two benzothiazole-2-thione molecules has been deprotonated upon coordination. The formation of the benzothiazole-2-thionato anion during the reaction of a neutral thione molecule with the $[Cu(PPh_3)_3Cl]$ has also been observed and is described earlier [37]. The Hg(1)–S(2A) bond distance is 2.726(2) Å while the C(2A)–S(2A) and C(2A)–N(3A) bond distances are 1.690(9) and 1.320(11) Å, respectively, indicating that this ligand has been coordinated through its neutral form. The Hg(1)–S(2A) bond length is longer than those found in $[HgBr_2(meimz2SH)]_2$ (Hg–S = 2.407(2) and 2.405(2) Å)

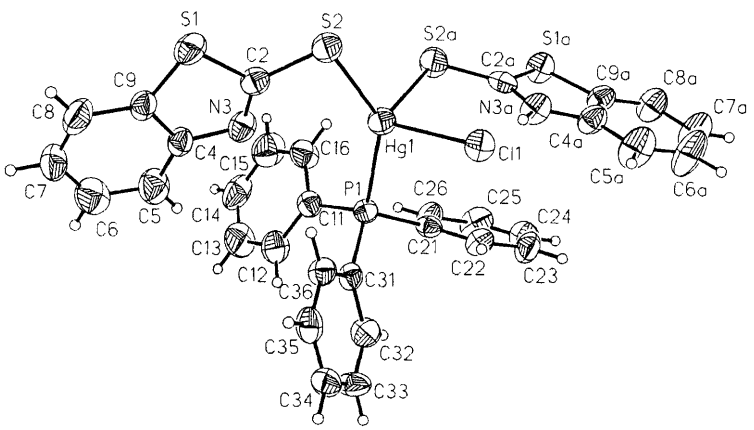

Fig. 1. Thermal ellipsoid representations of molecule **1** together with the atomic numbering scheme.

[20], $[Hg(ditet)_2Cl_2]$ (Hg–S = 2.49(1) and 2.50(1) Å) and in $[Hg(diditet)Cl_2]$ (Hg–S = 2.42(2) Å) [22], where thione ligands have been coordinated to the metal through their neutral form. The second Hg(1)–S(2) bond distance is 2.419(2) Å, while the corresponding C(2)–S(2) and C(2)–N(3) bonds are 1.726(9) and 1.288(11) Å, respectively, indicating a coordination through the anionic form of this ligand. The Hg–S bond length found earlier in $[Hg(PPh_3)_2(SCN_4Ph)_2]$ [30], where the ligand is coordinated to the mercury ion through its anionic form, is 2.566(3) Å. The Hg–P bond length is 2.453(2) Å and is similar to those found in $[Hg(PPh_3)_2(SCN_4Ph)_2]$ [30] (Hg–P = 2.500(3) Å), $[Hg(PPh_3)_2(CN)_2]$ [25] (Hg–P = 2.434(5) and 2.589(5) Å, respectively), $[Hg(PPh_3)_2(NO_3)_2]$ [25] (Hg–P = 2.451(1) Å) and in $[HgCl_2(PPh_3)_2]$ [28] (Hg–P = 2.462(2) and 2.478(2) Å). The Hg–Cl bond length is 2.633(2) Å and is longer than those measured in $[HgCl_2\{Ph_2P(S)CH_2CH_2(S)PPh_2\}]$ [3] (Hg–Cl = 2.447(3) and 2.442(3) Å, respectively), $[Hg(ditet)_2Cl_2]$ (Hg–Cl = 2.51(1) and 2.52(1) Å [22], $[\{HgCl_2(H_2L)\}_2]$ [38] (Hg–Cl = 2.532(6), 2.380(7), 2.585(6) and 2.489(7) Å) and in $[HgCl_2(PPh_3)_2]$ [28] (Hg–Cl = 2.559(2) and 2.545(3) Å). The Cl–Hg–S(2A) angle is 99.10(7)° indicating a N–H···Cl hydrogen bond while the Cl–Hg–S(2) angle is 108.23(8)° and is in accordance to those measured for the complex $[Hg(ditet)_2Cl_2]$ [22] (S(1)–Hg–Cl(1) = 108.6(3) and S(2)–Hg–Cl(1) = 104.3(3)). The P–Hg–S(2A) angle is 97.66(8)° and is in accordance to the corresponding angles found in $[Hg(PPh_3)_2(SCN_4Ph)_2]$ [30] (P–Hg–S = 100.37(6) and 95.7(1)°) while the P–Hg–S(2) angle is 140.79(7)°.

3.4. Structure of the $[Hg_2Cl_2(PPh_3)_2(pmt)_2]$ (2)

A view of molecule **2** is shown in Fig. 2, while selected bond lengths and angles are given in Table 3. The molecule is a covalent, binuclear complex which consists of two different moieties with tetrahedral geometry around each mercury(II) ion. One moiety, consists of a mercury(II) ion with two phosphorus atoms from phosphine ligands and two bridging chlorine atoms while the other, consists of a mercury(II) ion and two sulfur atoms of pyrimidine-2-thionato ligands. The whole molecule sits on a two-fold axis of symmetry passing through the two metal atoms. The two Hg–S bond lengths are 2.3513(11) Å and are in accordance with those found in $[HgBr_2(meimz2SH)]_2$ (Hg–S = 2.407(2) and 2.405(2) Å) [20], $[Hg(ditet)_2Cl_2]$ (Hg–S = 2.49(1) and 2.50(1) Å) and in $[Hg(diditet)Cl_2]$ (Hg–S = 2.42(2) Å) [22], while the two Hg–P bond lengths are 2.4826(9) Å and are similar to those found in $[Hg(PPh_3)_2(SCN_4Ph)_2]$ [30] (Hg–P = 2.500(3) Å), $[Hg(PPh_3)_2(CN)_2]$ [25] (Hg–P = 2.434(5) and 2.589(5) Å, respectively), $[Hg(PPh_3)_2(NO_3)_2]$ [25] (Hg–P = 2.451(1) Å) and in $[\{HgCl_2(PPh_3)_2\}_2]$ [29] (Hg–P = 2.406(7) Å). The two parts of the molecule are linked to each other by two chlorine atoms with Hg(1)–Cl(1) and Hg(2)–Cl(1) bond distances 2.5310(10) and 3.0472(10) Å, respectively. The corresponding bond distances between mercury(II) and bridging Cl atoms found in the $[\{HgCl_2(PPh_3)_2\}_2]$ complex [29] are Hg–Cl(2) = 2.623(8) Å and Hg–Cl(2^i) = 2.658(8) Å, respectively. The Cl(1)–Hg(1)–Cl(1^i), Hg(1)–Cl(1)–Hg(2) and the Cl(1)–Hg(2)–Cl(1^i) angles are 97.39(4), 92.70(3) and 77.21(4)°, respectively. The values of the Cl(2)–Hg–Cl(2^i) and Hg–Cl(2)–Hg^i angles measured in the $[\{HgCl_2(PPh_3)_2\}_2]$ complex [29] are 85.3(3) and 94.6(3)°, respectively. The P(1)–Hg(1)–P(1^i) angle is 116.32(4)°, slightly smaller than the value of the corresponding angle measured in $[Hg(PPh_3)_2(SCN_4Ph)_2]$ [30] (P1–Hg–P2 = 125.6(1)°). The S(42)–Hg(1)–S(42^i) angle is 168.11(5)°.

3.5. Computational study

The rather unusual formation of the complex $[Hg_2Cl_2(PPh_3)_2(pmt)_2]$ (**2**) prompted us to undertake a computational study in order to verify the factors leading the formation of this type of complex towards the formation of the $[Hg(PPh_3)(bzthztH)(bzthzt)Cl]$ (**1**) complex. As it has been evidenced, the energy of the LUMO lies 2.979 eV higher than the corresponding HOMO's energy in the case of complex **2** while the energy of the LUMO lies 3.618 eV higher than the corresponding HOMO's energy in the case of complex **1**. The differences in the HOMO–LUMO energy values computed could explain the stability of **2**. The calculated overlap population in the case of complex **1** is 0.342 and 0.657 e for the Hg(1)–Cl(1) and Hg(1)–P(1) bonds, respectively, and 0.330, 0.572 e for the two Hg(1)–S(2A) and Hg(1)–S(2) bonds. The calculated overlap population in the case of complex **2** is 0.639 e for the two Hg(1)–P bonds and 0.652 e for the two Hg(2)–S bonds, respectively, while the overlap population for the Hg(1)–Cl(1) and Hg(2)–Cl(1) bonds is.0.412 and 0.108 e, respectively. The calculated net charges for the Hg(1) and Hg(2) of complex **2** are –0.179 and 0.266, respectively.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 140 847 for compound **1** and 140 848 for compound **2**. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Two compounds, $[Ag_2(tren(mim)_3)]_n(NO_3)_{2n}\cdot nH_2O$ (**1**) and $[Ag_4(tren(mim)_3)_2](CF_3SO_3)_4\cdot 2H_2O$ (**2**), were obtained by self-assembly of AgX ($X = NO_3^-$, $F_3CSO_3^-$) with tren(mim)$_3$ (tren(mim)$_3$ = tris{2-[2-(1-methyl)imidazolyl]methyliminoethyl}amine). The crystal structures of **1** and **2** have been determined by X-ray diffraction analysis. In **1**, three arms of the ligand, which can be described as a scorpion-like ligand, function in both the usual bidentate chelate fashion and an unprecedented bidentate bridging mode in coordination to Ag(I) atoms; the ligands wrap the infinite Ag(I) wire with the adjacent Ag···Ag separation of approximately 3.0 Å, indicating weak metal–metal interaction, to furnish cationic helical chains. The ligand in **2** behaves in two different coordination fashions in comparison to the ligand in **1**. Two ligands encapsulate four Ag(I) atoms in an interlocking fashion. A pair of the tetranuclear cations related by an inversion center is connected to form an octanuclear cation through a ligand-unsupported metallic interaction between two Ag(I) atoms being separated at 3.117(2) Å and belonging to different tetranuclear cations. The ^{1}H NMR spectra of **1** and **2** in solution are virtually identical, indicating that **1** and **2** have similar structures in solution. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

Metal complexes of tripodal Schiff ligands are well explored with d- and f-block metals, which have been focused on the structural and physico-chemical properties as well as the possible application as magnetic resonance imaging agents, and the modeling of metalloenzymes such as superoxide dismutases [1,2]. Generally, these tripodal ligands are the condensation products of tris(2-aminoethyl)amine (tren) and aromatic aldehydes and contain three bidentate compartments (Scheme 1). They commonly function in the triple chelate mode, arising from the conjugation of the Schiff base group and thus complexation of these ligands with metal ions gives mononuclear complexes in six- or seven-coordination; in the later cases the amine nitrogen atom participates in coordination. A few exceptions have recently been found in some dinuclear complexes of the tripodal Schiff base tris[2-(3-methoxysalicylideneamino)ethyl]amine (tren(salmo)$_3$), in which a pair of metal atoms are bridged by the μ_2-phenolate groups [3]. In the present work, we report the synthesis and crystal structures of two novel chain-like complexes with a tripodal Schiff base as bridging agent, namely $[Ag_2(tren(mim)_3)]_n(NO_3)_{2n}\cdot nH_2O$ (**1**) and

$[Ag_4(tren(mim)_3)_2](CF_3SO_3)_4{\cdot}2H_2O$ (**2**) (tren(mim)$_3$ = tris{2-[2-(1-methyl)imidazolyl]methyliminoethyl}amine, see Scheme 1).

2. Experimental

2.1. Materials and physical measurements

All the reagents were commercially available and used as received. The C, H, N microanalyses were carried out with a Perkin–Elmer 240 elemental analyzer. IR spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Nicolet Impact 420 FTIR spectrometer. ^{1}H NMR spectra were recorded with an Inova 500NB spectrometer using TMS as internal reference and DMSO-d_6 as matrix.

2.2. Synthesis of metal complexes

2.2.1. $[Ag_2(tren(mim)_3)]_n(NO_3)_{2n}{\cdot}nH_2O$ (*1*)

1-Methylimidazole-2-carbaldehyde (3 mmol, 0.33 g) was added to a solution of tren (1 mmol, 0.15 g) in dried MeOH . The mixture was refluxed for 5 h, and was then added to a solution of $AgNO_3$ (2 mmol, 0.34 g) in MeCN. A colorless crystalline solid (**1**) was obtained by vapor diffusion of diethyl ether after 3 days. *Anal*. Calc. for $C_{21}H_{32}Ag_2N_{12}O_7$: C, 32.32; H, 4.13; N, 21.54. Found: C, 32.48; H, 3.97; N, 21.43%. IR data (KBr, cm^{-1}): 3486 m, 3114 m, 2811 m, 1637 s, 1482 s, 1440 s, 1426 s, 1377 sh 1285 s 1166 m, 1089 m, 1075 m, 1046 m, 835 m, 800 m, 779 m. ^{1}H NMR (500 MHz, DMSO-d_6): $\delta = 8.63$ (3 H, s, imine), 7.47 (3 H, s, imidazole ring), 7.19 (3 H, s, imidazole ring), 3.86–3.84 (4 H, m, C=N–CH_2), 3.82 (9 H, s, CH_3), 3.15 (2 H, s, C=N–CH_2), 2.94–2.91 (6 H, m, N–CH_2).

2.2.2. $[Ag_4(tren(mim)_3)_2](CF_3SO_3)_4{\cdot}2H_2O$ (*2*)

1-Methylimidazole-2-carbaldehyde (3 mmol, 0.33 g) was added to a solution of tren (1 mmol, 0.15 g) in dried MeOH. The mixture was refluxed for 5 h, then a solution of $AgCF_3SO_3$ (2 mmol, 0.52 g) in MeCN was added. A colorless crystalline solid (**2**) was obtained by vapor diffusion of diethyl ether after 3 days. *Anal*. Calc. for $C_{46}H_{64}Ag_4N_{20}O_{14}F_{12}S_4{\cdot}2H_2O$ (**2**): C, 28.94; H, 3.38; N, 14.68. Found: C, 29.18; H, 3.17; N, 14.95%. IR data (KBr, cm^{-1}): 3121 m, 2952 sh, 2864 m, 2811 m, 1637 s, 1482 s, 1440 s, 1635 m, 1271 s, 1166 s, 1082 m, 1032 s, 765 m, 639 s, 579 m, 519 m. ^{1}H NMR (500 MHz, DMSO-d$_6$): $\delta = 8.62$ (3 H, s, imine), 7.45 (3 H, s, imidazole ring), 7.18 (3 H, s, imidazole ring), 3.86–3.84 (4 H, m, C=N–CH_2), 3.82 (9 H, s, CH_3), 3.15 (2 H, s, C=N–CH_2), 2.93–2.89 (6 H, m, N–CH_2).

2.3. X-ray crystallography

Diffraction intensities for complexes **1** and **2** were collected at 293 K on a Siemens R3m diffractometer. Lorentz-polarization and absorption corrections were applied [4]. The structure solutions and full-matrix least-square refinements based on F^2 were performed with the SHELXS-97 and SHELXL-97 program packages [5], respectively. All the nonhydrogen atoms were refined anisotropically. Hydrogen atoms of the organic were generated geometrically (C–H 0.96 Å) and those of the aqua ligands were located from the difference maps; all hydrogen atoms were assigned the same isotropic thermal parameters and included in the structure-factor calculations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections incorporated [6]. The crystallographic data for **1** and **2** are summarized in Table 1. Selected bond distances and angles are given in Table 2.

3. Results and discussion

3.1. Crystal structures

3.1.1. $[Ag_2(tren(mim)_3)]_n(NO_3)_{2n}\cdot nH_2O$ (*1*)

The crystal structure of **1** features polymeric helical $[Ag_2(tren(mim)_3)]_n^{2n+}$ cations, nitrate anions and solvate water molecules. In the polymeric chain, each structural unit consists of a binuclear $[Ag_2(tren(mim)_3)]$ core, as shown in Fig. 1. The crystal structure shows that tren(mim)$_3$ acts in a very unusual fashion in coordination with the Ag(I) atoms. One of the arms functions in the usual bidentate chelate fashion to bind Ag1, whereas the other two arms act in an unusual bidentate bridging mode to ligate two Ag(I) atoms, as shown in Scheme 2(a); to our knowledge, such a bridging mode for Schiff bases has not been documented in the literature. Each of the later two arms uses its imidazole or imine nitrogen atom to bind Ag1, resulting in a highly distorted tetrahedral coordination geometry for Ag1. The remaining imine or imidazole nitrogen atom binds to Ag2 and Ag3, respectively. Both Ag2 and Ag3 are each located at a crystallographic inversion center and coordinated by a pair of imine nitrogen atoms or by a pair of imidazole nitrogen atoms in a linear arrangement, respectively. The structure is thus extended into infinite chains through the bridging coordination, in which the adjacent Ag···Ag separations are 2.9337(10) and 3.0533(11) Å for Ag1···Ag2 and Ag1···Ag3, respectively, and the metal atoms are arranged in a virtually linear fashion with the most distorted angle Ag2···Ag1···Ag3 at 158.76(2)°. The Ag···Ag distances are in accordance with the values previously reported in other Ag(I) complexes [7,8], and are well below the summed van der Waals radii of two silver atoms (3.44 Å) [9], indicating some extent of weak metal–metal interaction. Therefore, tren(mim)$_3$

Scheme 2.

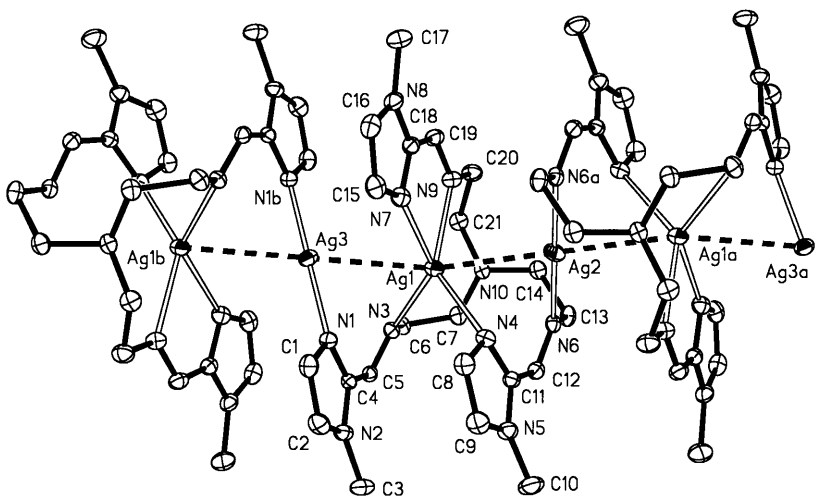

Fig. 1. ORTEP view of the coordination environment in **1**. Symmetry codes: (a) $1-x$, $1-y$, $-z$; (b) $-x$, $1-y$, $-z$.

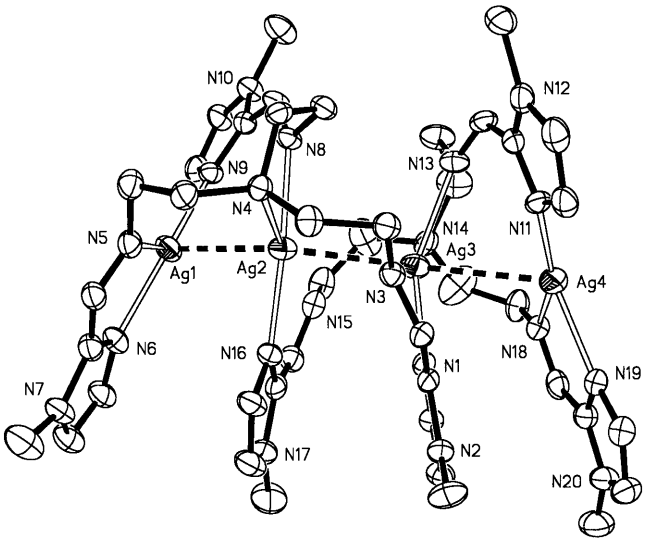

Fig. 2. ORTEP view of the $[Ag_4(tren(mim)_3)_2]^{4+}$ cation in **2**.

may be best described as a scorpion-like ligand, and it wraps the Ag(I) ions to furnish cationic helical wires. It is noteworthy that, although a number of linear oligonuclear metal complexes comprising Cr(II), Co(II), Ni(II), Rh(II), Ru(II), Pt(II,III) [10–14], as well as a linear trinuclear Ag(I) complex have been documented [8a], no analogous Ag(I) complex has been reported so far.

Detailed examination reveals that the average bond distance of Ag1–N(imine) (2.333 Å) and Ag1–N(imidazole) (2.451 Å) for the tetrahedral Ag(1) atom are significantly longer than the bond distances of Ag2–N(imine) (2.172(3) Å) and Ag3–N(imidazole) (2.137(3) Å) for the two linear coordinated Ag(I) atoms, indicating that the bond lengths are directly related to the coordination numbers. The bond angles of N–Ag1–N are from 71.260(11)–135.62(11)°, being markedly distorted from an idealized tetrahedron, such distortion is frequently observed in silver(I) chemistry. The lattice water molecule forms a hydrogen bond with the oxygen atom of the anion (O1w···O2 = 2.878(3) Å).

$[Ag_4(tren(mim)_3)_2](CF_3SO_3)_4\cdot 2H_2O$ (2). The crystal structure of **2** consists of discrete tetranuclear $[Ag_4(tren(mim)_3)_2]^{4+}$ cations, trifluoromethanesulfonate anions and water molecules. The tetranuclear $[Ag_4(tren(mim)_3)_2]^{4+}$ cation is depicted in Fig. 2, which comprises two $tren(mim)_3$ ligands and four Ag(I) atoms. The scorpion-like ligand behaves in a different coordination fashion in comparison to that found in **1**. One arm of each $tren(mim)_3$ uses its imine and imidazole nitrogen atom to bind Ag1 (or Ag4) in the bidentate chelate mode, the second arm bridges Ag1 and Ag2 (or Ag3 and Ag4) using its imidazole and imine nitrogen atoms, whereas the third arm links to Ag3 (or Ag2) using its imidazole nitrogen atom as a unique donor. The amine nitrogen atom also participates in coordination to Ag3 (or Ag2). It is worthy to note that there are three unusual bridging modes in **2**. One is similar to that found in **1** (Scheme 2(a)). The participation of the amine nitrogen atom in coordination yields two types of unusual bridging mode for the scorpion-like ligand, in which the amine nitrogen atoms bind a Ag(I) atom and a bidentate imidazole-imine entity chelates another Ag(I) atom (Scheme 2(b)), whereas another bidentate imidazole-imine entity uses only the imidazole nitrogen atom to ligate another Ag(I) atom (Scheme 2(c)). More interestingly, the ligand encapsulates the Ag(I) atoms in an interlocking fashion, being different to that found in **1**. A pair of the tetranuclear cations related by an inversion center is connected to form an octanuclear cation through a weak metallic interaction between Ag4 and Ag4a separated at 3.117(2) Å, as illustrated in Fig. 3. Since the four imidazole rings ligated to Ag4 and Ag4a are arranged in an off-set fashion, there is no significant $\pi-\pi$ interaction between imidazole groups from different tetramers, the weak metallic interaction between Ag4 and Ag4a can be described as ligand-unsupported, which is rarely observed [7b,c,15,16]. Although the Ag4···Ag4a distance is quite long, it is comparable to other ligand-supported metallic separations found in **2** (2.9279(9)–3.1313(9) Å) and **1**, and is also well below the summed van der Waals radii of two

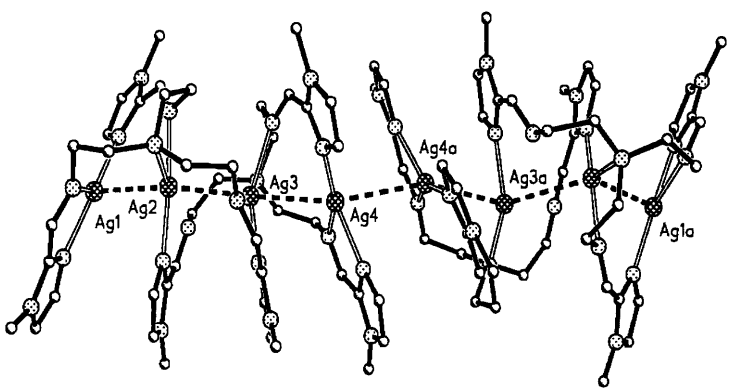

Fig. 3. Perspective view showing a dimer of the $[Ag_4(tren(mim)_3)_2]^{4+}$ cations connected by the weak Ag···Ag interaction in **2**.

silver atoms [9]. Each Ag(I) atom in the cation is coordinated in a distorted T-shape geometry, associated with a five-membered chelate ring, the metallic chain is thus in a zigzag fashion with the Ag···Ag···Ag angles in the range 116.44(3)–156.83(4)°. Among the average bond distances of Ag–N(imidazole) (2.190(6) Å), Ag–N(imine) (2.424(6) Å) and Ag–N(amine) (2.543(6) Å), Ag–N(imidazole) is the shortest while Ag–N(amine) is the longest. Finally, it should be noted that the counterions in **2** may play an important role in terminating the polymerization; the terminal Ag1 has weak interaction with one oxygen atom of the anion (Ag···O 2.967(7) Å). Similar to **1**, the lattice water molecule forms a hydrogen bond with oxygen atom of the anion (O1···F11 = 2.732(5) Å), and there are hydrogen bonds between the lattice water molecules (O1w···O2w = 2.727(6) Å).

3.2. Spectroscopy

The IR spectra of **1** and **2** show the strong bands at 1637 and 1440 cm^{-1} can be assigned to the symmetric stretching vibrations of –C=N– and –C=N–C=N–, respectively, implying direct coordination of the imine nitrogen atoms and imidazole nitrogen atoms [17]. The ^1H NMR spectra of **1** and **2**, having virtually identical patterns, indicate that they have similar structures in solution although they have different structures in the solid state. The structural differences in the solid state between **1** and **2** may apparently be attributed to the influence of the counter-ions in the crystallization process.

4. Conclusions

Self-assembly of the tripodal Schiff base containing imidazole groups with silver(I) salts yielded a tetranuclear and a polymeric helical silver(I) complex, which have been structurally characterized to exhibit three novel bridging modes for the ligands in coordination to Ag(I) atoms in the solid state, as well as ligand-unsupported weak Ag···Ag contacts. The ^1H NMR spectra implies that **1** and **2** have similar structures in solution. The different aggregations and helicities of the structures in the solid state may be attributed to the influence of the counter-ions in crystallization.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 120560 and 120561. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336033; e-mail: deposit @ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Two four-coordinate complexes of neodymium with 2,6-di-*tert*-butyl-4-methylphenolate have been synthesized and their single-crystal structures determined. Anhydrous $NdCl_3$ reacted with ArONa in a 1:3 molar ratio in THF at room temperature to yield the neutral four-coordinate complex $[(ArO)_3Nd(THF)]\cdot MePh$ (**1**), which crystallized as a solvate, in which three aryloxide ligands and one THF ligand are coordinated to neodymium to form a slightly distorted tetrahedron. The reaction of $NdCl_3$ with 4 equiv. of ArONa in THF gave $[(ArO)_4Nd][Na(THF)_6]$ (**2**). In this anion–cation pair compound, the neodymium and sodium atoms exhibit distorted tetrahedral and distorted octahedral coordination geometry, respectively. The average Nd–O(Ar) distance is 2.176 and 2.230 Å in complex **1** and **2**, respectively. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Synthesis; Crystal structure; Aryloxide; Neodymium; Anion–cation pair compound

1. Introduction

Lanthanide alkoxides and aryloxides have found a variety of applications as homogeneous catalysts for organic reactions [1] and precursors for organolanthanide syntheses [2] and high purity oxide materials [3]. The syntheses, structures and reactivities of alkoxo- and aryloxolanthanide complexes have recently attracted a great deal of attention [4–6]. Investigation into the chemistry of lanthanide complexes containing aryloxo ligands has produced complexes exhibiting a variety of structural types [7–9]. The coordination number and degree of oligomerization of the products can be controlled by varying the bulky substituents on the arene ring in the reaction of europium ingot with substituted phenols [9,10]. These facts are consistent with general expectations. From metathesis reactions, the neutral monomeric or dimeric complexes can be obtained when the bulky substituted phenoxides are used as ligands [11–13]. However, for a less bulky ligand, such as 2,6-diisopropyl phenoxide, anionic ate complexes containing alkali metals are obtained via bridging interactions to form one-dimensional chains, two-dimensional sheets or extended three-dimensional structures [14,15]. Recently, homoleptic anionic aryloxide–lanthanoid complexes have also been obtained by Clark and Deacon et al. using substituted phenoxides as ligands [16–18].

Previous studies with the 2,6-di-*tert*-butyl-4-methyl phenoxo ligand, *O*-C_6H_2-2,6-*tert*-Bu-4-Me, (OAr in this paper) have shown that it gives low-coordinate neutral monomeric complexes with scandium and samarium, $Sc(ArO)_3$ and $[Sm(ArO)_3(THF)]\cdot THF$, from the reaction of $LnCl_3$ with NaOAr [11,19]. To understand more about this reaction with the other lanthanide elements, we have studied the reaction of anhydrous $NdCl_3$ with 3 and 4 equiv. of NaOAr in THF, and the desired complex $[Nd(ArO)_3(THF)]\cdot MePh$ (**1**) and unusual compound $[Nd(ArO)_4][Na(THF)_6]$ (**2**) were synthesized. Single-crystal structure studies revealed that the latter is a disconnected anion–cation pair compound with the sodium well separated from the lanthanoid coordination sphere.

2. Experimental

All manipulations were performed under argon using the Schlenk technique. THF was distilled from sodium benzophenone ketyl before use. Anhydrous $NdCl_3$ was prepared according to the literature method [20]. NaOAr was prepared from the reaction of ArOH and Na in THF. Metal analyses were carried out using complexometric titration [21]. IR spectra were recorded on a Nicolet-550 FTIR spectrometer as KBr pellets. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM-300 spectrometer in C_6D_6.

2.1. Synthesis of [Nd(ArO)$_3$(THF)]·MePh (1)

A solution of NaOAr (15.7 cm^3, 13.59 mmol) in THF was slowly added to a suspension of $NdCl_3$ (1.135 g, 4.53 mmol) in 20 cm^3 THF at room temperature. After being stirred for 72 h, the NaCl was separated from the reaction mixture by centrifugation. The solvent was removed in vacuum and toluene was added to extract the product. The dissolved portion was removed by centrifugation. The filtrate was concentrated and cooled at −20°C for crystallization. Blue single crystals suitable for X-ray determination were obtained over a few days (yield 3.15 g, 72%). Found: Nd, 14.83. Calc. for [Nd(ArO)$_3$(THF)]·(MePh): Nd, 14.92%. IR absorptions (cm^{-1}): 2957(s), 2918(w), 2873(w), 1634(s), 1434(s), 1396(m), 1362(m), 1231(m), 1151(s), 1065(m), 1027(w), 864(s), 771(s), 460(m).

2.2. Synthesis of [Nd(ArO)$_4$][Na(THF)$_6$] (2)

A solution of NaOAr (25.0 cm^3, 21.56 mmol) in THF was slowly added to a suspension of $NdCl_3$ (1.352 g, 5.39 mmol) in 25 cm^3 THF at room temperature. After stirring for 72 h, the precipitate was removed from the reaction mixture by centrifugation. The solvent was removed in vacuum and toluene was added. The precipitate was separated and the solution concentrated, and then cooled at −20°C. The yellow crystals were obtained after several weeks (4.05 g, 51%). Found: Nd, 9.62. Calc. for [Nd(ArO)$_4$][Na(THF)$_6$]: 9.75%. IR absorptions (cm^{-1}): 2962(s), 2925(m), 2876(w), 1637(s), 1437(s), 1225(s), 1159(s), 864(m), 771(m), 507(s). ^1H NMR (C_6D_6): δ 7.16(8H, Ph), 2.35(12H, Me), 1.62 (48H, THF), −1.11(72H, Bu^t). ^{13}C NMR: 123.3(PhO), 88.7(PhO), 84.2(PhO), 74.9 (PhO), −9.3(THF), −19.8(Me), −26.8(THF), −28.9(Me), −29.4(Bu^t), −29.6(Bu^t).

2.3. Crystallography

Single crystals suitable for X-ray measurements were sealed in thin-walled glass capillaries under argon. Intensity data were collected in the variable ω scan mode on a Rigaku AFC 7R four-circle diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K. Crystallographic data are listed in Table 1.

The crystal structures of complexes **1** and **2** were determined by direct methods which yielded the positions of all non-hydrogen atoms. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were all generated geometrically (C–H bond lengths fixed at 0.96 Å), assigned appropriate isotropic thermal parameters and allowed to ride on their parent carbon atoms. All the H atoms were held stationary and were included in the structure factor calculation in the final stage of full-matrix least-squares refinement.

3. Results and discussion

3.1. Syntheses of the complexes

The metathesis reaction between anhydrous $NdCl_3$ and NaOAr in the molar ratio 1:3 in THF at room temperature, followed by crystallization from toluene, yielded the neutral four-coordinate neodymium com-

plex [Nd(ArO)$_3$(THF)]·MePh in high yield, as shown in Eq. (1).

$$NdCl_3 + 3NaOAr \xrightarrow{THF} (ArO)_3Nd(THF) + 3NaCl \quad (1)$$

This reaction is similar to the reaction of NaOAr with anhydrous $SmCl_3$ [19], but different from that of 2,6-diisopropylphenoxide which reacted with $NdCl_3$ in THF to produce K[Nd(OC$_6$H$_3$-Pr$^i_2$-2,6)$_4$] instead of Nd(OC$_6$H$_3$–Pr$^i_2$-2,6)$_3$ [14]. Subsequent studies have shown that $LnCl_3$ reacted with 4 equiv. of potassium 2,6-diisopropylphenoxide in THF, followed by crystallization from toluene, to form the 'ate' complex K[Ln(OC$_6$H$_3$–Pr$^i_2$-2,6)$_4$] in high yield as shown in Eq. (2) [15].

$$LnCl_3 + 4K\text{–}OC_6H_3\text{–}Pr^i_2\text{-}2,6 \xrightarrow[2.\ \text{Toluene}]{1.\ \text{THF}} K[Ln(OC_6H_3\text{–}Pr^i_2\text{-}2,6)_4 + 3KCL \quad (2)$$

The reaction of anhydrous $NdCl_3$ with 4 equiv. of NaOAr in THF at room temperature, did not give the 'ate' complex Na[Nd(OAr)$_4$], but rather produced the unusual compound [Nd(ArO)$_4$][Na(THF)$_6$] as illustrated in Eq. (3).

$$NdCl_3 + 4NaOAR \xrightarrow{THF} [(ArO)_4Nd][Na(THF)_6] + 3NaCl \quad (3)$$

^{1}H, ^{13}C NMR and IR studies show that there are not only phenolate ligand signals, but also THF signals. A single-crystal study reveals (see below) that compound **2** contains a discrete homoleptic aryloxoneodymium anion with the alkali metal cation well separated from the neodymium coordination sphere. To our knowledge, only three analogous complexes [Na(diglyme)$_2$][Nd(Odpp)$_4$], [Odpp = 2,6-diphenylphenolate, diglyme = bis(2-methoxyethyl) ether], [Na(diglyme)$_2$][Er(Odpp)$_4$] and [Na(DME)$_2$][Nd(Odpp)$_4$] (DME = 1,2-dimethoxyethane) have been recently reported in the literature [18]. Generally, unidentate coordinating or non-coordinating solvents were considered disadvantageous for ion pair complex formation. Watkin et al. reported that Sm(OC$_6$H$_3$–Pr$^i_2$-2,6)$_3$(THF)$_2$ reacted with one equiv. of LiC_5Me_5 in THF to form the lithium ate complex, which however reacted with an excess of TMEDA (tetramethylethylenediamine) to form a charge–separated salt [22]. In our case, the disconnected anion–cation pair compound can be crystallized from mixed THF–toluene solvent. This difference may be attributed to the large size of the substituents on the arene ring.

3.2. Structures

The molecular structures of compound **1** and **2** were determined by single-crystal studies. The selected bond lengths and angles are listed in Table 2.

3.2.1. Crystal structure of *[Nd(OAr)$_3$(THF)]·MePh* (**1**)

The molecular structure of [Nd(OAr)$_3$(THF)]·MePh is shown in Fig. 1. The compound is isostructural with [Sm(OAr)$_3$(THF)]·THF and the toluene solvent molecule replaces the THF molecule in the molecular packing [19]. The complex is a four-coordinate monomer with three aryloxo oxygen atoms and one THF oxygen atom around the neodymium forming a distorted tetrahedron. The coordination geometry around the metal is different from that in [Nd(Odpp)$_3$(THF)] which has a distorted trigonal bipyramidal array by forming an intramolecular π-bond [23]. Interestingly, in [Nd(Odpp)$_3$(DME)] [24], [Nd(Odpp)$_3$(THF)$_2$], [Nd(Odpp)$_3$(THF)] and Nd(Odpp)$_3$ [23], all of these compounds show distorted trigonal bipyramidal stereochemistry and the neodymium atoms are five- or seven-coordinate. Few examples of four-coordinate neodymium complexes are known. Evans and co-workers reported the structure of

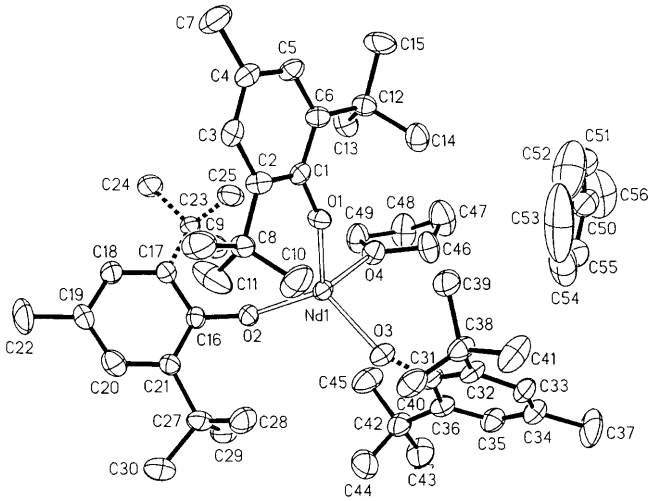

Fig. 1. Molecular structure of $[Nd(ArO)_3(THF)]\cdot(MePh)$.

a four-coordinate neodymium amide complex; however, to achieve steric saturation of the metal center, an agostic interaction between the α carbon and neodymium was observed [25]. The current difference in the coordination number can be attributed to the more bulky ArO ligand as compared to the Odpp ligand and amide.

The three aryloxo oxygen atoms around neodymium show a nearly trigonal planar array with Σ O–Nd–O = 351.7°; this value is comparable with those in $Nd(Odpp)_3(THF)$ (358.7°) and $Nd(Odpp)_3$ (353.2°) [23]. The Nd–O(Ar) distances range from 2.164(5) to 2.190(5) Å, giving the average Nd–O(Ar) distance 2.176 Å. This value is a little shorter than those in $[Nd(Odpp)_3(DME)]$ (2.191 Å) [24], $[Nd(Odpp)_3(THF)_2]$ (2.190 Å), $[Nd(Odpp)_3(THF)]$ (2.193 Å) [23], $K[Nd(OC_6H_3\text{–}Pr^i_2\text{-}2,6)$ (2.211 Å) [15] and comparable with that in $Nd(Odpp)_3$ (2.169 Å) [23]. Subtraction of the estimated radius (0.86 Å) [26] for four-coordinate Nd^{3+} from Nd–O(Ar) gives 1.31 Å, which is similar to those for $[Sm(OAr)_3(THF)]\cdot THF$ (1.31 Å) [19], and $Sc(OAr)_3$ (1.30 Å) [8], but a little longer than those for other aryloxo lanthanide complexes $[Yb(Odpp)_3(THF)_2]$ (1.27 Å) [27] $[La(Odpp)_3(THF)_2]$ (1.28 Å) [28], and $Yb(OC_6H_2Bu^t_3\text{-}2,4,6)_3(THF)$ (1.27 Å) [29]. The Nd–O(THF) distance is 2.444(6) Å, and a similar subtraction from this value gives 1.58 Å. This is much higher than the usual value 1.34 Å for organolanthanoid complexes [30], but still within the range for the complexes of bulky lanthanoid aryloxides [19,27,29].

3.2.2. Crystal structure of $[Nd(OAr)_4][Na(THF)_6]$ (2)

The molecular structure of **2** is comprised of a discrete $[Na(THF)_6]^+$ cation and a $[Nd(ArO)_4]^-$ anion (Fig. 2).

In the anion, the neodymium metal is coordinated to four oxygen atoms from aryloxide ligands in a pseudo-tetrahedral fashion. The stereochemistry around the neodymium atom is similar to that in $K[Nd(OC_6H_3\text{–}Pr^i_2\text{-}2,6)$[15], $[Na(diglyme)_2][Nd(Odpp)_4]$ and $[Na(diglyme)_2][Er(Odpp)_4]$ [18]. The Nd–O distances range from 2.202(6) to 2.256(7) Å, giving the average distance of 2.230 Å, which is somewhat longer than the average Nd–O(Ar) distance (2.176 Å) observed for complex **1**, although both of them have similar stereochemical arrangement around the central metal. This difference can be attributed to steric repulsion, as an additional ArO ligand replacing the THF ligand increases the steric repulsion among the ligands. It is also longer than that in the analogous aryloxide complex $[Na(diglyme)_2][Nd(Odpp)_4]$ [18], which is consistent with the fact that ArO is more bulky than Odpp. The Nd–O(Ar) distances in complex **2** are similar to those in $K[Nd(OC_6H_3Pr^i_2\text{-}2,6)_4]$ (average = 2.21 Å) [14] and $Na[Nd(Odpp)_4]$ (2.20 Å) [17,18], but slightly longer than those in $[Nd(Odpp)_3](THF)$ (2.193 Å) and $Nd(Odpp)_3$ (2.169 Å) [23]. The Nd–O distance is also longer than the Er–O(Ar) distance in

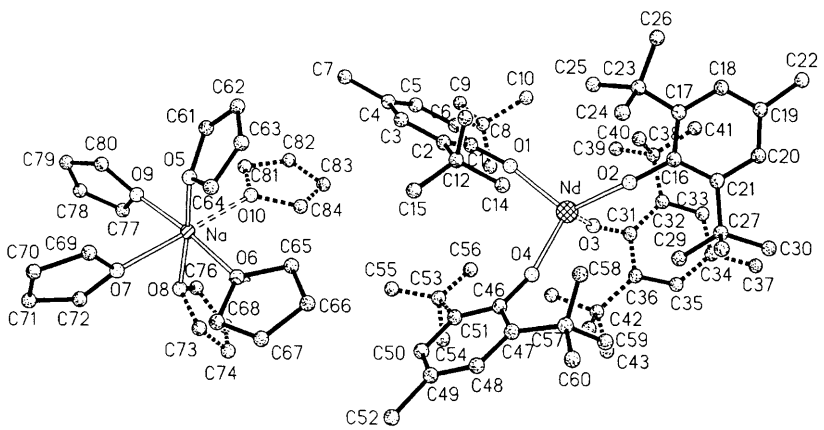

Fig. 2. Molecular structure of $[Nd(ArO)_4][Na(THF)_6]$.

$[Na(diglyme)_2][Er(Odpp)_4]$ even if the differences in ionic radii are considered [18]. This Nd–O(Ar) distance is very similar to $\langle Nd–O_{br}\rangle$ (2.211 Å) and apparently longer than $\langle Nd–O_{ter}\rangle$ (2.122 Å) of $Nd_2(O\text{-}2,3\text{-}Pr^i_2C_6H_3)_6$ [7]. The C–O distances of the phenolate ligands range from 1.34(1) to 1.36(1) Å, and are apparently shorter than the single bond length, reflecting substantial delocalization from oxygen into the aromatic rings. The average C–O bond length is 1.35 Å, and is similar to that in complex **1** (1.36 Å), $Yb(OC_6H_2Bu^t_3\text{-}2,4,6)_3(THF)$ (1.38 Å) [29], $[Yb(Odpp)_3(THF)_2]$ (1.33 Å) [27], and $[La(Odpp)_3(THF)_2]$ (1.31 Å) [28].

The six O–Nd–O angles range from 104.3(2) to 112.7(2)°, which is comparable with those angles in $[Na(diglyme)_2][Nd(Odpp)_4]$ [18]. But there are apparently differences from those in $K[(Nd(O\text{-}2,6\text{-}Pr^i_2C_6H_3)_4]$ [14], in which one of the six O–Nd–O angles (95.29°) deviates significantly from that of an ideal tetrahedron because of the interaction between the potassium atom and two aryloxide ligands. The Nd–O–C angles range from 144.6(7) to 167.9(7)°.

In the cation $[Na(THF)_6]^+$, the sodium ion is solvated and octahedrally bonded to the oxygen atoms of six THF molecules. The bond lengths of Na–O range from 2.32(2) to 2.49(2) Å and the angles for the two closest oxygen atoms to the sodium range from 83.6(7) to 97.4(6)°. These are slightly different from the values 2.380(5)–2.434(4), 2.340(10)–2.4410(10) Å and 88.2(2)–92.8(2), 88.8(4)–91.2(4)° in $[Na(THF)_6][(C_9H_7)_3Nd(\mu\text{-}Cl)Nd(C_9H_7)_3]$ [31] and $[Na(THF)_6][Cp_3Lu(\mu\text{-}H)LuCp_3]$ [32], respectively. Actually, in the last two compounds, the cations are centrosymmetrical, but in complex **2**, the O(5)–Na–O(8), O(6)–Na–O(9) and O(7)–Na–O(10) angles are 173.0(9), 173.6(7) and 174.7(5)°, respectively. These values show the cation is a distorted octahedron.

4. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 136299 for compound **1** and CCDC No. 136300 for compound **2**. Abstract

The reaction of $[ReO_2(PPh_3)_2I]$ with bis-diphenylphosphines (dpp) only produces complexes with general formula $[ReO_2(dpp)_2]^+$. However, when the ligand used in this work (bis(diphenylphosphinomethane) (dppm)) reacts with the same precursor an interesting Re(I) complex is also afforded. By changing the reaction conditions, *trans*-$[Re^VO_2(dppm)_2]^+$ and $[Re^I(dppm)_3]I$ were obtained and characterized. The crystal structure of $[Re(dppm)_3]I{\cdot}CH_3OH{\cdot}CH_2Cl_2$ is given. In this compound, the P atoms are arranged in a strongly distorted octahedral coordination polyhedron around the rhenium center. This is the first case of a tris(dppm) complex ever reported. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Rhenium; Re complexes; Re(I); *trans*-Dioxo Re(V) complexes; Phosphines; dppm

1. Introduction

In previous works [1,2], we have reported on the preparation and crystal structure of some *trans*-Re(V) dioxo complexes with didentate diphosphines, namely, $[ReO_2(dppe)_2]I$ and $[ReO_2(dppp)_2]PF_6$ (dppe = 1,2-bis-(diphenylphosphinoethane) and dppp = 1,3-bis-(diphenylphosphinopropane)). They were obtained by reaction of $[ReO_2(PPh_3)_2I]$ with the appropriate ligand. In both cases, the sole product was the dioxo compound, unchanged in the Re oxidation state. They are useful systems to study the influence of ring size on the coordination properties.

The next step in this study was to attempt the formation of a four-membered ring with this 5d-transition metal. This can be performed using dppm (bis-(diphenylphosphinomethane)) as chelating ligand. In any case, the formation of a highly strained ring is expected. For this reason most dppm complexes show one or two phosphines connecting two metallic centers. $Re_2Cl_4(\mu\text{-dppm})_2$, $Mo_2(dppm)_2X_4$ ($X = Cl^-$, NCS^-) and $Re_2Cl_5(dppm)_2$ are good examples of this behavior [3–5]. As an alternative, dppm can participate in mixed ligand complexes, by bonding the two phosphorus atoms to the same central atom. This fact has been reported for some Re complexes in different oxidation states: *fac*-$[Re^VOCl_3(dppm)]$, *mer*-$[Re^{III}Cl_3(dppm)(PPh_3)]$, *fac*-$[Re^{III}(NCH_3)Cl_3(dppm)]$, *trans*-$[Re^VNCl_2(dppm)(PPh_3)]$ and $[Re^VNCl(dppm)_2]Cl$ [6]. It is interesting to note that the synthesis of these complexes involves the reduction of Re, presumably by the diphosphine. The identification of compounds such as $[ReCl_3(dppm)(dppom)]$ and $[ReCl_4(dppom)]$ (dppom = $Ph_2PCH_2P(=O)Ph_2$), in which dppm is partially oxidized to dppom, points in this direction [6,7]. The coordination of dppom seems to be a way to change the strained four-membered ring of dppm to a five-membered one.

In any case, no tris(dppm)–Re complex has been reported up to now. The situation is not very different for other d-transition metals. No tris(dppm) complexes have been structurally elucidated. Only related compounds such as $\{[(Ph_2P)_2CH]_3V\}[Li(THF)_4](THF)_2$, in which dppm is deprotonated before coordination, have been reported [8].

In this work, we report on two new cationic complexes formed when $[Re^{V}O_2(PPh_3)_2I]$ reacts with dppm. During the development of procedures for the synthesis of *trans*-$[Re^{V}O_2(dppm)_2]^+$ by a substitution reaction, a novel cationic complex $[Re^{I}(dppm)_3]I$ was also obtained and characterized. This is the first time that a Re(I) complex has been prepared with dppm as the only didentate ligand. Dppm demonstrates the ability to act as didentate chelating ligand and its tendency to promote reductive reactions. The crystal structure of $[Re(dppm)_3]I{\cdot}CH_3OH{\cdot}CH_2Cl_2$ is the first case of a tris-(dppm) complex ever reported.

2. Experimental

2.1. Materials

All chemicals were of reagent grade and used as received. HPLC grade methanol and all other solvents (reagent grade) were used without further purification. Violet microcrystals of $[ReO_2(PPh_3)_2I]$ were obtained using the reported method [9] except for $NH_4[ReO_4]$, which was used in place of $H[ReO_4]$.

2.2. Physical measurements

IR spectra were recorded as KBr pellets on a Bomen MB FT-IR spectrophotometer. Proton NMR spectra were recorded at 200.133 MHz on a Bruker AC200 spectrometer. Peak positions in ppm are relative to TMS as external reference. $^{31}P\{^1H\}$ spectra were recorded on the same instruments operating at 81.015 MHz. Chemical shifts are relative to external 85% H_3PO_4 with downfield values reported as positive. Elemental analysis was accomplished on a Carlo Erba model 1108 elemental analyzer. Fast Atom Bombardment spectra were obtained from a 3-nitrobenzylalcohol matrix using a Micromass–Autospec spectrometer.

2.3. HPLC analyses

Chromatograms were obtained with an HPLC system by Merck, equipped with a variable wavelength monitor and a PRP-X200 (10 μm) cation exchange column (4 × 250 mm). A 0.02 M solution of NaCl in methanol was used as mobile phase with 1.5 ml min^{-1} flow. Detection was accomplished at 255 nm.

2.4. Potentiometry measurements

The potentiometric titrations were carried out in mixed solvent dioxane–water (70:30 v/v) solutions at 25 °C and ionic strength $I = 0.1$ mol dm^{-3} in KCl. Experimental details can be found elsewhere [1]. The autodissociation constant of the solvent pK_w was 16.0, in good agreement with reported data [10]. Measurements were taken of dppm and the complex at the concentrations $C = 1.0$, 1.5 and 2.0 mmol dm^{-3}, between pH values of 1.7 and 7.0. The experimental potentiometric data were analyzed by means of the SUPERQUAD program [11].

2.5. Preparation of the complexes

2.5.1. $[ReO_2(dppm)_2]I$ (**1**)

$[ReO_2(PPh_3)_2I]$ (0.30 g, 0.345 mmol) and dppm (1.5 g, 3.90 mmol) were stirred in dichloromethane (20 ml) for 10 min at room temperature (r.t.). A yellow solution was obtained. It was evaporated to dryness under vacuum at a temperature not higher than 30°C. From this crude material, the complex was extracted with freshly distilled methanol (5 × 10 ml). The pale yellow solution was filtered (through paper) and the solvent was evaporated again under similar conditions. The yellow solid was washed with ether (4 × 5 ml); yield 65–70%. The solid can be recrystallized from methanol; yield 70%. IR spectrum (ν, cm^{-1}): 3051 (s), 1483 (s), 1436 (vs), 1102 (s), 791 (s), 735 (vs), 725 (vs), 690 (vs), 504 (s), 477 (m), 279 (m), 247 (s). *Anal.* Calc. for $C_{50}H_{44}IO_2P_4Re$: C, 53.9; H, 4.0. Found: C, 53.8; H, 4.0%.

2.5.2. $[ReO_2(dppm)_2]PF_6$

Concentrated solutions of (**1**) showed the formation of a dark solid in CD_2Cl_2 while recording the NMR spectra. In spite of the color, IR spectrum of the solid proved to be essentially free dppm. Hexafluorophosphate salt was therefore prepared by adding a large excess of NH_4PF_6 to a methanolic solution of (**1**); yield: 40–50%. Selected NMR data (CD_2Cl_2, 293 K): ^1H NMR: 7.0–8.0 (m, 40H, C_6H_5), 5.41 ppm (t, $J_{P-H} = 5$ Hz, 4H, CH_2); $^{31}P\{^1H\}$: −45.9 ppm (s). *Anal.* Calc. for $C_{50}H_{44}F_6O_2P_5Re$: C, 53.1; H, 3.9. Found: C, 52.9; H, 4.1%.

2.5.3. $[Re(dppm)_3]I$ (**2**)

A mixture of $[ReO_2(PPh_3)_2I]$ (0.30 g, 0.345 mmol) and dppm (0.7 g, 1.90 mmol) was refluxed in freshly distilled methanol (20 ml) for 3 h. A clear yellow solution was obtained, from which a yellow crystalline solid was separated after cooling to r.t. The solid was washed with ether (4 × 5 ml); yield 25–30%. Suitable yellow crystals for X-ray diffraction were obtained by slow evaporation of a methanol–dichloromethane solution. IR spectrum (ν, cm^{-1}): 3050 (s), 1482 (s), 1433

(vs), 1310 (w), 1090 (s), 738 (vs), 726 (vs), 697 (vs), 513 (s), 485 (m), 408 (m). Selected NMR data (CD_2Cl_2, 293 K): ^1H NMR: 7.4–6.5 (m, 60H, C_6H_5), 5.51 ppm (s, broad, 6H, CH_2); $^{31}P\{^1H\}$: −50.3 ppm (s). *Anal*. Calc. for $C_{75}H_{66}IP_6Re$: C, 61.4; H, 4.5. Found: C, 61.6; H, 4.9%.

2.6. Crystallographic measurements and structure determinations

2.6.1. Crystal data

Colour: yellow. $C_{77}H_{72}Cl_2IOP_6Re$, $M = 1583.17$, orthorhombic, $a = 21.150(3)$, $b = 18.172(3)$, $c = 17.678(5)$ Å, $V = 6794(2)$ Å^3, space group $Pna2_1$, $Z = 4$, $D_{calc} = 1.548$ g cm^{-3}, μ(Mo Kα) = 2.509 mm^{-1}, $F(000) = 3176$, crystal size $0.36 \times 0.25 \times 0.22$ mm.

2.6.2. Structure determination

Data were collected at r.t. on a Rigaku AFC7S four-circle diffractometer [12] in the range $2.23 \leq \theta \leq 27.51°$, $-19 \leq h \leq 27$, $-7 \leq k \leq 23$, $-22 \leq l \leq 16$. A total of 8888 reflections were collected in the ω–2θ scan mode, of which 8825 were unique ($R_{int} = 1.64\%$) and 7381 ($I > 2\sigma(I)$) were used in the full-matrix least squares refinement with the SHELXL-97 program [13]. The structure was solved using the Patterson method with the SHELXS-97 program [14]. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at calculated geometrically suitable positions and refined riding on the corresponding atom, with isotropic thermal displacement parameter 1.2 times higher than the equivalent isotropic displacement parameter of the atoms bonded to them (1.5 times for the methanol solvent molecule). Final residuals were $R = 0.0312$ for a weighting scheme of $w^{-1} = (\sigma^2(F_o^2) + (0.0469P)^2 + 7.3285P)$ where $P = (F_o^2 + 2F_c^2)/3$. The goodness of fit (Goof) finished at 1.038. Mean final shift/esd was lower than 0.01. The maximum and minimum residual densities were 1.037 and −1.114 e Å^{-3}, respectively.

2.7. Calculations

Molecular mechanics calculations (MM) were performed using the MM+ force field implemented in the HyperChem package version 5.0. Geometry optimizations were carried out using the Polak–Ribière (gradient conjugated) method with a convergence criterion of 0.01 kcal mol^{-1}.

3. Results and discussion

The reaction product of $[Re^VO_2(PPh_3)_2I]$ with dppm is strongly affected by the reaction conditions. It has thus been possible to obtain Re complexes in different oxidation states. The composition of the solids, obtained by elemental analysis and confirmed by FABMS (see below), fitted with the formulae $[Re^VO_2(dppm)_2]I$ (**1**) and $[Re^I(dppm)_3]I$ (**2**). It is interesting to note that when preparation involves lower temperatures and larger dppm to Re molar ratios, the result is simply a substitution on the Re(V) core. But, if the reaction is carried out at a higher temperature and lower ligand to Re molar ratio, dppm is able to reduce the central atom and displace the two oxo groups, destroying the very stable $[ReO_2]^+$ core. The reduction of other Re precursors to yield stable dppm complexes has been previously reported [5,6], but this is the first time in which a Re(I) compound was obtained.

Positive fast atom bombardment mass spectroscopy of Pt(II) and Pd(II) dppm complexes has been previously discussed [15]. Re complexes follow a similar fragmentation pathway. The most prominent peaks of (**1**) were present at $m/z = 988$ [M$^+$ + H] and 603 [M$^+$ + H − dppm]. For (**2**), signals were found at 1335 [M$^+$ − 2H$_2$], 956 [M$^+$ + H − dppm], 877 [M$^+$ − H − dppm − Ph] and 755 [M$^+$ − H − dppm − Ph − PhP=CH$_2$].

The IR spectrum of $[Re^VO_2(dppm)_2]I$ showed a very strong absorption at 791 cm^{-1} characteristic of the linear $[O{=}Re{=}O]^+$ core. This vibration was in the expected range (775–836 cm^{-1}) for the asymmetric $[ReO_2]^+$ stretching [16]. The characteristic IR absorption of the $[O{=}Re{=}O]^+$ core is not present in (**2**), showing the complete substitution of the oxo ligands. In addition, it was also possible to observe in the IR spectra the characteristic vibrations of dppm. In particular, the scissoring of CH_2 groups (around 1483 cm^{-1}) and the P–CH_2 deformation band (around 1435 cm^{-1}) are present in the complexes (see Section 2). This is consistent with the presence of dppm in the compounds and rules out the possibility that it could be deprotonated in the complex (as, for example, in $\{[(Ph_2P)_2CH]_3V\}[Li(THF)_4](THF)_2$ [8]).

Selected bond distances and angles for $[Re(dppm)_3]I{\cdot}CH_3OH{\cdot}CH_2Cl_2$ are given in Table 1. Tables of coordinates, anisotropic temperature factors, hydrogen atom coordinates and a full listing of geometric data are available as supplementary data.

Fig. 1 illustrates the geometry and atom-numbering scheme. The structure consists of monomeric units of $[Re(dppm)_3]^+$, iodide as counterion and dichloromethane and disordered methanol as cocrystallization solvent molecules. The coordination polyhedron around Re(I) ion can be described as a distorted octahedron. The bond lengths for Re–P range from 2.400(2) to 2.467(2) Å and the P–Re–P angles for P atoms belonging to the same ligand from 68.01(6) to 69.08(6)°. No evidence for charge delocalization suggesting the presence of dppm as anion can be obtained from the structural results. On the contrary, the

Re–P*i*–C–P*j* torsion angles range from 17.1(3) to 20.3(3)°, for Re1–P3–C2–P4 and Re1–P5–C3–P6, respectively, clearly indicating non-planarity of the ligand skeleton (P*i* and P*j* belonging to the same dppm ligand). In a previously reported vanadium analogue ($\{[(Ph_2P)_2CH]_3V\}[Li(THF)_4](THF)_2$ [8]) two deprotonated dppm ligands exhibited very low torsion angles, 0.3° for V1–P4–C38–P3 and 1.7° for V1–P3–C83–P6, and only the third one corresponded to neutral dppm, with the torsion angle V1–P2–C13–P1, 14.8°.

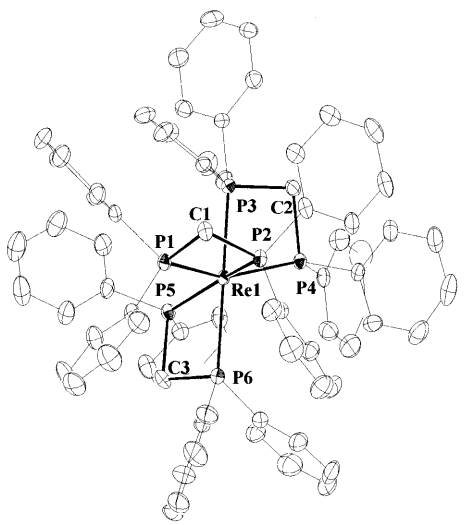

Fig. 1. ORTEP view [17] of the complex (**2**) with displacement ellipsoids drawn at 30% probability level. Hydrogens are omitted for clarity.

In spite of the distorted geometry of (**2**), the Re–P bonds present the usual lengths and fall within the range of values observed in other phosphine-containing Re complexes. Moreover, distance seems to be independent of the Re oxidation state [3].

As far as we know, this is the first structure of a tris(dppm) complex ever reported. Steric strain involved in the geometry of three four-membered rings supports the unusual appearance of these complexes. In order to know how strained the ligand in the complex is, we performed molecular mechanics calculations on the dppm. The optimized structure of dppm shows a P–C–P angle of 110.6°, not far from 106.2(3)° reported for the crystalline structure at −40°C [18]. As a second step, we optimized the structure of the ligand fixing the P–C–P angle (up to 60°) but allowing the rearrangement of the rest of the molecule. Fig. 2 shows the increase in the total energy at different P–C–P angles. As can be seen, the adjustment of the angle to 95° (the angle found in the structure of (**2**)) represents an increase of only 30% in the total energy of the molecule. This small angle does not seem to involve a large strain in the ligand, resulting in a very stable complex. The soft–soft interaction between the P atoms and the Re(I) center seems to be strong enough to compensate the strain of the three ligands.

The solid state structure found for the complexes is sustained in solution. The positive overall charge of the complexes in solution was checked by HPLC. Chromatograms in a cation exchange column show a characteristic peak at 3.9 (**1**) and 5.6 (**2**) min.

The ^1H and ^{31}P NMR spectra of the compounds agree with octahedral coordination. ^{31}P signals are very sharp, suggesting the diamagnetic character of the complexes. In particular the ^{31}P spectrum of (**1**) indicates that the two oxygens atoms are in *trans* position. Another remarkable result is the proton integration of the signals. Once more, the presence of two methylenic protons per ligand molecule is confirmed in solution.

It has been demonstrated that Re(V) dioxo complexes with didentate diphosphines, $[ReO_2(dppe)_2]^+$ and $[ReO_2(dppp)_2]^+$ can be protonated in dioxane–water (70:30 v/v) [1] according to:

$$[ReO_2(\text{phosphine})_2]^+ + 2H^+ \leftrightarrows [Re(OH)_2(\text{phosphine})_2]^{3+}$$

The titrations of $[ReO_2(dppm)_2]^+$ performed under the same conditions, show no protonation of the complex. The lower basicity of the oxo groups could be

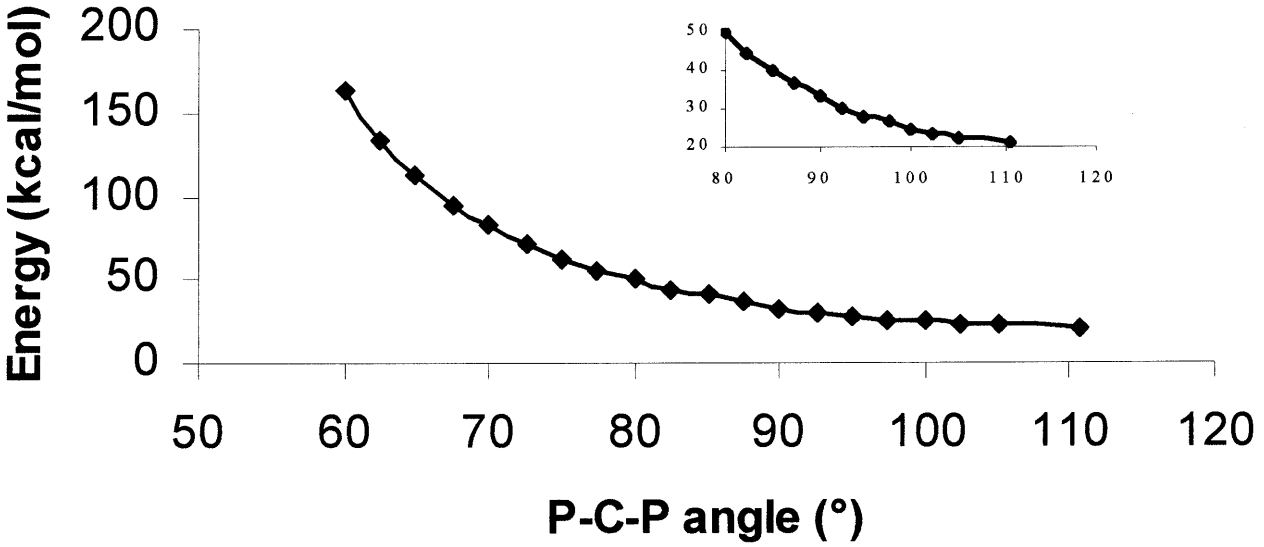

Fig. 2. Total energy of the dppm molecule as a function of the P–C–P angle, obtained by molecular mechanics calculations.

originated either in a short Re–O distance, which diminishes the availability of the lone pair of electrons of the oxygen atoms, or in the steric hindrance of the complex. IR stretching band at 791 cm^{-1} is almost at the same energy than those for $[ReO_2(dppe)_2]I$ and $[ReO_2(dppp)_2]I$ [1]. So, Re–O bond strength seems to be similar. This fact makes more probable the second argument.

For the free ligand, a simultaneous protonation of both phosphine groups is detected with $\log \beta_{12} = 3.04 \pm 0.06$ ($\chi^2 = 10.5$; $\sigma(E) = 3.50$). This value is in line with those for similar diphosphines [1].

4. Conclusions

In spite of many existing examples of complexes with dppm (including several transition metals), no reports could be found that include a tris(dppm) structure. Both the formation of a four-membered ring and the reductive character of the ligand seem to be the reason for this fact. All results reported in this work provide evidence of the formation of a tris(dppm) complex. The reasons why this unexpected compound is obtained seem to be the reductive character of the ligand, which promotes the reduction of the metallic atom, as well as the soft character of the Re(I) center. These results open up the study of a new aspect of the dppm characteristics in coordination chemistry.

5. Supplementary data

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC 133405 for compound **2**. Abstract

We have studied the metal-centered redox chemistry of unsubstituted cobalt–phthalocyanine (Co–Pc) and the cobalt complexes of the substituted ligands, cobalt–octaethylhexyloxyphthalocyanine (CoOEHPc), cobalt–tetramethoxyphthalocyanine (CoMeOPc), cobalt–tetraneopentoxyphthalocyanine (CoTNPPc), cobalt–tetraaminophthalocyanine (CoTAPc), cobalt–tetrasulfonatophthalocyanine (CoTSPc) and cobalt–hexadecafluorophthalocyanine ($CoPcF_{16}$) adsorbed on ordinary pyrolytic graphite (OPG). These complexes exhibit two distinct metal-centered reversible redox processes attributed to the Co(II)/Co(I) and Co(III)/Co(II) couples. The redox potentials of these couples are shifted according to the electron withdrawing or donating character of the groups located at the periphery of the phthalocyanine ligand, as seen by comparison to molecular orbital theoretical calculations. Correlations between the redox potential and the Hammett parameters of the substituents provide good linear correlations. The slopes of the linear free energy correlations give values of 0.41 and 0.49 V σ^{-1} for the Co(III)/Co(II) and Co(II)/Co(I) redox couples, respectively. We have also tested the electrocatalytic activity of these adsorbed phthalocyanines for the reduction of 2-hydroxyethyldisulfide. A plot of $\log i$ (current density at constant potential) versus the Co(II)/Co(I) redox potential gives a linear correlation where the rate of the reaction increases with the driving force of the catalyst, suggesting that that the reaction takes place via an outer-sphere mechanism. © 2000 Elsevier Science B.V. 1. Introduction

Metallophthalocyanines (MPcs) are continuously attracting the attention of many research groups due to the great variety of applications of these materials in different fields such as energy conversion of visible light [1–4] sensors, [5–7] catalysis [8], electrocatalysis [9], molecular semiconductors [10–12], and electrochromic materials [10]. Redox properties of these materials are important [13,14] as they are correlated to the corresponding charge transfer spectra [13] and to catalytic and electrocatalytic properties [8,9]. Redox processes in metallophthalocyanines can be located at the ligand and at the metal center [15,16], the phthalocyanine ring can undergo successive one-electron reduction and one-electron oxidation to yield the anion and cation radicals respectively. With redox-active metals, metal oxidation or reduction occurs at potentials between those corresponding to ligand reduction or oxidation. Reduction of the ligand is associated to the position of LUMO ($M(II)\text{–}Pc(-2) + e^- \rightleftarrows [(M(II)\text{–}Pc(-3)]^{-1}$) whereas oxidation of the ligand ($(M(II)\text{–}Pc(-2)) \rightleftarrows [(M(II)\text{–}Pc(-1)]^+ + e^-$) is associated to the position of the HOMO. MPc's having a metal that possesses energy levels lying between the HOMO and the LUMO of the phthalocyanine ligand, in general will exhibit redox processes centered on the metal. This is the case for the phthalocyanines of Cr, Mn, Co and Fe [14–16], which have open d-shell structures.

It has been demonstrated that substituents on the periphery of the phthalocyanine ligand strongly influence the solution redox chemistry of these materials. Electron-donating groups lead to a negative shift of the redox potentials and electron-withdrawing groups to a positive shift. This has been observed with both closed d-shell metals like copper and zinc and open d-shell metals like Co–phthalocyanines [14]. On the other hand, it has been demonstrated by several authors that phthalocyanine adsorbs very strongly on graphite electrodes and that is possible to examine their electrochemical and catalytic properties in the confined state, on the electrode surface [9,14,17–22]. We are particularly interested in exploring the catalytic activity of cobalt phthalocyanines for the electrochemical oxidation of thiols [9,17–21] and reduction of molecular oxygen [21,22] and in correlating these properties with the redox potentials of the Co(II)/Co(I) and Co(III)/Co(II) reversible couples in the adsorbed phthalocyanine.

[b] Estimated from Hammett parameters.

Lever [23–25], Orihashi [26,27] and Luk'yanets [28,29] have studied the variations of redox potentials of phthalocyanines with substituents, via the use of Hammett substituent constants and relatively good linear correlations have been found. All these studies have been carried out using the metallophthalocyanines dissolved in different solvents and there is only one report [30] using four phthalocyanine derivatives confined on the surface of a graphite electrode. One of the purposes of this work is to study the influence of substituents on the ligand on a great variety of cobalt phthalocyanine (adsorbed on graphite) to establish linear correlations between the Co(II)/Co(I) and Co(III)/Co(II) redox potentials with the sum of the Hammett constants. The variation of the electron density caused by the electron donating or electron withdrawing character of the substituent present on the periphery of the phthalocyanine ligand is discussed in terms of theoretical MO calculations. We also examine the effect of redox potential of the phthalocyanines on their activity for the electrochemical reduction of a 2-hydroxyethyldisulfide.

2. Results and discussion

Fig. 1 shows the structure of the phthalocyanines used in this work. We have reported in several papers the redox properties of cobalt phthalocyanine and derivatives, adsorbed on graphite electrodes and the results are summarized in Table 1. It can be seen from the data included in Table 1 that the formal potentials of both Co(III)/Co(II) and Co(II)/Co(I) redox couples are shifted to more positive values (compared with unsubstituted CoPc) by the effect of electron-withdrawing substituents in the ligand (F and $–SO_3^-$) and to more negative values by electron-donating groups ($–NH_2$, methoxy, neopentoxy and octaethylhexyloxy). Note that some values of the potentials of the Co(III)Co(II) redox couples of some phthalocyanines substituted with electron-withdrawing groups have been estimated using the Hammett parameters of the substituents, because those processes are shifted to potentials too positive, beyond the oxidation potential of the graphite substrate, and cannot be measured in aqueous solutions without damaging the electrode. The effect of the substituents on the redox potentials essentially agrees with previous reports that included other substituted cobalt phthalocyanines [14,30].

Figs. 2 and 3 compare the Co(III)/Co(II) and Co(II)/Co(I) formal potentials of the different adsorbed cobalt phthalocyanines with the energy of the highest occupied (HOMO) and the lowest unoccupied (LUMO) molecular orbital, calculated by PM3. In both cases, a linear

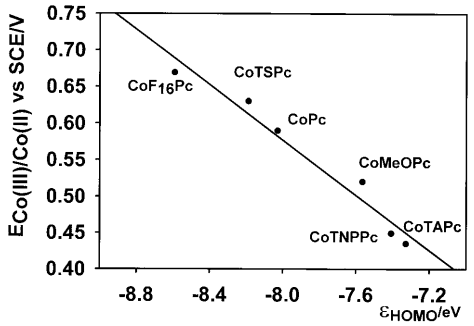

Fig. 2. Plot of Co(III)Co(II) redox potential vs. the energy of the HOMO in the phthalocyanine.

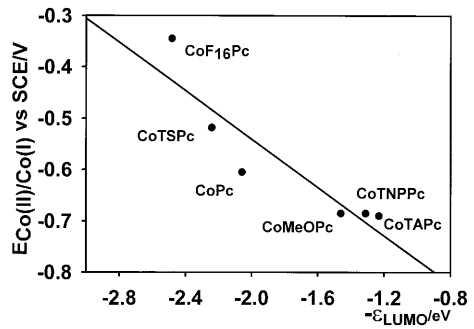

Fig. 3. Plot of Co(II)Co(I) redox potential vs. the energy (with negative sign) of the LUMO in the phthalocyanine.

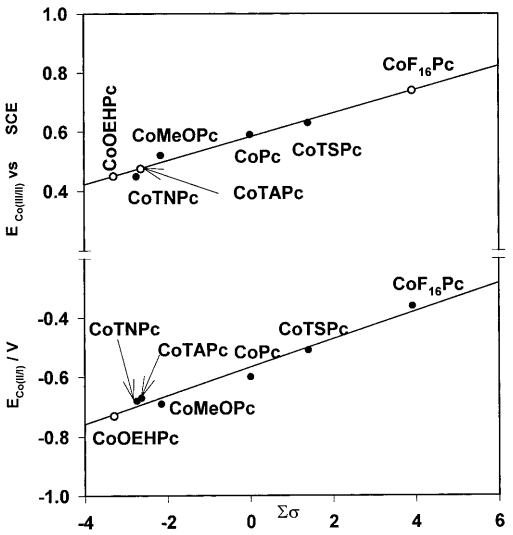

Fig. 4. Plot of Co(III)/Co(II) and Co(II)Co(I) redox potentials of the adsorbed cobalt phthalocyanines derivatives (at pH 13) vs. the Hammett $\Sigma\rho$ values. Open circles are calculated values, from Table 1.

correlation is obtained, which shows that electron-withdrawing groups F and $-SO_3^-$ stabilize the HOMO compared to Co–Pc. This is reflected in a more negative position of the energy of the HOMO. The opposite is true for electron-donating methoxy and neopenthoxy groups. Similar conclusions can be drawn from the energies of the LUMO. Note that energies of the HOMOs have negative values and energies of the LUMOs have positive values. This is why in the case of LUMO energies '$-\varepsilon_{LUMO}$' are plotted. The results in Figs. 2 and 3 essentially show the validity of the theoretical calculations, even though they have been performed only to the semi-empirical level. It is expected that those complexes with a more stable HOMO (more negative energy) will be more difficult to oxidize and will correspond to those having more positive redox potentials.

Fig. 4 illustrates plots of the Co(III)/Co(II) and Co(II)/Co(I) formal potentials of the adsorbed cobalt phthalocyanine derivatives versus the sum of the Hammett parameters of the corresponding substituent on the ligand. The Hammett parameters were obtained from the literature [31]. As pointed out by Lever [23], octasubstituted phthalocyanines such as CoOEHPc are single isomers. In contrast, the tetrasubstituted species CoTNPPc, CoTAPc, CoMeOPc, CoTSPc and CoTNPc are likely to be mixtures of isomers, randomly substituted in the two or three positions of each of the four benzene rings in the phthalocyanine ligand. There is no special reason that individual isomers will have significantly different formal redox potentials. For this reason, as suggested by Lever [23] the effect of the substituent can be correlated with the σ_p parameter (*para* substitution position) regardless of the position of the substituent, whether it is in the two or the three position in the peripheral benzene ring. In the case of the hexadeca substituted $CoF_{16}Pc$, σ parameters correspond to the arithmetical sum of the Hammett parameters in the *meta* and *para* positions. $CoF_{16}Pc$ is the only fully substituted phthalocyanine used in this study so eight fluoro groups are located at the *meta* position and eight fluoro groups in the *para* position. $\Sigma\sigma_p + \Sigma\sigma_m$ is 3.20, which fits well on the straight line. If we use only the *para* values, $\Sigma\sigma_p$ for 16 groups is 0.96, which falls well off the straight line corresponding to the Co(II)/(I) couple. The linear correlations in Fig. 4 have regression coefficients of 0.93 for the Co(III)Co(II) couple and 0.97 for the Co(II)/Co(I) couple using the data in the closed circles. The open circles for CoOEHPc correspond to data where the redox potentials are known but no data are available for the Hammett parameters, so the latter can be estimated from this figure. The opposite is true for $CoF_{16}Pc$ where the Hammett parameters are available but not the Co(III)/Co(II) redox potential. The estimated values are included in Table 1. The slopes of the lines are 0.041 V σ^{-1} for the Co(III)/Co(II) couple and 0.049 V σ^{-1} for the Co(II)/Co(I) couple, respectively. The value of 0.49 V σ^{-1} for the Co(II)/Co(I) couple compares well with 0.48 V σ^{-1} reported by Lever et al. [30] obtained from a plot using CoTNPPc, CoTAPc, CoPc and CoTSPc. It is interesting to comment at this point that the effect of substituents on the redox potentials of the phthalocyanines

is somewhat attenuated by the fact that these complexes are adsorbed on a graphite electrode. For complexes in solution, slopes are almost twice as large [23–25]. Lever et al. [30] have suggested that this could be attributed to the effect of the π-electronic system of the basal planes of the graphite substrate. This is only a speculation since redox data for a variety of substituted phthalocyanines adsorbed or immobilized on other electrode materials are not available.

Savéant et al. [32–35] have postulated in a series of papers that for outer sphere redox catalysis the redox potential of the catalyst represents the driving force of the reaction, and this was demonstrated for the reduction of vicinal alkyl dibromides. In fact it was possible to differentiate outer sphere from inner sphere redox catalysts by plotting $\log k$ (where k is the rate constant of the rate determining step) versus the redox potential of the catalyst. For outer-sphere catalysts, a straight line is obtained where $\log k$ increases with driving force. In a previous paper [20], we tested several substituted cobalt phthalocyanines adsorbed on graphite as catalysts for the electrochemical oxidation of 2-mercaptoethanol ($2R–SH \rightarrow R–SS–R + 2e^- + 2H^+$) and a plot of $\log k$ versus driving force (represented by the Co(II)/Co(I) redox potential) gives a straight line, but the rate of the reaction decreases with driving force. In other words this meant that the more the oxidative power of the phthalocyanine the less the activity for the oxidation of 2-mercaptoethanol. We attributed this observation to the fact that the oxidation of 2-mercaptoethanol activated by cobalt phthalocyanines proceeds by an inner-sphere mechanism and there other factors like the electronic coupling between donor (R–SH) and acceptor (Co–Pc), that control the rate of the reaction [20]. In this paper we have tested the catalytic activity of cobalt phthalocyanine derivatives for the reverse reaction, i.e. the reduction of 2-hydroxyethyldisulfide ($R-SS–R + 2e^- + 2H^+ \rightarrow 2R–SH$). In general the reduction of organic disulfides requires large overpotentials [36,37] and the R–SH/R–SS–R couple is very irreversible. This is associated with large activation energies as rupture of the sulfur–sulfur bond is involved [36].

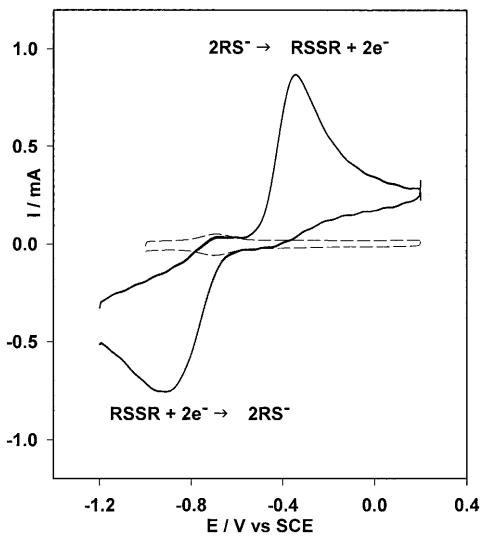

Fig. 5. Dashed lines: cyclic voltammogram of OPG modified with CoTNPPc in 0.2 M NaOH. Solid line, curve obtained after adding 0.0037 M of RSH and R–SSR to the electrolyte. Deaerated solutions. Scan rate: 0.1 V s^{-1}.

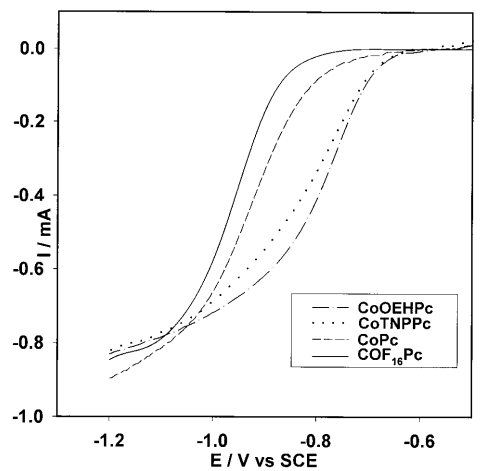

Fig. 6. Polarization curves obtained on a rotating OPG electrode modified with CoTNPPc in a solution containing 0.2 M NaOH + 0.0037 M of RSH and R–SS–R. Deaerated solution. Rotating rate 1000 rpm. Scan Rate 0.002 V s^{-1}.

In Fig. 5 the curve in dashed line illustrates the potentiodynamic response of the graphite electrode in alkaline media, modified with an adsorbed monolayer of CoTNPPc. The peak at ca. −0.685 V versus SCE corresponds to the Co(II)/Co(I) reversible couple in the adsorbed phthalocyanine. We use CoTNNPc as a typical example but similar curves are obtained with the other cobalt phthalocyanine derivatives. The curve in solid line shows a typical voltammogram obtained with the OPG/CoTNPPc modified electrode after adding 0.0037 M of both R–SS–R and R–SH to the electrolyte. The large separation between the reduction and oxidation wave (ca. 0.5 V) illustrates the irreversibility of the reaction from a kinetic point of view. A separation of 0.059 V should be observed for a one-electron transfer reversible process [38]. It also shows that the oxidation of the thiol occurs at potentials where Co(II) species predominate whereas the reduction of the disulfide occurs after the Co center is reduced to Co(I) in the adsorbed phthalocyanine.

Fig. 6 shows typical polarization curves obtained with a rotating disk OPG electrode modified with some Co–phthalocyanine derivatives taken as representative examples. A rotating disk electrode was used to minimize mass-transport limitations. The curves are shifted for the different cobalt phthalocyanine derivatives, which shows that its activity is influenced by the substituents present on the periphery of the phthalocyanine

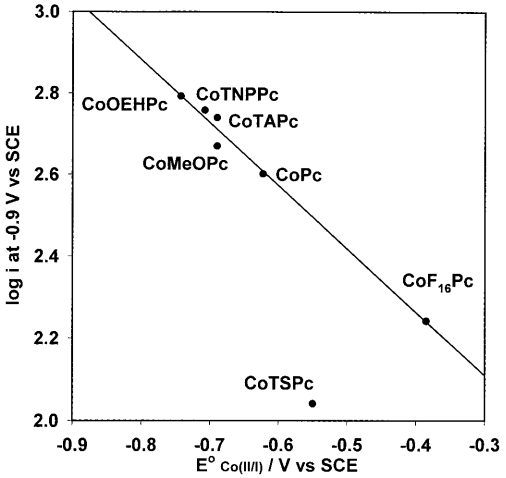

Fig. 7. Plot log log i (current density) versus the Co(II)/Co(I) redox potential for the reduction of 2-hydroxyethyldisulfide in 0.2 M NaOH.

ligand. This effect, however, is better illustrated in Fig. 7 where log i (current density at constant potential) for each phthalocyanine derivative is plotted versus the Co(II)/Co(I) redox potential. Note that we have used currents instead of the rate constants since the currents obtained experimentally are probably under mixed kinetic and mass transport control. However, the plot in Fig. 7 gives a qualitative idea of the dependence of the rates with the redox potential. The data point of Co–TSPc falls well off the straight line. This could be attributed to the negative charges on the four sulfonato groups on the periphery of the phthalocyanine ring. This could cause a change in the orientation of the adsorbed molecule on the graphite due to electrostatic repulsion at those negative potentials. Yeager et al. have suggested that CoTSPc adsorbs perpendicularly to the graphite based on in situ UV–Vis spectroscopic measurements of these molecules adsorbed on the basal plane of graphite [39]. If this is so, the graphite–Co distance would be larger compared with the other phthalocyanines and this could decrease the rate of the reaction. Apart from the data point of CoTSPc a straight line is obtained with the other phthalocyanines, which indicates that the rate of the reaction increases with driving force, i.e. the more the reductive power of the phthalocyanine the higher the activity for the reduction of the disulfide. This observation suggests that the reduction of the disulfide occurs via an outer-sphere mechanism, in contrast to what is found for the oxidation of the thiol [20]. This also indicates that the interaction of the disulfide with the cobalt center is weak. The opposite is true for the thiol. In fact, it has been demonstrated by visible spectroscopy that 2-mercaptoethanol, in alkaline media reduces the Co(II) center to Co(I) in cobalt tetrasulfonated phthalocyanine (CoTSPc) in solution [40]. In contrast, the disulfide has no effect on the spectrum of Co–TSPc. We have also demonstrated this by differential visible reflectance spectroscopy measurements [18] of Co–TSPc adsorbed on the basal plane of graphite electrodes. In alkaline medium the thiol L-cysteine reduces the adsorbed Co(II)TSPc to Co(I)TSPc. All this evidence indicates that thiols interact strongly with Co(II) but the disulfides do not. The plot in Fig. 7 indicates that the different adsorbed cobalt phthalocyanine derivatives, according to what has been suggested by Savéant [32–35], behave like outer-sphere redox catalysts, for the reduction of 2-dihydroxyethyldisulfide and probably for the reduction of other disulfides. Since the redox potential of these complexes is an important parameter in determining their catalytic and electrocatalytic activity, whether they act as outer or inner-sphere redox catalysts, it is interesting to establish linear correlations between their redox potential and the Hammett parameters of substituents in the periphery of the macrocyclic ligand. The same is valid for the semi-empirical theoretical calculations of the energies of the frontier orbitals of these molecules that correlate linearly with the redox potentials. In this fashion it is possible then to estimate redox potentials of phthalocyanines that cannot be measured directly from cyclic voltammograms as illustrated by some examples in this work and others given in the literature [23–30].

3. Experimental

3.1. Computational details

SCF molecular orbital theoretical calculations with full optimization using a PM_3 semiempirical procedure parametrized for transition metals were carried out for all substituted cobalt phthalocyanine with PC Spartan Pro package [41]. In all cases a doublet multiplicity (Co(II)) with an UHF (Unrestricted Hartree Fock) procedure was used.

Details about the origin and purification of the different substituted cobalt phthalocyanines are given in previous papers [18–20,22]. Adsorption of the complexes was achieved by placing a drop of 10^{-4} M solution of the complex on the electrode surface for 30 min. The solvent was dimethyl formamide for $CoPcF_{16}$, dimethylsulfoxide for CoPc, pyridine for CoMeOPc, CoTNPPc, CoTAPc and doubly-distilled water for CoTSPc. Adsorption of all complexes was verified by the appearance of typical peaks in the cyclic voltammograms of the modified electrodes. 2-Hydroxyethyldisulfide was spectroscopic grade from Riedel de Häen and was used as provided. Measurements were conducted on a BAS-100 potentiostat. The working electrode (Pine Instruments) was an ordinary pyrolytic graphite disk (OPG) of 0.44 cm^2. The electrode was

polished with 800 and 1200 grit emery paper and 1 μ alumina followed by ultrasonic treatment in purified water for 2 min. A saturated calomel electrode (SCE) was used as the reference, and a platinum spiral wire (14 cm^2, 99.99%, Aldrich) was used as the auxiliary electrode. The electrolyte (0.14 M NaOH + 0.5 M Na_2CO_3) was prepared from deionized, double-distilled water, and deaerated with ultra pure N_2. Electrolytes (NaOH, Na_2CO_3) were analytical grade from Merck.

Abstract

^{31}P NMR spectroscopy measurements were used to establish the course for the stoichiometric-dependent reactions between $[Au(PPh_3)]^+$ and $[Pt(C{\equiv}CPh)_2(dppf)]$ (**1**), which for equimolar amounts afford as the unique product $[Pt\text{-}\{\eta^3\text{-}C(C{\equiv}CPh){=}C(Ph)Au(PPh_3)\}(dppf)]^+$ (**2**), but any excess of **1** gives also $[Pt(\eta^2\text{-}PhC{\equiv}CC{\equiv}CPh)(dppf)]$ (**3**) [dppf = 1,1′-bis(diphenylphosphine)ferrocene]. Both compounds **2** and **3** were obtained straightforwardly by the reactions of **3** with $[Au(PPh_3)]^+$ and $[Pt(C_2H_4)(dppf)]$ with 1,4-diphenylbutadiyne, respectively. The X-ray crystal structure analysis of **3** confirmed a trigonal-planar coordination geometry about the platinum atom, and a bent η^2-coordinated diyne ligand. © 2000 Elsevier Science B.V. 1. Introduction

There has been a growing interest in metal-induced carbon–carbon bond-forming reactions of terminal alkynes [1]. In particular, one of the earliest experimental evidences of coupling reactions, mainly using d^8-metal complexes, has been provided by isolated *trans* and *cis*-$[Pt(C{\equiv}CPh)_2(PPh_3)_2]$, $[Pt(\eta^2\text{-}HC{\equiv}CPh)(PPh_3)_2]$, and 1,4-diphenylbuta-1,3-diyne products from the reaction between *cis*-$[PtCl_2(PPh_3)_2]$ and phenylacetylene [2]. Theoretical analysis and kinetics studies of oxidative addition and reductive elimination on d^8-metal-centered coupling of organic groups showed that a *cis* orientation or trigonal-planar geometry for the complex is necessary before occurrence of reductive elimination of the coupled product [3,4]. It is well established that the C–C elimination process at platinum(II) center is less favorable than for palladium counterparts, whereas the platinum intermediates are generally substitution-inerts in homogeneous catalysis, being therefore better candidates to carry out mechanistic studies [5,6].

One of our main objectives in the present paper was to find out whether the electrophilic metal reagent $[Au(PR_3)]^+$ behaves toward *cis*-alkynyl groups like its isolobal H^+ in formation of gold–butenynyl ligands [7,8]. This would be in contrast, therefore, to other electrophiles such $[Ag(PR_3)]^+$ and HgX_2 for which the reactions resulted in a coordinated metallic moiety at C≡C bonds of *cis*-$[Pt(C_6F_5)_2(C{\equiv}CR)_2]^{2-}$ [9]. To ascertain this premise, the reaction of complex **1** with $[Au(PPh_3)]^+$ was used as a model. The chelating dppf ligand was chosen due to its significant steric strain in square planar complexes, which ensures a *cis* configuration for the other two coordination sites. Consequently, it accelerates the formation of the coupling products [10].

2. Experimental

2.1. General

All manipulations were performed using general Schlenk and high-vacuum techniques. Solvents were appropriately dried and distilled under argon prior to use.

IR spectra were recorded as Nujol mulls on a JASCO IR 700 spectrometer, and calibrated relative to polystyrene at 1601 and 1028 cm^{-1}. The NMR spectra were recorded upon either BRÜKER AC300P (^1H 300.13, ^{13}C 75.47, ^{31}P 121.50 MHz) or VARIAN GEMINI 300 (^1H 300.08, ^{13}C 75.46, ^{31}P 121.47 MHz) Fourier-transform machines in $CDCl_3$, unless otherwise stated. ^1H and ^{13}C-{^1H} spectra were referenced to internal $SiMe_4$, and ^{31}P-{^1H} spectra referenced to external 85% H_3PO_4, and locked on the solvent deuterium signal. Reactions monitored by ^{31}P-{^1H} spectra were recorded in THF with the deuterium lock signal from D_2O, using a concentric glass capillary of this solvent in the 5 mm NMR sample-tube. Elemental analyses were performed on a Perkin–Elmer 2400 CHN microanalyzer. All percentages given are the averages of at least two independent determinations. 1,1′-Bis(diphenylphosphine)ferrocene (dppf) and phenylacetylene were purchased from Aldrich and used as received. [Ag][O_3SCF_3] (Aldrich) was recrystallized from ethyl ether–petroleum ether. 1,4-Diphenylbutadiyne [11] and the complexes [Pt(C≡CPh)$_2$(cod)] [11], [Au(PPh_3)Cl] [12] [$PtCl_2$(cod)] [13] and [Pt(cod)$_2$] [14] were prepared as described in the literature. Fresh and filtrated solutions of [Au(PPh_3)(THF)][O_3SCF_3] (0.50×10^{-2} mmol ml^{-1}) were used, prepared by an equimolar mixture of [Ag][O_3SCF_3] and [Au(PPh_3)Cl] in THF, which were stirred in the dark for 1 h, and filtered through a pad of diatomaceous earth.

2.2. Preparations

2.2.1. [Pt(C_2H_4)(dppf)] [15]

[Pt(cod)$_2$] (0.097 g, 0.23 mmol) was added in small portions to 15 ml of petroleum ether saturated with ethylene at 0°C. A solution of dppf (0.133 g, 0.24 mmol) in 15 ml of diethyl ether was then added, and the mixture stirred for 1 h at 25°C in an argon atmosphere. The resulting yellow solution was reduced to a small volume, affording a precipitate by bubbling ethylene through the solution at 0°C, which was washed with cold petroleum ether (3×5 ml) saturated with ethylene and dried under reduced pressure for 3 h. Yield of 0.167 g (93%). ^1H NMR: δ 2.14 [d, 4H, J(PtH) 60 Hz, J(PH) 2.8 Hz, C_2H_4]; 4.16 (s, 4H, η^5-C_5H_4P); 4.22 (s, 4H, η^5-C_5H_4P); 7.28–7.70 (m, 20H, C*H*, Ph); ^{31}P-{^1H} NMR: δ 29.1 [s, ^1J(PtP) 3684 Hz, Ph_2P]. *Anal.* Found: C, 55.16; H, 4.19. Calc. for $C_{36}H_{32}FeP_2Pt$: C, 55.61; H, 4.15%.

2.2.2. [Pt(C≡CPh)$_2$(dppf)] (1)

A stirred suspension of [Pt(C≡CPh)$_2$(cod)] (0.060 g, 0.12 mmol) in THF (10 ml) was treated with dppf (0.068 g, 0.12 mmol). After stirring for 1 h at 25°C, the resulting orange solution was concentrated under reduced pressure to ca. 2 ml. Addition of diethyl ether afforded a yellow solid, which was washed with diethyl ether and dried in vacuo for 2 h to give 0.089 g (78%). M.p. 225°C (dec.). IR: ν(C≡C) 2132 w, 2121 w cm^{-1}. ^1H NMR: δ 4.19 (s, 4H, η^5-C_5H_4P); 4.32 (s, 4H, η^5-C_5H_4P); 6.79 [dt, 4H, ^3J(HH) 5.4 Hz, ^4J(HH) 1.7 Hz, *o*-C*H*, C≡C*Ph*]; 6.4–7.02 (m, 6H, *m*-, *p*-C*H*, C≡C*Ph*); 7.31 [td, 8 H, ^3J(HH) 7.5 Hz, ^4J(HH) 1.3 Hz, *m*-C*H*, PPh_2]; 7.38 [td, 4H, ^3J(HH) 7.5 Hz, ^4J(HH) 1.3 Hz, *p*-C*H*, P*Ph*]; 7.85 [m, 8H, ^3J(PH) 11.2 Hz, ^3J(HH) 7.0 Hz, ^4J(HH) 1.3 Hz, *o*-C*H*, P*Ph*]. ^{13}C-{^1H} NMR: δ 72.82 (s, *C*H, η^5-C_5H_4P); 75.75 (t, *C*H, η^5-C_5H_4P); 75.82 [d, $|^1J(CP) + {}^2J(C\,P')|$ 61 Hz, *C*P, η^5-C_5H_4P]; 103.37 [dd, ^1J(PtC) 1132 Hz, $|^2J(CP) + {}^2J(CP')|$ 75 or 133 Hz, Pt*C*≡CPh]; 110.34 [m, ^2J(PtC) 308 Hz, $|^3J(CP) + {}^3J(CP')|$ 35.2 Hz, $^3J(CP) = \pm(36 \pm 2)$ Hz, $^3J(CP') = \pm(0.8 \pm 2)$ Hz, PtC≡*C*Ph]; 125.13 (s, *p*-*C*H, C≡C*Ph*); 127.21 (s, *m*-*C*H, C≡C*Ph*); 128.08 [t, $|^3J(CP) + {}^5J(CP')|$ 10.5 Hz, *m*-*C*H, P*Ph*]; 130.62 (s, *p*-*C*H, P*Ph*); 131.79 (s, *o*-*C*H, C≡C*Ph*); 133.44 [m, ^2J(PtC) 27 Hz, $|^1J(PC) + {}^3J(P'C)|$ 57.8 Hz, *ipso*-*C*, P*Ph*]; 135.19 [t, $|^2J(CP) + {}^4J(CP')|$ 11.5 Hz, *o*-*C*H, P*Ph*]. ^{31}P-{^1H} NMR: δ 15.1 [s, J(PtP) 2372 Hz]. *Anal.* Found: C, 62.70; H, 3.98. Calc. for $C_{50}H_{38}FeP_2Pt$: C, 63.10: H, 4.02%.

2.2.3. [Pt{η^3-C(C≡CPh)=C(Ph)AuPPh_3}(dppf)][O_3SCF_3] (2)

A stirred solution of **3** (0.075 g 0.078 mmol) in THF (5 ml) was treated with [Au(PPh_3)][O_3SCF_3] (0.080 mmol) in THF (16 ml) at °C. The resulting orange solution was stirred for 5 min at 5°C, and 10 min at r.t. The volume was reduced to 5 ml under vacuum, and fast addition of diethyl ether (10 ml) afforded yellow precipitate, which was washed with diethyl ether (3×5 ml) and dried under reduced pressure for 10 h. Yield of 0.106 g (87%). IR: ν(C≡C) not observed; ν(CF) 1270 vs, br; ν(SO) 1154 s, br; 1028 s, br cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.79 (s, 2H, η^5-C_5H_4P); 4.28 (s, 2H, η^5-C_5H_4P); 4.50 (s, 4H, η^5-C_5H_4P); δ 6.75–6.88 (m, 9H, Ph) 6.90–6.97 [td, ^3J(HH) 7.8 Hz, ^4J(HH) 1.9 Hz, 4 H, Ph]; 7.14–7.33 (m, 12 H, Ph); 7.40 [t, ^3J(HH) 7.8 Hz, 3 H, Ph]; 7.47–7.57 (m, 9 H, Ph); 7.59 (m, 4 H, *o*-CH, Ph, dppf); 7.81 [m, ^3J(PH) 11.3 Hz, ^3J(HH) 7.8 Hz, ^4J(HH) 1.4 Hz, 4 H, *o*-CH, Ph, dppf]. ^{31}P-{^1H} NMR ($CDCl_3$): δ 20.48 [dd, ^1J(PtP) 3036 Hz, J(PP′) 16.5 Hz, J(PP″) 8.9 Hz, Pt(dppf)]; 23.58 [t, ^1J(PtP) 4364 Hz, ^2J(PP) 18.9 Hz, J(PP′) 16.5 Hz, Pt(dppf)]; 35.15 [dd, J(PtP) 209 Hz, J(P′P″) 18.9 Hz, J(PP″) 8.9 Hz, Au(PPh_3)]. *Anal.* Found: C, 53.04: H, 3.13. Calc. for $C_{69}H_{53}AuF_3O_3FeP_3PtS$: C, 53.11; H, 3.43%.

*2.2.4. [Pt(η²-PhC≡CC≡CPh)(dppf)] (**3**)*

Method A. [Pt(cod)$_2$] (0.060 g, 0.15 mmol) was added in small portions to 15 ml of petroleum ether saturated with ethylene at 0°C. A solution of dppf (0.081 g, 0.15 mmol) in 15 ml of diethyl ether was added, and the mixture stirred for 1 h at 25°C in an argon atmosphere. 1,4-Diphenylbutadiyne (0.041 g, 0.203 mmol) was then added, and the solution stirred further for 1 h. The volatiles were evaporated, and the residue extracted from benzene (3 ml). Addition of 15 ml of petroleum ether gave a yellow solid, which was washed with petroleum ether (3 × 10 ml) and dried under reduced pressure. Yield of 0.107 g (77%). IR: ν(C≡C)$_{uncoord}$ 2166 m, ν(C≡C)$_{coord}$ 1720 m cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 3.95 (q, 2H, η⁵-C_5H_4P); 4.14 (t, J 1.6 Hz, 2H, η⁵-C_5H_4P); 4.32 (m, 2H, J 1.4 Hz, η⁵-C_5H_4P); 4.37 (dd, J 3.8 Hz, J 1.9 Hz, 2H, η⁵-C_5H_4P); 6.88–7.00 (m, 1H, *p*-C*H*, 2H, *m*-C*H*, PhC≡C); 7.15–7.38 (m, 19H, Ph); 7.71 [m, 4H, ^3J(PH) 11.3 Hz, ^3J(HH) 7.8 Hz, ^4J(HH) 1.9 Hz, *o*-C*H*, PPh_2]; 7.90 [m, 4H, ^3J(PH) 11.2 Hz, ^3J(HH) 8.0 Hz, ^4J(HH) 1.5 Hz, *o*-C*H*, PPh_2]. NMR ^{13}C {^{1}H} ($CDCl_3$): δ 71.02 [d, J(CP) 5.7 Hz, η⁵-C_5H_4P]; 72.08 [d, J(CP) 6.3 Hz, η⁵-C_5H_4P]; 74.29 [m, $|J(CP)+J(CP')|$ 9.5 Hz, η⁵-C_5H_4P]; 75.03 [q, $|J(CP)+J(CP')|$ 10.7 Hz, η⁵-C_5H_4P]; 80.07 [d, ^1J(CP) 51.4 Hz, CP, η⁵-C_5H_4P]; 82.77 [dd, J(CP) 12.99 Hz, J(CP′) 6.93 Hz, *C*≡CPh free]; 82.81 [dd, ^1J(CP) 50.8 Hz, ^3J(CP) 3.2 Hz, CP, η⁵-C_5H_4P]; 103.83 [d, J(PtC) 17.5 Hz, $|J(CP)+J(CP')|$ 7.4 Hz, C≡*C*Ph free]; 109.19 [dd, ^1J(PtC) 289 Hz, ^2J(CP) 78.0 Hz, ^2J(CP′) 5.5 Hz, η²-C≡C]; 125.52 [d, J(PtC) 12 Hz, $|J(CP)+J(CP')|$ 2.2 Hz, probably *ipso*-C, C≡C*Ph* free]; 126.40 (s, *p*-CH, C≡C*Ph*); 126.81 (s, *p*-CH, C≡C*Ph*); 127.77 (s, *m*-CH, C≡C*Ph*); 127.78 [d, $|J(CP)+J(CP')|$ 10.0 Hz, *m*-CH, PPh]; 127.95 (s, *m*-CH, C≡C*Ph*); 128.04 [d, $|J(CP)+J(CP')|$ 10.4 Hz, *m*-CH, PPh]; 129.34 [d, $|J(CP)+J(CP')|$ 1.4 Hz, *p*-CH, PPh); 129.90 [d, $|J(CP)+J(CP')|$ 1.0 Hz, *p*-CH, PPh]; 130.62 [d, ^4J(PtC) 37.3 Hz, $|J(CP)+J(CP')|$ 5.5 Hz, *o*-CH, η²-C≡C*Ph*]; 130.79 [d, J(PtC) 8.6 Hz, $|J(CP)+J(CP')|$ 1.9 Hz, *o*-CH, C≡C*Ph* free]; 132.36 [t, $|J(CP)+J(CP')|$ 19.0 Hz, J(PtC) 6.6 Hz, probably *ipso*-C, η²-C≡C*Ph*]; 134.00 [d, J(PtC) 20.4 Hz, $|J(CP)+J(CP')|$ 13.7 Hz, *o*-CH, P*Ph*]; 134.56 [d, J(PtC) 27.6 Hz, $|J(CP)+J(CP')|$ 14.4 Hz, *o*-CH, P*Ph*]; 135.90 [dd, ^2J(CP) 79.1 Hz, ^2J(CP′) 6.3 Hz, probably η²-C≡C]; 136.25 [d, J(PtC) 44.2 Hz, ^1J(CP) 44.6 Hz, ^3J(CP) 2.8 Hz, *ipso*-C, P*Ph*]; 136.90 [d, J(PtC) 36.7 Hz, ^1J(CP) 46.3 Hz, ^3J(CP) 2.5 Hz, *ipso*-C, P*Ph*]. ^{31}P-{^{1}H} NMR ($CDCl_3$): δ 22.1 [d, ^1J(PtP) 3630 Hz, ^2J(PP) 10.7 Hz, Ph_2*P*Pt]; 22.9 [d, ^1J(PtP) 3371 Hz, ^2J(PP) 10.7 Hz, Ph_2*P*Pt]. *Anal.* Found: C, 63.17; H, 4.00. Calc. for $C_{50}H_{38}FeP_2Pt$: C, 63.10; H, 4.02%.

Method B. A stirred solution of [Pt(C_2H_4)(dppf)] (0.160 g, 0.21 mmol) in THF (15 ml) was treated with 1,4-diphenylbutadiyne (0.050 g, 0.25 mmol) at r.t. After being stirred for 1 h, the resulting yellow solution was filtered through an alumina column and concentrated to 2 ml. Addition of diethyl ether and petroleum ether (1:1) afforded a yellow solid, which was washed with petroleum ether and dried under vacuum. Yield: 0.180 g (92%). *Anal.* Found: C, 63.17; H, 3.81. Calc. for $C_{50}H_{38}FeP_2Pt$: C, 63.10; H, 4.02%. The spectral data were identical with that of **3** prepared from the method A.

*2.2.5. Both **2** and **3** from the same reaction*

A solution of [Pt(C≡CPh)$_2$(dppf)] (0.033 g, 0.035 mmol) in THF (10 ml) was treated with [Au(PPh_3)(thf)][O_3SCF_3] (0.030 mmol) in THF (6 ml). After 3 h of stirring, the yellow solution was concentrated under reduced pressure, and diethyl ether added to the solution to give an orange precipitate, which was washed with diethyl ether (3 × 5 ml), and dried under vacuum for 2 h. This product was identified as **2**. Yield of 0.013 g (23%). *Anal.* Found: C, 53.00; H, 3.24. Calc. for $C_{69}H_{53}AuF_3O_3FeP_2PtS$: C, 53.11; H, 3.43%.

The supernatant liquid and washings were passed through an alumina column. Addition of 5 ml of petroleum ether yielded yellow crystalline solids, after leaving the solution stand overnight at −20°C. The crystals were washed with petroleum ether (3 × 5 ml), dried under reduced pressure, and identified as **3**. Yield of 0.010 g (30%). *Anal.* Found: C, 52.81; H, 2.98. Calc. for $C_{69}H_{53}AuF_3O_3FeP_3PtS$: C, 53.11; H, 3.43%. The spectral data were identical with those of **2** and **3** prepared before.

2.3. X-ray crystallography

Single crystals of **3** were grown from diethyl ether–petroleum ether 1:1 mixture. A yellow crystal (0.45 × 0.30 × 0.15 mm) of the compound was mounted on a glass fiber and used for intensity data collection. For data collection the unit cell dimensions and the orientation matrix were obtained from a least square fit of 25 reflections in the range $8.78 \le \theta \le 13.42°$. The automatic intensity search and indexing method indicated a cell belonging to the monoclinic crystal system with a P lattice. X-ray intensity data were recorded on an Enraf–Nonius CAD4 diffractometer employing the ω–2θ scan method with a scan speed of 45 sec/reflection. Every 60 min, the intensity and orientation of three standard reflections were confirmed; the observed intensity decay was less than 1.4% over the data collection. From the Bravais lattice and observed reflections, the space group was chosen to be $P2_1/n$. Lorentz and polarization corrections were made on the intensity data; due to the linear absorption coefficient of 3.96 mm^{-1} a semi-empirical absorption correction based on psi-scans was performed [16].

The structure was solved using the heavy-atom Patterson method employing SHELXS-97 [17] program and

all non-hydrogen atoms were located by subsequent Fourier difference synthesis. For structure refinement the SHELXL-97 [18] program was employed and the full-matrix least-squares method minimized on $\Sigma w(F_o^2 - F_c^2)^2$ where w is a weighting scheme indicated below. All non-hydrogen atoms were refined using anisotropic thermal parameters. Hydrogen atom sites were obtained geometrically and their displacement parameters were refined isotropically on a groupwise basis. For the final refinement of the structure, an isotropic extinction correction was included. The final refinements including 510 parameters converge to $R = 4.15$ and $R_w = 7.32\%$ with the weighting scheme, $w = 1/[s^2(F_o^2) + (0.0291P)^2 + 4.3290P]$ where $P = (F_o^2 + 2F_c^2)/3$.

*2.3.1. Crystal data: complex **3***

$C_{50}H_{38}FeP_2Pt$, $M = 951.68$, monoclinic, $a = 14.8059(2)$, $b = 17.6930(3)$, $c = 15.8196(2)$ Å, $\beta = 104.590(2)°$, space group $P2_1/n$, $Z = 4$, $V = 4010.48(10)$ Å^3.

3. Results and discussion

3.1. Synthesis and properties of complexes

Complex [Pt(C≡CPh)$_2$(dppf)] **1** is readily prepared in good yield from [Pt(C≡CPh)$_2$(cod)] [19] with the displacement of cod by dppf ligand (cod = 1,5-cyclooctadiene). Treatment of **1** with less of than 1 equiv. of [Au(thf)(PPh$_3$)][O$_3$SCF$_3$] in THF affords a mixture of [Pt{η^3-C(C≡CPh)=C(Ph)AuPPh$_3$}(dppf)]$^+$ (**2**) and [Pt(η^2-PhC≡CC≡CPh)(dppf)] (**3**). Concentration of the reactional solution, the less soluble complex **2** is selectively precipitated with diethyl ether. Crystallization of **3** is performed by adding petroleum ether into the supernatant and cooling. An increase in the relative amount of **1** towards two-fold excess in the reaction with [Au(PPh$_3$)]$^+$ favors the yield of **3**, as the main product. Complex **3** is reasonably stable in the solid state and in solution. Pure **2**, isolated as triflate salt, is stable as a solid, but is thermally unstable for prolonged periods in THF and CHCl$_3$ solutions. An authentic sample of **3** is prepared either by reaction of [Pt(cod)$_2$] with dppf and 1,4-diphenylbutadiyne in petroleum ether saturated with ethylene or by treatment of [Pt(C$_2$H$_4$)(dppf)] with diphenylbutadiyne. An alternative route for a rapid preparation of **2** in good yields is by treatment of **3** with [Au(PPh$_3$)]$^+$ in a 1:1 ratio.

3.2. Spectroscopic characterization

The IR spectrum of **1** exhibits two weak absorptions at 2132 and 2121 cm^{-1}, which correspond to the stretching frequencies of the *cis*-Pt(C≡CPh)$_2$ moiety. Compound **3** shows one band at 2166 cm^{-1} assignable to an uncoordinated alkyne, and another at 1720 cm^{-1}, owing to a carbon–carbon triple bond order is significantly reduced because of the coordination of the alkyne at the platinum atom.

A comparison between the ^{1}H NMR spectra of **1** (δ 4.19, and 4.32, 1:1) and **2** (δ 4.50, 4.28, and 3.79, 2:1:1) in the region of the cyclopentadienyl ring suggests a decrease in the symmetry of **2**. Whereas the spin system of **2** is AA′BB′CC′DD′, the single peak with double intensity is indeed two unresolved resonances [20]. The ^{1}H NMR spectrum of **3** exhibits four resonances with equal intensity for the chemically non-equivalent cyclopentadienyl protons and well-solved multiplets in the phenyl proton regions. Quaternary carbon resonances of the alkynyl ligands of **1** are observed at δ 103.4 [J(PtC) 1132 Hz] for C$_\alpha$ and at δ 110.3 [J(PtC) 308 Hz] for C$_\beta$ in the ^{13}C-{^{1}H} NMR spectrum. These carbons appear as the A part of AXX′ and AMXX′ spin system (M = ^{195}Pt, and X = ^{31}P) of a second-order spectrum, owing to the presence of chemically equivalent but magnetically non-equivalent ^{31}P nuclei.

^{31}P NMR data proved to be very useful for a better characterization of the complexes. Complex **1** displays only a singlet at high field (δ 15.1) with ^1J(PtP) of 2372 Hz, assigned to the phosphorus nuclei of the ligand dppf bound at the platinum atom. The presence of three sets of doublets in the spectrum of **2** reveals three distinct phosphorus nuclei environments. Two of these sets at δ 20.48 and 23.58, with very large platinum coupling constants ^1J(PtP) of 3036 and 4364 Hz, belong to the two P of the dppf. The smallest J(PtP) value is typical of a P atom lying *trans* to the stronger-field vinyl that is structurally well recognized, while the largest J(PtP) value shows a P atom *trans* to the weaker-field coordinated alkyne [21]. Interestingly, **2** has chemical shifts and ^1J(PtP) values near those observed for [Pt(η^3-allyl)(PR$_3$)$_2$]$^+$ [22], η^3-propargyl–allenyl [Pt(η^3-CH$_2$CCPh)(PPh$_3$)$_2$] [23], and butadienyl [Pt(η^3-CH$_2$CRCCH$_2$)(dppf)]$^+$ [24] complexes. Of particular relevance is the third set at lower field (δ 35.15) with a large J(PtP) 209 Hz, which is tentatively assigned to the P of the spacious Au(PPh$_3$) moiety bound at the vinyl group of the buta-1,3-diynyl ligand. However, we must bear in mind that we cannot rule out the possibility of an interaction between platinum and gold atoms. Additionally, a coupling constant of this magnitude is compared to those found for sp^3 carbon-bound P in complexes of the type [Pt{σ:η^2-C$_8$H$_{12}$(PR$_3$)}(dppe)]$^+$ (^3J(PtP) 223 Hz) [25], but is larger than in the bridged complex [Pt$_2$(μ-η^2,η^2-butadiyne)(PPh$_3$)$_4$] (^4J(PtP) 34 Hz) [26]. Unfortunately, no single-crystal of **2** was obtained for X-ray analysis. The basic structure of **2** appears analogous to [Ru(CO)$_2$\{C(C≡CPh)=C(Ph)HgCl\}Cl(PMe$_2$Ph)$_2$], which has the HgCl sub-

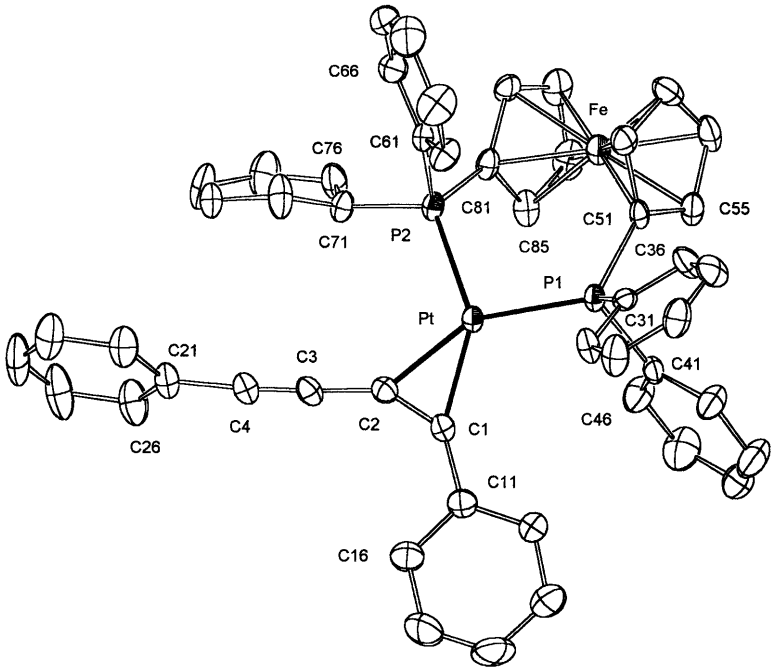

Fig. 1. ZORTEP plot with atom-labeling scheme of the structure of **3**; displacement ellipsoids at the 30% probability level.

stituent at 1-position of the η^1-but-1-en-3-yn-2-yl ligand, and also decomposes slowly in solution releasing $Me_3CC{\equiv}CC{\equiv}CCMe_3$ [27]. Taking into account a comparison between spectroscopic and reactivity data of **2** with known enynyl analogues [28], the compound **2** would be better described as an η^3-enynyl ligand rather than the alternate η^2,η^2 description. On the other hand, the assignment is unambiguous in complex **3**. The two near doublets at 22.1 and 22.9 ppm with large ^1J(PtP) of 3630 and 3371 Hz are typical of complexes [Pt(η^2-PhC≡CC≡CPh)L_2] (L = phosphine ligands) [20]. The identity of **3** is supported by X-ray study and an analogy with early data of η^2-coordinated diyne ligands, in which the complexes have been prepared and in some case structurally characterized by X-ray diffraction studies [29].

3.2.1. Crystal structure of *3*

The ZORTEP [30] drawing of the molecular structure of **3** is shown in Fig. 1. Selected bond distances and angles are given in Table 1. The list of the observed and calculated structure factors is available from the authors upon request.

The neutral complex shows a trigonal coordination of platinum by the η^2-coordinated Ph–C≡CC≡CPh ligand [Pt–C(1) = 2.050(7), Pt–C(2) = 2.040(7) Å], and the dppf ligand [Pt–P(1) = 2.2714(16), Pt–P(2) = 2.2679(18) Å]. Atoms P(1), P(2), C(2) and C(1) forms a plane (RMS deviation 0.021 Å), from which the Pt atom is moved away by 0.010(2) Å. The Pt atom is distanced 1.94 Å from the center of the C(1)–C(2) bond, and the Pt–C1 and Pt–C2 distances compare well with those reported earlier for acetylene platinum compounds [31]. The P1–Pt–P2 angle of 101.32(2)° is one the most striking feature of this bidentate ligand (95–103° range) [32].

Table 1
Selected bond lengths (Å) and angles (°) for **3** with e.s.d.s in parenthesis

Pt–C(2)	2.040(7)
Pt–C(1)	2.050(7)
Pt–P(2)	2.2679(18)
Pt–P(1)	2.2714(16)
C(1)–C(2)	1.293(9)
C(1)–C(11)	1.432(10)
C(2)–C(3)	1.394(9)
C(3)–C(4)	1.176(9)
C(2)–Pt–C(1)	36.9(2)
C(2)–Pt–P(2)	108.7(2)
C(1)–Pt–P(2)	145.50(19)
C(2)–Pt–P(1)	150.0(2)
C(1)–Pt–P(1)	113.14(19)
P(2)–Pt–P(1)	101.32(6)
C(2)–C(1)–C(1)	138.6(7)

C(4)–C(3)–C(2)	177.0(9)
Torsion angles	
C(1)–C(2)–P(2)–P(1)	3.0(5)
C(1)–P(1)–P(2)–C(2)	1.08(17)
C(12)–C(11)–C(1)–C(2)	175.7(9)
P(1)–C(51)–C(81)–P(2)	33.8(4)

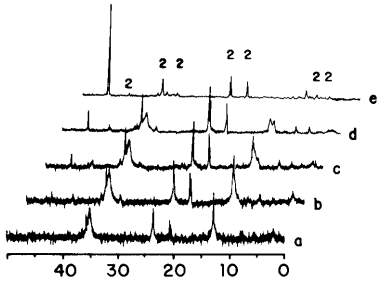

Fig. 2. Monitored ^{31}P-{^{1}H} NMR spectra (ppm) of the reaction mixture obtained by reaction between **1** and $[Au(PPh_3)]^+$ (1:1) in THF at times: (a) 15; (b) 30; (c) 45; (d) 90; (e) 300 min. The numbers **2** are the peaks due to this complex.

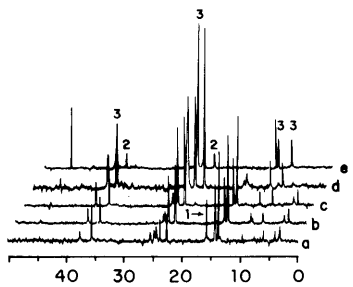

Fig. 3. Monitored ^{31}P-{^{1}H} NMR spectra (ppm) of the reaction between **1** and $[Au(PPh_3)]^+$ (2:1) in THF at times: (a) 15; (b) 30; (c) 45 min; (d) 3; (e) 12 h. The numbers **1**, **2**, and **3** are peaks due to these complexes.

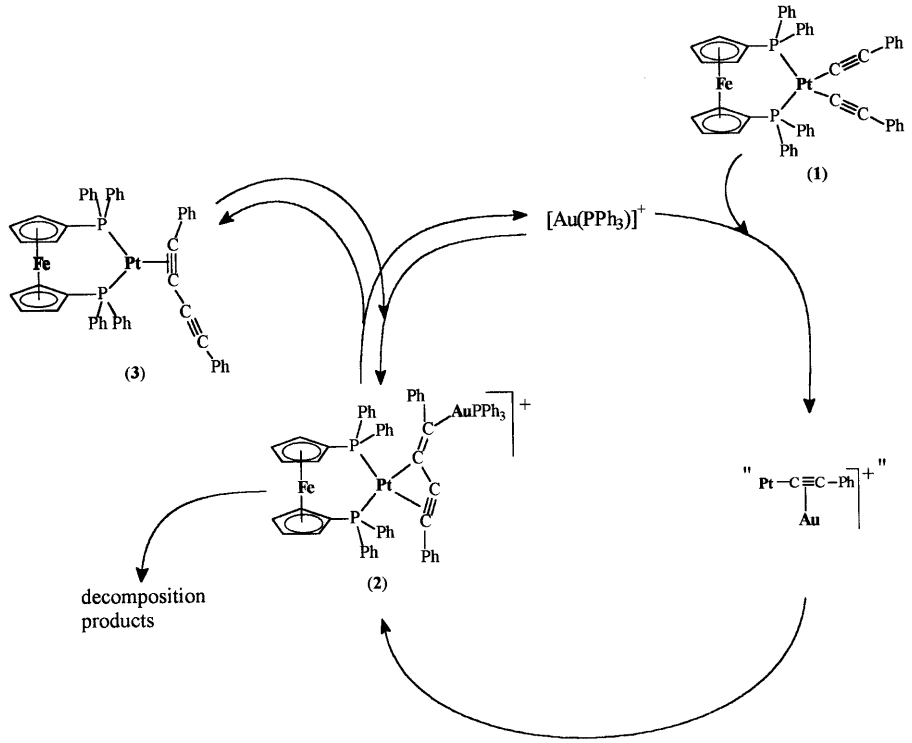
Due to the η^2-coordination, the C(1)–C(2) distance is elongated to 1.293(9) compared with 1.176(9) Å for the alkynyl fragment C(3)–C(4) with C–C-triple bond character, and C(1) becomes sp^2-character [C(2)–C(1)–C(11) = 138.6(7)°].

The ferrocenyl group deviates slightly from the local D_{5d} point symmetry demonstrated by the torsion angle P(1)–C(51)–C(81)–P(2) of 33.8(4)° and the observed angle of 2.7(2)° between both cyclopentadienyl rings. These five membered rings are essentially planar: C(51)–C(52)–C(53)–C(54)–C(55) (RMS deviation 0.0035 Å) and C(81)–C(82)–C(83)–C(84)–C(85) (RMS deviation 0.0014 Å), from which the Fe(II) ion is moved away by 1.640(3) and 1.642(3) Å, respectively.

All phenyl rings are almost planar with an average RMS deviation of 0.0201 Å. One of these phenyl rings is partially disordered in that atoms C(74), C(75) and C(76) split over to the alternative positions of atoms C(74A), C(75A) and C(76A) hawing complementary occupancy factors of 43, 45 and 47%, respectively.



3.2.2. The course of the reactions followed by ^{31}P NMR

One characteristic of the reactional system is the formation of species that resonate in different regions of the ^{31}P NMR spectrum, allowing the stages of the reactions to be monitored. Moreover, the previous spectroscopic data of the isolated species **1**–**3** have supported the assignments (see under Section 2). Decomposition products of **2**, detected in the solution by ^{31}P NMR data in Figs. 2 and 3, were an unidentified phosphine–gold product of $[Au(PPh_3)]^+$, which resonates at 45.5 ppm in the expected high-frequency region of gold complexes [33] and $[Pt(dppf)(H_2O)_2]^{2+}$ at 9.7 ppm [34].

Reaction between $[Au(PPh_3)]^+$ and **1** in equimolar amounts in THF, shown in Fig. 2, is accompanied by immediate growth of the resonances assigned to **2** [δ 20.4, 23.6 (P_2Pt), and 35.1 (PAu)]. The set of resonances observed at δ 35 (PAu), and at δ 13 (P_2Pt, ^{1}J(PtP) 2620 Hz), which disappears completely within 3–5 h, is assigned to the intermediate with gold π-coordinated at C≡C bonds of the (dppf)Pt(C≡CPh)$_2$ moiety. The assignment is in line with data for analogous systems, whereas the addition of electrophiles to the electron-rich β-carbon of metal acetylides is the best entry into vinylidene and enynyl complexes [35]. The activation of C≡C bonds by $Au(PPh_3)^+$ would allow further rearrangements, as shown in Scheme 1. The signals associated with **1** (15.1 ppm), $[Au(PPh_3)]^+$ (30.2 ppm), and **3** (22.1, and 22.9 ppm) were not detected in all these spectra. Therefore, the product **2**, without the participation of **1**, does not rearrange into butadiyne complex **3**.

The time evolution of the ^{31}P-{^{1}H} NMR spectra recorded for the reaction between **1** and $[Au(PPh_3)]^+$ in 2:1 molar ratio in THF are shown in the Fig. 3. Transient resonances of the precursor complex **1** remain for more than 30 min, while increase the characteristic signals of **3**. The extra set of close signals that arises at 13.5 ppm (^{1}J(PtP) = 2585 Hz) and 14.0 ppm (^{1}J(PtP) = 2504 Hz), and a unique singlet at 35.5 ppm (PAu) may now be attributed to two intermediates. Probably, an intermediate has a gold atom coordinated at C≡C bonds of two *cis*-Pt(C≡C)$_2$ moieties, because there is no signal for bonded PPh_3. Signals of **2** appear only after 45 min of reaction, and remain approximately constant during the measurements, while resonances of **3** grow significantly until becoming predominant at the end of the reaction. Subsequent spectra, registered over 1 day, reveal a nearly complete conversion of the precursors into the major complex **3**. Occasionally, such spectra exhibited an extra resonance at 34.2 ppm from residual [Au(PPh$_3$)Cl], which eliminates the presence of silver derivatives of **1** in solution. Therefore, when **1** is initially employed in excess, a second reaction between **2** and **1** occurs to produce **3**.

A reaction of **1** with **2** (1:1 ratio) has been carried out in THF to better understand the contribution of **2** to the overall-reaction. ^{31}P NMR spectra show immediate formation of **3** and the usual intermediates (at 13.5, 14.0, and 35.5 ppm), which converts into **2** during reaction (Fig. 4). As the signal of $[Au(PPh_3)]^+$ (30.2

Scheme 1. Pathways to the reaction between **1** and $[Au(PPh_3)]^+$ in THF.

ppm) is not present in all spectra, such results provide a diagnostic indication that the rapid rearrangement step of **2** to **3** depends strongly on the presence of **1** for sequestering $[Au(PPh_3)]^+$ from **2**. Inversely, since $[Au(PPh_3)]^+$ also promptly reacts with **3**, any trace of unreacted $[Au(PPh_3)]^+$ in solution is consumed by available **1** or **3**, closing the formal reaction cycle. This emergent result reinforces the conclusion that the reaction of **3** by $[Au(PPh_3)]^+$ leads to the gold derivative of a but-1-en-3-yn-2-yl ligand. Therefore, the reduction/oxidation occurs reversibly in these two stages under mild condition as a very facile process (see Scheme 1). Particularly interesting for the comprehension this reaction process with electrophilic gold was the protonation at a coordinated carbon of 1,4-diphenylbutadiyne ligand of the zerovalent complex $[Ru(\eta^2\text{-}PhC{\equiv}CC{\equiv}CPh)(CO)_2(PPh_3)_2]$ [36]. Moreover, reactions of hydrides $[RuH(O_2CCF_3C)(CO)(PPh_3)_2]$ [5b] and $[(PP_3)Ru(H)(H_2)][BPh_4]$ [37] with 1,4-diphenylbutadiyne also have provided an alternate synthetic method for 1,4-diphenylbut-1-en-3-yn-2-ylruthenium(II) complexes.

Considering these facts, the proposed reaction pathways for formation of products are now outlined in Scheme 1.

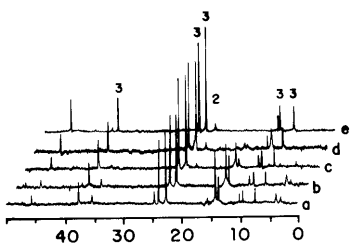


Fig. 4. Monitored $^{31}P\text{-}\{^1H\}$ NMR spectra (ppm) of the reaction between **1** and **2** (1:1) in THF at times: (a) 15; (b) 30 min; (c) 1.50; (d) 5; (e) 12 h. The numbers **2** and **3** are the peaks due to these complexes.

4. Supplementary data

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 133546. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We are very grateful to the CNPq-PADCT and CAPES-PROBRAL for financial support, Professor Dr J. Strähle (University of Tübingen) for the diffractometer facilities, and Dr B. Mann for his critical comments and his pertinent suggestions.

POLYHEDRON

The reaction of copper and iron species with thiuram sulfides: copper and iron dithiocarbamate derivatives

Luis I. Victoriano *

Facultad de Ciencias Químicas, Universidad de Concepción, Casilla 160-C, Concepción, Chile

Received 1 October 1999; accepted 18 April 2000

Abstract

The reaction chemistry of thiuram mono- and disulfides with copper(I), (II) and copper metal is reviewed. Cu(I) and the monosulfides afford adducts, while Cu(II) yields an oxidized form of the ligand, which is also obtained upon oxidation with ferric chloride or solutions of halogens. The disulfides and copper metal lead to Cu(I) dithiocarbamates, while oxidation of copper(I) species affords Cu(III)-containing mixed valence species. Similarly Cu(II) and the disulfides yield neutral Cu(III) complexes.

Keywords: Copper and iron species; Thiuram sulfides; Dithiocarbamate derivatives

1. Introduction

Thiuram sulfides, otherwise known as bis(*N*,*N*-dialkylthiocarbamoyl)sulfides, $R_2NC(S)S_nC(S)NR_2$ are the thiocarbamoyl esters of dialkyldithiocarbamic acids. The disulfides ($n = 2$) R_4tds are known on account of their biological activity, which leads to applications as fungicides, rubber vulcanization accelerators, agents of alcoholism therapy [1–3] and quite recently, as arrestors of human immunodeficiency virus infections such as AIDS [4]. This wide diversity of examples of biological activity has been attributed to a combination of at least two factors [5]: capability to fit into a receptor site and ability to undergo reversible redox reactions at suitable potentials. From this point of view, the equilibrium relating thiuram disulfides and dithiocarbamates is very relevant to the chemistry of the disulfides. A peculiarity of metal dithiocarbamate chemistry is the recognized ability of the ligands to stabilize unusually high oxidation states in transition metals, a property which has been attributed to the ligand ability to delocalize positive charge from the metal towards the periphery of the complex [6]. Thiuram disulfides are unique among thiolato-type ligands, in that reductive scission of the S–S bond leads to chelating systems (dithiocarbamate anions) which are particularly well suited to stabilize high oxidation states under the premise outlined above.

Coordination compounds containing ligands with sulfur atoms as donors have received much attention, due to their role as analogues of proteins containing metal–sulfur bonds [7]. Among these ligands, dithiocarbamates have been used to synthesize model compounds for enzyme activity [8,9]. Also, polynuclear metal dithiocarbamates may act as mineral analogues and thus as models of sulfide mineral degradation by microorganisms [10], a topic which has a strong relevance in connection with biolixiviation [11]. It must also be stated that one successful approach to the development of new metal sulfide catalysts involves thermolysis of discrete metal thio complexes containing coligands rich in sulfur, such as dithiocarbamates [12,13].

The monosulfides ($n = 1$) R_4tms, perhaps because they lack the wide breadth of applications known for the disulfides in agriculture and experimental medicine, have been much less extensively studied and where such studies deal with the subject of interaction of monosulfides and metal species, the field remains virtually unexplored. Exceptions have been reports dealing with the preparation and properties of the neutral complexes

MR_4tmsX_2 (M = Zn [14], Hg [15], Ni and Co [16]; X = halogen) or $M'R_4tmsX$ (M′ = Ag [17]) and of the cationic $[CrR_4tmsX_2]^+$ [18]. The spectroscopic properties of the latter complexes are inconsistent with a possible oxidative addition of the ligand to the metal center and it has been suggested that their electrochemistry be examined [19]. Thiuram monosulfides may also undergo C–S bond scission to give dithiocarbamate–metal–thiocarboxamido complexes or straightforward dithiocarbamates. Examples of the former are the reaction of monosulfides with tris(triphenylphosphine)–metal halides (metal = Rh and Pt) [20] or zero valent molybdenum complexes [21], while the interaction of a series of metal halides with thiuram monosulfides has afforded metal dithiocarbamates (metal = Ni^{2+}, Pt^{2+}, Cu^{2+}, Co^{3+} and Fe^{3+}) [22].

The present article intends to review the chemistry of thiuram sulfides and copper or iron metal species. Good compilations have appeared related to the general chemical properties of thiuram disulfides [1], and these reviews have covered the information then available on the interaction of such molecules with metal species. Also, the updates of Coucouvanis [7] and McCullough [8] on the chemistry of 1,1-dithiolate complexes constitute very informative first sources. More recently, Steggerda, Cras and Willemse have touched upon the subject [6].

Typical reactions of thiurams mono and disulfides with metal species fall under three distinct categories: (a) adduct formation; (b) ligand reduction with concomitant degradation to dithiocarbamate and/or thiocarboxamide ligands; and (c) thiuram oxidation. All of the above classes are found in the case of copper. We shall address each of these in the same order. Within each section thiuram disulfides will be treated first, followed by the monosulfides.

The following abbreviations are used throughout the text: R_4tms is *N*,*N*,*N*′,*N*′-tetraalkylthiuram monosulfide. Similarly, R_4tds stands for the corresponding disulfide, while *N*,*N*-dialkyldithiocarbamates are shortened to R_2dtc.

General preparative, instrumental and analytical techniques are described in the reports where the corresponding syntheses were first published. No attempt is made here to supply full experimental details for each of the preparations. The reader is directed to the original reports. Suitable references are found in Section 2.

2. Results and discussion

2.1. Adduct formation

Metal species which display a closed shell configuration typically react with thiuram disulfides to yield adducts, and copper(I) conforms to the rule.

Thus, R_4tms added to a cold slurry of cuprous halides in a suitable organic solvent yield solutions of the 1:1 adducts CuR_4tmsX (R = Me, Et, ^{i}Pr; X = Cl, Br, I, not all combinations) [23]. The products are typically deep orange to red diamagnetic solids soluble in organic solvents to yield non-conducting solutions. IR bands at ca. 350 cm^{-1} confirm coordination of Cu(I) to sulfur [24]. The solubility properties and low melting point of the complexes hint at a discrete non-ionic structure in the solid. This expectation is for the most part confirmed from the single crystal X-ray structure determinations [25]. Complexes $CuMe_4tmsX$ exist as chelated units formed by a molecule of the ligand and one of copper(I) halide. In all three cases, coordination about copper(I) is tetrahedral and is completed by sulfur and halogen. The chloro derivative is an S-bridged centrosymmetric dimer (see Fig. 1). All three copper–sulfur distances are slightly shorter in the chloro derivative.

The molecular structure of the bromo derivative corresponds to a polymer (Fig. 2). Association of basic chelated units generates long chains parallel to the *x* axis of the unit cell. The copper coordination is com-

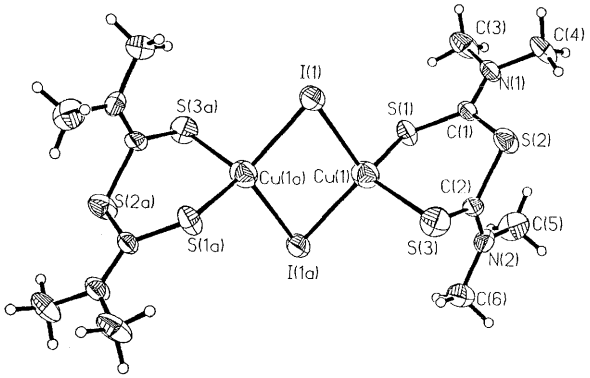

Fig. 3. The dimer $[CuMe_4tmsI]_2$.

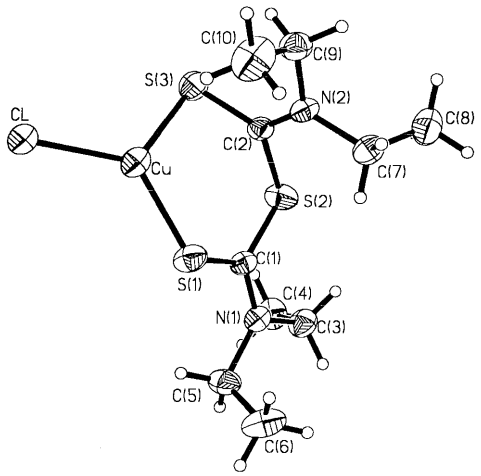

Fig. 4. The monomeric $[CuEt_4tmsCl]$.

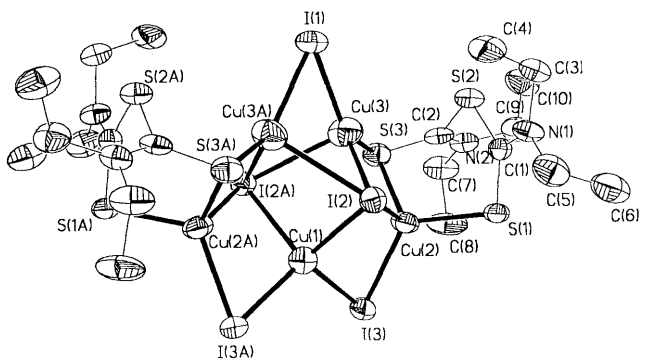

Fig. 5. The pentanuclear complex $[Cu_5(Et_4tms)_2I_5]$.

pleted by one bromine and three sulfur atoms. The iodo complex contains two μ-iodine bridged units of $CuMe_4tmsI$. As in the chloro and bromo derivatives, coordination about copper is tetrahedral and it is completed by two iodine and two sulfur atoms (Fig. 3).

Other CuR_4tmsX complexes (R = Et, X = Cl and Br [26]; R = ^{n}Pr, ^{i}Pr, X = Br [27]) feature monomers containing tricoordinate copper(I), a result which had been anticipated from the vibrational spectra [24]. The Cu–S distances are about 2.24 Å in the ethyl complexes, values which are noticeably shorter than those found in the methyl derivatives. This is attributed to the non-bridging nature of the sulfur atoms in the heavier alkyl homologues (Fig. 4).

Reaction of acetonitrile solutions of cuprous iodide and Et_4tms leads to a crystalline phase of composition $(CuI)_5(Et_4tms)_2$ [26,28]. The solid state structure of this aggregate may be described as formed by a central $(CuI)_3$ distorted octahedral element, and two additional $CuEt_4tmsI$ units fused to the central $(CuI)_3$ cage by means of sulfur and iodine bridges. The molecule displays a twofold crystallographic axis through one copper and one iodine, coincident with the long axial position of the 'octahedron' (Fig. 5).

The severely bent equatorial plane of the octahedron is defined by two additional copper and two iodine atoms. Each $CuEt_4tmsI$ unit contains one tetrahedral copper, a bidentate sulfur ligand and one iodine atom. These units are fused to two faces of the octahedron by means of two iodine bridges and by one sulfur bridge.

Discrete pentanuclear copper(I) complexes have been so far reported for $Cu_5(SPh)_7^{2-}$ [29] and $Cu_5X_7^{2-}$ (X = Br, I). The anion $Cu_5I_7^{2-}$ has been described as a pentagonal bipyramid of seven iodine atoms, where only slight deviations from C_{5h} symmetry occur [30]. In the bromo derivative, the pentagonal bipyramid of ligand atoms is more severely distorted [31]. With the hindsight afforded by the previous models we may now view the structure of the tetraethylthiuram monosulfide complex as consisting of the same basic structural unit, viz. a pentagonal bipyramid conformed by the two apical iodine atoms and by a distorted basal plane conformed by two sulfurs and three iodines. All copper atoms display tetrahedral coordination and appear as three distinct sets. The shortest metal–metal distance found (2.533(8) Å) rules out any possible metal–metal bonding. The iodine atoms are either μ_2- or μ_4-bridged and the shortest I···I contact (4.261 Å) compares well with the one found in $[Cu_2I_4^{2-}]$ [32] and other related systems [33].

The structure of the pentanuclear derivative is unique within a series of thiuram complexes known thus far. A variety of experimental conditions have failed to yield a mononuclear copper complex in combinations of copper(I) iodide and tetraethylthiuram monosulfide. Also, all efforts to isolate a species of higher nuclearity using combinations of different copper(I) halides and methyl, ^{n}Pr or ^{i}Pr substituents on the ligand have not met with any success. It is speculated that the kinetics of complexation might be slow in the case of $CuI–Et_4tms$, so that the available free CuI competes with the monomeric $CuEt_4tmsI$ for extension of the association.

Copper(II) sulfate and Me_4tms in acetonitrile lead to a solid phase $[CuL_2^+]_2SO_4^{2-}$. The crystal structure of this complex shows a CuS_4 chromophore where Cu(I) is

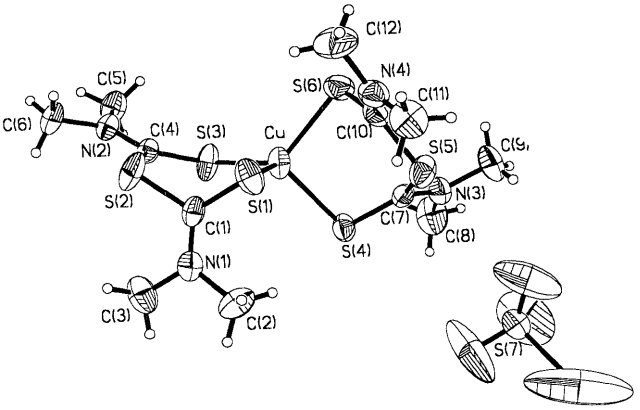
coordinated by two ligands in a strongly distorted tetrahedral environment (Fig. 6). The average Cu–S distance is 2.33 Å. The chelating rings display a boat conformation [34].

The tetrahedral and trigonal planar stereochemistries found in R_4tms complexes of copper(I) are not surprising. For d^{10} Cu(I), stereochemistry is dictated by charge and steric effects on the ligand, and tetrahedral and trigonal geometries are the norm [35].

The $CuMe_4$tmsX complexes show conductivities which are typical of non electrolites in acetonitrile or chloroform. Molecular weight determinations for the $CuMe_4$tmsBr derivative are consistent with a monomer. Such formulation in acetonitrile is not surprising, considering the strong coordination properties of the solvent. The halogen bridges present in the solid are broken and acetonitrile occupies the fourth coordination position on copper.

The temperature dependence of the ^{1}H NMR spectra of thiuram sulfides has been interpreted in terms of restricted rotation about the C–N bond which causes inequivalence of the alkyl groups and broadening of the signals at temperatures close to ambient [36]. This is apparent in the spectra of the complexed CuR_4tmsX and parent ligand. Two sets of CH_3 resonances are present in all the cases studied.

The spectra of $CuMe_4$tmsCl calls for additional comments. At room temperature the spectrum consists of four singlets of approximately equal height. The outer components are much broader and altogether account for three quarters of the overall integrated intensity. Below room temperature, and down to -10°C, the outer signals decrease in intensity (63% of the total) and the center of the system shifts slightly upfield (0.01 ppm). These changes are reversible and are attributed to the onset of a monomer–dimer equilibrium in solution. If the bond-making process of dimer formation from monomers were the only thermodynamically relevant event, one would expect the monomer–dimer equilibrium (exothermic) to shift to monomer at room temperature, and to dimer at lower temperatures. This allows one to assign the room temperature most intense signals as monomer, and in turn allows evaluation of the related equilibrium constant. The values thus obtained are 0.22 and 0.47 l mol^{-1} at 27 and -10°C, respectively. The limited temperature range available does not warrant further speculation as to the significance of the enthalpy value thus obtained for the dimerization process.



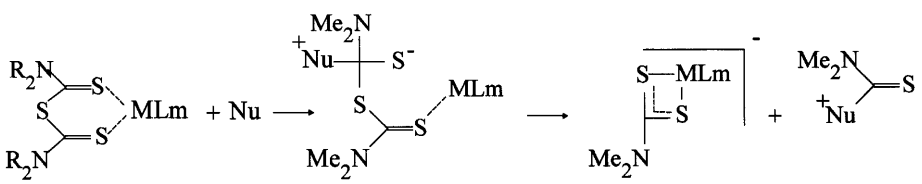


Fig. 6. The ionic complex $[Cu(Me_4tms)_2]^+$ SO_4^{2-} at room temperature.

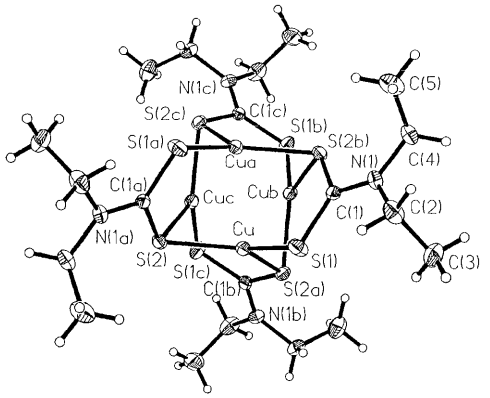
Solutions of $CuMe_4$tmsX complexes are not stable. Upon standing or heating, decomposition is observed. One of the decomposition products is the corresponding $Cu(Me_2dtc)_2$ compound, which has been isolated and characterized by melting point, IR and elemental analyses. The ability of tetraalkylthiuram monosulfides to generate metal dithiocarbamates has been used as a synthetic alternative to the preparation of the latter compounds [22]. It is now clear, after the work of McCleverty and Morrison that rupture of the C–S bond is a consequence of the nucleophilic attack on the thiocarbamoyl carbon, by a suitable agent [37] (Scheme 1).

Possible nucleophiles in our case are the solvent or the halide ions, but efforts to determine the fate of the missing dimethylthiocarboxamido residue have been unsuccessful.

2.2. Thiuram sulfides as oxidants — degradation to dithiocarbamates

Other reactions of metal containing species with thiuram sulfides are characterized by the oxidizing properties of the thiuram. Reduction of the ligand and scission of the S–S bond results in incorporation of the dtc fragments into the metal coordination sphere. As exemplified in the modern literature, rarely are these systems fully described by redox and complexation schemes alone. Bond breaking and extensive redistribution of the ligand systems are common. In many of the early studies the redox balance in the products isolated

Scheme 1.



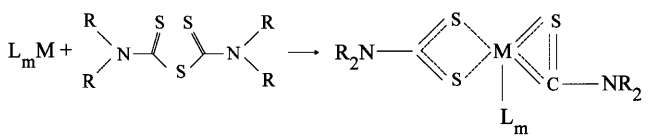


Fig. 7. The complex $[Cu(Et_2dtc)]_4$.

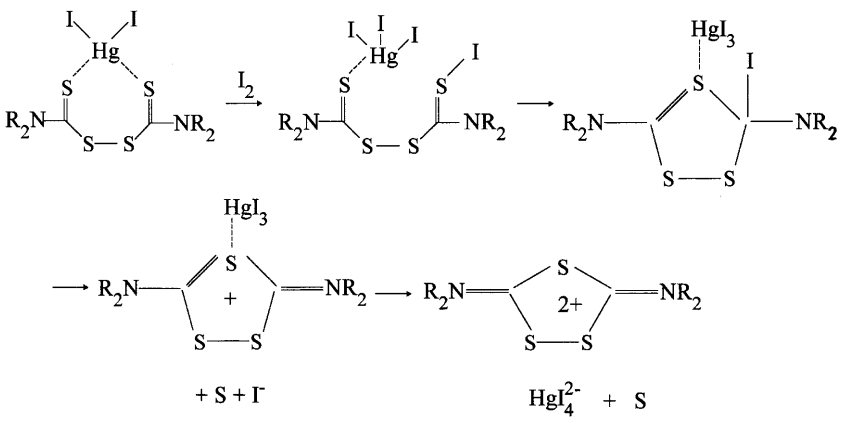
has not accounted for the observed reduction of the ligand [22]. In some cases, hypervalent metal states might be involved. This is now demonstrated in the case of copper(II) halides and thiuram disulfides [38]. Other systems may well behave in a similar manner. For example, tetramethylthiuram monosulfide reacts with the electron-rich species $Mo(CO)_3(MeCN)_3$ to produce a complex $[(CO)_2(Me_2NCS_2)Mo(Me_2NCS)]$ which contains bidentate dithiocarbamate and thiocarboxamide ligands [39] (Scheme 2).

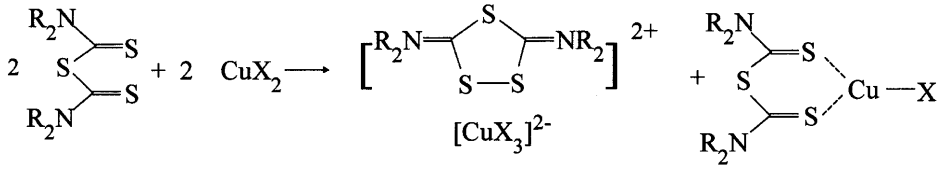
Other examples illustrating the oxidizing properties of the ligand towards copper are as follows.

2.2.1. Thiuram disulfides and copper metal

Oxidation of copper powder by carbon disulfide solutions of thiuram disulfides lead to dark solutions of $Cudtc_2$, which are reduced by excess metal to the cuprous Cudtc [40–42]. The crystal structure of the ethyl derivative features a tetrameric species $(CuEt_2dtc)_4$ where the copper atoms are arranged at the corners of a tetrahedron and all ligands are bidentate with singly bridging sulfur atoms [43]. A reexamination of the structure confirms all features described (Fig. 7). While well defined bis adducts are formed with triphenylphosphine, other donors such as dimethylsulfoxide, triphenylarsine, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine or tetramethylthiuram monosulfide have no effect on solutions of cuprous dithiocarbamates [42].



Scheme 2.



2.2.2. Thiuram disulfides and copper(I) halides

Mixed valence dithiocarbamates of general formulation $Cu_2(R_2dtc)_3X_2$ (X = Cl and Br, but not I) have been isolated by admixing solutions of Cu(I) halides and thiuram disulfides in different organic solvents [44]. IR and PE spectra are indicative of Cu(II) and Cu(III) mixtures in 1:1 mole ratios. A tentative formulation $Cu^{III}dtc_2^+$ $Cu^{II}dtcX_2^-$ is proposed [45]. Experiments performed with Me_4tds are more involved, since a variety of product compositions including CudtcCl, $Cu_4dtc_2Br_3$ and $Cu_3dtc_2Br_3$ are obtained. Based on magnetic data and spectral comparisons with known compounds, the following structures are respectively proposed. Dimeric, halogen bridged $Cu_2dtc_2Cl_2$, a polymeric network of $Cudtc_2$ and CuBr for $Cu_4dtc_2Br_3$ and ionic $Cudtc_2^+$ $Cu_2Br_3^-$ [46].

Copper(I) bromide reacts with R_4tds (R = Me, Et, ^{n}Pr and ^{n}Bu) in the appropriate soichiometric ratios to yield the compounds $Cu_n(dtc)_2Br_n$ ($n = 2$, 4 and 6). From IR, ESCA and magnetic measurements, the presence of the Cu(III)-containing cation $[Cu(dtc)_2]^+$ is inferred. The complexes are formulated as $[Cu(dtc)_2]^+$ $[Cu_{(n-1)}Br_n]^-$ [47,48]. Mixing equimolar ratios of the reactants leads to the series of complexes $Cu_2(dtc)_3X_2$ (R = Me, Et; X = Cl, Br, not all combinations) [48,49]. The crystal structure of $Cu_2(Et_2dtc)_3Br_2$ reveals chains of alternating $Cu(dtc)_2$ and $CuBr_2(dtc)$ units. The Cu–S bonds in the former are conspicuously shorter than in the latter. Therefore, the complexes seem to be better formulated as $[Cu(R_2dtc)]^+[CuX_2(R_2dtc)]^-$ [49].

Scheme 3.

Scheme 4.

2.2.3. Thiuram disulfides and copper(II) halides

Addition of copper(II) halides CuX_2 to tetrahydrofuran solutions of thiuram disulfides generate dark purple–blue $R_2dtcCuBr_2$ or brown–red $R_2dtcCuCl_2$ (R = Me, Et, ^{i}Pr). The diamagnetic products are characterized by abnormally high C–N and Cu–S stretching frequencies in the IR spectra and by high values of the observed binding energies in the photoelectron spectra. All the data are consistent with a formulation incorporating copper(III). A single crystal structure determination shows planar $C_2NCS_2CuBr_2$ monomeric units featuring a distorted square planar environment about Cu, with Cu–S and Cu–Br distances which are shorter than those found in related Cu(II) systems (Fig. 8) [50,51].

2.3. Ligand oxidation

Oxidation of metal dithiocarbamates may proceed further than the expected formation of thiuram disulfides, leading to the formation of cyclic five membered dications, usually stabilized by formation of anionic halogen complexes of the metal species. The mechanistic aspects of this oxidation are so far of a speculative nature and do not offer explanations as to the fate of the supernumerary sulfur atom (see Scheme 3). Reports dealing with this aspect of the chemistry of thiuram sulfides are as follows.

Iodine oxidation of $HgtdsI_2$ results in elimination of one sulfur atom and formation of the 3,5-bis(*N*,*N*-dialkyliminium)-1,2,4-trithiolane ($[R_4bitt\text{-}3]^{2+}$) dication referred to in the previous paragraph. This may come about through the ability of the thiocarbamoyl carbon to undergo nucleophilic attack by a suitable species.

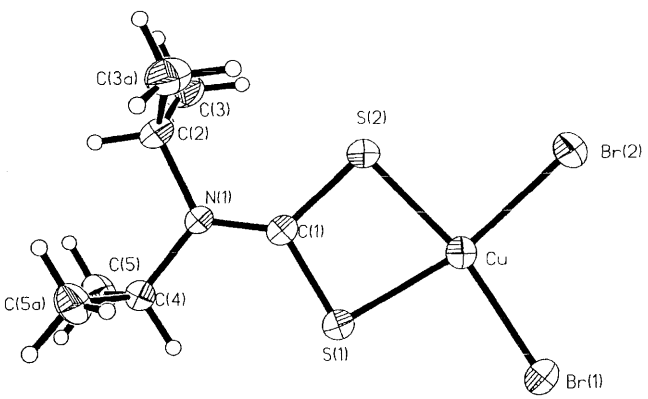


Fig. 8. The complex $[Br_2Cu\{(i\text{-}Pr)_2dtc]$.

Sulfur elimination may then follow [52]. A single crystal structure determination has confirmed the nature of the resulting $[R_4bitt\text{-}3]^{2+}HgI_4^{2-}$ species [53].

Related systems are exemplified by the reaction of Et_4tds with $FeCl_3$ [54] which results in $[Et_4bitt\text{-}3]^{2+}$ $2FeCl_4^-$, also accessible through halogen oxidation of $Fe(Et_2dtc)_3$ or $Fe(Et_2dtc)_2Cl$ [55]. A similar oxidation carried out on $Cu^I(Bu_2dtc)$ yields $[Bu_4bitt\text{-}3]^{2+}Cu_2X_6^{2-}$ (X = Cl, Br). In the absence of X-ray studies for these materials there seems to be a reasonable body of evidence based on IR spectroscopy, to support the structures proposed [55]. An interesting short lived species of formulation $[Et_4bitt\text{-}3]^{2+}2[Fe(Et_2dtc)_3]^-$ has been recently reported in a mass spectrometric study of oxidation products of $Fe(Et_2dtc)_3$ [56].

Formation of the $[R_4bitt\text{-}3]^{2+}$ cations is also apparent in reactions involving thiuram monosulfides. Thus, oxidation of the ligand accounts for reduction of two equivalents of copper(II) during the reaction of copper(II) halides with R_4tms (R = Me, Et), where one of the products isolated corresponds to the trihalocuprate(I) dianion of the $[R_4bitt\text{-}3]^{2+}$ cation [25] (see Scheme 4).

Other oxidizing agents used in the transformation of thiuram monosulfides to dialkyliminium trithiolanes have been $FeCl_3$ [57] and solutions of halogens [58].

Abstract

$[Ru(NH_3)_5H_2O]^{3+}$, $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$ were supported on the hydrated titanium alkoxide grafted on silica gel surface. The mononuclear complexes on the matrix surface have been characterized by specific surface area, elemental analysis, UV–Vis spectroscopy and electrochemical techniques (cyclic voltammetry, differential pulse polarography). These supported species exhibit one defined band on the visible region of the electronic spectrum: band $[Ru(NH_3)_5H_2O]^{3+}$ (668 nm), $[Ru(NH_3)_5Cl]^{2+}$ (676 nm) and $[Os(NH_3)_5H_2O]^{3+}$ (825 nm), attributed to $M^{III} \rightarrow Ti^{IV}$ (M = Ru(III) and Os(III)) metal to metal charge transfer process. For the mononuclear anchored species $[Ru(NH_3)_5H_2O]^{3+}$, $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$, the ($E_{1/2}$) for the M(III)/M(II) couple at 25°C are, respectively: -0.22, -0.28, and -1.15 V versus SCE. A formation of an oxo bridge Ti–O–M$(NH_3)_5$ (M = Ru, Os) and chloro bridge Ti–Cl–Ru$(NH_3)_5$ was postulated for the grafted complexes on the SiO_2/TiO_2 surface. © 2000 Elsevier Science B.V. Keywords: Silica; Titanium(IV); Ruthenium; Osmium

1. Introduction

The versatility of the techniques for the modification of silica gel [1–5] surface provide access to quite useful new materials [6–11]. One of the aspects of this technique is the grafting of titanium alkoxide on the silica gel surface followed by further hydrolysis yielding the respective oxide on its surface [11,12]. The thin film of TiO_2 on SiO_2 surface obtained by this procedure, strongly interacts [2,11,12] with the anion complexes $[Fe(CN)_6]^{4-}$ and $[Ru(CN)_6]^{4-}$. This interaction was assumed to be electrostatic in nature.

As a natural extension of the former work [2,11,12] the interaction of the thin film oxide with cations is investigated. This paper describes the electrochemical properties of $[Ru(NH_3)_5H_2O]^{3+}$, $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$ complex species immobilized on the titanium oxide surface.

In these complexes, whereas equatorial NH_3 ligands are well known to be kinetically inert regarding substitution reactions [13], the axial ligands Cl^- and H_2O, would exchange with other ligands in solution but at a slow rate [14–16]. The specific rate for water exchange in $[Ru(NH_3)OH_2]$ is 5×10^{-4} s^{-1} at 25°C [17] and 8.7×10^{-5} $M^{-1}s^{-1}$ at 40°C for chloride aquation [18] in $[Ru(NH_3]_5Cl]^{2+}$. Ti(IV) having a d^0 electronic configuration in solution phase is kinetically labile [19,20] and a similar behavior for the highly dispersed oxide on the silica surface should be expected. As the metal oxides are highly dispersed on the silica surface the coordination sites of titanium ions are not saturated due to the extensive Ti–O–Ti bond formation [21].

Thus, the Lewis acid sites coordinated with water or OH^- ligands can be easily replaced. Therefore, the formation of stable complexes of the robust species of ruthenium and osmium with the grafted titanium oxide acid center (Brønsted or Lewis) is likely to occur.

2. Experimental

2.1. Chemical reagents

All reagents and solvents were of analytical grade (Merck or Aldrich) and were used as purchased. All the manipulations with air sensitive compounds were carried under argon atmosphere using standard technique [22].

2.2. Specific surface area

The specific surface area S_{BET}, was determined by BET multipoint technique. The equipment used was a Micrometrics Flow Sorb II-2300 connected to a Flow Controller 2300 FC.

2.3. Silica functionalization with titanium(IV)

Silica gel (Merck) having a specific surface area $S_{BET} = 500 \pm 76$ m^2 g^{-1} average pore diameter of 0.60 nm and particle size between 0.025 and 0.20 nm, was activated by heating at 150°C under vacuum (10^{-3} torr) before use. About 70 g of this activated material were suspended in 150 cm^3 of dry toluene and after which, 24 cm^3 of tetrabutyl orthotitanate monomer (Aldrich) was added. The solid was mechanically stirred and refluxed for 6 h under argon atmosphere and then filtered and rinsed with 350 cm^3 of dry toluene. The solvent was eliminated by heating at 110°C.

The product obtained was carefully hydrolyzed and rinsed with demineralized water. The following equations can be written to represent the functionalization steps described above:

$$n(\equiv SiOH) + Ti(OR)_4 \leftrightharpoons (\equiv SiO)_n Ti(OR)_{4-n} + n HOR \quad (1)$$

$$(\equiv SiO)_n Ti(OR)_{4-n} + (4-n)H_2O \leftrightharpoons (\equiv SiO)_n Ti(OH)_{4-n} + (4-n)HOR \quad (2)$$

where ≡SiOH is silanol and OR is butoxide groups.

The specific surface area of $(\equiv SiO)_n Ti(OH)_{4-n}$ was $S_{BET} = 456 \pm 20$ m^2 g^{-1} and the amount of Ti was determined by X-ray fluorescence analysis as equal to 0.82 mmol g^{-1}.

Complexes of $[Ru(NH_3)_5H_2O]^{3+}$, $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$ were prepared, following procedures already described in literature [23–25].

2.4. Reaction of the complexes with ≡(SiO)$_n$Ti(OH)$_{4-n}$

These complex ions were grafted in a batch procedure, immersing about 0.5 g of $(\equiv SiO)_n Ti(OH)_{4-n}$, (for the sake of brevity, ≡TiOH), in 25 cm^3 of 1.0×10^{-3} M complex solution and the mixture shaken for 30 min. With the immobilization of these complexes on the matrix a change in the solid color from white to yellow is observed.

The solids were filtered, washed with water and dried under inert atmosphere. The resulting solids are designated as $\equiv Ti^{IV}ORu^{III}(NH_3)_5$, $\equiv Ti^{IV}ClRu^{III}(NH_3)_5$ and $\equiv Ti^{IV}OOs^{III}(NH_3)_5$ were stored in desiccators under vacuum (10^{-2} torr) and in the dark.

The amount of Ru and Os attached to the surface of silica, determined using X-ray fluorescence [11,12] and atomic absorption spectroscopy [2,5], were $(1.8 \pm 0.1) \times 10^{-2}$, $(2.2 \pm 0.1) \times 10^{-2}$ and $(1.3 \pm 0.1) \times 10^{-2}$ (mmol g^{-1}), respectively, for $\equiv Ti^{IV}ORu^{III}(NH_3)_5$, $\equiv Ti^{IV}ClRu^{III}(NH_3)_5$ and $\equiv Ti^{IV}OOs^{III}(NH_3)_5$.

Assuming that the chemical species are uniformly distributed on the matrix surface the average surface density, d, and the average intermolecular distance, l, of the attached ligands above cited, were estimated [3] by applying the equations:

$$d = (N \times N_A)/S_{BET} \quad (3)$$

$$l = (1/d)^{1/2} \quad (4)$$

where N is the number of moles of the chemical species per gram of silica and N_A is Avogadro's number. The results of these calculations are shown in Table 1.

Table 1
Chemical species, number of moles of chemical species (N), average surface density (d) and mean interatomic distance (l) of attached species on the silica gel

Silica	N (mmol g^{-1})	d (atom nm^{-2})	l (Å)
≡TiOH	8.2×10^{-1}	1.1	9.5
$\equiv Ti^{IV}ORu^{III}(NH_3)_5$	1.8×10^{-2}	2.4×10^{-2}	64
$\equiv Ti^{IV}ClRu^{III}(NH_3)_5$	2.2×10^{-2}	2.9×10^{-2}	59
$\equiv Ti^{IV}OOs^{III}(NH_3)_5$	1.3×10^{-2}	1.7×10^{-2}	77

2.5. Electrochemical measurements

Cyclic voltammetry and differential pulse polarography experiments were performed using a Princeton Applied Research (PAR) model 273 potentiostat/galvanostat. The three electrode system used in these studies consisted of a modified working electrode (modified carbon paste electrode), a reference saturated calomel electrode (SCE) and a platinum wire as the

auxiliary electrode. The voltammetric spectra of all complexes on the matrix (carbon paste mixture) were hindered by the potential range work of carbon paste (-1.1 to 1.1 V versus SCE) [26]. The measurements were carried out at 25°C. In these studies the criteria used to determine the couple M(III)/M(II) electrochemical reversibility was anodic current/cathodic current ratio approximately equal to 1.

2.6. Electronic spectra

The electronic spectra were recorded using a Hitachi U-3501 spectrophotometer. As the refraction index of carbon tetrachloride and the silica matrix are nearly the same [2], the supported complexes on the silica gel surface were immersed in spectra grade carbon tetrachloride and the electronic spectra of suspension were obtained using quartz cell of 1 mm path length.

The spectra obtained as described above were of very good agreement with those recorded using diffuse reflectance.

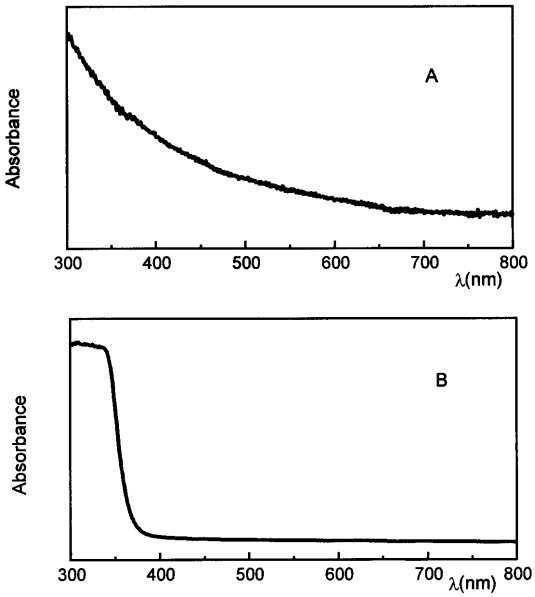

Fig. 1. Absorption spectra of (A) (SiO_2) and (B) titanium oxide dispersed on silica gel.

3. Results and discussion

The $[Ru(NH_3)_5H_2O]^{3+}$, $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$ complexes strongly interact with ≡TiOH in acid medium at pH about 3, whereas the $[Ru(NH_3)_6]^{3+}$ complex does not. The hydroxo group in ≡TiOH, is expected to be more labile than H_2O and Cl^- ligands in the $[Ru^{III}(NH_3)_5X]^{n+}$ complexes, $n = 3$, 2. Therefore, it is reasonable to assume that $[Ru^{III}(NH_3)_5X]^{n+}$ complexes bind to Ti(IV) using X as a bridging ligand. This interaction of the complexes with these titanium acid center at pH 3, although below the pH of zero point of charge (pH_{zpc} between 5.4 ± 1) [27,28], can take place according to the following scheme:

$$\equiv TiOH + H^+ \leftrightharpoons \equiv Ti^+ + H_2O \quad (5)$$

$$\equiv Ti^+ + [M(NH_3)_5H_2O]^{3+} \leftrightharpoons \equiv Ti\text{–}O\text{–}M(NH_3)_5^{2+} + 2H^+ \quad (6)$$

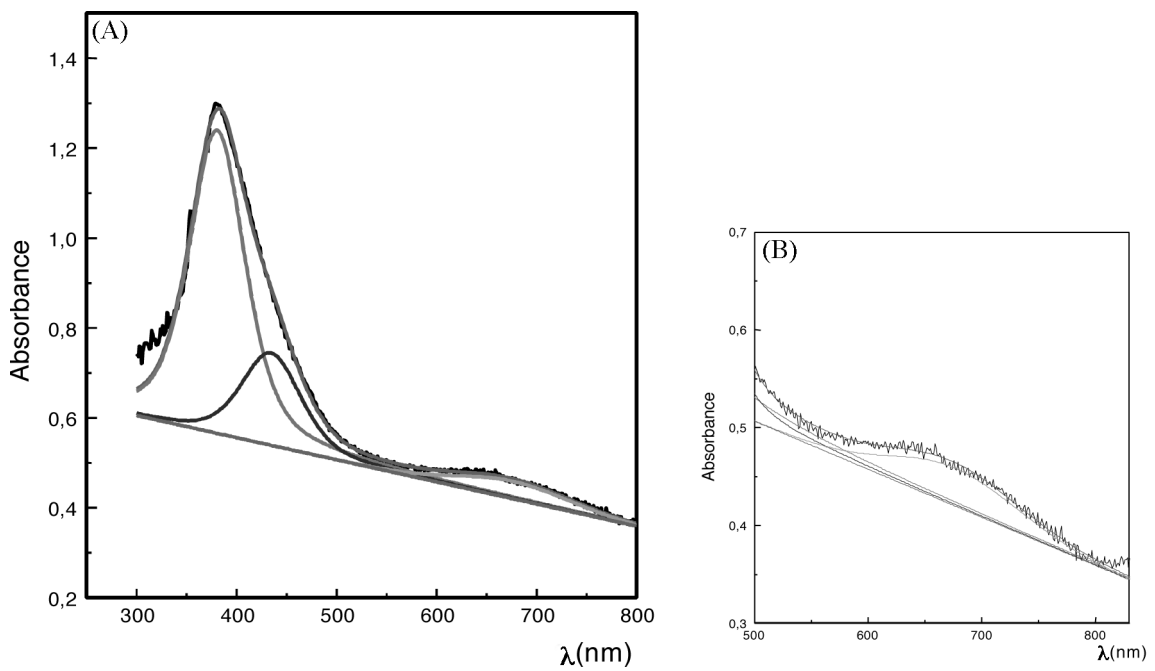

Fig. 2. Electronic absorption spectrum of grafted $[Ru(NH_3)_5Cl]^{2+}$ on the support ≡TiOH.

forming the oxo bridge between the metal and the grafted titanium oxide, or the chloro bridge:

$$\equiv Ti^{+} + [M(NH_3)_5Cl]^{2+} \leftrightharpoons \equiv Ti\text{–}Cl\text{–}M(NH_3)_5^{3+} \quad (7)$$

As the ligands in $[Ru(NH_3)_6]^{3+}$ are inert [16], the NH_3 are not able to act as bridging ligands, and since the titanium center would be as $\equiv Ti^{+}$, the hexaammine species were not able to anchor on the ≡TiOH surface.

Figs. 1(A,B) show the electronic spectra of the SiO_2 and ≡TiOH, respectively. The band gap energy for ≡TiOH was estimated as 3.34 eV that agrees fairly well with the value reported for the TiO_2/SiO_2 catalyst system [29]. This band gap is higher than for anatase (3.08 eV) which is consistent with the larger dispersion of titanium oxide on the silica gel surface (1.1 atom nm^{-2}) [29].

[f] Ref. [33].

Figs. 2 and 3 show the electronic spectra of the supported $[Ru(NH_3)_5Cl]^{2+}$ and $[Os(NH_3)_5H_2O]^{3+}$ species and Table 2 summarizes their more relevant spectral features.

Due to the absorption displayed by ≡TiOH at 350 nm (Fig. 1(B)) the analysis of the supported complexes spectra near 400 nm is very difficult. However, above 500 nm the electronic spectra of the grafted species are well defined. Therefore, by subtracting the support absorption and using gaussian fitting some tentative attributions have been carried out.

Both ruthenium complexes exhibit a band around 670 ± 10 nm. This band does not occur in the electronic spectra of the mononuclear pentaammine species in solution or in solid state. The energy of this transition is around 1.8 eV, therefore consistent with a Ru(III) → OTi(IV) (or Ru(III) → Ti(IV)) and a Ru(III) → ClTi(IV) metal to metal charge transfer (MMCT) process.

The grafted $[Os(NH_3)_5H_2O]^{3+}$ exhibits an absorption band at 825 nm (1.5 eV), which is not present in the electronic spectra of $[Os(NH_3)_5H_2O]^{3+}$ either in solution or in solid state. This band consistently positioned at lower energy in relation to the ones observed for the analogous Ru(III) complexes, was tentatively assigned to the charge transfer process Os(III) → OTi(IV).

In the range of potential studied (-1.0 to 1.0 V) the support ≡TiOH is not electroactive. The voltammetric spectra of the grafted $[Ru(NH_3)_5H_2O]^{3+/2+}$ complex is well defined as illustrated in Fig. 4.

Its is well known [34,35] that in solution ClO_4^- easily oxidizes $[Ru(NH_3)_5H_2O]^{2+}$ at room temperature according to:

$$8[Ru(NH_3)_5H_2O]^{2+} + ClO_4^- + 8H^+ \leftrightharpoons 8[Ru(NH_3)_5H_2O]^{3+} + Cl^- + 4H_2O \quad (8)$$

This reaction [36] is described to be first order in [Ru(II)] and in $[ClO_4^-]$ and zero order in $[H^+]$ (in the range from 10^{-3} to 10^{-2} M, $k = (2.6 \pm 0.1) \times 10^{-2}$ M^{-1}).

In our studies no evidence for the Ru(II) oxidation by perchlorate ion was observed. Indeed, the best defined cyclic voltammograms were obtained with $NaClO_4$ as a supporting electrolyte.

At first sight this behavior was not expected as a substantial oxidation of the electrochemically formed Ru(II) could occur under the conditions of the experiments ($NaClO_4$ 1.0 M). The inability of ClO_4^- to oxidize the anchored Ru(II) is probably due to matrix effects. The Ru(III) species dispersed on the matrix has a superficial density of 0.024 atom nm^{-2}, being the

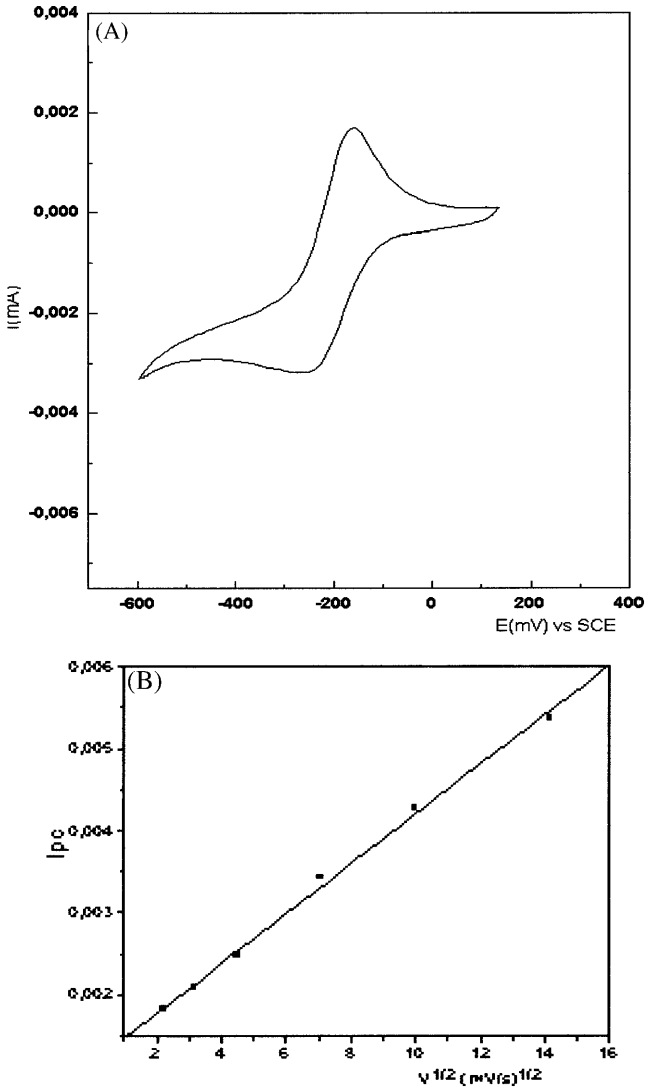

Fig. 4. Cyclic voltammograms using modified carbon paste electrode with $[Ru(NH_3)_5H_2O]$ grafted on the matrix. Conditions: $NaClO_4$ 1.0 M, 25°C; pH 3,1; $v = 20$ mV s^{-1}). The inserted graphic shows the dependence of cathodic peak with square root of the scan rates.

average distance between two ruthenium centers around 64 Å. The ClO_4^- reduction is a multi-step electron process [34], and as the ions' mobility in the carbon paste is certainly smaller than in solution, the chemical Ru(II) oxidation by ClO_4^- does not occur in the time scale of our experiments, the complete cycle was obtained in less than one minute.

For the anchored aqua ruthenium complex, the midipoint potential $E_{1/2} = (E_{pa} + E_{pc})/2$ was (-0.22 ± 0.01) V, $\Delta E_p = (E_{pa} - E_{pc}) = (0.10 \pm 0.02)$ V, and the ratio I_{pa}/I_{pc} was about (0.92 ± 0.02). The anodic and cathodic peaks intensities were directly proportional to the square root of the scan rates (see Fig. 4(B)), suggesting diffusion controlled process [37].

For the supported ruthenium ammines the peak to peak separation and $W_{1/2}$ values, (0.140 V $\pm$ 0.005) to $(W_{1/2})_a$ and $(W_{1/2})_c$ calculated from DPP data, are higher that the ones observed for the similar ions in solution. The insulator properties of SiO_2 [38] and the inability [19] of the ligands act as good electron density conductors, probably accounts on great part for these behavior.

The Os(III)/Os(II) couple in the polarogram of $\equiv Ti^{IV}OOs^{III}(NH_3)_5$ in the carbon paste electrode presents the mid-point potential with $E_{1/2} = -1.15 \pm 0.04$ V versus SCE and $I_{pa}/I_{pc} = 0.9 \pm 0.03$. The $W_{1/2}$ values calculated using DPP technique were 0.23 $(W_{1/2})_a$ and 0.25 V $(W_{1/2})_c$.

The electrochemical data of Table 2 for the supported and free complex ions in solution, suggest for the osmium and ruthenium species $\equiv Ti^{IV}OM^{III}(NH_3)_5$, a stabilization [34] of the metal center oxidation state(III) regarding to the (II) as a consequence of the association with the matrix.

Another interesting matrix effect manifestation can be observed in the $\equiv Ti^{IV}$–Cl–$Ru^{III}(NH_3)_5$ system.

The electrochemistry behavior of $[Ru(NH_3)_5Cl]^{2+}$ in aqueous has been already described [39,40]. In solution during the cathodic scan (1.0 to -0.6 V), only one wave is observed due to the reduction, Ru(III) to Ru(II), in $[Ru(NH_3)_5Cl]^{2+}$ ($E_{1/2} = -0.28$ V versus SCE) complex, which is followed by aquation of the halide ligand in the reduced complex, $k_{Cl^-} = 4.4$ s^{-1}. Thus, two waves are observed in the anodic scan: one is due to the remaining $[Ru(NH_3)_5Cl]^{2+}$ and the other originated by the oxidation of the $[Ru(NH_3)_5H_2O]^{2+}$ ($E_{1/2}$ -0.18 V versus SCE).

The cyclic voltammogram of the supported $[Ru(NH_3)_5Cl]^+$ (see Fig. 5) species exhibits only one

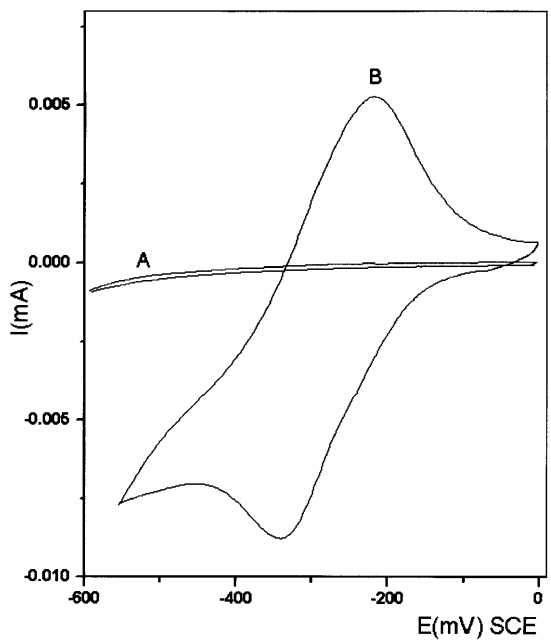

Fig. 5. Cyclic voltammograms using modified carbon paste electrodes: (A) matrix (≡TiOH) and (B) $[Ru(NH_3)_5Cl]]^{2+/+}$ grafted on the matrix ($NaClO_4$ 1.0 M, 25°C, pH 3.1; $v = 20$ mV s^{-1}).

coupled redox process: $E_{pc} = -0.34$ and $E_{pa} = -0.22$ V.

The ΔE_P for the supported $[Ru(NH_3)_5Cl]^{+2/+}$ is equal to (0.12 ± 0.01) V, is on agreement, within the limits of the experiment error with the value of $\Delta E_P = (0.10 \pm 0.01)$ V for the related $[Ru(NH_3)_5\ H_2O]^{3+/2+}$ supported system.

No distinct signal of a second electroactive species was detected, in anodic scan when the scan rate has changed from 0.005–0.5 V s^{-1} in the temperature range of 5–45°C. Therefore it seems unlikely that in the carbon paste electrode, a constrict environment, the bridge $\equiv Ti^{IV}$–Cl–Ru^{III} is disrupted, in the time scale of the experiment.

4. Conclusions

Electrochemical and spectroscopic measurements pointed out matrix effects over $[M(NH_3)_5H_2O]^{3+}$ (M = Ru(III) or Os(III)) and Ru $(NH_3)Cl]^{2+}$ grafted species. The well known fast reactions of Ru(II) with ClO_4^- and the aquation of Cl^- in the Ru $(NH_3)Cl]^{2+}$ in solution were not observed for the anchored species. The existence of a MMCT band due to the $M^{III} \rightarrow OTi^{IV}$ process and the observed shift in the $E_{1/2}$ values for the M(III)/M(II) couples in the anchored species suggest a stabilization of the M^{III} regarding the M^{II} oxidation state, as a consequence of the interaction with the matrix. Analyzing the reaction between the support and $[M(NH_3)_5H_2O]^{3+}$, $[M(NH_3)_5Cl]^{2+}$ and $[Ru(NH_3)_6]^{3+}$ a formation of a binuclear system Ti^{IV}–LM^{III}, where $L = O^{2-}$ or Cl^- has been proposed.

Abstract

Sol–gel zirconia was sulfated with sulfuric acid. Samples were analyzed with X-ray powder diffraction and thermogravimetry; crystalline phases were refined via Rietveld method. The samples annealed at 600°C crystallized into nanocrystalline tetragonal zirconia when they were prepared with acetic acid, but they crystallized into a mixture of zirconium sulfide, zirconium oxide sulfide, and zirconium sulfate when they were prepared with hydrochloric acid or ammonium hydroxide. The sulfation of the samples prepared with acetic acid also stabilized the tetragonal zirconia. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Sulfated zirconia; Tetragonal zirconia stabilization; Rietveld method; Zirconium sulfide; Zirconium oxide sulfide; Thermogravimetry of sol–gel ZrO_2

1. Introduction

Zirconia is an oxide with three polymorphs that are transformed between each other by annealing it. The room temperature polymorph has a monoclinic crystalline structure that is transformed into a tetragonal symmetry when it is annealed in air at 1170°C and eventually to a cubic symmetry when it is heated in air at 2370°C. The high-symmetry structures of zirconia can be also obtained at room temperature by dissolving in its structure atoms like Y, La, Ca and Mg, which substitute for zirconium atoms [1]. The electronic properties of these zirconia solid solutions will depend on the size and valence of the dissolved atom, providing a mechanism to produce materials with interesting properties for electronics [2–4]. When the room temperature high-symmetry zirconia solid solutions are under stress, their crystalline structure is transformed into the monoclinic symmetry of pure zirconia; this fact is used to produce high toughness materials [5].

The above observations are valid when the samples are synthesized at large temperatures to produce microcrystalline materials. But, when zirconia is produced via soft chemistry, new phenomena have been observed; for example, when it is prepared with the sol–gel technique its tetragonal phase appears at relative low temperatures [6], caused by the hydroxyls in its structure. In this case, the tetragonal phase is in reality a zirconia solid solution with the hydrogen in lattice positions that until now are unknown. Preliminary results [7] show that carboxyls can also be dissolved in zirconia to stabilize its tetragonal phase. In the two last mentioned solid solutions the hydrogen and carbon atoms should occupy interstitial sites of zirconia crystalline structure. This result is very interesting, because it gives another option on interpreting the stabilization of the tetragonal phase when pure zirconia is modified with sulfuric acid [8], which is a system of big interest in catalysis [9]. That means that in sulfated zirconia, sulfur atoms could be not only on the crystal surface but also in bulk: in the zirconia lattice interstitials. To have a better understanding of the observed behavior of sulfated zirconia, however, its crystallography must be analyzed in detail as a function of the different parameters involved in its synthesis and annealing.

Zirconia by itself has a good catalytic activity for alkylation and dehydration reactions and fine chemistry [10,11]. Recently, it has also been found that sulfated zirconia possesses important isomerization activity [12–15]. Sulfated zirconia also shows superacidity [16–19]: acid-site number in the sample considerably increases when sulfate ions are present, which is produced by the electron deficiency in the metal cations. The acidity depends on the structure of the crystalline phase; the tetragonal phase is the most active [20].

In the present work, we analyzed the effect on the atomic distribution of sol–gel zirconia when it is sulfated with sulfuric acid. The precise knowledge of this atom distribution will provide elements to interpret from a microscopic point of view the catalytic properties of sulfated zirconia, and the origin of its superacidity that facilitates paraffin isomerization reactions at low temperatures [21]. The present crystallographic study will also provide elements to understand the nature and structure of the observed highly acidic sites. Atom distribution was measured by using X-ray powder diffraction; when it was crystalline, the structure was refined with the Rietveld method. The evolution of this distribution was analyzed as a function of temperature, and correlated with the sample weight loss detected via thermogravimetry.

2. Experimental

2.1. Sample preparation

Zirconium *n*-butoxide (10.024 mol) was dissolved at 70°C in *tert*-butyl alcohol (150 ml), under continuous refluxing and stirring. The hydrolysis initiator, HCl for pH 3, $C_2H_4O_2$ for pH 5, and NH_4OH for pH 9, was added to the solution until reaching the desired pH. The solution with the initiator was stirred and refluxed for 10 min and eventually cooled to 50°C. Thereafter, the water (25.66 ml) was dropped into it, and its temperature was again raised to 70°C, at which it was continuously stirred and refluxed until gelling. Gels were dried in air at 100°C for 24 h. Next 1 g of dried sol–gel zirconia was uniformly impregnated with 25 ml of sulfuric acid.

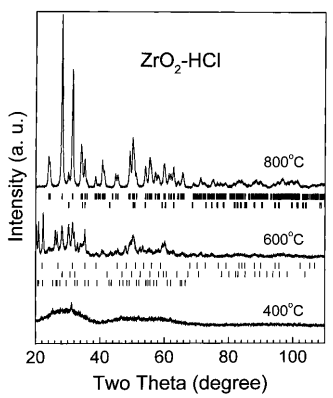

Fig. 1. X-ray diffraction pattern of the samples prepared with hydrochloric acid and annealed at different temperatures. The upper tick marks under the pattern of the sample annealed at 800°C correspond to monoclinic zirconia; the lower tick marks to tetragonal zirconia. The upper tick marks under the pattern of the sample annealed at 600°C correspond to ZrOS; the middle tick marks to ZrS_2, and the lower tick marks to $Zr(SO_4)_2$.

2.2. X-ray diffraction characterization

The crystalline structure of the samples was characterized by X-ray powder diffraction, and refined with the Rietveld technique. X-ray diffraction patterns of the specimens, prepared by packing sample powder into a glass holder, were measured at room temperature by using a Bruker D8-Advance diffractometer with Cu Kα radiation and a secondary beam monochromator. Intensity was measured by step scanning in the 2θ range between 20–110°, with a step of 0.02° and a measuring time of 2 s per point. Structure refinement was performed with DBWS-9411 code [22]; peak profiles were modeled with a pseudo-Voigt function that included average crystallite size as one of their fitting parameters [23]. Standard deviations, showing the variation of the last figures of the corresponding number, were given in parenthesis. When the number is a parameter obtained from the refinement, its standard deviation is not an estimate of the analysis as a whole, but only of the minimum possible probable error based on its normal distribution [24].

2.3. TGA characterization

This analysis was carried out in a thermoanalyzer Dupont model 950; it was performed in air from 25–1200°C at 20° min^{-1}. In order to eliminate synthesis residuals, before the thermoanalysis, sulfated samples were annealed at 400°C.

3. Results and discussion

All samples were amorphous when they were annealed below 450°C (Figs. 1–3), which reproduces previous reports for sulfated zirconia [8,25]. The amorphous character is typical for hydrated non-sulfated zirconia when it is annealed below 300°C; it is determined by the fast condensation, produced by their large number of possible nucleation sites, of the zirconyl clusters [6,26]. It is known that this zirconia is no more amorphous when it is annealed at 400°C, but a mixture of nanocrystalline tetragonal and monoclinic zirconia [6]. Therefore, the observed stabilization of the amorphous phase at 400°C in the present sulfated

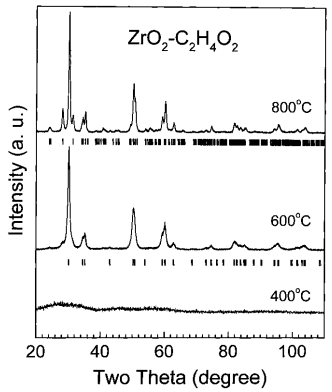

Fig. 2. X-ray diffraction pattern of the samples prepared with acetic acid and annealed at different temperatures. The tick marks under the pattern of the sample annealed at 800°C correspond to monoclinic zirconia; those under the pattern of the sample annealed at 600°C correspond to tetragonal zirconia.

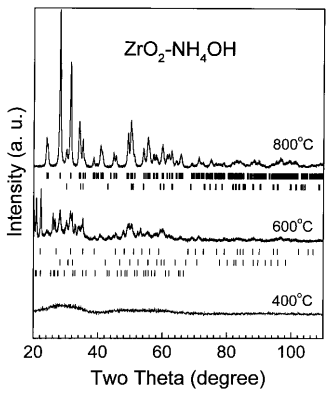

Fig. 3. X-ray diffraction pattern of the samples prepared with ammonium hydroxide and annealed at different temperatures. The upper tick marks under the pattern of the sample annealed at 800°C correspond to monoclinic zirconia; the lower tick marks to tetragonal zirconia. The upper tick marks under the pattern of the sample annealed at 600°C correspond to ZrOS; the middle tick marks to ZrS_2, and the lower tick marks to Zr $(SO_4)_2$.

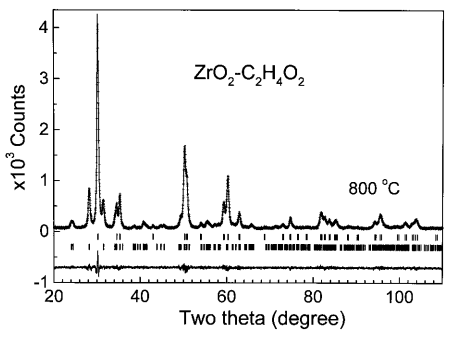

Fig. 4. Rietveld refinement plot of a sample prepared with acetic acid and annealed at 800°C. Crosses indicate the experimental data, while the calculated diffraction pattern and their difference with the experimental data are indicated with continuous lines. The upper tick marks correspond to tetragonal zirconia ($R_f = 0.008$), and the lower tick marks to monoclinic zirconia ($R_f = 0.02$).

zirconia samples should be produced by the presence of sulfate ions, which inhibit crystallization. Samples, however, crystallized when they were annealed at higher temperatures. Fig. 4 shows a typical Rietveld refinement plot, which corresponds to a sample prepared with acetic acid and annealed at 800°C.

In the samples synthesized with acetic acid as hydrolysis initiator, the tetragonal was the main phase when they were annealed at 600°C (Fig. 2 and Table 1). It is important to note, that the tetragonal phase concentration of 66(2) wt.% observed in the sulfated samples prepared with acetic acid and annealed at 800°C was larger than the concentration of 17(2) wt.% observed in the respective non-sulfated samples [6]. Because the only difference between sulfated and non-sulfated samples was the presence of the sulfate ions, the above result is an indication that sulfate ions are responsible of this additional stabilization of the tetragonal phase.

Recently, Bokhimi et al. [7] suggested that carbon atoms could be incorporated in the interstitial sites of the tetragonal zirconia lattice to stabilize it. This result could be extrapolated to the present case by assuming the presence of sulfate ions in the tetragonal phase with the sulfur atoms occupying the same interstitial sites that carbon atoms do. This would explain the stabilization of the tetragonal phase at 800°C prepared with acetic acid (Fig. 2 and Table 1). This proposition is totally new, because it has been always assumed that sulfate ions should be at the surface of the particles building the sample [8,25–29].

The stabilized tetragonal zirconia, prepared with acetic acid, was partially transformed into a monoclinic phase when samples were annealed to 800°C (Fig. 2 and Table 1). Its corresponding TGA curve showed a weight loss of 23% that occurred mainly between 500 and 700°C (Fig. 5). This weight loss was produced by evaporation from sample of those atom clusters associated with the sulfur, which can be represented with the formula SO_x. The fact that sulfate ions stabilized the amorphous structures suggests that since synthesis beginning they were in the neighborhood of zirconyl clusters, which are the zirconium oxide precursors. The neighboring contact between these atom clusters caused them to produce structures compatible with the characteristic distances between the atoms they are composed of.

In contrast to the above results, when hydrochloric acid or ammonium hydroxide were the hydrolysis initiators (Figs. 1 and 3 and Table 1), the tetragonal phase was only present in very small concentrations. Instead of this phase, monoclinic zirconia, zirconium sulfate, zirconium oxide sulfide [30], ZrOS, and zirconium sulfide [31], were formed in the traditional synthesis method, ZrOS and ZrS_2 are synthesized by heating the sample at 1300°C in flowing hydrogen sulfide [30].

Table 1
Phase composition and average crystallite size as a function of hydrolysis initiator and temperature for sulfated zirconia

Hydrolysis initiator	T (°C)	Tetragonal (wt.%)	Monoclinic (wt.%)	Tetragonal d (nm)	Monoclinic d (nm)
HCl	800	3.0(6)	97(3)	24(9)	30.3(8)
$C_2H_4O_2$	600	91(3)	8.7(2)	15.3(4)	10(1)
	800	66(2)	34(4)	28.4(1)	32(2)
NH_4OH	800	3.7(6)	96(3)	24(7)	29.5(7)

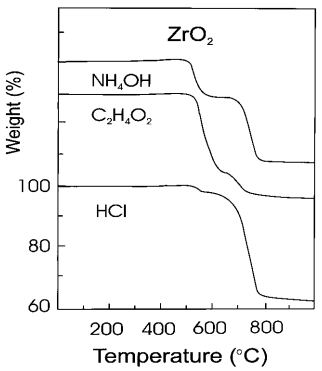

Fig. 5. TGA curves as a function of temperature of the samples prepared with different hydrolysis initiators.

For these hydrolysis initiators, the presence of Cl^- and ammonium ions avoided the contact between sulfate groups and zirconyl clusters to form the sulfur stabilized tetragonal phase. However, they catalyzed the synthesis of the above mentioned sulfur compounds, zirconium sulfate, zirconium oxide sulfide and ZrS_2, whose concentrations were not determined because the crystallography of their crystalline structures could not be refined; therefore, they were not reported in Table 1. But, since for these three compounds the main scattering centers of the X-rays were zirconium atoms, and the intensity of their main diffraction peaks was similar, then their concentrations were also similar. For these hydrolysis initiators, the above sulfur compounds were more stable than the sulfur in the tetragonal phase. However, they decomposed when the samples were annealed between 650–780°C (Fig. 4), and part of their byproducts evaporated, producing a weight loss of 31.7% for the samples prepared with HCl, and of 14.7% for those prepared with ammonium hydroxide. The samples annealed at 800°C did not contain any of these sulfur compounds and the only phase present was nanostructured monoclinic zirconia (Figs. 1 and 3 and Table 1).

According to the above results, when sulfated zirconia is used in catalysis or its properties are characterized, it is recommended to identify the phases in the sample prior to results interpretation, because these phases depend on synthesis conditions. This is especially important when synthesis is done by using sol–gel method.

4. Conclusions

Sulfating sol–gel zirconia with sulfuric acid stabilized the amorphous hydrated zirconium oxide phase. The crystalline phases that appeared in the initial crystallization step depended on the hydrolysis initiator used for the synthesis: when it was acetic acid, the formed phase was mainly tetragonal zirconia, but when it was hydrochloric acid or ammonium hydroxide the produced phases were mainly zirconium sulfate, zirconium oxide sulfide and zirconium sulfide, which disappeared when samples were annealed at 800°C. At this temperature, the tetragonal zirconia synthesized with acetic acid was very stable: its concentration was 66(2) wt.%. The present results put in alert to those who are studying or applying sulfated zirconia. Before the interpretation of their results, they must identify the crystalline phases in the samples. The present work also provides an alternative method for producing ZrOS and zirconium sulfide, at relatively low temperatures, without using hydrogen sulfide and high annealing temperatures.

Abstract

Experimental evidence for a dismutation equilibrium in the mixed-valence (MV) $[M^{n+}–M^{(n+1)+}]$ system type has been elusive and its existence can be established only when the oxidation–reduction processes involved are reversible. Previous research in the field of binuclear Cu(II)–Cu(II), Cu(I)–Cu(I) and the related MV Cu(II)–Cu(I) complexes allowed us to obtain electrochemical evidence for the disproportionation equilibrium in some of these systems. In this communication we report and discuss experiments with $[(RCOO)_2Cu(II)–Cu(I)(OOCR)_2]^-$ ($R = CH_3$, Ph) type MV complexes that give direct non-electrochemical experimental evidence for the presence in solution of the disproportion equilibrium:

$$2[(R–COO)_2Cu(II)–Cu(I)(OOC–R)_2]^- \Leftrightarrow (R–COO)_4Cu_2(II) + [(RCOO)_4Cu(I)_2]^{2-}$$

It was possible to isolate the different components of the disproportionation equilibrium by varying temperature and solvent conditions. To our knowledge, this is the first non-electrochemical experimental evidence of this equilibrium for copper MV complexes in solution. Furthermore, as is discussed in the text, these results may be the basis for giving an alternative point of view to that given in some studies already reported in the literature, which relate to solvent and temperature effects on the intensity and energy of the intervalence transfer bands and also to changes in the EPR spectra of MV species. © 2000 Elsevier Science B.V. 1. Introduction

Mixed-valence (MV) compounds have attracted a great deal of interest from several research groups. Different aspects of the electron transfer dynamics between the metal centers have been explored, as well as the chemical and the electrochemical behavior of such species [1]. Although the disproportionation reaction had been used in the past as a synthetic method [2], it was only in 1983 that Creutz et al. [3] postulated that a dismutation equilibrium related to the MV $[M^{n+}–M^{(n+1)+}]$ system must always be present. Nevertheless, the experimental evidence for this equilibrium has been elusive and its existence was established essentially by electrochemical methods when the oxidation–reduction processes involved are reversible [4]. For several years our research group has been working in the field of binuclear Cu(II)–Cu(II), Cu(I)–Cu(I) and the related MV Cu(II)–Cu(I) complexes as bioinorganic models [5]. For some of these systems it was possible to obtain electrochemical evidence for the disproportionation equilibrium [5c,6]. Continuing with this research, experiments were carried out in order to obtain single crystals to determine the X-ray crystal structure for copper carboxylate MV species. In this paper we report and discuss the results of such experiments which, although unsuccessful in obtaining the desired single crystals,

PII: S0277-5387(00)00491-5

provide direct experimental evidence that in the solution of the MV complex the following disproportionation equilibrium (1) is present:

$$2[(R–COO)_2Cu(II)–Cu(I)(OOC–R)_2]^- \Leftrightarrow (R–COO)_4Cu_2(II) + [(R–COO)_4Cu(I)_2]^{2-} \quad (1)$$

with ($R = CH_3$, Ph). To our knowledge, this is the first direct experimental non-electrochemical evidence for the existence of the disproportionation equilibrium for copper MV complexes in solution, and the shifts of such equilibrium when the system is externally perturbed. As will be discussed in the text, these results may be the basis for giving an alternative point of view to that given in some studies already reported in the literature, which relate to solvent and temperature effects on MV compounds.

2. Experimental

2.1. Reagents

All chemicals and solvents were analytical grade and used without further purification. Argon was used to provide an inert atmosphere and also for degassing solutions. For the freezing experiments, the solutions contained in a sealed tube under argon were frozen either with liquid nitrogen or in different cold temperature mixtures.

2.2. Physical measurements

UV–Vis spectra were recorded on a Milton Roy Spectronic 3000 Diode Array and on a Varian DMS 90 spectrophotometer and the EPR spectra in the x band (9.85 GHz) on a Bruker ECS 106 spectrometer using a rectangular cavity with a 50 kHz field modulation.

2.3. Synthesis

The MV $[(R–COO)_2Cu(II)–Cu(I)(OOC–R)_2]^-$ complex with $R = CH_3$ was generated photochemically from the Cu(II)–Cu(II) parent species in a nonaqueous solution by irradiation with UV-light in a stoppered cell [5a]. The MV species with R = Ph was obtained by mixing stoichiometric quantities of $[Cu(CH_3CN)_4]ClO_4$ and $[Cu(II)(BF_4)_2]\cdot nH_2O$ (Aldrich) in a benzoic acid–sodium benzoate buffer using methanol as solvent, under an inert atmosphere [6]. The crystallization of the MV species was tried by three different methods: (1) cooling the solution at different temperatures, (2) concentrating the solution by slow vacuum evaporation of the solvent and (3) adding, after evaporation, solvents of different polarities. Only method (2) succeeded in producing single crystals.

2.4. Crystal structure determination

Data were collected with a Siemens R3m/V 4 circle diffractometer. All calculations were performed with the Siemens SHELXTL-PLUS system of programs (PC version) [7].

3. Results

As mentioned in Section 2, three methods were used in order to obtain crystals of the MV species. The results of these are the following:

3.1. Temperature effects

Fig. 1 shows the UV–Vis spectrum of the violet MV $[(CH_3–COO)_2Cu(II)–Cu(I)(OOC–CH_3)_2]^-$ complex in 95/5% (v/v) methanol–acetic acid solution, at room

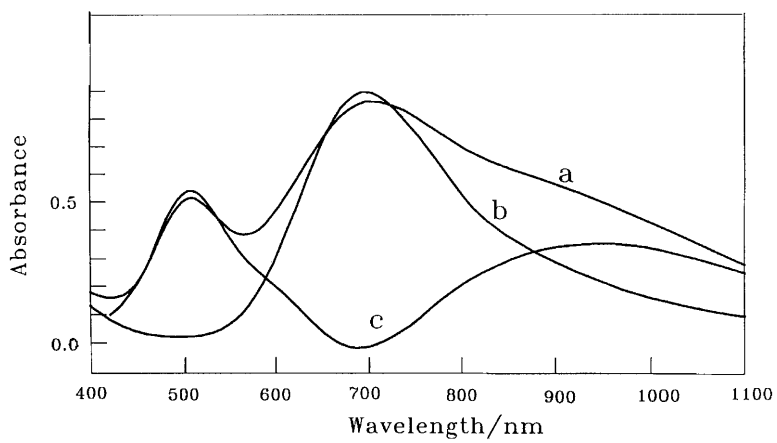

Fig. 1. UV–Vis and near IR spectra in 95/5% (v/v) methanol–acetic acid mixture as solvent for: (a) $[(CH_3–COO)_2Cu(II)–Cu(I)(OOC–CH_3)_2]^-$ MV complex generated by direct irradiation under inert atmosphere of the fully oxidized $[(CH_3–COO)_2Cu(II)–Cu(II)(OOC–CH_3)_2]$ complex whose spectrum is shown in b. (b) Non-degassed solution of $[(CH_3COO)_2Cu(II)–Cu(II)(OOC–CH_3)_2]$. (c) Differential spectrum of solution a in regard to b [5a].

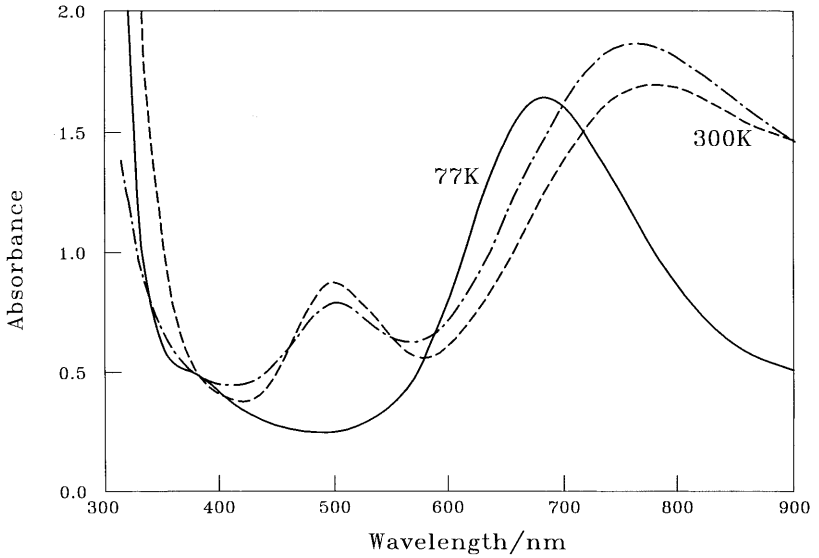

Fig. 2. Temperature effect on the UV–Vis spectra of the $[(C_6H_5–COO)_2Cu(II)–Cu(I)(OOC–C_6H_5)_2]^-$ MV complex in 4:1 ethanol–methanol solution, under inert atmosphere. (---) 300 K; (—) the same solution cooled to 77 K; (-·-·-) the same solution warmed up again to 300 K.

temperature (curve a). The spectrum for the corresponding fully oxidized $[(CH_3–COO)_2Cu(II)–Cu(II)(OOC–CH_3)_2]$ complex is also depicted (curve b). Finally, the differential spectrum (a minus b) is shown in curve c, exhibiting its two intervalence transfer (IT) bands at 508 and 960 nm [5a]. A clear temperature effect was observed for these intervalence bands: by lowering the temperature, the intensity of the IT bands decreases but, as the temperature is raised, the IT bands show up again in the spectrum. The EPR spectra also change with temperature: at room temperature, a seven-line pattern was observed, but at low temperature (77 K), the spectra mainly showed the four lines characteristic of the Cu(II) species.

The spectral pattern and behavior is maintained by other carboxylates, (e.g. R = Ph) with only slight changes in the position of the maxima. Specifically, Fig. 2 shows the changes with temperature of the UV–Vis spectrum of $[(C_6H_5–COO)_2Cu(II)–Cu(I)(OOC–C_6H_5)_2]^-$. As temperature decreases the intensity of the IT bands also decreases, disappearing completely at 77 K. No solid product is observed. At the same time, the color of the solution turns to the characteristic green color of the fully oxidized Cu(II)–Cu(II) compound. One additional experimental observation was made when the samples were taken out of the cooling media: although the solution was warmed by the surroundings, the intensity of its violet color continued to decrease. After a few minutes, the intensity started to rise and when room temperature was acquired, the IT bands at 508 and 1100 nm reappear — although with a slight intensity loss — and the solution showed the characteristic violet color. The process of losing and recovering the bands and the violet color of the solution by temperature changes is the same for both (R = CH_3 and Ph) MV species and can be repeated for several cycles.

3.2. Concentration effects

When the methanol solution of $[(C_6H_5–COO)_2Cu(II)–Cu(I)(OOC–C_6H_5)_2]^-$ was concentrated by solvent evaporation under nitrogen, calypso crystals were obtained. These crystals were isolated under strict anaerobic conditions. The X-ray crystal structure was determined (Fig. 3). It turned out to be exactly the same as that previously reported for the fully oxidized $[(C_6H_5–COO)_2Cu(II)–Cu(II)(OOC–C_6H_5)_2]$ complex [5b,8].

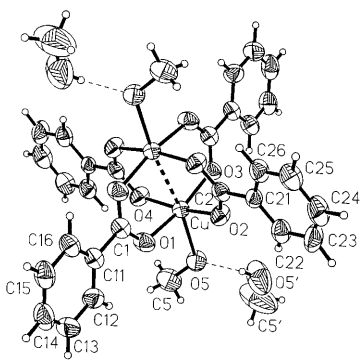

Fig. 3. Molecular structure of the crystals obtained by solvent evaporation of a solution of the $[(C_6H_5–COO)_2Cu(II)–Cu(I)(OOC–C_6H_5)_2]^-$ MV complex in equilibrium with $[(CH_3COO)_2Cu(II)–Cu(II)(OOC–CH_3)_2]$ and $[(CH_3COO)_2Cu(I)–Cu(I)(OOC–CH_3)_2]^{2-}$, as described in Eq. (1). Methanol as solvent, inert atmosphere.

3.3. Solvent polarity effects

When dichloromethane was added to the already concentrated methanolic solution of the R = Ph MV species (before any precipitation), a white solid was obtained; the white precipitate changes to a bluish-green color when exposed to air. On the other hand, when tetrahydrofurane was added, the violet color of the solution became more intense and the spectra showed an important concentration of the MV species

4. Discussion

As previously reported [5a,b] MV complexes of the type $[(R–COO)_2Cu(II)–Cu(I)(OOC–R)_2]^-$ have typical intervalence transfer bands in the 508–512 and 960–1100 nm ranges. The behavior observed in Fig. 2 may be understood in two ways: (1) as the temperature effect on the intensity of the IT band, or (2) as the dependence of the MV species concentration on temperature. Although there are many studies on the change of the energy of IT bands with either changes in temperature or in solvent [9], this is not the case for the IT band intensity dependence on temperature. Reports on this case are scarce. Nevertheless, considering that the IT band is a metal to metal charge transfer band (MMCT) results on temperature effects upon CT bands in general might be relevant. Worl and Meyer [10] reported experiments about temperature and pressure effects on the energy of the charge transfer (CT) $d_\pi \rightarrow \pi^*$ (bpy) band of the $[(bpy)Re(CO)_3Cl]$ complex in a 4:1 (v/v) ethanol–methanol mixture. Figure 1a therein reported, shows an increase in the intensity of the band when lowering the temperature from 298 to 100 K. The authors did not make a special reference to this point. However, according to this result, an inverse tendency to that observed in Fig. 2 should be expected for our system, i.e. the intensity should increase as the temperature is lowered. This seems to rule out the first interpretation given above, and therefore the results would suggest the dependence of the MV concentration on temperature. Taking into account: (a) that the concentration of the MV species is sensitive to changes in temperature, moving back and forth according to it and (b) some of the experimental details described, such as how the absorbance of the MV species in solution continues to decrease after the cooling process has ended — indicating that the system requires some time to adapt to the new conditions — shows that the possibility of an equilibrium in solution changing the concentration of the MV species should be considered. Furthermore, the solvent effect observed for the benzoate system (point 3 of Section 3) may be understood if the equilibrium is a disproportionation equilibrium as shown in Eq. (1). In this case, simple arguments as the charge differences of the three species present in solution, allows us to interpret the experimental results in the solvent polarity effects experiment as follows:

(a) In a polar solvent the uncharged Cu(II)–Cu(II) complex precipitates since the crystal X-ray structure of this solid coincides exactly with that previously reported for the $[(C_6H_5–COO)_2Cu(II)–Cu(II)-(OOC–C_6H_5)_2]$ complex [5b,8]. Thus, the equilibrium of Eq. (1) appears displaced to the right and therefore the IT band intensity decreases.

(b) The same effect (displacement of the equilibrium to the right (Eq. (1))) can be observed in nonpolar solvents, but in this case it is the higher charged complex $[(R–COO)_4Cu(I)]^{2-}$, which precipitates as a white solid.

(c) On the other hand, in a solvent of intermediate polarity such as THF, the $[(R–COO)_2Cu(II)–Cu(I)-(OOC–R)_2]^-$ species formation is favored and enhances its concentration, as shown by the increase in the intensity of the IT band. It was not possible to obtain crystals of the species under the experimental conditions used.

In a similar way, all the spectral changes observed for the MV systems described in this work, may be explained as a shifting of the disproportionation equilibrium and the dependence of the corresponding equilibrium constant, K_d, on temperature. But, taking into account that non-macrocyclic copper complexes, as the copper carboxylates, give several simultaneous equilibria in solution, the disproportionation equilibrium (Eq. (1)) may not be the only equilibrium present in solution. This situation made the evaluation of the K_d constant and its quantitative dependence with temperature and solvent more difficult.

Therefore, alternative suggestions for the experimental facts observed were tried in order to see if a different satisfactory explanation, other than the presence of the disproportionation equilibrium, could emerge.

(a) It is known that the binuclear acetate and benzoate complexes show monomer–dimer equilibrium, which has been taken into account in previous studies of these systems [5a]. On this basis, it could be possible to consider that the dimerization equilibrium — and not the disproportionation equilibrium — is governing the behavior of the system. The system could then be described by the simultaneous presence of the dimerization equilibrium (2):

$$2Cu(II) \Leftrightarrow Cu(II)–Cu(II) \quad (2)$$

(ligands omitted, for simplicity)

governed by $K_{dim}(T)$, and the Cu(II)–Cu(I) species (see Ref. [11] for the concentration values). When temperature decreases, $K_{dim}(T)$ also decreases [12], lowering the concentration of Cu(II)–Cu(II) and en-

hancing the monomeric Cu(II) concentration. However, this analysis cannot explain the disappearance of the Cu(II)–Cu(I) species at low temperature (77 K), nor can it explain its reappearance when the temperature is taken back to room temperature. The necessity of an additional equilibrium relating the Cu(II)–Cu(II) and Cu(II)–Cu(I) species makes itself evident.

(b) It is also possible to consider that the MV species is in equilibrium with the Cu(II) and Cu(I) monomer species:

$$\text{Cu(II)–Cu(I)} \Leftrightarrow \text{Cu(II)} + \text{Cu(I)} \quad (3)$$

The equilibrium would tend to the right when the temperature is lowered, therefore increasing the Cu(II) concentration, and eventually the Cu(II)–Cu(II) concentration. If this is the case, there is no reason to believe that the equilibrium

$$2\text{Cu(I)} \Leftrightarrow \text{Cu(I)–Cu(I)} \quad (4)$$

does not exist. Consequently, the following equilibria would be present in solution:

$$\text{Cu(II)–Cu(I)} \Leftrightarrow \text{Cu(II)} + \text{Cu(I)}$$

$$2\text{Cu(I)} \Leftrightarrow \text{Cu(I)–Cu(I)}$$

$$2\text{Cu(II)} \Leftrightarrow \text{Cu(II)–Cu(II)}$$

that — as a whole — are equivalent to the disproportionation equilibrium.

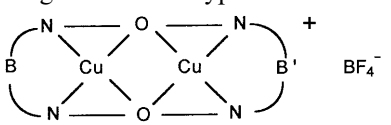
As an additional argument to this line of analysis, it should be taken into account that the Cu(II)–Cu(II) and Cu(I)–Cu(I) species were crushed out of the solution without lowering the temperature, and therefore these species should also be present at room temperature at some concentration.

From the preceding analysis, it can be concluded that it is not possible to explain the experimental behavior observed without considering the disproportionation equilibrium:

$$2[(\text{R–COO})_2\text{Cu(II)–Cu(I)(OOC–R)}_2]^- \Leftrightarrow (\text{R–COO})_4\text{Cu}_2\text{(II)} + [(\text{R–COO})_4\text{Cu(I)}_2]^{2-}$$

Other equilibria might also be present; however, they do not explain by themselves the main experimental evidence observed.

As an additional point, it should also be mentioned that the disproportionation equilibrium was taken into account to interpret the redox behavior of the $[(\text{CH}_3\text{–COO})_2\text{Cu(II)–Cu(I)(OOC–CH}_3)_2]^-$ and the Cu–mercaptoethylammine (Cu–MEA) systems previously reported [5c,13]. In these studies, and also in the electrochemical studies of the benzoate system [6], evidence for the following irreversible reaction for the Cu(I)–Cu(I) species was given:



$$\text{Cu(I)–Cu(I)} \Rightarrow \text{Cu}^0 + \text{Cu(II)}$$

This reaction could be responsible for the slight degree of irreversibility in completely recovering the intensity of the IT bands.

Finally, we want to call attention to the fact that the disproportionation equilibrium could also be used to explain, from another point of view, some EPR and spectroscopic results reported previously in the literature. In the following text, this will be applied to specific cases:

(1) Sigwart et al. [14] reported the change with temperature of the EPR spectrum of a copper–carboxylate MV species: at room temperature a seven-line pattern was observed indicating that the electron is equally delocalized on both coppers. At 77 K the EPR spectra shows a large number of lines. The authors indicated 'that this spectra probably represents contributions from both the mixed-valence complex and a Cu(II) species, since the complex tends to dissociate at temperatures below -50°C'. Nevertheless, as was shown for our systems, both EPR spectra can also be adequately interpreted if we have in mind the presence of the disproportionation equilibrium and the temperature effect on K_d. In fact, at room temperature the K_d value makes the delocalized Cu(II)–Cu(I) species predominant as detected by EPR (seven line spectrum); at low temperature, the disproportionation equilibrium shifts the Cu(II)–Cu(II) and Cu(I)–Cu(I) species (K_d (RT) < K_d (77 K)) to higher concentrations so the EPR spectra shows the simultaneous presence of the Cu(II)–Cu(II) binuclear species (four line EPR pattern) and the Cu(II)–Cu(I) MV species (seven line EPR spectra), since the Cu(I)–Cu(I) species is EPR silent. This interpretation is highly possible since in a previous paper [5a] it was shown that the structure of the Sigwart compound should be very similar to the binuclear $[(\text{R–COO})_2\text{Cu(II)–Cu(I)(OOC–R)}_2]^-$ complex reported in this work. The fact that the dimeric species remain in solution at 77 K is indicated by the presence of the 370 nm band (assigned to the binuclear species [15]) at this temperature (Fig. 2).

(2) Long and Hendrickson [16] report a series of seven MV binuclear Cu(II)–Cu(I) complexes with macrocyclic ligands of the type:

with substituents indicated as B and B′. Among the results, the authors report that the EPR spectra of four of the MV species studied changes from a seven line pattern at room temperature to a four line pattern in frozen solution, manifesting in the presence of an equilibrium in solution. Although the conproportionation constants K_c ($1/K_d$) for the species were determined electrochemically, the analysis of the results was made by the authors exclusively in terms of the localized–de-

localized character of the MV species: a delocalized Cu MV complex (room temperature) has a seven line spectra, while a localized Cu MV complex (frozen solution) shows only four lines corresponding to Cu(II). Nevertheless, the same changes could be interpreted as a direct consequence of the temperature effect on the disproportionation equilibrium. From this point of view, the equilibrium should shift so that at low temperature the main species in solution are the Cu(I)–Cu(I) EPR-silent derivative and the four-line Cu(II)–Cu(II) species, while at room temperature the main species would be the delocalized MV Cu(II)–Cu(I) complex, according to the seven-line pattern observed.

Other results in Long and Hendrickson's paper can also be explained if the conproportionation equilibrium is taken into account; for example, for the quite similar complexes **I** (with $B = B' =$ propylene) and **II** (with $B = B' =$ 2,2-dimethylpropylene), the electronic spectra show the same λ_{max}, but the authors report that the ε values are different, being greater for **I** than for **II**. Nevertheless, if we take into account that K_c is 4.3×10^6 for **I** and 3.7×0^6 for **II**, at the same analytical concentration, the actual concentration of the corresponding MV species is higher for **I**, resulting in an apparently higher extinction coefficient. Therefore, this difference could just be an artifact. Finally, although in the paper additional comparisons are made, considering others of the seven species studied, it is difficult to analyze them in detail since the systems compared might have more significant structural changes.

(3) The same type of analysis can be made for the complex $[(NH_3)_5Ru^{III}–NC–Fe^{II}(CN)_5]^-$ [9b]. The authors analyzed the changes in the energy of the IT band (E_{op}) with temperature, but the system also shows changes in the absorbance intensity, (we assume that the analytical concentration of the MV species is the same). The fact that in this case the intensity I of the intervalence band also increases as the temperature increases is particularly important. In fact, $I \alpha T$, which is again not expected if the absorbance change is taken as an effect of the temperature on the intensity of a charge transfer band. It would be interesting to analyze the effect on these intensity changes in different solvents in which the system was studied, but the authors did not make a special mention of this point, because their study was focussed on the E_{op} versus T changes.

5. Conclusions

1. The results reported in this work show that the MV $[(R–COO)_2Cu(II)–Cu(I)(OOC–R)_2]^-$ species in solution are in equilibrium with the corresponding Cu(II)–Cu(II) and Cu(I)–Cu(I) parent species, giving a direct non-electrochemical experimental evidence of the presence of the disproportionation equilibrium. The experimental behavior cannot be interpreted if this type of equilibrium is not taken into account. The equilibrium can be altered by external perturbations, such as temperature changes.
2. An inverse relation between the MV species concentration and temperature exists. Since the monomer–dimer equilibrium — that may also be present — is an exothermic process, the disproportionation equilibrium could be exothermic or endothermic. This dependence on temperature, in a certain sense, is an impedance to obtaining crystals of the MV species by temperature effects.
3. The disproportionation equilibrium accounts not only for the effect of the temperature on the intensity and energy of the IT bands, but also for the changes in the EPR spectra of the MV species with temperature, as was discussed in the text.
4. The disproportionation equilibrium should also be taken into account when the effect of the temperature on the energy of the IT band is studied. Changes in the concentration of the species will change the band intensity and therefore can distort the changes in λ_{max}, particularly when the IT transfer band overlaps to some extent with the absorption bands of other complexes present in the equilibrium.

[11] Experimentally, the MV complex was obtained in a 1.3×10^{-3} M concentration by irradiation of a 2.3×10^{-3} M solution of the Cu(II)–Cu(II) species; some Cu^0 solid was also formed [5a]. When oxygen was allowed to oxidize the solution, a concentration of 2.1×10^{-3} M for $[Cu]_{total}$ (expressed as dimer) and 1.7×10^{-3} M for the dimer, (determined from the absorbance at $\lambda = 700$ nm, where monomer and dimer absorb, and 370 nm where only dimer absorbs) was obtained [5a]. The concentration of the species in solution (if the disproportionation equilibrium is not taken into account) would then be 1.3×10^{-3} M, 4.8×10^{-4} M and 6.4×10^{-4} M for the MV, Cu(II) dimer, and Cu(II) monomer species, respectively.

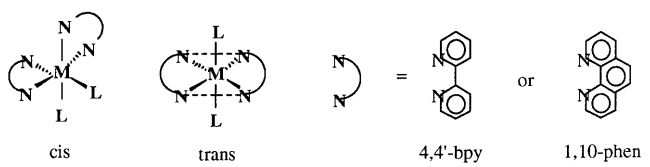
POLYHEDRON

Influence of L-type ligands on the relative stability and interconversion of *cis–trans*-$[Ru(phen)_2L_2]^{n+}$ type complexes. A theoretical study

J. Concepción, B. Loeb *, Y. Simón-Manso, F. Zuloaga*

Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 306, Santiago, Chile

Received 1 October 1999; accepted 10 January 2000

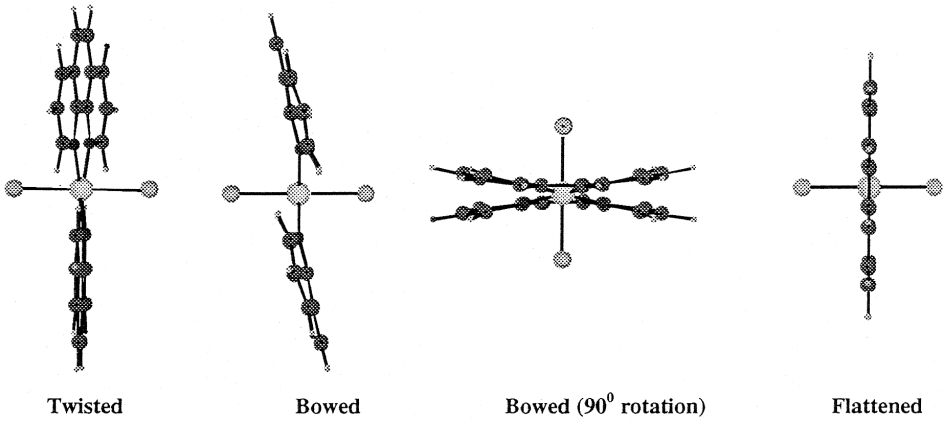


Abstract

Polipyridine complexes of type $[Ru(N\text{-}N)_2L_2]^{2+}$ are useful for the conversion of light into usable energy for which the *trans* geometry would be preferable. In this paper, the effect of distortion on *trans* structure stability was studied theoretically. A formal separation of the contributions was carried out, and it explained why the hydrogen repulsions are an important factor. A study of the main aspects related to the *cis–trans* isomers and also their mutual interconversion was analyzed. Calculations were carried out at the PM3, ZINDO and ab initio level. Energy differences between *trans* and *cis* isomers after full geometry optimizations for different L-ligands show a dependence on the L-ligand Jörgensen field strength parameter *f*. A driving coordinate was performed in order to determine the kinetic preferences for isomer formation. The analysis showed that the entrance of the second phenanthroline is favoured for the *cis* geometry in regard to the *trans* geometry. The activation barrier is also dependent on the L-ligand strength. The thermal *trans–cis* interconversion seems to be very improbable adiabatically (considering only one potential energy surface). © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Ruthenium; Phenanthroline; *Cis–trans*; MO calculations; Barriers; Field strength

1. Introduction



Ruthenium polypyridyl complexes of the type $[Ru(N\text{-}N)_2L_1L_2]^{n+}$ (N-N = 2,2′-bipyridine, 1,10-phenanthroline; L_1 and L_2 other ligands) have been widely studied in search of potential solar energy conversion systems [1]. Most of the work reported up until now is related to complexes having *cis* geometry, in spite of the fact that to exploit charge- and energy-transfer phenomena to their greatest effect, the *trans* geometry is more suitable [2]. Thus, the reported experimental work shows that there is a preferential formation for the *cis* isomer, and the interconversion to the *trans* isomer appears difficult to achieve.

Regarding the *trans* complexes, a significant distortion of the coordination sphere in the N_4 equatorial plane is generally observed. Two main types of distortion have been found experimentally [2c,3–6]: the twisted and the bowed configurations, as shown in Scheme 1 [3]. In the twisted configuration, each N-N ligand is planar, but twisted out of the equatorial plane of the octahedrically coordinated metal. In the bowed geometry the octahedral coordination is maintained but each N-N ligand is bent (for example non-planar bpy's) and the equatorial plane is distorted in such a way as to minimize the opposing hydrogen interactions [7]. A third geometry, called the tilt configuration, has also been reported [7] and it can be visualized as a special case of the bowed configuration where the degree of distortion of the equatorial N-N ligands changes from a minimum value (tilt configuration) to higher values of distortion (bowed configuration) depending upon the axial L_1, L_2 ligands. To our knowledge, there is no ruthenium $[Ru(N\text{-}N)_2L_1L_2]^{n+}$ type complex reported in a flattened configuration, presumably because it is not a ground state geometry.

Scheme 1.

For a long time the higher stability of the *cis* isomer with respect to the *trans* isomer for $[Ru(phen)_2L_2]^{2+}$ type complexes has been explained by invoking α-hydrogen steric interactions [2]. Thus, the strong tendency of the *trans* complex to isomerize to the *cis* form is related to this kind of interaction [2b].

In this paper the *cis–trans* problem in $[Ru(N\text{-}N)_2L_2]^{2+}$ (N-N = 1,10-phen) is theoretically explored in order to deduce conditions that experimentally favour the *trans* isomer formation. Several aspects like the origin of the distortion in the equatorial N_4 plane for *trans* complexes, the relative stability of one isomer over the other, and the *cis–trans* interconversion process among them are considered.

2. Computational methods

Geometry optimization of *cis* and *trans* isomers of $[Ru(phen)_2L_2]^{2+}$ type complexes were performed by using PM3(tm) semi-empirical methods as implemented in the SPARTAN package [8a]. Moreover, equilibrium geometries were checked for some cases by means of DFT ab initio calculations [8b] and by comparison with crystallographic data, when available. Hartree Fock (HF) ab initio, DFT and Gaussian calculations were used to calculate total energies. The HYPERCHEM package [8c] was also used for spectroscopic and electronic structure calculations. Total energy differences between complexes with different L ligands were also performed, allowing the comparison of the relative stability of isomers depending upon the strength of the ligand field. Finally, the *cis–trans* interconversion barrier was studied by investigating several possible models for this process.

3. Results and discussion

3.1. Distortion in the equatorial N_4 plane in *trans*-$[Ru(phen)_2L_2]^{n+}$ complexes

The potential energy surface for *trans* complexes of type $[Ru(phen)_2L_2]^{2+}$ was explored. Starting from different initial geometries, the optimization procedures led to the two experimentally observed distorted geometries (twisted and bowed) shown in Scheme 1, as well as to the absolutely planar (flattened) configuration. The latter is not a ground state geometry but a transition state (with only one imaginary vibrational frequency) and it should correspond to a connecting path among both distorted structures mentioned above. The bowed configuration is more stable than the twisted one in most cases, although the energy difference between both ground state minima is rather small. For example, for $L = Cl^-$ the total HF/3-21G* energy is -6465.39484 a.u. for the bowed geometry, and -6465.38620 a.u. for the twisted geometry, whereas for the transition state flattened geometry the total energy achieved corresponds to -6465.38084 a.u. These figures show that the bowed conformation is

Table 1
Activation barriers (kcal mol^{-1}) for several distortion effects on the equatorial plane in *trans*-$[Ru(phen)_2L_2]^{2+}$

Complex	Activation barriers (flattened – bowed)		
	DFT	PM3	RHF/3-21G*//PM3
$[Ru(phen)_2L_2]^{2+}$			
$L = NH_3$	7.686	1.213	4.201
$L = NH_2OH$	4.890	1.470	4.708
$L = F^-$	10.635	2.964	9.600
$L = Cl^-$	10.146	2.829	8.782
$[Ru(phen)_2]^{2+}$	11.163	4.519	6.955
[(phen)$_2$]	5.779	4.092	4.526

5.4 kcal mol^{-1} more stable than the twisted geometry and that the energy barrier from bowed to twisted amounts to 8.8 kcal mol^{-1}. Thus, the interconversion process is easy to achieve, at least in the gaseous phase.

Results for the energy barrier for a series of ligands such as NH_3, NH_2OH, Cl^- and F^- are given in Table 1. Different calculation methods (DFT, PM3, etc.) were employed. Independent of the method used, the tendency is that higher energy barrier values are obtained for axial ligands as $L = F^-$ or Cl^- in reference to NH_3 or its derivatives. This shows that the energy barrier values for the interconversion process from bowed to twisted depend strongly on the nature of the ligand L. It is important to point out that although the PM3(tm) results yield lower barrier values than ab initio DFT or HF/3-21G* calculations, they follow the same trend and seem appropriate to discuss experimental effects on this matter for larger complex structures.

Several factors can be responsible for the preference of the *trans* complexes to adopt a distorted geometry. The already invoked repulsion of the neighboring hydrogens in opposite phenanthrolines is one of them. The interaction between this same type of hydrogen and the axial ligands should also be considered, as well as a possible contribution of the metal. In this sense, the interconversion barrier can be considered as a thermodynamic sum of different factors, as pictured in Fig. 1. In order to evaluate these contributions additional calculations were carried out, as described below.

The geometries of the *trans* $[Ru(phen)_2L_2]^{2+}$ complexes for all L ligands were optimized in the distorted and totally flattened configurations. Next, in the optimized structures of both geometries, the L ligands were omitted and the geometry of the $[Ru(phen)_2]^{2+}$ residue optimized. Finally, the Ru metal was omitted, obtaining the $[(phen)_2]$ moiety. A single point energy calculation was carried out for this last residue. The results obtained for $[Ru(phen)_2]^{2+}$ and $[(phen)_2]$ are also included in Table 1. The latter represents the contribution of the α hydrogens repulsion to the barrier, ΔE_{HH}, while the difference between the $[Ru(phen)_2]^{2+}$ barrier and $[(phen)_2]$ barrier represents the metal contribution to it, ΔE_M. These contributions are the same for all complexes, and, for example, in HF-3-21G* they correspond to 4.5 and 2.4 kcal mol^{-1}, respectively. Finally, the L axial ligand contributions, ΔE_L, were determined as $[Ru(phen)_2L_2]^{2+}$-$[Ru(phen)_2]^{2+}$, and the results tabulated in Table 2. From HF/3-21G* results, it can be seen that axial amino ligands play the role of lowering the energy barrier between both ground state distorted geometries, whereas halide ligands have the opposite effect in reference to the $[Ru(phen)_2]^{2+}$ intermediate. Moreover, DFT and semi-empirical PM3(tm) calculations also predict a similar effect. When analyzing the central metal atom effect one finds that the influence of ruthenium(II) is to increase the energy barrier in reference to the $[(phen)_2]$ entity, although this time PM3 results do not assign any important role to it in comparison to the other ab initio methods. Clearly PM3 underestimates this metal atom effect and DFT methods seem to overestimate it. Finally, it should be pointed out that although the ΔE_{HH} contribution to the barrier is important its order of magnitude does not greatly exceed the other contributions, therefore this factor seems to have been overestimated in the literature.

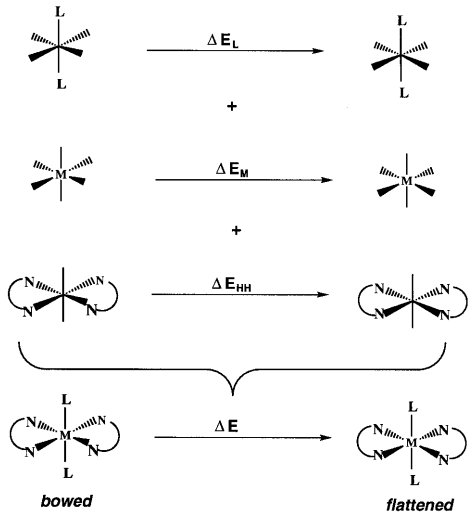

Fig. 1. Main factors that control the bowed → flattened thermodynamic interconversion barrier. ΔE_{HH}: α-hydrogen repulsion energy contribution; ΔE_L: L-ligands energy contribution; ΔE_M: metal energy contribution.

3.2. Relative stability of cis- and trans-$[Ru(phen)_2L_2]^{n+}$ complexes: energetic analysis

The total energy difference between the more stable of the *trans* configurations (bowed), and the corresponding *cis*, ΔE *trans–cis*, was calculated. ΔE *trans–cis* shows a dependence on the L ligand field strength, as can be seen in Fig. 2(a), where ΔE *trans–cis* is plotted against Jorgensen's *f* ligand field parameter [9]. In spite of the apparent data dispersion, a clear tendency is observed. A plot for a series of selected ligands (F^-, Cl^-, Br^- and I^-) is shown in Fig. 2(b). The linear curve fit gives a good correlation coefficient in this case ($R = 0.98$). The *f* value for I^- was estimated from theoretical considerations [10].[1] Noteworthy, for this ligand, the trans isomer is the more stable one.

Therefore, it can be concluded that although the *cis* isomer is generally more stable (as observed experimentally), weaker ligand fields tend to diminish the energy difference between both isomers. To get a deeper insight into the energetic and electronic reasons for this

[1] From density functional theory it is possible to obtain a relationship between the Jorgensen parameter and the Parr–Pearson indexes. Simón-Manso et al., manuscript in preparation.

preference, a complex with a weak ligand such as F^- was chosen. Since experimentally the most probable situation is one in which the phen ligand coordinates to Ru in a successive way, a ZINDO/S MO diagram was built considering $Ru(phen)F_2$ and (phen) as the original fragments to build the *cis* and *trans* $[Ru(phen)_2F_2]$ complexes. The molecular orbital diagram for the frontier orbitals of Fig. 3 shows that the 'donor' phen requires a smaller energy gap for the charge transfer process when confronted with the *cis* fragment 'acceptor'. The difference in energy gap between the HOMO(phen) and LUMO$[Ru(phen)F_2]$ for the *cis* and *trans* complex formation amounts to ~ 5.1 kcal mol^{-1} in favor of the *cis* final complex molecule.

ZINDO/S calculations were also performed at CI level, using approximately 700 configurations to reproduce the experimental electronic spectra of $[Ru(phen)_3]^{2+}$, *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ and *trans*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$. The results are shown in Table 3. The correlation between experimental and calculated data is satisfactory, especially in the case of metal to ligand charge transfer (MLCT) bands, where solvent effects can affect the position of the band.

3.3. Preferential formation of one isomer over the other: kinetic barrier

A first approach to estimate barriers for the formation of the two isomers was by a dissociative mechanism. Starting from the optimized geometry for *trans*- and *cis*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ complexes, a coordinate driving of the distance from ruthenium to one of the N atoms of one phenanthroline was performed. The initial point was the equilibrium Ru–N distance and the last one a value of 5.3 Å, with eight steps. The geometry of each step was fully optimized. This is equivalent to the barrier that generates when a phen ligand approaches a $[Ru(phen)(CH_3CN)_2]^{2+}$ moiety. The resulting potential energy coordinate diagram is shown in Fig. 4. It can be seen that the barrier to form the *trans* isomer is considerably higher than the one to form the *cis*. Also, it is observed that the maximum appears at about 4.4 Å in both cases, indicating that barriers are mainly electrostatic in character.

In another approach, a thermal twisting mechanism was considered to estimate barrier for interconversion between isomers. Starting from the optimized geometry for the *trans* complex, successive rotations around a 'bond' between ruthenium and a centroid formed by the two N atoms of the phenanthroline and one of the L axial ligands were performed. In each rotation, the dihedral angle between the N–N vectors of both

[b] OS, oscillator strength.

phenanthrolines was fixed and the geometries fully optimized. After a rotation in 120° the *cis* isomer was obtained. Although some information could be extracted, this type of rotation seems difficult to observe experimentally because dissociative tendencies are present in the intermediate steps. We considered in this route a purely thermal mechanism, but photochemical routes involving triplet excited states appear to be more appropriate for this [12].

It is interesting to note that the preference of a second phenanthroline to enter in *cis* rather than in *trans* position can be analyzed by making use of the hard and soft acid and base principle [13,7]. The use of the principle that locally 'soft likes soft' and 'hard likes hard' can give an insight to determine the specific sites at which the interaction between two chemical species is going to occur. In our case, it should help to determine if the second phen will enter in a *cis* or *trans* position. Thus, we want to find hardness values at the equatorial bond sites occupied by acetonitrile molecules and also at similar sites along axial bonds.

Ab initio calculations using HF/3-21G* were carried out for $[Ru(phen)(CH_3CN)_4]^{2+}$ and phen to build the hardness map [14] encoded into the molecular electronegativity value for the above complex and for phen. The results are given in Fig. 5 for the donor (less electronegative) phen molecule and for the acceptor (more electronegative) Ru complex. The method used is described elsewhere [13]. Briefly, two possibilities exist for this reaction, one of which is a *cis* substitution and the other a *trans* substitutions of two acetonitrile solvent molecules by the bidentate phen molecule. The isosurface is the molecular electrostatic potential at the molecular electronegativity value, which is the same at any region of the molecule after electronegativity equalization. Now the change in electronegativity against a change in electron number, that is, the hardness, has

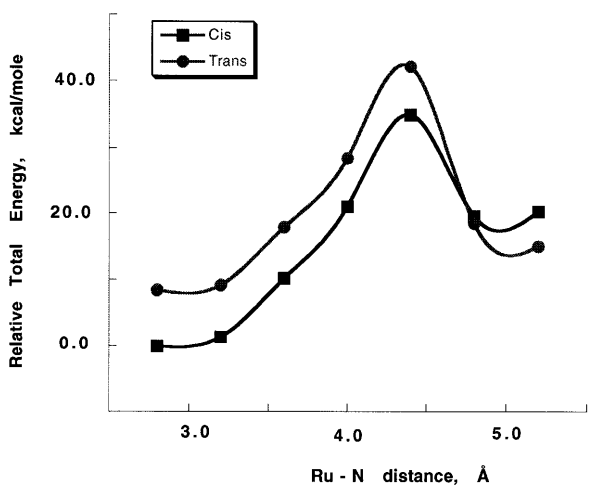

Fig. 4. Kinetic barrier for the formation of *cis*- and *trans*-$[Ru(phen)_2(CH_3CN)_2]^{2+}$ complexes from $[Ru(phen)(CH_3CN)_2]^{2+}$ and phenanthroline. Total energy values are relative to the lowest total energy value ($-120\ 826.9$ kcal mol^{-1}) used in the figure.

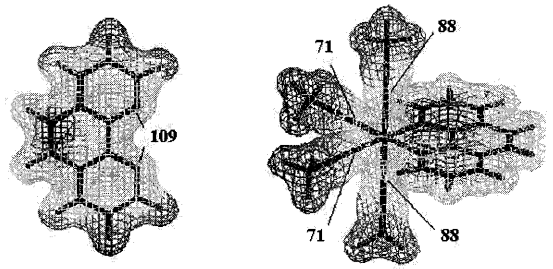

Fig. 5. Local hardness values (kcal mol^{-1}) for $[Ru(phen)(CH_3CN)_4]^{2+}$ and phenanthroline.

been encoded over that surface, yielding different values for it according to the molecule response to a given attack. Moreover, the HSAB principle states that the donor phen species (with a hardness value of 109 kcal mol^{-1} at N centers) is more willing to perform a nucleophilic attack over any of the axial sites of the acceptor Ru complex, at which the hardness value is 88 kcal mol^{-1}, forcing *cis* coordination by replacing acetonitrile molecules, one from the axial position and another from the equatorial position.

4. Conclusions

The results for the energetic analysis suggest that the thermodynamic difference between the *cis* and *trans* isomers is not sufficiently pronounced to justify the definite experimental preference to form the *cis* isomer. The kinetic factor is definitely more determinant. Thus, once a *trans* complex is formed it should be thermally stable. A good strategy to synthesize new *trans* complexes could be by derivatization of other known stable *trans* complexes.

Abstract

Polymeric complex films of cobalt–tetraaminophthalocyanine (Co–TAPc) and tetraaminophthalocyanine without the metallic center (H_2–TAPc) were grown potentiodynamically on either glassy-carbon or conducting-glass electrodes. The electrolyte used in the electropolymerization was a 0.1 M tetrabutylammonium perchlorate–DMF solution containing the monomer. The modified electrodes were characterized by UV–Vis spectroscopy, voltammetry and electrochemical impedance spectroscopy. The role of the Co(II) center and the performance of these polymeric electrodes as electrocatalysts for hydrazine oxidation in aqueous solutions of pH 13 are discussed. The results indicated that Co(II) is the species acting as the electronic receptor of hydrazine, thus enhancing the electrocatalytic effect of the poly(Co–TAPc) electrode. This was also confirmed by the charge transfer resistance values from electrochemical impedance spectroscopy obtained during hydrazine oxidation, i.e. about 6×10^3 Ω on the poly (H_2–TAPc) electrode and about 500 Ω on the poly(Co–TAPc) electrode. © 2000 Elsevier Science B.V. 1. Introduction

Metallophthalocyanine-modified electrodes have been extensively studied due to their application as electrocatalysts for numerous reactions such as oxygen reduction [1–18] or oxidation of hydrazine [9,12,19–25] and thiols (e.g. cysteine [26–30] and mercaptoethanol [31–34]). However, sometimes these modified electrodes may be unstable in aqueous solutions at low pH, which hinders their use in electrocatalysis. On the other hand, there are studies showing that the polymerization of metallophthalocyanines enhances their stability as well as their catalytic activity [35–39]. The nature of the ring substituents is decisive for the polymerization process to succeed [40–44] as well as to modify the macrocycle activity [45]. Besides that, the polymer structure is dependent on its synthesis procedure, since it directly affects the polymer conductivity [36,42,43,46] and therefore, its activity as electrocatalyst for different substrates [36,37,47]. All these factors make the comprehension of electrocatalysis phenomena on electrodes modified by polymeric complexes difficult. However, the adsorption of these monomeric or polymeric complexes on different metallic surfaces leads to films of nearly similar properties [47], when they are prepared by the same experimental conditions; therefore, comparisons can be made, for instance, between the electrocatalytic properties of a graphite electrode and another electrode modified with some of these complexes. Based on this assumption, information on the electrocatalysis of non-transparent electrodes modified with the polymeric complex can be obtained through the analysis of UV–Vis spectra of transparent electrodes modified with the same complex [47].

Phthalocyanines (Pc) have two allowed electronic transitions leading to two characteristic absorption bands in the UV–Vis spectrum: the Soret band, which appears at near-UV region (200–380 nm) and the Q band at 600–750 nm [48,49]. Both absorption bands correspond to π–π^* transitions (a_2u–eg and a_1u–eg, respectively) [48]. Besides that, during the reduction of phthalocyanines containing a first-series transition metal (Me–Pc), the first electronic transfer is related to the metallic center, and the second one to the ring [50]. As a result of the increase of charge density on the metallic center, another band, related to the metal–ligand charge transfer (CT band), appears between the Soret and Q bands [51,52]. In this paper, this charge transfer band is used to analyze the role of the transition metal on the electrooxidation of hydrazine catalyzed by poly(cobalt–tetraaminophthalocyanine)-modified glassy-carbon electrodes GC/poly(Co–TAPc). To do this, a series of electrochemical and spectroelectrochemical results are compared for GC/poly(Co–TAPc) and the glassy-carbon electrode modified with the polymer without cobalt, GC/poly(H_2–TAPc). In addition, some electric parameters of the modified electrodes as well as the kinetic nature of the electrooxidation of hydrazine taking place on their surface are explored using electrochemical impedance spectroscopy (EIS).

2. Experimental

Cobalt–tetraaminophthalocyanine (Co–TAPc), from MidCentury Co., was used without further purification. The ligand, TAPc, was synthesized using a modified procedure reported by Achar et al. [53,54]. The conducting transparent electrodes were prepared by SnO_2:F deposition on a glass sheet. The glassy-carbon electrodes, from Pine, had a working geometrical area of 0.19 cm^2 and were polished with 0.25-μm alumina before each experiment.

The electrosynthesis of both polymers (with and without Co) on either conducting-glass or glassy-carbon electrodes was performed by continuously cycling the electrode potential between -0.4 and 0.9 V (versus Ag/AgCl) at 100 mV s^{-1}, for 100 potentiodynamic cycles. The electrolyte used in the electropolymerization consisted of a 0.1 M tetrabutylammonium perchlorate–DMF solution containing the monomer: either Co–TAPc ($< 10^{-3}$ M, limited by saturation) or H_2–TAPc (10^{-3} M). The electrolyte was deaerated with nitrogen and kept at room temperature (r.t.). After the polymerization, the modified electrodes were rinsed with DMF, ethanol and then with twice-distilled water.

The electrochemical experiments were performed in a three-compartment glass cell, one for each of the electrodes: the working electrode, either glassy carbon (0.19 cm^2) or conducting glass (2 cm^2); the reference electrode, saturated Ag/AgCl; the counter electrode, a Pt coil (14 cm^2). On the other hand, the UV–Vis spectroelectrochemical experiments were performed in a one-compartment quartz cubette containing similar, but smaller, counter and reference electrodes.

All the characterizations (electrochemical and spectroscopic) of the previously grown poly(Co–TAPc) and poly(H_2–TAPc) were carried out in aqueous solutions of 0.1 M Na_2CO_3, 0.1 M $NaHCO_3$ and 0.1 M NaOH mixed at different proportions in order to attain the various pHs (8.2, 10 and 13), deaerated with pure N_2. The electrocatalysis of hydrazine oxidation was investigated using a 5×10^{-3} M hydrazine (hydrazinium sulfate, p.a. from Merck) solution in these aqueous electrolytes. The EIS measurements were carried out at potentiostatic conditions, at several potentials in the range -0.4 to 0.4 V. The frequency range extended from 5 mHz to 10 kHz and the ac potential perturbation was 10 mV (rms).

An AFCBP1 Pine bipotentiostat, along with PineChem 2.5 software, was used for the electropolymerization and to obtain data on the electrooxidation of hydrazine. A Varian Cary 1E Spectrometer, along with CaryWinUV software, and coupled to a Wenking POS 73 Potentioscan, was used to obtain the UV–Vis spectra. The electrochemical-impedance-spectroscopy (EIS) measurements were carried out with a PGSTAT20 Autolab/GPES potentiostat/galvanostat system from Eco Chemie, coupled to an Eco Chemie frequency response analyzer module.

3. Results and discussion

3.1. Spectroscopic characterization of poly(Co–TAPc) and poly(H_2–TAPc)

At open-circuit potential, the UV–Vis spectra of both polymers present the two characteristic absorption bands of phthalocyanines, the Soret and Q bands, as can be seen in Fig. 1. The wavelength at the maximum of the Soret band, λ_{max}, which appears at the near-UV region, could not be determined due to the nature of the transparent electrode employed. On the other hand, the Q band is clearly shown at λ in the range ca. 700 nm. The spectra A and B in Fig. 1 were taken from transparent-glass electrodes covered by a thin film of poly(Co–TAPc) and poly(H_2–TAPc), respectively, in aqueous solution of pH 8.2. These spectra did not show significant changes with the pH, in the analyzed range (8.2–13), at open circuit potential, E_{oc}. Nevertheless, as shown in Table 1, the E_{oc} values change as the modified-electrode/solution interface is modified with the pH.

The effect of applying negative potentials, with respect to E_{oc}, on the UV–Vis absorption bands of poly(Co–TAPc) and poly(H_2–TAPc) can be seen in Fig. 2. The more negative the potential applied on the glass/poly(Co–TAPc) electrode, the more evident becomes a new band at $\lambda = 400$–500 nm and two isosbestic points at 382 and 556 nm (Fig. 2(a)). This band, which appears between the Soret and Q bands, is reproducible for all the analyzed pH and can be attributed to the metal–ligand charge transfer transition (CT band), since its intensity is comparable with that of the Q band, which is a clear indication that this band is an allowed CT band and not a d–d band. Contrary to this, Fig. 2(b) shows that the shape of the spectrum of the glass/poly(H_2–TAPc) system is not affected by this potential variation. From the results of Fig. 2 one can infer that the CT band appearing at negative potentials on the glass/poly(Co–TAPc) electrode may correspond to the reduction of Co(II) to Co(I), with the transfer of one electron to the ligand TAPc. This would give rise to two species in equilibrium, i.e. Co(I)–TAPc⇔Co(II)–TAPc$^-$, related to the isosbestic points observed in the figure. Furthermore, Fig. 3 shows that no spectra modifications occur when positive potentials are applied on either electrode, except for a decrease of the intensity of the total spectrum. This decrease is probably caused by a structural change of the polymer due to the exit of cations from the bulk of the polymer in order to reestablish electroneutrality.

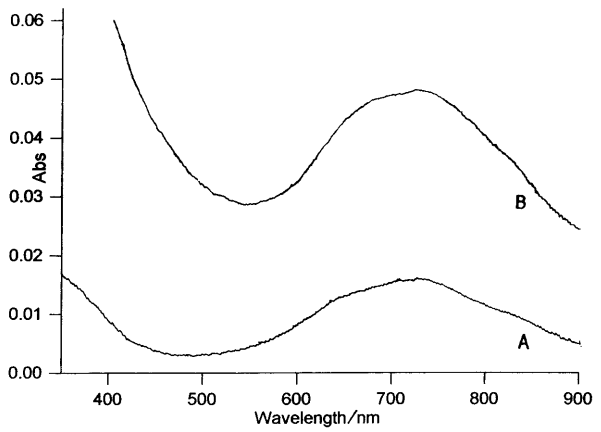

Fig. 1. UV–Vis spectra for the glass/poly(Co–TAPc) electrode (spectrum A) and for the glass/poly(H_2–TAPc) electrode (spectrum B) in aqueous solution (pH 8.2) saturated with N_2 at the open-circuit potential.

Table 1
Open-circuit potentials for poly(Co–TAPc) and poly(H_2–TAPc) on conducting glass modified electrodes, measured in aqueous solution saturated with N_2. (V vs. Ag/AgCl)

PH	E_{oc} (V)	
	poly(H_2–TAPc)	poly(Co–TAPc)
8.2	−0.092	0.014
10	−0.130	−0.012
13	−0.172	−0.071

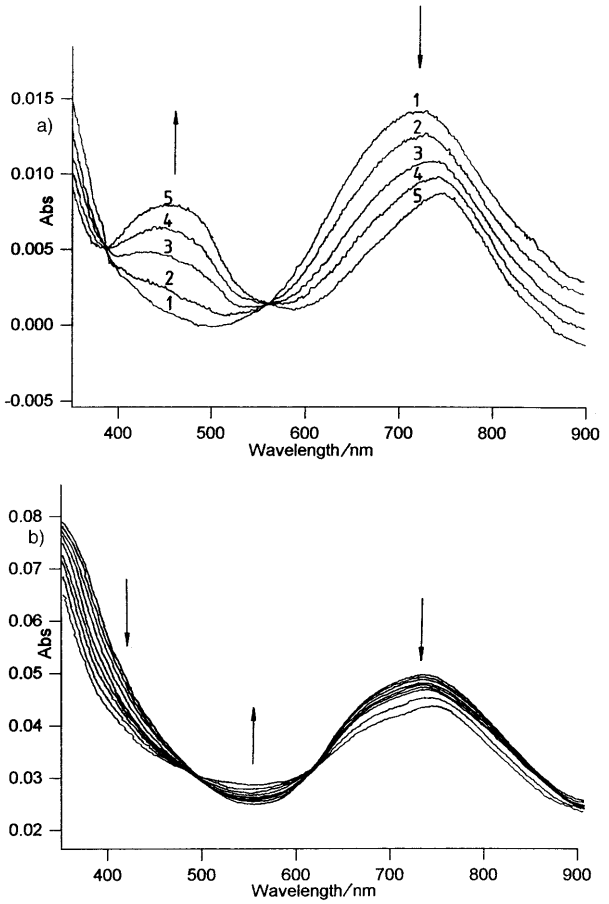

Fig. 2. (a) UV–Vis spectra for the glass/poly(Co–TAPc) electrode in aqueous solution (pH 8.2) saturated with N_2 at applied potentials increasingly more negative than the open-circuit potential: (1) 0.0 V, (2) −0.400 V, (3) −0.480 V, (4) −0.560 V and (5) −0.640 V versus Ag/AgCl. The arrows indicate the increase or the decrease of the intensity of the bands as the potential is made more negative. (b) Similar UV–Vis spectra for the glass/poly(H_2–TAPc) electrode: −0.040, −0.120, −0.200, −0.280, −0.360, −0.440, −0.520, −0.600 and −0.680 V versus Ag/AgCl.

3.2. Electrochemical characterization of poly(Co–TAPc) and poly(H_2–TAPc)

The voltammetric responses of both polymers previously electropolymerized on glassy carbon are shown in Fig. 4. Although the voltammetric profiles present the same redox peaks on either conducting glass or glassy carbon, the latter was preferred for the electrochemical analyses due to its smaller capacitive response and better peak current definition. By comparing voltammograms a and b in Fig. 4 one can attribute one of the redox peaks to the Co(II)/Co(I) couple in the complex polymer, ambiguously informed in the literature

[18,40,47,55]. Two couples, Ia/Ic and IIIa/IIIc, appearing for the modified electrodes either with or without Co, can be attributed to electron transfer processes in the ligand [18,40,47,55]. The IIa/IIc couple (at around -0.5 V) can be assigned to the metallic center Co(II)/Co(I), since it appears at a potential region where the charge-transfer band is also present (see Fig. 2(a)).

Both poly(Co–TAPc) and poly(H_2–TAPc) are stable when potentiodynamically synthesized on glassy carbon. In the pH range 8.2–13, the modified electrodes can be cycled in aqueous solutions without any change in their voltammetric profiles and the total charge involved. Fig. 4 also presents the stable i–E profile of both electrodes after several cycles (near 100) in the pH 13 electrolyte. The voltammograms obtained at pH 8.2 and 10 have the same features as the ones shown in this figure, though showing shifts of approximately 60 mV per pH unit for the peak potential values.

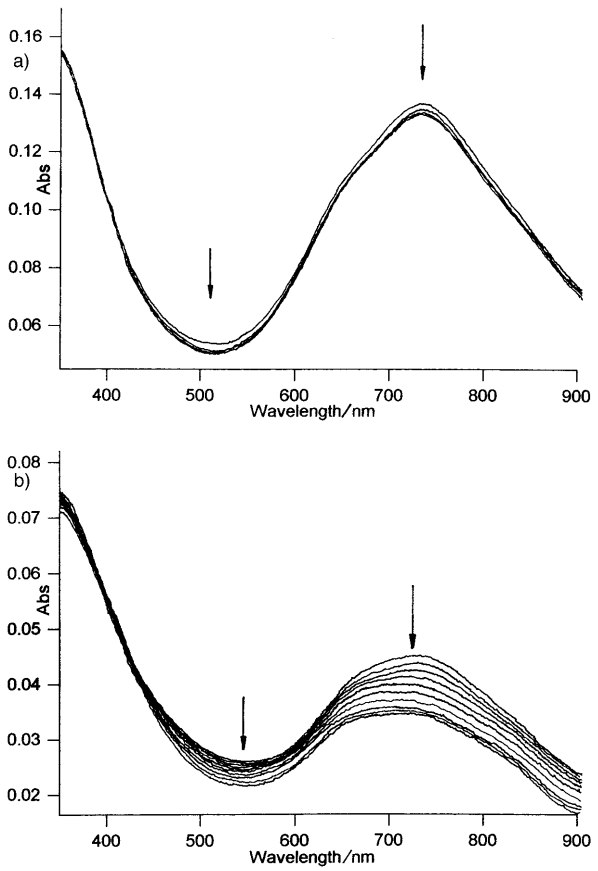

Fig. 3. (a) UV–Vis spectra for the glass/poly(Co–TAPc) electrode in aqueous solution (pH 8.2) saturated with N_2 at applied potentials increasingly more positive than the open-circuit potential (as indicated by the arrows): 0.230, 0.280, 0.360, 0.440 and 0.560 V versus Ag/AgCl. (b) Similar UV–Vis spectra for the glass/poly(H_2–TAPc) electrode: 0.114, 0.200, 0.280, 0.360, 0.440, 0.520, 0.600, 0.680, 0.760 and 0.800 V versus Ag/AgCl.

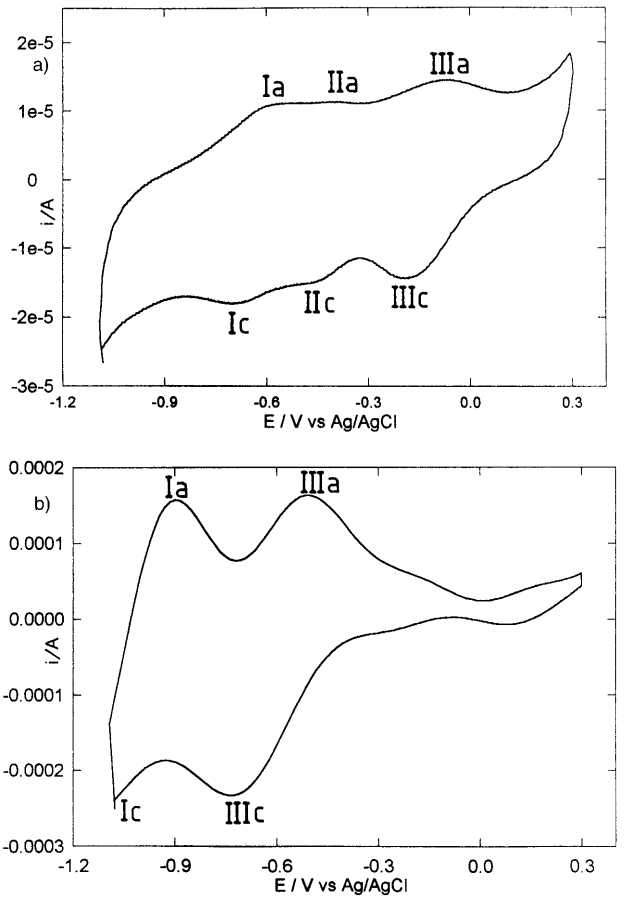

Fig. 4. (a) Cyclic voltammogram for GC/poly(Co–TAPc) electrode previously electrosynthesized by 100 continuous cycles between -0.400 and 0.90 V versus Ag/AgCl in 0.1 mol l^{-1} TBAP/DMF on a glassy-carbon electrode (GC). Sweep rate: 100 mV s^{-1}. Electrolyte: deaerated aqueous solution (pH 13). (b) Similar cyclic voltammogram for GC/poly(H_2–TAPc) electrode.

3.3. The role of the Co metallic center in the electrooxidation of hydrazine

The i–E responses for the electrooxidation of hydrazine on the GC/poly(Co–TAPc) and GC/poly(H_2–TAPc) electrodes are compared with the one on the blank electrode (bare glassy-carbon surface) in Fig. 5. The hydrazine oxidation is practically unnoted on the bare GC electrode, hardly noted on the poly(H_2–TAPc) electrode, but well noted on the poly(Co–TAPc) electrode. In the case of the poly(H_2–TAPc) electrode, the slight increase of the anodic current at potentials more positive than -0.3 V can be attributed to the catalytic oxidation of hydrazine by the ligand macrocycle. The poly(Co–TAPc) electrode clearly presents a strong electrocatalytic effect; furthermore, the onset of the oxidation process on this electrode occurs at smaller overpotentials. Though the oxidation was carried out under hydrodynamic conditions, N_2 generation on the poly(Co–TAPc) electrode at potentials more positive than -0.2 V is high enough to cause current oscilla-

tions and even the current decrease seen on the dotted curve in Fig. 5. The enhanced catalytic effect of the poly(Co–TAPc) electrode seems to be related to the metallic center, since the potential where the anodic current starts to increase coincides with the potential region of the Co(I)/Co(II) couple indicated in Fig. 4(a).

The spectroelectrochemical results for the oxidation of hydrazine on both the poly(Co–TAPc) and poly(H_2–TAPc) electrodes are shown in Figs. 6–8. Curve a in Fig. 6 shows a CT band even at open-circuit conditions (E_{oc} changes from -0.071 to -0.470 V when hydrazine is added to the electrolyte), indicating a charge transfer between hydrazine and the metallic center with the consequent reduction of Co(II) to Co(I). In the case of the poly(H_2–TAPc) electrode, the open-circuit potential also shows a significant change (from -0.172 to -0.385 V), but there is no change in its UV–Vis spectrum (see curve B of Fig. 6). In the case of poly(Co–TAPc) in the presence of hydrazine, as the potential is made more negative the CT band is increased and the Q band is decreased, while two isosbestic points become defined at 400 nm and 550 nm (Fig. 7(a)). On the other hand, these features are not present in the case of poly(H_2–TAPc), as can be seen in Fig. 7(b). In addition to this, Fig. 8 shows that for both electrodes there are no changes in the spectra as the potential is made more positive, except for an increase in the intensity of the bands in the whole spectra. However, this increase may be due to the accumulation of N_2 bubbles (product of hydrazine oxidation) at the polymer/solution interface, which leads to a change of the optical density of the system.

The results presented so far indicate that both polymers on glassy carbon catalyze the electro-oxidation of

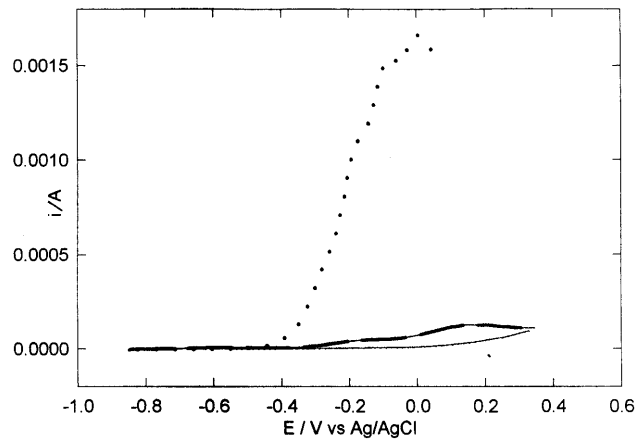

Fig. 5. Polarization curves for the electrodes of Fig. 4 and for a bare glassy-carbon (GC) electrode in the presence of 5 mmol l^{-1} hydrazine (same conditions as in Fig. 4). Potential sweep rate: 5 mV s^{-1}. Electrode rotation rate: 900 rpm. Doted line: GC/poly(Co–TAPc) electrode; hatched line: GC/poly(H_2–TAPc); continuous line: bare glassy-carbon electrode.

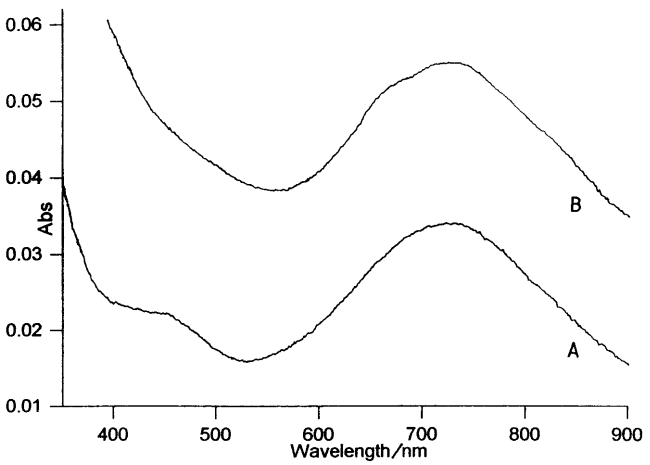

Fig. 6. UV–Vis spectra for the glass/poly(Co–TAPc) electrode (spectrum A) and for the glass/poly(H_2–TAPc) electrode (spectrum B) at the open-circuit potential in aqueous solution (pH 13) saturated with N_2 and containing 5 mmol l^{-1} hydrazine.

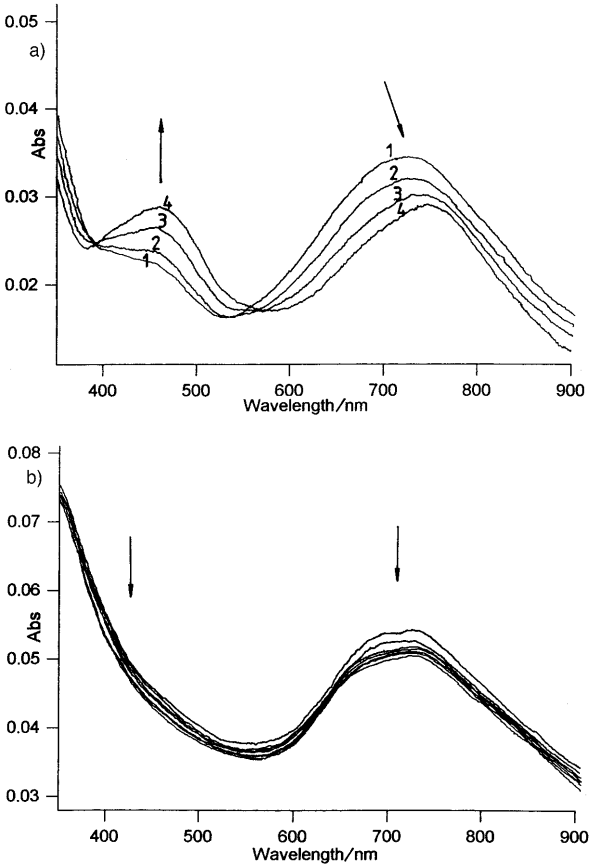

Fig. 7. (a) UV–Vis spectra for the glass/poly(Co–TAPc) electrode in aqueous solution (pH 13) containing 5 mmol l^{-1} hydrazine, saturated with N_2, at applied potentials increasingly more negative than the open-circuit potential: (1) -0.470 V, (2) -0.560 V, (3) -0.640 V and (4) -0.720 V versus Ag/AgCl. The arrows indicate the increase or the decrease of the intensity of the bands as the potential is made more negative. (b) Similar UV–Vis spectra for the glass/poly(H_2–TAPc) electrode: -0.400, -0.440, -0.480, -0.500, -0.560 and -0.600 V versus Ag/AgCl.

hydrazine in aqueous solutions. However, the polymer containing the Co center is a far more efficient electrocatalyst. One possible interpretation for this finding is that, even in the absence of applied potential (open-circuit conditions), hydrazine is able to transfer electronic charge to the polymer. If the polymer contains the metal, the charge receptor is the Co(II) center that reduces to Co(I), giving rise to the CT band. On the other hand, when the metal is absent in the polymeric matrix, hydrazine also transfers electronic charge to the ligand, but at a potential more positive than that for reducing the metal. Since the oxidation of hydrazine on poly(Co–TAPc) occurs at the potential region assigned to the Co(I)/Co(II) couple, it can be inferred that Co(II) is the species acting as the electronic receptor of hydrazine and enhancing the electrocatalytic effect of the poly(Co–TAPc) electrode. These ideas are supported by the E_{oc} changes for both polymers when hydrazine is added to the electrolyte, by the appearance of the CT band for poly(Co–TAPc) in contact with hydrazine, and by the two isosbestic points at negative potentials (related to the Co(I)–TAPc⇔Co(II)–TAPc$^-$ equilibrium).

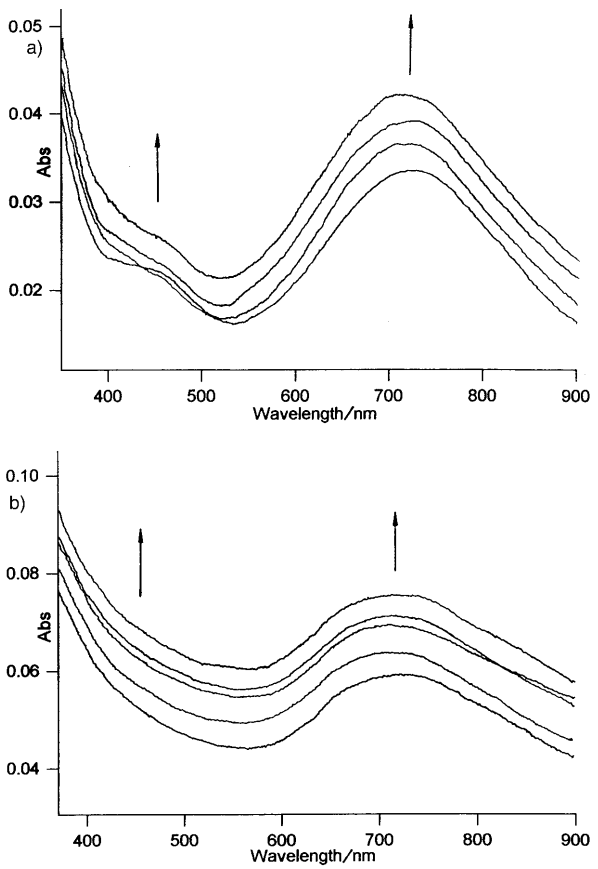

Fig. 8. (a) UV–Vis spectra for the glass/poly(Co–TAPc) electrode in aqueous solution (pH 13) containing 5 mmol l^{-1} hydrazine, saturated with N_2, at applied potentials increasingly more positive than the open-circuit potential (as indicated by the arrows): −0.120, 0.0, 0.040 and 0.160 V versus Ag/AgCl. (b) Similar UV–Vis spectra for the glass/poly(H_2–TAPc) electrode: −0.040, 0.100, 0.200, 0.300 and 0.400 V versus Ag/AgCl.

3.4. Electrical response of poly(Co–TAPc) and poly(H_2–TAPc) electrodes

Studies of the electrical properties of electrodes modified with macrocyclic molecules, using EIS, are not commonly found in the literature. Nevertheless, this technique is very useful to yield information on quantities such as the capacitance (C) or the charge transfer resistance (R_{ct}) of the electroactive interface, and to give additional information on the nature (activated charge transfer or diffusional control) of the electrocatalytic process under investigation. Data obtained from EIS measurements are usually presented in the form of complex–plane plots and Bode plots [56]. In the former, data of capacitive impedance ($Z_{imaginary}$) are plotted against the faradaic impedance (Z_{real}), while the latter is represented by plots of $\log|Z|$ versus $\log f$ or of phase angle versus $\log f$ ($|Z|$ is the impedance modulus and f the frequency).

Basically two approaches have been used to analyze impedance data of an electrode modified by a redox polymer: a kinetic model proposed by Gabrielli et al. [57], and another model proposed by Hunter et al. [58] stating that the charge transfer process occurring on an electroactive polymer phase reflects its interfacial properties and produces RC relaxation phenomena similar to those due to intercalation at an oxide/electrolyte interface. Both models lead to a physical interpretation for the impedance behavior of the modified electrode at different frequency regions:

(i) At high frequencies, one generally observes a charge transfer controlled process, defined by a semicircle in the complex–plane plot, whose characteristic time constant is related to the product of the charge transfer resistance (R_{ct}) and the double-layer capacitance of the polymer/solution interface (C_{dl}). The inverse of this quantity is the characteristic relaxation frequency for the process

$$\omega_{ct} = 1/(R_{ct}C_{dl}) \quad (1)$$

R_{ct} is determined from the semi-circle diameter [56].

(ii) At intermediate frequencies, diffusion of charge in the polymer film dominates the impedance spectrum; at this point, the complex–plane plot becomes linear with a slope of 45°. The frequency range where diffusional behavior may appear will depend on the film thickness and on the diffusion coefficient of the species.

(iii) At lower frequencies, the impedance is generally capacitive, i.e. the phase angle approaches 90°, reflecting the charge saturation set by the finite thickness of the polymer. In this case, a redox capacitance of the polymer, or low-frequency capacitance (C_{LF}) is

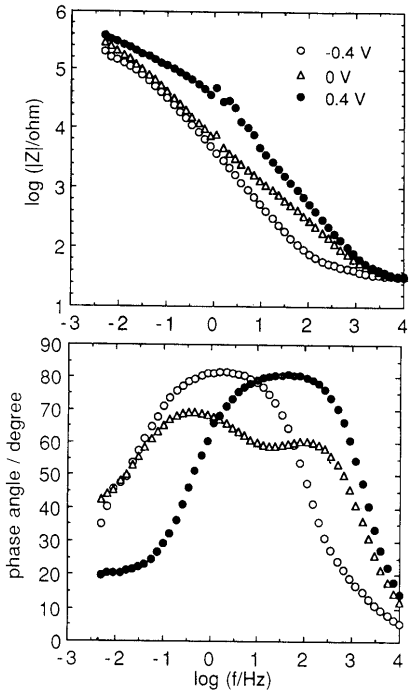

Fig. 9. Bode plots as a function of the applied potential for the GC/poly(Co–TAPc) electrode in aqueous solution (pH 13) saturated with N_2.

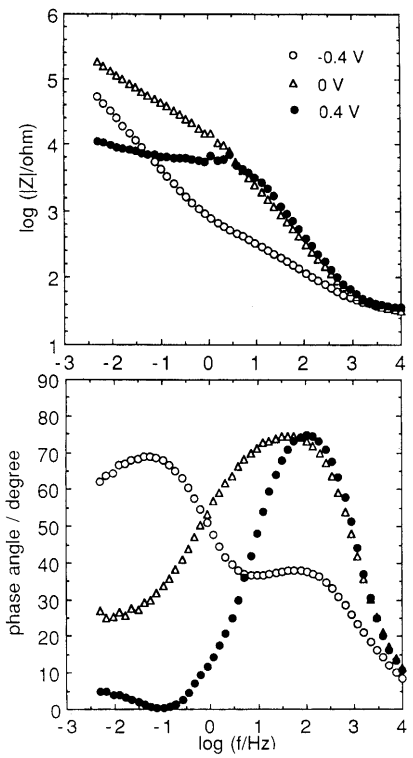

Fig. 10. Bode plots as a function of the applied potential for the GC/poly(H_2–TAPc) electrode in aqueous solution (pH 13) saturated with N_2.

defined. For very-thin films, the kinetic control region may overlap with the charge saturation and no diffusion region is defined. C_{LF} is proportional to the film thickness and to the total concentration of redox centers and can be obtained through [57,58]:

$$C_{LF} = 1/(2\pi f Z_{imag}) \quad (2)$$

A brief discussion of these models can be found elsewhere [59].

Impedance measurements were carried out for both poly(Co–TAPc) and poly(H_2–TAPc) electrodes immersed in the pH 13 electrolyte, containing hydrazine or not, at steady-state potentiostatic conditions. Figs. 9 and 10 show Bode plots for the polymeric electrodes in the electrolyte without any hydrazine, as a function of the applied potential. No charge saturation capacity can be seen in these spectra. The poly(Co–TAPc) electrode presents nearly capacitive behavior at -0.4 and 0.4 V, with a phase angle maximum of about 80° (lower part of Fig. 9). From the results of Fig. 9 (upper part), one can infer that the double-layer capacitance changes (from about 150 to about 15 μF cm^{-2}) when the oxidation state of the metallic center changes from Co(I) to Co(II); this can be attributed to a change in the polymer conformation with the potential, since Co(I) gives a less-distorted geometry for the complex macrocycle, thus leading to more redox sites at the polymer/electrolyte interface. On the other hand, the impedance results from Fig. 10 indicate that two relaxation processes with capacitive features appear for the polymeric electrode without Co center, at more negative potentials, which could be related to two different redox sites in the ring ligand.

EIS measurements for hydrazine oxidation on both electrodes were performed at -0.2 V (Figs. 11 and 12). This potential was chosen from the voltammograms of Fig. 5, where a net anodic catalytic current can be seen for both cases. The R_{ct} values for hydrazine oxidation on either electrode can be estimated from the plots

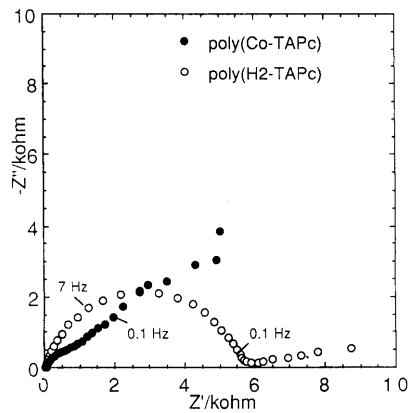

Fig. 11. Complex–plane plots at the applied potential of -0.2 V for the GC/poly(Co–TAPc) and the GC/poly(H_2–TAPc) electrodes in aqueous solution (pH 13) containing 5 mmol l^{-1} hydrazine, saturated with N_2.

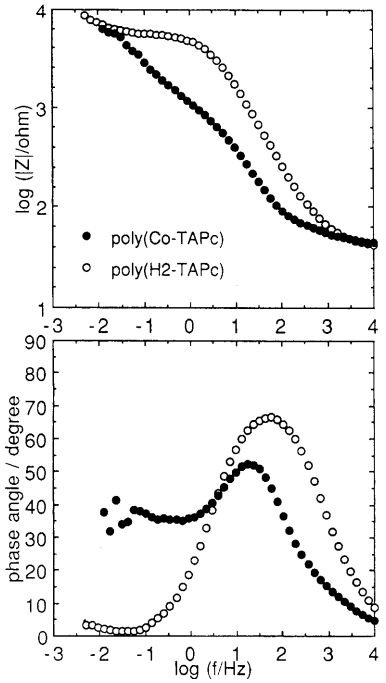

Fig. 12. Bode plots at the applied potential of −0.2 V for the GC/poly(Co–TAPc) and the GC/poly(H_2–TAPc) electrodes in aqueous solution (pH 13) containing 5 mmol l^{-1} hydrazine, saturated with N_2.

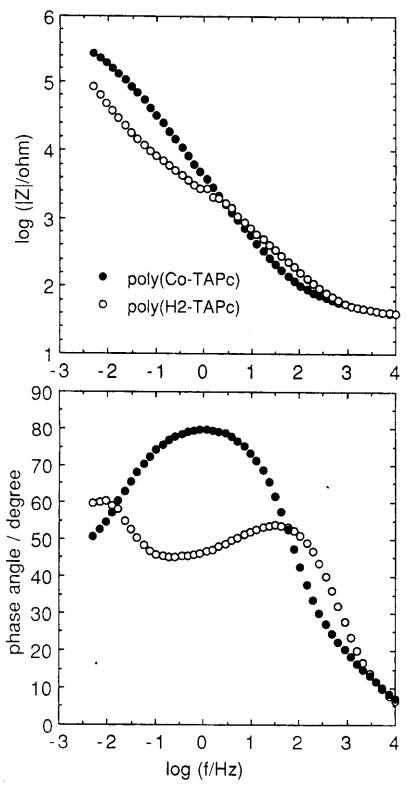

Fig. 13. Bode plots at the applied potential of −0.2 V for the GC/poly(Co–TAPc) and the GC/poly(H_2–TAPc) electrodes in aqueous solution (pH 13) saturated with N_2.

shown in Fig. 11, since both spectra present at the high-frequency region a semi-circle related to the faradaic process at the polymer/electrolyte interface. The R_{ct} value of about 500 Ω for hydrazine oxidation on poly(Co–TAPc) is much smaller than that on poly(H_2–TAPc) (about 6×10^3 Ω), confirming that the kinetic process is far more favored by the poly(Co–TAPc) material, as also indicated by the voltammetric results already presented. Furthermore, a diffusional feature can be seen in the low frequency range of Fig. 11, indicating that the thickness of these polymeric films, grown during 100 potentiodynamic cycles, is sufficient to set a diffusional regime of hydrazine species to the reaction centers. The scattering of the impedance data in the very-low-frequency limit on poly(Co–TAPc) is due to the formation of a considerable amount of the N_2 product on the electrode surface, giving rise to active area fluctuations and current instability.

Impedance studies on other redox-polymer electrodes, but in the absence of a reactant in the electrolyte, present values for R_{ct} of 100–500 Ω for glassy-carbon coated by [Ru(bpy)$_2$–poly(4′vinylpyridine)Cl]Cl [57], 300–2600 Ω for poly(vinylferrocene) on platinum [58] and 91 Ω for Ni(II)tetrakis(3-methoxy-4-hydroxyphenyl) porphyrin polymerized on glassy carbon [60].

Comparison of data obtained in the presence of hydrazine (Fig. 12) and in its absence (Fig. 13) shows that the presence of hydrazine in the electrolyte decreases the total impedance of the interface for both electrodes, but a higher effect can be noted for poly(Co–TAPc) electrode. Furthermore, the variation in the phase angle profile for the poly(H_2–TAPc) case, shown in Figs. 12 and 13 (below), from one well-defined capacitive relaxation process to two capacitive relaxation processes, is an indication that only one preferential redox site is active for hydrazine oxidation on this electrode.

4. Conclusions

The UV–Vis spectra of both poly(Co–TAPc) and poly(H_2–TAPc) retain the two characteristic absorption bands of phthalocyanines, the Soret and Q bands. When increasingly negative potentials (with respect to the open-circuit potential) are applied on the glass/poly(Co–TAPc) electrode, a new band becomes evident at $\lambda = 400$–500 nm and two isosbestic points develop at 382 nm and 556 nm. Considering that the spectrum of the glass/poly(H_2–TAPc) system is not affected by this potential variation, this band can be attributed to a metal–ligand charge transfer transition (CT band), i.e. to the reduction of Co(II) to Co(I), with the transfer of

one electron to the ligand TAPc, giving rise to two species in equilibrium, related to the isosbestic points observed: Co(I)–TAPc⇔Co(II)–TAPc$^-$. By comparing voltammograms for both systems, in the case of the glass/poly(Co–TAPc) electrode it was possible to clearly attribute one of the redox peaks (around -0.5 V) to the Co(II)/Co(I) couple in the complex polymer, since this peak appears at a potential region where the charge-transfer band is also present.

Although hydrazine oxidation was hardly noted on the poly(H_2–TAPc) electrode, it was well noted on the poly(Co–TAPc) electrode. This much enhanced catalytic effect of the poly(Co–TAPc) electrode seems to be related to the metallic center, since the potential where the anodic current starts to increase coincides with the potential region where the Co(I)/Co(II) couple was previously characterized. From the results obtained, it can be inferred that Co(II) is the species acting as the electronic receptor of hydrazine, thus enhancing the electrocatalytic effect of the poly(Co–TAPc) electrode. Furthermore, hydrazine was found to be oxidized by poly(Co–TAPc) even at open-circuit conditions, as evidenced by the appearance of a charge transfer band when hydrazine is added to the electrolyte, indicating a charge transfer between hydrazine and the metallic center, i.e. the reduction of Co(II) to Co(I). Hence, imposing anodic conditions on the poly(Co–TAPc) electrode enhances this oxidation by regenerating the Co(II) species in the polymer. Finally, the more favored electrocatalytic effect of poly(Co–TAPc) was also confirmed by the R_{ct} values obtained from EIS results during hydrazine oxidation, i.e. about 500 Ω on the poly(Co–TAPc) electrode compared with about 6×10^3 Ω on the poly(H_2–TAPc) electrode.

Abstract

The crystal structures, IR absorption spectra, emission spectrum of the europium compound, TG and DSC analyses of $Ln(pic)_3 \cdot MMNO \cdot 2H_2O$ (pic = picrate, Ln = La, Nd, Eu) complexes are reported. The crystals that were grown from methanolic solutions, are isomorphous belonging to the triclinic space group $P\bar{1}$. The Ln ions are coordinated to nine oxygen atoms, six of the picrate moieties, one of the MMNO and two of water molecules, giving rise to a tricapped trigonal prism. © 2000 Elsevier Science B.V. 1. Introduction

The hydrated lanthanide picrates and their structures have been described already [1–4]. Lanthanide picrate complexes with several organic neutral ligands are being studied in our laboratories. These complexes with (a) sulfoxides [5–17]; (b) phosphine oxides [18,19]; (c) *N*-oxides [20–23]; (d) amides [22,24–26]; (e) phosphoramides [27,28]; and (f) lactams [29] have been described.

In this article the preparation, characterization by CHN analyses, infrared absorption spectra, emission spectrum of the europium compound, TG and DSC analyses and the single crystal X-ray structure determination of the lanthanum, neodymium and europium picrate complexes with 4-methylmorpholine *N*-oxides (MMNO) are presented. Besides our continuing interest in lanthanide picrate complexes, the use of MMNO was aimed at determining whether the presence of the methyl group attached to the N–O had any influence on the ligand properties of this substance.

2. Experimental

Compounds with composition $Ln(pic)_3 \cdot 3MMNO$ were prepared by reaction of the hydrated picrates with MMNO in absolute ethanol [30]. Recrystallization from methanol at low temperature resulted in the complexes with general formula $Ln(pic)_3 \cdot MMNO \cdot 2H_2O$ (Ln = La, Nd, Eu). These complexes were characterized by microanalytical procedures using a Perkin–Elmer model 240 instrument. Infrared absorption spectra were recorded on a Nicolet FTIR 510 using KBr pellets. Emission spectrum of the solid europium compound was determined at room temperature and at 77 K using a Hitachi Perkin–Elmer-MPF-4 spectrofluorimeter. TG data

Table 1
Summary of analytical results (%)

Ln	Carbon		Hydrogen		Nitrogen	
	Theoretical	Experimental	Theoretical	Experimental	Theoretical	Experimental
La	28.3	28.4	2.2	2.3	14.3	14.3
Nd	28.1	28.4	2.2	2.3	14.3	14.2
Eu	27.9	28.2	2.1	2.3	14.2	14.3

were collected on a Shimadzu TGA-50, using a platinum cell, ~1.8 mg sample, dynamic air atmosphere (50 ml min^{-1}), heating rate of 2 K min^{-1}. DSC were obtained on a Shimadzu DSC-50, aluminum cell, ~1.8 mg sample, dynamic nitrogen atmosphere (50 ml min^{-1}), heating rate of 10 K min^{-1}. X-ray crystallographic data were recorded on an Enraf–Nonius CAD-4 Mach 3 diffractometer. In all cases, cell parameters were determined on the basis of 25 reflections; intensity data were obtained with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) and ω–2θ scan mode at room temperature (291 K). During data collection, the intensity of three standard reflections were monitored every 30 min of X-ray exposure time showing no significant decay. Structures were solved using the standard heavy-atom Patterson procedure and difference Fourier maps and refined by full-matrix least-squares. All non-H atoms were refined anisotropically. H-atoms were located on stereochemical grounds, except that of the water molecules that were found in a difference Fourier map, and refined in the riding model with an isotropic displacement parameter amounting to 1.2 times the value of the equivalent isotropic displacement parameter of the carrier atom. Programs used: SHELXS-86 [31], SHELXL-97 [32] and ZORTEP [33]. Data were corrected for Lorentz, polarization and absorption.

3. Results and discussion

Table 1 shows a summary of CHN-analyses, showing a good accordance with the composition Ln(pic)$_3$·MMNO·2H$_2$O. Infrared absorption spectra data are presented in Table 2. Picrate bands were attributed according to Yongchi et al. [2]. The frequencies obtained for ν_s NO$_2$ are indicative of picrate coordination through the phenoxo oxygen and an oxygen of one *ortho* nitro group, behaving as a bidentate. The bands attributed to νNO, according to Maï et al. [34] at 940–988 cm^{-1}, shifted to 907–937 cm^{-1}, are indicative of coordination of MMNO through the oxygen.

The emission spectrum of the europium compound (Fig. 1), determined at 77 K, shows one band attributed to $^5D_0 \rightarrow {}^7F_0$ (578 nm), three peaks due to $^5D_0 \rightarrow {}^7F_1$ (587.5, 592, 597 nm) and five peaks due to $^5D_0 \rightarrow {}^7F_2$ (612, 612.5, 614, 616, 619.5 cm^{-1}) were attributed to a C_{3v} symmetry around the central ion [35].

TG curves (Fig. 2) show the following steps: (a) loss of humidity (300–400 K); (b) loss of two coordi-

Table 2

nated water molecules (400–480 K); (c) loss of MMNO and decomposition of the picrate (480–720 K); (d) the residues at 860 K are the respective oxides, Ln_2O_3 (Ln = La, Nd, Eu).

From the DSC curves (Fig. 2) the following energies were determined (in kJ mol^{-1}): for step b, 82.6 (La), 103.6 (Nd) and 124.7 (Eu); for step c, −2909 (La), −2850 (Nd) and −2790 (Eu). Experimental details and results of the crystal structure determinations are listed in Table 3. Bond lengths and angles around the Ln ion are listed in Table 4. Complete sets of atomic coordinates, anisotropic thermal parameters and distances and angles have been deposited with the Cambridge Crystallographic Data Centre. A plot of the Eu compound and of its coordination polyhedron is shown in Figs. 3 and 4, respectively.

The Ln atoms are nine-coordinated by six oxygens of three independent bidentate picrate moieties, one of the MMNO and two independent water molecules in a tricapped trigonal prism shape. The coordination of each picrate occurs via the phenoxo oxygen and one oxygen of one of the *ortho* nitro group which occupy the capping positions on the square phases of the trigonal prism. The dihedral angle between the trigonal faces being of 5.3(1), 4.6(3), 5.40(6)° in the La, Nd and Eu complexes, respectively. The average distances Eu–$O_{phenoxo}$ of 2.353 Å and Eu–O_{NO} of 2.704 Å are comparable with those found in the 2-azacyclononanone [29] compound (2.345, 2.700 Å).

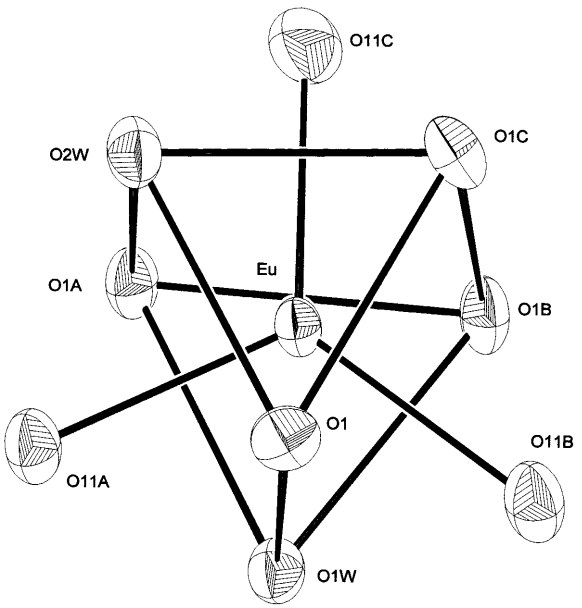

Fig. 4. Coordination polyhedron of the Eu complex.

The same trend is found for Nd, 2.399 and 2.725 Å in this work, and 2.418 and 2.676 Å in the hexamethylphosphoramide complex [25]. Several geometric parameters, introduced by Balic Zunic and Makovicky [36] and implemented in IVTON [37], in order to quantify the deformation of the coordination polyhedra as the centroid of the coordination polyhedra, i.e. the point in the coordination polyhedron with the minimum variance of distances to all ligands, the centroid–central atom distance (Δ), the average distance (r) from the centroid to the ligands, the standard deviation (σ_r) of the distances from the centroid to the ligands and the sphericity ($1-\sigma_r/r$) for the three coordination polyhedra, were calculated and are given in Table 5. It can be seen that the average centroid–ligand distances follows the lanthanidic contraction and that La complex presents the most distorted polyhedron while that of the

Table 6

Atom	q_2 (Å)	q_3 (Å)	Q (Å)	θ (°)
La	0.004(9)	0.574(9)	0.574(9)	0.4(9)
Nd	0.023(9)	0.57(1)	0.57(1)	2.3(9)
Eu	0.005(4)	0.579(4)	0.579(4)	0.5(4)

Table 7
Hydrogen bond parameters [a]

D–H···A	D···A (Å)	H···A (Å)	D–H···A (°)
O1W–H1W1···O1A^{i}	2.918(3)	2.12	145.8
O1W–H2W1···O1B^{i}	2.934(3)	2.20	136.4
O1W–H2W1···O31B^{i}	2.919(4)	2.20	135.0
O2W–H1W2···O22B^{ii}	2.871(4)	1.97	170.8
O2W–H2W2···O^{iii}	2.800(3)	1.94	154.4

[a] Symmetry operations: (i) $-x$, $-y$, $-z$; (ii) x, $y-1$, z; (iii) $1-x$, $-y$, $1-z$.

Eu complex is less distorted. This is also shown by the sphericity parameter. The bond valence parameters (R_{Ln-O}) calculated for these structures being of 2.1844 (2.172), 2.0603 (2.117) and 2.0256 (20.76) for La, Nd and Eu, respectively. The values in parenthesis are those tabulated by Brese and O'Keefe [38].

In the three complexes the ring in the MMNO assumes an almost perfect chair conformation, as shown by the Cremer and Pople's [39] parameters (Table 6), the exocyclic oxygen atom O(1) being axial while the methyl group is equatorial. Unlike what occurs in the $[(MMNO)_2Mn^{III}TPP](ClO_4)$ [40] complex where the N–O bond is shortened upon complexation [1.366(10) Å], in these complexes the N–O distances of 1.380(7), 1.390(3), 1.400(15) Å for the La, Nd and Eu compounds, respectively, are closer to those found in compounds where the O atom is not involved in coordination 'bonds' nor hydrogen bonds [41,42]. On the other hand, the O–N–CH_3 angles are in good agreement, within experimental accuracy, with the values found in Refs. [40–42].

The water molecules involved in intermolecular hydrogen bonds are shown in Table 7.

4. Supplementary data

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications No. CCDC 135296, 135297 and 135298. Copies of available material can be obtained, free of charge on application to the Director, CCDC, 12 Union Road, Cambridge, CH2 1EZ, UK (fax: +44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk).

Abstract

The complexes $RuCl_3(CTZ)_3{\cdot}2CH_3OH$ (**1**) and $RuCl_3(KTZ)_2(H_2O){\cdot}2H_2O$ (**2**) were prepared by reaction of $RuCl_3{\cdot}3H_2O$ with CTZ and KTZ, respectively, while $RuCl_2(KTZ)_2$ (**4**) was prepared by reaction of $RuCl_2(CH_3CN)_4$ with KTZ (CTZ = 1-[(2-chlorophenyl)diphenylmethyl-1*H*-imidazole, and KTZ = *cis*-1-acetyl-4-[4-[[2-(2,4-dichlorophenyl)-2-(1*H*-imidazol-1-ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl]piperazine. All the complexes were characterized by NMR spectroscopy and for the paramagnetic species EPR spectroscopy was also employed. The new compounds were tested for in vitro activity against cultures of epimastigotes of *Trypanosoma cruzi*, the causative agent of Chagas disease, and compared with $RuCl_2(CTZ)_2$ (**3**) (reported previously) in order to establish some structure–activity correlations. At concentrations of 10^{-6} M (DMSO), all the complexes showed higher activity than the parental organic drug against the epimastigote form of the parasite, and Ru(II) complexes seem to be more active than their Ru(III) counterparts for a given nitrogen-donor ligand. © 2000 Elsevier Science B.V. Keywords: Ruthenium; Clotrimazole; Ketoconazole; Paramagnetic; Metal complexes; *Trypanosoma cruzi*; Chagas

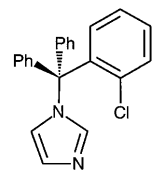
1. Introduction



Ruthenium complexes have shown promise in the development of several types of pharmaceutical, particularly as anticancer agents [1]. As part of our research program on novel chemotherapies against tropical diseases, we have been searching for new metal-based drugs with a low level of toxicity and high biological activity against parasites responsible for ailments like malaria [2] and Chagas disease [3]. The latter is caused by *Trypanosoma cruzi*, an hemoflagelate protozoon, which is transmitted to humans by a cone-nosed bug known as Reduviid or Triatomid. This endemic and essentially incurable illness afflicts close to 20 million people in the Latin American subcontinent, ranking as the third largest parasitic disease worldwide, after malaria and schistosomiasis [4]. In view of the urgent need for an effective treatment against Chagas disease, the most varied approaches have to be considered.

Some very encouraging results have been disclosed recently by Urbina et al. [5] and by others [6] using azole-type molecules which have been found to exert their therapeutic effect through a mechanism involving the inhibition of the biosynthesis of sterols essential for

the parasite. Another alternative which has been emerging from our laboratories as an interesting possibility makes use of such azoles (collectively known as SBIs, sterol biosynthesis inhibitors) as N-donor ligands in complexes of various metals; the general strategy we have been employing is the synthesis of metal derivatives of particular organic ligands which themselves have shown activity against *T. cruzi*, *e.g.* clotrimazole, CTZ = 1 - [(2 - chlorophenyl)diphenylmethyl-1*H* - imidazole) and ketoconazole, KTZ = *cis*-1-acetyl-4 - [4 - [[2 - (2,4 - dichlorophenyl) - 2 - (1*H* - imidazol - 1 - ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl] piperazine [5,6].

CTZ

KTZ

Recently, we described the synthesis and characterization of a series of metal–CTZ complexes (Ru, Rh, Pt, Au and Cu) which showed promising biological activity for the case of Chagas disease. The most efficacious compound against *T. cruzi* was the Ru(II) derivative $RuCl_2(CTZ)_2$ which prompted us to study it in greater detail; this led us to a preliminary proposal for a mechanism of therapeutic action according to which the metal complex first acts as a transport agent across the parasite's membrane, and it is subsequently hydrolyzed in order to liberate CTZ which goes on to produce its known SBI action. Since a synergistic effect due to the presence of the metal fragment was observed, together with intracellular disorganization at the level of the nucleus, it was thought that Ru–DNA binding provides an additional means of damaging the parasite, and some preliminary studies indicated that some Ru–DNA interaction was in fact taking place [3]. Nevertheless, other factors such as partition coefficients at the cellular level may be influencing the selective transport and toxicity effects required for antiparasitic activity; in order to gain further insight into the mode of biological action of our complexes, we have engaged on a systematic study aimed at establishing possible structure–activity correlations.

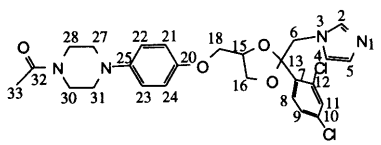
Both CTZ and KTZ in their free forms have been evaluated against *T. cruzi*, and the latter has been found to be more active than the former [5,6]. It is also known that both Ru(II) and Ru(III) covalently bind to DNA, the binding generally being faster for the divalent state [7,8]. In order to shed some additional light on the mechanism of anti *T. cruzi* action of metal–azole derivatives, in this paper we present the synthesis, characterization and some preliminary data on the in vitro evaluation of the biological activity of a new series of Ru complexes in both the (II) and (III) oxidation states, containing either CTZ or KTZ. In this way we hope to reach a better understanding of the relative importance of the two main components of our mechanistic proposal.

2. Experimental

2.1. General procedure

Solvents of analytical grade were distilled from appropriate drying agents immediately prior to use. CTZ, KTZ, and $RuCl_3 \cdot H_2O$ were used as received. $RuCl_2(CH_3CN)_4$ and $RuCl_2(CTZ)_2$ were prepared according to the literature and characterized by comparison of their IR and NMR spectra with reported values [4]. Elemental analyses were performed at the Chemistry Center (IVIC) on a Fisons analyzer EA 1108; IR spectra were recorded on a Nicolet 5DCX FT spectrometer while UV–Vis spectra were obtained by use of a diode array Hewlett Packard 8453 instrument fitted with deuterium and mercury lamps, using chloroform solutions (10^{-4} M) of the complexes. EPR spectra were measured at room temperature (r.t.) in a Varian E-line spectrometer working in the X-band ($v = 9.3$ Hz) with a cylindrical cavity and a homemade coaxial microwave coupler for the X-band; experimental conditions (microwave power and modulation field) were adjusted to avoid saturation of signal intensity. NMR spectra were obtained in DMSO-d_6 solutions at 500 MHz with 8000 data points on a Bruker AVANCE500 spectrometer, ^{1}H NMR shifts being recorded relative to residual resonances in the deuterated solvent. For the paramagnetic complexes the NMR spectra were obtained using a 90° pulse of 10 ms. An inversion-recovery pulse sequence (180°–τ–90°–Aq) was used to obtain nonselective proton longitudinal relaxation times (T_1) with the carrier frequency set at different positions to ensure the validity of the measurements. Signal:noise ratios were improved by applying a line-broadening factor of 30 Hz to the FID prior to Fourier transformation.

2.2. $RuCl_3(CTZ)_3 \cdot 2CH_3OH$ (1)



$RuCl_3 \cdot 3H_2O$ (154 mg, 0.59 mmol) was dissolved in freshly distilled methanol (15 ml), CTZ (876 mg, 2.54 mmol) in methanol (20 ml) was added to the solution which was stirred under reflux in a nitrogen atmosphere for 24 h. The volume of the solvent was reduced until precipitation began and the mixture was allowed to stand overnight at −10°C, after which the green solid obtained was filtered, washed with diethyl ether and dried under vacuum (yield, 480 mg, 62%). *Anal.* Calc. for $C_{68}H_{59}Cl_6N_6O_2Ru$: C, 62.5; H, 4.55; N, 6.4. Found: C, 62.1; H, 4.54; N, 6.9%. IR (cm^{-1}): ν(C=C) 1500, ν(C=N) 1440. λ_{max} ($CHCl_3$, 10^{-4} M) = 241, 325, 432 nm.

2.3. $RuCl_3(KTZ)_2(H_2O) \cdot 2H_2O$ (2)

$RuCl_3 \cdot H_2O$ (150 mg, 0.57 mmol) was dissolved in freshly distilled methanol (10 ml), KTZ (609 mg, 1.15 mmol) in methanol (20 ml) was added to the solution which was stirred under reflux in a nitrogen atmosphere for 24 h. The volume of the solvent was reduced until precipitation began and the mixture was allowed to stand overnight at −10°C, after which the brown solid obtained was filtered, washed with diethyl ether and dried under vacuum (yield, 70%). *Anal.* Calc. for $C_{52}H_{62}Cl_7N_8O_{11}Ru$: C, 47.1; H, 4.7; N, 8.5. Found: C, 46.8; H, 4.3; N, 8.3%. IR (cm^{-1}): ν(C=C) 1500, ν(C=N) 1440. λ_{max} ($CHCl_3$, 10^{-4} M) = 247, 296 nm.

2.4. $RuCl_2(KTZ)_2$ (4)

A 2:1 mixture of KTZ and $RuCl_2(CH_3CN)_4$ (60 mg, 0.18 mmol) was dissolved in methanol and allowed to react for 14 h at r.t., after which a white solid precipitated, which was filtered off, washed with diethyl ether and dried under vacuum (yield 60%). *Anal.* Calc. for $C_{52}H_{56}Cl_6N_8O_8Ru$): C, 50.6; H, 4.38; N, 9.09. Found: C, 51.3; H, 4.79; N, 9.28. IR (cm^{-1}): ν(C=C) 1510, ν(C=N) 1450. ^{1}H NMR ($CDCl_3$) δ, ppm: 7.92 (s, 1H) *H*(2); 7.69 (d, $J = 2.1$ Hz, 1H) *H*(11); 7.58 (d, $J = 8.7$ Hz, 1H) *H*(8); 7.46 (dd, $J^1 = 3.0$, $J^2 = 2.1$ Hz, 1H) *H*(9); 7.20 (s, 1H) *H*(4); 6.91 (s, 1H) *H*(5); 6.82 (AA′XX′, 4H) *H*(21), *H*(22), *H*(23), *H*(24); 4.62 (AB, 2H) *H*(6); 4.31 (m, 1H) *H*(15); 3.84 (m, 1H) *H*(18); 3.54 (m, 6H) *H*(27), *H*(31), *H*(16), *H*(18′); 3.43 (m, 1H) *H*(16′); 2.95 (dt, $J^1 = 3.3$, $J^2 = 4.9$ Hz, 4H) *H*(28), *H*(30); 2.02 (s, 3H) *H*(33). λ_{max} ($CHCl_3$, 10^{-4} M) = 247, 296 nm (Scheme 1).

Scheme 1. NMR numbering scheme for KTZ.

2.5. Biological tests against epimastigotes of *T. cruzi*

Tests were conducted following a method reported previously [5b]. An EP stock of the epimastigote form of *T. cruzi* was used throughout this study. The epimastigotes were cultured in liver infusion–tryptose medium supplemented with 10% calf serum at 28°C with strong stirring (120 rpm) as previously described; the cultures were initiated with a cell density of 2×10^6 epimastigotes per ml; CTZ, KTZ and compounds **1**–**4** were added as DMSO solutions (10^{-6} M) when the culture reached a cellular density of 10^7 epimastigotes per ml. Parasite proliferation was followed daily by the use of an electronic particle counter (model ZBI; counter Electronics, Inc, Hialeah, FL.) and by direct counting with an hemacytometer.

3. Results and discussion

3.1. Synthesis and characterization of the new ruthenium(III) CTZ and KTZ complexes

The Ru(III) complexes $RuCl_3(CTZ)_3$ (**1**) and $RuCl_3(KTZ)_2(H_2O) \cdot 2H_2O$ (**2**) were prepared by reaction of $RuCl_3 \cdot 3H_2O$ with CTZ (1:4) and KTZ (1:2), respectively, in methanol, yielding dark green (**1**) and brown (**2**) paramagnetic compounds which unfortunately did not provide crystals suitable for an X-ray structure determinations. The oxidation state of the ruthenium was confirmed by their characteristic rhombic EPR spectra, as shown by the data collected in Table 1. For both complexes the room temperature spectra displayed three absorption bands typical of low spin d^5 ions in an octahedral field; the theory of the EPR spectra of distorted octahedral low spin d^5 complexes (idealized t_{2g}^5, ground term $^2T_{2g}$) is well documented in the literature [9–11]. The spectra of **1** and **2** are rather compressed, g values being very close to one another in both complexes; this is attributable to a rhombic distortion with a very small anisotropy which can be ascribed to a considerable delocalization of the unpaired electron. Interestingly, an unusually high intensity of the low field line in both spectra indicates

Table 1
EPR spectroscopic data for the new Ru(III) complexes

Complex	g_1	g_2	g_3
$RuCl_3(CTZ)_3$ (**1**)	2.11	2.04	1.94
$RuCl_3(KTZ)_2(H_2O)_2 \cdot 2H_2O$ (**2**) [a]	2.22	2.21	2.07

[a] An unidentified paramagnetic impurity ($g = 2.00$) was observed in the spectrum of this compound.

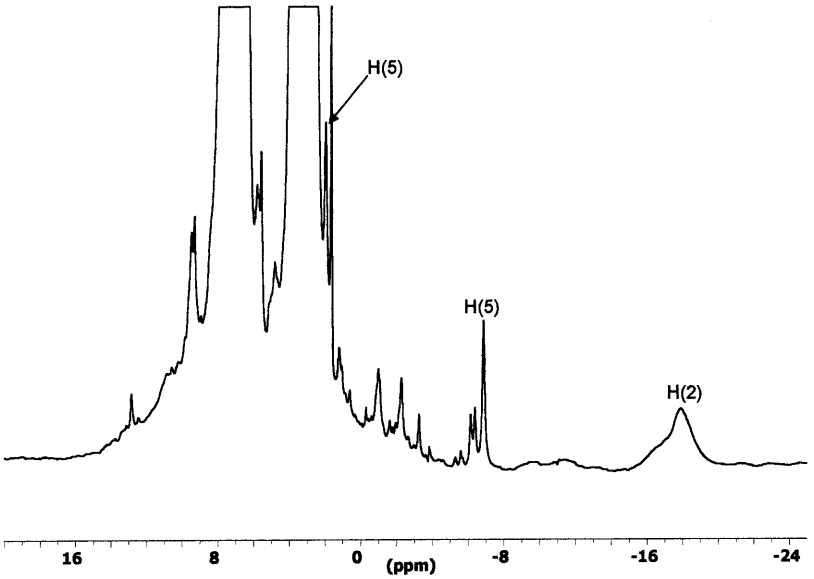


Fig. 1. ^{1}H NMR spectrum of $RuCl_3(CTZ)_3$ (**1**) in DMSO-d_6.

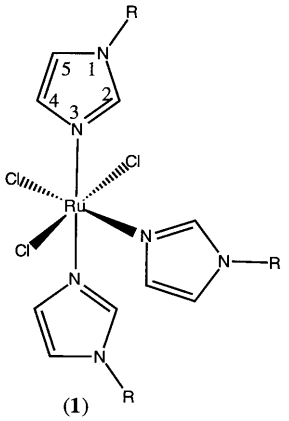
that the projection of the magnetic moment along the g_1 direction is large, as would be expected for systems with this type of symmetry. This spectral features are indicative also of a meridional rather than a facial structure for complex **1**; a facial Cl_3N_3 coordination would have a C_3 symmetry and therefore result in only two EPR signals [11]. A meridional arrangement of lower symmetry, which is in fact sterically more favorable for bulky ligands like CTZ, is also consistent with the NMR data presented below. In the case of **2** only two KTZ ligands can be accommodated around the ruthenium atom, presumably because of its larger size, so that the normal octahedral coordination sphere is probably attained by coordination of a water molecule; a rhombic EPR spectrum would be expected also in this case. By analogy with **1** and on the basis of NMR data reported below, a *mer* arrangement of the chlorides with two mutually *cis* KTZ ligands is the most likely stereochemistry for **2**.

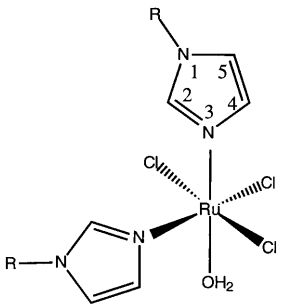
3.2. NMR spectra of Ru(III) complexes

Several Ru(III) complexes containing imidazoles and related *N*-heterocycles as ligands have attracted attention, mainly because of use as radiosensitizers and of their promising antitumor properties; those compounds have been well characterized in the solid state but their solution properties are less well understood [1]; some rather extensive reports on the spectroscopic properties of imidazole complexes of Ru(III) have come out of the groups of Clarke [10] and Beauchamp [12]. We have carried out a ^{1}H NMR study of the new paramagnetic Ru(III) complexes **1** and **2**; the relaxation times (T_1) of the protons, which in the free ligand are in the range 10–0.5 s, decrease upon complexation to 3.0–0.5 s for **1** and 2.3–0.5 s for **2** (for the signals in the diamagnetic region), as a result of the contribution of the unpaired electron to the fluctuating magnetic fields that affect the relaxation of the nuclei in these systems.



The spectrum of complex **1** in DMSO-d_6 (see Fig. 1) displays typical isotropically shifted signals for coordinated imidazoles at about -7 ppm (sharp, $T_1 = 10.1$ ms) and 2 ppm (sharp, $T_1 = 14$ ms), as well as a broad signal between -18 and -20 ppm; this high field signal is in fact composed of two peaks centered at about -17.5 and -16.5 ppm, with relative integrals of approximately 2:1 and T_1 values of 0.36 and 0.42 s, respectively (see Fig. 1). The sharp peak at 2 ppm is very close to strong signals in the diamagnetic region and therefore its integration is not reliable, but its relation to the peak at -7 ppm was established mainly on the basis of their very similar T_1 values, also close to those reported in the literature for related systems [10]. The paramagnetic region of this spectrum is further complicated by the appearance of other smaller signals between 1 and -14 ppm, possibly due to the formation of closely related solvation derivatives, as has been reported for *trans*-$[RuCl_4Im_2]^-$ in aqueous solution [12]. The spectrum of complex **2** in DMSO-d_6, shown in Fig. 2, is more straightforward as it exhibits three clearly distinct isotropically shifted signals located at -1.8 ppm (sharp), -8.7 ppm (broad) and -16.0 ppm (broad) with relative integrals 2:1:1 and T_1's of 11, 0.6, and 0.4 s. In CD_3OD two well separated signals are observed for H(5) at about -5.5 and -5.7 ppm.

On the basis of reported previously NMR spectra of other imidazoles coordinated to ruthenium(III) [10,12], the sharp signals at -5 and -2 ppm (in **1**) and at -1.8 ppm (in **2**) can be confidently assigned to the H5 protons of the CTZ and KTZ ligands, respectively. This imidazole proton is the one located furthest away from Ru and therefore it is the least affected by the paramagnetic influence of the metal center; as a result the H5 reso-



nances are the least broadened, but they experience significant upfield shifts.

As for the broad high-field signals, the situation is less clear cut, since previously reported data appear to be contradictory. Clarke's work on Ru(III)-imidazole complexes, which included extensive substitution studies in order to assign the proton resonances, concludes that the NMR signals for H(2) are broad and always appear at high fields, whereas the H(4) peak, also very broad, is generally shifted downfield although it may also be shifted upfield [10]. In contrast, Anderson and Beauchamp report spectra for Ru(III)–imidazole complexes in which two high field broad peaks are attributed to H(4) and H(2), respectively, on the basis of deuteration experiments [12]. In our case, deuteration or methylation of the ligands is not straightforward; however, the values of T_1 observed for the high field broad signals, taken together with their relative integrals and the EPR data discussed above, suggest that they correspond to two separate H(2) signals of nonequivalent CTZ (2:1) or KTZ (1:1) ligands, while the peaks corresponding to H(4) in both complexes were not observed probably because of their extreme broadness and possible location in the rather crowded diamagnetic region of the spectrum. The two separate signals observed for H(5) of **2** in CD_3OD are also in good agreement with two nonequivalent KTZ ligands.

From a perusal of the data available to us and the extensive known chemistry of Ru(III) [13], compound **1** is most likely octahedrally coordinated with the three *N*-donor atoms and the three chlorides in a *mer* stereochemistry so as to minimize the steric repulsion between the three bulky CTZ ligands; this implies that there are two (equivalent) mutually *trans* CTZ ligands while the third one is located *trans* to Cl, in accord with the 2:1 integral ratio observed for the H(2) protons in the NMR spectrum. Complex **2** is proposed to consist of an octahedral arrangement in which the three chlorines are in a meridional disposition and the two nonequivalent KTZ ligands are located mutually *cis*, thus requiring one to be *trans* to Cl, while the other is *trans* to the water molecule that completes hexacoordination.

[a] Complexes used as 10^{-6} M DMSO solutions. For details, see Section 2.

3.3. Ruthenium(II) complexes

The Ru(II) complexes **3** and **4** were prepared by displacement of the labile acetonitriles in $RuCl_2(CH_3CN)_4$ with 2 equiv. of the required ligand (CTZ or KTZ) in MeOH. We have described complex **3** in detail, as well as the X-ray structure of a closely related BTZ derivative (BTZ is the bromo analogue of the CTZ ligand) in a previous publication [3b]. These compounds are unusual diamagnetic 14-electron species with a distorted tetrahedral structure in an approximately C_{2v} arrangement of the donor atoms around the metal. Coordination through the unsubstituted N(3)-atom of the imidazole in **4** was deduced, as previously reported for **3**, from the displacement of the ^{1}H NMR signal of the proton located on the carbon atom α to that nitrogen (labeled H2 in Section 2), with respect to the free ligand ($\Delta\delta$ 0.48 ppm); this variation in chemical shift is by far larger than those observed for any other proton in the molecule. According to the analytical and NMR data and by analogy with **3**, complex **4** most likely possesses a tetracoordinated 14-electron Ru(II) configuration, which seems to be particularly adequate when the nitrogen-donor ligands are voluminous within a $RuCl_2N_2$ core. Although we have been unable to obtain crystals of **4** of X-ray quality, we presume that the structure of this complex is analogous to that of the $RuCl_2(BTZ)_2$ analogue.

(**3**, **4**)

3.4. In vitro activity of complexes **1**–**4** against epimastigotes of T. cruzi

The effect of DMSO solutions (10^{-6} M) of complexes **1**–**4** on the proliferation of in vitro cultures of the epimastigote form of *T. cruzi* (equivalent to the form present in the Reduviid vector [2]) was evaluated as described in the experimental section. Table 2 summarizes the results of such tests. The activities of the metal derivatives were all higher than the free parental compounds CTZ or KTZ, emphasizing our previous finding that binding to metal centers enhances the anti *T. cruzi* activity of azoles. Some interesting additional observations can be extracted from these preliminary biological data:

1. For CTZ, the Ru(II) complex displayed a noticeably higher activity (82.4% inhibition) than the Ru(III) derivative (73% inhibition). For KTZ the difference in activity observed was much less pronounced (73% for Ru(II) vs. 70% for Ru(III)).
2. The increase in efficacy of KTZ when attached to ruthenium is greater than that for CTZ; the trend in the activity ratio (Ru complex/free ligand) is Ru(II)–KTZ (3.60) > Ru(III)–KTZ (3.46) > Ru(II)–CTZ (1.35) > Ru(III)–CTZ (1.08).
3. At the concentrations used in this study, the most active compound was the Ru(II)–CTZ complex **3**.

In terms of our mechanistic proposal [3b], it is of interest to note that rapid metal–DNA binding is thought to be a key feature of the therapeutic action. It has been suggested that in order for DNA binding to take place, a chloro ligand must be replaced by water [14,15] but since Ru(III) is normally considered substitutionally inert in physiological conditions [16], activation by in situ reduction to a more labile Ru(II) species may actually be taking place [17]. The fact that Ru(II) appears to more active against *T. cruzi* than Ru(III) would then be in agreement with either a lower rate of hydrolysis for the Ru(III) compounds or with the need to reduce them to Ru(II) before they can exert their action. The hydrolysis of Ru(III) chloro–imidazole complexes has been studied in some detail by Anderson and Beauchamp [12] and we note that the NMR spectrum of complex **1** seems to indicate that solvolysis processes are indeed taking place in DMSO solution. Also interesting, the observed difference in activity between Ru(II) and Ru(III) was very small for KTZ, but if one takes into account that the Ru(III)–KTZ complex already contains a labile water in its coordination sphere, the need for a hydrolysis step is less pronounced. The larger increase in activity observed for KTZ with respect to CTZ as a result of coordination to Ru may be interpreted in terms of transport effects across the parasite's membrane, and/or, again, to the relative rates of hydrolysis for the different Ru complexes. Clearly more work is needed in order to further

clarify the mechanistic aspects of the observed biological activity, and a series of experiments aimed at addressing some of these issues are currently in progress.

Acknowledgements

CONICIT is gratefully acknowledged for the acquisition of the NMR spectrometer through the National NMR Laboratory at IVIC, and for funding to M.N. through Project S1-98000945. We thank Renee Lira for assistance in performing the biological tests.

Abstract

A series of new molybdenum complexes, $[Mo(NNH–CO–Ph)\{S_2CN(C_2H_5)_2\}_3]$ (**1**), $[Mo(NN–CO–C_6H_4–NO_2)\{S_2CN(C_2H_5)_2\}_3]$ (**2**), $[Mo(NNH–CO–Ph)\{S_2CN(CH_3)_2\}_3]$ (**3**), $[Mo(NN–CO–C_6H_4–NO_2)\{S_2CN(CH_3)_2\}_3]$ (**4**) have been synthesized, with *p*-nitrobenzoyldiazenido(1-) and benzoylhydrazido(2-) as ligands, and dialkyldithio-carbamatos as coligands. Reactions of these compounds with aqueous and methanolic HCl were carried out but the attempted separation of the aroyl group was unsuccessful. Only the reaction of **1** and **2** with HCl in methanol gave a product, identified as $[Mo\{S_2CN(C_2H_5)_2\}_4][MoCl_4(OCH_3)_2]$. The complexes were characterized by elemental analysis, IR spectroscopy, ^1H and ^{13}C NMR, and mass spectrometry. Single crystals of **2** were obtained and the crystal structure was determined. The Mo atom is heptacoordinated; one diazenido(1-) and three diethyldithiocarbamatos act as ligands. From the latter one sulfur is in *trans*-position to the diazenido-nitrogen atom and the other five sulfur atoms lie in a plane giving a distorted pentagonal-bipyramidal coordination. © 2000 Elsevier Science B.V. Keywords: Molybdenum; Hydrazido; Diazenido; Dialkyldithiocarbamato; Hydrazines

1. Introduction

There have been several recent studies concerning the reactivity of dinitrogen coordinated to transition metal ions. Besides substitution, the reactions that give rise to N_2 derivatives such as hydrazido(2-), (1-), or diazenido(1-) are the most interesting [1–4]. Similar intermediates can be obtained by reaction of hydrazines with dioxomolybdenum complexes; however, there are not many reports in the literature of acyl or aroyl hydrazido or diazenido complexes [5]. These ligands can act as monodentate or didentate and generate derivatives that may be considered as intermediates in a cyclic process of nitrogen fixation, similarly to some rhenium complexes with phosphine ligands [6]. The aroyl and acyl derivatives could also give azido(–NNH) or hydrazido(–NNH_2) complexes by breaking the C(O)–N bond in a solvolysis reaction. All aroyl hydrazines used in this work act as monodentate. The aroyl hydrazine derivatives with dimethyldithiocarbamato coligand are stable to solvolysis whereas those with diethyldithiocarbamato react under reflux to give tetradithiocarbamato complexes.

2. Experimental

2.1. Physical measurements

Melting points were obtained with a Melt-Temp II apparatus, using glass capillaries. Elemental analyses were performed at the Microanalyses Department of the Anorganisch-Chemischen Institut of Heidelberg Universität. IR spectra were recorded for solid dispersions of 5% samples in KBr by the reflectance technique in a Nicolet 510P FT-IR spectrometer. ^1H and ^{13}C NMR spectra were obtained at room temperature (r.t.)

in a Brucker Typ AC 300 spectrometer at 300 and 75 MHz respectively, using TMS as standard; $CDCl_3$ was used as solvent for all samples but $[MoO_2\{S_2CN(CH_3)_2\}_2]$, which was taken in $(CD_3)_2SO$. Mass spectra were recorded in a Finnigan Mat 8200 spectrometer using the FAB-Nibeol ionization technique. Small single crystals of **2** were obtained from THF solution. Crystal data were collected at −70°C with a Siemens–Stoe AED2 diffractometer using Mo Kα radiation, a graphite monochromator and omega-scan. The structure was solved by direct methods (SHELXS-86) [7]. The compound crystallizes with one half THF per molecule. The THF molecule is disordered. It was not possible to distinguish the oxygen from the carbon atoms, then the solvent molecule was refined for five carbon atoms with restrictions on the bond lengths and angles. The structure was refined by least-squares methods based on F_2 with all measured reflections (SHELXL-97 [8]) using anisotropic temperature factors for all non-hydrogen atoms except those of the THF molecule. Hydrogen atoms were inserted in calculated positions or as part of a rigid group (methyl).

2.2. Synthesis of the dioxocomplexes

2.2.1. Bis(dimethyldithiocarbamato)-dioxomolybdenum(VI), $[MoO_2\{S_2CN(CH_3)_2\}_2]$

A solution of 9.40 g (50 mmol) of $NaS_2CN(CH_3)_2\cdot 2.5H_2O$ in 100 ml H_2O was slowly added to a solution of 8.70 g (7 mmol) of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in 100 ml H_2O, with strong stirring. The pH was kept at about 2 by adding 1 M HNO_3. The obtained yellow precipitate was filtered off and washed with water, then dried under vacuum. Yield, 99%. The compound decomposes between 290–300°C. (Elemental analysis: *Anal*. Found: C, 28.13; H, 4.64; N, 6.40. Calc.: C, 28.30; H, 4.75; N, 6.60%).

2.2.2. Bis(diethyldithiocarbamato)dioxomolybdenum(VI), $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$

The previously described procedure was employed, using 10.00 g (44 mmol) of $NaS_2CN(C_2H_5)_2\cdot 3H_2O$ in 150 ml H_2O, and 10.00 g (8 mmol) of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in 150 ml H_2O. The yellow compound was recrystallized in 1:1 benzene: n-hexane. Yield, 95%. m.p., 133°C. (Elemental analysis: *Anal*. Found: C, 19.27; H, 3.34; N, 7.62; S, 34.27. Calc.: C, 19.56; H, 3.28; N, 7.60; S, 34.82%).

2.3. Synthesis of the aroylhydrazine derivatives

2.3.1. Benzoylhydrazido(2-)tris(diethyldithiocarbamato)-molybdenum(V), $[Mo(NNH\text{-}CO\text{–}Ph)\{S_2CN(C_2H_5)_2\}_3]$ (1)

A suspension of 1.00 g (2.36 mmol) of $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$, 0.60 g (2.66 mmol) of $NaS_2CN(C_2H_5)_2\cdot 3H_2O$, and 0.60 g (4.4 mmol) of $PhCONHNH_2$ in 20 ml methanol were boiled under reflux for 2 h with magnetic stirring. Longer times of reflux lead to lower yield, whereas shorter times cause the product to be contaminated with the reactants. The solvent was reduced to about 10 ml in a rotary evaporator and the solution was cooled to r.t. The orange solid thus obtained was filtered and washed with methanol, water, and again with a little methanol. The product was recrystallized in methanol and dried under vacuum. It can also be recrystallized in THF. Yield, 82%. The same product was obtained with 1:0:1 and 1:0:2 molar ratios of reactants respectively, but the yield decreased to 30 and 38%. Elemental analysis: *Anal*. Found: C, 38.31; H, 5.17; N, 10.14. Calc.: C, 39.21; H, 5.24; N, 10.39%.

2.3.2. Tris(diethyldithiocarbamato)-p-nitrobenzoyl-diazenido(1-)molybdenum(IV), $[Mo(NNCO\text{–}C_6H_4\text{–}NO_2)\{S_2CN(C_2H_5)_2\}_3]$ (2)

The procedure described above was employed, using 1.00 g (2.35 mmol) of $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$, 0.60 g (2.66 mmol) of $NaS_2CN(C_2H_5)_2\cdot 3H_2O$, and 0.80 g (4.41 mmol) of $O_2N\text{–}C_6H_4CONHNH_2$. The red solid was recrystallized in THF and dried under vacuum for one h at 35°C. Yield, 80%. With 1:0:2 molar ratio of reactants the same product was obtained in 35% yield. (Elemental analysis: *Anal*. Found: C, 38.27; H, 5.22; N, 11.09; S, 25.15. Calc. for $[Mo(NNCO\text{–}C_6H_4\text{–}NO_2)\{S_2CN(C_2H_5)_2\}_3]\cdot 0.5THF$: C, 38.18; H, 5.07; N, 11.13; S, 25.48%). Crystals for X-ray analysis were grown by dissolving the compound in THF at 20°C and then filtering. The solution was warmed at about 60°C and after 12 h red crystals were obtained.

2.3.3. Benzoylhydrazido(2-)tris(dimethyldithiocarbamato)molybdenum(V), $[Mo(NNHCO\text{–}Ph)\{S_2CN(CH_3)_2\}_3]$ (3)

The procedure as described above was employed, using 1.00 g (2.71 mmol) of $[MoO_2\{S_2CN(CH_3)_2\}_2]$, 0.55 g (2.92 mmol) of $NaS_2CN(CH_3)_2\cdot 2.5H_2O$, and 0.60 g (4.41 mmol) of $Ph\text{–}CO\text{–}NHNH_2$. The product was recrystallized in methanol or THF and dried under vacuum. Yield, 75%. The same product was obtained in 1:0:2 molar ratio of reactants, in 33% yield. (Elemental analysis: *Anal*. Found: C, 32.56; H, 4.10; N, 11.61. Calc: C, 32.59; H, 3.93; N, 11.88%).

2.3.4. Tris(dimethyldithiocarbamato)-p-nitrobenzoyldiazenido(1-)molybdenum(IV), $[Mo(NNCO\text{–}C_6H_4\text{–}NO_2)\{S_2CN(CH_3)_2\}_3]$ (4)

The procedure described above was employed, using 1.50 g (4.07 mmol) of $[MoO_2\{S_2CN(CH_3)_2\}_2]$, 0.90 g (4.79 mmol) of $NaS_2CN(CH_3)_2\cdot 2.5H_2O$, and 1.20 g (6.63 mmol) of $O_2N\text{–}C_6H_4\text{–}CO\text{–}NHNH_2$. The product was recrystallized in THF and dried under vacuum. Yield, 81%. The same product was obtained in 30%

yield when a 1:0:2 molar ratio of reactants was used. (Elemental analysis: *Anal*. Found: C, 30.85; H, 3.75; N, 13.10; S, 29.90. Calc.: C, 30.28; H, 3.49; N, 13.24; S, 30.31%).

2.4. Solvolysis of the hydrazido(2-) and diazenido(1-) derivatives

The solvolysis of **1**, **2**, **3**, and **4** was attempted in 5% and 10% NaOH in water and in methanol at r.t. for 24 h but no reaction was observed. The reactants decomposed when refluxed at 60°C for 2 h. The same compounds did not react with 37% HCl in water at r.t. for 24 h, neither with 5% HCl below 50°C. At 60°C decomposition of the reactants was observed. IR spectroscopy was used as a probe to monitor the course of the reactions.

Only the reaction of the diethyldithiocarbamato derivatives **1** and **2** with 2.5% HCl in methanol under reflux gave an identifiable product.

2.5. Tetrakis(diethyldithiocarbamato)molybdenum(V)-tetrachlorobis(methoxy) molybdate(V), $[Mo(S_2CN(C_2H_5)_2)_4][MoCl_4(OCH_3)_2]$ (**5**)

A suspension of 0.30 g of **1** in 15 ml of a solution of concentrated HCl 2.5% *v*/*v* in methanol was placed under reflux; after 45 min a green precipitate formed, that was filtered and washed with water, diethyl ether and n-hexane. Its m.p. (143°C) and mass spectra showed it to be the unstable known compound $[Mo\{S_2CN(C_2H_5)_2\}_4]$ [9]. After refluxing for 2 h, the resultant brown solution was evaporated in a rotary evaporator until about 4 ml, then it was warmed and diethyl ether added drop to drop, until a brown solid precipitated. The solid was filtered and washed at 0°C with diethyl ether and methanol. Then it was recrystallized in methanol and dried under vacuum. Yield, 27%. The product is insoluble in acetone, diethyl ether, chloroform, and dimethyl sulfoxide (Elemental analysis: *Anal*. Found: C, 26.72; H, 4.69; Cl, 14.34; N, 5.67; S, 25.94; Calc. for $[Mo\{S_2CN(C_2H_5)_2\}_4][MoCl_4(OCH_3)_2]$: C, 26.80; H, 4.74; Cl, 13.37; N, 6.44; S, 25.63). When **2** was allowed to react by the above described procedure the same products were obtained under the same conditions but in lower yield (**5** was formed in 20% yield).

2.6. Tris(diethyldithiocarbamato)acetylhydrazido(2-)-molybdenum(V), $[Mo(NNHCO–CH_3)\{S_2CN(C_2H_5)_2\}_3]$.

A suspension of 0.50 g (1.18 mmol) of $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$, 0.50 g (2.22 mmol) of $NaS_2CN(C_2H_5)_2 \cdot 3H_2O$, and 0.22 g (2.97 mmol) of $CH_3–CO–NHNH_2$ in 15 ml methanol was stirred for 12 h at r.t. The solution thus obtained was filtered and then evaporated until dryness in a rotary evaporator at 48°C. The resultant brown solid was suspended in 50 ml water and stirred for 30 min to dissolve and thus eliminate the excess of reactants. The precipitate was filtered and then washed with water, ethanol, and n-hexane. The product was recrystallized in ethanol; after three days brown microcrystals precipitated, which were filtered and washed with n-hexane, and diethyl ether. The product was dried under vacuum. Yield, 65%. ^{1}H NMR δ_H(solvent $CDCl_3$) 1.12–1.35 (18H, m, $6CH_3$), 1.95–2.20 (1H, br s, N–H), 2.17 (3H, s, CH_3–CO), 3.65–3.85 (12H, m, $6CH_2$).

2.7. Trisdiethyldithiocarbamatophenyldiazenido(1-)-molybdenum(IV), $[Mo(NNPh)\{S_2CN(C_2H_5)_2\}_3]$.

This compound was prepared following a published procedure [10].

3. Results and discussion

3.1. Synthesis of the compounds

The dioxocomplexes were synthesized by a modification of the procedure published by Moore and Larson [11]; the pH was kept below 2.0 with diluted HNO_3 in order to avoid contamination with the violet Mo(V) complex, $[\{Mo(S_2CNR_2)_2O\}_2O]$.

It has been published that the reactivity of dioxocomplexes against substituted hydrazines depends on several factors, such as the nature of the coligands and of the hydrazines, and the molar ratio of the reactants; for example, the number of substituents and the basicity of the hydrazines play an important role in the number of these that coordinate to the metal center [12–15]. In this work we found that condensation reactions between the dioxocomplexes and the hydrazides in the presence of the corresponding dialkyldithiocarbamate in methanol always give tris(dialkyldithiocarbamato) complexes of the type $[Mo(NNHCO–Ph)(S_2CNR_2)_3]$ and $[Mo(NNCO–C_6H_4–NO_2)(S_2CNR_2)_3]$ (R = $–CH_3$ or $–C_2H_5$). The same compounds are formed when no dialkyldithiocarbamate is added although in lower yield, since the additional dithiocarbamate has to be provided by decomposition of the original dithicarbamato complex.

The acyldiazenido- and acylhydrazido- ligands may be either monodentate when they are bound to the metal through the terminal nitrogen, or didentate when they are bound through the nitrogen and the oxygen. In addition, the monodentate ligand can bind the metal center in three different ways depending on the hydrazide from which it originates, as diazenido(1-), hydrazido(1-), or hydrazido(2-) [12,13]. These binding modes are shown in Fig. 1. In our case the two hydrazides act as monodentate ligands; *p*-nitrobenzohy-

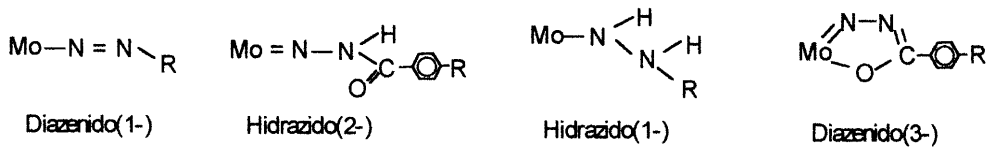

Fig. 1. Types of ligation and binding modes of the hydrazido ligands.

drazide is bound to the metal as diazenido(1-), and benzohydrazide as hydrazido(2-). A plausible explanation for this difference is that when the $-NO_2$ group is present, electron density is withdrawn from the nitrogen atom and therefore the N–H bond is unstable. Then the oxidation state of molybdenum is different with these ligands; it acts as Mo(IV) in diazenido(1-) complexes, and as Mo(V) in hydrazido(2-) complexes. The paramagnetism of the latter was proven by EPR, in which a signal at $g_{av} = 1.980$ is seen.

3.2. Reactivity of *p*-nitrobenzoyldiazenido(1-) and benzoylhydrazido(2-) complexes with acids and bases in aqueous and methanolic media

Compounds **1** and **3** are neither protonated nor deprotonated on the nitrogens of the diazenido or hydrazido ligands when boiled under reflux with base or acid in methanolic or aqueous medium. On the other hand, the same nitrogen atoms in compounds **2** and **4** are not protonated when reacting with acid in methanol, or in water. When **1** is allowed to react with HCl in methanol (2.5 ml concentrated HCl in 95 ml MeOH) under reflux, a green solid precipitates after 45 min. This precipitate is insoluble in water but soluble in chloroform, dichloromethane and acetone, indicating a non-ionic or slightly polar nature. In the solid state this compound is unstable to air, and even more in solution, and this makes difficult to take NMR spectra. The MS indicates this compound to be $[Mo(dedtc)_4]$[1], which is confirmed by its m.p., 143°C, similar to that reported in the literature [9]. The same compound was also obtained in 24% yield when **2** was allowed to react by the same procedure.

At longer reaction time (2 h) the oxidation product of $[Mo(dedtc)_4]$, $[Mo\{S_2CN(C_2H_5)_2\}_4][MoCl_4(OCH_3)_2]$ (**5**) was isolated, being the metal of the cation in the $5+$ oxidation state. Similar types of oxidation reactions have already been reported and are used for the synthesis of the cation [9,16]. Several ionic compounds that contain the $[Mo(S_2CN(C_2H_5)_2)_4]^+$ cation have been reported, which have been prepared from $[Mo_2O_2Cl_6]$ and $\{(C_2H_5)_2NH_2\}\{S_2CN(C_2H_5)_2\}$, or by oxidation of the corresponding Mo(IV) compounds [9,16,17]. The presence of the anion $[MoCl_4(OCH_3)_2]^-$ is proposed mainly on the basis of elemental analysis, since the compound is not soluble enough to allow to take NMR spectra; this anion has also been isolated from the reaction between $[Mo_2Cl_{10}]$ and CH_3OH [16].

3.3. IR spectroscopy

As expected, the dialkyldithiocarbamato coligands show IR bands due to the C=N stretching mode between 1540 and 1506 cm^{-1}, indicating a double bond character; bands due to C–S stretching are found between 1010 and 999 cm^{-1}; the C–H stretching for ethyl and methyl groups is shown in the region 2981–2858 cm^{-1}, the C–H bending modes appear as two bands around 1460 and 1380 cm^{-1} in the diethyldithiocarbamato complexes, and as only one band around 1395 cm^{-1} in the dimethyldithiocarbamato complexes [9,11,18]. The *p*-nitrobenzoyldiazenido and benzoylhydrazido ligands show bands for the =C–H stretching of the aromatic ring between 3071 and 3053 cm^{-1}, and also the out-of-plane =C–H bending modes of the aromatic rings around 700 cm^{-1}. Tables 1 and 2 show the positions of some selected bands. Two strong bands in the region 870–915 cm^{-1} assigned to *cis*-Mo=O stretchings are present in the dioxocomplexes, but disappear in the benzoylhydrazido- and *p*-nitrobenzoyldiazenidocomplexes, as expected.

The shift of the ν(C–O) and ν(N–N) IR bands according to the change in the CO bond order allows to determine whether the hydrazido and diazenido ligands act as mono- or didentate. If the IR spectrum shows bands assignable to ν(C=O) and ν(N=N), the ligand is acting as monodentate; on the other hand, if the ν(C=O) band disappears and the ν(N=N) band is

Table 1

$[Mo(NNH–CO–C_6H_5)(S_2CN(C_2H_5)_2)_3]$	1506.6	1002.1	2980.4	2935.1	2873.3
$[Mo(NN–CO–C_6H_4–NO_2)(S_2CN(C_2H_5)_2)_3]$	1511.4	1009.9	2979.4	2935.1	2872.4
$[Mo(NNH–CO–C_6H_5)(S_2CN(CH_3)_2)_3]$	1539.4	999.2	2928.3	2858.9	
$[Mo(NN–CO–C_6H_4–NO_2)(S_2CN(CH_3)_2)_3]$	1524.9	1008.9	2931.2	2861.0	

shifted to lower frequency, the ligand is didentate. The IR spectra of **1**, **2**, **3**, and **4** show two bands in the region 1640–1570 cm^{-1} that may be assigned to either ν(C=O), ν(N=N), δ(N–H), or ν(C=C) of the aromatic ring. This fact does not allow to establish the binding mode of the above mentioned ligands. In order to make a correct assignment, $[Mo(NNHCO–CH_3)\{S_2CN(C_2H_5)_2\}_3]$ and $[Mo(NN–Ph)\{S_2CN(C_2H_5)_2\}_3]$ were synthesized, the former lacking the aromatic group and the latter, the C=O group. The IR spectrum of the former also has the above mentioned bands, therefore it can be concluded that they do not originate from the ν(C=C) of the aromatic ring of the *p*-nitrobenzoyldiazenido or benzoylhydrazido ligand. The IR spectrum of the latter does not have the band around 1620 cm^{-1} that is present in the *p*-nitrobenzoyldiazenido- and benzoylhydrazido complexes, and therefore it should correspond to ν(C=O). On the other hand, the band around 1580 cm^{-1} can still be assigned to δ(N–H) or ν(N=N). Compounds **2** and **4** do not have H bound to N, as is concluded from the ^{1}H NMR spectra but the IR spectra still show this band that can then be assigned to ν(N=N). With the assignment of these bands we can conclude that the *p*-nitrobenzoyldiazenido and benzoylhydrazido ligands are acting as monodentate in all the complexes prepared. The band corresponding to ν(N=N) is found at higher energy in the *p*-nitrobenzoyldiazenido(1-) complexes (around 1592 cm^{-1}) than in the benzoylhydrazido(2-)complexes (around 1572 cm^{-1}). This can be interpreted in terms of the decreasing N=N bond order when the ligand also has an N–H bond, since part of the electron density that is involved in the N=N bond is shifted to N–H.

3.4. NMR spectroscopy

3.4.1. ^{1}H NMR

The ^{1}H NMR spectra of **1** and **2** show the signals of the hydrogens from the diethyldithiocarbamates as complex multiplets at $\delta = 1.15–1.35$ and at $\delta = 3.62–3.93$, which are the result of overlapping of some triplets and quadruplets, respectively; this fact suggests that these coligands are not equivalent in solution. In **3** and **4** the hydrogens of the methyl groups from the dimethyldithiocarbamates give rise to four peaks in the range $\delta = 3.26–3.40$. In **1** and **3** the hydrogens of the benzyl ring of the benzoylhydrazido(2-) appear as two triplets and one doublet in the region $\delta = 7.27–8.12$, as expected [14]. In **2** and **4**, the hydrogens of the aromatic ring from the *p*-nitrobenzoyldiazenido display a multiplet at $\delta = 8.05–8.25$.

^{1}H NMR allows to determine whether the ligand is hydrazido or diazenido, since the number of hydrogens bound to the nitrogens determine the kind of ligand. The spectra of **1** and **3** show a broad signal at $\delta = 1.60–1.85$ that disappears when D_2O is used. This behavior suggests that the band corresponds to the H bound to the non-coordinated N, then in these compounds the ligand is bound as benzoyl-hydrazido(2-); a similar signal was reported for $[MoO(NNHPh)\{S_2CN(C_2H_5)_2\}_2]$ [14]. When the hydrogen is bound to the coordinated nitrogen the signal is seen at higher chemical shift due to weaker binding, as found for $[Mo(NHNPh_2)(NNPh_2)(acac)Cl_2]$ and [Mo(NHNMePh)(NNMePh)(acac)Cl_2], where the signals appear by $\delta = 12$ [13]. Compounds **2** and **4** do not show signals assignable to hydrogen bound to nitrogen, and furthermore there are not changes in the spectra with D_2O, then the ligand is bound as a *p*-nitrobenzoyldiazenido(1-).

Compound **2** shows a quintuplet at $\delta = 1.80–1.90$ that corresponds to one of the signals of THF, from the hydrogens bound to the carbons distant from oxygen. This quintuplet is not observed when the compound has not been recrystallized. The hydrogens bound to the carbons next to oxygen show a signal at $\delta = 3.70–3.80$ that overlaps with the signals from the coligands.

The integration ratios for compounds **1**, **2**, **3**, and **4** are in agreement with the presence of three dialkyldithiocarbamato coligands and one *p*-nitrobenzoyldiazenido or benzoylhydrazido ligand.

3.4.2. ^{13}C NMR

The ^{13}C NMR spectra of **1** and **3** show four signals in the region $\delta = 127–135$ that correspond to the aromatic carbons from the benzoylhydrazido. In compounds **2** and **4**, four similar signals from the *p*-nitrobenzoyldiazenido are shown at 122–150. All four compounds show a signal at $\delta = 180$ that corresponds to C from the carbonyl group. The diethyldithiocarbamato coligands

from **1** and **2** give signals around $\delta = 12$ and 42–45 from the ethyl groups, whereas the methyl groups from **3** and **4** give signals at $\delta = 37$–41. All four compounds show two signals around $\delta = 200$ and 206 that correspond to the carbons bound to sulfur in the dialkyldithiocarbamates; of these, the former signal is approximately twice as intense as the latter, suggesting that only two of the coligands are equivalent and located on the same plane, which is consistent with a nearly decaedric geometry obtained for a seven coordination number.

3.5. Mass spectrometry

Compound **2** shows a Mo-isotopic multiplet with the most intense peak at m/z 721 which can be assigned to the protonated molecular ion, $[Mo(NNHCO–C_6H_4-NO_2)\{S_2CN(C_2H_5)_2\}_3]^+$. At m/z 542 another similar multiplet is found, that corresponds to the loss of the protonated ligand –NNHCO–C_6H_4–NO_2. The additional proton is not found in the ^{1}H NMR spectrum of the complex, therefore it is gained in the ionization process; these proton additions are common when the FAB-Nibeol ionization technique is used [19].

The mass spectrum of **5** shows a multiplet with the most intense peak at m/z 690, that can be assigned to the $[Mo\{S_2CN(C_2H_5)_2\}_4]^+$ ion, its isotopic distribution corresponds to a complex with one molybdenum atom; there are also multiplets at m/z 574, assigned to $[Mo-S\{S_2CN(C_2H_5)_2\}_3]^+$; m/z 542, assigned to $[Mo\{S_2CN-(C_2H_5)_2\}]_3^+$; m/z 426, assigned to $[MoS\{S_2CN-(C_2H_5)_2\}_2]^+$; and m/z 394, that corresponds to $[Mo\{S_2CN(C_2H_5)_2\}_2]^+$.

3.6. X-ray structure of $[Mo(NNCO-C_6H_4-NO_2)\{S_2CN(C_2H_5)_2\}_3]\cdot(0.5)THF$ (2)

The X-ray structure of this compound is shown in Fig. 2. Crystal data are listed in Table 3 and the selected bond lengths and angles, in Table 4. The complete atomic coordinates, bond lengths and angles have been deposited as Supporting Information. The Mo atom is heptacoordinated, the donor atoms are arranged in a distorted pentagonal bipyramid. The atoms N5 and S1 occupy the axial positions (N5–Mo1–S1 166.1(2)°), while the atoms S2, S3, S4, S5, and S6 are located in the equatorial plane. S2 connected via C1 to the axial atom S1 deviates strongly

from the plane through Mo1, S3, S4, S5 and S6. The MoS_2CNC_2 fragment from the diethyldithiocarbamato coligands is nearly planar as expected, and the bond distances lie in the expected ranges [9,20]. The Mo–N5–N4 group is nearly linear (175.4(9)°) indicating extensive electronic delocalization i.e., the Mo–N and N–N have double bond character or, in terms of the valence bond model, the N bound to Mo has sp hybridization. The Mo–N and N–N bond lengths (1.756(5) and 1.278(7) Å, respectively), are consistent with this character. Unfortunately, from X-ray studies it is not possible to establish whether the binding occurs as diazenido(1-) or hydrazido(2-), since comparison of bond lengths and angles (Mo–N–N–$R_{1\ or\ 2}$ fragment) for this ligands in similar compounds (Table 5) indicates that these values are within the same range. However, the double character of the Mo=N and N=N bonds is certain. There is a noticeable difference between these values and those observed for the hydrazido(1-) complexes, Mo–NH–NR_2, where the Mo–N and N–N bonds are single in character as indicated by the longer distances (1.95 and 1.38 Å, respectively), and smaller Mo–N–N angles (between 120 and 140°).

4. Conclusions

In the compounds prepared in this work, we found that bis(dialkyldithiocarbamato)-dioxocomplexes react with *p*-nitrobenzohydrazide and benzohydrazide to yield always seven-coordinate complexes, in which one oxo ligand is substituted by a hydrazide independently of the molar ratios of the hydrazide used, and the other oxoligand is substituted by an additional dialkyldithiocarbamato, even when this coligand is not added in the condensation reaction.

The aroyl hydrazines used in this work act as monodentate ligands, differently from the behavior reported for rhenium with phosphines as coligands, where the aroyl hydrazine preferentially coordinates in a didentate fashion.

Benzohydrazide and *p*-nitrobenzohydrazide have different behavior, the former gives ligands of hydrazido(2-) type while the latter, ligands of diazenido(1-) type. A plausible explanation for this difference is that when the $–NO_2$ group is present, electron density is withdrawn from the nitrogen atom and therefore the N–H bond is unstable. Molybdenum is reduced in this reactions, but the oxidation state of the metal is different in each ligand, thus Mo(V) complexes are obtained starting from Mo(VI) and benzohydrazide, while Mo(V) complexes are formed from *p*-nitrobenzohydrazide.

The study of IR spectra of the diazenido(1-) and hydrazido(2-) complexes, supported by the results of X ray diffraction and ^{1}H and ^{13}C NMR allows to make a

conclusive assignment of ν(C=O) and ν(N=N) vibrations, which in turn allows to establish the type of binding of the hydrazines as mono o didentate.

A singular behavior is observed for the dialkyldithiocarbamato coligands, since the number of these in the complexes successively increases in each step of the syntheses.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 137508. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Bimetallic films of Zn–Cd have been prepared from colloids using several organic solvents: acetone, 2-butanone, THF, 2-propanol and 2-methoxyethanol. The colloids were prepared by simultaneous codeposition of metals and solvents at 77 K. The bimetallic films and solids were obtained by evaporation under vacuum at room temperature (r.t.) A fully chemical characterization of bimetallic films and solids was carried out by different techniques such as elemental analysis, FT-IR spectroscopy, conductivity and thermal analysis. In the IR spectra for all solvents, except for ketones, the common absorption bands appear indicating no alteration upon incorporation of metal particles. The carboxylic band disappearance in ketones may be due to some kind of interaction with metallic particle surfaces. Thermograms showed that bimetallic solids present a decomposition temperature over 400°C. The electric conductivity studies indicated that our bimetallic solids are semiconductors. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

Nanoclusters with semiconductor behavior have been studied extensively [1–10]. The quantum size effect shifts the band gap of many semiconductors into the visible range and allows the possibility of nanocluster applications in light-emitting diodes. These practical applications of semiconductor nanoclusters have been hindered by surface problems due to non-radiative recombination, lowering the quantum yield of emission.

Another method of increasing the quantum yield of emission was reported more recently [11]. It involves the addition of an impurity to a quantum dot, producing a doped nanocrystalline material. Wang [12] reported a cluster of mixed semiconductors $Zn_xMn_{1-x}S$ being a magnetic semiconductor quantum dot. Manganese doped ZnS clusters have been studied by Bhargava [11,13,14] and Gallagher [15]. Sizes ranging from 35 to 75 Å were obtained and have shown photoluminescence quantum yields around 18%. Cohen [16] has synthesized semiconductor nanoclusters with controlled size and narrow size distributions using block copolymer films prepared by ring-opening methatesis polymerization. The presence of a pendant whole transport group [17] and an electron-transport group can provide, with an electrical access, to nanoclusters for device applications. Photoluminescence emission spectrum for a polymer film containing Mn-doped ZnS nanoclusters was reported [18]. The intensity of emission at 586 nm (Mn emission) was obtained as a function of the excitation wavelength. When the incident radiation decreases below 330 nm, ZnS nanoclusters begin to absorb light, and an increase in the manganese intensity is observed. The excitation of ZnS around 330 nm results in the emission at 586 nm. This proves an energy transfer from ZnS to Mn, which indicates that Mn is doped in the ZnS cluster.

Furthermore, CdS and Zn–Cd sulfide are useful as photoconductors of visible and infrared radiation [19]. These semiconductors are important to make more available photochemical and photovoltaic cells. The most promising photocell designs use their films of

photosensitizers interfaced with CdS in which the crystal lattice parameters of the two films are molded [20–22].

Herein, we report the results of the synthesis of zinc–cadmium films prepared from the evaporation of the solvents from colloidal dispersions prepared by chemical liquid deposition at 77 K. Films containing residual solvent of acetone, 2-butanone, THF, 2-propanol and 2-methoxyethanol are reported.

2. Experimental

2.1. Preparation of films

The films were prepared by slowly dripping the corresponding colloidal dispersions onto a substrate. To increase the speed of solvent evaporation a vacuum of 10^{-3} Torr was used over 4 h.

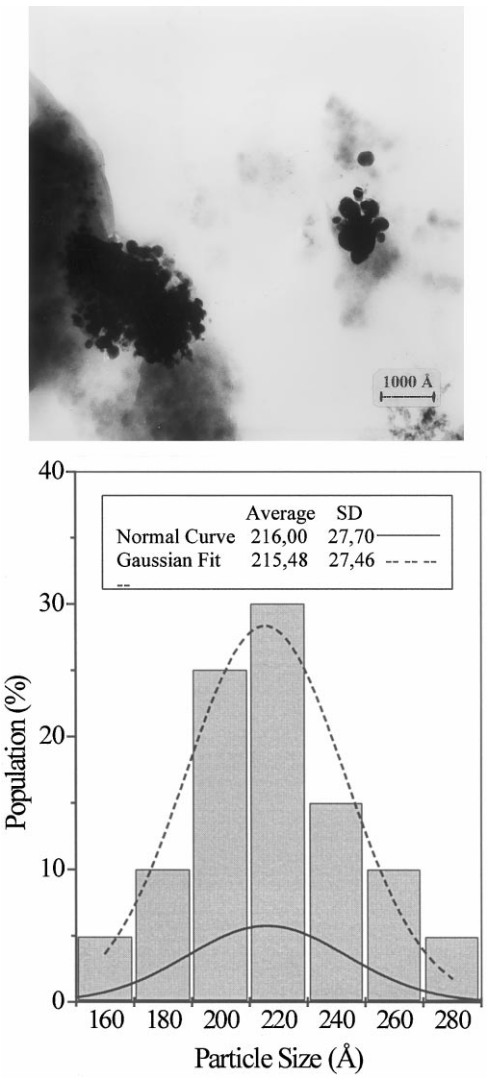

Fig. 1. The electron micrograph and histogram of Zn–acetone colloids. Magnification = 100 K. Mean size: $\mu = 216$, $\sigma = 27.70$ Å.

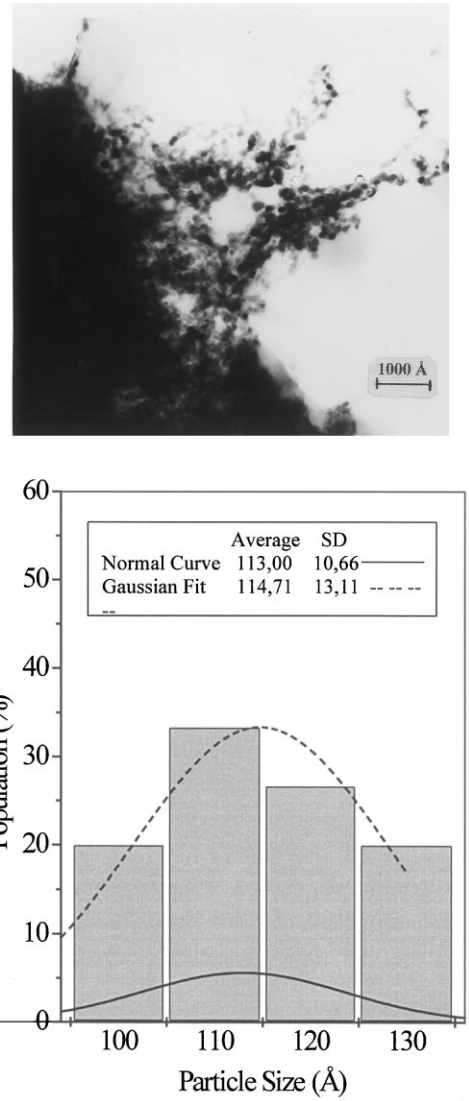

Fig. 2. The micrograph and histogram of Cd–acetone colloids. Magnification = 100 K. Mean size: $\mu = 113$, $\sigma = 10.66$ Å.

2.2. Thermogravimetric analysis

A Perkin–Elmer model TGA-7 thermogravimetric system with a microprocessor-driven temperature control unit and a TA data station, was used. The mass of the samples was generally in the range of 2–3 mg. The sample pan was placed in the balance system equipment and the temperature was raised from 25 to 550°C at a heating rate of 10°C min^{-1}. The weight of the sample pan was recorded continuously as a function of the temperature.

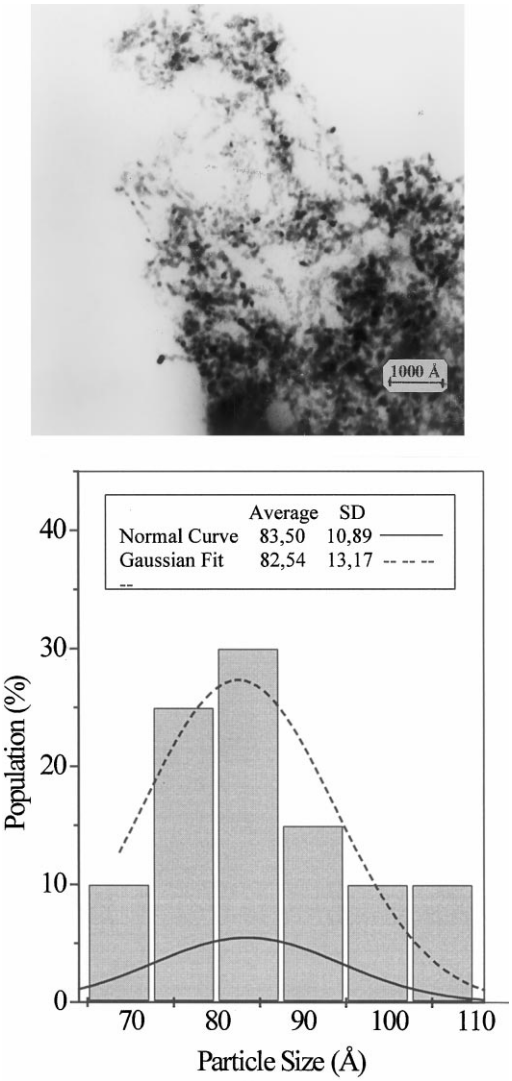

Fig. 3. The micrograph and histogram of Zn–Cd–acetone colloids. Magnification = 100 K. Mean size: $\mu = 83.50$, $\sigma = 10.89$ Å.

2.3. Infrared spectra

IR spectra were obtained using a Nicolet Magna 5PC Fourier transform infrared spectrometer. KBr pellets were prepared for all the films with 2% film concentration. A total of 128 scans were accumulated for each spectrum.

2.4. Elemental analysis

The active solids were analyzed in order to determine their elemental composition (C, H, O).

The Zn and Cd were determined by atomic absorption using a Perkin–Elmer 3100 model.

2.5. Infrared spectroscopy

The IR spectra were performed using a Nicolet Magna 5PC Fourier transform infrared spectrometer. The samples were prepared in a KBr pellet 2% w/w) at 15 000 lbs. The sample was carried out between 400 and 4000 cm^{-1} with 128 scans.

2.6. Conductivity

The electrical conductivity measurements were carried out using 120 mg sample and making a pellet at 16 600 psi.

The electrical resistance was measured using a RCL Fluke PM 6304 bridge and from the area and sample thickness the resistance was transformed to electrical resistivity, independent parameter of the sample size [23].

3. Results and discussion

The films and solids were prepared by solvent evaporation from the colloidal dispersions, using a flask connected to the vacuum line. After solvent evaporation the flask with the active solid is filled up with nitrogen gas to avoid the metal oxidation. The fine powder is later on used for complete characterization.

Acetone	3.56	43.89	4.35	20.84	27.36
Acetone	0.00	38.77	5.59	22.70	32.93

In order to distinguish the differences between the colloids and the bimetallic colloids we are measuring the particle size of the colloid, Cd colloid and Zn–Cd colloid prepared with acetone. Fig. 1 shows the Zn–acetone colloid with particle size, $\mu = 216$ Å but Fig. 2 exhibits Cd–acetone with a particle size of $\mu = 113$ Å. Fig. 3 shows the particle size of the alloy ($\mu = 83.5$ Å) being smaller than the independent metal colloids.

This is good evidence for the presence of the bimetallic clusters.

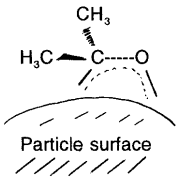
3.1. Elemental analysis

Table 1 summarizes the w/w percentage of each element forming the solids, which were obtained by solvent evaporation from the colloidal dispersions.

The elemental analysis shows the incorporation between 1–10% w/w of organic materials assuming only the C, H results.

In order to observe a better ration between the elements, the weight percentages were transformed in mole percentage. Table 2 summarizes the values.

It is observed that in most of the cases the initial mole relationship of the metal is constant (50% Zn, 50% Cd) and for acetone the change in the concentration calculated initially is also shown in Table 2.



In general, we can see an excess of oxygen moles with respect to carbon, e.g. for THF (C_4H_8O) for each four carbon moles one mole oxygen should exist, and in this case we can observe that the oxygen molar is three times greater than carbon. This could be due to the presence of Zn and Cd oxides on the surface of the particles which could be due to the high oxidation potential of these metals.

These solids are very reactive to moisture and can absorb oxygen and carbon dioxide very rapidly, which also produces severe modification in the analysis.

3.2. FT-IR spectroscopy

The FT-IR spectra obtained for Zn–Cd solids show absorption bands even though the solids exhibit a low amount of solvent incorporated. The most relevant bands in each spectrum are summarized in Table 3 [24].

Most of the solvents were incorporated to the fine particles without structural changes. The acetone shows a weak C=O stretching, mainly due to planar carbonyl interaction with the particle surfaces as shown here:

Following this statement, the carbonyl band should disappear for ketones. Besides, this interaction can explain the colloid stability for ketones, due to the formation of a bond with the surface, producing a steric barrier.

Figs. 4–6 show the IR spectra of some Zn–Cd solids.

It is observed in most of the spectrum bands near 3400 cm^{-1} which corresponds to ν_{OH}. Most of the films get humidity easily during the KBr pellet preparation [24]. Similar IR results were obtained for Cd films prepared with the same solvents [25].

Also, a band at 450 cm^{-1} has been found in all the bimetallic solids. This absorption is due to the zinc and cadmium oxides [26] on the surface of the films. The C–H stretching has disappeared in the Zn–acetone solid films after the oxidation process.

3.3. Thermogravimetric analysis

The decomposition temperatures of the Zn–Cd solids are summarized in Table 4.

It was observed that most of the solids show one decomposition stage over 400°C. This fact allows us to confirm the presence of a very stable bimetallic alloy.

The solids that exhibit two decomposition stages are those in which microanalysis indicates a greater amount of organic material. As an example, THF films exhibit carbon percentages, 4.6 and 6.1, but 2-

[a] The thermogram exhibits two decomposition temperatures.

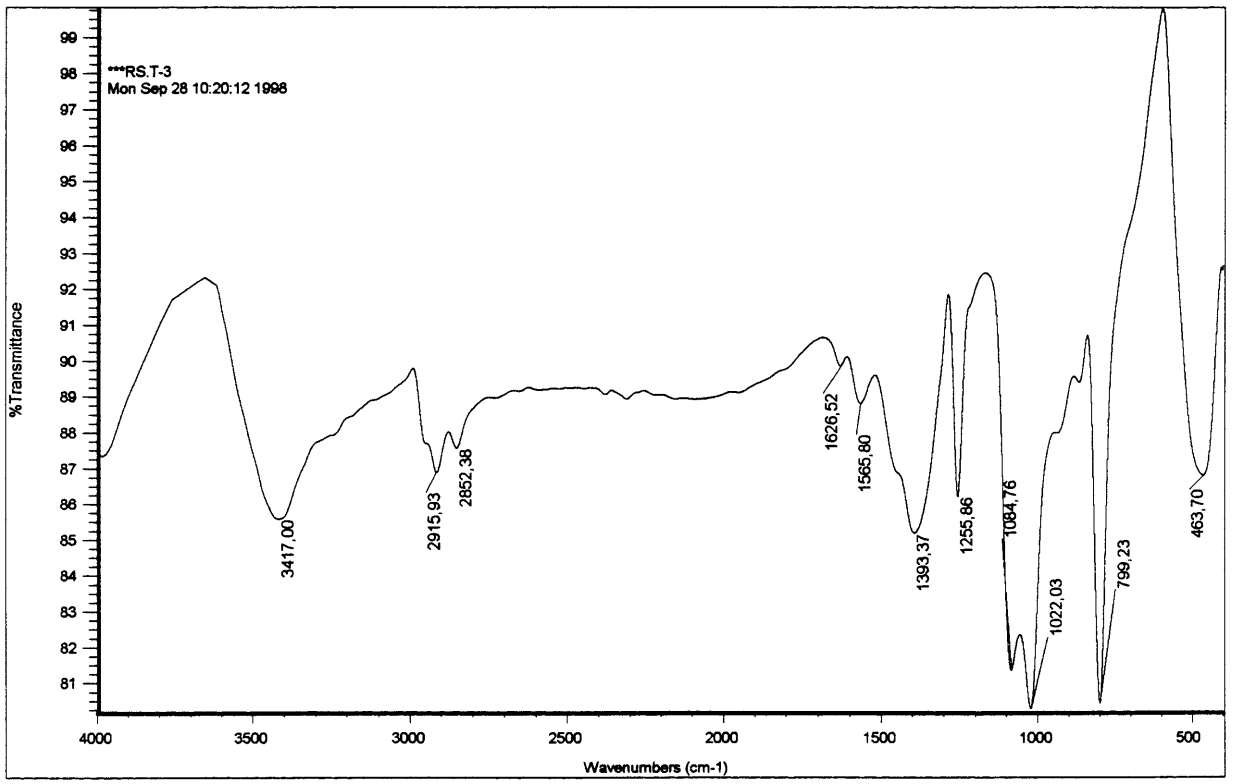

Fig. 4. FT-IR spectrum of (Zn–Cd)-2-butanol films in KBr pellet.

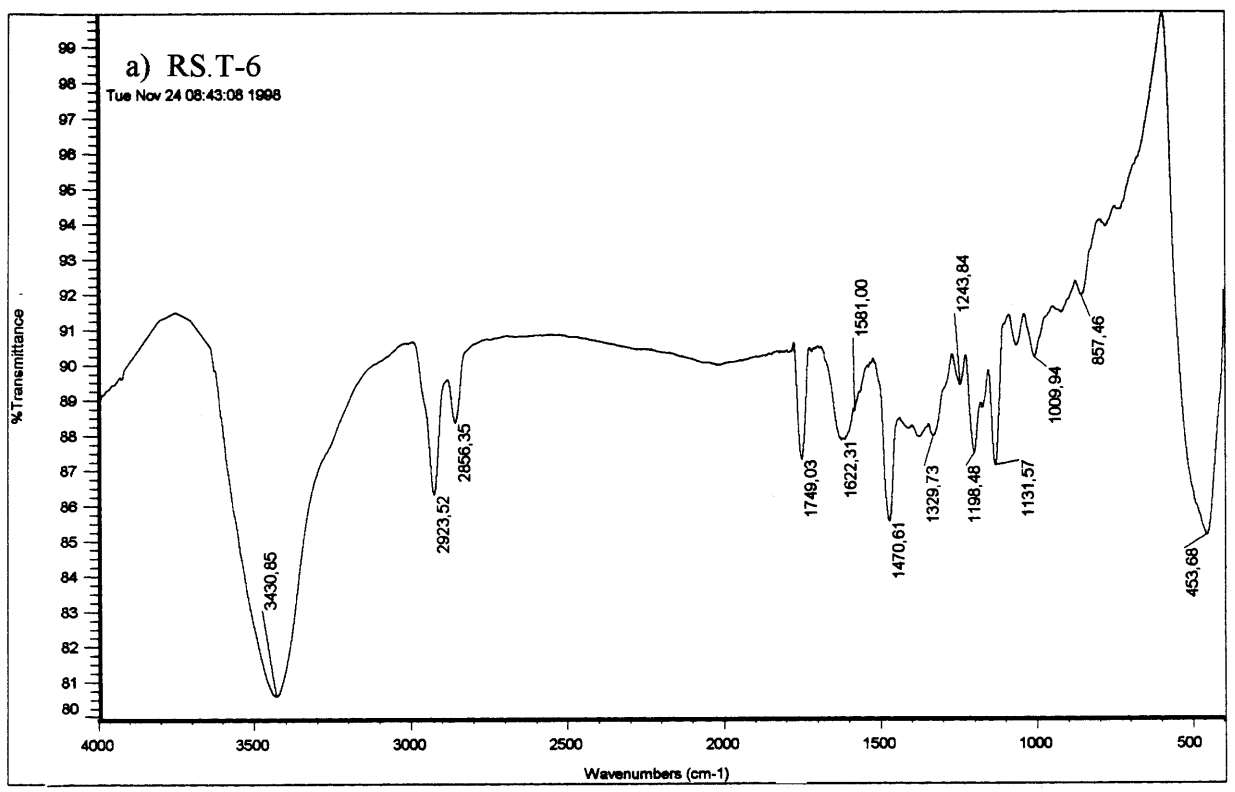

Fig. 5. FT-IR spectrum of (Zn–Cd)–acetone films in KBr pellet.

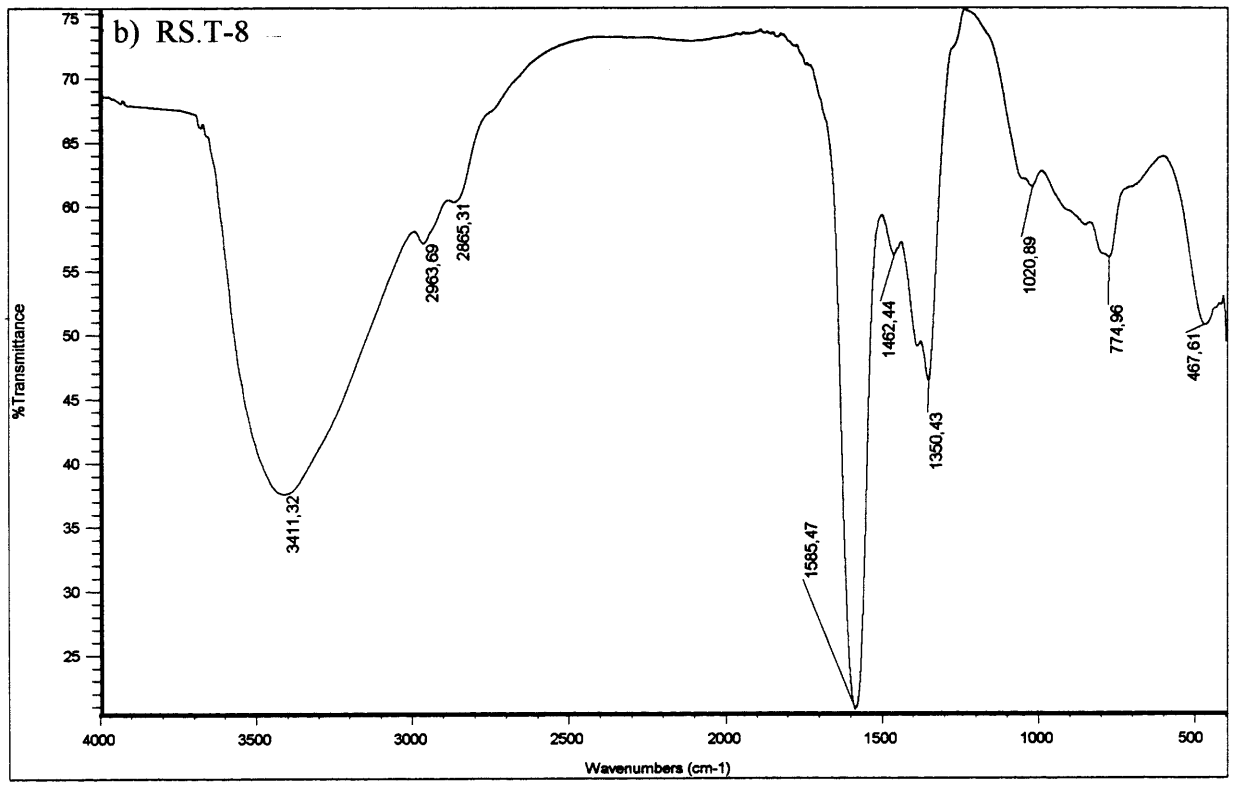

Fig. 6. FT-IR spectrum of (Zn–Cd)–THF films in KBr pellet.

propanol is 5.5% w/w. On the other hand, the other solvents only contain between 0.6 and 3.2% w/w.

This phenomenon can be explained if we consider that most of the organic solvents are physically adsorbed and not through a bond with the metal or bimetal particles. Another possibility is that solvents are occluded in the bimetal cluster particles. The electron micrograph shows spherical particles. Under these considerations we can conclude that the free solvents decompose first before the other bonded with the Zn–Cd films.

There are no tendencies in the decomposition temperatures as a function of concentration, solvent and metal percentage. For instance, the decomposition of the system is independent of the particle size or solvent structure, but is related to the amount and incorporation mechanism of the organic solvents.

It is interesting to observe that Zn–acetone [26] and Cd–acetone [25] films shown a T_D at 390 and 482°C, respectively. However, the (Zn–Cd) acetone films exhibited a T_D at 517 and 513°C, being different from the separate metals.

From the decomposition curves we can see that in most of the cases the solids are very stable without loss of weight until complete solid decomposition. This behavior is an advantage because we can have a great range of working temperatures important for future applications.

It is interesting to notice the 2-methoxyethanol films in which ($T_D = 507$°C), 2-propanol ($T_D = 505$°C), 2-butanol ($T_D = 493$°C) and acetone ($T_D = 482$°C) which are higher than the Zn melting point are showing the presence of the alloy. For THF a T_D higher than 460°C was also observed.

There is no relationship between the amount of weight loss during the decomposition and the amount of organic material obtained from the microanalysis. Most probable because the decomposition temperature near 500°C including the metal vaporization interferes with the TGA analysis.

3.4. Conductivity

The conductivity measurements were carried out for the (Zn–Cd) acetone solids. The study was performed to observe the influence of the metal percentage in the solids.

The electrical conductivities of the Zn–Cd solids are in the same range as semiconductors. These conductivities are lower than that for pure metals [27], 1.66×10^7 (s/m) for Zn and 1.38×10^7 (s/m) for Cd.

The decrease in conductivity with respect to the metals is due to the absence of a bulk structure in which the electrons can move with freedom, conducting electricity. However, we are in the presence of isolated metal particles, separated by a dielectric material [27],

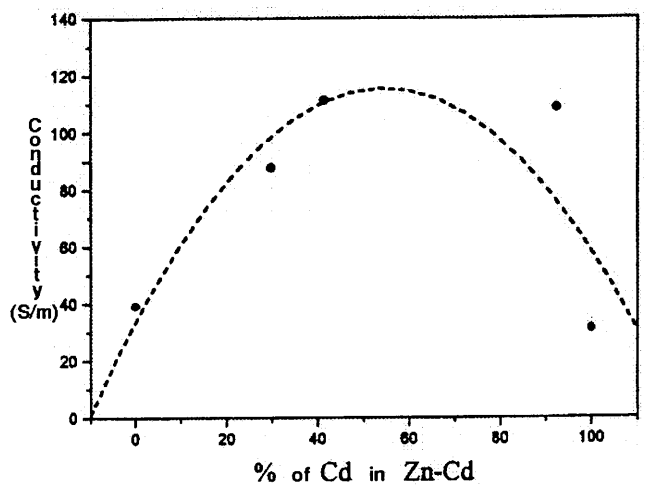

Fig. 7. Conductivity of (Zn_xCd_{1-x})–acetone films versus Cd percentage.

the organic solvent adsorbed on the surface of the metal clusters. Therefore, the conduction mechanism for these materials is different from that of the pure metals due to the availability of electrons to conduct electricity in each particle confined in potential holes separated by a greater energetic barrier (dielectric). Schmid has reported that the conduction for these metal clusters is of the tunnel effect type [28], where the electrons are excited to a higher energy level for electrical conductivity.

Another effect under study is the change in conductivity as a function of the percentage of metal incorporated in the solids. As we can observe in Fig. 7, there is an increase in the conductivity of the bimetallic solid with respect to the monometallics.

4. Conclusions

Metal films containing organometallic residues were obtained. The IR analysis showed the presence of the organic solvents in the films. These alloyed films or active powders containing solvents showed higher thermal stability than pure metals.

These active bimetallic films exhibit semiconductor properties which depend on the increase in the Cd content, keeping the measurements at r.t.

Received 13 October 1999; accepted 11 May 2000

Abstract

The characterisation of the physical properties of MgO powders, obtained from three commercial magnesium compounds, $MgSO_4 \cdot 7H_2O$, $MgNO_3 \cdot 6H_2O$ and $Mg(CH_3CO_2)_2 \cdot 4H_2O$ and the mineral dolomite (natural source from Mexico), synthesised by chemical precipitation, is presented. The decomposition of the precipitated $Mg(OH)_2$ was analysed by DTA/TGA and the crystallisation process was observed by XRD. The variation of the properties with the nature of the precursors at 960°C was studied: as the crystallite size, density, specific surface area, degree of agglomeration, and the total porosity. The microstructural differences between the MgO agglomerates were examined by SEM, at different temperatures. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Magnesia; Dolomite; Crystallite size; Degree of agglomeration; X-ray diffraction; SEM

1. Introduction

Magnesia (MgO) is the most important product of the magnesium compound industry. It is usually produced for commerce by the thermal decomposition of magnesite ($MgCO_3$), from magnesium hydroxide ($Mg(OH)_2$) obtained from a seawater process or from magnesium rich-brines as the mineral dolomite [1]. Mexico is one of the major producers of MgO; the states of Nuevo Leon and Coahuila contain large deposits of high-purity dolomite; major capacity expansions took place in 1992 when Industria Peñoles started with the production of high-purity electrofused MgO in Ramos Arizpe, Coahuila [1].

The most important process for the production of MgO from seawater or brine is based on the fact that $Mg(OH)_2$ can be precipitated from solutions of magnesium salts by the addition of a strong base. The $Mg(OH)_2$ precipitate is washed, filtered and then calcined to produce MgO. Decomposition of solutions of magnesium salts is also important for the synthesis of ceramic powders. Many alternative techniques have been developed offering advantages of easy preparation of oxide powders, accurate compositional control, homogeneity and high purity [2–6].

Caustic-calcined MgO is produced at temperatures < 900°C and characterised by its moderate to high chemical reactivity. This type of magnesia has numerous applications as mineral supplement for animal feeds, in fertilisers, as a raw material for various MgO chemicals, to manufacture ceramics, cements, paper, petroleum additives, etc. Meanwhile, calcined dolomite as a source of alkali is used in agriculture, to neutralise soil acidity and adds calcium and magnesium to it; it can also can be used in the manufacture of refractories, as mineral filler, as a constituent in a glass batch, etc. [1].

The physical properties of MgO powders are affected by the type of precursor, the temperature of calcination and the impurities. Actually, one of the main problems detected in the production of caustic magnesia powders is to achieve a real density near to the ideal value, in order to obtain ceramic bodies with suitable compacting conditions. The properties of refractories in industrial processes with low densities, present undesired characteristics such as the formation of low eutectic

PII: S0277-5387(00)00570-2

points due to the presence of impurities, vulnerability to chemical attack and a deficient mechanical resistance [7–9].

Studies on the synthesis of materials with appropriate refractory properties had been aimed to obtain powders with certain characteristics, which may help to improve the process of sintering [10]. Among these, the following can be mentioned: high surface area, uniform particle size and chemical homogeneity. The formation of large agglomerates must be avoided, since these generate fractures in their surroundings and if present in excess, they can accelerate or delay the sinterability phenomena. The morphology of powders of MgO has been observed using scanning electron microscopy (SEM), to study the origin of the degree of agglomeration in caustic MgO and to analyse the effects during the process of sintering [7,8,11,12].

The aim of this work was to study and characterise the physical properties of MgO powders obtained by chemical precipitation from three commercial chemical compounds to be compared with dolomite (natural source from Coahuila, Mexico). Different measurements were carried out at 960°C (the surface area, the primary particle size, the crystallite size and the apparent density) to determine the degree of agglomeration between the different types of precursor. The crystallization of magnesia was studied by X-ray diffraction, and the development of the morphology was observed by SEM.

2. Experimental

Powders of MgO were synthesised by chemical precipitation from four different types of precursors, three of them commercial reagent-grade hydrated salts: $MgSO_4 \cdot 7H_2O$, $MgNO_3 \cdot 6H_2O$ and $Mg(CH_3CO_2)_2 \cdot 4H_2O$ and from the mineral dolomite ($MgCO_3 \cdot CaCO_3$) obtained from Coahuila, Mexico. The chemical analysis of dolomite used in this experiment, measured by X-ray fluorescence with Cr radiation (Diano 8000), indicates a purity of 99.8%. The principal impurities (wt%) were SiO_2 (0.01), Al_2O_3 (0.01), Fe_2O_3 (0.04), Na_2O (0.02) and P_2O_5 (0.03). The purity, for the three reagent-grade salts, taken from the catalogues of the manufacturers (Productos Quimicos Monterrey, SA), was 99.8%.

Each hydrated compound was dissolved in deionized water at room temperature to yield 0.8 M, an excess of ammonium hydroxide (13 M) was added, and vigorously stirred at 50°C, pH 10. A white precipitate of $Mg(OH)_2$ was obtained, which was thoroughly washed with distilled water and dried at 100°C for 2 h. Magnesium hydroxide powders were calcined in Pt crucibles, at different temperatures to produce MgO powders. The heating treatment was carried out in electric furnaces under air atmosphere, from 500 to 1000°C, raising the temperature 100°C every 40 min.

Natural dolomite was initially milled to 200-mesh. The decarbonation procedure was done with a progressive heating from 500 to 800°C, with a stepwise of 100°C every 0.5 h. The sample was held for 2 h and finally the temperature was increased to 900°C (0.5 h) to obtain dolima (MgO·CaO). The hydration of dolima (0.9 M) was made with a vigorously agitation and then it was mixed with a $MgCl_2$ (0.5 M) solution at 50°C, pH 11. Once $Mg(OH)_2$ appeared as a precipitate, it was washed, dried and calcined under the same conditions described above, finally a powder of MgO was obtained.

The decomposition characteristics of the salts and dolomite were determined by simultaneous differential/thermogravimetric analysis (DTA/TGA, TA-Instruments model SDT-2960). The heating rate of the sample was 10°C min^{-1}, with a flowing N_2 atmosphere, using alumina as a reference material. The powders from each calcined treatment were characterised by X-ray diffraction and the crystallite size was calculated using the Scherrer's formula, using KCl as an internal standard. A Cu Kα radiation ($\lambda = 1.5405$ Å) and Ni filter was used. The difractograms were registered in a range of 10–115 2θ (30 kV, 20 mA), in a step-scan mode of 0.01° 2θ per step and counting for 5 s/step (model Siemens D-5000).

MgO apparent density was obtained by the liquid pycnometer method according to ASTM C699, using toluene; several measurements were done until data reproducibility was obtained. The specific surface area and primary particle size of MgO powders was measured by the BET technique (Ströhlein), N_2 as an absorption gas was used. The morphology of $Mg(OH)_2$ and MgO agglomerates at different temperatures were examined by SEM (Leica S440). Powders were pelletized and coated with carbon to avoid charging during exposure to the electron beam and covered with an Au thin film by sputtering in a vacuum system.

3. Results and discussion

The decomposition path of the precipitated, $Mg(OH)_2$, was studied by DTA/TGA analysis. Results obtained from the salts were similar. A very small and a strong endothermic peak was observed; the first peak is related to the dehydration processes at temperatures < 200°C and the second to the decomposition of magnesium hydroxide, the temperature was 420, 310 and 390°C, for sulfate, acetate and nitrate, respectively. Furthermore, sulfate salt shows a continuous weight loss of 7%, between 600 and 920°C. The total weight loss was around 40% (Fig. 1). These results are in good agreement with the ones presented elsewhere [4]. In the case of dolomite, the first endothermic peak was very strong with a weight loss of 13.44 wt% and the decom-

position reaction was held at 370°C with a weight loss of 25.9%; finally at 800°C evaporation of CO_2 occurs (Fig. 1). Therefore, the complete decomposition of the acetate and nitrate can be achieved at reasonably low temperatures (< 450°C); however for the dolomite and sulfate salt this was near 800 and 950°C, respectively.

The X-ray diffraction studies on the crystallisation process for the magnesium salts showed the formation

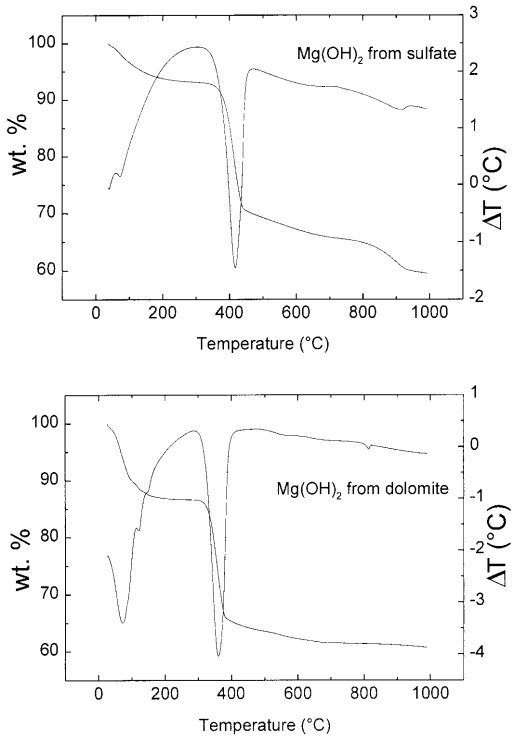

Fig. 1. DTA/TGA of $Mg(OH)_2$ obtained from two different precursors.

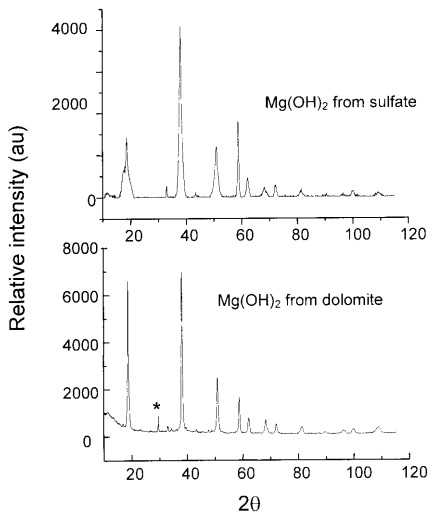

Fig. 2. Comparison of the X-ray diffraction patterns of $Mg(OH)_2$ at 100°C, between sulfate and dolomite. The latest shows the presence of $CaCO_3$ (*).

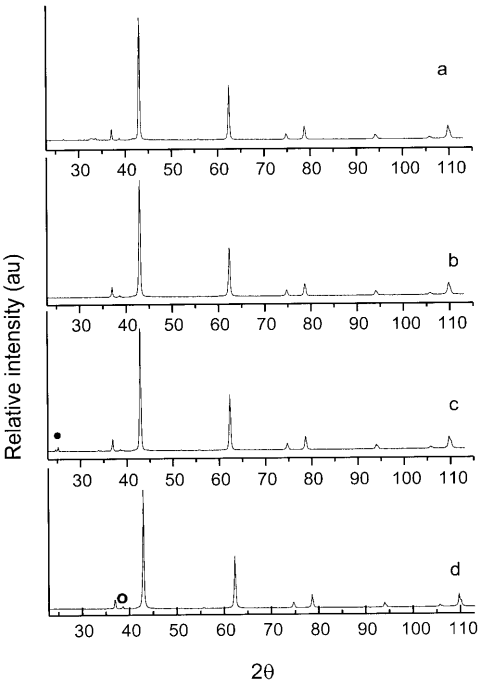

Fig. 3. Diffractograms of MgO powders obtained at 960°C from different precursors: (a) dolomite, (b) nitrate, (c) sulfate, (d) acetate. Traces of $MgSO_4$ (●) and NaF (○) are indicated.

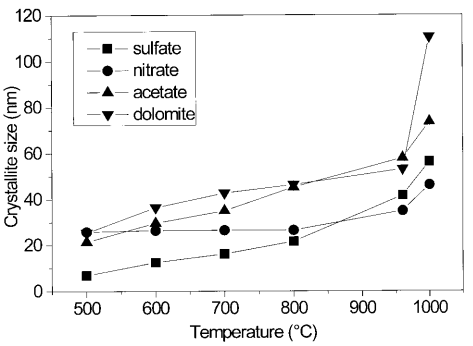

Fig. 4. Development of crystallite size with temperature on the crystallisation of MgO.

of brucite $Mg(OH)_2$ at 100°C with a very poor crystallinity, although dolomite presented stronger diffraction peaks as can be seen in Fig. 2. At higher temperature, crystals of periclase (MgO) were initially detected at 500°C after 40 min, with broad diffraction peaks, which became nice and sharp at 960°C, mainly on dolomite, since it had a higher crystallinity (Fig. 3). Additional diffraction lines were detected, as traces of NaF and magnesium sulfate phases.

Crystallite size was calculated, by means of Scherrer's equation [13] on the (200) diffraction maximum, obtained from the different powders heated 40 min at each temperature (500–1000°C). The behaviour of the crystallite growth with temperature is shown in Fig. 4. The results are very similar for the chemical com-

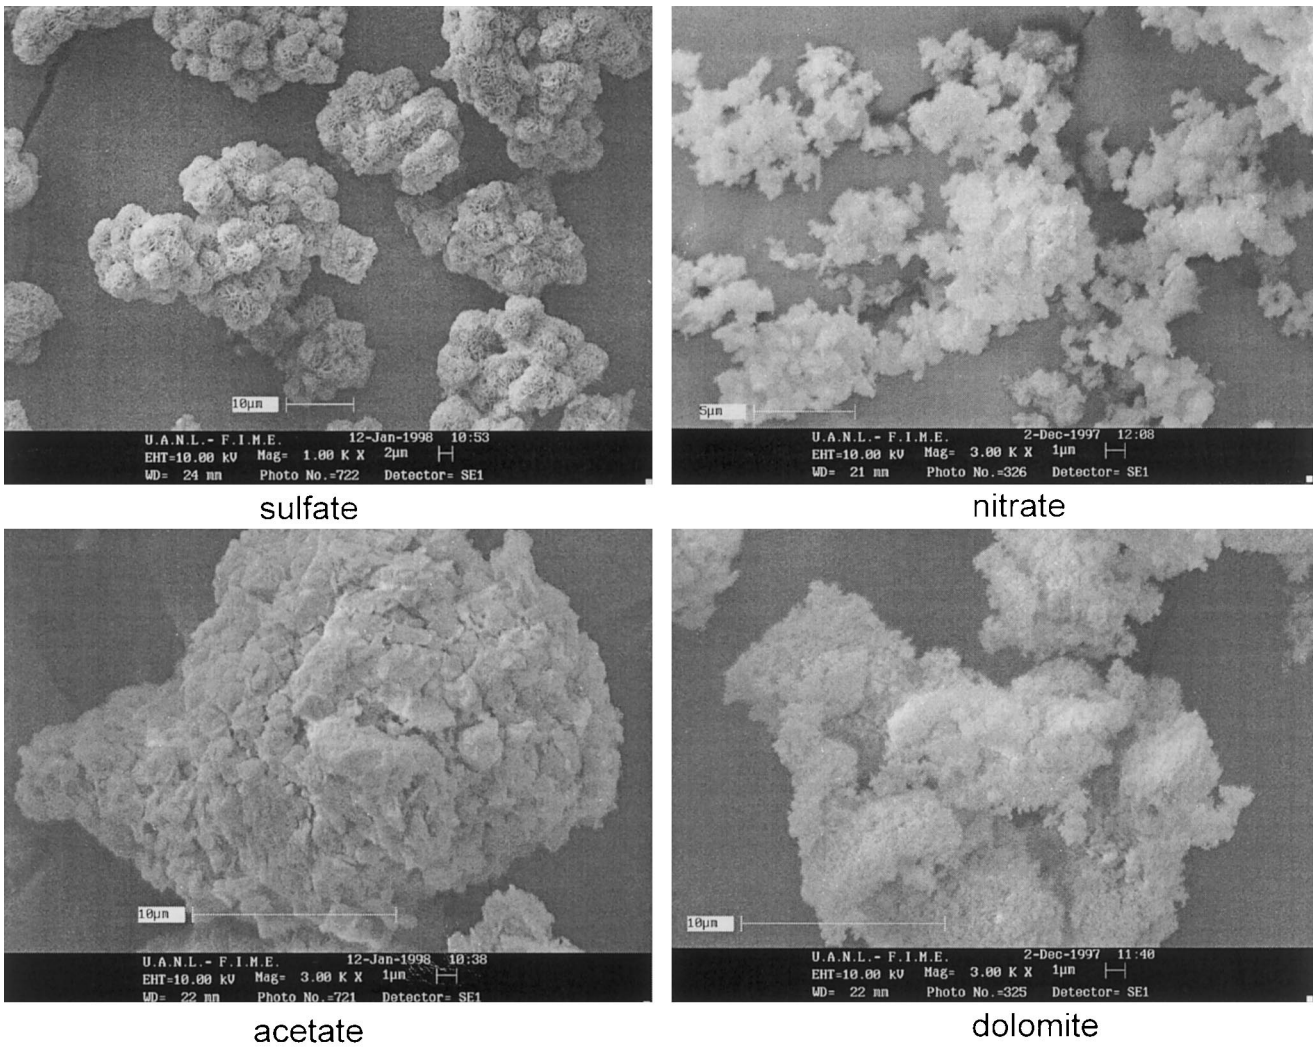

Fig. 5. Microstructure of $Mg(OH)_2$ powders obtained from the different precursors, heated at 100°C for 40 min.

pounds. Near to the decomposition temperature of brucite, the magnesium oxide formed has a very small crystallite size, showing a plateau with a slight increment, and with a crystallite growth of 10–40 nm. On raising the calcination temperature, over 850°C, a rapid increase in the crystallite size occurs; where dolomite had the highest value of 110 nm at 1000°C, which is double the value obtained for the other precursors. These data are in good agreement with the values reported in the literature for oxides prepared from different chemical precursor salts [14,15].

The apparent density measurements determined by pycnometry, ρ_{app}, at 960°C, are shown in Table 1. The density values of sulfate approach the theoretical data of periclase (3.59 g cm^{-3}), meanwhile, dolomite shows the lowest value probably due to the higher crystallite size. It has been reported that it is difficult to obtain high-density magnesia from purified raw materials [11].

Table 1
Physical properties of MgO powders obtained at 960°C (40 min) from different precursors

Precursor	ρ_{app} (g cm^{-3})	ρ_{DRX} (g cm^{-3})	Surface area [a] (m^2 g^{-1})	Surface area (m^2 g^{-1})	G_{BET} (nm)	G_{DRX} (nm)	G_{BET}/G_{DRX}	P_{tot} (%)
Sulfate	3.53	3.576	137.6	64.4	25.9	41.6	0.62	1.3
Nitrate	3.46	3.584	124.2	30.8	54.2	54.9	0.99	3.46
Acetate	3.44	3.581	105.0	28.9	57.7	57.9	0.99	3.94
Dolomite	3.42	3.585	47.3	16.5	101.1	53.1	1.90	4.60

[a] Values obtained for $Mg(OH)_2$ at 100°C, 40 min.

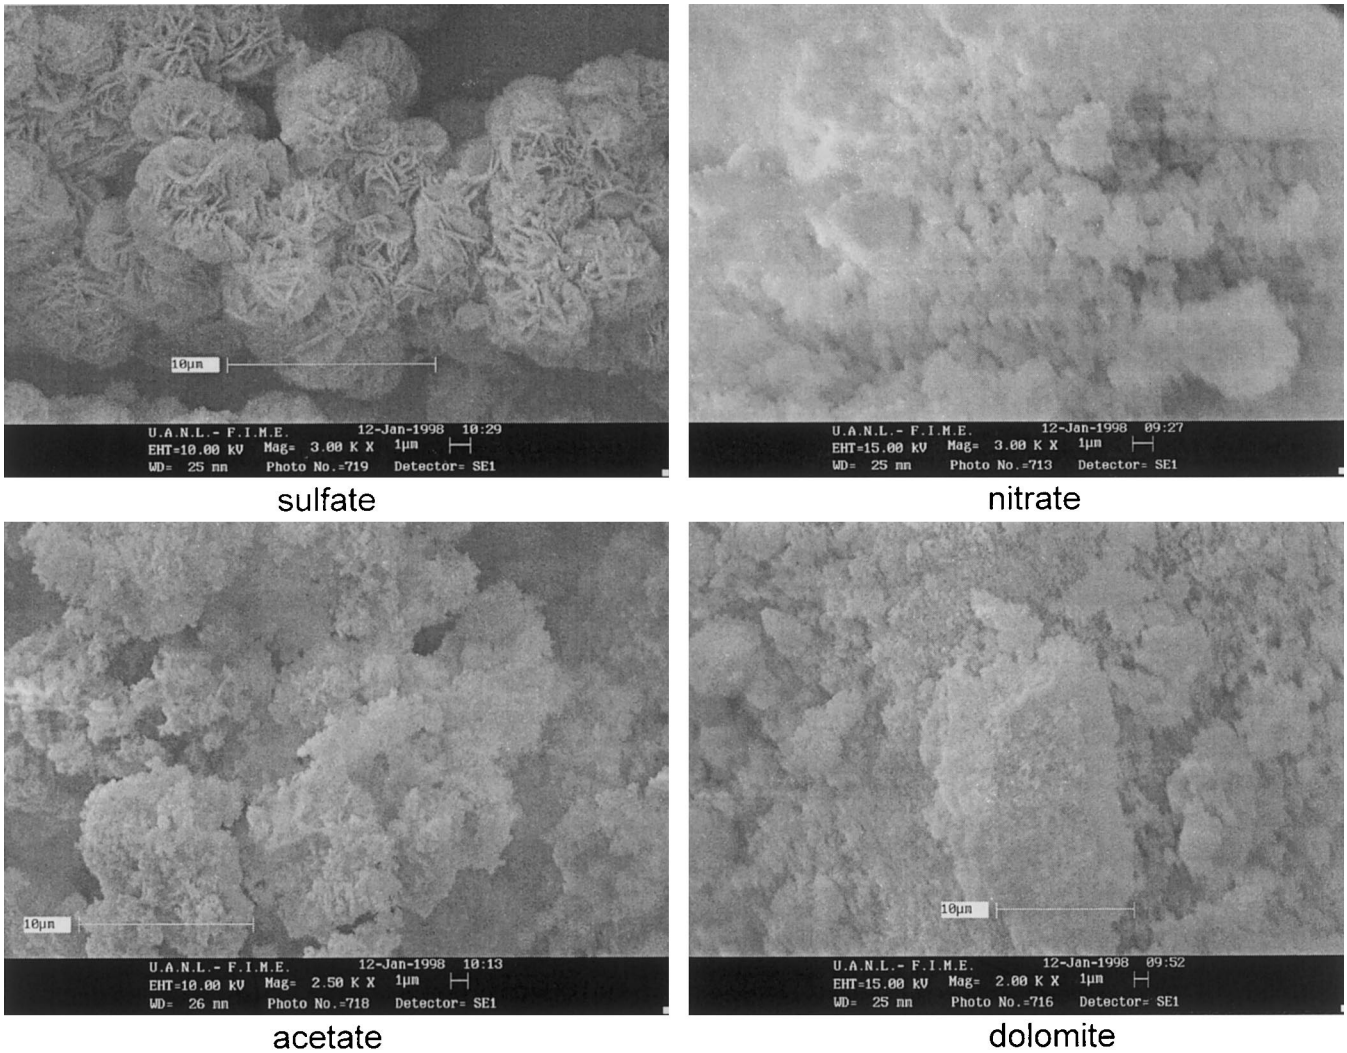

Fig. 6. SEM micrographs of MgO powders at 960°C, showing the formation of agglomerates.

Density from X-ray diffraction data was also calculated, ρ_{XRD} (same as ρ_{true}), using KCl as an internal standard and a least-square refinement program [16] to determine precisely the lattice parameter. The values obtained show good agreement with the theoretical value of periclase.

The percentage of total porosity in the different magnesia samples was calculated from

$$\%P_T = \left(1 - \frac{\rho_{app}}{\rho_{true}}\right) \times 100$$

according to [17], where the highest value was observed on powders derived from dolomite, 4.6%, and the lowest for sulfate, 1.3%. Acetate and nitrate had 3.5% and 3.9%, respectively.

The variation of the specific surface area for brucite and MgO powders can be observed in Table 1. The surface area values were higher for the powders obtained from the reagent-grade salts than those obtained from the mineral dolomite. In all cases MgO had a much lower value than the corresponding $Mg(OH)_2$. The samples obtained from sulfate show the highest values, which agrees with the smallest particle size. Meanwhile, nitrate and acetate show intermediate values. In contrast, the powders prepared from dolomite had values almost four and two orders of magnitude lower than the data obtained for sulfate and from nitrate and acetate, respectively. This effect can be related to the ρ_{app} value, which depends on the utilised precursor and the presence of impurities. The surface area obtained for periclase was in a good agreement with other reports [7,15], < 100 m^2 g^{-1}, but much higher than [14,18] due to the different route of preparation.

The degree of agglomeration G_{BET}/G_{XRD} was obtained from the primary particle size, G_{BET}, determined from the specific surface area, and from the crystallite size, G_{XRD} [8] (Table 1). The lowest agglomeration degree, 0.62, was for the sulfate sample. MgO powders obtained from the nitrate and acetate precursors were

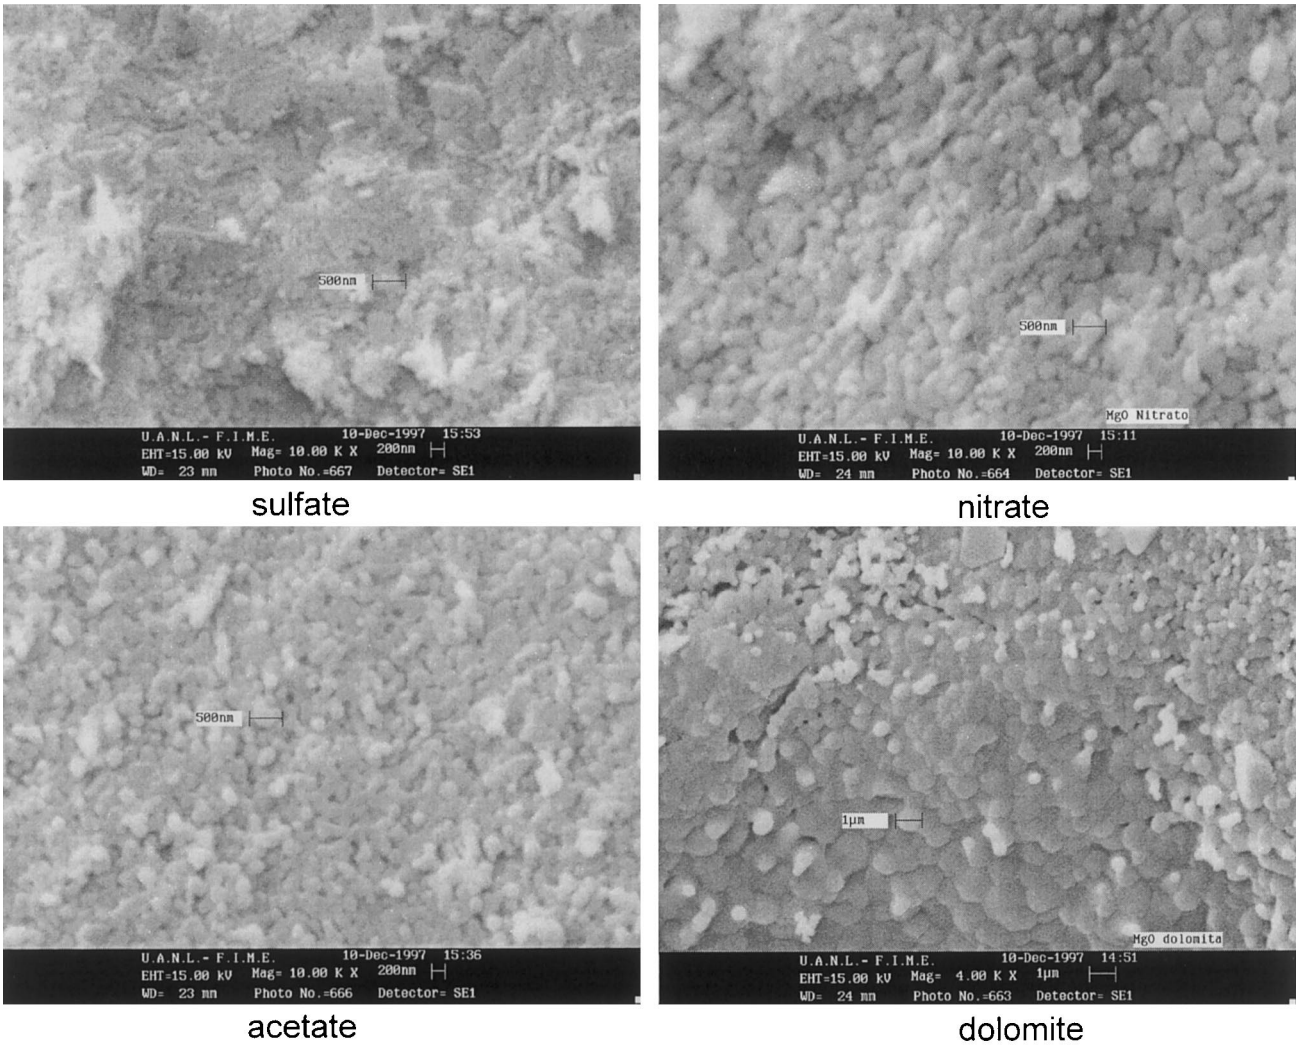

Fig. 7. Microstructure of MgO powders showing the initial stage of sintering at 1200°C (40 min).

nearly at unity, the ideal value, since the crystallite sizes were almost in accord with the primary particle sizes [8]. Meanwhile, the mineral dolomite almost doubles this value to 1.90; similar to the powder derived from the seawater magnesia process [7].

The analysis by SEM, showed the morphology of $Mg(OH)_2$ and MgO powders originating from different calcination temperatures (Figs. 5–7). At 100°C, the brucite phase is observed, which shows microstructural differences for the four precursors (Fig. 5). Samples derived from dolomite and nitrate are formed of small particles consisting of dispersed agglomerates between 5 and 10 μm, and acetate contains flakes forming large agglomerates (30 μm). At 960°C, the periclase powders for these three precursors show the presence of fine particles, less than 1 μm, forming agglomerates with a more homogeneous distribution (Fig. 6). Meanwhile, the microstructure of MgO powders calcined 1 h at 1200°C (Fig. 7), differed significantly from the precipitated hydroxide. The magnesium salt compounds showed the formation of grains with a homogeneous distribution (less than 500 nm), it was also possible to observe the initial formation of necks between particles. However, dolomite powders showed a more inhomogeneous distribution of grains, between 0.5 and 1 μm, with a higher porosity (dark zones between the grains) due to a rapid grain growth, which brings the entrapment of pores.

Magnesium hydroxide derived from sulfate show a plate-like shape, the particles were joined to each other forming spherical particles around 3 μm, which tend to form large agglomerates (30 μm). At higher temperature (960°C), a well-defined plate-like morphology was observed (with a high aspect ratio of length to thickness), which can be related to the periclase phase (Fig. 6); a similar morphology has been reported elsewhere [19]. Also, the particle size increases to 5 μm. A significant change in particle shape was observed at 1200°C, pseudomorph agglomerates were found in the calcined product (Fig. 7).

The powder activity provides the driving force for sintering, and increases with the surface area, thus with a decrease in the particle size. Moreover, a smaller value of G_{BET}/G_{XRD} indicates that the primary particle is composed of softer agglomerations of crystallites [20]. Therefore, magnesium oxide powders derived from sulfate, which showed the highest surface activity, had the softest agglomeration of crystallites among the four powders, as can be seen on the SEM image at 1200°C (Fig. 7).

It has been reported elsewhere [21], that a good densification of aggregates occurs when the growth of crystallites and pores are retarded. Therefore, from the G_{BET}/G_{DRX} data (Table 1), and from the images of SEM at 1200°C, we can conclude that powders from nitrate and acetate show the best physical properties. The mineral dolomite should be easily sintered to high-density bodies, and can be used to produce magnesia (which should be dead-burnt, i.e. chemically inactive) for the manufacture of heavy-duty basic refractories [17].

4. Conclusions

We present a comparative study on the characterisation of different physical properties of MgO powders prepared from three precursor magnesium salts and from the mineral dolomite. The samples were characterised by X-ray diffraction, thermal analysis, N_2 adsorption and SEM.

The samples at low temperatures are composed of brucite, and after 500°C pure periclase appears, where the degree of crystallinity increases with the temperature of calcination. The apparent density and the specific surface area for brucite and periclase show the following decreasing sequence: sulfate > nitrate > acetate > dolomite. Meanwhile, the particle size, the degree of agglomeration and the percentage of the total porosity, present the inverse tendency.

Magnesium powders from sulfate precursors, showed the best approach to the ideal density value, due to their high surface area, and consequently, to their smallest primary particle size. Also, the specific area value can be related to the microstructure of lamellars disposed around a central nucleus.

Microstructure studies showed that powders derived from acetate and nitrate promotes sufficient diffusion of matter into neck regions between individual particles, favouring the initial stage of sintering and a uniform grain growth. This agrees with the values obtained for the degree of agglomeration, which are near to one.

Dolomite had the biggest primary particle size due to it low surface area, therefore the degree of agglomeration is much higher in comparison with the magnesium salts. The rapid growth of crystallite size promotes the entrapment of pores between the grains, which is reflected in the higher total porosity value.

Abstract

The Fourier transform infrared and Raman spectra of solid uranyl bis(2-hydroxybenzaldehyde) were measured in the 4000–70 cm^{-1} region. The fundamental skeletal vibrational modes were assigned by comparison with the spectra of other uranyl complexes. The ligand bands in the complex were assigned with the aid of the infrared spectrum of the 2-hydroxybenzaldehyde calculated by the AM1 semi-empirical method, and with the aid of its experimental infrared absorption bands and Raman shifts. A normal coordinate analysis had been carried out to verify the experimental assignments of the $[UO_2L_2]$ framework. Force constants for the skeletal vibrations of this complex were calculated. The polarized Raman spectrum of 2-hydroxybenzaldehyde is also reported. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Fourier transform infrared and Raman spectra; Uranyl bis(2-hydroxybenzaldehyde); Force constants

1. Introduction

The Raman, resonance Raman and infrared spectra of potassium uranyl croconate were studied by Gonçalves et al. [1]. Recently, the Fourier transform infrared and Raman spectra of solid uranyl bis(2-hydroxy-1-naphthaldehyde) [2], abbreviated as $UO_2(2H1N)_2$, uranyl 2,4-pentanedionate: $UO_2(acac)_2$ [3], uranyl bis(1,3-diphenyl-1,3-propanedionate): $UO_2(HDBM)_2$ and uranyl bis(1,1,1,-trifluoro-2,4-pentanedionate): $UO_2(HBTF)_2$ [4] were studied. Reliable information from spectroscopic analysis on the infrared and Raman spectra of uranyl bis(2-hydroxybenzaldehyde), hereafter known as $UO_2(sal)_2$, is almost nonexistent in literature.

The aim of this paper is to report the Fourier transform infrared and Raman spectra (solid state) of $UO_2(sal)_2$, and to give the experimental assignments of the bands. The band assignments of the crystalline compound were made according the following criteria: (i) Comparison with another published uranyl complexes. (ii) Polarization studies on the Raman spectra of 2-hydroxybenzaldehyde. (iii) AM1 semiempirical calculations [5] were carry out in order to obtain the harmonic infrared spectra of the 2-hydroxy-belzaldehyde. (iv) By means of the correlation $C_{2v} \rightarrow C_s$, the fundamental ligand vibrational modes were identified and assigned. (v) A normal coordinate analysis (NCA) for the skeletal fundamentals assuming a local C_{2v} symmetry was done.

2. Experimental

$UO_2(sal)_2$ was prepared according to the synthesis proposed by Gómez Lara [6]. For the preparation of $UO_2(sal)_2$, stoichiometric quantities of an alcoholic solution of 2-hydroxybenzaldehyde were mixed with an aqueous solution of uranyl nitrate trihydrate, $UO_2(NO_3)_2 \cdot 3H_2O$. The solution was concentrated and was left to chill for crystallization.

The infrared spectrum of $UO_2(sal)_2$ was measured on a Nicolet 740 FT IR spectrometer. In the range of

4000–300 cm^{-1}, KBr pellets were used in the ratio of 1:10 ($UO_2(sal)_2$:KBr). For the 700–70 cm^{-1} range, polyethylene disks were used in the same proportion as above. The spectra were recorded with a resolution of 4 cm^{-1} for the higher region and 1 cm^{-1} for the lower region. The number of scans was 140 in both cases.

The infrared spectra of 2-hydroxybenzaldehyde in the range of 4000–600 cm^{-1} were measured using an FT IR tunnel cell (Axion Analytical). For measurements between 700 and 30 cm^{-1}, a polyethylene cell was used for liquids of 0.1 mm optical length. In this case the spectra were run on an FT IR Perkin–Elmer 2000 spectrometer.

[a] Plazeks rules applies to the depolarization of the fundamental frequencies: $0 < \rho < 6/7$ for totally symmetric modes of molecules of lower symmetry.

The Raman spectra of $UO_2(sal)_2$ and of 2-hydroxybenzaldehyde were measured on a 950 Nicolet FT Raman spectrometer equipped with an InGaAs detector, using 1064 nm radiation from a Nd-YAG laser. The resolution for the Raman spectra was of 2.0 cm^{-1} in both cases. The number of scans was 140.

In $UO_2(sal)_2$, such as in $UO_2(acac)_2$, $UO_2(HBTF)_2$, $UO_2(HDBM)_2$ and $UO_2(2H1N)_2$, the crystals did not exhibit the appropriate size and crystallinity to perform polarization measurement in the solid state. For 2-hydroxybenzaldehyde, the polarization measurements were made at 0 and 90°. The areas for the calculation of the depolarization ratio were obtained using the PEAK SOLVE software from Nicolet [7].

3. Results and discussion

3.1. Vibrational irreducible representation

Assuming a C_{2v} symmetry for the $UO_2(sal)_2$ complex, the $3n - 6 = 87$ vibrational modes can be distributed among the symmetry species:

$$\Gamma_{\text{vib.}} = 30a_1(\text{IR,R}) + 14a_2(\text{R}) + 15b_1(\text{IR,R}) + 28b_2(\text{IR,R})$$

3.2. Band assignments

3.2.1. 2-Hydroxybenzaldehyde ligands

Assuming a C_s symmetry, the vibrational modes can be described by the vibrational representation:

$$\Gamma_{\text{vib.}} = 28a' + 11a''$$

Due to the possibility of rotation of the OH group around the C–O bond, and the possibility of rotation of the –CHO group, four conformers were expected in the liquid state, one of them in *cis* position forming a H···O bond between the –OH and –CHO groups. The other three in the *trans* position.

Previous band assignment for this compound was reported by Radhi et al. [8]. The experimental vibrational assignments, which include Raman polarization measurements, are given in Table 1. The Raman spectra of 2-hydroxybenzaldehyde at 0 and 90° analyzer are shown in Fig. 1.

3.2.2. Infrared and Raman C–H stretching of the benzyl groups

For the $UO_2(sal)_2$ complex the ν(CH)ϕ for the benzyl groups can be divided into $4a_1 + 4b_2$ symmetry types. In the infrared spectrum it was possible to identified absorption bands at ~ 3040 cm^{-1} assigned as ν(CH)ϕ, and at 3010 cm^{-1} assigned as the combination band $1634 + 1379 = 3013$ cm^{-1}. The infrared spectrum for

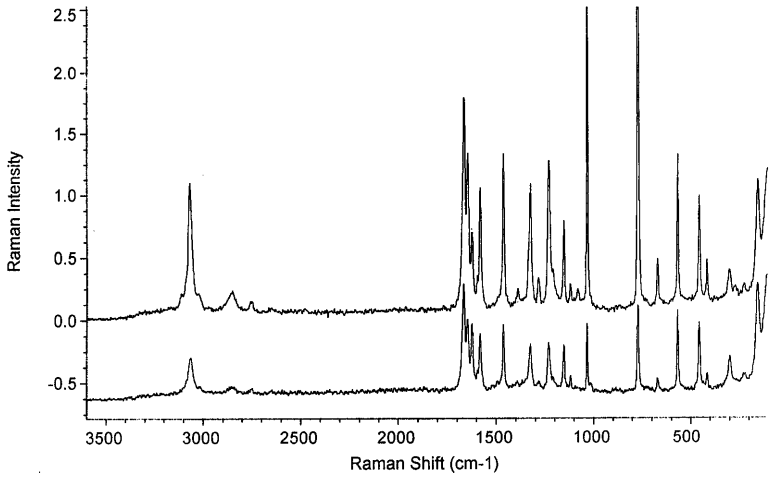

Fig. 1. Raman spectra of 2-hydroxybenzaldehyde at 0 and 90° analyzer (cm^{-1}).

the calculated conformers indicated a shift of approximately 13 cm^{-1} between the *cis* and *trans* C–H benzyl stretching, where the *cis* conformer presents the higher wavenumber. Due to the small number of allowed infrared and Raman active symmetry modes, A and B, and the poor resolution of the infrared spectrum of 2-hydroxybenzaldehyde in the benzyl stretching region, the experimental observed Raman bands were assigned to the calculated AM1 frequencies. In the Raman spectrum, bands of very weak intensity were observed at 3121, 3088, 3082sh, 3063, 3049, 3034, 3025 and 3014 cm^{-1}. In the Raman spectrum of the free ligand 2-hydroxybenzaldehyde, polarized bands at 3111, 3087, 3068 and 3023 cm^{-1} were observed. These bands can be correlated with the experimental and calculated ligand bands in the complex:

ν(CH)ϕ free ligand (C_s)	ν(CH)ϕ complex C_{2v}	AM1(*cis*)	AM1(*trans*)
3111 p (a')		3201 (3066)	3200 (3066)
3087 p (a')	3088 (a_1)	3194 (3060)	3194 (3060)
3068 p (a')	3063 (a_1)	3180 (3046)	3181 (3046)
3023 p (a')	3025 (a_1)	3174 (3041)	3163 (3030)

As can be seen, the AM1 calculated wavenumbers are overvalued. In Hollauer's work [9] on the AM1 model in the prevision of the CH vibrational frequencies, it is pointed out that the error in the AM1 calculated values is 4.2%. The values in parentheses were obtained using the correction proposed by Hollauer [9], and these values agree well with the experimental ones.

The Raman shift at 3121 cm^{-1} appears with very low intensity; for this reason it can be assigned as ν(CH)ϕ as b_2 symmetry type. The other Raman shifts that are assigned to b_2 symmetry are 3049, 3034(sh) and 3014 cm^{-1}.

3.2.3. External C–H stretching

These modes can be represented as $\Gamma_{CH} = a_1 + b_2$ and were observed in the Raman spectrum at 2897 (a_1) and at 2853 (b_2) cm^{-1}. In this case, the assignment of the symmetry type was done according to the intensity of the bands. The AM1-calculated infrared spectrum assigns these stretching at 3085 and 3089 cm^{-1}. The corrected values in 4.2% are 2955 and 2959 cm^{-1}, respectively.

3.2.4. C=O stretching

Due to the presence of four conformers in 2-hydroxybenzaldehyde, four wavenumber values for the ν(C=O) vibrational mode were expected. The infrared spectra shows absorption at 1658, 1635(sh), 1620 and 1598(sh) cm^{-1}. In the Raman spectrum, Raman shifts were found at 1663(p), 1645(dp), 1620(dp) and 1594(dp) cm^{-1}. The 1598(IR) and 1594(R) cm^{-1} wavenumbers can be assigned to the ν(C=O) vibrational mode for the *cis* conformer. The other values correspond to the ν(C=O) modes of the *trans* conformers, for which the AM1 model predict higher values than the *cis* conformer. Concerning the C=O stretching in the uranyl bis(2-hydroxybenzaldehyde) complex, the characteristic C=O wavenumber in the infrared and Raman spectra has a shift going to lower frequencies which must be considered, and by incorporating two 2-hydroxybenzaldehyde ligands to form the complex, the number of C=O stretching was increased.

Assuming a 'benzenoid resonance' structure of the 2-hydroxybenzaldehyde ligands by coordination with the UO_2^{2+} ion, equivalent internal coordinates for the C=O partial double bonds were considered. The vibrational representation for the stretching of these bonds is: $\Gamma_{C=O} = 2a_1 + 2b_2$. For the β-ketoenol complexes of Ni(II), Cu(II) and Zn(II), Thorton [10] assignments for the ν(C=O) vibrational modes were made at 1605, 1577 and 1598 cm^{-1}, respectively. For Pd(II)-acetylaceton-

ate and Cu(II) acetylacetonate the Junge and Musso's [11] assignments for the ν(C=O) stretching were for Pd(II) complex: ν_s(C=O) at 1555 cm^{-1}, ν_{as}(C=O) at 1378 cm^{-1}. For the Cu(II) complex: νs(C=O) at 1578 cm^{-1} and ν_{as}(C=O) at 1397 cm^{-1}. For $UO_2(sal)_2$, the assignments for the ν(C=O) stretching based on the above comparison and considering the intensities of the infrared and Raman bands, are:

ν_s(C=O)(a_1)	ν_{as}(C=O)(b_2)
1339(R)	1618(IR), 1616(R)
1307(IR), 1309(R)	1608(IR), 1600(R)

3.2.5. C=C stretching CCH and CCC bending of the benzene ring

In 2-hydroxybenzaldehyde, the irreducible vibrational representation for the C=C stretching is $\Gamma_{C=C} = 6$ Å. From the Hollauer study [9], in which were analyzed the CC stretching in 46 different molecules including aliphatic and cyclic compounds, the best straight line was defined by the equation $\nu(AM1) = 1.073[\nu(exp)] + 51.5$ with a correlation coefficient of 0.978. Using this equation, the prediction for the C=C stretching experimental wavenumbers is: 1619, 1603, 1507, 1468, 1338 and 1282 cm^{-1}, which gives an excellent basis to assign the experimental values found at: 1580(R), 1570(IR); 1564(IR), 1478(IR), 1458(R), 1452(IR) and 1320(IR), 1323(R) cm^{-1}.

In the uranyl bis(2-hydroxybenzaldehyde) complex, the vibration modes for the C=C stretching, CCH and CCC bending can be classified according to the representations:

$$\Gamma_{C=C} = 6a_1 + 6b_2,\ \Gamma_{CCH} = 4a_1 + 4b_2 \text{ and } \Gamma_{CCC} = 3a_1 + 3b_2$$

In benzene, wavenumbers between 1606 and 1028 cm^{-1} were assigned to the coupled modes Q(CC) + β(CCH) [12]. Higher contributions of the ΔQ(CC) internal coordinates in the coupled normal modes must be in the approximate region of 1650–1450 cm^{-1}. In the region of 1400–1000 cm^{-1} the contribution of the $\Delta\beta$(CCH) bending internal coordinates is higher [12].

For the coupling stretching and bending modes of the benzene rings, the approximate assignments were made observing the intensities of the bands in the infrared and Raman spectra. The principal contribution of the ΔQ(C=C) internal coordinates for the ν(C=C) coupled vibrational modes (wavenumbers in cm^{-1}) were found at: 1658(IR), 1665(R)(a_1); 1643(R)(a_1); 1635(IR) shoulder, 1634(R)(a_1); 1547(IR)(higher transmittance), 1540(R)(b_2); 1532(IR)(higher transmittance), 1537(R)(b_2); 1518(IR)(b_2); 1464(IR), 1461(R)(a_1); 1428(IR)(b_2); 1403(IR), 1402(R)(a_1) and 1392(IR)(b_2).

Analyzing the CCH bending in the uranyl complex, the AM1 calculated spectra for the ligand 2-hydroxybenzaldehyde was taken into account. The vibrational irreducible representation for the ligand CCH bending is $\Gamma_{CCH} = 4$ Å. The calculated AM1 wavenumbers were corrected by 8% according the suggestion given in [9]. The results in cm^{-1} units were:

AM1 (calculated)	AM1 8% corrected value	Experimental
1326	1220	1228
1285	1182	1205
1191	1096	1116
1173	1079	1076

With these results there was a basis for assigning the CCH bending in the uranyl complex, in which eight β(CCH) coupled modes were expected.

For the CCH bending or in plane β(CCH) vibrational coupled modes in the uranyl complex, the assignments are 1295(R)(a_1); 1270(IR)(b_2); 1244(IR), 1247(R)-(a_1); 1198(IR) (higher transmittance), 1200(R)(b_2); 1184(IR), 1191(R)(a_1); 1158(IR) (b_2); 1148(IR) 1147(R)-(a_1); 1033(R)(a_1).

In 2-hydroxybenzaldehyde, three γ(CCC) internal angle ring deformation of type symmetry were expected (from six internal coordinates, which represent these bending, three of them are redundant). The AM1 calculated wavenumber for these vibrational modes in the *cis* 2-hydroxybenzaldehyde were 692, 606 and 494 cm^{-1}. The experimental wavenumbers for the γ(CCC) bending were assigned at 754(IR), 768(R, p); 563(IR), 564(R, p); and 451(IR), 452(R, p).

The γ(CCC) bending modes in the complex were assigned at 760(IR), 768(R)(b_2); 584(IR), 586(R)(a_1) and 474(IR)(b_1) cm^{-1}.

3.2.6. Out of plane vibrational modes ρ(CH) and χ(CCCC) of the benzene rings

For the free ligand four ρ(CH) and three χ(CCCC) out of plane vibrational modes were expected. The AM1 calculated wavenumbers for the ρ(CH) modes in the *cis* 2-hydroxybenzaldehyde, were 1002, 969, 915 and 813 cm^{-1}. The torsion modes were ascribed at 712, 494 and 444 cm^{-1}. In the uranyl bis(2-hydroxybenzaldehyde) complex, these vibrational modes can be worked out according to the following symmetries: $\Gamma_{\rho(CH)} = 4a_2 + 4b_1$ and $\Gamma_{\chi(CCCC)} = 3a_2 + 3b_1$. The tentative assignment given in Table 2 for the out of plane bending is based on the previous $UO_2(2H1N)_2$ assignment [2] and by comparison with the assignment given through the semi-empirical AM1 calculations. The coupling vibrational modes between the ligands and the UO_2^{2+} ion are also given in Table 2.

Table 2
Infrared and Raman spectra of uranyl bis(2-hydroxy-benzaldehyde) (cm^{-1}) [a]

[a] Values for the intensity of the infrared and Raman spectra are expressed in $\%T$ and irradiance, respectively. For the Raman spectrum the intensities of the bands were scaled to the most intense band to which the value of 10 was assigned, corresponding to 16.39×10^{-3} (watts cm^2 per cm^{-1}) of irradiance.

3.2.7. U=O and U–O stretching modes

These vibrational modes can be represented as: $\Gamma_{UO}=3a_1+b_1+2b_2$, which can be subdivided as $\Gamma_{U=O}=a_1+b_1$ and $\Gamma_{U-O}=2a_1+2b_2$. In an earlier work, the band assignments for the framework vibrations of $UO_2(acac)_2$ [3], $UO_2(HBDM)_2$, $UO_2(HBTF)_2$ [4] and $UO_2(2H1N)_2$ [2] were reported. In all these cases, the axial strong bands pertaining to the ν_{as}(U=O) vibrational modes, were found at 926, 921, 908 and 920 cm^{-1}, respectively. In $UO_2(sal)_2$ the ν_{as}(U=O) was assigned to the strong infrared band at 924 cm^{-1} of b_1 symmetry type. The two b_2 equatorial U–O stretching were assigned at 544(IR,R) and 463(IR,R) cm^{-1}. The Raman shifts at 443 and at 433 cm^{-1} were assigned as ν_s(U–O) equatorial (a_1). As expected, these bands are more intense than their counterparts in the infrared spectrum. The ν_s(U=O) axial was assigned at 834(R)(very strong)–830(IR)(very weak) cm^{-1}.

3.2.8. Axial λ(OUO), and equatorial ω(OUO) and α(OUO) bending vibrations

For uranyl bis (2-hydroxy-1-naphthaldehyde),UO_2-$(2H1N)_2$, a C_{2v} symmetry was assumed [2]. In this complex, the axial and equatorial bending vibrations can be worked out according to the following representations:

$$\Gamma_{bend}=3a_1(IR,R)+2a_2(R)+2b_1(IR,R)+2b_2(IR,R)$$

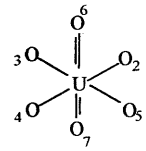
Valence force constants [a]

$f_{(U=O)} = 6.54 \pm 0.06$	$f_{(U-O)} = 1.98 \pm 0.02$	$f_{(OUO)axial} = 0.54 \pm 0.01$
$f_{(OUO)eq.} = 1.14 \pm 0.04$	$f_{(OUO)eq.} = 1.28 \pm 0.06$	$f_{(U=O,U=O)} = -0.08 \pm 0.05$
$f_{(U-O,U-O)ad} = -0.26 \pm 0.01$	$f_{(U-O,U-O)op.} = -0.03 \pm 0.01$	$f_{(OUO,OUO)} = -0.25 \pm 0.01$
$f_{(OUO,OUO)} = 0.36 \pm 0.02$	$f_{(OUO,OUO)eq.} = 0.37 \pm 0.04$	$f_{(OUO,OUO)eq.} = 0.46 \pm 0.02$
$f_{(U=O,OUO)} = -0.38 \pm 0.04$	$f_{(U=O,OUO)} = -0.06 \pm 0.23$	$f_{(U=O,OUO)} = -0.60 \pm 0.31$
$f_{(U-O,OUO)} = -0.02 \pm 0.04$ [a]		

[a] The units are: stretching force constants in (mdyn $Å^{-1}$), bending force constants in (mdyn Å). Stretch-bending interaction in (mdyn).



These bending can be subdivided as: $\Gamma_\lambda = a_1 + 2a_2 + 2b_1 + b_2$ (axial bending), $\Gamma_\omega = a_1$ and $\Gamma_\omega = a_1 + b_2$ (equatorial bending). For uranyl bis (2-hydroxybenzaldehyde), $UO_2(sal)_2$, the same structural framework can be considered as in $UO_2(2H1N)_2$. The wavenumbers correlation between these two complexes is:

$UO_2(2H1N)_2$ (C_{2v})	→	$UO_2(sal)_2$ (C_{2v})
260 (a_1)		278 (a_1)
251 (a_1)		246 (a_1)
198 (a_1)		187 (a_1)
273 (a_2)		223 (a_2)
246 (a_2)		216 (a_2)
216 (b_1)		218 (b_1)
140 (b_1)		198 (b_1)
243 (b_2)		261 (b_2)
		223 (b_2)

The Raman spectrum of $UO_2(sal)_2$ is illustrated in Fig. 2. Infrared and Raman spectra of $UO_2(sal)_2$ in the wavenumber region of 700–70 cm^{-1} are given in Fig. 3.

4. Normal coordinate analysis

A normal coordinate analysis for the framework structure of uranyl bis (2-hydroxybenzaldehyde) was carried out to aid the assignment of the observed wavenumbers. The skeletal structure and the internal coordinates can be described as:

	i	j		i	j	k		i	j	k
$\Delta(Q_1)$	1	6	$\Delta(\lambda_1)$	2	1	6	$\Delta(\lambda_7)$	4	1	7
$\Delta(Q_2)$	1	7	$\Delta(\lambda_2)$	3	1	6	$\Delta(\lambda_8)$	5	1	7
$\Delta(R_1)$	1	2	$\Delta(\lambda_3)$	4	1	6	$\Delta(\omega_1)$	2	1	5
$\Delta(R_2)$	1	3	$\Delta(\lambda_4)$	5	1	6	$\Delta(\omega_2)$	3	1	4
$\Delta(R_3)$	1	4	$\Delta(\lambda_5)$	2	1	7	$\Delta(\alpha)$	4	1	5
$\Delta(R_4)$	1	5	$\Delta(\lambda_6)$	3	1	7				

Geometrical parameters, which describe the framework structure of $UO_2(sal)_2$, were taken from the work of Zabokrzycka et al. [13]. The two pair of opposite planar angles OUO were chosen to be 87 and 93°. A modified general valence force field (MGVFF) potential function was used. The initial set of force constants to be refined was transferred from the force field values of $UO_2(2H1N)_2$ [2]. Force constants were adjusted to give the best wavenumber fit by a least-square procedure developed by Miyazawa [14] and Shimanouchi [15], using computer programs which have been reported previously [16]. The final valence force constants for the U=O and U–O bonds are $f_{(U=O)} = 6.54 \pm 0.06$ mdyn $Å^{-1}$ and $f_{(U-O)} = 1.98 \pm 0.02$ mdyn $Å^{-1}$. The experimental result of 6.54 mdyn $Å^{-1}$ reflects a lowering of the axial electron density through the effect of coordination with the salicylaldehyde ligands. The value of 1.98 mdyn $Å^{-1}$ is higher than the values found for $UO_2(acac)_2$, $UO_2(HBTF)_2$ and $UO_2(HDBM)_2$: 1.72, 1.71, and 1.95 mdyn $Å^{-1}$, respectively. A value of $f_{U=O} = 2.36$ mdyn $Å^{-1}$ was found for $UO_2(2H1N)_2$. The values of 1.98, 1.95 and 2.36 mdyn $Å^{-1}$ for the $UO_2(sal)_2$, $UO_2(HDBM)_2$ and $UO_2(2H1N)_2$ complex, reflect the resonance effect with the equatorial U–O bonds. The uranium–oxygen bond order can be calculated by Gordy's equation [17]: $N_{UO} = (f - 0.30)/(1.67[\chi_U \chi^2_{O/d}]^{3/4})$, where f is the U–O force constant,

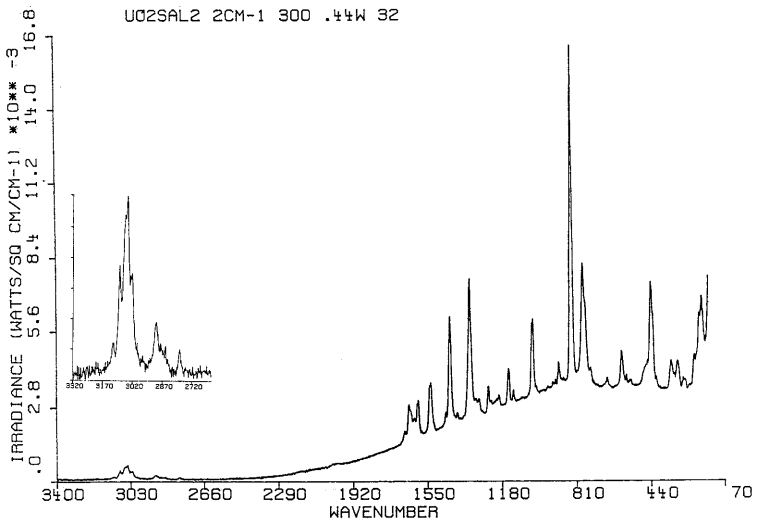


Fig. 2. Raman spectrum of uranyl bis (2-hydroxy-benzaldehyde) (cm^{-1}).

N_{UO} is the bond order, d is the U–O length and χ_U and χ_O are the U and O atom electronegativities. Using the Allred and Rochow [18] and Mulliken [19] electronegativities, the bond order for the U–O bond in $UO_2(sal)_2$ are 0.77 and 0.76, respectively.

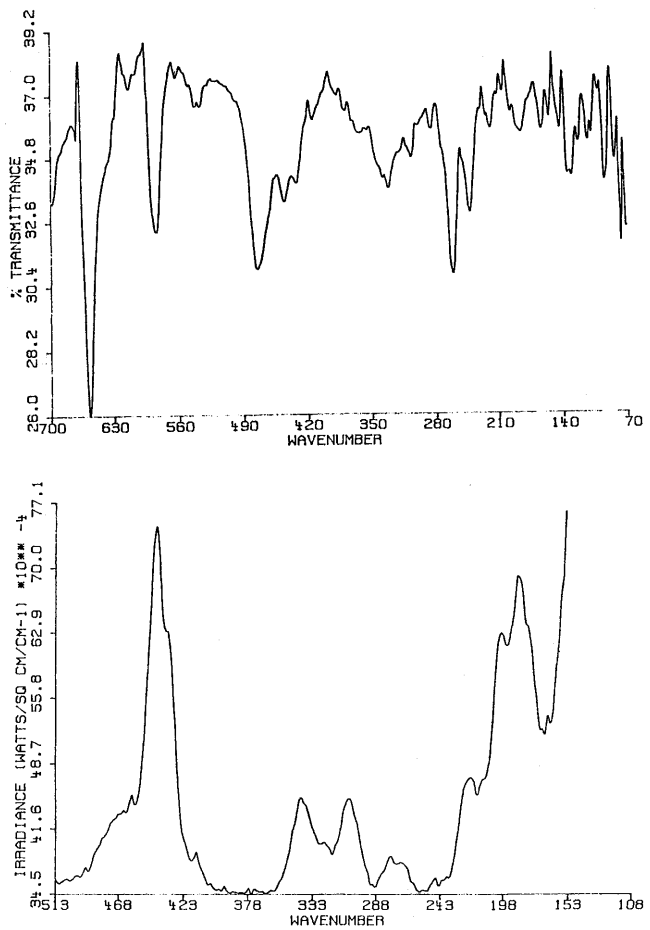

Fig. 3. Infrared and Raman spectra of uranyl bis (2-hydroxy-benzaldehyde) in the wavenumber region between 700 and 70 cm^{-1}.

According to the potential energy distribution (PED) results, there is no coupling between the ν(U=O) and ν(U–O) stretching modes in the a_1 symmetry types, and they can be considered as pure vibrational modes. In the a_1 symmetry type, coupling was found between the different equatorial angle bending and the axial bending mode appears without coupling. For the a_2 symmetry types, the two axial bending (represented as dependent internal coordinates) are coupled. For the b_1 symmetry type, PED reveals that the ν_{as}(U=O) is a pure vibrational mode. The axial bendings in this symmetry type are coupled to each other. In the b_2 symmetry type, the two ν(U–O) stretching modes, can be considered without coupling. For the bending vibrational modes the coupling is almost of 10% between them. The observed and calculated wavenumbers and the valence force constants are presented in Table 3.

Abstract

Neutral copper complexes of different composition (CuL^1_2 and CuL^2OAc) and structure were obtained by coupling the 1-phenyl(isopropyl)-3-methyl-4-(*N*-substituted)aldimino-5-oxy(thio,seleno)pyrazoles (HL^1),and2-hydroxy(tosylamino)-*N*-(8-quinolyl)benzaldimine (HL^2) with copper(II) acetate. According to X-ray structural data, the CuL^1_2 complexes possess the pseudotetrahedral structure, and the CuL^2OAc complexes, the square-pyramidal one. The complexes were studied by EXAFS spectroscopy. EXAFS spectral data on the nearest ligand environment show a good correlation with the X-ray structural results. © 2000 Elsevier Science B.V. 1. Introduction

Copper chelates with an N,S,O-ligand environment are of permanent interest as models to interpret special structural, spectral, and electronic properties of the active centers of 'blue' copper proteins [1–4]. Despite the fact that such complexes have been profoundly studied [1–15], the number of adequate models, describing unusual properties of 'blue' ensymes, is limited. At present, the biomimetic copper complexes on the basis of tris-pyrazolylborate ligand systems, reported by Kitajima et al. [16–19] are the only example modeling the main peculiarities of copper center of the type I.

Structures of some complexes (**IId**, **IV**, **V**) were determined by X-ray spectroscopy.

2. Experimental

2.1. Physical measurements

The Cu K-edge absorption spectra were measured at room temperature in transmission on a laboratory XAFS spectrometer [20] with a focussing quartz crystal-monochromator (1340). Fourier transform of the EXAFS spectra was carried out in the interval of wave vector of photoelectrons from $k = 2.5$ to 12.5 $Å^{-1}$, with weight function k^2. The square filter window isolated the significant Fourier transform peaks, which were then back-transformed into k-space. The best-fit distances (R), coordination numbers (N) and Debye–Waller (DW) factors were obtained from multishell fit in k-space using the back-scattering amplitude and the total phase shift calculated by the program FEFF7 [21]. In the least-squares fitting, the residual minimized and reported is $Q^2 \equiv (1/N)\Sigma k^2(\chi_I^{theor} - \chi_i^{exp})^2$ where the sum is over N data points of $k^2\chi$ between $K = 2$ and 12.5 $Å^{-1}$. The estimated uncertainty of best-fit experimental spectra to the model was less than 3%; that corresponds to an experimental error of interatomic distances and DW of 0.02 Å and 0.0005 $Å^2$, respectively.

2.2. Synthesis of ligands and complexes

The synthesis of aminomethylene derivatives **Ia**–**d** [13,15,22,23] and azomethines **IIa**,**b** [24] was carried out by interaction of ethanol or ether (0.01 M) solutions of the corresponding aldehydes with ethanol solutions (0.01 M) of amines. Solvents were purified by standard methods and distilled under argon atmosphere before use.

2.2.1. Complex *IIIa*

Hot methanol solution of copper acetate (0.1 g, 0.5 mmol) was added to hot methanol solution of the compound **Ia** (0.291 g, 1 mmol). The mixture was refluxed for 10–15 min. The brown crystalline solid formed is filtered, washed with hot ethanol and then with ether and dried in vacuo. (Yield 65%). Analytical data: Calc. for $C_{36}H_{32}N_6O_2Cu$: C, 66.70; H, 4.98; N, 12.97. Found: C, 66.43; H, 4.57; N, 12.65%.

2.2.2. Complexes *IIIb [15]*, *IIId [13]*, *IV*, *V [24]*

These were prepared according to the procedure described above.

2.2.3. Complex *IIIc*

An ethanol solution of copper acetate (0.1 g, 0.5 mmol) is added to hot ethanol solution of Ic (0.35 g, 1 mmol) by stirring under an argon atmosphere (0.35 g, 1 mmol). The mixture was refluxed for 5 min. The crystals formed were filtered, washed with ethanol and recrystallized from a toluene–heptane mixture. (Yield 78%). Analytical data: Calc. for $C_{36}H_{32}N_6Se_2Cu$: C, 56.14; H, 4.19; N, 10.91. Found: C, 55.95; H, 3.99; N, 10.72%.

3. Results and discussion

As expected, aminomethylene derivatives of 5-oxy(thio, seleno)pyrazole **Ia**–**d** in chloroform solution [25,26] have an enamine structure with a strong hydrogen bond NH···X. This is confirmed by the presence of doublet signals of NH group protons in the area $\delta =$ 13–15 ppm with $^3J_{NHCH} = 11$–14 Hz in their ^{1}H NMR spectra.

Structural data for the nearest environment of copper atoms in the chelates **IIIa**–**d**, **IV** and **V** were obtained using EXAFS spectroscopy. The Fourier transform magnitudes (FTM) of EXAFS spectra of the chelates **IIIa**–**d**, **IV**, **V** are shown in Fig. 1. Structural data obtained from fitting are presented in Table 1.

As is seen in Fig. 1, the main features of the FTM of complex **IIIa** include a large peak at $r = 1.6$ Å with a shoulder, corresponding to the first coordination sphere (CS) from light atoms N/O. This CS can be modeled well, when a copper atom in **IIIa** is surrounded by two oxygen atoms and two nitrogen atoms. The CS radii of

[a] The magnitude Q characterizes of quality of fit.

Cu–O and Cu–N are $R_O = 1.96$ Å and $R_N = 2.05$ Å, respectively (Table 1).

An additional peak with high r and higher amplitude in comparison with the peaks, corresponding to the CS of the light atoms N/O, is present in FTM of both **IIIb** and **IIId**. This additional peak is caused by the appearance of heavier sulfur atoms in the nearest environment of copper atoms. Very similar fits were obtained for both samples **IIIb** and **IIId** (Table 1). In the EXAFS analysis the CS can be simulated with two nitrogen atoms at $R_N = 1.97$–2.00 Å and two sulfur atoms at $R_S = 2.25$–2.27 Å. Thus, there is a good match between the distances derived from the EXAFS fit and those found in the crystal structure ($R_N = 1.982$ Å and $R_S = 2.2497$ Å) for **IIIb** and **IIId** (Table 1).

The FTM of **IIIc** is characterized by a further shift of the second main peak to a higher r, which is caused by the exchange of two sulfur atoms in the nearest environment of copper atoms by two selenium atoms. The distances of approximately 2.46 Å, obtained by the EXAFS fit, are typical for Cu–Se bonds [28].

The FTM EXAFS spectra of the complexes **IV** and **V** are shown in Fig. 2. Comparing them, two main differences are seen: slight changes in the position of the second and the third peaks and the appearance of a new peak with $r = 3.25$ Å in the FTM of **V**. The chosen model for **IV** with the coordination of the two oxygen atoms of the acetate group and three nitrogen atoms of the organic ligand to Cu atom allowed the best fit to be obtained. The structural parameters for complexes **IV** and **V** are shown in Table 1. The presence of a more distant carboxylate oxygen O* is typical for coordination of acetate groups [29]. The peaks in the area with

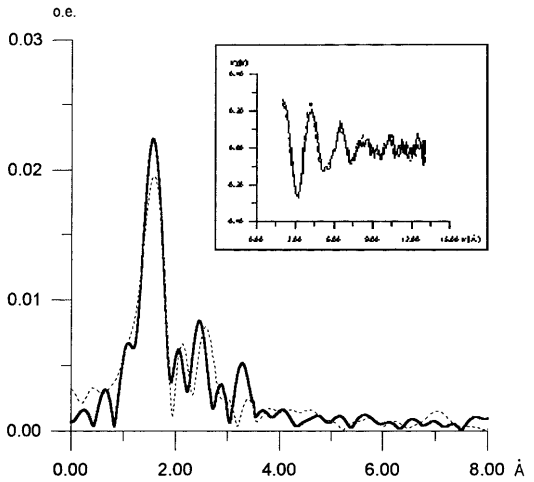

Fig. 2. FTM of the Cu K-edge EXAFS of the complexes **IV** (dash line) and **V** (solid line). The corresponding $k\chi(k)$ are shown in the insertion.

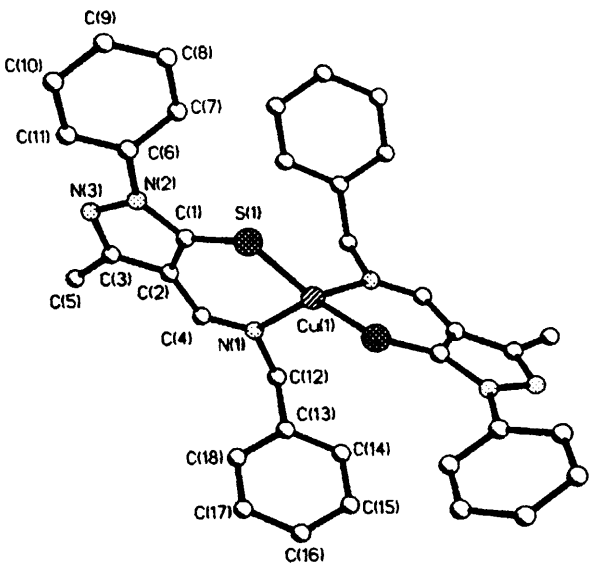

Fig. 3. Molecular structure of complex **IIIb**.

$r = 2.14$–2.16 Å which present in the FTM of both samples correspond to the distances $R_0* = 2.58$ Å for **IV** and $R_0* = 2.54$ Å for **V** (Table 1). This model was refined by the addition of a shell of five carbon atoms at $R_c = 2.96$–3.02 Å.

The most interesting feature in the FTM of complex **V** is the new peak at $r = 3.2$ Å. While it was also possible that this peak corresponds to the outer shells from carbon atoms of the azometnine ligand, the best fit was with the inclusion of the Cu–Cu interactions at $R = 3.53$ Å. The increase in the lower integration limit in the Fourier analysis (k_{min}) from 2.5 to 6.0 Å also shows that this outer shell consists of heavy atoms. This model is a good match with data found in the crystal structure for complex **V**.

Table 2
Selected bond lengths (Å) and valence angles (°) for complexes **IIIb**,**d**, **IV** and **V** according to the X-ray results

Complex	Bond	Å	Angle	°	Ref.
IIIb	Cu–S	2.2497(14)	S(1)CuN(1)	100.74(9)	[15,27]
	Cu–N	1.982(3)	S(1)CuS(1′)	98.47(6)	
			N(1)CuN(1′)	94.8(2)	
IIId	Cu–S	2.230(1)	S(1)CuN(1)	100.2(2)	[13]
	Cu–N	1.982(5)	S(1)CuS(1′)	90.92(8)	
			N(1)CuN(1′)	100.3(2)	
IV	Cu–N(1)	1.982(3)	N(1)CuN(2)	82.8(2)	[24]
	Cu–N(2)	1.990(4)	N(2)CuN(3)	162.7(2)	
	Cu–N(3)	1.952(4)	N(1)CuN(3)	90.3(2)	
	Cu–O(3)	1.949(3)	N(2)CuO(3)	91.5(2)	
	Cu–O(4)	2.646(5)	N(1)CuO(3)	162.6(2)	
			N(3)CuO(3)	99.4(2)	
			O(3)CuO(4)	54.9(2)	
V	Cu–O(1)	1.969(4)	O(1)CuO(1′)	79.2(2)	[24]
	Cu–O(3)	1.900(5)	O(1)CuO(3)	90.4(2)	
	Cu–N(1)	1.969(5)	O(1)CuN(1)	175.2(2)	
	Cu–N(2)	1.987(5)	O(1)CuN(2)	93.2(2)	
	Cu–O(1′)	2.528(4)	O(3)CuN(2)	172.6(2)	
			O(3)CuN(1)	93.2(2)	
			N(1)CuN(2)	83.5(2)	
			CuO(1)Cu	100.8(2)	

According to EXAFS fit, the Cu–Cu distance is $r = 3.53$ Å, which is typical for such bridges in natural metalloproteins [30].

Structures of some complexes were refined by X-ray structural analysis.

Among the compounds **IIIa**–**d**, **IV**, **V**, the complexes **IIIb**–**d** are of special interest, since they are the first representative compounds [1–13] of chalcogen-containing azomethinic metal chelates Cu(2+) with an open structure, which was determined by X-ray single-crystal diffraction [13,15]. In these chelates, a copper atom is in an *pseudo*-tetrahedral ligand environment N_2X_2, where X = S (complexes **IIIb**, Fig. 3, Table 2; **IIId**, Fig. 4, Table 2), X = Se (complex **IIIc**). Two planes NCuX of different metal cycles form dihedral angle **IIIb** 60.5° [15], **IIIc** 59.6°(preliminary X-ray single-crystal diffraction data), **IIId** 57.6° [13], respectively. Bond lengths of Cu–N and Cu–S (Table 2, Figs. 3 and 4) are 1.98 and 2.25 Å, respectively, similar to other tetracoordinate copper(II) chelates with an N,S-ligand environment [14]. The Cu–N distance in 'blue' copper proteins is 1.99–2.15 Å, the Cu–S distance is 2.07–2.17 Å [2,4], which is considerably shorter than those for reported biomimetic complexes [4]. The only example of model compounds, where it has been possible to register the same short bond length of Cu–S, is tris-pyrazolylborate copper complexes [16–19].

Due to the presence of the pyridyl fragment of the nitrogen atom in the complex **IIId**, it is possible to suppose the participation of the N-atom of the pyridine cycle in the formation of an additional bond. However, according to X-ray data (Table 2, Fig. 4), a nitrogen atom of a pyridine group does not form additional bonds with the copper atom and does not take part in intermolecular interactions [13]. In contrast to **IIId**, there is an additional coordination of the heterocyclic nitrogen atom in the compounds **IV** and **V**, which allows the expansion of a number of biomimetic copper complexes [3,15,27].

According to X-ray data (Table 2, Fig. 5) [23], the coordination polyhedron of **IV** is a tetragonal pyramid. The tridentate ligand is connected with the copper atom by means of three nitrogen atoms; together with the oxygen atom O(3) of the acetate group, this

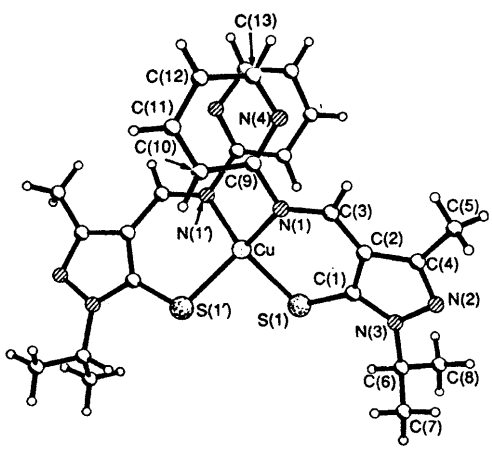

Fig. 4. Molecular structure of complex **IIId**.

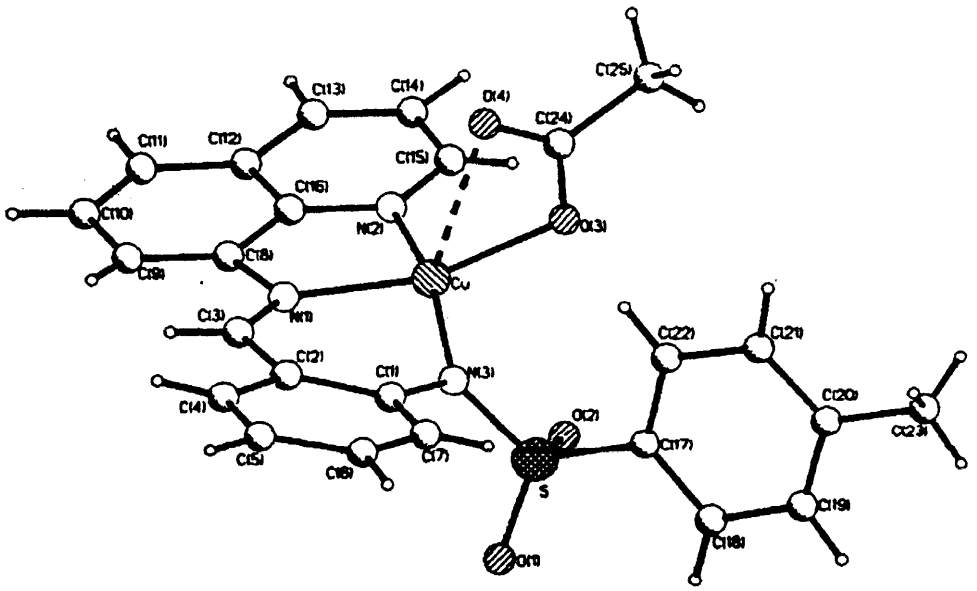

Fig. 5. Molecular structure of complex **IV**.

ligand forms an equatorial plane of a tetragonal pyramid. The apical top of this pyramid is occupied by the oxygen atom with a distance Cu–O(4) = 2.645 Å, which is slightly elongated, according to the Jahn–Teller effect. The base of the pyramid is tetrahedrally distorted: the deviation of the atoms from least-square plane is ±(0.24–0.28 Å).

As was shown by the results of X-ray structural investigation complex **V** possesses a dimeric structure which consists of two square-planar CuN_2O_2 coordination units connected one to another by the far Cu–O′ interaction. So the coordination polyhedron at the Cu atom is a square pyramid with a long apical bond (Fig. 6) [24].

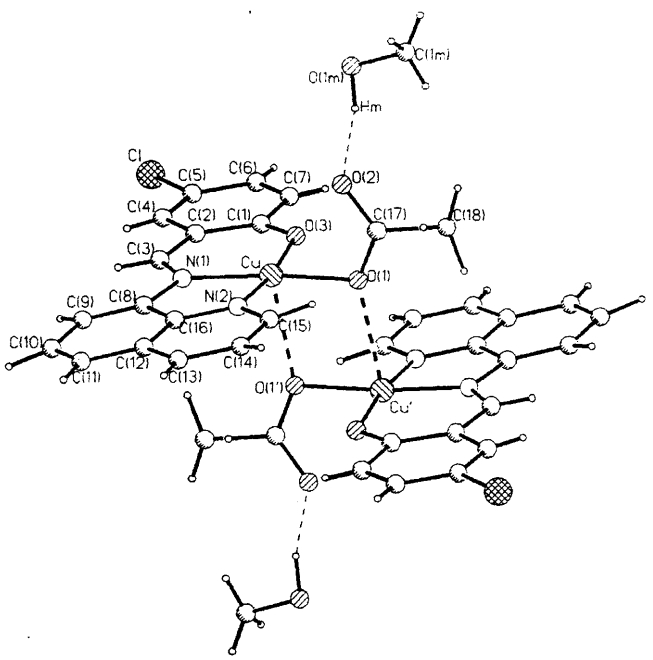

Fig. 6. Molecular structure of dimeric complex **V**.

4. Conclusions

As is shown, the structural data pertaining to the nearest-ligand environment of the central atom in the copper complexes synthesized, obtained by EXAFS spectroscopy, are in good agreement with the results obtained by X-ray single-crystal diffraction.

Received 27 May 2000; accepted 1 September 2000

Abstract

Binuclear copper(II) complexes of the ligands 3,6-bis(di-2-pyridylmethyl)pyridazine (bdpdz) and 3,6-bis[(6-methyl-2-pyridyl)(2-pyridyl)methyl]pyridazine (mbdpdz), Cu_2LX_4 (X = Cl, Br) were prepared and characterized by UV-visible spectra, conductivity and voltammetry. These complexes were used as a catalyst for the oxidation of 3,5-di-*tert*-butylcatechol to 3,5-di-*tert*-butyl-*o*-benzoquinone. The reaction rate was determined in the presence and absence of a base (KOH) in methanol. The kinetic data are interpreted postulating one reactive species towards molecular oxygen: a copper (I) complex, which is generated by a redox equilibrium between the binuclear copper(II) complex and the substrate. © 2000 Elsevier Science B.V. 1. Introduction

Quadridentate (N_4) ligands, based on pyridazine and phthalazine as the binucleating fragments involving nitrogen donor centers, have been shown to generate principally binuclear copper(II) complexes [1–3]. These symmetrically arranged complexes present antiferromagnetic coupling and positive reduction potentials, which makes them good model systems for the active sites of copper metalloproteins. These are characteristic features of certain binuclear copper protein sites, such us tree lactase ($E_{1/2} = 0.434$ V) [4] and tyrosinase ($E_{1/2} = 0.360$ V) [5].

We have broadened the scope of these biomimetic systems by preparing binuclear complexes with hexadentate (N_6) ligands, [Cu_2LX_4], which present the pyridazine spacer. (L = bdpdz: 3,6-bis(di-2-pyridylmethyl)-pyridazine and mbdpdz: 3,6-bis[(6-methyl-2-pyridyl)(2-pyridyl)methyl]pyridazine; X = Cl, Br). The syntheses and magneto-structural characterization of these compounds have been described previously [6,7].

Recently a large number of binuclear copper(II) complexes have been reported in the literature as model compounds of tyrosinase. [8–15]. In the present paper we report the UV–Vis spectroscopic and electrochemical studies of these binuclear species in methanol, together with their catechol oxidase activity.

2. Experimental

2.1. Reagents

All reagents and solvents were of high purity grade and were purchased from commercial sources and used as received unless noted otherwise. 3,6-bis(di-2-pyridylmethyl)pyridazine (bdpdz) and 3,6-bis[(6-methyl-2-

PII: S0277-5387(00)00573-8

pyridyl)(2-pyridyl)methyl] pyridazine (mbdpdz), and the corresponding $Cu_2(bdpdz)X_4$ and $Cu_2(mbdpdz)X_4$ complexes (X = Cl, Br) were prepared as reported elsewhere [6,7].

2.2. Measurements

The C, H, N elemental analyses were performed at CEPEDEQ (University of Chile) on a Fison-Carlo Erba EA 1108 model analyzer. Electronic spectra were recorded on a Perkin–Elmer Lambda 11 spectrophotometer using methanol (Chrom AR HPLC, Mallinckrodt) as a solvent.

Electrochemistry was performed in the methanol solution using 0.05 tetra-*n*-methyl ammonium perchlorate as an electrolyte. The cyclic voltammograms were recorded at a glassy carbon electrode, with a saturated calomel reference electrode and a Pt wire as an auxiliary electrode, on an EG&G Parr model 362 scanning potentiostat. All potential values are reported versus SCE.

Kinetic measurements were spectrophotometrically on a Unicam spectrophotometer, model UV-3, following the appearance of the reaction product, 3,5-di-*tert*-butylquinone (DTBQ), over time at 28°C (400 nm absorbance maximum, $\varepsilon = 1600\ M^{-1}\ cm^{-1}$ in methanol).

Conductance data, in methanol as a solvent, were obtained at 28°C on a Wayne Kerr Universal bridge.

3. Results and discussion

3.1. Spectral and conductivity studies

Conductance data indicate that all four complexes $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ (**1**), $[Cu_2(bdpdz)Br_4]CH_3CN$ (**2**), $[Cu_2(mbdpdz)Cl_4]\cdot 2H_2O$ (**3**), and $[Cu_2(mbdpdz)Cl_4]\cdot H_2O$ (**4**), correspond to 1:2 electrolytes in a methanol solution. The conductivity of the solutions does not change with time; thus indicating the dissociation of the halide ligands is instantaneous. All complexes have approximately the same conductance in a methanol solution (Table 1). The reported crystal structures show that in the solid state **1** is an ionic complex with one terminal chloro ligand, while **2** is a neutral species with two symmetrically disposed terminal bromo ligands [2]. The structures of **3** and **4** are unknown, since good quality crystals for X-ray diffraction were not obtained. The fact that the ionic complex **1** and the neutral complex **2** have similar conductivities suggests that the solvent replaces all terminal ligands. The binuclear structure of the complexes with the chloro or bromo bridges then remain intact in the solution.

The UV–Vis spectra show the typical absorption bands corresponding to d–d transitions of copper(II) in octahedral geometry (Table 1). The reflectance spectra of the chloro and bromo complexes with bdpdz, **1** and **2**, show bands centered at 775 and 780 nm, respectively. The bands of the copper(II) complexes in methanol solution are shifted towards higher energies with respect to the solid state spectra. This shift can be explained by the replacement of the terminal halogen ligands by solvent molecules. The effect is more pronounced for the bromo complex **2** where the two terminal bromides are replaced by the solvent, as compared with the chloro analogue that has only one terminal chloride.

Addition of 3,5-di-*tert*-butylcatechol ($DTBCH_2$), under anaerobic conditions, to a solution of the chloro complexes **1** and **3** did not produce a measurable change in the absorption spectra. For the bromo complexes **2** and **4** a decrease in absorbance as a function of the catechol concentration was clearly detected for the d–d bands. This decrease is rationalized by the following equilibrium:

$$\mathrm{Cu(II)–Cu(II)} + \mathrm{DTBCH_2} \overset{K}{\leftrightarrow} \mathrm{Cu(I)–Cu(I)} + \mathrm{DTBQ} + 2\mathrm{H^+} \quad (1)$$

The variation of the absorbance was used to estimate the value of $K = 1 \times 10^{-11}$ for the bromo complexes **2** and **4**. The fact that no measurables change in absorbance is observed for **1** and **3**, permits to predict lower values for K for these complexes.

Table 1
Spectral and conductivity data for complexes **1** to **4**

Compound	d–d (λ nm)		Λ_M (Ω^{-1} cm^2 mol^{-1}) (10^{-3} M methanol solution)

1	0.12 (0.30, 0.12) [a]	0.22, 0.40
2	0.13 (0.33, 0.14) [a]	0.22, 0.44
3	0.13	0.28; (0.36) [b]
4	0.14	0.44

[a] Second cycle.
[b] It appears as a shoulder on the signal at 0.28 V.

3.2. Electrochemistry

The redox behavior of the antiferromagnetically coupled binuclear copper(II) complex **1**, involving the chloro bridges, consists of a one-step two electron transfer at a positive potential of 0.12 V. The electrochemical data show that the reduction potentials of all four complexes do not depend significantly on the presence of the methyl groups substituted at the pyridine ring of the ligands (Table 2). The copper (I) complex is oxidized in a two step process at 0.22 and 0.40 V. The oxidized species formed in the first sweep towards reduction is different from the initially dissolved complex, since it reduces at 0.3 V during the second redox cycle. A typical voltammogram for complex **1** is shown in Fig. 1(A). The gross electrochemical behavior of the bromo complex **2** is similar.

The addition of $DTBCH_2$ to a solution of the copper complex **1** does not alter the peaks due to the Cu(II)/Cu(I) couple, observed in the voltammogram Fig. 1(B). However, if the voltammogram is recorded in the presence of base (Cu(II)–Cu(II):$DTBCH_2$:OH^- = 1:1:2) the followings peaks are observed Fig. 1(C):

1. During the first sweep towards oxidation a signal at 0.22 V and a second signal at 0.40 V are observed, corresponding to the one-electron re-oxidation of the copper (I) complex formed by the reaction with the catechol:

$$\text{Cu(II)–Cu(II)} + \text{DTBCH}_2 + 2\text{OH}^- \rightarrow \text{Cu(I)–Cu(I)} + \text{DTBQ} + 2\text{H}_2\text{O} \quad (2)$$

2. During the first sweep towards reduction a signal at -0.08 V is recorded corresponding to the reduction of the quinone in the presence of the copper (I) complex. An identical reduction peak is obtained for an in situ complex formation by a mixture of a solution of $Cu(AN)_4ClO_4$ with the corresponding ligand and quinone.

$$\text{Cu(I)–Cu(I)} + \text{DTBQ} + \text{e}^- \rightarrow [\text{Cu(I)–Cu(II)(DTBC}^{2-})] \quad (3)$$

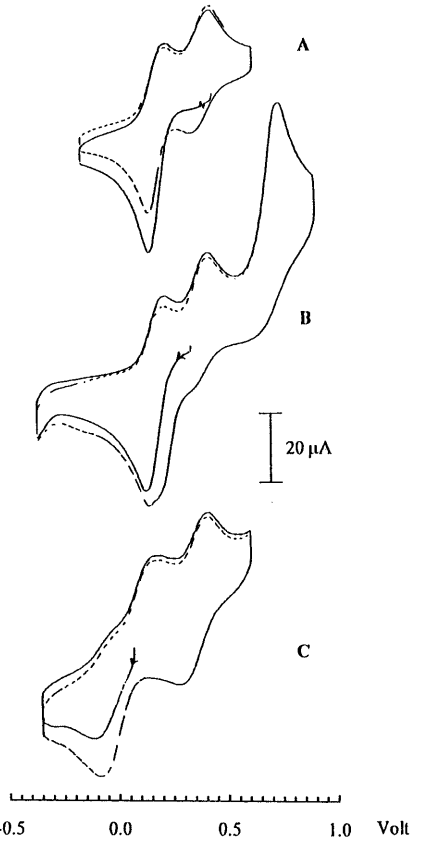

Fig. 1. Cyclic voltammograms for: (A) $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ (**1**) 5×10^{-4} M. (B) $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ and $DTBCH_2$ 5×10^{-4} M. (C) $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ and $DTBCH_2$ 5×10^{-4} M and KOH 1×10^{-3} M, scanning towards reduction. Electrolyte: 0.05 M tetra-*n*-butylammonium perchlorate in methanol.

A methanolic solution of pure quinone is reduced at -0.30 Volt.

3. Continuing the sweep towards oxidation, the [Cu(I)–Cu(II)($DTBC^{2-}$)] species produces quinone at 0.08 V.

$$[\text{Cu(I)–Cu(II)(DTBC}^{2-})] \rightarrow \text{Cu(I)–Cu(I)} + \text{DTBQ} + \text{e}^- \quad (4)$$

All four complexes exhibit the same general behavior just described, in the presence of added $DTBCH_2$ and a base.

3.3. Kinetic studies

Since DTBQ shows a characteristic band at 400 nm, the absorbance at this wavelength was used to measure the progress of the oxidation of the substrate $DTBCH_2$. The concentration of copper(II) complex, or the concentration of copper(I) complex generated by the redox reaction in presence of catechol, is too small to interfere with the measured absorbance value.

3.3.1. Kinetic data for the system without an added base (KOH)

The method of initial rates was used to determine the experimental kinetic law. The behavior of the system is similar for all four binuclear copper(II) complexes. Therefore the figures in the text refer mostly to [Cu(bdpdz)$Cl_3(H_2O)$]Cl, (**1**). Fig. 2 shows the data obtained for a concentration range of complex **1** of 2.0 to 60×10^{-6} M and at a constant concentration of $DTBCH_2$ (1×10^{-3} M). The non-linear dependence of the experimental rate on the analytical concentration of the complex can be rationalized in terms of the above mentioned equilibrium (1).

$$\text{Cu(II)–Cu(II)} + \text{DTBCH}_2 \overset{K}{\leftrightarrow} \text{Cu(I)} \text{–Cu(I)} + \text{DTBQ} + 2\text{H}^+ \quad (1)$$

The Cu(I)–Cu(I) species is assumed to be the actual reactive species towards oxygen and its concentration was calculated with the following equilibrium constant values: 1×10^{-12} (complex **1**), 1×10^{-11} (complex **2** and **4**) and 1×10^{-13} (complex **3**).

$$\text{Cu(I)–Cu(I)} + \text{O}_2 \rightarrow \text{Cu(II)–}(\text{O}^{2-})\text{–Cu(II)} \text{ (rate determining)} \quad (5)$$

The peroxo species generated in reaction (5) would rapidly decompose to give the Cu(II)–Cu(II) complex. Even though Casella et al. [8] report a combined mechanism in which, the possibility of direct oxidation of catechol by the peroxo binuclear copper(II) species is also considered together with the decomposition reaction, the former step has not been considered in the postulated mechanism. This due to the fact that in the catechol concentration range used in this study the reaction rate results independent of the substrate.

Since the kinetic runs were done at constant concentration of oxygen the experimental rate law becomes:

$$\text{Rate} = k[\text{Cu(I)–Cu(I)}]$$

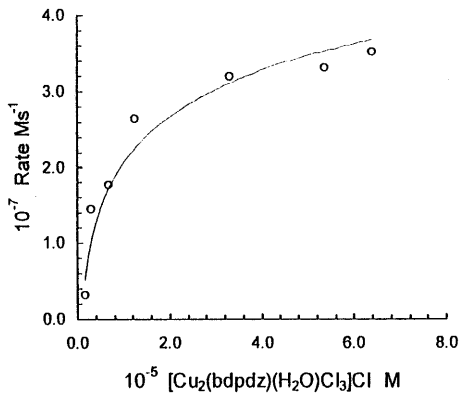

Fig. 2. Rate of oxidation of $DTBCH_2$ versus concentration of [Cu_2(bdpdz)(H_2O)Cl_3]Cl (**1**) at constant concentration of $DTBCH_2$ (1×10^{-3} M). ○: experimental data; --- simulated curve using $K = 1 \times 10^{-12}$ and $k = 0.04$ M s^{-1}.

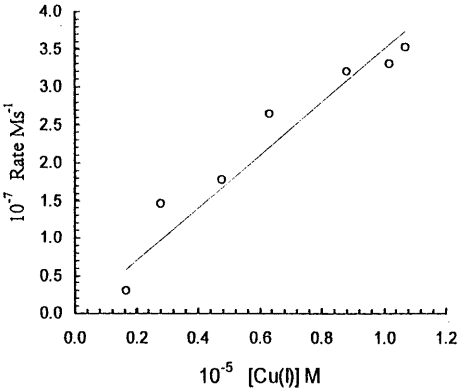

Fig. 3. Rate of oxidation of $DTBCH_2$ versus the calculated concentration of copper(I) complex derived from [Cu_2(bdpdz)(H_2O)Cl_3]Cl (**1**), using $K = 1 \times 10^{-12}$.

Fig. 3 shows the dependence of the rate on the calculated concentration of copper (I) complex for the oxidation of $DTBCH_2$ with dioxygen catalyzed by complex **1**. A linear relationship resulted for all four complexes. Calculated value for the experimental pseudo first order rate constants for complexes **1** to **4** are quoted in Table 3.

Complex **3** shows the greatest value for the rate constant while the complexes with the ligand without the methyl substituent show the lowest values. Complex **3** also shows the lowest value for the equilibrium constant equilibrium (1). These results indicate that the copper(I) complex formed is more easily oxidized, by molecular oxygen to the copper(II) state and that at least for the studied complexes the steric effect imposed by the substituent does not prevent the interaction of the substrate with the catalyst. Inspection of the potential values for the re-oxidation of the copper(I) complexes formed during the first sweep towards reduction shows that complex **3** is oxidized to copper(II)–copper(II) at a lower potential, in accordance with the kinetic results.

3.3.2. Kinetic data for the system with an added base (KOH)

Kinetic runs, carried out with concentration of complex **1** at constant values of 5.3×10^{-6} and 6.4×10^{-6} M and of $DTBCH_2$ at 1×10^{-3} M, showed a behavior which is depicted in Fig. 4. As the concentration of base increases the rate increases until a molar ratio of com-

Table 3
Kinetic and equilibrium constant data for complexes **1** to **4**

Compound	k (s^{-1})	K (equilibrium (1))
1	0.04	1×10^{-12}
2	0.03	1×10^{-11}
3	0.16	1×10^{-13}
4	0.05	1×10^{-11}

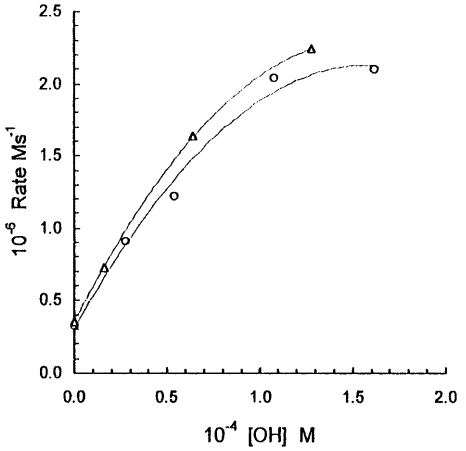

Fig. 4. Dependence of the rate of oxidation of $DTBCH_2$ on the concentration of base, at constant concentration of the catalyst; ○, $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ 5.3×10^{-5} M; △, $[Cu_2(bdpdz)(H_2O)Cl_3]Cl$ 6.4×10^{-5} M.

plex: OH of 1:2 is reached, the dependence of the rate on [OH] becomes independent above this ratio. The fact that an asymptotic value of the rate of production of DTBQ is observed as the concentration of the base is increased can be explained by the existence of equilibrium (1), which was detected by cyclic voltammetry.

Experimental data obtained for a series of kinetic runs at constant complex to base ratio of 1:2, where the copper(II) complex has been reduced completely to the copper(I) complex, show a linear dependence on this concentration. The reaction rates obtained from these experimental data permit to calculate a rate constant equal to that obtained from experiments without added base. This fact confirms that the used values of K are the correct ones.

The kinetic behavior of the studied binuclear copper(II)-complexes in the presence of base is different from the one observed earlier for mononuclear copper(II)-complexes $CuLCl_2$ (L = 6-methyl-2,2′-dipyridylmethane and 6,6′-dimethyl-2,2′-dipyridylmethane) [16]. In The case of these last compounds two active species towards molecular oxygen were detected, Cu(I)L and $Cu(II)L(DTBC^{2-})$, while in the present study a binuclear copper(I) is postulated. However, in both systems a similar equilibrium was observed in the absence of base, giving account of the reduction of the initial copper(II) species in the presence of catechol.

If the catecholase activity of the mononuclear Cu(I)L [16] and the Cu(I)–Cu(I) complex with the monomethylated ligands is compared, the binuclear species is found to be one order of magnitude more active.

Binuclear copper(II) complexes with square-pyramidal geometry and pyrazolate bridges reported by Urbach et al. [17] are found to be more efficient catalyst for the oxidation of 3,5-di-*tert*-butylcatechol. Even though the copper-copper distance reported for these complexes is of the same order of magnitude as for **1** and **2**, the geometry around the metal centers is quite different, since the latter are octahedral. This factor may explain in part the difference in the observed catecholase activity, as the interaction between the copper centers and the substrate is more favorable for the former complexes than for those reported in this paper. It has been shown that the electron transfer from catechol to copper(II) takes place only after the copper(II)-catecholate intermediate is formed. A suitable coordination site on the metal must exist for the formation of the intermediate [18]. Therefore the reported results reaffirm that the geometry around the copper ions is a dominant feature in determining the catalytic activity of synthetic model systems [19,20].

Bis-bipyridine hexa-aza-macrocycle complexes of zinc(II) and nickel(II) and the catalytic reduction of carbon dioxide

J. Canales [a], J. Ramirez [a], G. Estiu [b], J. Costamagna [a,*]

Received 1 October 1999; accepted 11 May 2000

Abstract

Aza-macrocyclic complexes have gained importance in catalysis for the activation of small molecules, like carbon dioxide. Bis-bipyridine hexa-aza-macrocycles efficiently co-ordinate as a tetradentate ligand, to give complexes of Zn(II), Ni(II) and other transition metal ions that are essentially planar. Spectroscopic, electrochemical and chemical characterizations of these systems are presented in this article. Electrochemical studies performed in a carbon dioxide atmosphere render preliminary information about its electrocatalytical reduction. Quantum chemical calculations are used to understand the origin of the manifested properties of both the ligands and the metal complexes. They show, in this case, the importance of delocalized π interactions, which are responsible for their different structural and electronic characteristics in protic and non-protic media. © 2000 Elsevier Science B.V. Keywords: Aza-macrocycles; Electroreduction; Carbon dioxide; Delocalized π interactions

1. Introduction

The synthesis and characterization of coordination compounds with aza-macrocyclic ligands has evolved during the last years as one of the main research areas in coordination chemistry [1–4]. Aza-type ligands appear as very promising for catalysis and are, thence, one of the most frequently discussed chelating systems in the related literature [5–11]. Not much interest has been focused, however, on azamacrocycles derived from the condensation of bipyridines, i.e. bis-bipyridine hexa-azamacrocycle (3,10-dihydrotetrapyrido [2,1,6-de:2′,1′,6′-gh:2″,1″,6″-kl:2‴,1‴,6‴-na] [1,3,5,8,12] hexa-aza-cyclotetradecine), bis-azabipy hereafter. The lack of information on this subject seems to be related to the low yield observed in the synthesis of these ligands [12–15]. However, recent publications have shown that the rigorous elimination of humidity, and the use of chromatographic separations lead to a significant increase in the yields. Additional information related to the spectroscopic and electrochemical properties of these ligands and of some of their transition metal complexes is now available [16,17]. It shows that the complexation capabilities of polyaza macrocycles are mainly governed by the macrocyclic ring size. Their N-functionalization, on the other hand, enhances the metal-ion selectivity and the stability of metal complexes through the co-ordination properties of pendant substituents [18].

Aza-macrocyclic ligands, as well as their coordination and organometallic compounds play important roles in catalysis in the activation of small molecules, showing catalytic activity in electrochemically assisted reactions with several substrates [19,20]. Carbon dioxide has been tested in some of these systems, in the search for a way of lowering its high reduction potential [21–23]. Ligands that favor low oxidation states and are effective for electron transfer processes are expected to behave more efficiently for this purpose [20].

Carbon dioxide is a small molecule of utmost importance for the production and/or energy storage in non-conventional resources. Its reduction is a process of applicability in ambient chemistry related issues, such as the synthesis of ecological naphtas or the control of

PII: S0277-5387(00)00574-X

the greenhouse effect, responsible for disruption in the natural environment [24]. Coordination compounds have shown catalytic activity toward these reactions, and have become very promising because they allow their rational optimization by means of properly designed modifications of either the ligand or the central metal atom. The first step towards this rational design relies on a detailed study of the structural, electronic and spectroscopic characteristics of these complexes, which will help to understand the main steps of the mechanisms involved in the catalytic mediation.

This article deals with the study of the aza-macrocycle, shown in Fig. 1, that results from the condensation of bipyridine precursors [13,14]. We focus on the spectroscopic, electrochemical and theoretical characteristics of this ligand and its Ni and Zn complexes. This knowledge will allow us to properly analyze their effect on the electro-activation of carbon dioxide.

2. Experimental

2.1. Instruments

Solid IR-TF spectra were registered using a Bruker IFS-66V spectrophotometer as KBr pellets in the 4000–400 cm^{-1} and polyethylene pellets in the 400–150 cm^{-1} ranges. ^1H NMR spectra in CD_3Cl, CD_3COOD, and CF_3COOH were registered using a Bruker AC-200P spectrophotometer; TMS has been used as an internal standard. UV–Vis spectra in chloroform and acetic acid solutions were registered using a Varian Cary 1E spectrophotometer. Zinc and nickel elemental analysis were performed using a Perkin–Elmer 2380 atomic absorption spectrophotomether. Carbon, nitrogen and hydrogen elemental analysis were performed using a Fisons EA 1108 apparatus. Melting points were registered using an Electrothermal IA9000 apparatus.

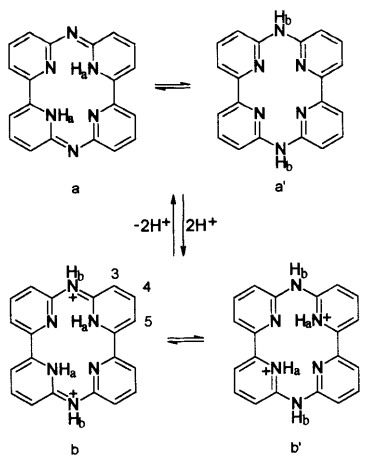

Fig. 1. Amine (**1a**, **1b**) and imine (**1a′**, **1b′**) tautomers of the bis-azabipy ligand.

2.2. Electrochemical procedures

The experiments were carried out on a PAR 173 potentiostat/galvanostat instrument with a PAR 175 model universal programmer coupled to a PAR 179 digital coulometer. The voltammograms and the simultaneous current intensity–time plots for electrolysis were registered in a X-Y Houston-Ommigraphic 2000 recorder. Cyclic voltammetry, and controlled potential electrolysis coulometry at room temperature (r.t.) (approximately 25°C) under either inert (N_2) or saturated CO_2 atmosphere were performed in a specially designed air-tight electrochemical cell with a double three-electrode system, to obtain cyclic voltammograms 'in situ' for the electrolytically generated products. All electrodes were introduced into the cell body by means of a ST glass joint, and caps with Teflon-faced-silicone septa were used for the needles that bubble and exit gases. Coulometric measurements were performed using a reticulated vitreous carbon (ERG) and a saturated calomel as working and reference electrodes, respectively. The last one was supplied by a vycor tip glass end. Platinum spiral wire counter electrode was separated by means of a salting bridge through sinterized glass ends. For cyclic voltammetry experiments a vitreous carbon-polished teflon-coated button was used as a working electrode. The reference and counter electrode were the same as above.

2.3. Synthesis

The reagents and solvents employed in the synthesis were analytical grade and were used without further purification. The synthetic procedures are mainly based on the literature [14,25], with some modifications that are indicated in the text. Fig. 2 shows a general scheme of the synthesis.

2.3.1. 6,6′-Dichloro-2,2′-bipyridine

2,2′-Bipyridine (20 g, 0.128 mol) were dissolved in 70 ml of dimethyl sulfate under nitrogen; the solution was refluxed until the appearance of a white hygroscopic solid, 1,1′-dimetil-2,2′-bipiridine sulfate, which was washed with ether under nitrogen and dissolved without further purification in 500 ml of water below 5°C for the following step. Potassium ferricianide (120 g,

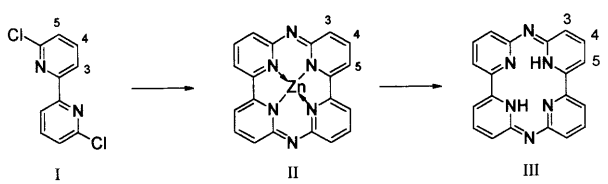

Fig. 2. General scheme of synthesis.

0.365 mol, dissolved in 400 ml of water) and sodium hydroxide (150 g, 3.75 mol, dissolved in 500 ml of water) were simultaneously added dropwise to the former solution for 3 h. The pH was adjusted to 8–9 with some drops of 37% hydrochloric acid at the end of the addition. The product, 1,1′-dimethyl-2,2′-bipyridine-6,6′(1H,1′H)-dione, was extracted with chloroform and precipitated by evaporation. It was recrystallized from chloroform, yielding 12 g. Then, 7 g, 0.0324 mol, were mixed under nitrogen with 15 g, 0.0719 mol, of phosphorus(V) chloride and 140 ml of phosphoryl chloride; the solution refluxed for 20 h and the excess of phosphoryl chloride removed by vacuum destilation. The remaining solid, 6,6′-dichloro-2,2′-bipyridine, was neutralized with ammonia and recrystallized from chloroform. Yield: 3.6 g, 50%; FTIR, ν (cm^{-1}): ν_{C-H}, 3035(s); ν_{C-C} and ν_{C-N}, 1575(m), 1545(m), 1418(m), ρ_{C-H}, 788(s); ν_{C-Cl}, 730(m). ^1H NMR in $CDCl_3$, δ (ppm): (see in Fig. 2(**I**)) H_3, 8.3(d); H_4, 7.7(t); H_5, 7.3(d).

2.3.2. Zn-bis-azabipy

6,6′-Dichloro-2,2′-bipyridine (2 g, 0.0089 mol) and ammonium tetrachloro zincate (15 g, 0.0712 mol), previously prepared from zinc chloride and ammonium chloride [25], were mixed in a mortar and then heated at 320–330°C under nitrogen over 6 h. The product was washed with water and 10% sodium hydroxide, and dried at 100°C and then sublimated at 200°C under vacuum for 3 h to separate a secondary product, 6,6′-diamino-2,2′-bipiridine. The remaining product, zinc azabipyridyl macrocycle, was dissolved in 5% acetic acid, reprecipitated with 10% sodium hydroxide and dried at 100°C. It melts above 400°C. Yield: 759 mg, 42%. *Anal.* Calc. for $ZnC_{20}N_6H_{12}\cdot 6H_2O$: C, 47.1; H, 4.7; N, 16.3; Zn, 12.9; Found: C, 47.7; H, 4.1; N, 16.5; Zn, 12.1%. FTIR, ν (cm^{-1}): ν_{C-N}, 1615(s), ν_{C-C} and ν_{C-N}, 1636(s), 1585(vs), 1544(s), 1470(vs), ρ_{C-H}, 795(m); ν_{Zn-N}, 428(m), 326(br), 275(w) (s, strong; vs, very strong; m, medium, br, broad, w, weak). ^1H NMR in CF_3COOH, δ (ppm) (see Fig. 2(**II**)): H_4, 8.4(t); H_5, 8.3(d); H_3, 7.6(d); H–N, 9.3(s) (d, doublet; t, triplet; s, singlet).

2.3.3. Bis-azabipi ligand [25]

Zinc bis-azabipy (760 mg, 1.90 mmol) was dissolved with stirring sulfuric acid (in 30 ml of 98%). Gaseous hydrogen chloride was bubbled in the solution during 6 h. Zinc chloride was separated by filtration and 25% ammonia was added to obtain a basic solution from which the azabipi ligand precipitates. It melts above 400°C. Yield: 316 mg, 35%. Color: orange. *Anal.* $C_{20}N_6H_{14}\cdot 6H_2O$: C, 53.8; H, 5.8; N, 19.1. Found: C, 52.5; H, 5.1; N, 18.8%. FTIR, ν (cm^{-1}): ν_{N-H}, 3400(s), 2800(w); ν_{C-N}, 1630(m); ν_{C-C}, 1587(m), 1534(vs), 1456(m); ρ_{C-H}, 784(m). ^1H NMR in CF_3COOH, δ (ppm) (see Fig. 1(**b**); Fig. 2(**III**)), H_3, 8.5(d); H_4, 8.6(t); H_5, 7.9(d); H_b, 10.4(s); H_a, 17.2(s).

2.3.4. Ni-bis-azabipy

This has been synthesized following a procedure described for analogous macrocyclic complexes derived from phenanthroline [17]: the azabipiridyl macrocycle (80 mg; 237.0 mmol) and nickel(II) acetate tetrahydrate (61.9 mg; 248.6 mmol), dissolved in nitrobenzene and benzyl alcohol, respectively, were mixed and refluxed under N_2 atmosphere with stirring during 3 h. The solution changed from orange to red. The red product was precipitated by addition of acetone, centrifuged and washed with nitrobenzene and water. A total of 40 mg of the complex (44% yield) were obtained after drying at 100°C. It melts above 400°C. Color: red. *Anal.* for $NiC_{20}N_6H_{12}$: C, 60.8; H, 3.1; N, 21.3; Ni, 14.9. Found: C, 60.5; H, 3.3; N, 20.5; Ni, 14.2%. IR-TF, ν (cm^{-1}), ν_{C-H}, 3075(w); ν_{C-N}, 1606(m); ν_{C-C}, 1554(m), 1480(vs), 1462(s); ρ_{C-H}, 785(m); ν_{N-M}, 470(m), 426(m), 327(w). ^1H NMR in CF_3COOH, δ (ppm), H_3, 8.3(s); H_4, 8.5(s); H_5, 7.7 (s); H-N, 10.6 (s).

2.4. Details of the computational procedure

X-ray diffraction data are not available for either the ligand or the coordination complexes. Thus, the first step of the study implies a full geometry optimization of the structures to be analyzed. Optimization is based on a minimization of the energy gradient, calculated analytically, using the BFGS algorithm to update the Hessian matrix in successive geometry cycles. PM3 and AM1 Hamiltonians [26] have been compared for the ligand and the Zn complex. Tautomer species that can coexist in equilibria have been considered for the ligand, in both their neutral and protonated forms (Fig. 1), as a way of modeling effect of protic and aprotic environments. Only PM3 calculations have been used to optimize the geometry of the Ni complex, as no parameters for Ni are available at the AM1 level. All self-consistent field (SCF) calculations were of the restricted Hartree Fock (RHF) type.

For the optimized structures, the electronic characteristics and the UV–Vis spectra have been examined by means of the INDO/S methodology [27,28], parametrized for spectroscopy [29–31], at the configuration interaction single (CIS) level of theory (ZINDO/S [32]). Several different CI calculations have been performed. As for the geometry optimization step, tautomeric and protonated structures were analyzed. The feasibility of the different structures has been decided on the basis of the best reproduction of the experimental spectra. With this objective in mind, not only monomers, but also more extended systems have been considered in order to model the different experimental situations.

A number of configurations larger than 1200 have been included in the CI calculations, which were generated by single electronic excitations from the upper 60

occupied to the lower 15 virtual orbitals, in both monomer and dimer compounds. This pattern was kept constant regardless of the size of the system. The orbital space has been selected to include all the n, and all the n and the d orbitals, for the ligand and the complexes, respectively. Oscillator strengths were evaluated with the dipole-length operator [33], retaining all one center terms. C_{2v} symmetry has been defined for the calculations whenever it applies.

3. Results and discussion

Results on electron transfer processes measured by cyclic voltammetry and coulometry; electronic spectra in solution for the bis-aza-bipy ligand and its Zn(II) and Ni(II) complexes; and geometry optimization and spectra interpretation through quantum chemical calculations will be shown and discussed next.

3.1. Electron transfer process: cyclic voltammetry and coulometry

In terms of potential applications to catalysis it is of particular interest to establish the nature of the redox processes and characterize them. In some cases, i.e. phthalocyanines, it is important to learn whether this process involves either one or both metal center together with the ligand [34]. We have reported cyclic voltammetry results in the cathodic region for Ni(II) and Cu(II) hexa-aza-macrocyclic complexes derived from phenantholine and suggested the stabilization of both Ni(I) and Cu(I) at -0.85 and -0.80 V versus SCE, respectively. Coulometric measurements indicate that these reactions involve one-electron reduction [35].

Fig. 3 shows electrochemical results of the bis-azabipy ligand and its nickel(II) complex in nitrogen and carbon dioxide in the cathodic region. The presence of a low-intensity redox process in the free ligand (in carbon dioxide) suggest that the CO_2 reduction process in the nickel(II) complex is probably occurring on the metal center [17]. The Zn azabipi complex shows a redox behavior similar to the free ligand, i.e. a significant catalytic process was not observed. Also depicted, in Fig. 3, is the clear modification of the cyclic voltammogram for the nickel complex, measured in carbon dioxide media. The intensity of the cathodic peak (approximately 1.5 V versus SCE) increases approximately three times when nitrogen is changed to carbon dioxide. Similar results have been obtained for fluorinated Ni(cyclam)$^{2+}$ complexes [34,36]. In addition, it has been found that coulometry by controlled potential electrolysis at -1.6 V in CO_2 medium has a constant intensity for a long period of time, while the behavior in nitrogen atmosphere is normal and shows one electron reduction process. The observed results confirm the electrocatalytic activity of the complexes for the reduction of carbon dioxide. Similar results have been previously observed in analogous systems such as Ni(cyclam)$^{2+}$ complexes [20,37]. The reduction of carbon dioxide might produce formic acid, -0.61 V; carbon monoxide, -0.52 V; formaldehyde, -0.48 V; methanol, -0.38 V or methane, -0.24 V (versus NHE), in multielectron transfer reactions [38]. A comparison of these electron transfers with the one-electron reduction of carbon dioxide to CO_2^-, -1.2 V; or to CO_2H, -0.60 V (versus NHE), shows that the thermochemical advantage is balanced by the kinetic constrains that are imposed by the requirement of multi-electron transfers. Adducts of CO_2 are probably involved in the reduction mechanism, as it has been found in radiolytic studies previously performed [39].

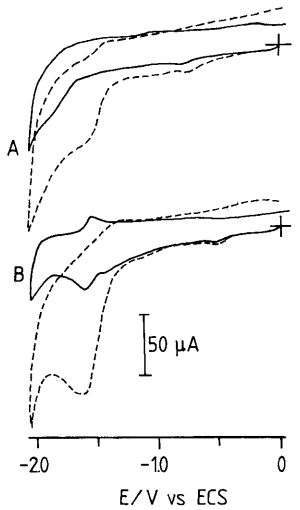

Fig. 3. Cyclic voltammograms, in *N*,*N*′-dimethylformamide, under N_2 (—) and CO_2 (----) for: (A) bis-azabipi; (B) Ni-bis-azabipi; approximately 0.1 mM; scan rate 0.2 V s^{-1}.

A quantitative evaluation of electrocatalytic properties such as turnover cycles, percentage of average current efficiency, selectivity by gas chromatographic identifications is currently being developed and will be published later.

3.2. Electronic spectra in solution

Bis-azabipy complexes are sparingly soluble in methanol and water. However, the solubility in these solvents increases by the addition of acids. Electronic spectra for the free ligand and the Zn(II) and Ni(II) complexes are shown in Fig. 4.

When the spectra obtained in protic and aprotic solvents are analyzed comparatively, the most important difference that becomes evident is related to the presence of a band structure in the visible region that only develops in the latter. As will be further discussed, the band in the visible region is assigned, on a theoret-

ical basis, to the influence of stabilizing intermolecular interactions originated in the delocalization of the pi system. On the other hand, the main influence of the protic solvent would be a protonation of the external nitrogen atoms of the macrocyclic ligand and complexes [15,16].

A previous quantum chemical INDO study of the geometry (INDO/1), electronic structure and spectroscopy (INDO/S) for phenanthroline and similar hexaazamacrocycle complexes have shown that the complexes, which are planar and neutral, bear a negative electronic density on the external nitrogen atoms [40]. The results are shown in Fig. 5 for the ligands under study and confirm the proposed protonation process [41].

3.3. Quantum chemical calculations

3.3.1. Bis-azabipy ligands

3.3.1.1. Geometry optimization. The tautomeric structures that can coexist in equilibrium in aprotic and protic media are shown in Fig. 1. Following previous publications [12–14,25] we will name them amine (**1a**, **1b**) and imine (**1a′**, **1b′**) tautomers.

Different optimized geometries result from PM3 and AM1 calculations for the deprotonated amine structure. Whereas PM3 stabilizes a completely planar structure, AM1 favors a bent one that minimizes the repulsion between the H atoms bonded to the inner nitrogens (Fig. 6(**A**)). This result is a consequence of the different parametrization used for the treatment of the hydrogen

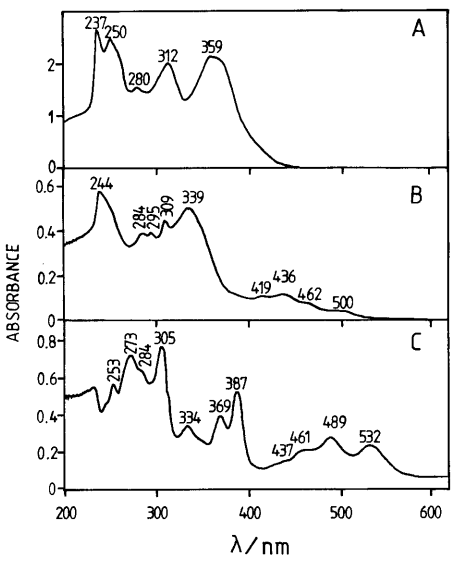

Fig. 4. UV–Vis spectra for: (A) bis-azabipy ligand 1.32×10^{-4} M in acetic acid; (B) bis-azabipy ligand 3.28×10^{-5} M in $CHCl_3$; and (C) Ni-bis-azabipy complex 1.27×10^{-4} M in $CHCl_3$.

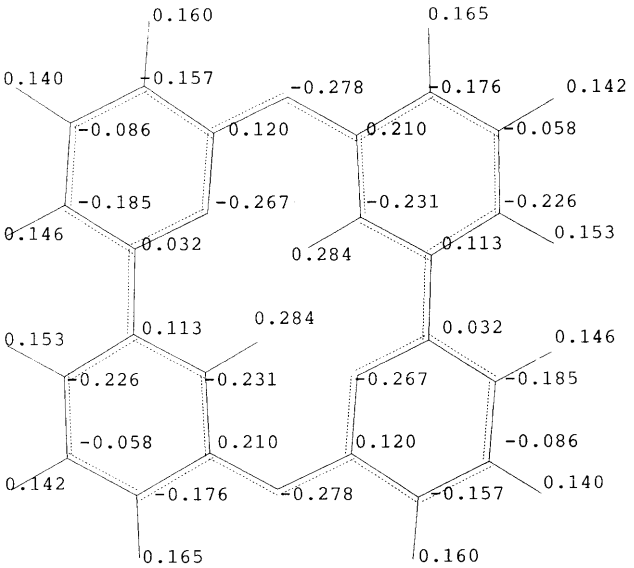

Fig. 5. Local density charges on the atomic centers of bis-azabipy ligand derived from AM1 calculations.

bond at both levels of calculation. The stabilization of H bonds between adjacent N-atoms define a more extended delocalized π system which is responsible for planarity. Due to the small energy difference between planar and bent structures, both of them have been considered for the calculation of the UV–Vis spectrum.

On the other hand, Fig. 7 shows that no planarity is associated to either the imine tautomer or the protonated structures. The stabilized geometry is the result of the influence of the aza bridge on the torsional angle defined by the pyridine rings, which is distorted from the value characteristic of biphenyl structures. Both effects converge to a NCCN angle close to 20°.

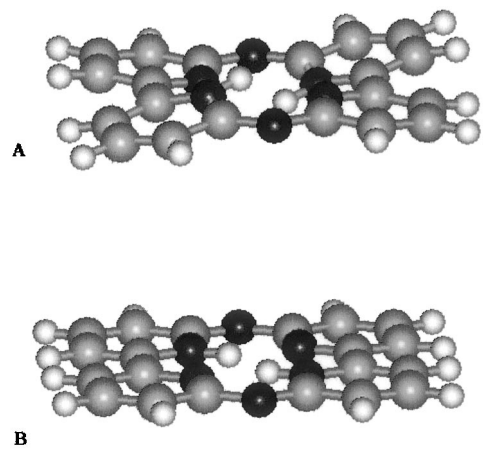

Fig. 6. Structural characteristics of the bis-azabipy ligand as result from AM1 (**A**) and PM3 (**B**) geometry optimizations. More details in the text.

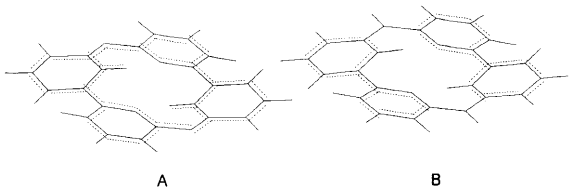

Fig. 7. Calculated structural characteristics of the bis-azabipy ligand in aprotic (**A**); and protic media (**B**).

In all the neutral structures, regardless of the semiempirical model used (AM1, PM3, ZINDO/S), a Mulliken population analysis shows the largest electron density located on the aza nitrogens.

3.3.1.2. UV–Vis spectroscopy. The UV–Vis spectrum of the macrocyclic ligand is largely dependent on the characteristics of the solvent, showing a band structure in the low energy region that only develops in non-protic environments (Fig. 4). This behavior has been previously explained on the basis of an amine–imine tautomeric equilibrium [12–14,25]. The fully conjugated amine form, stable in non-protic solvents, was supposed to be responsible of the low energy features, which disappear in protic media where the imine form becomes stabilized. However, no bands in the low energy region are predicted by the ZINDO/S CI calculations regardless of the planarity of the system or the tautomeric form considered.

Table 1 shows the observed electronic transition bands in UV–Vis region for 1.32×10^{-4} M bis-azabipy ligand in acetic acid. They are compared with the calculated bands for the system defined by a single molecule (Fig. 1(**b**)). Absorption bands start to develop in the 400 nm region. They are associated to electronic excitations from π orbitals, mainly centered on the aza N but delocalized in the π system, to fully delocalized π orbitals. The agreement between experimental and calculated spectra is remarkable. This evaluation is based on the consideration that some bands, as the lowest energy one, calculated as Laporte forbidden, can gain intensity through vibronic coupling.

When a single molecule is used to model the system in a non-protic media the spectrum of Table 2 (column 3) is calculated. No bands result for energy values lower than 420 nm. As the assignments are the same in this case and for protic media, it becomes evident that a more extended delocalized π system should be capable of decreasing the calculated energy of the transitions. We have modeled, thence, our system, by means of two ligand molecules, in a parallel arrangement (see Fig. 8(**A**)) that allows their mutual stabilization by π-interactions. Table 2 (column 1) shows the calculated electronic transition bands in UV–Vis region for our model system. They are compared (column 5) with the experimental bands for the bis-azabipy ligand in chloroform. The comparative analysis of the spectra demonstrate the feasibility of the model. The assignment of the transitions does not

change, relative to the monomers, but the orbitals involved are delocalized over the entire dimeric system.

The role of non-covalent interactions between aromatic moieties has been largely studied, as they influence the stability of nucleic acids [42], proteins [43], porphyrins and phtalocyanines, among others [44]. Because of the weak nature of the interactions, correlated ab initio calculations with split basis including polarization, define the minimum requirement for their proper computational modeling [45]. Semiempirical calculations are not parametrized for weak interactions and a geometry optimization at this level leads to the separation of the system in two monomeric units. Molecular mechanic force fields include non-bonded interactions in the van der Waals and electrostatic energy terms. They are capable of simulating the 'staking' stabilization between aromatic rings with a precision that compares the ab initio one [45].

We have preferred to use, for our calculations, the experimental information provided by the low energy features of the UV–Vis spectrum, and adjust the distance between the moieties until best fitting of the ZINDO/S-CI calculated spectrum to the experimental data. This procedure has been extensively tested [46,47], and its credibility is, nowadays, out of discussion. A dimer built up on the PM3 stabilized planar structure, with an interplanar separation of 3.3 Å between the monomers, defines the best model of the azamacrocycle ligand in non-protic media. This distance is in agreement with the one derived from molecular mechanics calculations, and is close to the one calculated in Ref. [45] for toluene dimers.

As has been previously mentioned, no dimerization is necessary to reproduce the spectrum in protic media (Table 1). Perfect agreement with experiment is attained when the ligand is modeled by the structure shown in Fig. 1(**b**). Protonation of the macrocycles destroy the stability of the dimers, a fact that is reflected, in the spectrum, in the lack of bands in the low-energy region (Fig. 4(A)).

3.3.2. Zn(II) and Ni(II) complexes

3.3.2.1. Geometry optimization. The structure of the zinc complex is slightly distorted from planarity in the orientation of the cycles, an effect originated in the position of the metal ion, which defines, with the co-ordinating nitrogen atoms, a square-based pyramidal structure (Fig. 8(**C**)). The same result is attained when either PM3 or AM1 calculations are performed.

A planar structure is calculated, on the other hand, for the nickel complex (Fig. 8(**B**)), as the smaller size of the Ni(II) ion is compatible with the size of the cavity defined by the co-ordinating nitrogen atoms.

A Mulliken population analysis describe the electronic distribution on the Zn(II) complex by a positive charge on the metal atom, counterbalanced by negative charges on the nitrogens. The positive charge is larger (0.68) after AM1 than after ZINDO/S (0.25) calculations, with the negative densities uniformly distributed on the N centers in the first case, but concentrated in the aza nitrogens in the second. A similar description holds for the Ni complex, which, at the ZINDO/S level of calculation, shows zero charge on the metal atom. AM1 and PM3 has not been considered for the electronic description of this complex. Whereas AM1 is not parametrized for Ni, PM3 is known to fail in the electronic description of systems containing amine groups [48,49]

3.3.2.2. UV–Vis spectroscopy. The influence of the solvent, previously described for the ligand, also becomes evident for the Zn(II) and Ni(II) complexes. A band structure develops in both cases, in the low energy region, in aprotic, but not in protic solvents (Fig. 4).

When the Zn(II) complex is considered, the low-energy region can only be reproduced when a dimeric model, with the monomers separated 3.8 Å, is used for the calculations. Results are shown in Table 3. The d orbitals of the metal lie very low in energy and are, thence, not involved in transitions. The transitions are originated, as in the case of the ligand, in electron promotions from π orbitals, mainly centered on the aza nitrogens (N) to π^* delocalized over the aromatic system.

The Ni complex is the unique case for which low energy bands are calculated even when a monomeric structure is considered (Table 4). They are associated, in the monomer, to $d \rightarrow d$ transitions. The best agreement with the experiment is attained, however, when calculations are based on a dimeric model, modeled on an interplanar separation of 3.4 Å (Table 4). For this model, $d \rightarrow d$ and $N \rightarrow \pi^*$ transitions share the low energy region. The best fitting to the experiment is attained, however, against the calculated $N \rightarrow \pi^*$ transitions, where N stands for the same orbital type previously described for the Zn complexes. We associate to the latter, which gain intensity through vibronic coupling, the origin of the bands around 500 nm.

Abstract

The aggregation properties of metallic 2,9,6,23-tetrasulfophthalocyanines MTSPc (M = Fe, Co, Ni, Cu and Al) embedded in transparent monolithic gels of silica prepared by the sol–gel method have been followed by UV–Vis spectroscopy. These studies are necessary to follow the various complex stages of the hydrolysis–condensation reactions forming the monolithic gels. In view of the fact that under the experimental conditions used in this work (OH)AlTSPc does not show any agglomeration tendencies, it has been used as a label to determine the optimum conditions for the inclusion of the MTSPc molecules. Dimethyl formamide (DMF) and pyridine (py) have been selected as agglomeration control agents. The utilization of DMF gives materials less prone to fracture and of better optical properties than those obtained by the use of pyridine. In the case of CuTSPc and CoTSPc species with DMF (4% v/v) some color fading in the gels was observed. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

There is at present a good deal of interest concerning the use of new materials as active laser devices and as optical converters of ultraviolet or infrared light into visible light. The last two decades have witnessed substantial efforts, thanks to which progress in our knowledge of the synthesis and the properties of metallic oxide glasses prepared by the sol–gel method has increased. Since 1984 [1], this procedure has allowed the trapping of many types of pigments in metallic oxide gels [2–7]. The optical and lasing properties of these systems have been studied [1,6,8]. However, the important group of macrocycles known as the metallic phthalocyanines (MPc) has been less well studied in this respect [9–12].

Semiconductivity, photoconductivity, as well as the catalytic and optical properties are quite important in metallic phtalocyanines. In recent years, these compounds received considerable attention because of their non-linear optical properties [13,14], the possibility of their use as optical limiters [15,16], and in optical information storage systems [17].

Phthalocyanine is a well known macrocyclic molecule featuring an 18-π conjugated electron system which imparts extremely high chemical and thermal stability to the macrocycle [17–21]. Many metallic phthalocyanines are known to have melting points, higher than 550°C [18], while demetallation, which occurs only in 16 M H_2SO_4 solution, depends on the central cation.

Non-substituted phthalocyanines are insoluble in common solvents such as water or ethanol, whereas those with substituent groups such as sulfo (–SO_3H) and carboxyl (–COOH) in the periphery of the macrocycle (Fig. 1), become soluble. In this work we synthesize the metallic 2, 9, 16, 23-tetrasulfophthalocyanines MTSPc (M = Fe, Co, Ni, Cu and Al) and study their inclusion in gels of silica obtained by the sol–gel method using tetraethoxysilane (TEOS) as a precursor.

It is a well known fact that free and metallic phthalocyanines dimerize and may even form larger and more complex aggregates. These aggregation phenomena are deleterious to the desired electrical, optical, and catalytic properties of these compounds. Thus, it is important to improve our understanding of the dimerization phenomenon and seek the means to avoid it. Exper

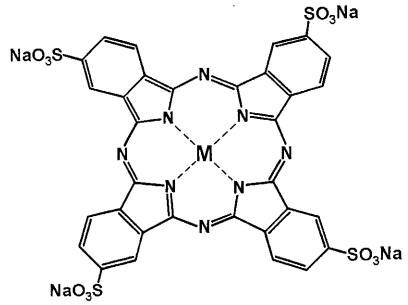

Fig. 1. Structure of tetra sodium salt of metallic 2,9,16,23-tetrasulfophthalocyanine, MTSPc (M = Fe, Co, Ni, Cu and Al).

imentally, it is found that dimer stability decreases in the series CuTSPc > H_2TSPc > FeTSPc > (VO)TSPc > CoTSPc [22].

Absorption spectra in the UV–Vis region were interpreted in terms of π–π^* transitions in the energy level diagram of the delocalized system of the macrocyclic ligand [23]. A typical spectrum of a monomeric metallic phthalocyanine is composed of two prominent bands, as well as of some other less important satellite bands (Fig. 2). The most intense band, known as the 'Q' band at around 670 nm is assigned to an $a_{1u}(\pi) \rightarrow e_g(\pi^*)$ transition while a less intense 'B', or 'Soret' band at around 350 nm is assigned to an $a_{2u}(\pi) \rightarrow e_g(\pi^*)$ transition [17]. A weak satellite band observed near 610 nm, known as the 'Q_{III}' band, is of vibrionic nature [24]. When the phthalocyanine macrocycle is allowed to dimerize, the UV–Vis spectrum is modified and only two bands are seen, namely: the Soret band at 340 nm and the type Q band at 630 nm. It has been found that the dimerization can be inhibited by using some solvents such as dimethyl formamide (DMF), pyridine (py), dimethylsulfoxide (DMSO), ethanol, etc. [25,26].

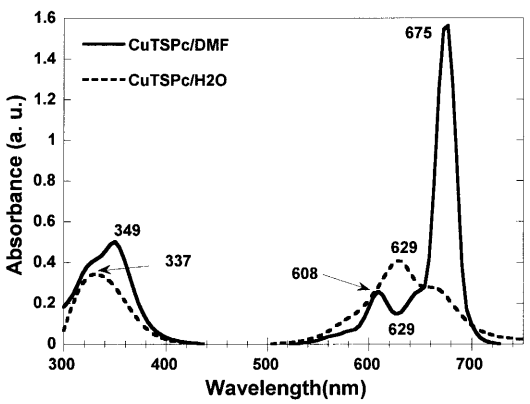

Fig. 2. UV–Vis absorption spectra of monomeric CuTSPc in (—) DMF and dimeric CuTSPc form in (---) water.

2. Experimental

Metallic tetrasulfophthalocyanines MTSPc were synthesized following the method of Weber and Buch [27].

The various components necessary to prepare the reacting sols were mixed using the following molar concentration ratios: [TEOS:H_2O:HCl:MTSPc] = [1:19:0.05:5×10^{-6}]. This mixture was prepared by the addition of 5.0 ml of the macrocyclic molecule solution (with or without aggregation control agent) to 19.8 ml of a homogeneous mixture of 9.8 ml of TEOS and 10 ml of a 0.234 M solution of HCl to give a final volume of 24.8 ml (V_f). To simplify, we state the quantity of aggregation control agent added in the 5 ml of the macrocyclic complex solution, as percent with respect to the final mixture volume.

These sols were divided in three subsets: to the first, 1% of pyridine is added, to the second, 2 or 4% of DMF is added, while no dimerization inhibiting agent is used in the last subset. The gelling sol mixtures were put into plastic cells and covered with parafilm paper. The gellation process is monitored by UV–Vis spectroscopy using a Cary 5E instrument. After monoliths separated from the cell walls (approx. 1400 h) small holes are made in the parafilm. Samples are dried at room temperature (r.t.) for 3 weeks. The final monoliths are then dried for 3 days at 70°C and 1 day at 120°C.

A second series of monoliths was prepared using CoTSPc sols, to which either 6 or 8% of DMF was added, while a last series of samples was prepared by adding either 2 or 4% of pyridine to the NiTSPc-containing sol.

3. Results and discussion

Preliminary exploratory experiments showed that the phenomenon of aggregation is totally inhibited in solutions containing 20% of DMF, 10% of pyridine, 40% of ethanol, or 60% of DMSO. Such high concentrations of the last two inhibiting agents give rise to extremely small, non-transparent and brittle monolithic gels. Thus, our efforts concentrated in the study of the dimerization inhibiting effects of DMF and pyridine.

The final volume of the monoliths is about one-tenth of that of the solution containing the polymerizing sol (V_f). (OH)AlTSPc does not show any chemical modification or dimerization while in aqueous solution or in gels; so we used it as a label which allowed us to find the proper conditions under which the gels obtained are strong and non brittle.

However, we have recently reported that if a gelling mixture containing (OH)AlTSPc plus 1% pyridine is used, formation of dimers via oxo-bridges is induce [28]. This fact is firmly based on the special features of

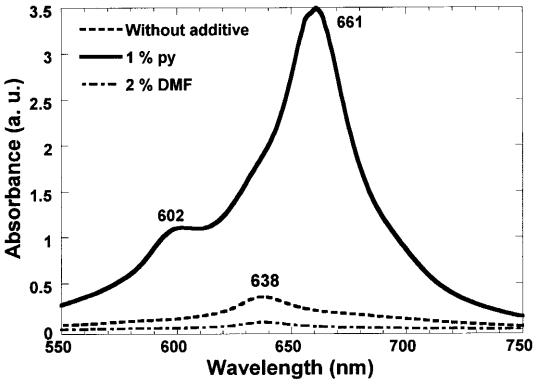

Fig. 3. UV–Vis absorption spectra of (OH)FeTSPc monolithic gels, obtained with and without addition of aggregation control additive, 1809 h after preparation.

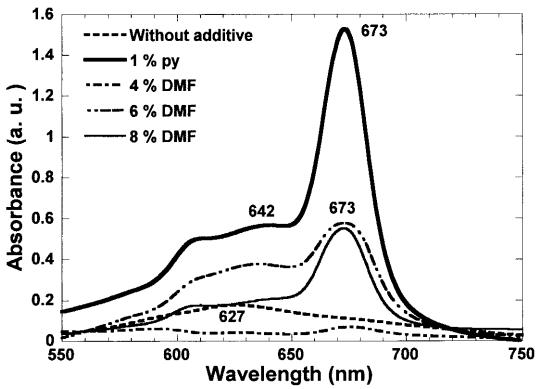

Fig. 4. UV–Vis absorption spectra of CoTSPc monolithic gels, obtained with and without addition of aggregation control additive, 2370 h after preparation.

the UV–Vis spectrum of the gel. We observe a Q band blue shifted 28 nm (674–646 nm), assigned to a μ-oxo dimer [29]. In other words, pyridine behaves as a base, with respect to Al(III) species, allowing the generation of the (O^-)AlTSPc anion which, bonding to a similar species forms the complex TSPcAl–O–AlTSPc [17,30–32]. We have also shown that the formation of this oxo-bridge complex is favored by the encapsulation conditions prevailing in the large cavities of the amorphous gel. This oxo-bridge complex does not form, for example, in a solution under reflux conditions. With the only exception of this important peculiarity, the Al(III) species stays unmodified if the pyridine concentration is lower than 0.2%.

Previous work shows that CuTSPc mixtures to which 1% of pyridine has been added, gel within 5 min after their preparation; however, these materials are non transparent and brittle. Similar mixtures to which DMF is added in concentrations between 2 and 8% give very strong and non-brittle materials which have lost their original blue color [28].

This phenomenon can be assigned to an interaction between DMF and the macrocycle of the CuTSPc molecule, leading to the formation of a species not far in nature to a lactam, involving the central Cu (II) ion and the nitrogen aza atoms of the macrocycle. The set of conjugated double bonds of the macrocycle is thus broken and the $\pi-\pi^*$ transitions necessary for the color to exist can no longer take place. One fact favoring the latter assumption is that the pH of the gelling solution is high enough to discard any possibility of macrocycle demetallation [18,19]. Even if this demetallation might take place, it is well known that the free macrocycle still features these strong $\pi-\pi^*$ transitions. Besides, we have observed that this phenomenon is seen only in the complexes of cations with an oxidation state of $+2$ which, by comparison with the M(III) complexes (OH)FeTSPc and (OH)AlTSPc, do not feature axial ligands. This fact leads us to think that DMF coordinates its nitrogen atom to these divalent cations at the same time that the oxygen of the carboxyl group interacts with the aza nitrogen atoms. A final consequence of this interaction is that the metallic complex loses its planarity.

When gels are prepared containing the species (OH)FeTSPc, using either DMF, or no dimerization inhibiting agent (Fig. 3), monoliths are obtained having the metallic species in the μ-oxo dimer form. However, if similar monoliths are prepared, containing this time 1% pyridine, one finds the species in the monomeric form predominantly, even after 1810 h.

A similar result is obtained with CoTSPc, which dimerizes easily if no additive is used (Fig. 4). Using 1% pyridine inhibits efficiently the formation of aggregates, but the gels obtained are not transparent and are very brittle. Furthermore, when 4% of DMF is added to sols containing CoTSPc, dimerization is inhibited weakly and the gels do not show any color, an observation similar to the one made in the case of the CuTSPc species.

In order to determine if higher concentrations of additives successfully inhibit dimerization, mixtures containing CoTSPc and 6 and 8% DMF were prepared (Fig. 4). It is found that though with 6% DMF dimerization is avoided at the start, the gels so obtained contain at the end, a mixture of the monomer and the dimer forms. Nevertheless, with 8% of DMF added, virtually all aggregation phenomena are inhibited, and the gels obtained are very strong, non-brittle, and the color does not fade with time.

For the case of gels containing the NiTSPc species, even though 1% pyridine is not enough to avoid dimerization, DMF concentrations higher than 4% are quite efficient for the same purpose (Fig. 5).

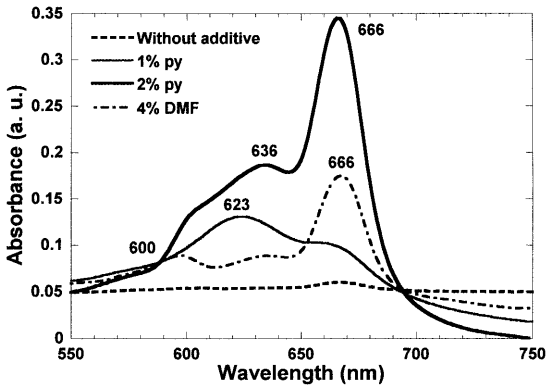

Fig. 5. UV–Vis absorption spectra of NiTSPc monolithic gels, obtained with and without addition of aggregation control additive, 1809 h after preparation.

4. Conclusions

It is possible to successfully avoid dimerization phenomena of metallic tetrasulfophthalocyanines trapped in monolithic silica gels if use is made of some inhibiting agents in appropriate minimum concentrations: 4% DMF, 2% pyridine, 8% ethanol or 12% DMSO. In practice, monoliths prepared with the last two agents, because of the high concentrations needed, are small, brittle and non-transparent which renders their utilization less interesting.

With DMF as the additive, the gels are normally stronger and of higher optical quality. However, CuTSPc and CoTSPc materials tend to fade with time because of interactions between DMF and the complex, which disrupt the conjugated double bond system of the organic macrocycle.

The use of DMF as a dimerization-inhibiting agent is efficient in the control of aggregation of MTSPc (M = Fe, Co, Ni) species embedded in gels of silica. The use of pyridine is equally effective, and though a lower concentration of the latter is necessary, the final monoliths are brittle and non-transparent; however, the use of these systems in catalysis is commendable.

The comparative study of gels prepared with the M(II)TSPc (M = Cu, Ni and Co) species and (OH)M(III)TSPc (M = Fe and Al) species has shown that loss of color in the monoliths and μ-oxo dimer formation take place easily.

POLYHEDRON

Foreword

This is the second issue of Polyhedron devoted to the Italian–Spanish Conference on Thermodynamics of Metal Complexes. The first one was published in 1999 and is referred to the meeting held in Girona (Spain) organised by Professors Victoria Salvadó and Antoni Llobet.

The first meeting on this field held in collaboration among the different Spanish and Italian researchers was organised in Peñíscola (Spain) by Professor Juan Faus of the University of Valencia in 1990, then each year alternatively in Italy and in Spain congresses on this field have been organised.

In 1999 the Xth Italian–Spanish Congress was organised in S. Martino al Cimino a little town near Viterbo (Italy) by Professor Aldo Napoli of the University of Tuscia (ISMEC'99).

Nearly one hundred researchers from different countries attended the congress, presenting several communications on different topics. Indeed, the congress has focused on most of the fundamental and applied aspects of interest on thermodynamics and equilibria of metal complexes and closely related topics: solution equilibria; thermodynamic properties and chemical structure correlations; computer methods for equilibrium studies; thermodynamics of ionic exchange; complexes in non aqueous solvents; complexes with macrocyclic ligands; complexes with biological, medicine or environmental interest; complexes with analytical and technical applications; host–guest binding studies; thermodynamic aspects of macromolecular or supramolecular interactions.

The meeting was organised into 1 h plenary lectures, 40 min keynotes, 20 min oral contributions and posters. The opening plenary lecture entitled 'Transition metal and anion complexes with dinucleating hexaaza macrocyclic ligands' was addressed by Professor Antoni Llobet of the University of Girona (Spain). Other plenary lectures were 'Solution speciation of bioactive Al(III) and VO(IV) complexes' by Thamás Kiss from Jòzsef Attila University of Szeged (Hungary), 'From Stability Constants to Speciation. A database which is both easy to access and easy to apply' by Gwyneth and Leslie Pettit, Academic Software (U.K.) and finally 'Simple polyazacyclophane receptors in anion recognition and catalysis' by Enrique Garcia España and co-workers.

Two keynotes were presented by Silvia Canepari from the University of Rome (Ligand properties of β-amino-alcohols) and by Vincenzo Romano from University of Palermo, Italy (The extension of equilibrium analysis).

For the present special issue of Polyhedron devoted to the ISMEC'99 symposium, we have selected 16 contributions which have been divided into five sections:

1. Reviews
2. Solution equilibria
3. Oxygen binding ligands
4. Structure
5. Others

The paper in Section (A) is the review of Professor Thamás Kiss and co-workers which deals with the importance of biospeciation of aluminum(III) and VO(IV) and the application of speciation results in understanding the biological effects of these elements.

Five papers in Section (B) are dedicated to solution equilibria of metal complexes by the teams of Professors Ciavatta, Pulidori, Portanova, Crisponi and Magrì.

In Section (C) two papers deal with oxygen binding (Professors Bianchi, Paoletti, Tinè and co-workers), one on the solubility of oxygen in water (Professor Braibanti).

Three papers in Section (D) refer to structural contributions by Professors Niclós and Llobet and finally in Section (E) works by Professors Malatesta, Micheloni, Secco and Bucci are reported.

Following the success of the previous meetings, in 2000 Professor E. Garcia España organised the XIth edition of the Spanish–Italian Congress on Thermodynamics of Metal Complexes in Valencia (Spain) from the 4th to 7th of June. The next meeting will be organised in Parma, Italy, in June 2001.

This paper is dedicated to the memory of Professor Kálmán Burger.

Abstract

The speciation of the toxic Al(III) and the beneficial VO(IV) in various biofluids and tissues is discussed in order to describe the solution state of these metal ions in the organism. The importance of ternary complex formation with relevant biomolecules is emphasized. The interactions of Al(III) and VO(IV) with oligopeptides are also dealt with. The importance of the biospeciation of Al(III) ion in its transport and involvement in neurological disorders, and of insulin mimetic VO(IV) complexes is discussed.

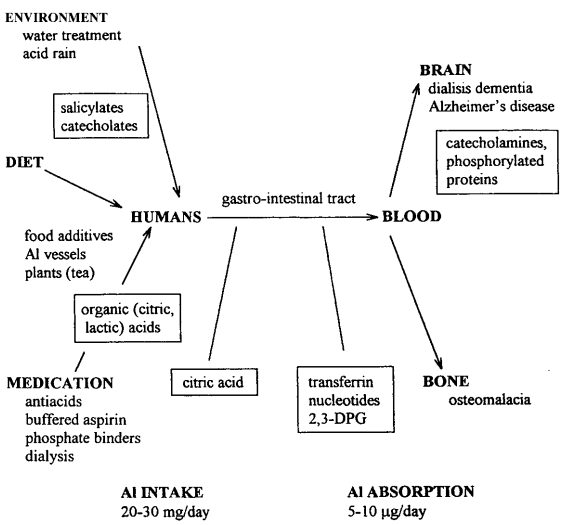
Keywords: Biospeciation; Al(III) complexes; VO(IV) complexes; Insulin-mimetics

1. Introduction

The chemical speciation of an element, either essential or toxic, may be of basic relevance as concerns its biology, as the chemical form in which an element enters the body mostly determines its absorption and transport properties, and hence in part its biological and physiological activities. It is also true that to some extent independently of how this essential or toxic element was absorbed (or the form, e.g. a metal ion-containing drug, in which it was administered), it undergoes transformation because of the possible ligand-exchange reactions with the many potential metal ion-binding biomolecules in the biofluids or tissues.

In biological fluids, a majority of the metal ions are bound to proteins. In fact, only a small proportion of them are bound to low-molecular-mass (l.m.m.) compounds, mainly amino acids, biophosphates, carboxylates or hydroxycarboxylates. Free metal aquaions exist in biological fluids only in extremely low concentrations, and at these concentrations cannot play a significant role in physiological processes. In contrast, metals bound to l.m.m. compounds play major roles in many biological processes, such as intestinal absorption, cell absorption, transport and renal excretion. An understanding of these processes requires an accurate knowledge of the proportions of the l.m.m. and protein-bound fractions of the metal ions and of the delicate equilibria which determine these proportions.

Specific experimental techniques such as gel filtration, ion chromatography, ultrafiltration, ultracentrifugation, atomic absorption spectrophotometry, etc., are available to separate and determine l.m.m. and high molecular mass (h.m.m.) bound metals. On the other hand, computer programs developed to deal with multiple chemical equilibria can be actively applied not only for speciation calculations of laboratory solutions, but also for the simulation of naturally occurring mixtures of metal ions and ligands [1].



The present paper gives a brief literature survey and an insight into our recent research connected with some biospeciation problems relating to the toxic aluminum and the beneficial vanadium. Several examples are provided to emphasize the importance of a knowledge of the solution state of these metals, and it is demonstrated how this speciation information may be used for a better understanding of the effects of these metal ions in biological systems.

2. Characterization of Al(III) binding to small biomolecules

Aluminium is a well-established neurotoxic element [2]. Scheme 1 gives the various routes through which Al can enter the human organism from the environment, the diet or medication. A total of 10–30 mg of Al is estimated to be ingested each day, but only a very small proportion of this Al (5–10 μg) is absorbed. In many countries, aluminum sulfate is used as a coagulant in water treatment. Acid rain considerably increases the Al load from the environment. Al compounds, e.g. alums, are used as additives in different food-producing processes, for instance as baking powder in some countries. Some plants, e.g. tea, can accumulate an enormous amount of Al: the Al content of old tea leaves can reach even 3%. A significant amount of Al(III) may be liberated from Al vessels used in the kitchen when acidic meals are cooked in them. Some antacids and buffered medicines also contain Al. Al can accumulate dangerously in children with an impaired renal function who are treated with orally taken Al(III)-containing phosphate binders. Some forms of medical treatment, e.g. long-term haemodialysis, can also elevate the Al level in humans if the water used has a high Al content. Under normal conditions, i.e. with a normal daily load and a healthy organism, this amount is well tolerated (although the physiological effects of long-term low aluminum load, e.g. from the drinking water are still not clear [3]), as a consequence of the efficient defence mechanism, involving the formation of poorly-soluble phosphates and hydroxides in the gastro-intestinal tract, which are easily excreted. However, an abnormally high Al load and/or with an impaired renal function, an excess of Al(III) can be absorbed and transported to various target organs, where it may accumulate and exert harmful effects, e.g. osteomalacia in the bones, microcytic anemia in the red blood cells, or neurodegenerative diseases in the brain.

Scheme 1.

Al(III) is a typical hard metal ion, and the most likely binding sites of $Al(H_2O)^{3+}$ in biosystems are therefore O donors, and especially negatively-charged O donors. Carboxylate, phenolate, catecholate and phosphate are the strongest Al(III) binders. Biomolecules containing such functions may be involved in the uptake and transport processes, and also in the biological and physiological actions of Al(III) in living systems. These small biomolecules (given in the frames in Scheme 1) are either of biological importance or can mimic larger biomolecules. For example, salicylate and catecholate derivatives can serve as good model compounds to study the metal ion- binding properties of the larger soil organic material humic and fulvic acids. Small organic acids, such as citric acid for example, are important small molecule Al binders in biological fluids. Transferrin plays an essential role in the Al(III) transport in the plasma. 2,3-Diphosphoglycerate is important in the binding and accumulation of Al(III) in the red blood cells, resulting in a special kind of anemia. Other phosphates, such as nucleosidephosphates, e.g. ATP, are widely distributed in living systems, and a large variety of the reactions which take place in living organisms involve ATP. Catecholamines occur in fairly high concentration in the brain, where other potent Al(III) binders, e.g. transferrin or citrate, occur at relatively low concentrations, so that catecholamines can be of importance in the binding of Al(III) in the brain. Phosphorylated proteins, which are rich in abnormal neurone degradation products occurring in various neurological disorders, may play roles in the accumulation of Al(III).

In recent years, we have studied the interactions of such small biomolecules with Al(III) and described the speciation and solution structures of the complexes formed [4–18], in order to obtain the necessary stability constants and knowledge promoting characterization the solution state of Al(III) in biological fluids and tissues. Because of the possibility of the rather slow formation of complicated oligonuclear mixed hydroxo complexes in many of these Al(III)–ligand systems, pH-potentiometric solution speciation measurements were carried out at different metal ion concentrations (usually at $c_{Al} = 1–4$ mmol dm^{-3}) and at various metal ion to ligand ratios (usually at 1:1–1:10), and thermodynamic equilibrium was rigorously checked [14,17,18]. Those titration points, when 10 min was not enough to reach thermodynamic equilibrium state were omitted from speciation calculations.

Table 1
Total concentrations of components in computer model [a] of serum

Components	Concentration l^{-1}
High molecular mass (h.m.m)	
Albumin	630 μmol
Transferrin	37.0 μmol
Histidine	77.0 μmol
Lactate	1.51 mmol
Oxalate	9.20 μmol
Low molecular mass (l.m.m.)	
Phosphate	1.10 mmol
Citrate	99.0 μmol
Carbonate	24.9 mmol
Cistine	10.9 μmol
Cysteine	33.0 μmol
Glycine	2.30 mmol
Glutamate	60.0 μmol
Sulfate	330 μmol
H^+ (free)	39.8 nmol
OH^- (free)	417 nmol
Al^{3+}	3.00 μmol
Ca^{2+} (free)	1.37 mmol
Mg^{2+} (free)	580 μmol
Zn^{2+}	10.0 μmol

[a] Data are taken from Ref. [19].

Table 2
Simulated species distribution of low molecular mass Al(III) in blood serum [a]

Protein-bound Al(III)	Al(III) l.m.m. fraction [b]	Refs.
80%	$[Al(CitH_{-1})(OH)]^{2-}$: 94%; $[Al(CitH_{-1})]^-$: 3%; $Al(PO_4)$: 1.5%; $[Al(Oxalate)(OH)_2]^-$: 1.4%	[23]
50%	$Al(PO_4)$: 62%; $[Al(CitH_{-1})]^-$: 23%; $[Al(PO_4)(CitH)]^{2-}$: 10%	[21]
57%	$Al(OH)_3$: 51%; $Al(PO_4)$: 41.5%; $[Al_2(PO_4)(OH)_2]^+$: 7.2%	[20]
83%	Al-citrate: 98%; Al-hydroxide: 2% (phosphate not considered)	[22]
81%	$[Al(PO_4)(OH)]^-$: 80%; $Al(PO_4)$: 2%; $[Al(CitH_{-1})]^-$: 10%; $Al(OH)_3$: 4%; $[Al(OH)_4]^-$: 3%	[19]
77%	Al-citrate: 80%; Al-phosphate: 20%	[16]

[a] Based on models reported in Ref. [25].
[b] Total is 100%.

3. Biospeciation of Al(III) in blood serum

Absorbed Al(III) is transported through the blood stream, but its speciation in the blood serum is still not known. The chemical composition of the serum given in Table 1 is taken from Ref. [19]. As listed in Table 2, different speciation models [16,19–24] have been reported in the literature.

As concerns the h.m.m. components, all models agree that most of the Al(III) is bound to transferrin; albumin, the other potential h.m.m. carrier protein, is a much weaker metal ion binder and is not assumed to be able to compete for a significant amount of Al(III) [25]. Among the l.m.m. binders, citrate and phosphate are the most important. Amino acids [17], lactic acid, oxalic acid [13] and inorganic anions are not competitive binders in the presence of citrate and phosphate [13,24]. The picture is much more controversial as concerns these l.m.m. Al(III) binders. Daydé et al. [20], Jackson [21] and Harris [19] propose inorganic phosphate as the main Al(III) binder, while Clevette and Orvig [22], Duffield et al. [23] and Öhman and Martin [24] suggest that citrate (Cit) is the only important l.m.m. binder. Our earlier results [16] led us to conclude that both the phosphato and citrato complexes of Al(III) contribute to the l.m.m. fractions in the blood plasma, although about 80% of the Al(III) binds to transferrin.

The reason of such contradictory results is the lack of reliable speciation data [13,26]. In the Al(III)–phosphate (A^{3-}) system, under model conditions in the mmol dm^{-3} concentration range precipitation occurs at $pH > 3.5$, and we need to extrapolate from these data to physiological conditions, which are entirely different from the model conditions. We used LFER relationships to obtain more reliable speciation data for the Al(III)–phosphate system: $\log \beta\ ([AlAH]^+) = 17.6$, $\log \beta\ (AlA) = 13.5$, $\log \beta\ ([AlAH_{-1}]^-) = 7.2$ at 25°C and $I = 0.2$ mol dm^{-3} (KCl) [14].

Further, there are rather slow oligomerization reactions in the Al(III)–citrate (A^{3-}) system, which are strongly concentration dependent. As first reported by Öhman [27,28], at mmol dm^{-3} model concentrations a trinuclear species $[Al_3(CitH_{-1})_3(OH)]^{4-}$ predominates in a wide pH range including the physiological pH, when the thermodynamic equilibrium state is monitored by potentiometric titration (equilibration may take hours, especially in equimolar metal ion to ligand solutions). This trinuclear species is formed, but in a rather slow process, via the interactions of mononuclear 1:1 and 1:2 complexes, which exist at the beginning of complex formation and also predominates at high excesses of ligand [29]. The slow formation of the trinuclear complex through one or two intermediate species is nicely demonstrated by the changes in the ^1H NMR spectra at pH ~ 5 (see Fig. 1); after mixing, the signals are poorly resolved, broad and merged, indicating dynamic changes in the system. The complexation processes and/or ligand exchange between the initially formed mononuclear complexes and the intermediate species seem to be fairly fast. In the equilibrium state the characteristic, but rather complicated pattern of the trinuclear complex $[Al_3(AH_{-1})_3(OH)]^{4-}$ predominates in the spectrum. It is a reasonable question whether this approach provides a realistic description of the Al(III) speciation under physiological conditions: when the Al(III) concentration really exceeds a few μmol dm^{-3}, the ligand excess for potential binders is at least 1000–

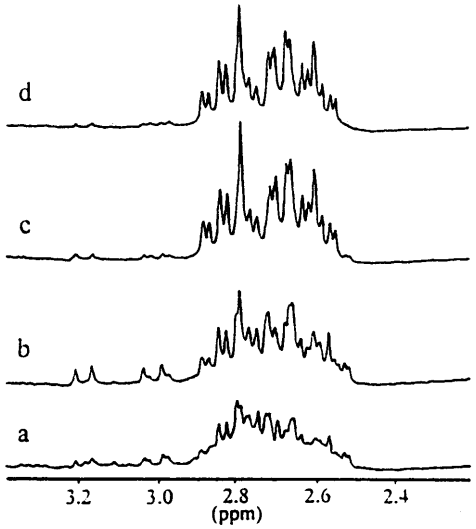

Fig. 1. ^{1}H NMR spectra of the Al(III)–citrate (A^{3-}) system, 1:1, at pH 5.0 as a function of time: (a) 15 min, (b) 40 min, (c) 10 h and (d) 30 h after mixing of the components, with $c_{Al(III)} = 0.04$ mol dm^{-3} (taken from Ref. [30]).

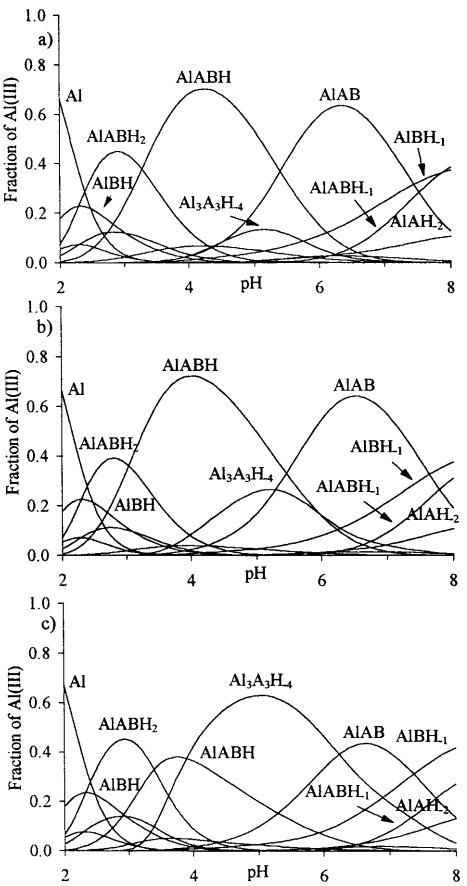

Fig. 2. Time-dependent speciation curves of Al(III)–citrate (A^{3-})–phosphate (B^{3-}) system at a 1:1:4 metal ion to ligand ratio: (a) 5 min, (b) 40 min and (c) 30 h after mixing of the components, with $c_{Al(III)} = 0.04$ mol dm^{-3}.

10 000-fold, and in consequence of the continuous metabolism, the biological fluids are open systems, which never reach real thermodynamic equilibrium. The problem of time-dependent speciation is a real challenge in Al(III) bioinorganic chemistry. Speciation model and stability constants for complexes formed in the Al(III)–citrate system at 25°C and $I = 0.2$ mol dm^{-3} (KCl) are as follows: $\log\beta$ ($[AlCitH]^{+}$) = 10.15, $\log\beta$ (AlCit) = 7.86, $\log\beta$ ($[AlCitH_{-1}]^{-}$) = 4.15, $\log\beta$ ($[AlCitH_{-2}]^{2-}$) = −1.71, $\log\beta$ ($[AlCit_2]^{3-}$) = 12.75, $\log\beta$ ($[AlCit_2H_{-1}]^{4-}$) = 7.94 and $\log\beta$ ($[Al_3(CitH_{-1})_3(OH)]^{4-}$) = 16.35 [30,31].

With a single exception, the results listed in Table 2 were obtained by ignoring the formation of ternary complexes between citrate and phosphate.

We recently have studied the Al(III)–citrate (A^{3-})–phosphate (B^{3-}) ternary system and monitored the time-dependent speciation by pH-potentiometry and multinuclear ^{1}H, ^{13}C and ^{31}P NMR spectroscopy. A detailed description of the role of time in the speciation of this system is given elsewhere [32]. Here, we focus only on the application of these results in order to obtain a reliable description of the speciation of Al(III) under serum conditions. The speciation curves obtained by pH-metry at different times after mixing of the necessary amounts of the stock solutions of Al(III) and citric acid adjusted to the required pH are shown in Fig. 2.

It can be seen that the ternary species $[AlABH]^{2-}$, $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$ predominate throughout the whole pH range from mixing until real thermodynamic equilibrium is reached. Time affects only the concentration of the trinuclear species, which is formed in a rather slow process from the mononuclear species $[AlAH_{-1}]^{-}$ and OH^{-}:

$$3[AlAH_{-1}]^{-} + H_2O = [Al_3(AH_{-1})_3(OH)]^{4-} + H^{+}$$

In the physiological pH range, Al(III) is bound in the ternary species $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$, and the binary species with phosphate, $[AlBH_{-1}]^{-}$, and citrate, $[AlAH_{-2}]^{2-}$. The results were rather surprising as the monodentate phosphate proved to be at least as efficient an Al(III) binder as the tridentate citrate. Multinuclear NMR measurements confirmed this result. It can be seen in Fig. 3, that when phosphate was added in twofold excess to a solution of the trinuclear species, the phosphate slowly displaced citrate from the oligomeric complex and in a few days the characteristic quartet of citrate was observed in the ^{1}H NMR spectrum.

Similarly, the ^{31}P NMR spectrum (Fig. 4) of the Al(III)–citrate–phosphate system at pH $\sim$7 exhibits three signals, a sharp resonance at $\sim$2 ppm, ascribed to free phosphate and two broad resonances at -3.3 and -13 ppm, ascribed to Al(III)-bound phosphates [14]. A comparison of the NMR spectrum with the speciation curves calculated for the experimental condi-

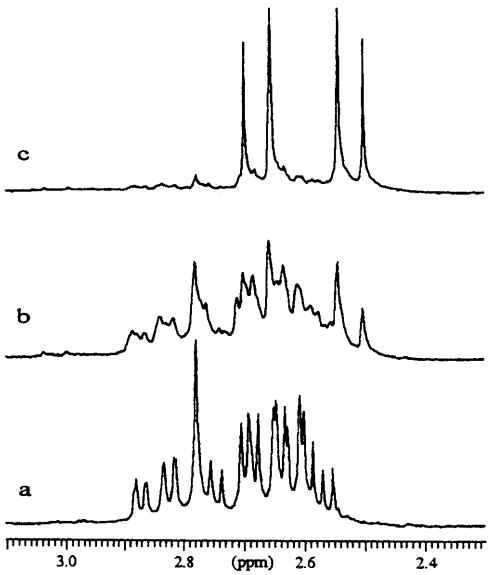

Fig. 3. ^{1}H NMR spectra at pH 7.4 of: (a) $[Al_3(CitH_{-1})_3(OH)]^{4-}$, 10 mmol dm^{-3}; (b) 10 h after the addition of phosphate to the sample in 20 mmol dm^{-3} concentration; and (c) 5 days after the addition of the phosphate to the solution (equilibrium state) (taken from Ref. [32]).

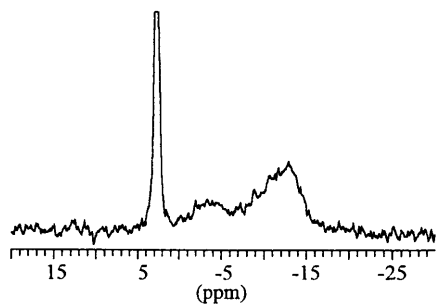

Fig. 4. ^{31}P NMR spectrum of the Al(III)–citrate (A^{3-})–phosphate (B^{3-}) system, 1:1:2, at pH 7.4 in the thermodynamic equilibrium state, with $c_{Al(III)} = 0.04$ mol dm^{-3}.

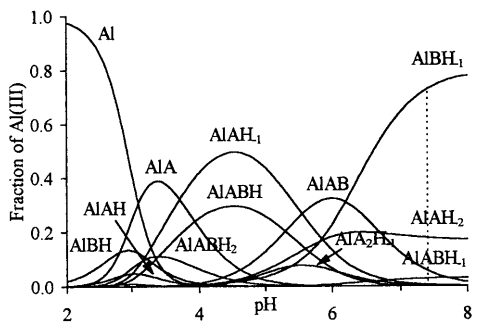

Fig. 5. Speciation curves for the complexes formed in the Al(III)–citrate (A^{3-})–phosphate (B^{3-}) system mimicking serum conditions: $c_{Al(III)} = 0.6$ μmol dm^{-3} (20% of the total $c_{Al(III)}$ in the serum, which is bound to l.m.m. ligands), $c_{citrate} = 99.0$ μmol dm^{-3}, and $c_{phosphate} = 1.1$ mmol dm^{-3}.

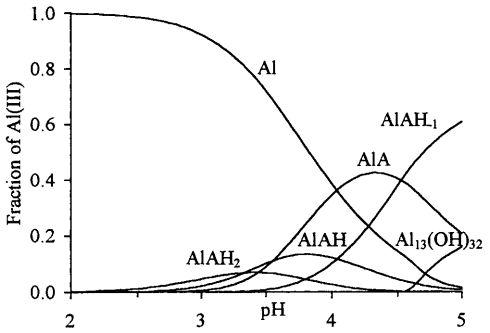
tions of the NMR measurements indicates practically complete agreement between the speciation results obtained by the two independent methods. Fig. 5 depicts the species distribution of Al(III) under plasma conditions. At physiological pH, phosphate seems to be the more efficient Al(III) binder, although citrate-bound Al(III) also occurs in significant concentration, in accordance with the results of Sadler et al. [33], who detected Al(III)-bound citrate in native serum by means of ^{1}H NMR.

4. Interactions of Al(III) with oligopeptides

Another Al(III) speciation problem relates to the interactions of Al(III) with proteins or peptides and their phosphorylated derivatives. This is connected with the involvement of Al(III) in Alzheimer's disease (AD), which is again a rather controversial issue [34]. There are probably a majority who deny any connection between Al(III) and AD. The crucial question is whether Al(III) is present at elevated concentrations in neurofibrillary (NF) tangles and/or senile plaques, which are common intracellular and extracellular markers of AD. According to our rather modest view, Al(III) is certainly not a causative factor in AD but it can be a risk factor as it can enhance plaque and tangle formation [35,36]. It has been clearly demonstrated by CD and FT-IR methods that Al(III) can interact with O-donors, such as Asp–COO^{-}, Glu–COO^{-} or Ser–OH, Thr–OH or Tyr–O^{-} rich fragments of β-amyloids or NF-proteins either via intramolecular complexation, causing conformational changes, or via intermolecular complex formation, linking peptide chains together through the carboxylates or phosphorylated Ser or Tyr sites. And this leads to the aggregation of neuronal degradation products.

The above mentioned results led us to attempt to obtain quantitative equilibrium-speciation and solution structural information concerning these interactions. Accordingly, we first studied the interactions of Al(III) with the building blocks of these compounds, i.e. amino acids, such as Asp, Glu, Ser, etc. [17], and also with phosphorylated Ser and Tyr [18]. Then we continued with small peptide model systems, first the Al(III)–Asp-Asp (H_3A) system. As demonstrated in Fig. 6, in the weakly acidic pH range the formation of mono complexes in different protonation states, $[AlAH_2]^{2+}$, $[AlAH]^{+}$, AlA and $[AlAH_{-1}]^{-}$ was detected, but, depending on the metal to ligand ratio, precipitation occurred at pH $\sim$5–6. This indicates that the terminal COO^{-} groups of Asp (or Glu) are not sufficient in such a small peptide to keep Al(III) in solution and to prevent precipitation of $Al(OH)_3$. To achieve this, a more specific arrangement of suitable side-chain donors is necessary.



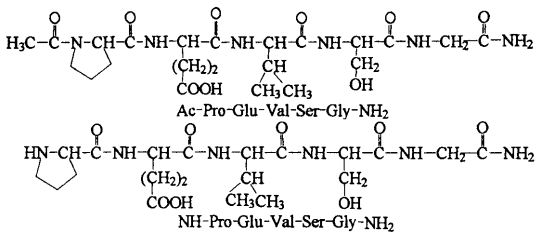


Fig. 6. Speciation curves for the complexes formed in the Al(III)–AspAsp (A^{2-}) system at a 1:4 metal ion to ligand ratio, with $c_{Al(III)} = 1.0$ mmol dm^{-3}.

Scheme 2.

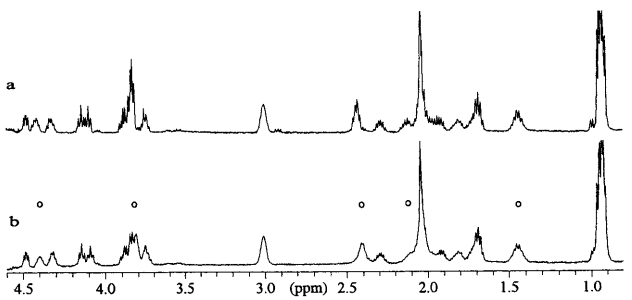

Fig. 7. ^{1}H NMR spectra of Ac–LysSerProValValGluGly (H_2A) at 4.0 mmol dm^{-3} at pH 4.0 (a) in the absence and (b) in the presence of 4.0 mmol dm^{-3} Al(III).

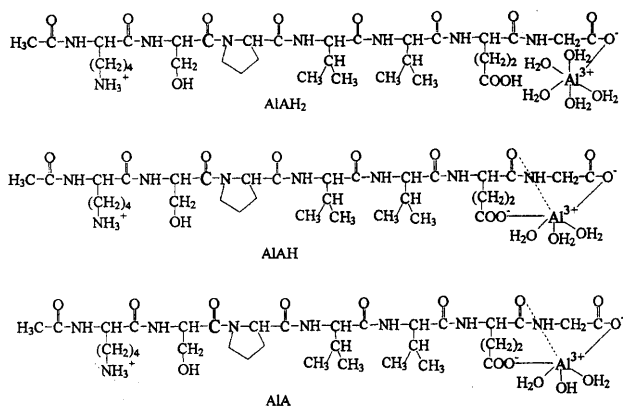

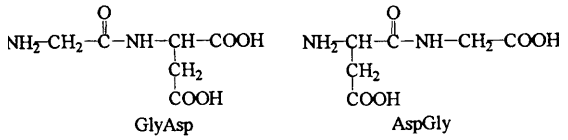

Fig. 8. Suggested binding modes in the Al(III) complexes of Ac–LysSerProValValGluGly (H_2A).

We have studied several penta- and heptapeptides. Only preliminary data are available on these systems at present and a full speciation and structural description of the Al(III) complexes formed with oligopeptides will be reported later. In the first group, pentapeptides were studied, which were rich in Glu and Ser, and had a protected C-terminus and a free or protected N-terminus, e.g. Ac–ProGluValSerGly–NH_2 (HA) and its analogue HN–ProGluValSerGly–NH_2 (HA)(see Scheme 2). We found that the Al(III)-binding capabilities of the peptides were stronger when they had a free Pro–NH function at the N-terminus. This is rather surprising as Al(III), is known [17,37] to have a low affinity for amines, and the N-terminal Pro–NH group is therefore not expected to be a strong binding site. As the C-terminal COO^- was blocked in both peptides, we would expect coordination via the side-chain Glu–carboxylate and Ser–alcoholate groups. Instead, coordination seems to be much more likely through the N-terminal donor groups. In a second group the peptides had a free C-terminus, but a blocked N-terminus. With these heptapeptides, 1:1 complexes could again be detected by pH-metry; for one of these peptides, Ac–LysSerProValValGluGly (H_2A, the formula is given in Fig. 8), the stability constants obtained were as follows: $\log \beta$ ($[AlAH_2]^{3+}$) = 17.11, $\log \beta$ ($[AlAH]^{2+}$) = 13.30, $\log \beta$ ($[AlA]^{+}$) = 9.36 $\log \beta$ ($AlAH_{-1}$) = 4.72, $\log \beta$ ($[AlAH_{-2}]^{-}$) = -0.42. ^{1}H NMR indicated a weak interaction of the peptide with Al(III) in the slightly acidic pH range. Fig. 7 depicts the ^{1}H NMR spectra of the peptide at pH ~ 4 in the absence and the presence of equimolar Al(III).

The significant selective line broadening indicates interactions between the peptide and the metal ion. The rate of the ligand-exchange reaction is roughly comparable with the NMR time scale; hence, there is no shift in the position of the resonances, and there is no increase in the number of signals. The preliminary assignments of the signals indicate mostly that the signals of the protons near the C-terminus undergo broadening mostly, which suggests that coordination starts at the terminal-COO^-, (complex $[AlAH_2]^{3+}$) and Al(III) then chelates through the terminal-COO^- of the peptide and the side chain-COO^- of Glu with participation of the central peptide-carbonyl, through the formation of a joint chelate system (complex $[AlAH]^{2+}$), and then parallel overlapping deprotonation of the non-coordinating protonated amino donor and a coordinated water molecule subsequently takes place ($[AlA]^{+}$, $AlAH_{-1}$ and $[AlAH_{-2}]^{-}$) (see Fig. 8). Two-dimensional carbon–proton correlation NMR measurements are in progress in order to achieve a complete assignment of the protons. Molecular dynamic calculations indicate favored arrangements of the terminal carboxylate and the side-chain-COO^- of Glu for the chelation of Al(III). It is interesting, however, that at

Scheme 3.

pH ~ 7 the two spectra (in the presence and absence of Al(III)) are barely different and direct coordination of Al(III) is therefore not confirmed. However, since no precipitation was observed in the solution, it is very likely that Al(III)-hydroxo species in some metastable state (which occurs fairly commonly in aqueous Al(III) solutions), form outer-sphere complexes through hydrogen-bonding with the hydrated oligopeptides. We are now going further with similar oligopeptides, and also with their phosphorylated derivatives, as interchain links involving Al(III) between oligopeptides can play an even more important role in the aggregation of neuropeptides, than intramolecular Al(III) binding.

To summarize, although the results are not always straightforward, these studies confirm that neurofilament non-phosphorylated peptides can bind Al(III), and this can trigger conformational changes resulting in aggregation processes of β-amyloids and NF tangles.

5. Characterization of VO(IV)–peptide interactions

Vanadium is an important trace metal with a great variety of physiological effects. It can act, for instance, as an enzyme regulator in various phosphate-metabolizing reactions, suggesting binding between vanadium and the protein side-chains [38]. In oxidation states III, IV and V, vanadium binds to transferrin, the essential metal ion transport protein in the serum [39]. Its interactions with oligopeptides in the physiological pH range, via coordination of the deprotonated peptide-N^- group, have been proved to involve vanadium in oxidation state V [40–42].

Vanadium in its high oxidation states $+4$ and $+5$ is a rather hard metal ion, like Al(III), and forms complexes of fairly high stability with ligands containing O-donor atoms, but it binds more weakly to N- or S-donor containing biogenic ligands [43] in solution. It was seen above that Al(III) is able to bind to peptides at either the N-terminal or the C-terminal end, involving mostly O-donor groups, but is not able to induce deprotonation and subsequent coordination of the peptide amide. And what about VO(IV)? The amide coordination of a few synthetic ligands to VO(IV) has been observed in the solid state [44]. Tasiopoulos et al. [45] recently isolated the first VO(IV) complexes of dipeptides containing a deprotonated peptide-N^- group. In aqueous solution, however, no unambiguous proof has been obtained for VO(IV)-promoted amide deprotonation and coordination, although this was strongly suggested in some glycine/alanine dipeptide complexes by CD and EPR measurements [46]. Among various binding isomers, a species with the usual (NH_2, N^-, COO^-) coordination involving deprotonated amide-N^- was also assumed at pH ~ 8. Interestingly, no amide deprotonation was observed with the tripeptide GlyGlyGly [47]. It has been found for many metal ions that the presence of a suitable anchoring donor which can bind metal ions strongly enough and promote deprotonation of the amide plays a crucial role in amide deprotonation [48]. In aqueous solution, the terminal-NH_2 is not a particularly good anchoring donor for the hard VO(IV) ion.

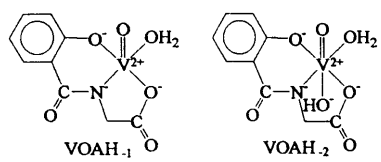
In order to make the arrangement of the donor groups more favorable for VO(IV) binding, we studied how the presence of an extra negatively charged O-donor side-chain COO^- group at the C- or N-terminus of simple dipeptides affects the VO(IV) binding of GlyAsp and AspGly (H_2A, Scheme 3) [49]. The results were very similar to those for simple dipeptides: no amide deprotonation could be detected with GlyAsp, but was suggested with AspGly at pH ~ 8 after dissolution of the precipitate $VO(OH)_2$. The side-chain O-donors near the terminal -NH_2 or COO^- groups did not favor amide deprotonation and coordination, as new competitive binding sites in chelating positions were developed in the molecules, and these bound the metal ions.

In the next step, the terminal $-NH_2$ group was replaced by a hard phenolate as anchoring donor group: the dipeptide analogue salicylglycine (SalGly) ($HOC_6H_4C(O)NHCH_2COOH$, 2-hydroxyhippuric acid, H_2A) proved to be an efficient VO(IV) binder: no precipitate occurred in the pH range 1–12, and EPR unambiguously indicated the presence of a N donor around the metal ion [50]. As may be seen in Table 3, the fairly high g values and low A values strongly suggest the presence of a coordinated amide-N^- in the equatorial plane of the species $[VOAH_{-1}]^-$ and $[VOAH_{-2}]^{2-}$ (Scheme 4).

We recently started investigations of the tripeptide analogue SalGly–L–Ala (H_2A) too, where the terminal amino acid is an L enantiomer, and thus we can also use CD to obtain information regarding the binding modes of the ligand. Our preliminary results indicate that both CD and EPR suggest coordination of the peptide-amides in the pH range 4–9. For example, a further decrease in the coupling constants A and an increase in the g factor of the complex $[VOAH_{-2}]^{2-}$ ($g_o = 1.983$, $A_o = 85$, $g_{\|} = 1.963$, $A_{\|} = 157$ and $g_{\perp} = 1.985$, $A_{\perp} = 51$) is a fairly unambiguous indications of the presence of N donors in the equatorial coordination sphere of VO(IV) (Scheme 5). Interestingly, with SalGlyAla the formation of various dimeric species pre-

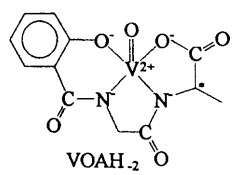
Table 3
Speciation and EPR data on VO(IV)–SalGly system [a]

Species	log β	g_o	A_o (10^{-4} cm^{-1})	$g_{\|}$	$A_{\|}$ (10^{-4} cm^{-1})	$g_{\perp}$	$A_{\perp}$ (10^{-4} cm^{-1})
$[VOAH]^+$	10.24(3)						
VOA	7.05(2)	1.964	101	1.938	175		
$[VOAH_{-1}]^-$	2.29(2)	1.971	92	1.949	165	1.980	57
$[VOAH_{-2}]^{2-}$	−5.28(3)	1.971	89	1.951	163	1.980	55
$[VOA_2H_{-1}]^-$	5.55(6)						



[a] Data are taken from Ref. [50].

dominates in the pH range 4–10 and through stepwise deprotonation of the species $[(VO)_2A_2]^{2-}$ to $[(VO)_2A_2H_{-4}]^{6-}$ the coordination mode changes from $2 \times (COO^-,=O,=O,O^-)$ to $2 \times (COO^-,N^-,N^-,O^-)$. The driving force of dimer formation is presumably the stacking interaction between the aromatic rings. The CD results suggest that the stepwise deprotonation and coordination of the amide start at the C-terminal end of the ligand. Accordingly, the terminal COO^- and not the phenolate seems to be the primary anchor. Further studies with various peptides, pseudopeptides and derivatives in a search for efficient anchors which can promote amide deprotonation are currently in progress in our laboratories. For example, in connection with the phenolate and carboxylate anchors, we have been studying the VO(IV) complexation with *N*,*N*′-bis(5-sulphosalicyl)ethylenediamine and *N*,*N*′-bis(malonyl)-ethylenediamine, when phenolate or carboxylate anchors, respectively, are available at both ends of the molecules. With various *N*-D-gluconylamino acids, EPR and CD measurements indicated the formation of species containing a deprotonated peptide-N^- donor. Alcoholic-OH groups of the sugar moiety in appropriate steric arrangements proved to be efficient anchors [51]. Similarly, thiolate-S^- in mercaptopropyonylglycine [52,53] and gluthathione [52,54,55] seem to be suitable anchoring donors towards VO(IV) to induce amide deprotonation not only in the solid state [52], but also in solution [53–55]. Phosphonic ($-PO_3^{2-}$) groups of diphosphono-dipeptides has been shown to act as efficient anchoring donors towards Cu(II) [56], and we are now studying their interactions with VO(IV).



6. Vanadium complexes as insulin mimetics

Vanadium is a nutritional element present in mammalian tissues. It is available in anionic and cationic forms, the most common ones under physiological conditions being vanadate(V) ($H_2VO_4^-$) and oxovanadium-(IV) (VO^{2+}). Many studies have been performed on the biological significance of vanadium compounds during the past two decades. The insulin-like effect of vanadium is one of the most noteworthy findings and the relationship between vanadium and diabetes mellitus has been extensively studied [57–60]. Since the first report of the insulin-mimetic activities of vanadium compounds in vitro in 1979 [57], and in vivo in 1985 [60], great efforts have been made to prepare vanadium-(IV) and vanadium(V) complexes of high biological activity and low toxicity which are readily absorbed. Among others Orvig et al. and Sakurai et al. prepared many oxovanadium(IV) complexes with various coordination modes, such as $VO(O_4)$ [61–63], $VO(S_2N_2)$ [64], $VO(S_4)$ [65,66], $VO(N_3O)$ [67], and $VO(N_2O_2)$ [68–70], and examined the relationship between their structures and insulin-mimetic activities by evaluating both the in vitro and the in vivo experimental results.

With regard to the coordination chemistry of VO(IV), fairly stable complexes can be expected with O-donor ligands, but not with N,S donors. These complexes will presumably decompose and liberate most of the carrier ligands when they dissolve after oral administration. Even if they form strong complexes at neutral pH, at the pH ~ 2 of the gastric juice in the stomach they will almost completely dissociate, being labile complexes. Accordingly, other biomolecules that are potential metal ion binders present in biological fluids may partially or completely displace the original VO(IV)-carrier molecules from the coordination sphere of the metal. Ternary complex formation should therefore be taken into account in a speciation description of these complexes in biological fluids. Such ternary complexes

Scheme 4.

Scheme 5.

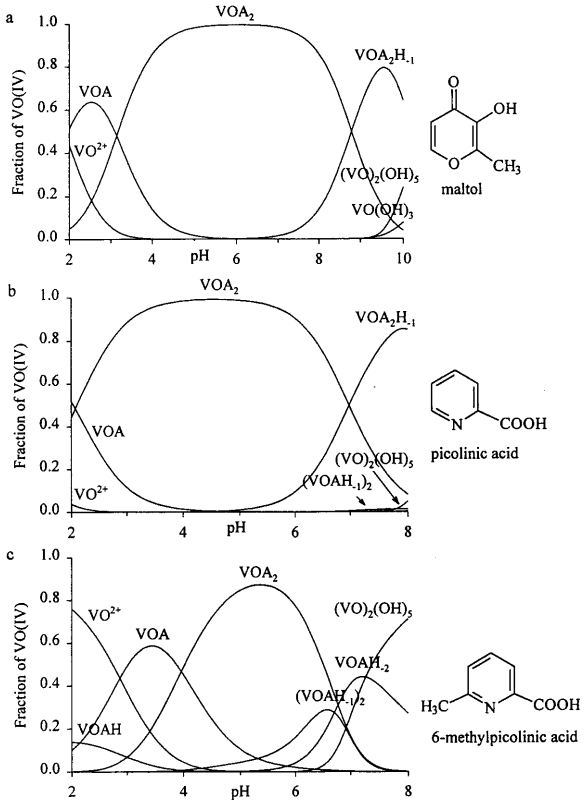


Fig. 9. Speciation curves for complexes formed in the systems: (a) Al(III)–maltolate (A^-), (b) VO(IV)–picolinate (A^-) and (c) VO(IV)–6-Me-picolinate (A^-) systems at a 1:4 metal ion to ligand ratio, with $c_{VO(IV)} = 0.002$ mol dm^{-3}. Calculated with stability constants reported in Refs. [71,72].

might be of great importance in the absorption and transport processes of the various potential insulin-mimetic drugs, such as VO(maltolate)$_2$, VO(picolinate)$_2$ and VO(6-Me-picolinate)$_2$ and even in their physiological activity. In order to describe the speciation of these insulin mimetics in various biological systems, we are currently studying their interactions with l.m.m. biomolecules in the organism, such as phosphate (gastro-intestinal tract), adenosinenucleotides (intracellular fluids), hydroxycarboxylic acids, lactic acid and citric acid (blood serum) and catecholamines, e.g. dopamine (brain). Here, mostly results on the ternary complex formation of VO(maltolate)$_2$ are presented [71].

7. Biospeciation of insulin-mimetic VO(IV) complexes in biofluids

We shall consider first the solution speciation of the insulin-mimetic compounds: VO(maltolate)$_2$, VO(picolinate)$_2$ and VO(6-Me-picolinate)$_2$ [71–73]. As may be seen in Fig. 9, mono and bis complexes are formed in these systems, but there are great differences between the stability constants of the complexes formed. Maltol forms the most stable complexes with the VO(IV) ion via the formation of five-membered chelates through the oxo and alcoholate groups. The neutral bis complex, which may have good membrane transport properties, exists in the pH range 5–7.5. Picolinic acid and 6-methylpicolinic acid also form mono and bis complexes via the pyridine N and carboxylate groups. However, the methyl group in 6-methylpicolinic acid has a very marked effect on the VO(IV)-binding capabilities of the ligands: presumably because of the steric effect of the methyl group, the stabilities of these complexes are significantly lower. This is more pronounced for the 1:2 complexes. In the VO(IV)–picolinic acid system, the bis complex is predominant in the pH range 2–7, while for 6-methylpicolinic acid VOA_2 exists in the pH range 4–6. The VO(IV)-binding abilities of the ligands studied exhibit the sequence maltol > picolinic acid > 6-methylpicolinic acid. The EPR parameters of the bis complexes listed in Fig. 10 also support this sequence. The value of the hyperfine constant, $A_{\|}$ increases, while the $g_{\|}$ value decreases in this direction, which reveals the formation of bonds with different strengths in these systems. The EPR results show that the bis complexes

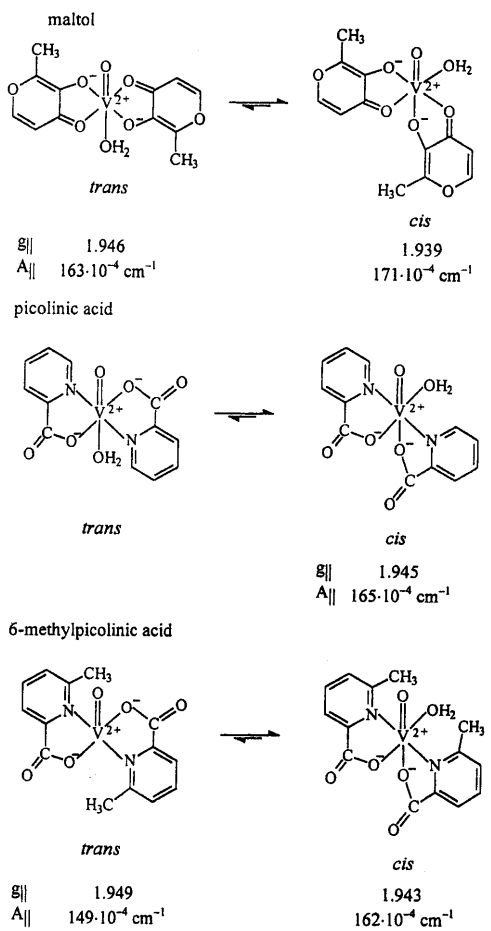

Fig. 10. Geometric isomers and EPR parameters of VO(maltolate)$_2$, VO(picolinate)$_2$ and VO(6-Me-picolinate)$_2$.

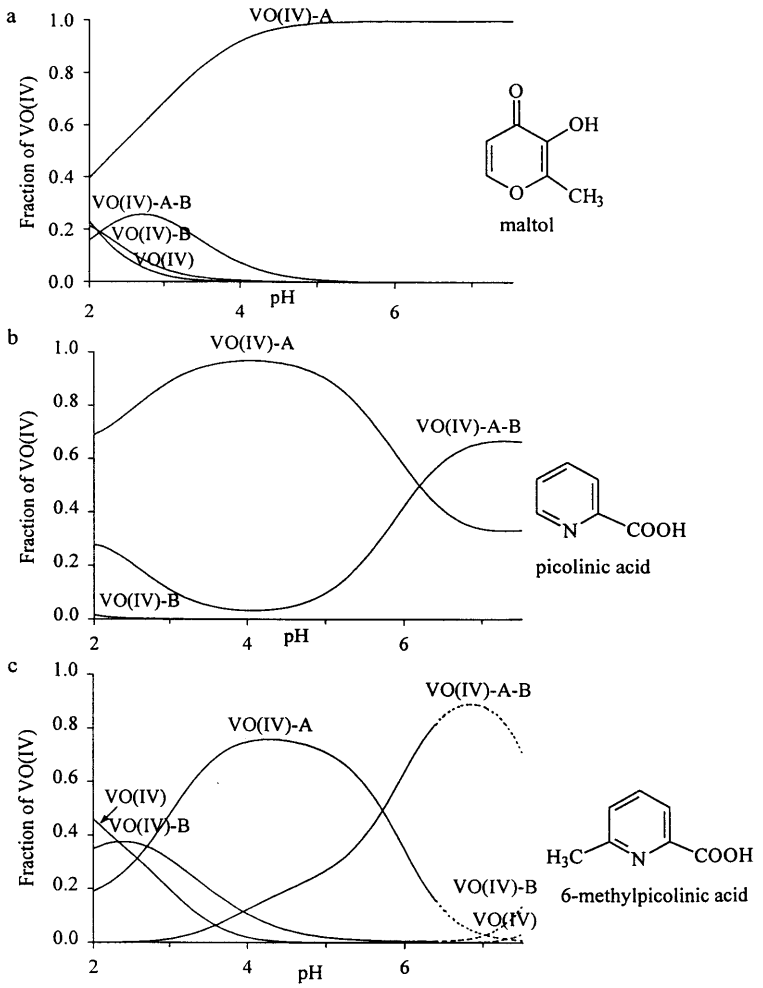

Fig. 11. Predominance diagram of the systems (a) VO(IV)–maltolate (A^-)–phosphate (B^{3-}), (b) VO(IV)–picolinate (A^-)–phosphate (B^{3-}), and (c) VO(IV)–6-Me-picolinate (A^-)–phosphate (B^{3-}) systems at a 1:5:5 metal ion to ligand ratio, with $c_{VO(IV)} = 0.001$ mol dm^{-3}.

form two geometric isomers, depending on the position of the solvent molecule in the coordination sphere of the VO(IV): the water molecule can be either *cis* or *trans* to the oxo group of the vanadium ion (see Fig. 10). In aqueous solution at room temperature and at neutral pH, the *cis* form of the bis complexes has been found to predominate with these three ligands. 6-Methylpicolinic acid proved to be the weakest VO(IV) binder, but it has the most hydrophobic character and hence its complex may provide a more efficient absorption via passive transport across the hydrophobic membranes [69].

Phosphate, as the most important l.m.m. component in the gastro-intestinal tract, may play a role in the absorption of these insulin-mimetic compounds. Predominance curves (the sum of the VO(IV) fractions bound in the binary complexes with ligand A or B and those bound in the ternary complexes with ligand A and B) for the systems VO(IV)–insulin mimetic (A^-)–phosphate (B^{3-}) are depicted in Fig. 11. It is seen that the parent complexes $[VOA]^+$ and $[VOA_2]°$ of maltol are the predominant species at pH >4, a range including the physiological pH, and the presence of phosphate affects the speciation of the VO(IV)–maltol system only slightly. Ternary complexes occur only in the pH range 2–4, but they never become predominant species. They are favored, however, with picolinic acid and 6-methylpicolinic acid. In the weakly acidic pH range and at neutral pH, mixed ligand complexes are the predominant species [72]. Accordingly, phosphate will certainly not affect the absorption of VO(maltolate)$_2$, but might have some (though not necessarily beneficial) influence on the absorption of the two picolinates. The ternary complexes are certainly charged species (the coordinating hydrogenphosphate HPO_4^{2-} a charge 2–, while the picolinate displaced by the phosphate molecule is mononegatively charged), in contrast with the neutral binary complex, and this may hinder at least the passive transport of VO(IV) through the membrane.

Adenosinenucleotides occurs in mmol dm^{-3} concentration in cellular fluids, and their interactions with

'exogenous' compounds in the organism are very likely. The predominance diagram for the VO(IV)–maltol (A^-)–ATP (B^{3-}) system (see Fig. 12) clearly indicates that maltol forms ternary complexes in the weakly acidic pH range (4.5–5.5), as detected by both pH-metry and EPR spectroscopy. The EPR spectra depicted in Fig. 13 show that a new species is present in practically the same pH range, and is presumably the mixed-ligand complex $[VOAB]^{2-}$. However, at physiological

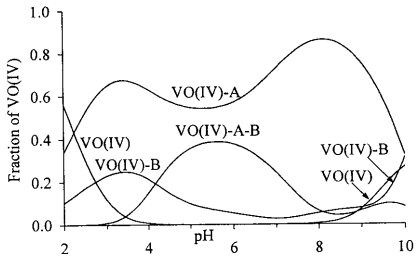

Fig. 12. Predominance diagram of the VO(IV)–maltolate (A^-)–ATP (B^{3-}) system at a 1:2:2 metal ion to ligand ratio, with $c_{VO(IV)} = 0.002$ mol dm^{-3}.

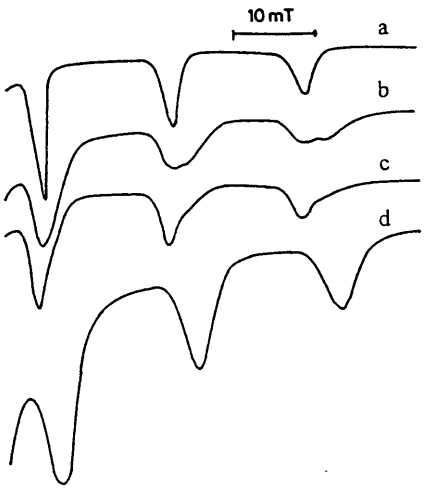

Fig. 13. High field parallel region of frozen solution EPR spectra (X band) recorded at 140 K: (a) VO(IV)–maltolate, 1:2, pH 5.5; (b) VO(IV)–maltol–ATP, 1:1:1, pH 4.5; (c) VO(IV)–maltol–ATP, 1:1:1, pH 5.5; (d) VO(IV)–ATP, 1:2, pH 5.5; $c_{VO(IV)} = 0.004$ mol dm^{-3} (taken from Ref. [71]).

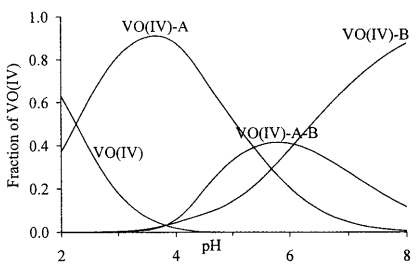

Fig. 14. Predominance diagram of the VO(IV)–maltolate (A^-)–dopamine (B^{2-}) system at a 1:2:2 metal ion to ligand ratio, with $c_{VO(IV)} = 0.002$ mol dm^{-3}.

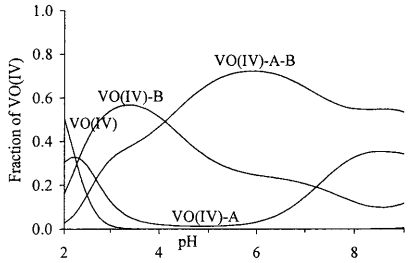

Fig. 15. Predominance diagram of the VO(IV)–maltolate (A^-)–citrate (B^{3-}) system at a 1:2:2 metal ion to ligand ratio, with $c_{VO(IV)} = 0.002$ mol dm^{-3}.

pH, maltol seems to be more competitive and VO(IV) is bound mostly to maltol. At pH >10, maltol is displaced and the ribose part of the nucleotides binds the metal [71].

The concentrations of catecholamines in the brain are fairly high. Catechol derivatives are extremely strong VO(IV) binders; they can even displace the oxo group of VO(IV) and form non-oxo $3 \times (O^-,O^-)$-coordinated tris complexes [74–76]. The high affinity of catecholates for VO(IV) is hindered in the acidic pH range because of the high proton competition on the phenolate functions. At the same time, maltol, which is also a strong VO(IV) binder, has a high affinity for VO(IV) in the acidic pH range, owing to the weaker proton competition on the maltolate chelating function. Accordingly, in the VO(IV)–maltol (A^-)–dopamine (B^{2-}) system, maltol is the predominant metal ion binder at pH <4.5; the ternary complexes of VOABH and $[VOAB]^-$ then become predominant up to pH ~ 6, while at around the physiological pH range the catechols are more efficient VO(IV) binders and displace maltol completely (see Fig. 14).

As discussed above, citrate is an important constituent of the blood serum: its concentration is ~ 0.1 mmol dm^{-3} (see Table 1). It generally behaves as a tridentate ligand in its complexes and is regarded as the strongest l.m.m. hard metal ion binder in the serum. As shown in Fig. 15, pH-metric speciation measurements and spectral studies unambiguously suggest enhanced ternary complex formation in the pH range 4–8. A considerable intensity decrease in the EPR spectrum of VO(IV)–citrate (B^{3-}) in neutral solution, due to the formation of oxo-bridged dinuclear species [77], is not observed, but the spectrum indicate the formation of new mononuclear complexes, presumably the ternary $[VOABH]^-$, $[VOAB]^{2-}$ and $[VOABH_{-1}]^{3-}$, in a wide pH range. These data strongly suggest that, if they meet, citrate will certainly react with $VO(maltolate)_2$, and this potential drug may be transported in the blood serum, presumably in the form of its ternary species with citrate. A more detailed study of the biospeciation of various insulin-mimetics in the serum is at present in progress in our laboratory.

Acknowledgements

This research was carried out in the frame of a COST D8 project. The authors wish to express their thanks to Professors G. Micera (University of Sassari, Italy), J. Costa Pessoa (University of Lisbon, Portugal), R. Bertani (C.N.R., Padova, Italy), M. Hollosi (Eotvos University, Budapest, Hungary), Zs. Majer (Eotvos University, Budapest, Hungary), Gy. Dombi (Medical University Szeged, Hungary), G. Toth (Medical University Szeged, Hungary) and P. Buglyo (Kossuth University, Debrecen, Hungary) for their valuable contributions to this work. Financial support was provided by the Hungarian Research Fund (OTKA T23776/97) and the Hungarian Ministry of Education (FKFP 0013/97).

Abstract

The complexation equilibria of Sn^{2+} ion with orthophosphate ions have been studied, at 25°C in 3 M $NaClO_4$ ionic medium, by potentiometric titrations with Sn^{2+}/Sn–Hg and glass electrodes. The concentrations of the metal and of the ligand ranged from 2.5×10^{-4} to 2.5×10^{-3} M and from 0.01 to 0.3 M, respectively. The hydrogen ion concentration varied between 0.1 and $10^{-5.8}$ M. The potentiometric data are consistent with the formation of the complexes: $SnH_2PO_4^+$, $Sn(H_2PO_4)_2$(aq), $SnH_2PO_4HPO_4^-$, $SnHPO_4$(aq), $Sn(HPO_4)_2^{2-}$, $Sn(HPO_4)_3^{4-}$ and $SnPO_4^-$. Stability constants for their formation in 3 M $NaClO_4$ and in dilute solution are reported. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Tin(II); Phosphato complexes; Solution equilibria; Speciation

1. Introduction

Cilley [1] has studied the reaction between Sn^{2+} and PO_4^{3-} ions at 25°C in 0.2 M $NaClO_4$ by measuring the solubility of the sparingly soluble $SnHPO_4 \cdot 0.5H_2O$ as a function of the orthophosphate concentration in the range 3×10^{-4}–0.09 M. The pH was kept constant at 2.48. Cilley explained the data by assuming the equilibria: $SnHPO_4(s) \rightleftarrows Sn^{2+} + HPO_4^{2-}$ (solubility product $= 1.5 \times 10^{-13}$), $Sn^{2+} + HPO_4^{2-} \rightleftarrows SnHPO_4(aq)$ and $Sn^{2+} + 3HPO_4^{2-} \rightleftarrows Sn(HPO_4)_3^{4-}$ with constants 6.7×10^7 and 1.1×10^{10}, respectively.

Measurements at a constant pH gives no information on the number of protons bound in the complex species. Furthermore, the solubility method does not allow any decision on whether the complexes are mono- or polynuclear in the central ion. It was, therefore, worth a reinvestigation of the system by potentiometric methods in an as wide as possible concentration range of the reagents.

In the present work the complex formation equilibria were investigated at 25°C in 3 M $NaClO_4$ ionic medium by potentiometric titrations based on Sn^{2+}/Sn–Hg as well as glass half-cells.

2. Experimental

2.1. Cells and equations

Titrations were carried out with cells (M) and (H)

$(-)$Sn(0.2%)–Hg/test solution/RE$(+)$ (M)

$(-)$RE/test solution/glass electrode$(+)$ (H)

where RE is the reference electrode: Ag/AgCl/0.01 M NaCl, 2.99 M $NaClO_4$/3 M $NaClO_4$. The test solutions had the general composition (molarities): $Sn(ClO_4)_2$ (C_M), $HClO_4$ (C_A), H_3PO_4 (C_0), NaH_2PO_4 (C_1), Na_2HPO_4 (C_2), $NaClO_4$ ($3\text{-}C_1\text{-}2C_2\text{-}C_A\text{-}2C_M$). Total phosphate concentration, $C_P = C_0 + C_1 + C_2$, was chosen to vary from 0.01 to 0.3 M. The hydrogen ion concentration ranged from 0.1 to $10^{-5.8}$ M. The C_M values were between 2.5×10^{-4} and 2.5×10^{-3} M. At $C_M < 2.5.10^{-4}$ M, the EMF of cell (M) reached constancy too slowly. The higher limit of C_M was imposed by the precipitation of solid Sn(II) phosphates.

The EMFs of cells (M) and (H) can be written at 25°C as Eqs. (1) and (2)

$$E_M = E_{0M} - 0.02958 \log([Sn^{2+}]y_M) - E_j \quad (1)$$

$$E_H = E_{0H} + 0.05916 \log([H^+]y_H) + E_j \quad (2)$$

in which E_{0M} and E_{0H} are constants in each run, y_M and y_H symbolize activity coefficients of Sn^{2+} and H^+ ions, respectively. E_j is the liquid junction potential

arising at the boundary: test solution/3 M $NaClO_4$. The standard states are chosen so that activity coefficients tend to unity as the composition of test solution approaches 3 M $NaClO_4$.

In each experiment, the E_0 values were determined from measurements with solutions of $C_A < 0.01$ and $C_M < 0.0025$ M where phosphate was absent. Under these conditions activity coefficients are with good approximation equal to unity and the liquid junction potential can be evaluated, in accordance with Biedermann and Sillén [2], from $E_j = -0.017[H^+]$. The $[Sn^{2+}]$ and $[H^+]$ values, obtained from C_M and C_A after a small correction for the hydrolysis of the Sn^{2+} ion [3], were inserted in Eqs. (1) and (2) to yield E_{0M} and E_{0H} constant to within $\pm 5 \times 10^{-5}$ V or better.

In the presence of phosphate, medium changes, caused by the replacement of inert ions with reagent species (mainly as $H_2PO_4^-$ ion), affect to some extent E_j and activity coefficients. E_j can be considered a function of $[H^+]$ and $[H_2PO_4^-]$, whilst the activity coefficients are essentially a function of $[H_2PO_4^-]$ only. As described elsewhere [4,5],

$$E_j = -0.017[H^+] - 0.003[H_2PO_4^-] \quad (3)$$

and

$$0.05916 \log y_H = 0.018[H_2PO_4^-] \quad (4)$$

On the other hand, the dependence of y_M on $[H_2PO_4^-]$ cannot be estimated exactly. As shown later, the substitution of $[Sn^{2+}]$ with $[Sn^{2+}]y_M$ has no serious consequences on the deduction of the composition of the reaction products. However, it affects the value of some equilibrium constants.

Values of $[H^+]$ and $[Sn^{2+}]y_M$ were calculated from Eqs. (1)–(4) and mass balances of C_P and $C_H = C_A + C_0 - C_2$. According to previous results [6], in our solutions H^+ and PO_4^{3-} ions associate to form, in addition to H_3PO_4, $H_2PO_4^-$ and HPO_4^{2-}, also $H_6(PO_4)_2$, $H_5(PO_4)_2^-$, $H_4(PO_4)_2^{2-}$ and $H_3(PO_4)_2^{3-}$. Then, in presence of $SnH_{-n}(H_2PO_4)_m^{2-n-m}$ complexes of molarity $c_{n,m}$, one has

$$C_P = [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + 2([H_6(PO_4)_2] + [H_5(PO_4)_2^-] + [H_4(PO_4)_2^{2-}] + [H_3(PO_4)_2^{3-}]) + \sum m c_{n,m} \quad (5)$$

$$C_H = [H^+] + [H_3PO_4] - [HPO_4^{2-}] + 2[H_6(PO_4)_2] + [H_5(PO_4)_2^-] - [H_3(PO_4)_2^{3-}] - \sum n c_{n,m} \quad (6)$$

Sufficiently accurate $[H_2PO_4^-]$ values could be deduced from Eq. (7) neglecting the last term, since $C_P \gg C_M$, and using constants of the H^+-PO_4^{3-} system determined previously [6]

$$C_P + C_H = [H^+] + [H_2PO_4^-] + 2[H_3PO_4] + 4[H_6(PO_4)_2] + 3[H_5(PO_4)_2^-] + 2[H_4(PO_4)_2^{2-}] + [H_3(PO_4)_2^{3-}] + \sum (m-n) c_{n,m} \quad (7)$$

First, preliminary $[H^+]$ and $[Sn^{2+}]y_M$ concentrations were calculated setting $[H_2PO_4^-] = C_P$. Then, a better value of $[H_2PO_4^-]$ was found from Eq. (7) and the cycle repeated to convergence.

The potentiometric titrations were performed according to two procedures: (1) at variable C_P while $[H^+]$ was maintained essentially constant; and (2) at constant C_P and variable $[H^+]$.

2.2. Reagents and analysis

Tin(II) perchlorate solutions of exactly known composition were prepared in situ by constant-potential coulometry employing electrolysis cell (C)

$$(-)\text{AE/test solution/Hg(Sn 0.2\%)}(+) \quad \text{(C)}$$

where AE = Hg/Hg_2Cl_2/0.1 M NaCl, 2.9 M $NaClO_4$/3 M $NaClO_4$. The test solution formed the anodic compartment and the anode was polarized at -0.4 V against RE, the reference electrode of cell (M). At this potential, current intensities higher than 2×10^{-3} A were recorded and the metal was oxidized as tin(II). Since no significant quantities of metal ions are transferred from test solution to the salt bridge, the [Sn(II)] equals half the number of Faradays passed per cubic decimeter of solution.

Tin amalgam was prepared by bringing into contact bidistilled mercury and tin metal, shot 99.999%, supplied by Aldrich, under dilute $HClO_4$ in an inert atmosphere of argon gas.

Argon gas, from commercial cylinders, was freed from traces of oxygen by passing it through 0.1 M chromium(II) chloride and then washed with water and ionic medium.

Sodium perchlorate, sodium mono- and dihydrogen phosphates and other chemicals were prepared as described elsewhere [6].

2.3. Apparatus

EMF measurements were carried out at 25.00 ± 0.02°C, by immersing the cell assembly in a silicone oil thermostat. The cell arrangement was similar to that described by Forsling et al. [7]. Silver/silver chloride electrodes were prepared according to Brown [8]. The glass electrode, type 60102-100, supplied by Metrohm, acquired stable potentials within 15 min after the addition of reagents. They remained constant within 5×10^{-5} V for several hours. An Amel Instruments potentiostat–galvanostat, model 2051, was employed as

constant potential source of the coulometric circuit. The current intensity–time integral was obtained with a computer controlled data acquisition unit. The potentiometric titrations were carried out with a programmable computer controlled data acquisition unit 3421A, supplied by Hewlett–Packard. The EMF of cell (H) was measured using a Keithley 642 Type Digital Electrometer.

3. Data and calculations

The primary data (C_P, C_M, $[Sn^{2+}]y_M$, $[H^+]$) were analyzed by graphical and numerical procedures to determine the composition of the reaction products $SnH_{-n}(H_2PO_4)_m^{2-n-m}$ and equilibrium constants $*\beta_{n,m}$ for their formation according to Eq. (8)

$$Sn^{2+} + nH_2O + mH_2PO_4^- \rightleftarrows SnH_{-n}(H_2PO_4)_m^{2-n-m} + nH^+, *\beta_{n,m} \quad (18)$$

The calculations were based on the mass balance Eqs. (5) and (9)

$$*C_M = C_M - \sum p[Sn_p(OH)_q^{2p-q}] = [Sn^{2+}](1 + \sum *\beta_{n,m}[H_2PO_4^-]^m[H^+]^{-n}y_M y_L^m y_H^{-n} y_{n,m}^{-1}) \quad (9)$$

where hydrolytic species $Sn_p(OH)_q^{2p-q}$ were accounted for according to Tobias [3] and y_M, y_L, y_H and $y_{n,m}$ are activity coefficients of Sn^{2+}, $H_2PO_4^-$, H^+ and $SnH_{-n}(H_2PO_4)_m^{2-n-m}$, respectively. The activity coefficient of a species 'i' in the medium scale is a function of $[H_2PO_4^-]$ and can be expressed, according to the specific interaction theory [9,10], as Eq. (10)

$$\log y_i = \{b(i, H_2PO_4^-) - b(i, ClO_4^-)\}[H_2PO_4^-] \quad (10)$$

in which b stands for the specific interaction coefficient. As $\log y_i$ is expected to deviate from zero by no more than ± 0.1, we may write Eq. (11)

$$y_i \approx 1 + 2.303\{b(i, H_2PO_4^-) - b(i, ClO_4^-)\}[H_2PO_4^-] = 1 + \xi_i[H_2PO_4^-] \quad (11)$$

Introducing Eq. (11) into Eq. (9) yields Eq. (12)

$$F = \log\{*C_M/([Sn^{2+}]y_M)\} = \log(1 + \sum \Phi_{n,m}[H_2PO_4^-]^m[H^+]^{-n}) \quad (12)$$

where for brevity

$$\Phi_{01} = *\beta_{01} - \xi_M \quad (13)$$

whereas for all other (n, m) values is valid Eq. (14)

$$\Phi_{n,m} = *\beta_{n,m} + *\beta_{n,(m-1)}\{(m-1)\xi_L - n\xi_H - \xi_{n,(m-1)}\} \quad (14)$$

Subscripts M, L, H and n, m refer respectively to Sn^{2+}, $H_2PO_4^-$, H^+ and $SnH_{-n}(H_2PO_4)_m^{2-n-m}$.

3.1. Graphical treatment

The data are represented in Figs. 1 and 2. To construct Fig. 1, $[H_2PO_4^-]$ values were found from Eq. (7) as described above. Since points of different C_M fall on the same curve, mononuclear complexes in tin predominate. Furthermore, data of forward titrations coincide within experimental uncertainty with those of reverse titrations. Therefore, true equilibrium was attained.

Points of different acidity form different curves (Fig. 1). Thus, complexes with $n \geq 0$ are present.

At a given $[H^+]$, the shape of the curve is consistent with the formation of complexes with $m = 1$ and 2. To ascertain the most probable n values the experimental plot was compared with model curves calculated with various n and $\Phi_{n,m}$. An acceptable fit, shown in Fig. 1, was found assuming the presence of $SnH_2PO_4^+$, $Sn(H_2PO_4)_2(aq)$, $SnH_{-1}(H_2PO_4)_2^-$, $SnH_{-1}(H_2PO_4)(aq)$ and $SnH_{-2}(H_2PO_4)_2^{2-}$ with $\Phi_{n,m}$ values given in Table 1.

To explain the data represented in Fig. 2 we simply assumed the species and $\Phi_{n,m}$ values deduced above. This model fits the measurements of $\log[H^+] \geq -3$ satisfactorily, but as shown by the dashed curves in Fig.

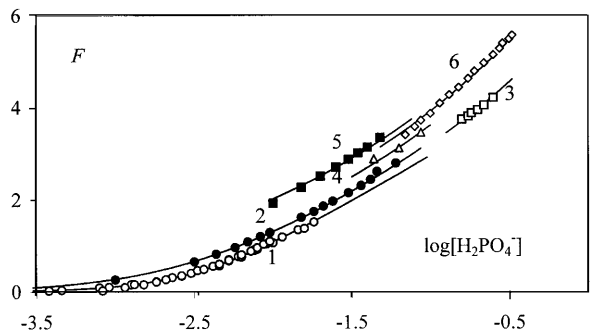

Fig. 1. F (Eq. (12)) as a function of $\log[H_2PO_4^-]$ for data of different acidity levels; $-\log[H^+](curve) = 1.0$ (1), 1.8 (2), 2.5 (3), 2.7 (4), 3.0 (6), 3.5 (5). The curves were calculated with the constants in Table 1.

Table 1
Survey of the calculated $\Phi_{n,m}$ and $*\beta_{n,m}$ values

(n, m)	$\log \Phi_{n,m}$ graphical	$\log \Phi_{n,m}$ least-squares (3σ)	$\log *\beta_{n,m}$

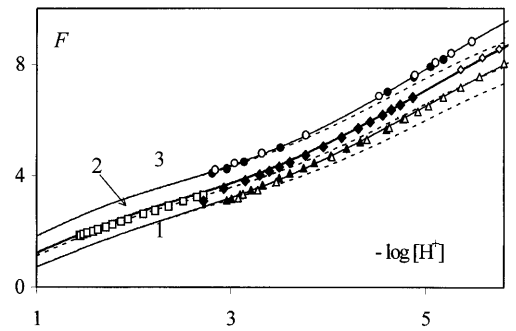

Fig. 2. F (Eq. (12)) as a function of $\log[H^+]$ at different phosphate concentrations: 0.05 (curve 1), 0.1 (curve 2) and 0.3 M (curve (3). Curves calculated with constants in Table 1. Dashed lines represent a model which neglects $SnH_{-2}(H_2PO_4)^-$ and $SnH_{-3}(H_2PO_4)_3^{4-}$ complexes.

Table 2
Equilibrium constants in the infinite dilution reference state

	log (equilibrium constant)
$Sn^{2+} + H_2PO_4^- \rightleftarrows SnH_2PO_4^+$	2.8 ± 0.2
$Sn^{2+} + 2H_2PO_4^- \rightleftarrows Sn(H_2PO_4)_2(aq)$	5.9 ± 0.2
$Sn^{2+} + HPO_4^{-2} \rightleftarrows SnHPO_4(aq)$	9.5 ± 0.2
$Sn^{2+} + H_2PO_4^- + HPO_4^{-2} \rightleftarrows SnHPO_4H_2PO_4^-$	10.3 ± 0.2
$Sn^{2+} + 2HPO_4^{-2} \rightleftarrows Sn(HPO_4)_2^{2-}$	13.4 ± 0.2
$Sn^{2+} + PO_4^{-3} \rightleftarrows SnPO_4^-$	18.0 ± 0.2
$Sn^{2+} + 3HPO_4^{-2} \rightleftarrows Sn(HPO_4)_3^{4-}$	12.9 ± 0.2

2, systematic deviations occur at lower acidities. A good explanation was obtained adding the complexes $SnH_{-2}(H_2PO_4)^-$ and $SnH_{-3}(H_2PO_4)_3^{4-}$. The most probable Φ_{21} and Φ_{33} values are given in Table 1.

3.2. Treatment by numerical methods

As a check of the results from the graphical approach the whole set of data was processed by the program SUPERQUAD [11]. The computer sought the minimum of the sum

$$U = \sum (Y - Y^{calc})^2 \quad (15)$$

where $Y = 0.02958 \log([Sn^{2+}]y_M)$ and Y^{calc} is a value calculated with a given set of parameters. The calculations were founded on the stoichiometric conditions (5), (6) and (12). It is important to observe that the last term in Eq. (5) was replaced by $\Sigma m\Phi_{n,m}[Sn^{2+}]y_M[H_2PO_4^-]^m[H^+]^{-n}$. This is not completely correct, however the difference between rigorous and approximate expressions is at most 0.2% therefore without appreciable effect on the final results. In the computations equilibrium constants of the phosphoric acid system and of the hydrolysis of the Sn^{2+} ion, taken from Ref. [3,6], were not allowed to vary. The best fit, $\sigma(Y) = 4 \times 10^{-4}$ V, was found by assuming the set of complexes evidenced graphically. The introduction of additional complexes, such as $Sn(H_2PO_4)_3^-$ or $Sn(PO_4)_2^{4-}$ or $Sn_2(OH)_2(H_2PO_4)_2(aq)$ or $Sn_3(OH)_4(H_2PO_4)_3^-$, did not produce lower agreement factors. The results, given in Table 1, are seen to match the graphical results satisfactorily.

4. Discussion

The Sn^{2+} and PO_4^{3-} ions form a series of ternary complexes $SnH_{-n}(H_2PO_4)_m^{2-n-m}$ with $(n, m) = (0, 1)$, $(0, 2)$, $(1, 1)$, $(2, 2)$, $(3, 3)$, $(1, 2)$ and $(2, 1)$. The complexes, except $SnH_{-1}(H_2PO_4)_2^-$, can formally be considered as binary of $H_2PO_4^-$ in $(0, 1)$ and $(0, 2)$, of HPO_4^{2-} for $n = m$ and of PO_4^{3-} in $(2, 1)$. The $(1, 2)$ species, on the other hand, is a mixed $H_2PO_4^- - HPO_4^{2-}$ complex. From equilibrium studies alone it is impossible to assess whether $SnHPO_4(aq)$ and $SnPO_4^-$ are effectively binary or ternary hydroxo complexes as $Sn(OH)H_2PO4(aq)$ and $Sn(OH)_2H_2PO_4^-$.

In agreement with (14) $^*\beta_{11} = \Phi_{11}$, $^*\beta_{21} = \Phi_{21}$, $^*\beta_{33} = \Phi_{33}$. To evaluate other $^*\beta_{n,m}$ from Eq. (14), we employed $\xi_L = 0$, since interaction coefficients of ions bearing the same charge sign are with good approximation equal to zero [9], $\xi_H = 0.70 \pm 0.05$, deduced by inserting Eq. (4) in Eq. (11), $\xi_M = -0.6 \pm 0.6$ and $\xi_{01} = \xi_{11} = \xi_{21} = -0.3 \pm 0.3$. The ξ parameter pertaining to the metal ion was estimated supposing that $b(Sn^{2+}, H_2PO_4^-)$ falls within -0.2 and 0.3 and setting $b(Sn^{2+}, ClO_4^-) = 0.30$, as calculated from the linear dependence of $b(i, ClO_4^-)$ with the reciprocal of the ionic radius of cations [9]. The ξ values of the complex species were estimated with the empirical rule suggested elsewhere [10]. The results of calculations of $^*\beta_{n,m}$ are given in Table 1. Only for $^*\beta_{22}$ and $^*\beta_{12}$ the effect of medium changes exceeds the experimental uncertainty.

The magnitude of the association constants in the infinite dilution reference state (Table 2) was found by assuming the validity of the specific interaction theory [9,10]. The equilibrium constants in Table 1 were transformed from molar to molal units using densities of $NaClO_4$ solutions compiled by Söhnel and Novotný [12]. Interaction coefficients were taken or estimated with rules given elsewhere [9,10]. The interaction coefficient of $Sn(HPO_4)_3^{4-}$ was set equal to $(3/2)b(Na^+, HPO_4^{2-})$. The extrapolated $^*\beta_{n,m}$ values were finally combined with the infinite dilution protolysis constants [13] $10^{-7.198}$, for $H_2PO_4^- \rightleftarrows HPO_4^{2-} + H^+$, and $10^{-12.35}$, for $HPO_4^{2-} \rightleftarrows PO_4^{3-} + H^+$, to yield the results in Table 2.

The stabilities of $SnHPO_4(aq)$ and of $SnPO_4^-$ are noticeable. This can be due to the particular structures of the complexes in which the phosphate group acts as a bidentate or a tridentate ligand. It also seems plausible that the complexes are mixed hydroxo species such as $Sn(OH)H_2PO_4(aq)$ and $Sn(OH)_2H_2PO_4^-$.

Abstract

Complex-formation equilibria of some dipeptides (glycyl-lysine, alanyl-lysine, histidyl-lysine and β-alanyl-lysine) with the Cu(II) ion have been studied in aqueous solution, at $I = 0.1$ mol dm^{-3} (KNO_3) and $T = 25$°C. Protonation and complex-formation constants have been determined potentiometrically; complex-formation model and species stoichiometry have been checked carefully by means of different spectroscopic techniques (visible absorption, CD, EPR). The structure of the main complex species is discussed, on the basis of thermodynamic data obtained by direct calorimetry. The formation of binuclear species is demonstrated and it is suggested that the side amino group of lysine participates in complex formation at alkaline pH values.

Keywords: Copper-dipeptide complexes; Glycyl-lysine; Alanyl-lysine; Histidyl-lysine; β-alanyl-lysine

1. Introduction

The side ε-NH_2 group of the lysine (Lys) residue in peptides and proteins is one of the potential donor sites for metal (especially copper) ion complexation. However, its coordination to the metal centre generally involves the formation of unusually large chelate rings. This fact, together with its high pK value, makes ε-NH_2–Cu(II) bond formation unfavourable at neutral or acidic pH [1]. The same is true for Lys itself [2]. On the other hand, in the alkaline pH range, metal ions become more competitive with respect to protons: ε-NH_2 coordination in binuclear complexes of Cu(II) and oligopeptides has been reported, both in solution [3–5] and in the solid state [6].

A case of special interest is represented by the human liver-cell growth-factor glycyl-histidyl-lysine (GHK), found in human plasma at a concentration of about 200 ng ml^{-1} [7]. GHK was found in the albumin and α-globulin fractions and it co-isolated with an approximately equimolar amount of copper and about one-fifth molar amount of iron [8]. GHK proved to stimulate the growth and differentiation of a number of cell lines [9] and, in general, to be a good serum substitute in cellular culture media. In further studies it was recognised that GHK is endowed with a wide range of biological activities, mainly in the acceleration of wound healing and bone repair [10]. GHK was found to act synergistically with copper and iron ions, and it has been suggested that it plays a role in cellular copper ion uptake [11]. A GHK structure–activity study revealed that the His-Lys sequence and Lys side chain are essential for its biological activity, and an action mechanism has been suggested in which the first two residues of the tripeptide bind a copper ion to form a 1:1 complex while the side chain of Lys is involved in the recognition with a hypothetical receptor on the cell surface [11].

In view of its importance, not only in metal ion complexation but also in metal–peptide biological activity, the behaviour of ε-amino-N of the Lys residue in Cu(II) complex formation has been investigated in depth by means of a number of experimental techniques. Four dipeptides were employed as ligands, i.e. glycyl-lysine (Gly-Lys, GK), alanyl-lysine (Ala-Lys, AK), histidyl-lysine (His-Lys, HK) and β-alanyl-lysine (β-Ala-Lys, β-AK).

2. Experimental

2.1. Materials

Dipeptides were high purity products (Sigma) and were used without further purification. Cu(II) nitrate was an extra pure Merck product. The concentration of a stock solution of this salt was determined by ethylenediaminetetraacetate titration. The carbonate-free stock solutions of KOH were prepared by diluting a saturated KOH (Aldrich, semiconductor grade) solution and then standardised potentiometrically by titrating with potassium hydrogen phthalate. The HNO_3 stock solution was prepared by diluting concentrated HNO_3 (Merck, Suprapur) and then standardised with KOH. All sample solutions were prepared with freshly tetradistilled CO_2-free water. The ionic strength was adjusted to 0.1 mol dm^{-3} by adding KNO_3 (Merck, Suprapur). Grade A glassware was employed throughout.

2.2. Potentiometric measurements

Potentiometric titrations were performed with the following equipment: an Orion EA 940 pH meter (resolution 0.1 mV, accuracy 0.2 mV) equipped with a combined glass electrode (Metrohm EA125); a Hamilton MicroLab M motor burette (resolution 0.1 μl, accuracy 0.2 μl) equipped with a Hamilton syringe (delivery volume 0.5 cm^3). The potentiometer and burette were interfaced with an IBM PS/2 model 30 computer with which the titrations were performed automatically by means of a suitable program written in IBM-BASIC. Constant-speed magnetic stirring was applied throughout. The temperature of the titration cell was kept at 25 ± 0.02°C by means of a Haake F3C circulation thermostat. UPP grade nitrogen, previously saturated with H_2O (0.1 mol dm^{-3} KNO_3, 25°C) was blown onto the test solution in order to maintain an inert atmosphere. The electrode couple was standardised on the $pH = -\log c_{H+}$ scale by titrating HNO_3 (0.01 mol dm^{-3}) with standard KOH at 25°C and $I = 0.1$ mol dm^{-3} (KNO_3), before each titration. Aliquots (2 cm^3) of sample solution, containing suitable amounts of Cu(II), HNO_3 and the ligands, were titrated with standard KOH in the 3–11 pH range; precipitate or opalescence were never observed. Copper concentration ranged from 2 to 5 mmol dm^{-3}, and metal-to-ligand ratios were 1:1, 1:2, 1:3. A minimum of four pairs of titrations for each copper–ligand system were performed.

2.3. Spectroscopic measurements

The absorption spectra were recorded with a Uvicon 931 (Kontron) spectrophotometer, with a glass cell (W110/S4, 1 cm path length); the temperature was controlled at 25.0 ± 0.1°C by means of a Kontron GTD-900 circulation thermostat.

EPR spectra were recorded on a Bruker ESP 300E spectrometer at X-band frequency (9.3 GHz) at 120 K. Circular dichroism (CD) spectra were recorded on a Jasco J 720 spectropolarimeter in the 800–200 nm range. Metal concentration in EPR, CD and visible measurements was adjusted from 2 to 3 mmol dm^{-3} and metal to ligand ratios were 1:1 and 1:2.

2.4. Calorimetric measurements

The $\Delta H°$ values were determined by titration calorimetry with a Tronac model 450 isoperibol calorimeter equipped with a 4 cm^3 reaction vessel. The calorimetric measurements were carried out titrating in double aliquots of 3 ml of solutions containing the metal and the ligand in the various ratios with a standard solution of HNO_3. The ionic strength was kept constant at $I = 0.1$ mol dm^{-3} by adding KNO_3. The ligand concentrations ranged from 5 to 9 mmol dm^{-3}. For each system at least 250 experimental points were utilised to calculate the thermodynamic quantities. The reaction heats, which were corrected for non-chemical contributions, which are particularly important when using small volume dewars [12], and for the dilution heats computed from literature data [13], were calculated by considering the calorie as equivalent to 4.184 J.

2.5. Calculations

Calculations concerning the $E°$ of the electrode system were performed by the least-square computer programs ESAB [14], which refines acid–base titration parameters, and BEATRIX [15] based on the Gran method. The Cu(II) complex formation constants were calculated by means of the least-square computer program SUPERQUAD [16]. To obtain the species distribution within the pH ranges explored, the computer programs DISDI [17] or HYSS [18] were used. Computer simulations of potentiometric titrations, useful in setting up the experimental conditions and comparing results with predictions, were obtained using the program SCALPO [19].

Protonation and complex-formation enthalpy and entropy were computed from experimental calorimetric titration by means of the computer program DOEC [20].

A pK_w value of 13.74 and a $\Delta H°_w = 13.35$ kcal mol^{-1}, determined by separate experiments, were employed in the calculations; the Cu(II) hydrolytic constants and corresponding formation enthalpies have been taken from Arena et al. [21].

Throughout, the accuracy of thermodynamic parameter values has been estimated as approximately

three times the precision value given by SUPERQUAD or DOEC, in the cumulative calculations, and it is expressed as deviation over the last significant figure.

3. Results and discussion

3.1. Ligand protonation

Thermodynamic parameters of ligand protonation are reported in Table 1.

The most basic group is the ε-amino group of the Lys residue: its protonation constant and related enthalpy value are practically identical for all the ligands considered and they are very close to those of free Lys and of a number of alkyl amines [22]. Most likely this group is too far from the rest of the molecule to be affected by the structural changes in the ligand. This result is in agreement with previous literature data referring to other oligopeptides having Lys as C-terminal residue [23]. Entropy change values are rather low: the protonation process does not involve any charge separation and reorganisation of the hydration spheres is minimal. The latter consideration appears to hold true for all protonation processes involving nitrogen atoms.

The terminal amino group is less basic than the ε-amino group of the Lys residue, due to the proximity of the electron-withdrawing carbonyl group of the peptide bond. In the case of β-AK the two groups are separated by an additional carbon atom and the terminal amino group pK value is 1.5 units higher than the other ligands. All these pK values are 1–1.5 units lower than those of the corresponding free amino acids [22] where the peptidic group is replaced by a carboxylate; only in the case of β-AK is the difference rather small (0.3 units) for the same reasons as indicated above.

Imidazole pK value of the His residue in HK is practically identical to that of free His (6.1 [22]), since it is not affected by the peptide linkage.

The pK value of the terminal Lys residue carboxylic group is much higher than that of free Lys (2.1 [22]), except in the case of HK, where the difference is smaller. In dipeptides, an amido group replaces the Lys α-amino group and its electron-withdrawing effect is reduced. When the first amino acid is His, the effect of the aromatic group is added to that of the peptide group. It is worth noting that, in the case of carboxylic group deprotonation, the process is almost entirely entropic: in fact, it consists of a charge separation and of a resulting large-scale reorganisation of the solvent around the reacting partners.

3.2. Cu(II)–Gly-Lys and Ala-Lys complexes

Thermodynamic parameters of Cu(II) complexes with the considered ligands are reported in Table 2. The corresponding distribution diagrams are shown in Fig. 1.

The results obtained for the Cu(II)–GK system are in good agreement with what was previously reported by Rainer and Rode [23], at 37°C, although they found some minor species (120 and $12-1$) in the alkaline pH range, instead of the binuclear complexes. It is also possible to compare the thermodynamic data reported in Table 2 with other literature data referring to dipeptides having Gly or Ala as C-terminal residue, in the place of Lys. However, to make such a comparison, it is necessary to 'clean' the data in Table 2, clearing away the contribution due to protonation of the side amino group of Lys. The results are also reported in Table 2 along with some reference data.

The species formed in the Cu(II)–GK system at the most acidic pH value is the 111 complex, which reaches only moderate concentrations before deprotonating. This is the analogue of the 110 species of the Cu(II)–GG system where one ligand is bound to the metal ion by means of its terminal amino group and the adjacent carbonyl oxygen [24] (NO species), as happens for most

oligopeptides [1]. The thermodynamic parameters reported in Table 2 (corrected for protonation) are in excellent agreement with those of the 110 complex of GG; in particular, the value of $\Delta H^{\circ}_{111} - \Delta H^{\circ}_{011}$ (7.1 kcal mol^{-1}) corresponds to the formation of a coordination bond between a neutral nitrogen and the Cu(II) ion [25]. Moreover, the wavelength of maximum absorption in the visible range (see Tables 3 and 4) is shifted to a value of about 745 nm at the pH of maximum formation of the 111 complex, as expected from the empirical calculation of Sigel and Martin [26] for the coordination of an amino and a carbonyl group to the Cu(II) ion.

It was not possible to determine the thermodynamic parameters of the 111 complex for the Cu(II)–AK system, most likely due to its low amount. However, spectral parameters in the pH range of interest are very similar to those of the Cu(II)–GK system, suggesting the presence of the same complex species.

Starting at pH 4.5 and working down to neutral pH, the 110 complex becomes the predominant species, involving practically all the Cu(II) ions present in solution. Following the literature [1,26] and comparing the thermodynamic data with those of the system Cu(II)–GG (Table 2), it can be suggested that in the 110 complex GK (or AK) is bound to the metal ion with its terminal amino and deprotonated peptido nitrogen atoms, thus forming a five-membered chelate ring; the terminal carboxylic group is most likely coordinated, in the equatorial plane of the complex, as well. The deprotonation pK value of the 111 complex, 3.86, confirms that the Cu(II) ion is able to promote amido group deprotonation at a pH value lower than 4 [26]. CD spectra show, in both these cases, the typical CT band, at about 313 nm, due to the coordination of a deprotonated amido nitrogen to the Cu(II) ion [27]. 'Cleaned' logβ, ΔH° and ΔS° values are similar to those found for the $11-1$ complex in the Cu(II)–GG system; these values take into account both the endothermic amido nitrogen deprotonation and its exothermic coordination to the metal ion. The slightly higher values of thermodynamic parameters found for the 110 complex in the Cu(II)–AK system could be ascribed to a possible minor contribution of the, undetected, 111 complex.

As the pH is raised, the 110 complex loses first one and then two protons, giving rise to the $11-1$ and

$11-2$ species. The ligand coordination in the complex's equatorial plane remains unchanged, the two protons being lost from a water molecule bound to copper and by the ε-NH_2 group of the Lys residue. The $11-2$ complex can be directly compared with the same $11-2$ species in the Cu(II)–GG system: both $\log\beta_{11-2}$ and ΔH°_{11-2} are higher in the case of GK and AK, suggesting the involvement of ε nitrogen in complex formation. In particular, the difference between the corresponding ΔH°_{11-2} values for AK and GG (5 kcal mol^{-1}) is close to the Cu–N bond formation enthalpy. Moreover, the CD spectra agree with this suggestion: at pH 10 a new band appears at 510 nm and it grows when the pH is raised, while the $11-2$ complex becomes the most abundant species. The corresponding EPR spectra show a significant decrease in the $g_{\parallel}$ value. The ε-amino-nitrogen coordination should be axial, since, in the pH range of interest, the visible spectra show a decrease in the transition energy and also the $A_{\parallel}$ value of EPR spectra is shifted to lower values.

In both the Cu(II)–GK and Cu(II)–AK systems binuclear species are formed, in the alkaline pH range, even at ligand-to-metal ratios equal to or higher than two. In particular, in both systems, the $22-2$ complex reaches high concentration levels (see Fig. 1). Binuclear complex formation was previously reported by Gergely and Nagypál [24] and by Brookes and Pettit [28] for the Cu(II)–GG system (see Table 2) while it was not found by Rainer and Rode [23] in the Cu(II)–GK system. The presence of binuclear species is supported by the low intensity of EPR spectra recorded at $pH > 10$, even if the signal does not completely disappear. Brookes and Pettit suggested, for the $22-3$ complex, an equatorial coupling of two $2N/COO^{-}$ mono-complexes, via one OH^{-} bridge; this hypothesis has been accepted by Gergely and Nagypál, on the basis of the entropy and enthalpy data. A similar structure can be suggested here for both the $22-1$ and $22-2$ complexes: both the ε-nitrogens should be protonated in the former while only one is protonated in the latter species. It is worth noting that the $\log K$ value of this deprotonation step ($=\log\beta_{22-1}-\log\beta_{22-2}=8.6$–$8.8$) is noticeably lower than the corresponding pK_{011}, suggesting that this deprotonation is assisted and promoted by copper ions. It is also worth observing that, once the protonation contribution of one ε-NH_2 group has been 'cleaned' away, both $\log\beta_{22-2}$ and ΔH°_{22-2} are significantly higher than the corresponding values for the Cu(II)–GG $22-3$ complex. Moreover, at pH 10, the CD band at 510 nm is already clearly visible in the Cu(II)–GK system, while the $11-2$ complex (see above) is only a minor species. All these results tip the scales in favour of the involvement of one deprotonated ε-NH_2 group in the $22-2$ complex formation.

Finally, in the presence of an excess of ligand, some bis-complexes also form in solution, the most important

of which is the 121 species. This complex becomes the main species at a pH value of about 8 and, assuming that both the ε-NH_2 groups are protonated, it is the analogue of the $12-1$ complex found in the Cu(II)–GG system. This hypothesis is confirmed by the 'cleaned' thermodynamic parameters of 121 complexes, reported in Table 2: they are very close to the corresponding reported values for the Cu(II)–GG system, especially in the case of AK. Both $\log\beta_{121}$ and ΔH°_{121} values are close to the sum of the values found for the corresponding 111 and 110 complexes, thus suggesting that one ligand should be coordinated in the $2N/COO^-$ way, while the other should be bidentate and coordinate to copper in the NO fashion. Obviously, is it not possible for both ligands to be bound to the metal in the equatorial plane of the complex: as a consequence, the bidentate ligand should be coordinated in an equatorial–axial manner, as first suggested by Kaneda and Martell [29]. This hypothesis is supported here by the spectroscopic results, which show only minor changes when the pH is raised from 6 (where the 110 complex dominates) to 8 (where the 121 complex is the most abundant species). Similar results were also reported by Shtyrlin et al. [30] in their spectrophotometric investigation of the Cu(II)–GG system.

3.3. Cu(II)–His-Lys complexes

The presence of four nitrogens which can act as donor atoms makes possible the formation of a rather large number of complexes of different stoichiometries, between HK and the Cu(II) ion, as already found with many His derivatives [31]. HK starts to bind copper at a pH value as low as 3 (see Fig. 2). It is interesting to note how different the distribution diagrams of the Cu(II)–HK look when the ligand-to-metal ratio is close to unity (Fig. 2a) or higher (Fig. 2b). The most relevant difference concerns the pH range around neutrality, where, in the first case, the binuclear 220 complex contains all the copper present in solution; conversely, in the second case, the 122 bis-complex largely dominates. This macroscopic and uncommon difference is reflected by spectroscopic results (see Tables 5 and 6).

The coordination of HK to copper starts in the usual NO manner, with the 112 complex, but the presence of the imidazole nitrogen allows the coordination mode to change, with the formation of the 2N (α-amino and π-imidazole) 111 complex, from pH approximately equal to 4. This is always the main species in the acidic pH range. Its $\log\beta_{111}$ value, 'cleaned' of the ε-NH_2 protonation of the Lys residue, is considerably higher than $\log\beta_{110}$ for the Cu(II)–GG system, as would be expected; the corresponding 'cleaned' ΔH°_{111} value (13 kcal mol^{-1}) reflects the coordination of two nitrogen atoms in the equatorial plane of the complex, as in the case of the Cu(II)–histamine binary 110 complex [25]. CD spectra for the 1:2 Cu(II)–HK ratio (Table 6) show an intense absorption band at about 330 nm; this can be attributed to a ligand-to-metal CT transition due to the $N_{imidazole}$–Cu bond. Visible spectra show an absorption maximum at about 650 nm which is slightly lower than expected [26] for a NH_2–$N_{imidazole}$ coordination and is instead compatible with the further interaction, in the equatorial plane, of the terminal carboxylic group, although this implies the formation of a nine-membered ring.

When the pH is raised over neutrality, if Cu(II) and HK are nearly equimolar, over 90% of the metal forms the binuclear 220 species. EPR spectra recorded in this pH range do not show any detectable signal. Corresponding CD spectra show some interesting features: at about 340 nm the CT band is overcome by a new band at about 320 nm, with the opposite sign of its $\Delta\varepsilon$ value, attributed to the formation of N_{amido}–Cu bond(s). Moreover, a distinct shoulder appears at about 502 nm, most likely due to the coordination of three nitrogen atoms to the same Cu(II) ion. The whole of these data can be rationalised suggesting that, as a first step, when the pH is increased, HK changes its coordination mode from bidentate $N_{amino}/N_{imidazole}$ to tridentate $N_{amino}/$

N_{amido}/COO^{-}, as reported for the Cu(II)–HG system [32]. However, in the present case, this complex (110) does not reach significant concentration levels: the presence of a free imidazole residue facilitates the formation of dimer species. The structure of the 220 binuclear complex should be similar to that found for L-carnosine in the solid state [33] and in the Cu(II)–glycyl-spinacine system [34]: the two metal centres of two 110 complexes

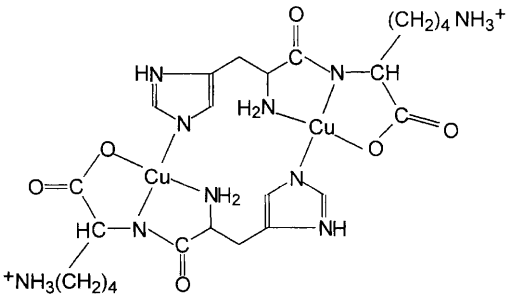

Fig. 3. Structural hypothesis for the Cu(II)–HK 220 complex. Charges around the metal centres are omitted for the sake of simplicity.

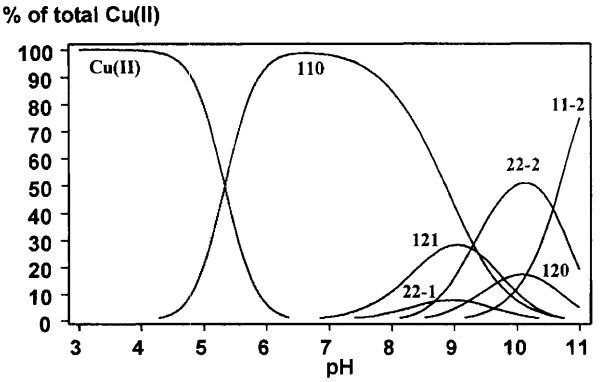

Fig. 4. Distribution diagrams of Cu(II)–β-AK complexes at 25°C and $I = 0.1$ mol dm^{-3} (KNO_3). [Cu(II)] = 4 mmol dm^{-3}; [β-AK] = 8 mmol dm^{-3}.

could be bridged by one or both the ligands, the τ-$N_{imidazole}$ atom of which is bound to the free equatorial plane position of the adjacent complex (see Fig. 3). Molecular models show that this arrangement does not give rise to molecular strain. The ΔH°_{220} value, 'cleaned' of two ε-NH_2 protonation contributions, is rather high but compatible with the coordination of two further nitrogens to copper ions, besides the tridentate coordination of the two ligands, described above. Deprotonation of the 220 complex gives rise to the $22-1$ binuclear species, most likely a hydroxo-complex, which never reaches high concentration levels.

If the ligand-to-metal ratio is 2 or higher, in the pH range from 5 to about 9, the bis-complex 122 largely prevails. In this complex the two ligands should both be bound to copper through their terminal amino and imidazole nitrogens, as suggested by Brookes and Pettit [31] for the 120 complex in the Cu(II)–HG system; the Lys ε-amino groups should be protonated. Once the two protonation contributions (12.5 kcal mol^{-1}) have been subtracted, the corresponding enthalpy of complex formation (49 kcal mol^{-1}, see Table 2) becomes 24 kcal mol^{-1}, a value compatible with the coordination of four nitrogens. The corresponding wavelength of maximum absorption (~ 630 nm) is noticeably higher than expected, and this can be explained by observing that the four nitrogen atom arrangement around the copper is most likely not strictly planar; CD spectra around pH 7 show two bands (at about 700 and 590 nm) compatible with a twisted $2 \times \{NH_2, N_{imidazole}\}$ binding.

At high pH values the 121 complex forms: the corresponding $\log K_{step}$ and ΔH°_{step} values (Table 2) are compatible with the hypothesis of Lys residue deprotonation, promoted by an apical interaction with the metal centre of the complex; the d–d absorption band shows a moderate shift towards lower wavelengths, while the $A\|$ value increases slightly. More important changes in spectroscopic data can be observed when the pH value is raised above 9, where, independently of the metal-to-ligand ratio, the new $11-1$ and $11-2$ complexes form. At a 1:2 metal-to-ligand ratio, the visible spectra show a decrease of about 20 nm in the wavelength of maximum absorption, while in CD spectra, signals appear at about 320 (pH 9) and 510 (pH 10); at a metal-to-ligand ratio of 1:1 a new intense band can be observed at about 250 nm as well. These results clearly mean a change in the coordination mode from bidentate $N_{amino}/N_{imidazole}$ to tridentate $N_{amino}/N_{amido}/COO^-$. When the pH is raised over 10, the ε-NH_2 group most likely interacts with the metal ion in axial position, as previously observed for the systems above, giving rise to the new CD bands (510 nm for 1:2 solutions and 250 for 1:1 solutions) observed.

3.4. Cu(II)–β-Ala-Lys complexes

Species distribution diagram for the Cu(II)–β-AK system is reported in Fig. 4, while thermodynamic parameters for complex formation equilibria are shown in Table 2. First of all it can be observed that, except for some minor complexes (120 instead of 121), the model is very close to the one previously discussed for AK. The system is dominated, from acidic pH to pH about 9, by the 110 complex, where the ligand is bound to copper in the normal tridentate $N_{amino}/N_{amido}/COO^-$ manner, with the formation of two adjacent rings which, in this case, are of different sizes, since there is one more carbon atom, separating the two nitrogens, than in the other ligands. The wavelength of maximum absorption in the visible region and the presence of the characteristic Cu(II)–N_{amido} band in the CD spectrum (at about 315 nm) confirm this structural hypothesis (see Table 7). The fact that the first chelate ring is larger is reflected by the fact that the values of the 'cleaned' thermodynamic parameters are lower than the corresponding data for the Cu(II)–GG, Cu(II)–GK and Cu(II)–AK complexes. Increasingly greater differences have been reported between the 110 complexes of Cu(II)–Ala and Cu(II)–β-Ala [22]. Moreover, it is worth noting that the molar absorption coefficients of

10.9	**11-2**	594	62			189	2.223

visible spectra recorded at different pH values are considerably lower than those found with the ligand discussed above, even though the complex formation is complete.

In the alkaline pH range some bis-complexes are formed, the most important of which is the 121 species. It most likely has a structure similar to that already discussed for the Cu(II)–AK system, but a lower formation constant, once 'cleaned' of the ε-NH_2 protonation contributions. The consequence is a low formation percentage. The loss of one proton from the 121 complex leads to the 120 species: the corresponding pK value (see Table 2) suggests the deprotonation of one ε-amino group, assisted by the Cu(II) ion. The hypothesis of an interaction between this side group and copper is also supported by the rather high 'cleaned' $\log\beta_{120}$ value, by the decrease in the visible wavelength of maximum absorption and by the increase in the $A_{\parallel}$ and corresponding decrease in $g_{\parallel}$ values of EPR spectra, when the pH exceeds 9. The same behaviour should be followed by the $22-2$ and $11-2$ complexes, as well. They are the main species in the most alkaline pH range: in fact the spectral data do not show significant variations when the pH is changed from 10 to 11. The structure of these complexes is most likely the same as discussed above for the other ligands.

4. Conclusions

The ε-NH_2 of the Lys residue proved to act as a good donor group for the Cu(II) ion at alkaline pH, where deprotonated mononuclear or binuclear complexes are formed. For the present systems no direct evidence could be put forward that this group can bridge two metal ions or two mononuclear complexes. The likely hypothesis is that ε-NH_2 may coordinate to the metal centre to which the ligand is bound, although its involvement in dimer formation cannot be excluded. No deprotonation of ε-NH_2 (and subsequent interaction with copper) was found at neutral pH: this result confirms that, under physiological conditions, the protonated Lys residue of metal-peptides can act as an 'anchor' for biological receptors [5,11].

Abstract

The reaction of iron(III) with chromium(III)–DTPA 'chelating agent' has been investigated, in aqueous solution, by measuring both hydrogen ion concentration and emf of the iron(III)/iron(II) couple. In acidic medium (pH < 2.3) and with ligand excess, a 1:1 (metal–ligand molar ratio) fully deprotonated complex has been evidenced. In the same experimental conditions the iron(III) reacts with iminodiacetic acid forming a similar 1:1 deprotonated species. The stability constants of the above equilibria have been calculated at 20°C in $NaClO_4$ 1.0 mol dm^{-3}. The comparison of these constants, considering the basicity of the ligands, proved the coordination of iron(III) occurs by one iminodiacetic group. The iron(III)–chromium(III)–DTPA complex has been precipitated and the solid compound characterized by IR and thermoanalytical techniques. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The research on the complexation reactions has always been of great interest because of the numerous applications, not only in the analytical field. It could flow from the transformation of two chemical species (the metal ion and the ligand) in a new compound (the complex) which has certain properties different from those of its components, assumed separately.

The above is confirmed by the recent application of the magnetic resonance imaging (MRI) in the study of the human body. In fact, the employment of this technique as diagnostic medium requires the use of paramagnetic contrast agents, i.e. species that have unpaired electrons. There are many transition and lanthanide metals with unpaired spins, but the main problem with these species in the native form is their toxicity. Investigation has been focused to create thermodynamically and kinetically stable complexes which, without altering paramagnetic properties of the metal ion, are much less toxic than both the metal ion and the ligand in the unbound state. Among the tested compounds, some complexes of strongly paramagnetic metal ions, such as chromium(III), iron(III) and gadolinium(III), with diethylenetriaminepentaacetic acid (DTPA, H_5L) seem to have both the required characteristics.

The chromium(III) - diethylenetriaminepentaacetate (CrL^{2-}) is a stable and very inert complex that can act as a chelating agent by the uncoordinated iminodiacetic group [1]. The reaction of this chelating agent with some metal ions has already been studied in aqueous solution as well as in the solid state [2–6].

In the present paper we report the main results found in the study of the reactions of iron(III) with chromium(III)–DTPA and with iminodiacetic acid (H_2Im) alone, in $NaClO_4$ 1.0 mol dm^{-3} aqueous solution, at 20°C. Moreover, some spectroscopic (IR), magnetic and thermal (TG and DSC) behavior of the complexes obtained in the solid state are described.

2. Experimental

2.1. Apparatus

The free hydrogen ion concentration ($[H^+]$) and that of iron(III) ($[Fe^{3+}]$) were measured with an Amel 337

potentiometer (precision 0.1 mV) by an Ingold glass electrode, calibrated in concentration units, and by a platinum wire, in the presence of iron(II) ions, respectively. The reference was an Ag/AgCl electrode, prepared according to Brown [7]. The calculated stability constants are referred to $t = 20°C$ and $I = 1$ mol dm^{-3} (sodium perchlorate).

The following electrochemical cells were employed

A(−)Glass El.	$Fe(ClO_4)_3 C_{M1}$ $Fe(ClO_4)_2 C_{M2}$ $HClO_4 C_H$ $NaClO_4(1.00 - C_H)$ M	$NaClO_4$ 1.00 M	$NaClO_4$ 0.99 M NaCl 0.01 M	Ag,AgCl(+)
B(−)Ag/AgCl	$NaClO_4$ 0.99 M NaCl 0.01 M	$NaClO_4$ 1.00 M	$Fe(ClO_4)_3 C_{M1}$ $Fe(ClO_4)_2 C_{M2}$ $HClO_4 C_H$ $NaClO_4(1.00 - C_H)$ M	Pt(+)

As the activity coefficients are unchanged in a constant ionic medium [8], the activities can be substituted by concentrations and the emf of cells A and B can be expressed, in mV units, by the following equations

$$E_A = E_A^\circ - 58.17 \log [H^+] = E_A^\circ - 58.17 \log C_H$$

$$E_B = E_B^\circ + 58.17 \log \frac{[Fe^{3+}]}{[Fe^{2+}]}$$

Perchloric acid (or sodium hydrogen carbonate) was added to maintain constant $[H^+]$ after each addition of the ligand solution (0.025 mol dm^{-3} of Na_2CrL or Na_2Im in $NaClO_4$ 1.0 mol dm^{-3}), so that the junction potential, which remain unchanged, was included in the $E°$ values. In each set of measurements, the value of E_A was constant and that of E_B° was calculated, in the absence of the ligand, by the iron concentrations (C_{M1} and C_{M2}). After each addition of the ligand the $[Fe^{3+}]$ was determined by the emf values, knowing the hydrolysis constants of iron(III) [9] and the equilibrium constants of the complexes iron(II)–chromium(III)–DTPA [4] and iron(II)–Im.

The thermal measurements were carried out using a Perkin–Elmer TGS-2 thermal analyzer, connected to a model 3600 Data Station, and a 1020 series DSC-7 thermal analysis system equipped with a multitasking software for instrument control and data analysis. Unless otherwise specified, thermogravimetry and differential scanning calorimetry runs were made on samples of about 1–2 mg (TG) and 0.3–0.5 mg (DSC) in a stream of nitrogen or oxygen (flow rate, 50 ml min^{-1}), heating rate 10°C min^{-1}.

IR spectra were recorded on a Perkin–Elmer FTIR 1600 grating spectrophotometer.

The measurements of the magnetic susceptibility were performed by the Gouy method at 8000 gauss in the temperature range 78–300 K. The instrument was calibrated with $Hg[Co(NCS)_4]$ [10].

2.2. Reagents

Iminodiacetic acid (BDH), diethylenetriaminepentaacetic acid, chromium(III) disodium salt hexahydrate (Aldrich), diethylenetriaminepentaacetic acid, and iron(III) disodium salt dihydrate (Aldrich) were used. The purity of these compounds was checked by potentiometric titration with sodium hydroxide and by thermal analysis.

Iron(III) perchlorate stock solution was prepared and standardized as already indicated [11].

Iron(II) perchlorate was prepared by catalytic reduction of iron(III) perchlorate over platinum black with purified hydrogen. Metal ion concentration was determined by permanganate titration.

Other chemicals were of analytical grade. Distilled–deionised water was used.

2.3. Preparation of the solid compound

The iron(III)–chromium(III)–DTPA complex was prepared by adding 25 cm^3 of ethanol to 50 cm^3 of an equimolar (40 mmol dm^{-3}) aqueous solution of iron(III) ions and CrL^{2-} 'metal–ligand chelating agent'. The violet precipitate was filtered off, washed with 1:1 water:ethanol ratio, then with ethanol and finally dried in vacuum, over silica gel. The chemical analysis of this compound suggested the formula $FeCrL(OH)(H_2O)_6$.

The chromium(III)–DTPA complex in the acid form $[H_2CrL(H_2O)_2]$ was prepared as reported in Ref. [2].

3. Results and discussion

3.1. Study in aqueous solution

The measurements were performed at several constant values of free hydrogen ions concentration in the

range $-\log[H^+]$ from 1.5 to 2.3 (at lower values the complexation reaction is almost negligible but at higher values hydrolysis of iron(III) ions becomes important). The iron(III) concentration was varied in the range from 0.5 to 2 mmol dm^{-3}, while the ligand concentration was progressively increased ($C_L/C_M = 1 \rightarrow 10$). In these experimental conditions it has been evidenced that iron(III) forms a 1:1 (metal:ligand molar ratio) fully deprotonated complex species with chromium(III)–DTPA. In fact, the same value of the stability constant (β_{101}) was obtained at different pH, iron(III) and ligand concentrations.

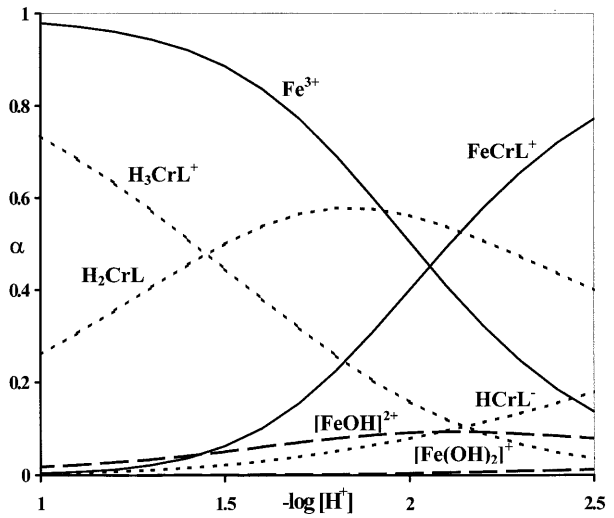

Fig. 1. Distribution diagram for the system iron(III)–chromium(III)–DTPA calculated at $t = 20°C$, $I = 1.0$ mol dm^{-3} [$NaClO_4$], $C_L/C_M = 2$ [where C_L and C_M are the analytical concentrations of the ligand ⟨chromium(III)–DTPA⟩ and metal ion ⟨iron(III)⟩].

[a] $t = 20°C$, $I = 1.0$ mol dm^{-3} $NaClO_4$.
[b] Estimated uncertainties represent standard deviations ($N \geq 5$).

The conditional stability constants (K') were calculated, at different values of acidity, according to the following equation:

$$K' = \frac{[FeCrL^+]}{[Fe^{3+}][CrL']}$$

where:

$$[FeCrL^+] = C_M - [Fe^{3+}]$$

$$[CrL'] = C_L - [FeCrL^+]$$

$[Fe^{3+}]$ = free iron(III) concentration determined by the emf values.

By each value of K', the stability constant (β_{101}) of the above complex has been calculated, using the equation:

$$\beta_{101} = K'\alpha_{CrL}$$

where:

$$\alpha_{CrL} = 1 + \Sigma\, \beta_{0i1}[H^+]^i$$

β_{0i1} is the protonation constant of the chromium–DTPA complex [1].

Fig. 1 shows how the mole fraction of each species, in the iron(III)–chromium(III)–DTPA system, changes with the acidity of the aqueous solution.

Also the reactions of iron(III) with iminodiacetic acid were investigated and only a similar 1:1 deprotonated species was evidenced. In order to calculate its stability constant, the values of the equilibrium constants of the iminodiacetic acid alone and those of the iron(II) complexes are needed. Therefore, they have been re-determined in our experimental conditions.

The overall results are collected in the Table 1.

By comparison of the obtained values of the stability constants, the iron(III) complex with iminodiacetic acid appears more stable than that with chromium(III)–DTPA, according to the greater basicity of the ligand. Furthermore, by calculating the ratio $\log \beta_{101}/\log \beta_{031}$ [12] nearly equal values for both ligands were obtained (0.80 for iminodiacetic acid and 0.78 for chromium (III)–DTPA) proving that in all cases the coordination of iron(III) occurs by one iminodiacetic group.

3.2. Study of the solid compounds

To improve the analysis of $FeCrL(OH)(H_2O)_6$ the IR spectrum of this complex was compared with those of the $H_2CrL(H_2O)_2$ and $Na_2FeL(H_2O)_2$ compounds.

In the heterobinuclear complex, the intense bands at 1652 and 1374 cm^{-1} (assigned to antisymmetric (ν_a) and symmetric (ν_s) stretching frequencies of coordinated carboxylate anion) with a difference $\Delta_\nu = 278$ cm^{-1} and the absence of the band at 1600 cm^{-1} [ionic or free carboxylate groups in $Na_2FeL(H_2O)_2$], as well as

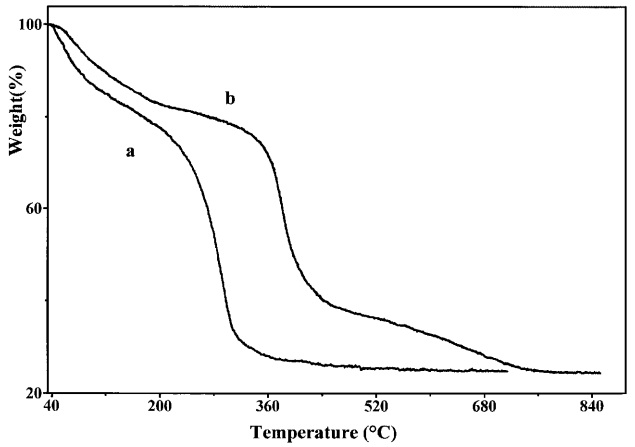

Fig. 2. TG curves in oxygen (a), and nitrogen (b), for FeCrL(OH)$(H_2O)_6$.

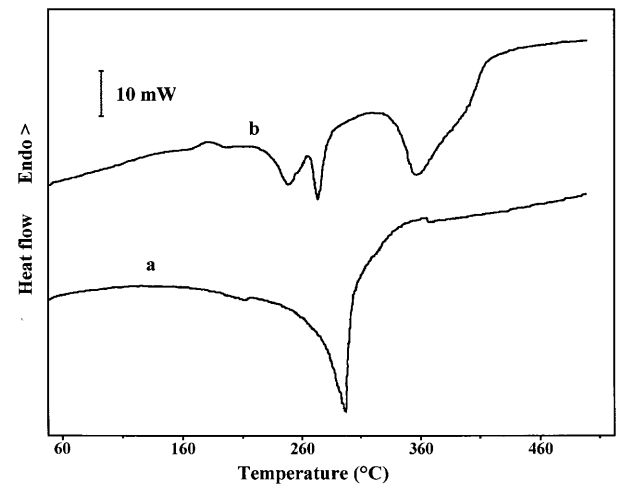

Fig. 3. DSC curves in oxygen for FeCrL(OH)$(H_2O)_6$ (a), and $Na_2FeL(H_2O)_2$ (b).

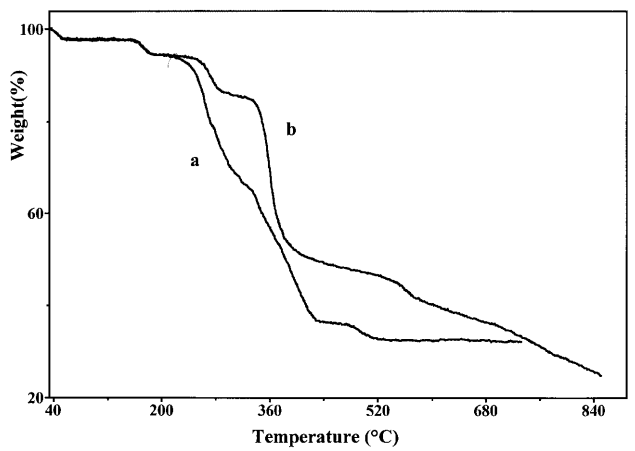

Fig. 4. TG curves in oxygen (a), and nitrogen (b), for $Na_2FeL(H_2O)_2$.

those at 1740–1705 cm^{-1} [COOH groups in $H_2CrL(H_2O)$], prove that all the carboxylate groups are involved in the metal ions chelation with high degree of covalence in the metal–oxygen bond [13].

The magnetic properties of the heterobinuclear complex were measured over a temperature range 78–300 K and the plot $1/\chi'_m$ versus T was a straight-line ($y = 12.978 + 0.426x$). The magnetic moment ($\mu = 4.35$ B.M.) and the Weiss constant ($\theta = -30.5$ K) were calculated from the slope and the intercept, respectively, on the T axis of the above line. These results prove the paramagnetic character of the complex and the formation of some degree of metal–metal interaction.

The thermal decomposition trend of the FeCrL(OH)$(H_2O)_6$ complex is greatly conditioned by the furnace atmosphere. According to termogravimetry in O_2 (Fig. 2, curve a), the dehydration reaction occurs up to approximately 120°C (for $6H_2O$, *Anal.* Calc. 17.38. Found 17.3%), beyond which the decomposition process of the anhydrous starts, first slowly (mass loss about 5% up to 185°C) then rapidly (maximum rate at 290°C). This is an oxidative process (Fig. 3, curve a) and occurs with a strong exothermic reaction ($t_p = 298$°C; $\Delta H = -4.5$ 10^3 kJ mol^{-1}). The decomposition is completed at 360°C and the residue, which remains constant up to 700°C, consists of Fe_2O_3 and Cr_2O_3 (*Anal.* Calc. 25.09. Found 25.0%). In the nitrogen atmosphere (Fig. 2, curve b), dehydration occurs in the same temperature range, but the decomposition of the anhydrous is delayed and occurs in two separate steps. The first, in the range 280–510°C (maximum rate at 380°C), forms a $Cr_2O_3 + Fe_2(CO_3)_3$ mixture (*Anal.* Calc. 35.71, Found 36.5%); the second (maximum rate at 655°C) gives at 760°C the same residue found in oxygen (found 25.0%). DSC curve shows only one, small, endothermic peak in this decomposition range ($t_p = 380$°C).

As the thermal behavior of the complex $Na_2FeL(H_2O)_2$ is unknown, we have extended this investigation to the above compound. According to the thermogram, the two water molecules of this complex depart in separate processes, the former up to 55°C and the latter in the range 140–180°C (*Anal.* Calc. 6.84. Found 6.9%). In the DSC curve (Fig. 3, curve b) an endothermic process is evident only in correspondence of the evolution of the second water molecule ($t_p = 185$°C; $\Delta H = 49$ kJ mol^{-1}). The anhydrous compound, in an oxygen atmosphere (Fig. 4, curve a), is stable up to about 210°C, then it decomposes through several steps partly overlapping one another. The thermal decomposition is completed at 520°C and the residue, stable up to 760°C at least, consists mainly of Fe_2O_3 and Na_2CO_3 (*Anal.* Calc. 35.32. Found 34.8%). This oxidative decomposition of the complex is evident in the DSC curve, which shows three strongly exothermic peaks of which two, partly overlapped, in the temperature range from 210–295°C ($t_p = 250$ and 275°C; $\Delta H = -1.2$ 10^3 kJ mol^{-1}) and one at $t_p = 359$°C ($\Delta H = -2.4$ 10^3 kJ mol^{-1}). In a dynamic N_2 atmosphere (Fig. 4, curve b), the anhydrous

compound is more stable (up to 240°C) and the decomposition is a two-step process with maximum rate at 265 and 352°C, respectively. The residue at 455°C likely consists of a $Fe_2(CO_3)_3$ and Na_2CO_3 mixture (*Anal.* Calc. 47.86. Found 47.8%) but it suffers a continuous mass loss and it does not reach a constant weight up to 840°C. The whole decomposition process, as expected, is connected with only weakly endothermic peaks.

Comparison of these data with those reported for analogous heterobinuclear chelates and chromium(III)–DTPA disodium salt chelating agent proves that iron(III) chelation causes a strong destabilising effect on the thermal stability of the compounds. Particularly, FeCrL(OH) complex is the least stable of all the studied compounds, with the exception of CuCrL.

Abstract

The formation of diethylenetriamine (dien) complexes of the lanthanide(III) ions has been studied in *N*,*N*-dimethylformamide (dmf) containing 0.1 mol dm^{-3} tetraethylammoniumtrifluoromethanesulfonate as constant ionic medium at 298 K. The stability constants have been obtained by potentiometry using the method of competitive reactions, silver(I) being the auxiliary central ion. The thermodynamic investigations have therefore been extended also to this metal ion. The data concerning lanthanide(III) complexation are well explained in terms of formation of two successive mononuclear complexes which are enthalpy stabilized, entropy changes being unfavourable. Dien coordinates with all N atoms both in ML and ML_2 lanthanide(III) complexes; with silver(I), tridentation is achieved only when the first mononuclear complex is formed. The trends in enthalpy and entropy values of the lanthanide(III) complexes are discussed taking into account the presence of multiple solvation equilibria which involve the bare ions and the complexes in solution. Comparison with similar data previously obtained in dimethylsulfoxide (dmso) both for the lanthanide(III)- and silver(I)-dien systems, shows the remarkable influence of the solvent on the thermodynamics of complex formation. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

Owing to their ability to give ionic bonding, combined with high charge density, high coordination number and rapid ligand exchange, the lanthanide(III) ions are rapidly gaining importance in homogeneous and heterogeneous catalysis and in coordination chemistry [1–5]. Moreover, they are extensively used as luminescent probes in biochemistry [6,7], as shift reagents in NMR [8] and, more recently, as contrast agents in magnetic resonance imaging (MRI) [9].

Due to their scientific, industrial and technological importance, any additional information concerning also particular aspects of the coordination chemistry of lanthanides would be of interest and utility.

So far much attention has been paid to the solution chemistry of lanthanide(III) ions in aqueous solution [1–3,10,11], where, as a consequence of the great tendency of lanthanide(III) ions to form hydroxo complexes, only slightly basic ligands have been studied. Progress in non-aqueous media, where strongly basic donors can also be investigated, has been rather slow [4,5,12–14] mainly because of the difficulty of working under anhydrous conditions with the 'water-hungry' Ln(III) ions.

With the goal of enhancing the understanding of Ln(III) coordination chemistry and with the prospective of an improvement of the methods used for rare earth separation, we have recently studied the thermodynamics of the complexation of lanthanide(III) ions in non-aqueous solutions. In particular, data have been reported on the complexation of rare earth ions by linear amines and polyamines in dimethylsulfoxide (dmso) [15–17] and acetonitrile (an) [18,19].

The investigations in dmso have shown that the formation constants of LnL_j complexes (L = ethylenediamine (en), $j = 1–3$; L = diethylenetriamine (dien) and

PII: S0277-5387(00)00541-6

triethylenetetramine (trien), $j = 1, 2$) increase almost linearly with increasing atomic number of the metal ions and that, for the same lanthanide(III) ion, $\log \beta_1$ values increase on going from en to dien to trien. These data, together with luminescence results, proved that polyamines are able to give a strong chelate effect in dmso while *n*-butylamine (*n*-but) is not able to coordinate Ln(III) in the same solvent [19], despite this ligand possessing a larger donor number than dmso (DN*n*-but = 42.0; $DN_{dmso} = 29.8$ [20]). On the other hand, it has been shown [19] that *n*-but is able to form strong complexes with partially undissociated lanthanide(III) trifluoromethanesulfonates (triflates) in a poorly coordinating solvent such as an ($DN_{an} = 14.1$ [20]). This emphasizes the great influence of the solvent on the composition and stability of the complexes.

As an extension of our previous work, we report here the results of a thermodynamic investigation on the complexation of Ln(III) ions with diethylenetriamine in anhydrous *N*,*N*-dimethylformamide (dmf), a solvent whose chemical and physical properties are intermediate between those of dmso and an, as shown by the values of the relative permittivities, ε, donor numbers, DN, and acceptor numbers, AN, reported for the various solvents: dmf, $\varepsilon = 36.7$, DN = 26.6, AN = 16.0; dmso, $\varepsilon = 46.4$, DN = 29.8, AN = 19.3; an, $\varepsilon = 36.0$, DN = 14.1, AN = 19.3 [21–23].

The stoichiometry and the stability constants of the complexes formed in solution have been obtained by means of potentiometric measurements using silver(I) as auxiliary competitive metal ion. Consequently, as required by this experimental procedure [24], preliminary determination of the silver(I) stability constants with the same ligand in dmf has been performed. The enthalpy changes have been determined by direct calorimetric titrations for all the lanthanide(III)-dien systems as well as for the silver(I)-dien system.

The present investigation was performed at 298 K using tetraethylammoniumtrifluoromethansulfonate (triflate) 0.1 mol dm^{-3} as supporting electrolyte.

2. Experimental

N,*N*-Dimethylformamide (Aldrich 99.9%) was distilled under reduced pressure and stored over 4 Å molecular sieves in a dark bottle. Ln(III) triflates were prepared from reaction of slight excess of the oxides (Aldrich 99.9%) with concentrated trifluoromethanesulfonic acid (triflic acid, Aldrich > 98%) in water. The excess of oxide was removed by filtration and the hydrated products ($Ln(trif)_3 \cdot nH_2O$, $trif = CF_3SO_3^-$, $n = 2,3$) were obtained in 2 weeks by slow evaporation of water under reduced pressure (at $t < 80$°C). The anhydrous salts were then obtained by heating the hydrated products in a Buchi TO-51 drying tube under high vacuum ($P < 10^{-4}$ Torr) at about 80°C. Stock anhydrous solutions of the salts were prepared by dissolving weighed amounts of these compounds in anhydrous dmf and were standardized by complexometry with EDTA [25].

The molar conductivities of solutions of some 1.00 and 10.0 mmol dm^{-3} Ln(III) triflates (respectively about 205 and 148 Ω^{-1} mol^{-1} cm^2) were measured with a Metrohm 712 conductometer and were found in good agreement with the accepted value for 1:3 electrolytes in dmf [26].

The Ag(I) triflate salt (Aldrich > 99%) and NEt_4trif (Fluka > 98%) were purified as described before [18,19]. The dien ligand was purified as described earlier [27] and the solutions of the ligand were prepared by dissolving weighed amounts of the anhydrous amine in anhydrous dmf. All solutions were prepared and stored in a glove box, under controlled atmosphere of N_2, with less than 2 ppm of water. The water content in the stock solutions (typically 10–30 ppm) was determined with a Metrohm 684 KF Coulometer.

2.1. Potentiometric measurements

The potentiometric apparatus and the titration procedure used were similar to those previously described [15,19]. The e.m.f. values were collected with a data acquisition system using an Amel model 338 pH-meter equipped with a Metrohm 6.0331.010 silver electrode as a working electrode and a Metrohm 6.0726.100 silver electrode as a reference. The e.m.f. values of cells containing Ln^{3+} and Ag^+ ions in the range $10^{-5} < [Ag^+] < 10^{-2}$ mol dm^{-3} proved that the silver(I) electrode behaved according to Nernst's law in our systems.

Each experimental series was carried out adding to a silver(I)–Ln(III) solution known amounts of the ligand solution with concentration C_L° ($100 < C_L^\circ < 300$ mmol dm^{-3}). In order to get reliable values for the formation constants and to check the absence of mixed Ag–L–Ln complexes in solution, at least three different initial concentrations of Ln(III) ($5.00 < C_{Ln}^\circ < 33.0$ mmol dm^{-3}) and at least two different silver(I) initial concentrations ($1.00 < C_{Ag}^\circ < 10.0$ mmol dm^{-3}) were used.

The same apparatus [19], in the absence of Ln(III) triflates, was used to obtain the e.m.f. data necessary to calculate the stability constants for the silver(I)-dien system in dmf ($1.00 < C_{Ag}^\circ < 20.0$ mmol dm^{-3}). To exclude moisture, all titrations were performed in a dry box. The computer program Superquad [28] was used for the calculation of the stability constants.

[a] Lanthanide(III) ionic radii in Å [31].

2.2. Calorimetric measurements

A Tronac model 87-558 precision calorimeter was employed to measure the heats of reaction. Thecalorimeter was checked by titration of tris(hydroxymethyl)aminomethane (tham) with a HCl standard solution in water. The experimental value of tham neutralization heat was found to be $\Delta H^\circ = -47.58$ kJ mol^{-1}, in good agreement with the accepted value of -47.53 ± 0.13 kJ mol^{-1} [29].

The calorimetric titrations were performed at 298.15 ± 0.02 K by adding known volumes of ligand solutions ($100 < C^\circ_L < 300$ mmol dm^{-3}) to 20 ml of lanthanide(III) ($5.00 < C^\circ_{Ln} < 33.0$ mmol dm^{-3}) or silver(I) ($2.00 < C^\circ_{Ag} < 20.0$ mmol dm^{-3}) solutions. In order to reach higher ligand-to-metal ratios, some 'reverse' calorimetric titrations were carried out. In these titrations Ln(III) ion solutions ≈ 100 mmol dm^{-3} were added to solutions of ligand ≈ 30 mmol dm^{-3}. The heats of dilution of the reactants, determined in separate runs, were found to be negligible. The computer program Letagrop Kalle [30] was used for the calculation of the enthalpy changes.

3. Results

The computer treatment of the potentiometric experimental data shows that the best fit is achieved when formation of two mononuclear successive complexes is taken into account for all the systems. The overall stability constants obtained from the potentiometric data minimization procedures, with the corresponding limits of error, are listed in Table 1 for the reactions $M + jL \rightarrow ML_j$ ($M = Ln^{3+}$ or Ag^+; L = dien and $j =$ 1,2). The enthalpy and entropy changes for the complex formation are also reported.

Fig. 1 shows plots of n, the average number of ligands per metal ion, versus $-\log[L]$ for the formation of dien complexes of La^{3+} and Lu^{3+}, where [L] is the free ligand concentration. The relationship $n = (C_L - n'C_{Ag} - [L]/C_M$ was used to calculate n, where n' is the average number of ligands bound to silver(I) ion and C_L is the analytical ligand concentration. The values of n' and [L] were obtained from the measured free silver(I) concentration calculated from the e.m.f. data and the stability constants of the silver(I) complexes. The overlapping of the complex-formation curves at differ-

(a) (○) C°_{La} 10.03, C°_{Ag} 1.98; (●) C°_{La} 27.78, C°_{Ag} 9.87; (b) (□) C°_{Lu} 9.57, C°_{Ag} 1.98; (■) C°_{Lu} 28.34, C°_{Ag} 9.87 mmol dm^{-3}. Only some of the experimental points, chosen at random, have been plotted. The full curves were calculated from the stability constants in Table 1.

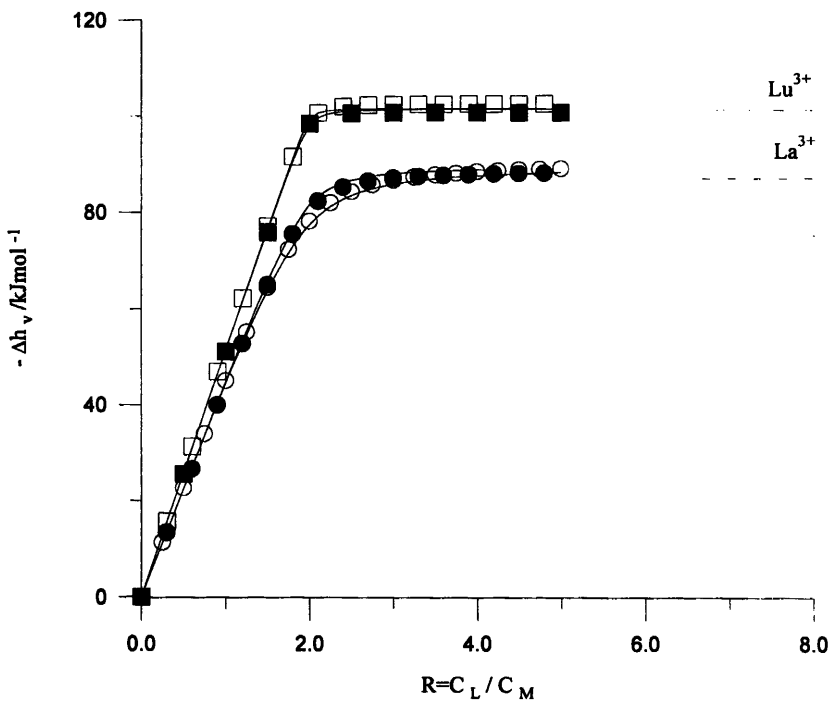

Fig. 2. The total molar enthalpy changes, Δh_v, as a function of $R = C_L/C_M$ for lanthanide(III)-dien systems in dmf. (a) (○) 8.02, (●) 20.52 mmol dm^{-3} in La^{3+}; (b) (□) 7.93, (■) 19.80 mmol dm^{-3} in Lu^{3+}. Only some of the experimental points, chosen at random, have been plotted. The solid lines have been calculated from the values of β_j and $\Delta H^{\circ}_{\beta_j}$ in Table 1. The dashed lines represent the values of enthalpy per mole of added metal obtained by the 'reverse' titrations (see text for details).

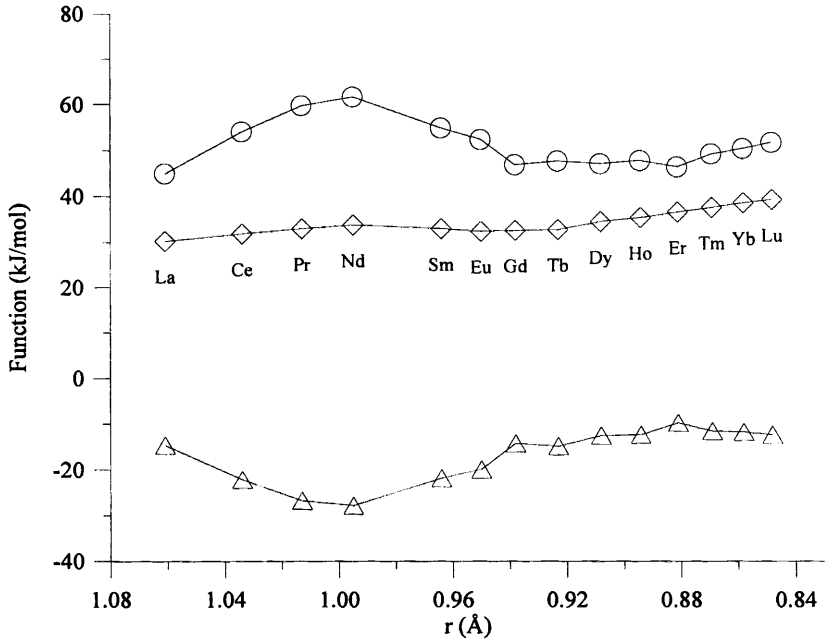

Fig. 3. Lanthanide(III)-dien thermodynamic functions for the 1:1 complex formation versus the ionic radius in dmf at 298 K and $I = 0.1$ mol dm^{-3}: (◇) $-\Delta G^{\circ}_{\beta_1}$; (○) $-\Delta H^{\circ}_{\beta_1}$; (△) $T\Delta S^{\circ}_{\beta_1}$.

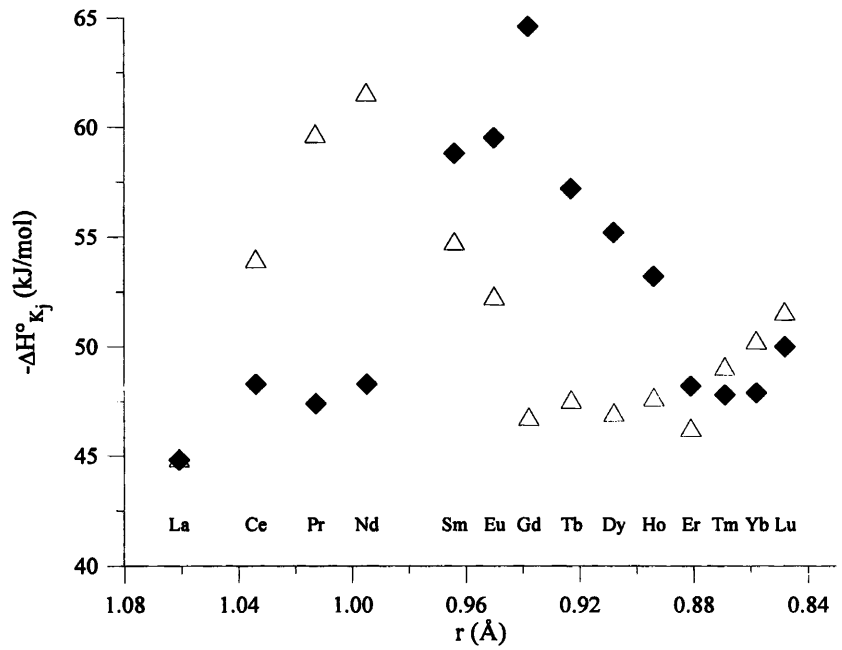

Fig. 4. Lanthanide(III)-dien stepwise $\Delta H^{\circ}_{K_j}$ functions versus the ionic radius in dmf at 298 K and $I = 0.1$ mol dm^{-3}: (△) ΔH°_{Kj}; (◆) ΔH°_{Kj}.

ent Ln^{3+}/Ag^{+} ratios and their shapes, indicate that neither polynuclear nor mixed complexes are formed in appreciable amounts and that two successive complexes are formed in stepwise equilibria.

The total heats of reaction per mole of metal ion, Δh_v, are reported as a function of $R = C_L/C_M$ in Fig. 2 for La and Lu respectively. The dotted lines in Fig. 2 refer to the values of enthalpy per mole of metal added, $\Delta h'_v$, obtained by the 'reverse' titrations. $\Delta h'_v$ is equal to Δh_v at $R \geq 2$ for the Lu(III)-system excluding the formation of higher complexes beyond the second one. For the La(III)-dien system the direct and reverse curves superimpose at slightly higher R values, as expected given the lower stabilities for the two complexes formed.

The experimental heats of reaction and the overall stability constants in Table 1 were used to calculate the full lines in Fig. 2. The experimental data fit is quite

good, indicating that the systems are described satisfactorily. Similar results are obtained for the other lanthanides.

The trend in the thermodynamic functions for the 1:1 lanthanide(III) complex formation in dmf are reported in Fig. 3 versus the lanthanide ionic radius [31]. In Fig. 4 the same plot has been drawn for the stepwise enthalpy functions, $\Delta H^{\circ}_{K_1}$ and $\Delta H^{\circ}_{K_2}$.

Some potentiometric and calorimetric titrations were also performed in dmf using the uncoordinating perchlorate as background anion [4]. No differences were observed between the data obtained with perchlorate and triflate for lanthanum and lutetium systems, so the safer triflate [19] was used in this study.

4. Discussion

4.1. Lanthanide(III)-dien systems

The data in Fig. 3 show that the stability constants of the 1:1 lanthanide(III) complexes increase almost regularly from La to Nd and from Tb to Lu, whereas almost constant values are observed from Nd to Tb. This trend, likely due to different factors acting in opposite directions, is unexpected as the increasing charge density along the series should give a monotonous increase of the stability constants [1,5].

The analysis of the enthalpy and entropy values accompanying the complex formation gives an explanation for the observed trend.

The negative enthalpy values here found (Table 1) are typical of reactions involving complexation of metal ions by neutral ligands in aprotic solvents [5,12,13,17,19,32,33]. The entropy terms, also negative, oppose the complex formation. Likely, the release of solvent molecules from the coordination sphere of the metal cations, which always accompanies complexation, does not compensate the decrease in internal entropy of the ligand and the negative entropy change due to the loss of translational entropy of the reagents when the complexes are formed.

The stability constants and the enthalpy changes of the 1:1 Ln(III)-dien complexes in dmf are much higher amd more exothermic, respectively, than those in dmso where dien was shown to act as tridentate [17]. Moreover, the thermodynamic data here reported are quite different from our unpublished results which indicate much lower stabilities and exothermicities for the complexation of lanthanides(III) by the unidentate *n*-butylamine (*n*-but) in dmf [34]. Thus, both the stability constants and the enthalpies of formation indicate that dien forms inner sphere complexes acting as tridentate in dmf too.

The trends of the $\Delta H^{\circ}_{\beta_1}$ and $\Delta S^{\circ}_{\beta_1}$ values along the lanthanide series show several discontinuities. Fig. 3 shows that the $-\Delta H^{\circ}_{\beta_1}$ values increase remarkably in the order La < Ce < Pr < Nd, then steadily decrease from Nd to Gd and thereafter slightly increasing values are observed until Lu(III). The variation of $-\Delta S^{\circ}_{\beta_1}$ along the series is similar to $-\Delta H^{\circ}_{\beta_1}$. A series of successive solvation equilibria can explain these trends. The increasing exothermicity from La to Nd can be interpreted by taking into account that La–Nd ions are present in dmf solutions in two differently solvated species. Cossy and Merbach and Pisaniello [35,36] have evidenced that the equilibrium (Eq. (1)) occurs for La, Ce, Pr and Nd ions:

$$[Ln(dmf)_9]^{3+} \rightleftharpoons [Ln(dmf)_8]^{3+} + dmf \quad (1)$$

and that this equilibrium is shifted to the right in the order La < Ce < Pr < Nd. As ΔH° for Eq. (1) is positive ($\Delta H^{\circ} = +14.8$ kJ mol^{-1} and $\Delta S^{\circ} = +69$ J K^{-1} mol^{-1} for Nd [37]), the complexation of $[Ln(dmf)_9]^{3+}$ would be less exothermic than that of $[Ln(dmf)_8]^{3+}$ to give the same $[LnL(dmf)_x]^{3+}$ species. Thus, the systematic increase in $-\Delta H^{\circ}_{\beta_1}$ from La to Nd might reflect the decrease of the desolvation enthalpy on going toward higher *Z*. The entropy changes, which decrease from La to Nd, agree with this hypothesis.

The eight-coordinated $[Ln(dmf)_8]^{3+}$ species predominates from Nd to Lu [4]. The decrease of $-\Delta H^{\circ}_{\beta_1}$ and $-\Delta S^{\circ}_{\beta_1}$ from Nd to Gd could be reasonably explained by admitting a second solvation equilibrium (Eq. (2)) that involves in this case the complexes formed instead of the bare ions and that is progressively shifted to the right from Nd to Gd.

$$[LnL(dmf)_x]^{3+} \rightleftharpoons [LnL(dmf)_{x-1}]^{3+} + dmf \quad (2)$$

In this scheme, the slight increase of $-\Delta H^{\circ}_{\beta_1}$ from Gd^{3+} to Lu^{3+} may be related to a situation where both the equilibria (1) and (2) are almost completely shifted to the right and so the enthalpy change mainly depend on the charge density of the metal ion.

The similarity of the thermodynamic functions for the formation of La^{3+} and Gd^{3+}-dien complexes as well as the difference between the $\Delta H^{\circ}_{\beta_1}$ and the $\Delta S^{\circ}_{\beta_1}$ for the formation of La/Gd-dien and Nd-dien complexes (~ 16 kJ mol^{-1} and ~ 45 J K^{-1} mol^{-1}, respectively), which are close to the binding parameters of a dmf molecule (Eq. (1)), nicely fit this interaction scheme.

The values of K_1/K_2 (in the range $10–10^2$) are not so helpful in describing the behaviour of the second ligand in $[Ln(dien)_2]^{3+}$; on the other hand the high exothermicity associated with the stepwise formation of the bis-dien complex (Fig. 4) suggests that also in this case dien behaves as tridentate.

The above mentioned interaction scheme, based on desolvation equilibria, can be successfully employed to explain also the thermodynamics of formation of the second complex. As previously suggested, 1:1 dien complexes of the lighter lanthanides (La–Nd) have the same

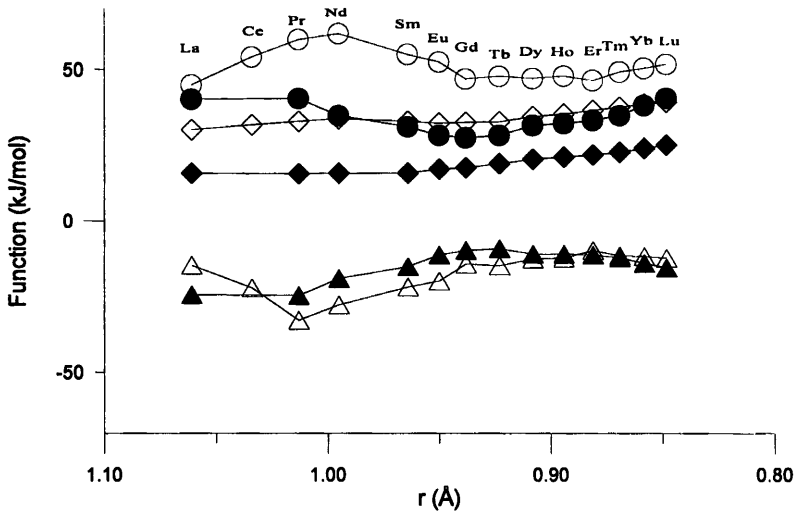

Fig. 5. Lanthanide(III)-dien thermodynamic functions for the 1:1 complex formation versus the ionic radius in dmf ((◇) $-\Delta G^{\circ}_{\beta_1}$; (○) $-\Delta H^{\circ}_{\beta_1}$; (▲) $T\Delta S^{\circ}_{\beta_1}$) and dmso ((◆) $-\Delta G^{\circ}_{\beta_1}$; (●) $-\Delta H^{\circ}_{\beta_1}$; (△) $T\Delta S^{\circ}_{\beta_1}$) at 298 K and $I = 0.1$ mol dm^{-3}.

coordination number. Thus, the slight increase of the stepwise $-\Delta H^{\circ}_{K_2}$ observed from La(III) to Nd(III) is due to the increase of the metal-ligand interaction in the hypothesis that Eq. (3) is the only equilibrium in solution.

$$[\mathrm{LnL(dmf)}_x]^{3+} + \mathrm{L} \rightleftharpoons [\mathrm{LnL_2(dmf)}_{x-n}]^{3+} + n\,\mathrm{dmf} \quad (3)$$

From Nd to Gd, equilibrium (2) is more and more shifted to the right. After gadolinium, all the 1:1 complexes have the same coordination number. So, the increase of $-\Delta H^{\circ}_{K_2}$ for the 1:2 Nd–Gd complexes is due to the lower energy required to desolvate $[\mathrm{LnL(dmf)}_x]^{3+}$ complexes to obtain species with the same stoichiometry. The decrease of the heat of reaction from Gd to Er, is likely due to the equilibrium (4) involving the solvation sphere of the ML_2 complex and shifted to the right in the order Gd < Tb < Dy < Ho < Er.

$$[\mathrm{LnL_2(dmf)}_y]^{3+} \rightleftharpoons [\mathrm{LnL_2(dmf)}_{y-1}]^{3+} + \mathrm{dmf} \quad (4)$$

From Er to Lu both the 1:1 and 1:2 complexes of the lanthanides have the same stoichiometry, so no large difference in the $-\Delta H^{\circ}_{K_2}$ values is expected, and observed, along this series.

The trend in the stepwise entropy values agree, also in this case, with the proposed interaction scheme.

For comparison, in Fig. 5 the thermodynamic data for the Ln(III)-dien complexes in dmf and in dmso [17] are plotted. It can be observed that the lanthanide(III)-dien complexes are always more stable and more enthalpy stabilized in dmf than in dmso: this feature is an example of the remarkable influence of the solvent in complex formation. In fact, although the difference in DN between dmf and dmso is low [20], nevertheless it is sufficient to highly favor complexation reactions in dmf. In this context it is noteworthy to underline that in dmso monoamines do not coordinate lanthanide(III) ions, while in dmf they do [34].

The order of magnitude of the entropy changes and the general trends of entropy and enthalpy values versus the ionic radii are similar in the two solvents. From this, it follows: (i) solvation equilibria similar to those proposed here might be taken into account also to explain the data obtained in dmso;(ii) the solvent bulk does not seem to be significantly influenced by the coordination of a neutral ligand to a lanthanide ion. So, the specific interactions of the solvent and of the ligand with the metal ion should be considered mainly responsible for the stability trends along the lanthanide series.

4.2. Silver(I)-dien system

Negative values of enthalpy and entropy are obtained also for this system as a consequence of the formation of strong covalent Ag–N bonds and the relatively weak solvation of the species [23].

The 1:1 complex formed in dmf is much more stable than the analogous tridentate complex in dmso for which $\log \beta_1 = 7.46$ [38]. The silver ion is tetrahedrally coordinated both in dmso and in dmf [39] and the similarity of thermodynamic data (in dmso $\Delta H^{\circ}_{\beta_1} = -78.2$ and $T\Delta S^{\circ}_{\beta_1} = -32.5$ kJ mol^{-1}) suggests retention of this structure when complexation occurs in both solvents. Therefore, it is likely that dien behaves as tridentate also in dmf, forming two fused five-membered chelate rings with the fourth tetrahedral position occupied by a solvent molecule[3].

[3] Tridentation is moreover confirmed by a comparison with preliminary values of $\log \beta_1$ and $\Delta H^{\circ}_{\beta_1}$, respectively about 4.80 (0.06) and −36 (2) kJ mol^{-1}, obtained in our laboratory for silver(I) complexation with the unidentate *n*-butylamine in dmf.

The very high value of the ratio $K_1/K_2 \approx 10^7$, together with the stepwise enthalpy and entropy values associated with the formation of AgL_2^+ complex ($\Delta H^\circ_{k_2} = -18.4$ and $T\Delta S^\circ_{k_2} = -1.5$ kJ mol^{-1}) are in agreement with the formation of one five-membered chelate ring by each of the two ligands.

The higher stability of the silver(I) complexes in dmf with respect to dmso can be mainly attributed to the weaker solvation of metal ion in the former solvent. Transfer functions from dmf to dmso of silver(I) are in fact $\Delta G^\circ_{tr,dmf\rightarrow dmso} = -14.0$ and $\Delta H^\circ_{tr,dmf\rightarrow dmso} = -18.3$ kJ mol^{-1} [40].

Comparison of the thermodynamic stabilities of the complexes in dmf and in water gives a good example of the ligand solvation influence in these complexation reactions. In fact, despite the larger solvation of metal ion in dmf than in water [40], the thermodynamic stability of the 1:1 complex in water is lower than in dmf ($\log \beta_{1(water)} = 6.10$ [10]). This can be connected with the larger solvation of the amine in water, through strong hydrogen bonds, which evidently compensates for the stronger solvation of Ag^+ in dmf ($\Delta G^\circ_{tr,H_2O\rightarrow dmf} = -21$ and $\Delta H^\circ_{tr,H_2O\rightarrow dmf} = -35$ kJ mol^{-1} [40]).

Abstract

The coordination of Pt(II) with different mercapto and dimercapto compounds has been studied using both potentiometric titration at 25°C in KCl 0.1 M and UV–Vis spectroscopy. The slow complex formation kinetics has been followed spectrophotometrically for several days on samples with different ligand molar fractions ranging from 0.1 to 1, keeping the ligand and metal concentration below 8×10^{-4} M. For the potentiometric titration, the ligand concentrations were kept constant at 10^{-3} M, and the 0.25, 0.5, 0.75 and 1.00 metal/ligand ratios were titrated in the pH range 2.5–11 for each ligand. The solutions were kept in a thermostatted bath at 25°C for 2 days before titration. The stabilization of the absorbance values under these conditions after 2 days, and the back titration with hydrochloric acid 0.1 M, led us to conclude that the proper equilibrium complex formation is reached under these conditions. Using KCl 0.1 M as an ionic strength medium, the reported formation constants are referred to the complexation reaction starting from $[PtCl_4]^{2-}$. Some models are proposed on the basis of the estimated stoichiometries.

1. Introduction

The use of chelating agents in the treatment of human metal intoxication is a field of great interest to health sciences [1–4]. Particularly, platinum intoxication is an important side effect suffered by patients treated with the antitumour drug *cis*-dichlorodiammine platinum(II) (cisplatin). Nephrotoxicity is the most serious complication due to cisplatin treatment: this has been ascribed to Pt^{2+} binding by sulphide groups of proteins in kidney tubules [5]; as a consequence, several studies have shown that compounds containing thiolic groups can reduce the toxicity of this drug without affecting its antitumour activity [6–8].

The principal aspect of platinum(II) behaviour that is to be taken into account when planning a chelating therapy, is that platinum is strongly bounded intracellularly [9]. A chelating agent such as DMSA (*meso*-2,3-dimercapto succinic acid), however, is not capable of permeating cell membranes at a physiological pH, because of its high charge due to deprotonations of the carboxylic groups. Nevertheless, thanks to the properties of DMSA in the treatment of heavy metal poisoning, in other words its low toxicity and good adsorption in the intestinal tract, it could be used as an oral chelator. This has added considerable interest to the study of its lipophilic analogues, monomethyl and dimethyl dimercapto succinates, that could be used conveniently in platinum chelation.

In this paper we present the equilibrium studies of both monomethyl and dimethyl dimercapto succinates and their parent compound, *meso*-2,3-dimercapto succinic acid (DMSA), as well as those of mercaptosuccinic acid, which is similar to DMSA except for the fact that it has only one –SH binding group. The formulas of the studied molecules are shown in Table 1.

Table 1
Names, formulae and acronyms of the used compounds

mercapto succinic acid	*meso*-2,3-dimercapto succinic acid	*meso*-monomethyl dimercapto succinate	*meso*-dimethyl dimercapto succinate
COOH CHSH CH_2 COOH	COOH CHSH CHSH COOH	COOH CHSH CHSH $COOCH_3$	$COOCH_3$ CHSH CHSH $COOCH_3$
MSA	**DMSA**	**MMS**	**DMS**

The ionization constants of the above molecules, determined in a previous work [10] are reported in Table 2.

2. Experimental

2.1. Reagents

The KOH standard solutions, potassium tetrachloroplatinate(II) 99.99%, KCl, mercapto succinic acid, and *meso*-2,3-dimercapto succinic acid were Aldrich products; monomethyl and dimethyl dimercapto succinates were synthesized according to Gerecke [11]. The commercial compounds were used without further purification, the others were checked by elemental analysis with a CHN-S Fisons instrument and by ^{13}C NMR and IR spectra.

The daily procedure for use of the solutions of DMSA and its derivatives is as described in a previous work on Pd(II) complexes [12]. The Pt(II) solution was prepared by dissolving the weighted amount of potassium tetrachloroplatinate(II) in a KCl 0.1 M aqueous solution.

Table 2
Ionization constants for the four molecules in Table 1 [a]

	pK_{C1}	pK_{C2}	pK_{S1}	pK_{S2}
Mercapto succinic acid	3.12(1)	4.52(1)	10.24(3)	
meso-2,3-Dimercapto succinic acid	2.71(1)	3.43(2)	9.65(3)	12.05(3)
meso-Monomethyl dimercapto succinate	2.80(1)		7.15(2)	9.98(2)
meso-Dimethyl dimercapto succinate			5.23(1)	7.32(3)

[a] pK_{C1} and pK_{C2} refer to the ionization of the first and second COOH, pK_{S1} and pK_{S2} to the ionization of the first and second SH. Values in parentheses are standard deviations of the last significant figure.

2.2. Potentiometric measurements

Titrations were performed on a Dosimat 665 Metrohm automatic titrator connected to a Metrohm 691 pH meter. We used a thermostatted glass cell equipped with a magnetic stirring system, a Metrohm glass electrode for highly alkaline solutions, a thermometric probe, a microburet delivery tube, an inlet–outlet tube for argon, and a salt bridge connected with the reference cell, filled with a KCl 0.1 M solution, in which a saturated calomel electrode was dipped. The solutions were titrated at 25°C with carbonate-free KOH 0.1 M. The electrode was calibrated for hydrogen ion concentration by titrating HCl with KOH in KCl 0.1 M; the resulting data were analysed with the Gran [13] procedure using our GRANPLOT program. The ionization and formation constants were calculated with the PSEQUAD program [14]. All the solutions at variable ligand/metal ratios were stored at 25°C for 2 days before potentiometric analysis because of their very slow complexation. For each ligand we titrated 20 ml of the ligand–Pt(II) mixtures at an ionic strength of 0.1 M KCl with KOH 0.1 M. The ligand was always 10^{-3} M, while Pt(II) was varied according to the following ligand/metal molar ratios: 4:1, 4:2, 4:3 and 4:4. The number of experimental points for each titration was 100 in the 2.5–11 pH range. The reversibility of the equilibria was proved by carrying out an acidic titration after each basic titration.

2.3. Kinetic measurements

The formation reaction was monitored with a Hewlett–Packard 8452 diode array spectrophotometer. The absorption spectra of the samples with 8×10^{-4} M ligand and metal concentrations at an ionic strength 0.1 M of KCl were recordered every 5 min for 2 days in a 1 cm cell at 25°C.

In all the experiments the reaction proceeded under pseudo-first-order conditions and the absorbance increase due to the complex formation is given by the equation

$$A = p_1 \exp(-t/\tau) + p_2 \quad (1)$$

where τ is the relaxation time, p_1 and p_2 are constants

connected to absorbance values of reagents and products.

The kinetic measurements were evaluated fitting Eq. (1) to the absorbance value at several wavelengths, using the Marquardt algorithm. No systematic deviations between the experimental points and the fitted curves were observed.

3. Results and discussion

Platinum(II) equilibria are infrequently studied because of the inherent difficulties that are basically of two kinds: the presence of multiple equilibria with Cl^- and OH^-, and the kinetic slowness in reaching equilibrium. The equilibria among Pt(II) and chloride are quantitatively shifted to $[PtCl_4]^{2-}$ when KCl 0.1 M is used as an ionic strength medium. The reported formation constants are thus referred to the complexation reaction which starts from $[PtCl_4]^{2-}$. These conditions are quite similar to the actual plasma (103 mM in chloride) [15] in the treatment of Pt(II) poisoning in humans. As regards the slowness in reaching equilibrium, we proved that the limiting step was the complex formation when ligand and metal ions were mixed together.

The complex requires hours to form, while the equilibrium is reached rapidly after each base addition. Therefore each titration started 2 days after prepearing the ligand–Pt mixture, and delay times of 1 min between base additions were applied. The experimental titration curves were fitted with the models and the formation constants reported in Table 3, using the PSEQUAD program. Table 3 also shows the pK values for the deprotonation steps, that are reported for a better reading.

The experimental titration data for mercapto succinic acid (MSA) were fitted using a model $Pt_2L_4H_x$ with x ranging from 6 to zero; a possible structure of $Pt_2L_4H_6$ could be that presented in Fig. 1 in which the two platinum(II) ions are held together by two sulphur bridges, and the square planar coordination is completed by two ligand molecules bonded to the platinum(II) ions via the sulphide and carboxylic groups.

Table 3
Models, ligand/metal ratios of each model, logarithm of formation constants, and pK of complex deprotonations estimated for the systems with the four studied ligands [a]

Model	L/M	log(β)	pK	Model	L/M	log(β)	pK
MSA				MMS			
$Pt_2L_4H_6$	2	92.9		$Pt_2L_3H_4$	1.5	73.3	
$Pt_2L_4H_5$		88.6	4.3	$Pt_2L_3H_3$		70.0	3.3
$Pt_2L_4H_4$		84.0	4.6	Pt_2L_3H		58.3	5.8
$Pt_2L_4H_3$		78.5	5.5	PtL_2H_3	2	46.9

$Pt_2L_4H_4$		85.6	6.6				
$Pt_2L_4H_3$		77.0	8.6				
Pt_2L_4H		56.1	10.5				

[a] The individual standard deviations of log(β) are not reported in the table, but they all range between 0.1 and 0.3.

This complex, which was completely formed at pH 3, loses the first two protons at pK 4.3 and 4.6. These values are comparable to pK 4.52 relating to the second ionization of the free ligand. The remaining four protons are lost at progressively higher pK values 5.5, 6.2, 7.7 and 9.6, because of an increasing negative charge on the complex.

On considering the *meso*-2,3-dimercapto succinic acid (DMSA), two different complexes appear, one with a similar stoichiometry to mercaptosuccinic acid, the other characterized by three ligands binding two Pt(II) ions. The structures tentatively proposed for these complexes in the most protonated form are shown in Fig. 2.

The difference between these two complexes consists in the substitution of one of the bridge ligands by a μ-water molecule. The structures in Fig. 2B, where

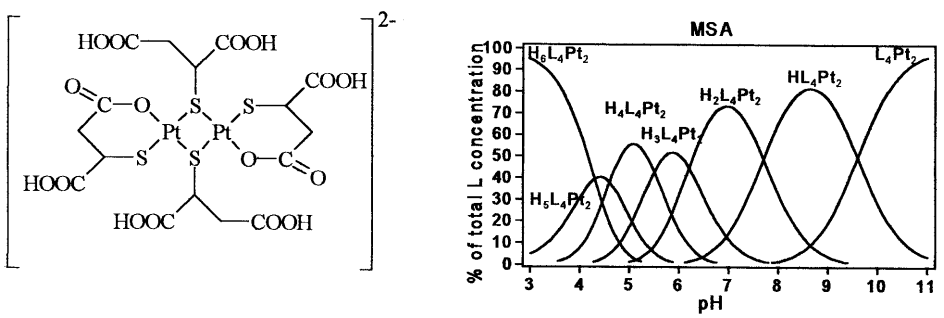

Fig. 1. The distribution curves for the MSA–Pt(II) system are reported on the right as a function of pH, [Pt(II)] being 1 mM and [MSA] 2 mM. A possible structure for the $H_6L_4Pt_2$ complex is proposed on the left.

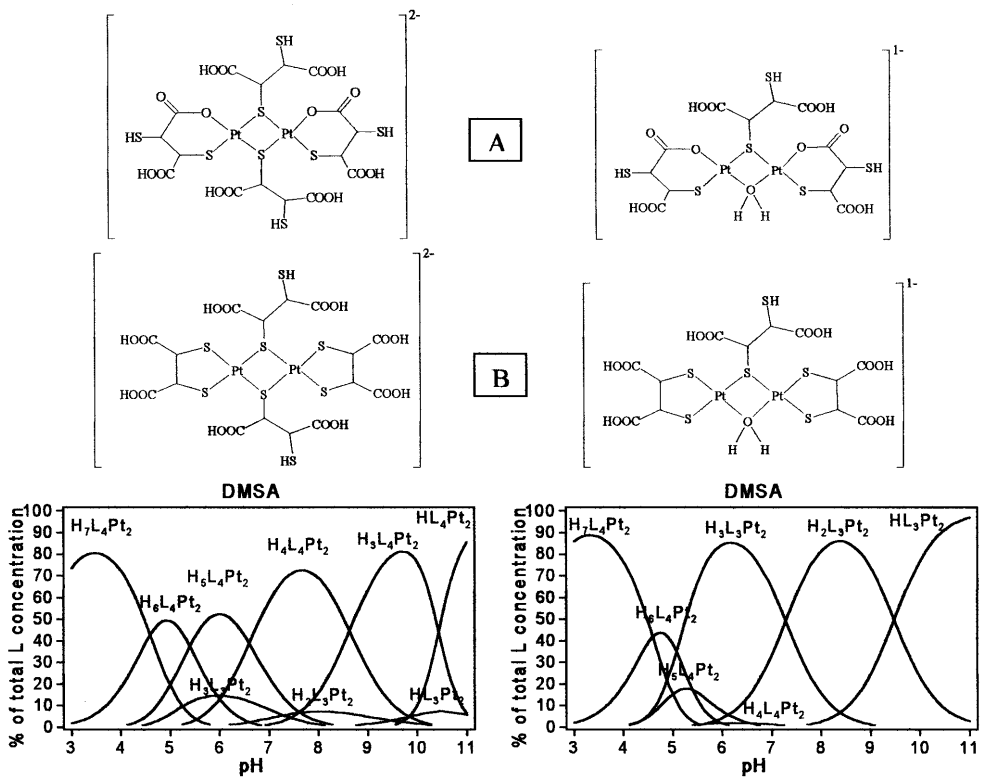

Fig. 2. The distribution curves for the DMSA–Pt(II) system are presented in the lower part, [DMSA] being always 2 mM and [Pt(II)] 2 mM in the right plot and 1 mM in the left. Possible structures of $Pt_2L_4H_{10}$ (left) and $Pt_2L_3H_7$ (right) are shown in the upper part. The structures A and B differ in the coordination of the external ligands.

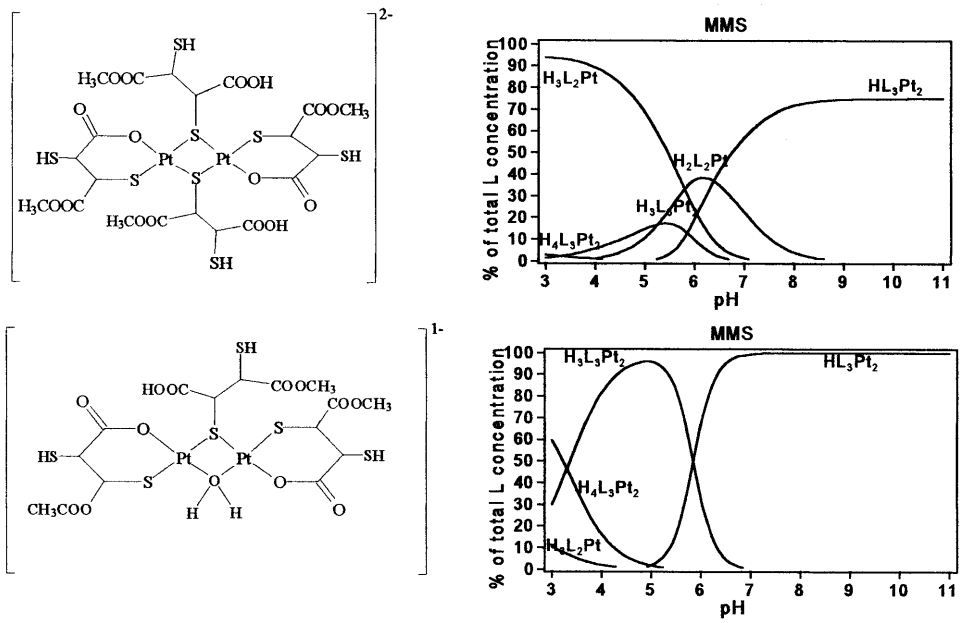

Fig. 3. The distribution curves for the MMS–Pt(II) system are presented on the right, [MMS] being always 2 mM and [Pt(II)] 2 mM in the upper plot and 1 mM in the lower. Possible structures of $Pt_2L_4H_6$ and $Pt_2L_3H_4$ are shown respectively in the upper and lower parts.

coordination of external ligands takes place using both mercapto groups, are as acceptable as those in Fig. 2A. The existing species at pH 3 loses three protons from carboxylic groups, unlike the complex with mercapto succinic acid. This is also consistent with the fact that the two carboxylic groups in DMSA are more acidic respectively by 0.4 and 1.1 pK units (see Table 2).

The model derived for *meso*-monomethyl dimercapto succinate (MMS), can be represented by the structures proposed in Fig. 3. The two stoichiometries, which

seem different at first sight, can actually be represented by very similar structures. In fact, as in the case of MSA and DMSA, PtL_2H_3 can be assumed to have the structure in the upper left part of Fig. 3. In such a model it is supposed that only one mercapto group per ligand will take part in coordination. Ionization at pK 5.8 therefore, which is slightly higher than in the free ligand both for the negative -2 charge on the entire molecule and for the inductive effect of Pt(II) coordination at the mercapto group, relates to the carboxylic group. For the same reasons, the deprotonation of –SH groups not implied in complexation takes place at pK values greater than 11 and is not experimentally observed in potentiometric measurements.

$Pt_2L_3H_4$, which appears at a 1:1 L/M ratio, can be represented with the structure in the lower left part of Fig. 3, which is very similar to the upper part, and differs only by the substitution of a bridge ligand between two Pt(II) ions with a μ-water. The latter ionizes at pK 3.3, while the only carboxylic group loses its proton at the same pK 5.8 as with $Pt_2L_3H_4$. With MMS, as with DMSA, two structures are possible when the ligand binds through the two –SH groups.

On the other hand the behaviour of *meso*-dimethyl dimercapto succinate (DMS) is quite different. At high L/M ratios, the PtL_4H_4 species is formed, where each ligand behaves as monodentate. The first two of the second –SH protons of each ligand is lost at 6.6 and 8.9, respectively at a lower and higher value than that of the free ligand 7.32. The loss of the last two protons is not experimentally observed. At lower L/M ratios a $Pt_2L_3H_2$ species is formed as in the previously observed complexes for DMSA and its monomethyl derivative. In this case the $Pt_2L_3H_2 \rightarrow Pt_2L_3H$ transition, i.e. the formation of the second pentatomic ring, occurs at pK 3.4. Here this is the only possible structure, since a coordinating carboxylic group is not available (Fig. 4).

For all four ligands, a strong increase in absorbance was observed in the 250–450 nm range during the formation reaction (Fig. 5), but no significant spectrophotometric changes were observed during the basic titration of the samples. For this reason, potentiometric measurements were used to determine formation constants and the kinetics of the complex formation was monitored through changes in the absorption spectra. These changes are very similar in all systems.

Spectra were decomposed using the SPECPEAK program [16] in four Gaussian peaks with maxima at about 250, 275, 315 and 365 nm. Absorbance data at these wavelengths for samples with a 1:1 Ligand/metal ratio fit Eq. (1) well and a first-order observed kinetic constant ($k = 1/\tau$) can be determined.

The observed kinetic constants measured at the peak at 275 nm are 6.8×10^{-5} s^{-1} for mercaptosuccinic acid (MSA), 7.3×10^{-6} s^{-1} for *meso*-2,3-dimercapto succinic acid (DMSA), 1.4×10^{-5} s^{-1} for *meso*-monomethyl dimercapto succinate (MMS), and 2.6×10^{-5} s^{-1} for *meso*-dimethyl dimercapto succinate (DMS). Therefore, the formation of complexes between these ligands and Pt(II) follows a very slow kinetics.

Generally speaking, the lower the number of close binding groups (–SH and/or –COOH), the faster the complex formation reaction (MSA and DMS). The slowest reaction is for DMSA, which has two –SH and two –COOH groups.

The tendency of platinum to form polynuclear planar complexes is well known. With MSA, which is the

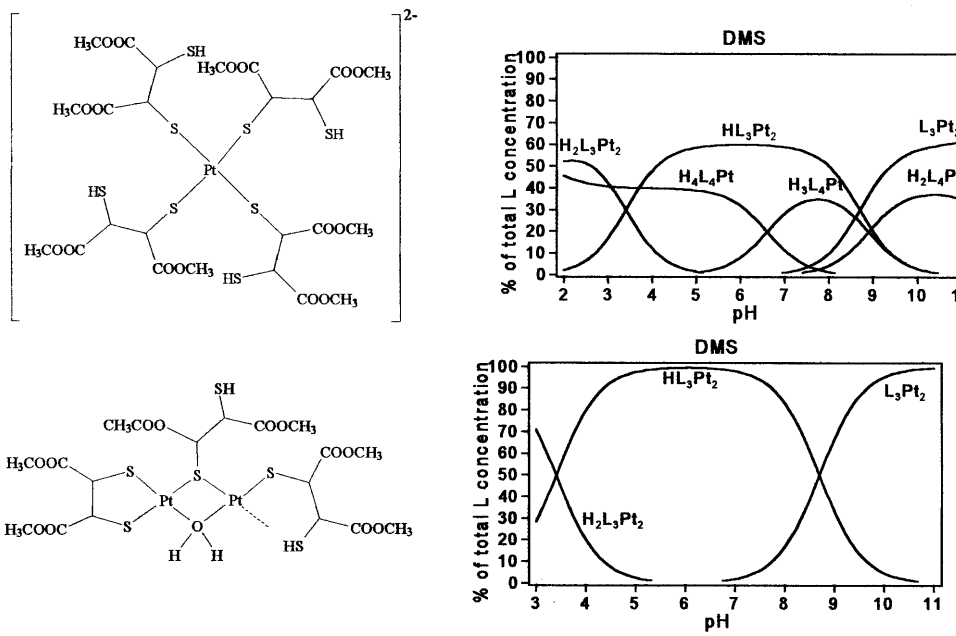

Fig. 4. The distribution curves for the DMS–Pt(II) system are presented on the right, [DMS] being always 2 mM and [Pt(II)] 2 mM in the upper plot and 1 mM in the lower. The possible structures of $Pt_4L_4H_4$ (upper) and $Pt_2L_3H_2$ (lower) are shown on the left.

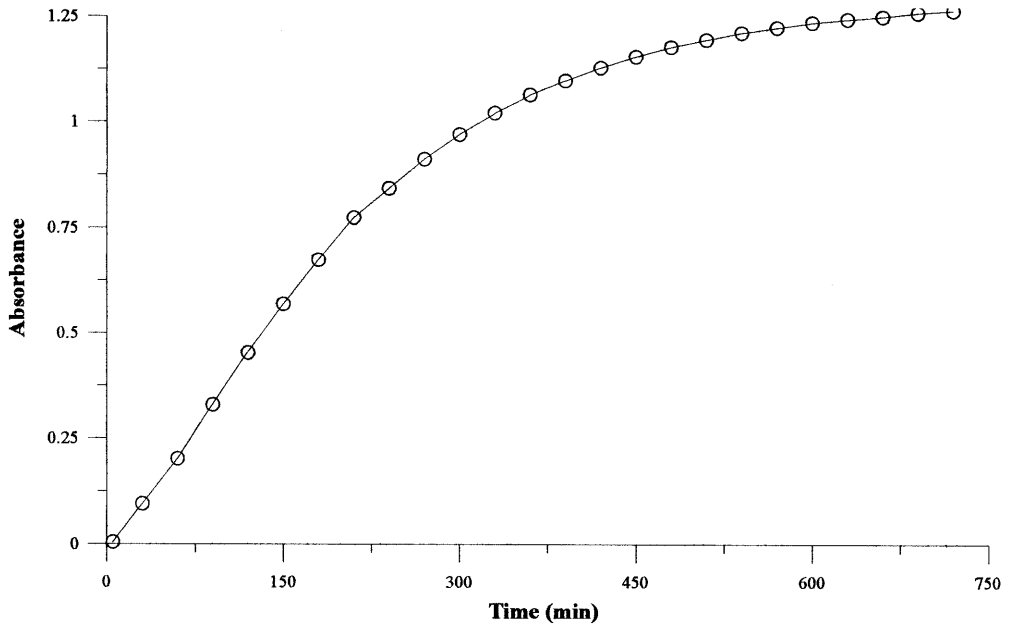

Fig. 5. Height of the peak at 275 nm versus time for the reaction of complex formation between Pt(II) and meercapto succinic acid.

ligand with the fastest complexation with Pt(II), in the case of only one –SH group, the structure proposed in Fig. 1 cannot be extended to form polynuclear complexes, because no free –SH groups are available to form bridges with other Pt(II) atoms. This could explain the faster reaction. In the other cases, the free –SH groups allow the proposed structures to spread in two dimensions. The formation of a more complex structure would justify both the slower kinetics and the powdery aspect of the isolated solids, which never crystallize. In the particular case of DMSA, which is the ligand with the slowest kinetics, the fact that it has a higher tendency to form a precipitate compared to the other ligands also after 2 days, confirms that due to its four binding groups a more complex structure is formed.

Dedicated to the late Professor Sergio Cabani.

Abstract

The equilibria involving the uptake of dioxygen (O_2) to the dicobalt(II) complexes of the macrocyclic ligands [27]aneN_9 (1,4,7,10,13,16,19,22,25-nonaazacycloheptacosane) and [30]aneN_{10} (1,4,7,10,13,16,19,22,25,28-decaazacyclotriacontane), and of the acyclic polyamine Me_2octaen (1,25-dimethyl-1,4,7,10,13,16,19,22,25-nonaazapentacosane) have been studied by potentiometric measurements in 0.15 mol dm^{-3} $NaClO_4$ aqueous solution at 298.1 ± 0.1 K, and the relevant equilibrium constants have been reported. All three ligands form stable oxygenated complexes of the type $[Co_2L(O_2)]^{4+}$ and $[Co_2L(O_2)OH]^{3+}$, in which the O_2 molecule is bound in the end-on mode to a single metal ion. In the case of the macrocyclic complexes the coordination of O_2 and OH^- reveals a cooperativity effect, i.e. a significant stability increase is observed when one of these species coordinates to a dinuclear complex containing the other one, with respect to the same reactions involving $(Co_2L)^{4+}$. This behaviour suggests the interaction via hydrogen bonding between the two species (O_2 and OH^-) coordinated to different cobalt(II) ions. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The binding, transport, and activation of molecular oxygen by metal complexes is a topic of wide current interest due to the many implications that such metal containing systems have in both biomimetic and abiotic processes involving dioxygen (O_2) [1–6]. In this respect, Co(II) complexes with polyamine ligands containing binding units suited either for the coordination of a single metal ion or for the assembling of dimetallic centres have proved particularly useful [1].

Among the authors who have supported the investigation in this field, the late Professor Sergio Cabani, to whom this paper is dedicated, gave an important contribution to the understanding of the thermodynamic and kinetic aspects governing dioxygen uptake [6–17].

Polynuclear metal complexes able to bind dioxygen can be used as biomimetic models for natural non-heme respiratory proteins, such as hemocyanin and hemerythrin. Hemocyanin is a dinuclear copper(I) protein typical of molluscs and arthropods, while hemerythrin is a protein, containing two iron(II) ions at its active site, occurring among several marine invertebrates. These proteins bind O_2 according to different coordination modes: (i) coordination to both metal centres to form a peroxide-bridging complex in oxyhemocyanin; (ii) end-on coordination to a single metal centre in oxyhemerythrin [18]. Among dioxygen complexes containing dimetallic centres, the bridging oxyhemocyanin-like coordination is the most common O_2 binding mode.

In hemocyanin the two Cu(I) ions display equal coordination environments, while in hemerythrin the two Fe(II) are differently coordinated [18]. It has been recently noted that dinuclear complexes of ligands containing different coordination sites are able to bind

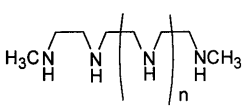
PII: S0277-5387(00)00543-X

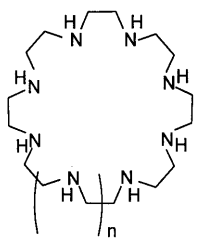
dioxygen, providing important new reactivity patterns, and may be useful as model systems for hemerythrin, reproducing the situation in which dioxygen is bound to one of the metal ions but is reduced by two electrons, one from each of the metals, to form a peroxide ligand bound to one metal [19].

In order to get insight into the relation between the coordination environment of dicobalt(II) complexes and their oxygenation properties, we have undertaken a thermodynamic study on the dioxygen uptake to the dicobalt(II) complexes of the polyamines [27]aneN_9, [30]aneN_{10} and Me_2octaen. The first two ligands have a macrocyclic structure while the third one is an acyclic ligand. [27]aneN_9 and Me_2octaen contain an odd number of donor atoms and form dinuclear complexes in which the metal ion has a different coordination environment (see Scheme 1).



2. Experimental

2.1. Reagents



The ligands Me_2octaen, [27]aneN_9 and [30]aneN_{10} were synthesised as described previously [20–22] and used as their hydrochloric salts.

2.2. E.m.f. measurements

All pH-metric measurements ($pH = -\log[H^+]$) were carried out in 0.15 mol dm^{-3} $NaClO_4$, CO_2-free solutions at 298.1 ± 0.1 K, by using equipment and the methodology that has previously been described [23]. The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NaOH solutions, and determining the equivalent point by Gran's method [24]. This allows one to determine the standard potential $E°$ and the ionic product of water ($pK_w = 13.73(1)$ at 298.1 ± 0.1 K in 0.1 mol dm^{-3} $NaClO_4$). Measurements performed to determine the equilibrium constants for the formation of the dioxygen complexes were carried out by maintaining a constant pressure (1 atm) of O_2 in the potentiometric cell. The concentration of O_2 in solution (1.21×10^{-3} mol dm^{-3}), at the operating pressure, temperature and ionic strength, was obtained from published data [25]. The complexation reactions are rather slow; for this reason 30 min were allowed to elapse after each titration (NaOH solution) addition in order to get stable e.m.f. readings. At least three potentiometric titrations (about 100 data points for each one) were performed for each system in the pH range 2.5–10.5. In order to ensure the achievement of equilibrium conditions, a reduced number of experimental points (10–15) was obtained for each system, in separated experiments performed by adopting longer equilibration times (2 h). In all experiments the ligand concentration [L] was varied in the range 0.5×10^{-3}–1×10^{-3} mol dm^{-3}, while the metal ion concentration [M] was [M] = 2[L], in order to vary the ratio between O_2 and complex concentrations. A modification of the computer program HYPERQUAD [26] was used to calculate the equilibrium constants of the oxygenated complexes from e.m.f. data. Such modification was made in order to consider the presence of a chemical species (O_2) involved in the complexation equilibria, whose free concentration is kept constant during the measurement. Ligand protonation [20–22] and metal ion complexation [27,28] constants employed in the calculations were determined in previous works under anaerobic conditions. All titration curves, including those obtained with longer equilibration times, were treated either as a single set or as separated entities without significant variation in the value of the stability constants.

3. Result and discussion

3.1. Cobalt(II) complexes

As indicated by previous studies [27,28], Me_2octaen, [27]aneN_9 and [30]aneN_{10} are able to form both mono and dinuclear Co(II) complexes under anaerobic conditions. Due to the large number of amine groups constituting their molecular structure, these ligands display a particular propensity to form dinuclear complexes. As a matter of fact, in solutions containing ligand and Co(II) in 1:2 molar ratios, the mononuclear complexes formed by Me_2octaen and [27]aneN_9 are minor species, while [30]aneN_{10} forms only dinuclear complexes (Fig. 1).

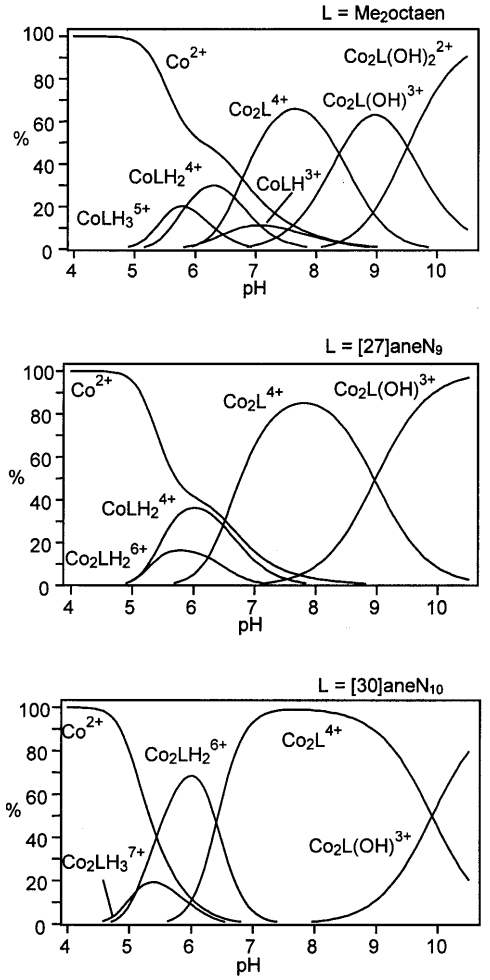

Fig. 1. Speciation diagrams for the anaerobic systems Co(II)/L (L = Me_2octaen, [27]aneN$_9$, [30]aneN$_{10}$). [L] = 1×10^{-3} mol dm^{-3}, [Co(II)] = 2×10^{-3} mol dm^{-3}; 0.15 mol dm^{-3} $NaClO_4$, 298.1 K.

As shown by the species distribution diagrams reported in Fig. 1, such dinuclear complexes form very stable hydroxylated species, indicating that the complexes present a good tendency to coordinate additional species from the medium. This is, of course, a promising starting point for the use of such compounds as O_2 binders.

3.2. Dioxygen binding

As expected, the binuclear complexes of the three ligands considered in this work are able to bind molecular oxygen giving rise to the formation of stable oxygenated complexes. The equilibrium constants determined for the O_2 complexes are reported in Table 1, while Fig. 2 displays the distribution diagrams of the complexed species formed as a function of pH in the systems Co(II)/O_2/L (L = ligands).

In contrast with the complexation equilibria taking place under anaerobic conditions [27,28], in the presence of dissolved O_2 only dicobalt(II) complexes are formed in solution containing the ligand and metal ion in a 1:2 molar ratio. This applies for all three ligands, in spite of the fact that in the absence of O_2 Me_2octaen and [27]aneN$_9$ would also form mononuclear species. Evidently the dinuclear complexes of the three ligands are more efficient, from a thermodynamic point of view, than the mononuclear one in the binding of molecular dioxygen.

It is quite interesting to note that the binding of O_2 prevents the formation of protonated complexes. A comparison of the species distribution diagrams reported in Figs. 1 and 2 for the anaerobic and aerobic systems, respectively, clearly visualises this aspect. Such behaviour indicates that the binding of O_2 to the metal centres gives rise to a strengthening of the metal to ligand bonds, overcoming the competitive effect of ligand protonation, and promoting the coordination of all donor atoms even in acidic solutions. On the other hand, the oxygenated complexes display a good ability to form hydroxylated species from neutral (Me_2octaen, [27]aneN$_9$) or slightly alkaline ([30]aneN$_{10}$) pH values (Fig. 2).

As shown by the equilibrium constants for the addition of O_2 to $(Co_2L)^{4+}$, the complex of the acyclic Me_2octaen ligand displays a greater ability to bind molecular dioxygen (Table 1) than the complexes of the macrocyclic ones ([27]aneN$_9$, [30]aneN$_{10}$), while among the macrocyclic complexes, the $(Co_2L)^{4+}$ species formed by [27]aneN$_9$ bind O_2 more strongly than the

dicobalt(II) complex of [30]aneN_{10}. A similar stability trend was also observed for the addition of OH^- to the dinuclear not-oxygenated complexes. While the different binding abilities of the macrocyclic complexes can be interpreted in terms of different numbers of coordination sites available on the metal centres for the exogen ligands, a justification for the greater binding ability of the acyclic complex with respect to the macrocyclic one is not simple, especially in the absence of structural information. A previous study dealing with the kinetics of O_2 binding by the Co(II)/[30]aneN_{10} system suggested that the dioxygen molecule acts as monodentate ligand coordinating to the binuclear complex in a end-on fashion [14]. Such kinetic information is consistent with the present thermodynamic data, since a bridging coordination of the O_2 molecule to the complex would fulfil the coordination sphere of both metal ions, opposing the binding of further species, such as OH^-. On the contrary, $[Co_2[30]aneN_{10}(O_2)]^{4+}$ displays a very good tendency to bind OH^-.

By considering the close similarity between the binding features of $[Co_2[30]aneN_{10}]^{4+}$ and $[Co_2[27]aneN_9]^{4+}$ towards both O_2 and OH^- (Table 1), an end-on coordination of O_2 is also expected to occur with the latter complex.

It is noteworthy that O_2 and OH^- manifest a clear cooperativity in the binding to the dicobalt(II) complexes of the macrocyclic ligands. As a matter of fact, a significant stability increase is observed (Table 1) when one of this species coordinates to a dinuclear complex containing the other one, with respect to the same reactions involving $(Co_2L)^{4+}$ (compare the equilibrium constants for reactions 2 and 3 with those for 4 and 1, respectively, reported in Table 1). A similar cooperativity can be explained by assuming a direct interaction via hydrogen bonding between O_2 and OH^- in the complexes, as observed in oxyhemerythrin [18]. In a previous paper [29] dealing with Ni(II) complexes it was shown that in the crystal structure of $\{Ni_2[30]aneN_{10}(H_2O)_2\}^{4+}$ the two coordination sites occupied by the water molecules are located on opposite sides of the centrosymmetric dinuclear complex, and spectral data obtained for the same compound suggested that the same structure is maintained in solution. If a similar structure also occurs for the analogous dicobalt(II) complexes in solution, and considering that the binding of O_2 and OH^- should occur at the positions occupied by the water molecules, the dicobalt(II) complex would require an important reorganisation to allow the formation of an hydrogen bond between the coordinated oxygen molecule and the hydroxide ion.

The uptake of molecular oxygen to the dicobalt(II) complex of the acyclic ligand Me_2octaen displays different thermodynamic characteristics with respect to the analogous complexes with [27]aneN_9 and [30]aneN_{10}. As already observed, the dicobalt(II) complex with the acyclic ligand Me_2octaen is a strong O_2 binder but, in contrast to the behaviour of the macrocyclic complexes, the equilibrium constants for the binding of O_2 and OH^- (Table 1) do not suggest any cooperative effect.

In the absence of structural information regarding both the oxygenated complex and the non-oxygenated one, it is rather difficult to give an interpretation of such thermodynamic properties displayed by the dicobalt(II) complex of Me_2octaen. Nevertheless, both the spectral features of the oxygenated complexes and the kinetic data for O_2 uptake are quite similar for all three ligands considered here [30], suggesting that the coordination mode adopted by O_2 in the oxygenated complexes should also be the same for all three ligands. Hence, we expect that in $[Co_2Me_2octaen(O_2)]^{4+}$ and $[Co_2Me_2octaen(O_2)OH]^{3+}$ the dioxygen molecule is end-on bound to a single metal centre, although it seems unable to give rise to hydrogen bonding interaction with OH^- in the hydroxylated complex. Assuming

that in this complex O_2 and OH^- are bound to different Co(II) ions, the absence of hydrogen bonding between the two species could be ascribed to a greater ability of dinuclear complexes with the acyclic, more flexible ligand in locating the metal centres at a longer distance to reduce the electrostatic repulsion between positive charges.

Alternatively, both O_2 and OH^- might be coordinated to the same metal centre in $[Co_2Me_2octaen(O_2)OH]^{3+}$. The experimental information we have presently collected does not allow us to exclude such possibility.

4. Conclusions

Dicobalt(II) complexes with ligands Me_2octaen, [27]aneN_9, and [30]aneN_{10} of the type $(Co_2L)^{4+}$ and $[Co_2L(OH)]^{3+}$ are efficient receptors of molecular dioxygen in aqueous solution, giving rise to the formation of $[Co_2L(O_2)]^{4+}$ and $[Co_2L(O_2)(OH)]^{3+}$ oxygenated species. In the case of the macrocyclic complexes, cooperativity is observed in the binding of O_2 in the presence of coordinated OH^- and vice versa, the presence of one of these species in the complex assisting the coordination of the other one via direct hydrogen bonding as observed in hemerythrin. This evidence suggests that the uptake of O_2 and OH^- takes place on different metal centres, the dioxygen molecule being in end-on coordination mode. On the other hand, the dicobalt(II) complex with the acyclic ligand Me_2octaen does not display any cooperativity in the binding of O_2 and OH^-, in spite of the fact that $[Co_2Me_2octaen]^{4+}$ presents a higher tendency than macrocyclic complexes to bind O_2. Nevertheless, both the spectral features of the oxygenated complexes and the kinetic data for O_2 uptake are quite similar for all three ligands, suggesting that, in the case of Me_2octaen, O_2 is also end-on coordinated to cobalt.

The kinetics of O_2 binding, of which a few aspects have been anticipated in this paper, is the subject of a concurrent publication [30].

Abstract

We consider here the kinetics of the reaction of formation of dioxygenated Co(II) complexes with the binucleating ligands 1,23-bis(methylamino)-3,6,9,12,15,18,21-heptaazatricosane (Me_2Octaen), 1,4,7,10,13,16,19,22,25-nonaazacycloheptacosane ([27]aneN_9), 1,4,7,10,13,16,19,22,25,28-decaazacyclotriacontane ([30]aneN_{10}), and 1,4,7,10,13,16,19,22,25,28,31-undecaazacyclotritriacontane ([33]aneN_{11}). The most important result is that the Co(II) complexes with these polyamines in aqueous solution and at room temperature are very flexible in binding dioxygen: by changing the value of the ligand to cobalt concentration ratio ($R = C^0_L/C^0_{Co}$) and the pH of the solution, it is possible to modulate the dioxygen uptake obtaining two-to-one or one-to-one, Co/O_2 superoxo complexes. As to the kinetics of the formation of these complexes, we find that the rate-determining step is the transformation of a cobalt-ligand precursor complex, inert towards dioxygen, to yield an active form, whereas the reaction of dioxygen uptake is fast in all the investigated systems. © 2000 Elsevier Science B.V. 1. Introduction

The ability of Co(II) complexes to bind molecular dioxygen has been the subject of intensive studies both for modeling biological dioxygen carriers and for possible applications in transport, storage or activation of molecular dioxygen [1–7]. The structure of these synthetic dioxygen carriers, as well as the kinetics and thermodynamics of their formation, is strongly affected by the nature of the ligand. Simple tetraazotate or pentaazotate ligands form oxygenated Co(II) complexes in which dioxygen bridges two complexed subunits. The thermodynamics and the kinetics of the formation of these complexes have been extensively studied by some of the authors (N.C., R.P. and M.R.T.) under the guidance of the late Prof. Sergio Cabani to whom this work is dedicated [8–15]. In this work we consider the kinetic features of the reaction of formation in aqueous solution of the dioxygen adducts of Co(II) complexes with some dinucleating ligands.

The use of polynucleating ligands represents an evolution in synthetic Co(II) dioxygen carriers. These ligands contain a sufficient number of oxygen and/or nitrogen donor centers to coordinate more than one Co(II) ion and can act as biomimetic models of natural non-heme type (hemerythrin, hemocyanin) carriers. Martell et al. [16] examined the Co(II) complexes with the dinucleating ligands BISTREN, BISDIEN and BISBAMP in aqueous solution and obtained several interesting results. The Co_2(II)BISTREN complex shows an unexpected low affinity with dioxygen and a very slow metal-centered degradation to Co_2(III)BISTREN complexes. As a consequence, the Co_2(II)BISTREN-(μO_2)(μOH)[1] complex is a very good dioxygen carrier and many cycles of uptake-release of O_2 are possible by simply heating and cooling its aqueous solutions. More recently, Bosnich has pointed out the interest, as oxygenation catalysts, of suitable designed bimetallic peroxo-complexes where dioxygen is bound to one metal [17].

As a part of general research within our laboratories involving the synthetic systems for dioxygen transport and activation, we have begun the study of the thermodynamics and the kinetics of the reaction of formation of dioxygenated Co(II) complexes with large polyazaalkanes. Owing to their ability to form dinuclear complexes, large polyazaalkanes are good candidates for studying O_2 binding; actually they produce two binding sites in which the two Co(II) ions possess variable surroundings in geometry and number of coordinated donors atoms. The ligands considered in this work are the acyclic polyamine 1,23-bis(methylamino)-3,6,9,12,15,18,21-heptaazatricosane (Me_2Octaen) and the macrocyclic polyamines 1,4,7,10,13,16,19,22,25-nonaazacycloheptacosane ([27]aneN_9), 1,4,7,10,13,16,19,22,25,28-decaazacyclotriacontane ([30]aneN_{10}), and 1,4,7,10,13,16,19,22,25,28,31-undecaazacyclotritriacontane ([33]aneN_{11}). They react with cobalt under anaerobic conditions forming mononuclear or dinuclear complexes, depending on the ligand/cobalt concentration ratio and on the pH of the solution. The acidity constants of the protonated ligands [18–21] and the equilibrium formation constants of their Co(II) complexes in anaerobic conditions have been previously determined [22–24]. Some preliminary results, concerning dioxygenated Co(II) complexes with these ligands, have been already reported [25,26].

2. Experimental

2.1. Materials

The ligands were prepared according to the procedure previously described: Me_2Octaen [18], [27]aneN_9 [19], [30]aneN_{10} [20], [33]aneN_{11} [21]. They have been used as hydrochloride salts. Their purity was checked by elemental and NMR analysis. All other chemicals were reagent-grade products and were used without further purification.

2.2. Apparatus

Dioxygen concentration was measured by means of a Beckman Oxygen Analyser (model 0260) equipped with an oxygen electrode capable of measuring oxygen concentrations up to a maximum of 199.0 ppm. The electrode was calibrated in air-saturated 0.15 mol dm^{-3} $NaClO_4$ aqueous solutions [9,12]. The cell was designed to contain the oxygen sensor, a glass electrode for pH measurements, and two openings for introducing the reagents by means of microsyringes or titration microburettes. It was filled, leaving no vapour space, with aqueous solutions of the ligand in 0.15 mol dm^{-3} $NaClO_4$ saturated with dioxygen or with air and adjusted to the selected pH values. The solution was thermostated at 298.1 ± 0.1 K and magnetically stirred. Known amounts of $Co(NO_3)_2$ were added and the pH of the solution was kept constant to the selected value by adding known amounts of NaOH stock solutions as long as the reaction of formation of the dioxygen adducts proceeded. A Crison Micro TT 2050 automatic titrating system equipped with a combined glass electrode was used for the pH measurements and NaOH additions. The glass electrode was calibrated as a hydrogen concentration probe by titration of known amounts of HCl with CO_2-free NaOH solutions. In this investigation pH is defined as the logarithm of a concentration, $-\log [H^+]$. The free dioxygen concentration in solution, C_{O_2}, has been monitored, during the dioxygen binding reaction, as a function of time in experiments carried out at different pH values and at different values of the cobalt/ligand concentration ratio $R = C^0_L/C^0_{Co}$, where C^0_L and C^0_{Co} are, respectively, the initial concentration of the ligand and of cobalt. The dioxygen bound/cobalt concentration ratio as a function of time, $R_{O_2}(t)$, was calculated as $R_{O_2}(t) = (C^0_{O_2} - C_{O_2}(t))/C^0_{Co}$, where $C^0_{O_2}$, is the initial dioxygen concentration. Spectrophotometric measurements were performed at 298.1 K by using a Perkin–Elmer Lambda 6 UV–Vis spectrophotometer and a Hewlett–Packard 8452 Diode Array spectrophotometer equipped with a rapid mixing apparatus (Applied Photophysics model RX1000) with an empirical dead-time lower than 1.5×10^{-2} s. Both the measuring cell and the mixing device were thermostated at 298.1 ± 0.1 K.

3. Results and discussion

3.1. Characterization of the oxygenated complexes

The characterization of the oxygenated Co(II) complexes with Me_2Octaen, [27]aneN_9, [30]aneN_{10}, and [33]aneN_{11}, and the study of the kinetics of their formation and of their further evolution has been carried out by means of the analysis of the binding dioxygen curves, proton balances, and UV–Vis spectra, carried out in a large field of the cobalt/ligand concentration ratio (R ranging from 0.5 to 2) and of the pH of the solution (from 7 to 12). In each experiment the values of R and pH were selected in order to ensure that only mononuclear or only dinuclear Co(II)/L precursor complexes were present in anaerobic conditions.

Fig. 1 shows some dioxygen binding curves, $R_{O_2}(t)$, for the system Co/[27]aneN_9/O_2. This phenomenology is common to all the systems considered in this work with only minor differences.

The combined analysis of the whole set of the dioxygen binding curves and of potentiometric measurements allows us to obtain a significant picture of the nature and of the formation conditions of the various dioxy-

gen adducts. The main features of the formation processes can be summarised as follows: (i) at $R = 0.5$ and pH ranging from 7 to 10, a dinuclear complex of stoichiometry $Co_2LO_2(OH)_j$ ($j = 0, 1$) rapidly forms, the number of bound hydroxo groups depending on the pH of the solution; (ii) at $R = 0.5$ and pH > 11.3, the step of formation of this complex is slowed down and is followed by the slow consumption of a further equivalent of dioxygen; (iii) at $R > 1.5$ and pH > 8, the investigated polyazaalkanes form oxygenated mononuclear cobalt complex $CoLH_j(O_2)$ ($j = 0, 1$ depending on the pH of the solution). We will describe the main features and the behavior of these complexes by distinguishing between dinuclear and mononuclear species. In any case it is important to put in evidence two interesting results which emerge from our analysis. The first is that the Co(II) complexes with these polyamines are very flexible in bonding dioxygen: by changing the value of the ligand/cobalt concentration ratio and the pH of the solution, it is possible to obtain one-to-one or two-to-one Co/O_2 dioxygen adducts. The second result is that one-to-one Co(II) dioxygen complexes form in aqueous solution and at room temperature. This is a rather unusual behavior for synthetic dioxygen carriers and, to the best of our knowledge, only a few cases are reported in the literature [27–29].

3.2. Dinuclear complexes

At $R = 0.5$ and pH ranging from 7 to 10, $Co_2LO_2(OH)_j$ ($j = 0, 1$) is the prevailing oxygenated species for all the ligands considered in this work, the number of bound hydroxo groups depending on the pH of the solution. The formation constants of these complexes are reported in the first paper of this series [30]. The stability trends observed for the formation of such oxygenated complexes are in agreement with a complex structure of superoxo type, in which dioxygen is end-on bonded to a single cobalt atom. A similar not-bridging arrangement of the coordinated dioxygen molecule seems to be also in agreement with the rather long metal to metal distance, ranging from 5.75 to 7.26 Å, observed in several crystal structures of dinuclear complexes with [30]aneN$_{10}$ [31,20].

Fig. 2 shows the UV–Vis spectrum of the $Co_2LO_2(OH)_j$ complex and its evolution in time, when the ligand is Me_2Octaen. Two absorption bands with maxima at $\lambda = 320$ nm and at $\lambda = 395$ nm are initially present, but they tend to slowly disappear while a new band arises with a maximum at $\lambda = 370$ nm. The UV–Vis spectrum is the same between pH 7 and 10, but the rate of the transformation increases as the pH increases. The decay at $\lambda = 320$ nm obeys a first-order kinetic law, the molar extinction coefficient at $t = 0$ and the half-life time being $\varepsilon_{320} = 6165 \pm 60$ mol^{-1} dm^3 cm^{-1} and $t_{1/2} = 60 \pm 5$ min at pH 7 and $\varepsilon_{320} = 6110 \pm 80$ mol^{-1} dm^3 cm^{-1} and $t_{1/2} = 11.5 \pm 0.5$ min at pH 10. Such spectral evolution is essentially due to a conformational rearrangement of the oxygenated acyclic complex. An analogous behavior is displayed by the Co(II) complexes with the macrocyclic polyazaalkanes, but the spectral evolution is slower than for the acyclic Me_2Octaen and becomes slower and slower as the dimension of the macrocyclic ring increases; for [30]aneN$_{10}$ and [33]aneN$_{11}$ it overlaps with the reaction of irreversible oxidation which leads to the decrease of the absorbance in the spectral range 300–500 nm.

In order to study the kinetics of the formation of the $Co_2LO_2(OH)_j$ complex, the absorbance has been monitored at $\lambda = 320$ nm, by means of a diode array spec-

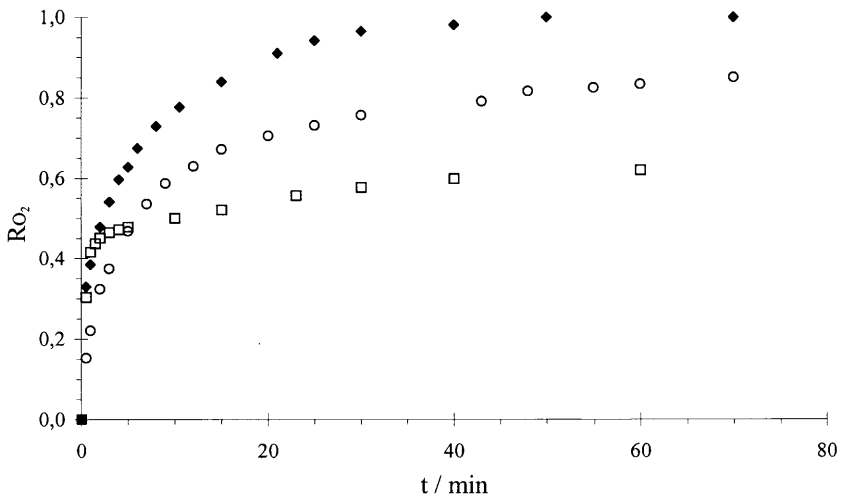

Fig. 1. Dioxygen binding curves, $R_{O_2}(t)$, for Co(II)–[27]aneN$_9$ complexes in aqueous solution at various R and pH: $C^0_{Co} = 4.43 \times 10^{-4}$ mol dm^{-3}, $R = 0.5$, pH 9.8 (□); $C^0_{Co} = 3.67 \times 10^{-4}$ mol dm^{-3}, $R = 0.5$, pH 11.4 (○); $C^0_{Co} = 3.98 \times 10^{-4}$ mol dm^{-3}, $R = 2$, pH 8.5 (◆). $R_{O_2}(t) = (C^0_{O_2} - C_{O_2}(t)/C^0_{Co}$; $R = C^0_L/C^0_{Co}$.

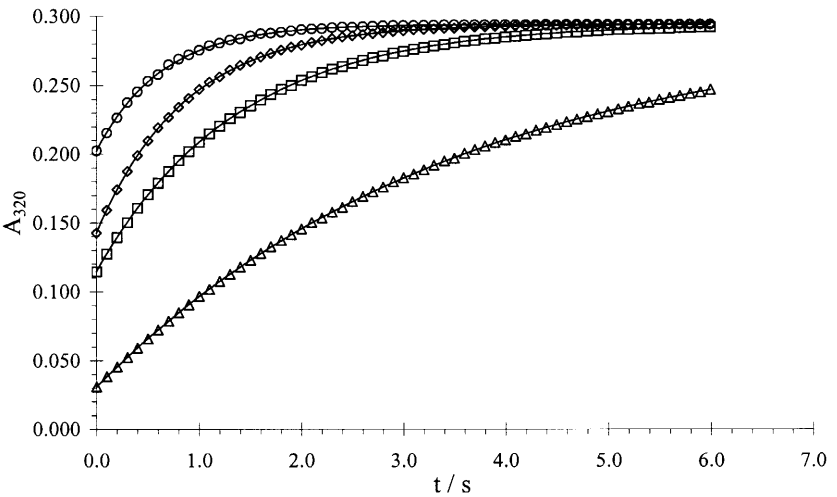

Fig. 3. Absorbance at $\lambda = 320$ nm as a function of time for the system $Co/Me_2Octaen/O_2$ (continuous lines are the fitting curves): $C^0_{Co} = 9.64 \times 10^{-5}$ mol dm^{-3}; $C^0_L = 4.82 \times 10^{-5}$ mol dm^{-3}; $C^0_{O_2} = 2.04 \times 10^{-4}$ mol dm^{-3}; pH 8.40 (△), pH 8.94 (□), pH 9.40 (◇), pH 9.94 (○).

trophotometer equipped with a rapid mixing apparatus. For each system, oxygenated solutions of the ligand were mixed with oxygenated solutions containing $Co(NO_3)_2$. The solutions were saturated with dioxygen or with air at 1 atm. Spectrophotometric measurements were carried out at different cobalt concentrations in the pH range from 8.4 to 10 by using solutions of the ligand suitably buffered with sodium tetraborate and NaOH. Each experiment was repeated at least five times.

The kinetic behavior is independent of the initial dioxygen concentration, indicating that O_2 is involved only in a fast step following the rate-determining one. In Fig. 3, we report, as an example, the experimental results of single runs at four pH values for the system $Co/Me_2Octaen/O_2$. The increase of the absorbance at 320 nm strongly depends on pH and exhibits a positive intercept at $t = 0$. By considering that only the oxygenated complexes absorb at 320 nm, this intercept indicate that a first rapid reaction leading to formation of an oxygenated complex immediately occurs. This reaction, too fast to be studied with our apparatus, is followed by a second slower process which falls in the range-time of our instrumentation and can so be monitored. The kinetics of this second process follows a first-order law:

$$A = A^0 + (A^\infty - A^0)(1 - e^{-\eta t}) \quad (1)$$

where η is the apparent kinetic constant whereas A^0 and A^∞ represent the absorbance values at $t = 0$ and $t = \infty$, respectively. The parameters A^0, A^∞ and η were determined by means of a least-square procedure and

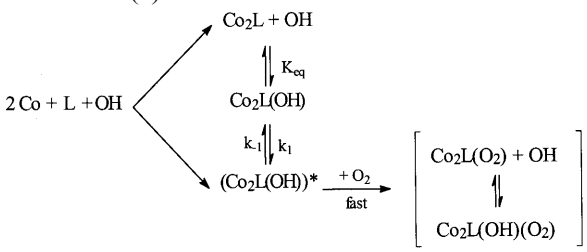

Table 1

[a] Determined by independent potentiometric measurements [22–24].

their reproducibility was of 5% on A^0, 1% on A^∞ and 3% on η. In the same figure the calculated functions are compared with the experimental data. A^0 and η depend on the pH.

By considering that preliminary results on the kinetics of formation of the dinuclear Co_2L complexes in anaerobic conditions indicate that the formation of these complexes seems to be faster than the slower reaction of formation of their dioxygen adducts, the experimental behavior is consistent with the following mechanism (2):

(2)

where the kinetic controlling step is the transformation of the cobalt-ligand precursor complex to yield an active form. The precursors, Co_2L, Co_2LOH, and Co_2LOH^*, exhibit different reactivities toward dioxygen, Co_2LOH^* being the most active form. Co_2LOH^* directly formed by the reaction of the cobalt with the ligand, immediately binds dioxygen and this reaction is responsible of the absorption at $t = 0$. Because the Co_2LOH^* concentration is higher at higher pH, A^0 increases with pH. The slow step involve the formation of the intermediate species Co_2L, and Co_2LOH the latter being converted in the active form Co_2LOH^* in the rate-determining step. Thereafter the rate of the formation of the oxygenated complex is controlled by the rate of formation of Co_2LOH^*.

According to this mechanism the apparent kinetic constant of the slow step, η, depends on the pH as:

$$\eta = \frac{k_1 K_{eq}[OH]}{1 + K_{eq}[OH]} + k_{-1} \quad (3)$$

where $K_{eq} = [Co_2LOH]/([Co_2L][OH])$. The values of K_{eq} and k_1 reported in Table 1 for all the systems with the different ligands, have been obtained by means of a non-linear best-fitting procedure on Eq. (3). The value of k_{-1} is in any case too small to be determined with sufficient precision, indicating that the equilibrium between the two hydroxo species is largely displaced towards the active one. The agreement between the experimental and calculated η values is very good for all the investigated systems (see as an example Fig. 4). The values of log K_{eq} obtained by this procedure are in fair agreement with the log K_{eq} values already determined by independent potentiometric measurements [22–24].

The different reactivity of the two equilibrium species, Co_2LOH and Co_2LOH^*, can be justified if one considers that the coordination positions of the cobalt atom not occupied by the nitrogen atoms of the ligand in Co_2LOH are directed towards the inner part of the

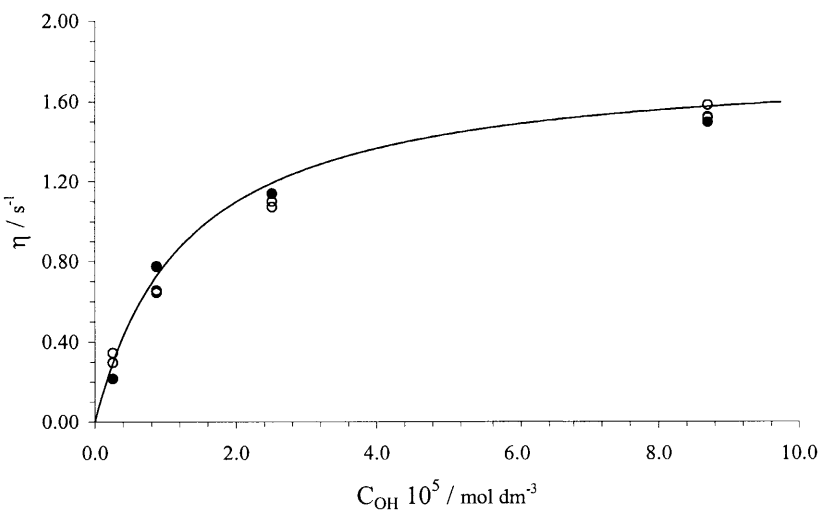

Fig. 4. Dependence of the apparent kinetic constant of formation of the $Co_2Me_2OctaenO_2(OH)_j$ complex, η, from the OH^- concentration, C_{OH}. Continuous line represents the fitting curve; (○) are the experimental η values obtained in measurements carried out at $C^0_{O_2} = 2.0 \times 10^{-4}$ mol dm^{-3}; (●) are the experimental η values in measurements carried out at $C^0_{O_2} = 1.0 \times 10^{-3}$ mol dm^{-3}.

Table 2
Values of the kinetic constants k_1 and k_2 for the formation of the $Co_2L(O_2)(OH)_2^*$ and $Co_2L(O_2)_2(OH)_2^*$ complexes, respectively ($R = 0.5$ and pH >11.5)

Ligand	$k_1 \times 10^3$ (s^{-1})	$k_2 \times 10^3$ (s^{-1})
Me_2Octaen	5.2 ± 0.7	0.68 ± 0.09
[27]aneN_9	4.3 ± 0.5	0.12 ± 0.06
[30]aneN_{10}	2.2 ± 0.6	0.05 ± 0.02
[33]aneN_{11}	3.3 ± 0.7	0.22 ± 0.09

complex molecule requiring a molecular rearrangement in order to expose the cobalt ion to the dioxygen attack or, as suggested by the thermodynamic study [30], the Co_2LOH species needs a rearrangement in order to give rise to a $Co_2L(OH)(O_2)$ complex stabilized by direct interactions via hydrogen bonding between the bound O_2 and OH^- species.

The inspection of the k_1 values in Table 1 shows that the reaction $Co_2LOH \rightarrow Co_2LOH^*$ is faster the more flexible the ligand is. The largest value of k_1 corresponds to the reaction with the acyclic Me_2Octaen whereas, concerning the series of the cyclic ligands, k_1 increases with the cycle size.

At $R = 0.5$ and pH >11, $Co_2L(OH)_2$ is the prevailing species in anaerobic conditions for Me_2Octaen [6,23]. Although the formation of dihydroxo dicobalt(II) complexes with the macrocyclic ligands was not observed in the speciation study performed at pH <10.5 [22], these species are formed in more alkaline solutions (pH >11) as demonstrated by proton balance measures we have performed in the pH range 11.0–11.5. The reaction of dioxygen uptake at these R and pH values is much slower than at lower pH and its course has been followed by monitoring the dioxygen consumption as a function of time through measurements of the free dioxygen concentration in solution, C_{O_2}. We observe a first dioxygen uptake-which occurs in about 10 min and consumes about 0.5 mols of dioxygen per mole of cobalt — followed by a further slower dioxygen consumption. The kinetics of these reactions does not depend on the initial dioxygen concentration and C_{O_2} changes according to the kinetic law of a two-step first-order mechanism. Additional UV–Vis spectrophotometric measurements at 320 nm show an initial increase and a subsequent decrease of absorbance. These results indicate the formation of non-negligible amounts of an intermediate species and support the following reaction scheme:

$$Co_2L(OH)_2 \underset{k_1}{\rightarrow} (Co_2L(OH)_2)^* \overset{+O_2}{\underset{\text{fast}}{\rightarrow}} Co_2L(OH)_2(O_2) \underset{k_2}{\rightarrow} (Co_2L(OH)_2(O_2))^* \overset{+O_2}{\underset{\text{fast}}{\rightarrow}} \text{products} \quad (4)$$

where the kinetic controlling steps are the transformation of the precursor $Co_2L(OH)_2$ and the intermediate $Co_2L(O_2)(OH)_2$ species in order to give the active forms $Co_2L(OH)_2^*$ and $Co_2L(O_2)(OH)_2^*$. According to this scheme the function $C_{O_2} = f(t)$ is given by:

$$C_{O_2} = C^0_{O_2} - C^0_{Co} + \frac{C^0_{Co}}{(k_1 - k_2)}\left(\frac{k_1}{2} - k_2\right) e^{-k_1 t} + \frac{C^0_{Co}}{(k_1 - k_2)} \frac{k_1}{2} e^{-k_2 t} \quad (5)$$

By means of a non-linear best-fitting procedure we obtained the k_1 and k_2 values reported in Table 2.

As an example in Fig. 5 the experimental C_{O_2} values are compared with the calculated curve for the Co(II)-[33]aneN_{11} system. In Fig. 6 the concentration as a function of time of the Co_2[33]ane$N_{11}(O_2)(OH)_2$ intermediate, as calculated by using the kinetic constants determined from dioxygen consumption, is compared with that obtained by spectrophotometric data at 320

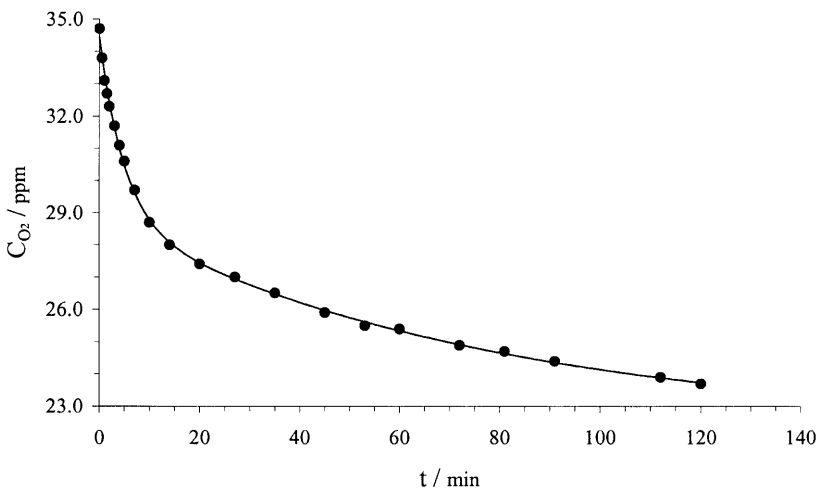

Fig. 5. Evolution of the free dioxygen concentration, C_{O_2}, in solution for the system Co(II)/[33]aneN_{11}/O_2 at $R = 0.5$ and pH >11.5. Continuous line represents the fitting curve; (●) are the experimental values ($C^0_{Co} = 4.06 \times 10^{-4}$ mol dm^{-3}; $C^0_L = 2.03 \times 10^{-4}$ mol dm^{-3}; $C^0_{O_2} = 1.08 \times 10^{-3}$ mol dm^{-3}; pH 11.50).

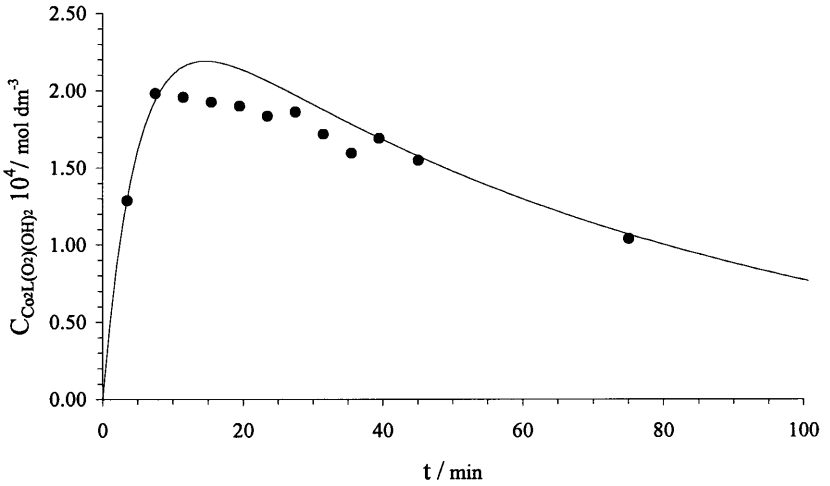

Fig. 6. Evolution with time of the concentration of the species $Co_2[33]aneN_{11}(O_2)(OH)_2$ calculated by the kinetic constants determined from oxygen consumption (continuous line), and by independent spectrophotometric measurements at 320 nm (●).

nm. The agreement between the data obtained with the two methods is good for all the ligands here considered.

The analysis of the k_1 values in Table 2 shows that the presence of the second hydroxo group in the cobalt-ligand precursor complex slows down the rate of formation of a species reactive towards dioxygen.

As shown by the spectral modifications occurring along with the dioxygen uptake process, the final complex species obtained at pH >11.5 after consumption of one equivalent of O_2 per metal ion has undergone a significant transformation with respect to the precursor complex. Nevertheless, the nature of such final di-cobalt(II) complex as well as the actual fate of the oxygen consumed in the last stage of the process remain an intriguing issue. While in the case of the 9-dentate ligands Me_2Ocaten and [27]aneN_9 the formation of a $Co_2L(O_2)_2(OH)_2$ species, in which at most one nitrogen donor atom of the ligand would not be involved in the coordination, could be invoked to rationalize the overall process the formation of a similar complex seems less probable with [30]aneN_{10} and [33]aneN_{11} considering the marked tendency these ligands have in involving all their donor atoms in metal ion coordination.

Further studies are being undertaken to identify the nature of these final complex species.

3.3. Mononuclear complexes

At $R>1.5$ and pH >8, the investigated polyazaalkanes form with the cobalt mononuclear complexes [6] able to bind one dioxygen molecule. The kinetics of formation of these oxygenated complexes has been studied by monitoring the decay of the dioxygen concentration in solution as a function of time. Several measurements were carried out at different values of R, pH (ranging from 8 to 11), and initial dioxygen concentration.

The kinetic behavior is similar to that of the dinuclear complex at the lower pH values. The binding curves show an initial rapid step ($1 \div 2$ min) up to a R_{O_2} ratio ranging from 0.05 to 0.2 and a second slow process (about 2 h) up to $R_{O_2}=1$. R_{O_2} is the bound dioxygen/cobalt concentration ratio. In this latter process C_{O_2} decays according to a first order kinetic law:

$$C_{O_2} = C^0_{O_2} - C^0_{Co}(1 - e^{-k_1 t}) \quad (6)$$

The experimental behavior is consistent with the mechanism (7):

$$\mathrm{Co + LH_j} \rightleftharpoons \mathrm{CoLH_j} \xrightarrow{k_1} \mathrm{(CoLH_j)^*} \xrightarrow[\text{fast}]{+O_2} \mathrm{CoLH_j(O_2)} \quad (7)$$

$CoLH_j^*$ is responsible for the first rapid dioxygen uptake, the slow process, independent of pH, being kinetically controlled by the transformation of $CoLH_j$ to yield the active form $CoLH_j^*$. This mechanism suggests that in the two equilibrium species $CoLH_j$ and $CoLH_j^*$ ($j=0$, 1 depending on the pH value) the metal ions are characterized by different coordination environments containing, presumably, six and five nitrogen atoms of the ligand in $CoLH_j$ and $CoLH_j^*$, respectively.

In Table 3 are reported the values of the kinetic constants, k_1, obtained by means of a non-linear best

Table 3

[33]aneN_{11}	1.0 ± 0.2

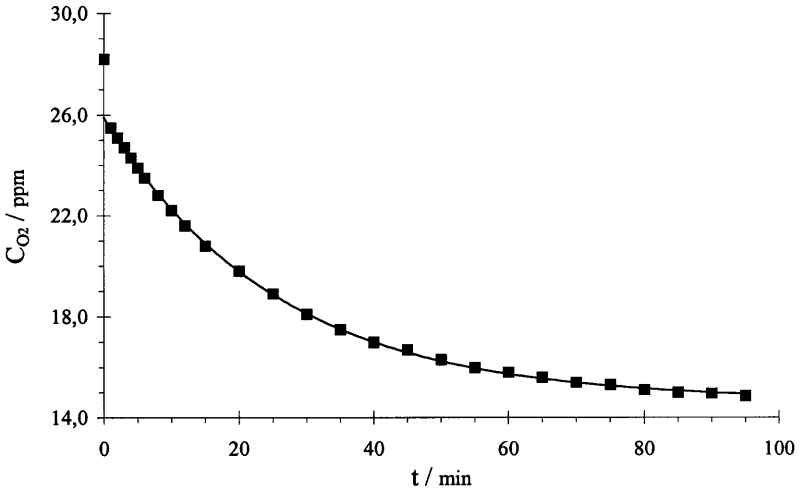

Fig. 7. Evolution of the free dioxygen concentration, C_{O_2}, in solution for the system CoII)/[30]aneN$_{10}$/O$_2$ at $R > 1.5$. Continuous line represents the fitting curve; (■) are the experimental values ($C^0_{Co} = 4.25 \times 10^{-4}$ mol dm^{-3}; $C^0_L = 7.61 \times 10^{-4}$ mol dm^{-3}; $C_{O_2} = 8.81 \times 10^{-4}$ mol dm^{-3}; pH 8.14).

fitting procedure to Eq. (6). Fig. 7 compares the experimental and calculated dioxygen concentration decay for the system Co/[30]aneN$_{10}$/O$_2$. The agreement is very good for all the ligands considered in this work.

The k_1 values given in Table 3 show that the formation of the active species is slower for the Me$_2$Octaen complex than for the more strained macrocyclic complexes.

4. Conclusions

The reaction of dioxygen addition on Co(II) complexes with the polyazaalkanes considered in this work shows some relevant differences if compared with the same reaction on Co(II) complexes with the ligands previously studied [8–15] both for the type of dioxygen adducts formed and for the kinetics of their formation. In fact, Co(II) bound to simple ligands form, in aqueous solution and at room temperature, μ-peroxo complexes in which the dioxygen bridges two cobalt ions of different subunits. The formation of end-on oxygenated complexes in water requires superstructured ligands able to form a protective cavity around the metal atom to prevent the reaction with another Co(II) complex forming a bridged μ-peroxocomplex. Examples of this kind of supramolecular structures are provided by the cobalt-cyclidenes superoxo complexes [27,28] and by oxygenated coboglobins [32–34]. Although polyazaalkanes are ligands with a relatively simple structure, nevertheless they form with cobalt mononuclear or dinuclear Co(II) complexes able to bind dioxygen giving end-on superoxo structures.

The complex behavior of these ligands arises from the manifold complexed structures they give with cobalt in solution: this is well highlighted by the kinetics of formation of their dioxygen adducts. The rate of formation of these adducts is slower than for Co(II) complexes with simple ligands and the determining rate step is in all cases the formation of an equilibrium species active towards dioxygen.

Solubility of oxygen and inert substances in water

A. Braibanti *, E. Fisicaro, C. Compari

Pharmaceutical Department, Applied Physical Chemistry Section, University of Parma, I-43100 Parma, Italy

Abstract

The solubility of oxygen in water at different temperatures has been analysed in the light of a statistical thermodynamic model. According to the model, the oxygen–water system is considered as a convoluted ensemble consisting of a *reacting* system, formed by oxygen molecules and structured solvent with enthalpy difference ΔH^{ϕ} between discrete enthalpy levels, and of a *non-reacting* system with continuous distribution of enthalpy levels. The enthalpy change of the reaction between oxygen and water, as determined either by measuring the solubility of substances in water at different temperatures either by measuring heat calorimetrically, is partially absorbed by some n_w water molecules. The relaxed water molecules occupy part of the cavity formed around solute. The part of heat absorbed, ΔH_w depends linearly upon the temperature and causes the observed changes with temperature of apparent enthalpy ΔH_{app} for the dissolution of oxygen and many other inert substances in water. The number n_w is proportional to the size of solute as shown by comparison with noble gases and other inert substances slightly soluble in water. The solubilization process of all these substances is clearly analogous. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Solubility; Oxygen; Solubilization enthalpy; Solubilization entropy; Cavity

1. Introduction

With the aim of studying the properties of perfluorocarbon emulsions used as injectable oxygen carriers which show enhanced capability of dissolving oxygen in aqueous solution, we have undertaken an analysis of the solubilization process of gaseous oxygen in water. The analysis of the thermodynamic parameters of the dissolution process in water of oxygen and other non-polar substances, either gaseous or liquid, has been connected [1–20] to the study of the so-called 'hydrophobic bond'. We have now examined the dissolution of oxygen and other inert substances in water in the light of a statistical thermodynamic molecular model [21–24]. The model is based on the distinction between *non-reacting* systems, with continuous distribution of enthalpy levels and *reacting* systems, with discrete quantized distribution of enthalpy levels. A *non-reacting* system is represented by a canonical partition function:

$$\zeta_A = \exp(s/R) = \exp(h/RT) \quad (1)$$

where s and h are partial molar entropy and enthalpy, respectively, whereas a *reacting* system is represented by a grand canonical partition function:

$$Z_M = \exp(-\Delta G^{\phi}/RT) \quad (2)$$

where ΔG^{ϕ} is the free energy change of the reaction. An ensemble composed of *reacting* species and *non-reacting* solvent W is represented by a convoluted partition function obtained as the product of partition functions:

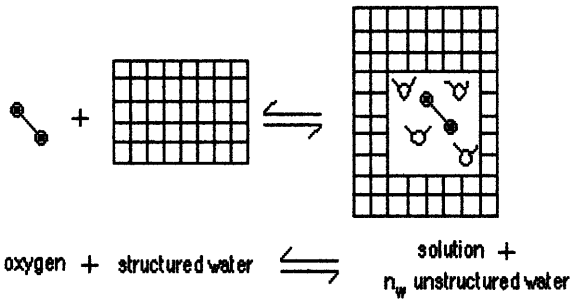

Fig. 2. The solubilization process of oxygen in water is determined by formation of a zone with n_w destructured water molecules in the cavity around solute.

$$\Xi_{MW} = Z_M \zeta_W \tag{3}$$

The model is suited to explain the changes of thermodynamic functions with the temperature in aqueous systems.

The affinity function in thermodynamic space [21–24]

$$(-\Delta G^{\phi}/RT) = \ln Z_M \tag{4}$$

in particular for oxygen or any inert gas solubility, takes the form

$$(-\Delta G^{\phi}_{app}/RT) = 2.302 \lg x_2 \tag{5}$$

where the solubility is identified, as usually with the molar fraction x_2 at unit pressure, with index 2 indicating the solute. At unit pressure, the molar fraction, x_2 is the reciprocal of the Henry constant, K_H. When the affinity function $\lg x_2$ for oxygen measured at different temperatures [25] is plotted against the reciprocal temperature $(1/T)$, it appears as a curve with a minimum at temperature $T = 400$ K (Fig. 1).

Analogous behaviour is shown by many other inert substances dissolved in water at different temperatures [26–28]. The analogy suggests that the molecular mechanisms underlying the dissolution processes of inert substances in water are similar to one another. The proposed mechanism consists in the formation of a cavity around the solute which is partially occupied, together with the solute, by some destructured water molecules (Fig. 2).

The solubility of a gas such as oxygen in water can be treated as a heterogeneous equilibrium between oxygen O_2 and x water molecules W followed by a homogeneous equilibrium:

$$O_2 + xW = (O_2W_x) = (O_2W_{(x-n_w)}) + n_wW \tag{6}$$

where xW is the portion of the bulk solvent involved in the solubilization process, and $O_2W_{(x-n_w)}$ is the oxygen molecule trapped in a cavity. The n_w water molecules are no more structured as in the bulk solvent. The constant of this equilibrium is:

$$K_s = [O_2W_{(x-n_w)}][W]^{n_w}/[O_2] \tag{7}$$

At constant gas pressure, the concentration $[O_2W_{(x-n_w)}]$ measures the solubility. With these assumption, Eq. (7) can be rewritten as a function of solubility product:

$$P_s = [W]^{n_w}/K_H = x_2[W]^{n_w} \tag{8}$$

where P_s includes the conversion factor deriving from the inhomogeneity of the concentration scales of gas and water and $K_H = 1/x_2$ is the Henry constant. By taking the logarithm of Eq. (8), we move from probability space to thermodynamic space [23]:

$$\ln x_2 = \ln P_s - n_w \ln[W] \tag{9}$$

The solubility can be expressed in thermodynamic space ($\ln x_2 = -\Delta G^{\phi}_{app}/RT$) as the function of the reciprocal temperature by a polynomial.

By calculating the first derivative of the polynomial with respect to the reciprocal temperature, we get at any temperature T:

$$\{\partial \ln x_2/\partial (1/T)\}_T = \{\partial \ln P_s/\partial(1/T)\}_T - n_w\{\partial \ln[W]/\partial(1/T)\}_T \tag{10}$$

which can be identified for a combinations of enthalpies

$$-\{\Delta H_{app}\}_T = -\{\Delta H^{\phi}\}_T + \{\Delta H_w\}_T \tag{11}$$

The left hand member, $\{\Delta H_{app}\}_T$ can be obtained from Eq. (10) from the first derivative at $T \to \infty$ of $\ln x_2 = f(1/T)$. The enthalpy $\{\Delta H^{\phi}\}_T$ can be assumed that at a first approximation it is constant, $\{\Delta H^{\phi}\}_T = \Delta H^{\phi}$. On the other hand, the enthalpy $\{\Delta H_w\}_T$ of the second term of r.h.s. of Eq. (12) can be obtained from the dependence of ln[W] upon T which can be expressed [27] as:

$$-n_w \partial \ln[W]/\partial \ln T = n_w C_{p,w}/R \tag{12}$$

where $C_{p,w}$ is the molar heat capacity of water. Eq. (12) is the mathematical expression of the concept of *thermal equivalent dilution* [29].

By transformation into the derivative with respect to $1/T$, Eq. (12) yields:

$$n_w T \partial \ln[W]/\partial(1/T) = \{-\Delta H_w/R\}_T = n_w C_{p,w} T/R \tag{13}$$

By combining Eq. (12) with Eq. (13) we get:

$$\Delta H_{app} = \Delta H_0 + n_w C_{p,w} T \tag{14}$$

where n_w is the number of water molecules involved in the reaction and $C_{p,w}$ is the molar isobaric heat capacity of water ($C_{p,w} = 75.38$ J mol^{-1} K^{-1}).

We recall that the slope of the affinity function of Fig. 1 at each point is given by the van't Hoff equation:

$$\partial(-\Delta G^{\phi}_{app}/RT)/\partial(1/T) = -\Delta H_{app}/R \tag{15}$$

Therefore, the slope of the curve at each point depends on the enthalpy of the dissolution process in water for any inert substance. The slope of the solubility curve, however, is changing with the temperature and reaches

zero at the minimum of the solubility curve. In particular, for the dissolution of oxygen or any other similar substance such as noble gases, nitrogen, hydrogen, etc., the solubility data are interpolated by a polynomial:

$$\lg x_2 = a + by + cy^2 + \cdots \quad (16)$$

with $y = 1/T$. For oxygen, the data reported in Fig. 1 give $a = -2.001$, $b = 2.209$, and $c = 0.424$ whereby values of ΔH_{app} at each temperature can be calculated from the derivative of Eq. (16) at $T \to \infty$. When the calculated values ΔH_{app} are plotted against T, the enthalpy values come out to be a linear function of T according to the Eq. (14), which is the result of an extrapolation of the solubility curve to $T \to 0$. Even if the enthalpy is measured calorimetrically at different temperatures [27], the values conform to Eq. (14).

Eq. (14) shows how the apparent enthalpy, ΔH_{app} is a linear function of the variable temperature, T with slope $\Delta C_{p,app} = n_w C_{p,w}$. This means that the contribution to heat by solvent molecules participating in the solubilization process should depend linearly upon the absolute temperature and hence should produce a change of the tangent, $\{-\Delta H_{app}/R\}_T$ of the solubility curve, what is actually observed (cf. Fig. 1). The linear dependence of ΔH_{app} upon T is shown in general by the substance examined either if the enthalpy is calculated from the tangent of the solubility curve or if it is experimentally determined by calorimetry. The slope of the line, which is different for each solute and increases with the complexity of the solute molecule gives the number of water molecules, n_w involved in the reaction.

The model has been successfully applied to other problems, to treat changes with the temperature of the solubility in water of inert gases and liquids, of denaturation enthalpy, and of micelle formation enthalpy. In all these processes, the enthalpy can be expressed as a linear function of the temperature.

The specific contribution of the number n_w of solvent molecules depends on the size of solute molecule. This can be shown by the series of gases of Table 1. Values of n_w, when plotted against parameters which are proportional to the size of solute such as the polarizability volume (Fig. 3), appear to be continuous functions of these parameters. When treating denaturation enthalpy of macromolecules, values of n_w grow up to values of a 100 or more.

By interpreting these series of processes in terms of a homogeneous molecular mechanism, a possible formation of a cavity to lodge the solute, can be put forward. The number n_w is then related to destructuring ($n_w > 0$) of water molecules around the solute as shown in Fig. 2. Roughly speaking n_w depends on the surface of the

solute although it is less than the number of water molecules needed to occupy the whole surface. These water molecules, according to the model of Hinz [12] and that of Costa and Silveston [10,11], should be relaxed water molecules occupying a cavity around the solute. The extrapolated enthalpy corresponds to the reaction between oxygen (or gas) and structured water before some heat is absorbed by relaxed water molecules. Actually, values of $\Delta H°$ are well correlated with n_w (Fig. 4). The correlation equation:

$$\Delta H° = 13.239 - 31.239 n_w \quad (17)$$

allows the calculation of enthalpy change per water molecule which is $\Delta h_w = -31.2$ kJ mol^{-1} per water. The order of magnitude of enthalpy change is about that for hydrogen bonds.

The entropy of the solubilization process can be calculated from the minimum of solubility. The free energy change at the minimum ΔG^{ϕ}_{min} is equal to $-T\Delta S^{\phi}_{min}$ and this property can also be employed to obtain thermodynamic functions of the solubilization process of oxygen and other substances in water (Table 2). The point of minimum solubility T_{min} is the point at which the solubilization process is adiabatic ($\Delta H^{\phi}/R = 0$). Below this temperature, the solubility of nonpolar substances has the unusual property of increasing in magnitude as the temperature is lowered. This fact is paralleled by the hydrophobic interaction effect which is decreasing in magnitude as the temperature is lowered. The parallelism is a further good argument for searching connections between the two processes. At T_{min} the affinity function $-\Delta G^{\phi}/T_m$ is equal to the entropy change:

$$-\Delta G^{\phi}/T_{min} = \Delta S^{\phi} \quad (18)$$

The values of entropy change for different compounds can be plotted against $(1/T_{min})$. A nice correlation (Fig. 5) is obtained:

$$\Delta S^{\phi} = -69.96 + 19\ 107\ (1/T_{min}) \quad (19)$$

indicating that the entropy change is composed of two parts, $\Delta S^{\phi}_a = -70.0$ J K^{-1} mol^{-1} independent of temperature and $\Delta S^{\phi}_b = 19\ 107\ (1/T_{min})$ J K^{-1} mol^{-1}. The latter portion is dependent upon the temperature and can be considered as an enthalpy change divided by temperature:

$$\Delta S^{\phi}_b = \Delta H^{\phi}_b\ (1/T_{min}) \quad (20)$$

with $\Delta H^{\phi}_b = 19.11$ kJ mol^{-1} indicating an endothermic process of cavity formation.

2. Conclusions

The logarithm of solubility $\lg x_2$ of oxygen in water at different temperatures is a measure of the affinity between gas and water. The enthalpy change of the solubilization process is a linear function of temperature. The dependence of enthalpy from the temperature is a consequence of the involvement of some water molecules. This behaviour is common to any inert gas and indicates that the molecular mechanism underlying the solubilization process is general. The experimental enthalpy data either obtained from solubility equilibria

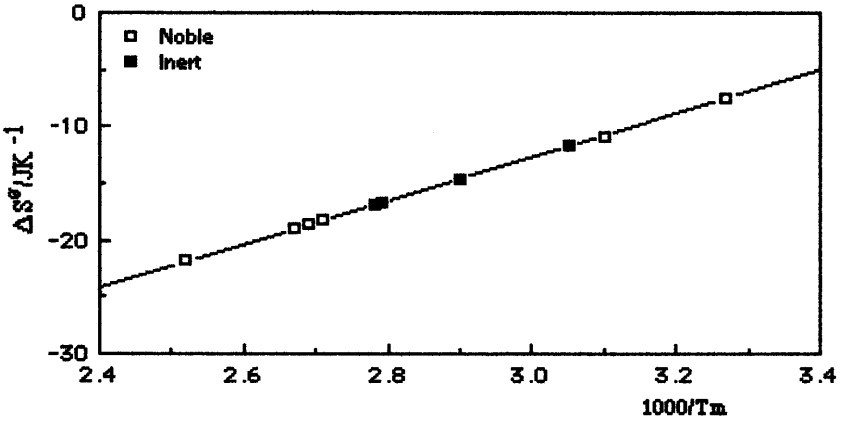

Fig. 5. Entropy change for solubilization of oxygen and inert gases in water as a function of $(1/T_{min})$.

or from calorimetric experiments are consistent with the formation of a cavity in structured water to allocate the solute. Some water molecules, the number dependent on the size of solute, become relaxed and absorb part of the enthalpy released by the reaction between water and gas. The reaction between gas and water is exothermic with enthalpy change $\Delta h_w = -31.2$ kJ mol^{-1}per water molecule. This energy is a little greater than free energy for hydrogen bonds $\Delta G_{HB} \approx -28$ kJ mol^{-1} and it is explained by considering that solubilization in water takes place by overcoming water–water hydrogen bonds. On the other hand, the solubilization process is entropically disfavoured by the entropy change $\Delta S_a^{\phi} = -70.0$ J K^{-1} mol^{-1} for transfer of a gas molecule into the cavity and entropically favoured by the endothermic reaction ($\Delta H_b^{\phi} = 19.11$ kJ mol^{-1}) for cavity formation. In conclusion, the analysis of the solubilization process of oxygen in water in comparison with the solubilization process of other inert gases has led to values of enthalpy and entropy changes of the process which are in reasonable balance with the free energy change of hydrogen bond formation.

Abstract

N-(Carbamoylmethyl)iminodiacetic [$H_2ADA = H_2NCOCH_2N(CH_2CO_2H)_2$)] has been crystallised from water and characterised by X-ray crystallography (final value $R_1 = 0.051$). This compound exhibits a zwitterionic structure ($H_2ADA^{\pm}$) whose conformation is stabilised by an intra-molecular hydrogen bond interaction between the 'ammonium' hydrogen atom and the *O*-amide atom as acceptor one. All the other polar bonds give hydrogen bonds, which link adjacent zwitterions, one of them is a rather symmetrical and linear link (170(2)°). The appropriate stoichiometric reaction of nickel(II) hydroxycarbonate, $NiCO_3{\cdot}2Ni(OH)_2{\cdot}4H_2O$, and H_2ADA in water yields crystalline, green samples of *cis*-diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II), [Ni(ADA)$(H_2O)_2$] (**I**). Its single crystal X-ray diffraction study was also carried out (final $R_1 = 0.031$). The crystal of complex **I** consists of slightly asymmetrical, octahedral coordination units linked in a three-dimensional network stabilised by hydrogen bonds where the water molecules play the most relevant role. Coordination bond distances in **I** (Å): Ni(1)–N(1) = 2.072(2), Ni(1)–O(11) = 2.051(2), Ni(1)–O(21) = 2.045(2) and Ni(1)–O(31, amide) = 2.065(2) with ADA, and Ni(1)–O(1) = 2.000(2) and Ni(1)–O(2) = 2.106(2) with aqua ligands. ADA acts as tetradentate chelating ligand, which is in contrast with chelating and bridging functions for such ligand in the polymeric Cu(II) derivative, where the metal exhibits a square base pyramidal coordination (type 4 + 1). © 2000 Elsevier Science B.V. All rights reserved.

Keywords: *N*-(Carbamoylmethyl)iminodiacetic acid; *N*-(2-Amidomethyl)-iminodiacetic acid; *N*-(2-Acetamide)-iminodiacetic acid; *cis*-Diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II); Molecular and crystal structure; Magnetic and spectral properties; Thermal stability

N-Carbamoylmethyl-iminodiacetic acid or *N*-(2-amidomethyl)iminodiacetic acid (also named *N*-(2-acetamide)iminodiacetic acid) [$H_2ADA = H_2NCOCH_2N(CH_2CO_2H)_2$)] is widely used in biological buffers of pH 6.0–7.4. Since many years, metal ion-ADA chelation in solution has been studied for a variety of divalent ions (M = Mg, Ca, Sr, Ba, Mn, Co, Ni, Cu, Zn, Cd, Hg, Pb) [1]. These initial results of Schwarzenbach et al. have been partially supported by more recent studies [2–5] about the stoichiometry and stability of ADA complexes in solution. These works also showed cases where the de-protonation reaction of the primary amide takes place for $M(ADA)_2$ chelates (M = Co or Zn) [2]. Cu(II) de-chelation has also been claimed upon ADA amide de-protonation [6,7]. In contrast, studies concerning ADA complexes in solid state are scarce ones. In fact, crystal structure determinations were limited to only two different *oxo*-ADA–vanadium compounds [8–10] both having ADA as a tripodal-tetradentate ligand. It is worth noting that the structure of the free acid H_2ADA has not been reported, in spite of being a commercially available and widely used

chelating agent. In addition, studies on ADA–metal chelates in solid state seem a suggestive matter as a source of structural information of the chelating role of the ADA bivalent anion [$H_2NCOCH_2N(CH_2CO_2^-)_2$] as well as of the way in which its 'primary amide' group could be involved in the chelation of different metal ions. In this sense and as a part of our program on mixed-ligand Cu(II) complexes [11] we have synthesised and reported very recently for the first time the structure of compounds poly-[(*N*-carbamoylmethyl-iminodiacetato)copper(II) monohydrate], $\{[Cu(ADA)]\cdot H_2O\}_n$ [13], (imidazole)(*N*-carbamoylmethyl-iminodiacetato)-copper(II), [Cu(ADA)(ImH)] [12] and (2,2′-bipyridine)-(*N*-carbamoylmethyl-iminodiacetato)copper(II) three-hydrate, $[Cu(ADA)(bipy)]\cdot 3H_2O$ [13]. Such XRD studies [12,13] are our precedent reports in this series and they revealed again that ADA acts as tripodal-tetradentate but with remarkable differences in its ligand roles as well as in the coordination polyhedron of Cu(II) atom. The aim of this work is to report the structure of H_2ADA itself and to extend our contribution on ADA chelates to other metal ions with the synthesis and study of the structure and properties of its nickel(II) derivative.

1. Experimental

1.1. *N*-carbamoylmethyl-iminodiacetic acid (H_2ADA)

This compound was purchased from Aldrich. Crystals suitable for X-ray structure determination were obtained by re-crystallisation of the commercial available product in water. To this purpose, 500 mg of H_2ADA were dissolved in approximately 80 ml of doubly-distilled water, with stirring and heating (approximately 60°C) for 2 h. The resulting solution was left to cool and then filtered over a crystallisation dish. Evaporation at room temperature (r.t.) produces abundant and well-shaped crystals of this free acid, which were collected by filtration and air-dried.

1.2. Synthesis of cis-diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II), $[Ni(ADA)(H_2O)_2]$, complex **I**

It was obtained by stoichiometric reaction of $NiCO_3\cdot 2Ni(OH)_2\cdot 4H_2O$ (250.9 mg, 0.66 mmol, Merck) and H_2ADA (380.3 mg, 2 mmol) in doubly-distilled water (100 ml) in a Kitasato flask, heating ($t < 50$°C) and stirring under reduced pressure (to remove the CO_2, by-product) for 1 h. Then the reacting mixture was heated and stirred 20 h at 60°C. The resulting clear and green solution was left to cool and then slowly filtered to remove an almost inappreciable amount of non-reacted NiO (insoluble by-product). After 3 weeks of slow evaporation at r.t. (remaining volume of 10–15 ml) the solution was filtered over a little crystallisation dish which was partially covered with a watch glass. That reduces the evaporation rate. After several days, well-shaped green crystals of complex **I** appeared, many of them were suitable for X-ray diffraction studies. For a few days, additional amounts of product were collected by the same way. If super-saturation of mother liquor arises, the addition of little volumes of water and ethanol and further slow evaporation of the solution induce again the crystallisation process. The product was collected by filtration, washed with a little of cool water and air-dried. It can be re-crystallised several times from water. Yield: variable but usually $< 55\%$. Calc. for complex **I** ($C_6H_{12}N_2NiO_7$): C, 25.48; H, 4.28; N, 9.90; Ni, 20.75. Found: C, 25.19; H, 4.36; N, 9.72; Ni, 20.7% (complexometry [14]).

1.3. X-ray data collection and reduction, structure solution and refinement

A colourless prismatic crystal of H_2ADA or a green plate crystal of $[Ni(ADA)(H_2O)_2]$ was mounted on a glass fibre and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $8.834 < \theta < 18.278$ or of $9.551 < \theta < 20.927$, respectively, in an Enraf Nonius MACH3 automatic diffractometer [15]. Data were collected at 293 K using Mo Kα radiation ($\lambda = 0.71073$ Å) and the ω-scan technique, and corrected for Lorentz and polarisation effects [16]. A semi-empirical absorption correction (ψ-scan) was made [17]. The structure was solved [18] by direct methods or by Paterson and Fourier methods, respectively, which revealed the position of all non-hydrogen atoms, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [19]. All hydrogen atoms were located from difference Fourier maps and were refined isotropically. Atomic scattering factors were from the 'International Tables for X-ray Crystallography' [20]. Molecular graphics were prepared with the programs PLATON-97 or PLATON-98 [21] or ZORTEP [22]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

1.4. Physical measurements

Nickel(II) titration was carried out by standard EDTA complexometry [14]. For this purpose, a sample (534.9 mg) of compound **I** was placed in a precipitation device (250 ml) and mineralised with 2 N sulphuric acid (10 ml) and 10 N hydrogen peroxide (5 ml) solutions. The mineralisation process of the complex would be carried out covering the reaction device of the resulting

green solution with a watch glass and then smoothly heating it a few minutes. Such reaction and the decomposition of H_2O_2 (in excess) lead to an acid solution of nickel(II) sulfate which was quantitatively diluted with doubly-distilled water into a volumetric flask (250 ml). Aliquots (25 ml) of this solution were diluted with approximately 100 ml of doubly-distilled water in the corresponding Erlenmeyer flasks. Each aliquot was added of buffer solution pH 10 (ammonia/ammonium chloride, 10 ml) and murexide (Merck, mixed at a 1:2000 ratio with potassium nitrate) as metal-indicator. Such mixtures were heated to approximately 60°C prior to initiate each titration with 10^{-2} M Na_2H_2EDTA (Merck) solution (standardised with a reference $ZnCl_2$ solution and eriochrome black T (Merck) as indicator [14]). Elemental analysis (C, H and N) were performed in the Scientific Instrumental Centre of the University of Granada as described earlier [11]. FTIR spectra were obtained by the KBr disc technique (with KBr Aldrich FTIR grade) on a Nicolet FTIR 20SXB or a Jasco FTIR 410 instrument. Thermogravimetric studies of both compounds (22–550°C) in air flow (100 ml min^{-1}) and the corresponding spectra of evolved gases were recorded using a Shimazu Thermobalance TGA-DTG-50H coupled with a FTIR Nicolet Magma 550 (and a mass spectrometer Fisons Thermolab). The electronic (reflectance) spectrum of **I** (175–3300 nm) was obtained in a Cary 5E spectrophotometer. The magnetic susceptibility of **I** was measured in the temperature range 80–300 K using a Manics DM magnetometer. The susceptometer was calibrated with mercury tetrakis(thiocyanato)cobaltate(II). Corrections for the diamagnetism (122×10^{-6} cm^3 mol^{-1}) were estimated from Pascal constants [23].

2. Results and discussion

2.1. Structure and properties of *N*-(carbamoylmethyl)iminodiacetic acid (H_2ADA)

Bond lengths and angles between non-hydrogen atoms and hydrogen bond distances and angles of this compound are given in Table 2. The crystal consists of a hydrogen bonded network of molecules where all polar N–H and O–H bonds are involved as 'H-donor' in this interactions. The acid dissociation constants of H_2ADA=H_2L have pK_a values ($I = 0.1$ (KNO_3) and 25°C) of $pK_0 = 1.59 < pK_1 = 2.31 \ll pK_2 = 8.98$ for the dissociation of the species H_3L^+ (cationic), H_2L (neutral), and HL^- (anionic), respectively [2]. Consequently it should be assumed that its protonated species and, in particular, its neutral molecule will exist as a zwitterion in solution (such as $H_2ADA^{\pm}$ for the molecular species). Our structural results indicate that the molecule also exists as a dipolar ion in solid state, and it represents the asymmetric unit of the crystal.

Two structural features of this amino-polycarboxylic acid seem of major interest. Firstly, its conformation seems intra-stabilised by only one hydrogen bond which is made up by the ammoniun proton with the O(31) amide atom as 'acceptor'. In spite of that, the C(32)–O(31) bond distance (1.231(3) Å) is not lengthened compared to the averaged distance of the C=O(amide) bond in primary amides (1.24(1) Å) [24]. The distance (2.590(3) Å) and angle (113(2)°, close to the tetrahedral angle) of this intra-molecular hydrogen bond agree reasonably well with those reported for a variety of amino-polycarboxylic acids such as iminodiacetic acid and many others [25]. It is worth noting that the *O*-amide atom should be preferred to a negatively

charged *O*-carboxylate atom. This is not the case for other *N*-substituted-iminodiacetic acids having a suitable 'acceptor' atom in the *N*-side chain. In such compounds the ammonium hydrogen atom forms a hydrogen bond with the 'acceptor' atom of the *N*-side chain as well as with one ('bifurcated' cases [25–27]) or with two ('trifurcated cases' [25,28]) *O*-carboxylate atoms of the acetate arms. Secondly, carboxylic and carboxylate groups from pairs of adjacent dipolar ions $H_2ADA^{\pm}$ (related by the symmetry code # 1 = i: $-x+1/2$, $y+1/2$, $-z+3/2$) are linked by a rather short, symmetrical and nearly linear hydrogen bond O(12)–H(12)···O(22^{i}) with an overall distance of 2.477(2) Å and angle of 170(2)° (see Fig. 1 and Table 2). This unique hydrogen bond is consistent with the rather similar ratio of carbon–oxygen bond distances (Å) in the two linked 'carboxyl' groups, C(12)–O(12)/C(12)–O(11) (1.272(3)/1.222(3)) = 1.041 and C(22)–O(22)/C(22)–O(21) (1.297(3)/1.212(3)) = 1.070. Indeed it is on the basis of the small difference in such ratios that the acid hydrogen atom could be formally assigned to the O(12) atom. In other words, the consideration of a carboxylic –C(12)O(11)O(12)H(12) group and a carboxylate –C(22)O(21)O(22)$^{-}$ one to the zwitterion H_2ADA in the crystal (as depicted in Fig. 1) is in some ways a practical approach or a simplification.

With necessary caution, we can attempt to correlate our crystal structure results with the high pK_a value of the studied amino-amide acid derivative. With this aim, it is instructive to consider that H_2ADA acid is the result of replacing the secondary amino hydrogen atom from the iminodiacetic acid (H_2IDA=HN(CH_2CO_2H)$_2$) by the *N*-(2-amidomethyl) or *N*-(carbamoylmethyl) arm. It is generally assumed that this latter neutral group (–CH_2CONH_2) displays a moderate electron withdrawing effect ($-I$) [24] but in fact it should be operative in the hydrogen bonding intra-stabilisation, as our structural results have stated. These two effects will act in an opposite sense and the final state should depend on the balance within them. Several sets of acidity (pK_a) or protonation constants are available for H_2IDA acid or IDA(2$-$) ion, respectively, for a ionic strength of $I = 0.1$ M (KNO_3) and 25°C [29]. For example, a complete set of pK_a dissociation constant values, p$K_0 = 1.80$, p$K_1 = 2.58$ and p$K_2 = 9.27$, for the three dissociation steps of the cationic species (H_3IDA^{+}) of iminodiacetic acid is available [30]. Consequently, it can be seen that the three pK_a values of H_2ADA are approximately 0.2–0.3 pK_a units lower than the corresponding values of H_2IDA.

Concerning the vibrational properties, the relative simplicity of groups in H_2ADA molecule allow us the following tentative assignations of bands (wave-numbers in cm^{-1}) in its IR spectrum [31]: ν(OH) of carboxylic group at 3400–3384, $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ of primary amide group at 3320 and 3250, ν_{as} and ν_s of CH_2 at 3014 and 2990, and 3295, ν(C=O) of carboxylic group at approximately 1730 (shoulder), $\nu_{as}(COO^{-})$ overlapped with ν(C=O) of primary amide group (also called 'amide I' band) at 1700, and $\delta(NH_2)$ of this latter group (so-called 'amide II' band) at 1681, $\delta(CH_2)$ at 1442, and $\nu_s(COO^{-})$ at 1366. In this connection it is interesting to keep in mind that certain assignations concerning the amide primary group are only the best approximations. These are the cases of 'amide I and II' bands. The former is not due to a pure C=O stretching mode but is appreciably coupled with a C–N stretch and to some extent with the –NH_2 band [31a]. There is more controversy over the amide II band, but it is generally accepted that it is mainly due to the scissoring mode of the –NH_2 amide group. A band at 3050 cm^{-1} is assigned to a combination mode $\delta(NH_2$, amide) + $\nu_s(COO^{-}$, carboxylate group) (1681 + 1366 = 3047). Concerning the zwitterionic form of this compound, an interesting finding is a series of weak bands observed in the region of 2880–2000 cm^{-1} (in our case at 2860, 2825 and 2730 cm^{-1}, among others). They are frequently observed in the IR spectrum of amino-polycar-

boxylic acids hydrochlorides. The band at 2730 can be related with the stretching mode of the ammonium group $-N^{+}-H$ [31b,32]. In this connection, it should be noted that the asymmetric stretching mode of the carboxylate group (expected in the range 1600–1560 cm^{-1}) is moved to higher frequencies and overlapped in a broad band near 1700 cm^{-1}. Both effects are consistent with the unique symmetrical and nearly linear hydrogen bond linking the carboxylic and carboxylate group. The TG analysis with FTIR spectra of evolved gases of an anhydrous sample (7.053 mg) in air flow shows two overall pyrolytic steps (207–335 and 335–500°C) with production of H_2O, CO_2, CO, NH_3, NO and NO_2. The decomposition starts with the production of H_2O, CO_2 and traces of CO suggesting that it corresponds to the decarboxylation of two hydrogen bonded *N*-carboxymethyl arms (207–215°C).

2.2. Structure and properties of *cis*-diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II)

Selected bond lengths and angles between non-hydrogen atoms and hydrogen bond distances and angles of this compound are given in Table 3. Complex **I** consist of molecular units $[Ni(ADA)(H_2O)_2]$ (see Fig. 2). Each molecule represents the asymmetric unit of the crystal, and eight molecules compose the unit cell. The crystal is built up by means of a three-dimensional hydrogen bonding network involving all polar bonds, from the $-NH_2$ amide group of the ADA ligand and O–H bonds of aqua ones (Table 3). The atoms N(1), O(11), O(21) and O(31, amide) of the tetradentate ADA^{2-} ion and the atoms O(1) and O(2) of coordinated water molecules define an octahedral surrounding to the nickel(II) atom. That is recognised as the most common geometry for nickel(II) coordination compounds [33] as it is observed in a host of nickel(II) complexes with an extremely wide range of mono- and polydentate ligands. The four donor atoms of the tripodal ligand ADA are similar in length (average 2.058(2) Å) whereas the two *cis*-Ni–O(water) bonds (2.000(2) and 2.102(2) Å) are the shortest and the longest ones. Additionally the *trans*-angles involving such Ni–O(water) bonds (175.6 and 179.3(1)°) are close to 180°, but the *trans*-angle O–Ni–O with donors of chelating ADA is significantly the closest (163.8(1)°). As a consequence, both ADA and aqua ligands are responsible in some way for the moderate but irregular distortion of the Ni(II) coordination polyhedron. Otherwise the internal geometry of the Ni(II) coordination and ADA ligand have usual values compared to related compounds. This includes the ADA ligand in known metal–ADA complexes [8–10,12,13], several Ni–IDA chelates [34] and a variety of compounds involving Ni(II)–O(amide) bonds [35]. These latter compounds include diaqua-tetrakis(acetamide)nickel(II) [35a], bis-(iminodiacetamide)nickel(II) diperchlorate [35d] and bis-(imidazole) (nitrilopropionamidediacetato) nickel(II) monohydrate [35g].

The tripodal chelating role of ADA represents the formation of two nearly coplanar Ni–glycinate-like rings and a third Ni–glycinamide-like one, all three sharing the Ni–N(1, amino) bond. The mean planes of both Ni–glycinate-like rings (P(2) and P(3) involving

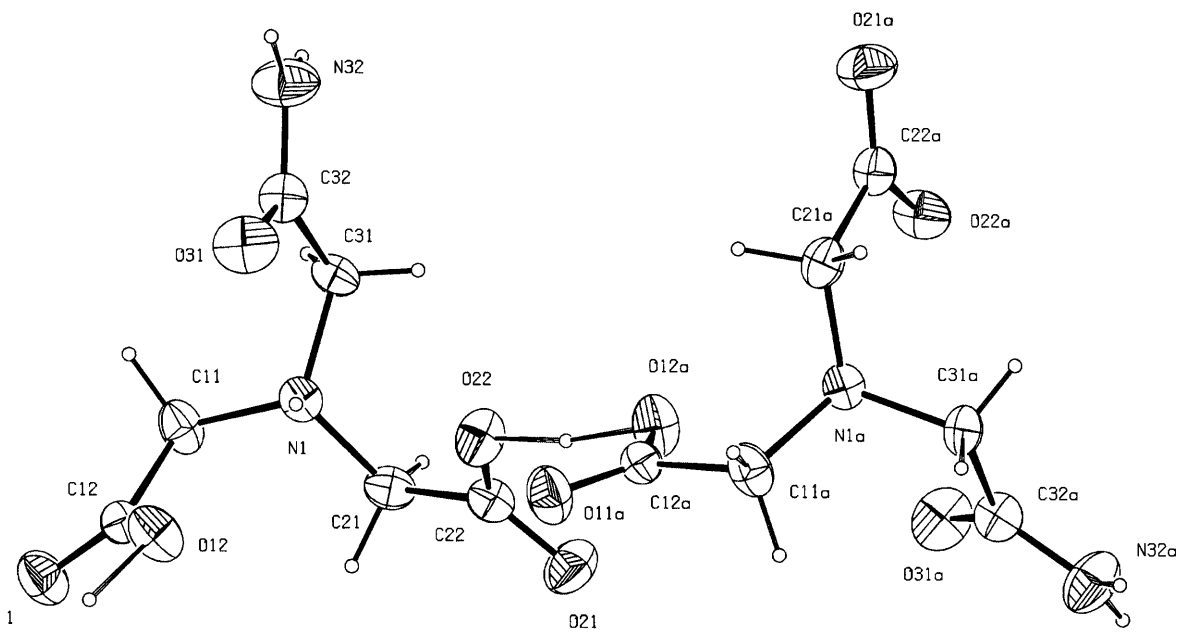

Fig. 1. Structure of the acid *N*-(carbamoylmethyl)iminodiacetic acid (H_2ADA) showing the symmetrical and nearly linear inter-molecular hydrogen bond between two adjacent zwitterions. Symmetry code $a = \#1 = i$: $-x+1/2,\ y+1/2,\ -z+5/2$.

[a] Symmetry transformations used to generate equivalent atoms: i: # 1 = $x-1/2$, $y+1/2$, z; ii: # 2 = $-x$, $-y$, $-z$; iii: # 3 = $x+1/2$, $y+1/2$, z; iv: # 4 = $-x+1/2$, $y-1/2$, $-z+1/2$; v: # 5 = $-x$, y, $-z+1/2$; vi: # 6 = $1-x$, $1-y$, $1-z$; vii: # 4 = $1/2-x$, $1/2+y-$, $1/2-z$.

O(11) and O(21) atoms, respectively) define a dihedral angle of 81.1°. The mean plane P(4) of Ni–glycinamide-like ring defines dihedral angles of 80.5° and 18.5° with P(2) and P(3) planes, respectively. The most distorted chelate ring is that involving the O(11) atom, with maximum deviations of −0.034 and 0.029 Å for O(11) and C(11) atoms, respectively, from the mean plane P(2) of the five atoms forming such a ring. These three chelate rings exhibit slightly distorted asymmetric-envelope conformation, rather common for α-amino-acidato and α-aminopolycarboxylato ligands in its metal ion chelates (with both carbon atoms lying on the same side of the plane defined by its corresponding atoms Ni, N and O of each ring) [36]. In this respect, the greatest unequal deviations correspond to C(21) (0.44 Å) and C(22) (0.69 Å) from the plane of Ni(1)N(1)(21) atoms.

The IR spectrum of complex **I** permits the identification of bands from main characteristic absorption modes expected for aqua and ADA ligands. The following tentative assignations can be made (wave-numbers in cm^{-1}) in its IR spectrum: ν(OH) of the aqua ligand at 3436 and 3364, $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ of the primary amide group at approximately 3300 (as a shoulder of the second ν(OH) band) and 3160, $\nu_{as}(CH_2)$ at 2992 and 2973, $\nu_s(CH_2)$ at 2931 and 3910, ν(C=O) of the primary amide group (also called 'amide I' band) at 1667, $\delta(H_2O)$ at 1627, $\delta(NH_2)$ of this latter group (also called 'amide II' band) overlapped with $\nu_{as}(COO^-)$ at 1603 and 1587, $\delta(CH_2)$ at 1471 and 1433, and $\nu_s(COO^-)$ at 1391. The difference $\Delta(COO) = \nu_{as}(COO) - \nu_s(COO) = 196\ cm^{-1}$ is in accordance with the expected mainly ionic nature of the Ni(II)–O(carboxylato) bonds. Obviously, in this spectrum the ν_{as}(C=O) of carboxylic group (as a shoulder at approximately 1730 cm^{-1} in the ligand spectrum) is now missing. The two bands of the primary amide group have lower frequencies in the complex spectrum than in that of the H_2ADA. Such displacements should be regarded with care because, as mentioned above, the bands 'amide I and II' are not pure C=O stretching and scissoring $-NH_2$ amides, respectively [28a]. The TG analysis (with FTIR spectra of evolved gases) of an anhydrous sample of complex **I** (7.221 mg) in air flow shows two rather separate steps (165–275 and 275–400°C). The first step corresponds to the water loss (exp. 13.329%, calc. for $2H_2O$ 12.737%). The second one is that of the ADA pyrolysis with production of H_2O, CO_2, CO (traces), N_2O and NH_3, and NO_2. The ADA decomposition starts slowly with production of H_2O, CO_2 and traces of N_2O suggesting that it corresponds to the *N*-carbamoylmethyl arm of the ligand. But such process shows a very sharp weight loss near to 378°C with overlapped production of the referred gasses. The dehydration and ADA pyrolysis leaves a residue of crude NiO (exp. 27.023%, calc. for pure NiO 26.410%). The electronic spectrum shows bands $\nu_1 = 9560$ (shoulder at approximately 14250), $\nu_2 = 16077$ and $\nu_3 = 25445\ cm^{-1}$

due to the electronic transitions $^3A_{2g}(F) \rightarrow {}^3T_{2g}$ (with a shoulder for $^3A_{2g}(F) \rightarrow {}^1E_g$), $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$. This spectrum is typical of an octahedral Ni(II) surrounding [33]. Since it can be assumed that $\nu_1 = 10\ Dq = \Delta_o$, a value of 856 cm^{-1} is obtained for the Racah parameter B', that is 83% of the B parameter in the free ion. These data are in accordance with the predominant ionic nature of the Ni(II) atom in the complex **I**. The values of Δ_o and B' in this compound are higher than those of hexaaquanickel(II) (8500 and 945 cm^{-1}, respectively) as expected for the substitution of four aqua ligands with the ADA one. Indeed the Δ_o values yield the following series of complexes: $[Ni(H_2O)_6]^{2+} < [Ni(ADA)(H_2O)_2] < [Ni(NH_3)_6]^{2+}$ ($\Delta_o = 10750\ cm^{-1}$) $< [Ni(en)_3]^{2+}$ ($\Delta_o = 11200\ cm^{-1}$) [33]. These spectral data support the placement of ADA ligand between aqua and ammonia or ethylendiamine in the nephelauxetic series. A plot of $1/\chi$ data versus T (K) ($T = 80$–298 K) is linear (with a statistical r^2 factor of 0.9993) according to a Curie–Weiss behavior, $\chi_{mol} = C/(T - \theta)$ (Fig. 3). The Curie constant is $C = 1.10$ K·emu·mol^{-1} and a Weiss constant of $\theta = 5.58$. The experimental value of μ_{eff} for Ni(II) atom in the studied complex **I** is 2.97 BM, in accordance with the molecular and crystal structure here reported where the shortest inter-metallic Ni–Ni[vi] distances is 5.193(1) Å (symmetry code vi: $\#6 = 1 - x, 1 - y, 1 - z$). This value lies within the range of typical experimental ones (2.8–3.5 BM) in mononuclear octahedral Ni(II) complexes with a $^3A_{2g}$ ground state [37]. It is slightly higher than the spin-only one ($\mu_{eff} = g[S(S+1)]^{1/2} = 2.83$) suggesting that there is a small orbital angular moment contribution to the effective magnetic moment of the nickel(II) atom.

3. Concluding remarks

The nickel(II) atom exhibits an octahedral coordination in the molecule of complex **I**, which represents a common feature for this metal(II) ion. However, that differs from the square base pyramidal coordination reported for the corresponding copper(II) derivative which has a polymeric structure [12]. In addition, it is worth noting that two *cis*-aqua ligands in the nickel(II) complex gives the possibility for further studies of mixed-ligand complexes of such a metal ion, ADA, and a variety of mono- and bi-dentate ligands. At present, we continue working to evaluate these possibilities [38] on the basis of our present results and keeping in mind the structure of bis(imidazole)(nitrilopropionamidediacetato)nickel(II) monohydrate [35g] reported some years ago.

Abstract

Stoichiometric reaction of $CoCO_3\cdot Co(OH)_2\cdot 2H_2O$, or $NiCO_3\cdot 2Ni(OH)_2\cdot 4H_2O$ with H_2ADA and imidazole (Him) in water yields crystalline samples of compounds aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)metal(II), $[M(ADA)(Him)(H_2O)]\cdot 1.5H_2O$ (M = Co, compound **I**, dark pink; M = Ni, compound **II**, bluish). Single-crystal X-ray diffraction studies were carried out. Both complexes are isostructural (orthorhombic system, space group *Pna*2(1), $Z = 8$). These crystals consist of slightly asymmetrical octahedral coordination units linked in a tridimensional network stabilised by hydrogen bonds where all N–H bonds of ADA and Him and probably O–H bonds of water molecules are involved. The asymmetric unit has two independent but very similar complex molecules and three water ones. Coordination bond distances for **I** (average in Å): Co–N(amino) = 2.14(1), Co–O(carboxyl) = 2.06(1), Co–O(carboxyl) = 2.08(1) and Co–O(amide) = 2.15(1) with ADA, Co–N(Him) = 2.04(1), and Co–O(aqua) = 2.13(1). Coordination bond lengths for **II** (average in Å): Ni–N(amino) = 2.08(1), Ni–O(carboxyl) = 2.04(1), Ni–O(carboxyl) = 2.06(1) and Ni–O(amide) = 2.012(1) with ADA, Ni–N(Him) = 2.01(1), and Ni–O(aqua) = 2.12(1). The ADA ligand acts as a tripodal tetradentate chelating one. On the basis of the octahedral structures of $[Ni(ADA)(H_2O)_2]$, reported in the literature, and of the new compounds, it is concluded that there is a preference for the N(Him)donor atom to occupy the *trans*-position to the M–N(ADA) bond. © 2000 Elsevier Science B.V. N-carbamoylmethyl-iminodiacetic acid also named *N*-(2-acetamido)-iminodiacetic acid or *N*-(2-amidomethyl)-iminodiacetic acid [$H_2ADA{=}H_2NCOCH_2N(CH_2CO_2H)_2$)] is a well known chelating agent, also used in 'biological buffers' of pH 6.0–7.4 [1]. Metal(II) ion–ADA chelation in solution has been known for a long time (metal = Mg, Ca, Sr, Ba, Mn, Co, Ni, Cu, Zn, Cd, Hg, Pb) [2]. The results of this study agree with more recent ones [3–6] about the stoichiometry and stability of ADA complexes in solution [2] which show that 'primary amide' deprotonation reactions for ML_2 chelates of Co(II) or Zn(II) [3] can arise in alkaline solutions. In alkaline solutions, Cu(II) dechelation processes have also been claimed upon ADA amide deprotonation [7,8].

Several papers have appeared in recent years concerning the mixed-ligand complexes of a variety of

metal ions and ADA as primary ligand. Such compounds have salicylhydroxamate [9a], thiosemicarbazide [9b], dithiocarbazate [9b], aromatic acids [9c], amino acids [9d,e] or salicylic acid derivatives [9f] as secondary ligands. A certain number of such mixed-ligand metal complexes having ADA have been obtained in solid state and characterised by spectral and other physico-chemical methods. However structural studies in this context were noticeably limited to one aqua–*oxo*-ADA complex with vanadium(IV) [10] and the potassium salt of an *oxo*-peroxo-ADA-vanadium(V) complex [11,12]. In such compounds, ADA acts as a tripodal-tetradentate ligand.

The structural research of ADA–metal chelates in solid state seems a useful tool because it can provide information about the chelating role of the divalent anion $H_2NCOCH_2N(CH_2CO_2^-)_2$. Particular interest focuses on the way in which its 'primary amide group' takes part in metal ion chelation. In this sense and as a part of our studies on mixed-ligand Cu(II) complexes having IDA or IDA-derivatives and *N*-heterocyclic ligands, we have synthesised for the first time the compound (imidazole)(*N*-carbamoylmethyl-iminodiacetato)-copper(II), [Cu(ADA)(ImH)] [13a]. In recent reports we reported the structures of compounds $\{[Cu(ADA)]\cdot H_2O\}_n$ and $[Cu(ADA)(bipy)]\cdot 3H_2O$ (bipy = 2,2′-bipyridine) [13b] and of the H_2ADA acid itself and the nickel derivative *cis*-$[Ni(ADA)(H_2O)_2]$ [13c]. Again, the XRS study of these complexes has revealed that ADA acts as a tripodal-tetradentate ligand. In the case of the octahedral Ni(II)–ADA chelate, the *cis*-coordination of both aqua ligands suggests several possibilities for substitution by other ligands which we consider in our research projects. For example, replacing only one water molecule by an imidazole (Him) in this latter complex, two different possibilities of linking Him ligand to the nickel(II) atom arise. These are in *cis*- or *trans*-position versus the metal–N(ADA) bond. The aim of the present work is to find an answer to this question. In this connection, we report the synthesis, crystal structure and properties of two new mixed-ligand complexes of nickel(II) or cobalt(II) having aqua, ADA and Him as choice ligand set.

1. Experimental

1.1. Synthesis of aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)-metal(II) sesquihydrate for cobalt(II) and nickel(II)

$[M(ADA)(Him)(H_2O)]\cdot 1.5H_2O$, compounds **I** (Co) or **II** (Ni), were obtained by stoichiometric reaction between $CoCO_3\cdot Co(OH)_2\cdot 2H_2O$ (252.2 mg, 1 mmol, Merck, Co ≥ 47%) or $NiCO_3\cdot 2Ni(OH)_2\cdot 4H_2O$ (250.0 mg, 0.67 mmol, Merck, Ni ≥ 47%) and H_2ADA (380.3 mg, 2 mmol, Aldrich, 98%) in water (100 ml) in a Kitasato flask, heating ($t < 50$°C) and stirring under reduced pressure (to remove the CO_2 by-product) for 3 h. These mixtures were still stirred 24 h at ~60°C and then slowly filtered to remove an almost inappreciable amount of non-reacted CoO or NiO (insoluble by-products). The pH of the reacting mixtures was not controlled during the synthesis processes. The resulting pink or green solutions were left to cool and imidazole (136.2 mg, 2 mmol, Merck, >99%) was added with stirring, which produces colour intensification (Co) or a change to a bluish colour (Ni). After 3 weeks of slow evaporation at room temperature (the remaining volume being 10–15 ml) the solutions were filtered over a small crystallisation dish and covered with a watch glass to reduce the rate of evaporation. After several days, well-shaped dark pink or bluish crystals of complexes **I** or **II**, respectively, appeared, which were suitable for X-ray diffraction studies. Additional amounts of products were formed again and collected in the same way. If mother liquor super-saturation arises, the addition of small volumes of water and ethanol and slow evaporation as before can induce the crystallisation. These products were collected by filtration, washed with a little of cool water and carefully air-dried. They can be re-crystallised several times from water. Yield: variable but usually <60%. *Anal.* Calc. for compound $C_9H_{17}CoN_4O_{7.5}$ (**I**): C, 30.01; H, 4.76; N, 15.56; Co, 16.36. Found: C, 30.20; H, 4.95; N, 15.65; Co, 16.27%. *Anal.* Calc. for complex $C_9H_{17}N_4NiO_{7.5}$ (**II**): C, 30.03; H, 4.76; N, 15.57; Ni, 16.31. Found: C, 30.27; H, 4.64; N, 15.36; Ni, 16.24%.

1.2. X-ray data collection and reduction, structure solution and refinement

A prismatic crystal of compound **I** (dark pink) or **II** (bluish) was mounted on a glass fibre and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $7.794 < \theta < 11.448$ or of $9.966 < \theta < 10.501$, respectively, in an Enraf Nonius MACH3 automatic diffractometer [14]. Data were collected at 293 K using Mo Kα radiation ($\lambda = 0.71073$ Å) and the ω-scan technique, and corrected for Lorentz and polarisation effects [15]. A semi-empirical absorption correction (ψ scan) was made [16]. The structure was solved by direct methods [17] and subsequent difference Fourier maps and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [18]. All hydrogen atoms were located in their calculated positions (C–H 0.93–0.97 Å) and were refined using a rigid model. Hydrogen atoms of water were not located. The absolute configuration was established [19].

Atomic scattering factors were taken from the 'International Tables for X-ray Crystallography' [20]. Molecular graphics were prepared with the program PLATON-98 [21]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

1.3. Physical measurements

Cobalt(II) or Nickel(II) titration was carried out by standard EDTA complexometry using xilenol orange as metallochromic indicator [22a]. Alternative procedures using murexide indicator in weak alkaline solution (for Co and Ni) or alizarin complexone in weak acid solution (for Co) are available [22b]. For this purpose an accurately weighted sample (≥ 0.5 g) of each of the studied compounds was mineralised with 2 N sulphuric acid and hydrogen peroxide solutions in a precipitation vessel covered with a watch glass. The reaction and decomposition of H_2O_2 in excess were favoured by heating carefully and the resulting green solution of nickel(II) sulfate or pink solution of cobalt(II) sulfate was quantitatively diluted with doubly-distilled water into a 250 ml volumetric flask. Aliquots (25 ml) of these solutions were titrated as described elsewhere [13c,22]. Elemental analysis (C, H, N) were performed in the Scientific Instrumental Centre of the University of Granada as described earlier [13]. Infrared (IR) spectra were obtained by the KBr disc technique on a Nicolet FTIR 20SXB or a JASCO FTIR 410 instrument. TG (pyrolysis) of studied compounds and analysis of evolved gases were recorded (295–775 K) in air flow (100 ml min^{-1}) using a Shimazu Thermobalance TGA-DTG-50H coupled with an IR-FT Nicolet Magma 550 (and mass spectrometer Fisons Thermolab). Electronic (reflectance) spectra (175–3300 nm) were obtained in a Cary 5E spectrophotometer. The magnetic susceptibilities of **I** and **II** were measured in the temperature range 80–300 K using a Manics DM magnetometer. The susceptometer was calibrated with mercury tetrakis(thiocyanato)-cobaltate(II). Corrections for the diamagnetism of ligands and metal atom (150×10^{-6} cm^3 mol^{-1} for both compounds) were estimated from Pascal constants [23,24].

2. Results and discussion

2.1. Molecular and crystal structure of aqua(N-carbamoylmethyl-iminodiacetato)metal(II) sesquihydrate with cobalt(II) or nickel(II) ions

Selected bond lengths and angles between non-hydrogen atoms and hydrogen bonding data of compounds **I** and **II** are given in Tables 2 and 3, respectively. From the data shown in Tables 1–3, it follows that both compounds are isostructural. Consequently, they could be discussed at the same time. The crystal of these compounds consist of complex units [M(ADA)(Him)(H_2O)] (hereafter M = Co or Ni) and non-bonded to the metal water molecules linked in a tridimensional hydrogen bonding network involving all polar N–H bonds of the ADA amide group and Him ligand, and probably O–H bonds of water molecules (see Tables 2 and 3). The asymmetric unit of the crystal of such compounds contains twice the formula (see Fig. 1 for nickel(II) derivative). Thus, each asymmetric unit contains two non-equivalent complex molecules from a crystallographic point of view and three non-coordinated water molecules. However, these complex

molecules are very similar from a chemical point of view. In both compounds the octahedral coordination polyhedron of the metal(II) atom is built up by means of the atom N(amino), two O(carboxyl) ones and the O(amide) donor of the tetradentate ADA^{2-} ion as well as the N(pyridine-like) atom of the Him ligand plus the O(aqua) donor of the coordinated water molecule. As regards the cobalt(II) derivative, it is widely recognised that such a $3d^7$ transition divalent metal ion adopts two major stereochemistries, distorted octahedral and tetrahedral [25]. In this connection, the ligand polarisability plays a discriminating role. Less polarisable or hard donors (as most O donor and N(amine) ones) favour octahedral structures in pink to violet cobalt(II) coordination compounds [25]. The reported case falls in this group and consequently its stereochemistry will be considered normal. On the other hand, the octahedral coordination of nickel(II) atom in compound **II** should be expected because it has been recently reported for $[Ni(ADA)(H_2O)_2]$ [13c] and it is the most frequent stereochemistry for this $3d^8$ divalent transition metal ion [25]. In contrast, it is worth noting that the structure of an analogous mixed-ligand Co(II)–ADA–H_2O complex remains unknown and all attempts to obtain X-ray quality crystals of this compound in our laboratories have been unsuccessful. Because the effective ionic radii of octahedral Ni(II) (0.72 Å [26]) and Co(II) (0.745 Å, high spin [25]) are very similar, there is no comment to add about the isostructural feature in the studied compounds. Otherwise the M(II) coordination polyhedron and the internal geometry of the ADA ligand have usual bonds and angles compared with related compounds. That includes known metal–ADA complexes [8–10,12,13], cobalt(II)–IDA chelates [27] or nickel(II)–IDA ones [28] as well as a variety of mixed-ligand complexes of cobalt(II) [29] or nickel(II) [30] having from one to four Him ligands.

The metal chelation of the tripodal ADA ligand in **I** and **II** represents the formation of two nearly coplanar M–glycinate-like rings and one M–glycinamide-like one sharing the M–N(amino) bond. One of the M–glycinate-like rings falls nearly coplanar to the plane [M, N(Him), O(aqua)] (hereafter so-called G ring). This chelate ring is less distorted (deviations from its mean ring plane ranging 0.00–0.08 Å) than the other two ones. Moreover such a G ring exhibits a slightly puckered configuration (both carbon atoms displaced at opposite side of its plane N–M–O) in complex units of Co(1) and Ni(1) atoms, and a slightly asymmetrical envelope configuration (both carbon atoms at the same side of its N–M–O plane) in complex units of Co(2) and Ni(2) atoms [30]. The remaining M–glycinate-like ring and the M–glycinamide-like one are nearly coplanar to each other (angle between mean planes of $14.4 \pm 1.7°$). These rings fall not coplanar/ nearly perpendicular to the plane [M, N(Him), O(aqua)] (and then, hereafter will be so-called R and R′ rings, respectively). All R and R′ chelate rings in the studied compounds (max. deviations of the atoms from its mean ring plane ≤ 0.28 Å) are significantly more distorted than the corresponding G one (max. deviations of the atoms from its mean ring plane ≤ 0.08 Å). In addition, these rings adopt invariably an asymmetrical envelope configuration (with both carbon atoms at the same side of its N–M–O plane) rather common in metal-amino acid chelates and closely related compounds [31].

On the other hand, the Him ligand is, as expected, planar within 0.03(1) Å. The metal ion is out of the Him plane at a distance ranging from only 0.008(1) Å for Ni(1) up to 0.130(1) Å for Ni(2) (being of 0.050(1) and 0.076(1) Å for Co(1) and Co(2) cases, respectively). The Him plane is slightly twisted ($< 10°$) versus the mean plane defined by its N(pyridine-like) donor atom and the three ADA donors involved in the R and R′ chelate rings. This fact means that the heterocyclic

[a] Symmetry transformations used to generate equivalent atoms: i: # 1 = $x-1/2$, $-y+3/2$, z; ii: # 2 = x, $y-1$, z; iii: # 3 = $x+1/2$, $-y-3/2$, z; iv: # 4 = x, $y+1$, z.

ligand falls nearly perpendicular to the other two sets of roughly coplanar four donor atoms. An interesting structural correlation follows the structures of compounds **I** and **II**. That is, the preference of Him ligand for the *trans*-position to the N(ADA) donor one. Such correlation can not be inferred either from the structure of the complex [Cu(ADA)(Him)] [13a] because of its five-coordinated stereochemistry or from the structure of the closely related octahedral complex in the compound bis(imidazole)(nitrilopropionamide-diacetato)-nickel(II) monohydrate [30k] because of the presence of two Him ligands together with a tetradentate nitrilopropionamide-diacetate(2 −) ion.

It seems instructive to carry out a comparison of averaged coordination bond distances and *trans*-angles in [Ni(ADA)(H_2O)$_2$] [13c] and compounds **I** and **II** (Table 4). The following insights arise: (1) It should be noted the remarkable similarity of the average value for all six metal–ligand bond lengths. Such similarity is obviously higher for the two closely related nickel(II) compounds (with and without the Him ligand instead of an aqua one). (2) In these three compounds, the coordination bonds to four donor atoms of the tripodal ligand ADA are noticeably similar in length to each other (being more significant for [Ni(ADA)(H_2O)$_2$]). (3) In both new compounds the longest bond is that of M–O(amide). That is not observed for the diaqua–ADA–nickel(II) complex. (4) *Trans*-angles involving a M–O(aqua) bond or the M–N(Him) bond are nearly close to 180° (ranging from 173.7° to 179.3°) but the remaining *trans*-angle O(carboxyl)–M–O(amide) with both donors from ADA chelating ligand is significantly below this angle (in the range of 156–164°). These data reveal that the main source of the moderate but irregular distortion at the M(II) coordination polyhedron in the studied compounds arises from the chelate ring

(b) Spectrum at $t = 33.659$ min from second step with bands of water, CO_2, CO (traces) and ammonia. (c) Spectrum at $t = 37.620$ min from the beginning of third step showing bands of water, CO_2, CH_4, N_2O, NO and NO_2.

constraints in the tripodal ADA ligand. In this connection, it is worth noting that just the most distorted set of four nearly coplanar donor atoms in compounds **I** and **II** is that of the four oxygen ones (three from ADA, one from aqua). Indeed these four oxygen atoms define a folded square with a mean plane P[4(O)] from which both *trans*-pairs of oxygen donor atoms are displaced similarly but in opposite sense ($\pm 0.13(2)$ Å),

whereas the atoms of the other two sets of roughly coplanar four-donor ones deviates $< 0.06(2)$ Å from its corresponding mean plane. The metal atom is also largely moved (0.20–0.29(2) Å) out of such P[4(O)] plane towards the Him ligand (whereas the deviation of the metal atom from the other two referred mean planes is $< 0.04(2)$ Å).

2.2. Properties of aqua(*N*-carbamoylmethyl-iminodiacetato)metal(II) sesquihydrate for cobalt(II) and nickel(II)

The TG analysis in air-flow (with FTIR spectra of evolved gases) of compounds **I** and **II** are similar and show three steps. The first step (85–187°C for **I** and 135–235°C for **II**) corresponds to the loss of non-coordinated water, as it is supported by FTIR spectra (Fig. 2(a)). The other two steps corresponds to the overlapped pyrolysis of organic ligands (Fig. 2(b,c)) to give probably Co_2O_3 or $NiO{\cdot}Ni(NO_3)_2$ at 425°C. The weight loss and evolved gases in the second step (187–335°C, Fig. 2(b) for compound **I**) correspond to the loss of coordinated water plus the 2-amidomethyl arm of ADA, the organic ligand which begins the oxidative pyrolysis.

Since the isostructural relationship of compounds **I** and **II**, their IR spectra are extremely similar. They allow the identification of the main characteristic absorption bands (wave-numbers in cm^{-1}) expected for aqua and ADA ligands [32]: A very broad band (3800–2500) including ν(OH) of water, $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ of primary amide group at 3330 and 3141(3128), ν(C=O) of primary amide group ('amide I' band) at 1675, $\delta(H_2O)$, $\delta(NH_2)$ ('amide II' band) and $\nu_{as}(COO^-)$ overlapped at 1610 (1611), δ(N–H) of Him at 1542, and $\nu_s(COO^-)$ at 1403. Difference $\Delta(COO) = 207 \pm 1$ cm^{-1} in accordance with the expected ionic nature of the M(II)–O(carboxylato) bonds.

Electronic spectra of compounds **I** and **II** are typical of Co(II) (ground state $^4T_{1g}(F)$) and Ni(II) (ground state $^3A_{2g}(F)$) octahedral complexes, respectively. The spectrum of **I** shows bands at $\nu_1 = 8420$, $\nu_2 = 16\,100$ (shoulder) and $\nu_3 = 19\,350$ cm^{-1}, which fall between those of the hexaaqua-ion and the $[Co(NH_3)_6]^{2+}$ ion [25]). The spectrum of **II** shows bands $\nu_1 = 9930$ (shoulder at $\sim 14\,500$), $\nu_2 = 16\,420$ and $\nu_3 = 25\,975$ cm^{-1}. It can be assumed that $\nu_1 = 10\,Dq = \Delta_o$, and a value of 856 cm^{-1} is obtained for the Racah parameter B', 83% of the B parameter in the free ion. Δ_o and B' in **II** are higher than those of *cis*-diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II) [13c] as expected for the substitution of one aqua ligand by Him.

For both compounds studied, a plot of $1/\chi$ data versus T (K) ($T = 80$–290 K) is linear (with a statistical factor r^2 of 0.9997) according to a Curie–Weiss behaviour, $\chi_{mol} = C/(T - \theta)$, (see Fig. 3(a) for cobalt(II) case). The experimental value of the effective magnetic moment (μ_{eff}) for the metal(II) atom is 5.10 or 3.22 BM for **I** or **II**, respectively, within the corresponding ranges for mononuclear high-spin octahedral cobalt(II) [25] or in octahedral nickel(II) [26], in agreement with the structures reported, where the shortest inter-metallic distances are > 7 Å.). The μ_{eff} value for the cobalt(II) complex largely exceeds the spin-only value [24] suggesting that there is an appreciable contribution of orbital angular momentum [25]. That can be attributed to its T ground term resulting in temperature-dependent orbital contributions to the magnetic moment. Accordingly, experimental values of μ_{eff} fall of with decreasing temperature (Fig. 3(b)).

3. Concluding remarks

Compounds **I** and **II** have octahedral stereochemistry for cobalt(II) and nickel(II) atoms, respectively, a rather common coordination for these metal(II) ions in moderate ligand fields. Such stereochemistry has been also observed in *cis*-diaqua(*N*-carbamoylmethyl-iminodiacetato)-nickel(II) [13c], the 'parent' complex of

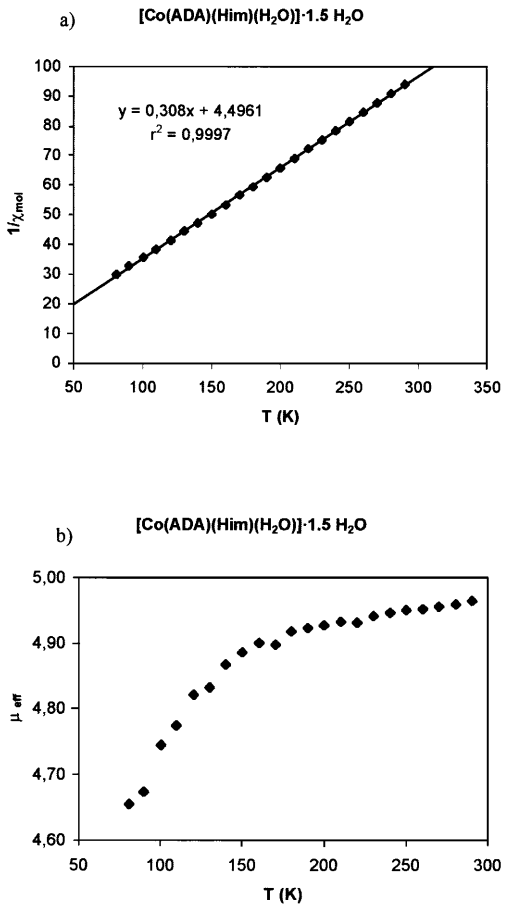

Fig. 3. Magnetic properties of compound **I**. (a) A plot of $1/\chi_{mol} = f(T)$: (◆, experimental; solid straight line represents the best theoretical fit to the linear form of the Curie–Weiss law). (b) Dependence of the effective magnetic moment versus the temperature.

compound **II**. This is in contrast to the distorted square-base pyramidal coordination found in the corresponding copper(II) derivatives, $\{[Cu(ADA)]\cdot H_2O\}_n$ (which has a polymeric structure [13b]) and [Cu(ADA)(Him)] [13a].

On the basis of the octahedral Ni(II) coordination in the above referred chelates, new structural relationships can be inferred [13c]. This study reveals that imidazole comes in the complex $[Ni(ADA)(H_2O)_2]$ replacing the aqua ligand just in *trans* to the bond Ni(II)–N(amino) with ADA. This ligand substitution reaction does not seem to cause significant changes in bond lengths and angles around the Ni(II) atom. In compounds **I** and **II**, one aqua ligand remains linked to the metal atom. That could permit further ligand substitution reactions. This possibility promotes new studies on mixed-ligand metal complexes with ADA and a variety of mono- and bi-dentate ligands.

The structure of the aqua–ADA–cobalt(II) complex remains unknown. Efforts will be made to cover this lack of information. On the other hand, at this moment, all known structures show ADA as an effective tripodal tetradentate ligand [11–13]. This feature suggests a remarkable ligand flexibility, but additional studies for metal ions with different crystallo-chemical properties will be required.

4. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC no. 134849 for compound $[Co(ADA)(Him(H_2O)]\cdot 1.5H_2O$ (**I**) and CCDC no. 134848 for compound $[Ni(ADA)(Him)(H_2O)]\cdot 1.5H_2O$ (**II**). Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Acknowledgements

This paper is devoted to the memory of Prof. Sergio Cabani (University of Pisa, Italy) recently deceased. He encouraged many contributions on thermodynamics and kinetics of metal complexes. We are grateful to the Dirección General de Enseñanza Superior e Investigación Científica, MEC, Spain, for financial support (Project PB-98-0605-C03-03). A.C. thanks the Xunta de Galicia for the financial support (Project XUGA20309B97). A research grant to E.B.A. from Ministerio de Educación y Cultura is gratefully acknowledged.

Abstract

A structural classification of dimers, containing the $Cu(\mu\text{-}Cl)_2Cu$ core, based on data obtained from X-ray diffraction analysis reported in the literature has been performed. In these complexes, the local geometry around the copper metal center is generally a square pyramid, with a different degree of distortion towards a trigonal bipyramid. The global geometry of the dinuclear complex can be described in terms of the relative arrangement of the two square pyramids, giving rise to three types of geometries, termed: coplanar bases, parallel bases and perpendicular bases. Ideal models representing these geometries were defined and EH calculations were performed in each case, showing the different molecular orbitals involved in their corresponding frontier orbitals, together with their energy. EH calculations were also carried out for dimers embodying different type of structural distortions from the ideal models. The results obtained from those EH calculations have proven to be extremely useful for the proper interpretation and correlation of the magnetic data and dimer structure for those $Cu(\mu\text{-}Cl)_2Cu$ complexes reported in the literature. © 2000 Elsevier Science B.V. Keywords: Magnetic properties; Dimers; Geometrical distortions; Magnetostructural correlations

1. Introduction

The magnetic properties of transition metal complexes are of tremendous importance both from a basic research point of view and also because of their multiple technological applications [1–3]. As a consequence, there has been substantial interest, over the years, in correlating magnetic properties and molecular structure. On the other hand, the propagation of magnetic information over large distances is a topic that has attracted considerable interest in recent years [4–10].

For dihydroxo bridged dinuclear copper complexes [11–24], a good degree of success has been accomplished in correlating structure and magnetic properties. In sharp contrast, no unique magneto-structural correlation has been found for dichloro bridged dinuclear copper complexes. Furthermore, a recent report has presented a new compound that constitutes the first example of a ferromagnetic dinuclear copper with a spin-ladder disposition and moderate interactions [25].

Given the current interest in dinuclear dichloro bridged copper complexes, we have undertaken a theoretical analysis on the different geometrical factors that influence their electronic and magnetic properties, in order to offer a framework for future reference.

2. Experimental

Molecular orbital calculations have been carried out using CACAO 4.0 (computer-aided composition of atomic orbitals) [26], which is a program based on extended Hückel (EH) type of analysis.

Ideal models were used as the starting point of our analysis. In the models, the N atoms of the ligands were substituted for simple amino groups. EH calculations for complex $[Cu_2(dpt)_2Cl_2]Cl_2$ (**34**) (see Table 1) [25], showed that there is no significant difference for both energies and frontier orbital topologies between the real complex and the model.

For each model, all bonding angles between Cu and the bonded ligand atoms, arranged in a *cis* fashion, were taken as 90°. All Cu–N bond distances were taken as 2.0 Å, while we distinguished between basal and apical Cu–Cl bond distances. The former was taken as 2.51 Å, whereas we used 2.70 Å for the latter. In the perpendicular bases case, we took both Cu–Cl bond distances as 2.51 Å.

The three models used, together with the drawing of their corresponding HOMO and LUMO frontier orbitals, are depicted in Fig. 1.

Throughout the present paper, the description of atomic orbital participation is only considered if it has a contribution of more than 1% to the corresponding molecular orbital.

3. Results and discussion

A number of dichloro bridged dicopper complexes have been reported in the literature so far [25,27–53]. At first glance their molecular structure shows that there is a whole variety of bond distances and angles, in sharp contrast with dihydroxo bridged dicopper complexes, that display a more homogeneous behavior from this perspective. Moreover, a closer examination of their structural parameters shows that, in dihydroxo bridged copper complexes, the geometry around the copper metal center is basically a square pyramid. The two pyramids are spatially arranged so that they share a basal edge, which contains the two OH^- bridging ligands, and the corresponding apical positions are

[b] COP stands for coplanar bases, PAR for parallel bases and PER for perpendicular bases.

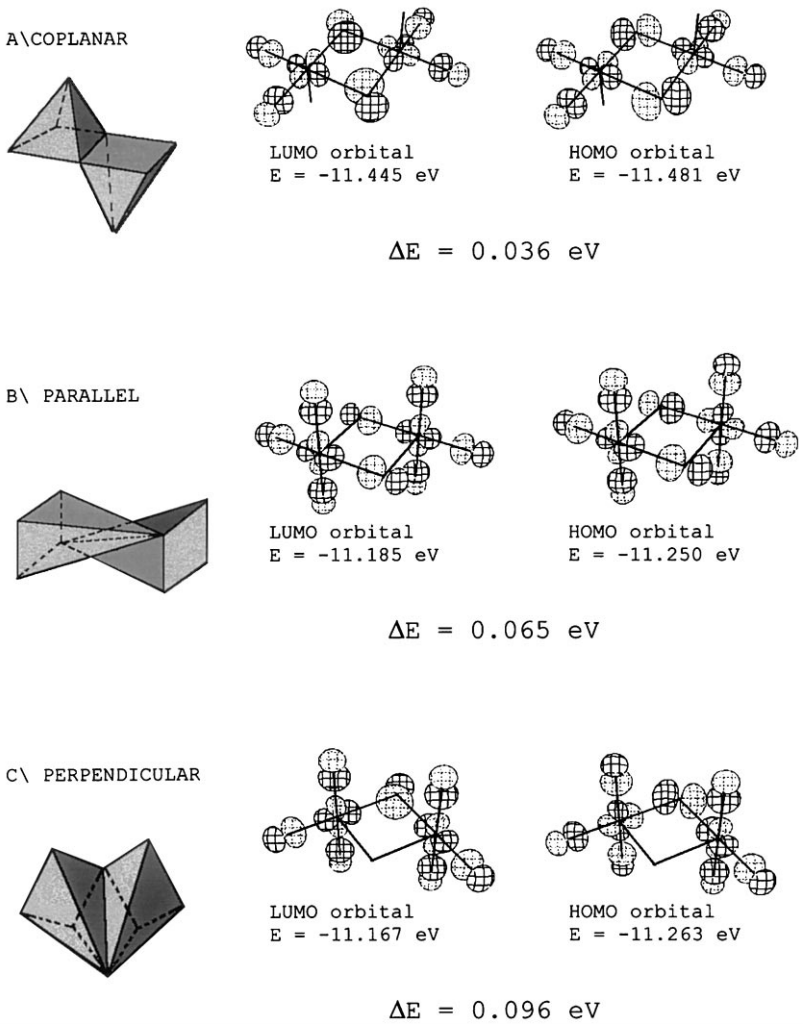

Fig. 1. Polygon arrangements found for $N_3Cu(\mu\text{-}Cl)_2CuN_3$ type of dimers together with their EH calculated HOMO and LUMO frontier orbitals for ideal models (see Section 2 for details): (A) coplanar bases; (B) parallel bases; (C) perpendicular bases.

situated in opposite directions. This geometry, termed coplanar bases, is shown in Fig. 1(A) for the homologous Cu_2Cl_2 complexes, and it is invariably the type of structural arrangement observed for most of dihydroxo bridged complexes reported to date.

For dinuclear dichlorobridged pentacoordinated copper complexes, the local geometry around the copper metal center is also generally a square pyramid, although the degree of distortion is somewhat greater than in the hydroxo case. In sharp contrast, and due to the relatively larger bond distances and angles presented, dichloro bridged complexes exhibit two more different geometries with regard to the relative arrangement of squared pyramids, besides to the coplanar bases case. Those two new geometries are termed parallel bases and perpendicular bases, and are represented in Fig. 1(B and C), respectively.

3.1. Ideal models

In the parallel bases case, the two square pyramids share a base-to-apex edge so that the Cl atom situated at the vertex of one base becomes the apical vertex of the other square pyramid, and just the opposite happens for the other Cl bridging ligand. In the perpendicular bases case, the two square pyramids share a base to apex edge, but now the apical chloro ligand of one pyramid is also the apical of the other one, and the same happens for the other chloro ligand: in both pyramids it lies on the base.

Fig. 1 presents, for the three possible geometries adopted by dinuclear dichloro bridging copper com-

plexes, the schematic structural drawings, idealized polygon arrangements and the drawings and energies of EH calculated frontier orbitals based on ideal models. EH analysis for the ideal coplanar bases case gives an energy gap of 0.036 eV between HOMO and LUMO orbitals (see Fig. 1(A)) which, in turn, are about 0.8 eV above occupied orbitals. The calculations indicate, for the HOMO orbital, the following orbital participation: Cu d orbitals, 42%; N p orbitals, 32%; basal Cl p orbitals, 24%. For LUMO orbital: Cu d orbitals, 44%; N p orbitals, 32%; basal Cl p orbitals 24%. The contribution from the apical N ligand to both frontier orbitals is less than 1%. A summary of the results obtained from EH analysis performed for the three different arrangements is shown in Table 2.

As it can be observed in Fig. 1, the Cu metal centers use $d_{x^2-y^2}$ type orbitals for a σ^* interaction with p_N and p_{Cl} orbitals, for any of the structural arrangements. For the coplanar bases case, the LUMO orbital is an antisymmetric $d_{Cu}-d_{Cu}$ orbital combination, whereas the HOMO orbital is a $d_{Cu}-d_{Cu}$ symmetric combination. For both parallel and perpendicular bases cases, the LUMO orbital is the symmetric combination of these $d_{Cu}-d_{Cu}$ orbitals, and the HOMO corresponds to the antisymmetric one.

In the frontier orbitals, for the parallel bases case, each bridging Cl ligand interacts, in a sigma fashion, only with one of the Cu metals. It is interesting to note that, for perpendicular bases case, the contribution to frontier orbitals of the apical Cl ligand is less than 1% in both HOMO and LUMO orbitals.

3.2. Distortions from ideal models

In this section we described how frontier orbitals topology and energy were affected by structural distortions. The distortions chosen are those that lead to the type of distorted structures found for real complexes, or those that help to understand the magnetic behavior of copper dimers reported in the literature.

3.2.1. Coplanar bases

The first distortion considered in this case consists on an elongation of the Cu–Cl bond distances, maintaining bond angles intact, therefore producing a symmetric enlargement of the squared core. As the Cu–Cl distance is progressively enlarged from 2.2 to 2.8 Å, the energy gap between frontier orbitals is gradually decreased. At this point the two orbitals are nearly degenerate. This is due to the fact that, as the Cu–Cl bond distance is increased, the effective bonding decreases and therefore the two Cu centers become basically independent.

The second distortion considered was a symmetric increase and decrease of the Cu–Cl–Cu bond angles that produces, as a consequence, a decrease and increase of the Cu–Cl bond distances, respectively. In this case, the frontier orbitals energy gap reaches a minimum at CuClCu bond angle equal to 90°; for this angle, the overlap between the p_{Cl} orbitals and the d_{Cu} orbitals is practically identical in both HOMO and LUMO orbitals, due to the orthogonality of p_{Cl} orbitals involved (see Fig. 1(A)). As the angle is increased, both orbitals increase in energy, but the LUMO increases at a faster pace. On the other hand, when the angle decreases, both frontier orbitals do stabilize, but now the HOMO does it faster.

The third distortion considered was the Cu geometrical transformation from a square pyramid (sqp) to a trigonal bipyramid (tbp)(see Fig. 2). In this case, the frontier orbitals energy and the gap remain practically constant over the exerted distortion. However, orbital composition and shape are substantially different. The frontier orbitals involved in the tbp geometry resemble now a orbital (Fig. 2(C)), and some degree of participation from the apical ligand orbitals was found.

3.2.2. Parallel bases

For this geometry we have considered two different distortions. The first distortion, represented in Fig. 3, consisted on the transformation of a sqp to tbp geome-

Table 2
Energies and participation of atomic orbitals to HOMO and LUMO orbitals calculated for ideal models

Geometry type	Coplanar bases	Parallel bases	Perpendicular bases
Energy GAP between HOMO and LUMO orbitals (eV)	0.036	0.065	0.096
Energy above occupied orbitals (eV)	0.8	1.5	1.3
HOMO Cu d orbitals participation (%)	42	44	42
HOMO N p orbitals participation (%)	32	44	42
HOMO basal Cl p orbitals participation (%)	24	12	12
LUMO Cu d orbitals participation (%)	44	42	44
LUMO N p orbitals participation (%)	32	44	44
LUMO basal Cl p orbitals participation (%)	24	10	10

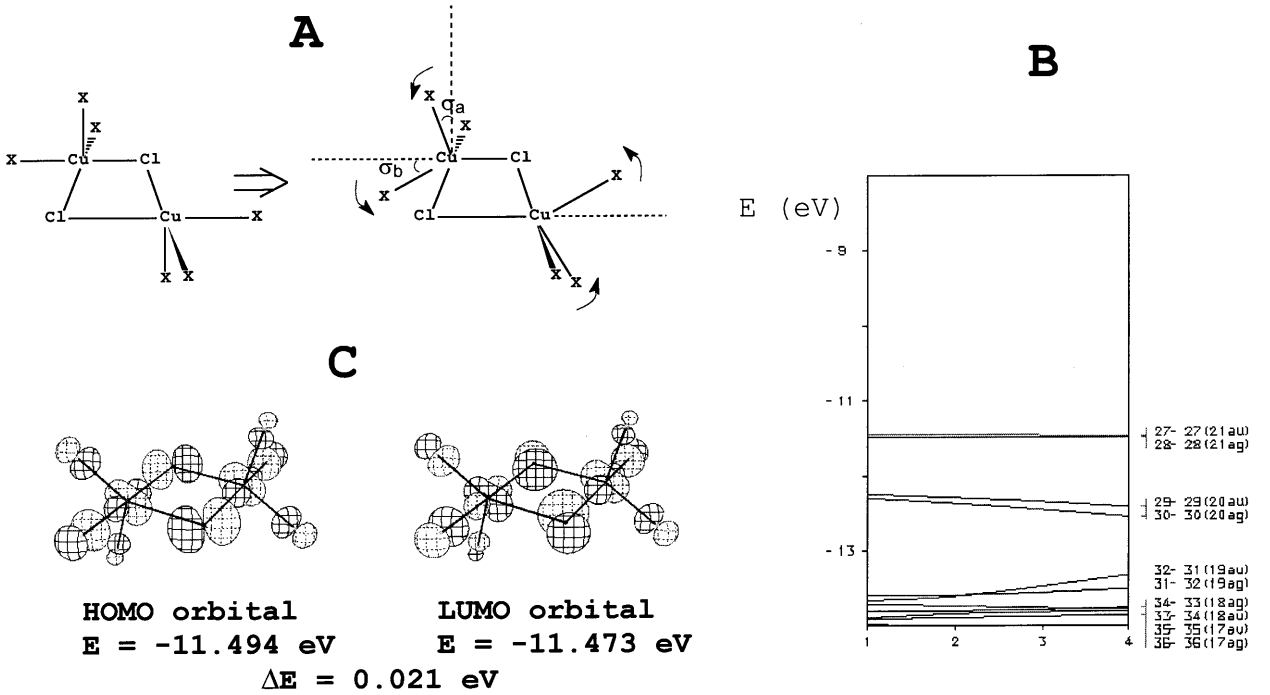

Fig. 2. Distortion from the coplanar bases ideal model. (A) Schematic diagram showing the applied distortion from sqp to tbp through a modification of the indicated angles σ_a (apical) and σ_b (basal). (B) Walsh diagram showing the energy as function of synchronized variations of σ_a and σ_b (step 1: initial idealized coplanar bases; step 2: $\sigma_a = 5°$, $\sigma_b = 10°$; step 3: $\sigma_a = 10°$, $\sigma_b = 20°$; step 4: $\sigma_a = 15°$, $\sigma_b = 30°$). (C) Drawing of HOMO and LUMO frontier orbitals obtained in step 4.

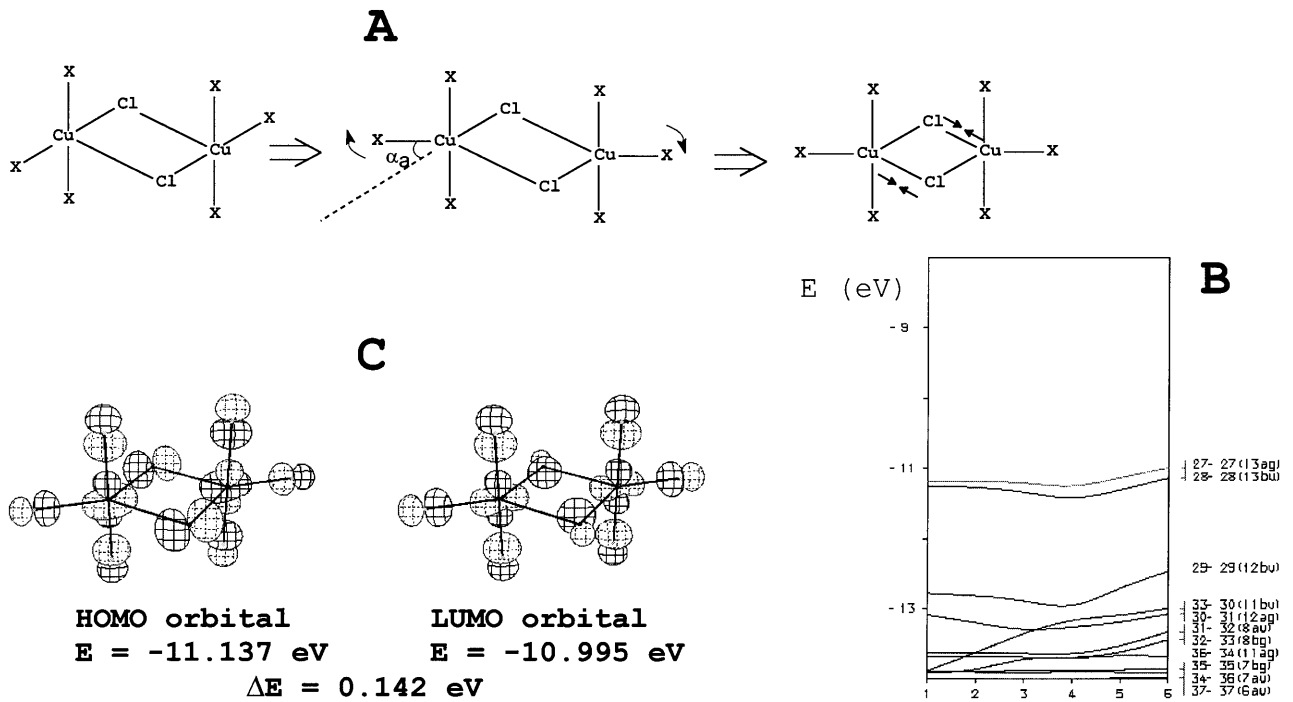

Fig. 3. Distortion from the parallel bases ideal model I. (A) Schematic diagram showing the applied distortion from sqp to tbp through a modification of the indicated bond angles and distances. (B) Walsh diagram showing the energy as function of angle (step 2–4) and bond (step 5–6) variations (step 1: initial idealized parallel bases; step 2, 3 and 4, $\alpha_a = 15$, 30 and 45°, respectively; step 4, 5 and 6 Cu–Cl bond distance 2.7, 2.5 and 2.3 respectively). (C) Drawing of HOMO and LUMO frontier orbitals obtained in step 6.

try for the Cu metal center. As in the previous case, the d_{Cu} metal orbitals involved change from type to, and some overlap between each bridging Cl and both Cu metal centers is observed. In sharp contrast with the previous case, an important increase of the gap takes place here. As shown in Fig. 3(B), this is mainly due to the angular variation (step 2–4) since upon decreasing bond distances (step 5 and 6) both

frontier orbitals increase in energy, but in similar magnitudes.

The second distortion described consisted, first, on the modification of bond angles for terminal ligands, reaching 120° (see Fig. 4, steps 2–3), and then increasing Cu–Cl bond distances (steps 5–6). The final step of this distorsion was a tbp type of geometry, frequently observed in real cases. The angular alteration produced a strong increase on the gap, which was then progressively decreased as the distances were elongated. Nevertheless, the final geometry still possesses a much higher gap than the initial. Again, the d_{Cu} metal orbitals involved change from $d_{x^2-y^2}$ type to d_{z^2}, and an effective overlap is observed between the two Cu metal centers through both the bridging chlorines.

It is worth mentioning that in the present case, the two distortions described produce a substantial increase in the energy gap with regard to the ideal model.

3.2.3. Perpendicular bases

The first distortion studied in this case involved the variation of the Cu–Cl–Cu bond angle for the apical bridging chloro ligand, maintaining the rest of the structural parameters constant except, obviously, the Cu–Cl(apical) bond distance. Upon applying this variation the gap remains constant, in agreement with the fact that the orbitals belonging to this ligand do not participate in the frontier orbitals (see Fig. 1(C)).

A second variation consisted on the same type of distortion, but now applied to the Cu–Cl(basal) bond angle (see Fig. 5). In this case, a direct relationship between the bond angle and the energy gap was found. That is, as the angle decreases (from 94.18 to 86.10), the energy gap increases, nearly linearly, from 0.045 to 0.140 eV (see Walsh diagram in Fig. 5(B)).

A third distortion consisting on synchronized variation of both apical and basal Cu–Cl–Cu bond angles gave the same results as in the previous case, as expected.

3.3. Magneto-structural correlations

Structural and magnetic data for a series of dinuclear dichlorobridged copper complexes are presented in Table 1. As can be observed, either ferromagnetic or antiferromagnetic coupling can be found for real compounds. Those of PAR type of geometry present, in general, smaller values of $\Delta E_{S\text{-}T}$ than the coplanar bases geometry dimers.

Two different type of correlations between structure and magnetic properties for dichlorobridged copper dimers can be found in the literature. One of them relates the magnetic interaction to α/R (Fig. 6(A)) [51], where α represents the Cu–Cl–Cu angle, and the second one finds a dependence of $\Delta E_{S\text{-}T}$ on the angle α (Fig. 6(B)) [52]. In both cases, it can be noticed that the majority of complexes are situated along two different lines. Therefore, there are no simple structural parameters that can correlate structure and magnetic properties. A closer examination of the graphs reveals that complexes with the same type of geometry are gathered

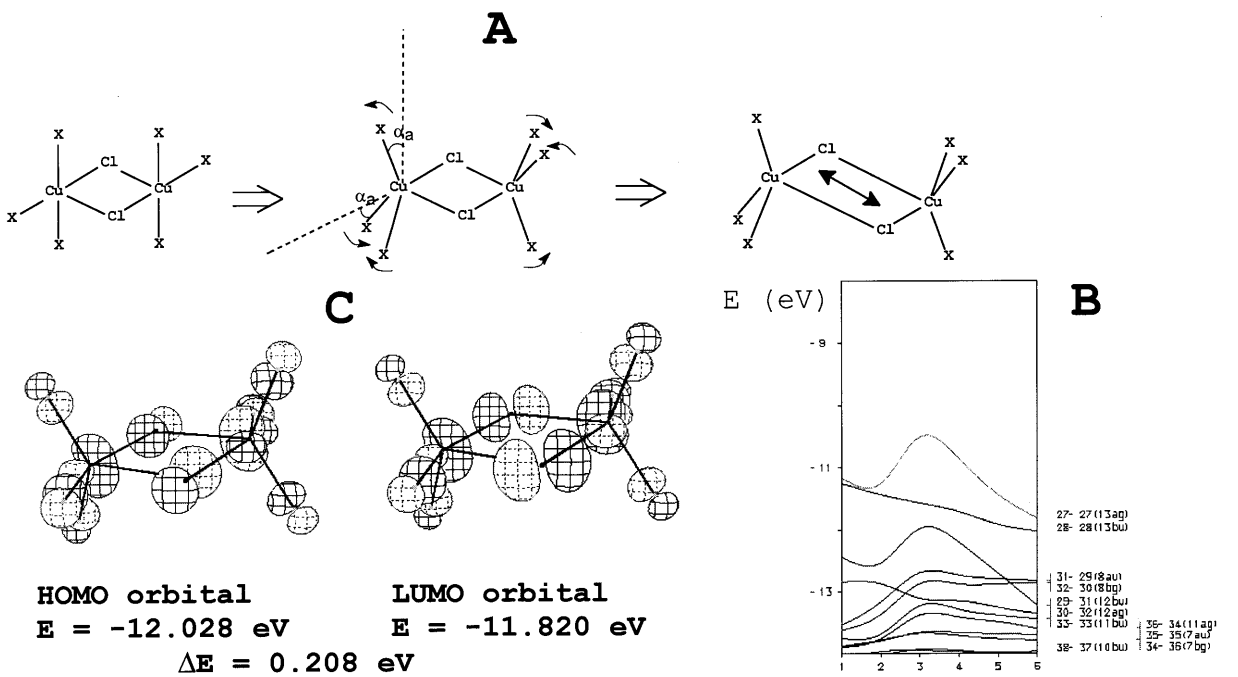

Fig. 4. Distortion from the parallel bases ideal model II. (A) Schematic diagram showing the applied distortion from sqp through a modification of the indicated bond angles and distances. (B) Walsh diagram showing the energy as function of angle (step 2–3) and bond (step 4–6) variations (step 1: initial idealized parallel bases; step 2 and 3, $\alpha_a = 15$ and 30°, respectively; step 3, 4, 5 and 6 Cu–Cl bond distance 2.51, 2.60, 2,8 and 3.04, respectively). (C) Drawing of HOMO and LUMO frontier orbitals obtained in step 6.

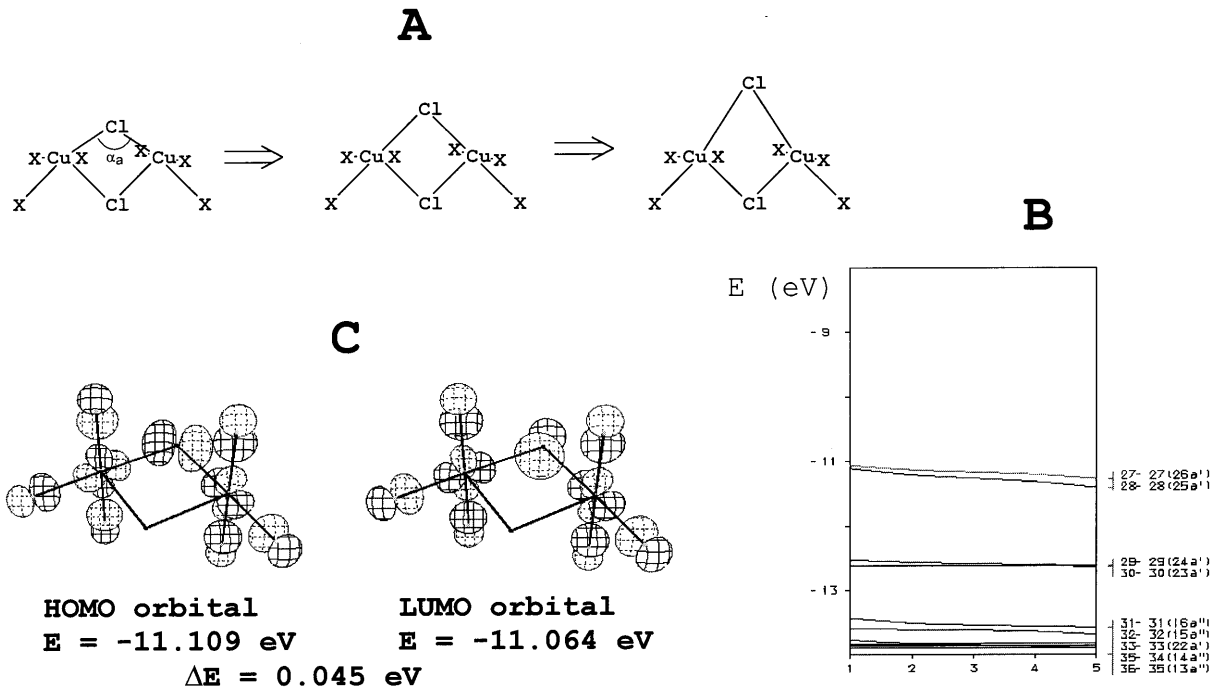

Fig. 5. Distortion from the perpendicular bases ideal model. (A) Schematic diagram showing the applied distortion through a modification of the indicated bond angle. (B) Walsh diagram showing the energy as function of the α_a angle (step 3: initial idealized perpendicular bases; step 1, 2, 4 and 5, $\alpha_a = 94.18$, 91.47, 88.56, and 86.10°, respectively). (C) Drawing of HOMO and LUMO frontier orbitals obtained in step 1.

close to straight lines, and that complex $[Cu_2(dpt)_2Cl_2]Cl_2$ (**34**) [25], which is the only one with perpendicular bases arrangement, is not placed close to any of the previous lines. The line that fits the magnetic behavior of complexes with a coplanar bases type of geometry (graph in Fig. 6(A)) has a slope of -95.54 $cm^{-1}/(°/Å)$ and an intercept at 41.56°/Å. In the graph in Fig. 6(B), the corresponding straight line has a slope of -48.65 $cm^{-1}/°$ and the intercept at 95.1°.

For this geometry, the modification of the Cu–Cl–Cu bond angle, either above or below 90°, produces a significant increment of the gap (see Section 3.2.1). Since all complexes reported to date, and belonging to this type of symmetry, have Cu–Cl–Cu bond angles higher than 90°, it follows that the higher the Cu–Cl–Cu bond angle the more antiferromagnetic character, which is actually what is found experimentally (see Fig. 6(B)) [52].

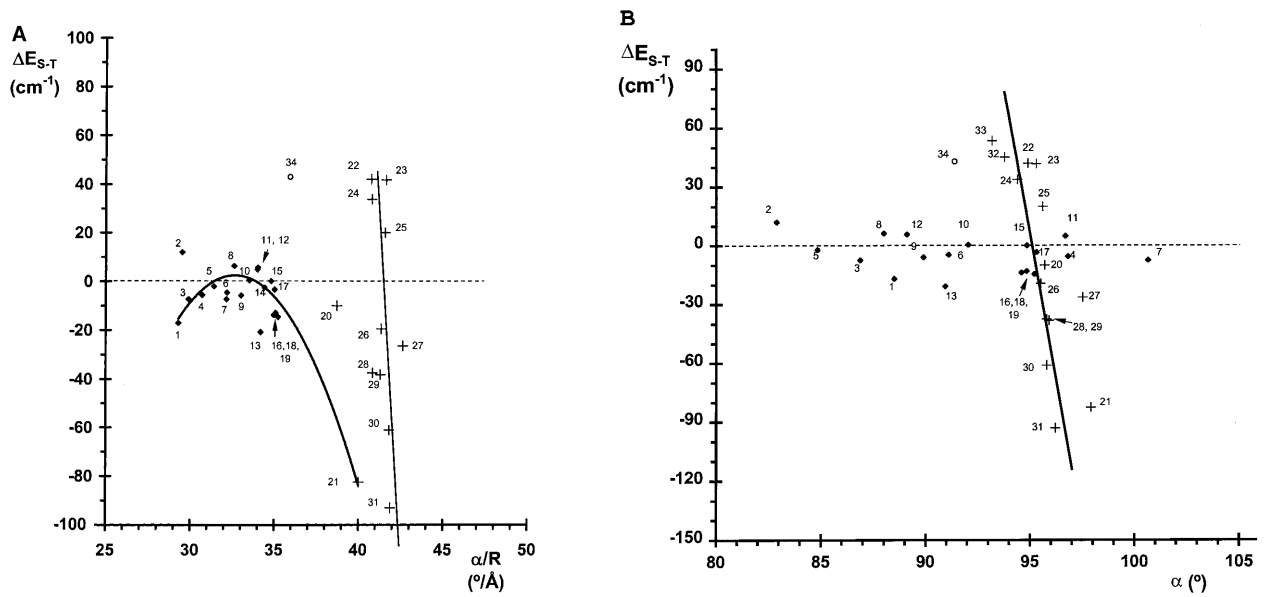

Fig. 6. Magneto-structural correlations: (A) $\Delta E_{S\text{-}T}$ (cm^{-1}) versus α/R (°/Å) and (B) $\Delta E_{S\text{-}T}$ (cm^{-1}) versus α (°) for $Cu(\mu\text{-}Cl)_2Cu$ dimers.

In sharp contrast, for this arrangement, a change of the local copper geometry from sqp by tbp practically does not change the gap. As a consequence of this, complexes **21**, **22**, **23**, **25** and **27**, bearing coplanar bases type of geometry, deviate from the established linearity (see Fig. 6(B)) basically due to the type of distortion depicted in Fig. 2(A), which involves a deviation, from their original position, of the apical ligand (with a σ_a angle) and of one of the terminal basal ligands (with a σ_b angle), leading to a tbp type of geometry around each copper atom. The complexes undergoing this type of distortion show an enhancement of the forecasted ferromagnetic character, then being placed on the right side of the straight line in Fig. 6(B). This is in agreement with the overlap theory proposed by Khan [54,55] in which this type of distortion is responsible for the increase of the effective Cu–Cl–Cu orbital overlap (the apical ligands also contribute to the HOMO and LUMO orbitals, see Fig. 2(B)) and, as a consequence, of the ferromagnetic contribution to the coupling constant *J*.

EH calculations for the ideal parallel bases type of geometry (Fig. 1(B)) show that the magnetic interaction between the copper metal centers will take place mainly through a π* type of interaction between the Cu $d_{x^2-y^2}$ and the apical p_{Cl} orbitals. Therefore in this geometry very small magnetic coupling constants (*J*) are expected which again is consistent with the experimental values listed in Table 1. What is interesting in this case, is that small geometric deviations produce large gaps as shown in Fig. 3 and Fig. 4. As a consequence of those two effects, the complexes adopting this type of symmetry are randomly scattered close to the *x* axis. Complex **21** [53], was originally assigned as forming part of the correlation followed by the compounds marked with rhombus in Fig. 6(A) [51].The fact that this complex in both graphs (Fig. 6(A and B)) is aligned close to the complexes with the coplanar type of geometry demands a reexamination of its geometrical classification. Indeed, a careful inspection of its structural parameters combined with its magnetic properties clearly shows that it is much better defined as having a coplanar bases type of geometry with a slight distortion of the local Cu geometry towards tpb. This result invalidates the empirical magnetostructural correlation proposed early by Hatfield and coworkers [51]. It is also worth mentioning that complexes **1**, **13**, **16**, **18** and **19,** which also belong to the parallel bases type of geometry, are the ones situated farther from the *x*-axis. This is due to the presence of other coordinating atoms than N, whose overall effect is an increase of the antiferromagnetic character.

Up to now there is only one fully characterized complex that presents the perpendicular bases type of geometrical arrangement [25]. For this complex, as mentioned in a previous section, only orbitals of the basal Cl bridging ligand participate in frontier orbitals. Thus from a magnetic point of view the system can be described as having only one bridging ligand. However the apical Cl has a key role in overcoming the steric hindrance leading to a $Cu–Cl_{(basal)}–Cu$ bond angle of only 91.4°. For a monobridged core the Cu–Cl–Cu bond angle would be much higher due to steric repulsions and therefore this would substantially change magnetic properties. As a result of this low angle, the overlap between $d_{Cu} - p_{Cl(basal)} - d_{Cu}$ is very similar for both frontier orbitals thus yielding relatively close energies. This similarity of energies for the HOMO and LUMO orbitals is in turn consistent with the experimental ferromagnetic behavior displayed by the complex.

In contrast with the coplanar bases type of symmetry, here the decrease of the $Cu–Cl_{(basal)}–Cu$ angle from 94.18 to 86.10° produces a nearly linear increase of the gap. Therefore if more complexes existed with this type of symmetry, this theoretical analysis would predict a very good magneto-structural correlation with the $Cu–Cl_{(basal)}–Cu$ angle.

As a summary, complexes bearing the $Cu(\mu\text{-}Cl)_2Cu$ core need to be classified in terms of their relative arrangement of square pyramids into coplanar, parallel and perpendicular bases. EH calculations indicate that in each case a completely different type of orbitals is involved in their respective frontier orbitals. Distortions from ideal models provides understanding of the different structural parameters that influence the energy gap between frontier orbitals and therefore allows to forecast the behavior of their magnetic properties.

Activity coefficients of 3:3 electrolytes in aqueous solutions

Francesco Malatesta *, Sara Trombella, Ambrogio Giacomelli, Massimo Onor

Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via Risorgimento 35, 56126 Pisa, Italy

Dedicated to the memory of Professor Sergio Cabani.

Abstract

Activity coefficients of 3:3 electrolytes have not been liable to determination until 1994, when one of the authors devised a new type potentiometric cell able to trace $La[Fe(CN)_6]$ down to about 5×10^{-6} mol kg^{-1}. $La[Co(CN)_6]$, $[Co(en)_3][Co(CN)_6]$, and $[Co(en)_3][Fe(CN)_6]$, are now studied by the same method. Like $La[Fe(CN)_6]$, these electrolytes display in the dilute regions large negative deviations from the limiting slope instead of the moderate positive deviations predicted by the Debye–Hückel theory. Although the negative deviations can be easily interpreted in terms of only a partial dissociation, one should not conclude that the 3:3 salts are only sparingly dissociated. Theoretical calculations are presented, showing how long-range interactions, in a population of non associated $+3$ and -3 charged spheres, are able to produce effects that simulate the behaviour of a weak electrolyte. Preliminary information is provided of an unexplored method, here devised, to determine the mean activity coefficients in mixed electrolyte solutions. © 2000 Elsevier Science B.V. 1. Introduction

About 1 century since Lewis' concept of the activity coefficient [1] and 76 years since the Debye–Hückel theory [2], experimental and theoretical information regarding 3:3 electrolytes is still lacking. Only in the last few years have potentiometric cells suitable for such salts and for the high dilution levels required become available [3–11], and only $La[Fe(CN)_6]$ has been studied appropriately [6]. Owing to the paucity of experimental data, essentially all restricted to $La[Fe(CN)_6]$, theoretical treatments have not been able to reach ultimate conclusions either. For instance, the conductivity data for $La[Fe(CN)_6]$ have long been interpreted as evidence of a significant association of the electrolyte, comparable to formic acid [12]; conversely, the activity coefficients recently determined with the method of the liquid membrane cells [6] have proved identical to those expected for a theoretical model of charged spheres free from any association, the so-called 'primitive' model [6,7]. (The only partial dissociation of $La[Fe(CN)_6]$ evidenced from the conductivity data relies on a theoretical framework that is incorrect for high-charge electrolytes).

As no general value can be obtained from $La[Fe(CN)_6]$ alone, three more salts of the same 3:3 type, lanthanum hexacyanocobaltate(III), tris(ethylenediamine)cobalt(III) hexacyanocobaltate(III), and tris(ethylenediamine)cobalt(III) hexacyanoferrate(III) are now examined. These salts are sparingly soluble, e.g. $[Co(en)_3][Fe(CN)_6]$ does not reach 5×10^{-4} mol kg^{-1}, but this does not represent a problem, as the liquid membrane cells in many electrolytes are able to provide stable and reproducible emf values down to 1×10^{-5} mol kg^{-1} and less. Moreover, a later reported thermodynamic relationship (Eq. (3)), allows us to derive the values of the activity coefficients of a 3:3 electrolyte from the corresponding relative activity coefficients, regardless of the ability of directly performing extrapolation to zero for the 3:3 electrolyte.

2. Experimental

2.1. Apparatus

The fundamentals of the method, cell design, and instrumentation, are the same as in the previous papers [3–9]. The cells used in the present study, are

$$Ag,\ AgCl\ |\ KCl(m_0)\ |\ K^+\ |\ K_3X(m_1)\ |\ X^{3-}\ |\ AX(test;\ m)\ |\ A^{3+}\ |\ ACl_3(m_2)\ |\ AgCl,\ Ag \quad \text{(cell 1)}$$

for the 3:3 salts (AX), and

$$Ag,\ AgCl\ |\ KCl(m_3)\ |\ Cl^-\ |\ ACl_3(test;\ m)\ |\ A^{3+}\ |\ ACl_3(m_2)\ |\ AgCl,\ Ag \quad \text{(cell 2)}$$

$$Ag,\ AgCl\ |\ KCl(m_0)\ |\ K^+\ |\ K_3X(m_1)\ |\ X^{3-}\ |\ K_3X\ (test;\ m)\ |\ K^+\ |\ KCl(m_2)\ |\ AgCl,\ Ag \quad \text{(cell 3)}$$

$$Ag,\ AgCl\ |\ KCl(m_3)\ |\ Cl^-\ |\ KCl(test;\ m)\ |\ K^+\ |\ KCl(m_2)\ |\ AgCl,\ Ag \quad \text{(cell 4)}$$

for the auxiliary salts ACl_3, K_3X, and KCl. Cells of very similar structure have been described elsewhere, including the recent assemblage details [6,9]. Briefly, sections $|K^+|$, $|X^{3-}|$, etc. indicate the organic phases (the 'membranes') able to interchange the corresponding ions (but no ions of opposite sign) with the neighbouring aqueous solutions. $|K^+|$ and $|A^{3+}|$ are composed of the salts KTFPB and $A(TFPB)_3$ dissolved in 2-nitrophenyl octyl ether, $|X^{3-}|$ of the liquid salts $(TDA)_3Fe(CN)_6$ or $(TDA)_3[Co(CN)_6]$, without solvent, and $|Cl^-|$ of TDACl dissolved in 3,4-dichlorotoluene. $TFPB^-$ stands for *tetrakis*[3,5-bis(trifluoromethyl)-phenyl] borate anion, $(C_8H_3F_6)_4B^-$, and TDA^+ for tetradodecylammonium cation, $(C_{12}H_{23})_4N^+$. The two chains of phases (Ag, AgCl, the aqueous solutions, and the membranes) lying on the left and on the right of the test solution (test; m) are assembled in two PTFE hallow cylinders, to form two composite electrodes, for the anion (shown in Fig. 1) and the cation. These electrodes are dipped in a larger vessel, also made of PTFE, containing the test solution (approximately 15 cm^3). A small magnetic bar (approximately 5×2 mm, usually at a rotation rate of approximately 1–3 rps), ensures moderate stirring conditions. The entire assembly is contained in an air bath thermostat at 25.00 ± 0.02°C. In order to monitor the temperature a platinum resistance thermometer (± 0.001 K) is used.

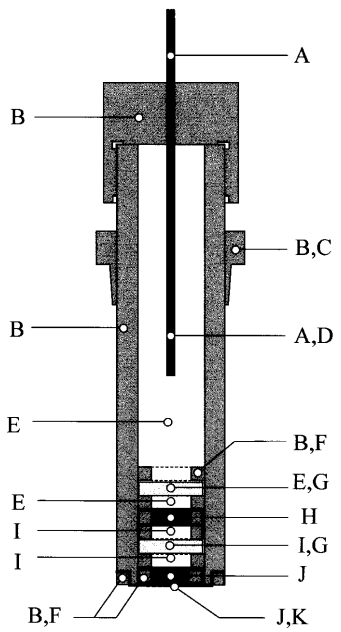

Fig. 1. Diagram of the anion responsive electrode: A = silver; B = PTFE; C = sliding ring; D = silver chloride; E = KCl solution (m_0); F = pressing ring; G = fritted glass; H = $|K^+|$, the potassium-exchange liquid membrane (17% KTFPB in NPOE); I = K_3X solution (m_1); J = $|X^{3-}|$, the anion-exchange liquid membrane, $(TDA)_3[Co(CN)_6]$ or $(TDA)_3[Fe(CN)_6]$ as appropriate; K = one of the four sheets of porous PTFE which bracket the two liquid membranes.

Emf measurements were performed using a Digital Adret Electronique 103A DC-current and voltage standard as supplier for potentials (± 0.001 mV) and a Keithley 614 electrometer (input impedance $> 10^{14}$ Ω) as null point (± 0.01 mV) detector. The measurements take ca. 90 min per solution, 60 of which as waiting time, and 30 for the emf readings — one every five min, whose average values and standard deviations are reported in the tables of the experimental results.

2.2. Reagents

Preparation and purification of the membrane salts KTFPB, $[Co(en)_3](TFPB)_3$, $La(TFPB)_3$, TDACl, $(TDA)_3[Fe(CN)_6]$, and $(TDA)_3[Co(CN)_6]$, are described elsewhere [3–5,11]. The salts KCl, $LaCl_3 \cdot nH_2O$ ($n \cong 7$), $[Co(en)_3]Cl_3$, $K_3[Fe(CN)_6]$, and $K_3[Co(CN)_6]$, were all derived from stocks of purified salts used in previous works [3–6,11,13]. $La[Co(CN)_6]$, $[Co(en)_3][Co(CN)_6]$, and $[Co(en)_3][Fe(CN)_6]$ were obtained by metathesis from $LaCl_3$ or $[Co(en)_3]Cl_3$, and $K_3[Co(CN)_6]$ or $K_3[Fe(CN)_6]$, as appropriate. While $La[Co(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$ were of good quality, crude $[Co(en)_3][Fe(CN)_6]$ contained considerable amounts of potassium ions, and required leaching, and prolonged digestion in hot water, and later in cold water, under stirring conditions (some soluble unidentified red compounds were formed during digestion in hot water). The resulting salt was free of potassium, and the UV–Vis spectra of its solutions (λ range, 200–550 nm) coincided with the sum of $K_3[Fe(CN)_6]$ and $[Co(en)_3]Cl_3$.

$La[Co(CN)_6]$, $[Co(en)_3][Co(CN)_6]$, and $[Co(en)_3][Fe(CN)_6]$ were analyzed for water content by acidimetric titration, via cation exchange (Dowex $50w \times 8$ resin in the hydrogen form) dropping the resulting acid on a weighed excess of Na_2CO_3, then back-titrating (to the potentiometric end-point in the

case of $H_3[Fe(CN)_6]$) with standard HCl. The same method was also applied to lanthanum chloride. The resulting molecular weights were, respectively, 425.9 ± 1.9 (theoretical, 426.00 for $La[Co(CN)_6]\cdot 4H_2O$), 473.2 ± 1.5 (theoretical, 472.29 for $[Co(en)_3][Co(CN)_6]\cdot H_2O$), and 481.3 ± 3.5 (intermediary between 469.20, theoretical for $[Co(en)_3][Fe(CN)_6]\cdot H_2O$, and 487.21, theoretical for $[Co(en)_3][Fe(CN)_6]\cdot 2H_2O$; 1.67 ± 0.02 mol of water per mol of salt on average). For verification, $[Co(en)_3][Co(CN)_6]$ and $[Co(en)_3][Fe(CN)_6]$ were oven heated at reduced pressure (10–20 mbar). Significant weight losses were observed between 50 and 80°C, and were consistent with 1 mol of water (1.08 ± 0.12) per mol of salt for $[Co(en)_3][Co(CN)_6]$, and 1.6–1.7 (1.63 ± 0.09) for $[Co(en)_3][Fe(CN)_6]$. For $La[Co(CN)_6]$, the check analyses were performed by precipitation as oxalate and determination as La_2O_3; once again, the results were consistent with 4 (3.8 ± 0.3) mol of water per mol of salt.

All solutions were prepared by weight, from the salts or the corresponding standardized solutions as appropriate.

2.3. Principles and procedures

In the absence of interfering amounts of foreign ions able to enter the membranes, the emf values of cells such as cells 1–4 obey the relationship (Eq. (1)) [3,10]:

$$E = E^* + [(v_+ + v_-)/(z_+ v_+ F)]RT \ln m\gamma_{\pm\,\mathrm{dir}} \quad (1)$$

where z_+ is the charge of the cation, v_+ and v_- the number of cations and anions in the electrolyte, and (Eq. (2)) [10]:

$$\ln \gamma_{\pm\,\mathrm{dir}} = \ln \gamma_\pm + [w/(v_+ + v_-)] \ln a_1 \quad (2)$$

where a_1 is the activity of water in the test solutions and w the number of water molecules that follow one 'molecule' of the electrolyte when its ions leave the test solution and enter the neighboring membranes. In this respect, La^{3+} carries 12 molecules of water when entering the membrane [5]. $[Co(en)_3]^{3+}$, $[Co(CN)_6]^{3-}$ and $[Fe(CN)_6]^{3-}$ are, expectedly, nonhydrated. The difference between $\ln \gamma_\pm$ and $\ln \gamma_{\pm\,\mathrm{dir}}$ can generally be neglected if $m < 0.01$ mol kg^{-1}. E^* depends on the choice for m_0, m_1, etc. inside the invariant sections of the cell (the 'electrodes'), and also includes the numeric constant allowing for the fact that we use m instead of $m_\pm$ in Eq. (1).

Like $E°$ for classic cells without transport, E^* is generally identified by an extrapolation to ionic strength zero, with the aid of a 'guideline' like the Debye–Hückel theory (DHT), Bjerrum's ion-pair theory, etc. No problems are generally encountered for 1:1, 1:2 and 1:3 electrolytes, as the different guidelines lead to the same extrapolation values, when applied to the very diluted solutions permitted by the liquid membrane cells. Unfortunately, the diluted solutions of the 2:2, 2:3, and 3:3 electrolytes deviate from the limiting slope in the 'wrong' (in terms of DHT) direction. Bjerrum's ion-pair theory, Mayer's theory, and the numerical accurate integration of the Poisson–Boltzmann equation (IPBE), which imply (like DHT) a single adjustable parameter a, predict these reverted deviations, and prove reliable for the 2:2 and 2:3 electrolytes [8,9,11,13]. However, for a 3:3 electrolyte, even starting from a dilution level beyond 10^{-5} mol kg^{-1}, the extrapolation process may be critical. Thus, a different method able to by-pass the extrapolation problem is used [5]. Cells 1–4 correspond to alternate ways of assembling the same set of four electrodes and four solutions, and a useful thermodynamic relationship (Eq. (3)) links their E^* values [5]:

$$E^*(AX) = E^*(ACl_3) + E^*(K_3X) - E^*(KCl) - RTF^{-1} \ln 9 \quad (3)$$

Eq. (3) makes it possible to calculate the unknown value E^* of the 3:3 salt as a combination of those of much easier determination, of two 1:3 and one 1:1 auxiliary salts. There is no need for any new extrapolation for ACl_3, K_3X, and KCl, as their activity coefficients are already known [3–6,11,14–17]. Thus, four emf measurements at a known concentration, for AX, ACl_3, K_3X and KCl, can suffice to obtain $E^*(AX)$. As the value of E^* is liable to change, the relevant information is more conveniently stored in the form of the value of the activity coefficient, $\gamma_{\pm\,\mathrm{ref}}$, of a reference solution.

3. Results and discussion

The activity coefficient values that Eq. (3) yields, are $\ln \gamma_{\pm\,\mathrm{ref}} = -1.241 \pm 0.015$ for 1.000×10^{-3} m $La[Co(CN)_6]$, -1.515 ± 0.014 for 4.048×10^{-4} m $[Co(en)_3][Co(CN)_6]$, and -1.301 ± 0.015 for 2.242×10^{-4} m $[Co(en)_3][Fe(CN)_6]$. In turn, these values rely on $\ln \gamma_{\pm\,\mathrm{ref}} = -0.242$ (± 0.004 estimated) for 1.000×10^{-3} m $LaCl_3$ [5,14], -0.345 ± 0.003 for 2.000×10^{-3} m $K_3[Co(CN)_6]$ [11,15], -0.257 (± 0.004 estimated) for 1.000×10^{-3} m $[Co(en)_3]Cl_3$ [4,16], -0.265 (± 0.004 estimated) for 1.000×10^{-3} m $K_3[Fe(CN)_6]$ [6], and -0.0357 ± 0.0003 for 1.000×10^{-3} m KCl [3,17]. The ranges of uncertainty of the 3:3 salts are those of the auxiliary salts, combined with the variance of $E^*(AX)$ (three to four sequential runs for cell 1 and cell 4 alternate to cell 2 and cell 3). Should some correction be needed by any of the component salts, let us consider that a shift $\Delta \ln \gamma_\pm$ for the 1:3 (1:1) salt shifts the 3:3 salt by two (three) times this quantity, in the same direction.

[b] The errors are inclusive of the uncertainty of the reference point.

Tables 1–3 report the experimental values for the different solutions of the 3:3 salts. The measurements are divided into different series, any of which starts, and terminates, in the reference solution. When reloading the cell, leaching effects occur at membrane surfaces, and may cause shifts, that summate along the series (relaxation is slow). To counterbalance the effect, the calculation of the relative activity coefficients, via Eq. (1), rely on E_{ref} values that are estimated by interpolation, between the extreme values of the series.

The trend of the activity coefficients (including $La[Fe(CN)_6]$ [6] for comparison) is shown in Fig. 2. There are no appreciable differences between $[Co(CN)_6]^{3-}$ and $[Fe(CN)_6]^{3-}$, but $[Co(en)_3]^{3+}$ differs very much from La^{3+}. The activity coefficients display the characteristic negative deviations from the limiting law (i.e. opposite in direction to predicted by DHT), typical of the high charge electrolytes, whose interpretation is often given in terms of ion association. The ion–ion cloud electrostatic interactions are also capable of causing the same effects. For 2:2, 2:3, and 3:3 electrolytes, DHT fails to reproduce the primitive model even in the sign of the second derivative of $\ln \gamma_{\pm}$ in the origin. Under these conditions, the behaviour of the primitive model can only be guessed from the predictions of other approximations of a higher level. The Mayer theory [18], and IPBE [19,20], are possible examples. Even Bjerrum's theory of ion pairs is to be considered as an approximate treatment of the primitive model, as the fictitious 'ion pair' is a short-cut to avoid the untraceable problem of the radial distribution functions in the closer neighbourhood of an ion, not an

[a] The range of uncertainty is inclusive of the uncertainty of the reference point.

additional chemical species [21]. All these treatments agree, qualitatively, on the occurrence of negative deviations in the dilute solutions of the high charge electrolytes.

From a quantitative point of view, the Mayer theory found unsatisfactory for $La[Fe(CN)_6]$ [3,7] for $m > 10^{-3}$ mol kg^{-1} (a consideration that extends to the practically identical $La[Co(CN)_6]$), is totally unfit for

$[Co(en)_3][Co(CN)_6]$ and $[Co(en)_3][Fe(CN)_6]$. Clearly, with these extreme salts the truncation of the cluster series [22] causes a much earlier failure than usual. Conversely, IPBE and the Bjerrum theory of the ion pair maintain an astounding ability to trace the experimental curves (Fig. 3). Except for the extreme dilution levels (where H^+, OH^-, and the ions released by the membranes cause increasing interference) the IPBE approximation, for a around 0.46 nm for $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$, and 0.66 nm for $La[Fe(CN)_6]$ and $La[Co(CN)_6]$, agrees with the activity coefficients of the actual salts, approximately within the experimental error. The same observations apply to Bjerrum's theory, excluding the slightly different values requested for a. Once allowance has been made for the ion-cloud electrostatic interactions, even the impressive negative deviations displayed by $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$ do not require any additional hypothesis such as ion association.

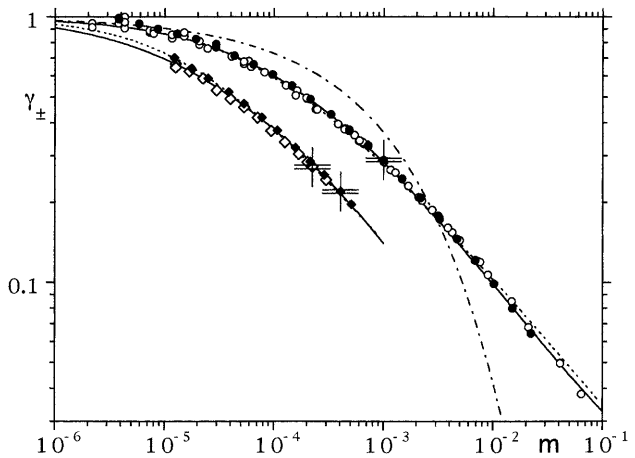

Fig. 2. Activity coefficients of $[Co(en)_3][Co(CN)_6]$ (◆), $[Co(en)_3][Fe(CN)_6]$ (◇), $La[Co(CN)_6]$ (●), and $La[Fe(CN)_6]$ (from Ref. [6]; ○), as a function of molality, compared with the Debye–Hückel limiting law (– · – · –), IPBE (full lines, $a = 0.66$ nm the upper, $a = 0.46$ nm the lower) and Bjerrum theory (dotted lines, $a = 0.67$ nm the upper, $a = 0.51$ nm the lower).

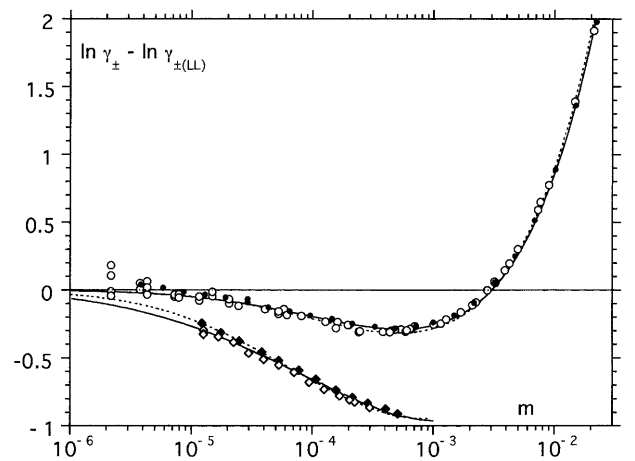

Fig. 3. An expanded view of the deviation of the activity coefficients of the 3:3 salts from the limiting law, in the dilute regions. For comparisons, the trend predicted for the primitive model, according to IPBE and the Bjerrum theory. Symbols as in Fig. 1.

The moderate, residual differences visible in Figs. 2 and 3, at the highest dilutions, between IPBE and the Bjerrum curves for $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$, are derived in part by the calculation (at very high dilution, our IPBE chains [20] lose precision), and in part correspond to a different prediction of the behaviour of the primitive model using the two treatments. We are unable to decide which trend is more correct. As an application of Murphy's laws, around 10^{-5} mol kg^{-1} (where even the experimental results are no longer very accurate) $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$ seem to suggest an IPBE-like and a Bjerrum-like trend respectively, as if the real salts, too, were not aware of the correct trend to be obeyed. Application of improved calculation methods (e.g. those from Outhwaite [23]) will be advisable in the future.

It is worth mentioning that the original Bjerrum treatment assumes $q = z^2e_0/(2\varepsilon kT)$ as the cut-off distance d that discerns between 'free ions' and 'ion pairs'. For a 3:3 electrolyte in water, $q = 3.22$ nm at 298 K; correspondingly, the fictitious association constant of the ion pairs takes the considerable value of 3.9×10^4 for $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$ ($a \approx 0.51$ nm), and of 8.3×10^3 for $La[Co(CN)_6]$ and $La[Fe(CN)_6]$ ($a \approx 0.67$ nm). As Guggenheim noted [24], there are no particularly sound reasons for imposing $d = q$. By choosing a different value for d, the value of the 'association constant', the 'associated' and 'free' ion fractions, and the activity coefficient of the 'free ions' change; however, after the recombination of the contributions of the free ions and ion pairs, the activity coefficients one obtains are found to be substantially unchanged. These considerations also apply to the 'extreme' conditions of the solutions of $[Co(en)_3][Fe(CN)_6]$ and $[Co(en)_3][Co(CN)_6]$; e.g. imposing $d = 5$ nm (instead of 3.22 nm) does not cause appreciable deviation out of the thickness of the relevant curve of Fig. 2, even in the concentration regions where the discrepancies between IPBE and the Bjerrum theory are appreciable. Under these conditions, however, the value of K_{ass} does not vary appreciably either, only from 3.93×10^4 to 4.04×10^4. This narrow range of variation for K_{ass} may suggest the occurrence of ion pairs as real chemical species, but this is an extrapolation of a mathematical concept that takes its origin from a particular way of facing the primitive model, is probably incorrect. As a matter of fact, the UV–Vis spectra of the solutions, measured at approximately 4×10^{-4} mol kg^{-1} (i.e. in a situation where the electrolyte would be about 80% associated) do not evidence any discrepancy from the mathematical sum of the corresponding 1:3 and 3:1 salts.

The a values are appreciably smaller than those expected from the ionic radii of the corresponding ions [25]; i.e. ion–ion interactions are stronger than they should be for a population of spheres of correct size and charge, in a continuum having the same dielectric properties as bulk water. This fact can suggest the actual presence of some association effects. However, it is worth considering that, when the primitive model is used to simulate a real system, the only available parameter, a, is forced to carry all the model deficiencies. In particular, the model counterbalances the effect of the decreased value of the average dielectric constant, in the closer neighbourhoods of an ion, by simulating a lower value for the ion–ion distances. The higher values for a, of the lanthanum salts compared with tris(ethylenediamine) cobalt(III) salts, should be related to the different character of the hydration shells of the corresponding ions (lanthanum, for instance, carries 12 molecules of water [5], while $[Co(en)_3]^{3+}$ does not carry any water [4], when entering the oil phase of the respective membrane).

4. Conclusions

The present study of 3:3 electrolytes provides sound experimental information on a class of salts, whose behaviour has been a mystery for a long time. Together with the 2:3 electrolytes (also unknown before our investigations [2,5,11]), 2:2 electrolytes (whose activity coefficients in literature, now revised, have in some cases been found biased by 10–16% [6,7]), 1:4 electrolytes (still untreated), and also 1:3 and 1:2 electrolytes, whose systematic revision is in progress (systematic errors by 2–6% are possible, for salts explored only in the concentration range covered by the isopiestic measurements), these results intend to provide a solid basis of reliable and precise data, aimed at supporting theoretical treatments. The final goal, however, is to reach a definite insight also in the much more important field of mixed electrolyte solutions, viz. to be able to obtain reliable predictions for chemical equilibrium and kinetics in real situations of practical interest.

Mixed electrolytes are a much harder subject than single electrolytes, not only because of the difficulties involved by theoretical treatments, but, even more, because of the lack of general experimental methods able to validate the theory, determining the real values of the activity coefficients in mixed solutions. The data available are so far limited to: (i) electrolytes liable to be studied with cells without transport (e.g. HCl in the presence of other ionic species); and (ii) saturated solutions of sparingly soluble salts in the presence of other salts. The methods so far available have been reviewed by Harned and Robinson [26]. By connecting a membrane to classic electrodes, only a limited number of further situations have become accessible, e.g. a membrane electrode for M^{n+}, matched to a silver | silver chloride electrode, makes it possible to study MCl_n in the presence of other salts of the same cation. However, the liquid membrane cells, owing to their very nature, are unable to provide a real answer to the problem of mixed solutions [3].

With regard to this problem, we shall now suggest a very simple idea which, like the liquid membrane cells that solve the problem of the single electrolytes, can solve the problem of the mixed electrolyte solutions with a single anion. Let us consider two phases, Mix (composed of an aqueous solution of the electrolytes A_aX_x, B_bX_y, C_cX_z, etc.; X^{t-}, the anion), and Org, a hydrophobic solution (in a hydrocarbon, or some more polar solvent if needed) of a neutral carrier, L for short, insoluble in water. Let L be able to keep selectively A^{s+} rather than the other cations. If the two phases are allowed to reach equilibrium, A^{s+} (but no other cations in appreciable amounts), together with the equivalent quantity of X^{w-}, will exist both in Mix and Org. The chemical potentials will be the same, $\mu(A_aX_x, \text{Mix}) = \mu(A_aX_x, \text{Org})$. In turn, $\mu(A_aX_x, \text{Org})$ can be calibrated by separate experiments, equilibrating Org with a series of solutions of pure A_aX_x in water, where the activities are known or can be determined. All we need is to be able to identify the equilibrium concentration in the various phases with sufficient precision.

Method settlement will require the selection, or synthesis, of suitable neutral carriers. The latter should be: (i) sufficiently insoluble in the aqueous phase (even in the coordinated, ionic, form $[AL]^{s+}$), as it is necessary to leave the number of significant Mix components unchanged; (ii) sufficiently selective, as it is needed to leave $\mu(A_aX_x, \text{Org})$ the same, as it would be in the complete lack of other salts dissolved in Org; (iii) not so strong, as to yield $[AL]^{s+}$ quantitatively, independently of the activity of A_aX_x in the aqueous phase. Unfortunately, there seems to be no realistic possibilities of also finding the required features in a ligand for anions; otherwise, the limitation of the presence of a single anion would cease.

As far as we know, nobody has so far utilized or even devised this route. There is no doubt that solving the practical difficulties implied by the method is no simple matter; nevertheless, a difficult track is better than no track at all, and the obvious importance of the activity coefficients in mixed electrolyte solutions could justify the efforts.

Synthesis and ligational properties of a new tetra-azamacrocycle containing an anisolic function

Mauro Formica, Vieri Fusi* [1], Mauro Micheloni* [2], Roberto Pontellini, Paolo Romani

Institute of Chemical Sciences, University of Urbino, P.za Rinascimento 6, I-61029 Urbino, Italy

Abstract

The synthesis and characterization of the new tetra-azamacrocycle 1,4,7,10-tetraaza[12]-(2,6)anisolephane (**L**) are reported. The stepwise basicity constants were determined using potentiometric (0.15 mol dm^{-3} NMe_4Cl, 298 ± 0.1 K) and NMR (^1H and ^{13}C) techniques. **L** behaves as a tetraprotic base: $\log K_1 = 9.62$; $\log K_2 = 9.03$; $\log K_3 = 5.44$; $\log K_4 = 1.9$. NMR experiments allowed the determination of the protonation sequence. The influence of the anisolic group inside the macrocyclic cavity upon the basicity behaviour is discussed. The equilibrium constants of the species formed by **L** with Co(II), Cu(II), Zn(II), Cd(II) and Pb(II) are reported and discussed. The formation constants for the oxygenated species $[CoLO_2]^{2+}$, $[CoLHO_2]^{3+}$ and $[CoL(OH)O_2]^{+}$ are: $\log K = 7.6(1)$, 15.8(1) and −1.3(1), respectively. © 2000 Elsevier Science B.V. Keywords: Macrocycles; Synthesis; Complexes; Equilibria

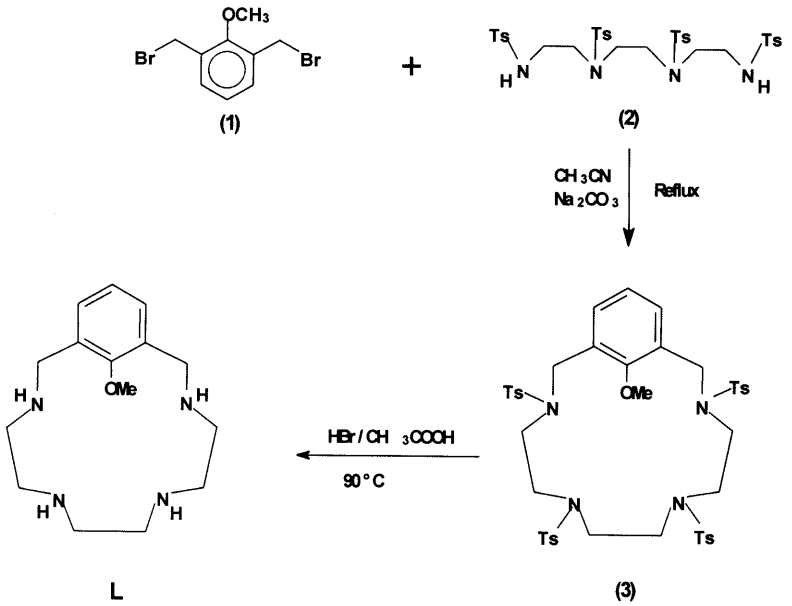
1. Introduction

Synthetic macrocycles are a growing class of compounds with varying chemistry, a wide range of different molecular topologies and sets of donor atoms [1–10]. The chemical properties of macrocyclic complexes can be tuned to force metal ions to adopt unusual coordination geometry.

In the present study, a new aza-macrocycle containing the anisolic function, which can be seen as precursor of the phenolic fragment, was synthesized. The crowding of its macrocyclic cavity together with the low number of coordination sites available allows this ligand to form metal complexes without saturating the coordination request of the metal centre. The acid–base behaviour of the ligand and its coordination properties toward some transition metal ions are reported. In the case of the cobalt(II) complexes the reversible addition of molecular oxygen has been investigated.

2. Results and discussion



2.1. Synthesis

The synthetic pathway used to obtain ligand **L** is depicted in Scheme 1. The reaction employed to obtain the tosylated macrocycle (**3**), a modification of the Richman–Atkins method,[11] involves the cyclization of the tosylated polyamine (**2**) with 1 equiv. of the 2,6-bis(bromomethyl)anisole (**1**), in the presence of an alkaline carbonate base. The pure product, derived using a 1 + 1 cyclization scheme, is easily reached by recrystallization from CH_3CN. Finally, by treating (**3**) with a mixture of $HBr–CH_3COOH$ and phenol it is possible to selectively remove the tosyl groups, obtaining the macrocycle **L** in good yield as tetrahydrobromide salt. It should be noted that this synthetic procedure is a promising route by which to produce other azamacrocycles containing the anisole function by substitution of (**2**) with tosylated open-chain polyamine compounds. Moreover, after removal of the ethereal methyl group of the anisole, compound **L** can give a new aza-macrocycle having the phenol group as coordinating and optical sensor group.

2.2. Solution studies

2.2.1. Protonation of *L*

The protonation equilibria of **L** were studied in a 0.15 mol dm^{-3} NMe_4Cl aqueous solution at 298 ± 0.1 K by means of potentiometric pH ($-\log[H^+]$) measurements; the results are reported in Table 1. Compound **L** binds up to four protons in aqueous solution in the pH range 2–11 investigated. The equilibrium constants of the first two protonation steps are very similar, with $\log K_2$ only slightly smaller than $\log K_1$ (see Table 1). This is a clear indication that the two protonation sites do not influence each other significantly. Another characteristic of the basicity behaviour of **L** is that the values themselves of $\log K_1 = 9.62$ and $\log K_2 = 9.03$, are very low compared with those of tetra-azamacrocycles not having any group inside the macrocyclic cavity [12]. These results indicate that the presence of the bulky anisolic group strongly influences the first two protonation sites of **L**, isolating them and preventing the formation of the hydrogen bond network which usually stabilizes the protonated species in tetra-azamacrocycles [12]. As expected, in the third protonation step the basicity of **L** is significantly reduced: $\log K_3 = 5.44$ (see Table 1); this reduction in basicity can be explained by the electrostatic repulsion between positively charged nitrogen atoms, which is even more marked in the last protonation step where four positive charges are forced to stay close each other.

Further information on the protonation mechanism of **L** was obtained by recording ^1H and ^{13}C NMR spectra in aqueous solution at various pH values. All the peak assignments were made on the basis of ^1H–^1H homonuclear and ^1H–^{13}C heteronuclear correlation experiments at the different pH values studied. The ^{13}C NMR spectrum of **L** at pH 12, where the unprotonated amine predominates in solution, exhibits nine peaks at δ 46.3 ppm attributed to the carbon atoms C3, 47.7 (C1), 48.0 (C2), 48.2 (C4), 62.7 (C9), 125.8 (C8), 132.3 (C7), 134.2 (C5) and 159.8 (C6). The ^1H spectrum at the same pH shows a singlet at 2.41 ppm attributed to the hydrogen atoms of the ethylenic chain H1 integrating four protons, a multiplet at 2.58 (eight protons, the hydrogens of the ethylenic chains H2 and H3 a doublet at 3.53 (two protons, the hydrogens $H4_A$ of the methylenic chain), a singlet at 3.84 (three protons, the hydrogens of the methyl group), a doublet at 4.17 (two protons, the hydrogens $H4_B$ of the methylenic chain), a triplet at 7.21 (one proton, the hydrogen of the aromatic group H8) and a doublet at 7.34 (two protons, the aromatic protons H7). The methylenic chains (H4) in the ^1H spectrum give rise to an AB coupling system ($\nu_A = 4.17$, $\nu_B = 3.53$ ppm, $J_{AB} = 14.1$ Hz). Moreover, the ^{13}C NMR spectrum presents only one resonance for the same group (C4). This aspect is probably due to the bulk of the ethereal methyl group which precludes the

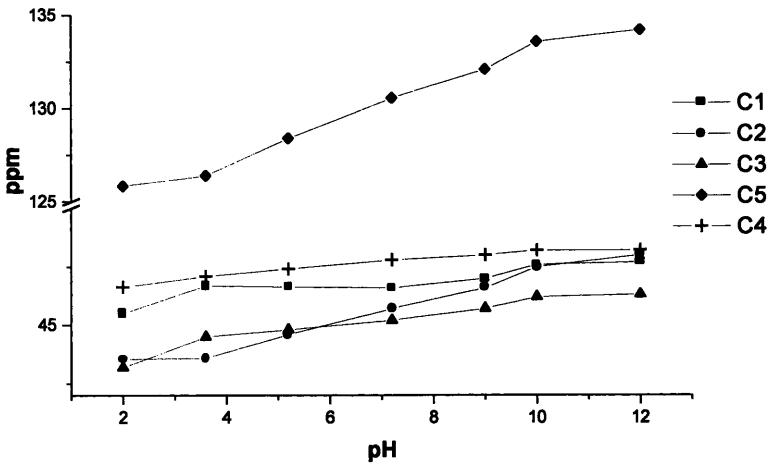

Fig. 2. Experimental ^{1}H NMR chemical shifts of **L** as a function of pH.

free rotation of the aromatic group inside the macrocyclic cavity, giving rise to a C_s time-averaged symmetry which is preserved throughout all the pH range investigated.

Figs. 1 and 2 show, respectively, the most significant ^{1}H and ^{13}C chemical shifts of **L** as a function of pH. In the pH range 7–11, in which two protons bind to the ligand, all the signals of the hydrogen atoms in α position to the nitrogen atoms exhibit a marked downfield shift (Fig. 1). This suggests that all the four nitrogen atoms are involved in the stabilization of the two acidic protons, with the two protons located on alternate nitrogen atoms as expected on the basis of a simple electrostatic model. This hypothesis was confirmed by ^{13}C NMR spectra recorded in the same pH range (Fig. 2), which show the upfield shift of all the resonance of the carbon atoms in β position with respect to the four nitrogen atoms, in good agreement with the β shift reported for protonation of polyamines [13].

In the pH range 3–5, where the triprotonated species are formed, only the hydrogen atoms H3 and H4, in α with respect to the nitrogen atoms in benzylic position, experience a considerable downfield shift, while the other resonances remain unchanged. Moreover, only the carbon signals C2 and C7, in β position with respect to the same nitrogen atoms, show an upfield shift. This suggests that the third protonation step involves only the benzylic nitrogen atom showing a proton disposition such as that depicted in Fig. 3. The fourth protonation step, which occurs only at low pH values, is instead located on the remaining free nitrogen atom.

2.2.2. Metal complexes

Table 2 reports the stability constants of complexed species of **L** with different metal ions. Under the exper-

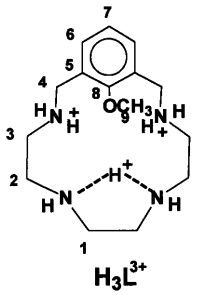

Fig. 3. Atom labelling of **L** and protonation sites for the triprotonted species.

imental conditions investigated, only mononuclear species are formed, which are much less stable than complexes formed with related tetra-azamacrocycles without any group within the macrocyclic cavity [12]. The presence of the hindering anisolic group reduces the ability of the ligand to adapt itself to the stereochemical requirements of the bound metal ion. Even the Cu(II) ion forms a 1:1 complex much less stable ($\log K_{ML} = 14.4$) than those formed with other tetra-azamacrocycles [12]. All of the other metal ions investigated form protonated species $[ML H]^{3+}$; in any case, if we consider the addition of one proton to the mononuclear species $[ML]^{2+}$ to form $[ML H]^{3+}$, the equilibrium constant is always very high (see Table 2) and comparable to that of the protonation of the free ligand (see Table 1). This is a clear indication that the nitrogen atom, which accepts the proton in the metal complex, is at most weakly interacting with the central metal ion. In the case of Co(II) and Zn(II), even the stepwise addition of the second proton to form the diprotonated species $[ML H_2]^{4+}$ (see Table 2) is characterised by a high constant, indicating that very likely a second nitrogen atom is either weakly or not at all involved in binding the metal ion. This situation with the metal ion binding sites not engaged, make the Co(II) complexes able to reversibly bind molecular oxygen. The following equilibria were found: (a) $Co^{2+} + L + O_2 = [CoLO_2]^{2+}$, $\log K = 7.6(1)$; (b) $Co^{2+} + L + H^+ + O_2 = [CoLHO_2]^{3+}$, $\log K = 15.8(1)$; (c) $Co^{2+} + L + O_2 + H_2O = [CoL(OH)O_2]^+ + H^+$, $\log K = -1.3(1)$.

3. Experimental

3.1. Synthesis

Compounds 2,6-bis(bromomethyl)anisole **1** [14] and *N*,*N*′,*N*″,*N*‴-tetrakis(*p*-tolysulphonyl)-3,6-dioctane-1,8-diamine **2** [15] were prepared as reported in the literature. All reactions were carried out in inert atmosphere.

3.1.1. 1,4,7,10-Tetrakis(p-tolylsulphonil)-1,4,7,10-tetraaza[12]-(2,6)anisolephane (3)

Over a period of 4 h, a solution of **1** (2.9 g, 0.01 mol) in 100 cm^3 of acetonitrile was added to a refluxing suspension of **2** (7.6 g, 0.01 mol) and of Na_2CO_3 (5.3 g, 0.05 mol) in 250 cm^3 of acetonitrile. The reaction mixture was maintained under reflux for a further 5 days, after which the mixture was cooled to room temperature (r.t.) and the resulting suspension was evaporated under reduced pressure. The crude product was suspended in chloroform (150 cm^3) and the suspension was filtered. The organic layer was evaporated under reduced pressure, giving a white solid which was recrystallized in a minimum amount of hot acetonitrile. Yield: 7.1 g (79%). *Anal.* Calc. for $C_{43}H_{50}N_4O_9S_4$: C, 57.70; H, 5.63; N, 6.26. Found: C, 57.9; H, 5.7; N, 6.4%. MS (FAB): 896 ($M + H^+$). ^1H NMR ($CDCl_3$, 25°C): 2.23 (s, 12H), 2.38 (s, 4H), 2.51 (m, 8H), 4.26 (d, 2H), 4.39 (s, 4H), 4.58 (d, 2H), 7.21 (t, 1H), 7.36 (d, 8H), 7.79 (d, 4H), 7.83 (d, 4H), 7.96 (d, 2H) ppm. ^{13}C NMR ($CDCl_3$, 25°C): 21.8, 46.2, 47.2, 49.2, 63.8, 125.9, 127.5, 127.6, 129.4, 130.0, 130.2, 131.9, 135.6, 135.9, 143.8, 144.0, 156.9 ppm.

3.1.2. 1,4,7,10-tetraaza[12]-(2,6)anisolephane (L4HBr)

Tetratosylated macrocycle **3** (4.5 g, 5.0 mmol) and phenol (47 g, 0.5 mol) were dissolved in HBr–CH_3COOH (33%, 450 cm^3). The solution was stirred at 90°C for 22 h. The resulting suspension was filtered and the solid washed with CH_2Cl_2 for several times. The yellowish solid was recrystallized from a water–ethanol mixture to give **L** as its tetrahydrobromide salt. Yield: 2.3 g (76%). *Anal.* Calc. for $C_{15}H_{30}N_4Obr_4$: C, 29.93; H, 5.02; N, 9.31. Found: C, 29.7; H, 5.1; N, 9.2%. MS (FAB): 279 ($M + H^+$). ^1H NMR D_2O, (pH 3, 25°C): 3.17 (s, 4H), 3.33 (m, 4H), 3.43 (m, 4H), 4.01 (s, 3H),

3.2. General

3.2.1. NMR spectroscopy

^{1}H, ^{13}C spectra were recorded on a Bruker AC-200 instrument, operating at 200.13 and 50.33 MHz, respectively. In ^{1}H NMR experiments peak positions are reported in relation to HOD (4.75 ppm), dioxane was used as a reference standard in ^{13}C NMR spectra ($\delta = 67.4$ ppm). For the spectra recorded in $CDCl_3$, the peak positions are reported with respect to TMS. Small amounts of NaOD or DCl solutions were added to a solution of the ligand to adjust the pD. The pH was calculated from the measured pD values using the following relationship: $pH = pD - 0.40$ [16].

3.2.2. Spectrophotometric titrations

Absorption spectra were recorded on a Varian Cary-100 spectrophotometer.

3.2.3. Potentiometric measurements

All potentiometric measurements were carried out in 0.15 mol dm^{-3} Me_4NCl at 298.1 ± 0.1 K, in the pH range 2.5–10, using the fully automatic equipment that has been already described [17]. The EMF data were acquired with the PASAT computer program [18]. The electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method [19], which gives the standard potential $E°$ and the ionic product of water K_w. At least three measurements were performed. The HYPERQUAD computer programs were used to process the potentiometric data and calculate the protonation constants [20].

Abstract

The kinetics and the equilibria of complex formation between Ni(II) and 1,25-dimethyl-1,4,7,10,13,16,19,22,25-nonaazapentacosane (Me_2Octaen) have been investigated in aqueous solution between pH 3 and 4.5 by the stopped-flow method and UV spectrometry. Me_2Octaen is a linear polyamine made by the union of eight *en* units bearing two methyl residues at the ends of the chain. Spectrophotometric titrations and kinetic experiments indicated that below pH 4.5 the binding of Ni(II) to the ligand gives rise to several 1:1 complexes differing in their degree of protonation, whereas above pH 4.5 binuclear complexes are formed as well. Concerning the mononuclear species, the ratios of the formation to the dissociation rate constants are in agreement with the equilibrium constants measured by static spectrometry. The analysis of the kinetic data reveals that the mostly reactive form of the ligand (denoted in its fully protonated form as H_9L^{9+}) is H_5L^{5+}, whereas the much more abundant species H_6L^{6+} yields only a minor contribution to the overall process of complex formation. Measurements at different ionic strengths have shown positive salt effects, as expected for reactive processes involving particles with charges of the same sign. Addition of sodium acetate resulted in a large enhancement of the rate of the complex formation reaction, whereas the complex dissociation rate was found to be almost insensitive to the presence of the buffer. Analogous, although more modest, effects have been found with sodium chloroacetate. This behaviour is explained by assuming that the anion of the buffer could bind to Ni^{2+} and/or to the ligand, thus reducing the repulsion between the positively charged reaction partners. © 2000 Elsevier Science B.V. 1. Introduction

The kinetics of the binding of divalent metal ions to linear polyamines have been subjected to thorough investigations in past decades [1–7] since these ligands appeared to behave anomalously with respect to most ligands (including ammonia). Rorabacher et al. [1,2] measured the rates of complex formation between Ni^{2+} and a variety of oligoamines (ranging from *en* to *tetren*) and observed that the reactivity of these ligands toward Ni^{2+} was higher than that predicted by the Eigen–Wilkins argument [8]. This observation led Rorabacher [2] to postulate a special mechanism, defined as internal conjugate base (or ICB) mechanism, the key feature of which is the formation of a hydrogen bridge between a water molecule in the inner coordination shell of the metal ion and a nitrogen atom of the polyamine. The hydrogen bridge can exert two effects: the first results in the stabilisation of the outer-sphere complex, whose formation is a prerequisite for replacement of coordinated water by the ligand [8]. The second (more modest) effect consists in the labilisation of the remaining five coordinated water molecules. Both effects contribute to the enhancement of the rate of the binding process. The more recent availability of longer polyamines makes this kind of study even more interesting, owing to the ability of the ligand not only to form polynuclear species [9], but also to interact with anions of different nature [10].

In this paper we present the results of an investigation of the binding of Ni(II) to Me_2Octaen [1,25-dimethyl-1,4,7,10,13,16,19,22,25-nonaazapentacosane], a linear polyamine represented in Fig. 1 in its fully unprotonated form. This investigation, besides being of

interest in itself, can provide useful information about the mode of binding of Co(II) to polynucleating ligands. Since Co(II) and Ni(II) are known to form complexes with the same mechanism [8], mechanistic details gained from this study could be profitably used to throw light on the mechanism of formation of oxygenated complexes of Co(II).

2. Experimental

2.1. Materials

Me_2Octaen was synthesised and purified as described elsewhere [9]. Nickel perchlorate (Fluka) was dissolved in 0.01 mol dm^{-3} perchloric acid in order to prevent precipitation of the hydroxide. The obtained stock solution was standardised by EDTA titrations at pH 10 using murexide as an indicator [11]. All other chemicals were analytical grade and were used without further purification. Doubly distilled water was used to prepare the solutions and as a reaction medium. All measurements were performed at ionic strength 0.1 mol dm^{-3} obtained by suitable additions of sodium perchlorate.

2.2. Physical measurements

2.2.1. Equilibria

Spectrophotometric titrations were performed with a Perkin–Elmer lambda 17 spectrophotometer equipped with thermostated cell holders able to maintain the temperature constant with fluctuations within ± 0.1°C. Increasing amounts of nickel perchlorate were added by a microsyringe directly into the measuring cell containing a known volume (usually 2 ml) of the ligand solution. The data were subsequently analysed by a non-linear least-square fitting procedure provided by the Jandel (AISN software) program.

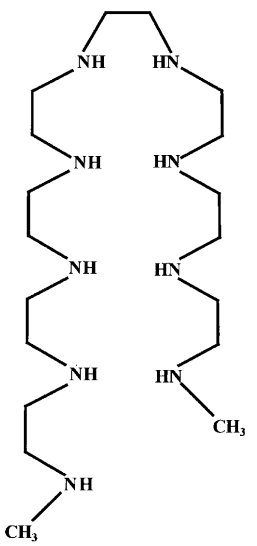

Fig. 1. Me_2Octaen represented in its neutral, fully unprotonated form.

The acid dissociation constants of the ligand were measured by pH titrations. These were performed by a Crison Micro TT 2050 automatic titrator equipped with a combined glass electrode. The instrument was calibrated by titrating an exactly known amount of HCl with NaOH. Current pH measurements were performed with a PHM 84 research pH meter (Radiometer, Copenhagen). A suitable calibration procedure [12] enabled us to convert the pH meter output into hydrogen ion concentration.

2.2.2. Kinetics

The course of the complex formation reaction was monitored at 230 nm using a stopped-flow apparatus constructed in our laboratory. A Hi-Tech SF-61 mixing unit was coupled to a spectrophotometric line through two optical guides. The UV radiation produced by a Hamamatsu L248102 'quiet' lamp was passed through a Bausch and Lomb 338875 high intensity monochromator and then split into two beams. The reference beam was sent directly to a 1P28 photomultiplier. The measuring beam was sent through an optical quartz guide to the observation chamber and then through a second optical guide, to the measuring photomultiplier, also 1P28. The outputs of the two photomultipliers were balanced before each shot and the signal revealing the course of the reaction was sent to a Tektronix 2212 digital oscilloscope with a maximum sampling rate of 4000 data points in 200 μs and a minimum sampling rate of 4000 data points in 500 s. Finally, the acquired signal was transferred to a personal computer via a GPIB interface and analysed by a non-linear least-square procedure expressly devised to fit multiexponential functions [13]. Chemical relaxation experiments were performed on a temperature-jump instrument manifactured by Messanlagen studien geselleshaft (Göttingen, Germany).

3. Results and discussion

3.1. Equilibria

The acid dissociation constants of Me_2Octaen were determined by gradual neutralisation with NaOH of the ligand initially present in the fully protonated form, H_9L^{9+}. Since both the equilibria and the kinetics are strongly dependent on the ionic strength, it was found important to use acid dissociation constants of Me_2Octaen determined under conditions identical to those of the kinetic study ($I = 0.1$ mol dm^{-3} ($NaClO_4$), $T = 25$°C). The values are reported in Table 1 where, for comparison, the literature data at $I = 0.15$ mol

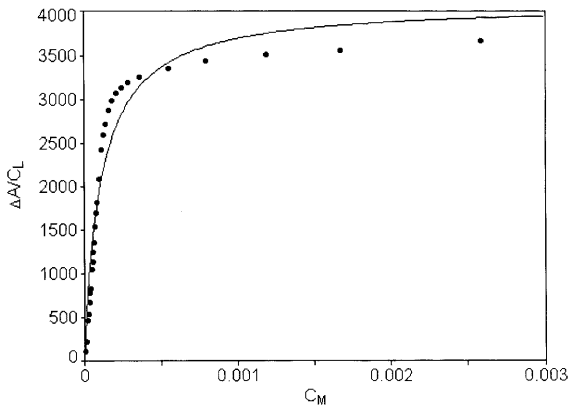

Fig. 2. Spectrophotometric titration of the nickel(II)–Me_2Octaen system. pH 4.8, $I = 0.1$ mol dm^{-3}, $T = 25$°C, $\lambda = 230$ nm. The continuous line deviating from experiment is calculated neglecting the binuclear species.

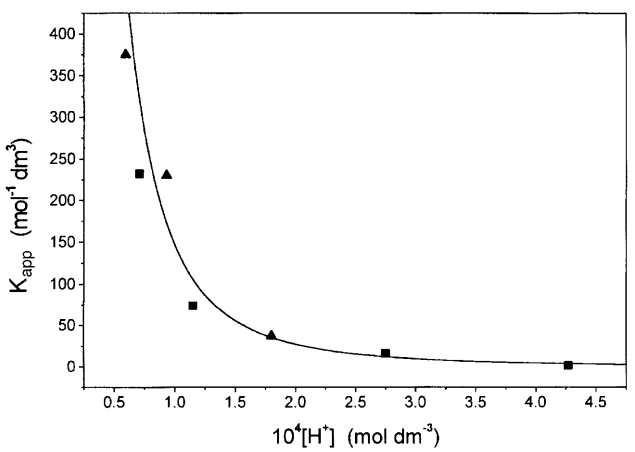

Fig. 3. Dependence of the apparent stability constant for the Ni(II)–Me_2Octaen complex, K_{1app}, on $[H^+]$. ▲, Thermodynamics, ■, kinetics. $I = 0.1$ mol dm^{-3}, $T = 25$°C.

dm^{-3} are also given [9]. The spectrophotometric titrations were carried out at 230 nm by using solutions of the ligand as much diluted as possible. Under these circumstances very small amounts of buffer are sufficient to prevent noticeable acidity variations during titration. At constant pH the equilibria of the system could be conveniently described by the apparent reactions

$$M_f + L_f \rightleftharpoons ML_T \quad (1)$$

$$2M_f + L_f \rightleftharpoons M_2L_T \quad (2)$$

where M_f and L_f indicate the free reactants, whereas ML_T and M_2L_T indicate the total mononuclear and binuclear species respectively. The equilibrium constants of reactions (1) and (2), denoted as K_{1app} and K_{2app} respectively, have been evaluated by a non-linear least-square procedure applied to the equation

$$\Delta A/C_L = \frac{\Delta\varepsilon_1 K_{1app}[M] + \Delta\varepsilon_2 K_{2app}[M]^2}{1 + K_{1app}[M] + K_{2app}[M]^2} \quad (3)$$

where $\Delta A = (A - \varepsilon_L C_L - \varepsilon_M C_M)$, C_L and C_M are the total ligand and metal concentrations, [M] is the metal equilibrium concentration, $\Delta\varepsilon_1 = \varepsilon_{ML} - \varepsilon_L$, $\Delta\varepsilon_2 = \varepsilon_{M2L} - \varepsilon_L$ and ε_i is the molar extinction coefficient of the ith species participating in reactions (1) and (2). The optical path length is 1 cm. The method of analysis is shown in Fig. 2 where the continuous line deviating from experiment represents the trend calculated disregarding the formation of the binuclear complex. However, the deviations between calculated and experimental trends become less and less evident as the pH is decreased, until they disappear for pH values less than 4.5. This finding indicates that below that pH value only mononuclear complexes are formed, in agreement with previous potentiometric results [9].

Owing to the complexity of the system, we have concentrated our attention on the results obtained at pH values between 3.3 and 4.5. The best representation of the dependence of K_{1app} on the hydrogen ion concentration is provided by the equation

$$K_{1app} = \left(A + \frac{B}{[H^+]}\right)\alpha_{H_5L} \quad (4)$$

A plot of K_{1app} versus $[H^+]$ is shown in Fig. 3. The equilibrium parameters A and B were obtained by a non-linear least-square fitting to Eq. (4) and the continuous line represents the calculated trend. Models requiring replacements of α_{H_5L} by α_{H4L} or by α_{H6L} gave definite deviations from the experimental trend and models leading to three term equations did not improve the results. These findings enable us to state that the prevailing species between pH 3.3 and 4.5 are MH_5L^{7+} and MH_4L^{6+} and that $A = K_5$, $B = K_4K_{A5}$ and that the values of K_4, K_5 and $K_{C5} = K_{A5}K_4/K_5$ are reported in Table 1 in logarithm form. Our value of log K_4 is in fair

agreement with the literature datum [14] of 7.43, obtained at $I = 0.15$ mol dm^{-3}. Note that the equilibrium constants of the individual steps are defined as $K_i = [MH_iL]/[M][H_iL]$, $K_{Ai} = [H][H_{i-1}L]/[H_iL]$, $K_{Ci} = [H][MH_{i-1}L]/[MH_iL]$ and $\alpha_{H_5L} = [H_5L]/C_L$.

3.2. Kinetics

The kinetic experiments were carried out under pseudo first-order conditions. Below pH 4.5 the kinetic curves are fitted by single exponential functions. For pH values between 4.5 and 5.0 the curves become biexponential only for $C_M > 5 \times 10^{-3}$ mol dm^{-3}, whereas above pH 5.0 two exponentials are observed even at the lowest of the employed metal ion concentrations ($C_M = 1 \times 10^{-3}$ mol dm^{-3}). Fig. 4 shows a stopped-flow signal recorded at pH 5.5. The experimental points are perfectly fitted by a biexponential curve whereas the monoexponential fit displays remarkable deviations from experiment, as indicated by the smooth continuous line. Fig. 5 shows the metal ion concentration dependence of the observed time constant, $1/\tau$, measured below pH 4.5 where only reaction (1) contributes to the kinetic behaviour of the system. For $C_M \gg C_L$ the observed time constant is expressed by the relationship

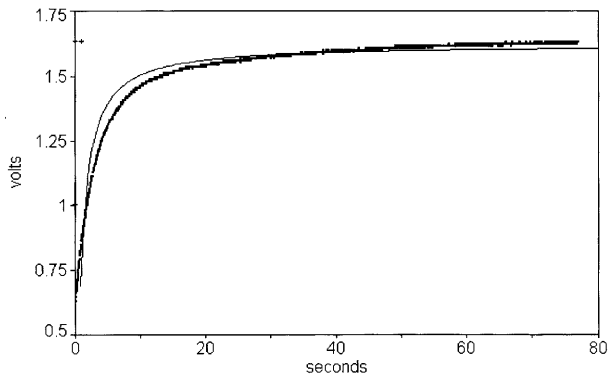

Fig. 4. Stopped-flow experiments for the Ni(II)–Me$_2$Octaen system, $C_L = 1 \times 10^{-4}$ mol dm^{-3}, $C_M = 0.025$ mol dm^{-3}, pH 5.5, $I = 0.1$ mol dm^{-3}, $T = 25$°C, $\lambda = 230$ nm. The curve is biexponential and indicates that mononuclear and binuclear complexes are being formed. The continuous line deviating from experiment is calculated according to a single exponential.

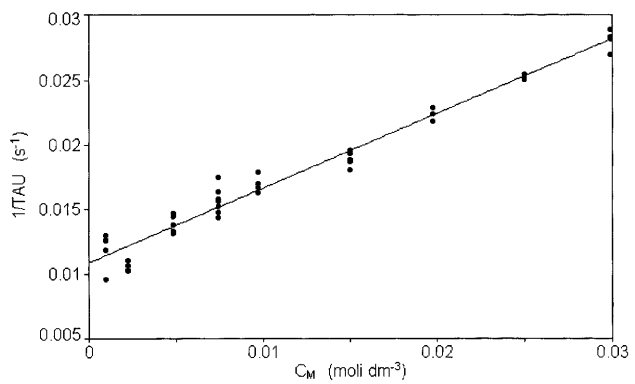

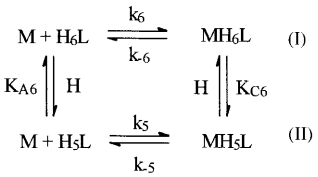

Fig. 5. Dependence of $1/\tau$ on the metal concentration for the Ni(II)–Me$_2$Octaen system, pH 3.94, $I = 0.1$ mol dm^{-3}, $T = 25$°C.

$$\frac{1}{\tau} = k_f C_M + k_d \quad (5)$$

where k_f and k_d are respectively the formation and dissociation rate constants of reaction (1) and could be evaluated from slope and intercept of the straight line of Fig. 5. Both the apparent rate constants change with $[H^+]$. This observation not only confirms the existence of several acid–base equilibria between the differently protonated forms of the ligand and between the differently protonated forms of the mononuclear complex, but could also indicate which forms are able to bind the metal ion. In the investigated range of pH ($3.3 \leq pH \leq 4.5$) the species H_3L^{3+}, H_2L^{2+} HL^+ and L could not make any contribution to the reaction rate, owing to their extremely low concentrations. All the remaining species, in principle, should be considered as possible candidates to participate in the binding process. The model which, among the tested ones, provides the best representation of the kinetic behaviour is that depicted below (charges have been omitted for the sake of simplicity):

According to the above reaction scheme the dependence of k_f and k_d on the hydrogen ion concentration is provided by the relationships

$$k_f = \left(k_5 + \frac{k_6[H^+]}{K_{A6}}\right)\alpha_{H_5L} \quad (6)$$

$$k_d = \left(k_{-5} + \frac{k_{-6}[H^+]}{K_{C6}}\right)\alpha_{MH_5L} \quad (7)$$

where $\alpha_{H_5L} = [H_5L]/C_L$ and $\alpha_{MH_5L} = [MH_5L]/C_L$. The values of the rate parameters are $k_5 = 20.6$ mol^{-1} dm^3 s^{-1}, $k_6 = 0.154$ mol^{-1} dm^3 s^{-1}, $k_{-5} = 0.059$ s^{-1} and $k_{-6}/K_{C6} = 67$ mol^{-1} dm^3 s^{-1}.

Fig. 6 shows the dependence of k_f on $[H^+]$ whereas the dependence of k_d on $[H^+]$ is shown in Fig. 7. The continuous lines represent the calculated values according to Eqs. (6) and (7) respectively. It should be noted that a good representation of the experiments is also obtained by considering only H_5L^{5+} as the reactive species. In such a case the analysis of the data yields $k_5 = 22.2$ mol^{-1} dm^3 s^{-1} and $k_{-5} = 0.061$ s^{-1}. These results, being very similar to those obtained including

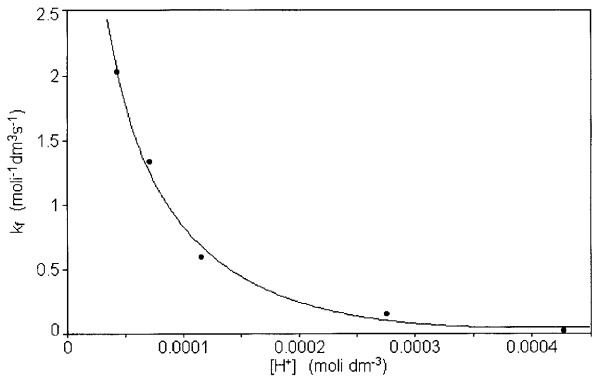

Fig. 6. Dependence of k_f on the hydrogen ion concentration for the Ni(II)–Me_2Octaen system, $I = 0.1$ mol dm^{-3}, $T = 25$°C. The continuous line is calculated according to Eq. (5).

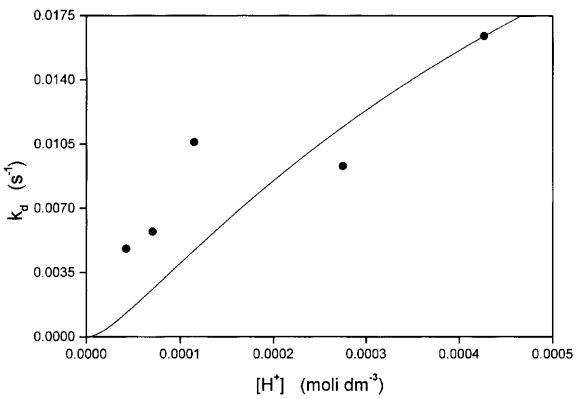

Fig. 7. Dependence of k_d on the hydrogen ion concentration for the Ni(II)–Me_2Octaen system, $I = 0.1$ mol dm^{-3}, $T = 25$°C. The continuous line is calculated according to Eq. (6).

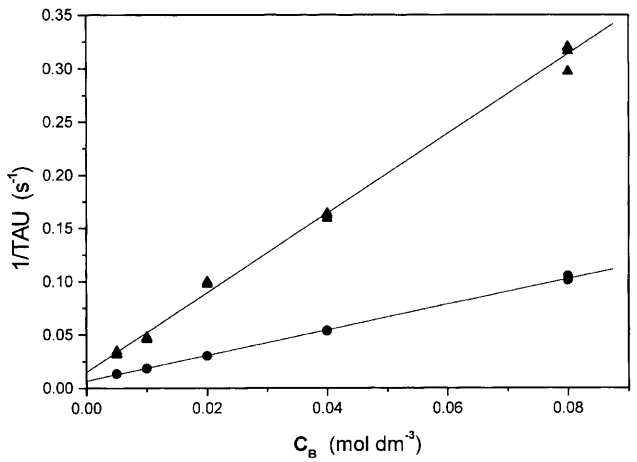

Fig. 8. Dependence of $1/\tau$ on the sodium acetate concentration (C_B) for the Ni(II)–Me_2Octaen system. ▲ $C_M = 3.0 \times 10^{-2}$ mol dm^{-3}, ● $C_M = 9.8 \times 10^{-3}$ mol dm^{-3}, pH 4.37, $I = 0.1$ mol dm^{-3}, $T = 25$°C.

step I as well, indicate that the contribution of this step to the overall reaction is of minor importance and that H_5L^{5+} is the main reactive species in the investigated range of pH.

3.3. The ionic strength effect

Changes of ionic strength from 0.1 mol dm^{-3} to 0.25 mol dm^{-3} by addition of sodium perchlorate lead to an increase by a factor 2 in k_f and to an even larger decrease in k_d. The effect on k_d should be fully ascribed to the influence of the ionic strength on α_{MH_5L}, because the specific rates of dissociation of the complexes, k_{-5} and k_{-6}, corresponding to monomolecular processes, are scarcely sensitive to salt effects. By contrast, the change observed in k_f should be ascribed to a combination of a secondary salt effect (influence on α_{H_5L}) and a primary salt effect (influence on k_5 and k_6). However the system of equilibria involved in the reaction mechanism is too complex to enable us to provide a quantitative evaluation of the experiments.

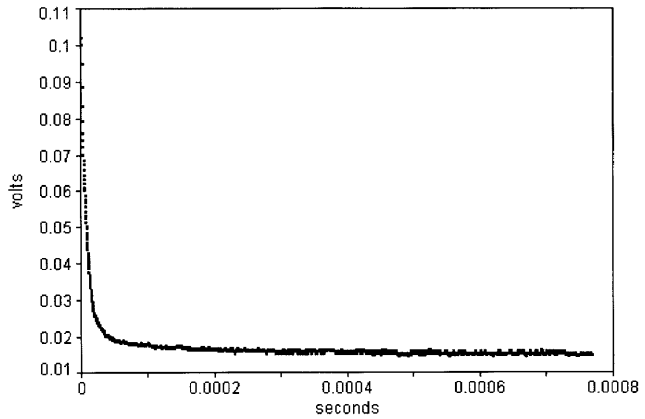
3.4. The buffer effect

Fig. 8 shows that $1/\tau$ changes linearly with the concentration of sodium acetate for two series of experiments both performed at pH 4.2, but differing in the metal concentration. The slope and the intercept values of the straight line associated with the set of experiments performed at $C_M = 3 \times 10^{-2}$ mol dm^{-3} are higher than the corresponding values derived from experiments performed at $C_M = 9.8 \times 10^{-3}$ mol dm^{-3}. Additionally, two series of experiments were carried out by changing C_M at constant C_B (total buffer concentration) and pH. The reaction parameters in the presence of buffer were derived from plots like that of Fig. 5 and are collected in Table 2. One can observe that buffer addition influences mainly the apparent complex formation constant k_f^b whereas the complex dissociation constant k_d^b remains almost unaffected (the superscript b indicates that the reaction parameters have been derived in the presence of buffer). In the light of these results, the expression for the time constant could be written in the form of eq. (8) where $(k_f + k'_f C_B)$ and $(k_d + k'_d C_B)$ correspond respectively to k_f^b and k_d^b of Table 2.

$$\frac{1}{\tau} = (k_d + k'_d C_B) + (k_f + k'_f C_B) C_M \quad (8)$$

Table 2
The buffer effect. Values of the apparent rate constants, k_f^b (mol^{-1} dm^3 s^{-1}) and k_d^b (s^{-1}) for the Ni(II)–Me_2Octaen system in the presence of different concentrations of sodium acetate (C_B); pH 4.37, $I = 0.1$ mol dm^{-3}, $T = 25$°C

C_B (mol dm^{-3})	k_f^b (mol^{-1} dm^3 s^{-1})	k_d^b (s^{-1})
0.02	2.1	4.5×10^{-3}
0.08	12.5	6.1×10^{-3}



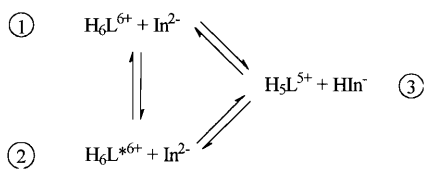


Fig. 9. Temperature jump experiment on the Me_2Octaen–chlorophenol red system. Two relaxation effects are clearly observable. $C_L = 5 \times 10^{-5}$ mol dm^{-3}, $C_{ind} = 1 \times 10^{-4}$mol dm^{-3}, pH 5.5, $I = 0.1$ mol dm^{-3}, $T = 25$°C, $\lambda = 570$ nm.

Qualitatively similar, but less pronounced, effects were obtained in the presence of sodium chloroacetate.

The most common interpretation forwarded to explain the buffer effect on reactions in which hydrogen ions have to be removed from the reaction site is based on the idea that the process of proton removal would be rate determining [15]. In order to assess whether such an explanation could hold for our system as well, the rate of the proton transfer reaction between Me_2Octaen and chlorophenol red, an acid–base indicator with p$K_A = 6.0$, was measured by the temperature-jump method. Fig. 9 shows a kinetic curve recorded at pH 5.5. Two relaxation effects, differing in the time scale by a factor of about 20, are visible. The pH of the solution is sufficiently low to ensure the exclusion of any contribution to the rate of proton transfer coming from the hydrolysis path. A possible contribution from the protolysis path could not be detected since its relaxation time, calculated with the help of the Debye equation [16], turns out to be 0.3 μs, which is much faster than the instrumental heating time (4 μs). Under these circumstances only a single relaxation effect, ascribed to the direct proton exchange between ligand and indicator, should be observed. The presence of two effects reveals that proton exchange is not a simple step. However, the observed behaviour could be rationalised by assuming that the protonated ligand is distributed between two forms, one of which, indicated as H_6L^{*6+}, is characterised by an internal hydrogen bridge of the type $>N\cdots H-N<$. The proton transfer process in such a case is reasonably represented by the cycle

(9)

which displays two relaxation effects. The first of these effects should be associated with the unhindered proton exchange step 1⇔3. This step is fast in both directions, actually displaying its maximum (diffusion controlled) velocity in the thermodynamically favoured direction $1 \rightarrow 3$ and a velocity only slightly lower in the reverse direction $3 \rightarrow 1$ because the ΔpK value is small ($pK_{Hin} - pK_{H6L} = 0.26$). The experimental relaxation time of this effect is $\tau_{fast} = 8$ μs, which agrees with the value of 7 μs calculated by the Debye equation [16]. In contrast, the second relaxation effect, which is associated mainly with the hindered proton exchange step 2⇔3, displays a longer relaxation time ($\tau_{slow} = 140$ μs). This result could be rationalised by considering that the transfer of the proton from H_6L^{*6+} to In^{2-} requires an additional amount of energy to break the intramolecular hydrogen bond present in H_6L^{*6+}. From the value of $1/\tau_{slow}$ the approximate value of 10^8 mol^{-1} dm^3 s^{-1} has been derived for the rate constant of the process $2 \rightarrow 3$. Such a value is more than one order of magnitude lower than that expected for a non-hindered proton transfer reaction but, still, is very high. This fact enables us to exclude that the process of ligand deprotonation in the Ni(II)–Me_2Octaen system could be rate determining. The rate enhancement observed by buffer addition should be thus rationalised otherwise.

A reasonable explanation of the buffer effect can be given if one takes into account the ability of the buffer anion to interact with the metal ion giving species of reduced charge like $NiOAc^+$. In addition, OAc^- could interact with Me_2Octaen giving ligand–anion complexes, thus reducing the positive charge of the ligand as well. Such a kind of complex between organic anions and polyamines has been already observed [10]. Charge reduction on both the reaction partners means reduction of electrostatic repulsion and, consequently, rate enhancement.

We could try now to evaluate the ICB effect displayed by the Ni(II)–Me_2Octaen system by comparing $k^*_{H_5L}$, the first-order rate constant for the conversion of the outer-sphere to the inner-sphere complex in the Ni(II)–H_5L system, with the rate constant of the analogous conversion in the Ni(II)–NH_3 system. According to the Eigen and Tamm argument [17], the second-order rate constant for the binding of Ni^{2+} ion to H_5L^{5+} should be given by the relationship $k_5 = K_{os}k^*_{H_5L}$, where K_{os} is the stability constant of the outher sphere complex. By using the Eigen–Fuoss equation [18,19] one could estimate $K_{os} = 2.6 \times 10^{-5}$ mol^{-1} dm^3 for a distance between the charge centres of 5×10^{-8} cm. This leads to $k^*_{H_5L} = 8.5 \times 10^5$ s^{-1}, whereas the value of k^*_{NH3} for the Ni(II)–NH_3 system [2,4] is 4.6×10^3 s^{-1}. Thus the observed ICB effect is

$$k^*_{H_5L}/k^*_{NH_3} = 185 \quad (10)$$

Note that this value does constitute a lower limit since, to be more precise, the above ratio should be multiplied by a factor larger than unity which accounts for steric and statistical effects [6]. The ICB effect for the Ni(II)–*en* system is 200 [6]. The closeness of this to our result suggests that both ligands bind to Ni(II) with the same mechanism, irrespective of the chain length, a mechanism where the formation of the first Ni–N< bond is rate determining [2].

Abstract

The spectroscopic characteristics (IR and diffuse reflectance) and the thermal properties (TG, DTG and DSC) of the solid compounds obtained by the reaction of diclofenac (DH) with manganese(II), iron(II), cobalt(II), nickel(II), copper(II) and zinc(II) are reported and discussed. The complexes agreed with the empirical formula $MeD_2 \cdot (H_2O)_x$ and the metal ions are co-ordinated through the carboxylate group of the ligand. The furnace atmosphere (N_2 or O_2) greatly influences the thermal decomposition trend of the complexes, less their thermal stability. On the contrary, the initial decomposition temperature depends on the co-ordinated metal ion, especially in the case of iron(II) and copper(II) compounds, which are much less stable than other complexes. © 2000 Elsevier Science B.V. Keywords: Diclofenac; Metal(II) compounds; Spectroscopic properties; Thermal properties

1. Introduction

Diclofenac (DS), sodium salt of [2-[(2,6-dichlorophenyl)amino]phenyl] acetic acid, is a potent non-steroidal anti-inflammatory agent for the treatment of rheumatoid arthritis. The pharmacological effects of this drug are thought to be related to the inhibition of the conversion of arachidonic acid to prostaglandins, which are the mediators of the inflammatory process [1–3].

The literature reports several methods for determination of diclofenac [4–19] but only few data on the complexing ability of this drug with metal ions [20–26].

In a previous paper [27] we reported the main results of an extensive investigation on chemical, spectroscopic and thermoanalytical behaviour of DS and proposed new methods for its determination in pharmaceutical formulations. Since it is well-known that the interaction of the metal ions may influence the biological activity of drugs administered for therapeutic reasons, because many drugs act via chelation or by inhibiting the activity of metal-enzymes, in the present paper we extend the above study on the reaction of diclofenac with the Irving and Williams series of divalent metal ions: manganese(II), iron(II), cobalt(II), nickel(II), copper(II) and zinc(II).

2. Experimental

2.1. Apparatus

UV–Vis spectra were acquired with 1 cm quartz cells on a Perkin–Elmer 320 UV–Vis spectrophotometer connected to a model 3600 Data Station equipped with software packages 'IF-320', for instrument control. The scan speed was adjusted at 30 nm min^{-1}, slit width = 1 nm, response time = 0.5 s. The spectrophotometer was connected with a 'Colora' ultra-thermostat (25.0 ± 0.1°C).

IR and diffuse reflectance spectra were recorded using a Perkin–Elmer 1600 FT-IR and a Beckman DGB spectroreflectometer.

The thermal measurements were carried out using a Perkin–Elmer TGS-2 thermal analyser, connected to a model 3600 Data Station, and a 1020 series DSC-7 thermal analysis system equipped with a multitasking software for instrument control and data analysis. Unless specified otherwise, thermogravimetry and differen-

tial scanning calorimetry runs were made on sample of about 1–2 mg (TG) and 0.3–0.5 mg (DSC) in a stream of nitrogen or oxygen (flow rate, 50 ml min^{-1}, heating rate 10°C min^{-1}).

The acidity of the aqueous solutions was checked with an Orion EA 940 pH-meter with an Orion 81-02 Ross combination pH electrode.

Millipore filtering apparatus fitted with 0.45 μm membrane discs.

2.2. Reagents

Diclofenac sodium salt 'Sigma' was used without further purification. Purity of dry material, checked by potentiometric titration, was 99.8% ($S_r = 0.05\%$, $N = 5$). The metal ions were in the form of perchlorate 'Aldrich'.

Distilled, deionised and, if necessary, O_2 and/or CO_2-free water was used. All other chemicals were of analytical-reagent grade.

2.3. Preparation of the solid compounds

The following general procedure was applied: 20 cm^3 of 0.01 mol dm^{-3} aqueous solution of the metal ion were added to 40 cm^3 of 0.01 mol dm^{-3} aqueous solution of the ligand ($C_L/C_M = 2$), maintaining the pH of the mixture in the range from 5.5 to 6, by the addition of small quantities of NaOH solution. The mixture was stirred for about 2 h, at room temperature, and then the precipitate was filtered off, washed with water and dried in vacuo, over silica gel, for at least 48 h.

The analysis of all the solid compounds agreed with the empirical formula $MD_2 \cdot (H_2O)_x$ [where M and D are, respectively the metal and the diclofenate ions and $x = 0$ for M = Fe(II), $x = 1$ for M = Mn(II), Co(II), Ni(II), $x = 3$ for Cu(II) and $x = 4$ for Zn(II)].

The compounds were prepared also in hot aqueous solution [23] achieving the same results.

3. Results and discussion

The main data of the spectroscopic and thermoanalytical investigation are summarised in Tables 1 and 2.

Because all the complexes showed similar spectroscopic characteristics and thermal behaviour, for the sake of brevity, we give below, as an example, a more detailed discussion of the first compound of the series and only a short presentation of the related studies of other complexes underlining its peculiar features.

3.1. Bis(dichlorophenylaminophenylacetato)manganese(II)

This compound, a pale pink powder, has the empirical formula $Mn(C_{14}H_{10}Cl_2NO_2)_2 \ (H_2O)$.

It is slightly soluble in water, but soluble in ethanol and this solution exhibits a spectrum with two maxima at $\lambda = 445$ nm and $\lambda = 370$ nm.

The diffuse-reflectance spectrum, which shows only a weak band at about 21 300 cm^{-1}, does not give a sure proof of the stereochemistry of the complex, because of the interference of the ligand absorption which mask the d–d bands.

The IR spectrum (Fig. 1) shows a strong band at 3570 cm^{-1} attributed to the presence of co-ordinated water. In fact, this band is absent in the anhydrous compound obtained by heating the sample at 150°C (see TG curves). The single band at 3320 cm^{-1} (ν_{NH}), similar to that found for diclofenac in the protonated form [27], instead of the two strong bands at 3388 cm^{-1} (ν_{NH}) and 3260 cm^{-1} ($\nu_{NH\cdots O}$ due to intramolecular hydrogen bonding), which appears in DS [22], proves the co-ordination of the metal ion through the carboxylate groups, but it can't exclude that there is an interaction between NH group and the metal ion. This hypothesis is confirmed by the $\nu_{as\,COO^-}$ and $\nu_{s\,COO^-}$ bands. The difference $\Delta_\nu = (1554-1420 =)134$ cm^{-1} is less than that of the DS free ion [$\Delta_\nu = (1572-1402 =)$ 170 cm^{-1}] as expected for bidentate co-ordination.

[a] Decomposition temperature range (water loss in O_2 occurs as in N_2 and it is not reported).
[b] t_{max} is the temperature of the maximum decomposition rate (by DTG analysis of TG curves).
[c] Volatile products and supposed residues are reported in brackets.

The thermal decomposition trend of this complex is greatly conditioned by the furnace atmosphere. According to thermogravimetry in O_2 (Fig. 2, curve a) this compound loss its water molecule in the temperature range from 105 to 125°C (*Anal*. Calc.: 2.74, Found: 2.7%) and the anhydrous is stable up to about 223°C. The first decomposition process takes place between 223 and 280°C, with about 20% weight loss, and it is a two-step overlapped process ($t_{max} = 236$ and 247°C). Upon further heating the sample slowly loses mass up to about 390°C, then the decomposition speeds up suddenly with a new two-step partly overlapped process ($t_{max} = 485$ and 520°C). At 585°C the residue consists mainly of Mn_3O_4 (*Anal*. Calc.: 11.61, Found: 11.8%) or a mixture of different oxides. In N_2 atmosphere (Fig. 2, curve b) the thermal behaviour is similar to that in O_2 only up to 223°C, then the decomposition rate increases ($t_{max} = 250$°C) and, with an apparent one-step process, at 280°C the residue is about 19% (*Anal*. Calc. for $MnCO_3$: 17.50%). This residue slowly loses mass (about 1.6% up to 440°C) then, between 440 and 700°C, it changes into the final metal oxide. DSC curves (Fig. 3,

curves a and b) confirm the influence of the furnace atmosphere on the decomposition mechanism of the complex showing exo- and/or endothermic peaks connected with the weight losses in TG. An endothermic process accompanies the water evolution ($t_p = 120$°C; $\Delta H = 46$ kJ mol^{-1}) both in O_2 and N_2 atmosphere. Then, several exothermic reactions characterise the oxidative thermal decomposition of the complex, whereas, in N_2, the initial decomposition stage occurs with an exothermic reaction partly neutralised by the overlapped endothermic one. Another wick endothermic peak appears up to 500°C.

3.2. Other complexes

All the complexes are fairly soluble in water and soluble in ethanol.

The diffuse reflectance spectra suggest an octahedral geometry around the metal ion for cobalt(II), nickel(II) and copper(II) complexes [23,28] whereas in the case of iron(II) and zinc(II) as reported for manganese(II) compound, the ligand interference is enough to mask the d–d bands.

A comparison of the IR spectra, in the range from 1700 to 1300 cm^{-1}, with those of the ligand in sodium (DS) and protonated (DH) form suggests the carboxylic group is involved in the metal ions complexation and the formed oxygen-metal bond has a different degree of covalent character: in the Fe(II), Co(II) and Ni(II) complexes the bonding is primarily ionic whereas in Cu(II) complex it is primarily covalent [29]. The Cu(II), Ni(II) and Zn(II) complexes show a strong absorption at 3550 cm^{-1} attributed to OH stretching of co-ordinated water molecules.

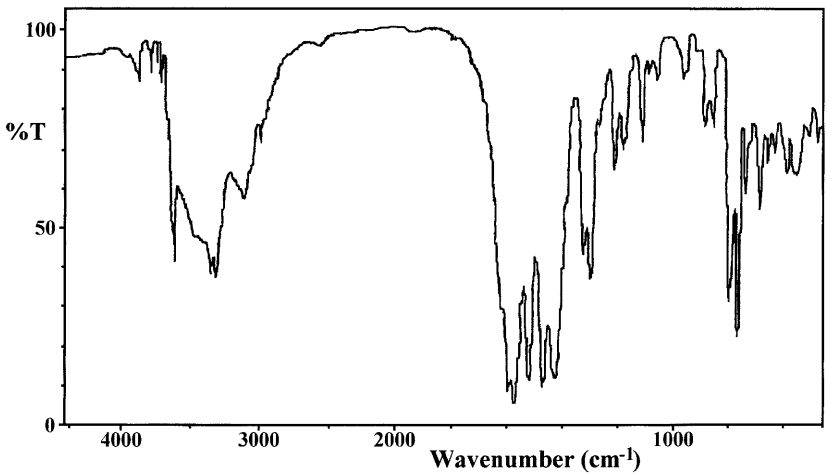

Fig. 1. IR spectra (KBr disc) of bis(dichlorophenylaminophenylacetato)manganese(II).

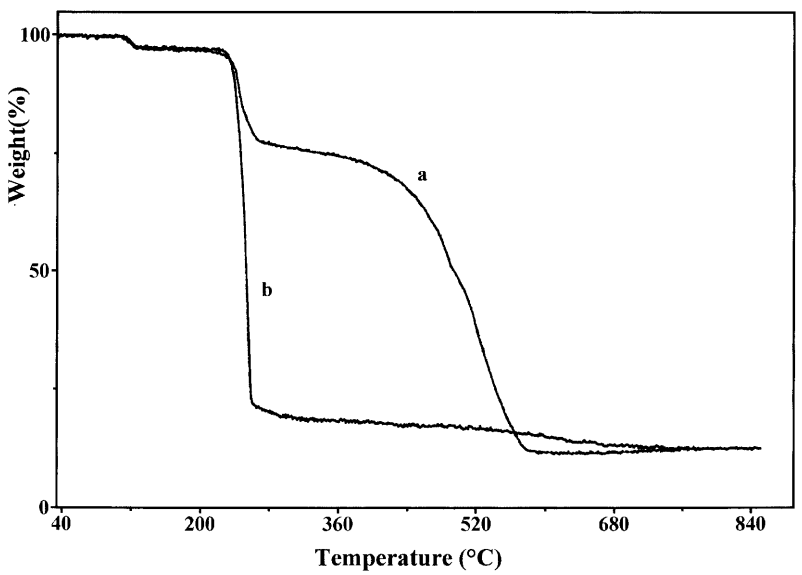

Fig. 2. TG of bis(dichlorophenylaminophenylacetato)manganese(II) in O_2 (curve a) and in N_2 (curve b) atmosphere.

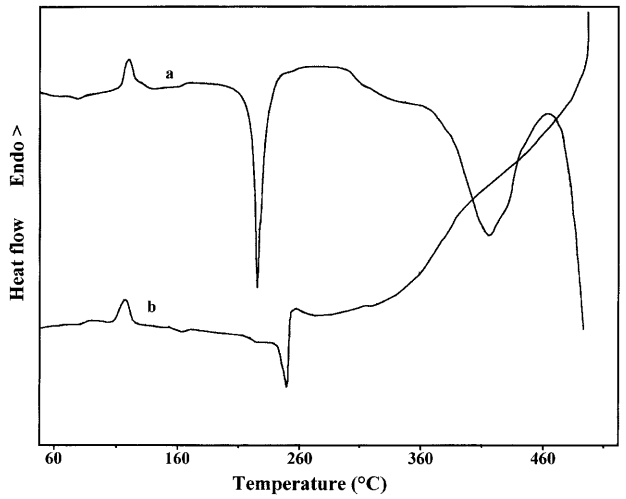

Fig. 3. DSC of bis(dichlorophenylaminophenylacetato)manganese(II) in O_2 (curve a) and in N_2 (curve b) atmosphere.

According to the thermograms (TG) in a dynamic O_2 atmosphere, the water content of the complexes departs at temperature up to about 125°C. The anhydrous compounds are more stable than DH ($t_d = 140$°C) but less than DS ($t_d = 265$°C) [27]. The thermal decomposition occurs through a multi-step process, so conclusion is drawn that the partial reactions take place consecutively, partly overlapping one another. At about 650°C the residues consist mainly of the metal oxides. In a dynamic N_2 atmosphere the first decomposition step occurs at the same temperature than in O_2 but with a more quick and a higher mass loss. An exception is the thermal behaviour of the iron(II) complex. The decomposition delay observed in N_2 can be explained by the inhibition of the oxidative decomposition of the complex, which probably occurs through iron(II) to iron(III) transition. In fact, in O_2, the decomposition begins with an exothermic peak at 145°C whereas DSC in N_2 shows an endothermic peak at about 175°C.

4. Conclusions

This study enriches the knowledge of diclofenac with some aspects of its complexing ability and, although the reaction medium is very different from the biological environment, however the obtained results enable to suppose that the administration of this drug for long time could decrease the bioavailability of some important metal ions. In fact diclofenac reacts with divalent metal ions forming 1:2 (metal to ligand ratio) very slightly water-soluble complexes, so much so that the stability constants were not determined.

The spectroscopic analysis of the solid compounds proved the carboxylate group of the ligand is involved in the complexation reaction with different degree of covalency in the formed metal(II)–oxygen bonds and, with regard to cobalt(II), nickel(II) and copper(II) complexes, an octahedral geometry around the metal ion.

The thermal analysis evidenced a great dependence of the thermal decomposition trend of these complexes by the furnace atmosphere. It was found that, in nitrogen, the decomposition occurs through the $MeCO_3$ intermediate (this mechanism was particularly evident in TG curves of manganese(II), iron(II), cobalt(II) and zinc(II) compounds). The kind of the bonded metal ion influenced the thermal stability order that, calculated by the initial decomposition temperature (t_d) of the anhydrous compounds (in N_2), resulted $Zn > Ni \geq Co \geq Mn \gg Fe > Cu$. It does not agree fully with that expected for analogous series of metal(II) complexes [30] leading to suppose different structures and/or inter–intramolecular interactions. In particular we emphasise the thermal behaviour of iron(II) complex, the only one precipitated in anhydrous form. This compound, as found in a precedent case [31], is more stable than copper(II) complex only and, in O_2 atmosphere, it becomes the least stable of all the analysed complexes. This behaviour could be justified by the initial oxidation reaction of iron(II) to iron(III) that favours the thermal decomposition of the compound.

Received 14 June 2000; accepted 27 July 2000

Abstract

Two new metavanadates, $Cu(tn)_2(VO_3)_2$ (tn = 1,3-diaminopropane) and $Ni(NH_3)_2(VO_3)_2$, have been prepared under hydrothermal conditions and their single-crystal structures determined by X-ray diffraction. Both structures consist of corner-sharing VO_4 tetrahedral chains with complex cations occupying the interchain positions. While there dominantly exist electrostatic interactions between the $Cu(tn)_2^{2+}$ fragments and the vanadium oxide chains in $Cu(tn)_2(VO_3)_2$, the $Ni(NH_3)_2^{2+}$ moieties in the $Ni(NH_3)_2(VO_3)_2$ bridge the vanadium oxide chains into a three-dimensional framework structure by Ni–O covalent interactions. The magnetic properties were measured in the temperature ranging from 4 to 275 K. It is shown that $Cu(tn)_2(VO_3)_2$ possesses well-separated Cu^{2+} centers and that the magnetic behavior of $Ni(NH_3)_2(VO_3)_2$ can be explained based on a one-dimensional Ising model. © 2000 Elsevier Science B.V. 1. Introduction

Self-assembly of inorganic molecular precursors or subunits in a quest for supramolecular chemistry is one of the highly recognized areas of chemical research [1]. The significant contemporary interest in organic/inorganic hybrid materials reflects their diverse applications or potential applications in the areas such as catalysis, molecular electronics, magnetism and photochemistry [2]. The chemistry of the transition metal-phosphates, prepared by hydrothermal synthetic techniques, has been extensively studied due to their inherent potential for the development of supramolecular chemistry [3]. The recent success in the hydrothermal assembly of the low-dimensional and microporous oxometalate hybrid materials using metal coordination complexes suggests a novel approach towards rational synthesis of metal oxide/organic solids [4–8].

As a continuation of our effort in the hydrothermal assembly of metal oxide-based solid materials, we seek to explore the assembly of the vanadate anions and the coordination complexes [9]. We report herein the syntheses, structures, IR spectra and magnetic properties of two new hybrid solids, $Cu(tn)_2(VO_3)_2$ (**1**) and $Ni(NH_3)_2(VO_3)_2$ (**2**), where tn = 1,3-diaminopropane. Both structures consist of one-dimensional chains, formed by corner-sharing VO_4 tetrahedra. The chains are similar to those found in anhydrous metavanadates, such as $LiVO_3$ [10], $NaVO_3$ [11], KVO_3, NH_4VO_3 and $TlVO_3$ [12]. While there mainly are electrostatic interactions between the $Cu(tn)_2^{2+}$ fragments and the vanadium oxide chains in the structure of **1**, the adjacent chains in the structure of **2** are held together through $\{Ni(\mu\text{-}O)_4N_2\}$ octahedral moieties, and forming a three-dimensional framework.

2. Experimental

2.1. General procedures

Reagents were purchased commercially and used without further purification. The hydrothermal reaction was carried out in 17 ml of Teflon-lined stainless steel autoclaves under autogenous pressure with a fill factor of approximately 40%. The reactants were stirred briefly before heating. The infrared spectra were obtained on a Perkin-Elmer FTIR 2000 Spectrometer with pressed KBr pellets in the 4000–400 cm^{-1} region. The magnetic susceptibility data were measured using Quantum Design PPMS 6000 magnetometer in the temperature range from 4 to 275 K at an applied magnetic field of 5 kG. The diamagnetic corrections were estimated form Pascal's constants.

2.2. Synthesis of $Cu(tn)_2(VO_3)_2$

A mixture of V_2O_5 (0.135 g), CuO (0.058 g), 1,3-diaminopropane (0.38 ml), H_3BO_3 (0.653 g) and H_2O (7.0 ml) in a mole ratio of 1:1:5.8:14.4:533 was heated at 165°C for 48 h. This gave deep brown prismatic crystals of **1** as major product (in the yield of approximately 80% based on vanadium), and a small amount of H_3BO_3 was found. The acidity of the medium kept pH $\sim$9.5 before and after the synthesis. Attempts to synthesize **2** without H_3BO_3 proved unsuccessful. *Anal.* Calc. for $C_6H_{20}CuN_4O_6V_2$: C, 17.59; H, 4.92; N, 13.68; V, 24.87. Found: C, 17.52; H, 4.89; N, 13.74; V, 24.80%.

2.3. Synthesis of $Ni(NH_3)_2(VO_3)_2$

A mixture of NH_4VO_3 (0.117 g), $Ni(NO_3)_2{\cdot}6H_2O$ (0.174 g), and H_2O (5.5 ml) in a mole ratio of 1:0.6:389 was heated at 130°C for 48 h.The acidity of the medium kept the value of pH at approximately 5.5 before and after the synthesis. Green thin plates of **2** were purely obtained from the above hydrothermal reaction, and the yield was approximately 85% based on vanadium. *Anal.* Calc. for $H_6N_2NiO_6V_2$: H, 2.08; N, 9.64; V, 35.05. Found: H, 2.10; N, 9.59; V, 35.11%.

2.4. X-ray crystallography

X-ray diffraction data on crystals of **1** with $0.26 \times 0.18 \times 0.10$ mm and of **2** with $0.25 \times 0.15 \times 0.10$ mm were collected on a Rigaku AFC5R four-circle diffractometer at 23°C with graphite-monochromated Mo Kα ($\lambda = 0.71069$ Å), the scan mode being ω–2θ at a scan speed of 8° min^{-1} in ω. Cell dimensions were refined using 25 reflections in the rang $20 < 2\theta < 30°$. The diffraction data were corrected for Lorentz and polarization effects.

The structures were solved by direct methods using SHELXS-86 software package [13]. All non-hydrogen atoms in both structures were refined anisotropically by the full-matrix least-squares methods. All hydrogen atoms were localized in the difference electron density maps and included in the refinements with fixed positional and isotropically thermal parameters. The refinements of the structures were performed using SHELXL-93 crystallographic software package [14]. The crystallographic data are given in Table 1.

3. Results and discussion

3.1. Syntheses and infrared spectra

In principle, the hydrothermal technique has many variables, which can affect the result significantly. The H_3BO_3 in the preparation of **1** takes a role as the acid buffering agent. This species appears to be needed in the syntheses, although it is not incorporated in the final structure. Without H_3BO_3 or H_3BO_3 replaced by CH_3COOH, attempts to synthesize **1** proved fruitless and black $(H_3N(CH_2)_3NH_3)V_4O_{10}$, which was reported previously[15], was obtained. On the other hand, $NH_4V_3O_8$ [16] is formed under very similar synthetic conditions to those employed for compound **2** except for the initial pH value of **6** rather than 5.5. It is shown that the kinetic parameters (nucleation, crystal, etc.) are important and strongly influenced by small changes of the synthetic parameters.

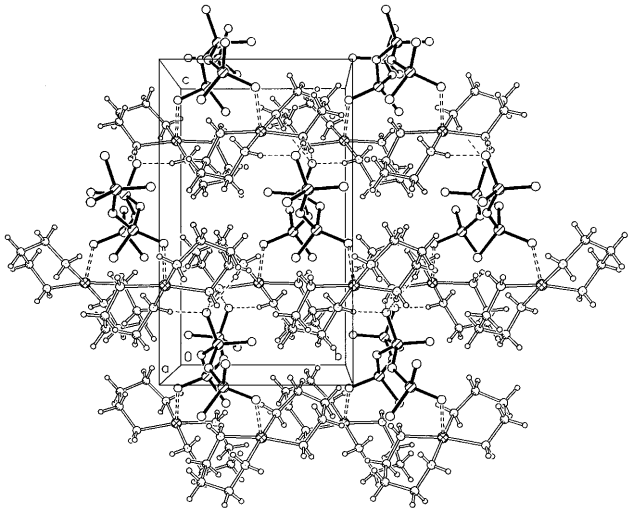

Fig. 1. The packing of $Cu(tn)_2(VO_3)_2$ showing the hydrogen bonds, where cross-hatched circles for Cu, stripped ones for V, big open ones for O, dotted ones for N, shaded ones for C, and small open ones for H.

The bands at 952 and 905 cm^{-1} in the IR spectrum of 1977 and 933 cm^{-1} in **2** are related to the VO_2 symmetric stretching involving the exterior oxygen atoms and to that involving the backbone oxygen atoms, respectively [17]. The bands at 832 in **1** and 835 cm^{-1} in **2** are assigned to the VO_2 antisymmetric stretching, while the feature at 635 in **1** and 639 cm^{-1} in **2** are attributed to the symmetric and antisymmetric stretching of V–O–V.

3.2. Structure of $Cu(tn)_2(VO_3)_2$

The metavanadate anion in the structure of compound **1** consists of infinite one-dimensional chains of corner-sharing VO_4 tetrahedra, which extend parallel to the *a* axis, as shown in Fig. 1. The complex cations $Cu(tn)^{2+}$ provide charge balance and are located between the chains.

The vanadium oxide chains are similar to those found in other anhydrous metavanadates, such as $LiVO_3$ [10], $NaVO_3$ [11], KVO_3, NH_4VO_3 and $TlVO_3$ [12]. As listed in Table 2, two crystallographically-independent vanadium sites V(1) and V(2) both exhibit distorted geometry. The oxygen atoms shared by two adjacent VO_4 tetrahedra have longer V–O bond lengths ranging from 1.782(8) to 1.811(8)Å, while the terminal vanadly oxygen atoms have shorter V–O bond lengths between 1.614(9) and 1.660(7) Å. The values are in good agreement with those found in metavanadates MVO_3 ($M = Li^+$, Na^+, K^+, NH_4^+ and Tl^+) [10–12]. Valence sum calculations [18] resulted in 4.96 for V(1) and 5.08 for V(2), both very close to the ideal value of 5 for V(V).

The $Cu(tn)_2^{2+}$ complexes are arranged alternately on each side of the vanadium oxide chain. The copper atom adopts a CuN_4 square planar geometry, where the four nitrogen atoms come from two bidentate ligands 1,3-diaminopropane with Cu–N distances between 2.005(8) and 2.039(8) Å. The least-square plane is defined by the four nitrogen atoms with the mean deviation of 0.057 Å. The copper atom protrudes from the plane by 0.119(5) Å. The closest distance between

[a] Symmetry codes: (a) $x+1/2, -y+3/2, z$; (b) $x-1/2, -y+3/2, z$; (c) $-x+1, -y+1, z-1/2$; (d) $-x+1/2, y-1/2, z-1/2$.

Cu and O is 2.406(8) Å for Cu(1)···O(1). If this interaction is considered significant, the environment around the copper atom can be also viewed as distorted square-pyramidal geometry connected to every other vanadium site in the vanadium oxide chains. As depicted in Fig. 2, the two chelate rings each composed of Cu and C, N atoms of 1,3-diaminopropane illustrate a distinctly chainlike configuration.

There exists extensive hydrogen bonding between the N–H groups from the complex fragments $Cu(tn)_2^{2+}$ and the oxygen atoms from the inorganic anion chains, with N···O interatomic distances ranging from 2.91(1) to 3.17(1) Å (see Fig. 1).

3.3. Structure of $Ni(NH_3)_2(VO_3)_2$

The substitute of $Cu(tn)_2^{2+}$ by $Ni(NH_3)_2^{2+}$ conduced to compound **2**. Figs. 3 and 4 are two projections of the structure of **2** along the *a* and *b* directions, respectively.

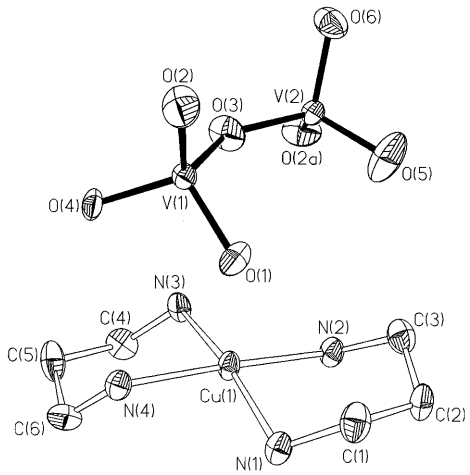

Fig. 2. The asymmetric unit in $Cu(tn)_2(VO_3)_2$, showing the metal-atom coordination environments with 50% probability displacement ellipsoids.

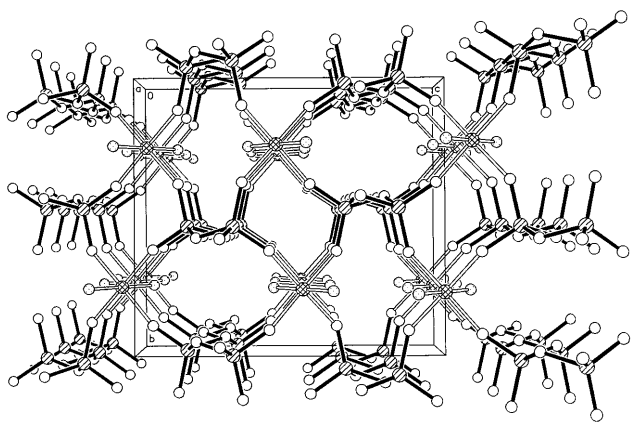

Fig. 3. The structure of $Ni(NH_3)_2(VO_3)_2$ projected along the *a* axis,where cross-hatched circles for Ni, stripped ones for V, open ones for O, and dotted ones for N.

The three-dimensional framework structure of **2** is built up from the corner-sharing VO_4 tetrahedral chains hold together by the complex fragments $Ni(NH_3)_2^{2+}$ through the Ni–O covalent interactions.

The coordination spheres centered V and Ni atoms are shown in Fig. 5. Four oxygen atoms are coordinated to V(1) with a distorted tetrahedral geometry. As listed in Table 3, the two oxygen atoms bridging two adjacent VO_4 tetrahedra have longer V–O bond distances of 1.800(3) and 1.802(3) Å, and the others linking one VO_4 tetrahedron and one NiO_4N_2 octahedron have shorter V–O bond distances of 1.632(3) and 1.652(3) Å. Although these values are in accord with those observed in metavanadates MVO_3 ($M = Li^+$, Na^+, K^+, NH_4^+ and Tl^+) [10–12], the shorter V–O

[a] Symmetry codes: (a) $-x+1$, $y+1/2$, $-z+1$; (b) $-x+1$, $-y$, $-z+1$; (c) x, $-y+1/2$, z; (d) $x-1/2$, y, $-z+3/2$; (e) $x+1/2$, y, $-z+3/2$; (f) $x+1/2$, $-y+1/2$, $-z+3/2$.

bond lengths are slightly shorter than those found in recently reported metavanadates with the coordination cations covalently attached to the anion chains, such as $Cu(en)(VO_3)_2$ (1.670 and 1.687Å), $Cu(bpy)(VO_3)_2$ (1.667Å), $Cu(bpy)_2(VO_3)_2$ (1.678Å) [5] and $Cu(dien)(VO_3)_2{\cdot}H_2O$ (1.687 Å) [19]. Valence sum calculations [18] were 5.10 for V. It is close to the ideal value for V(V). The octahedral geometry about each nickel atom is nearly ideal, with no derivations of more than 4° from the ideal octahedral geometry. In the six coordination atoms of each Ni atom, apart from the two nitrogen atoms from two NH_3 ligands with Ni–N distances of 2.037(4) and 2.060(4) Å, the four oxygen atoms come from the four adjacent vanadium oxide chains surround each $Ni(NH_3)_2^{2+}$ fragment with Ni–O distances of 2.035(3) and 2.029(3) Å.

The structure of **2** along the *a* axis, as illustrated in Fig. 3, shows a screw-like spiral arrangement of seemingly six-membered rings composed of O–O edges of four VO_4 tetrahedra and two NiO_4N_2 octahedra or 12-membered rings counting metal and oxygen atoms individually. A cell unit is passed through four such channels with two in a left-handed fashion and the others in a right-handed fashion. Along the *b* axis, the structure also illustrates left- and right-handed six-membered spiral channel arrangements (Fig. 4). There are the angles of 90° and 84.4° between the two types of six-membered cross-sectional rings in the left- and right-handed spiral channels along the *a* and *b* axes, respectively. Fig. 3 also shows that the four-membered windows formed by two VO_4 and two NiO_4N_2 polyhedra packed in the *a* direction.

It is notable that the connections between complex fragments and metavanadate chains in **2** are different from those in **1** and in other known coordination cation metavanadates. The electrostatic interactions are dominant between the fragments and the metavanadate chains in **1** and $Ni(en)_3(VO_3)_2$ [9]. In $Cu(bpy)_2(VO_3)_2$ [5] and $Cu(dien)(VO_3)_2{\cdot}H_2O$ [19], each complex fragment is covalently bound through a single oxygen atom to very other tetrahedral unit in the vanadium oxide chain. In $Cu(en)(VO_3)_2$, $Cu(bpy)(VO_3)_2$ [5] and $Cu(NH_3)_2(VO_3)_2$ [20], each copper atom adopts a square planar configuration with two oxygen atoms from adjacent VO_4 units in the chain. However, each complex fragment in **2** is joined to its four adjacent vanadium oxide chains into a three-dimensional framework. These differences may originate from the nature of the transition metal ions employed. While the copper(II) ion favors four-coordinated square-planar or five-coordinated square-pyramidal geometry because of its strong Jahn–Teller effects, the nickel(II) ions tends to six-coordinated octahedral geometry.

In the structure of **2**, significant hydrogen bonding between H(4) on N(2) and O(3) with nitrogen–oxygen distance of 2.806(4) Å is observed, as listed in Table 3.

3.4. Magnetic properties

The temperature dependencies of the magnetic susceptibilities and inverse susceptibilities of **1** are illustrated in Fig. 6. The effective magnetic moment (μ_{eff}) of **1** at 275 K ($1.79\mu_B$), determined from the equation $\mu_{eff} = 2.828(\chi_m T)^{1/2}$, is consistent with that expected for an isolate paramagnetic system with $S = 1/2$ ($\mu_{eff} = 1.73\mu_B$). The χ_m^{-1} versus T curve is almost linear in the whole temperature range, suggesting principally paramagnetism in **1**. The magnetic susceptibility data was analyzed with the Curie–Weiss law:

$$\chi_m = Ng^2\mu_B^2 S(S+1)/3k(T-\theta) \quad (1)$$

A least-squares fit obtains the parameters, $g = 2.06(5)$, $\theta = 0.04(2)$ K and the agreement factor $F = [\Sigma(\chi_{obs} - \chi_{cal})^2/\Sigma\chi^2_{obs}]^{1/2} = 0.124\%$. The very small θ demonstrates that no distinct magnetic interactions exist. The nearest Cu···Cu distance in the structure of **1** is greater than 7.22 Å, and the exchange couplings thus can have to be excluded.

The magnetic behavior of compound **2** is shown in Fig. 7. The μ_{eff} value of **2** per nickel(II) at 275 K is $2.95\mu_B$. It is greater than the spin-only value for $S = 1$ ($\mu_{eff} = 2.83\mu_B$), indicating the presence of a ferromagnetic coupling between Ni(II) ions. This is further suggested by a positive Weiss constant $\theta = +5.27(4)$ K, derived from the Curie–Weiss law fit in the temperature ranging from 25 to 275 K (Fig. 7). In the structural parameters of **2**, the magnetic super-exchange would most likely occur through the –Ni–O–V–O–Ni– bonding pathway with nearest Ni···Ni distance of 5.419(1) Å. It is shown that a one-dimensional $S = 1$ Ising model with ion anisotropy can explain well the origin of the magnetic super-exchange interactions in **2**.

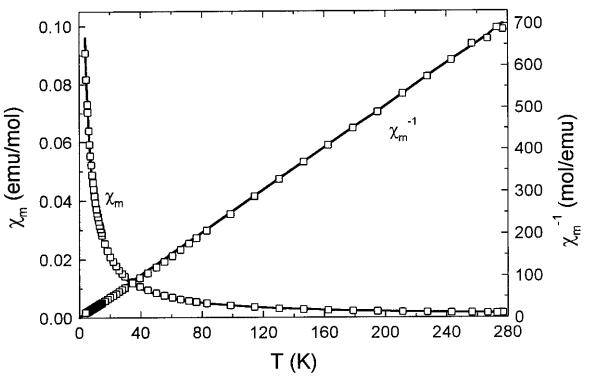

Fig. 6. Thermal variations of the magnetic susceptibility (χ_m) and inverse susceptibility data (χ_m^{-1}) of $Cu(tn)_2(VO_3)_2$, where □ plots for observed results and solid lines for fitting calculations based on the Curie–Weiss law.

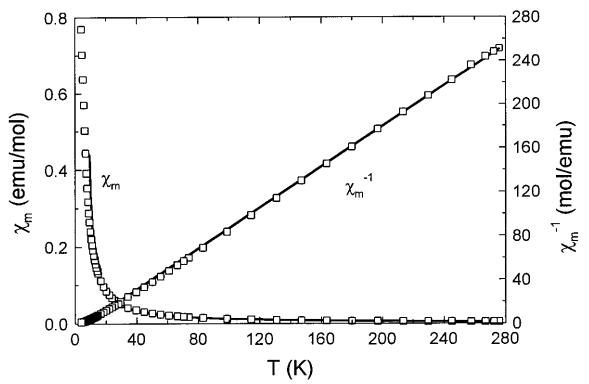

Fig. 7. Thermal variations of the magnetic susceptibility (χ_m) and inverse susceptibility data (χ_m^{-1}) of $Ni(NH_3)_2(VO_3)_2$, where □ plots for observed results, and solid lines attached χ_m and χ_m^{-1} for fitting calculations based on the one-dimensional Ising model and the Curie–Weiss law, respectively.

The behavior of a one-dimensional Ising linear chain has been described by O'Brien [21]. The equation to describe the effect of a molecular exchange field is:

$$\chi_m = \frac{Ng^2\mu_B^2 S(S+1)}{kT} \frac{e^{2d}(e^j\lambda_+ - 1 + e^j)}{F_\lambda} \quad (2)$$

where J is the exchange parameter, D is the zero-field splitting parameter, $d = D/2kT$, $j = 2J/kT$, and λ_+ and F_λ are complicated expressions in terms of D and J, as defined in [21].

The magnetic susceptibility data of **2** was analyzed with Eq. (2). A least-square fit using $T > 15$ K data shows the parameters, $J/k = 2.58(5)$ K, $D/k = -1.26(4)$ K, $g = 2.36(5)$ and $F = 0.424\%$. The positive J value demonstrate a ferromagnetic exchange propagated between paramagnetic centers, and the negative D denotes that the $M_s = 0$ states lies below the $M_s = \pm 1$ states in the nickel octahedral field.

In conclusion, this paper demonstrates two new examples of hydrothermally assembling vanadium oxides through the templating effects of transition metal complexes for preparation of composite organic/inorganic solids. The title compounds show two interaction types between coordination complexes and vanadium oxides. While compound **1** dominantly possesses the electrostatic interactions between the fragments and the vanadium oxide chains, the coordination groups in **2** are covalently bound to the vanadium oxide, and form a three-dimensional framework structure. This suggests that templates, along with the hydrothmal parameters, may influence the resulted structural complexity. Varying the reactive conditions and combining different transition element complexes with oxides, materials with potentially interesting and useful properties may be synthesized.

4. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 145084 for compound **1** and CCDC No. 145085 for compound **2**. Abstract

The binuclear complex $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3{\cdot}2H_2O$ (Hpht = hydrogen phthalate and phen = 1,10-phenanthroline) has been synthesized and structurally characterized. The structure consists of unsymmetrical di-μ-carboxylato-bridged $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]^+$ cation, one NO_3^- anion and two H_2O solvate molecules. The temperature dependence of the magnetic susceptibilities of the complex have been studied in the range 5–300 K, giving the exchange coupling parameter $J = -79.2\ cm^{-1}$, indicating a moderately strong antiferromagnetic interaction between the copper(II) ions within the binuclear unit. © 2000 Elsevier Science B.V. Keywords: Carboxylato-bridged copper(II) complex; Crystal structure; Magnetic properties

1. Introduction

The magneto-structural characterization of binuclear copper(II) complexes has played a key role in the development of magnetochemistry [1,2]. One of the more appealing examples concerns the carboxylato-bridged binuclear copper(II) complexes. Among several types, the antiferro-magnetically coupled tetra- and di-μ-carboxylato-bridged binuclear copper(II) complexes have been extensively studied [3–7]. For tetra-μ-carboxylato-bridged dicopper(II) complexes, the strong intramolecular antiferromagnetic interaction has been observed in the range -160 to $-350\ cm^{-1}$ depending on the nature of carboxylic acid and the apical ligand [9]. The mechanism of this interaction has been demonstrated to be a superexchange of magnetic $d_{x^2-y^2}$ orbitals through the bridging acetates. In di-μ-carboxylato-bridged binuclear copper(II) complexes, the magnetic exchange coupling is still antiferromagnetic, but the strength of this exchange coupling becomes weaker than in the above tetra-μ-carboxylato-bridged binuclear copper(II) series. Tokii et al. [8] have ascribed this diminished coupling predominantly to the fact that the latter complexes contain only two bridging carboxylates in contrast to four in the above series.

The magneto-structural relationship for symmetrically carboxylato-bridged copper(II) complexes shows the magnitude of the exchange coupling dependence on the number of bridges and Cu–O–Cu(α) angle [9]. The present work stems from our interest in exploring this correlation for unsymmetrical carboxylato-bridged copper(II) complexes. Herein we present the synthesis, crystal structure and magnetic properties of $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3{\cdot}2H_2O$.

2. Experimental

2.1. Materials

1,10-Phenanthroline, copper(II) nitrate trihydrate and sodium azide were purchased from commercial sources and used as received.

2.2. Synthesis of $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3\cdot 2H_2O$

An enthanolic solution (10 ml) of 1,10-phenanthroline hydrate (1 mmol, 198 mg) was added to a solution of $Cu(NO_3)_2\cdot 3H_2O$ (1 mmol, 241 mg) in ethanol (10 ml), then mixed with an ethanolic solution (10 ml) of phthalic acid (1 mmol, 166 mg) followed by the addition of an aqueous solution (5 ml) of sodium azide (1 mmol, 65 mg). The reaction mixture was stirred at room temperature (r.t.) for 1 h, then filtered and the filtrate, on slow evaporation at r.t., gave blue crystals after 1 week. *Anal*. Calc. for $C_{40}H_{32}N_6O_{17}Cu_2$: C, 48.24; H, 3.21; N, 8.43. Found: C, 47.29; H, 3.15; N, 8.33%.

2.3. Measurements

Elemental analysis for C, H and N were carried out on a Perkin–Elmer model 240 elemental analyzer. Variable temperature magnetic susceptibilities were measured on an MPMS-7 SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all constituent atoms, and the magnetic moments were calculated using the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1} per Cu(II)).

3. Crystal structure determination and refinement

A blue crystal ($0.30 \times 0.25 \times 0.20$) was selected and mounted in Bruker Smart 1000 diffractometer equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The data were collected at r.t. and a total of 19 213 reflections were collected in the range $0.96 < \theta < 26.41°$ including 8323 independent reflections ($R_{int} = 0.0588$). Selected crystallographic data are given in Table 1. The structure was solved with direct methods using the SHELXS-97. The H atoms were assigned with common isotropic displacement factors and included in the final refinement by use of geometrical restraints. Full matrix least-squares refinement on F^2 was carried out using SHEHXL-97 and the goodness-of-fit on F^2 was 0.978. The final agreement factor values are $R_1 = 0.0470$, $wR = 0.1047(I > 2\sigma)$, $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $wR_2 = (\Sigma\, w(|F_o|^2 - |F_c|^2)^2/\Sigma\, w|F_o|^2)^2$. Selected bond distances and angles are given in Table 2.

4. Result and discussion

4.1. Description of the structure of $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3\cdot 2H_2O$

The structure of the title complex is made up of the di-μ-carboxylato-bridged $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]^+$ cation, one NO_3^- anion and two H_2O solvate molecules. The labeled diagram of $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3\cdot 2H_2O$ is shown in Fig. 1. The coordination around each copper(II) atom is distorted square–pyramidal with two nitrogen atoms of a phenanthroline, two oxygen atoms of the carboxylate groups of hydrogen phthalate and one

water O(5) and one nitrate O(6) occupy the apical positions for Cu(1) and Cu(2), respectively. In two basal planes, the average Cu–N distance is 1.99 Å and the Cu–O distance is 1.95 Å, in good agreement with those structurally analogous complexes [8,10,11]. The deviations of Cu(1) from the N(1), N(2), O(1), O(3) plane and Cu(2) from the N(3), N(4), O(2), O(4) plane are 0.2008 and 0.1544 Å, respectively. The values of the two axial Cu–O bonds are 2.251(3) and 2.219(4) Å for NO_3^- and H_2O, respectively, which are longer than those of the basal planes. The deprotonated carboxylate groups act as *syn–syn* carboxylato bridges which connect the two basal planes of the copper(II) ions, whereas protonated carboxylate remains uncoordination. The Cu(1)···Cu(2) distance is 3.154 Å. Unlike symmetrically carboxylato-bridged copper(II) complexes, the Cu–O–C angles of the title complex are over the greater range 123.6(3)–136.8(3)°. One uncoordinated water and one uncoordinated carboxylate oxygen form an intramolecular hydrogen bond (2.598 Å and 174.43° for O(10)···O(17) and O(10)···H(17w)–O(17), respectively). The intermolecular hydrogen bond occurs between the uncoordinated carboxylate of one unit and one coordinated water of another (2.561 Å and 160.30° for O(12)···O(16) and O(12)···H(16w)–O(16), respectively). The dihedral angle between the two basal planes around the copper(II) ions is 24.4° and the angle between two phen planes is 2.0°.

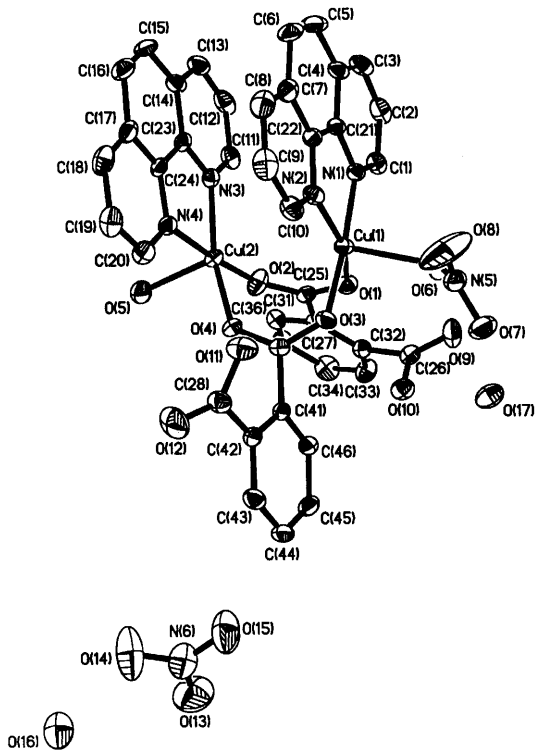

Fig. 1. The labeled diagram of the complex $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3{\cdot}2H_2O$. Thermal ellipsoids are at the 30% probability level.

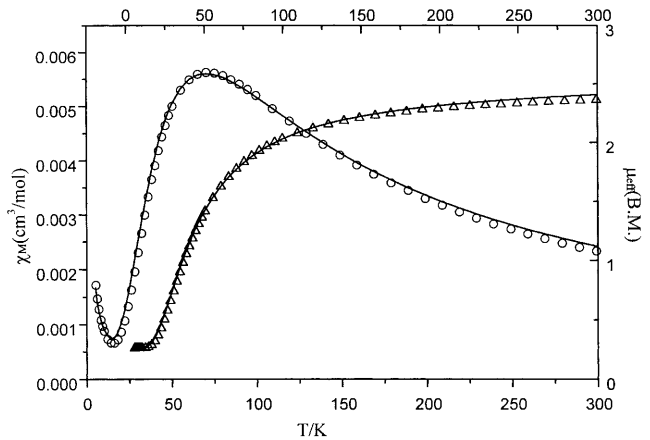

Fig. 2. Plots of χ_M (○) and μ_{eff} (△) of $[Cu_2(phen)_2(Hpht)_2(NO_3)(H_2O)]NO_3{\cdot}2H_2O$ versus T. Solid lines represent the best theoretical fits.

4.2. Magnetic properties

The Variable-temperature magnetic susceptibility of the title complex was measured in the temperature range 5–300 K and the results are shown in Fig. 2. For the complex, the χ_M values increase as the temperature decreases, reaching a maximum at about 100 K, then decreases on cooling and increases again below 10 K, which indicates that antiferromagnetic interaction occurs between Cu(1) and Cu(2). The μ_{eff} value at r.t. is 2.30 B.M., which is smaller than the expected value for two uncoupled copper(II) ions. According to the structure of the present complex, we use Bleaney–Bowers equation [12] to fit the magnetic susceptibility data. In addition, to obtain satisfactory results at low temperature, the paramagnetic monomeric impurity ρ was introduced [2]. Following the equation, we obtained a very satisfactory fit for the data in the range 5–300 K. $J = -79.2\ cm^{-1}$, $g = 2.02$, $\rho = 0.010$, $R = 3.0 \times 10^{-6}$ (R is an agreement factor defined as $R = \Sigma[(\chi_M)_{obs} - (\chi_M)_{calc}]^2/\Sigma[(\chi_M)_{obs}]^2$). From this data, a moderately strong antiferromagnetic interaction exists in the title complex and it is smaller than the corresponding values reported for the tetra-μ-carboxylate-bridges species [4,13,14]. This may be explained by the reduced overlap between the atomic orbitals of the copper atoms and the appropriate Mos of the carboxylato bridge as the number of carboxylate bridges decreases [15]. Wieghardt [9] has proposed a parametric approach to the J value by means of the relationship between J/n and the Cu–O–C bond angle (α) in which n is the number of carboxylate bridges. For the title complex, the Cu–O–C bond angles change over the greater range 123–136° because of the unsymmetrical carboxylate bridges, however, if the average Cu–O–C bond angle (129.5°) was considered, the experimental results obey Wieghardt's proposition.

We can compare the structure and magnetic properties with those reported for the $[Cu_2(CH_3CO_2)_2(phen)_2(H_2O)_2](NO_3)_2{\cdot}4H_2O$ complex [8] which is structurally analogous. For this complex, the Cu–O–C bond angle is 128° and the magnetic exchange coupling is $-86\ cm^{-1}$ between copper(II) ions. In the title complex, the average Cu–O–C bond angle is 129.5°, which is greater than that of the previous complex, therefore a smaller magnetic exchange interaction would be expected and it is agreement with experimental results ($J = -79.2\ cm^{-1}$).

In conclusion, the number of bridges and the Cu–O–C bond angle for unsymmetrical carboxylato-bridged binuclear copper(II) complexes determined the magnitude of magnetic exchange between the copper(II) ions.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 146141 for the title compound. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Spectral characteristics of the copper(III) and nickel(III) coordination compounds with open-chain and macrocyclic dioxotetraamines

Yaroslaw D. Lampeka *, Sergey P. Gavrish

L.V. Pisarzhevskii Institute of Physical Chemistry of the National Academy of Sciences of Ukraine, Prospekt Nauki 31, Kiev 03039, Ukraine

Abstract

Electronic absorption spectra of copper(III) and nickel(III) complexes with open-chain and macrocyclic ligands containing two amide and two amine groups have been described. The absorption bands assigned to the σ- (high-energy) and π- (low energy) LMCT transitions show definite dependence on the structure of the ligands. Thus, the spectra of the complexes with a five-membered chelate ring bearing an isolated carbonyl group are most closely related to the spectra of metal(III) peptides. In some cases the splitting of the σ-LMCT band is observed. Two absorption bands are also characteristic for the spectra of oxamide derived complexes, though several nickel(III) compounds display only a low-energy π-LMCT transition. The most typical spectral feature of the coordination compounds of malonamide derived ligands is the lack of well-resolved low energy bands which could be assigned to π-LMCT transitions and only one band is observed in the UV region which apparently includes both possible transitions. © 2000 Elsevier Science B.V. 1. Introduction

Because of their biological relevance the stability, structure and spectral characteristics of metal complexes with oligopeptides have been the subjects of numerous investigations for many years [1,2]. The ability of such amide-containing ligands to stabilise the high oxidation states of transition metal ions, in particular, copper(III) and nickel(III), and the presence of these metal(III) ions in active sites of native enzymes lent a further impetus to the study of these compounds [3,4].

However, in spite of a wide variability of oligopeptides studied as the ligands, almost all works done were restricted to the compounds built up from α-amino-acid residues. When co-ordinated to the metal ions such ligands form only five-membered chelate rings with each ring bearing one carbonyl oxygen (Chart 1), thus the complexes are very similar from a structural point of view. It is evident that only two variables both exerting mainly electronic effects, i.e. the substituents R^n (typically aliphatic group) and the number of deprotonated amide groups, can be taken into consideration when the influence of ligand structure on the properties of this type complexes is considered. Therefore, it seems quite expectable that irrespective of the ligand structure the electronic absorption spectra of metal(III) oligopeptide complexes are very similar with negligible influence of the substituent R^n, though a moderate bathochromic shift of absorption bands is observed when the number of deprotonated amide groups in the complexes is reduced [5,6].

Metal complexes of non-peptidic tetradentate ligands containing two amide and two amine donor groups represent the class of compounds which can be successfully used as appropriate structural models to mimic the properties of oligopeptide complexes. At the same time, much higher structural variability is inherent of these compounds – both structural parameters (open-chained or macrocyclic nature of the ligand, the size and the set of chelate rings) and electronic characteristics (the number and relative position of carbonyl oxygen atom(s) in chelate rings, the nature of the substituent in the macrocycle) can be varied. Therefore, the study of physicochemical properties of the complexes formed by this class of ligands allows one to gain deeper insight into the question how the metal ion and the ligand are interacting in oligopeptide complexes.

In the ranges of our investigation of the thermodynamic and kinetic aspects of redox behaviour of the complexes with non-peptidic amides, the series of nickel and copper compounds with ligands shown in Fig. 1 was studied by different physicochemical methods [7–14]. The goal of the present work is to discuss the main peculiarities of electronic absorption spectra of metal(III) compounds of this type and to establish the influence of the ligand structural parameters on spectral characteristics. In addition, the comparison of these data with spectral properties of copper(III) and nickel(III) ions in some naturally occurring enzymes could serve as useful tool in elucidation of the structure of their active sites.

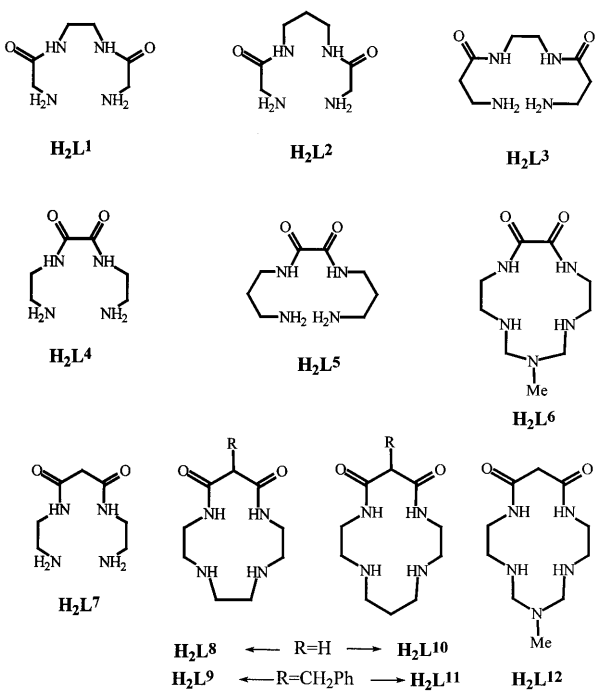

Fig. 1. Ligands containing two amide and two amine groups.

2. Experimental

Amide ligands H_2L^n and their copper(II) and nickel(II) complexes $M^{II}L$ were obtained as described [11]. Corresponding metal(III) compounds $M^{III}L$ were generated in aqueous solution in situ by oxidation of starting $M^{II}L$ complexes with potassium peroxodisulfate. Electronic absorption spectra were recorded on Specord M-40 and Specord UV–Vis (Karl Ceiss, Jena) spectrophotometers.

The values of molar extinction coefficient ε for the metal(III) complexes were determined as follows. 0.5 cm^3 of 5.0×10^{-3} mol dm^{-3} $K_2S_2O_8$ solution was added to 1.0 cm^3 of 2.5×10^{-3} mol dm^{-3} $M^{II}L$ solution and after some time (1.5–10 min, depending on the rate of the oxidation reaction for a given complex) 0.5 cm^3 of 4.0×10^{-1} mol dm^{-3} $HClO_4$ was added. After recording the absorption, 0.5 cm^3 of 1.2×10^{-4} mol dm^{-3} $K_4[Fe(CN)_6]$ solution was added and the absorption was measured again. This procedure was repeated several times. Extinction coefficients were calculated from the drop of absorption after addition of hexacyanoferrate(II) solution with an accuracy of about 5%.

3. Results and discussion

3.1. Solution properties of the complexes

The interaction of copper(II) and nickel(II) ions with diamidodiamines H_2L^n proceeds with the abstraction of two protons from the ligands and leads to the formation of neutral species $M^{II}L$, thus this equilibrium is pH-dependent. It is completely shifted to the formation of the complexes in neutral or mildly alkaline solutions. The metal(III) compounds $M^{III}L^+$ were obtained via oxidation of corresponding metal(II) complexes with peroxodisulfate and their authenticity was confirmed by the redox titration (vide supra) and, for nickel(III) species, by EPR measurements [11]. The choice of this oxidant was determined by its high redox potential and by the fact that neither it itself nor the products of its reduction absorb in the visible and near UV spectral region. The disadvantage of using of such an oxidant consists in insufficiently high rates of its redox reaction. In the cases when the rates of the formation of $M^{III}L^+$ and its redox decomposition were comparable we were unable to reach full conversion of $M^{II}L$ into $M^{III}L^+$, and for some complexes (CuL^3, CuL^5, NiL^3, NiL^8, NiL^9) no accumulation of essential amounts of $M^{III}L^+$ was observed at all.

The method of generation of $M^{III}L^+$ species presumes that in neutral aqueous solutions some amounts of starting $M^{II}L$ complexes persist which prevent accurate determination of the positions and intensities of absorption bands of oxidised forms. To overcome this

Table 1

complication and to register the spectra of 'pure' metal(III) compounds, the well known property of metal(II) complexes to dissociate rapidly in acidic solutions was used [15]. $M^{III}L^+$ are much more stable under these conditions [7]. Thus, extinction coefficients of UV absorption bands were determined as described in Section 2 by redox titration with $K_4[Fe(CN)_6]$. Reaction of ferrocyanide with peroxodisulfate can be neglected since the interaction of copper(III) and nickel(III) species with $[Fe(CN)_6]^{4-}$ is very fast [16]. This is also supported by the fact that the ε values obtained in such a way were independent on the concentration of $S_2O_8^{2-}$ used to generate metal(III) complexes.

3.2. Spectra of the metal(III) peptide complexes

As follows from the literature data [17,18] UV–Vis spectra of copper(III) oligopeptide complexes are typically characterised by the presence of two intensive absorption bands in the region 40 000–25 000 cm^{-1}. Based on their intensities and keeping in mind the high oxidation state of the metal ion, one can conclude that these bands have a ligand-to-metal charge-transfer (LMCT) nature. Sometimes ligand field (LF) transitions are also observed in such systems as band with moderate intensity located at approximately 22 000 cm^{-1} but in the majority of complexes it is masked with low-energy LMCT absorption. In principle, LMCT transition could originate from the orbitals of different donor atoms of the ligand – deprotonated amide nitrogen, amine nitrogen or carboxylate oxygen. Since the same spectral patterns are characteristic of the complexes with the donor set consisting of only amidic nitrogen atoms, it is assumed that the main contribution to the spectra observed is made by LMCT transitions from N_{amide} while CT bands from the donor atoms of other chemical nature, if present, are overlapped with those. The presence of two LMCT bands in the spectra of copper(III) peptide complexes is explained by the fact that the $N_{amide} \rightarrow Cu^{III}$ component of the metal chromophore has both σ- and π-symmetry molecular orbitals relative to copper(III)-N_{amide} bond. Among the two bands observed, the assignment of the low-energy one to π- and high-energy band to σ-LMCT is based on the analysis of the charge transfer spectra of other transition metal complexes [19].

In general, the spectra of nickel(III) oligopeptide complexes are similar to those of the copper(III) species. They are also characterised by two absorption bands in the UV (approximately 40 000 cm^{-1}) and near UV (approximately 30 000 cm^{-1}) regions with relatively high intensities ($\log \varepsilon$ approximately 3–4). Analogously, the high energy band is assigned to the σ- and the low-energy band to the π-LMCT transition [6].

3.3. Spectra of the metal(III) complexes with diamidodiamine ligands

Analogously to the spectra of oligopeptide compounds, the solution spectra of the metal(III) complexes with the ligands under consideration are characterised by the presence of several intensive absorption bands in

Table 2
Spectral characteristics [a] of the nickel(III) complexes with diamidodiamine ligands in aqueous solution containing 0.1 mol dm^{-3} $HClO_4$

the UV and near UV region (Tables 1 and 2). However, the number of bands observed and general shapes of the spectra in these cases differ from the those of the former and show definite dependence on the structure of the ligands.

Generally, from the point of view of structural peculiarities, the complexes studied can be classified into three groups.

The first group comprises the metal(III) compounds with the ligands H_2L^1 and H_2L^2. The main structural motif present in $M^{III}L^1$ and $M^{III}L^2$ is the five-membered chelate ring bearing isolated carbonyl group. It is just the fragment which is inherent of peptide complexes (see Chart 1). Therefore, it comes as no surprise that their CT spectra most closely resemble those of oligopeptide complexes – as for the former, two well-resolved absorption bands are characteristic of these compounds (Tables 1 and 2, as an example the spectra of $M^{III}L^2$ are shown in Fig. 2).

It seems quite reasonable, similar to the literature data (vide supra), to assign the high- and low-energy bands to σ- and π-LMCT transition, respectively (see Tables 1 and 2). At the same time, distinct splitting of one of these bands is observed for these compounds that is especially evident for $M^{III}L^2$ (Fig. 2). The question, what band having either σ- or π-LMCT nature is split, is ambiguous, since low real symmetry of the chromophore permits both σ- and π-transition to be split into two allowed transitions [17]. Based on the relative intensities of the bands and the distances between the maxima of components we are inclined to believe that the lowering of symmetry removes the degeneracy of the band corresponding to the σ-LMCT transition. This is further confirmed by analogous assignment of the split bands in the copper(III) complex of cyclic tetrapeptide *cyclo*-(β-alanylglycine-β-alanylglycine) [20].

The second structural group consists of complexes formed by both the open-chain and macrocyclic ligands having oxamide fragment, H_2L^4, H_2L^5 and H_2L^6. As for the former group, the only characterised copper(III) complex with this type of ligand, $[Cu^{III}L^4]^+$, possesses two absorption bands which can be assigned to σ- (high-energy) and π- (low-energy) LMCT transitions (Fig. 3). Similar spectral patterns are characteristic also for the nickel(III) complex with H_2L^5. At the same time, in the spectra of the nickel complexes with a 5,5,5-set of chelate rings ($Ni^{III}L^4$ and $Ni^{III}L^6$) only one absorption band is present (Fig. 3). Accepting that this band corresponds to π-type of LMCT, as is quite reasonable, one can conclude that σ-LMCT transition in these compounds must be located at $\nu > 40\,000$ cm^{-1} and thus be higher than for all other types of complexes studied.

The third group includes the coordination compounds of the ligands derived from malonamide, i.e. forming a six-membered chelate ring bearing two carbonyl groups (H_2L^7–H_2L^{12}). The most typical feature of the spectra of these compounds is the lack of well-resolved low energy bands that could be assigned to π-LMCT transitions. Instead, only one broad non-symmetric band is observed which apparently includes both σ- and π-transitions (Fig. 4). A redistribution of the

relative intensities of the constituents of a single band observed when an benzyl substituent is introduced in the malonamide fragment can serve as indirect evidence confirming this suggestion (Fig. 5). In our opinion, such an effect can be assigned to the interaction of the π-system of the aromatic ring with π-electrons of the chromophore influencing the MO diagram of the molecule as a whole.

Thus, the results obtained show that the CT spectra of copper(III) and nickel(III) complexes with diamidodiamines, despite being characterised by the absorption bands of a similar nature, show a distinct dependence on the structure of the ligands. As far as the energy of the σ-LMCT transition is considered, it is the highest for the first two groups of copper(III) complexes and essentially lower for malonamide derivatives, while quite the opposite picture is observed for the energy of the π-LMCT band. An analogous tendency is also observed for the energy of the σ-LMCT transition in the case of nickel(III) complexes, but the dependence of the π-LMCT energies on the structure of the ligands in this case differs. Though again this band has the lowest energy in the complexes of the first group, it is nearly the same for the remaining compounds. It was shown formerly for the copper(III) peptide complexes that the energy separation ΔE between the two CT bands varies in the ranges $(10.4 \div 12.6) \times 10^3$ cm^{-1} and is dependent on the number of α-methyl groups in the ligand [5,21]. In the present case the range of ΔE is much higher (from approximately 5×10^3 cm^{-1} for malonamide ligands to 13.9×10^3 cm^{-1} for CuL^1 or CuL^2, see Table 1) and is not connected with the inductive effect of the substituents.

It was shown also that the increase of the number of deprotonated amide groups in the coordination sphere of the copper(III) and nickel(III) oligopeptide complexes results in the blue shift of the π-LMCT bands and is accompanied by the lowering of the formal $M^{III/II}L$ couple potentials E_f [5,6]. In the present case the spectral changes are determined by the variation of the structural characteristics of the ligands, not by the nature of the donor atoms. Therefore, it was of interest to estimate whether an analogous relationship between spectral and redox characteristics can be valid for the non-peptide type of complexes. The analysis of available data allows one to conclude that, for the copper complexes for which a distinct π-LMCT band can be identified, its energy decreases in the series CuL^4–CuL^1–CuL^2, thus correlating with the increase of the E_f values (cf. with 0.49, 0.59 and 0.75 V versus SCE [11], respectively). In general, a similar tendency is inherent also for the nickel(III) species – the redox potentials of the complexes derived from oxamide ligands are much less positive (by approximately 70–100 mV) than for the compounds with H_2L^1 and H_2L^2 [11] which are characterised by a lower energy of π-LMCT transition as compared to the former. At the same time, this correlation can not be considered as general. For example, copper(III) complexes with isomeric ligands H_2L^2 and H_2L^7 possess very similar redox potentials [11] but are characterised by different absorption spectra. The same is also true for the nickel complexes with these ligands.

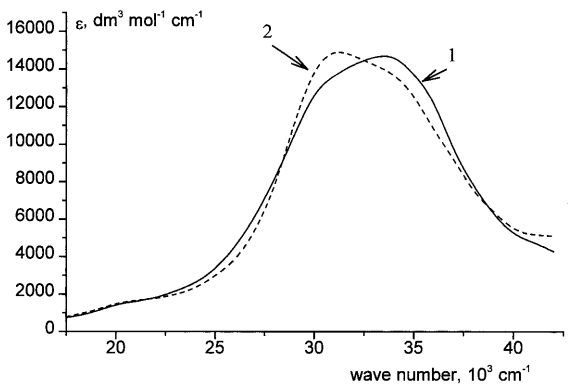

Fig. 5. Absorption spectra of $Cu^{III}L^{10}$ (1) and $Cu^{III}L^{11}$ (2) in 0.1 mol dm^{-3} $HClO_4$.

In addition to the electronic transitions discussed above, one more band in the visible region is present in the spectra of several copper(III) complexes (Table 1). Based on its relative low intensity and as well on the dependence of its energy on the set of chelate rings in complexes one can assign it to the ligand field transition in the low-spin d^8 electron configuration of the copper(III) ion. An analogous band, though at lower energy, was observed formerly in the copper(III) complex of tetraglycine [21].

To summarise, the results of our study of the spectra of copper(III) and nickel(III) complexes revealed that open-chain and macrocyclic ligands containing two amide and two amino groups can be considered as appropriate structural models of oligopeptides. In general, spectral characteristics of metal(III) complexes with these ligands have much in common with the spectra of oligopeptide compounds. For both types of species the absorption bands observed in the UV and visible spectral region have a ligand-to-metal charge transfer nature (LMCT) and depending on their energy were assigned to σ- (high-energy) and π- (low energy) LMCT transitions. At the same time, in contrast to oligopeptide coordination compounds, the spectral characteristics of the complexes under consideration show a definite dependence on the structure of the ligands despite a similar chromophore of the metal ions. Thus, the spectra of the complexes possessing a five-membered chelate ring with isolated carbonyl group are most closely related to the spectra of metal(III) peptides displaying two well-resolved absorption bands. In some cases the splitting of the σ-LMCT band is observed. Two absorption bands are also

present in the spectra of complexes with oxamide derived ligands which form a five-membered chelate ring bearing vicinal carbonyl groups, though in several nickel(III) compounds of this type only low-energy π-LMCT transition is observed. The most typical spectral feature of the coordination compounds of malonamide derived ligands is the lack of well-resolved low energy bands which could be assigned to π-LMCT transitions and only one broad non-symmetric band is observed in the UV region which apparently includes both possible transitions.

Abstract

Reactions of C_2Cl_3HgX (X = C_2Cl_3, Cl, Br) with the potential bidentate ligands, bis(diphenylphosphino)methane, 2,4′-bipyridyl, 4,4′-bipyridyl and 2,2′-dipyridyl disulfide(PySSPy), in a 2:1 molar ratio have been studied and the thermal and infrared spectral characteristics of the products have been examined. Complexes were isolated for $(C_2Cl_3)_2Hg$ and C_2Cl_3HgCl in all cases apart from between $(C_2Cl_3)_2Hg$ and the diphosphine. The diphosphine and 2,2′-dipyridyl disulfide formed 1:1 complexes (**7**, **6**) with C_2Cl_3HgCl, whereas with $(C_2Cl_3)_2Hg$ the latter ligand formed [$\{(C_2Cl_3)_2Hg\}_2$(PySSPy)] (**3**) which on standing formed C_2Cl_3HgSPy (**12**). 4,4′-Bipyridyl and 2,4′-bipyridyl differed in the stoichiometry of the isolated complexes. $(C_2Cl_3)_2Hg$ formed 1:1 complexes (**1**, **2**) with both ligands whereas C_2Cl_3HgCl formed a 1:1 complex (**4**) with the former ligand but a 1:2 complex (**5**) with the latter. All four ligands caused disproportionation of C_2Cl_3HgBr with resulting isolation of the mercury(II) bromide complexes (**8**–**11**). The structure of [$(C_2Cl_3)_2Hg$ (4,4′-bipyridyl)] (**1**) shows that only one nitrogen is weakly coordinated to mercury so that C–Hg–C is approximately linear in the monomeric structure but there are four intramolecular chlorines closer to mercury than the sum of the van der Waals radii. The C–Hg–S angle in [C_2Cl_3Hg(2-pyridyl thiolate)] (**12**) is only slightly distorted from linearity due to secondary bonding to nitrogen. There are two weak intramolecular contacts between mercury and chlorine and two intermolecular mercury–sulfur contacts to form pairs of molecules which form double chains along the *b* axis. [$HgBr_2$(2,2′-dipyridyl disulfide)] (**10**) is polymeric and contains four-coordinate mercury with the ligand bridging between mercury atoms via coordination to nitrogen. © 2000 Elsevier Science B.V. Keywords: Trichlorovinyl; Mercury(II); Crystal structures; Complexes; Bidentate ligands

1. Introduction

Unlike the mercury(II) halides which form a wide range of complexes [1], mercury dialkyls form few complexes. The presence of electronegative substituents in the organic group attached to mercury or replacement of one of the organic groups by a halogen enhances the Lewis acidity of mercury, so that bis(trinitromethyl) mercury [2] and bis(pentafluorophenyl) mercury [3] are stronger acceptors than the unsubstituted compounds. Likewise trichlorovinylmercury chloride and bromide [4] are slightly stronger acceptors than bis(trichlorovinyl)mercury [5] with bidentate chelating ligands.

Coordination between mercury and a hetero atom in the same molecule has been increasingly used to explain the several anomalies in physical properties of organomercury compounds as well as interpret many of their reactions [6]. In particular, special features of infrared (IR), NQR spectra, dipole moments as well as anomalous effects of ortho substituents are explained

by such coordinative interactions [7–9]. X-ray structure determination and electron diffraction are often used to ascertain the possible presence of these interactions and unusual features in the ^{35}Cl NQR spectra of a range of chlorinated organomercurials have been ascribed to intramolecular interaction of chlorine and mercury. [10–24]. While NQR data indicate the possibility of secondary Hg–Cl bonding in complexes of bis(trichlorovinyl)mercury [5], the X-ray structure of the 3,4,7,8-tetramethyl-1,10-phenanthroline complex did not provide any conclusive evidence [25]. In furtherance of our studies on the coordination behaviour of chlorovinylmercurials and Hg···Cl secondary interactions, we have studied the reactions and determined the crystal structures of some of the complexes formed by such organomercurials with potential bidentate ligands in which the positions of the donor atoms renders chelation improbable.

2. Experimental

The ligands were commercially available and were used without further purification. Microanalyses were carried out by Elemental Micro-Analysis Ltd at Beaworthy. Thermal measurements were recorded using a Mettler TA 3000 thermal analyser. Samples were heated at a rate of 10°C min^{-1} under a flow of nitrogen of 50 cm^3 min^{-1}. IR spectra (2000–600 cm^{-1}), were recorded as KBr discs using an ATI Mattson Genesis Series FTIR spectrometer using WINFRIST software. Melting points were obtained using an electrothermal melting point apparatus and are uncorrected.

2.1. Reagents

Bis(trichlorovinyl) mercury (m.p. 72–73°C, lit. [26] 72–73°C), trichlorovinylmercury chloride (m.p. 105–107°C, lit. [26] 109°C) and trichlorovinylmercury bromide (m.p. 98–100°C, lit. [26] 99–100°C) were prepared as previously described.

2.2. Preparation of complexes

The complexes were prepared by adding an ethanolic solution of the ligand to the organomercurial also in ethanol in 1:2 mole ratio, the solutions being warmed where necessary to dissolve the materials. After mixing the solutions, solvent was evaporated to crystallisation and the deposit then recrystallised and dried in vacuo. A representative synthesis is shown below. Solvents for recrystallisation, analytical data, melting points and appearance are reported in Table 1.

2.2.1. Preparation of [{$(C_2Cl_3)_2Hg$}$_2$(2,2′-dipyridyl disulfide)] (3)

A warm solution of 2,2′-dipyridyl disulfide (0.23 g, 1.04 mmol), dissolved in ethanol (25 cm^3), was added to bis(trichlorovinyl)mercury (0.92 g, 1.99mmol) also dissolved in ethanol. The clear solution was evaporated to low volume (10 cm^3) and the deposit filtered off and recrystallised from ethanol/water as colourless needles. Yield: 0.46g, 40%.

2.3. X-ray crystallography

Crystals of **1**, **10** and **12**, suitable for X-ray analysis, were grown by slow evaporation of ethanolic solutions of the complexes.

Cell dimensions and intensity data were recorded at 298 K, using a Nonius Kappa CCD area detector diffractometer mounted at the window of a rotating anode operating at 50 kV, 90 mA, with a molybdenum anode (λ(Mo Kα) = 0.71073 Å). The crystal-to-detector distance was 30 mm and ϕ and Ω scans (2° increments, 10 s exposure time) were carried out to fill the Ewald sphere. Data collection and processing were carried out using the programs COLLECT [27], DENZO [28] and MAXUS [29] and an empirical absorption correction was applied using SORTAV [30,31].

The structures were solved via direct methods [32] and refined by full-matrix least-squares [32] on F^2. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms for **1** were located from the difference map and fully refined, whilst hydrogen atoms for **10** and **12** were placed in idealised positions and refined using a riding model. Summary details are presented in Table 2.

3. Results and discussion

Reactions between $(C_2Cl_3)_2Hg$, C_2Cl_3HgCl and C_2Cl_3HgBr and a range of bidentate ligands, bis-(diphenylphosphino)methane, 2,4′-bipyridyl, 4,4′-bipyridyl, 2,2′-dipyridyl disulfide and 4,4′-dipyridyl disulfide were studied by reaction of the mercurial and ligand in 2:1 mole ratio in ethanolic solution. The ligands chosen differed from the chelating ligands studied earlier [4,5] such that in the case of 2,4′-bipyridyl, 4,4′-bipyridyl and 4,4′-dipyridyl disulfide, the positions of the donor atoms precluded chelation, whereas for bis(diphenylphosphino)methane and 2,2′-dipyridyl disulfide the size of ring which would be formed in chelation is improbable. A surprising variety of stoichiometries for the isolated complexes was found and the structural possibilities for these complexes are shown in I–IV (R = C_2Cl_3, R′ = C_2Cl_3, Cl or Br and L ∼ L is the bidentate ligand). Bis(phenylethynyl)-mercury forms only 2:1 complexes with 4,4′-bipyridyl and 4,4′-dipyridyl disulfide which are expected to be of type III [33].

We initially attempted to obtain the crystal structure of the parent organomercurial, bis(trichlorovinyl)-mercury, to ascertain if there was crystallographic evidence for secondary Hg–Cl interactions to support the NQR evidence found earlier [5]. The molecule was triclinic but, despite repeated attempts, the structure was not amenable to solution. However, we were able to determine the structure of two other trichlorovinylmercury complexes and these can be compared with the structures of the wide range of organomercurials which have recently been reviewed [34].

Bis(diphenylphosphino)methane does not complex with the weak acceptor $(C_2Cl_3)_2Hg$ but with the stronger Lewis acid C_2Cl_3HgCl a 1:1 complex (**7**) was isolated. Chelation is improbable in this complex due to the bite of the ligand and it is most likely to be of type II in which the ligand acts as a bridge between mercury atoms, thereby resulting in four-coordinate mercury, although a type I structure, in which the ligand is monodentate with a pendant phosphine group and the mercury only three coordinate, is possible.

2,4′-Bipyridyl forms complexes of different stoichiometry with $(C_2Cl_3)_2Hg$ and C_2Cl_3HgCl. The weaker acceptor $(C_2Cl_3)_2Hg$ forms a 1:1 complex (**2**), steric effects preventing the entry of a second ligand into the coordination site around mercury and the similarity in the IR spectrum of this complex and the 4,4′-bipyridyl complex of $(C_2Cl_3)_2Hg$, whose crystal structure has

been determined, is indicative of a type I complex. The stronger acceptor C_2Cl_3HgCl is less sterically encumbered than $(C_2Cl_3)_2Hg$ and forms the usual four-coordinate mercury(II) (**5**) by attachment of two 2,4′-bipyridyl ligands. Both of these trichlorovinylmercurials form 1:1 complexes with 4,4′-bipyridyl for which the $(C_2Cl_3)_2Hg$ complex (**1**) has been confirmed crystallographically to be monomeric and of type I, whereas C_2Cl_3HgCl (4,4′-bipyridyl) may be associated (type II) due to less steric crowding around mercury, though the similarity in the IR spectra of the two complexes suggests similar structures. The structure of the 1:1 complex (**1**) of $(C_2Cl_3)_2Hg$ with 4,4′-bipyridyl is shown in Fig. 1, with selected bond lengths and angles in Table 3. The molecule is centrosymmetric and the most notable features of the structure are (i) the slight distortion of the C–Hg–C angle (169.9(3)°) from linearity, reflecting the tendency of organomercury compounds towards linearity in contrast to mercury(II) halides which tend to become pseudotetrahedral, (ii) the long Hg–N bond (2.690(6) Å, cf. 2.00–2.20 Å in a wide range of Hg–N compounds [34]) indicating only weak interaction, (iii) only one of the nitrogen atoms in the bipyridyl is coordinated to mercury, also indicative of weak coordination and (iv) the two intramolecular contacts between Hg and Cl(1) and Cl(3) (3.318(5) and 3.346(6) Å, respectively) and in the symmetry related other half of the molecule. Though these Hg···Cl contacts are less than the sum of the van der Waals radii, they appear to be an inherent feature of the structure and do not reflect significant intramolecular shortening of the Hg···Cl distances due to secondary interactions as these would tend to narrow the angles around C(1) and C(2), adjacent to mercury, to less than 120°. The Cl(1)–C(1)–Hg angle is in fact normal (120.3(3)°) for an sp^2 hybridised carbon and the C(1)–C(2)–Cl angles are slightly greater than 120° with the Cl(2)–C(2)–Cl(3) angle being significantly less (112.3(3)°), The planes of the two pyridine rings are twisted by 37.6(3)° to reduce interactions between hydrogens on neighbouring rings. Thus the complex is of type I, rather than the expected polymeric arrangement of type II in which both nitrogens would be coordinated to different mercury atoms, reflecting the poor acceptor character of $(C_2Cl_3)_2Hg$ compared to $HgBr_2$ for which the 2,2′-dipyridyl disulfide complex has both nitrogens coordinated to different mercury atoms (type II). This weak interaction between a variety of ligands and organomercurials in which mercury only undergoes slight distortion from linearity on complexation with nitrogen containing Lewis bases has previously been demonstrated [25].

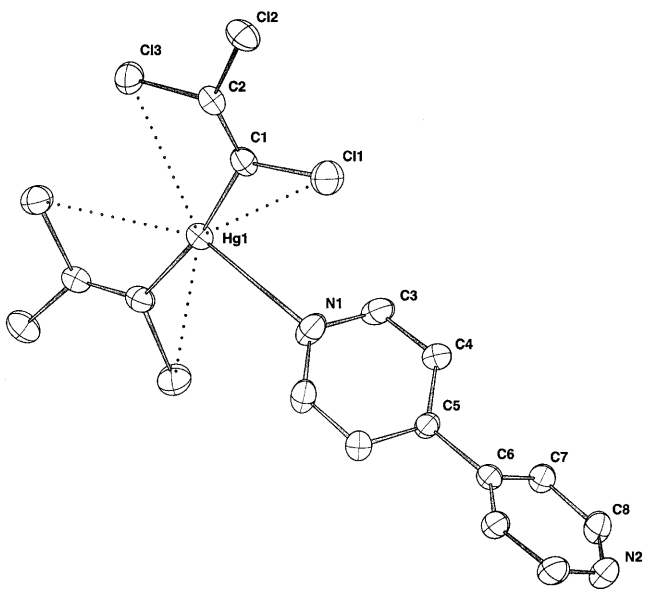

Fig. 1. Molecular structure of $[(C_2Cl_3)_2Hg(4,4'bipyridyl)]$ (**1**) with ellipsoids at 30% probability.

Although 4,4′-dipyridyl disulfide formed brown solutions with the trichlorovinylmercurials, from which complexes could not be isolated, 2,2′-dipyridyl disulfide does form isolable complexes with C_2Cl_3HgX (X = C_2Cl_3, Cl). Bis(trichlorovinyl)-mercury being a relatively weak acceptor [5] requires only one nitrogen atom per mercury to satisfy its coordination deficiency and thus forms $[(C_2Cl_3)_2Hg]_2$-(2,2′-dipyridyl disulfide) (**3**) (type III) although a weak interaction with sulfur may occur. An attempt to obtain the crystal structure of this complex which is analogous to the 2:1 adduct of bis-(pentafluorophenyl)mercury(II) and bis(diphenylarsino)-methane, whose structure was determined with a high *R* value almost 30 years ago [35] showed that, on standing, cleavage of the disulfide bond had occurred and the structure obtained was that for C_2Cl_3HgSPy (**12**). Heterocyclic thionates have been prepared in situ by splitting the disulfide bond of a heterocyclic disulfide either thermally or photochemically and organometallic chelate complexes of heterocyclic thionates have been prepared by these means [36]. The stronger, less sterically crowded, acceptor C_2Cl_3HgCl [4] require two nitrogen atoms for coordinative saturation and so forms a 1:1 complex (**6**) which is likely to be polymeric (type II) as found for the corresponding mercury(II) bromide complex described herein.

The structure of $C_2Cl_3Hg(PyS)$ (**12**) is shown in Fig. 2 with bond lengths and angles in Table 3. The crystal structure of MeHg(PyS) has been described previously [37] and also $Me_2Tl(PyS)$ and $Me_2Sn(PyS)_2$ [38]. In the former complex the ligand is η^1-sulfur donating with secondary bonding to nitrogen and to two neighbouring thionate sulfur atoms so that the overall geometry around mercury is distorted trigonal bipyramidal [37]. In the thallium compound the ligand is η^1-nitrogen donating with secondary Tl···S bonding to the ligand and also to a neighbouring ligand so that the metal becomes five-coordinate, whereas in the tin compound the metal becomes octahedrally coordinated as the lig-

and is S,N-chelating [38]. In $C_2Cl_3Hg(PyS)$ (**12**) the complex contains essentially two-coordinate mercury(II) with a shorter η^1-sulfur donating ligand than in the methyl analogue (2.350(6) cf. 2.374(2) Å). The C–S bond length (1.82(3) Å) (cf. 1.776(1) Å in the methyl analogue) lies in the range for a single bond, showing that the ligand is in the thiol form. There is a secondary interaction with nitrogen (Hg–N = 2.809(7) Å) which results in slight distortion from linearity at mercury (170.7(7)°). This distortion is larger than the 176.4(2) found in the methyl analogue [37] but there is a shorter Hg–C bond length (2.06(2) Å) than in the methyl compound (2.089(7) Å) and in $(C_2Cl_3)_2Hg(4,4'\text{-bipy})$ (2.083(5) Å) due to less steric crowding around mercury. In addition to the Hg(1)···N(1) interaction there are two further intramolecular contacts, less than the sum of the van der Waals radii (Hg(1)···Cl(3), 3.271(5) Å and Hg(1)···Cl(2), 3.374(4) Å), as well as two intermolecular contacts ($Hg(1)\cdots S(1)^{I}$, 3.329(3) Å and $Hg(1)\cdots S(1)^{II}$, 3.359(5) Å). The intermolecular contacts link adjacent molecules into pairs (Fig. 2) and these are linked by contacts above and below (Fig. 3) to form double chains along the *b* axis. Mercury, C6, C7 and all of the chlorine atoms are coplanar as also found in the structure of **1**.

Reaction of C_2Cl_3HgBr with 2,2′-dipyridyl disulfide gave a crystalline complex that was initially thought to be a 1:1 complex on the basis of the analytical data, like the corresponding chloride. However the peaks due to C=C and C–Cl appeared to be absent in its IR spectrum. The X-ray structure of the compound showed it to be the 1:1 complex (**10**) of mercury(II) bromide which had similar theoretical C, H and N analytical data to that for the C_2Cl_3HgBr complex. Data for both are shown in Table 1 for comparison. Bis(diphenylphosphino)methane, 4,4′-bipyridyl and 2,4′-bipyridyl also caused disproportionation of C_2Cl_3HgBr resulting in the formation of the 1:1 complexes (**11**, **8**) of $HgBr_2$ with the former two ligands and $HgBr_2(2,4\text{-bipy})_2$ (**9**) with the latter.

The structure of $[HgBr_2(PySSPy)]_n$ (**10**) is shown in Fig. 4 and selected bond lengths and angles in Table 3. The structure consists of a pseudotetrahedral distribution around mercury of two bromines and two nitrogens from different 2,2′-dipyridyl disulfide molecules, thus creating a polymeric chain with the ligand bridging two mercury atoms, as found for the chloro analogue [39]. There are no mercury–sulfur interactions as the Hg–S distances (3.586(7), 3.732(7) Å) are very long. The Hg–Br distances (2.4468(7), 2.4671(7) Å) are similar to those found in $HgBr_2(pyridine)_2$ (2.478(3), 2.483(3) Å [40]), whereas the Hg–N distances (2.529(5), 2.633(5) Å) are significantly longer (2.38(2). 2.39(2) Å) but are similar to those found in the chloro analogue (2.527(5), 2.632(3) Å) [39]. The Br–Hg–Br angle is remarkably large (153.01(3)°) and is similar to that found in the corresponding chloride (154.8(1)°), result-

	412–480	mass loss 15.5% leaving 17.8% residue

[a] Mass loss and residue are expressed as % of the mass of the original compound.

ing from bridging by the nitrogen ligand whereas in a chelate complex such as (*N*,*N*,*N*′,*N*′-tetramethyl-*o*-phenylenediamine)$HgBr_2$ [41] the Br–Hg–Br angle is 123.04(8)° and N-Hg-N is 73.2(4)° compared to 83.75(19)° in the bromide described herein and 81.1(2)° in the chloride analogue [39]. The other angles and distances are similar to those found in the free ligand [42].

Comparison of the IR spectra of the complexes with those of the parent mercurials show that the strong absorptions at 1530 and 845 cm^{-1} due to C=C and C–Cl vibrations respectively are not significantly moved on complexation. The most notable feature of the spectra is the increase in intensity of the 845 cm^{-1} peak in $[\{(C_2Cl_3)_2Hg\}_2(2,2'\text{-dipyridyl disulfide})]$ (**3**) compared to the free ligand and the $(C_2Cl_3)HgCl(2,2'\text{-dipyridyl disulfide})$ complex (**6**). The spectra of all the complexes show bands which are characteristic of the parent organomercurials and the ligands. However, it is to be noted that the bands of the ligands are only slightly modified in the complexes. The similarity in the IR spectra of the 2,2′-dipyridyl disulfide complexes with those of 2,2'-bipyridyl complexes [4,5] leads us to the conclusion that coordination takes place through nitrogen in all cases rather than sulfur, since the weak nature of the Hg–N interaction in organomercury–nitrogen complexes as illustrated by the crystal structure of $(C_2Cl_3)_2Hg$(3,4,7,8-tetramethyl-1,10-phenanthroline in which C–Hg–C is little distorted from linearity and the Hg–N bonds are long [25] and the low coordination number of the metal is unlikely to modify the spectra significantly.

The thermal characteristics of the complexes are shown in Table 4. For some of the complexes, e.g. $(C_2Cl_3)_2Hg(4,4'\text{-bipy})$ (**1**) mass loss occurred in a single step, though often over a wide temperature range, usually leaving a slight residue, doubtless from thermal degradation of the complexes. In two cases mass losses corresponded closely with values expected for the formation of intermediates in the decomposition schemes as shown below:

$$[\{(C_2Cl_3)_2Hg\}_2(2,2'\text{-dipyridyl disulfide})] \xrightarrow{155-227^\circ C} (C_2Cl_3)_2Hg\uparrow + (C_2Cl_3)_2Hg(2,2'\text{-dipyridyl disulfide})$$

(mass loss found 38.8%; calc. 40.4%)

$$\xrightarrow{227-387^\circ C} 2,2'\text{-dipyridyldisulfide} + (C_2Cl_3)_2Hg\uparrow$$

(mass loss found 39.0%; calc. 40.4%)

$$(C_2Cl_3)HgCl(Ph_2PCH_2PPh_2) \xrightarrow{182-323^\circ C} (C_2Cl_3)HgCl\uparrow + Ph_2PCH_2PPh_2$$

(mass loss found 53.1%; calc. 51.7%)

For the remaining complexes decomposition was complex and, though in some cases the TG traces showed evidence for the formation of intermediates, it was not possible to predict the nature of these simply from the mass losses.

4. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge

Crystallographic Data Centre, CCDC No. 146176 for compound **1**, CCDC No. 146177 for compound **12** and CCDC No. 146178 for compound **10**. Received 15 June 2000; accepted 14 August 2000

Abstract

Four novel $[Sr(thd)_2(L)]_n$ ($n = 2$; L = diethylenetriamine (**I**), $n = 1$; L = triethylenetetramine (**II**), tetraethylenepentamine (**III**), and tris(2-aminoethyl)amine (**IV**)) complexes were synthesized by the reaction of $Sr(thd)_2$ with corresponding polyamines in THF and characterized by FTIR, ^1H NMR and single-crystal X-ray crystallography. Complex **I** exists as a dimmer in the solid state in which two strontium atoms are bridged by two thd ligands. Complexes **II** and **III** exist as monomers in the solid state and in both complexes, the polyamine ligands are coordinated to the central strontium atom in a meridional fashion, with the two thd ligands on opposite sides of the neutral ligand plane. Complex **IV** also exist as a monomer in the solid state. In this molecule, strontium atom is eight-coordinate with all of the nitrogens of the amine ligand and all oxygens of the thd ligand binding to the metal atom. The amine ligand is coordinated to one side of the metal atom and resulting in a *cis*-relationship. Thermogravimetric analysis shows that complexes **I**, **II**, **III** and **IV** are sufficiently volatile and sublimed without residue. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Strontium; Polyamine ligand; Thd ligand; Precursor

1. Introduction

There has been a continuing interest in the synthesis of alkaline earth metal β-diketonate complexes (particularly Ca, Sr and Ba), because they have been used as promising metal organic chemical vapor deposition (MOCVD) precursors for perovskite metal oxides and ceramic superconductors [1,2]. A useful MOCVD precursor must not only have appropriate reactivity for the desired film growth process but also low volatility and stable vapor pressure characteristics [3]. Monomeric complexes are expected to exhibit an enhanced volatility in comparison to oligomeric complexes because of minimizing intermolecular solid-state interactions and connectivities. Heavier alkaline earth metal bis(β-diketonate) complexes usually exist as oligomeric species ($Ca_3(thd)_6$ [4], $Sr_3(thd)_6$(H–thd) [5], and $Ba_4(thd)_8$ [6]) (thd = 2,2,6,6-tetramethyl-3,5-heptanedionate) in the solid state. They have relatively low volatility and undergo severe deterioration during storage. They have also unstable vapor pressure as a result of tendency to oligomerize. The main reason for these problems is, among other factors, the large size of the heavier Group II metal ions. To circumvent this problem, recent research interests have been focused on the synthesis of coordinatively saturated Group II metal precursors by introducing ancillary Lewis base ligands. For example, polyether adducts of strontium and bar-

ium complexes, $Sr(Ph_2acac)_2$(tetraglyme) [7], $Sr(thd)_2$-(tetraglyme) [7], $Ba(thd)_2$(triglyme) [8], $Ba(thd)_2$-(tetraglyme) [7] are reported. Although these adduct complexes exist as monomeric, exhibiting higher vapor pressure than those of $[M(thd)_2]_n$ complexes, the low Lewis acidity of barium and strontium ions weaken the bonding of the adducted polyether chain resulting in dissociation of polyether ligands upon attempted sublimation of the solid and thus have unstable vapor pressure [7,9]. Another approach to improve the volatility and vapor pressure stability of precursors is the introduction of fluorinated β-diketonate ligands [10–13]. However, in many cases, the use of fluorinated β-diketonates necessitates the addition of water vapor as a reactant gas to prevent the formation of undesirable metal fluorides [14,15]. Polyamine adducts of strontium and barium complexes, $Sr(hfac)_2(bpy)_2$ [16](hfac = 1,1,1,5,5,5 - hexafluoro - 2,4 - pentanedionate, bpy = 2,2′-dipyridyl), $Ba(hfac)_2(Phen)_2$ [17](Phen = *o*-phenanthroline), $Ba(thd)_2$(pmdt) (pmdt = 1,1,4,7,7-pentamethyldiethylenetriamine) [18], $Ba(thd)_2$(hmtt) (hmtt = 1,1,4,7,10,10 - hexamethyltriethylenetetramine) [18], $[Ba(thd)_2(diethylenetriamine)]_2$ [19], $[Ba(thd)_2$-(triethylenetetramine)$]_2$ [19] and $[Ba(tfa)_2(hmtt)]$(tfa = 1,1,1,-trifluoro-2,4,-pentanedionate) [20], $[Ba(thd)_2$-(pmdt)](pmdt = pentamethyldiethylenetriamine) [20] $[Ba(thd)_2(hmtt)]$(hmtt = hexamethyltriethyleneteramine) [21] have also been reported recently and proven to be effective in reducing molecular aggregation through the coordinative saturation. Because of the increased basicity of amines compared to ethers, it is expected that nitrogen-donor ligands make stronger bonds with metal than analogous oxygen-donor ligands. In this respect, when the polyamines were introduced as neutral ligands to the metal diketonates, it was expected that precursors would exhibit more stable thermal behavior than polyether adducts and simple monodentate Lewis base adducts.

In this article, we report the synthesis and characterization of $[Sr(thd)_2(L)]_n$ ($n = 2$; L = diethylenetriamine, $n = 1$; L = triethylenetetramine, tetraethylenepentamine, and tris(2-aminoethyl)amine) complexes which can be used as potential MOCVD precursors for ferroelectric BST($(Ba,Sr)TiO_3$) thin films.

2. Experimental

All manipulations were performed using standard Schlenk line techniques and under dinitrogen atmosphere. Tetrahydrofuran (THF) was distilled after being refluxed with sodium/benzophenone. Acetonitrile, *n*-pentane, *n*-hexane were distilled after being refluxed over CaH_2 before use. Diethylenetriamine, triethylenetetramine, and tetraethylenepentamine (Aldrich) were used as received. $[Sr(thd)_2]_n$ was synthesized from strontium metal and Hthd in anhydrous THF.

2.1. $[Sr(thd)_2(diethylenetriamine)]_2$ (I)

A 250-ml Schlenk flask was charged with $Sr(thd)_2$ (6.61 mmol, 3 g) and a stirring bar. To this flask 100 ml of THF was added via cannula and then diethylenetriamine (6.66 mmol, 0.72 ml) was injected slowly by syringe while stirring at an ambient temperature. The reaction mixture was stirred for a further 4 h and then filtered through a fine porosity funnel. The solvent was removed by vacuum, 30 ml of acetonitrile was then added to the resulting oily crude product, and the solution was stirred for 10 min. Finally white powders were isolated by filtration and dried under vacuum. Yield: 85%. Colorless crystals for single-crystal X-ray structural determination were grown from hot *n*-hexane solutions. M.p. 128–135°C. Calc. for $C_{52}H_{102}N_6O_8Sr_2$: C, 56.03; H, 9.22; N, 7.54. Found: C, 56.20; H, 9.27; N, 7.58%. FTIR: $\nu(NH_2,NH)$; 3386, 3340, 3293 cm^{-1}, ν(C=O); 1596 cm^{-1}. ^1H NMR (benzene-d_6): δ (CH in thd ligand); 5.81 (*s*,1H), δ (CH_3 in thd ligand); 1.31 (*s*,18H), δ (CH_2 in amine ligand); 2.37 (br,2H), 2.22 (br,2H).

2.2. $[Sr(thd)_2(triethylenetetramine)]$ (II)

A 250-ml Schlenk flask was charged with Sr(thd)2 (6.61 mmol, 3 g) and a stirring bar. To this flask 100 ml of THF was added via cannula and then triethylenetetramine (6.71 mmol, 1.00 ml) was injected slowly by syringe while stirring at an ambient temperature. The reaction mixture was stirred for a further 12 h and filtered through a fine porosity funnel. The solvent was removed by vacuum, 30 ml of acetonitrile was then added to the resulting oily crude products and stirred for 10 min. Finally white powders were isolated by filtration and dried under vacuum. Yield: 90%. Colorless crystals for single-crystal X-ray structural determination were grown from hot *n*-hexane solutions. M.p. 100–106°C. Calc. for $C_{28}H_{56}N_4O_4Sr$: C, 56.01; H, 9.40; N, 9.33. Found: C, 56.25; H, 9.78; N, 9.70%. FTIR: $\nu(NH_2,NH)$; 3382, 3359, 3281, 3316 cm^{-1}, δ (C=O); 1596 cm^{-1}. ^1H NMR (benzene-d_6): δ (CH in thd ligand); 5.82 (*s*,1H), δ (CH_3 in thd ligand); 1.34 (*s*,18H), δ (CH_2 in amine ligand); 2.45 (*d*,2H), 2.22 (br,4H).

2.3. $[Sr(thd)_2(tetraethylenepentamine)]$ (III)

A 250-ml Schlenk flask was charged with $Sr(thd)_2$ (6.61 mmol, 3 g) and a stirring bar. To this flask 100 ml of THF was added via cannula and then tetraethylenepentamine (6.64 mmol, 1.26 ml) was injected slowly by syringe stirring at ambient temperature. The reaction mixture was stirred for a further 12 h and filtered

through a fine porosity funnel. The solvent was removed by vacuum, 30 ml of acetonitrile was then added to the resulting oily crude products and then stirred for 10 min. Finally white powders were isolated by filtration and dried under vacuum. Yield: 85%. Colorless crystals for single-crystal X-ray structural determination were grown from hot *n*-hexane solutions. M.p. 84–90°C. Calc. for $C_{30}H_{61}N_5O_4Sr$: C, 56.00; H, 9.56; N, 10.88. Found: C, 56.12; H, 9.86; N, 10.73%. FTIR: ν(NH_2,NH); 3394, 3332, 3281 cm^{-1}, ν(C=O); 1596 cm^{-1}. ^1H NMR (benzene-d_6): δ (CH in thd ligand); 5.74 (*s*,1H), δ (CH_3 in thd ligand); 1.31 (*s*,18H), δ (CH_2 in amine ligand); 2.66 (*d*,2H), 2.46 (*d*,4H), 2.22 (br,2H).

2.4. [Sr(thd)$_2$(tris(2-aminoethyl)amine)] (IV)

A 250-ml Schlenk flask was charged with Sr(thd)$_2$ (6.61 mmol, 3 g) and a stirring bar. To this flask 100 ml of THF was added via cannula and then tris(2-aminoethyl)amine (6.68 mmol, 1.00 ml) was injected slowly by syringe stirring at an ambient temperature. The reaction mixture was stirred for a further 12 h and filtered through fine porosity funnel. The solvent was removed by vacuum, 30 ml of acetonitrile was then added to the resulting oily crude products and stirred for 10 min. Finally white powders were isolated by filtration and dried under vacuum. Yield: 85%. Colorless crystals for single-crystal X-ray structural determination were grown from hot *n*-hexane solutions. M.p. 76–84°C. Calc. for $C_{24}H_{56}N_4O_4Sr$: C, 56.01; H, 9.40; N, 9.33. Found: C, 56.12; H, 9.34; N, 9.27%. FTIR: ν(NH_2,NH); 3370, 3332 cm^{-1}, ν(C=O); 1596 cm^{-1}. ^1H NMR (benzene-d_6): δ (CH in thd ligand); 5.80 (*s*,1H), δ (CH_3 in thd ligand); 1.35 (*s*,18H), δ (CH_2 in amine ligand); 2.29 (*d*,3H), 1.93 (*d*,3H).

2.5. X-ray crystallography

Single crystals of complexes **I**, **II**, **III** and **IV** were obtained directly from saturated *n*-hexane solutions. All of the crystals were subsequently mounted into glass capillary under N_2 atmosphere and then sealed. A summary of the X-ray diffraction data is presented in Table 1. The diffraction data was collected at an ambient temperature on Bruker P4 four circle diffractometer using Mo–K_α radiation. The intensity data was collected using a θ–2θ step scan technique and for all data sets the condition of the crystal was monitored by measuring two standard reflections. The solutions of structures **I**, **II**, **III** and **IV** were carried out by a combination of heavy atom Patterson techniques, direct methods, and Fourier techniques. The refinements of the structures by full-matrix-least-squares methods were based on 9051 unique reflections ($2\theta = 45$, $I > 2\sigma$) for **I**, 8485 unique reflections ($2\theta = 45$, $I > 2\sigma$) for **II**, 2455 unique reflections ($2\theta = 45$, $I > 2\sigma$) for **III**, and 2283 unique reflections ($2\theta = 45$, $I > 2\sigma$) for **IV**. Anisotropic temperature factors were used for all non-hydrogen atoms in **I**, **II**, **III**, and **IV**. At the current stage of refinement on 779 parameters for **I**, 715 parameters for **II**, 212 for **III**, and 206 for **IV** with all atoms present in the asymmetric units, $R = 0.0693$, $R_w = 0.1612$ for **I**, $R = 0.0700$, $R_w = 0.1755$ for **II**, $R = 0.0559$, $R_w = 0.1448$ for **III**, and $R = 0.0813$, $R_w = 0.2088$ for **IV**.

2.6. Other physical measurements

^{1}H NMR spectra (300 MHz) were obtained with Varian Gemini 300 spectrometer. Infrared spectra were measured with a Nicolet Magna-IR 760 spectrometer. CHN analyses were obtained with Thermoquest EA-1110 CHNS analyzer. A controlled thermal analysis of the complexes was investigated using a Perkin–Elmer TGA7 thermogravimetric analyzer, connected to a DECpc personal computer via a TAC 7/DX thermal analysis instrument controller. The weight of the samples investigated was between 6 and 8 mg. The measurements were performed in alumina crucibles under an atmosphere of flowing dry nitrogen gas (25 cm^3 min^{-1}), using heating rates of 5°C min^{-1}.

3. Results and discussion

3.1. Synthesis

The large ionic radius of barium and strontium metal ions (1.18 Å (Ba^{2+}) and 1.35 Å (Sr^{2+}) for C.N. = 6) render coordinatively unsaturation to their complex with average size ligands [22]. Therefore these metal ions will display typically high coordination numbers and their compounds often spontaneously oligomerize. The barium and strontium β-diketonate complexes $M(thd)_2$ exist as tetramer and trimer, respectively, and are highly sensitive to moisture. We have investigated the reaction of the homoleptic $M(thd)_2$ (M = Ba and Sr) complexes with chelating N-donor lewis base ligands. Our previous studies [19] reveal that polyamine ligands can efficiently saturate the coordination sphere of the barium cation and reduce the molecular aggregation. We have investigated the reaction of the homoleptic $Sr(thd)_2$ complexes with the chelating N-donor lewis base ligands. The strontium bis(diketonate) with polyamine adduct complexes $[Sr(thd)_2(L)]_n$ ($n = 2$; L = diethylenetriamine (**I**), $n = 1$; L = triethylenetetramine (**II**), tetraethylenepentamine (**III**), and tris(2-aminoethyl)amine (**IV**)) can be obtained from the reaction shown in Scheme 1. The reaction of $Sr(thd)_2$ with one equivalent of polyamines in THF solution proceeds readily at an ambient temperature, under N_2 atmosphere, to give a pale yellow solution. The crude white products were purified by recrystalization in *n*-hexane solution and the slightly excess polyamine can be removed easily by washing with acetonitrile. All of the complexes were obtained as colorless crystals in an excellent yield on the crystallization from saturated hot *n*-hexane solution.

Scheme 1.

The complexes **I**, **II**, **III** and **IV** are highly soluble in non-polar hydrocarbon solvents such as *n*-pentane, *n*-hexane and in polar solvents like diethylether, THF and toluene but insoluble in CH_3CN. If 2 equivalents of polyamines are used in the preparation of **I**, **II**, **III**, and **IV** then generally oily products result. Also, all of the complexes **I**, **II**, **III** and **IV** are readily dissolved in small amounts of polyamines. This indicates that the complexes are highly soluble in an excess of the Lewis base, presumably forming more highly ligated complexes. When the commercially available hydrated complex $Sr(thd)_2{\cdot}H_2O$ was used as starting materials, the yield was very low and unidentified insoluble powders in hydrocarbon solvents were precipitated. All complexes are relatively stable in air and moisture. The melting points of **I**, **II** and **III** are 128–135, 100–106, 84–90, and 76–84°C respectively, which are significantly lower than that of $Sr(thd)_2$ (200–203°C).

3.2. Spectroscopic data

All of the complexes were characterized by IR, NMR, and elemental analysis. The infrared spectrum of **I**, **II**, **III**, and **IV** exhibit the characteristic N–H stretching vibrational peaks from the amine ligand in the region 3200–3400 cm^{-1}. Also all of the complexes show strong absorption bands at 1596 cm^{-1} due to the C=O stretching vibrational peaks from thd ligands. ^{1}H NMR spectra of all four complexes in C_6D_6 show only a characteristic signal for one type of thd and polyamine ligand environment at room temperature. The ethylene proton resonances of coordinated polyamines are broad and unresolved sharply in all four spectra. The integration ratio of thd to polyamine ligand was observed to be 2:1 which indicate all four complexes have $Sr(thd)_2(L)$ formula in solution state which are in agreement with elemental analyses. Analytical and spectroscopic data for all four complexes are in accordance with the structures determined by X-ray crystallography, discussed in detail in the following section.

3.3. Single-crystal X-ray structures

To investigate the structure in the solid state, X-ray single–crystal structural studies were undertaken for all four complexes, which reveal that **I** exists as a dinuclear complex, $[Sr(thd)_2(diethylenetriamine)]_2$. On the other

hand, **II**, **III**, and **IV** exist as mononuclear complexes, [Sr(thd)$_2$(triethylenetetramine)], [Sr(thd)$_2$(tetraethylenepentamine)], [Sr(thd)$_2$(tris(2-aminoethyl)amine)], respectively. The selected bond distances and angles of complex **I**, **II**, **III**, and **IV** are presented in Tables 2 and 3.

3.4. [Sr(thd)$_2$(diethylenetriamine)]$_2$ (I)

The single-crystal X-ray structure of complex **I** is shown in Fig. 1. In complex **I**, each strontium metal is a eight coordinate, with a distorted propellane fashion, where a terminal amine ligand and three thd ligands are coordinated to strontium metal. The two strontium atoms are bridged by two thd ligands, in which two amine ligands and two terminal thd ligands are coordinated as *trans* fashion. Each strontium atom in complex **I** is coordinated with three nitrogen atoms (Sr–N average 2.77 Å) from diethylenetriamine and five oxygen atoms, two from the terminal thd ligand and three from the bridging thd ligand. The distances in bridging Sr–O_{thd} (average 2.634 Å) are significantly longer than those in terminal chelating ones (average 2.521 Å) as expected. The O–Sr–O chelate angles for the terminal thd ligands are 67.6(3)° (O(1)–Sr(1)–O(2)) and 69.6(3)°(O(5)–Sr(1)–O(6)). These values are larger than those observed in bridging thd ligands (66.7(2)° for O(3)–Sr(1)–O(4) and 66.2° for O(7)–Sr(1)–O(8)). The N–Sr–N angles for amine ligands are nearly identical and are in the range from 62.4(5)°–63.6(5)°.

3.5. [Sr(thd)$_2$(triethylenetetramine)] (II)

For complex **II**, there are two molecules in the asymmetric unit that are nearly identical within the precision of experiment. In Fig. 2, their structures and relative positioning were illustrated. In each molecule, strontium atom is eight coordinate with all of the nitrogens of the triethylenetetramine ligand and all oxygens of the thd ligand binding to the metal atom. Both Sr(1) and Sr(2) are coordinated in an meridional fashion by triethylenetetramine ligands, with two bidentate thd ligands on opposite sides of the amine ligand mean plane. This coordination environment is similar to the coordination pattern found in eight coordinated Ba and Ca triglyme adducts, Ca(thd)$_2$(triglyme) and Ba(thd)$_2$-(triglyme) complexes [8], but is different from those in Sr(hfac)$_2$(bpy)$_2$ [16], where the central Sr atom is eight coordinated with two hfac moieties on one side and the two bpy ligands on the other side. The Sr–O thd distances are in the range from 2.480(7)–2.555(6) Å (average 2.513 Å) for Sr(1) and from 2.458(6)–2.511(6) Å (average 2.491 Å) for Sr(2) which are slightly shorter than those in complex **I**. The Sr–N distances (average 2.75 Å in each molecule) are slightly shorter than those of complex **I**. The O–Sr–O chelate angles for the terminal thd ligands in both molecules are little different (average 67.95 (O–Sr(1)–O) and 68.8°(O–Sr(2)–O) and are comparable for those in complex **I**. The N–Sr–N angles for amine ligands are nearly identical and are in the range from 63.1(4)–64.6(3)°.

3.6. [Sr(thd)$_2$(tetraethylenepentamine)] (III)

The single-crystal X-ray structure of complex **III** is shown in Fig. 3. Strontium atom and N(1) atom are located on crystallographic 2-fold axis, and thus half of the molecule had to be determined. Strontium atom is nine coordinate with all of the nitrogens of the tetra-

ethylenepentamine ligand and all oxygens of the thd ligand binding to the metal atom. The amine ligand is observed to be located on a meridional plane, with two bidentate thd ligands lying respectively above and below the plane. Similar coordination fashion was found in those of $Ba(thd)_2$(tetraglyme) [7], $Ba(hfa)_2$(tetraglyme) [25], $Ca(hfa)_2$(tetraglyme) [8] and $Ca(thd)_2$(tetraethylenepentamine) [26] complexes. But in the case of Ca complexes, only four out of five donor atoms in the ancillary ligand are coordinated to the central Ca atom and coordination number is eight in those complexes.

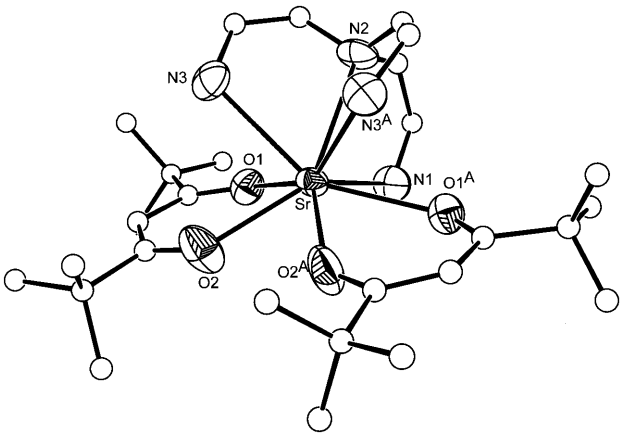

Fig. 4. Molecular structure and labeling of $[Sr(thd)_2$(tris(2-aminoethyl)amine)] (**IV**). Thermal ellipsoids as drawn by ORTEP represent the 40% probability surfaces. Hydrogen atoms have been omitted for clarity. Symmetry-generated atoms have the suffix A.

This difference between our strontium analogues and other barium analogues may be due to the smaller ionic radius of the Ca cation than those of barium and strontium. The Sr–O thd distances are in the range from 2.515(4)–2.576(4)Å (average 2.546 Å) which are apparently longer than those in complex **I** and **II**. These longer Sr–O distances in complex **III** reflect the strong chelating effect and higher denticity of tetraethylenepentamine ligand. The Sr–N(1) distance (2.720 Å) is significantly shorter than that of Sr–N(2) (2.768 Å) and Sr–N(3)(2.786 Å). The O–Sr–O chelate angles for the thd ligands are 67.26(12)° and the N–Sr–N angles for amine ligands are in the range from 61.5(4)–64.0(3)°.

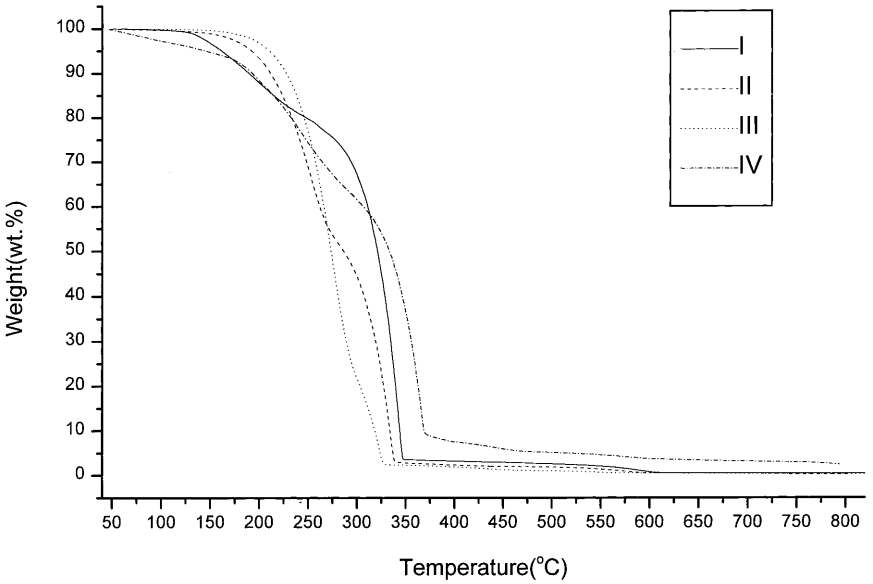

Fig. 5. Thermogravimetric analyses of complexes **I**, **II**, **III** and **IV** under N_2 with a temperature ramp of 5°C min^{-1}.

3.7. [Sr(thd)$_2$(tris(2–aminoethylene)amine)] ((IV)

The single-crystal X-ray structure of complex **IV** are shown in Fig. 4. The molecule in **IV** occupies a crystallographic mirror plane in which strontium, N(2) and N(3) atoms are located on a mirror plane. In this molecule, strontium atom is eight coordinate with all of the nitrogens of the amine ligand and all oxygens of the thd ligand binding to the metal atom. The amine ligand is coordinated to one side of the metal atom and resulting in a *cis*–relationship of the thd ligands with an O–M–O angle of 66.1(2). This coordination environment is similar to the coordination pattern found in $Sr(hfac)_2(bpy)_2$ [16], $[Ba(hfac)_2(CH_3OCH_2CH_2)_3N]$ [23], but is different from those in complex **II**, **III** and polyglyme adducts of barium and strontium β-diketonates, where polyamine or polyglyme ligands are coordinated to metal atom in meridional fashion with two β-diketonate moieties being positioned on either side of this plane. The Sr–N distances show different patterns in two molecules.

3.8. Thermal analyses

Thermogravimetric data for complexes **I**, **II**, **III** and **IV** which were collected under an N_2 atmosphere with a 5°C min^{-1} temperature ramp rate are shown in Fig. 4. It is immediately apparent that all complexes are sufficiently volatile and sublime or evaporate without residue. Upon heating under nitrogen, complex **I** and **II** undergo two major steps of weight loss. The first weight loss occurs at ca 100–250°C (ca. 20%) for **I** and ca 150–275°C (ca. 45%) for **II** and this represents the loss of amine ligand in the complexes. A similar result was reported earlier for [Sr(thd)(tetraglyme)] complex [7] in which the loss of tetraglyme ligand occurs at 150–260°C. The DSC plot for complex **I** and **II** reveals only two endotherms. The first sharp isotherms are attributed to the melting, centered at 134.21°C for **I** and 105.52°C for **II** which are in agreement with a visual observation. The second broad isotherms are centered at 342.39°C for **I** and 359.69°C for **II**, which are presumably due to separation and evaporation of amine ligand. However in complexes **III** and **IV**, there is no evidence for loss of amine ligand. Fig. 4 shows that complex **III** and **IV** sublime and vaporize without decomposition over the temperature range ca. 150–330°C and ca. 100–370°C, respectively. The DSC plot for complex **III** and **IV** reveals only one endotherm centered at 88.29°C for **III** and 70.96°C for **IV** which is attributed to the melting. All four complexes show enhanced thermal stability than those of $Sr(thd)_2$(H–thd) [24] and $Sr(thd)_2$(tetraglyme) [7]. In $Sr(thd)_2$(H–thd) complex, the loss of H–thd occurs below 200°C and followed by sublimation of the remaining $[Sr(thd)_2]_n$ between ca. 270–390°C to give a residue of 3.4% Fig. 5.

4. Conclusion

A new class of volatile strontium bis(diketonate) with polyamine adducts has been successfully synthesized and characterized. From the molecular structures determined by single-crystal X-ray analyses, it is possible to explain that the minimum coordination number for saturating strontium cation coordination sphere is 8. In fact, coordinatively unsaturated $Sr(thd)_2$(diethylenetriamine) (coordination number 7) exist as a dimmer by bridging one of oxygen atom from thd ligand in adja-

cent molecule and thus satisfy coordinative saturation number 8. On the other hand, coordinatively saturated complexes **II**, **III** and **IV** exist as monomer. These complexes, when compared to $Sr(thd)_2$, offer the advantages of air/moisture stability and enhanced thermal stability. Therefore it is expected that these complexes are promising MOCVD precursors for BST thin films.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 145280 for complex **I**, CCDC No. 145281 for complex **II**, CCDC No. 145282 for complex **III** and CCDC No. 145283 for complex **IV**. Abstract

Magnesium aryloxides were prepared in a variety of solvents through the reaction of dibutyl magnesium with sterically varied aryl alcohols: 2,6-dimethylphenol (H-DMP), 2,6-diisopropylphenol (H-DIP), and 2,4,6-trichlorophenol (H-TCP). Upon using a sufficiently strong Lewis-basic solvent, the solvated monomeric species $Mg(DMP)_2(py)_3$ (**1**, py = pyridine), $Mg(DIP)_2(THF)_3$, (**2a**, THF = tetrahydrofuran) $Mg(TCP)_2(THF)_3$ (**3**) were isolated. Each of these complexes possesses a five-coordinate magnesium that adopts a trigonal bipyramidal geometry. In the absence of a Lewis base, the reaction with H-DIP yields a soluble trinuclear complex, $[Mg(DIP)_2]_3$ (**2b**). The Mg metal centers in **2b** adopt a linear arrangement with a four-coordinate central metal while the outer metal centers are reduced to just three-coordinate. Solution spectroscopic methods suggest that while **2b** remains intact, the monomeric species (**1**, **2a**, and **3**) are involved in equilibria which facilitate intermolecular ligand transfer. © 2000 Elsevier Science B.V. Keywords: Magnesium; Aryloxide; Structure; Adduct

1. Introduction

Magnesium alkoxides ($Mg(OR)_2$) were first prepared and reported in the early 1900s [1–3]. Since that time they have found applications in such areas as Ziegler–Natta catalyst support precursors [4] and reagents for organic synthesis [5,6]. Although they are widely used, only a handful of structurally characterized $Mg(OR)_2$ complexes have been reported, including, the complex structure for the methoxide methanolate, $Mg(OMe)_2 \cdot 3.5MeOH$ [7], two tetrameric alkoxyether magnesium aggregates, $[Mg_4(OCH_2CH(CH_2)_3O)_6Cl_2]$ [8] and $[Mg(OCH(CH_3)CH_2OCH_3)_2]_4$ [9], and a siloxide, $[(RSiO_3)_2(R(OH)SiO_2]_2Mg(THF)_5$ where R = (2,6-*i*-$Pr_2C_6H_3$)(Me$_3$Si)N [10]. A number of magnesium aryloxides have also been reported including a series of dimeric complexes prepared by Ittel et al. ($[Mg(OAr)_2]_2$ where OAr = $OC_6H_2(CMe_3)_2Me$ (BHT), $OC_6H_2(CMe_3)_2$ (BHB)) [11] and a similar fluorinated derivative, $Mg(OC_6H_2(CF_3)_3)_2(THF)_3$, reported by Roesky et al. [12].

We have utilized a series of sterically and electronically varied aryloxide ligands (where OAr = $OC_6H_3(Me)_2$-2,6 (DMP), $OC_6H_3(CHMe_2)_2$-2,6 (DIP), and $OC_6H_2(Cl)_3$-1,3,5 (TCP) to further probe the structural aspects of $Mg(OAr)_2$. Aryloxides were chosen as they can be easily derivatized and often result in complexes with increased solubility and decreased oligomerization. Products isolated were identified by single crystal X-ray diffraction as $Mg(DMP)_2(py)_3$ (**1**), $Mg(DIP)_2(THF)_3$ (**2a**), $[Mg(DIP)_2]_3$ (**2b**), and $Mg(TCP)_2(THF)_3$ (**3**).

2. Experimental

All compounds were handled under an inert atmosphere using standard glovebox or Schlenk techniques. Toluene, tetrahydrofuran (THF), and hexanes were dried over and distilled from Na/benzophenone immediately prior to use. Pyridine was dried over and distilled from CaO. The following chemicals were obtained from Aldrich and used as received: 1.0 M di-*n*-butylmagnesium in heptane ($Mg(Bu)_2$), 2,6-dimethylphenol (H-DMP), 2,6-diisopropylphenol (H-DIP), and 2,4,6-trichlorophenol (H-TCP). ^1H and ^{13}C NMR solution spectral data were collected on a Brucker 400 MHz spectrometer. All spectra were referenced against the residual proton impurity in the appropriate dried, deuterated solvent. FTIR data were obtained on a Bruker Vector 22 using KBr pressed pellets under a N_2 purge. Elemental analyses were performed on a Perkin–Elmer 2400 CHN-S/O Elemental Analyzer.

2.1. $Mg(DMP)_2(py)_3$ (**1**)

$Mg(Bu)_2$ (71.4 ml, 25 mmol) was placed in a 500 ml three-neck round bottom, diluted with THF (37 ml) and pyridine (18.5 ml), and cooled to 0°C in an ice bath. A solution containing H-DMP (17.51 g, 68.5 mmol) dissolved in THF (50 ml) was transferred slowly via cannula to the cooled $Mg(Bu)_2$ solution. The reaction mixture was allowed to warm slowly to room temperature (r.t.) and stirred overnight. The resulting clear, colorless solution was then heated to reflux temperature for 2 h. The solution was then allowed to cool and the solvent removed in vacuo yielding an off-white powder. Yield: 30.3 g (84.2%). ^1H NMR (400.1 MHz, pyridine-d_5) δ 7.23 (d, 2H, $OC_6H_3(CH_3)_2$-2,6, $^3J_{H-H}=$ 7.2 MHz), 6.67 (t, 1H, $OC_6H_3(CH_3)_2$-2,6, $^3J_{H-H}=7.2$ MHz), 2.47 (s, 6H, $OC_6H_3(CH_3)_2$-2,6). FTIR (KBr pellet, cm^{-1}) 3066(m), 3007(w), 2958(w), 2920(m), 2899(w), 2851(w), 1589(m), 1472(s), 1437(s), 1324(m), 1268(w), 1211(m), 1090(m), 1068(w), 1036(w), 1009(w), 878(w), 752(s), 699(s), 623(w), 548(w), 425(m). *Anal.* Calc. for $C_{31}H_{33}MgN_3O_2$: C, 73.89; H, 6.60; N, 8.33. Found: C, 72.58; H, 6.43; N, 7.96%.

2.2. $Mg(DIP)_2(THF)_3$ (**2a**)

$Mg(Bu)_2$ (34 ml, 34 mmol) was diluted with THF (35 ml) and cooled in an ice bath. A solution containing H-DIP (12.22 g, 68.5 mmol) dissolved in THF (15 ml) was slowly cannula transferred to the $Mg(Bu)_2$ solution. The reaction mixture was warmed to room temperature and allowed to stir for 4 h yielding a clear colorless solution. The solvent was removed in vacuo yielding an off-white powder. Yield: 18.8 g (93%). ^1H NMR (400.1 MHz, THF-d_8) δ 6.77 (4H, d, OC_6H_3-2,6-$CH(CH_3)_2$, $^3J_{H-H}=7.6$ Hz), 6.27 (2H, t, OC_6H_3-2,6-$CH(CH_3)_2$, $^3J_{H-H}=7.6$ Hz), 3.50 (4H, sept, OC_6H_3-2,6-$CH(CH_3)_2$, $^3J_{H-H}=6.8$ Hz), 1.13 (12H, d, OC_6H_3-2,6-$CH(CH_3)_2$, $^3J_{H-H}=6.8$ Hz). FTIR (KBr pellet, cm^{-1}) 2961(s), 2868(m), 1588(w), 1438(s), 1361(m), 1346(w), 1285(w), 1261(m), 1192(w), 1151(w), 1108(w), 1040(m), 888(m), 860(w), 743(m), 695(w), 589(w), 557(w), 405(w). *Anal.* Calc. for $C_{36}H_{58}MgO_5$: C, 72.65; H, 9.82. Found: C, 73.04; H, 9.43%.

2.3. $[Mg(DIP)_2]_3$ (**2b**)

$Mg(Bu)_2$ (25 ml, 25 mmol) was diluted with toluene (25 ml) and cooled to 0°C in an ice bath. A solution containing H-DIP (8.95 g, 68.5 mmol) dissolved in toluene (10 ml) was cannula transferred to the $MgBu_2$ solution. The reaction mixture was warmed to r.t. and allowed to stir overnight yielding a colorless clear solution. The solvent was removed in vacuo resulting in an off-white gummy solid. The solid was washed with hexanes (50 ml) and dried to yield an off-white free-flowing powder. Yield: 8.4 g (89%). ^1H NMR (400.1 MHz, C_6D_6) δ 7.04 (4H, dd, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=7.8$ Hz, $^4J_{H-H}=1.5$ Hz), 7.03 (4H, d, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=7.6$ Hz), 6.831 (2H, t, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=7.6$ Hz), 6.825 (4H, dd, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=7.8$ Hz, $^3J_{H-H}=$ 7.7 Hz) 6.73 (dd, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=$ 7.7 Hz, $^4J_{H-H}=1.5$ Hz), 3.62 (4H, sept, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=6.8$ Hz), 2.71 (4H, sept, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=6.8$ Hz), 2.38 (4H, sept, $OC_6H_3\{CH(CH_3)_2\}_2$-2,6, $^3J_{H-H}=6.7$ MHz), 1.42 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.8$ Hz), 1.37 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.8$ Hz), 1.10 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.8$ Hz), 0.96 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.7$ Hz), 0.79 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.7$ Hz), 0.34 (12H, d, $OC_6H_3\{CH(CH_3)_2\}$-2,6, $^3J_{H-H}=6.8$ Hz). FTIR (KBr pellet, cm^{-1}) 3066(w), 3027(w), 2961(s), 2870(m), 1590(w), 1452(m), 1438(s), 1346(w), 1321(w), 1284(w), 1260(m), 1193(m), 1110(w), 1042(w), (907(w), 843(m), 754(s), 686(w), 574(w), 508(w), 417(w). *Anal.* Calc. for $C_{24}H_{34}MgO_2$: C, 76.09; H, 9.05. Found: C, 75.18; H, 8.91%.

2.4. $Mg(TCP)_2(THF)_3$ (**3**)

A THF (5 ml) solution containing H-TCP (2.33 g, 11.8 mmol) was added (via cannula transfer) to a 0°C solution containing $Mg(Bu)_2$ (5.9 ml, 5.9 mmol) diluted with THF (6 ml). The resulting clear colorless solution was stirred at r.t. overnight followed by removal of the solvent in vacuo to yield a white solid. Yield: 3.45 g (92%). ^1H NMR (400.1 MHz, THF-d_8) δ 7.12 ($OC_6H_2Cl_3$). FTIR (KBr pellet, cm^{-1}) 2988(m), 2890(m), 1566(w), 1480(s), 1388(w), 1325(w), 1245(m), 1174(w), 1038(s), 911(w), 896(w), 876(w), 861(w),

852(w), 803(w), 788(m), 759(s), 735(w), 596(w), 494(m), 433(w). *Anal.* Calc. for $C_{24}H_{28}Cl_6MgO_5$: C, 45.50; H, 4.46. Found: C, 43.63; H, 4.08%.

2.5. X-ray structure determinations

Data collection parameters for all compounds are given in Table 1. Additional information is supplied in the Supporting Information. A suitable crystal of each sample was mounted on a glass fiber from a pool of Fluorolube™ HO-125 then immediately placed under a liquid N_2 stream on a Bruker AXS diffractometer. The radiation used was graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Lattice determination and data collection were carried out using SMART software [13]. Data reduction was performed using SAINT+ software [14]. Structure solution and refinement was performed using SHELXTL-5.1 software [15]. Absorption correction using SADABS [16] in SHELXTL-5.1 was carried out only for **3**. The structures were solved using direct methods and yielded positions for the heavy atoms. Subsequent Fourier synthesis gave the remaining non-hydrogen atom positions. Hydrogen atoms were fixed in positions of ideal geometry and refined within the XSHELL software [17]. These idealized hydrogen atoms had their isotropic temperature factors fixed at 1.2 or 1.5 times the equivalent isotropic U of the C atoms to which they were bonded. The final refinements include anisotropic thermal parameters on all non-hydrogen atoms. Disorder in the isopropyl methyl groups on the phenyl rings of **2b** was noted (C71 and C72). Acceptable thermal parameters were obtained by refining over two partially occupied positions. Due to the disorder, hydrogen atoms were not assigned to C71 or C72.

3. Results and discussion

3.1. Syntheses

The $Mg(OAr)_2$ isolated in this study were prepared by the reaction of $Mg(Bu)_2$ with 2 equiv. of the appropriate HOAr (Eq. (1)). Typically, the $Mg(OAr)_2$ products were insoluble in standard non-polar solvents, however, when the reaction was carried out in the presence of a *sufficiently* strong Lewis-basic solvent (L), a soluble adduct was formed (Eq. (2)). For example, in the reaction with H-TCP, use of THF as a solvent resulted in the formation of a soluble product while the reaction with H-DMP yielded a soluble species *only* when a stronger Lewis base (i.e. pyridine) was available.

$$Mg(Bu)_2 + 2HOAr \rightarrow [Mg(OAr)_2]_n + 2H\text{-}Bu \quad (1)$$

$$Mg(Bu)_2 + 2HOAr + xsL \rightarrow [Mg(OAr)_2](L)_3 + 2H\text{-}Bu \quad (2)$$

In contrast, $Mg(DIP)_2$ was found to yield a soluble product independent of the solvent employed. However, the aggregate size was found to vary depending on the presence or absence of a donor solvent.

The generation of a heteroleptic product was attempted (in the presence of a Lewis base) through the reaction of $Mg(Bu)_2$ with 1 equiv. of H-DIP to form

[a] $R_1 = \sigma \| F_o | - | F_c \| / \sigma | F_o |$.

[b] $wR_2 = \left[\Sigma[w(F_o^2 - F_c^2)^2] / \Sigma[w(F_o^2)^2] \right]^{1/2}$.

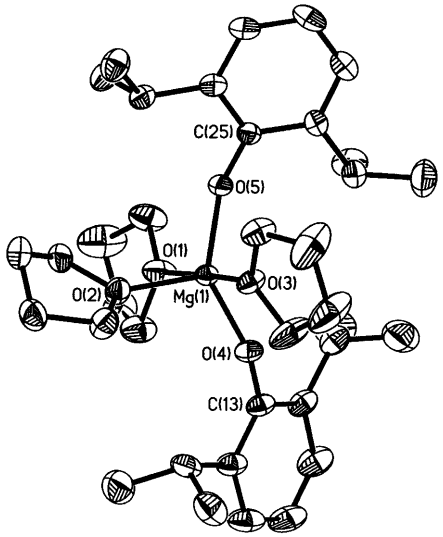

Fig. 1. Thermal ellipsoid plot of $Mg(DMP)_2(py)_3$ (**1**). Ellipsoids are drawn at 30% probability and protons are omitted for clarity.

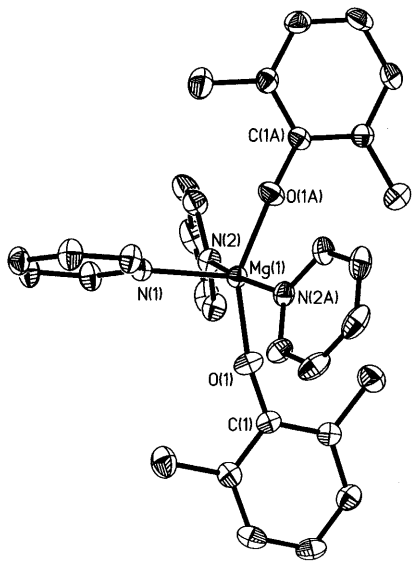

Fig. 2. Thermal ellipsoid plot of $Mg(DIP)_2(THF)_3$ (**2a**). Ellipsoids are drawn at 30% probability and protons are omitted for clarity.

the 'BuMg(DIP)' intermediate, **4**, followed by the addition of 1 equiv. of H-TCP to give the mixed ligand product, 'Mg(DIP)(TCP)$(L)_x$', **5**. Eqs. (3) and (4) summarize the reaction path for the general mixed-ligand case. The stability of the alkyl/aryloxy intermediate, **4**, toward disproportionation was not rigorously established.

$$Mg(Bu)_2 + 2HOAr + xsL \rightarrow [(Bu)Mg(OAr)]_n + H\text{-}Bu \quad (3)$$

$$[(Bu)Mg(OAr)]_n + 2HOAr' + xsL \rightarrow [Mg(OAr)(OAr')]_n + H\text{-}Bu \quad (4)$$

Work by Ashby et al. on similar alkyl/alkoxy species (i.e. MeMg(OR)) revealed that, while the mixed species did not disporportionate and could be isolated as crystalline solids, they were often involved in complex solution equilibria [18]. Unfortunately, a single crystalline product could not be isolated for the mixed alkoxide, **5**. This likely results from subsequent disproportionation of the heteroleptic product to give a complex mixture which includes both homoleptic $Mg(OAr)_2$ species.

3.2. Solid-state structures

Compounds **1**, **2a**, and **3** were isolated as monomeric complexes with five-coordinate, trigonal bipryamidal (tbp) Mg cations. Figs. 1–3 show the thermal ellipsoid plots of complexes **1**, **2a**, and **3**, respectively, and a summary of their metrical data is listed in Table 2. For each complex, the two OAr and a coordinated solvent occupy the equatorial positions with the remaining two solvent molecules located in the axial sites. The stronger ligand (i.e. OAr) avoids geometrical arrangements that force a *trans* configuration. This arrangement for $Mg(OAr)_2(L)_3$ has been previously observed by Roesky et al. in $(Mg(OC_6H_2(CF_3)_3)_2(THF)_3)$ using a fluorinated aryloxide [12]. In **2a** and **3** the donor solvent is THF while pyridine fills in the coordination sphere of **1**. The average Mg–O bond lengths for the aryloxides in **1**, **2a** and **3** do not deviate significantly from each other (1.90, 1.90, and 1.91 Å, respectively). The O–M–O angles involving the alkoxide oxygens are 15–20° larger than ideal likely due to their steric bulk. However, the largest deviation occurs for the DMP analog, **1**, which possesses the least hindering aryloxide. The same complex also displays the largest deviation in linearity for the axial solvent sites. Both of these observations can be accounted for by the stronger *trans* influence of pyridine in **1** over THF in **2a** and **3**.

Due to the absence of a Lewis base, the structure of **2b** differs significantly from the monomeric complexes previously discussed. Oligomerization is the only means by which the low-oxidation state magnesium cation can satisfy its coordination sphere. The number of bridging OAr was minimized by the bulky isopropyl substituents on the phenyl ring resulting in a trimeric product as can be seen in Fig. 4. Table 3 contains a partial list of the interatomic distances observed in **2b**. The three Mg atoms are nearly linear at 176° with Mg···Mg distances of 2.91 Å. The central Mg cation adopts a four-coordinate distorted tetrahedral environment employing four bridging OAr ligands. While the outer metal centers and each of their three ligated oxygens are coplanar, one of the O–M–O angles surrounding each outer Mg is significantly smaller than the idealized 120°. This angle is constrained by one of two four-membered rings. The average Mg–O distance in **2b** is 1.91 Å and

is almost identical to the averages for the five-coordinate monomeric complexes.

Control over the nuclearity of $Mg(OAr)_2$ based upon solvent choice has been previously observed by Ittel et al. [11]. They reported a series of dimeric magnesium aryloxide complexes, $[Mg(OAr)_2]_2$ where OAr = $OC_6H_2(CMe_3)_2Me$ (BHT), $OC_6H_2(CMe_3)_2$ (BHB), which maintained their solid-state structures in non-donor solvents. The dinuclear BHT and BHB derivatives were also found to be very soluble in donor solvents. However, based upon NMR studies, the dimers appeared to be disrupted by Lewis-basic solvents forming tetrahedral monomeric complexes, '$M(OAr)_2(solv)_2$'. The bulkiest ligand, DIP, in this study gave a three- and four-coordinate solvent-free trinuclear complex and five-coordinate monomeric solvent adduct. In contrast, the BHT and BHB ligands are more sterically hindering and allow only three-coordinate dimeric solvent-free magnesium centers and four-coordinate monomers even in the presence of small Lewis bases. Nuclearity dependence on solvent has also been documented for the '$Y(DMP)_3$' system in which both monomeric and dimeric products could be isolated [19]. However, instead of isolating an adduct and a solvent-free species as observed for the Mg examples, both yttrium complexes possess coordinated solvent.

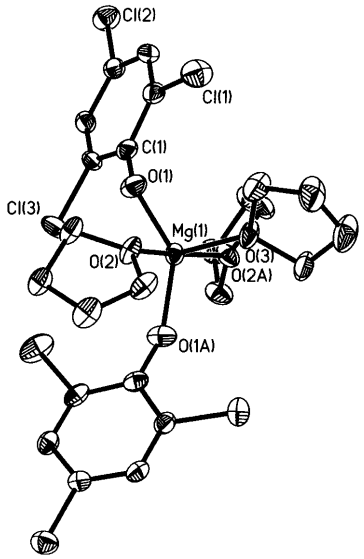

Fig. 4. Thermal ellipsoid plot of $[Mg(DIP)_2]_3$ (**2b**). Ellipsoids are drawn at 30% probability and protons are omitted for clarity.

Ongoing work in our laboratory has revealed a similar solvent dependence on the nuclearity of lithium aryloxides [20].

3.3. Solution structures

Metal alkoxides often display dynamic behavior in solution thereby accessing structural configurations not observed in the solid state. This possibility was investigated for **1**–**3** and **5** using solution spectroscopic methods. The ^{1}H NMR of the solvated monomers (**1**, **2a**, and **3**) revealed a single ligand environment. This observation can be explained in two possible ways: (i) the complexes remain monomeric in solution, or (ii) the complexes are involved in a dynamic process that is fast on the NMR time scale. In an effort to distinguish between these two possibilities, the solution behavior of the heteroleptic complex, **5** $[Mg(TCP)(DIP)(THF)_x]$, was investigated.

While the ^{1}H NMR of **5**, was expected to contain a single environment for each TCP and DIP ligand (analogous to the homoleptic compounds, **2a** and **3**), two environments for each ligand were observed. The presence of a single sterically hindered product could be ruled out by the observation of two triplets arising from the *para* proton on the phenyl ring of the DIP. A single product, possessing no symmetry, would give rise to a doublet of doublets from coupling to two inequivalent *meta* protons. Therefore, an equilibrium in which the heteroleptic and homoleptic products interconvert (Eq. (5)) must be considered.

$$2\underset{\mathbf{5}}{Mg(DIP)(TCP)(THF)_x} \rightleftharpoons \underset{\mathbf{3}}{Mg(TCP)_2(THF)_x} + \underset{\mathbf{2a}}{Mg(DIP)_2(THF)_x} \quad (5)$$

An equilibrium was observed in this system through the addition of a large amount of **3** to a solution of **5**. The phenyl region of the NMR spectrum for the mixture revealed just one doublet and one triplet for the DIP ligand, a large peak corresponding to the excess **3** as well as a much smaller TCP resonance. The observable phenyl resonances must arise from the remaining heteroleptic species, **5**. The large excess of **3** has caused the equilibrium in Eq. (5) to shift toward **5** and has diminished **2a** to the extent that it is only detectable as a very small doublet in the methyl region of the spectrum. Ligand transfer is likely an associative process

Table 3
Selected bond distances (Å) and bond angles (°) for $[Mg(DIP)_2]_3$ (**2b**)

Bond distances				
Mg···Mg	Mg(1)···Mg(2)	2.917(1)	Mg(2)···Mg(3)	2.913(1)

	O(1)–Mg(2)–O(3)	139.84(8)	O(6)–Mg(3)–O(5)	141.70(8)
(μ-OAr)–Mg–(μ-OAr)	O(2)–Mg(2)–O(3)	83.44(6)	O(3)–Mg(1)–O(4)	135.82(7)
	O(2)–Mg(1)–O(3)	81.97(6)	O(3)–Mg(1)–O(5)	112.05(7)
	O(2)–Mg(1)–O(4)	115.53(7)	O(4)–Mg(1)–O(5)	82.34(6)
	O(2)–Mg(1)–O(5)	138.34(7)	O(4)–Mg(3)–O(5)	83.47(7)
Mg–(μ-OAr)–Mg	Mg(1)–O(2)–Mg(2)	97.14(7)	Mg(1)–O(4)–Mg(3)	97.15(7)
	Mg(1)–O(3)–Mg(2)	97.45(7)	Mg(1)–O(5)–Mg(3)	96.94(7)

accomplished through the formation of a dimeric or oligomeric intermediate. This dynamic process should be considered general for $Mg(OAr)_2(L)_3$ (**1**, **2a**, and **3**) complexes and, although not detectable by NMR, must occur in solutions of the homoleptic monomeric species as well.

Solution ^1H NMR of **2b** confirms that the solid-state structure remains intact upon dissolution in non-coordinating solvents. The solid-state structure reveals two OAr environments (bridging and terminal). If the molecule is fluxional or monomeric in solution, a single OAr environment would be expected. If the molecule remains intact with rapid and free rotation about all O–C bonds, only two methyl doublets should be present in a 2:1 ratio (two bridging:one terminal). In the ^1H NMR spectrum of **2b**, six equal intensity methyl doublets are observed indicating that the molecule remains trimeric in solution. The additional resonances further suggest that rotation about the C–O bonds is greatly hindered thereby reducing the time-averaged symmetry. This rotation is likely impeded by the bulky isopropyl substituents on the phenyl rings. Their steric bulk may be sufficient such that isopropyl groups on ligands bridging the same Mg centers cannot adopt an eclipsed configuration. If this is the case, then the molecular symmetry is reduced to D_3 (no mirror planes) and the molecule should exhibit two methyl signals from the terminal ligands and four from the bridging ligands. Such steric congestion may render the bridging oxygens sufficiently labile as to be replaced by coordinating solvent (Eq. (6)). Indeed, when **2b** is dissolved in THF-d_8, the resulting spectrum is identical to that observed for crystalline **2a**.

$$[\underset{\mathbf{2b}}{Mg(DIP)_2}]_3 \overset{THF}{\rightarrow} 3\underset{\mathbf{2a}}{Mg(DIP)_2}(THF)_3 \quad (6)$$

4. Conclusions

A series of magnesium aryloxides was prepared by the reaction of $Mg(Bu)_2$ with a variety of HOAr and identified in the solid state as $Mg(DMP)_2(py)_3$ (**1**), $Mg(DIP)_2(THF)_3$ (**2a**), $[Mg(DIP)_2)]_3$ (**2b**), and $Mg(TCP)_2(THF)_3$ (**3**). Oligomeric species were generally obtained in the absence of a donor solvent. Through exposure to THF, five-coordinate monomers were readily obtained for the TCP, **3**, and DIP, **2a**, analogs. Although the TCP and DMP products are both oligomeric in the absence of a Lewis base, a stronger donor (i.e. pyridine) was required to disrupt the insoluble DMP species. The necessity of a stronger donor can be attributed to the differing acidity of their parent HOAr. Presence of chlorine substituents on the TCP ring results in a lower pK_a for H-TCP and thus removes electron density from the aryloxide oxygen. Bridging OAr oxygens in $[Mg(TCP)_2]_n$ should then be more labile in comparison to those in the oligomeric $[Mg(DMP)_2]_n$. Conversely, a steric argument can be made for the ease of the trinuclear (**2b**) to monomer (**2a**) conversion observed for the DIP products. Solution NMR studies revealed that the trinuclear species, **2b**, remained intact (in non-coordinating solvents), while the monomeric complexes are components of an equilibrium that facilitates intermolecular ligand transfer. The variation in nuclearity observed in this work and for analogous complexes (BHT and BHB) [11] suggests that through judicious choice of ligand and solvent it is possible to isolate soluble $Mg(OAr)_2$ species with tailored aggregate sizes.

5. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 143924, 143925, 143926, and 143927. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Structure and chemical bonding in *cis*- and *trans*-$M(NO)_2(O_2CR)_2$ (M = Cr and Mo) complexes

Ludmiła Szterenberg [a], Szczepan Roszak [b], Renata Matusiak [a], Antoni Keller [a,*]

Received 28 February 2000; accepted 18 August 2000

Abstract

New *cis*- and *trans*-nitrosyl complexes of the formula $M(NO)_2(O_2CR)_2$ (M = Cr and Mo) were synthesized and characterized spectroscopically. The supporting theoretical studies indicate the deviation of molecules from their ideal geometries. The most striking consequence is the deformation of the ON–M–NO fragment from its linear form, in *trans* complexes. This deformation leads to the additional weak ν_s(NO) vibration. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Nitrosyl complex; Chromium; Molybdenum; Carboxylate; DFT

1. Introduction

The unique physical and chemical properties of metal nitrosyl complexes [1–9], their importance related to biological and medical aspects [10–15], and their potential application in organic synthesis [16] have led to the constant interest in these compounds observed for more then 100 years [17]. The molecular unit $\{M(NO)_x\}^n$ (n is the number of d electrons of the metal [2]) is formed, inside which the electron density can move within a wide range. The relation between electronic density distribution in $\{M(NO)_x\}^n$ and the nature of the central atom and other coordinated ligands is still an important issue in structural physicochemistry, biochemistry (because of the biological importance of some complexes ([10–15]) and in catalysis. Complexes of this group are known as catalysts of oxidation [18–23], hydrogenation [24–26], oligomerization and polymerization [27–33], isomerization [34–38], and metathesis [23–34,39,40] reactions. The most active catalysts of the reaction of olefin metathesis are nitrosyl complexes of molybdenum [34,41–43] and tungsten [43,39,44]. These compounds also catalyze oligomerization and polymerization reactions of alkenes and alkynes [30–33,45,46].

The nitrosyl complexes with ligands coordinated via oxygen atoms are especially important. Carbene complexes of the type $[M(NO)_2(=CHR)L_2(AlCl_2)_2]$ (M = Cr, Mo; L = alkoxy or carboxylate ligands), were obtained in reactions of dinitrosyl complexes of the $\{M(NO)_2(OR)_2\}_n$ and $M(NO)_2(O_2CR)_2$ type with $RAlCl_2$ [32,47,48]. In the case of molybdenum, stable alkylidene complexes are formed. Here, coordinated alkylidene ligands have nucleophilic character in spite of the low oxidation state of the metals. Thus, these compounds are different carbene complexes than the Fischer (low oxidation states, electrophilic carbene ligands) or Schrock (high oxidation state, nucleophilic carbene ligands) compounds. In the synthesis of these compounds, $RAlCl_2$ plays two roles — as an alkylating agent, but first of all it is a Lewis acid, emptying the coordination sites at the metal due to breaking the bridging (in polymeric complexes) or chelate bonds [32,47,48]. A similar effect is also caused by other Lewis acids, like $M'Cl_4$ (M′ = Ti, Sn) [31–33]. Terminal acetylenes, present in such systems, could generate the formation of dinitrosylcarbene (vinylidene) catalysts. These complexes should contain low oxidation state metals. Their stoichiometries, $M(NO)_2(=CRR')L_2(LA)_2$, are similar to those of the dinitrosylcarbene complexes obtained earlier in our laboratory [32,47,48], but the carbene groups are electrophilic in character.

2. Experimental

All experiments presented here were performed under an argon atmosphere using standard Schlenk techniques and vacuum-line procedures. Solvents were purified and distilled under argon from appropriate agents. The *trans* complexes $[Cr(NO)_2(CO)_2(MeNO_2)_2](BF_4)_2$, $[Cr(NO)_2(MeNO_2)_4](BF_4)_2$ and $\{Cr(NO)_2(OR)_2\}_n$ (R = Et, ^{i}Pr) were prepared according to the published procedure [32]. The IR spectra were measured on an Impact 400 (Nicolet) spectrophotometer. The ^{1}H NMR spectra were recorded using a Bruker 300 spectrometer and referenced to Me_4Si. Molecular weights were determined using a Perkin–Elmer 115 instrument.

2.1. Synthesis of trans-$Cr(NO)_2(O_2CMe)_2$ (1) and trans-$Cr(NO)_2(O_2CCPh_3)_2$ (2)

NaO_2CR (8.6 mmol, R = CH_3, CPh_3) in MeOH was added to $[Cr(NO)_2(CO)_2(MeNO_2)_2](BF_4)_2$ or $[Cr(NO)_2(MeNO_2)_4](BF_4)_2$ (4.3 mmol) in $MeNO_2$ (20 ml) at room temperature. The reaction mixtures were stirred for 15 min after which the solutions were filtered and removed under vacuum. The complexes were extracted from the remainder with a small amount of CH_2Cl_2 and precipitated with hexane.

2.2. $Cr(NO)_2(O_2CMe)_2$

IR (Nujol mulls): ν(NO) 1778 sh, 1698 vs; $\nu_{as}(CO_2)$ 1580 vs, $\nu_s(CO_2)$ 1421 s. ^{1}H NMR (in CD_3CN at 20°C): δ 2.10 (s, 6H, CH_3) ppm. *Anal.* Calc. for $C_4H_6CrN_2O_6$: C, 20.88; H, 2.63; N, 12.17. Found: C, 20.96; H 2.70; 12.01%.

2.3. $Cr(NO)_2(O_2CCPh_3)_2$

IR (Nujol mulls): ν(NO) 1777 sh, w, 1696 vs; $\nu_{as}(CO_2)$ 1559 vs, $\nu_s(CO_2)$ 1447 m. ^{1}H NMR (in acetone-d_6 at 20°C): δ 7.26 (m, 30H, Ph) ppm. *Anal*. Calc. for $C_{40}H_{30}CrN_2O_6$: C, 69.97; H, 4.40; N, 4.08. Found: C, 70.08; H, 4.51; N, 4.00%.

2.4. Synthesis of cis-$\{Cr(NO)_2(OR)_2\}_n$ (R = Et (**3a**), ^{i}Pr (**4a**))

A solution of *trans*-$\{Cr(NO)_2(OEt)_2\}_n$ in toluene was stirred for 30 min at 60°C. The green precipitate of the *cis*-isomer was filtered off, washed with CH_2Cl_2 and dried in vacuo.

Table 3
Calculated and experimental frequencies ν(NO) (cm^{-1}) and intensities I (km mol^{-1}) for *cis*- and *trans*-$M(NO)_2(O_2CCH_3)_2$ (M = Cr, Mo) [a]

3. Details of theoretical studies

The studies presented here were performed applying density functional theory (DFT) [49]. The DFT approach utilized Becke's three parameters hybrid functional (B3LYP) [50], based on earlier works [51,52]. Calculations were performed within the LanL2DZ [53,54] basis set. Additional calculations were performed with the LanL2DZ basis supplemented by the single five-component d function on heavy atoms. The exponents of polarization functions for chromium and molybdenum are 0.058317 and 0.1270, respectively. Exponents for other atoms were adopted from Huzinaga et al. [55]. The computations presented were made using the program GAUSSIAN-94 [56].

4. Results and discussion

The structure and the nature of bonding in nitrosyl complexes were discussed in 1974 by Enemark and Feltham [2]. In the case of dinitrosyl complexes possessing the $\{M(NO)_2\}^n$ fragment the important problem concerns the N–M–N angle. The number of d electrons, n, determines the linearity ($D_{\infty h}$) or nonlinearity (C_{2v}) of the N–M–N angle. The six-coordinated dinitrosyl complexes of Group 6 metals should contain the nonlinear $M(NO)_2$ fragment. All the structurally characterized compounds, including $Mo(NO)_2TTP$, possess nitrosyl ligands in the *cis* position [6,57]. However, the dinitrosylchromium complex $[Cr(NO)_2(MeCN)_4](PF_6)_2$, synthesized 30 years ago by Connolly et al. [58], is *trans* with regard of the nitrosyl groups. Only a single band in the region of the ν(NO) frequency was observed in the IR spectrum of this compound. The replacement of acetonitrile ligands by sulfur chelating ones ($S_2CNEt_2^-$

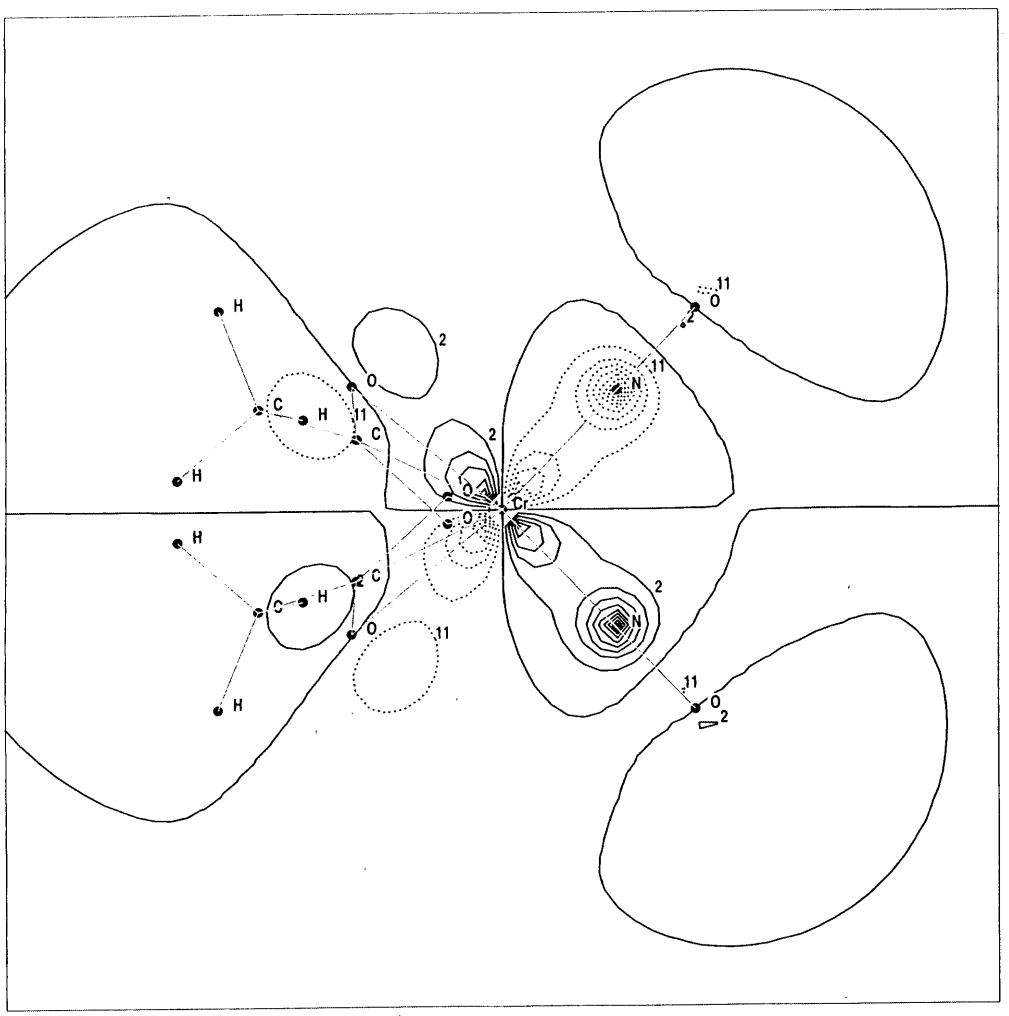

Fig. 3. The HOMO-1 for the *cis*-$Cr(NO)_2(O_2CR)_2$ molecule plotted in the N–Cr–N plane. The contour lines from 1–12 are positive (increasing order), from 13–17 are negative (decreasing order). The contour 1 denotes zero. The spacing between lines is 0.0125 units. Note the σ character of the Cr–N bond in the orbital.

and/or $S_2C_2(CN)_2^{2-}$) leads to the formation of respective *cis*-dinitrosylchromium complexes. Recently, the *trans*-dinitrosylmolybdenum complexes with Schiff bases were also synthesized [59]. A number of diatomic *trans*-dinitrosylchromium complexes were obtained in our laboratory [32]. The reaction of complexes containing the *trans*-$[Cr(NO)]^{2+}$ core with M^IOR ($M^I = Na$, Li) leads to the formation of respective *trans* complexes. A similar reaction Eq. (1) yields dicarboxylatochromium complexes, i.e. $Cr(NO)_2(O_2CR)_2$ (where $R = CH_3$ or CPh_3).

$$[Cr(NO)_2(CO)_2(MeNO_2)_2](BF_4)_2 \quad \text{or} \quad \underset{(L = MeCN \text{ or } MeNO_2)}{[Cr(NO)_2L_4](BF_4)_2} + 2NaO_2CR \underset{(R = Me\ (\mathbf{1})\ \text{or}\ CPh_3\ (\mathbf{2}))}{\rightarrow} Cr(NO)_2(O_2CR)_2 + 2NaBF_4 \quad (1)$$

The brown complex **1**, soluble in donor solvents (MeCN, $MeNO_2$, MeOH) is polymeric ($\{Cr(NO)_2(O_2CMe)_2\}_n$). The $\Delta\nu(CO_2) = \nu_{as} - \nu_s$ splitting equals 151 cm^{-1} confirms the above [60,61]. Very low $\Delta\nu(CO_2)$ values (< 105) generally indicate chelation [61]. For example, in $[Mo(NO)_2(O_2CMe)_2]\cdot MeOH$, $\Delta\nu(CO_2)$ is 97 cm^{-1} [62]. The ^1H NMR spectrum of **1** in CD_3NO_2 contains one methyl proton signal at 2.10 ppm.

Complex **2** (soluble in CH_2Cl_2, benzene, toluene, CCl_4) exists in the monomeric form as indicated by its molecular weight (Found: 683.91. Calc. for $Cr(NO)_2(O_2CCPh_3)_2$: 686.68). The $\Delta\nu(CO_2)$ value for chelate triphenylacetate ligands is 112 cm^{-1}. The ^1H NMR spectrum (in CD_2Cl_2 at 20°C) exhibits a multiplet at 7.26 ppm due to phenyl protons. The IR spectra of **1** and **2** are similar to all the *trans*-dinitrosylchromium complexes [32,58] and are characterized by a single strong band at 1700 cm^{-1} related to the ν(NO) vibration. However weak shoulders at 1778 and 1777 cm^{-1} may also be observed.

Dinitrosylchromium complexes with alkoxy ligands (i.e. *trans*-$\{Cr(NO)_2(OR)_2\}_n$, R = Et (**3**), ^{i}Pr (**4**)), when heated (60°C) in noncoordinating solvents, undergo isomerization to *cis* complexes (**3a**, **4a**). However, only the *cis*-$\{Cr(NO)_2(OEt)_2\}_n$ (**3a**) complex was obtained in pure form, as a brown powder soluble only in polar solvents. Complex **4** partially disintegrates during such treatment, while complex **2** does not isomerize at all and at higher temperatures decomposes. Complex **1** is not soluble in noncoordinating solvents.

The IR spectra of complexes **3a** and **4a** (see Section 2) contain two ν(NO) frequencies characteristic for the *cis*-$\{Cr(NO)_2\}^6$ unit (C_{2v} symmetry), corresponding to symmetric and asymmetric stretching motions of the N–O bond. The ν(CO) frequencies of RO^- ligands (e.g. for R = Et 1093, 1050 and 1025 cm^{-1}) may indicate the presence of bridging as well as terminal alkoxy ligands in these complexes [32,63]. The ^1H NMR spectrum of the complex **3a** (see Section 2) also confirms the above. It contains two resonance signals for the CH_2 and CH_3 protons corresponding to the terminal and bridging ethoxy ligands.

Reactions of complexes **2** and **3** with Lewis acids (e.g. $SnCl_4$) induce similar *trans*-$[Cr(NO)_2] \rightarrow$ *cis*-$[Cr(NO)_2]$ transformations, in 1:1 as well as in 1:2 molar ratios of reagents. The adducts *cis*-$[Cr(NO)_2(OEt)_2(SnCl_4)]$ (**5**) and *cis*-$[Cr(NO)_2(O_2CCPh_3)_2(SnCl_4)_2]$ (**6**) are produced in such reactions. Their IR spectra contain two characteristic ν(NO) frequencies. The character of the spectrum of complex **5**, in the range of ν(OEt) frequencies, indicates the bridging and terminal coordination of ethoxy ligands [32,63]. Examination of the ^1H NMR spectrum (see Section 2) also leads to the same conclusion.

4.1. Theoretical results

Theoretical studies were performed for the $M(NO)_2(O_2CMe)_2$ (M = Cr and Mo) complexes. The valence orbitals of chromium and molybdenum undergo the d^5s^1 hybridization which leads to a trigonal bipyramid structure. In the molecules studied, however, the metal–acetate rings destroy the perfect D_{4h} symmetry. Two equilibrium structures were located (Fig. 1) with the *cis* isomers (C_2 symmetry) being more stable then its *trans* partners (C_{2v} symmetry) (Tables 1 and 2). The X-ray structures for the *trans*-dinitrosyl complexes of Group 6 metals are unknown. The main structural difference between the ideal structures of the *cis* and *trans* isomers concerns the N–M–N angle. In the ideal *trans* structure the ON–M–NO fragment is linear. The studies performed, however, indicated a significant deviation from linearity with the N–M–N angle being 130.1 and 163.6° for Cr and Mo compounds, respectively. In the case of the *cis* isomers N–M–N angles of 92.0° (Cr) and 91.0° (Mo) are close to the values found for the perfect geometry (90.0°). The M–N–O branch was also found to be nonlinear. It was noted several years ago [64] that slightly bent M–N–O fragments are a common feature of polynitrosyl complexes. The electronic rationalization of this phenomenon was given by Kettle [65]. In an every molecule studied, the O–M–O angles of metal–acetate rings amount to about 60°, again far from the 90° expected for the ideal D_{2h} symmetry. This distortion leads to two different M–O bonds within the same ring.

The vibrational spectra of studied compounds reflects the geometry of the molecules. Two different frequencies for NO vibrations (asymmetrical and symmetrical) were expected and both are observed. The calculated and experimental frequencies are presented in Table 3. The most striking effect comparing this structure to the ideal is that there are two, instead of just one, vibra-

tional motions for NO in the *trans* case. The frequencies calculated applying the LanL2DZ basis set closely reproduces the available experimental spectra. The extension of the basis set by the polarization functions, however, leads to the systematically higher values of frequencies which have to scaled by 0.9 to reproduce experimental data. This scaling factor reflects the quality of the method and the basis set applied. The excellent agreement of the smaller basis results with experimental values has to be treated with caution. The differences between asymmetric and symmetric modes of N–O vibrations are reproduced satisfactorily. The calculated ratio of Iv_s/Iv_{as} is also close to that observed experimentally. This agreement gives us confidence in the calculations performed for *trans* isomers where experimental results are scarce. The inflection observed in the wide band of the *trans* isomer in the Cr based molecule fits the theoretically found symmetric vibration. The much lower ratio of Iv_s/Iv_{as} (0.14) for the *trans* isomer compared to that of the *cis* form (0.43) is consistent with molecular structures. The weak symmetric band would vanish in the case of the perfect D_{4h} structure. Table 4 collects the ν(NO) frequencies and relative intensities Iv_s/Iv_{as} of other known *cis*- and *trans*-dinitrosyl complexes of chromium and molybdenum.

The nature of bonds formed by the metal are similar in Cr and Mo compounds. The analysis of bonding performed here is based on the Mulliken population analysis. The two highest molecular orbitals (Figs. 2 and 3) describe the Me–NO bonds. These bonds are covalent, and may be described as two three-centered N–Me–N σ and π bonds. The central metal atom donates 0.5 of an electron to the acetate rings, although the total loss of electrons in d orbitals amounts to 1.2 electrons. Due to the rearrangement of the electronic density of metal, its s orbitals gain 0.4 of an electron, while 0.3 of an electron is shifted to the metal p orbitals. The involvement of p orbitals in the formation of bonds indicates the deviation from the d^5s hybridization and in effect the distortion of the perfect D_{2h} symmetry. The electronic structure of the center of coordination is similar in both the *cis* and *trans* isomers, and is visible as an almost equal occupation of the orbitals on the central atom.

5. Conclusions

The number of d electrons in the $\{M(NO)_2\}^n$ fragment determines its structural properties. The six-coordinated dinitrosyl complexes of Group 6 metals should have the *cis* form. However, *trans* isomers containing Cr or Mo are also known (Tables 3 and 4) and some of them were synthesized in this work. X-ray structures are not known for *trans*-dinitrosyl complexes of Group 6. Based on the previous IR studies [32,50,51], D_{2h} symmetry was expected for *trans* structures with a linear ON–M–NO fragment.

Theoretical studies determined two isomers (Fig. 1): *cis* (C_2 symmetry) and *trans* (C_{2v} symmetry), with the *cis* forms being energetically more stable (Tables 1 and 2). The *trans* NO groups are divided by a plane defined by the acetate rings. The latter structures are significantly distorted from ideal geometries. The expected D_{2h} symmetry of *trans* complexes, due to the nonlinearity of the ON–M–NO fragment, is lowered to C_{2v}. This distortion is observed as an additional symmetric NO vibration. The weak band corresponding to ν_s(NO) may be easily hidden in the strong one associated with the ν_{as}(NO) vibrational motion. In the case of compounds **1** and **2**, the single bands at about 1700 cm^{-1} is related to ν_{as}(NO), but weak shoulders at 1778 and 1777 cm^{-1} may correspond to the symmetrical NO vibrations. The reasonable reproduction of the properties of the *cis* isomers gives confidence for the overall theoretical studies presented. The calculated intensities of observed bands are comparable in the *cis* case, while the second (symmetrical) vibration in the *trans* molecule is barely seen. The calculations led to the distortion of ON–M–NO structures in every isomer studied. The study of structures of other complexes would help to answer if this is a property of Cr and Mo complexes only or if this is a more general feature of nitrosyl complexes. The M–N–O branches were also distorted from linearity in every structure studied. The geometry optimization also indicated a significant deformation of the acetate rings. Different lengths of M–O bonds within the same rings were observed.

The electronic density rearrangement on the central atom is almost the same in both *cis* and *trans* isomers. The change in the electronic density is due to the transfer of electrons from d orbitals to the acetate rings (0.5 electron) and s and p orbitals (0.7 electron).

The reported results, including the charge distribution picture on the central and ligand atoms confirm the suggested mechanism of the formation of carbene and vinylidene catalysts in *cis*-$M(NO)_2(O_2CR)_2$–Lewis acid and $\{M(NO)_2(OR)_2\}_n$–Lewis acid systems [31–33,47,48,54,66]. The favorable conditions for the electrophilic attack of Lewis acid molecules on the carboxylate ligand oxygen atoms are in the equatorial plane (M1O3O14N9N11 plane in Fig. 1). In the same plane, on the side opposite to the NO groups, carbene and vinylidene ligands will coordinate.

Abstract

The synthesis and characterization of the complexes CuX_2L_2 {where $X = CH_3CHClCOO^-$, $CH_3CCl_2COO^-$ or $ClCH_2CHClCOO^-$, and L = nicotinamide (na), isonicotinamide (ina) or methyl-3-pyridylcarbamate (mpc)} are reported. Characterization of the compounds was based on elemental analysis, IR, electronic and EPR spectra. All the CuX_2L_2 compounds seem to possess octahedral copper(II) stereochemistry with differing tetragonal distortion. Complex $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ was also studied by X-ray analysis. The structure of $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ is centrosymmetric. The Cu(II) atom is *pseudo*-octahedrally *trans*-coordinated by four carboxylic oxygen atoms of α,α-dichloropropionate anions [Cu(1)–O(1) = 1.959(2) Å (2 ×) and Cu(1)–O(2) = 2.677(2) Å (2 ×)], and by two nitrogen atoms two methyl-3-pyridylcarbamate ligands [Cu(1)–N(1) = 1.981(2) Å (2 ×)]. The antibacterial effects have been tested on various strains of bacteria, yeasts and micromycetes. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Copper(II); Chloropropionate; Crystal structure; EPR; Bio-activity

1. Introduction

Some derivatives of propionic acid, as for example, 2-(2-fluorophenyl)propionic acid and 2-(4-isobutylphenyl)propionic acid are used as an antirheumatic drugs. These acids, like other antirheumatic drugs, inhibit the biosynthesis of prostaglandins, but they differ from most of them having an additional inhibitory effect on prostaglandin receptors [1].

The interaction of copper(II) atom, which plays a vital role in a number of quite different biological processes, with therapeutically administered drugs is a subject of considerable interest [2].

On the basis of spectral and magnetic properties of some copper(II) chloropropionate with nicotinamide, a *pseudo*-octahedral environment around the copper(II) atom was proposed [3]. The aim of this study is to investigate the complexation of copper(II) chloro- and dichloropropionate complexes with nicotinamide (na), isonicotinamide (ina) and methyl-3-pyridylcarbamate (mpc). The compounds of the composition CuX_2L_2 ($X = CH_3CHClCOO^-$, $CH_3CCl_2COO^-$ or $ClCH_2CHClCOO^-$ and L = na, ina or mpc) were prepared and studied by spectral methods, as well as their bio-activities.

The complex $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ was also studied by X-ray analysis. These structure data are discussed and compared with other copper(II) compounds.

Bio-activity of the complexes was tested on *Micrococcus luteus*, *Bacillus subtilis*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Saccharomyces cerevisiae*, *Candida albicans* and *Aspergillus niger*.

2. Experimental

2.1. Preparation of compounds

A solution of the sodium salt of α-chloropropionic, α,α-dichloropropionic or α,β-dichloropropionic acid was prepared and pH adjusted to 4.5–5 and an aqueous solution of copper(II) sulfate in the molar ratio 1:2 was added. These were left to stand at room temperature (r.t.), and the green products of the composition $CuX_2 \cdot nH_2O$ ($n = 1$, 0, 1, respectively) were isolated.

The copper(II) compounds of composition CuX_2L_2 ($X = CH_3CHClCOO^-$, $CH_3CCl_2COO^-$ or $ClCH_2$-$CHClCOO^-$ and L = nicotinamide (na); isonicotinamide (ina) or methyl-3-pyridylcarbamate (mpc)) were prepared by reaction between CuX_2 and L in hot methanol solution (1.75×10^{-2} mol of CuX_2 and a small amount of the corresponding free acid were dissolved in 50 ml of methanol). To this blue–green solution was added 3.5×10^{-2} mol of L in 50 ml of methanol. The resultant blue solution was concentrated to approximately 50 ml and cooled to r.t. The blue or violet microcrystalline precipitate was filtered, washed with cold methanol and dried at r.t. Crude products were recrystallized from methanol ($CuX_2(na)_2$ and $CuX_2(ina)_2$) or acetone ($CuX_2(mpc)_2$) solution. Fine crystals were isolated and washed with cold methanol. Elemental analyses of isolated copper(II) compounds are given in Table 1.

2.2. Spectroscopic studies

Electronic spectra in the region from 10 000 to 28 000 cm^{-1} were measured with a Perkin–Elmer 450 spectrophotometer using a Nujol suspension. EPR spectra of microcrystalline samples were run on a Varian model E4 spectrometer at r.t. Infrared spectra of the compounds were recorded in the range 400–3600 cm^{-1} using the Magma-750 FTIR.

2.3. Structure determination

Data collection and cell refinement were carried out using SYNTEX $P2_1$ diffractometer software [4]. Intensity data were corrected for Lorenz and polarization factors. The structure was solved by the heavy atom method with SHELXS-86 [5], and subsequent Fourier synthesis using SHELXL-93 [6], anisotropic thermal parameters were refined for all non-hydrogen atoms. Geometrical analysis was performed using SHELXL-93 [6]. The structure was drawn using ORTEP-III [7]. The final parameters after refinement are summarized in Table 3. Selected inter-atomic distances and bond angles are given in Table 4.

2.4. Bio-test

The antimicrobial activity of the newly prepared copper(II) complexes was evaluated by a dilution method in test tubes [8] using G^+ bacterial strains *Micrococcus luteus* CCM 1569, *Bacillus subtilis* CCM 2216 and G^- bacterial strains *Escherichia coli* CCM 5172, *Pseudomonas aeruginosa* CCM 1960. The effect of these compounds on the yeasts *Saccharomyces cerevisiae* CCY 22-3-1 and *Candida albicans* CCY 29-3-15. Cultivation of bacteria was on nutrient broth medium and yeasts on malt extract. The cultures of bacteria and

yeasts were incubated on medium during static culturing for 2 days at 28°C. The time course of absorbance (A_{600}) was determined in three experiments. The filamentous fungi *Aspergillus niger* F-384 was tested by a macrodilution technique on solidified broth medium during static culturing for 4 days at 28°C [9].

Chromatographically pure compounds were dissolved in dimethylsulfoxide. The concentration of complexes under study ranged from 10^{-5} to 4 mmol l^{-1}.

The antimicrobial activity was characterized by the IC_{50} values (concentration of a derivative which inhibits microbial growth by 100%). The IC_{50} and MIC values were read from toxicity curves.

3. Results and discussion

The IR spectra of the studying compounds show the carboxylate stretching frequencies $\nu_{as}(COO^-)$ at ~ 1600 cm^{-1} and $\nu_s(COO^-)$ at 1420 cm^{-1} (Table 2). The stretching vibration of the C=N bond in the pyridine ring (nicotinamide, isonicotinamide or methyl-3-pyridylcarbamate) appears at 1590 cm^{-1}, and on complexation a shift to higher frequencies is observed [10]. In the compounds this shift to about 1615 cm^{-1} (Table 2) may suggest bond formation by the copper(II) atom to the pyridine ring nitrogen, thereby increasing the dipolar contribution of C=N in the heterocyclic ring.

The electronic spectra of the compounds show intraligand transition bands (Table 2). These types of d–d spectrum are typical for a tetragonal arrangement around Cu(II) atom. The electronic spectrum of α-$[Cu(CH_3CHClCOO)_2(ina)_2]$ exhibits the band at about 14 900 cm^{-1}, while β-$[Cu(CH_3CHClCOO)_2(ina)_2]$ at 14 166 cm^{-1}. The higher value of the band of the α-isomer indicates a somewhat greater tetragonal distortion about the Cu(II) atom for the α- than the β-isomer.

As can be seen in Table 2, the intraligand transition bands range from 14 166 cm^{-1} for β-$[Cu(CH_3CHClCOO)_2(ina)_2]$ to 16 129 cm^{-1} for $[Cu(CH_3CCl_2COO)_2(mpc)_2]$. The 'blue-shift' of d–d band indicates that tetragonal distortion increases in the given order.

EPR spectra of the powdered isomers (α- and β-$[Cu(CH_3CHClCOO)_2(ina)_2]$) are *pseudo*-rhombic. While the EPR spectra of $[Cu(CH_3CCl_2COO)_2(na)_2]$ [1] and $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ are isotropic. In all remain-

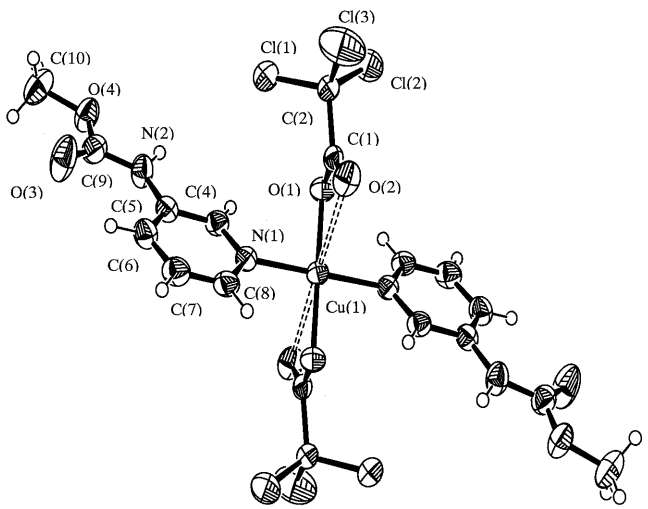

Fig. 1. Perspective of complex $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ (**9**), with the atom numbering scheme. Thermal ellipsoids are drawn at the 50% probability level.

ing samples, the spectra are of axial type. The g-values are given in Table 2.

The structure of $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ is shown in Fig. 1. As one can see, the stereochemistry around the Cu(II) centre may be described as an axially elongated octahedral. Molecules of the complex lie on a crystallographic inversion centre, with the Cu(II) atom coordinated by the pyridyl N atoms of two different methyl-3-pyridylcarbamate molecules and by an O atom from each of the two α,α-dichloropropionate anions to give a *trans*-square-planar arrangement, with Cu–N(1) and Cu–O(1) bond distances of 1.981(2) and 1.959(2) Å, respectively. The remaining carboxylate O atoms in each α,α-dichloropropionates participates in much longer axial bonding, Cu–O(2) 2.677(2) Å, to complete an axially elongated octahedral environment about Cu(II). The C(1)–O(1) and C(1)–O(2) distances [1.251(4) and 1.223(4) Å, respectively] are significantly different.

The α,α-dichloropropionate chelate angle O(1)–Cu–O(2) is very acute at 54.0(1)°. The two chlorine atoms and the methyl carbon atom of the group $-CCl_2CH_3$ are disordered occupying three statistical positions, presented by Cl(1), Cl(2) and Cl(3) with the site occupancy factors of 0.741(5), 0.618(5) and 0.641(6), respectively.

In Table 4 are given selective bond distances (Å) and bond angles (°) for the familiar structures of $[Cu(CH_3CCl_2COO)_2(mpc)_2]$ and $[Cu(CH_3CH_2COO)_2(mpc)_2]\cdot 0.25H_2O$ [11]. As can be seen, the Cu–N as well as Cu–O bond distances are somewhat longer in the former than in the latter. There are at least two reasons, the first α,α-dichloropropionate is much bulky than propionate and the second there is somewhat 'lower' electronic densities on O atoms in the former than in the latter.

On the basis of spectral data, for all remaining copper compounds, can be proposed a tetragonal bipyramidal coordination about copper(II) atoms with a different degree of distortion.

The results of preliminary screening are presented in Table 5; this shows the tested compounds differ in their bio-activities againts bacteria, yeasts and micromycetes:

1. Bio-activities of the compounds increase in the sequence > micromycetes < yeasts < bacteria.
2. The compounds are more active against G^- that G^+ bacteria. From the G^- bacteria, *P. aeruginosa* is more resistance than the other one. The reason for the resistance is that *P. aeruginosa* contains the most effective enzymes. These enzymes are available to destroy PCP, PCB, pesticides and some other pollutants.
3. The complex $[Cu(CH_3CCl_2COO)_2(na)_2]$, which is most active against *A. niger* at 1 mmol l^{-1}, was growing instead of a black colony a white one. *A niger* lost the spores and therefore lost its reproductive ability. When the white colony was added on cultivation medium without the compound, the colony became black again.
4. Nicotinamid as a neutral ligand is a part of the pyridine nucleotides as NAD^+ and $NADP^+$, which takes a part in redox reactions. These are most important for transfer of hydrogen in the cell breath (biological oxidation).

4. Supplementary material

Received 23 June 2000; accepted 18 August 2000

Abstract

Racemic 6,6′-disubstituted-1,1′-bi-2-naphthols H_2X_2bino (X = H, Br) and corresponding binaphthyl acetates react with trisdiolatetungsten(VI) complexes [W(eg)$_3$] and [W(eg)(pin)$_2$] (eg = ethanediolate dianion, pin = pinacolate dianion) forming heteroleptic complexes [W(X_2bino)(diolato)$_2$]. The X-ray crystal structure determinations confirmed that the isolated compounds are made of monomeric tris(diolate)tungsten(VI) molecules in which the central tungsten atom is bonded to six oxygen atoms forming a distorted octahedral coordination sphere around the metal ion. © 2000 Elsevier Science B.V. Keywords: Binaphtholato complexes; Tungsten(VI); X-ray structures

1. Introduction

Chelating oxygen donor ligands, e.g. 1,1′-bi-2-naphthols have confirmed to be useful chiral accessories in enantiospecific organic syntheses with early transition metals [1,2]. The hard Lewis-base character of the phenoxide group makes these compounds ideal for attaching to the metal ions having high oxidation states. Therefore, binaphtholates of Ti(IV), Zr(IV), W(VI) and Mo(VI), often with other ligands, have been used successfully to catalyse organic reactions [3]. For example, tungsten(VI) chlorocomplexes with substituted binaphtholato ligands are known to be suitable catalyst precursors for ring-opening metathesis polymerisation of norbornene [4]. They can be prepared by a direct alcoholysis reaction between WCl_6 and corresponding binaphthol, when the composition of these compounds is depending on the substituents in 3 and 3′ positions of used binaphthol molecules. 3,3′-Ph_2-1,1′-bi-2-naphthol ($H_2$33′Phbino) reacts with WCl_6 forming a monosubstituted [W(33'Phbino)Cl_4], while sterically less hindered 3,3′-Me_2-1,1′-bi-2-naphthol ($H_2$33′Mebino) forms a complex *cis*-[W(33'Mebino)$_2Cl_2$]. Racemic H_2bino with no substituents in *ortho* positions reacts with WCl_6 producing a mixture of different isomers of trisdiolato complex [W(bino)$_3$].

The reactions of metal alkoxides with phenols or phenyl acetates are easy approaches to the metal phenoxides, as presented by the following equations:

$$M(OR)_n + xArOH \leftrightarrow M(OR)_{n-x}(OAr)_x + xROH \quad (1)$$

$$M(OR)_n + xR'C(O)OAr \leftrightarrow M(OR)_{n-x}(OAr)_x + xR'C(O)OR \quad (2)$$

These reactions, alcohol-exchange and transesterification, has confirmed to be useful in the preparation of metal phenoxides [5]. They are very efficient methods, especially if suitable metal alkoxides can be easily prepared from metal oxides, because they make it possible to avoid the use of air and moisture sensitive metal chlorides.

As a part of our ongoing project related to the tungsten catalysed olefin metathesis reactions, we are interested in the use of diolate complexes of W(VI) as air-stable starting materials for catalytically active systems [6]. We have earlier studied preparation of W(VI) phenoxides by the reaction of [W(eg)$_3$] (**1**) (eg = ethyleneglycolate, 1,2-ethanediolate dianion) with

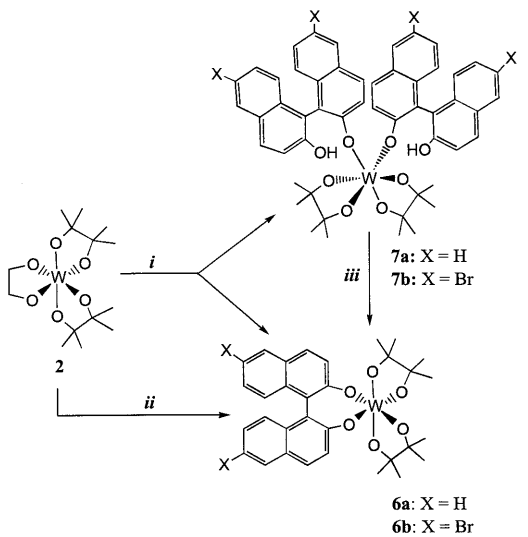
phenyl acetates [7]. In the present study, we have employed the above-mentioned ligand-exchange reactions to prepare new binaphtholate complexes of W(VI). Syntheses and structural studies of $[W(X_2bino)(eg)_2]$ (X = H, Br) and $[W(X_2bino)(pin)_2]$ (pin = pinacolate, 2,3-dimethyl-2,3-butanediolate dianion) are reported.



2. Results and discussion

2.1. Synthesis of the $[W(X_2bino)(eg)_2]$ (5) complexes

Mixed-ligand complexes of the type $[W(X_2bino)(eg)_2]$ (**5**) were prepared by the reaction of **1** with a stoichiometric amount of racemic 6,6′-X_2-1,1′-bi-2-naphthols (H_2X_2bino) (**3**) in a toluene solution at reflux temperature (see path *i* in Scheme 1 The identical compounds were also prepared by using corresponding binaphthyl acetates ($Ac)_2X_2bino$ (**4**) as ligand precursors (see path *ii* in Scheme 1). Binaphthyl acetates reacted slowly in toluene, but more readily if chlorobenzene was used as a reaction medium. As the reaction employing free binaphthol can be promoted by fractionating out the liberated ethanediol as a toluene azeotrope, it seems to lead to the better yields (according to TLC analyses).

Scheme 1. (i)H_2X_2bino/PhMe, reflux; (ii)$X_2bino(Ac)_2$/PhCl, reflux; (ii)$2H_2pin$/PhMe.

Scheme 2. (i)H_2X_2bino/PhMe, reflux; (ii)$X_2bino(Ac)_2$/PhCl, reflux; (iii)xylene, reflux.

However, the use of binaphthyl acetates as starting materials is preferred due to the good solubility of ligand precursor in common solvents, which avails purification by recrystallisation from CH_2Cl_2 or toluene. Compounds **5** are orange crystalline materials, stable as solids when stored under an atmosphere of dry air or nitrogen. They are moderately soluble in chlorinated hydrocarbons, ethers and aromatic solvents but practically insoluble in hexane. The crystals of **5** obtained from CH_2Cl_2 contain about 1/4 molecule of CH_2Cl_2 per one molecule of $[W(X_2bino)(eg)_2]$.

Our attempts to further substitute eg ligands by chlorides and prepare compounds of type $[W(bino)Cl_4]$ failed. Treatment of complexes **5** with a variety of chloride sources (HCl, $AlCl_3$, AcOCl, and $SOCl_2$) always led to the formation of dark solids. Extraction of these solids by toluene resulted in the isolation of small amounts of $[W(bino)_3]$, which seems to be a thermodynamically more stable product than heteroleptic binaphtholate chlorides [4]. Our efforts to prepare complexes of type $[W(bino)_2(eg)]$ or $[W(bino)_3]$ were unsuccessful as reaction of **1** with 2 or 3 equiv. of H_2bino (or its diacetate) yields complex **5** and unreacted ligand precursor.

2.2. Synthesis of the $[W(X_2bino)(pin)_2]$ (6) complexes

Complexes of the type **6** formed when ethanediolato ligands of compounds **5** were substituted by 2 equiv. of pinacol (see path *iii* in Scheme 1.). The substitution reactions were carried out in refluxing toluene and the product was purified by column chromatography. Yellow, air-stable crystalline compounds **6** are soluble in common organic solvents and can be crystallised from hot hexane. In the case **6a** the unit cell contains 1/2 molecule of hexane per one molecule of $[W(bino)(pin)_2]$. These compounds were also prepared from pinacolate complex $[W(eg)(pin)_2]$ (**2**), which reacts readily with binaphthols in refluxing toluene (path *i* in Scheme 2.). This reaction leads also to the formation of minor quantities of $[W(pin)_2(X_2Hbino)_2]$ (**7**) (see below). Compounds **6** are as well formed if complex **2** is allowed to react with binaphthol acetates in chlorobentsene at reflux temperature, but reactions are remarkably slower and long reaction times (few days) are required to reach practical yields (path *ii* in Scheme 2).

2.3. Formation of $[W(pin)_2(X_2Hbino)_2]$ (7) complexes

Synthesis of complexes **6** from pinacolato complex **2** and binaphthols leads also to the development of bis(hydrogenbinaphtholato) complexes $[W(pin)_2(HX_2bino)_2]$ (**7**) in small quantities (see path *i* in Scheme 2). These by-products can be turned to compounds **6** by heating in xylene at reflux temperature. Compounds **7** are soluble in chlorinated solvents and toluene. They

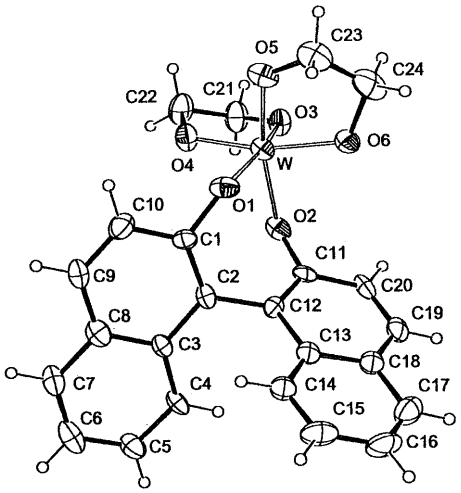


Fig. 1. An ORTEP [13] drawing of complex [W(bino)(eg)$_2$] (**5a**) with 30% probability ellipsoids.

can be crystallised from a hexane–toluene mixture as orange prisms. X-ray analysis of **7a** showed that in these compounds the hydrogendiolate groups act as monodentate phenoxides. Our earlier studies have shown that simple non-*ortho*-substituted phenols can not displace the any of the diolate ligands from the first coordination sphere of trisdiolato complexes. It was interesting to notice that two bulky difunctional phenols can replace ethanediolato ligand from **2** and then both coordinate in a monofunctional manner to a W(VI) centre.

2.4. Structures of complexes

Compounds **5a**, **6a** and **6b** form monomeric molecules in which six oxygen donors surround the central tungsten atoms (Figs. 1–3). The distorted octahedral WO_6 units are generally similar in all these compounds, as seen from the bonding parameters presented in Table 1. Bonding parameters of diolato groups are also closely similar to the parameters reported for the tungsten(VI) diolato complexes with simple phenoxides, e.g. [W(eg)$_2$(OPhR$_2$-2,6)$_2$] and [W(pin)$_2$(OPh)$_2$] [7,8]. In the solid state, compounds **5a** and **6a** adopt a $\Delta(\lambda\lambda\lambda)$ (or its optical isomer $\Lambda(\delta\delta\delta)$) configuration, whereas in **6b** bino ligand and one pin ligand has a λ conformation and another pin ligand is settled to δ conformation, the whole structure showing $\Delta(\lambda\lambda\delta)$ configuration. The ^{1}H NMR spectra of compounds **5** and **6** show typical resonances for bino ligands [4]. In the aliphatic region of the spectra of complexes **5** are seen multiplets for diolate groups, which implies that there are two different environments for these methylene protons. The aliphatic resonances in the spectra of compounds **6** indicate that all pinaco-

W–O(3)–C	121.0(8)	120.8(4)	122.6(4)
W–O(4)–C	120.7(8)	120.5(3)	121.4(4)
W–O(5)–C	121.3(8)	121.4(3)	121.5(4)
W–O(6)–C	118.1(8)	119.6(3)	120.9(4)

late methyl groups have different environments. The different signals for the axial and equatorial methyl groups are indications of a rigid chelate ring, which prevents fast transformations of the ligand configuration. Similar signals for ethanediolate and pinacolate hydrogens are seen in the spectra of comparable W(VI) phenoxides, e.g. $[W(eg)_2(OPhR_2\text{-}2,6)_2]$ and $[W(pin)_2(OPh)_2]$ [7,8].

The structure of compound **7a** is depicted in Fig. 4 and its main structural parameters are shown in Table 2. It is a six-coordinated W(VI) complex with two bidentate pin ligands (one in a λ and the other in a δ conformation) and two monodentate hydrogennaphtholato ligands in *cis*-positions. Only one proton of the phenolic OH groups takes part in H-bonding. This is a quite weak intramolecular H-bond, which is indicated by the O6···O1 distance of 2.947(9) Å.

In order to get information of the influence of more bulky ligand X to a $W(pin)_2X_2$-coordination unit (X is a monodentate phenolate type ligand) we can compare the W–O bond parameters of $[W(pin)_2(Hbino)_2]$ to those of $[W(pin)_2(OPh)_2]$ [8]. In former W–O(alif.) bond lengths are from 1.876(5) to 1.940(5) Å while in the latter they are from 1.889(5) to 1.920(5) Å. The W–O(arom.) bond lengths in **7a** are 1.908(6) and 1.932(5) Å while in $[W(pin)_2(OPh)_2]$ they are 1.884(5) and 1.916 Å. The *trans*-O(alif.)–W–O(alif.) angles are 169.3(2) and 163.2(2)° for **3a** and $[W(pin)_2(OPh)_2]$, respectively. All *trans*-O(alif.)–W–O(arom.) angles are 169.3(2) in both compounds are about 160° (159.7 and 158.8° in **7a** compared to 160.2 and 163.6° in $[W(pin)_2(OPh)_2]$). The above suggests that two bulky X^- ligands can distort the coordination sphere of $W(pin)_2X_2$-unit making it probably more labile. The ^1H NMR spectra of compounds **7** show complicated pattern of signals for monodentate binaphtholato ligands. The resonances of the aliphatic protons indicate that all pinacolate methyl groups have different environments. The different signals for the axial and equatorial methyl groups are indications of a rigid chelate ring, which prevents fast transformations of the ligand configuration

3. Conclusion

Our studies on the synthesis of mixed W(VI) diolate-phenoxides continue as an extension of our search for novel catalyst precursors for olefin metathesis. We have shown that trisdiolatotungsten(VI) complexes $[W(eg)_3]$ and $[W(eg)(pin)_2]$ (eg = ethanediolate dianion, pin = pinacolate dianion) reacts with 6,6′-disubstituted-1,1′-bi-2-naphthols *rac*-H_2X_2bino (X = H, Br) and corresponding binaphthyl acetates forming heteroleptic complexes $[W(X_2bino)(diolate)_2]$. $[W(X_2bino)(eg)_2]$ reacts further with pinacol to form $[W(X_2bino)(pin)_2]$. The X-ray crystal structure determinations confirm that compounds are monomeric molecules presenting distorted octahedral coordination around the W(VI) cation.

4. Experimental

Chemicals were from commercial origins and were used without subsequent purification. Trisdiolatotungsten(VI) complexes **1** and **2** were prepared as described earlier [9]. Racemic binaphthols and binaphthyl acetates were prepared using published procedures [10–12]. Preparative TLC was carried out using 20 × 20 cm plates made from aqueous slurries (Aldrich, silica gel G) followed by drying in air at 80°C. CH_2Cl_2 was used as an eluent in analytical TLC (Merck, Silica Gel 60). NMR spectra were recorded on Bruker AM-200 spectrometer. IR spectra were measured on a Mattson Galaxy FTIR spectrometer as Nujol mulls. Elemental analyses were obtained using a Perkin–Elmer CHNS-Analyzer 2400. Samples were dried in vacuo at 40°C for 2 h before elemental and spectral analyses.

*4.1. Preparation of the $[W(X_2bino)(eg)_2]$ (**5**) complexes (where X = H (**5a**) or Br (**5b**)*

4.1.1. Method A. From binaphthols

Complex **1** (1.0 mmol, 365 mg) was heated with 1 equiv. of binaphthol **3** in 50 ml of toluene at reflux to

form a red solution. The H_2eg that formed was removed by azeotropic distillation with toluene. After 6 h the solvent was removed in vacuo, the red oily residue was dissolved in CH_2Cl_2 and filtered. Drastic reduction of the solution volume and refrigeration at −20°C yielded orange–red crystalline products. Compounds **5a** ($R_f = 0.35$) and **5b** ($R_f = 0.40$) were isolated in yields 48% (285 mg) and 43% (320 mg), respectively. Analytical samples were purified by preparative TLC in 50-mg scale (CH_2Cl_2 as an eluent) followed by extraction with CH_2Cl_2 and drying in vacuo. Crystals of **5a** for X-ray measurements were obtained after slow evaporation of CH_2Cl_2. For **5a**: δ_H ($CDCl_3$, standard $SiMe_4$): 7.90 (m, 4H, aromatics), 7.40 (d, 2H, aromatics), 7.25 (m, 6H, aromatics), 5.60 (m, 4H, CH_2), 5.20 (m, 4H, CH_2). IR: 1327(s), 1271(w), 1242(s), 1219(s), 1155(w), 1061(vs), 1030(vs), 955(s), 918(s), 860(w), 828(m), 818(s), 779(m), 758(s), 733(m), 660(s), 629(vs), 606(vs), 594(s), 552(s), 540(s), 529(m). Found: C, 48.6; H, 3.4. $C_{24}H_{20}O_6W$ requires C, 49.0; H, 3.5%. For **5b**: δ_H ($CDCl_3$, standard $SiMe_4$): 8.03 (2H, aromatics), 7.79 (d, 2H, aromatics), 7.44 (d, 2H, aromatics), 7.25 (d, 2H, aromatics), 7.10 (d, 2H, aromatics), 5.55 (m, 4H, CH_2), 5.20 (m, 4H, CH_2). IR: 1327(s), 1271(w), 1242(s), 1219(s), 1155(w), 1061(vs), 1030(vs), 955(s), 918(s), 860(w), 828(m), 818(s), 779(m), 758(s), 733(m), 660(s), 629(vs), 606(vs), 594(s), 552(s), 540(s), 529(m). Found: C, 38.4; H, 2.2. $C_{24}H_{18}Br_2O_6W$ requires C, 38.7; H, 2.5%.

4.1.2. Method B. From binaphthyl acetates

Complex **1** (reaction scale 1.0 mmol) was heated with 1 equiv. of binaphthyl acetate **4** in 30 ml of chlorobenzene at reflux for 16 h to form a red solution. The bulk of the solvent was removed by distillation and finally at reduced pressure. The red oily residue were dissolved in CH_2Cl_2 and filtered. Drastic reduction of the solution volume and refrigeration at −20°C yielded orange–red microcrystals in yields of 54% (320 mg) for **5a** and 53% (395 mg) for **5b**, respectively. Compounds were identical to those prepared by method A.

4.2. Preparation of the [W(X$_2$bino)(pin)$_2$] (6) complexes (where X = H (6a) or Br (6b)

4.2.1. Method A. From binaphthols

To the solution of **2** (0.5 mmol, 240 mg) in toluene (50 ml) was added 1 equiv. of binaphthol **3**. The solution was allowed to reflux for five hours, and the H_2eg that formed was removed by azeotropic distillation. After the solvent had been removed in vacuo, the orange residue was purified by flash chromatography (30% of toluene in hexane as an eluent). Compounds were crystallised from hot hexane to give orange prisms in yields of 73% (255 mg) for **6a** ($R_f = 0.83$) and 68% (290 mg) for **6b** ($R_f = 0.90$), respectively. For **6a**: δ_H ($CDCl_3$, standard $SiMe_4$): 7.89 (m, 4H, aromatics), 7.42 (d, 2H, aromatics), 7.23 (m, 6H, aromatics), 1.55 (6H, CH_3), 1.31 (6H, CH_3) 1.27 (6H, CH_3), 1.09 (6H, CH_3). IR: 1460(s), 1377(s), 1329(s), 1270(w), 1242(s), 1217(m), 1140(vs), 1072(m), 1010(w), 955(vs), 900(s), 885(vs), 818(s), 770(m), 756(s), 733(s), 716(s), 669(m), 631(vs), 604(s), 567(w), 515(m). Found: C, 54.2; H, 5.0. $C_{32}H_{36}O_6W$ requires C, 54.9; H, 5.2%. For **6b**: δ_H ($CDCl_3$, standard $SiMe_4$): 8.02 (2H, aromatics), 7.81 (d, 2H, aromatics), 7.46 (d, 2H, aromatics), 7.24 (d, 2H, aromatics), 7.08 (d, 2H. aromatics), 1.53 (6H, CH_3), 1.31 (6H, CH_3), 1.27 (6H, CH_3) 1.09 (6H, CH_3). IR: 1462(s), 1375(s), 1329(s), 1267(w), 1240(s), 1217(m), 1142 (vs), 1067(m), 1003(w), 951(vs), 906(m), 889(vs), 876(s), 814(m), 735(w), 716(s), 629(vs), 590(w), 525(w). Found: C, 45.2; H, 4.1. $C_{32}H_{34}Br_2O_6W$ requires C, 44.8; H, 4.0%. The synthesis of complex **6a** was accompanied also by the formation of 12 mg of complex **7a** ($R_f = 0.45$), which was crystallised from a hot hexane–toluene mixture (5 + 5 ml). Formation of **7b** was also detected by TLC ($R_f =$ 0.55), but only negligible amounts of that was isolated. Compounds **7** were turned quantitatively to compounds **6** by heating in xylene at reflux temperature (b.p. = 135°C). For **7a**: δ_H ($CDCl_3$, standard $SiMe_4$): 8.00–7.68 (several peaks, 6H, aromatics), 7.50 (m, 6H. aromatics), 7.35 (m, 6H, aromatics), 7.27 (m, aromatics), 1.35 (6H, CH_3), 1.26 (6H, CH_3), 1.15 (6H, CH_3) 1.09 (6H, CH_3).IR: 3418(br), 1460(s), 1375(s), 1335(s), 1270(w), 1256(s), 1233(vs), 1217(m), 1175(m), 1142(vs), 1072(m), 1010(w), 990(vs), 955(vs), 900(s), 887(vs), 812(vs), 770(m), 746(s), 733(s), 716(s), 669(w), 631(vs), 617(s), 592(m), 515(m). Found: C, 64.0; H, 5.2. $C_{52}H_{50}O_8W$ requires C, 63.3; H, 5.1%.

4.2.2. Method B. From binaphthyl acetates

Complex **2** (0.5 mmol, 24 mg) was heated with 1 equiv. of binaphthyl acetate (**4**) in 30 ml of chlorobenzene at reflux temperature for 3 days to form a red solution. The solvents were removed at reduced pressure, and red oily residues were purified as described above to obtain compounds in yields of 31% (110 mg) **6a** and 32% (145 mg) for **6b**, respectively. Compounds were identical to those prepared by method A.

4.2.3. Method C. From complexes 5

To the red solution of complex **5** (reaction scale 0.5 mmol) in 50 ml of toluene was added pinacol (140 mg, 1.2 mmol) and the mixture was heated at reflux. The colour of the solution turned yellow during reaction. The H_2eg that formed was removed by azeotropic distillation with toluene during 6 h. Compounds were separated and purified as described above to obtain

Abstract

The reaction of 2-(diphenylphosphino)-*N*-[2-(diphenylphosphino)benzylidene]benzeneamine (PNCHP) with sulfur in a 1:1 molar ratio shows the phosphorus atom nearest the imine nitrogen to be preferentially oxidised. The overall product distribution, determined by synthesising each component independently, is: 50% 2-(diphenylphosphinothioyl)-*N*-[2-(diphenylphosphino)-benzylidene]benzeneamine (SPNCHP), 7% 2-(diphenylphosphino)-*N*-[2-(diphenylphosphinothioyl)benzylidene]benzeneamine (PNCHPS) and 27% 2-(diphenylphosphinothioyl)-*N*-[2-(diphenylphosphinothioyl)benzylidene]benzeneamine SPNCHPS (27%) with 16% of the reactant, PNCHP, remaining. The structures of PNCHP and SPNCHP have been determined by single-crystal X-ray diffraction. The PNCHP molecule has an approximate centre of symmetry with the two phosphorus atoms adopting a *trans* orientation with respect to each other. The two phosphorus atoms in SPNCHP also adopt a *trans* arrangement to minimise non-bonded steric interactions. The –CH=N– 'bridge' linking the two phenyl rings is not coplanar with its associated phenyl ring. The single crystal X-ray structure of the solvate, $SPNCHP{\cdot}CH_2Cl_2$, shows that the extent of this non-planarity is influenced by the presence of a CH_2Cl_2 solvent of crystallisation. Reaction of PNCHP with the strong acids, $HClO_4$ and HBF_4 results in protonation of the imine nitrogen followed by nucleophilic attack on the imine carbon by the phosphorus nearest the imine nitrogen to form the phosphonium salt [$\overline{PNHCH}$P]X (X = ClO_4 and BF_4), the structures of which have been determined by X-ray crystallography. A new P–C bond is formed thus producing a five-membered heterocyclic ring. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The chemistry of mixed donor multidentate ligands containing organophosphorus and nitrogen donors is appearing more frequently in the literature in such diverse areas as chiral complexes in catalysis [1], stabilized oxygen carriers [2], cyclometallation [3], building blocks in radiopharmacology [4] and resolving agents [5]. The non-dissociative character of chelating polyphosphines may be a disadvantage in some catalytic processes whereas hybrid polydentate ligands offer the possibility of supplying vacant coordination sites at the metal by dissociation of an N or O or P donor [6–8]. In this paper we report the single crystal X-ray structure and some fundamental reactivity studies towards sulfur and acid on the new hybrid ligand, 2 - (diphenylphosphino) - *N* - [2 - (diphenylphosphino)-benzylidene]benzeneamine (PNCHP), which binds to a range of metals [9–12] (Scheme 1).

2. Results and discussion

2.1. Oxidation of PNCHP and its synthetic components with sulfur

In an effort to understand the reactivity of PNCHP we have examined its oxidation with sulfur since its inequivalent phosphorus atoms provide an opportunity to investigate if there is any preference for one site or the other when the molecule is oxidised by one mole equivalent of sulfur. The ^{31}P-{^{1}H} NMR spectrum of such a reaction mixture showed resonances at 42.2, 41.9, 41.1, 35.8, 33.6, −13.9 and −15.3 ppm plus the signals at −14.2 and −14.8 ppm for unreacted PNCHP.

To identify the possible products independent syntheses of the three sulfur oxidised species, viz. SPNCHP, PNCHPS and SPNCHPS, were undertaken (Scheme 2). The amino phosphine, 2-PNH$_2$, was oxidised with S to produce 2-aminophenyldiphenylphosphine sulfide (2-SPNH$_2$) which was reacted with 2-PCHO to give SPNHCP. Similarly, PNCHPS was prepared by oxidising the aldehyde substituted phosphine, 2-PCHO, with sulfur to produce phenyl-2-carbaldehydediphenylphosphine sulfide (2-SPCHO) which was then reacted with 2-PNH$_2$. Finally, oxidation of PNCHP with sulfur in a 1:2 mole ratio resulted in SPNCHPS. The mass spectra (LSIMS) of all three sulfur derivatives of PNCHP exhibited peaks corresponding to [MH]$^+$ protonated parent ions. However, in addition for SPNCHPS, a peak at m/z 746, assignable to the [M + Cs]$^+$ ion, was observed which must arise from the interaction of the disulfide with the caesium ion beam in the mass spectrometer. Indeed, it is possible to isolate stable metal ion complexes with this ligand, e.g. the three coordinate copper(I) complex, [Cu(SPNCHPS)]ClO$_4$ [13].

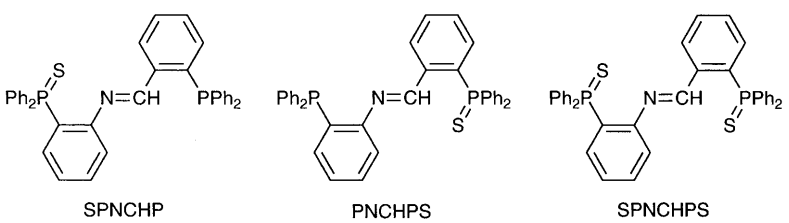

Table 1
Selected ^{1}H and ^{31}P-{^{1}H} NMR data for the compounds [a]

Compound	^{1}H (δ (ppm))	^{31}P-{^{1}H} (δ (ppm)) [b]
2-PNH$_2$	4.14 [s, broad, 2H(NH$_2$)	−20.2
2-PCHO	10.50 [d, J = 5.5 Hz [c], 1H(CHO)]	−11.6
2-SPNH$_2$	5.16 [s, broad, 2H(NH$_2$)]	39.8
2-SPCHO	10.71 [s, 1H(CHO)]	40.3

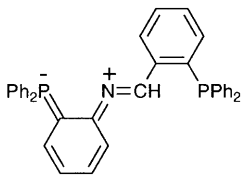
[c] ^{4}J(PH)/Hz.



Selected ^{1}H and ^{31}P-{^{1}H} NMR data for 2-SPCHO, 2-SPNH$_2$, SPNCHP, PNCHPS, SPNCHPS as well as their un-oxidised precursors are given in Table 1. The ^{31}P-{^{1}H} NMR data show the chemical shifts for the phosphorus(III) atoms occur in the range −11 to −20 ppm whereas the signals for the phosphorus(V) atoms lie in the range 40–42 ppm. The isomers PNCHPS and SPNCHP may be clearly distinguished from one another since the chemical shift for each type of phosphorus atom is different in both compounds. Similarly SPNCHPS may be distinguished from PNCHPS and SPNCHP. Comparing the values observed for the mono-phosphine sulfides with those seen for the precursor molecule (Table 1) would suggest that the PNCHP signal at −14.2 ppm can be assigned to the P atom nearest to the imine nitrogen and one at −14.8 ppm to the other P.

In the ^{1}H NMR spectrum for 2-PCHO a doublet signal is observed at 10.50 ppm for the aldehyde proton and for PNCHP the imine proton resonance near 8.92 ppm is also a doublet as a result of ^{4}J(P–H) coupling. A decoupling experiment for PNCHP shows that the imine proton is not coupled to the phenyl protons. When the phosphorus atom nearest to the imine or aldehyde protons is oxidised with sulfur to form PNCHPS and 2-SPCHO the imine and aldehyde protons appear as singlets, the ^{4}J(P–H) coupling now being reduced.

SPNCHP PNCHPS SPNCHPS

Scheme 2. Structures of SPNCHP, PNCHPS and SPNCHPS.

Scheme 3. Possible resonance structure of PNCHP.

In contrast, when the phosphorus atom nearest the imine N of PNCHP is oxidised to give SPNCHP, the imine proton resonance remains as a doublet [^4J(P–H) 6.2Hz], thus allowing the two isomers PNCHPS and SPNCHP to be distinguished. In the fully oxidised compound SPNCPS the imine proton is observed as a singlet resonance.

Returning to the reaction of PNCHP with one mole equivalent of sulfur, the ^{31}P-{^{1}H} NMR spectrum is now easily assigned. The major product is SPNCHP (50%) with a minor amount of its isomer PNCHPS (7%), as well as SPNCHPS (27%) and unreacted PNCHP (16%). The fact that the PNCHPS:SPNCHP ratio is not 1:1 suggests that the phosphorus atom nearest the imine nitrogen is more reactive than the other. This is supported by the possible resonance structure which shows an enhanced basicity for this phosphorus atom (Scheme 3).

This would account for the observed results since the first step in the reaction of tertiary phosphines with elemental sulfur is the nucleophilic attack of the P atom on an S atom of the S_8 ring to produce a chain species, e.g. $Ph_3P^+–S–(S)_6–S^-$. The rate of reaction has been observed to increase with electron releasing substituents on the aromatic ring of the phosphine [14].

The synthesis of an isomeric pair of tertiary phosphine sulfides is rare and is successful in this case because of the synthetic methods utilised above. Seyferth et al. [15] first prepared the unsymmetrical ligand $Ph_2P(S)CH_2PR^1R^2$ (R^1, R^2 are alkyl groups) and others have been synthesised by Grim et al. [16] The preparations involve the production of $Ph_2P(S)CH_2Li$ from Ph_3PS and CH_3Li, followed by reaction of the appropriate R_2PCl. Careful control of reaction conditions are required and yields range from 10 to 50%. When $Ph_2P(S)CH_2PMe_2$ is heated to approximately 160°C in diglyme, the transfer of sulfur from the less basic diphenyl phosphine site to the more basic dimethyl phosphine site occurs [17]. A similar experiment with PNCHPS in boiling toluene does not yield SPNCHP.

2.2. Single-crystal structures of PNCHP, SPNCHP and SPNCHP·CH_2Cl_2

The phosphine sulfide precursor, PNCHP, crystallises with two crystallographically distinct, but chemically identical, molecules in the asymmetric unit. One of these molecules is depicted in Fig. 1 with selected bond distances and angles for both. Each molecule has an approximate centre of symmetry at the mid-point of the –C=N– imine bond, giving each an overall *trans* configuration. It is unlikely that the difference in the imine bond length between N(1)–C(3) and N(4)–C(2) is a real effect but both clearly establish the multiple bond character. The range of P–C bond lengths and C–P–C angles are in agreement with those found in other tertiary phosphines [18]. Calculation of planes of 'best fit' through the phenyl rings and the –N=CH– bridge shows that some rotation has occurred about the C(phenyl)–N and C(phenyl)–C bonds but there are differences in these rotations for the two molecules. In molecule A the plane through atoms N(1), C(3), C(112), C(312) makes angles of 36.8(3) and 35.0(4)° with phenyl rings C(111)–C(116) and C(311)–C(316), respectively. This is in contrast with the comparable angles in molecule B of 7.4(8) and 7.7(8)° between the planes containing atoms N(2), C(4), C(212), C(412) and

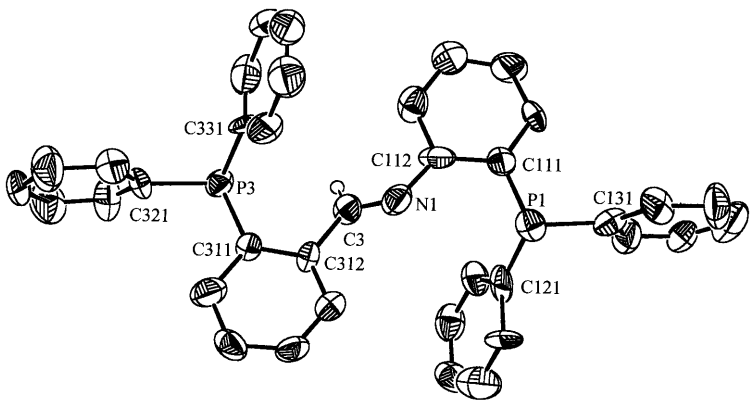


Fig. 1. ZORTEP [26] diagram of PNCHP (molecule A). The thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°) for molecule A: N(1)–C(3) 1.298(6), N(1)–C(112) 1.394(13), C(3)–C(312) 1.481(13), C(3)–N(1)–C(112) 123.3(7), N(1)–C(3)–C(312) 118.9(6); for molecule B: N(4)–C(2) 1.229(6), N(4)–C(412) 1.358(14), C(2)–C(212) 1.491(13), C(2)–N(4)–C(412) 126.9(7), N(4)–C(2)–C(212) 124.8(6).

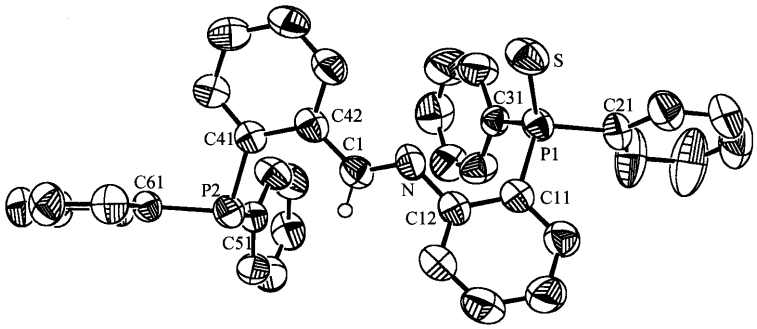

Fig. 2. ORTEP3 [27] diagram of SPNCHP. The thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°) for SPNCP: P(1)–S 1.945(2), C(1)–N 1.257(6), C(1)–C(42) 1.476(7), N–C(12) 1.423(6), N–C(1)–C(42) 122.2(5), C(1)–N–C(12) 122.7(4); for SPNCHP·CH_2Cl_2: P(1)–S 1.939(2), C(1)–N 1.261(5), C(1)–C(42) 1.455(5), N–C(12) 1.404(4), N–C(1)–C(42) 124.0(4), C(1)–N–C(12) 122.0(4).

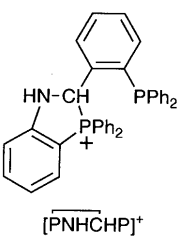
the rings C(211)–C(216) and C(411)–C(416), respectively. As well, the two phenyl rings in both molecule A and molecule B are approximately parallel to one another and this results in a 'step' occurring in each. In molecule A ring atoms C(111)–C(116) are displaced by approximately 0.51 Å from the plane of atoms C(311)–C(316) whereas a smaller 'step' of approximately 0.18 Å is observed in molecule B.



A diagram of the SPNCHP molecule is shown in Fig. 2 with selected bond lengths and angles for it, and the CH_2Cl_2 solvate. The data show a close correspondence between the two sets of distances and angles. For example, the P–S bond lengths at 1.945(2) and 1.939(2) Å are not significantly different and are in good agreement with the range of distances (1.92–1.97 Å [19]) found for other tertiary phosphine sulfides and indicate some multiple bond character. The S–P–C angles (mean 113.6 and 113.5° for the two structures) are all greater than the C–P–C angles in line with the presence of the larger S atom. However, the C–P–C angles show some differences at the two P atoms, with those associated with P(1) being a little larger than their counterparts at P(2) (mean C–P(1)–C 105.1 and 105.1°; mean C-P(2)–C 102.2 and 102.5° for the two structures respectively). The most notable difference observed between the two structure determinations is associated with the planes of 'best fit' data. For SPNCHP·CH_2Cl_2 the plane containing the 'bridge' atoms [N, C(1), C(12), C(42)] lies at an angle of 31° to the plane containing the aromatic ring atoms C(11)–C(16) and 23° to the plane of atoms C(41)–C(46). However, in the non-solvated structure the comparable angles are 39° and 5°. In neither structure are the aromatic rings on either side of the imine bridge parallel to one another. In the solvated structure the two aromatic rings make an angle of approximately 11° with one another whereas in the non-solvated counterpart the angle is 35°. Thus it appears that there is considerable flexibility in the molecule and the precise overall geometry is influenced not only by electron delocalisation but also by crystal packing forces.

2.3. Reaction of PNCHP with acid

When aqueous acids, such as $HClO_4$ and HBF_4, are added to PNCHP in ethanol/dichloromethane solution the yellow solution goes colourless immediately. On standing, in the presence of the acid, the white salt, [$\overline{\text{PNHCH}}$P]X (X = ClO_4 and BF_4), is isolated. The appearance of two singlet phosphorus signals at approximately 38 and −17 ppm (Table 1) in the NMR is indicative of the presence of a phosphonium salt as well as free phosphine. The single crystal X-ray structures (see below) showed the compounds contain a five-membered ring phosphonium salt (Scheme 4).

For the perchlorate salt, the ^{13}C-{^1H} NMR spectrum showed a quartet (due to coupling to the two P nuclei) at 59.6 ppm [^1J(P–C) 56.8 and ^3J(P–C) 27.4 Hz] assignable to the ring carbon (the former imine C). Consistent with this is the disappearance of the ν(C=N) stretching frequency in the IR spectrum of the products and the appearance of a ν(N–H) stretching frequency at approximately 3300 cm^{-1}. As well in the IR, strong bands are seen near 1100 cm^{-1} assignable to the ν(Cl–O) or ν(B–F) frequency of ionic perchlorate or tetrafluoroborate [20]. For the perchlorate, the conductivity in nitromethane was 78 S cm^2 mol^{-1} consistent with a 1:1 electrolyte [21].

It can be envisaged that the cation, [$\overline{\text{PNHCH}}$P]$^+$, is formed by the initial protonation of the imine nitrogen followed by nucleophilic attack by the most basic phosphine atom on the imine carbon with subsequent elec-

[$\overline{\text{PNHCH}}$P]$^+$

Scheme 4. Structure of [$\overline{\text{PNHCH}}$P]$^+$.

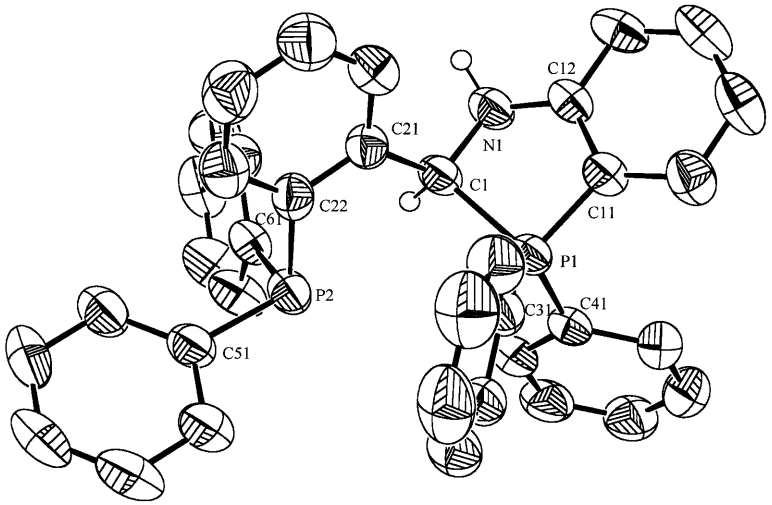


Fig. 3. ZORTEP [26] diagram of the cation in $[\overline{PNHC}HP]ClO_4$. The thermal ellipsoids are drawn at the 40% probability level. Selected bond lengths (Å) and angles (°) for $[\overline{PNHC}HP]ClO_4$: P(1)–C(11) 1.671(4), P(1)–C(1) 1.935(4), N(1)–C(12) 1.346(5), N(1)–C(1) 1.399(5), C(11)–C(12) 1.438(6), C(11)–P(1)–C(1).91.4(2), C(12)–N(1)–C(1) 111.5(4), N(1)–C(1)–P(1) 103.0(3); for $[\overline{PNHC}HP]BF_4$: P(1)–C(11) 1.755(5), P(1)–C(1) 1.856(5), N(1)–C(12) 1.367(6), N(1)–C(1) 1.444(6), C(11)–C(12) 1.389(7), C(11)–P(1)–C(1) 93.0(2), C(12)–N(1)–C(1) 116.5(4), N(1)–C(1)–P(1) 100.6(3).

tron re-arrangement to produce a five-membered ring phosphonium salt. Addition of base, such as triethylamine, reverses the reaction to re-form PNCHP.

2.4. Single-crystal X-ray structures of $[\overline{PNHC}HP]X$ ($X = ClO_4$ and BF_4)

The structure of the salt of the $[\overline{PNHC}HP]^+$ cation is given in Fig. 3 with selected bond lengths and angles for both salts ($X = ClO_4$ and BF_4). The structures show that there is a five-membered heterocyclic ring with P(2) being assigned as the tertiary phosphorus atom and P(1) as the quaternary phosphonium one. The ring carbon, C(1), is chiral and the salts crystallize as racemic mixtures. The bond lengths and angles found in the two structures are similar; hence the discussion will focus on mean bond parameters. The N(1)–C(1) bond length at 1.422 Å is considerably longer than expected for a C=N imine bond [as found in PNCHP (mean 1.258 Å) for example]. However, it is shorter than expected for a C–N single bond (1.47 Å [22]) as is N(1)–C(12) at 1.357 Å which suggests some electron delocalisation around this region of the ring. The average P–C bond distance in the two cations is 1.804 Å. Both the longest and shortest P–C distances are associated with the heterocyclic ring, viz. P(1)–C(1) 1.896 Å and P(1)–C(11) 1.713 Å. The ring C(11)–P(1)–C(1) angle at 92.2° is considerably smaller than the other angles about this atom [100.2(2)–115.5(2)°] presumably due to the steric constraints imposed by the rest of the ring. In fact it is comparable to the C–P–C angle [88.2(4)°] in the similar five-membered ring of 1*H*-1,3,-benzazaphosphole [23]. The atoms in the heterocyclic ring deviate considerably from coplanarity. A calculation of the plane of 'best fit' through the three ring atoms, P(1), C(1) and C(11), shows that C(12) and N(1) lie above this plane by 0.362(7) and 0.585(7) Å for the perchlorate and by 0.398(8) and 0.552(8) Å for the tetrafluoroborate.

3. Conclusions

The two phosphorus atoms in the PNCHP molecule are inequivalent, the one nearer the imine nitrogen being more readily oxidised by elemental sulfur than the other. This same phosphorus atom is involved in forming a P–C bond when PNCHP is treated with strong acid. The product is the cyclic phosphonium salt, $[\overline{PNHC}HP]^+$, which contains a five-membered PCNCC heterocyclic ring.

4. Experimental

Solvents were purified and dried in the usual manner and all reactions were performed under dinitrogen or argon. 2 - (Diphenylphosphino) - *N* - [2 - (diphenylphosphino)-benzylidene]benzeneamine (PNCHP) [12], phenyl-2-carbaldehydediphenylphosphine (2-PCHO) [24] and 2-aminophenyldiphenylphosphine (2-PNH_2) [25] were prepared according to literature methods. Microanalyses were performed by the Campbell Microanalytical Laboratory, University of Otago. Nuclear magnetic resonance (NMR) spectra were recorded on a JEOL GX270W spectrometer and infrared (IR) spectra on a BIORAD FTS-40 instrument as Nujol mulls between KBr discs. Mass spectra were obtained using a

Varian BG70-250S double focussing magnetic sector mass spectrometer by the method of liquid secondary ion mass spectrometry (LSIMS) at the Horticulture and Food Research Institute of New Zealand Limited, Palmerston North. Samples were dissolved in CH_2Cl_2 with *m*-nitrobenzylalcohol as a matrix.

4.1. Syntheses

4.1.1. Phenyl-2-carbaldehydediphenylphosphine sulfide (2-SPCHO)

2-PCHO (0.290 g, 1.0 mmol) and sulfur (0.032 g, 1.0 mmol) were dissolved in 15 cm^3 of toluene and the solution was heated under reflux for 30 min. After standing at 4°C for 1 day the cream coloured product that formed was filtered and washed with toluene. Yield: 0.32 g, 65%. Found: C, 70.52; H, 4.92; S, 9.70. Calc. for $C_{19}H_{15}OPS$: C, 70.81; H, 4.66; S, 9.94%. M.p. 117–119°C. MS: *m*/*z* (relative intensity) 323 (100%) $[MH]^+$. IR: 639 cm^{-1} [*ν*(PS)].

4.1.2. 2-Aminophenyldiphenylphosphine sulfide (2-SPNH$_2$)

2-PNH_2 (0.416 g, 1.5 mmol) and sulfur (0.048 g, 1.5 mmol) were dissolved in 15 cm^3 of CH_2Cl_2 and 8 cm^3 of ethanol and the solution refluxed for 80 min. After standing at room temperature (r.t.) for 1 day, white needles of the product which formed were filtered and washed with ethanol. Yield: 0.40 g, 85%. Found: C, 69.90; H, 5.65; N, 4.64; S, 10.03. Calc. for $C_{18}H_{16}NPS$: C, 69.90; H, 5.18; N, 4.53; S, 10.36%. M.p. 184–185°C. MS: *m*/*z* (relative intensity) 310 (100%) $[MH]^+$. IR: 628 cm^{-1} [*ν*(PS)].

4.1.3. 2-(Diphenylphosphinothioyl)-N-[2-(diphenylphosphino)benzylidene]benzeneamine methanol hemisolvate (SPNCHP·0.5MeOH)

2-PCHO (0.464 g, 1.6 mmol), 2-$SPNH_2$ (0.469 g, 1.6 mmol) and toluene-*p*-sulfonic acid (8 mg) were added to benzene (200 cm^3). The solution was refluxed under argon for 7 h using a Dean–Stark trap. Upon removal of the solvent with a rotary evaporator the resulting yellow oil was dissolved in a small amount of CH_2Cl_2 and methanol added until crystallisation began. After standing overnight at 4°C, pale yellow crystals of the product were filtered off and washed with methanol and dried in vacuo. Yield: 0.76 g, 83%. Found: C, 75.79; H, 5.53; N, 2.66; S, 5.81. Calc. for $C_{37.5}H_{31}NO_{0.5}P_2S$: C, 75.38; H, 5.19; N, 2.35; S, 5.36%. M.p. 189–191°C. MS: *m*/*z* (relative intensity) 582 (100%) $[MH]^+$. IR: 1613 [*ν*(C=N)], 632 cm^{-1} [*ν*(PS)].

4.1.4. 2-(Diphenylphosphino)-N-(2-diphenylphosphinothioyl)benzylidene]benzeneamine methanol hemisolvate (PNCHPS·0.5MeOH)

This was prepared by a method similar to that for SPNCHP·0.5MeOH above, with the new reagents 2-SPCHO (0.208 g, 0.64 mmol), 2-PNH_2 (0.178 g, 0.64 mmol) and toluene-*p*-sulfonic acid (8 mg). Yield: 0.20 g, 52%. Found: C, 75.28; H, 5.36; N, 2.55. Calc. for $C_{37.5}H_{31}NO_{0.5}P_2S$: C, 75.38; H, 5.19; N, 2.35%. M.p. 224–225°C. MS: *m*/*z* (relative intensity) 582 (100%) $[MH]^+$. IR: 1620 [*ν*(C=N)], 634 cm^{-1} [*ν*(PS)].

4.1.5. 2-(Diphenylphosphinothioyl)-N-[2-diphenylphosphinothioyl)benzylidene]benzeneamine (SPNCHPS)

To a solution of PNCHP (110 mg, 0.20 mmol) dissolved in 15 cm^3 CH_2Cl_2 and 4 cm^3 ethanol was added sulfur (14 mg, 0.40 mmol) After 30 min heating under reflux, the solution changed colour from orange to yellow and on standing overnight at r.t. a light yellow precipitate of the product formed. This was recrystallised from a $CHCl_3$–toluene mixture. Yield: 0.11 g, 88%. Found: C, 72.14; H, 4.81; N, 2.34; S, 10.57. Calc. for $C_{37}H_{29}NP_2S_2$: C, 72.43; H, 4.73; N, 2.28; S, 10.44%. M.p. 301–303°C. MS: *m*/*z* (relative intensity) 746 (18%) $[M + Cs]^+$, 614 (55%) $[MH]^+$. IR: 1614 [*ν*(C=N)], 635 cm^{-1} [*ν*(PS)].

4.1.6. Reaction of PNCHP with sulfur in a 1:1 molar ratio

PNCHP (0.138 g, 0.25 mmol) and sulfur (0.008 mg, 0.25 mmol) were dissolved in 10 cm^3 CH_2Cl_2 and 2.5 cm^3 ethanol and the solution refluxed for 10 min. The reaction solution was taken to dryness by rotary evaporation and the solid which formed redissolved in $CDCl_3$ for a ^{31}P-{^1H} NMR spectrum. The following compounds were identified (see Section 2): PNCHP, SPNCHP, PNCHPS and SPNCHPS.

4.1.7. [PNHCHP]ClO_4

To PNCHP (0.22 g, 0.4 mmol) dissolved in cold ethanol–dichloromethane was added aqueous $HClO_4$ (0.5 mmol). A clear solution resulted and on standing for 2 days [PNHCHP]ClO_4 crystallised. The product was filtered off, washed with ethanol and dried in vacuo. Yield 0.20 g 76%. Found: C, 67.91; H, 4.67; N, 2.43. Calc. for $C_{37}H_{30}ClN\ O_4P_2$: C, 68.37; H, 4.65; N, 2.15%. MS: *m*/*z* (relative intensity) 550 (100%) $[M–ClO_4]^+$. IR: 3280 [*ν*(NH)], 1103 cm^{-1} [*ν*(ClO)].

4.1.8. [PNHCHP]BF_4

This was prepared using the above method for [PNHCHP]ClO_4 but using tetrafluoroboric acid. Found: C, 69.54; H, 4.78; N, 2.09; P, 9.72. Calc. for $C_{37}H_{30}BF_4NP_2$: C, 69.72; H, 4.74; N, 2.20; P, 9.72%. IR: 3303 [*ν*(NH)], 1064 cm^{-1} [*ν*(BF)].

4.2. Determination of crystal structures

Single crystals of PNCHP, SPNCHP and SPNCHP·CH_2Cl_2 were grown from dichloromethane–

methanol and of the salts, [PNHCHP]ClO_4 and [PNHCHP]BF_4, from dichloromethane–ethanol. All crystals were secured to the end of a glass fibre with cyanoacrylate glue and mounted on a CAD4 diffractometer with a graphite monochromator. Intensity data were collected at room temperature with Mo Kα radiation ($\lambda = 0.71073$ Å). No absorption corrections were applied. Crystallographic data are summarised below. Initially for PNCHP the distinction between the C and N atoms of the C=N imine bond was not clearcut and this raised the possibility of there being disorder, giving rise to centrosymmetric data and the space group $P2_1/c$. This hypothesis was tested but rejected on the basis of systematic absence violations and on the statistical evidence which strongly favoured a non-centrosymmetric space group. As well, refinement in $P2_1/c$ was much less satisfactory. The labels were eventually assigned mainly on the basis of the lengths of the (C,N)–C(phenyl) bonds and with reference to the relative thermal parameters of the imine bridge atoms. For all structures, anisotropic thermal parameters were assumed for all non-hydrogen atoms. Hydrogen atoms were included at calculated sites riding on the atoms to which they were attached and with fixed thermal parameters except for HN(1) attached to N(1) in both [PNHCHP]ClO_4 and [PNHCHP]BF_4. These latter H were located from difference maps but once located were not refined.

4.2.1. Crystal data for PNCHP

$C_{37}H_{29}NP_2$, $M = 549.55$, monoclinic, $a = 15.026(3)$, $b = 11.600(2)$, $c = 17.261(3)$ Å, $\beta = 98.51(3)°$, $U = 2975.5(9)$ Å^3, $T = 293$ K, space group $P2_1$ (no. 4), $Z = 2$, μ(Mo Kα) 0.173 mm^{-1}, 5736 reflections measured, 5515 unique ($R_{int} = 0.0131$). The final $wR_2[I > 2\sigma(I)] = 0.0996$, $R_1[I > 2\sigma(I)] = 0.0469$.

4.2.2. Crystal data for SPNCHP

$C_{37}H_{29}NP_2S$, $M = 581.61$, monoclinic, $a = 19.200(4)$, $b = 10.122(4)$, $c = 17.040(3)$ Å, $\beta = 111.30(5)°$, $U = 3085(1)$ Å^3, $T = 293$ K, space group $P2_1/c$ (no. 14), $Z = 4$, μ(Mo Kα) 0.235 mm^{-1}, 5618 reflections measured, 5413 unique ($R_{int} = 0.0821$). The final $wR_2[I > 2\sigma(I)] = 0.1432$, $R_1[I > 2\sigma(I)] = 0.0612$.

4.2.3. Crystal data for SPNCHP·CH_2Cl_2

$C_{38}H_{31}Cl_2NP_2S$, $M = 666.54$, triclinic, $a = 8.766(2)$, $b = 9.637(3)$, $c = 21.160(4)$ Å, $\alpha = 101.71(2)$, $\beta = 94.69(2)$, $\gamma = 102.34(2)°$, $U = 1695.2(7)$ Å^3, $T = 293$ K, space group $P\bar{1}$ (no. 2), $Z = 2$, μ(Mo Kα) 0.326 mm^{-1}, 6370 reflections measured, 4558 unique ($R_{int} = 0.0239$). The final $R_1[I > 2\sigma(I)] = 0.0772$.

4.2.4. Crystal data for [PNHCHP]ClO_4

$C_{37}H_{30}ClNO_4P_2$, $M = 650.01$, monoclinic, $a = 10.161(2)$, $b = 9.286(2)$, $c = 35.447(7)$ Å, $\beta = 90.97(3)°$, $U = 3344$ (1) Å^3, $T = 293$ K, space group $P2_1/c$ (no. 14), $Z = 4$, μ(Mo Kα) 0.250 mm^{-1}, 6578 reflections measured, 5800 unique ($R_{int} = 0.013$). The final $wR_2[I > 2\sigma(I)] = 0.1403$, $R_1[I > 2\sigma(I)] = 0.0524$.

4.2.5. Crystal data for [PNHCHP]BF_4

$C_{37}H_{30}BF_4NP_2$, $M = 637.37$, monoclinic, $a = 8.950(2)$, $b = 19.188(4)$, $c = 18.656(4)$ Å, $\beta = 99.39(3)°$, $U = 3160.9(12)$ Å^3, $T = 298$ K, space group $P2_1/n$ (no. 14), $Z = 4$, μ(Mo Kα) 0.189 mm^{-1}, 5925 reflections measured, 5546 unique ($R_{int} = 0.0382$). The final $wR_2[I > 2\sigma(I)] = 0.1368$, $R_1[I > 2\sigma(I)] = 0.0548$.

5. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 146136 for PNCHP, CCDC No. 146137 for SPNCHP, CCDC No. 146138 for SPNCHP·CH_2Cl_2, CCDC No. 146139 for [PNHCHP]BF_4 and CCDC No. 146140 for [PNHCHP]ClO_4. Abstract

The cluster $[Ru_3Ir(CO)_8(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**3**) has been isolated from the reaction of $[Ru_3(CO)_{12}]$ with $[Ir(^tBu_2PH)_3Cl]$ in refluxing toluene. The analogous reaction of $[Ru_3(CO)_{12}]$ with $[Au(^tBu_2PH)Cl]$ in refluxing THF gave $[Ru_3Au(CO)_{10}(\mu\text{-}Cl)(^tBu_2PH)]$ (**4**) in good yield. The single-crystal X-ray structure analyses reveal both clusters to contain a Ru_3M butterfly skeleton. With respect to the EAN electron count of 62e, **3** can be considered as electron-rich (64e), while **4** is electron-poor (60e). © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Ruthenium; Iridium; Gold; Electron-rich; Cluster; Phosphido-bridged; Crystal structures

Heterometallic metal clusters are of current interest in view of their site-selective reactivity and synergetic effects in catalytic reactions [1]. Recently, we reported the synthesis and X-ray crystal structures of the phosphido-bridged heterometallic clusters $[Ru_3Ir(CO)_7(\mu\text{-}H)_2(\mu_3\text{-}Cl)(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**1**) and $[Ru_3Rh(CO)_7(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**2**) [2,3]. These compounds were obtained by condensation of $[Ru_3(CO)_{12}]$ with mononuclear complexes $[M(^tBu_2PH)_3Cl]$ (M = Rh, Ir). An important feature in these reactions is, that the latter complexes bear secondary phosphine ligands, which are able to form phosphido bridges upon thermolysis. It seems that such reactions preferably work for 4d and 5d metal complexes. On the contrary, the thermal reaction of tri-ruthenium-dodecacarbonyl with $[\{Cu(^tBu_2PH)Cl\}_4]$ affords only homotrinuclear ruthenium clusters, i.e. the copper complex acts merely as ligand transfer reagent [4]. In this paper, we describe new results on the reactions of $[Ru_3(CO)_{12}]$ with $[Ir(^tBu_2PH)_3Cl]$ and $[Au(^tBu_2PH)Cl]$, respectively, yielding two novel tetrametallic butterfly clusters with Ru_3M core.

1. Results and discussion

1.1. Reaction of $[Ru_3(CO)_{12}]$ with $[Ir(^tBu_2PH)_3Cl]$

A more intense study of the ^{31}P NMR spectra of crude product mixtures, obtained from reactions of $[Ru_3(CO)_{12}]$ with $[Ir(^tBu_2PH)_3Cl]$ in refluxing toluene, showed beside the cluster **1** and the compound $[Ru_3(CO)_8(\mu\text{-}H)_2(\mu_3\text{-}PBu^t)(^tBu_2PH)]$, respectively, another unidentified product containing phosphido bridging ligands. Now we could show that using a molar ratio of 1:2 (Ru_3/Ir) results in decreased yields of **1** but leads instead to enhanced yields in the novel product (**3**). After column chromatography on alumina with hexane–diethylether mixtures the novel cluster

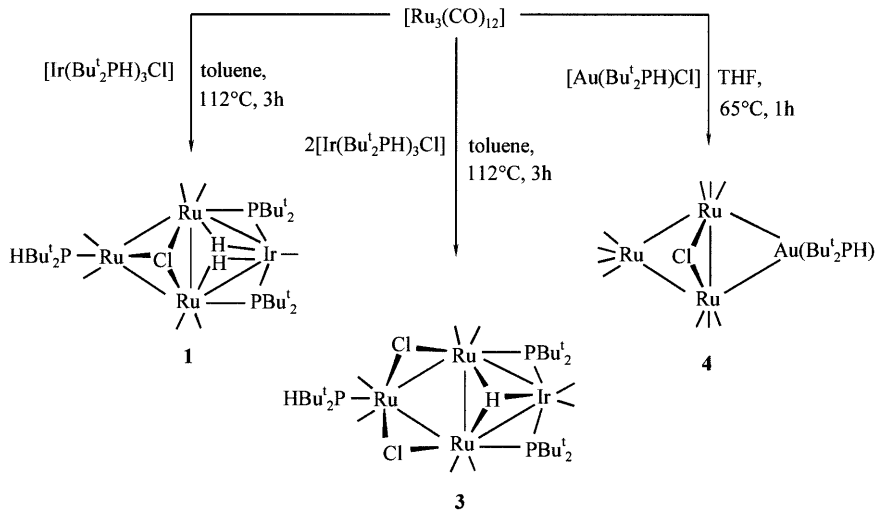
PII: S0277-5387(00)00561-1



$[Ru_3Ir(CO)_8(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**3**) could be isolated in approximately 55% yield (Scheme 1). The molecular structure of **3** in the solid has been unambiguously established by X-ray crystallography (vide infra). Thus it could be shown that a closely related iridium analogue to the complex $[Ru_3Rh(CO)_7(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**2**) exists. However in contrast to **2**, electron counting reveals the cluster **3** to be a species containing 64 cluster valence electrons (c.v.e.). By the effective atomic number rule (EAN) for a butterfly configured tetrametal core with five metal-metal bonds 62 c.v.e. are predicted. Therefore, **3** has be to considered as electron-rich cluster [5].

The IR spectrum of **3** in the solid exhibits ν(CO) absorption bands only in the region characteristic of carbonyls in a terminal coordination mode. The $^{31}P\{^1H\}$ NMR spectrum of this compound consists of a signal at δ 267.2 (d, $^3J_{PP} = 15.4$ Hz, μ-P^tBu_2) and a corresponding resonance at δ 45.6 (t, $^3J_{PP} = 15.4$ Hz, $^tBu_2PH$). These data indicate two chemically equivalent phosphorus nuclei of two phosphido bridges across metal-metal bonds which couple with a phosphorus nucleus of a phosphine ligand. A comparison of the ^{31}P chemical shifts for the phosphido bridges in **1** and **3** shows that these ligands resonate for **3** at higher field (**1**: δ 318.2). That is a further indication exhibiting **3** as an electron-rich cluster. (These upfield shifts correlate with increased Ru–P–Ru angles and therefore with an elongation of the Ru–Ru bonds bridged by the phosphido groups.) In accordance with the ^{31}P NMR results, the ^1H NMR spectrum of **3** exhibits the corresponding signals for both phosphine and phosphido ligands. Furthermore a resonance in the metal hydride region at δ −13.77 (t, $^2J_{PP} = 15.5$ Hz, 1H, μ-H) is observed. According to the splitting pattern of the three phosphorus nuclei in the $^{31}P\{^1H\}$ NMR spectrum and the lack of a second coupling in the hydride signal in the proton NMR spectrum a capping position (μ_3) of the hydride on the Ru_2Ir triangle is assumed. Furthermore, the mass spectrum of **3** also confirms the composition; the molecular ion peak and fragment peaks resulting from successive loss of carbonyl ligands were observed.

In the context with the electron-precise compound **2** the evidence of a hypothetical electron-rich cluster $[Ru_3Rh(CO)_8(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ is of interest. In the course of some investigations on **2** we have to note that no reaction of **2** with carbon monoxide under normal conditions (1 bar CO, r.t.) for several hours could be realized. The unchanged starting material was recovered as indicated by NMR measurements. At elevated pressure (60 bar CO, 24 h) a reaction occurs and investigations in this field are under way.

1.2. Reaction of $[Ru_3(CO)_{12}]$ with $[Au(^tBu_2PH)Cl]$

As mentioned above the synthesis of heteronuclear Ru_3Cu frameworks failed by reaction of $[Ru_3(CO)_{12}]$ with the copper(I) complex containing both the chloro and the secondary phosphine ligand. In this context we were interested in the reaction of the ruthenium carbonyl with $[Au(^tBu_2PH)Cl]$ (**5**), which was described by Schmidbaur and Aly [6]. Thus, treatment of **5** with equimolar amounts of $[Ru_3(CO)_{12}]$ in refluxing THF for 30 min results in a colour change of the solution from orange to deep red. Removal of the solvent and recrystallization from hexane yields deep red crystals which were identified by elemental analysis, spectroscopic means, and crystal structure analysis as $[Ru_3Au(CO)_{10}(\mu\text{-}Cl)(^tBu_2PH)]$ (**4**) (Scheme 1). The IR spectrum of **4** in the solid shows ν(CO) absorption bands only in the region characteristic of terminal carbonyl groups. The $^{31}P\{^1H\}$ NMR spectrum of **4** shows merely a singlet at δ 90.55 ($^tBu_2PH$). Therefore,

the cluster contains only one terminal phosphine ligand, i.e. not any phosphido bridge was formed in the course of the reaction. In accordance with the $^{31}P\{^1H\}$ NMR spectrum, the proton NMR spectrum of **4** exhibits the corresponding signals for the phosphine ligand at δ 4.37 (d, $J_{PH} = 334.5$ Hz, $^tBu_2PH$) and 1.40 (d, $^3J_{PH} = 15.8$ Hz, $^tBu_2PH$). The mass spectrum of **4** confirms the composition, i.e. the molecular ion peak and fragments resulting from successive loss of carbonyl groups were observed.

*1.3. Molecular structures of $[Ru_3Ir(CO)_8(\mu_3\text{-}H)(\mu\text{-}Cl)_2(\mu\text{-}P^tBu_2)_2(^tBu_2PH)]$ (**3**) and $[Ru_3Au(CO)_{10}(\mu\text{-}Cl)(^tBu_2PH)]$ (**4**)*

Compound **3** crystallizes from hexane in the monoclinic space group $P2_1/a$ with four molecules in the unit cell. A representation of the molecule is shown in Fig. 1, selected bond lengths and angles are listed in Table 1. The molecule possesses a butterfly configured tetrametal framework with the iridium occupying one of the wing tips. The metal core is folded with a dihedral angle of 144.96(1)° between the planes [Ru(1)–Ru(2)–Ru(3)] and [Ru(1)–Ru(2)–Ir]. For the compounds **1** and **2** corresponding dihedral angles of 166° and 149°, respectively, were found. The Ru_3Ir core of **3** can be discussed as closed tetrametal framework, although the hinge bond Ru(1)–Ru(2) is with 3.1176(7) Å considerably elongated and the two Ru–Ir bonds can also be considered as long. Therefore, **3** can be discussed as an electron-rich M_4 cluster [5]. The other two Ru–Ru bonds in the Ru_3 triangle are shorter and in good accordance with the closely related situation in **2** [for **2**: Ru(1)–Ru(3), 2.953(1); Ru(2)–Ru(3), 2.956(1) Å]. However, compound **2** is not directly comparable with **3**, because cluster **2** is a 62 c.v.e. species. Nevertheless, an elongated hinge bond was also detected in **2**, and up to now an explanation for this circumstance is lacking.

The presence of two or more phosphido bridges is often a recurring feature of formally electron-rich clusters as outlined by Carty and coworkers [5]. These bridging ligands practise a stabilizing influence towards fragmentation even in the case if an excess of electrons in the cluster core is present. From our laboratory we can confirm this by the closed 52e-cluster $[Ru_3(CO)_9(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ [7], whereas the closed 50e-cluster $[Ru_3(CO)_6(\mu\text{-}Cl)_3(\mu\text{-}P^tBu_2)(^tBu_2PH)]$ contains only one phosphido bridge [4]. An inspection of the metal-metal distances in the Ru_3Ir clusters **1** and **3** yields a generally expanded metal framework for **3** [**1**: Ru(1)–Ru(2), 2.651(1); Ru(1)–Ru(3), 2.798(1); Ru(2)–Ru(3), 2.724(1); Ru(1)–Ir, 2.748(1), Ru(2)–Ir, 2.720(1) Å; for **3** see Table 1]. As reviewed by Carty and coworkers the cluster expansion of **3** shows the form of three long and two normal bonds, and in the first instance one would expect a similar situation as described for the 64e clusters $[Ru_4(CO)_{13}(\mu\text{-}PR_2)_2]$ (R = Ph, ^{i}Pr, OEt, N^{i}Pr$_2$; **5a–d**) [5,8]. However a remarkable difference between the structures of **5a–d** and **3** exists: the Ru_4 butterfly frameworks of **5a–d** are almost planar with dihedral angles between the two Ru_3 triangles of 173°–180°, whereas **3** is more folded (145°). Therefore, it seems not meaningful to use the EHMO calculations for **5a–d**,

which include a distribution of the additional two electrons in an antibonding molecular orbital localized on the $M_3(\mu\text{-}PR_2)_2$ triangle [8]. The hydrido ligand in **3** could not be located directly during the X-ray analysis, however by means of the observed NMR data (vide supra) a capping position of the latter on the Ru_2Ir triangle is reasonable to assume. In contrast to the molecule of **2**, in which the rhodium bears only one carbonyl group, the coordination sphere of the iridium in **3** is completed by a further carbonyl ligand. The same effect was observed in the two complexes $[CoRh(CO)_4(\mu\text{-}H)(\mu\text{-}P^tBu_2)(^tBu_2PH)]$ [9] and $[CoIr(CO)_5(\mu\text{-}H)(\mu\text{-}P^tBu_2)(^tBu_2PH)]$ [10]. Thus, that confirms the tendency of the iridium to pursuit of higher coordination numbers.

Compound **4** crystallizes from hexane in the triclinic space group $P\bar{1}$ with two molecules in the unit cell. The molecular structure of **4** is shown in Fig. 2, selected bond lengths and angles are summarized in Table 2. The molecule exhibits a 'butterfly' tetrametal framework with the gold atom in one of the wing tip positions. A localized bonding description in butterfly clusters suggests a total valence electron count of 62. Because **4** exhibits only 60 c.v.e the compound can be considered in the sense of the EAN rule as electron-poor species. The metal core of **4** is strongly folded with a dihedral angle of 120.11(1)° between the planes [Ru(1)–Ru(2)–Ru(3)] and [Ru(1)–Ru(2)–Au]. A closely related molecular structure was described for the cluster $[Ru_3Au(CO)_{10}(\mu\text{-}Cl)(PPh_3)]$ (**6**) [11]. The geometric features and bondlength characteristics between **4** and **6** are in very good agreement. As described for the latter, also we found that **4** is only stable under mild conditions, i.e. heating in solvents with higher boiling points like THF leads to rapid decomposition. Attempts to synthesize phosphido-bridged heteronuclear clusters containing gold failed by this way.

2. Experimental

2.1. General considerations

All reactions were performed under argon atmosphere, using conventional Schlenk techniques. Solvents were dried over sodium/benzophenone ketyl or molecular sieves and were distilled under argon prior to use. Starting materials were either commercially available or were prepared as described before: $[Ir(^tBu_2PH)_3Cl]$ [12]; $[Au(^tBu_2PH)Cl]$ was prepared in analogy to the synthesis of $[Au(Ph_2PH)Cl]$ [13]. IR spectra were obtained using a Mattson 5000 instrument. The NMR spectra were recorded on a Bruker WP 200 spectrometer (^1H at 199.975 MHz, reference TMS; $^{31}P\{^1H\}$ NMR at 80.950 MHz, reference 85% H_3PO_4 as external standard). The mass spectra were obtained on a Hitachi Perkin–Elmer RMU 6, Nermag R 30-10 instrument. The elemental analyses were performed by the Analytisches Laboratorium des Institutes für Organische Chemie, Martin-Luther-Universität Halle.

2.2. Preparation of *[Ru$_3$Ir(CO)$_8$(μ_3-H)(μ-Cl)$_2$(μ-P^{t}Bu$_2$)$_2$(^{t}Bu$_2$PH)]* (**3**)

A mixture of [Ir(^{t}Bu$_2$PH)$_3$Cl] (1.33 g, 2 mmol) and [Ru$_3$(CO)$_{12}$] (0.64 g, 1 mmol) was heated in refluxing toluene (40 cm^3) for 3 h. After cooling to room temperature (r.t.) and removing the solvent, the remaining residue was extracted three times with 20 ml portions of heptane. The volume of the combined extracts was reduced to 10 cm^3 and separated by column chromatography on alumina with hexane as eluent. The orange–red fraction contains complex **3** which was crystallized from hexane at −30°C. Yield: 0.68 g (55%) based on [Ru$_3$(CO)$_{12}$].

2.2.1. Analytical data for **3**

Found: C, 31.47, H, 4.52, Cl, 5.83, P, 7.89; Calc. for $C_{32}H_{56}Cl_2IrO_8P_3Ru_3$: C, 31.30, H, 4.60, Cl, 5.77, P, 7.57%. IR (KBr pellet, cm^{-1}): ν(CO): 2020(s), 1991(s), 1962(m), 1940(s), 1915(sh). ^{1}H NMR ($CDCl_3$): δ 5.14 (d, $J_{PH} = 326.4$ Hz, 1H, ^{t}Bu$_2$P*H*), 1.54 (d, $^3J_{PH} = 14.8$ Hz, 18H, ^{t}Bu$_2$PH), 1.52 (d, $^3J_{PH} = 15.2$ Hz, 36H, μ-P^{t}Bu$_2$), −13.77 (t, $^2J_{PH} = 15.5$ Hz, 1H, μ-H). ^{31}P{^{1}H} NMR ($CDCl_3$): δ 267.2 (d, $^3J_{PP} = 15.5$ Hz, μ-*P*^{t}Bu$_2$); 45.7 (t, $^3J_{PP} = 15.5$ Hz, ^{t}Bu$_2$*PH*). Mass spectrum: $m/z = 1228$ $[M]^+$, 1200 $[M-CO]^+$, 1172 $[M-2CO]^+$, 1144 $[M-3CO]^+$, 1116 $[M-4CO]^+$, 1088 $[M-5CO]^+$, 1060 $[M-6CO]^+$, 1032 $[M-7CO]^+$, 1004 $[M-8CO]^+$.

2.3. Preparation of *[Ru$_3$Au(CO)$_{10}$(μ-Cl)(^{t}Bu$_2$PH)]* (**4**)

A sample of [Au(^{t}Bu$_2$PH)Cl] (0.38 g, 1 mmol) was dissolved in 30 cm^3 of THF in a Schlenk tube and [Ru$_3$(CO)$_{12}$] (0.64 g, 1 mmol) was added. The mixture was stirred under reflux for 30 min. After cooling to r.t. and removal of the solvent, the residue was dissolved with hexane (30 cm^3). The complex **4** was crystallized from the hexane solution at −30°C as red crystals. Yield: 0.69 g (72%) based on [Ru$_3$(CO)$_{12}$].

2.3.1. Analytical data for **4**

Found: C, 22.34, H, 2.11, Cl, 4.02, P, 3.05; Calc. for $C_{18}H_{19}AuCl_{10}O_{10}PRu_3$: C, 22.48, H, 1.99, Cl, 3.69, P, 3.22%. IR (KBr pellet, cm^{-1}): ν(CO): 2088(m), 2050(s), 2024(vs), 1987(vs), 1976(sh), 1966(m), 1955(s). ^{1}H NMR ($CDCl_3$): δ 4.37 (d, $J_{PH} = 334.5$ Hz, 1H, ^{t}Bu$_2$P*H*), 1.40 (d, $^3J_{PH} = 15.8$ Hz, ^{t}Bu$_2$PH). ^{31}P{^{1}H} NMR (C_6D_6): δ 90.55 (s, ^{t}Bu$_2$PH). Mass spectrum: $m/z = 962$ $[M]^+$, 934 $[M-CO]^+$, 906 $[M-2CO]^+$, 878 $[M-3CO]^+$, 850 $[M-4CO]^+$, 822 $[M-5CO]^+$, 794 $[M-6CO]^+$, 766 $[M-7CO]^+$.

2.4. X-ray crystal structure determinations of **3** and **4**

Crystal data, data collection and refinement parameters are summarized in Table 3. Crystals of **3** and **4** suitable for X-ray diffraction studies were grown by crystallization from hexane. For data collection the diffractometer Stoe-IPDS was used. The structure was solved by direct methods and refined on F^2 [14]. The refinement of the crystal structure of **4** showed, that there is some positional disorder in the P^{t}Bu$_2$ groups. There seem to be two alternative orientations of the phosphido groups which are only 0.88 Å apart from each other. Therefore, the disorder could not be resolved completely and only a splitting of the phosphorus positions (ratio 77:23) could be taken into account.

3. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge

Crystallographic Data Centre, CCDC No. 142329 for **3** and CCDC No. 142328 for **4**. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank the Kulturministerium des Landes Sachsen-Anhalt and the Fonds der Chemischen Industrie for financial support as well as Degussa AG for a generous loan of $RuCl_3 \cdot 3H_2O$ and $HAuCl_4 \cdot 3H_2O$.

Abstract

The ligand 1-phenyl-3-methyl-5-hydroxy-4-pyrazolyl phenyl ketone (PMBP) isonicotinoyl hydrazone (H_2L) was prepared by condensation of PMBP with isoniazid. Seven complexes of rare earth metals with H_2L were synthesized and characterized on the basis of elemental analyses, IR, UV, ^1H NMR spectra and thermal analyses. The general formula of the complexes is $Ln(HL)_3{\cdot}3.5H_2O$ (where Ln(III) = La, Eu, Gd, Tb, Dy, Ho and Er). X-ray diffraction analysis showed that the coordination polyhedron of the Eu complex is a tricapped trigonal prism. The La and Eu complexes possess antitumor activity, and the inhibitory rates for leukemia cells (L_{1210}) are 87.1% and 78.5%, respectively. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Rare earth complex; Crystal structure; Antitumour activity; Hydrazone

1. Introduction

Complexes of Schiff bases with paramagnetic metal ions have received the most attention as a new class of potential magnetic resonance imaging (MRI) contrast agent [1–3], and manganese Schiff base complexes have been demonstrated to be effective as imaging agents for liver and kidneys [3]. In addition, a great many Schiff base complexes with metals have also provoked wide interest because they possess a diverse spectrum of biological and pharmaceutical activities, such as antitumor and antioxidative activities, as well as the inhibition of lipid peroxidation and so on [4–9]. Our previous works showed that the light rare earth complexes with PMBP-isonicotinoyl hydrazone (H_2L) have certain scavenger effects on $OH^{\bullet}$ and $O_2^{-\bullet}$ radicals, and inhibitory action on lipid peroxidation [10]. In order to investigate further their pharmaceutical activity, several additional rare earth complexes have been synthesized on the basis of our previous work, and the crystal structure of the Eu complex was determined by X-ray diffraction analysis (Fig. 1).

2. Experimental

2.1. Material

1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP) and isoniazid were produced in China. The hydrated rare earth (III) chlorides were prepared by dissolving Ln_2O_3 in concentrated HCl, then crystallizing the products. All chemicals used were of analytical grade.

[a] $U = \Omega^{-1}\ cm^2\ mol^{-1}$.

2.2. Physical measurements

Carbon, hydrogen and nitrogen were analyzed on a Carlo Erba 1106 elemental analyzer. The metal contents of the complexes were determined by titration with EDTA volumetric method using xylenol orange tetrasodium salt (1% alcoholic solution) as an indicator [11]. Infrared spectra (4000–400 cm^{-1}) were determined with KBr optics on a Nicolet 5DX IR spectrophotometer. Ultraviolet spectra were recorded on a Shimadzu UV-240 spectrophotometer. The thermal behavior was monitored on a PCT-2 differential thermal analyzer. The molar conductance values were determined in ethanol on a DSS-11A conductivity meter. An orange yellow crystal of the Eu complex ($0.50 \times 0.44 \times 0.36$ mm) was mounted on a Siemens P_4 diffractometer, and determined with Mo Kα radiation. Intensities were measured using $\theta/2\theta$ scan technique, 2θ range $3.44 \leq 2\theta \leq 54.98°$ ($h = -1$–24, $k = -24$–1, $l = -1$–44); 6295 independent reflections were collected with Siemens XSCANS program at 295(2) K, 5452 observed [$I > 3\sigma(I)$] which were used to solve the structure and least-squares refinement. The diffraction data were corrected by the LP factor; absorption correction was made semi-empirically from ψ-scans. The europium atom was located from a Patterson function and the other non-hydrogen atoms from Fourier synthesis. The structure was refined by full-matrix least-squares on F^2. All hydrogen atoms, except ones on C_{11} and C_{12}, were located from a difference-Fourier synthesis. The final R index [$I > 2\sigma(I)$] was equal to 0.0457 ($R_w = 0.1394$), $\Delta/\sigma_{max} = 1.304$, $F(000) = 4368$, μ(Mo Kα) = 0.0940 cm^{-1}. All calculation was completed on a PC486 computer with the SHELXTL 5.03 program.

2.3. Preparation of the ligand

1.08 g of isoniazid (8 mmol) and 2.23g of PMBP (8 mmol) were dissolved in ethanol (300 ml), and refluxed on a water bath for 1 h [10]. The color of the solution changed from light yellow to deep red. After cooling to room temperature, a large amount of red precipitate separated out. The product was purified by crystallization with anhydrous ethanol, yield 82%. m.p. 244–245°C. *Anal.* Found: C, 69.43; H, 4.89; N, 17.08. Calc. for $C_{23}H_{19}N_5O_2$: C, 69.50; H, 4.82; N, 17.26%. ^{1}H NMR (DMSO-d_6), δ (ppm): 1.50 (3H, singlet, CH_3); 7.10–7.90 (11H, multiplet, 2 phenyl, –NH–); 8.20 (2H, doublet, $J = 6$ Hz, H^3, H^5 of pyridine ring); 8.76 (2H, broadband, H^2, H^6 of pyridine ring).

2.4. Preparation of the complexes

1.58 g of ligand H_2L (8 mmol) was added to water (80 ml), the pH of which was adjusted to 7 by the addition of an aqueous solution of NaOH (10%); the solution turned light yellow. Then a solution of $EuCl_3 \cdot 6H_2O$ (3 mmol) in water (20 ml) was added dropwise to the system. After stirring at 50°C for 0.5 h, a yellow precipitate was separated by filtration, washed several times with water, and hot ethanol, respectively, and dried in a vacuum, yield]: 65% (Table 1). The other complexes were also synthesized by this method.

20 mg of Eu complex was dissolved in 20 ml of methanol, then the solution was filtrated and diluted with 40 ml of ethanol. After a week at room temperature, the crystalline complex separated out. *Anal.* Found: C, 58.46; H, 4.38; N, 14.54; Eu, 10.31. Calc. for $EuC_{69.5}H_{63}N_{15}O_{10}$: C, 58.77; H, 4.47; N, 14.79; Eu, 10.70%.

3. Results and discussion

All complexes are yellow, soluble in DMSO, ethanol and methanol, a little soluble in water, insoluble in benzene and diethyl ether. The molar conductivity of the complexes is around 3.24–8.51 $\Omega^{-1}\ cm^2\ mol^{-1}$ in ethanol (Table 1). This shows that all the complexes are non-electrolytes in ethanol [12]. The elemental analyses

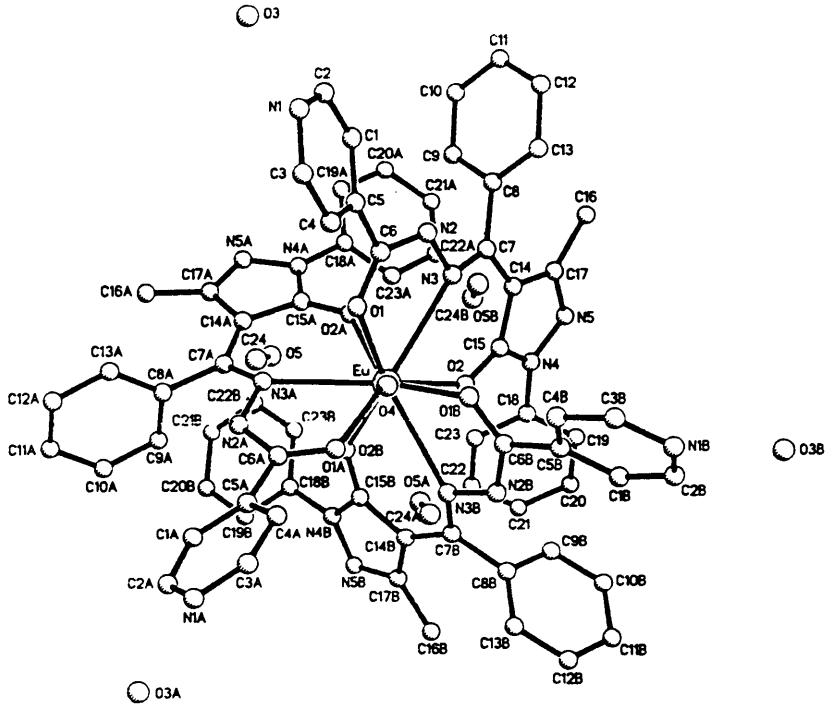

Fig. 2. Structure of the Eu complex.

(Table 1) show the formula of the complexes is $Ln(HL)_3{\cdot}3.5H_2O$ (Ln = La, Eu, Gd–Er), with three and a half H_2O for each complex confirmed by thermal analyses.

3.1. Description of the crystal structure

The crystal of the Eu complex is rhombohedral, space group R_3 with $Z = 6$, unit-cell dimensions $a =$ 19.1354(11), $b = 19.1354(11)$, $c = 33.918(4)$ Å, $\alpha = \beta =$ 90°, and $\gamma = 120°$, $V = 10756(2)$ Å^3, $D_c = 1.316$ g cm^{-3}. The complex in water is a yellow powder, but it is an orange yellow crystal after crystallizing in a mixed solvent of methanol and ethanol (1:2). The formula of the complex in the crystalloid form is $C_{69.5}H_{63}$-$EuN_{15}O_{10}$. It is different from the complex in powder form, which has been confirmed by elemental analyses. X-ray diffraction analyses show that there are not only three and a half lattice waters but also a half methanol molecule in each complex unit, $Eu(HL)_3{\cdot}3.5H_2O{\cdot}$ $0.5HOCH_3$ (Fig. 2), and six complex units in the unit cell. The coordination polyhedron is a tricapped trigonal prism configuration with the nine-coordinate atoms composed of three nitrogens and six oxygens from three ligand (HL–) (Fig. 3). The crystal is a highly symmetric rhomb with a principal axis, 3, of symmetry. Some important bond lengths and angles are given in Tables 2 and 3, respectively. The data for C6–O1 (1.231 Å) and C15–O2 (1.268 Å) bond lengths show that the carbonyl 6 is still a double bond, but carbonyl 15 inclines to a monobond in the complexes (Fig. 1). The C6–N2 is similar to a double bond, confirmed by C15–N4 (1.365 Å) > C6–N2 (1.325 Å) > C7–N3 (1.304 Å). All of these demonstrate that the oxygen (O2) of carbonyl 15 takes part in coordination by the enolic form, and its active hydrogen is replaced by Eu,

but those (O1) of the carbonyl 6 do not have the enolic form. The data of plane 1 (Table 4) indicate that the five-membered ring composed of Eu, O1, C6, N2 and N3 with the six-membered ring Eu, N3, O2, C7, C14 and C15 is coplanar, forming a large conjugation chelate ring.

3.2. Thermal analysis

Some data of thermal analyses are listed in Table 5. The DTA curves of the complexes have an endothermic peak between 86 and 90°C, the corresponding TG curves show that the weight loss in each complex is equal to three and a half water molecules. These results are in accordance with the compositions of the complexes determined by elemental analyses. Three exothermic peaks appear around 346–363, 458–478 and 628–701°C, respectively. Initial temperature of decomposition is greater than 346°C; this indicates that the thermal stability of the complexes is higher than that of the free ligand which decomposes at 278°C.

3.3. Ultraviolet spectra

UV spectral data of complexes are listed in Table 6. The free ligand exhibits a strong absorption band at 298 nm, and a shoulder peak at 286 nm. The complexes yield two new peaks at approximately 366 and 383 nm, respectively. The two absorption bands approach the region observed. This shows that there is a large conjugate system formed by enolization of the ligand in the complexes. Therefore, the complexes should be a chelate containing both a five-membered and a six-membered ring. This is a reason why the complexes exhibit high thermal stability.

3.4. Infrared spectra

The main stretching frequencies of the IR spectra of the ligand (H_2L) and its complexes are tabulated in Table 7. The aqueous ν(OH) for the complexes appears at 3350 cm^{-1}. $\nu(C_{(6)}{=}O)$ and $\nu(C_{(15)}{=}O)$ vibrations of the free ligand are at 1616 and 1560 cm^{-1}, respectively; these peaks for the complexes shift to 1602, 1434–1441 cm^{-1}. $\Delta\nu$ ($\nu_{ligand} - \nu_{complex}$) of carbonyls 6 and 15 is equal to 14, and 119–126 cm^{-1}. δ_{NNH} vibrations of the free ligand at 1532 cm^{-1} and its complexes at 1539–

Table 8
Test results of inhibitory tumor cells [a]

Complex	Tested cells	Dose (μg ml^{-1})	Effect	Result	Inhibitory rate (%)
$La(HL)_3{\cdot}3.5H_2O$	HCT-8	10, 1	>10	−	
	L1210	10, 1	<10	+	87.1, 32.4
$Eu(HL)_3{\cdot}3.5H_2O$	HCT-8	10, 1	<10	+	53.5, 0
	L1210	10, 1	<10	+	78.5, 12.5
$H_2L{\cdot}LaCl_3$	HCT-8	10, 1	>10	−	
	L1210	10, 1	>10	−	

[a] 'Effect' means that the tested complex, of dose less than 10 μg ml^{-1}, has an inhibitory effect for the tested cells; 'Result' is the result of 'Effects', + having an inhibitory effect, − no inhibitory effect; 'Inhibitory rate' is 100%(control group − test group)/control group.

1546 cm^{-1} show that the active hydrogen of the –NHN= group still exists in the complexes. The band at 456 cm^{-1} is assigned to ν(M–O). All of these demonstrate that the oxygens of carbonyl have formed a coordinate bond with the rare earth metal ions, one of which ($C_{(15)}$=O) is in the enolic form as confirmed above by the crystal structure analyses. The band at 1588 cm^{-1} for the free ligand is assigned to the ν(C=N) stretch; it shifts to 1571–1574 cm^{-1} for its complexes. The weak bands at 405–410 cm^{-1} are assigned to ν(M–N). This further confirms that the nitrogen of the imino-group bonds to rare earth metal ions. All of these data confirm the fact that there is a conjugate chelate ring formed by ligand enolization in the complexes. This is consistent with the results of the crystal structure of the Eu complex.

3.5. Antitumor activity

Test results of the complexes, $La(HL)_3{\cdot}3.5H_2O$ and $Eu(HL)_3{\cdot}3.5H_2O$, for hepatic carcinoma (HCT-8), and leukemia cells (L_{1210}) are summarized in Table 8. It is clear that both complexes can affect L_{1210} cells. The inhibitory rates of $La(HL)_3{\cdot}3.5H_2O$ and $Eu(HL)_3{\cdot}3.5H_2O$ for L_{1210} cells are 87.1% and 78.5% respectively, and that of the Eu complex for HCT-8 cells is 53.5%, but free ligand H_2L and $LaCl_3$ cannot affect L_{1210} and HCT-8 cells. This shows that the coordination improves the antitumor activity of the two complexes. The acute toxicity data of tested complexes are summarized in Table 9. LD_{50} values of $La(HL)_3{\cdot}3.5H_2O$ and $Eu(HL)_3{\cdot}3.5H_2O$ are 348.9 ± 32 mg kg^{-1} and 279.1 ± 31 mg kg^{-1}, respectively. The toxic

Table 9
Acute toxicity data of La and Eu complexes for mice

Number	Dose (mg kg^{-1})	Number of mice tested	Number of dead mice

POLYHEDRON

Redox responsive binuclear complexes using 5,6-dihydroxy-1,10-phenanthroline as a bridging ligand: synthesis, characterization and physicochemical studies

Atindra D. Shukla, Amitava Das *

Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, Gujarat, India

Received 21 June 2000; accepted 23 August 2000

Abstract

A set of new binuclear complexes has been synthesized and characterized using redox active bridging ligands (BL), 5,6-dihydroxy-9,10-phenanthroline ($dpcatH_2$) and $M(bipy)_2Cl_2$ (M is Ru(II) or Os(II))/$Ru(tpzea)Cl_2$ (tpzea is tris(*N*-pyrazolyl ethyl) amine) as the building blocks. For all binuclear complexes a large degree of stabilization of the semiquinone (sq) state for the $Ru(bpy)_2(dpsq)^+$ fragment has been observed. UV–Vis, electrochemical and spectroelectrochemical studies clearly show that the first two redox processes involve only the bridging ligand. Further experimental results show that auxiliary ligands coordinated to the metal center do not have any appreciable effect on the redox behavior of the bridging ligand. © 2000 Elsevier Science B.V. Keywords: Synthesis; Semiquinone; Ruthenium; Spectroelectrochemical studies; Redox

1. Introduction

The study of electronic interaction between two redox active metal centers with well defined structure, linked by a conjugated bridging ligand, has attracted much recent attention [1]. For multicomponent systems in which each component is a complex metal moiety, the bridging ligand (BL) plays a crucial role in successful design as it determines the separation, relative spatial arrangement of the metal core and the electronic interaction between the ends [2]. However, until now much attention has focused on the use of redox-innocent bridging ligands or linkers in which metal-based redox processes precede bridge-based. The use of non-innocent redox active bridging ligands offers the possibility to modulate the energy of the bridging ligand with a change in potential and thus to affect or manipulate the electronic coupling of the redox active metal cores that it links [3]. Metal complexes containing 'non-innocent' dioxolene ligands (member of catechol-semiquinone-quinone redox series) as one of the binding sites in a binucleating bridging ligand are important as its redox activity is retained even when coordinated to a metal core. Thus 5,6-dihydroxy-1,10-phenanthroline ($dpcatH_2$) is one of the most versatile bridging ligands in this regard [3–9] as it has pendant 1,10-phenanthroline and catechol as two chelating centers with well explored coordination chemistry of their respective mononuclear components. Also, the effect of an auxiliary ligand on redox processes involving the bridging ligand is relevant in the context of the tuning of the redox and magnetic properties of these binuclear complexes. Recently we have reported binuclear complexes derived from a bischelating ligand having 2,2′-bipyridyl (bpy) and catechol as the coordinating sites [8]. Having a much shorter and more planar structure, $dpcatH_2$ is expected to transmit better electronic interaction between the metal centers. In this paper we report the synthesis, characterization, physicochemical and spectroelectrochemical studies of homo and hetero binuclear complexes using $dpcatH_2$ as the bridging ligand. Also, both N–N bound and O–O bound monometallic complexes have been synthesized for comparison of the physicochemical properties with those of bimetallic species.

2. Experimental

Microanalyses (C, H, N) were performed using a Perkin–Elmer 4100 elemental analyzer. IR spectra were recorded as KBr pellets using a Perkin–Elmer spectrum GX 2000 spectrometer. Electronic spectra were recorded on a Shimadzu UV-3101 PC spectrophotometer. ^{1}H NMR spectra were recorded on a Bruker 200 MHz FT NMR (model Avance-DPX 200). Fast-atom bombardment measurement was carried out on a VG-ZAB instruments using 3-nitrobenzyl alcohol as matrix. EPR spectra were recorded at room temperature and at 77 K on a Bruker ESP-300 spectrometer. Electrochemical experiments were performed using a CH 660A (USA) electrochemical instrument; a conventional three-electrode cell assembly was used. Saturated Ag/AgCl as reference and platinum as working electrodes were used for this purpose. Ferrocene was added at the end of each experiment as internal standard; all potentials are quoted versus the ferrocene/ferrocenium (Fc/Fc^+) couple. Spectra of the electro-reduced/oxidized species were recorded either by a Shimadzu UV-3101 PC model under dinitrogen atmosphere or in situ with a fiber optic deep probe attached to an Ocean Optics 2000 CCD spectrophotometer.

$Ru(bpy)_2Cl_2\cdot 2H_2O$ [10], $Os(bpy)_2Cl_2$ [11], $[\{Ru(bpy)_2\}_2(bpesq)]$ [8], $Ru(DMSO)_4Cl_2$ [12], tris(*N*-pyrazolyl ethyl) amine (tpzea) [13], 5,6-dihydroxy-1,10-phenanthroline ($dpcatH_2$) [14] and ferrocenium hexafluorophosphate ($FcPF_6$) [15] were prepared following known methods. $[Bu_4N]PF_6$ was used as background electrolyte for electrochemical studies. Acetonitrile, used as solvent in electrochemical analysis, was dried and distilled before use. All reactions were performed under argon atmosphere.

2.1. Synthesis

2.1.1. *[Ru(2,2′-bipy)$_2$dpcatH$_2$](PF$_6$)$_2$ (I)*

$Ru(bpy)_2Cl_2\cdot 2H_2O$ (200 mg, 0.385 mmol) and 97.5 mg (0.46 mmol) of $dpcatH_2$ were refluxed in 50 cm^3 ethanol–water mixture (1:1; v/v) for 7 h and then concentrated under vacuo to $\sim$10 cm^3. To this, a saturated aqueous solution of KPF_6 was added and kept refrigerated overnight. A dark red precipitate was filtered off, air dried and the crude product was purified by column chromatography using silica column and CH_3CN-saturated aqueous solution of NH_4PF_6 (98:2%, v/v) as eluant. The first major fraction was collected and concentrated in vacuo ($\sim$5 cm^3). Excess NH_4PF_6 was removed by solvent extraction in the aqueous layer. The desired compound was collected in the CH_2Cl_2 layer and dried in vacuo. Yield: 155 mg, 44%. *Anal.* Found: C, 42.0; H, 2.6; N, 9.1. Calc. for $RuC_{32}H_{24}N_6O_2P_2F_{12}$: C, 41.97; H, 2.62; N, 9.18%. FAB MS: m/z 913 (M^+, $\sim$2%), 768 ($M^+ - PF_6$, $>$5%), 623 ($M^+ - 2PF^6$, 30%). IR (KBr, cm^{-1}): 3445 (br, –OH), 1610, 1580 (C=C and C=N), 835 (PF_6^-). ^{1}H NMR (200 MHz, CD_3CN): δ 8.62–8.59 (6H, m), 8.13 (4H, t, 5.9Hz), 8.08 (2H, d, 5.6Hz), 7.98 (4H, d, 5.6Hz), 7.58 (2H, t, 5.6Hz), 7.51 (4H, t, 5.9Hz).

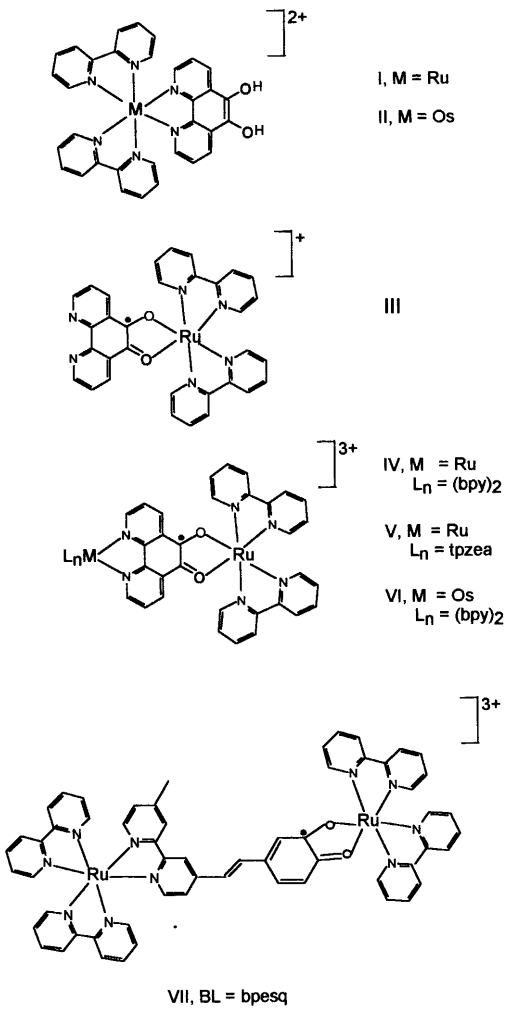
2.1.2. *[Os(bpy)$_2$dpcatH$_2$](PF$_6$)$_2$ (II)*

$Os(2,2'\text{-bipy})_2Cl_2\cdot 2H_2O$ (100 mg, 0.164 mmol), and $dpcatH_2$ (47 mg, 0.164 mmol) were refluxed in 50 cm^3 ethanol–water (1:1, v/v) for 24 h and then concentrated under vacuo to $\sim$10 cm^3. The desired complex was precipitated by adding saturated aqueous solution of KPF_6 and filtered off. This was purified following a method similar to that for complex **I**. The first orange–brown fraction was collected and dried. Excess of NH_4PF_6 was removed in the aqueous layer while the desired complex was partitioned in the CH_2Cl_2 layer and dried in vacuo. Yield: 62 mg, 38%. *Anal.* Found: C, 39.0; H, 2.4; N, 8.3. Calc. for $OsC_{32}H_{24}N_6O_2P_2F_{12}$: C, 38.25; H, 2.39; N, 8.4%. FAB MS: m/z 1004 (M^+, $\sim$3%), 859 ($M^+ - PF_6$, $\sim$5%), 714 ($M^+ - 2PF_6$, 25%). IR (KBr, cm^{-1}): 3449 (br. –OH), 1604, 1585 (C=C and C=N), 840 (PF_6^-). ^{1}H NMR (200 MHz, CD_3CN): δ 8.45–8.37 (6H, m), 8.1 (4H, m), 8.02 (2H, d, 5.4Hz), 7.89 (4H, d, 5.4Hz), 7.53–7.49 (6H, m).

2.1.3. *[Ru(bpy)$_2$(dpsq)](PF$_6$) (III)*

$Ru(bpy)_2Cl_2\cdot 2H_2O$(200 mg, 0.385 mmol), $dpcatH_2$ (110 mg, 0.385 mmol) and KOH (44 mg, 0.78 mmol) were refluxed in ethanol (50 cm^3) for 6 h. To this resulting mixture $FcPF_6$ (0.127 mg, 0.385 mmol) was added and stirred at room temperature for 30 min. Then the desired compound was precipitated after reducing the volume to $\sim$5 cm^3 and adding aqueous KPF_6 solution. The purification procedure is similar to that for complex **I**. Yield: 145 mg, 49%. *Anal.* Found: C, 49.4; H, 3.0; N, 10.6%. Calc. for $RuC_{32}H_{22}N_6O_2PF_6$: C, 50.0; H, 2.86; N, 10.94%. FAB MS: m/z 768 (M^+, $\sim$2%), 623 ($M^+ - PF_6$, $<$10%). IR (KBr, cm^{-1}): 1612, 1590 (C=C, C=N), 1446 (semiquinone stretching), 835 (PF_6^-).

2.1.4. *[{Ru(bpy)$_2$}$_2$dpsq](PF$_6$)$_2$ (IV)*



Method 1: $Ru(bpy)_2Cl_2\cdot 2H_2O$ (200 mg, 0.385 mmol) and $dpcatH_2$ (40.8 mg, 0.192 mmol) were refluxed under argon in 50 cm^3 water–ethanol mixture (1:1, v/v) for 7 h. To this, $FcPF_6$ (127 mg, 0.385 mmol) was added and stirred at room temperature for 30 min. Ethanol was removed under vacuo, aqueous KPF_6 solution was added and kept refrigerated overnight. A dark red color precipitate appeared which was filtered and the desired complex was purified following a procedure similar to that for complex **I**. Yield: 250 mg, 44%.

Method 2: Complex **I** (100 mg, 0.11 mmol), $Ru(bpy)_2Cl_2\cdot 2H_2O$ (52 mg, 0.1 mmol) and KOH (11.2 mg, 0.2 mmol) were refluxed in C_2H_5OH–CH_3CN mix-

ture (10:1, v/v) under argon for 3 h. Following workup the procedure is similar to that of method 1. Yield: 180 mg, 74%. *Anal.* Found: C, 42.2; H, 2.6; N, 9.6%. Calc. for $Ru_2C_{52}H_{38}N_{10}O_2P_3F_{18}$: C, 42.42; H, 2.58; N, 9.52%. FAB MS: m/z 1326 ($M^+ - PF_6$, $<2\%$), 1181 ($M^+ - 2PF_6$, $\sim 5\%$), 1036 ($M^+ - 3PF_6$, $\sim 15\%$). IR (KBr, cm^{-1}): 1608, 1585 (C=C and C=N), 1444 (semiquinone streaching), 840 (PF_6^-).

2.1.5. *[Ru(2,2′-bipy)$_2$dpsqRu(tpzea)](PF$_6$)$_3$ (V)*

$Ru(DMSO)_4Cl_2$ (168 mg, 0.35 mmol) was added to a methanolic solution (~ 30 cm^3) of tpzea (100 mg, 0.33 mmol) and was allowed to stir at 50°C for 30 min. The color of the solution changes from pale yellow to bright orange. To this resulting reaction mixture, KOH (48 mg, 0.68 mmol) and complex **I** (315 mg, 0.34 mmol) were added and refluxed for 3 h. The color of the solution changes to reddish brown. The volume of the solution was reduced to ~ 15 cm^3, aqueous KPF_6 was added and kept refrigerated overnight. The precipitate was filtered off, dried and purified by column chromatography following the method adopted for complex **IV**. Yield: 175 mg, 32%. *Anal.* Found: C, 39.3; H, 3.0; N, 12.3%. Calc. for $Ru_2C_{47}H_{43}N_{13}P_2O_3F_{18}$: C, 38.68; H, 2.95; N, 12.48%. FAB mass: m/z 1168 ($M^+ - 2PF_6$, $\sim 5\%$), 1023 ($M^+ - 3PF_6$, 15%). IR (KBr, cm^{-1}): 1607, 1600 (C=C, C=N), 1442 (semiquinone stretching), 840 (PF_6).

Scheme 1.

2.1.6. *[Os(2,2′-bipy)$_2$dpsqRu(2,2′-bipy)$_2$](PF$_6$)$_3$ (VI)*

$Os(bpy)_2Cl_2$ (60 mg, 0.104 mmol) and complex **III** (85 mg, 0.11 mmol) were refluxed in ethanol–water 1:1 (50 cm^3) for 24 h. The volume of reaction mixture was reduced to about 10 cm^3 and the desired complex was precipitated by adding excess aqueous KPF_6 solution. Crude product was filtered, air dried and purified by column chromatography in a similar fashion adopted for complex **I**, and the second major brown fraction was collected and dried. Excess NH_4PF_6 was removed by solvent extraction in the aqueous layer, while pure compound was collected in the CH_2Cl_2 layer and dried in vacuo. Yield: 30 mg, 20%. *Anal.* Found: C, 39.4; H, 2.4; N, 9.0%. Calc. for $OsRuC_{52}H_{38}N_{10}O_2P_3F_{18}$: C, 40.0; H, 2.43; N, 8.97%. FAB mass: m/z 1415 ($M^+ - PF_6$, $\sim 1\%$), 1270 ($M^+ - 2PF_6$, 3%), 1125 ($M^+ - 3PF_6$, $\sim 8\%$). IR (KBr, cm^{-1}): 1610, 1597 (–C=C, –C=N), 1440 (semiquinone stretching), 843 (PF_6).

3. Results and discussion

3.1. Synthesis and characterization

Proposed formulations for all the complexes (Scheme 1) were confirmed by elemental analysis, FAB mass analysis, UV–Vis, IR and ^1H NMR or ESR spectroscopy. Complexes **I** and **II** were prepared by reaction of $dpcatH_2$ with $M(bpy)_2Cl_2$ (M is Ru(II) for **I** or Os(II) for **II**) and were purified by column chromatography. In the absence of externally added base, $dpcatH_2$ preferentially coordinates to Ru(II) and Os(II) centers via N–N binding site of the phen functionality. However, in the presence of KOH, $dpcatH_2$ exists in solution as $dpcat^{2-}$ and reacts with $Ru(bpy)_2Cl_2$ via dioxolene binding site. Isolated complex **III** is found to be paramagnetic and is in the semiquinone (dpsq) oxidation state (vide infra). $Ru(bpy)_2(dpcat)$ complex forms initially, and partially converts to the $Ru(bpy)_2(dpsq)^+$ fragment during aerobic work-up. To ensure the complete conversion to the semiquinone form, crude reaction mixture was treated with 1 equiv. of $FcPF_6$ at room temperature for 30 min and single product was isolated. Complex **III**, having a pendant N–N donor phen group available for further coordination, was used as a precursor for synthesis of the complexes **IV**, **V** and **VI**. For synthesis of complex **V**, $Ru(tpzea)Cl_2$ was generated in situ as characterization of this complex was difficult for its extreme hygroscopic nature.

Table 2
Effect of solvent on λ_{max} (nm) for $Ru(\pi) \rightarrow sq(\pi^*)$ MLCT transition

Complex	CH_2Cl_2	C_2H_5OH	$HCON(CH_3)_2$
III	915	926	933
IV	929	943	949
V	934	982	989

3.2. UV–Vis spectral studies

Details of the electronic spectra of these complexes are presented in Table 1. Complexes **I** and **II** have spectra similar to those reported for $Ru(bpy)_2(phen)^{2+}$ and $Os(bpy)_2(phen)^{2+}$ respectively [16]. Complex **III** shows a more intense and red shifted MLCT band than that reported for $Ru(bpy)_2(sq)^{+}$ species ($\lambda_{max} = 890$ nm and $\varepsilon = 6.4 \times 10^3$ dm^3 mol^{-1}, sq is the semiquinone form of 1,2-dihydroxybenzene [17,18]. The observed red shift is due to the lower energy of the orbital based on the semiquinone fragment in complex **III** as compared to $Ru(bpy)_2(sq)^{+}$ species; this can be explained on the basis of extended conjugation in the bridging ligand, dpsq. This is further supported by the higher red shift observed for $Ru(d\pi) \rightarrow dpsq(\pi^*)$ charge transfer in complex **VII** for more extended delocalization in $bpecatH_2$ [8]. Higher ε value and transitional dipole moment for the $Ru(d\pi) \rightarrow dpsq(\pi^*)$ transition is understandable, as the semiquinone fragment in complex **III** is more electronegative than that in $Ru(bpy)_2(sq)^{+}$ [17–20]. The spectrum for complex **IV** is very similar to the combined spectra for complexes **I** and **III**. Higher values for λ_{max} and ε for the $Ru(d\pi) \rightarrow dpsq(\pi^*)$ transition (Table 1) are due to the coordination of the pendant N–N donor phen functionality to the Ru(II) center of the cationic $Ru(bpy)_2^{2+}$ fragment. The spectrum for complex **VI** shows bands ascribable to each of the two chromophores, $Ru(bpy)_2(dpsq)$ and $Os(bpy)_2(phen)$, with appreciable blue shift (840 nm) for the $Ru(d\pi) \rightarrow dpsq(\pi^*)$ transition (Table 1). This can only be explained if one considers that greater extension of the metal d-orbitals for osmium can enhance the metal–ligand back bonding and better energy match with the dpsq fragment compared to the Ru counterpart in complex **IV**. However, the spectrum in this region is complicated by an absorption band (~ 690 nm) attributed to $Os(d\pi)bpy(^3\pi^*)$ singlet to triplet transition [21]. Higher full width at half maximum (fwhm) values for complexes **IV** and **V** compared to **III** are due to the large Franck–Condon barrier to the MLCT transition. For the valence trapped model the $Ru(d\pi) \rightarrow sq(\pi^*)$ transition results in a charge separated state consisting of partially Ru(III) and dpcat, which is expected to be associated with appreciable nuclear reorganization and accounts for the higher fwhm value. Moreover, the dependence of λ_{max} of the $Ru(d\pi) \rightarrow sq(\pi^*)$ transition for complexes **III**, **IV** and **V** on solvent polarity (Table 2) is also indicative of the solvent stabilization of a charge separated species. As predicted by earlier work for a similar feature in related complexes to a transition from an $Ru(d\pi)$ to semiquinone based singly occupied molecular orbital (SOMO), we attribute this transition as $Ru(d\pi) \rightarrow sq(SOMO\ \pi^*)$ transition [3a,8,22].

3.3. Electrochemical studies

All complexes were studied by cyclic and square wave voltammetry in MeCN and results are summarized in Table 3 (all potentials are quoted versus the Fc/Fc^{+} couple). Both complexes **I** and **II** show anticipated redox processes in addition to an irreversible oxidation process. Peak potential for this irreversible process ($\sim +0.45$ V) is determined by square wave voltammogram. 1,2-dihydroxy benzene is known to undergo oxidation to form quinone, which involves loss of protons and is expected to be irreversible in aprotic solvents, e.g. MeCN [23]. For complex **III**, there is a quasireversible Ru(II)/(III) couple (1.10 V) along with two ligand centered reductions at extreme negative potential (-1.90 and -2.08 V) for two coordinated bpy groups. In addition to these, two reversible redox processes are present. These can be assigned to two dioxolene-based processes, dpcat/dpsq couple at -0.40 V and dpsq/dpq couple at 0.27 V. For complex **IV**, in

Table 3
Electrochemical data for complexes [a]

Complex	Dioxolene-based redox process	Ru(II/III) couple	Os(II/III) couple	bpy-Based reduction
I	0.7 [b]	1.02 (90)		−1.90, −2.08
II	0.68 [b]		0.95 (100)	−1.88, −2.05
III	0.27, −0.40 (80)	1.10 (90)		−1.87, −2.07
IV	0.26 (75), −0.48 (80)	1.15 (130)		−1.8, −1.92, −2.1
V	0.27 (90), −0.42 (100)	0.73 (qr), 1.12 (85)		−1.76, −2.07
VI	0.13 (95), −0.55 (85)	1.14 (95)	1.00 (110)	−1.83, −1.9, −1.98, −2.15

[a] Recorded in CH_3CN at a scan rate of 100 mV s^{-1}; potentials are in volts versus the Fc/Fc^+ couple. For nearly reversible waves, peak–peak separation (mV) values are given in parentheses.
[b] Not reversible, qr quasireversible.

addition to the phen/bpy-based reductions at extreme negative potentials, three reversible one-electron processes are observed; two are dioxolene based (dpcat/dpsq redox couple at −0.48 V and dpsq/dpq redox couple at 0.26 V) and the third is in fact two overlapping seemingly reversible Ru(II)/(III) couples of $Ru(bpy)_2(dpphen)^{2+}$ and $Ru(bpy)_2(dpsq)^+$ fragments (Fig. 1). Neither cyclic nor square wave voltammetry could clearly distinguish these two processes. The presence of a cationic $Ru(bpy)_2(phen)^{2+}$ core makes dpsq → dpcat reduction easier (−0.69 V for $Ru(bpy)_2(sq)^+$ [9,17,18]) whereas dpsq → dpq oxidation (+0.16 V for $Ru(bpy)_2(sq)^+$ [9,17,18]) is difficult. Behavior of complex **VI** is very similar to that of complex **IV**; a reversible Os(II)/(III) couple appears at 1.0 V and Ru(II)/(III) couples of $Ru(bpy)_2(sq)$ and Ru(tpzea)phen fragments appear at 1.12 and 0.73 V respectively. The redox process dpsq → dpcat has become difficult by 70 mV, while the dpsq → dpq process has become easier by 130 mV. This agrees well with the UV–Vis spectral observation (vide supra) and is concomitant with the fact that closer energy matching of the π^*_{BL} and Os(dπ) orbitals results a stronger π-interaction and leads to a more efficient electronic drain on the bridging ligand and thereby facilitates the oxidation processes, dpsq → dpq. Further it is also possible to quantify the extent of stabilization of the dpsq state by evaluating the conproportionation constant, K_c ($\log K_c = \Delta E°/0.059$), where $\Delta E°$ is the difference between the two well resolved, reversible one-electron steps associated with BL for the ligand based process. Thus, K_c(sq) values (2sq ⇄ q + Hq) calculated for complexes **III**–**VI** are in the order of $\sim 10^{10}$, emphasizing the large degree of stabilization of the semiquinone state.

3.4. Spectroelectrochemical studies

To obtain further information about the spectral changes associated with the change in the redox states of the binding ligand, spectroelectrochemical studies were carried out. UV–Vis data of complexes **III**–**VII** for various redox states of the BL are summarized in Table 3 and reveal that these complexes show rich spectral responses to the variation in applied potential. Fig. 2A shows the changes in spectral features of complex **III** when the bridging ligand is selectively reduced from dpsq to the dpcat oxidation state by bulk electrolysis at −0.4 V (versus Ag/AgCl); the MLCT band for Ru(dπ) → sq(π*) transition at 929 nm decreases while increases in absorbance at 650, 545 and 440 nm were observed. Shoulders at ∼560 and 650 nm are assigned to intraligand dpcat(π) → dpphen(π*) and interligand dpcat(π) → bpy(π*) charge transfer transitions. Fig. 2B shows successive changes in spectral features on selective oxidation of the binding mode from semiquinone to quinone species by bulk electrolysis at 0.8 V (versus Ag/AgCl); absorbance at 938 nm is replaced by a much weaker and broader band λ_{max} at ∼1000 nm, attributed to the Ru(dπ) → q(π*) MLCT process. The observed red shift is presumably due to better π-acidic nature of the quinone ligand. Fig. 2C

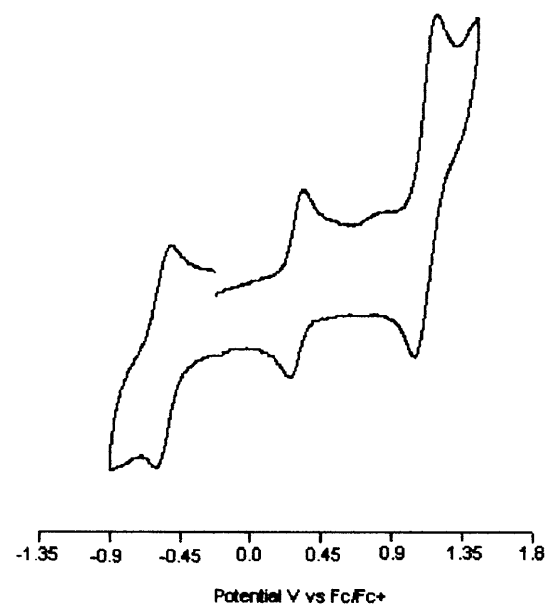

Fig. 1. Cyclic voltammogram of complex **IV** recorded at 500 mV s^{-1} in CH_3CN.

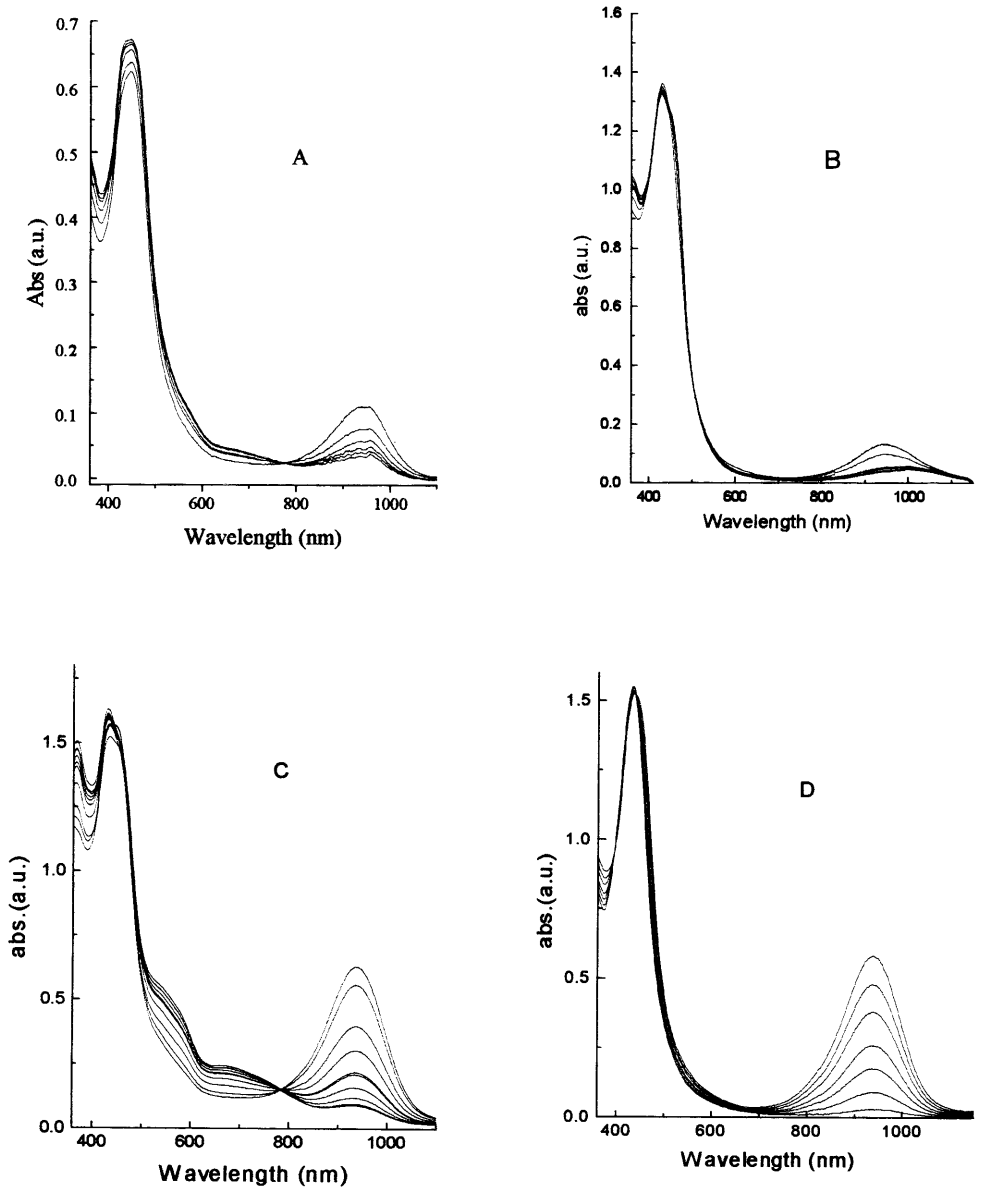

Fig. 2. UV–Vis spectra recorded during bulk electrolysis: (a) complex **III** selectively reduced at −0.40 V (versus Ag/AgCl standard electrode), (b) complex **III** selectively oxidized at 0.8 V (versus Ag/AgCl standard electrode), (c) complex **IV** selectively reduced at −0.40 V (versus Ag/AgCl standard electrode), (d) complex **IV** selectively oxidized at 0.8 V (versus Ag/AgCl standard electrode).

shows the changes in spectral features for complex **IV**, similar to that for **III**, except better resolved shoulders appear at 550 and 660 nm for cat(π) → bpy/phen(π^*) transitions respectively. The observed red shift of ~10 nm is due to coordination of a cationic Ru(II) species at the remote side of BL. This is further supported by the fact that on selective reduction of the dpsq → dpcat state in complex **VII**, the same intraligand charge transfer band appears at much lower energy (595 nm) as extended conjugation in BL is responsible for lowering the energy of the substituted bpy ligand which is coordinated to the remote $Ru(bpy)_2$ core, whereas the shoulder at 662 nm for interligand charge transfer (bpecat(π) → bpy(π^*)) remains unaffected with the change in BL. This further reveals that a change either in conjugation or coordination at the remote side of BL does not affect the energy for the dpcat(π) → dpbpy(π^*) transition. For selective oxidation of the dpsq to dpq binding mode, the spectral change recorded is almost identical to that observed for complex **III** (Fig. 2D). Spectroelectrochemical behavior of complex **V** is almost identical to that of complex **III**. This can be explained if one considers that tpzea, being a much weaker π-acceptor ligand compared to bpy in complex **IV**, does not have any appreciable MLCT (Ru($d\pi$) → tpzea(π^*)) transition and thereby cannot influence the electron density of the BL and the spectral behavior of the complex. However, unambiguous assignment of the spectroelec-

trochemical response of complex **VI** is difficult due to the number of overlapping absorption bands at the region of the $Ru(d\pi) \rightarrow BL(\pi^*)$ transition.

3.5. ESR spectroscopy

Complexes **III**–**VI** are paramagnetic due to the semiquinone coordinating mode and were studied by ESR spectroscopy. All these complexes show a room temperature spectrum consisting of a broadened free radical signal centered at $g \approx 2.003$ in acetonitrile. At 77 K (in a frozen CH_3CN–toluene glass), spectra recorded do not show any hyperfine structure and are apparently an axial spectrum with $g_\perp \approx 1.98$ and $g_\parallel \approx 2.050$. The difference between $g_\perp$ and $g_\parallel$ is smaller than that observed for other Ru(II)–sq complexes [17,18]; but the apparent axial symmetry suggests that the MO containing the unpaired electron for both complexes is partially localized on the metal and is consistent with the electronic spectral studies.

4. Supplementary material

Supplementary information (1 page) concerning the spectroscopic data is available from the authors (A.D.) on request.

[20] Transitional dipole strength (D) is related to the oscillator strength (f) (K.A. Gscheidner Jr., L. Eyring, Handbook of Physics and Chemistry of Rare Earths, Elsevier, 1998) by $D = (2.127 \times 10^{-30} f)/\nu_o$ [ν_o is the wavenumber for $Ru(d\pi) \rightarrow$ dpsq(π^*), MLCT transition] and f is related to the fwhm $\nu_{1/2}$ by $f = 4.60 \times 10^{-9}\ \varepsilon_{max}\ \nu_{1/2}$ (P. Chen, T.J. Meyer, Chem. Rev. 98 (1998) 1439). Thus, D values for complexes **III**, **IV**, and **V** are found to be 9.68×10^{-37}, 1.42×10^{-35} and 1.69×10^{-36} respectively. Evaluation of f and D for the same transition of complex **VI** was difficult due to a number of overlapping absorption bands in that region.

Oxovanadium(IV) complexes of quinic acid. Synthesis, characterization and potentiometric study

Y. Allegretti, E.G. Ferrer, A.C. González Baró, P.A.M. Williams *

Centro de Química Inorgánica (CEQUINOR), Facultad de Ciencias Exactas, Universidad Nacional de La Plata, C. Correo 962, 1900 La Plata, Argentina

Received 27 May 2000; accepted 21 August 2000

Abstract

The synthesis, characterization and speciation of the VO^{2+}–quinic acid system is described. Three new solid complexes were obtained: $[VO(quin)(H_2O)_3]$ (**I**), $Na_4[VO(quin)_2SO_4]\cdot 4H_2O$ (**II**) and $Na_6[VO(quin)_2SO_4]\cdot 4H_2O$ (**III**), at pH 3.5, 6 and 12, respectively. They were characterized by elemental analysis, diffuse reflectance, FTIR and Raman spectroscopies, and thermal behavior. Their stability constants were determined at 298 K and at a constant ionic strength of 0.150 M using potentiometric methods. In aqueous solution three different complexes appeared as the main species at the pH values indicated above as shown in the species distribution curves. Up to pH 8 the system behaves as a 2-hydroxyacid/metal-like compound, while at higher pH further deprotonations were observed, which resulted in the formation of sugar–VO^{2+}-like complexes. UV–Vis spectra were also reported. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

Vanadium is thought to be a trace metal in most higher animals and it is known to be essential to some organisms, including tunicates and mushrooms. The best evidence for a biological role of this element comes from bacteria and plants (vanadium containing nitrogenase and haloperoxidases) [1]. Vanadium has the exceptional ability to interact with biomolecules in both cationic and anionic forms and in its several oxidation states. Among its biological functions, many important therapeutic effects have been described, including hormonal, cardiovascular, anticarcinogenic and insulin mimetic activities [2]. The coordination chemistry and reactivity of vanadium plays a predominant role. Because of the physiological relevance of this metal, its complexation behavior with organic ligands is of great interest for a better understanding of the interactions with biomolecules.

Quinic acid (quin), Fig. 1 is a precursor of shikimic acid and it can be used as a carbon source when incorporated in the synthesis pathway. Shikimic acid is involved in the biosynthesis of many natural products which contain an aromatic ring, including essential amino acids and folic acid, in microorganisms and plants [3]. It is also used as raw material, or building block, in the synthesis of new pharmaceutical preparations that are still under clinical trials phase. Quin is a naturally occurring hydroxy compound, with antimicrobial effects [4]. It is involved in plant metabolism as a metal carrier because of its polyglycolic nature. It also participates in the photosynthetic process, where the presence of metal ions, in the form of coordination compounds, modifies the effect of the ligand itself [5]. The ester of quinic acid with caffeic acid (chlorogenic

acid) is the fruit's first line of defense against fungal invasion. It occurs widely in fruits other than grapes.

The oxovanadium(IV)–vanadyl cation interacts with sugar molecules in the presence of extra substituents (e.g. carboxylate) that anchor the VO^{2+} at low pH values in solution [6–9]. Once bonded to the metal, the ligand can deprotonate the OH groups and coordinate through these positions. Only sugars containing *cis* OH groups can adopt the mentioned chelating behavior. The polyhydroxy-substituted ring of quin has also typical characteristics of a sugar molecule. The interest in the study of its interaction with vanadyl(IV) arises from the several functionals available for binding: both 2-hydroxy acid and deprotonated *cis* diol groups can coordinate the metal center. There is a little information about the crystal structure of metal complexes with quin [10] and only few reports related to vanadium [11]. In the present work, three VO^{2+} quin complexes were precipitated from solutions at different pH values. The solids were characterized by IR and Raman spectroscopies and thermal analysis. The electronic spectra of solutions were analyzed and the species distribution diagram was obtained by potentiometric titrations.

2. Experimental

2.1. Reagents and instrumentation

All chemicals were of analytical grade and were used without further purification. Quinic acid, $VOSO_4 \cdot 5H_2O$ and $VOCl_2$ (50% aqueous solution) were purchased from Sigma, Merck and Carlo Erba, respectively.

IR spectra of powdered samples were measured with a Bruker IFS 66 FTIR-spectrophotometer from 4000 to 400 cm^{-1} in the form of pressed KBr pellets.

Raman spectra were obtained with a Spex-Ramalog double monochromator spectrometer, using the 514.5 nm line of an argon ion laser for excitation. The rotating disk technique was used, in order to avoid burning of the compound by the laser light.

Electronic absorption spectra were recorded on a Hewlett–Packard 8453 diode-array spectrophotometer, using 1 cm quartz cells. Diffuse reflectance spectra were performed with a Shimadzu UV-300 instrument, using MgO as an internal standard. Thermogravimetric (TG) and differential thermal analysis (DTA) were performed on a Shimadzu system (models TG-50 and DTA-50, respectively), working in an oxygen flow (60 ml min^{-1}) and at a heating rate of 10°C min^{-1}. Sample quantities ranged between 10 and 20 mg. Al_2O_3 was used as a DTA standard. Vanadium contents were determined by the tungsto-phosphovanadic method [12] and sodium by flame photometry. C, H and S were determined using Carlo Erba EA 1108 equipment.

2.2. Potentiometric titrations

The EMF measurements were determined with a Schott Gerate TS165 pH meter and the added volumes were measured using a Techware (Sigma) Digitrate (25 ml).

$VOSO_4 \cdot 5H_2O$ was used without further purification and dried at 60°C until constant weight. The 'formula weight' was re-calculated ($VOSO_4 \cdot 4.84H_2O$; 250.12) on the basis of a thermogravimetric analysis, before preparing the solutions. NaCl was dried until constant weight and stored in a desiccator. All solutions were made in freshly boiled tridistilled water cooled under a constant flow of nitrogen. The solutions were freshly prepared prior to their use. Diluted solutions of HCl (Merck) were standardized against TRISMA-base (hydroxymethyl aminomethane). Diluted NaOH solutions were prepared from a saturated NaOH solution and standardized against the HCl. In order to assess the degree of carbonate contamination, the method of Gran [13] was used. Cell compartments were kept at 25 ± 0.1°C with circulating water from a thermostated bath. The ionic strength was fitted at 0.150 M with NaCl in the solutions. The glass electrode was calibrated separately in a solution with known $[H^+]$ before and after each titration.

In a first step, ligand solutions were titrated with standard NaOH, in the absence of metal, to determine the pK_a value. Further, titrations of the vanadium/ligand solution were performed in order to establish the equilibria in the H^+/quin/VO^{2+} system.

The formation constants denoted β_{pqr} correspond to the general notation:

$$pM^{2+} + qL^{2-} + rH^+ \leftrightarrow (M^{2+})_p(L^{2-})_q(H^+)_r$$

A value of $pK_w = 13.76$ (corresponding to $\log \beta_{00\text{-}1} = -13.76$) was assumed for the experimental conditions ($T = 298$ K, $I = 150$ mM).

2.3. Preparative

The solid complexes were prepared mixing 1 mmol of $VOSO_4 \cdot 5H_2O$ with 2 mmol of quinic acid, under nitrogen atmosphere.

2.3.1. Compound $[VO(quin)(H_2O)_3]$ (I)

A mixture of 15 ml of methanol in 5 ml of water was used as the solvent. The solution was cooled with an ice bath and the pH was adjusted with $NaOCH_3$ to 3.5. After 15 min of stirring a light blue precipitated was formed. The solid was filtered under vacuum, washed with cooled methanol and dried over $CaCl_2$. Yield: 81%. *Anal.* Calc.. for $C_7H_{16}O_{10}V$: C, 27.00; H, 5.14; V, 16.40. Found: C, 27.24; H, 4.90; V, 16.75%.

2.3.2. Compound $Na_4[VO(quin)_2SO_4]\cdot 4H_2O$ (II)

The reactants were added to 5 ml of water. The pH of the solution was fitted to a final value of 6 with solid $NaHCO_3$. The excess of bicarbonate was eliminated by filtration. The addition of absolute ethanol to the resulting solution produced a violet precipitate, which was filtered, washed with absolute ethanol and dried in an oven at 60°C. Yield: 75%. *Anal.* Calc. for $C_{14}H_{28}Na_4O_{21}VS$: C, 23.76; H, 3.96; Na, 13.01; S, 4.53; V, 7.21. Found: C, 24.00; H, 3.85; Na, 13.5; S, 4.30; V, 7.55%.

2.3.3. Compound $Na_6[VO(quin)_2SO_4]\cdot 4H_2O$ (III)

Quinic acid and vanadyl sulfate were dissolved in 5 ml of water. Solid NaOH was added until a final pH value of 12 was reached. Addition of excess absolute ethanol produced the precipitation of a green solid complex. The microcrystalline powder was filtered, washed with absolute ethanol and dried at 60°C. Yield: 53%. *Anal.* Calc. for $C_{14}H_{26}Na_6O_{21}VS$: C, 22.37; H, 3.46; Na, 18.38; S, 4.26; V, 6.79. Found: C, 22.45; H, 3.44; Na, 18.82; S, 4.53; V, 7.03%.

3. Results and discussion

3.1. UV–Vis spectra

At pH 3.5 three different components in solution exist simultaneously. The majority species is VO(quin) (63.8%), as detected by potentiometric titrations (see below). Free VO^{2+} is present at 17.8% and $VO(quin)_2$ at 15.5%. The subtraction of the bands corresponding to the two latter species in their respective percentages gave the electronic spectrum of VO(quin) with bands at: 568 nm (9.05 M^{-1} cm^{-1}) and 790 nm (30.06 M^{-1} cm^{-1}). The typical electronic spectrum of $[VO(H_2O)_5]^{2+}$ consists of three bands: $b_2 \rightarrow e$, $b_2 \rightarrow b_1$ and $b_2 \rightarrow a_1$ (generally obscured by overlapping with a charge transfer band), corresponding to a C_{4v} geometry [14]. When carboxylate coordinates to vanadyl(IV) the $b_2 \rightarrow e$ and the $b_2 \rightarrow b_1$ bands shifts to the red and to the blue, respectively, due to the stronger ligand crystal field [15–22].

The spectrum of the violet single species present at pH 6 show bands at 415 nm (21.6 M^{-1} cm^{-1}), 530 nm (22.60 M^{-1} cm^{-1}), 615 nm (18.00 M^{-1} cm^{-1}) and 780 nm (14.40 M^{-1} cm^{-1}). These four bands are typical of 2-hydroxyacids coordinated to vanadyl(IV) cation, forming chelate complexes with two ligand molecules coordinating the metal ion through the carboxylate and deprotonated hydroxyl groups and are indicative of the predominance of the *trans* isomer in solution [6,10].

At pH 12 the typical three-band pattern corresponding to the interaction of VO^{2+} with sugars is observed [7,8,23]. The new bands are located at 422 nm (18.60 M^{-1} cm^{-1}), 542 nm (19.20 M^{-1} cm^{-1}) and 664 nm (16.00 M^{-1} cm^{-1}). The considerable variation in the UV–Vis spectrum is in accordance with the variation on the donor set involved in the VO^{2+} coordination When increasing the pH of the solution consecutive proton dissociation of the hydroxyl groups of the coordinated ligands takes place. This dissociation is followed by coordination of the second hydroxyl function (replacing carboxylate), i.e. the formation of two chelate rings involving four deprotonated hydroxyl groups [7,8,23–33]. In these complexes the carboxylate group acted as the anchoring site for oxovanadium(IV) ion. In the absence of a binding site readily available at low pH, the hydrolysis of oxovanadium(IV) is favored over complex formation with the ligand.

3.2. Diffuse reflectance spectra

The diffuse reflectance data agree with the UV–Vis spectrum. In complex **I** obtained at pH 3.5 two bands located at 550 and 780 nm were observed denoting coordination of the vanadyl(IV) cation through the carboxylate group of quinic acid, as has already been stated in the difference UV–Vis spectrum. Complex **II**, obtained at pH 6, shows four bands at 415, 530, 615 and 780 nm. The three bands of complex **III** appeared at 425, 525 and 660 nm.

3.3. Infrared spectra

From the data in Table 1 the following can be stated:

1. The ν(COOH) band of the free ligand splits into two components when the coordination occurs, Table 1. The Δ value $[\nu_a(COO^-) - \nu_s(COO^-)]$ of complexes **I** and **II** (approximately 270 cm^{-1}) is in

Table 1
Assignments of some characteristic IR bands (cm^{-1}) of quinic acid and $[VO(quin)(H_2O)_3]$ (**I**), $Na_4[VO(quin)_2SO_4]\cdot 4H_2O$ (**II**) and $Na_6[VO(quin)_2SO_4]\cdot 4H_2O$ (**III**) [a]

Quinic acid	I	II	III	Assignments
1681 (vs)				ν(COOH)
	1635 (s)	1634 (s)	1631 (s)	$\nu_a(COO^-)$
	1363 (m)	1363 (m)	1457 (m)	$\nu_s(COO^-)$
1228 (s)	1186 (sh)			δ(C–OH)
		1131 (vs)	1131 (vs)	$\nu(SO_4^{2-})$
		996 (s)	996 (s)	$\nu(SO_4^{2-})$
	1151 (s)	1157 (m)	1152 (m)	see text
1137 (vs)	1116 (s)	1118 (s)	1125 (s)	see text
1079 (s)	1089 (sh)	1086 (s)	1086 (sh)	see text
1062 (s)	1067 (s)	1066 (s)	1062 (s)	see text
	986 (s)	968 (s)	929 (s)	ν(V=O)
		631 (s)	638 (s)	$\nu(SO_4^{2-})$

613 (m)	613 (m)			

[a] vs, very strong; s, strong; m, medium; w, weak; sh, shoulder.

agreement with a unidentate coordination of the carboxylate group. Complex **III** exhibits a significantly lower Δ value (ca. 174 cm^{-1}) suggesting that the carboxylate group is present in an ionic form without coordination to the metal center [34].

2. The free sulfate anion have a T_d point group. Of the four fundamentals, only ν_3 and ν_4 are IR active (1104 (vs) and 613 (s) cm^{-1}, respectively). When sulfate coordinates to a metal, its symmetry is lowered and the spectrum is affected due to the changes in the selection rules and different modes can be activated depending on its coordination mode [34]. The bands located at 1131 (vs), 996 (s), 631 (s) and 619 (s) cm^{-1} in the spectra of **II** and **III** indicate the presence of the sulfate anion in those complexes. The absence of the $\nu_3(SO_4^{2-})$ strong band at 1170 cm^{-1} allows us to discard the bridging bidentate coordination of this group. The strong band at 996 cm^{-1} ($\nu_1(SO_4^{2-})$) together with the strong $\nu_4(SO_4^{2-})$ band in the 600–650 cm^{-1} range are indicative of a unidentate coordination of the sulfate group. The absence of the very strong band in the 1150–1000 cm^{-1} range allowed a conclusion that the solid **I**, obtained at pH 3.5, is a unique species. Neither $VOSO_4$ nor complex **II**, present in the solution, coprecipitated with it. When the complexes were precipitated at pH ≥ 6 the sulfate is involved in the coordination sphere, as mentioned above.
3. In order to record the bands that are masked by the sulfate anion, the complexes at pH 6 and 12 were prepared in a similar manner, using $VOCl_2$ instead of $VOSO_4$. For carbohydrates, the bands in the 1200–1060 cm^{-1} region are assigned as a coupling of C–O and C–C vibrations with some C–O–H and C–C–H bending components [35,36]. The band of the free ligand at 1137 cm^{-1} splits into two components in the three complexes. This fact can be indicative of either coordination or deprotonation of the C–OH groups.
4. When vanadyl(IV) interacts with carboxylate anion (complex **I**) the position of the ν(V=O) band is located at approximately 990 cm^{-1} [19,22,37]. The intermediate value of ν(V=O) observed in complex **II** is characteristic of complexes of hydroxycarboxylates with oxovanadium(IV) [6,38]. The decrease in the V=O IR stretch from compound **I** to **II** can be explained on the basis of the sulfate coordination. The position of ν(V=O) in the spectrum of **III**, is the same of that for the vanadyl complexes with sugars, denoting that the coordination occurs through the deprotonated hydroxy groups [7,9,31]. The weakening of the V=O bond in compound **III** [7,29–33,38] can be due to an increase of the σ-donor character of the ligands in the coordination sphere of the vanadium center.

3.4. Raman spectra

In order to determine sulfate anion and carboxylate group stretching modes, Raman spectra were recorded. Fluorescence is observed in the case of complex **II** so the Raman spectrum was measured with the complex prepared using $VOCl_2$ instead of $VOSO_4$. The most important features have been observed (Table 2):

1. The intensity of the antisymmetric stretching COO^- band lowered and the symmetric mode is increased with respect to the FTIR, as expected.
2. Raman active modes of sulfate anion shown in complex **III** are in agreement with the lowering of symmetry caused by coordination.
3. Typical bands of the sugar moiety are observed.
4. The ν(V=O) remains in the same position as the IR spectra with higher intensity.

3.5. Thermogravimetric behavior

The thermal behavior of the free ligand and the three complexes was investigated by means of TG and DTA measurements under O_2 atmosphere up to 1000°C (Fig. 2).

3.5.1. Quinic acid

The degradation starts at 150°C with a loss of 10.12% accompanied by a medium endothermic peak located at 172.5°C (s, *endo*) (DTA signal). Finally, two consecutive events are observed with losses of 84.54% (322.5°C, s, *exo*) and 4.62% (472°C, m, *exo*), respectively.

3.5.2. Complex *I*

As can be seen from the thermogram shown in Fig. 2 the three water molecules are removed in two steps,

[a] vs, very strong; s, strong; m, medium; w, weak; sh, shoulder.

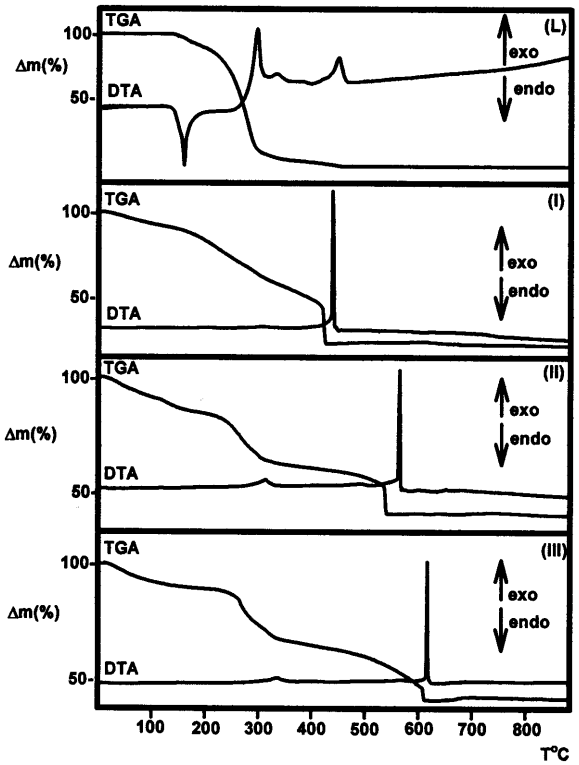

Fig. 2. TG and DTA curves of the thermal decompositions of quinic acid (L), $[VO(quin)(H_2O)_3]$ (**I**), $Na_4[VO(quin)_2SO_4]\cdot 4H_2O$ (**II**) and $Na_6[VO(quin)_2SO_4]\cdot 4H_2O$ (**III**). Oxygen flow: 50 ml min^{-1}, rate: 10°C min^{-1}.

with losses of 5.57% and 11.57% in the ranges of 50–100°C and 100–230°C, respectively. The theoretical mass loss is 5.78% for the first water molecule and 11.74% for the two remaining molecules, in excellent agreement with the observed values. After dehydration a complex series of consecutive events is observed: 9.94%, 13.58% (328°C, w, *exo*), 28.27% (445°C, vs, *exo*), 2.04%. The weight of the residue at 1000°C is 29.03% in good agreement with the theoretical value (29.26%). The total stoichiometry of this process is proposed as follows:

$$2[VO(quin)(H_2O)_3] \xrightarrow{O_2} V_2O_5 + \text{volatile products}$$

3.5.3. Complex *II*

The loss of two water molecules of hydration occurs in the 25–85°C range ($\Delta\omega_{exp} = 5.39\%$ and $\Delta\omega_{calc} = 5.09\%$). This step is followed by the loss of the two remaining water molecules in the 85–145°C range ($\Delta\omega_{exp} = 5.04\%$ and $\Delta\omega_{calc} = 5.09\%$). Two successive degradation steps 27.07% (337°C, vw, *exo*) and 20.13% (568°C, vs, *exo*) leads to the final residue at 1000°C. The overall reaction pattern can be formulated as:

$$2Na_4[VO(quin)_2SO_4]\cdot 4H_2O \xrightarrow{O_2} 2Na_2SO_4 + V_2O_5 + 2Na_2O + \text{volatile products}$$

for which a mass loss of 58.28% is calculated, in good agreement with the experimental value of 57.63%.

3.5.4. Complex *III*

The dehydration occurs in a single stage and covers the 25–160°C range with the elimination of four water molecules ($\Delta\omega_{exp} = 9.79\%$ and $\Delta\omega_{calc} = 9.59\%$). Immediately after, the decomposition is accompanied by three successive steps with losses of 16.58%, 9.02% (358°C, vw, *exo*) and 17.27% (587°C, vw, *exo*; 633°C, vs, *exo*). The total degradation is postulated as:

$$2Na_6[VO(quin)_2SO_4]\cdot 4H_2O \xrightarrow{O_2} 2Na_2SO_4 + V_2O_5 + 4\ Na_2O + \text{volatile products}$$

with a theoretical total residue of 47.54% at 1000°C (exp. residue = 47.34%).

The final residues of the three complexes have been characterized on the basis of IR spectroscopy. In all cases V_2O_5 is detected. The presence of this oxide is also demonstrated by a very weak endothermic DTA signal in the 660–670°C range corresponding to the melting point (658°C) [39].

The thermal studies performed suggest that complex **I** is more stable than the other complexes because of the higher degradation temperature (approximately 230°C). The presence of the sulfate anion in the coordination sphere of complexes **II** and **III** may enhance their reactivity.

3.6. Potentiometric titrations

The acidity constants for quinic acid were determined from three titrations using pK_a values and Best calculation programs [40]. Solutions of 20 mM quinic acid were titrated with NaOH over a 2.3–12 pH range. In these conditions only the first two deprotonation constants ($\log\beta_{012} = 15.32$ and $\log\beta_{011} = 12.0$) could be estimated. These data compare well with literature values [41]. On these basis L^{2-} has been considered as the proper component of the system, even when the ligand has three more potential acidic protons.

To estimate the formation constants of the ternary system $VO^{2+}/L^{2-}/H^+$ the data collected from four titrations were analyzed with BEST and SUPERQUAD [42] calculation programs.

The experiments were performed on a 2.3–12 pH range. Total vanadyl(IV) concentration in the titration vessel was 10 mM while the ligand concentration was 20 mM. The usual criteria used to select equilibrium models of speciation using these sorts of programs (CHI^2 and *R* values, S.D. values, etc.) was the comparison with the spectroscopic results.

In Table 3 the proposed species and the corresponding β values for this system are shown. Due to the very low total vanadium concentration in the experimental

conditions the $(VO)_2(OH)_2^{2+}$ species was neglected. The species distribution as a function of pH was obtained with the SPECIES program (see Fig. 3).

It can be seen that complexation occurs in the whole pH range, according to the spectroscopic results and physicochemical characterization discussed above. No precipitation nor hydrolysis of VO^{2+} species was observed during the experiments. At the initial pH value of 2.3, potentiometric titration curves of quinic acid with and without vanadyl(IV) are not superimposable indicating that complex formation occurs at low pH. This observation is consistent with the fact that monodentate carboxylate binding takes place. Carboxylic protons are strongly acidic in the vanadyl complexes than in the free ligand as can be seen in Fig. 3 ($pK_{a1} = 3.32$).

In the 2.3–6.0 pH range more than one species contributes to the electronic spectrum of the solution in a significant percentage. At pH between 6 and 8, the titration curve corresponds to that of only one main species. This was confirmed by UV–Vis spectroscopy. The position of the bands is similar to that of α-hydroxy-acid complexes with vanadyl(IV) [6,11]. From Fig. 3 it can be seen that at least four different species coexist in solution with a reaccomodation of the ligand around the metal center. Finally, at pH 12 a new deprotonation of the ligand takes place and the majority of species correspond to an alkoxide-linked complex. Since $VO(OH)_3^-$ is present in such small amounts its UV spectrum could not be observed and the spectrum shows mainly the three-band pattern of VO^{2+}/carbohydrate complexes [7,8,23–33].

Table 3
Composition, notation and formation constants (β) for the $VO^{2+}/L^{2-}/H^+$ system (0.150 M NaCl, 25°C) [a]

Species	Formula	log β
012	LH_2	15.32
011	LH	12.00
110	ML	11.56
11-1	MLH_{-1}	6.28
120	ML_2	22.01
12-1	ML_2H_{-1}	11.34
12-2	ML_2H_{-2}	0.54

[a] In the final calculation log β for vanadium hydrolysis products were: −5.50, −17.90 and −21.85 for MH_{-1}, MH_{-3} and M_2H_{-5}, respectively.

Abstract

The synthesis and spectroscopic, magnetic and structural characterization of a complex of copper(II) with hexanoic acid, $Cu_2(O_2CC_5H_{11})_4$ are described. The same complex is formed by synthesis using either CuO or Cu_2O. The compound exhibits a typical dinuclear paddle-wheel type structure, consisting of two copper(II) ions in square-pyramidal geometry bridged by four carboxylate anions in the *xy* plane. The IR spectrum shows that the $\Delta\nu_{COO}$ for this complex appears at 171 cm^{-1} which corresponds to a bridging bidentade mode of coordination of carboxylate-to-metal. Elemental analysis, EPR spectra and TG analysis were also performed. The magnetic susceptibility measurement confirms the antiferromagnetic nature of the copper–carboxylate coupling which is in agreement with the X-ray crystallography results. © 2000 Elsevier Science B.V. 1. Introduction

Due to their varied geometric structures and physicochemical properties, copper(II) complexes have received considerable attention in the last years. They have several applications in many areas which include biochemical and industrial ones.

The complexes with carboxylic acids are very interesting [1] because they can contain two or more antiferromagnetically coupled metal centers [2–9]. Since each carboxylate oxygen atom has two lone pairs they can either have only one lone pair involved in the coordination resulting in a dinuclear paddle-wheel structure or have the second lone pair donated to a metal ion of another paddle-wheel structure resulting in a polymeric structure. Although polymeric structures can also occur when the ligand bridges two units, it seems that all anhydrous copper(II) carboxylates adopt the structure in which the bridge is between the metal of one paddle-wheel like structure and the carboxylate of a second one [10]. Several copper(II) alcanoates have been studied [4,5,9–12]. All these compounds have a molar susceptibility anomalously low compared to those of other copper(II) compounds and show a paramagnetic susceptibility with a maximum at about 270 K, falling steeply with the decreasing of temperature[12].

Usually copper(II) carboxylates are prepared from copper(II) acetate and the corresponding carboxylic acid [13], or $CuSO_4 \cdot 5H_2O$ and the sodium salt of the carboxylic acid [3,14,15] or any other compound of copper(II), such as carbonate [11,12] and the corresponding carboxylic acid.

In this paper, copper(II) hexanoate was prepared by reaction of both cupric and cuprous oxides with hexanoic acid. In both cases the resulting compound was

anhydrous copper(II) hexanoate. The synthesis of the complex starting from cuprous oxide represents the inverse reaction of thermal decomposition of copper(II) carboxylates in the presence of reducing agents as described in the literature [16]. The resulting copper(I) complex is easily oxidized on exposure to the atmosphere. We also describe its structure, spectroscopic and magnetic properties. Up to now this compound had been synthesized only from copper(II) acetate [13] and also did not have its crystal structure and other properties studied. We found references [11,13,16,17] that describe the IR spectra of some anhydrous copper(II) carboxylates, but only in the region between 4000 and 400 cm^{-1}. Here, we performed IR spectra in this region and in the range from 600 to 50 cm^{-1}.

2. Experimental

2.1. Synthesis and chemical characterization of the complex

Syntheses were carried out through the reaction of both cuprous and cupric oxides with hexanoic acid. All chemicals and solvents used were commercially available reagent grade ones, with no further treatment.

The green crystals, which were formed in both cases after several days reaction, were vacuum filtered, thoroughly washed with acetone and left to dry at room temperature (r.t.). In the case of the reaction with cuprous oxide it appeared at the same time a deposit of metallic copper.

The crystal obtained from cuprous oxide will be called crystal A and the one obtained from cupric oxide will be called crystal B. Both complexes were practically insoluble in water, ethanol and acetone.

The copper content was determined by atomic absorption spectrometry in a Varian AA5 Instrument. A total of 5.0 mg of the compound was digested with a small amount of nitric acid and diluted to 50 ml. The measurements were taken using the wavelength of 324.7 nm and a slit of 0.1 nm.

Carbon, hydrogen and oxygen determinations were performed in an elemental analyzer EA 1110 from CE Instruments. The composition, in %, found for crystal A and crystal B can be seen in Table 1.

2.2. Magnetic measurements

Temperature dependent (2–298 K) magnetization data were recorded on a SQUID magnetometer (MPMS Quantum Design) in an external magnetic field of 1 T. The experimental susceptibility data were corrected for underlying diamagnetism by use of tabulated Pascal's constants.

Electron paramagnetic resonance measurements were carried out both in the crystals and the green solution from which the crystals were formed, on a Bruker 300 E ESR spectrometer operating at X-band frequency (9.45 GHz at 77 K) using a rectangular standard cavity TE 102, with signal modulation at 100 kHz, modulation amplitude 7.052 Gauss and microwave potency of 4.01×10^{-1} mW.

2.3. Physical measurements

IR spectra of the studied crystals were obtained in a Nicolet 760 Magna IR spectrometer with 128 scans and a spectral resolution of 4 cm^{-1}, at r.t. For the spectrum over the wave-number range from 4000 to 400 cm^{-1}, the crystals were pressed into pellets with KBr and the instrument was equipped with a KBr beam splitter and a DTGS detector with CsI windows. Over the wave-number range from 600 to 50 cm^{-1}, the crystals were pressed with polyethylene and the instrument was equipped with a solid substance and a DTGS detector.

Thermogravimetric analysis was performed with a Perkin–Elmer TGA 7. The temperature range used was from 20 to 900°C, with a scanning rate of 10.0°C min^{-1}.

2.4. X-ray structure analysis

A crystal of copper(II) hexanoate (crystal A) was mounted in the Enraf-Nonius CAD4 diffractometer, and using 25 reflections automatically centered, the cell parameters were obtained and refined [18]. Crystal data and numerical details on collection and refinement are presented in Table 2. The intensity data were reduced to F_o and corrected by absorption factor according to an empirical method, ψ-scan [19,20].

The structure was solved by SIR-92 [21], difference Fourier synthesis, and refined on F^2 by full-matrix least-squares using the SHELXL-97 [22]. The hydrogen atoms were positioned geometrically and a riding model was used during the refinement, with U_{iso} amounting to 1.5 (methyl H atoms; C–H = 0.97 Å)

or 1.2 (for the remaining; C–H = 0.98 Å) times the value of U_{eq} of the atom to which they are attached. All non-hydrogen atoms were refined anisotropically. The maximum and minimum electron density observed at the end of refinement were 0.43 (0.88 Å from Cu) and −0.30 (1.36 Å from O_2).

Crystal B showed the same X-ray results.

3. Results and discussion

23.1. General

Starting from cuprous oxide, the synthesis of the anhydrous copper(II) hexanoate led to the formation of a green solution and a deposit of metallic copper almost immediately after the addition of the cuprous oxide to the hexanoic acid. Several days after, small green needle-shaped crystals of X-ray quality were formed. The deposition of metallic copper shows that the copper(I) disproportionates into copper(II) and metallic copper: $2Cu^{1+} \leftrightarrow Cu^0 + Cu^{2+}$. Then, the Cu(II) ions react with the hexanoic acid to give the desired complex. This synthesis led to a yield of 68%. When cupric oxide was used, the formation of the green solution was observed a month after the addition of the reagent and it took several months for the deposition of the same green needle-shaped crystals. This synthesis gave a yield of 57%.

Elemental analysis of the crystals corresponds in both cases to the copper(II) hexanoate. The structures were determined and were shown to consist of dinuclear paddle-wheel like units.

All other experimental data obtained for both complexes and which are described below were similar and permitted the conclusion that they were the same compound.

3.2. X-ray crystallography

The molecular structure of copper(II) hexanoate representation is given in Fig. 1. The copper–copper distance is 2.5791(5) Å, and metal centers are bridged by four hexanoate ligands. The extended polymeric structure (Fig. 2) consists of chains of dimeric units with adjacent non-bonded coppers separated by 3.2357(5) Å. Selected bond lengths and angles are given in Table 3.

Both copper atoms have a distorted square-pyramidal geometry, with equatorial Cu–O distance of the O involved in the chain extension being slight longer than

the others three Cu–O_{eq} distances. The copper distance to the basal plane is 0.1743(6) Å, and the apical Cu–O bond length is 2.206(1) Å.

The results presented agree well with those determined for plenty of polymeric copper(II) carboxilates [4,5,9,12,23–30].

3.3. Infrared spectrum

The IR spectra of the compounds produced in both preparations were similar and showed the asymmetric and symmetric stretching vibrations of methyl and methylene groups, ν_{as} and ν_s (CH_3 and CH_2) at wavenumbers that correspond to hydrocarbons with oxygen atoms (see Table 4) [31].

The asymmetric and symmetric stretching vibrations of the coordinate carboxylate groups, $\nu_{COO,\ as}$ and $\nu_{COO,\ s}$ appear at 1588 (crystal A), 1589 (crystal B) and 1417 cm^{-1} (crystal A and B), respectively, and are characteristic of dicopper tetracarboxylates [32]. Several authors [2,3,13,16,32–35] have proposed that the position of these two bands ($\Delta\nu_{COO} = \nu_{COO,\ as} - \nu_{COO,\ s}$) helps to elucidate the type of carboxylate-to-metal complexation structure present in a given metal carboxylate. It was also found in the literature that a $\Delta\nu_{COO}$ band at approximately 150–170 cm^{-1} corresponds to a bridging bidentade mode of coordination, while chelating bidentade structures usually appears at approximately 100 cm^{-1}. These modes of coordination are shown in Fig. 3(I) and (II). Note that the complexes studied have a $\Delta\nu_{COO} = 171$ cm^{-1} for crystal A and 172 cm^{-1} for crystal B, corresponding to a bridging bidentade mode of coordination which is in agreement with the results of X-ray crystallography.

The comparison of the bands found in the spectra of our complexes at 387 (or 386) and 341 cm^{-1} with those of similar systems [36] leads to the conclusion that they could be Cu–O vibrations. The main bands and their assignments are shown in Table 4.

3.4. TG analysis

The decomposition of $Cu_2(O_2CC_5H_{11})_4$ was observed by TG analysis. A TG curve of crystal A is presented in Fig. 4. Our experiment showed that the anhydrous copper(II) hexanoate was stable up to 120°C. At this temperature it began to decompose releasing water, carbon monoxide and a mixture of metallic copper and cuprous oxide. After 287°C the copper and the cuprous

oxide were gradually oxidized to cupric oxide, which maintained a constant weight up to 900°C [37]. The same behavior was found for crystal B. The final product of the thermal decomposition of crystal A approximately corresponds to cupric oxide and for crystal B to a mixture of CuO, Cu_2O and Cu. Similarly, CuO is the thermal decomposition product of copper(II) formate, acetate and propionate complexes [14,16,38]. The residual mass data are given in Table 5.

3.5. Magnetic susceptibility

Mononuclear copper(II) complexes have essentially temperature-dependent magnetic moments, in the range of 1.75–2.20 BM [39–43] indicating interactions between unpaired electrons. On the other hand, there is a class of copper(II) complexes that have moments smaller than these values, which are attributed to the magnetic exchange of an antiferromagnetic nature. This can be due to either the formation of a weak bond between two copper atoms or a superexchange process via the intervening oxygen [44]. These compounds have pairs of Cu(II) ions which are held close together and are so strongly coupled that the compound is diamagnetic [39,43,45,46]. In this second class we may include anhydrous copper(II) hexanoate. The values formed for copper(II) hexanoate suggest that the structure might be a distorted square-pyramidal as it is confirmed in the polymeric structure (Fig. 2).

At 290 K the anhydrous copper(II) hexanoate exhibits a μ_{eff} value of 2.10 BM, which is lower than the theoretical value of $\mu_{eff} = 2.44$ BM expected for compounds with two non-coupled spins of $S_1 = S_2 = 1/2$. It indicates that the system is weakly coupled at r.t.

By lowering the temperature from 290 to 2 K, the μ_{eff} decreases monotonically, approaching a broad minimum of 0.15 BM at 2 K. This value is very near to that of $S = 0$, expected for the ground state of an antiferromagnetically coupled dinuclear copper(II) complex.

The magnetic analysis was carried out using the Heisenberg–Dirac–van Vleck model [47] based on the spin Hamiltonian for an isotropic magnetic exchange, $H = -2JS_1 \cdot S_2$, where $S_1 = S_2 = 1/2$ for the cupric ion.

A full-matrix diagonalization approach performed by the JULE software [48] was employed to fit the experimental data. The approach includes exchange ($-2JS_1 \cdot S_2$) and Zeeman interactions, together with axial single-ion zero-field interactions (DS_Z^2) when necessary. The best fit shown as the solid line in Fig. 5 yields $J = -156\ cm^{-1}$, and $g_1 = g_2 = 2.174$ and $\rho = 1\%$ (paramagnetic impurity) confirms the antiferromagnetic nature of the couplings. The solution is not unique and small variation of the J value (-162 to $-154\ cm^{-1}$) with further changes in the g values ($2.14 \leq g \leq 2.18$) also gave an acceptable fitting.

These data are in excellent agreement with the expected values for two antiferromagnetic copper(II) ions bounded to carboxylate bridges. Such compounds were extensively investigated in the past years [49] and the coupling can be attributed to a super-exchange mechanism acting via the carboxylate π-bonds.

3.6. Electronic paramagnetic resonance

Both crystals gave no EPR signals in spite of being a Cu(II) complex; this also confirms its antiferromag-

netism [2]. The green solution of both preparations gave an EPR signal that indicates the presence of copper(II) (Fig. 6). In the case of the solution prepared with hexanoic acid and cuprous oxide this observation leads to the conclusion that the Cu(I) was oxidized to Cu(II).

4. Conclusions

All the experimental data obtained for both compounds synthesized from hexanoic acid with either cuprous oxide or cupric oxide are quite similar. For this reason it can be concluded that they are the same compound. The oxidation and reduction of copper(I) to metallic copper and copper(II) in the presence of hexanoic acid leads to a more efficient reaction than the one that occurs when cupric oxide is used.

The results obtained here are in concordance with those of several polymeric copper(II) carboxylates.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 136713. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

A series of nine new lanthanide(III) complexes of the type $[Ln(PBH)_2(NO_3)_2]NO_3{\cdot}xH_2O$ (PBH = 2-pyridinecarboxaldehyde benzoylhydrazone) have been prepared and studied by IR, UV–Vis and mass spectra. In addition the crystal structures of $PBH{\cdot}H_2O$ and $[Er(PBH)_2(NO_3)_2]NO_3{\cdot}1.5H_2O$ have been solved. Erbium atom is ten-coordinate and the coordination polyhedron is best described as a distorted bicapped square antiprism. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Lanthanide; Erbium complex; Hydrazone

1. Introduction

The chemistry of the trivalent lanthanide ions has expanded rapidly in the last 40 years. The interest in the lanthanide complexes is chiefly ruled by their promising utilization due to their low toxicity and their powerful paramagnetic and luminescent properties [1–3]. Even though the lanthanide complexes are associated with important biological uses as diagnostic tools [4–7]. It is known that a considerable amount of work has been done on complexes with hydrazones because of their ability to chelate with metal ions [8–19], but little work has been reported on crystal structures of such derivatives of lanthanide elements [20–22]. In the course of our studies of the chemistry of lanthanide chelate compounds we have prepared and characterized a considerable number of chelates containing hydrazones as ligands, thus we report here a series of nine new lanthanide(III) complexes of the type $[Ln(PBH)_2(NO_3)_2]NO_3{\cdot}xH_2O$, the crystal structure of the erbium complex and the structure of the free ligand.

2. Experimental

2.1. Starting materials and procedures

Lanthanide nitrates (99.9%) $Ln(NO_3)_3{\cdot}xH_2O$ ($x = 5$ for Eu, Tb, Dy, Ho, Er, Yb and $x = 6$ for Y, Nd, Gd) were purchased from Aldrich Chemicals and were used without further purification. Lanthanide salts were stored in a dessicator to prevent hydration. The PBH ligand was prepared as previously described [23]. All solvents were reagent grade and anhydrous. Microanalyses (C, H, N) were taken with a Perkin–Elmer analyzer model 2400. Melting points were determined with a Büchi silicon oil bath apparatus and are uncorrected. Molar conductivities were measured on a WTW model LF 530 conductivity bridge employing a calibrated immersion type cell, which had a cell constant of 0.996. This represents a mean value calibrated at 25°C with potassium chloride solutions. Temperatures were controlled with an accuracy of ± 0.1°C using a Haake thermoelectric circulating system of water. Experimental and theoretical details for the conductivity measurements were reported elsewhere [24]. Room temperature magnetic susceptibility measurements in solid state were

0277-5387/00/$ - see front matter © 2000 Elsevier Science B.V. All rights reserved.
PII: S0277-5387(00)00580-5

done with a Johnson Matthey magnetic susceptibility balance MSB-MKI type. IR spectra were recorded in the 4000-250 cm^{-1} region on a Perkin–Elmer 1650 FT-IR spectrophotometer using KBr pellets. Calibration of frequency reading was made with polystyrene film. Electronic spectra in the region 200–1100 nm were measured on a Shimadzu-160A dual beam spectrophotometer using 1 cm, teflon stoppered, quartz absorption cells. The absorption spectra of solid compounds were measured on mulls that were prepared by grinding the dry solid and then regrinding it into a paste with paraffin oil (Nujol). This paste was spread on a disk of filter paper; the proper thickness of the sample was determined by trial and error. A disk of filter paper, dampened with paraffin oil, was placed in the reference position. All spectroscopic measurements were made at room temperature ($\sim$20°C). Mass spectra were measured on a RMU-6L Hitachi Perkin–Elmer mass spectrometer with ionization source of T-2p type operating at 70 eV.

2.2. Ligand

The ligand 2-pyridinecarboxaldehyde benzoylhydrazone (PBH), was prepared according to a procedure reported elsewhere [23] and recrystallized a minimum of three times from a hot methanol–water mixture. The ligand was crystallized from an acetonitrile solution by slow evaporation at 20–22°C. After a few days prismatic crystals were isolated from the solution. Analytical data for PBH are summarized in Table 1.

2.3. Preparation of Y, Nd, Eu, Gd, Tb, Dy, Ho, Er, and Yb complexes of PBH. General procedure

A methanol solution (5 ml) of PBH (973 mg, 4 mmol) was added slowly to a methanol solution (5 ml) of the appropriate lanthanide nitrate hydrated (2 mmol). The solution was allowed to stand at 20–22°C. After a few days crystals were isolated from the solution. Crystals suitable for the X-ray structure determination were obtained only in the case of Er-complex. The crystals were of poor quality, fragile and usually twinned. After inspection of a big number of crystals by microscopy a transparent crystal was isolated and used for data collection. Table 1 reports analytical data of the compounds.

2.4. Crystal structure determinations

The X-ray data for PBH were collected on a Kuma KM-4 diffractometer using graphite monochromatized Cu Kα radiation. The structure was solved by direct methods using the SHELXS-97 program [25]. Full-matrix least squares refinement was carried on F^2 with SHELXS-97 program [26]. All non hydrogen atoms have been refined anisotropically. The hydrogen atoms have been placed in calculated positions and refined using a riding model.

The data for the Er-complex were collected on a KumaCCD diffractometer using graphite monochromatized Mo Kα radiation with detector-to-crystal distance of 6 cm. More than a hemisphere of reciprocal space was covered by combination of four sets of exposures; each set had a different φ-angle (0, 90, 180, 270) and each exposure of 30s covered 0.75° in ω. Coverage of the unique set is over 98% complete. The collected data were reduced using the program KM4RED [27]. The structure was solved by direct methods with the program SHELXS-97 [25] and refined by full-matrix least-squares on F^2 with SHELXL-97 program [26]. Non-coordinated nitrate anion has been found disordered over two positions with occupancy factor equal to 1/2. A relatively high electron density maximum at hydrogen bond distance from its symmetry equivalent at position $1-x$, y, $1.5-z$ and at hydrogen bond dis-

tance to N(9A) and O(2D) has been attributed to a water molecule. Because this water molecule was situated only 1 Å from O(1C) of the disordered nitrate ion its occupancy has to be fractional and equal to that of the nitrate anion D. The disordered nitrate anions and disordered water molecule have been refined with isotropic displacement parameters. All other non-hydrogen atoms have been refined anisotropically. The hydrogen atoms have been placed in calculated positions and refined using a riding model. Restraints have been imposed on bond distances, angles and planarity of disordered nitrate groups. Crystallographic and structure determination data, for both structures, are listed in Table 2.

3. Results and discussion

3.1. General characteristics

The PBH is a white crystalline solid. The analytical results agree with the molecular formula $C_{13}H_{13}N_3O_2$ ($PBH\cdot H_2O$). The $[Ln(PBH)_2(NO_3)_2]NO_3\cdot xH_2O$ complexes synthesized and investigated in this work were crystalline solids. The analytical results agree with the molecular formula $LnC_{26}H_{22}N_9O_{11}\cdot nH_2O$ where $n=0.5$ for Ln=Nd complex, $n=1$ for Gd and Tb complexes, $n=1.5$ for Eu, Dy, Ho and Er complexes and $n=2$ for Y and Yb complexes. The complexes can be easily dissolved in alcohol, methanol, acetonitrile, dimethylformamide and dimethylsulfoxide but they are not soluble in nonpolar organic solvents. The room temperature magnetic moments of the complexes, corrected for diamagnetism, show very little deviation from van Vleck values [28], indicating minor participation of 4f-electrons in the bond formation. The molar conductivity measurements show that the complexes are 1:1 electrolytes.

3.2. Description of the structure of the ligand

The crystals of PBH are made up of orthorhombic unit cells, each containing eight monomeric $C_{13}H_{11}N_3O$ molecules and eight water molecules. A displacement ellipsoid plot of the PBH molecule with the atomic numbering is shown in Fig. 1, selected bonds lengths and angles are given in Table 3. The bonds and angles observed in this structure are normal and the molecule

is in the keto tautomeric form. The C(7)–O(8) [1.224(2)] and N(9)–N(10) [1.373(2) Å] bond lengths indicate bond orders of two and one, respectively, confirming that the crystal contains the keto tautomer [29]. The structural conformation of the molecule is the *E* isomer (at the N(10)=C(11) double bond), the most common conformation for analogous derivatives [30]. The dihedral angles between the mean planes of the phenyl and pyridine rings is 28.23(9)°; these two rings make angles of 22.64(10) and 5.65(9)° with the central hydrazone mean plane [O(8)–C(7)–N(9)–N(10)–C(11)]. The hydrazone molecules are approximately aligned perpendicular to the *a*-axis. The crystal structure is stabilized by extensive hydrogen bonding involving the water and the hydrazone molecules. The water molecule present is involved in a variety of N–H···O, O–H···O, C–H···O and H–O···N hydrogen bonds. Selected hydrogen-bond parameters are given in Table 4.

3.3. Description of the structure of $[Er(C_{13}H_{11}N_3O)_2(NO_3)_2]NO_3\cdot 1.5H_2O$

The X-ray study revealed that the crystals of $[Er(PBH)_2(NO_3)_2]NO_3\cdot 1.5H_2O$ are made up of monoclinic unit cells, each containing eight monomeric complex cations $[Er(PBH)_2(NO_3)_2]^+$, 16 ionic nitrates with occupancy of 1/2 and 16 water molecules eight of which have occupancy of 1/2. A diagram of the molecular structure and the atom numbering system used is shown in Fig. 2. The two ligand molecules coordinated with the same metal atom are labeled A and B. Selected bond lengths and angles are given in Table 5. The Er^{III} atom is ten-coordinate by linking to two tridentate PBH ligands and two bidentate nitrate ligands. Non-coordinated nitrate anion has been found to be disordered over two positions with occupancy factor equal to 1/2. The linking of the PBH ligand to the metal atom is accomplished through the pyridine nitrogen, the azomethine nitrogen and the carbonyl oxygen. Thus two five-membered chelate rings are formed.

As expected, the situation with respect to the coordination polyhedra for ten-coordination is complex. Three polyhedra are generally considered [31]: the bicapped square antiprism, the bicapped dodecahedron, and a polyhedron of C_{2v} symmetry derived from the triangular faced dodecahedron. Calculation of the ligand–ligand repulsion energies, reported elsewhere [32], shows that the bicapped square antiprism is the favored arrangement. In our case the coordination polyhedron around the Er atom is a distorted bicapped square antiprism and is shown in Fig. 3. O(2B), O(8B), O(2A), N(13B) define the one square face of the polyhedron

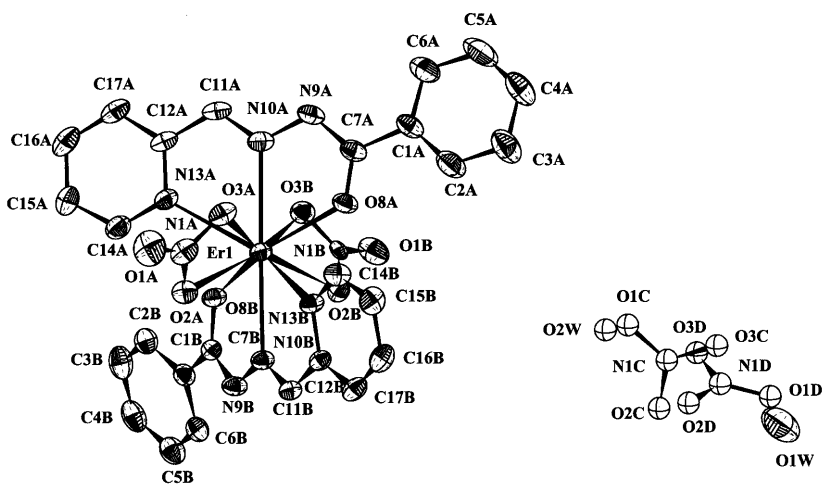

Fig. 2. Crystal structure of $[Er(C_{13}H_{11}N_3O)_2(NO_3)_2]NO_3\cdot 1.5H_2O$ showing the atom numbering scheme. The thermal ellipsoids are drawn at 30% probability; hydrogen atoms are omitted for clarity.

O(8B)–Er(1)–O(2A)	85.53(10)		

and O(3B), O(8A), O(3A), N(13A) define the other. The two capping atoms are N(10A) and N(10B). The polygon formed by N(13A), . . . , O(3B) is very close to a square. The internal angles range from 85.18(12)–95.90(13)° averaging to 89.55°; the sides of this face have lengths in the interval [2.868, 3.552] Å with a mean value of 3.157 Å. The figure formed by O(2A), . . . , O(8B) is less distorted than the other with internal angles in the range 93.07–87.31° and sides from 2.969–3.266 Å. The two square faces are essentially parallel and the angle between them is 0.92(12)°. The angle N(10A)–Er(1)–N(10B) is 178.04(11)° slightly distorted from the ideal value of 180°. Similar coordination geometry was found in other ten-coordinate lanthanides, e.g. in tetraaquatri(nitrato)yttrium(III) dihydrate [33] and $HLa(EDTA){\cdot}7H_2O$ [34].

The Er–O distances range between 2.361(3) and 2.465(3) Å. Similarly the Er–N distances range between 2.535(3) and 2.603(3) Å. These distances are considerably shorter than the corresponding distances observed in the analogous Ce-complex: $[Ce(NO_3)_3(PBH)_2]{\cdot}CH_3COCH_3{\cdot}2H_2O$ [22]. The Ce–O distances range between 2.528(3) and 2.759(4) Å and the Ce–N distances range between 2.725(4) and 2.848(4) Å. In both PBH ligands coordinated with erbium the benzene and pyridine rings have normal dimensions. The dihedral angles between the mean planes of the pyridine and phenyl rings is 9.2(3)° in the coordinated PBH molecule A and 13.4(3)° in B, respectively.

In each nitrate group the non coordinated O-atom is closer to N [1.203(10) and 1.212(7) Å] than the other two [1.237(5)–1.293(5) Å] and the metal bound O–N–O angles [115.34(46) and 116.57(30)°] are significantly smaller than the other O–N–O angles [118.75(40)–124.68(36)°], which is a common property of all bidentate nitrate groups [35].

All the water molecules are involved in hydrogen bond formation with PBH ligands. The crystal structure is stabilized by a complicated hydrogen-bond network in which imine hydrogen forms a hydrogen bond with a water oxygen atom. One oxygen of each non-coordinated nitrate ion is hydrogen bonded to a water molecule. Additional hydrogen bonding occurs between water–water molecules. A diagram showing this network is given in Fig. 4. Selected hydrogen bond lengths and angles are given in Table 6.

3.4. IR spectroscopic studies

The IR spectra of the complexes in the region 4000–250 cm^{-1} are analyzed in comparison with that of the free ligand. This data gives evidence for the coordination of the PBH to the metal ion via two nitrogen atoms and one oxygen. The complexes and the free PBH show an IR band at 3420–3490 cm^{-1}. This band is reasonably attributable to the water molecule. The vibration attributable to the ν(N–H) mode is observed at 3186 cm^{-1} for the free ligand and at 3191–3220 cm^{-1} for the complexes. This fact suggests that PBH function as a neutral ligand to the lanthanide(III) ions [36]. For the complexes, the bands assignable to the ν(C=O) and ν(C=N) vibrations are observed at 1608–1610 cm^{-1} and 1567–1572 cm^{-1}, respectively, whereas the corresponding bands for the free ligand are ob-

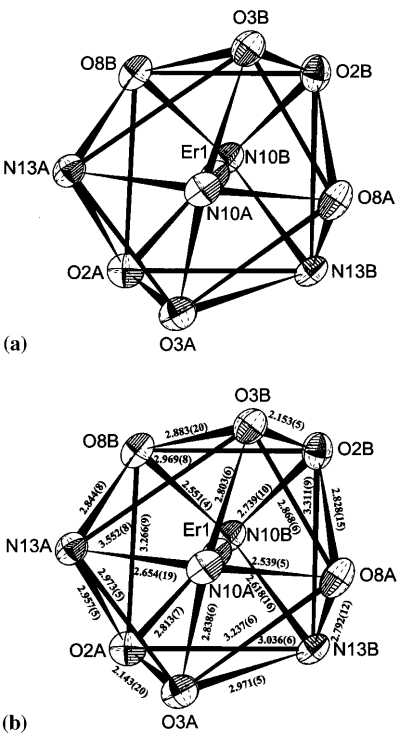

Fig. 3. (a) The coordination polyhedron around each Er^{3+} ion. (b) The coordination polyhedron around each Er^{3+} ion. Dimensions of the edges are in Å.

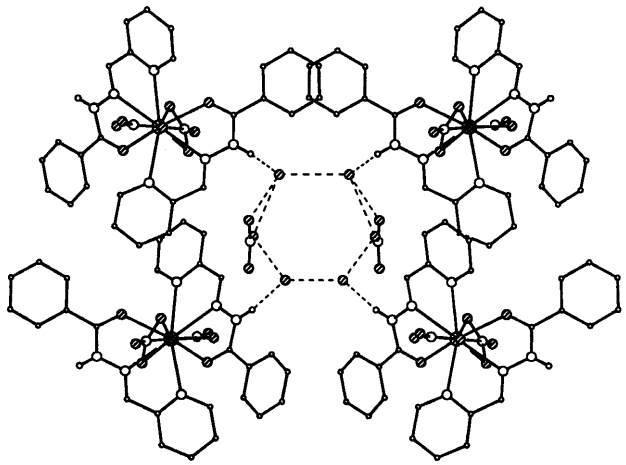

Fig. 4. View of the hydrogen bond network of Er-complex.

served at 1657 and 1600 cm^{-1}, respectively. The shifts of the ν(C=O) and ν(C=N) vibrations of the bonds toward lower wave numbers on complexation indicate that carbonyl oxygen and azomethine nitrogen coordinate to the metal [36]. The low energy pyridine ring in-plane and out-of-plane vibrations observed in the spectrum of the ligand at 625 and 406 cm^{-1}, respectively, whereas the corresponding bands for the complexes are shifted to higher frequencies at 633–634 and 415–422 cm^{-1}, respectively, which is a good indication of the coordination of the heterocyclic nitrogen [37] (Table 7).

The infrared spectra of the complexes demonstrate the presence of coordinated and ionic nitrates. The two strong bands associated with the asymmetric stretch (C_{2v} symmetry, coordinated NO_3^- group) appear at 1473–1478 and 1284–1311 cm^{-1}. The separation of the nitrate stretching fundamentals at $\sim$1400 and $\sim$ 1300 cm^{-1} ($\Delta\nu$) has been used as a criterion to distinguish between the degree of covalency of the nitrate coordination [37]. $\Delta\nu$ increases as the coordination of the nitrate group increases for monodentate to bidentate and/or bridging. The magnitude is used to establish the type of nitrate coordination. In our complexes $\Delta\nu \sim 170$ cm^{-1} and is typical of bidentate bonding of nitrates [37]. The band at 1384 cm^{-1} is characteristic for ionic nitrates (D_{3h} symmetry, free NO_3^- ion). The data indicate that the chelates contain both coordinated bidentate and ionic nitrate groups.

3.5. Electronic spectral studies

The electronic spectral data of the lanthanide(III) complexes both in the solid state (Nujol) and in solutions of DMF are similar (Table 8). The assignments are made by comparison with Carnall's data on aqueous solutions [38]. This suggests that the complexes seem to maintain the same stereochemistry in solid and solution phases. The electronic spectral data of the complexes and the PBH recorded in methanol (Table 9) and Nujol (Table 10) and they are almost identical. The ligand shows an intense absorption band at 44 444 (methanol solution), 40 322 cm^{-1} (Nujol) which shifts to a higher wavelength with increasing solvent polarity and is assigned to $\pi \rightarrow \pi^*$ transition of the rings [17]. A red shift is observed for this transition when the nitrogen of the pyridine ring is metal coordinated [17]. The position of the maximum varies between the chelates of different lanthanides (38 000–45 000 cm^{-1}). Another intense absorption band in the region $\sim$33 000 cm^{-1} in the spectrum of the free ligand is attributed to intraligand transition of $\pi \rightarrow \pi^*$ type located mainly on the C=N group [17]. This band also occurs in the spectra of the complexes, but is shifted toward higher frequencies, a fact which further supports the coordination of the hydrazones via azomethine nitrogen atom. A third intense band appears in the 24 000–29 000 cm^{-1} region which is assigned to an $n \rightarrow \pi^*$ transition located on the carbonyl group. Complex formation through the carbonyl group should cause a blue shift of

the $n \rightarrow \pi^*$ transition. In our complexes this band is shifted by 1000–2000 cm^{-1}. The electronic spectral data of the complexes further support the coordination of the ligand to the lanthanide through the carbonyl oxygen, azomethine nitrogen and pyridine nitrogen.

3.6. Mass spectral studies

The electron impact mass spectra of all the complexes and the PBH are summarized in the Table 11. The mass spectrum of the Eu complex shows fragments due to $[Eu(NO_3)_2(PBH)_2]^{+\bullet}$ radical cation and $[Eu(NO_3)_2(PBH)]^+$ cation, which are formed from the expulsion of the $-NO_3^{\bullet}$ and after the $[PBH]^{\bullet}$ radical from the molecular ion of the complex. The fragment due to $\{[Y(NO_3)_2(PBH)]NO_3\}^{+\bullet}$ radical cation is formed from the expulsion of the $[PBH]^{\bullet}$ radical from the molecular ion of the complex (Fig. 5). The spectra of Y and Dy complexes show fragments due to $[Y(PBH_{an})]^{2+}$ and $[Dy(PBH_{an})]^{2+}$, respectively (PBH_{an} represents the anionic form of the PBH). The major peaks of the spectra of all complexes can be explained following the fragmentation path of the PBH (Fig. 6).

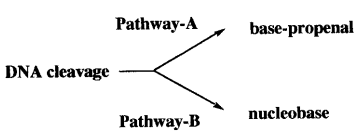
Received 2 May 2000; accepted 1 September 2000



Abstract

The release of nucleobases from oligonucleotides (12-mer, d(5′-CGCTTTAAAGCG)$_2$, 8-mer, d(5′-AAACGTTT)$_2$, 7-mer, d(TCGCGCG)$_2$, and 6-mer, d(CGCGCG)$_2$) by copper(II) complex and hydrogen peroxide systems was investigated in terms of HPLC. The [Cu(bdpg)Cl]Cl complex gave a large quantity of free nucleobases in the reaction mixture, but the activities of other compounds, such as [Cu(tpa)Cl]ClO_4, were much lower than that of the (bdpg)-complex; where (bdpg) and (tpa) represent a *N*,*N*-bis(2-pyridylmethyl) derivative of β-alanineamide and 2-aminomethylpyridine, respectively. The above results and the electrospray mass spectral data on the solutions strongly suggest that the remarkable activity of the (bdpg)-compound is due to the high electrophilic nature of the copper(II)–hydroperoxide adduct, whose formation is greatly promoted through hydrogen bonding with the amide-oxygen atom coordinated to the copper(II) atom, and this electrophilic copper(II)–peroxide adduct attacks the sugar ring of nucleoside, to give the corresponding hydroxylated species, and from which free nucleobases are released.

Keywords: Release of free nucleobases from oligomers; Copper(II)–peroxide adduct; DNA cleavage; Electrospray mass spectrometry

1. Introduction

Two types of monomeric products have been isolated and identified during Fe-BLM mediated degradation of DNA: free nucleobase and base propenal (see Scheme 1) [1]. The base-propenal formation requires O_2 in addition to that required to form activated-BLM and is accompanied by DNA strand scission and phosphoglycolate termini production. The free base release requires no additional O_2 and is accompanied by production of an oxidatively damaged sugar in the intact DNA strand [2,3]. At present there is no clear elucidation as to why two ways are present in the strand scission of DNA.

Scheme 1.

In order to clarify the origin of the presence of two pathways in DNA cleavage reaction, we have investigated the DNA degradation by several metal compounds including Fe(III) and Cu(II) compounds in the presence of hydrogen peroxide (for the chemical structures of the ligands, see Fig. 1) [4–6]. As the results indicate, we have found that the copper(II) complexes used in our previous studies are divided into two types based on the activity of DNA degradation, e.g. [Cu(bdpg)Cl]$^+$ complex effects the complete degradation of DNA (pBR322, supercoiled Form I), however [Cu(tpa)Cl]$^+$ complex gives only Form II DNA under the same experimental conditions (for the chemical structures of the ligands, see Fig. 1). This difference observed for DNA cleavage reaction in [Cu(bdpg)Cl]$^+$ and [Cu(tpa)Cl]$^+$ was also observed in the different

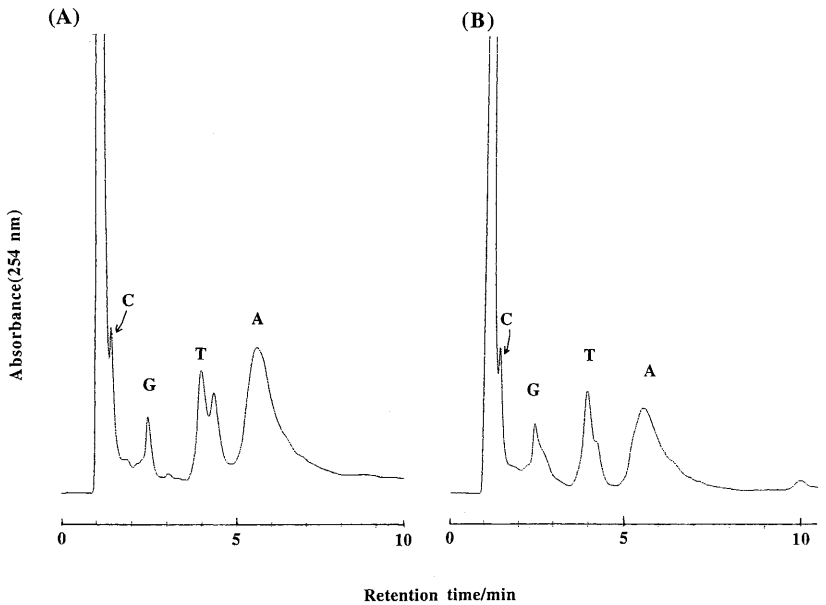

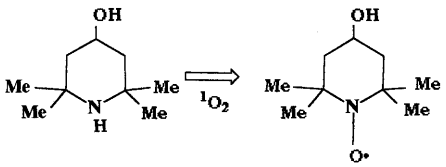

Fig. 2. HPLC of the solution containing a copper(II) complex, H_2O_2, and 8-mer measured at 60 min after H_2O_2 was added. Peaks at 1.44, 2.46, 4.05 and 5.51 min were attributed to C (cytosine), G (guanine), T (thymine), and A (adenine), respectively, confirmed by the use of authentic samples. The peak at 4.32 min observed for the (bdpg)-complex is not known. (A): [Cu(bdpg)Cl]Cl; (B): $[Cu(dpgs)Cl]ClO_4$.

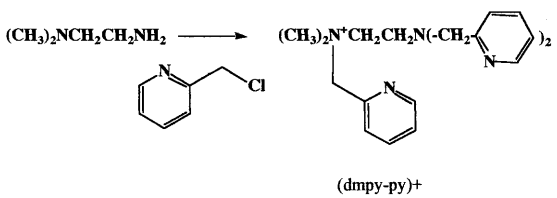
behavior towards the spin-trapping reagent for singlet oxygen ($^1\Delta_g$), 2,2,6,6-tetramethyl-4-piperidinol (TMPN); i.e. the former complex gives no nitrone radical in the reaction with TMPN, however much formation of the nitrone radical was observed when TMPN was reacted with $[Cu(tpa)Cl]^+$ complex in the presence of hydrogen peroxide (see the scheme below) [5]. This is suggesting that the structure and reactivity of a copper(II)–hydroperoxide adduct are highly affected by the peripheral organic group and also TMPN, and demonstrating that the different DNA cleavage patterns observed for the copper(II) compounds should be due to the different reactivity of the copper(II)–peroxide adduct formed during the course of the reaction [5].



TMPN nitrone radical

In order to confirm the validity of our conclusion on the intrinsic active-species for the DNA cleavage reaction, in this study we have investigated the degradation of several oligomers by the copper(II)–H_2O_2 systems in terms of HPLC, and we have also measured the electrospray mass spectra (ESI-MS) of the solutions.

2. Experimental

2.1. Materials

Chemical structures of the ligands used in this study are illustrated in Fig. 1. The ligands except for (dmpy-py), were obtained according to the published method [4,5,7]. From the reaction mixture of *N*,*N*-dimethylaminoethylamine (1 mol) and picolyl chloride (2 mol), we have obtained the $[Cu(dmpy\text{-}py)Cl](ClO_4)_2$, where three molecules of picolyl chloride reacted with one molecule of *N*,*N*-dimethylaminoethylamine (see below), which is quite different from the case of *N*,*N*-diethylaminoethylamine.

(dmpy-py)+

2.2. Crystal structure determination of $[Cu(dmpy\text{-}py)Cl](ClO_4)_2$

A blue–green prism having approximate dimensions of $0.3 \times 0.3 \times 0.5$ mm was mounted on a glass fiber. All measurements were made on a Rigaku AFC5S diffractometer with graphite monochromated Mo Kα radiation and a 12 kW rotating anode generator at Saga University. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections, and the crystal data of the compounds are summarized in Table 1. The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on the observed reflections ($I > 3.00\sigma(I)$), and $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [(\Sigma\ \omega(|F_o| - |F_c|)^2/\Sigma\ \omega|F_o|^2)]^{1/2}$ were listed in Table 1. Neutral atom scattering factors were taken from Cromer and Weber [8]. Anomalous dispersion effects were included in $F_{calc.}$ The values for $\Delta F'$ and $\Delta F''$ were those of Cromer [9]. All calculations were performed using TEXSAN the crystallographic software package of Molecular Structure Corporation [10].

2.3. HPLC containing the oligomer, copper(II) complex, and hydrogen peroxide

A copper(II) complex was dissolved in the solution (20 ml) containing an oligomer (12-mer, d(5′-CGCTTTAAAGCG)$_2$, 8-mer, d(5′-AAACGTTT)$_2$, 7-mer, d(TCGCGCG)$_2$, and 6-mer, d(CGCGCG)$_2$, purchased from Rikaken Co., Nagoya, Japan; the latter two oligomers are left-handed Z-DNA [11]), and the mixture was treated with hydrogen peroxide; final concentrations are $[Cu^{2+}] = 1.67$ mM, $[H_2O_2] = 16.7$ mM, and oligomer, 0.2 mM in Tris–HCl buffer (pH 7.8). The reaction mixture was stirred under air at 298 K, and analyzed by HPLC ($5C_{18}$-AR column, eluted with 10% methanol solution containing 0.1 mol of ammonium acetate [12] at a flow rate of 1.6 ml min^{-1}; detected by absorbance at 254 nm; see Fig. 2). The quantity of detected nucleobases was evaluated by measuring the area of HPLC peak by the use of the authentic sample (see Fig. 3 and Table 2).

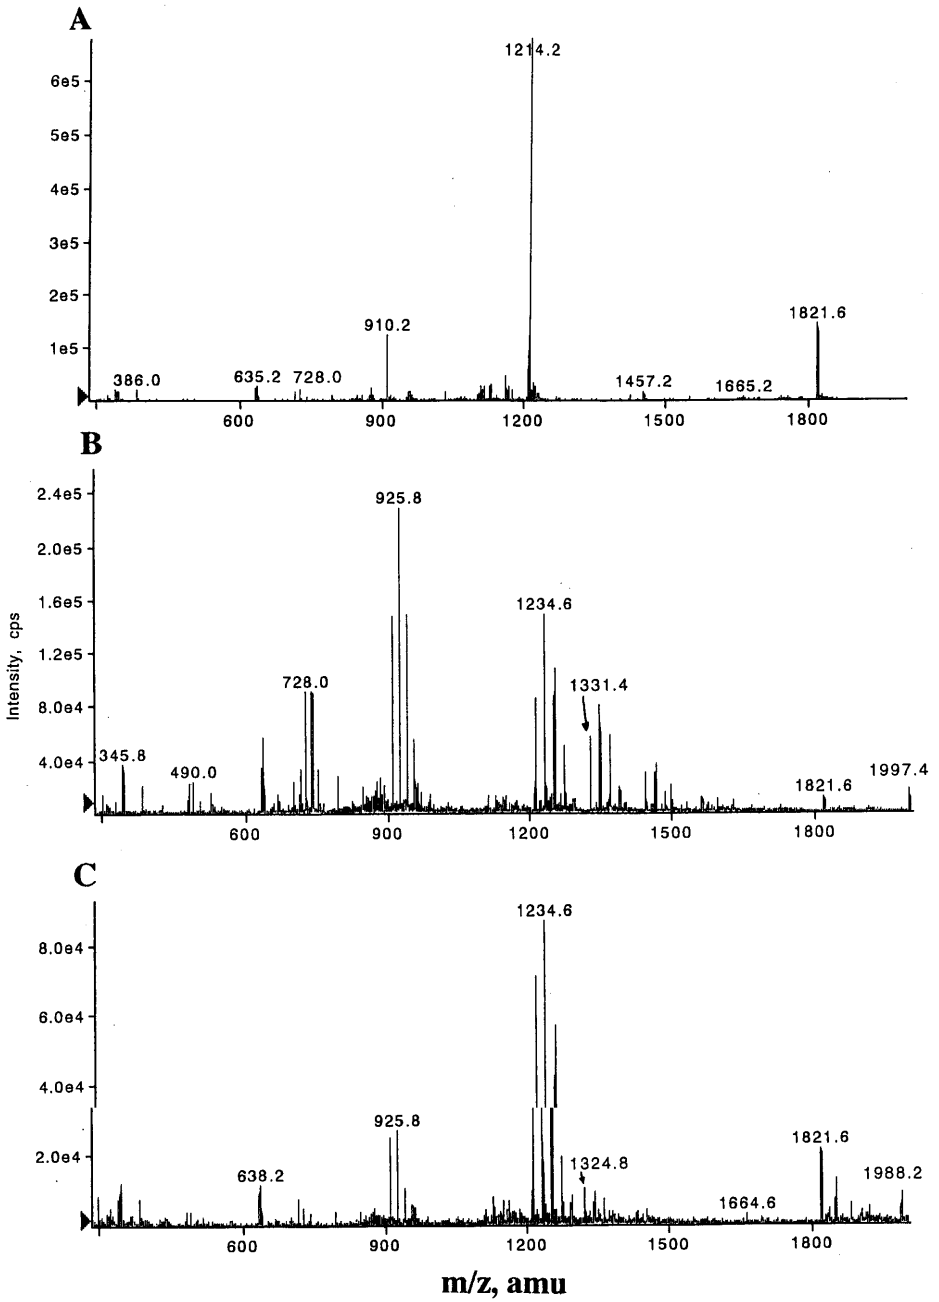

Fig. 5. ESI-mass spectra (negative pattern) of solutions containing 12-mer and copper(II) complex. (A): 12-mer; (B): 12-mer + [Cu(tpa)Cl]ClO_4; (C): 12-mer + [Cu(bdpg)Cl]Cl.

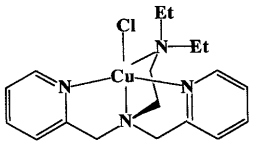
2.4. ESI-mass spectrometry



ESI-mass spectra were obtained with an API 3000 triple quadrapole mass spectrometer at the Institute for Molecular Science, Okazaki, Japan. At first, the solutions of a metal chelate (5 mM aqueous solution) and oligomer (300 μM aqueous solution) were prepared. The metal complex (6 μl) and oligomer (20 μl) solutions were then mixed, and the ESI-mass spectra of the solution was measured after the addition of ammonium acetate (2μl, 150 mM) and acetonitrile (30 μl).

3. Results and discussion

3.1. Structural features of copper(II) compounds

The crystal structure of [Cu(dmpy-py)Cl]$(ClO_4)_2$ is illustrated in Fig. 4; the copper(II) compound contains a tridentate *N*,*N*-bis(2-pyridylmethyl)amine moiety and chloride ion in the basal plane; in this compound the ligand contains a positive nitrogen atom as shown before and this positive nitrogen atom cannot coordinate to a copper(II) ion, leading to the square planar

four-coordinated species. In the case of *N*,*N*-diethylaminoethylamine, a tetradentate ligand (dtpy) is obtained, and from this a square pyramidal five-coordinated complex was prepared (see the figure below) [13].

(1)

[Cu(dtpy)Cl]$^+$

The structure of [Cu(bdpg)Cl]$^+$ is a square pyramide [7] and is similar to those of complexes with (dpgs), (dtpy), and others [5,7]. The [Cu(tpa)Cl]$^+$ is a trigonal bipyramide.

3.2. ESI-MS

The interaction between a metal compound and oligomer was extensively studied by Stubbe et al. by the use of NMR spectroscopy, especially for cobalt-bleomycins (Co-BLM) [14–16]. We have recently confirmed the binding of Fe-BLM towards several oligomers in terms of ESI-mass spectroscopy [17]. In this study, we have investigated the interaction between copper(II) chelate and oligomer (12- and 8-mers) in terms of the ESI-MS.

As shown in Fig. 5, we can observe several peaks in the ESI-mass spectra (negative pattern) of the 12-mer. Based on the calculated isotope patterns, the signals at $m/z = 1821.6$, 1214.2, 910.2, and 728.0 are attributed to (-2), (-3), (-4), and (-5) species of the single strand 12-mer. The signal at $m/z = 1457.2$ is due to (-5) species of the double-strand. When a copper(II) complex was added to the solution containing NH_4CH_3COO and 12-mer, new signals have appeared as shown in Fig. 5 traces B and C and also Table 3. Strong signals in the range $m/z = 1234.6$–1275 and 925.8–957 are due to species of acetic acid adducts of 1214.2 and 910.2 species, respectively (see also Table 3). The signals at $m/z = 1331.4$ and 1997.4 are due to [1:1] adduct of the Cu(II)–(tpa) complex and single-strand 12-mer, as determined by the calculated isotope patterns. Corresponding signals are observed at $m/z =$ 1324.8 and 1988.2 in the case of the (bdpg)-complex (see Fig. 5, trace C and Table 3). Analogous signals due to the 1:1 adduct have been observed for all the solutions containing a copper(II) complex (see Table 3). Although the peak intensity is very small, the signals due to species where 2 or 3 copper(II) complexes are bound to a single-strand chain are detected in the spectra (see Table 3). The results obtained for 8-mer (in the positive pattern) were illustrated in Fig. 6. The peaks at $m/z = 1205.6$, 1606.8 and 2409.4 may be attributed to $(+2)$, $(+3)$, and $(+4)$ species of the double-strand of 8-mer. The peaks at $m/z = 1381.2$ (trace B in Fig. 6) and 1371.0 (trace C in Fig. 6) can be assigned to the copper-bound species ([1:1] in single-strand, or [2:1] in the double-strand where two copper compounds are bound to the double-strand) for the Cu(II)–(tpa) and Cu(II)–(bdpg) complexes, respectively. In this case, the binding of multiple copper(II)

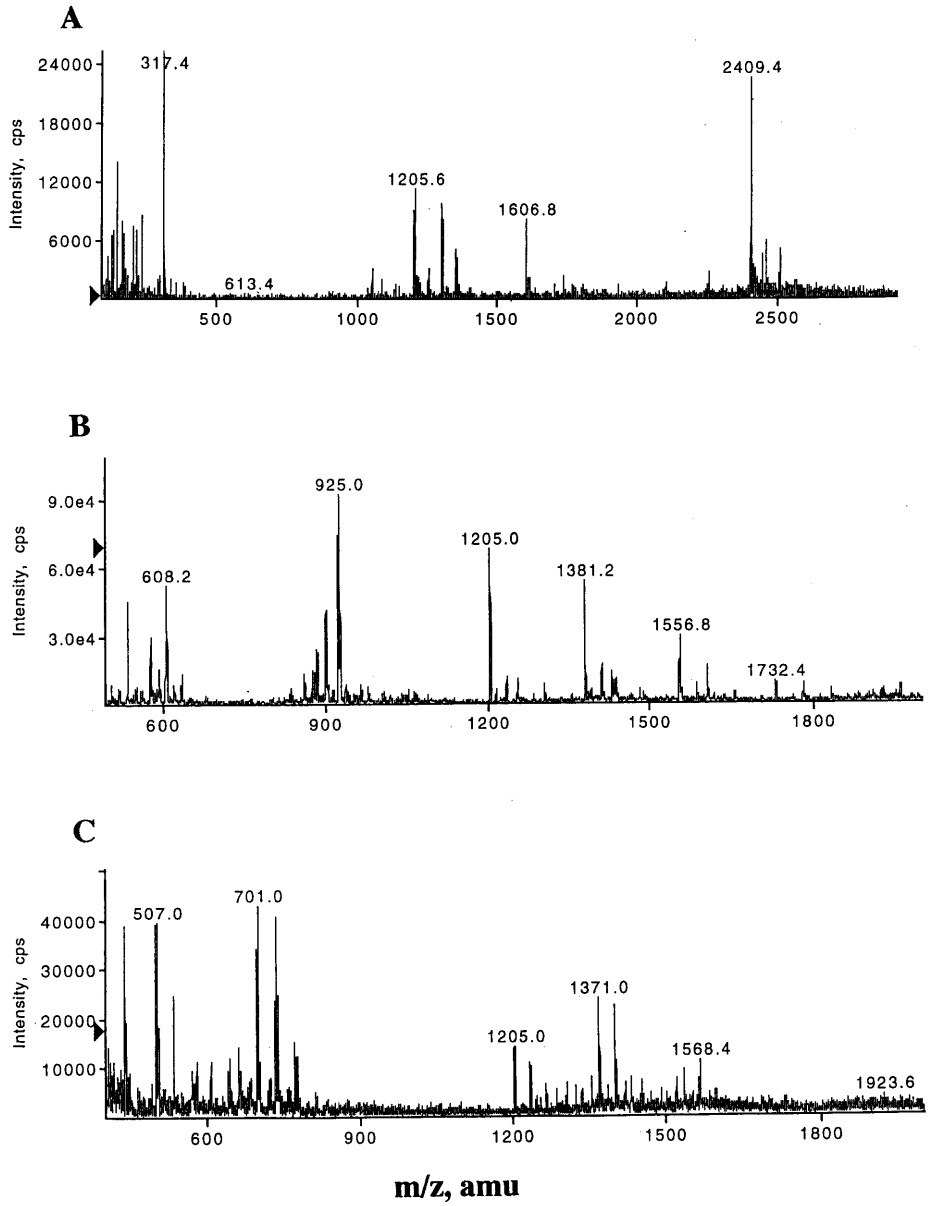

Fig. 6. ESI-mass spectra (positive pattern) of solutions containing 8-mer and copper(II) complex. (A): 8-mer; (B): 12-mer + [Cu(tpa)Cl]ClO_4; (C): 12-mer + [Cu(bdpg)Cl]Cl.

complexes towards a single-strand was also found (2 or 3 copper(II) complexes to single-strand; see Table 4). These clearly demonstrate that the copper(II) complexes used in this study show high affinity towards DNA strand at the oxygen atom of the phosphoric bridge (see Fig. 7), although its position is not specified by the compound as exemplified in the HPLC results described below.

When hydrogen peroxide was added to the solution containing a copper(II) complex and oligomer ($[H_2O_2]/[Cu^{2+}] = 10$), the ESI-mass spectrum remains unchanged in the case of [Cu(tpa)Cl]ClO_4 (see Fig. 8), but the main signals observed for the solution containing [Cu(bdpg)Cl]Cl and the oligomer have disappeared. In the latter case, the disappearance of the signals should be due to degradation of the oligomer by the addition of hydrogen peroxide; which is consistent with the results obtained in HPLC developed in the later section.

3.3. Release of nucleobases from oligomers and DNA cleavage reaction

As stated in the previous section [4,5] we have reported that the copper(II) complexes used in our

previous studies are divided into two types based on the activity for DNA (supercoiled) degradation, e.g. $[Cu(bdpg)Cl]^+$ and $[Cu(dpgs)Cl]^+$ effect the complete degradation of DNA (pBR322, supercoiled Form I), however $[Cu(tpa)Cl]^+$ and other compounds used in this study give only Form II DNA under the same experimental conditions. In order to get more detailed information on this problem, we have investigated the reaction between the copper(II) complex and oligomer in the presence of hydrogen peroxide, and the part of the results is represented in Fig. 2. According to the work by Hecht et al. [18] the Fe(III)–BLM–H_2O_2 system gives much cytosine and cytosine–propenal in the reaction with the 12-mer under aerobic conditions, and their result was reconfirmed in this study.

Table 4
Assignment of main peaks in ESI-mass spectra (m/z, positive pattern) of 8-mer (copper complex binds with DNA stand as+2 charged species with dissociation of chloride or perchlorate ions)

8-mer	2409.4	[double-strand+$2H^+$]$^{2+}$
	1606.8	[double-strand+$3H^+$]$^{3+}$
	1205.6	[double-strand+$4H^+$]$^{4+}$
8-mer+[Cu(tpa)Cl]ClO_4	1381.2	[(double-strand)+2Cu(II)-complex)]$^{4+}$

	1537.4	[(double-strand-$4H^+$) +4Cu(II)-complex)]$^{4+}$
8-mer+[Cu(dpgs)Cl]ClO_4	1363.6	[(double-strand) +2Cu(II)-complex)]$^{4+}$
	1523.0	[(double-strand-$4H^+$) +4Cu(II)-complex)]$^{4+}$
	1682.0	[(double-strand-$8H^+$) +6 Cu(II)-complex]$^{4+}$

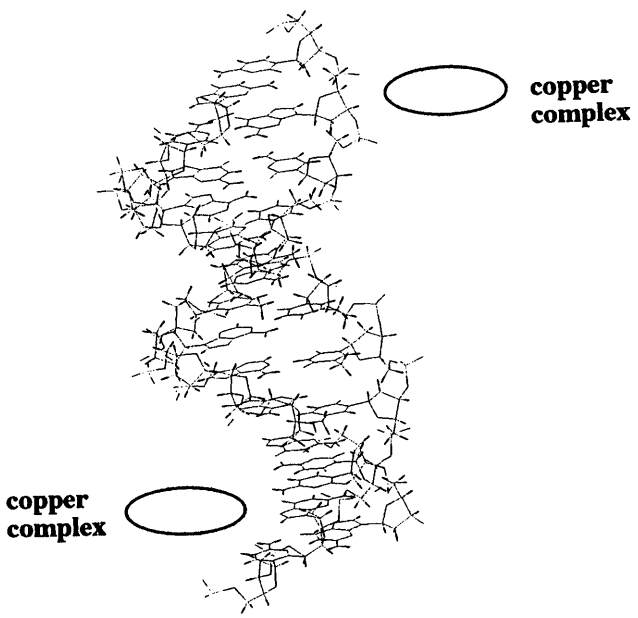

Fig. 7. Schematic illustration of binding of copper(II) complex to double-strand 12-mer.

We have found that the $[Cu(bdpg)Cl]^+$ complex gave large quantities of four nucleobases in the reaction with the 12-mer (see Fig. 9 and Table 2), however release of the free nucleic acids is much smaller in the cases of (tpa) and (dpgt), and other compounds (see Fig. 9). The formation of cytosine–propenal was not detected for all the copper(II)–H_2O_2 systems examined. The order of the activity to release the nucleic acids from 12-mer is as follows: (bdpg) > (dpgs) ≫ (dtpy) ∼ (dpgt) ∼ (dmpy-py) ∼ (tpa). The positive charge on the ligand of the (dmpy-py)-complex has little effect on the reaction. Similar results were found when other oligomers were used instead of 12-mer (see Figs. 10–12). The release of four nucleobases from 12-mer by the Cu(II)–(bdpg) complex indicates that this complex binds to 12-mer randomly; the binding position of the copper(II) complex is not specified by the chelate structure; this is quite different from that of Fe-BLM towards DNA. Since multiple binding of copper(II) complexes towards DNA single strand has no effect on the cleavage behavior of the copper(II) compounds (see the case of 8-mer in Table 2), it seems quite likely that the intrinsic active species for DNA cleavage is a monomeric copper species.

Based on the previous [5,19,20] and present results, and generally accepted proposal that the release of free nucleobases occurs through the formation of the 4′-hydroxylated form of the sugar moiety [1,21–24] it seems quite reasonable to consider that the remarkable activity of the (bdpg)-compound is due to its high electrophilic nature of a copper(II)–hydroperoxide adduct (see Scheme 2), whose formation is greatly promoted through hydrogen bonding with the amide–oxygen atom coordinated to the copper(II) atom, and this electrophilic copper(II)–peroxide adduct attacked to the sugar ring of nucleoside, to give the corresponding hydroxylated species, and from which free nucleobases have been released. The poor activities of other compounds to degrade the oligomers should be due to their negligible ability to form a peroxide adduct, as exemplified in many reactions [7,25]. These discussions clearly support our previous proposal that in the case of Cu-(tpa) complex, formation and activation of a copper(II)–peroxide adduct is assisted by the organic groups of supercoiled DNA chains (see Scheme 3), and that the reactivity of the peroxide adduct thus formed

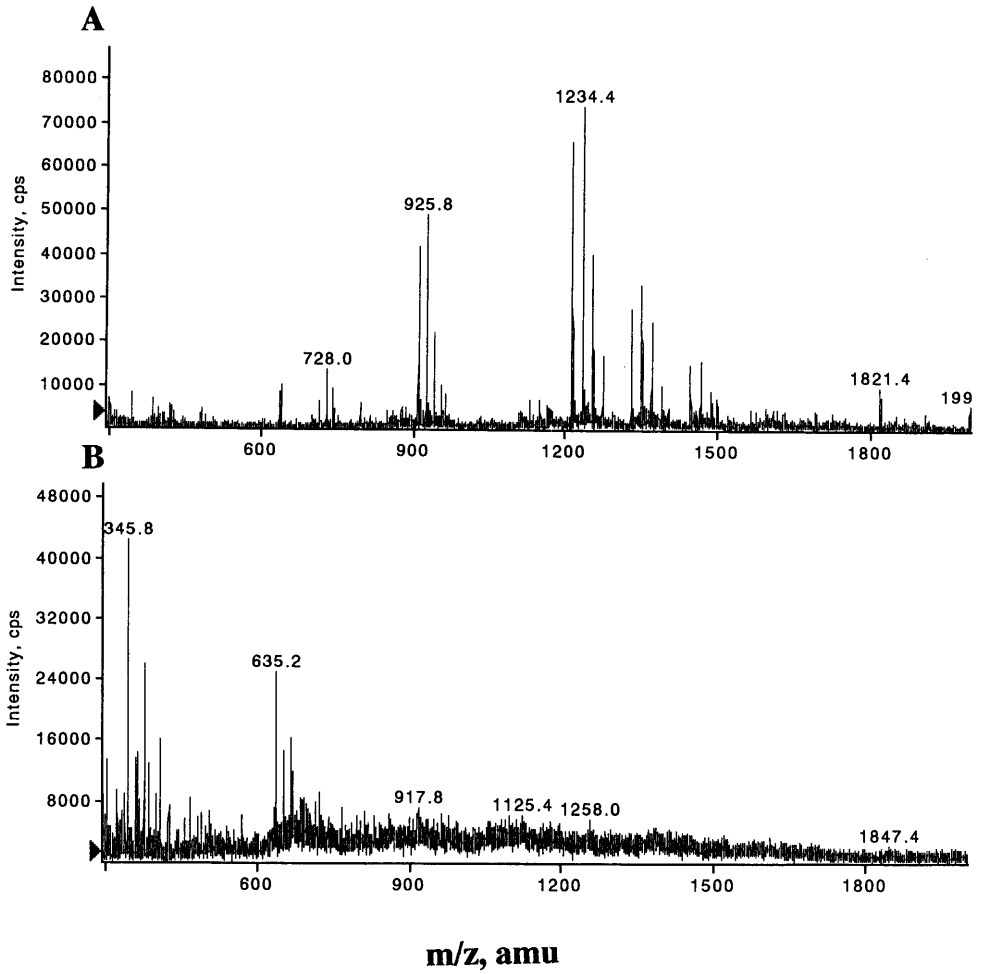

Fig. 8. ESI-mass spectra (negative pattern) of solutions containing 12-mer, copper(II) complex, and hydrogen peroxide. (A): $[Cu(tpa)Cl]ClO_4$; (B): [Cu(bdpg)Cl]Cl.

is quite different from that of the Cu–(bdpg) compound; the latter may explain the fact [4,5] that the $[Cu(bdpg)Cl]^+$ complex effects the complete degradation of DNA (pBR322, supercoiled Form I); however, $[Cu(tpa)Cl]^+$ complex gives only Form II DNA under the same experimental conditions.

Synthesis and characterization of two tris-chelate complexes of cobalt(III) with 3,5-dimethyl-1-(*N*-methyl/ethyl)thiocarbamyl-pyrazole (HL_1, HL_2) — biologically important bidentate ligands with one ambidentate donor site

Received 26 April 2000; accepted 2 August 2000

Abstract

Cobalt(III) complexes, of two potentially pyrazole-derived bidentate ligands (with one ambidentate donor site), 3,5-dimethyl-1-(*N*-methyl/ethyl)thiocarbamylpyrazole (HL_1 for *N*-methyl, HL_2 for *N*-ethyl) have been synthesized and characterized by elemental analyses, IR, UV–Vis and ^{1}H NMR spectral studies. The structure of $Co(L_2)_3$ has been determined by single-crystal X-ray diffraction studies. The complex (triclinic, space group $P\bar{1}$) has a distorted octahedral structure with the ambidentate ligands coordinated to the Co(III) ion as uninegative bidentate chelating agents via the pyrazole ring nitrogen (tertiary) and the thiocarbamyl iminyl nitrogen atoms. The distortion from the regular octahedral geometry is ascribed to the stereochemical limitations imposed by the planar bidentate ligands. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Cobalt(III) complex; Thiocarbamylpyrazole; Spectroscopic study; X-ray crystal structure

1. Introduction

The well-documented bio-activity of pyrazole-derivatives often ascribed to the chelation phenomena [1,2] with trace metal ions has generated a significant growth of literature in the coordination chemistry of pyrazole-derived ligands, amply reflected through review articles of Trofimenko [3–5]. In continuation of our recent report [6] on the synthesis and structural characterization of Cu(II) and Ni(II) complexes with 3,5-dimethyl-1-(*N*-methyl/ethyl) thiocarbamylpyrazole, (HL_1, HL_2, respectively, Fig. 1), the present communication aims at reporting the synthesis and spectroscopic characterization of two cobalt(III) complexes with the same ligands (HL_1, HL_2) together with X-ray crystal structure studies of $Co(L_2)_3$. However, while in the $Ni(L_2)_2$ complex [6] the two ligand molecules in their deprotonated forms bind individually, the Ni(II) ion through the pyrazole ring nitrogen (tertiary) and thiolato sulfur (of thiocarbamyl group), the present Co(III) species have their individual three deprotonated ligands bonded through the expected ring nitrogen (Pz ring) and iminyl nitrogen (of thiocarbamyl group) to the central metal ion. Thus the ambidentate nature of the ligands at their thiocarbamyl end is finally established through the supportive evidence of the crystal structure analysis of the present $Co(L_2)_3$ complex (Fig. 2).

2. Experimental

2.1. Chemicals

Solvents and reagents were obtained from commercial sources and used without further purification. Spectrograde solvents were used for spectral and conductance measurements. $CDCl_3$ (Aldrich) was used for recording ^{1}H NMR spectral data.

2.2. Preparation

The ligands 3,5-dimethyl-1-(*N*-methyl)thiocarbamylpyrazole [HL_1] and 3,5-dimethyl-1-(*N*-ethyl)-thiocarbamylpyrazole [HL_2] were synthesized and characterized according to the method as described in our recent report [6].

The metal complexes were prepared by reacting an ethanolic solution (15 cm^3) of $CoCl_2 \cdot H_2O$ (1.19 g, 0.005 mol), with an ethanolic solution (15 cm^3, 0.015 mol) of the appropriate ligand. The pH of the solution was adjusted to approximately 8 by dropwise addition of dilute ammonia (1:1) solution. The result was a dark red (for HL_1) and an orange–red (for HL_2) solution, and after concentration at water-bath temperature, this afforded a dark red compound (for HL_1) and an orange–red compound (for HL_2) approximately 70% in each case. The compounds were collected by filtration, washed with cold ethanol and dried over fused calcium chloride. The X-ray quality crystals for $Co(L_2)_3$ were grown by slow evaporation of an acetonitrile solution of the complex at room temperature.

The different instrumental techniques used for characterization of the compounds have been described in our earlier reports [6,7]. Analytical data are presented in Table 1.

2.3. Crystallography

A single crystal of dimensions ($0.4 \times 0.6 \times 0.4$ mm) of the complex, $Co(L_2)_3$ was selected and mounted on an automatic Enraf–Nonius CAD-4 diffractometer equipped with a graphite monochromator and Mo Kα radiator ($\lambda = 0.71013$ Å). Unit-cell dimensions and intensity data were measured at 293 K.

The structure was solved by direct methods refined by full-matrix least-squares based on F^2 with anisotropic thermal parameters for non-hydrogen atoms using XCAD-49 (data reduction) and SHELXTL (absorption correction, structure solution/refinement and molecular graphics). The H-atoms were included in structure factor calculations in their idealized positions. The crystallographic data are summarized in Table 3 and the final positional parameters are available as supplementary material (see Section 5).

3. Results and discussion

When $CoCl_2 \cdot 6H_2O$ in ethanol was stirred with the title ligands HL_1 and HL_2 in air, (the pH was approximately 8, made by dilute ammonia solution), an immediate color change took place demonstrating a facile complex formation reaction. The most probable oxidizing agent in these syntheses is dioxygen. However, no attempt was made to monitor the metallation reaction under strictly anaerobic conditions.

These cobalt(III) complexes were isolated as dark red and orange–red microcrystalline solids which were highly soluble in polar organic solvents. The molar conductance values for the complexes in methanol indicate their nonelectrolytic nature. The complexes are diamagnetic as expected for a spin-paired d^6-ion.

3.1. Spectral studies

The breathing motion of the pyrazole ring is shifted to a higher frequency upon complexation and is consistent with pyrazole ring nitrogen (tertiary) coordination. Coordination of the pyrazole ring nitrogen to cobalt(III) is further suggested by the shift of the ν(C=N) band (at 1585 cm^{-1} for HL_1 and at 1560 cm^{-1} for HL_2) to higher frequency by 5–15 cm^{-1} upon complexation along with the occurrence of the ν(Co–N) band at 265 cm^{-1} in the complexes. This also conforms with our earlier report [6]. The disappearance of the broad ν(N–H) band at 3390–3210 cm^{-1} in the free ligand spectra after complexation suggests that deprotonation of the ligand takes place prior to the metallation reaction. The thioamide I band (at 1255 cm^{-1} for HL_1 and at 1260 cm^{-1} for HL_2), which contains considerable ν(C=S) character, is of the same intensity in the complexes and is found almost at the same frequency, suggesting noncoordination of the metal through sulfur after deprotonation. Participation of the thiocarbamyl iminyl nitrogen in coordination is indicated by a red-shift of 10–15 cm^{-1} of the ligand ν(C–N) mode (1570 cm^{-1} for HL_1 and at 1545 cm^{-1} for HL_2) of the thioacetamide II band [8,9] after complexation. The band at approximately 260 cm^{-1} in both complexes in their far IR spectra indicated the presence of ν_{Co-N} (thiocarbamyl).

The visible absorption spectra of the Co(III) complexes may be expected theoretically to consist of transitions from the $^1A_{1g}$ ground state to other singlet states [9,10]. Although the entire energy-level pattern is not known in greater detail, usually the complex species of Co(III) give rise to two spin-allowed and two spin-forbidden ligand field bands in the solid-state spectrum of an authentic Co(III) octahedral species [11,12]. However, the diffuse reflectance spectra of the complexes, under discussion, consist of only one broad band at approximately 24 000 cm^{-1} corresponding to one spin-allowed transition ($^1A_{1g} \rightarrow {}^1T_{2g}$) for the low-spin Co(III) octahedral species. Methanolic solutions of the complexes, in addition to showing the intra-ligand charge transfer band at approximately 33 000 cm^{-1} ($\varepsilon \sim 21\,000$ l cm^{-1} mol^{-1}), display an $N \rightarrow Co^{III}$ charge-transfer transition (LMCT) at approximately 25 300 cm^{-1} ($\varepsilon \sim 3\,500$ l cm^{-1} mol^{-1}). In the electronic spectra of the present complexes, however, no d–d band is observed, probably due to the intrusion of tails of intense charge-transfer bands into the visible portion of the spectra which masks the expected d–d bands.

Table 2 represents a listing of the ^1H NMR assignments for both the ligands (HL_1 and HL_2) and their Co(III) complexes in order to have supportive evidence regarding the bonding sites of the ligands towards the Co(III) ion which has also been inferred from IR spectral studies as previously discussed. The disappearance of the broad singlet at δ 9.18 (for HL_1) and 9.07 (for HL_2) in the free ligand upon complexation strongly suggests that deprotonation of the iminothioketo form of the free ligands takes place during the complexation process. The C_4–H (ring) signal in the complex is shifted downfield from its original position in the uncomplexed ligand upon coordination of the tertiary nitrogen of the pyrazole ring, which reduces electron density at C_4 (ring Pz). The coordination of the pyrazole ring nitrogen is further substantiated by the shifting of both C_3– and C_5–CH_3 protons towards the lower fields as shown in Table 2. Coordination of the uninegative nitrogen atom of the –C(S)–$\overset{\ominus}{N}$–R group (R = CH_3 for HL_1 and CH_3–CH_2– for HL_2) to the central Co(III) ion is substantiated by the deshielding of the primary –CH_3 protons for HL_1 and both secondary and primary (–CH_3) protons of HL_2 bonded to the coordinating

iminyl nitrogen. In the case of the $Co(L_2)_3$ complex, the $–CH_2–$ protons being relatively close to the above donor site in the complex suffer a relatively higher amount of downfield shift ($\delta = 0.44$ ppm) than the $–CH_3$ protons ($\delta = 0.31$ ppm) which is as a result of being positioned one carbon away from the donor N atom. ^{1}H NMR spectra thus provide tacit support for the bonding characteristics of the primary ligand (HL_1/HL_2) in forming complexes with cobalt(III) through pyrazolyl ring nitrogen (^{2}N) and the iminyl nitrogen of the substituted thiocarbamyl group.

3.2. Description of the crystal and molecular structure of the $Co(L_2)_3$ complex

A perspective view of the complex together with the atom numbering scheme is shown in Fig. 2. Selected bond lengths and bond angles are listed in Table 4. The compound consists of a discrete mononuclear $[Co(C_8H_{12}N_3S)_3]$ neutral unit. The cobalt(III) ion in the complex, $Co(L_2)_3$ is in a six-coordinate environment of six nitrogen atoms from the three ligand molecules to form a CoN_6 chromophore. Each ligand molecule behaves as a bidentate *N*,*N*-chelating agent via the pyrazolyl ring nitrogen atom and the thiocarbamyl nitrogen atom. The ligands are present as singly deprotonated bidentate ones. The deprotonation, which actually takes place from the imino nitrogen of the thiocarbamyl group, is not accompanied by tautomerisation to the 'thiol' form. For the sake of convenience, these three molecules of the ligand are designated as ligand **1**, ligand **2** and ligand **3**, and the individual atoms in the ligand are identified with suffix **1**, **2** and **3** where necessary.

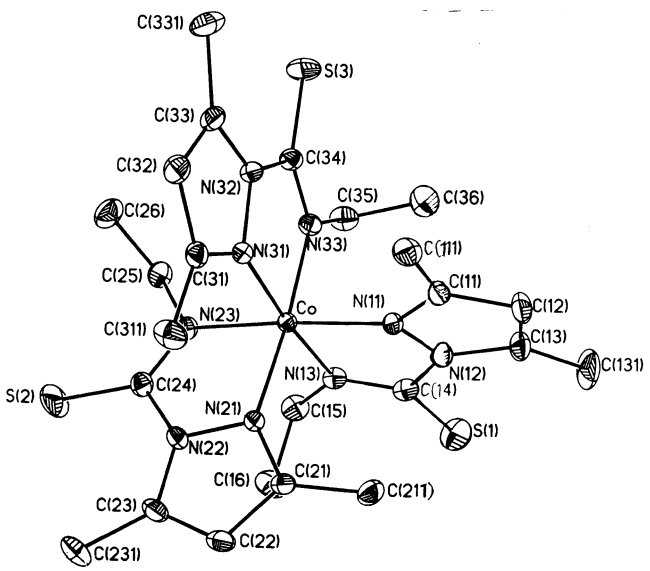

Fig. 2. A perspective view of the complex $Co(L_2)_3$ showing atom numbering scheme.

The cobalt atom is in an octahedral environment, with similar types of donor atom (either pyrazolyl N or thiocarbamyl N) from three ligand molecules occupying a facial plane. The best description of the geometry around cobalt is obtained when N(13), N(21), N(31) and N(33) are considered to form a square plane and N(11) and N(23) act as axial donor sites. Angles generated at the Co(III) center by the chelating donor points (pyrazolyl N and thiocarbamyl N) differ slightly in the three coordinating ligands (Table 4). It appears that the angles at the Co(III) center in the chelate rings are controlled to some extent by the ligand geometry. The coordination sphere of the cobalt atom in the present complex may be considered as a distorted octahedron. The twelve angles subtended at the Co(III) ion by the adjacent donor atoms range from 81.25(8) to 96.28(8)° compared to 90° required for a perfect octahedron. This distortion from the idealized geometry may be attributed to the restricted bite angles imposed by the planar bidentate ligands. From the study of all the bond angles around the central cobalt atom, it is evident that except for the three angles (viz., N(11)–Co–N(33), N(13)–Co–N(21) and N(23)–Co–N(31) angles, 88.29(8), 88.19(8) and 88.08(8)°, respectively) no other angles in this six-coordinated cobalt(III) complex are close to idealized values expected for a regular octahedral geometry, indicating that distortion is a common phenomenon in tris-ligand cobalt(III) complexes of planar *N*,*N* bidentate chelating agents. The average Co^{III}–N(pyrazole) distance in the complex is the same within experimental error, the average value being 1.934(2) Å. The average Co^{III}–N(thiocarbamyl) length is 1.931(2) Å which is close to the Co^{III}–N(pyrazole) length. The observed average Co–N bond distance is, however, shorter than that (1.947 Å) found in the complex $[Co(L4M)_2]BF_4$ [13] (L4M = anion (loss of ^{3}N proton) of 2-acetylpyridine-^{4}N-methylthiosemicarbazone) and longer than that (1.918 Å) in the complex $[Co(MPzSB)_2]Cl$ [14]

(MPzSB = anion (loss of ^{3}N proton) of *S*-benzyldithiocarbazate of 5-methyl-3-formyl pyrazole). For the ligand moiety, the interatomic distances and angles are within normal ranges.

4. Conclusion

In continuation of our earlier report [6], this study reports the characterization of cobalt(III) complexes with two potentially bidentate pyrazole-derived ligands with one ambidentate donor site at the thiocarbamyl part. Since the substituted thiocarbamyl sites function as ambidentate donor, the mode of binding to different metal ions depends upon the relative softness or hardness of the metal ions. The difference in the ligational behavior at the thiocarbamyl part towards Ni(II) and Co(III) ions is reasonably ascribed to a strong coordination of harder base N (of thiocarbamyl part) with harder Co(III) ion and that of softer base S with softer Ni(II) ion.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic, CCDC No. 141946 for compound $Co(L_2)_3$. Copies of this information may be obtained free of charge from The Director, CCDC, Data Center, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk).

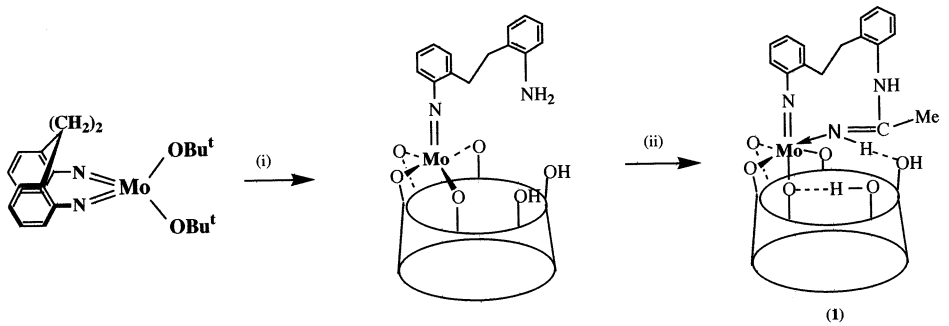
Abstract

Treatment of *p-tert*-butylcalix[6]areneH_6 (H_6L) with $[Mo(OBu^t)_2\{[2,2'\text{-}(N)\text{-}C_6H_4]_2(CH_2CH_2)\}]$ in refluxing toluene affords, after work-up, the complex $[Mo(2\text{-}NC_6H_4CH_2CH_2C_6H_4NHC(Me)NH\text{-}2')LH_2]\cdot 4MeCN$ (**1**), which contains an 11-membered metallocyclic ring as characterised by Synchrotron X-radiation. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: 11-Membered metallocyclic ring; Synchrotron radiation; Metallocalix[6]arene



The chemistry of transition metal complexes of the simplest of the calixarenes, the calix[4]arene system, is relatively well developed [1]. In general, these complexes retain the cone-like conformation of the parent ligand [2]. By contrast, transition-metal compounds containing the larger ring systems are still quite rare [3], presently being restricted to W (calix[5]), and Ti (calix[6]), Pt, Pd, Re (diphosphinite of calix[6]) and Zr, Ti, V, Mo (calix [6] and [8]). In recent work we have been investigating routes to imidometal calixarenes, for example, treatment of $[Mo(NAr)_2(OBu^t)_2]$ ($Ar = C_6H_3Pr^i_2\text{-}2,6$) with calix[4]arene$H_4$ (H_4L^1) and calix[8]areneH_8 (H_8L^2) affords, via alkoxide and imido displacement reactions, the novel mono and dimetallocalixarene complexes $[Mo(NAr)L^1(NCMe)]$ and $[\{Mo(NAr)(NCMe)\}_2L^2]$, respectively [4]. Since we had already characterised the first chelating or *ansa* bis(imido) metal derivatives [5], we chose to prepare a range of metallocalix[n]arene species with pendant amino functionalities utilising the bis(imido) complex $\{Mo(OBu^t)_2[(2\text{-}NC_6H_4)_2CH_2CH_2]\}$ and the alkoxide/imido displacement methodology. Here we describe a novel metallocalix[6]arene complex $[Mo(2\text{-}NC_6H_4CH_2CH_2C_6H_4NHC(Me)NH\text{-}2')LH_2]$ (**1**), containing an 11-membered metallocyclic ring formed on intramolecular insertion of the pendant amino group into a molybdenum–acetonitrile bond.

Treatment of the chelating bis(imine) complex $[Mo(OBu^t)_2\{[2,2'\text{-}(N)\text{-}C_6H_4]_2(CH_2CH_2)\}]$[5] with H_6L in toluene affords, after work-up, the complex $[Mo(2\text{-}NC_6H_4CH_2CH_2C_6H_4NHC(Me)NH\text{-}2')LH_2]$ (**1**)[1]. Stoichiometrically, **1** is formed via loss of two molecules of *tert*-butanol followed by proton transfer to N(2) to release a pendant amino group – see Scheme 1. The intermediate formed prior to the addition of acetonitrile must therefore contain two phenolic groups. The IR spectrum of this intermediate contains a broad feature (weak) in the ν(N–H) region (3364 cm^{-1}) together with a strong ν(C–N) stretch at approximately 1270 cm^{-1}. A second broad feature at 3124 cm^{-1} is assigned to ν(OH), which appears as a broad singlet (integrating to 2 H) at δ 10.38 ppm in the ^{1}H NMR (C_6D_6). Following addition of acetonitrile, an intramolecular insertion of the pendant NH_2 group into a molybdenum–acetonitrile bond, in an analogous fashion to the reaction of $[ReCl_4(NCMe)_2]$ with aniline [6], results in

[1] Satisfactory elemental analyses have been obtained. $[Mo(OBu^t)_2\{[2,2'\text{-}(N)\text{-}C_6H_4]_2(CH_2CH_2)\}]$[4] (1.0 g, 2.22 mmol) and *p-tert*-butylcalix[6]areneH_6 (2.1 g, 2.16 mmol) were refluxed in toluene (40 cm^3) for 12 h. After allowing to cool to room temperature, the volatiles were removed under reduced pressure and the residue extracted with MeCN (30 cm^3). Prolonged standing at ambient temperature afforded small red–brown prisms (0.89 g, 28%). Selected spectroscopic data for **1**: ^{1}H NMR ($CDCl_3$, 298 K): δ 4.94 [d, $^2J_{HH}$ 12 Hz, $ArCH_2Ar$], 4.73 [d, $^2J_{HH}$ 14 Hz, $ArCH_2Ar$], 4.45 [d, $^2J_{HH}$ 13 Hz, $ArCH_2Ar$], 3.48 [d, $^2J_{HH}$ 12 Hz, $ArCH_2Ar$], 3.38 [d, $^2J_{HH}$ 14 Hz, $ArCH_2Ar$], 3.13 [d, $^2J_{HH}$ 14 Hz, $ArCH_2Ar$]. IR: ν(NH) 3350w(sh), ν(OH) 3132, 3124bs, ν(C=N) 1628s, ν(Mo–O) 825, 800m.

Scheme 1. Reagents and conditions: (i) H_6L, toluene, reflux, 12 h; (ii) MeCN, ~72 h.

an amidine ligand bound to the metal centre through the imine nitrogen. Small crystals of **1**, only suitable for an X-ray diffraction analysis using synchrotron radiation[2] [6], were grown from acetonitrile at room temperature in approximately 30% yield. The molecular structure is shown in Fig. 1, with selected bond lengths and angles given in the caption. The core geometry is best described as distorted octahedral with angles ranging from 83.7(3) to 96.2(3)°. The bite angle [N(1)–Mo(1)–N(3)] of the metallocyclic ring is 94.4(3)°, the conformation of which is somewhat folded with the aromatic rings approximately coplanar and separated by a CH_2CH_2 step. The distance of 1.742(8) Å for the Mo(1)–N(1) bond and 1.388(11) Å for the N–C(*ipso*) bond, combined with Mo(1)–N(1)–C(1) angle of 173.1(7)°, are consistent with a linear arylimido ligand, which is reflected in the long *trans* Mo(1)–O(4) bond length [2.051(6) Å versus 1.905(6) for O(2), 1.953(6) for O(1) and 1.989(6) Å for O(3)]. The amidine(imine) to Mo bond length [2.162(8) Å] is indicative of a dative bond, hence indicating a formal +VI oxidation state for the molybdenum centre. The macrocycle (L^1) adopts a severly twisted 'hump-like' or partial cone

[2] X-ray crystallography. Crystal data for **1**·4MeCN ($C_{82}H_{97}MoN_3O_6{\cdot}4C_2H_3N$), $M = 1480.78$, monoclinic, space group $P2_1/c$, $a = 28.412(3)$, $b = 11.3105(14)$, $c = 25.466(3)$ Å, $\beta = 94.651(3)°$, $V = 8156.7(16)$ Å^3, $T = 160$ K, $Z = 4$, μ (Mo Kα) $= 0.218$ mm^{-1}, crystal size $0.02 \times 0.06 \times 0.12$ mm, 43 324 data measured of which 15 738 were unique, $R_{int} = 0.125$, all unique data used in refinement against F^2 values to give final $wR = 0.3523$ (on F^2 for all data), $R = 0.1339$ {for 9320 data with $F^2 > 4\sigma(F^2)$}. Silicon 111 monochromated Synchrotron radiation ($\lambda = 0.6878$ Å) at Daresbury SRS Station 9.8 was used as described previously [6]. Twofold positional disorder was modelled with restraints for some calixarene *p*-^{t}Bu groups.

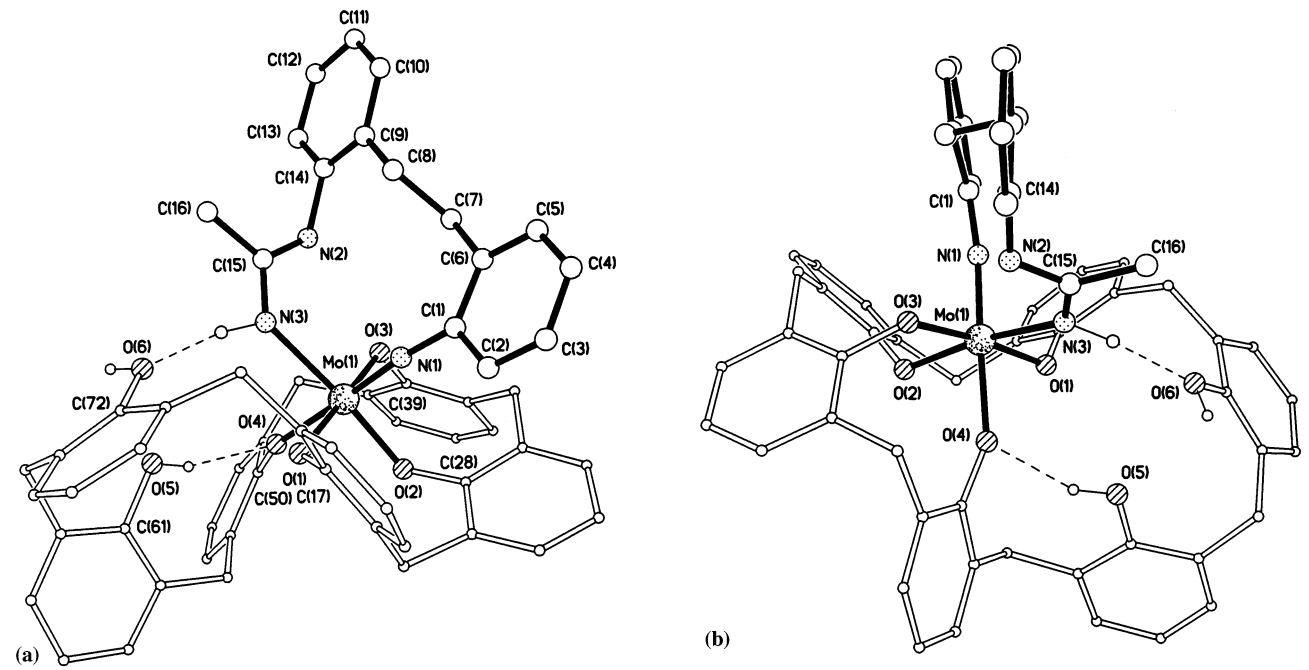

Fig. 1. (a) Molecular structure of **1**. Selected dimensions (Å and °): Mo(1)–N(1) 1.742(8), Mo(1)–N(3) 2.162(8) 2.162(8), Mo(1)–O(1) 1.953(6), Mo(1)–O(2) 1.905(6), Mo(1)–O(3) 1.989(6), Mo(1)–O(4) 2.051(6); Mo(1)–N(1)–C(1) 173.1(7), M0(1)–N(3)–C(15) 133.2(6). (b) Molecular structure of **1** showing the stepped geometry of the *N*,*N*-chelate ligand. Selected H-bond dimensions (Å and °): O(4)···H 1.90, O(6)···H 1.91; O(5)–H···O(4) 157, N(3)–H···O(6) 169.

(up-up-out) conformation, only previously seen for the palladium(II) chloride complex $[PdCl_2L^1P]$ (where L^1P is a calix[6]arene derived diphosphite) [3b]. The phenolic protons of O(5) and O(6) are involved in intramolecular H-bonding with O(4) and N(3), respectively, which results in the lowered stretching constants for ν(PhO–H) (see caption to Fig. 1(b) for H-bond geometry).

Received 28 June 2000; accepted 30 August 2000

Abstract

Nickel(II) complexes of the tripodal ligand (MPz_3tren) of the general formula $[Ni(MPz_3tren)]X_2\cdot nH_2O$ (X = Cl, Br, NO_3, ClO_4 and BF_4; $n = 0$ for Cl and Br; $n = 0.5$ for NO_3, ClO_4 and BF_4) have been prepared by template methodology and characterised by elemental analyses, magnetic susceptibility and conductivity measurements at RT, IR and electronic spectra. The molar conductivities measured in MeOH for all the complexes show them to be 1:2 electrolytes. The hexadentate character of the ligand in all the complexes is inferred from IR spectral studies. The electronic spectra in solid state and in MeOH solution suggest octahedral geometry for all the complexes. The structure of $[Ni(MPz_3tren)](BF_4)_2\cdot 0.5H_2O$ has been determined by single-crystal X-ray diffraction studies (monoclinic, $c2/c$). Nickel(II) is in a trigonal antiprismatic N_6 donor environment and the crystal structure is stabilised by a network of strong H-bonding. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Ni(II) complexes; Tripodal ligand; Crystal structures; Spectroscopic studies

1. Introduction

Currently, there is a growing interest in defining the coordination chemistry of tripodal ligands [1–4]. Transition metal complexes with these ligands display special physical, chemical or structural properties, such as unusual conformation, high thermodynamic stability and virtual kinetic inertness. Furthermore, these ligands can serve as precursors to the synthesis of interesting macrobicyclic [5,6] compounds which usually require high-dilution techniques [7] or the use of metal ions as templates [8,9] for their formation. We have synthesised the present hexadentate tripodal ligand with six nitrogen donor sites in situ following a method that does not employ high-dilution conditions. The title tripodal ligand upon formation of the octahedral complexes by wrapping around the metal ion leaves an open face with three groups positioned in such a way that it may be capped by suitable reagents. One of the advantages in this procedure is that the donor atoms as well as the substituents in the tripodal arms may be varied which may result in tuning the shape of the metal-ion containing cavity described by the resulting macrobicyclic ligands. The conformations of the complexes formed by these ligands must be influenced by the balance between a number of factors including (a) the electronic configuration and size of the metal ion, (b) the geometric and electronic properties of the ligand and (c) the repulsions between atoms in different ligand arms.

Complexes of metal ions with pyrazole-derived ligands are of great importance in part because of their pharmacological interest [10]. The publication of several reviews and books covering various aspects of pyrazole-derived ligands is witness to the great importance attached to them [11–14]. Most of the metal chelates of tripodal ligands have been derived from Tren [tris(2-aminoethyl) amine] and pyridine containing carbonyl compounds. However, no work has been initiated on the metal chelates of similar ligands derived from Tren and 5-methyl-pyrazole-3-carbaldehyde. In the present paper, we report the synthesis and characterisation of a few nickel(II) complexes of tris[4-(3-(5-methylpyrazole)-3-aza-3-butenyl]amine (henceforth abbreviated as MPz_3tren, Fig. 1). The structural aspects of these complexes are confirmed by the X-ray crystallographic studies on a representative complex, $[Ni(MPz_3tren)](BF_4)_2{\cdot}0.5H_2O$.

2. Experimental

All physical measurements and analytical procedures were similar to those described previously [15,16].

2.1. Preparation of the complexes

A template methodology by interaction of the reactants viz., 5-methylpyrazole-3-carbaldehyde and Tren in the presence of nickel(II) salts has yielded the reported metal chelates. A 20 cm^3 methanolic solution of 5-methylpyrazole-3-carbaldehyde (0.003 mol, 0.33 g) was refluxed with a 10 cm^3 methanolic solution of Tren (0.001 mol, 0.146 g) for 2 h. Divalent nickel salt (0.001 mol) dissolved in a minimum quantity of methanol (10 cm^3) was added to the refluxing mixture, discontinuing the reflux further. A few drops of methanolic solution of ammonia were also added to the mixture to adjust the pH to approximately 8. The solution was stirred continuously for 2–3 h at room temperature (r.t.). The mixture was filtered and concentrated to half of its original volume and kept at r.t. for slow evaporation for 3 days. The complexes were filtered, washed with cold methanol and dried over fused $CaCl_2$.

The blue–violet crystals, so isolated for $[Ni(MPz_3tren)](BF_4)_2{\cdot}0.5H_2O$ were found to be suitable for X-ray diffraction studies.

2.2. X-ray crystallography

The crystal, a blue–violet prism of approximate dimensions $0.42 \times 0.60 \times 0.58$ mm was measured on an Enraf-Nonius CAD-4 diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) and a graphite monochromator at -80°C. The unit cell dimensions were obtained from a least-squares fit to the setting angles of 25 accurately determined reflections. The data were collected using the ω–2θ scan technique with a 2θ range of 4–55° and were corrected by an empirical method for absorption and Lorentz and polarisation effects. Calculations were carried out using XCAD-49 (data reduction), SHELXTL (absorption corrections, structure solution refinement and molecular graphics). Crystal data and details of data collection are listed in Table 1.

The structure was solved using direct methods and refined on F^2 by full-matrix least-squares techniques with anisotropic displacement factors for all non-hydrogen atoms. The positions of the hydrogen atoms were calculated from the geometry of the molecular skeleton and their thermal displacement parameters were refined isotropically on a groupwise basis. Selected bond lengths and angles for the complex are reported in Table 2.

3. Results and discussion

3.1. Crystal structure of $[Ni(MPz_3tren)](BF_4)_2\cdot 0.5H_2O$

A perspective view of the complex $[Ni(MPz_3tren)](BF_4)_2\cdot 0.5H_2O$ is shown in Fig. 2. The structure consists of a $[Ni(MPz_3tren)]^{2+}$ cation and a BF_4^- anion. In the crystal structure the potentially heptadentate MPz_3tren ligand coordinates to the metal through the three imine and the three pyrazole nitrogen atoms. Three imine nitrogen atoms are at the vertices of one equilateral triangle and three pyrazole nitrogen atoms are at the vertices of another. Another similar type tripodal ligand tris[4-(2-pyridyl)-3-aza-3-butenyl]amine(Py_3tren) which has also six potential N-donor sites (except the bridgehead one) has been found [17] to bind nickel(II) in a similar fashion. Among the distances from the metal to the seven potentially ligating atoms, the tertiary amine N(7) is longer. Thus, the direct interaction between N(7) (bridgehead) and the metal ion is small compared to the interactions with the other six nitrogen atoms [18].

The coordination polyhedron of the said complex is best described as trigonal antiprism (TAP). Even that is not a perfect description because there is some trigonal distortion (rotation of opposing triangular faces tending towards a trigonal prism) of the complex. The σ-only ligand field splitting pattern for a trigonal antiprism (D_3) consists of three levels a_1 (d_z^2), 1e ($d_{x^2-y^2}$, d_{xy}) and 2e (d_{xz},d_{yz}). The lone pair of the tertiary nitrogen atom (bridgehead, i.e. N7) capping the trigonal antiprismatic face interacts directly with the a_1 orbital. The Ni–N(7) distance (3.275 Å) in the complex is 0.125 Å longer than the sum of the van der Waal's radii ($r_{Ni-VDW} + r_{N-VDW} = 3.15$ Å) and the

N(2CB)···F(11A)	2.803
O(1WA)···F(12A)	2.743
Ni–N(bridgehead, OB)	3.27

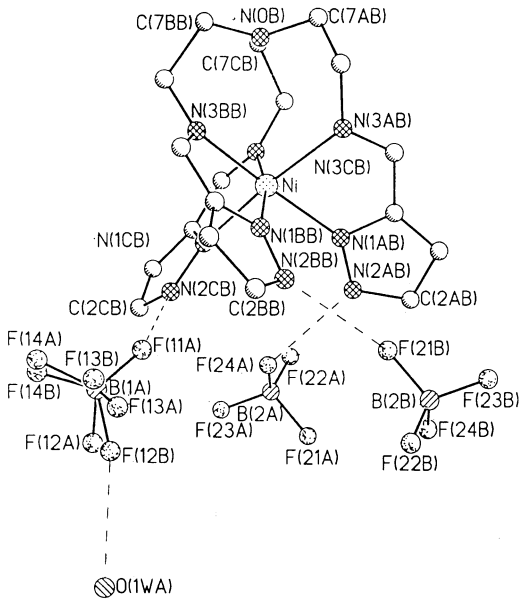

Fig. 3. A portion of the packing diagram of the $[Ni(MPz_3tren)](BF_4)_2 \cdot 0.5H_2O$ showing hydrogen bonding as dotted lines.

bridgehead nitrogen is thus uncoordinated [19]. The above observed distance is almost same as the value obtained for $[Ni(Py_3tren)](BF_4)_2$ and $[Ni(Py_3tren)](PF_6)_2$ [2] which are 3.227(4) and 3.235(4) Å, respectively, where Py_3tren = tris[4-(2-pyridyl)-3-aza-3-butenyl]amine. The remaining six Ni–N bond distances (excluding the bridgehead) are considerably shorter than the sum of the van der Waal's radii. The average value being 2.103(3) Å is, however, comparable to the reported value for the crystal structure of bis[3-hydroxyiminobutanone(4-phenyl thiosemicarbazone] nickel(II) nitrate monohydrate [2.047(6) Å] [20] and that of bis-{*S*-methyl-β-*N*-(6-methylpyrid-2-yl)methylinedithiocarbazato}nickel(II) complex [2.103(6) Å] [21].

It is also noteworthy that the bond angle C–N–C at the N(7) is ~118° which also agrees well with that in $[Ni(Py_3tren)](BF_4)_2/(PF_6)_2$ [2]. The tertiary amine nitrogen atom N(7) corresponds to a three-ribbed umbrella that has been inverted by the winds. As the a_1 and 1e levels are filled, the repulsion increases which is reflected through the increment of Ni–N(7) distance resulting in the flattening of the umbrella.

From the survey of non-bonding distances (Table 3) it is evident that all the pyrazolyl nitrogen atoms N(2AB), N(2BB) and N(2CB) are strongly hydrogen bonded with the fluorine atoms F(24A), F(21B) and F(11A), respectively, of three BF_4^- ions (Fig. 3). Each of two BF_4^- ions bridges two asymmetric units through severe H-bonding interactions involving F(24) and F(21) with pyrazolyl N atom (uncoordinated). Again the third pyrazolyl N-atom (also uncoordinated) of the third arm of the ligand molecule in the complex is also H-bonded with the third BF_4^- ion which is further H-bonded with a water molecule in the crystal lattice. However, the third BF_4^- ion is disordered.

Thus in crystal lattice, the molecules are interconnected to give a three dimensional network through significantly strong H-bonding interactions.

3.2. Vibrational and electronic spectra

The analytical data of the metal complexes are given in Table 4, which show that chelates may be represented by the general formula $[Ni(MPz_3tren)]X_2 \cdot nH_2O$ where X = Cl, Br, NO_3, ClO_4 and BF_4; $n = 0$ for Cl, Br; $n = 0.5$ for NO_3, ClO_4, BF_4. The molar conductance values in methanol show that these complex species are 1:2 electrolytes [22]. The magnetic moments of the complexes lie in the 3.09–3.25 BM range at r.t. and are close to the predicted values for octahedral geometry around the metal atom [23].

The IR spectra of all the complexes, except the chloro and the bromo, exhibit a hump around 3530 cm^{-1} which infer the presence of lattice water in these

Table 4

complexes [24]. There is no absorption band at approximately 1670 cm^{-1} due to the free aldehyde group [25]. The absence of stretching and bending vibrations of the (C–O) group at approximately 1530 and 1275 cm^{-1} substantiates the absence of this group [25]. The strong bands appearing at approximately 1590 ± 10 cm^{-1} may be assigned to ν(C=N) vibrations and point towards the coordinated azomethine groups [26,27]. The appearance of a strong band at approximately 1050 cm^{-1} in the spectra of the metal chelates indicates the tertiary nitrogens of the Pz rings as the possible binding sites [28]. This is also in conformity with our previous work [15,16] and X-ray crystallographic studies of several pyrazole-metal complexes [29–31]. Therefore, it is clear from the IR spectra that the three NH_2 groups of Tren have condensed with the three aldehyde groups of three 5-methylpyrazole-3-carbaldehyde molecules to give rise to an N_6 arrangement of three azomethine and three pyrazole ring (tertiary) nitrogen atoms equally suitable for coordination.

The diffuse reflectance spectra of the complexes exhibit three main bands in the region at approximately 10 822–11 299 cm^{-1}(ν_1); 17 035–18 083 cm^{-1}(ν_2) and 27 322–27 932 cm^{-1}(ν_3). Octahedral nickel(II) complexes are characterised by three spin-allowed ligand field bands [32] corresponding to transition from the $^3A_{2g}$ ground state to the $^3T_{2g}$, $^3T_{1g}$ and $^3T_{1g}$(P) excited states. Calculation of ligand field parameters [32] for the complexes gives $D_q = 1082–1130$ cm^{-1}, $B = 778–796$ cm^{-1} and $\beta = 0.5$ (in all cases). These data are quite consistent with those of authentic octahedral Ni(II) species as reported by earlier authors [33,34].

The solution electronic spectra of the complexes recorded in methanol are characterised by two bands in the region at approximately 10977–11299 cm^{-1} ($\varepsilon \sim 9.88–25.71$ l mol^{-1} cm^{-1}) and approximately 17 482–19 084 cm^{-1} ($\varepsilon \sim 13.62–29.38$ l mol^{-1} cm^{-1}) assignable to ν_1 and ν_2 bands, respectively. These bands are not significantly different from those in the solid state thereby suggesting no electronic or geometric change upon dissolution of the complexes in the said solvent. The ν_3 band is masked by the high intensity charge transfer band at approximately 40 000 cm^{-1} which is probably a result of an intraligand transition. In addition, the extent of distortion from ideal octahedral geometry is reflected in the intensities and sometimes splitting of these bands. For complexes which are octahedral or slightly distorted from the octahedral, molar absorption coefficients lie below 30 l mol^{-1} cm^{-1}. The intensities of the two ligand-field bands obtained for the complexes are consistent with their near-octahedral structure. Various bands in the spectra do not follow any regular pattern and they seem to be anion independent.

4. Supplementary material

Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC no. 145858. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Acknowledgements

Acknowledgement is made to the University Grants Commission, New Delhi, India for awarding a Research Fellowship to S.P. and also for the financial assistance to S.K.K. The authors also like to thank Dr. K. Pramanik of IACS, Calcutta for his helpful suggestion about the crystal structure description. Finally, the authors wish to thank Professor N. Saha, Vice-Chancellor of Kalyani University, India for his valuable suggestion and help during the entire period of work.

Abstract

The reactions of $ReO(OEt)Cl_2L_2$, L = py, PPh_3 or $ReOCl_3(Me_2S)(OPPh_3)$, with spirohydrophosphorane $HP(OCMe_2CMe_2O)_2$ – abbreviated here as HP ~ O – in toluene yield $ReOCl_2(P \sim O)L$ complexes, L = py (**1**), PPh_3 (**2**) and $OPPh_3$ (**3**), respectively. The encountered bidentate phosphite pinacolato $(OCMe_2CMe_2O)POCMe_2CMe_2O^-$ ligand ($P \sim O^-$) is afforded by means of a spirophosphorane ring-opening reaction. All the pink–violet compounds **1**–**3** were characterised by NMR, IR and UV–Vis spectroscopies. The structure of *trans*-$ReOCl_2(P \sim O)PPh_3$ (**2**) was determined crystallographically. The rhenium atom adopts distorted octahedral geometry with a *trans* multiply bonded terminal oxo ligand ($Re–O_t = 1.698(2)$ Å) *trans* to pinacolate oxygen (Re–O = 1.880(2) Å). Two phosphorus atoms as well as two chlorides are mutually in a *trans* arrangement. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Spirophosphorane ring-opening; Phosphite diolato(1 −) ligand; Crystal structures

1. Introduction

The chemistry of pentacoordinate phosphorus and, in particular, spirophosphorane compounds has been an area of extensive investigation for some time [1]. However, to our knowledge, there are few reports on their metal coordination ability. Basically there are two known routes to obtain transition metal derivatives of spirophosphorane: replacement of the chloride ion in chlorophosphorane with a metal carbonyl anion [2] and deprotonation of spirohydrophosphorane, both resulting in corresponding metal phosphoranide complexes [3,4]. In most of these cases, spirophosphorane ligands coordinate only via phosphorus atoms forming monodentate metallophosphorane arrangements. On the other hand, cyclic hydrophosphoranes are known to be in equilibrium with ring-opened hydroxyl tautomers tricoordinate towards phosphorus (Eq. (1)) [5].

(1)

Several factors, e.g. temperature, solvent basicity, ring size and the bulkiness of substituents on the ring may affect the distribution of tautomers [6]. This points to another possible way of coordination by hydrophosphorane as a ligand, i.e. through a bidentate ring-opened hydroxyl tautomer.

This paper reports on the synthesis and structural characterisation of oxo-rhenium(V) complexes containing a phosphite pinacolato(1 −) $(OCMe_2CMe_2O)POCMe_2CMe_2O^-$ anionic ligand ($P \sim O^-$) which derives from a corresponding tautomeric form of spirophosphorane HP ~ O (Eq. 1).

2. Experimental

2.1. General procedures

All preparations were performed in an atmosphere of dry, oxygen-free nitrogen using conventional Schlenk techniques. Solvents were carefully dried and deoxygenated by standard methods [7]. $ReOCl_2(OEt)py_2$ [8] was prepared by modified procedure described below. $ReOCl_3(Me_2S)(OPPh_3)$ [9], $ReOCl_2(OEt)(PPh_3)_2$ [10] were obtained according to the literature procedures. Pinacol $HOCMe_2CMe_2OH$, triethylamine NEt_3 and phosphorus trichloride PCl_3 were purified according to the standard procedures [7].

2.2. Instrumentation

The IR and FIR measurements were made in KBr pellets either with Nicolet FTIR Impact 400 or in Nujol with Brucker IFS 113V. ^1H, ^{13}C, ^{31}P NMR spectra were obtained on a Bruker AMX (300 MHz for H NMR). The chemical shifts δ are given in ppm towards the TMS (^1H, ^{13}C) and H_3PO_4 (^{31}P) using deuterated solvents as lock and reference (^1H, ^{13}C), respectively. UV–Vis spectra in CH_2Cl_2 solution were obtained on a HP 8452A. Elemental analyses were performed on a Perkin–Elmer 2400 CHN by the Laboratory of Elemental Analyses in our Department.

2.3. Synthesis of the ligand

The ligand $HP(OCMe_2CMe_2O)_2$, 2,2,3,3,7,7,8,8-octamethyl-1,4,6,9-tetraoxa-5-phospha(5-P^v) spiro[4.4]-nonane (HP ~ O) was readily obtained in a route adopting general procedures described in the literature [11]. To a stirred solution of pinacol $(Me_2COH)_2$ (11.8 g, 0.1 mol) and NEt_3 (20.9 cm^3, 0.15 mol) in diethyl ether (250 cm^3) at 0°C, the solution of PCl_3 (4.4 cm^3, 0.05 mol) in ethyl ether (40 cm^3) was slowly added in a dropwise manner. After that, the mixture was stirred for 10 h at room temperature (r.t.). The solution was filtered and evaporated to dryness. The crude product was extracted with pentane and crystallised twice from pentane in a freezer to give the pure spirophosphorane ligand (5.28 g, 40% yield).

^1H NMR ($C^2H_2Cl_2$, 25°C): δ 1.0 (s, 12, CH_3), 1.1 (s, 12, CH_3), 7.5 (d, 1, $J_{PH} = 810$Hz); $^{31}P\{^1H\}$ NMR ($C_6^2H_6$, 25°C): δ −40.15 (s), ^{31}P NMR −40.15 (d, $J_{PH} = 796$Hz); ^{13}C NMR ($C_6^2H_6$, 25°C) δ 23.65, 23.95, 24.18, 24.33 (CH_3), 78.48s, 78.5s (CCH_3); IR (KBr, cm^{-1}) 1150s, 1218s ν(C–O–P), 2385m ν(P–H).

2.4. Synthesis of the complexes

2.4.1. *cis*-$ReOCl_2(P \sim O)py$ (1)

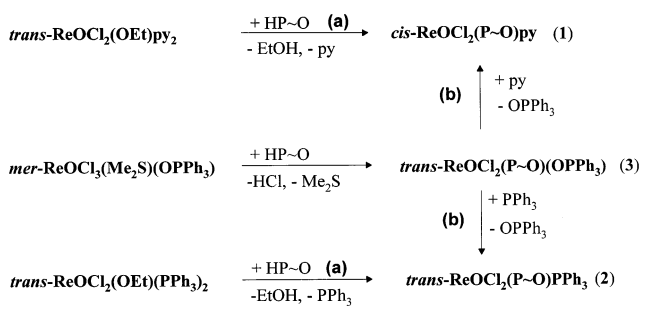
(a) A suspension of the blue complex $ReOCl_2$-$(EtO)py_2$ (0.87 g, 1.82 mmol) and spirophosphorane ligand HP ~ O (0.96 g, 3.64 mmol) in toluene (30 cm^3) was refluxed for 4 h until the starting rhenium compound reacted and a light-violet crystalline solid was afforded. The product was filtered, washed with Et_2O and dried in vacuo (0.98 g, 88%). Pure **1** was recrystallised from dichloromethane/ethyl ether solution as pink–violet crystals. (b) A suspension of the pink–violet complex $ReOCl_2(P \sim O)OPPh_3$ (**3**) (0.1053 g, 0.129 mmol) and pyridine (0.02 cm^3, 0.258 mmol) in toluene (25 cm^3) was refluxed for 4 h until the started rhenium compound reacted and a light-violet solid was afforded. The product was filtered, washed with toluene and diethyl ether, dried under vacuum (0.061 g, 75.9%). *Anal.* Calc. for $C_{17}H_{29}O_5Cl_2NPRe$ (mol. wt. calc. 615.5): C, 33.17; H, 4.75; Cl, 11.51; N, 2.27; P, 5.03; Found: C, 31.83; H, 4.58; Cl, 12.46; N, 2.29; P, 3.71%; IR (KBr, cm^{-1}) 958vs ν(Re=O), 931s, 1020s ν(C–O–P), 1604 ν(C=N); FIR (nujol, cm^{-1}) 249s, 291s, 303s ν(Re–Cl), ν(Re–N), ν(Re–P).

2.4.2. *trans*-$ReOCl_2(P \sim O)(PPh_3)$ (2)

(a) A mixture of $ReOCl_2(OEt)(PPh_3)_2$ (0.8 g, 0.95 mmol), toluene (40 cm^3) and spirophosphorane ligand HP ~ O (0.50 g, 1.90 mmol) was stirred and boiled for 6 h until the starting compound reacted and deep-orange solution appeared. The solution was concentrated by half to obtain a pink–violet precipitate of **2**.The product was filtered, washed with Et_2O and dried under vacuum (0.6 g, 80% yield). (b) A suspension of the pink–violet complex $ReOCl_2(P \sim O)OPPh_3$ (**3**) (0.10 g, 0.12 mmol) and PPh_3 (0.06 g, 0.24 mmol) in toluene (25 cm^3) was refluxed for 4 h until the starting rhenium compound reacted and an orange solution appeared. The solution was concentrated in vacuo to obtain pink precipitate. The product was filtered, washed with toluene and diethyl ether, dried under vacuum (0.078 g, 80%). *Anal.* Calc. for $C_{30}H_{39}O_5Cl_2P_2Re$ (mol. wt. calc. 798.7): C, 45.11;H, 4.92; Cl, 8.87; P, 7.75; Found: C, 45.40; H, 4.73; Cl, 8.76; P, 7.64%; IR (KBr, cm^{-1}) 955vs ν(Re=O) 940s, 1020s ν(C–O–P); FIR (nujol, cm^{-1}) 228m, 252s, 303s ν(Re–Cl), ν(Re–P).

2.4.3. *trans*-$ReOCl_2(P \sim O)(OPPh_3)$ (3)

A suspension of $ReOCl_3(Me_2S)(OPPh_3)$ (0.5 g, 0.77 mmol) and HP ~ O (0.61 g, 2.31 mmol) in toluene was stirred and boiled until the starting rhenium compound reacted (4 h) and a pink–orange solution appeared. The solution was concentrated by half to obtain a pink–violet precipitate of **3**. The product was filtered, washed with absolute ethyl alcohol, ethyl ether and dried under vaccum (0.29 g, 61% yield). The crude **3** was recrystallised from toluene/dichloromethane solution. *Anal.* Calc. for $C_{30}H_{39}O_6Cl_2P_2Re$ (mol. wt. calc.



814.7): C, 44.23; H, 4.83; Cl, 8.70; P, 7.60; Found: C, 44.7; H, 4.71; Cl, 8.41; P, 8.05%; IR (KBr, cm^{-1}) 956vs ν(Re=O), 993s, 1025s ν(C–O–P); FIR (nujol, cm^{-1}) 249s, 254s, 303s ν(Re–Cl), ν(Re–P).

2.4.4. *trans-ReOCl$_2$(OEt)py$_2$ [8]*

A suspension of $ReOCl_3(Me_2S)(OPPh_3)$ (2 g, 3.08 mmol) and pyridine (0.75 cm^3, 9 mmol) in freshly distilled dry ethanol (100 cm^3) was stirred and boiled until the starting rhenium compound reacted and the dark-blue colour of solution appeared (2 h). The solution was cooled in an ice bath to obtain blue crystals. The product was filtered and washed with ethyl alcohol and diethyl ether. Yield 1.18 g (81%).

2.5. Crystallography

Pink-violet prisms of the *trans*-$ReOCl_2(P\sim O)PPh_3$ complex (**2**) suitable for X-ray structural analysis were obtained by slow diffusion of Et_2O vapour into CH_2Cl_2 solution. Table 1 summarises the data relevant to structure analyses. All measurements of the crystal were performed on a Kuma KM4CCD κ-axis diffractometer, with graphite-monochromated Mo Kα radiation. The crystal was positioned at 65 mm from the KM4CCD camera. A total of 612 frames were measured at 0.75° intervals with a counting time of 30 s. The data were corrected for Lorentz and polarisation effects. No absorption correction was applied. Data reduction and analysis were carried out using the Kuma Diffraction (Wrocław) programs. The structure was solved by means of heavy atom methods using SHELXS-97 and refined by the full-matrix least-squares method on all F^2 using SHELXL-97 procedures [12]. Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included from the $\Delta\rho$ maps and refined with isotropic thermal parameters. Atomic positional and thermal parameters, as well as lists of bond lengths and angles were deposited as supplementary material.

3. Results and discussion

3.1. Synthesis and characterisation of the $ReOCl_2(P\sim O)L$ complexes

Neutral oxo-rhenium(V) complexes containing a bidentate phosphite pinacolato ligand $P\sim O^-$, which derives from a tautomer of the corresponding hydrophosphorane $HP\sim O$ (Eq. 1), can be obtained via routes outlined in Scheme 1. All three direct syntheses of the $ReOCl_2(P\sim O)L$ complexes (L = py (**1**), PPh_3 (**2**), $OPPh_3$ (**3**)) were carried out in boiling toluene solutions, both to move the tautomeric equilibrium into a phosphite form and to facilitate the separation of sparingly soluble **1**–**3** from reaction mixtures. Apart from the reaction employing $ReOCl_3(Me_2S)(OPPh_3)$ as the substrate, rhenium alkoxide compounds seem to be the precursors of choice in preparation of these complexes. A twofold molar excess of a moisture sensitive $HP\sim O$ ligand in reactions with $ReOCl_2(OEt)py_2$ or $ReOCl_2(OEt)(PPh_3)_2$ is sufficient to afford complexes **1** and **2** in yields of approximately 85% (route (a)). In the case of parent $ReOCl_3(Me_2S)(OPPh_3)$, a larger excess of $HP\sim O$ is required, possibly to trap liberating HCl. Complexes **1** and **2** can also be obtained in a simple ligand substitution reaction (route (b)) starting with the most labile complex **3**. Complexes **1**, **2** and **3** are obtained as pink–violet solids stable in air and moderately soluble in CH_2Cl_2, except for the more soluble **3**,

which is also soluble in CH_3CN and slightly soluble in $C_6H_5CH_3$.

The hybrid phosphite pinacolato ligand $P\sim O^-$ containing both 'soft' phosphorus and 'hard' alkoxide oxygen donor atoms stabilise the rhenium centre in the intermediate oxidation state (5+) [13]. While the reduction of $ReOCl_3L_2$ (L = py, PR_3, $P(OR)_3$) complexes using phosphines PR_3 is quite feasible [14], compounds **1**–**3** do not undergo reduction to the corresponding rhenium(III) complexes. Attempted oxidation reaction with H_2O_2 resulted in $P\sim O^-$ ligand decay.

The IR spectra of **1**–**3** show intensive bands characteristic for coordinated ligands. The ν(Re=O) bands at about 950 cm^{-1} were discerned by means of subtraction of the free $HP\sim O$ spectrum, due to partial overlapping $P\sim O^-$ ligand vibrations in the same (1000–900 cm^{-1}) spectral region. These bands are in the usual range of ν(Re=O) stretching vibrations [15] (e.g. *trans*-$ReOCl_2(OEt)L_2$: L = py 962 cm^{-1} [8a], PPh_3 946 cm^{-1} [16], *trans*-$ReOCl_2(OMe)py_2$, 960 cm^{-1} [17]) and suggest *trans* coordination mode O=Re–O– of oxygen donor atoms in complexes **1**–**3**. The ν(Re–Cl) bands for complexes **1**–**3** in FIR spectra were not confidently identified because in the same spectral region (350–250 cm^{-1}) ν(Re–N) and ν(Re=P) vibrations also occur [18].

NMR spectra, which are more informative, are summarised in Table 2. The ^{1}H NMR spectrum of **1** at r.t. shows eight singlets of equal intensity in the aliphatic range (0.8–1.6 ppm) indicating the non-equivalence of all the eight methyl groups in $P\sim O^-$ ligand. The spectrum in the aromatic region, consisting of two triplets and one doublet, is typical of coordinated pyridine. Apart from the broadening and a small upfield shift of signals at low temperature (220 K), the pattern of resonances is preserved. NMR data indicate C_1 symmetry of metal-ligand arrangements and suggest *cis* geometry of chloride ions for complex **1** (Chart 1). Unlike complex **1**, complexes **2** and **3** have disparate patterns of NMR spectra. Their ^{1}H NMR spectra at r.t. exhibit only four singlets (Table 2) due to the eight methyl groups of the $P\sim O^-$ ligand. It might suggest C_S symmetry around the metal centre for complexes **2** and **3** and *trans* geometry of chloride ions (Chart 1). However, complexes **2** and **3** exhibit variable temperature ^{1}H NMR spectra. At low temperature (203 K), the spectrum of **3** consists of eight singlets related to the eight methyl groups. As the temperature is raised, these signals broaden and coalesce ultimately to give four single sharp resonances noticed at r.t. Thus, these results demonstrate the fluxional behaviour of the ligand $P\sim O^-$, presumably consisting of two concomitant conformation changes, that of the chelating metallacycle –ReOCCOP– and that of the phosphorus cycle –POCCO–. Furthermore, while the ^{31}P{^{1}H} NMR spectrum of **1** shows a singlet, the spectra of **2** and **3** are connected with the AX system and comprised of two doublets with $^2J_{PP}$ 585 Hz and $^3J_{PP}$ 44 Hz, respectively. These data indicate a vertical coupling of the two phosphorus atoms [13a,19] and ultimately corroborate the anticipated C_S symmetry of **2** and **3**.

cis -**1** [OC-6-52] *trans* - **2,3** (L=PPh_3, $OPPh_3$) [OC-6-13]

Chart 1.

Other characteristic features of the complexes **1**–**3** are their pink–violet colour and their UV–Vis spectra. Electronic absorption spectra are summarised in Table 2. The large extinction values ε at about 300 nm imply CT bands. On the other hand, low values of ε for two visible absorption bands (at about 500 and 650 nm) are consistent with ligand field electronic transitions nd-σ*d and nd-π*d usually observed for metal complexes with the $4-5d^2$ electronic configuration [15,20]. Similar absorption bands are also shown by other complexes with a meridional arrangement of O_{oxo}, $P\sim O$ donor atoms, e.g. 662 nm (ε 23), 526 (56) for *trans*-

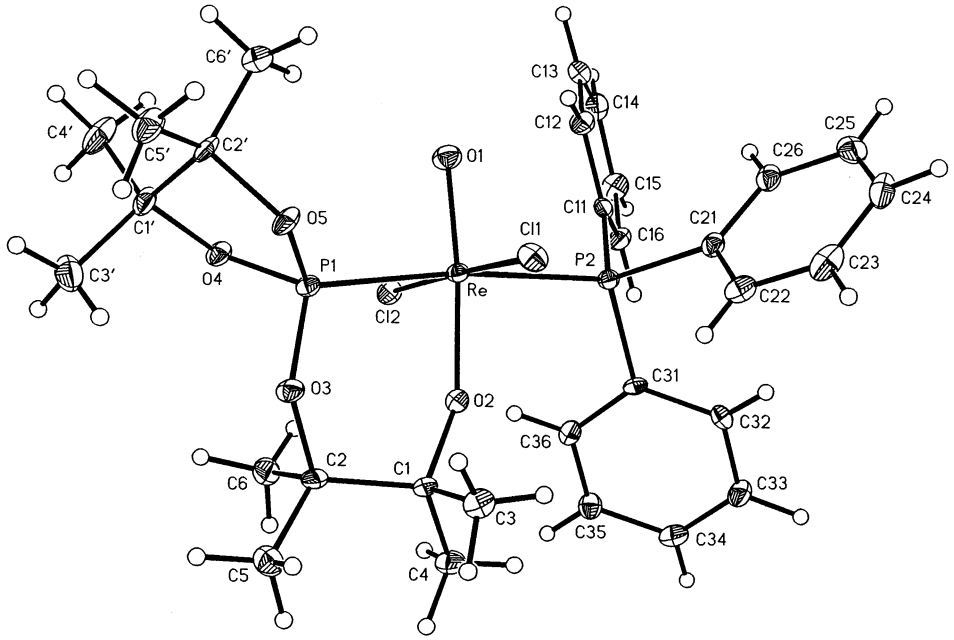

Fig. 1. Crystallographic structure of *trans*-$ReOCl_2(P \sim O)(PPh_3)$ (**2**).

$ReOCl_2(OEt)(PPh_3)_2$, and 830 (15), 610 (80) for *cis*-$ReOCl(OC_6H_4PPh_2)_2$, as reported elsewhere [21]. In order to determine the molecular structure of **2**, we undertook single crystal X-ray analysis.

3.2. Crystal structure of *trans*-$ReOCl_2(P \sim O)(PPh_3)$ (**2**)

The molecular structure of **2** is shown in Fig. 1 and salient bond lengths and angles are summarised in Table 3. Complex **2** has a six-coordinate distorted octahedral geometry with three sets of donor atoms: chlorides, both phosphorus and two oxygens in *trans* arrangements, respectively. Thus, the local coordination symmetry at rhenium is near C_S. The rhenium atom lies out of P(1)Cl(1)P(2)Cl(2) equatorial mean plane by 0.1 Å toward the terminal oxo ligand. The rhenium oxo ligand distance Re–O(1) of 1.698(2) Å is short and fits well into the usual range of multiply bonded mono-oxo groups (1.69 Å mean value) [15]. Also the Re–O(2) (pinacolate) bond length of 1.880(2) Å is shortened in a way characteristic of the *trans* O=Re–O(alcoholate) arrangement, in which total bond order in O=Re–O is close to four [22]. Similarly, both *trans* Re–Cl(1) and Re–Cl(2) distances 2.403(1) and 2.405(1) Å, respectively are in the normal range (2.35–2.45 Å) for complexes of this type [22b,23]. However, the Re–P bond lengths show some disparities. Whereas the Re–P(2) (phosphine) bond length at 2.532(1) Å appears to be within the wide range (2.42–2.57Å) reported for analogous PR_3 derivatives [19,22–24], the Re–P(1) (phosphite) distance of 2.388(1) Å in **2** is rather short. This shortening can be explained by the strong π-acceptor character of the phosphite moiety [25] and is consistent with the Re–P distances reported for other phosphite derivatives [26]. The distortions from an ideal rhenium-centred octahedron are also manifested in related angle distributions. The bite angle P(1)–Re–O(2) is acute (81.80(6)°), while the *trans*-related angle P(2)–Re–O(1) is obtuse (95.57(7)°). The angles O(1)–Re–O(2) 173.17(9)°, P(1)–Re–P(2) 172.98(3)° and Cl(1)–Re–Cl(2) 177.40(2)° accomplish non-linear axes in an approximate octahedron. Both phosphorus-pertinent cycles are puckered. The six-membered metal-containing cycle is fixed to the δ-skew half chair conformation with the torsion angle O(2)–Re–P(1)–O(3) = 10.4°, whilst the five-membered phosphorus cy-

Abstract

The synthesis and crystal structures of three ytterbium(III) complexes of homoazacalixarenes are reported. In all cases, the complexes are obtained without addition of a base, the protons of the complexing phenolic moieties being transferred to the amine groups upon complexation. The 1:1 complex between *p*-chloro-*N*-benzylhexahomotriazacalix[3]arene (**1**) and $Yb(NO_3)_3$ is analogous to the neodymium(III) complex reported previously, with the metal ion bound to three phenoxide groups and three nitrate ions. A second 1:1 complex is obtained with $Yb(NO_3)_3$ and *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene (**2**), in which the metal ion is bound to two phenoxide groups only. The replacement of nitrate by triflate counter-ions results in the formation of a 1:2 'sandwich' complex with **1**, in which two divergent calixarene molecules are bridged by the metal ion, the counter-ions being non-bonding. © 2000 Elsevier Science B.V. Keywords: Ytterbium(III); Lanthanides; Calixarenes; Homoazacalixarenes; Crystal structure

1. Introduction

When dissolved in a basic medium, calixarenes unmodified on the lower rim are poly-aryloxide ligands well suited for complexation of lanthanide and actinide (mainly uranyl) ions [1]. We have recently started an investigation of homoazacalixarenes [2], in which at least one methylene bridge is replaced by a CH_2–N(R)–CH_2 group, as ligands for those ions [3,4]. The first results obtained showed that a specificity of azacalixarenes, by comparison with classical calixarenes and homooxacalixarenes, was to give complexes without addition of a basic agent, the protons of the complexing phenolic groups being transferred to the amine groups, which results in a poly-zwitterionic form of the ligand being the complexing species. Crystal structure determinations evidenced similar features in the complex of neodymium(III) nitrate with *p*-chloro-*N*-benzylhexahomotriazacalix[3]arene (**1**) (Scheme 1) [3] and in those of uranyl nitrate with **1** or *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene (**2**) [4]. In all cases, the mononuclear complexes formed are neutral and the metal ion, bound to two (UO_2^{2+}) or three (Nd^{3+}) phenoxide groups, remains bound to its nitrate counter-ions. Notwithstanding the usual bonding to phenoxide groups, the location of the metal ion is different from that in comparable phenolic calixarene and homooxacalixarene complexes. The oxacalixarene analogous to **1**, *p-tert*-butylhexahomotrioxacalix[3]arene gives μ-aryl-

oxo-bridged dimeric complexes with lanthanide(III) ions, in which the metal ions are displaced out of the plane defined by the three oxygen atoms towards the calixarene cavity [5]. In the case of uranyl ion complexes of homooxacalixarenes, the metal ion is located close to the mean plane defined by the bonding oxygen atoms of the calixarene [1b,c,6]. On the other hand, in the case of the homoazacalixarenes **1** and **2**, the positive charges located on the nitrogen atoms, in the calixarene framework, push the cation out of the plane of the bonding atoms, towards the exterior of the macrocycle. It ensues that, in the resulting complexes, the metal ion has a dissymmetrical environment, with about one half of the space occupied by the calixarene donor atoms and the other half by the counter-ions. In order to investigate the possibility of obtaining other coordination modes, we investigated the complexes formed with a lanthanide ion smaller than Nd^{3+} and with different counter-ions. We report herein the synthesis and the crystal structures of three ytterbium(III) complexes with the two azacalixarenes **1** and **2**, with, in the case of **1**, two different counter-ions, i.e. the nitrate ion used in the previous studies and the less-coordinating triflate (trifluoromethanesulfonate, $CF_3SO_3^-$) ion.

2. Experimental

2.1. Synthesis

The ligands *p*-chloro-*N*-benzylhexahomotriazacalix[3]arene (**1**) and *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene (**2**) were synthesized as reported previously [3,4].

2.1.1. *[Yb(NO$_3$)$_3$(**1**)]·2CH$_3$CN (**3**)*

Compound **1** (0.070 g, 0.08 mmol) was dissolved in 10 ml of CH_3CN–$CHCl_3$ (1:1) and a solution of $Yb(NO_3)_3{\cdot}5H_2O$ (0.070 g, 0.15 mmol) in 10 ml of CH_3CN was added dropwise, giving a pale yellow solution immediately. Single crystals suitable for X-ray crystallography were obtained upon slow evaporation of the solution. FAB-MS: m/z 1075.2 corresponding to $[Yb(NO_3)_2\ (\mathbf{1}) - 2H^+]$; 1012.2 corresponding to the loss of a nitrate ion; 949.2 corresponding to the loss of another nitrate ion; such successive departures of nitrate ions have already been observed in the case of the related neodymium complex [3]. The microanalysis results were unsatisfactory, having been performed on a mixture of crystals and heterogeneous powder.

2.1.2. *[Yb(NO$_3$)$_3$(**2**)][Yb(NO$_3$)$_3$(**2**)(CH$_3$CN)]·CH$_3$CN·CHCl$_3$·3H$_2$O (**4**)*

Compound **2** (0.160 g, 0.22 mmol) was dissolved in 10 ml of CH_3CN–$CHCl_3$ (1:1) and a solution of $Yb(NO_3)_3{\cdot}5H_2O$ (0.100 g, 0.22 mmol) in 10 ml of CH_3CN was added dropwise, giving a pale yellow solution immediately. Single crystals suitable for X-ray crystallography were obtained by slow evaporation of the solution. Three mass peaks were detected by FAB-MS: m/z 952.1 corresponding to $[Yb(NO_3)\ (\mathbf{2}) - 2H^+]$; 890.1 corresponding to the loss of a nitrate ion and $2H^+$; 719.2 corresponding to the loss of the metal ion and H^+. Anal. Calc. for $[UO_2(NO_3)_2\ (\mathbf{3})]{\cdot}CHCl_3{\cdot}H_2O$, $UC_{46}H_{45}Cl_6N_5O_{12}$: C, 50.31; H, 4.52. Found: C, 50.27; H, 4.55%.

2.1.3. *[Yb(**1**)$_2$](CF$_3$SO$_3$)$_3$·3CH$_3$CN (**5**)*

Compound **1** (0.050 g, 0.06 mmol) was dissolved in 15 ml of CH_3CN–$CHCl_3$ (1:1) and a solution of $Yb(CF_3SO_3)_3$ (0.020 g, 0.03 mmol) in 10 ml of CH_3CN was added dropwise, giving a pale yellow solution immediately. Single crystals suitable for X-ray crystallography were obtained by slow evaporation of the solution. ^{1}H NMR (200 MHz, 1:1 mixture of $CDCl_3$–CD_3CN) in ppm referenced to TMS: δ 7.50 (s, 6H, Ar–H); 7.32 (s, 9H, Ar–H); 6.98 (bs, 6H, Ar–H_{calix}); 4.76 (bs, 12H, Ar_{calix}–CH_2–N); 3.75 (bs, 6H, Ar–CH_2–N). FAB-MS: five mass peaks were detected: m/z 2029.1 corresponding to $[Yb(CF_3SO_3)_2\mathbf{1}]$; 1879.1 corresponding to the loss of another triflate ion and the related peak at 940.1 for the doubly charged ion; 1729.1 corresponding to the loss of the last triflate ion and the related peak at 865.1 for the doubly charged ion.

2.2. Crystallography

The data were collected on a Nonius Kappa-CCD area detector diffractometer [7] using graphite-monochromated Mo Kα radiation (0.71073 Å). The crystals were introduced in Lindemann glass capillaries with a protecting 'Paratone' oil (Exxon Chemical Ltd.) coating. The data were processed with DENZO-SMN [8]. The structures were solved by direct methods with SHELXS-97 [9] and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [10]. Absorption effects were corrected empirically with the program MULABS from PLATON [11]. Hydroxyl and ammonium protons were introduced as found on the Fourier difference maps whereas all other hydrogen atoms were introduced at calculated positions (except in the disordered parts in **3** and on the chloroform and water molecules in **4**). All hydrogen atoms were treated as riding atoms with a displacement parameter equal to 1.2 (OH, NH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. All non-hydrogen atoms were refined anisotropically, except the disordered ones in **3** and the oxygen atoms of the water molecules in **4**. Special features are indicated in the following.

2.2.1. Compound 3

One benzyl group and one acetonitrile molecule were found disordered over two sites each. Each of those benzyl positions overlaps one of the positions of the acetonitrile molecule. The occupation factors have been refined so as to take into account the impossibility for two overlapping positions to be simultaneously occupied. The two other acetonitrile molecules have been affected with a 0.5 occupation factor in order to keep reasonable displacement parameters. The disordered benzyl groups have been refined as idealized hexagons and some soft restraints have been applied to the badly resolved acetonitrile molecules.

2.2.2. Compound 5

In order to respect electroneutrality as well as to obtain physically significant displacement parameters, one of the triflate counter-ions was affected with a 0.5 occupation factor. One of the solvent acetonitrile molecules, located close to this triflate anion, was equally affected with a 0.5 occupation factor in order to take into account the impossibility of a simultaneous occupation of both sites.

Crystal data and structure refinement parameters are given in Table 1 and selected bond lengths and angles in Table 2. The molecular plots were drawn with SHELXTL [12]. All calculations were performed on a Silicon Graphics R5000 workstation.

3. Results and discussion

The asymmetric unit in $[Yb(NO_3)_3(\mathbf{1})]\cdot 2CH_3CN$ (**3**) comprises one molecule, without any crystallographic symmetry (Fig. 1), which is similar to the neodymium(III) complex molecule already reported [3]. The three nitrogen atoms are protonated and involved in bifurcated $(N–H)^+\cdots O^-$ hydrogen bonds with the two

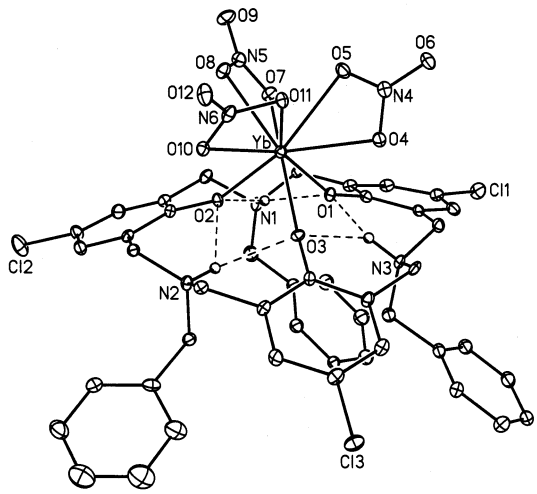

Fig. 1. View of complex **3**. Hydrogen bonds in dashed lines. Ammonium protons represented as small spheres of arbitrary radii. Other hydrogen atoms and solvent molecules omitted for clarity. Only one component of the disordered parts is represented.

neighboring phenoxide oxygen atoms. The Yb^{3+} cation is displaced by 1.489(4) Å from the mean plane defined by O(1), O(2) and O(3), i.e. somewhat less than Nd^{3+} (1.591(2) Å), in agreement with coordination bond lengths shorter by 0.115 Å. The coordination number is nine (whereas it is six in the Lu^{3+} complex of *p-tert*-butylhexahomotrioxacalix[3]arene), and the geometry of the coordination polyhedron is that of a very distorted tricapped trigonal prism. The values of the dihedral angles between the three phenolic rings and the mean plane defined by the phenolic oxygen atoms are 12.6(5), 21.2(4) and 26.4(4)°, different from those in the neodymium complex and indicating a more symmetrical, pseudo-trigonal, conformation. The cavity is far more shallow than in the uranyl or lanthanide ion complexes of *p-tert*-butylhexahomotrioxacalix[3]arene [5,6b], in which the closer approach of the cation pushes the three bonding oxygen atoms away from each other. The mean plane defined by the three amine nitrogen atoms is close to being parallel to that defined by the three phenoxide oxygen atoms (dihedral angle 2.2(4)°), the distance between the two planes being about 1.04 Å. Apart from the slight modifications reported above, the replacement of Nd^{3+} (ionic radius 0.995 Å) by Yb^{3+} (0.858 Å) has no effect on the overall structure of the complex. In the case of complexes with *p-tert*-butylhexahomotrioxacalix[3]arene, the more notable effect when replacing Lu^{3+} (0.85 Å) by La^{3+} (1.061 Å), apart from slight geometrical modifications of the calixarene conformation, is the involvement of the three ether oxygen atoms in coordination in the second case, whereas only one is coordinated in the first one.

The asymmetric unit in $[Yb(NO_3)_3(\mathbf{2})][Yb(NO_3)_3(\mathbf{2})(CH_3CN)]\cdot CH_3CN\cdot CHCl_3\cdot 3H_2O$ (**4**) comprises two different molecules, noted A and B (Fig. 2), which does not possess any symmetry element. In both of them, the cation is located outside the lower rim array and is bound to two phenoxide oxygen atoms only, in a manner similar to that observed in the uranyl ion complex of **2** [4]. The protons of the two bonding oxygen atoms from the calixarene have been transferred to the two nitrogen atoms, which results in the formation of a cyclic hydrogen bonding array. The conformation of the calixarene, with a pseudo-symmetry plane containing the nitrogen atoms and perpendicular to the mean plane of the molecule, is different from that of its uncomplexed form, which contains bifurcated hydrogen bonds, and close to that in the uranyl ion complex. The main difference between molecules A and B lies with the environment of the Yb^{3+} cation, which is eight-coordinated in A and nine-coordinated in B, the three nitrate ions in the latter molecule being arranged differently to permit the bonding of an acetonitrile molecule. In both cases, the four oxygen atoms are located in a plane (rms deviation 0.04 and 0.02 Å in A and B,

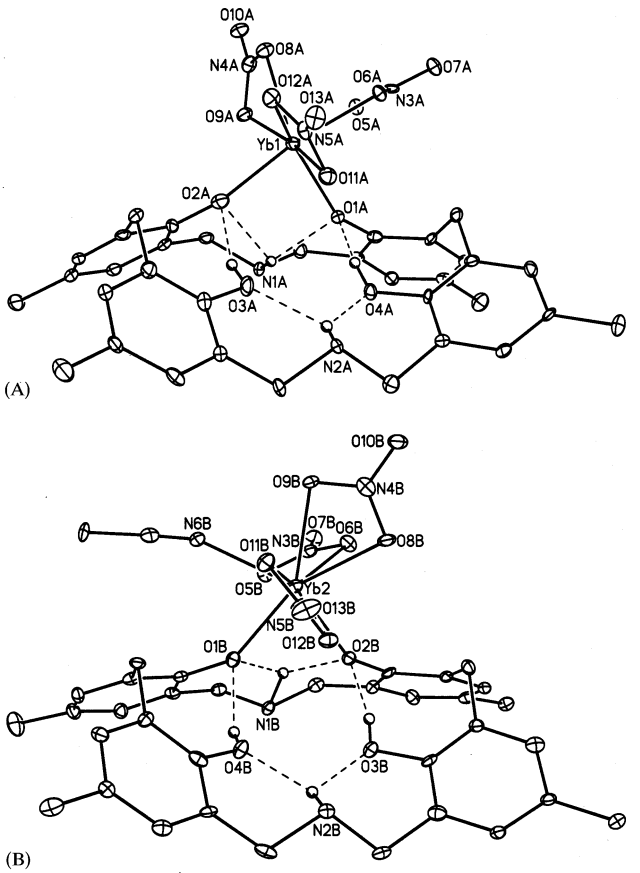

Fig. 2. View of molecules A and B in complex **4**. Hydrogen bonds in dashed lines. Hydroxyl protons represented as small spheres of arbitrary radii. Other hydrogen atoms, benzyl groups and solvent molecules omitted for clarity.

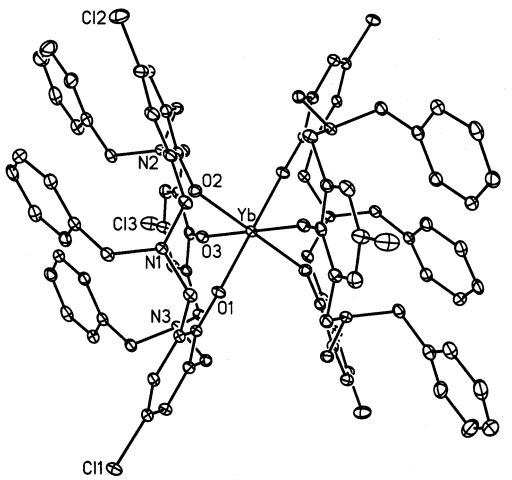

Fig. 3. View of complex **5**. Hydrogen atoms and hydrogen bonds, counter-ions and solvent molecules omitted for clarity.

respectively) with the Yb^{3+} cation located at 1.397(7) and 1.450(6) Å from this plane. The two amine nitrogen atoms are inequivalent with respect to this plane, N(1) being far more distant from it (2.43(1) in A, 2.30(1) Å in B) than N(2) (0.46(1) in A, 0.68(1) Å in B). This is

related to the more 'vertical' position of the phenolic rings adjacent to N(1) (mean dihedral angle with the O_4 mean plane 64(1)°, including both molecules) with respect to those adjacent to N(2) (20(6)°). The same conformation has been observed in the uranyl ion complex.

The complex $[Yb(\mathbf{1})_2](CF_3SO_3)_3\cdot 3CH_3CN$ (**5**) shows the effect of changing the counter-ion on the stoichiometry and geometry of the complex. Whereas the nitrate ions in **3**, **4** and the cases reported previously [3,4] remained coordinated to the metal cation, the less-coordinating triflate ion is not bound to it, which permits the formation of a centrosymmetric 'sandwich' complex by coordination of a second calixarene moiety (Fig. 3). As in complex **3**, the three amine groups are protonated and involved in bifurcated hydrogen bonds with the three phenoxide groups. The Yb^{3+} cation is located at 1.355(2) Å from the mean plane defined by the three oxygen atoms, i.e. nearer to it than in **3**, which is related to lower Yb–O bond lengths in **5** (mean value 2.18(3) Å) than in **3** (2.23(2) Å) as a consequence of a lower coordination number. The six-coordinate metal cation in **5** is in a quite regular octahedral environment (mean angle between adjacent Yb–O bonds 90(5)°). One of the phenolic rings is more tilted than the two other ones and also than those in **3**, the dihedral angles being 42.0(2), 11.89(8) and 15.9(1)°. Such an arrangement comprising two divergent calixarene molecules centered on one metal ion (or an assemblage of metal ions) has already been often encountered with various metal ions and has also been intentionally devised recently [13] in order to obtain koiland-type molecules [14]. The three flexible benzyl arms in **5**, if properly oriented by a guest, could in

Abstract

The reaction of Cp(dppe)FeI with the ligands 2,2′- and 4,4′-dithiobispyridine ($S_2(Py)_2$) give the mononuclear or binuclear complexes of the type [Cp(dppe)Fe-$S_2(Py)_2$]PF_6, [Cp(dppe)Fe–SPy]PF_6 or [{Cp(dppe)Fe}$_2$-μ-SPy]$(PF_6)_2$ depending on the reaction condition. Reaction of Cp(dppe)FeI with dithiobispyridines in presence of $TlPF_6$ as halide abstractor and using CH_2Cl_2 as a solvent gives the complexes [Cp(dppe)Fe-4,4′-$S_2(Py)_2)_2$]PF_6 (**1**) and [CpFe(dppe)-2,2′-$S_2(Py)_2$]PF_6 (**2**) whereas the same reaction using CH_3OH as a solvent and NH_4PF_6 as the halide abstractor leads to the formation of the Fe^{III}–thiolate complex [Cp(dppe)Fe-2,2′-SPy]PF_6 (**3**) and the mixed-valence complex [Cp(dppe)Fe^{III}-μSPy-Fe^{II}(dppe)Cp]$(PF_6)_2$ (**4**). Magnetic and ESR measurements are in agreement with one unpaired electron delocalized between them. Mössbauer data indicate clearly the presence of two different iron sites, each one of the N-bonded and S-bonded iron atoms, with intermediate oxidation state Fe^{II}–Fe^{III}. An electron transfer intervalence absorption was observed for this complex at 780 nm (in CH_2Cl_2). By applying the Hush theory the intervalence parameters were obtained; $\alpha = 0.028$, $H_{ab} = 361\ cm^{-1}$ which indicate Class II Robin–Day. Estimation of the rate electron transfer affords a value $k_{th} = 6.5 \times 10^6\ s^{-1}$. Solvent effect on the intervalence transition follow the Hush prediction for high dielectric constants solvents which permit the evaluation of the outer and inner-sphere reorganizational parameters, which were analyzed and discussed. The electronic interaction parameters compare well with those found for electron transfer in metalloproteins. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Thiolate-bridged complexes; Mixed-valence; Electron-transfer; Iron

1. Introduction

A variety of metalloproteins are known to contain sulfur as part of the coordination environments of metal ions [1–9]. Iron, copper and the molybdenum ion are especially common in metalloenzymes containing sulfur ligands. In several of such metalloproteins the metal–thiolate bond is involved in the active site [5–9], specifically iron–thiolate clusters are involved in the electron transfer behavior of ferredoxin and cytochrome P_{450}, [5–8]. Thus, the enzyme sulfite reductase from *Escherichia coli* (EcSiR) which catalyzes the reduction of sulfite to sulfide contains a covalently bridged cluster-siroheme assembly [9]. The bridging ligand is probably a cysteinyl sulfur atom but this can not be proven from the X-ray data. The assimilatory sulfide reductase from *Desulfovibrio vulgaris* (DvSiR) has been proposed to contain a moiety Fe_4S_4–S–Siroheme, however no X-ray structure data is available for such enzymes [9]. Mixed-valence complexes in which two metals enter are connected by a bridging group provide a simple and useful model for comparison with most complex biological systems [10,11]. In the case of iron–thiolate containing metalloproteins, no available iron–thiolate–iron mixed valence models have been reported [12–15].

In previous work [16,17] we have shown that the products of the reaction of organic disulfide with Cp(dppe)FeI depend on the reaction conditions i.e. solvent and halide abstractor used (see Scheme 1).

Now we have investigated the reaction of Cp(dppe)-FeI with 2,2′-dithiobispyridine and with 4,4′thiolate–irondithiobispyridine ligands. Potentially, dithio-

bispyridines can act as a N and S monodentate ligand and as a N and S bridging ligand between two metal centers. Examples of some of these coordination types have appeared recently [18,19].

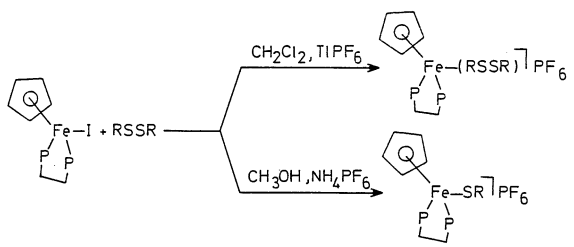
2. Results and discussion

The reaction of Cp(dppe)FeI with 2,2′-dithiobispyridine and with 4,4′-dithiobispyridine afford different products (see Scheme 2) depending on the solvent and halide abstractor used. Thus, the reaction of CpFe(dppe)I with dithiobispyridines in the presence of $TlPF_6$ and using CH_2Cl_2 as a solvent gives the complexes [Cp(dppe)Fe-2,2′-S_2(py)]PF_6 (**1**) and [Cp(dppe)-Fe-4,4′-S_2(py)]PF_6 (**2**). On the other hand the same reaction with 2,2-dithiopyridine and using methanol as the solvent and NH_4PF_6 as the halide abstractor gives the blue thiolate iron(III) complex [CpFe(dppe)-Spy]PF_6 (**3**).

Thus the reaction of Cp(dppe)FeI with 4,4′-dithiobispyridine, in CH_3OH as the solvent and in presence of NH_4PF_6 affords the unexpected thiolate bridged valence mixed complex [Cp(dppe)Fe^{III}-4-SPy-Fe^{II}(dppe)Cp]$(PF_6)_2$ (**3**).

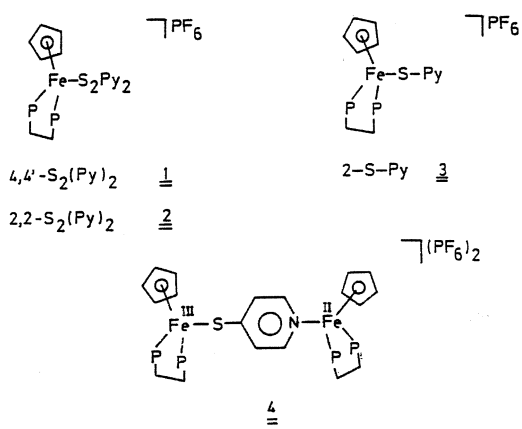
The formation of the bridging pyridinethiolate ligand arises from the oxidative addition of the organometallic fragment Cp(dppe)Fe^+ by the 4,4′-dithiobispyridine ligand followed by coordination of the pyridine pendant nitrogen by other CpFe(dppe)$^+$ fragment. In this reaction the ligand has the dual role: affording the S–N moiety as well as oxidizing the fragment from [Cp(dppe)Fe^{II}]$^+$ to [Cp(dppe)Fe^{III}]$^{+2}$

$$Py–SS–Py + 2e^- \rightarrow 2S–Py^- \quad (1)$$



A limited number of complexes of pyridine-4-thiol are known; however, coordination occurs usually at the sulfur atom in the thione form [18–23]. The most usual pyridine-2-thiol can act as an unidentate, bidentate or bridging ligand, the latter being the most common coordination mode.

In complexes **1** and **2,** dithiopyridine acts as a disulfide ligand [24,25]. Their IR spectra exhibit the expected bands of the CpFe(dppe) moiety [26] as well as those of the PySSPy ligand and PF_6 anion [27]. ^{1}H NMR signals of the disulfide ligands are observed normally [28]. Values are given in Section 4. The ^{13}P NMR spectra of the complexes **1** and **2** show the typical singlet signal of dppe in [Cp(dppe)FeL]PF_6 complexes [29,30], and the septet corresponding to the PF_6^- anion. UV–Vis spectra of the complexes exhibit one d–d absorption band around 450 nm typical of [Cp(dppe)FeL]PF_6 complexes where L is neutral donor ligand [29,30]. The formation of the Fe^{II}-dithioeter complex instead of the Fe^{III}-thiolate complex can be explained by the low dielectric medium of the reaction (CH_2Cl_2), as well as by the low acidic environment provided by the iodide abstractor, $TlPF_6$ salt [16,17].



In complex **3**, the formation of a thiolate ligand instead of the disulfide complex can be due to the high dielectric (CH_3OH) and acidic medium (NH_4PF_6). On the other hand the possible formation of the binuclear complex by coordination of the pendant nitrogen pyridine side of the 2,2′-dithiopyridine to an Cp(dppe)Fe^+ fragment (as occurs with the 4,4′-dithiopyridine reaction, see below) is precluded probably due to steric effect of the bulky Cp(dppe)Fe moiety [16,17].

The violet mixed-valence complex [Cp(dppe)Fe^{III}-4-S(Py)-Fe^{II}(dppe)Cp]$(PF_6)_2$ (**4**) was characterized by elemental analysis, IR, ESR, Mössbauer and UV–Vis spectroscopy as well as electrochemical and magnetic methods. An NMR characterization of this complex was precluded due to their paramagnetism. On the other hand, despite many attempts, it was not possible to grow single crystals of this complex, therefore structural determination could not be made. The IR spectrum showed the typical bands for the Cp(dppe)Fe moiety [26] and the expected band at 838 cm^{-1} corresponding to $\nu(PF_6)$. Bands of the thiobispyridine group appear around 1570 cm^{-1}.

At room temperature a value of $\mu_{eff} = 1.4$ BM in solid state (considering the two iron atoms) is in good agreement with the expectation of one unpaired electron by two iron atoms $\mu_{eff} = 1.22$ BM, spin-only value.

[c] Dichloromethane solution, $[NBu_4]PF_6$ as supporting electrolyte.
[d] Half-wave potential assigned to the iron link to the nitrogen atom.
[e] Half-wave potential assigned to the iron link to the sulfur atom.

The same reduced value with respect to that calculated ($\mu_{teo} = 1.7$ BM) can be due to some antiferromagnetic interaction in solid state. Detailed magnetic temperature studies are in progress.

The ESR spectrum of complex **4** in solid state showed a single broad band with no observable coupling. The g values extracted from spectra are collected in Table 1. The broadening can be attributed to the exchange interaction between two magnetically nonequivalent sites (Fe–S; Fe–N) [31]. A similar single signal was observed in the ESR of the mixed valence complex Cp*Fe(dppe)–CH=CH–CH=CH–Fe(dppe)Cp* [32]. On the other hand, the ESR spectrum in CH_2Cl_2 solution at room temperature also exhibits a single sharp signal at $g = 2.0685$ G (see Fig. 1(a)). At low temperature (77 K) in solid state a single, but broader signal than expected, is observed ($g = 2.0841$ G). In a dichloromethane solution (see Fig. 1(b)) at 77 K, the spectrum shows three separated features corresponding to the three components of the g tensor as expected for d^5 low spin iron(III) complexes in pseudooctahedral geometry [33,34]. Hyperfine coupling with the 2 equiv. ^{31}P nuclei with partial resolution was observed AP(43G) [31]. As recently documented [33], the observation of this behavior may constitute definitive evidence for delocalization of mixed valence complexes in the EPR time scale. Thus this suggests a decrease in electron-delocalization at low temperature.

The ^{57}Fe Mössbauer spectrum of **4** is shown in Fig. 2. The observed parameters are listed in Table 1. It is well known that Mössbauer spectroscopy is very useful to identify the oxidation states of iron in mixed-valence compounds [35–42]. Mononuclear iron(II) complexes of the type (η^5-C_5R_5)Fe(dppe)R exhibits Mössbauer parameters in the range $\delta = 0.13$–0.28; $\Delta E_Q = 1.95$–2.08 while that for similar iron(III) derivatives, parameters are in the range $\delta = 0.25$–0.35 mm s^{-1} and $\Delta E_Q = 0.76$–0.8 mm s^{-1}. Then ΔE_Q is characteristic, of the oxidation state of the iron metal. For binuclear mixed valence iron complexes, the presence of two distinct doublets in the spectrum is diagnostic of a localized valence whereas observation of a single average doublet is diagnostic of detrapped valence. The spectrum of complex **4** showed a two-doublet signal with quadrupole splitting and isomer shift values corresponding to intermediate states Fe^{II}–Fe^{III}. The parameters found for complex **4** are in agreement with some intermediate situation, showing some average valence II–III, which suggests a certain degree of delocalization of the electron. The presence of two similar signals indicate two slight different iron sites which can arise from the asymmetry of the bridging ligand, which induce different iron environments (the asymmetry of

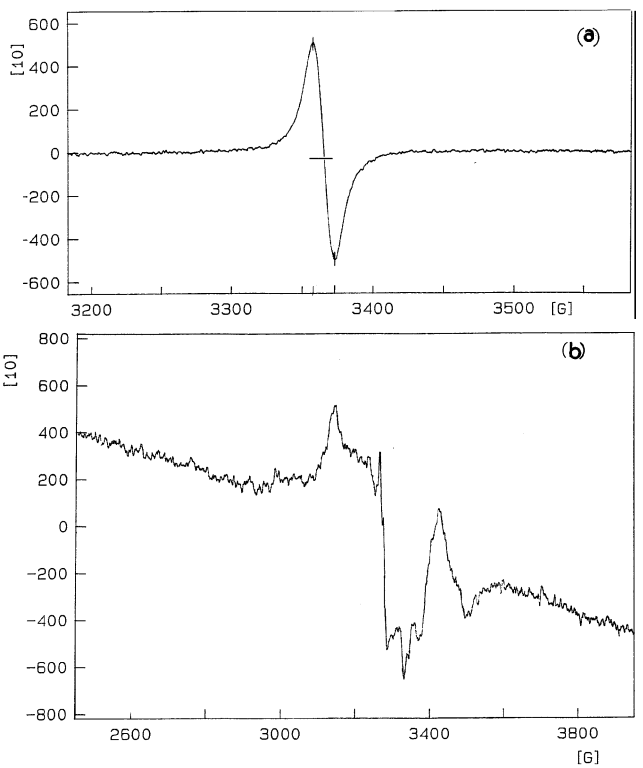

Fig. 1. EPR spectra of complex **4** in dichloromethane solution (a) at room temperature and (b) at 77 K.

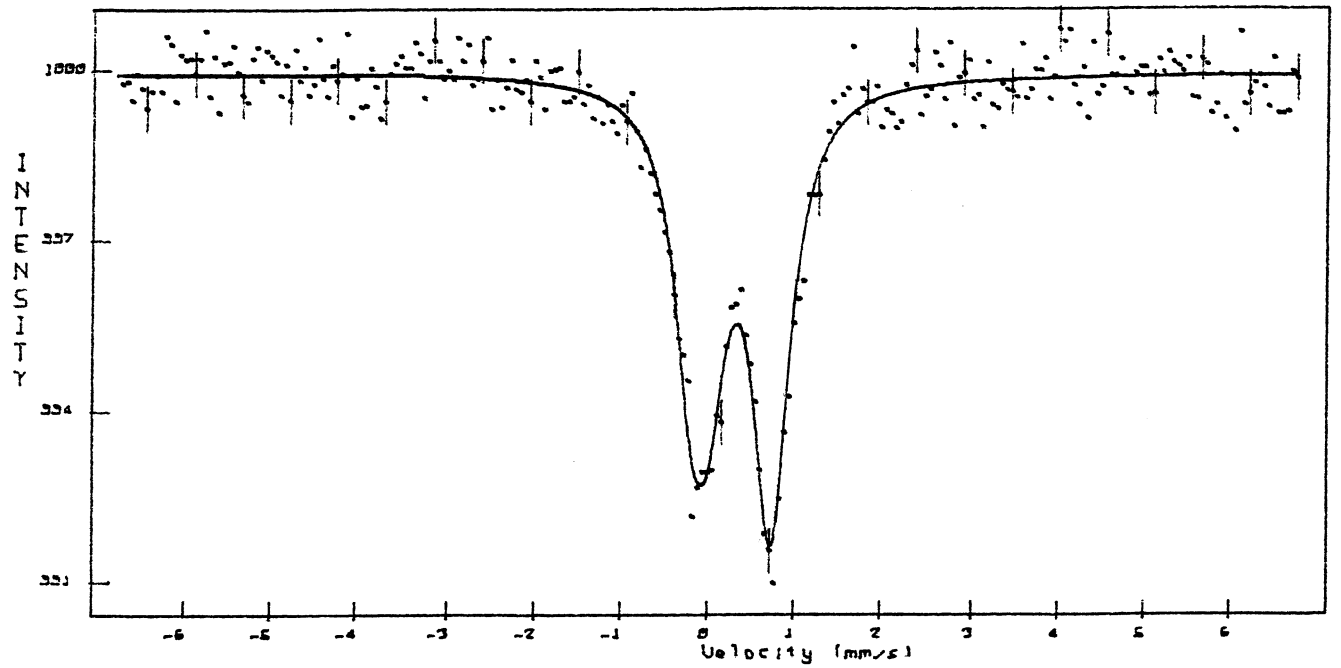

Fig. 2. Mössbauer spectrum of complex **4** at room temperature.

the ligand, see structure in Scheme 2, is also shown by the results of the UV–Vis, which shows the presence of Fe^{III}–S as well as Fe^{III}–N chromophores, see below) Consistent with this, the presence of two Fe^{III} centers having different auxiliary ligands and linked with a symmetrical bridge exhibit two slightly different signals ($\delta = 0.192, \ -0.033$ mm s^{-1}) but almost the same quadrupole values (1.978, 1.958 mm s^{-1}). A localized valence situation may induce the presence of a signal with high quadrupole values (>1.9 mm s^{-1}) corresponding to Fe^{II} as well as a signal at low quadrupole values (<0.9 mm s^{-1}) corresponding to Fe^{III}. For instance the Fe^{II}–Fe^{III} localized mixed valence complex $[Cp^*Fe(CO)_2C{\equiv}CC{\equiv}CCp^*Fe(dppe)]PF_6$ exhibit two doublets slightly separated with ΔE_Q 1,990; 0,865, corresponding to the Fe^{II} and Fe^{III} centers, respectively [39]. If complex **4** holds a localized Fe^{II}–Fe^{III} situation, a signal with a ΔE_Q value near 1.9, as is observed in $[CpFe(dppe)(NCCH_3]PF_6$ (having a Fe–N bond exhibits a quadrupole value of 1.96 mm s^{-1}[42]), might be observed. Hence the highest quadrupole value for complex **4** suggests clearly the presence of a detrapped valence situation. Thus data for complex **4** compares well with data for another delocalized Fe^{II}–Fe^{III} valence mixed complexes: $Cp^*Fe(dppe)$–C≡C–C_6H_4–C≡C–$Fe(dppe)Cp^*)PF_6$ $\Delta E_Q = 1.1$ mm s^{-1} [37], Cp^*-$Fe(dppe)$=C=CH–CH=C=$Fe(dppe)Cp^*)PF_6$ $\Delta E_Q = 1.3$ mm s^{-1} [35], and $(Cp^*Fe(dppe)$–C≡C–C≡C–Fe-$(dppe)Cp^*)PF_6$ $\Delta E_Q = 1.0$ mm s^{-1} [32]. The ΔE_Q value for the complex **4** is also in agreement with the Fe^{II}–Fe^{III} average-mixed-valence complexes, biferricenium$^+$TCA$^-$·2TCAA, $\Delta E_Q = 0.903$, and 1′,6′-diiodobiferrocene, $\Delta E_Q = 1.20$ mm s^{-1} [40]. Most recently [41] the detrapped Fe^{II}–Fe^{III} mixed-valence complexes $[Fe^{II}Fe^{III}(bpmp)(L)][BF_4]_2$ exhibit ΔE_Q values in the range 0.88–1.02 mm s^{-1}, similar to the values found for complex **4**. Mössbauer spectroscopy can also be used to monitor the intramolecular electron transfer rate in mixed valence compounds in solid state. When the intermetallic electron transfer rate is slower than 10^6 s^{-1}, localized valence is observed, whereas observation of a single average-valence quadrupole doublet is diagnostic of an electron transfer faster than 10^9 s^{-1}. Then the electron transfer rate for the complex **4** in solid state could be near 10^9 s^{-1}.

The UV–Vis spectrum of the complex **4** (see Fig. 3) exhibits, in addition (without maxima) to the characteristic absorptions of $[Cp(dppe)Fe^{II}L]^+$ L = neutral donor ligand around 450 nm [29,30], the typical absorption band of the iron(III)–thiolate chromophores around 560 nm [16,17]. This corroborates the presence of Fe^{III}–S as well as the Fe^{II}–N bond in the proposed structure of the mixed-valence complex. For comparison purposes, λ_{max} is 439 nm for the complex $[Cp(dppe)Fe$–$NC_5H_5]PF_6$ [29,30], while λ_{max} for the complex $[Cp(dppe)Fe$–$S_2(Py)_2]PF_6$ is 450 nm. The broad band around 790 nm is not present in the mononuclear precursors $[Cp(dppe)Fe$–$NC_5H_5]PF_6]$, [29] nor $[Cp(dppe)Fe$–$SR]PF_6$ [16,17], then it was assigned to an intervalence transition (IT) $Fe^{II} \rightarrow Fe^{III}$ [43,44]. Consistently with this, upon reduction with Red Al (sodium bis (2-methoxy ethoxy) aluminum) this intervalence band disappears as is shown in Fig. 3.

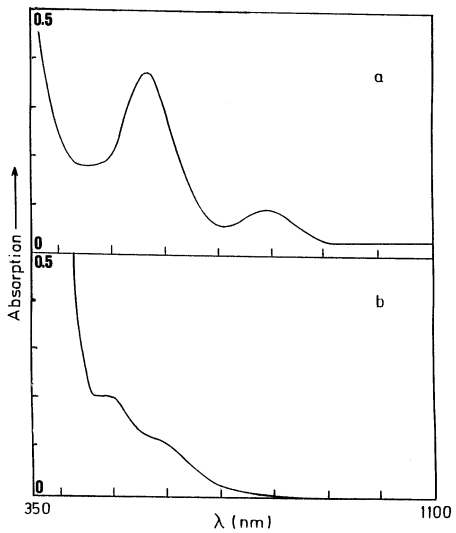

Fig. 3. UV–Vis spectra of (a) the complex [{Cp(dppe)Fe}$_2$-μ-S(Py)](PF$_6$)$_2$ before the reduction; (b) after reduction with Red Al.

Information about the electron transfer interaction between the metallic centers can be obtained by applying the Hush theory [45–47]. According to this model, the degree of electronic delocalization (α) can be calculated from Eq. (2) (Table 2).

$$\alpha^2 = \frac{(4.2 \times 10^{-4})\varepsilon_{max} v_{1/2}}{v_{max} d^2} \quad (2)$$

where v_{max} and $v_{1/2}$ are given in cm^{-1} and the intermetallic distance in Å. Since the d value for complex **4** is unknown, we have used an average value (7.6 Å), obtained from Fe–S in CpFe(CO)$_2$SC$_2$H$_5$ [48] and from mean values [49] for S–C, C=C and Fe–N (pyridine) bonds. This is an approximation usually used and accepted in the absence of the most reliable crystallographic data [43,44]. The estimated value in CH_2Cl_2 $\alpha = 0.028$ indicate an interaction Class II Robin–Day [50,51]. Values calculated in other solvents are similar as is shown in Table 3. The degree of interaction between the metal center can be estimated through the electronic coupling element H_{ab} [10,43,44,52].

$$H_{ab}\ (cm^{-1}) = \frac{2.06 \times 10^{-2}(\varepsilon_{max} v_{max} \Delta v_{1/2})^{1/2}}{d} \quad (3)$$

The value 361 cm^{-1} suggests a moderate electronic interaction between the metal centers similar to that found in mixed-valence complexes with large bridge ligands containing pyridine groups linked to the metals [53]. Comparisons of H_{ab} values are displayed in Table 3. This value is close to that observed for some metalloproteins [5–8]. The thermal first-order electron transfer rate constant can be expressed as [43,44,50,51,50–53]:

$$K_{th} = [H_{ab}^2/h][\pi/kT\lambda]^{1/2} e[-E_a/RT] \quad (4)$$

where λ is the reorganization energy of the electron transfer, which can be calculated from the maximum of the IT absorption band of the electron transfer by $E_{op} = \lambda$ and the activation energy E_a can be estimated from:

$$E_a = [\lambda^2/4\lambda] \quad (5)$$

The value calculated $K_{th} = 6.5 \times 10^6$ is in general of the order for rate constants for other mixed-valence complexes (containing pyridine bridging ligands) as can be viewed from Table 3. Thus this value compares well with electron transfer rate estimated recently for some metalloproteins [5–8].

Solvent dependence of intervalence transition of a mixed valence complex gives information about reorganizational energy arising from rearrangements of the inner and outer coordination spheres [10,45–47,50,51]. From a dielectric continuum model, Hush derived the expression:

$$E_{op} = \lambda = \lambda_i + \lambda_0 = \lambda + e^2(1/2a_1 + 1/2a_2 - 1/a) \times (1/D_{op} - 1/D_s) \quad (6)$$

where λ and λ_0 are the inner and outer-sphere reorganizational parameters respectively, e is the unit electron charge, a_1 and a_2 are the molecular radius of the redox sites, d is the internuclear separation and D_{op} and D_s are the optical and static dielectric constants of the

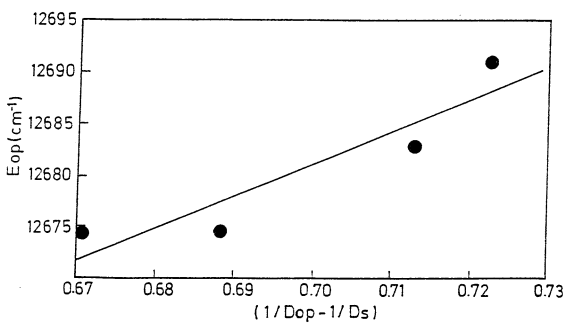
medium. The intercept of the near linear plot E_{op} versus $(1/D_{op}-1/D_s)$ for the several solvents (see Fig. 4) affords the approximate λ_i value, $\lambda_i = 12\,470\ cm^{-1}$ (the solvent CH_2Cl_2 fall out from correlation is due probably to the ion pairing effects [43,44]). From Eq. (6), the value for λ_0 can be calculated ($\lambda_0 = 227\ cm^{-1}$).

The low value of the outer-sphere reorganization contribution respect to the inner-sphere reorganization appears to be associated to the spherical symmetry of the groups $(\eta^5\text{-}C_5R_5)Fe(dppe)^+$ [11,43,44,54]. The high variations of the metal–ligand bond distances during the electron-transfer indicated by the high values of λ_i, appears to be characteristic of mixed-valence complexes containing the moiety $(\eta^5\text{-}C_5R_5)Fe(dppe)^+$ (compare for instance with $[\{Cp^*Fe(dppe)\}_2\text{-}\mu\text{-}(C\equiv C–(C_6H_4)_n–C\equiv C)](PF_6)_2$, $n=0,\ 1$ $\lambda_i = 7100\ cm^{-1}$, $\lambda_0 = 500 cm^{-1}$ [35]) however an inverse tendency $\lambda_0 > \lambda_i$ has been reported recently for $[\{CpFe(dppe)\}_2\text{-}\mu\text{-}CN]PF_6$ [43,44]. The high delocalized behaviour for **4** in spite of the high inner reorganizational energies can be due to a considerable contribution from the vibrational modes of the bridging ligand to the reorganization energy [55,56]. The total reorganization energy $\lambda = 12\,697\ cm^{-1}$ is slightly higher than those reported for electron transfer in metalloproteins, which is reasonable because of the most bulky environment of the active site of metal proteins.

The cyclic voltammogram for the $[\{CpFe(dppe)\}_2\text{-}\mu\text{-}SPy](PF_6)_2$ complex exhibits two close, one electron electrochemical quasi-reversible waves. Values are shown in Table 1. The first at 0.26 V is chemically quasi-reversible ($i_{p_c}/i_{p_a} = 1.25$) and can be assigned to the oxidation of the Fe–Py moiety by comparison with data for $[CpFe(dppe)L]PF_6$ complexes [29,30]. On the other hand the lowest oxidation at 0.11 V (although not well defined) is electrochemically quasi-irreversible ($\Delta E_p = 0.08$ V), but chemically irreversible and is assigned to the Fe^{III}–S/Fe^{II}–S couple [57,58]. Thus an irreversible oxidation peak at 1.3 V corresponding to the oxidation of R–SS–R, as well as a quasi-irreversible oxidation peak at -0.55 V assigned to the oxidation of RS^- were observed, behavior typical of the redox properties of $[CpFe(dppe)SR]PF_6$ [57] and other metal–thiolate complexes [58]. Although the second oxidation wave described above is chemically irreversible, a rough estimation can be made of the comproportionation constant $K_c = 3.5\times10^2$ for the reaction:

$$[Fe^{II}-S-py-Fe^{II}]^+ + [Fe^{III}-Spy-Fe^{III}]^{3+} \overset{K_c}{\rightleftarrows} 2[Fe^{II}-Spy-Fe^{III}]^{2+} \quad (7)$$

The relatively high value of K_c agrees with the relatively high electron coupling between the iron centers and also provides a more efficient electron delocalization than X = methylene, ethylene and acetylene groups (considering the NC_5H_4–X–C_5H_4N moiety) [53]. Data shown in Table 3 also suggests that the thiolate bridging ligand is more efficient in electron delocalization than organic sulfide ligands (R_2S), but somewhat less efficient than the disulfide ligands. These conclusions are in agreement with the rate of redox chromium exchange reactions,



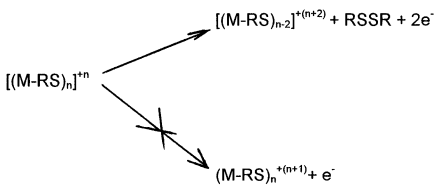


Fig. 4. Plot of E_{op} versus $(1/D_{op}-1/D_s)$ for the mixed valence complex $[Cp(dppe)Fe\text{-}S(Py)Fe(dppe)Cp]\ (PF_6)_2$.

$$*Cr^{2+} + [(H_2O)_5CrSR]^{2+} \Leftrightarrow Cr^{2+} + [(H_2O)_5^{*}CrSR]^{2+} \quad (8)$$

where the rates of reduction were found to be fast mediated by the thiolate sulfur ligand which functions as an extremely efficient electron-transfer bridge between chromium(II) and chromium(III) [1]. It is interesting to note that the only sulfur ligand bridging in mixed-valence complexes are sulfides and disulfides, then the complex $[\{Cp(dppe)Fe\}_2\text{-}\mu S(Py)](PF_6)_2$ is to our knowledge the first thiolate acting as a bridge of the form M–SR–M between metal centers in mixed valence compounds $[LnM\text{–}X\text{–}MLn]^{z+}$ X = bridging ligand [59,60].

The unexpected formation of the Fe^{III}–Fe^{II} thiolate complex can be explained assuming the formation of the iron(III)–thiolate mononuclear complex — the expected product using CH_3OH as a solvent and NH_4PF_6 as a halide abstractor — and subsequently the coordination of the nitrogen coordination pendant site by an $Cp(dppe)Fe^{+}$ fragment. To our knowledge this is the first Fe^{II}–Fe^{III} mixed valence complex, containing an thiolate ligand bridge [12–15,59,60] where the Fe^{III} is bonded to the sulfur–thiolate and the Fe^{II} is linked to some donor atom contained in R.

The scarcity of mixed-valence compounds containing this type of bridging ligand can be due to the difficulty in obtaining the mixed-valence complex by oxidation of the corresponding Fe^{II}-(μ-thiolate)–Fe^{II} complex owing to the known oxidation of the thiolate ligand instead the oxidation of the metallic center:

The efficient electron transfer between the iron centers through the pyridinethiolate ligand can be explained by the effective π-system formed by overlapping of the SOMO($Cp(dppe)Fe^{III}$)–HOMO($S\text{-}C_6H_5$) orbitals as well as HOMO($Cp(dppe)Fe^{II}$)–LUMO(NC_5H_5) overlap. The electron transfer from Fe^{II} to the pyridine ring can involve the HOMO of the fragment Cp(dppe)Fe which is π in character [16,17] and the LUMO of pyridine which also has π character [61] (see Fig. 5).

On the other hand electron transfer from the pyridine–thiolate ligand to $Cp(dppe)Fe^{III}$ fragment [16,17] through the thiolate side can involve the HOMO of the thiolate [62,63] which has a π character and the π-SOMO orbital of the Fe^{III} fragment. The possible π system involved in the Fe^{II}–Fe^{III} electron transfer is depicted in Fig. 5. In this orbital interaction diagram the structure of the iron–pyridine moiety was established according to data from iron–pyridine complexes

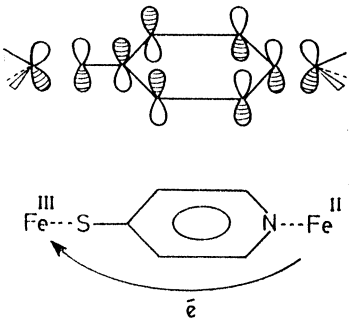

Fig. 5. Molecular orbitals probably involved in the electron transfer process. Interaction of the pyridine and thiolate side of the pyridinethiolate ligand with the iron fragments was deduced from HOMO of thiolate and LUMO of pyridine (see text).

[64] and those for the iron–thiolate side of the bridging ligand was made according to iron–thiolate structural data [16,17,48]. HOMO-thiolate [62,63] and LUMO-pyridine [61] was according literature data. SOMO of $Cp(dppe)Fe^{2+}$ and HOMO of $Cp(dppe)Fe^{+}$ has been reported previously [16,17].

3. Conclusions

From the study of the reaction of Cp(dppe)FeI with dithiopyridines, a new mixed valence binuclear complex containing a thiolate bridge was isolated and identified. The nature of the Fe^{III}–Fe^{II} interaction through the thiolate bridge, determined from ESR, Mössbauer and the Hush parameters, appears to be similar to the electron transfer in some metalloproteins, although the reorganizational energy is greater in the binuclear model than the biological systems. Recent studies on electron transfer between sulfur surface modified gold electrodes and cytochrome *c* reveal that the 4-pyridinethiolate ligand can act as an efficient bridge conductor between the cytochrome and the electrode [65].

4. Experimental

All reactions were carried out under purified N_2 or Ar using standard Schlenk techniques and the solvents used (methanol, dichloromethane, diethyl ether and *n*-hexane) were appropriately distilled and dried before use. The precursor complex Cp(dppe)FeI was prepared according to literature methods [42,66]. 4,4′- and 2,2′-dithiobispyridine, $[NBu_4]PF_6$, NH_4PF_6, (Aldrich) were used as received. $TlPF_6$ (**caution**! Thallous salts are very poisonous and should be handled with caution) was prepared from Tl_2CO_3 and HPF_6. IR spectra were recorded as KBr pellets on a FT-Bruker 66V spectrometer.

NMR spectra were run in CD_2Cl_2 or $(CD_2)_2CO$ solution at room temperature (r.t.) on a Bruker AMX 300 spectrometer with TMS(H) $\delta = 0.0$ ppm as internal standard or 85% H_3PO_4 and downfield positive to the reference as external standard for the ^{31}P measurements. UV–Vis spectra were run on a Varian DMS-9 spectrophotometer with 1 cm optical path cuvettes. Cyclic voltammetry was carried out at r.t. in CH_2Cl_2 using a Parc model 370 electrochemistry system equipped with a three electrode device, employing a glassy carbon working electrode, platinum wire, counter electrode and saturated calomel reference electrode. Solution was 10^{-3} M in the complex and 0.1 M in Bu_4PF_6 as supporting electrolyte. Under the same experimental conditions $E_{1/2}$ for the ferrocene/ferrocenium couple was 0.45 V with separations of about 0.060 V. Magnetic measurements were carried out by a Gouys method at r.t. (25°C) on a Johnson Matthey balance using mercury terathiocyanate cobaltate(II) as the calibrate. ESR spectra were carried out using an ESR Bruker ECS 106 spectrometer using a rectangular mode cavity with a 50 Hz field modulation. The measurements were made with the microwave band X (9.79 G Hz). For the solid sample the crushed powder was used. The Mössbauer spectrum, as a fine powder sample was obtained in a conventional spectrometer with constant acceleration. The source was 10mCi^{57} Co in a Pd matrix. The gamma ray detection was carried out with a Reuter–Stoke detector connected to an Ortec amplifying and selecting system. A 1024 channel Camberra multichannel analyzer was used for the acquisition of information. The reported shift values are relative to iron.

4.1. Reaction of Cp(dppe)FeI with 2,2′-dithiobispyridine in CH_2Cl_2

A mixture of 0.15 g (0.23 mmol) of Cp(dppe)FeI [31] and 0.08 g (0.36 mmol) of 2,2′-dithiobispyridine in 30 ml dichloromethane and in the presence of 0.16 g $TIPF_6$ (0.46 mmol) was stirred at r.t. for 24 h. The solution was filtered through Celite and the filtrate was concentrated under reduced pressure to a volume of $\approx$10 ml. Then 5 ml of an *n*-hexane–diethyl ether 1:1 mixture was added. The brown–orange precipitate was washed twice with diethyl ether and dried under vacuo. Yield 0.16 g; 78%. *Anal.* Found: C, 56.68; H, 4.09; N, 2.7. Calc. for $C_{41}H_{37}N_2F_6S_2P_3Fe$: C, 55.69; H, 4.18; N 3.16%.

Ir (KBr, cm^{-1}): 1088 $\nu(C_5H_5)$; 698 ν(dppe); 1576 $\nu(S_2(Py_2))$; 840 $\nu(PF_6)$.

^1H NMR (acetone-d_6 solution, ppm) 8.46m,7.68m,7.65m,7.23m $S_2(Py)_2$; 7.33m dppe; 4.76s Cp; 3.4m CH_2. ^{31}P NMR (acetone-d_6 ppm) 92.4 dppe; -138.8 PF_6.

4.2. Reaction of Cp(dppe)FeI with 4,4′-dithiobispyridine in CH_2Cl_2

A solution of Cp(dppe)FeI 0.15 g (0.23 mmol) and 4,4′-dithiobispyridine 0.08 g (0.36 mol) in the presence of $TIPF_6$ 0.16 g (0.46 mmol) in 30 ml dichloromethane was stirred at r.t. for 24 h. The separation procedure, similar to that above for 2,2′-dithiobispyridine, affords red–brown solid. Yield 0.14 g; 68%. *Anal.* Found: C, 55.7; H, 4.2; N, 3.2. Calc. for $C_{41}H_{37}F_6N_2S_2P_3Fe$: C, 55.65; H, 4.18; N, 3.16%.

Ir (Kbr, cm^{-1}) 1082 $\nu(C_5H_5)$; 694 ν(dppe); 1565 $\nu(S_2(Py)_2)$; 847 $\nu(PF_6)$.

^1H NMR (acetone-d_6 cm^{-1}) 7.62m, 7.54m, 7.41m, 7.19m S_2 $(Py)_2$; 7.33m (dppe) 4.76s C_5H_5; 3.4m CH_2. ^{31}P NMR (acetone-d_6 ppm) 92.3 dppe; -138.8 PF_6.

4.3. Reaction of Cp(dppe)FeI with 4,4′-dithiobispyridine in CH_3OH

Cp(dppe)FeI 0.15 g (0.23 mmol) was stirred with 4,4′-dithiobispyridine 0.08 g (0.36 mmol) in the presence of NH_4PF_6 0.06 g (0.37 mmol) in CH_3OH (30 ml) for 24 h at r.t. The solvent was evaporated under vacuo and the black solid residue was extracted with dichloromethane (15 ml). Upon addition of a 1:1 mixture of *n*-hexane–diethyl ether, a blue–black microcrystals precipitated which were washed several times with diethyl ether and dried under reduced pressure. Yield approximately 70%. *Anal.* Found: C, 55.98; H, 4.17; N, 1.1. Calc. for $C_{67}H_{62}NF_{12}SP_6Fe_2$: C, 55.93; H, 4.31; N, 0.97%.

Ir (KBr, cm^{-1}) 1094 $\nu(C_5H_5)$; 695 ν(dppe); 1565 $\nu(S_2(Py)_2)$; 839 $\nu(PF_6)$.

4.4. Reaction of Cp(dppe)FeI with 2,2′-dithiobispyridine in methanol

Cp(dppe)FeI 0.15 g (0.23 mmol) and 2,2′-dithiobispyridine 0.08 g (0.36 mmol) in the presence of NH_4PF_6 0.06 g (0.37 mmol) in CH_3OH (30 ml) were stirred for 24 h at r.t. Separation and purification procedures similar to the above reaction with 4,4′-dithiobispyridine afford a blue solid. Yield 0.13 g; 65%. *Anal.* Found: C, 55.9; H, 4.3; N, 1.7. Calc. for $C_{36}H_{33}F_6NSP_3Fe$: C, 55.82; H, 4.26; N, 1.8%.

Ir (KBr, cm^{-1}) 1094 $\nu(C_5H_5)$; 695 ν(dppe); 1565 $\nu(S_2Py)$; 838 $\nu(PF_6)$

Abstract

The reaction of an ethanolic solution of copper(II) pyridinecarboxylates $CuX_2 \cdot nH_2O$ (where X is nicotinate (nic) ($n = 0$) or isonicotinate (isonic) ($n = 4$)) with ethylenediamine (en) in a molar ratio of 1:2 lead to the isolation of solid tetragonally distorted octahedral complexes of the type $[Cu(en)_2(H_2O)_2]X_2 \cdot nH_2O$ ($n = 1$ for nic; $n = 0$ for isonic). The analogous reaction of $CuX_2 \cdot nH_2O$ with diethylenetriamine (dien) in a molar ratio of 1:1 leads to the formation of square-pyramidal pentacoordinated complexes of the type $[CuX(dien)(H_2O)]X$. On the other hand, the reaction of equimolar quantities of copper(II) nitrate and dien with nicotinate anions (equimolar quantities of pyridinecarboxylic acid and NaOH) in ethanolic solutions gives a solid monomeric complex $[Cu(nic)(NO_3)dien)(H_2O)] \cdot H_2O$ in which the coordination polyhedron around the Cu(II) atom is a $(4 + 1 + 1)$ distorted tetragonal bipyramid. Based on the molecular structure the electronic and IR spectra are discussed. Moreover, the results of the quantitative determination of antimicrobial activity of the isonic complexes $[Cu(isonic)_2(H_2O)_4]$, $[Cu(en)_2(H_2O)_2](isonic)_2$, $[Cu(isonic)(dien)(H_2O)](isonic)$, as well as isonicotinic acid, ethylenediamine and diethylenetriamine alone are discussed. © 2000 Elsevier Science B.V. Keywords: Chelating ligands; Crystal structures; Copper(II) complexes; Pyridinecarboxylate complexes; Antimicrobial activity

1. Introduction

Carboxylatocopper(II) complexes are interesting from both a chemical and biological point of view. Different possible coordinations of the carboxyl group to the central atom lead to the existence of compounds with distinct crystal structures. Pyridinecarboxylic acid and its derivatives possessing very interesting pharmaceutical properties constitute an important group of anthelmintics and vitamins. It is known that some drugs act via chelation [1] or via inhibition of metalloenzymes [2], but little is known about the modification of activity of most drugs when their ligating potential is utilized.

Synthesis, spectral and thermal properties of various complexes $CuX_2 \cdot nH_2O$ (where X is pyridine-3-carboxylate or nicotinate (nic) and pyridine-4-carboxylate or isonicotinate (isonic); $n = 0$–4) have been reported [3,4]. Only a few structures of $[CuX_2(H_2O)_4]$ [5] and their adducts with chelating ligands 1,10-phenanthroline and 2,2′-bipyridine have been reported [6,7]. Different coordination modes of the pyridinecarboxylate (coordinated not only through the carboxylate group, but also through the nitrogen atom of the pyridine ring) lead to formation of mononuclear [5] or polynuclear [6,7] structures. Recently, we have studied [8] the adducts of Cu(II) isonicotinate with ethylenediamine (en) and diethylenetriamine (dien), prepared $[Cu(en)_2(H_2O)_2](isonic)_2$ and $[Cu(isonic)(dien)(H_2O)_{1.5}] \cdot 0.5SO_4 \cdot 2.5H_2O$ and solved their structures by X-ray analysis.

In the present paper, we report as a part of our investigation of metal ion–drug interactions the complexation of isonic and nic in the presence of en and dien. The stereochemistry and the mode of ligand coordination in solid copper(II) complexes have been determined by IR and electronic measurements. The crystal and molecular structure of one of the products, $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$, has also been solved. Moreover, for some of the isonicotinate complexes antimicrobial activity has been determined.

2. Experimental

2.1. Chemical reagents

All the chemicals used were of reagent grade and without further purification. All organic reagents were purchased from Aldrich; their purity was checked by IR spectra.

2.2. Analysis and physical measurements

Copper was determined by electrolysis after mineralization of the complexes; carbon, hydrogen, nitrogen and sulfur were determined by microanalytical methods (Carlo Erba Instruments EA 1180). Besides the elemental analysis, the water content in the hydrates was determined from thermogravimetrical curves. The yields of products were related to the metal contents in the reacting mixtures. Analytical data for solid complexes are given in Table 1.

Electronic spectra (9000–50 000 cm^{-1}) of the powdered samples in nujol mulls were recorded at room temperature (r.t.) on a Specord 200. IR spectra in the region of 100–4000 cm^{-1} were recorded on a Philips Analytical PU 9800 FTIR spectrometer and on a Magna 750 spectrometer at r.t. Spectra of solid samples were obtained in nujol mulls and KBr pellets (1 wt%).

2.3. X-ray structure determination

Data collection and cell refinement (see Table 2) for the complex $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$ were carried out using a KUMA KM4 diffractometer and software [9]. The diffraction intensities were corrected for Lorentz-polarization effects. The structure was solved by Patterson methods using XFPS [10] and subsequent Fourier difference maps. Anisotropic thermal parameters were refined for all non-hydrogen atoms. All hydrogen atoms were found from the difference Fourier maps and their positional parameters refined. Geometrical analysis was performed using SHELXL-93 [11]. The structure of the complex was drawn by ORTEP [12] (Fig. 1). Basic crystallographic data are summarized in Table 2.

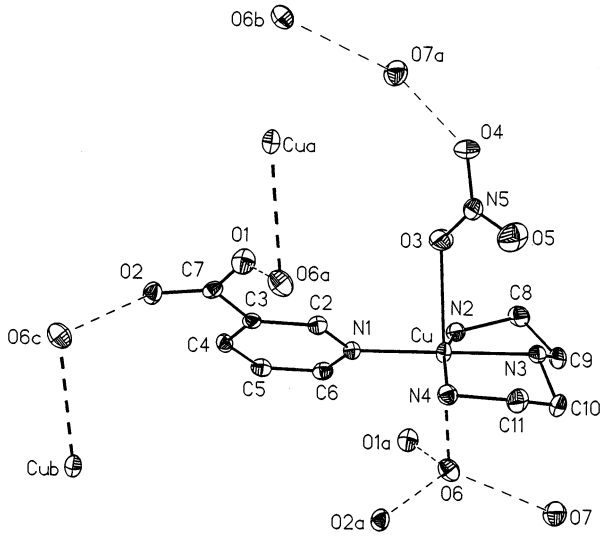

Fig. 1. ORTEP plot of $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$ also indicating the hydrogen bonds interconnecting neighbouring molecules (thermal ellipsoids are shown at the 50% probability level).

2.4. Preparation of the complexes

$[Cu(nic)_2]$ was prepared similarly as described by Kleinstein [4]. Aqueous solution (10 cm^3) of the nicotinic acid and an equimolar quantity of sodium hydroxide (10 mmol) were added to 30 cm^3 of an aqueous solution of copper(II) sulfate (5 mmol), and the reaction mixture was refluxed for 15 min. The blue precipitate was filtered off in a nearly quantitative yield (95%).

The violet complex $[Cu(en)_2(H_2O)_2](nic)_2\cdot H_2O$ was formed in an ethanolic solution (30 cm^3) of $[Cu(nic)_2]$ (1.25 mmol) by adding ethylenediamine (in the molar ratio of 1:2). Similarly, the blue complexes $[Cu(nic)(dien)(H_2O)](nic)$ and $[Cu(isonic)(dien)(H_2O)](isonic)$ were formed in an ethanolic solution (30 cm^3) of 1.25 mmol $[Cu(nic)_2]$ or $[Cu(isonic)_2(H_2O)_4]$ [8] by adding diethylenetriamine (in the molar ratio of 1:1), respectively. All resulting solutions were left to slowly evaporate at r.t. In isolating the above complexes, it was necessary to add acetone to the concentrated solution. Precipitates of the complexes were filtered off, washed with ethanol and finally dried in vacuo (yields of the complexes $[Cu(en)_2(H_2O)_2](nic)_2\cdot H_2O$, $[Cu(nic)(dien)(H_2O)](nic)$ and $[Cu(isonic)(dien)(H_2O)](isonic)$ were 66, 72 and 75%, respectively).

The blue crystals of $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$ were obtained dissolving copper(II) nitrate (1.25 mmol) and dien (1.25 mmol) in 20 cm^3 of ethanol. The solution was heated for 1 h at 70°C, then 20 cm^3 of an aqueous solution of the nicotinic acid and an equimolar quantity of sodium hydroxide (1.25 mmol) were slowly added. The resulting solution was left to slowly evaporate at r.t. In isolating the crystals, it was necessary to add a few cm^3 of acetone to the concentrated reaction solution. Well-shaped crystals, suitable for X-ray structure analysis, were collected after a few hours by filtration, washed with acetone and finally dried in vacuo (yield 83%).

2.5. Antimicrobial assays

The antimicrobial activity of the isonic complexes $[Cu(isonic)_2(H_2O)_4]$, $[Cu(en)_2(H_2O)_2](isonic)_2$, $[Cu(isonic)(dien)(H_2O)](isonic)$, as well as isonicotinic acid, ethylenediamine and diethylenetriamine alone was evaluated by a macrodilution method using G^+ *Staphylococcus aureus* CCM 3953, G^- *Escherichia coli* CCM 3988 and the yeasts *Candida parapsilosis* (purchased from the Laboratory of Medical Mycology, Postgraduate Medical Institute, Bratislava) in L-shaped tubes. The cultures of bacteria and yeasts were incubated under vigorous shaking [13]. The efficiency of prepared compounds on filamentous fungi *Rhizopus oryzae*, *Alternaria alternata*, *Fusarium moniliforme* (obtained from the Collection of Microorganisms of Department of Biochemistry and Microbiology, Slovak University of Technology), *Botrytis cinerea* CCM F-16 and *Microsporum gypseum* (received from the Laboratory of Medical Mycology, Postgraduate Medical Institute, Bratislava) was tested by macrodilution technique on solidified broth medium during static culturing [14].

Chromatographically pure compounds were dissolved in dimethylsulfoxide, its final concentration never exceeded 1.0 vol.% in either control or treated samples. The concentration of tested compounds used in all experiments ranged from 1.0 to 10.0 mmol l^{-1} for filamentous fungi and from 0.125 to 5.0 mmol l^{-1} for yeasts and bacteria.

The antimicrobial activity was characterized by the IC_{50} values (concentration of a compound which in comparison to the control inhibits the growth of microorganisms to 50%) and MIC values (minimal inhibitory concentration of a compound which inhibits microbial growth by 100%). The IC_{50} and MIC values were read from toxicity curves.

MIC experiments on subculture dishes were used to assess the minimal microbicidal concentration (MMC). Subcultures were prepared separately in Petri dishes containing competent agar medium and incubated at 30°C for 48 h (bacteria, yeasts) and at 25°C for 96 h (filamentous fungi). The MMC value was taken as the lowest concentration which showed no visible growth of microbial colonies in the subculture dishes.

3. Results and discussion

3.1. Crystal structure description of complex $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$

In the structure of $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$ (Fig. 1) the coordination polyhedron around the Cu(II) atom is a $(4+1+1)$ distorted tetragonal bipyramid, where three of the equatorial positions are occupied by three nitrogen atoms of the diethylenetriamine ligand, the Cu–N distances ranging from 2.017(2) to 2.035(2) Å (Table 3) and the N–Cu–N angles for dien being nearly the same [N2–Cu–N3 84.95(6)° and N3–Cu–N4 85.14(6)°, respectively], while in the fourth equatorial position the nic anion is coordinated through the nitrogen atom of the pyridine ring with the Cu–N1 distance of 2.025(2) Å. One axial position is occupied by the oxygen atom O3 of the NO_3^- anion at a distance of 2.457(2) Å, the other axial position being occupied by the oxygen atom O6 of a water molecule at a considerably longer distance of 2.716(2) Å.

A system of hydrogen bonds is interconnecting each of the molecules with other molecules (a) via the coordinated water molecule (O6) which creates two hydrogen bonds [2.708(2) and 2.731(2) Å, respectively] with two carboxyl oxygen atoms O1a, O2a of two different neighbouring molecules and a hydrogen bond [2.851(2) Å] with the uncoordinated water molecule (O7), (b) via the two carboxyl oxygen atoms O1, O2 with the water molecules (O6a, O6c), and (c) via the nitrate oxygen atom O4 creating a hydrogen bond [2.817(2) Å] with the uncoordinated water molecule (O7a).

3.2. Spectroscopic data

All the typical features of IR spectra are clearly compatible with the structural characteristics of the complexes under study.

The most characteristic bands in the IR spectra correspond to carboxyl group stretching vibrations in the expected regions [15]. The carboxylate stretching frequencies $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ for each of the complexes under study are given in Table 4. The difference between the antisymmetric stretch and symmetric stretch, which gives information on the carboxylate bonding mode for the complexes, could not be determined accurately due to an overlap of $\nu_{as}(COO^-)$ with the stretching vibration of C=N of the pyridine ring. Moreover, the positions of the absorption bands are strongly affected by hydrogen bonding interactions of the carboxyl group of nic or isonic with other ligands as confirmed by the crystal structures of some of the complexes. However, considerable splitting of bands assigned to $\nu_{as}(COO^-)$ and $\nu_s(COO)$ for anhydrous $[Cu(nic)_2]$ confirms that the nicotinic acid anion as a ligand is most probably coordinated via a bridging carboxyl group.

The *N*-coordination of the nicotinate or isonicotinate in complexes $[Cu(nic)_2]$, $[Cu(isonic)_2(H_2O)_4]$, $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$ and $[Cu(isonic)(dien)(H_2O)_{1.5}]\cdot 0.5SO_4\cdot 2.5H_2O$ is in agreement with the positions of absorption bands in the region from 650 to 667 cm^{-1} and in the region from 423 to 447 cm^{-1}, respectively, which are due to in-plane ring deformation and out-of-plane deformation of the coordinated pyridine ring [15]. However, the positions of bands above 450 cm^{-1} can not be assigned accurately, because they are obscured with the Cu–O stretching frequencies [16] (Table 4). On the other hand, in the IR spectra of both complexes $[Cu(en)_2(H_2O)_2](nic)_2\cdot H_2O$ and $[Cu(en)_2(H_2O)_2](isonic)_2$, which contain en, medium bands are observed at 620 and 615 cm^{-1} as well as at 398 and 395 cm^{-1}, respectively, which are assigned to in-plane ring deformation and out-of-plane deformation of a non-coordinated pyridine ring [15].

In the spectra of complexes $[Cu(nic)(dien)(H_2O)](nic)$ and $[Cu(isonic)(dien)(H_2O)](nic)$ the positions of bands assigned to in-plane ring deformation and out-of-plane deformation are characteristic for a coordinated as well as for a non-coordinated pyridine ring [15].

In the IR spectrum of complex $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$, strong bands were observed at 1313 and 1007 cm^{-1} which were assigned to $\nu_s(NO_2)$ and

[c] Mixed bands or some of the observed bands also belong to another vibrational mode.

ν(NO), typical for the unidentate coordination mode of nitrato groups [15] (see the crystal structure).

The electronic spectra (Table 4) of both complexes $[Cu(nic)(dien)(H_2O)](nic)$ and $[Cu(isonic)(dien)(H_2O)]$-(nic) exhibit a broad asymmetrical band with a maximum at 16 900 and 16 600 cm^{-1} (band I) and shoulders on its low energy side which are typical for five-coordinated copper(II) complexes with almost a square-pyramidal structure [17]. The solid-state electronic spectra of all other copper(II) complexes under study (Table 4) exhibit a symmetrical broad ligand field band with a maximum in the range of 18 500 to 13 500 cm^{-1}. For some of the complexes, there is also a charge transfer band at about 30 000 cm^{-1} (band II). This type of d–d spectrum is typical for tetragonally distorted octahedral copper(II) complexes [17].

3.3. Structure of solid complexes

The reaction of ethanolic solution of copper(II) pyridinecarboxylates $CuX_2\cdot nH_2O$ (where X is nic or isonic, $n = 0$ and 4, respectively) with en in a molar ratio of 1:2 lead to isolation of solid complexes of the type $[Cu(en)_2(H_2O)_2]X_2\cdot nH_2O$ ($n = 1$ and 0) which contain uncoordinated pyridinecarboxylate anions. Moreover, the crystal structure of $[Cu(en)_2(H_2O)_2](isonic)_2$, which comprises $[Cu(en)_2(H_2O)_2]_2$, cations and isonicotinate anions, has been determined [8]. The four N atoms of en form the coordination plane around the copper(II) atom, and oxygen atoms of the water molecules, lying in the axial positions, complete an elongated octahedral coordination sphere. The analogous reaction of $CuX_2\cdot nH_2O$ with dien in a molar ratio of 1:1 leads to formation of pentacoordinated complexes of the type $[CuX(dien)(H_2O)]X$ (X = nic or isonic), which contain coordinated and non-coordinated pyridinecarboxylate anions. In these complexes the copper(II) atom is coordinated in a square-pyramidal arrangement by three N atoms of dien and one N atom of the pyridine ring of nic or isonic in equatorial positions, and by one water molecule in an axial position. The analogous structure of the pentacoordinated complex cation has been found by X-ray structure analysis [18] for $[Cu(isonic)(dien)(H_2O)]PF_6$. On the other hand, the reaction of equimolar quantities of copper(II) sulfate or nitrate and dien with pyridinecarboxylate anions (equimolar quantities of pyridinecarboxylic acid and NaOH) in ethanolic solutions gives solid monomeric complexes $[Cu(isonic)(dien)(H_2O)_{1.5}]\cdot 0.5SO_4\cdot 2.5H_2O$ [8] and $[Cu(nic)(NO_3)(dien)(H_2O)]\cdot H_2O$, respectively. The crystal structure of the sulfate complex contains two cations — a pentacoordinated $[Cu(isonic)(dien)(H_2O)]^+$, and a hexacoordinated $[Cu(isonic)(dien)(H_2O)_2]^+$ sulfate anions and water molecules. In the crystal structure of the nitrate complex the coordination polyhedron around the Cu(II) atom is a (4 + 1 + 1) distorted tetragonal bipyramid (see Section 3.1).

All the above complexes with chelating ligands (en and dien) are monomeric, and the complexes with en contain only non-coordinated pyridinecarboxylate anions, while the complexes with dien contain both non-coordinated and *N*-coordinated anions. In the case of the sulfate or nitrate complexes only *N*-coordinated anions in the equatorial plane are present. On the other hand, another type of nic coordination has been revealed by a previous structure determination of the polymeric complex [Cu(nic)(1,10-phenanthroline)(aqua)$_2$]$NO_3 \cdot 2H_2O$ [6] in which the nicotinate anions bridge the adjacent Cu(II) atoms through both the pyridine N atom and the carboxyl O atom to form zigzag polymeric chains along the *b* axis. Similarly, in the complex [Cu(nic)(2,2′-bipyridine)(aqua)]$NO_3 \cdot 2H_2O$ [7], the nicotinate anions bridge the adjacent Cu(II) atoms through both the pyridine N atom and the carboxyl group to form infinite chains. The carboxyl group of the nicotinate anion coordinates to the Cu(II) atom as a chelate.

3.4. Antimicrobial activities

Results of the quantitative determination of anti microbial activity, characterized by the IC_{50} and MIC values of the isonic complexes [Cu(isonic)$_2$(H_2O)$_4$], [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$,[Cu(isonic)(dien)(H_2O)](isonic), as well as isonicotinic acid, ethylenediamine and diethylenetriamine alone are presented in Table 5. From among the tested compounds, the compound [Cu(isonic)$_2$(H_2O)$_4$] has shown the highest antibacterial activity against G^+ *S. aureus* ($IC_{50} = 1.9$ mmol.l^{-1}). Isonicotinic acid (isonicH) at a concentration of 5 mmol l^{-1} has not influenced the *S. aureus* growth, inhibition of the bacteria growth by compound [Cu(isonic)$_2$(H_2O)$_4$] at the same concentration was approximately 90%. Although ethylenediamine (en) alone has partially inhibited the *S. aureus* growth, ($IC_{50} = 2.6$ mmol l^{-1}), this influence has not manifested itself with [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$. The effect of the compounds on G^- *E. coli* was considerably lower. IsonicH at a concentration of 5 mmol.l^{-1} did not influence the *E. coli* growth, inhibition of the growth by complexes [Cu(isonic)$_2$(H_2O)$_4$], [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$, and [Cu(isonic)(dien)(H_2O)](isonic) at the same concentration was approximately 50% ($lC_{50} = 5$ mmol l^{-1}).

The highest effect against the yeasts *C. parapsilosis* was observed for the compounds [Cu(isonic)$_2$(H_2O)$_4$] and [Cu(isonic)(dien)(H_2O)](isonic) ($IC_{50} = 2.1$ and 3.3 mmol l^{-1}). While isonicotinic acid alone at a concentration of 5 mmol l^{-1} has not inhibited the yeasts growth, growth inhibition by the compounds [Cu(isonic)$_2$(H_2O)$_4$] and [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$ at the same concentration was 70–80%. Similarly as in the case of *S. aureus* the partial inhibitory activity of en against *C. parapsilosis* ($IC_{50} = 3.7$ mmol l^{-1}) was not observed in the activity of its Cu-adduct ([Cu(en)$_2$(H_2O)$_2$](isonic)$_2$, $IC_{50} > 5$ mmol l^{-1}).

The growth of filamentous fungi, phytopathogenic fungi *B. cinerea*, *F. moniliforme* and a dermatophytic fungus *M. gypseum* was practically not influenced by

the tested copper compounds at a concentration of 10 mmol l^{-1} ($IC_{50} > 10$ mmol l^{-1}). The growth of *R. oryzae* was most significantly inhibited by the compounds [Cu(isonic)(dien)H_2O](isonic) and [Cu(isonic)$_2$-(H_2O)$_4$], $IC_{50} = 2.2$ and 3.7 mmol l^{-1}, respectively. The inhibition activity decreases in the order [Cu(isonic)-(dien)H_2O](isonic) > [Cu(isonic)$_2$(H_2O)$_4$] > [Cu(en)$_2$-(H_2O)$_2$](isonic)$_2$ > dien > isonic = en. The copper(II) adducts — compounds [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$ and [Cu(isonic)(dien)H_2O](isonic) — have partially inhibited the growth of *A. alternata* (approximately at the same level, $IC_{50} = 5$ mmol l^{-1}) and also strongly inhibited sporulation.

4. Supplementary material

Supplementary materials including all atomic coordinates (Table S1), anisotropic displacement parameters for non-hydrogen atoms (Table S2) and all interatomic distances and bond angles (Table S3) for the compound [Cu(nic)(NO_3)(dien)(H_2O)]·H_2O have been deposited with the Cambridge Crystallographic Data Centre, CCDC no. 147398. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www.http://www.ccdc.cam.ac.uk). Observed and calculated structure factors are available on request from the authors.

Supplementary material (available from the authors) concerning the antimicrobial activities include figures S1–S6 containing graphs on: growth inhibition of *S. aureus* by [Cu(isonic)$_2$(H_2O)$_4$] (Fig. S1); growth inhibition of *C. parapsilosis* by [Cu(isonic)$_2$(H_2O)$_4$] (Fig. S2); colony growth inhibition of *R. oryzae* by [Cu(isonic)$_2$-(H_2O)$_4$] (Fig. S3); colony growth inhibition of *R. oryzae* by [Cu(isonic)(dien)(H_2O)]isonic (Fig. S4); colony growth inhibition of *A. alternata* by [Cu(en)$_2$(H_2O)$_2$]-(isonic)$_2$ (Fig. S5); effect of [Cu(en)$_2$(H_2O)$_2$](isonic)$_2$ on the sporulation of *A. alternata* (Fig. S6).

Tetrakis(triphenylphosphine oxide) complexes of the lanthanide nitrates; synthesis, characterisation and crystal structures of $[La(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ and $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$

Abstract

The reaction of $Ln(NO_3)_3\cdot 6H_2O$ (Ln = La, Ce, Pr or Nd) with a sixfold excess of Ph_3PO in acetone formed $[Ln(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$. The crystal structure of the La complex shows a nine-coordinate metal centre with four phosphine oxides, two bidentate and one monodentate nitrate groups, and PXRD studies show the same structure is present in the other three complexes. In CH_2Cl_2 or Me_2CO solutions, ^{31}P NMR studies show that the complexes are essentially completely decomposed into $[Ln(Ph_3PO)_3(NO_3)_3]$ and Ph_3PO. Similar reactions in ethanol gave $[Ln(Ph_3PO)_3(NO_3)_3]$ only. In contrast for Ln = Sm, Eu or Gd, only the $[Ln(Ph_3PO)_3(NO_3)_3]$ are formed from either acetone or ethanol solutions. For the later lanthanides Ln = Tb–Lu, acetone solutions of $Ln(NO_3)_3\cdot 6H_2O$ and Ph_3PO gave $[Ln(Ph_3PO)_3(NO_3)_3]$ only, even with a large excess of Ph_3PO, but from cold ethanol $[Ln(Ph_3PO)_4(NO_3)_2]NO_3$ (Ln = Tb, Ho–Lu) were obtained. The structure of $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$ shows an eight-coordinate metal centre with four phosphine oxides and two bidentate nitrate groups. In solution in CH_2Cl_2 or Me_2CO the tetrakis-complexes show varying amounts of decomposition into mixtures of $[Ln(Ph_3PO)_3(NO_3)_3]$, $[Ln(Ph_3PO)_4(NO_3)_2]NO_3$ and Ph_3PO as judged by $^{31}P\{^1H\}$ NMR spectroscopy. The $[Ln(Ph_3PO)_3(NO_3)_3]$ also partially decompose in solution for Ln = Dy–Lu, forming some tetrakis(phosphine oxide) species. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Lanthanides; Phosphine oxides; X-ray structures

1. Introduction

Phosphine oxides have proved popular ligands for complexing to lanthanide metal ions and are used widely in solvent extraction and separation processes for the lanthanides [1]. The reaction of Ph_3PO with lanthanide nitrates in ethanol or acetone in an Ln:Ph_3PO ratio $1:\leq 4$ produces the $[Ln(Ph_3PO)_3(NO_3)_3]$ which contain nine-coordinate metal centres based upon three phosphine oxides and three bidentate nitrates [2–5]. A lower Ln:Ph_3PO ratio in ethanol gives $[Ln(Ph_3PO)_2(EtOH)(NO_3)_3]$ which also contain nine-coordinate metal ions. There are also reports of $Ln(Ph_3PO)_4(NO_3)_3$ complexes [2] formed only by certain lanthanide ions, whose structures are unclear. None of the tetrakis(Ph_3PO) complexes have been characterised structurally and the spectroscopic data are limited and inconclusive. Here we report some systematic attempts to prepare $Ln(Ph_3PO)_4(NO_3)_3$ complexes for all the lanthanides (except Pm); a number of the known $[M(Ph_3PO)_3(NO_3)_3]$ were also synthesised to provide comparative spectroscopic data. We have reported elsewhere [6] the synthesis and characterisation of $[Y(R_3PO)_4(NO_3)_2]NO_3$ ($R_3 = Ph_3$, Ph_2Me, Me_3), and $[Sc(Ph_2MePO)_4(NO_3)_2]NO_3$.

resulted in precipitation of complexes of formula $[M(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$. The La and Ce complexes have been described briefly before [2], but contrary to that report, we find that Pr and Nd also form analogous complexes. The fifth lanthanide, Pm, is radioactive and unavailable, but the next, samarium formed only the known [2] $[Sm(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$ under similar conditions (see Section 2.2). The CsI disc IR spectra each show single intense and broad ν(PO) vibrations at approximately 1155–1160 cm^{-1} with ill-defined shoulders at higher frequency, for M = La, Ce, Pr and Nd, and no band corresponding to free Ph_3PO at 1195 cm^{-1}, which demonstrates that all four phosphine oxides are coordinated, and suggests a relatively symmetric geometry. The C=O vibration of the acetone is approximately 1705 cm^{-1} lowered from the vapour phase value of 1740 cm^{-1}, but the X-ray structure of the lanthanum complex shows the acetone is not coordinated, and similar lowering is found in $[Eu(Ph_3PO)_3(NO_3)_3]\cdot Me_2CO$ [4]. The nitrate vibrations are difficult to identify but bands at approximately 1475, 1310, 1030, and 815 cm^{-1} are tentatively associated with the bidentate nitrate groups. Careful comparisons of the CsI disc spectra of $[M(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ and $[M(Ph_3PO)_3(NO_3)_3]$ (M = La or Ce) were made in an attempt to identify the monodentate nitrate group vibrations; weak bands at 1227 and 825 cm^{-1} are tentatively attributed to this group, but in such complex spectra any assignment is not definitive. In 10^{-3} mol dm^{-3} solution in either Me_2CO or CH_2Cl_2[1] the complexes are non-electrolytes, and the conductivities do not increase with added Ph_3PO.

The $[M(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ are usually obtained as powders, and attempts to grow crystals from pre-isolated complexes from acetone or chlorocarbons gave crystals of the corresponding $[M(Ph_3PO)_3(NO_3)_3]$. Small thin plates of $[La(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ were obtained directly from one synthesis, and the X-ray crystal structure (below) showed the lanthanum to be nine-coordinate, bonded to four phosphine oxides, two bidentate and one monodentate nitrate groups. X-ray powder diffraction showed that the Ce, Nd and Pr samples had very similar patterns and all four showed strong similarities with the chief difference being the relative intensities of the two strongest lines at 2θ 8° (I_1) and 10° (I_2). For the La compound, comparison between the observed ($I_1 < I_2$) and calculated [7] ($I_1 > I_2$) patterns showed differences which we believe are due to

[1] Although neither acetone nor CH_2Cl_2 is regarded as an ideal solvent for conductance measurements, they were used in the present case for consistency with the NMR measurements.

the platy nature of the La crystallites. (The powder XRD was recorded on the same sample that yielded the single crystal.) The calculated relative intensity of these lines matches the Nd and Pr sample very well and we conclude that all four samples are likely to be isomorphous with the same or very similar structures.

The $^{31}P\{^{1}H\}$ NMR spectrum (Table 1) of $[La(Ph_3PO)_4(NO_3)_3]$ shows a very broad resonance at 300 K of δ 33.3 (CH_2Cl_2) or 35.3 (Me_2CO), which on cooling the solution resolve into two resonances in the ratio 3:1 identified as $[La(Ph_3PO)_3(NO_3)_3]$ and Ph_3PO by comparison of the chemical shifts. Addition of Ph_3PO to either solution showed fast exchange on the phosphorus NMR timescale at 300 K, but on cooling separate resonances are resolved. Addition of a fivefold molar excess of Ph_3PO and cooling to 190 K failed to generate any new resonance showing that even in the presence of excess ligand, the tetrakis complex is essentially completely dissociated into Ph_3PO and the corresponding tris complex. The Ce, Pr and Nd complexes behave similarly (Table 1), with the added complication that contact shifted $^{31}P\{^{1}H\}$ NMR resonances of these paramagnetic complexes show a large temperature variation, and some line broadening [8]. In these three complexes, exchange with added Ph_3PO is slow at 273 K in CH_2Cl_2 solution. Of the first four lanthanide(III) ions, only La is diamagnetic and ^{139}La has far from ideal nuclear properties for NMR studies (^{139}La, 99.9%, $I = 7/2$, $Q = 0.21 \times 10^{-28}$ m^2, $\Xi = 14.13$ MHz, $D_c = 336$) although spectra from some complexes have been recorded successfully [9]. However attempts to observe ^{139}La spectra from solutions of $[La(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ in either acetone or CH_2Cl_2 solution failed. Nor were we any more successful with $[La(Ph_3PO)_3(NO_3)_3]$ or $[La(Ph_3PO)_2(EtOH)(NO_3)_3]$, and it seems that the combination of ligand lability and the moderate quadrupole moment result in unobservable broad lines, consequent from fast relaxation.

2.2. $[M'(Ph_3PO)_3(NO_3)_3]$ ($M' = Sm$, Eu or Gd)

The reaction of $M'(NO_3)_3\cdot 6H_2O$ ($M' = Sm$, Eu or Gd) with Ph_3PO ($1: \geq 3$) in either acetone or ethanol[2] gave only the known [2] $[M'(Ph_3PO)_3(NO_3)_3]$ (from acetone as solvates $[M'(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$). Moreover the $[M'(Ph_3PO)_3(NO_3)_3]$ are non-electrolytes in CH_2Cl_2 solutions, and the conductances do not increase significantly on addition of Ph_3PO (twofold molar excess). The $^{31}P\{^{1}H\}$ NMR spectrum of $[Sm(Ph_3PO)_3(NO_3)_3]$ in CH_2Cl_2 is a single relatively sharp line at δ 32.5. Addition of a tenfold molar excess of Ph_3PO to this solution showed only resonances for the tris complex and free ligand. For $[Eu(Ph_3PO)_3(NO_3)_3]$ the $^{31}P\{^{1}H\}$ NMR spectrum was a singlet at δ -121, but on addition of a tenfold molar excess of Ph_3PO a weak resonance at δ -101 was seen (integral $\sim 5\%$ of that of the tris-complex), possibly due to the formation of some tetrakis(phosphine oxide) complex. We have not observed a $^{31}P\{^{1}H\}$ NMR spectrum from solutions of $[Gd(Ph_3PO)_3(NO_3)_3]$, presumably due to unfavourable relaxation, but since solutions of $[Gd(Ph_3PO)_3(NO_3)_3]$ plus excess Ph_3PO are non-electrolytes, it seems that formation of a tetrakis(phosphine oxide) complex in solution does not occur to any great extent.

2.3. $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ ($M'' = Tb$, Ho, Er, Tm, Yb or Lu)

The reaction of $Lu(NO_3)_3\cdot 6H_2O$ with a four–sixfold excess of Ph_3PO in acetone gave only the $[Lu(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$ consistent with literature reports [2]. However, using a Lu:Ph_3PO ratio of $1: \geq 6$ in ice-cold ethanol resulted in a $Lu(Ph_3PO)_4(NO_3)_3$ complex. Cousins and Hart [2] reported that this reaction yielded the ethanol solvate $[Lu(Ph_3PO)_4(NO_3)_3]\cdot EtOH$, from which the ethanol was removed on heating in vacuo. However, in our hands the unsolvated complex was obtained, shown most clearly by the X-ray crystal structure of the complex described below, the crystals used being obtained directly from the synthesis. The crystal structure of the lutetium complex shows an eight-coordinate metal centre with two chelating nitrates and four phosphine oxides and one ionic nitrate group (below). In the IR spectrum we identified weak peaks at approximately 1360, 1350 and 833 cm^{-1} which are absent in the corresponding spectrum of $[Lu(Ph_3PO)_3(NO_3)_3]$, and which may be tentatively associated with the ionic nitrate group [10]. The $^{31}P\{^{1}H\}$ NMR spectrum of $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$ in CH_2Cl_2 solution at 300 K revealed a sharp resonance at δ 39.0 and a very weak broader feature at approximately δ 35.5. On cooling this solution to 200 K the spectrum consisted of a relatively sharp resonance at 38.0, a weaker feature at 36.3 and some Ph_3PO at 27.0. Integration of the 200 K spectrum shows that the δ 38.0:36.3:27.0 features have approximate intensity ratios 20:3:2. Addition of excess Ph_3PO to this solution at 200 K resulted in the disappearance of the feature at δ 36.3. The conductivity of a 10^{-3} mol dm^{-3} solution of $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$ in CH_2Cl_2 was $\Lambda_M = 19$ Ω^{-1} cm^2 mol^{-1}, which increased slightly in the presence of excess Ph_3PO. These values may be compared with that of 22 Ω^{-1} cm^2 mol^{-1} for a similar concentration of $[N^nBu_4][BF_4]$, and shows that the lutetium complex approximates to a 1:1 electrolyte. Although CH_2Cl_2 has been criticised as a solvent for conductance measurements [11], it was used here to maintain the same

[2] We confirm the report of Cousins and Hart [2] that traces of solid $[Ln(Ph_3PO)_2(EtOH)(NO_3)_3]$ cause preferential crystallisation of this ethanol complex even from solution with high Ph_3PO:Ln ratios.

solvent system used for the NMR studies. Taken together, the $^{31}P\{^1H\}$ NMR results and conductance data suggest that $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$ is present mostly as the tetrakis(Ph_3PO) cation in chlorocarbon solution, with only a small amount of decomposition into Ph_3PO, possibly $[Lu(Ph_3PO)_3(NO_3)_3]$ (which due to its very similar phosphorus shift may not show a resonance resolved from that of the tetrakis complex). A further unidentified minor species with $\delta = 36.3$ at 200 K and which undergoes fast exchange with Ph_3PO at ambient temperatures (which $[Lu(Ph_3PO)_3(NO_3)_3]$ does not) is present also, and this is lost in the presence of a large excess of Ph_3PO.

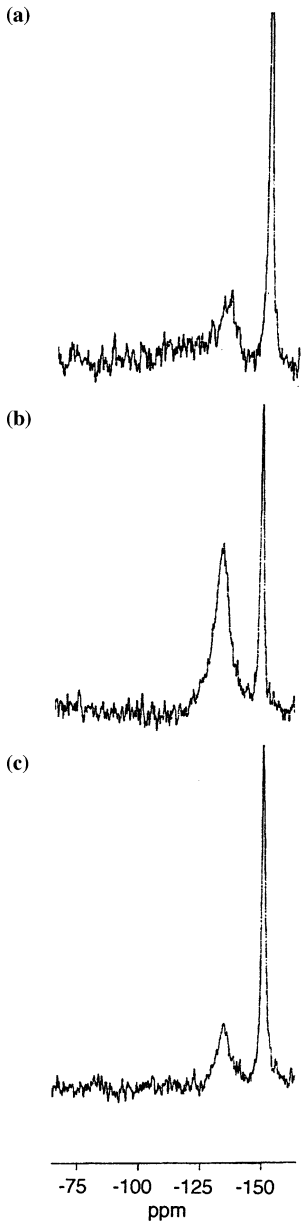

Fig. 1. $^{31}P\{^1H\}$ NMR spectra of (a) $[Ho(Ph_3PO)_4(NO_3)_2]NO_3$; (b) $[Ho(Ph_3PO)_3(NO_3)_3]$; and (c) $[Ho(Ph_3PO)_3(NO_3)_3]$ + excess Ph_3PO: all in CH_2Cl_2–$CDCl_3$ solutions at 300 K.

For the elements Tb, Ho, Er, Tm and Yb, $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ complexes separated slowly from the appropriate nitrate salts and Ph_3PO in a 1: ≥ 6 ratio in ethanol solution below 0°C. If concentrated solutions were used (resulting in immediate precipitation of solid) or crystallisation occurred at room temperature, impure materials or even $[M''(Ph_3PO)_2(EtOH)(NO_3)_3]$ were sometimes formed. The crude complexes sometimes appear to incorporate some ethanol of solvation, which is removed on gentle warming in vacuum. Curiously several attempts to isolate $[Dy(Ph_3PO)_4(NO_3)_2]NO_3$ resulted in samples which based upon analysis, IR and ^{31}P NMR spectra appeared to contain both $[Dy(Ph_3PO)_4(NO_3)_2]NO_3$ and $[Dy(Ph_3PO)_2(EtOH)(NO_3)_3]$, and the pure tetrakis(phosphine oxide) complex has so far eluded us. The IR spectra (CsI disc) of the $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ are very similar to that of the Lu complex, and they are assigned similar structures in the solid state. However, in CH_2Cl_2 solutions the behaviour is more complex: for example most have molar conductances (see Section 3) approximately half those expected for 1:1 electrolytes, which increase significantly on addition of Ph_3PO but are still less than that of the Lu analogue. In CH_2Cl_2 solution the $^{31}P\{^1H\}$ NMR spectra show in each case (except M″ = Tb for which no resonances were observed probably due to extreme line-broadening) two resonances, one relatively sharp and one much broader (Table 1), and upon addition of excess Ph_3PO to such solutions, the sharper resonance increases in relative intensity and the broader one decreases, and a third resonance due to Ph_3PO is also present (Fig. 1 shows a typical example). However even with a large (~ tenfold molar) excess of Ph_3PO it does not appear to be possible to suppress the broader resonance completely. $^{31}P\{^1H\}$ NMR spectra were also obtained from solutions of the corresponding $[M''(Ph_3PO)_3(NO_3)_3]$ in CH_2Cl_2 and these showed for each M″ the two resonances due to coordinated phosphine oxide with identical chemical shifts to those obtained from solutions of the tetrakis complexes. Similar behaviour was observed for $[Y(Ph_3PO)_4(NO_3)_2]NO_3$ and $[Y(Ph_3PO)_3(NO_3)_3]$ [6], although the yttrium system was also studied by ^{89}Y NMR spectroscopy, which allowed direct deduction of the number of bound phosphine oxides via the resolved phosphorus couplings. Thus we conclude that dissolution of $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ or $[M''(Ph_3PO)_3(NO_3)_3]$ in CH_2Cl_2 results in a mixture of both complexes[3], which are not exchanging rapidly on the NMR timescale with Ph_3PO, but for which the proportion of the tetrakis(phosphine

[3] For the $[M''(Ph_3PO)_3(NO_3)_3]$ solutions mass balance requires another M″ species is formed, since none are seen in the $^{31}P\{^1H\}$ NMR spectra, these are probably phosphine oxide free, although the identity remains unclear (see also Ref. [6]).

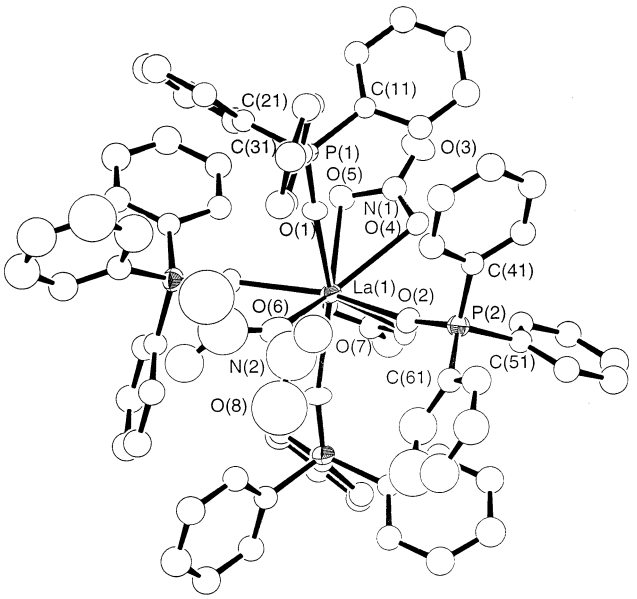

Fig. 2. Structure of $[La(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$ showing the atom numbering scheme. The ellipsoids are drawn at the 30% probability level.

oxide) complex is increased easily by addition of excess Ph_3PO. We noted above that $[M''(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$ were easily obtained pure from acetone solution, and hence we also recorded $^{31}P\{^1H\}$ NMR spectra for two examples $[M''(Ph_3PO)_3(NO_3)_3]$ and $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ (M′ = Ho or Er) from acetone solutions. These spectra also showed that both tris- and tetrakis(phosphine oxide) complexes were present in acetone solution, but whilst the solid $[M''(Ph_3PO)_4(NO_3)_2]NO_3$ dissolve easily in acetone, $[M''(Ph_3PO)_3(NO_3)_3]$ dissolve with difficulty, and hence the ready isolation of the tris-complex from acetone reflects its low solubility, rather than different solution speciation. The mixture of complexes in solution also accounts for the conductance data reported above. For dysprosium, $[Dy(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$ was isolated easily from acetone solutions, and on dissolution in CH_2Cl_2, the $^{31}P\{^1H\}$ NMR spectrum showed a broad resonance at δ −139 ($W_{1/2}$ = 2000 Hz) and a sharper feature at −199 ($W_{1/2}$ = 480 Hz), the relatively intensities of the resonances shifting in favour of the latter on addition of excess Ph_3PO. The resonance at δ −199 is thus assigned to $[Dy(Ph_3PO)_4(NO_3)_2]NO_3$, suggesting the behaviour is similar to the other later metals, and our failure to isolate this complex presumably reflects unfavourable solubilities (similar behaviour was observed in $Y(NO_3)_3$–Ph_2MePO or Me_3PO systems [6]).

2.4. Crystal structure of $[La(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$

Crystals for this and the following structure were only obtained from the bulk preparation. It has not proved possible to grow crystals by usual routes and the crystals used, cleaved from a clump of plates, were both small and of modest quality. The structure consists of discrete molecules with the La and O(6) atoms located on a twofold axis (Fig. 2, Table 2(a)). The La atom is coordinated by four O atoms from Ph_3PO in an approximately square planar arrangement. Two bidentate nitrate ligands are on one side of the square plane and a disordered monodentate NO_3 on the other side. The O(6)–La(1)–O(P) angles are all $<90°$ and the phosphine oxide groups bend away from the two bidentate nitrate groups. The geometry of the Ph_3PO is unexceptional and the monodentate coordination of one nitrate is seen clearly in the La(1)–O–N angles which are 98°(av) for the two bidentate NO_3 groups and 134° for the single monodentate group and the La(1)···O(7) distance (4.3 Å). The solvate Me_2CO is also on a twofold axis. The bond distances to La may be compared with $[La(Ph_3PO)_3(NO_3)_3]\cdot EtOH\cdot CHCl_3$

[a] Symmetry operation: $i = -x, y, 1/2-z$.
[b] Symmetry operation: $i = 1/2-x, 1/2-y, z$.

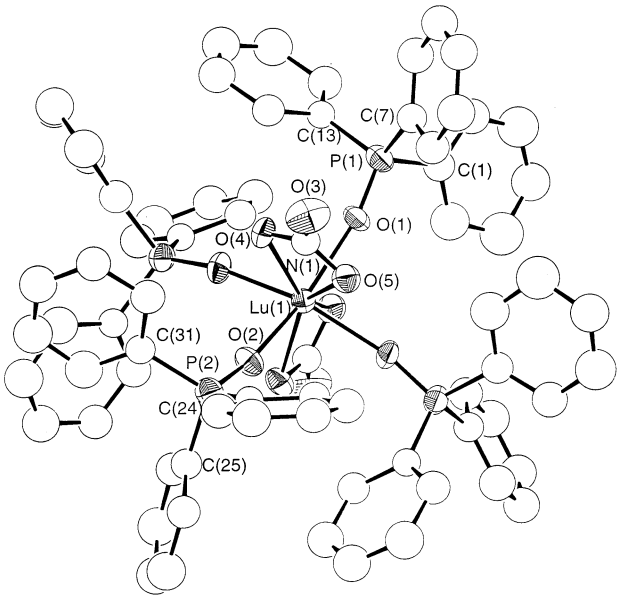

Fig. 3. Structure of the cation in $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$ showing the atom numbering scheme. The ellipsoids are drawn at the 40% probability level.

[14] which is the *mer* pseudo-octahedral isomer (with the bidentate NO_3 being regarded conceptually as a monatomic group). Here the La–O(P) seem a little shorter (2.373, 2.427, 2.415 Å) than in the present compound and the La–O(N) (2.583–2.681 Å) are very similar (Table 2(a)). (Note that the bond lengths were calculated from the coordinates in the Cambridge structural database [12], refcode Kakruj and no e.s.d.s are available). All our attempts to grow crystals of $[La(Ph_3PO)_3(NO_3)_3]$ from petroleum ether (40–60°C)–CH_2Cl_2 or Et_2O–CH_2Cl_2 gave small poor quality crystals of a CH_2Cl_2 solvate which again was the *mer* isomer [13]. As our results parallel those of Huang et al. [14] but were marginally poorer, the data are not reported.

2.5. Crystal structure of $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$

The crystal structure of the lutetium complex shows an eight-coordinate metal centre with two chelating nitrates and four phosphine oxides, and one ionic nitrate group (see Fig. 3 and Table 2(b)). The Lu atom is located on a twofold axis and following our earlier formalism can be regarded as *trans* pseudo-octahedral. The nitrate ion (N(1)) is symmetrically coordinated to Lu but does not show the distortions in bond lengths and angles noted in the La complexes but this is probably a reflection of the data quality. The ionic nitrate is also on a twofold axis but shows disorder, which was partially modelled. The closest structural analogue appears to be the $[La(Ph_3PO)_4(NO_3)_2]^+$ cation in $[La(Ph_3PO)_4(NO_3)_2]_2[Ni(C_4N_2S_2)_2]\cdot 2CH_3OH$ [15]. The mean La–O(P) (2.404) and La–O(N) (2.602 Å) are longer than the corresponding Lu values (2.200, 2.418 Å) reflecting the smaller ionic radius of Lu^{3+}.

3. Experimental

Physical measurements were made as described previously [6]. $^{31}P\{^1H\}$ NMR spectra were obtained at 145.5 MHz on a Bruker AM360 from solutions in CH_2Cl_2–5% $CDCl_3$, and with chemical shifts reported relative to external 85% H_3PO_4. The lanthanide (La, Ce, Sm, Lu, Tm, Tb) nitrate hexahydrates and Ph_3PO were obtained from Aldrich and used as received. Other lanthanide nitrates (Yb, Pr, Nd, Gd, Er, Ho, Dy, Eu) were made by reacting an excess of the appropriate M_2O_3 with hot aqueous HNO_3, filtering off unreacted oxide and pumping the solution to dryness in vacuum. The synthesis of $[Ln(Ph_3PO)_3(NO_3)_3]\cdot 2Me_2CO$ for all of the lanthanide nitrates was carried out as described [2], and several $[Ln(Ph_3PO)_3(NO_3)_3]$ were made in solvate free form from ethanol. Our IR data are in agreement with literature values to ± 2 cm^{-1} and hence are not given. The $^{31}P\{^1H\}$ NMR data have not been reported previously and are given in Table 1 for comparison.

The syntheses used for other complexes were generally similar and representative examples are described.

3.1. $[Ce(Ph_3PO)_4(NO_3)_3]\cdot Me_2CO$

An ice-cold solution of Ph_3PO (2.68 g, 10 mmol) in acetone (10 cm^3) was added to one of cerium(III) nitrate hexahydrate (0.43 g, 1.0 mmol) in acetone (15 cm^3). The solution was left at ambient temperature for 24 h when white crystals separated. Yield 0.73 g (50%). *Anal.* Found: C, 60.1; H, 4.5; N, 2.7. Calc. for $C_{75}H_{66}CeN_3O_{14}P_4$: C, 60.2; H, 4.4; N, 2.8%. Λ_M (CH_2Cl_2, 10^{-3} mol dm^{-3}) = 10 Ω^{-1} cm^2 mol^{-1}.

3.3. Crystal structure determinations

Small modest-quality crystals of both materials were obtained from the preparation and diffraction data were measured on either a Rigaku AFC7S (Lu) or Nonius ccd (La) diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å).

3.3.1. $[La(Ph_3PO)_4(NO_3)_3.]\cdot Me_2CO$

The data were collected as triclinic even though data collection software suggested a monoclinic cell and solved in space group $P\bar{1}$ (no. 2) ($Z = 2$) using PATT in SHELXS-86 [16]. From La, P and some of the phenyl rings, the model was developed by standard methods. The third NO_3 group was difficult to locate; the O bonded to La was clear but the remaining NO_2 was very weak in the difference Fourier maps. The resulting structure showed excellent two-fold symmetry about the La atom except for the weak NO_2 residue.

The data were transformed to the monoclinic C lattice and the structure solution repeated with La(1) and O(6) now located on a twofold axis in the space group $C2/c$. The symmetry now requires that either the monodentate NO_3 lies on the twofold axis or is off-axis and disordered and the latter is found. N(2), O(7) and O(8) appeared as the three largest peaks on a

later Fourier map and restraints (DFIX) were used on N–O and O···O distances around N(2). The phenyl rings were constrained to be regular hexagons. The R factor was lower for the $C2/c$ space group and this is regarded as the preferred model. Full-matrix least-squares refinement on F^2 was carried out using SHELXL-97 [17] (Table 3).

3.3.2. $[Lu(Ph_3PO)_4(NO_3)_2]NO_3$

Althought the data were weak, SHELXS-86 [16] gave a plausible solution for the Lu, P and some lighter atoms which was developed into a model for the cation with Lu positioned on a twofold axis (4c site). The NO_3 anion was identified with both N(2) and O(6) again on a twofold (4d) site, but too many peaks were found in the difference Fourier map to account for the remaining eightfold O(7) atom and a disordered model (O(7A), O(7B) with restraints added) was adopted. Full-matrix least-squares refinement on F^2 was carried out using SHELXL-97 [17] with anisotropic Lu, P and O(1) to O(5) atomic displacement parameters only. Apart from two peaks close to Lu and one near the disordered NO_3 group all peaks in the residual electron density are <1.0 e Å^{-3}.

4. Conclusions

Although all the lanthanides form $[Ln(Ph_3PO)_2(EtOH)(NO_3)_3]$ and $[Ln(Ph_3PO)_3(NO_3)_3]$ complexes, the tetrakis(phosphine oxide) complexes exhibit a varying pattern along the series. For the largest four ions La–Nd (Ln^{3+} radii: 104.5–98 pm) [18] nine-coordinate $[Ln(Ph_3PO)_4(\eta^2\text{-}NO_3)_2(\eta^1\text{-}NO_3)]$ are formed. For the smaller later metals Tb–Lu (Ln^{3+} radii: 92–86 pm) the complexes contain the eight-coordinate cations $[Ln(Ph_3PO)_4(\eta^2\text{-}NO_3)_2]NO_3$, whilst tetrakis complexes do not seem to form under similar conditions for the middle elements Sm–Gd. Whilst this might seem simply a consequence of the differing steric demands of Ph_3PO and nitrate groups operating against a background of decreasing metal cation radius, the solution behaviour (especially the ^{31}P NMR data) show other factors are involved. For the earlier metals La–Gd only $[Ln(Ph_3PO)_3(NO_3)_3]$ are present in solution even with excess Ph_3PO, for Tb–Tm $[Ln(Ph_3PO)_4(NO_3)_2]^+$ and $[Ln(Ph_3PO)_3(NO_3)_3]$ are both present, and for the later elements Yb and Lu, $[Ln(Ph_3PO)_4(NO_3)_2]^+$ show little decomposition in solution. This suggests that the affinity for Ph_3PO over nitrate increase down the series. We note that Y^{3+} (90 pm) conforms to this pattern. These studies are currently being extended to Ph_2MePO and Me_3PO complexes to explore these factors further, and preliminary data show, for example, that solid $[La(Ph_2MePO)_4(NO_3)_3]$ contains ten-coordinate La with three bidentate nitrate ions [19].

5. Supplementary data

Crystallographic data for the structures have been deposited with the Cambridge Crystallographic Data Centre (CCDC) and given numbers 139145 (Lu) and 147405 (La). Copies of the data can be obtained upon

request from CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, quoting the deposition numbers (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank Professor M.B. Hursthouse for the data collection on the Nonius ccd diffractometer, Dr P.F. Henry for the powder X-ray diffraction measurements, and M. Bosson for preliminary studies of the Pr and Nd complexes.

Abstract

A tridentate Schiff base ligand $[(CH_3)_2NCH_2CH_2N{=}C(CH_3)C_6H_4OH)]$ (LH) has been synthesized from 2-hydroxyacetophenone and 2-dimethylaminoethylamine. This ligand forms the neutral complexes $[Co(L)(N_3)\{o\text{-}(CH_3C{=}O)C_6H_4O\}]$ (**1**) and $[Co(L)(SCN)\{o\text{-}(CH_3C{=}O)C_6H_4O\}]\cdot 1/2H_2O$ (**2**) in presence of equivalent amount of Co(II) acetate, and sodium azide for **1** and sodium thiocyanate for **2**. The complexes have been characterized by spectroscopic and crystallographic methods. The coordination geometry around Co(III) in both the complexes is distorted octahedral with one tridentate ligand L, one bidentate 2-hydroxyacetophenone and one monodentate azide for **1** and thiocyanate for **2**. The azide and thiocyanate ligands in the two complexes occupy different positions relative to the coordination sites of L. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Cobalt; 2-Hydroxyacetophenone; Azide; Thiocyanate; Crystal structure

1. Introduction

Cobalt(III) complexes derived from symmetrical and nonsymmetrical Schiff bases have drawn considerable attention in the past for their important biological applications [1–3]. Many model complexes of cobalt in both +2 and +3 oxidation states have been prepared and investigated, with particular emphasis on the reactivity of the metal ions in the transmethylation reaction and the reversible absorption of molecular oxygen [4–6]. In contrast, Co(III) complexes with uninegative tridentate Schiff base ligands have received less attention. We therefore carried out a study on the synthesis, structural characterization and reactivity of monomeric Co(III) mixed-ligand complexes derived from uninegative Schiff base ligands and η^1-bonded 2-hydroxyacetophenone. Aldehyde and ketone complexes of transition metals have been known from many years, but related studies on the formation and reaction of such complexes have been reported only relatively recently [7–12]. It has been found that both aldehydes and ketones can coordinate with metal centres in either η^1 or η^2 bonding mode and rarely in the η^3 fashion [7], and the bonded aldehydes and ketone groups can undergo various types of chemical transformation. These types of complexes are also used as catalysts in organic synthesis. Hersh and co-workers [13,14] have characterized an η^1-aldehyde complex of tungsten, which was used as a catalyst for Diels–Alder reaction [13,14]. The optically active η^2-aldehyde complex of rhenium was found to produce an optically active alcohol [15]. The structural studies on aldehyde complexes reveal that cationic-aldehyde complexes exhibit an η^1-bonding mode, while the neutral complexes show an η^2-bonding mode [16].

Recently Bharadwaj and co-workers [17] reported several η^1-aldehyde complexes of Mn(III), Fe(III) and Cu(II) metal ions. In the Mn(III) complexes, the bonded aldehyde group was reported to react readily with reagents such as 2-aminophenol, 2-aminothiophenol and 2-aminoethanol, producing mononuclear neutral Mn(III) complexes. The Cu(II) complex showed catalytic activity in the oxidation of olefins to epoxides in the presence of 2-methylpropanol and molecular oxygen. In a previous paper, we [18] described the synthesis and characterization of a neutral complex of

PII: S0277-5387(00)00584-2

M(III), where the aldehyde group of salicylaldehyde is bonded to the metal in an η^1-mode. In this complex, the salicylaldehyde ligand showed enhanced reactivity towards primary monoamine and formed mixed-ligand complexes of Mn(III). To our knowledge, the structurally characterized 2-hydroxyacetophenone complex of Co(III) has not been reported so far. In the present article we report on the synthesis and characterization of two mixed-ligand complexes of Co(III) where the carbonyl group of 2-hydroxyacetophenone is bonded to the metal ion in an η^1-fashion.

2. Experimental

Reagent grade 2-hydroxyacetophenone (Merck), $Co(OAc)_2{\cdot}4H_2O$, sodium azide and sodium thiocyanate (Loba Chemie), and 2-dimethylaminoethylamine (Fluka) were used as received. Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. Infrared spectra were recorded on a Perkin–Elmer 883-IR instrument as KBr pellets and electronic spectra were recorded on a Hitachi U-3400 (UV–Vis-NIR) spectrophotometer from a solution in methanol. ^1H and ^{13}C NMR spectra were recorded on a Bruker DPX-300 in $CDCl_3$ with TMS as internal standard. Magnetic susceptibilities were measured at room temperature using a vibrating sample magnetometer.

2.1. Synthesis of the ligand

The Schiff base ligand $(CH_3)_2NCH_2CH_2N{=}C(CH_3)C_6H_4OH$ (LH) was obtained by boiling a methanolic solution (25 ml) of 2-hydroxyacetophenone (1 mmol) and 2-dimethylamino-ethylamine (1 mmol) for 30 min under reflux. The orange solution containing the ligand was purified by column chromatography [silica gel (SRL) 60–120 mesh size, light petroleum–ethyl acetate mixture], and the purity confirmed by elemental analyses and ^1H NMR spectrum [^1H NMR (300 MHz): $\delta = 2.1$(s), 2.4(s), 2.8(t), 3.4(t), 6.9(m), 13.0(s)].

2.2. Synthesis of [Co(L)(N_3){o-($CH_3C{=}O$)C_6H_4O}] (1)

$Co(OAc)_2{\cdot}4H_2O$ (1 mmol, 0.249 g) in 5 ml methanol and an equivalent amount of 2-hydroxyacetophenone (0.12 ml) were added to a methanolic solution of the Schiff base ligand (1 mmol, 0.021 g). The resulting mixture was stirred for 5 min with addition of sodium azide (1 mmol, 0.065 g) in a minimum amount of water. On standing overnight, dark brown crystals of **1** were formed, which were collected by filtration and dried in vacuo over P_2O_5. *Anal.* Found: C, 54.22; H, 5.50; N, 15.71. Calc. for $C_{20}H_{24}CoN_5O_3$: C, 54.43; H, 5.48; N, 15.86%. ^1H NMR (300 MHz): δ (ppm) = 1.94(s), 2.22–2.78(m), 4.01(s), 6.48–6.66(m), 6.90–7.00(m), 7.43–7.61(m), 7.76(d). ^{13}C NMR (75 MHz): δ (ppm) = 18.54 (–N=C–CH_3), 28.41 (–C(CH_3)=O), 47.94 (N–CH_3), 52.12 (N–CH_3), 55.45 (N–CH_2–), 63.02 (N–CH_2–), 201.56 (C=O), 172.24 (C–O), 166.23 (C=N).

2.3. Synthesis of [Co(L)(NCS){o-($CH_3C{=}O$)C_6H_4O}]·1/2H_2O (2)

$Co(OAc)_2{\cdot}4H_2O$ (1 mmol, 0.249 g) in 5 ml methanol and an equivalent amount of 2-hydroxyacetophenone were added to a methanolic solution of the Schiff base ligand (1 mmol, 0.21 g). The mixture was stirred for 5 min with the addition of sodium thiocyanate (1 mmol, 0.081 g) in a minimum amount of water. Dark brown crystals appeared within 3 h, which were collected by filtration and dried in vacuo over P_2O_5. *Anal.* Found: C, 55.52; H, 5.32; N, 9.07. Calc. for $C_{21}H_{25}CoN_3O_{3.5}S$: C, 54.08; H, 5.40; N, 9.00%. ^1H NMR (300 MHz): δ (ppm) = 1.99(s), 2.46–2.87(m), 3.49(s), 4.09(s), 6.42–6.50(m), 6.79(d), 6.95–7.07(m), 7.45(d). ^{13}C NMR (75 MHz): δ (ppm) = 18.96 (–N=C–CH_3), 27.02 (–C(CH_3)=O), 48.75 (N–CH_3), 51.04 (N–CH_3), 54.32 (N–CH_2–), 62.0 (N–CH_2–), 202.21 (C=O), 171.73 (C–O), 167.80 (C=N).

2.4. X-ray crystallography

Crystallographic measurements were made at 150 K on an Enraf–Nonius Kappa CCD area detector diffractometer mounted at the window of a FR591 rotating anode generator for **1** [19] and on an Enraf–Nonius Turbo CAD4 diffractometer (non-profiled ω scan) for **2** [20] using Mo Kα radiation ($\lambda = 0.71073$ Å). Accurate cell parameters were obtained by least-squares refinement of the diffractometer angles for the entire data set in a 10° ϕ range for **1** and for 25 reflections in the range $17.0 < \theta < 18.0°$ for **2**. Absorption corrections were carried out by using multiple and symmetry related data measurements via the program SORTAV [21] for **1** and DIFABS [22] for **2**. The structures were solved by a direct method (SHELXS-86) [23] and refined by full-matrix least-squares on F^2 using all unique data (SHELXL-96) [24]. In both structures, the phenyl rings were treated as idealized hexagons (C–C = 1.390 Å, C–C–C = 120.0°). Crystals of **2** contained a disordered water solvate, for which two oxygen positions (occupancies 0.12 and 0.38) were refined with an ISOR = 0.01 restraint. Two partially occupied hydrogen atoms were obtained from difference map, which were included in the model but not refined. Other hydrogen atoms in both the structures were included in calculated positions (riding model) with U_{iso} tied with the U_{eq} of the parent atom. A summary of the crystallographic data and refinement details, and important bond lengths and angles for both complexes are given in Tables 1 and 2, respectively.

3. Results and discussion

The analytical data for the complexes **1** and **2** are in good agreement with the calculated values. The diamagnetic character of the complexes indicated that the cobalt atom in both cases has a low spin d^6 configuration and $+3$ oxidation state.

3.1. Infrared and NMR spectroscopy

The IR stretching frequencies for the metal bonded imine group and the η^1-bonded carbonyl group are very similar [25,26]. Strong peaks at ca. 1610 cm^{-1} for both complexes are attributable to the imine and η^1-bonded carbonyl stretching vibrations. The $\nu(N_3)$ appeared at 2035 cm^{-1} for **1** and ν(CN) for (SCN) was found at 2120 cm^{-1} for **2**. The ^1H and ^{13}C NMR spectra of the complexes are consistent with the X-ray determined structures (discussed below). In the spectrum of the free ligand, the OH proton appears at 13 ppm; this signal is absent in the spectra of the complexes, which suggests that the cobalt atom is bonded to the ligand through the replacement of the phenolic hydrogens. The ^1H NMR signals for both the complexes are basically similar, with those for **1** being slightly broader than in **2**. In ^{13}C NMR, the signals for the C=O and C=N groups are comparable. These features suggest structural similarity between the two complexes. The signals for all other aromatic and aliphatic carbon atoms appear at the usual positions.

3.2. Electronic spectroscopy

Two main bands, $^1A_{1g}\rightarrow{}^1T_{1g}$ and the $^1A_{1g}\rightarrow{}^1T_{2g}$, are normally observed in the d–d spectra of Co(III) complexes. In the present case, however, we observed only the lower energy band at 552 nm ($\varepsilon=540$ dm^3 mol^{-1} cm^{-1}) for **1** and at 555 nm ($\varepsilon=290$ dm^3 mol^{-1} cm^{-1}) for **2**. The higher energy band was probably obscured by the ligand to metal charge transfer band.

3.3. Crystal structures

The molecular structures of $[Co(L)(N_3)\{o\text{-}(CH_3C{=}O)C_6H_4O\}]$ (**1**) and $[Co(L)(NCS)\{o\text{-}(CH_3C{=}O)C_6H_4O\}]$ (**2**) are shown in Figs. 1 and 2, respectively, and important bond lengths and bond angles both compounds are listed in Table 2. The atom numbering scheme adopted is the same for both compounds except the azide and thiocyanate anions. Crystals of **2** also contain 0.5 molecule of H_2O per mole of complex, which is partially occupied and disordered, and is not shown in the figure.

In both compounds, the Co(III) ion is hexacoordinated with a N_3O_3 donor set arising from one tridentate Schiff base ligand (L), one bidentate 2-hydroxyacetophenone, and one monodentate azide (**1**) or thiocyanate (**2**). The coordination geometry is distorted octahedral in both cases, with the *trans* and *cis* angles lying in the ranges 176.39(12)–178.4(2) and 86.02(11)–96.06(12)°, respectively. The basic geometry is very similar in the two compounds but there are significant differences in the arrangements of the ligands around the metal atoms. This is evident from Figs. 1 and 2, in which the molecules are viewed approximately along the normal to the plane of the N(1), N(2) and O(1) donor atoms of the ligand L. If we consider these three atoms of L to occupy three corners of the equatorial plane, then the fourth corner is occupied by the phenolate oxygen [O(3)] in **1** but by the keto oxygen [O(2)] in **2**. This also means that the keto oxygen on **1** and the phenolate oxygen in **2** occupy one of the axial sites in the respective octahedron. The other axial position is occupied by the azide group in **1** and by the thiocyanate group in **2**. It is important to note that, in the former, the azide group lies *trans* to the O(2) atom of the acetophenolate ligand, whereas in the latter the thiocyanate group lies *trans* to the O(3) atom of the same ligand. The $[Co(L)(L')\{o\text{-}(CH_3C{=}O)C_6H_4O\}]$ (L′=NNN or NCS) molecules in the present work clearly represent two structural isomers of an octahedral complex containing one tridentate, one bidentate and one unidentate ligands.

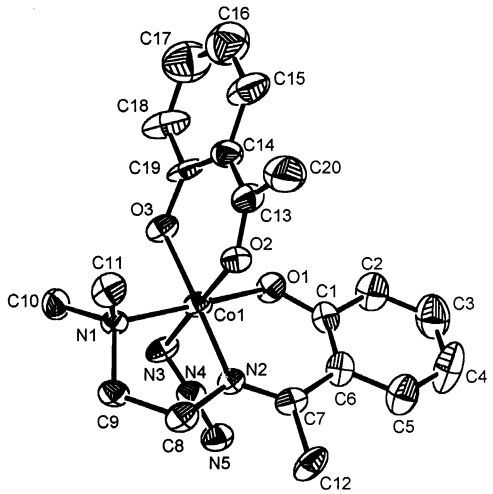

Fig. 1. X-ray structure of **1** with atom numbering scheme. The thermal ellipsoids are drawn at 40% probability level. For clarity, the hydrogen atoms are not shown.

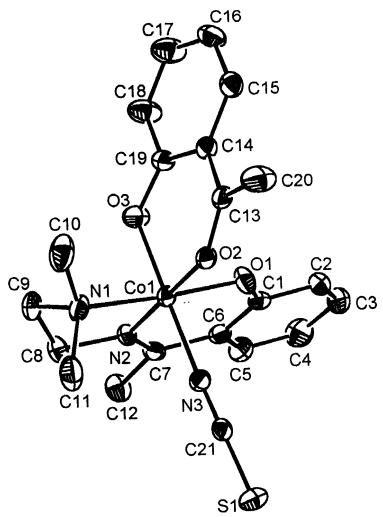

Fig. 2. X-ray structure of **2** with atom numbering scheme. The thermal ellipsoids are drawn at 40% probability level. For clarity, the hydrogen atoms are not shown.

The corresponding Co–O and Co–N distances in the two molecules are quite close. In fact, the Co(1)–N(1), Co(1)–N(2), Co(1)–O(1) and Co(1)–O(3)/O(2) distances in the equatorial plane in the two molecules are virtually identical [2.007(5), 1.895(5), 1.860(5) and 1.902(4) Å respectively in **1**, and 2.007(3), 1.893(3), 1.850(3) and 1.911(2) Å in **2**]. The Co–N(1) distance is ca. 0.12 Å longer than the Co–N(2) distance and reflects the different state of hybridization of the two nitrogen atoms. In both **1** and **2**, the Co–O distances fall in the range reported for other Schiff base complexes of Co(III) [5,6]. It may be noted here that the Co–O distances in the equatorial plane in the present complexes do not depend on the nature of the oxygen atom, i.e. whether it belongs to the phenolate (**1**) or the keto group (**2**). In contrast, the Co–O distances in the axial positions seem to be affected by the nature of the ligand *trans* to it. Thus the Co(1)–O(2) distance [1.905(5) Å] in **1** is somewhat longer than the Co–O(3) distance [1.860(3) Å] in **2**, which may be the result of greater *trans* influence of the azide compared with the thiocyanate group. In **1**, the bond lengths involving the azide group, Co(1)–N(3), N(3)–N(4) and N(4)–N(5) distances are 1.937(6), 1.199(7) and 1.163(7) Å, respectively, and are comparable to the corresponding values in other Co(III) azido complexes [27,28]. The azide group is almost linear [N(5)–N(4)–N(3) = 177.1(7)°] and coordinates to the cobalt atom in a bent fashion [N(4)–N(3)–Co(1) = 116.6(5)°]. In **2**, the NCS group is

also linear [N(3)–C(21)–S(1) = 179.5(4)°] and nearly coaxial with the Co(1)–N(3) bond [C(21)–N(3)–Co(1) = 175.0(3)°]. The N–C and C–S distances [1.160(5) and 1.628(4) Å, respectively] are comparable with the corresponding distances in other molecules, e.g. 1.146(4) and 1.638(3) Å in $[Ni(pn)(py)_2(NCS)_2]$ [19]. The corresponding geometry parameters in the tridentate and bidentate ligands in **1** and **2** are comparable. The N(2)–(C7) distance [1.293(8) Å (**1**), 1.294(5) Å (**2**)] clearly indicates its double bond character. The NCH_2CH_2N chelate adopts a *gauche* conformation in both the molecules. Of the C–O distances, those in the keto group are somewhat shorter than those in the phenolate groups.

4. Supplementary data

Full details of data collections and structure determinations have been deposited with the Cambridge Crystallographic Data Centre, CCDC nos. 146 366 (**1**) and 146 367 (**2**). POLYHEDRON

Copper(II)-activated transformation of azomethine to imidate: synthetic and structural studies

Nimma Rajaiah Sangeetha, Satyanarayan Pal, Samudranil Pal *

School of Chemistry, University of Hyderabad, Hyderabad 500 046, India

Received 29 June 2000; accepted 20 September 2000

Abstract

The Schiff base 2-pyridine–carboxaldehyde 4-dimethylaminobenzoylhydrazone (HL, **1**) was prepared by reacting 2-pyridine–carboxaldehyde and 4-dimethylaminobenzoylhydrazine in a 1:1 molar ratio in methanol. Reaction of HL (**1**) with $Cu(O_2CCH_3)_2{\cdot}H_2O$ (in a 1:1 molar ratio) in methanol afforded a dinuclear copper(II) complex, $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]{\cdot}2H_2O$ (**2**). The azomethine functionality (–CH=N–) of **1** is converted to imidate (–C(OMe)=N–) in the complexed ligand L'^-. Molecular structures of both **1** and **2** were determined by X-ray crystallographic studies. The dinuclear molecule of **2** is centrosymmetric and contains two monoatomic bridging acetate groups. Each copper(II) centre is in a square-pyramidal N_2O_3 coordination sphere. The ligand, L'^- coordinates the metal ion via the pyridine-N, the imidate-N, and the deprotonated amide-O atoms. One of the acetate oxygen atoms completes the N_2O_2 square-plane. The oxygen of the symmetry-related acetate fills the apical coordination site. Structural parameters are consistent with both copper ions being in a +2 oxidation state. The room temperature magnetic moment is 1.89 μ_B (per Cu). In powder phase the complex displays an axial EPR spectrum at 298 K. The complex is nonconducting in methanol solution. The electronic spectrum shows a ligand field absorption at 680 nm and charge transfer bands in the range 426–215 nm. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Copper(II); Azomethine; Imidate; Crystal structures

1. Introduction

Continuing interest in the metal-assisted transformations of organic functionalities is primarily due to the quest for convenient synthetic methods and regio- and stereoselective processes [1–5]. We have been working on the transition-metal complexes of amide containing aroylhydrazones to obtain high-valent metal complexes and amide oxygen bridged dinuclear species. Our interest is to study the effect of amide protonation and deprotonation on the coordination geometry, metal redox and interaction between metal centres in dinuclear species [6–11]. In our attempt to prepare a bivalent copper complex by treating pyridine-N, imine-N and amide-O donor 2-pyridine–carboxaldehyde 4-dimethylaminobenzoylhydrazone (HL, **1**) with $Cu(O_2CCH_3)_2{\cdot}H_2O$ in methanol, we have observed an interesting reaction in which the azomethine group present in HL is transformed to imidate in the complex, $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]{\cdot}2H_2O$ (**2**). The syntheses and X-ray structures of the free hydrazone and the copper(II) complex of the transformed ligand are described in this report.

2. Experimental

The chemicals and solvents used in this work were of analytical grade available commercially and were used without further purification.

2.1. Preparation of HL (*1*)

To a methanol solution (30 cm^3) of 4-dimethylaminobenzoylhydrazine (380 mg, 2.12 mmol), 0.2 cm^3 (225 mg, 2.10 mmol) of 2-pyridine–carboxaldehyde was added and the mixture was refluxed for 6 h. The solution was then evaporated on a steam bath to 5 cm^3

and cooled to room temperature. A light yellow crystalline solid separated was collected by filtration, washed with *n*-hexane and dried in air. Yield: 462 mg (82%). Found: C, 67.0; H, 5.9; N, 20.8. Calc. for $C_{15}H_{16}N_4O$: C, 67.15; H, 6.01; N, 20.88%. ^{1}H NMR data [δ (J) (ppm (Hz)) (multiplicity)]: $N(CH_3)_2$, 3.03 (s); azomethine-H, 9.53 (s); amide-H, 8.21 (s); aroyl H-atoms, 6.68 (9) (d), 7.85 (9) (d); pyridine H-atoms, 7.25 (m), 7.7 (m), 8.12 (8) (d), 8.56 (5) (d). Electronic spectral data in CH_3OH solution [λ_{max} (ε) (nm (mol^{-1} dm^3 cm^{-1}))]: 417sh (2100), 345 (33 500), 302 (15 000), 290sh (14 000), 232sh (10 100). Selected IR bands (cm^{-1}): 3216m, 1636s, 1608s, 1557s, 1526s, 1470m, 1435m, 1375m, 1339m, 1283s, 1194s, 1134s, 1069m, 1028m, 947m, 918m, 824s, 781m, 756m, 667m, 598w, 523w.

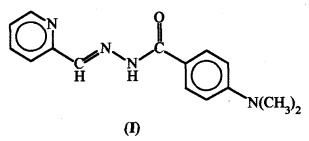
2.2. Preparation of $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]\cdot 2H_2O$ (2)

A methanol solution (15 cm^3) of $Cu(O_2CCH_3)_2\cdot H_2O$ (25 mg, 0.125 mmol) was added to another methanol solution (25 cm^3) of 2-pyridine–carboxaldehyde 4-dimethylaminobenzoylhydrazone (HL) (34 mg, 0.127 mmol). The brown mixture was refluxed for 1 h. The clear brown solution was cooled to room temperature and 40 cm^3 of xylene was added followed by slow evaporation in air at room temperature. A dark crystalline solid separated in about 2 weeks and was collected by filtration and dried in air. The single crystal for structure determination was chosen from this material. Yield obtained by this procedure was 17 mg (31%). Found: C, 49.2; H, 4.9; N, 12.5. Calc. for $Cu_2C_{36}H_{44}N_8O_{10}$: C, 49.37; H, 5.06; N, 12.79%. Electronic spectral data in CH_3OH solution [λ_{max} (ε) (nm (mol^{-1} dm^3 cm^{-1}))]: 680sh (120), 426 (32 500), 304sh (13 100), 281 (15 300), 238sh (15 500), 215sh (18 000). Selected IR bands (cm^{-1}): 3468w, 1636s, 1601s, 1528w, 1462m, 1379s, 1329s, 1263m, 1188s, 1057w, 964w, 936m, 824m, 793m, 752m, 683m, 650m, 611m, 494w.

2.3. Physical measurements

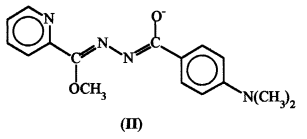
Microanalytical data (C,H,N) were obtained with a Perkin–Elmer model 240C elemental analyser. Infrared spectra were collected by using KBr pellets of the compounds on a JASCO-5300 FT-IR spectrophotometer. A Shimadzu 3101-PC UV–Vis/NIR spectrophotometer was used to obtain the electronic spectrum. A ^{1}H NMR spectrum of HL in $CDCl_3$ solution was recorded on a Bruker 200 MHz spectrometer using $Si(CH_3)_4$ as internal standard. A JEOL FE-3X spectrometer was used to collect the X-band EPR spectrum. The spectrum was calibrated with respect to DPPH ($g = 2.0037$). Magnetic susceptibilities were measured by using a Cahn magnetic susceptibility system consisting of a model 4600 adjustable gap electromagnet and a model 1000 electrobalance. Diamagnetic corrections calculated from Pascal's constants [12] were used to obtain the molar paramagnetic susceptibilities. Electrical conductivity measurements were performed by using a Digisun conductivity meter model DI-909.

2.4. X-ray crystallography



Single crystals of HL (**1**) were obtained by slow evaporation of a methanol solution. One of these solvent loss sensitive crystals was taken in a glass capillary with mother liquor and sealed. The crystal of complex **2** was mounted at the end of a glass fibre. The data were collected on an Enraf–Nonius Mach3 diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) by ω-scan method at 293 K. Unit cell parameters of **1** and **2** were determined by the least-squares fit of 25 reflections having 2θ values in the range 18–23 and 19–22°, respectively. Intensities of three check reflections were measured after every 1.5 h during the data collection. No decay was observed in the 22 h (**1**) and 49 h (**2**) of exposure to X-radiation. The ψ-scans [13] of four reflections with θ and χ values in the ranges 3–13 and 85–87°, respectively, were used for the empirical absorption correction of the dataset of **2**.

The structures were solved by direct methods and refined by full-matrix least-squares on F^2 and difference-Fourier techniques. The structure of **1** was solved in the space group $P2_1/c$. The asymmetric unit consists of a molecule of **1** with one methanol molecule. The copper(II) complex crystallises as dihydrate (**2**) in the space group *Pccn* and the asymmetric unit contains half of the dinuclear species and one water molecule. For both structures, all the non hydrogen atoms were refined anisotropically. Hydrogen atoms were added at idealised positions for structure factor calculations, but not refined. Calculations were done using the programs of XTAL software [14] for data reduction, DATCOR program [15] for absorption correction and SHELX-97 programs [16] for structure solution and refinement. The ORTEX6a package [17] was used for molecular graphics. Crystal parameters and refinement residuals are listed in Table 1.



3. Results and discussion

3.1. Synthesis

The hydrazone (HL, **1**) was prepared by condensing 1 equiv. of 2-pyridine–carboxaldehyde with 1 equiv. of 4-dimethylaminobenzoylhydrazine in boiling methanol. The procedure is similar to that reported earlier [18,19]. The elemental analysis, infrared and ^{1}H NMR spectral data are as expected for structure **I**.

(I)

(II)

The complex (**2**) was obtained as a crystalline solid in ~30% yield by reacting $Cu(O_2CCH_3)_2{\cdot}H_2O$ with HL in a 1:1 molar ratio in hot methanol, followed by addition of xylene to the deep brown reaction mixture and slow evaporation in air. The remaining mother liquor was of light yellow colour. The elemental analysis of the complex is satisfactory with the empirical formula $Cu(O_2CCH_3)(L')(H_2O)$, where L'^- is the deprotonated form (**II**) of the transformed HL.

The hydrazone (HL) was synthesised in methanol and can be recrystallized from the same solvent. Thus, the azomethine to imidate conversion happens after it coordinates the metal ion. There are at least two possible pathways for the transformation of the azomethine group of the copper(II)-coordinated hydrazone: (i) a nucleophilic attack at the polarised azomethine carbon by a methoxide followed by one electron reduction of the coordinated metal ion, homolytic cleavage of (OMe)C–H and formation of (OMe)C=N, and finally aerial oxidation of copper(I) to copper(II) and (ii) addition of methanol to the polarised azomethine group followed by oxidation to the final product, $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]$ by a portion of the copper(II) complex initially formed. The low yield of $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]$ with respect to total copper supports this second hypothesis. Addition of water or alcohol to a metal ion coordinated azomethine group has been reported [20,21]. In the presence of water, coordinated azomethine to amide conversion has been observed before and a mechanism similar to (ii) has been suggested [22].

Table 1

[a] $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$.

[b] $wR_2 = \{\Sigma[(F_o^2-F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $w = 1/[\sigma^2(F_o^2)+(aP)^2+bP]$, where $a = 0.0875$ and 0.0888 for **1**·CH_3OH and **2**, respectively, and $b = 0.0$ for both.

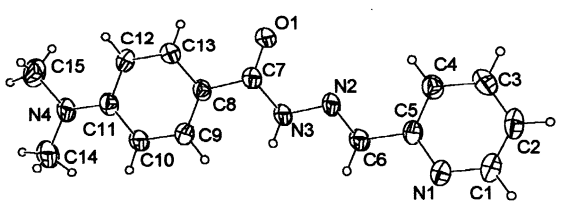

Fig. 1. Molecular structure of HL with the atom-labelling scheme. All atoms are represented by their 40% probability thermal ellipsoids.

3.2. Physical properties of $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]{\cdot}2H_2O$ (2)

The complex (**2**) is electrically nonconducting in methanol solution. In solid state the room temperature (298 K) magnetic moment (1.89 μ_B) per metal ion is very close to the spin-only moment for a d^9 system indicating no significant spin–spin interaction.

At room temperature the complex in powder phase displays an axial EPR spectrum ($g_\parallel = 2.28$ and $g_\perp = 2.09$). No hyperfine splitting is observed. Such spectra are typical for square-planar or square-pyramidal copper(II) species [23,24]. Similar powder EPR spectra have been observed for dicopper(II) complexes containing two monoatomic bridging acetate ions [11,24].

A weak band observed at 3468 cm^{-1} in the infrared spectrum of the complex is likely to be due to the lattice H_2O molecules [25]. The peak observed at 1636 cm^{-1} is possibly due to the ν_{as} stretch of the unidentate acetate group [25]. The origin of the strong peak at 1601 cm^{-1} is probably the =N–N=C(O^-)– moiety of the ligand [26,27].

The electronic spectrum of the complex in methanol shows a weak absorption at 680 nm followed by several intense absorptions in the range 426–215 nm. Weak bands observed in the range 620–675 nm for copper(II) complexes of Schiff bases and related ligands are assigned to d–d transitions [9,11,28,29]. The intense absorptions are most probably due to the ligand-to-metal charge transfer and intraligand transitions.

3.3. Description of structures

The molecular structure of the hydrazone (HL) is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. The molecule is essentially planar. The largest and smallest deviations from the least-squares plane observed are 0.108(3) and −0.001(3) Å for N4 and C11, respectively. The mean deviation from the least-squares plane is 0.051 Å. The C7–O1 (1.224(3) Å)

[a] Symmetry transformation used to generate equivalent atoms: $-x+1, -y, -z$.

and C7–N3 (1.362(3) Å) distances are consistent with the keto form of the amide functionality. The C6–N2 (1.271(3) Å) is typical for a C=N distance. The bond distances and angles in the pyridine and the benzene rings are unexceptional. The methanol molecule is hydrogen bonded with the amide-O of the hydrazone. The distance between the methanol oxygen and the amide-O is 2.753(3) Å.

The structure of the dinuclear complex, $[Cu_2(\mu\text{-}O_2CCH_3)_2L'_2]$ is illustrated in Fig. 2. Selected bond distances and angles are given in Table 3. The unit cell contains eight $Cu(O_2CCH_3)(L')(H_2O)$ fragments as asymmetric units. Each two $Cu(O_2CCH_3)(L')$ moieties form four centrosymmetric dinuclear molecules. The acetate ions are monoatomic bridging. The water molecules are hydrogen bonded with the nonbridging oxygen atoms of the acetate ions. The O3···O(water) distance is 2.809(9) Å. Each copper(II) centre is in distorted square-pyramidal N_2O_3 coordination geometry. The tridentate planar ligand binds the metal centre via the deprotonated amide-O, the imidate-N and the pyridine-N atoms. The oxygen of one of the acetates completes the N_2O_2 square-plane. The oxygen of the symmetry related acetate fills the apical site. There is a noticeable distortion of the basal plane towards tetrahedral geometry. The deviations of O1 and N1 from the mean plane are 0.11 and 0.10 Å, respectively, whereas those of O2 and N2 are -0.08 and -0.12 Å, respectively. The metal centre is 0.15 Å above the mean plane towards the apical O2′. The chelate bite angles in the five-membered rings formed by the amide-O and the imidate-N, and the pyridine-N and the imidate-N are very similar. The average value is 80.3°. Comparison of the N–N (1.376(6) Å), N–C (1.330(7) Å) and C–O (1.286(7) Å) distances in the $=N-N=C(O^-)-$ fragment of the coordinated ligand (L′) with the corresponding distances (Fig. 1, Table 2) in HL clearly suggests the deprotonation of the amide functionality in the complex. The C=N distance (1.280(7) Å) of the imidate moiety is identical with that (1.271(3) Å) of the azomethine group in HL. The Cu–N(pyridine) distance is comparable with the distances observed for other structurally characterised copper(II) complexes containing coordinated pyridine-N [30,31]. The distance corresponding to the Cu–N(imidate) bond is similar to the Cu–N(imine) distances reported earlier [8,9,11,32–36]. As expected the metal to deprotonated amide-O distance is shorter than that in complexes where copper(II) is coordinated to protonated amide-O [8,34–36]. The Cu–O–Cu′ bridge angle is 104.48(17)° and the metal–metal distance is 3.373(1) Å. The planar Cu_2O_2 fragment is unsymmetrical with respect to the Cu–O distances (Cu–O2, 1.948(4) Å and Cu–O2′, 2.309(4) Å). Such Cu–O distances (one short and one long) have been observed before in some dinuclear copper(II) complexes containing similar monoatomic bridging acetate [11,24,37–40].

4. Concluding remarks

In an attempt to prepare a copper(II) complex from a methanolic medium using 2-pyridine–carboxaldehyde 4-dimethylaminobenzoylhydrazone (HL), a transformation of the azomethine group of HL to imidate in the complex has been realised. The common method for the

preparation of imidates is the Pinner synthesis. In this method nitriles are treated with hydrogen halide in the presence of alcohol [41,42]. There is a report of imidate formation by reacting Schiff base with *t*-butylhypochloride in alcohol [43]. However, to the best of our knowledge no example of a metal ion activated azomethine to imidate transformation was previously known.

5. Supplementary material

Crystallographic data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK on request, quoting the deposition numbers CCDC-145601 and 145602 for **1**·CH_3OH and **2**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: depsit@ccdc.cam.uk or www: http://www.ccdc.cam.ac.uk).

Polyhedron 19 (2000) 2739–2770

POLYHEDRON

Subject Index to Volume 19

Ab initio methods
Cyclic phosphazenes, Electronic structures, Group theory, 389
Absorption spectra
Imidazole derivatives, Transition metal complexes, Crystal structure, Stability constants, 2183
Absorption spectroscopy
α,α′-Bis(pyrazolyl)-*m*-xylene, Copper(II) complexes, X-ray structure, Network structures, Electron spin resonance, 719
π-acceptors
Discotic complexes, Columnar complexes, Liquid crystals, Dithiolene, 267
Acetamidate
Trirhenium(III) clusters, Rhenium clusters, Dimolybdenum(II), MALDI, Mass spectroscopy, 1245
Acetonitrile
Macrocyclic polyether 18-crown-6, Alkaline earth metal ions, Transition metal ions, 1681
Acetylacetonates
Iridium, Halogenation, 1097
α-Acetylenic alcohols
Isomerization, Rearrangement, Heterobimetallic titanium–copper systems, 1693
Acid–base congeners
Dicopper complexes, Solvent-derived ancillary ligands, 1909
Acid–base
Dithiolene, Nickel, Dinuclear complexes, Solvatochromism, Carbon disulfide, 1283
Acid dissociation constants
Acidopentaaminecobalt(III) complexes, ESCA studies, ESI + mass spectra, 971
Acidopentaaminecobalt(III) complexes
ESCA studies, ESI + mass spectra, Acid dissociation constants, 971
Activity coefficients
3:3 Electrolytes, Electrolytic solutions, High-charge salts, High valency electrolytes, Mixed electrolytes, 2493
Acylthiourea
Platinum(II), Sulfoxide, *N*,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)thiourea, NMR, Chemotherapeutic agents, 1347
Addition reactions
Alkoxyalkynes, Aminoalkynes, Organophosphorus halides, Organosilane halides, Organogermane halides, Pd-catalyzed cross-coupling reactions, 597
Additions
Alkylation, Insertions, Nucleophilic, Schiff bases, Titanium, 177
Adduct
Magnesium, Aryloxide, Structure, 2557
Aerial oxidation of aldehydes
Molybdenum complexes, 1133
Aggregation
Sol–gel, Tetrasulfophthalocyanines, Monolith, Macrocycle, Silica, 2383
Alanate
Alane, Aluminum hydride, Alumoxane, Reduction, 1649
Alane
Aluminum hydride, Alanate, Alumoxane, Reduction, 1649
β-alanyl-lysine
Copper-dipeptide complexes, Glycyl-lysine, Alanyl-lysine, Histidyl-lysine, 2409
Alanyl-lysine
Copper-dipeptide complexes, Glycyl-lysine, Histidyl-lysine, β-alanyl-lysine, 2409
Alcohol oxidation
Ruthenium, Polypyridine, Terpyridine, Electrocatalytic oxidation, Isomerization, 1049
Al(III) complexes
Biospeciation, VO(IV) complexes, Insulin-mimetics, 2389
Alkaline Earth
Calcium, H-bonding, Inorganic Polymers, X-ray structure, 1783
Alkaline earth metal ions
Macrocyclic polyether 18-crown-6, Acetonitrile, Transition metal ions, 1681
Alkaline earth metals
Heterobimetallic diethanolaminates, Homobimetallic diethanolaminates, 77
Alkaline metal extraction
Phthalocyanine complexes, Phthalonitrile derivatives, Crown-ether, Copper, Nickel, Cobalt, 115
Alkaloid synthesis
Nitrosobenzene cycloaddition, Regioselectivity, Organoiron compounds, Decomplexation, Heterocycloaddition trap, 569
Alkene
Phosphine, Polymerization, Hydroboration, Copper(I) complexes, 1271
Alkenylation
Enamine, Pyrrole, 545
Alkenylsilanes
Hydrosilylation, $RhI(PPh_3)_3$, Polyaddition, Stereodivergent, 567
Alkoxides
Indium tin oxide, Surface modification, Interfaces, 505
Alkoxides
Molybdenum, Nitrides, Synthesis, X-ray structures, NMR fluxionality, Pseudorotation, 1363
Alkoxides
Scandium, Crystal structures, Volatility, 705
Alkoxide
Tin, Tin dioxide, Sol–gel, β-Diketonate, 2069
Alkoxo compounds of oxovanadium(V)
Crystal structure of compounds of oxovanadium(V), Hydrazonato compounds of oxovanadium(V), Oxovanadium(V) dimers, Reactivity of bis(β-dionato)-oxovanadium(IV) chelates, Hydrazonato tridentate Schiff base ligands, 2003
Alkoxyalkynes
Aminoalkynes, Addition reactions, Organophosphorus halides, Organosilane halides, Organogermane halides, Pd-catalyzed cross-coupling reactions, 597
Alkylation
Additions, Insertions, Nucleophilic, Schiff bases, Titanium, 177
Alkyl-substituted pyridines
Oxomolybdenum(V) compounds, Clusters, $Mo_2O_4^{2+}$ unit, Pyridine, 1219
Alkyl-substituted pyridines
Solvothermal synthesis, Crystal structures, Oxomolybdenum(V) coordination compounds, Mo(V, VI) compounds, 1407
Alkyne complexes
Multimetallic, Cobalt carbonyl complexes, Tungsten(II), Chain triphos-bridged, 1585
Alkynes
Functionalized metalloalkynes, Olefins, Polymetallated olefins, Titanium, 563
Allenes
C–H activation, Intramolecular bonds, Titanium, Metallacycles, Carbometalation, 879

PII: S0277-5387(00)00653-7

Allylation
Aqueous reactions, Esters, Indium, Indium compounds, Pyridines, 549
π-Allyl complexes
Allylic substitutions, Iridium, Regioselectivity, Stereoselectivity, Phosphites, 557
Allyl complexes
Palladium, Platinum, Thiolate complexes, 1627
Allylic alkylation
Axially chiral phosphinamine, Hydroboration, Quinazolines, 541
Allylic substitutions
π-Allyl complexes, Iridium, Regioselectivity, Stereoselectivity, Phosphites, 557
Alternating chain
Dimer complex, Crystal structure, Magnetic properties, 1461
Aluminum complexes
1-Aza-allyl, Bismuth complexes, Crystal structures, Gallium complexes, 471
Aluminum hydride
Alane, Alanate, Alumoxane, Reduction, 1649
Alumoxane
Alane, Aluminum hydride, Alanate, Reduction, 1649
Amberlite anion-exchange resin
Aromatic amines, Oxalate anions, Metal–oxalate complexes, Oxidation, Homogeneous and heterogeneous, 1317
Amido
Diimine, Dimer, Hydroxo, Palladium, Platinum, 155
Amine oxide
Methanolysis, Rhenium, Osmium, Carbonyl, Methylcarbonate, 641
Amino acids
closo-Dodecaborate, Oxonium derivatives, Functional derivatives, Boron neutron capture therapy, 627
α-Aminoacylsilanes
β-Amino alcohols, Lewis acid, Silylcupration, Statine analogues, 529
β-Amino alcohols
α-Aminoacylsilanes, Lewis acid, Silylcupration, Statine analogues, 529
Aminoalkynes
Alkoxyalkynes, Addition reactions, Organophosphorus halides, Organosilane halides, Organogermane halides, Pd-catalyzed cross-coupling reactions, 597
(2-Aminoethyl)(3-aminopropyl)amine
Nickel(II)selenocyanate, Bis(3-aminopropyl)amine, Bis(2-aminoethyl)-methylamine, Thermochromism, 1903
1-(2-Aminoethyl)pyrrolidine
Nickel(II)thiocyanate, Crystal structures, *cis*/*trans* Isomers, 1803
Aminophosphate complexes
Palladium(II) complexes, Metallocycles, Spectroscopy, Antitumour activity, 937
Aminopolyphosphonates
Potentiometry, Equilibria, Stability constants, Manganese(II), Cobalt(II), Nickel(II) complexes, UV–VIS spectra, 2083
Aniline polymerization
Copper phosphonates, Intercalation compounds, 765
Anion–cation pair compound
Synthesis, Crystal structure, Aryloxide, Neodymium, 2243
Anticancer drugs
Rhodium(II) complexes, Rhodium(II) carboxylates, Rhodium sulfosalicylate, Thermogravimetric analysis, Spectroscopic analysis, 1305
Antiferromagnetic interactions
Dinuclear, Pryrazolyl groups, 2215
Antimicrobial activity
Chelating ligands, Crystal structures, Copper(II) complexes, Pyridinecarboxylate complexes, 2689
Antimonides
Arsenides, Metathesis, Phosphides, 829
Antimony
Homoleptic silyl complexes, Arsenic, 1639
Antitumor activity
Transition metals, Synthesis, Structural characterization, 217
Antitumour activity
Palladium(II) complexes, Metallocycles, Aminophosphate complexes, Spectroscopy, 937
Antitumour activity
Rare earth complex, Crystal structure, Hydrazone, 2599
Antitumour
Streptonigrin, 2,2′-Bipyridyl, 6,6′-Dicarboxy-2,2′-bipyridyl, Zinc, 1067
Aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)cobalt(II) sesquihydrate
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
Aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
Aqueous reactions
Allylation, Esters, Indium, Indium compounds, Pyridines, 549
Arene coordination
Dirhodium(II) compounds, Trifluoroacetate, One-dimensional polymers, π-Complexes, Crystal structures, 1829
Aromatic amines
Amberlite anion-exchange resin, Oxalate anions, Metal–oxalate complexes, Oxidation, Homogeneous and heterogeneous, 1317
Aromatic diamines
Transition metal complexes, Terephthalate ions, Crystal structures, Spectral data, 1415
Arsenic
Homoleptic silyl complexes, Antimony, 1639
Arsenides
Antimonides, Metathesis, Phosphides, 829
Aryloxide
Magnesium, Structure, Adduct, 2557
Aryloxide
Synthesis, Crystal structure, Neodymium, Anion–cation pair compound, 2243
Aryloxide
Titanium, Tantalum, Nobium, Bisphenol, Hydrogenation, 35
Ascorbic acid
Kinetics, Manganese(IV), Electroprotic reactions, 1213
Asorption spectra
Copper(III), Nickel(III), Dioxotetraamines, Macrocyclic ligands, 2533
Aspartate
Lead(II), Structures, 649
Asymmetrical complexes
Cadmium(II) complexes, Schiff-base ligands, Symmetrical complexes, Heptadentate ligands, 1633
Asymmetric alkylation
Asymmetric rearrangements, Chiral ligands, Chiral sulfoxides, Palladium catalysts, 525
Asymmetric rearrangements
Asymmetric alkylation, Chiral ligands, Chiral sulfoxides, Palladium catalysts, 525
Asymmetric synthesis
Hydroformylation, Organocopper reagents, Catalysis, Domino reactions, 513
Asymmetric synthesis
Kainoids, Boronic esters, Pyrrolidine, 587
Axially chiral phosphinamine
Allylic alkylation, Hydroboration, Quinazolines, 541
1-Aza-allyl
Aluminum complexes, Bismuth complexes, Crystal structures, Gallium complexes, 471
Aza-macrocycles
Electroreduction, Carbon dioxide, Delocalized π interactions, 2373
Aza–oxa crowns
Macrocyclic ligands, Naphthylmethyl fluorescent groups, 1867
Azide
Cobalt, 2-Hydroxyacetophenone, Thiocyanate, Crystal structure, 2707
Azido-bridged nickel(II) compounds
Crystal structures, Magnetic properties, 1575
Azoimine
Ru–bipyridine, Tris-chelates, X-ray structures, Electrochemistry, Emission spectra, 1925

Azomethine
Copper(II), Imidate, Crystal structures, 2713
Azomethynic copper metallochelates
Synthesis, EXAFS investigation, 2361
Azoxybenzene deoxygenation
Dioxomolybdenum dipicolinate, Oxygen-atom transfer, 2141

Barriers
Ruthenium, Phenanthroline, *Cis–trans*, MO calculations, Field strength, 2297
^{9}Be NMR spectroscopy
Beryllium, Phosphato complexes, Solution equilibria, ^{31}P NMR spectroscopy, Speciation, 1043
Benzil-α-monoxime
Transition metal complexes, Electronic spectral data, Oximes, 1687
Benzolamide
Divalent metals, Zinc, Copper, Diethylenetriamine, Ternary complexes, 725
Benzothiazole-2-thione
Mercury(II) complexes, Triphenylphosphine, pyrimidine-2-thione, Crystal structures, 2231
Beryllium
Phosphato complexes, Solution equilibria, ^{31}P NMR spectroscopy, ^{9}Be NMR spectroscopy, Speciation, 1043
Bidentate ligands
Trichlorovinyl, Mercury(II), Crystal structures, Complexes, 2539
Bidentate Schiff base ligands
Dichloromanganese(IV) complexes, Tetradentate Schiff base ligands, Crystal structures, Photosystem II, 2039
Bimetallic complexes
Crystal structures, Palladium complexes, Platinum complexes, Diphosphine complexes, Tetraphosphine complexes, 913
Bimetallic complexesw
Molybdenum(II), Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Bimetallic films
Colloids, FT-IR, Conductivity, Thermal analysis, 2337
Binaphtholato complexes
Tungsten(VI), X-ray structures, 2579
Binuclear copper compounds
Crystal structures, Magnetism, Oxalato-bridged compounds, 1105
Binuclear Cu(II) complexes
Magnetic properties, Electrochemistry, ESR, 1769
Binuclear manganese(II) complex
Binuclear nickel(II) complex, Crystal structures, Magnetic properties, Tris(6-methyl-2-pyridylmethyl)amine, 1559
Binuclear nickel(II) complex
Binuclear manganese(II) complex, Crystal structures, Magnetic properties, Tris(6-methyl-2-pyridylmethyl)amine, 1559
Binuclear zinc complexes
Heterocyclic bis(thiosemicarbazone), Heptacoordinate complexes, Organotin(IV) complexes, 841
Binucleating hexa-aza macrocycle
Copper(II), Nickel(II), Cobalt(II), Zinc(II), Crystal structures, Phosphotriester, Hydrolysis, 1485
Binucleating ligand
Nickel complexes, Copper complexes, Crystal structures, Redox chemistry, 2011
Bioactive groups
Phosphorothiates, Organotin(IV), Cholesteryl, 1539
Bio-activity
Copper(II), Chloropropionate, Crystal structure, EPR, 2573
Biomimetics
Calcium phosphates, Biomineralization, Liposomes, 357
Biomineralization
Calcium phosphates, Biomimetics, Liposomes, 357
Biospeciation
Al(III) complexes, VO(IV) complexes, Insulin-mimetics, 2389
2,2′-Bipyridine
1,8-Bis(dimethylamino)naphthalene, Boron-11 NMR, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
4,4′-Bipyridine
Coordination polymers, Copper(II) complexes, Cadmium(II) complexes, 1809
1,4-Bipyridine
Mononuclear, Tungsten pentacarbonyl complexes, 1,2-Bis(4-pyridyl)ethane, 1621
2,2′-Bipyridyl
Streptonigrin, 6,6′-Dicarboxy-2,2′-bipyridyl, Antitumour, Zinc, 1067
Bis(2-aminoethyl)methylamine
Nickel(II)selenocyanate, Bis(3-aminopropyl)amine, (2-Aminoethyl)(3-aminopropyl)amine, Thermochromism, 1903
Bis(3-aminopropyl)amine
Nickel(II)selenocyanate, (2-Aminoethyl)-(3-aminopropyl)amine, Bis(2-aminoethyl)methylamine, Thermochromism, 1903
2,6-Bis(2-benzimidazolyl)pyridine
Chromium(III) complexes, Tris(2-benzimidazolylmethyl)amine, 2-Guanidinobenzimidazole, 2-(2-Pyridyl)benzimidazole, Crystal structures, 1821
Bis(η-cyclopentadienyl)titanium(IV)
Crystal structures, Diphenylphosphinoacetate, Heterometallics, Nicotinate, Thiophenoxyacetate, 757
1,8-Bis(dimethylamino)naphthalene
2,2′-Bipyridine, Boron-11 NMR, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
Bis(methyldiphenylphosphonio)methylide salts
Gold(I) complexes, Cationic ylide ligand, P-alkylation, 1837
Bismuth complexes
Aluminum complexes, 1-Aza-allyl, Crystal structures, Gallium complexes, 471
Bismuth
Thioether, Coordination polymers, Crystal structures, Electrospray, 849
Bisphenol
Titanium, Tantalum, Nobium, Aryloxide, Hydrogenation, 35
Bisphosphines
Heterocyclic thiones, Palladium(II) complexes, Platinum(II) complexes, Pyridyl, 899
α,α′-Bis(pyrazolyl)-*m*-xylene
Copper(II) complexes, X-ray structure, Network structures, Absorption spectroscopy, Electron spin resonance, 719
Bis(pyrazolyl)silanes
Zinc, Crystal structures, Nitrogen-donor ligands, 1815
1,2-Bis(4-pyridyl)ethane
Mononuclear, Tungsten pentacarbonyl complexes, 1,4-Bipyridine, 1621
4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione
Copper, Cobalt, Nickel, Palladium, dmit, 4,5 - bis(2 - pyridylmethylsulfanyl) - 1,3-dithiole-2-thione, 665
4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione
Copper, Cobalt, Nickel, Palladium, dmit, 4,5 - bis(2 - pyridylethylsulfanyl) - 1,3-dithiole-2-thione, 665
Bonding
Hydroborates, Lithium, Titanium(IV), Crystal structures, 1579
Boron
Halogenated carborane anions, Cobalt bis(dicarbollide), Carborane, Halogenation, 1777
Boronic esters
Kainoids, Asymmetric synthesis, Pyrrolidine, 587
Boron neutron capture therapy
closo-Dodecaborate, Oxonium derivatives, Functional derivatives, Amino acids, 627
Boron-11 NMR
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
Bpy ligands
Polypyridine ligands, Ruthenium(II) complexes, 1975
Bridged structures
Crystal structures, Heteronuclear multiple bond coherence, *N*-Tosyl ligands, Zinc porphyrin complexes, 413
Bridging ligands
Butadienyl, Chiral substituents, Molybdenum, 791

Bridging oxygen atoms
μ-oxo-Bridged cations, Crown ether complexation, Crystal structures, 1799
Bromide
Platinum(II), Platinum(IV), Porphyrins, Electrochemistry, Voltammetry, 1057
Bulky phosphine
X-ray structure, Cone angle, Two-coordinate gold complex., 2211
Butadienyl
Bridging ligands, Chiral substituents, Molybdenum, 791

Cadmium complexes
Mercury complexes, Sulfamides, X-ray structure, Zinc complexes, 991
Cadmium halides
2-Pyridineformamide, Thiosemicarbazone, Crystal structures, 1873
Cadmium(II) complexes
4,4′-Bipyridine, Coordination polymers, Copper(II) complexes, 1809
Cadmium(II) complexes
Schiff-base ligands, Symmetrical complexes, Asymmetrical complexes, Heptadentate ligands, 1633
Cadmium(II)
Zinc(II), Mercury(II), Tris(2-benzimidazolylmethyl)amine, X-ray diffraction structures, NMR data, 1479
Caesium ion
Calixcrowns, Sodium ion, Perrhenate ion, Pertechnetate ion, Nuclear reprocessing, 1749
Calcium
H-bonding, Inorganic Polymers, Alkaline Earth, X-ray structure, 1783
Calcium phosphates
Biomimetics, Biomineralization, Liposomes, 357
Calixarenes
Ytterbium(III), Lanthanides, Homoazacalixarenes, Crystal structure, 2673
Calixcrowns
Caesium ion, Sodium ion, Perrhenate ion, Pertechnetate ion, Nuclear reprocessing, 1749
Carbacylamidophosphate
Lanthanide, NMR, X-ray data, 2203
Carboalumination
1,5-diene, Cross coupling, Terpenoids, Palladium, 591
Carbometalation
C–H activation, Intramolecular bonds, Titanium, Metallacycles, Allenes, 879
Carbon dioxide
Aza-macrocycles, Electroreduction, Delocalized π interactions, 2373
Carbon dioxide
Dimethyl carbonate, Homogeneous catalysis, Mechanism, Supercritical conditions, 573
Carbon disulfide
Dithiolene, Nickel, Dinuclear complexes, Acid–base, Solvatochromism, 1283
Carbonyl
Amine oxide, Methanolysis, Rhenium, Osmium, Methylcarbonate, 641
Carbonyl clusters
Solvothermal synthesis, Polytelluride, Iron telluride, Iron cluster, Iron carbonyl, 1995
Carborane
Halogenated carborane anions, Cobalt bis(dicarbollide), Boron, Halogenation, 1777
Carbosilanes
Dendrimers, Platinum catalysts, Hydrosilation, 1031
Carboxylate and sulfonate substituted pyridines
Tungsten(II), Propiolic acid, Water soluble complexes, 2171
Carboxylate complexes
Copper complexes, Dinuclear complexes, Crystal structures, Cuprous oxide, Cupric oxide., 2621
Carboxylate
Nitrosyl complex, Chromium, Molybdenum, DFT, 2565
Carboxylates
Crystal structures, Ruthenium, Dimethyl sulfoxide, Complexes, Catalysis, 1589
Carboxylato-bridged copper(II) complex
Crystal structure, Magnetic properties, 2529
Carcinogenic
Chromium, Nucleotides, 417
Catalase
Manganese complexes, Schiff bases, Manganoenzymes, Photolysis, Dioxygen, 47
Catalysis
Chromium, Salen, Manganese, Enantioselection, Nozaki–Hiyama–Kishi reaction, 537
Catalysis
Crystal structures, Ruthenium, Dimethyl sulfoxide, Carboxylates, Complexes, 1589
Catalysis
Hydroformylation, Organocopper reagents, Asymmetric synthesis, Domino reactions, 513
Catalysis
Oxidation, 3,5-Di-*tert*-butylcatechol, Kinetics, Copper binuclear complexes, 2367
Catalysis
Zirconocene, Crystal structures, Olefin polymerizations, 1941
Catalysts
Palladium(II) complexes, Peptides, Hydrolysis, 959
Catecholborane
Reactivity, 1063
Catechols
Macrocyclic ligands, Oxovanadium complexes, ESR parameters, Distorted square-pyramid, Hydrophobic cavities, 1167
Cationic ylide ligand
Gold(I) complexes, Bis(methyldiphenylphosphonio)methylide salts, P-alkylation, 1837
Cavity
Solubility, Oxygen, Solubilization enthalpy, Solubilization entropy, 2457
Cd(II)
Hg(II), tachpyr, Torsion angles, Twist angles, Zn(II), 1155
CdS nanoclusters
Ruthenium(II) polypyridyls, Functionalized nanoclusters, Mesophase materials, Molecular devices, 331
C–H activation
Intramolecular bonds, Titanium, Metallacycles, Allenes, Carbometalation, 879
Chagas
Ruthenium, Clotrimazole, Ketoconazole, Paramagnetic, Metal complexes, *Trypanosoma cruzi*, 2319
Chain triphos-bridged
Multimetallic, Cobalt carbonyl complexes, Tungsten(II), Alkyne complexes, 1585
Chelated fluoroboron cations
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Boron-11 NMR, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
Chelating ligands
Crystal structures, Copper(II) complexes, Pyridinecarboxylate complexes, Antimicrobial activity, 2689
Chemotherapeutic agents
Platinum(II), Sulfoxide, *N*,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)thiourea, Acylthiourea, NMR, 1347
Chiral-at-metal complexes
Configurational stability, Epimerisation, Equilibria, X-ray structure analyses, 1519
Chiral catalysts
Porphyrins, Hemoprotein models, Epoxidation, Olefins, 581
Chiral complexes
Macrocycles, Lanthanide complexes, NMR of paramagnetic compounds, 465
Chiral ligands
Asymmetric alkylation, Asymmetric rearrangements, Chiral sulfoxides, Palladium catalysts, 525
Chiral nematic phases
Metallomesogens, Rhenium, Nematic phases, 249
Chiral substituents
Bridging ligands, Butadienyl, Molybdenum, 791
Chiral sulfoxides
Asymmetric alkylation, Asymmetric rearrangements, Chiral ligands, Palladium catalysts, 525
Chloride metathesis
Palladium(II) complexes, Platinum(II) complexes, X-ray crystallography, Heterodifunctional ligands, 695
Chloroboranes
Hydroboration, Polysilazanes, Precursors, Vinylsilanes, 323
Chloropropionate
Copper(II), Crystal structure, EPR, Bioactivity, 2573

Cholesteryl
Phosphorothiates, Organotin(IV), Bioactive groups, 1539
Chromium
Carcinogenic, Nucleotides, 417
Chromium(III) complexes
Tris(2-benzimidazolylmethyl)amine, 2-Guanidinobenzimidazole, 2,6-Bis(2-benzimidazolyl)pyridine, 2-(2-Pyridyl)benzimidazole, Crystal structures, 1821
Chromium(III)
Iron(III), DTPA, Complexes, Thermal properties, Thermodynamics, 2421
Chromium
Nitrosyl complex, Molybdenum, Carboxylate, DFT, 2565
Chromium
Salen, Manganese, Catalysis, Enantioselection, Nozaki–Hiyama–Kishi reaction, 537
Chromium
Selenoether, Telluroether, Sulfur macrocycles, Molybdenum, Tungsten, 1373
Ciprofloxacin
Iron(III), Solution equilibria, Surfactants, 1085
cis - Diaquabis(2,2′ - bipirydyl)chromium(III)
Kinetics, Substitution, Mechanism, Octacyanomolybdate(IV), Octacyanotungstate(IV), 2225
cis - Diaqua(*N* - carbamoylmethyl - iminodiacetato)nickel(II)
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Amidomethyl)-iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, Molecular and crystal structure, Magnetic and spectral properties, Thermal stability, 2463
Cis–trans isomerism
Crystal structures, 1,2-Diamino-2-methylpropane, Nickel(II)nitrite, 1015
cis/*trans* Isomers
Nickel(II)thiocyanate, 1-(2-Aminoethyl)pyrrolidine, Crystal structures, 1803
Cis–trans
Ruthenium, Phenanthroline, MO calculations, Barriers, Field strength, 2297
closo-Dodecaborate
Oxonium derivatives, Functional derivatives, Amino acids, Boron neutron capture therapy, 627
Clotrimazole
Ruthenium, Ketoconazole, Paramagnetic, Metal complexes, *Trypanosoma cruzi*, Chagas, 2319
Cluster compounds
Molybdenum complexes, Tellurium-rich compounds, De-tellurium reaction, Crystal structures, 925
Cluster
Ruthenium, Iridium, Gold, Electron-rich, Phosphido-bridged, Crystal structures, 2593
Clusters
Mercury, Thiocyanante, Host–guest chemistry, 871
Clusters
Oxomolybdenum(V) compounds, $Mo_2O_4^{2+}$ unit, Pyridine, Alkyl-substituted pyridines, 1219
Cobalt bis(dicarbollide)
Halogenated carborane anions, Boron, Carborane, Halogenation, 1777
Cobalt carbonyl complexes
Multimetallic, Tungsten(II), Alkyne complexes, Chain triphos-bridged, 1585
Cobalt complexes
Crystal structures, 855
Cobalt complexes
Schiff bases, Spin crossover, Photosensitive ligands, LD-LISC effect, 1643
Cobalt complexes
Thiosemicarbazones, Electrochemistry, Iron complexes, EPR of iron complexes, Nickel complexes, 2059
Cobalt complex
Zinc complexes, α-Ketoglutaric acid, Thiosemicarbazones, Crystal structures, Spectroscopic properties, 1895
Cobalt
Copper, Nickel, Palladium, dmit, 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione, 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione, 665
Cobalt
Crystal structures, Magnetic properties, Dinuclear complexes, Manganese, Nickel, 93
Cobalt
Dioxygen carriers, Dinuclear complexes, Dinucleating ligands, Polyamines, Kinetics, Dioxygen binding, 2447
Cobalt
Dioxygen carriers, Dioxygen binding, Polynuclear complexes, Polyamines, Thermodynamics of complexation, 2441
Cobalt
Electrocatalysis, Nitric oxide, Oxidation, Phthalocyanine, Reduction, 229
Cobalt
2-Hydroxyacetophenone, Azide, Thiocyanate, Crystal structure, 2707
Cobalt(II)
Binucleating hexa-aza macrocycle, Copper(II), Nickel(II), Zinc(II), Crystal structures, Phosphotriester, Hydrolysis, 1485
Cobalt(II) complexes
Crystal structures, Iron(II) complexes, Octadentate ligands, 431
Cobalt(II) complexes
Electrochemical synthesis, Crystal structures, Tosylamide complexes, 1607
Cobalt(II) complexes
Pyridine *N*-oxide ligands, Zinc(II) complexes, X-ray structures, Magnetic susceptibility, 2195
Cobalt(II) complex
Syntheses, Crystal structures, Nickel(II) complex, 4-(*p*-Methylphenyl)-3,5-bis-(pyridin-2-yl)-1,2,4-triazole, ESIMS, 2019
Cobalt(II)
Cyanamidonitrate, Electronic spectra, Imidazole ligands, IR spectra, Nickel(II), X-ray crystallography, 1021
Cobalt(III) complex
Thiocarbamylpyrazole, Spectroscopic study, X-ray crystal structure, 2651
Cobalt(III)
Copper(II), NMR spectroscopy, Pyridylmethyl-tetraazadecane, 1447
Cobalt(II)
Potentiometry, Equilibria, Stability constants, Manganese(II), Nickel(II) complexes, Aminopolyphosphonates, UV–VIS spectra, 2083
Cobalt
Phthalocyanine complexes, Phthalonitrile derivatives, Crown-ether, Copper, Nickel, Alkaline metal extraction, 115
Colloids
Bimetallic films, FT-IR, Conductivity, Thermal analysis, 2337
Columnar complexes
Discotic complexes, Liquid crystals, π-acceptors, Dithiolene, 267
Complexation chemistry
Crystal structures, 1,10-Phenanthroline, 495
Complexation
D-Gluconic acid, D-Galactonic acid, D-Gulonic acid, Praseodymium(III), 1567
Complexes
Crystal structures, Ruthenium, Dimethyl sulfoxide, Carboxylates, Catalysis, 1589
π-Complexes
Dirhodium(II) compounds, Trifluoroacetate, One-dimensional polymers, Arene coordination, Crystal structures, 1829
Complexes
Iron(III), Chromium(III), DTPA, Thermal properties, Thermodynamics, 2421
Complexes
Lanthanides(III), Silver(I), Diethylenetriamine, *N*,*N*-dimethylformamide, Thermodynamics, 2427
Complexes
Macrocycles, Synthesis, Equilibria, 2501
Complexes
Platinum, Sulfimides, Hydrogen bonding, 2077
Complexes
Trichlorovinyl, Mercury(II), Crystal structures, Bidentate ligands, 2539
Conductivity
Colloids, Bimetallic films, FT-IR, Thermal analysis, 2337
Cone angle
Bulky phosphine, X-ray structure, Two-coordinate gold complex., 2211
Configurational stability
Chiral-at-metal complexes, Epimerisation, Equilibria, X-ray structure analyses, 1519
π-Conjugation
Ferrocenylporphyrin, Electrochemical communication, Intramolecular hydrogen bonding, NH tautomerism, 1961

Contrast agents
Crystal structures, Diethylenetriaminepentaacetate, Lanthanides, Neodymium, 771
Cooperative vibronic transitions
Infrared spectroscopy, Raman spectroscopy, Electronic absorption spectroscopy, Crystal structures, Hypophospite complexes, Two-centre transitions, 863
Coordination compounds
Uranium, Thorium, Tetraphenylimidophosphinate ligand, X-ray crystal structures, 1699
Coordination.
Dithiocarboxylate, Vanadium(IV), Magnetism, EPR, Infrared, 2155
Coordination
Iron, Phthalocyanine, Dopamine, Serotonin, 1355
Coordination modes
Electron spin resonance, Copper(II) complexes, Histamine, L-Histidine, Isomerism, 1123
Coordination modes
ESR, Copper(II) complexes, Glycyl-L-histidine, Formation constants, Isomerism, 2049
Coordination polymers
4,4′-Bipyridine, Copper(II) complexes, Cadmium(II) complexes, 1809
Coordination polymers
Bismuth, Thioether, Crystal structures, Electrospray, 849
Copper and iron species
Thiuram sulfides, Dithiocarbamate derivatives, 2269
Copper binuclear complexes
Oxidation, Catalysis, 3,5-Di-*tert*-butylcatechol, Kinetics, 2367
Copper
Cobalt, Nickel, Palladium, dmit, 4,5-bis-(2 - pyridylmethylsulfanyl) - 1,3 - dithiole-2-thione, 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione, 665
Copper complexes
Binucleating ligand, Nickel complexes, Crystal structures, Redox chemistry, 2011
Copper complexes
Carboxylate complexes, Dinuclear complexes, Crystal structures, Cuprous oxide, Cupric oxide., 2621
Copper complexes
Crystal structures, Metavanadate complexes, Nickel complexes, Hydrothermal synthesis, Magnetic properties, 2521
Copper complexes
Crystal structures, Nickel complexes, Schiff bases, Uracil, 689
Copper complexes
Schiff bases, X-ray structure, 5-Phenylazosalicylaldehyde, Cyclic voltammetry, 607
Copper complexes
Silver complexes, Gold complexes, 743
Copper complexes
Thiosemicarbazones, Macrocyclic ligands, Electrochemistry, Dithio-Schiff base complexes, 441
Copper compounds
Tetrathiometalate, Nonlinear optical properties, Synthesis, Crystal structures, Dppm, 1545
Copper-dipeptide complexes
Glycyl-lysine, Alanyl-lysine, Histidyl-lysine, β-alanyl-lysine, 2409
Copper
Divalent metals, Zinc, Benzolamide, Diethylenetriamine, Ternary complexes, 725
Copper
Equilibrium, Mixed valence, Disproportionation, Temperature effects, 2289
Copper
gem-Diol,di-2-pyridyl ketone, Di(2-pyridyl)methanediol, Crystal structures, 623
Copper(I) bromide complexes
Heterocyclic thione complexes, Diphosphine complexes, Dinuclear complexes, Crystal structures, 1615
Copper(I) complexes
Crystal structures, Electronic spectra, Emission spectra, Pyrazine carboxamide complexes, Vibrational spectra, 601
Copper(I) complexes
Di-2-pyridyl ketone, Crystal structures, Electronic and IR spectra, 1465
Copper(I) complexes
Phosphine, Alkene, Polymerization, Hydroboration, 1271
Copper(II)
Azomethine, Imidate, Crystal structures, 2713
Copper(II)
Binucleating hexa-aza macrocycle, Nickel(II), Cobalt(II), Zinc(II), Crystal structures, Phosphotriester, Hydrolysis, 1485
Copper(II)
Chloropropionate, Crystal structure, EPR, Bio-activity, 2573
Copper(II)
Cobalt(III), NMR spectroscopy, Pyridylmethyl-tetraazadecane, 1447
Copper(II) complexes
4,4′-Bipyridine, Coordination polymers, Cadmium(II) complexes, 1809
Copper(II) complexes
α,α′-Bis(pyrazolyl)-*m*-xylene, X-ray structure, Network structures, Absorption spectroscopy, Electron spin resonance, 719
Copper(II) complexes
Chelating ligands, Crystal structures, Pyridinecarboxylate complexes, Antimicrobial activity, 2689
Copper(II) complexes
Deltakephalins, Stability constants, 241
Copper(II) complexes
Deprotonated pyridine-2,6-dicarboxamide ligands, Singly hydroxo-bridged, Crystal structures, Magnetism, 1423
Copper(II) complexes
Dinuclear and polynuclear, Crystal structures, Equatorial–apical bridge, Paramagnetic, 1593
Copper(II) complexes
Dinucleating alkoxide ligands, X-ray structures, Hetero-bridged complexes, Magnetism, Magneto-structural trends, 1429
Copper(II) complexes
Electron spin resonance, Coordination modes, Histamine, L-Histidine, Isomerism, 1123
Copper(II) complexes
ESR, Glycyl-L-histidine, Formation constants, Coordination modes, Isomerism, 2049
Copper(II) complexes
N-salicylidenearoylhydrazines, X-ray crystal structures, Molecular structures, Magnetic properties, Infrared spectra, 949
Copper(II)
Diamines, Uridine, Uridine 5′-monophosphate, 1145
Copper(II)
1,4-Diazacycloheptane, Trichloroacetate, Crystal structures, 1881
Copper(II)–edta-type complexes
Crystal structures, Stereochemistry, 1
Copper(III)
Asorption spectra, Nickel(III), Dioxotetraamines, Macrocyclic ligands, 2533
Copper(I,II) complexes
α,β-Unsaturated carboxylates, Triphenylphosphine, Magnetic properties, Crystal structures, 891
Copper(II) imidazolate ternary complexes
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazole ternary complexes, X-ray crystal structures, Molecular structures, Magnetic properties, Infrared spectra, 1181
Copper(II) imidazole ternary complexes
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazolate ternary complexes, X-ray crystal structures, Molecular structures, Magnetic properties, Infrared spectra, 1181
Copper(II), nickel(II) and zinc(II) complexes
Mixed-ligand complexes, Solution equilibrium, Hydroxamic acid, 1727
Copper(II)–peroxide adduct
Release of free nucleobases from oligomers, DNA cleavage, Electrospray mass spectrometry, 2639
Copper–iron complexes
Cyano-bridge, Crystal structures, IR spectra, 1935
Copper(I) thiocyanate complexes
Methyl nicotinates, Ethyl nicotinates, Ethyl isonicotinate complexes, Crystal structures, Trigonal planar anions, 615
Copper phosphonates
Aniline polymerization, Intercalation compounds, 765
Copper
Phthalocyanine complexes, Phthalonitrile derivatives, Crown-ether, Nickel, Cobalt, Alkaline metal extraction, 115

Coupling reactions
Palladium catalyzed reactions, Halide ions, Protonolysis, 577
CPMAS ^{13}C NMR spectroscopy
Thorium(IV), Uranium(IV), Dicarboxylate complexes, X-ray crystallography, 1757
CP-MAS NMR
Tetra-aza ligands, Nickel complex, Template reaction, 2149
CPMAS
Zn(II) complexes, 1,2,4-Triazolo-[1,5α]-pyrimidine, ^{15}N NMR, HETCOR, 965
Cross coupling
1,5-diene, Terpenoids, Carboalumination, Palladium, 591
Cross-coupling
Platinum, Gold, Diyne, X-ray, 2261
15-Crown-5 complexes
Liquid clathrates, X-ray crystallography, Oxonium ion, 85
Crown ether complexation
μ-oxo-Bridged cations, Crystal structures, Bridging oxygen atoms, 1799
Crown-ether
Phthalocyanine complexes, Phthalonitrile derivatives, Copper, Nickel, Cobalt, Alkaline metal extraction, 115
Crown
Uranium, Uranyl, Phosphate, Crystal structures, 1551
Cryoscopy
Cyanocuprates, Ionic, Reactivity, Structures, 553
Crystal engineering
Dimolybdenum, Dimolybdenum diolates, 375
Crystallite size
Magnesia, Dolomite, Degree of agglomeration, X-ray diffraction, SEM, 2345
Crystallographic
Selenium, Tungsten analogue, Refluxing, 2127
Crystal structure
Alternating chain, Dimer complex, Magnetic properties, 1461
Crystal structure
Carboxylato-bridged copper(II) complex, Magnetic properties, 2529
Crystal structure
Cobalt, 2-Hydroxyacetophenone, Azide, Thiocyanate, 2707
Crystal structure
Copper(II), Chloropropionate, EPR, Bioactivity, 2573
Crystal structure
Imidazole derivatives, Transition metal complexes, Absorption spectra, Stability constants, 2183
Crystal structure of compounds of oxovanadium(V)
Alkoxo compounds of oxovanadium(V), Hydrazonato compounds of oxovanadium(V), Oxovanadium(V) dimers, Reactivity of bis(β-dionato)oxovanadium(IV) chelates, Hydrazonato tridentate Schiff base ligands, 2003
Crystal structure
Rare earth complex, Antitumour activity, Hydrazone, 2599
Crystal structures
Aluminum complexes, 1-Aza-allyl, Bismuth complexes, Gallium complexes, 471
Crystal structures
Azido-bridged nickel(II) compounds, Magnetic properties, 1575
Crystal structures
Binuclear copper compounds, Magnetism, Oxalato-bridged compounds, 1105
Crystal structures
Binuclear nickel(II) complex, Binuclear manganese(II) complex, Magnetic properties, Tris(6-methyl-2-pyridylmethyl)-amine, 1559
Crystal structures
Binucleating hexa-aza macrocycle, Copper(II), Nickel(II), Cobalt(II), Zinc(II), Phosphotriester, Hydrolysis, 1485
Crystal structures
Binucleating ligand, Nickel complexes, Copper complexes, Redox chemistry, 2011
Crystal structures
Bis(η-cyclopentadienyl)titanium(IV), Diphenylphosphinoacetate, Heterometallics, Nicotinate, Thiophenoxyacetate, 757
Crystal structures
Bismuth, Thioether, Coordination polymers, Electrospray, 849
Crystal structures
Bridged structures, Heteronuclear multiple bond coherence, *N*-Tosyl ligands, Zinc porphyrin complexes, 413
Crystal structures
Chelating ligands, Copper(II) complexes, Pyridinecarboxylate complexes, Antimicrobial activity, 2689
Crystal structures
Chromium(III) complexes, Tris(2-benzimidazolylmethyl)amine, 2-Guanidinobenzimidazole, 2,6-Bis(2-benzimidazolyl)-pyridine, 2-(2-Pyridyl)benzimidazole, 1821
Crystal structures
Cis–trans isomerism, 1,2-Diamino-2-methylpropane, Nickel(II)nitrite, 1015
Crystal structures
Cluster compounds, Molybdenum complexes, Tellurium-rich compounds, Detellurium reaction, 925
Crystal structures
Cobalt complexes, 855
Crystal structures
Cobalt(II) complexes, Iron(II) complexes, Octadentate ligands, 431
Crystal structures
Complexation chemistry, 1,10-Phenanthroline, 495
Crystal structures
Contrast agents, Diethylenetriaminepentaacetate, Lanthanides, Neodymium, 771
Crystal structures
Copper complexes, Carboxylate complexes, Dinuclear complexes, Cuprous oxide, Cupric oxide., 2621
Crystal structures
Copper, *gem*-Diol,di-2-pyridyl ketone, Di(2-pyridyl)methanediol, 623
Crystal structures
Copper(I) bromide complexes, Heterocyclic thione complexes, Diphosphine complexes, Dinuclear complexes, 1615
Crystal structures
Copper(I) complexes, Di-2-pyridyl ketone, Electronic and IR spectra, 1465
Crystal structures
Copper(I) complexes, Electronic spectra, Emission spectra, Pyrazine carboxamide complexes, Vibrational spectra, 601
Crystal structures
Copper(II), Azomethine, Imidate, 2713
Crystal structures
Copper(II) complexes, Deprotonated pyridine-2,6-dicarboxamide ligands, Singly hydroxo-bridged, Magnetism, 1423
Crystal structures
Copper(II) complexes, Dinuclear and polynuclear, Equatorial–apical bridge, Paramagnetic, 1593
Crystal structures
Copper(II), 1,4-Diazacycloheptane, Trichloroacetate, 1881
Crystal structures
Copper(II)–edta-type complexes, Stereochemistry, 1
Crystal structures
Copper(I,II) complexes, α,β-Unsaturated carboxylates, Triphenylphosphine, Magnetic properties, 891
Crystal structures
Copper–iron complexes, Cyano-bridge, IR spectra, 1935
Crystal structures
Copper(I) thiocyanate complexes, Methyl nicotinates, Ethyl nicotinates, Ethyl isonicotinate complexes, Trigonal planar anions, 615
Crystal structures
Cu dimers, Di-(2-pyridyl)ketone, Ferromagnetic dimers, Magnetic properties, Spin triplet, 1005
Crystal structures
Cu^{2+} porphyrin complexes, Protonated porphyrins, SAT complexes, Electron spin resonance, Nuclear magnetic resonance, 633
Crystal structures
Cyclic voltammetry, Nickel bisdithiolenes, Strong near-IR absorption, 425
Crystal structures
Diazafluorenone aroylhydrazone, Transition metal aroylhydrazone complexes, Enolization, ^1H NMR spectroscopy, IR, 1295
Crystal structures
Dichloromanganese(IV) complexes, Bidentate Schiff base ligands, Tetradentate Schiff base ligands, Photosystem II, 2039

Crystal structures
Diethyltin, Pyridoxine, 813
Crystal structures
Dirhodium(II) compounds, Trifluoroacetate, One-dimensional polymers, Arene coordination, π-Complexes, 1829
Crystal structures
Electrochemical synthesis, Cobalt(II) complexes, Tosylamide complexes, 1607
Crystal structures
Electrochemistry, EPR, Nickel(II)/(III) complexes, Schiff base complexes, 655
Crystal structures
2-Ethyl-3-hydroxy-4-pyranonate, Ethylmaltol, 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate, Tin(IV), Titanium(IV), 399
Crystal structures
Europium(III) complexes, Non-planar conjugated ligands, Fluorescence spectra, 785
Crystal structures
Fac isomers, Isomerization, Lanthanide chloride complexes, Octahedral complexes, 199
Crystal structures
Hydroborates, Lithium, Titanium(IV), Bonding, 1579
Crystal structures
Imidazole, Schiff base, Silver complexes, 2237
Crystal structures
Infrared spectroscopy, Raman spectroscopy, Electronic absorption spectroscopy, Hypophospite complexes, Cooperative vibronic transitions, Two-centre transitions, 863
Crystal structures
Lanthanide complexes, Picrate, 4-Methylmorpholine, *N*-Oxide, TG, DSC, 2313
Crystal structures
Lanthanide picrate, PBD, Fluorescence, 779
Crystal structures
Magnetic properties, Dinuclear complexes, Manganese, Cobalt, Nickel, 93
Crystal structures
Manganese(II) complexes, Fumaric acid, Fungitoxic activity, 1205
Crystal structures
Mercury(II) complexes, Triphenylphosphine, Benzothiazole-2-thione, pyrimidine-2-thione, 2231
Crystal structures
Mercury(II) halides, Phosphine complexes, 1719
Crystal structures
Metavanadate complexes, Nickel complexes, Copper complexes, Hydrothermal synthesis, Magnetic properties, 2521
Crystal structures
Molybdenum complexes, Tungsten complexes, Pyrazine complexes, Peroxo ligands, 1503
Crystal structures
Molybdenum(II), Tungsten(II), *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Crystal structures
Molybdenum, Oxocluster complexes, Hantzsch synthesis, Hexanuclear molybdenum(V) complexes, 1471
Crystal structures
Molybdenum–oxo complexes, Photochemistry, Photooxidation, Phosphines, Phosphine oxides, 1437
Crystal structures
Molybdenum, Tantalum, Trimetallic alkoxides, 1791
Crystal structures
Mo–S clusters, Electronic structures, Layer-like packing, 733
Crystal structures
Nickel complexes, Copper complexes, Schiff bases, Uracil, 689
Crystal structures
Nickel(II), Iron(II), Electronic spectra, 1333
Crystal structures
Nickel(II), Mononuclear compounds, Nitrito ligands, Magnetic measurements, 225
Crystal structures
Nickel(II)thiocyanate, 1-(2-Aminoethyl)-pyrrolidine, *cis*/*trans* Isomers, 1803
Crystal structures
Ni(II) complexes, Tripodal ligand, Spectroscopic studies, 2661
Crystal structures
Nitrosonaphthol, Ruthenium nitrosonaphthol complexes, 7
Crystal structures
Organolanthanide complexes, Ether-side chain cyclopentadienyl, Cyclooctatetraenyl, 453
Crystal structures
μ-oxo-Bridged cations, Crown ether complexation, Bridging oxygen atoms, 1799
Crystal structures
Oxovanadium(V) alkoxides, Mononuclear chelation, Hydrogen bonded helical structures, 931
Crystal structures
Palladium complexes, Platinum complexes, Diphosphine complexes, Tetraphosphine complexes, Bimetallic complexes, 913
Crystal structures
Palladium, Hydroxo complexes, Pyrazolylalkane complexes, 1395
Crystal structures
Phosphine sulfides, Phosphonium salt, 2585
Crystal structures
Platinum complexes, 3-methylpiperidine, Dicarboxylates, Synthesis, 983
Crystal structures
Platinum(II) complexes, Piperidine, Synthesis, 975
Crystal structures
1,3-propylenediaminetetraacetate, Cu(II) complexes, Mn(II) complexes, Thermal properties, Magnetic properties, 1175
Crystal structures
2-Pyridineformamide, Thiosemicarbazone, Cadmium halides, 1873
Crystal structures
Rhenium, Metal clusters, Sulfur, Selenium, Tellurium, 437
Crystal structures
Ruthenium, Dimethyl sulfoxide, Carboxylates, Complexes, Catalysis, 1589
Crystal structures
Ruthenium, Iridium, Gold, Electron-rich, Cluster, Phosphido-bridged, 2593
Crystal structures
Scandium, Alkoxides, Volatility, 705
Crystal structures
Solvothermal synthesis, Oxomolybdenum(V) coordination compounds, Mo(V, VI) compounds, Alkyl-substituted pyridines, 1407
Crystal structures
Spirophosphorane ring-opening, Phosphite diolato(1 −) ligand, 2667
Crystal structures
Sulfamethizole, Metal complexes, Spectroscopic properties, 1859
Crystal structures
Syntheses, Cobalt(II) complex, Nickel(II) complex, 4-(*p*-Methylphenyl)-3,5-bis-(pyridin-2-yl)-1,2,4-triazole, ESIMS, 2019
Crystal structures
Synthesis, Macrocyclic polyamine ligand, Manganese complexes, Octa- and hepta-coordination, 2095
Crystal structures
Tetrathiometalate, Nonlinear optical properties, Synthesis, Copper compounds, Dppm, 1545
Crystal structures
Thiolate, Electrochemistry, Macrocycle, 1887
Crystal structures
Thiophosphoryl guanidines, Platinum complexes, 809
Crystal structures
Thiosemicarbazone, Isatin, Zinc, Lead, Hexamethyleneimine, Metal(II) complexes, 1255
Crystal structures
Transition metal complexes, Terephthalate ions, Aromatic diamines, Spectral data, 1415
Crystal structures
Trichlorovinyl, Mercury(II), Complexes, Bidentate ligands, 2539
Crystal structures
Uranium, Uranyl, Phosphate, Crown, 1551
Crystal structure
Synthesis, Aryloxide, Neodymium, Anion–cation pair compound, 2243
Crystal structures
Zinc, Bis(pyrazolyl)silanes, Nitrogen-donor ligands, 1815
Crystal structures
Zinc complexes, Cobalt complex, α-Ketoglutaric acid, Thiosemicarbazones, Spectroscopic properties, 1895

Crystal structures
Zinc complexes, Lead(II) complexes, Maltol, 3-Hydroxy-4-pyranone, 3-Hydroxy-4-pyridinone, 1,2-Dimethyl, 129
Crystal structures
Zinc, Tris-pyrazolylborate, Electrochemistry, 109
Crystal structures
Zirconocene, Catalysis, Olefin polymerizations, 1941
Crystal structure
Ytterbium(III), Lanthanides, Calixarenes, Homoazacalixarenes, 2673
CT photochemistry
Ternary copper(II) complexes, Diselenocarbamate and dithiophosphate ligands, 2177
Cu dimers
Crystal structures, Di-(2-pyridyl)ketone, Ferromagnetic dimers, Magnetic properties, Spin triplet, 1005
Cu(II) complexes
Effortil, Structures, Stability constants, EPR, Magnetochemical data, 1843
Cu(II) complexes
1,3-propylenediaminetetraacetate, Mn(II) complexes, Crystal structures, Thermal properties, Magnetic properties, 1175
Cu(II) complex
Structure, Triaminoguanidinium(2 +) ion, 1737
Cu^{2+} porphyrin complexes
Crystal structures, Protonated porphyrins, SAT complexes, Electron spin resonance, Nuclear magnetic resonance, 633
Cupric oxide.
Copper complexes, Carboxylate complexes, Dinuclear complexes, Crystal structures, Cuprous oxide, 2621
Cuprous oxide
Copper complexes, Carboxylate complexes, Dinuclear complexes, Crystal structures, Cupric oxide, 2621
Cyanamidonitrate
Cobalt(II), Electronic spectra, Imidazole ligands, IR spectra, Nickel(II), X-ray crystallography, 1021
Cyano-bridge
Copper–iron complexes, Crystal structures, IR spectra, 1935
Cyanobridged complexes
Mixed-valence complexes, Ruthenium–edta complexes, Ferricyanide, Intramolecular electron transfer, 1339
Cyano-bridged heteropolynuclear complexes
Molecular magnets, Iron complexes, Nickel complexes, Ferromagnetic coupling, 1967
Cyanocuprates
Cryoscopy, Ionic, Reactivity, Structures, 553
Cyclic oligomers
Thiophenes, Ferrocenes, 291
Cyclic phosphazenes
Ab initio methods, Electronic structures, Group theory, 389
Cyclic voltammetry
Crystal structures, Nickel bisdithiolenes, Strong near-IR absorption, 425
Cyclic voltammetry
Schiff bases, Copper complexes, X-ray structure, 5-Phenylazosalicylaldehyde, 607
Cyclic voltammetry
Thiopyrimidine, Rhenium(V) complexes, Rhenium(III) complexes, UV–Vis–NIR, IR, ^{1}H NMR spectra, 2163
Cycloadditions
Dienes, Indium, Magnesium, Trienes, 533
Cycloalkenes
Thioacetal, Titanocene(II), Ring-closing metathesis, Intramolecular carbonyl olefination, Heterocyclic compounds, 593
Cyclooctatetraenyl
Organolanthanide complexes, Ether-side chain cyclopentadienyl, Crystal structures, 453
Cymene
Nitration, Pyrazolyl, Ruthenium, Structure, Synthesis, 475

Decomplexation
Nitrosobenzene cycloaddition, Regioselectivity, Organoiron compounds, Heterocycloaddition trap, Alkaloid synthesis, 569
Degree of agglomeration
Magnesia, Dolomite, Crystallite size, X-ray diffraction, SEM, 2345
Delocalized π interactions
Aza-macrocycles, Electroreduction, Carbon dioxide, 2373
Deltakephalins
Copper(II) complexes, Stability constants, 241
Dendrimers
Carbosilanes, Platinum catalysts, Hydrosilation, 1031
Density functional theory
Vanadium, Vanadyl, Terpyridine, 69
Deoxycholic acid
Ferrocene derivatives, Inclusion compounds, Molecular motion, ^{57}Fe Mössbauer spectroscopy, Powder X-ray diffraction patterns, 205
Deprotonated pyridine-2,6-dicarboxamide ligands
Copper(II) complexes, Singly hydroxo-bridged, Crystal structures, Magnetism, 1423
De-tellurium reaction
Cluster compounds, Molybdenum complexes, Tellurium-rich compounds, Crystal structures, 925
DFT
Nitrosyl complex, Chromium, Molybdenum, Carboxylate, 2565
D-Galactonic acid
D-Gluconic acid, D-Gulonic acid, Praseodymium(III), Complexation, 1567
D-Gluconic acid
D-Galactonic acid, D-Gulonic acid, Praseodymium(III), Complexation, 1567
D-Gulonic acid
D-Gluconic acid, D-Galactonic acid, Praseodymium(III), Complexation, 1567
Dialkoxo-bridged binuclear Cu(II) complexes
Model of metal–guanine interaction, Single crystal structures, Thermal decompostion, Theophylline, Diethanolamine-(2,2′-iminodiethanol), 457
Dialkyldithiocarbamato
Molybdenum, Hydrazido, Diazenido, Hydrazines, 2327
Diamines
Copper(II), Uridine, Uridine 5′-monophosphate, 1145
1,2-Diamino-2-methylpropane
Cis–trans isomerism, Crystal structures, Nickel(II)nitrite, 1015
1,4-Diazacycloheptane
Copper(II), Trichloroacetate, Crystal structures, 1881
Diazafluorenone aroylhydrazone
Transition metal aroylhydrazone complexes, Crystal structures, Enolization, ^{1}H NMR spectroscopy, IR, 1295
Diazenido
Molybdenum, Hydrazido, Dialkyldithiocarbamato, Hydrazines, 2327
6,6′-Dicarboxy-2,2′-bipyridyl
Streptonigrin, 2,2′-Bipyridyl, Antitumour, Zinc, 1067
Dicarboxylate-based compounds
Hybrid copper(II) compounds, Magnetic properties, Layered magnets, Long-range ferromagnetism, 259
Dicarboxylate complexes
Thorium(IV), Uranium(IV), CPMAS ^{13}C NMR spectroscopy, X-ray crystallography, 1757
Dicarboxylates
Platinum complexes, 3-methylpiperidine, Synthesis, Crystal structures, 983
Dichloromanganese(IV) complexes
Bidentate Schiff base ligands, Tetradentate Schiff base ligands, Crystal structures, Photosystem II, 2039
Diclofenac
Metal(II) compounds, Spectroscopic properties, Thermal properties, 2515
Dicopper complexes
Solvent-derived ancillary ligands, Acid–base congeners, 1909
1,5-diene
Cross coupling, Terpenoids, Carboalumination, Palladium, 591
Dienes
Cycloadditions, Indium, Magnesium, Trienes, 533
Diethanolamine(2,2′-iminodiethanol)
Dialkoxo-bridged binuclear Cu(II) complexes, Model of metal–guanine interaction, Single crystal structures, Thermal decompostion, Theophylline, 457
Diethyldithiocarbamate
Palladium, Diphosphines, Tetrachlorometallate anions, X-ray crystal structures, 1511

Diethylenetriamine
Divalent metals, Zinc, Copper, Benzolamide, Ternary complexes, 725
Diethylenetriamine
Lanthanides(III), Silver(I), *N*,*N*-dimethylformamide, Complexes, Thermodynamics, 2427
Diethylenetriaminepentaacetate
Contrast agents, Crystal structures, Lanthanides, Neodymium, 771
Diethyltin
Crystal structures, Pyridoxine, 813
Dihydrodithiins
Thiiranes, Tungsten carbonyls, 521
Diimine
Amido, Dimer, Hydroxo, Palladium, Platinum, 155
β-Diketonate
Alkoxide, Tin, Tin dioxide, Sol–gel, 2069
Dimer
Amido, Diimine, Hydroxo, Palladium, Platinum, 155
Dimer complex
Alternating chain, Crystal structure, Magnetic properties, 1461
Dimers
Magnetic properties, Geometrical distortions, Magnetostructural correlations, 2483
Dimethyl carbonate
Carbon dioxide, Homogeneous catalysis, Mechanism, Supercritical conditions, 573
Dimethyl sulfoxide
Crystal structures, Ruthenium, Carboxylates, Complexes, Catalysis, 1589
1,2-Dimethyl
Zinc complexes, Lead(II) complexes, Maltol, 3-Hydroxy-4-pyranone, 3-Hydroxy-4-pyridinone, Crystal structures, 129
Dimolybdenum
Crystal engineering, Dimolybdenum diolates, 375
Dimolybdenum diolates
Crystal engineering, Dimolybdenum, 375
Dimolybdenum(II)
Trirhenium(III) clusters, Rhenium clusters, Acetamidate, MALDI, Mass spectroscopy, 1245
Dinuclear and polynuclear
Copper(II) complexes, Crystal structures, Equatorial–apical bridge, Paramagnetic, 1593
Dinuclear
Antiferromagnetic interactions, Pryrazolyl groups, 2215
Dinuclear complexes
Copper complexes, Carboxylate complexes, Crystal structures, Cuprous oxide, Cupric oxide., 2621
Dinuclear complexes
Copper(I) bromide complexes, Heterocyclic thione complexes, Diphosphine complexes, Crystal structures, 1615
Dinuclear complexes
Crystal structures, Magnetic properties, Manganese, Cobalt, Nickel, 93
Dinuclear complexes
Dioxygen carriers, Cobalt, Dinucleating ligands, Polyamines, Kinetics, Dioxygen binding, 2447
Dinuclear complexes
Dithiolene, Nickel, Acid–base, Solvatochromism, Carbon disulfide, 1283
Dinucleating alkoxide ligands
Copper(II) complexes, X-ray structures, Hetero-bridged complexes, Magnetism, Magneto-structural trends, 1429
Dinucleating ligands
Dioxygen carriers, Cobalt, Dinuclear complexes, Polyamines, Kinetics, Dioxygen binding, 2447
Dioxomolybdenum dipicolinate
Oxygen-atom transfer, Azoxybenzene deoxygenation, 2141
Dioxotetraamines
Asorption spectra, Copper(III), Nickel(III), Macrocyclic ligands, 2533
Dioxygen binding
Dioxygen carriers, Cobalt, Dinuclear complexes, Dinucleating ligands, Polyamines, Kinetics, 2447
Dioxygen binding
Dioxygen carriers, Cobalt, Polynuclear complexes, Polyamines, Thermodynamics of complexation, 2441
Dioxygen carriers
Cobalt, Dinuclear complexes, Dinucleating ligands, Polyamines, Kinetics, Dioxygen binding, 2447
Dioxygen carriers
Dioxygen binding, Cobalt, Polynuclear complexes, Polyamines, Thermodynamics of complexation, 2441
Dioxygen
Manganese complexes, Schiff bases, Manganoenzymes, Photolysis, Catalase, 47
Diphenylphosphinoacetate
Bis(η-cyclopentadienyl)titanium(IV), Crystal structures, Heterometallics, Nicotinate, Thiophenoxyacetate, 757
Diphosphine complexes
Copper(I) bromide complexes, Heterocyclic thione complexes, Dinuclear complexes, Crystal structures, 1615
Diphosphine complexes
Crystal structures, Palladium complexes, Platinum complexes, Tetraphosphine complexes, Bimetallic complexes, 913
Diphosphines
Palladium, Diethyldithiocarbamate, Tetrachlorometallate anions, X-ray crystal structures, 1511
Diphosphines
Palladium, Platinum, Nitrite, Isomerism, Fluxionality, 1329
Di-2-pyridyl ketone
Copper(I) complexes, Crystal structures, Electronic and IR spectra, 1465
Di-(2-pyridyl)ketone
Crystal structures, Cu dimers, Ferromagnetic dimers, Magnetic properties, Spin triplet, 1005
Di(2-pyridyl)methanediol
Copper, *gem*-Diol,di-2-pyridyl ketone, Crystal structures, 623
Dirhodium(II) compounds
Trifluoroacetate, One-dimensional polymers, Arene coordination, π-Complexes, Crystal structures, 1829
Discotic complexes
Columnar complexes, Liquid crystals, π-acceptors, Dithiolene, 267
Diselenocarbamate and dithiophosphate ligands
CT photochemistry, Ternary copper(II) complexes, 2177
Disodium or dipotassium 1,3-di(carboxylatomethyl)-5-aryl-1,3,5-diazaphosphorinanes
Water-soluble phosphines, Phosphino amino acid salts, 1455
Disproportionation
Equilibrium, Copper, Mixed valence, Temperature effects, 2289
Distorted square-pyramid
Catechols, Macrocyclic ligands, Oxovanadium complexes, ESR parameters, Hydrophobic cavities, 1167
Disulfide
Peptides, Transition metal ions, 1849
Disulfide reduction
Substituted cobalt phthalocyanines, Redox properties, Hammett parameters, Frontier orbitals, 2255
Disulfides
Thioureides, Dithiocarbamates, Tetrahedral coordination, 1279
Ditelluroether
Osmium, X-ray structures, 235
3,5-Di-*tert*-butylcatechol
Oxidation, Catalysis, Kinetics, Copper binuclear complexes, 2367
Dithiadiazolyl radicals, 1163
Dithiocarbamate derivatives
Copper and iron species, Thiuram sulfides, 2269
Dithiocarbamates
Disulfides, Thioureides, Tetrahedral coordination, 1279
Dithiocarbamates
Rhodium(II), 123
Dithiocarboxylate
Vanadium(IV), Magnetism, EPR, Infrared, Coordination., 2155
Dithiolate complexes
Ruthenium, Osmium, X-ray structures, 1073
Dithiolene
Discotic complexes, Columnar complexes, Liquid crystals, π-acceptors, 267
Dithiolene
Nickel, Dinuclear complexes, Acid–base, Solvatochromism, Carbon disulfide, 1283
1,3-dithiole-2-thione-4,5-dithiolates
dmit complexes, Zinc dmit compounds, Zincates, 821
Dithiophosphinates
Low-pressure metal organic chemical vapour deposition, II/VI Semiconductors, 211

Dithio-Schiff base complexes
Thiosemicarbazones, Macrocyclic ligands, Electrochemistry, Copper complexes, 441
Divalent metals
Zinc, Copper, Benzolamide, Diethylenetriamine, Ternary complexes, 725
Diyne
Platinum, Gold, Cross-coupling, X-ray, 2261
dmit complexes
1,3-dithiole-2-thione-4,5-dithiolates, Zinc dmit compounds, Zincates, 821
dmit
Copper, Cobalt, Nickel, Palladium, 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione, 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione, 665
DNA cleavage activities
Tetraazamacrocyclic ligand, Transition metal, Synthesis, Structural characterization, Stability constants, 1527
DNA cleavage
Release of free nucleobases from oligomers, Copper(II)–peroxide adduct, Electrospray mass spectrometry, 2639
Dodecanuclear
Mo–Cu–S cage cluster, Interstitial group, 2189
Dolomite
Magnesia, Crystallite size, Degree of agglomeration, X-ray diffraction, SEM, 2345
Domino reactions
Hydroformylation, Organocopper reagents, Catalysis, Asymmetric synthesis, 513
Dopamine
Iron, Phthalocyanine, Serotonin, Coordination, 1355
dppm
Rhenium, Re complexes, Re(I), *trans*-Dioxo Re(V) complexes, Phosphines, 2249
Dppm
Tetrathiometalate, Nonlinear optical properties, Synthesis, Copper compounds, Crystal structures, 1545
DSC
Crystal structures, Lanthanide complexes, Picrate, 4-Methylmorpholine, *N*-Oxide, TG, 2313
DTPA
Iron(III), Chromium(III), Complexes, Thermal properties, Thermodynamics, 2421

Effortil
Cu(II) complexes, Structures, Stability constants, EPR, Magnetochemical data, 1843
Electrocatalysis
Cobalt, Nitric oxide, Oxidation, Phthalocyanine, Reduction, 229
Electrocatalytic oxidation
Ruthenium, Polypyridine, Terpyridine, Alcohol oxidation, Isomerization, 1049
Electrochemical communication
Ferrocenylporphyrin, π-Conjugation, Intramolecular hydrogen bonding, NH tautomerism, 1961
Electrochemical studies
Heterodinuclear complexes, Homodinuclear complexes, Luminescence properties, Osmium(II) complexes, Ruthenium(II) complexes, Syntheses, 1233
Electrochemical synthesis
Cobalt(II) complexes, Crystal structures, Tosylamide complexes, 1607
Electrochemical synthesis
Mononuclear complexes, Phenoxo bridges, Polyhydroxyl ligands, Polynuclear complexes, Schiff base ligands, 185
Electrochemistry
Azoimine, Ru–bipyridine, Tris-chelates, X-ray structures, Emission spectra, 1925
Electrochemistry
Binuclear Cu(II) complexes, Magnetic properties, ESR, 1769
Electrochemistry
Crystal structures, EPR, Nickel(II)/(III) complexes, Schiff base complexes, 655
Electrochemistry
Naphthylazoimidazoles, Platinum(II), PtN_4 coordination, X-ray structures, 1263
Electrochemistry
Platinum(II), Platinum(IV), Bromide, Porphyrins, Voltammetry, 1057
Electrochemistry
Thiolate, Macrocycle, Crystal structures, 1887
Electrochemistry
Thiosemicarbazones, Iron complexes, EPR of iron complexes, Nickel complexes, Cobalt complexes, 2059
Electrochemistry
Thiosemicarbazones, Macrocyclic ligands, Copper complexes, Dithio-Schiff base complexes, 441
Electrochemistry
Zinc, Tris-pyrazolylborate, Crystal structures, 109
3:3 Electrolytes
Activity coefficients, Electrolytic solutions, High-charge salts, High valency electrolytes, Mixed electrolytes, 2493
Electrolytic solutions
3:3 Electrolytes, Activity coefficients, High-charge salts, High valency electrolytes, Mixed electrolytes, 2493
Electronic absorption spectroscopy
Infrared spectroscopy, Raman spectroscopy, Crystal structures, Hypophospite complexes, Cooperative vibronic transitions, Two-centre transitions, 863
Electronic and IR spectra
Copper(I) complexes, Di-2-pyridyl ketone, Crystal structures, 1465
Electronic spectra
Cobalt(II), Cyanamidonitrate, Imidazole ligands, IR spectra, Nickel(II), X-ray crystallography, 1021
Electronic spectra
Copper(I) complexes, Crystal structures, Emission spectra, Pyrazine carboxamide complexes, Vibrational spectra, 601
Electronic spectral data
Transition metal complexes, Oximes, Benzil-α-monoxime, 1687
Electronic spectra
Nickel(II), Iron(II), Crystal structures, 1333
Electronic structures
Ab initio methods, Cyclic phosphazenes, Group theory, 389
Electronic structures
Mo–S clusters, Crystal structures, Layer-like packing, 733
Electron-rich
Ruthenium, Iridium, Gold, Cluster, Phosphido-bridged, Crystal structures, 2593
Electron spin resonance
α,α′-Bis(pyrazolyl)-*m*-xylene, Copper(II) complexes, X-ray structure, Network structures, Absorption spectroscopy, 719
Electron spin resonance
Copper(II) complexes, Coordination modes, Histamine, L-Histidine, Isomerism, 1123
Electron spin resonance
Crystal structures, Cu^{2+} porphyrin complexes, Protonated porphyrins, SAT complexes, Nuclear magnetic resonance, 633
Electron-transfer
Thiolate-bridged complexes, Mixed-valence, Iron, 2679
Electrooxidation of hydrazine
Polymeric metallophthalocyanines, Modified electrodes, Poly(cobalt–tetraaminophthalocyanine), Impedance spectroscopy, 2303
Electroprotic reactions
Kinetics, Manganese(IV), Ascorbic acid, 1213
Electroreduction
Aza-macrocycles, Carbon dioxide, Delocalized π interactions, 2373
Electrospray
Bismuth, Thioether, Coordination polymers, Crystal structures, 849
Electrospray mass spectrometry
Pentafluoro-cyclotriphosphazene, Pentachloro-cyclotriphosphazene, X-ray structures, 2101
Electrospray mass spectrometry
Release of free nucleobases from oligomers, Copper(II)–peroxide adduct, DNA cleavage, 2639
Emission spectra
Azoimine, Ru–bipyridine, Tris-chelates, X-ray structures, Electrochemistry, 1925
Emission spectra
Copper(I) complexes, Crystal structures, Electronic spectra, Pyrazine carboxamide complexes, Vibrational spectra, 601
Enamine
Alkenylation, Pyrrole, 545

Enantioselection
Chromium, Salen, Manganese, Catalysis, Nozaki–Hiyama–Kishi reaction, 537
Enolization
Diazafluorenone aroylhydrazone, Transition metal aroylhydrazone complexes, Crystal structures, ^{1}H NMR spectroscopy, IR, 1295
Enthalpy
Yttrium, Rare earth elements, Hydrolysis, Ionic strength, Spectrophotometry, 99
Epimerisation
Chiral-at-metal complexes, Configurational stability, Equilibria, X-ray structure analyses, 1519
Epoxidation
Porphyrins, Hemoprotein models, Chiral catalysts, Olefins, 581
EPR
Copper(II), Chloropropionate, Crystal structure, Bio-activity, 2573
EPR
Crystal structures, Electrochemistry, Nickel(II)/(III) complexes, Schiff base complexes, 655
EPR
Dithiocarboxylate, Vanadium(IV), Magnetism, Infrared, Coordination, 2155
EPR
Effortil, Cu(II) complexes, Structures, Stability constants, Magnetochemical data, 1843
EPR of iron complexes
Thiosemicarbazones, Electrochemistry, Iron complexes, Nickel complexes, Cobalt complexes, 2059
EPR spectroscopy
Rhenium, Nitrido complexes, Imido complexes, X-ray structures, 1741
EPR spectroscopy
Vanadium, Molybdenum, Heteropolyoxometalate, IR spectroscopy, UV–Vis spectroscopy, 1917
Equatorial–apical bridge
Copper(II) complexes, Dinuclear and polynuclear, Crystal structures, Paramagnetic, 1593
Equilibria
Chiral-at-metal complexes, Configurational stability, Epimerisation, X-ray structure analyses, 1519
Equilibria
Macrocycles, Synthesis, Complexes, 2501
Equilibria
Me_2Octaen, Polyamines, Nickel(II), Kinetics, Stopped-flow, 2507
Equilibria
Potentiometry, Stability constants, Manganese(II), Cobalt(II), Nickel(II) complexes, Aminopolyphosphonates, UV–VIS spectra, 2083
Equilibrium constants
Molybenum(VI) cations, Thermodynamic quantities, 907
Equilibrium
Copper, Mixed valence, Disproportionation, Temperature effects, 2289
Erbium complex
Lanthanide, Hydrazone, 2629
ESCA studies
Acidopentaaminecobalt(III) complexes, ESI + mass spectra, Acid dissociation constants, 971
ESI + mass spectra
Acidopentaaminecobalt(III) complexes, ESCA studies, Acid dissociation constants, 971
ESIMS
Syntheses, Crystal structures, Cobalt(II) complex, Nickel(II) complex, 4-(*p*-Methylphenyl)-3,5-bis(pyridin-2-yl)-1,2,4-triazole, 2019
ESR
Binuclear Cu(II) complexes, Magnetic properties, Electrochemistry, 1769
ESR
Copper(II) complexes, Glycyl-L-histidine, Formation constants, Coordination modes, Isomerism, 2049
ESR parameters
Catechols, Macrocyclic ligands, Oxovanadium complexes, Distorted square-pyramid, Hydrophobic cavities, 1167
Esters
Allylation, Aqueous reactions, Indium, Indium compounds, Pyridines, 549
Ether-side chain cyclopentadienyl
Organolanthanide complexes, Cyclooctatetraenyl, Crystal structures, 453
Ethylenimine
Immobilization, 3-Mercaptopropyltrimethoxysilane, Silica gels, 367
2-Ethyl-3-hydroxy-4-pyranonate
Crystal structures, Ethylmaltol, 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate, Tin(IV), Titanium(IV), 399
Ethyl isonicotinate complexes
Copper(I) thiocyanate complexes, Methyl nicotinates, Ethyl nicotinates, Crystal structures, Trigonal planar anions, 615
Ethylmaltol
Crystal structures, 2-Ethyl-3-hydroxy-4-pyranonate, 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate, Tin(IV), Titanium(IV), 399
Ethyl nicotinates
Copper(I) thiocyanate complexes, Methyl nicotinates, Ethyl isonicotinate complexes, Crystal structures, Trigonal planar anions, 615
Europium compounds
Hydrotris(pyrazolyl)borate ligands, Luminescence studies, X-ray crystal structures, 1707
Europium(III) chloride
Lanthanide complex, Tridentate chelate, 2135
Europium(III) complexes
Crystal structures, Non-planar conjugated ligands, Fluorescence spectra, 785
EXAFS investigation
Synthesis, Azomethynic copper metallochelates, 2361
Fac isomers
Crystal structures, Isomerization, Lanthanide chloride complexes, Octahedral complexes, 199
Fast atom bombardment mass spectrometry
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Boron-11 NMR, Chelated fluoroboron cations, Fluorine-19 NMR, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
^{57}Fe Mössbauer spectroscopy
Deoxycholic acid, Ferrocene derivatives, Inclusion compounds, Molecular motion, Powder X-ray diffraction patterns, 205
Ferricyanide
Mixed-valence complexes, Ruthenium–edta complexes, Cyanobridged complexes, Intramolecular electron transfer, 1339
Ferrocene derivatives
Deoxycholic acid, Inclusion compounds, Molecular motion, ^{57}Fe Mössbauer spectroscopy, Powder X-ray diffraction patterns, 205
Ferrocenes
Cyclic oligomers, Thiophenes, 291
Ferrocenophane
Inorganic polymers, Silanol, Mössbauer spectroscopy, Ring-opening polymerization, 275
Ferrocenylporphyrin
π-Conjugation, Electrochemical communication, Intramolecular hydrogen bonding, NH tautomerism, 1961
Ferroelectric oxides
Metal–organic chemical vapour deposition, Precursors, Lead scandium tantalate, 351
Ferromagnetic coupling
Molecular magnets, Cyano-bridged heteropolynuclear complexes, Iron complexes, Nickel complexes, 1967
Ferromagnetic dimers
Crystal structures, Cu dimers, Di-(2-pyridyl)ketone, Magnetic properties, Spin triplet, 1005
Field strength
Ruthenium, Phenanthroline, *Cis–trans*, MO calculations, Barriers, 2297
Fluorescence
Lanthanide picrate, PBD, Crystal structures, 779
Fluorescence spectra
Crystal structures, Europium(III) complexes, Non-planar conjugated ligands, 785
Fluorine-19 NMR
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Boron-11 NMR, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, 1,10-Phenanthroline, 2,2′,6′,2″-Terpyridine, 165
Fluxionality
Palladium, Platinum, Nitrite, Diphosphines, Isomerism, 1329
Force constants
Fourier transform infrared and Raman spectra, Uranyl bis(2-hydroxybenzaldehyde), 2353

Formation constants
ESR, Copper(II) complexes, Glycyl-L-histidine, Coordination modes, Isomerism, 2049
Formation constants
meso-2,3-Dimercaptosuccinic acid, Potentiometry, UV–Vis spectroscopy, Ionization constants, Kinetic measurements, 2435
Fourier transform infrared and Raman spectra
Uranyl bis(2-hydroxybenzaldehyde), Force constants, 2353
Frontier orbitals
Substituted cobalt phthalocyanines, Redox properties, Hammett parameters, Disulfide reduction, 2255
FT-IR
Colloids, Bimetallic films, Conductivity, Thermal analysis, 2337
Fumaric acid
Manganese(II) complexes, Crystal structures, Fungitoxic activity, 1205
Functional derivatives
closo-Dodecaborate, Oxonium derivatives, Amino acids, Boron neutron capture therapy, 627
Functionalized metalloalkynes
Alkynes, Olefins, Polymetallated olefins, Titanium, 563
Functionalized nanoclusters
CdS nanoclusters, Ruthenium(II) polypyridyls, Mesophase materials, Molecular devices, 331
Fungitoxic activity
Manganese(II) complexes, Fumaric acid, Crystal structures, 1205

Gallium complexes
Aluminum complexes, 1-Aza-allyl, Bismuth complexes, Crystal structures, 471
gem-Diol,di-2-pyridyl ketone
Copper, Di(2-pyridyl)methanediol, Crystal structures, 623
Geometrical distortions
Magnetic properties, Dimers, Magnetostructural correlations, 2483
Glycyl-L-histidine
ESR, Copper(II) complexes, Formation constants, Coordination modes, Isomerism, 2049
Glycyl-lysine
Copper-dipeptide complexes, Alanyl-lysine, Histidyl-lysine, β-alanyl-lysine, 2409
Gold complexes
Copper complexes, Silver complexes, 743
Gold(I) complexes
Cationic ylide ligand, Bis(methyldiphenylphosphonio)methylide salts, P-alkylation, 1837
Gold
Photochemistry, Surface chemistry, Photochemical metal organic deposition, Lithography, 343
Gold
Platinum, Cross-coupling, Diyne, X-ray, 2261
Gold
Ruthenium, Iridium, Electron-rich, Cluster, Phosphido-bridged, Crystal structures, 2593
Group theory
Ab initio methods, Cyclic phosphazenes, Electronic structures, 389
2-Guanidinobenzimidazole
Chromium(III) complexes, Tris(2-benzimidazolylmethyl)amine, 2,6-Bis(2-benzimidazolyl)pyridine, 2-(2-Pyridyl)benzimidazole, Crystal structures, 1821

Halide ions
Palladium catalyzed reactions, Coupling reactions, Protonolysis, 577
Halocarbonyls
Molybdenum(II), Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, 147
Halogenated carborane anions
Cobalt bis(dicarbollide), Boron, Carborane, Halogenation, 1777
Halogenation
Halogenated carborane anions, Cobalt bis(dicarbollide), Boron, Carborane, 1777
Halogenation
Iridium, Acetylacetonates, 1097
Halogen exchange reactions
Iron carbonyl halides, NMR, XAFS spectroscopy, Matrix isolation, 1493
Hammett parameters
Substituted cobalt phthalocyanines, Redox properties, Frontier orbitals, Disulfide reduction, 2255
Hantzsch synthesis
Molybdenum, Oxocluster complexes, Crystal structures, Hexanuclear molybdenum(V) complexes, 1471
H-bonding
Calcium, Inorganic Polymers, Alkaline Earth, X-ray structure, 1783
Heck reactions
Palladium, Phosphane, Sulfane, Ligands, Mechanism, 517
Helical structures
Supramolecular chemistry, Transition metals, X-ray crystal structures, 23
Hemoprotein models
Porphyrins, Chiral catalysts, Epoxidation, Olefins, 581
Heptacoordinate complexes
Heterocyclic bis(thiosemicarbazone), Organotin(IV) complexes, Binuclear zinc complexes, 841
Heptadentate ligands
Cadmium(II) complexes, Schiff-base ligands, Symmetrical complexes, Asymmetrical complexes, 1633
HETCOR
Zn(II) complexes, 1,2,4-Triazolo-[1,5α]-pyrimidine, ^{15}N NMR, CPMAS, 965
Heterobimetallic diethanolaminates
Alkaline earth metals, Homobimetallic diethanolaminates, 77
Heterobimetallic titanium–copper systems
α-Acetylenic alcohols, Isomerization, Rearrangement, 1693
Hetero-bridged complexes
Dinucleating alkoxide ligands, Copper(II) complexes, X-ray structures, Magnetism, Magneto-structural trends, 1429
Heterocyclic bis(thiosemicarbazone)
Heptacoordinate complexes, Organotin(IV) complexes, Binuclear zinc complexes, 841
Heterocyclic compounds
Thioacetal, Titanocene(II), Ring-closing metathesis, Intramolecular carbonyl olefination, Cycloalkenes, 593
Heterocyclic thione complexes
Copper(I) bromide complexes, Diphosphine complexes, Dinuclear complexes, Crystal structures, 1615
Heterocyclic thiones
Bisphosphines, Palladium(II) complexes, Platinum(II) complexes, Pyridyl, 899
Heterocycloaddition trap
Nitrosobenzene cycloaddition, Regioselectivity, Organoiron compounds, Decomplexation, Alkaloid synthesis, 569
Heterodifunctional ligands
Palladium(II) complexes, Platinum(II) complexes, Chloride metathesis, X-ray crystallography, 695
Heterodinuclear complexes
Electrochemical studies, Homodinuclear complexes, Luminescence properties, Osmium(II) complexes, Ruthenium(II) complexes, Syntheses, 1233
Heterometallic aryloxides
Lithium niobate, Monomeric compounds, Niobium, Percursors, 1037
Heterometallics
Bis(η-cyclopentadienyl)titanium(IV), Crystal structures, Diphenylphosphinoacetate, Nicotinate, Thiophenoxyacetate, 757
Heteronuclear catalysts
Immobilization, Nanoparticles, Sol–gel matrices, 509
Heteronuclear multiple bond coherence
Bridged structures, Crystal structures, *N*-Tosyl ligands, Zinc porphyrin complexes, 413
Heteropolyoxometalate
Vanadium, Molybdenum, IR spectroscopy, UV–Vis spectroscopy, EPR spectroscopy, 1917
Heteroscorpionate tris(3-*R*-pyrazolyl)borate cobalt(II) complexes
Structures, NMR, 2119
Hexamethyleneimine
Thiosemicarbazone, Isatin, Crystal structures, Zinc, Lead, Metal(II) complexes, 1255
Hexanuclear clusters
Metallamacrocycles, Manganese complexes, Pentadentate ligands, Hydrophobic aliphatic tripled tails, 1985

Hexanuclear molybdenum(V) complexes
Molybdenum, Oxocluster complexes, Hantzsch synthesis, Crystal structures, 1471
Hg(II)
Cd(II), tachpyr, Torsion angles, Twist angles, Zn(II), 1155
High acidity
Polyoxometalate, Oxyhalide, Molybdenum, X-ray structure, 43
High-charge salts
3:3 Electrolytes, Activity coefficients, Electrolytic solutions, High valency electrolytes, Mixed electrolytes, 2493
High valency electrolytes
3:3 Electrolytes, Activity coefficients, Electrolytic solutions, High-charge salts, Mixed electrolytes, 2493
Histamine
Electron spin resonance, Copper(II) complexes, Coordination modes, L-Histidine, Isomerism, 1123
Histidyl-lysine
Copper-dipeptide complexes, Glycyl-lysine, Alanyl-lysine, β-alanyl-lysine, 2409
^{1}H NMR spectroscopy
Diazafluorenone aroylhydrazone, Transition metal aroylhydrazone complexes, Crystal structures, Enolization, IR, 1295
Homoazacalixarenes
Ytterbium(III), Lanthanides, Calixarenes, Crystal structure, 2673
Homobimetallic diethanolaminates
Alkaline earth metals, Heterobimetallic diethanolaminates, 77
Homodinuclear complexes
Electrochemical studies, Heterodinuclear complexes, Luminescence properties, Osmium(II) complexes, Ruthenium(II) complexes, Syntheses, 1233
Homogeneous and heterogeneous
Aromatic amines, Amberlite anion-exchange resin, Oxalate anions, Metal–oxalate complexes, Oxidation, 1317
Homogeneous catalysis
Carbon dioxide, Dimethyl carbonate, Mechanism, Supercritical conditions, 573
Homoleptic silyl complexes
Arsenic, Antimony, 1639
Host–guest chemistry
Mercury, Clusters, Thiocyanante, 871
Hush theory
Iron complexes, Mixed valence, TCNE complexes, TCNQ complexes, 137
Hybrid copper(II) compounds
Dicarboxylate-based compounds, Magnetic properties, Layered magnets, Long-range ferromagnetism, 259
Hybrid materials
Sol-gel, NMR, Siloxane, Silicon-29, Oxygen-17, 315
Hydrazido
Molybdenum, Diazenido, Dialkyldithiocarbamato, Hydrazines, 2327
Hydrazines
Molybdenum, Hydrazido, Diazenido, Dialkyldithiocarbamato, 2327
Hydrazonato compounds of oxovanadium(V)
Alkoxo compounds of oxovanadium(V), Crystal structure of compounds of oxovanadium(V), Oxovanadium(V) dimers, Reactivity of bis(β-dionato)oxovanadium(IV) chelates, Hydrazonato tridentate Schiff base ligands, 2003
Hydrazonato tridentate Schiff base ligands
Alkoxo compounds of oxovanadium(V), Crystal structure of compounds of oxovanadium(V), Hydrazonato compounds of oxovanadium(V), Oxovanadium(V) dimers, Reactivity of bis(β-dionato)-oxovanadium(IV) chelates, 2003
Hydrazone
Lanthanide, Erbium complex, 2629
Hydrazone
Rare earth complex, Crystal structure, Antitumour activity, 2599
Hydroborates
Lithium, Titanium(IV), Bonding, Crystal structures, 1579
Hydroboration
Allylic alkylation, Axially chiral phosphinamine, Quinazolines, 541
Hydroboration
Phosphine, Alkene, Polymerization, Copper(I) complexes, 1271
Hydroboration
Polysilazanes, Precursors, Vinylsilanes, Chloroboranes, 323
Hydroformylation
Organocopper reagents, Catalysis, Asymmetric synthesis, Domino reactions, 513
Hydrogenation
Pyriding N-oxides, Metal complexes, Structures, 835
Hydrogenation
Titanium, Tantalum, Nobium, Aryloxide, Bisphenol, 35
Hydrogen bonded helical structures
Oxovanadium(V) alkoxides, Mononuclear chelation, Crystal structures, 931
Hydrogen bonding
Complexes, Platinum, Sulfimides, 2077
Hydrogen bonding
Phosphoranes, Pentacoordination, X-ray structure, 63
Hydrolysis
Binucleating hexa-aza macrocycle, Copper(II), Nickel(II), Cobalt(II), Zinc(II), Crystal structures, Phosphotriester, 1485
Hydrolysis
Palladium(II) complexes, Catalysts, Peptides, 959
Hydrolysis
Yttrium, Rare earth elements, Enthalpy, Ionic strength, Spectrophotometry, 99
Hydrophobic aliphatic tripled tails
Metallamacrocycles, Hexanuclear clusters, Manganese complexes, Pentadentate ligands, 1985
Hydrophobic cavities
Catechols, Macrocyclic ligands, Oxovanadium complexes, ESR parameters, Distorted square-pyramid, 1167
Hydrosilation
Dendrimers, Carbosilanes, Platinum catalysts, 1031
Hydrosilylation
Alkenylsilanes, $RhI(PPh_3)_3$, Polyaddition, Stereodivergent, 567
Hydrothermal synthesis
Crystal structures, Metavanadate complexes, Nickel complexes, Copper complexes, Magnetic properties, 2521
Hydrotris(pyrazolyl)borate ligands
Europium compounds, Luminescence studies, X-ray crystal structures, 1707
Hydroxamic acid
Mixed-ligand complexes, Solution equilibrium, Copper(II), nickel(II) and zinc(II) complexes, 1727
Hydroxo
Amido, Diimine, Dimer, Palladium, Platinum, 155
Hydroxo complexes
Palladium, Pyrazolylalkane complexes, Crystal structures, 1395
2-Hydroxyacetophenone
Cobalt, Azide, Thiocyanate, Crystal structure, 2707
3-Hydroxy-4-pyranone
Zinc complexes, Lead(II) complexes, Maltol, 3-Hydroxy-4-pyridinone, 1,2-Dimethyl, Crystal structures, 129
3-Hydroxy-4-pyridinone
Zinc complexes, Lead(II) complexes, Maltol, 3-Hydroxy-4-pyranone, 1,2-Dimethyl, Crystal structures, 129
Hypophospite complexes
Infrared spectroscopy, Raman spectroscopy, Electronic absorption spectroscopy, Crystal structures, Cooperative vibronic transitions, Two-centre transitions, 863

II/VI Semiconductors
Dithiophosphinates, Low-pressure metal organic chemical vapour deposition, 211
Imidate
Copper(II), Azomethine, Crystal structures, 2713
Imidazole-carboxylate chelating ligands
Polynuclear manganese-carboxylate clusters, Paramagnetic NMR, 2111
Imidazole derivatives
Transition metal complexes, Crystal structure, Absorption spectra, Stability constants, 2183
Imidazole ligands
Cobalt(II), Cyanamidonitrate, Electronic spectra, IR spectra, Nickel(II), X-ray crystallography, 1021
Imidazole
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473

Imidazole
Schiff base, Silver complexes, Crystal structures, 2237
Imido complexes
Rhenium, Nitrido complexes, EPR spectroscopy, X-ray structures, 1741
Immobilization
Ethylenimine, 3-Mercaptopropyltrimethoxysilane, Silica gels, 367
Immobilization
Heteronuclear catalysts, Nanoparticles, Sol–gel matrices, 509
Impedance spectroscopy
Polymeric metallophthalocyanines, Modified electrodes, Electrooxidation of hydrazine, Poly(cobalt–tetraaminophthalocyanine), 2303
Inclusion compounds
Deoxycholic acid, Ferrocene derivatives, Molecular motion, ^{57}Fe Mössbauer spectroscopy, Powder X-ray diffraction patterns, 205
Indenyl
Planar chiral, Structure, Yttrium, Lanthanum, Tetrahydroborate, 1955
Indium
Allylation, Aqueous reactions, Esters, Indium compounds, Pyridines, 549
Indium compounds
Allylation, Aqueous reactions, Esters, Indium, Pyridines, 549
Indium
Cycloadditions, Dienes, Magnesium, Trienes, 533
Indium tin oxide
Surface modification, Alkoxides, Interfaces, 505
Infrared
Dithiocarboxylate, Vanadium(IV), Magnetism, EPR, Coordination., 2155
Infrared spectra
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazole ternary complexes, Copper(II) imidazolate ternary complexes, X-ray crystal structures, Molecular structures, Magnetic properties, 1181
Infrared spectra
N-salicylidenearoylhydrazines, Copper(II) complexes, X-ray crystal structures, Molecular structures, Magnetic properties, 949
Infrared spectroscopy
Raman spectroscopy, Electronic absorption spectroscopy, Crystal structures, Hypophospite complexes, Cooperative vibronic transitions, Two-centre transitions, 863
Inorganic Polymers
Calcium, H-bonding, Alkaline Earth, X-ray structure, 1783
Inorganic polymers
Ferrocenophane, Silanol, Mössbauer spectroscopy, Ring-opening polymerization, 275
Insertion reactions
Platinum(II) complexes, Platinum–tin bimetallics, 2,3,5,6-Tetrakis(α-pyridyl)-pyrazine, 739
Insertions
Additions, Alkylation, Nucleophilic, Schiff bases, Titanium, 177
In situ X-ray diffraction
Intercalation, Layered compounds, Solid state, Synchrotron radiation, 297
Insulin-mimetics
Biospeciation, Al(III) complexes, VO(IV) complexes, 2389
Intercalation compounds
Aniline polymerization, Copper phosphonates, 765
Intercalation
In situ X-ray diffraction, Layered compounds, Solid state, Synchrotron radiation, 297
Interfaces
Indium tin oxide, Surface modification, Alkoxides, 505
Interstitial group
Dodecanuclear, Mo–Cu–S cage cluster, 2189
Intramolecular bonds
C–H activation, Titanium, Metallacycles, Allenes, Carbometalation, 879
Intramolecular carbonyl olefination
Thioacetal, Titanocene(II), Ring-closing metathesis, Cycloalkenes, Heterocyclic compounds, 593
Intramolecular electron transfer
Mixed-valence complexes, Ruthenium–edta complexes, Ferricyanide, Cyano-bridged complexes, 1339
Intramolecular hydrogen bonding
Ferrocenylporphyrin, π-Conjugation, Electrochemical communication, NH tautomerism, 1961
Ionic
Cryoscopy, Cyanocuprates, Reactivity, Structures, 553
Ionic strength
Yttrium, Rare earth elements, Hydrolysis, Enthalpy, Spectrophotometry, 99
Ionization constants
meso-2,3-Dimercaptosuccinic acid, Potentiometry, UV–Vis spectroscopy, Formation constants, Kinetic measurements, 2435
IR
Diazafluorenone aroylhydrazone, Transition metal aroylhydrazone complexes, Crystal structures, Enolization, ^{1}H NMR spectroscopy, 1295
Iridium
Acetylacetonates, Halogenation, 1097
Iridium
π-Allyl complexes, Allylic substitutions, Regioselectivity, Stereoselectivity, Phosphites, 557
Iridium
Ruthenium, Gold, Electron-rich, Cluster, Phosphido-bridged, Crystal structures, 2593
Iron carbonyl halides
NMR, XAFS spectroscopy, Halogen exchange reactions, Matrix isolation, 1493
Iron carbonyl
Solvothermal synthesis, Polytelluride, Iron telluride, Iron cluster, Carbonyl clusters, 1995
Iron cluster
Solvothermal synthesis, Polytelluride, Iron telluride, Iron carbonyl, Carbonyl clusters, 1995
Iron complexes
Hush theory, Mixed valence, TCNE complexes, TCNQ complexes, 137
Iron complexes
Molecular magnets, Cyano-bridged heteropolynuclear complexes, Nickel complexes, Ferromagnetic coupling, 1967
Iron complexes
Thiosemicarbazones, Electrochemistry, EPR of iron complexes, Nickel complexes, Cobalt complexes, 2059
Iron(II) complexes
Crystal structures, Cobalt(II) complexes, Octadentate ligands, 431
Iron(III)
Chromium(III), DTPA, Complexes, Thermal properties, Thermodynamics, 2421
Iron(III)
Ciprofloxacin, Solution equilibria, Surfactants, 1085
Iron(II)
Nickel(II), Crystal structures, Electronic spectra, 1333
Iron
Phthalocyanine, Dopamine, Serotonin, Coordination, 1355
Iron
Selenium, Sulfur, Synthesis, Reaction, 713
Iron telluride
Solvothermal synthesis, Polytelluride, Iron cluster, Iron carbonyl, Carbonyl clusters, 1995
Iron
Thiolate-bridged complexes, Mixed-valence, Electron-transfer, 2679
IR spectra
Cobalt(II), Cyanamidonitrate, Electronic spectra, Imidazole ligands, Nickel(II), X-ray crystallography, 1021
IR spectra
Copper–iron complexes, Cyano-bridge, Crystal structures, 1935
IR spectra
Vanadium complexes, Quinic acid complexes, Raman spectra, Thermal behavior, Potentiometric titrations, 2613
IR spectroscopy
Vanadium, Molybdenum, Heteropolyoxometalate, UV–Vis spectroscopy, EPR spectroscopy, 1917
Isatin
Thiosemicarbazone, Crystal structures, Zinc, Lead, Hexamethyleneimine, Metal(II) complexes, 1255
Isomerism
Electron spin resonance, Copper(II) complexes, Coordination modes, Histamine, L-Histidine, 1123

Isomerism
ESR, Copper(II) complexes, Glycyl-L-histidine, Formation constants, Coordination modes, 2049
Isomerism
Palladium, Platinum, Nitrite, Diphosphines, Fluxionality, 1329
Isomerization
α-Acetylenic alcohols, Rearrangement, Heterobimetallic titanium–copper systems, 1693
Isomerization
Crystal structures, *Fac* isomers, Lanthanide chloride complexes, Octahedral complexes, 199
Isomerization
Ruthenium, Polypyridine, Terpyridine, Electrocatalytic oxidation, Alcohol oxidation, 1049

Kainoids
Boronic esters, Asymmetric synthesis, Pyrrolidine, 587
Ketoconazole
Ruthenium, Clotrimazole, Paramagnetic, Metal complexes, *Trypanosoma cruzi*, Chagas, 2319
α-Ketoglutaric acid
Zinc complexes, Cobalt complex, Thiosemicarbazones, Crystal structures, Spectroscopic properties, 1895
Kinetic control
Monophasic hybrid materials, Silsesquioxane gels, Sol–gel polymerization, 307
Kinetic measurements
meso-2,3-Dimercaptosuccinic acid, Potentiometry, UV–Vis spectroscopy, Formation constants, Ionization constants, 2435
Kinetics
Dioxygen carriers, Cobalt, Dinuclear complexes, Dinucleating ligands, Polyamines, Dioxygen binding, 2447
Kinetics
Manganese(IV), Ascorbic acid, Electroprotic reactions, 1213
Kinetics
Me_2Octaen, Polyamines, Nickel(II), Equilibria, Stopped-flow, 2507
Kinetics
Oxidation, Catalysis, 3,5-Di-*tert*-butylcatechol, Copper binuclear complexes, 2367
Kinetics
Substitution, Mechanism, *cis*-Diaquabis(2,2′-bipirydyl)chromium(III), Octacyanomolybdate(IV), Octacyanotungstate(IV), 2225

Lanthanide
Carbacylamidophosphate, NMR, X-ray data, 2203
Lanthanide chloride complexes
Crystal structures, *Fac* isomers, Isomerization, Octahedral complexes, 199
Lanthanide complexes
Crystal structures, Picrate, 4-Methylmorpholine, *N*-Oxide, TG, DSC, 2313
Lanthanide complexes
Macrocycles, Chiral complexes, NMR of paramagnetic compounds, 465
Lanthanide complex
Tridentate chelate, Europium(III) chloride, 2135
Lanthanide
Erbium complex, Hydrazone, 2629
Lanthanide picrate
PBD, Fluorescence, Crystal structures, 779
Lanthanides
Contrast agents, Crystal structures, Diethylenetriaminepentaacetate, Neodymium, 771
Lanthanides(III)
Silver(I), Diethylenetriamine, *N*,*N*-dimethylformamide, Complexes, Thermodynamics, 2427
Lanthanides
Phosphine oxides, X-ray structures, 2697
Lanthanides
Phthalocyanines, Naphthalocyanines, Porphyrins, Raman, Sandwich complexes, 1381
Lanthanides
Ytterbium(III), Calixarenes, Homoazacalixarenes, Crystal structure, 2673
Lanthanum
Planar chiral, Structure, Indenyl, Yttrium, Tetrahydroborate, 1955
Layered compounds
In situ X-ray diffraction, Intercalation, Solid state, Synchrotron radiation, 297
Layered magnets
Hybrid copper(II) compounds, Dicarboxylate-based compounds, Magnetic properties, Long-range ferromagnetism, 259
Layer-like packing
Mo–S clusters, Crystal structures, Electronic structures, 733
LD-LISC effect
Schiff bases, Cobalt complexes, Spin crossover, Photosensitive ligands, 1643
Lead(II)
Aspartate, Structures, 649
Lead(II) complexes
Zinc complexes, Maltol, 3-Hydroxy-4-pyranone, 3-Hydroxy-4-pyridinone, 1,2-Dimethyl, Crystal structures, 129
Lead scandium tantalate
Metal–organic chemical vapour deposition, Precursors, Ferroelectric oxides, 351
Lead
Thiosemicarbazone, Isatin, Crystal structures, Zinc, Hexamethyleneimine, Metal(II) complexes, 1255
Lewis acid
α-Aminoacylsilanes, β-Amino alcohols, Silylcupration, Statine analogues, 529
L-Histidine
Electron spin resonance, Copper(II) complexes, Coordination modes, Histamine, Isomerism, 1123
Ligands
Heck reactions, Palladium, Phosphane, Sulfane, Mechanism, 517
Liposomes
Calcium phosphates, Biomimetics, Biomineralization, 357
Liquid clathrates
15-Crown-5 complexes, X-ray crystallography, Oxonium ion, 85
Liquid crystals
Discotic complexes, Columnar complexes, π-acceptors, Dithiolene, 267
Lithium
Hydroborates, Titanium(IV), Bonding, Crystal structures, 1579
Lithium niobate
Heterometallic aryloxides, Monomeric compounds, Niobium, Percursors, 1037
Lithography
Photochemistry, Surface chemistry, Photochemical metal organic deposition, Gold, 343
Long-range ferromagnetism
Hybrid copper(II) compounds, Dicarboxylate-based compounds, Magnetic properties, Layered magnets, 259
Low-pressure metal organic chemical vapour deposition
Dithiophosphinates, II/VI Semiconductors, 211
Luminescence properties
Electrochemical studies, Heterodinuclear complexes, Homodinuclear complexes, Osmium(II) complexes, Ruthenium(II) complexes, Syntheses, 1233
Luminescence studies
Europium compounds, Hydrotris(pyrazolyl)borate ligands, X-ray crystal structures, 1707

Macrocycles
Lanthanide complexes, Chiral complexes, NMR of paramagnetic compounds, 465
Macrocycle
Sol–gel, Aggregation, Tetrasulfophthalocyanines, Monolith, Silica, 2383
Macrocycles
Synthesis, Complexes, Equilibria, 2501
Macrocycle
Thiolate, Electrochemistry, Crystal structures, 1887
Macrocyclic ligands
Asorption spectra, Copper(III), Nickel(III), Dioxotetraamines, 2533
Macrocyclic ligands
Catechols, Oxovanadium complexes, ESR parameters, Distorted square-pyramid, Hydrophobic cavities, 1167
Macrocyclic ligands
Naphthylmethyl fluorescent groups, Aza–oxa crowns, 1867
Macrocyclic ligands
Thiosemicarbazones, Electrochemistry, Copper complexes, Dithio-Schiff base complexes, 441
Macrocyclic polyamine ligand
Crystal structures, Synthesis, Manganese complexes, Octa- and hepta-coordination, 2095

Macrocyclic polyether 18-crown-6
Acetonitrile, Alkaline earth metal ions, Transition metal ions, 1681
Magnesia
Dolomite, Crystallite size, Degree of agglomeration, X-ray diffraction, SEM, 2345
Magnesium
Aryloxide, Structure, Adduct, 2557
Magnesium
Cycloadditions, Dienes, Indium, Trienes, 533
Magnetic and spectral properties
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Amidomethyl)-iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, *cis*-Diaqua(*N* - carbamoylmethyl - iminodiacetato)nickel(II), Molecular and crystal structure, Thermal stability, 2463
Magnetic measurements
Nickel(II), Mononuclear compounds, Crystal structures, Nitrito ligands, 225
Magnetic properties
Alternating chain, Dimer complex, Crystal structure, 1461
Magnetic properties
Azido-bridged nickel(II) compounds, Crystal structures, 1575
Magnetic properties
Binuclear Cu(II) complexes, Electrochemistry, ESR, 1769
Magnetic properties
Binuclear nickel(II) complex, Binuclear manganese(II) complex, Crystal structures, Tris(6-methyl-2-pyridylmethyl)amine, 1559
Magnetic properties
Carboxylato-bridged copper(II) complex, Crystal structure, 2529
Magnetic properties
Copper(I,II) complexes, α,β-Unsaturated carboxylates, Triphenylphosphine, Crystal structures, 891
Magnetic properties
Crystal structures, Cu dimers, Di-(2-pyridyl)ketone, Ferromagnetic dimers, Spin triplet, 1005
Magnetic properties
Crystal structures, Dinuclear complexes, Manganese, Cobalt, Nickel, 93
Magnetic properties
Crystal structures, Metavanadate complexes, Nickel complexes, Copper complexes, Hydrothermal synthesis, 2521
Magnetic properties
Dimers, Geometrical distortions, Magnetostructural correlations, 2483
Magnetic properties
Hybrid copper(II) compounds, Dicarboxylate-based compounds, Layered magnets, Long-range ferromagnetism, 259
Magnetic properties
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazole ternary complexes, Copper(II) imidazolate ternary complexes, X-ray crystal structures, Molecular structures, Infrared spectra, 1181
Magnetic properties
N-salicylidenearoylhydrazines, Copper(II) complexes, X-ray crystal structures, Molecular structures, Infrared spectra, 949
Magnetic properties
1,3-propylenediaminetetraacetate, Cu(II) complexes, Mn(II) complexes, Crystal structures, Thermal properties, 1175
Magnetic, spectral and thermal properties
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, 2473
Magnetic susceptibility
Pyridine *N*-oxide ligands, Cobalt(II) complexes, Zinc(II) complexes, X-ray structures, 2195
Magnetism
Copper(II) complexes, Deprotonated pyridine-2,6-dicarboxamide ligands, Singly hydroxo-bridged, Crystal structures, 1423
Magnetism
Crystal structures, Binuclear copper compounds, Oxalato-bridged compounds, 1105
Magnetism
Dinucleating alkoxide ligands, Copper(II) complexes, X-ray structures, Hetero-bridged complexes, Magneto-structural trends, 1429
Magnetism
Dithiocarboxylate, Vanadium(IV), EPR, Infrared, Coordination, 2155
Magnetochemical data
Effortil, Cu(II) complexes, Structures, Stability constants, EPR, 1843
Magnetostructural correlations
Magnetic properties, Dimers, Geometrical distortions, 2483
Magneto-structural trends
Dinucleating alkoxide ligands, Copper(II) complexes, X-ray structures, Hetero-bridged complexes, Magnetism, 1429
MALDI
Trirhenium(III) clusters, Rhenium clusters, Acetamidate, Dimolybdenum(II), Mass spectroscopy, 1245
Maltol
Zinc complexes, Lead(II) complexes, 3-Hydroxy-4-pyranone, 3-Hydroxy-4-pyridinone, 1,2-Dimethyl, Crystal structures, 129
Manganese
Chromium, Salen, Catalysis, Enantioselection, Nozaki–Hiyama–Kishi reaction, 537
Manganese complexes
Crystal structures, Synthesis, Macrocyclic polyamine ligand, Octa- and hepta-coordination, 2095
Manganese complexes
Metallamacrocycles, Hexanuclear clusters, Pentadentate ligands, Hydrophobic aliphatic tripled tails, 1985
Manganese complexes
Schiff bases, Manganoenzymes, Photolysis, Catalase, Dioxygen, 47
Manganese
Crystal structures, Magnetic properties, Dinuclear complexes, Cobalt, Nickel, 93
Manganese(II) complexes
Fumaric acid, Crystal structures, Fungitoxic activity, 1205
Manganese(II)
Potentiometry, Equilibria, Stability constants, Cobalt(II), Nickel(II) complexes, Aminopolyphosphonates, UV–VIS spectra, 2083
Manganese(IV)
Kinetics, Ascorbic acid, Electroprotic reactions, 1213
Manganoenzymes
Manganese complexes, Schiff bases, Photolysis, Catalase, Dioxygen, 47
Mass spectroscopy
Trirhenium(III) clusters, Rhenium clusters, Acetamidate, Dimolybdenum(II), MALDI, 1245
Matrix isolation
Iron carbonyl halides, NMR, XAFS spectroscopy, Halogen exchange reactions, 1493
Mechanism
Carbon dioxide, Dimethyl carbonate, Homogeneous catalysis, Supercritical conditions, 573
Mechanism
Heck reactions, Palladium, Phosphane, Sulfane, Ligands, 517
Mechanism
Kinetics, Substitution, *cis*-Diaquabis(2,2′-bipirydyl)chromium(III), Octacyanomolybdate(IV), Octacyanotungstate(IV), 2225
11-Membered metallocyclic ring
Synchrotron radiation, Metallocalix[6]arene, 2657
Me_2Octaen
Polyamines, Nickel(II), Equilibria, Kinetics, Stopped-flow, 2507
3-Mercaptopropyltrimethoxysilane
Ethylenimine, Immobilization, Silica gels, 367
Mercury
Clusters, Thiocyanante, Host–guest chemistry, 871
Mercury complexes
Cadmium complexes, Sulfamides, X-ray structure, Zinc complexes, 991
Mercury(II) complexes
Triphenylphosphine, Benzothiazole-2-thione, pyrimidine-2-thione, Crystal structures, 2231
Mercury(II) halides
Phosphine complexes, Crystal structures, 1719

Mercury(II)
Trichlorovinyl, Crystal structures, Complexes, Bidentate ligands, 2539
Mercury(II)
Zinc(II), Cadmium(II), Tris(2-benzimidazolylmethyl)amine, X-ray diffraction structures, NMR data, 1479
meso-2,3-dimercaptosuccinic acid
Multinuclear NMR, Tungsten, 193
meso-2,3-Dimercaptosuccinic acid
Potentiometry, UV–Vis spectroscopy, Formation constants, Ionization constants, Kinetic measurements, 2435
Mesophase materials
CdS nanoclusters, Ruthenium(II) polypyridyls, Functionalized nanoclusters, Molecular devices, 331
Metal clusters
Rhenium, Sulfur, Selenium, Tellurium, Crystal structures, 437
Metal complexes
Pyriding N-oxides, Hydrogenation, Structures, 835
Metal complexes
Ruthenium, Clotrimazole, Ketoconazole, Paramagnetic, *Trypanosoma cruzi*, Chagas, 2319
Metal complexes
Sulfamethizole, Crystal structures, Spectroscopic properties, 1859
Metal(II) complexes
Thiosemicarbazone, Isatin, Crystal structures, Zinc, Lead, Hexamethyleneimine, 1255
Metal(II) compounds
Diclofenac, Spectroscopic properties, Thermal properties, 2515
Metallacycles
C–H activation, Intramolecular bonds, Titanium, Allenes, Carbometalation, 879
Metallamacrocycles
Hexanuclear clusters, Manganese complexes, Pentadentate ligands, Hydrophobic aliphatic tripled tails, 1985
Metallation
Osmium, X-ray structures, 1081
Metallocalix[6]arene
11-Membered metallocyclic ring, Synchrotron radiation, 2657
Metallocycles
Palladium(II) complexes, Aminophosphate complexes, Spectroscopy, Antitumour activity, 937
Metallomesogens
Rhenium, Nematic phases, Chiral nematic phases, 249
Metal–organic chemical vapour deposition
Precursors, Lead scandium tantalate, Ferroelectric oxides, 351
Metal–oxalate complexes
Aromatic amines, Amberlite anion-exchange resin, Oxalate anions, Oxidation, Homogeneous and heterogeneous, 1317
Metathesis
Antimonides, Arsenides, Phosphides, 829
Metavanadate complexes
Crystal structures, Nickel complexes, Copper complexes, Hydrothermal synthesis, Magnetic properties, 2521
Methanolysis
Amine oxide, Rhenium, Osmium, Carbonyl, Methylcarbonate, 641
Methylaluminoxane (MAO)
Palladium(II) complexes, Mixed donor ligands, *Trans*-influence, X-ray crystallography, Norbornene, Polymerization, 1601
Methylcarbonate
Amine oxide, Methanolysis, Rhenium, Osmium, Carbonyl, 641
1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate
Crystal structures, 2-Ethyl-3-hydroxy-4-pyranonate, Ethylmaltol, Tin(IV), Titanium(IV), 399
4-Methylmorpholine
Crystal structures, Lanthanide complexes, Picrate, *N*-Oxide, TG, DSC, 2313
Methyl nicotinates
Copper(I) thiocyanate complexes, Ethyl nicotinates, Ethyl isonicotinate complexes, Crystal structures, Trigonal planar anions, 615
3-methylpiperidine
Platinum complexes, Dicarboxylates, Synthesis, Crystal structures, 983
Mixed donor ligands
Palladium(II) complexes, *Trans*-influence, X-ray crystallography, Methylaluminoxane (MAO), Norbornene, Polymerization, 1601
Mixed electrolytes
3:3 Electrolytes, Activity coefficients, Electrolytic solutions, High-charge salts, High valency electrolytes, 2493
Mixed-ligand complexes
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Aqua(imidazole)(*N*-carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N*-carbamoylmethyl - iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
Mixed-ligand complexes
Solution equilibrium, Hydroxamic acid, Copper(II), nickel(II) and zinc(II) complexes, 1727
Mixed-valence complexes
Ruthenium–edta complexes, Ferricyanide, Cyanobridged complexes, Intramolecular electron transfer, 1339
Mixed valence
Equilibrium, Copper, Disproportionation, Temperature effects, 2289
Mixed valence
Hush theory, Iron complexes, TCNE complexes, TCNQ complexes, 137
Mixed-valence
Thiolate-bridged complexes, Electron-transfer, Iron, 2679
Mn(II) complexes
1,3-propylenediaminetetraacetate, Cu(II) complexes, Crystal structures, Thermal properties, Magnetic properties, 1175
MO calculations
Ruthenium, Phenanthroline, *Cis–trans*, Barriers, Field strength, 2297
Mo–Cu–S cage cluster
Dodecanuclear, Interstitial group, 2189
Model of metal–guanine interaction
Dialkoxo-bridged binuclear Cu(II) complexes, Single crystal structures, Thermal decompostion, Theophylline, Diethanolamine(2,2′-iminodiethanol), 457
Modified electrodes
Polymeric metallophthalocyanines, Electrooxidation of hydrazine, Poly(cobalt–tetraaminophthalocyanine), Impedance spectroscopy, 2303
Molecular and crystal structure
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Amidomethyl)-iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, *cis*-Diaqua(*N* - carbamoylmethyl - iminodiacetato)nickel(II), Magnetic and spectral properties, Thermal stability, 2463
Molecular and crystal structures
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)cobalt(II) sesquihydrate, Magnetic, spectral and thermal properties, 2473
Molecular devices
CdS nanoclusters, Ruthenium(II) polypyridyls, Functionalized nanoclusters, Mesophase materials, 331
Molecular magnets
Cyano-bridged heteropolynuclear complexes, Iron complexes, Nickel complexes, Ferromagnetic coupling, 1967
Molecular motion
Deoxycholic acid, Ferrocene derivatives, Inclusion compounds, ^{57}Fe Mössbauer spectroscopy, Powder X-ray diffraction patterns, 205
Molecular structures
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazole ternary complexes, Copper(II) imidazolate ternary complexes, X-ray crystal structures, Magnetic properties, Infrared spectra, 1181
Molecular structures
N-salicylidenearoylhydrazines, Copper(II) complexes, X-ray crystal structures, Magnetic properties, Infrared spectra, 949
Molybdenum
Bridging ligands, Butadienyl, Chiral substituents, 791
Molybdenum complexes
Aerial oxidation of aldehydes, 1133
Molybdenum complexes
Cluster compounds, Tellurium-rich compounds, De-tellurium reaction, Crystal structures, 925

Molybdenum complexes
Tungsten complexes, Pyrazine complexes, Peroxo ligands, Crystal structures, 1503
Molybdenum
Hydrazido, Diazenido, Dialkyldithiocarbamato, Hydrazines, 2327
Molybdenum(II)
Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Molybdenum
Nitrides, Alkoxides, Synthesis, X-ray structures, NMR fluxionality, Pseudorotation, 1363
Molybdenum
Nitrosyl complex, Chromium, Carboxylate, DFT, 2565
Molybdenum
Oxocluster complexes, Hantzsch synthesis, Crystal structures, Hexanuclear molybdenum(V) complexes, 1471
Molybdenum–oxo complexes
Photochemistry, Photooxidation, Phosphines, Phosphine oxides, Crystal structures, 1437
Molybdenum
Polyoxometalate, Oxyhalide, X-ray structure, High acidity, 43
Molybdenum
Selenoether, Telluroether, Sulfur macrocycles, Chromium, Tungsten, 1373
Molybdenum
Tantalum, Trimetallic alkoxides, Crystal structures, 1791
Molybdenum
Vanadium, Heteropolyoxometalate, IR spectroscopy, UV–Vis spectroscopy, EPR spectroscopy, 1917
Molybenum(VI) cations
Equilibrium constants, Thermodynamic quantities, 907
Monolith
Sol–gel, Aggregation, Tetrasulfophthalocyanines, Macrocycle, Silica, 2383
Monomeric compounds
Heterometallic aryloxides, Lithium niobate, Niobium, Percursors, 1037
Mononuclear chelation
Oxovanadium(V) alkoxides, Crystal structures, Hydrogen bonded helical structures, 931
Mononuclear complexes
Electrochemical synthesis, Phenoxo bridges, Polyhydroxyl ligands, Polynuclear complexes, Schiff base ligands, 185
Mononuclear compounds
Nickel(II), Crystal structures, Nitrito ligands, Magnetic measurements, 225
Mononuclear
Tungsten pentacarbonyl complexes, 1,4-Bipyridine, 1,2-Bis(4-pyridyl)ethane, 1621
Monophasic hybrid materials
Silsesquioxane gels, Kinetic control, Sol–gel polymerization, 307
$Mo_2O_4^{2+}$ unit
Oxomolybdenum(V) compounds, Clusters, Pyridine, Alkyl-substituted pyridines, 1219
Mo–S clusters
Crystal structures, Electronic structures, Layer-like packing, 733
Mössbauer spectroscopy
Ferrocenophane, Inorganic polymers, Silanol, Ring-opening polymerization, 275
Mo(V, VI) compounds
Solvothermal synthesis, Crystal structures, Oxomolybdenum(V) coordination compounds, Alkyl-substituted pyridines, 1407
Multimetallic
Cobalt carbonyl complexes, Tungsten(II), Alkyne complexes, Chain triphos-bridged, 1585
Multinuclear NMR
meso-2,3-dimercaptosuccinic acid, Tungsten, 193

N-(2-Acetamide)-iminodiacetic acid
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Amidomethyl)-iminodiacetic acid, *cis*-Diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II), Molecular and crystal structure, Magnetic and spectral properties, Thermal stability, 2463
N-(2-acetamido)-iminodiacetic acid
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-amidomethyl)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
N-(2-Amidomethyl)-iminodiacetic acid
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, *cis*-Diaqua(*N* - carbamoylmethyl-iminodiacetato)nickel(II), Molecular and crystal structure, Magnetic and spectral properties, Thermal stability, 2463
N-(2-amidomethyl)-iminodiacetic acid
N-carbamoylmethyl-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl - iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
Nanoparticles
Heteronuclear catalysts, Immobilization, Sol–gel matrices, 509
Naphthalocyanines
Phthalocyanines, Porphyrins, Raman, Sandwich complexes, Lanthanides, 1381
Naphthylazoimidazoles
Platinum(II), PtN_4 coordination, Electrochemistry, X-ray structures, 1263
Naphthylmethyl fluorescent groups
Macrocyclic ligands, Aza–oxa crowns, 1867
N-(Carbamoylmethyl)iminodiacetic acid
N-(2-Amidomethyl)-iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, *cis*-Diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II), Molecular and crystal structure, Magnetic and spectral properties, Thermal stability, 2463
N-carbamoylmethyl-iminodiacetic acid
N-(2-amidomethyl)-iminodiacetic acid, *N*-(2-acetamido)-iminodiacetic acid, Imidazole, Mixed-ligand complexes, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)nickel(II) sesquihydrate, Aqua(imidazole)(*N* - carbamoylmethyl-iminodiacetato)cobalt(II) sesquihydrate, Molecular and crystal structures, Magnetic, spectral and thermal properties, 2473
Nematic phases
Metallomesogens, Rhenium, Chiral nematic phases, 249
Neodymium
Contrast agents, Crystal structures, Diethylenetriaminepentaacetate, Lanthanides, 771
Neodymium
Synthesis, Crystal structure, Aryloxide, Anion–cation pair compound, 2243
Network structures
α,α′-Bis(pyrazolyl)-*m*-xylene, Copper(II) complexes, X-ray structure, Absorption spectroscopy, Electron spin resonance, 719
NH tautomerism
Ferrocenylporphyrin, π-Conjugation, Electrochemical communication, Intramolecular hydrogen bonding, 1961
N′-2-Hydroxypropyl derivatives
N′-2-Pyridylmethyl derivatives, Stability constant, 2027
Nickel bisdithiolenes
Crystal structures, Cyclic voltammetry, Strong near-IR absorption, 425
Nickel complexes
Binucleating ligand, Copper complexes, Crystal structures, Redox chemistry, 2011
Nickel complexes
Crystal structures, Copper complexes, Schiff bases, Uracil, 689
Nickel complexes
Crystal structures, Metavanadate complexes, Copper complexes, Hydrothermal synthesis, Magnetic properties, 2521
Nickel complexes
Molecular magnets, Cyano-bridged heteropolynuclear complexes, Iron complexes, Ferromagnetic coupling, 1967
Nickel complexes
Thiosemicarbazones, Electrochemistry, Iron complexes, EPR of iron complexes, Cobalt complexes, 2059

Nickel complex
Tetra-aza ligands, CP-MAS NMR, Template reaction, 2149
Nickel
Copper, Cobalt, Palladium, dmit, 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione, 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione, 665
Nickel
Crystal structures, Magnetic properties, Dinuclear complexes, Manganese, Cobalt, 93
Nickel
Dithiolene, Dinuclear complexes, Acid–base, Solvatochromism, Carbon disulfide, 1283
Nickel(II)
Binucleating hexa-aza macrocycle, Copper(II), Cobalt(II), Zinc(II), Crystal structures, Phosphotriester, Hydrolysis, 1485
Nickel(II)
Cobalt(II), Cyanamidonitrate, Electronic spectra, Imidazole ligands, IR spectra, X-ray crystallography, 1021
Nickel(II) complexes
Potentiometry, Equilibria, Stability constants, Manganese(II), Cobalt(II), Aminopolyphosphonates, UV–VIS spectra, 2083
Nickel(II) complex
Syntheses, Crystal structures, Cobalt(II) complex, 4-(*p*-Methylphenyl)-3,5-bis-(pyridin-2-yl)-1,2,4-triazole, ESIMS, 2019
Nickel(III)
Asorption spectra, Copper(III), Dioxotetraamines, Macrocyclic ligands, 2533
Nickel(II)/(III) complexes
Crystal structures, Electrochemistry, EPR, Schiff base complexes, 655
Nickel(II)
Iron(II), Crystal structures, Electronic spectra, 1333
Nickel(II)
Me_2Octaen, Polyamines, Equilibria, Kinetics, Stopped-flow, 2507
Nickel(II)
Mononuclear compounds, Crystal structures, Nitrito ligands, Magnetic measurements, 225
Nickel(II)nitrite
Cis–trans isomerism, Crystal structures, 1,2-Diamino-2-methylpropane, 1015
Nickel(II) piperidinedithiocarbamate complexes
Synthesis, X-ray structure, 1713
Nickel(II)selenocyanate
Bis(3-aminopropyl)amine, (2-Aminoethyl)(3-aminopropyl)amine, Bis(2-aminoethyl)methylamine, Thermochromism, 1903
Nickel(II)thiocyanate
1-(2-Aminoethyl)pyrrolidine, Crystal structures, *cis*/*trans* Isomers, 1803
Nickel
Phthalocyanine complexes, Phthalonitrile derivatives, Crown-ether, Copper, Cobalt, Alkaline metal extraction, 115
Nicotinate
Bis(η-cyclopentadienyl)titanium(IV), Crystal structures, Diphenylphosphinoacetate, Heterometallics, Thiophenoxyacetate, 757
Ni(II) complexes
Tripodal ligand, Crystal structures, Spectroscopic studies, 2661
Niobium
Heterometallic aryloxides, Lithium niobate, Monomeric compounds, Percursors, 1037
Nitration
Cymene, Pyrazolyl, Ruthenium, Structure, Synthesis, 475
Nitric oxide
Cobalt, Electrocatalysis, Oxidation, Phthalocyanine, Reduction, 229
Nitrides
Molybdenum, Alkoxides, Synthesis, X-ray structures, NMR fluxionality, Pseudorotation, 1363
Nitrido complexes
Rhenium, Imido complexes, EPR spectroscopy, X-ray structures, 1741
Nitrile-bridged complexes
Molybdenum(II), Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Seven-coordinate complexes, Halocarbonyls, 147
Nitrite
Palladium, Platinum, Diphosphines, Isomerism, Fluxionality, 1329
Nitrito ligands
Nickel(II), Mononuclear compounds, Crystal structures, Magnetic measurements, 225
Nitrobenzene catalytic reduction
Rhodium complexes, 2-picoline, Water gas shift reaction, 487
Nitrogen-donor ligands
Zinc, Bis(pyrazolyl)silanes, Crystal structures, 1815
Nitrosobenzene cycloaddition
Regioselectivity, Organoiron compounds, Decomplexation, Heterocycloaddition trap, Alkaloid synthesis, 569
Nitrosonaphthol
Crystal structures, Ruthenium nitrosonaphthol complexes, 7
Nitrosyl complex
Chromium, Molybdenum, Carboxylate, DFT, 2565
NMR data
Zinc(II), Cadmium(II), Mercury(II), Tris(2-benzimidazolylmethyl)amine, X-ray diffraction structures, 1479
NMR fluxionality
Molybdenum, Nitrides, Alkoxides, Synthesis, X-ray structures, Pseudorotation, 1363
NMR
Heteroscorpionate tris(3-*R*-pyrazolyl)-borate cobalt(II) complexes, Structures, 2119
NMR
Iron carbonyl halides, XAFS spectroscopy, Halogen exchange reactions, Matrix isolation, 1493
NMR
Lanthanide, Carbacylamidophosphate, X-ray data, 2203
NMR of paramagnetic compounds
Macrocycles, Lanthanide complexes, Chiral complexes, 465
NMR
Platinum(II), Sulfoxide, *N*,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)thiourea, Acylthiourea, Chemotherapeutic agents, 1347
NMR
Sol-gel, Hybrid materials, Siloxane, Silicon-29, Oxygen-17, 315
NMR spectroscopy
Copper(II), Cobalt(III), Pyridylmethyl-tetraazadecane, 1447
N,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)thiourea
Platinum(II), Sulfoxide, Acylthiourea, NMR, Chemotherapeutic agents, 1347
N,*N*-dimethylformamide
Lanthanides(III), Silver(I), Diethylenetriamine, Complexes, Thermodynamics, 2427
N,*N*′-Ethylenebis(amino acid)
Oxovanadium(IV) complexes, TG-DTA, 1311
^{15}N NMR
Zn(II) complexes, 1,2,4-Triazolo-[1,5α]-pyrimidine, HETCOR, CPMAS, 965
Nobium
Titanium, Tantalum, Aryloxide, Bisphenol, Hydrogenation, 35
Nonlinear optical properties
Tetrathiometalate, Synthesis, Copper compounds, Crystal structures, Dppm, 1545
Non-planar conjugated ligands
Crystal structures, Europium(III) complexes, Fluorescence spectra, 785
Norbornene
Palladium(II) complexes, Mixed donor ligands, *Trans*-influence, X-ray crystallography, Methylaluminoxane (MAO), Polymerization, 1601
N-Oxide
Crystal structures, Lanthanide complexes, Picrate, 4-Methylmorpholine, TG, DSC, 2313
Nozaki–Hiyama–Kishi reaction
Chromium, Salen, Manganese, Catalysis, Enantioselection, 537
N′-2-Pyridylmethyl derivatives
N′-2-Hydroxypropyl derivatives, Stability constant, 2027
N-salicylidenearoylhydrazine copper(II) complexes
Copper(II) imidazole ternary complexes, Copper(II) imidazolate ternary complexes, X-ray crystal structures, Molecular structures, Magnetic properties, Infrared spectra, 1181
N-salicylidenearoylhydrazines
Copper(II) complexes, X-ray crystal structures, Molecular structures, Magnetic properties, Infrared spectra, 949

N-Salicylidene derivatives
Schiff base complexes, X-ray structures, Zn(II) complexes, 673
N-Tosyl ligands
Bridged structures, Crystal structures, Heteronuclear multiple bond coherence, Zinc porphyrin complexes, 413
Nuclear magnetic resonance
Crystal structures, Cu^{2+} porphyrin complexes, Protonated porphyrins, SAT complexes, Electron spin resonance, 633
Nuclear reprocessing
Calixcrowns, Caesium ion, Sodium ion, Perrhenate ion, Pertechnetate ion, 1749
Nucleophilic
Additions, Alkylation, Insertions, Schiff bases, Titanium, 177
Nucleotides
Carcinogenic, Chromium, 417

Octa- and hepta-coordination
Crystal structures, Synthesis, Macrocyclic polyamine ligand, Manganese complexes, 2095
Octacyanomolybdate(IV)
Kinetics, Substitution, Mechanism, *cis*-Diaquabis(2,2′-bipirydyl)chromium(III), Octacyanotungstate(IV), 2225
Octacyanotungstate(IV)
Kinetics, Substitution, Mechanism, *cis*-Diaquabis(2,2′-bipirydyl)chromium(III), Octacyanomolybdate(IV), 2225
Octadentate ligands
Crystal structures, Cobalt(II) complexes, Iron(II) complexes, 431
Octahedral complexes
Crystal structures, *Fac* isomers, Isomerization, Lanthanide chloride complexes, 199
Olefin polymerizations
Zirconocene, Crystal structures, Catalysis, 1941
Olefins
Alkynes, Functionalized metalloalkynes, Polymetallated olefins, Titanium, 563
Olefins
Porphyrins, Hemoprotein models, Chiral catalysts, Epoxidation, 581
One-dimensional polymers
Dirhodium(II) compounds, Trifluoroacetate, Arene coordination, π-Complexes, Crystal structures, 1829
O,O-Alkylene dithiophosphate acids and ligands
Organotellurium(IV), 407
o-Phenylenediacetonitrile
Molybdenum(II), Tungsten(II), Crystal structures, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Organocopper reagents
Hydroformylation, Catalysis, Asymmetric synthesis, Domino reactions, 513
Organogermane halides
Alkoxyalkynes, Aminoalkynes, Addition reactions, Organophosphorus halides, Organosilane halides, Pd-catalyzed cross-coupling reactions, 597
Organoiron compounds
Nitrosobenzene cycloaddition, Regioselectivity, Decomplexation, Heterocycloaddition trap, Alkaloid synthesis, 569
Organolanthanide complexes
Ether-side chain cyclopentadienyl, Cyclooctatetraenyl, Crystal structures, 453
Organophosphorus halides
Alkoxyalkynes, Aminoalkynes, Addition reactions, Organosilane halides, Organogermane halides, Pd-catalyzed cross-coupling reactions, 597
Organophosphoryl polyoxotungstate
Polyoxometalate, Synthesis, ^{183}W NMR, 125
Organosilane halides
Alkoxyalkynes, Aminoalkynes, Addition reactions, Organophosphorus halides, Organogermane halides, Pd-catalyzed cross-coupling reactions, 597
Organotellurium(IV)
O,O-Alkylene dithiophosphate acids and ligands, 407
Organotin(IV) complexes
Heterocyclic bis(thiosemicarbazone), Heptacoordinate complexes, Binuclear zinc complexes, 841
Organotin(IV)
Phosphorothiates, Bioactive groups, Cholesteryl, 1539
Organotin(IV)
Poly(pyrazol-1-yl)alkanes, X-ray structure, 381
Organotin(IV)
Poly(triazol-1-yl)alkanes, X-ray structure, 1949
Osmium
Amine oxide, Methanolysis, Rhenium, Carbonyl, Methylcarbonate, 641
Osmium
Ditelluroether, X-ray structures, 235
Osmium
Dithiolate complexes, Ruthenium, X-ray structures, 1073
Osmium(II) complexes
Electrochemical studies, Heterodinuclear complexes, Homodinuclear complexes, Luminescence properties, Ruthenium(II) complexes, Syntheses, 1233
Osmium
Silica, Titanium(IV), Ruthenium, 2277
Osmium
Triphenylphosphine, 2-(Phenylazo)-pyridine, Synthesis, Structures, Reactivities, 1227
Osmium
X-ray structures, Metallation, 1081
Oxalate anions
Aromatic amines, Amberlite anion-exchange resin, Metal–oxalate complexes, Oxidation, Homogeneous and heterogeneous, 1317
Oxalato-bridged compounds
Crystal structures, Binuclear copper compounds, Magnetism, 1105
Oxidation
Aromatic amines, Amberlite anion-exchange resin, Oxalate anions, Metal–oxalate complexes, Homogeneous and heterogeneous, 1317
Oxidation
Catalysis, 3,5-Di-*tert*-butylcatechol, Kinetics, Copper binuclear complexes, 2367
Oxidation
Cobalt, Electrocatalysis, Nitric oxide, Phthalocyanine, Reduction, 229
Oximes
Transition metal complexes, Electronic spectral data, Benzil-α-monoxime, 1687
μ-oxo-Bridged cations
Crown ether complexation, Crystal structures, Bridging oxygen atoms, 1799
Oxocluster complexes
Molybdenum, Hantzsch synthesis, Crystal structures, Hexanuclear molybdenum(V) complexes, 1471
Oxo ligands
Thiolates, Titanium, Trimers, 1139
Oxomolybdenum(V) compounds
Clusters, $Mo_2O_4^{2+}$ unit, Pyridine, Alkyl-substituted pyridines, 1219
Oxomolybdenum(V) coordination compounds
Solvothermal synthesis, Crystal structures, Mo(V, VI) compounds, Alkyl-substituted pyridines, 1407
Oxonium derivatives
closo-Dodecaborate, Functional derivatives, Amino acids, Boron neutron capture therapy, 627
Oxonium ion
15-Crown-5 complexes, Liquid clathrates, X-ray crystallography, 85
Oxovanadium complexes
Catechols, Macrocyclic ligands, ESR parameters, Distorted square-pyramid, Hydrophobic cavities, 1167
Oxovanadium(IV) complexes
N,*N*′-Ethylenebis(amino acid), TG-DTA, 1311
Oxovanadium(IV) complexes
Pyridinecarboxylic acids, pH-metry, Spectral studies, Speciation, 55
Oxovanadium(V) alkoxides
Mononuclear chelation, Crystal structures, Hydrogen bonded helical structures, 931
Oxovanadium(V) dimers
Alkoxo compounds of oxovanadium(V), Crystal structure of compounds of oxovanadium(V), Hydrazonato compounds of oxovanadium(V), Reactivity of bis(β-dionato)oxovanadium(IV) chelates, Hydrazonato tridentate Schiff base ligands, 2003
Oxygen-atom transfer
Dioxomolybdenum dipicolinate, Azoxybenzene deoxygenation, 2141
Oxygen-17
Sol-gel, NMR, Hybrid materials, Siloxane, Silicon-29, 315
Oxygen
Solubility, Solubilization enthalpy, Solubilization entropy, Cavity, 2457

Oxyhalide
Polyoxometalate, Molybdenum, X-ray structure, High acidity, 43

P-alkylation
Gold(I) complexes, Cationic ylide ligand, Bis(methyldiphenylphosphonio)methylide salts, 1837
Palladium
Amido, Diimine, Dimer, Hydroxo, Platinum, 155
Palladium catalysts
Asymmetric alkylation, Asymmetric rearrangements, Chiral ligands, Chiral sulfoxides, 525
Palladium catalyzed reactions
Halide ions, Coupling reactions, Protonolysis, 577
Palladium complexes
Crystal structures, Platinum complexes, Diphosphine complexes, Tetraphosphine complexes, Bimetallic complexes, 913
Palladium
Copper, Cobalt, Nickel, dmit, 4,5-bis(2-pyridylmethylsulfanyl) - 1,3 - dithiole - 2-thione, 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione, 665
Palladium
1,5-diene, Cross coupling, Terpenoids, Carboalumination, 591
Palladium
Diethyldithiocarbamate, Diphosphines, Tetrachlorometallate anions, X-ray crystal structures, 1511
Palladium
Heck reactions, Phosphane, Sulfane, Ligands, Mechanism, 517
Palladium
Hydroxo complexes, Pyrazolylalkane complexes, Crystal structures, 1395
Palladium(II) complexes
Bisphosphines, Heterocyclic thiones, Platinum(II) complexes, Pyridyl, 899
Palladium(II) complexes
Catalysts, Peptides, Hydrolysis, 959
Palladium(II) complexes
Metallocycles, Aminophosphate complexes, Spectroscopy, Antitumour activity, 937
Palladium(II) complexes
Mixed donor ligands, *Trans*-influence, X-ray crystallography, Methylaluminoxane (MAO), Norbornene, Polymerization, 1601
Palladium(II) complexes
Platinum(II) complexes, Chloride metathesis, X-ray crystallography, Heterodifunctional ligands, 695
Palladium
Platinum, Nitrite, Diphosphines, Isomerism, Fluxionality, 1329
Palladium
Platinum, Phosphine thiocarbonates, 499
Palladium
Platinum, Selenium, Tellurium, 751
Palladium
Platinum, Thiolate complexes, Allyl complexes, 1627
Paramagnetic
Copper(II) complexes, Dinuclear and polynuclear, Crystal structures, Equatorial–apical bridge, 1593
Paramagnetic NMR
Polynuclear manganese-carboxylate clusters, Imidazole-carboxylate chelating ligands, 2111
Paramagnetic
Ruthenium, Clotrimazole, Ketoconazole, Metal complexes, *Trypanosoma cruzi*, Chagas, 2319
PBD
Lanthanide picrate, Fluorescence, Crystal structures, 779
Pd-catalyzed cross-coupling reactions
Alkoxyalkynes, Aminoalkynes, Addition reactions, Organophosphorus halides, Organosilane halides, Organogermane halides, 597
Pentachloro-cyclotriphosphazene
Pentafluoro-cyclotriphosphazene, X-ray structures, Electrospray mass spectrometry, 2101
Pentacoordination
Phosphoranes, X-ray structure, Hydrogen bonding, 63
Pentadentate ligands
Metallamacrocycles, Hexanuclear clusters, Manganese complexes, Hydrophobic aliphatic tripled tails, 1985
Pentafluoro-cyclotriphosphazene
Pentachloro-cyclotriphosphazene, X-ray structures, Electrospray mass spectrometry, 2101
Peptides
Disulfide, Transition metal ions, 1849
Peptides
Palladium(II) complexes, Catalysts, Hydrolysis, 959
Percursors
Heterometallic aryloxides, Lithium niobate, Monomeric compounds, Niobium, 1037
Peroxo ligands
Molybdenum complexes, Tungsten complexes, Pyrazine complexes, Crystal structures, 1503
Perrhenate ion
Calixcrowns, Caesium ion, Sodium ion, Pertechnetate ion, Nuclear reprocessing, 1749
Pertechnetate ion
Calixcrowns, Caesium ion, Sodium ion, Perrhenate ion, Nuclear reprocessing, 1749
1,10-Phenanthroline
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Boron-11 NMR, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 2,2′,6′,2″-Terpyridine, 165
1,10-Phenanthroline
Crystal structures, Complexation chemistry, 495
Phenanthroline
Ruthenium, *Cis–trans*, MO calculations, Barriers, Field strength, 2297
Phenolic ligands
Ruthenium, Synthesis, Structure, Redox properties, 1663
Phenolic ligands
Ruthenium, Synthesis, Structure, Redox properties, 1673
Phenoxo bridges
Electrochemical synthesis, Mononuclear complexes, Polyhydroxyl ligands, Polynuclear complexes, Schiff base ligands, 185
2-(Phenylazo)pyridine
Osmium, Triphenylphosphine, Synthesis, Structures, Reactivities, 1227
5-Phenylazosalicylaldehyde
Schiff bases, Copper complexes, X-ray structure, Cyclic voltammetry, 607
pH-metry
Oxovanadium(IV) complexes, Pyridinecarboxylic acids, Spectral studies, Speciation, 55
Phosphane
Heck reactions, Palladium, Sulfane, Ligands, Mechanism, 517
Phosphates
Ruthenium, X-ray crystal structures, 801
Phosphate
Uranium, Uranyl, Crown, Crystal structures, 1551
Phosphato complexes
Beryllium, Solution equilibria, ^{31}P NMR spectroscopy, ^{9}Be NMR spectroscopy, Speciation, 1043
Phosphato complexes
Tin(II), Solution equilibria, Speciation, 2403
Phosphides
Antimonides, Arsenides, Metathesis, 829
Phosphido-bridged
Ruthenium, Iridium, Gold, Electron-rich, Cluster, Crystal structures, 2593
Phosphine
Alkene, Polymerization, Hydroboration, Copper(I) complexes, 1271
Phosphine complexes
Mercury(II) halides, Crystal structures, 1719
Phosphine oxides
Lanthanides, X-ray structures, 2697
Phosphine oxides
Molybdenum–oxo complexes, Photochemistry, Photooxidation, Phosphines, Crystal structures, 1437
Phosphines
Molybdenum–oxo complexes, Photochemistry, Photooxidation, Phosphine oxides, Crystal structures, 1437
Phosphines
Rhenium, Re complexes, Re(I), *trans*-Dioxo Re(V) complexes, dppm, 2249
Phosphine sulfides
Crystal structures, Phosphonium salt, 2585
Phosphine thiocarbonates
Platinum, Palladium, 499

Phosphino amino acid salts
Water-soluble phosphines, Disodium or dipotassium 1,3-di(carboxylatomethyl)-5-aryl-1,3,5-diazaphosphorinanes, 1455
Phosphinophenols
Rhenium, 1111
Phosphite diolato(1 −) ligand
Spirophosphorane ring-opening, Crystal structures, 2667
Phosphites
π-Allyl complexes, Allylic substitutions, Iridium, Regioselectivity, Stereoselectivity, 557
Phosphonium salt
Crystal structures, Phosphine sulfides, 2585
Phosphoranes
Pentacoordination, X-ray structure, Hydrogen bonding, 63
Phosphorothiates
Organotin(IV), Bioactive groups, Cholesteryl, 1539
Phosphotriester
Binucleating hexa-aza macrocycle, Copper(II), Nickel(II), Cobalt(II), Zinc(II), Crystal structures, Hydrolysis, 1485
Photochemical metal organic deposition
Photochemistry, Surface chemistry, Lithography, Gold, 343
Photochemistry
Molybdenum–oxo complexes, Photooxidation, Phosphines, Phosphine oxides, Crystal structures, 1437
Photochemistry
Surface chemistry, Photochemical metal organic deposition, Lithography, Gold, 343
Photoisomerization
Ruthenium, 1193
Photolysis
Manganese complexes, Schiff bases, Manganoenzymes, Catalase, Dioxygen, 47
Photooxidation
Molybdenum–oxo complexes, Photochemistry, Phosphines, Phosphine oxides, Crystal structures, 1437
Photosensitive ligands
Schiff bases, Cobalt complexes, Spin crossover, LD-LISC effect, 1643
Photosystem II
Dichloromanganese(IV) complexes, Bidentate Schiff base ligands, Tetradentate Schiff base ligands, Crystal structures, 2039
Phthalocyanine
Cobalt, Electrocatalysis, Nitric oxide, Oxidation, Reduction, 229
Phthalocyanine complexes
Phthalonitrile derivatives, Crown-ether, Copper, Nickel, Cobalt, Alkaline metal extraction, 115
Phthalocyanine
Iron, Dopamine, Serotonin, Coordination, 1355
Phthalocyanines
Naphthalocyanines, Porphyrins, Raman, Sandwich complexes, Lanthanides, 1381
Phthalonitrile derivatives
Phthalocyanine complexes, Crown-ether, Copper, Nickel, Cobalt, Alkaline metal extraction, 115
2-picoline
Nitrobenzene catalytic reduction, Rhodium complexes, Water gas shift reaction, 487
Picrate
Crystal structures, Lanthanide complexes, 4-Methylmorpholine, *N*-Oxide, TG, DSC, 2313
Piperidine
Platinum(II) complexes, Synthesis, Crystal structures, 975
Planar chiral
Structure, Indenyl, Yttrium, Lanthanum, Tetrahydroborate, 1955
Platinum
Amido, Diimine, Dimer, Hydroxo, Palladium, 155
Platinum catalysts
Dendrimers, Carbosilanes, Hydrosilation, 1031
Platinum complexes
Crystal structures, Palladium complexes, Diphosphine complexes, Tetraphosphine complexes, Bimetallic complexes, 913
Platinum complexes
3-methylpiperidine, Dicarboxylates, Synthesis, Crystal structures, 983
Platinum
Complexes, Sulfimides, Hydrogen bonding, 2077
Platinum complexes
Thiophosphoryl guanidines, Crystal structures, 809
Platinum
Gold, Cross-coupling, Diyne, X-ray, 2261
Platinum(II) complexes
Bisphosphines, Heterocyclic thiones, Palladium(II) complexes, Pyridyl, 899
Platinum(II) complexes
Insertion reactions, Platinum–tin bimetallics, 2,3,5,6-Tetrakis(α-pyridyl)-pyrazine, 739
Platinum(II) complexes
Palladium(II) complexes, Chloride metathesis, X-ray crystallography, Heterodifunctional ligands, 695
Platinum(II) complexes
Piperidine, Synthesis, Crystal structures, 975
Platinum(II)
Naphthylazoimidazoles, PtN_4 coordination, Electrochemistry, X-ray structures, 1263
Platinum(II)
Platinum(IV), Bromide, Porphyrins, Electrochemistry, Voltammetry, 1057
Platinum(II)
Sulfoxide, *N*,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)-thiourea, Acylthiourea, NMR, Chemotherapeutic agents, 1347
Platinum(IV)
Platinum(II), Bromide, Porphyrins, Electrochemistry, Voltammetry, 1057
Platinum
Palladium, Nitrite, Diphosphines, Isomerism, Fluxionality, 1329
Platinum
Palladium, Phosphine thiocarbonates, 499
Platinum
Palladium, Selenium, Tellurium, 751
Platinum
Palladium, Thiolate complexes, Allyl complexes, 1627
Platinum–tin bimetallics
Insertion reactions, Platinum(II) complexes, 2,3,5,6-Tetrakis(α-pyridyl)-pyrazine, 739
4-(*p*-Methylphenyl)-3,5-bis(pyridin-2-yl)-1,2,4-triazole
Syntheses, Crystal structures, Cobalt(II) complex, Nickel(II) complex, ESIMS, 2019
^{31}P NMR spectroscopy
Beryllium, Phosphato complexes, Solution equilibria, ^{9}Be NMR spectroscopy, Speciation, 1043
Polyaddition
Alkenylsilanes, Hydrosilylation, $RhI(PPh_3)_3$, Stereodivergent, 567
Polyamine ligand
Strontium, Thd ligand, Precursor, 2547
Polyamines
Dioxygen carriers, Cobalt, Dinuclear complexes, Dinucleating ligands, Kinetics, Dioxygen binding, 2447
Polyamines
Dioxygen carriers, Dioxygen binding, Cobalt, Polynuclear complexes, Thermodynamics of complexation, 2441
Polyamines
Me_2Octaen, Nickel(II), Equilibria, Kinetics, Stopped-flow, 2507
Poly(cobalt–tetraaminophthalocyanine)
Polymeric metallophthalocyanines, Modified electrodes, Electrooxidation of hydrazine, Impedance spectroscopy, 2303
Polyhydroxyl ligands
Electrochemical synthesis, Mononuclear complexes, Phenoxo bridges, Polynuclear complexes, Schiff base ligands, 185
Polymeric metallophthalocyanines
Modified electrodes, Electrooxidation of hydrazine, Poly(cobalt–tetraaminophthalocyanine), Impedance spectroscopy, 2303
Polymerization
Palladium(II) complexes, Mixed donor ligands, *Trans*-influence, X-ray crystallography, Methylaluminoxane (MAO), Norbornene, 1601
Polymerization
Phosphine, Alkene, Hydroboration, Copper(I) complexes, 1271
Polymetallated olefins
Alkynes, Functionalized metalloalkynes, Olefins, Titanium, 563
Polynuclear complexes
Dioxygen carriers, Dioxygen binding, Cobalt, Polyamines, Thermodynamics of complexation, 2441

Polynuclear complexes
Electrochemical synthesis, Mononuclear complexes, Phenoxo bridges, Polyhydroxyl ligands, Schiff base ligands, 185
Polynuclear manganese-carboxylate clusters
Imidazole-carboxylate chelating ligands, Paramagnetic NMR, 2111
Polyoxometalate
Organophosphoryl polyoxotungstate, Synthesis, ^{183}W NMR, 125
Polyoxometalate
Oxyhalide, Molybdenum, X-ray structure, High acidity, 43
Poly(pyrazol-1-yl)alkanes
Organotin(IV), X-ray structure, 381
Polypyridine ligands
Bpy ligands, Ruthenium(II) complexes, 1975
Polypyridine
Ruthenium, Terpyridine, Electrocatalytic oxidation, Alcohol oxidation, Isomerization, 1049
Polysilazanes
Hydroboration, Precursors, Vinylsilanes, Chloroboranes, 323
Polytelluride
Solvothermal synthesis, Iron telluride, Iron cluster, Iron carbonyl, Carbonyl clusters, 1995
Poly(triazol-1-yl)alkanes
Organotin(IV), X-ray structure, 1949
Porphyrins
Hemoprotein models, Chiral catalysts, Epoxidation, Olefins, 581
Porphyrins
Phthalocyanines, Naphthalocyanines, Raman, Sandwich complexes, Lanthanides, 1381
Porphyrins
Platinum(II), Platinum(IV), Bromide, Electrochemistry, Voltammetry, 1057
Potentiometric titrations
Vanadium complexes, Quinic acid complexes, IR spectra, Raman spectra, Thermal behavior, 2613
Potentiometry
Equilibria, Stability constants, Manganese(II), Cobalt(II), Nickel(II) complexes, Aminopolyphosphonates, UV–VIS spectra, 2083
Potentiometry
meso-2,3-Dimercaptosuccinic acid, UV–Vis spectroscopy, Formation constants, Ionization constants, Kinetic measurements, 2435
Powder X-ray diffraction patterns
Deoxycholic acid, Ferrocene derivatives, Inclusion compounds, Molecular motion, ^{57}Fe Mössbauer spectroscopy, 205
Praseodymium(III)
D-Gluconic acid, D-Galactonic acid, D-Gulonic acid, Complexation, 1567
Precursors
Hydroboration, Polysilazanes, Vinylsilanes, Chloroboranes, 323
Precursors
Metal–organic chemical vapour deposition, Lead scandium tantalate, Ferroelectric oxides, 351
Precursor
Strontium, Polyamine ligand, Thd ligand, 2547
Propiolic acid
Tungsten(II), Carboxylate and sulfonate substituted pyridines, Water soluble complexes, 2171
1,3-propylenediaminetetraacetate
Cu(II) complexes, Mn(II) complexes, Crystal structures, Thermal properties, Magnetic properties, 1175
Protonated porphyrins
Crystal structures, Cu^{2+} porphyrin complexes, SAT complexes, Electron spin resonance, Nuclear magnetic resonance, 633
Protonolysis
Palladium catalyzed reactions, Halide ions, Coupling reactions, 577
Pryrazolyl groups
Dinuclear, Antiferromagnetic interactions, 2215
Pseudohalogens
Selenocyanogen, Thiocyanogen, 681
Pseudorotation
Molybdenum, Nitrides, Alkoxides, Synthesis, X-ray structures, NMR fluxionality, 1363
PtN_4 coordination
Naphthylazoimidazoles, Platinum(II), Electrochemistry, X-ray structures, 1263
Pyrazine carboxamide complexes
Copper(I) complexes, Crystal structures, Electronic spectra, Emission spectra, Vibrational spectra, 601
Pyrazine complexes
Molybdenum complexes, Tungsten complexes, Peroxo ligands, Crystal structures, 1503
Pyrazolylalkane complexes
Palladium, Hydroxo complexes, Crystal structures, 1395
Pyrazolyl
Cymene, Nitration, Ruthenium, Structure, Synthesis, 475
Pyridinecarboxylate complexes
Chelating ligands, Crystal structures, Copper(II) complexes, Antimicrobial activity, 2689
Pyridinecarboxylic acids
Oxovanadium(IV) complexes, pH-metry, Spectral studies, Speciation, 55
2-Pyridineformamide
Thiosemicarbazone, Crystal structures, Cadmium halides, 1873
Pyridine *N*-oxide ligands
Cobalt(II) complexes, Zinc(II) complexes, X-ray structures, Magnetic susceptibility, 2195
Pyridine
Oxomolybdenum(V) compounds, Clusters, $Mo_2O_4^{2+}$ unit, Alkyl-substituted pyridines, 1219
Pyridines
Allylation, Aqueous reactions, Esters, Indium, Indium compounds, 549
Pyriding N-oxides
Metal complexes, Hydrogenation, Structures, 835
Pyridoxine
Crystal structures, Diethyltin, 813
2-(2-Pyridyl)benzimidazole
Chromium(III) complexes, Tris(2-benzimidazolylmethyl)amine, 2-Guanidinobenzimidazole, 2,6-Bis(2-benzimidazolyl)pyridine, Crystal structures, 1821
Pyridyl
Bisphosphines, Heterocyclic thiones, Palladium(II) complexes, Platinum(II) complexes, 899
Pyridylmethyl-tetraazadecane
Copper(II), Cobalt(III), NMR spectroscopy, 1447
pyrimidine-2-thione
Mercury(II) complexes, Triphenylphosphine, Benzothiazole-2-thione, Crystal structures, 2231
Pyrrole
Enamine, Alkenylation, 545
Pyrrolidine
Kainoids, Boronic esters, Asymmetric synthesis, 587

Quinazolines
Allylic alkylation, Axially chiral phosphinamine, Hydroboration, 541
Quinic acid complexes
Vanadium complexes, IR spectra, Raman spectra, Thermal behavior, Potentiometric titrations, 2613

Raman
Phthalocyanines, Naphthalocyanines, Porphyrins, Sandwich complexes, Lanthanides, 1381
Raman spectra
Vanadium complexes, Quinic acid complexes, IR spectra, Thermal behavior, Potentiometric titrations, 2613
Raman spectroscopy
Infrared spectroscopy, Electronic absorption spectroscopy, Crystal structures, Hypophospite complexes, Cooperative vibronic transitions, Two-centre transitions, 863
Rare earth complex
Crystal structure, Antitumour activity, Hydrazone, 2599
Rare earth elements
Yttrium, Hydrolysis, Enthalpy, Ionic strength, Spectrophotometry, 99
Reaction
Iron, Selenium, Sulfur, Synthesis, 713
Reactivities
Osmium, Triphenylphosphine, 2-(Phenylazo)pyridine, Synthesis, Structures, 1227
Reactivity
Catecholborane, 1063
Reactivity
Cryoscopy, Cyanocuprates, Ionic, Structures, 553

Reactivity of bis(β-dionato)oxovanadium(IV) chelates
Alkoxo compounds of oxovanadium(V), Crystal structure of compounds of oxovanadium(V), Hydrazonato compounds of oxovanadium(V), Oxovanadium(V) dimers, Hydrazonato tridentate Schiff base ligands, 2003
Rearrangement
α-Acetylenic alcohols, Isomerization, Heterobimetallic titanium–copper systems, 1693
Re complexes
Rhenium, Re(I), *trans*-Dioxo Re(V) complexes, Phosphines, dppm, 2249
Redox chemistry
Binucleating ligand, Nickel complexes, Copper complexes, Crystal structures, 2011
Redox properties
Ruthenium, Phenolic ligands, Synthesis, Structure, 1663
Redox properties
Ruthenium, Phenolic ligands, Synthesis, Structure, 1673
Redox properties
Substituted cobalt phthalocyanines, Hammett parameters, Frontier orbitals, Disulfide reduction, 2255
Redox
Synthesis, Semiquinone, Ruthenium, Spectroelectrochemical studies, 2605
Reduction
Alane, Aluminum hydride, Alanate, Alumoxane, 1649
Reduction
Cobalt, Electrocatalysis, Nitric oxide, Oxidation, Phthalocyanine, 229
Refluxing
Crystallographic, Selenium, Tungsten analogue, 2127
Regioselectivity
π-Allyl complexes, Allylic substitutions, Iridium, Stereoselectivity, Phosphites, 557
Regioselectivity
Nitrosobenzene cycloaddition, Organoiron compounds, Decomplexation, Heterocycloaddition trap, Alkaloid synthesis, 569
Re(I)
Rhenium, Re complexes, *trans*-Dioxo Re(V) complexes, Phosphines, dppm, 2249
Release of free nucleobases from oligomers
Copper(II)–peroxide adduct, DNA cleavage, Electrospray mass spectrometry, 2639
Rhenium
Amine oxide, Methanolysis, Osmium, Carbonyl, Methylcarbonate, 641
Rhenium clusters
Trirhenium(III) clusters, Acetamidate, Dimolybdenum(II), MALDI, Mass spectroscopy, 1245
Rhenium(III) complexes
Thiopyrimidine, Rhenium(V) complexes, Cyclic voltammetry, UV–Vis–NIR, IR, ^{1}H NMR spectra, 2163
Rhenium
Metal clusters, Sulfur, Selenium, Tellurium, Crystal structures, 437
Rhenium
Metallomesogens, Nematic phases, Chiral nematic phases, 249
Rhenium
Nitrido complexes, Imido complexes, EPR spectroscopy, X-ray structures, 1741
Rhenium
Phosphinophenols, 1111
Rhenium
Re complexes, Re(I), *trans*-Dioxo Re(V) complexes, Phosphines, dppm, 2249
Rhenium(V) complexes
Thiopyrimidine, Rhenium(III) complexes, Cyclic voltammetry, UV–Vis–NIR, IR, ^{1}H NMR spectra, 2163
$RhI(PPh_3)_3$
Alkenylsilanes, Hydrosilylation, Polyaddition, Stereodivergent, 567
Rhodium complexes
Nitrobenzene catalytic reduction, 2-picoline, Water gas shift reaction, 487
Rhodium(II) carboxylates
Rhodium(II) complexes, Rhodium sulfosalicylate, Thermogravimetric analysis, Spectroscopic analysis, Anticancer drugs, 1305
Rhodium(II) complexes
Rhodium(II) carboxylates, Rhodium sulfosalicylate, Thermogravimetric analysis, Spectroscopic analysis, Anticancer drugs, 1305
Rhodium(II)
Dithiocarbamates, 123
Rhodium sulfosalicylate
Rhodium(II) complexes, Rhodium(II) carboxylates, Thermogravimetric analysis, Spectroscopic analysis, Anticancer drugs, 1305
Rietveld method
Sulfated zirconia, Tetragonal zirconia stabilization, Zirconium sulfide, Zirconium oxide sulfide, Thermogravimetry of sol–gel ZrO_2, 2283
Rigid and flexible ligands
Self-assembly, Supramolecules, X-ray structure, 1117
Ring-closing metathesis
Thioacetal, Titanocene(II), Intramolecular carbonyl olefination, Cycloalkenes, Heterocyclic compounds, 593
Ring-opening polymerization
Ferrocenophane, Inorganic polymers, Silanol, Mössbauer spectroscopy, 275
Ru–bipyridine
Azoimine, Tris-chelates, X-ray structures, Electrochemistry, Emission spectra, 1925
Ruthenium
Clotrimazole, Ketoconazole, Paramagnetic, Metal complexes, *Trypanosoma cruzi*, Chagas, 2319
Ruthenium
Crystal structures, Dimethyl sulfoxide, Carboxylates, Complexes, Catalysis, 1589
Ruthenium
Cymene, Nitration, Pyrazolyl, Structure, Synthesis, 475
Ruthenium
Dithiolate complexes, Osmium, X-ray structures, 1073
Ruthenium–edta complexes
Mixed-valence complexes, Ferricyanide, Cyanobridged complexes, Intramolecular electron transfer, 1339
Ruthenium(II) complexes
Bpy ligands, Polypyridine ligands, 1975
Ruthenium(II) complexes
Electrochemical studies, Heterodinuclear complexes, Homodinuclear complexes, Luminescence properties, Osmium(II) complexes, Syntheses, 1233
Ruthenium(II) polypyridyls
CdS nanoclusters, Functionalized nanoclusters, Mesophase materials, Molecular devices, 331
Ruthenium
Iridium, Gold, Electron-rich, Cluster, Phosphido-bridged, Crystal structures, 2593
Ruthenium nitrosonaphthol complexes
Crystal structures, Nitrosonaphthol, 7
Ruthenium
Phenanthroline, *Cis–trans*, MO calculations, Barriers, Field strength, 2297
Ruthenium
Phenolic ligands, Synthesis, Structure, Redox properties, 1663
Ruthenium
Phenolic ligands, Synthesis, Structure, Redox properties, 1673
Ruthenium
Phosphates, X-ray crystal structures, 801
Ruthenium
Photoisomerization, 1193
Ruthenium
Polypyridine, Terpyridine, Electrocatalytic oxidation, Alcohol oxidation, Isomerization, 1049
Ruthenium
Silica, Titanium(IV), Osmium, 2277
Ruthenium
Synthesis, Semiquinone, Spectroelectrochemical studies, Redox, 2605

Salen
Chromium, Manganese, Catalysis, Enantioselection, Nozaki–Hiyama–Kishi reaction, 537
Sandwich complexes
Phthalocyanines, Naphthalocyanines, Porphyrins, Raman, Lanthanides, 1381
SAT complexes
Crystal structures, Cu^{2+} porphyrin complexes, Protonated porphyrins, Electron spin resonance, Nuclear magnetic resonance, 633
Scandium
Alkoxides, Crystal structures, Volatility, 705
Schiff base complexes
Crystal structures, Electrochemistry, EPR, Nickel(II)/(III) complexes, 655

Schiff base complexes
N-Salicylidene derivatives, X-ray structures, Zn(II) complexes, 673
Schiff base
Imidazole, Silver complexes, Crystal structures, 2237
Schiff-base ligands
Cadmium(II) complexes, Symmetrical complexes, Asymmetrical complexes, Heptadentate ligands, 1633
Schiff base ligands
Electrochemical synthesis, Mononuclear complexes, Phenoxo bridges, Polyhydroxyl ligands, Polynuclear complexes, 185
Schiff bases
Additions, Alkylation, Insertions, Nucleophilic, Titanium, 177
Schiff bases
Cobalt complexes, Spin crossover, Photosensitive ligands, LD-LISC effect, 1643
Schiff bases
Copper complexes, X-ray structure, 5-Phenylazosalicylaldehyde, Cyclic voltammetry, 607
Schiff bases
Crystal structures, Nickel complexes, Copper complexes, Uracil, 689
Schiff bases
Manganese complexes, Manganoenzymes, Photolysis, Catalase, Dioxygen, 47
Selenium
Crystallographic, Tungsten analogue, Refluxing, 2127
Selenium
Iron, Sulfur, Synthesis, Reaction, 713
Selenium
Palladium, Platinum, Tellurium, 751
Selenium
Rhenium, Metal clusters, Sulfur, Tellurium, Crystal structures, 437
Selenocyanogen
Pseudohalogens, Thiocyanogen, 681
Selenoether
Telluroether, Sulfur macrocycles, Chromium, Molybdenum, Tungsten, 1373
Self-assembly
Rigid and flexible ligands, Supramolecules, X-ray structure, 1117
Semiquinone
Synthesis, Ruthenium, Spectroelectrochemical studies, Redox, 2605
SEM
Magnesia, Dolomite, Crystallite size, Degree of agglomeration, X-ray diffraction, 2345
Serotonin
Iron, Phthalocyanine, Dopamine, Coordination, 1355
Seven-coordinate complexes
Molybdenum(II), Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Halocarbonyls, 147
Silanol
Ferrocenophane, Inorganic polymers, Mössbauer spectroscopy, Ring-opening polymerization, 275
Silica gels
Ethylenimine, Immobilization, 3-Mercaptopropyltrimethoxysilane, 367
Silica
Sol–gel, Aggregation, Tetrasulfophthalocyanines, Monolith, Macrocycle, 2383
Silica
Titanium(IV), Ruthenium, Osmium, 2277
Silicon-29
Sol-gel, NMR, Hybrid materials, Siloxane, Oxygen-17, 315
Siloxane
Sol-gel, NMR, Hybrid materials, Silicon-29, Oxygen-17, 315
Silsesquioxane gels
Monophasic hybrid materials, Kinetic control, Sol–gel polymerization, 307
Silver complexes
Copper complexes, Gold complexes, 743
Silver complexes
Imidazole, Schiff base, Crystal structures, 2237
Silver(I)
Lanthanides(III), Diethylenetriamine, *N*,*N*-dimethylformamide, Complexes, Thermodynamics, 2427
Silylcupration
α-Aminoacylsilanes, β-Amino alcohols, Lewis acid, Statine analogues, 529
Single crystal structures
Dialkoxo-bridged binuclear Cu(II) complexes, Model of metal–guanine interaction, Thermal decompostion, Theophylline, Diethanolamine(2,2′-iminodiethanol), 457
Singly hydroxo-bridged
Copper(II) complexes, Deprotonated pyridine-2,6-dicarboxamide ligands, Crystal structures, Magnetism, 1423
Sodium ion
Calixcrowns, Caesium ion, Perrhenate ion, Pertechnetate ion, Nuclear reprocessing, 1749
Sol–gel
Aggregation, Tetrasulfophthalocyanines, Monolith, Macrocycle, Silica, 2383
Sol–gel
Alkoxide, Tin, Tin dioxide, β-Diketonate, 2069
Sol–gel matrices
Heteronuclear catalysts, Immobilization, Nanoparticles, 509
Sol-gel
NMR, Hybrid materials, Siloxane, Silicon-29, Oxygen-17, 315
Sol–gel polymerization
Monophasic hybrid materials, Silsesquioxane gels, Kinetic control, 307
Solid state
In situ X-ray diffraction, Intercalation, Layered compounds, Synchrotron radiation, 297
Solubility
Oxygen, Solubilization enthalpy, Solubilization entropy, Cavity, 2457
Solubilization enthalpy
Solubility, Oxygen, Solubilization entropy, Cavity, 2457
Solubilization entropy
Solubility, Oxygen, Solubilization enthalpy, Cavity, 2457
Solution equilibria
Beryllium, Phosphato complexes, ^{31}P NMR spectroscopy, ^{9}Be NMR spectroscopy, Speciation, 1043
Solution equilibria
Ciprofloxacin, Iron(III), Surfactants, 1085
Solution equilibria
Tin(II), Phosphato complexes, Speciation, 2403
Solution equilibrium
Mixed-ligand complexes, Hydroxamic acid, Copper(II), nickel(II) and zinc(II) complexes, 1727
Solvatochromism
Dithiolene, Nickel, Dinuclear complexes, Acid–base, Carbon disulfide, 1283
Solvent-derived ancillary ligands
Dicopper complexes, Acid–base congeners, 1909
Solvothermal synthesis
Crystal structures, Oxomolybdenum(V) coordination compounds, Mo(V, VI) compounds, Alkyl-substituted pyridines, 1407
Solvothermal synthesis
Polytelluride, Iron telluride, Iron cluster, Iron carbonyl, Carbonyl clusters, 1995
Speciation
Beryllium, Phosphato complexes, Solution equilibria, ^{31}P NMR spectroscopy, ^{9}Be NMR spectroscopy, 1043
Speciation
Oxovanadium(IV) complexes, Pyridinecarboxylic acids, pH-metry, Spectral studies, 55
Speciation
Tin(II), Phosphato complexes, Solution equilibria, 2403
Spectral data
Transition metal complexes, Terephthalate ions, Aromatic diamines, Crystal structures, 1415
Spectral studies
Oxovanadium(IV) complexes, Pyridinecarboxylic acids, pH-metry, Speciation, 55
Spectroelectrochemical studies
Synthesis, Semiquinone, Ruthenium, Redox, 2605
Spectrophotometry
Yttrium, Rare earth elements, Hydrolysis, Enthalpy, Ionic strength, 99
Spectroscopic analysis
Rhodium(II) complexes, Rhodium(II) carboxylates, Rhodium sulfosalicylate, Thermogravimetric analysis, Anticancer drugs, 1305
Spectroscopic properties
Diclofenac, Metal(II) compounds, Thermal properties, 2515

Spectroscopic properties
Sulfamethizole, Metal complexes, Crystal structures, 1859
Spectroscopic properties
Zinc complexes, Cobalt complex, α-Ketoglutaric acid, Thiosemicarbazones, Crystal structures, 1895
Spectroscopic studies
Ni(II) complexes, Tripodal ligand, Crystal structures, 2661
Spectroscopic study
Cobalt(III) complex, Thiocarbamylpyrazole, X-ray crystal structure, 2651
Spectroscopy
Palladium(II) complexes, Metallocycles, Aminophosphate complexes, Antitumour activity, 937
Spin crossover
Schiff bases, Cobalt complexes, Photosensitive ligands, LD-LISC effect, 1643
Spin triplet
Crystal structures, Cu dimers, Di-(2-pyridyl)ketone, Ferromagnetic dimers, Magnetic properties, 1005
Spirophosphorane ring-opening
Phosphite diolato(1 −) ligand, Crystal structures, 2667
Stability constant
N′-2-Pyridylmethyl derivatives, *N*′-2-Hydroxypropyl derivatives, 2027
Stability constants
Copper(II) complexes, Deltakephalins, 241
Stability constants
Effortil, Cu(II) complexes, Structures, EPR, Magnetochemical data, 1843
Stability constants
Imidazole derivatives, Transition metal complexes, Crystal structure, Absorption spectra, 2183
Stability constants
Potentiometry, Equilibria, Manganese(II), Cobalt(II), Nickel(II) complexes, Aminopolyphosphonates, UV–VIS spectra, 2083
Stability constants
Tetraazamacrocyclic ligand, Transition metal, Synthesis, Structural characterization, DNA cleavage activities, 1527
Statine analogues
α-Aminoacylsilanes, β-Amino alcohols, Lewis acid, Silylcupration, 529
Stereochemistry
Copper(II)–edta-type complexes, Crystal structures, 1
Stereodivergent
Alkenylsilanes, Hydrosilylation, $RhI(PPh_3)_3$, Polyaddition, 567
Stereoselectivity
π-Allyl complexes, Allylic substitutions, Iridium, Regioselectivity, Phosphites, 557
Stopped-flow
Me_2Octaen, Polyamines, Nickel(II), Equilibria, Kinetics, 2507
Streptonigrin
2,2′-Bipyridyl, 6,6′-Dicarboxy-2,2′-bipyridyl, Antitumour, Zinc, 1067
Strong near-IR absorption
Crystal structures, Cyclic voltammetry, Nickel bisdithiolenes, 425
Strontium
Polyamine ligand, Thd ligand, Precursor, 2547
Structural characterization
Tetraazamacrocyclic ligand, Transition metal, Synthesis, Stability constants, DNA cleavage activities, 1527
Structural characterization
Transition metals, Synthesis, Antitumor activity, 217
Structure
Cu(II) complex, Triaminoguanidinium-(2 +) ion, 1737
Structure
Cymene, Nitration, Pyrazolyl, Ruthenium, Synthesis, 475
Structure
Magnesium, Aryloxide, Adduct, 2557
Structure
Planar chiral, Indenyl, Yttrium, Lanthanum, Tetrahydroborate, 1955
Structure
Ruthenium, Phenolic ligands, Synthesis, Redox properties, 1663
Structure
Ruthenium, Phenolic ligands, Synthesis, Redox properties, 1673
Structures
Cryoscopy, Cyanocuprates, Ionic, Reactivity, 553
Structures
Effortil, Cu(II) complexes, Stability constants, EPR, Magnetochemical data, 1843
Structures
Heteroscorpionate tris(3-*R*-pyrazolyl)borate cobalt(II) complexes, NMR, 2119
Structures
Lead(II), Aspartate, 649
Structures
Osmium, Triphenylphosphine, 2-(Phenylazo)pyridine, Synthesis, Reactivities, 1227
Structures
Pyriding N-oxides, Metal complexes, Hydrogenation, 835
Substituted cobalt phthalocyanines
Redox properties, Hammett parameters, Frontier orbitals, Disulfide reduction, 2255
Substitution
Kinetics, Mechanism, *cis*-Diaquabis(2,2′-bipirydyl)chromium(III), Octacyanomolybdate(IV), Octacyanotungstate(IV), 2225
Sulfamethizole
Metal complexes, Crystal structures, Spectroscopic properties, 1859
Sulfamides
Cadmium complexes, Mercury complexes, X-ray structure, Zinc complexes, 991
Sulfane
Heck reactions, Palladium, Phosphane, Ligands, Mechanism, 517
Sulfated zirconia
Tetragonal zirconia stabilization, Rietveld method, Zirconium sulfide, Zirconium oxide sulfide, Thermogravimetry of sol–gel ZrO_2, 2283
Sulfimides
Complexes, Platinum, Hydrogen bonding, 2077
Sulfoxide
Platinum(II), *N*,*N*-Dialkyl-*N*′-(3-*R*-benzoyl)thiourea, Acylthiourea, NMR, Chemotherapeutic agents, 1347
Sulfur
Iron, Selenium, Synthesis, Reaction, 713
Sulfur macrocycles
Selenoether, Telluroether, Chromium, Molybdenum, Tungsten, 1373
Sulfur
Rhenium, Metal clusters, Selenium, Tellurium, Crystal structures, 437
Supercritical conditions
Carbon dioxide, Dimethyl carbonate, Homogeneous catalysis, Mechanism, 573
Supramolecular chemistry
Helical structures, Transition metals, X-ray crystal structures, 23
Supramolecules
Rigid and flexible ligands, Self-assembly, X-ray structure, 1117
Surface chemistry
Photochemistry, Photochemical metal organic deposition, Lithography, Gold, 343
Surface modification
Indium tin oxide, Alkoxides, Interfaces, 505
Surfactants
Ciprofloxacin, Iron(III), Solution equilibria, 1085
Symmetrical complexes
Cadmium(II) complexes, Schiff-base ligands, Asymmetrical complexes, Heptadentate ligands, 1633
Synchrotron radiation
In situ X-ray diffraction, Intercalation, Layered compounds, Solid state, 297
Synchrotron radiation
11-Membered metallocyclic ring, Metallocalix[6]arene, 2657
Syntheses
Crystal structures, Cobalt(II) complex, Nickel(II) complex, 4-(*p*-Methylphenyl)-3,5-bis(pyridin-2-yl)-1,2,4-triazole, ES-IMS, 2019
Syntheses
Electrochemical studies, Heterodinuclear complexes, Homodinuclear complexes, Luminescence properties, Osmium(II) complexes, Ruthenium(II) complexes, 1233
Synthesis
Crystal structure, Aryloxide, Neodymium, Anion–cation pair compound, 2243
Synthesis
Crystal structures, Macrocyclic polyamine ligand, Manganese complexes, Octa- and hepta-coordination, 2095

Synthesis
Cymene, Nitration, Pyrazolyl, Ruthenium, Structure, 475
Synthesis
EXAFS investigation, Azomethynic copper metallochelates, 2361
Synthesis
Iron, Selenium, Sulfur, Reaction, 713
Synthesis
Macrocycles, Complexes, Equilibria, 2501
Synthesis
Molybdenum, Nitrides, Alkoxides, X-ray structures, NMR fluxionality, Pseudorotation, 1363
Synthesis
Nickel(II) piperidinedithiocarbamate complexes, X-ray structure, 1713
Synthesis
Organophosphoryl polyoxotungstate, Polyoxometalate, ^{183}W NMR, 125
Synthesis
Osmium, Triphenylphosphine, 2-(Phenylazo)pyridine, Structures, Reactivities, 1227
Synthesis
Platinum complexes, 3-methylpiperidine, Dicarboxylates, Crystal structures, 983
Synthesis
Platinum(II) complexes, Piperidine, Crystal structures, 975
Synthesis
Ruthenium, Phenolic ligands, Structure, Redox properties, 1663
Synthesis
Ruthenium, Phenolic ligands, Structure, Redox properties, 1673
Synthesis
Semiquinone, Ruthenium, Spectroelectrochemical studies, Redox, 2605
Synthesis
Tetraazamacrocyclic ligand, Transition metal, Structural characterization, Stability constants, DNA cleavage activities, 1527
Synthesis
Tetrathiometalate, Nonlinear optical properties, Copper compounds, Crystal structures, Dppm, 1545
Synthesis
Transition metals, Structural characterization, Antitumor activity, 217

tachpyr
Cd(II), Hg(II), Torsion angles, Twist angles, Zn(II), 1155
Tantalum
Molybdenum, Trimetallic alkoxides, Crystal structures, 1791
Tantalum
Titanium, Nobium, Aryloxide, Bisphenol, Hydrogenation, 35
TCNE complexes
Hush theory, Iron complexes, Mixed valence, TCNQ complexes, 137
TCNQ complexes
Hush theory, Iron complexes, Mixed valence, TCNE complexes, 137
Tellurium
Palladium, Platinum, Selenium, 751
Tellurium
Rhenium, Metal clusters, Sulfur, Selenium, Crystal structures, 437
Tellurium-rich compounds
Cluster compounds, Molybdenum complexes, De-tellurium reaction, Crystal structures, 925
Telluroether
Selenoether, Sulfur macrocycles, Chromium, Molybdenum, Tungsten, 1373
Temperature effects
Equilibrium, Copper, Mixed valence, Disproportionation, 2289
Template reaction
Tetra-aza ligands, CP-MAS NMR, Nickel complex, 2149
Terephthalate ions
Transition metal complexes, Aromatic diamines, Crystal structures, Spectral data, 1415
Ternary complexes
Divalent metals, Zinc, Copper, Benzolamide, Diethylenetriamine, 725
Ternary copper(II) complexes
CT photochemistry, Diselenocarbamate and dithiophosphate ligands, 2177
Terpenoids
1,5-diene, Cross coupling, Carboalumination, Palladium, 591
2,2′,6′,2″-Terpyridine
2,2′-Bipyridine, 1,8-Bis(dimethylamino)-naphthalene, Boron-11 NMR, Chelated fluoroboron cations, Fast atom bombardment mass spectrometry, Fluorine-19 NMR, 1,10-Phenanthroline, 165
Terpyridine
Ruthenium, Polypyridine, Electrocatalytic oxidation, Alcohol oxidation, Isomerization, 1049
Terpyridine
Vanadium, Vanadyl, Density functional theory, 69
Tetra-aza ligands
CP-MAS NMR, Nickel complex, Template reaction, 2149
Tetraazamacrocyclic ligand
Transition metal, Synthesis, Structural characterization, Stability constants, DNA cleavage activities, 1527
Tetrachlorometallate anions
Palladium, Diethyldithiocarbamate, Diphosphines, X-ray crystal structures, 1511
Tetradentate Schiff base ligands
Dichloromanganese(IV) complexes, Bidentate Schiff base ligands, Crystal structures, Photosystem II, 2039
Tetragonal zirconia stabilization
Sulfated zirconia, Rietveld method, Zirconium sulfide, Zirconium oxide sulfide, Thermogravimetry of sol–gel ZrO_2, 2283
Tetrahedral coordination
Disulfides, Thioureides, Dithiocarbamates, 1279
Tetrahydroborate
Planar chiral, Structure, Indenyl, Yttrium, Lanthanum, 1955
2,3,5,6-Tetrakis(α-pyridyl)pyrazine
Insertion reactions, Platinum(II) complexes, Platinum–tin bimetallics, 739
Tetraphenylimidophosphinate ligand
Uranium, Thorium, Coordination compounds, X-ray crystal structures, 1699
Tetraphosphine complexes
Crystal structures, Palladium complexes, Platinum complexes, Diphosphine complexes, Bimetallic complexes, 913
Tetrasulfophthalocyanines
Sol–gel, Aggregation, Monolith, Macrocycle, Silica, 2383
Tetrathiometalate
Nonlinear optical properties, Synthesis, Copper compounds, Crystal structures, Dppm, 1545
TG
Crystal structures, Lanthanide complexes, Picrate, 4-Methylmorpholine, *N*-Oxide, DSC, 2313
TG-DTA
Oxovanadium(IV) complexes, *N*,*N*′-Ethylenebis(amino acid), 1311
Thd ligand
Strontium, Polyamine ligand, Precursor, 2547
Theophylline
Dialkoxo-bridged binuclear Cu(II) complexes, Model of metal–guanine interaction, Single crystal structures, Thermal decompostion, Diethanolamine(2,2′-iminodiethanol), 457
Thermal analysis
Colloids, Bimetallic films, FT-IR, Conductivity, 2337
Thermal behavior
Vanadium complexes, Quinic acid complexes, IR spectra, Raman spectra, Potentiometric titrations, 2613
Thermal decompostion
Dialkoxo-bridged binuclear Cu(II) complexes, Model of metal–guanine interaction, Single crystal structures, Theophylline, Diethanolamine(2,2′-iminodiethanol), 457
Thermal properties
Diclofenac, Metal(II) compounds, Spectroscopic properties, 2515
Thermal properties
Iron(III), Chromium(III), DTPA, Complexes, Thermodynamics, 2421
Thermal properties
1,3-propylenediaminetetraacetate, Cu(II) complexes, Mn(II) complexes, Crystal structures, Magnetic properties, 1175
Thermal stability
N-(Carbamoylmethyl)iminodiacetic acid, *N*-(2-Amidomethyl)-iminodiacetic acid, *N*-(2-Acetamide)-iminodiacetic acid, *cis*-Diaqua(*N*-carbamoylmethyl-iminodiacetato)nickel(II), Molecular and crystal structure, Magnetic and spectral properties, 2463

Thermochromism
Nickel(II)selenocyanate, Bis(3-aminopropyl)amine, (2-Aminoethyl)(3-aminopropyl)amine, Bis(2-aminoethyl)methylamine, 1903
Thermodynamic quantities
Equilibrium constants, Molybenum(VI) cations, 907
Thermodynamics
Iron(III), Chromium(III), DTPA, Complexes, Thermal properties, 2421
Thermodynamics
Lanthanides(III), Silver(I), Diethylenetriamine, *N*,*N*-dimethylformamide, Complexes, 2427
Thermodynamics of complexation
Dioxygen carriers, Dioxygen binding, Cobalt, Polynuclear complexes, Polyamines, 2441
Thermogravimetric analysis
Rhodium(II) complexes, Rhodium(II) carboxylates, Rhodium sulfosalicylate, Spectroscopic analysis, Anticancer drugs, 1305
Thermogravimetry of sol–gel ZrO_2
Sulfated zirconia, Tetragonal zirconia stabilization, Rietveld method, Zirconium sulfide, Zirconium oxide sulfide, 2283
Thiiranes
Dihydrodithiins, Tungsten carbonyls, 521
Thioacetal
Titanocene(II), Ring-closing metathesis, Intramolecular carbonyl olefination, Cycloalkenes, Heterocyclic compounds, 593
Thiocarbamylpyrazole
Cobalt(III) complex, Spectroscopic study, X-ray crystal structure, 2651
Thiocyanante
Mercury, Clusters, Host–guest chemistry, 871
Thiocyanate
Cobalt, 2-Hydroxyacetophenone, Azide, Crystal structure, 2707
Thiocyanogen
Pseudohalogens, Selenocyanogen, 681
Thioether
Bismuth, Coordination polymers, Crystal structures, Electrospray, 849
Thiolate-bridged complexes
Mixed-valence, Electron-transfer, Iron, 2679
Thiolate complexes
Palladium, Platinum, Allyl complexes, 1627
Thiolate
Electrochemistry, Macrocycle, Crystal structures, 1887
Thiolates
Oxo ligands, Titanium, Trimers, 1139
Thiophenes
Cyclic oligomers, Ferrocenes, 291
Thiophenoxyacetate
Bis(η-cyclopentadienyl)titanium(IV), Crystal structures, Diphenylphosphinoacetate, Heterometallics, Nicotinate, 757
Thiophosphoryl guanidines
Platinum complexes, Crystal structures, 809
Thiopyrimidine
Rhenium(V) complexes, Rhenium(III) complexes, Cyclic voltammetry, UV–Vis–NIR, IR, ^{1}H NMR spectra, 2163
Thiosemicarbazone
Isatin, Crystal structures, Zinc, Lead, Hexamethyleneimine, Metal(II) complexes, 1255
Thiosemicarbazone
2-Pyridineformamide, Crystal structures, Cadmium halides, 1873
Thiosemicarbazones
Electrochemistry, Iron complexes, EPR of iron complexes, Nickel complexes, Cobalt complexes, 2059
Thiosemicarbazones
Macrocyclic ligands, Electrochemistry, Copper complexes, Dithio-Schiff base complexes, 441
Thiosemicarbazones
Zinc complexes, Cobalt complex, α-Ketoglutaric acid, Crystal structures, Spectroscopic properties, 1895
Thioureides
Disulfides, Dithiocarbamates, Tetrahedral coordination, 1279
Thiuram sulfides
Copper and iron species, Dithiocarbamate derivatives, 2269
Thorium(IV)
Uranium(IV), Dicarboxylate complexes, CPMAS ^{13}C NMR spectroscopy, X-ray crystallography, 1757
Thorium
Uranium, Coordination compounds, Tetraphenylimidophosphinate ligand, X-ray crystal structures, 1699
Tin
Alkoxide, Tin dioxide, Sol–gel, β-Diketonate, 2069
Tin dioxide
Alkoxide, Tin, Sol–gel, β-Diketonate, 2069
Tin(II)
Phosphato complexes, Solution equilibria, Speciation, 2403
Tin(IV)
Crystal structures, 2-Ethyl-3-hydroxy-4-pyranonate, Ethylmaltol, 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate, Titanium(IV), 399
Titanium
Additions, Alkylation, Insertions, Nucleophilic, Schiff bases, 177
Titanium
Alkynes, Functionalized metalloalkynes, Olefins, Polymetallated olefins, 563
Titanium
C–H activation, Intramolecular bonds, Metallacycles, Allenes, Carbometalation, 879
Titanium(IV)
Crystal structures, 2-Ethyl-3-hydroxy-4-pyranonate, Ethylmaltol, 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate, Tin(IV), 399
Titanium(IV)
Hydroborates, Lithium, Bonding, Crystal structures, 1579
Titanium(IV)
Silica, Ruthenium, Osmium, 2277
Titanium
Oxo ligands, Thiolates, Trimers, 1139
Titanium
Tantalum, Nobium, Aryloxide, Bisphenol, Hydrogenation, 35
Titanocene(II)
Thioacetal, Ring-closing metathesis, Intramolecular carbonyl olefination, Cycloalkenes, Heterocyclic compounds, 593
Torsion angles
Cd(II), Hg(II), tachpyr, Twist angles, Zn(II), 1155
Tosylamide complexes
Electrochemical synthesis, Cobalt(II) complexes, Crystal structures, 1607
trans-Dioxo Re(V) complexes
Rhenium, Re complexes, Re(I), Phosphines, dppm, 2249
Trans-influence
Palladium(II) complexes, Mixed donor ligands, X-ray crystallography, Methylaluminoxane (MAO), Norbornene, Polymerization, 1601
Transition metal aroylhydrazone complexes
Diazafluorenone aroylhydrazone, Crystal structures, Enolization, ^{1}H NMR spectroscopy, IR, 1295
Transition metal complexes
Electronic spectral data, Oximes, Benzil-α-monoxime, 1687
Transition metal complexes
Imidazole derivatives, Crystal structure, Absorption spectra, Stability constants, 2183
Transition metal complexes
Terephthalate ions, Aromatic diamines, Crystal structures, Spectral data, 1415
Transition metal ions
Disulfide, Peptides, 1849
Transition metal ions
Macrocyclic polyether 18-crown-6, Acetonitrile, Alkaline earth metal ions, 1681
Transition metals
Helical structures, Supramolecular chemistry, X-ray crystal structures, 23
Transition metals
Synthesis, Structural characterization, Antitumor activity, 217
Transition metal
Tetraazamacrocyclic ligand, Synthesis, Structural characterization, Stability constants, DNA cleavage activities, 1527
Triaminoguanidinium(2 +) ion
Cu(II) complex, Structure, 1737
1,2,4-Triazolo-[1,5α]-pyrimidine
Zn(II) complexes, ^{15}N NMR, HETCOR, CPMAS, 965
Trichloroacetate
Copper(II), 1,4-Diazacycloheptane, Crystal structures, 1881
Trichlorovinyl
Mercury(II), Crystal structures, Complexes, Bidentate ligands, 2539

Tridentate chelate
Lanthanide complex, Europium(III) chloride, 2135
Trienes
Cycloadditions, Dienes, Indium, Magnesium, 533
Trifluoroacetate
Dirhodium(II) compounds, One-dimensional polymers, Arene coordination, π-Complexes, Crystal structures, 1829
Trigonal planar anions
Copper(I) thiocyanate complexes, Methyl nicotinates, Ethyl nicotinates, Ethyl isonicotinate complexes, Crystal structures, 615
Trimers
Oxo ligands, Thiolates, Titanium, 1139
Trimetallic alkoxides
Molybdenum, Tantalum, Crystal structures, 1791
Trimetallic complexes
Molybdenum(II), Tungsten(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Triphenylphosphine
Copper(I,II) complexes, α,β-Unsaturated carboxylates, Magnetic properties, Crystal structures, 891
Triphenylphosphine
Mercury(II) complexes, Benzothiazole-2-thione, pyrimidine-2-thione, Crystal structures, 2231
Triphenylphosphine
Osmium, 2-(Phenylazo)pyridine, Synthesis, Structures, Reactivities, 1227
Tripodal ligand
Ni(II) complexes, Crystal structures, Spectroscopic studies, 2661
Trirhenium(III) clusters
Rhenium clusters, Acetamidate, Dimolybdenum(II), MALDI, Mass spectroscopy, 1245
Tris(2-benzimidazolylmethyl)amine
Chromium(III) complexes, 2-Guanidinobenzimidazole, 2,6-Bis(2-benzimidazolyl)pyridine, 2-(2-Pyridyl)benzimidazole, Crystal structures, 1821
Tris(2-benzimidazolylmethyl)amine
Zinc(II), Cadmium(II), Mercury(II), X-ray diffraction structures, NMR data, 1479
Tris-chelates
Azoimine, Ru–bipyridine, X-ray structures, Electrochemistry, Emission spectra, 1925
Tris(6-methyl-2-pyridylmethyl)amine
Binuclear nickel(II) complex, Binuclear manganese(II) complex, Crystal structures, Magnetic properties, 1559
Tris-pyrazolylborate
Zinc, Crystal structures, Electrochemistry, 109
Trypanosoma cruzi
Ruthenium, Clotrimazole, Ketoconazole, Paramagnetic, Metal complexes, Chagas, 2319
Tungsten analogue
Crystallographic, Selenium, Refluxing, 2127
Tungsten carbonyls
Thiiranes, Dihydrodithiins, 521
Tungsten complexes
Molybdenum complexes, Pyrazine complexes, Peroxo ligands, Crystal structures, 1503
Tungsten(II)
Carboxylate and sulfonate substituted pyridines, Propiolic acid, Water soluble complexes, 2171
Tungsten(II)
Molybdenum(II), Crystal structures, *o*-Phenylenediacetonitrile, Bimetallic complexesw, Trimetallic complexes, Nitrile-bridged complexes, Seven-coordinate complexes, Halocarbonyls, 147
Tungsten(II)
Multimetallic, Cobalt carbonyl complexes, Alkyne complexes, Chain triphos-bridged, 1585
Tungsten
meso-2,3-dimercaptosuccinic acid, Multinuclear NMR, 193
Tungsten pentacarbonyl complexes
Mononuclear, 1,4-Bipyridine, 1,2-Bis(4-pyridyl)ethane, 1621
Tungsten
Selenoether, Telluroether, Sulfur macrocycles, Chromium, Molybdenum, 1373
Tungsten(VI)
Binaphtholato complexes, X-ray structures, 2579
Twist angles
Cd(II), Hg(II), tachpyr, Torsion angles, Zn(II), 1155
Two-centre transitions
Infrared spectroscopy, Raman spectroscopy, Electronic absorption spectroscopy, Crystal structures, Hypophosphite complexes, Cooperative vibronic transitions, 863
Two-coordinate gold complex.
Bulky phosphine, X-ray structure, Cone angle, 2211

α,β-Unsaturated carboxylates
Copper(I,II) complexes, Triphenylphosphine, Magnetic properties, Crystal structures, 891
Uracil
Crystal structures, Nickel complexes, Copper complexes, Schiff bases, 689
Uranium(IV)
Thorium(IV), Dicarboxylate complexes, CPMAS ^{13}C NMR spectroscopy, X-ray crystallography, 1757
Uranium
Thorium, Coordination compounds, Tetraphenylimidophosphinate ligand, X-ray crystal structures, 1699
Uranium
Uranyl, Phosphate, Crown, Crystal structures, 1551
Uranyl bis(2-hydroxybenzaldehyde)
Fourier transform infrared and Raman spectra, Force constants, 2353
Uranyl
Uranium, Phosphate, Crown, Crystal structures, 1551
Uridine
Copper(II), Diamines, Uridine 5′-monophosphate, 1145
Uridine 5′-monophosphate
Copper(II), Diamines, Uridine, 1145
UV–Vis–NIR, IR, ^1H NMR spectra
Thiopyrimidine, Rhenium(V) complexes, Rhenium(III) complexes, Cyclic voltammetry, 2163
UV–VIS spectra
Potentiometry, Equilibria, Stability constants, Manganese(II), Cobalt(II), Nickel(II) complexes, Aminopolyphosphonates, 2083
UV–Vis spectroscopy
meso-2,3-Dimercaptosuccinic acid, Potentiometry, Formation constants, Ionization constants, Kinetic measurements, 2435
UV–Vis spectroscopy
Vanadium, Molybdenum, Heteropolyoxometalate, IR spectroscopy, EPR spectroscopy, 1917

Vanadium complexes
Quinic acid complexes, IR spectra, Raman spectra, Thermal behavior, Potentiometric titrations, 2613
Vanadium(IV)
Dithiocarboxylate, Magnetism, EPR, Infrared, Coordination, 2155
Vanadium
Molybdenum, Heteropolyoxometalate, IR spectroscopy, UV–Vis spectroscopy, EPR spectroscopy, 1917
Vanadium
Vanadyl, Terpyridine, Density functional theory, 69
Vanadyl
Vanadium, Terpyridine, Density functional theory, 69
Vibrational spectra
Copper(I) complexes, Crystal structures, Electronic spectra, Emission spectra, Pyrazine carboxamide complexes, 601
Vinylsilanes
Hydroboration, Polysilazanes, Precursors, Chloroboranes, 323
VO(IV) complexes
Biospeciation, Al(III) complexes, Insulin-mimetics, 2389
Volatility
Scandium, Alkoxides, Crystal structures, 705
Voltammetry
Platinum(II), Platinum(IV), Bromide, Porphyrins, Electrochemistry, 1057

Water gas shift reaction
Nitrobenzene catalytic reduction, Rhodium complexes, 2-picoline, 487

Water soluble complexes
Tungsten(II), Carboxylate and sulfonate substituted pyridines, Propiolic acid, 2171
Water-soluble phosphines
Phosphino amino acid salts, Disodium or dipotassium 1,3-di(carboxylatomethyl)-5-aryl-1,3,5-diazaphosphorinanes, 1455
^{183}W NMR
Organophosphoryl polyoxotungstate, Polyoxometalate, Synthesis, 125

XAFS spectroscopy
Iron carbonyl halides, NMR, Halogen exchange reactions, Matrix isolation, 1493
X-ray crystallography
Cobalt(II), Cyanamidonitrate, Electronic spectra, Imidazole ligands, IR spectra, Nickel(II), 1021
X-ray crystallography
15-Crown-5 complexes, Liquid clathrates, Oxonium ion, 85
X-ray crystallography
Palladium(II) complexes, Mixed donor ligands, *Trans*-influence, Methylaluminoxane (MAO), Norbornene, Polymerization, 1601
X-ray crystallography
Palladium(II) complexes, Platinum(II) complexes, Chloride metathesis, Heterodifunctional ligands, 695
X-ray crystallography
Thorium(IV), Uranium(IV), Dicarboxylate complexes, CPMAS ^{13}C NMR spectroscopy, 1757
X-ray crystal structure
Cobalt(III) complex, Thiocarbamylpyrazole, Spectroscopic study, 2651
X-ray crystal structures
Europium compounds, Hydrotris(pyrazolyl)borate ligands, Luminescence studies, 1707
X-ray crystal structures
Helical structures, Supramolecular chemistry, Transition metals, 23
X-ray crystal structures
N-salicylidenearoylhydrazine copper(II) complexes, Copper(II) imidazole ternary complexes, Copper(II) imidazolate ternary complexes, Molecular structures, Magnetic properties, Infrared spectra, 1181
X-ray crystal structures
N-salicylidenearoylhydrazines, Copper(II) complexes, Molecular structures, Magnetic properties, Infrared spectra, 949
X-ray crystal structures
Palladium, Diethyldithiocarbamate, Diphosphines, Tetrachlorometallate anions, 1511
X-ray crystal structures
Ruthenium, Phosphates, 801
X-ray crystal structures
Uranium, Thorium, Coordination compounds, Tetraphenylimidophosphinate ligand, 1699
X-ray data
Lanthanide, Carbacylamidophosphate, NMR, 2203
X-ray diffraction
Magnesia, Dolomite, Crystallite size, Degree of agglomeration, SEM, 2345
X-ray diffraction structures
Zinc(II), Cadmium(II), Mercury(II), Tris-(2-benzimidazolylmethyl)amine, NMR data, 1479
X-ray
Platinum, Gold, Cross-coupling, Diyne, 2261
X-ray structure analyses
Chiral-at-metal complexes, Configurational stability, Epimerisation, Equilibria, 1519
X-ray structure
α,α′-Bis(pyrazolyl)-*m*-xylene, Copper(II) complexes, Network structures, Absorption spectroscopy, Electron spin resonance, 719
X-ray structure
Bulky phosphine, Cone angle, Two-coordinate gold complex, 2211
X-ray structure
Cadmium complexes, Mercury complexes, Sulfamides, Zinc complexes, 991
X-ray structure
Calcium, H-bonding, Inorganic Polymers, Alkaline Earth, 1783
X-ray structure
Nickel(II) piperidinedithiocarbamate complexes, Synthesis, 1713
X-ray structure
Organotin(IV), Poly(pyrazol-1-yl)alkanes, 381
X-ray structure
Organotin(IV), Poly(triazol-1-yl)alkanes, 1949
X-ray structure
Phosphoranes, Pentacoordination, Hydrogen bonding, 63
X-ray structure
Polyoxometalate, Oxyhalide, Molybdenum, High acidity, 43
X-ray structure
Rigid and flexible ligands, Self-assembly, Supramolecules, 1117
X-ray structures
Azoimine, Ru–bipyridine, Tris-chelates, Electrochemistry, Emission spectra, 1925
X-ray structures
Binaphtholato complexes, Tungsten(VI), 2579
X-ray structure
Schiff bases, Copper complexes, 5-Phenylazosalicylaldehyde, Cyclic voltammetry, 607
X-ray structures
Dinucleating alkoxide ligands, Copper(II) complexes, Hetero-bridged complexes, Magnetism, Magneto-structural trends, 1429
X-ray structures
Dithiolate complexes, Ruthenium, Osmium, 1073
X-ray structures
Lanthanides, Phosphine oxides, 2697
X-ray structures
Molybdenum, Nitrides, Alkoxides, Synthesis, NMR fluxionality, Pseudorotation, 1363
X-ray structures
Naphthylazoimidazoles, Platinum(II), PtN_4 coordination, Electrochemistry, 1263
X-ray structures
Osmium, Ditelluroether, 235
X-ray structures
Osmium, Metallation, 1081
X-ray structures
Pentafluoro-cyclotriphosphazene, Pentachloro-cyclotriphosphazene, Electrospray mass spectrometry, 2101
X-ray structures
Pyridine *N*-oxide ligands, Cobalt(II) complexes, Zinc(II) complexes, Magnetic susceptibility, 2195
X-ray structures
Rhenium, Nitrido complexes, Imido complexes, EPR spectroscopy, 1741
X-ray structures
Schiff base complexes, *N*-Salicylidene derivatives, Zn(II) complexes, 673

Ytterbium(III)
Lanthanides, Calixarenes, Homoazacalixarenes, Crystal structure, 2673
Yttrium
Planar chiral, Structure, Indenyl, Lanthanum, Tetrahydroborate, 1955
Yttrium
Rare earth elements, Hydrolysis, Enthalpy, Ionic strength, Spectrophotometry, 99

Zincates
1,3-dithiole-2-thione-4,5-dithiolates, dmit complexes, Zinc dmit compounds, 821
Zinc
Bis(pyrazolyl)silanes, Crystal structures, Nitrogen-donor ligands, 1815
Zinc complexes
Cadmium complexes, Mercury complexes, Sulfamides, X-ray structure, 991
Zinc complexes
Cobalt complex, α-Ketoglutaric acid, Thiosemicarbazones, Crystal structures, Spectroscopic properties, 1895
Zinc complexes
Lead(II) complexes, Maltol, 3-Hydroxy-4-pyranone, 3-Hydroxy-4-pyridinone, 1,2-Dimethyl, Crystal structures, 129
Zinc
Divalent metals, Copper, Benzolamide, Diethylenetriamine, Ternary complexes, 725
Zinc dmit compounds
1,3-dithiole-2-thione-4,5-dithiolates, dmit complexes, Zincates, 821
Zinc(II)
Binucleating hexa-aza macrocycle, Copper(II), Nickel(II), Cobalt(II), Crystal structures, Phosphotriester, Hydrolysis, 1485

Zinc(II)
Cadmium(II), Mercury(II), Tris(2-benzimidazolylmethyl)amine, X-ray diffraction structures, NMR data, 1479
Zinc(II) complexes
Pyridine *N*-oxide ligands, Cobalt(II) complexes, X-ray structures, Magnetic susceptibility, 2195
Zinc porphyrin complexes
Bridged structures, Crystal structures, Heteronuclear multiple bond coherence, *N*-Tosyl ligands, 413
Zinc
Streptonigrin, 2,2′-Bipyridyl, 6,6′-Dicarboxy-2,2′-bipyridyl, Antitumour, 1067
Zinc
Thiosemicarbazone, Isatin, Crystal structures, Lead, Hexamethyleneimine, Metal(II) complexes, 1255
Zinc
Tris-pyrazolylborate, Crystal structures, Electrochemistry, 109
Zirconium oxide sulfide
Sulfated zirconia, Tetragonal zirconia stabilization, Rietveld method, Zirconium sulfide, Thermogravimetry of sol–gel ZrO_2, 2283
Zirconium sulfide
Sulfated zirconia, Tetragonal zirconia stabilization, Rietveld method, Zirconium oxide sulfide, Thermogravimetry of sol–gel ZrO_2, 2283
Zirconocene
Crystal structures, Catalysis, Olefin polymerizations, 1941
Zn(II)
Cd(II), Hg(II), tachpyr, Torsion angles, Twist angles, 1155
Zn(II) complexes
Schiff base complexes, *N*-Salicylidene derivatives, X-ray structures, 673
Zn(II) complexes
1,2,4-Triazolo-[1,5α]-pyrimidine, ^{15}N NMR, HETCOR, CPMAS, 965
