Abstract

The hexadentate complex $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (**1**) (where 1,3-pdta represents the 1,3-propanediaminetetraacetate ion) has been prepared and isolated and its structure established by X-ray crystallography. The structure converged to $R = 0.030$ for 1537 observed reflections. The Cu(II) ion is surrounded by two nitrogen atoms and four oxygen atoms of the ligand, making a tetragonally elongated octahedron ($T = 0.868$). The Mg cation is bonded octahedrally to six water molecules. Both complex ions utilize a two-fold symmetry axis that is present in the crystal. The conformations of the chelate rings were found to be *envelope* for the glycinates and *skew-boat* for the six-membered diamine (T) ring. Comparison of the structures of the hexadentate copper(II)–edta-type complexes shows an expected variation in their stereochemistry, depending on the structure of the ligand. Infrared (carboxylate region) and electronic absorption spectra are also given. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Copper(II)–edta-type complexes; Crystal structures; Stereochemistry

1. Introduction

Many transition metal ions take a coordination number of six when complexed with the ethylenediaminetetraacetate ion (edta), and such hexadentate $[M(edta)]^{n-}$ complexes are well known: M = Co(III) [1,2], Cr(III) [3], Fe(III) [4,5], Mn(III) [6,7], Zn(II) [8], Cu(II) [8–11], Co(II) [12,13] and Ni(II) [14]. The format for describing the various chelate rings formed in these types of chelates was credited to Weakliem and Hoard [1]. The ethylenediamine ring is referred to as the E ring, the axially coordinated glycinate ring as the R ring, and the equatorially coordinated glycinate ring as the G ring. The G rings in these types of complexes are more strained than the R rings because the sum of the ring angles of the latter is closer to the expected value for a five-membered chelate ring with glycinate. Another ligand displaces a G ring more easily than an R ring [15], and such a complex of $[Cu(H_2edta)(H_2O)]$ (the edta acting as a pentadentate) has been well established [16].

The ethylenediaminetetra-3-propionate ion (edtp), forming four β-alaninate rings, is likely to function as a hexadentate with larger metal ions: M = Co(III) [17], Cr(III) [17], Ni(II) [18] or Rh(III) [19]. Contrary to this, the edtp ligand acts as a pentadentate in the square-pyramidal $[Cu(edtp)]^{2-}$ complex, and this dominant geometry has been verified crystallographically [20]. However, the tetragonal octahedral Cu(II) complexes of some other edta-type ligands that form six-membered rings, such as the favoured *trans*(O_6)-Cu(II) isomers of 1,3-propanediamine-*N*,*N*′-diacetate-*N*,*N*′-di-3-propionate ion (1,3-pddadp) and the Λ-*trans*(O_5)-Cu(II) isomer of the 2*S*,2*S*′-ethylenediamine-*N*,*N*′-disuccinate ion (*SS*-edds), have also been established [21–23].

With respect to $[M(edta)]^{n-}$ [1–14], the in-plane strain is eased for the $[M(1,3\text{-pdta})]^{n-}$ complexes containing an in-plane six-membered diamine (T) ring, as evidenced by their crystal structures [24–27].

This study deals with the preparation of an octahedral hexadentate complex, $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (**1**), for which X-ray data are reported. Structural parameters of this complex and the other tetragonal octahedral Cu(II)–edta-type complexes are compared and discussed in relation to their stereochemistry, the structure of the ligand and the size of its chelate rings. Infrared (IR) and electronic absorption spectral data of the studied complex are also reported.

2. Experimental

All commercially obtained reagent-grade chemicals were used without further purification.

2.1. Preparation of barium(1,3-propanediaminetetraacetate) dihydrate, $Ba_2(1,3\text{-pdta})\cdot 2H_2O$

The barium salt of 1,3-propanediaminetetraacetic acid was prepared according to the procedure of Wayh and Hamm [28], with a minor modification. The condensation mixture of 1,3-propanediamine (15 g, 0.20 mol) and chloroacetic acid (96 g, 0.91 mol) in aqueous KOH solution was prepared; deposited KCl was removed by filtration. A hot solution of $BaCl_2\cdot 2H_2O$ (98 g, 0.40 mol in 200 cm^3 of H_2O) was then added to the mixture, which was stirred (90°C) for 2 h. The white precipitate of $Ba_2(1,3\text{-pdta})\cdot 2H_2O$, which was practically insoluble in water, was filtered, washed with warm water and air-dried ($\approx$100 g).

Found: C, 21.04; H, 2.63; N, 4.53; Ba, 44.74; H_2O, 5.90%. Calc. for $Ba_2(1,3\text{-pdta})\cdot 2H_2O$, $Ba_2C_{11}H_{18}N_2O_{10}$ (FW = 612.93): C, 21.55; H, 2.96; N, 4.57; Ba, 44.81; H_2O, 5.88%.

The barium salt of the ligand was used directly for the preparation of the corresponding hexadentate Cu(II) complex.

2.2. Preparation of magnesium(1,3-propanediaminetetraacetato)cuprate(II) octahydrate, $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (1)

$Cu(SO_4)\cdot 5H_2O$, 7.50 g (0.0300 mol) in 100 cm^3 of H_2O, was stirred at 80°C for 10 min. To this solution, solid $Ba_2(1,3\text{-pdta})\cdot 2H_2O$ (18.39 g, 0.0300 mol) was added and the blue solution (pH $\sim$7) was then stirred at 80°C for 3 h. The deposited $BaSO_4$ was removed by filtration. The obtained filtrate was then poured into a 5×60 cm column containing Dowex 1X8 (200–400 mesh) anion-exchange resin in the Cl^- form. The column was then washed with H_2O and eluted with 0.05 M $MgCl_2$ ($\sim$0.5 cm^3/min). The obtained eluate was reduced to a volume of 150 cm^3 and allowed to stand at room temperature for several days. The crystals of $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ were collected, washed with ethanol, then ether, and air-dried; the yield was 10 g (66%). Found: C, 24.84; H, 4.84; N, 5.04%. Calc. for $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (**1**), $MgCuC_{11}H_{30}N_2O_{16}$ (FW = 534.21): C, 24.73; H, 5.66; N, 5.24%.

2.3. Physical measurements

$Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (**1**): a pale-blue crystal having approximate dimensions of $0.35\times 0.40\times 0.45$ mm, obtained from an aqueous solution, was used for data collection. Intensity measurements were made on a four-circle KM-4 (KUMA Diffraction) diffractometer using graphite monochromated Mo Kα radiation (293°K).

Crystal data: $MgCuC_{11}H_{30}N_2O_{16}$ (F_w = 534.21), orthorhombic, space group *Pnna*, a = 13.264(3), b = 11.711(4), c = 13.684(4) Å, V = 2125.6 Å^3, Z = 4, D_c = 1.669 g cm^{-3}, $F(000)$ = 1116, μ(Mo Kα) = 11.38 cm^{-1}. The cell constants and the orientation matrix were obtained from a least-squares fit of 48 centred reflections with θ in the range 7.7–12.5°. The structure was solved by direct methods using SHELXS-86 [29] and refined by least-squares techniques with SHELXL-93 [30], to $R1 = 0.030$ ($wR2 = 0.079$) for 1537 reflections ($I > 2\sigma(I)$) of 2114 reflections collected in the range $2.14 < \theta < 26.05°$. The intensity data were corrected for Lorentz and polarization effects as well as for absorption. The non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were refined using a riding model with isotropic temperature factors 30% higher than the isotropic equivalent for the atom to which the hydrogen atom was bonded. The function minimized was $\Sigma[w(F_o^2 - F_c^2)^2]$ with $w = 1/[\sigma^2(F_o)^2 + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$, a = 0.0453 and b = 0.46. The final difference map showed minima and maxima ranging from -0.57 to 0.29 e Å^{-3}. A Siemens Stereochemical Workstation was used to prepare drawings [31].

IR spectra were recorded on a JASCO FT/IR-5300 spectrophotometer using KBr pellets. Electronic absorption spectra were recorded on a Varian Cary 17D spectrophotometer. For these measurements 1×10^{-2} M aqueous solutions were used. Electronic reflectance spectra were run on a Varian Cary 2300 spectrophotometer. Elemental microanalyses for carbon, hydrogen, nitrogen and barium were performed by the Microanalytical Laboratory, Faculty of Chemistry, University of Belgrade.

3. Results and discussion

3.1. Description of the crystal structure of $Mg[Cu(1,3\text{-pdta})]\cdot 8H_2O$ (1)

An ORTEP drawing of the complex anion, $[Cu(1,3\text{-pdta})]^{2-}$, is shown in Fig. 1; the numbering scheme adopted for the respective atoms is also given. Bond lengths and valency angles are listed in Table 1.

The structural unit consists of $[Cu(1,3\text{-pdta})]^{2-}$ and $[Mg(H_2O)_6]^{2+}$ octahedra and two water solvent molecules, all of which lie on a special position in the unit cell. The

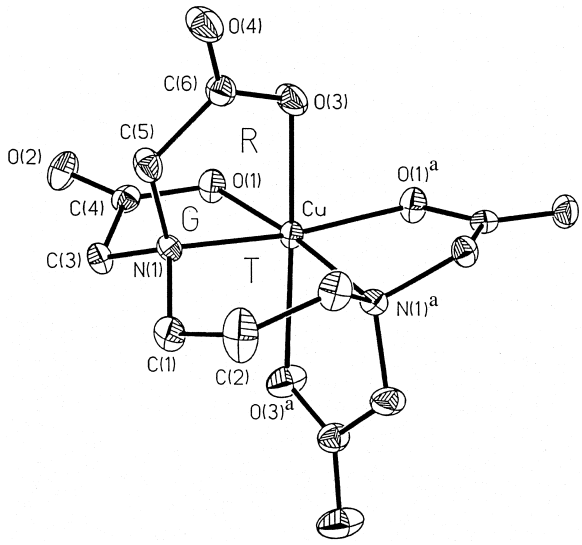

Fig. 1. View of the $[Cu(1,3\text{-pdta})]^{2-}$ octahedron with labelling scheme. Thermal ellipsoids were drawn with 40% probability.

[b] Symmetry codes: $x, -y-0.5, -z+0.5$.

highest symmetry (C_2) axis of the complex passes through the Cu, Mg and C(2) atoms and bisects the N(1)–Cu–N1(1)[a] bond angle, making the two glycinate (R) rings (as well as the G rings) identical. The Cu–O bond distances differ considerably, the equatorial and axial distances being 1.974(2) and 2.272(2) Å, respectively (Table 1). The four basal atoms N(1), N(1)[a], O(1) and O(1)[a] are nearly coplanar and the Cu(II) ion lies in this plane. The *cis* angles at the Cu(II) ion (Table 1) range from 80.2(6) to 96.8(1)° and the *trans* angles are 171.3(1) and 172.4(1)°. The six-membered diamine (T) ring (Fig. 1) adopts a *skew-boat* conformation (λ for the enantiomorph presented in Fig. 1 having Δ configuration). The R rings are nearly planar and are in an *envelope* conformation. The G rings are much more puckered and are halfway between an *envelope* and a *twist* conformation.

An increase of the backbone ring in the complex **1** causes significant changes in equatorial valency angles. We observed widening of N–Cu–N valency angle (96.8(1)°; Table 1) compared with those of hexadentate $[Cu(edta)]^{2-}$ [8–11] (av. 88.5(0.9)°), whereas the equatorial N–Cu–O valency angles in these structures were nearly the same. However, the O–Cu–O angle of complex **1**, 96.2(1)°, was larger than the 90° expected for a regular octahedron, but much less with respect to those of hexadentate Cu(II)–edta complexes (av. 106.7(2.7)°).

$[Cu(1,3\text{-pdta})]^{2-}$ octahedra form discrete units, a phenomenon that is not common either in $[Cu(edta)]^{2-}$ [8–11] or in $[M(1,3\text{-pdta})]^{-}$ complexes [24–27]. The discrete Cu(II) and Mg(II) complex ions are arranged in the unit cell in a very much the same way as in the sodium chloride structure. This packing is determined by an extended network of hydrogen bonds predominantly involving the water molecules coordinated to Mg(II) (acting as donors) and carboxylate oxygens (acting as acceptors).

3.2. Structural parameters correlating stereochemistry of tetragonal octahedral Cu(II)–edta-type complexes

Tetragonal octahedral Cu(II)–edta-type complexes of known structure are listed in Table 2 (complexes **1**–**8**); copper–ligand bond-length data are also given. Within these complexes (oxygen ligands) the variation in R_S is less ($\sim$0.04 Å) than that in R_L ($\sim$0.2 Å) and, as expected [32–35], there is an increase in the value of R_S (not exactly for **1**, **5** and **6**) as T increases. The extent of distortion of these complexes is restricted by the chelation of the multidentate edta-type ligand and depends on its structure. The parameter (T) for listed complexes increases in the order: $\mathbf{2} \le \mathbf{3} < \mathbf{4} < \mathbf{5} < \mathbf{6} < \mathbf{1} < \mathbf{7} < \mathbf{8}$. The tetragonality ($T$) of these complexes increases with the decreasing number of six-membered rings incorporated in the complex (complexes **2**, **3**, **4** and **1**; Table 2). Complexes **2** [21] and **3** [22], containing the 1,3-pddadp ligand and forming three six-membered rings (*trans*(O_6) coordination), are much more elongated and have a tetragonality ($T \sim 0.80$) the same as that obtained for tetragonal octahedral complexes [34,35]. Other complexes listed in Table 2 (complexes **1** and **4**–**8**, *trans*(O_5) coordination) have higher T values of 0.818–0.884 (for oxygen ligands) and 0.902 for **8** (for nitrogen ligands), as was observed for elongated rhombic octahedral complexes [34]. We observed that the variation in tetragonalities of edta complexes (complexes **5**–**7**; Table 2) depends on the packing in their crystal structures and interaction of the axially coordinated carboxylate group involved in the covalent bond with

the counter ion. Generally, the stereochemistry of the copper(II) ion present varies from elongated tetragonal octahedral (complexes **1** and **3**), through elongated rhombic octahedral (complex **2**) to (in approximation) the square-based pyramidal configuration (complexes **4**–**8**) (Table 2).

3.3. Spectral characteristics of the complex

The complex studied (**1**) exhibits one very strong band in an expected IR carboxylate region (at 1601 cm^{-1}) corresponding to the asymmetric stretching vibrations of the five-membered (glycinate) rings. This band shows evidence of separation (the small band at 1693 cm^{-1}) and should be expected to be overlapped by the $\delta(H_2O)$ mode. One strong band of $\nu_s(COO^-)$ at 1404 cm^{-1} was also recorded.

The ligand field absorption spectra are considered only for complexes forming six-membered (T) rings and having the same 5–6–5 combination of the ring members in the G plane (studied complex (**1**) and complexes **2** and **3** of known structures and spectral characteristics [21,22]; Table 3). All blue complexes having C_2 molecular symmetry (in approximately C_2 for **2**) exhibit single unsymmetrical absorption bands. These bands can be assigned to the d_{z^2}, d_{xy}, d_{xz}, $d_{yx} \rightarrow d_{x^2-y^2}$ transitions with a $d_{x^2-y^2}$ ground state. The reflectance spectra of complexes **1**, **2** and **3**, with respect to data taken from solution (Table 3), are only slightly changed and retain almost the same shape and position of the band maxima, suggesting that the geometry of these complexes is the same in both, solution and solid state. In the case of [Cu(1,3-pdta)]$^{2-}$ (**1**), with respect to **2** and **3** (*trans*(O_6) coordination), the stronger axial interaction increases the energy of the d_{z^2} orbital and the energy of the $d_{x^2-y^2}$ orbital would therefore be lowered. The lowering of the energy of the d–d transitions for **1** would be expected and is found (Table 3).

Table 3
Absorption data (solution or solid state) for hexadentate Cu(II)–edta-type complexes forming six-membered diamine rings

Complex	ν ($10^3 \times cm^{-1}$) [a]	ε	Ref.
[Cu(1,3-pdta)]$^{2-}$ (**1**)	14.16 (~14.17)	86	This work
trans(O_6)-[Cu(1,3-pddadp)]$^{2-}$ (**3**)	14.97 (~14.97)	80	[22]
trans(O_6)-[Cu($H_2$1,3-pddadp)] (**2**)	15.97 (~15.97)	54	[21,22]

[a] Data for reflectance spectra are given in parentheses.

Supplementary data

Crystallographic data have been deposited with the CCDC (12 Union Road, Cambridge, CB2 1EZ, UK) and are available on request, quoting deposition number 116779.

Received 6 July 1999; accepted 13 October 1999

Abstract

A monosubstituted decarbonylation reaction was performed on *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)$_2$] (*cis*-NO, *cis*-O) (**A**), *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)$_2$] (*trans*-NO, *cis*-O) (**B**), *cis*-,*cis*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)$_2$] (**C**), *trans*-,*cis*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)$_2$] (**D**) and *cis*-,*trans*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)$_2$] (*cis*-NO, *trans*-O) (**E**) with donor ligand (L) 4-phenylpyridine (ppy), 4-{2-(9-anthryl)vinyl}pyridine (avpy) or triphenylphosphine (PPh_3) to give substituted complex *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**1a**, L = ppy; **2a**, L = avpy; **3a**, L = PPh_3), *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**1b**, L = ppy), *cis*-,*cis*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)L] (**1c**, L = ppy; **2c**, L = avpy), *trans*-,*cis*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)L] (**1d**, L = ppy; **2d** L = avpy) or *cis*-,*trans*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)L] (**1e**, L = ppy). Progressive substitution of the carbonyl ligands of **A** by tributylphosphine (PBu_3) or functionalized pyridine 4-formylpyridine (fpy), 4-ethylpyridine (epy) or 4-dimethylaminopyridine (mapy) gave a centrosymmetric bisubstituted complex *trans*-,*trans*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$L$_2$] (**8a**, L = PBu_3; **9a**, L = fpy; **10a**, L = epy; **11a**, L = mapy) together with the corresponding mono-CO-substituted complex *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**4a**, L = PBu_3; **5a**, L = fpy; **6a**, L = epy; **7a**, L = mapy). The electronic absorption spectra and metal-localized oxidation formal potentials changed significantly for the bisubstituted complexes compared with the monosubstituted ones. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

1-Nitroso-2-naphthol (referred to as 1,2-naphthoquinone-1-oxime, abbreviated as 1-nqoH) was the first organic substance that was found to form precipitates with metal ions [1]. This reagent and its isomer 2-nitroso-1-naphthol (1,2-naphthoquinone-2-oxime, 2-nqoH) have been used extensively for analytical purposes [2,3]. Metal complexes containing these ligands have attracted much attention; however, most of the studies have been concerned with first-row transition metals. It is well documented that direct coordination of first-row transition metal salts with these ligands or their sodium salts gives complexes of M(nqo)$_2$ [4–6] or M(nqo)$_3$ [7,8] type, which normally exist in oligomeric form. Charalambous and coworkers demonstrated that the internal redox reactions of Cu(nqo)$_2$ upon treatment with amine [9] or triphenylphosphine [10] led to the deoxygenation of the 1,2-naphthoquinone-mono-oximato ligands. Cu(nqo)$_2$ can also form adducts with acetone [11] or H_2O [12]. The structural analyses by X-ray crystallography that are available on these adducts reveal an interesting coordination mode in which the 1,2-naphthoquinone-mono-oximato moiety acts as a bidentate ligand and chelates to the central metal atom through the nitroso nitrogen atom and the naphtholic oxygen atom.

Charalambous and his group also demonstrated rhodium, iridium and ruthenium complexes derived from 1,2-naphthoquinone-mono-oxime that were produced through direct coordination of the metal salt with the ligand or its sodium salt [13,14]. Structural analyses of the complexes containing pyridine in their coordination sphere, such as [pyH][Ir(1-nqo)(py)Cl$_3$] [13] and [Ru(1-nqo)$_2$(py)$_2$]·1.5py [14], were available. However, the chemistry of second-row transition metals with these ligands has not been well established. Recently, we demonstrated that the reaction between triruthenium dodecacarbonyl and 1-nqoH or 2-nqoH lead to the mononuclear complexes *cis*-,*cis*- and *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)$_2$] [15] or *cis*-,*cis*- and *trans*-,*cis*-[Ru{η^2-O$C_{10}H_6$N(O)}$_2$(CO)$_2$] [16], respectively. As a continuation of our studies on this type of complex, we document here the progressive carbonyl substitution reaction by

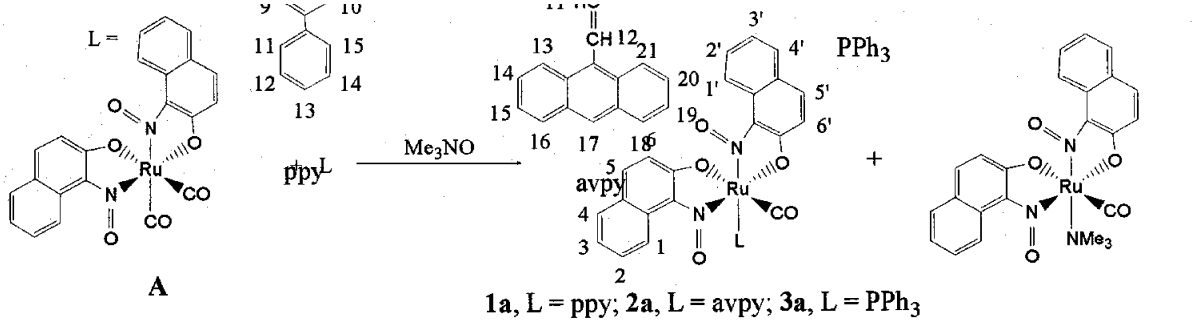
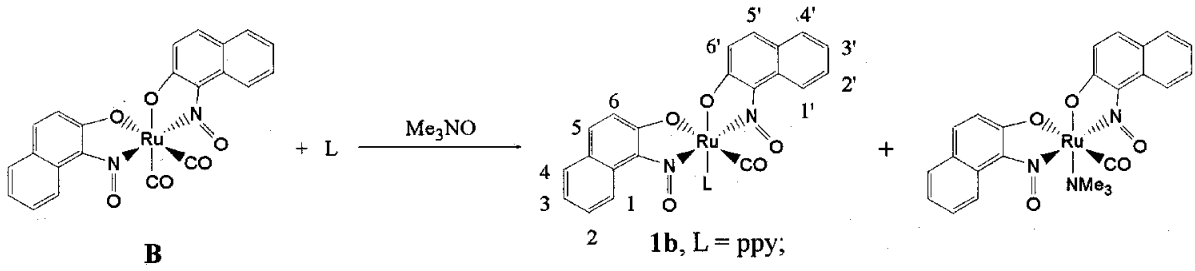
pyridine- and phosphine-type donor ligands in which an unusual structural rearrangement occurs in the bicarbonyl substitution reactions. The properties of some substituted complexes are also investigated by electronic absorption spectroscopy and electrochemical techniques.

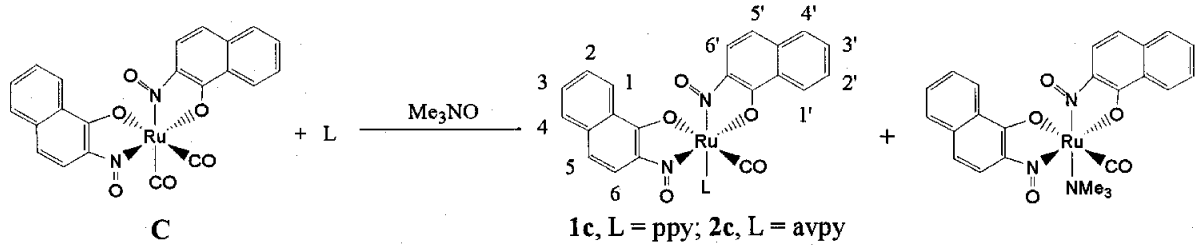
2. Results and discussion



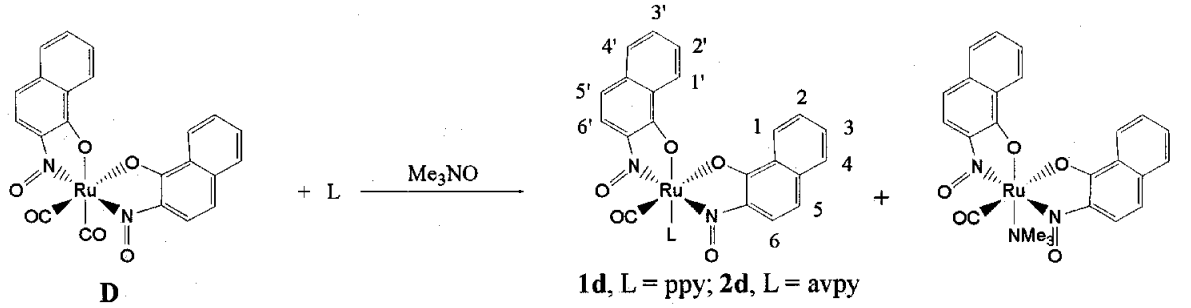
2.1. Monocarbonyl substitution reaction



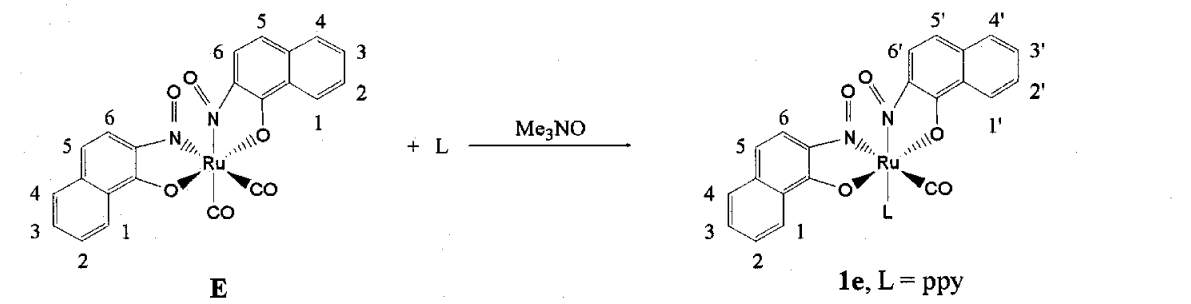
A monocarbonyl substitution reaction of the ruthenium carbonyl complexes derived from 1,2-naphthoquinone-1-oxime, *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$(CO)_2$] (**A**) and *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2(CO)_2$] (**B**) [15], or the complexes derived from 1,2-naphthoquinone-2-oxime, *cis*-,*cis*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2(CO)_2$] (**C**) and *trans*-,*cis*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2(CO)_2$] (**D**) [16], with donor ligand (L) 4-phenylpyridine (ppy) or 4-{2-(9-anthryl)vinyl}pyridine (avpy), respectively, was performed by the addition of trimethylamine *N*-oxide to the reaction mixture at room temperature. The desired complex with one carbonyl substituted by pyridine donor ligand, *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**1a**, L = ppy; **2a**, L = avpy), *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**1b**, L = ppy), *cis*-,*cis*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2$(CO)L] (**1c**, L = ppy; **2c**, L = avpy) or *trans*-,*cis*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2$(CO)L] (**1d**, L = ppy; **2d**, L = avpy), is obtained as the major product with a small amount of NMe_3-substituted complex *cis*-,*cis*- or *trans*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)(NMe_3)] [17]; *cis*-,*cis*- or *trans*-,*cis*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2$(CO)(NMe_3)] [16] is obtained upon thin-layer chromatographic (TLC) separation using CH_2Cl_2–n-hexane as eluent (Scheme 1). Complexes **2a**, **2c** and **2d** are too light sensitive to allow study of their conducting properties, and the CO-substituted complex of **B** by avpy cannot be isolated and characterized because of its instability. When *cis*-,*cis* complexes (**A** or **C**) are used as the starting material, the reaction proceeds through the substitution of a carbonyl *trans* to the oximato group, which demonstrates the strong *trans* influence of this group. Substitution by triphenylphosphine (PPh_3) was also performed on **A** and again the carbonyl *trans* to the oximato group was replaced by donor ligand to give *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)(PPh_3)] (**3a**) as the major product together with a small amount of *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)(NMe_3)] (**12a**).



Reaction of **C** with avpy leads to a new orange compound (**E**) in addition to the carbonyl-substituted products. The chromatographic behaviour of **E** is very similar to that of **C**. Only after repeated TLC separation could we isolate **E** in sufficient purity for characterization. The ^{1}H NMR spectrum of **E** shows no pyridine ring signal but one set of proton signals for the 2-nqo ligands. Its infrared (IR) spectrum shows two strong bands in the region of carbonyl absorption, which is consistent with a *cis*-dicarbonyl arrangement [16]. Single crystal X-ray analysis (see Fig. 6) revealed that **E** is the isomer of **C** and **D** with the formula *cis*-,*trans*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2(CO)_2$]. This isomer could not initially be detected in the reaction of $Ru_3(CO)_{12}$ with 2-nitroso-1-naphthol [16]. The naphtholic groups in **E** are *trans* to each other and both CO groups are also *trans* to oximato groups. We believe that isomer **E** was formed in very small quantity during the reaction of $Ru_3(CO)_{12}$ and 2-nitroso-1-naphthol. However, in the presence of isomer **C**, it is very difficult to separate and purify **E**, but, upon careful substitution of **C** by the pyridine type of nucleophile, the existence of **E** becomes apparent. **E** can also undergo carbonyl substitution by ppy under similar reaction conditions to give *cis*-,*trans*-[Ru{η^2-$OC_{10}H_6$N(O)}$_2$(CO)(ppy)] (**1e**) in which a CO group *trans* to oximato is replaced by ppy (see Fig. 7).



2.2. Bicarbonyl substitution reaction



Higher ligand and Me_3NO to metal ratios and extended reaction time are required to substitute two carbonyl groups by donor ligand (L) tributylphosphine (PBu_3) or *para*-functionalized pyridine 4-formylpyridine (fpy), 4-ethylpyridine (epy) or 4-dimethylaminopyridine (mapy) when using **A** as the starting material. Upon TLC separation, a light purple (when using PBu_3 as donor ligand) or a purple-blue (when using fpy, epy or mapy as donor ligands) complex is obtained together with the reddish-brown monocarbonyl-substituted product *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)L] (**4a–7a**) (**4a**, L = PBu_3; **5a**, L = fpy; **6a**, L = epy; **7a**, L = mapy) and *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$(CO)(NMe_3)] (**12a**) (Scheme 2), in which the donor ligand replaces the carbonyl *trans* to the oximato nitrogen atom as in **1a–3a**. In ^{1}H NMR spectra, the new complex shows one set of donor ligand signals and one set of 1-nqo ligand signals in an integral ratio of 1:1. There is no significant feature in the IR spectra in the region of carbonyl absorption, and the mass-spectrometric (MS) data show that the molecular formula is consistent with the bisubstitution complex *trans*-,*trans*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2L_2$] (**8a**, L = PBu_3; **9a**, L = fpy; **10a**, L = epy; **11a**, L = mapy). X-ray analysis of **8a** (see Fig. 8) confirms that both of the carbonyls in **A** are substituted by phosphine ligands that are *trans* to each other, with the two 1-nqo ligands located in an equatorial coordination plane containing the ruthenium metal centre. Due to the steric effect, both the oximato and naphtholic groups also adopt the *trans* configuration, as in [Cu{η^2-N(O)$C_{10}H_6$O}$_2$]·2$(CH_3)_2$CO [11]. The structure of the molecule is consistent with its ^{1}H NMR and ^{31}P NMR spectroscopic data. The *para*-functionalized pyridine substitution products (**9a–11a**) should have the same ligand spatial orientation since they have very similar ^{1}H NMR spectra for 1-nqo ligands to that of **8a**. For the reaction of **A** with the donor ligand, only mono-CO-substituted complex is detected in the first 24 h of reaction; the bi-CO-substituted complex is detected after 48 h, which indicates that the substitution evolves progressively. We suspect that the ligand rearrange-

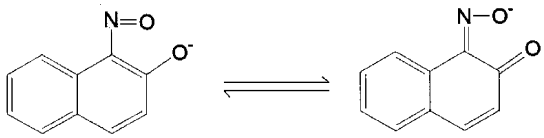
ment takes place in the second CO substitution, rather than first the formation of the *cis*-,*cis*-bisubstituted complex followed by ligand rearrangement.



2.3. Characterization

The IR spectra of monosubstituted complexes show one strong carbonyl band ranging from 1976 to 1989 cm^{-1}, which is lower than that of the starting dicarbonyl complexes. This is because, when one CO group is substituted by a weaker π acid ligand (phosphine or pyridine), there will be a greater donation of dπ electrons from the metal to the vacant π* orbital of CO than when two CO groups are present at *cis* positions [18]. ^1H NMR spectra show definite signals for 1,2-naphthoquinone-mono-oximato and donor ligand, respectively. The assignment of the signals proceeds on the basis of ^1H–^1H correlation spectroscopy (COSY) for most of the complexes, or in a similar manner (Table 1) [17,19].

The electronic absorption spectral data for the series of carbonyl-substituted complexes (**1a**, **3a–12a**) together with those of the starting material (**A**) and 1-nqoH ligand are summarized in Table 2. The spectra of **6a** and **10a** in CH_2Cl_2 in the visible region are shown in Fig. 1.

The electronic spectra of mono-CO-substituted complexes are dominated in the visible region by two absorption bands, with the high energy band appearing at nearly the same absorption maximum (about 420 nm) as that of the starting material (**A**). Early work by Chatterjee [20] showed that a similar band appeared for the copper complex of 1-nitroso-2-naphthol [$Cu(NOC_{10}H_6O)_2$] (420 nm) and the corre-

sponding ligand in an alkaline medium (425 nm). The band was assigned as charge resonance between structures (I) and (II).

(I) (II)

The low-energy intense band (10^3 dm^3 mol^{-1} cm^{-1} < ε < 10^4 dm^3 mol^{-1} cm^{-1}) which appears at 480 nm for **A** and red-shifts as one CO is substituted by a donor ligand should be assigned as ruthenium to 1-nqo charge transfer. Pyridine or phosphine is a good σ donor and a poor π acceptor compared with carbonyl; thus, the substitution of CO by these two ligands will result in destabilization of the ground state and stabilization of the excited state for metal-to-ligand charge transfer (MLCT) to 1-nqo and the band will shift to lower energy as a result [21]. The MLCT band of phosphine substitution complexes (**3a** and **4a**) appears to be at higher energy than that of pyridine substitution complexes (**1a**, **5a**−**7a**); this is because phosphine is a better π acceptor and a poorer σ donor than pyridine.

In the spectra of bicarbonyl-substituted complexes, the MLCT to 1-nqo band red-shifts further with a higher extinction coefficient ($\varepsilon > 10^4$ dm^3 mol^{-1} cm^{-1}). The functional group at the *para* position of the pyridine ring has some influence on the energy of this band. As the functional group changes from electron-withdrawing to electron-donating (from formyl to dimethylamino), the band shifts to a lower energy (from 568 to 592 nm). This trend further supports the band as charge transfer to 1-nqo rather than to pyridine since the donating group in the pyridine ring further destabilized the ground state and stabilized the excited state for MLCT to 1-nqo. Compared with its *cis*-,*cis* analogue, the *trans*-,*trans* spatial orientation of ligands shows a more intense ($\varepsilon > 10^4$ dm^3 mol^{-1} cm^{-1}) lower energy MLCT band than *trans*-[Ru(NH$_3$)$_4$L$_2$] (L = pyridyl ligand) [22,23]. The high energy band is very sensitive to the *para* functional group on the pyridine ring. As the *para* functional group on the pyridine ring changes from withdrawing (formyl) to donating (dimethylamino), this band blue-shifts from 515 to 476 nm, indicating that the withdrawing group contributes to lowering the energy of the accepting π* orbital and the donating group contributes to raising it; thus this band should be assigned as MLCT to the pyridine ligand [24].

2.4. Crystallographic studies

X-ray analyses have been carried out on prisms of **3a**, **7a**, **8a**, **1b**, **1c**, **E** and **1e**, which were obtained by slow evaporation of the corresponding solvent mixture at −20°C. The molecular structure and selected bond parameters of complex **3a** are shown in Fig. 2 and Table 3, respectively. A distorted octahedral coordination of the ruthenium metal centre is revealed and the molecule consists of two 1-nqo ligands, a triphenylphosphine and a carbonyl group. The two 1-nqo ligands chelate to the ruthenium centre with the naphtholic oxygen [Ru–O(2) 2.088(2) Å; Ru–O(4) 2.071(2) Å] and oximato nitrogen [Ru–N(1) 2.072(3) Å; Ru–N(2) 2.000(3) Å] atoms to form a five-membered ring [O(2)–Ru–N(1) 77.8(1)°; O(4)–Ru–N(2) 79.5(1)°] as in the par-

age N–O bond distance of the nitroso group is 1.260(4) Å, which is within the range of most metal complexes with N-bonded nitroso groups such as [Cu{η^2-N(O)$C_{10}H_6$O}$(PPh_3)_2$] [1.287(13) Å] [10], [Hpy][Ir{η^2-N(O)$C_{10}H_6$O}(py)Cl_3] (py = pyridine) [1.274(8) Å] [13] and the parent complex *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$O}$_2$$(CO)_2$] [1.258(5) and 1.256(5) Å] [15]. The two naphtholic oxygen atoms as well as the two nitroso nitrogen atoms of the two 1-nqo ligands are located *cis* to each other. The carbonyl group is *trans* to the naphtholic oxygen [O(4)–Ru–C(1) 173.3(1)°] in one 1-nqo ligand and the phosphine *trans* to the oximato group [N(1)–Ru–P 170.31(9)°] in another 1-nqo ligand, with the carbonyl and the phosphine *cis* to each other [P–Ru–C(1) 90.7(1)°]. The

[a] In CH_2Cl_2. ε is the molar extinction coefficient.

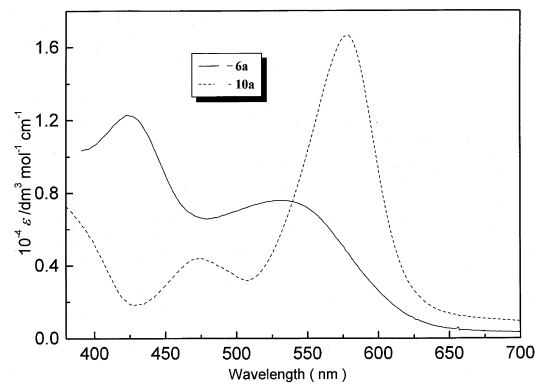

Fig. 1. Comparison of electronic absorption spectra of **6a** and **10a** in CH_2Cl_2.

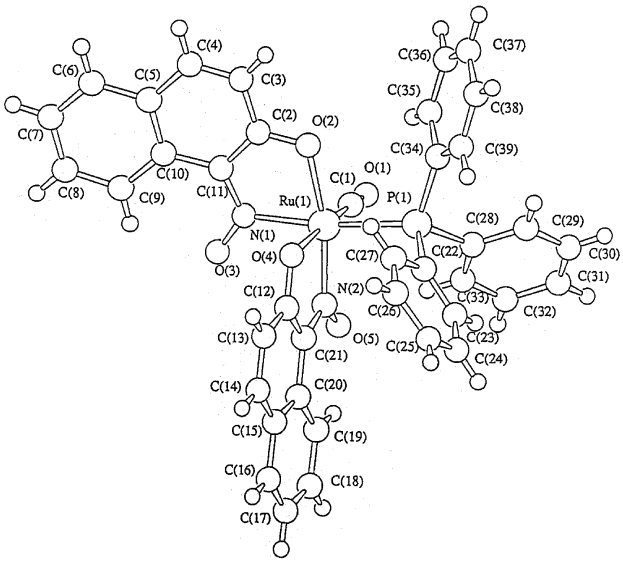

Fig. 2. The molecular structure of *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$)}$_2$(CO)(PPh_3)] (**3a**), showing the atom numbering scheme.

Ru–P distance of 2.372(1) Å is comparable to other ruthenium phosphine complexes such as [Ru(pyca)$_2$(PPh_3)$_2$]·2MeOH [2.397(1) Å] (Hpyca = pyridine-2-carboxylic acid) [25].

Fig. 3 shows the molecular structure of **7a** and the selected bond parameters are listed in Table 3. The molecule of **7a** also adopts an approximately octahedral coordination around the ruthenium centre as in **3a**, but the position *trans* to the oximato group in one 1-nqo ligand is occupied by 4-dimethylaminopyridine. The pyridine ligand is coordinated to the ruthenium centre via its nitrogen atom with a Ru–N(3) bond length of 2.129(5) Å, which is comparable with the distance between the ruthenium centre and the nitrogen atom of pyridine *trans* to the oximato group [2.120(4) Å] in [Ru{η^2-N(O)$C_{10}H_6$O}$_2$(py)$_2$] [14]. The bond distance between the ruthenium centre and the oximato nitrogen atom *trans* to the pyridine ring [Ru–N(1) 2.029(5) Å] is shorter than when it is *trans* to phosphine in **3a** [2.072(3) Å] and when it is *trans* to carbonyl in the parent complex **A** [2.062(4) Å] [15], indicating the *trans* influence of the pyridine ring. The same ligand spatial orientation of complexes **3a** and **7a** results in very similar ^{1}H NMR signals for 1-nqo ligands. The other complexes derived from **A** (**1a–2a**, **4a–6a**) did not yield single crystals of X-ray quality; however, they all have very similar ^{1}H NMR signals for the 1-nqo ligands to that of **3a** and **7a**. Hence, their structures can be proposed to have the same ligand orientation as **3a** and **7a**.

The molecular structure of **1b** and the selected bond parameters are given in Fig. 4 and Table 3, respectively. The structure is similar to that of **7a**, with the two 1-nqo ligands, 4-phenylpyridine and a carbonyl group around the ruthenium centre in a distorted octahedral geometry. In contrast, the oximato nitrogen atoms are *trans* to each other [N(1)–Ru–N(2) 169.2(5)°] whereas the naphtholic oxygen atoms of the two 1-nqo ligands are also in a *cis* configuration [O(2)–Ru–O(4) 86.0(3)°].

The molecular structure of **1c** is depicted in Fig. 5 and the relevant structural parameters are listed in Table 3. The ruthenium centre adopts an approximately octahedral geometry as in **1b** but with two 2-nqo ligands chelating to the ruthenium centre instead of 1-nqo ligand. Both the naphtholic oxygen atoms as well as the oximato nitrogen atoms of the two 2-nqo ligands are in a *cis* configuration. The nitrogen atom of the pyridine ring coordinates to the ruthenium centre *trans* to an oximato group [N(1)–Ru–N(3) 170.7(8)°] of the 2-nqo ligand. From ^{1}H NMR data, the molecular structure of **2c** can be presumed to have the same ligand spatial orientation as in **1c**.

Fig. 6 shows the molecular structure of **E** and selected bond parameters are given in Table 4. The structure of **E** is very similar to *trans*-,*cis*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)$_2$] (**D**) [16] but with the naphtholic oxygen atoms *trans* to each other [O(2)–Ru–O(2*) 170.2(1)°] instead of the *trans* arrangement of oximato nitrogen atoms in **D** [16]. In contrast, there is a crystallographically imposed 2-fold rotational axis through the central ruthenium atom, resulting in exactly the same coordination configuration for the two 2-nqo ligands with the same bond length as Ru–N [2.076(3) Å] and Ru–O [2.061(2) Å], which is comparable to the isomer **D**. This configuration is consistent with the ^{1}H NMR spectrum in which only one set of signals for 2-nqo ligands appears. Both of the carbonyl groups are located *trans* to the oximato nitrogen atom in the 2-nqo ligand [N(1)–Ru–C(1) 174.5(1)°] with the same Ru–C bond length of 1.919(4) Å, which is longer than that in **D** [1.87(2) and 1.90(2) Å] [16].

Fig. 7 shows the molecular structure of complex **1e**; the selected structure parameters are listed in Table 3. The configuration of the molecule is a distorted octahedron around the ruthenium centre similar to the parent complex **E**, with a 4-phenylpyridine ligand occupying the position of one carbonyl in **E**. The bond length between the ruthenium centre and the coordinated pyridine nitrogen atom is 2.11(2) Å, which is comparable to that in **7a** [2.129(5) Å] in which the pyridine ligand is also located *trans* to the nitroso group. The bond distance between this nitoso nitrogen atom and the ruthenium centre is also shortened [Ru–N(1) 2.01(2) Å] compared with the parent complex **E** [Ru–N 2.076(3) Å]. The structures of **3a**, **7a**, **1b**, **1c** and **1e** confirm that no rearrangement of the two coordinated naphtholic oximato ligands occurred during substitution; thus it can be assumed that, in the molecular structures of **1d** and **2d**, one carbonyl *trans* to a naphtholic oxygen atom was substituted by the pyridine ligand (Scheme 1).

The molecular structure and selected bond parameters of complex **8a** are shown in Fig. 8 and Table 5, respectively. The structure is centrosymmetric and the geometry of the central ruthenium atom is a slightly distorted octahedron. The 1-nqo ligands coordinate to the central ruthenium atom through the naphtholic oxygen and the oximato nitrogen atoms to give a five-membered chelate ring. The two chelate rings locate in an equatorial plane containing the ruthenium metal centre as in [Cu(1-nqo)$_2$]·2$(CH_3)_2$CO [11] and

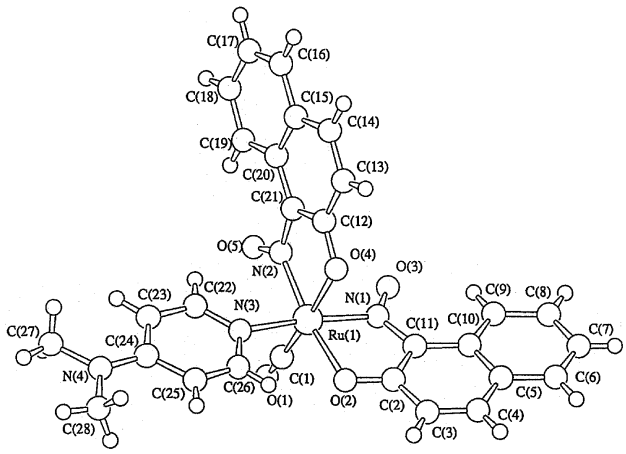

Fig. 3. The molecular structure of *cis*-,*cis*-[Ru{η^2-N(O)$C_{10}H_6$)}$_2$(CO)(mapy)] (**7a**), showing the atom numbering scheme.

[Cu(2-nqo)$_2$]·H_2O [12], and the PBu_3 ligands lie nearly perpendicular to the plane with a deviation of 3.3(6)°. As far as we are aware, this configuration is the first structurally characterized example of ruthenium nitrosonaphthol complexes. The Ru–O distance of the naphtholic group is 2.076(5) Å and the Ru–N distance is 2.011(7) Å, which is comparable with the bond length between the ruthenium centre and the oximato nitrogen atom [2.029(5) Å] *trans* to the nitrogen atom of pyridine in **7a**. The N–O bond distance is found to be 1.266(8) Å, which is in reasonable agreement with previously mentioned complexes [10,11,13–15]. The structure of other bisubstituted complexes (**9a**–**11a)** can be deduced to have the same ligand spatial orientation as that of **8a** from the very similar ^{1}H NMR signals for 1-nqo ligands and the one set of signals for the two pyridine ligands.

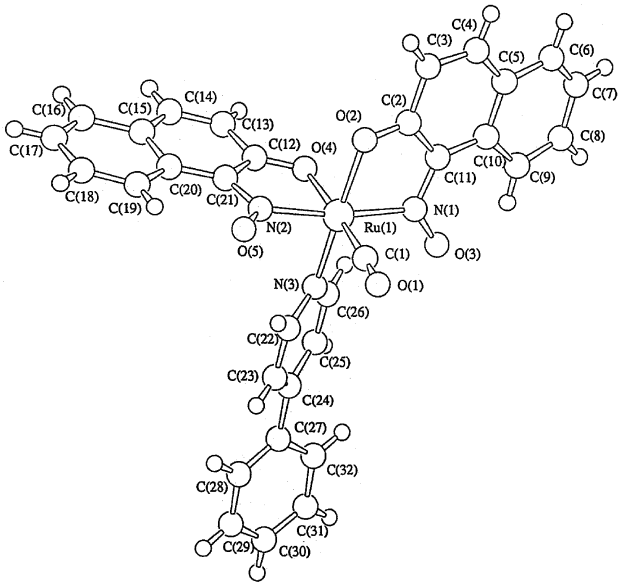

Fig. 4. The molecular structure of *trans*-,*cis*-[Ru{η^2-$N(O)C_{10}H_6$}$_2$(CO)(ppy)] (**1b**), showing the atom numbering scheme.

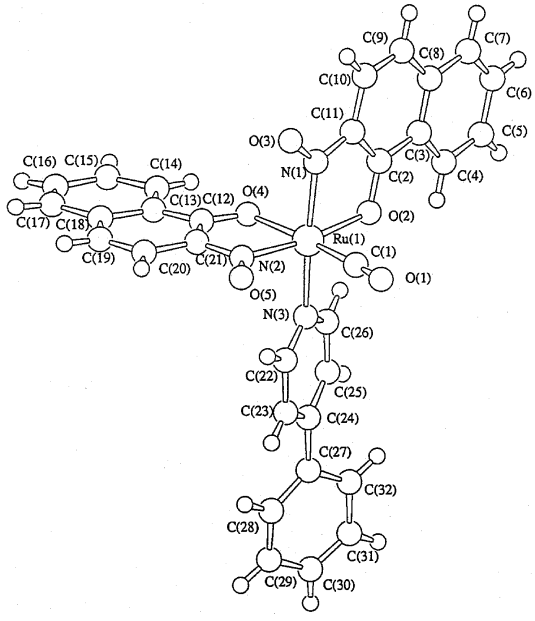

Fig. 5. The molecular structure of *cis*-,*cis*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)(ppy)] (**1c**), showing the atom numbering scheme.

2.5. Electrochemical studies

The redox potentials of the pyridyl complexes and the parent compound **A** were obtained by cyclic voltammetry in acetonitrile and are listed in Table 6. Representative cyclic voltammograms of **10a** and **6a** are shown in Fig. 9.

The cyclic voltammograms of bisubstituted complexes **9a**–**11a** are characteristic of a reversible one-electron process on the positive side. The peak presents an anodic-to-cathodic peak separation of 69–78 mV, which is close to the theoretical separation (59 mV at 25°C). The effect of variation of the pyridyl ligand on the formal potential of the peak is very similar to that of the Ni(II)/Ni(III) couple in nickel quinone-mono-oxime complexes [Ni(MeQ)$_2$(py)$_2$] (MeQ = 4-methyl-1,2-benzoquinone-2-oximato; py = pyridine, 4-methylpyridine and 4-aminopyridine, respectively) [26]. The peak can be similarly assigned to the Ru(II)/Ru(III) couple as that for Ni(II)/Ni(III) in [Ni(cbqo)$_2$] (cbqo = 4-chloro-1,2-benzoquinone-2-oximato) which appeared at 0.64 V (vs. ferrocene/ferrocenium) as a quasi-reversible one-electron oxidation process [27]. Some tris-1,2-quinone-2-oxime complexes also show a similar metal-based redox process [26,28–30]. Other Ru(II) complexes have an oxidation potential near to that of the Ru(II)/Ru(III) couple; for example, [Ru(NH$_3$)$_5$(isn)](PF$_6$) (isn = isonicotinamide) and [Ru(NH$_3$)$_5$(pz)](PF$_6$)

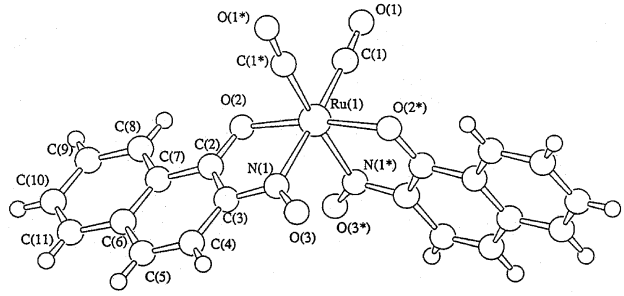

Fig. 6. The molecular structure of *cis*-,*trans*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)$_2$] (**E**), showing the atom numbering scheme.

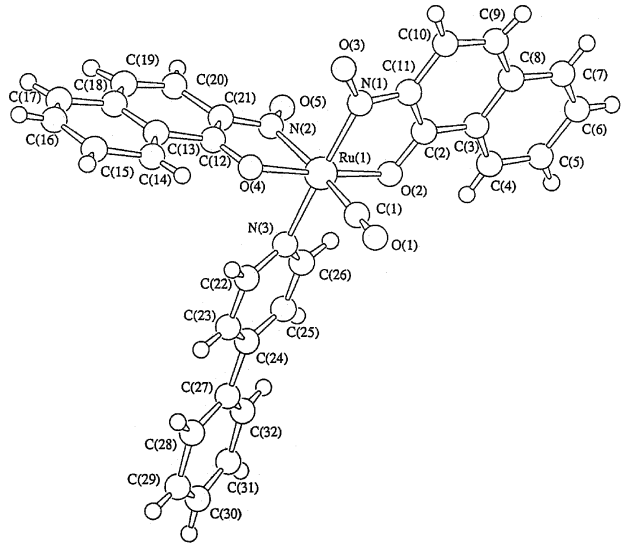

Fig. 7. The molecular structure of *cis*-,*trans*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)(ppy)] (**1e**), showing the atom numbering scheme.

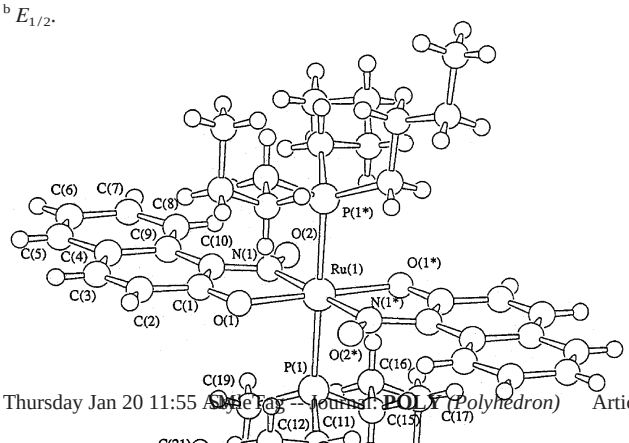
[a] Symmetry code: *$2-x, -y, 2-z$.



(pz = pyrazine) have $E_{1/2}$ values of 0.115 and 0.225 V (vs. Ag/Ag^+), respectively [31]. The monosubstituted complexes **1a**, **5a–7a** and **12a** exhibit an irreversible oxidation peak, which is a significantly positive shift to the potential common for the Ru(II)/Ru(III) couple [21,24] from that for the bisubstituted complexes. This may be due partly to the change in the surrounding ligands, which stabilizes Ru(III) less than Ru(II), and partly to the change of spatial orientation of the ligands. The parent complex (**A**) exhibits a more positive oxidation potential, which is due to the appearance of two carbonyl groups with slightly better π acceptor and poor σ donor properties, thus favoring the destabilization of Ru(III) relative to Ru(II) [22]. A similar effect was observed for poly$[Ru(II)(vbpy)_2(py)_2]^{2+}$ (vbpy = 4-vinyl-4′-methyl-2,2′-bipyridine; py = pyridine), where the oxidation potential shifted from 0.89 V to 0.39 V and further to −0.03 V (vs. Ag/Ag^+) as one and two py were progressively replaced by Cl^- [32]. However, the possibility of ligand-centred oxidation could not be eliminated because a similar compound, 2-propanone oxime, showed an irreversible oxidation peak at 1.47 V (vs. NHE) [33].

The change of the donor ligand results in a change of electronic absorption spectra and electrochemical properties in the same direction. As the donor ligand becomes more electron-donating, the oxidation potential becomes more cathodic and the band of MLCT to 1-nqo decreases in energy, both of them showing stabilization of Ru(III) compared to Ru(II) by the more electron-donating ligand.

Table 6
Formal potentials for complexes **1a**, **5a − 7a**, **9a − 12a** and **A** [a]

Complex	$[E^{\circ\prime}(ox)]$	$[E^{\circ\prime}(red)]_1$	$[E^{\circ\prime}(red)]_2$	$[E^{\circ\prime}(red)]_3$	$[E^{\circ\prime}(red)]_4$

[a] All potentials are in volts vs. Ag (0.1 mol dm^{-3} Ag^+). In MeCN, containing 0.1 mol dm^{-3} TBAH.
[b] $E_{1/2}$.

3. Experimental

All manipulations were carried out under nitrogen using standard Schlenk techniques. Chemicals were purchased from commercial sources (Aldrich, Strem) and used as received unless stated otherwise. The compounds *cis*-,*cis*- and *trans*-,*cis*-$[Ru\{\eta^2\text{-}N(O)C_{10}H_6O\}_2(CO)_2]$, *cis*-,*cis*- and *trans*-,*cis*-$[Ru\{\eta^2\text{-}OC_{10}H_6N(O)\}_2(CO)_2]$ were prepared according to our previously described procedure [15,16]. Trimethylamine *N*-oxide (Aldrich) was dried by azeotropic distillation in benzene and sublimed prior to use. Dichloromethane and acetonitrile were distilled from CaH_2. Preparative thin-layer chromatographic (TLC) plates were prepared

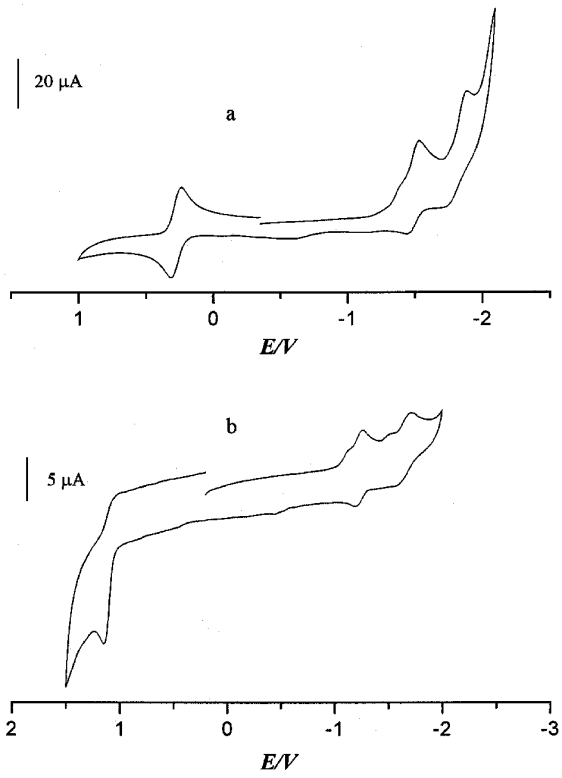

Fig. 9. Cyclic voltammograms of **10a** (a) and **6a** (b) in MeCN containing 0.1 mol dm^{-3} Bu_4NPF_6; glassy carbon working electrode; $AgNO_3$ reference electrode (Ag 0.1 mol dm^{-3}); scan rate, 50 mV s^{-1}.

were recorded on a Finnigan MAT 95 mass spectrometer. Electronic absorption spectra were obtained on a Hewlett-Packard 8453 spectrophotometer at room temperature. Cyclic voltammetric experiments were carried out using a Princeton Applied Research Model 273A potentiostat/galvanostat. All electrochemical data were obtained using acetonitrile containing 0.1 mol dm^{-3} n-tetrabutylammonium hexafluorophosphate (TBAH) as a supporting electrolyte at room temperature, with a gas-sealed (argon) two-compartment cell, equipped with a glassy carbon working electrode, a $AgNO_3$ reference electrode (Ag 0.1 mol dm^{-3}) and a platinum wire as the auxiliary electrode.

3.1. Preparation of cis-,cis- (1a) and trans-,cis- (1b) [Ru{η²-N(O)C₁₀H₆O}₂(CO)(ppy)]

Solid samples of *cis-,cis*-[Ru{η^2-N(O)$C_{10}H_6O$}$_2$(CO)$_2$] (**A**) or *trans-,cis*-[Ru{η^2-N(O)$C_{10}H_6O$}$_2$(CO)$_2$] (**B**) (50 mg, 0.1 mmol) and the donor ligand 4-phenylpyridine (ppy) (17 mg, 0.11 mmol) were dissolved in 40 cm^3 of CH_2Cl_2 at room temperature. A CH_2Cl_2 solution (10 cm^3) of Me_3NO (7.5 mg, 0.1 mmol) was added dropwise to this and an instantaneous colour change from orange to reddish-brown was observed. After stirring for 1 h, the solvent was removed in vacuo and the residue was chromatographed by TLC using a solvent mixture of n-hexane–CH_2Cl_2 (1:1, v/v) as eluent to afford three bands. The first, orange, band was unreacted **A** or **B**. The second, reddish-brown, band was *cis-,cis*-[Ru{η^2-N(O)$C_{10}H_6O$}$_2$(CO)(NMe$_3$)] or *trans-,cis*-[Ru{η^2-N(O)$C_{10}H_6O$}$_2$(CO)(NMe$_3$)] and the third fraction of reddish-brown colour was **1a** or **1b**. Reddish-brown crystals of **1b** were obtained by slow evaporation of cyclohexane–$CHCl_3$ solution at −20°C. (Found for **1a**: C, 61.2; H, 3.5; N, 6.5%. Found for **1b**: C, 61.2; H, 3.6; N, 6.6%. Calc. for $C_{32}H_{21}N_3O_5Ru_1$: C, 61.1; H, 3.4; N, 6.7%).

3.2. Preparation of cis-,cis- (1c) and trans-,cis- (1d) [Ru{η²-OC₁₀H₆N(O)}₂(CO)(ppy)]

A procedure analogous to that of the preparation of **1a** and **1b** was followed, using *cis-,cis-* or *trans-,cis*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)$_2$] (**C** or **D**) as starting material; a colour change from red to dark purple indicated completion of the reaction. TLC separation using a solvent mixture of n-hexane–CH_2Cl_2 (1:1, v/v) as eluent gave three bands. The first red band for the reaction of **D** was the unreacted starting material (**D**). The second band was dark purple *cis-,cis*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)(NMe$_3$)] or *trans-,cis*-[Ru{η^2-$OC_{10}H_6N(O)$}$_2$(CO)(NMe$_3$)] and the third fraction, also dark purple, was **1c** or **1d**. Dark purple crystals of **1c** were obtained by slow evaporation of cyclohexane–$CHCl_3$ solution at −20°C. (Found for **1c**: C, 61.1; H, 3.3; N, 6.7%. Found for **1d**: C, 61.3; H, 3.4; N, 6.7%. Calc. for $C_{32}H_{21}N_3O_5Ru_1$: C, 61.1; H, 3.4; N, 6.7%).

3.3. Preparation of cis-,cis-[Ru{η²-N(O)C₁₀H₆O}₂(CO)(PPh₃)] (3a)

A procedure analogous to that for the preparation for **1a** and **1b** was followed, using triphenylphosphine (PPh_3) (29 mg, 0.11 mmol) as donor ligand and observing the colour change from orange to brown to ensure completion of the reaction. TLC separation using a solvent mixture of n-hexane–CH_2Cl_2 (2:3, v/v) as eluent gave three bands. The first orange band was unreacted starting material (**A**). The second band was reddish-brown **12a** and the third fraction, orange-red in colour, was **3a**. Orange-red crystals of **3a** were obtained by slow evaporation of n-hexane–CH_2Cl_2 solution at −20°C. (Found: C, 63.6; H, 3.5; N, 3.7; P, 4.1%. Calc. for $C_{39}H_{27}N_2O_5P_1Ru_1$: C, 63.7; H, 3.7; N, 3.8; P, 4.2%).

3.4. Preparation of cis-,cis-[Ru{η²-N(O)C₁₀H₆O}₂(CO)(avpy)] (2a)

A solid sample of complex **A** (50 mg, 0.1 mmol) and the donor ligand 4-{2-(9-anthryl)vinyl}pyridine (avpy) (31 mg, 0.11 mmol) were dissolved in 40 cm^3 of CH_2Cl_2 at room temperature. A CH_2Cl_2 solution (10 cm^3) of Me_3NO (7.5 mg, 0.1 mmol) was added dropwise to this solution mixture in the dark. After stirring for 1 h, the solvent was removed in vacuo and the residue was separated by TLC using the solvent mixture of n-hexane–CH_2Cl_2 (1:5, v/v) as eluent to afford three bands. The entire procedure until the separation was protected from light by aluminium foil. The first orange band was unreacted **A**. The second, reddish-brown, band was **12a**;

the third fraction, reddish-brown in colour, was **2a**, which should be protected from the light. (Found: C, 66.7;H, 3.7;N, 5.6%. Calc. for $C_{42}H_{27}N_3O_5Ru_1$: C, 66.8; H, 3.6; N, 5.6%).

3.5. Preparation of cis-,cis- (2c) and trans-,cis- (2d) [Ru{η²-OC₁₀H₆N(O)}₂(CO)(avpy)]

A procedure analogous to that for the preparation of **2a** was followed by using **C** or **D** as starting material. After completion of reaction and upon TLC separation, protected from light, using the solvent mixture n-hexane–CH_2Cl_2 (1:5, v/v) as eluent, the first red band for reaction of **D** was found to be the unreacted starting material. In the reaction using **C** as starting material, the first band was *cis-,trans-*[Ru{η²-$OC_{10}H_6N(O)$}$_2$(CO)$_2$] (**E**) which was orange in colour and at the exact position on the TLC plate as **C**. The second band was the dark purple *cis-,cis-* or *trans-,cis-*[Ru{η²-$OC_{10}H_6N(O)$}$_2$(CO)(NMe$_3$)]; the third fraction, also dark purple, was **2c** or **2d**, and should be also kept from light. Orange crystals of **E** were obtained by slow evaporation of n-hexane–CH_2Cl_2 solution at −20°C. (Found for **2c**: C, 66.6; H, 3.5; N, 5.7%. Found for **2d**: C,66.8; H, 3.7; N, 5.7%. Calc. for $C_{42}H_{27}N_3O_5Ru_1$: C, 66.8; H, 3.6; N, 5.6%. Found for **E**: C, 52.6; H, 2.3; N, 5.6%. Calc. for $C_{22}H_{12}N_2O_6Ru_1$: C, 52.7;H, 2.4; N, 5.6%).

*3.6. Separation of **E** from **C***

A solid sample of **E** (50 mg, 0.1 mmol) dissolved in a minimum amount of CH_2Cl_2 was re-chromatographed by TLC using a solvent mixture of n-hexane–diethyl ether (10:1, v/v) as eluent. Two bands appeared: the first, red, band was **C** (47 mg, 94%; $R_f = 0.30$); the second, orange, band was **E** (2 mg, 4%; $R_f = 0.25$).

3.7. Preparation of cis-,trans-[Ru{η²-OC₁₀H₆N(O)}₂(CO)(ppy)] (1e)

A procedure analogous to that for the preparation of **1a** and **1b** was followed using **E** as the starting material. TLC separation was conducted using the same eluent to afford two bands. The first, orange, band was the unreacted starting material (**E**); the second, dark-brown, band was *cis-,trans-*[Ru{η²-$OC_{10}H_6N(O)$}$_2$(CO)(ppy)] (**1e**). Dark-brown crystals of **1e** were obtained by slow evaporation of n-hexane–$CHCl_3$ solution at −20°C. (Found: C, 61.2; H, 3.4; N, 6.8%. Calc. for $C_{32}H_{21}N_3O_5Ru_1$: C, 61.1; H, 3.4; N, 6.7%).

3.8. Preparation of cis-,cis-[Ru{η²-N(O)C₁₀H₆O}₂(CO)(PBu₃)] (4a) and trans-,trans-[Ru{η²-N(O)C₁₀H₆O}₂(PBu₃)₂] (8a)

A procedure analogous to that for the preparation of **1a** and **1b** was followed, using tributylphosphine (PBu_3) as donor ligand, with ligand:metal and Me_3NO:metal ratios of 5:1 and 2:1, respectively. The reaction period of 2 days ensured completion of the reaction. TLC separation of the dark-brown residue using a solvent mixture of n-hexane–CH_2Cl_2 (1:2, v/v) as eluent gave three bands. The first, bright purple, band was *trans-,trans-*[Ru{η²-$N(O)C_{10}H_6O$}$_2$(PBu_3)$_2$] (**8a**), the second, reddish-brown, band was *cis-,cis-*[Ru{η²-$N(O)C_{10}H_6O$}$_2$(CO)(PBu_3)] (**4a**), the third fraction being **12a**. Bright purple crystals of **8a** were obtained by slow evaporation of n-hexane solution at −20°C. (Found for **4a**: C, 58.5; H, 5.7; N, 4.2; P, 4.4%. Calc. for $C_{33}H_{39}N_2O_5P_1Ru_1$: C, 58.7; H, 5.8; N, 4.2; P, 4.6%. Found for **8a**: C, 62.2; H, 7.7; N, 3.2; P, 7.1%. Calc. for $C_{44}H_{66}N_2O_4P_2Ru_1$: C, 62.2; H, 7.8; N, 3.3; P, 7.3%).

3.9. Preparation of cis-,cis-[Ru{η²-N(O)C₁₀H₆O}₂(CO)L] (5a, L = fpy; 6a, L = epy; 7a, L = mapy) and trans-,trans-[Ru{η²-N(O)C₁₀H₆O}₂L₂] (9a, L = fpy; 10a, L = epy; 11a, L = mapy)

A procedure analogous to that for the preparation of **4a** and **8a** was followed, using *para*-functionalized pyridine as donor ligand; the colour change was from orange to dark blue. After completion of the reaction, the dark blue residue was separated by TLC using a solvent mixture of n-hexane–CH_2Cl_2 (1:5 to 1:6, v/v) as eluent to give three bands. The first band was reddish-brown **12a**. The second, reddish-brown, band was *cis-,cis-*[Ru{η²-$N(O)C_{10}H_6O$}$_2$(CO)(py)] (**5a–7a**) and the third, purple-blue, fraction was *trans-,trans-*[Ru{η²-$N(O)C_{10}H_6O$}$_2$(py)$_2$] (**9a**–**11a**). Reddish brown crystals of **7a** were obtained by slow evaporation of n-hexane − CH_2Cl_2 solution at −20°C. (Found for **5a**: C, 55.7; H, 3.0; N, 7.3%. Calc. for $C_{27}H_{17}N_3O_6Ru_1$: C, 55.9; H, 3.0; N, 7.2%. Found for **9a**: C, 58.1; H, 3.2; N, 8.6%. Calc. for $C_{32}H_{22}N_4O_6Ru_1$: C, 58.3; H, 3.4; N, 8.5%. Found for **6a**: C, 58.2; H, 3.5; N, 7.3%. Calc. for $C_{28}H_{21}N_3O_5Ru_1$: C, 58.0; H, 3.6; N, 7.2%. Found for **10a**: C, 62.0; H, 4.5; N, 8.3%. 4. Crystallography

Single crystals of **3a**, **7a**, **8a**, **1b**, **1c**, **E** and **1e** for X-ray analysis were obtained as described above. A crystal of **3a** was mounted on top of a glass fibre using epoxy resin, whereas crystals of **7a**, **8a**, **1b**, **1c**, **E** and **1e** were sealed in Lindemann glass capillaries. Crystal intensity data were collected on a MAR research image-plate scanner using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) for unit-cell determination and data collection. The intensity data were corrected for Lorentz and polarization effects. An approximation to absorption correction by inter-image scaling was also applied. Summaries of the crystallographic data, structure solution and refinement are given in Table 7. Scat-

tering factors were taken from Cromer and Waber [34] and anomalous dispersion effects were included in *Fc* [35]. The position of ruthenium atom were determined by direct methods (SIR92) [36]. The remaining non-hydrogen atoms were determined by subsequent Fourier and Fourier-difference techniques. The structures were refined by full-matrix least-squares analysis on F with all non-hydrogen atoms refined anisotropically until convergence was reached. The hydrogen atoms of the organic moieties were generated in their ideal positions (C–H, 0.95 Å). They were included in the structure factor calculations on a Silicon-Graphics computer using the program package TEXSAN [37]. The R values for most of the complexes are reasonally good, except for **1b**, **1c** and **1e**. This is probably due to the positional disorder associated with the solvent molecules present in the crystal.

Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, on request, quoting deposition number 129645.

Received 16 July 1999; accepted 30 September 1999

Abstract

A range of symmetrical 4′,4″-disubstituted 2,2′:6′,2″:6″,2‴-quaterpyridines has been prepared and their coordination behaviour with metal ions having a preference for tetrahedral and octahedral geometries has been studied. The new ligands reacted with copper(I) and silver(I) salts to form dinuclear double-helical complexes; reaction with nickel(II) or cobalt(II) salts gave mononuclear species. The crystal structures of three mononuclear complexes are reported and demonstrate that the ligand binds in a tetradentate mode to the equatorial plane of the octahedral metal centre. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Helical structures; Supramolecular chemistry; Transition metals; X-ray crystal structures

1. Introduction

Oligopyridines are versatile ligands that form coordination complexes with almost all metal ions [1–6]. We and others have investigated the coordination behaviour of 2,2′:6′,2″:6″,2‴-quaterpyridine (**1**) [2,7–35] and have shown that coordination to octahedral six-coordinate metal centres results in the formation of mononuclear complexes, whereas bonding to four-coordinate tetrahedral metal ions gives dinuclear double-helical complexes [4,5]. As part of our ongoing interest in the use of supramolecular interactions in the synthesis of extended dendritic or starburst systems [36,37], we intended to incorporate a dinuclear double helicate at the centre of a metallodendrimer using 2,2′:6′,2″:6″2‴-quaterpyridines bearing substituents on the two central rings. However, we have recently shown that the introduction of substituents onto the terminal rings of 2,2′:6′,2″:6″,2‴-quaterpyridines results in significant changes in the coordination behaviour and has a major effect on the pitch of helicates. Accordingly, we decided to make preliminary investigations of the coordination behaviour of symmetrical 4′,4″-disubstituted 2,2″:6′,2″:6″,2‴-quaterpyridines.

2. Experimental

2.1. General procedures

Infrared spectra were recorded on a Mattson Genesis Fourier-transform spectrophotometer with samples in compressed KBr discs. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on Varian Gemini 300, Bruker AM 400 or WM 250 spectrometers. Electron impact (EI) and fast atom bombardment (FAB) mass spectra were recorded using Kratos MS-50, Kratos MS-890, VG 70-250 or Kratos MS-902 instruments; for FAB spectra the sample was loaded using acetonitrile as a solvent and 3-nitrobenzyl alcohol as supporting matrix. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra were measured using a PerSeptive Biosystems Voyager-RP Biospectrometry Workstation. Electrochemical measurements were performed with an Eco Chemie Autolab PGSTAT 20 system using platinum bead working and auxiliary electrodes with an Ag/AgCl electrode as reference, purified acetonitrile as solvent and 0.1 M $[Bu^n_4N][BF_4]$ as supporting electrolyte. Ferrocene was added at the end of each experiment as an internal reference. *N*-[2-(2-Pyridyl)-2-oxethyl]pyridinium iodide was prepared according to the procedure in the literature [38]. All other compounds were used as supplied.

2.2. 1,6-Diarylhexa-1,5-diene-3,4-diones (9–14)

Piperidine (0.2 ml, 0.17 g, 20 mmol) and glacial acetic acid (0.12 ml, 20 mmol) were added to a stirred solution of diacetyl (0.88 ml, 0.86 g, 10 mmol) and the substituted benzaldehyde (40 mmol) in methanol (5 ml). The mixture was heated under reflux for 2 h and then the methanol and unreacted diacetyl were removed in vacuo. The solution was placed in a freezer overnight and the orange crystals that had formed were isolated by filtration.

2.3. 4′,4″-Diaryl-2,2′:6′,2″:6″,2‴-quaterpyridines (3–8)

The appropriate 1,6-diarylhexa-1,5-diene-3,4-dione (0.5 mmol) was added to a solution of *N*-[2-(2-pyridyl)-2-oxethyl]pyridinium iodide (0.4 g, 1 mmol) and anhydrous ammonium acetate (4 g, excess) in ethanol (40 ml) and the mixture heated under reflux for 4 h. After cooling, the off-white precipitate was filtered off and recrystallized from ethanol to give the desired ligand.

*2.8. Crystal structure determinations of [Ni(**4**)(MeCN)$_2$][PF_6]$_2$ (**15**), [Ni(**3**)(OAc)(MeOH)][PF_6]·2MeOH·H_2O (**16**) and [Co(**3**)(OAc)(MeCN)][PF_6]·1.64MeCN·0.36·H_2O (**17**)*

In each case, crystals were grown by the diffusion of diethyl ether vapour into a solution of the crude complex in acetonitrile. Measurements were made, as previously described, using an Enraf-Nonius CAD4 diffractometer [41]. The conditions used for crystallographic data collection and structure refinement are summarized in Table 1; selected geometric data are given in Table 2. Structures were elucidated by direct methods using SIR92 [42]. Anisotropic least-

squares full-matrix refinement was carried out on all non-hydrogen atoms using the program CRYSTALS [43] and a Chebychev weighting scheme [44]. The positions of the hydrogen atoms were determined geometrically.

For compound **15**, a poor dataset was obtained and the structure was refined against F^2 using all the data. For **17**, problems were encountered refining disordered solvent molecules. The space around the special position 0.5, 0, 0.5 is occupied by MeCN and H_2O molecules. The frequency was not constrained during refinement, but the total site occupancy was fixed to 1. The ratio of 0.64–0.36 suggests that the two solvent molecules can have two alternative orientations created by the centre of symmetry, or that two MeCN molecules are present in the cavity without H_2O. Another disordered MeCN molecule has been localized in the difference map. The two alternating positions have been refined using appropriate restraints. Because of difficulties in centering the sample on the diffractometer using the oil-drop method at low temperature, psi-scans did not give a good estimate of the absorption; refinement was therefore made using DIFABS [45].

3. Results and discussion

3.1. Ligand synthesis

2,2′:6′,2″:6″,2‴-Quaterpyridine (**1**) was first synthesized in 1938 by the high-temperature coupling of 6-halo-2,2′-bipyridines in the presence of copper powder [28]; this method has also been utilized in the preparation of **2** [23]. More recently, nickel reagents have been utilized for the synthesis of **1** [7]. The preparation of 4′,4″-disubstituted ligands by the coupling reactions of halo-2,2′-bipyridines is not easy, but they can be obtained using the methodology described by Sorenson [40]. We have shown that diacetyl is an excellent precursor for the formation of oligopyridines and that the 4′,4″-diaryl-substituted compounds **3** and **4** can be prepared from this starting material [39].

We have now extended this methodology to the preparation of a range of 4′,4″-disubstituted-2,2′:6′,2″:6″,2″-quaterpyridines (**3**–**8**), which were synthesized according to Scheme 1. The reaction of diacetyl with the appropriate substituted

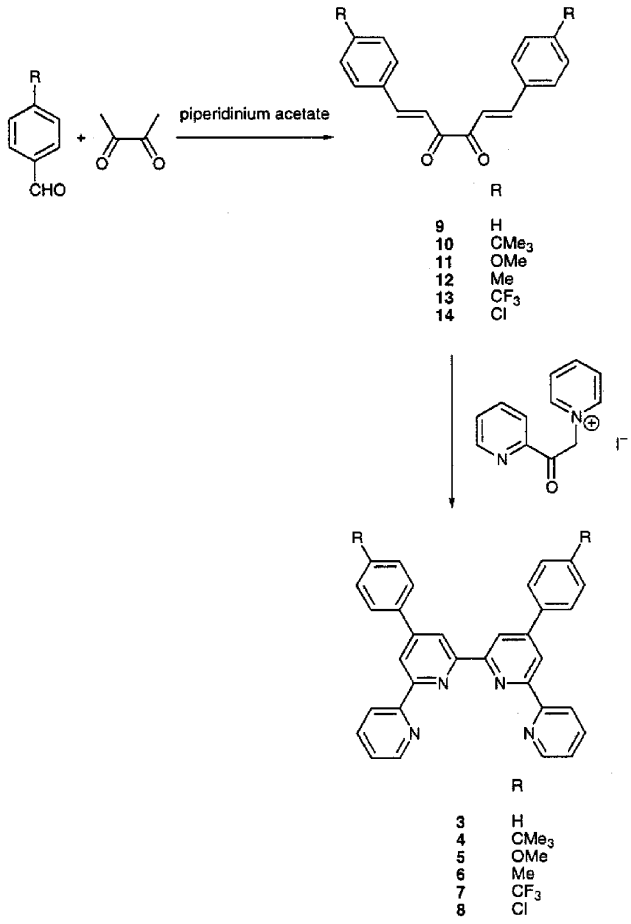
benzaldehyde in MeOH with piperidinium acetate as catalyst resulted in the formation of 1,6-diarylhexa-1,5-diene-3,4-diones **9**–**14** as bright orange crystals. Although the yields were poor, unreacted material can be recovered; moreover, the convenience of this synthesis and the low cost of the starting materials make these attractive intermediates for oligopyridine synthesis. The compounds were all isolated with the *E,E* configuration, as confirmed by the observation of a single AB system with a coupling constant J_{AB} of $\approx$16 Hz in each of the ^{1}H NMR spectra. The carbonyl group of the enone gives rise to a characteristic absorption in the IR spectrum, with $\bar{\nu}$ = 1669–1679 cm^{-1}. Characterization data for these compounds are collated in Section 2.



The quaterpyridines **3**–**8** were isolated as off-white solids in yields of 30–60% from the reaction of **9**–**14** with the Kröhnke reagent, *N*-[2-(2-pyridyl)-2-oxethyl]pyridinium iodide [38], in the presence of ammonium acetate. The ^{1}H NMR spectra of these compounds are characteristic, with ligands **3**–**6** giving nine resonances and **7** and **8** giving only eight resonances. All of the chemical shifts and coupling constants were within the normal ranges and the spectra were fully assigned (see Section 2) by inspection, comparison with known compounds and by correlation spectroscopy (COSY).

3.2. Complexes with metals favouring tetrahedral coordination

The four nitrogen donor atoms of quaterpyridine ligands can be partitioned into two didentate bipyridine domains upon interaction with metal ions favouring tetrahedral coordination, because it is not possible for all four donors to occupy the vertices of a tetrahedron [1–5].

3.2.1. Copper(I) complexes

Copper(I) forms dinuclear double-helical complexes with 2,2′:6′,2″:6″,2‴-quaterpyridines [1–5] in which the precise geometrical properties are dependent upon the nature and position of any ligand substituents. The reaction of **3**–**8** with an equimolar amount of [Cu(MeCN)$_4$][PF$_6$] in methanol under nitrogen gave deep red–brown solutions from which the salts [Cu$_2$L$_2$][PF$_6$]$_2$ (L = **3**–**8**) were isolated as solids varying in colour from red–brown through purple to black in 50–90% yield. Microanalysis confirmed the 1:1 metal:ligand stoichiometry, and evidence for the dinuclear structures came from mass spectrometry, which revealed ions corresponding to {[Cu$_2$L$_2$][PF$_6$]}$^+$ and {[Cu$_2$L$_2$]}$^+$ in each case (where L represents quaterpyridine (qtpy) or substituted quaterpyridine). Molecular modelling combined with structural data for a number of [Cu$_2$L$_2$]$^{2+}$ complexes confirms that a dinuclear formulation requires a double-helical structure; no

Scheme 1.

Table 3

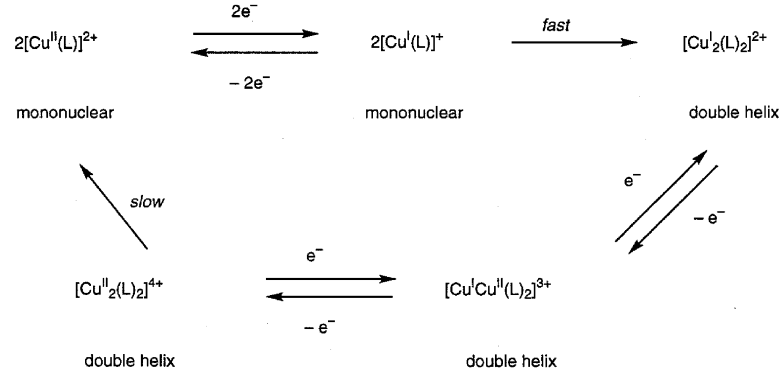
$[Cu_2(\mathbf{4})_2]^{2+}$	0.044	−0.294	0.338
$[Cu_2(\mathbf{5})_2]^{2+}$	0.028	−0.331	0.359
$[Cu_2(\mathbf{6})_2]^{2+}$	0.133	−0.370	0.503
$[Cu_2(\mathbf{7})_2]^{2+}$	0.270	−0.371	0.641
$[Cu_2(\mathbf{8})_2]^{2+}$	0.071	−0.289	0.360



achiral structure is possible. The ^{1}H NMR spectra of CD_3COCD_3 or CD_3CN solutions of the complexes were simple and assigned with the aid of ^{1}H NMR COSY experiments. Only nine (**3**–**6**) or eight (**7**, **8**) different proton environments were observed, indicating a single symmetrical solution species. Comparison with the ^{1}H NMR spectra of solutions of $[Cu_2(qtpy)_2][PF_6]_2$, for which X-ray data have established a double-helical solid-state species, indicates that the solution species are similar. Although the ^{1}H NMR data cannot distinguish between dinuclear and mononuclear solution species, we have used chiral ligands to unambiguously establish that the solution species are dinuclear [17]. Taken in conjunction with the electrochemical data, we can now confidently state that the 4′,4″-disubstituted quaterpyridine ligands give dicopper(I) double-helical complexes in both the solid state and solution. The complexes are indefinitely stable in air in the solid state or in MeCN, although they are slowly oxidized in MeOH solution.

The electronic spectra of the dicopper(I) complexes in MeCN solution show absorption maxima at very similar wavelengths (550–555 and 438–445 nm), with the exception of the complex with **7**, which is significantly red-shifted (563 and 448 nm). Compared with $[Cu_2(qtpy)_2][PF_6]_2$ (λ_{max} 543, 432 nm) [11], the metal-to-ligand charge transfer (MLCT) bands of the complexes with **3**–**8** have been red-shifted, consistent with the lowering of the energy of the ligand π^* acceptor orbital upon the introduction of the conjugated aromatic substituents.

The dicopper(I) complexes are all electrochemically active and show irreversible metal-centred oxidation and reduction processes (Table 3) together with ligand-based reductions at ≈ -1.50 and ≈ -1.75 V. The separation between the metal-centred processes is variable and the data are in accord with earlier studies of simple quaterpyridine derivatives and are compatible with the electrochemical processes outlined in Scheme 2 [22–25].

3.2.2. Silver(I) complexes

The reaction of **3**–**7** with an equimolar amount of AgOAc in methanol gave pale yellow solutions from which the salts $[Ag_2L_2][PF_6]_2$ (L = **3**–**7**) were isolated as white solids in 58–92% yield. Microanalysis confirmed the 1:1 metal:ligand formulations and mass spectrometry confirmed a dinuclear

Scheme 2.

formulation. Arguments similar to those presented above lead to unambiguous assignment of dinuclear double-helical structures to both solid-state and solution species. The ^{1}H NMR spectra of CD_3COCD_3 or CD_3CN solutions of the complexes were simple and only nine (**3**–**6**) or eight (**7**) proton environments were observed, indicating a single symmetrical solution species. The complexes are air-stable both in the solid state and in solution.

All of the complexes exhibit an irreversible process in the range -0.30 and -0.4 V (versus Fc/Fc^+), leading to complex decomposition and plating of silver on the electrode.

All of these data are in accord with the formation of dinuclear double-helical complexes (Scheme 3) with copper(I) and silver(I) in which the 4′,4″-substituents will, at most, control the pitch of the double helix. Despite numerous attempts, we have been unable to obtain X-ray-quality crystals of copper or silver complexes with any of these ligands. As the original aim was to ascertain that the introduction of the 4′,4″-substituents did not affect the formation of dinuclear double helicates, the non-structural evidence was strong enough for us to develop more highly functionalized quaterpyridine ligands for use as dendritic cores [46]. Fig. 1 shows an MM2 minimized structure representing the dicopper(I) complex with **3**. The crystallographic coordinates for the $[Cu_2(qtpy)_2]^{2+}$ cation were taken [9,11] and the 4′- and 4″-H atoms replaced by phenyl groups. The core structure was constrained and the phenyl groups were minimized. There are no short contacts between the substituents and the dinuclear core, and the phenyl substituents are arrayed in a quasi-tetrahedral fashion.

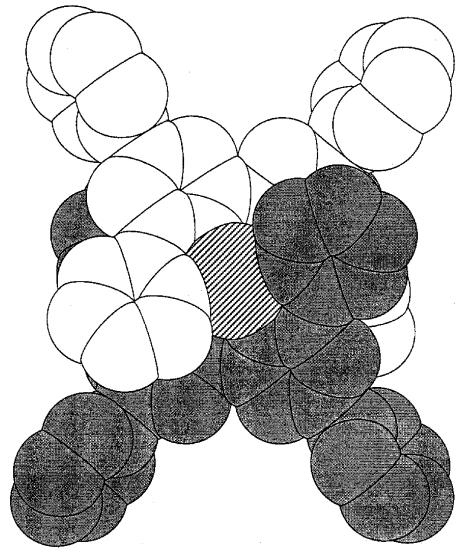


Fig. 1. Modelled structure of the dicopper(I) double helicate obtained with **3**, showing the distribution of the aryl substituents. For clarity, hydrogen atoms have been omitted and one of the ligand strands has been shaded.

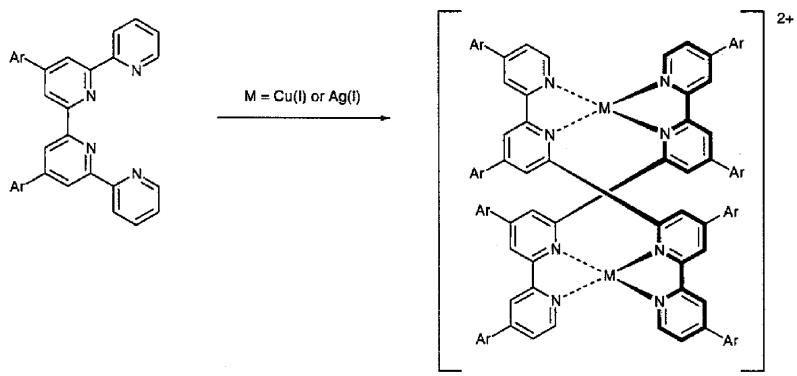

3.3. Complexes with metals favouring octahedral coordination

Octahedral metal centres could form two types of complexes with quaterpyridine ligands: (a) the four nitrogen donors of the ligand could occupy the equatorial sites of a mononuclear octahedral complex, or the ligand could be partitioned into two bipyridine domains to give (b) a dinuclear double helix with two additional ligands per metal centre or (c) a dinuclear triple helix. Modelling suggests that the triple helix (c) is too strained with quaterpyridine ligands, but both (a) and (b) should be possible. Although known structures of cobalt(II) [29,30] and nickel(II) [7,11] complexes are all of type (a), the desired $\{M''(bpy'')_2X_2\}$ coordination subunit is present in the dinuclear double-helical complexes $[M_2(qpy)_2(OAc)]^{3+}$ (M = Ni, Co; qpy = 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine; X_2 = OAc). We hoped that the introduction of substituents onto the quaterpyridine might force the adoption of structure (b).

3.3.1. Nickel(II) complexes

The reaction of **3**–**7** with an equimolar amount of nickel(II) acetate in MeOH or EtOH gave yellow solutions from which yellow-green salts were obtained upon the addition of $[NH_4][PF_6]$. In all cases, microanalysis indicated complexes with a 1:1 M:L stoichiometry. It was also apparent that a number of additional ligands or anions were present in each case. In particular, microanalysis indicated that acetate was present in many of the isolated complexes. Because we had previously characterized the acetate-free mononuclear cations $[Ni(qtpy)(S)_2]^{2+}$ (S = MeCN or H_2O), we hoped that the inclusion of acetate was evidence for the formation of the dinuclear double helices.

The precise species formed depended upon the ligand, but isolated complexes included $\{[NiL(OAc)(S)][PF_6]\}_n$

Scheme 3.

(L = **3**, **6**, **7**, S = MeCN, H_2O) and $\{[NiL(S)_2][PF_6]_2\}_n$ (L = **4**, **5**, S = MeCN, H_2O). Mass spectrometry only provided evidence for the formation of mononuclear complexes in each case (see Section 2), although the complexes containing acetate gave ions $\{NiL(OAc)(PF_6)\}^+$ and $\{[NiL(OAc)\}^+$, thereby providing evidence for coordination of the carboxylate. The ^1H NMR spectra of acetone solutions of the complex were very broad, with paramagnetically shifted resonances observed between δ 10 and 100. It has not been possible to assign these spectra fully, but they are consistent with the formation of a single, symmetrical, solution species. Cyclic voltammetry of MeCN solutions of the complexes revealed no nickel(II/III) redox processes, but in each case two-ligand-centred reduction was observed at ≈ -1.60 and -1.85 V. IR spectroscopy did not provide unambiguous data regarding the coordination mode of the carboxylate in the complexes containing acetate. The mass-spectrometric data suggest that the substituted quaterpyridine ligands form mononuclear complexes similar to those formed with quaterpyridine itself. In order to confirm this and to establish the nature of the acetate in these complexes, we determined the solid-state structures of $[Ni(\mathbf{4})(MeCN)_2][PF_6]_2$ and $[Ni(\mathbf{3})(OAc)(MeOH)][PF_6]\cdot 2MeOH\cdot H_2O$.

3.3.2. Crystal structures of $[Ni(\mathbf{4})(MeCN)_2][PF_6]_2$ and $[Ni(\mathbf{3})(OAc)(MeOH)][PF_6]\cdot 2MeOH\cdot H_2O$

The crystal structures of $[Ni(\mathbf{4})(MeCN)_2][PF_6]_2$ and $[Ni(\mathbf{3})(OAc)(MeOH)][PF_6]\cdot 2MeOH\cdot H_2O$ were determined; the relevant data are presented in Tables 1 and 2. The crystal structure of $[Ni(\mathbf{4})(MeCN)_2][PF_6]_2$ (**15**) revealed a mononuclear complex with a pseudo-octahedral cation containing an equatorial **4** ligand and two axial acetonitrile ligands (Fig. 2), closely resembling that in $[Ni(qtpy)(MeCN)_2]^{2+}$ [7,11]. The quaterpyridine is near planar with interplanar angles of 1.9°, 4.7° and 2.6° between the pyridine rings. The aryl substituents are twisted out of the plane of the ligand, one by 21.7° and the other by 35.1°. Nickel(II) is slightly too small to fit in the ligand cavity and the pyridine rings flex inwards towards the metal ion, resulting in small distortions quantified by the bite angles: ∠N(1)–Ni(1)–N(2), 76.4(4)°; N(2)–Ni(1)–N(3), 79.7(4)°; ∠N(3)–Ni(1)–N(4), 76.3(4)°. As expected, the metal–ligand bond lengths to the central pyridyl rings are longer than those to the terminal rings: $Ni–N_{terminal}$, 2.11(1), 2.091(9) Å; $Ni–N_{central}$, 1.982(9), 2.06(1) Å. The axial ligands are close to ideally located: ∠N(5)–Ni(1)–N(6), 174.5(4)°. There are no short contacts between the cations and anions in the lattice.

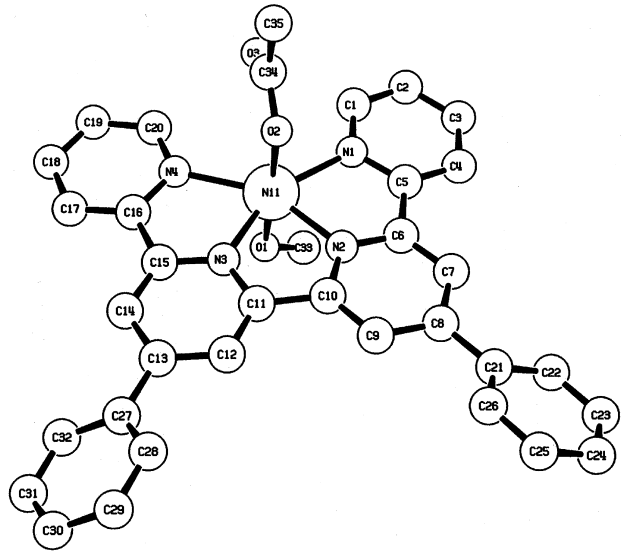

Fig. 3. Molecular structure of the cation present in $[Ni(\mathbf{3})(OAc)(MeOH)][PF_6]\cdot 2MeOH\cdot H_2O$; hydrogen atoms have been omitted for clarity.

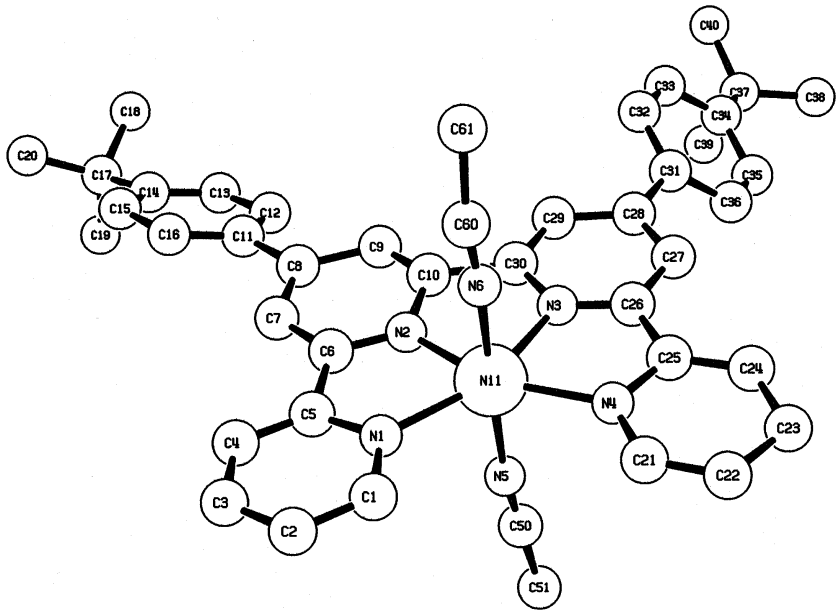

Fig. 2. Molecular structure of the cation present in $[Ni(\mathbf{4})(MeCN)_2][PF_6]_2$; hydrogen atoms have been omitted for clarity.

Analysis of the crystal structure also revealed [Ni(**3**)(OAc)(MeOH)][PF_6] (**16**) contains a mononuclear cation, with an equatorial **3** ligand and axial MeOH and monodentate acetate ligands (Fig. 3). The quaterpyridine is near planar (interplanar angles between pyridine rings of 5.3°, 1.2° and 3.6°), but the phenyl substituents are twisted out of this plane, one by 23.7° and the other by 27.2°. Bond lengths and angles involving the nickel and the quaterpyridine ligand resemble those for **15** (Table 2). The axial ligands are again near-ideally located: ∠O(1)–Ni(1)–O(2), 176.4(2)°. The acetate is monodentate (Ni(1)···O(3), 3.004 Å), with the non-coordinated oxygen lying in the void between the two terminals rings of the quaterpyridine ligand. Consequently, there are two short (2.642, 2.606 Å) contacts between the carboxylate O(3) and the H^6 protons of the terminal rings (Fig. 4). There are no other short contacts between the cations and anions in the lattice. To conclude, in the two structures discussed, the quaterpyridines behave as tetradentate ligands occupying the equatorial sites in near-octahedral cations.

3.3.3. Cobalt(II) complexes

The reaction of **3**–**7** with an equimolar amount of cobalt(II) acetate in MeOH or EtOH gave orange solutions from which orange salts were obtained upon the addition of [NH_4][PF_6]. In general, the isolated complexes closely resembled those with nickel(II), and microanalysis indicated complexes with a 1:1 M:L stoichiometry with additional ligands or anions present. Once again, acetate was present in many of the isolated complexes. On standing in air, some of the complexes decomposed to give green powders.

Mass spectrometry indicated only the formation of mononuclear complexes (see Section 2). We have shown that ^{1}H NMR spectroscopy is a powerful technique for the study of paramagnetic cobalt(II) complexes [47] and, in each case, shifted resonances were observed in the range −20 to 170 ppm. A typical example is seen for the complex [Co(**3**)(OAc)(H_2O)][PF_6], which in CD_3CN solution exhibits ten resonances at δ 6, 9, 12, 22, 32, 40, 50, 71, 72, 159. The resonance at δ 6 is tentatively assigned to the acetate group on the basis of signal intensity. Cyclic voltammetry of MeCN solutions of the complexes showed no cobalt(II/III) redox processes, but ligand-centred reduction was observed at ≈ −1.60 and −1.85 V. The data suggest that the substituted ligands form mononuclear cobalt(II) complexes similar to those formed with nickel(II). In order to confirm this we have determined the solid-state structure of [Co(**3**)(OAc)(MeCN)][PF_6]·1.64MeCN·0.36H_2O.

*3.3.4. Crystal structure of [Co(**3**)(OAc)(MeCN)][PF_6]·1.64MeCN·0.36H_2O (**17**)*

Recrystallization of [Co(**3**)(OAc)(H_2O)][PF_6] from MeCN gave orange crystals of [Co(**3**)(OAc)(MeCN)][PF_6]·1.64MeCN·0.36H_2O. Severe problems were encountered in the refinement of this structure as a result of extensive disorder of the lattice solvent molecules; data are presented in Tables 1 and 2. Discussion centres upon the mononuclear [Co(**3**)(OAc)(MeCN)]$^+$ cation, the structure of which is presented in Fig. 5. The cation is best described as seven-coordinate and contains an equatorial **3** ligand, an axial MeCN and an axial chelating but asymmetric didentate acetate ligand. The quaterpyridine is essentially planar (interplanar angles 2.5°, 0.2°, 0.4°) with the phenyl substituents twisted out of the plane by 10.1° and 26.9°. The metal–ligand bond lengths to the central pyridyl rings are longer than those to the terminal rings. The major difference from the cation in **16** arises in the bonding mode of the acetate. In the the nickel(II) complex, the acetate is essentially monodentate, with the non-bonded contact Ni(1)…O(3) greater than 3 Å; in complex **17**, the two Co…= distances are similar (2.171(4) and 2.293(3) Å), with the shorter contact being to the 'axial' position and the longer to the oxygen bent into the void between the terminal pyridine rings. Once again, ≈2.5 Å contacts between O(2) and the pyridine H^6 protons are observed.

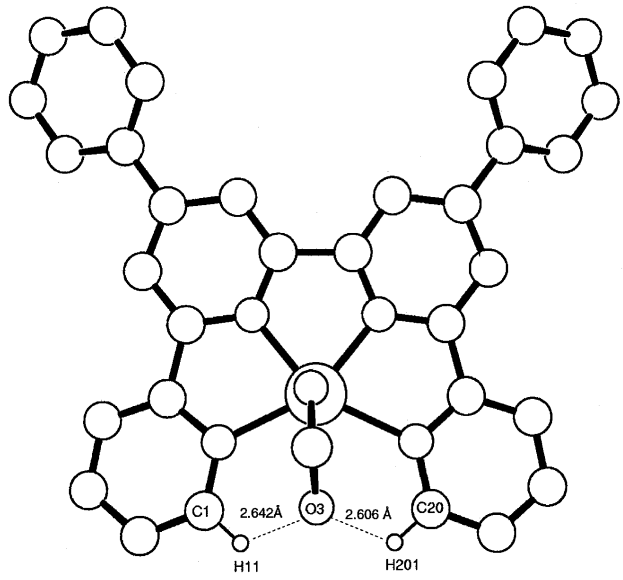

Fig. 4. A view of the cation present in [Ni(**3**)(OAc)(MeOH)][PF_6]·2MeOH·H_2O, showing the contacts between the acetate and pyridine H^6; all hydrogen atoms except H(11) and H(201) have been omitted for clarity, as have the methanol ligand and the acetate methyl group.

4. Conclusions

A series of 2,2′:6′,2″:6″,2‴-quaterpyridine ligands bearing substituents in the 4′- and 4″-positions have been prepared and their coordination chemistry has been investigated. Incorporation of the substituents does not change the basic patterns of reactivity: with silver(I) and copper(I), dinuclear double helicates are formed, whereas, with cobalt(II) and nickel(II), a variety of mononuclear structures are formed.

Supplementary data

Supplementary data are available, upon request, from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, quoting the deposition numbers 124959, 124960 and 124961.

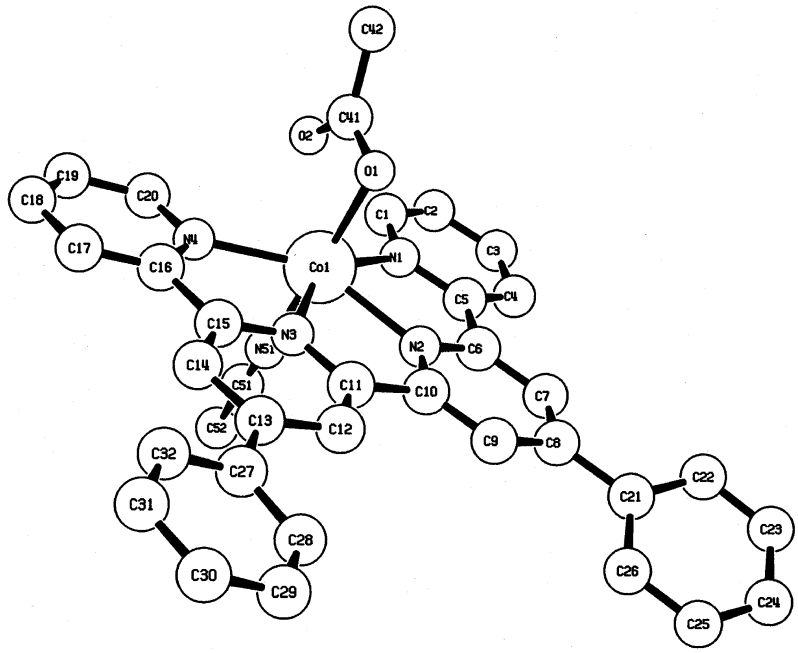

Fig. 5. Molecular structure of the cation present in $[Co(\mathbf{3})(OAc)(MeCN)][PF_6]\cdot 1.64MeCN\cdot 0.36H_2O$; hydrogen atoms have been omitted for clarity.

POLYHEDRON

Group 4 and 5 metal derivatives of 2,2′-methylene-bis(6-phenylphenoxide)

Douglas R. Mulford, Phillip E. Fanwick, Ian P. Rothwell *

Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, IN 47907, USA

Received 21 June 1999; accepted 29 September 1999

Abstract

Addition of the phenol 2,2′-methylene-bis(6-phenylphenol) [$(HOC_6H_3Ph)_2CH_2$] (**1**) (1 equiv. per Ti) to hydrocarbon solutions of [$TiCl_4$] or [$Ti(OPr^i)_4$] leads to dimeric products [$Ti\{(OC_6H_3Ph)_2CH_2\}Cl_2]_2$ (**2**) and [$Ti\{(OC_6H_3Ph)_2CH_2\}(\mu\text{-}OPr^i)(OPr^i)]_2$ (**3**). Structural studies show **2** ($CHCl_3$ solvate) to consist in the solid state of two tetrahedral titanium centers linked by one end of two di-aryloxide ligands. In contrast, **3** contains five-coordinate titanium atoms linked directly by two bridging isopropoxide ligands. Treatment of [MCl_5] (M = Nb, Ta) with 1 equiv. of **1** leads to sparingly soluble trichlorides **4** and **5** which react with pyridine to form soluble adducts [$M\{(OC_6H_3Ph)_2CH_2\}Cl_3(py)$] (M = Nb, **6**; M = Ta, **7**). Compounds **6** and **7** are isostructural in the solid state (benzene solvates) with a *mer* arrangement of chloride groups and the pyridine *trans* to one of the di-aryloxide oxygen atoms. Treatment of **7** with PMe_2Ph leads to the products [$Ta\{(OC_6H_3Ph)_2CH_2\}Cl_3(PMe_2Ph)$] (**8**) and [$HPMe_2Ph$][$Ta\{(OC_6H_3Ph)_2CH_2\}Cl_4$] (**9**). Structurally characterized **9** (benzene solvate) presumably arises via the presence of trace amounts of water during workup. Reaction of **1** with [$Ta(NMe_2)_5$] allows isolation of derivatives [$Ta\{(OC_6H_3Ph)_2CH_2\}_2(NMe_2)(HNMe_2)$] (**10**) (*cis*-nitrogen atoms by NMR) and [H_2NMe_2][$Ta\{(OC_6H_3Ph)_2CH_2\}_3$] (**11**) depending on the stoichiometry. The anion in **11** was shown by crystallography to contain an octahedral arrangement of oxygen atoms about the tantalum metal center. The crystallographic study of **11** is complicated by a disorder of the cation and partial occupancies for the three types of benzene solvate molecule. The niobium trichloride **4** acts as a catalyst precursor for benzene hydrogenation although with lower activity than reported for monodentate aryloxide precursors. During the catalysis the *ortho*-phenyl rings of the di-aryloxide ligand are not hydrogenated. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Titanium; Tantalum; Nobium; Aryloxide; Bisphenol; Hydrogenation

1. Introduction

There has recently been increased interest in the chemistry of 2,6-di-aryl-phenoxide ligation attached to early d-block metal centers [1–8]. Part of this work has been stimulated by the demonstrated ability of niobium and tantalum hydride compounds containing aryloxide ligation to catalyze the hydrogenation of a variety of arene substrates [9]. In the case of 2,6-diphenylphenoxide ligands, both partial and total intramolecular hydrogenation of *ortho*-phenyl rings has been observed [10,11]. As an extension of this research we have examined the early d-block metal chemistry of the chelating ligand 2,2′-methylene-bis(6-phenylphenol) [$(HOC_6H_3Ph)_2CH_2$] (**1**) [12]. This paper reports the synthesis and characterization of Group 4 and 5 metal derivatives of this ligand as well as an evaluation of the hydrogenation activity of niobium and tantalum catalyst precursors.

2. Results and discussion

2.1. Synthesis and spectroscopy of compounds

The addition of the parent phenol 2,2′-methylene-bis(6-phenylphenol) ($(HOC_6H_3Ph)_2CH_2$ **1**) (1 equiv. per Ti) to hydrocarbon solutions of [$TiCl_4$] or [$Ti(OPr^i)_4$] leads to formation of the corresponding mono(di-aryloxide) compounds **2** and **3** respectively (Scheme 1). The di-chloride **2** is only sparingly soluble and hence purification was difficult. The ^1H NMR spectrum of **2** in C_6D_6 is not very informative, showing, in addition to the aromatic resonances, a single pair of doublets for the methylene protons CH_2 of the ligand. Previous work on 2,2′-methylene-bisphenoxides [13–17] has shown that the puckered eight-membered ring formed by chelation to metal centers undergoes slow flipping on the NMR timescale. Hence the methylene protons in the chelate backbone are typically diastereotopic at ambient temperatures. The ^1H NMR spectral data for **3** are equally uniform-

Scheme 1.

ative, simply showing broad resonances for the di-aryloxide ligands and OPr^i groups.

The reaction of **1** with the chlorides $[M_2Cl_{10}]$ (M = Nb, Ta) produces sparingly soluble trichlorides $[M_2\{(OC_6H_3Ph)_2CH_2\}Cl_3]$ (M = Nb, **4**; M = Ta, **5**) (Scheme 2). Previous work with monodentate aryloxides has shown that for bulky ligands square pyramidal structures are formed for trichlorides $[M(OAr)_2Cl_3]$ (M = Nb, Ta; OAr = $OC_6H_3Bu^t_2$-2,6, various 2,6-diphenylphenoxides) with an axial aryloxide [18,19]. With a slightly smaller aryloxide a dimeric structure $[(ArO)_2Cl_2Ta(\mu\text{-}Cl)]_2$ is formed, where the 2,6-di-isopropylphenoxide ligands are *trans* to the bridging chloride groups [20]. Previously the compound $[Nb\{(OC_6H_2Bu^t_2\text{-}4,6)_2CH_2\}_2Cl]$ has been reported and shown to adopt a tbp structure with an equatorial cloride [17].

Scheme 2.

In the case of **4** and **5**, the bidentate aryloxide is probably not sufficiently bulky to generate a monomeric environment. A dimeric structure in hydrocarbon solvents is consistent with the low solubility, but whether there are chloride or aryloxide bridges is unknown. The addition of the donor ligand pyridine leads to much more soluble adducts $[M\{(OC_6H_3Ph)_2CH_2\}Cl_3(py)]$ (M = Nb, **6**; M = Ta, **7**, Scheme 2). In the ^1H NMR spectra of **6** and **7** (Fig. 1), well resolved sharp multiplets are observed. The diastereotopic methylene protons in the chelate ring are separated by over 2 ppm. The solid state structure (vide infra) would lead to a virtual plane of symmetry in the molecule if the eight-membered chelate were undergoing rapid flipping. The sharp AX pattern observed for the methylene group of **6** and **7** shows that inversion is much slower than the NMR timescale. A similar phosphine adduct of **7** is generated by addition of PMe_2Ph. In this case the resulting product **8** shows broad ligand resonances consistent with partial ligand dissociation in solution. During the workup of **8**, a few well-formed crystals of a salt identified as $[HPMe_2Ph][Ta\{(OC_6H_3Ph)_2CH_2\}Cl_4]$ (**9**) were obtained. It is believed that adventitious amounts of water led to the formation of **9** which has the elements of HCl added to **8**.

The addition of **1** to $[Ta(NMe_2)_5]$ is found to lead to a mixture of substitution products (serious safety concerns have been raised with respect to the original procedure [21], for the synthesis of $[Ta(NMe_2)_5]$, see [22]). With 2 equiv. of **1**, a six-coordinate dimethylamine adduct is produced of formula $[Ta\{(OC_6H_3Ph)_2CH_2\}_2(NMe_2)(HNMe_2)]$ (**10**) (Scheme 2). In the ^1H NMR spectrum of **10** two diastereotopic methylene groups CH_2 indicate non-equivalence of the two di-aryloxide ligands. The spectrum also shows a pair of broad doublets at δ 1.73 and 0.87 ppm. These we assign to the diastereotopic HN*Me*$_2$ methyl groups shifted upfield of their normal position by the anisotropy of adjacent phenyl groups of the aryloxides. Two geometries are possible for six-coordinate **10** (Scheme 2). In one the amine is located *trans* to the amido nitrogen while in the second these groups are mutually *cis*. The assigned *cis*-geometry (Scheme 2) automatically gives rise to non-equivalent di-aryloxide groups as well as diastereotopic HN*Me*$_2$ methyl groups. Even if the di-aryloxide rings in the *trans* geometry fold so as to become non-equivalent, they will still maintain a plane of symmetry through the Ta-HNMe$_2$ group. The reaction of $[Ta(NMe_2)_5]$ with the bulkier ligand 2,2′-methylene-bis(6-tert-butyl-4-methylphenoxide) has been shown to produe $[Ta\{(OC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2\}(NMe_2)_3]$ with one amide and di-aryloxide oxygen atom *trans* within a tbp structure [16]. When more than 2 equiv. of **1** are reacted with $[Ta(NMe_2)_5]$, a mixture (NMR) is produced from which a sparingly soluble product **11** precipitates. This compound was identified by crystallographic methods as a salt, $[H_2NMe_2][Ta\{(OC_6H_3Ph)_2CH_2\}_3]$ (**11**). Disorder of the cation and the presence of three benzene molecules of solvate complicated solution of the crystal structure of **11**. Two of the benzene molecules had partial occupancies of 0.59 and

0.72, respectively, possibly due to loss of solvent from the unit cell. However, the anion clearly contains a tantalum metal center chelated by three di-aryloxide ligands (vide infra).

2.2. Structural studies

The solid-state structures of **2**, **6**, **7**, **9** and **11** were determined (Tables 1–5, Figs. 2–6). All five compounds formed crystals containing solvent molecules within the unit cell. In the case of **2**, two molecules of chloroform per di-titanium unit were present while the other four compounds contained varying amounts of benzene of solvation. Previous work on the bulky ligand 2,2′-methylene-bis(6-tert-butyl-4-methylphenol) ($(HOC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2$) has led to the isolation of a series of monomeric species $[Ti\{(OC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2\}X_2]$ (X = Cl, OR, R) [13].

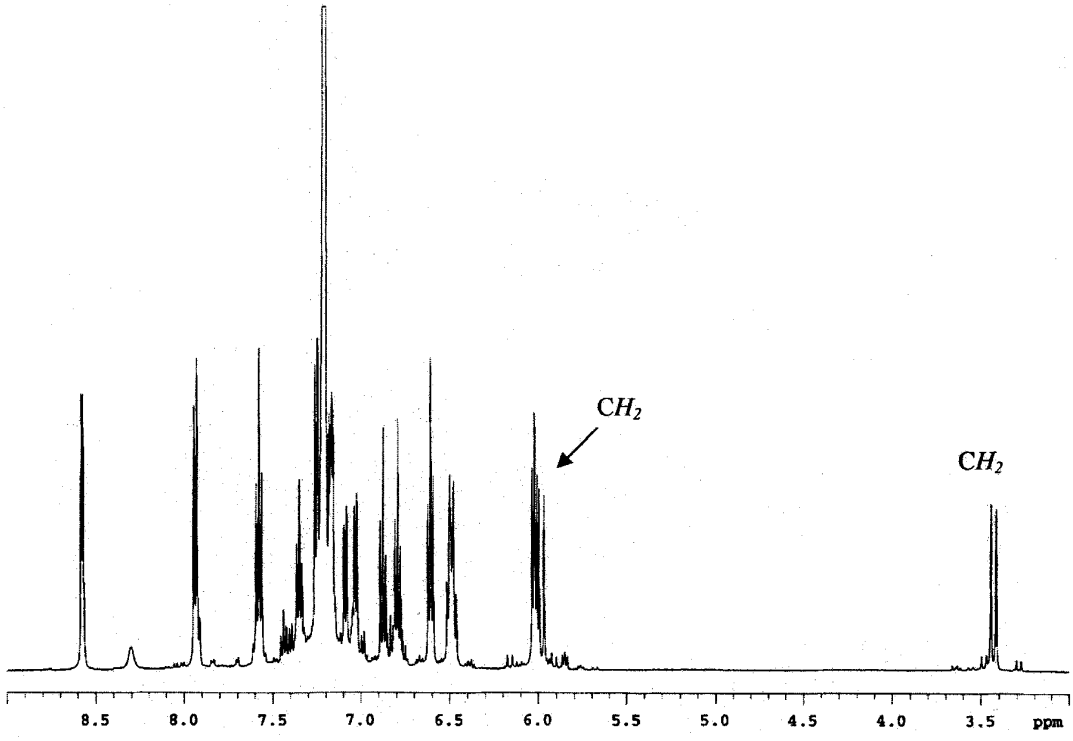

Fig. 1. ^1H NMR (C_6D_6, 500 MHz) of $[Nb\{(OC_6H_3Ph)_2CH_2\}Cl_3(py)]$ (**6**).

Structural studies show a pseudo-tetrahedral geometry about Ti with O–Ti–O angles of 106.5(2)° (X = Cl) and 112.7(2)° (X = Me). In the case of the dichloride a five-coordinate thf adduct was also isolated and structurally characterized as

pseudo-trigonal bipyramidal about Ti with the thf axial and *trans* to one end of the chelating di-aryloxide [15]. The O–Ti–O angle of 96.2(1)° for the chelate shows the flexibility of the eight-membered ring in occupying coordination sites about the metal center. In contrast the dichloride **2** can be seen to adopt a dinuclear structure in the solid state (Fig. 2). Each Ti metal center is pseudo-tetrahedral and bound to one end of two di-aryloxides. The O–Ti–O angle is 111.7(2)°, only slightly larger than that found for $[Ti\{(OC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2\}Cl_2]$. The question arises as to what factors are important in determining whether a monomeric structure is formed or a dimeric unit as in **2**. The dimeric structure does

not contain either chloro or oxygen bridges which might alleviate the electron deficiency of the metal center. It may very well be that the bulkier *ortho*-tert-butyl substituents preclude formation of a dimer. However, an electronic rationale for the dimeric structure is that it allows for larger Ti–O–Ar angles. In monomeric $[Ti\{(OC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2\}Cl_2]$ these angles are 143.6(4) and 155.8(4)° while in **2** they open up to 161.9(5) and 168.2(5)°. This could imply greater oxygen-p to metal-d π-bonding. However, the Ti–O distances in $[Ti\{(OC_6H_2Bu^t\text{-}6\text{-}Me\text{-}4)_2CH_2\}Cl_2]$, 1.760(4) and 1.742(4) Å, are essentially identical to values of 1.746(5) and 1.754(5) Å found for **2**. It is now well established that the degree of π-donation does not correlate with M–O–Ar angles for early d-block metal aryloxides [23,24]. It appears that a larger database of related compounds is needed to reach any conclusions concerning the relative stabilities of these two structural motifs. The formation of dimeric units has been enforced by use of fluorenediol ligation where the di-aryloxide structure precludes chelation [25].

A data set collected on the isopropoxide **3** indicates a dimeric structure in the solid state with terminal chelated di-aryloxide and bridging isopropoxides as shown in Scheme 1. Unfortunately the refinement could not be completed owing to disorder among the methyl units of the Pr^i groups [26]. It would appear in this case that the electron deficiency of the titanium atoms is relieved by the formation of alkoxide bridges leading to a pseudo square pyramidal geometry about each metal center.

Both of the pyridine adducts **6** and **7** have been structurally characterized (Figs. 3 and 4). A large number of adducts $[M(OAr)_x(Cl)_{5-x}(L)]$ (M = Nb, Ta; OAr = various monodentate aryloxides; L = O, N or P donor ligands) have been reported [20]. Structural studies of the tri-chlorides ($x = 3$) show a *cis-mer* geometry with the donor ligand *trans* to one of the aryloxides. These molecules consistently show a distortion from octahedral geometry in which four of the anionic ligands are bent towards the *cis*-donor ligand. This distortion has been studied theoretically [20,27]. It can be seen that compounds **6** and **7** are related to the previously isolated monodentate aryloxide complexes. The chloride ligands are arranged in a *mer* fashion with the pyridine *trans* to one of the chelating aryloxide oxygen atoms. The O–M–O angles are 93–94°, again showing the flexibility of this ligand. The metal–ligand distances (Tables 2 and 3) are very similar to those reported for *cis-mer*-$[M(OC_6H_3Pr^i_2\text{-}2,6)_2Cl_3(py)]$ (M = Nb, Ta). In order to quantify the distortion from octahedral geometry in adducts of this type, the parameter $\Sigma\alpha$ defined as follows, $\Sigma\alpha = \Sigma[(cis\text{-L-M-X}) - 90]$, was introduced [20]. The value of $\Sigma\alpha$ is −17.6 and −17.0 for **6** and **7**, respectively. These values are slightly smaller than values of −23.5 and −22.6 found in *cis-mer*-$[M(OC_6H_3Pr^i_2\text{-}2,6)_2Cl_3(py)]$ (M = Nb, Ta) but still indicate a significant distortion from octahedral geometry.

The molecular structures of the anions in **9** and **11** (Figs. 5 and 6) are unexceptional. In both cases the geometry about the metal center is very close to octahedral. The O–Ta–O angle in **9** of 91.5(1)° accommodates the octahedral geometry very well. The bite of the three chelates in the anion of **11** scans the range 89.8(2)–93.8(2)°. Also in tris(chelate) **11** the folding of the chelate rings is such that there are two types of di-aryloxide. Unfortunately the lack of solubility of this compound precluded confirmation of this by NMR. The closest analog of **9** is the salt $[HPMe_2Ph][Nb(OC_6H_3Pr^i_2\text{-}2,6)_3Cl_3]$ formed as a minor product by addition of PMe_2Ph to $[Nb(OC_6H_3Pr^i_2\text{-}2,6)_2Cl_3]$ [20]. The anion in tris(chelate) **11** can be related to the hexa(aryloxide) anion $[Nb(OC_6H_3Me_2\text{-}3,5)_6]$ [28].

2.3. Reactivity studies

The potential of the trichloride compounds **4** and **5** as catalyst precursors for the hydrogenation of arene rings was evaluated. A sample of the trichloride (0.5 mmol) was placed in benzene and activated with a standardized solution of n-BuLi (3 equiv.). The resulting mixture (20 ml total volume) was pressurized with H_2 (1200 psi) and heated at 120°C for 24 h. The tantalum compound showed no detectable activity for benzene hydrogenation. However, the niobium precursor **4** did produce cyclohexane (80 equiv. per Nb). This compares with 240 equiv. previously reported to be produced by the precursor $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$ under the same conditions [9]. Under these conditions in the presence of 20 equiv. of PPh_3, compound **4** showed some conversion to $PCyPh_2$ and PCy_2Ph, but the activity was much lower than when the monodenate precursor $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$ was used. Analysis of these reaction mixtures after hydrolysis showed (NMR and GC) the presence of **1** with only very minor signals that may be attributable to cyclohexyl phenols. It therefore appears that the chelation of the di-aryloxide at niobium metal centers inhibits the intramolecular hydrogenation of the *ortho*-phenyl rings, a reaction that is facile for monodentate *ortho*-phenylphenoxides [10,11].

3. Experimental

3.1. General

All operations were carried out under a dry nitrogen atmosphere or in vacuo either in a Vacuum Atmosphere Dri-Lab or by standard Schlenk techniques. Hydrocarbon solvents were dried by distillation from sodium/benzophenone and stored under dry nitrogen. Reagents were purchased from Aldrich Chemical Co. and were dried over 3 Å molecular sieves prior to use. The ^1H NMR spectra were recorded on a Varian Associates Gemini 200 and a General Electric QE-300 spectrometer and were referenced using protio impurities of commercial benzene-d_6 as an internal standard. Microanalytical data were obtained in-house at Purdue. All high-pressure reactions were performed in a Parr model 4561, 300

ml internal volume minireactor. The X-ray diffraction studies were completed in-house at Purdue University.

3.2. Synthesis of compounds

3.2.1. [Ti{$(OC_6H_3Ph)_2CH_2$}Cl_2]$_2$ (2)

To a suspension of 2,2′-methylene-bis(6-phenylphenol) (4.23 g, 12.0 mmol) in benzene (100 ml) was added [$TiCl_4$] (2.0 g, 10.5 mmol) by standard Schlenk techniques under a dry N_2 atmosphere. The resulting red solution was stirred for 3 h before being dried in vacuo to produce a red solid which was washed twice with pentane to yield compound **2**. Yield 4.10 g (83.2%). *Anal.* Calc. for $TiCl_2O_2C_{25}H_{18}$: C, 63.99; H, 3.86; Cl, 15.11. Found: C, 62.41; H, 4.03; Cl, 15.31%. ^{1}H NMR ($CDCl_3$, 30°C): δ 7.16–7.56 (m, 16H, aromatics); 4.32 (d, 1H, CH_2); 3.92 (d, 1H, CH_2). Crystals suitable for X-ray diffraction were obtained from $CHCl_3$–pentane mixtures.

3.2.2. [Ti{$(OC_6H_3Ph)_2CH_2$}(μ-OPr^i)(OPr^i)]$_2$ (3)

A mixture of 2,2′-methylene-bis(6-phenylphenol) (24.6 g, 69.8 mmol) and [$Ti(OPr^i)_4$] (20.0 g, 70.4 mmol) in benzene (100 ml) was stirred for 1 h then dried in vacuo. The resulting red/orange solid was washed three times with hexane and recrystallized from toluene. The resulting orange plate-like crystals of **3** were dried in vacuo. Yield 13.85 g (38.1%). *Anal.* Calc. for $TiO_4C_{31}H_{32}$: C, 72.01; H, 6.24. Found: C, 72.17; H, 6.25%. ^{1}H NMR (C_6D_6, 30°C): δ 7.45 (d, 2H, aromatic); 7.09 (m, 12H, aromatic); 6.73 (t, 2H, aromatic); 4.35 (broad, 2H, C*H*Me_2); 4.19 (broad, 1H, CH_2); 3.45 (broad, 1H, CH_2); 0.85 (broad, 12H, CH*Me*$_2$).

3.2.3. [Nb{$(OC_6H_3Ph)_2CH_2$}Cl_3] (4)

A sample of 2,2′-methylene-bis(6-phenylphenol) (13.3 g, 37.76 mmol) was added to a solution of [$NbCl_5$] (10.2 g, 37.7 mmol) in benzene (100 ml) to give a red solution which was stirred for 5 h under a dry N_2 atmosphere. The resulting red/brown precipitate of **5** was dried in vacuo. Yield 17.5 g (84%). *Anal.* Calc. for $NbCl_3O_2C_{25}H_{18}$: C, 54.63; H, 3.30; Cl, 19.35. Found: C, 53.89; H, 3.40; Cl, 17.33%. ^{1}H NMR (C_6D_6, 30°C): δ 6.65–7.24 (m, 16H, aromatics); 3.10 (s, 2H, CH_2).

3.2.4. [Ta{$(OC_6H_3Ph)_2CH_2$}Cl_3] (5)

A sample of 2,2′-methylene-bis(6-phenylphenol) (1.02 g, 2.89 mmol) was added to a solution of [$TaCl_5$] (1.02 g, 2.87 mmol) in benzene (25 ml) to give a brown/red solution which was stirred for 1.5 h under a dry N_2 atmosphere. The resulting yellow/orange precipitate of **4** was dried in vacuo. Yield 1.47g (75%). *Anal.* Calc. for $TaCl_3O_2C_{25}H_{18}$: C, 47.10; H, 2.84; Cl, 16.68. Found: C, 47.10; H, 2.84; Cl, 14.59%. ^{1}H NMR (C_6D_6, 30°C): δ 6.65–7.44 (m, 16H, aromatics); 3.24 (s, 2H, CH_2).

3.2.5. [Nb{$(OC_6H_3Ph)_2CH_2$}Cl_3(py)] (6)

To a suspension of **4** (0.50 g, 0.91 mmol) in benzene was added pyridine (0.13 g 1.64 mmol, 1.80 equiv.) and the resulting solution was stirred for 1 day during which time the solution changed from brown to red. The solution was layered with pentane and the resulting solid **6** was washed once with pentane and dried in vacuo. Yield 0.48 g (83.0%). *Anal.* Calc. for $NbNO_2Cl_3C_{30}H_{23}\cdot 0.5C_6H_6$: C, 59.35; H, 3.92; N, 2.10; Cl, 15.92. Found: C, 58.82; H, 4.06; N, 2.14; Cl, 16.04%. ^{1}H NMR (C_6D_6, 30°C): δ 8.48 (d, aromatic); 7.83 (d, aromatic); 7.48 (t, aromatic); 7.16 (d, aromatic); 6.78 (t, aromatic); 6.70 (t, aromatic); 6.51 (t, aromatic); 6.39 (d, aromatic); 5.93 (t, aromatic); 5.88 (d, 1H, CH_2); 3.33 (d, 1H, CH_2).

3.2.6. [Ta{$(OC_6H_3Ph)_2CH_2$}Cl_3(py)] (7)

To a suspension of **5** (0.50 g, 0.78 mmol) in benzene was added pyridine (0.09 g 1.14 mmol, 1.5 equiv.) resulting in the formation of a yellow solution. The solution was layered with pentane causing yellow crystals of **7** to form, which were dried in vacuo. Yield 0.30 g (52.8%). *Anal.* Calc. for $TaNO_2Cl_3C_{30}H_{23}\cdot 0.5C_6H_6$: C, 52.44; H, 3.47; N, 1.85; Cl, 14.07. Found: C, 51.77; H, 3.81; N, 1.50; Cl, 13.94%. ^{1}H NMR (C_6D_6, 30°C): δ 8.52 (d, aromatic); 7.84 (d, aromatic); 7.47 (t, aromatic); 7.14 (d, aromatic); 6.77 (t, aromatic); 6.70 (t, aromatic); 6.50 (t, aromatic); 6.43 (d, aromatic); 5.93 (t, aromatic); 5.81 (d, 1H, CH_2); 3.42 (d, 1H, CH_2).

3.2.7. [Ta{$(OC_6H_3Ph)_2CH_2$}Cl_3(PMe_2Ph)] (8) and [$HPMe_2Ph$][Ta{$(OC_6H_3Ph)_2CH_2$}Cl_4] (9)

To a suspension of **5** (0.32 g, 0.50 mmol) in benzene was added PMe_2Ph (0.155 g, 1.12 mmol) and the solution was stirred for 20 min. Yellow powder of **8** formed overnight and was washed twice with pentane and dried in vacuo. Yield 0.35 g (70%). *Anal.* Calc. for $TaO_2Cl_3PC_{33}H_{29}$: C, 51.08; H, 3.79; P, 3.99; Cl, 13.71. Found: C, 50.82; H, 3.83; P, 3.61; Cl, 13.57%. ^{1}H NMR (C_6D_6, 30°C): δ 6.89–7.17 (m, 21H, aromatic); 5.95 (broad, 1H, CH_2); 3.25 (broad, 1H, CH_2); 1.026 (s, 6H, P*Me*$_2$Ph). ^{31}P NMR (C_6D_6, 30°C): δ −10.536 (s, 1P, *P*Me_2Ph). Layering of the supernatant with pentane resulted in the formation of a few well formed crystals of **9** (benzene solvate) presumably due to adventitious amounts of moisture. ^{1}H NMR (C_6D_6, 30°C): δ 6.89–7.17 (m, 21H, aromatic); 5.95 (broad, 1H, CH_2); 3.25 (broad, 1H, CH_2); 0.489 (d, 6H, P*Me*$_2$Ph). ^{31}P NMR (C_6D_6, 30°C): δ −10.505 (d, 1P, H*P*Me_2Ph, $^2J_{P\text{-}H}$ = 461.43 Hz).

3.2.8. [Ta{$(OC_6H_3Ph)_2CH_2$}$_2$(NMe_2)($HNMe_2$)] (10)

To a suspension of [$Ta(NMe_2)_5$] (0.25 g, 0.62 mmol) in benzene was added 2,2′-methylene-bis(6-phenylphenol) (0.44 g, 1.24 mmol) by standard Schlenk techniques under an N_2 atmosphere. The solution was stirred for 2 h and allowed to stand overnight before being dried in vacuo to produce a yellow powder. The resulting powder was suspended in a minimum amount of benzene and layered with pentane, resulting in the formation of a yellow crystalline material. Yield 0.486 g (78.4%). *Anal.* Calc. for $TaN_2O_4C_{54}H_{49}\cdot C_6H_6$: C, 68.70; H, 5.28; N, 2.67. Found: C,

68.84; H, 5.33; N, 2.44%. ^{1}H NMR (C_6D_6, 30°C): δ 6.73–7.86 (m, 32H, aromatics); 6.41 (d, 1H, CH_2); 5.56 (d, 1H, CH_2); 3.59 (d, 1H, CH_2); 3.46 (d, 1H, CH_2); 2.51 (s, 16H, NCH_3); 1.73 (d, 3H, HNCH_3); 0.87 (d, 3H, HNCH_3).

*3.2.9. [H_2NMe_2][Ta{($OC_6H_3Ph)_2CH_2$}$_3$] (**11**)*

To a suspension of [Ta(NMe_2)$_5$] (0.25 g, 0.62 mmol) in benzene was added 2,2′-methylene-bis(6-phenylphenol) (0.66 g, 1.86 mmol) by standard Schlenk techniques under an N_2 atmosphere. Upon stirring for 1 h a small amount of **11** was formed as a white precipitate which was isolated. Upon standing, the supernatant produced a few crystals of **11** (benzene solvate) suitable for X-ray analysis. *Anal*. Calc. for $TaNO_6C_{77}H_{62}\cdot 2C_6H_6$: C, 74.52; H, 5.20; N, 1.00. Calc. for $TaNO_6C_{77}H_{62}\cdot 3C_6H_6$: C, 75.43; H, 5.33; N, 0.93. Found: C, 74.22; H, 5.40; N, 1.65%. The crystals analyzed by crystallography contained 2.31 equiv. of benzene per Ta within the unit cell.

3.2.10. Hydrogenation experiment

A sample of [Nb{($OC_6H_3Ph)_2CH_2$}Cl_3] (**4**) (0.28 g, 0.51 mmol) was suspended in benzene (17 ml, 400 equiv.) in a 50 nl round bottomed flask. To this was added n-BuLi (3 equiv. in hexane). The flask containing the mixture was placed in a Parr model 4561, 300 ml high pressure minireactor and pressurized to 1200 psi hydrogen and heated to 80°C for 24 h. After cooling, a small amount of the resulting solution was diluted with C_6D_6 and the degree of hydrogenation (20%, 80 equiv.) of cyclohexane determined by ^{1}H.

4. Supplementary data

Crystal data and data collection parameters are contained in Tables 6 and 7. Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC numbers 133328 (**2**), 133329 (**6**), 133330 (**7**), 133331 (**9**) and 133332 (**11**). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033) or e-mail deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk.

Received 2 August 1999; accepted 21 October 1999

Abstract

Reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ with concentrated hydrochloric acid in an aprotic solvent yields a molecular molybdenum oxychloride anion $[Mo_2O_5Cl_4]^{2-}$ as a tetra-*n*-butylammonium salt. X-ray structural analysis of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]\cdot 1/3(C_2H_5)_2O$ revealed that the dimeric anion consists of two MoO_3Cl_3 octahedra sharing a common face with a relatively long Mo–Mo distance (3.279 Å). The compound has the highest acidity as a polynuclear molybdate isolated so far. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Polyoxometalate; Oxyhalide; Molybdenum; X-ray structure; High acidity

1. Introduction

Since the discovery of molybdophosphate by Berzelius, many isopoly- and heteropoly-molybdates have been isolated and structurally characterized [1,2]. Their structures vary from relatively simple $[Mo_2O_7]^{2-}$ [3] to highly complex $[Mo_{36}O_{112}(H_2O)_{18}]^{8-}$ [4]. On the other hand, their acidity values *Z* [5–7] are confined in a narrow range of 1.0–2.0. The existence of a dimeric cation that has a *Z* value of 3 was repeatedly postulated in different solution studies [8–13], but such a species has never been isolated. Recently, we have isolated a novel molybdenum oxychloride anion that has the same *Z* value as this proposed dimer. Here we report its synthesis and structural characterization.

2. Experimental

2.1. Reagents, solvents, and general procedures

The following were purchased from commercial sources and used without further purification: concentrated hydrochloric acid, B_2O_3, and $Na_2MoO_4\cdot 2H_2O$ (Kishida), and P_2O_5 (Wako). Acetonitrile, diethyl ether, and acetone (Kishida or Wako) were distilled under N_2 atmosphere before use over P_2O_5, sodium benzophenone ketyl, and B_2O_3, respectively. Procedures described in the literature [14] were followed for the preparation of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$. Elemental analysis was performed by Toray Research Center, Shiga, Japan. Infrared spectra were recorded from mineral oil (Nujol) mulls between KBr plates on a Hitachi I-3000 spectrometer. Absorptions are described as follows: strong (s), medium (m), weak (w), and shoulder (sh).

2.2. Preparation of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]$

Concentrated hydrochloric acid (0.085 ml, 1.0 mmol) was added to a solution of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ (0.20 g, 0.25 mmol) in 2 ml of acetonitrile. The resulting pale yellow solution was refluxed under N_2 atmosphere for 1 h. A small amount of yellow crystals that formed on cooling the solution to ambient temperature was filtered off, and the filtrate was evaporated under vacuum to yield a crude product as a colorless tacky solid. The crude product was crystallized by dissolving it into 4 ml of acetone, adding 10 ml of diethyl ether to the solution, heating the mixture to boiling, filtering off a small amount of solid that formed, and allowing the filtrate to stand at ambient temperature for several hours. The colorless plate-shaped crystals thus obtained weighed 0.037 g (0.041 mmol, 16%) after drying under vacuum. *Anal*. Calc. for $C_{32}H_{72}N_2Mo_2Cl_4O_5$: C, 42.77; H, 8.08; N, 3.12; Cl, 15.78; Mo, 21.4. Found: C, 42.56; H, 7.94; N, 3.15; Cl, 15.62; Mo, 21.3%. IR (Nujol, 1000–400 cm^{-1}): 942 (s), 912 (s), 878 (m), 798 (w), 736 (m), 722 (m), 690 (s), 670 (sh), 546 (m).

2.3. Crystal structure determination

Diffraction data from a colorless plate shaped crystal were collected on a Siemens SMART CCD diffractometer [15] at 115 K. The structure was solved by the direct method using the SHELXS-97 [16] program and was refined by the full-matrix least-squares method on F^2 with the SHELXL-97 [17] program for 822 parameters and 16564 independent reflections. Mo, Cl and O atoms were refined with anisotropic displacement parameters. Hydrogen atoms were refined with the riding model. Crystallographic data for $3[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]\cdot(C_2H_5)_2O$: empirical formula $Mo_6Cl_{12}O_{16}N_6C_{100}H_{226}$, space group $P2_1/c$, $a=28.723(6)$, $b=16.357(3)$, $c=29.692(6)$ Å, $\beta=104.25(3)°$, $Z=4$, crystal size $0.30\times0.15\times0.04$ mm, $\lambda=0.7107$ Å, $T=115$ K, $R[F_o^2>2\sigma(F_o^2)]=0.065$, $R_w[F_o^2>2\sigma(F_o^2)]=0.166$ ($R=\sum||F_o|-|F_c||/\sum|F_o|$, $R_w=[\sum w(F_o^2-F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$, $w=1/[\sigma^2(F_o^2)+(0.070P)^2+103.0P]$, where $P=(F_o^2+2F_c^2)/3$). The anions A and B are roughly related by a center of symmetry at (0.25 0.25 0.25), with which the space group would be $I2/a$. Lattice centering with respect to these anions leads to much smaller intensities for the reflections with $h+k+l=2n+1$ than those with $h+k+l=2n$. However, the refinement with the space group $P2_1/c$ using both reflection classes is essential for the successful refinement of the anions C and D and the tetra-*n*-butylammonium cations. An asymmetric unit contains four independent $[Mo_2O_5Cl_4]^{2-}$ anions, six tetra-*n*-butylammonium cations and one diethyl ether molecule of crystallization. Two of the four independent $[Mo_2O_5Cl_4]^{2-}$, anions C and D, are disordered and their occupancies were refined with the constraint that the sum of them is 1.0. Selected geometric parameters are listed in Table 1.

Table 1
Interatomic distances (Å) and angles (°) for $[Mo_2O_5Cl_4]^{2-}$ anions

	Anion			
	A	B	C	D

Mo2–Cl3	2.701(2)	2.695(2)	2.680(4)	2.651(7)
Mo2–Cl4	2.691(2)	2.698(2)	2.629(3) [a]	2.802(3) [a]
Mo1–O5–Mo2	118.3(2)	118.2(2)	117.5(5)	122.0(10)
Mo1–Cl3–Mo2	74.62(5)	75.04(5)	75.09(10)	75.03(19)
Mo1–Cl4–Mo2	74.98(5)	74.83(5)	76.63(8) [a]	70.93(8) [a]

[a] $Cl4_C$ and $Cl4_D$ are located very close to each other, expected to be 0.26 Å apart. Thus, a Cl atom representing superimposed image of these two Cl was introduced and was refined with the occupancy factor of 1.0. Distances and angles involving this Cl atom are therefore less reliable.

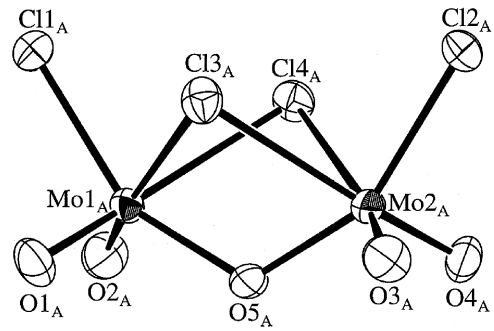

Fig. 1. Perspective view of the anion A. Displacement ellipsoids are scaled to enclose 50% probability levels.

3. Results and discussion

Reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ [14] with concentrated hydrochloric acid in acetonitrile yields a novel molybdenum oxychloride anion as a tetra-*n*-butylammonium salt.

$$[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]+4HCl\rightarrow$$
$$[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]+2H_2O$$

X-ray structural analysis revealed that single crystals of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]\cdot1/3(C_2H_5)_2O$ are composed of $[(n\text{-}C_4H_9)_4N]^+$ cations, diethyl ether molecules of crystallization, and discrete $[Mo_2O_5Cl_4]^{2-}$ (**1**) anions having the structure shown in Fig. 1. The dimeric oxychloride anion consists of two octahedral MoO_3Cl_3 units sharing a common face, where all the Cl atoms are positioned *trans* to the O atoms. The Mo–O bond lengths in **1** are comparable to those found in the face-sharing dioctahedral units of $[(CH_3)_2AsMo_4O_{15}H]^{2-}$ [18–20], $[AsMo_8O_{30}H_2]^{5-}$ [21], $[AsMo_8O_{30}]^{7-}$ [21], $[Mo_4O_{10}(O_3PCH_2PO_3)_2]^{4-}$ [22], $[(Bu^tP)_2Mo_6O_{24}]^{4-}$ [22], $[Mo_4O_{12}F_3]^{3-}$ [23], $[Mo_2O_6F_3]^{3-}$ [24], $[(C_{14}H_8)Mo_4O_{15}(OH)]^{2-}$ [25], $[CeMo_{12}O_{42}]^{8-}$ [26], and many molybdate–polyalcohol complexes [23,27–31]. The Mo···Mo distance in **1**, however, is 3.279 Å and unusually long for a face-sharing octahedral molybdenum(VI) compound. The corresponding distances are 3.163 Å in $[(CH_3)_2AsMo_4O_{15}H]^{2-}$, 3.193 and 3.188 Å in $[AsMo_8O_{30}H_2]^{5-}$, 3.113 Å in $[AsMo_8O_{30}]^{7-}$, 3.129 and 3.122 Å in $[Mo_4O_{10}(O_3PCH_2PO_3)_2]^{4-}$, 3.106 and 3.245 Å in $[(Bu^tP)_2Mo_6O_{24}]^{4-}$, 3.152 Å in $[Mo_4O_{12}F_3]^{3-}$, 3.205 Å in $[Mo_2O_6F_3]^{3-}$, 3.143 Å in $[(C_{14}H_8)Mo_4O_{15}(OH)]^{3-}$, 3.13 Å in $[CeMo_{12}O_{42}]^{8-}$, and 3.14 Å [32] in different dimeric molybdate–polyalcohol compounds. More interestingly, the molybdenum–oxygen bond lengths and angles (and hence the Mo···Mo distance) in **1** are extremely similar to those of the $(MoO_3)_6$ rings found in Anderson type [33–40] and $X_2Mo_6O_{18}$ type ($X=CH_3AsO_3$, $H_2NC_6H_4AsO_3$, AsO_4, MoO_4, VO_4, TeO_3) [31,41–46] structures. It might be better to describe the structure of **1** as

a Mo_2O_5 unit cut out from a $(MoO_3)_6$ ring and coordinated by four chloride ligands rather than to depict it as two MoO_3Cl_3 octahedra sharing a common face. In fact, the IR spectrum of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5Cl_4]$ exhibits a feature characteristic for the compounds that have a $(MoO_3)_6$ ring (see Section 2) and it is impossible to distinguish the current compound from an Anderson type polymolybdate by IR spectra alone.

As mentioned earlier, **1** has a very high acidity ($Z=3$). Just like $[Mo_2O_7]^{2-}$ ($Z=1$) opened up a new synthetic route and aspect in polymolybdate chemistry that had been traditionally constrained by the chemical nature of MoO_4^{2-} ($Z=0$), the current compound is expected to serve as an entree to the chemistry of polymolybdates of higher acidity.

Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK on request, quoting the deposition number CCDC 132906.

Received 30 June 1999; accepted 13 October 1999

Abstract

New [$Mn^{II}L(H_2O)_2$] and [$Mn^{III}L(H_2O)_2$]ClO_4 complexes, where L are substituted *N*,*N*′-bis(salicylidene)propane-1,3-diamine (H_2*salpn*) ligands have been prepared and thoroughly characterised by elemental analysis, IR and mass spectroscopy, conductivity and magnetic measurements at room temperature (and, in the case of **1**, at variable temperature). Cyclic and normal pulse voltammetry measurements were also performed. All these studies support an octahedral geometry around the metal with the Schiff base in the equatorial plane acting as tetradentate and solvent molecules in the axial positions. Crystallographic characterisation of **6** confirms this geometry and shows a supramolecular structure involving π–π stacking and hydrogen bonding interactions. The ability to split water by these complexes and their catalase activity has also been studied. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Manganese complexes; Schiff bases; Manganoenzymes; Photolysis; Catalase; Dioxygen

1. Introduction

The existence of natural catalysts with a manganese centre raises the question of whether other synthetic complexes can mimic the reactivity of these biological sites. This has prompted the vast interest developed by bioinorganic chemists in manganese complexes as models for water photoinduced oxidation or catalysts with catalase-like activity, for example.

Photosynthetic organisms have a high ability for conversion of light energy to chemical energy under favourable conditions [1]. The oxygen-evolving complex (OEC), which induces the oxidation of water to dioxygen, is thought to contain a cluster of four manganese atoms [2,3].

The binding domain for the manganese cluster remains an issue of uncertainty; nevertheless, data on the physical structure of the metal centre have been recently summarised and provide a model for the catalytic site [4]. The most popular model, according to EXAFS experiments by Klein and coworkers [5], implies a natural site composed by two di-μ-oxo $Mn_2(\mu\text{-}O)_2$ units linked by a μ-oxo-bis-μ-carboxylate bridge. Hoganson and Babcock [6] proposed that a tyrosine radical is involved in the water oxidation process by abstraction of hydrogen atoms from substrate water molecules bound as terminal ligands to two of the four manganese ions.

The advances in the knowledge of the natural OEC structure have been accompanied by the synthesis of artificial models [7,8]. However, those tetramanganese synthetic models, designed in an attempt to reproduce the structure of the natural centre [9–11], have not had much success in mimicking the natural OEC properties. We focused our efforts on the study of some types of monomers and dimers [12–14], in order to find artificial catalysts for the decomposition of water. We have reported some μ-aquo dimeric manganese-Schiff base complexes [12,15] containing coordinated water molecules with a Mn–Mn distance of about 5 Å which possesses this ability. These complexes have shown a polymeric array in their solid state supramolecular structure [16] due to π stacking and hydrogen bonding, involving the phenyl rings of the Schiff base, the coordinated water molecules and even the perchlorate counterions.

On the other hand, catalases protect organisms from oxidative damage by removing the appreciable levels of hydro-

gen peroxide produced during O_2 metabolism in cells. The hydroxyl radicals, derived from the peroxide, are potent oxidants which are capable of oxidising all cellular components they come in contact with [17].

L-edge X-ray absorption spectroscopy measurements indicate that the octahedral component of the ligand field, which splits the valence 3d orbitals of the reduced *Lactobacillus plantarum* Mn catalase, is about 1.1 eV. This is a typical value for a manganese centre surrounded by O or N ligands, with a coordination number of six [18]. Furthermore, some manganese complexes with derivative *salpn* ligands have shown excellent ability for the disproportionation of hydrogen peroxide [19].

As a result of these previous findings, it seems that manganese Schiff base complexes could be functional models for the reactivity of the manganese OEC active site or manganese catalases. Thus, we extended our investigations on this type of compound to new complexes containing substituted Schiff base ligands, in order to find a correlation Schiff base/structure/activity (Scheme 1).

2. Experimental

2.1. Chemicals

Salicylaldehydes (Maybridge), 1,3-diaminopropane (Aldrich), manganese(II) perchlorate hexahydrate (Fluka) and *p*-benzoquinone (Aldrich) were used as received without further purification.

2.2. Physical measurements

Elemental analyses were performed on a Carlo Erba model 1108 CHNS-O elemental analyser. The IR spectra were recorded as KBr discs on a Nicolet PC5 FT-IR spectrophotometer and UV–Vis spectra on a Hewlett-Packard 8452A instrument. ^{1}H NMR spectra were recorded on a Bruker WH 300 MHz spectrometer using $CDCl_3$ as solvent and $SiMe_4$ as an internal reference. FAB mass spectra were recorded on a Kratos MS50 TC spectrometer connected to a DS90 data system, using metanitrobenzyl alcohol as a matrix. Λ_M was measured by using a WTW type LF 3 conductivimeter. Room temperature magnetic susceptibilities were measured using a Digital Measurement system 1660 vibrating magnetometer operating at 5000 G. $HgCo(NCS)_4$ was employed as a susceptibility standard. Magnetic susceptibility measurements in the 5–300 K temperature range were obtained using a SQUID magnetometer operating at 5000 G.

2.3. Electrochemical measurements

All measurements were performed using an EG&G PAR model 273 potentiostat, controlled by EG&G PAR model 270 software. A Metrohm model 6.1204.000 graphite disc coupled to a Metrohm model 628-10 rotating electrolyte device was used as a working electrode. A saturated calomel electrode was used as a reference and a platinum wire as an auxiliary electrode.

All measurements were made with ca. 10^{-3} mol dm^{-3} solutions of the complexes in dimethylformamide using 0.2 mol dm^{-3} NBu_4PF_6 as a supporting electrode. Cyclic voltammetry measurements were performed with a static graphite electrode, whilst direct current and pulse voltammograms were recorded with the graphite disc rotating at 2000 rev min^{-1}.

2.4. Preparation of the ligands

The symmetrical Schiff bases (R-*salpn*) were prepared in an analogous manner by the reaction of the corresponding substituted salicylaldehyde with diamine. This can be typified by the following preparation.

To an ethanol solution (100 ml) of 1,3-diaminopropane (0.84 ml, 9.82 mmol) was added 3Br,5Cl-salicylaldehyde (4.63 g, 19.64 mmol). This mixture was refluxed in a round bottom flask fitted with a Dean Stark trap to remove the water produced during the reaction. After refluxing for 3 h, the solution was concentrated to yield a yellow solid. The product was collected by filtration, washed with diethyl ether and dried in air.

Yields were almost quantitative.

2.5. Complex preparation

All the complexes were synthesised by air oxidation of the solution made up from $Mn(ClO_4)_2 \cdot 6H_2O$ and the Schiff base [20]. A typical preparation is outlined below.

$[MnL^1(H_2O)_2]ClO_4$ (**1**), 2.85 mmol (1.0 g) of H_2L^1 were dissolved in 100 ml of a 1:1 methanol–ethanol mixture and 2.85 mmol (1.03 g) of $Mn(ClO_4)_2 \cdot 6H_2O$ were added to the initial yellow solution which changed to green. (**Caution**: Although no problems have been encountered in this work, perchlorates are potentially explosive and should be handled in only small quantities and with care!) After stirring for 10 min, 5.70 mmol (0.23 g) of NaOH, dissolved in a small quantity of water, were added and the mixture turned dark. The progress of the reaction was followed by TLC for three days and the mixture was then filtered. The complex was obtained from the filtrate as a brown solid after crystallisation. It was isolated by filtration and washed with diethyl ether and dried in air, yield: 0.80 g, 52% (Found: C, 37.7; H, 3.5; N, 5.3. Calc. for $MnC_{17}H_{18}Cl_3N_2O_8$: C, 37.8; H, 3.3; N, 5.2%).

$[MnL^2(H_2O)_2]$ (**2**), 2.69 mmol (1.0 g) of H_2L^2; 2.69 mmol (0.97 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 5.38 mmol (0.22 g) of NaOH; yield: 1.12 g, 86% (Found: C, 44.5; H, 3.9; N, 12.2. Calc. for $MnC_{17}H_{18}N_4O_8$: C, 44.3; H, 3.9; N, 12.2%).

$[MnL^3(H_2O)_2]ClO_4$ (**3**), 1.62 mmol (0.6 g) of H_2L^3; 1.62 mmol (0.59 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 3.24 mmol (0.13 g) of NaOH; yield: 0.71 g, 82% (Found: C, 45.4; H, 4.8; N, 5.1. Calc. for $MnC_{21}H_{28}ClN_2O_{10}$: C, 45.1; H, 5.0; N, 5.0%).

$[MnL^4(H_2O)_2]ClO_4$ (**4**), 1.96 mmol (1.0 g) of H_2L^4; 1.96 mmol (0.71 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 4.0 mmol (0.16 g) of NaOH; yield: 0.62 g, 47% (Found: C, 29.9; H, 2.2; N, 4.1. Calc. for $MnC_{17}H_{16}Br_2Cl_3N_2O_8$: C, 29.5; H, 2.3; N, 4.0%).

$[MnL^5(H_2O)]$ (**5**), 1.87 mmol (1.0 g) of H_2L^5; 1.87 mmol (0.68 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 3.77 mmol (0.15 g) of NaOH; yield: 1.05 g, 91% (Found: C, 33.0; H, 2.4; N, 8.6. Calc. for $MnC_{17}H_{14}Br_2N_4O_7$: C, 33.0; H, 2.6; N, 9.0%).

$[MnL^6(H_2O)_2]ClO_4$ (**6**), 2.0 mmol (1.0 g) of H_2L^6; 2.0 mmol (0.72 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 4.0 mmol (0.16 g) of NaOH; yield: 0.82 g, 61% (Found: C, 33.5; H, 3.2; N, 4.1. Calc. for $MnC_{19}H_{22}Br_2ClN_2O_{10}$: C, 33.2; H, 3.2; N, 4.1%).

$[MnL^7(H_2O)_2]ClO_4$ (**7**), 2.49 mmol (1.0 g) of H_2L^7; 2.49 mmol (0.90 g) of $Mn(ClO_4)_2 \cdot 6H_2O$; 4.98 mmol (0.20 g) of NaOH; yield: 1.20 g, 85% (Found: C, 42.2; H, 4.5; N, 4.6. Calc. for $MnC_{21}H_{28}ClN_2O_{12}$: C, 42.7; H, 4.7; N, 4.7%).

2.6. Irradiation experiments

The irradiation of aqueous solutions of the manganese complexes was carried out in a colourless two-neck glass flask (1 l) placed in a metacrilate thermostatted water-bath. In a typical experiment a magnetically stirred solution of **1** (10^{-5} mol; 4.9 mg) and *p*-benzoquinone (2×10^{-4} mol; 21.6 mg) in deoxygenated, deionised water was irradiated with light from a 200 W tungsten lamp for 24 h. The solution was connected to a UV spectrophotometer through a peristaltic pump and a flow cell. One neck of the flask was closed by a septum whilst an oxygen meter Oxi 92 entered into the solution through the other neck of the flask, to measure the amount of oxygen evolved during the irradiation. Oxygen readings were recorded as percentage dissolved oxygen where 100% corresponds to a fully saturated aqueous solution at 25°C (6 $cm^3\ O_2\ dm^{-3}$) and 0% corresponds to no dissolved oxygen.

Reproducible results were obtained with this method provided that the temperature of the bath remained constant (25.0 ± 0.1°C) and a constant stirring rate was also maintained.

2.7. Catalase probes

Oxidation of 2,2′-azinobis(3-ethylbenzothiazoline)-sulfonic (ABTS) acid with H_2O_2 was tested in the presence of the complexes at ca. pH 7. An aqueous solution of ABTS (50 μl; 0.009 M; 4.5×10^{-7} mol) and a methanol solution of the complex (10 μl; 10^{-3} M; 10^{-8} mol) were added to water (3 ml). The oxidation of ABTS starts immediately after addition of an aqueous solution of H_2O_2 (50 μl; 10 M; 5×10^{-4} mol).

2.8. X-ray diffraction studies

Crystals of **6** suitable for X-ray studies were obtained by slow evaporation of an ethanol solution of the complex. Crystal data for **6**: $C_{42}H_{52}Br_4Cl_2Mn_2N_4O_{20}$, triclinic, space group $P\bar{1}$, $a = 14.224(10)$, $b = 19.509(7)$, $c = 10.337(7)$ Å, $\alpha = 89.98(5)$, $\beta = 112.14(5)$, $\gamma = 89.83(5)°$, $Z = 2$, Mo Kα radiation, $\lambda = 0.71073$ Å, $T = 293(2)$ K, dark brown colour, crystal size $0.40 \times 0.35 \times 0.20$ nm. Measurements were made on a Rigaku AFC6S diffractometer (transmission 0.3222–0.5280). 9759 reflections were collected (theta range for data collection from 1.04 to 25.00°) giving 9335 unique data with $R_{int} = 0.1111$; the completeness to $2\theta = 25.00$ is 99.7%. All data were corrected for Lorentz polarisation effects. The structure was solved by direct methods [21] and refined using full-matrix least-squares [22] on F^2. An absorption correction (psi scan technique) was applied. Non-hydrogen atoms were

refined anisotropically. Hydrogen atoms were included in idealised positions. At convergence, $wR = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[wF_o^2)_2]\}^{1/2} = 0.1830$ for all data, conventional $R = 0.0656$ on F values of 9335 reflections with $I > 2\sigma(I)$, goodness of fit 0.977 for all F^2 values and 692 refined parameters. A final difference synthesis contained no features outside the range 0.604 to -0.589 e Å^{-3}.

3. Results and discussion

3.1. IR spectroscopic studies

All the complexes show similar IR spectral features (Table 1), exhibiting a strong band between 1641–1611 cm^{-1} attributable to ν(CN), which is shifted 4–31 cm^{-1} lower than in the free Schiff base ligand.

Complexes **1**, **3**, **4**, **6** and **7** show broad unsplit bands at ca. 1100 cm^{-1}, together with bands at 630 cm^{-1}, that are indicative of the presence of a non-coordinated perchlorate counterion. These stretching frequencies were not observed for complexes **2** and **5**.

3.2. Mass spectra

FAB mass spectra show peaks relating to fragments $[MnL]^+$ for all the complexes, indicating the coordination of the ligand to the metal centre (Table 1). No traces of dimeric peaks were found and the presence of the $[MnL(OH_2)_2]^+$ fragment can be deduced from some minor peaks.

3.3. Magnetic studies

The magnetic moments in BM are listed in Table 1. Those complexes formulated as $[MnL(H_2O)]ClO_4$ exhibit room temperature magnetic moments close to the spin-only value of 4.9 BM, as expected for a high-spin magnetically diluted d^4 manganese(III) ion. Complexes containing the 5-NO_2-substituted ligands show magnetic moments close to the spin-only value of 5.9 BM, which agree with the presence of a high-spin d^5 magnetically diluted manganese(II) ion in **2** and **5**.

Magnetic studies at variable temperature have been done for **1** (between 300 and 40 K) and the magnetic behaviour is illustrated in Fig. 1. This study shows little or no antiferromagnetic interaction between neighbouring metal centres. This behaviour is typical of magnetically diluted manganese atoms and is in accordance with the quite long Mn···Mn distance (5.17(1) Å) [23].

3.4. Crystallographic studies

Slow evaporation of an ethanol solution of **6** gives crystals, suitable for X-ray diffraction studies, of $[MnL^6(EtOH)(H_2O)]ClO_4$. The crystal structure is shown in Fig. 2 and main bond distances and angles in Table 2.

The monomer is composed of an approximately octahedral $[MnL^6(EtOH)(H_2O)]^+$ cation with a crystallographically independent ClO_4^- anion. The planar tetradentate Schiff-base ligand is tightly bound to the manganese(III) ion via the N_{imine} and O_{phenol} atoms (Mn–N_{imine} bond lengths of 2.017(17) and 2.029(17) Å and Mn–O_{phenol} bond lengths of 1.863(13) and 1.868(14) Å). A capping water molecule (Mn–O_{water} 2.203(15) Å) and a coordinated ethanol molecule (Mn–$O_{ethanol}$ 2.275(14) Å) from the crystallisation solvent, complete the coordination sphere of the distorted octahedral manganese centre. The ability of the ethanol sol-

vent to displace a water molecule during crystallisation, shows the bond lability of such coordinated molecules, which can be substituted by other substrates in catalytic processes.

The superstructure of the complex involves associations via a combination of π–aryl interactions and hydrogen bonds between capping water and phenoxy and methoxy oxygen atoms of the neighbouring Schiff base ligand (see Fig. 2). An extended spiral is formed as consequence of these interactions. This results in Mn–Mn distances of 5.08 Å, which are quite short for monomeric compounds; these types of systems have been reported in the literature [24] as μ-aquo dimers. We have previously proposed this type of structure as the active species in the photolytic splitting of water following a mechanism originally reported by us [15].

Recrystallisation of **1** gave crystals suitable for single-crystal X-ray diffraction studies. However, **1** shows the same crystal structure as a compound previously reported by us [23]. The related complex was obtained by a different method, by reorganisation of a MnL_2 complex (where L represents the asymmetrical Schiff base obtained by condensation of 8-amino-4-methyl-5-azaoct-3en-2-one and 5-chlorosalicyladehyde) in solution.

We have proposed a mechanism [25] for this rearrangement process which we have found a few times for unsymmetrical ligands; this reorganisation in solution indicates the higher stability of the symmetrical versus the unsymmetrical compound in this medium.

The crystal structure of **1** has essentially the same highlights as **6**. This fact, together with the comparison of other physical properties for all the complexes presented in this work, suggests a similar structure for all of them. Subsequently reported structures of comparable compounds support this idea [16,26].

3.5. Conductivity measurements

The conductivity data suggest a non-ionogenous nature for **2** and **5**, considering that their Λ_M values in DMF are 11.7 and 22.1 μS, respectively. In contrast, Λ_M values in acetone range from 115 to 140 μS for complexes **1**, **3**, **4**, **6** and **7**, indicating a behaviour attributable to 1:1 electrolytes [27].

3.6. Electrochemical studies

Cyclic voltammograms of the complexes were measured in dimethylformamide (DMF) over a potential range from +1.00 to −1.00 V. In DMF solution, all the complexes exhibit a quasi-reversible one-electron reduction–oxidation wave, which at slow scan rates of about 0.02 V s^{-1} is reversible (Fig. 3, Table 3). The reduction waves of **1**, **3**, **6** and **7** (−0.06, −0.13, −0.04, −0.35 V versus saturated calomel electrode, SCE) are observed at slightly negative potentials; meanwhile **2**, **4** and **5** have reduction waves (0.108, 0.04 and 0.168 V) at positive potentials.

Normal pulse voltammetry confirms the reversible nature of these systems. Thus cathodic or anodic currents were observed by this technique with reference to the current observed without electroactive compounds.

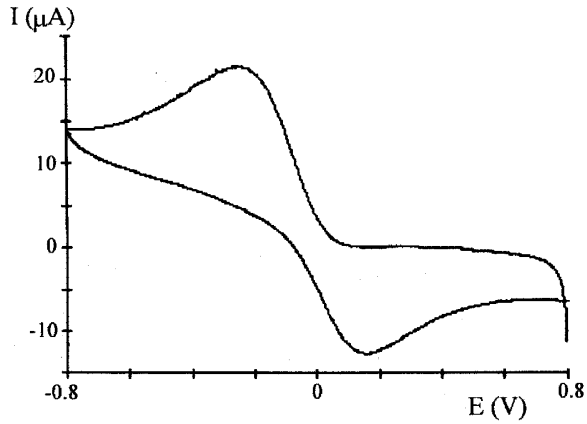

Fig. 3. Cyclic voltammogram for **6** at a scan rate of 0.02 V s^{-1}.

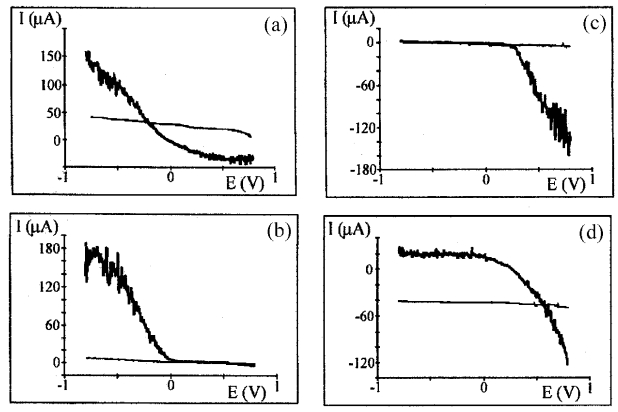

Fig. 4. Normal pulse voltamograms for **5** and **6**: (a) and (b) are, respectively, anodic and cathodic scans of **6**, a Mn(III) complex; (c) and (d) are, respectively, anodic and cathodic scans of **5**, a Mn(II) compound.

The study of these species by pulse voltammetry allows us to distinguish between Mn^{II} and Mn^{III} complexes as we have already reported [28].

Mn^{III} complexes (**1**, **3**, **4**, **6** and **7**) showed anodic and cathodic currents when an anodic potential scan was performed, but when a cathodic potential scan was used, only cathodic currents were observed (Fig. 4). This behaviour implies that only the oxidised forms of the implied redox systems Mn^{II}–Mn^{III} are present in solution.

However, **2** and **5** (Mn^{II} complexes) present the opposite behaviour: when the initial potentials were more positive than the wave range, both anodic and cathodic currents were observed, meanwhile only an anodic current was recorded when the initial potentials were more negative than the wave voltage range (Fig. 4). The presence of the redox systems Mn^{II}–Mn^{III} in reduced forms is in accordance with these voltammograms.

Magnetic measurements of the complexes have confirmed these oxidation states proposed by electrochemical studies.

The stabilisation of the manganese oxidation states (II), (III) or (IV) in complexes obtained by the Boucher method, is attributed to the electron donor or electron withdrawing character of the substituents about the phenyl ring of the Schiff base [28,29]. Thus, strong electron-withdrawing groups (e.g. nitro) stabilise Mn^{II} complexes and strong donor substituents lead to Mn^{IV} complexes [30–32].

3.7. Water photolysis experiments

The experiments were carried out in the presence of *p*-benzoquinone, a water-soluble hydrogen-atom acceptor. Photoactivated *p*-benzoquinone is able to abstract hydrogen atoms from H_2O [33]. Consequently, the role of this molecule in our system is similar to that of tyrosine in the natural PSII, as recent studies have pointed out [6].

Irradiation of Mn(III) complexes and *p*-benzoquinone solutions results in an increased dioxygen concentration in solution, as monitored by using an O_2 electrode (Table 4, Fig. 5) and conversion of the quinone to a hydroquinone, as determined by spectrophotometric monitoring of the reaction.

Awad and Anderson [34] have carried out a mechanistic quantum study of the photogeneration of O_2 from H_2O coordinated to active Mn^{III} complexes in the presence of *p*-benzoquinone. They suggest the possibility of dimerization by this type of $[LMn^{III}(H_2O)_2]$ monomers via μ-aquo bridges. They also propose that the H_2O molecules bonded to Mn^{III} in the monomer or as bridges in the Mn^{III} dimer starts off the reaction sequence by transferring a hydrogen atom to an O^- created by a $\pi^* \leftarrow n$ optical excitation in *p*-benzoquinone. As a result of this process, Mn^{III} is oxidised to Mn^{IV} and OH^- groups are tightly bound (Mn–O bond distance of 1.64 Å). The deprotonation of the OH^- groups is feasible because they are sufficiently polarised. The di-μ-oxo Mn^{IV} complex,

which forms either by oxidation of the H_2O-bridged Mn^{III} dimer or by dimerisation of oxidised monomers, cannot release O_2 because it is too stable. However, the disproportionation of two dimers together through a four-manganese intermediate can evolve O_2. This tetramanganese intermediate is reminiscent of the proposed structure of the natural OEC in the PSII.

In the case of the present complexes, it can be seen from Table 4 that most of them show slight catalytic activity. Complexes **1** and **4** show the highest rate of oxygen evolution. Thus, they have the greatest ability to split water. A comparison of these complexes shows one point in common: both of them contain a chlorine substituted Schiff base. These results confirm previous assumptions [15,32] and although it is not possible to establish a general pattern, it seems clear that halide substitution over the aromatic rings of the Schiff bases favours the photolytic activity.

3.8. Catalase probes

ABTS is a colourless water-soluble compound used for clinical peroxidase assays because of its excellent characteristics [35,36]. ABTS on oxidation forms a stable green cation radical ($ABTS^+$) with several strong absorptions in the visible and near-IR [37]. The formation of $ABTS^+$ is monitored conveniently at its wavelengths of 415, 650, 735 and 815 nm [38] and measured quantitatively at $\lambda = 650$ nm, since $\varepsilon = 12\,000\ M^{-1}\ cm^{-1}$ has been determined. The oxidation potentials of ABTS and the fully reduced species to provide $ABTS^+$ are invariable over a wide range of pH. In the absence of the complex, a solution of ABTS and H_2O_2 is stable for several hours without showing any formation of $ABTS^+$. The reaction of ABTS with H_2O_2 in the presence of **1**–**7** generates $ABTS^+$ and the characteristic absorption bands of this species could be established (Table 4, Fig. 6). Further oxidation to the corresponding dication [39] was not observed.

Nevertheless, the rate of formation of $ABTS^+$ of about 2% or even less indicates a poor capacity of disproportionation of H_2O_2 by the complexes. The present compounds do not seem to be efficient functional models for the reactivity of the manganese catalases, in contrast with other Mn–Schiff base systems. These results suggest the need for dimanganese sites involved in the catalase activity, since the monomeric complexes are insufficient models for this aim.

Probably, compounds of this type are able to bind directly the substrate, H_2O_2, by displacement of a water ligand molecule, but a subsequent oxidation of the hydroperoxide to

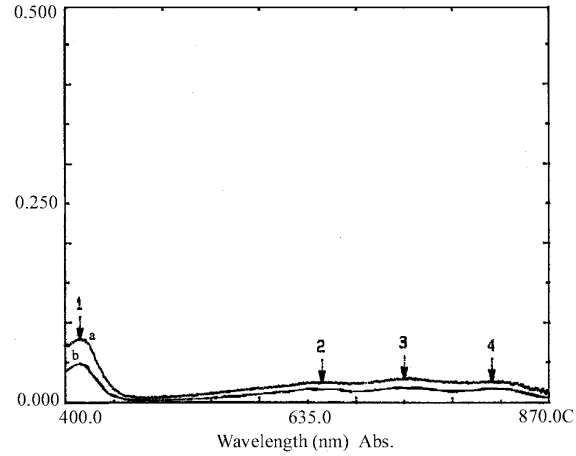

Fig. 6. UV–Vis absorption spectra of (a) $ABTS + H_2O_2 +$ **3**, (b) $ABTS + H_2O_2$, each recorded 10 min after mixing the solutions. (1) λ = 415; (2) λ = 650; (3) λ = 735; (4) λ = 815.

generate O_2 is forbidden, as this would involve an intramolecular two-electron transfer reaction that would reduce the manganese atom(s). The electrochemical studies of the present complexes showed their facility for one-electron oxidation–reduction between Mn^{II}–Mn^{III}, by reversible processes at potentials near to 0 V. Thus, we suppose that two manganese atoms are necessary for the implied two-electron transfer reaction. Thus, this binuclear system could suffer a two-electron reduction from {III,III} to {II,II}. Although crystallographic studies indicate an interaction between monomers by π stacking and H bonding, this feature is not enough to involve neighbouring manganese atoms in the electron transfer reaction once the substract is bound to the metal centre. The moderate extension of the catalase reaction for our complexes suggests a monomer/aquo-bridged dimer equilibrium in aqueous solution as reported for similar compounds [40].

The test of the catalase activity for new characterised manganese monomeric/dimeric complexes might confirm or reject their role in this catalysis because alternative mechanisms have been proposed [41] and monomers should not be set aside yet. In this sense, further studies are necessary in order to find better synthetic models of manganese catalases and to determinate their mechanism of action.

Supplementary data

Supplementary data are available from the CCDC, 12 Union road, Cambridge CB2 1EZ, UK on request, quoting the deposition number 127776.

Abstract

Complex formation between oxovanadium(IV) and several pyridinecarboxylic acids (picolinic acid, 3-hydroxypicolinic acid and 2-hydroxynicotinic acid) was studied in aqueous solution by pH-potentiometric and spectroscopic (electron paramagnetic resonance and electronic absorption) techniques. The results demonstrated that picolinic acid forms mono and bis complexes with the VO(IV) ion, coordinated through the pyridine nitrogen and the carboxylate group. The pyridine nitrogen is also involved in the complexation of VO(IV) by 3-hydroxypicolinic acid and 2-hydroxynicotinic acid in the acidic pH range, but as the pH is increased deprotonation of the phenolic hydroxy group occurs and complexes with salicylate-type (COO^-,O^-)-coordination are formed. In the VO(IV)–3-hydroxypicolinic acid system, the ligand coordinates to the metal ion in a tridentate fashion via the (N,COO^-,O^-) donor set, forming a tetrameric complex $(VOA)_4$ in the pH range 6–8. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Vanadium is an important trace element for different organisms. Oxovanadium(IV) and vanadate(V) are the main species present in solution under physiological conditions. The physiological effects are in many cases a consequence of the good complexation behaviour of the VO^{2+} ion, and the chemical similarity between phosphate and vanadate. A few vanadium compounds seem to have therapeutic effects [1]. One of the results of the intensive investigation of vanadium over the past two decades has been the discovery that vanadium compounds have insulin-mimetic properties [2]. Among others, bis(picolinato)oxovanadium(IV) [$VO(pic)_2$] has proved to be an orally active and long-acting insulin-mimetic compound with which insulin-dependent diabetes mellitus (IDDM) may be treated in rats [3].

Vanadium in its oxidation states +4 and +5 is able to interact with metal ion binders of biological systems containing negatively charged oxygen donors such as carboxylate, phenolate, phosphate, phosphonate, catecholate and hydroxamate [4–10]. Its interactions with small biomolecules containing nitrogen and sulfur atoms are weaker than those with oxygen donors. Picolinic acid (pyridine-2-carboxylic acid) contains a carboxylic group, which has significant affinity for the VO(IV) ion, and a pyridine nitrogen in a sterically favourable position to this group. Hence, the formation of (N,COO^-) chelates can be expected.

Pyridinecarboxylic acids and their derivatives are present in many natural products. They are also of special interest to medicinal chemists because of the wide variety of physiological properties displayed by the natural and also many synthetic derivatives [11]. Metal complexes of pyridinecarboxylic acids are particularly interesting model systems because of their physiological properties.

Complex formation in the VO(IV)–picolinic acid system was studied earlier [12–16], but to our knowledge, no data on the formation of VO(IV) complexes with 3-hydroxypicolinic acid or 2-hydroxynicotinic acid have been reported so far.

The interactions of VO(IV) with picolinic acid in the absence and presence of some dicarboxylic acids (oxalic, phthalic and maleic acids) has been studied by potentiometry. The formation of (N,COO^-)-coordinated 1:1 and 1:2 VO(IV)–picolinate chelates and the hydrolysis of VOA were indicated. In the ternary systems, 1:1:1 mixed ligand com-

PII S0277-5387(99)00323-X

plexes were also observed [12]. The results were recently confirmed by Duma and Hancock, who also detected the formation of complexes of the same type, VOA and VOA_2 [13]. The tendency of the VO(IV)–picolinate chelates to undergo hydrolysis was studied by Kaden and Fallab, who provided spectrophotometric evidence that OH^- is in a *trans* position to the VO group in the mixed hydroxo complex $VOA_2(OH)$ [14]. The bis(picolinato)oxovanadium(IV) complex has been isolated in the solid form and characterised by elemental analysis, visible and IR absorption, electron spin resonance spectra, magnetic susceptibility and partition coefficient. The relationship between its structure and insulin-mimetic activity has also been examined [15].

Vanadium in oxidation states other than +4 also forms stable complexes with picolinic acid. The synthesis, structural characterisation and reactivity of a highly stable vanadium(III) complex of picolinic acid, $V(pic)_3 \cdot H_2O$, have been reported. An X-ray diffraction study revealed that the pyridine nitrogen and the carboxylate oxygen are coordinated to the metal ion and the vanadium is in a highly distorted octahedral environment [17].

The interactions of vanadate(V) with picolinic acid, 3-hydroxypicolinic acid and 2-hydroxynicotinic acid in aqueous solution have been studied by using ^{51}V NMR spectroscopy [18]. Picolinic acid proved to form mono and bis chelates, although interaction between the pyridine-N and vanadate(V) is not favoured. 3-Hydroxypicolinic acid forms a mixture of complexes, through condensation of vanadate with the nitrogen and carboxylate and possibly with the carboxylate and the hydroxy groups. 2-Hydroxynicotinic acid reacts as a weak chelating ligand to give a complex in which the carboxylate and the adjacent OH group are coordinated to the vanadate [18].

In the present work we have studied the complexation of VO(IV) with picolinic acid, 3-hydroxypicolinic acid or 2-hydroxynicotinic acid (Scheme 1) in order to establish how the position of a further strong VO(IV)-binder, a phenolate, affects the binding properties of the ligand. We report here the coordination properties of the above-mentioned three pyridinecarboxylic acids with the VO(IV) ion. Their solution speciation was studied by pH-potentiometric and spectral (EPR and electronic absorption) methods.

Scheme 1.

2. Experimental

2.1. Chemicals

The ligands (Sigma or Fluka products of the highest available quality) were used without further purification. Their purities were checked and the exact concentrations of solutions were determined by the Gran method [19]. The oxovanadium(IV) stock solution was prepared as described in Ref. [20] and standardised for metal ion concentration by permanganate titration and for hydrogen ion concentration by potentiometry, using the appropriate Gran function. The ionic strength was adjusted to 0.20 mol dm^{-3} KCl in each solution studied. In all cases, the temperature was 25.0 ± 0.1°C.

2.2. Potentiometric measurements

The stability constants of the proton and VO(IV) complexes of the ligands were determined by pH-potentiometric titration of 25.0 cm^3 samples. The ligand concentration was 0.004 mol dm^{-3} or 0.006 mol dm^{-3} and the metal ion to ligand molar ratio was 0:1, 1:1, 1:2 or 1:4 (plus 1:6 and 1:8 for the VO(IV)–2-hydroxynicotinic acid system).

pH was measured with a Radiometer pHM 84 instrument equipped with a Metrohm combined glass electrode, calibrated for hydrogen ion concentration according to Irving et al. [21]. pK_w calculated from strong acid–strong base titrations was 13.76 ± 0.01. The titrations of the systems were performed in the pH range 2–11, or until precipitation occurred, with a carbonate-free KOH solution of known concentration ($\sim$0.2 mol dm^{-3}) under an argon atmosphere, in order to avoid the oxidation of the metal ion.

Equilibria corresponding to the formation of the hydroxo complexes of VO(IV) were taken into account in the calculation of the stability constants of the complexes. The following species were assumed: $[VO(OH)]^+$ ($\log \beta_{1-1} = -5.94$), $[(VO)_2(OH)_2]^{2+}$ ($\log \beta_{2-2} = -6.95$, calculated from the data published by Henry et al. [22], the Davies equation being used to take into account the different ionic strengths), $[VO(OH)_3]^-$ ($\log \beta_{1-3} = -18.0$) and $[(VO)_2(OH)_5]^-$ ($\log \beta_{2-5} = -22.0$, taken from Ref. [23]).

The concentration stability constants $\beta_{pqr} = [M_pA_qH_r]/[M]^p[A]^q[H]^r$ were calculated with the PSEQUAD computer program [24].

2.3. Spectroscopic measurements

In order to confirm the speciation results and establish the binding modes of the ligands in the complexes, spectral measurements were performed. Anisotropic X-band EPR spectra (9.15 GHz) were recorded at 140 K in aqueous solutions, with a Varian E-9 spectrometer using quartz tubes. As usual, the samples for low-temperature measurements contained a few drops of DMSO to ensure good glass formation in frozen solutions. Absorption spectra were recorded with a Hewlett

Packard HP 8453 spectrophotometer. All manipulations and titrations were carried out under an atmosphere of argon.

3. Results and discussion

The protonation constants of picolinic acid (HA), 3-hydroxypicolinic acid (H_2A) and 2-hydroxynicotinic acid (H_2A) are listed in Table 1. The significant decreases in acidity of the carboxylic group in the 3-hydroxypicolinic acid and 2-hydroxynicotinic acid ligands ($\log K(COO^-) \sim 1$) can be attributed to the formation of intramolecular hydrogen-bonding between the COO^- and the phenolic-OH, and in the case of picolinic acid between the COO^- and NH^+ groups, which makes the liberation of the first proton more favoured. The protonation constant of the pyridine nitrogen is about 10^5, as in pyridine itself ($\log K = 5.24$ [25]) and its derivatives 3-hydroxypyridine ($\log K = 4.89$ [26]) and nicotinic acid ($\log K = 4.66$ [26]). The basicity of the phenolic group is increased significantly as compared with phenol ($\log K = 9.82$ [27]), 2-hydroxypyridine ($\log K = 9.5$ [26]) and 3-hydroxypyridine ($\log K = 8.50$ [26]). The phenolic pK of the ligands is high, as in the case of salicylic acid ($\log K = 13.4$ [28]). This is again a result of stabilisation of the monoprotonated, hydrogen-bonded forms of the ligands. The protonation constants presented here for these ligands are in good agreement with those reported in previous papers, when the difference in ionic strength is taken into account [13–16,29,30].

3.1. Complexes of picolinic acid

Picolinic acid forms mono and bis complexes with the VO(IV) ion (Table 2). The concentration distribution curves for the complexes formed as a function of pH are depicted in Fig. 1. The complexation starts with formation of complexes VOA and VOA_2 at pH < 2 [16]. In VOA, the pyridine nitrogen and the carboxylate group of the ligand coordinate to the metal ion and form a five-membered chelate. The EPR spectra confirm this binding mode, as the mono-chelated species VOA has the following parameters: $g_\parallel = 1.939$, $A_\parallel = 175 \times 10^{-4}$ cm^{-1}. The bis complex is the predominant species in the pH range 3–6.5. The spectral parameters remain unchanged in this pH range, which suggests the exclusive formation of a single species ($g_\parallel = 1.945$, $A_\parallel = 165 \times 10^{-4}$ cm^{-1}, λ_{max} (ε (mol^{-1} cm^{-1} dm^3)) 735 nm (35), 547 nm (16) (shoulder)). On the basis of the additivity rules for the coupling constant of VO(IV) complexes [31], the EPR parameters could be supportive of two N donors in the equatorial plane of the metal ion. The behaviour of the system suggests a *cis* geometrical isomeric form, in which one of the ligands occupies two equatorial sites, while the other adopts an equatorial–axial coordination mode, presumably with the carboxylate group as the apical donor, and a water molecule in *cis* position to the oxo group of VO(IV) completes the donor set in the equatorial plane [15]. In fact, in the presence of an excess of ligand, deprotonation of the complex VOA_2 occurs, with p$K = 6.98$. This value is lower than expected for the ionisation of a weakly bound axial water molecule, and suggests the deprotonation of an equatorial water molecule. Therefore, both the observation of an EPR-active species VOA_2H_{-1} and the concomitant spectral change ($g_\parallel = 1.947$, $A_\parallel = 160 \times 10^{-4}$ cm^{-1}) support the *cis* arrangement of the coordinating ligands in VOA_2. At pH > 8, stepwise displacement of the ligands by hydroxide ion takes place and through a dihydroxo bridged mixed hydroxo complex $(VOAH_{-1})_2$, and results in the formation of oligonuclear binary hydroxo complexes, which is supported by the disappearance of the EPR signal.

3.2. Complexes of 3-hydroxypicolinic acid

Because of the spatial arrangement of the donor groups, the molecule can form complexes with metal ions through the pyridine nitrogen and carboxylate group (picolinate-like coordination) or carboxylate and phenolate groups (salicylate-like coordination). For steric reasons, the three donor groups cannot coordinate to the same metal ion simultaneously. Stability constants for the VO(IV) complexes of 3-

hydroxypicolinic acid, and the derived equilibrium constants calculated for different complex formation steps, are listed in Tables 3 and 4. For comparison, some derived equilibrium constants for the VO(IV) complexation of picolinic acid and salicylic acid are also listed in Table 4.

Analysis of the pH-potentiometric titration curves indicates the liberation of two protons per ligand molecule, by pH ~ 5, i.e. the formation of a species with the stoichiometry VOA or $(VOA)_n$. All dissociable protons can be liberated from the ligand molecule by pH ~ 5 only through its tridentate coordination: in the case of bidentate picolinate-type or salicylate-type coordination, the non-coordinated third donor (phenolate-O or pyridine-N, respectively) remains protonated. Molecular modelling indicates that tridentate coordination cannot occur in monomeric, dimeric or trimeric forms; the tetrameric complex is the lowest oligomer where the steric conditions allow this type of coordination. Accordingly, titration curves were evaluated with a tetrameric species $(VOA)_4$ in addition to the relevant mononuclear complexes.

A comparison of the derived equilibrium data calculated for the VO(IV)–3-hydroxypicolinato complexes involving the different binding modes with those of the VO(IV)–picolinic acid and VO(IV)–salicylic acid model systems suggests the dominant binding modes in the complexes (see Table 4). In the equations for the calculation of these derived constants, 3-hydroxypicolinic acid is denoted as (H)A(H) (more precisely $^{+}$HNAOH, in which $^{+}$HN means the imino group, while OH means the phenolic-OH group).

The speciation curves calculated with the stability constants listed in Table 3 are depicted in Fig. 2. The EPR spectra of the 1:2 VO(IV)–ligand system at different pH values are shown in Fig. 3. It is seen from the speciation diagram that complexation starts with the formation of VOAH in the acidic pH range. The ligand coordinates through the pyridine nitrogen and the carboxylate group, as in the VO(IV)–picolinic acid complex. This binding mode is confirmed by comparison of the EPR parameters of the complex VOAH ($g_{\parallel} = 1.938$, $A_{\parallel} = 174 \times 10^{-4}$ cm^{-1}) with those of VOA formed with picolinic acid (vide extra) and by the good agreement between the derived constants (see first row in Table 4).

In the pH range 3–5, the complex VOA_2H_2 is also formed in considerable amounts at a ligand excess. In this complex, a $2\times$(N,COO$^-$) coordination mode and a *cis* arrangement are again consistent with the derived data of the two bis

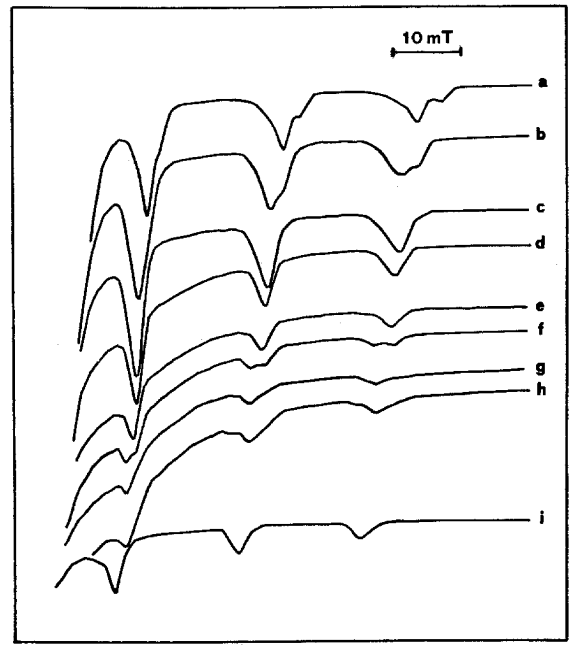

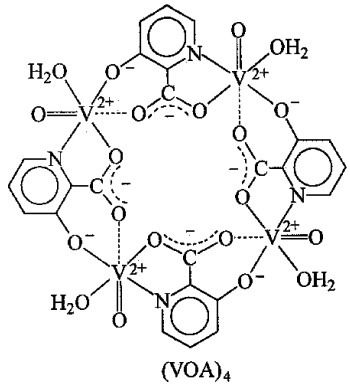

Fig. 3. High field parallel region of frozen solution EPR spectra (X-band) recorded at 140 K on the VO(IV)–3-hydroxypicolinic acid 1:2 system at various pH values: (a) 1.95, (b) 2.30, (c) 3.00, (d) 6.30, (e) 7.35, (f) 8.35, (g) 9.13, (h) 10.20, (i) 10.95. $c_{VO(IV)} = 0.004$ mol dm^{-3}.

complexes (cf. log $K = 5.76$ for VOA_2H_2 and log $K = 5.45$ for $VO(pic)_2$). The low values of $\log(K_1/K_2)$, indicating the favoured coordination of the second ligand, confirm picolinate-like binding. However, on the basis of the EPR parameters (cf. $g_\parallel = 1.940$, $A_\parallel = 170 \times 10^{-4}$ cm^{-1} for VOA_2H_2 and $g_\parallel = 1.945$, $A_\parallel = 165 \times 10^{-4}$ cm^{-1} for VOA_2 formed with picolinic acid), a *cis* arrangement involving one of the N atoms in the apical position is more likely. The salicylate-like (COO^-,O^-)-coordination mode in these species VOAH and VOA_2H_2 (with the protonated pyridine nitrogen) is less likely, as substantiated by a comparison of the derived constants and the EPR parameters (see the data in rows 2, 4 and 5 of Table 4).

As discussed above, an oligomeric complex, presumably $(VOA)_4$, is assumed in the pH range 6–8. Molecular modelling demonstrates that, while dimeric or trimeric species involve considerable steric hindrance, a cyclic tetramer can be formed without any strain provided that one of the carboxylate oxygens coordinates to vanadium in the apical position and there is a water molecule in the equatorial plane of the metal ion (see Scheme 2). The EPR results also suggest the oligonuclear model: in the pH range 6–8, a broad, featureless band is observed at $g = 2$, indicating a significant interaction between the paramagnetic centres (Fig. 4). This broad band is superimposed by signals due to mononuclear complexes formed at low concentration. The visible spectral parameters for this complex (λ_{max} (ε (mol^{-1} cm^{-1} dm^3)) 775 nm (43), 550 nm (20) (shoulder)) are similar for those of 1:2 VO(IV)–salicylate (775 nm (42), 562 nm (27)) [27].

Scheme 2.

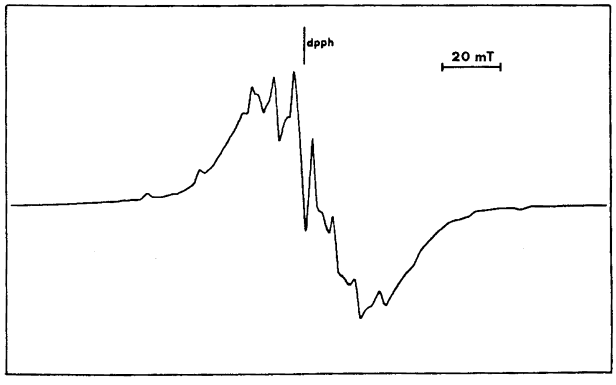

Fig. 4. Frozen solution EPR spectrum recorded at 140 K on the VO(IV)–3-hydroxypicolinic acid 1:1 system at pH 7.65. $c_{VO(IV)} = 0.004$ mol dm^{-3}.

At an excess of ligand, in addition to formation of the tetrameric species, stepwise deprotonation of the complex VOA_2H_2 occurs. These processes are accompanied by a continuous rearrangement from the picolinate-like coordination to the salicylate-type coordination via a mixed binding mode. The EPR parameters of the complex VOA_2H ($g_\parallel = 1.943$, $A_\parallel = 167 \times 10^{-4}$ cm^{-1}) indicate a (N,COO^-)(COO^-,O^-) donor set, with the stronger N and O donors in the equatorial plane. The parameters for VOA_2 ($g_\parallel = 1.946$, $A_\parallel = 165 \times 10^{-4}$ cm^{-1}) are similar to those of some salicylate derivatives (e.g. $g_\parallel = 1.947$, $A_\parallel = 166 \times 10^{-4}$ cm^{-1} for the complex VOA_2 of 2,4-dihydroxybenzoic acid [28]) and again indicate $2 \times (COO^-,O^-)$ coordination with the stronger donors in the equatorial plane of the metal ion. The complex VOA_2 loses a proton from the coordinated water molecule with p$K = 10.47$ and a mixed hydroxo complex is formed ($VOA_2H_{-1} = VOA_2(OH)$) with EPR parameters $g_\parallel = 1.950$ and $A_\parallel = 161 \times 10^{-4}$ cm^{-1}. The EPR detection of this species indicates that in VOA_2 the two ligands adopt a *cis* arrangement, with a carboxylate group in the axial position. The deprotonation of the water molecule, i.e. replacement of the water molecule by a hydroxo ligand, is consistent with the spectral change. The p*K* value is significantly higher than the corresponding one measured with picolinic acid (see Table 2), probably as a consequence of the negative charge of VOA_2.

3.3. Complexes of 2-hydroxynicotinic acid

2-Hydroxynicotinic acid is a constitutional isomer of 3-hydroxypicolinic acid (Scheme 1). The stability constants and speciation curves for the VO(IV) complexes of 2-hydroxynicotinic acid (Table 5, Fig. 5) reveal that the complex-forming properties of 2-hydroxynicotinic acid are rather different from those of 3-hydroxypicolinic acid. Depending on the metal ion to ligand ratio, a precipitate starts to form in the pH range pH 4–5.5 in samples with 1:1, 1:2 or 1:4 metal ion to ligand ratios; this dissolves by pH > 9, where only binary hydroxo complexes of VO(IV) can be detected. However, titrations could be carried out without precipitation

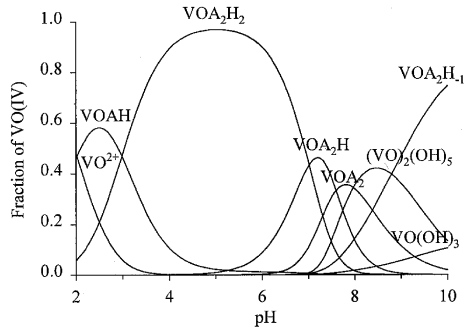

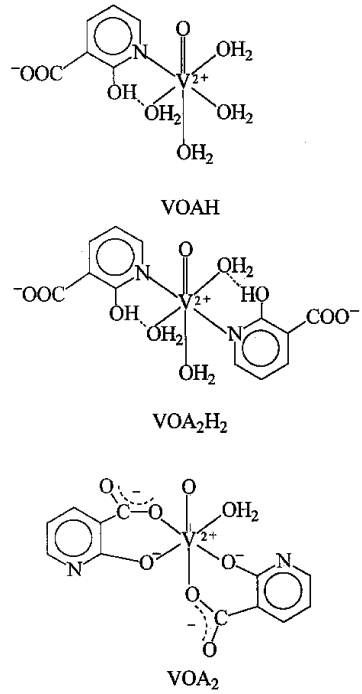

Fig. 5. Speciation curves for complexes formed in the VO(IV)–2-hydroxynicotinic acid system, $c_{VO(IV)} = 0.0006$ mol dm^{-3} and $c_{ligand} = 0.0036$ mol dm^{-3}.

throughout the whole pH range at metal ion to ligand ratios of 1:6 and 1:8. It is seen in Fig. 5 that at low pH, complexation starts with the monoprotonated 1:1 complex VOAH (λ_{max} (ε (mol^{-1} cm^{-1} dm^3)) 780 nm (30), 600 nm (12)), while the species VOA_2H_2 (λ_{max} (ε (mol^{-1} cm^{-1} dm^3)) 803 nm (49), 595 nm (24)) is predominant in the pH range 3.5–6.5. This latter neutral complex has rather low solubility in water and is precipitated at lower excesses of ligand. For example, at a metal ion concentration of 4×10^{-3} mol dm^{-3} precipitation of the complex is almost complete by pH ~ 5.5 and samples display hardly any EPR activity. However, in more dilute solutions at a metal ion concentration of 5×10^{-4} mol dm^{-3} and at high excesses of ligand (higher than 1:6), oversaturated solutions are probably formed, this being the reason why this complex could be studied by both potentiometry and spectroscopy. The derived equilibrium constant calculated for the VO(IV) complexes of 2-hydroxynicotinic acid and for comparison for those of salicylic acid may help us to suggest the most likely binding modes of the ligands in the complexes formed. For instance, the equilibrium constant obtained for the 1:1 complex VOAH of 2-hydroxynicotinic acid assuming salicylate-type (COO^-,O^-) coordination mode is in fairly good agreement with that for the analogous complex of salicylic acid (see rows 1 and 4 in Table 6). There is, however, a large difference in the ratio of the stepwise formation constants of the 1:1 and 1:2 complexes ($\log(K_1/K_2)$) of 2-hydroxynicotinic acid and salicylic acid (see rows 3 and 6 in Table 6), that cannot be explained. Accordingly, salicylate-type coordination of the ligand in the protonated complexes VOAH and VOA_2H_2 is very unlikely.

Table 6
Some derived constants for the VO(IV) complexes of 2-hydroxynicotinic acid and salicylic acid at 25.0 ± 0.1°C and $I = 0.20$ mol dm^{-3} (KCl)

Ligand	Reaction	log K
2-Hydroxynicotinic acid	VO + (H)A = VO(H)A	12.32
	VO(H)A + (H)A = VO(H)$_2$A$_2$	11.43
	$\log(K_{VOAH}/K_{VOA_2H_2})$	0.89
Salicylic acid [27]	VO + A = VOA	12.97
	VOA + A = VOA_2	9.84
	$\log(K_{VOA}/K_{VOA_2})$	3.13

In fact, the EPR data ($g_\parallel = 1.938$, $A_\parallel = 175\times10^{-4}$ cm^{-1} for VOAH; $g_\parallel = 1.942$, $A_\parallel = 168\times10^{-4}$ cm^{-1} for VOA_2H_2) are more consistent with the coordination of nitrogen donors. Similar parameters have been observed for the monodentate coordination of imidazole and pyrazole ligands to VO(IV) (imidazole: $g_\parallel = 1.938$, $A_\parallel = 177\times10^{-4}$ cm^{-1} for VOA, $g_\parallel = 1.943$, $A_\parallel = 171\times10^{-4}$ cm^{-1} for VOA_2; pyrazole: $g_\parallel = 1.937$, $A_\parallel = 176\times10^{-4}$ cm^{-1} for VOA, $g_\parallel = 1.941$, $A_\parallel = 172\times10^{-4}$ cm^{-1} for VOA_2) [32]. The stability constant derived for the complex with monodentate coordination of pyridine nitrogen ($\log K_{VO(H)A} = \log K_{VOAH} - \log K_{HA} = 5.40$), however, is significantly higher than expected and only about one order of magnitude lower than that for the VO(IV)–picolinate chelate ($\log K_{VOA} = 6.66$). Therefore, it can be supposed that in the protonated complexes VOAH and VOA_2H_2, in addition to the pyridine nitrogen, the protonated phenolic-OH also coordinates, presumably in an indirect way through hydrogen bonding between this phenolic-OH group and an equatorial water molecule in the VO(IV) coordination sphere (see Scheme 3). Support for the above conclusion is provided by the spectral changes accompanying the stepwise deprotonation of the complex VOA_2H_2. Two species, VOA_2H and VOA_2, are formed, with pK = 7.02 and 7.60, respectively. A comparison of the EPR spectral parameters ($g_\parallel = 1.945$, $A_\parallel = 166\times10^{-4}$ cm^{-1}) for VOA_2 with those for 3-hydroxypicolinic acid and other salicylate derivatives (vide extra) clearly indicates a structural rearrangement of the complex to the salicylate-type (COO^-,O^-) binding mode (Scheme 3). On the other hand, the parameters for VOA_2H ($g_\parallel = 1.941$, $A_\parallel = 173\times10^{-4}$ cm^{-1}) point to a mixed coordination (COO^-,O^-)(N, H_2O) with a *cis* arrangement, i.e. the N donor is in the apical position.

Scheme 3.

At pH > 8 and at high ligand excess, A:M > 6, a species VOA_2H_{-1} is formed by deprotonation of the complex VOA_2 ($pK = 8.38$). The EPR parameters ($g_{\parallel} = 1.947$, $A_{\parallel} = 162 \times 10^{-4}\ cm^{-1}$) are consistent with a *cis* arrangement of the ligands, which brings two strong O^- donors, a COO^- and an OH^- ion, into the equatorial coordination sites, while the second carboxylate group occupies the axial position. This may suggest that VOA_2 also adopts a *cis* arrangement (or that there is an equilibrium between the *cis* and *trans* isomeric forms). Above pH 8 hydroxide ions displace the ligands from the coordination sphere and oligonuclear binary hydroxo complexes of VO(IV) are formed.

4. Conclusions

The interactions between VO(IV) and several ligands containing pyridine nitrogen, such as picolinic acid and its hydroxy derivatives 3-hydroxypicolinic and 2-hydroxynicotinic acids, were investigated in order to clarify the effects of the positions of the donor groups in the ligands on their complex-forming properties. In the acidic pH range, 3-hydroxypicolinic acid behaves like picolinic acid, forming chelated complexes through the pyridine nitrogen and the carboxylate oxygen. In the pH range 6–8, a very stable tetramer $(VOA)_4$, containing tridentately coordinated ligands is detected, while at higher pH values bis complexes involving salicylate-type (COO^-,O^-) coordination are formed. The VO(IV) complexes of 2-hydroxynicotinic acid involve pyridine nitrogen-phenolic hydroxyl (N, OH) binding mode in the acidic pH range and salicylate-type (COO^-,O^-) coordination in the weakly basic pH range. Both 3-hydroxypicolinic acid and 2-hydroxynicotinic acid contain a salicylate (COO^-,O^-) donor set in addition to a pyridine nitrogen. The stability data and spectral behaviour of the complexes suggest that a pyridine nitrogen in a position adjacent to a carboxylate group is a more effective binding site for VO(IV) than that adjacent to a phenolic hydroxyl group.

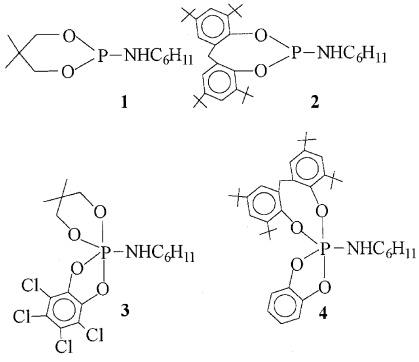
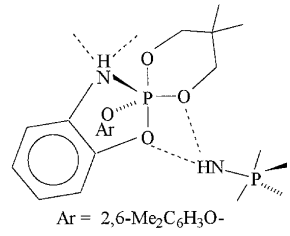
Received 30 June 1999; accepted 15 October 1999

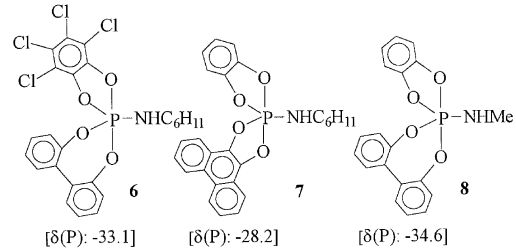


Abstract

Several pentacoordinated phosphoranes with a primary amino substituent have been synthesized by oxidative addition reactions on a cyclic phosphite. X-ray structures of three of these, i.e. $(C_6H_{11}NH)P(2,2'\text{-}O\text{-}C_6H_4\text{-}C_6H_4\text{-}O)(1,2\text{-}O_2C_6Cl_4)$ (**6**), $(C_6H_{11}NH)P(9,10\text{-}O_2C_{14}H_8)(1,2\text{-}O_2C_6H_4)$ (**7**) and $(MeNH)P(2,2'\text{-}O\text{-}C_6H_4\text{-}C_6H_4\text{-}O)(1,2\text{-}O_2C_6H_4)$ (**8**) have been determined. While **6** does not show hydrogen bonding interactions involving the NH proton, compound **7** is a weak dimer with hydrogen bonding interactions between the NH proton and the apical oxygen of the catecholate ring. By contrast in **3**, although hydrogen bonding again involves the NH proton and apical oxygen of the five-membered catecholate ring, a polymeric chain structure is formed. ©2000 Elsevier Science Ltd All rights reserved.



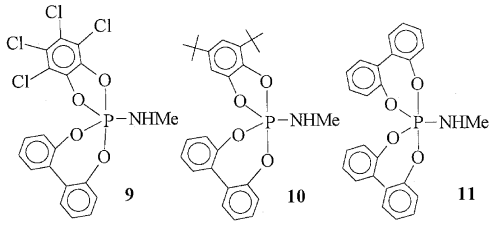
Keywords: Phosphoranes; Pentacoordination; X-ray structure; Hydrogen bonding



1. Introduction

We have been interested in looking at hydrogen bonding interactions and their influence on the structures of cyclic phosphorus compounds. We feel that studies such as these could be important in understanding the nature of the pentacoordinated transition state in the reactions of phosphates conducted in protic media (see Ref. [1] and references cited therein). In this direction we have recently reported the synthesis and X-ray structures of compounds **1**–**4**, all of which possess a cyclohexylamino group [2].

Although hydrogen bonding involving the NH proton and one of the ring oxygens was observed in the tricoordinated compounds **1** and **2**, a similar feature was not observed in the corresponding pentacoordinated structures **3** and **4**. In contrast to this, studies on the phosphorane **5** revealed hydrogen bonding involving an NH proton and a ring oxygen [3]. This



prompted us to examine the primary amino substituted phosphoranes further. Herein we report the synthesis and structures of three such phosphoranes **6**–**8**. We also report the synthesis of **9**–**11** bearing a primary amino group.

2. Experimental

Chemicals were procured from Aldrich or from local manufacturers; they were purified when required. Solvents were purified according to standard procedures [4]. NMR spectra were recorded on a Bruker 200 MHz spectrometer. Chemical shifts ($CDCl_3$, ppm) were measured against tetramethylsilane (^1H, ^{13}C) or ext. 85% H_3PO_4. IR spectra were recorded on a Perkin-Elmer 1310 spectrophotometer. Elemental analysis was performed on a Perkin-Elmer 240C CHN analyzer.

The precursors ($C_6H_{11}NH$)P(1,2-$O_2C_6H_4$) (**12**; δ(P) 139.8) and ($C_6H_{11}NH$)P(2,2′-O-C_6H_4-C_6H_4-O) (**13**; δ(P) 151.0) were prepared by following a reported procedure [5].

*2.1. Preparation of (MeNH)P(2,2′-O-C_6H_4-C_6H_4-O) (**14**)*

Into a stirred solution of ClP(2,2′-O-C_6H_4-C_6H_4-O) [5] (3.00 g, 11.97 mmol) in diethyl ether at −60°C was condensed an excess of methylamine gas for 0.5 h at −60°C. The residue, obtained after filtration and removal of solvent, was subjected to vacuum distillation to afford **14** as a viscous liquid (b.p. 180°C/3 mm Hg). Yield 2.7 g (93%). ^1H NMR: δ 2.63 (dd, 3H, P–NHCH_3, ^3J(HH) = 5.8 Hz, ^3J(P–H) = 9.2 Hz), 2.95–3.15 (m, 1H, N*H*), 7.25–7.46 (m, 8H, Ar–*H*). ^{31}P NMR: δ 150.8. IR: 3399 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{13}H_{12}NO_2P$: C, 63.67; H, 4.90; N, 5.71. Found: C, 63.50; H, 4.85; N, 5.62%.

*2.2. Preparation of ($C_6H_{11}NH$)P(2,2′-O-C_6H_4-C_6H_4-O)-(1,2-$O_2C_6Cl_4$) (**6**), ($C_6H_{11}NH$)P(9,10-$O_2C_{14}H_8$)-(1,2-$O_2C_6H_4$) (**7**), (MeNH)P(2,2′-O-C_6H_4-C_6H_4-O)-(1,2-$O_2C_6Cl_4$) (**9**) and (MeNH)P(2,2′-O-C_6H_4-C_6H_4-O)-(3,5-(Bu^t)$_2$-1,2-$O_2C_6H_2$) (**10**)*

These compounds were prepared by the reaction of the respective aminophosphite with the corresponding quinone in yields of >85%. A typical procedure for the synthesis of **9** is given below.

To a solution of **14** (0.99 g, 4 mmol) in toluene (5 ml) was added *o*-chloranil (1.00 g, 4 mmol) slowly (5 min) under nitrogen. The mixture was stirred for 10 min more and allowed to stand. Compound **9** was obtained as a crystalline solid over a period of ca. 2 days in a yield of 94%.

A similar procedure was adopted to prepare **6** and **10**. In the case of **7**, the two reactants were heated in neat condition at 150°C for 1/2 h; the solid obtained after cooling was recrystallized from CH_2Cl_2–hexane (1:1) mixture.

6: M.p. 170°C. ^1H NMR: δ 0.81–1.85 (m, 10H, cyclohexyl–CH_2), 3.20–3.40 (m, 2H, N*H* + NC*H*), 7.15–7.48 (m, 8H, Ar–*H*). ^{31}P NMR: δ −34.7. *Anal*. Calc. for $C_{24}H_{20}Cl_4NO_4P$: C, 51.54; H, 3.58; N, 2.51. Found: C, 51.46; H, 3.51; N, 2.60%.

7: M.p. 88–90°C. ^1H NMR: δ 0.86–3.40 (m, 12H, cyclohexyl–*H* + N*H*), 6.93–8.68 (m, 12H, Ar–*H*). ^{31}P NMR: δ −28.2. IR: 3310 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{26}H_{24}NO_4P$: C, 70.09; H, 5.44; N, 3.14. Found: C, 69.95; H, 5.32; N, 3.08%.

9: M.p. 214–216°C. ^1H NMR: δ 2.72 (dd, 3H, ^3J(HH) = 5.0 Hz, ^3J(HH) = 13.4 Hz, PNHCH_3), 3.30–3.40 (m, 1H, N*H*), 7.03–7.59 (m, 8H, Ar–*H*). ^{31}P NMR: δ −33.0. IR: 3402 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{19}H_{12}Cl_4NO_4P$: C, 46.46; H, 2.46; N, 2.85. Found: C, 46.41; H, 2.41; N, 2.91%.

10: M.p. 142–144°C. ^1H NMR: δ 1.32 (s, 9H, C(CH_3)$_3$), 1.35 (s, 9H, C(CH_3)$_3$), 2.76 (dd, 3H, ^3J(HH) = 5.1 Hz, ^3J(PH) = 12.8 Hz, NHCH_3), 3.19–3.30 (m, 1H, N*H*), 6.82–7.61 (m, 10H, Ar–*H*). ^{31}P NMR: δ −34.7. IR: 3403 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{27}H_{32}NO_4P$: C, 69.65; H, 6.94; N, 3.00. Found: C, 69.58; H, 6.85; N, 2.94%.

*2.3. Preparation of (MeNH)P(2,2′-O-C_6H_4-C_6H_4-O)-(1,2-$O_2C_6H_4$) (**8**) and (MeNH)P(2,2′-OC_6H_4-C_6H_4O)$_2$ (**11**): typical procedure for **8***

To a stirred solution of the phosphite **14** (0.3 g, 1.22 mmol) in toluene (10 ml) maintained at −60°C was added first *N*-chlorodiisopropylamine (0.16 g, 1.22 mmol) in toluene (3 ml) and then catechol (0.13 g, 1.22 mmol) in toluene (3 ml) over a period of (total) 15 min with continuous stirring. The reaction mixture was brought to 30°C, stirred overnight and filtered. Solvent was removed and the residue crystallized from toluene (5 ml) to give **8**. Yield 0.4 g (93%). M.p. 146–148°C. ^1H NMR: δ 2.70 (dd, 3H, ^3J(HH) = 5.0 Hz, ^3J(PH) = 13.0 Hz, NHCH_3), 3.10–3.25 (m, N*H*), 6.78–7.57 (m, 12H, Ar–*H*). ^{31}P NMR: δ −34.6. IR: 3435 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{19}H_{16}NO_4P$: C, 64.58; H, 4.57; N, 3.96. Found: C, 64.54; H, 4.50; N, 3.85%.

In the above reaction, if catechol is added first, followed by *N*-chlorodiisopropylamine, the reaction mixture shows other products (~50%) in addition to **8** (see Fig. 1).

Compound **11** was prepared similarly, but in this case the order of addition did not matter and compound **11** was obtained in >85% yield. **11**: M.p. 136–138°C. ^1H NMR: δ 2.77 (dd, 3H, ^3J(HH) = 4.9 Hz, ^3J(PH) = 12.7 Hz, NHCH_3), 3.34–3.46 (m, 1H, N*H*), 7.21–7.55 (m, 16H, Ar–*H*). ^{31}P NMR: δ −38.2. IR: 3443 cm^{-1} (ν(NH)). *Anal*. Calc. for $C_{25}H_{20}NO_4P$: C, 69.91; H, 4.70; N, 3.26. Found: C, 70.21; H, 4.75; N, 3.35%.

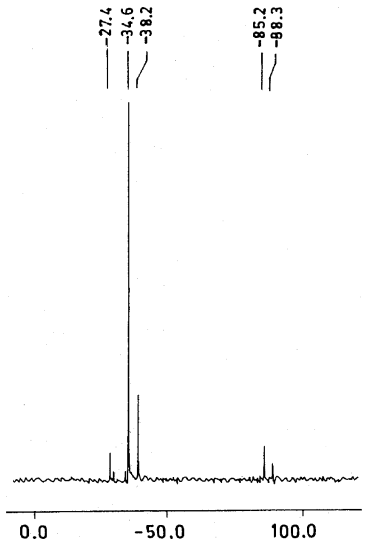

Fig. 1. The ^{31}P NMR spectrum (0 to −100 ppm) of the product mixture from reaction of the cyclic phosphite **14** with catechol and $ClN(Pr^i)_2$; catechol was added first to the phosphite.

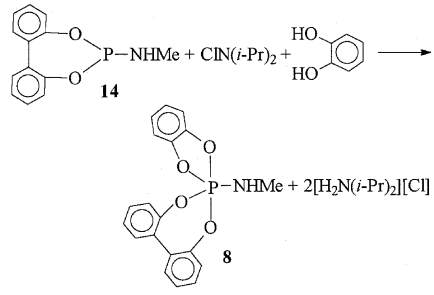

2.4. X-ray crystallography

X-ray data were collected on a Stoe-Siemens-Huber diffractometer (compound **6** at 153 K) or an Enraf-Nonius MACH3 diffractometer (compounds **7** and **8** at 293 K) using monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The structures were solved by direct methods; all non-hydrogen atoms were refined anisotropically [6–8]. For the hydrogen atoms bonded to carbon, the riding model was used. The hydrogens bonded to nitrogens were located in a difference map. They were refined with distance restraints. Crystal data are summarized in Table 1.

3. Results and discussion

3.1. Synthesis and spectroscopy

Synthesis of compounds **6**, **7**, **9** and **10** is achieved by oxidative addition of the corresponding quinone to the cyclic phosphites $(C_6H_{11}NH)P(1,2\text{-}O_2C_6H_4)$ (**12**), $(C_6H_{11}NH)$-$P(2,2'\text{-}O\text{-}C_6H_4\text{-}C_6H_4\text{-}O)$ (**13**) and $(MeNH)P(2,2'\text{-}O\text{-}C_6H_4\text{-}C_6H_4\text{-}O)$ (**14**) as the case may be. Compounds **8** and **11** were obtained by the *N*-chlorodiisopropylamine route [10,11] which is represented in Eq. (1) for **8**.

(1)

In this reaction involving the aminophosphites, the order of addition of the reagents is important. Instead of adding $ClN(Pr^i)_2$ first followed by diol, if the diol is added first and

then $ClN(Pr^i)_2$, other side reactions also take place; thus if the former order is maintained in Eq. (1), compound **8** is formed exclusively whereas if the latter order is followed, other pentacoordinated and hexacoordinated phosphorus species are formed as shown by ^{31}P NMR in Fig. 1 [12]. What is interesting is the observation of two signals in the hexacoordinated phosphorus region at −85.2 and −88.2 ppm. On the basis of available literature, these signals may be ascribable to compounds of the type $[MeNH_3]^+[P(2,2'\text{-}OC_6H_4\text{-}C_6H_4O)(1,2\text{-}O_2C_6H_4)_2]^-$ or $[MeNH_3]^+[P(1,2\text{-}O_2C_6H_4)_3]^-$ [13,14]. Thus here, in addition to exchange of the amino group by the catecholic –OH, ring exchange also appears to be taking place and the signal in the ^{31}P NMR in Fig. 1 at −38.2 ppm is assignable to compound **11**. Such an exchange reaction, however, is not observed in an analogous reaction of **14** with 2,2′-biphenol.

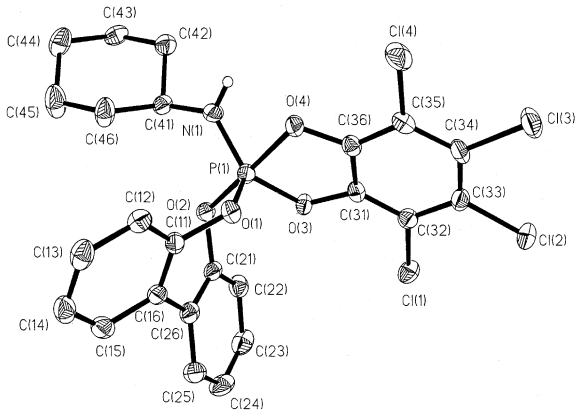

Fig. 2. Molecular structure of **6** (probability level of displacement ellipsoids 50%).

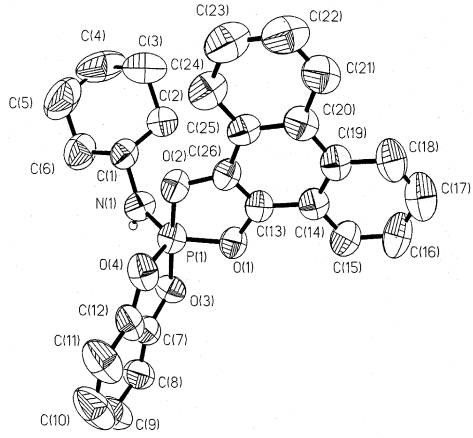

Fig. 3. Molecular structure structure of **7** (probability level of displacement ellipsoids 50%).

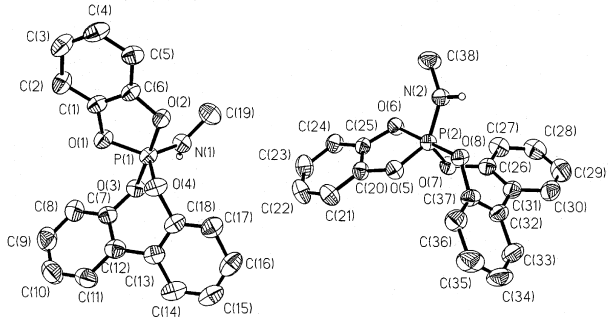

Fig. 4. Molecular structure of **8**; both the molecules in the asymmetric unit are shown (probability level of displacement ellipsoids 50%).

The ^{31}P NMR spectra of **6**–**11** in solution are consistent with a pentacoordinated structure. The peak for the (7 + 7) ring compound **11** appears upfield to (7 + 5) ring compounds **8**–**10** and the (5 + 5) ring compound **7** has the most downfield chemical shift in this series. In the ^1H NMR spectra, the methyls of the methylamino group show up as a doublet of a doublet in the P(III) precursor **14** (δ 2.63, $^3J(HH) = 5.8$ Hz; $^3J(PH) = 9.2$ Hz) as well as as in the phosphoranes ($^3J(HH) = 5.0$ Hz, $^3J(HH) = 13.0$ Hz for **11**), but the $^3J(PH)$ value is greater for the pentacoordinated systems. At least in **8**, dilution broadens the N*H*CH_3 signal, although no discernible change in the δ value is noticed.

3.2. X-ray structural analysis

The molecular structures of **6**–**8** are shown in Figs. 2–4 respectively. Selected bond parameters are given in Tables 2–4.

All the three compounds have a trigonal bipyramidal geometry around phosphorus with the cyclic substituents spanning apical-equatorial dispositions. As expected, the P–O(apical) bonds are longer than the P–O(equatorial) bonds; the P–O bonds in the five-membered rings are comparatively longer than those found in the seven-membered ring. The P–O distances in the seven-membered ring in **6** or **8**, however, are slightly longer than those observed in the phosphate ester **15** [15].

15

The P–N bonds in the three compounds are in the range 1.607–1.620 Å and thus are significantly shorter than the accepted P–N single bond length [16,17]. It is thus intriguing to note that in a large number of cases, whether phosphorus is tri-, tetra- or penta-coordinated (like that reported here), the formal P–N single bond is very short and close (or equal) in length to those in cyclophosphazenes where unsaturated P–N bonds are expected [18]. These distances for selected compounds are given in Table 5. At the moment this is only an observation and a detailed analysis encompassing all these classes of compounds would be more revealing as regards the the nature of the P–N bond.

The five-membered rings are nearly planar in all three structures. The seven-membered rings in **6** and **8** show a conformation between a twist boat and a boat [20]; this is analogous to that in the hexacoordinated structures reported previously [12].

In contrast to **15** where hydrogen bonding is present, in **6** such a feature is absent. Even in the the (5+5) spirophosphorane **7**, the closest intermolecular N–O distance is 3.312 Å [21]. The molecules organize themselves as weakly hydrogen bonded dimers (Fig. 5) with only the apical oxygen O(3) of the catecholate residue involved in hydrogen bonding. A stronger interaction is observed in **8**. Here primarily the atoms N(1) and O(2) of molecule 1 as well as N(2) and O(6) of molecule 2 are involved in hydrogen bonding interactions; the relevant intermolecular N–O contact distances are 2.981 and 3.126 Å respectively. In contrast to the dimer formation in **7**, hydrogen bonding in **8** results in a chain structure (Fig. 6). Again only the apical oxygens of the catecholate residue are involved in significant hydrogen bonding.

To summarize, in the reaction of aminophosphites with diols/$ClN(Pr^i)_2$ the order of addition of the diol and $ClN(Pr^i)_2$ to the phosphite is important. Where there is no significant steric inhibition, hydrogen bonding in primary amino substituted tetraoxyphosphoranes is observed; this interaction involves the *apical* oxygens (and not the *equatorial* ones) of the trigonal bipyramidal structure. This observation is perhaps useful in arriving at probable transition state

Vanadium complexes as models for vanadium species of marine organisms. Synthesis, X-ray structure of oxo(*O*,*O*-sulfate)(2,2′:6′,2″-terpyridine)vanadium(IV) hydrate, and density functional geometry optimization analysis of vanadyl complexes

Claudia Pifferi, Maria Pia Picchi, Renzo Cini *

Received 30 June 1999; accepted 15 October 1999

Abstract

The addition of an alcoholic solution of 2,2′:6′,2″-terpyridine (terpy) to a vanadyl sulfate ($VOSO_4 \cdot 3H_2O$) aqueous solution (molar ratio 1:1) produced a dark green solution from which brown single crystals suitable for X-ray diffraction studies grew within 12 h. The crystals contain neutral complex molecules [VO(terpy)(*O*,*O*-SO_4)] and water molecules (at a ratio 1:0.5). The complex molecules have a hexa-coordinate vanadium(IV) center linked to the three nitrogen atoms from terpy, to the apical *oxo* ligand and to two oxygen atoms from sulfate. The analysis of the geometrical parameters relevant to the VSO_4 group shows some significant distortion of the SO_4^{2-} ligand upon chelation to the V(IV)O core. The two S–O(d, donor) bonds (lengths: 1.495(3) *trans* to *oxo*; 1.546(3) Å *cis* to *oxo*) are stretched differently when compared to the S–O(t, terminal) bonds (1.447(3) Å). The effect is not due to packing forces but comes from electronic effects. This is shown by a DFT geometry optimization analysis carried out at the density functional B3LYP/LANL2DZ level on model complexes of the type $[VO(H_2O)]^{2+}$, $[VOL]^{2+}$ (L, *N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H), $[VO(H_2O)_2L]^{2+}$ and [VOL(*O*,*O*-SO_4)]. This analysis shows also that the $[VOL]^{2+}$ moiety has a very large affinity for the sulfate anion; the formation energy at the gas phase for [VOL(*O*,*O*-SO_4)] from $[VOL]^{2+}$ and SO_4^{2-} is -448.11 kcal mol^{-1}, much higher than the corresponding value for $[VO(H_2O)_2L]^{2+}$ (-91.47). This can be a rationale for the role vanadyl–sulfate interactions play in blood cells of Ascidians. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Vanadium; Vanadyl; Terpyridine; Density functional theory

1. Introduction

The discovery by Henze that Ascidian blood cells contain high concentrations of vanadium and that the blood cell lysis produces sulfuric acid [1] raised interest and much research work has been done since then on the matter [2–5]. It is generally accepted that vanadium is stored mainly in the unstable state V(III) [2]. However 5–10% of vanadium is estimated as *oxo* vanadium(IV) (vanadyl, VO^{2+}) and it can occur as an intermediate of a reductive process after vanadate has been absorbed from sea water, or by O_2-oxidation of V(III). At least for Ascidian *ceratodes*, V(III)-sulfate and vanadyl sulfate species are invoked for interpreting NMR, EXAFS and EPR data from blood cells [2].

Some vanadium complexes are insulin mimics and have been tested in humans for the treatment of diabetes [6–8]. The molecular mechanism through which such vanadium complexes act is not known.

Research efforts on coordination chemistry of vanadium have increased significantly after the discovery of vanadium enzymes [9] such as vanadium haloperoxidase which is widely present in marine algae. The catalyst is involved in the production of halogenated species and contains vanadium(V). The coordination environment of vanadium is not fully understood. EXAFS analysis of the reduced vanadium(IV) enzyme is indicative of a pseudo-octahedral coordination sphere consisting of a strongly bound *oxo* donor and five weakly bound light atoms (O or N) [10].

It is evident that all research efforts devoted to detailed analysis of the molecular and electronic structures of V(V), vanadyl and V(III) complexes contribute to throwing light on the field. On the basis of this reasoning and as a continuation of projects from this laboratory to investigate vanadium complexes related to biological systems [11], we wish to

report here on the synthesis and the crystal and molecular structure of the title compound at 173 K and on a DFT geometry optimization analysis of model vanadyl complexes performed at the density functional B3LYP/LANL2DZ level.

2. Experimental

2.1. Starting materials

Commercial reagent-grade chemicals $VOSO_4 \cdot 3H_2O$ (Aldrich) and 2,2′:6′,2″-terpyridine (terpy, Fluka) were used without further purification.

2.2. Preparation of $[VO(O,O\text{-}SO_4)(C_{15}H_{11}N_3)] \cdot 0.5H_2O$, $\mathbf{1} \cdot 0.5H_2O$

A clear aqueous solution of $VOSO_4 \cdot 3H_2O$ (8 mg, 0.037 mmol; 2 ml H_2O) was mixed with a clear alcoholic solution of terpy (9 mg, 0.039 mmol; 1 ml EtOH). The dark green solution, stored at room temperature, produced brown crystals within 12 h. The crystals were collected through suction filtration, washed with a few drops of cold water, then with 1 ml of EtOH, stored in air at room temperature for 4 h and finally stored in a closed vessel at 5°C. Yield: 10 mg, 67%. *Anal*. Calc. for $C_{15}H_{12}N_3O_{5.5}SV$ ($\mathbf{1} \cdot 0.5H_2O$; 405.3): C, 44.45; H, 2.98; N, 10.37. Found: C, 44.02; H, 2.70; N, 10.03%.

2.3. X-ray crystallographic study

A brown crystal was chosen at the polarizing microscope and mounted on a glass fiber for the X-ray data collection which was performed at 173 K through a Siemens P4 diffractometer. The unit cell dimensions were refined by a least-squares algorithm using 27 randomly selected high intensity reflections in the range $10 \leq 2\theta \leq 30°$. Selected crystallographic data are reported in Table 1. A total of 2770 reflections (2301 considered observed) were collected in the range $4 \leq 2\theta \leq 47°$ and corrected for Lorentz polarization and absorption (ψ-scan method) effects. Three reflections monitored during the collection (every 97) did not show any appreciable decay.

The structure was solved using the Patterson and Fourier techniques of SHELX 97 [12]. All the hydrogen atoms were located from the Fourier-difference map and their positions were refined freely. The model was refined by full-matrix least-squares methods. The non-hydrogen atoms were refined anisotropically, whereas all the hydrogen atoms were treated isotropically and their thermal parameters were restrained to 1.2 times the U_{eq} of the atoms to which they are bound. The oxygen atom of the free water molecule sits on a crystallographic two-fold axis so that the occupancy for O(1W) was assigned the value of 0.5.

All the calculations were carried out using Pentium 200 MHz machines with SHELX 97 [12] and PARST 97 [13] packages, as well as the molecular graphics XPMA-ZORTEP 98 [14] and ORTEP 32 [15] software.

2.4. Computational procedure

All the density functional calculations were performed using the GAUSSIAN94/DFT [16] package implemented on a CRAY C90 and an Origin 2000 SG machine located at CINECA (Interuniversity Computing Center), Bologna, Italy. Geometry optimizations, energy calculations and population analysis were obtained by using the B3LYP method [17,18] and the LANL2DZ [16] basis set. This consists of 6-31G like functions for non-transition metal atoms and a valence double-zeta basis set for 3s, 3p, 3d and 4s electrons and orbitals along with an effective core potential (Hay and Wadt [19]) for the metal. All the geometrical parameters were fully optimized without symmetry constraints. Other details are as those reported in Ref. [20]. The molecules optimized were $[VO(H_2O)]^{2+}$, $[VO(NH{=}CH{-}CH{=}N{-}C(=CH_2){-}CH{=}NH)]^{2+}$, $[VO(H_2O)_2(NH{=}CH{-}CH{=}N{-}C(=CH_2){-}CH{=}NH)]^{2+}$ and $[VO(NH{=}CH{-}CH{=}N{-}C(=CH_2){-}CH{=}NH)(O,O\text{-}SO_4)]$. The starting structure of the coordination sphere for the optimization of the complex molecules was very close to that found at the solid state for $[VO(terpy)(O,O\text{-}SO_4)]$ (**1**), except that terpy was substituted by $NH{=}CH{-}CH{=}N{-}C(=CH_2){-}CH{=}NH$ in the model complexes. For better reproduction of S-containing molecules, polarization functions should be taken into account. In fact the computation of SO_4^{2-} at the B3LYP/LANL2DZ level (6-31G basis set for all the atoms) does not reproduce well the S–O bond distance (computed, 1.678 Å; experimental solid state, 1.49 [21]). Results are much better at the B3LYP/6-3G** level (computed S–O, 1.537 Å) and at RHF/6-31G** (1.497). Attempts to optimize the

[VO(*N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H)(*O*,*O*-SO_4)] model molecule at the 6-31G** level for the S atom did not succeed. Therefore, it was decided to use the B3LYP/LANL2DZ level also for the sulfur-containing [VO(*N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H)(*O*,*O*-SO_4)] molecule. All the molecules were fully optimized excluding the [VO(*N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H)(*O*,*O*-SO_4] model molecule which was optimized by the following procedure: (1) the structure of the V(*N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H) moiety was that of the fully optimized [VO(H_2O)$_2$(*N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H)]$^{2+}$ molecule and it was fixed; (2) all the geometrical parameters for the $VOSO_4$ group were freely refined; (3) the starting geometry of the $N_3V(O)SO_4$ group was roughly C_s; (4) the optimization produced first a saddle point structure for maximum force and rms force shifts of 0.000359, 0.000079 (Gaussian 94 criteria, 0.000450, 0.000300, respectively), and for maximum displacement and rms displacement 0.037317, 0.007613 (Gaussian 94 criteria, 0.001800, 0.001200, respectively), the symmetry remained C_s. These conditions were reached after 18 cycles of refinement or ca. 50 h cpu time of a SG Origin 2000 machine. The optimization was then continued up to convergence on the basis of the Gaussian 94 criteria (ca. 100 h cpu time), the symmetry was C_1.

Molecular drawings were obtained through XPMA-ZORTEP [14] and ORTEP 32 [15] packages implemented on a Pentium machine.

3. Results and discussion

3.1. X-ray structure analysis

A drawing of the complex molecule and of the proximal water molecule of **1**·0.5H_2O is reported in Fig. 1(a). Selected bond distances and angles are listed in Tables 2 and 3.

The vanadium(IV) center has a pseudo-octahedral coordination sphere consisting of the three nitrogen atoms (N(1), N(2), N(3)) from the terpy ligand and one oxygen atom (O(2)) from the chelating SO_4^{2-} anion in the equatorial positions; the *oxo* (O(1X)) donor and a second oxygen atom (O(1)) from SO_4^{2-} are in the apical positions. The metal atom is displaced 0.3842(8) Å from the plane defined by the equatorial N(1)/N(2)/N(3)/O(2) set, towards O(1X) and the bond angles between the V–O(1X) vector, and the V–N and VO(2) vectors range between 96.3(1) (N(3)) and 107.6(1)° (N(2)), so that the coordination sphere assumes the typical umbrella shape of V(IV)OL_5 groups.

The V–O(1X) distance is 1.593(3) Å, in nice agreement with previously reported data for vanadyl sulfate, 1.59 (rombohedral) and 1.63 (tetragonal) [21], [VO(H_2O)(ada)] (H_2ada, *N*-(carbamoylmethyl)iminodiacetic acid; V–O(*oxo*), 1.601(2) Å) [10] and analogous complexes; with [VO(H_2O)(Hhida)] (H_3hida, *N*-(2-hydroxyethyl)-iminodiacetic acid; V–O(*oxo*), 1.596(5) Å) [6] and with [VO(mp)$_2$]$^{2-}$ (H_2mp, 2-mercaptophenol; V–O, 1.611(5) Å) [22].

The V–N bond distances are 2.124(3), 2.037(3) and 2.131(3) Å for N(1), N(2) and N(3), respectively, showing the common feature of a strongest coordination linkage of

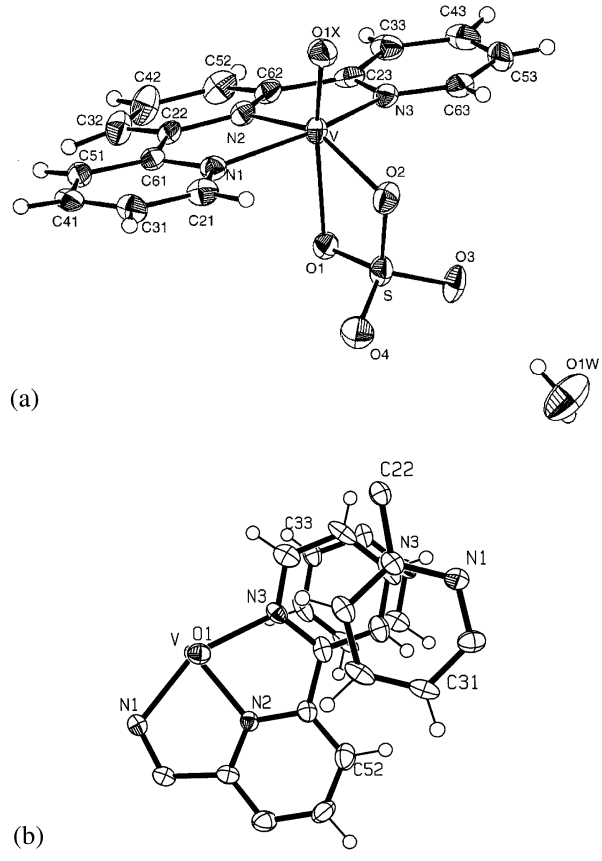

Fig. 1. (a) Drawing of the complex molecule and the proximal water molecule for **1**·0.5H_2O. The ellipsoids enclose 30% probability. (b) The diagram shows a selected stacking interaction between terpy moieties in the structure of **1**·0.5H_2O.

the middle nitrogen of the terpy ligand. The only structure containing the terpy ligand bound to a vanadium(IV) center which could be found through the Cambridge Structural Database on requesting the combination of the words *vanadium* and *terpyridine* is [$V(S_2)_2$(terpy)] [23]. In this case the three V–N bond distances are 2.112(2), 2.083(2) and 2.118(2) Å and have a similar trend to that of the present structure. Complexes of terpy with other metals show the same trend, too; see for example [(terpy)Cu(oxalate)-VO(oxalate)(H_2O)] [24].

The two V–O(sulfate) bond distances have very different values: 1.996(3) and 2.239(3) Å for O(2) and O(1), respectively, the O(1) donor experiencing a high *trans influence* from the *oxo* donor, as expected. The O(1)–V–O(1X), O(2)–V–O(1X) and O(1)–V–O(2) bond angles are 169.2(1), 102.4(1) and 66.8(1)° in agreement with a steric strain imposed by a coordination four-member ring. The V–O(sulfate) bond distances are 2.03 and 2.04 Å for the two forms of vanadyl sulfate in both of which the SO_4^{2-} ions bridge four octahedrally coordinate vanadium centers [21].

The structure of the sulfate molecule undergoes significant distortions from pure T_d symmetry upon complexation. The S–O(d, donor) bond distances (1.495(3), O(1); 1.546(3) Å, O(2)) are significantly larger than the S–O(t, terminal) bond lengths (1.455(3), O(3); 1.439(3) Å, O(4)). The O(3) atom interacts with the water molecule via a H-bond. The S–O bond distance for sulfate anions not significantly covalently liked to *block d* metal ions is reported to be 1.49 in Ref. [21], and is in the range 1.452(4)–1.491(4) Å (average, 1.468(4)) for the compound [$Cu(oaoH_2)_2(H_2O)]SO_4$ ($oaoH_2$, oxamide oxime) [25]. For this latter structure the longest S–O distance (1.491(4)) has to be related to a strong H-bond between the sulfate oxygen and the H_2O ligand.

The sulfate ligand which bridges two copper atoms in [$Cu(oaoH_2)(H_2O)(\mu$-$SO_4)]_2$ and [$Cu(oaoH_2)(H_2O)(\mu$-$SO_4)]_n$ has S–O(b, bridging) distances of 1.481(3) (average) and 1.489(3) Å, respectively [25].

The vanadium(II) complex [$V(bpy)_2$(*O*,*O*-SO_4)] has S–O(d) and S–O(t) bond lengths of 1.500(3) and 1.446(3) Å [26], respectively.

It is evident from these data that, at least at the solid state, the S–O(d) bond lengths enlarge upon coordination to the metal or upon H-bonding formation, whereas the S–O(t) bond lengths shorten upon the formation of metal–O(d) bonds. This work proves that the lengthening effect caused on a S–O(d) bond (namely, S–O(2)) is significant and much larger than that found for the other S–O(d) bond (namely, S–O(1)). In fact the S–O(2) length is close to the S–OH bond distance (up to 1.541 Å) found for the hydrogen sulfate anion of monoclinic $N(CH_3)HSO_4$ at 175 K [27] and to the S–OH bond distance (1.537(3)) found for the salt [$(C_6H_5)_2SONH_2$]HSO_4 [28].

The bond angles with respect to sulfur are in the range 100.6(1)–113.6(2)° in the structure of **1**, the smallest values belong to O(1)–S–O(2) as expected because it is part of the flat four-member ring. This value is even smaller than the corresponding value reported previously for [$V(bpy)_2$(*O*,*O*-SO_4)] (102.0(1)°) [26].

Therefore, the (terpy)V=O unit has a high affinity for the sulfate anion (as appears from the short V–O(2) bond distance) and it is particularly suited to induce a sort of activation on SO_4^{2-} because of the highly different electronic and steric effects induced by the *oxo* ligand and the donor atoms from terpy.

The terpy ligand deviates significantly from planarity. The dihedral angles between the three rings are as high as 7.7(2)° (rings 1/2) 3.7(1)° (rings 1/3) and 7.9(2)° (rings 2/3); the vanadium atom deviates from the least squares planes of 0.1938(8), −0.1994(8) and 0.1755(8) Å when compared

to the position of O(1X). The bond distances and angles for the terpy moiety have normal values.

The analysis of the crystal packing shows several interesting intermolecular interactions. First, the terpy ligand is involved in strong stacking interactions mostly through the two peripheral pyridine rings, as depicted in Fig. 1(b). The shortest stacking interatomic distance is 3.274(8) Å, between two C(51) atoms of molecules located at x, y, z and $-x+1, y, -z+2.5$. Second, a complicated web of hydrogen bonds links all the molecules in the crystal. The water molecule (O(1W)) bridges two complex molecules through the O(3) atoms: O(1W)···O(3), 2.891(5) Å; O(1W)–H···O(3), 178(6)°. The water molecule also has two C–H(53)··· O(1W) hydrogen bonds. The *oxo* ligand is surrounded by at least four H atoms from terpy moieties, the shortest contact distance being C(43)H···O(1X), 2.71(5) Å. All the oxygen atoms of sulfate interact also with hydrogen atoms from terpy moieties.

3.2. Density functional analysis

The geometry optimized molecules are pictured in Figs. 2–5. The total energy for the optimized molecules is reported in Table 4. The formation energy for selected formal reactions is reported in Table 5. Selected bond distances and bond angles are listed in Tables 6 and 7, respectively. Atomic coordinates can be retrieved from Supporting Material.

Structures of molecules: The optimized structure of L, *N*H=CH–CH=*N*–C(=CH_2)–CH=*N*H, has C–N bond distances of 1.300 Å and the backbone C–C bond lengths in the range 1.419–1.491 in agreement with values found in the solid state for the terpy ligand of **1**·0.5H_2O. The angles around the N atoms are also in acceptable agreement with those for terpy. The overall conformation of the optimized L

$[VOL]^{2+} + SO_4^{2-} \rightarrow [VOL(O,O\text{-}SO_4)]$ (C_1)	−448.11
$[TiOL]^{2+} + SO_4^{2-} \rightarrow [TiOL(O,O\text{-}SO_4)]$ (C_1)	−458.01

ligand can be described as EZEE (Fig. 2(a)), different from the EZZE conformation (Fig. 2(b)) of the starting structure and from that of the N–C–C–N–C–C–N backbone of terpy in the structure of **1**. The energy gap between the EZEE and EZZE conformations as computed at the B3LYP/6-31G level is 16.91 kcal mol^{-1}. The instability of the EZZE structure comes from the steric hindrance between a hydrogen atom from the =CH_2 arm and a second hydrogen atom from the backbone. Short intramolecular H···H contacts are also present within the chelating terdentate terpy ligand. These steric repulsions are probably one of the reasons for deviations from coplanarity of the three aromatic rings of terpy in the solid state structure of **1**.

The V–O(*oxo*) bond distance increases significantly from 1.537 Å, VO^{2+}, to 1.557 Å, $[VO(H_2O)]^{2+}$, showing that even the addition of a weak field ligand such as H_2O in the *trans* position weakens appreciably the V–O(*oxo*) bond. The hexacoordinate $[VO(H_2O)_2L]^{2+}$ and $[VOL(O,O\text{–}SO_4)]$ complexes have V–O(*oxo*) bond lengths of 1.581 and 1.608 Å respectively, in excellent agreement with the value found for **1** in the solid state.

The V–O(H_2O, *trans*) bond distances are 2.023 and 2.254 Å for the $[VO(H_2O)]^{2+}$ and $[VO(H_2O)_2L]^{2+}$ species,

Table 6
Selected bond distances (Å) for the molecules optimized at the DFT-B3LYP/LANL2DZ level, unless otherwise specified. t, terminal; d, donor; *trans* and *cis* are referred to the *oxo* ligand

Molecule	S–O(t)	S–O(d)	V=O	V–O(*trans*)	V–O(*cis*)	V–N(2) [a]	V–N(5) [a]	V–N(8) [a]
SO_4^{2-}	1.678

($VOSO_4$, C_s)		1.773						
$[VOL(O,O\text{-}SO_4)]$	1.606	1.719	1.608	2.247	1.932	2.108	2.100	2.099
($VOSO_4$, C_1)	1.633	1.766						

[a] The numbering of the atoms is that reported in Figs. 2–5.
[b] Oxygen atoms were applied the 6-31G basis set.

Table 7
Selected bond angles (°) for the molecules optimized at the DFT B3LYP/LANL2DZ level

Molecule	O(t)–S–O(t)	O(d)–S–O(d)	O=V–O(*trans*)	O=V–O(*cis*)	O(S/H)–V–O(S/H)	O=V–N(5)
$[VOL]^{2+}$						107.8
$[VO(H_2O)_2L]^{2+}$			168.3	89.9	78.6	101.4
$[VOL(O,O\text{-}SO_4)]$ (C_1)	118.9	91.8	176.7	110.1	73.1	102.5

showing that the *cis*-L ligand has a large effect. It is worth noting that the computed V–O(*trans*) distance of [VOL(*O*,*O*-SO_4)] is 2.226–2.247 Å, close to the value computed for the diaqua-derivative and in excellent agreement with the experimental value for **1** (2.239(3) Å).

The computed V–O(*cis*) bond distance is 2.078 Å for $[VO(H_2O)_2L]^{2+}$ and 1.932 Å for [VOL(*O*,*O*-SO_4)], showing that the V–sulfate bond is much stronger than the V–water linkage at that coordination site (the strength of the vanadyl sulfate interaction is reflected in the value of the bond formation energy, see below).

The computed V–N bond lengths reproduce well the experimental solid state values; the largest difference between experiment (for **1**) and theory (for [VOL(*O*,*O*-SO_4)]) is 0.063 Å.

As mentioned above (Section 2.4) the S–O bond distances are overestimated (up to 0.18 Å), compared to experimental values, when the basis set is 6-31G for all the first, second and third raw elements. A certain overestimation (ca. 0.05 Å) persists on using 6-31G set for first and second raw elements, and 6-31G** type orbitals for sulfur. However the relative changes caused by chelation of sulfate to the VOL^{2+} group on the S–O bond distances are well estimated at the B3LYP/LANL2DZ level. The S–O(t) vectors undergo a shortening effect upon complexation of 0.04 Å (found for **1**, based on the S–O distance of 1.49 [21]), whereas the computed effect is 0.06 Å. Similarly, the found and computed lengthening of S–O(d, *cis* to *oxo*) is 0.06 and 0.08 Å, respectively.

The structures of $[TiOL]^{2+}$ and [TiOL(*O*,*O*-SO_4)] (C_1) were also optimized for comparison purposes. The computed Ti–O(*cis*) bond distance is 1.877 Å whereas the Ti–O(*trans*) bond length is 2.302 Å. The equatorial oxygen of sulfate is more strongly linked to the metal than the axial oxygen, when compared to the vanadyl complex.

Metal–ligand binding energies: The computed formation energy for $[VO(H_2O)]^{2+}$ is −90.54 kcal mol^{-1}, lower than that of $[Zn(H_2O)]^{2+}$ (−108.40) [20] and higher than that of $[Zn(H_2O)(Imz)]^{2+}$ (Imz, imidazole) (−81.80) [20] from $[Zn(Imz)]^{2+}$ and H_2O. The formation of $[VOL]^{2+}$ from L-EZZE is exothermic for −321.12 kcal and it compares well with the value for $[Zn(H_2O)(Imz)_3]^{2+}$ from $[Zn(H_2O)]^{2+}$ and 3Imz (−298.22 kcal) [29].

The addition of two water molecules to $[VOL]^{2+}$ has a small enthalpic effect (−91.47 kcal) but, interestingly, the addition of the sulfate anion produces a high amount of energy: −448.11 kcal. The latter enthalpic effect is even higher than the formation energy of the tetra-coordinate $[Zn(H_2O)(Imz)_3]^{2+}$ molecule from Zn^{2+}, H_2O and 3Imz (−406.6 kcal) [20]. Even though these values are computed at the gas phase and solvation effects can play a very important role, it is evident that sulfate and N_3VO^{2+} groups have a large affinity. It has to be noted that the high enthalpic effect of the addition of sulfate is not peculiar to the $[VOL]^{2+}$ species. In fact the formal reaction of the sulfate anion with $[TiOL]^{2+}$ to give [TiOL(*O*,*O*-SO_4)] (C_1) produces an even larger amount of energy, −458.01 kcal.

Atomic charges: The atomic charges calculated from the Mulliken population analysis are listed in Table 8. The charge on the V atom decreases down to 1.839*e* from 4, upon V–O(*oxo*) bond formation. The effect of donation from H_2O trans to *oxo* is small: charge on V for $[VO(H_2O)]^{2+}$, 1.632*e*. On the contrary, the addition of L to VO^{2+} has a large effect: charge on V for $[VOL]^{2+}$, 1.185*e*. As expected, chelating sulfate causes a larger effect than two water molecules on the charge of V: 0.927*e* for [VOL(*O*,*O*-SO_4)], 1.057*e* for $[VO(H_2O)_2L]^{2+}$.

The atomic charge of the *oxo* donor is highly influenced by the coordination environment on vanadium: it is 0.161*e* for vanadyl, 0.087*e* for $[VO(H_2O)]^{2+}$ and −0.239*e* for $[VO(H_2O)_2L]^{2+}$. The large negative charge on the *oxo* donor of [VOL(*O*,*O*-SO_4)], −0.368*e*, is in agreement with the presence of several short (C)H···O(*oxo*) contacts found in the crystal structure of **1**·0.5H_2O. The atomic charges on the hydrogen atoms of the L ligand of the [VOL(*O*,*O*-SO_4)] molecule are in the range 0.240–0.357*e*. The charges on the oxygen atoms of the sulfate ligand are highly negative and this explains why several (S)O···H(H_2O) and (S)O···H(C) interactions exists at the solid state for **1**·0.5H_2O.

Computed vibrational frequencies: The IR ν(V–O(*oxo*)) stretching frequency for $[VO(H_2O)]^{2+}$ is 999.1 cm^{-1}, the intensity of the absorption being weak–medium (52.0 km mol^{-1}). The IR ν(V–O(H_2O)) stretching frequency for the same molecule is 489.1 cm^{-1}, weak–medium (38.2), whereas the ν(O–H) stretching frequencies are 3489.0 and 3558.6 cm^{-1} and intense (558.3 and 388.7).

Table 8
Selected atomic charges (*e*) from the Mulliken population analysis at the B3LYP/LANL2DZ level (terms *cis* and *trans* are relevant to the position of the *oxo* ligand; t, terminal)

Molecule	O(*oxo*)	O(*trans*)	O(*cis*)	O(t)	N(2)	N(5)	N(8)	S	V

L(EZZE)					−0.218	0.022	−0.246		
VO^{2+}	0.161								1.839
$[VO(H_2O)]^{2+}$	0.087	−0.805							1.632
$[VOL]^{2+}$	−0.157				−0.493	−0.376	−0.545		1.185
$[VO(H_2O)_2L]^{2+}$	−0.239	−0.753	−0.740		−0.453	−0.285	−0.503		1.057
[VOL(*O*,*O*-SO_4)] (C_1)	−0.368	−0.593	−0.618	−0.576	−0.385	−0.267	−0.403	1.252	0.927

4. Conclusion

This work produced the structural characterization of the first complex ever reported of vanadyl with chelating sulfate and a terdentate polypyridine. The X-ray analysis gave accurate geometrical parameters for the complex molecule and in particular for the vanadyl–sulfate grouping. From this, it is evident that the sulfate anion has a strong interaction with the vanadyl group mostly through the oxygen atom which occupies the equatorial position. The chelation causes a large distortion of the sulfate tetrahedron with a significant elongation of a S–O bond and a shortening of two S–O bonds. The angles around sulfur are also significantly altered. The result is a type of activation of SO_4^{2-} towards SO_3. Similar effects happen for the *oxo*-titanium(IV) derivative.

The molecular orbital analysis carried out on several isolated molecules confirms that: (1) the $(terpy)VO^{2+}$ and SO_4^{2-} molecules have a large affinity as estimated by an enthalpic contribution for the formal reaction of -448.11 kcal; (2) the distortion of the sulfate ligand found in the crystal of $\mathbf{1}\cdot 0.5H_2O$ has electronic intramolecular origin and it does not depend significantly on the packing forces inside the crystal; (3) bond distances and bond angles for a $N_3V(O)O_2$ grouping can be excellently reproduced at the B3LYP/LANL2DZ level of computation.

POLYHEDRON

Synthesis and characterization of homo- and heterobimetallic diethanolaminates of alkaline earth metals

M. Sharma, A. Singh* [1], R.C. Mehrotra* [2]

Department of Chemistry, University of Rajasthan, Jaipur-302 004, India

Received 4 August 1999; accepted 20 October 1999

Abstract

Heteroleptic heterobimetallic isopropoxide diethanolaminate derivatives of the type $\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}$ (M = Mg, Ca, Sr, Ba) have been prepared by the reactions of homometallic precursor derivatives $H_2M\{(OC_2H_4)_2NH\}_2$ (**1a**–**1d**) with $Al(OPr^i)_3$ in 1:2 molar ratio in benzene. The insoluble homometallic precursor derivatives (**1a**–**1d**) have been synthesized by two alternative routes: (1) reactions of $M(OPr^i)_2$ with diethanolamine in 1:2 molar ratio; and (2) reactions of the metals Mg, Ca, Sr and Ba with diethanolamine in 1:2 molar ratio in refluxing toluene. The new homo- and heterobimetallic diethanolaminate derivatives have been characterized by elemental analysis, molecular weight measurements and spectroscopic [IR, NMR (^1H, ^{13}C, ^{27}Al)] studies. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Alkaline earth metals; Heterobimetallic diethanolaminates; Homobimetallic diethanolaminates

1. Introduction

Although homo- and heterobimetallic triethanolaminate derivatives of a number of metals have been reported [1–3], the corresponding diethanolaminates are still rare, except the reported [1] synthesis of homometallic diethanolaminates of B, Al, Ge, Sn and Nb as well as those of organosilicon [4] and organogermanium [5].

During the last few decades, we have been interested in the development of coordination chemistry of non-classical chelating ligands [3,6,7] (i.e. alkoxometallates such as $Al(OPr^i)_4^-$, $Zr_2(OPr^i)_9^-$, $Nb(OPr^i)_6^-$, etc.), which led to the emergence of diverse structural patterns and recognition of the potentiality of such derivatives as important precursors in the sol–gel process for the synthesis of advanced mixed-metal oxide systems. The organic chelating ligands such as β-diketones [8], carboxylic acids [9], amino alcohols and other polyhydroxy alcohols [10–13] have been found to play an important role in modulating the reactivity of the highly reactive metal alkoxides to such an extent that formation of gel during the hydrolysis process can be accomplished instead of precipitation.

In view of the above, we report herein for the first time the synthesis and characterization of heterobimetallic diethanolaminates of alkaline earth metals, which assume special significance due to the importance of barium as a constituent of superconducting mixed-metal oxide systems [14,15]. Further, the diethanolaminate group as a chelating ligand possesses potential advantages, such as ability to (1) control the reactivity of metal alkoxides; (2) reduce the nuclearity of the oligomeric metal alkoxides; and (3) enhance the volatility and solubility (in common organic solvents) of the resulting derivatives.

2. Experimental

All the preparative reactions were performed under strictly anhydrous conditions. Benzene (BDH), isopropyl alcohol (BDH), n-hexane and toluene (BDH) were dried and purified [16,17] by the usual methods. Diethanolamine was purified by distillation at 213°C, 760 mm.

$Al(OPr^i)_3$ was prepared by the literature method [1]. Freshly cut and dried pieces of alkaline earth metals (Ca, Sr, Ba) were used. Magnesium was used as a foil.

Strontium, barium and aluminium were estimated [18] gravimetrically as strontium sulphate, barium sulphate and aluminium oxinate, respectively. Magnesium and calcium were estimated volumetrically by complexometric titrations using eriochrome black-T as indicator. Nitrogen was estimated [18] by the Kjeldahl method.

Infrared spectra (4000–200 cm^{-1}) were recorded on a Nicolet Magna-550 spectrophotometer in Nujol mulls. NMR

PII S0277-5387(99)00327-7

spectra for ^{1}H (in $CDCl_3$ or dimethylsulphoxide, DMSO-d_6), ^{13}C (in CCl_4 or DMSO) and ^{27}Al (in CCl_4 or C_6H_6) were recorded on a JEOL FX 90 Q spectrometer. Molecular weights of soluble derivatives were measured ebullioscopically in benzene using a Gallenkamp ebulliometer with thermistor sensing device.

2.1. Syntheses

Homometallic diethanolaminate derivatives of alkaline earth metals have been prepared either by the reactions of metals or of metal isopropoxides with diethanolamine. Reactions of these insoluble bisdiethanolaminates of alkaline earth metals, $H_2M\{(OC_2H_4)_2NH\}_2$ with $Al(OPr^i)_3$ in 1:2 molar ratio yielded soluble products with the composition $\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}$.

Alternatively, the heterobimetallic isopropoxide-diethanolaminate derivatives have also been prepared by the (1:2) reactions of $M\{Al(OPr^i)_4\}_2$ with diethanolamine.

Due to similarity in the methods of preparation of the new derivatives, the preparation of only one typical compound of each type is described below, while preparative and analytical details for other compounds are listed in Tables 1–4.

2.1.1. Synthesis of homometallic derivative $H_2Ba\{(OC_2H_4)_2NH\}_2$

Surface-cleaned Ba metal (0.75 g, 5.46 mmol) and diethanolamine (1.15 g, 10.92 mmol) were taken in toluene (~50 ml), and refluxed for ~10 h. Removal of the volatiles

Table 1

under reduced pressure yielded a colourless powdery solid (1.88 g, 98%). Analytical details are listed in Table 1.

Freshly prepared $Ba(OPr^i)_2$ (1.17 g, 4.58 mmol) was taken in a solution containing diethanolamine (0.96 g, 9.14 mmol), in benzene (~70 ml). The mixture was refluxed for ~6 h, and the isopropyl alcohol in the azeotrope was estimated periodically until the distillate showed negligible presence of isopropyl alcohol. After removal of the volatiles from this suspension, a colourless solid powder was obtained (1.56 g, 97%). Analytical details are listed in Table 2.

2.1.2. Synthesis of heterobimetallic diethanolaminate derivative $\{Al(OPr^i)_2\}_2\{Ba[(OC_2H_4)_2NH]_2\}$

$H_2Ba\{(OC_2H_4)_2NH\}_2$ (0.73 g, 2.11 mmol) and $Al(OPr^i)_3$ (0.86 g, 4.20 mmol) were taken in benzene solution (~70 ml), which was refluxed for ~6 h under a fractionating column with continuous removal and oxidimetric estimation of the liberated isopropyl alcohol. After completion of the reaction, the solvent was removed under reduced pressure from this yellow coloured solution, yielding a yellow coloured powder (1.26 g, 98%), which on recrystallization from n-hexane and toluene mixture at −20°C yielded the title derivative (1.07 g, 85%). Analytical details are listed in Table 3.

2.1.3. Synthesis of $Ba\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$

The reaction mixture containing freshly prepared $Ba\{Al(OPr^i)_4\}_2$ (2.45 g, 3.69 mmol) in benzene solution (~50 ml) and diethanolamine (0.78 g, 7.38 mmol) was refluxed under a fractionating column for ~6 h with contin-

uous collection of the liberated isopropyl alcohol, which was periodically estimated. On completion of the reaction (as indicated by negligible reduction of $K_2Cr_2O_7$), the resulting solution was dried under reduced pressure to afford a light yellow solid (2.39 g, 97%), which was recrystallized in 76% yield from n-hexane and toluene mixture at −20°C. Analytical details are listed in Table 4.

3. Results and discussion

Reactions of alkaline earth metals with diethanolamine in 1:2 molar ratio in refluxing toluene yield insoluble derivatives according to the following reaction:

$$M + 2HN(C_2H_4OH)_2 \xrightarrow[\sim 18\ h]{C_6H_5CH_3} H_2M\{(OC_2H_4)_2NH\}_2\downarrow + H_2\uparrow \quad (1)$$

(1a) : M = Mg
(1b) : M = Ca
(1c) : M = Sr
(1d) : M = Ba

The synthesis of Mg and Ca derivatives by the above route requires a small amount (∼1 ml) of isopropyl alcohol and $HgCl_2$ as a catalyst.

As the preparation of the derivatives **1a**–**1d** by reaction (1) requires ∼18 h of refluxing, these derivatives have been precipitated out slowly at room temperature by mixing diethanolamine in benzene solution of $M(OPr^i)_2$ in 1:2 molar ratio. This mixture is refluxed under a fractionating column with continuous removal of liberated isopropyl alcohol:

$$M(OPr^i)_2 + 2HN(C_2H_4OH)_2 \xrightarrow[\sim 8\ h]{C_6H_6} H_2M\{(OC_2H_4)_2NH\}_2\downarrow + 2Pr^iOH\uparrow \quad (2)$$

(1a) : M = Mg
(1b) : M = Ca
(1c) : M = Sr
(1d) : M = Ba

Interestingly, the reactions of the above insoluble derivatives (**1a**–**1d**) with $Al(OPr^i)_3$ in 1:2 molar ratio in refluxing benzene afford soluble heterobimetallic isopropoxide-diethanolaminate derivatives (**2**–**5**) and 2 mol of isopropyl alcohol, which is quantitatively fractionated out with benzene in the form of an azeotrope:

$$H_2M\{(OC_2H_4)_2NH\}\downarrow + 2Al(OPr^i)_3 \xrightarrow[\sim 6\ h]{C_6H_6}$$

$$\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}_2 + 2Pr^iOH\uparrow \quad (3)$$

where M = Mg (**2**), M = Ca (**3**), M = Sr (**4**) and M = Ba (**5**).

The reactions of $M\{Al(OPr^i)_4\}_2$ derivatives with diethanolamine in 1:2 molar ratio can be represented by Eq. (4). These products could be expected to have a composition of the type $M\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$:

$$M\{Al(OPr^i)_4\}_2 + 2(HOC_2H_4)_2NH \xrightarrow[\sim 6\ h]{C_6H_6}$$

$$M\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2 + 4Pr^iOH\uparrow \quad (4)$$

where M = Mg (**6**), M = Ca (**7**), M = Sr (**8**) and M = Ba (**9**).

It would be interesting to investigate the tendencies (if any) of the interconversion of the structural form of products **6**–**9** with those represented by **2**–**5**.

All these colourless homo- and heterobimetallic diethanolaminate derivatives (**1**–**9**) are moisture-sensitive. On heating, compounds **1a**–**1d** tend to decompose around 280°C; compounds **2**–**9** appear to be more stable, but decompose around 350°C without melting. The insoluble nature of the homometallic derivatives (**1a**–**1d**) in benzene precluded molecular weight measurements. These derivatives (**1a**–**1d**) are insoluble in common organic solvents, but freely soluble in DMSO, whereas the heterobimetallic derivatives (**2**–**9**) are soluble in common organic solvents and display a monomeric nature in benzene.

3.1. IR spectra

The diethanolamine ligand shows infrared absorptions [19] (in cm^{-1}) at: 3475 (br) νO–H, 3274 (br) νNH, 2950 (br) νC–H, 1447 $\delta_s(CH_2)$, 905 (br) νC–C and 1060 νC–H.

The homometallic derivatives (**1a**–**1d**) show broad absorptions (Table 5) in the regions 3298–3281 νOH, 3188–3175 νNH, 900–830 νC–C, 1063–1008 νC–O and 576–547 νM–O [6,7] (M = Mg, Ca, Sr, Ba). A comparison of νNH data for the above metal derivatives with that of the free ligand shows lowering of 85–100 cm^{-1}, indicating the possibility of coordination through nitrogen to the central metal atom. Furthermore, the shifting of νOH in homometallic derivatives to lower wave numbers tends to indicate the possibility of extensive hydrogen bonding, making them insoluble due to polymerization, as observed [2] in the case of $H_3La\{(OCH_2CH_2)_3N\}_2$.

The heteroleptic heterobimetallic derivatives (**2**–**9**) show absorptions (Table 5) characteristic of both the isopropoxy (1175–1140, 1127–1096, νOPr^i, 1079–1032 νC–O) and the diethanolaminate groups (3189–3161 νNH, 2939–2905 νC–H) as well as absorption bands at 675–611 νAl– and 577–436 νM–O. The lowering (58–146 cm^{-1}) of νNH compared with that of uncomplexed diethanolamine ligand indicates the possibility of involvement of nitrogen in bonding.

3.2. NMR spectra

The ^1H NMR spectrum of diethanolamine shows signals at δ 2.80 (t (J = 6.1 Hz), CH_2N), 3.80 (t (J = 6.1 Hz), CH_2O) and 4.37 (broad, N*H* and O*H*).

The ^1H NMR spectra (Table 6) of homometallic derivatives $H_2M\{(OC_2H_4)_2NH\}_2$ (**1a**–**1d**) show triplet (J = 6.1 Hz) at δ 2.60–2.68 (CH_2N), broad peaks at 3.37–3.70

7	$Ca\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$	1.26(d (J=6.0 Hz), 24H, CHMe_2); 2.64(br, 8H, CH_2N); 2.95(br, 8H, CH_2O); 3.80(br, 2H, NH); 4.16(sept (J=6.0 Hz), 4H, CHMe$_2$)	57.20
8	$Sr\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$	1.25(d (J=6.0 Hz), 24H, CHMe_2); 2.55(br, 8H, CH_2N); 3.06(br, 8H, CH_2O); 3.73(br, 2H, NH); 4.18(sept (J=6.0 Hz), 4H, CHMe$_2$)	59.20
9	$Ba\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$	1.26(d (J=6.0 Hz), 24H, CHMe_2); 2.60(br, 8H, CH_2N); 3.00(br, 8H, CH_2O); 3.71(br, 2H, NH); 4.23(sept (J=6.0 Hz), 4H, CHMe$_2$)	61.55

(CH_2O) and 4.41–4.74 (OH+NH). The low field shifting ($\sim$0.04–0.32 ppm) of OH and NH protons indicates involvement of these groups in bonding. Further, the appearance of only a single set of resonances indicates rapid hydrogen isomerism.

The heteroleptic heterobimetallic derivatives $\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}$ (**2–5**) and $M\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$ (**6–9**) show peaks (Table 7) at δ 2.42–2.64 (br, CH_2N), 2.86–3.00 (br, CH_2O), 3.61–3.84 (br, NH), 1.21–1.26 (d (J=6.0 Hz), CHMe_2) and 4.13–4.36 (sept (J=6.0 Hz), CHMe$_2$).

The ^{13}C NMR spectrum of diethanolamine shows signals at δ 50.54 (CH$_2$N) and 59.70 (CH$_2$O), whereas these signals in the derivatives (**1a–1d**) are observed at δ 49.13–50.69

(CH_2N) and 58.02–59.48 (CH_2O). The mixed-ligand derivatives (**2**–**9**) show peaks due to isopropoxo groups at δ 25.62–28.44 ($CHMe_2$) and 62.75–66.73 ($CHMe_2$) as well as due to the diethanolamino groups at δ 49.13–50.69 (CH_2N) and 58.02–59.13 (CH_2O).

The heterobimetallic derivatives (**2**–**9**) exhibit ^{27}Al NMR chemical shifts in the range δ 58–66, characteristic of tetrahedral [20–22] aluminium compounds.

4. Suggested structures

The insolubility of the products **1a**–**1d** in non-polar organic solvents (e.g. C_6H_6) indicated their polymeric nature, which may be due either to association through diethanolaminate bridges or to the core structure (Fig. 1) with the chelated diethanolaminate ligand becoming associated through hydrogen bonding. The latter possibility appears to be more feasible as these insoluble homometallic diethanolaminates readily yield monomeric bimetallic derivatives (**2**–**5**) in which hydrogen bonding is not possible.

The plausible structure for **1a**–**1d** shown in Fig. 1 is in conformity with spectroscopic (IR, ^{1}H, ^{13}C) data. Similarly, the spectroscopic data (including ^{27}Al NMR) for the heterometallic derivatives (**2**–**5**) are consistent with the plausible structure depicted in Fig. 2.

The broad ^{27}Al NMR signals at δ 57–63 and insignificant change in the position of νNH with that of the diethanolamine ligand for the derivatives **6**–**9** (prepared by the interaction of $M\{(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2$ with diethanolamine in 1:2 molar ratio) tend to favour the structure shown in Fig. 3.

It may, however, be pointed out that, due to the significant size and electronegativity differences between alkaline earth metals and aluminium, shifting of diethanolaminate moieties from aluminium to the alkaline earth metal centres may be possible to render coordinatively saturated structures similar to that shown in Fig. 2.

Such type of shifting of a chelating ligand (e.g. $Zr_2(OPr^i)_9^-$) from the smaller less electropositive Cd to the larger more electropositive Ba atom has been recently established X-ray crystallographically by Veith et al. [23] for the product obtained by the reaction shown below:

$$[Zr_2(OPr^i)_9]CdI + KBa(OPr^i)_3 \longrightarrow \{Zr_2(OPr^i)_9\}Cd\{Ba(OPr^i)_3 + KI\downarrow$$

$$\downarrow$$

$$\{Zr_2(OPr^i)_9\}Ba\{Cd(OPr^i)_3\}$$

Although repeated efforts to obtain crystals suitable for X-ray crystallography have not been yet successful, the solubility of the heterometallic derivatives $\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}$ (**2**–**5**) and in contrast to the insolubility of homometallic precursors $H_2\{M[(OC_2H_4)_2NH]_2\}$ (**1a**–**1d**) in hydrocarbon solvents along with no tendency of the derivatives (**2**–**9**) to eliminate $Al(OPr^i)_3$ even on heating up to 200°C, 0.1 mm, confirm their individuality beyond any reasonable doubt, and the structures suggested to be acceptable on the basis of the spectroscopic data discussed in the text are in conformity with suggested plausible structures.

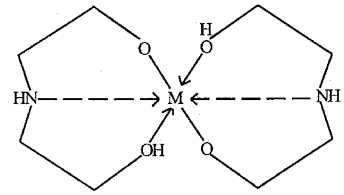

Fig. 1. Proposed structure for the derivatives $H_2M\{(OC_2H_4)_2NH\}_2$; M = Mg (**1a**), Ca (**1b**), Sr (**1c**), Ba (**1d**). Dashed lines represent the tentative involvement of coordination through nitrogen depending upon the size of the metal atom.

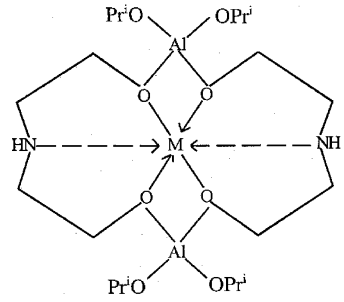

Fig. 2. Proposed structure for the derivatives $\{Al(OPr^i)_2\}_2\{M[(OC_2H_4)_2NH]_2\}$ (**2**–**5**).

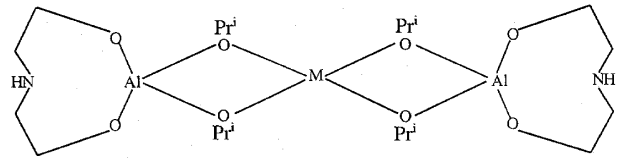

Fig. 3. Proposed logical structure for the derivatives $M\{Al(OPr^i)_2[(OC_2H_4)_2NH]\}_2$ (**6**–**9**).

Abstract

The reactions of $Mn(CO)_5Br$, $Fe(CO)_5$ and $Co_2(CO)_8$ with $HCl_{(g)}$ in the presence of 15-crown-5 and H_2O in toluene have been explored. These reactions were promoted with the use of UV radiation and formed liquid clathrates almost immediately upon reaction. For each metal species, oxidation of the metal center from either [+1] (for Mn) or [0] (for Fe, Co) to [+2] occurred. For manganese, the Mn^{II} species $[Mn^{II}(H_2O)_2 \cdot 15\text{-crown-5}][Br^-Cl^-]$ (**1**) was obtained from the liquid clathrate layer in the reaction mixture. For iron the Fe^{II} species $[Fe^{II}Cl(H_2O) \cdot 15\text{-crown-5}][H_5O_2^+][Fe^{II}Cl_4^{2-}]$ (**2**) rapidly formed, and for cobalt the Co^{II} species $[Co^{II}(H_2O) \cdot 15\text{-crown-5}]$-$[H_9O_4^+][Co^{II} \cdot 15\text{-crown-5}][H_9O_4^+][Co^{II}(H_2O) \cdot 15\text{-crown-5}][Co^{II}Cl_4^{2-}]_4$ (**3**) was deposited from the liquid clathrate layer. It was established by X-ray crystallography that each species contains a seven-coordinate metal center with pentagonal bipyramidal stereochemistry. Complex **1** is a hydrogen-bonded single-stranded polymer through bridging halide atoms. Complex **2** has a $H_5O_2^+$ oxonium ion hydrogen-bonded to the cations and complex **3** has a remarkable H_2O–Co^{2+}–$H_9O_4^+$–Co_2^+–$H_9O_4^+$–Co_2^+–H_2O cationic chain. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: 15-Crown-5 complexes; Liquid clathrates; X-ray crystallography; Oxonium ion

1. Introduction

We have isolated a number of complexes from liquid clathrate systems in which we are able to stabilize H_3O^+ in aromatic media [1–9]. For this, we use the coordinating power and the lipophilic nature of 18-crown-6. Further, we are able to use these cations to prepare liquid clathrates in which simple transition metal species act as counterions [6–9]. In moving to the smaller crown ethers which are not suitable for the isolation of H_3O^+ because of the limited diameter of the macrocycle, we find interesting results, with 12-crown-4, where a range of oxonium ions $[H^+ \cdot (H_2O)_n]$, $n = 1$, 2 and 3 were isolated, and with 15-crown-5, $H_5O_2^+$ spanned successive crown ethers [10,11]. In these complexes, the oxonium ions, while hydrogen bonded to the crown ethers, were bound to the faces of the crowns and participated with other molecules in the crystal to form a network of hydrogen-bonded ions.

We now present a study of similar systems with 15-crown-5 and the first row transition metals manganese, iron and cobalt. In moving to first row transition metal ions, the metal center can compete with oxonium ions for coordination sites within the crown ether. It has been established that metal complexation by a crown ether can readily occur if the ratio of the metal ion diameter to the crown cavity diameter (R) falls within the range 0.75–0.90 [12]. For first row transition metals, this is readily achieved for 15-crown-5 (diameter 1.7–2.2 Å [13]); however, for 12-crown-4 (diameter 1.2–1.5 Å [13]) and 18-crown-6 (diameter 2.6–3.2 Å [14]), complexation by the crown does not typically occur. X-ray studies have indicated that transition metal ions have a weaker affinity for crown ethers than non-transition metals. Typically the crowns are hydrogen-bonded to metal-coordinated water molecules, rather than being bound directly to the metal ion [15]. Therefore, an investigation for the propensity of the

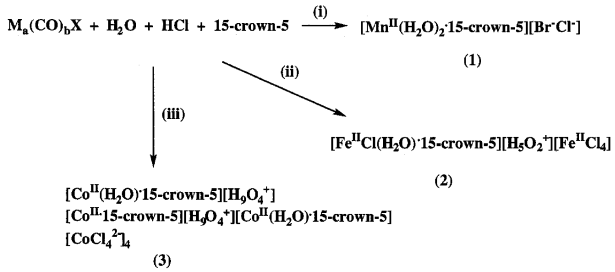
PII S0277-5387(99)00328-9



crown ether to coordinate either the transition metal ions (where the size of the ion is perfectly suited for complexation) or an oxonium species appeared to be warranted.

As part of our study of liquid clathrate systems [16–18], particularly of the $[H_3O^+ \cdot 18\text{-crown-6}]$ ion, we have now investigated the formation of anionic manganese, iron and cobalt complexes of the $[(H_2O)_nH^+ \cdot 15\text{-crown-5}]$ system. Our studies of transition metal complexes existing within liquid clathrate media displays the potential for catalytically active species being formed within these systems.

Herein we report the synthesis and crystal structures of $[Mn^{II}(H_2O)_2 \cdot 15\text{-crown-5}][Br^-Cl^-]$ (**1**), $[Fe^{II}Cl(H_2O) \cdot 15\text{-crown-5}][H_5O_2^+][Fe^{II}Cl_4^{2-}]$ (**2**) and $[Co^{II}(H_2O) \cdot 15\text{-crown-5}][H_9O_4^+][Co^{II} \cdot 15\text{-crown-5}][H_9O_4^+][Co^{II}(H_2O) \cdot 15\text{-crown-5}][Co^{II}Cl_4^{2-}]_4$ (**3**), which were all isolated from aromatic media. All three species display seven-coordinate metal centers with pentagonal bipyramidal geometry. In complex **1**, the hybrid chloride/bromide species was isolated. In complexes **2** and **3**, oxonium ions were evident and were involved in hydrogen-bonding frameworks. Complex **3** contained an $[H_9O_4^+]$ oxonium ion which bridged successive Co^{2+} centers, representing an unusual case where a cation is involved as a ligand on a cationic metal center.

2. Preparation of complexes

Complexes studied in this investigation were synthesized according to the novel reaction conditions presented in Scheme 1. In all reactions the reaction mixture quickly separated into two phases yielding liquid clathrate species. The upper layer in these reactions was neat toluene, while the metal complexes formed were completely dissolved within the clathrate layer. Reactions were performed in contact with air, followed by sealing the reaction vessel from aerial contact. Promotion of CO removal was aided by irradiating the reaction mixtures with UV light. In all reactions oxidation of the metal center occurred, from [+1] to [+2] for **1** and from [0] to [+2] for **2** and **3**. In other reactions where we have performed the experiment in the total exclusion of oxygen, no oxidation of the metal center takes place. Instead, for chromium and tungsten we have formed complexes of the type $[M(CO)_5Cl^-]$ [9].

Scheme 1. Reagents and conditions: (i) M = Mn, $a = 0$, $b = 5$, X = Br, toluene, UV; (ii) M = Fe, $a = 0$, $b = 5$, X = O, toluene, UV; (iii) M = Co, $a = 2$, $b = 8$, X = O, toluene, UV.

In the reactions reported herein we obtained seven-coordinate metal species, where complexation of the metal center by the 15-crown-5 macrocycle took place. In complexes **2** and **3**, the oxonium ions $[H_5O_2^+]$ and $[H_9O_4^+]$ were isolated. In complex **1** where $Mn(CO)_5Br$ was used as the source of metal, the chloride/bromide hybrid was produced. These reactions are similar to those that we have established in forming other oxonium ion-crown ether complexes of transition metals [6–9].

Reaction conditions throughout were optimized to yield liquid clathrates and X-ray-quality crystals. To identify the species present in the liquid clathrate layers, all the compounds investigated were structurally authenticated using X-ray crystallography. The complexes were obtained in moderate yields, and no attempts were made to maximize the yields.

3. Structural results

Details for the diffraction experiments are given in Section 5 and Table 1. Selected bond distances and angles for complexes **1**–**3** are shown in Tables 2–4.

3.1. $[Mn^{II}(H_2O)_2 \cdot 15\text{-crown-5}][Br^-Cl^-]$ (1)

This complex does not crystallize as discrete anions and cations, but rather as one-dimensional polymeric strands held together by hydrogen bonding where the $[Mn^{II}(H_2O)_2 \cdot 15\text{-crown-5}]$ cations hydrogen-bond through the terminal water molecules to Br^- and Cl^- (Fig. 1).

The cation resides on a two-fold axis (through Mn and O(1)) and exists as a distorted pentagonal bipyramidal structure. The Mn center is bound to five equatorial crown oxygen atoms and two axial water molecules. The Mn–Wat length is

3.2. $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5][H_5O_2^+][Fe^{II}Cl_4^{2-}]$ (**2**)

In this complex the $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5]$ cations and the $[Fe^{II}Cl_4^{2-}]$ anions are held together in a hydrogen-bonded network through the $[H_5O_2^+]$ ions (see Fig. 2).

In the $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5^+]$ cation, the geometry around the Fe center is a distorted pentagonal bipyramid, bound to five equatorial crown oxygen atoms and a water and chloride ligand in the axial positions. The bonding parameters around the Fe(2) center are (Å): Fe(2)–Cl(5), 2.472(5) Å; Fe(2)–Wat, 2.15(1) Å; and Fe(2)–O(crown), average = 2.21(3). The Cl(5)–Fe(2)–Wat angle is 175.2(4)°, while the Wat–Fe(2)–O(crown) and Cl(5)–Fe(2)–O(crown) angles are in the range 81.5(5)–93.7(6)° and 86.1(4)–98.0(3)° respectively, and reflect the distortion from a regular pentagonal bipyramid. The O(crown)–Fe(2)–O(crown) angles of 71.4(5)–73.1(5)° and 141.8(5)–144.8(5)° are typical of this stereochemistry. The Fe^{II} center resides 0.08 Å out of the plane generated by the crown oxygen atoms.

The $[H_5O_2^+]$ oxonium ions form a hydrogen-bonded array with the $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5^+]$ cations and $[FeCl_4^{2-}]$ anions, where the oxonium ions bridge the Cl(5) ligands of the cation with the Cl(1) and Cl(4) ligands of the anion. These distances of Oa···Cl(1) 3.130, Oa···Cl(4) 3.152 and Ob···Cl(5) 3.023 and 3.024 Å are within the accepted limits for this type of hydrogen bonding [19]. The Oa···Ob distance of 2.337 Å is relatively short for this type of ion, and indicates a strong hydrogen bond [20]. Typical O···O distances of 2.41–2.45 Å are found in $[H_5O_2^+]$ oxonium ions [21].

The $[FeCl_4^{2-}]$ anions exhibit a typical tetrahedral array.

3.3. $[Co^{II}(H_2O)\cdot 15\text{-crown-}5][H_9O_4^+][Co^{II}\cdot 15\text{-crown-}5][H_9O_4^+][Co^{II}(H_2O)\cdot 15\text{-crown-}5][Co^{II}Cl_4^{2-}]_4$ (**3**)

In this complex two $[Co^{II}(H_2O)\cdot 15\text{-crown-}5]$ cations are bridged through $[H_9O_4^+]$ ions to a central $[Co^{II}\cdot 15\text{-crown-}5]$ ion. The bridging $[H_9O_4^+]$ ions coordinate the terminal $[Co^{II}(H_2O)\cdot 15\text{-crown-}5]$ ions through the Co centers (see Fig. 3). $[Co^{II}Cl_4^{2-}]$ counterions, which exhibit the typical tetrahedral array, balance the charge of the compound.

In the structure of the cations, the central $[Co^{2+}\cdot 15\text{-crown-}5]$ ion resides on a center of inversion. The crown is 50:50 disordered, which is a requirement for the molecule to reside on a center of inversion. The three Co^{2+} centers have pentagonal bipyramidal stereochemistry. The remarkable feature of this structure is the Co^{2+} being spanned by cationic $H_9O_4^+$. For the two terminal Co atoms there is a water molecule and an oxygen of the $H_9O_4^+$ in axial positions and five oxygen atoms from the ring in equatorial positions. The central Co atom also has five equatorial oxygen atoms, but has an oxygen of the $H_9O_4^+$ in each axial position. The two

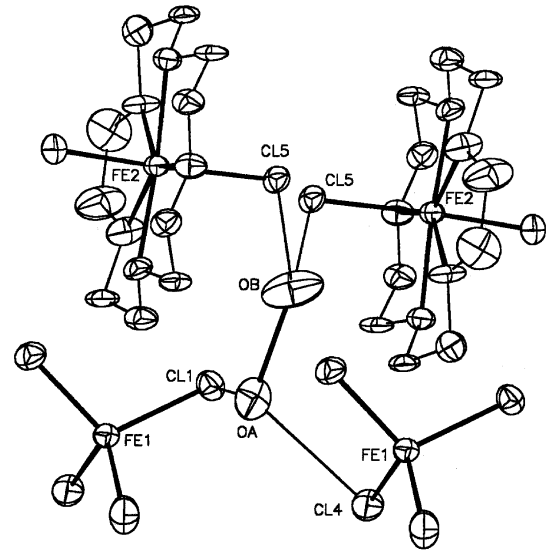

Fig. 2. Arrangement of the anions and cations in $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5][H_5O_2^+][Fe^{II}Cl_4^{2-}]$ (**2**), showing the hydrogen bonding between the $[H_5O_2^+]$ ion and the $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-}5]$ cations and $[Fe^{II}Cl_4^{2-}]$ anions. Bonding distances (Å): Fe(2)–Cl(5), 2.472(5); Fe(2)–Wat, 2.15(1); average Fe(2)–O(crown), 2.21(3).

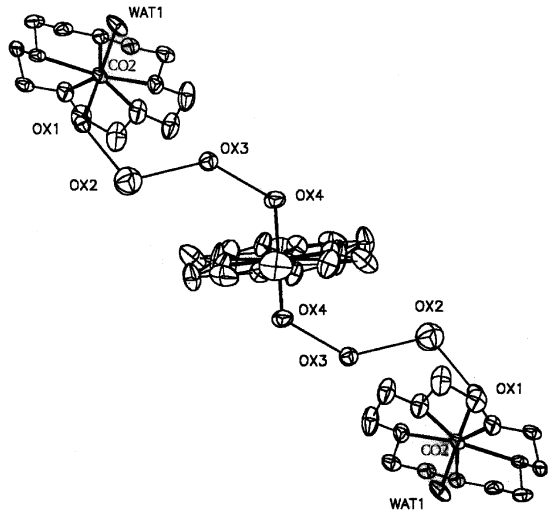

Fig. 3. Structure of the $[Co^{II}(H_2O)\cdot 15\text{-crown-}5][H_9O_4^+][Co^{II}\cdot 15\text{-crown-}5][H_9O_4^+][Co^{II}(H_2O)\cdot 15\text{-crown-}5]$ oligomeric cationic strand in **3**. Bonding distances (Å): Co(2)–Ox(1), 2.06(1); Ox(1)···Ox(2), 2.573; Ox(2)···Ox(3), 3.036; Ox(3)···Ox(4), 2.585; Co(1)–Ox(4), 2.06(1).

$H_9O_4^+$ oxonium ions link together the three cobalt containing 15-crown-5 molecules in a polycationic strand terminated by water molecules. The average Co–O(crown) distances are 2.20(4) Å. The Co–Ox distances are both 2.06(1) Å, the Ox(2)···Ox(3) distance is 3.036 Å and the Ox(1)···Ox(2) and Ox(3)···Ox(4) distances are 2.573 and 2.585 Å. Further intermolecular Cl···H–O hydrogen-bondings between the $[CoCl_4^{2-}]$ anions and the oxonium ions and the terminal H_2O molecule are evident (Cl···O distances 3.067–3.483 Å). These intermolecular hydrogen-bonding contacts terminate the oligomeric cationic strand. The Co^{II} center resides 0.01 Å out of the plane defined by the crown oxygen atoms.

4. Discussion

The preparation of the complexes herein is a novel approach: a metal in its [0] or [+1] oxidation state is treated with HCl gas under UV radiation. The products isolated are of lowest energy which self-assemble from the liquid clathrate medium. We have shown in other publications that this self-assembly is a rather general approach for similar oxonium ion/crown ether complexes of transition metal coordination compounds [6–9].

In all other preparations of transition metal complexes we have utilized metal [0] carbonyls as starting materials. In the case of the manganese complex we used $Mn(CO)_5Br$ to ascertain the generality of this type of reaction. To our surprise, the product obtained was the chloride/bromide hybrid species (**1**). In this reaction, there must be sufficient quantities of HBr produced to remain in solution for further reaction. When we performed the analogous reaction in the presence of 18-crown-6, we isolated the known complex $[H_3O^+\cdot 18\text{-crown-}6]_2[MnCl_4^{2-}]$ [22,23].

For complexes **2** and **3**, oxonium ions were isolated, which formed hydrogen-bonded networks throughout the structure (see below).

In the three complexes discussed, complexation by 15-crown-5 occurred, forming seven-coordinate pentagonal bipyramidal structures. For Mn^{II}, Fe^{II} and Co^{II}, values of *R* (the ratio of the metal ion diameter to the crown cavity diameter) are 0.61–0.78, 0.71–0.92 and 0.68–0.88, respectively. Complexation of the metal by a crown ether can readily occur if *R* falls within the range 0.75–0.90 [9]. In all three cases the metal center resides between 0.01 and 0.13 Å out of the plane of the crown oxygen atoms, and thus snugly fits within the macrocycle. When we perform the analogous reactions in the presence of 18-crown-6 instead of 15-crown-5 the $[H_3O^+\cdot 18\text{-crown-}6]$ complexes of $[MnCl_4^{2-}]$, $[FeCl_4^-]$ and $[CoCl_4^{2-}]$ are isolated [6–8,22]. For 18-crown-6 (diameter 2.6–3.2 Å [14]), *R* values of 0.42–0.51, 0.49–0.60 and 0.47–0.57 are obtained for Mn, Fe and Co, and therefore complexation by the crown does not occur. In contrast to reports that transition metal ions have a weaker affinity for crown ethers than non-transition metals [15], we have shown that, for 15-crown-5, complexation is readily achieved. In all three cases, the crown has a greater tendency to complex the transition metal than to coordinate oxonium ions, as in 18-crown-6 and 12-crown-4 complexes (but also 15-crown-5 where the metal does not 'fit' the crown) [6–11].

There are several reports of seven-coordinate pentagonal bipyramidal stereochemistry for manganese(II) [24,25]. In these, the seven-coordinate Mn^{II} complex $[Mn(HL)(OH_2)_2Cl]Cl\cdot H_2O$ [L = 2,6-diacetylpyridine-mono-(2-aminobenzoylhydrazone)] was characterized by X-ray crystallography [24]. In another, $(MnBr_2)_2$(benzo-15-crown-5)·3/2acetone·H_2O was characterized spectroscopically [25]. The data were consistent with either (1) the Mn^{II} center having eight-coordination comprising five ether oxygens, one oxygen from acetone and two bridging halogens to a second tetrahedrally bound transition metal ion, or (2) the metal having pentagonal bipyramidal geometry in the cation and tetrahedral geometry in the anion. While we obtained neither of these two types of species in **1**, by analogy with complexes **2** and **3** the structure of $(MnBr_2)_2$(benzo-15-crown-5)·3/2acetone·H_2O is most likely that described in (2).

The hydrogen bonding displayed in complex **1**, where the halide ions are bridging successive $[Mn^{II}(H_2O)_2\cdot 15\text{-crown-}5]$ ions and have O···Hal separations of 3.16 Å, this length is slightly longer than typical O–H···Cl separations of 3.10 Å and shorter than expected O–H···Br distances [19]. These distances support the hybrid model found in the X-ray crystallography. Although the protons on the water molecules were not found, the Hal–O–Hal angle of 99.4° suggests that the O–H···Hal linkage is close to linear.

The seven-coordinate pentagonal bipyramidal structure of iron(II) is known in $[Fe(L')(OH_2)_2][BF_4]_2$ (the structure of L′ is shown in Fig. 4) where there are five equatorial

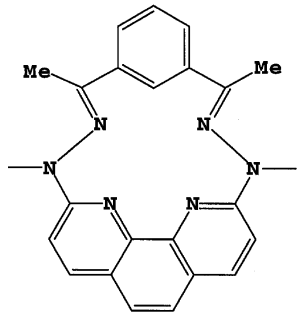

Fig. 4. The structure of L′.

nitrogen atoms and two axial water molecules [26]. The structure we obtained is similar to that postulated using spectroscopic evidence for Mn, Co and Ni complexes of benzo-15-crown-5 [25] except that we isolated a complex with an axial H_2O and Cl^- ligands with a bridging $H_5O_2^+$ molecule between the cations and anions.

The O···Cl distances of 3.01–3.15 Å between the chloride ligands and the $[H_5O_2^+]$ ion in **2** are typical. The O···O separation in the $[H_5O_2^+]$ ion (2.337 Å) is rather short and suggests a strongly hydrogen-bonded oxonium ion [20]. Emsley has stated that a hydrogen bond of >0.3 Å less than the sum of the van der Waals radii of the two elements is classified as a strong hydrogen bond [20]. In this case the O···O separation is some 0.46 Å less than the sum of the van der Waals radii for oxygen [27]. Typical O···O separations in $[H_5O_2^+]$ ions is 2.40–2.45 Å [21].

The seven-coordinate pentagonal bipyramidal stereochemistry for cobalt is not uncommon [14,28]. Compound **3** is closely related to $[Co^{2+}(H_2O)_2\cdot 15\text{-crown-5}][NO_3^-]_2$ [14]. The outstanding difference between the two structures is that, for the NO_3^- species, the nitrate anion is hydrogen-bonded to the axial water molecule, whereas in the present case the axial H_2O molecules are hydrogen-bonded to a positively charged cation, H_3O^+, with further water molecules generating the oligomeric cationic strand of $H_9O_4^+$ and Co^{2+}.

In the linear-chain $[H_9O_4^+]$ ions in compound **3**, the Ox(2)···Ox(3) distance of 3.036 Å precludes the $[H_9O_4^+]$ structure from being considered as an $H_5O_2^+$ ion with terminal H_2O molecules as in the case of $[(H_5O_2^+)(H_9O_4^+)(\text{benzo-15-crown-5})_2][UOCl_4]$ [29]. Typical O···O separations in $H_5O_2^+$ range from 2.40 to 2.45 Å. The Ox(1)···Ox(2) and Ox(3)···Ox(4) distances of 2.573 and 2.585 Å are surprisingly short, being bound to the positive Co^{2+} center. In the uranium complex above the corresponding distances are 2.60 and 2.66 Å [29].

It is interesting to note that, while cationic ligands for metal complexes have been sought for many years, self-assembly of single components in the present system have succeeded where designed systems have often failed [30–33].

5. Experimental

$Mn(CO)_5Br$ and $Fe(CO)_5$ were obtained from Aldrich Chemical Co., $Co_2(CO)_8$ from Alfa and HCl gas was purchased from Atlas Co. Complexes **1**–**3** were prepared exposed to air, prior to the reaction mixture being sealed in an air-tight screw-top tube. In all cases, yields were moderate ($\sim$70–80%), but reactions were conducted to obtain X-ray-quality crystals, so no attempts were made to optimize yields. Attempts at obtaining microanalytical data were thwarted by solvent loss, so are not reported.

*5.1. Preparation of $[Mn^{II}(H_2O)_2\cdot 15\text{-crown-5}][Br^-Cl^-]$ (**1**)*

To a sample of 15-crown-5 (1.00 g, 4.50 mmol) in toluene, was added H_2O (0.08 g, 4.50 mmol) and $Mn(CO)_5Br$ (1.24 g, 4.50 mmol) and stirred rapidly for 15 min. $HCl_{(g)}$ was then rapidly bubbled through the mixture for approx. 1 h while irradiating with UV radiation. A colorless liquid clathrate separated from the solvent during the addition of $HCl_{(g)}$. Colorless crystals of the title complex deposited from the liquid clathrate layer after approx. 24 h.

*5.2. Preparation of $[Fe^{II}Cl(H_2O)\cdot 15\text{-crown-5}][H_5O_2^+]$-$[Fe^{II}Cl_4^{2-}]$ (**2**)*

To a sample of 15-crown-5 (0.80 g, 3.62 mmol) in toluene, was added H_2O (0.065 g, 3.62 mmol) and $Fe(CO)_5$ (0.71 g, 3.62 mmol) and stirred rapidly for 15 min. $HCl_{(g)}$ was then rapidly bubbled through the mixture for approx. 1 h while irradiating with UV radiation. During this time a colorless liquid clathrate separated from the toluene layer. Colorless crystals of the title complex deposited from the liquid clathrate layer after approx. 30 h.

*5.3. Preparation of $[Co^{II}(H_2O)\cdot 15\text{-crown-5}][H_9O_4^+]$-$[Co^{II}\cdot 15\text{-crown-5}][H_9O_4^+][Co^{II}(H_2O)\cdot 15\text{-crown-5}]$-$[Co^{II}Cl_4^{2-}]_4$ (**3**)*

A sample of 15-crown-5 (0.80 g, 3.62 mmol) was moistened with distilled water (0.065 ml, 3.62 mmol) and approx. 100 ml of toluene added. $Co_2(CO)_8$ (1.24 g, 3.62 mmol) was then added and $HCl_{(g)}$ was rapidly bubbled through the mixture for approx. 1 h while irradiating with UV light. After this time, a bright blue liquid clathrate separated from the solvent. Bright blue crystals of the title complex deposited from the clathrate layer after approx. 24 h.

5.4. Collection of X-ray diffraction data, and solution and refinement of the structures

Single crystals of **1**, **2** and **3** were sealed in thin-walled glass capillaries under an atmosphere of toluene. Final lattice parameters as determined from the least-squares refinement of the angular settings of 24 high-angle reflections ($2\theta > 30°$) accurately centered on an Enraf-Nonius CAD4 diffractometer are given in Table 1. A summary of data collection parameters is also given in Table 1. An empirical absorption correction based on psi scan data was performed. Calculations were

carried out using the SHELX system of computer programs [34].

Positions of heavy atoms were determined from a three-dimensional Patterson function. All other non-hydrogen atoms were located from a difference-Fourier synthesis. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms on the water molecules and oxonium ions in **1**, **2** and **3** were not located on the difference map. All other hydrogen atoms were placed at calculated positions and their parameters were not refined. The halides in compound **1** were disordered over two sites. The structure was successfully refined with each halide site being occupied by 50% Br^- and 50% Cl^-. In compound **2**, there was high thermal motion in C(8), C(9), O(a) and O(b), but the model refined successfully. In compound **3** the 15-crown-5 molecule on the central Co^{2+} was 50:50 disordered over two sites, and Ox(3) and one of the $CoCl_4^{2-}$ were also disordered. They were refined successfully. Refinements converged with $R = 0.062$ for 922 observed reflections for **1**, $R = 0.083$ for 1733 observed reflections for **2**, and $R = 0.072$ for 2629 observed reflections for **3**.

Supplementary data

Crystallographic data for the structures have been deposited with the Cambridge Crystallographic Data Centre (CCDC deposition numbers CCDC 132777, CCDC 132778, CCDC 132779). Copies of the data can be obtained upon request from CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, quoting the deposition numbers.

POLYHEDRON

Synthesis, crystal structure and magnetic properties of novel dinuclear complexes of manganese, cobalt and nickel with 4-acetylbispyrazolone

Luqin Yang *, Wenzheng Jin [1], Jianhua Lin

State Key Laboratory of Rare Earth Materials Chemistry and Applications, College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, PR China

Received 24 June 1999; accepted 28 October 1999

Abstract

Five novel transition metal complexes, $MnL \cdot 2C_2H_5OH \cdot 3H_2O$ (**1**), $MnL \cdot 2.5DMF \cdot 0.5H_2O$ (**2**), $Co(HL)(NO_3) \cdot C_2H_5OH$ (**3**), $CoL \cdot 2.5H_2O$ (**4**), and $NiL \cdot C_2H_5OH \cdot 2H_2O$ (**5**), have been synthesized and characterized. H_2L represents bis(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,5-pentanedione (L^{2-} and HL^- are the deprotonated forms of H_2L). Spectroscopic data reveal that the title complexes are dimers. The tetraketone ligand L coordinates to the metal ions through two β-diketonates. The β-diketonate is mainly in the delocalized enol form. The enol-keto form β-diketone (HL^-, one β-diketone remains in keto form and the other is in deprotonated enol form) also exists in the Co complex **3**. The crystal structure of $MnL \cdot 2.5DMF \cdot 0.5H_2O$ (**2**) was determined by X-ray diffraction. The ligand L is in a bridging mode connecting two metal ions. Mn^{2+} is six-coordinated with a distorted octahedral coordination sphere. A variable temperature magnetic susceptibility investigation showed that a weak antiferromagnetic exchange interaction exists between the metal centers in the complexes. The $2J$ values based on $\boldsymbol{H} = -2J/\boldsymbol{S}_1\boldsymbol{S}_2$ are -0.71 cm^{-1} (Mn1), -1.96 cm^{-1} (Co2), -1.74 cm^{-1} (Co3), and -2.02 cm^{-1} (Ni).

1. Introduction

Molecular based materials are a promising frontier research field in both chemistry and materials science [1–3], and has attracted great interest recently. Metal complexes play an important role in the design and synthesis of molecular materials [4]. Some β-diketonate manganese complexes show extraordinary structures and interesting magnetic properties [5]. Owing to their effective properties with respect to extracting metal ions, β-diketone compounds have attracted most interest in recent decades. They can also be used in laser materials, proton NMR shift reagents, MOCVD, the petroleum industry, and analytical chemistry [6–10]. There are only a few reports on poly-β-diketone complexes [11]. 4-Acetyl-bipyrazolone is a new type of chelating ligand which contains two β-diketones. It is more efficient than 4-acetyl-pyrazolone derivatives in extracting hard Lewis acid metal ions [12] and can form different types of coordination compounds owing to the use of four donor sites in its molecule. The rare earth complexes of bispyrazolone show very strong fluorescence [13–18] and some also have antitumor activity in vitro, and high herbicidal activities. Based on the structure of the tetraketone, it should be efficient in forming multinuclear complexes. In order to investigate the magnetic and fluorescence properties of multinuclear complexes, we synthesized a series of multinuclear transition metal and rare earth complexes. To our knowledge, no crystal structures of bispyrazolone transition metal complexes have been reported in the literature. Recently we obtained the single structure of a manganese complex. This paper reports the crystal structure of the novel manganese complex with 1,5-bis(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,5-pentanedione. The magnetic properties of complexes Mn(II), Co(II), Ni(II) were also studied.

2. Experimental

2.1. Materials and measurements

1,5-bis(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,5-pentanedione (H_2L) was synthesized according to the method

described in the literature [19]. $Ni(ClO_4)_2 \cdot 6H_2O$ was prepared by our laboratory. The other reagents used for synthetic experiments were of analytical grade available commercially without further purification.

Elemental analyses were carried out on a Perkin-Elmer 240 analyzer. FAB-MS was carried out on a HS-ZAB spectrometer. TG and DTA were carried out on a LCT-1 thermoanalyzer. FT-IR spectra were carried out on a magna 750 IR spectrometer. Solid state reflection UV–Vis spectra were recorded on a Shimadzu UV-3100 spectrophotometer. Variable temperature magnetic susceptibilities were measured on an extracting sample magnetometer CF-1. Di-magnetic corrections were made using Pascal's constants. Effective magnetic moments of complexes were calculated with $\mu_{eff} = 2.828(\chi T)^{1/2}$.

2.2. Preparation of complexes

$MnL \cdot 2C_2H_5OH \cdot 3H_2O$ (**1**). An ethanolic solution containing 1 mmol $MnAc_2 \cdot 4H_2O$ was added to the ethanolic solution containing 1 mmol H_2L with magnetic stirring. The resulting solution was refluxed for 20–25 h. Then the fine crystalline precipitate was collected and washed with ethanol, dried in vacuo at room temperature. The yield of complex was above 85%. The product was obtained as a light pink solid. Found: C, 54.52; H, 5.72; N, 8.55. Calc. for $C_{29}H_{40}N_4O_9Mn$: C, 54.12; H, 6.22; N, 8.71%. IR (KBr, cm^{-1}): 1614 (vs, ν(C=O)), 1531 (w, ν(C=C)), 1489 (vs, ν(C=O)). Thermogravity (TG): 82°C, loss weight 16.2% (calc. for $2C_2H_5OH$, 17.1%, endothermic); 82–268°C, loss weight 8.2% (calc. for $3H_2O$, 8.4%, endothermic). Molar conductivity Λ_M(DMF) = 5.8 S cm^2 mol^{-1}. UV–Vis: 336 nm.

$CoHL(NO_3) \cdot C_2H_5OH$ (**3**). This pink crystalline solid product was obtained following a similar procedure as described for compound **1** by replacing $MnAc_2 \cdot 4H_2O$ with $Co(NO_3)_2 \cdot 6H_2O$. Found: C, 53.11; H, 4.90; N, 11.30. Calc. for $C_{27}H_{29}N_5O_8Co$: C, 53.12; H, 4.75; N, 11.48%. IR(KBr, cm^{-1}): 1661, 1642 (s, ν(C=O)), 1621 (vs, ν(C=O)), 1501 (vs, ν(C=O)). TG: 62–149°C, loss weight 7.2% (calc. for C_2H_5OH, 7.5%, endothermic); 255°C, loss weight 9.8% (calc. for HNO_3, 10.0%, exothermal). Λ_M(DMF) = 75 S cm^2 mol^{-1}.

$CoL \cdot 2.5H_2O$ (**4**). 2 mmol NaOH aqueous solution (0.6 mol^{-1}) was added to an ethanolic solution containing 1 mmol H_2L with stirring. A light yellow–orange solution was obtained (pH 5–6). Then an ethanolic solution containing 1 mmol $CoCl_2 \cdot 6H_2O$ was added to the above solution under magnetic stirring. Stirring was continued at room temperature for about 10 h. The precipitate was collected and washed thoroughly with ethanol, water, ethanol, respectively, then dried in vacuo over P_2O_5 at room temperature. The product was obtained as a pink solid. The yield was above 85%. Found: C, 55.39; H, 4.65; N, 10.49. Calc. for $C_{25}H_{27}N_4O_{6.5}Co$: C, 54.94; H, 4.95; N, 10.26%. IR (KBr, cm^{-1}): 1611 (vs, ν(C=O)), 1530 (w, ν(C=C)), 1494 (vs, ν(C=O)). TG: 74°C, loss weight 8.4% (calc. for $2.5H_2O$, 8.2%, endothermic). UV–Vis: 340, 562, 1164, 1374 nm.

$NiL \cdot C_2H_5OH \cdot 2H_2O$ (**5**). The light green solid product was obtained following a similar procedure as described for compound **1** by replacing $MnAc_2 \cdot 4H_2O$ with $Ni(ClO_4)_2 \cdot 6H_2O$. Found: C, 55.34; H, 5.43; N, 9.21. Calc. for $C_{27}H_{32}N_4O_7Ni$: C, 55.60; H, 5.49; N, 9.61%. IR (KBr, cm^{-1}): 1616 (vs, ν(C=O)), 1534 (w, ν(C=C)), 1504, 1494 (vs, ν(C=O)). Λ_M(DMF) = 4.2 S cm^2 mol^{-1}. FAB-MS (M/e): 1002 [Ni_2L_2, M^+], 562 [Ni_2L, M − 2], 502 [NiL, M + 1]. UV–Vis: 327, 661, 723, 1122 nm.

2.3. Preparation, X-ray data collection, structure determination and refinement of a single crystal of $Mn_2L_2 \cdot 5DMF \cdot H_2O$ (2)

The colorless single crystals of $Mn_2L_2 \cdot 5DMF \cdot H_2O$ (**2**) were obtained by slowly evaporating the DMF solution of complex **1** at ambient temperature for over 2 months. They lost the solvent molecules easily in air.

A single crystal of $C_{32.5}H_{40.5}MnN_{6.5}O_7$ with dimensions $0.05 \times 0.15 \times 0.30$ mm was mounted on an Enraf-Nonius CAD-4 X-ray diffractometer. The data were measured using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) in the θ range 4.5–23° with an ω–2θ scan mode. Accurate cell parameters were obtained from a least squares fit of the setting angles of 25 reflections with θ range 8.93–12.74° at 299 ± 1 K. The data collection gave 5237 reflections from which 4787 were independent ($R_{int} = 0.058$). 1824 reflections were considered to be observed ($I \geq 2\sigma(I)$) and were used in the following refinement. A correction for Lorentz polarization effects was applied to the data.

Crystals are triclinic, space group $P\bar{1}$, with a = 10.773(5), b = 13.397(5), c = 14.811(3) Å, α = 65.04(3), β = 70.93(3), γ = 80.54(3)°, V = 1831(1) Å^3, M_r = 689.18, Z = 2, D_x = 1.254 g cm^{-3}, μ = 3.946 cm^{-1}.

The structure was solved with direct methods. The positions of two manganese ions were located on an E-map. All the other non-hydrogen atoms were determined from the successive difference Fourier synthesis.

The entire structure was refined by the full-matrix least-squares technique with anisotropic thermal parameters for all of the non-hydrogen atoms, except for the uncoordinated solvent molecules for which the isotropic thermal parameters were used. The agreement factors were $R = \sum||F_o| - |F_c||/\sum|F_o| = 0.067$ and $wR = [\sum w(||F_o|^2 - |F_c|^2|/\sum|F_o|^2)]^{1/2} = 0.072$ (unit weights for all observed reflections).

3. Results and discussion

3.1. Constituent and general properties

The composition of the complexes was determined by elemental analyses, FT-IR and TG analysis. The molar ratio M:L in all the complexes is 1:1. The tetraketone ligand H_2L

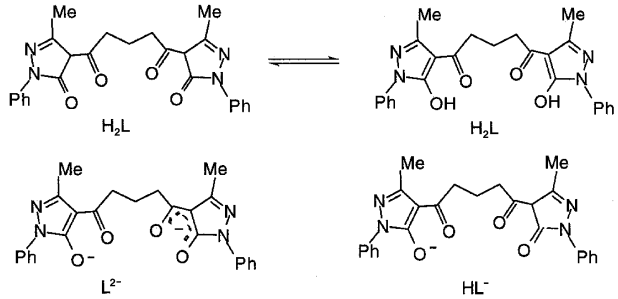

Fig. 1. Structures of of H_2L, HL^- and L^{2-} (one tautomer of each).

is coordinated to the metal ions as HL^- in complex **3** and as L^{2-} in the other complexes (Fig. 1).

All the complexes are insoluble in water or ethanol, but dissolve in DMF or DMSO. The molar conductivity of complexes in DMF shows that complex **3** is a 1:1 electrolyte and the others are non-electrolytes [20].

Thermal analyses (TG and DTA) of the complexes indicate that they lose the solvent molecules below 150°C with an endothermic peak in DTA. When the temperature is above 280°C, the complexes are decomposed into metal oxides with strong exothermic DTA peaks.

The FAB-mass spectrum of the nickel complex was also recorded. In the FAB-mass spectrum of the nickel complex (DMF), the largest mass number 1002 can be assigned to a Ni_2L_2 (M^+) fragment, 562 to Ni_2L $(M-2)^+$, and 502 to NiL $(M+1)^+$. All these fragments indicate that the complex is a dimer. The zinc complex appears also to be a dimer from FAB-MS and this is verified by its crystal structure [21]. TG analysis and IR spectra of the complexes confirmed the existence of some coordinated solvent molecules. The liquid–liquid extraction of copper ion with bipyrazolone has two extracts: 1:2 and 2:2 (metal ion/ligand molar ratio). The 2:2 extract is a dimer [22]. For the 1:2 ratio it is easy to form a coordination polymer, and the solid copper(II) [21] and VO(II) (not published) complexes have this kind of structure. Given their similar solubilities, the structures of Mn(II), Co(II) and Ni(II) complexes may be analogous. The primary molecular structures of Co(II) and Ni(II) are similar to that of $Mn_2L_2 \cdot 5DMF \cdot H_2O$.

The solid state reflection UV–Vis spectra of the complexes were recorded. d–d-Transitions are observed in Co, Ni complexes: 562, 1164, 1374 nm for **4** and 661, 723, 1122 nm for **5** The absorption around 320–360 nm in Mn, Co, Ni can be attributed to the L–L* transition of coordinated ligand.

3.2. Crystal structure

A perspective view of complex **2** is shown in Fig. 2. Selected bond distances and bond angles are listed in Table 1.

In the molecule $Mn_2L_2 \cdot 5DMF \cdot H_2O$, L behaves as a tetradentate ligand, acting as a bis-bidentate ligand. The ligand L is a bridge connecting the two manganese ions with its two β-diketone groups. The complex is binuclear and each manganese ion is six-coordinated. The six-coordination oxygen atoms come from two tetraketone ligands L (O1, O2, O3a, O4a) and two dimethylformamide molecules (O41, O51). The bond distance Mn–O ranges from 2.123 (Mn–O2) to 2.178 Å (Mn–O51) (mean Mn–O 2.143 Å). The coordination polyhedron of the manganese ion is a distorted octahedron (Fig. 3). The dihedral angle between plane 1 (O1, O4, O3, O41) and plane 2 (O1, O2, O3′, O51) is 89.36°; the angle between plane 1 and plane 3 (O2, O4′, O41, O51) is 89.62°; the angle between plane 2 and plane 3 is 86.43°; the angle between plane 4 (O1, O2, O4′) and plane 10 (O3′, O41, O51) is 12.71°; the angle between plane 5 (O1, O2, O41) and plane 11 (O3′, O4′, O51) is 168.34°; the angle between plane 6 (O1, O41, O51) and plane 8 (O2, O3′, O4′) is 15.19°; the angle between plane 7 (O1, O4, O51) and plane 9 (O2, O3′, O41) is 5.56°.

β-Diketones in the ligand H_2L are all in the deprotonated form (L^{2-}). From the bond distances C=O (O1–C17, 1.266; O2–C1, 1.26; O3–C5, 1.21; O4–C27, 1.25 Å) and the connecting C–C distances (C1–C2, 1.56; C1–C18, 1.39; C17–C18, 1.45; C4–C5, 1.53; C5–C28, 1.44; C27–C28, 1.45 Å) it can be deduced that the β-diketones are in delocalized form.

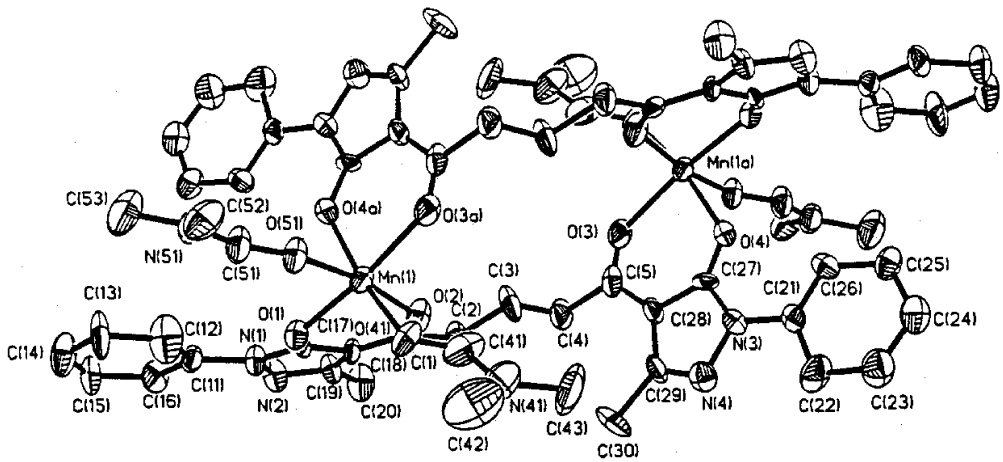

Fig. 2. Molecular structure of $Mn_2L_2 \cdot 5DMF \cdot H_2O$.

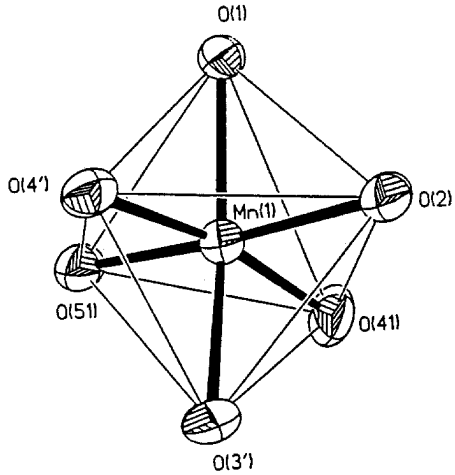

Fig. 3. Coordination geometry of manganese in $Mn_2L_2 \cdot 5DMF \cdot H_2O$.

The resonance structure of the β-diketonate is similar to that in the diterbium complex [23,24] (in forms I or IV, Fig. 4). The benzene ring and the connected pyrazolone ring are approximately coplanar. The dihedral angles between them are 7.23° (plane 12 (C11–C16) and plane 13 (N1–N2, C17–C19)) and 3.27° (plane 14 (C21–C26) and plane 15 (N3–N4, C27–C29)). C20, C1 and O1 are in the connected pyrazolone plane 13 with the maximum deviation −0.12 Å (O1). C30, C5 and O4 are in plane 15 with the maximum deviation −0.074 Å (C5). The dihedral angles between planes 12 and 14, planes 12 and 15, and planes 13 and 15 are 90.56, 91.65 and 98.86°, respectively. The two benzene planes in ligand L^{2-} are almost perpendicular.

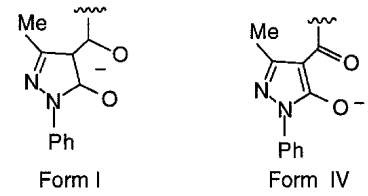

Fig. 4. The resonance structures of the β-diketonates in $Mn_2L_2 \cdot 5DMF \cdot H_2O$.

There are some changes in bond distances and angles when DMF is coordinated to manganese ions (Table 1). The uncoordinated DMF and water are distributed through the crystal lattice. There is a tetragonal hole in the molecule of the manganese complex.

3.3. FT-IR spectra

The complexes have similar IR spectra which differ from that of H_2L. In the FT-IR spectra of the complexes, the absorption assigned to $\nu(Ac^-)$ or $\nu(ClO_4^-)$ does not appear in the spectra of the manganese and nickel complexes. The ligand H_2L must coordinate to metal ions with the deprotonated enol form L^{2-}. The appearance of $\nu(NO_3^-)$ (at 1380 cm^{-1}, typical ionic NO_3^- absorption) in the cobalt complex **3** is indicative of the mono deprotonated HL^-. The molar conductivity and elemental analysis of complex **3** are in accordance with this observation. The IR spectra verify the formation of the complexes [25].

The stretching vibrations of C=O shift to lower frequencies in the complexes (1611–1616 and 1480–1504 cm^{-1}), compared to the free ligand H_2L which shows peaks at 1621, 1562, 1500 cm^{-1}. This indicates the carbonyl groups of ligand L coordinate directly to metal ions. The peaks at 1661, 1642 cm^{-1} in the cobalt complex **3** can be assigned to the keto form $\nu(C{=}O)$ of HL^-. Both enol and keto β-diketones exist in complex **3**. The weak absorption around 1532 cm^{-1} in all complexes is assigned to $\nu(C{\cdots}C)$, which comes from delocalized β-diketonate. This assignment is verified by FT-Raman spectra of a similar zinc complex. This vibration shows a very strong peak in Raman spectra. The result is in accordance with the delocalized diketone form of ligands in the complexes.

The weak sharp peak at 3605–3625 cm^{-1} in Ni and Co (**4**) complexes reveals the existence of crystalline water in these complexes. The broad, strong absorption around 3400 cm^{-1} in all the complexes is assigned to the stretching OH vibration of water and ethanol molecules. There is a weak

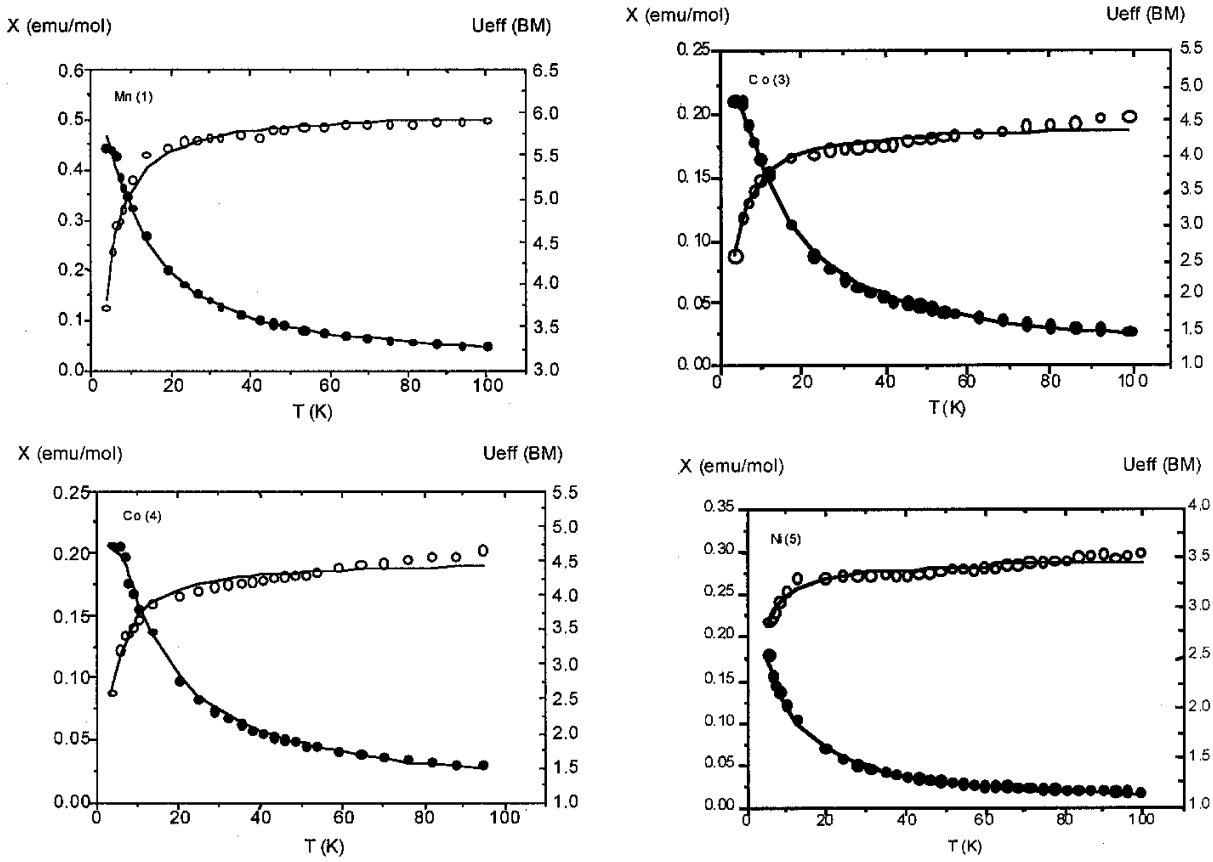

Fig. 5. Temperature dependence of magnetic susceptibility (χ–T) and moment (μ_{eff}–T) per molar metal ion for complexes (the symbols represent experimental values, the curves are fitted lines).

shoulder peak around 1630 cm^{-1} in complexes **1**, **4** and **5**, which can be assigned to the δHOH of water [26].

3.4. Magnetic properties

Variable temperature dependent magnetic susceptibilities of complexes were measured in the range 2–100 K. Fig. 5 shows the temperature dependent magnetic susceptibilities and the effective magnetic moments of the complexes.

The magnetic moments of binuclear complexes decrease smoothly above 20 K on decreasing the temperature. The changes become more rapid at lower temperature. The data of effective magnetic moments indicate some antiferromagnetic interaction exists in the complexes.

The susceptibility data of complexes are fitted with the binuclear magnetic equations [27–29] deduced from the Hamiltonian $\boldsymbol{H} = -2J\boldsymbol{S}_1\boldsymbol{S}_2$.

Table 2
Magnetic parameters

Complex	g	$2J$ (cm^{-1})	$F\times10^3$
Mn(1)	2.03	−0.71	0.48
Co(3)	2.28	−1.86	1.3
Co(4)	2.32	−1.96	7
Ni(5)	2.46	−2.02	8

$$\chi_A = N\beta^2 g^2 (kT)^{-1} AB^{-1}$$

Mn^{2+} (d^5, $S=5/2$): $A = 55+30X^{10}+14X^{18}+5X^{24}+X^{28}$;

$B = 11+9X^{10}+7X^{18}+5X^{24}+3X^{28}+X^{30}$

Co^{2+} (d^7, $S=3/2$): $A = 14+5X^6+X^{10}$;

$B = 7+5X^6+3X^{10}+X^{12}$

Ni^{2+} (d^8, $S=1$): $A = 5+X^4$;

$B = 5+3X^4+X^6$

where $X = \exp[-J/kT]$; N, g, β, k and T have their usual meanings; J is the exchange integral between metal ions in binuclear unit and χ_A the susceptibility per mole metal ion. The agreement factor F, is defined as $\Sigma(\chi_i^{obs}-\chi_i^{calc})^2$-$(\chi_i^{obs})^{-1}$ [30,31].

A good agreement factor is reached in fitting the experimental susceptibility data. The results are given in Table 2. Small negative $2J$ values indicate weak antiferromagnetic interaction exists between metal ions in the binuclear unit for Mn, Co and Ni complexes. The $-2J$ values have the order $J_{Ni^{2+}-Ni^{2+}}(Ni^{2+}, d^8, S=1) > J_{Co^{2+}-Co^{2+}}(Co^{2+}, d^7, S=3/2) > J_{Mn^{2+}-Mn^{2+}}(Mn^{2+}, d^5, S=5/2)$, which is in accordance with the order predicted by Hoffmann for different spin interaction centers [32]. The small $2J$ value is also in agreement with the molecular structure. The saturated chain is not an efficient bridge conducting the magnetic exchange inter-

action between metals. The two cobalt complexes have similar $2J$ and g values, which may indicate the similarity in coordination structures. The g values of complexes are also in accordance with the octahedron coordination structures of transition metal ions.

Supplementary data

Supplementary crystallographic data for the manganese complex are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition number CCDC 127572.

[30] The spin-orbital interaction in Co(II) (d^7, $S=3/2$) complexes was not considered directly. All the effects which make S not a good quantum number were included in the g value (assuming S is a good quantum number when using this simplified model). The zero field splitting of Ni(II) (d^8, $S=1$) was not considered. Given no maximum value in the χ_A–T curve in the range of temperature measured, the zero field splitting of Ni(II) may occur at very low temperature.

Comparative hydrolysis behavior of the rare earths and yttrium: the influence of temperature and ionic strength

Greta D. Klungness, Robert H. Byrne *

University of South Florida, Department of Marine Science, St. Petersburg, FL 33701, USA

Received 24 June 1999; accepted 11 October 1999

Abstract

In this work two techniques are used to determine hydrolysis constants (β_1*(M)) of yttrium and the rare earths (YREEs), where β_1*(M) = [MOH^{2+}][H^+][M^{3+}]$^{-1}$. Potentiometric experiments were conducted on time scales as long as 15 min and spectrophotometric experiments were complete on time scales much shorter than 500 ms. The stability constant patterns produced by both procedures are in excellent agreement. Potentiometric results obtained over a temperature range between 25 and 55°C indicate that enthalpies appropriate to YREE hydrolysis can be reasonably approximated as ΔH^0(M) = 11.3 kcal mol^{-1} for all YREEs. The dependence of YREE hydrolysis constants on temperature (T), ionic strength (I), and YREE identity (M) can be expressed as $\log \beta_1$*(M) = $\log {}^0\beta_1$*(M) − {2.044$I^{1/2}$/(1 + 5.52$I^{1/2}$) + 1.84 × $10^{-3}I$} − 2446K/T + 8.204 where the $\log {}^0\beta_1$*(M) values, appropriate at 25°C and zero ionic strength, are given as follows: $\log {}^0\beta_1$*(Y) = −7.80, $\log {}^0\beta_1$*(La) = −8.81, $\log {}^0\beta_1$*(Ce) = −8.34, $\log {}^0\beta_1$*(Pr) = −8.32, $\log {}^0\beta_1$*(Nd) = −8.18, $\log {}^0\beta_1$*(Sm) = −7.84, $\log {}^0\beta_1$*(Eu) = −7.76, $\log {}^0\beta_1$*(Gd) = −7.83, $\log {}^0\beta_1$*(Tb) = −7.64, $\log {}^0\beta_1$*(Dy) = −7.59, $\log {}^0\beta_1$*(Ho) = −7.56, $\log {}^0\beta_1$*(Er) = −7.52, $\log {}^0\beta_1$*(Tm) = −7.39, $\log {}^0\beta_1$*(Yb) = −7.24, $\log {}^0\beta_1$*(Lu) = −7.27. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Yttrium; Rare earth elements; Hydrolysis; Enthalpy; Ionic strength; Spectrophotometry

1. Introduction

Solution equilibria strongly influence the environmental behavior of the trivalent rare earths and yttrium (YREE). Important environmental YREE species include carbonate, hydroxide, sulfate, fluoride and chloride complexes. Among all the equilibria currently known to influence YREE solution speciation in natural waters, hydrolysis equilibria are probably the least well understood.

The first hydrolysis step for trivalent YREEs, written as

$$M^{3+} + H_2O \Leftrightarrow MOH^{2+} + H^+ \quad (1)$$

can be quantitatively characterized with hydrolysis constants written in the form

$$\beta_1^*(M) = [MOH^{2+}][H^+][M^{3+}]^{-1} \quad (2)$$

where M^{3+} is a trivalent YREE and brackets denote concentrations of each indicated species. Previous experimental determinations of β_1*(M) do not provide a coherent representation of YREE hydrolysis behavior. The $\log \beta_1$*(M) data shown in Fig. 1 [1–27] at zero ionic strength exhibit an overall range of approximately two orders of magnitude. These data show no discernable pattern in the magnitudes of $\log \beta_1$*(M) across the YREE series other than a general, but poorly defined, increase between the lightest rare earth elements (REEs) and the heaviest REEs. In addition to the very large range in previous $\log \beta_1$*(M) estimates for the YREEs, there are essentially no previous observations of the influence of temperature and ionic strength on YREE hydrolysis constants. In view of the extreme paucity of experimental $\log \beta_1$*(M) data obtained using consistent procedures for all YREEs, and the absence of $\log \beta_1$*(M) data obtained over a range of temperatures and ionic strengths, further experimental observations are required over a range of conditions appropriate to the natural environment.

In this work two procedures have been used to determine the hydrolysis constants of yttrium and all rare earths (except Pm). Both methods involve measurement of pH in solutions buffered by M^{3+}/MOH^{2+} hydrogen ion exchange-couples. In the first procedure, pH is measured spectrophotometrically with *meta*-cresol purple, a pH indicator calibrated previously [28] at ionic strengths appropriate to seawater. Spectrophotometric pH measurements in systems buffered by M^{3+}/

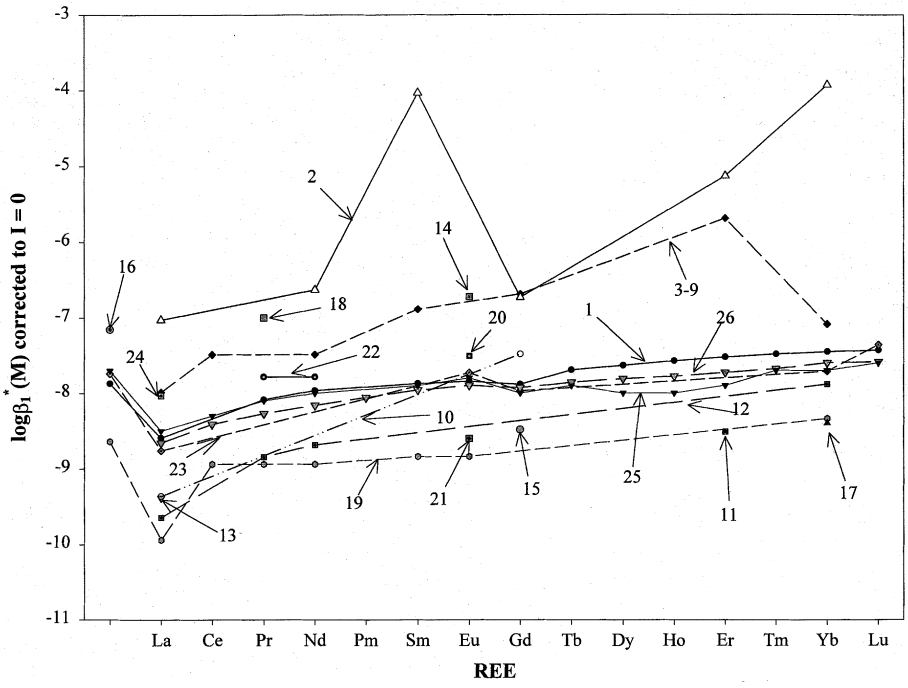

Fig. 1. Hydrolysis constant estimates at 25°C and zero ionic strength. Ionic strength corrections were performed using the hydrolysis behavior of Fe^{III} as an appropriate analog [27].

MOH^{2+} couples involved the use of a stopped flow rapid scan spectroscopy system to observe pH via indicator absorbance ratios on a time scale of zero to 500 ms. This procedure was used as a means of separating the first hydrolysis step (Eq. (1)) from slower hydrolysis steps leading to formation of solid $M(OH)_3(s)$. The second measurement procedure involved the use of electrodes to measure pH in solutions having much higher total metal concentrations but lower pH (higher $[M^{3+}]/[MOH^{2+}]$ ratios) than those in our spectrophotometric experiments. These measurements at low pH substantially lowered the saturation state of our solutions with respect to formation of solid $M(OH)_3(s)$. The overall experimental design in this work acknowledges the importance of obtaining consistent results using independent methodologies. Direct comparisons are obtained between potentiometrically and spectrophotometrically derived log β_1*(M) results at 25°C and ionic strength (I) equal to 0.7 molar. Additional potentiometric results at $I=0.7$ molar are used to determine log β_1*(M) at 40°C and 55°C. Finally, log β_1*(M) is determined at $I=0.1$ molar and 25°C for all YREEs, and the ionic strength dependence of log β_1*(Ho) is observed at 25° for ionic strengths between 0.04 and 5.4 molar.

2. Analytical procedures

2.1. Theory

The potentiometric and spectrophotometric procedures used to determine log β_1*(M) in this work account for all significant acid–base equilibria. The metal ion buffers used in potentiometric experiments were composed by combining acidic solutions, containing $HClO_4$ and either dissolved $M(ClO_4)_3$ or $M(NO_3)_3$, with solutions of NaOH. These acid and base titrants were added to solutions containing $NaClO_4$ as the background electrolyte. The charge balance equation describing the final buffered solution at equilibrium is

$$3[M^{3+}]+2[MOH^{2+}]+[H^+]+[Na^+]-[ClO_4^-]-[OH^-]=0 \quad (3)$$

The concentrations of M^{3+} and MOH^{2+} in this buffer can be expressed as

$$M_T=[M^{3+}](1+\beta_1^*(M)[H^+]^{-1})=[M^{3+}]+[MOH^{2+}] \quad (4)$$

where M_T is the total concentration of a given YREE. The $[Na^+]$ and $[ClO_4^-]$ concentrations in Eq. (3) have four sources: $NaClO_4$, $HClO_4$, $M(ClO_4)_3$ and NaOH. The Na^+ and ClO_4^- added as $NaClO_4$ are balanced ($[Na^+]=[ClO_4^-]$) and need not be considered in Eq. (4). As such, the difference between $[Na^+]$ and $[ClO_4^-]$ in Eq. (4) equals the $[Na^+]$ added as NaOH minus $[ClO_4^-]$ added as $HClO_4$ and $M(ClO_4)_3$. Thus we can write

$$[Na^+]-[ClO_4^-]=[\Delta]-3M_T \quad (5)$$

where $[\Delta]$ can be conceptualized as the concentration of base (NaOH) added in excess of acid ($HClO_4$), and $3M_T$ is the concentration of ClO_4^- in solution from added $M(ClO_4)_3$. Combining Eqs. (3)–(5), Eq. (2) can be written as

$$\log \beta_1^* = -\mathrm{pH} + \log\left\{\frac{[\Delta]+[H^+]-K_w[H^+]^{-1}}{M_T-[\Delta]+K_w[H^+]^{-1}-[H^+]}\right\} \quad (6)$$

Under the conditions of each experiment both $[H^+]$ and $[OH^-]$ (i.e. $K_w[H^+]^{-1}$) are small (≤ 2 μmol dm^{-3}) whereby the final term in Eq. (6) is nearly equal to the term $\log [MOH^{2+}]/[M^{3+}]$. For each experiment, performed at constant temperature and ionic strength, the terms Δ and $M_T-\Delta$ were held very nearly constant. In this case, the pattern of $\log \beta_1^*(M)$ values in each experiment was very nearly identical to the pattern of directly observed equilibrium pH values.

The equations used in our spectrophotometric experiments are identical to those used in our potentiometric experiments with one exception. Spectrophotometric experiments contained two forms of *m*-cresol purple, L^{2-} and HL^-. Consequently, two additional terms must be added to Eq. (3). These terms, $-2[L^{2-}]-[HL^-]$, are added to the left side of Eq. (3). Additionally, since our indicator solutions were composed by dissolving Na_2L in NaOH, the $[Na^+]$ term in Eq. (3) must include the additional Na^+ added to solutions along with *m*-cresol purple. In spectrophotometric experiments, $\log \beta_1^*(M)$ values can also be calculated using Eq. (6). However, in this case $[\Delta]$ includes the following term

$$2[L]_T-2[L^{2-}]-[HL^-]=[HL^-] \quad (7)$$

Consequently, whereas Eq. (6) is used to calculate $\log \beta_1^*(M)$ directly in potentiometric experiments, as used in spectrophotometric experiments one additional term ($[HL^-]$) is added to the term $[\Delta]$ in Eq. (6).

2.2. Methods

Potentiometric $\log \beta_1^*(M)$ determinations were conducted by mixing two solutions and measuring solution pH over a 15 min period. One of these two solutions consisted of a rare earth element, total concentration 0.01 molar, in $NaClO_4$ at $[H^+]=1\times10^{-4}$. The second solution was a 0.1 N volumetric standard NaOH solution. The mixture of these solutions produced a buffering ratio ($[\Delta]/(M_T-[\Delta])$ on the order of 0.11, whereby the measured solution pH was approximately one log unit more positive than the $\log \beta_1^*(M)$ appropriate to a given element.

Two experiments were conducted at 25°C and 0.7 molar ionic strength (I) and two experiments at $I=0.7$ molar were conducted at each of two higher temperatures (40 and 55°C). Two additional experiments were conducted at 25°C and 0.1 molar ionic strength. The procedures described above were conducted using all YREEs except Pm. Experiments at 25°C were also conducted using a single element (Ho) over a range of ionic strengths between 0.04 and 5.4 molar.

The glass electrode used in these experiments was calibrated on the free hydrogen ion concentration scale by titrating unbuffered $NaClO_4$ with a standard $HClO_4$ solution which had been calibrated against a standard NaOH solution (0.1 N NaOH). In all cases, the Orion Ross-type combination electrode used in this work exhibited Nernstian behavior. The acidic solutions used in each experiment were freshly prepared prior to each experiment. Each acidic solution was stored in a plastic beaker under an atmosphere of ultra high purity N_2, and was thermostated at the desired experimental temperature prior to mixing. The basic solution was kept in its original container and placed in the temperature bath to maintain the appropriate temperature prior to mixing. Experiments were initiated by combining a small volume of the standard NaOH solution with a large volume of each solution containing a 0.01 molar YREE. The NaOH addition was made with a variable capacity Eppendorf pipette. All pipettes used in this work were calibrated gravimetrically. Replicate gravimetric/volumetric analyses indicated that volumetric additions were accurate to $\pm 1\%$ or better. In all potentiometric experiments, a Lauda K-4R thermocooler was used to provide constant thermal conditions (25, 40, 55°C). These temperatures were monitored directly in each experimental solution and were constant to ± 0.1°C. Prior to additions of the NaOH titrant, the combination electrode was equilibrated in the acidic YREE-containing solution until the electrode potential was constant within ± 0.1 mV for 5 min. The small $K_w[H^+]^{-1}$ terms in Eq. (6) were calculated using the ionic strength dependence of K_w in $NaClO_4$ summarized by Baes and Mesmer [25], and the temperature dependence of Harned and Owen [29].

The procedures used in spectrophotometric experiments were nearly identical to the procedures used in the potentiometric work. In spectrophotometric experiments the pH term in Eq. (6) is calculated as

$$\mathrm{pH} = \mathrm{p}K_2 + \log\left(\frac{R-e_1}{e_2-e_3R}\right) \quad (8)$$

where pK_2 refers to the HL^- dissociation constant, R is a measured absorbance ratio at the absorbance maxima of L^{2-} and HL^- (578 and 434 nm), and the terms e_1, e_2 and e_3 are molar absorptivity ratios [25,30,31]. The use of *meta*-cresol purple and Eq. (8) to measure the pH of seawater on the total hydrogen ion concentration scale is described in Clayton and Byrne [28]. On the free hydrogen ion concentration scale pH ($-\log[H^+]$) is higher than the total scale pH (expressed as $\mathrm{pH}_T = -\log[H^+]_T$ where $[H^+]_T = [H^+] + [HSO_4^-]$) by 0.14 log units [32]. Consequently, $pK_2 = 8.1456$ at 25°C and $I=0.7$ molar ionic strength. Subsequent to calculating pH in each spectrophotometric experiment using absorbance ratios (R), the term $[HL^-]$ which is included in the $[\Delta]$ term of Eq. (8) is given as

$$[HL^-] = [L]_T\left(1+\frac{K_2}{[H^+]}\right)^{-1} \quad (9)$$

Spectrophotometric experiments involved the use of an OLIS RSM-1000 to measure absorbance ratios at a rate of 1000 scans per second. Using absorbance observations at the

isosbestic point of *m*-cresol purple, the instrument was adjusted to mix two solutions in a one to one ratio. One solution consisted of 4×10^{-5} molar *m*-cresol purple (25°C) and either 1×10^{-3} molar or 6×10^{-4} molar NaOH in 0.7 molar $NaClO_4$ (25°C). The second solution consisted of a 2×10^{-3} molar YREE in 0.7 molar $NaClO_4$ (25°C) at $[H^+]=1\times10^{-4}$. Each of these solutions as well as the mixing and measurement chambers were submerged in a thermostated solution whose temperature (25°C) was constant within ±0.1°C. Nine absorbance scans, recorded against an absorbance baseline obtained using pure 0.7 molar $NaClO_4$, were used to construct an average pH profile for each YREE. Maximum absorbance ratios, generally obtained between 70 and 80 ms, were used to calculate the pH used for log β_1*(M) calculations in Eq. (6).

2.3. Materials

Potentiometric analyses (pH determinations) were conducted using a Corning model 129 pH meter in the absolute millivolt mode. The pH electrode used in this work was an Orion Ross-type combination electrode (Orion no. 8102BN). The volumetric pipettes used in this were Eppendorf variable capacity 100–1000 μl and 1000–5000 μl pipettes.

Yttrium and rare earth element oxides (99.99%) were obtained from Aldrich, Milwaukee, WI. Ce, Pr, and Tb were obtained as $Ce(NO_3)_3$, $Pr(NO_3)_3$, and $Tb(NO_3)_3$ (99.99%). YREE stock solutions were prepared by dissolving salts in perchloric acid to make solutions that were 0.1 molar in each YREE and 0.01 molar in $HClO_4$. Solutions were stored in glass volumetric flasks (250 ml) and the YREE concentration of each flask was determined via ICP-MS analysis using YREE standards obtained from SPEX (Metuchen, NJ). Anhydrous $NaClO_4$ was obtained from Sigma (St. Louis, MO). $NaClO_4$ (4 molar) stock solutions were prepared by (a) dissolving $NaClO_4$ in MilliQ water (Millipore), (b) adding sufficient NaOH to raise the pH to values between 10 and 11, (c) filtering these solutions through clean 0.4 μm polycarbonate membrane filters (Poretics® Products, Livermore, CA) after storage in a sealed volumetric flask overnight. Each solution was subsequently acidified to pH 4.0 to avoid uptake of CO_2 and was likewise stored in a glass volumetric flask.

Perchloric acid was obtained from Aldrich (Milwaukee, WI). The concentrations of concentrated $HClO_4$ standard solutions were determined titrimetrically using volumetric standard NaOH solutions obtained from Fisher Scientific (Pittsburgh, PA). *Meta*-cresol purple salts were obtained from Eastman Kodak (Rochester, NY). Ultra high Purity N_2 was obtained from Air Products and Chemicals Inc. (Allentown, PA).

3. Results

3.1. YREE hydrolysis patterns

Equilibrium pH values for each potentiometric experiment were based on millivolt readings recorded 5 min after mixing. Typical pH profiles through time are shown in Fig. 2. Typical pH profiles for spectrophotometric experiments are shown in Fig. 3. The decrease in solution pH after the observed maxima was anticipated at the high pH of these experiments owing to polymerization/precipitation reactions. Fig. 4 shows the results of two potentiometric log β_1*(M) determinations at 25°C along with the average log β_1*(M) results for five spectrophotometric experiments at 25°C. The standard errors shown in Fig. 4 refer to the spectrophotometric average. The potentiometric results in Fig. 4 were obtained using a buffer ratio ($[MOH^{2+}]/[M^{3+}]$) on the order of 0.11, whereby the measured pH in each experiment was approximately 1 unit above the Fig. 4 calculated log β_1*(M) values. Two buffer ratios were used in the spectrophotometric experiments, $[MOH^{2+}]/[M^{3+}]\cong0.43$ and $[MOH^{2+}]/[M^{3+}]\cong1$. While the absolute magnitudes of spectrophotometrically derived log β_1*(M) values varied significantly in these experiments (as reflected by the standard errors shown in the figure), the pattern of log β_1*(M) values across the series of YREEs was highly consistent in every spectrophotometric and potentiometric experiment. This observation indicates that the log β_1*(M) standard errors shown for each YREE are highly correlated. Notably, the averaged log β_1*(M) results obtained using spectrophotometric procedures are in excellent agreement with the result of each potentiometric experiment. The only exception to this generalization is seen in the hydrolysis behavior of Ce. Spectrophotometric experiments, conducted on very short time scales, provide a sequence of log β_1*(M) values for La, Ce and Pr that are closely consistent with the patterns of hydrolysis constants estimated for these elements using linear free energy relationships [26]. While it is possible to suggest that accessibility to the tetravalent oxidation state, unique to Ce in aqueous solutions, may be responsible for the observed Ce anomaly, Ce oxidation is expected to be extremely slow under these experimental conditions. As such, the origin of the Fig. 4 discrepancies in log β_1*(Ce) values estimated from spectrophotometric and potentiometric procedures is uncertain.

Fig. 5 compares the grand average of all potentiometric and spectrophotometric experiments performed at 25°C and 0.7 molar ionic strength with the results of two potentiometric experiments performed at 25°C and 0.1 molar ionic strength. The standard errors shown on this graph refer to the seven experiments performed at 0.7 molar ionic strength. The potentiometrically derived log β_1*(M) patterns in this figure are in excellent agreement with the spectrophotometrically and potentiometrically derived patterns shown in Fig. 4 and indicate that the log β_1*(M) pattern across the YREE series

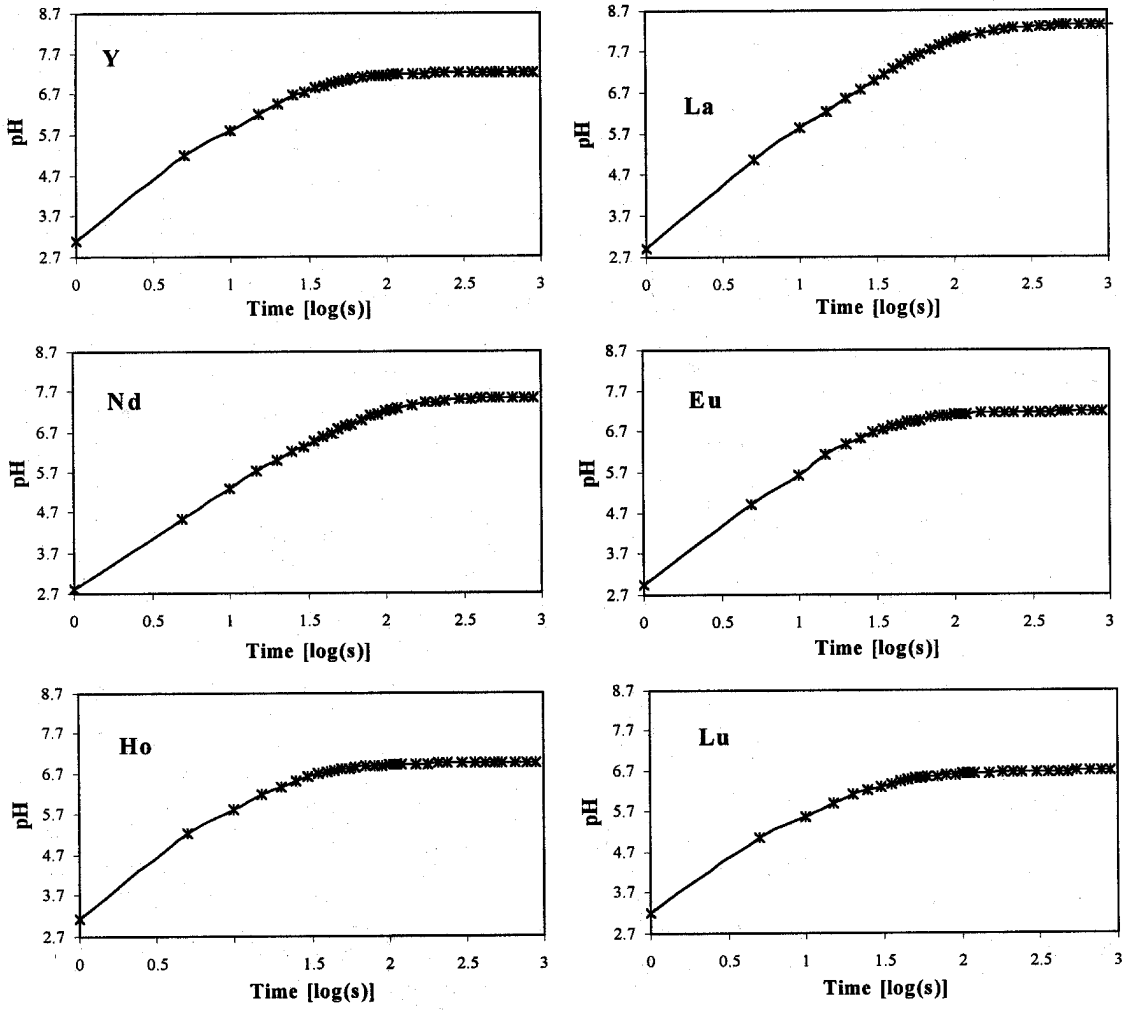

Fig. 2. Representative potentiometric data vs. time.

is insensitive to changes in ionic strength. Constancy in YREE stability constant patterns over a range of ionic strengths has also been observed for YREE complexation by NTA^{3-} [33] and F^- [34].

The log β_1*(M) observations obtained in our work (Fig. 5) are broadly consistent with the observations of Frolova (Fig. 1). However, our work indicates that comparative YREE hydrolysis constants deviate significantly from the generally smooth patterns observed by Frolova [1]. In the present study prominent variations in slope (log β_1*(M) plotted against atomic number) are observed between Gd and Lu. Similar variations have also been observed for CO_3^{2-} complexation constants [35] obtained via solvent exchange analysis and for F^- complexation [34,36] obtained via specific ion electrode and ion exchange analysis.

In spite of the close similarity in the ionic radii of Ho^{3+} and Y^{3+} [37], the hydrolysis behavior of Y^{3+} is intermediate to that observed for Sm^{3+} and Eu^{3+} (Fig. 5). This is consistent with behavior expected for Y^{3+} and REE complexation by a highly covalent ligand [38]. Yttrium is a harder ion than any of the rare earths [39]. It is more weakly complexed than Ho in cases where REE–ligand interactions are significantly covalent [40], and is more strongly complexed than Ho^{3+} for bonding which is strongly electrostatic in character.

3.2. Influence of ionic strength on log β_1*(M)

On the basis of the observed insensitivity of log β_1*(M) patterns to variations in ionic strength, our investigations of the influence of ionic strength on YREE hydrolysis were confined to a single element, Ho. The log β_1*(M) results obtained for Ho between ionic strengths 0.04 molar and 5.7 molar are shown graphically in Fig. 6. As is the case for log β_1*(M) results obtained potentiometrically at ionic strengths 0.7 and 0.1 molar, the results shown in Fig. 6 were obtained with a $[HoOH^{2+}]/[Ho^{3+}]$ ratio on the order of 0.11. Since a relatively high Ho^{3+} concentration ($[Ho^{3+}]$) was used in these experiments, the ionic strength range in these measurements did not include values smaller than 0.04. The ionic strength dependence of the data shown in Fig. 6 was described quantitatively using an equation identical in

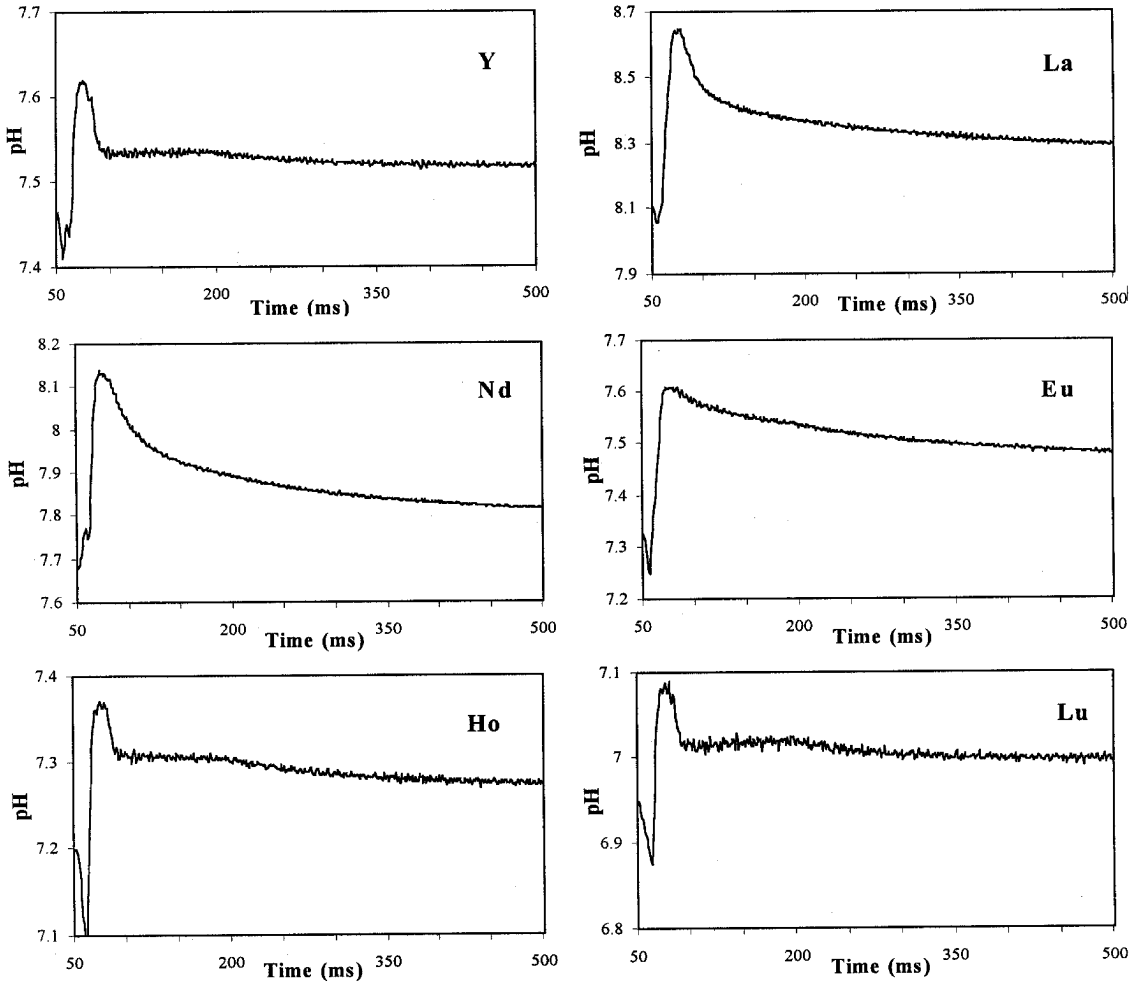

Fig. 3. Representative spectrophotometric data vs. time.

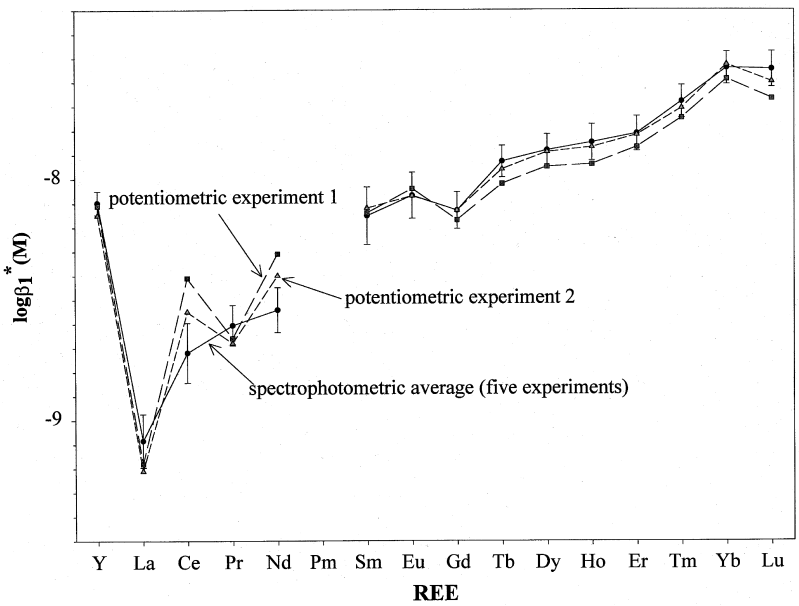

Fig. 4. Log β_1*(M) determinations at $I = 0.7$ molar and 25°C. Average of five spectrophotometric experiments with standard errors plus the results of two potentiometric experiments.

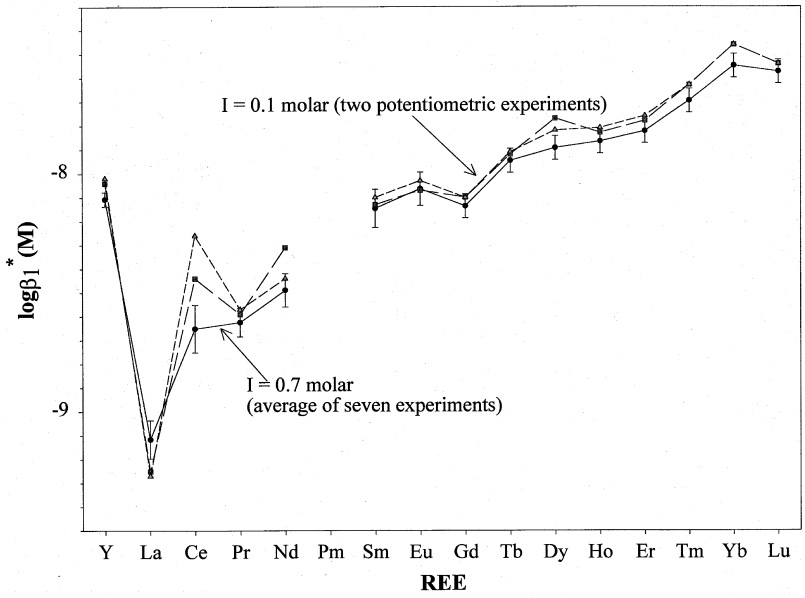

Fig. 5. Average log β_1*(M) determinations for all experiments at $I=0.7$ molar and 25°C plus the results of two potentiometric experiments at 25°C and $I=0.1$ molar. The standard errors shown in this figure refer to the seven experiments performed at 0.7 molar ionic strength.

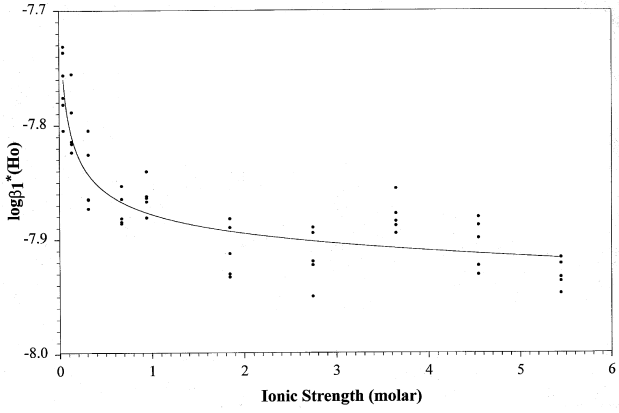

Fig. 6. Ionic strength dependence of log β_1*(Ho) at 25°C. Note that the difference ($\cong 0.05$) between log β_1*(M) for heavy REEs at 0.7 molar and 0.1 molar ionic strengths (Fig. 5) is consistent with the observations shown in this figure.

form to that employed in descriptions of YREE complexation by F^- and NTA^{3-}. The best fit curve in Fig. 6 is given by

$$\log \beta_1^*(\mathrm{Ho}) = \log {}^0\beta_1^*(\mathrm{Ho}) - 2.044 I^{1/2} / (1+5.52 I^{1/2}) - 1.84\times10^{-3} I \quad (10)$$

where $\log {}^0\beta_1^*(\mathrm{Ho}) = -7.56$ is the hydrolysis constant appropriate to 25°C and zero ionic strength.

3.3. Temperature dependence of YREE hydrolysis constants

The temperature dependence of YREE hydrolysis constants was determined by conducting additional potentiometric experiments at 40 and 55°C. The results shown in Fig. 7 are the average of two potentiometric experiments at $I=0.7$ molar for each temperature. Fig. 7 shows that the patterns of log β_1*(M) values obtained at 40 and 55°C closely resemble the patterns obtained potentiometrically at 25°C. The log β_1*(M) data in Fig. 7 were fitted using the van't Hoff equation. The enthalpy values obtained in these fits are given in Table 1. The average ΔH^0(M) value for all YREEs is 11.3 kcal mol^{-1}. In consideration of the standard errors given with each ΔH^0(M) estimate in Table 1, this enthalpy is in good agreement with values obtained for all elements except Ce. Enthalpies ranged from 13.6 kcal mol^{-1} for Ce to 10 kcal mol^{-1} for Yb and Lu. The standard errors given with each ΔH^0(M) value in Table 1 indicate that reaction enthalpies appropriate to Eq. (1) are much better defined for the heavy rare earths than is the case for for the lightest rare earths (La–Nd).

The results obtained in this work allow log β_1*(M) values to be calculated over a wide range of temperatures and ionic strengths. Table 2 provides the grand average YREE hydrolysis constants appropriate at 25°C and the ionic strength of

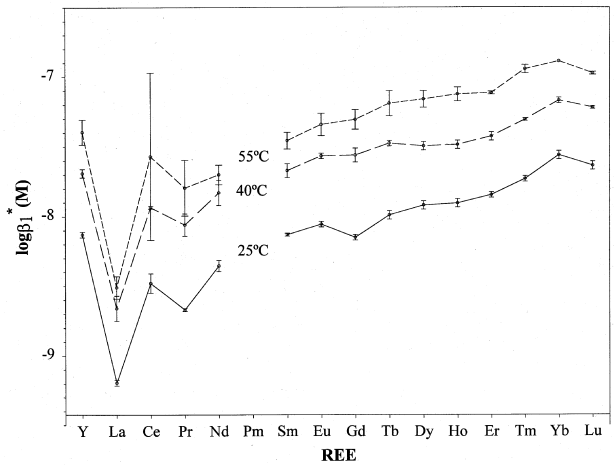

Fig. 7. Potentiometric log β_1*(M) results (0.7 molar) at 25, 40 and 55°C. Error limits shown in this figure indicate the range in log β_1*(M) for two measurements at each temperature.

Table 1
Enthalpy data (kcal mol^{-1}) for YREE hydrolysis

REE	$\Delta H \pm$ S.E.
Y	11.0 ± 1.1

seawater (0.7 molar). The $\log {}^0\beta_1^*(M)$ values given in Table 2 were calculated using the ionic strength behavior observed for Ho, and the average $\log \beta_1^*(M)$ results obtained for all experiments performed at 25°C and 0.7 molar ionic strength. Using $\Delta H^0(M) = 11.3$ kcal mol^{-1} as a reasonable approximation for all YREEs, hydrolysis constants can be estimated as a function of temperature and ionic strength (I) with the following equation

$$\log \beta_1^*(M) = \log {}^0\beta_1^*(M) - \{2.044 I^{1/2}/(1+5.52 I^{1/2}) + 1.84\times10^{-3} I\} - 2446 K/T + 8.204 \quad (11)$$

where T is the temperature in degrees Kelvin and $\log {}^0\beta_1^*(M)$ values are given in Table 2.

4. Conclusions

The $\log \beta_1^*(M)$ values obtained in this work are in general agreement with the previous measurements of Frolova [1]. However, observations obtained in the present study show much more structure than the Frolova [1] results. The nearest neighbor $\log \beta_1^*(M)$ relationships observed for YREEs in this work are broadly consistent with those observed in LFER characterizations of YREE stability constants with a wide variety of organic ligands [26,39]. The nearest neighbor hydrolysis constants observed in our study also resemble YREE stability constant patterns observed for CO_3^{2-} and F^- complexation [34–36].

Our hydrolysis constant observations indicate that for surface seawater at 25°C (pH ≅ 8.2) the ratio $[MOH^{2+}]/[M^{3+}]$ varies from values smaller than unity for La to values on the order of five for Lu. The enthalpy values obtained for the first YREE hydrolysis step are in good agreement with values predicted [41] using the enthalpy estimation systematics of Baes and Mesmer [42]. For the enthalpies observed in the present work ($\Delta H^0 = 11.3$ kcal mol^{-1}) YREE hydrolysis constants are predicted to decrease by more than a factor of four between 25°C and temperatures characteristic of the deep ocean ($0°C \le t \le 6°C$). Consequently MOH^{2+} is a minor species for the YREEs in ocean waters relative to carbonate complexes, MCO_3^+ and $M(CO_3)_2^-$.

Hydrolysis constants have been advocated as proxies for metal ion adsorption constants appropriate to the surfaces of metal oxides and hydrous oxides and organic particles [43–47]. The application of surface complexation models to YREEs has generally involved the use of $\log \beta_1^*(M)$ values obtained from linear free energy relationships [26] or the hydrolysis data recommended by Baes and Mesmer [25]. The $\log \beta_1^*(M)$ data obtained in the present work provide a basis for refined YREE scavenging models (adsorptive transport) in seawater and freshwater systems.

Abstract

Complexation of hydrated $Zn(BF_4)_2$ by 1-{pyrid-2-yl}-3-{2′,5′-dimethoxyphenyl}pyrazole (L^1) in MeCN, followed by layering with Et_2O, affords a white polycrystalline material analysing as $[Zn(L^1)_2](BF_4)_2 \cdot 2H_2O$ (**1**). Reaction of **1** with $K[Tp^{Ph}]$, $K[Tp^{Tol}]$ or $K[Tp^{PhF}]$ ($[Tp^{Ph}]^-$ = tris-{3-phenylpyrazolyl}borate; $[Tp^{Tol}]^-$ = tris-{3-[4-methylphenyl]pyrazolyl}borate; $[Tp^{PhF}]^-$ = tris-{3-[4-fluorophenyl]-pyrazolyl}borate) in 4:1 CH_2Cl_2:MeCN gives $[Zn(L^1)(Tp^{Ph})]BF_4$ (**2**), $[Zn(L^1)(Tp^{Tol})]BF_4$ (**3**) and $[Zn(L^1)(Tp^{PhF})]BF_4$ (**4**) in low-to-moderate yields. The single crystal structure of **2** shows a five-coordinate zinc ion, with a very distorted square-pyramidal geometry. A variable temperature NMR study of **2** in CD_2Cl_2 demonstrates a fluxional process involving libration of the L^1 ligand within one 'wedge' of the $[Tp^R]^-$ tripod. Cyclic voltammograms of **1**–**3** in CH_2Cl_2/0.5 M $NBu^n{}_4PF_6$ or MeCN/0.1 M $NBu^n{}_4PF_6$ each show one irreversible L^1-based oxidation at $E_{pa} = +1.0$–1.1 V versus ferrocene/ferrocenium, and two principle daughter waves at $E_{pc} = 0.0$ V and $E_{1/2} = -0.5$ V. This differs from the cyclic voltammograms of their previously published copper-containing analogues, which do not show oxidative EC reactivity. The reasons for these differences, and the nature of the decomposition products of zinc-coordinated $[L^{1\bullet}]^+$, are discussed. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Zinc; Tris-pyrazolylborate; Crystal structures; Electrochemistry

1. Introduction

We have recently described the complexes $[Cu(L^1)(Tp^R)]BF_4$ (L^1 = 1-{pyrid-2-yl}-3-{2′,5′-dimethoxyphenyl}pyrazole; $[Tp^R]^-$ = tris-{3-phenylpyrazolyl}borate ($[Tp^{Ph}]^-$), tris-{3-[4-methylphenyl]pyrazolyl}borate ($[Tp^{Tol}]^-$), tris-{3-[4-fluorophenyl]pyrazolyl}borate ($[Tp^{PhF}]^-$); Scheme 1), which exhibit an intramolecular π–π stacking interaction between the pendant dimethoxyphenyl substituent of L^1 and a $[Tp^R]^-$ aryl moiety [1]. The cyclic voltammograms of these complexes in CH_2Cl_2/0.5 M $NBu^n{}_4PF_6$ at room temperature contain a fully reversible one-electron oxidation by cyclic voltammetry, attributable to oxidation of the L^1 dimethoxyphenyl moiety to a radical cation [1]. In contrast, however, $[Cu(L^1)(Tp^{Cy})]BF_4$ (Cy = cyclohexyl) shows an *irreversible* ligand oxidation under the same conditions [2]. We therefore proposed that the π–π stacking interaction in $[Cu(L^1)(Tp^R)]^+$ (R = Ph, Tol, PhF) was kinetically stabilising the $[Cu(L^{1\bullet+})(Tp^R)]^{2+}$ oxidation product [1], a suggestion that appeared to be confirmed by the spectroscopic characterisation of the extremely long-lived species $[Cu(L^{1\bullet+})(Tp^R)]^{2+}$ (R = Ph, PhF; Scheme 1) [2]. This is a result of relevance to the

Scheme 1. Ligands referred to in this study.

properties of amino acid radicals in proteins, several examples of which are involved in π–π stacking interactions to neighbouring aromatic side-chains [3], as well as to the production of molecule-based conducting or magnetic materials [4].

As a complement to these initial studies, we were eager to prepare analogues of $[M(L^1)(Tp^R)]^+$ (M = Cu) containing a diamagnetic metal ion. In principle, this would allow the characterisation of the intramolecular π–π stacking interaction in solution by ^{1}H NMR spectroscopy, as well as removing Cu-based spectroscopic features that complicate the characterisation of $[M(L^{1\bullet+})(Tp^R)]^{2+}$ by EPR and UV–Vis spectroscopies. We therefore describe here the synthesis, solid state and solution structures and electrochemistry of $[Zn(L^1)(Tp^{Ph})]BF_4$. Throughout this paper, the Trofimenko nomenclature scheme for tris-pyrazolylborate ligands is employed [5].

2. Experimental

All manipulations were carried out in air. $Zn(BF_4)_2\cdot xH_2O$ ($x\approx2$, Aldrich) and all solvents were used as supplied. L^1 [1], K[Tp] [6], K[Tp*] [7], $K[Tp^{Ph}]$ [8], $K[Tp^{Tol}]$ [9] and $K[Tp^{PhF}]$ [1] were prepared by the literature procedures.

2.1. $[Zn(L^1)_2](BF_4)_2\cdot 2H_2O$ (1)

A mixture of L^1 (0.40 g, 1.4×10^{-3} mol) and $Zn(BF_4)_2\cdot xH_2O$ ($x\approx2$; 0.17 g, 7.2×10^{-4} mol) in MeCN (25 cm^3) was stirred at room temperature for 1 h, affording a colourless solution, which was filtered, concentrated and layered with Et_2O. White microcrystals formed over several days (yield 0.54 g, 89%). *Anal*. Found: C, 46.0; H, 4.0; N, 10.0. Calc. for $C_{32}H_{34}B_2F_8N_6O_6Zn$: C, 45.9; H, 4.1; N, 10.0%. IR (cm^{-1}): 1614m, 1532m, 1495s, 1480s, 1444s, 1331m, 1304m, 1290m, 1266m, 1244m, 1221m, 1184m, 1060vs, 1049s, 934m, 787m, 722m, 521m. FAB mass spectrum (fragment, %): 645 ($[^{65}Zn(L^1)_2(OH_2)]^+$, 17), 627 ($[^{65}Zn(L^1)_2]^+$, 3), 364 ($[^{65}Zn(L^1)(OH_2)]^+$, 100) with correct isotopic distributions. ^{1}H NMR (CD_3CN, 298 K): δ 8.52 (d, 2.7 Hz, 1H, Pz H^5), 8.25 (vbr, 1H, Py H^6), 8.14 (t, 7.7 Hz, 1H, Py H^4), 7.82 (d, 7.7 Hz, 1H, Py H^3), 7.39 (br, 1H, Py H^5), 6.82 (br, 1H, Pz H^4), 6.67 (br, 2H, Ph H^3+H^4), 6.44 (br, 1H, Ph H^6), 3.82 (s, 3H, OCH_3), 3.17 (s, 3H, OCH_3).

2.2. $[Zn(L^1)(Tp^{Ph})]BF_4$ (2)

A solution of $K[Tp^{Ph}]$ (0.12 g, 2.4×10^{-4} mol) and $[Zn(L^1)_2](BF_4)_2\cdot2H_2O$ (0.20 g, 2.4×10^{-4} mol) in 4:1 CH_2Cl_2:MeCN (25 cm^3) was stirred at room temperature for 1 h. Filtration and concentration of the colourless solution, followed by layering with Et_2O, afforded pale yellow crystals (yield 0.065 g, 31%). *Anal*. Found: C, 58.6; H, 4.3; N, 14.2. Calc. for $C_{43}H_{37}B_2F_4N_9O_2Zn$: C, 59.0; H, 4.3; N, 14.4%. IR (cm^{-1}): 2496w, 1615m, 1579m, 1530s, 1494s, 1306m, 1264m, 1220m, 1185m, 1060vs, 953m, 766m, 730m, 701m, 521m. FAB mass spectrum (fragment, %): 786 ($[^{65}Zn(L^1)(H^{11}B\{pz^{Ph}\}_3)]^+$, 100), 642 ($[^{65}Zn(L^1)(H^{11}B\{pz^{Ph}\}_2)-H]^+$, 7), 505 ($[^{65}Zn(H^{11}B\{pz^{Ph}\}_3)]^+$, 48), 361 ($[^{65}Zn(H^{11}B\{pz^{Ph}\}_2)-H]^+$, 44), 346 ($[^{65}Zn(L^1)]^+$, 13) with correct isotopic distributions. NMR spectra (CD_2Cl_2, 298 K) ^{1}H: δ 8.28 (d, 2.8 Hz, 1H, L^1 Pz H^5), 7.95 (d, 2.3 Hz, 3H, Tp^{Ph} Pz H^5), 7.91 (pseudo-td, 8.8 and 1.6 Hz, 1H, L^1 Py H^4), 7.69 (d, 8.8 Hz, 1H, L^1 Py H^3), 7.50 (d, 4.9 Hz, 1H, L^1 Py H^6), 7.11 (m, 9H, Tp^{Ph} Ph $H^{2/6}+H^4$), 6.98 (m, 6H, Tp^{Ph} Ph $H^{3/5}$), 6.79 (dd, 9.0 and 3.1 Hz, 1H, L^1 Ph H^4), 6.76 (d, 2.8 Hz, 1H, L^1 Pz H^4), 6.70 (d, 9.0 Hz, 1H, L^1 Ph H^3), 6.61 (dd, 8.8 and 4.9 Hz, L^1 Py H^5), 6.34 (d, 2.3 Hz, 3H, Tp^{Ph} Pz H^4), 5.96 (d, 3.1 Hz, 1H, L^1 Ph H^6), 3.51 (s, 3H, L^1 OCH_3), 3.48 (s, 3H, L^1 OCH_3). ^{13}C: δ 156.1, 154.8, 154.7, 153.1, 148.3 (L^1 Py C^2+Pz C^3+Ph C^2+C^5), 148.4 (L^1 Py C^6), 145.6 (L^1 Py C^4), 140.0 (Tp^{Ph} Pz C^5), 133.4 (Tp^{Ph} Pz C^1), 131.2 (L^1 Pz C^5), 130.7 (Tp^{Ph} Ph C^4), 130.0, 129.0 (Tp^{Ph} Ph $C^{2/6}+C^{3/5}$), 123.8 (Tp^{Ph} Ph C^1), 117.3, 115.7 (2C), 114.2, 113.1, 109.5 (L^1 Py C^3+C^5+Pz C^4+Ph $C^3+C^4+C^6$), 106.5 (Tp^{Ph} Pz C^4), 57.1 (L^1 OCH_3), 56.8 (L^1 OCH_3).

2.3. $[Zn(L^1)(Tp^{Tol})]BF_4$ (3)

Method as for **2**, using $K[Tp^{Tol}]$ (0.13 g, 2.4×10^{-4} mol). The product was a white microcrystalline solid (yield 0.065 g, 22%). *Anal*. Found: C, 59.5; H, 4.7; N, 13.9. Calc. for $C_{46}H_{43}B_2F_4N_9O_2Zn$: C, 60.3; H, 4.7; N, 13.7. IR (cm^{-1}): 2508w, 1616m, 1578w, 1531m, 1492s, 1331m, 1305m, 1292m, 1263m, 1220m, 1182m, 1060vs, 952m, 819m, 776m, 732m, 721m, 521m. FAB mass spectrum (fragment, %): 828 ($[^{65}Zn(L^1)(H^{11}B\{pz^{Tol}\}_3)]^+$, 100), 547 ($[^{65}Zn(H^{11}B\{pz^{Tol}\}_3)]^+$, 46), 389 ($[^{65}Zn(H^{11}B\{pz^{Tol}\}_2)-H]^+$, 59), 281 ($[L^1]^+$, 26) with correct isotopic distributions. NMR spectra (CD_2Cl_2, 298 K) ^{1}H: δ 8.61 (d, 2.8 Hz, 1H, L^1 Pz H^5), 8.06 (d, 8.8 Hz, 1H, L^1 Py H^3), 7.96 (pseudo-t, 8.8 Hz, 1H, L^1 Py H^4), 7.84 (d, 2.3 Hz, 3H, Tp^{Tol} Pz H^5), 7.44 (d, 5.0 Hz, 1H, L^1 Py H^6), 6.93 (d, 8.0 Hz, 6H, Tp^{Tol} Ph $H^{3/5}$), 6.75 (m, 8H, Tp^{Tol} Ph $H^{3/5}+L^1$ Pz H^4+L^1 Ph H^4), 6.63 (d, 8.8 Hz, 1H, L^1 Ph H^3), 6.57 (dd, 8.8 and 5.0 Hz, L^1 Py H^5), 6.27 (d, 2.3 Hz, 3H, Tp^{Tol} Pz H^4), 6.00 (d, 3.1 Hz, 1H, L^1 Ph H^6), 3.51 (s, 3H, L^1 OCH_3), 3.41 (s, 3H, L^1 OCH_3), 2.22 (s, 9H, Tp^{Tol} CH_3). ^{13}C: δ 154.3, 152.7, 152.6, 151.2, 146.5 (L^1 Py C^2+L^1 Pz C^3+L^1 Ph C^2+L^1 Ph C^5), 146.4 (L^1 Py C^6), 143.5 (L^1 Py C^4), 139.1 (Tp^{Tol} Pz C^5), 137.7 (Tp^{Tol} Pz C^1), 130.2 (L^1 Pz C^5), 128.7, 126.8 (Tp^{Tol} Ph $C^{2/6}+C^{3/5}$), 128.4 (Tp^{Tol} Ph C^4), 121.4 (L^1 Ph C^1), 117.9, 115.5, 115.2, 113.9, 113.1, 111.0 (L^1 Py C^3+C^5+Pz C^4+Ph $C^3+C^4+C^6$), 104.3 (Tp^{Tol} Pz C^4), 55.2 (L^1 OCH_3), 54.8 (L^1 OCH_3), 21.0 (Tp^{Tol} CH_3).

2.4. $[Zn(L^1)(Tp^{PhF})]BF_4$ (4)

Method as for **2**, using $K[Tp^{PhF}]$ (0.13 g, 2.4×10^{-4} mol). The white solid thus obtained (0.085 g) was recrystallised

three times from CH_2Cl_2:Et_2O (yield 0.015 g, 7%). *Anal.* Found: C, 55.8; H, 3.9; N, 13.2. Calc. for $C_{43}H_{34}B_2F_7N_9O_2Zn$: C, 55.6; H, 3.7; N, 13.6. IR (cm^{-1}): 2493w, 1610m, 1578w, 1532s, 1494s, 1306w, 1263w, 1221s, 1183m, 1156m, 1060vs, 954m, 841m, 780m, 734m, 722m, 605m, 521m. FAB mass spectrum (fragment, %): 840 ($[^{65}Zn(L^1)(H^{11}B\{pz^{PhF}\}_3)]^+$, 100), 678 ($[^{65}Zn(L^1)(H^{11}B\{pz^{PhF}\}_2)–H]^+$, 5), 559 ($[^{65}Zn(H^{11}B\{pz^{PhF}\}_3)]^+$, 26), 397 ($[^{65}Zn(H^{11}B\{pz^{PhF}\}_2)–H]^+$, 38), 346 ($[^{65}Zn(L^1)]^+$, 8) with correct isotopic distributions. NMR spectrum (CD_2Cl_2, 298 K) ^1H: δ 8.38 (d, 2.7 Hz, 1H, L^1 Pz H^5), 7.95 (pseudo-t, 8.5 Hz, 1H, L^1 Py H^4), 7.93 (d, 2.3 Hz, 3H, Tp^{PhF} Pz H^5), 7.78 (d, 8.5 Hz, 1H, L^1 Py H^3), 7.54 (d, 4.3 Hz, 1H, L^1 Py H^6), 7.07 (dd, 8.2 and 5.4 Hz, 6H, Tp^{PhF} Ph $H^{2/6}$), 6.89 (d, 2.8 Hz, 1H, L^1 Pz H^4), 6.81 (dd, 9.2 and 3.0 Hz, 1H, L^1 Ph H^4), 6.72 (m, 8H, Tp^{PhF} Ph $H^{3/5}$ + L^1 Py H^5 + L^1 Ph H^3), 6.33 (d, 2.3 Hz, 3H, Tp^{PhF} Pz H^4), 6.04 (d, 3.0 Hz, 1H, L^1 Ph H^6), 3.50 (s, 3H, L^1 OCH_3), 3.47 (s, 3H, L^1 OCH_3).

2.5. X-ray structure determination of $[Zn(L^1)(Tp^{Ph})]BF_4$

Diffusion of Et_2O into a solution of the complex in CH_2Cl_2 yielded pale yellow–green plates. Experimental details for the structure determination are given in Table 1. The structure was solved by direct methods (SHELXTL Plus [10]), and developed by least-squares refinement against $|F^2|$ (SHELXL93 [11]). During refinement, the BF_4^- anion was found to be disordered by rotation about the B(2)–F(1) bond. This was modelled using two orientations with a 60:40 occupancy ratio, with all B–F and F···F distances restrained to be equal. All non-H atoms with occupancy >0.5 were refined anisotropically, while H atoms were placed in calculated positions.

2.6. Other measurements

IR spectra were obtained as Nujol mulls pressed between KBr windows between 400–4000 cm^{-1} using a Perkin–Elmer Paragon 1000 spectrophotometer. NMR spectra were run on a Bruker DPX250 spectrometer, operating at 250.1 MHz (^1H) and 62.9 MHz (^{13}C); low temperature ^1H spectra were obtained using a Bruker AM400 instrument operating at 400.1 MHz. Positive ion fast atom bombardment (3-NOBA matrix) mass spectra were performed on a Kratos MS890 spectrometer. Microanalyses were performed by the University of Cambridge Department of Chemistry microanalytical service. All electrochemical measurements were carried out using an Autolab PGSTAT20 voltammetric analyser, in CH_2Cl_2 or MeCN containing 0.5 or 0.1 M $Bu^n_4NPF_6$, respectively, as supporting electrolyte. Cyclic voltammetric experiments involved the use of a double platinum working/counter electrode and a silver wire reference electrode; all potentials quoted in the text are referenced to an internal ferrocene/ferrocenium standard and were obtained at a scan rate of 100 mV s^{-1}.

Table 1
Experimental details for the single crystal structure determination of $[Zn(L^1)(Tp^{Ph})]BF_4$ (**2**)

Formula	$C_{43}H_{37}B_2F_4N_9O_2Zn$

[c] $P=(F_o^2+2F_c^2)/3$.

3. Results and discussion

Our initial attempts to prepare $[Zn(L^1)(Tp^{Ph})]BF_4$ followed the same method employed for its copper-containing analogues [1]. However, in contrast to the copper system, treatment of hydrated $Zn(BF_4)_2$ with equimolar amounts of L^1 and $K[Tp^{Ph}]$ in a variety of solvents gave only an intractable mixture of products. Reactions of $[ZnCl(Tp^{Ph})]$ [12,13] or $[Zn(O_2CMe)(Tp^{Ph})]$ [12] with L^1 in the presence of $NaBF_4$ or $AgBF_4$ were similarly unsuccessful. We therefore sought an alternative route to our target compounds.

Treatment of hydrated $Zn(BF_4)_2$ with 2 molar equivalents of L^1 in MeCN yields a colourless solution, from which a white polycrystalline material can be isolated upon layering with ether. This material analyses reproducibly as $[Zn(L^1)_2](BF_4)_2\cdot2H_2O$ (**1**), a formulation supported by IR spectroscopy, which shows the presence of L^1 and BF_4^- only, and FAB mass spectrometry, which exhibits a highest molec-

ular ion corresponding to $[^{65}Zn(L^1)_2(OH_2)]^+$, at $m/z=$ 645. The ^1H NMR spectra of this compound in CD_3CN or CD_3NO_2 exhibit the correct number of peaks expected for coordinated L^1, but are rather broadened. This presumably reflects fluxionality or partial solvolysis of the zinc centre upon dissolution. We have been unable to grow X-ray quality crystals of **1**, so its molecular structure remains uncertain. In particular, it is unclear whether **1** contains tetrahedral $[Zn(L^1)_2]^{2+}$ centres analogous to the isoelectronic complex $[Cu(L^1)_2]BF_4$ [14], or whether one or both of the water molecules present in **1** are metal bound to afford a higher coordination number zinc ion.

Reaction of $[Zn(L^1)_2](BF_4)_2\cdot 2H_2O$ with 1 equiv. of $K[Tp^{Ph}]$ or $K[Tp^{Tol}]$ in 4:1 CH_2Cl_2:MeCN at room temperature gives cloudy, very pale yellow solutions; filtration, concentration and addition of a large excess of Et_2O to these solutions affords white microcrystalline products in variable yields ranging from 20–35%. These solids analysed as the desired products $[Zn(L^1)(Tp^{Ph})]BF_4$ (**2**) and $[Zn(L^1)(Tp^{Tol})]BF_4$ (**3**) without further purification. In contrast, however, analogous reactions involving $K[Tp^{PhF}]$ gave white solid products of variable composition by microanalysis. Multiple recrystallisations of these crude solids from $CH_2Cl_2\cdot Et_2O$ did afford small amounts of analytically pure $[Zn(L^1)(Tp^{PhF})]BF_4$ (**4**), however. The reduced efficiency of this synthesis for **4** compared to **2** and **3** may relate to the reduced nucleophilicity of the $[Tp^{PhF}]^-$ ligand, caused by its electron-withdrawing fluoro substituents (the donor capabilities of pyrazolylborates are sensitive to the nature of the pyrazole 3-substituents [15]). Owing to the small amounts of **4** available, and since its solution properties are likely to be identical to those of **2** and **3**, only basic characterisation of this compound was undertaken.

The assignment of **2**–**4** as the desired compounds was supported by IR spectroscopy, which demonstrated the presence of L^1, BF_4^- and the appropriate pyrazolylborate. It was also supported by NMR spectroscopy (see below), and by FAB mass spectrometry which in each case gave a highest molecular ion corresponding to $[^{65}Zn(L^1)(Tp^R)]^+$ (R = Ph, $m/z=787$; R = Tol, $m/z=828$; R = PhF, $m/z=840$). In none of these mass spectra were molecular ions attributable to $[^{65}Zn(L^1)_2]^+$ ($m/z=627$) or $[^{65}Zn(Tp^R)_2]^+$ (R = Ph, $m/z=947$; R = Tol, $m/z=1031$; R = PhF, $m/z=1055$) observed. In addition, the IR spectra of microcrystalline **2**–**4** are almost superimposable on that of single crystals of **2** (see below). Both of these latter observations suggest that **2**–**4** are homogeneous solids, containing the $[Zn(L^1)(Tp^R)]^+$ (R = Ph, Tol, PhF) complex cations only.

Under the conditions used to prepare **2**–**4**, reactions of **1** with K[Tp] or K[Tp*] were unsuccessful, the resultant solutions yielding impure powders when layered with ether or pentane which did not give reproducible microanalyses. In the latter case a small number of crystals of $[Zn(Tp^*)_2]$ [16] also formed, implying that the reduced cone angles of these smaller pyrazolylborates [15] were allowing ligand disproportionation products to form from these reactions. In contrast to **4**, repeated recrystallisations of the products of these reactions did not yield pure material.

X-ray-quality crystals of **2** were grown from CH_2Cl_2/Et_2O. The structure shows one cation and anion per asymmetric unit, lying on a general position (Fig. 1, Table 2). The complex adopts the expected five-coordinate geometry, the closest contact between Zn(1) and the dimethoxyphenyl pendant being Zn(1)···C(66) = 3.557(5) Å. In contrast to the $[Cu(L^1)(Tp^R)]^+$ complexes [1], which adopt a near-regular square-pyramidal coordination sphere with one lengthened apical Cu–N bond, the geometry about Zn(1) is rather distorted. The pattern of three short and two long Zn–N distances (Table 1) is suggestive of a trigonal bipyramidal geometry, which would implicate N(3) and N(5) as the axial donors (Fig. 1). However the 'τ' index of Addison and Reedijk [17], which can vary between 0 and 1 corresponding to the limiting square-pyramidal or regular trigonal-bipyramidal geometries respectively, is only 0.28 for **2**. This is at the low end of the range observed for other known $[Zn(L)(Tp^R)]$ (L = bidentate ligand) species, all of which exhibit a 'three

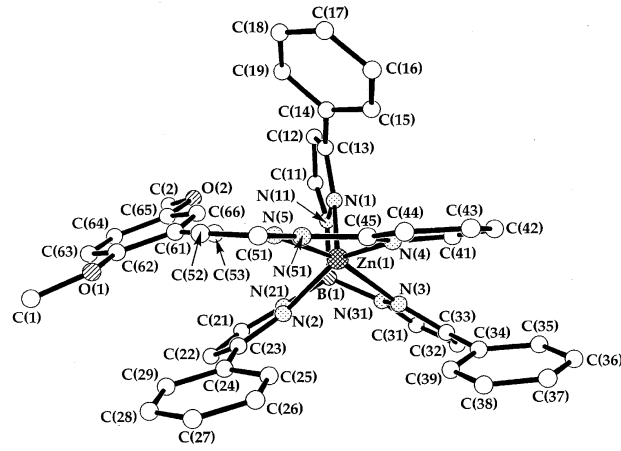

Fig. 1. View of the $[Zn(L^1)(Tp^{Ph})]^+$ cation in the single crystal structure of **2**, showing the atom numbering scheme employed. For clarity, all H atoms have been omitted.

short, two long' pattern of bond lengths to zinc and show $\tau = 0.21$–0.64 [18–22]. By comparison, τ for $[Cu(L^1)(Tp^{Ph})]BF_4$ is 0.19 [1].

The change in geometry between **2** and its Cu(II) analogue corresponds to a ca. 15° twist of the L^1 ligand about the central metal ion. This has the effect of weakening the π-stacking interaction in **2** between the Tp^{Ph} Ph ring (C(24)–C(29)) and L^1 dimethoxyphenyl pendant (C(61)–C(66)), since while these two moieties are still nearly coplanar (dihedral angle 9.0(2)°), their centroids are offset by 3.5 Å. By comparison, in $[Cu(L^1)(Tp^R)]BF_4$ the centroids of the two stacked arene rings are offset by 3.0 Å [1], which is an ideal value for an attractive stacking interaction between two monocyclic arenes [23].

The room temperature ^1H NMR spectra of **2**–**4** in CD_2Cl_2 exhibit the expected number of peaks and integral ratios for a 1:1 L^1:$[Tp^{Ph}]^-$ stoichiometry, and display three-fold symmetry of the pyrazolylborate ligand. This is inconsistent with the geometry of **2** in the crystal, for which each $[Tp^{Ph}]^-$ pyrazole ring is chemically distinct, and suggests that these zinc centres are fluxional in this solvent. For **2**, near 220 K, decoalescence of the $[Tp^{Ph}]^-$ Pz H^4 peak (6.34 ppm (d, 3H) at 298 K) into two peaks at δ 6.46 (1H) and 6.23 (2H) ppm is observed; partial decoalescence of the $[Tp^{Ph}]^-$ Pz H^5 and C_6H_5 peaks also takes place at this temperature. Similarly, a ^{13}C spectrum of **2** at 208 K showed splitting of the following resonances from the $[Tp^{Ph}]^-$ ligand: Pz C^3 (156.1 ppm at 298 K) into 154.1 (1C) + 153.3 (2C); Pz C^4 (104.7) into 104.2 (1C) + 104.7 (2C); Pz C^5 (140.0) into 137.9.2 (1C) + 138.3 (2C); Ph C^1 (133.4) into 132.9 (1C) + 130.3 (2C). These results strongly suggest that dissolution of **2** does not result in ligand disproportionation, and shows that the low temperature NMR structure of **2** contains a plane of symmetry through the $[Tp^{Ph}]^-$ ligand. This could either correspond to a static trigonal-bipyramidal geometry at zinc in solution, or to a fluxional process involving libration of coordinated L^1 within one 'wedge' defined by two of the $[Tp^{Ph}]^-$ pyrazole rings (Scheme 2). Given the irregular coordination geometry shown by **2** in the crystal, the latter scenario seems more likely.

The cyclic voltammogram (CV) of **1** in CH_2Cl_2/0.5 M $NBu^n_4PF_6$ at room temperature consists of an oxidation at $E_{pa} = +1.11$ V versus ferrocene/ferrocenium at a scan rate ν of 100 mV s^{-1}. This process is irreversible between $10 \leq \nu \leq 1000$ mV s^{-1} and has two associated daughter peaks: a weak irreversible reduction at $E_{pc} = 0.00$ V and a stronger *quasi*-reversible process at $E_{1/2} = -0.45$ V ($\Delta E_p = 150$ mV at 100 mV s^{-1}). An essentially identical CV was obtained in MeCN/0.1 M $NBu^n_4PF_6$, with no additional processes being observed (Fig. 2(a)). The CVs of **2** and **3** in CH_2Cl_2/0.5 M $NBu^n_4PF_6$ also exhibit an irreversible oxidation, at $E_{pa} = +1.00 \pm 0.01$ V. For both compounds this process becomes slightly *quasi*-reversible at higher scan rates, with I_{pc}:$I_{pa} \approx 0.15$ at $\nu = 1000$ mV s^{-1}. Weak daughter peaks associated with this oxidation were also observed at similar potentials to those exhibited by **1**, at $E_{pc} = -0.05$ V and

Scheme 2. Proposed fluxional process undergone by **2** in solution at low temperatures.

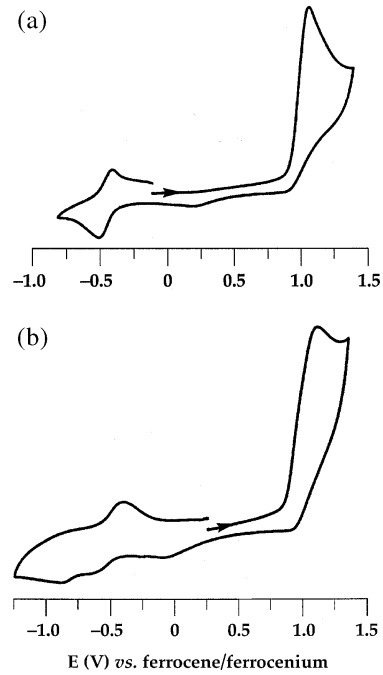

Fig. 2. Cyclic voltammograms in MeCN/0.1 M $NBu^n_4PF_6$ at 298 K with $\nu = 100$ mV s^{-1} of (a) **1** and (b) **2**.

$E_{1/2} = -0.50$ V. This suggests that **1** and **2** undergo the same EC processes at the anode. The CVs of **2** and **3** in MeCN have a similar form to those in CH_2Cl_2 (Fig. 2(b)), but with the following small differences: the initial oxidation occurs at the slightly higher potential of $E_{pa} = 1.10 \pm 0.02$ V; the daughter peaks are significantly more intense; and an additional daughter wave at $E_{pc} = -0.89$ V is also present. As expected, no electrochemical processes attributable to the zinc ion were detected within the solvent window for any of these compounds.

The irreversible oxidation exhibited by **1**–**3** can be assigned to the oxidation of each coordinated L^1 ligand to a $[L^{1\bullet}]^+$ radical cation [1,14,24]. From our previous work, the site of oxidation is the non-coordinated dimethoxyphenyl moiety on each ligand [1,2]. Interestingly, the CVs of free L^1, $[Cu(L^1)_2](BF_4)_2$ and $[Cu(L^1)(Tp^R)]BF_4$ (R = Ph, Tol, PhF) each exhibit no daughter products arising from decomposition of $[L^{1\bullet}]^+$ under these conditions [1], suggesting that the EC processes observed for **1**–**3** must be promoted by the zinc ion. Although precedent exists for 1,4-dialkoxybenzenes to undergo oxidative electropolymerisation under cer-

tain conditions [25], there was no evidence for polymer formation in the CVs of **1**–**3**. However, 1,4-dimethoxybenzyl radical cations are also known to be susceptible to nucleophilic attack at the 1- and 4-positions [26–28] following electrooxidation. In particular, a metal-promoted hydrolysis of electrooxidised 1,4-dimethoxy-2,5-di-*tert*-butylbenzene to 2,5-di-*tert*-butyl-1,4-benzoquinone has been reported [28]; a similar oxidative hydrolysis could conceivably take place for **1** owing to its lattice or ligated water content. However, the *quasi*-reversible daughter wave shown by **1** at -0.45 V is about 0.5 V more positive than that expected for a putative aryl-substituted benzoquinone EC product [29]. Hence, the nature of the EC reaction undergone by **1**–**3** is uncertain.

The irreversibility of the L^1-based oxidation shown by **2** and **3** contrasts with the behaviour of $[Cu(L^1)(Tp^R)]BF_4$ (R = Ph, Tol), which exhibit a chemically reversible ligand oxidation at $E_{1/2} = +0.97$ V [1]. This appears to support our proposition that the species $[Cu(L^{1\bullet+})(Tp^R)]^{2+}$ are kinetically stabilised by the presence of an intramolecular π–π stacking interaction [1,2], since in the crystal structure of **2** this π–π interaction is geometrically less favourable than in its copper-containing congener (see above). Additional investigations of this phenomenon using other metal/ligand systems are in progress, and will be reported in due course.

Supplementary data

The full crystallographic data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition number 134090.

Received 11 May 1999; accepted 10 November 1999

Abstract

A new generation of soluble metallophthalocyanine derivatives (**5a**, **5b**, **6a**, **6b**, **7b**, **8b** and **8b**·2KSCN) bearing four 14-membered [1,4,8,11] dioxadiaza macrocycles, 14-membered [1,4,8,11] diazadithia-macrocycles or 14-membered [1,4,8,11] diazadithia-macrocycles fused to a 15-membered crown-ether have been prepared by cyclotetramerization of the newly synthesized dicyano macrocycle (**3a**, **3b** and **4b**) in the presence of appropriate metal salts in non-aqueous solvents. The *N*-tosylated derivatives are extensively soluble in apolar solvents. The interaction of the alkaline metal salts with the crown-ether groups of the complex **8b** resulted in products of less solubility. Elemental analysis results and IR, UV–Vis, ^{1}H NMR, mass spectral data on the newly synthesized intermediates and all phthalocyanines are in accordance with the proposed structures. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Phthalocyanine complexes; Phthalonitrile derivatives; Crown-ether; Copper; Nickel; Cobalt; Alkaline metal extraction

1. Introduction

Phthalocyanines and metallophthalocyanines, commonly used for many years as dyes and catalysts, have recently undergone an enormous renaissance [1–3]. Over the last 20 years or so, a new generation of phthalocyanine derivatives with purpose-designed substitution patterns has been developed [4–9]. Thanks to the development of the methodology of synthesis during the last two decades, these compounds and many of their derivatives exhibit properties that are interesting for many potential technical applications in a variety of new high technology fields such as semiconductor devices, molecular electronics, electrochromic display devices, photovoltaic and solar cells, gas sensors, synthetic metals, liquid crystals, non-linear optics, optical disks, electrophotography, and photodynamic cancer therapy [1,2,10,11]. The rich coordination chemistry of phthalocyanine complexes has encouraged researchers to 'tailor' specific products with certain properties which are required for high technology applications. The two variables are the central metal ion and peripheral substituents: when the possibility of inserting a great number of different metal ions into the phthalocyanine core is combined with the unlimited number and type of substituents, the variety of novel products is infinite. The introduction of bulky substituents on the peripheral position of the macrocycle increases drastically their solubility in organic solvents. In addition to solubility, the spectral and electrochemical properties of phthalocyanines are also strongly influenced by the peripheral substituents on the macrocycles [12–15].

Our work has been heavily engaged in the synthesis of new phthalocyanines with various functional groups and/or macrocycles. Among these we may cite the N-, O- and S-containing functionalities such as crown ethers [16–20], monoaza [21], tetraaza, tetrathia [22,23], diazatrioxa [24], tetraaza double layer and some homo- and heteropentanuclear complexes [8,20,24–26]. In all these macrocycle-substituted phthalocyanines so far, the starting point is 4,5-bis(bromomethyl)-1,2-dibromobenzene or 4,5-dichlorophthalonitrile which has been substituted with O- and S-nucleophiles through base-catalyzed nucleophilic aromatic displacement [16,27].

In the present work, as a further part of our previous studies on phthalocyanines with multifunctional substituents, starting from 4,5-bis(2′-aminophenoxy)-1,2-dicyanobenzene and 4,5-bis(2′-aminophenolsulfanyl)-1,2-dicyanobenzene (**1a** and **1b**), we report here for the first time a generalizable procedure for the preparation and characterization of a benzo-fused 14-membered dioxadiaza macrocycle, 14-membered

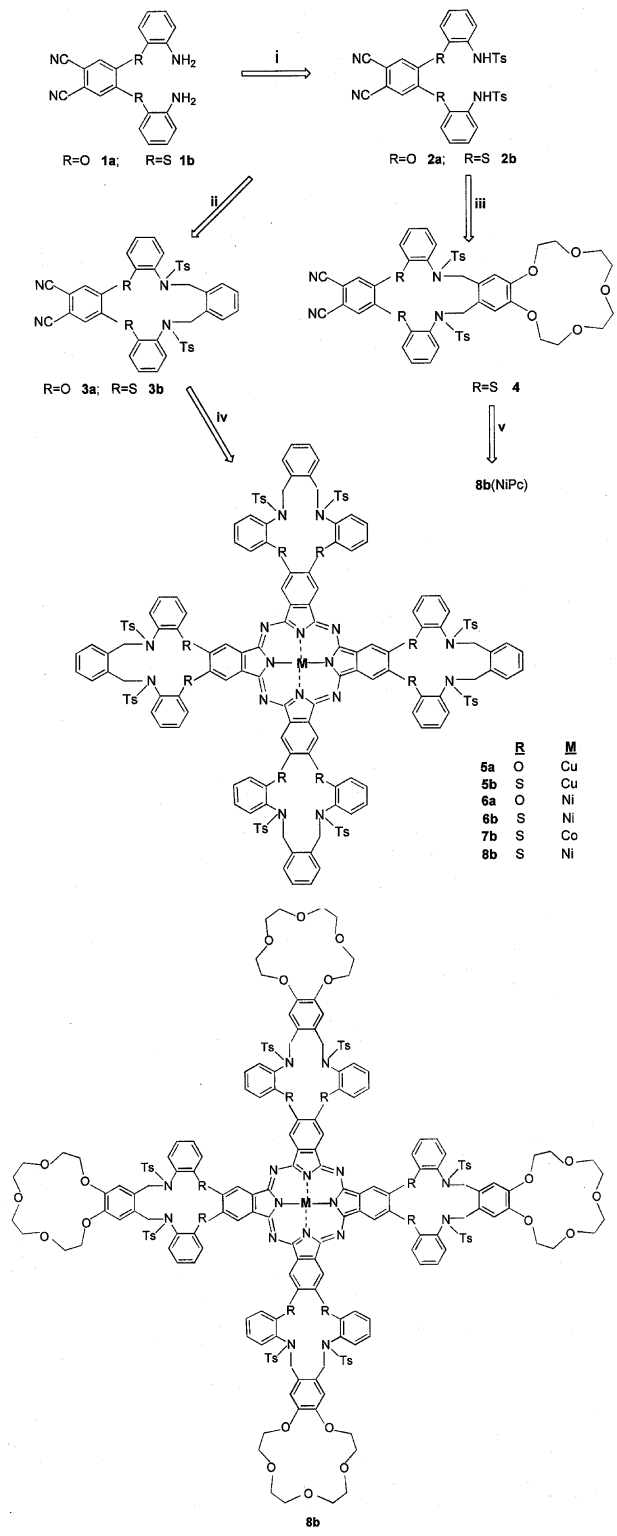
diazadithia macrocycle or 14-membered diazadithia macrocycle fused to a crown-ether, and metal phthalocyanines (Cu, Ni, Co) derived from these macrocycles. In this way, we introduce new derivatives carrying four N_2S_2 or N_2O_2 macrocycles on the periphery [8,27].

2. Experimental



FTIR (KBr) spectra were measured on an ATI-Unicom-Mattson 1000 spectrometer using KBr pellets. Elemental analyses (C, H and N) were carried out at the instrumental analysis laboratory of Tubitak Gebze Research Center. ^{1}H NMR spectra were recorded on a Bruker 200 MHz spectrometer using $CDCl_3$ and DMSO-d_6 (99.9%). Mass spectra (EI and FAB) were measured on a VG-Zubspec GS-MS spectrometer. The metal contents of some complexes were determined with a Hitachi 180-80 atomic absorption spectrometer in solution prepared by decomposition of the compounds in conc. HCl and conc. HNO_3 (3:1) solution followed by dilution in water. The homogeneity of the products was tested at each step by TLC (SiO_2–chloroform, $CHCl_3$:MeOH).

2.1. Materials and synthesis

4,5-Dichloro-1,2-benzendicarboxylic acid was purchased from Aldrich Chemical Co. and used as received. 4,5-Dichloro-1,2-dicyanobenzene was synthesized according to reported procedures [8,27] by a multistep reaction sequence; yield 75%, m.p. 182°C. 4′,5′-bis(chloromethyl)(benzo-15-crown-5) was prepared from benzo-15-crown-5 and *p*-formaldehyde in the presence of conc. HCl by the reported procedure [26]; yield 88%, m.p. 146–148°C. As a multifunctional ligand, 4,5-bis(2′-aminophenoxy)-1,2-dicyanobenzene and 4,5-bis(2′-aminophenolsulfanyl)-1,2-dicyanobenzene (**1a** and **1b**) were synthesized starting from 2-aminophenol, 2-aminothiophenol and 4,5-dichloro-1,2-dicyanobenzene with maximum caution via base-catalyzed nucleophilic aromatic displacement of 4,5-dichloro-1,2-dicyanobenzene with O- and S-nucleophiles, respectively [8,27] (Scheme 1); yield 73%; for **1b** the yield was rather low (20%). Owing to instability of the amines **1a** and **1b**, all the preparations described below require the use of freshly prepared and purified samples of these ligands.

*2.2. 4,5-bis(2′-p-tolylsulfanylaminophenoxy)-1,2-dicyanobenzene (**2a**)*

4,5-bis(2′-aminophenoxy)-1,2-dicyanobenzene (**1a**), (0.1 g, 0.32 mmol) was dissolved in dry pyridine (7 ml) under nitrogen and powdered toluene-*p*-sulfonylchloride (0.14 g, 0.75 mmol) was added portionwise over 0.5 h to the stirred and ice-salt-cooled solution at −10°C. Stirring and cooling of the reaction mixture was continued for 1.5 h at −10°C, then the mixture was stirred at room temperature overnight. The solution was poured slowly on ice (100 g)

Scheme 1. (i) *p*-toluenesulfanylchloride, pyridine, −10°C; (ii) K_2CO_3, DMF, 1,2-bis(bromomethyl)benzene; (iii) K_2CO_3, DMF, 4′,5′-bis(chloromethyl)[benzo-15-crown-5], 35°C; (iv) quinoline, ethylene glycol in the presence of anhydrous $CuCl_2$, $NiCl_2$, $CoCl_2$; (v) quinoline, anhydrous $NiCl_2$.

and diluted with water (100 ml). The precipitated ditosylate was filtered off and washed with water (100 ml) until neutral, then with cold ethanol and diethyl ether. The creamy colored

ditosylate was crystallized from ethanol and chromatographed (silica gel, chloroform). Recrystallization from EtOH (20 ml) gave the pure ditosylate. This compound is soluble in chloroform, dichloromethane, THF, DMSO, DMF and pyridine. Yield of **2a** 0.05 g (22%); m.p. 182°C. *Anal*. Calc. for $C_{34}H_{26}N_4O_6S_2$: C, 62.76; H, 4.00; N, 8.61. Found: C, 62.35; H, 3.99; N, 8.20%. IR (KBr, cm^{-1}): ν 3250 (–NH), 3060 (Ar, C–H), 2950–2840 (aliph, –CH), 2220 (–C=N), 1590 (N–H bending), 1490, 1340–1150 (SO_2), 1280, 1260, 1120, 980, 830, 700, 670, 575, 510. ^{1}H NMR (200 MHz, DMSO-d_6, ppm): δ 10.2 (s, 2H, aromatic N–H), 7.9 (s, 2H, Ar–H), 6.6–7.6 (m, 16H, Ar–H), 2.3 (s, 6H, CH_3). EI MS *m/z* 649.1 $[M^+ - 1]$.

*2.3. 4,5-bis(2′-p-tolylsulfanylaminothiophenoxy)-1,2-dicyanobenzene (**2b**)*

4,5-bis(2′-aminophenolsulfanyl)-1,2-dicyanobenzene (**1b**) (1 g, 2.67 mmol) was dissolved in dry pyridine (10 ml) under nitrogen at −10°C in the presence of cold-salt-ice bath. Powdered toluene-*p*-sulfonylchloride (1.12 g, 5.94 mmol) was added portionwise to the stirred and ice-cold solution over a period of 1.5 h at a rate such that the temperature of salt and reaction mixture never exceeded 0°C. Stirring and cooling was continued for 3 h at −10°C then the mixture was stirred at room temperature overnight. After 16 h at room temperature, the reaction mixture was poured over crushed ice (200 g). The precipitated ditosylate was filtered off and washed with water until neutral (100 ml) or free of any pyridine residue, and with cold ethanol and diethyl ether. Recrystallization from EtOH (30 ml) gave the pure ditosylate. This compound is soluble in chloroform, dichloromethane, THF, DMSO, DMF and pyridine. Yield of **2b** 1.4 g (76.87%); m.p. 267°C. *Anal*. Calc. for $C_{34}H_{26}N_4O_4S_4$: C, 59.82; H, 3.81; N, 8.21. Found: C, 59.55; H, 3.70; N, 7.95%. IR (KBr, cm^{-1}): ν 3250, 3020, 2950–2840, 2200, 1600, 1480, 1370, 1250, 1150, 1100, 970, 810, 790, 610, 500. ^{1}H NMR (200 MHz, DMSO-d_6): δ 10.1 (s, 2H, Ar–NH), 7.6 (s, 2H, Ar–H), 6.7–7.5 (m, 16H, Ar–H), 2.25 (s, 6H, Ar–CH_3). EI MS *m/z* 682 (54) $[M^+]$.

*2.4. Diazadithia macrocycle (**3a**) and dioxadiaza macrocycle (**3b**)*

Compound **2a** (0.15 g, 0.23 mmol) or compound **2b** (0.157 g, 0.23 mmol) was dissolved in dry DMF (10 ml) under nitrogen containing finely ground anhydrous excess K_2CO_3 (0.067 g, 0.048 mmol) for **2a** and (0.070 g, 0.51 mmol) for **2b** and the mixtures were stirred for 1 h at 30°C. A solution of 1,2-bis(bromomethyl)benzene 0.061 g (0.23 mmol) for **2a** and 0.061 g (0.23 mmol) for **2b** in dry DMF (10 ml) was added dropwise over 0.5 h and the mixture was stirred at the same temperature for 48 h. It was then poured on ice-water (100 g) and stirred for 20 min. The precipitate was filtered off, washed successively with water until the filtrate was neutral, then with cold ethanol, diethyl ether and dried in vacuo. Recrystallization from toluene + EtOH gave a creamy colored product. This compound was soluble in chloroform, dichloromethane, DMF, DMSO. Yield of compound **3a** 0.08 g (46.25%); m.p. 167°C. *Anal*. Calc. for $C_{42}H_{32}N_4O_6S_2$: C, 67.02; H, 4.25; N, 7.44. Found: C, 66.87; H, 4.33; N, 7.39%. IR (KBr, cm^{-1}): ν 3040 (–Ar–CH), 2925 (aliph–CH), 2200 (–C=N), 1370–1150 (SO_2), 1260, 1050, 950, 760, 670, 500. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.70–6.73 (m, 22H, tosyl Ar–H and Ar–H), 4.50 (s, 4H, CH_2–N), 2.40 (s, 6H, Ar–CH_3). EI MS (70 eV) *m/e* (%) 751 (27) $[M^+ - 1]$. Yield of compound **3b** 0.11 g (61.08%); m.p. 180°C. *Anal*. Calc. for $C_{42}H_{32}N_4O_4S_4$: C, 64.29; H, 4.08; N, 7.14. Found: C, 63.87; H, 4.12; N, 6.95%. IR (KBr, cm^{-1}): ν 3060 (Ar, –CH), 2930 (aliph–CH), 2210 (–C=N), 1350–1150 (SO_2), 1210 (R–S–R), 1070, 840, 550, 490. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.50–6.40 (m, 22H, tosyl Ar–H and Ar–H), 4.32 (s, 4H, Ar–CH_2–N), 2.35 (s, 6H, Ar–CH_3). EI MS (70 eV) *m/z* (%) 784 (28) $[M^+]$.

*2.5. Bicyclic dicyano compound **4***

Compound **2b** (0.1 g, 0.15 mmol) was dissolved in dry DMF (10 ml) containing finely ground anhydrous K_2CO_3 excess (0.044 g, 0.32 mmol) and stirred under nitrogen at 35°C for 1 h. A solution of 4,5-bis(chloromethyl)[benzo-15-crown-5] (0.08 g, 0.29 mmol) in dry DMF (7 ml) was added dropwise over 2 h and the mixture was stirred at the same temperature (35–40°C) for 60 h. The reaction mixture was then poured onto ice-water (100 g) and stirred for 1 h. The precipitate was filtered off, washed successively with water until the filtrate was neutral, then washed with ethanol, diethyl ether and dried in vacuo. Recrystallization from EtOH (10 ml) gave the pure bicyclic dicyano compound. This compound is soluble in chloroform, dichloromethane, DMSO and DMF. Yield of **4** 0.02 g (14.06%); m.p. 197°C. *Anal*. Calc. for $C_{50}H_{46}N_4O_5S_4$: C, 61.60; H, 4.72; N, 5.75. Found: C, 61.10; H, 4.32; N, 5.65%. IR (KBr, cm^{-1}): ν 3020 (Ar–CH), 2920 (aliph, C–H), 2220, 1480, 1370–1150 (SO_2), 1210 (R–S–R), 1100, 950, 840, 700, 660, 550. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.74–7.62 (s, 8H, tosyl Ar–H), 7.86 (s, 2H, Ar–H), 6.64 (s, 2H, –CH_2), 4.25 (s, 4H, Ar–CH_2–N), 2.40 (s, 6H, Ar–CH_3), EI MS (70 eV) *m/e* (%) 974 (15) $[M^+]$.

*2.6. [Octakis(N-p-tosyl)tetrakis(macrocycle)phthalocyaninato]copper(II) (**5a** and **5b**)*

A mixture of **3a** (0.1 g, 0.13 mmol), **3b** (0.1 g, 0.13 mmol), anhydrous $CuCl_2$ (~0.0033 g, 0.033 mmol) and TMU or quinoline (0.3 ml) was heated and stirred at 100°C in a sealed tube for 5 h under nitrogen. After cooling to room temperature, the dark green mixture was diluted with EtOH (15 ml) and crude product was precipitated. It was filtered off and washed with the solvent to remove the unreacted organic impurities. The procedure was repeated three times. The dark greenish-blue powders (**5a** and **5b**) were then iso-

lated by silica gel column chromatography with chloroform. These compounds are soluble in chloroform, dichloromethane, DMSO, DMF and quinoline. Yield of **5a** 0.010 g (9.57%); m.p. > 200°C. *Anal*. Calc. for $C_{168}H_{128}N_{16}O_{24}S_8Cu$: C, 65.63; H, 4.16; N, 7.29. Found: C, 65.19; H, 3.94; N, 6.86%. IR (KBr, cm^{-1}) ν 3060 (Ar, C–H), 2930 (aliph, C–H), 1600, 1490, 1370–1160 (SO_2), 1250 (R–O–R), 1050, 875, 780, 590, 500. FAB$^+$ MS *m/z* 3074.5 [$(M+H)^+$]. Yield of **5b** 0.016 g (15.60%); m.p. > 200°C. *Anal*. Calc. for $C_{168}H_{128}N_{16}O_{16}S_{16}Cu$: C, 63.00; H, 4.03; N, 6.99. Found: C, 62.70; H, 4.00; N, 6.84%. FAB$^+$ MS (matrix: trifluoroaceticacid-glycerine) *m/z* 3199.5 [M^+].

*2.7. [Octakis(N-p-tosyl)tetrakis(macrocycle)phthalocyaninato]nickel(II) (**6a** and **6b**)*

A mixture of **3a** (0.1 g, 0.13 mmol), **3b** (0.1 g, 13 mol), anhydrous $NiCl_2$ (0.0050 g, 0.038 mmol) and quinoline (0.5 ml) was heated and stirred at 190°C for 6 h in a sealed glass tube under nitrogen. After cooling to room temperature, the dark blue mixture was diluted with ethanol (5 ml) until the crude product precipitated and the product was filtered off and washed with the same solvent hot. The dark green metallophthalocyanine was isolated on a silica gel column with $CHCl_3$ as the eluent. The products were soluble in chloroform, dichloromethane, DMSO, DMF, quinoline and THF. Yield of **6a** 0.015 g (14.10%); m.p. > 200°C. *Anal*. Calc. for $C_{168}H_{128}N_{16}O_{24}S_8Ni$: C, 65.75; H, 4.17; N, 7.30. Found: C, 65.23; H, 4.34; N, 7.00%. IR (KBr, cm^{-1}): ν 3050–2940 (Ar, C–H, aliph, C–H), 1600, 1470, 1450, 1360 (SO_2), 1240 (R–O–R), 1170 (SO_2), 1070, 990, 790, 600, 510. ^{1}H NMR (200 MHz, DMSO-d_6): δ 7.97–6.95 (m, 88H, tosyl Ar–H and Ar–H), 4.45 (s, 16H, Ar–CH_2–N), 2.43 (s, 24H, Ar–CH_3). FAB$^+$ MS *m/z* 3066 [M^+]. Yield of compound **6b** 0.020 g (18.8%); m.p. > 200°C. *Anal*. Calc. for $C_{168}H_{128}N_{16}O_{16}S_{16}Ni$: C, 63.11; H, 4.00; N, 7.01. Found: C, 62.82; H, 3.91; N, 6.86%. IR (KBr, cm^{-1}): ν 3040 (Ar, C–H), 2930 (aliph, C–H), 1600, 1450, 1370 (SO_2), 1230 (R–S–R), 1150 (SO_2), 1060, 880, 750, 610, 500. ^{1}H NMR (200 MHz, DMSO-d_6): δ 7.78–6.73 (m, 88H, tosyl Ar–H and Ar–H), 4.30 (s, 16H, Ar–CH_2–N), 2.36 (s, 24H, Ar–CH_3). FAB$^+$ MS *m/z* 3194 [$(M^+ + H)^+$].

*2.8. [Octakis(N-p-tosyl)tetrakis(macrocycle)phthalocyaninato]cobalt(II) (**7b**)*

A mixture of dicyano compound **3b** (0.15 g, 19 mmol), anhydrous $CoCl_2$ (0.0069 g, 0.054 mmol), and anhydrous ethylene glycol (4 ml) was heated and stirred at 200°C for 10 h under nitrogen in a round-bottom flask. After cooling to room temperature the reaction mixture was treated with EtOH (10 ml) and water to precipitate the dark green product, and then with EtOH to remove the unreacted organic materials. The blue-greenish powder was dissolved in chloroform (10 ml) and the solution filtered. The product was purified by column chromatography with silica gel (chloroform as the eluent). This product is soluble in chloroform, dichloromethane, THF, DMSO, DMF and quinoline. Yield 0.011 g (7.19%); m.p. > 200°C. *Anal*. Calc. for $C_{168}H_{128}N_{16}O_{16}S_{16}Co$: C, 63.08; H, 4.00; N, 7.01. Found: C, 62.93; H, 3.93; N, 6.86%. IR (KBr, cm^{-1}): ν 3040 (Ar, C–H), 2930 (aliph, C–H), 1600, 1490, 1460, 1400, 1350 (SO_2), 1240 (R–S–R), 1150 (SO_2), 1120, 1100, 860, 750, 690, 600, 510.

*2.9. Two-fold macrocycle substituted nickel(II) phthalocyanine (**8b**)*

A mixture of **4** (0.1 g, 0.10 mmol), anhydrous $NiCl_2$ (0.037 g, 0.030 mmol) and anhydrous quinoline (0.4 ml) in a sealed tube was heated and stirred at 195°C for 5 h under nitrogen. After cooling to room temperature, it was treated with ethanol (5 ml), the product was filtered off and washed with the same solvent hot, then with ethyl acetate, acetone and diethyl ether to remove unreacted organic materials. The product was dissolved in $CHCl_3$ (10 ml) and to the solution was added dropwise successively warm ethanol, ethyl acetate and acetone. The procedure was repeated several times to purify two-fold nickel(II) phthalocyanine. Finally, this product was purified by column chromatography with silica gel (chloroform as eluent); yield 0.010 g (9.87%); m.p. > 200°C. *Anal*. Calc. for $C_{200}H_{184}N_{16}S_{16}O_{36}Ni$: C, 60.69; H, 4.65; N, 5.66. Found: C, 60.01; H, 4.53; N, 5.44%. IR (KBr, cm^{-1}): ν 3020 (Ar, C–H), 2920 (aliph, C–H), 1600, 1590, 1350 (SO_2), 1260 (R–S–R), 1150 (SO_2), 1060, 970, 830, 690. ^{1}H NMR (200 MHz, DMSO-d_6): δ 7.91–6.61 (m, 22H, tosyl Ar–H and Ar–H), 4.62–3.54 (m, 80H, CH_2 of aryl, CH_2–O, CH_2–N), 2.38 (s, 24H, Ar–CH_3).

*2.10. Synthesis of the adduct of alkali metal salt with [ML] (**8b**·KSCN)*

To a stirred solution of the nickel phthalocyanine **8b** (0.07 g, 0.000018 mmol) dissolved in chloroform (20 ml) was added a solution of the desired alkali metal salt KSCN (0.0082 g, 0.000085 mmol, 10% in excess) in ethanol (5 ml) and the mixture was heated at 50°C for 8 h, then cooled to room temperature. The compound was filtered off, then it was washed successively with chloroform, ether and dried under vacuum. Yield 0.042 g (60%); m.p. > 200°C. *Anal*. Calc. for **8b**·2KSCN: C, 58.15; H, 4.41; N, 6.04. Found: C, 58.10; H, 4.17; N, 5.92%. IR (KBr, cm^{-1}): ν 3060, 3030 (Ar–CH), 2970, 2910 (aliph, CH), 2050 (KSCN), 1620, 1580, 1370 (SO_2), 1260 (R–S–R), 1150 (SO_2), 1120–1100 (C–O–C), 1040, 970, 790, 550.

3. Results and discussion

As in the case of most of the other substituted phthalocyanines, a rational method for the synthesis of this type

of compound is to start with the 4,5-dibromo-1,2-bis(bromomethyl)benzene and 4,5-dichloro-1,2-dicyano derivative of the corresponding macrocycle compound. To overcome difficulties such as low yields in the conversion from the dibromo derivatives by a Rosenmund von Broun reaction into dicarbonitrile and in order not to obtain other phthalocyanines except CuPc, new macrocycles were designed directly by the phthalonitrile unit from the beginning [8,25,27].

Recently, 1,2-dichloro-4,5-dicyanobenzene was used to prepare 4,5-disubstituted phthalonitrile derivatives, such as 4,5-bis(2′-aminophenoxy)-1,2-dicyanobenzene and 4,5-bis(2′-aminophenolsulfanyl)-1,2-dicyanobenzene (**1a** and **1b**) through base-catalyzed nucleophilic aromatic displacement [8,27].

The aromatic amine groups of 4,5-disubstituted-1,2-dicyanobenzene were then tosylated in pyridine at −10°C with *p*-toluenesulfonylchloride to protect amino groups and to make use of the high reactivity of tosylamides in further cyclization reactions. Under weak carbonate base conditions, 1,2-bis(bromomethyl)benzene reacts with the 1,2-bis(2′-*p*-tolylsulfanylaminophenoxy)-1,2-dicyanobenzene (**2a**) or 1,2-bis(2′-*p*-tolylsulfanylaminothiophenoxy)-1,2-dicyanobenzene (**2b**) to form the 14-membered dioxadiaza or 14-membered diazadithia macrocycles **3a** and **3b**. On the other hand, 4,5-bis(chloromethyl)benzo-15-crown-5 reacts with the 1,2-bis(2′-*p*-tolylsulfanylaminothiophenoxy)-1,2-dicyanobenzene in DMF at 35°C to form crown-ether fused 14-membered [1,2,8,11] diazadithia macrocycle (bicyclic compounds) (**4**). The yield in ring-closure reaction between two bifunctional reactants is relatively low (14%).

Compounds **3a**, **3b** and **4** were converted into desired metal phthalocyaninates **5a**, **5b**, **6a**, **6b**, **7b**, **8b** by using anhydrous metal salts ($CuCl_2$, $NiCl_2$, $CoCl_2$) in the presence of anhydrous solvents with high boiling points (e.g. quinoline or ethylene glycol) [1,28–30]. The yields of these reactions were rather low depending on the metal ions, as encountered for phthalocyanines with other bulky groups [15,26].

The most characteristic feature of complexes **5a**, **5b**, **6a**, **6b**, **7b** and **8b** is their high solubility in common organic solvents, e.g. chloroform, dichloromethane, dimethylformamide, dimethylsulfoxide. The two-fold substitution in **8b** results in a more bulky group on the periphery, so the solubility is higher than for the other phthalocyanines [15,19,24–26]. The crude dark-green cyclotetramerization products required final column chromatography with silica gel for purification. All attempts at detosylation of phthalocyanines to form pentanuclear phthalocyanine complexes in conc. sulfuric acid at 125°C for 5 h failed owing to decomposition of the phthalocyanines [23–25].

The interaction of the alkali metal salts with crown-ether groups of complex **8b** results in less solubility. The alkali metal binding ability of **8b**, having four crown-ether units, was estimated by solvent extraction of alkali metal picrates. Highest affinity was observed for K^+ amongst alkali metal cations. The stoichiometry of the complex isolated from a mixture of **8b** and KSCN was also found to be 1:2 [15,16,19].

Elemental analysis results and the spectral data (^{1}H NMR, UV–Vis, IR, MS) of all the new products are consistent with the assigned formulations.

In the IR spectra of **1a** and **1b**, the intense absorption bands at 2220 and 3460–3340 cm^{-1} for **1a** and 2200, 3450–3350 cm^{-1} for **1b**, respectively, corresponding to the $–NH_2$ groups, disappear after the conversion to the tosylamino compounds. The rest of the spectra of **1a** and **1b** resembles closely that of **2a** and **2b** including the characteristic vibrations of aromatic –CH, ethers (R–O–R), (R–S–R), –CN and other groups. On formation of 14-membered macrocycle and 14-membered crown-ether fused bicyclic compounds, the peaks related to tosylamino groups in **2a** and **2b** at 3350 and 1150 disappear and aliphatic peaks of macrocycles appear. In the case of crown-ether substituted 14-membered macrocycles, the extra aliphatic peaks coming from crown-ether appear in the finger-trace region. A diagnostic feature of the formation of phthalocyanines from cyano derivatives **3a**, **3b** and **4** is the disappearance of sharp intense –CN vibration bands at 2220 cm^{-1} of the reactants in the IR spectrum. The same similarities in the IR spectrum of the ligands (**3a**, **3b** except **4**) were seen in the IR spectrum of the phthalocyanines attached to the same macrocycle moieties, except **8b** for which were seen additional aliphatic, aromatic and etheric peaks (CH_2–O–). Upon the complexation of **8b** with alkali metal, vibration of the SCN^- counter anion in the case of **8b**·KSCN appears at 2050 cm^{-1}.

^{1}H NMR spectra of **2a**, **2b** and **3a**, **3b** are almost identical, with only small changes in shifts. With the addition of D_2O in **2a** and **2b**, the chemical shifts of tosylamide from about 5 to 10 ppm peaks disappear after deuterium exchange. The difference between the two spectra of tosylated amino and free amino groups **1a**, **1b** and **2a**, **2b** is clear from the presence of sulfonamide bands in **2a**, **2b** and **4** at 10.2, 10.1 ppm, respectively. In addition to aromatic protons in diazadithia, dioxadiaza or crown-ether bicyclic compounds **3a**, **3b**, **4**, $–CH_2N$ in **3a**, **3b** and the etheral protons ($–CH_2O$) of crown-ether in **4** appear at 4.50, 4.32, 4.25 ppm, respectively. ^{1}H NMR spectra of phthalocyanines **6a**, **6b**, **8b** show very small downfield shifts when compared to spectra of dinitrile starting materials **3a**, **3b**, **4**. ^{1}H NMR measurements were precluded owing to the paramagnetic nature of the copper(II) phthalocyanines **5a**, **5b** and cobalt(II) phthalocyanine **7b** [1]. ^{1}H NMR spectra of phthalocyanines **6a**, **6b** and **8b** are rather broad, owing probably to the aggregation of phthalocyanine which is frequently encountered at the concentrations used for NMR [1]. The signals for the tosyl aromatic and aromatic protons of the phthalocyanine core in **6a**, **6b** and **8b** appear as expected at 7.97–6.95, 7.78–6.73, 7.91–6.61 ppm, respectively as multiplets, and those for the tosyl aromatic and aromatic protons of the macrocycle dicyano starting materials **3a**, **3b**, **4** appear at 7.70–6.73, 7.50–6.40, 7.74–7.62 ppm respectively as multiplets. Phthalocyanines containing 14-membered dioxadiaza, diazadithia, crown-ether fused-

diazadithia macrocycles show typical electronic spectra with two absorption regions at 600–700 and 300–350 nm as Q and B bands. The UV–Vis spectra of the phthalocyanines **5a**, **5b**, **6a**, **6b**, **7b**, **8b** in chloroform and **8b**·KSCN in DMSO show Q-band absorption at 683, 694, 673, 684, 690, 674, 677 nm and B-band absorption at 343, 327, 342, 335, 330, 342, 343 nm (Table 1 and Fig. 1). These values are consistent with the results obtained previously for similar phthalocyanines [16,24,25]. An increase in the concentration leads to aggregation which is easily monitored by the position of the Q-band which is shifted to shorter wavelengths, and to a decrease in molar absorption coefficient [15–26]. In order to test the effect of the central metal ion on the changes in the Q-band, the spectra of all phthalocyanines **5**–**8** in apolar solvents have been carefully investigated (Table 1) [12–26]. The obvious effect of alkali metal ions complexed in the crown-ether groups on the Q-band transition of the phthalocyanine unit should be appreciated. Compared with the spectrum of **8b**·KSCN in DMSO, the shoulder around 648 nm is present to a lesser extent but shows no appreciable change with concentration [15–26].

A close investigation of the mass spectra of phthalonitrile derivatives **2a**, **2b**, **3a**, **3b**, **4** and phthalocyanines **5a**, **5b**, **6a**, **6b** confirmed the proposed structures. The mass spectra of **5a**, **5b**, **6a**, **6b** were obtained by the FAB technique using matrix (matrix: trifluoroaceticacid–glycerine) in the region of molecular ion peaks [M^+] *m/z* 3074.5 [$(M+H)^+$], *m/z* 3199.5 [M^+], *m/z* 3066 [M^+], *m/z* 3194 [$(M+H)^+$] with the other various mass fragments (especially [M^+–tosyl], [M^+–2tosyl], [M^+–3tosyl], [M^+–4tosyl] and the others). The mass spectra results obtained from **1a** and **1b** are interpreted in our previous paper [8].

Table 1
Electronic spectral data for the phthalocyanine complexes in chloroform

Compound	λ_{max} (nm) ($10^{-4}\varepsilon$ ($dm^3\ mol^{-1}\ cm^{-1}$))			
5a [a]	683 (14.7)	620 (4.0)	602 (3.2)	343 (14.5)
5b [a]	694 (12.5)	652 (3.2)	626 (3.1)	327 (7.1)

4. Conclusions

We have presented new dicyano starting materials (ligands) and their conversion to metallophthalocyanines that are soluble in a number of solvents. We have extended the range of reactions further than in former works. We succeeded in alkali-metal binding to the endocyclic cavity of crown-ethers by alkali metal ions, causing distinct changes in the UV–Vis spectrum compared with those of the diazadithia macrocycle substituted compounds. Among the alkaline metal cations, the highest affinity was observed for K^+ which can be attributed to sandwich-type adduct formation between 15-crown-5 units and the cation. The approach described here allows the preparation of a wide number of novel penta and nona nuclear complexes whose properties will be the subject of future reports.

Observations concerning the constitution of some 'rhodium(II) dithiocarbamato complexes'

George Exarchos, Stephen D. Robinson *

Department of Chemistry, King's College London, Strand, London WC2R 2LS, UK

Received 13 August 1999; accepted 18 October 1999

Abstract

Mononuclear rhodium(II) dithiocarbamato complexes 'Rh(S_2CNR_2)$_2$(PPh_3)' and 'Rh(S_2CNR_2)$_2$', (R = Me, Et) have been shown to be mixtures of various rhodium(III) dithiocarbamato complexes. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Rhodium(II); Dithiocarbamates

1. Introduction

The coordination chemistry of rhodium(II) is dominated by the numerous diamagnetic binuclear rhodium(II/II) complexes with the now familiar quadruple bridged 'lantern' structure [1,2]. Examples of mononuclear paramagnetic rhodium(II) complexes are known but remain relatively rare [3,4]. The latter are purported to include two pairs of dithiocarbamato derivatives, 'Rh(S_2CNR_2)$_2$(PPh_3)' and 'Rh(S_2CNR_2)$_2$', (R = Me, Et), obtained from the reactions of $RhCl_2(NO)(PPh_3)_2$ with the appropriate sodium dithiocarbamate salt in cold and refluxing benzene respectively [5]. Although the reactions apparently involved the reduction of rhodium(III), no mention was made of precautions to exclude air. In connection with our current work on bis(dithiocarbamato) complexes of bivalent metals [6], we sought to repeat these syntheses with a view to investigating further the chemistry of the rhodium(II) products and, hopefully, developing a parallel route to analogous iridium complexes Ir(S_2CNR_2)$_2$ containing that metal in the rare bivalent state. Unfortunately, we have been unable to confirm the formation of the reported rhodium(II) dithiocarbamato complexes. Instead only rhodium(III) species, notably the simple tris(chelate) species Rh(S_2CNR_2)$_3$, could be detected.

2. Experimental

2.1. Attempted preparation of the complexes 'Rh(S_2CNR_2)$_2$(PPh_3)' (R = Me, Et)

The preparations were conducted as reported in the original paper [5], using the prescribed ratio of rhodium complex to sodium dithiocarbamate salt, and were then repeated using stoichiometric amounts (1:2 ratio). The reactions were also repeated using (a) a reaction time of 72 h in place of 6 h, and (b) acetone as solvent in place of benzene. In each case the prescribed work-up procedure was followed and products identical in appearance to those described in the original paper were obtained.

2.2. Reaction of $RhBr_2(NO)(PPh_3)_2$ with NaS_2CNEt_2

Stoichiometric amounts of $RhBr_2(NO)(PPh_3)_2$ and NaS_2CNEt_2 (1:2 ratio) were stirred together in cold benzene for 72 h, and the mixture then filtered and worked up in the prescribed manner.

2.3. Attempted preparation of the complexes 'Rh(S_2CNR_2)$_2$' (R = Me, Et)

The reactions were conducted as reported in the original paper [5] and gave orange crystalline products identical in appearance to those previously described.

3. Results and discussion

The original report on the synthesis of adducts $Rh(S_2CNR_2)_2(PPh_3)$ in cold benzene specified, either by error or by design, the use of a stoichiometric deficiency of dithiocarbamate salt. The syntheses were therefore attempted using the prescribed quantities of reagents and repeated using stoichiometric amounts. In each case the reagents failed to react or even dissolve to any appreciable extent within the allotted 6 h period of stirring. The reaction times were therefore extended to 72 h, and the mixtures filtered prior to work-up in the prescribed manner. In an attempt to overcome the solubility problem, the reactions were also repeated using cold acetone as solvent. Yellow products, similar in appearance to those described in the original paper [5], were obtained in each case. However, the $^{31}P\{^1H\}$ NMR spectra of the products showed none of the paramagnetic shifts or line broadening effects expected for mononuclear rhodium(II) species. Instead they displayed an array of sharp doublets ($^1J_{Rh-P}$ ca. 80–120 Hz) characteristic of rhodium(III) triphenylphosphine species [7,8], together with singlets at δ 29.90 and 44.05 attributable to Ph_3PO and Ph_3PS respectively. In addition, proton NMR spectra reveal the presence of significant amounts of the tris(dithiocarbamato) complexes $Rh(S_2CNR_2)_3$, particularly when the higher amounts of dithiocarbamate salt were employed. Thus the characteristic pattern arising from the diastereotopic methylene protons of $Rh(S_2CNEt_2)_3$ is clearly visible in the spectrum of the diethyldithiocarbamate reaction products.

In an attempt to identify the various rhodium(III) triphenylphosphine intermediates present in these reaction mixtures, a parallel series of reactions involving the corresponding bromo complex, $RhBr_2(NO)(PPh_3)_2$, was undertaken. Two doublets (δ 34.23, $^1J_{Rh-P}$ 115 Hz and δ 33.18, $^1J_{Rh-P}$ 119.5 Hz) common to both series are attributed to halide free intermediates. However, we have not been able to make definitive assignments for these resonances or for the further five doublets seen in the spectra recorded for the products of the various $RhCl_2(NO)(PPh_3)_2$ based reactions.

The reaction of $RhCl_2(NO)(PPh_3)_2$ with sodium diethyldithiocarbamate in refluxing benzene gave an orange crystalline material similar in appearance to that originally reported [5]. However, the spectroscopic properties of this product are identical with those displayed by an authentic sample of $Rh(S_2CNEt_2)_3$ prepared from $RhCl_3 \cdot 3H_2O$. In particular the ^1H NMR spectrum displayed the resonance pattern characteristic for ethyl groups containing diastereotopic methylene protons which would be expected for the ethyl groups in octahedral $Rh(S_2CNEt_2)_3$ but not for those in square planar $Rh(S_2CNEt_2)_2$.

Attempts to obtain rhodium(II) dithiocarbamato complexes by excluding air from the syntheses were unsuccessful; in all cases good yields of the corresponding rhodium(III) products were obtained. Finally, attempts to achieve a rational synthesis of $Rh(S_2CNEt_2)_2$ from $Rh_2(O_2CMe)_4$ and NaS_2CNEt_2, similar to that previously employed in the syntheses of $[NBu^n_4]_2[Rh\{S_2C_2(CN)_2\}_2]$ [9], afforded instead good yields of the rhodium(III) species $Rh(S_2CNEt_2)_3$. We therefore conclude that the original report concerning the syntheses and characterisation of mononuclear rhodium(II) dithiocarbamato complexes is in error, and that such complexes, if accessible, are likely to prove highly susceptible to oxidation to the trivalent state.

Synthesis and spectroscopic characterization of organophosphoryl polyoxotungstates $[C_6H_{11}P(O)]_2X^{n+}W_{11}O_{39}^{(8-n)-}$ ($X^{n+} = P^{5+}$, Si^{4+}, B^{3+}, Ga^{3+})

Zhen-Gang Sun, Qun Liu, Jing-Fu Liu *

Department of Chemistry, Northeast Normal University, Changchun 130024, PR China

Received 7 July 1999; accepted 14 October 1999

Abstract

In the presence of NBu_4Br acting as a phase-transfer reagent, the monovalent polyoxotungstates α-$X^{n+}W_{11}O_{39}^{(12-n)-}$ (X = P, Si, B, Ga) react with electrophilic cyclohexane phosphonyl chloride to give hybrid organophosphoryl polyoxotungstates $[(C_6H_{11}P(O)]_2$-$XW_{11}O_{39}^{(8-n)-}$, which have been characterized by elemental analysis and IR, ^{31}P and ^{183}W NMR spectroscopy. The six-line ^{183}W spectra indicate that the hybrid anions possess C_s symmetry in solution. According to spectroscopic observations and chemical analyses, the hybrid anion consists of an α-$[XW_{11}O_{39}]$ framework on which are grafted two equivalent $C_6H_5P(O)$ groups through P–O–W bridges. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Derivatized polyoxometalates have received increasing attention during the last 20 years owing to their potential use in catalysis, medicine and materials science [1]. It has been recognized for a long time that, by grafting appropriate organic and organometallic groups onto the polyoxometalate surface, the solubility and other physical properties of the complexes may be modified, which would increase their utility and versatility in catalysis and various medical applications, including antiviral and antitumoral chemotherapy [2–4]. The reactivity of lacunary polyoxotungstates with organic and organometallic groups has been summarized [5]. To date, the reaction of lacunary polyoxotungstates with organophosphonic acid has been reported rarely, except for a unique study by Kim et al. [6] on PhPO derivatives of monovalent tungstophosphate and tungstosilicate, and that of Mayer and Thouvenot [7] on RPO derivatives of trivalent tungstophosphate. As a continuation of these studies, we report here the synthesis and spectroscopic characterization of the title compounds $[C_6H_{11}P(O)]_2XW_{11}O_{39}^{(8-n)-}$ (X = P, Si, B, Ga).

2. Experimental

2.1. Reagents and apparatus

All reagents were of analytical or guaranteed purity. CH_3CN was distilled over P_2O_5 and used immediately. Sodium and potassium salts of $X^{n+}W_{11}O_{39}^{(12-n)-}$ (X = P, Si, B, Ga) were prepared using procedures describd in the literature [8,9]. Cyclohexanephosphonyl chloride was prepared according to a published method [10]. IR spectra were recorded on an Alpha Centauri FTIR spectrometer (2000–400 cm^{-1} range) with KBr pellets. ^{31}P NMR spectra were recorded with a JNM-FX-100 NMR spectrometer, and chemical shifts were given with respect to external 85% H_3PO_4 for ^{31}P in CD_3CN. ^{183}W NMR spectra were recorded at 16.64 MHz on a Unity-400 spectrometer using a 10-mm diameter NMR tube at 20°C; chemical shifts were referenced to 2 M Na_2WO_4 in D_2O.

2.2. Preparation of the compounds

2.2.1. $[NBu_4]_3[C_6H_{11}P(O)]_2PW_{11}O_{39}$ (1)

α-$Na_7PW_{11}O_{39}\cdot 13H_2O$ (1.42 g, 0.5 mmol) and NBu_4Br (0.97 g, 3 mmol) were suspended in CH_3CN (25 ml), and an acetonitrile solution of $C_6H_{11}POCl_2$ (0.201 g, 1 mmol in 15 ml of acetonitrile) was added dropwise under vigorous

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(99)00326-5

stirring. The flask was sealed with a septum stopper, and the mixture was stirred for 48 h at room temperature. After separation of a white solid (NaCl, NaBr and traces of $Na_7PW_{11}O_{39}$), the resulting solution was concentrated on a rotary evaporator, and was then diluted with 100 ml of absolute ethanol to produce a white precipitate. The white precipitate was isolated by filtration, and the solid isolated was reprecipitated again from 5 ml of acetonitrile solution by adding 100 ml of ethanol to give 1.1 g (49.12%) of a white powder. Found: C, 19.31; H, 3.58; N, 1.19; P, 2.82; W, 55.82. Calc. for $C_{60}H_{130}N_3O_{41}P_3W_{11}$: C, 19.65; H, 3.50; N, 1.15; P, 2.54; W, 55.23%.

2.2.2. $[NBu_4]_4[C_6H_{11}P(O)]_2SiW_{11}O_{39}$ (2)

This compound was similarly synthesized from α-$K_6Na_2SiW_{11}O_{39}\cdot 13H_2O$ (2.54 g, 0.8 mmol), NBu_4Br (1.29 g, 4 mmol) and $C_6H_{11}POCl_2$ (0.32 g, 1.6 mmol). Yield: 1.4 g (44.87%). Found: C, 23.48; H, 4.30; N, 1.47; Si, 0.74; P, 1.62; W, 51.62. Calc. for $C_{76}H_{166}N_4O_{41}P_2SiW_{11}$: C, 23.36; H, 4.25; N, 1.43; Si, 0.72; P, 1.59; W, 51.84%.

2.2.3. $[NBu_4]_4H[C_6H_{11}P(O)]_2BW_{11}O_{39}$ (3)

This compound was similarly synthesized from α-$K_7NaHBW_{11}O_{39}\cdot 13H_2O$ (2.54 g, 0.8 mmol), NBu_4Br (1.29 g, 4 mmol) and $C_6H_{11}POCl_2$ (0.32 g, 1.6 mmol). Yield: 1.35 g (43.41%). Found: C, 26.72; H, 4.33; N, 1.48; B, 0.26; P, 1.61; W, 52.14. Calc. for $C_{76}H_{167}N_4O_{41}P_2BW_{11}$: C, 26.54; H, 4.29; N, 1.44; B, 0.28; P, 1.59; W, 52.06%.

2.2.4. $[NBu_4]_4K[C_6H_{11}P(O)]_2GaW_{11}O_{39}$ (4)

This compound was similarly synthesized from α-$K_9GaW_{11}O_{39}\cdot 13H_2O$ (2.64 g, 0.8 mmol), NBu_4Br (1.29 g, 4 mmol) and $C_6H_{11}POCl_2$ (0.32 g, 1.6 mmol). Yield: 1.28 g (40.15%). Found: C, 22.62; H, 4.24; N, 1.45; Ga, 1.72; K, 0.96; P, 1.59; W, 50.68. Calc. for $C_{76}H_{166}N_4KO_{41}P_2GaW_{11}$: C, 22.89; H, 4.17; N, 1.41; Ga, 1.76; K, 0.98; P, 1.56; W, 50.79%.

2.3. Chemical analyses

Tungsten, phosphorus, silica, boron and gallium were determined by means of inductively coupled plasma–Auger electron spectroscopy (ICP–AES). K was determined by atomic absorption spectroscopy. C, H, N were determined using a PE-2400 elemental analyzer.

3. Results and discussion

3.1. Synthesis

The monovalent polyoxotungstates α-$X^{n+}W_{11}O_{39}{}^{(12-n)-}$ react with electrophilic cyclohexane phosphonyl chloride in acetonitrile to yield organic/inorganic species $[C_6H_{11}P(O)]_2\,X^{n+}W_{11}O_{39}{}^{(8-n)-}$ ($X^{n+}=P^{5+}$, Si^{4+}, B^{3+}, Ga^{3+}), using NBu_4Br acting as a phase-transfer reagent. The overall reaction is:

$$X^{n+}W_{11}O_{39}^{(12-n)-}+C_6H_{11}P(O)Cl_2 \xrightarrow[NBu_4Br]{MeCN} [C_6H_{11}P(O)]_2X^{n+}W_{11}O_{39}^{(8-n)-}$$

After filtration of a white solid consisting of NaCl, NaBr or KCl, KBr and a small amount of unchanged sodium or potassium polyoxotungstate, the acetonitrile solution contains a single hybrid anionic species, which has been isolated as its tetrabutylammonium salt. Elemental analysis results are consistent with the formulation of the title compounds. In contrast, the reaction between the sodium salt of α-$[PW_{11}O_{39}]^{7-}$ with $C_6H_{11}P(O)Cl_2$ in water did not show any evidence for the attachment of the organic group. This indicates that the anhydrous condition is needed for the reaction of $C_6H_{11}P(O)Cl_2$ with the lacunary polyoxotungstate. In addition, direct reaction of the lacunary precursor with $C_2H_5OP(O)Cl_2$ in acetonitrile does not give any isolable product, showing that a highly electrophilic organophosphonoyl moiety is needed for the above reaction.

3.2. Infrared spectra

The infrared spectra of all the compounds are very similar; all data and IR assignments are given in Table 1. The P–O stretching vibration bands of the organic group and central PO_4 moiety are observed between 1000 and 1060 cm^{-1} and the highest wavenumber (1120–1150 cm^{-1}) is assigned to the stretching vibration of the P–C bond of the $C_6H_{11}P(O)$ unit. The low wavenumber region ($\nu<1000$ cm^{-1}) is characteristic of the W–O stretching and bending vibration in the polyoxotungstate. It is of interest to compare the ν_3 stretching modes of the PO_4 unit (F_2) [11] for compound **1** with the IR spectra of the other structurally related anions. It is well known that a decrease in symmetry from T_d (XW_{12}) to C_s (XW_{11}) leads to splitting of the ν_3 vibration (F_2) of the PO_4 group into two components. The value of the splitting, $\Delta\nu$, is decreased when the triply bridging oxygen of the PO_4 unit interacts with a transition metal ion [11,12].

It can be seen from Table 1 that the value of $\Delta\nu$ is decreased when two organophosphoryl groups are bound in the cavity, and the stretching vibrational bands, ν_{as} ($W=O_{ter}$) and ν_{as} ($W–O_b–W$), are shifted to a higher frequency than those of the starting lacunary polyanions. This effect is attributed to a partial saturation of the polyoxometallic moiety through attachment of RPO units.

3.3. ^{31}P NMR spectra

The attachment of phosphoryl groups onto the polyoxotungstate surface is demonstrated by the resonances in the ^{31}P NMR spectra, which are all distinct from that of $C_6H_{11}P(O)Cl_2$ (Table 2).

Table 1
Comparison of infrared stretching frequencies (cm^{-1})

Q_3PW_{12} [a]	$Q_4H_2NaPW_{11}$ [a]	Compound				Assignment
		1	**2**	**3**	**4**	
		1120	1148	1144	1119	ν (P–C)
		1043	1042	1039	1026	ν_{as} (P–O) [b]
1080	1107	1060				ν_{as} (P–O) [c]
	1051	1027

[d] X = Si, B, Ga.

Table 2
^{31}P NMR data for $[C_6H_{11}P(O)]_2X^{n+}W_{11}O_{39}^{(8-n)-}$

Compound	Chemical shift (δ, ppm)
$C_6H_{11}P(O)Cl_2$	58.5
$[Bu_4N]_3[C_6H_{11}P(O)]_2PW_{11}O_{39}$	34.2, −13.7
$[Bu_4N]_4[C_6H_{11}P(O)]_2SiW_{11}O_{39}$	31.4
$[Bu_4N]_4H[C_6H_{11}P(O)]_2BW_{11}O_{39}$	35.2
$[Bu_4N]_4K[C_6H_{11}P(O)]_2GaW_{11}O_{39}$	29.9

The ^{31}P NMR spectrum of compound **1** exhibits two lines at 34.2 and −13.7 ppm with a relative intensity of 2:1 (see Fig. 1). The high-frequency resonance is attributed to the phosphoryl group, and the low-frequency singlet is assigned to the central PO_4 unit of the polyoxotungstate. This chemical shift, which is intermediate between that of the starting lacunary anion α-$[PW_{11}O_{39}]^{7-}$ ($\delta = -10.4$ ppm) and that of α-$[PW_{12}O_{40}]^{3-}$ ($\delta = -14.9$ ppm), is in accord with a partially saturated tungstophosphate structure. The relative intensity is consistent with the grafting of only two phosphoryl groups. A heteropolyanion with a Keggin structure becomes the C_s lacunary polyanion $X^{n+}M_{11}O_{39}^{(12-n)-}$ after losing one heavy atom and its terminal oxygen, which contains three W_3O_{13} triads and one W_2O_{10} diad. These anions have a hole surrounded by five oxygen atoms, one O_a, two O_b and two O_c (see Fig. 2).

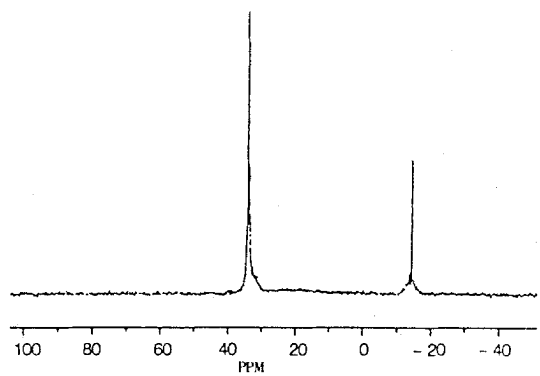

Fig. 1. The ^{31}P NMR spectrum of compound **1** in CD_3CN (0.075 M).

When two double-bonded phosphoryl groups each bridges two of the five oxygen atoms that define the hole in the lacunary polyanion, there are two possibilities, i.e. the groups can bridge the oxygens such that they are either unequivalent or equivalent. The single resonance in the ^{31}P NMR spectra indicates that the mode of attachment of the organic groups to the lacunary anion is equivalent, i.e. each organic group is connected to two W atoms belonging to a triad and a diad, respectively (see Fig. 3).

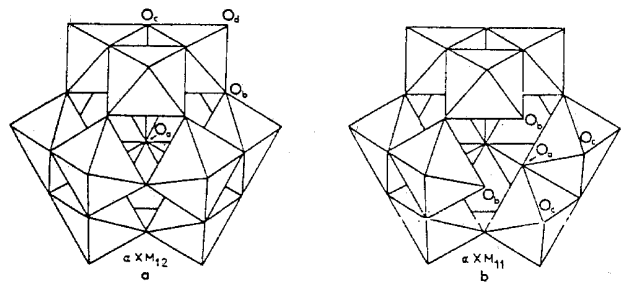

Fig. 2. Idealized structures of α-XM_{12} (Keggin structure) (a) and α-XM_{11} (defective Keggin structure) (b). O_a, oxygen shared by three MO_6 octahedra and the XO_4 tetrahedron; O_b and O_c, oxygen linked to two different M atoms; O_d, terminal unshared oxygen.

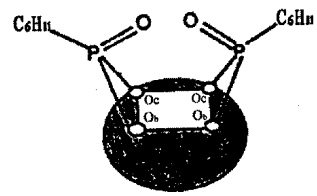

Fig. 3. Schematic representation of α-$[C_6H_{11}P(O)_2]X^{n+}W_{11}O_{39}^{(8-n)-}$.

Table 3
^{183}W NMR data for $[C_6H_{11}P(O)]_2X^{n+}W_{11}O_{39}^{(8-n)-}$

Compound	Chemical shift ($-\delta$, ppm)
$[Bu_4N]_3[C_6H_{11}P(O)]_2PW_{11}O_{39}$	80.9(2), 82.9(2), 96.6(1), 103.1(2), 113.5(2), 121.5(2)
$[Bu_4N]_4[C_6H_{11}P(O)]_2SiW_{11}O_{39}$	82.5(2), 98.3(2), 111.2(1), 123.5(2), 140.1(2), 180.9(2)
$[Bu_4N]_4H[C_6H_{11}P(O)]_2BW_{11}O_{39}$	91.9(2), 110.3(2), 115.7(1), 122.2(2), 190.3(3), 196.8(2)
$[Bu_4N]_4K[C_6H_{11}P(O)]_2GaW_{11}O_{39}$	62.5(2), 70.9(1), 93.1(2), 96.3(2), 126.3(2), 147.9(2)

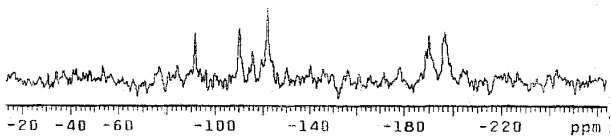

Fig. 4. The ^{183}W NMR spectrum of compound **3** in CD_3CN (0.08 M).

3.4. ^{183}W NMR spectra

The ^{183}W NMR spectrum of compound **3** and chemical shifts of all compounds are shown in Fig. 4 and Table 3, respectively.

The ^{183}W NMR spectra of all species consist of six peaks, establishing that all species have C_s symmetry in solution. This feature was observed for other derivatives of Keggin-type heteropolytungstates that bear organometallic ligands [13].

4. Conclusions

The sodium or potassium of $X^{n+}W_{11}O_{39}^{(12-n)-}$ (X = P, Si, B, Ga) and tetra-n-butylammonium bromide (NBu_4Br) were suspended in acetonitrile, and an acetonitrile solution of $C_6H_{11}POCl_2$ was added dropwise under vigorous stirring. After filtration, the resulting solution was concentrated and was then diluted with absolute ethanol to produce a white precipitate; the solid isolated was reprecipitated again from acetonitrile solution by adding absolute ethanol. Despite all our efforts to grow suitable crystals of the $C_6H_{11}(O)$ derivatives of $X^{n+}W_{11}O_{39}^{(12-n)-}$ (X = P, Si, B, Ga), no X-ray diffraction study was possible. Thus the compounds have to be characterized in solid state by IR spectroscopy and in the CD_3CN solution by ^{31}P and ^{183}W NMR. This hybrid anion consists of an α-$[XW_{11}O_{39}]$ framework on which are grafted two equivalent $C_6H_5P(O)$ groups through P–O–W bridges; each organic group is connected to two W atoms belonging to a triad and diad, respectively.

Abstract

The structures of bis-(3-hydroxy-4-pyronato)zinc(II) {bis-maltolato-zinc(II), $Zn(malt)_2 \cdot 1.5H_2O$}, bis-(1,2-dimethyl-3-hydroxy-4-pyridinonato)zinc(II) {$Zn(L1)_2 \cdot 7H_2O$}, and bis-(1,2-dimethyl-3-hydroxy-4-pyridinonato)lead(II) {$Pb(L1)_2 \cdot 7H_2O$}, determined by X-ray diffraction techniques, are reported. The zinc in {$Zn(L1)_2 \cdot 7H_2O$} is five coordinated; in $Zn(malt)_2 \cdot 1.5H_2O$ zinc occurs in both five- and six-coordination. $Pb(L1)_2 \cdot 7H_2O$ is dimeric; each lead has five oxygens, two of them bridging, in its coordination shell. All three compounds contain water molecules coordinated to the metal; both L1 complexes also contain water of crystallisation in the form of extended chains. All three compounds are extensively hydrogen bonded. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Zinc complexes; Lead(II) complexes; Maltol; 3-Hydroxy-4-pyranone; 3-Hydroxy-4-pyridinone; 1,2-Dimethyl; Crystal structures

1. Introduction

There has in recent years been growing interest in chelating ligands of the 3-hydroxy-4-pyranone (**1**) and 3-hydroxy-4-pyridinone (**2**) type, both for the control of levels of metals in the body and for their oral administration for diagnostic or therapeutic purposes [1].

1 2

Thus they have been proposed both for the introduction of iron to anaemic patients and for the removal of excess of iron from patients suffering from bodily overload as in thallasaemia or haemochromatosis. Their use to reduce aluminium levels in the body and thus perhaps to slow the progress of dementias has been suggested; they may also have a role to play in the administration of, for example, ^{67}Ga or ^{111}In radiopharmaceuticals or of gadolinium for magnetic resonance imaging (MRI) [2].

Zinc is an essential element for man. It plays a central, if still only dimly understood, role in a number of healing processes. Zinc citrate [3], probably acting as a convenient source of bio-active $Zn^{2+}(aq)$ [4], appears to aid dental care by inhibiting plaque formation [5]. Indeed, the beneficial therapeutic effects of compounds of zinc have been recognised for at least a thousand years [6]. More recently the isotopes ^{63}Zn and ^{69m}Zn have found application in radiopharmaceuticals. Absorption of zinc depends strongly on the form in which it is administered. It appears that the simple aqua-ion $Zn^{2+}(aq)$ and its phytate complex [7] are not well absorbed, but that complexes with citrate, histidine [8], prolinate, several EDTA-derivatives [3], and 3-hydroxy-4-pyranones and 3-hydroxy-4-pyridinones [9] are absorbed by the body. The determination of stability constants for zinc(II) complexes of a number of maltol derivatives [10] may point to a new route for the administration of zinc.

In contrast to zinc, lead is, of course, toxic [11,12], though this fact did not prevent the use in former times of lead(II) acetate for the treatment for diarrhoea and currently for the darkening of grey hair, nor of lead(II) acetate, stearate, and

PII S0277-5387(99)00330-7

oleate for certain skin complaints, nor of lead(II) iodide in ointment for application to arthritic swellings [13]. Again there are lead isotopes of radiopharmaceutical value: ^{203}Pb has proved useful in tomography [14]; ^{212}Pb may prove valuable as a source of the very cytotoxic ^{212}Bi [15].

For both zinc and lead, there is thus a need for ligands and complexes which can be orally administered. Several chelators are available for the treatment of lead poisoning, including EDTA, penicillamine, thiohydroxamates [16] and 2,3-dimercapto-propane-1-sulfonate [17], but a cheap, simple, user-friendly (maltol is a benign natural product, much used in the baking industry) chelator would be a useful addition to the lead detoxification armoury.

A great deal is known about the preparation, structures, and solvation characteristics of tris-hydroxy-pyronato– and tris-hydroxy-pyridinato–metal(III) complexes; much less is known about analogous bis-ligand complexes of metal(II) ions. The crystal structure of bis(1,2-dimethyl-3-hydroxy-4-pyridinonato)zinc(II) has been determined, but does not appear to have been published [18]; crystal structures of two ternary ruthenium(II)–bis-maltolate complexes have been reported [19]. As an essential preliminary to a planned study of solvation of such bis-ligand metal(II) complexes, we have prepared three zinc and lead complexes and determined their crystal structures by X-ray methods. None of the complexes had the hoped for simple anhydrous structure, which meant that they were not suitable for the assessment of solvation through solubility measurements. However, the complexes revealed several interesting features, both in relation to the coordination environment of the metal centres and to the extensive hydrogen-bonding in each structure, which are described below.

2. Experimental

2.1. Preparation of complexes

Bis-maltolato-zinc(II) (**3**) was prepared by dissolving 2.0 g zinc sulfate heptahydrate in the minimum amount of water and adding this solution to a solution containing 2.0 g maltol dissolved in the minimum amount of a 1:1 methanol:water mixture. Aqueous ammonia (S.G. 0.880) was added dropwise to raise the pH to 7. The volume of the solution was reduced to half by gentle heating, and the resultant solution left to stand overnight. 2.25 g (91% yield) of orange-tinged white crystals were obtained. Recrystallisation from 1:1 methanol:water gave colourless needle-shaped crystals; m.p. 199–202°C (dec).

Bis-(3-hydroxy-1,2-dimethyl-4-pyridinonato)zinc(II) (**4**) was prepared by adding 0.4 g of ligand to 0.2 g zinc(II) chloride dissolved in 10 ml methanol, and bringing the pH to 7 by dropwise addition of dilute sodium hydroxide solution. The solution was concentrated to 5 ml on a water bath; clear colourless crystals appeared on cooling. The yield was 0.52 g (90%); the product decomposed above 190°C.

Bis-(3-hydroxy-1,2-dimethyl-4-pyridinonato)lead(II) (**5**) was prepared by dissolving lead dichloride (0.5 g) and ligand (0.5 g) in 10 ml methanol; the pH of the solution was raised to 8 by dropwise addition of dilute sodium hydroxide solution. The solution was concentrated to 5 ml on a water bath, then cooled in ice. Colourless crystals appeared during the course of 24 h. The yield was 0.81 g (72%); the product decomposed above 190°C.

2.2. X-ray crystallography

Block-shaped sections of crystals of **3**, **4**, and **5** suitable for X-ray crystallography were obtained by appropriate cutting of needle-shaped crystals from recrystallised material prepared as described in the preceding paragraphs. Crystal data for **3**, **4**, and **5**, and a summary of data collection and structure refinement parameters are given in Table 1. See also Supplementary data. Data were measured on a Siemens P4 diffractometer at 293 K using graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å) with omega scans. Crystals were glued onto glass fibres. Unit cell dimensions were determined by least-squares refinement of optimised setting angles. The data were corrected for Lorentz and polarisation effects. The structures were solved by Patterson methods (SHELXS86), and refined by full-matrix least-squares on F^2 using SHELXTL/PC. The H atoms bonded to O in **3** and **4** were located from difference Fourier maps; (O)H atoms in **5** were neither located nor included in refinement. All C(H) atoms were included in calculated positions (C–H = 0.96 Å). Located and calculated H atoms were fixed as riding on the bonded atom with isotropic displacement parameters proportional to the U_{iso} value of that atom. All non-H atoms were refined with anisotropic displacement parameters.

3. Results and discussion

We start by dealing with the main features and metal environment for each compound separately. Thereafter we discuss the angles subtended at the metal ions in the three complexes, then some features of the geometry of the coordinated ligands, and finally deal with hydrogen-bonding in our complexes.

3.1. Metal ion coordination: bis-maltolatozinc(II)

The structure of bis-maltolatozinc(II) is shown in Fig. 1, with selected bond distances and angles given in Table 2. The overall structure can be viewed as layers of ABA sandwiches, i.e. …ABA…ABA…, with layers A consisting of five-coordinated zinc complexes, layers B of the six-coordinate complexes. The structure shows two unusual features, the occurrence in the unit cell of two molecules with different coordination numbers, five and six, for the zinc ion, and that the five-coordinate zinc ion is in an approximately square-pyramidal coordination environment. Zn1 is on a centre of

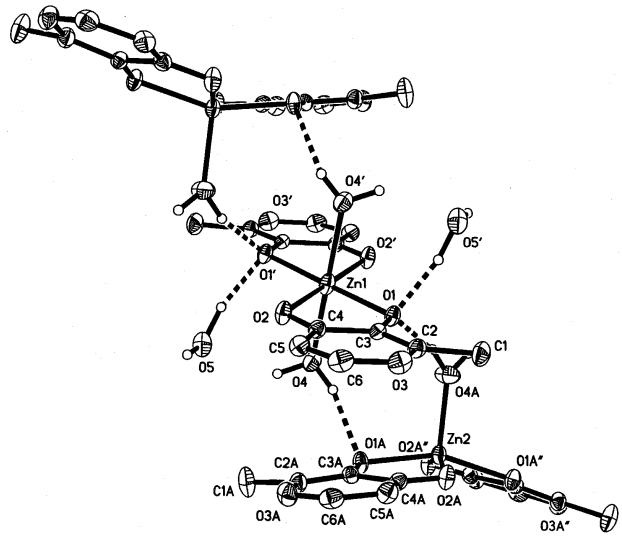

Fig. 1. Molecular structure of **3** showing 30% displacement ellipsoids; (C)H atoms are omitted for clarity. Single prime atoms are generated by a centre of symmetry ($1-x$, $1-y$, $-z$); double prime atoms are generated by a 2-fold axis through Zn2 and O4a ($-x$, $1+y$, $1/2-z$).

symmetry, with a unique half molecule and primed ligand atoms generated by $1-x$, $1-y$, $-z$. Zn2 is on a 2-fold axis, with the half molecule generated by $-x$, $1+y$, $1/2-z$; one water is associated with the asymmetric unit. Another example of a metal occurring in both five- and six-coordination in a compound is provided by the tetranuclear iron compound $Fe_4Cl_8(thf)_6$ [20]. Further examples of five-coordinated zinc include a modelled carbonic anhydrase derivative containing a second, more distant, water molecule [21], and others which appear below.

The zinc to water-oxygen distance in the five-coordinated aqua-ion is 2.01 Å. This may be compared with the value of 2.20 Å in $Zn(acac)_2\cdot H_2O$ (where the zinc is in coordination

geometry intermediate between trigonal-bipyramidal and square-pyramidal, though closer to the latter) [22], with zinc–oxygen distances of between 1.99 and 2.31 Å in the approximately trigonal-bipyramidal $[Zn(H_2O)_5]^{2+}$ entity in crystals of penta-aquazinc(II) bis(3,3′,3′-phosphinetriyltripropionato)dizincate(II,II), [23] and with Zn–OH_2 = 2.00 Å in $[Zn(bipy)(O_2CCCl_3)_2(H_2O)]$, where the water ligand is equatorial [24]. The coordination number of the zinc in the $[Zn(maltolate)_2(H_2O)]$ units is indubitably five, with no evidence for even a weak interaction at the vacant sixth coordination site. One has to go further than 5 Å from the metal in this direction before finding the nearest neighbouring atom. Indeed two oxygen atoms of water ligands (O4, Fig. 1) in octahedral $[Zn(maltolate)_2(H_2O)_2]$ units (see below) in the adjacent layer of the sandwich are, at 3.94 Å, closer than this, but on the same side of the zinc as the coordinated water (O4A).

In the octahedral aqua-ion, the two waters are *trans* to each other, with Zn–O rather long at 2.26 Å; Zn–O is, for example, 2.03 Å in the octahedral $[Zn(H_2O)_4Cl_2]$ entities in zinc chloride hydrate ($ZnCl_2 \cdot 4/3H_2O$) and 2.08 Å in the octahedral aqua-ion $Zn(H_2O)_6^{2+}$ in aqueous solution [25,26]. The complex $[Zn(dimethyl\text{-}3\text{-}oxopentanedioate)_2(H_2O)_2]$ has a structure analogous to that of the present $[Zn(maltol)_2(H_2O)_2]$; the pentanedioate complex has Zn–O = 2.18 Å to the mutually *trans* water ligands, 2.02 and 2.08 Å to the other coordinated oxygens [27]. We are very interested in establishing metal to water distances in an analogous copper(II) bis-aqua bis-pyronato-species, but unfortunately our extensive efforts to grow a suitable single crystal have so far been unsuccessful.

The zinc to maltol-oxygen distances are all within the relatively narrow range of 2.01 to 2.08 Å, normal for zinc to coordinated oxygen bond lengths. The two maltolate ligands are effectively in the *trans* configuration to each other in the planar $Zn(maltolate)_2$ unit in the octahedral species.

3.2. Metal ion coordination: bis(1,2-dimethyl-3-hydroxy-4-pyridinonato)zinc(II)

The zinc ion is five-coordinated in this complex, again with a distorted square-pyramidal geometry around the metal ion. Selected bond distances and angles are listed in Table 3; atom numbering is shown in Fig. 2. The zinc to water-oxygen distance is 2.05 Å, marginally longer than in the five-coordinate zinc-maltol species. The zinc to hydroxypyridinonate-oxygen distances are between 2.02 and 2.05 Å, within the range for zinc-maltol. As is the case for the $[Zn(maltolate)_2(H_2O)]$ units in the maltol complex, the coordination number of the metal is again indubitably five, with no significant interaction along the axis in the opposite direction to the coordinated water. Fig. 2 shows how the water molecules containing O7′, O8′, and O9′ effectively block the sixth coordination site at the zinc without themselves interacting with the metal.

3.3. Metal ion coordination: bis(1,2-dimethyl-3-hydroxy-4-pyridinonato)lead(II)

An atom-numbered view of this complex, with water of crystallisation, is shown in Fig. 3, with selected bond distances and angles listed in Table 4. Here the main structural interest lies in the binuclear nature of the complex, with additional interest in whether the lone pair on the lead has a

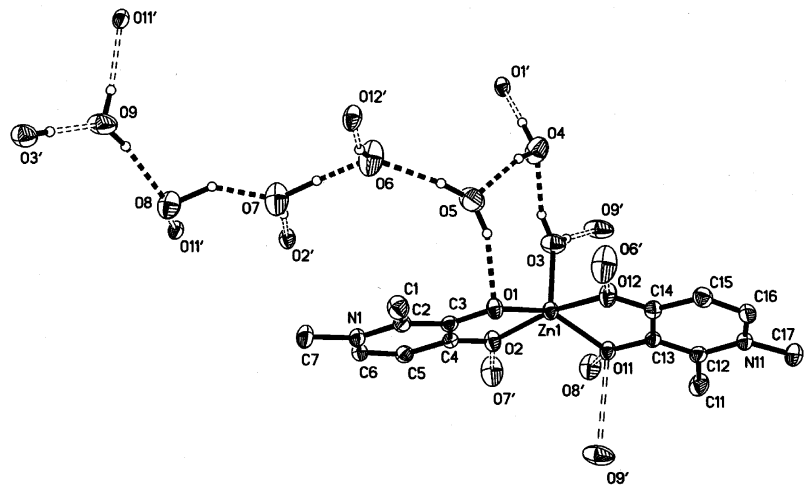

Fig. 2. Molecular structure of **4** showing 30% displacement ellipsoids; (C)H atoms are omitted for clarity. Full dashed lines show O–H···O hydrogen bonds; open dashed lines and primed atoms indicate extended symmetry-related hydrogen bonds.

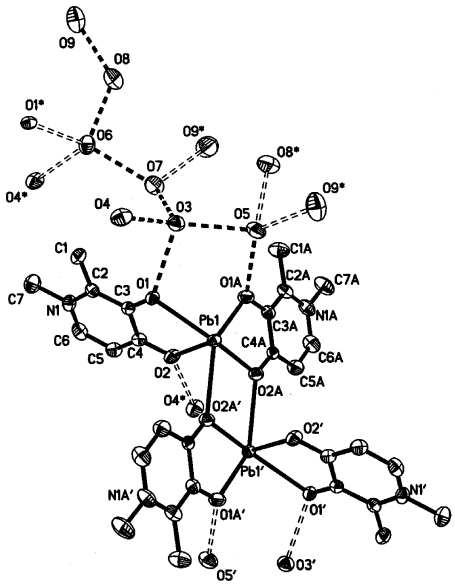

Fig. 3. Molecular structure of **5** showing 30% displacement ellipsoids; (C)H atoms are omitted for clarity. Single prime atoms are generated by a centre of symmetry $(1-x, 1-y, -z)$. Full dashed lines show show probable O–H···O hydrogen bonds (O···O < 2.9 Å); open dashed lines and starred atoms indicate further symmetry-related hydrogen bonds.

significant stereochemical influence. The lead complex has the expected 2:1 ligand:metal stoichiometry, but instead of containing monomeric entities it consists of binuclear molecules each containing two ligands bridging through one of their oxygen atoms. There are several examples of dinuclear copper(II) complexes with bridging 2-pyridinone ligands [28], but we believe this is the first dinuclear complex with 4-pyridinonate bridges. The $Pb_2(\mu\text{-}O)_2$ moiety is a parallelogram with ∠O–Pb–O = 67°; the Pb–O distances are 2.38 and 2.68 Å.

The coordination geometry around lead(II) continues to be a matter of interest [29], especially the extent to which the lone pair is stereochemically active. It has long been realised that a lone pair on lead(II) is in general less stereochemically active than one in an analogous tin(II) compound [30,31]. Nonetheless, at least two recently published structures indicate stereoactive lone pairs in lead(II) complexes [32,33]. In the present complex, each lead atom has only five oxygen atoms in its coordination shell: two bridging oxygens, the second oxygen donor from one of the bridging ligands,

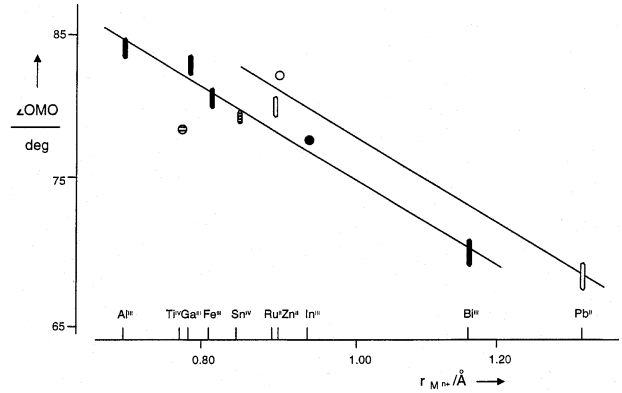

Fig. 4. Relation between ligand chelate bite angles subtended by coordinated 3-hydroxy-4-pyranonate and 3-hydroxy-4-pyridinonate ligands and ionic radii of the respective central metal ions. ○ M^{2+}; ● M^{3+}; ⊜ M^{4+}; elongated symbols cover the range of bite angles for cases where more than one structure has been determined, or where there are two or more different bite angles in a given complex.

and two oxygen atoms from a non-bridging ligand. There is thus space for a stereoactive lone pair, and indeed the arrangement of the oxygens around the lead strongly suggest that the lone pair is playing a significant stereochemical role. There is a stereoactive lone pair in the closely related tris-ethylmaltolato-bismuth(III) complex [34].

3.4. Angles subtended at the metal

The ligand L1 subtends a much smaller angle at lead, 67.6° and 69.5° (the former for the non-bridging ligand), than either L1 or maltol at zinc. It seemed to us likely that this was simply a consequence of the larger size of lead(II) and therefore we assembled data on the angles subtended at metals by coordinated 3-hydroxy-4-pyranones and 3-hydroxy-4-pyridinones. The data are presented graphically in Fig. 4, which suggests a close correlation between bite angle and metal radius [3] for M^{2+} (lower line) and for M^{3+} (upper line). The correlations for the two oxidation states are parallel but separate. The very limited data (two compounds) for M^{4+} do not quite conform to the pattern for the M^{2+} and M^{3+} complexes. This may, however, be a reflection on the published estimate for the ionic radius for Sn^{4+} rather than deviation from the pattern for M^{2+} and M^{3+}.

3.5. Coordinated ligand geometry

The carbon–oxygen and carbon–carbon bond distances in the chelate rings of tris-1,2-dimethyl-3-hydroxypyridinato–metal(III) complexes reveal significantly greater bond delocalisation than in the parent ligand. This is shown in Fig. 5, which also contains bond distances for our zinc(II) and lead(II) bis-ligand analogues. The difference between the two carbon–oxygen bond lengths in the chelate rings of $Zn(L1)_2$ is not significantly different from the analogous

[3] In the absence of a published ionic radius for Ru^{2+} we have used an estimated value of 0.88 Å, derived from published estimates for Ru^{3+} and Ru^{4+}; O–Ru–O angles are from Ref. [19].

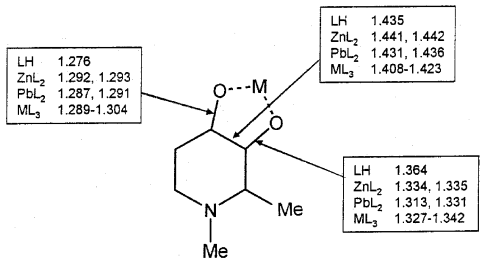

Fig. 5. Comparison of intra-ligand bond distances in the chelate rings of the bis-ligand complexes of zinc and of lead with analogous distances in tris-ligand metal(III) and in the free ligand, for the ligand 3-hydroxy-1,2-dimethyl-4-pyridinonate.

differences for tris-ligand metal(III) complexes, consistent with greater delocalisation in the chelated ligand than in the free ligand. However, the carbon–carbon bond distances in the chelate rings of the zinc(II) complex are, within their respective uncertainties, the same as in the free ligand, in contrast to its shortening in the chelate rings of the metal(III) complexes. Analogous comments can be made about the lead complex, whose binuclear structure seems to have no significant effect on ligand geometry.

The differences in bond length that we are seeking are comparable in magnitude to their uncertainties, but it would not be unreasonable to suggest that the pattern of carbon–oxygen and carbon–carbon bond distances in the chelate rings and in the free ligand is consistent with slightly greater π-delocalisation in the metal(II) complexes than in the free ligand, and again slightly greater in the metal(III) complexes. Unfortunately we have so far been unable to grow crystals of the zirconium(IV) complex $Zr(L1)_4$ of sufficient quality for X-ray diffraction investigation, while our structural data on related tin(IV) and titanium(IV) compounds [35] are not strictly comparable since the ligand in these cases is a 2-ethyl analogue of 1,2-dimethyl-3-hydroxypyridinate, and there are also chloride ligands on the metal in both cases. We are therefore unable to test our suggestion of a dependence of π-delocalisation on metal cation charge by comparison with metal(IV) analogues.

3.6. Hydrogen-bonding

Since the description of the first structure of a complex of this type, i.e. $Al(L1)_3 \cdot 12H_2O$ [36], it has been clear that this class of complex is extensively hydrogen bonded. The hydrogen bonding usually involves water–water, water–donor atom, and inter-ligand interactions. Several tris-ligand–metal(III) complexes of 3-hydroxy-4-pyranones and 3-hydroxy-4-pyridinones exist as dodecahydrates, which contain chains of water molecules which are hydrogen bonded both to each other and to ligand-oxygen-donor atoms. This creates a three-dimensional framework of water molecules with embedded molecules of complex, a type of clathrate structure.

Both our L1 complexes are heavily hydrated, if less so than the dodecahydrates just mentioned, with seven waters per metal ion in both the zinc and the lead complex. The waters of crystallisation in both these L1 complexes form extended chains, which are themselves hydrogen bonded to donor oxygen atoms. This is apparent from Figs. 2 and 3. It is noteworthy that the O–O distances between adjacent water molecules are essentially within the same range as the O–O distances between water and donor oxygen. The ranges are 2.714–2.824 and 2.701–2.815 Å, respectively.

By way of contrast, our zinc-maltol complex is lightly hydrated, with only 1.5 water molecules per zinc. All these water molecules are coordinated to zinc ions. The water in the five-coordinated zinc units is hydrogen bonded to ligand-oxygen in adjacent six-coordinated zinc units; the water in the latter is also coordinated to ligands in the former. As noted above, the layer structure of the zinc-maltol complex (shown in Fig. 1) consists of ABA sandwiches, A consisting of five-coordinated, B of six-coordinated complexes. There is strong A···B···A inter-layer hydrogen-bonding interaction, but there are no hydrogen-bonding interactions between adjacent ABA 'sandwiches'.

Supplementary data

All other crystallographic data may be obtained from the Cambridge Crystallographic Data Centre, where CIF files have been deposited (Deposition Numbers 129249 for **3**, 129250 for **4**, and 129251 for **5**).

Abstract

Reaction between the π-accepting tetracyanoethene (TCNE) or tetracyano-*p*-quinodimethane (TCNQ) ligands and the π-electron-rich organometallic species $Cp(dppe)Fe^{+}$ results in the formation of the complexes $[\{Cp(dppe)Fe\}_n\{\eta^n\text{-TCNX}\}](PF_6)_n$ ($n=1$, 2 and 4). Infrared spectroscopy, magnetic moment measurements, electron-spin resonance (ESR) and cyclic voltammetry data indicate a net transfer of one π electron to the TCNX acceptor ligand. The polynuclear complexes have an intense intervalence electron transfer absorption band in the near-infrared region. The values for the intervalence parameters $\alpha=0.02$–0.06 and $V_{ab}=200$–$600\ cm^{-1}$ indicate that these complexes can be classified as class II according to Robin-Day. Estimation of the rate of electron transfer affords values in the order of $10^8\ s^{-1}$, which are compared and discussed with values estimated for other polynuclear systems containing TCNE and TCNQ ligands as bridges. The solvent effect on the intervalence transition follows Hush's prediction for highly polar solvents, thereby permitting evaluation of the reorganizational energy. For the related series $[\{Cp(dppe)Fe\}_n\text{–}(\mu\text{-X})](PF_6)_n$, the reorganization energy appears to depend mainly on the inner reorganization energy through changes to vibrational modes of the bridge. Reorganizational energy is not as important in determining the electron transfer rate as the activation energy, E_a. A linear relationship is found between the rate constant $\ln(k_{et})$ and the activation energy. These results can be discussed within the Marcus theory of electron transfer. The fast and efficient electron transfer between the metal fragments is discussed using molecular orbital arguments. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Hush theory; Iron complexes; Mixed valence; TCNE complexes; TCNQ complexes

1. Introduction

Tetracyanoethene (TCNE) and the related tetracyano-*p*-quinodimethane (TCNQ) are molecules that present interesting acceptor properties, which are associated with their unusual electrical and magnetic behaviour [1–4]. TCNE and TCNQ can act as σ ligands (via the nitrile-N lone pair) as a π-type arrangement (via the C=C olefinic bond in TCNE) or 'free' (ion pair) mode II (Fig. 1) [5].

Many coordination compounds with considerable metal ligand delocalization have been reported [6–10]. Several special features make such compounds interesting for practical purposes: (1) intense charge-transfer absorption bands in the visible and near-infrared regions can make such systems useful as dyes for information storage using optic fibre and diode laser [11,12]; (2) the communication between metal-connected ligands and/or ligand-connected metals has received attention in the area of low-dimensional polymers with electron-propagating capabilities and within the concept of 'molecular electronics' [13]; (3) the existence of several close-lying and easily accessible redox transitions renders

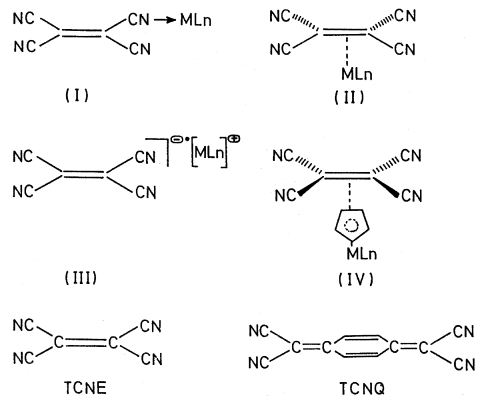

Fig. 1. Coordination modes of TCNE and TCNQ ligands.

PII S0277-5387(99)00331-9

these compounds suitable as 'electron reservoirs', especially because small structural changes during the redox transitions of extensively delocalized systems favour rapid electron transfer due to the small reorganization barriers [14–16].

Non-reduced TCNE and TCNQ are rather poor ligands for metal centres; however, on electron uptake by back-donation or full reduction with one or two electrons, they can bind metal fragments via modes I–IV.

In connection with points (2) and (3), we report here the preparation of the complexes $[\{Cp(dppe)Fe\}_n\{\eta^n\text{-TCNX}\}](PF_6)_n$ and the study of the intermetallic electron transfer in the following polynuclear systems:

$[Cp(dppe)Fe(TCNE)]PF_6$ (**1**)
$[\{Cp(dppe)Fe\}_2(TCNE](PF_6)_2$ (**2**)
$[Cp(dppe)Fe(TCNQ)]PF_6$ (**3**)
$[\{Cp(dppe)Fe\}_4(TCNQ](PF_6)_4$ (**4**)

While several di- and polynuclear complexes with extensive π delocalization including the metal centre have been reported [6–10], no detailed quantitative studies on the electron transfer via TCNE and TCNQ bridges have been reported.

We have selected the fragment $Cp(dppe)Fe^+$ because its electron richness permits efficient electronic delocalization [11–21], it binds strongly to nitrogen cyanide containing ligands [22–25] and the iron in the fragment is electrochemically active [11–21].

2. Results and discussion

2.1. Mononuclear complexes

$Cp(dppe)FeI$ reacts with an excess of TCNE or TCNQ in the presence of NH_4PF_6 or $TlPF_6$ in CH_3OH or CH_2Cl_2, respectively, to give dark black–green solids whose elemental analysis and spectroscopic properties agree with the mononuclear formulation $[Cp(dppe)Fe(TCNX)]PF_6$. As observed for another d^5 paramagnetic mononuclear complex $[(C_5R_5)Mn(CO)_2(\eta^1\text{-TCNX})]$ and others [8–10], magnetic resonance investigations of complexes **1** and **3** have been hampered by the paramagnetism of the complexes. The dark-black colour is typical of complexes of the type $Cp(dppe)Fe^{III}$ [19–21]. Additional evidence for the reduction of the TCNX ligand is provided by from IR spectra [5] (see Table 1). As for other monodentate TCNX complexes, three ν_{CN} bands were observed [26] as expected for the non-symmetrically bound ligands [5,27–33]. The ν_{CN} IR bands are quite intense and shifted to lower wavenumbers compared to those of the free, non-reduced ligands. This indicates nitrile-N coordination and sizeable back-donation of π electron density from the metal fragments to the TCNX ligand [5,27–33]. The ν_{CN} wavenumber of the complexes lies between those of the free anion radicals and the values found for the dianions.

Thus, the mononuclear complexes are distinguished from polynuclear complexes and from the free ligands as the highest intensity is displayed by the low-energy band for the polynuclear systems [6–10]. In the IR spectra of complexes **1** and **3** the highest intensity corresponds to the high-energy band. IR bands for the $Cp(dppe)Fe^+$ fragment appear normally [34]; the main values are displayed in Table 1.

2.1.1. Magnetic measurements

Magnetic moments for complexes **1** and **3** are typical values for $[Cp(dppe)FeX]^+$ complexes [19,20], corresponding to one unpaired electron in low spin Fe^{III}. The unpaired electron arising from the radical $TCNX^-$ could not be observed due to spin coupling between them in solid state.

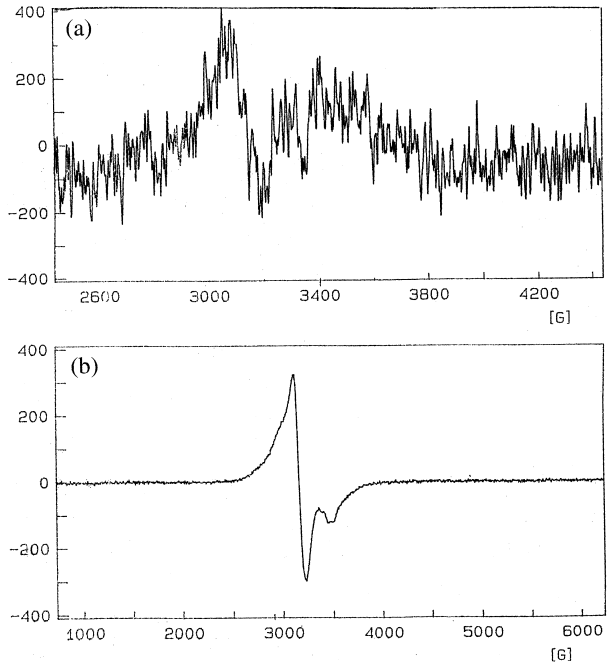

Fig. 2. ESR spectra of complex **1** in CH_2Cl_2 solution (a) and in solid state (b) at room temperature.

The ESR data discussed below are also in agreement with this argument. Values are shown in Table 2.

2.1.2. ESR spectra

The ESR spectra of mononuclear complexes **1** and **3** at room temperature in solid state exhibit one single signal, characteristic of $Cp(dppe)Fe^{III}X$ complexes [35–37]. Three well-separated features corresponding to the three components of the **g** tensor — expected for low symmetry pseudo-octahedral piano–stool complexes — were observed (see Fig. 2). Data are shown in Table 2. This indicates that the signal observed in both cases may correspond to the unpaired electron centred on the metal. The signal corresponding to the $TCNE^-$ and $TCNQ^-$ radical ligands was not observed, probably due to intramolecular spin coupling between the $TCNX^-$ molecules in the solid state. Consistent with this, in CH_2Cl_2 solution the ESR spectra of **1** and **3** exhibit several complex signals with various features (see Fig. 2), which presumably include the signal of $Cp(dppe)Fe^{III}L$ as well as the signals of $TCNX^-$. As found for other $LnM(\eta^1\text{-}TCNX^-)$ complexes [38,39], owing to the lowered symmetry, 16 (four different nitrogen) or 1296 (four different nitrogen and four different ^1H) lines for TCNE and TCNQ, respectively, could be observed.

2.1.3. Cyclic voltammetry

Mononuclear systems are reduced at more negative potentials than TCNX ligands (Table 3). This is a consequence of metal-to-ligand electron transfer in the ground state, which leaves either the single reduced ligand or the oxidized metal fragment available for reduction at relatively negative potentials.

Oxidation of the complexes is almost always irreversible; it may thus be safely assumed that these are metal-based. Thus peak potentials of about 0.7–0.8 V versus SCE

Table 3
Electrochemical data [a] for TCNX ligands and their complexes

Compound	$E^{ox}_{1/2}$ (metal)	E^{red}_1 (0/1−) [d]	E^{red}_2 (−/2−) [d]
TCNE		0.18	−0.85
$[Cp(dppe)Fe(TCNE)]PF_6$ (**1**)	0.83 [b]	−0.61	−0.95
$[\{Cp(dppe)Fe\}_2(TCNE)](PF_6)_2$ (**2**)	0.89, 0.70 [c]	−0.53	−0.88
TCNQ		0.25	−0.31
$[Cp(dppe)Fe(TCNQ)]PF_6$ (**3**)	0.78 [b]	−0.49	−0.70
$[\{Cp(dppe)Fe\}4(TCNQ)](PF_6)_4$ (**4**)	0.93, 0.75 [c]	−0.65	−0.80

[b] Anodic peak potential are given for irreversible oxidation processes.
[c] Two very near quasi-reversible waves were observed.
[d] Quasi-reversible waves.

(saturated calomel electrode) for complexes [Cp(dppe)-Fe(nitrile)]PF_6 have been observed [22–25].

2.1.4. Electronic spectroscopy

Complexes **1** and **3** exhibit intense bands at about 545 and 619 nm, which are typical of the absorption behaviour of [Cp(dppe)Fe^{III}L]$(PF_6)_2$ complexes [17–21] (Fig. 3). Table 2 summarizes the data obtained. No absorption was observed above 700 nm. This constitutes strong evidence for the Fe^{III}–($TCNX^-$) state because Fe^{II}–NCR complexes exhibit only one band at about 450 nm [40].

2.2. Polynuclear complexes

TCNE or TCNQs react with an excess of Cp(dppe)FeI in the presence of NH_4PF_6 or $TlPF_6$ in CH_3OH or CH_2Cl_2, respectively, to give black–green solids of composition {[Cp(dppe)Fe]$_2$TCNE}$(PF_6)_2$ and {[Cp(dppe)Fe]$_4$-TCNQ}$(PF_6)_4$. Similarly to complexes **1** and **3**, NMR studies are precluded due to the paramagnetism of the complexes. In agreement with this, the related complex [$Ru(NH_3)$]$_4$–(μ-TCNX)]$^{10+}$ is also paramagnetic [7]. No suitable crystals were obtained for X-ray structural determination of the complexes.

2.2.1. Infrared spectra

As pointed out by Kaim [8] and others [28], for [MLn]$_n$–(TCNX) complexes some information about the structure of the complexes can be obtained from IR spectroscopy. The number and the pattern of bands observed by IR depend on the symmetry of the complexes; for the binuclear systems [MLn]$_2$–(μ-TCNX) three isomers can be expected: 1,2-*trans* (C_{2h}), 1,2-*cis* (C_{2v}) or 1,1′ (C_{2v}). According to their symmetry, two or four bands could be observed for the isomers 1,2-*trans*, 1,1-*cis* or 1,2-*cis*, respectively. This is consistent with IR data for [MLn]$_n$–(μ-TCNX) complexes having a 1,2-*trans* geometry: [$(PPh_3)_2$(CO)Ir]$_2$TCNE [29], (2176(m), 2097 vs); [L′L_2Cu(μ-TCNE)CuL_2]$_n$ [30], (2190, 2147); [$Rh_2(O_2CCF_3)_4$]$_2$TCNE [31], (2230, 2210); [Tl(18-crown-6)TCNQ] [32], (2181, 2154); [$Ru(PPh_3)_2$]$_2$TCNQ [33] (2170, 2140).

In agreement with this, the binuclear complex **2** exhibits two bands (one as a shoulder), suggesting the 1,2-*trans* configuration for this complex. This is the favoured configuration for bulky fragments [5] such as CpFe(dppe). As expected for tetranuclear complexes (with a slightly perturbed D_{2h} symmetry), two bands are observed for complex **4**. Thus complexes [$Ru(NH_3)_5$–(μ_4-TCNX)] and [C_5Me_5–$Mn(CO)_2$]$_4$–(μ_4-TCNX) exhibit bands at: 2163, 2121 cm^{-1} for the Ru–TCNE complex; 2153, 2096 cm^{-1} for the Ru–TCNQ complex; 2160, 2110 cm^{-1} for the Mn–TCNE complex; and 2170, 2105 cm^{-1} for the Mn–TCNQ complex. As observed for similar $(MLn)_2TCNX^{n+}$ and $(MLn)_4$-$TCNX^{n+}$ complexes the highest intensity is displayed by the low-energy band, behaviour that is characteristic of polynuclear systems [6–10].

2.2.2. Magnetic measurements

The low magnetic moment for the binuclear complex **2** could be due to the delocalization of the unpaired electron between the two iron atoms, which couple antiferromagnetically with the unpaired electron of the $TCNE^-$ ligand. On the other hand the tetranuclear complex **4** exhibits the highest magnetic moment, which could be due to the complex interaction of several paramagnetic Fe^{III} centres. Similar magnetic moments have been observed for tetranuclear {[Cp*Mn(CO)$_2$]$_4$–(μ-TCNE)} complexes [6–10].

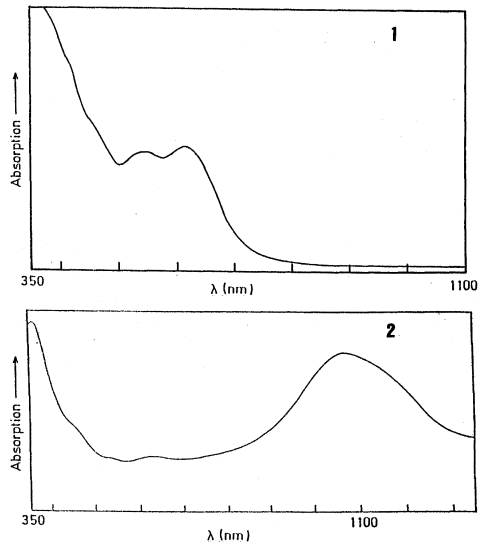

Fig. 3. Electronic absorption spectra of complexes **1** and **2** in CH_2Cl_2 solution.

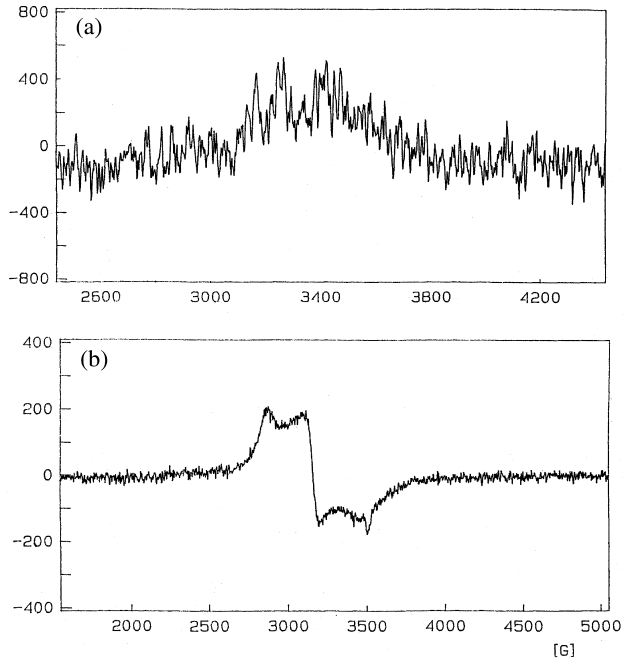

Fig. 4. ESR spectra of compound **2** in CH_2Cl_2 solution (a) and in solid state (b) at room temperature.

Table 4
Intervalence band parameters and derived electronic coupling parameter for the mixed-valence complexes [a]

[a] In CH_2Cl_2 solution.

2.2.3. ESR spectra

The ESR spectrum of compound **2** in solid state shows a broad line exhibiting recognizable anisotropic features (Fig. 4), behaviour typical of delocalized mixed-valence systems [35–37]. The spectrum of compound **4** displays a similar pattern with the **g** factors summarized in Table 3. As observed for other multinuclear Ru–TCNX compounds [7], the ESR signal for the radical $TCNX^-$ ligand was not observed. In CH_2Cl_2 solution, similarly to the mononuclear complexes, the signal of the iron centre as well as the complex signal of the organic $TCNX^-$ radical were observed (see Fig. 4).

2.2.4. UV–Vis spectra

The UV–Vis spectra of complexes **2** and **4** revealed, in addition to absorptions typical for $Cp(dppe)Fe^{III}L$ [17–21] and $Cp(dppe)Fe^{II}L$ [40] chromophores, a new absorption band at about 1100 nm. The electronic spectrum of compound **2** in CH_2Cl_2 is shown in Fig. 3.

These observations coupled with data on similar $Cp(dppe)Fe^{III}$–L–$Fe^{II}(dppe)Cp$ systems [11–21] allow us to assign this near-IR band to an intervalence transfer transition. Thus, on reducing the mixed valence complexes **2** and **4** with Red Al, sodium bis(2-methoxyethoxy)aluminium hydride, the intervalence absorption disappears.

2.2.5. Cyclic voltammetry

The reduction potential of the polynuclear complexes with TCNE and TCNQ (Table 3) are more negative than those of the corresponding free ligands; this is consistent with the electron transfer involved in the formation of the complexes, leaving the ligands as $TCNX^-$ or $TCNX^{2-}$.

Table 5
Electronic interaction parameter and electron transfer rate constants for **2**, **4** and other polynuclear mixed-valence complexes containing TCNE and TCNQ bridges

Complexes	V_{ab} (cm^{-1})	k_{et} (seg^{-1})

[b] This work.

$$(Cp(dppe)Fe^{II})^+ + TCNX \rightarrow (Cp(dppe)Fe^{III}\text{–}[TCNX])^{\bullet -} \quad (1)$$

In the oxidation region of the metal fragment, the cyclic voltammogram exhibits two non-well-defined waves which probably involve the oxidation of the metal centres. The difference in peak potential indicates a considerable coupling between the metal centres. From the wave separation, the comproportionation constant, K_c, relative to the following equilibrium:

$$Fe^{II}\text{–}TCNX\text{–}Fe^{II} + Fe^{III}\text{–}TCNX\text{–}Fe^{III} \leftrightarrow 2Fe^{II}\text{–}TCNX\text{–}Fe^{III} \quad (2)$$

can be computed as $K_c = 1626$ and 1202 for complexes **2** and **4**, respectively. The relatively high K_c values indicate a considerable electronic interaction between the iron atoms.

2.2.6. Electronic interaction in the mixed-valence species

Information about the degree of metal–metal interaction in the mixed-valence complexes can be obtained from the intervalence absorption band using the Hush formalism [11–16,41–45]. According to this, the degree of delocalization parameter is given by the formula:

$$\alpha = \frac{(4.2\times10^{-4})\,\varepsilon_{max}\Delta\nu_{1/2}}{\nu_{max}d^2} \quad (3)$$

where $\Delta\nu_{1/2}$ is the bandwidth at half-maximum (cm^{-1}), ε_{max} is the maximum extinction coefficient, ν_{max} is the band position (cm^{-1}) and d is the metal–metal distance in Å. Because no X-ray determination is available for complexes **2** and **4**, the metal–metal distance was estimated from structural data for similar complexes [46–48]. The α values shown in Table 4 indicate a class II Robin-Day system.

On the other hand the electronic coupling term, V_{ab}, can be determined by the following formula [41–45]:

$$V_{ab} = \alpha^{1/2}\nu_{max} \quad (4)$$

The calculated values, displayed in Table 4, indicate a more or less strong metal–metal coupling, although somewhat less than for the cyanide ligand. From intervalence transfer transition data for other organometallic systems, the interaction parameter V_{ab} was estimated using Eq. (4). Values shown in Table 5 for other complexes indicate that metallic fragments such as $(NH_3)_5Ru$ permit a stronger interaction than the iron fragment, which can be due to steric hindrance of the $Cp(dppe)Fe^+$ arising from the bulky dppe [46]. From data

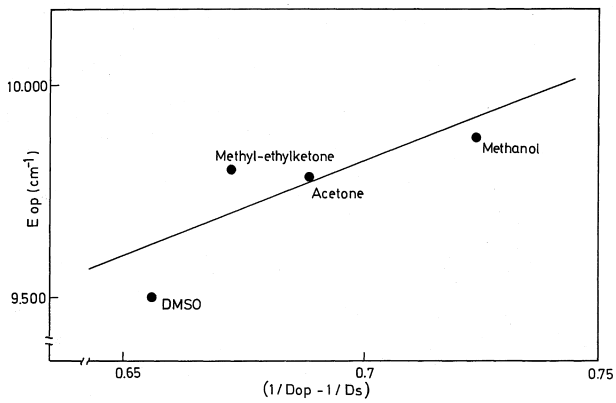

Fig. 5. Plot of intervalence absorption energy for E_{op} vs. $(1/D_{op}-1/D_s)$.

in Table 5, it can also be concluded that the interaction between the metal centres is highly dependent on the nature of the organometallic fragment.

An approximate estimation of the rate of electron transfer between the metal centres in complexes **2** and **4** can be made using the expression [41–45]:

$$k_{th}=\left[\frac{2\pi(V_{ab})^2}{h}\right]\left[\frac{\pi}{KTE_m}\right]^{1/2}\left[e\left(-\frac{E_a}{RT}\right)\right] \quad (5)$$

where $E_m=E_{op}$ and $E_a=[(E_m)^2/4E_m]$. E_m, the total reorganization energy, has two components: the outer-reorganization energy E_o, and the inner-reorganization energy E_i; thus $E_m=E_i+E_o$.

Although these equations differ in absolute values from those measured experimentally, comparison for a related series of compounds is valid [18]. The values about $10^8\ s^{-1}$ calculated for compounds **2** and **4** indicate a fast electron transfer between the iron atoms. Similar rates are obtained using Eq. (5) for other organometallic systems, as can be seen in Table 5. The similar k_{et} values, notwithstanding the different organometallic fragment, mean that the nature of the bridge is most important in determining the electron transfer rate. It is interesting to compare the TCNX ligands as bridges with the cyanide bridging ligand for which electron-transfer rates of $10^4\ s^{-1}$ were estimated in the mixed-valence complexes $[Cp(dppe)Fe–CN–MLn]PF_6$ (MLn = $Cp(dppe)Fe$, $Mn(CO)_2(dppm)P(OPh)_3$) [18].

The solvent effect on the intervalence transition gives information about the reorganization energy arising from rearrangements of the inner and outer coordination spheres [49,50]. With the assumption of a dielectric continuum model, the dependence of E_{op} on solvent polarization is given by:

$$E_{op}=E_i+E_o \quad (6)$$

$$E_{op}=E_i+e^2\left(\frac{1}{2a_1}+\frac{1}{2a_2}-\frac{1}{d}\right)\times\left(\frac{1}{D_{op}}-\frac{1}{D_s}\right)$$

The intercept of a plot of E_{op} versus $(1/D_{op}-1/D_s)$ for several solvents affords the E_i values (Fig. 5 and Table 6). From Eq. (6) the outer-sphere reorganizational parameters E_o can be estimated. Values for complexes **2** and **4** and for other complexes containing the CpFe(dppe) moiety are shown in Table 6. Some comments can be made from this data: comparing the E values for complexes **2** and **4**, mostly larger variations on the outer-reorganizational parameters than for the inner-reorganization values are observed (differences of 21% on E_i and of 43% on E_o are observed). This can be explained by the similar metal–ligand vibration modes involved in the electron-transfer process. Attention must be drawn to the high inner-reorganization energies involved in electron-transfer events in the complex $\{[Cp(dppe)]_2–(\mu\text{-}S–C_5H_5N)\}(PF_6)_2$. This may be due to an enhanced change on vibrational modes of the thiopyridine ligand upon electron transfer.

It is interesting to note that, although the complexes displayed in Table 7 all have the same fragment CpFe(dppe), the reorganization energy is very different. For instance, compare $E_m=12\,697\ cm^{-1}$ for $[CpFe(dppe)]_2–(\mu\text{-}S–C_5H_5N)](PF_6)_2$ [21] with $E_m=6038\ cm^{-1}$ for $\{[CpFe(dppe)]_2–\mu\text{-}CN\}PF_6$ [18].

This means that, for this series, the reorganizational energy is highly dependent on some properties of the bridge ligand. Because the data in Table 7 indicate that the main contribution to the reorganizational energy arises from the inner-reorganization energy, the observed variations E_m might stem from changes in the vibrational mode of the bridging ligand.

Recent studies of electron transfer in the mixed-valence systems $[(NC)_5M^{II}–CN–Ru^{III}(NH_3)_5]^-$ (M = Fe or Ru)

Table 6
Solvent dependence of the intervalence transition in complexes **2** and **4**

Complex	Solvent	E_{op} (cm^{-1})	$(1/D_{op}-1/D_s)$	E_i (cm^{-1})	E_o (cm^{-1})	E_m

4	CH_2Cl_2	9978	0.5899			

Table 7
Solvent reorganization energies [a] for complexes **2**, **4** and other related complexes containing the moiety CpFe(dppe)$^+$

Complex	E_i (cm^{-1})	E_o (cm^{-1})	E_m (cm^{-1})
[{CpFe(dppe)}$_2$–(μ-TCNE)](PF$_6$)$_2$	8394	1448	9842
[{CpFe(dppe)}$_4$–(μ-TCNQ)](PF$_6$)$_4$	6621	2587	9208
[{CpFe(dppe)}$_2$–(μ-S–C$_5$H$_4$N)](PF$_6$)$_2$	12470	227	12697
[{CpFe(dppe)}$_2$–(μ-CN)]PF$_6$	2096	3942	6038

[a] Values of E_m, E_i and E_o were determined from E_{op} vs. $(1/D_{op}-1/D_s)$ plots. Values for complexes other than complexes **2** and **4** were taken from [11–21].

have shown that a large part of the reorganization energy comes from modes assigned to the bridging ligand [51,52].

Comparing the reorganizational values with electron-transfer rates it can be observed that there does not exist a correlation between them. According to semiclassical electron-transfer theory [41–45], electron-transfer reaction rates (k_{et}) are governed by three parameters (Eq. (5)): (1) the electronic coupling (V_{ab}) between reactants and products, (2) the free-energy change for the reaction (ΔG°) and (3) the total reorganization energy.

From Tables 5 and 7 it can be seen that no correlation exists between k_{et} and the electron coupling or the reorganization energy. However, the electron-transfer rate appears to be related to ΔG° through the relation $E_a=(E_{op})^2/(E_{op}-\Delta G^\circ)$. In fact, a linear correlation between $\ln(k_{th})$ and E_a holds, as shown in Fig. 6. Furthermore, this expression has the shape of the most general and simple relationship between k_{et} and E_a, the classical Marcus equation $k_{et}=Ae(-E_a)$ [41–45]. We believe that this is a remarkable example where the general electron rate theory of Marcus works well in mixed-valence complexes.

*2.3. Nature of the electron transfer in binuclear complexes **2** and **4***

The efficient and fast electron transfer between the metal centres in complexes **2** and **4** can be explained by considering the molecular orbitals involved in the Fe–N interaction. These can be adequately established from an orbital interaction diagram built from the molecular orbital (MO) fragments of CpFe(dppe)$^+$ and nitriles [53–56]. As shown in Fig. 7, the HOMO of complexes involves a π-delocalized molecular orbital throughout the Fe–TNCX–Fe moiety.

3. Experimental

All operations were conducted under a pure dinitrogen or argon atmosphere using standard Schlenk and glovebox techniques. Solvents were dried according to established protocols and degassed prior to use. Unless otherwise specified, reagents were obtained from commercial supplies and used as received. Magnetic measurements were carried out by Gouy's method at room temperature using a Johnson Matthey magnetic susceptibility balance with tetrathiocyanate cobaltate(II) as calibrant balance. ESR spectra were recorded on Bruker ECS 106 spectrometer. FTIR spectra were recorded on an FT–IR Perkin Elmer 2000 spectrophotometer. Electronic absorption spectra were recorded on a Shimadzu UV 160. Cyclic voltammetry was performed on a three-electrode configuration (glassy-carbon working electrode, satured calomel as reference) with 0.1 M solution of NH_4PF_6 as electrolyte support in CH_2Cl_2. Cp(dppe)FeI was prepared as previously reported [22–25].

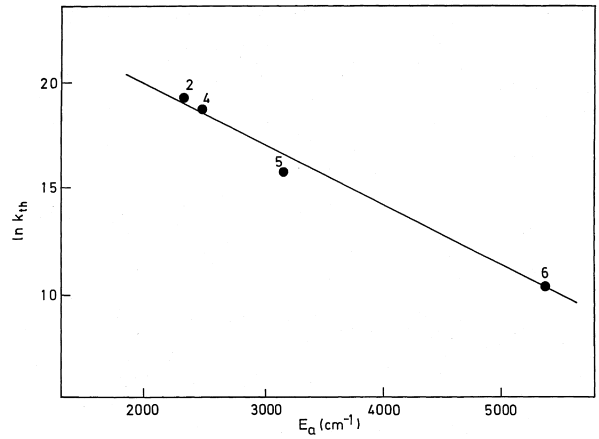

Fig. 6. Estimated electron-transfer rates vs. activation energy E_a for complexes **2**, **4**, {[CpFe(dppe)]$_2$–(μ-S–C$_5$H$_4$N)}(PF$_6$)$_2$ (**5**) and {[CpFe(dppe)]$_2$–(μ-CN)} PF$_6$ (**6**).

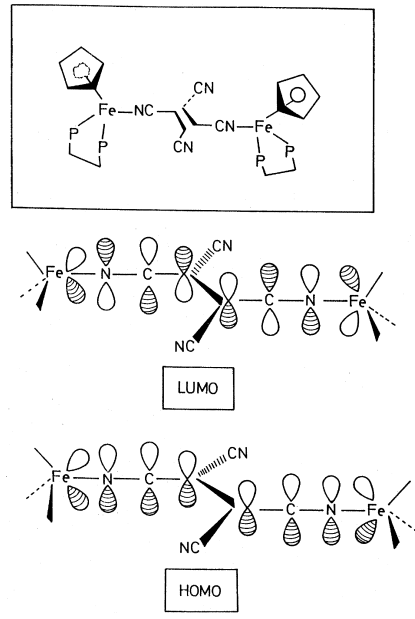

Fig. 7. Proposed HOMO-LUMO of complexes **2** and **4**.

3.1. [Cp(dppe)Fe–(TCNE)]PF_6 (**1**)

A solution of Cp(dppe)FeI (70 mg, 0.10 mmol) in 20 ml of CH_3OH was added dropwise over 0.03 g, 0.23 mmol of $C_2(CN)_4$ and 0.03 g, 0.18 mmol of NH_4PF_6. The mixture was stirred at room temperature for 24 h. The reaction mixture was then evaporated to dryness, and the solid residue redissolved in 30 ml and the solution filtered through Celite and evaporated to about 15 ml. After this a black solid was formed, which was decanted and washed twice with hexane–ether and dried in vacuo. Yield: 28 mg (29%). *Anal*. Calc. for $C_{41}H_{29}F_6N_4P_3Fe \cdot CH_2Cl_2$: C, 52.08; H, 3.54; N, 6.38. Found: C, 51.73; H, 4.02; N, 5.90%.

3.2. [{Cp(dppe)Fe}$_2$–(μ-TCNE)]$(PF_6)_2$ (**2**)

To a solution of Cp(dppe)FeI, 0.15 g, 0.23 mmol in 10 ml of CH_3OH, was added dropwise slowly over 0.015 g, 0.11 mmol of $C_2(CN)_4$ in 20 ml of CH_3OH in the presence of NH_4PF_6 (0.03 g, 0.18 mmol). The mixture was stirred at room temperature for 24 h and then concentrated to dryness under reduced pressure. The solid was dissolved in CH_2Cl_2 (30 ml) and filtered through Celite. The solution was concentrated in vacuum to about 15 ml and the black solid precipitated was washed twice with hexane–ether and dried in vacuo. Yield: 0.045 g (28%). *Anal*. Calc. for $C_{72}H_{58}F_{12}N_8P_2Fe_2$: C, 62.26; H, 4.4; N, 5.0. Found: C, 61.7; H, 5.0; N, 5.0%.

3.3. [Cp(dppe)Fe–(TCNQ)]PF_6 (**3**)

A solution of Cp(dppe)FeI, 0.15 g, 0.23 mmol in 10 ml of CH_3OH, was added dropwise over 0.07 g, 0.34 mmol of TCNQ and in the presence of NH_4PF_6 (0.06 g, 0.36 mmol). Following the procedure outlined for separation and purification of compound **1**, 0.2 g of black solid was obtained. Yield: 68%. *Anal*. Calc. for $C_{43}H_{33}F_6N_4PFe \cdot CH_2Cl_2$: C, 55.43; H, 3.6; N, 5.8. Found: C, 54.3; H, 3.0; N, 4.8%.

3.4. [{Cp(dppe)Fe}$_4$–(μ-TCNQ)]$(PF_6)_4$ (**4**)

To a solution of Cp(dppe)FeI, 0.15 g, 0.23 mmol in 20 ml of CH_3OH, was added dropwise slowly over 0.03 g, 0.14 mmol of TCNQ in 20 ml of CH_3OH in the presence of NH_4PF_6 (0.04 g, 0.25 mmol). The mixture was stirred at room temperature for 24 h. Separation and purification procedures similar to that for compound **3** afforded a black powder. Yield: 0.2 g (48%). *Anal*. Calc. for $C_{136}H_{120}F_{24}N_4P_4Fe_4 \cdot 2CH_2Cl_2$: C, 57.09; H, 4.2; N, 1.96. Found: C, 55.39; H, 4.26; N, 2.6%.

3.5. Preparation of complexes **1–4** using $TlPF_6$ as halide abstractor and CH_2Cl_2 as solvent

Similar compounds were obtained using the following typical procedure.

3.5.1. [Cp(dppe)Fe–(TCNE)]PF_6

A mixture of 0.15 g, 0.25 mmol of Cp(dppe)FeI, 0.04 g, 0.31 mmol of TCNE and 0.16 g, 0.45 mmol of $TlPF_6$ (**caution**: thallous salts are very poisonous and should be handled with care) in 30 ml of CH_2Cl_2 was stirred at room temperature for 3 days. The solution was then filtered through Celite and the filtrate was removed in vacuo to about 15 ml. The black solid precipitated was isolated by decantation and washed twice with n-hexane–ether, and dried in vacuo to give 0.12 g, 60% yield.

Abstract

Treatment of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with 2 equiv. of *o*-phenylenediacetonitrile ($1,2\text{-}C_6H_4(CH_2CN)_2$) gives the complexes $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**1** and **2**) via displacement of the acetonitrile ligands. The tungsten complex $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**) has been characterised crystallographically. The geometry surrounding the coordination sphere is capped octahedral with a carbonyl group in the unique capping position, an iodide and two carbonyls in the capped face and an iodide and two nitrogen atoms from nitrile groups in the uncapped face. Reactions of **1** and **2** with equimolar amounts of L (L = PPh_3, $AsPh_3$, $SbPh_3$, $P(OPh)_3$) affords $[MI_2(CO)_3(NCMe)L]$, which followed by an in situ reaction with 1 equiv. of $1,2\text{-}C_6H_4(CH_2CN)_2$ gives the new mixed ligand complexes $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}L]$ (**3**–**10**) in high yield. Reaction of $[MI_2(CO)_3(NCMe)_2]$ and $[MI_2(CO)_3(NCMe)(PPh_3)]$ with 2 and 1 equiv. of L^1 ($L^1 = [WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**)) gives the first trimetallic $[MI_2(CO)_3L^1{}_2]$ (**11** and **12**) and bimetallic $[MI_2(CO)_3L^1(PPh_3)]$ (**13** and **14**) *o*-phenylene diacetonitrile bridged complexes in high yield. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Since our initial report in 1986 [1], of the synthesis and characterisation of the bis(acetonitrile) complexes $[MX_2(CO)_3(NCMe)_2]$ (M = Mo or W; X = Br or I), we have described the preparation and structural characterisation of a number of seven-coordinate complexes of molybdenum(II) and tungsten(II) containing ligands with one nitrile functional group attached to the metal [2–12]. Hitherto, no examples with ligands containing two nitrile functional groups have been reported of any type of seven-coordinate complexes of molybdenum(II) and tungsten(II).

In this paper we describe the reactions of the seven-coordinate complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) and $[MI_2(CO)_3(NCMe)L]$ (L = PPh_3, $AsPh_3$, $SbPh_3$ or $P(OPh)_3$) with the bis(nitrile) functionalised ligand *o*-phenylenediacetonitrile ($1,2\text{-}C_6H_4(CH_2CN)_2$). The molecular structure of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ is also discussed. The structure of $[WI_2(CO)_3\{1,2\text{-}C_6H_4\text{-}(CH_2CN)_2\text{-}N\}_2]$ shows that only one nitrile group is attached to the tungsten in this complex. In view of this observation, we also describe the synthesis and characterisation of the first trimetallic and bimetallic *o*-phenylenediacetonitrile-bridged complexes $[MI_2(CO)_3L^1{}_2]$ (M = Mo, W; $L^1 = [WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$) and $[MI_2\text{-}(CO)_3L^1(PPh_3)]$.

2. Experimental

The seven-coordinate complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) [1] and $[MI_2(CO)_3(NCMe)L]$ (L = PPh_3, $AsPh_3$, $SbPh_3$, $P(OPh)_3$) [4], were prepared by literature methods. All chemicals were purchased from commercial sources, and CH_2Cl_2 was dried over calcium hydride and distilled before use.

Elemental analyses (C, H and N) were determined using a Carlo Erba elemental analyser MOD 1108 (using helium

[a] Spectra recorded as thin $CHCl_3$ films between NaCl plates.

as a carrier gas). The IR spectra were recorded as thin $CHCl_3$ films between NaCl plates on a Perkin–Elmer 1600 series FTIR spectrophotometer. ^1H (referenced to $SiMe_4$) NMR spectra were recorded using a Bruker AC 250 MHz NMR spectrometer. Molecular weights were determined by Rast's method [13], using camphor as the standard.

2.1. $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (2)

To a stirred solution of $[WI_2(CO)_3(NCMe)_2]$ (0.50 g, 0.83 mmol) in CH_2Cl_2 (20 cm^3) was added 1,2-$C_6H_4(CH_2CN)_2$-*N* (0.260 g, 1.66 mmol). After stirring the solution at room temperature for 1 h, the mixture was filtered and the solvent removed in vacuo to give a red–brown powder of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**). Recrystallisation from CH_2Cl_2–Et_2O (50:50 ratio) and cooling to −17°C gave suitable single crystals for X-ray analysis. Yield of pure product 0.518 g, 75%.

A similar reaction of $[MoI_2(CO)_3(NCMe)_2]$ with 2 equiv. of 1,2-$C_6H_4(CH_2CN)_2$ in CH_2Cl_2 at room temperature gives $[MoI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**1**) after recrystallisation from CH_2Cl_2–Et_2O. See Tables 1–3 for physical, analytical and spectroscopic data.

2.2. $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}(PPh_3)]$ (4)

To a stirred solution of $[WI_2(CO)_3(NCMe)_2]$ (0.500 g, 0.83 mmol) in CH_2Cl_2 (20 cm^3) was added PPh_3 (0.218 g, 0.83 mmol). After 1 min, 1,2-$C_6H_4(CH_2CN)_2$ (0.130 g, 0.83 mmol) was added, and the solution was stirred at room temperature for a further 30 min, after which filtration, followed by removal of the solvent in vacuo, gave the yellow complex $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}(PPh_3)]$ (**4**), which was recrystallised from CH_2Cl_2–Et_2O (yield 0.694 g, 89%).

Similar reactions of $[MI_2(CO)_3(NCMe)_2]$ with 1 equiv. of L (L = PPh_3 (1 min), $AsPh_3$ (3 min), $SbPh_3$ (5 min), or

[a] Spectra recorded in $CDCl_3$ (+25°C, referenced to $SiMe_4$).

P(OPh)$_3$ (5 min)) in CH_2Cl_2 gives [$MI_2(CO)_3$(NCMe)L], followed by an in situ reaction of an equimolar amount of 1,2-$C_6H_4(CH_2CN)_2$ affords [$MI_2(CO)_3${1,2-C_6H_4-$(CH_2CN)_2$-*N*}L] (**3**, **5–10**). The complexes are then recrystallised from CH_2Cl_2–Et_2O to give the pure products. For physical, analytical and spectroscopic data, see Tables 1–3.

2.3. [$MoI_2(CO)_3L^1{}_2$] (**11**)

To a stirred solution of [$MoI_2(CO)_3(NCMe)_2$] (0.093 g, 0.18 mmol) in CH_2Cl_2 (20 cm^3) was added [$WI_2(CO)_3${1,2-$C_6H_4(CH_2CN)_2$-*N*}$_2$] (L^1) (0.30 g, 0.36 mmol). After stirring at room temperature for 15 h, the mixture was filtered and the solvent removed in vacuo to give a dark brown powder of [$MoI_2(CO)_3L^1{}_2$] (**11**). Recrystallisation from CH_2Cl_2–Et_2O (50:50 ratio) and cooling to −17°C gave pure complex **11**. Yield of pure product 0.239 g, 63%. Molecular weight for complex **11** 2102; molecular weight found by Rast's method [13] 1933.

A similar reaction of [$WI_2(CO)_3(NCMe)_2$] with 2 equiv. of L^1 in CH_2Cl_2 gives the trimetallic complex [$WI_2(CO)_3L^1{}_2$] (**12**). See Tables 1–3 for physical, analytical and spectroscopic data. Molecular weight for complex **12** 2190; molecular weight found by Rast's method [13] 2442.

2.4. [$WI_2(CO)_3L^1(PPh_3)]\cdot CH_2Cl_2$ (**14**)

To a stirred solution of [$WI_2(CO)_3(NCMe)_2$] (0.300 g, 0.50 mmol) in CH_2Cl_2 was added PPh_3 (0.13 g, 0.50 mmol). After 1 min, [$WI_2(CO)_3${1,2-$C_6H_4(CH_2CN)_2$-*N*}$_2$] (0.414 g, 0.50 mmol) was added, and the solution was stirred at room temperature for a further 15 h, after which filtration, followed by removal of the solvent in vacuo, gave the light brown complex [$WI_2(CO)_3L^1(PPh_3)]\cdot CH_2Cl_2$ (**14**), which was recrystallised from CH_2Cl_2–Et_2O. Yield of pure product 0.568 g, 71%. Molecular weight for complex **14** 1618; molecular weight found by Rast's method [13] 1717.

A similar reaction of [$MoI_2(CO)_3(NCMe)_2$] with 1 equiv. of PPh_3 for 1 min in CH_2Cl_2 followed by an in situ addition of L′ gave the bimetallic complex [$MoI_2(CO)_3L^1(PPh_3)$] (**13**) which was recrystallised from CH_2Cl_2–Et_2O. Molecular weight for complex **13** 1530; molecular weight found by Rast's method [13] 1333.

2.5. X-ray crystallography

Single crystals for X-ray crystallography of [$WI_2(CO)_3${1,2-$C_6H_4(CH_2CN)_2$-*N*}$_2$] (**2**) were grown as described in Section 2.1.

Selected bond lengths and angles are given in Table 4. $C_{25}H_{22}I_2N_4O_4W$; *M* 880.12; orthorhombic; space group *Pnma*; $a=8.531(9)$, $b=19.69(2)$, $c=17.74(2)$ Å; $U=2980(5)$ Å^3; $Z=4$; $D_{calc}=1.962$ Mg m^{-3}; $\mu=5.983$ mm^{-1}; $F(000)=1648$; reflections collected 9337; independent reflections 2858 ($R_{int}=0.0707$).

Data were collected with Mo Kα radiation using the MAR-research Image Plate System. The crystal was positioned at 70 mm from the Image Plate. 95 frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [14]. The structure was solved using direct methods with the SHELX86 program [15]. The molecule had crystallographic C_s symmetry. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions. A solvent ethanol molecule was located and given 50% occupancy. An empirical absorption correction was carried out [16]. The structure was then refined on F^2 using SHELX [17]. Final *R* indices ($I>2\sigma(I)$) were $R_1=0.0759$, $wR_2=0.1826$ with *R* indices (all data) $R_1=0.0923$, $wR_2=0.1986$. All calculations were carried out on a Silicon Graphics R4000 Workstation at the University of Reading.

3. Results and discussion

The seven-coordinate starting materials $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) used in this research have been prepared by reacting *fac*-$[M(CO)_3(NCMe)_3]$ (prepared in situ [18]) with an equimolar amount of I_2 at 0°C. [1]. In an attempt to see whether the ligand *o*-phenylenediacetonitrile can act as a chelate ligand, the reactions of equimolar amounts of $[MI_2(CO)_3(NCMe)_2]$ and 1,2-$C_6H_4(CH_2CN)_2$ in CH_2Cl_2 at room temperature for varying periods of time were carried out, giving only oily products which were difficult to isolate in a pure state. From the results of the next section, whereby the reaction of $[MI_2(CO)_3(NCMe)_2]$ with 2 equiv. of 1,2-$C_6H_4(CH_2CN)_2$ gives the bis-monodentately attached *o*-phenylenediacetonitrile complexes $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**1** and **2**), as expected, it is likely that 1,2-$C_6H_4(CH_2CN)_2$ cannot behave as a simple chelate ligand in this system. This was confirmed by the X-ray crystal structure of the tungsten derivative (Fig. 1), which shows the unattached nitrile groups are well away from possible coordination to the tungsten as a chelate ligand. It is likely that reaction of $[WI_2(CO)_3(NCMe)_2]$ with an equimolar amount of 1,2-$C_6H_4(CH_2CN)_2$ initially gives the mixed nitrile complex $[WI_2(CO)_3(NCMe)\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}]$, which probably dimerises to give $[\{W(\mu\text{-}I)I(CO)_3(1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N)\}_2]$, as we have previously observed with other mixed monodentate nitrogen donor ligand complexes [19].

Reaction of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with 2 equiv. of 1,2-$C_6H_4(CH_2CN)_2$ in CH_2Cl_2 at room temperature affords the acetonitrile displaced products $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**1** and **2**) in 72% (**1**) and 75% (**2**) yield. Complexes **1** and **2** have been characterised by elemental analysis (C, H and N) (Table 1), IR (Table 2) and ^{1}H NMR spectroscopy (Table 3) and for M = W, by X-ray crystallography. The complexes are very soluble in CH_2Cl_2 and $CHCl_3$, but only slightly soluble in diethyl ether. The complexes are air sensitive in the solid state and in solution, however, the complexes can be stored for prolonged periods of time under an inert atmosphere. The IR spectrum of, for example, **2** has, as expected, three carbonyl bands in the solution state spectrum ($CHCl_3$) at 2070, 2029 and 1948 cm^{-1}, similar to other bis(nitrile) complexes previously described [2–7]. The spectrum also shows bands due to coordinated nitrile at 2361 cm^{-1}, and unbound nitrile at 2306 cm^{-1}, which is confirmed by the X-ray crystal structure shown in Fig. 1.

Single crystals suitable for X-ray analysis of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**) were grown from a CH_2Cl_2–Et_2O (50:50) concentrated solution of **2** at −17°C. The molecular structure of **2** is shown in Fig. 1, together with the atomic numbering scheme. The molecule has crystallographic C_s symmetry. The metal atom is seven-coordinate, being bonded to three carbonyls, two iodides and two substituted methyl cyanides. The geometry of the structure can be described as a distorted capped octahedron similar to the structures $[WI_2(CO)_3(NCR)_2]$ (R = Me, Et) [9]. A carbonyl group is in the unique capping position (W–C(200) 1.98(3) Å), with the capped face containing one iodide (I(3) (W–I(3) 2.872(3) Å) and two more carbonyl groups at W–C(100) 1.98(3) Å. The uncapped face is occupied by the two nitrogen atoms (2.195(10) Å), and the remaining iodide W–I(2) 2.810(3) Å. The crystallographic mirror plane

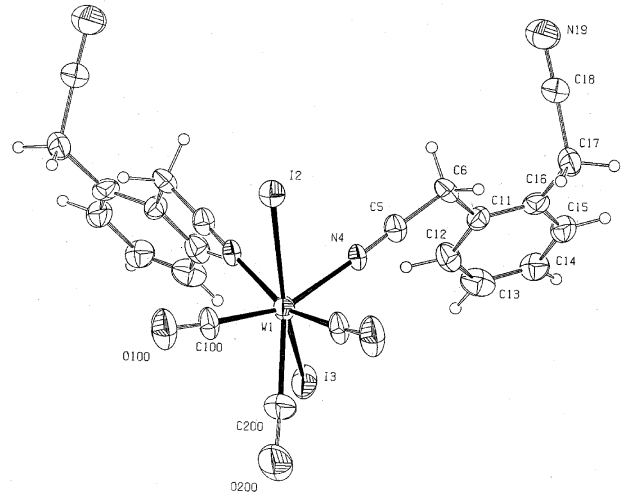

Fig. 1. The structure of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**) with the atomic numbering scheme. Ellipsoids are shown at 30% occupancy. Hydrogen atoms are shown as small circles of arbitrary radii.

passes through the metal W, both iodides and the capping carbonyl atom. It is interesting to note that an equivalent crystallographic mirror plane is observed in $[WI_2(CO)_3(NCR)_2]$ [9,10]. As in those structures, the bond to the iodide in the capped face is significantly longer than the bond to the iodide in the uncapped face where there is less steric crowding. The dimensions in the metal coordination sphere are listed in Table 4. The room temperature ^1H NMR spectra (Table 3) of **1** and **2** showed the expected resonances for the monodentate donor *o*-phenylenediacetonitrile ligands. A number of unsuccessful attempts to obtain low temperature ^{13}C NMR spectra of **2** were made, and although resonances for the nitrile groups were obtained, the resonances of coordinated carbon monoxide groups could not be observed.

Treatment of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with an equimolar amount of L (L = PPh_3, $AsPh_3$, $SbPh_3$ or $P(OPh)_3$) in CH_2Cl_2 at room temperature gives $[MI_2(CO)_3(NCMe)L]$, which when reacted in situ with 1 equiv. of 1,2-$C_6H_4(CH_2CN)_2$, yields the mixed ligand complexes $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}L]$ (**3–10**) in high yield. Complexes **3–10** have been characterised by elemental analysis (C, H and N), IR and ^1H NMR spectroscopy (Tables 1–3). The complexes are considerably less soluble than complexes **1** and **2** in CH_2Cl_2 and $CHCl_3$, and only very slightly soluble in diethyl ether, except for the $P(OPh)_3$ complexes **9** and **10**, which are more soluble. Complexes **3–10** are more stable in air than complexes **1** and **2**, however, they still decompose in solution when exposed to air. The IR spectra (Table 2) for complexes **3–10** all show three carbonyl bands, in similar positions to other related mixed-ligand complexes of the type $[MI_2(CO)_3(NCR)L]$ (M = Mo or W; R = Me, Et or Ph; L = PPh_3, $AsPh_3$, $SbPh_3$ or $P(OPh)_3$), and since the X-ray crystal structures of $[WI_2(CO)_3(NCR)(AsPh_3)]$ (R = Et, Ph) [3] and $[WI_2(CO)_3(NCMe)(PPh_3)]$ [11] have been described previously, and have either distorted capped trigonal prismatic or distorted capped octahedral geometries [20–24], it is likely that complexes **3–10** will have similar structures. The IR spectra also show two nitrile bands at approximately 2360 and 2300 cm^{-1} for the coordinated and uncoordinated nitrile groups for complexes **3–10**, which confirm the expected monodentate coordination mode of the *o*-phenylenediacetonitrile ligand in these complexes.

The mechanisms of these acetonitrile replacement reactions are likely to proceed via dissociative mechanisms, since the complexes $[MI_2(CO)_3(NCMe)_2]$ and $[MI_2(CO)_3(NCMe)L]$ obey the effective atomic number rule. Also Tripathi et al. [25] have previously prepared and isolated the 16-electron complexes $[MoX_2(CO)_3L]$ (X = Cl, Br or I; L = PPh_3, $AsPh_3$ or $SbPh_3$), which are proposed as intermediates as shown in Scheme 1.

Having prepared and structurally characterised the tungsten complex $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**) which has the *o*-phenylenediacetonitrile coordinated in a monodentate fashion, this section describes the successful

(i) $[MI_2(CO)_3(NCMe)_2] \rightarrow [MI_2(CO)_3(NCMe)] + NCMe$

(ii) $[MI_2(CO)_3(NCMe)] + L \rightarrow [MI_2(CO)_3(NCMe)L]$

(iii) $[MI_2(CO)_3(NCMe)L] \rightarrow [MI_2(CO)_3L] + NCMe$

(iv) $[MI_2(CO)_3L] + 1,2\text{-}C_6H_4(CH_2CN)_2 \rightarrow [MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}L]$

Scheme 1. Proposed mechanism for the formation of $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}L]$ from $[MI_2(CO)_3(NCMe)_2]$.

attempts to prepare and characterise the first *o*-phenylenediacetonitrile-bridged complexes of tungsten(II). Reaction of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with 2 equiv. of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (L^1) in CH_2Cl_2 at room temperature affords the trimetallic complexes $[MI_2(CO)_3L^1{}_2]$ (**11** and **12**). Complexes **11** and **12** have been characterised in the normal manner (Tables 1–3). The trimetallic nature of complexes **11** and **12** was confirmed by molecular weight measurements using Rast's method [13] (see Section 2.3). Several attempts were made to obtain mass spectrometric data but, as with many of our diiodo-complexes, no parent ion was observed. These complexes represent the first bridging nitrile complexes of this type to be described. The complexes are air sensitive in solution, and must be stored in the solid state under a dinitrogen atmosphere. They are soluble in CH_2Cl_2 and $CHCl_3$, but only slightly soluble in Et_2O and hydrocarbon solvents. The IR spectra for complexes **11** and **12** show bands for the *o*-phenylenediacetonitrile groups at 2360, 2309 cm^{-1} (for **11**) and 2359, 2309 cm^{-1} (for **12**).

The structures of both the acetonitrile complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo [12] or W [9]) have been determined crystallographically and are very similar, based on a capped octahedron with a carbonyl ligand capping an octahedral face which has two terminal carbonyl groups and an iodo ligand. Also, the structure of the tungsten nitrile ligand **2** has also been determined (see Fig. 1). If the acetonitrile ligands have been replaced in a stereoselective manner, the geometry of the products would be as shown in Fig. 2. The IR and ^1H NMR data conform with the proposed structure. Many unsuccessful attempts were made to grow suitable single crystals for X-ray analysis of **11** and **12** using a wide range of mixed solvent and temperature conditions.

Reaction of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with 1 equiv. of PPh_3 gives, after 1 min, $[MI_2(CO)_3(NCMe)(PPh_3)]$, which reacts in situ with an equimolar amount of L^1 ($[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$) to afford the new bimetallic complexes $[MI_2(CO)_3(L^1)(PPh_3)]$ (**13** and **14**) in good yield. Complexes **13** and **14** have been fully characterised (Tables 1–3), and also the bimetallic nature was confirmed by molecular weight measurements using Rast's method [13] (see Section 2.4). Complex **14** was confirmed as a CH_2Cl_2 solvate by repeated elemental analyses and ^1H NMR spectroscopy. Since the structure of the tungsten complex $[WI_2(CO)_3(NCMe)(PPh_3)]$ has been determined crystallographically and has distorted capped octahedral geometry, the most likely structure for **13** and **14** might be as shown in Fig. 3. Many unsuccessful attempts were made to grow suitable single crystals for X-ray analysis of **13** and **14**

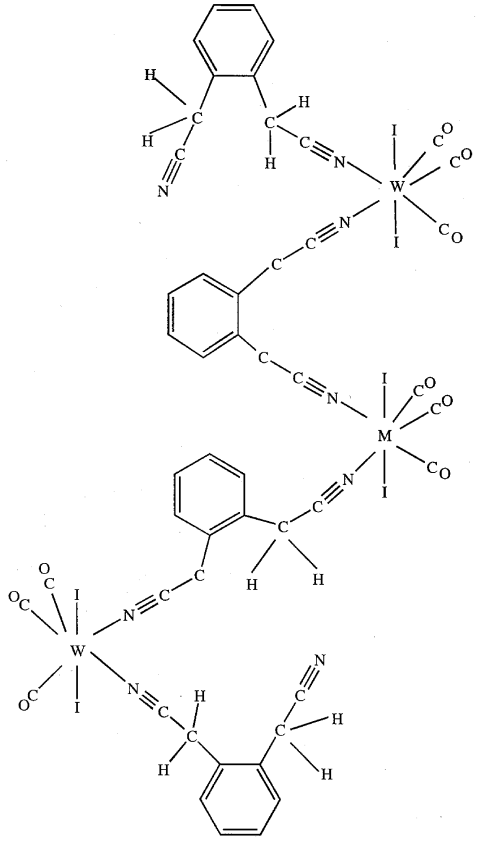

Fig. 2. Proposed structure of the trimetallic complexes $[MI_2(CO)_3(L^1)_2]$ (**11** and **12**) ($L^1 = [WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**)).

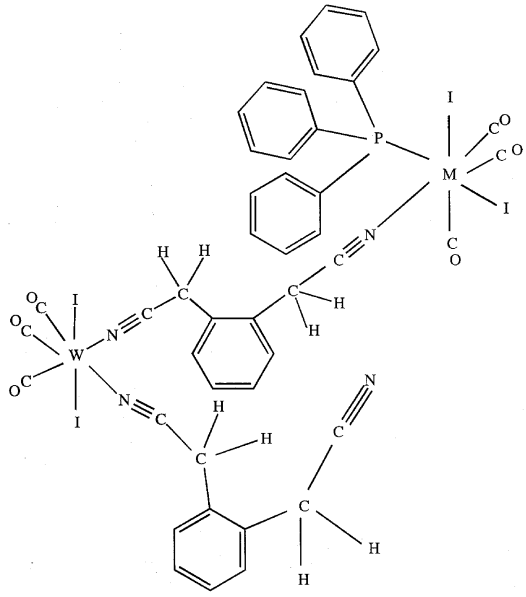

Fig. 3. Proposed structure of the bimetallic complexes $[MI_2(CO)_3L^1(PPh_3)]$ (**13** and **14**).

using a wide range of mixed solvent and temperature conditions. However, it should be noted that we have very recently [26] obtained the X-ray crystal structure of the related succinonitrile-bridged tungsten complex $[\{WI_2(CO)_3(PPh_3)\}_2\{\mu\text{-}NC(CH_2)_2CN\}]$. This also conforms with a more definitive assignment of the bimetallic and trimetallic nature of complexes **11–14.** IR and ^{1}H NMR data (Tables 2 and 3) conform with the structure shown in Fig. 3.

4. Conclusions

In conclusion, the potentially chelating ligand, 1,2-$C_6H_4(CH_2CN)_2$ coordinates in a monodentate manner in the seven-coordinate complexes $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (M = Mo and W) and $[MI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}L]$ described in this paper. The molecular structure of $[WI_2(CO)_3\{1,2\text{-}C_6H_4(CH_2CN)_2\text{-}N\}_2]$ (**2**) shows definitively that *o*-phenylenediacetonitrile is coordinated in a monodentate manner in these complexes. In view of these observations, the use of **2** as a novel monodentate nitrile donor ligand has been successfully explored, and two trimetallic ($[MI_2(CO)_3L^1{}_2]$ $L^1 = \mathbf{2}$) and two bimetallic ($[MI_2(CO)_3L^1(PPh_3)]$) complexes have been successfully prepared and characterised during the course of this work.

Dinuclear diimine palladium(II) and platinum(II) hydroxo and amido complexes: synthesis and X-ray crystal structures

S. Kannan, A.J. James, P.R. Sharp *

Department of Chemistry, University of Missouri-Columbia, Columbia, MO 65211, USA

Received 9 August 1999; accepted 5 October 1999

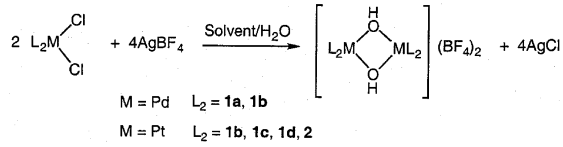
Abstract

Treatment of L_2MCl_2 with $AgBF_4$ in wet tetrahydrofuran (THF)–CH_2Cl_2 or wet CH_2Cl_2–ethanol yields the dinuclear palladium(II) and platinum(II) hydroxo complexes $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$ (L_2 = diimine, M = Pd, Pt). Reaction of the dihydroxo bridged complexes with aromatic amines ($ArNH_2$) yields the corresponding diamido bridged complexes $[L_2M(\mu\text{-}NHAr)]_2(BF_4)_2$. $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$ is unstable in methanol and converts to $[L_2M(\mu\text{-}OMe)]_2(BF_4)_2$. The structures of several of these complexes were determined by single crystal X-ray diffraction and show the expected edge-shared square-planar Pt centers with bridging hydroxo, methoxo, or amido groups. Attempts to deprotonate the hydroxo and amido complexes were not successful. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Amido; Diimine; Dimer; Hydroxo; Palladium; Platinum

1. Introduction

The synthesis and chemistry of palladium(II) and platinum(II) hydroxo and amido complexes have attracted interest for their relevance to the anti-tumor activity of Pt(II) complexes [1,2] and to the formation of C–O and C–N bonds in synthesis and catalysis [3–15]. The hydroxo complexes are also useful as synthetic precursors taking advantage of the nucleophilic character of the hydroxo ligand [8,15–22].



We have been interested in these complexes for their conjugate acid relationship to oxo and imido complexes, which are also relevant to C–O and C–N bond-forming reactions in catalytic processes [23–31]. The majority of our work in this area has been limited to phosphine ligand systems. Our initial attempts to expand to pyridine and bipyridine ligand systems met with limited success due to the poor solubility of the complexes [32]. Reports of soluble Pt(II) and Pd(II) complexes with non-cyclic diimine ligands [33–36] prompted us to explore the hydroxo and amido chemistry of Pt(II) and Pd(II) with these diimine ligands. This work is reported here.

2. Results

2.1. Hydroxo complexes

Treatment of L_2MCl_2 (see Scheme 1 for identification of L_2) with $AgBF_4$ in wet solvents yields the dinuclear hydroxo complexes $[L_2M_2(\mu\text{-}OH)]_2(BF_4)_2$:

The hydroxo group is detected in the IR spectra of the complexes as a broad band at 3526–3550 cm^{-1}. ^1H NMR spectra show the expected diimine peaks. The hydroxo proton peaks are typically broad with shift values that depend on the

Scheme 1.

PII S0277-5387(99)00338-1

metal and the solvent. Negative shifts are observed in $CDCl_3$ and in CD_2Cl_2. The Pd complexes typically give the lowest shift values (-2.70 and -3.02 ppm) with the Pt complexes just below 0 ppm (-0.60 to -0.63 ppm). Negative hydroxo group shifts are common for Pt and especially Pd hydroxo complexes in non-hydrogen-bonding solvents [17,21,37–40]. In deuterated acetone, the hydroxo peak shift values for the Pt complexes are positive and are found in the range 3.22–3.80 ppm. The downfield shift in acetone is presumably the result of hydroxo group hydrogen bonding to the acetone.

The dinuclear nature of the complexes is confirmed by X-ray crystal structure determinations on two of the complexes (M = Pd, L_2 = **1a** and M = Pt, L_2 = **1d**). ORTEP (Oak Ridge thermal ellipsoid plot) drawings are given in Figs. 1 and 2. An abbreviated summary of crystal data and data collection and processing is given in Table 1. Selected bond distances and angles are listed in Table 2. The expected μ-hydroxo groups, edge bridging two square planar metal centers, are observed for the cationic portions. The bond distances within the two structures are essentially identical. A difference in the two structures is observed in the M_2O_2 'diamond' core. The Pd core is non-planar with a fold angle at the O–O hinge of 140°. The Pt structure is almost planar with a fold angle of 170°. Other differences, related to the fold angle, are the metal–metal distances and the M–O–M angles. The metal–metal distance and the M–O–M angle are greater for Pt. Although there is doubt in the positions of the hydroxo group hydrogen atoms (located in a difference Fourier but not refined for Pd and ideal hydrogen bonded to THF positions for Pt), the hydrogen atoms are *cis* for Pd and *trans* for Pt. Detailed analysis of such structures reveals small energy differences between planar and non-planar forms [41–44].

2.2. Amido complexes

The dihydroxo complexes react readily with aromatic amines yielding the corresponding amido-bridged dinuclear complexes $[L_2M_2(\mu\text{-NHAr})]_2(BF_4)_2$:

M = Pd L_2 = **1a** Ar = *p*-$NO_2C_6H_4$, *p*-MeC_6H_4

M = Pt L_2 = **1b** Ar = Ph, *p*-MeC_6H_4

IR spectra of the diamido complexes show the presence of the bridging NH groups at 3248–3281 cm^{-1}. ^1H NMR spectra show the diimine ligand and broad peaks for the NH groups. The NH peaks are at positive shift values. Although the data are limited, the shift values in $CDCl_3$ appear to be lower for Pd (0.45 ppm) than for Pt (1.81 and 1.82), as is observed for the dihydroxo complexes.

The structure of two of the diamido complexes (M = Pd, L_2 = **1a**, Ar = *p*-$NO_2C_6H_4$; M = Pt, L_2 = **1b**, Ar = *p*-tol) were determined. ORTEP diagrams are shown in Figs. 3 and 4. An

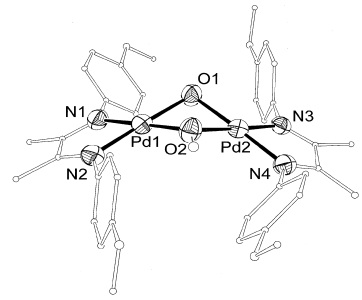

Fig. 1. ORTEP drawing of the cationic portion of $[L_2Pd(\mu\text{-OH})]_2(BF_4)_2$ (L_2 = **1a**).

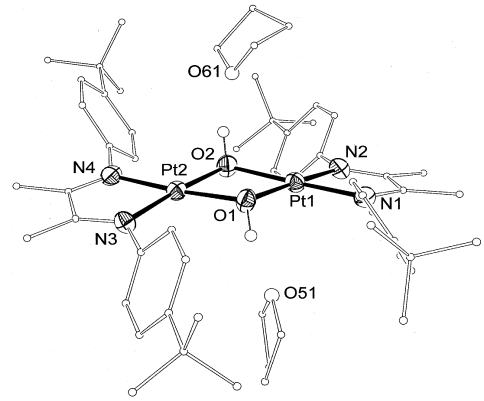

Fig. 2. ORTEP drawing of the cationic portion of $[L_2Pt(\mu\text{-OH})]_2(BF_4)_2$ (L_2 = **1d**) including hydrogen-bonded THF molecules.

abbreviated summary of crystal data and data collection and processing is given in Table 1. Selected bond distances and angles are listed in Table 3. The cationic portions of the structures consist of two edge-shared square-planar Pt centers with bridging NHAr groups. As with the hydroxo complexes above, bond distances within the two structures are essentially identical, but the Pd structure is non-planar while the Pt structure is planar (by symmetry). The fold angle for the Pd complex is 156°. The folding is again reflected in the metal–metal distances and the M–N–M angles, which are greater for the planar Pt structure. The amido group hydrogen atoms are at ideal calculated positions.

2.3. Attempted deprotonations

The reactions of the complexes with $LiN(SiMe_3)_2$ were investigated with the intent of forming oxo and imido complexes by deprotonation of the hydroxo and amido groups. Black precipitates, believed to be Pd metal, are obtained for the reactions of the Pd complexes. The Pt complexes generally gave a series of intense color changes (violet, blue, green, yellow, green and finally red) on addition of base. ^1H NMR spectra of the final red–brown products show broad resonances in the aliphatic and aromatic region. We were unable to purify or crystallize the products.

2.4. Miscellaneous

In at least one case the hydroxo complex reacts with alcohols. Slow evaporation of a solution of $[L_2Pd(\mu\text{-OH})]_2$-

3. Discussion

Diimine ligands have drawn attention recently for their great flexibility in synthesis and their tuneability to give desired electronic and steric properties [33–36]. Here we have shown that these ligands may be used to generate hydroxo and amido Pt and Pd dimers. The reaction that gives the hydroxo complexes has been used extensively in the synthesis of Pt and Pd hydroxo complexes. Chloride removal from L_2PdCl_2 and L_2PtCl_2 with Ag salts of non-coordinating anions has yielded binuclear hydroxo complexes for L = phosphines, arsines, pyridine, bipy, amines and sulfoxides [14,15,22,32,37,45–52]. Monomeric aqua and hydroxo complexes $[L_2M(OH_2)_2]^{2+}$ and $[L_2M(OH)_2]$, trinuclear hydroxo complexes $[L_2M(\mu\text{-}OH)]_3^{3+}$ and tetranuclear hydroxo complexes $[L_2M(\mu\text{-}OH)]_4^{4+}$ have also been isolated for some of these ligand systems [15,22,46,47,53–62]. Equilibria between these various species have been studied and are pH dependent [15,22,46,60,63,64]. We observe only the dimeric hydroxo complexes under the conditions employed.

[a] Atoms with a ‘′’ suffix are symmetry-related to those without the suffix.

Aminolysis of the hydroxo complexes to amido complexes has been less extensively applied and, for Pt and Pd, has been restricted to phosphine and aryl/alkyl ligand systems [17,38,65]. Our synthesis of the diimine amido complexes provides the first examples of Pt and Pd diamido complexes supported by diimine ligands.

4. Experimental

Experiments were routinely performed in air except for the reactions using $LiN(SiMe_3)_2$, which were conducted under a dinitrogen atmosphere in a Vacuum Atmospheres Corporation drybox, or by Schlenk techniques. Solvents and reagents were reagent grade and used as received except in the reactions of $LiN(SiMe_3)_2$, where the solvents were dried by standard methods. Solvent mixtures were prepared on a volume basis. Ethanol was 95%. The diimine ligands were prepared from the corresponding diketones by reported methods [35]. The starting chloro compounds L_2MCl_2 (M = Pd or Pt, L_2 = diimine) were prepared by procedures similar to those previously reported [36]. ^1H and ^{19}F NMR spectra were recorded on a Bruker AMX-250 spectrometer using internal trimethylsilane (TMS) (^1H) and external $CFCl_3$ (^{19}F) as references. Chemical shifts are reported in ppm with negative values upfield of the reference. IR spectra were recorded on a Nicolet 550 Magnum FTIR spectrometer using mineral oil

mulls between NaCl plates. Frequencies are reported in cm^{-1}. Spectra were recorded at ambient temperatures unless otherwise indicated. M-H-W Laboratories (Arizona) or National Chemical Consulting, Inc. (New Jersey) performed the microanalyses (inert atmosphere).

4.1. Preparation of $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$

4.1.1. M = Pd, L_2 = **1a**

A THF (5 ml) solution of $AgBF_4$ (510 mg, 2.63 mmol) was added to a stirred CH_2Cl_2–THF (1:1, 50 ml) suspension of L_2PdCl_2 (600 mg, 1.27 mmol) containing a few drops of water. The mixture immediately precipitated AgCl. Stirring was continued for 3 h and then the mixture was filtered through a bed of diatomaceous earth. The clear red–orange filtrate was evaporated to dryness. The residue was dissolved in 2 ml of CH_2Cl_2 and filtered. The filtrate was layered with 3 ml of THF and cooled at −20°C overnight. The resulting red–orange crystalline product was filtered-off, washed with cold THF and ether, and dried. Recrystallization from CH_2Cl_2–THF afforded red–orange crystals. Yield: 420 mg (66%). *Anal*. Calc. (found) for $C_{36}H_{42}B_2F_8N_4O_6Pd_2 \cdot THF$: C, 44.3 (44.4); H, 4.6 (4.6); N, 5.2 (5.2)%. Crystals for the X-ray analysis were grown from CH_2Cl_2–DME.

^{1}H NMR (CD_2Cl_2): −2.70 (br s, 2H, OH), 2.27 (s, 12H, CH_3), 3.87 (s, 12H, OCH_3), 6.65 and 6.96 (m, 16H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −150.6. IR: 3550 (OH), 1604 (C=N), 1050 (B–F).

4.1.2. M = Pd, L_2 = **1b**

The procedure was similar to that used for M = Pd, L_2 = **1a** and gave the product as a yellow solid. Yield: 97%. *Anal*. Calc. (found) for $C_{36}H_{42}N_4O_2B_2F_8Pd_2$: C, 45.6 (45.2); H, 4.5 (4.1); N, 5.9 (5.8)%.

^{1}H NMR (CD_2Cl_2): −3.02 (s, 2H, OH), 2.24 (s, 12H, CH_3), 2.41 (s, 12H, CH_3), 6.9 (s, 16H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −148.7. IR: 3539 (OH), 1606 (C=N), 1063 (B–F).

4.1.3. M = Pt, L_2 = **1b**

A solution of $AgBF_4$ (355 mg, 1.83 mmol) in ethanol (5 ml) was added to a stirred CH_2Cl_2–ethanol (1:1, 40 ml) suspension of L_2PtCl_2 (485 mg, 0.91 mmol). The solution was stirred for 3 h and then filtered to remove AgCl. The clear red–brown filtrate was evaporated in air and the residue was extracted with 3 ml of CH_2Cl_2 and filtered. The filtrate was layered with 5 ml of ether and stored at −20°C overnight. The resulting red–brown crystals were filtered-off, washed with ether, and dried. Recrystallization from CH_2Cl_2–THF gave red–brown crystals. Yield: 480 mg (93%). *Anal*. Calc. (found) for $C_{36}H_{42}N_4O_2B_2F_8Pt_2 \cdot H_2O$: C, 37.8 (37.9); H, 3.9 (3.7); N, 4.9 (4.8)%.

^{1}H NMR (CD_2Cl_2): −0.60 (s, 2H, OH), 2.08 (s, 12H, CH_3), 2.47 (s, 12H, CH_3), 7.02 (d, J_{HH} = 8.3 Hz, 8H, C_6H_4), 7.11 (d, J_{HH} = 8.3 Hz, 8H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −150.1. IR: 3634 (H_2O), 3534 (OH), 1633 (C=N), 1060 (B–F).

4.1.4. M = Pt, L_2 = **1c**

The procedure was similar to that used for M = Pt, L_2 = **1b** and gave the product as a red–brown solid. Yield: 90%. *Anal*. Calc. (found) for $C_{48}H_{66}N_4O_2B_2F_8Pt_2 \cdot H_2O$: C, 43.9 (44.2); H, 5.2 (5.1); N, 4.3 (4.1)%.

^{1}H NMR ($CDCl_3$, broad poorly resolved peaks): −0.61 (s, 2H, OH), 0.88 and 1.26 (m, 12H and 12H, $CH_3CH_2CHCH_3$), 1.56 (m, 8H, $CH_3CH_2CHCH_3$), 2.04 (s, 12H, CH_3), 2.58 (m, 4H, $CH_3CH_2CHCH_3$), 7.09–7.26 (br, 16H, C_6H_4).

^{1}H NMR (acetone-d_6): 0.90 (t, J_{HH} = 7.3 Hz, 12H, $CH_3CH_2CHCH_3$), 1.31 (dd, J_{HH} = 6.9, 1.0 Hz, 12H, $CH_3CH_2CHCH_3$), 1.68 (quint, J_{HH} = 7.3 Hz, 8H, $CH_3CH_2CHCH_3$), 2.15 (s, 12H, CH_3), 2.74 (sext, J_{HH} = 7.0 Hz, 4H, $CH_3CH_2CHCH_3$), 3.22 (s, 2H, OH), 7.25 (d, J_{HH} = 8.5 Hz, 8H, C_6H_4), 7.34 (d, J_{HH} = 8.5 Hz, 8H, C_6H_4). ^{19}F NMR ($CDCl_3$): −153.5. IR: 3598 (H_2O), 3526 (OH), 1630 (C=N), 1060 (BF).

4.1.5. M = Pt, L_2 = **1d**

The procedure was similar to that used for M = Pt, L_2 = **1b** and gave the product as a red–brown crystalline solid. Recrystallization from CH_2Cl_2–THF gave red–brown crystals. Yield: 85.6%. *Anal*. Calc. for $C_{48}H_{66}N_4O_2B_2F_8Pt_2 \cdot H_2O$: C, 43.9 (43.8); H, 5.2 (5.2); N, 4.2 (4.2)%.

^{1}H NMR (acetone-d_6): 1.36 (s, 36H, Bu^t), 2.06 (s, 12H, CH_3), 3.80 (s, 2H, OH), 7.22 (d, 8.5 Hz, J_{HH} = 8H, C_6H_4), 7.46 (d, J_{HH} = 8.5Hz, 8H, C_6H_4). ^{19}F NMR (acetone-d_6): −150.0. IR: 3600–3542 (br, OH), 1629 (C=N), 1063 (BF).

4.1.6. M = Pt, L_2 = 2

The procedure was similar to that used for M = Pt, L_2 = **1b** and gave the product as a red–brown solid. Yield: 97%. *Anal*. Calc. for $C_{72}H_{82}O_2N_4B_2F_8Pt_2$: C, 54.1 (53.9); H, 5.2 (5.3); N, 3.5 (3.4)%. The hydrogen atom numbering scheme in the ^{1}H NMR spectra is taken from [36].

^{1}H NMR (CD_2Cl_2): −0.63 (s, 2H, OH), 1.00 (d, J_{HH} = 6.8 Hz, 24H, $CH(CH_3)_2$), 1.37 (d, J_{HH} = 6.8 Hz, 24H, $CH(CH_3)_2$), 3.17 (sept, J_{HH} = 6.8 Hz, 8H, $CH(CH_3)_2$), 7.00 (d, J_{HH} = 7.3 Hz, 4H, H_3), 7.38 (d, J_{HH} = 7.8 Hz, 8H, H_{10}), 7.62, 7.66 (overlapping t, J_{HH} = 7.9 Hz, 8H, H_4 and H_{11}), 8.45 (d, J_{HH} = 8.3 Hz, 4H, H_5).

^{1}H NMR (acetone-d_6): 0.99 (d, J_{HH} = 6.8 Hz, 24H, $CH(CH_3)_2$), 1.50 (d, J_{HH} = 6.8 Hz, 24H, $CH(CH_3)_2$), 2.77 (s, 2H, OH), 3.44 (sept, J_{HH} = 6.8 Hz, 8H, $CH(CH_3)_2$), 6.84 (d, J_{HH} = 7.3 Hz, 4H, H_3), 7.52 (d, J_{HH} = 7.8 Hz, 8H, H_{10}), 7.72, 7.75 (overlapping t, J_{HH} = 7.6 Hz, 8H, H_4 and H_{11}), 8.57 (d, J_{HH} = 8.3 Hz, 4H, H_5). ^{19}F NMR (CD_2Cl_2): −152.5. IR: 3535 (br, H_2O, OH), 1642 (OH), 1607 (C=N), 1061 (BF).

4.2. Preparation of $[L_2M(\mu\text{-}NHAr)]_2(BF_4)_2$

4.2.1. M = Pd, L_2 = **1a**, Ar = p-$NO_2C_6H_4$

p-Nitroaniline (15 mg, 0.108 mmol) was slowly added to a stirred 1,2-dichloroethane solution (2 ml) of $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$ (55 mg, 0.054 mmol). The mixture was stirred for 5 min and then filtered. The clear red–orange filtrate was stored in a closed vial at room temperature. Red crystals deposited overnight. These were filtered-off, washed with cold 1,2-dichloroethane, and dried. Yield: 64 mg (94%). *Anal*. Calc. (found) for $C_{48}H_{50}O_8N_8B_2F_8Pd_2$: C, 45.0 (45.1); H, 4.0 (4.1); N, 8.9 (8.9)%.

^{1}H NMR (DMSO-d_6): 1.87 (s, 12H, CH_3), 2.15 (s, 2H, NH), 3.81 (s, 12H, OCH_3), 6.09 (br s, 4H, amido-C_6H_4), 6.59 (br s, 8H, C_6H_4), 7.22–7.42 (br m, 12H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −149.1. IR: 3271 (NH), 1609 (C=N).

4.2.2. M = Pd, L_2 = **1a**, Ar = p-tol

p-Toluidine (28.5 mg, 0.266 mmol) was slowly added to a stirred CH_2Cl_2 (5 ml) solution of $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$ (120 mg, 0.118 mmol). The mixture immediately turned dark red–orange and was stirred for 2 h. The solution was reduced in volume to 2 ml, layered with ether and stored at −20°C overnight. The resulting orange solid was filtered-off, washed with ether, and dried. Yield: 125 mg (88.6%). *Anal*. Calc. (found) for $C_{50}H_{56}N_6B_2F_8O_4Pd_2$: C, 50.4 (49.9); H, 4.7 (4.4); N, 7.1 (7.1)%.

^{1}H NMR ($CDCl_3$): 0.45 (s, 2H, NH), 2.06 (s, 12H, CH_3), 2.17 (s, 6H, amido-CH_3), 3.81 (s, 12H, OCH_3), 5.88 (d, J_{HH} = 8.2 Hz, 4H, amido-C_6H_4), 6.31 (br d, J_{HH} = 8 Hz, 4H, C_6H_4), 6.37 (d, J_{HH} = 8.2 Hz, 4H, amido-C_6H_4), 6.45 (m, 4H, C_6H_4), 6.99 (br d, J_{HH} = 8 Hz, 4H, C_6H_4), 7.44 (br d, J_{HH} = 8 Hz, 4H, C_6H_4). ^{19}F NMR ($CDCl_3$): −149.8. IR: 3281, 3238 (NH), 1604 (C=N).

4.2.3. M = Pt, L_2 = **1b**, Ar = p-tol

The procedure was similar to that used for M = Pd, L_2 = **1a**, Ar = *p*-tol and gave the product as a red–brown solid. Yield: 85%. *Anal*. Calc. (found) for $C_{50}H_{56}N_6B_2F_8Pt_2 \cdot H_2O$: C, 45.4 (45.5); H, 4.4 (4.1); N, 6.4 (6.4)%.

^{1}H NMR (CD_2Cl_2): 1.81 (s, 12H, CH_3), 2.20 (s, 6H, amido-CH_3), 2.43 (s, 12H, CH_3), 3.07 (br s, 2H, NH), 6.01 (br d, J_{HH} = 7 Hz, 4H, C_6H_4), 6.08 (d, 8.1 Hz, 4H, C_6H_4), 6.43 (d, 8.1 Hz, 4H, C_6H_4), 6.83 (br d, J_{HH} = 7 Hz, 4H, C_6H_4), 7.44 (br s, 8H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −151.0. IR: 3256 (br, NH), 1609 (C=N), 1060 (BF).

4.2.4. M = Pt, L_2 = **1b**, Ar = Ph

Aniline (17 mg, 0.18 mmol) in 1,2-dichloroethane (1 ml) was slowly added to a 1,2-dichloroethane (2 ml) solution of $[L_2M(\mu\text{-}OH)]_2(BF_4)_2$ (100 mg, 0.089 mmol). The mixture was stirred for 3 h. Then the solution was reduced in volume to 1 ml, layered with ether (2 ml), and stored at −20°C overnight. The red–brown crystalline product was filtered-off, washed with ether, and dried. Yield: 98 mg (86%). *Anal*. Calc. (found) for $C_{48}H_{52}N_6B_2F_8Pt_2$: C, 45.2 (45.2); H, 4.1 (3.9); N, 6.6 (6.4)%.

^{1}H NMR (CD_2Cl_2): 1.82 (s, 12H, CH_3), 2.43 (s, 12H, CH_3), 3.08 (br, 2H, NH), 5.99 (br m, 4H, C_6H_4), 6.20 (br d, J_{HH} = 8 Hz, 4H, Ph), 6.62 (m, 4H, Ph), 6.79 (m, 6H, Ph and C_6H_4), 7.59 (br d, J_{HH} = 8 Hz, 8H, C_6H_4). ^{19}F NMR (CD_2Cl_2): −151.2. IR: 3256, 3248 (NH), 1628(C=N), 1059 (BF).

4.3. Reactions with $LiN(SiMe_3)_2$

4.3.1. Pd complexes

A 1 ml solution of $LiN(SiMe_3)_2$ (33 mg, 0.198 mmol) was slowly added to a stirred suspension of $[L_2Pd(\mu\text{-}OH)]_2(BF_4)_2$, L_2 = **1a** (100 mg, 0.098 mmol) in THF. The solution immediately turned black and deposited a black solid assumed to be palladium metal. The reaction was repeated at −30°C with similar results. Identical results were obtained with L_2 = **1b** and with $[L_2Pd(\mu\text{-}NHAr)]_2(BF_4)_2$, L_2 = **1a**, Ar = *p*-$NO_2C_6H_4$ and *p*-tol.

4.3.2. Pt complexes

A 1 ml solution of $LiN(SiMe_3)_2$ (21 mg, 0.125 mmol) was slowly added to a stirred suspension of $[L_2Pt(\mu\text{-}OH)]_2(BF_4)_2$, L_2 = **1c** (70 mg, 0.062 mmol) in THF. A flash of violet was observed on the surface at the point of contact but this changed immediately to blue on stirring. Within a few minutes the solution became green followed by green–yellow and finally red. The clear red solution was stirred for 2 h and evaporated to dryness. The resulting red–brown powder was washed with ether and dried. Attempts to crystallize the product were unsuccessful. ^{1}H NMR spectra of the crude product were very broad. Similar results were obtained at −30°C and with L_2 = **1b**, **1c** and **1d** and with $[L_2Pt(\mu\text{-}NHAr)]_2(BF_4)_2$, L_2 = **1b**, Ar = Ph and *p*-tol. However, with $[L_2Pt(\mu\text{-}NHAr)]_2(BF_4)_2$, L_2 = **1b**, Ar = *p*-$NO_2C_6H_4$, a reasonably stable dark-blue solution was obtained but the ^{1}H NMR spectrum, while not broad, contained many peaks.

4.4. Reaction of $[L_2Pd(\mu\text{-}OH)]_2(BF_4)_2$ (L_2 = **1a**) with MeOH

$[L_2Pd(\mu\text{-}OH)]_2(BF_4)_2$ was suspended in methanol and stirred overnight. Slow evaporation of the resulting clear red–brown solution yielded red–brown crystals and yellow solid starting material ($[L_2Pd(\mu\text{-}OH)]_2(BF_4)_2$). One of the red–brown crystals was subjected to X-ray diffraction analysis and shown to be $[L_2Pd(\mu\text{-}OMe)]_2(BF_4)_2$.

4.5. Reaction of $[L_2Pt(\mu\text{-}OH)]_2(BF_4)_2$ (L_2 = **1b**) with $BF_3 \cdot OEt_2$

Two drops of $BF_3 \cdot OEt_2$ were added to a stirred red–brown dichloromethane solution of $[L_2Pt(\mu\text{-}OH)]_2(BF_4)_2$ (100 mg). The mixture became dark-red and was filtered and stored in a closed vial for 12 h. The resulting red crystals

were subjected to X-ray diffraction study and proved to be $[L_2Pt(\mu\text{-}Cl)]_2(BF_4)_2$. Poor solubility prevented characterization by NMR.

4.6. Crystal structure analyses

Crystal data, reflection collection and processing parameters, and solution and refinement data are summarized in Table 1. Full details are available from the CCDC. Crystals were mounted by pipetting crystals and mother liquor into a pool of heavy oil. A suitable crystal was selected and removed from the oil with a glass fiber. With the oil-covered crystal adhering to the end of the glass fiber the sample was transferred to a N_2 cold stream on the diffractometer and data were collected at 173 K.

Supplementary data

Full crystal structure information has been deposited with the Cambridge Crystallographic Data Centre (deposition numbers CCDC 133158-CCDC 133163).

Acknowledgements

The Division of Chemical Sciences, Office of Basic Energy Sciences, Office of Energy Research, US Department of Energy (grant DE-FG02-88ER13880) is gratefully acknowledged for financial support of this work. Grants from the National Science Foundation provided a portion of the funds for the purchase of the X-ray (NSF-CHE-9011804) and NMR (grants 8908304 and 9221835) equipment.

POLYHEDRON

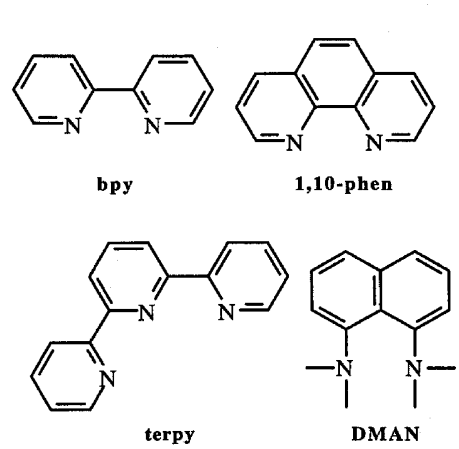
Chelated fluoroboron cations
II. Synthesis and NMR studies involving aromatic chelating ligands

J. Stephen Hartman *, James A.W. Shoemaker [1]

Department of Chemistry, Brock University, St. Catharines, Ontario L2S 3A1, Canada

Received 2 August 1999; accepted 10 October 1999

Abstract



Possible methods of formation of chelated fluoroboron cations $(DD)BF_2^+$ and $(DD)BFX^+$, where DD is 2,2′-bipyridine (bpy), 1,10-phenanthroline (1,10-phen), 2,2′,6′,2″-terpyridine (terpy) and 1,8-bis(dimethylamino)naphthalene (DMAN, 'proton sponge'), have been investigated, primarily by ^{19}F and ^{11}B NMR and fast atom bombardment mass spectrometry. The most successful method involves displacement of weakly basic isoxazole (ISOX) and heavy halide ion from $ISOX \cdot BF_2X$ and $ISOX \cdot BFX_2$ (X = Cl, Br). Displacement of pyridine from $py \cdot BF_2Cl$ and $py \cdot BFCl_2$ is less effective because pyridine, more basic than isoxazole, competes with the chelating donor in forming fluoroboron cations when displaced from its adducts. 1,10-Phen, terpy and DMAN form $(DD)BF_2^+ \cdot BF_4^-$ when reacted with $Et_2O \cdot BF_3$ or with $ISOX \cdot BF_3$ under our conditions, but bpy does not. None of these chelating ligands can displace pyridine from $(py)_2BF_2^+ \cdot PF_6^-$ under conditions that are effective with tertiary-amine chelating donors. $(1,10\text{-Phen})BF_2^+$ but not the other $(DD)BF_2^+$ species is attacked by dimethylsulfoxide (DMSO), to form first $(DMSO)_2BF_2^+$ and finally $DMSO \cdot BF_3$. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: 2,2′-Bipyridine; 1,8-Bis(dimethylamino)naphthalene; Boron-11 NMR; Chelated fluoroboron cations; Fast atom bombardment mass spectrometry; Fluorine-19 NMR; 1,10-Phenanthroline; 2,2′,6′,2″-Terpyridine

1. Introduction

There have been sporadic reports of the formation of chelated BF_2^+ cations with bidentate N-donor ligands over the past 30 years. Typically the ligand has been reacted with $Et_2O \cdot BF_3$ at room temperature or with BF_3 at −196°C, followed by slow warming [1–6]. The resulting species have been identified, but not very convincingly in some cases, by elemental analysis and/or by NMR [5–7]. Our studies [8–12] of the formation of fluoroboron cations by heavy halide ion displacement from mixed boron trihalide adducts [13], initially by monodentate ligands [8–11], have provided new approaches to the formation of chelated fluoroboron cations. Using these approaches we have formed BF_2^+, $BFCl^+$ and $BFBr^+$ cations of tertiary-amine chelating ligands [12], and established the conditions required to form the chelated cation, compared with those that give only the bis-BF_3 adduct $F_3B \cdot DD \cdot BF_3$. We now report our extension of these studies to aromatic N-donor chelating ligands, which behave very differently from the saturated-amine chelating ligands.

2,2′-Bipyridine (bpy), 1,10-phenanthroline (1,10-phen), and 2,2′,6′,2″-terpyridine (terpy) are well-known chelating ligands which coordinate to a wide range of metal ions [14,15], while 1,8-bis(dimethylamino)naphthalene (DMAN; also known as 'proton sponge') is noteworthy for its very high Bronsted basicity ($pK_b^1 = 1.7$) [4,16] but very high steric hindrance about the nitrogens which inhibits its reactivity with Lewis acids. All but terpy have been reported to form difluoroboron cations [5,6], as well as dichloroboron

[5,6,17] and (except for DMAN) dibromoboron [17] cations.

Kinetic simulations, based on Janzen's 'coordination model' of reaction mechanisms [18], indicate that reactions of bidentate nitrogen donor molecules with BF_3 should give only the non-chelated bis-BF_3 adduct $F_3B \cdot DD \cdot BF_3$ rather than the chelated $(DD)BF_2^+ \cdot BF_4^-$ [19]. This is borne out in some cases [20,21], whereas in other cases the chelated species do form in high yield [1,2]. Preliminary work in Janzen's laboratory, involving reaction of ethylenediamine (en) and bpy with BF_3 in a variety of solvents, has given only low yields of chelated $(en)BF_2^+$ and $(bpy)BF_2^+$ under only a few of the reaction conditions tried, and even in these cases these products are always accompanied by much larger amounts of the corresponding bis-BF_3 adduct [22]. We here explore the formation of chelated fluoroboron cations of aromatic chelating ligands from the BF_3 sources $Et_2O \cdot BF_3$ and isoxazole $\cdot BF_3$, in addition to their formation by heavy halide ion displacement from mixed boron trihalide adducts.

2. Experimental

2.1. Materials and methods

Materials were handled with standard inert-atmosphere Schlenk line and glove bag techniques. 2,2′-Bipyridine (Aldrich, 99+%), 1,10-phenanthroline (Aldrich, 99+%), 2,2′,6′,2″-terpyridine (Aldrich, 98%), and 1,8-bis(dimethylamino)naphthalene (Aldrich, 99%) were used without further purification. All chelating donors were stored in desiccators over Drierite. Boron trifluoride (Aldrich, 99.5%), boron trifluoride etherate (Aldrich), boron trichloride (Matheson, 99.5%) boron tribromide (Aldrich, 99.9%), isoxazole (Aldrich 99%) (ISOX), ammonium hexafluoro-

ISOX

phosphate (Aldrich, 95+%), and pyridine (Aldrich, 99.5%) were handled as described previously [9,10,12]. Solvents were used without further purification, and were dried as described previously [12].

Most ^{19}F and ^{11}B spectra were obtained on a Bruker AC-200 4.7 Tesla multinuclear Fourier transform NMR spectrometer operating at 188.31 MHz (^{19}F) and 64.20 MHz (^{11}B), using 5 mm NMR tubes. ^{19}F spectra were obtained with 16K FIDs, 16K zero-filling, and spectral windows of up to 35 000 Hz, with between 256 and 4096 30° pulses and a relaxation delay of 1.0 s. The 90° pulse length was 6.6 μs. ^{19}F chemical shifts are accurate to ± 0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (-162.7 ppm from $CFC1_3$), and are reported in ppm from $CFC1_3$. $^1J_{BF}$ coupling constants are accurate to ± 1 Hz. ^{11}B spectra were obtained with 16K FIDs, 16K zero-filling, and spectral windows of up to 6400 Hz, with between 256 and 4096 30° pulses and a relaxation delay of between 0.5 and 10 s. The 90° pulse length was 17.1 μs. ^{11}B chemical shifts are accurate to ± 0.1 ppm and were externally referenced to $Et_2O \cdot BF_3$. The NMR data were manipulated using WIN NMR software, normally with the application of 1.5 Hz of line broadening (^{19}F).

Some ^{19}F, ^{11}B, and $^{11}B\{^{19}F\}$ NMR spectra were obtained at 30°C on a Bruker DRX-500 11.7 Tesla multinuclear Fourier transform NMR spectrometer (McMaster University) operating at 470.53 MHz (^{19}F) and 160.46 MHz (^{11}B) using between 40 and 128 30° pulses with 32K FIDs. The 90° pulse durations were 7.5 μs (^{19}F) and 15.0 μs (^{11}B). Spectral windows of 42 016 Hz (^{19}F) and 40 000 Hz (^{11}B) were used. $^{11}B\{^{19}F\}$ decoupling experiments used selective and broad band decoupling pulse power between 25 and 35 dB.

^1H, ^1H–^1H COSY and ^{13}C spectra were obtained on a Bruker DPX-300 7.4 Tesla multinuclear Fourier transform NMR spectrometer operating at 300.13 and 75.45 MHz, respectively, and referenced to internal tetramethylsilane (TMS).

^{11}B solid state magic angle spinning (MAS) NMR spectra were obtained on a Bruker DPX-300 7.4 Tesla multinuclear Fourier transform NMR spectrometer operating at 96.29 MHz, using a Bruker MAS probe with 4 mm spinners (capacity ~100 mg) and spin rates of 5–12.5 KHz. Between 256 and 2048 scans were obtained, with relaxation delays of 0.5–5.0 s between scans. 32K data points were obtained, and Fourier transformed with 5–15 Hz of line broadening. Trimethyl borate was used as the external standard, with its chemical shift being set to 18.3 ppm from $Et_2O \cdot BF_3$.

Positive and negative ion FAB spectra were obtained on a Concept 1S double beam mass spectrometer with 8 kV accelerating voltage, using Xe collision gas at 7.5 W power. Data were collected on a Kratos DART data system with SUN Spectrostation 10, using XMACH3 software. 3-Nitrobenzyl alcohol (NBA) was used as the liquid matrix. This matrix can protonate bases, so protonated-base FAB peaks, which are often of high intensity, can be generated in the instrument; they do not necessarily indicate a high concentration of protonated base in the original sample.

The $py \cdot BF_nCl_{3-n}$, $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$ adduct systems were prepared in Schlenk vessels (using methods previously described [9,11]) and transferred either directly to NMR tubes (for the pyridine adduct systems with all products soluble) or to 2 ml septum-capped GC–MS vials (Hewlett Packard) for ease of centrifugation of precipitates and solvent removal (for the ISOX adduct systems which normally give insoluble products). Typical reactions of the $py \cdot BF_nCl_{3-n}$, $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$ systems with the chelating donors were carried out using 20–25 mg of $py \cdot BF_3$ or $ISOX \cdot BF_3$ in 0.5–1.0 ml of $CHCl_3$ or $CDCl_3$, with the appropriate amount of BCl_3 or BBr_3 added to give the desired F:Cl or F:Br ratio. The chelating ligand (neat if liquid; in concentrated solution in chloroform if

solid) was added by syringe to the mixed boron trihalide adduct solution (followed by stirring if in an NMR tube; very rapid precipitation occurs with many ISOX systems). With the $py \cdot BF_nCl_{3-n}$ system a standard ratio of reagents corresponding to $py \cdot BF_3$:BCl_3:chelating donor = 5:2:3:5 was used. With the $ISOX \cdot BF_nCl_{3-n}$, system, two standard ratios of reagents were used: 'fluorine-rich', with ISOX:BF_3:BCl_3:chelating donor = 2:1:1:2; and 'chlorine-rich', with ISOX:BF_3:BCl_3:chelating donor = 4:1:3:4. With the $ISOX \cdot BF_nBr_{3-n}$ systems, similar ratios were used: 'fluorine-rich', ISOX:BF_3:BBr_3:chelating donor = 5:2:3:5; and 'bromine-rich', ISOX:BF_3:BBr_3:chelating donor = 4:1:3:4.

Reactions of $Et_2O \cdot BF_3$ and $ISOX \cdot BF_3$ with the chelating donors were carried out by adding neat $Et_2O \cdot BF_3$, or $ISOX \cdot BF_3$ dissolved in the reaction solvent, to 1–15 ml of solution containing 20–100 mg of the chelating donor in benzene, chloroform, acetone, or diethyl ether. Mole ratios of $Et_2O \cdot BF_3$ or $ISOX \cdot BF_3$ to chelating donor varied from 3:1 to 1:1.

$(py)_2BF_2^+ \cdot PF_6^-$ was prepared by a modification of the method used previously [9], involving precipitation from a 1:1 chloroform–ethanol solution. Reactions of $(py)_2BF_2^+ \cdot PF_6^-$ with the chelating donors were attempted in acetone solutions containing 20 mg ml^{-1} of $(py)_2BF_2^+ \cdot PF_6^-$, to which a 2- or 10-fold molar excess of chelating donor was added.

2.2. Specific reactions

2.2.1. $Py \cdot BF_nCl_{3-n}$ plus bpy

The clear colourless solution turned pink on standing, with white crystals of $(bpy)BF_2^+ \cdot Cl^-$ and $(py)_2BF_2^+ \cdot Cl^-$ precipitating. Positive ion FAB mass spectra of the solution: $py \cdot H^+$ [80 *m/z* (3.1%)]; $bpy \cdot H^+$ [157 *m/z* (100%)]; $(bpy)BF_2^+$ [205 *m/z* (2.1%)]; $(py)_2BF_2^+$ [207 *m/z* (8.6%)]. Positive ion FAB mass spectra of the white crystals: $bpy \cdot H^+$ [157 *m/z* (100%)]; $(bpy)BF_2^+$ [205 *m/z* (63.2%)]; $(py)_2BF_2^+$ [207 *m/z* (47.8%)]. These crystals were soluble in sulpholane. ^{19}F signals: $(bpy)BF_2^+$, −154.0 ppm [splittings due to $^1J_{BF}$ not visible]; $(py)_2BF_2^+$, −155.7 ppm [$^1J_{BF}$ = 22.8 Hz]; BF_4^-, −152.8 ppm [9]. In the less viscous 3:1 acetone–sulpholane mixed solvent the $(bpy)BF_2^+$ signal is split into a 1:1:1:1 quartet [$^1J_{BF}$ = 23.4 Hz].

2.2.2. $Py \cdot BF_nCl_{3-n}$ plus 1,10-phen

1,10-Phen reacted with $py \cdot BF_2Cl$, to give $(1,10\text{-phen})BF_2^+$ along with $(py)_2BF_2^+$ and some BF_4^-, detected by ^{19}F NMR (Table 1). White crystals precipitated over ten days. Positive ion FAB mass spectra of the crystals and the

solution did not give a detectable $(1,10\text{-phen})BF_2^+$ signal, but only $1,10\text{-phen}\cdot H^+$ and $(py)_2BF_2^+$ signals.

2.2.3. $Py\cdot BF_nCl_{3-n}$ plus terpy

Terpy reacted with $py\cdot BF_2Cl$, giving $(terpy)BF_2^+$ along with BF_4^- and $(py)_2BF_2^+$ after 48 h, as detected by ^{19}F NMR. White crystals precipitated, apparently the chloride salts of $(terpy)BF_2^+$ and $(py)_2BF_2^+$. Positive ion FAB mass spectra of the solution: $terpy\cdot H^+$ [234 m/z (100%)]; $(terpy)BF_2^+$ [282 m/z ($\sim$2%)]; $(py)_2BF_2^+$ [207 m/z (5.4%)]. Positive ion FAB mass spectra of the white crystals: $terpy\cdot H^+$ [234 m/z (100%)]; $(terpy)BF_2^+$ [282 m/z (4.3%)]; $(py)_2BF_2^+$ [207 m/z (12.4%)].

2.2.4. $ISOX\cdot BF_nCl_{3-n}$ plus bpy

A pink precipitate formed immediately, and the colourless supernatant liquid gave ^{11}B and ^{19}F NMR spectra consistent with very low concentrations of $(bpy)BF_2^+$, $(bpy)BFCl^+$, $(bpy)BCl_2^+$ and BF_4^- (Table 1). Positive ion FAB mass spectra of the precipitates obtained from the fluorine-rich and chlorine-rich reaction mixtures gave signals as follows (with peak intensities from the fluorine-rich reaction mixture listed first): $(bpy)BF_2^+$ [205 m/z (100%; 100%); $(bpy)BFCl^+$ [221 m/z (29.1%; 69.2%)]; $(bpy)BCl_2^+$ [237 m/z (0.0%; 19.4%)]. ^{11}B and ^{19}F spectra of the precipitate, dissolved in 3:1 acetone–sulpholane or nitromethane, confirm the presence of $(bpy)BF_2^+$, $(bpy)BFCl^+$ and BF_4^- (only a trace in the chlorine-rich sample), plus (in the chlorine-rich sample) $(bpy)BCl_2^+$ and a large amount of BCl_4^- (7.7 ppm).

2.2.5. $ISOX\cdot BF_nCl_{3-n}$ plus 1,10-phen

An orange precipitate formed immediately, and the yellow supernatant liquid gave ^{11}B and ^{19}F NMR spectra indicating very low concentrations of $(1,10\text{-phen})BFCl^+$, $(1,10\text{-phen})BCl_2^+$ (chlorine-rich sample only) and BF_4^-. Positive ion FAB mass spectra of the precipitate (fluorine-rich and chlorine-rich samples, respectively): $1,10\text{-phen}\cdot H^+$ [181 m/z (100%; 100%)]; $(1,10\text{-phen})BF_2^+$ [229 m/z (95.7%; 85.8%)]; $(1,10\text{-phen})BFCl^+$ [245 m/z (25.7%; 54.0%)]; $(1,10\text{-phen})BCl_2^+$ [261 m/z (0.0%; 6.7%)]. ^{11}B and ^{19}F NMR spectra of the precipitate, dissolved in 3:1 acetone–sulpholane or nitromethane, confirm the presence of $(1,10\text{-phen})BF_2^+$, $(1,10\text{-phen})BFCl^+$ and BF_4^-, plus (in the chlorine-rich sample) $(1,10\text{-phen})BCl_2^+$ and a large amount of BCl_4^-. Both ^{11}B NMR spectra and positive ion FAB mass spectra show that the amount of $(1,10\text{-phen})BCl_2^+$ is less than the amount of $(bpy)BCl_2^+$ in the correspconding bpy system.

2.2.6. $ISOX\cdot BF_nCl_{3-n}$ plus terpy

A very small amount of brown precipitate formed immediately, and the yellow supernatant liquid gave ^{11}B and ^{19}F NMR spectra indicating the presence of $(terpy)BF_2^+$, $(terpy)BFCl^+$, BF_4^- and (in the chlorine-rich sample) $(terpy)BCl_2^+$. FAB mass spectra obtained from the chloroform solution (fluorine-rich) gave peaks corresponding to: $terpy\cdot H^+$ [234 m/z (100%)]; $(terpy)BF_2^+$ [282 m/z (90.1%)]; $(terpy)BFCl^+$ [298 m/z (29.1%)]. FAB mass spectra of the precipitate gave peaks corresponding to (fluorine-rich and chlorine-rich samples, respectively): $terpy\cdot H^+$ [234 m/z (85.8%; 99.6%)]; $(terpy)BF_2^+$ [282 m/z (100%; 41.1%)]; $(terpy)BFCl^+$ [298 m/z (29.6%; 100%)]; $(terpy)BCl_2^+$ [314 m/z (0.0%; 14.9%)]. (The proportion of $(terpy)BFCl^+$ in the chlorine-rich sample appeared to be much larger from the FAB spectrum than from the ^{11}B NMR spectrum.) ^{11}B and ^{19}F NMR spectra of the precipitate, dissolved in 3:1 acetone–sulpholane or nitromethane, confirmed the presence of $(terpy)BF_2^+$, $(terpy)BFCl^+$, BF_4^-, plus (in the chlorine-rich sample) $(terpy)BCl_2^+$ and a large amount of BCl_4^-.

2.2.7. $ISOX\cdot BF_nCl_{3-n}$ plus DMAN

Reaction of DMAN with the chlorine-rich $ISOX\cdot BF_nCl_{3-n}$ solution gave a series of colour changes over several hours: successively yellow, orange, brown, red, gold, and brown, before settling on deep purple. Strong ^{11}B NMR signals arose that can be assigned to BCl_4^- (6.9 ppm), $BFCl_3^-$ (7.0 ppm [$^1J_{BF}=81.8$ Hz]), and $BF_2Cl_2^-$ (5.0 ppm [$^1J_{BF}=54.8$Hz]) [10,23]. This was confirmed by ^{19}F NMR showing that $BFCl_3^-$ and $BF_2Cl_2^-$ were indeed the major fluorine-containing species, making up over 50% of the total ^{19}F intensity: -95.4 ppm [$^1J_{BF}=81.6$ Hz]; -105.4 ppm [$^1J_{BF}=54.7$ Hz], respectively [10,23]. Typical ^{11}B signal intensities were: BCl_4^- and $BFCl_3^-$ (overlapping), 53%; BF_2Cl_2, 27%; broad signals in the 4 to 1 ppm region, 20%. Only in the presence of an excess of DMAN to ISOX, and with heating at 50°C, did significant amounts of $(DMAN)BF_2^+$ form: ^{11}B 1:2:1 triplet at 1.9 ppm [$^1J_{BF}=30.3$ Hz] (lit.: 2.3 ppm, $^1J_{BF}=27$ Hz [4]; 1.9 ppm [5]; the chemical shifts were listed as negative values in these papers because the old sign convention was in use, with positive values to low frequency, (high field); ^{19}F 1:1:1:1 quartet at -164.4 ppm [$^1J_{BF}=30.3$ Hz]. NMR signals of unreacted $ISOX\cdot BCl_3$ and $ISOX\cdot BFCl_2$ were still present. The positive ion FAB mass spectrum showed only two major species: $DMAN\cdot H^+$ [215 m/z (100%)]; $(DMAN)BF_2^+$ [263 m/z (5.6%)].

2.2.8. $ISOX\cdot BF_nBr_{3-n}$ plus bpy

A yellow precipitate formed immediately on addition of $ISOX\cdot BF_nBr_{3-n}$ to chloroform solutions containing bpy; BF_4^- in low concentration was the only species detectable in the supernatant liquid by ^{19}F NMR. FAB mass spectra of the precipitate gave peaks corresponding to (fluorine-rich and bromine-rich samples, respectively): $bpy\cdot H^+$ [157 m/z (37.2%, 42.9%)]; $(bpy)BF_2^+$ [205 m/z (29.2%, 18.3%)]; $(bpy)BBr^+$ [246 m/z (21.4%, 17.6%)]; $(bpy)BFBr^+$ [265 m/z (5.7%, 5.7%)]; $(bpy)BBr_2^+$ [327 m/z (100%, 100%)]. Thus $(bpy)BBr_2^+$ predominates in the solids prepared from both fluorine-rich and bromine-rich reaction mixtures. The precipitate, dissolved in nitromethane, gave ^{19}F and ^{11}B NMR signals corresponding to $(bpy)BF_2^+$,

(bpy)$BFBr^+$, (bpy)BBr_2^+ and BF_4^-. The ^{11}B multiplets of the difluoro- and fluorobromoboron cations overlap at 4.7 Tesla, but are readily distinguished at 11.7 Tesla.

2.2.9. ISOX·BF_nBr_{3-n} plus 1,10-phen

A brown oil settled out over several hours, following which only BF_4^- in low concentration could be detected in the supernatant liquid by ^{19}F and ^{11}B NMR. NMR monitoring, carried out before the oil began to separate, on a bromine-rich sample (equimolar 1,10-phen and total ISOX) indicated very rapid reaction of ISOX·BF_2Br and ISOX·$BFBr_2$, only their reaction products (1,10-phen)BF_2^+ and (1,10-phen)-$BFBr^+$ being detectable in the initial spectrum. ISOX·BF_3 and ISOX·BBr_3 reacted slowly, giving further (1,10-phen)BF_2^+ from the BF_3 adduct and (1,10-phen)BBr_2^+ from the BBr_3 adduct, as the oil began to separate. The oil gave FAB mass spectral peaks consistent with (fluorine-rich and chlorine-rich samples, respectively): 1,10-phen·H^+ [181 *m/z* (100%, 100%)]; (1,10-phen)BF_2^+ [229 *m/z* (35.3%, 45.8%)]; (1,10-phen)BBr^+ [270 *m/z* (3.7%, 7.3%)]; (1,10-phen)$BFBr^+$ [289 *m/z* (8.1%, 16.4%)]; (1,10-phen)BBr_2^+ [351 *m/z* (12.3%, 30.8%)]. The oil, dissolved in nitromethane, gave ^{11}B and ^{19}F NMR signals arising from (1,10-phen)BF_2^+, (1,10-phen)$BFBr^+$, (1,10-phen)BBr_2^+ and BF_4^-, with the fluorine-rich system giving more BF_4^- and less (1,10-phen)BBr_2^+.

2.2.10. ISOX·BF_nBr_{3-n} plus terpy

NMR monitoring of a bromine-rich sample (equimolar terpy and total ISOX) showed very rapid reaction of ISOX·BF_2Br and ISOX·$BFBr_2$, giving (terpy)BF_2^+ and (terpy)$BFBr^+$, but slow reaction of ISOX·BF_3 and ISOX·BBr_3. The resulting homogeneous yellow solutions gave ^{11}B and ^{19}F spectra consistent with (terpy)BF_2^+, (terpy)$BFBr^+$, (terpy)BBr_2^+ and BF_4^-, the 4.7 Tesla ^{11}B signals of (terpy)BF_2^+ and (terpy)$BFBr^+$ being poorly resolved. Removal of the chloroform left a brown oil which dissolved in nitromethane to give well-resolved NMR signals. The chloroform solution, and the oil respectively, gave FAB mass spectral peaks that correspond to: terpy·H^+ [234 *m/z* (100%, 73.9%)]; (terpy)BF_2^+ [282 *m/z* (24.2%, 71.1%)]; (terpy)BBr^+ [323 *m/z* (2.5%, 11.2%)]; (terpy)$BFBr^+$ [342 *m/z* (5.4%, 6.0%)]; (terpy)BBr_2^+ [404 *m/z* (15.3%, 100%)].

2.2.11. ISOX·BF_nBr_{3-n} plus DMAN

Multiple colour changes occurred, similar to those observed with DMAN plus ISOX·BF_nCl_{3-n}. ^{19}F NMR monitoring of bromine-rich samples of DMAN and ISOX·BF_nBr_{3-n} showed very rapid reaction of ISOX·BF_2Br (minutes), slower reaction of ISOX·$BFBr_2$ (hours) and very slow reaction of ISOX·BF_3 and ISOX·BBr_3 (days); (DMAN)BF_2^+ was the only identifiable haloboron cation. No mixed tetrahaloborate anion ($BF_nBr_{4-n}^-$) NMR signals [23] were detected. The positive ion FAB mass spectrum of the solution showed the same two species as on reaction with ISOX·BF_nCl_{3-n}: DMAN·H^+ [215 *m/z* (100%)]; (DMAN)BF_2^+ [263 *m/z* (6.7%)].

2.2.12. Bpy plus $Et_2O·BF_3$

Reaction of bpy with $Et_2O·BF_3$ in 1:1 ether–acetone, chloroform, or benzene at mole ratios of $Et_2O·BF_3$ to bpy of 1:1, 2:1 and 3:1 gave either bpy$H^+·BF_4^-$ as principal product in some attempts (^{19}F chemical shift −150.5 ppm), or a precipitate as principal product which, dissolved in nitromethane, gave a broad ^{19}F peak at −150.2 ppm (no splittings visible) and an ^{11}B peak at −0.6 ppm. These NMR parameters are inconsistent with those observed for (bpy)BF_2^+ as obtained by substitution reactions of the mixed boron trihalide adducts (Table 1), and could arise from the mono- or the bis-BF_3 adduct of bpy, by analogy with known chemical shifts of pyridine adducts [9]; bis-BF_3 adducts of chelating tertiary-amine donors have chemical shifts very similar to those of the mono-BF_3 adducts [12]. Elemental analysis of the precipitate from a bpy:$Et_2O·BF_3$ = 1:3 system in benzene solvent: C, 46.84; H, 2.98; N, 10.92%. Calc. for bpy·$(BF_3)_2$: C, 41.16; H, 2.76; N. 9.60%. Calc. for bpy·BF_3: C, 53.62; H, 3.60; N, 12.50%. Calc. for bpy·$H^+·BF_4^-$: C, 49.23; H, 3.71; N, 11.48%. The results are the most consistent with 1.5 BF_3 units per bpy unit, i.e. a mixture of bpy·BF_3 and bpy·$(BF_3)_2$.

2.2.13. Bpy plus ISOX·BF_3

Reaction of bpy with ISOX·BF_3 in chloroform gives the same insoluble species as on reaction with $Et_2O·BF_3$ (similar broad ^{19}F peak at −150.2 ppm in nitromethane). Attempted reaction of bpy with ISOX·BF_3 (and also with $Et_2O·BF_3$) in nitromethane gave a more complex ^{19}F spectrum, with broad peaks at −139.9, −141.4 and −150.5 ppm, in addition to the broad signal at −150.2 ppm arising from the bpy·BF_3 species. (BF_3 alone, bubbled into nitromethane, gives a broad ^{19}F singlet, apparently the BF_3 adduct, at −146.7 ppm.) Positive ion FAB mass spectra gave no evidence of (bpy)BF_2^+ in any of these samples.

2.2.14. 1,10-Phen plus $Et_2O·BF_3$

Addition of $Et_2O·BF_3$ to a benzene solution containing 1,10-phen in a mole ratio of $Et_2O·BF_3$:1,10-phen = 1:1 gave rapid formation of a white precipitate which, when dissolved in nitromethane, gave a ^{19}F signal at −149.8 ppm [$^1J_{BF}$ = 24.4 Hz] arising from (1,10-phen)BF_2^+ (also seen in the mixed boron trihalide displacement studies described above; Table 1) and a BF_4^- signal (−150.5 ppm) with twice the intensity. ^1H NMR and ^1H–^1H COSY NMR spectra (obtained in acetonitrile-d_3) showed that only half of the 1,10-phen had reacted with the $Et_2O·BF_3$, the remainder forming 1,10-phen·H^+. Addition of $Et_2O·BF_3$ to a benzene solution of 1,10-phen in a $Et_2O·BF_3$:bpy mole ratio of 2:1 gave a white precipitate which, dissolved in acetonitrile-d_3, gave ^{19}F signals at −149.2 ppm [$^1J_{BF}$ = 23.4 Hz] [(1,10-phen)BF_2^+] and −150.0 ppm (BF_4^-) in a 1:2 ratio. ^1H and ^{13}C NMR spectra showed that over 95% of the 1,10-phen had

formed (1,10-phen)BF_2^+. ^{1}H chemical shifts in acetonitrile-d_3: δ 9.36 [5.23 Hz (d) (1H)]; 9.22 [8.36 Hz, 0.72 Hz (dd) (1H)]; 8.44 [(s) (1H)]; 8.41 [8.40 Hz, 5.41 Hz (dd) (1H)]. ^{13}C chemical shifts (ppm) in acetonitrile-d_3: 146.2; 145.9; 129.6; 129.2; 128.6; 126.9. Positive ion FAB mass spectra of the precipitate gave peaks at 229 m/z [(1,10-phen)BF_2^+] (100%) and 181 m/z [1,10-phen·H^+] (46.5%). Negative ion FAB mass spectra gave a small peak at 403 m/z [(1,10-phen)$BF_2^+ \cdot (BF_4^-)_2$] in addition to the main peak at 87 m/z [BF_4^-].

2.2.15. 1,10-phen plus ISOX·BF_3

(1,10-Phen)$BF_2^+ \cdot BF_4^-$ also formed readily on reacting a chloroform solution of ISOX·BF_3 with 1,10-phen in a 2:1 mole ratio. Found: C, 45.70; H, 2.83; N, 9.01%. Calc.: C, 45.64; H, 2.55; N, 8.87%.

2.2.16. Terpy plus $Et_2O \cdot BF_3$

Addition of $Et_2O \cdot BF_3$ to terpy solutions in 1:1 ether–acetone or benzene, at $Et_2O \cdot BF_3$ to terpy mole ratios of 1:1, 2:1 and 3:1, gave a pale yellow precipitate over several minutes. The precipitate, dissolved in nitromethane, gave a ^{19}F signal at −145.2 ppm [$^1J_{BF}$ = 25.2 Hz] (also seen in the mixed boron trihalide displacment studies described above), arising from (terpy)BF_2^+, and a much larger BF_4^- signal at −150.5 ppm, the ratio of the two signals varying from 1:6 to 1:20 in different samples. ^{1}H spectra and ^{1}H–^{1}H COSY spectra (obtained in acetonitrile-d_3) showed that only 10–30% of the terpy had reacted with the $Et_2O \cdot BF_3$ in different samples, the remainder having formed terpy·$H^+ \cdot BF_4^-$. Positive ion FAB mass spectra of the precipitate gave peaks at: 282 m/z [(terpy)BF_2^+] (100%); 234 m/z [terpy·H^+] (58.2%). Negative ion FAB mass spectra gave a small peak at 240 m/z [(BF_4^-)(NBA); NBA is the matrix liquid, 3-nitrobenzoic acid] in addition to the base peak at 87 m/z [BF_4^-].

2.2.17. Terpy plus ISOX·BF_3

(Terpy)$BF_2^+ \cdot BF_4^-$ also formed on reacting a chloroform solution of ISOX·BF_3 with terpy in a 2:1 mole ratio. The yields for the yellow precipitate are similar to those reported above with $Et_2O \cdot BF_3$.

2.2.18. DMAN plus $Et_2O \cdot BF_3$

Addition of $Et_2O \cdot BF_3$ to a solution of DMAN in benzene, in a $Et_2O \cdot BF_3$:DMAN ratio of 1:1, gave a red precipitate after 24 h which, dissolved in nitromethane, gave a ^{19}F signal at −162.2 ppm [$^1J_{BF}$ = 29.2 Hz], consistent with (DMAN)BF_2^+, and a BF_4^- signal at −150.5 ppm, of relative intensities 1:1.9. ^{19}F NMR parameters in acetonitrile-d_3 are very similar: (DMAN)BF_2^+, −162.5 ppm [$^1J_{BF}$ = 29.2 Hz]; BF_4^-, −150.0 ppm. ^{1}H NMR indicated that only half of the DMAN had formed (DMAN)BF_2^+. A DMAN:$Et_2O \cdot BF_3$ ratio of 1:2 caused more than 95% of the DMAN to form (DMAN)BF_2^+, as shown by a combination of ^{19}F, ^{1}H, and ^{13}C NMR studies and confirmed by the high intensity of the positive ion FAB signal arising from (DMAN) BF_2^+. ^{1}H chemical shifts in acetonitrile-d_3: δ 8.21 [8.29 Hz (d) (1H)]; 8.15 [7.89 Hz (d) (1H)]; 7.83 [8.13 Hz (t) (1H)]; 3.44 [(s) (3H)]. ^{13}C chemical shifts (ppm) in acetonitrile-d_3: 139.4; 136.2; 131.9; 128.5; 122.7; 52.9. Positive ion FAB mass spectra of the precipitate gave peaks at: 263 m/z [(DMAN)BF_2^+] (100%); 248 m/z [(DMAN-Me)BF_2^+] (9.9%); 215 m/z [DMAN.H^+] (86.8%); 200 m/z [(DMAN-Me)·H^+] (4.7%). Negative ion FAB mass spectra gave a small peak at 437 m/z [(DMAN)-$BF_2^+(BF_4^-)_2]^-$ in addition to the base peak at 87 m/z [BF_4^-].

2.2.19. DMAN plus ISOX·BF_3

(DMAN)$BF_2^+ \cdot BF_4^-$ also formed readily on reacting a chloroform solution of ISOX·BF_3 with DMAN in a 2:1 mole ratio, with similar yield for the red precipitate as when $Et_2O \cdot BF_3$ was used.

3. Results and discussion

3.1. Reactions with py·BF_nCl_{3-n} adducts

Bpy, 1,10-phen and terpy react with py·BF_2Cl, but with none of the other py·BF_nCl_{3-n} (n = 0–3) adducts, in chloroform over a period of several days, to form the chelated (DD)BF_2^+ cations, identified by their ^{19}F and ^{11}B NMR signals (^{19}F 1:1:1:1 quartet, ^{11}B 1:2:1 triplet, Table 1) and by positive ion fast atom bombardment mass spectra. Fig. 1 shows ^{19}F NMR monitoring of the reaction with bpy. The ^{19}F 1:1:1:1 quartet of py·BF_2Cl diminishes and a poorly resolved 1:1:1:1 quartet of (bpy)BF_2^+ appears, along with signals of BF_4^- and (py)$_2BF_2^+$. The latter arises from displacement of Cl^- from py·BF_2Cl by free pyridine (which was itself displaced from py·BF_2Cl by the chelating ligand). In all three

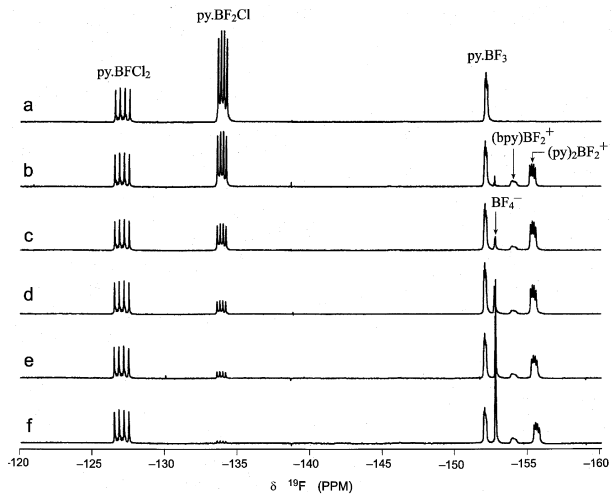

Fig. 1. 188.31 MHz ^{19}F NMR spectra of the py·BF_nCl_{3-n} (n = 0–3) adducts in $CDCl_3$ (mole ratio py:BF_3:BCl_3 = 5:2:3). (a) Initial solution; (b) after addition of bpy (same number of moles as moles of pyridine present) and standing for 2 days at room temperature; (c–f) same as (b) after standing for a total of 4 days (c), 6 days (d), 8 days (e), 10 days (f).

systems white crystals precipitate on standing, while the $(DD)BF_2^+$ and $(py)_2BF_2^+$ ^{19}F signal intensities decrease compared to the $py \cdot BF_3$ and $py \cdot BFCl_2$ ^{19}F signal intensities. The latter two signals stay constant except for a slight diminution of the $py \cdot BF_3$ signal, which seems to be related to the growth of the BF_4^- signal, as illustrated in Fig. 1. Both $(DD)BF_2^+$ and $(py)_2BF_2^+$ precipitate as their chloride salts, $(DD)BF_2^+ \cdot Cl^-$ being less soluble than $(py)_2BF_2^+ \cdot Cl^-$. No intermediate non-chelated $(py)(DD)BF_2^+$ species could be detected by NMR, unlike the situation with tertiary-amine chelating donors [12]. Furthermore, the three aromatic chelating ligands react with $py \cdot BF_2Cl$ much more slowly (days versus hours) than the tertiary-amine chelating ligands [12], and the yields are much poorer. Yields vary in the order $(bpy)BF_2^+ > (terpy)BF_2^+ > (1,10\text{-phen})BF_2^+$, i.e., inversely with ligand steric hindrance and rigidity. The most hindered ligand, DMAN, does not react with any of the $py \cdot BF_nCl_{3-n}$ adducts under the same conditions.

3.2. Reactions with $ISOX \cdot BF_nX_{3-n}$ (X = Cl, Br) adducts

Isoxazole, a much weaker base than pyridine, is much more easily displaced from its adducts than pyridine is from the corresponding pyridine adducts, and also differs from pyridine in being more easily displaced than Cl^- or Br^- [12]. Thus the $ISOX \cdot BF_nCl_{3-n}$ adducts are much more reactive than their pyridine analogues, and the $ISOX \cdot BF_nBr_{3-n}$ adducts are still more reactive due to the greater ease of displacement of Br^- than Cl^-. Because of this the mixed boron trihalide adducts of isoxazole are attractive intermediates for preparing chelated fluoroboron cations. However, they suffer from the disadvantage of an unfavourable halogen redistribution equilibrium, and do not form in large amounts. ^{11}B NMR spectra of the equilibrated $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$ adduct systems (Fig. 2) illustrate this. Especially in the F,Br system, the mixed-halogen adducts are present in very small proportions.

Halogen redistribution in mixed boron trihalide adducts occurs spontaneously at room temperature when the donor–acceptor bond is sufficiently weak [13], i.e. with isoxazole but not with pyridine. The equilibria among mixed- and unmixed-halogen adducts can be expressed as the equilibrium constants K_1 and K_2, as follows [24]:

$$K_1 = \frac{[D \cdot BF_2X][D \cdot BX_3]}{[D \cdot BFX_2]^2} \quad (1)$$

$$K_2 = \frac{[D \cdot BF_3][D \cdot BFX_2]}{[D \cdot BF_2X]^2} \quad (2)$$

These can be near-statistical ($K_1 = K_2 = 0.33$) or, with soft donors, can strongly favour the unmixed-halogen over the mixed-halogen adducts (see Table 1 of [13]). The latter situation is in accord with Pearson's 'symbiotic principle' [25]: hard ligands tend to cluster together on a central atom, as do soft ligands. In accord with this principle, fluorine-heavy halogen redistribution equilibria increasingly favour

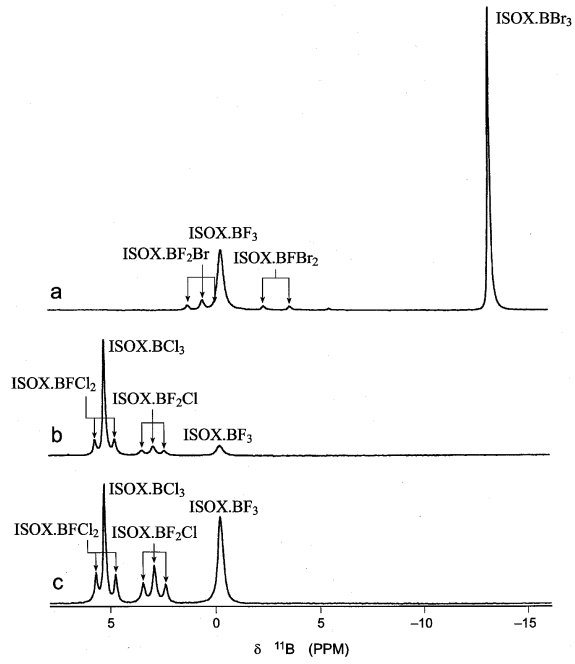

Fig. 2. 64.20 MHz ^{11}B NMR spectra of $CDCl_3$ solutions of $ISOX \cdot BF_nX_{3-n}$, illustrating the much greater concentration of unmixed-halogen than mixed-halogen adducts at equilibrium at ambient temperature (22°C). (a) $ISOX \cdot BF_nBr_{3-n}$ (mole ratio $ISOX:BF_3:BBr_3 = 4:1:3$); (b) $ISOX \cdot BF_nCl_{3-n}$ (mole ratio $ISOX:BF_3:BCl_3 = 4:1:3$); (c) $ISOX \cdot BF_nCl_{3-n}$ (mole ratio $ISOX:BF_3:BCl_3 = 2:1:1$).

the unmixed-halogen adducts over the mixed-halogen adducts as the heavy halogen changes from Cl to Br to I. This trend occurs in the isoxazole adduct system, as illustrated in Fig. 2. The spectra of Fig. 2 correspond to equilibrium constants K_1 and K_2 of 7.8 and 0.58 for the $ISOX \cdot BF_nCl_{3-n}$ system, and 42 and 2.5 for the $ISOX \cdot BF_nBr_{3-n}$ system. [K_1 is always larger than K_2 (Table 1 of [13]), consistent with favouring the only 'all-soft' adduct, $D \cdot BCl_3$, when the donor molecule is soft.] Despite this strong discrimination against the synthetically useful mixed-halogen adducts in the equilibrium mixture, their concentrations are sufficient to give detectable amounts of reaction products, mixed however with products of reaction of the more abundant BCl_3 and BBr_3 adducts. Our routinely used 'fluorine-rich' and 'heavy halogen-rich' proportions of reagents optimize the amounts of the desirable $ISOX \cdot BF_2X$ and $ISOX \cdot BFX_2$ adducts, respectively.

Bpy, 1,10-phen and terpy react with all of the $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$ adducts, displacing heavy halide and generating mixtures of $(DD)BF_2^+$, $(DD)BFX^+$ and $(DD)BX_2^+$ (X = Cl, Br), along with some BF_4^- and, from chlorine-rich $ISOX \cdot BF_nCl_{3-n}$ samples, a large amount of BCl_4^-. There is insufficient tetrahaloborate ion present to balance the cation charge, consistent with the principal counterion being chloride or bromide ion.

The Cl- and Br-containing systems differ in that Cl^- can displace ISOX from its BCl_3 adduct, giving BCl_4^- (^{11}B chemical shift 6.7 ppm [23]), whereas there is no evidence for BBr_4^- formation in the Br-containing system (expected

^{11}B chemical shift −24.1 ppm [23]; note that the chemical shifts of [23] are converted to ppm to *high* frequency from $Et_2O \cdot BF_3$, from the opposite sign convention used in the original paper). ^{11}B MAS NMR spectra of the solids that precipitate from the chlorine- and bromine-rich reaction mixtures of bpy with $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$, and ^{11}B NMR spectra of the same materials dissolved in nitromethane, are shown in Figs. 3 and 4, respectively. There are no absorptions within 20 ppm of the BBr_4^- chemical shift position. (F,Br exchange, rapid on the NMR time scale at room temperature [23], would be likely if both BF_4^- and BBr_4^- were present [23], but there is no exchange averaging of the BF_4^- signal.) Although resolution is poor in the ^{11}B MAS NMR spectra (Fig. 3), consistent with strong dipolar coupling to ^{19}F [26], the major peaks are consistent with those in nitromethane solution (Fig. 4) and with the chemical shift ranges of the closely related non-chelated $py_2BF_2^+$, py_2BFX^+ and $py_2BX_2^+$ [9].

Unlike the situation with tertiary-amine chelating donors which readily displace ISOX and form intermediate monodentate (DD)BF_nX_{3-n} adducts before undergoing chelation [12], no non-chelated boron trihalide adducts of bpy, 1,10-phen, terpy or DMAN could be detected by NMR. Such monodentate species are very unlikely on steric grounds for 1,10-phen and DMAN in which the nitrogens are held close together, but are plausible for bpy and terpy. Indeed, the monodentate analogue of bpy, 2-phenylpyridine, reacts readily with the $ISOX \cdot BF_nX_{3-n}$ adducts to give the corresponding 2-Phpy$\cdot BF_nX_{3-n}$ adducts, the ^{19}F resonances of which are shifted from 12–20 ppm to the high frequency of the corresponding py$\cdot BF_nX_{3-n}$ adduct signals (e.g. 2-Phpy$\cdot BF_3$ absorbs at −139.1 ppm), indicative of high steric hindrance at the donor site [27], although some of the effect could arise from the ring current of the phenyl group. Our inability to detect monodentate bpy$\cdot BF_nX_{3-n}$ and terpy$\cdot BF_nX_{3-n}$ species is consistent with the low steric hindrance of two-coordinate pyridine nitrogen giving very efficient ring closure. The increased pre-organization [28] of the more rigid aromatic ligands, with the second donor site being held close to the boron atom once the first site coordinates, would also assist in ring closure.

Bromine-containing systems usually react more rapidly than their chlorine-containing analogues, so it is unusual that bpy, 1,10-phen and terpy all react rapidly with the $ISOX \cdot BF_nCl_{3-n}$ adducts (giving precipitates), while only bpy reacts equally rapidly with the $ISOX \cdot BF_nBr_{3-n}$ adducts. With the slower-reacting 1,10-phen and terpy the reaction could be monitored by NMR, and in both cases the $ISOX \cdot BF_nBr_{3-n}$ adducts react in the order $BF_2Br \geq BFBr_2 > BF_3 > BBr_3$; i.e. the mixed-halogen adducts and especially the BF_2Br adduct are the most reactive, consistent with our previous studies of haloboron cation formation [8–12].

DMAN reacts very differently than the other chelating donors. With the $ISOX \cdot BF_nCl_{3-n}$ adducts the reaction favours formation of BCl_4^- and the mixed tetrahaloborate anions $BFCl_3^-$ and $BF_2Cl_2^-$ over formation of (DMAN)BF_2^+. Only in the presence of an excess of DMAN over ISOX, and with heating to 50°C, are significant amounts of (DMAN)BF_2^+ produced. Neither (DMAN)$BFCl^+$ nor (DMAN)BCl_2^+ are formed under our conditions, despite a

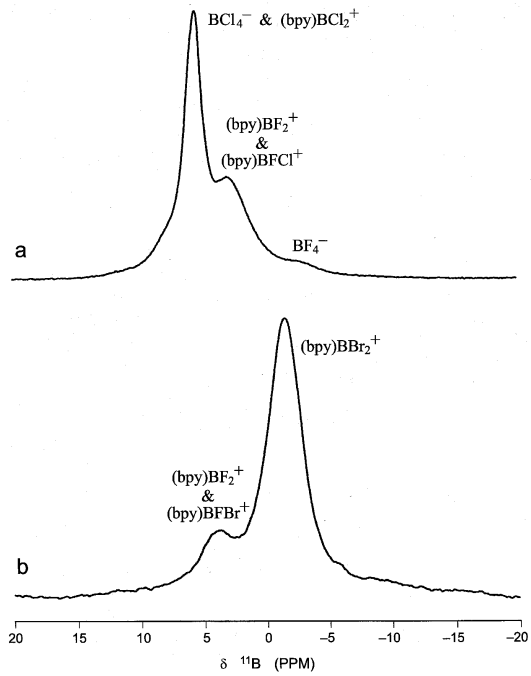

Fig. 3. 96.29 MHz ^{11}B magic-angle spinning NMR spectra of the precipitates formed on reaction of chloroform solutions of $ISOX \cdot BF_nX_{3-n}$ (mole ratio ISOX:BF_3:BX_3 = 4:1:3) with bpy (same number of moles as total moles of ISOX). (a) $ISOX \cdot BF_nCl_{3-n}$ plus bpy; (b) $ISOX \cdot BF_nBr_{3-n}$ plus bpy. No BBr_4^- signal was present at −26 ppm (off scale).

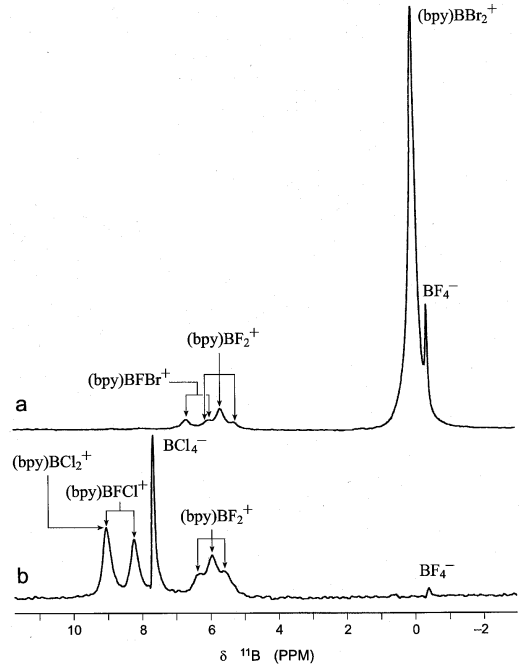

Fig. 4. 64.20 MHz ^{11}B NMR spectra of the precipitates of Fig. 3, dissolved in nitromethane. (a) $ISOX \cdot BF_nBr_{3-n}$ plus bpy; (b) $ISOX \cdot BF_nCl_{3-n}$ plus bpy.

previous report of the existence of $(DMAN)BCl_2^+$ [5]. Also, in some samples we are able to detect short-lived ^{11}B NMR signals in the three-coordinate boron region of the spectrum (at about 35, 24 and 16 ppm), in the early stages of the reaction; these disappear as the tetrahaloborate peaks grow (Fig. 5). These samples also appear to give off a small amount of a volatile material which fumes on contact with air, consistent with the behaviour of such three-coordinate boron compounds as BCl_3. (However, the ^{11}B chemical shift of BCl_3 in chloroform is 46.2 ppm, so BCl_3 does not give rise to one of these signals.)

DMAN reacts with the $ISOX \cdot BF_nBr_{3-n}$ adducts to give multiple colour changes similar to those observed when it reacts with the $ISOX \cdot BF_nCl_{3-n}$ adducts, but there are no corresponding mixed tetrahaloborate ion ($BF_nBr_{4-n}^-$ or $BF_mCl_nBr_{4-(m+n)}^-$) NMR signals [23]. If such species form at all they are too short-lived to detect. These anions undergo chemical exchange that is rapid on the NMR time scale [23], but there is no averaged ^{19}F NMR signal consistent with this. $(DMAN)BF_2^+$ is the only new fluorine-containing species formed, besides a very small amount of an unknown species absorbing near −151 ppm, which may be BF_4^-. Unlike the corresponding reaction with the $ISOX \cdot BF_nCl_{3-n}$ adducts, no transitory ^{11}B NMR signals could be detected in the three-coordinate boron region. DMAN reacts with the $ISOX \cdot BF_nBr_{3-n}$ adducts in the order $ISOX \cdot BF_2Br$ (minutes) ≫ $ISOX \cdot BFBr_2$ (hours) ≫ $ISOX \cdot BF_3 \sim ISOX \cdot BBr_3$ (days) (Fig. 6). Fluorine–bromine exchange must occur among the $ISOX \cdot BF_nBr_{3-n}$ adducts in order to give primarily a BF_2-containing product.

The unusual reaction of DMAN with the $ISOX \cdot BF_nCl_{3-n}$ adducts, giving the mixed chlorofluoroborate ions and BCl_4^- as primary products, is reminiscent of the behaviour of amidine $\cdot BF_nCl_{3-n}$ adduct systems [10]. Similar colour changes occurred, the mixed chlorofluoroborate ions were produced (including BF_3Cl^-, which is formed in only very small amounts in the present case) and protonated amidine was the counterion to the $BF_nCl_{4-n}^-$ anions (or ions). In the amidine systems the $BF_nCl_{4-n}^-$ anions forms only in the presence of excess boron trihalide [10], and we proposed a concerted mechanism involving dichlorocarbene formation from chloroform, assisted by free boron trihalide which would increase the effective basicity of the amidines which are not normally basic enough to drive carbene formation [29]. DMAN is almost as basic as the amidines in our previous study ($pK_b^1 = 1.7$, compared with 1.1 and 0.5 for the amidines [10]), but the DMAN reactions contrast with the amidine reactions in that the $BF_nCl_{4-n}^-$ anions form under excess base conditions as well. The extreme differences in steric hindrance, low in the amidines but very high in DMAN, no doubt contribute to the differences in behaviour. DMAN can only with great difficulty take up a second proton despite its very high affinity for the first proton, which led to the term 'proton sponge' for this and related compounds [30,31]. DMAN is too hindered to form simple covalent Lewis acid–base complexes, and this apparently allows boron to briefly become

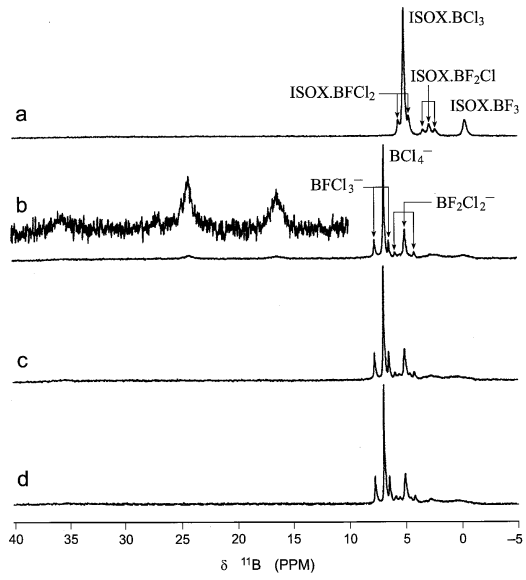

Fig. 5. 64.20 MHz ^{11}B NMR spectra of the $ISOX \cdot BF_nCl_{3-n}$ ($n = 0$–3) adducts in $CDCl_3$ (mole ratio $ISOX:BF_3:BCl_3 = 4:1:3$). (a) Initial solution. (b) After addition of DMAN (same number of moles as moles of ISOX present) and standing for 4 min at room temperature (inset spectrum: 10-fold vertical expansion); the $ISOX \cdot BCl_3$ peak overlaps the central peak of the $BF_2Cl_2^-$ triplet. (c) After standing for 8.4 min. (d) After standing for 17 min.

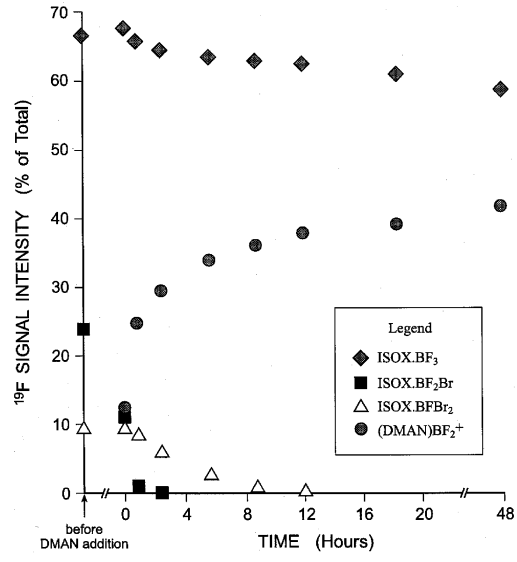

Fig. 6. Plot of relative ^{19}F signal intensity versus time for the reaction of DMAN with $ISOX \cdot BF_nBr_{3-n}$ in $CDCl_3$ (mole ratio $ISOX:BF_3:BBr_3:DMAN = 4:1:3:4$).

three-coordinate during the reaction of DMAN with the $ISOX \cdot BF_nCl_{3-n}$ adducts. The identities of the three-coordinate species are not obvious. Further studies are required to identify these and to determine the mechanism of reaction of DMAN with the $ISOX \cdot BF_nCl_{3-n}$ adducts.

Few $D \cdot BF_nCl_{3-n}$ systems give rise to the $BF_nCl_{4-n}^-$ anions , but it is of interest that they do form in the (tetramethylurea) $\cdot BF_nCl_{3-n}$ adduct system, which unlike the DMAN or amidine systems does not involve an especially

strong base [32]. Much remains to be learned about halogen redistribution in such systems.

3.3. Reactions of chelating ligands with $Et_2O \cdot BF_3$ and $ISOX \cdot BF_3$

$Et_2O \cdot BF_3$ is a well-known laboratory reagent; its very weak donor–acceptor bond readily dissociates, providing a convenient source of BF_3 for many uses including formation of BF_3 adducts of stronger donors and, in some favourable cases, formation of chelated $(DD)BF_2^+ \cdot BF_4^-$ species [1–6]. $ISOX \cdot BF_3$ behaves much like $Et_2O \cdot BF_3$ as a source of $(DD)BF_2^+ \cdot BF_4^-$, being successful with the same chelating donors. 1,10-Phen, terpy and DMAN, but not bpy, readily form the chelated $(DD)BF_2^+ \cdot BF_4^-$ on reaction with either $Et_2O \cdot BF_3$ or $ISOX \cdot BF_3$, along with large amounts of $DD \cdot H^+ \cdot BF_4^-$ unless the BF_3 source is present in excess. None of 1,10-phen, terpy or DMAN give any evidence of BF_3 adduct formation.

In contrast, bpy under the same conditions does not form $(bpy)BF_2^+$, a species which we have prepared by reaction with the mixed boron trihalide adducts and which is readily identifiable by NMR and by FAB MS. Instead our product gives analytical results consistent with 1.5 BF_3 units per bpy unit, i.e. a mixture of $bpy \cdot BF_3$ and $bpy \cdot (BF_3)_2$. The contrast between bpy and the other aromatic donors is striking. Not even trace amounts of $(bpy)BF_2^+$ are formed. Two overlapping ^{19}F 1:1:1:1 quartets of similar chemical shift, each poorly resolved, from $bpy \cdot BF_3$ and $bpy \cdot (BF_3)_2$, might account for the broadness and absence of fine structure of our ^{19}F signal.

$(bpy)BF_2^+ \cdot BF_4^-$ was previously reported to form under very similar conditions [5,6]. However, elemental analysis, which cannot distinguish this species from its coordination isomer the bis-BF_3 adduct, was the only evidence provided for the structure. Our results indicate that the previous workers actually isolated the bis-BF_3 adduct. Our bpy-BF_3 adduct has a similar ^{11}B chemical shift in DMSO (0.0 ppm) to the values reported for $(bpy)BF_2^+ \cdot BF_4^-$ by Axtell et al. (0.6 ppm) [6] and by Koch and Madelung (1.6 ppm) [5], whereas the actual $(bpy)BF_2^+$, synthesized by us from the mixed-halogen adducts, appears at 5.7 ppm in nitromethane. Furthermore, our $(bpy)BF_2^+$ does not react with DMSO, whereas the materials prepared by Axtell et al. and by Koch and Madelung reacted readily. This confirms that neither Axtell et al. nor Koch and Madelung prepared $(bpy)BF_2^+ \cdot BF_4^-$, but instead the bis-BF_3 adduct. Koch and Madelung suggested that $(bpy)BF_2^+$ undergoes rapid solvolysis by DMSO and reacts before it can be detected in solution by NMR, whereas the rigid $(1,10\text{-phen})BF_2^+$ is much more stable towards DMSO [5]. Our results show that the opposite is true.

The rigidity and steric hindrance of 1,10-phen and DMAN, with their two nitrogens held close together, should strongly hinder the formation of the mono-BF_3 adducts and preclude the formation of the bis-BF_3 adducts, and indeed over 95% of these ligands can be incorporated into the $(DD)BF_2^+$ species. Terpy is more flexible and like bpy should be able to form mono- and bis-BF_3 adducts, or even the tris-BF_3 adduct, but these are not observed. We detect $(terpy)BF_2^+$ instead, but only a small proportion (up to 30%) of terpy can be incorporated into $(terpy)BF_2^+$. It is not clear why bpy gives only adduct under the same conditions, but terpy is clearly an intermediate case: it does form the chelated cation but not in the high yields obtained with 1,10-phen and DMAN.

3.4. Reaction of chelated fluoroboron cations with DMSO

Previous attempts to prepare $(bpy)BF_2^+ \cdot BF_4^-$ and $(1,10\text{-phen})BF_2^+ \cdot BF_4^-$ involved the use of DMSO as solvent [5,6]. However, DMSO is a potent Lewis base, and we have shown that it reacts readily with $(py)_2BF_2^+$ to form $(DMSO)_2BF_2^+$ [33]. The more recent of the previous studies showed that DMSO solvolysis of $(1,10\text{-phen})BF_2^+ \cdot BF_4^-$ does indeed occur [5]. However, these authors assigned the ^{11}B NMR signals incorrectly. The $(DMSO)_2BF_2^+$ signal (2.2 ppm, $^1J_{BF} = 12.5$ Hz) was assigned to $(1,10\text{-phen})BF_2^+$, while the true $(1,10\text{-phen})BF_2^+$ signal (9.0 ppm; $^1J_{BF}$ unresolved) was tentatively assigned to $1,10\text{-phen} \cdot BF_3$, a species that we have not been able to prepare and that seems unlikely because of high steric hindrance. We here describe the reactions of DMSO with our chelated fluoroboron cation systems.

^{11}B NMR monitoring of the reaction of $(1,10\text{-phen})BF_2^+ \cdot BF_4^-$ with an excess of DMSO (Fig. 7) shows the transitory appearance of a small $(DMSO)_2BF_2^+$ signal (identified in a separate study [33]) after 6 min of reaction as the $(1,10\text{-phen})BF_2^+$ signal diminishes. The $(DMSO)_2BF_2^+$ signal (with 1:2:1 triplet structure that shows up more

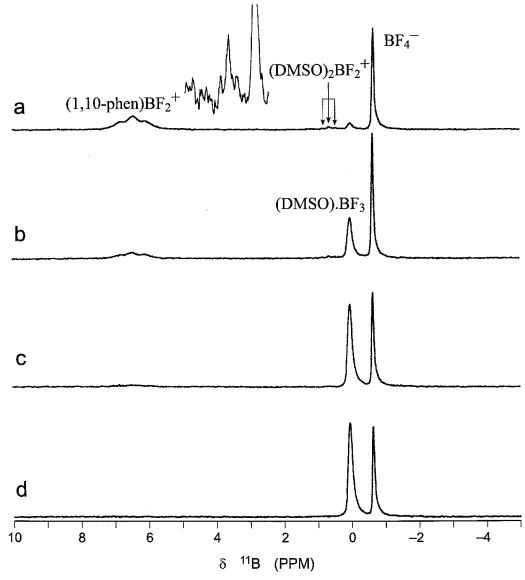

Fig. 7. 64.20 MHz ^{11}B NMR spectra of $(1,10\text{-phen})BF_2^+ \cdot BF_4^-$ in acetonitrile-d_3, following addition of a 4-fold molar excess of DMSO, after standing for: (a) 6 min (inset spectrum: 20-fold vertical expansion); (b) 12 min; (c) 24 min; (d) 72 min.

clearly in the expansion of Fig. 7a) never becomes large. Instead, fluorine redistribution occurs, the ionic $(DMSO)_2BF_2^+ \cdot BF_4^-$ converting to its covalent coordination isomer $DMSO \cdot BF_3$. The (1,10-phen)BF_2^+ signal is no longer detectable after 72 min. The BF_4^- signal intensity decreases but does not disappear as $DMSO \cdot BF_3$ becomes predominant, consistent with the remaining BF_4^- being present as the counterion of protonated 1,10-phen.

In samples prepared from mixed boron trihalide adducts and containing (1,10-phen)$BFCl^+$ and (1,10-phen)BCl_2^+ as well as (1,10-phen)BF_2^+, as chloride salts in nitromethane, only (1,10-phen)BF_2^+ reacts with a large excess of DMSO, to form first $(DMSO)_2BF_2^+$ and eventually $DMSO \cdot BF_3$. Samples containing (1,10-phen)BF_2^+, (1,10-phen)$BFBr^+$ and (1,10-phen)BBr_2^+, as bromide salts in nitromethane, behave similarly, with only (1,10-phen)BF_2^+ reacting. In these systems in which the predominant counterion of (1,10-phen)BF_2^+ is chloride or bromide, the conversion of (1,10-phen)BF_2^+, with two fluorines per boron, into $DMSO \cdot BF_3$, with three fluorines per boron, must involve further halogen redistribution reactions. These remain to be investigated.

None of the bpy-containing haloboron cations, (bpy)BF_2^+, (bpy)$BFCl^+$, (bpy)BCl_2^+, (bpy)$BFBr^+$ or (bpy)BBr_2^+, that are present in samples prepared by various methods as described earlier, react with a large excess of DMSO over 48 h at room temperature. (Terpy)BF_2^+ and (terpy)BBr_2^+ are similarly unreactive, but (terpy)$BFBr^+$, present in the same solution, does react with DMSO with the appearance of a new and not yet explained ^{11}B signal at about 22 ppm, in the three-coordinate boron spectral region.

(DMAN)$BF_2^+ \cdot BF_4^-$ is unreactive with DMSO, not surprisingly in view of its high steric hindrance. $(Quinuclidine)_2BF_2^+$, also highly sterically hindered, is unreactive with various Lewis bases [11]. Surprisingly, the less hindered (ethylenediamine)BF_2^+ does not react with DMSO over a period of several months [34].

3.5. Attempted reactions with $(py)_2BF_2^+ \cdot PF_6^-$

None of bpy, 1,10-phen, terpy or DMAN react with $(py)_2BF_2^+ \cdot PF_6^-$ in acetone solution under conditions that allow pyridine to be displaced by saturated-amine chelating donors to give chelated (DD)BF_2^+ [12], or by quinuclidine to give (py)(quinuclidine)BF_2^+ [11]. This is consistent with the steric hindrance and inflexibility of the aromatic donors. Instead there is decomposition of $(py)_2BF_2^+ \cdot PF_6^-$, requiring weeks at 20°C or hours at 50°C, with $py \cdot H^+$ and BF_4^- being major products. With DMAN, small amounts of BF_3OH^- [35,36] and additional unidentified fluorine-containing species also form. The reactions of $(py)_2BF_2^+ \cdot PF_6^-$, including decomposition in the presence of bases such as these, will be discussed elsewhere [33].

3.6. NMR parameters

The ^{19}F chemical shifts and $^1J_{BF}$ values reported here follow established patterns [37]. The ^{19}F and ^{11}B NMR parameters of the chelated species (Table 1) are fairly typical of haloboron cations except for a chelation shift to high frequency (low field). Table 1 includes NMR parameters for a few analogous non-chelated species for comparison. The chelation shift is less regular than was observed previously with tertiary-amine chelating donors [12], probably because of competing ring current effects which differ in their effectiveness in different species. The ^{19}F chemical shifts of $(py)_2BF_2^+$ and (bpy)BF_2^+ differ by only 1.2 ppm but their ^{11}B chemical shifts differ by about 3 ppm. (Bpy)BCl_2^+ and (bpy)BBr_2^+ also show ^{11}B chelation shifts to higher frequency ($+0.6$ and $+3.6$ ppm, respectively) compared with the analogous bis-pyridine species. There are large ^{19}F chemical shift differences among the (DD)BF_2^+ cations (5.9 ppm between the bpy and 1,10-phen cations, and a further 4.6 ppm between the 1,10-phen and terpy cations), whereas the ^{11}B chemical shifts of these species cover a range of only 1.3 ppm. The $^1J_{BF}$ values of the aromatic (DD)BF_2^+ cations are within a few Hz of each other, as are the $^1J_{BF}$ values of the corresponding (DD)$BFCl^+$ and (DD)$BFBr^+$ cations. (DMAN)BF_2^+ has NMR parameters typical of tertiary-amine ligands, the greatest similarity in chemical shifts being to $(Me_3N)_2BF_2^+$, although the $^1J_{BF}$ value of the chelated system is appreciably smaller. Chemical shift comparisons are limited by the need to use both $CHCl_3$ and CH_3NO_2 as solvents in different systems due to solubility limitations. ^{11}B chemical shifts are usually about 1 ppm to lower frequency in nitromethane and ^{19}F shifts differ by up to 1.5 ppm in either direction between the solvents.

4. Conclusions

Chelated fluoroboron cations of aromatic donors are accessible by displacement reactions from mixed boron trihalide adducts, and in most cases by reaction of the chelating ligand with $Et_2O \cdot BF_3$ or $ISOX \cdot BF_3$, but not by displacement of pyridine from $py_2BF_2^+$. Bipyridyl, unlike 1,10-phenanthroline, terpyridyl, or 1,8-bis(dimethylamino)naphthalene (DMAN), does not form the chelated difluoroboron cation on reaction with $Et_2O \cdot BF_3$ or $ISOX \cdot BF_3$, but this ion is readily formed by displacement of donor and heavy halide ion from $py \cdot BF_2Cl$, $ISOX \cdot BF_2Cl$ and $ISOX \cdot BF_2Br$. Reaction of DMAN with the $ISOX \cdot BF_nCl_{3-n}$ and $ISOX \cdot BF_nBr_{3-n}$ adduct systems has unique features, apparently related to DMAN's combination of high Bronsted basicity and low Lewis basicity, that merit further investigation.

Abstract

Schiff base ligands have been prepared by the condensation of 2-aminofluorene with salicylaldehyde (**1**, flusalH) or 3-methoxy-2-hydroxybenzaldehyde (**2**, MeOflusalH). Compound **1** reacts with $TiCl_4$ in a 1:1 stoichiometry to afford [$TiCl_3$(flusal)] (**3**) and in a 2:1 ratio to yield [$TiCl_4$(flusalH)$_2$] (**4**). The reaction of excess $TiBz_4$ with compound **1** results in the isolation of the octahedral Ti(IV) complex [Ti(flusal)$_2$(flusalaBz)$_2$] (**5**). Crystallographic and spectroscopic data for the latter indicate a complex containing two Schiff base ligands present as conventional N,O chelates and a further two ligands in which the C=N function is reduced by the addition of benzyl and hydrogen moieties producing an O-bound species with pendant amine. The single crystal X-ray diffraction structure of compound **1** has been obtained and compared with the published data for compound **5**. Similar ligand alkylation to that observed in compound **5** is also achieved by the reaction of organolithium reagents with compounds **1** and **2**; the reaction of PhLi and compound **2** followed by aqueous hydrolysis affords MeOflusalaPhH (**6**). Although reactivity does occur between $TiCl_4$ and compound **6**, the products could not be fully characterised. Thus tetradentate reduced Schiff base ligands were synthesised by the reaction of salenH_2 with MeLi or PhLi, giving salenaMe_2H_2 (**7**) and salenaPh_2H_2 (**8**), respectively. Reaction of compound **8** and $TiCl_4$ affords the quadruply deprotonated amido complex [Ti(salenamidoPh_2)] (**9**), which hydrolyses in air to the μ-oxo amine complex [Ti(salenaPh_2)O] (**10**). ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The recent interest in group 4 complexes incorporating the fluorenyl ligand stems from the discovery that *ansa*-metallocene zirconium complexes containing linked fluorenyl-cyclopentadienyl ligands are involved in the syndiospecific polymerisation of α-olefins [1–11]. Examples of unsupported fluorenyl coordination to group 4 metals are far less numerous than the corresponding indenyl and cyclopentadienyl moieties [12]; the preparation of [(η^5-$C_{13}H_9$)$_2$-$TiCl_2$], from sodium fluorenyl and titanium(IV) chloride, and of [(η^5-$C_{13}H_9$)(η^5-C_5H_5)$TiCl_2$], from thallium fluorenyl and [$CpTiCl_3$], are the only examples of titanium(IV) metallocene precursors containing the fluorenyl moiety [13,14], although a large number of monodithiocarbamate derivatives have been synthesised from [(η^5-$C_{13}H_9$)$_2TiCl_2$] [15]. Recently bis-fluorenyltitanium(0) has also been formed by metal vapour deposition (MVD) methods [16]. In the present work the relative coordination affinities of Schiff base and fluorenyl moieties contained within potentially chelating ligands are assessed. Part of this work has previously been the subject of a brief communication [17].

2. Results and discussion

2.1. Titanium(IV) complexes of flusalH and derivatives

Schiff base ligands can be readily formed by the condensation of 2-aminofluorene and salicylaldehyde (**1**, flusalH) or 3-methoxy-2-hydroxybenzaldehyde (**2**, MeOflusalH) (Table 1). The synthetic route, outlined in Scheme 1, is conventional and employs published methods [18]. Although compounds **1** and **2** appear visually very different in colour, visible reflectance spectra display similar features, with a shift in absorbance to higher wavelength occurring as

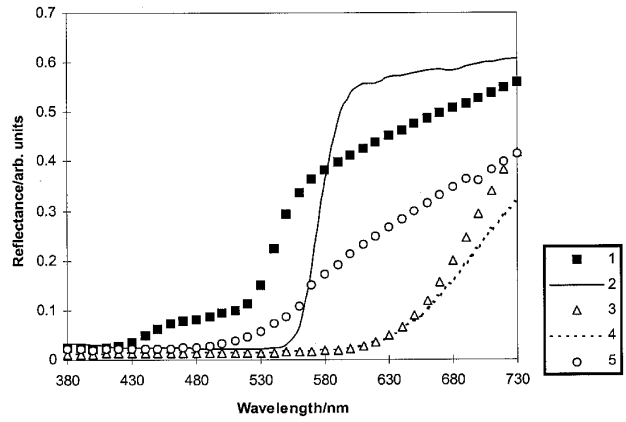
Scheme 1. Synthesis and reactivity of compounds **1** and **2**.

a consequence of the electron donating methoxy substituent in compound **2** (Fig. 1). Considering the coordination potential of compounds **1** and **2**, it is of note that the pK_a of fluorene is significantly larger than that of indene or cyclopentadiene [19]. Moreover, the extended delocalisation of charge within the deprotonated fluorene results in far lower coordination affinities than either indenyl or cyclopentadienyl moieties. Thus, the stoichiometric reaction of titanium(IV) chloride and compound **1** in dichloromethane yields the deep red complex [$TiCl_3$(flusal)] (**3**), which on the basis of IR evidence displays ligand bonding through the Schiff base moiety by chelation of nitrogen and the deprotonated oxygen centre. The significant change in colour from compound **1** to compound **3** is common in Schiff base systems and does not imply more complex interactions or processes (Fig. 1). Although the formation of compound **3** is entirely normal, it is of note that compound **3** is nominally five coordinate . The fact that this compound strongly retains solvent, and affords an insoluble high melting solid once dried, suggests six coordinate geometry is achieved by the formation of halide bridged dimers. Molecular weight measurements for related 1:1 complexes have been indicative of such behaviour [20]. Reaction of titanium(IV) chloride with two equivalents of compound **1** in tetrahydrofuran (THF) yields a red sticky and intractable solid which retains solvent. After suspension in dry, deaerated acetone, [$TiCl_4$(flusalH)$_2$]·$(Me)_2CO$ (**4**) is isolated as a free-flowing powder from which acetone is not liberated even at elevated temperatures in vacuo. The insolubility of compound **4** limits the extent of its characterisation (Table 1); however, the various forms of Schiff base denticity and deprotonation have been explored in detail for both titanium(IV) and zirconium(IV) [20–24]. By analogy with this work it is possible to suggest that compound **4** exists as a six coordinate complex containing N-bound ligands in which acetone hydrogen bonds to the phenolic protons of the pendant OH functionalities. It is the presence of the latter and their interactions with solvents which are likely to cause the difficulties in handling and drying the complex [25–27].

Complexes **3** and **4** are typical Schiff base complexes in which the fluorenyl moiety is entirely passive. To induce reactivity at this centre, interaction with organometallic reagents was examined. Since considerable problems are associated with the alkylation of group 4 Schiff base complexes using alkyllithium and Grignard reagents [28,29], compound **1** was reacted directly with $TiBz_4$ [17]. Thus, the addition of compound **1** to a hexane solution of $TiBz_4$ (1:1.2) at −20°C affords, after work-up, the complex [Ti(flusal)$_2$(flusalaBz$_2$)$_2$] (**5**) (Scheme 1). ^{1}H NMR data are consistent with the crystallographic characterisation of the complex [17], which indicates the presence of two chelating flusal ligands in the octahedral titanium(IV) coordination sphere. The remaining sites are occupied by reduced Schiff base ligands, reduction having occurred as a consequence of benzyl and hydrogen addition to the C=N moieties to afford pendant amine functions. IR data are also consistent with amine and imine absorbances being observed. Once again there is no



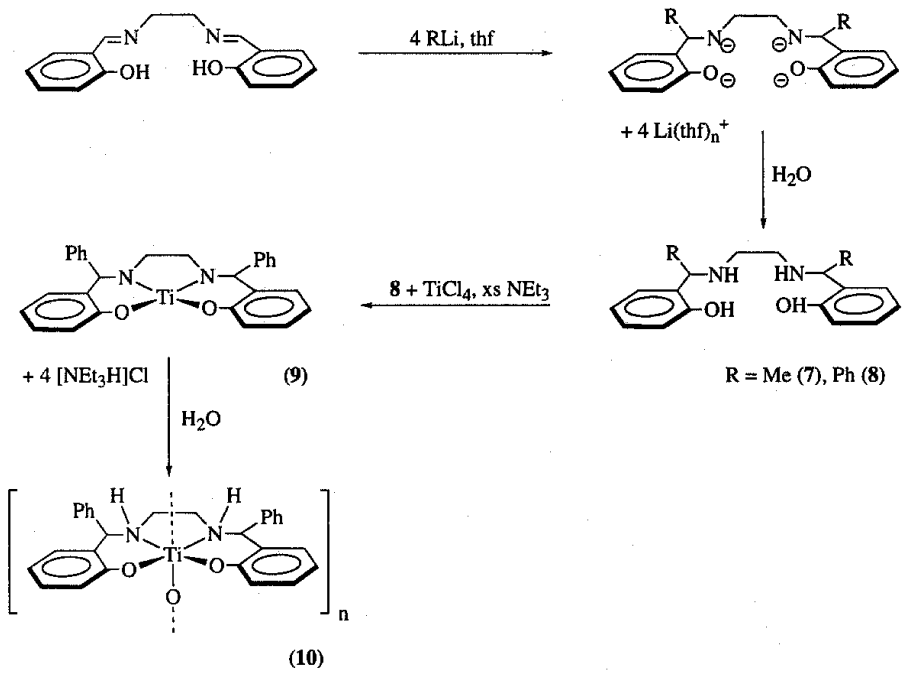


Fig. 1. Diffuse reflectance visible spectra of compounds **1–5**.

evidence for reactivity at the fluorene moiety. However, these extended aromatic systems do appear to influence the overall structure; π–π interaction of the fluorene groups of the two reduced ligands inducing a *cis* orientation of the monodentate donors.

A mechanistic appreciation of the formation of compound **5** is difficult to obtain, although several groups have considered the reactivity of systems containing alkyl functionalities, Schiff base ligands and group(4) metals [28–32]. Although direct interaction of metal and alkyl groups can occur, reactivity is complicated by the potential for metal reduction and/or nucleophilic attack of the alkyl at the Schiff base C=N group resulting in amide formation. The isolation of compound **5** extends the latter reactivity, with imine reduction to amines resulting from the effective addition of benzyl and hydrogen moieties to the C=N group. It has not proved possible to follow this process stepwise, although Bz migration to the coordinate d flusalH ligand followed by intramolecular proton transfer is clearly realistic. Such a mechanism has been explored using the reactivity of compounds **1** and **2** with organolithium reagents.

2.2. Reactivity of organolithium reagents with flusalH and derivatives

Three equivalents of organolithium reagent are consumed in the reaction of compound **1** with PhLi or n-BuLi and of compound **2** with MeLi or t-BuLi. Reaction stoichiometry suggests that highly air-sensitive intermediates are formed as a consequence of the deprotonation at hydroxyl and 9-fluorenyl protons, and nucleophilic alkyl attack at the imine centre (Scheme 1). Aqueous hydrolysis protonates all three basic sites leaving imine reduction by R-addition as the single permanent change. The formation of amines is confirmed in each reaction by the observation of parent ions in the respective mass spectra, with additional characterisation of the product obtained from the reaction of compound **2** and PhLi, i.e. MeOflusalaPhH (**6**) (Table 1). Since reducing the reaction stoichiometry to a 2:1 RLi/ligand ratio results in the complete recovery of compounds **1** and **2**, it can be assumed that the relative pK_a of the three acidic sites is OH < 9-fluorenyl

Scheme 2. Synthesis and reactivity of compounds **7** and **8**.

<HC=N. This view is supported by the reactivity observed between compound **1** or **2** and $Li[N(SiMe_3)_2]$. Addition of excess $Li[N(SiMe_3)_2]$, followed by hydrolysis, results in the quantitative recovery of compounds **1** and **2**. Although steric control cannot be ignored, this behaviour suggests that this less basic reagent is not capable of nucleophilic attack at the imine moiety.

The reactivity of compounds **1** and **2** with organolithium reagents demonstrates the general principle that nucleophilic alkyl attack at the imine function, followed by protonation, can afford amines. However, clear differences in selectivity are apparent. The 1:1.2 **1**/$TiBz_4$ reaction stoichiometry which affords compound **5** provides an excess of alkylating agent, but titanium coordination and stoichiometric availability of phenolic protons moderate reactivity. As a consequence, it can be proposed that the initial N,O coordination of the Schiff base ligand enhances intramolecular nucleophilic attack of the Bz moiety and facilitates intramolecular proton transfer. That imine alkylation remains marginal is demonstrated by the 50:50 ratio of amine and imine moieties in compound **5**. However, it is evident that in the formation of compound **5** imine reactivity is preferred to that of the fluorene function, a clear contrast to the reactivity observed with organolithium reagents.

The reactivity of compound **6** and $TiCl_4$ also provides a useful contrast to the formation of compound **5**. It is apparent that reactivity occurs between compound **6** and $TiCl_4$; however, the insolubility of the products precludes the separation and characterisation of what appears to be several metal-containing complexes. The elimination of HCl from the reaction $TiCl_4$ with ammine and amine ligands is well established, and such reactivity may be the source of multiple products here [33]. To increase the potential to form a single characterisable product, quadradentate reduced Schiff base ligands were prepared by the reaction of $salenH_2$ with organolithium reagents.

2.3. Synthesis and reactivity of reduced salenH_2 ligands

In an analogous manner to the reaction of flusalH and organolithium reagents, the reaction of MeLi or PhLi, followed by aqueous hydrolysis, affords $salenaMe_2H_2$ (**7**) and $salenaPh_2H_2$ (**8**), respectively (Scheme 2). Stoichiometric reaction of compound **8** and $TiCl_4$ in the presence of NEt_3 results in complete deprotonation of the N_2O_2 donor set and the isolation of [Ti(salenamidoPh_2)] (**9**). Similar tetra-anionic species have been synthesised using reduced Schiff base ligands and zirconium(IV) [34]. In the latter, the octahedral geometry is completed by pyridine coordination. Although compound **9** is nominally four coordinate, the classical octahedral geometry may be completed by intermolecular dative bonding by the oxygen centres. Such behaviour is well established in the corresponding titanium Schiff base chemistry [31,32,35,36]. Compound **9** is unstable in moist air, undergoing rapid hydrolysis to the polymeric μ-oxo diamine complex [Ti($salenaPh_2$)O] (**10**). Once again the relative stability of such μ-oxo species has been demonstrated by the formation of a number of dimeric, oligomeric and polymeric complexes in which the μ-oxo group is readily identified by a strong ν(Ti–O) IR vibration [32,37,38].

2.4. Crystallographic characterisation of N-2-fluorenyl-(salicylideneimine) (1)

Crystallographic characterisation of *N*-2-fluorenyl-(salicylideneimine) allows direct structural comparison with

the titanium complex **5**. Structural elucidation of compound **1** indicates similarities with the bond lengths and angles that are observed in single crystal X-ray diffraction studies of the fluorene and simple Schiff base ligands such as salenH_2 [39,40], Fig. 2. Comparison of geometries in the deprotonated flusal and reduced flusala ligands of compound **5** with compound **1** demonstrates the effects of both coordination and reduction (Table 2). The imine flusalH bond, N(1)–C(14), is slightly elongated in the coordinate d Schiff base of compound **5**, although it must be noted that the O(1)···H···N(1) hydrogen bond of flusalH is replaced by metal coordination in compound **5**. Thus, the relatively modest elongation on titanium coordination must be viewed in the context of substituting one Lewis acid interaction at N(1) with another. More significantly, lengthening of the same bond occurs by reduction in the pendant amine of the same complex — clearly a direct consequence of changing bond order. The corresponding nitrogen–fluorene linkages, N(1)–C(12), shorten in both metal-bound forms. Perhaps most notably, little change in the C(12)–N(1)–C(14) bond angle occurs between the hydrogen bonded free Schiff base and the reduced flusala moiety of compound **5**, despite the change from sp^2 to sp^3 hybridisation. In contrast, the coordinated imine moiety displays a shift towards sp character — a feature which may optimise a Ti(dπ)–N(pπ) interaction. Moreover, the significant structural changes which occur on coordination help to rationalise the differing functional group selectivity observed for the reactivity of RLi or $TiBz_4$ with compound **1**.

3. Conclusion

Titanium(IV) complexes containing Schiff base ligands and their reduced analogues may be synthesised by direct reaction of metal salt and ligand. More complex reactivity occurs between Schiff base ligands and the organotitanium reagent $TiBz_4$, involving partial imine alkylation and reduction. Reduced ligands can react with $TiCl_4$ to afford amido functionalities, which may themselves be hydrolysed to regenerate coordinate d amines. Thus by manipulation of reagents and conditions a range of ligand-centred transformations involving imine, amine and amido functionalities may occur within the group 4 metal coordination sphere.

4. Experimental

4.1. Crystallographic characterisation

Recrystallisation of compound **1** from THF–Et_2O using vapour diffusion techniques gave yellow-brown crystals ($0.07\times0.07\times0.11$ mm) suitable for single crystal X-ray analysis. Data collection and structure solution of compound **1** was performed using previously described methods, resulting in the following crystal data [41–44].

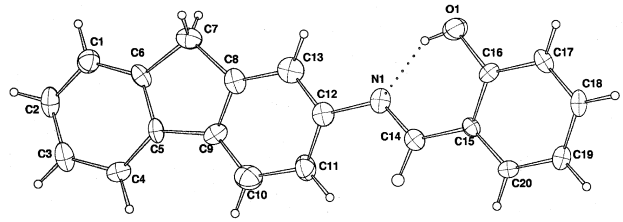

Fig. 2. Single crystal X-ray structure of compound **1**.

Table 2
Bond lengths and angles in **1** and **5**

Molecular dimensions	**1**	**5** [a]	
		Flusal moiety	Flusala moiety
Bond lengths (Å)			
N(1)–C(12)	1.469(5)	1.409(10)	1.379(12)
N(1)–C(14)	1.272(5)	1.317(10)	1.449(10)

[a] From [17].

Crystal data for $C_{18}H_{15}NO$ (**1**): $M=285.33$; monoclinic; space group $P2_1a$, $a=11.048(42)$, $b=7.936(15)$, $c=15.899(35)$ Å; $\beta=97.39(8)°$; $U<1478.3(6)$ Å^3; $D_c=1.371$ g cm^{-3}; $Z=4$; $T=145(2)$ K; $\mu=0.084$ mm^{-1}; $F(000)=600$; λ(Mo Kα) = 0.71069 nm; $2.58<\theta<25.07$; total observed reflections = 2124; observed reflections [$I>2\sigma(I)$] 734; $R=0.0489$; $R_w=0.0958$ (observed data).

4.2. Data collection and structure solution

Collection, FAST TV area detector; absorption correction, DIFFABS (min./max. factors 0.748 and 1.324, respectively); solution, direct methods (SHELXS-86); refinement, full matrix least squares on F^2 (SHELX-92), non-hydrogen atoms anisotropic, hydrogen atoms riding.

4.3. Synthetic procedures

Solvents were dried using standard methods. All titanium reactions were performed under nitrogen [32]. RLi reagents [R = Me, Ph, n-Bu, t-Bu, N(SiMe$_3$)$_2$] were purchased from Aldrich. 2-Aminofluorene, lithiumfluorenyl and $TiBz_4$, were prepared using published methods [18,45–47]. ^{1}H NMR spectra were obtained at 270 MHz in $CDCl_3$ unless stated otherwise. Elemental analysis and important characterisation data are given in Table 1.

*4.3.1. N-2-Fluorenyl(salicylideneimine), flusalH (**1**)*

The ligand was prepared by the dropwise addition of one equivalent of 2-aminofluorene in THF to an ethanolic solution of freshly distilled salicylaldehyde. After refluxing for 1 h the solution was cooled to afford crude compound **1**, which was washed in Et_2O and dried in vacuo. Recrystallisation of the crude material from ethanol–chloroform gave compound **1** as a yellow-brown crystalline solid (80%). ^{1}H NMR: δ 3.95 (s, 2H, CH_2), 6.92–7.84 (m, 11H, aromatic), 8.70 (s, 1H, CH), 13.30 (s, 1H, OH). EI^+ MS: *m/z* 285 (100%, $[\mathbf{1}]^+$). IR (Nujol) (cm^{-1}): ν(C=N) 1618, ν(O–H) 3460.

*4.3.2. N-2-Fluorenyl(3-methoxysalicylideneimine) (**2**)*

Compound **2** was prepared by the same method as compound **1** and recrystallised from ethanol (75% yield). ^{1}H NMR ($CDCl_3$): δ 3.94 (s, 3H, MeO) and (s, 2H, CH_2) (methylene protons obscured by the methoxy resonance), 6.84–7.83 (m, 11H, Ph), 8.71 (s, 1H, CH), 13.83 (s, 1H, OH). EI^+ MS: *m/z* 316 (100%, $[2+H]^+$). IR (Nujol) (cm^{-1}): ν(C=N) 1618, ν(O–H) 3460.

*4.3.3. [$TiCl_3$(flusal)] (**3**)*

A toluene solution of titanium(IV) chloride (1.0 M, 3.15 cm^3, 3.15 mmol) was added dropwise to compound **1** (0.9 g, 3.2 mmol) in CH_2Cl_2 (approx. 30 cm^3). A deep red precipitate immediately formed. The solution was refluxed for 1 h, after which the solid was separated by filtration, washed with hexane (5×10 cm^3) and dried in vacuo to afford compound **3** as a maroon free-flowing solid. Yield: 1.3 g (95%). Compound **3** is insufficiently soluble to obtain ^{1}H NMR spectroscopic data. FAB^+ MS: *m/z* 437 (15%, $[\mathbf{3}]^+$). M.p. dec.: 306–310°C.

*4.3.4. [$TiCl_4$(flusalH)$_2$] (**4**)*

Compound **1** (2.0 g 7.0 mmol) in THF (approx. 50 cm^3) was treated with titanium(IV) chloride (1.0 M, 3.5 cm^3, 3.5 mmol). A deep red solid precipitated, after which the solution was refluxed for 1 h. The colourless solvent was then decanted from the solid which was washed with THF (2×30 cm^3), also resulting in colourless extracts. The solid was slurried in acetone and cooled to −20°C. After 1 day, decantation of the solvent and drying in vacuo gave 2.8 g of [$TiCl_4$(flusalH)$_2$]·Me_2CO (**4**) as a deep red, air-stable solid in quantitative yield. Insolubility precluded ^{1}H NMR spectroscopic characterisation. FAB^+ MS: *m/z* 286 (100%, $[1+H^+]$), 348 (40%, [Ti(=O)(flusal)]$^+$). IR (Nujol) (cm^{-1}): ν(C=O) 1645, ν(C=N) 1620, ν(O–H) 3361.

*4.3.5. [Ti(flusal)$_2$(flusalaBz$_2$)$_2$] (**5**)*

Compound **1** (0.50 g, 1.8 mmol) was added in a single portion to a hexane solution (20 cm^3) of $TiBz_4$ (0.87 g, 2.1 mmol) at −20°C. The dark brown precipitate which formed over 0.5 h was filtered, washed with hexane and extracted with toluene. The resultant brown solution becomes progressively pale orange. Addition of hexane and storage at −20°C affords toluene solvated compound **5** over about 3 days. ^{1}H NMR: δ 3.22 (m, 4H, Ph*CH*$_2$CHNH), 3.72 (s, 2H, 9-fluorene CH_2), 3.96 (s, 2H, 9-fluorene CH_2), 4.18 (s, 2H, PhCH$_2$CH*NH*), 4.60 (m, 2H, PhCH$_2$*CH*NH), 6.67–7.86 (m, 54H, aromatic), 8.75 (s, 2H, *CH*). FAB^+ MS: *m/z* 268 (100%, $[\mathbf{1}]^+$), 1368 (10%, $[\mathbf{5}]^+$). IR (Nujol) (cm^{-1}): ν(C=N) 1612(s), ν(N–H) 3376(s), 3389(s).

*4.3.6. N-2-Fluorenyl(α-phenyl-3-methoxysalicylideneamine) (**6**)*

Compound **2** (3.0 g, 9.5 mmol) in THF (approx. 40 cm^3) was cooled to −20°C and PhLi (1.8 M, 15.9 cm^3, 28.6 mmol) was added dropwise. During addition the solution developed a deep red colour. After stirring for 1 h, deaerated distilled water was added. The mixture was diluted with Et_2O and the organic layer was separated. The aqueous layer was shaken with two portions of Et_2O (approx. 2×30 cm^3) and the combined organic fractions were dried over magnesium sulfate. Following filtration the solvent was removed under reduced pressure to yield crude compound **6** (3.7 g, ≈96%) as a gelatinous, off-white solid. Recrystallisation from THF–Et_2O afforded cream, crystalline material. ^{1}H NMR: δ 1.18 (s br, 1H, *NH*), 3.68 (s, 2H, *CH*$_2$), 3.83 (s, 3H, *CH*$_3$O), 4.40 (s br, 1H, *OH*), 5.82 (s, 1H, CH), 6.73–6.83, 7.07–7.35 (m, Ph). FAB^+ MS: *m/z* 393 (55%, $[\mathbf{6}]^+$). IR (Nujol) (cm^{-1}): ν(N–H) 3414, 3475 (vs), ν(O–H) 1375.

Similar reactions carried out using compounds **1** and **2** with other organolithium reagents afforded products analogous to compound **6**. These products did not lend themselves to crystallisation and thus produced ^{1}H NMR spectra containing residual solvent, and tolerable but somewhat variable elemental analysis. However, molecular ions of significant intensity could be recorded in each case. Thus *N*-2-fluorenyl(α-phenyl-salicylideneamine) [EI MS: *m/z* 363, 85%] and *N*-2-fluorenyl(α-n-butyl-salicylideneamine) [FAB^+ MS: *m/z* 344, 100%] were recovered from the reaction of compound **1** with phenyllithium and butyllithium, respectively. The methoxyl derivatives *N*-2-fluorenyl(α-methyl-3-methoxysalicylideneamine) [FAB^+ MS: *m/z* 331, 20%] and *N*-2-fluorenyl(α-t-butyl-3-methoxysalicylideneamine) [FAB^+ MS: *m/z* 374, 100%] were also isolated from the reaction of compound **2** with methyllithium and t-butyllithium.

*4.3.7. N,N′-(1,2-Ethlyenebis(α-methylsalicylaldamine)] (**7**)*

An ET_2O solution of methyllithium (1.4 M, 21.3 cm^3, 29.9 mmol) was added dropwise to a THF solution of salenH_2 (2.0 g, 7.46 mmol) at −20°C. The resultant colourless solution was stirred for 1 h before deaerated, distilled water was added (approx. 20 cm^3). Addition of Et_2O produced two layers. After separation, the aqueous layer was washed with ether (3×30 cm^3). The combined organic phases were concentrated, dried with $MgSO_4$ and further reduced to produce a paste which was recrystallised from THF–Et_2O to afford compound **7** (1.0 g, 45%). ^{1}H NMR (CD_2Cl_2): δ 1.38 (s, 3H, *Me*), 1.41 (s, 3H, *Me*), 1.53 (b s, *NH*), 2.66 (m, 2H,

CH_2), 2.79 (m, 2H, CH_2), 3.88 (q, 2H, *CH*), 6.70–7.13 (m, 8H, *Ph*), 11.03 (bs *OH*). EI MS: m/z 300 (100%, $[\mathbf{7}]^+$).

*4.3.8. N,N′-(1,2-Ethylenebis(α-phenylsalicylaldamine)] (**8**)*

The compound was prepared by the same route as compound **7**, giving a white solid in 80% yield. ^{1}H NMR: δ 1.42 (b s, *NH*), 2.93 (m, 4H, CH_2), 4.88 (s, 2H, *CH*), 6.72–7.31 (m, 18H, *Ph*), 11.50 (bs *OH*). FAB$^+$ MS: m/z 425 (30%, $[\mathbf{8}]^+$).

*4.3.9. [Ti(salenamidoPh$_2$)] (**9**)*

A toluene solution of compound **8** (1.76 g, 4.15 mmol) and triethylamine (3.5 cm^3, 25 mmol) was treated dropwise with $TiCl_4$ (1.0 M toluene, 4.15 cm^3, 4.15 mmol). After stirring for 12 h, an orange solution was filtered from the precipitated $[NEt_3H]Cl$, and after concentration and addition of hexane afforded compound **9** as a brown crystalline solid (1.8 g, 90%). FAB$^+$ MS: m/z 468 (50%, $[\mathbf{9}]^+$).

*4.3.10. [Ti(salenaPh$_2$)O] (**10**)*

An orange toluene solution of compound **9** (1.0 g, 2.14 mmol) was filtered in air and rapidly formed a pale yellow precipitate. After 0.5 h the precipitate was filtered and washed with dry hexane to afford compound **10** (1.8 g, 93%). Compound **10** could be crystallised from CH_2Cl_2–Et_2O as an analytically pure microcrystalline solid. FAB$^+$ MS: m/z 955 (100%, $[\mathbf{10}_2 - O]^+$).

5. Supplementary data

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC, No. 127639. Copies of this information can be obtained free of charge from The Director, CCDC, 12, Union Road, Cambridge CB2 1EZ (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

Mono- and polynuclear neutral complexes have been obtained by direct electrochemical reaction of metal anodes with the potentially heptadentate and tetracompartmental ligand *N,N′*-bis(3-hydroxysalicylidene)-1,3-diamino-2-propanol (H_5L). Physicochemical data suggest that the ligand behaves as a di- or tetra-anion in mono- and polynuclear complexes, respectively. Metal ions are held together by μ-phenoxo oxygen bridges in polynuclear complexes. Nickel and copper environments are distorted to tetrahedral and square-planar, respectively. Zinc and cadmium could be hexa-coordinated in the mononuclear complexes. Finally, iron and cobalt ions seem to be in pseudo-octahedral fields. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Electrochemical synthesis; Mononuclear complexes; Phenoxo bridges; Polyhydroxyl ligands; Polynuclear complexes; Schiff base ligands

1. Introduction

Attempts to obtain homodinuclear nickel and copper(II) complexes from *N,N′*-bis(3-hydroxysalicylidene)-1,3-diamino-2,2-dimethylpropane, following an accepted procedure for this type of ligand, were unsuccessful [1]. Usually, di- and polynuclear complexes are prepared by refluxing the appropriate metal(II) acetate and LiOH in methanol with the previously prepared mononuclear complex. However, a homodinuclear iron(III) complex containing this ligand has been prepared using template synthesis [2].

Recently, we have synthesised and structurally characterised $Cu_3(SB)(H_2SB)\cdot 2H_2O$ [3] and $Zn_8(SB)_4(H_2O)_3\cdot 3CH_3CN$ [4], which contain the symmetrical hexadentate Schiff base *N,N′*-bis(3-hydroxysalicylidene)-1,4-diaminobutane. A notable feature of this ligand, that we found previously, is that it shows a high ability to hold together metal ions by μ-phenoxo oxygen bridges. In fact, it can simultaneously coordinate up to five metal centres in different ways, resulting in complex structures. An additional interest in the study of these systems is that the bis-helical [4+4+4] compound $Cu_3(SB)(H_2SB)\cdot 2H_2O$ presents some intermetallic distances, and a metal centre triangular array, similar to those observed in some copper proteins [3,5,6].

Here we describe the direct electrochemical synthesis and structural characterisation of mono- and polynuclear Fe, Co, Ni, Cu, Zn and Cd(II) complexes with the symmetrical and potentially tetracompartmental Schiff base ligand *N,N′*-bis(3-hydroxysalicylidene)-1,3-diamino-2-propanol (H_5L).

2. Experimental

2.1. Materials

Iron, cobalt, nickel, copper, zinc and cadmium were used as sheets 0.5 mm thick. 2,3-Dihydroxybenzaldehyde and 1,3-diamino-2-propanol were commercial products (Aldrich) and were used without further purification, as were all solvents. The Schiff base ligand was prepared by condensation of the aldehyde and the diamine, in 2:1 molar ratio, and refluxing in chloroform for 3 h.

[a] The amount of metal was calculated in accordance with the quantitative yield with respect to the amount of ligand in the processes: $2M_{(s)} + H_5L_{(MeCN)} \rightarrow [M_2(HL)(H_2O)_x]_n + 2H_{2(g)}$ and $M_{(s)} + H_5L_{(MeCN)} \rightarrow M(H_3L)(H_2O)_x + H_{2(g)}$.
[b] Voltage to produce a current of 10 mA.

2.2. Complexes synthesis

The electrochemical method [7] has been widely employed by us [3,4,8–11] in the synthesis of mono- and polynuclear complexes. The cell was a 100 cm^3 tall form beaker fitted with a rubber bung through which the electrical leads entered. The metal anode, which had been previously weighed, was suspended from a platinum wire; a second platinum wire was the cathode. H_5L, 0.1–0.2 g, was dissolved with heat in about 80 ml of acetonitrile. Then, a small amount of tetramethylammonium perchlorate (about 10 mg) was added as supporting electrolyte. (Caution: although no problem has been encountered in this work, all perchlorate compounds are potentially explosive, and should be handled in small quantities and with great care.) Direct current was obtained from a purpose-built DC power supply. Applied voltages of between 8.5 and 27.7 V allowed sufficient current flow to obtain the solution of the required mass of metal anodes (see Table 1). The electrolysis times were calculated with respect to the amount of ligand and in accordance with the following reactions: $M_{(s)} + H_5L \rightarrow M(H_3L)(H_2O)_x + H_{2(g)}$ and $2M_{(s)} + H_5L \rightarrow [M_2(HL)(H_2O)_x]_n + 2H_{2(g)}$. Metal solved is calculated after re-weighing the anode. The experimental conditions for the synthesis of complexes are set out in Table 1. In all cases, hydrogen was evolved at the cathode. Cells can be summarised as: $M_{(+)}|MeCN + H_5L|Pt_{(-)}$.

Solid products were readily isolated from the electrolysis solution by filtration. The insoluble products obtained were washed with acetonitrile and diethyl ether to remove any excess ligand and vacuum dried.

The amount of metal solved was evaluated in order to postulate an empirical formula for the complexes and the processes involved in their synthesis. The calculated E_f value is useful for the latter. Electrodes were cleaned with a dilute HCl solution.

2.3. Physicochemical measurements

Elemental analyses of C, H, N and O were carried out on a Fisons Instruments EA 1108 CHNS-O. The empirical formulae deduced from these results are listed in Table 2.

A Varian E-109 spectrometer together with an ITC503 Oxford cryogenic system were used to perform electron paramagnetic resonance (EPR) measurements at 9.3 GHz (X band). The spectrometer is equipped with a rectangular resonant cavity and 100 kHz field modulation. A HP5352B frequency counter was used to measure the microwave frequency. A powdery sample of $[Cu_2(HL)(H_2O)]_n$ was measured at 4.0 K. The EPR spectrum was acquired and digitised by a microcomputer equipped with a standard data acquisition card with an analogue to digital converter. Magnetic susceptibilities were measured using a SQUID magnetometer. Diamagnetic corrections were made using Pascal's constants.

^1H NMR spectra were recorded on a Bruker 300 AC spectrometer. The positive ion electrospray mass spectra up to 1000 *m/z* were registered on an LC/MSD HP1100 spectrom-

[a] Data are expressed in percentages. Calculated values are in parentheses.

eter at 190 V with acetonitrile as solvent. IR spectra were recorded as KBr pellets on a FT-IR Mattson Instruments 2020 spectrophotometer. Diffuse reflectance spectra were recorded on a Shimadzu UV-3103 PC spectrophotometer. Electronic spectra in solution were registered on a HP 8452 A diode array spectrophotometer. Melting points were measured on a Gallenkamp apparatus.

The water content and decomposition temperature were evaluated using a PL differential scanning calorimeter. Tests were performed in air. Aluminium was used as reference material. The temperature programme used was a gradient from 30 to 600°C for 1 h.

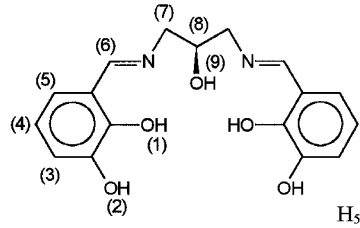
3. Results and discussion

As mentioned in Section 1, a N_2O_2 coordinated mononuclear iron complex and a homodinuclear iron(III) compound with *N*,*N*′-bis(3-hydroxysalicylidene)-1,3-diamino-2,2-dimethylpropane using N_2O_2 and O_4 donor sets have been obtained. However, when the metal ion was nickel(II) or copper(II), homodinuclear complexes could not be prepared [1].

We have found that the anodic oxidation of iron, cobalt, nickel, copper, zinc and cadmium in the presence of H_5L is a simple and efficient route to obtain homopolynuclear complexes. The variation in the amount of metal solved, which is controlled by means of the reaction time and voltage, leads to mono- or polynuclear complexes. Only in the case of copper do these conditions seem not to be critical, at least for the times and voltages tested. Thus, even when mild reaction conditions are used, such as low voltage and short electrolysis time, the electrochemical method yields only the polynuclear copper compound. Complexes have been studied by elemental analysis (Table 2), IR and mass spectrometry and, in appropriate cases, by ^{1}H NMR and UV–Vis spectroscopy, thermal analysis, magnetism or EPR. The data allow identification of the coordination site and the geometry of the molecule.

All the powdery solids isolated are light- and air-stable, but their behaviour in solution appears to be different. Complexes gradually lose Schiff base ligand to yield new compounds in which water (in a higher ratio than for original complexes) and/or hydroxo groups are present. As an example, a mixture of compounds can be obtained from water or ethanol solutions of $Zn(H_3L)(H_2O)_2$. The elemental analyses of successive isolated mixtures show a significant and gradual decrease of the C, H and N percentage values, and IR spectroscopy shows an increase of the ν(OH) intensity at about 3400 cm^{-1}, as well as the presence of two new bands. One band, at about 1060 cm^{-1}, is attributed to the Zn–O–H bending mode, and the other, near 470 cm^{-1}, is probably due to ν(Zn–O).

Finally, we have found that cadmium oxidation (for 3960 s at 17 V and 5 mA) in the presence of a dimethylsulfoxide (DMSO) solution containing $Zn(H_3L)(H_2O)_2$ yields $[Cd_2(HL)(H_2O)_2]_n$, similar to that prepared by direct electrochemical synthesis. [Found: C, 34.0; H, 2.6; N, 4.5. Calc. for $C_{17}H_{20}Cd_2N_2O_7$: C, 34.8; H, 3.1; N, 4.8%. ν_{max} (cm^{-1}): 3415 (OH), 1626 (CN), 1458 and 1261 (CO)]. This behaviour seems to correspond to a transmetalation process [12,13].



3.1. Efficiency

In keeping with previous practice, we have measured the electrochemical efficiency, which is defined as the quantity of metal dissolved per faraday of charge. E_f values are listed in Table 1. The values close to 0.5 mol F^{-1} are in keeping with a one-step mechanism for the redox reaction at the anode. The E_f value for $[Cu_2(HL)(H_2O)]_n$ (1.0 mol F^{-1}) implies a reaction to form a Cu(I) complex at the anode followed by an oxidative addition reaction to give the Cu(II) complex. Such oxidation steps have been previously observed for other copper complexes [14].

3.2. ^{1}H NMR spectroscopy

^{1}H NMR spectra of H_5L and diamagnetic mononuclear complexes were recorded in DMSO-d_6. Data are listed in

Table 3
^{1}H NMR data (in ppm) for diamagnetic compounds using DMSO-d_6 as solvent

H_5L

Compound	2H(1)	2H(2)	2H(6)	2H(5)	2H(3)	2H(4)	1H(9)	1H(8)	4H(7)
H_5L	13.69 b	8.89 b	8.48 s	6.86 d	6.83 d	6.63 t	5.35 b	4.00 b	3.80 d, 3.60 d

$Cd(H_3L)(H_2O)_2$			8.13 s	6.62 d	6.60 d	6.27 t		3.85	3.85, 3.58

Table 3. The very low solubility of polynuclear compounds prevents their study. Assignment of signals is according to our experience with similar Schiff bases [15] and the literature [2,16]. The symmetry of the ligand makes its spectrum very simple. For the free ligand, all O*H* protons are detectable as three broad signals. The presence of the hydroxyl group in the aliphatic chain causes a split of the signal attributed to H(7) protons. The aromatic proton in the *ortho* position with respect to the iminic group is observed downfield (6.86 ppm), very near to the proton sited in close proximity to the outer phenolic OH. The remaining aromatic proton shows a signal at higher field (6.63 ppm).

For $Zn(H_3L)(H_2O)_2$, hydroxylic and outer phenolic oxygen atoms remain protonated and are apparently not coordinated, as reported for several other compounds [16–19]. The absence of the inner phenolic protons and the strong shift of the outer O*H* signal confirm the complexation of zinc ion in the inner N_2O_2 compartment of the ligand. The low solubility of $Cd(H_3L)(H_2O)_2$ makes its study difficult. Thus, the fact that H(2) and H(9) were not observed is probably due to the low intensity of these broad signals. An upfield shift with respect to the free ligand is observed for all the proton signals of these metal complexes, excluding those assigned as H(7) which are not significant.

In contrast with our observations [20] and those described for similar Schiff base complexes when the metal was nickel [2], the complexation of zinc or cadmium into the inner N_2O_2 compartment produces a marked change in the relative positions of H(2) and H(6) signals. This is caused by the weak upfield shift undergone by H(6), whereas for nickel complexes both H(2) and H(6) signals suffer an equivalent shift. However, the resulting difference between H(2) and H(6) signals after coordination is not very different from that found before. The correct assignment of the H(2) signal was confirmed by the observation of its absence after a small addition of D_2O. The presence of the metal centre also produces a slight and opposite shift of both H(7) and H(8), which results in a unique signal at 3.89 ppm.

The conjugation of C=N bonds with the aromatic rings limits the geometric variety of the mononuclear complexes containing salpn-type ligands. Thus, it is very common to find square-planar or octahedral coordination geometries with the Schiff base donor atoms occupying equatorial positions [15–17]. In analogy with those described for Mn(III) complexes containing 2-OH-salpn [17] and according to the empirical formulae of these complexes, we propose an octahedral geometry for $Zn(H_3L)(H_2O)_2$ and $Cd(H_3L)(H_2O)_2$ with water molecules in axial positions.

3.3. ES mass spectroscopy

Positive ion electrospray (ES) mass spectra for mononuclear complexes show peaks related to fragments of the type $M(H_3L)$ between 384 and 441 *m/z*. This indicates the ligand coordination to the metal centre. Some important mass peaks are given in Table 4. The low solubility of the polynuclear iron and cadmium complexes makes their study difficult.

The observation of peaks related to fragments of the type $M_2(HL)$ at about 450 *m/z* for polynuclear complexes shows that each ligand unit coordinates at least two metal centres. Although this could be indicative of both metal ions occupying the inner N_2O_2 and the outer O_4 compartments, the presence of peaks corresponding to heavier fragments such as $M_3(HL)_2$ at about 840 *m/z* and $M_4(HL)_2$ near to 900 *m/z*, for Co(II), Ni(II), Cu(II) and Zn(II) complexes, indicates that metal ions could be coordinated to two different ligand units, as observed for $Cu_3(SB)(H_2SB)\cdot 2H_2O$ [3] and $Zn_8(SB)_4(H_2O)_3\cdot 3CH_3CN$ [4]. These facts seem to be in agreement with a polymeric behaviour of the complexes rather than with a monomeric one.

The low abundance for the peaks considered is very probably due to the low solubility and high fragmentation of the

Table 4
Some important mass peaks, colour, UV–Vis and magnetic moment (at room temperature) for the studied compounds

Compound	Mass peaks (m/z)	Colour	λ (nm)	μ_B

complexes. Thus, two weak peaks, one at 331 *m/z* for H_5L, and another attributable to $M(H_3L)$ fragments, are detected in most of the spectra.

3.4. Differential scanning calorimetry (DSC) results

Coordinated and/or lattice water is present in all complexes. Thermal analyses of iron, copper and cadmium compounds show a water loss (endothermic peak) under an air flux in the range 77–85°C. Some of the DSC data are given in Table 5. DSC thermograms exhibit one or two endothermic peaks in the range 230–410°C. These peaks are usually associated with some decompositions, reductions or phase transitions. All compounds decompose without melting between 388 and 434°C.

DSC thermograms for $Cd(H_3L)(H_2O)_2$ and $[Cd_2(HL)(H_2O)_2]_n$ are shown in Fig. 1. Their thermal behaviour is quite different, as expected for two compounds of different nature. Exothermic processes in the 210–350°C range usually correspond to chemical reactions such as polymerisations that seem to occur for $Cd(H_3L)(H_2O)_2$. Decomposition of mono- and polynuclear cadmium complexes occurs at about 434°C; however, for the polynuclear complex, this is followed by a transformation between 450 and 550°C. Endothermic processes seem to be more important in $[Cd_2(HL)(H_2O)_2]_n$ than in $Cd(H_3L)(H_2O)_2$.

$[Cu_2(HL)(H_2O)]_n$ suffers endothermic decomposition at about 388°C, leading to a final compound that is stable up to 600°C. The decomposition product was characterised as CuO, in agreement with X-ray powder diffraction analyses. This decomposition temperature is significantly lower than those reported [21] for $[CuLa(L^1)(NO_3)]\cdot H_2O$ (550°C) and $[CuBa(L^1)]\cdot 2H_2O$ (480°C), leading to $CuLa_2O_4 + CuO$ and $CuBa_2O_4$, respectively [H_4L^1: *N,N′*-bis(3-hydroxysalicylidene)-1,2-diaminoethane].

3.5. Electron spectroscopy, magnetic susceptibility and EPR results

The free ligand spectrum in methanol solution shows two strong bands at about 225 and 270 nm, two shoulders at about 290 and 330 nm and, finally, another band of medium intensity at about 425 nm. All complexes display intense absorption bands in the range 225–425 nm that are clearly charge transfer bands in origin. Therefore, the electronic spectra of all the complexes, in the solid state or in solution, are characterised by low-intensity absorption bands or shoulders that can be associated with d–d transitions. Data are listed in Table 4.

Solid state susceptibility measurement for $[Cu_2(HL)(H_2O)]_n$ showed a magnetic moment (per complex) of 2.41 μ_B at 270 K. The diffuse reflectance spectrum of this complex shows a clear shoulder at about 620 nm (Fig. 2) which was also observed in methanol, ethanol, dimethylformamide (DMF) and DMSO solutions. This suggests that, even in donor solvents, the copper environments are similar in both

Table 5

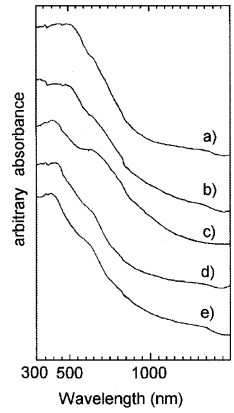

Fig. 2. Diffuse reflectance spectra for (a) $[Co_2(HL)(H_2O)_2]_n$ (b) $Co(H_3L)(H_2O)_3$, (c) $[Cu_2(HL)(H_2O)]_n$ (d) $Ni(H_3L)(H_2O)$ and (e) $[Ni_2(HL)(H_2O)_2]_n$.

phases. Although the observed energy is somewhat lower than those generally quoted for copper(II) in a square-planar field, similar absorption bands have been assigned to this geometry [17,22]. We ascribe this discrepancy to a tetrahedral distortion.

The EPR spectrum of $[Cu_2(HL)(H_2O)]_n$ at 4 K is characteristic of a magnetically non-dilute Cu(II) compound with like metal environments. The usual line around the $\mathbf{g} = 2$ region is observed in Fig. 3. This line shows rhombic or axial symmetry characteristics without hyperfine coupling. This could be explained by an exchange coupling between copper ions. These local symmetries are in good agreement with the postulated molecular structure for $[Cu_2(HL)(H_2O)]_n$.

The diffuse reflectance spectra (Fig. 2) of $Ni(H_3L)(H_2O)$ and $[Ni_2(HL)(H_2O)_2]_n$ show a shoulder and a low-intensity

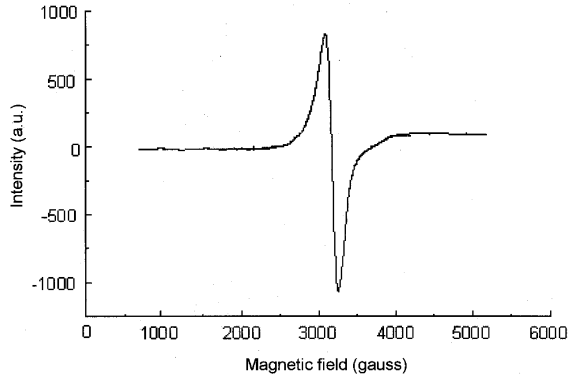

Fig. 3. X-band EPR spectrum of $[Cu_2(HL)(H_2O)]_n$ at 4.0 K.

band at about 630 and 1250 nm, respectively, that are characteristic of nickel(II) ions in tetrahedral coordination environments. The lower energy band can be attributed to the $^3A_2 \leftarrow {}^3T_1(F)$ and the higher one to $^3T_1(P) \leftarrow {}^3T_1(F)$ transitions. The low solubility of these nickel complexes in ethanol solutions prevents the detection of the expected shoulders. The $\mu_{spin\text{-}only}$ calculated value for Ni(II) is 2.8 μ_B and thus octahedral complexes, with not a very significant orbital contribution, lie in the range 2.9–3.3 μ_B. However, magnetic moments of tetrahedral compounds, with a temperature-dependent orbital contribution, are found to lie in the range 3.2–4.1 μ_B. Electron delocalisation on to the ligands and distortions from ideal tetrahedral symmetry reduce the μ value towards $\mu_{spin\text{-}only}$. The room temperature magnetic moments observed for $Ni(H_3L)(H_2O)$ and $[Ni_2(HL)(H_2O)_2]_n$ (3.8 and 3.6 μ_B, respectively) are in keeping with a tetrahedral geometry. This is in contrast with $Ni(H_2L^2)$, which is characterised as square-planar in the literature [1] ($H_4L^2 = N,N'$-bis(3-hydroxysalicylidene)-1,2-diaminomethylpropane).

UV–Vis data for $Co(H_3L)(H_2O)_3$ in solid state and solution suggest a high-spin distorted octahedral Co(II) environment. The spectra show two shoulders at about 490 and 620 nm, and a low-intensity band at about 1300 nm (only in solid state; Fig. 2) which is attributed to $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)(\nu_3)$, $^4A_{2g} \leftarrow {}^4T_{1g}(F)(\nu_2)$ and $^4T_{2g}(P) \leftarrow {}^4T_{1g}(F)(\nu_1)$ transitions, respectively. The low solubility of $[Co_2(HL)(H_2O)_2]_n$ prevents its study in ethanol and DMF solution. Its solid state spectrum is similar to that obtained for the mononuclear cobalt complex and, consequently, a pseudo-octahedral geometry can also be postulated. However, it must be noted that this study does not exclude other possibilities such as five coordinations and various non-regular structures. The room temperature magnetic moments observed for $Co(H_3L)(H_2O)_3$ and $[Co_2(HL)(H_2O)_2]_n$, with values of 5.0 and 6.6 μ_B (per complex), respectively, are in keeping with the postulated geometry.

The diffuse reflectance studies for $Fe(H_3L)(H_2O)_2$ and $[Fe_2(HL)(H_2O)_5]_n$ are almost identical and suggest that these complexes could have the same geometry. They display a multicomponent band with a maximum absorption between 250 and 525 nm but no bands are detected about 1000 (high spin octahedral field) or 2500 nm (tetrahedral field). Magnetic moments of tetrahedral iron(II) complexes are reported to lie in the range 5.0–5.4 μ_B, but these high values are difficult to explain. High-spin distorted octahedral iron(II) complexes mostly show magnetic moments about 5.2 μ_B in magnetically dilute compounds. Thus, the value of 5.0 μ_B calculated for $Fe(H_3L)(H_2O)_2$ is not far from that. Consequently, the Fe(II) environment could be pseudo-octahedral in this mononuclear complex. This is supported by the described tendency of the ligand to give square-planar or octahedral complexes [15–17].

3.6. Infrared spectroscopy

The most characteristic IR bands of the complexes in which ligands are coordinated via both nitrogen and oxygen atoms are listed in Table 6. They have been assigned following the literature [2]. A comparison of the spectra of free ligand and complexes shows a remarkable similarity in the range 1650–1200 cm^{-1}. ν(C=N), ν(C=O) and ν(C–O) are present as three very strong bands in the ranges 1630–1650, 1450–1460 and 1235–1260 cm^{-1}, respectively.

ν(C–O) is significantly affected by the coordination to the metal ions. Thus, an up-frequency shift between 10 and 20 cm^{-1} was detected. The same tendency was observed for ν(C=O), but, in this case, the shift was between 5 and 10 cm^{-1}. ν(C=N) was also shifted (± 10 cm^{-1}) because of the complexation. The split broad band at about 3250 and 3360 cm^{-1} is due to disappearance of the phenol OH groups of the ligand, and a very broad band at about 3400 cm^{-1} is now present in all complexes. The presence of this broad band is associated with coordinated and/or solvated water molecules, but unfortunately interferes with the observation of uncoordinated hydroxyl groups [16] in mono- and polynuclear complexes. Finally, no significant differences are observed in the spectra of polynuclear complexes compared with those of the corresponding mononuclear compounds.

Table 6
Some significant IR bands (cm^{-1}) for the compounds (as KBr pellets)

Compounds	ν(O–H)	ν(C=N)	ν(C=O)	ν(C–O)
H_5L	3360 s, 3250 s	1640 vs	1460 vs	1235 vs

4. Conclusions

We have demonstrated the versatility of the potentially heptadentate ligand *N,N′*-bis(3-hydroxysalicylidene)-1,3-diamino-2-propanol. The presence of four phenolic groups seems to result in high nuclearity. It could behave simply as a mononucleating N_2O_2 donor or could even be simultaneously coordinated up to four metal centres in $O_2+ONO+ONO+O_2$ compartments. All the oxygen atoms could act as bridges between the metal centres. However, we have not detected any evidence of coordination through the hydroxyl group of the methylene chain, which remains protonated in these neutral complexes.

Therefore, the metal environment in mononuclear complexes can be described as N_2O_2 coordinated in the inner compartment, whereas, for polynuclear complexes, at least two possible coordinating behaviours are in accordance with the $[M_2(L)(H_2O)_x]_n$ formula, the chemical nature of the metal centres and the data from their mass spectra. A schematic representation of these is shown in Fig. 4.

A first alternative (Fig. 4a) could be that each ligand coordinates a metal ion in its inner N_2O_2 compartment, and it also could coordinate two more metal centres through both phenolic oxygen atoms of each aldehyde residue. These would be in O_4 environments, where *cis* sites would be occupied by outer phenolic oxygen atoms and μ-phenoxo bridges for tetra-coordinated metal centres. This tricompartmental behaviour $(O_2+N_2O_2+O_2)$ has been previously observed for both $Cu_3(SB)(H_2SB)\cdot 2H_2O$ [3] and $Zn_8(SB)_4(H_2O)_3\cdot 3CH_3CN$ [4].

A second possibility (Fig. 4b) would consist of each ligand unit acting as tetranucleating by coordination of two metal ions to both inner *NO* donor sets, as we have previously reported [3,11]. Another two metal ions could be coordinated through the outer *O* atoms and μ-phenoxo bridges. Coordination environments would be completed by two neighbouring ligand units, resulting in NO_3 chromophores for tetra-coordinated metal centres. This could occur if a ligand behaved as H_2SB in $Cu_3(SB)(H_2SB)\cdot 2H_2O$, but being totally deprotonated $(O_2+ON+NO+O_2)$.

Physicochemical data of the studied complexes suggest that nickel and copper environments are pseudo-tetrahedral and square-planar, respectively. Additionally, iron and cobalt ions seem to be in pseudo-octahedral fields, due to the presence of coordinated water molecules. Finally, zinc and cadmium could be also hexa-coordinated in mononuclear complexes.

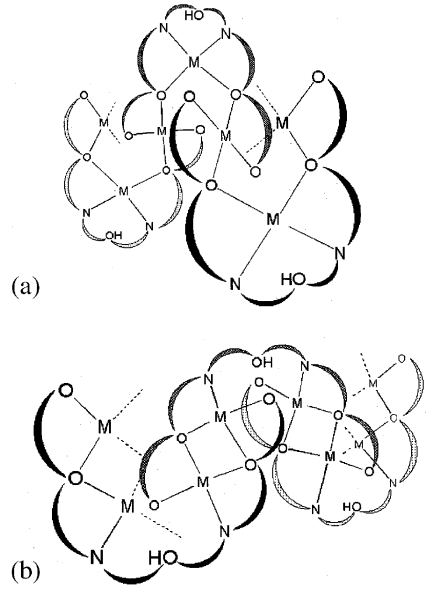

Fig. 4. Schematic representation of two possible polynucleating ligand behaviours using their $O_2+N_2O_2+O_2$ (a) or $O_2+ON+NO+O_2$ (b) donor sets.

POLYHEDRON

A multinuclear NMR study of the complexation of W(VI) with *meso*-2,3-dimercaptosuccinic acid (DMSA)

M. Madalena Caldeira, M. Luísa Ramos, Gilberto G. Pereira, Victor M.S. Gil *

Abstract

Meso-2,3-dimercaptosuccinic acid (DMSA), which is used as an antidote for heavy metal poisoning and in complexes of ^{99m}Tc for diagnostic purposes, forms several complexes with tungsten(VI) in aqueous solutions, as found by ^{1}H, ^{13}C, ^{17}O and ^{183}W NMR spectroscopy. In the pH range ~4–7, there are four complexes in which the acid acts as a bidentate ligand through one carboxyl group and the adjacent sulfhydryl group (a dominant 2:2 species and three 1:2 metal–ligand isomers are proposed) and 2:1 complexes in which the ligand is twisted in order to use the four binding groups. It is proposed that in both the 2:2 and 2:1 cases the S atoms bridge the two W atoms. At lower pH, the acid is again predominantly a tetradentate ligand in m:n associations with the metal (m > n). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: *meso*-2,3-dimercaptosuccinic acid; Multinuclear NMR; Tunsgsten

1. Introduction

2,3-Dimercaptosuccinic acid (DMSA; HO_2C-CHSH-CHSH-CO_2H), in both the *meso* form and as the racemic mixture, has been used in pharmacology for more than four decades, mainly as an antidote for heavy metal poisoning, particularly lead(II), in humans [1–5]; more recently, DMSA has been used as the complexing agent in the administration of technetium (^{99m}Tc) for diagnostic purposes [6–9]. Several research groups have compared the antidotal actions of *meso*- and *rac*-DMSA and studied the biotransformation of the acid, in addition to more chemically oriented studies [10–12]. In particular, the ionization and the complexation equilibria have been discussed in terms of the conformations of the acids [12]. One of the advantages of the racemic mixture is the greater solubility of the complexes in water. One disadvantage is that it leads to a greater loss of endogenous zinc(II) than the *meso* form, because of differences in the formation constants of the complexes [13].

The complexation of DMSA with metal oxo ions has been reported in two cases: (1) oxovanadium(IV) complexes [14] in relation to the importance of V–S coordination in various biomolecules; and (2) arsenate and arsenite complexes in connection with the biotransformation of arsenic and the transfer of arsenite from glutathione to dithiols [15]. In the presence of As(V), the acid is readily oxidized and the formation of a 2:3 (metal–ligand) complex with As(III) was proposed involving only the SH groups as donors [15]. With V(IV), the carboxyl groups are also involved in chelation [14]. As for As(V), the oxo ions of vanadium(V) and molybdenum(VI) are strong oxidizing agents of DMSA, but the same does not apply to tungstate. Comparison with the complexes of W(VI) with tartaric acid [16,17] and with thiolactic [18] and thiomalic acids [19] leads us to expect the formation of stable complexes of DMSA with tungsten(VI). Tungsten is the active centre of some enzymes. It was only recently found that this metal can have a positive biological role, contrary to the traditional view of W as an antagonist of the biological functions of Mo (for a review, see [20]). In this paper we report the complexation of W(VI) with *meso*-2,3-dimercaptosuccinic acid in aqueous solution, at various pH and concentration conditions. Multinuclear magnetic resonance spectroscopy was used in one and two dimensions.

2. Experimental

Commercially available dihydrate sodium tungstate and *meso*-DMSA were used. Because of the low solubility of the acid, the metal–ligand mixtures were prepared by adding the

PII S0277-5387(99)00342-3

appropriate amount of the solid acid to the tungstate solutions. D_2O solutions were used throughout. The concentration range for the metal and the ligand was 0.025–2.0 M and 0.10–1.0 M, respectively. The pH was adjusted by adding DCl and NaOD in D_2O. Drastic changes of concentration were avoided in order to reduce local disturbances of equilibria that may be slow to disappear. The pH* values quoted (from 2.5 to 9) are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers.

The NMR spectra were obtained on a Varian UNITY-500 spectrometer. The residual water signal was reduced using the Presat sequence.

3. Results and discussion

The ^{1}H NMR spectrum due to the CH groups of the acid in aqueous solution is a singlet, but the doublet corresponding to the ^{13}C–H satellites shows an HH vicinal coupling constant which varies from 10.3 to 11.4 Hz on increasing pH* from 2.1 to 7.5. This proves that, irrespective of ionization of the carboxylic groups, the *meso*-2,3-DMSA exists preferentially in the conformation:

In this conformation, the repulsion between the bulky sulfhydryl groups is minimized. Essentially the same result is found for methanol–water mixtures as a solvent of lower dielectric constant.

In the presence of sodium tungstate, and depending on the molar ratio and on pH, a large number of signals (at higher frequency relative to free ligand) is observed corresponding to bound ligand. Except at low pH and in the presence of excess of metal ion, free ligand is also present, in slow exchange (in the NMR time scale) with the bound ligands. Apart from one set of broad signals close to the residual water (DHO) signal, each bound ligand gives rise to two comparatively sharp doublets of equal intensity (AX spectrum) instead of singlets. The vicinal HH coupling constant is now directly obtained. A set (six AX spectra) dominant at moderate pH ($\sim$4–7) and for metal–ligand molar ratios equal or below to 1 (group A complexes) shows couplings between 7.5 and 9.2 Hz and proton shifts that vary from 0.3 to 0.6 ppm for one of the doublets and from 0.9 to 1.2 ppm for the other, as illustrated in Fig. 1 and tabulated in Table 1. In the same pH range but for metal–ligand molar ratios greater than 1, a set of four to six broad singlets are recorded at 1.2–1.4 ppm to high frequency of free ligand (group B complexes).

At low pH ($\sim$3) and for metal–ligand ratios greater than 1, a set of five well-resolved AX spectra of about the same intensity are recorded, showing splittings that lie between 3.0 and 3.8 Hz and high-frequency shifts relative to free ligand

[a] δ values are in ppm relative to Me_4Si, using *tert*-butyl alcohol ($\delta_H = 1.2$) as internal reference; *J* values are in Hz.

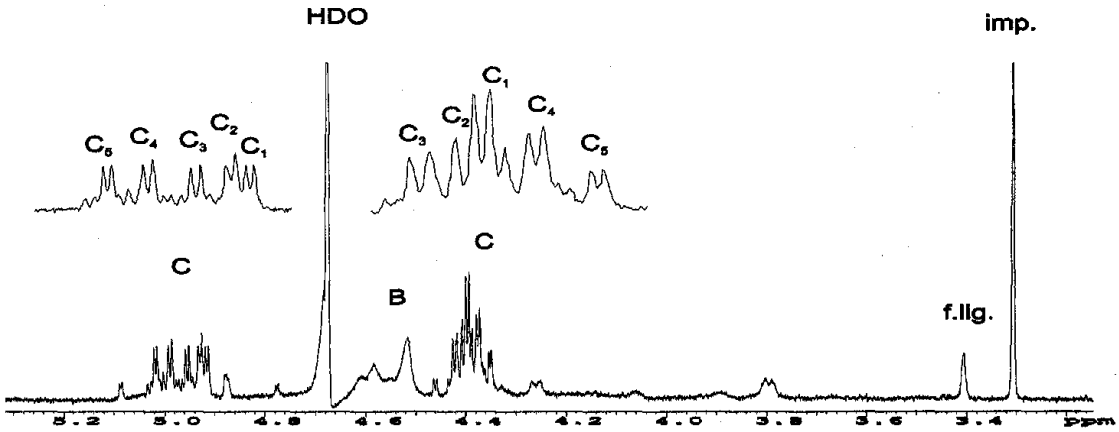

Fig. 2. 500 MHz ^{1}H NMR spectrum of a 0.40 M:0.10 M solution of sodium tungstate and *meso*-DMSA in D_2O, pH* 2.9, 298 K. f. lig. denotes free ligand; imp. denotes ligand impurity.

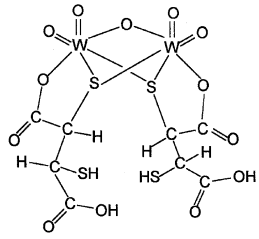
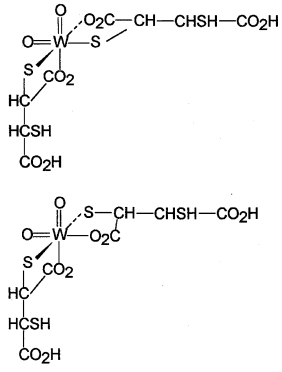
of about 1.0 and 1.6 ppm (group C complexes) (Fig. 2 and Table 1). Some weaker signals are also detected in the latter case. The assignment of each pair of doublets in each AX spectrum was made on the basis of the coupling constants and, in the case of doubt, by proton decoupling and COSY spectra.



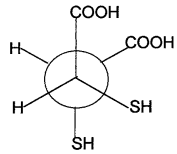
The number of complexes is likely to be smaller than the number of spectra of bound ligand, as magnetic non-equivalence of ligands may occur in complexes having more than one ligand molecule. For example, the AX spectra a_3 and a_3' in Fig. 1 always have the same intensity irrespective of pH and concentration conditions, and the same is found for a_4 and a_4'. This suggests that each of these pairs of AX spectra arise from the same complex, probably having 1:2 (metal–ligand) stoichiometry. Accordingly, there will be four complexes in group A. When a Job's plot is constructed based on the ^{1}H NMR intensities for complexes A, at pH* 5.5, a clear maximum at 1:1 is obtained for the dominant complex, A_1, which points to an n:n stoichiometry. Due to the presence of various competing species, no other firm conclusion can be directly extracted from that plot alone, but 1:2 complexes are likely to be formed by analogy with thiolactic [18] and thiomalic acids [19] and tartaric acid [16,17].

The existence of one small high-frequency proton shift (0.3–0.6 ppm) upon complexation together with a higher one (0.9–1.2 ppm) indicate the involvement of only one sulfhydryl group in complexes A, whereas the observation of high-frequency shifts (1.0–1.6 ppm) for both CH protons in complexes B and C show that both S atoms are bound to the metal. This is corroborated by the corresponding ^{13}C shifts relative to free ligand in the same conditions. In fact, for complex A (at pH* 5.5), high-frequency complexation shifts between 4.0 and 5.0 ppm are observed for the ^{13}C bonded to the more deshielded H atom, and almost no shift for the other. For complexes B and C, the two ^{13}C(SH) complexation shifts (at pH* 2.8) lie in the range 7–8 ppm. Whenever necessary,

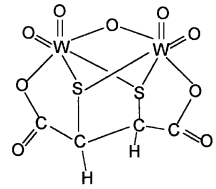


the assignment of the ^{13}C signals was made by running HETCOR 2D spectra.

Complexes A also involve only one of the carboxylate groups in bonding to the metal, as shown by a high-frequency shift on complexation (in the range 5–7 ppm) of one of the CO_2^- groups, together with a low-frequency shift of about −0.8 ppm for the other group. On the other hand, both carboxylate ^{13}C signals of complexes B and C shift between 7 and 8 ppm to high frequency, which shows that both carboxylate groups now participate in complexation.



Based on the above data, we can propose that the acid acts as a bidentate ligand in complexes A, involving one carboxylic group and the adjacent SH group, irrespective of the stoichiometry being n:n or 1:2. The conformation of DMSA is slightly changed on complexation, as indicated by HH couplings of 7.5–9.2 Hz in the complexes compared with 10–11 Hz in the free ligand. Since a 1:1 complex, involving two water molecules bound to the metal, is not expected to be particularly stable, we propose a 2:2 species with the following structure, in which the ligand molecules are magnetically equivalent:



Regarding complexes having 1:2 stoichiometry, we note that several diastereoisomers are possible, for example:

In complexes B and C, the ligand acts as tetradentate and undergoes much alteration of conformation on binding to the metal. In fact, the HH coupling constants recorded for complexes C lie between 3.0 and 3.8 Hz, showing that the conformation of bound DMSA is now close to:

The same conclusion must apply to complexes B, as the line width of each signal is about 3 Hz. In spite of this conformational change, a molecular model suggests that it is highly unlikely that a tetradentate DMSA molecule is bound to just one W atom. The same has been recently advanced in the case of complexes of DMSA with tin [21]. The formation of several polynuclear species must then occur. This is corroborated by the fact that complexes B are dominant for high metal–ligand molar ratios. One of the possible structures is

which is similar to that previously found by X-ray diffraction for a 2:1 complex of Mo(VI) with L-dithiothreitol [22].

Broad ^1H NMR signals are a result of complexes B having close proton resonances (a range of 0.2 ppm) that no longer correspond to first-order spectra.

The proposal of similar metal centres, $W_2O_5^{2+}$, for the most abundant complexes A and B (2:2 and 2:1 species, respectively), which are present in a 1.0:1.0 M W(VI)–*meso*-DMSA solution in D_2O, at pH* 7.0, is corroborated by the occurrence of ^{183}W resonances between +579 and +592 ppm with respect to an external reference of Na_2WO_4 in D_2O (pH* 9.5), besides the three signals due to uncomplexed $W_7O_{24}^{6-}$ (at +269, −92 and −179 ppm) [23,24]. Values close to +600 ppm were also recorded for the systems W(VI)–thiolactic acid and W(VI)–thiomalic acid. The ^{17}O spectra of the same solution shows the signals of $W_7O_{24}^{6-}$ (terminal and bridging O atoms) [23,24] and some new signals: a major peak at +534.5 ppm (relative to D_2O as external reference) which lies in the region of W=O resonances [25] and a smaller one at +270.8 ppm in the region of W–O–W signals [25]. This also points to the presence of a $W_2O_5^{2+}$ moiety in the 2:2 and 2:1 complexes.

For a 2.0:0.5 M solution at pH* 4.3, where complexes B dominate, we have again several ^{183}W signals between +580 and +593 ppm (besides those of $W_7O_{24}^{6-}$). An additional and sharp signal appears at −120 ppm, the resonance of the α-metatungstate ion, α-$H_2W_{12}O_{40}^{6-}$ [23]. A similar signal has been detected in solutions of tungstate and mandelic or isocitric acids and attributed to 2:2 complexes involving two oxygen bridges [17]. We prefer to attribute the above resonance to the isopolyanion expected to be present at low pH, but additional studies are necessary.

Regarding signals C, dominant for high metal–ligand molar ratios and low pH, which are the conditions for polytungstate anions to be present in significant concentrations, we again propose an m:n complexation, with m > n. The fact that there are five AX spectra in this set, all with approximately the same intensity, suggests that a major polynuclear complex C is present involving five ligands in slightly different magnetic conditions. However, further studies are needed to clarify this and other points of such a complicated

system. We therefore plan to go back to our previous work on simpler systems [18,19] and carefully run ^{17}O and ^{183}W NMR spectra.

Abstract

Complexes of $[LnCl_3L]$ (Ln = La, Nd, Sm, Eu, and L = diethylene glycol dimethyl ether, diglyme; Ln = La, Pr, and L = dimethoxyethane, DME) were prepared from the lanthanide oxides and hydrogen chloride, which was formed in situ from chlorotrimethylsilane and water. When hexamethylphosphoramide (HMPA) was added to the suspension of the prepared DME and diglyme complexes in toluene, *fac*-$[LnCl_3(HMPA)_3]$ (Ln = La, Pr, Nd, Sm, Eu, Gd) complexes, isomorphous according to the unit cell determination, were formed. The crystal structure of $[SmCl_3(HMPA)_3]$ was determined. Each samarium atom is octahedrally coordinated by three chlorine atoms and three HMPA molecules, which are distributed in a facial mode. The exchange of coordinated and free HMPA, as well as the reversible *fac–mer* isomerization of $[LaCl_3(HMPA)_3]$, was observed by variable temperature ^1H NMR spectroscopy. The associative mechanism of the exchange and isomerization was proposed. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; *Fac* isomers; Isomerization; Lanthanide chloride complexes; Octahedral complexes

1. Introduction

An important source of information regarding the reactivity of coordination and organometallic compounds are studies of fluxionality, isomerization [1] and ligand exchange [2]. Transition metal six-coordinate complexes are rather rigid [3]. On the other hand, the small crystal-field splitting and larger ionic radii of six-coordinate lanthanide complexes promise enhanced fluxionality and facile coordination sphere extension [4]. The isolation of solid state six-, seven- and eight-coordinate complex ions $[Ln(NCS)_n]^{(n-3)-}$ ($n = 6$, 7, 8) [5], six-coordinate $[LnCl_3(HMPA)_3]$ (HMPA = hexamethylphosphoramide) [6] and seven-coordinate $[LaBr_3(HMPA)_4]$ [7] suggests that little energy is required for transition among six-, seven- and eight-coordinate species. The facile dissociation and binding of ligands are important for the catalytic activity of coordination and organometallic compounds.

The growing interest in the reactivity of lanthanide compounds is stimulated by their use as versatile reagents and catalysts [8–12]. The solution dynamics of eight- and higher coordinate solvated lanthanide ions [4] and the lanthanide magnetic resonance imaging agents [13] have attracted much interest, but six-coordinate lanthanide compounds have been studied less intensively.

We report on the synthesis of new $[LnCl_3(DME)]$ (Ln = La, Pr; DME = dimethoxyethane) and $[LnCl_3$-(diglyme)] (Ln = La, Nd, Sm, Eu; diglyme = diethylene glycol dimethyl ether) complexes directly from the corresponding lanthanide oxides and chlorotrimethylsilane. Two similar synthetic routes for the preparation of lanthanide chloride complexes have been reported, the first starting from lanthanide metals and chlorotrimethylsilane [14] and the second from lanthanide oxides using tionyl chloride [15]. The $[LnCl_3(DME)]$ (Ln = La, Pr) and $[LnCl_3(diglyme)]$ (Ln = La, Nd, Sm, Eu) complexes were used in the preparation of *fac*-$[LnCl_3(HMPA)_3]$ (Ln = La, Pr, Nd, Sm, Eu, Gd) isomers. The solution dynamics of $[LaCl_3(HMPA)_3]$ are also described.

2. Experimental

2.1. Materials

All manipulations were carried out under an atmosphere of purified argon using Schlenk tubes or in a dry box. Lan-

thanide oxides (Aldrich), diglyme (Fluka), DME (Fluka), chlorotrimethylsilane (Aldrich) and HMPA (Aldrich) were used as received. Tetrahydrofuran (THF) and toluene were dried with Na–K alloy and distilled before use.

2.2. Physical measurements

The samples were ground in a Nujol mull and IR spectra were recorded on a Perkin-Elmer 1720X instrument between 400 and 4000 cm^{-1}.

The chlorine content was determined by a potentiometric titration of chlorine ions with silver nitrate. The lanthanide content was determined by gravimetric analysis. Elemental analyses were obtained using a Perkin-Elmer 2400 CHN analyser at the University of Ljubljana (Department of Organic Chemistry).

The ^{1}H, ^{31}P and ^{139}La NMR spectra were recorded on a Bruker DPX 300 spectrometer. Variable temperature spectra were recorded using the variable temperature controller of the spectrometer. Deuterated toluene was dried with potassium and distilled under reduced pressure.

2.3. Synthesis

2.3.1. [$LaCl_3$(DME)]

To 0.440 g (1.35 mmol) of La_2O_3 were added 12.91 g (143 mmol) of DME, 13.09 g (121 mmol) of $(CH_3)_3SiCl$ and 0.10 g (5.55 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 0.904 g (99.8% yield) of the complex [$LaCl_3$(DME)] was gained. Found: La, 42.0; Cl, 31.5. Calc. for [$LaCl_3$(DME)]: La, 41.4; Cl, 31.7%. IR (Nujol) (cm^{-1}): 1082 s, 1041 vs, 1019 s, 1001 s and 858 s.

2.3.2. [$LaCl_3$(diglyme)]

To 0.330 g (1.01 mmol) of La_2O_3 were added 35 ml of THF, 13.71 g (126 mmol) of $(CH_3)_3SiCl$, 0.850 g (6.3 mmol) of diglyme and 0.120 g (6.7 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 0.769 g (100% yield) of the complex [$LaCl_3$(diglyme)] was gained. Found: La, 36.5; C, 18.96; H, 3.55. Calc. for [$LaCl_3$(diglyme)]: La, 36.6; C, 18.99; H, 3.72%. IR (Nujol) (cm^{-1}): 1289 w, 1261 m, 1213 vw, 1090 vs, 1064 m, 1048 vs, 1005 m, 951 m, 873 s, 832 m, 801 m.

2.3.3. [$LaCl_3$(HMPA)$_3$]

2.3.3.1. Method A. HMPA (0.850 g, 4.74 mmol) was added to a suspension of [$LaCl_3$(DME)] (0.238 g, 0.710 mmol) in toluene (25 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$LaCl_3$(HMPA)$_3$] grew out of the solution during slow evaporation of the solvent. The crystals were filtered off and washed with pentane three times. Found: La, 17.4; C, 27.58; H, 7.00; N, 15.83. Calc. for [$LaCl_3$(HMPA)$_3$]: La, 17.7; C, 27.62; H, 6.95; N, 16.10%. IR (Nujol) (cm^{-1}): 1302 s, 1193 m, 1163 m, 1130 vs, 1067 w, 986 vs, 802 w, 752 s, 482 m. ^{1}H NMR (300 MHz, [D_8]toluene): δ 2.50, J(PH) 9Hz. ^{31}P NMR (121 MHz, [D_8]toluene): δ 26.1.

2.3.3.2. Method B. HMPA (0.700 g, 3.91 mmol) was added to a suspension of [$LaCl_3$(diglyme)] (0.338 g, 0.891 mmol) in toluene (20 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$LaCl_3$(HMPA)$_3$] grew out of the solution during slow evaporation of the solvent. Found: La, 17.4; C, 27.41; H, 7.00; N, 15.86. Calc. for [$LaCl_3$(HMPA)$_3$]: La, 17.7; C, 27.62; H, 6.95; N, 16.10%. IR (Nujol) (cm^{-1}): 1303 s, 1194 m, 1163 m, 1130 vs, 1067 w, 988 vs, 753 s, 482 m.

2.3.4. [$PrCl_3$(DME)]

To 0.495 g (0.48 mmol) of Pr_6O_{11} were added 13.6 g (151 mmol) of DME, 13.6 g (125 mmol) of $(CH_3)_3SiCl$ and 0.10 g (5.55 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 0.950 g (96.8% yield) of the dark brown complex [$PrCl_3$(DME)] was gained. Found: Cl, 31.0. Calc. for [$PrCl_3$(DME)]: Cl, 31.5%. IR (Nujol) (cm^{-1}): 1082 s, 1039 vs, 1019 s, 1001 s, 859 s.

2.3.5. [$PrCl_3$(HMPA)$_3$]

HMPA (1.06 g, 5.92 mmol) was added to a suspension of [$PrCl_3$(DME)] (0.289 g, 0.86 mmol) in toluene (25 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$PrCl_3$(HMPA)$_3$] grew out of the solution during slow evaporation of the solvent. Found: C, 27.51; H, 6.89; N, 15.68. Calc. for [$PrCl_3$(HMPA)$_3$]: C, 27.55; H, 6.93; N, 16.06%. IR (Nujol) (cm^{-1}): 1302 s, 1261 w, 1195 m, 1165 m, 1131 vs, 1068 w, 986 vs, 802 w, 759 s, 481 m.

2.3.6. [$NdCl_3$(diglyme)]

To 0.340 g (1.01 mmol) of Nd_2O_3 were added 20 ml of THF, 12.86 g (118 mmol) of $(CH_3)_3SiCl$, 0.890 g (6.6 mmol) of diglyme and 0.120 g (6.7 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 0.777 g (100% yield) of the pale violet complex [$NdCl_3$(diglyme)] was gained. Found: Nd, 37.6; C, 18.90; H, 3.75. Calc. for [$NdCl_3$(diglyme)]: Nd, 37.5; C, 18.73; H, 3.67%. IR (Nujol) (cm^{-1}): 1290 w, 1260 s, 1213 w, 1091vs, 1048 vs, 1006 s, 953 m, 875 s, 834 m, 803 m.

2.3.7. [$NdCl_3$(HMPA)$_3$]

HMPA (0.640 g, 3.75 mmol) was added to a suspension of [$NdCl_3$(diglyme)] (0.338 g, 0.878 mmol) in toluene (15 ml). A clear solution resulted immediately and the colour changed to light blue. Bright, pale blue crystals of the complex [$NdCl_3$(HMPA)$_3$] grew out of the solution during slow evaporation of the solvent. Found: Nd, 18.7; C, 27.12; N, 15.43; H, 6.81. Calc. for [$NdCl_3$(HMPA)$_3$]: Nd, 18.3; C, 27.43; N, 15.99; H, 6.91%. IR (Nujol) (cm^{-1}): 1302 s, 1193 m, 1163 m, 1133 vs, 1064 w, 986 vs, 759 s, 481 m.

2.3.8. [$SmCl_3$(diglyme)]

To 0.490 g (1.41 mmol) of Sm_2O_3 were added 20 ml of THF, 12.96 g (119 mmol) of $(CH_3)_3SiCl$, 0.930 g (6.93 mmol) of diglyme and 0.080 g (4.44 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 1.099 g (100% yield) of the complex [$SmCl_3$(diglyme)] was gained. Found: Sm, 38.0; C, 18.47; H, 3.55. Calc. for [$SmCl_3$(diglyme)]: Sm, 38.4; C, 18.44; H, 3.61%. IR (Nujol) (cm^{-1}): 1290 w, 1261 w, 1245 w, 1092 vs, 1064 s, 1048 vs, 1006 m, 954 m, 876 vs, 834 m, 824 m, 803 w.

2.3.9. [$SmCl_3(HMPA)_3$]

2.3.9.1. Method A. HMPA (0.710 g, 3.96 mmol) was added to a suspension of [$SmCl_3(DME)_2$] (0.296 g, 0.677 mmol) [16] in toluene (28 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$SmCl_3(HMPA)_3$] grew out of the solution during slow evaporation of the solvent. Found: Sm, 19.3; C, 27.39; H, 6.82; N, 15.42. Calc. for [$SmCl_3(HMPA)_3$]: Sm, 18.9; C, 27.22; H, 6.85; N, 15.87%. IR (Nujol) (cm^{-1}): 1303 s, 1196 m, 1169 m, 1135 vs, 1067 w, 986 vs, 759 s, 482 m.

2.3.9.2. Method B. HMPA (0.580 g, 3.24 mmol) was added to a suspension of [$SmCl_3$(diglyme)] (0.265 g, 0.678 mmol) in toluene (25 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$SmCl_3(HMPA)_3$] grew out of the solution during slow evaporation of the solvent. Found: Sm, 19.4; C, 27.05; N, 15.64; H, 6.97. Calc. for [$SmCl_3(HMPA)_3$]: Sm, 18.93; C, 27.22; N, 15.87; H, 6.85%. IR (Nujol) (cm^{-1}): 1302 s, 1193 m, 1167 m, 1134 vs, 1068 m, 985 vs, 798 w, 752 s, 481 m.

2.3.10. [$EuCl_3$(diglyme)]

To 0.340 g (0.97 mmol) of Eu_2O_3 were added 20 ml of THF, 10.54 g (97 mmol) of $(CH_3)_3SiCl$, 0.790 g (5.89 mmol) of diglyme and 0.130 g (7.2 mmol) of water. The suspension was stirred for 4 days and after drying in vacuo 0.760 g (99.8% yield) of the white complex [$EuCl_3$(diglyme)] was gained. Found: Eu, 39.0; C, 18.2; H, 3.52. Calc. for [$EuCl_3$(diglyme)]: Eu, 38.72; C, 18.36; H, 3.60%. IR (Nujol) (cm^{-1}): 1290 w, 1261 m, 1245 w, 1213 vw, 1092 vs, 1049 vs, 1006 m, 955 m, 877 s, 835 m, 825 w, 803 vw.

2.3.11. [$EuCl_3(HMPA)_3$]

HMPA (1.10 g, 8.20 mmol) was added to a suspension of [$EuCl_3$(diglyme)] (0.77 g, 1.96 mmol) in toluene (40 ml). A clear solution resulted immediately. Bright, colourless crystals of the complex [$EuCl_3(HMPA)_3$] grew out of the solution during slow evaporation of the solvent. Found: Eu, 19.30; C, 27.23; N, 15.38; H, 6.86. Calc. for [$EuCl_3(HMPA)_3$]: Eu, 19.09; C, 27.16; N, 15.84; H, 6.84%. IR (Nujol) (cm^{-1}): 1301 m, 1195 m, 1170 m, 1137 vs, 1068 w, 986 vs, 759 s, 482 m.

2.3.12. [$GdCl_3(HMPA)_3$]

To 0.410 g (1.13 mmol) of Gd_2O_3 were added 20 ml of THF, 13.18 g (121 mmol) of $(CH_3)_3SiCl$, 0.850 g (6.33 mmol) of diglyme and 0.130 g (7.2 mmol) of water. The suspension was stirred for 5 days and dried in vacuo. The dried residual was suspended in toluene (25 ml) and 1.60 g (10.9 mmol) HMPA was added. The white powder partly dissolved. The insoluble substance was filtered off. Bright, colourless crystals of the complex [$GdCl_3(HMPA)_3$] grew out of the solution during slow evaporation of the solvent. Found: Gd, 19.9; C, 26.90; N, 15.56; H, 6.93. Calc. for [$GdCl_3(HMPA)_3$]: Gd, 19.6; C, 26.98; N, 15.73; H, 6.79%. IR (Nujol) (cm^{-1}): 1303 s, 1193 m, 1170 m, 1138 vs, 1067 w, 985 vs, 798 vw, 753 m, 481 m.

2.4. Crystal structure determination

Hygroscopic crystals of [$LnCl_3(HMPA)_3$] (Ln = La, Pr, Nd, Sm, Eu, Gd) were fixed and covered by nail polish and used for cell determination on an Enraf-Nonius CAD-4 diffractometer with graphite monochromatized Mo Kα radiation, $\lambda = 0.7107$. Accurate unit cell parameters of [$LnCl_3(HMPA)_3$] (Ln = La, Pr, Nd, Sm, Eu, Gd) were obtained from a least-squares refinement of the angular settings of 75 reflections $8 < \theta < 15°$. Crystals of [$LnCl_3(HMPA)_3$] (Ln = La, Pr, Nd, Sm, Eu, Gd) are monoclinic, with space group $P2_1/c$, no. 14, $C_{18}H_{54}N_9Cl_3O_3P_3Ln$, $Z = 4$; unit cell parameters are presented in Table 1.

A colourless block-shaped crystal of [$SmCl_3(HMPA)_3$], with dimensions $0.4 \times 0.5 \times 0.6$ mm, sealed in a capillary purged with argon was used for data collection. Intensities were collected at 293(2) K in the ω scan mode to $2\theta_{max} = 28°$ in the range h 0 to 20, k 0 to 26, l −31 to 31; 19 139 total data were measured; equivalent reflections merged into a set

Table 1
Unit cell parameters of [$LnCl_3(HMPA)_3$] (Ln = La, Pr, Nd, Sm, Eu, Gd)

Ln	a (Å)	b (Å)	c (Å)	β (°)	V (Å^3)
La	15.885(1)	20.326(2)	23.820(2)	90.04(1)	7705(2)
Pr	15.826(4)	20.285(5)	23.679(6)	90.00(2)	7602(6)
Nd	15.794(9)	20.215(7)	23.686(7)	90.14(8)	7562(6)
Sm	15.783(1)	20.179(2)	23.606(2)	90.18(1)	7518(2)
Eu	15.772(3)	20.152(3)	23.571(3)	90.01(1)	7492(3)
Gd	15.774(2)	20.147(3)	23.557(3)	90.03(1)	7486(3)

of 11 007 independent reflections, $R_{int} = 0.029$, 6961 with $I > 2.5\sigma(I)$ were observed. Correction was made for analytical absorption. The structure was solved by direct methods, with full-matrix least-squares refinement; H atoms at calculated positions with isotropic temperature factors were included only in structure factor calculations. In the final least-squares cycle there were 6961 reflections and 667 variables. The final R factors were $R = 0.086$ and $R_w = 0.091$, and goodness-of-fit was 1.103. All calculations were performed with the Xtal3.4 system of crystallographic programs [17].

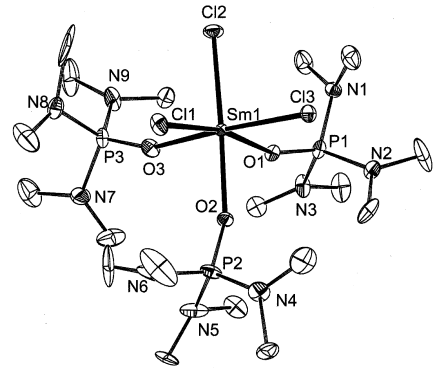
3. Results and discussion

3.1. Synthesis and characterization

Chlorotrimethylsilane reacts with water, generating hydrogen chloride in situ. The generated hydrogen chloride reacts with lanthanide oxides in dimethoxyethane giving the complexes $[LnCl_3(DME)]$ (Ln = La, Pr), as well as with diglyme in tetrahydrofuran resulting in $[LnCl_3(diglyme)]$ (Ln = La, Nd, Sm, Eu). The method is very simple since the syntheses are carried out at room temperature and the side products, HCl and $(CH_3)_3SiOSi(CH_3)_3$, are volatile and easily removed. All prepared products are anhydrous based on the absence of OH stretching bands in the IR spectra. $[LaCl_3(DME)]$ and $[PrCl_3(DME)]$ were prepared for the first time in the same way as previously described $[SmCl_3(DME)_2]$ [16]. The very low solubilities of $[LnCl_3(DME)]$ in common solvents hamper the preparation of single crystals and also suggest the polymeric structure of the compounds, in contrast to the monomeric $[LnCl_3(DME)_2]$ [18–20]. This indicates a possible structural diversity in $[LnCl_3(DME)_n]$ complexes as previously reported for $[LnCl_3(THF)_n]$ [20–28]. The stoichiometry of the prepared diglyme complexes has been found in the octahedral $[ScCl_3(diglyme)]$ [29]. We tried to prepare more soluble $[LnCl_3L]$ (L = diglyme, DME) derivatives by introducing ligand HMPA. When HMPA was added to a suspension of the prepared $[LnCl_3L]$ (L = DME, diglyme) in toluene, the complexes $[LnCl_3(HMPA)_3]$ were formed in high yield in all cases. The syntheses of $[MCl_3(HMPA)_3]$ (M = all rare earth, Sc) have been already reported [6]. The X-ray structure determination of the previously prepared $LnCl_3(HMPA)_3$ (Ln = Pr, Dy, Yb) revealed the meridional distribution of the ligands in the octahedron [30–32]. The ^1H NMR spectrum of $[LaCl_3(HMPA)_3]$ from our synthesis suggested a facial isomer. The X-ray structure analysis of the prepared $[SmCl_3(HMPA)_3]$ confirmed the proposed facial distribution of the ligands. The prepared $[LnCl_3(HMPA)_3]$ (Ln = La, Pr, Nd, Eu, Gd) complexes are isomorphous to the *fac*-$[SmCl_3(HMPA)_3]$ isomer according to the unit cell determination (Table 1). Decreasing volumes of the unit cells from lanthanum to gadolinium complexes are expected, due to lanthanide contraction.

3.2. Crystal structure of $[SmCl_3(HMPA)_3]$

The molecular structure of $[SmCl_3(HMPA)_3]$ is shown in Fig. 1 and selected bond lengths and angles are listed in Table 2. An asymmetric unit consists of two slightly different molecules. This is in contrast to the *mer* isomers with only one molecule in the asymmetric unit [30–32], resulting in the doubling of the unit cell volume in the *fac* compounds. The coordination polyhedron around samarium in *fac*-$[SmCl_3(HMPA)_3]$ is a slightly distorted octahedron with angles Cl–Sm–O from 168.0(4) to 173.1(4)°. The angles between chlorine atoms are wider, Cl–Sm–Cl, from 93.2(2) to 98.0(3)° and sharper between oxygen atoms, O–Sm–O, from 81.4(5) to 87.6(5)°. The bond lengths are from 2.657(8) to 2.680(7) Å for Sm–Cl and from 2.290(13) to 2.388(18) Å for Sm–O. The values for bond lengths are between those listed for *mer*-$[PrCl_3(HMPA)_3]$ [30] and *mer*-$[DyCl_3(HMPA)_3]$ [31], as expected. Sm–Cl bond lengths are also similar to those in the seven-coordinate com-



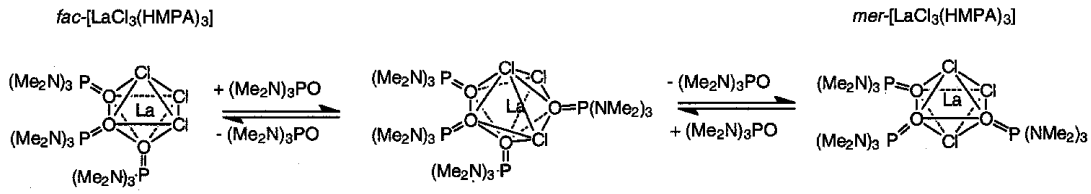


Fig. 1. The molecular structure of $[SmCl_3(HMPA)_3]$. Hydrogen atoms are omitted for clarity.

Table 2

Scheme 1. The proposed mechanism of *fac–mer* isomerization and HMPA exchange in $[LaCl_3(HMPA)_3]$. The central seven-coordinate species is either an interchange transition state, an intermediate or a stable molecule.

plexes $[SmCl_3(THF)_4]$ (2.635–2.683) [26] and $[SmCl_3(DME)(THF)_2]$ (2.646–2.668) [33].

The six-coordinate complexes of lanthanide chlorides include *mer*-$[LnCl_3(HMPA)_3]$ (Ln = Pr, Dy, Yb) [30–32] and *mer*-$[LnCl_3(THF)_3]$ (Ln = Yb, Lu) [28,34], as well as complexes with bulky ligands in a facial conformation: $[CeCl_3(OAsPh_3)_3]$ [35], $[GdCl_3(C_7H_8O_2)_3]$ [36], $[YbCl_3(C_6H_{10}O_2)(THF)_2]$ [27] and $[PrCl_3(CCl_3C(O)N(H)P(O)(NEt_2)_2)_3]$ [37].

3.3. The NMR solution dynamics study of $[LaCl_3(HMPA)_3]$

The existence of *fac* and *mer* isomers of $[PrCl_3(HMPA)_3]$ prompted us to study *fac–mer* isomerization. The ^{1}H NMR spectrum of $[LaCl_3(HMPA)_3]$ shows a doublet consistent with three equivalent HMPA ligands in the *fac* isomer (Fig. 2a). The doublet in the ^{1}H NMR spectrum of the sample containing only traces of free HMPA[1] is converted (at 362 K in 2.5 h) to two doublets in the approximate ratio of intensities of 2:1, consistent with the formation of the *mer* isomer (Fig. 2b, c). The change is reversible, the slow reappearance of the *fac* isomer being observed at room temperature (Fig. 2d, e). Splitting of the doublet at 362 K was not detected, either with the sample containing pure $[LaCl_3(HMPA)_3]$ or in the solution containing $[LaCl_3(HMPA)_3]$ and HMPA in the molar ratio 1:0.5.

The addition of free HMPA to the $[D_8]$toluene solution of $[LaCl_3(HMPA)_3]$ causes a shift of the HMPA resonance in the ^{1}H NMR spectra to the lower frequency, suggesting the fast exchange of free and coordinated HMPA. The shifts of 0.043 and 0.055 ppm were observed after addition of 3 and 9 moles of HMPA to 1 mole of complex, respectively. The separated resonances of free HMPA at lower frequency and of coordinated HMPA at higher frequency were observed at 182 K in a 0.01 M toluene solution containing equimolar amounts of $[LaCl_3(HMPA)_3]$ and free HMPA (Fig. 3). The resonances coalesced at 196 K.

We propose a reversible *fac–mer* isomerization of $[LaCl_3(HMPA)_3]$ by an associative mechanism (Scheme 1). However, we are not able to distinguish between the associative interchange mechanism and seven-coordinate intermediate. An equilibrium of $[LaCl_3(HMPA)_3]$ and $[LaCl_3(HMPA)_4]$ also can not be excluded, since $[LaBr_3(HMPA)_4]$ was isolated in the solid state [7]. The

[1] Crystals of $[LaCl_3(HMPA)_3]$ were taken in a dry box from the mother liquor containing free HMPA, gently dried with paper and dissolved in deuterated toluene.

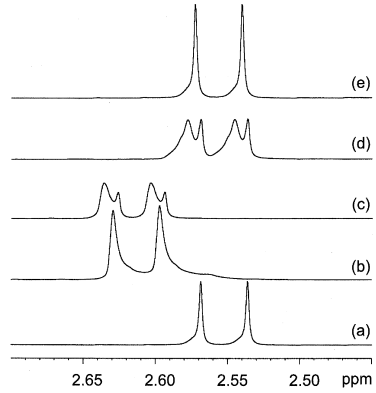

Fig. 2. The ^{1}H NMR spectra of $[LaCl_3(HMPA)_3]$ with traces of free HMPA during thermal treatment ($[D_8]$toluene solution). (a) Starting spectrum at 303 K. The sample was then heated to 362 K, and after 0.5 and 2.5 h at this temperature spectra (b) and (c) were recorded. The sample was cooled down to 303 K and after 1 h the spectrum (d) was recorded. The sample was then left at 298 K for 36 h, and the spectrum (e) resulted.

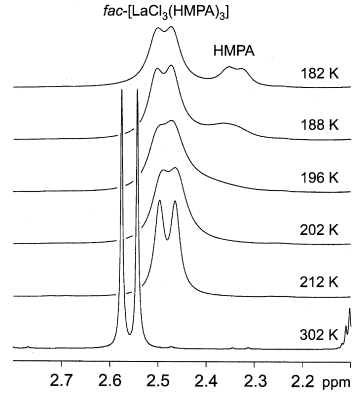

Fig. 3. The variable temperature ^{1}H NMR spectra of $[LaCl_3(HMPA)_3]$ with added free HMPA (molar ratio 1:1, $[D_8]$toluene solution).

fac isomer is dominant at room temperature and the *mer* isomer at 362 K.

According to the proposed mechanism, the exchange and isomerization are second-order reactions, depending on the concentrations of the complex and free HMPA. The exchange of two different environments of HMPA ligand in *mer*-$[LaCl_3(HMPA)_3]$ is slow on the ^{1}H NMR time scale only in the presence of traces of free HMPA (Fig. 2c, d). At a 1:0.5 molar ratio of complex to free HMPA, only one HMPA resonance was observed at 362 K, indicating the fast exchange of all the coordinated HMPA molecules in *mer*-$[LaCl_3(HMPA)_3]$ and free HMPA.

The coalescence of resonances of free and coordinated HMPA at 196 K gave a second-order rate constant k_2(196

K) of $1.0(2)\times10^{4}\ M^{-1}\ s^{-1}$ and $\Delta G^{\neq}(196\ K) = 32\pm1$ kJ/mol.

Only a broad ^{31}P NMR singlet was observed for *fac* and *mer* isomers of $[LaCl_3(HMPA)_3]$. We were not able to detect a ^{139}La NMR resonance.

4. Conclusions

The *fac*-$[LnCl_3(HMPA)_3]$ (Ln = La, Pr, Nd, Sm, Eu, Gd) complexes were prepared by the reaction of $[LnCl_3L]$ (L = diglyme and DME) with excess HMPA at room temperature in toluene solution. The previously reported *mer*-$[PrCl_3(HMPA)_3]$ was obtained by the reaction of $PrCl_3$ in hot ethanol, crystallized at 0°C and then recrystallized from benzene [6,30]. The ^{1}H NMR study of $[LaCl_3(HMPA)_3]$ shows exchange of coordinated and free HMPA. In addition, *fac*-$[LaCl_3(HMPA)_3]$ observed in toluene solution at room temperature is reversibly converted to the *mer* isomer at 362 K in the presence of traces of free HMPA. The conversion was not observed without free HMPA. On this basis, the mechanism was proposed for reversible *fac–mer* isomerization in the presence of free HMPA. However, the polar solvent ethanol, used in the synthesis of *mer*-$[PrCl_3(HMPA)_3]$ [6,30], could alter the relative stabilities of *fac* and *mer* isomers, making the *mer* isomer more stable at 0°C. *mer*-$[PrCl_3(HMPA)_3]$ could not be converted to the *fac* isomer during recrystallization from non-polar benzene since no free HMPA was present.

Supplementary data

Crystallographic data concerning the crystal structure determination of $[SmCl_3(HMPA)_3]$ are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, on request, quoting deposition number CCDC 132917.

Abstract

^{57}Fe Mössbauer spectroscopy shows that the molecular motion of haloferrocenes enclathrated in deoxycholic acid is similar to that of ferrocene in deoxycholic acid but the onset temperature of the precession and anisotropic vibration of haloferrocenes as a whole in the deoxycholic acid becomes higher as the interaction increases between deoxycholic acid and the halogen atoms in the ferrocene derivatives. It is also shown that increasing the number of halogen atoms has a tendency to increase the interaction with the host lattice. Powder X-ray diffraction patterns show that all the inclusion compounds have similar crystal structures, and the unit cell volume of haloferrocenes enclathrated in deoxycholic acid decreases with increasing van der Waals radius of the halogen atom. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Crystal engineering has become a major problem in chemistry [1]. Control of the solid state structure of supramolecule substances can provide us with a wide range of new molecular-based materials. One of the strategies to construct crystals is the use of host–guest phenomena. The onset and cessation of the rotational motion of guest molecules having dipole moments in the host lattice result in a change of dielectric constant, giving the possibility of making a molecular-based switch. Therefore, there is considerably current interest in the dynamics of guest molecules in host lattices [2]. It is known that deoxycholic acid forms a channel in the solid state, and that it includes a variety of organic molecules. Miki et al. first reported an X-ray diffraction study of the ferrocene (FcH)–deoxycholic acid (DCA) (1:2) inclusion compound; the FcH was fixed in the DCA channel [3]. Using NMR methods, Imashiro et al. detected a precession of FcH in the DCA inclusion compound [4].

^{57}Fe Mössbauer spectroscopy is a useful technique to investigate molecular motion in inclusion compounds [5]. Recently, the present author applied ^{57}Fe Mössbauer spectroscopy to study the molecular motion of FcH in the DCA channel [6]. The existence of the precession was confirmed and it was first suggested, using ^{57}Fe Mössbauer spectroscopy, that an anisotropic vibration of the FcH molecule as a whole is coupled with the precession.

In the present study, the molecular motion of haloferrocenes having dipole moments such as monochloro- (FcCl), monobromo- (FcBr), monoiodo- (FcI), 1,1′-dichloro- ($FcCl_2$), 1,1′-dibromo- ($FcBr_2$) and 1,1′-diiodoferrocene (FcI_2) (Scheme 1) enclathrated in DCA was investigated by means of ^{57}Fe Mössbauer spectroscopy and was compared with that of the ferrocene molecule enclathrated in DCA. The molecular motion of 1,1′-dimethylferrocene ($FcMe_2$) in DCA was also investigated and compared with those of haloferrocenes in DCA to bring out the interaction of the halogen atoms and the DCA lattice. The crystal data obtained from powder X-ray diffraction patterns were compared with

Scheme 1. Guest molecules: FcH (X = Y = H), FcCl (X = Cl, Y = H), FcBr (X = Br, Y = H), FcI (X = I, Y = H), $FcCl_2$ (X = Y = Cl), $FcBr_2$ (X = Y = Br), FcI_2 (X = Y = I), $FcMe_2$ (X = Y = Me).

each other, and revealed an interesting contraction of the unit cell volume with an increase in the van der Waals radius of the substituent, which suggests an apparent interaction of the halogen atoms and the host lattice.

2. Experimental

All haloferrocenes were synthesized according to the usual procedure [7] and the purity was confirmed by ^{1}H NMR. The 1,1′-dimethylferrocene used was commercially available (Aldrich). The needle-like crystals of the ferrocene derivative–DCA (1:2) inclusion compounds were obtained from methanol solution except for FcI–DCA, which was obtained from butanol solution. The presence of inclusion compounds was confirmed by powder X-ray diffraction patterns and elemental analyses. Found for FcCl–DCA: C, 69.33; H, 9.07%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_9FeCl)$: C, 69.26; H, 8.92%. Found for FcBr–DCA: C, 66.63; H, 8.79%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_9FeBr)$: C, 66.34; H, 8.54%. Found for FcI–DCA: C, 63.58; H, 8.71%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_9FeI)$: C, 63.49; H, 8.18%. Found for $FcCl_2$–DCA: C, 67.19; H, 8.99%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_8FeCl_2)$: C, 66.97; H, 8.53%. Found for $FcBr_2$–DCA: C, 62.27; H, 8.36%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_8FeBr_2)$: C, 61.70; H, 7.86%. Found for FcI_2–DCA: C, 57.79; H, 7.55%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{10}H_8FeI_2)$: C, 57.16; H, 7.25%. Found for $FcMe_2$–DCA: C, 72.10; H, 9.91%. Calc. for $C_{24}H_{40}O_4 \cdot 1/2(C_{12}H_{14}Fe)$: C, 72.10; H, 9.50%.

Powder X-ray diffraction patterns were measured using Cu Kα radiation (RIGAKU) at room temperature.

A ^{57}Co (Rh) source moving in a constant acceleration mode was used for ^{57}Fe Mössbauer spectroscopic measurements. Variable-temperature ^{57}Fe Mössbauer spectra were obtained in the range of 80–363 K using a Toyo Research spectrometer, a proportional counter and a continuous-flow cryostat or home-built high-temperature apparatus. All spectra were measured on powdered samples. The isomer shift values are referred to a metallic iron foil at room temperature. The Mössbauer parameters were obtained by least-squares fitting to Lorentzian peaks. The error limits of isomer shift, quadrupole splitting values, half-width and area ratio are 0.005 mm s^{-1}, 0.010 mm s^{-1}, 0.005 mm s^{-1} and 0.035, respectively.

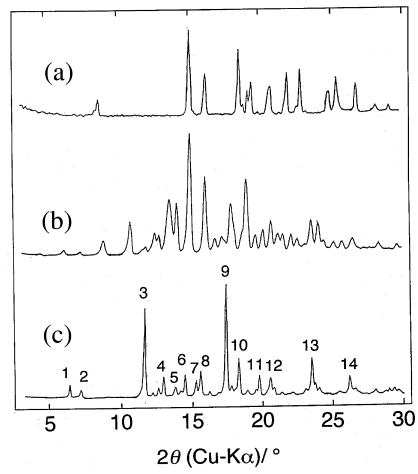

Fig. 1. Powder X-ray diffraction patterns at room temperature of chloroferrocene (a), DCA (b) and the chloroferrocene–DCA inclusion compound (c). The indices obtained using the orthorhombic lattice constants of FcH–DCA are: 1 (010), 2 (110), 3 (310), 4 (001), 5 (020), 6 (220), 7 (211), 8 (301), 9 (510), 10 (420), 11 (130), 12 (321), 13 (430), 14 (530).

3. Results and discussion

The powder X-ray diffraction patterns for chloroferrocene, DCA and the chloroferrocene–DCA inclusion compound are shown in Fig. 1. It can easily be seen from Fig. 1 that the pattern for the chloroferrocene–DCA inclusion compound is not the superposition of those of chloroferrocene and DCA. The patterns from chloroferrocene and DCA are not observed in the inclusion compound. The pattern of FcCl–DCA is similar to that of ferrocene–DCA. It is known that the ferrocene molecule is fixed in the DCA channel in the ratio 1:2 [3]. It can be judged from the similarity of the patterns that chloroferrocene is also included in the DCA lattice in a similar manner, and that the ratio of FcCl–DCA is 1:2. The elemental analysis also supports the ratio. We suppose here that the crystal structure of FcCl–DCA is the same as that of FcH–DCA. In this situation, the reflections of FcCl–DCA can be indexed by using the orthorhombic lattice constants of FcH–DCA. The indices are also shown in Fig. 1. By using these indices we calculated the lattice constants of FcCl–DCA; these are summarized in Table 1. The unit cell volume of FcCl–DCA is larger than that of FcH–DCA. Other inclusion compounds show similar powder X-ray diffraction patterns; the calculated crystal data are also summarized in Table 1.

Variable-temperature ^{57}Fe Mössbauer spectra of the FcCl–DCA inclusion compound are shown in Fig. 2. The Möss-

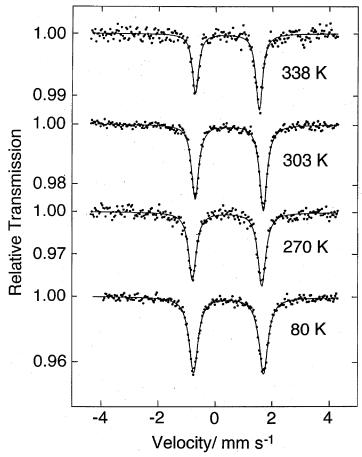

Fig. 2. Variable-temperature ^{57}Fe Mössbauer spectra of chloroferrocene–DCA inclusion compound.

bauer parameters are summarized in Table 2. It can easily be seen that the symmetric doublets are observed at low temperatures, whereas at high temperatures the doublet becomes asymmetric. It can also be seen that the quadrupole splitting (QS) values at high temperatures are smaller than those at low temperatures. Variable-temperature ^{57}Fe Mössbauer spectra of the FcBr–DCA inclusion compound also showed a similar temperature dependence at higher temperatures. The Mössbauer parameters are also summarized in Table 2.

The temperature dependences of the area intensity ratio of the high-energy peak to the low-energy peak and of the QS values in the ^{57}Fe Mössbauer spectra of FcCl–DCA and FcBr–DCA are shown in Figs. 3 and 4, respectively, compared with those of FcH–DCA. It can be seen from Fig. 3 that the doublets are symmetric from 80 to ~300 K for FcCl–DCA and from 80 to ~320 K for FcBr–DCA, whereas at higher temperatures the doublet becomes asymmetric in intensity. The asymmetry in intensity for FcCl–DCA appears above ~300 K, which is higher than that for FcH–DCA (~270 K) and is lower than that for FcBr–DCA (~320 K). The asymmetry in intensity increases with increase in temperature as is the case for FcH–DCA. It is known that the asymmetry of the doublet is caused by a preferred orientation of the molecule and/or an anisotropic recoilless fraction (Gol'danskii–Karyagin effect) [8,9]. The anisotropic recoilless fraction is independent of the orientation of the sample. It is thought that the present asymmetry in intensity is due to the Gol'danskii–Karyagin effect, because the samples in the present study were powdered and the asymmetry showed a temperature dependence. The effect of preferred orientation does not change with a change of temperature. The asymmetric doublet observed at high temperatures reverted to a symmetric doublet upon remeasuring the same sample at low temperatures. It is known that the electric field gradient (V_{zz}) of FcH is positive [10]. It is also known that the introduction of substituents to FcH has little effect upon the electric field gradient at the iron nucleus [11]. Therefore, we assume that the electric field gradients in the present derivatives are positive as is the case of FcH. In this case ($V_{zz} > 0$) the increase in the area ratio of the high-energy peak to the low-energy peak means that the vibration in a direction perpendicular to the molecular axis becomes more intense than that in a direction parallel to the axis at high temperatures ($\langle u_z^2 \rangle < \langle u_{x,y}^2 \rangle$) for the axially symmetric crystal [12]. We suppose here from

[b] Area intensity ratio of the high-energy peak to the low-energy peak in the doublet.

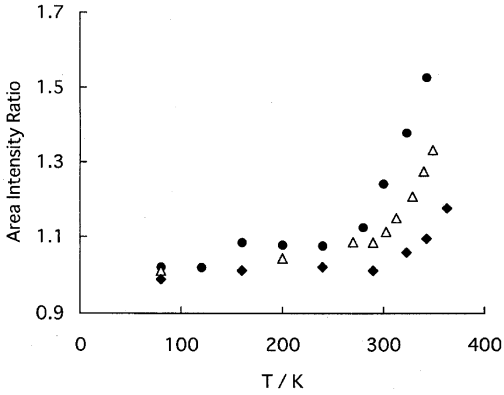

Fig. 3. Temperature dependence of the area intensity ratio of the high-energy peak to the low-energy peak in the ^{57}Fe Mössbauer doublet: ●, FcH–DCA; △, FcCl–DCA; ◆, FcBr–DCA.

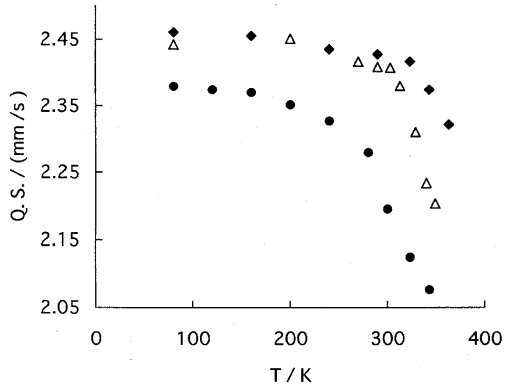

Fig. 4. Temperature dependence of the quadrupole splitting value in the ^{57}Fe Mössbauer spectra: ●, FcH–DCA; △, FcCl–DCA; ◆, FcBr–DCA.

the results of powder X-ray diffraction patterns that the crystal structure of the present inclusion compound is the same as that of FcH–DCA. In the FcH–DCA inclusion compound, DCA makes a channel and the ferrocene molecules are included in this channel in such a way that the molecular axis of ferrocene is perpendicular to the channel. In this case it can be supposed that the direction with the larger mean square amplitude of vibration is the channel direction. It is thought that $\langle u_y^2 \rangle$ is the channel direction. Although the axial symmetry does not hold in the present case, we can easily imagine the relation of $\langle u_x^2 \rangle \approx \langle u_z^2 \rangle$ and $\langle u_y^2 \rangle \gg \langle u_z^2 \rangle$. The temperature dependence of the area ratio in the present ^{57}Fe Mössbauer spectra is not inconsistent with the crystal structure.

The QS values for FcCl–DCA and FcBr–DCA are larger than those of FcH–DCA at the same temperature. It can be seen from Fig. 4 that the QS values of FcCl–DCA are almost constant from 80 to ~300 K and the values decrease suddenly above ~300 K. The QS values of FcBr–DCA are also almost constant from 80 to ~320 K and the values decrease suddenly above ~320 K. The onset temperature (~300 K) for FcCl–DCA is higher than that for FcH–DCA (~280 K) and is lower than that for FcBr–DCA (~320 K). The temperatures are consistent with those at which the doublet starts to become asymmetric in intensity. The changes can be explained by the precession of the FcCl and FcBr molecules in the DCA channel, as is the case of FcH in the DCA lattice [6]. The precession of the FcH molecule in the DCA channel is also suggested from the solid-state NMR [4]. The electric field gradient depends on the precession angle. The electric field gradient decreases in proportion to the cosine of the precession angle. Thus the decrease in the QS value is explained by the precession of guest molecules. It can be thought that the precession angle increases with increasing temperature.

As mentioned in Section 2, the FcI–DCA inclusion compound was not obtained from methanol solution. One possible reason for this may be a stronger interaction of methanol–DCA than of FcI–DCA. The inclusion compound was produced using butanol as solvent. It was not obtained as needle-like crystals but rather as a powder, whereas the other inclusion compounds in the present study, as well as FcH–DCA, were obtained as needle-like crystals. This difference might reflect the poor fit of the FcI molecule into the DCA lattice in the FcI–DCA obtained from butanol solution. The elemental analysis shows that the ratio of DCA to FcI is still 2.

The asymmetry of the FcI–DCA doublet was easily observed even at room temperature, and the asymmetry became larger with increasing temperature, but the abrupt decrease of the QS value was not observed. It is puzzling that, in the FcI–DCA inclusion compound, the changes of asymmetry in the intensity and of the QS values are not consistent with each other. One of the reasons for the discrepancy between the onset temperatures of asymmetry in intensity and of the decrease in the QS value may be the poor fit of FcI into the DCA lattice. This poor fit makes the anisotropic vibration of the FcI molecule in the channel direction easier as a whole and does not make room for the precession.

The 1,1′-diiodoferrocene (FcI_2)–DCA inclusion compound was easily obtained from methanol solution. This difference in the inclusion phenomena between FcI–DCA and FcI_2–DCA remains unexplained. The variable-temperature ^{57}Fe Mössbauer spectra of FcI_2–DCA are shown in Fig. 5.

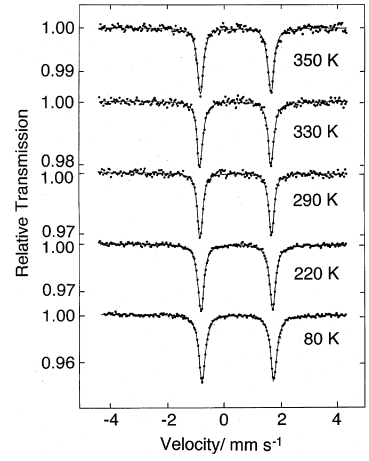

Fig. 5. Variable-temperature ^{57}Fe Mössbauer spectra of 1,1′-diiodoferrocene–DCA inclusion compound.

Symmetric doublets are observed and they do not show the remarkable asymmetry in intensity with increasing temperature, which is contrary to the results for monohaloferrocene–DCA. 1,1′-Dibromoferrocene ($FcBr_2$)–DCA also did not show remarkable temperature dependences, while evidence of molecular motion is observed in 1,1′-dichloroferrocene ($FcCl_2$)–DCA at high temperature. The temperature dependences of the area intensity ratio of the high-energy peak to the low-energy peak and of the QS values in the ^{57}Fe Mössbauer spectra of FcI_2–DCA, $FcBr_2$–DCA and $FcCl_2$–DCA are shown in Figs. 6 and 7, respectively. The large asymmetry in intensity for FcX_2 (X = Cl, Br, I) at high temperatures was not seen in Fig. 6 as compared with Fig. 3. The abrupt decrease of the QS values for FcX_2 (X = Cl, Br, I) at high temperatures was also not seen in Fig. 7 as compared with Fig. 4. The results observed in the halogen-disubstituted ferrocene derivatives in the DCA lattice contrast with those observed in the halogen-monosubstituted derivatives in DCA. It may be supposed that increasing the number of halogen atoms tends to increase the interaction with DCA.

For purposes of comparison we measured the variable-temperature ^{57}Fe Mössbauer spectra of 1,1′-dimethylferrocene ($FcMe_2$)–DCA (Fig. 8). The temperature dependences of the asymmetry in intensity and of the QS values for $FcMe_2$–DCA are also plotted in Figs. 6 and 7, respectively. The doublet becomes asymmetric in intensity and the QS value becomes smaller with increasing temperature abruptly over ~300 K. The temperature is higher than that of ferrocene–DCA because of the steric effect of the methyl substituents. The results in the methyl-disubstituted derivative–DCA show a major contrast with those in halogen-disubstituted derivative–DCA. We attribute this difference between them to an apparent interaction of halogen atoms with deoxycholic acid.

To investigate the difference among DCA inclusion compounds with the series of haloferrocenes we rechecked the results of powder X-ray diffraction patterns, which revealed that the crystal structures in the present study are similar to that of FcH–DCA inclusion compound. As described above, the reflections were indexed by using the orthorhombic lattice constants of FcH–DCA. The crystal data were calculated using the indices obtained from the assumption that the crystal structures in the present inclusion compounds are the same as that of FcH–DCA. Table 1 summarizes the crystal data. Surprisingly it can be seen that, in the monohaloferrocene series, the volume of the unit cell becomes smaller upon increasing the van der Waals radius of the halogen atom. It can also be seen in the dihaloferrocene series that the volume of the unit cell becomes smaller upon increasing the van der Waals radius of the halogen atom. The unit cell volumes of the dihaloferrocenes are smaller than those of the corresponding monohaloferrocenes having the same halogen substituents. In the extreme case, the unit cell volume of FcI_2–DCA is smaller than that of FcH–DCA. The van der Waals radius of the methyl group is 2.0 Å [13], which is slightly larger than that of bromine. An interesting point is that all the unit cell volumes of FcX_2–DCA (X = Cl, Br, I) are smaller than that of $FcMe_2$–DCA in spite of the larger van der Waals radius of iodine. The difference in the temperature dependence of the ^{57}Fe Mössbauer spectra between $FcMe_2$–DCA and FcX_2–

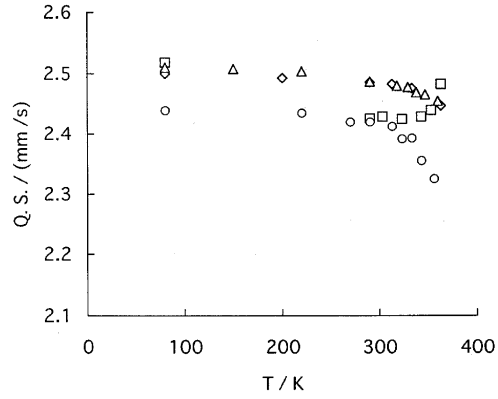

Fig. 7. Temperature dependence of the quadrupole splitting value in the ^{57}Fe Mössbauer spectra: ◇, $FcCl_2$–DCA; □, $FcBr_2$–DCA; △, FcI_2–DCA; ○, $FcMe_2$–DCA.

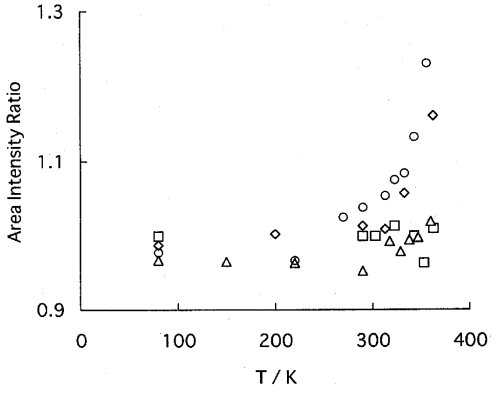

Fig. 6. Temperature dependence of the area intensity ratio of the high-energy peak to the low-energy peak in the ^{57}Fe Mössbauer doublet: ◇, $FcCl_2$–DCA; □, $FcBr_2$–DCA; △, FcI_2–DCA; ○, $FcMe_2$–DCA.

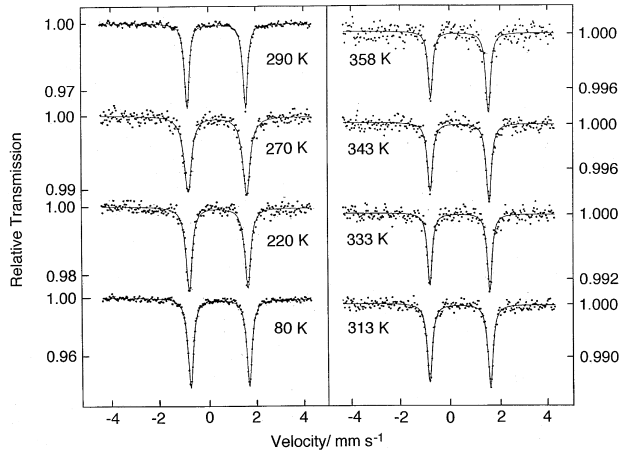

Fig. 8. Variable-temperature ^{57}Fe Mössbauer spectra of 1,1′-dimethylferrocene–DCA inclusion compound.

DCA (X = Cl, Br, I) clearly reveals the existence of the interaction between halogen atoms and the DCA lattice.

Deoxycholic acid has both hydrophobic and hydrophilic planes. It is known that the ferrocene molecule is enclathrated into the hydrophobic plane of deoxycholic acid [3]. The similarity of the present X-ray powder patterns suggests that the halogen-substituted ferrocenes and 1,1′-dimethylferrocene are also enclathrated into the hydrophobic plane of the DCA. FcCl–DCA shows a lower onset temperature than FcBr–DCA, suggesting that the interaction is not an electrostatic one. The enclathrated position and the results of X-ray powder patterns show that the increased van der Waals interaction raises the onset temperature.

It can be concluded that there is an apparent van der Waals interaction between halogen atom in the ferrocene derivatives and the DCA lattice. The interaction suppresses the precession and anisotropic vibration of the ferrocene derivatives as a whole in the DCA lattice. At higher temperatures the precession and anisotropic motion start. In the disubstituted haloferrocenes, these motions are almost unable to begin because of the increased interaction of the halogen atoms in the ferrocene derivatives and the DCA lattice. The precession of the haloferrocenes will result in a change of dielectric constant, which results in a molecular-based switch. Finally, the onset temperature can be controlled by changing the identity and number of the halogen atoms.

Abstract

Bis(diisobutyldithiophosphinato)cadmium(II) (**1**) and bis(diisobutyldithiophosphinato)zinc(II) (**2**) have been synthesised and their X-ray single crystal structures determined. Both compounds have been used as precursors to grow thin films of CdS and ZnS, respectively, by low-pressure metal organic chemical vapour deposition (LP-MOCVD). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Dithiophosphinates; Low-pressure metal organic chemical vapour deposition; II/VI Semiconductors

1. Introduction

Dithiophosphinates have many important industrial and agricultural applications, including solvent extraction reagents for metals [1], insecticides and pesticides, flotation agents for mineral ores and additives to lubricant oils [2]. Metal complexes of such ligands have the potential to be new precursors for use in low-pressure metal organic chemical vapour deposition (LP-MOCVD). The deposition of II/VI semiconductors had been previously achieved with zinc and cadmium dimethyldithiophosphinates by Takahashi et al. [3]. They grew good-quality ZnS and CdS films on silver-plated glass substrates between 400 and 500°C. Films grown on normal glass substrates were of poor quality in terms of thickness even when grown at higher substrate temperatures.

In the present paper we report the X-ray crystal structures of the new compounds bis(diisobutyldithiophosphinato)-cadmium(II) (**1**) and bis(diisobutyldithiophosphinato)-zinc(II) (**2**), their comparison with those of $[Zn(S_2PEt_2)_2]_2$ [4], $[Zn(S_2PPr^n_2)_2]_2$ [5], $[Cd(S_2PEt_2)_2]_2$ [6–8] and $[Cd(S_2PPh_2)_2]_2$ [9], and the growth of thin films of CdS and ZnS by LP-MOCVD.

2. Experimental

2.1. Chemicals

Sodium diisobutyldithiophosphinate (50% solution in water) was obtained from Aldrich Chemical Co. Ltd. Zinc sulfate (99%) and cadmium sulfate (99%) and solvents were obtained from BDH.

2.2. Physical measurements

NMR spectra were recorded using a Bruker AM250 pulsed Fourier transform instrument. Infrared spectra were carried out using a Matteson Polaris FT-IR spectrometer as Nujol mulls; mass spectra were recorded by a micromass Autospec-Q using micromass OPUS software. An electron impact energy of 70 eV at 10^{-7} Torr was used to initiate mass fragmentation. Melting points were measured in sealed tubes with an electrothermal melting point apparatus and are uncorrected. Microanalyses were carried out by the Imperial College London service. X-ray powder diffraction (XRD) analysis was performed using a Siemens D500 automated diffractometer. Samples were mounted flat and scanned from 10 to 60° in steps of 0.04°, with a count time of 2 s. Scanning electron microscopy (SEM) and energy dispersive analytical X-ray analysis (EDAX) was carried out on a JEOL J535CM scanning electron microscope with a LINK QX2000 energy

PII S0277-5387(99)00352-6

dispersive X-ray analysis unit. Thermogravimetric analysis (TGA) was carried out using a Shimadzu TGA-50 at a rate of 10°C min^{-1}.

2.3. Synthesis

2.3.1. $[Cd(S_2P^iBu_2)_2]_2$ (1)

Cadmium diisobutyldithiophosphinate was prepared by the method of Kuchen et al. [10]. In a typical reaction $3CdSO_4 \cdot 8H_2O$ (2.76 g, 11 mmol) in aqueous solution was reacted with sodium diisobutyldithiophosphinate (5 g, 22 mmol) in aqueous solution. The white precipitate formed (5.24 g, 9.9 mmol, 90% yield) was filtered under vacuum, washed with distilled water and recrystallised from acetone to give transparent cubic crystals. Yield 8.24 g (70.7%), m.p. 125°C. (Found: C, 36.3; H, 7.0. Calc.: C, 36.2; H, 6.8%.)

^{1}H NMR ($CDCl_3$, 500 MHz) δ (ppm): 1.13 (d, 24H, $^3J_{H-H}$ = 6.6 Hz, CH_3), 2.17 (dd, 8H, $^3J_{H-H}$ = 6.1 Hz, CH_2), 2.36 (m, 4H, $^3J_{H-H}$ = 6.5 Hz, CH). ^{13}C{^{1}H} NMR ($CDCl_3$, 125 MHz) δ (ppm): 24.72 (d, J_{P-C} = 9.02, CH_3), 25.34 (d, J_{P-C} = 4.31, CH), 48.56 (d, J_{P-C} = 44.65, CH_2). ^{31}P NMR ($CDCl_3$, 202 MHz) δ (ppm): 76.79 (s). IR major bands and tentative assignments: 588 cm^{-1}, ν(Cd–S); 758 cm^{-1}, ν(P=S). Mass spectrum (m/z): M^+ 532 $[Cd(S_2P^iBu_2)_2]_2$, base peak 57 $\{CH_2CH(CH_3)_2\}$, 87 $\{PCH_2CH(CH_3)_2\}$, 177 $\{SP[CH_2CH(CH_3)_2]_2\}$, 209 $\{S_2P[CH_2CH(CH_3)_2]_2\}$, 323 $\{CdS_2P[CH_2CH(CH_3)_2]_2\}$, 419 $\{PS_2CdS_2P[CH_2CH(CH_3)_2]_2\}$.

2.3.2. $[Zn(S_2P^iBu_2)_2]_2$ (2)

This was prepared from sodium diisobutyldithiophosphinate and zinc sulfate by a similar method to that for compound **1**. Solid product crystallised from acetone to give transparent crystals. Yield 7.8 g (73%), m.p. 112°C. (Found: C, 39.6; H, 7.4. Calc.: C, 39.7; H, 7.5%.)

^{1}H NMR ($CDCl_3$, 500 MHz) δ (ppm): 1.13 (d, 24H, $^3J_{H-H}$ = 6.6 Hz, CH_3), 2.08 (dd, 8H, $^3J_{H-H}$ = 6.2 Hz, CH_2), 2.35 (m, 4H, $^3J_{H-H}$ = 6.5 Hz, CH). ^{13}C{^{1}H} NMR ($CDCl_3$, 125 MHz) δ (ppm): 25.04 (d, J_{P-C} = 9.0, CH_3), 25.44 (d, J_{P-C} = 4.5, CH), 48.29 (d, J_{P-C} = 43.0, CH_3). ^{31}P NMR ($CDCl_3$, 202 MHz) δ (ppm): 74.56 (s). IR major bands and tentative assignments: 602 cm^{-1}, ν(Zn–S); 767 cm^{-1}, ν(P=S). Mass spectrum (m/z): M^+ 482 $[Zn(S_2P^iBu_2)_2]_2$, base peak 426 $\{(CH_3)_2CHCH_2PS_2ZnS_2P[CH_2CH(CH_3)_2]_2\}$, 57 $\{CH_2CH(CH_3)_2\}$, 87 $\{PCH_2CH(CH_3)_2\}$, 177 $\{SP[CH_2CH(CH_3)_2]_2\}$, 209 $\{S_2P[CH_2CH(CH_3)_2]_2\}$, 273 $\{ZnS_2P[CH_2CH(CH_3)_2]_2\}$, 368 $\{PS_2ZnS_2P[CH_2CH(CH_3)_2]_2\}$.

2.4. Growth of CdS or ZnS

CdS and ZnS films were deposited from $[Cd(S_2P^iBu_2)_2]_2$ and $[Zn(S_2P^iBu_2)_2]_2$, respectively, using a home-made cold-wall low-pressure reactor (10^{-2} Torr), described in detail elsewhere [11]. Glass substrates were used and these were heated by the action of a quartz halogen lamp on a graphite susceptor. The $[Cd(S_2P^iBu_2)_2]_2$ precursor was held in a tube furnace [12] heated at temperatures between 400 and 450°C.

2.5. X-ray crystallography

2.5.1. Crystal data for compound 1

$C_{32}H_{72}P_4S_8Cd_2$, M = 1062.1, monoclinic, space group $P2_1/c$ (no. 14), a = 11.140(2), b = 12.070(2), c = 18.836(3) Å, β = 92.54(1)°, V = 2530.1(7) Å^3, Z = 2 (the molecule has crystallographic C_i symmetry), D_c = 1.394 g cm^{-3}, μ(Mo Kα) = 13.2 cm^{-1}, $F(000)$ = 1096, T = 293 K; clear prisms, 0.50 × 0.33 × 0.20 mm, Siemens P4/PC diffractometer, ω-scans, 4467 independent reflections. The structure was solved by direct methods; the non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.051, wR_2 = 0.113 for 2990 independent observed absorption corrected reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 50°$] and 208 parameters [13].

2.5.2. Crystal data for compound 2

$C_{32}H_{72}P_4S_8Zn_2$, M = 968.0, orthorhombic, space group $Fdd2$ (no. 43), a = 48.602(2), b = 11.665(1), c = 18.000(1) Å, V = 10205(1) Å^3, Z = 8 (the molecule has crystallographic C_2 symmetry), D_c = 1.260 g cm^{-3}, μ(Cu Kα) = 55.5 cm^{-1}, $F(000)$ = 4096, T = 293 K; clear platy prisms, 0.37 × 0.33 × 0.13 mm, Siemens P4/PC diffractometer, ω-scans, 2167 independent reflections. The structure was solved by direct methods; the major occupancy non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.057, wR_2 = 0.155 for 1718 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 127°$] and 221 parameters. The polarity of the structure was unambiguously determined by a combination of R-factor tests [R_1^+ = 0.0571, R_1^- = 0.0580] and by use of the Flack parameter [$x^+ = -0.03(19)$, $x^- = +1.03(19)$] [13].

3. Results and discussion

Compounds **1** and **2** were both prepared by the reaction of sodium diisobutyldithiophosphinate with cadmium or zinc sulfate. Both are soluble in most organic solvents and can be recrystallised from acetone at room temperature to give transparent crystals. Compounds **1** and **2** gave satisfactory elemental analysis and were further characterised by NMR (^{1}H, ^{13}C, ^{31}P), IR, TGA and X-ray methods. Both compounds are stable at room temperature for a period of months.

3.1. X-ray structures

The cadmium complex (**1**) has a classic C_i symmetric two-step ladder (or 'chair') structure (Fig. 1) of type 23 for the central eight-membered $Cd_2S_4P_2$ ring [2]. This geometry contrasts with the C_2 symmetric 'boat' conformation observed for the closely related isopropoxide ligand $Cd_2[(i$-

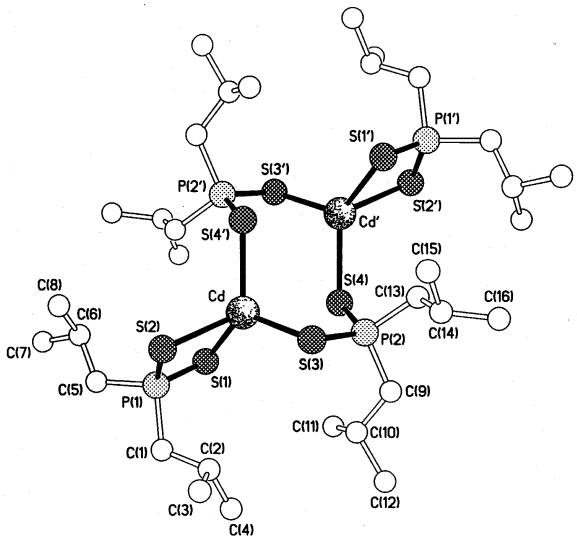

Fig. 1. The molecular structure of the C_i symmetric complex (**1**), showing its 'chair' conformation.

$C_3H_7O)_2PS_2]_4$ (**1***) [14]. The pattern of bonding within the eight-membered ring is similar, however, with both the Cd–S and P–S bonds in compound **1** being, in all but one instance, longer then their counterparts in the isopropoxide analogue **1*** (Table 1). The four-membered chelate ring has a slightly folded geometry (ca. 9° about the S···S vector) with both Cd–S and P–S bonds that are distinctly asymmetric, an asymmetry that was observed for the Cd–S bonds in **1*** but not for the P–S bonds. The geometry at cadmium is severely distorted tetrahedral, with angles ranging between 78.82(6) and 128.63(7)°, the acute angle being associated with the bite of the chelating ligand (Table 2). Indeed, the coordination geometry could almost be considered as distorted trigonal pyramidal, with S(1), S(3) and S(4′) forming the basal plane and S(2) in the apical position. The cadmium atom lies only 0.20 Å out of this basal plane, whereas it lies between 0.95 and 1.08 Å out of the planes of the other three faces. A similar distortion of the coordination geometry is present in compound **1***, where the cadmium lies 0.41 Å out of the basal plane of the trigonal pyramid [14]. Distortions from tetrahedral geometry at the phosphorus centres are relatively small. The packing of the molecules is largely dominated by the hydrophobic isobutyl groups, and there are no short intermolecular S···S contacts.

X-ray analysis of the zinc complex (**2**) shows that it adopts a geometry for the $Zn_2S_8P_4$ core that is virtually identical to that seen in the cadmium and zinc complexes with *O*,*O*-diisopropylphosphordithioate (compounds **1*** and **2***, respectively) (Fig. 2) [14]. Indeed, a best fit of the 14 heteroatoms of the two zinc structures has a root mean square deviation of only 0.078 Å, with a maximum deviation of 0.096 Å for P(2)/P(2′). The four-membered chelate ring, as in the cadmium structure (**1**), has a slightly folded geometry (ca. 10° about the S···S vector) and also has noticeably asymmetric Zn–S distances; the differences in the P–S bond lengths are not statistically significant (Table 1). A consequence of the change from the 'chair' conformation for the

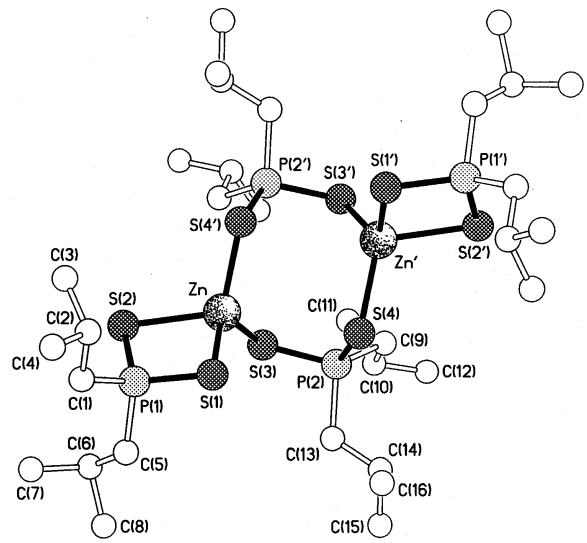

Fig. 2. The molecular structure of the C_2 symmetric complex (**2**), showing its 'boat' conformation.

eight-membered metallocyclic ring in the cadmium complex (**1**) to the 'boat' conformation seen here is a marked difference in the transannular M···S distances which are shorter in the cadmium 'chair' conformer [3.112(2) Å] than in the zinc 'boat' conformer [3.399(4) Å]. There are similar, but not quite so pronounced, distortions in the tetrahedral geometry at the metal centre (Table 2), with the zinc atom lying only 0.45 Å out of the S(1), S(3), S(4′) basal plane. There are no short intermolecular contacts of note.

It has previously been postulated that a probable reason for a change from a C_i symmetric chair to a C_2 symmetric boat conformation for the central eight-membered metallocyclic ring for phosphordithioates/dithiocarbamates is a consequence of the packing requirements of the differently sized R groups. Both the cadmium [15,16] and zinc [17] diethyldithiocarbamate species have a C_i symmetric chair conformation, whereas the corresponding cadmium and zinc diisopropylphosphordithioate complexes (**1*** and **2***, respectively) both have the C_2 symmetric 'boat' conformation (see above). In the present study we see the cadmium (**1**) and zinc (**2**) diisobutylphosphordithioate complexes exhibiting C_i chair and C_2 boat conformations, respectively. We therefore consider that both conformations are likely to occur for both species, and that consequently different polymorphs may be accessible under alternative crystallisation conditions.

3.2. Growth work

CdS thin films were grown onto glass substrates using bis(diisobutyldithiophosphinato)cadmium(II) under different conditions. Good-quality films were grown at a substrate temperature of 400–450°C (Fig. 3). The films grown at higher temperature gave slightly larger crystallites (Fig. 3b). The EDAX pattern gave peaks for cadmium and sulfur that indicated a slight excess of cadmium (0.97:1.00). SEM showed that the films are crystalline with an average crystallite size of 0.1 μm. The XRD pattern showed the films to be hexagonal (Table 3 and Fig. 4). The films grown at lower temperature during the same period of time were very thin and difficult to characterise by XRD. TGA showed that both complexes start subliming at ca. 273°C and decompose at ca. 375°C (Fig. 5). No growth occurred below 250°C precursor temperature. Bis(diisobutyldithiophosphinato)cadmium(II) appears to be less volatile than the corresponding dithiocarbamates [18–22] and hence the growth rate is lower.

Only very thin films of ZnS were grown using bis(diisobutylthiophosphinato)zinc(II), even at higher growth tem-

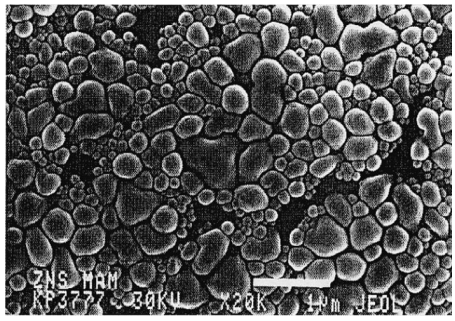

Fig. 6. SEM of ZnS thin films grown on glass at 450°C.

perature. The XRD pattern showed a broad hump, indicating the amorphous nature of the films. SEM (Fig. 6) also confirmed that the films are powdery and the EDAX pattern showed that the Zn:S ratios are close to 1:1. Dithio derivatives of zinc precursors give thin powdery films at ca. 450°C [18]. In general, zinc dithiocarbamato or dithiophosphinato derivatives are not good precursors for the growth of ZnS by LP-MOCVD, but may be useful as precursors for the growth of TOPO (trioctylphosphine oxide)-capped nanoparticles of ZnS [23].

4. Conclusions

Two new compounds, bis(diisobutyldithiophosphinato)-cadmium(II) (**1**) and bis(diisobutyldithiophosphinato)-zinc(II) (**2**), have been synthesised and characterised by NMR (^{1}H, ^{13}C, ^{31}P), IR, TGA and X-ray single crystal methods. The structures of both compounds are based on dimers with eight-membered metallocyclic rings, $M_2S_4P_2$, formed by chelating and bridging of dithiophosphinate ligands. The cadmium complex has a 'chair' conformation whereas the zinc complex has a 'boat' conformation.

The two complexes have been used as precursors to grow thin films of CdS and ZnS, respectively, onto glass substrates by LP-MOCVD. The cadmium complex gave crystalline hexagonal CdS films whereas the zinc complex gave only amorphous films. The films grown were characterised by XRD, EDAX and SEM. Dithiophosphinate of cadmium and zinc proved to be less volatile than the corresponding dithiocarbamates; hence, the growth rate was lower. However, these complexes can be useful precursors for the growth of nanocrystals of ZnS or CdS by thermolysis in tricotylphosphineoxide (TOPO), where volatility of the precursors is not a requirement.

Received 3 September 1999; accepted 22 November 1999

Abstract

A new tetraazamacrocyclic ligand (L) with four neutral 2-cyanoethyl pendent groups, and its divalent transition-metal complexes $[Co(L)(NO_3)]NO_3 \cdot H_2O$ (**1**), $[Ni(L)(NO_3)]NO_3 \cdot 3H_2O$ (**2**) and $[Cu(L)(H_2O)](NO_3)_2$ (**3**) have been synthesized. The crystal structures of **1** and **3** have been determined by X-ray analysis. In complex **1** the cobalt atom is coordinated by four nitrogen atoms and two oxygen atoms of a nitrate anion, which define a distorted octahedron. The other nitrate ion lies in the lattice as a counter ion. Complex **3** is five-coordinated by four nitrogen atoms and an axial aqua ligand, which form a tetragonal pyramid. In complex **3** the two nitrate anions exist as counter ions. Pharmaceutical tests showed that all three metal complexes exhibit antitumor activity against HL-60 and BEL-7404 tumor cell lines in vitro, even at a concentration of 10^{-8} mol l^{-1}. Complex **1** can partially cleave supercoiled pBR 322 DNA to form nicked DNA in aerobic solution, and complex **3** can convert double strand DNA into nicked DNA completely in the presence of MPA. Complex **3** causes perturbation to K562 tumor cell lines in the G_1 phase. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Transition metals; Synthesis; Structural characterization; Antitumor activity

1. Introduction

Successful applications of several 1,4,7,10-tetraazacyclododecane (cyclen) stem mainly from their use as models for protein–metal binding sites in biological systems [1–4], and as selective complexants of metallic ions [5–8], i.e. therapeutic reagents for the treatment of metal intoxication [9,10]. Recently, interest has focussed on the synthesis of macrocyclic complexes with potential medicinal applications, as contrast-enhancing agents in magnetic resonance imaging (MRI) [11,12], as NMR shift and relaxation reagents [13,14], and in RNA cleavage catalysis [15,16]. The effective anti-solid tumor drug *cis*-platinum has been found to form a covalent 1,2-intrastrand adduct at N^7 of the guanine base of DNA [17,18]. Screening new metal complexes with antitumor activity is among our research interests. It has been reported that macrocyclic complexes with a tetraazamacrocyclic ligand, such as cyclen, cyclam and bicyclam, exhibit antitumor or anti-HIV virus activity [19–23]. These potential and versatile applications are stimulating researchers to exploit new cyclen-based ligands and complexes with potential chemical, biological and catalytic properties.

In this paper we report the synthesis of a new cyclen-based ligand, with four neutral pendent groups at N sites, and its metal complexes. X-ray diffraction was used to determine the structure of $[Co(L)(NO_3)]NO_3 \cdot H_2O$ (**1**) and $[Cu(L)(H_2O)](NO_3)_2$ (**3**). Complexes **1**, **2** and **3** show antitumor activity against HL-60 and BEL-7404 tumor cell lines in vitro with MTT and SRB assays. Having found that these three complexes exhibited antitumor activity, we wanted to determine possible mechanisms for this behavior. In a study of the cell cycle, complex **3** was found to perturb the G_1 phase. In preliminary tests, complex **3** showed effective direct interaction on double strand DNA in the presence of a reductant. This result provided a rationale for the antitumor activity of these metal complexes in relation to DNA.

2. Results and discussion

2.1. Synthesis of ligand and complexes

The starting macrocyclic parent cyclen was synthesized according to the method reported by Atkins [24] and Bünzli [25] with improved yield by detosylation in 48% HBr–acetic acid. Although Weisman reported a new and simple synthetic route for cyclen, the initial material is not easily obtainable [26]. The new ligand L was synthesized conveniently via Michael addition according to Scheme 1.

N-alkylation with alkylating reagents, such as alkyl or aryl halide as nucleophile attacking reagents, are common in the synthesis of DOTA and TETA [27–29]. In our synthesis of a similar macrocyclic ligand, 1,4,7,10-tetrakisbenzyl-1,4,7,10-tetraazacyclododecane, benzyl chloride was used as the alkylating reagent. Even in the presence of a transphase catalyst, triethylbenzylammonium chloride, the yield was still not higher than 54% [30]. Accordingly, four neutral pendent cyanoethyl groups were easily introduced into the parent tetraazamacrocycle in high yield (86%) using Michael addition reaction with acrylonitrile as the alkylating reagent, which can make full use of the initial material cyclen. An excessive amount of acrylonitrile was used to produce tetrakisalkylated L to suppress the formation of mono-, di- or tri-substituted products, and L was further purified by recrystallization from $CHCl_3$–EtOH as white needles. This is a versatile route for the synthesis of similar neutral functionalized tetraazamacrocyclic ligands.

The new ligand was treated with 1 equiv. of divalent transitional metal ions in different solvents to produce 1:1 complexes. The results of elemental analysis (C, H, N) indicated stoichiometric formulas $[M(L)(NO_3)]NO_3 \cdot H_2O$ (M = Co, $n = 1$; M = Ni, $n = 3$) and $[M(L)(H_2O)](NO_3)_2$ (M = Cu, $n = 1$). Whether the nitrate ions coordinate with central metal ions can be revealed by the IR spectrum. The IR spectra of the nitrato complexes contain bands of both coordinated and ionic nitrates in complexes **1** and **2**. The bands around 1460 and 1320 cm^{-1} are due to ν(N=O) (ν_1) and $\nu_{asym}(NO_2)$ (ν_5), respectively, of the coordinated nitrate. The $\nu_{sym}(NO_2)$ vibration (ν_2) at 1030 cm^{-1} is characteristic of a bidentate chelating nitrate. The separation ($\Delta\nu$) of the nitrate stretching fundamentals ($\nu_1 - \nu_5$) has been used as a criterion to distinguish between mono- and bidentate chelating nitrates, increasing as the coordination changes from mono- to bidentate or bridging, The magnitude of this separation ($\Delta\nu = 153$ and $\Delta\nu = 132$ for Co and Ni complexes, respectively) is indicative of bidentate coordination of the nitrate ion [31]. The strong and sharp band around 1384 cm^{-1} is characteristic of ionic nitrate [32]. In complex **3**, only the characteristic band of ionic nitrate was observed at 1385 cm^{-1}. In all three complexes the broad and medium intensity band at ca. 3425 cm^{-1} is due to the symmetric and anti symmetric O–H stretching vibrations of lattice water. From the aforementioned IR data it can be concluded that there are two kinds of nitrate ion in complexes **1** and **2**, whereas only ionic nitrate ions exist in complex **3**. The X-ray diffraction results of Co (**1**) and Cu (**3**) substantiate this conclusion.

Scheme 1. Synthetic route for L and complexes **1**, **2** and **3**.

Molar conductance measurements were carried out in freshly prepared DMSO solution at 25°C and 10^{-3} mol l^{-1}. The values for these complexes are 96(1), 84(2) and 57(3) scm^{-1} mol^{-1}, respectively, all suggesting 1:1 electrolytes in the measuring solution [33].

2.2. Structure of complexes *1* and *3*

The crystal structures of complexes **1** and **3** were determined by X-ray diffraction, which supported the existence of ion pairs in these two complexes. An ORTEP drawing of the $[Co(L)(NO_3)]^+$ ion in complex **1** is shown in Fig. 1. The central Co atom coordinates with N(1), N(2), N(3), N(4),

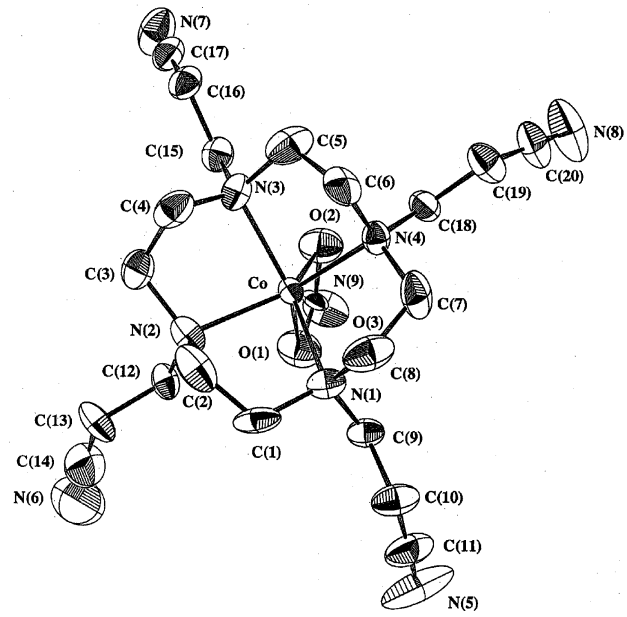

Fig. 1. Perspective view of the $[Co(L)(NO_3)]^+$ cation in **1** showing the atom labeling scheme. Thermal ellipsoids are drawn at 50% probability level. The hydrogen atoms are omitted for clarity.

O(1) and O(2) which define a distorted octahedral geometry. The teraazamacrocyclic ligand serves as a tetradentate ligand and the four pendent groups are not coordinated with the central metal atom. Two oxygen atoms of the nitrate ion coordinate to the cobalt atom bidentately. The equatorial basal nitrogen atoms (N(1), N(2), N(3) and N(4)) lie in one plane with mean deviation 0.0222 Å. The cobalt atom is displaced from this plane by −0.8411 Å. The Co, O(1), O(2), O(3) and N(9) atoms are coplanar with mean deviation 0.0039 Å. The dihedral angle between these two least-squares planes is 90.26°. Selected bond distances and angles are shown in Table 1.

In the cation $[Cu(L)(H_2O)]^{2+}$, complex **3**, the Cu atom coordinates to four nitrogen atoms of L and an aqua ligand, which define a tetragonal pyramid (Fig. 2). The nitrogen atoms are coplanar with mean deviation 0.0053 Å, and Cu deviates from this plane by 0.492 Å. Selected bond lengths and angles are shown in Table 1. Comparing the structure of both complexes, one nitrate ion lies in the coordination sphere of the Co atom in **1** as a bidendate ligand, but neither nitrate ion is bound to the Cu atom in **3**. The reason may be attributed to the fact that the ionic radius of Co is larger than that of Cu, which makes the Co coordination sphere less saturated and more accessible to an additional ligand. Thus Co tends to form a six-coordinated complex, whereas Cu easily forms a four or five-coordinated complex.

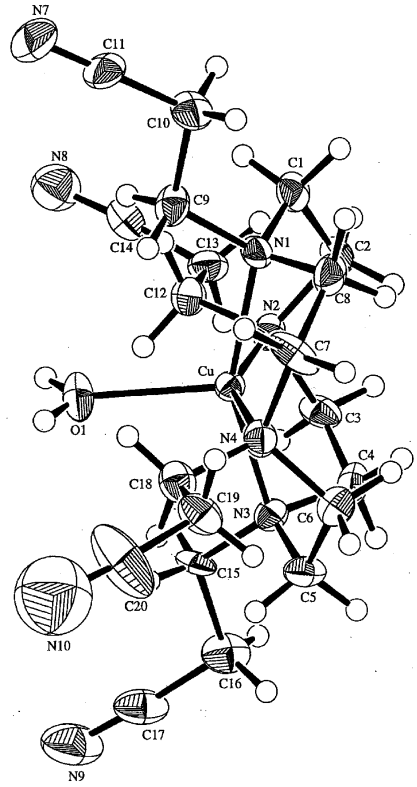

Fig. 2. Perspective view of the $[Cu(L)(H_2O)]^{2+}$ ion in **3** showing the atom labeling scheme. Thermal ellipsoids are drawn at 50% probability level. The hydrogen atoms are omitted for clarity.

3. Pharmaceutical results and discussion

3.1. Antitumor activity in vitro

All three complexes exhibited promising antitumor activity in vitro, especially against the BEL-7404 cell line. Even when the concentration of complexes was diluted to 10^{-8} mol l^{-1}, the antitumor activity could still be observed. Complexes **2** and **3** showed higher than 10% antitumor activity. The percentages of growth inhibition against HL-60 and BEL-7404 tumor cell lines are listed in Table 2. All complexes are effective at a concentration of 10^{-4} mol l^{-1} against HL-60 tumor cell lines. However, the antitumor activity decreased quickly to zero after the concentration of complexes was diluted to 10^{-6} mol l^{-1}.

3.2. Perturbation of K562 tumor cell cycle progression

The changes in cell cycle after exposing K562 tumor cell lines to two concentrations (10 and 50 μmol l^{-1}) for 24 h are shown in Fig. 3.

From Fig. 3, complex **3** caused a significant increase in the proportion of cells in the G_1 phase, from 26.57 to 40.45%. Accompanied by a decrease in the S phase, from 54.38 to 46.91%, a slight change was observed in the G_2–M phase at the same time, from 19.05 to 10.65 to 12.64%.

The results show that complex **3** regulated an important cell cycle-related mechanism: the progression of proliferating cells through the G_1 phase. This indicates that cells continue to undergo mitosis but cannot get past the G_1 phase into the S phase and fail to trigger DNA synthesis. Nevertheless, this possible explanation needs to be verified by further experiments.

Table 2
The percentage of growth inhibition data

Complex	Cell line						
	HL-60		BEL-7404				
	10^{-4}	10^{-5}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}
$[Co(L)(NO_3)]NO_3 \cdot H_2O$	94.7	86.0	100	97.8	31.9	5.5	4.4
$[Ni(L)(NO_3)]NO_3 \cdot 3H_2O$	93.0	57.0	96.7	95.6	19.8	7.7	14.3
$[Cu(L)H_2O](NO_3)_2$	42.1	0	63.3	15.6	78.0	5.6	10.0

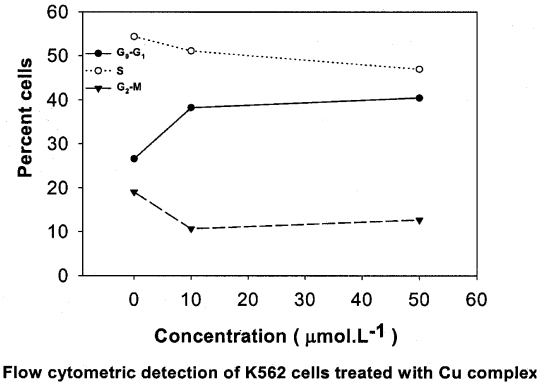

Fig. 3. The perturbation of the cell cycle by complex **3**.

3.3. Measurements of the interaction with pBR 322 DNA

In light of some reports [34–36] that these kinds of complexes can catalyze the hydrolysis of diphosphoresters under physiological conditions, which would effectively cleave DNA, we planned to investigate whether these complexes have direct interactions with DNA, so we treated them with supercoiled DNA. Fig. 4 shows the preliminary electrophoresis result of the interaction of Co complex **1** with pBR 322 DNA. Line 1 is the control group with DNA alone, and lines 2–4 are the measuring groups with concentration varying from 10^{-4} to 10^{-6} mol l^{-1}. From line 2 and line 4 it can be observed that the amount of nicked DNA increased, but supercoiled DNA still existed. The Co complex can only partially cleave double helix DNA to form nicked DNA. At a concentration of 10^{-5} mol l^{-1} the complex has no interaction with DNA.

Interestingly, we found that the Cu complex **3** can cleave supercoiled DNA to nicked and linear DNA at the same time. From Fig. 5 it can be observed that the circular supercoiled DNA is converted to nicked DNA via single-strand cleavage (lanes 2–4). With the increase in complex concentration, the supercoiled DNA decreased and was finally completely converted to nicked and linear DNA. In order to deduce the possible mechanism of this cleavage, we repeated the experiment in the presence of MPA (2-mercaptopropionic acid) as a reducing agent. Under this experimental condition, no linear DNA was formed as no apparent change was observed in lines 3–7 in Fig. 6. However, in line 6 the supercoiled DNA almost completely converted to nicked DNA. This result is similar to that found for the Cu–salen complex as chemical

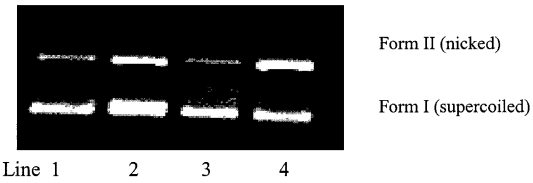

Fig. 4. Effect of Co (**1**) on supercoiled pBR 322 DNA after incubation for 2 h at 37°C. Line 1: control, DNA alone. Line 2: 100 μmol l^{-1} Co (**1**) + DNA. Line 3: 10 μmol l^{-1} Co (**1**) + DNA. Line 4: 1 μmol l^{-1} Co (**1**) + DNA. Forms I and II refer to the supercoiled double helix DNA and nicked DNA, respectively.

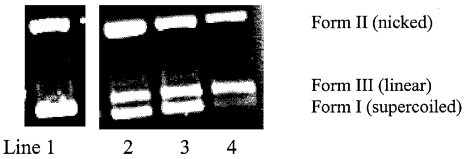

Fig. 5. Cleavage of pBR 322 DNA to nicked and linear DNA with Cu (**3**). Line 1: DNA alone. Line 2: 10 μmol l^{-1} Cu (**3**) + DNA. Line 3: 50 μmol l^{-1} Cu (**3**) + DNA. Line 4: 100 μmol l^{-1} Cu (**3**) + DNA.

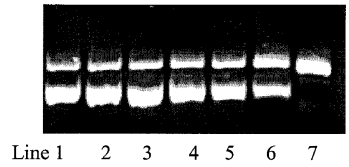

Fig. 6. Effect of Cu (**3**) on supercoiled pBR 322 DNA in the presence of MPA. Line 1: DNA alone. Line 2: MPA + DNA. Line 3: 10 μmol l^{-1} Cu (**3**) + DNA + MPA. Line 4: 20 μmol l^{-1} Cu (**3**) + DNA + MPA. Line 5: 40 μmol l^{-1} Cu (**3**) + DNA + MPA. Line 6: 100 μmol l^{-1} Cu (**3**) + DNA + MPA. Line 7: 500 μmol l^{-1} Cu (**3**) + DNA + MPA.

nuclease reported by Bailly and co-workers [37,38], who suggested that the reactive species in this cleavage were oxygen-based radicals. As pointed out by Sigman et al. [39], the four-coordinated Cu complex were more favorable for cleavage than the six-coordinated Co(II) complex, owing to its facilitative conformation. In many cases Cu(I) was the major active species. In our case, the experimental conditions are different, which means two different cleaving mechanisms may co-exist. Further work is in progress to elucidate the detailed mechanism of antitumor activity of these complexes.

4. Experimental

All reactions were carried out under nitrogen, using solvents which were distilled before use. Cyclen was synthesized

according to the literature. The synthetic route of L is shown in Scheme 1.

NMR spectra were obtained on a Varian GEMINI-300 instrument. IR spectra were recorded in the range 4000–400 cm^{-1} on a Perkin–Elmer 599B spectrometer, as KBr disk. Mass spectra were recorded on a Varian MAT-711 instrument. Microanalyses (C, H, and N) were performed with a Vario EL elemental analyzer.

4.1. Synthesis of ligand

4.1.1. Preparation of 1,4,7,10-tetraazacyclododecane

1,4,7,10-teraazacyclododecane was synthesized according to the scheme reported by Atkins and Bünzli without the isolation of the disodium salt of *N*,*N*′,*N*″-tris(*p*-tolylsulfonyl)diethylenetriamine, m.p. 124–125°C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 2.51 (s, 4H, NH), 2.10 (s,16H, CH_2). *Anal*. Found: C, 55.80; H, 11.72; N, 32.64. Calc. for $C_8H_{20}N_4$: C, 55.78; H, 11.70; N, 32.52%.

4.1.2. Preparation of 1,4,7,10-tetra(2-cycanoethyl)-1,4,7,10-tetraazacyclododecane

Cyclen (172 mg, 10 mmol) in 25 ml acrylonitrile was stirred at room temperature for 2 h then refluxed at 40°C for more than 4 h. The excessive acrylonitrile was removed in vacuo, and the oily residue was crystallized from 20 ml $CHCl_3$–EtOH (1:1) mixed solution. A white precipitate was collected by vacuum suction, and dried in vacuo with P_2O_5. Yield 330 mg, 86%, m.p.110°C. *Anal*. Found: C, 62.15; H, 8.60; N, 29.16. Calc. for $C_{20}H_{32}N_8$: C, 62.47; H, 8.34; N, 29.14%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 2.52 (t, $J_{H-H}=5$, 7, 8H, CH_2CN), 2.68 (s, 16H, NCH_2CH_2N), 2.76 (t, $J_{H-H}=6$, 8, 8H, NCH_2C). EI mass spectrum m/z (assignment, relative intensity): 384 (M^+, 8%), 330 ((M–$CH_2CH_2CN)^+$, 1%), 276 ((M–2$CH_2CH_2CN)^+$, 10%), 222 ((M–3$CH_2CH_2CN)^+$, 18%), 138 (N–$(NCH_2CH_2N)_3^+$, 100%), 53 ($CH_2CH_2CN^+$, 58%). IR spectrum (KBr pellet, cm^{-1}): 2956m, 2806s, 2245s, 1380s, 1097s, 1020s, 737m.

4.2. Synthesis of complexes

4.2.1. [Co(L)(NO_3)]$NO_3\cdot H_2O$ (1)

To the solution of L (96 mg, 0.25 mmol) in 5 ml CH_2Cl_2 was added dropwise $Co(NO_3)_2\cdot 6H_2O$ (73 mg, 0.25 mmol) in 15 ml CH_3OH. The reaction solution was stirred for 12 h at room temperature. Pink solids were filtered and washed with CH_2Cl_2–CH_3OH mixed solution until the filtrate was transparent. The pink solids deposited were dissolved in a minimum amount of water and layered with acetone to precipitate red crystals suitable for X-ray diffraction. Yield 122 mg, 83% (based on L), m.p. 250°C. *Anal*. Found: C, 41.32; H, 5.84; N, 24.16. Calc. for [Co(L)(NO_3)](NO_3)H_2O: C, 41.03; H, 5.85; N, 23.92%. EI mass spectrum m/z: 567 (M^+, Co(L)$(NO_3)_2$). IR (KBr pellet, cm^{-1}): 3438m, 3100m, 2930m, 2252m, 1512s, 1464s, 1385s, 1311s, 1064m, 748w, 594w.

4.2.2. [Ni(L)(NO_3)](NO_3)$\cdot 3H_2O$ (2)

To a solution of L (96 mg, 0.25 mmol) in ethanol was added hydrated $Ni(NO_3)_2\cdot 6H_2O$ (73 mg, 0.25 mmol) in 15 ml methanol. The color of the solution turned rapidly from light green to blue which indicated the occurrence of metal coordination. After filtration in vacuo, the light green solid was washed repeatedly with CH_2Cl_2 and CH_3OH, and then dried under IR light. Yield 133 mg, 86% (based on L), m.p. 232°C. *Anal*. Found: C, 38.32; H, 6.05; N, 22.85. Calc. for [Ni(L)(NO_3)](NO_3)$\cdot 3H_2O$: C, 38.67; H, 6.16; N, 22.54%. FAB mass spectrum m/z: 443 $[L+Ni]^+$, 409 $[L+Na+2H]^+$. IR (KBr pellet, cm^{-1}): 3438(br, m), 3100w, 2950w, 2253m, 1612w, 1512s, 1450m, 1385s, 1318m, 1261s, 1022m, 748w, 594w.

4.2.3. [Cu(L)(H_2O)](NO_3)$_2$ (3)

To a solution of L (192 mg, 0.5 mmol) in 20 ml ethanol was added $Cu(NO_3)_2\cdot H_2O$ (120 mg, 0.5 mmol) and 10 ml ethanol. A blue precipitate formed quickly and the reaction mixture was stirred at room temperature for 12 h. After filtration, the solid complex was washed with CH_2Cl_2 and ether and dried at 50°C for 24 h. Yield 250 mg, 86% (based on L). Crystals suitable for X-ray diffraction were obtained by slow ether diffusion into DMF solution at room temperature, m.p. 240°C. *Anal*. Found: C, 41.21; H, 5.72; N, 24.05. Calc. for [Cu(L)]$(NO_3)_2\cdot H_2O$: C, 41.34; H, 5.72; N, 24.10%. IR (KBr pellet, cm^{-1}): 3345m, 3100w, 2964m, 2253m, 1612w, 1512s, 1465m, 1385s, 1260s, 748w, 596w.

4.3. Crystallography

Crystal data for **1** were measured on an Enraf-Nonius CAD-4 diffractometer equipped with Mo Kα radiation ($\lambda=0.71073$ Å) in the range $3<2\theta<54°$ in $\omega/2\theta$ scanning mode at room temperature (295 K) [40]. The data were corrected for Lorentz and polarization effects, and an absorption correction with empirical scanning technique was applied. Reflections with $I>3\sigma(I)$ were considered to be observed and were used in the following refinements. The structure was solved by direct methods [41–43]. All calculations were performed on a macro VAX 3100 computer with TEXSAN V2.0 package. The non-hydrogen atoms were determined with successive Fourier difference syntheses. The final refinement was done by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms ($w=1/[\sigma^2(F)+0.001F^2]$). The coordinates of hydrogen atoms were located according to theoretical models [44,45].

Crystal data for **3** were collected on a Rigaku AFC 7R diffractometer with graphite-monochromated Mo Kα radiation ($\lambda=0.071069$ Å) using the $\omega/2\theta$ mode at 20°C to a maximum 2θ value of 50.0°. An empirical correction, applied using the program DIFABS [46], resulted in correction factors ranging from 0.89 to 1.00. The structure was solved by direct methods [47] and expanded using Fourier techniques [48]. Some non-hydrogen atoms were refined anisotropi-

cally, while the rest were refined isotropically. All hydrogen atoms were introduced in calculated positions. All calculations were performed using the TEXSAN crystallographic software package [49]. Details of data collection and structure refinement are listed in Table 3.

4.4. Cytotoxicity for tumor cells

Three complexes were tested versus two tumor cell lines: HL-60 (human lymphocytic leukemia) and BEL-7404 (human hepatocellular carcinoma). All tumor cells were cultivated in RPMI-1640 medium supplemented with 10% calf serum, 100 units ml^{-1} of penicillin, and 100 μg ml^{-1} of streptomycin. Cells were harvested from exponential-phase maintenance cultures, counted by trypan blue extrusion, and dispensed within 96-well culture plates. Non-adherent cells (HL-60) were added to the complexes after distribution and were measured by MTT assay [50]. Adherent tumor cells (BEL-7404) were allowed to adhere for 24 h before addition of complexes and were measured by SRB assay [51]. The duration of exposure of all tumor cells to complexes was 72 h. Cell inhibition was expressed in terms of the percentage of control absorbance ($\pm$1% SD%) following subtraction of mean blank absorbance in the concentration range 10^{-4}–10^{-8} mol l^{-1}. The percentages of growth inhibition data of three complexes are shown in Table 2.

4.5. Analysis of cell cycle

K562 leukemia cells, 3×10^6, were exposed to complex **3** at concentrations of 0, 10 and 50 μmol l^{-1} for 24 h. Cells were then fixed by 70% ethanol (v/v), washed twice in phosphate-buffered saline solution (PBS) and stained with PBS containing 10 μg ml^{-1} propidium iodide (PI) for 30 min at room temperature in the dark. For each sample, a minimum of 10^4 cells were analyzed by flow cytometry (FACSalibur, Becton Dickinson, USA). Results were analyzed using CELLQUEST and ModFIT for mac V1.01 (Becton Dickinson, USA) and expressed as the percentage of cells found in each phase of the cell cycle.

4.6. DNA electrophoresis

Each reaction mixture contained 4 μl of supercoiled pBR322 DNA, 5 μl of the tested complex at the desired concentration and 2 μl DMSO as solvent. In the case of Cu (**3**), 2 μl MPA (2.5 mmol l^{-1}) was added as reducing reagent. After incubation at 37°C for 2 h, 1 μl of loading buffer (0.25% bromophol blue, 0.25% xylene cyanol, 30% glycerol in H_2O) was added to each tube and the mixed solution was loaded on 1% agarose gel. The electrophoresis was carried out for 2 h at 50 V in TBE buffer (89 mM tris-borate, pH 8.3, 1 mmol l^{-1} EDTA). Gels were stained with ethidium bromide (1 μg ml^{-1}) for 30 min prior to being photographed under UV light. Figs. 5 and 6 give the electrophoresis results of DNA cleavage on agarose gel.

Table 3
Crystallographic data for $[Co(L)(NO_3)](NO_3)_2\cdot H_2O$ (**1**) and $[Cu(L)(H_2O)](NO_3)_2$ (**3**)

	1	**3**

Received 2 August 1999; accepted 18 November 1999

Abstract

The new complex $[Ni(en)_2(NO_2)_2]NaClO_4 \cdot H_2O$ (**1**), where en is ethylenediamine, has been synthesised and characterised crystallographically. Each nickel atom is placed in a pseudo-octahedral environment with two nitrite groups and two diamines. Between these $[Ni(en)_2(NO_2)_2]$ units, there are sodium and perchlorate ions, and one water molecule. Magnetic susceptibility data, measured from 4 to 120 K, show non-interaction between the metals, as is usual in mononuclear compounds following the Curie law. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Nickel(II); Mononuclear compounds; Crystal structures; Nitrito ligands; Magnetic measurements

1. Introduction

The nitrite ion can coordinate to metal ions in a variety of ways. Monodentate coordination may occur either through nitrogen to give a nitro complex or through oxygen to give a nitrito complex. Bidentate coordination is known to take place either by chelation or by forming a bridge [1]. For this reason, there is a great variety of polynuclear complexes, such as dinuclear [2,3], trinuclear [2,4], pentanuclear [5], heptanuclear [6] and one-dimensional complexes [7–11].

Focusing our attention on ethylenediamine (en), different complexes have been obtained [1,3,5,7,10,12–15] under specific experimental conditions. Our aim is to study the conditions necessary to form dinuclear or polynuclear rather than mononuclear compounds. Unfortunately, this cannot always be achieved.

We present here the synthesis used to obtain a polynuclear complex, but following which only a mononuclear compound was formed. This mononuclear compound is interesting and different from other mononuclear compounds [12–15] because it presents different octahedral units of Ni(II) and Na linked to each other in a sheet. Usually mononuclear compounds have been obtained showing two different formulae: (a) a neutral complex $[Ni(amine)_2(NO_2)_2]$ with two terminal nitrite ligands and (b) a cationic complex $[Ni(amine)_2(NO_2)]X$ with a chelate nitrite ligand. In the present case, the Ni(II) units are neutral, but the complex shows the novelty of cocrystallising with sodium perchlorate. So **1** has been obtained in a fortuitous way.

This new compound $[Ni(en)_2(NO_2)_2]NaClO_4 \cdot H_2O$ (**1**), where (en) is ethylenediamine, has been characterised by its crystal structure and magnetic measurements, as well as IR spectra and elemental analysis.

2. Experimental

Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of material should be prepared and it should be handled with care.

2.1. Synthesis of $[Ni(en)_2(NO_2)_2]NaClO_4 \cdot H_2O$

4 mmol of ethylenediamine (en) dissolved in 10 ml of water were added with stirring to an aqueous solution (20 ml) of 4 mmol of nickel(II) perchlorate hexahydrate. 2 mmol of sodium nitrite in 5 ml of water were added to the green solution formed. Slow evaporation of the resulting solution

PII S0277-5387(99)00370-8

gave red planar crystals of **1** several days later. *Anal*. Calc. for $C_4H_{18}ClN_6NaNiO_9$: C, 11.7; H, 4.4; Cl, 8.6; N, 20.4. Found: C, 11.4; H, 4.2; Cl, 8.5; N, 20.0%. Yield 62%.

2.2. Spectral and magnetic measurements

The IR spectrum (4000–400 cm^{-1}) was recorded from KBr pellets on a Nicolet 520 FTIR spectrophotometer. Magnetic measurement of a polycrystalline sample was carried out on a MANICS-DSM8 susceptometer equipped with an Oxford Instruments liquid helium cryostat, working in the temperature range 4–120 K, and a Bruker E15 magnet. The magnetic field was approximately 16000 G. Diamagnetic corrections were estimated from the Pascal tables.

2.3. Crystallography

$[Ni(en)_2(NO_2)_2]NaClO_4 \cdot H_2O$ (**1**). A prismatic crystal ($0.1 \times 0.1 \times 0.2$ mm) was selected and mounted on an Enraf-Nonius CAD4 four-circle diffractometer. The crystallographic data, conditions retained for the intensity data collection, and some features of the structure refinement are listed in Table 1. Unit-cell parameters were determined from the automatic centring of 25 reflections ($12 < \theta < 21°$) and refined by the least-squares method. Intensities were collected with graphite monochromatized Mo Kα radiation, using the $\omega/2\theta$ scan-technique. 2778 reflections were measured in the range $2.22 < \theta < 29.96°$. 2022 reflections were assumed as observed, applying the condition $I > 2\sigma(I)$. Three reflections were measured every 2 h as orientation and intensity control; significant intensity decay was not observed. Lorentz polarisation but not absorption corrections were made. The structure was solved by direct methods, using the SHELXS computer program [16] and refined by the full-matrix least-squares method with the SHELX93 computer program [17], using 2563 reflections. The function minimised was $\Sigma w(|F_o|^2 - |F_c|^2)^2$, where $w = [\sigma^2(I) + (0.0397P)^2]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$, f, f' and f'' were taken from international tables [18]. The extinction coefficient was 0.0000(11). All H atoms were computed and refined with an overall isotropic temperature factor using a riding model. The final $R(F)$ factor was 0.043, $wR(|F|^2) = 0.089$ and goodness of fit was 1.050 for all observed reflections. The number of refined parameters was 204. The maximum shift/esd was 0.001; the mean shift/esd was 0.07. Maximum and minimum peaks in final difference synthesis were 0.609 and -0.506 e $Å^{-3}$, respectively.

3. Results and discussion

3.1. IR data

The IR spectrum shows the characteristic bands attributable to the ligands. The nitrite ligand has three vibrational modes: $\nu_{N=O}$ appears at 1273, 1215 cm^{-1} (m), ν_{N-O} at 1326 cm^{-1} (m), and δ at 827 cm^{-1} (w). The bands attributable to (en) appear in the characteristic zone for each vibration: at about 3200 cm^{-1} (N–H); in a wide range between 3000 and 2870 cm^{-1} (C–H); and finally at about 1450 cm^{-1} (C–N). The perchlorate ion shows two main bands centred at 1130 and 625 cm^{-1}.

3.2. Description of the structure

The complex crystallises in the monoclinic system, space group $P2_1/n$ with FW = 411.39, $a = 9.199(2)$, $b = 13.504(5)$, $c = 13.191(9)$ Å, $V = 1552.8(13)$ Å^3, $Z = 4$, $R = 0.0438$, $R_w = 0.0897$. The structure of **1** has three units: two different crystallographic $[Ni(en)_2(NO_2)_2]$ units and another in which there is a sodium ion linked to six oxygens, four from nitrito ligands, one from a perchlorate anion and the other from a water molecule. Each nitrite is coordinated to the Ni(II) by the nitrogen atom, and to the sodium ion by its oxygen. A labelled scheme is shown in Fig. 1. The main bond lengths and angles are gathered in Table 2. We can describe the structure by considering the three units. There are two different pseudo-octahedrally coordinated nickel atoms, with the same environment but different bond parameters. The distance between the nickel atoms is 6.740 Å. The two different nitrito groups are in *trans* arrangement. The Ni–N(diamine) distances are between 2.084 and 2.093 Å. The distances corresponding to Ni–N(nitrite) are 2.133(3) and 2.153(3) Å for Ni(1)–N(3) and Ni(2)–N(6), respectively. The N–Ni–N angles in *trans* arrangement are always 180°, and in *cis* arrangement they are almost 90°; the N(diamine)–Ni–N(diamine) angle is the smallest (82.57°) for the unit with Ni(1), and the largest (97.43°) for the other. The rings formed by diamine with Ni(II) for the unit with Ni(1) form a plane, and with Ni(2) they show a skew-

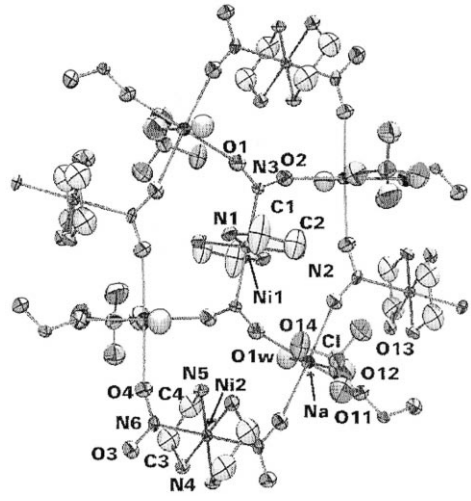

Fig. 1. ORTEP drawing with labelled scheme of $[Ni(en)_2(NO_2)_2]$-$NaClO_4 \cdot H_2O$.

envelope conformation. The chelate ring around Ni(1) is disordered because of the great thermal motion of the C(1) atom. Turning to the unit with the sodium ion, the distances Na–O range from 2.384 to 2.420 Å (oxygen from nitrite and water) whereas the oxygen from the perchlorate ion is at the greatest distance (2.515 Å). The O–Na–O angles in *trans* arrangement are between 170.09 and 177.82°. The same angles in *cis* arrangement are different from 90°, ranging from 79.35 to 96.35°. Each Ni(II) has four nickel atoms in its neighbourhood and four sodium atoms in the next neighbourhood. In the same way, each Na has four different sodium atoms in its neighbourhood and then four nickel atoms. The different entities that form this compound are linked by weak hydrogen bonds, between the nitrogen of (en) and the oxygen of nitrito ligand and perchlorate ion. The orientations of the two $[Ni(en)_2(NO_2)_2]$ units are different: the unit with Ni(1) (Fig. 2) follows the crystallographic [101] axis and the unit

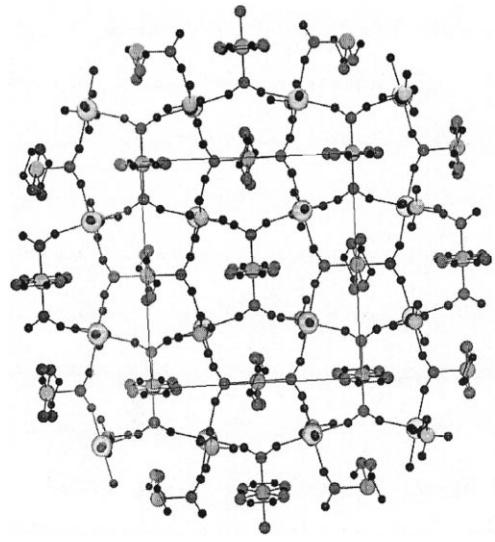

Fig. 2. Ionic sheet with the different units of $[Ni(en)_2(NO_2)_2]$-$NaClO_4 \cdot H_2O$.

with Ni(2) follows the *a* axis. In the (010) plane there are $[Ni(en)_2(NO_2)_2]$ and sodium units alternately.

3.3. Magnetic results

The magnetic susceptibility measurements were carried out in the temperature range 4–120 K. The $\chi_M T$ versus T, χ_M versus T and χ_M^{-1} versus T plots for **1** are shown in Fig. 3. The room temperature $\chi_M T$ value was 1.09 cm^3 K mol^{-1} corresponding to an isolated nickel atom with $g > 2.00$ and was practically constant in the temperature range analysed to 40 K, in which $\chi_M T$ increases to 1.445 cm^3 K mol^{-1} at 5 K. This compound exhibits a quasi-Curie law behaviour with a slight increase after 40 K. This increase in $\chi_M T$ is caused by weak ferromagnetic interactions between the different units of nickel through the sodium cations in the crystal net.

In order to quantify the magnetic behaviour, the experimental data χ_M versus T were fitted to the expression [19] for an isolated nickel ion with ferromagnetic intermolecular interactions:

$$\chi_M = \frac{2Ng^2\mu_\beta^2 S(S+1)}{3kT - zJS(S+1)}$$

where

$$\frac{zJS(S+1)}{3k} = \theta$$

The results of this fit show that the interaction between the different units is very weak. To verify this, we extrapolated the χ_M^{-1} versus T data. As the θ found is positive ($-\theta/C = -2.24$ cm^{-3} mol), we can conclude that the intermolecular interactions are ferromagnetic.

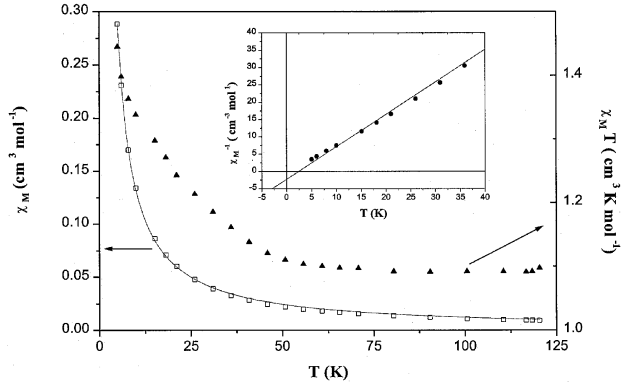

Fig. 3. $\chi_M T$, χ_M and χ_M^{-1} (insert) vs. T plots in the temperature range 4–120 K of a polycrystalline sample of **1**. The solid line corresponds to the best fit.

Supplementary data

Refined atom coordinates, calculated hydrogen coordinates ($\times 10^4$) and anisotropic displacement parameters for non-hydrogen atoms (Å$\times 10^3$) are included in the supplementary material. Observed and calculated structural factors are available on request. Supplementary material has been deposited at the Cambridge Crystallographic Data Centre as publication number CCDC 132682.

Interaction of nitric oxide with cobalt(II) tetrasulfophthalocyanine

Sibulelo Vilakazi, Tebello Nyokong *

Department of Chemistry, Rhodes University, Grahamstown 6140, South Africa

Received 18 August 1999; accepted 30 November 1999

Abstract

The interaction of nitric oxide (NO) with cobalt(II) tetrasulfophthalocyanine [Co(II)TSPc]$^{4-}$ has been studied. Coordination of NO is accompanied by electron transfer from the central metal in [Co(II)TSPc]$^{4-}$, the resulting complex being represented as [(NO$^-$)Co(III)TSPc]$^{4-}$. The rate constant for the formation of this species is $k_f = 142 \pm 7$ dm^3 mol^{-1} s^{-1} and an equilibrium constant of $3.0 \pm 0.5 \times 10^5$ dm^3 mol^{-1} was obtained. When adsorbed to a glassy carbon electrode, [Co(II)TSPc]$^{4-}$ catalyses the oxidation and reduction of NO, with a detection limit of the order of 10^{-9} mol dm^{-3}. Ammonia and hydroxylamine are some of the reduction products obtained for the reduction of NO on [Co(II)TSPc]$^{4-}$-modified glassy carbon electrodes. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Interest in the chemistry of nitric oxide (NO) has intensified in the last few years due to its importance in biological systems including neurotransmission, vascular dilation, cytotoxicity, immune response and regulation of blood pressure [1,2]. Excess concentrations of NO have been implicated as a major factor in a number of conditions, such as septic shock, and Parkinson's and Alzheimer's diseases [3,4]. There has been a surge of interest in the nature of coordination of NO to metalloporphyrins [4–13]. NO interacts with hemoglobin, myoglobin and cytochrome P450 forming NO compounds [14]. NO has a short half-life (depending on the concentration of oxygen) and has high reactivity with oxygen and hydrogen peroxide [1]. Current methods of detecting NO are indirect, relying on the measurement of secondary species such as nitrite and nitrate after removal from biological systems. Measurement of NO using bioassay, chemiluminescence and UV–Vis spectroscopy do not allow for in vivo detection, and require chemical pretreatment of the sample. Thus there is a growing interest in electrochemical sensors for analysis of NO in cells [15–18], based on its electrocatalytic oxidation. Nickel(II) and iron(II) porphyrin complexes and unmetallated porphyrin have been employed in modifying electrodes for the detection of NO [19–27]. The mechanism for the catalytic oxidation of NO by metalloporphyrins is not well understood. For example, the Ni(III)/Ni(II) couple has been implicated in NO determination using electrodes modified with nickel(II) porphyrin complexes [19,20], but other researchers have reported that the Ni(III)/Ni(II) couple plays no role in the electrocatalytic oxidation of NO [25].

Metallophthalocyanine (MPc) complexes have been used successfully as electrocatalysts for many reactions [28–36]. There are only a few reports on the interaction between NO and MPc complexes [37–42]. The use of MPc complexes for the electrocatalytic reduction or oxidation of NO still needs to be explored. It has recently been suggested that [CoTSPc]$^{4-}$ bound to immobilized imidazole-modified silica gel can be used as a water-soluble NO sorbent that does not dimerize, and hence can be used for the removal of NO from flue gas streams [37]. The present study explores the electrocatalytic oxidation and reduction of NO on glassy carbon electrodes modified with cobalt(II) tetrasulfophthalocyanine ([CoTSPc]$^{4-}$; Fig. 1). We also report on the kinetics and equilibria for the interaction between NO and [CoTSPc]$^{4-}$.

2. Experimental

2.1. Materials

Cobalt(II) tetrasulfophthalocyanine (Na_4[Co(II)TSPc]) was synthesized and purified according to the method of

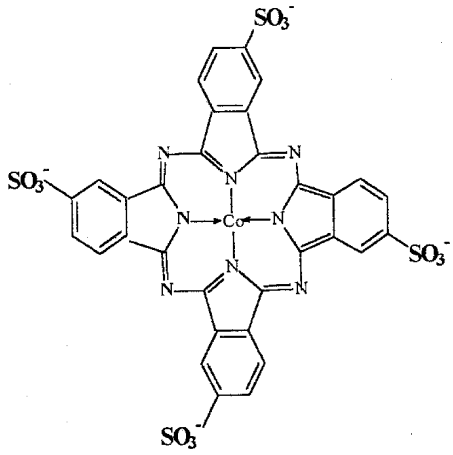

Fig. 1. Molecular structure of cobalt(II) tetrasulfophthalocyanines.

Weber and Busch [43]. NO was prepared by adding saturated sodium nitrite dropwise to a 0.2 mol dm^{-3} solution of H_2SO_4 under nitrogen atmosphere. The NO produced was passed through a column containing solid KOH to remove higher oxides and then bubbled into nitrogen-saturated deionized water. NO solutions in water were prepared freshly before use and kept in glass flasks fitted with a rubber septum. NO concentration in water was determined using the method proposed by Ascenzi et al. [38] or calculated using the reported solubility of 2.2×10^{-3} mol dm^{-3} at 25°C and 1.00 atm [38]. Tetraethylammonium perchlorate (TEAP) was recrystallized from ethanol before use as an electrolyte. Dimethylformamine (DMF) was freshly distilled.

2.2. Electrochemical methods

Electrochemical data were collected with the Bio-Analytical Systems (BAS) model CV-50W voltammetric analyser. For cyclic voltammetry, a glassy carbon electrode (GCE; 3.0 mm diameter) was used as a working electrode and a platinum wire as an auxiliary electrode. The reference electrode was the Ag|AgCl (3 mol dm^{-3} KCl). Concentrations of Na_4[Co(II)TSPc] in water were in the 10^{-4} to 10^{-3} mol dm^{-3} range for cyclic voltammetry. Phosphate buffers pH 4 and 7 were employed for electrochemical experiments. In some experiments sodium sulfate (0.05 mol dm^{-3}) was employed as an electrolyte. For non-aqueous solutions TEAP was employed as an electrolyte.

For electrocatalytic reactions, a glassy carbon electrode modified with Na_4[Co(II)TSPc] (CoTSPc-GCE) was employed as a working electrode. The glassy carbon was modified by anodic electrodeposition from a 10^{-3} mol dm^{-3} solution of $[CoTSPc]^{4-}$ in DMF containing 0.1 mol dm^{-3} TEAP as an electrolyte, as reported before [44]. The deposition was carried out by scanning repetitively at 100 mV s^{-1} between −0.2 and 1.0 V versus Ag|AgCl (non-aqueous). Prior to coating, the GCE was polished with alumina on a Buehler felt pad, followed by soaking in dilute nitric acid and rinsing in water, acetone and the solvent of interest. For bulk electrolysis, a two-compartment cell was employed, with a platinum plate of area 2.2 cm^2 as counter electrode and an Ag|AgCl (3 mol dm^{-3} KCl) reference electrode. The GCE modified by electrodeposition was used as a working electrode for bulk electrolysis. A nitrogen atmosphere was maintained for all electrochemistry experiments. Concentrations of NO were of the order of 10^{-4} to 10^{-3} mol dm^{-3} for electrocatalytic studies. Yields of ammonia were determined by the Nessler method [45] and by monitoring the absorbance at 400 nm. Hydroxylamine was determined spectroscopically using the specific test described in the literature [9].

2.3. Kinetics and equilibria

Kinetic and equilibrium studies were run at 21.0 ± 0.5°C and monitored with a Cary 1E UV–Vis spectrophotometer. We monitored the appearance of the spectra due to the product formed following the addition of NO to solutions of $[CoTSPc]^{4-}$ in water. Typically, a known volume of the aqueous solution of $[CoTSPc]^{4-}$ was added to a cell of 1 cm pathlength and deaerated using nitrogen. Then a known volume of a deaerated aqueous solution of NO was added to the cell and the spectra monitored with time. Bubbling of nitrogen into the cell was continued while adding the NO solution. The cell was fitted with a stopper to avoid oxygen affecting the reaction. Concentrations of $[CoTSPc]^{4-}$ were kept constant at 5.0×10^{-6} mol dm^{-3}, whereas NO concentrations were varied from 1.4×10^{-5} to 5.6×10^{-5} mol dm^{-3}. Concentrations of $[CoTSPc]^{4-}$ in water were determined using the published extinction coefficient of 5.8×10^4 mol^{-1} dm^3 cm^{-1} [46]. Since the concentration of the NO was larger than that of $[CoTSPc]^{4-}$ by a factor of at least 10, pseudo-first-order conditions were assumed for kinetic studies. Solid CoTSPc-NO was prepared by bubbling NO into aqueous solutions of $[CoTSPc]^{4-}$ and allowing the solvent to evaporate.

IR spectra were recorded using a Perkin–Elmer Spectrum 2000 IR spectrophotometer.

3. Results and discussion

3.1. Interactions with NO

The electronic absorption spectral properties of $[CoTSPc]^{4-}$ are well known. Like other tetrasulfonated phthalocyanines, this species forms aggregates in aqueous solution. The electronic absorption spectrum is explained in terms of the monomer/dimer equilibrium. The lower energy band near 670 nm has been attributed to the monomeric species and the higher energy band near 620 to the dimeric species [46]. On coordination of molecules such as nitrite and histidine, the peak due to the monomer increases in intensity and shifts to longer wavelengths, whereas the peak due to the dimeric species decreases in intensity [47,48]. Fig. 2 shows spectral changes that were observed when NO was added to solutions

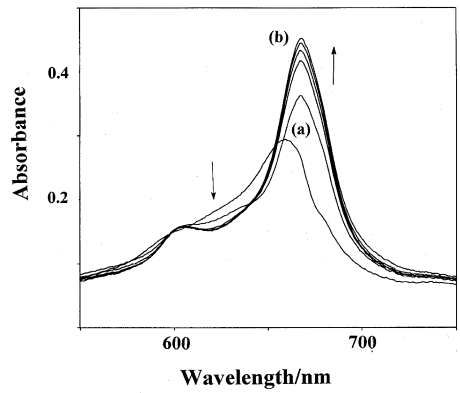

Fig. 2. Electronic absorption spectral changes observed on addition of NO (3.5×10^{-5} mol dm^{-3}) to aqueous solutions of [Co(II)TSPc]$^{4-}$. (a) Spectra immediately after addition of NO; (b) spectra 30 min after addition of NO.

of [Co(II)TSPc]$^{4-}$. The monomeric peak of [CoTSPc]$^{4-}$ was observed at 659 nm before addition of NO (Fig. 2a). The spectrum is typical for [CoTSPc]$^{4-}$ in water, at low electrolyte concentrations; the peak due to the monomer dominates under these conditions [46]. On addition of NO to [Co(II)TSPc]$^{4-}$, a shift in the peak due to the monomer, from 659 to 667 nm, was observed. The intensity of the peak at 667 nm increased isosbestically with time (Fig. 2b). The shift in spectrum is associated with the coordination of NO to the [CoTSPc]$^{4-}$ species. A shift and increase in the monomeric peak of the [CoTSPc]$^{4-}$ species on coordination of histidine and nitrite have been reported [47,48]. An increase and shifting of the monomer peak of [CoTSPc]$^{4-}$ was also observed upon formation of an adduct between this species and oxygen. Oxygen was carefully excluded from the solutions containing NO and [CoTSPc]$^{4-}$ and no spectral changes were observed for [CoTSPc]$^{4-}$ in the absence of NO. Thus the spectral changes shown in Fig. 2 are associated with the formation of an adduct between NO and [CoTSPc]$^{4-}$.

X-ray photoelectron spectroscopy studies have indicated oxidation of the central metal in FePc and CoPc when the complexes are exposed to NO [41]. Electron transfer from Ni(II) to NO has also been implicated during coordination of NO to [Ni(II)TSPc]$^{4-}$, resulting in the formation of the [(NO$^-$)Ni(III)TSPc]$^{4-}$ species [39]. Oxidation of Co(II)Pc to a Co(III)Pc species was also implicated on interaction of NO with CoPc [42]. We suggest that oxidation of the central metal also occurs on coordination of NO to the [CoTSPc]$^{4-}$ species, forming a Co(III)TSPc-NO complex. Oxidation of [CoTSPc]$^{4-}$ using chemical oxidants (e.g. bromine) resulted in the spectrum similar to that shown in Fig. 2b. The lack of an isosbestic point with the spectra of the starting complex in Fig. 2 is most likely a result of the two processes, coordination of NO to [CoTSPc]$^{4-}$ and the subsequent electron transfer between the two molecules, occurring simultaneously.

In nitrosyl complexes, ν(NO) ranges from 1500 to 1900 cm^{-1}. ν(NO) for cobalt tetrakis(*N*-methyl-2-pyridyl)-porphine [Co(2-TMpyP)(NO)] was observed at 1722 cm^{-1} [9] and for CoPc(NO) at 1680 cm^{-1} [42]. IR spectra of the solid formed by reacting [Co(II)TSPc]$^{4-}$ with NO showed a new band at 1730 cm^{-1}, in the range for coordinated NO. This value is higher than those reported for NO coordinated to cobalt porphyrins. Generally oxidized cobalt porphyrin complexes show ν(NO) values at higher frequencies than neutral complexes [12]. Thus the higher ν(NO) values for the (NO)CoTSPc complex could be a consequence of the oxidation of [Co(II)TSPc]$^{4-}$ to [Co(III)TSPc]$^{3-}$ following coordination of NO. As mentioned above, oxidation of [Ni(II)TSPc]$^{4-}$ to [Ni(III)TSPc]$^{3-}$ following coordination of NO has been observed. The IR spectra of the Ni(III)TSPc(NO$^-$) complex showed ν(NO) at 1660 cm^{-1} [39], much lower than the value reported here for the Co(III)TsPc(NO) complex. Vibrational frequencies of NO greater than 1700 cm^{-1} have been associated with linear geometry of M–N=O and those of lower frequency to a bent geometry [39]. The observation of ν(NO) at 1730 cm^{-1} suggests a bent geometry for the Co–NO bond in the CoTSPc(NO) complex. Oxidation of NO to NO_2^- is likely following its coordination to CoTSPc. NO_2^- stretching frequencies were observed at 1401, 1306 and 830 cm^{-1} in Co(III)2-TMpyP(NO). We did not observe new IR bands in this region for the CoTSpc(NO) complex.

The coordination of NO to [Co(II)TSPc]$^{4-}$ can be represented by Eq. (1):

$$[\mathrm{Co(II)TSPc}]^{4-} + \mathrm{NO} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} [(\mathrm{NO}^-)\mathrm{Co(III)TSPc}]^{4-} \quad (1)$$

The number of NO molecules coordinated to the [Co(II)TSPc]$^{4-}$ species was determined using the standard equation [37,42]:

$$\log\left[\frac{A_{eq}-A_0}{A_\infty - A_{eq}}\right] = \log K + n\log[\mathrm{NO}] \quad (2)$$

where A_{eq} is the equilibrium absorbance at 667 nm, A_0 is the absorbance before addition of NO; A_∞, the absorbance after complete formation of the [(NO$^-$)Co(III)TSPc]$^{4-}$ complex, was determined from the final absorbance at 667 nm. Fig. 3a shows a plot of $\log[(A_{eq}-A_0)/(A_\infty - A_{eq})]$ versus log[NO]. A linear plot with a slope $n = 0.97 \pm 0.07$ was obtained, showing that only one molecule of NO is coordinated. The equilibrium constant (K) was determined from the intercept to be $3.0 \pm 0.5 \times 10^5$ dm^3 mol^{-1}.

Plots of the observed rate constant (k_{obs}) versus the concentration of NO were linear (Fig. 3b), showing that the coordination is first-order in NO and obeys the rate law:

$$k_{obs} = k_f[\mathrm{NO}] + k_r \quad (3)$$

where k_f is the rate constant for the formation of the [(NO$^-$)Co(III)TSPc]$^{4-}$ species according to Eq. (1) and k_r is the dissociation of this complex. Least-square analysis of the data presented in Fig. 3b gave $k_f = 142 \pm 7$ dm^3 mol^{-1} s^{-1} from the slope, and $k_r = 5.4 \pm 0.8 \times 10^{-4}$ s^{-1} was

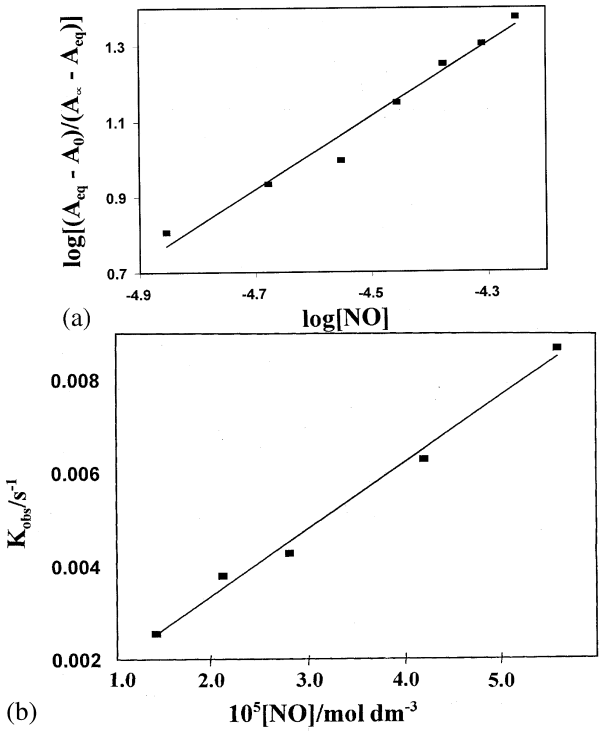

Fig. 3. (a) Plot of $\log[(A_{eq}-A_0)/(A_\infty-A_{eq})]$ vs. log[NO]. (b) Plot of the observed rate constant (k_{obs}) vs. the concentration of NO, for the formation of $[(NO)^-Co(III)TSPc]^{4-}$ species.

obtained from the intercept. Using these values of rate constants, the value of the equilibrium constant for NO coordination to $[Co(II)TSPc]^{4-}$ was estimated to be $K_1 = 2.6\times10^5$ dm^3 mol^{-1} from the relationship $K_1 = k_f/k_r$, which is in excellent agreement, within experimental error, with the value determined above from the equilibrium data.

Table 1 compares the values of the rate constant for the coordination of NO to $[Co(II)TSPc]^{4-}$ with the values for its coordination to iron(II) porphyrin, metmyoglobin and hemoglobin. The values for the coordination of NO to the latter three molecules is much higher than the value for the coordination to $[Co(II)TSPc]^{4-}$. A low rate constant was also reported for the coordination of NO to manganese porphyrin complexes [11]. Axial ligand exchange reactions occur more slowly for CoPc than for FePc complexes [49]. The equilibrium constant for the coordination of NO to $[Co(II)TSPc]^{4-}$ was, however, much larger than for coordination of NO to the Fe(II) porphyrin, metmyoglobin and hemoglobin complexes (Table 1).

3.2. Electrocatalysis

Typical cyclic voltammograms for the reduction of NO on an unmodified GCE and on a GCE modified with $[Co(II)TSPc]^{4-}$ are shown in Fig. 4. On CoTSPc-GCE, a catalytic peak was observed at -0.96 V versus Ag|AgCl for the reduction of NO (Fig. 4b). The voltammogram for the reduction of NO on unmodified GCE is shown in Fig. 4a. The cyclic voltammogram of the adsorbed CoTSPc in buffer alone did not show any peaks. The reduction currents for NO observed on GCE modified with $[Co(II)TSPc]^{4-}$ are much higher than the currents observed for the reduction of the same concentration of NO on an unmodified GCE. The peak currents for the reduction of NO on GCE modified with

Table 1
Equilibrium and rate constants for coordination of NO

Complex	K (dm^3 mol^{-1})	k_f (dm^3 mol^{-1} s^{-1})	Ref.

Metmyoglobin	1.4×10^4	1.9×10^5	[14]
Hemoglobin		2.5×10^7	[14]
$[Co(II)TSPc]^{4-}$	3.0×10^5	142	this work

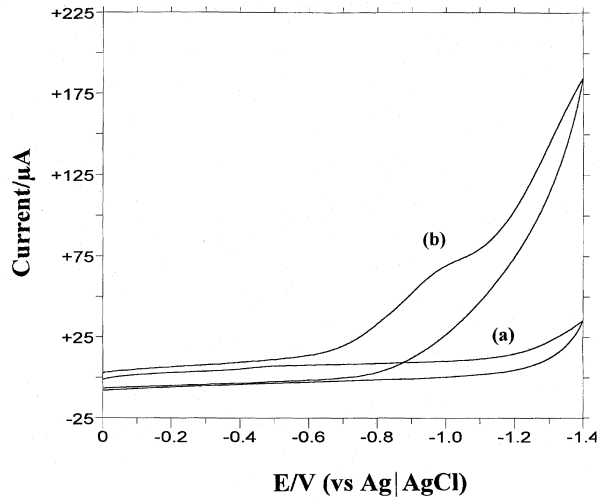

Fig. 4. Cyclic voltammogram for the reduction of 1.0×10^{-5} mol dm^{-3} NO on (a) unmodified GCE and (b) CoTSPc-GCE. Scan rate 100 mV s^{-1}.

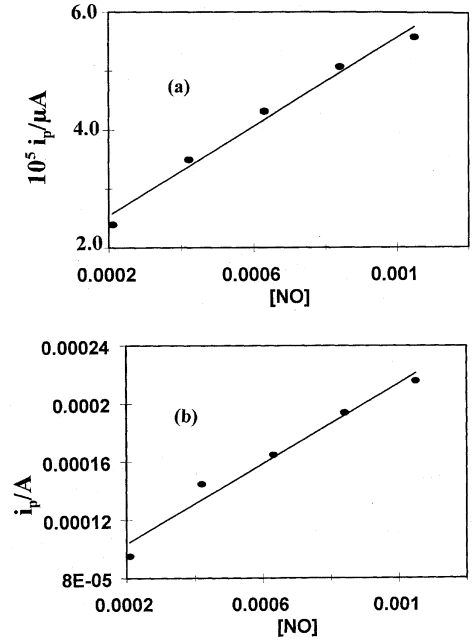

Fig. 5. Plot of the variation of the catalytic currents for (a) reduction and (b) oxidation of NO on CoTSPc-GCE vs. the concentration of NO. Scan rate 100 mV s^{-1}.

$[Co(II)TSPc]^{4-}$ increased with increase in NO concentration as shown in Fig. 5a. The modified electrode showed stability towards the reduction of NO in that the currents did not decrease appreciably with scan number. The peak at -0.96 V versus Ag|AgCl is almost at the same potential as that observed for reduction of NO (-0.93 V) on CoPc-modified GCE [42]. The pH of the media plays an important part in the catalytic reduction or oxidation of NO. The peak for the catalytic reduction of NO in water containing sodium sulfate was observed at -1.2 V versus Ag|AgCl. When the pH 7 buffer was employed the peak was observed at -1.1 V versus Ag|AgCl.

The cyclic voltammograms for the oxidation of NO on an unmodified GCE and on GCE modified with CoTSPc are shown in Fig. 6. There is a considerable enhancement in the oxidation currents of NO when GCE is modified with $[Co(II)TSPc]^{4-}$ compared with unmodified GCE. A weak broad peak is observed for NO on unmodified GCE near 1.1 V. On CoTSPc-GCE, the oxidation peak for NO is well resolved and observed at 1.08 V. The enhancement in oxidation currents when CoTSPc-GCE is employed shows that the $[Co(II)TSPc]^{4-}$ species acts as a catalyst for the oxidation of NO. The currents for the oxidation of NO on CoTSPc-GCE increased with increase in NO concentration, as shown in Fig. 5b. The lowest concentration of NO that could be determined using either the oxidation or reduction of NO on CoTSPc-GCE was of the order of 10^{-9} mol dm^{-3}.

Bulk electrolysis of solutions containing NO at potentials for the catalytic reduction on CoTSPc-GCE gave $n \approx 5$, where n is the number of electrons involved in the reaction. This suggests that ammonia could be one of the reduction products of NO. Analysis of the solution obtained following bulk electrolysis did confirm the presence of ammonia with yields of about 25%. The current efficiency for ammonia production was determined to be 89%. Hydroxylamine was also found to be one of the products.

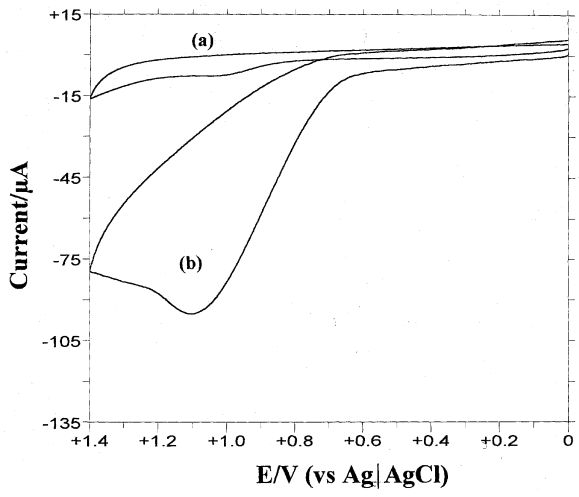

Fig. 6. Cyclic voltammogram for the oxidation of 2.1×10^{-4} mol dm^{-3} NO on (a) unmodified GCE and (b) CoTSPc-GCE. Scan rate 100 mV s^{-1}.

In conclusion, NO has been shown to coordinate to $[Co(II)TSPc]^{4-}$. The coordination is accompanied by electron transfer from the central Co(II) metal and the formation of $[(NO^{-})Co(III)TSPc]^{4-}$ species. The rate constant for the formation of this species is much lower than those reported for the interaction of NO with metmyoglobin, iron(II) porphyrin and hemoglobin. $[Co(II)TSPc]^{4-}$ adsorbed on GCE catalyses both the reduction and oxidation of NO. The lowest concentration of NO that could be detected on GCE modified with $[Co(II)TSPc]^{4-}$ was of the order of 10^{-9} mol dm^{-3}.

Abstract

The complexes *trans*-$[OsCl_2(L\text{-}L)_2]$ (L-L = *o*-$C_6H_4(TeMe)_2$, $RTe(CH_2)_3TeR$ (R = Ph or Me)) have been prepared from *trans*-$[OsCl_2(dmso)_4]$ and the ditelluroethers in ethanol. The reaction of $[OsCl_2(PPh_3)_3]$ with the ditelluroethers or $MeSCH_2CH_2SMe$ or $MeSe(CH_2)_3SeMe$ in ethanol in the presence of NH_4PF_6 gave *trans*-$[OsCl(PPh_3)(L\text{-}L)_2]PF_6$. The complexes have been characterised by analysis, IR, UV–Vis and multinuclear NMR spectroscopy. The reaction of OsO_4–HCl–EtOH with $PhTe(CH_2)_3TePh$ results in chlorination of the ligand to $PhTeCl_2(CH_2)_3TePhCl_2$, identified by single-crystal X-ray study. The X-ray structure for *trans*-$[OsCl_2\{PhTe(CH_2)_3TePh\}_2]$ is reported. The reaction of $[OsCl_2(dmso)_4]$ with the distibine $Ph_2Sb(CH_2)_3SbPh_2$ affords *trans*-$[OsCl_2\{Ph_2Sb(CH_2)_3SbPh_2\}_2]$ which has also been characterised crystallographically. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Osmium forms compounds in formal oxidation states ranging from 8 to −2 and as a consequence has an extremely rich coordination chemistry [1]. However, the absence of labile osmium precursors in the medium oxidation states can make some types of complex difficult to prepare. For example, whilst a wide range of bidentate and polydentate phosphine and arsine complexes of Os(II), Os(III) and Os(IV) are readily made starting from OsO_4–HX–ROH (X = Cl, Br or I) or $[OsX_6]^{2-}$ [1], obtaining complexes with Group 16 donors has proved considerably more difficult. Direct reaction of $[OsX_6]^{2-}$ with dithioethers [2] or diselenoethers [3] generates $[OsX_4(L\text{-}L)]$ type complexes in poor yield, whilst from OsO_4–HX–EtOH and the ligands at low temperatures unstable osmyl complexes $[OsO_2X_2(L\text{-}L)]$ form [4,5]. Further reduction to, for example, $[OsX_2(L\text{-}L)_2]$ does not appear possible by this route. We were interested in extending our previous studies of ditelluroether complexes with platinum group metals, Pt or Pd [6–8], Ir [6,7], Ru or Rh [8], to osmium and report our investigations below.

2. Results and discussion

The reaction of OsO_4–conc. HCl–EtOH with the three ditelluroether ligands (L-L = *o*-$C_6H_4(TeMe)_2$, or $RTe(CH_2)_3TeR$ (R = Me or Ph)) at 0°C gave brownish-purple solids leaving a dark red solution. These solids lacked the very strong $\nu(OsO_2)$ IR vibration at ca. 850 cm^{-1} typical of *trans*-$[OsO_2Cl_2(L'\text{-}L')]$ (L′-L′ = dithioether or diselenoether) [4,5], ruling out the formation of osmyl species. A similar result was reported with Me_2Te [4,5]. Since telluroethers are both stronger reducing agents and less able to stabilise high oxidation states than their lighter analogues [6–8], their failure to stabilise Os(VI) is not unexpected, but it was hoped that reduction would lead to Os(III) or Os(IV) complexes. The brownish-purple solids have UV–Vis spectra typical of Os(IV), in fact the major features are very similar to those of $[OsCl_6]^{2-}$ [9] and were weakly paramagnetic, which would suggest either Os(IV) and/or Os(III) compounds were present. However, after long accumulations each sample gave a single sharp ^{125}Te NMR resonance at very high frequencies (δ (^{125}Te) ca. 800–900) which would seem to indicate that at least some of the tellurium was present in a diamagnetic material, the shifts being in the range [10] typical of R_2TeCl_2 species. A pale brown crystal was grown (from MeCN) from the $PhTe(CH_2)_3TePh$ reaction and the

PII S0277-5387(99)00376-9

structure solution revealed the diamagnetic tellurium compound to be $PhCl_2Te(CH_2)_3TePhCl_2$.MeCN [1]. The structure is shown in Fig. 1 and selected bond length and angle data are in Table 1. The structure is typical of R_2TeCl_2 type compounds, with $PhCl_2TeCH_2TePhCl_2$ the closest structurally characterised example [11]. The environment about each Te is based upon a distorted trigonal bipyramid with axial $TeCl_2$ groups and with one equatorial position vacant, presumably occupied by the lone pair. The Te–Cl bonds 2.504(2)–2.524(1) Å lie within the usual range [11], and the structure is unexceptional, but serves to identify unequivocally a significant product of the reactions described above.

Similar brownish-purple materials are formed on refluxing $[NH_4]_2[OsCl_6]$ with the ditelluroethers in alcohols. Notably none of the crude materials gave ^{125}Te NMR resonances in the ranges we subsequently observed for the $[OsCl_2(L\text{-}L)_2]$ complexes (below). Although we have been unable to separate any pure osmium species from these reactions, it is clear that the target $[OsCl_2(L\text{-}L)_2]$ are not present in significant amounts.

An alternative route to *trans*-$[OsCl_2(L\text{-}L)_2]$ from Os(II) starting materials was sought, although as indicated in Section 1, most Os(II) materials are kinetically very inert and introducing moderate donor ligands like telluroethers is not easy. We found that the recently characterised [12] *trans*-$[OsCl_2(dmso)_4]$ (dmso = dimethylsulfoxide) reacted with the ditelluroethers under reflux in ethanol to produce poor to moderate yields of *trans*-$[OsCl_2(L\text{-}L)_2]$ as orange or red solids. The isolated complexes are air stable and generally poorly soluble in chlorocarbons or MeCN, which to some extent limited solution spectroscopic studies. Red crystals of $[OsCl_2\{PhTe(CH_2)_3TePh\}_2]$ were obtained by evaporation of a $CHCl_3$ solution of the complex, and the structure solution (Table 2, Fig. 2) revealed a *trans* pseudo-octahedral molecule with the osmium on the inversion centre and with both ditelluroethers in *meso* form. Although the crystals are not isomorphous, the structure is very similar to that previously found in *trans*-$[RuCl_2\{PhTe(CH_2)_3TePh\}_2]$ [8]. The Os–Cl bond length, 2.450(4) Å, is comparable with those found in $[OsCl_2\{Ph_2PCH_2CH_2PPh_2\}_2]$ (2.434(1) Å) [13] and $[OsCl_2\{H_2C{=}C(PPh_2)_2\}_2]$ (2.431(1) Å) [14]. There are no literature data on Os^{II}–TeR_2 bonds, but those in the present complex (2.616(1), 2.6135(9) Å) are, as might be expected, similar to the Ru–Te bonds in the Ru^{II} analogue (2.6247(3), 2.6194(3) Å) [8].

[1] Although $RCl_2Te(CH_2)_nTeRCl_2$ prepared from $RTe(CH_2)_nTeR$ and Cl_2 are white or cream, our crystals were brown, presumably owing to traces of an osmium species.

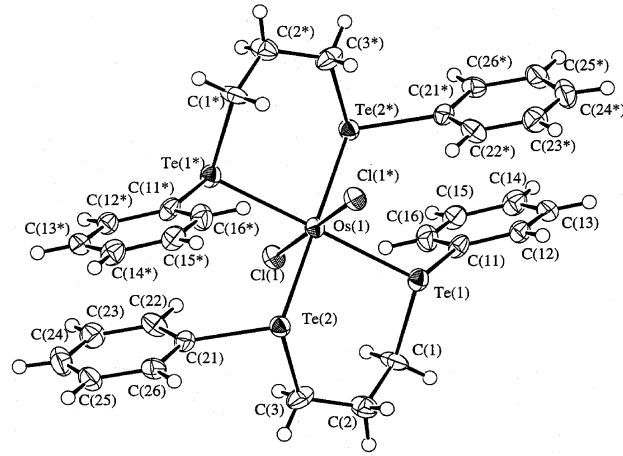

Fig. 2. View of the structure of $[OsCl_2\{PhTe(CH_2)_3TePh_2\}$ with numbering scheme adopted. Ellipsoids are drawn at 40% probability. Atoms marked * are related by a crystallographic inversion centre. H-atoms are omitted for clarity.

The three $[OsCl_2(L\text{-}L)_2]$ complexes have very similar spectroscopic properties (Section 3) including two d–d bands in the range 21000–26000 cm^{-1} as expected for a low spin d^6 complex with local D_{4h} symmetry [9]. The poor solubility made it very difficult to obtain ^{125}Te NMR spectra, but after very long accumulations several resonances were present in each complex, consistent with a mixture of invertomers, showing that pyramidal inversion is slow on the NMR time scale in these systems. As we have discussed elsewhere [8], it is not possible to assign resonances to individual isomers. Notably, for comparable complexes, the $\delta(^{125}Te)$ are found at considerably higher frequency in the ruthenium complexes [8] compared with the present osmium examples, an effect also found for corresponding ruthenium and osmium phosphines [15]. Cyclic voltammetry of the complexes in CH_2Cl_2 revealed a single reversible oxidation for each ($[OsCl_2\{MeTe(CH_2)_3TeMe\}_2]$ +0.35 V versus SCE; $[OsCl_2\{PhTe(CH_2)_3TePh\}_2]$ +0.18 V; $[OsCl_2\{o\text{-}C_6H_4(TeMe)_2\}_2]$ +0.43 V), which contrasts with the quasi-reversible or irreversible oxidations observed in the ruthenium analogues [8], reflecting the expected greater stability of the M(III) state for osmium.

Although $[OsCl_2(dmso)_4]$ provided a satisfactory starting material for the synthesis of the ditelluroether complexes it is still not ideal, and attempts to prepare $[OsCl_2(L'\text{-}L')_2]$ (L′-L′ dithioether or diselenoether) similarly usually result in mixtures containing $[OsCl(dmso)(L'\text{-}L')_2]^+$, $[OsCl_2(dmso)_2(L'\text{-}L')]$ and $[OsCl_2(L'\text{-}L')_2]$, which are not readily separated, and we have not obtained useful amounts of the last complexes.

The reactions of $[OsCl_2(PPh_3)_3]$ with 2 equiv. of the Group 16 ligands in EtOH in the presence of $[PF_6]^-$ gave moderate yields of $[OsCl(PPh_3)(L\text{-}L)_2]PF_6$ (L-L = $RTe(CH_2)_3TeR$, R = Me or Ph), $[OsCl(PPh_3)(MeSCH_2CH_2SMe)_2]PF_6$ and $[OsCl(PPh_3)\{MeSe(CH_2)_3SeMe\}_2]PF_6$ as yellow or brown solids. The complexes are air stable solids which show $[OsCl(PPh_3)(L\text{-}L)_2]^+$ as the highest mass ions in their ES^+ mass spectra. The UV–Vis spectra are uninformative, showing only the $\pi \rightarrow \pi^*$ transitions of the Ph-groups and charge transfer transitions in the near-UV which tail into the visible obscuring the d–d bands, although the absence of significant features below 20000 cm^{-1} confirms the oxidation state as Os(II). The ^1H NMR spectra of the ditelluroether compounds are complex and not very helpful, but the $^{31}P\{^1H\}$ NMR spectra are more useful. For $[OsCl(PPh_3)\{PhTe(CH_2)_3TePh\}_2]PF_6$, in addition to the septet at δ −145 due to $[PF_6]^-$ there are two singlets at −10.5 and −11.8 with approximate intensities 2:1 showing the presence of two major invertomers. The corresponding $^{125}Te\{^1H\}$ NMR spectrum showed five doublets in the range δ 450–565 with $^2J(^{125}Te\text{–}^{31}P)$ of ca. 60–90 Hz. In the case of $[OsCl(PPh_3)\{MeTe(CH_2)_3TeMe\}_2]PF_6$ the $^{31}P\{^1H\}$ NMR spectrum reveals one major invertomer δ −14.5 and there are four doublets in the $^{125}Te\{^1H\}$ NMR spectrum and four δ(Me) resonances in the ^1H NMR spectrum. This is consistent with one invertomer as the major solution form with one *meso* and one *DL* ditelluroether. The pattern of invertomers in these two cases is very similar to that observed in the ruthenium analogues [8]. For the $[OsCl(PPh_3)\{MeSe(CH_2)_3SeMe\}_2]PF_6$ the $^{31}P\{^1H\}$ NMR spectrum shows a singlet at −14.0 and the septet at −145. There are singlets for the Me and CH_2 groups of the diselenoether in the ^1H NMR spectrum. Whilst at first sight this might be taken to indicate one isomer with high symmetry, we were unable to observe a ^{77}Se NMR spectrum from this complex, which suggests that pyramidal inversion is occurring. Finally, for $[OsCl(PPh_3)\{MeS(CH_2)_2SMe\}_2]PF_6$ there is a singlet in the $^{31}P\{^1H\}$ NMR spectrum at δ −15.1, and broad singlets at δ 2.44 and 2.7 (in addition to the Ph multiplet) in the ^1H NMR spectrum, consistent with fast inversion in the dithioether complex. The poor solubility and the number of possible invertomers make these systems poorly suited to VT NMR studies, but comparison of the room temperature spectra shows the usual trends [16,17] in pyramidal inversion barriers Te > Se > S are present.

The reaction of $[OsCl_6]^{2-}$ with Ph_3Sb in alcohols readily yields *mer*-$[OsCl_3(Ph_3Sb)_3]$ which can be reduced by excess ligand and $NaBH_4$ to *trans*-$[OsCl_2(Ph_3Sb)_4]$ [18,19], but attempts to carry out corresponding reactions with ditertiary stibines failed. As a further test of the usefulness of $[OsCl_2(dmso)_4]$ we reacted this with $Ph_2Sb(CH_2)_3SbPh_2$ in ethanol, and readily obtained good yields of yellow *trans*-$[OsCl_2\{Ph_2Sb(CH_2)_3SbPh_2\}_2]$. The spectroscopic data (Section 3) are unexceptional and compare well with the corresponding data on *trans*-$[OsCl_2(Ph_3Sb)_4]$ [18,19] and *trans*-$[OsCl_2(diphosphine)_2]$ [20]. Yellow crystals of *trans*-$[OsCl_2(Ph_2Sb(CH_2)_3SbPh_2)_2]$ were obtained from CH_2Cl_2, and the structure determined. The molecule is shown in Fig. 3 and significant bond lengths and angles are in Table 3. The structure reveals a centrosymmetric molecule, with the d(Os–Cl) 2.477(2) Å typical of an Os(II) centre [13,14]. The d(Os–Sb) 2.5933(8), 2.6030(4) Å are very similar to those in *trans*-$[OsCl_2(Ph_3Sb)_4]$ (2.611(2)–2.630(2) Å) [21].

3. Experimental

Physical measurements were made as described previously [8].

3.1. *[Os{MeTe(CH$_2$)$_3$TeMe}$_2$Cl$_2$]*

$[Os(dmso)_4Cl_2]$ (151 mg, 0.155 mmol), $MeTe(CH_2)_3TeMe$ (100 mg, 0.307 mmol) in MeOH (70 cm^3) were refluxed for 16 h. The solvent was removed in vacuo and CH_2Cl_2 added (2 cm^3). The orange solution was filtered and Et_2O added to precipitate an orange solid. Yield: 0.05 g, 36%. *Anal*. Found: C, 12.9; H, 2.6. Calc. for $C_{10}H_{24}Cl_2OsTe_4$: C, 13.1; H, 2.6%. ^1H NMR ($CDCl_3$, 300 MHz): δ 1.94–3.15 (m, $CH_2 + CH_3$). $^{125}Te\{^1H\}$ NMR ($CDCl_3/CH_2Cl_2$, 113 MHz): δ 236, 267, 274, 286, 293, 329, 339. IR spectrum

3.7. $[OsCl(PPh_3)\{PhTe(CH_2)_3TePh\}_2]PF_6$

The method used was the same as described in Section 3.4, giving a yellow solid. Yield: 87%. *Anal*. Calc. for $C_{48}H_{47}ClF_6OsP_2Te_4$: C, 37.5; H, 3.0. Found: C, 37.9; H, 2.4%. Electrospray mass spectrum (MeCN) *m/z*: found M^+ 1391; calc. for $[^{192}Os^{35}Cl(PPh_3)(PhTe(CH_2)_3TePh)_2]^+$ 1401. IR (CsI disc): 3050 (w), 2932 (w), 1477 (w), 1435 (m), 1362 (m), 1088 (m), 1017 (w), 938 (s), 735 (s), 688 (s), 558 (m), 536 (m), 454 (w), 250 (m). ^{1}H NMR (300 MHz $CDCl_3$): δ 2.2 (m), 2.9–3.3 (m), 7.0–7.8 (m). $^{31}P\{^1H\}$ (145 MHz, $CH_2Cl_2/CDCl_3$): δ −10.5(s), −11.8(s), −145 (septet). $^{125}Te\{^1H\}$ NMR (114 MHz, $CH_2Cl_2/CDCl_3$): δ 454, 463, 499, 540, 565.

3.8. $[OsCl_2(Ph_2Sb(CH_2)_3SbPh_2)_2]$

$[OsCl_2(dmso)_4]$ (0.05 g, 0.09 mmol) and $Ph_2Sb(CH_2)_3SbPh_2$ (0.16 g, 0.27 mmol) were refluxed together in ethanol (10 cm^3) for 3 h. The solvent was removed in vacuo, CH_2Cl_2 added to the residue, the solution filtered and the orange product precipitated with Et_2O. Yield: 0.045 g, 35%. *Anal*. Calc. for $C_{54}H_{52}Cl_2OsSb_4\cdot CH_2Cl_2$: C, 43.1; H, 3.4. Found: C, 43.1; H, 2.8%. Electrospray mass spectrum (MeCN) *m/z*: found M^+ 1450. calc. for $[^{192}Os^{35}Cl_2(Ph_2{}^{121}Sb(CH_2)_3{}^{121}SbPh_2)_2]^+$ 1446. IR (CsI disc): 3066 (m), 3049 (m), 1480 (w), 1432 (s), 1360 (m), 1102 (m), 1069 (s), 998 (m), 727 (s), 695 (s), 451 (s), 267 (m). UV–Vis spectrum (CH_2Cl_2): $\nu_{max}=30860$ (sh), ($\varepsilon_{mol}=2200$), 22230 (sh) cm^{-1} (250 dm^3 mol^{-1} cm^{-1}). $^{13}C\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$): δ 15.8, 24.3, 128–137. CV CH_2Cl_2: reversible +0.3 V versus SCE.

3.9. X-ray structure determination of $PhTeCl_2(CH_2)_3TeCl_2Ph\cdot MeCN$, $[OsCl_2\{PhTe(CH_2)_3TePh\}_2]$ and $[OsCl_2\{Ph_2Sb(CH_2)_3SbPh_2\}_2]\cdot 2CH_2Cl_2$

Details of the crystallographic data collection and refinement parameters are given in Table 4. Data collection used a Rigaku AFC7S four-circle diffractometer operating at 150 K (except for $PhCl_2Te(CH_2)_3TePhCl_2\cdot MeCN$, 295 K), using graphite-monochromated Mo Kα X-ray radiation ($\lambda=0.71073$ Å). For $PhCl_2Te(CH_2)_3TePhCl_2\cdot MeCN$ (295 K) preliminary psi-scans showed no significant absorption. The structure was solved by direct methods [22] and refined by iterative cycles of least-squares refinement [23]. All non-H atoms were refined anisotropically and H atoms were placed in fixed, calculated positions. Selected bond lengths and angles are given in Table 1. For $[OsCl_2\{PhTe(CH_2)_3TePh\}_2]$ preliminary psi scans did not provide a satisfactory absorption correction, hence, with the model at isotropic convergence, the data were corrected for absorption using DIFABS [24]. and for $[OsCl_2\{Ph_2Sb(CH_2)_3SbPh_2\}_2]\cdot 2CH_2Cl_2$ the data were corrected for absorption using psi-scans. Both Os structures were solved by heavy atom methods [25] and developed by iterative cycles of full-matrix least-squares refinement [23] and difference Fourier syntheses. All fully occupied non-H atoms were refined anisotropically and H-atoms were placed in fixed, calculated positions (the H atoms associated with the disordered CH_2Cl_2

Received 13 September 1999; accepted 1 December 1999

Abstract

Potentiometric and spectroscopic data have shown that deltakephalin and its derivatives containing the α-hydroxymethylserine (HmS) residue in the second and in the second and sixth positions form the same series of complexes: CuHL, CuL, $CuH_{-1}L$, $CuH_{-2}L$ and $CuH_{-3}L$ (1N to 4N binding mode). The alcoholic groups in the amino acid side chain are very effective in the stabilization of the complexes formed (the protonation corrected stability constants, log *K**, values of 4N complexes are −22.55 and −21.15 for deltakephalin and its derivative containing the HmS residue in the second and sixth positions, respectively). There is no evidence for the direct involvement of alcoholic groups of HmS in binding of Cu^{2+} ions and there is no indication of binding through the tyrosine-phenolate oxygen atoms, either. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Copper(II) complexes; Deltakephalins; Stability constants

1. Introduction

α-Hydroxymethylserine (HmS) belongs to the family of α,α-dialkyl amino acids, which are useful replacements for proteinaceous amino acids because of their strong secondary structure-promoting effects and the increased proteolytic stability of the resulting peptides [1,2]. One can expect that in addition to generating specific constraints on the conformational freedom of the peptide chain, HmS would furnish peptides with enhanced hydrophilicity, advantageous for an increase in bioavailability. Preferred conformations of peptides derived from HmS and its *O*,*O*-isopropylidene protected derivative HmS (Ipr) have been reported recently [3,4]. Interest in HmS is stimulated also by its potential to increase the stability of metal complexes. The involvement of the protonated hydroxyl groups of HmS or Ser may stabilize complexes at lower pH [5–11], whereas direct binding of deprotonated hydroxyl oxygen occurring at high pH makes these amino acids efficient chelating agents above pH 8 [5,6,8–11]. The presence of HmS residues in oligopeptides may increase by almost four orders of magnitude the stability constants of copper(II) complexes as compared to homo-oligopeptides such as oligoalanine [11]. This result indicates that there are very effective indirect interactions involving the α-hydroxymethyl side chains, which stabilize the complexes formed.

In the present work the copper(II) complexes of deltakephalin Tyr-(D)-Thr-Gly-Phe-Leu-Thr (**1**) and its analogues Tyr-HmS-Gly-Phe-Leu-Thr (**2**) and Tyr-HmS-Gly-Phe-Leu-HmS (**3**) containing α-hydroxymethylserine were examined.

Deltakephalin (**1**) is an opioid agonist, highly selective toward δ-receptors. In analogues **2** and **3** one or both threonine residues are replaced by α-hydroxymethylserine bearing the additional OH group.

2. Experimental

2.1. Peptide synthesis

Hexapeptide analogues **2** and **3** of deltakephalin **1** were synthesized applying fragment condensation (3 + 3) strategy with the use of TBTU (*O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate) [12] as the coupling reagent. The *O*,*O*-isopropylidene (Ipr) protected α-hydroxy-

methylserine [13] was incorporated into a peptide chain applying HATU (*O*-7-azabenzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate) [14] or mixed anhydride [15] method. The benzyl type protective groups were removed from the fully protected hexapeptides by hydrogenation (24–72 h) in the presence of 10% Pd/charcoal catalyst on a Parr apparatus at room temperature and a pressure of 4 kg cm^{-2}. The Boc (t-butoxycarbonyl) and Ipr were then removed by treatment with 90% aq. TFA (trifluoroacetic acid) for 15 min. After evaporation, the products were purified by preparative HPLC. The homogeneity of title hexapeptides was checked by TLC (thin-layer chromatography, butanol:acetic acid:water 3:1:1) and by analytical HPLC (linear gradient over 25 min: 10–40% of acetonitrile in water + 0.1% TFA). FAB-MS spectra were recorded on an APO Electron (MI 12001E) spectrometer. The purity of peptide ligands was checked by potentiometry.

2.2. Potentiometric measurements

Stability constants for proton and Cu^{2+} complexes were calculated from pH-metric titrations carried out in argon atmosphere at 298 K using a total volume of 2.0 cm^3. Alkali was added from a 0.250 cm^3 micrometer syringe which was calibrated by both weight titration and the titration of standard materials.

Experimental details: ligand concentration 2×10^{-3} mol dm^{-3}; metal-to-ligand ratio 1:1.5; ionic strength 0.1 mol dm^{-3} (KNO_3); pH-metric titration on a MOLSPIN pH-meter system using a microcombined glass–calomel electrode, calibrated in concentration using HNO_3 [16]; number of titrations 4; method of calculation SUPERQUAD [17]. The samples were titrated in the pH region 2.5–10.5. Standard deviations (σ values) quoted were computed by SUPERQUAD and refer to random errors only. They are, however, a good indication of the importance of the particular species involved in the equilibria.

2.3. Spectroscopic measurements

EPR spectra were recorded on a Bruker ESP 300E spectrometer at X-band frequency (9.3 GHz) at 120 K. CD spectra were recorded on a Jasco J-600 spectropolarimeter in the range 200–750 nm. The latter results are expressed in $\Delta\varepsilon = \varepsilon_l - \varepsilon_r$, where $\Delta\varepsilon$ is evaluated at the maximum concentration of the particular species as obtained from potentiometric data. Absorption spectra were recorded on a Beckman DU650 spectrophotometer. The metal concentration in all spectroscopic measurements was adjusted to 2×10^{-3} mol dm^{-3} and the metal-to-ligand molar ratio was 1:1.5.

3. Results and discussion

Calculated protonation constants for the studied ligands are given in Table 1. Deltakephalin and its α-hydroxymethylated derivatives (H_3L) have three protonation centres, the phenolate oxygen of the tyrosine residue (log *K* value 9.93–9.67), the terminal amino group (log *K* value 7.24–7.14) and the carboxylate group (log *K* value 3.43–3.25). The acidity of the phenolic proton in the studied ligands is comparable to that measured for N-terminal tyrosine residues in the enkephalin, enkephalin analogues and fragments of the casomorphin series studied previously [18,19]. The insertion of D-threonine or α-hydroxymethylserine into the second position has only a slight effect on the acidity of the amino group of the studied peptides compared to methionine enkephalin (Met-EN, Table 1). The presence of the HmS residue on the C-terminal deltakephalin derivative does not affect the carboxylate p*K* value, similar to results determined for other peptides containing this residue [10,11].

According to potentiometric data calculations, deltakephalin and its α-hydroxymethylated derivatives form with Cu^{2+} ions the series of complexes CuHL, CuL, $CuH_{-1}L$, $CuH_{-2}L$ and $CuH_{-3}L$ (charges omitted for simplicity). The stability constants of copper(II) complexes are collected in Table 2, where $\beta(CuH_jL) = [CuH_jL]/[Cu^{2+}][H]^j[L]$. The species distribution curves are shown in Fig. 1 and the spectroscopic parameters of the complexes formed are given in Table 3.

The coordination pattern for all studied Cu^{2+}–ligand systems was found to be the same with bonding commencing at the N-terminal amino-NH_2 site followed by sequential deprotonation and coordination of neighbouring peptide nitrogens.

[c] Log K for protonation of Tyr-O^- in deltakephalins calculated from log $\beta(CuH_{-2}L) - \log \beta(CuH_{-3}L)$.
[d] Log $K^* = \log \beta(CuH_jL) - \log \beta(H_2L)$ (or $\beta(HL)$ with Gly-Gly-Gly-Gly-Gly).

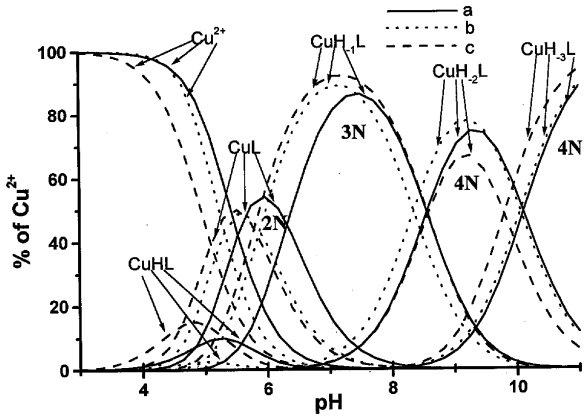

Fig. 1. Comparision of the species distribution curves for 1:1 mixtures of Cu^{2+} with Tyr-D-Thr-Gly-Phe-Leu-Thr (a), Tyr-HmS-Gly-Phe-Leu-Thr (b) and Tyr-HmS-Gly-Phe-Leu-HmS (c) ($C_{Cu(II)} = 0.001$ mol dm^{-3}).

In all these cases the first complex to form, starting at low pH, was the CuHL species, which may be regarded as comparable to the CuL complex of pentaglycine with an additional protonated phenolic residue (on Tyr[1]). The CuHL complex is of low concentration, and it is a minor component of the complex equilibria in Cu^{2+}–linear peptide systems with 1N coordination {NH_2, CO} [20,21]. This species cannot be supported by spectroscopic data because of its low concentration (Fig. 1). With increasing pH, this complex loses the amide proton to give a species of stoichiometry CuL. The EPR parameters $A_\parallel = 170$–180 G and $g_\parallel = 2.251$–2.246, d–d transition energy of 631–622 nm and the presence in the CD spectra of an $N^- \Rightarrow Cu^{2+}$ charge transfer transition at 317–290 nm are consistent with the 2N coordination {NH_2, N^-, CO} of the peptides to copper(II) ions (Table 3) [20].

At pH 6–9, the $CuH_{-1}L$ complex with {NH_2, $2N^-$, CO} coordination mode is formed. This binding mode is easily seen in the EPR, absorption and CD spectra (Table 3). The d–d transition at 561–552 nm, the parameters of the CD spectra as well as $A_\parallel = 191$–198 G and $g_\parallel = 2.213$–2.206 correspond to the three nitrogen bonding mode [20].

Above pH 7, this complex loses the next amide proton to give a $CuH_{-2}L$ species which has four nitrogen donor centres arranged in a square planar geometry around the central copper(II) ion (Fig. 1). The shift of absorption maximum to 526–506 nm, and the EPR parameters $A_\parallel = 213$–201 G,

[a] d–d transition.
[b] $N^- \Rightarrow Cu^{2+}$ charge transfer transition.
[c] $NH_2 \Rightarrow Cu^{2+}$ charge transfer transition.

$g_\parallel = 2.195$–2.172 suggest coordination of the nitrogen donor atom to the copper(II) (Table 3) [20].

Increasing the pH above 8 results in the formation of a species of formula $[CuH_{-3}L]$. This complex has similar bonding mode to that of $[CuH_{-2}L]$ species, with the phenolic oxygen deprotonated. The EPR, CD and absorption parameters of $CuH_{-3}L$ species are similar to those obtained for the $CuH_{-2}L$ complex (Table 3).

The phenolate-O of the Tyr residue does not coordinate to the metal ion which is supported by complete absence of the characteristic charge-transfer band in the CD spectrum at 420 nm (Table 3) [22], and the protonation constant of the $[CuH_{-3}L]$ complex (9.80–10.11) is comparable to that for protonation of the Tyr residue in the free ligand (9.67–9.93) (Tables 1 and 2).

According to the potentiometric data, there is no evidence for the direct involvement of alcoholic groups of HmS in bonding copper(II) ions in the studied pH range (2.50–10.50) because no additional deprotonations are observed in the complexes formed.

Spectroscopic results are in good agreement with potentiometric results indicating the formation of the complexes 1N to 4N.

The stability constants for complexes formed with deltakephalin and its derivatives can be corrected for the phenolate protonation constant of the Tyr residue by subtracting the protonation constant of the $[CuH_{-3}L]$ complex from each to give log values for the stability constants of 1N to 4N complexes (Table 2). These values obtained for deltakephalin are comparable with those for methionine-enkephalin (Met-EN) and pentaglycine. Incorporation of α-hydroxymethylserine into the peptide sequence causes a distinct gain in stability for 3N and 4N complexes. The stability gain of 1.5 log units versus deltakephalin is seen for

the 3N and 4N complexes with the derivative of deltakephalin containing HmS residue in the second and sixth positions.

Stabilization of complexes may be quantified in a number of ways, including by comparing the equilibria:

$$Cu^{2+} + R\text{–}NH_3^+ \Leftrightarrow H^+ + (R\text{–}NH_2)Cu^{2+}$$

Assuming that the phenolic-O^- group of the Tyr residue is protonated, this may be represented by $\log K^* = \log \beta(CuH_jL) - \log \beta(H_2L)$. Values of $\log K^*$ for complexes with 1N to 4N coordination (i.e. j is 1, 0, -1 and -2, respectively) are given in Table 2. These values are the protonation corrected stability constants which are useful for comparing the ability of ligands to bind a metal ion. The data for $\log K^*$ collected in Table 2 for deltakephalin and its derivatives clearly indicate that the incorporation of the second HmS residue in the sixth position causes an increase in stability of a 1N complex by about 1 log unit compared to a derivative containing only one residue of HmS in the second position (Table 2). The amide nitrogen of the HmS residue in the sixth position does not coordinate copper(II) ions but two protonated alcoholic groups of this residue may participate in the stabilization of the 1N complex by the formation of hydrogen bonds with side chains of peptide or with the molecule of water coordinated to the copper(II) ion in the axial position [5–11].

The presence of HmS residues in chelate rings around Cu^{2+} ions in tri-HmS peptide causes an increase in the stability constant of 3N $[CuH_{-2}L]$ species by almost four orders of magnitude when compared to trialanine [11]. The insertion of the HmS residue in the second position of deltakephalin increases the stability ($\log K^*$, Table 2) of the 3N and 4N species by one order of magnitude when compared to deltakephalin. This increase in stability may originate from the partial shielding of the Cu^{2+} binding site from the bulk of the solution both from above and below the coordination plane [23,24]. The HmS residue in the sixth position may also shield the Cu^{2+} binding site. The stabilization of the 1N complex may suggest the presence of this residue above or below the coordination plane.

The stability of copper(II) complexes of deltakephalin derivative containing two HmS residues in the second and sixth positions is comparable to that of the pentapeptide fragment of ANF, Asn-Ser-Phe-Arg-Tyr-NH_2 ($\log K^*$ values in Table 2) [25]. This high stability of the formed complexes may result from the highly organized side chain structures of peptides in copper(II) complexes.

4. Conclusions

α-Hydroxymethylserine residue incorporated into deltakephalin has a distinct influence on the stability of copper(II) complexes. The incorporation of this residue in the second position of this oligopeptide increases the stability of 3N and 4N complexes by about 1 log unit of magnitude compared to deltakephalin. The amide nitrogen of the HmS residue coordinates the copper(II) ions, and two alcoholic groups are situated above and below the coordination plane and may cause shielding of the Cu^{2+} bonding site from the bulk of the solution. The increase in stability of the 1N complex after incorporation of the second HmS residue in the sixth position may suggest further shielding of the Cu^{2+} bonding site (the formation of hydrogen bonds).

Structure–property relationships in *ortho*-metallated imine complexes of Re(I)

Marie-Andrée Guillevic, Mark J. Danks, Sarah K. Harries, Simon R. Collinson, Andrew D. Pidwell, Duncan W. Bruce *

Abstract

Two series of imine liquid crystals, one chiral the other not, have been synthesised and their Re(I) complexes have been prepared. The results have allowed comparisons of the effect of the nature of the terminal group and the position of the imine link on the mesomorphism of both the ligands and the complexes. Broadly speaking, the imines exhibit smectic C and nematic mesophases or, if the terminal chain is chiral, their chiral analogues. Complexation leads to the formation of only a nematic or chiral nematic phase at temperatures which are significantly lower than those for the ligand. ©2000 Elsevier Science Ltd. Keywords: Metallomesogens; Rhenium; Nematic phases; Chiral nematic phases

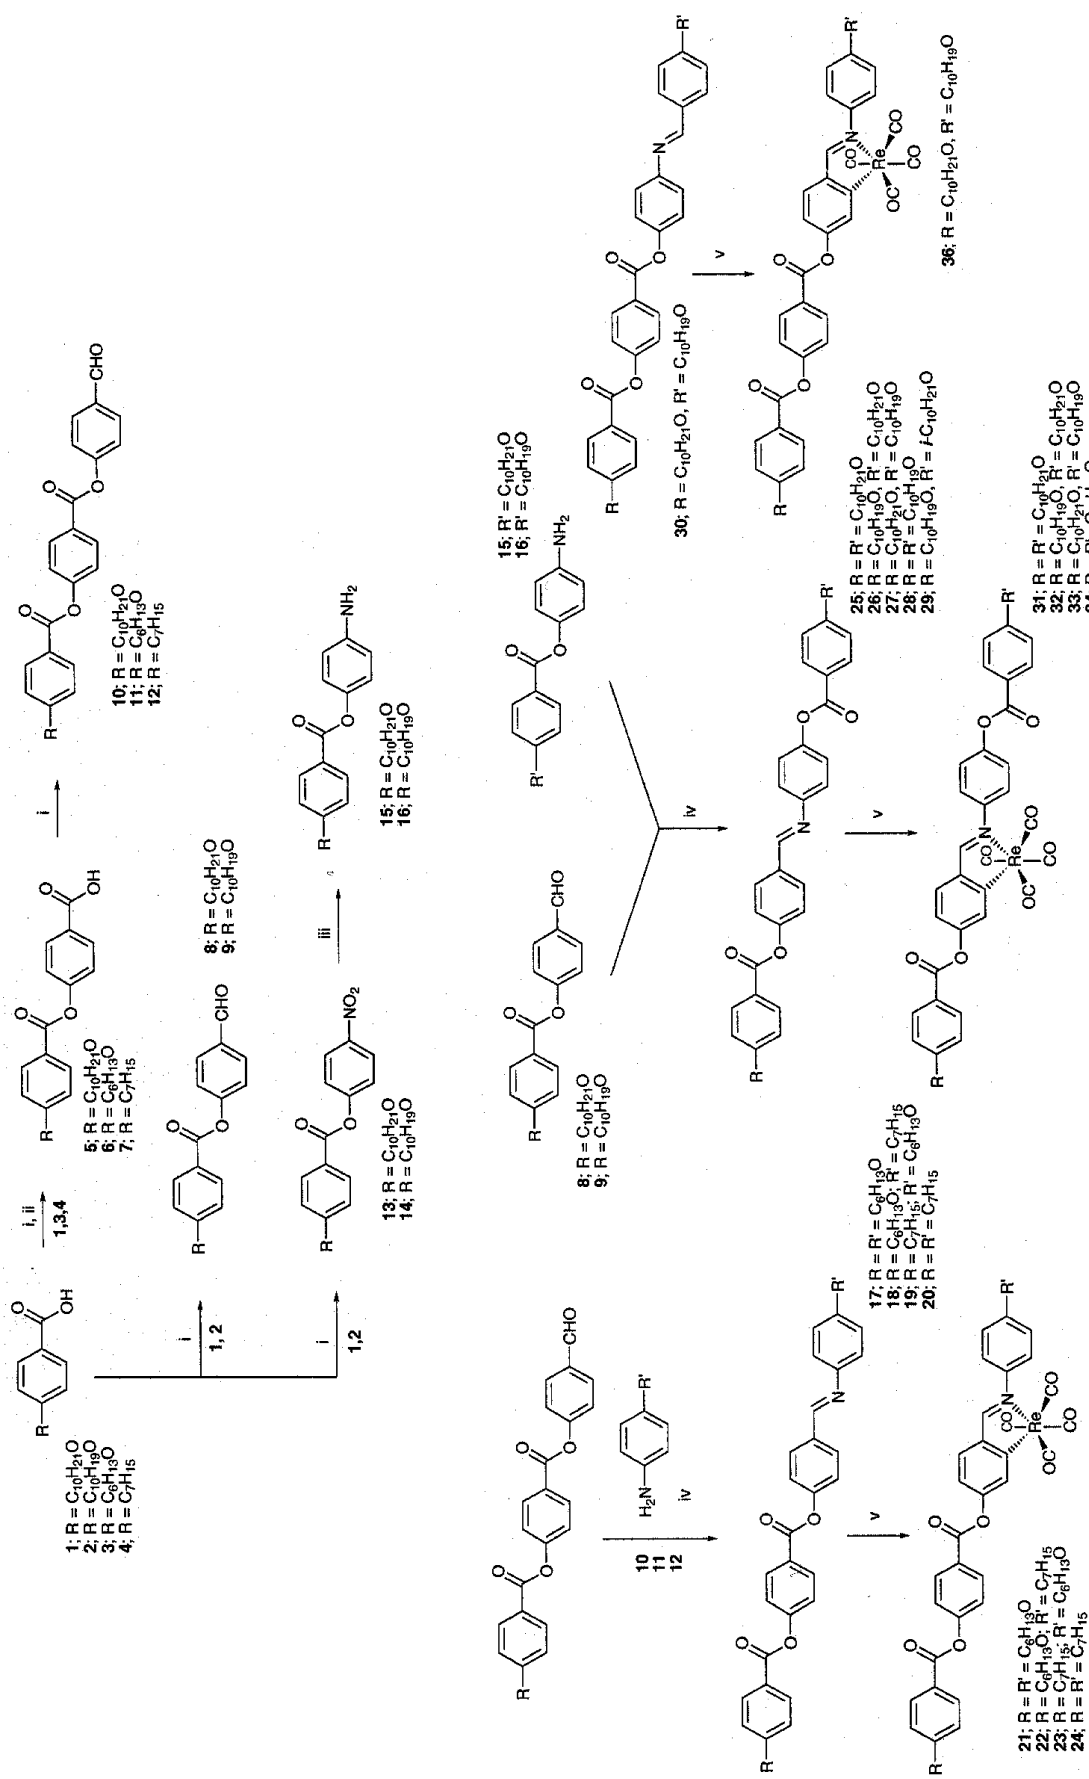
1. Introduction

The study of metal-containing liquid crystals (metallomesogens) has become an active area of interest both to inorganic chemists and to liquid crystal scientists in the last fifteen years or so. In expanding the field, groups have sought to increase the number of metallic elements that may be incorporated into liquid-crystal materials and to understand the relevant structure–property relationships in order to exert control over key parameters, such as melting and clearing points [1]. For many years, the literature of calamitic (rod-like) liquid crystals was dominated by complexes in which the metal was in a planar, four-coordinate environment, therefore necessarily restricting the metals which could be used. As part of our studies in this area, we became interested in the incorporation of metals with higher coordination numbers [2], which led to the synthesis of *ortho*-metallated complexes of Mn(I) [3,4]and Re(I) [5,6], diazabutadiene [7,8] and 2,2′-bipyridine [9,10] complexes of Re(I) and acetylene complexes of Rh(III) [11].

Liquid crystals rely on the presence of anisotropic dispersion forces to stabilise their mesophases, and these arise from a shape anisotropy of the molecules, generally coupled with a significant anisotropy of polarisability. However, while highly anisotropic motifs can be realised with a planar, four-coordinate metal centre, the addition of two extra ligands to generate formally octahedral coordination is likely to reduce significantly the overall anisotropy (see e.g. Ref. [7]). However, we found that this problem could be circumvented if the *liquid-crystalline* ligand were made sufficiently anisotropic so that the perturbation represented by the two 'extra' ligands could be screened out and, therefore, tolerated.



Of all of these systems, the *ortho*-metallated systems (Fig. 1) presented mesophases at the lowest temperatures, with melting points of around 120°C and clearing points as low as about 70°C. We therefore decided that these systems were worthy of greater study in order to minimise further transition temperatures and make them amenable to physical investigation. In this paper, we present the results of investigations which looked at both the introduction of chirality and the removal of the dipolar oxygen in the terminal chains.

2. Synthesis of the ligands and the complexes

The synthetic routes are outlined in Scheme 1. Alkoxybenzoic acids (**1**–**4**) and alkoxybenzaldehydes were obtained via a Williamson ether reaction between the relevant bromoalkane and either ethyl 4-hydroxybenzoate or 4-hydroxybenzaldehyde, followed by hydrolysis of the ethyl 4-alkoxybenzoate in the former case. Alkoxybenzoyloxy-

Scheme 1. Synthetic route to the ligands and complexes. Reagents and conditions: (i) DCC–DMAP–CH_2Cl_2; (ii) Pd–C, H_2; (iii) $SnCl_2$; (iv) EtOH–THF, room temperature, cat. AcOH; (v) [$ReMe(CO)_5$], toluene, reflux, N_2. *i*-$C_{10}H_{21}O$ refers to the hydrogenated citronellyloxy group (see text).

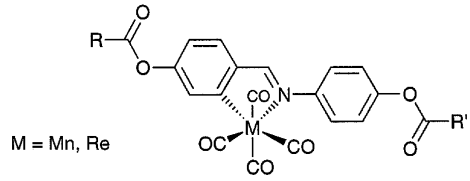

Fig. 1. General structure of the *ortho*-metallated complexes of Mn(I) and Re(I).

benzoic acids (**5**–**7**) were then obtained by esterification of the alkoxybenzoic acid with benzyl 4-hydroxybenzoate, followed by hydrogenolysis of the benzylalkoxybenzoyloxybenzoate; alkoxybenzoyloxybenzoyloxybenzaldehydes (**10**–**12**) were then obtained by subsequent esterification with 4-hydroxybenzaldehyde. Alkoxybenzoyloxynitrobenzenes (**13**, **14**) were obtained by esterification of alkoxybenzoic acids with 4-nitrophenol, and the corresponding amines (**15**, **16**) were obtained by reduction of the nitro group using tin(II) chloride. The target imines (**17**–**20** and **25**–**30**) were synthesised by reaction of a benzaldehyde with an aniline in an ethanol–THF mix with ethanoic acid as catalyst. Two imines are a little different. Thus, **30** was obtained from **5** by esterification with 4-hydroxynitrobenzene, reduction to the amine with $SnCl_2$ and then reaction with 4-citronellyloxybenzaldehyde. For imine **29**, the double bond in the citronellyloxy group is hydrogenated as on one occasion, the reduction of the nitro group in **14** was carried out using hydrogen over palladium on charcoal. The metal complexes (**21**–**24** and **31**–**36**) were finally obtained by reaction of the imine with $[ReMe(CO)_5]$ in toluene at reflux for 20 h. Some of the reactions were carried out only once which accounts for the unoptimised yields in some steps.

3. Mesomorphism of the ligands and their metal complexes

The mesomorphism will be discussed by considering the ligands and complexes in two groups; thus, the chiral and non-chiral materials will be considered separately.

3.1. Non-chiral ligands and complexes

Thermal data are collected in Table 1 and summarised for the ligands in Fig. 2. The ligands (**17**–**20**) differed from those we had synthesised previously in that the imine group used for binding the rhenium was now in a terminal rather than a central bridging position. Although a direct comparison is not possible, consideration of the behaviour of related ligands [3,4,12,13] suggests that the transition temperatures are not greatly affected. The mesomorphism is also similar, showing smectic C and nematic phases and, in some cases, a crystal smectic J phase [14]. However, the interesting comparison is within this series where we have started with an imine with two terminal alkoxy chains, and then gradually replaced them with alkyl chains of the same length. What we see clearly is that the imine with two terminal alkoxy chains (**17**) has the most stable crystal phase and the most stable nematic phase, clearing at 340°C. However, when one alkyl chain is introduced (**18**, **19**), a crystal J phase is observed, the melting point comes down and the nematic phase is reduced in stability. These reductions are greater when the alkoxy chain is found at the end nearest the imine group (**19**). Lowest of all, however, are the transition temperatures found in the imine where both terminal chains are alkyl (**20**). These phenomena can simply be explained by considering the dipolar contri-

bution made by the oxygen in the alkoxy systems. Thus, intermolecular dipolar interactions will be greater leading to more stable phases.

When the complexes are considered (**21**–**24**), the first point to note is that the mesomorphism changes in as much as the smectic phase(s) seen in the ligands are totally suppressed and only a nematic phase is seen; this is discussed below. Secondly, we find that the clearing points of the complexes are well over 100°C lower than those of the corresponding ligands. Thirdly, we see that exactly the same trend is followed in terms of the stability of the nematic phase, which clears at 204°C in **21**, dropping to 160°C in **24**. The melting points also drop as the number of alkyl chains increases, but an important feature is that these melting points are significantly higher than those observed in complexes we had synthesised previously where the site of metallation was in the centre of the molecule. In these last cases, melting points were in the region of 120–130°C. Indeed, for **23** and **24**, the situation was such that while the nematic phase stability had dropped, the melting point had not and so the phases appeared monotropically. Interestingly, cooling the nematic led to a metastable crystal phase (Table 1, Crys′)which melted back to the nematic at 112 and 125°C for **23** and **24**, respectively.

[a] Not seen by DSC.

On formation of the complexes, a large, metal tetracarbonyl group is introduced as a lateral substituent. In a very simple way, it is easy to envisage that such a large substituent, particularly near to the centre of a molecule, will disrupt its ability to pack into smectic layers, thus destabilising the smectic C and crystal smectic J phase. However, although the nematic wins out over the smectic phases, the presence of the lateral [$M(CO)_4$] group reduces the molecular anisotropy and thus the attendant anisotropic dispersion forces, which leads to a much lower nematic phase stability in the complexes. Without evidence of the crystal structure (it is not straightforward to grow crystals of such systems), it is a little more difficult to begin to understand the greater stability of the crystal phase of these complexes, but one simple explanation might be as indicated in Fig. 3 where it is possible to envisage a more efficient packing of molecules when the [$Re(CO)_4$] group is situated towards the end of the molecule (Fig. 3(b)) than when it is situated towards the middle (Fig. 3(a)).

3.2. Chiral ligands and complexes

Thermal data are collected in Table 2 and summarised for the ligands in Fig. 4. In this series, for the most part the core was kept the same and the terminal chain was varied. The

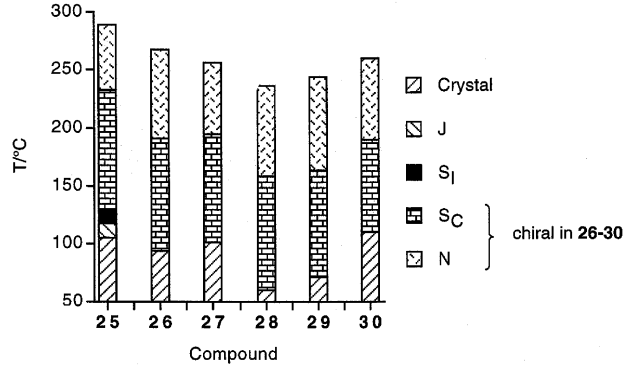

Fig. 4. Graphical illustration of the mesomorphism of the ligands **25**–**30**.

parent compound had two terminal decyloxy chains which were systematically replaced by citronellyloxy chains. Two other compounds are included, namely one (**30**) in which the imine group was moved away from the centre of the molecule as is the case with the series above, and another (**29**) where during preparation, the double bond of one of the citronellyl groups was inadvertently hydrogenated. Rhenium(I) complexes of each ligand were also obtained.

The parent ligand, **25**, melted at 104°C to give a crystal J phase [14] which then gave way to a smectic I phase at 117°C which was characterised on the basis of its optical texture [15]. Then followed a smectic C phase at 129°C and a nematic phase at 232°C which cleared at 288°C. This behaviour is similar to that reported for related ligands which we have described previously [3,4]. When the citronellyl group was introduced at the end of the molecule closest to the *C*-end of the imine link (**26**), the crystal phase was destabilised and melting to a S_C* (chiral smectic C phase) occurred at 93°C; the characteristic [15] petal texture of the S_C* phase is shown in Fig. 5. The S_C* phase was also destabilised with respect to the non-chiral analogue and the phase transition into the N* (chiral nematic or cholesteric) phase was seen at 191°C; the characteristic [15] planar texture of the N* phase is shown in Fig. 6. The N* phase cleared at 267°C. When the citronellyl group was introduced at the end of the molecule closest to the *N*-end of the imine link (**27**), similar destabilisation was observed (Crys 101 S_C* 195 N* 256 I), the transition temperatures of **26** and **27** being broadly similar. However, when both of the terminal groups were citronellyl (**28**), the changes in transition temperature were much more pronounced and the ligand melted at 60°C into a S_C* phase before passing into a N* phase at 158°C and clearing at 236°C. The transition temperatures of **29** in which the citronellyl group at the *C*-end of the molecule was hydrogenated were very similar. Finally, we can see that by moving the imine group within the molecule (**30**), there is little effect on the mesomorphism as the transition temperatures are broadly similar to those of both **26** and **27**.

The overall trend in behaviour in the above ligands can be understood by considering the differences between the decyloxy and citronellyloxy chains (Fig. 7). A decyloxy chain was chosen for this study as it has the same number of carbon atoms as the citronellyl group. Thus, in the former case the chain is not branched in any way and so offers only enhancement of the molecular anisotropy, whereas the latter offers both a double bond (which often appears to lead to a reduction in transition temperatures [16]) and, more significantly, a chain branched in two places. As a branched chain, citronellyl now has the possibility to disrupt the anisotropy of the ligand and so packing in both the crystal state and the mesophases will not be so efficient, leading to a reduction in transition temperatures. Where there are *two* such chains (**28**) then this effect becomes further emphasised and so the transition temperatures drop even further. Of course, the branching also introduces chirality into the system which is responsible for the formation of S_C* and N* phases, rather than their non-

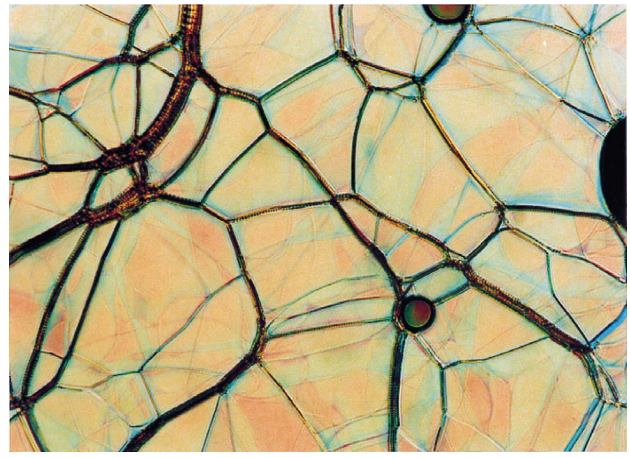

Fig. 5. Petal texture of the S_C* phase of ligand **27** at 109°C, obtained on heating.

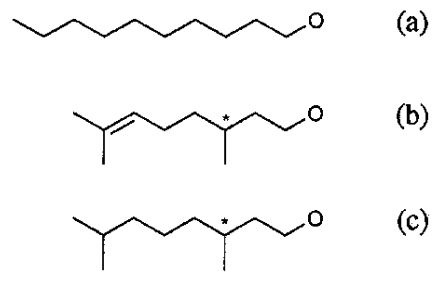

Fig. 7. Structure of the decyloxy chain (a), the citronellyloxy chain (b) and its hydrogenated analogue (c).

chiral counterparts seen in the parent ligand (**25**). Chiral phases [17] are of great technological relevance as the S_C* phase is that used in ferroelectric liquid crystal displays, while the N* phase is responsible for thermochromic effects in liquid crystals (e.g. strip thermometers).

The mesomorphism of the complexes (**31**–**36**) differed from that of the ligands in that now the S_C* phase disappeared and the N* phase was the only one observed. These materials

are therefore interesting from a more general point of view as there are very few metallomesogens known which exhibit a chiral nematic phase which are not derived from dinuclear palladium mesogens [18–21]. In common with the complexes considered above, the melting and clearing points were significantly reduced in comparison with the ligands. The mesomorphism of the complex **31** whose ligand (**25**) possessed only non-chiral decyloxy chains was broadly similar to that found in previous examples [5,6], showing a nematic phase from 133–160°C. However, on the introduction of a chiral citronellyl group, the stability of the nematic phase was reduced and the N* phase cleared at 142°C (**32**) or 132°C (**33**). However, the difference in these two complexes was in the stability of the crystal phase and its relation to the nematic. Thus, in **32** in which the citronellyl group was at the *C*-end of the ligand, the crystalline phase melted at 121°C while in **33**, in which the citronellyl group was at the other end of the ligand, the crystal melted at 137°C so that in fact the N* phase was monotropic. Such differences in crystal phase stability for such similar complexes are rather difficult to explain, at least in the absence of crystal structure data. When both terminal chains were citronellyl (**34**), the melting point stayed relatively high at 130°C, but the stability of the N* phase dropped even further than in **32** and **33** and could not be seen before crystallisation set in at around 110°C. The behaviour of **35** in which one citronellyl group was hydrogenated was very similar. Finally, an interesting comparison is that between the behaviour of **36** (in which the imine group was moved towards the end of the molecule as in the first series of ligands and complexes considered in this paper), **32** and **33** (in which the imine group was in the centre of the molecule) and the complexes **21**–**24**. Thus, in **21**–**24** we saw rather high transition temperatures which we attributed to a more efficient packing of complexes when the $[Re(CO)_4]$ fragment is attached to one end of the ligand. In **36**, which possesses longer chains, one of which is chiral, this effect is clearly still present, evident by comparison with the clearing points for **32** and **33** where the N* phase is destabilised by about 16°C.

4. Conclusions

In this systematic study, we have examined how changes in the nature of the ligand have affected the mesomorphism of some complexes of Re(I). It is interesting that we find that many of the trends seen in the ligands are reflected in the behaviour of the complexes, although there are aspects of the ligand design which have a profound effect on the shape of the complex formed which in turn influence the mesomorphism, leading to some synergy between ligand- and complex-derived effects.

5. Experimental

Elemental analyses were determined by the University of Exeter Microanalysis Service. NMR spectra were recorded on either a Bruker ACF-300 or a Bruker DRX-400 spectrometer, where the chemical shifts are reported relative to the internal standard of the deuterated solvent used. Analysis by DSC was carried out on a Perkin–Elmer DSC7 instrument using heating and cooling rates of either 5 or 10 K min^{-1}. Analysis by hot stage microscopy was carried out using an Olympus BH40 microscope equipped with a Link-Am HFS91 hot stage, TMS92 controller and LNP2 cooling unit. Solvents were purified by standard methods before use. 4-Heptylbenzoic acid, 4-hexyloxyaniline and 4-heptylaniline were obtained from Aldrich.

5.1. Preparation 4-decyloxybenzoic acid (1)

Ethyl 4-hydroxybenzoate (8.31 g, 0.05 mol) and 1-bromodecane (16.59 g, 0.075 mol) were added to a suspension of potassium carbonate (27.64 g, 0.2 mol) and dibenzo-18-crown 6 (0.01 g) in butanone (290 cm^3). The solution was heated at reflux for 72 h. Water (250 cm^3) was added and the organic layer extracted with DCM (4×150 cm^3). The combined organic extracts were dried over anhydrous $MgSO_4$, filtered and evaporated under reduced pressure to give a yellow oil. Potassium hydroxide (3.4 g, 0.06 mol) was dissolved in ethanol (200 cm^3, 95%) and added to the yellow liquid, the resulting solution was heated at reflux for 3 h and cooled. Water (200 cm^3) was added, followed by hydrochloric acid (concentrated) until pH 1. The white solid was filtered and recrystallised from ethanol (95%) and dried under vacuum to give a pure white solid. Yield 7.22 g (52%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.88 (t, 3, CH_3), 1.24 (m, 14, 7CH_2), 1.81 (q, 2, CH_2CH$_2$O), 4.02 (t, 2, CH_2O), 6.92 (AA′XX′, 2, $J=8.9$ Hz, H12), 8.04 (AA′XX′, 2, $J=8.9$ Hz, H13).

(*S*)-4-Citronellyloxybenzoic acid (**2**) and hexyloxybenzoic acid (**3**) were similarly prepared in yields of 68 and 60%, respectively. Spectroscopic parameters were identical except for details of the NMR in the region of the alkyl chain. ^{1}H and ^{13}C NMR data are given for **2**. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.97 (d, 3, CH_3CH), 1.26 (m, 2, CH_2CH), 1.40 (m, 1, C*H*CH$_3$), 1.62 (s, 3, CH_3C=), 1.69 (s, 3, CH_3C=), 1.86 (m, 2, CH_2CH$_2$O), 2.03 (m, 2, CH_2), 4.08 (t, 2, CH_2O), 5.11 (m, 1, C*H*=C), 6.94 (AA′XX′, 2, $J=9.0$ Hz, H12), 8.05 (AA′XX′, 2, $J=9.0$ Hz, H13). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$): δ 17.7 (C8), 19.5 (C7), 25.4 (C6), 25.7 (C2), 29.5(C1), 35.9 (C9), 37.1 (C5), 66.6 (C10), 114.2 (C12), 121.3 (C14), 124.6 (C4), 131.9 (C3), 132.3 (C13), 163.6 (C11), 171.0 (C15).

5.2. Preparation of 4-decyloxybenzoyloxy-4′-benzoic acid (5)

4-Decyloxybenzoic acid (**1**) (7.22 g, 0.026 mol) was added to a suspension of DCC (5.36 g, 0.026 mol), DMAP (0.015 g) and benzyl 4-hydroxybenzoate (5.93 g, 0.026 mol) in CH_2Cl_2 (300 cm^3) and stirred under nitrogen for 18 h. The off-white precipitate was filtered and the filtrate con-

centrated to an off-white solid. The crude product was purified by column chromatography (SiO_2, eluent CH_2Cl_2) and a colourless solid was obtained after evaporation of the solvent. The solid was dissolved in THF (200 cm^3), then triethylamine (5 cm^3) and a palladium on carbon catalyst (5%) was added to the solution. After saturating with hydrogen gas, the solution was filtered and washed with CH_2Cl_2. The solvent was evaporated and the colourless solid was recrystallised from ethanol (95%) and dried under vacuum to give a pure colourless solid. Yield 4.07 g (39%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.90 (t, 3, CH_3), 1.28 (m, 14, 7 CH_2), 1.83 (m, 2, CH_2CH$_2$O), 4.06 (t, 2, CH_2O), 7.00 (AA′XX′, 2, J = 9.00 Hz, H12), 7.35 (AA′XX′, 2, J = 9.00 Hz, H17), 8.16 (AA′XX′, 2, J = 9.00 Hz, H13), 8.20 (AA′XX′, 2, J = 9.00 Hz, H18).

4-Hexyloxybenzoyloxy-4′-benzoic acid (**6**) and 4-heptylbenzoyloxy-4′-benzoic acid (**7**) were similarly prepared in yields of 45 and 42%, respectively. NMR parameters were almost identical to those of **5**, except in the aliphatic region.

5.3. Preparation of (S)-4-citronellyloxybenzaldehyde

(*S*)-(+)-Citronellylbromide (5.0 g, 0.023 mol) and 4-hydroxybenzaldehyde (1.83 g, 0.015 mol) were added to a suspension of potassium carbonate (8.29 g, 0.06 mol) and dibenzo-18-crown 6 (0.01 g) in butanone (150 cm^3). The solution was heated at reflux under nitrogen for 24 h. Water (150 cm^3) was added to the solution and the organic layer extracted with CH_2Cl_2 (200 $cm^3 + 3 \times 100$ cm^3). The combined organic extracts were dried over anhydrous $MgSO_4$, filtered and evaporated to give a yellow oil. The crude product was purified by column chromatography (SiO_2, eluent $CHCl_3$:hexane, 3:1 v/v) and the solvent evaporated to give the pure yellow oil. Yield 2.82 g (72%). IR (NaCl plates): ν_{CO} 1700 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.96 (d, 3, CH_3CH), 1.26 (m, 2, CH_2CH), 1.39 (m, 1, CHCH$_3$), 1.61 (s, 3, CH_3C=), 1.68 (s, 3, CH_3C=), 1.83 (m, 2, CH_2), 2.01 (m, 2, CH_2CH$_2$O), 4.08 (t, 2, CH_2O), 5.10 (m, 1, CHC=), 6.98 (AA′XX′, 2, J = 8.7 Hz, H12), 7.82 (AA′XX′, 2, J = 8.9 Hz, H13), 9.87 (s, 1, CHO). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$): δ 17.7 (C8), 19.5 (C7), 25.4 (C6), 25.7 (C2), 29.5 (C1), 35.9 (C9), 37.1 (C5), 66.7 (C10), 114.8 (C12), 124.5 (C4), 129.8 (C14), 131.4 (C3), 132.0 (C13), 164.2 (C11), 190.7 (C15).

5.4. Preparation of 4-decyloxybenzoyloxy-4′-benzaldehyde (*8*)

4-Decyloxybenzoic acid (2.79 g, 0.01 mol) was added to a suspension of DCC (2.06 g, 0.01 mol), 4-hydroxybenzaldehyde (1.22 g, 0.01 mol) and DMAP (0.05 g) in CH_2Cl_2 (200 cm^3) and stirred under nitrogen for 18 h. The colourless precipitate was filtered and the filtrate evaporated to give an off-white solid. The crude product was purified by column chromatography (SiO_2, eluent DCM) and the solvent evaporated to give a pure colourless solid. Yield 3.14 g (82%). *Anal*. Found: C, 75.1; H, 7.3. Calc. for $C_{24}H_{30}O_4$: C, 75.4; H, 7.9%. IR (KBr): ν_{CO2} 1737, ν_{CHO} 1699 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.89 (t, 3, CH_3), 1.28 (m, 14, 7 CH_2), 1.83 (q, 2, CH_2CH$_2$O), 4.05 (t, 2, CH_2O), 6.99 (AA′XX′, 2, J = 9.0 Hz, H12), 7.40 (AA′XX′, 2, J = 8.5 Hz, H17), 7.97 (AA′XX′, 2, J = 8.6 Hz, H18), 8.14 (AA′XX′, 2, J = 8.9 Hz, H13), 10.03 (s, 1, CHO).

4-(*S*)-Citronellyloxybenzoyloxy-4′-benzaldehyde (**9**), 4-decyloxybenzoyloxy-4′-benzoyloxy-4″-benzaldehyde (**10**), 4-hexyloxybenzoyloxy-4′-benzoyloxy-4″-benzaldehyde (**11**) and 4-heptylbenzoyloxy-4′-benzoyloxy-4″-benzaldehyde (**12**) were similarly prepared from **1**, **5**, **6** and **7** in yields of 76, 56, 20 and 50%, respectively.

5.5. Preparation of (S)-citronellyloxy-4-nitrobenzene

(*S*)-(−)-Citronellol (5.0 g, 0.032 mol) was dissolved in dimethylsulfoxide (50 cm^3). To the solution was added *p*-nitrochlorobenzene (5.04 g, 0.032 mol), and the mixture was stirred at 40°C for 10 min. Sodium hydride (0.84 g, 0.032 mol, 80% dispersion in oil) was added and the mixture heated to 70°C for 1.5 h. The green–black solution was quenched with water (30 cm^3) and acidified with HCl (2 mol dm^{-3}). The red solution was extracted with diethyl ether (2 × 30 cm^3) and the combined extracts dried over anhydrous Na_2SO_4. After filtering and evaporating the solvent, a deep red oil was obtained. The crude product was purified by column chromatography (SiO_2, eluent hexane:diethyl ether 5:1 v/v) and the solvent evaporated to give a pure yellow oil. Yield 6.47 g (73%). IR (NaCl plates): $\nu_{NO(asymmetric)}$ 1518 (broad), $\nu_{NO(symmetric)}$ 1380 cm^{-1} (sharp). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.97 (d, 3, CH_3CH), 1.25 (m, 2, CH_2CH), 1.39 (m, 1, CHCH$_3$), 1.61 (s, 3, CH_3C=), 1.69 (s, 3, CH_3C=), 1.86 (m, 2, CH_2CH$_2$O), 2.01 (m, 2, CH_2CH=), 4.08 (t, 2, CH_2O), 5.10 (m, 1, CHC=), 6.94 (AA′XX′, 2, J = 9.3 Hz, H12), 8.20 (AA′XX′, 2, J = 9.3 Hz, H13). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$): δ 17.7 (C8), 19.5 (C7), 25.4 (C6), 25.7 (C2), 29.4 (C1), 35.9 (C9), 37.0 (C5), 67.2 (C10), 114.4 (C12), 124.4 (C4), 125.9 (C13), 129.6 (C14), 131.5 (C3), 164.2 (C11).

5.6. Preparation 4-(S)-citronellyloxybenzoyloxy-4′-nitrobenzene (*14*)

(*S*)-4-Citronellyloxybenzoic acid (**2**) (2.76 g, 0.01 mol) was added to a suspension of DCC (2.06 g, 0.01 mol), *p*-nitrophenol (2.59 g, 0.01 mol)and DMAP (0.02 g) in CH_2Cl_2 (200 cm^3) and stirred under nitrogen for 18 h. The precipitate was filtered and the solvent evaporated to give a yellow oil. The crude product was purified by column chromatography (SiO_2, eluent DCM) and the solvent evaporated to give a pure pale yellow oil. Yield 3.47 g (87%). IR (NaCl plates): ν_{CO} 1740, $\nu_{NO(asymmetric)}$ 1512 (broad), $\nu_{NO(symmetric)}$ 1378 cm^{-1} (sharp). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.99 (d, 3, CH_3CH), 1.26 (m, 2, CH_2CH), 1.41 (m, 1, CHCH$_3$), 1.62 (s, 3, CH_3C=), 1.70 (s, 3, CH_3C=), 1.88 (m, 2,

CH_2CH_2O), 2.02 (m, 2, CH_2C=), 4.10 (t, 2, CH_2O), 5.12 (m, 1, C*H*C=), 6.99 (AA′XX′, 2, J=9.0 Hz, H12), 7.40 (AA′XX′, 2, J=9.2 Hz, H17), 8.14 (AA′XX′, 2, J=9.0 Hz, H13), 8.31 (AA′XX′, 2, J=9.2 Hz, H18). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 17.7 (C8), 19.5 (C7), 25.4 (C6), 25.7 (C2), 29.5 (C1), 35.9 (C9), 37.1 (C5), 66.8 (C10), 114.6 (C12), 120.5 (C15), 122.6 (C17), 124.5 (C4), 125.2 (C18), 131.4 (C3), 132.5 (C13), 145.3 (C19), 156.1 (C14), 163.9 (C16), 164.1 (C11).

4-Decyloxybenzoyloxy-4′-benzoyloxy-4″-nitrobenzene (**13**) was similarly prepared in 80% yield.

*5.7. Preparation of 4-(S)-citronellyloxybenzoyloxy-4′-aniline (**16**)*

To a suspension of 4-decyloxybenzoyloxy-4′-benzoyloxy-4″-nitrobenzene (**14**) (1.7 g, 0.00428 mol) in ethanol (20 cm^3, absolute) were added 5 equiv. of $SnCl_2 \cdot H_2O$ (4.83 g, 0.0214 mol). The mixture was heated to reflux under nitrogen for 18 h, cooled to room temperature and poured onto ice. The pH was adjusted to 8 by addition of NaOH (2 mol dm^{-3}) and the organic layer extracted with ethyl acetate (100 $cm^3 + 2 \times 50$ cm^3). The combined extracts were dried over anhydrous Na_2SO_4, filtered and the filtrate evaporated to give a brown oil. The crude product was purified by column chromatography (SiO_2, eluent diethyl ether:hexane 4:1 v/v) and the solvent evaporated to give a viscous yellow oil. Yield 1.01 g (64%). IR (NaCl plates): ν_{NH} 3458, ν_{NH} 3373, ν_{CO} 1726 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 0.98 (d, 3, CH_3CH), 1.26 (m, 2, CH_2CH), 1.40 (m, 1, C*H*CH_3), 1.61 (s, 3, CH_3C=), 1.70 (s, 3, CH_3C=), 1.86 (m, 2, CH_2CH_2O), 2.04 (m, 2, CH_2C=), 3.65 (s, 2, NH_2), 4.09 (t, 2, CH_2O), 5.12 (m, 1, C*H*C=), 6.71 (AA′XX′, 2, J=8.8 Hz, H18), 6.96 (AA′XX′, 2, J=9.0 Hz, H17), 6.99 (AA′XX′, 2, J=8.8 Hz, H12), 8.12 (AA′XX′, 2, J=9.0 Hz, H13). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 17.6 (C8), 19.5 (C7), 25.4 (C6), 25.7 (C2), 29.5 (C1), 36.0 (C9), 37.1 (C5), 66.6 (C10), 114.2 (C12), 115.7 (C18), 121.9 (C15), 122.4 (C17), 124.6 (C4), 131.4 (C3), 132.2 (C13), 144.1 (C19), 163.3 (C16), 165.5 (C11).

4-Decyloxybenzoyloxy-4′-aniline (**15**) was similarly prepared in 55% yield.

*5.8. Preparation of the imines: 4-citronellyloxybenzoyloxy-4′-benzylidene-4″-decyloxybenzoyloxy-4‴-aniline (**26**)*

To a suspension of 4-(*S*)-citronellyoxybenzoyloxy-4′-benzaldehyde (**9**) (0.71 g, 0.00187 mol) and 4-decyloxybenzoyloxy-4′-aniline (**15**) (0.69 g, 0.00187 mol) in ethanol (60 cm^3, absolute) and THF (20 cm^3) were added a few drops of acetic acid (glacial). The mixture was heated at reflux under nitrogen for 1 h and then cooled to room temperature. The solid was filtered, crystallised from ethanol (absolute):THF (60:1 v/v) and dried under vacuum to yield a pure off-white solid. Yield 0.74 g (54%). *Anal.* Found: C, 76.7; H, 8.1; N, 2.0. Calc. for $C_{47}H_{57}O_6N$: C, 77.1; H, 7.9; N, 1.9%. IR (KBr): ν_{CO} 1728, $\nu_{C=N}$ 1625 cm^{-1} (weak). ^1H NMR (400 MHz, $CDCl_3$): δ 0.90 (t, 3, CH_3), 0.99 (d, 3, CH_3CH), 1.29 (m, 16, 8 CH_2), 1.47 (m, 1, C*H*CH_3), 1.63 (s, 3, CH_3C=), 1.70 (s, 3, CH_3C=), 1.85 (m, 4, 2 CH_2CH_2O), 2.05 (m, 2, C*H*=C), 4.09 (2 t, 4, $2CH_2O$), 5.12 (m, 1, C*H*=C), 6.98 (AA′XX′, 2, J=9.0 Hz, H28), 6.99 (AA′XX′, 2, J=9.0 Hz, H12), 7.24 (AA′XX′, 2, J=9.0 Hz, H18), 7.29 (AA′XX′, 2, J=9.0 Hz, H17), 7.35 (AA′XX′, 2, J=8.6 Hz, H23), 7.98 (AA′XX′, 2, J=8.6 Hz, H22), 8.16 (AA′XX′, 2, J=9.0 Hz, H27), 8.16 (AA′XX′, 2, J=9.0 Hz, H13), 8.50 (s, 1, –C*H*=N–).

All other imines (**17**–**20** and **25**–**30**) were similarly prepared. Yields and analytical data are collected in Table 3.

*5.9. Preparation of the rhenium(I) complexes: complex **24***

To a suspension of 4-heptylbenzoyloxy-4′-benzoyloxy-4″-benzylidene-4‴-heptylaniline (**20**) (0.050 g, 0.080 mmol) in toluene (20 cm^3) was added pentacarbonylmethylrhenium(I) (0.030 g, 0.088 mmol). The reaction mixture was stirred under reflux for 20 h, under a nitrogen atmosphere, and then was cooled to room temperature and the solvent removed. The yellow solid was dissolved in CH_2Cl_2 and purified by column chromatography on alumina with CH_2Cl_2 as eluent. The solution was concentrated and hexane was added to give the pure yellow solid in 80% yield (0.059 g). ^1H NMR (400 MHz, CD_2Cl_2): δ 0.92 (t, 6, $^3J_{HH}$=7.00 Hz, CH_3), 1.35 (m, 16, CH_2), 1.68 (m, 4, CH_2CH_2Ph), 2.70 (t, 2, $^3J_{HH}$=7.80 Hz, CH_2Ph), 2.75 (t, 2, $^3J_{HH}$=7.80 Hz, CH_2Ph), 7.10 (dd, 1, $^3J_{HH}$=8.00 Hz, $^4J_{HH}$=4.00 Hz, H18),

Abstract

We report the preparation, structure and magnetic properties of a series of multilayer copper(II) hydroxy-dicarboxylates. These are prepared by anion-exchange, starting from copper(II) hydroxy-acetate $Cu_2(OH)_3(OAc)\cdot H_2O$. The acetate ion is substituted for *n*-methylene dicarboxylates $O_2CXCO_2^{2-}$, with $X=(CH_2)_n$ and $n=1$ to 8. Similar exchange reactions are carried out with unsaturated dicarboxylate anions ($X=(CH)_n$, with $n=2$, 4 and $X=C_4H_6$). The compounds, of general formulation $Cu_2(OH)_{4-x}(XC_2O_4)_{x/2}\cdot zH_2O$, exhibit a layered structure with a step-like variation of the basal spacing, according to *n* parity. IR spectroscopy indicates that the carboxylate functions are linked to the metal ions, each aliphatic chain bridging adjacent hydroxide layers. Only compounds with $n=2$, 4 and 8 show a net magnetic moment within copper(II) layers. For the short chain anions, an antiferromagnetic order occurs at low temperature, with a metamagnetic transition in low field, except for the unsaturated dicarboxylate $Cu_2(OH)_{1.92}(C_4H_6C_2O_4)_{1.04}\cdot 0.22H_2O$ which exhibits a long-range ferromagnetic order at $T_C=13$ K. For the long-chain anion, $X=C_8H_{16}$, a ferrimagnetic 3d order is stabilized below $T_C=17$ K. On the basis of structural and magnetic findings, a comparison is made between the saturated and unsaturated aliphatic chain compounds. This study provides new insight on the influence of π electrons on the ordering between magnetic layers. Finally, preliminary results for the cobalt(II) *trans*-hexenedioate analog indicate that a 3d ferromagnet is obtained below $T_C=56.5$ K, thus emphasizing the key role of the in-plane spin–spin correlations on the ordering temperature. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Since the first report by Gamble et al. on superconducting properties of the intercalated compound 2H–TaS_2 [1], the past quarter of a century has witnessed substantial efforts in the development of intercalation chemistry. The combination at the nanometer scale of molecular species and inorganic layered networks has been at the origin of a new class of systems, the organic–inorganic hybrid multilayer compounds. A variety of layered host structures exhibiting structural flexibility such as clays, chalcogenides or layered double hydroxides (LDH) [2–6] have been investigated in view of promoting intercalation reactions. Basically, the ability of these inorganic networks to undergo ionic exchange, or redox or acido-basic reactions, and the resulting effect on electronic properties, has initiated attractive applications in various fields, such as supported catalysis, non-linear optics or therapeutic treatments of trace element deficiencies [7,8].

The studies of hybrid multilayer compounds exhibiting coupled physical properties, i.e. whose properties differ from those of individual assemblies, represent a major challenge today. Striking results have been reported in photo-induced magnetic and conducting materials [9,10], and in systems combining two basic properties, such as conductivity and magnetism or optics and magnetism, for instance [11–14]. Thus, a multi-functional system has been achieved by intercalation of the hyperpolarizable dimethylamino-*N*-methyl stilbazolinium (DAMS) chromophore in between $MnPS_3$ inorganic layers [15,16]. The obtained compound exhibits both a net magnetic moment below 40 K, and remarkable non-linear optical properties (two orders of magnitude those of urea).

A large number of such cation-exchangeable layered compounds are known, in which the intercalated species favor pillared structures, but it can be emphasized that, usually, no real chemical bond exists between the guest and host subnetworks [17,18]. The cohesion is basically due to electro-

PII S0277-5387(99)00355-1

static or van der Waals interactions, and when available to weak hydrogen bond couplings.

In contrast, anion-exchangeable layered compounds are scarce, probably because the anions are usually strongly bonded to the metal ions, and form the framework of the crystal.

Exchange of interlamellar anions by organic species (dicarboxylic acid anions) was first reported by Miyata and Kumura [19]. The interlayer arrangement of anionic surfactant has been extensively studied in layered double hydroxides (LDHs) $[M^{II}_{1-x}M^{II}_{1-x}M^{III}_{x}(OH)_2]^{x+}A_x^-$ consisting of positively charged hydroxide layers, separated by A^- anions counter-balancing the positive charge of the layers [20,21]. In such compounds, the stabilization of two valence states for the metal ions induces a statistic disorder in the inorganic layers.

Basically, the chemistry of simple hydroxides with botallackite-type structure appears to be more adapted for the design of hybrid materials with outstanding magnetic properties. Yamanaka et al. [22] have investigated the exchange reactions in the layered copper(II) compound $Cu_2(OH)_3(CH_3COO)\cdot H_2O$. The acetate anion located in the interlayer space may easily be substituted by halides, NO_3^-, ClO_4^- or MnO_4^- anions, giving 2d triangular arrays of metal ions, with interlayer spacing depending closely on the size of the exchanged anion.

The use of large organic species (i.e. aliphatic chain anions) coordinating the metal ion enables tuning of the basal spacing, and accordingly drastic modification of the magnetic properties [23–27]. Thus, *n*-alkyl chain molecules involving a single anionic function (carboxylate or sulfate anion) have been used to separate basic layers (Fig. 1(a)).

In that case, the organic spacers exhibit a saturated carbon chain, whose length is mediated by the number of carbon atoms, up to 40 Å [23–26,28,29]. The magnetic interaction within layers is highly dependent on the nature of the anionic function and the chain stacking, so that ferro-, ferri- or antiferromagnetic behavior may be stabilized. Clearly, the *n*-alkyl chains do not participate directly in interlayer interaction (they may be viewed as 'neutral' pillars) but they modulate the distance between magnetic sheets, and as a result influence through-space magnetic interactions. We have shown that, owing to dipolar coupling [30], ferromagnetic 3d order is stabilized when the basal spacing becomes large enough (>10 Å). The interaction mechanism between ferromagnetic layers is then mainly driven by the divergence of the in-plane spin–spin correlation length when the temperature is decreased. Such systems appear to be good prototypes of monolayer magnets interacting through classical dipolar interactions.

Similarly, radical-based anions have been grafted onto copper(II) and cobalt(II) hydroxide layers [31–33]. The most interesting results are obtained for imino-nitroxide benzoate (imb) species coordinating cobalt(II) ions, giving $Co_2(OH)_{3.5}(imb)_{0.5}\cdot H_2O$ [31,33]. Such systems are good examples of hybrid multilayer ferromagnets, with a strong coupling between organic and inorganic networks.

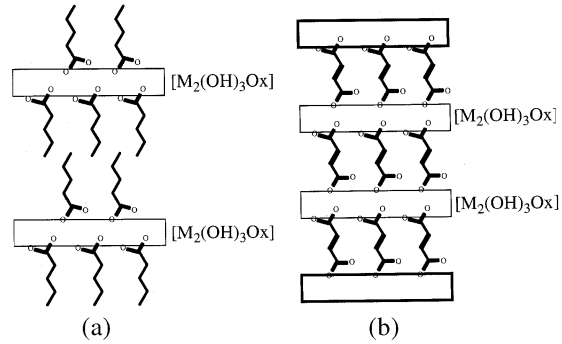

Fig. 1. Structural models showing the packing of aliphatic chains in layered metal hydroxides for (a) mono-carboxylate anions, (b) dicarboxylate anions.

Anionic exchange in divalent metal hydroxide compounds thus appears promising for the design of new multiproperty systems. It is however worthwhile to be able to control the connection between magnetic layers. For this purpose, we have focused on the design of dicarboxylate-based compounds, involving difunctional *n*-methylene, or *n*-alkenylene bridging anions between adjacent magnetic layers (Fig. 1(b)). From the comparison of hybrid systems with saturated and unsaturated aliphatic chains, basic insight is expected to result on the role of π electrons in the interlayer exchange mechanism.

We discuss here the synthesis and structure–property correlations for a series of copper(II)-based dicarboxylates ($n=1$ to 8). On the basis of structural and magnetic findings, a comparison is made with the cobalt(II) analog for the *trans*-hexenedioate anion.

2. Grafting of dicarboxylate anions

2.1. Experimental

The products were characterized by powder X-ray diffraction by using a Siemens D500 diffractometer in the Bragg–Brentano geometry (Co $K\alpha_1$, 1.78897 Å). Thermogravimetric analysis of the compounds was performed with a Setaram TGA 92 thermobalance up to 1000 K under air. Magnetic data ($\chi(T)$, $\chi_{ac}(T)$, $M(H)$) were collected from a Faraday-type equipment (Manics DSM10) and a SQUID magnetometer (Quantum Design MPMS*XL*) covering the temperature and field ranges 2–300 K, 0–5 T. A.c. susceptibility measurements were performed in a ± 3.5 Oe field (20 Hz). Fourier transform IR (FTIR) spectra were obtained in KBr pellets on an ATI-Mattson spectrometer, in the range 400–4000 cm^{-1}.

2.2. Synthesis

A series of copper(II) hydroxy-dicarboxylates has been prepared by anionic exchange. The starting hydroxy-acetate

[a] Meta, AF, Ferri, and F hold for the meta-, antiferro-, ferri- and ferromagnetic states, respectively.
[b] The θ values are determined from the high temperature variation of susceptibility, $\chi^{-1} = (T-\theta)/C$.

$Cu_2(OH)_3(OAc)\cdot H_2O$ is synthesized by titration of copper acetate by potassium hydroxide with the OH:Cu = 3:2 molar ratio [23,25,26]. Then, the acetate ions are exchanged for *n*-methylene dicarboxylate anions $XC_2O_4^{2-}$, with $X = (CH_2)_n$ and $n = 1$ to 8. Similar exchange reactions have been achieved with unsaturated dicarboxylate anions by using the fumaric ($X = C_2H_2$), *trans*-hexenedioic ($X = C_4H_6$) and muconic ($X = C_4H_4$) acid salts. Following the usual procedure [23,25,26], $Cu_2(OH)_3(OAc)\cdot H_2O$ powder (1 mmol) is dispersed into 30 ml of an aqueous solution (0.25 M) of the corresponding sodium dicarboxylate ($XC_2O_4Na_2$), at room temperature. After one day, the exchange is completed by repeating once the treatment of the reaction product with a fresh dicarboxylate solution, for two days. The precipitate of green crystal powder is washed with alcohol, then dried at 40°C. The general formulation of the compounds, given in Table 1, is $Cu_2(OH)_{4-x}(XC_2O_4)_{x/2}\cdot zH_2O$, with $1.0 < x < 2.4$ and $0.1 < z < 1.6$.

The cobalt(II) derivative with *trans*-hexenedioate ($X = C_4H_6$) anion is synthesized starting from pink hydroxy-nitrate $Co_2(OH)_3(NO_3)$. The latter is obtained by slow hydrolysis of an aqueous solution (3.5 M) of $Co(NO_3)_2\cdot H_2O$ by KOH (1 M), with OH:Co = 1.3, at 95°C [34]. The exchange reaction is carried out as above, with *trans*-hexenedioic acid salt for a 5:1 molar ratio between the sodium salt and the starting hydroxy-nitrate. The reaction is carried out at 45°C, within 20 h, under argon flux. The pH is set to 7.5 by addition of NaOH at the beginning of the reaction. The bluish-green crystal powder is washed with alcohol and dried at 40°C. The general formulation of the compounds is given in Table 1.

The stoichiometries in dicarboxylate and water of the above compounds agree with C, H and H_2O chemical analysis within less than 0.3 mass per cent. The amount of Cu is determined from the weight loss at 500°C under air (final product, CuO). The amount of Co is determined from the weight loss at 700°C under air (final product, Co_3O_4).

2.3. Structure

All the compounds exhibit a lamellar structure as is evident from their XRD patterns which show, in the low 2θ range, intense 00*l* diffraction lines, up to at least the third harmonic (Fig. 2). This corresponds to the stacking periodicity of the hydroxide-based layers (basal spacing). During the exchange process, the completeness of the reaction is checked by the abrupt change in peak position, by comparison with the starting materials $Cu_2(OH)_3(OAc)\cdot H_2O$ ($d_{001} = 9.3$ Å) or $Co_2(OH)_3(NO_3)$ ($d_{001} = 6.93$ Å). The other reflections (*hkl* with *h* and $k \neq 0$) are much smaller, and exhibit usual enlargement for disordered pillared compounds with turbostratic disorder [35]. Despite the poor quality of crystallographic data, the diffraction patterns may be analyzed using hexagonal or pseudo-hexagonal unit cells, as for the monocarboxylate derivatives [23,25,26]. The similarity of XRD

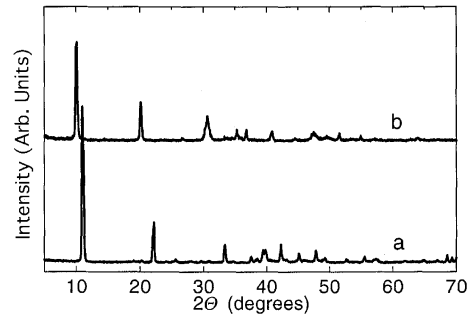

Fig. 2. Powder X-ray diffraction patterns of (a) $Cu_2(OH)_3(OAc)\cdot H_2O$, and (b) $Cu_2(OH)_{1.92}(C_4H_6C_2O_4)_{1.04}\cdot 0.22H_2O$ showing the shift of 00*l* diffraction lines.

patterns to those of $Cu_2(OH)_3(OAc)\cdot H_2O$ or $Co_2(OH)_3(NO_3)$ suggests that the local structure of the hydroxide-based layers remains quasi-unchanged after exchange reaction. In turn, the color change of the cobalt(II) exchanged compound (bluish-green) points to the occurrence of tetrahedral sites for the metal ion, and accordingly a structural modification of the inorganic layers.

The experimental basal spacing (interlayer distance) for copper(II) dicarboxylate compounds is given in Table 1. The variation of d_{001} with the chain length (n) is plotted in Fig. 3 for saturated *n*-methylene dicarboxylate anions. The basal spacing shows a step-like variation, in agreement with *n*-parity, which is related to the systematic change of orientation of the carboxylate groups in each bridging unit. For a given parity, a linear variation of d_{001} is observed, in agreement with the length of the exchanged anion. The slopes of the two straight lines (Fig. 3) are different, indicating a different tilt angle of the molecules with respect to the normal plane defined by the layers. The tilt angles are 42.9 and 25.7° for odd and even n values, respectively. The inorganic layer thickness deduced from the extrapolated values of d to $n=0$ differs by ca. 2 Å between the odd (8.3 Å) and even (6.3 Å) series. The mean value (7.3 Å) is close to the basal spacing reported for the parent compound $Cu_2(OH)_3NO_3$ ($d=6.95$ Å), exhibiting a Brucite-like structure [34,36]. This suggests that the hydroxide-based layers in the exchanged compounds are identical to those of the copper(II) hydroxy-nitrate, showing a quasi-planar triangular array of copper(II) ions in octahedral surrounding. Such a structural model for the inorganic layer is also found for the copper(II) hydroxy-acetate [37,38].

For unsaturated dicarboxylate anions, very close basal spacings are observed (0–0.2 Å step aside), compared to the corresponding saturated derivative.

The cobalt(II) compound is characterized by a basal spacing larger than that of the copper(II) analog by about 3.2 Å. Such a difference, already emphasized for the monocarboxylate series, is due to a larger thickness of the inorganic layer [39]. As noted above, the color change after anion-exchange points to the presence of cobalt(II) ions in tetrahedral surrounding. It can be predicted that the local structure of the metal-based layers is close to that of $Zn_5(OH)_8(NO_3)_2\cdot 2H_2O$ [40] or $Co_7(OH)_{12}(NO_3)_2\cdot zH_2O$ [41]. In these compounds, the inorganic 2d network consists of a median layer of transition metals in OH site, with metal vacancies at the apex of which lie two metal ions in T_d symmetry. The latter are surrounded by three oxygen atoms of the median layer completed by an oxygen atom belonging to nitrate.

In the frame of this model structure for the cobalt(II) compound, the organic anions could be connected through carboxylate moities to the Co(T_d) metal ions, and occupy the space in between the layers with water molecules.

Characteristic IR spectra of the exchanged compounds are displayed in Fig. 4 for representative samples. The presence of a broad feature in the hydroxyl stretching region (3000–3600 cm^{-1}) corresponds to lattice water, according to quantitative analysis (Table 1). A set of superimposed bands (Fig. 4(a)) is attributed to free CuO–H and CO–H hydrogen bonds. The spectra of the quasi-anhydrous compounds (Fig. 4(c)) present only one intense free O–H band at 3560–3570 cm^{-1}. The presence of organic molecules is confirmed by several bands around 2950 cm^{-1} which are attributed to C–H vibrations. The carboxylate doublet is clearly identified at 1530–1580 cm^{-1} and 1400–1430 cm^{-1}. The first one corresponds to the C=O stretch, and may include water for a small contribution (a more or less pronounced shoulder at ca. 1610 cm^{-1} is observed for hydrated compounds). From the position of the band, it is likely that the carboxyl groups are bonded to copper(II). The doublet is unique, indicating that the two carboxylate functions are linked to the layers, according to the charge balance between the organic and inorganic sub-networks. Finally, a relatively strong band around 870 cm^{-1}, attributed to the out-of-plane γ(OH–O) vibration [42], is recorded for five compounds, namely the succinic (864 cm^{-1}), adipic (864 cm^{-1}), *trans*-hexenedioic (873 cm^{-1}), muconic (884 cm^{-1}) and sebacic (895 cm^{-1}) acid derivatives. This particular feature is not observed for the cobalt(II) compound.

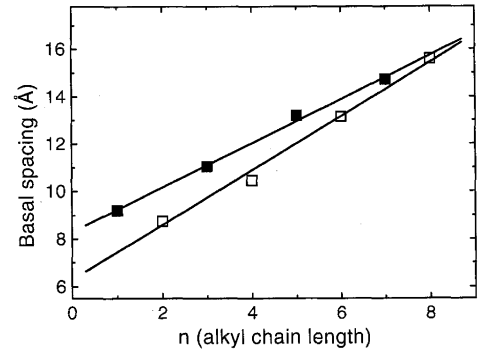

Fig. 3. Variation of the basal spacing as a function of n in copper(II) *n*-methylene dicarboxylates. Linear variations are observed for odd and even series.

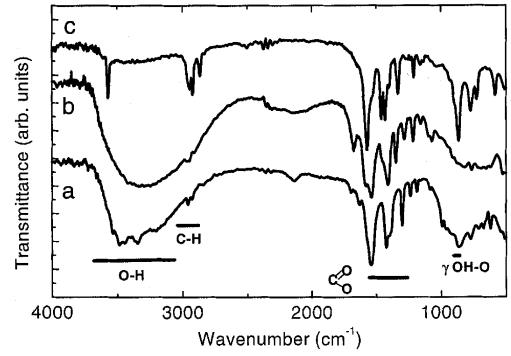

Fig. 4. IR spectra for (a) $Cu_2(OH)_{2.90}(C_2H_4C_2O_4)_{0.55}\cdot 0.58H_2O$, (b) $Cu_2(OH)_{2.76}(C_3H_6C_2O_4)_{0.62}\cdot 1.62H_2O$ and (c) $Cu_2(OH)_{2.08}(C_4H_8C_2O_4)_{0.96}\cdot 0.13H_2O$.

2.4. Magnetic properties

The magnetic properties of the copper(II)-based compounds involving *n*-methylene dicarboxylate bridging anions

are shown to be very sensitive to the spatial extension of the organic chains, as summarized in Table 1, but no clear correlation can be drawn.

Most of the studied compounds exhibit a 2d antiferromagnetic (AF) behavior over the whole temperature range, as illustrated by the continuous decay of the χT product at decreasing temperature (Fig. 5). There is no evidence of bulk ordering in the investigated temperature range. Only compounds with $n=2$, 4 and 8 show ferro or ferrimagnetic 2d behavior, in other words copper(II) layers with a net magnetic moment. For the saturated $n=2$ (succinate) anion, the variation of χT (Fig. 6) is very similar to that of the acetate derivative [23,25,26]. Upon cooling, a constant χT value is obtained down to 50 K, then a slight increase up to 0.95 cm^3 $K\ mol^{-1}$ at 11.2 K, suggesting weak ferromagnetic (F) in-plane interactions. At lower temperature, the drop of χT agrees with interlayer AF interactions, promoting a 3d long-range order. In turn, the unsaturated derivative ($X=C_2H_2$) shows clearly an AF behavior over the whole temperature range. Note that such a variation cannot be explained by a change of the basal spacing, but is due most likely to slight modification in the local structure of the inorganic layer, inducing a change of sign of the exchange coupling. Such a magnetic dependence is well documented for copper(II) systems which appear to be very sensitive to the metal–oxygen–metal bridging angle [43,44].

The most striking results are noticed for the $n=4$ anions with saturated ($X=C_4H_8$) and unsaturated ($X=C_4H_6$ and $X=C_4H_4$) aliphatic chains, noted hereafter **4₀**, **4₁** and **4₂**, respectively. These compounds, which only differ by the number of double bonds of the anionic spacer (0 to 2), are characterized by very close basal spacings (10.45 to 10.22 Å), and as a result have analogous structures.

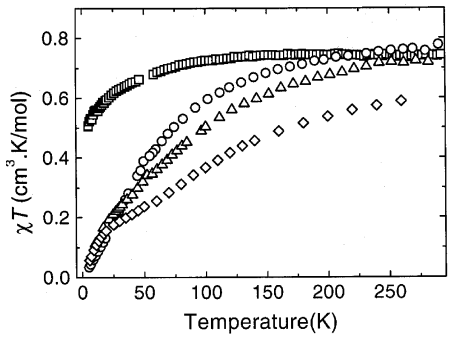

Fig. 5. Temperature dependence of the χT product for copper(II) *n*-methylene dicarboxylates with $n=1$ (□), 3 (○), 5 (△) and 7 (◇).

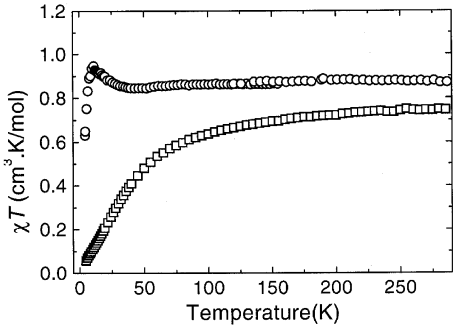

Fig. 6. Temperature dependence of the χT product for the copper(II) dicarboxylates $Cu_2(OH)_3(XC_2O_4)_{0.5}$ with the saturated ($X=C_2H_4$) (○), and unsaturated ($X=C_2H_2$) (□) bridging anions.

A strong and regular increase of χT is observed upon cooling down (Fig. 7), characteristic of significant in-plane ferromagnetic interactions, with a maximum at 15.7 K for **4₀**, 13.0 K for **4₁** and 16.0 K for **4₂**. The main difference occurs at low temperature, since **4₀** and **4₂** show an AF long-range ordering with a metamagnetic transition for $H_C=2250$ and 2040 Oe, respectively (inset of Fig. 7), while **4₁** exhibits a characteristic ferromagnetic transition. This is evidenced from the strong divergence of χT at low temperature (factor 10 with respect to **4₀**), and the variation of a.c. susceptibility (Fig. 8). The T_C value recorded from the maximum of χ'_{ac} is found to be 13.0 K. The variation of magnetization, plotted in the inset of Fig. 8, agrees with a ferromagnetic order between copper(II) layers. The hysteretic effect at 4 K is small (around 100 Oe), indicating that the anisotropy of magnetic moments is weak.

A fit of the magnetic susceptibility has been performed in the paramagnetic regime to determine the in-plane exchange interaction between copper(II) ions. Using the high temperature series expansions [45,46] for the spin-1/2 2d Heisen-

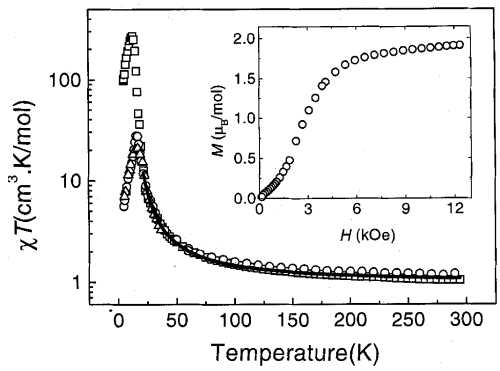

Fig. 7. Temperature dependence of the χT product for the copper(II) dicarboxylates involving the saturated, $X=C_4H_8$ (○), and the unsaturated $X=C_4H_6$ (□) and $X=C_4H_4$ (△) bridging anions. The full line corresponds to the best fit, using HTS expression for the susceptibility [45,46].The inset shows the metamagnetic transition of $M(H)$ for the saturated dicarboxylate.

berg triangular lattice [1], a very good agreement between theory and experimental findings is obtained for $J/k = 27$ K ($H = -J\sum S_iS_j$) (Fig. 7). Note that above T_C, the χT variation is well fitted from the sum of Arrhenius-like contributions, $a\exp(E_1/kT) + 0.86\exp(E_2/kT)$ with $a = 5.10^{-6}$, $E_1/k = 287$ K and $E_2/k = 52.6$ K, (Fig. 9), showing clearly two regimes for the magnetic behavior (0.86 gives the high temperature Curie constant). Thus, above 25 K, χT is well described by an exponential decay whose activation energy corresponds roughly to $2J$. In the vicinity of T_C, the variation of χT is depicted by a rapidly diverging function, with a strong activation energy, indicating that interlayer interactions are no longer negligible.

Preliminary experiments have been performed for the cobalt(II) *trans*-hexenedioic ($X = C_4H_6$) parent compound. The χT plot (Fig. 10) shows a slight decay from room temperature down to 100 K (11.7 cm^3 K mol^{-1}), due to the spin–orbit coupling effect, then a sharp divergence below 65 K with a maximum of 575 cm^3 K mol^{-1}, pointing to a long-range ferromagnetic ordering. A.c. susceptibility measurements confirm the occurrence of a magnetic ground-state with an out-of-phase signal below $T_C = 56.5$ K.

Finally, the long-chain compound $n = 8$ (sebacic acid) exhibits a very different magnetic behavior (Fig. 11). The χT product decreases on cooling from 0.8 cm^3 K mol^{-1} at room temperature down to 0.44 cm^3 K mol^{-1} at 40 K, then displays a very rapid increase below 20 K. As already mentioned for copper(II) *n*-alkyl carboxylate derivatives [23,25,26], such a χT variation is characteristic of a ferrimagnetic low-lying spin-state for copper(II) layers. Owing to the nature of the in-plane exchange pathways, which involve oxygen atoms from OH^- and $O_2CC_8H_8CO_2^{2-}$, it can be stated that the triangular network is likely strongly distorted and ordered sub-networks with uncompensated magnetic ground-state take place. It follows that an antiferromagnetic spin-1/2 triangular model is irrelevant to determine the in-plane exchange constants.

Nevertheless, the paramagnetic behavior is well described by the relationship $a\exp(E_1/kT) + b\exp(E_2/kT)$, with $a = 0.05$, $b = 0.92$, $E_1/k = 64.6$ K and $E_2/k = -62.5$ K, which indicates clearly two competing regimes. At high temperature, the activation energy E_2 agrees with an AF coupling, while in the vicinity of T_C, the E_1 value indicates a ferromag-

[1] $\chi T = \frac{Ng^2\mu_B^2}{k}\sum_n^{\infty}\frac{a_n}{n!}\left(\frac{-J}{4kT}\right)^n$

$a_0 = 0.25$, $a_1 = -1.5$, $a_2 = 12$, $a_3 = -102$, $a_4 = 900$, $a_5 = -10584$, $a_6 = 195432$, $a_7 = -3411504$, $a_8 = 22723392$, $a_9 = 449551104$, $a_{10} = 17698680192$, $a_{11} = -1884636552960$, $a_{12} = 15953277445632$, $a_{13} = 3244354478011392$.

netic alignment of the resulting spins. The overall Curie constant is given by the sum $a+b$.

At low temperature, the transition towards a magnetic ground-state is evidenced from a.c. susceptibility data (Fig. 12). An out-of-phase signal is observed below $T_C = 17$ K, which is slightly higher than for **4_1**.

The occurrence of long-range ferrimagnetic order is confirmed by a characteristic hysteretic effect in the $M(H)$ curve at $T = 4$ K (inset of Fig. 11). On close examination of the remnant value of magnetization, it may be stated, on the basis of the Stoner–Wohlfarth model developed for single-domain particles with uniaxial anisotropy [47], that about half of copper(II) moments are uncompensated at low temperature, owing likely to the presence of two sub-networks.

3. Concluding remarks

The mechanism responsible for the low temperature magnetic behavior of hybrid systems made of metal hydroxide layers separated by large organic spacers, such as *n*-alkyl sulfate or carboxylate, is now well understood [25,26,39]. Owing to the nature of the ligands, the alkyl chains do not participate directly in the interlayer coupling but noticeable change may be induced on the in-plane exchange mechanism, in particular for copper(II) compounds whose behavior is closely related to the structural features [43,44].

Similarly, either F or AF behavior is observed for copper(II) dicarboxylates, without a clear relationship with the value of the basal spacing. Nevertheless, it can be pointed out that some insight on the correlation with the local structure arises from IR spectroscopy. Thus, a band is observed in the range 864–895 cm^{-1} for copper(II) compounds exhibiting ferro or ferrimagnetic layers, only. Further, it is worth noticing that these systems involve aliphatic chains with even parity, i.e. corresponding to a fixed tilt angle of the bridging anion. This condition for stabilizing magnetic copper(II) layers appears to be significant but not sufficient, as illustrated by the AF behavior of the compounds with $X = C_2H_2$ and C_6H_{12}. A small variation of the anion tilt angle is likely responsible for a slight structural modification of the layer itself, and accordingly for the exchange mechanism within copper(II) layers.

Let us focus now on the low temperature behavior of the saturated dicarboxylate compounds with metal layers showing a ferro or ferrimagnetic spin arrangement, in accordance with the χT variation in the paramagnetic regime.

In these systems, the situation depends to a large extent on the interlayer spacing. For $n = 2$ and 4, a very weak interlayer interaction stabilizes a 3d AF order, and a metamagnetic transition occurs in low field, as already mentioned for monocarboxylate compounds [25,26]. When the spacing is made larger ($n = 8$), a spontaneous magnetization is observed, with a characteristic hysteretic effect, which can only be explained by considering dipolar through-space interactions between ferromagnetically coupled layers [30]. Indeed the strength of the dipolar interaction energy between magnetic layers at a distance *r* apart, varies as r^{-1} for the systems under consideration, so that it is by far the driving contribution for distances larger than 10–11 Å [48].

Clearly, this description fails for the unsaturated ($X = C_4H_6$) bridging anion compound, since bulk ferromagnetism is stabilized for a basal spacing $d = 10.22$ Å, very close to that of the saturated analog. Even if it can be claimed that the *d* turning value is about 10–11 Å, a different mechanism, taking into account the polarization by π electrons, must be involved to explain the occurrence of long-range ferromagnetism.

Further, for the conjugated derivative ($X = C_4H_4$), an AF ground-state takes place with a metamagnetic transition in low field, according to the spin polarization in the conjugated π system. The number of double bonds in the bridging anion is thus an essential feature to control the coupling between magnetic layers.

Finally, the magnetic study of this series of hybrid compounds shows that spectacular and unexpected behaviors may be obtained, depending on the basal spacing and the π character of the bridging species. In this respect, these systems differ markedly from the classical layered hybrid compounds, mostly because they provide a new class of multilayer magnets with possible electronic transfers between adjacent layers. Such hybrid systems may be viewed as good candidates for tunneling magnetoresistance effects.

Abstract

In order to investigate the influence of the central metal on mesomorphism and π-acceptor properties of the octa-alkoxy-substituted metal complexes, novel homologs, bis[di(*n*-alkoxy)phenyldithiolene]palladium and bis[di(*n*-alkoxy)phenyldithiolene]platinum (*n*-alkoxy = $C_nH_{2n+1}O$, $n=1$ to 12), have been synthesized. The mesophases were established by microscopic observations, DSC, and temperature-dependent X-ray diffraction techniques. As reported previously, the nickel complexes show a Col_h mesophase for $n=5$ to 12. On the other hand, the present palladium and platinum complexes show a Col_h mesophase for $n=4$ to 12 and $n=6$ to 12, respectively. Thus, they give the Col_h mesophase for a shorter length of alkoxy chain in the order Pd, Ni, Pt. For $6 \leq n \leq 12$, the clearing points become higher in the order Pt < Ni < Pd. The intracolumnar stacking distances of these Ni, Pd and Pt complexes were observed at 3.64 ± 0.02, 3.56 ± 0.03, and 3.73 ± 0.02 Å, respectively. Thus, they gave a longer stacking distance in the order Pt > Ni > Pd. Hence, the order of stacking distances is apparently related to the order of clearing points. Moreover, the Pt, Ni and Pd complexes show reduction potentials at -0.09 ± 0.01, -0.055 ± 0.005, and $0.00 \leq 0.01$ V (versus SCE in CH_2Cl_2), respectively. They become better π-acceptors in the order Pt < Ni < Pd. We reveal from the electronic absorption spectra that the LUMO energy level of these metal complexes decreases in the order Pt < Ni < Pd, and that the back donation of electrons from the central metal to the ligand occurs more in the same order Pt < Ni < Pd. This results in better π-acceptor properties in the order Pt < Ni < Pd for the present complexes. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Since the first organic metal TTF–TCNQ was found in 1972, many organic one-dimensional conductors have been studied [2,3]. The one-dimensional conductors form an infinite columnar structure with stacking of the planar molecules, and an electron-conducting path is formed along the one-dimensional axis. On the other hand, discotic (disk-like) liquid crystals were discovered in 1977 and similarly form a columnar structure, so that the application of disk-like liquid crystals to one-dimensional conductors has been studied [4–11]. In particular, disk-like liquid crystals of organic transition metal complexes form a one-dimensional chain of the central metal in the columnar axis direction which is favorable for high conductivity [12–17].

As shown in Fig. 1, Bélombé suggested in 1983 that a special one-dimensional columnar structure might show high conductivity [18]. In this columnar structure, the π-acceptor dithiolene metal complex and the π-donor glyoximato metal complex are mutually piled up. This special structure not only has the one-dimensional chain of the central metals but also has the mutual arrangement of S and N atoms in the surroundings to form four pseudo $(SN)_x$-like chains. $(SN)_x$ is well known to show superconductivity. Hence, we thought that if these core complexes could be substituted by long chains, they would become columnar liquid crystals and show high conductivity. We previously succeeded in the synthesis of octa-long-chain-substituted π-donor glyoximato metal complexes (M = Ni, Pd, Pt). According to our expectation, these complexes have columnar mesophases [19–23]. The oxida-

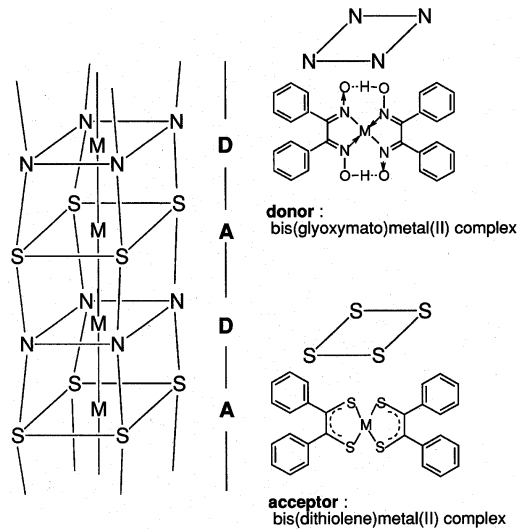

Fig. 1. Schematic representation of the one-dimensional conductor composed of a metal–metal linear chain surrounded by four $(SN)_x$-like chains [18].

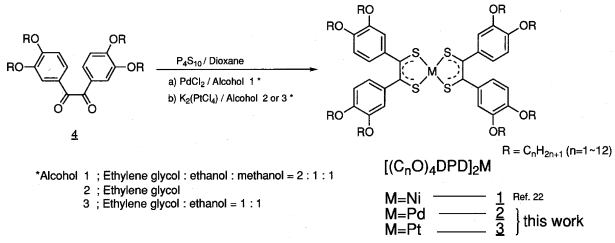

Fig. 2. Synthetic route for the bis[1,2-bis(3′,4′di-*n*-alkoxyphenyl)ethane-1,2-dithiolene]metal complexes.

tion potentials are approximately constant irrespective of the central metal [24]. On the other hand, for the π-acceptor dithiolene metal complexes, only synthesis of the octa-long-chain-substituted bis(diphenyldithiolene)nickel complexes (**1** in Fig. 2) has been successful. These Ni complexes also showed columnar liquid crystalline phases. Their reduction potentials are −0.05 to −0.06 V irrespective of the length of the alkoxy chains [25]. These nickel complexes are the first π-acceptor columnar liquid crystals.

In this study, we have, hence, synthesized novel Pd and Pt complexes **2** and **3** (Fig. 2), to obtain better π-acceptor dithiolene metal complexes in the homologs of octa-long-chain-substituted dithiolene metal complexes. We investigated the influence of central metal species on the π-acceptor and liquid crystal properties. Interestingly, the disk-like Pd and Pt complexes synthesized here exhibit the same Col_h mesophase as the Ni complexes. More interestingly, the Pd complexes exhibit the highest clearing points and the broadest temperature range of the mesophases, and are the best π-acceptor columnar mesogens in these three kinds of metal complexes. We wish to report here the liquid crystal and π-acceptor properties of these interesting octa-long-chain-substituted dithiolene metal complexes.

2. Experimental

2.1. Synthesis

The synthetic route for the $[(C_nO)_4DPD]_2Pd$ ($n=1$ to 12) (**2**) and $[(C_nO)_4DPD]_2Pt$ ($n=1$ to 12) (**3**) complexes is shown in Fig. 2. The detailed procedure of preparation of these complexes is the same as described by us previously, except for the solvent for metal salts [26]. By modification of the solvent (Fig. 2), we succeeded for the first time in syntheses of the target complexes, $[(C_nO)_4DPD]_2Pd$ ($n=1$ to 12) (**2**) and $[(C_nO)_4DPD]_2Pt$ ($n=1$ to 12) (**3**). Tables 1 and 2 summarize the solvents for metal salts, the elemental analysis data, the yields, the recrystallization solvents, and the colors of the virgin state of these complexes. The detailed procedures are described for the representative $[(C_{12}O)_4DPD]_2Pd$ and $[(C_{12}O)_4DPD]_2Pt$ complexes, as follows.

[c] EtOH, ethanol.

*2.1.1. Bis[1,2-bis(3′,4′-di-n-dodecyloxyphenyl)ethane-1,2-dithiolene]palladium (**2**)*

To dioxane (86 ml), phosphorus pentasulfide (1.78 g, 4.03 mmol) and 3,3′,4,4′-tetradodecyloxybenzil (**4**) (1.90 g, 2.01 mmol) were added and then the mixture was refluxed for 9 h under a nitrogen atmosphere. The hot reaction mixture was filtrated to remove the precipitates. To the hot filtrate was added palladium(II) chloride (0.18 g, 1.0 mmol) dissolved in about 50 ml of a mixed solvent of ethylene glycol:ethanol:methanol = 2:1:1(v/v/v). The reaction mixture was refluxed for 2 h under a nitrogen atmosphere. After the reflux, about 100 ml of ethanol was added to the reaction mixture. After cooling to room temperature, it was filtered to collect the precipitates. The target complex was the precipitate on the filter paper. Purification was carried out by silica gel column chromatography (*n*-hexane:benzene = 1:1 (v/v), $R_f = 0.67$) and recrystallization from a mixed solvent of *n*-hexane and ethanol to give 0.38 g of **2** as black crystals. Yield 18%.

^{1}H NMR ($CDCl_3$, TMS) δ (ppm): 0.88 (t, $J = 5$ Hz, 24H), 1.12–1.91 (m, 160H), 3.76 (t, $J = 6$ Hz, 8H), 3.99 (t, $J = 6$ Hz, 8H), 6.81–7.25 (m, 12H).

IR (KBr pellet, cm^{-1}): 2920, 2860, 1600, 1510, 1350.

*2.1.2. Bis[1,2-bis(3′,4′-di-n-dodecyloxyphenyl)ethane-1,2-dithiolene]platinum (**3**)*

To dioxane (93 ml), phosphorus pentasulfide (1.88 g, 4.23 mmol) and 3,3′,4,4′-tetradodecyloxybenzil (**4**) (2.00 g, 2.11 mmol) were added and then the mixture was refluxed for 5 h under a nitrogen atmosphere. The hot reaction mixture was filtrated to remove the precipitates. To the hot filtrate was added potassium tetrachloroplatinate(II) (0.44 g, 1.1 mmol) dissolved in 20 ml of a mixed solvent of ethylene glycol:ethanol = 1:1 (v/v). The reaction mixture was refluxed for 2 h under a nitrogen atmosphere. After cooling to room temperature, the precipitates appeared and the reaction mixture was filtered to collect the precipitates. The target complex was the precipitate on the filter paper. Purification was carried out by silica gel column chromatography (*n*-hexane:benzene = 1:1 (v/v), $R_f = 0.67$) and recrystallization from a mixed solvent of *n*-hexane and ethanol to give 0.63 g of **3** as black crystals. Yield 28%.

^{1}H NMR ($CDCl_3$, TMS) δ (ppm): 0.94 (t, $J = 5$ Hz, 24H), 1.09–2.16 (m, 160H), 3.77 (t, $J = 5$ Hz, 8H), 3.99 (t, $J = 5$ Hz, 8H), 6.69–7.12 (m, 12H).

IR (KBr pellet, cm^{-1}): 2920, 2860, 1600, 1510, 1350.

2.2. Measurements

The final products were identified by elemental analysis, ^{1}H NMR and IR spectra using a Perkin–Elmer elemental analyzer 240B, a JEOL JNM-FX90A, and a JASCO A-100, respectively. The phase transition behaviors of these compounds were observed by an OLYMPUS BH2 polarizing microscope equipped with a heating plate controlled by a thermoregulator, Mettler FP80 and FP82, and measured with a Shimadzu DSC-50 differential scanning calorimeter. To establish the mesophases, powder X-ray patterns were measured with Cu Kα radiation using a Rigaku Geigerflex equipped with a hand-made heating plate controlled by a thermoregulator. The electrochemical properties were determined in dichloromethane solutions containing 0.1 M of tetrabutylammonium perchlorate as supporting electrolyte. Cyclic voltammograms were obtained with a hand-made potentiostat and recorded with a Yokogawa Electric Works type 3086X-Y recorder. The measurements were made at a glassy carbon working electrode versus saturated calomel electrode (SCE). Electronic spectra were measured with a Hitachi 330 spectrophotometer.

[c] These Col_h phases were identified not by X-ray diffraction but by microscopic observation of the natural textures.

3. Results and discussion

3.1. Mesomorphic properties

As summarized in Tables 3 and 4, some of these compounds have several crystalline phases including metastable phases, whereas the $[(C_nO)_4DPD]_2Pd$ ($n=4$ to 12) and $[(C_nO)_4DPD]_2Pt$ ($n=6$ to 12) complexes have only one enantiotropic columnar mesophase. Each of the $[(C_nO)_4DPD]_2Pd$ ($n=4$ to 12) and $[(C_nO)_4DPD]_2Pt$ ($n=6$ to 12) complexes exhibits a fan-shaped texture when the isotropic liquid is cooled. This texture can usually be observed for a Col_h mesophase.

To establish this mesophase, temperature-dependent X-ray diffraction measurements were carried out. Fig. 3 shows an X-ray diffraction pattern of the mesophase of the $[(C_5O)_4DPD]_2Pd$ complex at 130°C. The X-ray diffraction data are summarized in Table 5. As can be seen from this table, the eight narrow peaks located at the lower angle region agree with a two-dimensional hexagonal lattice; a diffuse band around 4.5 Å ($2\theta \cong 20°$) corresponds to the melting of the alkoxy chains, and another diffuse band centered at 3.38 Å (around $2\theta = 25°$) corresponds to fluctuation of the intermolecular disk distance in the one-dimensional molecular stack. Hence, this mesophase could be identified as a Col_h mesophase. Similarly, each of the mesophases of the other $[(C_nO)_4DPD]_2Pd$ ($n=4$, 6 to 12) and $[(C_nO)_4DPD]_2Pt$ ($n=8$ to 12) complexes could also be identified as a Col_h mesophase by X-ray structural analyses. Since the $[(C_nO)_4DPD]_2Pt$ ($n=6$, 7) complexes in the homologous series show a narrow temper-

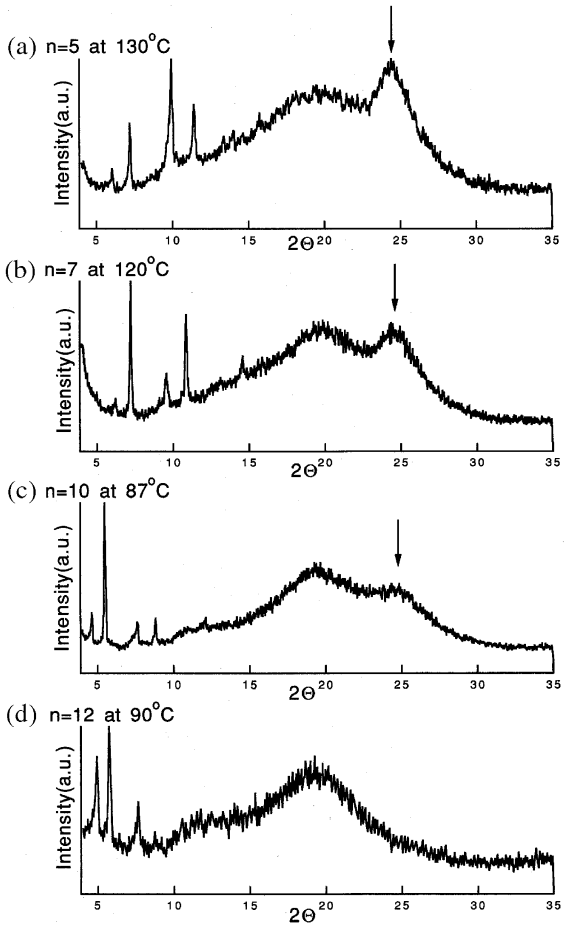

Fig. 4. X-ray diffraction patterns of the Col_h mesophases of the $[(CnO)_4DPD]_2Pd$ complexes ($n = 5$, 7, 10, 12).

ature range for the mesophase, X-ray diffraction measurements were not carried out and these Col_h mesophases were identified only from their fan-shaped textures.

The X-ray diffraction patterns of the Col_h mesophases of $[(C_nO)_4DPD]_2Pd$ ($n = 5$, 7, 10, 12) complexes are shown in Fig. 4. As can be seen from these patterns, the diffraction peak around $2\theta = 25°$ which corresponds to fluctuation of the interdisk distance, becomes broader and smaller with increasing chain length. This means that the order of the interdisk distance is higher for the shorter alkoxy chains, whereas it is lower for the longer chains. It is very interesting that the order decreases gradually and continuously when the chains become longer. Consequently, we could not tell where the disordered columnar phase starts. In our opinion, it is impossible to distinguish clearly between the ordered and disordered columns. Therefore, these present mesophases are only denoted as Col_h.

We have previously reported the liquid crystallinity of the $[(C_nO)_4DPD]_2Ni$ ($n = 1$ to 12) complexes [25]. The phase transition temperatures of the homologous Ni, Pd and Pt complexes, **1**, **2** and **3**, are plotted against the number of carbon atoms (n) in the alkoxy chains in Fig. 5, to investigate the influence of central metal atom on the mesomorphism. For $n = 4$, only the Pd complex gives a Col_h mesophase, and for $n = 5$, the Pd and Ni complexes give the Col_h mesophases but the Pt complex does not. For $n \geq 6$, the Col_h mesophase can be observed for all the Pd, Ni and Pt complexes. Thus, the liquid crystallinity appears more easily in the order Pt, Ni and Pd complexes with shorter chains.

The central metal atoms in these mesogens for $n = 6$ to 12 also influence the clearing points and the temperature range of the mesophase. These clearing points are highest for the Pd complexes, middle for the Ni complexes, and lowest for the Pt complexes. The temperature ranges of the mesophases are widest for the Pd complexes, middle for the Ni complexes

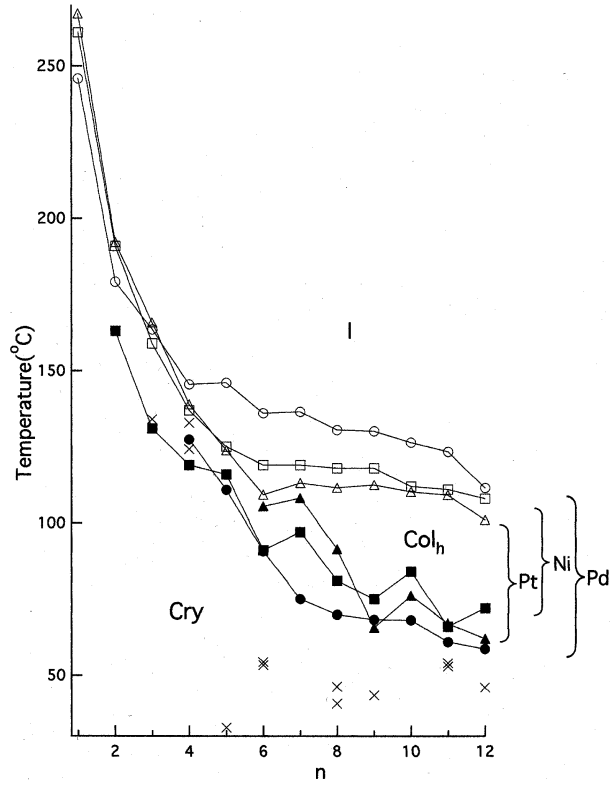

Fig. 5. Phase transition temperatures vs. the number of carbon atoms (n) in the alkoxy chains of the metal complexes **1**–**3**. Nomenclature: Cry = crystal, Col_h = hexagonal columnar mesophase, Ni, Pd, Pt = $[(C_nO)_4DPD]_2M$ ($n = 1$–12, M = Ni, Pd, Pt).

and narrowest for the Pt complexes, in the same order as the clearing points. Hence, the liquid crystallinities are greatly affected by the central metal species.

The lattice constants of the mesophases for the Ni, Pd and Pt complexes are plotted against the number of carbon atoms in the alkoxy chains in Fig. 6. The lattice constants of these three metal complexes gave almost the same linear relationship, irrespective of the central metal atom. Hence, the two-dimensional hexagonal lattice constants are not affected by the central metal species. The interdisk distances could be observed as 3.56 ± 0.03 Å for the Pd complexes, 3.64 ± 0.02 Å for the Ni complexes, and 3.73 ± 0.02 Å for the Pt complexes. Thus, the interdisk distances for the Pd complexes are the narrowest among these three metal complexes. That is to say, the intermolecular interaction in the column is strongest for the Pd complexes, forming the tightest and most stable columns, which may cause the highest clearing points. In contrast, the interdisk distances for the Pt complexes are the widest. The intermolecular interaction in the column is the smallest for the Pt complexes, and the columns can be most easily destroyed into disks, which may cause the lowest clearing points. Hence, the order of these clearing points $Pt < Ni < Pd$ may result from the order of the interdisk distances $Pt > Ni > Pd$.

Thus, contrary to our expectation of a smooth progression for Ni to Pt, the Pd complexes are very special. This reminds us that the calamitic bis(*p*-*n*-alkylstyryl-1,2-dithiolato)-nickel and bis(*p*-*n*-alkylstyryl-1,2-dithiolato)platinum are liquid crystalline but the palladium complexes are not [27].

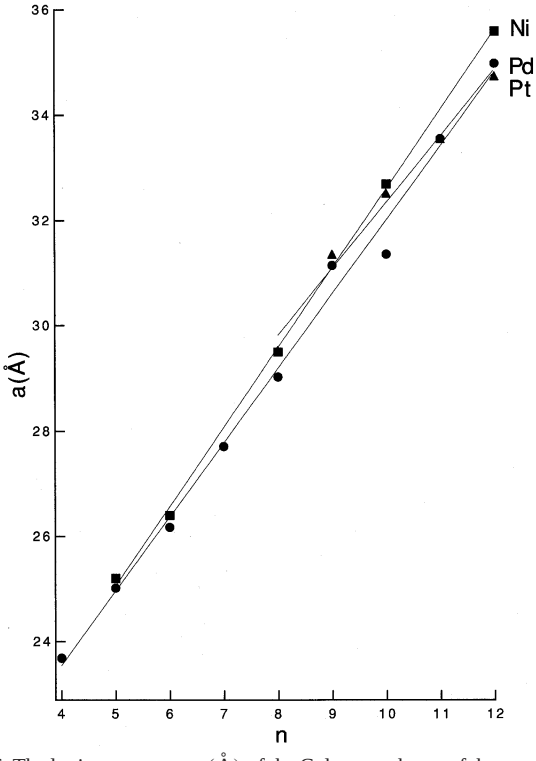

Fig. 6. The lattice constants a (Å) of the Col_h mesophases of the complexes **1**–**3** vs. the number of carbon atoms (n) in the alkoxy chains.

3.2. Electrochemical properties

Each of the cyclic voltammograms of the Pd and Pt complexes for $n = 1$ to 12 was reversible and almost the same. The reduction potentials obtained were -0.09 ± 0.01 V for the Pt complexes, -0.055 ± 0.005 V for the Ni complexes, and 0.00 ± 0.01 V for the Pd complexes. Thus, the values are nearly constant for each of the three metal complexes, irrespective of the chain length. This means that the π-acceptor columnar mesogens can be obtained without impairment of the π-acceptor ability, by introduction of the long chains to each of the bis(dithiolene)metal complexes.

Interestingly, the reduction potentials become more positive in the order $Pt < Ni < Pd$, so that the π-acceptor ability becomes better in the same order. Hence, the Pd complexes are the best π-acceptor columnar mesogens.

The left side of Fig. 7 illustrates the energy levels of the HOMO (Φ_{HOMO}) and LUMO (Φ_{LUMO}) of the dithiolene nickel core complex NiBDT calculated by Herman et al. [28]. Here, E_F, V, e and ΔE_{red} are the constant Fermi level of the counter electrode, an applied voltage, elementary electric charge, and a measured reduction potential, respectively. Eqs. (1) and (2) can be set up as follows:

$$\Phi_{LUMO} = E_F - eV \quad (1)$$

$$\Delta E_{red} = eV \quad (2)$$

So, Eq. (3) can be derived from Eqs. (1) and (2)

$$\Phi_{LUMO} = E_F - \Delta E_{red} \quad (3)$$

Hence, the more positive the reduction potential ΔE_{red} becomes, the more negative the LUMO Φ_{LUMO} becomes. That is to say, the better the π-acceptor ability becomes, the

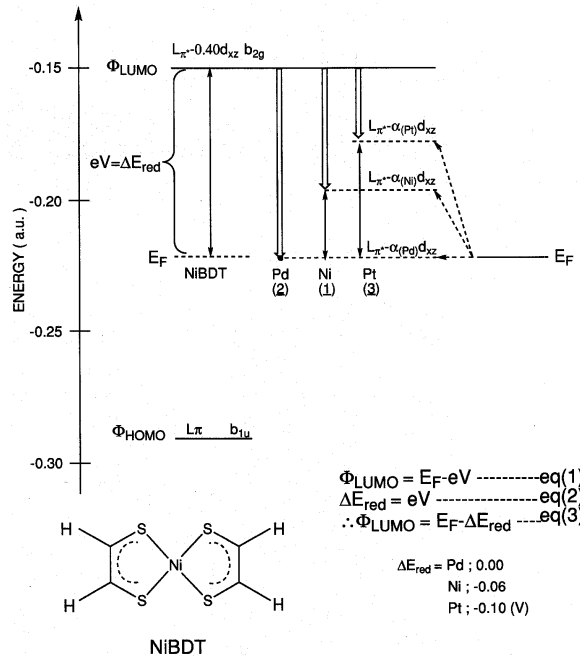

Fig. 7. HOMO and LUMO of NiBDT [26] and the $[(C_nO)_4DPD]_2M$ ($n = 1$–12, M = Ni, Pd, Pt) complexes **1**–**3**.

lower the energy level of the LUMO becomes. To compare the reduction potentials ΔE_{red} of the present metal complexes, the ΔE_{red} values become more positive in the order Pt < Ni < Pd. Hence, it can be derived from Eq. (3) that the Φ_{LUMO} levels become more negative in the order Pt < Ni < Pd, as illustrated on the right side of Fig. 7: the Φ_{LUMO} level against the constant Fermi level is the most positive for the Pt complexes, middle for the Ni complexes and the most negative for the Pd complexes. The Φ_{LUMO} for Pd complexes is situated nearly at the same level as the Fermi level.

This should be dependent on the extent of the contribution from the d_{xz} orbital to the ligand π* orbital which is in the order Pt < Ni < Pd, because the calculation by Herman et al. revealed that the Φ_{LUMO} orbital of NiBDT is formed by mixing of the ligand π* orbital and the central nickel d_{xz} orbital (L_{π^*}–0.40d_{xz}) [28].

3.3. Electronic absorption spectra

Electronic spectra of the [$(C_{12}O)_4$DPD]$_2$M (M = Ni, Pd, Pt) complexes are shown in Fig. 8. These data are listed together with the data for NiBDT in Table 6. Dithiolene metal complexes are well known to have a strong absorption in the near-IR region. The absorption wavelength λ_{max} is easily affected by the substituent groups and the central metals. It has been reported that λ_{max} can be assigned to the allowed HOMO–LUMO transition between the molecular orbitals which spread all over the complex [28–30]. As can be seen from Fig. 8, the absorption bands of the present

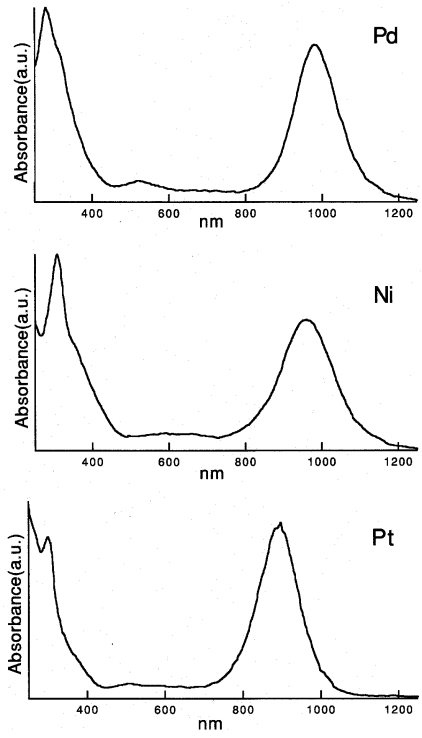

Fig. 8. Electronic absorption spectra of the [$(C_{12}O)_4$DPD]$_2$M complexes in $CHCl_3$: 1.0×10^{-4} M (250–1250 nm), 1 mm cell.

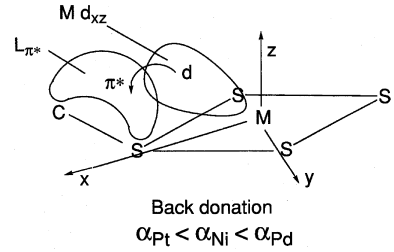

Fig. 9. Back donation of electron from the d_{xz} orbital of the central metal to the π* orbital of the ligand (L_{π^*}) in the [$(C_nO)_4$DPD]$_2$M (n = 1–12, M = Ni, Pd, Pt) complexes **1**–**3**.

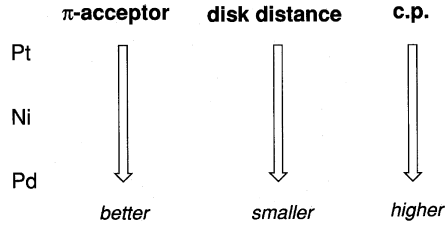

HOMO(L_π) → LUMO(L_{π^*}–αd_{xz}) transition could be observed around 800–1000 nm in the near-IR region. The λ_{max} shifts to longer wavelength in the order of the Pt complex (898 nm), the Ni complex (957 nm), and the Pd complex (979 nm), which means that the energy gap between the HOMO and LUMO levels becomes smaller in this order. Since the HOMO orbital consists only of the ligand π orbital without any contribution from the d orbital as calculated by Herman et al. [28], the HOMO energy levels may be constant. Hence, the decrease in the energy gap shows that the LUMO energy level goes down (Fig. 7). This is consistent with the electrochemical properties mentioned above.

Fig. 9 illustrates the d_{xz} orbital of the central metal (M d_{xz}) and the π* orbital of the ligand (L_{π^*}). The LUMO of the complexes is stabilized by the electron delocalization which originates from the back donation (α) of electron from the d_{xz} orbital of the central metal to the L_{π^*} orbital of the ligand. Hence, the LUMO of these complexes is denoted L_{π^*}–αd_{xz} (Fig. 7). Thus, the LUMO energy level of these metal complexes decreases in the order Pt < Ni < Pd, which implies that the back donation (α_M) of electrons from the central metal to the ligand occurs more in the order M = Pt < Ni < Pd (Fig. 9). Hence, it is apparent that the better the π-acceptor ability, the larger is the back donation occurring.

4. Conclusions

In this study, we have succeeded in the synthesis of the novel π-acceptor columnar liquid crystalline dithiolene Pd

and Pt complexes. All the dithiolene metal complexes with Ni, Pd and Pt as the central metal (**1**, **2** and **3**, respectively) show the same Col_h mesophase. The π-acceptor ability of these metal complexes becomes better in the order Pt < Ni < Pd. It was revealed by electrochemical measurements and electronic spectral measurements that the extent of the back donation of electrons from the central metal to the ligand becomes larger in the same order Pt < Ni < Pd. More interestingly, it was found by X-ray structural analyses that the interdisk distance becomes smaller in the same order Pt > Ni > Pd. This means that the more densely the disks are compacted in the column, the stronger the interdisk interaction in the column becomes in the order Pt < Ni < Pd. This is the reason why the columns are difficult to break up into disks in the order Pt < Ni < Pd when these metal complexes are heated, and why their clearing points become higher in the same order. Hence, apparently there is a good relationship between the intramolecular back donation and the intermolecular disk distance for these metal complexes. The conductivities of these complexes also attract our further interest.

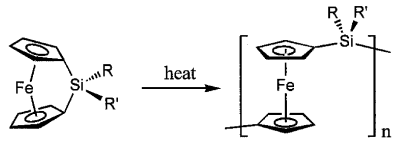
Abstract

Reaction of dichlorodiferrocenylsilane, Fc_2SiCl_2 (**4**) (Fc = (η-C_5H_4)Fe(η-C_5H_5)), with dilithioferrocene $fcLi_2 \cdot TMEDA$ (fc = (η-C_5H_4)$_2$Fe, TMEDA = *N*,*N*,*N*,*N*-tetramethylethylenediamine) afforded the novel trimetallic [1]silaferrocenophane **5**, $fcSiFc_2$, in 77% yield. A single crystal X-ray diffraction study of ferrocenophane **5** showed the presence of significant disorder but revealed that the molecule possesses a highly strained structure where the tilt-angle between the planes of the cyclopentadienyl rings of the ferrocenophane is 20–22°, typical of strained silicon-bridged [1]ferrocenophanes. The Fe···Fe distances in **5** are 5.434, 5.537, and 5.687 Å, and metal–metal interactions are evident as redox coupling was detected in the cyclic voltammogram of this species. Differential pulse voltammetry resolved three oxidation waves at 0, 0.22, and 0.45 V relative to the ferrocene/ferrocenium couple. Mössbauer spectroscopy proved useful in corroborating the structure of **5**, as the two distinct Fe environments present were readily resolved ($\delta = 0.424(5)$ mm s^{-1}, d, $\Delta E_q = 2.242(5)$ mm s^{-1}, 2 Fe; $\delta = 0.414(5)$ mm s^{-1}, d, $\Delta E_q = 1.930(5)$ mm s^{-1}, 1 Fe). Further characterization of **5** by IR and Raman spectroscopy was also undertaken. Ring-opening addition of HCl across a strained Si–C bond of **5** afforded chlorotriferrocenylsilane, Fc_3SiCl (**6**), in 81% yield. Subsequent hydrolysis of **6** afforded a silanol Fc_3SiOH (**7**) with three ferrocenyl substituents. Single crystal X-ray diffraction of **7** revealed that the compound crystallizes as hydrogen-bonded dimers. When heated, **5** was found to undergo thermal ring-opening polymerization (ROP) to afford cyclic oligomeric species $[fcSiFc_2]_x$ (**9**$_x$, $x = 2$ or 3) and an insoluble polymeric material $[fcSiFc_2]_n$ (**8**). Copolymers **10** were obtained when **5** was heated in the presence of dimethyl[1]silaferrocenophane, $fcSiMe_2$ (**1a**). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Ferrocenophane; Inorganic polymers; Silanol; Mössbauer spectroscopy; Ring-opening polymerization



1. Introduction

As a result of recent synthetic advances, polymers that incorporate transition metals in the main chain are attracting renewed attention. Such materials are of considerable interest because of their interesting chemical and physical properties, and in certain cases they may serve as useful precursors to novel ceramic materials (for recent examples of transition metal-based polymeric materials, see, for example [1–8]). Ferrocene, which is cheap, stable, tunable, and possesses very interesting properties, represents a particularly attractive structural moiety to include in a polymer main chain. With this in mind, we have previously shown that strained silicon-bridged [1]ferrocenophanes such as **1a** undergo thermal ring-opening polymerization (ROP) to afford high molecular weight ($M_n > 10^5$) poly(ferrocenylsilanes) (e.g. **2a**) when heated in the melt [9,10] (an atom abstraction ROP route to poly(ferrocenes) with disulfide spacers was published shortly prior to Ref. [9]). Subsequent extensive work has shown that the resulting poly(ferrocenylsilanes) and analogous materials formed by the ROP methodology possess a range of interesting properties [11–14]; for the work of other groups on poly(ferrocenylsilanes) and related materials, see [15–17]. Of particular significance is the observation that these ring-opened poly(ferrocenes) (as exemplified by **2a**) display two reversible oxidation waves (redox coupling, $\Delta E = 0.21$ V) by cyclic voltammetry (CV), which is indicative of

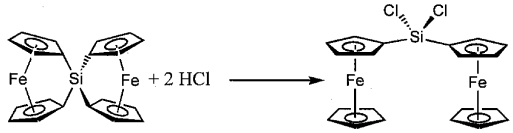
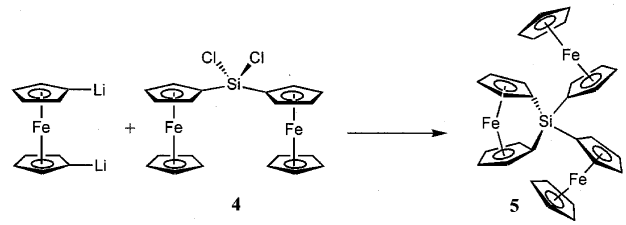
significant metal–metal interactions along the polymer main chain [9,11,12].



1a (R = R' = CH_3) **2a** (R = R' = CH_3)
1b (R = Fc; R' = CH_3) **2b** (R = Fc; R' = CH_3)

We and Pannell and co-workers have investigated monomer **1b**, fcSiMeFc (Fc = (η-C_5H_4)Fe(η-C_5H_5), fc = (η-C_5H_4)$_2$Fe) with a single ferrocenyl substituent at Si and have shown that thermal ring-opening polymerization (ROP) of this species proceeds to give the high molecular weight poly(ferrocenylsilane) **2b** [18–20]. Cyclic voltammetry of **2b** showed evidence for metal–metal interactions between both skeletal ferrocene units and the ferrocenyl side groups [19,20]. Even more extensive metal–metal interactions would be anticipated in analogous poly(ferrocenes) with two ferrocenyl substituents at silicon. We therefore report in this paper the synthesis, characterization, and ROP of the sterically encumbered [1]silaferrocenophane, fcSiFc$_2$ (**5**). In addition to studies of the ROP of **5** we have also investigated the use of this species as a precursor to compounds with three ferrocenyl substituents via stoichiometric ring-opening reactions.

2. Results and discussion



2.1. Synthesis of diferrocenyl[1]silaferrocenophane 5

We have recently shown that the red, air-stable, easily accessible spirocyclic [1]ferrocenophane **3** undergoes ring-opening addition of 2 equiv. of HCl to afford diferrocenyldichlorosilane **4** in very high (ca. 90%) yield [21,22]. Subsequent reactions with **4** have been used to generate a range of interesting species such as siloxanediols and cyclosiloxanes with ferrocenyl substituents at Si [23].

3 **4**

Reaction of **4** with 1 equiv. of fcLi$_2$·TMEDA in THF afforded [1]silaferrocenophane **5** as air-stable, red crystals in 77% yield after work-up (Scheme 1). The ^{13}C NMR data of the product were consistent with the proposed structure for **5**, showing four peaks due to Cp rings of the ferrocenyl substituents and three resonances assigned to the ferrocenophane. The chemical shifts for the resonances assigned to the *ipso* carbon atoms of **5** were observed at 65.4 and 35.0 ppm (C_6D_6). Specifically, the resonance at 65.4 ppm results from the *ipso* carbon atom of the ferrocenyl substituents, while the

4 **5**

Scheme 1.

resonance of the *ipso* carbon atom of the ferrocenophane was observed at 35.0 ppm. The latter value represents a large upfield shift compared to unstrained species, characteristic to [1]ferrocenophanes [24]. In the ^{1}H NMR spectrum of **5**, four pairs of triplets due to Si bound Cp rings and an intense singlet due to the free Cp ring of the ferrocenyl substituents were observed, consistent with the structure. The ^{29}Si chemical shift ($\delta = -15.5$ ppm in $CDCl_3$) is upfield from the resonance observed in **4** (15.2 ppm). The chemical shift for this resonance also lies between the ^{29}Si NMR signals observed for tetraferrocenylsilane ($\delta = -10.1$ ppm) and spirocyclic [1]ferrocenophane **3** ($\delta = -16.6$ ppm) [22]. The additional shielding observed in **3** and **5** might be attributed to a weak dative Fe···Si interaction, and is consistent with the single crystal X-ray structure and Mössbauer data (vide infra) for **5**.

Like other [1]ferrocenophanes, **5** shows a red shift in the λ_{max} in the UV–Vis spectrum relative to analogous ring-opened species. Thus, upon forming the ferrocenophane, the λ_{max} shifts from 448 nm in **4** to 474 nm in **5** (in CH_2Cl_2). This maximum is not as high as for other [1]silaferrocenophanes (e.g. 487 nm for **1a** in CH_2Cl_2), most likely because of the contribution from the superimposed absorption peak of the ferrocenyl substituents. Mass spectrometry of **5** showed the molecular ion ($m/z = 582$) as the major peak.

2.2. X-ray structural determination of 5

To confirm the formation of the [1]ferrocenophane **5**, a single crystal X-ray diffraction study was performed. Red single crystals of **5** were isolated by slow evaporation of a solution of **5** in CH_2Cl_2 under a nitrogen atmosphere. A summary of cell contents and data collection parameters is included in Table 1. A summary of important structural features is provided in Table 2.

[1]Ferrocenophane **5** crystallizes in monoclinic space group $P2_1/c$. Unfortunately, the compound displays static disorder, but the X-ray study does confirm the synthesis of the strained ferrocenophane **5**. A molecular structure showing the disordered structure solution is shown in Fig. 1(a). Primarily two configurations of the ferrocenophane are distributed among the molecular sites in the structure; these are shown separately in Fig. 1(b,c). Bond lengths and bond angles, summarized in Table 2, are reasonable and typical of other ferrocenophanes and ferrocenylsilanes and, in particular, are similar to those for **1b** which was structurally characterized by Pannell et al. [20]. Furthermore, the Cp ligands

of the ferrocenyl substituents are essentially planar and parallel and the Cp ligands of the ferrocenophane moiety are planar and eclipsed, as expected. The ferrocenophane has a ring tilt of 20–22°, consistent with that observed in other [1]silaferrocenophanes. While the disorder of the C atoms is too large for meaningful comparison, the Si atom and three Fe atoms are not disordered. Surprisingly, these four atoms are coplanar (mean deviations of 0.002 Å from the least-squares plane). As the Fe···Fe distances are only 5.43–5.69 Å in the structure, metal–metal interactions are expected to be detected in the electrochemistry of **5**. The Fe···Si distance for the ferrocenophane in **5** is 2.73 Å, only slightly greater than the sum of the covalent radii of Fe and Si (2.42 Å) [25], suggesting a weak Fe···Si dative interaction.

The molecular arrangement of **5** in the crystal structure is intriguing. The molecules are organized into planes where all of the Si and Fe atoms lie in the *ab* plane. Within that plane, each molecule has six closest neighbours, spaced at 9.12, 10.5, and 11.0 Å (two at each Si···Si distance). For the closest contacts (9.12 Å length), the ferrocenophane moieties are arranged along the Si···Si axis. Fig. 2 shows a picture of the *ab* plane in the structure, illustrating the distribution of the monomers. Between the planes, some of the molecules are separated by only 7.96 Å (Si···Si) with other interplane Si···Si distances of 8.72 and 8.90 Å. Where the separation is only 7.96 Å, the orientation is such that the ferrocenophane moieties are closer to the bridging Si atoms of the other molecule, although the *ipso*-C···Si contacts are still quite long.

*2.3. Electrochemistry of **5***

Recently, several papers have appeared that report the preparation and electrochemical behavior of complexes containing multiple ferrocene moieties [22,23]; for leading references see [26]. These studies contribute to our understanding of how biological systems deliver several electron equivalents to redox sites [27]. For example, it has been

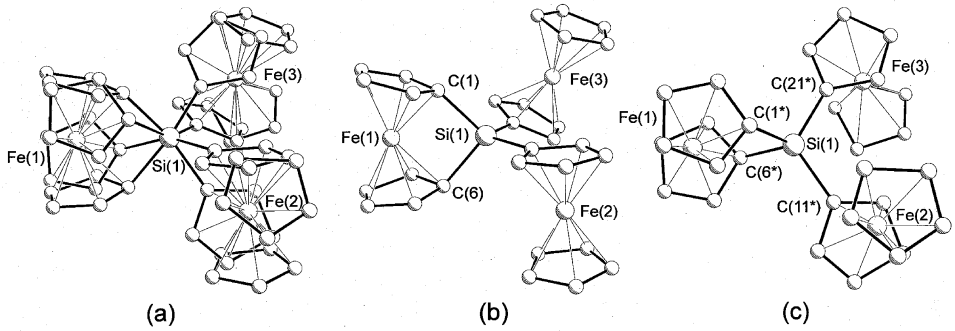

Fig. 1. (a) The structure of the [1]silaferrocenophane **5** shows two independent molecular conformations in the lattice. (b,c) The structure of the two distinct molecules observed in the molecular sites of **5**.

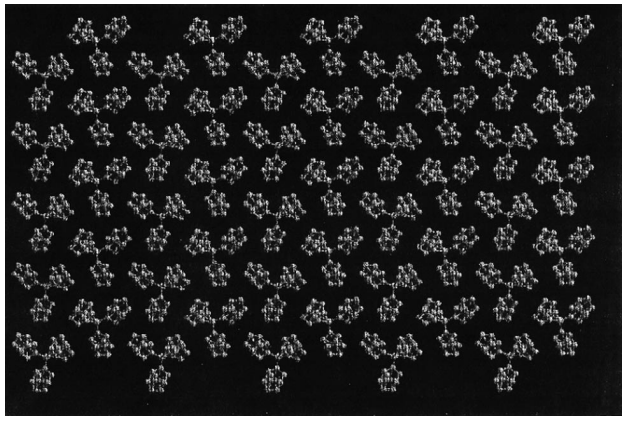

Fig. 2. A projection of the *ab* plane in [1]silaferrocenophane **5**.

demonstrated that the four Fe centers in cytochrome C_3 undergo electron transfer at very similar potentials, the spread of the four Fe^{II}/Fe^{III} $E_{1/2}$ values being only 0.11 V [28]. The electrochemistry of ferrocenophane **5** was investigated by cyclic voltammetry and differential pulse voltammetry (DPV). Owing to precipitation of the tri-oxidized cation in various solvents, the CV was not useful. DPV in dichloromethane, however, showed three oxidation waves as predicted for compound **5**; this is illustrated in Fig. 3. The three oxidation waves were observed at ca. 0, 0.22, and 0.45 V (referenced to the ferrocene/ferrocenium couple), indicating strong electronic interactions between all three metal centers. Thus, after the first Fe is oxidized, the potential required to oxidize the second center is raised. Most likely, the first two

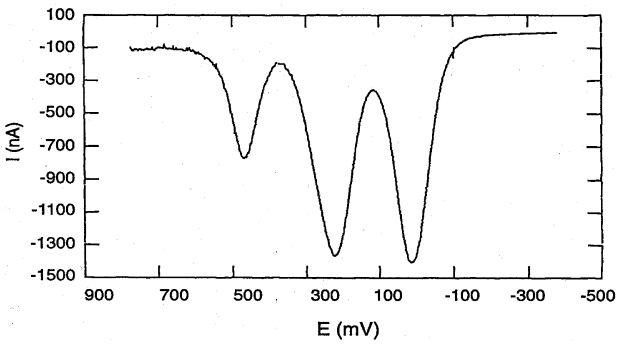

Fig. 3. Differential pulse voltammetry (DPV) of **5** referenced to the ferrocene/ferrocenium couple (dichloromethane).

oxidation waves correspond to oxidation of the ferrocenyl substituents for which the Fe centers would experience the least amount of Coulombic repulsion. Upon oxidizing the third Fe, the tri-oxidized cation precipitated, accounting for the decreased intensity of the third peak relative to the first two.

The spread of the four potentials in tetraferrocenylsilane is 0.42 V, implying appreciable interactions between the ferrocenyl moieties as they are successively oxidized [22]. However, this is less than in compound **5**, where the total spread is 0.45 V. This fact implies that the oxidation of the ferrocenophane imparts a larger amount of Coulombic repulsion upon the other ferrocenyl substituents than oxidation of a ferrocenyl substituent at Si. It may be concluded that single Si bridging atoms allow significant interactions between ferrocenyl substituents in their multiply ferrocenyl-substituted complexes.

2.4. Mössbauer study of 5

The Fe environments of ferrocene and its derivatives have been thoroughly investigated by Mössbauer spectroscopy [29–32]. Studies of [1]ferrocenophanes have indicated a reduced quadrupolar splitting relative to ferrocene (2.37 mm s^{-1}) while the isomer shift is virtually unchanged (0.44 mm s^{-1}) [24]. Silver has postulated that a weak iron-to-heteroatom interaction is the cause of the change in quadrupolar splitting, although the issue is still debated [33]. The Mössbauer spectrum of **5** was obtained at room temperature and is shown in Fig. 4. Clearly, the raw data appear skewed and immediately suggested the presence of more than two peaks in the spectrum. Moreover, the full widths at half-maximum (FWHM) of the peaks (when the spectrum was fitted with only two peaks) were unusually large for crystalline ferrocene derivatives. An automatic peak pick and optimization found two pairs of peaks, as shown in the deconvolution in Fig. 4. The broad doublet has an isomer shift, δ, of 0.424(5) mm s^{-1} and a quadrupolar splitting, ΔE_q, of 2.242(5) mm s^{-1}, similar to ferrocene and unstrained ferrocene derivatives. Thus, the latter absorption is attributed to Fe in the ferrocenyl substituents. On the other hand, the inner doublet has an isomer shift, δ, of 0.414(5) mm s^{-1} and a quadrupolar splitting, ΔE_q, of 1.930(5) mm s^{-1}, consistent

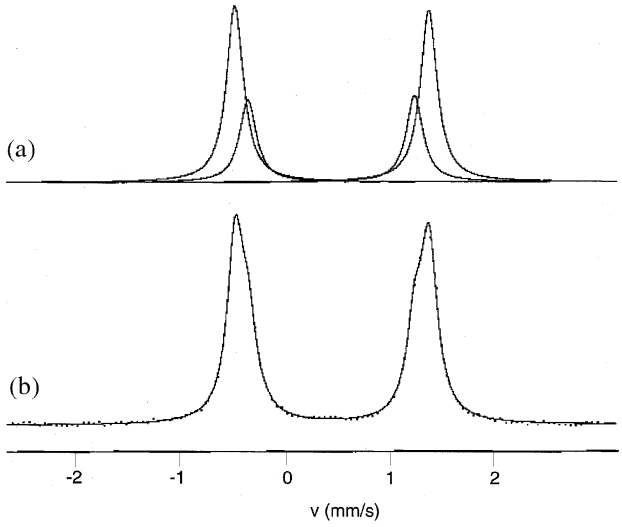

Fig. 4. The Mössbauer spectrum of **5** and fit are shown at the bottom. The deconvolution of the peaks into two quadrupolar doublets is shown on the top. The original data are shown as points.

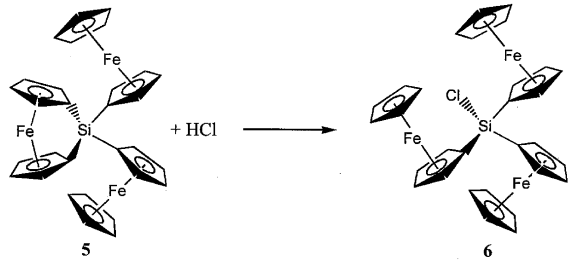
with a [1]silaferrocenophane [33]. These peaks are attributed to the Fe in the ferrocenophane ring of compound **5**. Furthermore, the intensity of the narrow peaks is half (49.8% total area, 49.3% amplitude) of the broad peaks, as expected for the structure of ferrocenophane **5** (assuming that the recoil free-fractions for the ^{57}Fe in the ferrocenyl substituents and the ferrocenophane are equivalent).

2.5. Vibrational spectra of 5

The vibrational properties of **5** were investigated by IR and Raman spectroscopies. Table 3 lists the observed IR and Raman peaks along with their assignments. Most of the peaks could be assigned by analogy with ferrocene and other ferrocene-containing compounds we have studied. It is worth noting that the Raman spectrum of ferrocenophane **5** resembles the spectra of both compound **3** and tetraferrocenylsilane. A medium intensity, sharp peak observed at 706 cm^{-1} in **5** is also observed in compound **3** (714 cm^{-1}), but not in tetraferrocenylsilane. This may be a νC–Si for the ferrocenophane. In contrast, a medium intensity peak observed at 1161 cm^{-1} in **5** is characteristic of the ferrocenyl substituents as it was observed at 1159 cm^{-1} in tetraferrocenylsilane, but not in compound **3**. Interestingly, the ring breathing modes in **5** were observed at 1106 and 1117 cm^{-1} for the ferrocenyl substituents and ferrocenophane, respectively. For comparison, the same vibration was observed at 1111 cm^{-1} in tetraferrocenylsilane, 1107 cm^{-1} in diferrocenylsilanediol, and 1119 cm^{-1} in spirocyclic [1]silaferrocenophane **3** [21,22].



2.6. Addition of hydrogen chloride to 5

When **5** was treated with 1 equiv. of HCl, a single product was isolated (Scheme 2). ^{1}H and ^{13}C NMR spectra and mass spectrometry identified the material as the novel chlorosilane, Fc_3SiCl (**6**). The ^{29}Si NMR spectrum of **6** showed one resonance at 11.5 ppm, substantially deshielded with respect to the starting compound **5** ($\delta = -15.5$ ppm). In addition, the UV–Vis spectrum showed a peak at 456 nm, blue shifted from the starting monomer **5** ($\lambda_{max} = 474$ nm). The product showed the molecular ion as the major peak in the mass

spectrum. An IR spectrum of **6** was consistent with the structure, showing the signature of ferrocenyl substituents as well as a Si–Cl stretch at 536 cm^{-1} (νSi–Cl = 552 cm^{-1} for Ph_3SiCl) [34].

2.7. Hydrolysis of *6*

To extend our investigations of silanols with bulky ferrocenyl substituents, we hydrolyzed chlorosilane **6** to give the silanol with three ferrocenyl substituents Fc_3SiOH (**7**) in 80% yield (Scheme 3). NMR data were consistent with the assigned structure, but the chemical shifts were found to be concentration dependent. Resonances in the ^{13}C NMR spectrum of **7** assigned to the cyclopentadienyl ligands attached to Si were observed to vary by up to 0.5 ppm. In addition, small changes in the ^{1}H NMR spectrum were evident, with the proton attributed to the OH group observed at 2.0 ppm in dilute samples and at 2.2 ppm in more concentrated samples.

Interestingly, silanol **7** has been previously claimed as a byproduct in the Friedel–Crafts silylation of ferrocene in 5% yield [35]. The only data reported were the appearance and

Scheme 3.

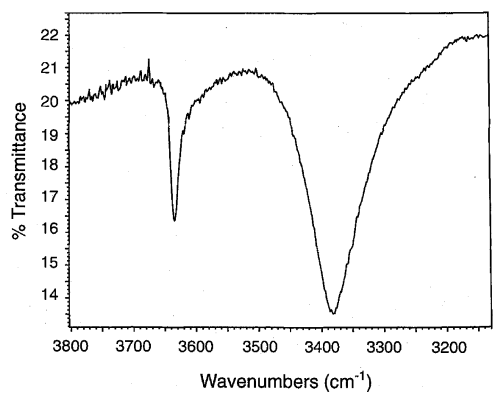

Fig. 5. IR spectrum of silanol **7** in the O–H stretching region.

the melting point (193.5–195°C), which is slightly higher than our observed melting point of 185–186.5°C.

Compound **7** was investigated in the solid-state by IR spectroscopy. In addition to the bands usually observed for Fc substituents, we assign three intense bands to Si–O stretching: 903 (m), 1003 (s), 1031 (s) cm^{-1}. In the O–H stretching region (Fig. 5), two intense peaks were observed: a sharp band at 3635 cm^{-1} and a broader, more intense band at 3382 cm^{-1}. The former is assigned to O–H stretching where the H is not participating in hydrogen bonding. For comparison, $(PhMe_2Si)_3CSiH_2(OH)$ has a band at 3623 cm^{-1} in dilute CCl_4 [36]. The band observed at lower frequency for **7** is attributed to O–H stretching where the H is active in hydrogen bonding; this frequency is usual for hydrogen-bonded OH groups.

2.8. Structural determination of *6*

In order to characterize **6** completely, a single crystal X-ray diffraction study was undertaken. Crystal data and collection parameters are summarized in Table 1. Selected bond lengths and bond angles for **6** are provided in Table 4. Compound **6** crystallizes in the monoclinic space group $P2_1/c$. Fig. 6 illustrates the structure of **6**. The Si–Cl bond length of 2.080(1) Å is normal; for example, the Si–Cl bond length in Ph_3SiCl is 2.077(1) Å [37]. Also, the Si–C bond lengths are normal for ferrocenylsilanes. Although the C–Si–C bond angles (average 111.3°) are significantly larger than the C–

Si–Cl bond angles (average 107.6°), the distortion is not caused by the steric hinderance of the ferrocenyl substituents as similar distortions from tetrahedral geometry are observed in Ph_3SiCl [38]. Each of the Cp rings on the ferrocenyl groups is essentially planar and the ferrocenyl groups show very small ring tilts of 0.8, 2.0, and 3.0°. The ferrocenyl groups are separated by only 5.517, 5.969, and 6.208 Å (Fe···Fe distances) in the solid state.

2.9. Structural determination of 7

Hydrogen-bonding in silanols may lead to interesting hydrogen-bonded structures [36]. We have recently reported novel hydrogen-bonding motifs for silanediols and siloxanediols with ferrocenyl substituents on Si [21,23]. Diferrocenylsilanediol crystallizes in hydrogen-bonded dimers which are in turn linked into a chain by hydrogen-bonding between the dimers. Tetraferrocenyldisiloxanediol crystallizes as two stacked hydrogen-bonded chains running parallel to the *c*-axis. When cocrystallized with hexaferrocenylcyclotrisiloxane, tetraferrocenyldisiloxanediol was observed to form hydrogen-bonded helices with dichloromethane. Comparison of the hydrogen-bonding motifs in silanols may also give a measurement of the relative bulkiness of the subsitutents on Si. For example, silanols with highly sterically hindered substituents (e.g. $PhCH_2$, $(PhMe_2Si)_3C$, mesityl, etc.) are often monomeric in the solid state or display weak H–π interactions [36]. As the substituent size changes, a variety of hydrogen-bonded structures are observed, including dimers (e.g. $(Me_3Si)_3CSiPh_2OH$ and (fluorenyl)$SiPh_2OH$), tetramers (e.g. Ph_3SiOH and Bu^t_2SiFOH), and chains (e.g. $(CH_2{=}CH)(OH)CHSiPh_2OH$) [36]. To investigate the solid-state structure of a silanol with three ferrocenyl substituents, a single-crystal structure determination of **7** was undertaken.

Crystals of **7** were grown at −55°C in dichloromethane. Silanol **7** crystallizes in the orthorhombic space group $P2_12_12_1$ with $Z=8$. Crystal data parameters are summarized in Table 1 and selected bond lengths, intramolecular distances, and bond angles are given in Table 5. Fig. 7 shows the structure of the two molecules (A and B) in the asymmetric unit. Silanol **7** crystallizes as isolated dimers which possess one O–H···O hydrogen bond (O···O separation of 2.726(4) Å and O···H···O angle of 177.7°). This agrees with the IR spectroscopy of **7** where vibrations were observed that are attributed to OH groups either participating or not participating in hydrogen-bonding. The silanol $(Me_3Si)_3CSiPh_2OH$ also crystallizes as a dimer with an O–O separation of 2.85(2) Å [39]. In **7**, the Si–O bond lengths of molecules A (1.638(3) Å) and B (1.651(3) Å) are typical of silanols [39].

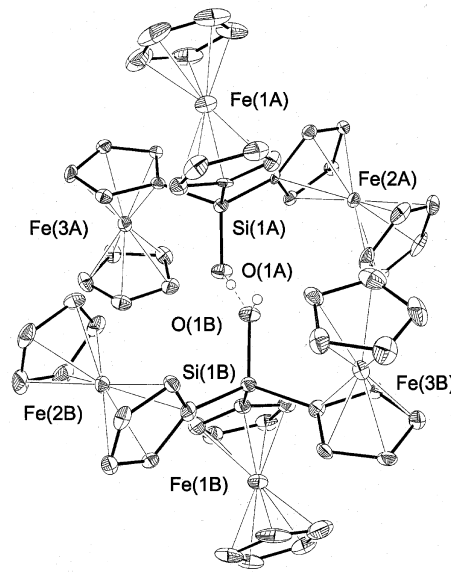

Fig. 7. The structure of the two molecules (A and B) present in the asymmetric unit for silanol **7**. Thermal ellipsoids are drawn at the 50% probability level.

2.10. Thermal ROP of 5

The thermal behavior of **5** was investigated by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The TGA, DTGA (differential thermogravimetric analysis), and DSC traces are shown in Fig. 8. TGA showed a small weight loss at 230°C (ca. 1–2%) followed by a larger weight loss (ca. 52 wt.%) peaking at 425°C (onset 360°C), giving an overall ceramic yield of 46% at 600°C. When examined by DSC at 5°C min^{-1}, **5** undergoes thermal ROP in the solid-state between ca. 150–230°C, peaking at

217°C. Although the curve appears unusual, it is reproducible.

When a sample of **5** was heated under vacuum in a Pyrex tube at 250°C, the monomer was consumed and a 37% yield of THF-insoluble material (**8**) was obtained. There was absolutely no evidence of melting during the polymerization as the powder appeared unchanged (except for a slight change in color). Solid-state ^{13}C CP-MAS NMR showed a peak at 68.7 ppm with a shoulder at 71.8 ppm, consistent with Cp ligands. ^{29}Si CP-MAS NMR displayed a single resonance at -11.6 ppm. For comparison, tetraferrocenylsilane, which is a good model for polymerized **5**, shows a single resonance at $\delta = -10.1$ ppm (CD_2Cl_2). Powder X-ray diffraction (PXRD) of the material indicated that it was amorphous, with a single broad halo centered at $2\theta = 17.5°$, $d = 5.06$ Å attributed primarily to diffraction from adjacent Fe atoms. Unfortunately, the solid was insoluble in common organic solvents such as $CHCl_3$, toluene, THF, DMSO, and DMF.

8

The low yield of polymer suggested that there was a substantial amount of oligomeric product formed. Polymerizations were performed from 175 to 240°C to identify the optimal temperature for obtaining oligomeric material. When a sample was sealed under vacuum in a Pyrex tube and heated at 200°C for 24 h, an orange–brown powder was obtained. The powder was completely dissolved in $CHCl_3$ and the resulting solution was filtered through neutral alumina. The dark orange filtrate was then evaporated to dryness, leaving an orange–brown powder in 92% yield. Gel permeation chromatography of the mixture showed a bimodal molecular weight distribution with a peak at $M_w = 5000$ and a small amount of higher molecular weight material ($M_w = 90000$). The material with the lower molecular weight is most likely a mixture of oligomers, for which the molecular weight is highly overestimated as a consequence of the skeletal rigidity relative to the polystyrene calibration standards. Mass spectrometry of the crude mixture showed peaks which could be assigned to $2M^+$ (**9_2**) and $3M^+$ (**9_3**) ($m/z = 582$ for M^+) and logical fragments of those (e.g. $2M^+$–FcH, $3M^+$–FcH). In fact, the dimer **9_2** and trimer **9_3** appear to have similar fragmentation patterns. Fig. 9 shows the mass spectrum obtained from a thermal treatment of **5** at 205°C, where peaks attributed to **9_2**$^+$ and **9_3**$^+$ are observed at $m/z = 1164$ and $m/z \approx 1747$ (note that the mass spectrometer calibration appeared to drift by ± 1 a.m.u. between 1200–2400 a.m.u.). Traces of fragments that would be expected from a cyclic tetramer **9_4** were also observed. ^1H NMR spectra of the oligomeric mixtures were deceptively simple owing to overlapping peaks in the Cp region (4–5 ppm). The ^{13}C NMR spectrum of the oligomeric mixture from the preparation at 205°C showed 2 *ipso*-Cp resonances (67.9, 68.6 ppm), a large resonance due to free Cp ligands at 68.8 ppm, and eight resonances due to CH groups on Cp ligands attached to Si. These resonances are consistent with a mixture of predominantly two cyclic oligomers. Integration of the peaks in the ^{13}C NMR spectrum, assuming the Cp environments are similar, gave an approximate ratio of 3:1 for the quantity of the two products. A single peak was observed in the ^{29}Si NMR spectrum at -11.9 ppm, a reasonable position for cyclic oligomers (cf. $\delta = -11.6$ ppm for the polymer $[fcSiFc_2]_n$). The mixture of oligomers may have the same ^{29}Si NMR chemical shift as the magnetic environments of the Si atoms are very similar (cf. ^{29}Si NMR of **2a** ($\delta = -6.4$ ppm) [9] and $[fcSiMe_2]_2$ ($\delta = -6.5$ ppm) [40]). Furthermore, no end groups were observed in the NMR spectra of the oligomers, consistent wth a cyclic structure. We believe that the combination of mass spectrometry and NMR spectroscopy identifies the soluble oligomers as mainly the cyclic dimer **9_2** and trimer **9_3** in an approximate 3:1 ratio.

9_2 **9_3**

The NMR spectra of the mixture obtained at 200°C were very similar to those of the sample prepared at 205°C, although for the former case a small quantity of an additional

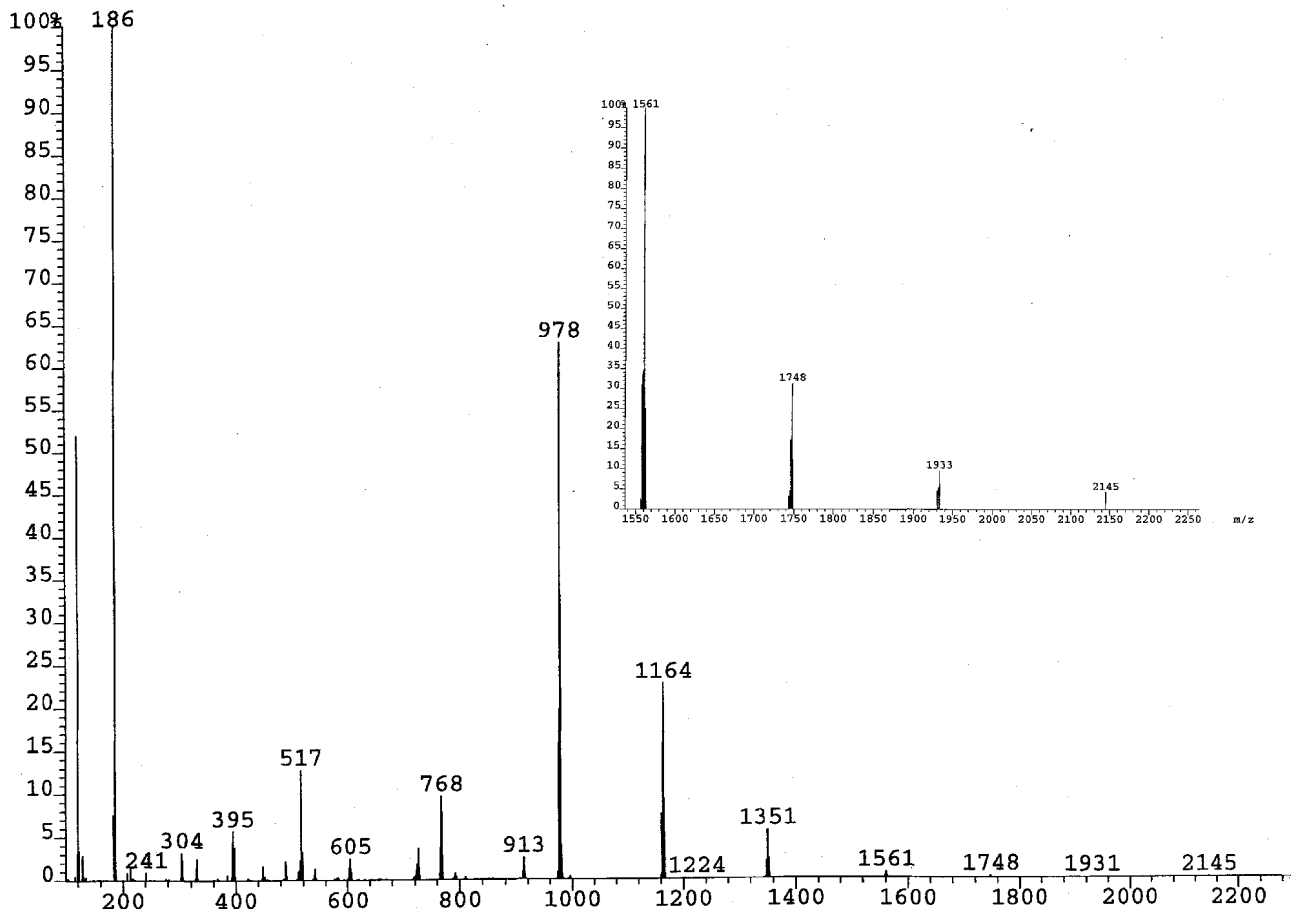

Fig. 9. Mass spectrum (EI) of cyclic oligomers obtained from thermolysis of **5** at 205°C. The inset shows the $m/z = 1500$–2300 portion of the spectrum expanded ca. 100 times.

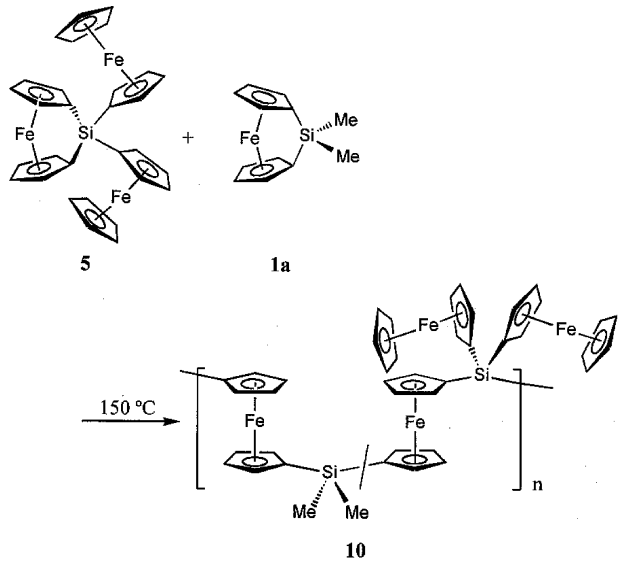
product was observed in the ^{13}C NMR spectrum, which could be due to larger oligomers. The ^{1}H NMR spectrum was nearly identical and the ^{29}Si NMR spectrum showed only a single resonance at -12.2 ppm. Cyclic oligomers are the major product of the thermal ROP at low (ca. 200°C) temperatures.

This is the first observation of cyclic oligomers in the thermal ROP of a [1]silaferrocenophane. Although transition metal catalyzed ROP of **1a** yields cyclic oligomeric byproducts, only high molecular weight polymer has been previously obtained from the thermal ROP of [1]silaferrocenophanes [41–43]. Our results demonstrate that the polymerization behavior of the [1]ferrocenophane may be altered by incorporating very bulky substituents (i.e. ferrocenyl groups), favoring cyclization over linear polymer formation. This is an important consideration for mechanistic investigations.

The observation of cyclic oligomers from the solid-state thermal ROP of **5** has intriguing possible mechanistic implications for the thermal ROP of [1]silaferrocenophanes. To date, very little is known about the mechanism for the ring-opening polymerization of [1]ferrocenophanes [43]. Experiments have indicated that polymerization of [1]silaferrocenophanes proceeds with cleavage of the strained Si–C bond (instead of the Fe–Cp bond) [43]. It has been suggested that the mechanism may involve a spontaneous Si–C cleavage or possibly involves a small impurity (e.g. water or amine) to facilitate the heterolytic or homolytic cleavage of the Si–C bond. In the present case, the fact that the cyclization occurs in the solid-state suggests that a mechanism in which the transformation proceeds without the aid of a minor impurity is most likely as the diffusion of a trace molecular impurity through the solid would be extremely slow. This does not necessarily apply to other [1]ferrocenophanes, particularly those which undergo thermal ROP in the melt (e.g. **1a**) where an impurity could realistically initiate the polymerization process.

It is worth noting that monomer **5** possesses the bulkiest substituents ever attached to a [1]silaferrocenophane (our study of silanols with ferrocenyl substituents has suggested that the bulkiness of substituents obeys the following order: Mes > Fc ≈ Cy > Ph) [21,23]. These bulky groups would hinder the union of two monomers to form a cyclic, 4-centered $[Si\cdots C]_2$ transition state that would form in a metathesis reaction, where two Si atoms would become 5-coordinate. We feel that a metathesis mechanism is unlikely for the polymerization of **5** in the solid-state.



Another interesting observation is that only soluble oligomers were formed in the polymerization performed at

200°C; no insoluble material (**8**) was obtained. If the [1]ferrocenophane spontaneously formed a ring-opened, highly reactive intermediate (via heterolytic or homolytic cleavage of a Si–C bond of the ferrocenophane moiety, for example), reaction with other monomers would be expected to be very slow owing to the steric hinderance at Si in **5**. This would favor the formation of the small cyclic species we have observed at lower temperatures.

From the crystal structure, we have noted that compound **5** is arranged into planes in which the ferrocenophanes each possess two closest intraplanar Si···Si contacts (9.12 Å). Between the layers, dimeric closest contacts (7.96 Å) are present. The bulkiness of the ligands most likely prevents free rotation of the molecule, but may still allow for vibration and translation, particularly at high temperature. If a reactive species spontaneously formed at 200°C by breaking an Si–C bond, the reactive species could undergo a translation within the plane or out of the plane such that it could react with another molecule of **5**. This might explain the prevalence of the cyclic dimer and trimer detected in the oligomerization reactions. Although the intermolecular Si···Si contacts seem very long, the Si···Si separations in the linear pentamer $FcSiMe_2[fcSiMe_2]_3Fc$ are 6.9–7.0 Å [44]. Thus, translation of a ring-opened [1]ferrocenophane by only 1 Å would be necessary to bridge the Si atoms by a ferrocenyl group. The mechanistic ideas we postulate concerning the solid-state ROP of **5** may not be general to [1]silaferrocenophanes which usually undergo thermal ROP in the melt.

2.11. Attempted transition-metal catalyzed polymerizations and thermal copolymerizations of 5

As thermal polymerization gave a mixture of cyclic oligomers, we felt that one may be preferentially formed by a transition-metal catalyzed ROP of **5**. Monomer **5** was treated with several catalysts (Table 6) at different temperatures, but nearly the only substance observed in ^1H and ^{13}C NMR spectra of the crude reaction mixture was unreacted starting material.

5 **1a**

10

Table 6
Reaction conditions for attempted transition-metal catalyzed polymerization reactions for **5**

Catalyst	Solvent	Temperature (°C)	Time (h)
Karstedt's	toluene	reflux	21
Karstedt's	toluene	60	8
$[Rh(1,5\text{-}COD)_2][OTf]$	toluene	80	1.5
$(COD)PdCl_2$	C_6D_6	25	28
$(COD)PdCl_2$	toluene	60	12

Since the homopolymer of **5** was insoluble, we attempted to form soluble copolymers **10** with monomer **1a**. Although **1a** and **5** undergo thermal ROP at significantly different temperatures, we felt that **5** may dissolve in the melt of **1a** and be initiated by reactive chain ends formed during the polymerization. Copolymers were prepared by combining between 10 and 50 mol% of **5** with **1a** in a Pyrex tube and heating for 36 h at 150°C. Upon work-up, soluble material was obtained in each case. Gel permeation chromatography proved the molecular weight distribution of each polymer to be monomodal (e.g. a polymer formed starting with 25 mol% of **5** showed $M_n = 49900$, PDI = 1.97). Unfortunately, because of the long relaxation time for the Si of the $[fcSiFc_2]$ units and the absence of protons nearby (for DEPT), the relative amount of **1a** and **5** incorporated into the polymers could not be determined accurately by ^{29}Si NMR. A sample prepared with 40% of **5** showed two ^{29}Si NMR resonances at -6.5 and -9.7 ppm, consistent with segments derived from **1a** and **5**, respectively. Solid-state ^{29}Si CP-MAS NMR spectroscopy was also used to determine the Si environments present in the samples. Samples prepared with 25% and 40% of **5** showed two ^{29}Si CP-MAS NMR resonances at -6.7 and -12.0 ppm, assigned to segments derived from **1a** and **5**, respectively. In one polymer (11 mol% of **5**), three resonances were present in the solid-state ^{29}Si CP-MAS spectrum, at -7.1, -9.7, and -12.3 ppm; the NMR spectrum of this copolymer is illustrated in Fig. 10. The resonance at $\delta = -7.1$ ppm is assigned to $[fcSiMe_2]$ segments, the resonance at $\delta = -12.3$ ppm is assigned to $[fcSiFc_2]$ segments, and the resonance at $\delta = -9.7$ ppm is assigned to switching groups between the segments. ^{13}C NMR and ^1H NMR provided

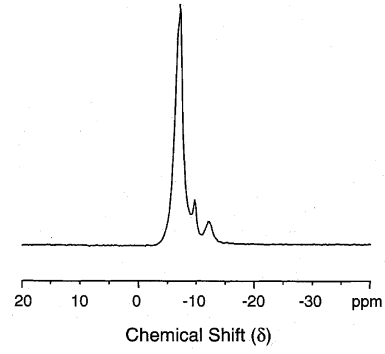


Fig. 10. Solid-state ^{29}Si CP-MAS NMR spectrum of a copolymer **10** prepared with 11 mol% **5**.

evidence that **5** was indeed incorporated into the copolymers. Samples prepared with 15–50% of **5** showed two methyl resonances, at −0.9 ppm and 1.0 ppm in the ^{13}C NMR spectrum, consistent with polymer segments derived from **1a** and switching groups, respectively. Because of the small amount of **5** that was generally incorporated, peaks attributed to segments derived from **5** in the copolymer were not well resolved. In the solution ^{1}H NMR spectrum of the copolymers, additional peaks were certainly present in the Cp region, but also were not well resolved. Two methyl resonances were observed, including a peak due to segments of **2a** at 0.4 ppm and a switching group at 0.05 ppm. Integration of these peaks gave switching group:**2a** ratios of 0.23, 0.46, 0.10, 0.05, and 0.04 for copolymers prepared with 10, 15, 25, 40, and 50 mol% of **5**, respectively. A possible explanation for the decrease in switching groups when the proportion of **5** used exceeded 15 mol% is that more insoluble polymer containing segments derived from **5** (which was removed prior to NMR) were obtained as the initial amount of **5** was increased. Powder X-ray diffraction showed a new amorphous halo present at $2\theta = 17.5°$ when **5** was incorporated, in addition to a broad halo centered at $2\theta = 14.5°$ characteristic of homopolymer **2a**. DSC of the homopolymer **2a** shows a glass transition (T_g) at 33°C and a melt at 120–145°C. None of the copolymers showed the glass transition (T_g) or melt for polymer **2a**, indicating that the copolymers probably possessed random structures, consistent with the observation of a large quantity of switching groups in the copolymer when small (<20 mol%) quantities of **5** were used. However, second-order transitions were observed at 60 and 54°C for copolymers derived from monomer mixtures containing 25% and 50% of **5**, respectively.

Our results indicate that copolymers of **1a** and **5** formed, but much less of **5** was incorporated than expected from the initial ratio of monomers. This is not surprising, considering the bulkiness of **5** relative to **1a**: the reactivity ratios of **1a** and **5** must be very different. The difficulty in ring-opening **5** has already been demonstrated by its resistance to undergo transition-metal catalyzed polymerization. There did not appear to be any correlation between the amount of **5** in the reaction mixture and the amount of **5** incorporated into the polymer. For example, in one sample prepared with 50% of **5**, the soluble material showed no evidence for incorporation of **5** into the polymer. This may be due to insolubility of polymers containing large amounts of **5**. Another difficulty that complicated characterization was that the copolymers became less soluble as they were repeatedly precipitated. This suggests that plasticizing oligomers or impurities (e.g. solvent) facilitate the dissolution of these materials.

3. Conclusions

We have synthesized a novel [1]ferrocenophane with two very bulky ferrocenyl substituents, **5**. Characterization by single crystal X-ray diffraction, NMR spectroscopy, IR, and Raman spectroscopy corroborated the structure. The Mössbauer spectrum of **5** resolved the quadrupole doublets of the ferrocenophane and ferrocenyl substituents. Differential pulse voltammetry of **5** resolved three oxidation waves ($\Delta E = 0.22$, 0.23 V). Ferrocenophane **5** is a convenient precursor to triferrocenylsilane derivatives. Chlorotriferrocenylsilane was synthesized from the ring-opening addition of HCl to **5** and was structurally characterized. Subsequent hydrolysis yielded a silanol with three bulky ferrocenyl substituents on Si. X-ray diffraction revealed that the silanol crystallizes in hydrogen-bonded dimers, characteristic of silanols with very bulky substituents. Ferrocenophane **5** undergoes thermal ring-opening polymerization in the solid state to afford insoluble polymer together with soluble, cyclic oligomers. This represents the first observation of cyclic oligomers from the thermal ROP of a [1]silaferrocenophane and may be associated with the steric hinderance of the ferrocenyl moieties. Copolymers of **5** with dimethyl[1]silaferrocenophane were prepared, but the amount of **5** incorporated into the copolymer **10** could not be controlled due to insolubility of polymer blocks made from **5**. Future work will involve the separation of the cyclic oligomers obtained from thermal ROP of **5** for further characterization.

4. Experimental

4.1. Materials

Dilithioferrocene·TMEDA, dimethyl[1]silaferrocenophane **1a**, and diferrocenyldichlorosilane **4** were prepared by literature methods [9,21,45]. Hydrogen chloride (1.0 M in diethyl ether) was purchased from Aldrich and was used without further purification. Triethylamine was obtained from Aldrich and was distilled from Na prior to use.

4.2. Equipment

All reactions and manipulations were carried out under an atmosphere of prepurified nitrogen using either Schlenk techniques or an inert-atmosphere glovebox (Innovative Technologies) unless otherwise noted. Solvents were dried by standard methods, distilled, and stored under nitrogen. Solution 400 MHz ^{1}H NMR spectra, 100.5 MHz ^{13}C NMR spectra, and 79.5 MHz ^{29}Si NMR spectra were recorded on a Varian Unity 400 spectrometer and were referenced externally to TMS. Molecular weights were estimated by gel permeation chromatography (GPC) using a Water Associates liquid chromatograph equipped with a 510 HPLC pump, U6K injector, ultrastyragel columns with pore sizes of 10^3 and 10^5 Å, and a Waters 410 differential refractometer. A flow rate of 1.0 ml min^{-1} was used and samples were dissolved in a solution of 0.1% NBu_4Br in THF. The GPC was calibrated with nine monodisperse polystyrene standards. Solid-state 79.5 MHz ^{29}Si and 100.5 MHz ^{13}C CP-MAS NMR spectra were obtained on a Bruker DSX 400 spectrometer. Powder

X-ray diffraction patterns were obtained on a Siemens D5000 X-ray diffractometer using Ni-filtered Cu Kα radiation ($\lambda = 1.54178$ Å). UV–Vis spectra were obtained in CH_2Cl_2 (ca. 5×10^{-4} M) on a Perkin–Elmer Lambda 900 UV–Vis/near-IR spectrometer using a 1 cm quartz cuvette. IR spectra were obtained as Nujol mulls or KBr pellets with a Nicolet Magna-IR 550 spectrometer. FT-Raman spectra were collected on a Bomems MB-157 FT-spectrometer with a Spectra Physics diode pumped Nd:YLF laser (1064 nm, 350 kHz repetition rate). The instrument was configured in 180° backscattering mode using sealed glass capillary tubes to hold the neat, crystalline samples. Electron impact (EI) mass spectra were obtained with a VG 70-250S mass spectrometer. As the calibration file used for measuring the mass spectra of the oligomers was an old FAB file and the very high masses are approaching the limit of the instrument, drifts of ± 1 a.m.u. are not surprising. Thermogravimetric analyses were obtained on a Perkin–Elmer TGA-7 analyzer equipped with a TAC-7 instrument controller. Samples were heated at a rate of 10°C min^{-1} under a flow of N_2. Differential scanning calorimetry was performed on a Perkin–Elmer DSC-7 analyzer equipped with a TAC-7 instrument controller. The instrument was calibrated with the melting points of cyclohexane and indium and samples were heated at a rate of 5°C min^{-1}. Differential pulse voltammetry of **5** was performed under ambient conditions under N_2 by analysis of a 0.31 mM solution at a glassy carbon electrode in dichloromethane using a PAR model 174 potentiostat using 1 s drop time and 25 mV modulation amplitude settings. Potentials in this paper are given versus the ferrocene/ferrocenium couple. Room-temperature ^{57}Fe Mössbauer spectra were obtained using a Ranger Scientific Inc. VT-1200 instrument with a MS-1200 digital channel analyzer. The γ-ray source was a 6 mCi ^{57}Co sample supplied by Amersham. The data were collected in a -15.8 to $+15.8$ mm s^{-1} range and referenced to Fe powder. Data were acquired long enough to obtain a suitable fit to standard independent Lorentzian line shapes for sinusoidal baselines. Melting points were determined on a Fisher–Johns hot-stage melting point apparatus and are uncorrected.

*4.3. Synthesis of diferrocenyl[1]silaferrocenophane **5***

A solution of **4** (2.235 g, 4.76 mmol) in ca. 20 ml of THF was added dropwise via cannula to a stirring suspension of dilithioferrocene·TMEDA (1.25 g, 3.98 mmol) in THF (ca. 125 ml) chilled to −78°C under N_2. The mixture was warmed to room temperature over a period of 2 h during which time the color of the solution became darker red. After refluxing the solution at 60–70°C for 1.5 h, the solution was notably darker than before. The solvent was removed under vacuum, leaving an orange and red residue. The crude solid was washed with ca. 20 ml of toluene and the brown mother liquors were discarded (a small amount of hexane soluble compound in the toluene wash was identified by ^{1}H NMR as Fc_3SiCl, a by-product that could be expected if any FcLi was present). Subsequent extraction with dichloromethane (ca. 200 ml) gave a light orange–red solution and a fine white precipitate (LiCl) which was removed by filtration. Recrystallization from dichloromethane afforded 1.480 g (2.54 mmol, 64%) of **5** as an orange powder. An additional 0.312 g (0.536 mmol, 13%) of product was obtained from the supernatant solution, for a total yield of 77% (1.792 g, 3.08 mmol). The product is a red, air stable crystalline solid.

Data for **5**. ^{13}C NMR ($CDCl_3$) $\delta = 77.3$ (Si–Cp), 76.0 (Si–Cp), 74.8 (Si–Cp), 71.3 (Si–Cp), 69.0 (Cp), 64.8 (*ipso*-C), 34.8 (*ipso*-C) ppm. ^{13}C NMR (C_6D_6) $\delta = 77.9$ (Si–Cp), 76.5 (Si–Cp), 75.2 (Si–Cp), 71.6 (Si–Cp), 69.3 (Cp), 65.4 (*ipso*-C), 35.0 (*ipso*-C) ppm. ^{1}H NMR ($CDCl_3$) $\delta = 4.64$ (t, $^3J_{HH} = 1.62$ Hz, 4H, Cp), 4.5–4.6 (m, 8H, Cp), 4.36 (t, $^3J_{HH} = 1.59$ Hz, 4H, Cp), 4.26 (s, 10H, Cp) ppm. ^{1}H NMR (in C_6D_6) $\delta = 4.61$ (t, $^3J_{HH} = 1.69$ Hz, 4H, Cp), 4.55 (t, $^3J_{HH} = 1.61$ Hz, 4H, Cp), 4.39 (t, $^3J_{HH} = 1.61$ Hz, 4H, Cp), 4.36 (t, $^3J_{HH} = 1.67$ Hz, 4H, Cp), 4.20 (s, 10H, Cp) ppm. ^{29}Si NMR ($CDCl_3$) $\delta = -15.5$ ppm. UV–Vis (CH_2Cl_2) $\lambda_{max} = 474$ nm ($\varepsilon = 505$ l mol^{-1} cm^{-1}). MS (EI, 70 eV) m/z (rel. intensity) = 582 (100, M^+), 517 (26, M^+–C_5H_5), 396 (19, M^+–FcH), 340 (18, M^+–FcH–Fe), 186 (68, FcH^+), 121 (36, $C_5H_5Fe^+$). HRMS for $C_{30}H_{26}SiFe_3$: calc. $m/z = 581.9852$; found $m/z = 581.9827$.

*4.4. Synthesis of chlorotriferrocenylsilane **6***

With a syringe, 1.2 ml of HCl (1 M in ether) was added dropwise to a stirred solution of 0.563 g of **5** (0.967 mmol) in 50 ml CH_2Cl_2. The solution changed color from red–orange to yellow–orange. The solvent was removed under vacuum, leaving a yellow solid. After the solid was dissolved in a minimum of warm hexanes/CH_2Cl_2 (ca. 1:3), the solution was filtered to remove oxidized species. Once again, the solvent was removed under vacuum and the product was recrystallized from dichloromethane to give yellow crystals in 81% yield (0.485 g, 0.784 mmol).

Data for **6**. ^{13}C NMR ($CDCl_3$) $\delta = 73.9$ (Si–Cp), 71.2 (Si–Cp), 69.0 (Cp), 68.8 (*ipso*-Cp) ppm. ^{1}H NMR ($CDCl_3$) $\delta = 4.44$ (t, $^3J_{HH} = 1.7$ Hz, 6H, Cp), 4.37 (t, $^3J_{HH} = 1.7$ Hz, 6H, Cp), 4.13 (s, 15H, Cp) ppm. ^{29}Si NMR ($CDCl_3$) $\delta = 11.5$ ppm. UV–Vis (CH_2Cl_2) $\lambda_{max} = 456$ nm ($\varepsilon = 412$ l mol^{-1} cm^{-1}). MS (EI, 70 eV) m/z (rel. intensity) = 618 (100, M^+), 462 (8, M^+–CpFeCl), 397 (53, M^+–FcCl), 367 (9, M^+–FcH–C_5H_5), 331 (8, M^+–FcCl–C_5H_5), 276 (15, M^+–FcCl–FeCp), 186 (12, FcH^+), 121 (11, $CpFe^+$), 93 (13, $CpSi^+$). M.p. 228–229.5°C. IR (KBr pellet) 3088(m), 3082(m), 1411(m), 1381(w), 1356(m), 1350(w), 1300(m), 1190(s), 1179(m), 1166(s), 1107(s), 1055(m), 1034(s), 1022(s), 998(s), 891(w), 867(w), 843(w), 836(s), 821(s), 632(m), 627(m), 618(w), 589(w), 556(m), 542(m), 536(s), 498(m), 483(s), 475(s), 468(s) cm^{-1}. HRMS for $C_{30}H_{27}ClSiFe_3$: calc. $m/z = 617.9619$; found $m/z = 617.9608$.

4.5. Synthesis of triferrocenylsilanol **7**

A solution of 0.177 g (0.286 mmol) of **6** in 50 ml ether was treated with 0.50 ml (3.6 mmol) of triethylamine at room temperature. Using a pipette, 0.5 ml of H_2O (28 mmol) was added dropwise. The solution was then warmed to 40°C in a water bath and maintained there for 30 min. Solvent was removed by rotary evaporation, leaving a yellow residue. The crude product was dissolved in CH_2Cl_2 and the solution was filtered. Large orange crystals were obtained within hours at −55°C. The crystals were isolated on a Buchner funnel, washed with hexanes, and dried under vacuum. Compound **7** was obtained as orange crystals in 80% yield (138 mg, 0.230 mmol).

Data for **7**. ^{13}C NMR ($CDCl_3$) δ=74.2 (Si–Cp), 71.4 (Si–Cp), 69.6 (*ipso*-Cp), 69.0 (Cp) ppm. ^{1}H NMR ($CDCl_3$) δ=4.47 (s, 6H, Cp), 4.40 (s, 6H, Cp), 4.20 (s, 15H, Cp), 2.02 (s, 1H, OH) ppm. ^{29}Si NMR ($CDCl_3$) δ=−2.4 ppm. UV–Vis (CH_2Cl_2) λ_{max}=456 nm (ε=384 l mol^{-1} cm^{-1}). MS (EI, 70 eV) m/z (rel. intensity)=600 (100, M^+), 535 (6, M^+–C_5H_5), 469 (6, MH^+–2(C_5H_5)), 414 (7, M^+–FcH), 349 (28, M^+–FcH–Cp), 305 (16), 186 (5, FcH^+). M.p. 185–186.5°C. *Anal*. Calc.: C, 60.04; H, 4.70; N, 0.00. Found: C, 59.10; H, 4.57; N, 0.14. IR (Nujol mull) 3635(s), 3382(vs), 1367(m), 1349(m), 1299(m), 1189(m), 1167(s), 1105(s), 1054(m), 1031(s), 1003(s), 903(s), 873(m), 859(m), 850(m), 832(m), 820(s), 813(s), 633(m), 557(m), 543(m) cm^{-1}. Raman (crystals) 3106(s), 3084(m), 3077(m), 1411(m), 1382(m), 1367(w), 1187(w), 1164(s), 1106(vs), 1062(m), 1038(m), 1001(w), 398(m), 387(m), 365(w), 326(s), 308(s), 267(w), 229(w), 211(w) cm^{-1}.

4.6. Synthesis of the insoluble homopolymer ***8***

Ferrocenophane **5** (0.35 g, 0.6 mmol) was sealed under vacuum in a Pyrex polymerization tube. The tube was heated for 8 h at 250°C in an oven. After the polymerization tube cooled to room temperature, the contents were stirred overnight in ca. 25 ml of THF. The product was isolated on a Buchner funnel, washed with THF, and dried under vacuum for 12 h at 60°C to yield 0.13 g (37%) of yellow–orange powder.

Data for **8**. ^{13}C{^{1}H} CP-MAS NMR (100.5 MHz, spin rate 6 kHz, recycle delay 3s, contact time 1 ms, ramped contact pulse) δ=71.8 (Si–Cp), 68.7 (Cp) ppm. ^{29}Si{^{1}H} CP-MAS NMR (79.5 MHz, spin rate 6 kHz, recycle delay 10s, contact time 1 ms, ramped contact pulse) δ=−11.6 ppm. PXRD broad halo at 17.5° 2θ, 5.06 Å *d*-spacing (FWHM=2.2°). *Anal*. Calc.: C, 61.90; H, 4.82. Found: C, 61.13; H, 4.78.

4.7. Synthesis of cyclic oligomers ***9***

Ferrocenophane **5** (146 mg, 0.251 mmol) was sealed under vacuum in a Pyrex polymerization tube. The sample was heated at 200°C for 24 h, during which time it changed color from orange–red to orange–brown. Also, a small quantity (ca. 1 mg) of orange crystals were present on the glass. The tube was broken open and the powder was separated from the crystals. The powder dissolved entirely in 20 ml of $CHCl_3$, giving an orange solution, which was then filtered through ca. 5 cm of neutral alumina (~150 mesh). The solvent was removed by rotary evaporation, yielding 134 mg (92%) of orange–brown soluble material. NMR spectroscopy, mass spectrometry, and GPC indicated that the soluble product is primarily cyclic dimer ($\mathbf{9_2}$) and trimer ($\mathbf{9_3}$).

Data for **9** (prepared at 200°C). ^{13}C NMR ($CDCl_3$) δ=74.3 (Si–Cp), 74.1 (Si–Cp), 73.8 (Si–Cp), 72.0 (Si–Cp), 71.0 (Si–Cp), 70.7 (Si–Cp), 70.4 (Si–Cp), 68.9 (Si–Cp), 68.7 (Cp), 67.8 (Si–Cp) ppm. ^{1}H NMR ($CDCl_3$) δ=3.7–4.6 (Cp, m) ppm. ^{29}Si NMR ($CDCl_3$) δ=−12.2 ppm. MS (EI, 70 eV) m/z (rel. intensity)=1558 (1, $\mathbf{9_3}^+$–FcH), 1350 (7, $\mathbf{9_3}^+$–fc_2Si), 1164 (28, $\mathbf{9_2}^+$), 978 (100, $\mathbf{9_2}^+$–FcH), 768 (38, $\mathbf{9_2}^+$–FcH–210), 517 (18, $Fc_2SiCpFe^+$),186 (63, FcH^+).

Data for **9** (prepared at 205°C). ^{13}C NMR ($CDCl_3$) δ=74.8 (Si–Cp), 74.3 (Si–Cp), 73.8 (Si–Cp), 72.6 (Si–Cp), 71.5 (Si–Cp), 71.0 (Si–Cp), 70.7 (Si–Cp), 70.5 (Si–Cp), 68.8 (Cp), 68.6 (Si–Cp), 67.9 (Si–Cp) ppm. ^{1}H NMR ($CDCl_3$) δ=3.7–4.6 (Cp, m) ppm. ^{29}Si ($CDCl_3$) δ=−11.9 ppm. MS (EI, 70 eV) m/z (rel. intensity)=1748 (<1, $\mathbf{9_3}^+$), 1561 (1, $\mathbf{9_3}^+$–FcH), 1351 (7, $\mathbf{9_3}^+$–fc_2Si), 1164 (24, $\mathbf{9_2}^+$), 978 (65, $\mathbf{9_2}^+$–FcH), 768 (12, $\mathbf{9_2}^+$–fc_2Si), 517 (13, $Fc_2SiCpFe^+$), 186 (100, FcH^+).

We tentatively assign the fragments at m/z=768 and 1350–1351 to $\mathbf{9_2}^+$–fc_2Si and $\mathbf{9_3}^+$–fc_2Si, respectively, as fc_2Si is a stable product that could be eliminated during ionization.

4.8. Attempted synthesis of copolymers (***10***) of ***5*** and ***1a***

Copolymers were prepared by a general procedure. Ferrocenophanes **1a** and **5** were ground in an agate mortar and combined in the appropriate ratio to give a sample size of approximately 300 mg. The monomers were sealed under vacuum inside a Pyrex polymerization tube and heated for 36 h at 150°C in an oven. The crude red polymer was dissolved in THF (ca. 10 ml) and the soluble fraction (obtained by filtration) was added dropwise to a stirring solution of 300 ml of hexanes. The polymer was collected in a Buchner funnel and dried under vacuum overnight at 60°C. The polymers were not very soluble, and solution NMR of the soluble fractions showed traces of solvent present in the polymers. However, this solvent was not observed by solid-state NMR spectroscopy, indicating that only a very small amount of solvent was entangled in the polymer chains. We attempted to remove all of the solvent by performing the precipitation into pentanes, but solvent was still detected in the polymer. Samples were prepared using 10, 11, 15, 25, 40, and 50 mol% of **5**. Characterization for three representative preparations are given below.

Data for **10** prepared with 10 mol% of **5** (PFMS=**2a**, PFFS=**8**). ^{13}C NMR ($CDCl_3$) δ=74.3 (Cp), 73.6 (Cp),

73.3 (PFMS–Cp), 72.6 (Cp), 71.6 (Cp), 71.4 (PFMS–Cp), 70.4 (Cp), 68.8 (Cp), 68.0 (*ipso*-Cp), −0.9 (CH_3, PFMS) ppm. ^{1}H NMR ($CDCl_3$) δ = 3.9–4.5 (Cp), 0.42 (s, CH_3, PFMS–Si–PFMS), 0.07 (s, CH_3, PFMS–Si–PFFS) ppm. ^{29}Si NMR ($CDCl_3$) δ = −6.56 (PFMS) ppm. GPC (THF, versus polystyrene) M_n = 23900 (PDI = 1.76).

25 mol% of **5**. ^{13}C NMR ($CDCl_3$) δ = 74.6 (Cp), 73.7 (Cp, PMFS), 72.1 (Cp), 71.9 (Cp, PFMS), 71.0 (Cp), 69.2 (Cp), 1.0 (CH_3, PFMS–Si–PFFS), −0.5 (CH_3, PFMS–Si–PFMS) ppm. ^{1}H NMR ($CDCl_3$) δ = 3.9–4.5 (Cp), 0.45 (s, CH_3, PFMS–Si–PFMS), 0.08 (CH_3, PFMS–Si–PFFS) ppm. ^{29}Si{^{1}H} CP-MAS NMR (79.5 MHz, spin rate 6 kHz, recycle delay 10s, contact time 4 μs) δ = −6.7 (PFMS), −12.0 (PFFS) ppm. GPC (THF, versus polystyrene) M_n = 49900 (PDI = 1.97).

40 mol% of **5**. ^{13}C-NMR (100.5 MHz, $CDCl_3$) δ = 74.4 (Cp), 73.5 (Cp, PMFS), 71.8 (Cp), 71.6 (Cp, PFMS), 70.6 (Cp), 69.0 (Cp), 67.9 (*ipso*-Cp), 1.0 (Cp, CH_3, PFMS–Si–PFFS), −0.9 (s, CH_3, PFMS–Si–PFMS) ppm. ^{1}H NMR ($CDCl_3$) δ = 3.9–4.6 (Cp), 0.42 (s, CH_3, PFMS–Si–PFMS), 0.06 (s, CH_3, PFMS–Si–PFFS) ppm. ^{29}Si-NMR (79.5 MHz, $CDCl_3$) δ = −6.51 (PFMS), −9.68 (PFFS) ppm. ^{29}Si{^{1}H} CP-MAS NMR (79.5 MHz, spin rate 6 kHz, recycle delay 10s, contact time 4 μs) δ = −6.6 (PFMS), −12.0 (PFFS) ppm. GPC (THF, versus polystyrene) M_n = 42100 (PDI = 1.87).

4.9. Attempted transition-metal catalyzed polymerization of 5

Conditions used for the attempts to react **5** with a transition-metal catalyst are listed in Table 6. In a typical preparation, ca. 60–100 mg of **5** were combined with ca. 10–20 ml of solvent and ca. 1% of the transition-metal catalyst (Rh(1,5-COD)$_2$ triflate, (1,5-COD)$PdCl_2$, or Karstedt's catalyst) and treated at 25–110°C. After the appropriate time, the reaction mixture was evaporated to dryness, dissolved in $CDCl_3$, and filtered to remove a brown insoluble material. ^{1}H and ^{13}C NMR spectra of the soluble fraction were consistent with unreacted monomer **5** and, in a few of the attempts, a small amount of a ferrocene-containing by-product which was not further characterized.

4.10. Crystallographic structural determination

Selected crystal, data collection, and refinement parameters for **5**, **6**, and **7** are provided in Table 1. Selected inter- and intramolecular bond distances for **5**, **6**, and **7** are given in Tables 2, 4 and 5, respectively. Crystals of **5**–**7** were each mounted on a glass fiber and coated with epoxy glue.

Intensity data for compound **5** were collected at 293(2) K on a Siemens P4 diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The ω scan technique was applied with variable scan speeds. Intensities of three standard reflections were measured every 100 reflections; the crystal showed negligible decay (<1%) during the data collection. A semi-empirical absorption correction was applied using the SHELXA-90 routine in SHELXL. The positions of all atoms for **5** were determined by direct methods using Siemens SHELXTL PC [46]. All Fe and Si atoms were refined anisotropically and C and H atoms were refined with isotropic thermal parameters by full-matrix least squares to minimize $\sum w(F_o^2 - F_c^2)^2$. The data showed two distinct orientations of the ferrocenophane (illustrated in Fig. 1(b,c)). Refinement with these two molecules present in equal abundance gave a solution which was chemically and structurally consistent. Bond lengths and angles within the structure display large ESDs as a consequence of the static disorder, but are reasonable when compared with similar structures.

Data for **6** were collected on a Siemens P4 diffractometer equipped with a SMART/CCD detector. The systematic absences in the diffraction data are uniquely consistent for the reported space group. The structure was solved using direct methods, completed by subsequent difference Fourier syntheses and refined by full-matrix least-squares procedures. All non-hydrogen atoms were refined with anisotropic displacement coefficients and the hydrogen atoms were treated as idealized contributions. All software and sources of the scattering factors are contained in the SHELXTL (5.03) program library [46].

Data for **7** were collected on a Nonius Kappa-CCD diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). The data from 180×1° ϕ scans were integrated and scaled using the Denzo-SMN package [47]. The structure was solved and refined using the SHELXTL package [46]. Refinements were by full-matrix least squares on F^2 using all data (negative intensities included). All hydrogen atoms were included in calculated positions and treated as riding atoms. All non-hydrogen atoms were refined with anisotropic thermal parameters.

Supplementary data

Crystallographic data for **5**–**7** have been deposited with the CCDC (12 Union Road, Cambridge, CB2 1EZ, UK) and are available on request quoting deposition numbers CCDC 132620, 132638, and 132621, respectively.

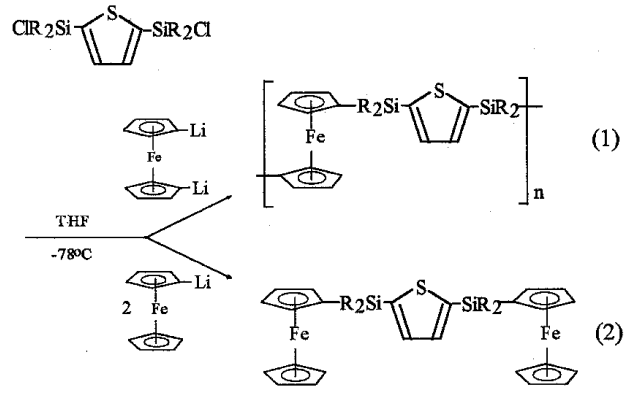
Received 26 July 1999; accepted 17 August 1999

Abstract



The reaction between 1,1′-dilithioferrocene and 2,5-bis(chlorodimethylsilyl)thiophene (**I**), leads to a series of cyclic oligomers of basic formulation [Fc-$SiMe_2$-TH-$SiMe_2$]$_n$ (**II**); Fc = (η^5-C_5H_4)$_2$Fe, TH = C_4H_2S. The material $n = 2$, **IIa**, has been completely characterized by spectroscopic and single crystal X-ray diffraction. Cyclic voltammetric analysis of **IIa** illustrates two reversible redox processes, indicating a significant interaction between the two ferrocenylene units despite the 5 atom bridge. By comparison, the monomeric analog Fc-$SiMe_2$-TH-$SiMe_2$-Fc (**III**), Fc = (η^5-C_5H_5)Fe(η^5-C_5H_4), prepared from the reaction of mono-lithioferrocene with **I**, exhibits a single redox process, even though there is the same bridge between the two Fe centers. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Cyclic oligomers; Thiophenes; Ferrocenes

1. Introduction

The interesting properties of polythiophenes are well studied [1] and recently the synthesis and study of thiophene-substituted derivatives of the Group 14 elements has also received attention due to their potential as electroactive materials [2–5]. We have an interest in similar ferrocenyl-substituted Group 14 materials [6–17], and now report studies aimed at the introduction of both the ferrocene and thiophene units into a silicon-containing molecular structure. We hope to produce monomers, oligomers and polymers with interesting structural and electrical properties. As a general procedure for the synthesis of such systems we have used the chemistry outlined in Eqs. (1) and (2) in which either monolithioferrocene or dilithioferrocene is reacted with a 2,5-(chlorosilyl)thiophene (**Ia** R = Me; **Ib** R = Ph).

Whereas the reaction of dilithioferrocene with **I** would, in theory, yield polymeric materials, the use of monolithioferrocene, [Fc]$^-$Li$^+$, was to provide monomers from which the basic optical and electrochemical properties of the system 2,5-bis(ferrocenylsilyl)thiophene could be obtained.

2. Results and discussion

The reaction between 2,5-bis(chlorodimethylsilyl)thiophene, **Ia**, and dilithioferrocene, Eq. (1), resulted in the formation of a series of low molecular weight cyclic oligomers. We attempted to separate these materials by column chromatography and were able to obtain the first of this series, **IIa,** $n = 2$, as pure red crystals. The spectroscopic data for **IIa** are recorded in Table 1 and its structure is presented in Fig. 1, and selected bond angles and lengths in Table 2.

[a] Spectra were recorded in C_6D_6 with the exception of **IV** which was recorded in $CDCl_3$.

The structure of **IIa** possesses normal bond lengths and angles and the cycle shows no structural sign of ring strain. The two ferrocene groups are completely eclipsed, as noted in Fig. 1(b), and the two thiophene groups are positioned in opposition to each other.

At the present time we have been unable to characterize completely the remainder of the product obtained from the reaction described in Eq. (1). Fast atom bombardment MS indicated the presence of trimeric (m/e = 1147) and tetrameric (m/e = 1529) analogs of **IIa** and the NMR data recorded in Table 1 are consistent with this observation. However, other materials are also present, witness for example the ^{29}Si NMR signals at −15.2 and −4.85 ppm. We continue to study this system.

The reaction outlined in Eq. (2) was satisfactory for the formation of monomeric 2,5-bis(ferrocenyldimethylsilyl)-thiophene, **III**, and the diphenylsilyl analog **IV**, in good yield. The spectroscopic data for **III** and **IV** are in accord with their proposed structures and are recorded in Table 1. The single crystal structure of **III** is recorded in Fig. 2, and representative bond lengths and angles are presented in Table 2. This complex was synthesized to provide baseline data to facilitate the analysis of polymeric and oligomeric analogs.

The related bond lengths and angles of **IIa** can be compared to those of **III** and it is immediately clear that there are no truly significant differences between the two sets. The single exception to this generality are the possibly shorter silicon–thiophene–carbon bond lengths in **IIa** (Si1–C1 = 1.861(3) and Si2–C4a = 1.864(2) Å) compared with those in **III** (Si1–C1 = 1.874(3) and Si2–C1 = 1.872(5) Å). In both structures there are essentially no dihedral angles between the two cyclopentadienyl rings in the ferrocene units, and the thiophene rings are planar with normal bond lengths and angles. The key distinction between the two structures are the

two intramolecular Fe···Fe distances. For **IIa** this distance is 7.57 Å, whereas for **III** it is significantly longer at 11.28 Å, and this will impact many properties, vide infra.

One of the diagnostic features of polyferrocenyl and ferrocenylene complexes and materials is their capacity to exhibit more than a single redox process even though the iron containing groups are nominally identical. We have previously noted that in the α, ω diferrocenyl oligosilanes, $Fc(SiMe_2)_nFc$, when the bridging chain is equal or greater than 4, the two ferrocenyl groups do not interact and only a single redox process is observed via cyclic voltammetry [11]. Shorter chains result in two distinct processes: an initial step involving oxidation of alternate Fc groups, and a second step where the presence of a neighboring ferrocenium ion raises the oxidation potential of the remaining ferrocenylene groups. The transmission of the electronic effects from a ferrocenium ion to a neighboring unoxidized Fe center can be a through bond inductive effect, or through space. Silicon atom bridges and acetylenic bridges effectively facilitate such through bond interactions [11,18]. The degree to which the ferrocene groups in **IIa** and **III** can interact in this manner was investigated by cyclic voltammetry. Complex **IIa** exhibited two discrete redox processes when the experiment was performed in CH_2Cl_2; $E_{ox} = 0.51$ V and $E_{ox} = 0.56$ V, $E_{red} = 0.48$ V and $E_{red} = 0.41$ V (relative to Ag/Ag^+). In acetonitrile, a superior coordinating solvent in which the positive charge is better delocalized, only a single process was observed, $E_{ox} = 0.56$ V, $E_{red} = 0.48$ V. By contrast, regardless of the solvent, only a single process was observable when complex **III** was examined, $E_{ox} = 0.56$ V, $E_{red} = 0.46$ V. These results clearly show that the capacity for interaction between the ferrocenium ion and the unoxidized ferrocenylene group can occur through space as well as via an atomic backbone. It is not surprising that in **III**, where the two Fe atoms are separated by >11 Å, the two redox processes are equivalent.

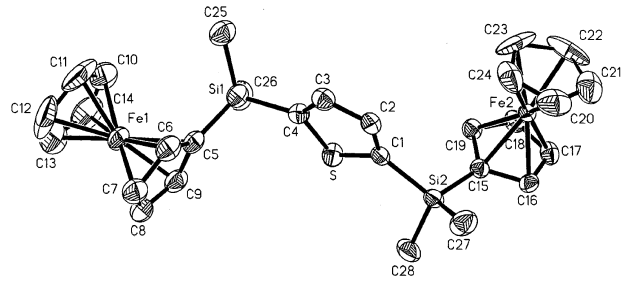

Fig. 2. Crystal structure of **III**.

3. Experimental

All reactions were performed with dry oxygen free solvents in N_2 or Ar atmospheres. Analyses were perfromed by Galbraith Laboratories Inc.; NMR were recorded on a Bruker 250 MHz instrument. LRMS was obtained from the Nebraska Center for Mass Spectrometry. Electrochemical analysis was performed as previously reported, with tetraethylammonium tetrafluoroborate as supporting electrolyte [11].

3.1. Synthesis of 2,5-bis(hydridodimethylsilyl)thiophene [2]

In a 250 ml flask, equipped with a reflux condenser, rubber septum and dropping funnel was added 13.3 g (55 mmol) of

2,5-dibromothiophene in 20 ml of THF to 2.90 g (119 mol) of Mg and 0.4 g I_2 in 100 ml of dry THF. The formation of the Grignard was initiated by mild external heating with a hair dryer and then an exothermic reaction occurred. After complete addition, 3 h, the flask was cooled on an ice bath and 10.4 g (110 mmol) of Me_2SiHCl in 20 ml of THF was added over 20 min. The reaction mixture was stirred overnight and then the solvent removed in vacuo. The crude product was extracted into hexane and filtered. Distillation of the liquid residue after removal of the hexane yielded 6.1 g (30 mmol, 55%) of the title compound, b.p. 90ºC/8 mm Hg.

3.2. Chlorination of 2,5-bis(hydridodimethylsilyl)thiophene [2]

In a 100 ml side-arm flask, 3 g (15 mmol) of 2,5-bis(hydridodimethylsilyl)thiophene was added slowly to a catalytic amount of $PdCl_2$ (0.2 g) in 40 ml of carbon tetrachloride. The reaction was monitored by IR spectroscopy and after 30 min the Si–H stretching frequency at $\sim$2128 cm^{-1} had disappeared. The solvent was removed in vacuo and the liquid product was distilled to yield 2,5-bis(chlorodimethylsilyl)thiophene, (b.p. 125–130ºC/14 mm Hg, 2.12 g, 7.8 mmol, 52%).

3.3. Reaction of 2,5-bis(chlorodimethylsilyl)thiophene with dilithioferrocene

To a 40 ml hexane slurry of 1,1′-dilithioferrocene·tmeda (prepared from ferrocene (3.0 g, 16 mmol), *n*-butyllithium (24.4 ml of a 1.6 M solution) and 5.8 ml of freshly distilled TMEDA in 150 ml of hexane) [19] was added dropwise 2.7 g (10 mmol) of bis-2,5(chlorodimethylsilyl)thiophene at −78°C. The mixture was stirred for 1 h at this temperature and then permitted to warm to room temperature and stirred overnight. After filtration the solvent was removed in vacuo to produce a brown oily material which was dissolved in the minimum of hexane and placed upon a 2×25 cm silica gel column (60–200 mesh). Development with hexane produced two distinct bands. The initial yellow band was collected and after removal of solvents produced 50 mg (0.07 mmol, 14%) of **IIa** as a red powder which was further purified by recrystallization from hexane, m.p. 230–234°C. A second band eluted with hexane yielded an orange–red oil, **II*n***.

*3.4. Synthesis of 2,5-bis(ferrocenyldimethylsilyl)thiophene (**III**)*

A solution of ferrocenyllithium (prepared from the reaction of 9.28 ml of 1.6 M *n*-butyllithium with 1.0 g (2.4 mmol)

of FcHgCl) was added dropwise to 1.0 g (3.7 mmol) of 2,5-bis(chlorodimethylsilyl)thiophene in 30 ml of THF at −78°C. The mixture was stirred overnight and then the solvent was removed in vacuo. The product was extracted with hexane, and the solution filtered. After removal of the solvent di-*n*-butylmercury was distilled to leave a gummy residue. This was dissolved in the minimum of hexane and placed upon a 10×2 cm silica gel column (60–200 mesh) and eluted with hexane. An orange band developed and was collected, the solvent removed and the final residue recrystallized from hexane to yield **III**, 1.2 g (2.1 mmol, 57%), m.p. 77°C.

Also prepared by the same general route, in 65% yield, was 2,5-bis(ferrocenyldiphenylsilyl)thiophene (**IV**) from the reaction of ferrocenyllithium and 2,5-bis(chlorodiphenylsilyl)thiophene.

3.5. Structural analysis of *IIa* and *III*

An orange crystal of approximate dimensions 0.32×0.44×0.80 mm (**IIa**) and an orange–yellow crystal approximately 0.60×0.60×0.40 mm in size (**III**) were mounted on glass fibers in a random orientation. Intensity data were collected at room temperature for **IIa** and −100°C for **III**, which decayed under the X-ray beam at room temperature, using a Siemens/Bruker four circle diffractometer with graphite-monochromated Mo Kα radiation, $\lambda = 0.71073$ Å. Unit cell parameters and standard deviations were obtained by least-squares fit of 25 reflections randomly distributed in reciprocal space in the 2θ range of 15–30°. The ω-scan technique was used for intensity measurements in both cases. A range of 1.4° in ω and variable speed of 3.00 to 20.00 ° min^{-1} was used for **IIa** and a 1.2° ω-range and a 3.00 to 15.00° min^{-1} speed for **III**. Background counts were taken with stationary crystal and total background time to scan time ratio of 0.5. Three standard reflections were monitored in both cases every 97 reflections and showed no significant decay for **IIa** and an average intensity decay of 8.2% for **III** even at −100°C. The data were corrected for Lorentz and polarization effects but only **IIa** was corrected semi-empirically for absorption giving a min./max. transmission ratio of 0.221/0.254.

Both structures were solved by direct methods and refined using the PC-version of the SHELXTL PLUS crystallographic software by Siemens. Full-matrix least-squares refinement minimizing $\sum w(F_o - F_c)^2$ was carried out with anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were placed at calculated positions (C–H 0.96 Å; $U_H = 0.08$) during refinements. The weighing scheme has the form $w^{-1} = \sigma^2(F) + gF^2$ and the final R factors the form $R = \sum |F_o - F_c| / \sum F_o$ and $R_w = [w|F_o - F_c|^2 / \sum wF_o^2]^{1/2}$. Relevant crystal and refinement data are provided in Table 3 and selected bond lengths and angles are provided in Table 2. The structures of **IIa** and **III** are illustrated in Figs. 1 and 2, respectively.

4. Supplementary data

Crystallographic data for structures **IIa** and **III** are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk), quoting the deposition numbers CCDC 140477 (**IIa**) and CCDC 140478 (**III**).

POLYHEDRON

Time-resolved, in situ X-ray diffraction studies of intercalation in lamellar hosts

Dermot O'Hare *, John S.O. Evans [1], Andrew Fogg, Stephen O'Brien

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, UK

Received 25 April 1999; accepted 29 August 1999

Abstract

Energy dispersive X-ray diffraction (EDXRD) has been used to perform in situ kinetic studies on the intercalation of a range of guest molecules in layered lattices. The kinetics of the intercalation of cations (K^+, PyH^+ ($Py = C_5H_5N$), NMe_4^+) and the long chain ammonium ions $C_{12}TMA$, $C_{16}TMA$, $C_{18}TMA$ ($C_{12}TMA$ = dodecyltrimethylammonium, $C_{16}TMA$ = hexadecyltrimethylammonium and $C_{18}TMA$ = octadecyltrimethylammonium) into crystals of $MnPS_3$ have been determined. These reactions are very fast, and in some cases novel transient phases are observed. The rate of cobaltocene, $Co(\eta\text{-}C_5H_5)_2$, intercalation in layered metal dichalcogenides ZrS_2, 2H-SnS_2, 2H-$SnSe_2$, 2H-TaS_2, 2H-NbS_2, 1T-TaS_2 and TiS_2 has also been investigated. Integrated intensities of the Bragg reflections have been used to determine the extent of reaction (α) versus time for each of these reactions. A number of kinetic models have been considered, including the Avrami–Erofeyev ($m = 1.5$) deceleratory nuclei-growth model and statistical simulation. The concentration and solvent dependence of the rate of $Co(\eta\text{-}C_5H_5)_2$ intercalation into 2H-SnS_2 has also been determined. Surprisingly, we find that the rate of intercalation is invariant to the initial $Co(\eta\text{-}C_5H_5)_2$ concentration over a wide concentration range. The rate of intercalation of the lithium salts (LiX; X = Cl, Br, NO_3 and OH) into Gibbsite (γ-$Al(OH)_3$) giving the layered double hydroxides $[LiAl_2(OH)_6]X \cdot nH_2O$ (X = Cl, Br, NO_3 and OH) and $[LiAl_2(OH)_6]_2SO_4 \cdot nH_2O$ has been studied. The temperature dependence of the rate of intercalation of LiCl yields an activation energy of 27 kJ mol^{-1}. The reaction was also found to be half order with respect to the initial concentration of LiCl. Time-resolved in situ energy dispersive X-ray powder diffraction (EDXRD) spectra have been recorded following the addition of an aqueous solution of hexadecyltrimethylammonium chloride ($C_{16}H_{33}N^+Me_3Cl^- = C_{16}TMACl$) to kanemite ($NaHSi_2O_5 \cdot 3H_2O$). The diffraction data suggest that initially a layered phase forms due to intercalation of the alkylammonium ions which then transforms into a silicate-organic mesophase which is the precursor to the hexagonal mesoporous silicate, FSM-16. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Some of the earliest and most extensive studies of the kinetics of intercalation reactions were carried out using graphite crystals. For example, classic experiments performed by Hooley and co-workers investigated the gain in weight of a graphite flake under a bromine atmosphere [1,2]. Until recently, only two time-resolved diffraction studies on metal chalcogenide intercalation have been reported [3–7]. The study by Riekel and Schollhorn measured time-resolved neutron diffraction data during the intercalation of 2H-TaS_2 with $NH_3(g)$. However, the available levels of beam flux, whilst high by neutron standards, necessitated either very large sample sizes ($\sim$15 g) or long acquisition times, making a thorough, quantitative study under varying reaction conditions of temperature, concentration and particle size unfeasible. Moreover, because of the large incoherent scattering from hydrogen atoms by neutrons, the samples studied had to be highly deuterated, an expensive and not always achievable prerequisite for other intercalation reactions. Even taking all these previous experiments into consideration, we still have a fairly rudimentary understanding of the intimate mechanism of intercalation reactions. Knowledge of the critical factors which control the rates of these reactions is based on a limited range of experiments. We still commonly use the schematic illustration shown in Fig. 1 to describe these reactions, which undoubtedly greatly oversimplifies the true picture.

In recent years, the technological and experimental advances in energy dispersive powder diffraction (EDXRD) using synchrotron X-ray sources have provided new possi-

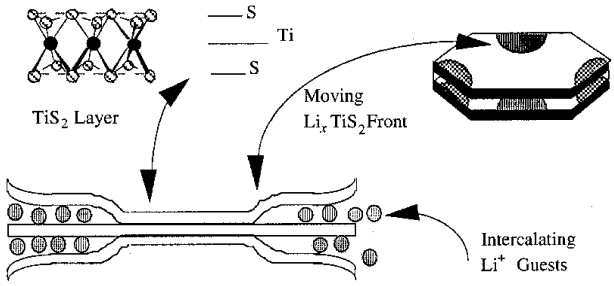

Fig. 1. Schematic representation of the intercalation of a guest into a layered dichalcogenide host lattice.

bilities for the solid state kineticist [8–11]. The markedly higher intensity (several orders of magnitude) over conventional laboratory X-ray sources means that good quality spectra can now be obtained from milligram samples on a time-scale of seconds, making kinetic studies on fast intercalation reactions a realisable goal. We have recently constructed and commissioned a number of environmental cells for measuring time-resolved energy dispersive X-ray diffraction data of intercalation reactions [12–14].

In this paper we will review some of the significant observations we have made to date concerning our investigations into the kinetics of intercalation reactions using in situ, time-resolved X-ray diffraction.

2. Kinetics of intercalation reactions

2.1. Intercalation of cations in metal hexathiohypodiphosphates

The transition metal hexathiohypodiphosphates, MPS_3 (M = Mn, Fe, Ni, Cd), have been shown to intercalate a wide range of guest ions and molecules. In recent years they have been shown by Clement and co-workers to exhibit a unique type of intercalation reaction. MPS_3 (M = Mn, Cd, Fe) reacts spontaneously with aqueous solutions of ionic salts, G^+X^- (where G^+ can range from simple ionic species such as K^+ and NH_4^+ to species as large as, for example, cobaltocenium cations), to give compounds of general formula $Mn_{1-x}PS_3\{G\}_{2x}(H_2O)_y$ [15–17]. In these compounds, charge balance has been maintained by the loss of one Mn^{2+} ion from the intralayer region for every two G^+ ions that are intercalated in the interlayer region.

We have studied the kinetics of K^+, PyH^+ (Py = C_5H_5N), NMe_4^+ and the long chain ammonium ions $C_{12}TMA$, $C_{16}TMA$, $C_{18}TMA$ ($C_{12}TMA$ = dodecyltrimethylammonium, $C_{16}TMA$ = hexadecyltrimethylammonium and $C_{18}TMA$ = octadecyltrimethylammonium) intercalation into sub 90 μm crystals of $MnPS_3$ in water between room temperature and 120°C using time-resolved in situ EDXRD [18]. In a typical experiment, solutions of the appropriate reagents were preheated to the reaction temperature, remotely injected into a 5 ml flask containing the stirred host lattice, and the X-ray diffraction pattern of the resulting suspension monitored as a function of time. Under these conditions the diffraction pattern could be recorded over a 20–4 Å *d*-spacing range in as little as 10 s, allowing the direct observation of the disappearance of the host lattice and growth of the product phase.

Kinetic information was extracted from each experiment by integration of the 001 Bragg reflection using a Gaussian peak fitting routine [19]. The time dependence for pyH^+ intercalation in $MnPS_3$ is shown in Fig. 2. The errors on the integrated areas are small and contained within the data points. The integrated intensities were subsequently converted to the extent of the reaction, α, using the relationship (Eq. (1)):

$$\alpha_{hkl}(t)=\left(\frac{I_{hkl}(t)}{I_{hkl}(t_\infty)}\right) \quad (1)$$

The kinetics of intercalation were analysed following the method of Hulbert, who showed that the general rate expression for nucleation growth reactions developed by Avrami takes the form of Eq. (2) [20–24]. A summary of the least squares fits of such an expression to the experimental data and the rate parameters of the fits are given in Table 1.

$$\ln\frac{1}{1-\alpha}=(kt)^m \quad (2)$$

where α represents the extent of reaction at time *t*.

A number of important conclusions can be drawn from this study. Firstly these intercalation reactions occur extremely rapidly, with half-lives of the order of a minute or less. These exchange intercalation reactions appear to be some of the fastest known molecular intercalation reactions. Secondly the reactions occurred cleanly via a two-phase reactant to product route, and no phenomena such as staging were observed. These systems obey rate expressions similar to those found for the intercalation reactions of other host lattices, and the rate of formation of the product phase and disappearance of the host lattice obey identical rate laws.

The intercalation of dodecyltrimethylammonium bromide ($C_{12}TMABr$) into $MnPS_3$ at 120°C has also been studied using in situ energy dispersive X-ray powder diffraction. The reaction proceeds smoothly and affords a stable crystalline

Table 1
Kinetic rate parameters for the intercalation of various guest species into some lamellar hosts: experimental rates have been fitted to a rate expression $\alpha = [1 - \exp(-kt)^m]$

Host	Guest	Temperature (°C)	m	k (10^{-3} s^{-1})	$t_{1/2}$ (s)
$MnPS_3$	K^+	33	1.0	12.0	55
$MnPS_3$	pyH^+	33	1.0	20	43
$MnPS_3$	NMe_4^+	51	1.0	88	59
$MnPS_3$	NMe_4^+	60	1.0	20	35
$MnPS_3$	$C_{12}TMA$ [a]	120	1.5	6.3	435

[a] $C_{12}TMA$ = dodecyltrimethylammonium.

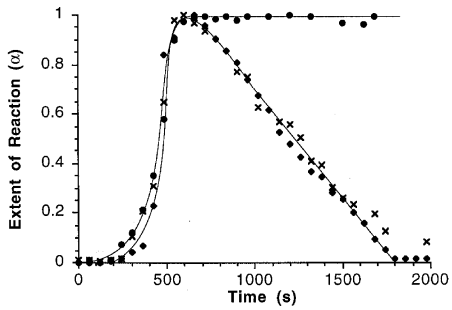

Fig. 3. Plot of extent of reaction (α) vs. time for the following reactions: (●) $C_{12}TMABr$ with $MnPS_3$ in water at 120°C; (×) $C_{16}TMABr$ with $MnPS_3$ in water at 120°C; (♦) $C_{18}TMABr$ with $MnPS_3$ in water at 70°C. $\alpha = I_{hkl}(t)/I_{hkl}(t = I_{max})$ for the (002) Bragg reflection in each case.

compound. The X-ray diffraction pattern of the product can be indexed on a hexagonal unit cell with a *c*-lattice parameter of 11.26 Å. Integration of the (001) Bragg reflection with respect to time is shown in Fig. 3. The half-life for the reaction at 120°C is ca. 400 s with the reaction essentially complete in 700 s. The increase in the interlamellar spacing of 4.77 Å is consistent with the packing of the dodecyltrimethylammonium ions parallel to the planes of the host lattice (Fig. 4). Elemental analysis is consistent with a formulation of this intercalate as $Mn_{0.92}PS_3(C_{12}TMA)_{0.16}$.

However, dramatically different behaviour was observed when we monitored the intercalation of the larger hexadecyl- and octadecyltrimethylammonium bromides ($C_{16}TMABr$ and $C_{18}TMABr$) in $MnPS_3$. For both reactions, we observed the growth of a series of Bragg reflections which can be indexed to a unit cell with *c*-lattice parameters of 33.8 and 36.2 Å for the hexadecyl- and octadecyltrimethylammonium reactions, respectively. These large *c*-lattice parameters correspond to interlayer expansions of ca. 27.3 and 29.7 Å for the hexadecyl- and octadecyltrimethylammonium intercalates, respectively. A plot of the time dependence of the integrated intensities of the Bragg reflections due to these intercalate phases shows that the initial rates of intercalation of all three ammonium cations are essentially equal, suggesting that the rate-determining step in each of these reactions is the separation of the $MnPS_3$ layers. However, for reactions involving the intercalation of $C_{16}TMA^+$ and $C_{18}TMA^+$, the peak intensities of the intercalate phases start

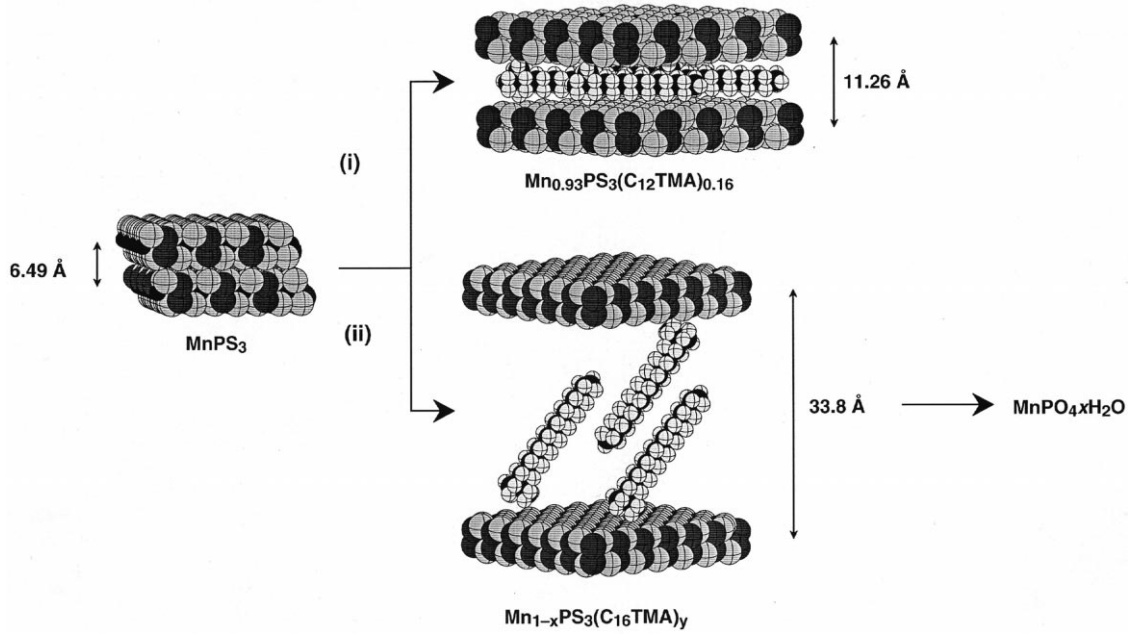

Fig. 4. Synthesis of long chain ammonium intercalates of $MnPS_3$: (i) $MnPS_3$ (150 mg) + $C_{12}TMABr$ (1 mmol) in 5 cm^3 water at 120°C, (ii) $MnPS_3$ (150 mg) + $C_{16}TMABr$ (1 mmol) in 5 cm^3 water at 120°C.

to decrease gradually after ca. 600 s and after approximately 30 min no reflections are observed in the energy window of the detector (Fig. 5). The resulting grey powder which can be collected from the reaction mixtures is identical from both reactions and is poorly crystalline. Both elemental microanalysis and X-ray microprobe analysis suggest that it has composition $MnPO_4 \cdot xH_2O$ although the unit cell dimensions do not match any of the known manganese phosphates or hydrogen phosphates.

Intercalation of the intermediate length tetradecyltrimethylammonium bromide (C_{14}TMABr) in $MnPS_3$ gives rise to a complex reaction. Different behaviour has been observed when the reaction was monitored in situ on three different occasions. The first attempt showed the transient formation of a new phase which could be indexed with a *c*-lattice parameter of 31.6 Å; on a second occasion a different phase was observed with a *c*-lattice parameter of 11.5 Å, which co-formed with a small amount of the previous phase. On another occasion only the phase with a 11.5 Å lattice parameter could be detected. A plot of the unit cell dimension versus the number of carbon atoms for the guest molecule, C_nTMA^+ ($n = 14$, 16, and 18), is linear. The gradient of this plot is 1.15 Å per C. Assuming the guest molecules form a monolayer between the $MnPS_3$ layers, then this suggests that the guest ions are oriented at ca. 65° to the host layers. In addition, it seems reasonable to postulate that the C_{14}TMA cation is just at the critical length where the energy difference between the guests lying parallel to the host layers or at an angle of 65° to the layer plane is very small.

2.2. Kinetics of intercalation of cobaltocene into lamellar metal chalcogenide hosts

Redox-active organometallic compounds can be intercalated into the metal dichalcogenides either by direct reaction, ion-exchange, or by electrochemical routes [25]. This significant reaction was first reported in 1975 when Dines described the intercalation of the metallocenes cobaltocene ($Co(Cp)_2$; $Cp = \eta$-C_5H_5) and chromocene ($Cr(Cp)_2$) into a range of metal disulfides (MS_2: M = Ti, Zr, Nb, Ta and Sn) [26,27]. Since then these materials have been extensively studied due to their fascinating structural and electronic properties. In general, the ability of an organometallic molecule to intercalate in a layered lattice has been based on empirical rules. Therefore we were excited at the possibility of being able to determine quantitatively the kinetics of these reactions and also of being able to investigate whether intermediate novel phases are formed during the course of the reaction.

We have investigated the kinetics of intercalation of $Co(Cp)_2$ into a range of layered metal dichalcogenides using in situ time-resolved EDXRD [19,28]. We were particularly interested to determine whether the variation in the rates of these intercalation reactions could be correlated with the chemical properties of the hosts. Fig. 6 summarises the extent of reaction $\alpha(t)$ versus time (t) for the intercalation of $Co(Cp)_2$ into ZrS_2, SnS_2, $SnSe_2$ and 2H-TaS_2. In each case

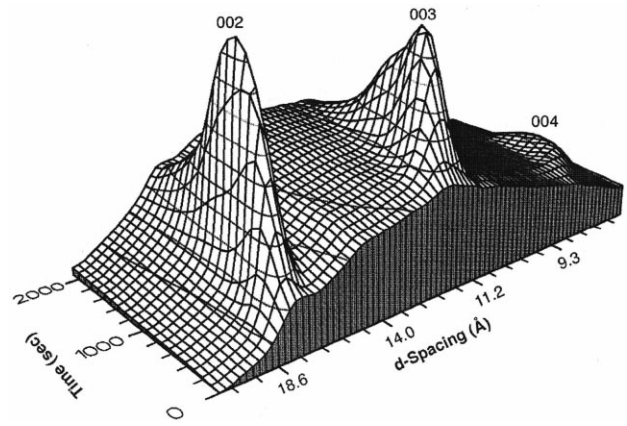

Fig. 5. Time-resolved energy dispersive X-ray diffraction of the reaction of C_{16}TMABr with $MnPS_3$ in H_2O at 120°C.

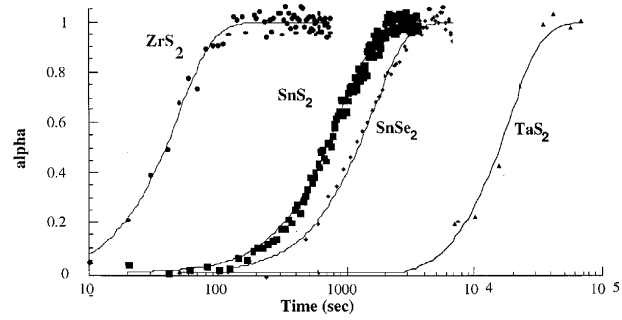

Fig. 6. Extent of reaction (α) vs. time for intercalation of $Co(Cp)_2$ into a range of metal dichalcogenides: ● ZrS_2, 8°C; ■ SnS_2, 20°C; ◆ $SnSe_2$, 50°C; ▲ $TaSe_2$, 120°C. The lines are fits to the Avrami deceleratory nuclei-growth model, $\alpha = 1 - \exp(-k(t - t_0))^{1.5}$.

the reaction yields first stage intercalation compounds of chemical composition $MX_2\{Co(Cp)_2\}_{0.30 \pm 0.05}$. In all cases we observed the smooth growth of intensity of the reflections due to the intercalate phases with increased *c*-lattice constants of 5.35 ± 0.02 Å. No intermediate phases of higher order staging are observed in any of these reactions. What is immediately striking about the data shown in Fig. 6 is the extreme variation in the rate of the reaction for each of the host lattices. For all the reactions, we tried to keep identical conditions; each host was sieved to a particle size distribution between 90–250 mm and the same amount of $CoCp_2$ solution was injected into each sample. Unfortunately, we had to vary the temperature of the reactions in order to collect data on a reasonable timescale. A summary of the rate constants (k_{obs} (s^{-1})) and half-life ($t_{1/2}$) for these reaction is shown in Table 2.

For SnS_2, ZrS_2 and $SnSe_2$ we have also investigated the rate of intercalation as a function of the initial $Co(Cp)_2$ concentration. In each case, varying concentrations of cobaltocene solution (enough volume to provide a 2:1 molar excess with respect to the host) were injected onto 200 mg of the host lattice at a convenient temperature for kinetic analysis. Fig. 7 shows each of the $\alpha(t)$ curves for the intercalation of cobaltocene into SnS_2 at 20°C for a range of initial $Co(Cp)_2$ concentrations.

Table 2
The half-lives and Avrami rate constants for the intercalation of $Co(Cp)_2$ into a range of lamellar metal dichalcogenides at 20 and 120°C (particle size 60–90 μm, in dimethoxyethane)

Host	20°C		120°C	
	Half-life (s)	$k\times10^3/s^{-1.5}$	Half-life (s)	$k\times10^3$ ($s^{-1.5}$)
ZrS_2	23	34.1	<5	400–600 [a]
2H-SnS_2	475	1.64	31	25.3
2H-SnSSe			225	
2H-$SnSe_2$	6730	0.12	410	1.92
2H-TaS_2			16000	0.05
2H-$NbSe_2$			2960	0.26
1T-TaS_2			>16000	<0.05 [b]
TiS_2			>60000	<0.01

[a] At 120°C this is too fast to measure accurately with the time resolution available; the range of values for k is an estimate based on extrapolation of lower temperature results.
[b] Shortage of beam time prevented full analysis. The reaction was significantly slower than that of 2H-TaS_2.

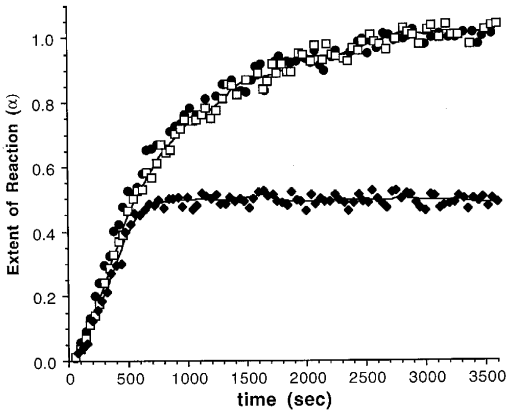

Fig. 7. Extent of reaction vs. time for the intercalation of $CoCp_2$ into SnS_2 at 20°C for a range of guest stoichiometries; the data are extracted from integration of the host (001) reflection such that $\alpha=1$ corresponds to complete loss of coherent diffraction from the host lattice. Data shown are for guest:host molar ratios of 1:1 (●), 0.33:1 (□) and 0.1:1 (♦).

Data could be fitted to Eq. (2) and, for the complete range of initial $Co(Cp)_2$ concentrations studied (10–70 mg cm^{-3}), the measured rate constants and half-lives are invariant within experimental error. Therefore, we conclude that the nucleation and diffusion rate are independent of $Co(Cp)_2$ concentration over the range investigated. The invariance on guest concentration and the congruency of the reaction kinetic curves suggest a number of issues. Firstly, the similarity in the sigmoidal nature of the extent of reaction curve for each system implies a consistent mechanism and a consistent ratio between the rates of nucleation and diffusion. Secondly, the diffusion of guest molecules to the host surface is insignificant with respect to the reaction rate.

If this is an example of a more general phenomenon, this observation has significant practical implications. The zero-order dependence in the guest concentration means that in future experiments it should not be necessary to use a large excess of guest molecules to expedite these reactions. This would be especially useful if the guests are expensive or particularly difficult to synthesise.

2.3. Kinetics of intercalation of lithium salts in aluminium hydroxide

The intercalation of LiCl in Gibbsite (γ-$Al(OH)_3$) is a remarkable example of an intercalation reaction in which both the cation and the anion are simultaneously intercalated in the host lattice [29–32]. The product of the reaction is $[LiAl_2(OH)_6]Cl\cdot H_2O$ which is a layered double hydroxide with a well ordered structure [33–35]. We have studied this reaction using time-resolved in situ EDXRD. In all cases the reactions proceeded directly to the first stage intercalation product and no other crystalline intermediate phases were observed. A typical set of in situ EDXRD spectra for intercalation of LiCl are shown in Fig. 8. The major peak that is observed to grow with time in this energy window corresponds to the (002) Bragg reflection of $[LiAl_2(OH)_6]Cl\cdot H_2O$ at $E=49.1$ keV ($d=7.65$ Å) while the (001) Bragg reflection of Gibbsite at $E=77.0$ keV ($d=4.85$ Å) decays in intensity. We can resolve no changes in the peak position or peak width at half maximum during the growth of the intercalate Bragg peaks. This is probably not too surprising

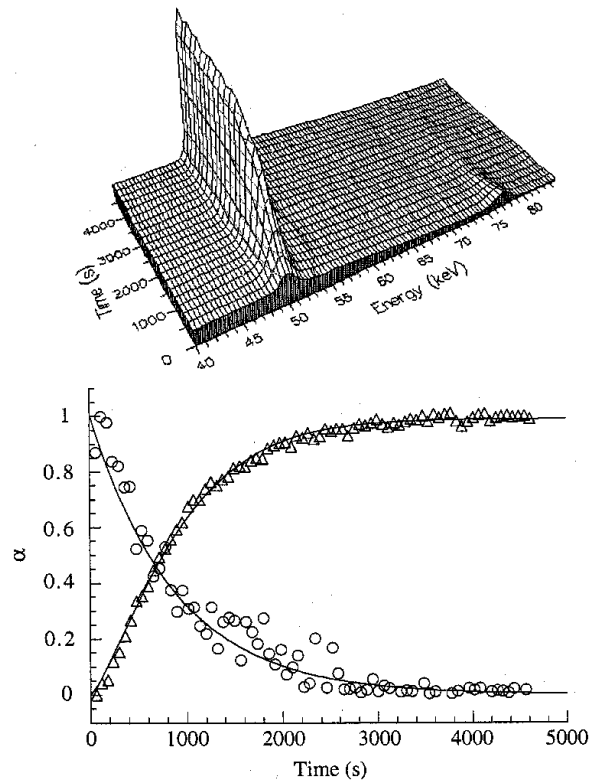

Fig. 8. (a) Time resolved in situ energy dispersive X-ray powder diffraction data showing the course of the reaction between Gibbsite and a 7.5 M aqueous solution of LiCl at 120°C giving $[LiAl_2(OH)_6]Cl\cdot H_2O$. (b) Plot of extent of reaction (α) of the (001) Bragg reflection ($E=77.1$ keV, $d=4.85$ Å) of the Gibbsite (○) and the (002) Bragg reflection of $[LiAl_2(OH)_6]Cl\cdot H_2O$ ($E=49.1$ keV, $d=7.65$ Å) (△) as a function of time.

given that the detector momentum resolution using post sample molybdenum slits is typically $\Delta E/E = 0.0115$.

Kinetic information was extracted from each experiment by integration of the (002) Bragg reflection of $[LiAl_2(OH)_6]Cl \cdot H_2O$. The errors on the integrated areas are small and contained within the data points. The integrated intensities were subsequently converted to the extent of the reaction (α) using the relationship Eq. (1): least-squares fits of the $\alpha(t)$ data are to the Avrami–Erofe'ev rate expression (Eq. (2)). We have investigated the rate of intercalation of LiCl in Gibbsite as a function of both temperature and LiCl concentration.

2.3.1. Effect of temperature

The temperature dependence of the intercalation reaction between a 10 M aqueous solution of LiCl and Gibbsite was investigated over the range 60–140°C. Fig. 9 plots the extent of reaction against time for the temperatures studied and it is clear that the rate of reaction has a marked temperature dependence. In each case the Avrami–Erofe'ev equation (Eq. (2)) has been fitted to the data. Furthermore, plots of reduced time ($t/t_{0.5}$) versus extent of reaction for the different temperatures are superimposable within experimental error, implying a consistent mechanism for the intercalation reaction over the whole temperature range.

The Avrami exponents obtained from the least-squares fits for all the data sets fell in the range 0.8–1.2, though a value of $m = 1.0$ gives a satisfactory fit to the majority of the experimental results. Assuming Avrami–Erofe'ev kinetics to be relevant, this indicates a two-dimensional diffusion controlled nucleation-growth model following instantaneous nucleation. In this case the Avrami–Erofe'ev equation becomes $\alpha = [1 - \exp(-kt)]$.

The validity of Eq. (2) for the whole process can be confirmed by a Sharp–Hancock analysis. In each case this analysis yields a single straight line over the whole reaction, implying that the Avrami–Erofe'ev kinetics discussed above are a good description of this system. Further evidence for this model can be obtained by consideration of the intersection of the host and intercalate curves. The intersection is at $\alpha = 0.5$, implying that loss of coherent diffraction from the host is matched by gain in coherence of the product. In cases where nucleation is random, the rate of loss of coherent diffraction from the host lattice exceeds the rate of growth of the product phase leading to the intersection being at $\alpha < 0.5$.

From the kinetic data obtained from the above analysis, it is possible to extract an activation energy for the intercalation of LiCl into Gibbsite using the Arrhenius expression, $k = A\exp(-E_a/RT)$. A plot of ln k versus $1/T$ yields a value of $E_a = 27$ kJ mol^{-1}. This compares with a value of $E_a = 41$ kJ mol^{-1} obtained from a study of the temperature dependence of the rate of intercalation of cobaltocene ($Co(\eta\text{-}C_5H_5)_2$) in SnS_2.

2.3.2. Effect of concentration

The effect of LiCl concentration on the intercalation reaction was studied at 120°C over the range 4–20 M. The reaction

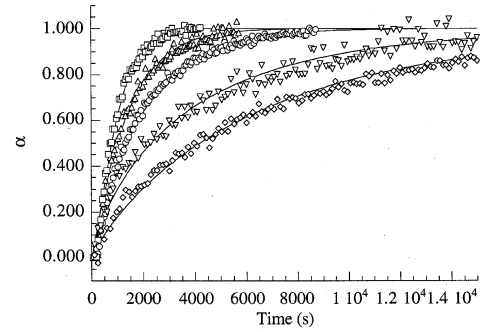

Fig. 9. Extent of reaction (α) against time (t) for the intercalation of LiCl into Gibbsite over a range of temperatures: 140°C (□), 120°C (△), 100°C (○), 80°C (▽) and 60°C (◇). Data for 110°C and 90°C have been omitted for clarity. The data have been fitted using the Avrami–Erofe'ev equation.

with 4 M LiCl did not go to completion in 4 h and no reactions were observed in 2 h for concentrations below this level. From the plots of extent of reaction against time shown in Fig. 10 it can be seen that the reaction rate is strongly dependent on the initial concentration of LiCl. In each case the Avrami–Erofe'ev equation has been fitted to the data. The observation of a dependence of rate of the reaction on the concentration of the guest is in contrast to previous studies on the intercalation of metallocenes into metal dichalcogenides which were found to be zeroth order with respect to the guest concentration. As for the temperature dependence reactions, plots of extent of reaction against reduced time are superimposable within experimental error, suggesting that the same mechanism is occurring in each case. This can be further confirmed by analysis of the Avrami exponents obtained from the curve fitting and from the Sharp–Hancock plots which lie in the range 1.0–1.5 though taking a value of 1.0 again gives a satisfactory fit to the majority of the data. This indicates a two-dimensional diffusion controlled nucleation-growth model following instantaneous nucleation, as was observed for the temperature dependence data. The kinetic parameters are summarised in Table 3.

The order of reaction with respect to LiCl concentration can be determined from a plot of ln k against ln[LiCl] which is shown in Fig. 11. The gradient of this plot is 0.52, indicating

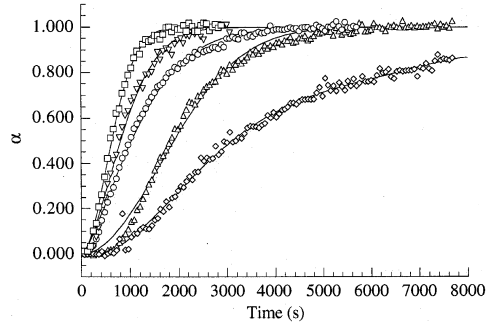

Fig. 10. Extent of reaction (α) against time (t) for the intercalation of LiCl into Gibbsite over a range of initial guest concentrations: 20 M (□), 15 M (▽), 10 M (○), 5 M (△), and 4 M (◇). Data for 12 M and 7.5 M guest solutions have been omitted for clarity.

Table 3
Summary of the kinetic parameters obtained from the Sharp–Hancock analysis of the intercalation of LiCl into Gibbsite for varying initial LiCl concentrations

[LiCl] (mol^{-1})	m [a]	k (s^{-1}) [b]	$t_{0.5}$ (s)
20	1.47	1.21×10^{-3}	600
15	1.40	1.09×10^{-3}	780
12	1.27	9.16×10^{-4}	900
10	1.00	7.40×10^{-4}	960
7.5	1.37	6.86×10^{-4}	1050
5	1.45	6.16×10^{-4}	1830
4	1.26	2.89×10^{-4}	3180

[a] From a least-squares fit to Eq. (2).
[b] From a least-squares fit to $\alpha = [1-\exp(-kT)]$.

that the reaction is half order with respect to [LiCl]. This gives the rate equation as:

$$\text{rate} \propto k[\text{LiCl}]^{0.5}$$

2.4. Intercalation of ammonium ions in the layered silicate kanemite

The synthesis of mesoporous materials has been one of the most topical and rapidly moving fields in solid state chemistry of the last decade. The mechanism of formation of these materials is very poorly understood but is clearly an important issue. The synthetic approach originally reported by Kresge et al. [36] led to the development and investigation of the M41S family of mesoporous molecular sieves [37–39]. The three phases obtained from the M41S synthesis methods are hexagonal (MCM-41), cubic (MCM-48), and lamellar (MCM-50), of which the microscopy and diffraction data are reminiscent of surfactant/water binary systems. Beck et al. initially proposed a liquid crystal template (LCT) mechanism [37]. This mechanistic model served to illustrate the concept of aggregate molecular templating, but was quickly modified to include the role of the silicate anionic species. This model is better described as a process of cooperative assembly, as a result of favourable electrostatic interactions at the inorganic–organic interface [37,40–43].

Another approach, developed by Kuroda and co-workers, takes advantage of the ability of long chain alkyltrimethylammonium cations to intercalate into the single layered polysilicate, kanemite. This was an extension of the intercalation chemistry originally reported by Beneke and Lagaly [44]. Kuroda and co-workers initially reported that the formation of the silicate-surfactant complex [45,46], followed by removal of the surfactant, led to the formation of a hexagonal mesoporous silicate [47,48]. These materials can be tailor made with single size distribution channels in the range 20–40 Å. The mesoporous silicate material denoted FSM-16 is produced by intercalation of hexadecyltrimethylammonium cationic surfactants, and the formation process is representative of the transformation of two-dimensional layers to a three-dimensional framework [49].

We have recorded time-resolved in situ EDXRD spectra following the addition of an aqueous solution of heaxdecyltrimethylammonium chloride ($C_{16}H_{33}N^{+}Me_3Cl^{-}$ = C_{16}TMACl) to kanemite ($NaHSi_2O_5\cdot 3H_2O$) at 70°C over a period of 3 h. The spectra are shown accumulated as a three-

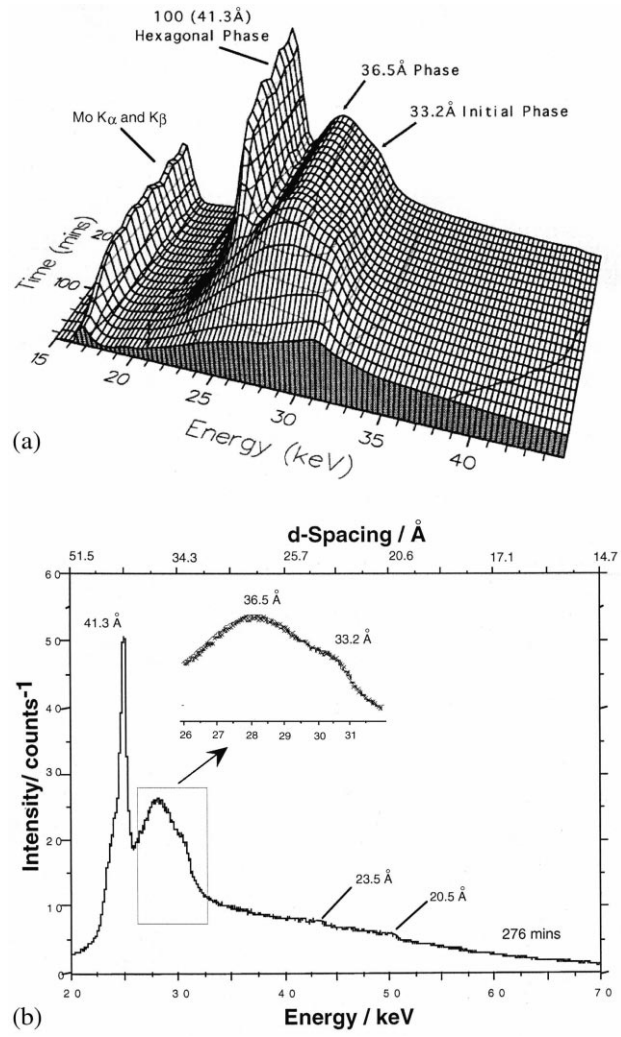

Fig. 12. (a) Three-dimensional stacked plot showing the energy dispersive powder X-ray diffraction spectra recorded following addition of 0.1 M hexadecyl-trimethylammonium chloride ($C_{16}TMA^{+}Cl^{-}$) to kanemite in water at 70°C. (b) The final in situ EDXRD spectrum taken after reaction completion, showing all observable diffraction features.

dimensional stacked plot in Fig. 12(a), along with the final spectrum recorded after 276 min (Fig. 12(b)) which clearly indicate the diffraction peaks present.

The stacked and single spectra can be described as a series of broad Bragg reflections viewed in energy space, that arise due to the growth of 'crystalline' silica-surfactant mesophases from the medium. A stirred suspension of kanemite at this pH and temperature showed only a broad featureless background, thus overwhelming X-ray scattering due to the silicate particles can be ruled out. We expect the coherent X-ray scattering at these low angles (high *d*-spacing) to produce broad Bragg reflections due to the convolution of the small ordered domain size of the silica-surfactant mesophases and the resolution function of the diffractometer setup.

Following the addition of the 0.1 M solution of C_{16}TMACl, a Bragg reflection grows in at a *d*-spacing of ca. 32 Å within 10 min. The *d*-spacing of this reflection increases gradually throughout the course of the reaction, reaching a constant value of 33.2 Å after 30 min. Subsequently, a second even broader Bragg reflection grows in with a *d*-spacing of ca. 36 Å, reaching a maximum after approximately 100 min. Once this Bragg reflection has reached its maximum intensity, we observe the growth of a series of reflections at *d*-spacings of 41.3, 23.5 and 20.5 Å. These reflections can be indexed as the (100), (110) and (200) Bragg reflections corresponding to a hexagonal symmetry mesophase ($a = 47.7$ Å, $2d_{100}/\sqrt{3}$). After pH adjustment with HCl to 8.5 to promote silanol condensation, filtration and calcination, FSM-16 is formed. The in situ diffraction data shown in Fig. 12(a) clearly show that the hexagonal (41 Å) silica-mesophase forms before dissolution of all the crystalline silicates.

It is highly likely that the intermediate phase with *d*-spacing of 33.2 Å has a layered, two-dimensional structure. A series of 00*l* reflections with *c*-lattice constant of 30.5 Å was observed in the laboratory X-ray powder diffraction pattern together with the Bragg reflections of the hexagonal phase from the untreated filtrate isolated after the reaction. It is reasonable to assume that the (00*l*) reflections belong to the lamellar phase observed by in situ EDXRD, and the increased *d*-spacing of the (001) reflection is due to swelling in the reaction medium. This has been observed in the intercalation chemistry of kanemite [50]. An interlayer separation of ca. 30 Å is consistent with intercalated $C_{16}TMA^+$ ions with an estimated length of ca. 23 Å and a silicate layer of approximately 6 Å thick. Lamellar phases appear to be common to all kanemite-surfactant reactions regardless of chain length. Recovery of this lamellar phase from the reaction mixture is possible by filtering the product before the reaction is complete and prior to addition of 1.0 M HCl. However, calcination of this sample led to a condensed amorphous phase, and collapse of any porous structure.

Given the current interest in template assisted crystallisation, these experiments clearly demonstrate the power of time-resolved, in situ diffraction measurements to monitor and help unravel the complex interactions of surfactant molecules with inorganic lattices. In this example, we have not only determined the kinetics of these reactions but also observed novel transient metastable phases that would probably have gone undetected using conventional laboratory procedures.

3. Conclusions

A range of environmental cells are now available to study the kinetics of intercalation into microcrystalline samples using time-resolved X-ray powder diffraction. The use of energy dispersive powder diffraction techniques enables reactions with half-lives of minutes to days to be examined. The design of the experiment allows a wide variety of solid–liquid reactions besides intercalation reactions to be studied with minimal turn-around time and experiments are currently underway to extend these opportunities to other classes of reactions.

Acknowledgements

We would like to thank the Leverhulme Trust, British Council, and the CIBA foundation for financial support and EPSRC for access to the Synchrotron Radiation Source, Daresbury Laboratory. We also thank Dr S.M. Clarke, Daresbury Laboratory and the technical staff at the SRS for helping in the design and construction of the experimental cell.

POLYHEDRON

Influence of the nature of the catalyst on the textural properties of organosilsesquioxane materials

Geneviève Cerveau, Robert J.P. Corriu *, Eric Framery

Laboratoire de Chimie Moléculaire et Organisation du Solide, UMR 5637, Université Montpellier II, cc 007, Place E. Bataillon, 34095 Montpellier Cedex 5, France

Received 27 April 1999; accepted 20 July 1999

Abstract

The hydrolytic sol–gel polymerization of molecular organosilicon precursors with a 'rigid' geometry 1,4-$C_6H_4[Si(OMe)_3]_2$ (**1**) and a 'flexible' geometry 1,4-$C_6H_4[CH_2CH_2Si(OMe)_3]_2$ (**2**) was investigated varying the nature of the catalyst. They were hydrolyzed under nucleophilic catalysis using non-ionic species such as dimethylformamide (DMF), dimethylaminopyridine (DMAP), *N*-methylimidazole (NMI) and hexamethylphosphorotriamide (HMPT) in THF. The effect of the concentrations of both the precursor and the catalyst was studied. Molecular precursor **1** led always to hydrophobic solids with degrees of condensation lying in the range 55–67%. These solids were mainly microporous exhibiting high specific surface areas. The densities lay in the range 1.37–1.42 g cm^{-3}. By contrast, the precursor **2** led to hydrophobic solids with no significant specific surface area. Degrees of condensation ranged between 59 and 74% and the densities between 1.27 and 1.31 g cm^{-3}. The nature of the catalyst (ionic or non-ionic) involved in the hydrolytic sol–gel polymerization of molecular organosilicon precursors appeared to be of great influence on the textural properties of the resulting solids. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Monophasic hybrid materials; Silsesquioxane gels; Kinetic control; Sol–gel polymerization

1. Introduction

The elaboration of monophasic organic inorganic materials by sol–gel type processes allows the introduction of a wide variety of organic [1–6] or organometallic [7–10] moieties into silica matrices. In such materials both organic and inorganic units are bound through at least two stable Si–C bonds. We have shown that the nature of the organic group has a fundamental influence on the properties of the hybrid solids [11]. Whether the organic group is 'rigid' or 'flexible' drastically influences the arrangement of organic units in the solid: a short-range order has been demonstrated chemically, showing that these monophasic hybrid materials can be nanostructured [2]. Moreover, we have pointed out the importance of all the kinetic parameters involved in the hydrolysis polycondensation reactions: the nature of the catalyst, concentration of the reagents, nature of the hydrolysable group, solvent, etc. [11]. All these parameters have great influence on the textural properties of the resulting xerogels. Although the difficulties encountered in reproducing experiments in sol–gel chemistry have not always been reported by the authors, it is important to point out that the reproducibility depends strongly on a precise control of the kinetic parameters of the hydrolytic polycondensation process. Experiments must be performed very precisely under the same experimental conditions, as is the norm for physico–chemical experiments: very dry solvents, precise control of concentrations, purity of the catalyst, etc. From these observations, we have proposed that the sol–gel type polymerization corresponds to a kinetically controlled process. The macroscopic data which permit the texture of the solid to be described are highly dependent on all of the parameters which control the kinetics of the hydrolytic polycondensation reaction.

In order to support further the argument for kinetic control, we have considered the effect of unusual nucleophilic catalysts. We report here the effect of non-ionic species such as dimethylformamide (DMF), dimethylaminopyridine (DMAP), *N*-methylimidazole (NMI) and hexamethylphosphorotriamide (HMPT). In organosilicon chemistry, these catalysts are known for inducing chemical reactions at silicon by nucleophilic activation [12–14]. However, they are less efficient than F^- and they are not used in sol–gel chemistry. The only exception is the hydrolysis of $Si(OMe)_4$ [15] with the longer gelation times observed in a few experiments.

Since the reactivity of these catalysts is drastically different from the reactivity observed with classical catalysts (acid, bases and F^-), we have studied here the influence of these catalysts on the textural properties of xerogels obtained from two previously explored precursors with respectively a 'rigid' and a 'flexible' geometry [11,16].

2. Experimental

Syntheses of precursors and preparation of the gels were carried out under argon using a vacuum line and Schlenk tube techniques [17]. Solvents and catalysts were dried and distilled before use. Compound 1,4-$C_6H_4[Si(OMe)_3]_2$ (**1**) was prepared according to literature procedures [18], while 1,4-$C_6H_4[CH_2CH_2Si(OMe)_3]_2$ (**2**) was commercial and was purified before use.

Solid state NMR spectra were obtained with a Bruker FTAM 300 spectrometer: ^{13}C CP MAS NMR at 75.47 MHz, recycling delay 5 s and contact time 5 ms; ^{29}Si CP MAS NMR at 59.62 MHz, recycling delay 10 s and contact time 2 ms. The spinning rate was 5000 Hz in all cases. Chemical shifts are given relative to tetramethylsilane.

Specific surface areas, pore volumes and pore size distribution were determined using a Micromeritics Gemini III 2375 apparatus. The density of the materials was determined by a pycnometry measurement with helium using a Micromeritics Accupyc 1330 apparatus.

Elemental analyses were carried out by the Service de Micro-Analyse du CNRS. Oxygen percentages were deduced by difference.

Affinity of xerogels for water ($E_{0.6}$) was determinated by measurement of weight increase of the solid in a 60% humidity atmosphere at 25°C. This atmosphere was obtained with a saturated NaBr solution under vacuum.

Preparation of silsesquioxane gels: The preparation of the gels was carried out according to the following general procedure. The preparation of xerogel **1A1** is given as an example. To 2.86 g (9 mmol) of **1** in 9 ml of THF was added a solution of 6.4 μl (6.57 mg, 90 μmol) of DMF and 486 μl (486 mg, 27 mmol) of water in 8.50 ml of THF. The mixture was warmed to 30°C and after 7 days a monolithic gel had formed. After further ageing for 6 days at 30°C, the solid was collected, then ground and washed twice with ethanol, acetone and diethyl ether. The resulting solid was dried at 120°C in vacuo for 3 h yielding 1.70 g of a white powder **1A1**. The gel time was dependent on concentration of the precursor and on the catalyst (DMF, DMAP, NMI or HMPT), and its concentration. It varied between 1 h and several days. The experimental conditions and the elemental analyses of the xerogels obtained from **1** and **2** are reported in Tables 1 and 2.

3. Results

The molecular precursors **1** and **2** (Scheme 1) containing phenylene units with two different geometries were investigated. The sol–gel polymerization of **1** and **2** was performed in THF at 30°C. Four nucleophilic and non-ionic catalysts were used: DMF, DMAP, NMI and HMPT (Scheme 2). Two concentrations of precursor (0.5 mol l^{-1} and 1.0 mol l^{-1}) were investigated, and in each case the amount of catalyst was 1 mol% and 5 mol%. All of the xerogels obtained were identified by CP MAS NMR spectroscopy and elemental analysis. The texture of the solids was studied by measuring specific surface area, porosity and density.

[a] Ideal formula $C_{10}H_{12}O_3Si_2$.

Scheme 1. Molecular precursors.

Scheme 2. Sol–gel process.

*3.1. Sol–gel processing of **1***

The hydrolysis polycondensation of precursor **1** was performed according to the reaction described in Scheme 2. A stoichiometric amount of water was used. In all cases monolithic translucent gels formed within periods of time varying from several hours to several days. The gels were aged for 6 days at 30°C and were then ground and washed with ethanol, acetone and diethyl ether. The resulting powders were dried in vacuo at 120°C for 3 h.

*3.2. Spectroscopic and textural data for xerogels obtained from **1***

NMR data: The ^{13}C and ^{29}Si CP MAS NMR characteristics of the xerogels were determined. In all cases the ^{13}C CPMAS NMR spectra showed the presence of the organic fragment. They displayed two resonances at δ 133.6 ppm (aromatic carbons) and δ 50.7 ppm (residual methoxy groups). The organic fragments were not modified in the solids and the Si–C bonds were not cleaved during the hydrolysis polycondensation process. This was confirmed by the ^{29}Si CP MAS NMR analysis which revealed the absence of signal in the range -90 to -110 ppm corresponding to $SiO_{4/2}$ substructures [19,20]. The ^{29}Si CP MAS NMR spectra exhibited signals indicating that the condensation was incomplete in all cases. Resonances assigned to substructures T^0 (C–Si(OR)$_3$, δ -54.4 ppm), T^1 (C–Si(OR)$_2$(OSi), δ -62.0 ppm), T^2 (C–Si(OR)(OSi)$_2$, δ -69.5 ppm) and T^3 (C–Si(OSi)$_3$, δ -78.0 ppm) were observed in most of the cases. Interestingly, no T^0 substructures were detected when the concentrations of the precursor and the catalyst were 1 mol l^{-1} and 5 mol%, respectively. CP MAS spectroscopy is not quantitative. However, it has been shown [11,21] that single pulse experiments do not reveal any significant variation in relative peak intensity from the CP MAS spectra when there are no hydrogen atoms in the direct vicinity of the studied nucleus. Thus the percentages of the different T^x units, obtained by deconvolution of the spectra have been determined and are reported in Table 3. The degrees of condensation for all of the xerogels obtained from **1** lay in the range 55–67% whatever the catalyst and the concentrations of both the catalyst and the precursor (Table 3). The elemental analyses reported in Table 1 showed that the hybrid gels deviated from the ideal stoichiometry based on totally polycondensed silsesquioxane materials and were in agreement with the degrees of condensation deduced from NMR data. The hybrid network can be described approximately as siloxane chains with bridging units and with average of one uncondensed OH or OMe group per silicon atom.

Hydrophilic character: All the solids obtained from **1** exhibited a moderate to high affinity for water. Weight

[a] Obtained by deconvolution of spectra.

increases in a 60% humidity atmosphere at 25°C ($E_{0.6}$) are reported in Table 4. These values are consistent with the presence of few organic and many hydroxyl groups at the surface.

Texture of the solids: The specific surface areas of the xerogels were determined (Table 4). 35-point adsorption/desorption isotherm plots were used [22]. The specific surface areas were evaluated using the BET equation [23]. Values were very high whatever the catalyst and the concentrations, with the exception of **1C1** and **1D1** which exhibited no significant specific surface areas. The adsorption/desorption isotherms of **1B5M** and **1C5M** are shown in Fig. 1. The shape of the curves was characteristic of microporous solids with different mesoporous contributions [24]. The determination of the porous volume by the BJH method [25] and the evaluation of the microporous volume by analysis of the *t*-plot diagram were performed in each case. The percentages of micropores in the different gels are reported in Table 4. They lay in the range 50–74% depending on the catalyst and the concentrations.

Helium picnometry: The density of the materials was determined by a picnometry measurement with helium. The values of the density are reported in Table 4. They were between 1.37 and 1.42 g cm^{-3}.

3.3. Sol–gel processing of *2*

The organic precursor **2** was hydrolyzed under the same conditions as **1**. Monolithic translucent gels formed in all cases within periods of time varying from several hours to several days. The same processing was used, and xerogels were isolated as white powders.

Table 4
Textural characteristics of hybrid materials obtained from **1**

Xerogel	$E_{0.6}$ (%)	BET (m^2 g^{-1})	μ_{pores} (%)	Density (g cm^{-3})
1A1	19	530	74	1.39
1B1	20	670	63	1.40
1C1	8	<10		1.39

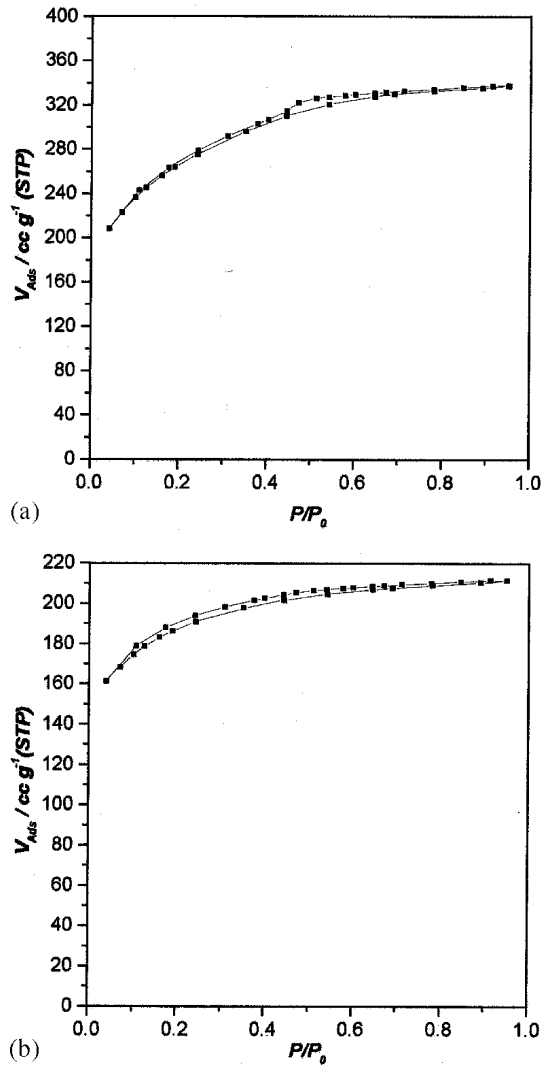

Fig. 1. N_2 adsorption–desorption isotherms of xerogels **1B5M** (a) and **1C5M** (b).

3.4. Spectroscopic and textural data of xerogels obtained from **2**

NMR data: The solid state NMR spectra of xerogels obtained from **2** clearly showed that the Si–C bond was not cleaved during the sol–gel condensation. ^{13}C CP MAS NMR spectra exhibited resonances at δ 143.6 and 127.6 ppm due to aromatic carbons, two at δ 29.1 and 14.8 ppm attributed to CH_2 carbons and one at δ 50.1 ppm corresponding to residual methoxy groups in all cases. When the catalyst was DMAP and NMI, the ^{29}Si CP MAS NMR spectra of xerogels displayed the four resonances assigned to T^0 (δ −42.5 ppm), T^1 (δ −49.6 ppm), T^2 (δ −58.2 ppm), and T^3 (δ −67.5 ppm) substructures whatever the concentrations of catalyst and precursor. Interestingly, when DMF and HMPT were employed, T^0 substructures were not observed. However, the degrees of condensation were evaluated and found to be in the same range (59–74%) whatever the catalyst (Table 5). The hybrid network can be described as siloxane chains with bridging units and with an average of one OR (R = H or Me) group per silicon atom.

Hydrophilic character: The affinity for water of all the xerogels obtained from **2** was very low (Table 6).

Texture of the solids: The nitrogen BET measurements gave no significant specific surface area in any of the samples ($< 10\ m^2\ g^{-1}$).

Helium picnometry: The densities of the gels obtained from **2** are reported in Table 6. The values ranged between 1.27 and 1.31 g cm^{-3}.

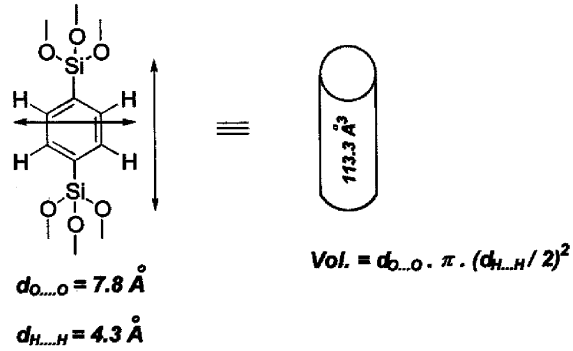
4. Discussion



The results presented here show that the nature of the nucleophilic reagent used as catalyst during the hydrolysis polycondensation process has an influence on the textural properties of the resulting silsesquioxane materials. However, the essential parameter is the nature of organic group: 'rigid' or 'flexible' as previously established [11].

The molecular precursor **1** containing a 'rigid' organic group led to solids with similar levels of condensation lying in the range 55–68% whatever the concentrations of the precursor and the catalyst. These values are comparable to those already observed with ionic catalysts (nucleophile, acid or base) in MeOH and in THF. However, the range observed was narrower (63–67%) [16]. In most of the cases, the xerogels obtained from **1** were porous, exhibiting high specific surface areas and absence of narrow pore size distribution. The solids were mainly microporous, the microporous volume being 50–74% of the total porous volume (Table 4), depending on the catalyst and the concentrations. The same xerogels prepared under ionic nucleophile, basic, or acid catalysis exhibited similar microporous volume (50–60%) when the solvent was MeOH, whereas in THF the microporosity was higher (75–82%) [16]. The xerogels obtained from **1** described here exhibited, in almost all cases, an affinity for water lower than the hydrophilicity obtained with a ionic catalyst [16]. The values lay below 20% (8–20%) with the exceptions of **1B1M** and **1B5M** which were 27 and 24%, respectively. In the case of ionic catalysts, the hydrophilicity was always found to be above 20% (20–31%) [11,16]. The densities of the solids obtained from the 'rigid' precursor **1** lay in the range 1.37–1.42 g cm^{-3}. They appeared slightly lower than in the case of ionic catalysts in THF (range 1.39–1.46 g cm^{-3}) [26]. This difference could be attributed to a different distribution of the residual hydroxy or alkoxy groups within the hybrid network although the degrees of condensation were similar (55–68% for non-ionic catalysts and 63–67% for ionic catalysts). In fact the ^{29}Si CP MAS NMR spectra showed resonances corresponding to mainly T^1, T^2 and T^3 substructures. In some cases T^0 units were also

observed. The percentages estimated for the T^1, T^2 and T^3 units were similar in most cases (Table 3). On the other hand, when the hydrolysis was performed in THF with an ionic catalyst, the main substructures were T^2 and T^3 with the major unit T^2 ($\sim$64%) [11]. In this case most of the silicon atoms are C–Si(OR)$(OSi)_2$ whereas with non-ionic catalysts more C–Si$(OR)_2$(OSi) units are present, corresponding to a less dense solid.

When the molecular precursor contained a 'flexible' organic group **2**, the solids obtained had similar levels of condensation lying in the range 59–74% whatever the catalyst (Table 5). These solids appeared less polycondensed when compared to the corresponding solids reported previously [11] and obtained with ionic catalysis in THF (range 73–87%). In all cases the solids obtained from **2** were hydrophobic and had no significant specific surface area. The densities of the xerogels obtained from the 'flexible' precursor **2** lay between 1.27 and 1.31 g cm^{-3} (Table 6). They were lower than those obtained with an ionic catalyst in THF (range 1.32–1.37 g cm^{-3}) [26]. In this case the lower densities observed could be explained by the difference observed for the degrees of condensation: the more the xerogel is polycondensed, the higher is the density. In agreement with ionic catalysts in THF, only T^2 (38%) and T^3 (62%) substructures are observed [11,16] whereas with non-ionic catalysts T^1, T^2 and T^3 (in some cases T^0) substructures are detected (Table 5).

The xerogels obtained from **1** appeared more dense ($d_{av} = 1.39$ g cm^{-3}) than those obtained from **2** ($d_{av} = 1.28$ g cm^{-3}). Furthermore, the volume occupied by the organic group is larger in the solids obtained from **2** than in those obtained from **1**. In the same space, the number of units is lower in the case of **2** and consequently so is the density of the hybrid solid. Using the experimental values of densities, an estimate of the average volume occupied by each organic precursor can be made. The average volume occupied by one moiety is equal to the ratio $(dN/M_W)^{-1}$, where d is the density of the hybrid xerogel, N is Avogadro's number and M_W the molecular weight for $O_{1.5}Si–R–SiO_{1.5}$ [27]. The value obtained for **1** is $V_{exp}^{\mathbf{1}} = 2.15 \times 10^{-22}$ cm^3 and for **2**, $V_{exp}^{\mathbf{2}} = 3.07 \times 10^{-22}$ cm^3. These values can be compared to the volume occupied by the organic moiety calculated by molecular simulation. It was calculated assuming that the unit occupies a space with a cylindrical shape (Scheme 3). The calculated volumes are $V_{calc}^{\mathbf{1}} = 1.13 \times 10^{-22}$ cm^3 and $V_{calc}^{\mathbf{2}} = 1.76 \times 10^{-22}$ cm^3. The experimental volume appeared greater than the calculated volume in both cases. This result indicates that the organic units are not closely packed in the hybrid solid since the rigid spacer occupied 1.9 times the theoretical volume in the hybrid network and 1.75 times for the flexible one. This result may be expected since, in the xerogels obtained from **2**, the organic group is more flexible rendering the solid less compressed and consequently the hybrid network is less organized than with a rigid spacer [28]. Another possibility to explain the difference between calculated and observed volumes could be to take into account the presence of T^0 and T^1 units which might occupy more space than T^2 and T^3 units. It would be of interest to find a possible relationship between the degrees of condensation and the densities. In the case of **1** and **2**, quantitative reliable ^{29}Si SPE MAS NMR spectra have been collected and compared to the ^{29}Si CP MAS NMR spectra [11]. The SPE MAS and CP MAS percentages found for the different T^x units were comparable in both cases. Although the degrees of condensation lay between 55 and 68% in the case of **1** and 59 and 71% for **2**, the densities did not change: 1.38–1.40 g cm^{-3} and 1.27–1.30 g cm^{-3}, respectively. This allows us to eliminate this hypothesis and to consider that the differences between the densities originate from the different organization of organic units within the solid. Moreover, we have shown by chemical methods that the solids obtained from the 'rigid' precursor had a short-range order whereas those obtained from the 'flexible' precursor can be described as solids consisting of cross-linked chains.

Scheme 3. Theoretical calculation of the volume of xerogels obtained from precursor **1**.

5. Conclusions

The results presented here illustrate the close connection between the textural properties of hybrid solids obtained by the sol–gel route and the nature of the catalyst used in the hydrolytic polycondensation. The solids obtained by the sol–gel process are better described as kinetically controlled solids rather than thermodynamically unstable materials [29]. Changing the nature of the nucleophilic catalyst did not modify drastically the main features already established and the determining parameter for the texture of the xerogels is the structure of the organic precursor, 'rigid' or 'flexible'. However, some important differences appeared particularly in the textural properties of the hybrid xerogels when non-ionic catalysts are used. Molecular precursor **1** containing a 'rigid' organic group led to non-porous solids when the catalyst is NMI or HMPT (xerogels **1C1** and **1D1**). These are the only cases where no significant specific surface area has been obtained with this precursor. With non-ionic catalysts both hydrophilicity and densities of the solids were lower than with ionic catalysts. Similar degrees of condensation were obtained. However, T^0 substructures were observed with non-

ionic catalysts. By contrast, when the organic precursor contained a more 'flexible' organic group, the texture, the degree of condensation and the density of the resulting solids were strongly dependent on the nature of the catalyst. In the case of the non-ionic nucleophilic catalysts, the lower densities might correspond to a different arrangement of the organic units within the hybrid network.

The results reported here strengthen the importance of the kinetic control of the solid formation and open new possibilities for controlling the texture of the solids.

POLYHEDRON

Nuclear magnetic resonance techniques for the structural characterization of siloxane–oxide hybrid materials

Florence Babonneau *, Jocelyne Maquet

Chimie de la Matière Condensée, Université Pierre et Marie Curie/CNRS, 4 Place Jussieu, 75252 Paris cedex 05, France

Received 2 August 1999; accepted 9 October 1999

Abstract

The objective of this paper is to discuss the appropriateness of various solution and solid state NMR techniques to describe structural aspects of siloxane–oxide hybrid systems prepared by sol-gel processes. Co-hydrolysis of organosilanes and metallic alkoxides can promote either self-condensation or co-condensation reactions between the different precursors, and this will control the structural homogeneity of the final network. Solution state ^{29}Si and ^{17}O NMR can give unique information on the formation and stability of co-condensing species. In the final gels, solid state ^{29}Si MAS used in conjunction with cross-polarization (CP) and related two-dimensional ^{29}Si–^{1}H heteronuclear NMR correlation techniques, provides detailed information on dipole–dipole coupled ^{29}Si and ^{1}H species among different molecular moieties. Finally, the use of ^{17}O MAS NMR with the newly developed MQ MAS sequence that provides a direct identification of the various oxo bridges will be discussed. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Sol-gel; NMR; Hybrid materials; Siloxane; Silicon-29; Oxygen-17

1. Introduction

Sol-gel processing of siloxane–oxide hybrid materials [1] is an area of rapid growth due to the wide variety of potential applications of these systems [2]. The flexibility of this synthetic approach — a large variety of precursors and low synthesis temperatures — offers the potential molecular engineering of composition and properties of a diverse range of solid product materials. The intimate mixing of molecular precursors in organic solvents allows organic and inorganic components to be associated at the molecular level, in order to form real organic–inorganic nanocomposites.

These systems are typically prepared from hydrolysis and condensation reactions of molecular precursors, such as organically modified alkoxysilanes $R_xSi(OR')_{4-x}$ ($x=1,2$), and metal alkoxides, $M(OR'')_4$ (M = Si, Ti or Zr) whose reactivities may be different. Both self-condensation (Eq. (1)) and co-condensation (Eq. (2)) reactions can occur, and this will influence the nature of the condensed species formed in solution.

Self-condensation:

$$\equiv Si–OH + RO–M\equiv \rightarrow \equiv Si–O–M\equiv \quad (R=Et, H) \qquad (1)$$

Co-condensation:

$$\equiv Si–OH + RO–Si\equiv \rightarrow \equiv Si–O–Si\equiv \qquad (2)$$

$$\equiv M–OH + RO–M\equiv \rightarrow \equiv M–O–M\equiv$$

A complex series of chemical reactions can occur at each stage of the synthesis procedure, not only in solution (hydrolysis and condensation), but also during aging before gelation, and then during drying. They will thus strongly influence the process of network formation, and the structural properties of the final materials. NMR plays an important role in the characterization of these systems, since local environments of several nuclei can be probed in solution as well as in solid samples.

The objective of this paper is to review the various solution and solid state NMR techniques that have been, or can be, used in this field, and to discuss the type of information they provide, as well as their limitations.

2. Solution NMR techniques

The steps that initiate the formation of the siloxane–oxide hybrid network can be followed by solution NMR techniques. A primary objective is often to characterize the various oxo-bridges formed through either self-condensation (Si–O–Si

* Corresponding author.

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(99)00361-7

and M–O–M) or co-condensation (Si–O–M) reactions between the organically modified alkoxysilane and the metal alkoxide.

Both ^{29}Si and ^{17}O NMR lend themselves well to such investigations and potentially species M also, if it possesses a NMR active isotope.

^{29}Si is a spin 1/2 species that has a natural abundance of 4.7%; it is 2.1 times more sensitive than ^{13}C, but is usually characterized by long spin relaxation T_1 times [3]. Single-pulse experiments may be quite long, typically 15–30 min for concentrated systems ($c(\mathrm{Si}) \geq 1$ M) such as those used in classical sol-gel preparations, which limits reactions that can be examined.

^{17}O is a spin 5/2 nucleus with a very low natural abundance (0.037%) and low sensitivity compared to ^{13}C (6×10^{-2}), but usually very short T_1 values due to an efficient quadrupolar relaxation mechanism [4]. ^{17}O NMR spectra of concentrated sol-gel systems can be recorded using samples containing ^{17}O in natural abundance, but with typically long measurement times [5]. Moreover, ^{17}O NMR spectra are often dominated by a strong solvent signal (usually from an alcohol), which accounts at least partly for why this technique has not been used extensively until recently, when ^{17}O enriched water has been used as a reactant [6,7]. In addition to the large gain in sensitivity obtained even for relatively low ^{17}O enrichments (10 at.%), selectivity is also enhanced by ^{17}O incorporation preferentially at certain sites, for example in hydroxyl groups (M–*O*H) and oxo bridges (M–*O*–M). This leads to an increase in their detectability compared to the un-enriched R*O*H and M–*O*R groups. As applied specifically to the characterization of siloxane–oxide systems, solution state ^{29}Si and ^{17}O NMR present separate advantages and limitations, mainly depending on the nature of the oxide component.

2.1. Siloxane–silica systems

Siloxane–silica composites are usually prepared from co-hydrolysis in acidic medium of a difunctional $R_2Si(OR')_2$ or trifunctional $RSi(OR')_3$ organosilane and a tetraalkoxysilane, such as tetraethoxysilane (TEOS), $Si(OEt)_4$. The extent of condensation of the network versus time (which represents the number of alkoxy groups which transform in oxo bridges) depends strongly on the nature of the organosilanes as illustrated in Fig. 1. Electronic inductive effects of the organic substituent are responsible for the higher reactivity of organosilanes compared to TEOS under acidic conditions and have already been reported [8,9]. The extremely fast reactions of triethoxysilane (TREOS, $HSi(OEt)_3$) and methyldiethoxysilane (MDES, $MeHSi(OEt)_2$) may be due to additional steric effects: the presence of the very small H-substituent can favor the nucleophilic attack of the water molecule at the Si center [10].

Due to these large differences in reactivities, one might wonder whether co-hydrolysis of two organosilanes, $R_xSi_A(OR')_{4-x}$ and $R_ySi_B(OR')_{4-y}$ would lead to a homogeneous distribution of the Si units. The type of oxo-bridges that should be distinguished and quantified is Si_A–*O*–Si_B. The ^{29}Si NMR experiment seems suitable in this case, since all the metallic sites can be detected, and over a rather large chemical shift range, which renders the technique sensitive to nearest neighbors, next nearest neighbors and cyclic species.

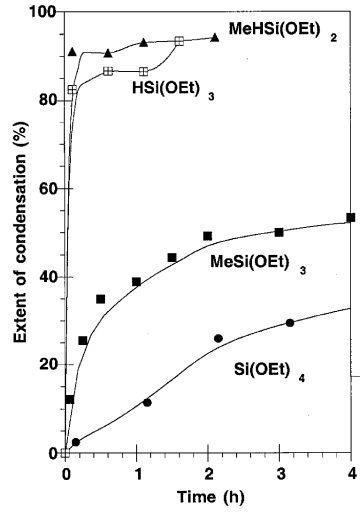

Fig. 1. Extent of condensation of a selected number of organosilanes: $Si(OEt)_4$, $MeSi(OEt)_3$, $HSi(OEt)_3$ and $MeHSi(OEt)_2$ extracted from ^{29}Si in situ solution state NMR. The composition of the starting solutions was: EtOH/Si = 2; H_2O/OEt = 1; pH 2 (HCl).

Several systems have been investigated, mainly using low hydrolysis ratios ($h = H_2O/Si < 0.5$), to prevent extensive condensation, and co-condensed species have been identified in DMDES/TEOS ($Me_2Si(OEt)_2/Si(OEt)_4$) [11], RTES/TEOS ($RSi(OEt)_3/Si(OEt)_4$, R = Me, Et, *n*-Oct, Ph) [12,13], and MDES/TREOS ($MeHSi(OEt)_2/HSi(OEt)_3$) [14] systems. Fig. 2 illustrates the results obtained with a co-hydrolyzed solution of MTES (T units) and TEOS (Q units) in a 1:1 molar ratio. Besides the peaks assigned to monomers (T_0 and Q_0 units) which are not represented in the figure, peaks due to T_1 units are seen at -50.50 and -50.65 ppm

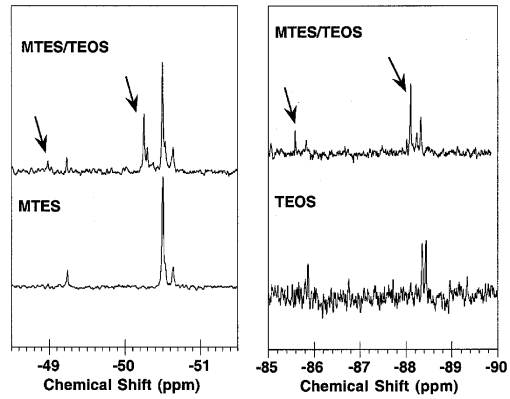

Fig. 2. ^{29}Si solution state NMR spectra of three hydrolyzed solutions of MTES, TEOS and MTES/TEOS in a 1:1 molar ratio (EtOH/Si = 4; H_2O/OEt = 0.1; pH 2 (HCl); aging time 2 days). Arrows indicate signals due to co-condensed species.

(Me*Si*(OEt)$_2$–O–) and at −49.25 ppm (Me*Si*(OEt)(OH)–O–), and due to Q_1 units at −88.35 and −88.44 ppm (*Si*(OEt)$_3$–O–) and at −85.87 ppm (*Si*(OEt)$_2$(OH)–O–). In the co-hydrolyzed system, additional peaks are present due to T–Q species, at −50.25 and −50.29 ppm (Me*Si*(OEt)$_2$–O–), −48.98 ppm (Me*Si*(OEt)(OH)–O, −88.11 and −88.20 ppm (*Si*(OEt)$_3$–O–) and −85.60 ppm (*Si*(OEt)$_2$(OH)–O–). Formation of co-condensed species is accompanied by a lowfield shift, but this never exceeds a few tenths of ppm. These small differences require high spectral resolution in order to identify the various condensed species.

For higher hydrolysis ratios ($h \geq 1$) as reactions proceed, the increasing number of species which are produced leads to a significant number of signals, together with a line broadening [15,16]. Assignments related to the first (*C* or *O* atoms) and second (–*O*R or –*O*–Si groups) nearest neighbors can be safely done, and lead to an estimation of the extent of condensation reactions for the various precursors (Fig. 1). However, definitive conclusions regarding the presence of co-condensed species require sensitivity to the third nearest neighbors, which is difficult to achieve with extensive signal overlap. Unambiguous identification of different Si environments has however been performed recently by using polarization transfer techniques, DEPT [17] and INEPT [18], adapted for systems with multiple heteronuclear coupling constants. More powerful would be two-dimensional ^{29}Si–^{29}Si correlation NMR techniques [19,20], which could describe directly the connectivity existing between different Si sites. But these experiments are very time consuming, mainly due to the low natural abundance of ^{29}Si nuclei, and thus somewhat inappropriate for systems in constant evolution.

Unlike ^{29}Si, the ^{17}O chemical shift range, for such siloxane–silica systems, is short since only Si–*O*–Si bridges are formed. This may prevent clear differentiation between the various oxo bridges. Evidence for co-condensation reactions was unambiguous in the DMDES/TEOS [7,15,21], and MTES/TEOS [7,12,15] systems, but totally obscure in the MDES/TREOS [22] system due to extensive signal overlap, even for low hydrolysis ratio ($H_2O/OEt = 0.1$). Fig. 3 shows the results obtained for a co-hydrolyzed solution of MDES (D^H units) and TEOS. Despite their large difference of reactivities (Fig. 1), a peak due to the formation of oxo bridges between D^H and Q units is shown [10]. Interestingly, no peak due to (Q)–O–(Q) species is present, showing that MDES reacts faster than TEOS, favoring the exclusive formation of (D^H)–O–(D^H) and (D^H)–O–(Q) species. One can notice that the ^{17}O NMR signals are broad, due to the short relaxation times of the quadrupolar ^{17}O nuclei. Variable-temperature experiments have been tried for increasing resolution, but only a modest improvement was obtained on the MTES/TEOS system [12].

In more complex systems with a bulky R group and higher hydrolysis ratio [16], spectral assignment turns out to be very difficult, and conclusions somewhat disappointing. However, co-hydrolysis reactions of MTES/TEOS and DMDES/TEOS have been followed in situ [15], and revealed the formation of co-condensed (D)–O–(Q) and (T)–O–(Q) species, stable with aging time. But in the case of highly reactive organosilanes such as MDES and TREOS, loss of signals can be observed due to the formation of highly condensed species, characterized by long correlation times, τ_c, which shorten even more the relaxation times.

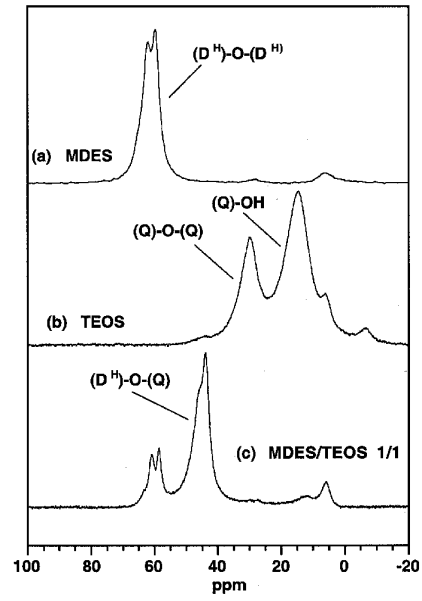

Fig. 3. ^{17}O solution state NMR spectra of three hydrolyzed solutions of (a) MDES, (b) TEOS and (c) MDES/TEOS in a 1:1 molar ratio (EtOH/Si = 4; $H_2O/OEt = 0.1$; pH 2 (HCl); aging time 2 days).

2.2. Siloxane–titania or siloxane–zirconia systems

In this case, the oxo-bridges formed through co-condensation reactions are Si–O–M (M = Ti, Zr). ^{29}Si NMR experiments will only detect the Si sites, and distinction between Si–O–Si and Si–O–M bridges can be subtle. Reaction of titanium isopropoxide [23] or zirconium *n*-propoxide [24] with a pre-hydrolyzed solution of DMDES causes the appearance of new signals in the ^{29}Si NMR spectrum, tentatively but not definitively assigned to the formation of Si–O–M bonds, because of a lack of chemical shift references. Recently, NMR investigations have been performed on several crystalline cyclic titanodiphenylsiloxanes, providing some chemical shift values for Si centers with Si–O–Si and Si–O–Ti bondings [25–27].

For such systems, ^{17}O NMR is a very powerful tool because of the large chemical shift range. This gives interesting clues for the identification of the various oxo-bridges [6,28,29]: 50–70 ppm for Si–*O*–Si, 250–300 ppm for Si–*O*–Ti, 300–400 ppm for μ_4-Ti–*O*–Ti, 500–600 ppm for μ_3-Ti–*O*–Ti, 700–800 ppm for μ_2-Ti–*O*–Ti, 200 ppm for Si–*O*–Zr, 300–350 ppm for μ_4-Zr–*O*–Zr, and 350–400 ppm for μ_3-Zr–*O*–Zr. Introduction of this technique was a real breakthrough in the characterization of siloxane–titania and siloxane–zirconia hybrid systems. It allows the unambiguous identification of Si–O–Ti and Si–O–Zr bond formation in solution, and the

demonstration of their low stability in solution during aging [6,27,30].

3. Solid state NMR techniques

3.1. ^{29}Si CP MAS NMR

The siloxane–oxide hybrid networks, obtained after gelation and drying, can be characterized by solid state NMR techniques. The most commonly used technique is the single-pulse ^{29}Si magic angle spinning (MAS) experiment [31] from which the relative amount of the various Si units and degree of condensation of the siloxane network can be readily extracted. However, for quantitative reliable data, long repetition delays should be used, because of long T_1 relaxation times for most of the units (10–50 s) [32]. Interestingly, addition of paramagnetic chromium ions, even in small amounts, to decrease relaxation times is not recommended if quantitative data are to be obtained, since part of the total NMR signal intensity cannot be detected [32]. In some particular cases, variation of chemical shift versus gel composition can indicate the level of homogeneity of the network, as illustrated in Fig. 4. The D^H and T units in gels prepared from MDES/TEOS and MTES/TEOS mixtures show continuous low field shifts when they are incorporated in a network with an increasing number of Q units: this suggests a progressive change in the nature of the neighboring sites of the observed units, indicative of a large tendency for the two systems to form co-condensed species.

Direct information that relates to the spatial distribution of the various units is more difficult to reach. Two-dimensional ^{29}Si MAS NMR studies have already been performed on crystalline zeolite structures [33], and also on silicate glasses [34]. These experiments provide precise descriptions of the connectivities of silicon sites, but usually require the preparation of ^{29}Si-enriched samples, which is rather expensive. Studies performed in natural abundance were however reported on crystalline samples, Q_8M_8 cubane [35] and zeolites [36], but are time-consuming.

In these systems, the presence of protonated groups directly bonded to some Si units makes the use of ^{29}Si–{^{1}H} cross-polarization (CP) technique very valuable. Based on magnetization transfer between abundant (here ^{1}H) and rare spins, this technique has been largely developed, coupled with MAS and high power proton decoupling [37], to increase the sensitivity of low abundant nuclei (^{13}C, ^{29}Si, ^{15}N). Cross-polarization dynamics is usually described within the framework of spin thermodynamics considering two reservoirs corresponding to the abundant *I*-spin (^{1}H) and the rare *S*-spin (^{29}Si). This model predicts an exponential build-up of *S*-spin magnetization in the rotating frame, characterized by $1/T_{IS}$. Analysis of the variation of peak intensities versus contact time gives access to T_{IS}, the cross-relaxation time, which is directly related to the ^{29}Si–^{1}H dipolar coupling and thus to the ^{29}Si–^{1}H distances [37]. It could thus bring structural information about the proton environment of each detected Si site. The rare spin must be within approximately 10 Å of a proton to facilitate polarization transfer [31]. However, the dipolar coupling can be partially averaged by molecular motions, and direct correlation between T_{IS} and proton environment can thus be made only for rigid networks which is not usually the case for sol-gel derived siloxane–oxide networks. Glass transition temperatures have been reported between 37 and 93°C in the MTES/TEOS system [38], and between −43 and −119°C in the MDES/TREOS system [14]. Quantitative interpretation of the CP dynamics should thus be carried out in these systems with some caution.

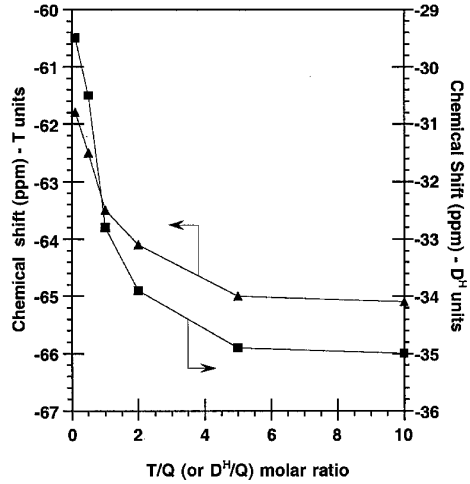

Fig. 4. Variation of chemical shift for the T and D^H units in dried gels prepared from co-hydrolysis of MDES/TEOS and MTES/TEOS in various molar ratios (EtOH/Si = 2; H_2O/OEt = 1; pH 2 (HCl)).

Indeed, the main difficulty encountered in a one-dimensional CP experiment is the uncertain nature of the protons that are actually the source for magnetization transfer. This prevents any definitive conclusions concerning the proximity between ^{1}H and ^{29}Si nuclei. A very elegant application of the CP technique can circumvent this problem: the use of two-dimensional ^{1}H–^{29}Si CP MAS heteronuclear NMR correlation. This experiment was first introduced to characterize surface species on silica and zeolites [39]. Fig. 5 shows the results of the ^{1}H–^{29}Si connectivity experiment carried out on a gel prepared by co-hydrolyzing MDES and TREOS in a 1:1 ratio. One should first note that MAS at 4 kHz gives good resolution on the one-dimensional ^{1}H spectrum. This is related to the presence of motions that can partially average the strong ^{1}H–^{1}H dipolar couplings. It makes possible a clear distinction between the Si–CH_3 (δ = 0.2 ppm) and Si–*H* (δ = 4.6 ppm) signals, and thus allows identification of the sources of polarization transfer. This is why this two-dimensional sequence is so powerful compared to the equivalent one-dimensional experiment: protons responsible for the polarization transfer to a given Si site can be identified, and thus spatial proximity established.

In the present example, at short contact time (50 μs), only correlations between the two types of Si units and the Si–*H*

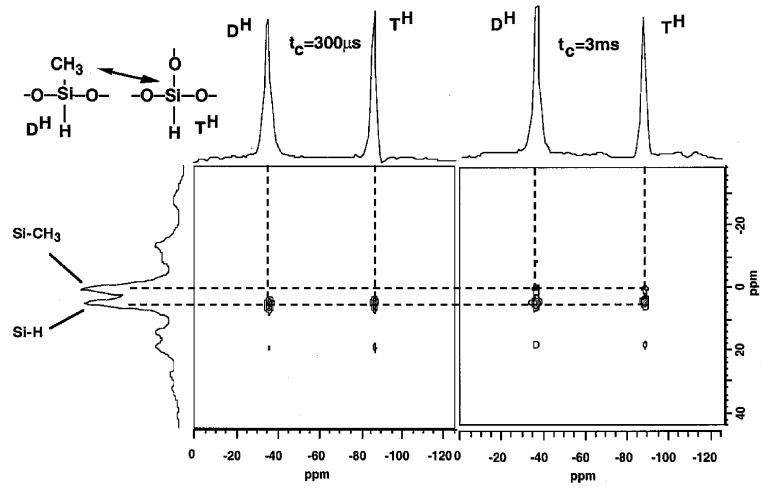

Fig. 5. Contour plot of the two-dimensional ^{1}H–^{29}Si correlation experiment on a gel prepared from co-hydrolysis of MDES and TREOS in a 1:1 molar ratio ($H_2O/OEt = 1$; $EtOH/Si = 2$; pH 2 (HCl)). Experimental parameters are the following: Bruker MSL300 spectrometer; spinning rate 4 kHz; contact time 50 μs and 3 ms; repetition time 5 s; 128 individual experiments with 48 scans each.

proton sources are present, indicating that the polarization transfer to ^{29}Si nuclei occurs only from the directly bonded ^{1}H nuclei. At longer contact times (3 ms), correlations are observed not only between the methyl groups and the D^H units, but also between these methyl groups and the T^H units. The variation in intensity of the correlation peaks with the contact time (Fig. 6) allowed us to extract the cross-relaxation T_{IS} times, characteristic of the ^{29}Si–^{1}H distances: as expected, they are found to be similar and around 100 μs [40] for the correlation peaks between the Si–*H* protons and the two Si sites. More surprisingly, they are also found to be similar (and around 1.5 ms) for the correlation peaks between the Si–CH_3 protons and the two Si units; this suggests a close spatial proximity between the D^H and T^H units.

Similar two-dimensional ^{1}H–^{29}Si heteronuclear NMR correlation experiments have been performed on different siloxane–silica systems prepared from MTES and TEOS [41], or PhTES and TEOS [32], with analogous conclusions: a good distribution of the siloxane and silica units within the hybrid network.

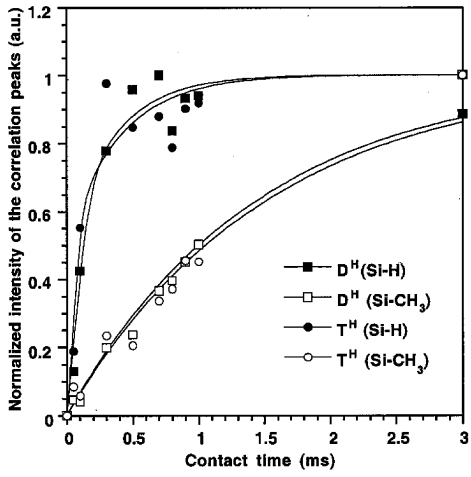

Fig. 6. Variation, with contact time, of the intensity of the correlation peaks observed in the two-dimensional ^{1}H–^{29}Si correlation experiment presented in Fig. 5.

3.2. ^{17}O MAS NMR

3.2.1. Siloxane–titania, siloxane–zirconia and borosiloxane systems

As previously mentioned, the large chemical shift range that can be found for siloxane–titania or siloxane–zirconia systems, makes ^{17}O solid state MAS NMR very attractive to identify the various oxo-bridges present in the hybrid networks.

In the solid state, enrichment of the samples is necessary, at least 10 at.%, but 20 at.% and higher is recommended. But the main problem with a quadrupolar nucleus, such as ^{17}O ($I = 5/2$) is a broadening of the central transition $|-1/2\rangle \leftrightarrow |+1/2\rangle$, due to a partial averaging under MAS of the second-order quadrupolar interaction. This may prevent observation of chemically non-equivalent sites, if their chemical shift difference is too small.

A ^{17}O MAS NMR study on SiO_2–TiO_2 gels has already been reported, showing the presence of the various Si–*O*–Si, Si–*O*–Ti and Si–*O*–Ti bonds [42,43]. Fig. 7 represents the ^{17}O MAS NMR spectrum obtained on a gel prepared from DMDES and $Ti(OPr^i)_4$. The three main signals are respectively assigned to Si–*O*–Si (60 ppm), μ_3-Ti–*O*–Ti (530 ppm), and μ_4-Ti–*O*–Ti (340 ppm) bonds. As already reported [44], the linewidth of the Ti–*O*–Ti resonances is dominated by chemical shift dispersion effects, rather than by quadrupolar effects, allowing the identification of the peak position with the chemical shift. The same is found here for the Si–*O*–Si resonance of the siloxane component, in contrast to the case of the Si–*O*–Si resonance in silica gel, which is characterized by a typical second order quadrupolar pattern ($C_Q \approx 4.7$ MHz) [45]. This suggests a high mobility for the D units in this sample, which may partially average the large quadrupolar interaction. No Si–*O*–Ti resonance, expected

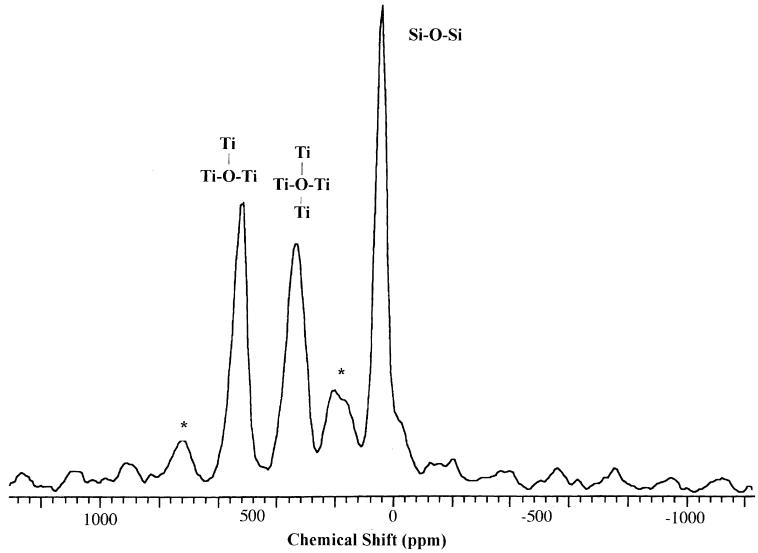

Fig. 7. ^{17}O MAS NMR spectrum of a dried gel prepared from DMDES and $Ti(OPr^i)_4$ (Si/Ti molar ratio 70/30), following a two-step synthetic procedure using 20 at.% enriched $H_2{}^{17}O$ [6]. The spectrum has been recorded on a Chemagnetics CMX-500 spectrometer with a Hahn–Echo sequence, synchronized on the rotor frequency (12.5 kHz). * spinning side bands.

around 300 ppm [44], is clearly present, which suggests a low number, if any, of the corresponding bridges. Indeed, this is in agreement with a solution study, which shows the very low stability of the Si–O–Ti bonds during aging [6]. The gel can thus be described as a nanocomposite with siloxane-rich and titania-rich domains. The ^{29}Si MAS NMR spectrum is characteristic of long polydimethylsiloxane (PDMS) chains [6]. A study using cross-polarization (CP) between ^{29}Si and ^{1}H shows however a low amount of Si units in constrained environment, certainly close to the titania-rich domains [6]. Interestingly, the resonances due to Ti–*O*–Ti bonds are very similar to those obtained on amorphous titania gels, indicating a network formed with μ_3 and μ_4 oxo bridges [29].

^{17}O MAS NMR is really a valuable tool not only to characterize siloxane–titania, but also siloxane–zirconia systems [46–48]. For siloxane–alumina systems, the chemical shift range for the various oxo bridges is quite short, and could prevent signal assignments based on this parameter. But as already reported for aluminosilicates [49], the quadrupolar coupling constant (C_Q) could be the best discriminator of such units. Consequently, the newly developed multiple quantum (MQ) MAS NMR technique [50] offers improved spectral resolution as already demonstrated on an aluminosilicate glass [44], for which complete resolution of Si–O–Si and Si–O–Al fragments has been obtained.

This technique has also been recently extended to borosilicate glasses [51], to distinguish between Si–*O*–Si, Si–*O*–B and B–*O*–B bridges. Similar results have been obtained on polyborosiloxane gel prepared from $EtSi(OEt)_3$ and $B(OEt)_3$ according to a published procedure [52] (Fig. 8). The two-dimensional MQ MAS spectrum [53]shows two peaks on the isotropic dimension at -48 ppm and at -60 ppm. For a spin-5/2 nucleus, the observed resonance frequency in the isotropic dimension of MQ MAS is given by [50]:

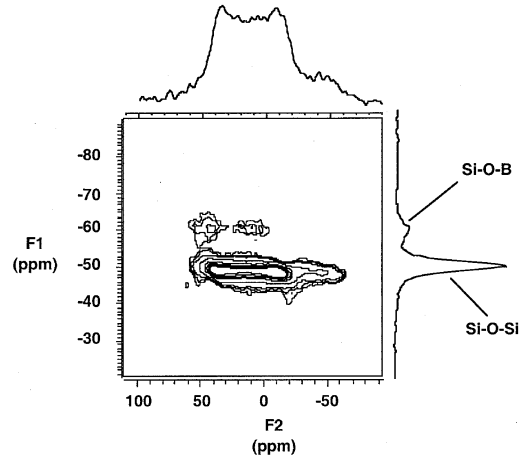

Fig. 8. ^{17}O 3Q MAS NMR spectrum for a polyborosiloxane gel prepared from $EtSi(OEt)_3$ and $B(OEt)_3$ (B/Si = 0.16). The experiment has been recorded on a DSX400 Bruker spectrometer using the shifted echo sequence [53].

$$\delta_{F1} = -\frac{17}{31}\delta_{iso} - \frac{8\times10^6}{93}\frac{\nu_Q^2}{\nu_0^2}\left(1+\frac{\eta^2}{3}\right)$$

with $\nu_Q = 3C_Q/[2I(2I-1)]$ and ν_0 the Larmor frequency of the observed nucleus (54.2 MHz). Simulations of the corresponding MAS projections give the following parameters for the two types of oxo species: Si–O–Si ($\delta_{iso} = 59$ ppm; $C_Q = 4.75$ MHz; $\eta = 0$) and Si–O–B ($\delta_{iso} = 75$ ppm; $C_Q = 4.80$ MHz; $\eta = 0$). No B–O–B species, expected to be at $\delta_{F1} \approx -70$ ppm [51] could be detected in agreement with the ^{11}B MAS NMR study [52].

3.2.2. Siloxane–silica systems

In siloxane–silica systems, the identification of the various oxo-bridges by ^{17}O MAS NMR is not obvious because of a

short chemical shift range for the various Si–*O*–Si species and very similar quadrupolar coupling parameters. For example, (T)–O–(T) units in a gel prepared from MTES are characterized by $\delta_{iso} = 64$ ppm, $C_Q = 4.5$ MHz, $\eta = 0$, while (Q)–O–(Q) units in a TEOS-derived silica gel give $\delta_{iso} = 40$ ppm, $C_Q = 5.1$ MHz, $\eta = 0$ [54]. Nevertheless, the MQ MAS sequence has also been successfully applied to organically modified silicates prepared from various mixtures of MTES and TEOS (Fig. 9) [54]. The isotropic projections for the gels prepared from respectively T and Q units show a peak at $\delta_{F1} = -63$ ppm ((T)–O–(T)) and -51 ppm ((Q)–O–(Q)). In the mixed TQ gels, an additional peak is present at an intermediate position $\delta_{F1} \approx -57$ ppm that corresponds to (T)–O–(Q) bridges. The isotropic chemical shift values and quadrupolar parameters have been extracted from the simulations. $C_Q = 5$ MHz and $\eta = 0$; δ_{iso} varies from 48 to 50 ppm, depending on the composition, and is in good agreement with those found in solution [15]. Quantification of the various oxo-bridges has been extracted by simulating the one-dimensional MAS spectra recorded at two magnetic fields (7 and 9.4 T) [54]: it shows in all samples a large amount of (T)–O–(Q) species, suggesting the excellent homogeneity of these gel networks.

4. Conclusions

This paper has reviewed the use of ^{29}Si and ^{17}O solution and solid state NMR techniques, to characterize the formation and resultant molecular network structures of siloxane–oxide hybrid systems. For siloxane–silica systems, ^{29}Si NMR is generally more sensitive to local structural features and thus is more informative than ^{17}O. Powerful two-dimensional heteronuclear correlation NMR methods (e.g. ^{29}Si–^{1}H) expand significantly the spectral resolution achievable, allowing the spatial proximities of different species (e.g. ^{29}Si and ^{1}H) to be probed especially for organically modified silicates. For siloxane–titania and siloxane–zirconia systems, ^{17}O NMR is generally more informative than ^{29}Si NMR because of the large ^{17}O chemical shift range. In systems for which the characteristic parameters of the various oxo bridges — isotropic chemical shift and quadrupolar coupling constant — are quite similar, such as polyborosiloxanes or polysiloxanes, the newly developed MQ MAS sequence has been successfully used to obtain resolved spectra, and to identify the different oxo species. The coupling with the one-dimensional ^{17}O MAS experiment allows quantification of the various oxo-bridges and a better description of the final network, in terms of phase separation.

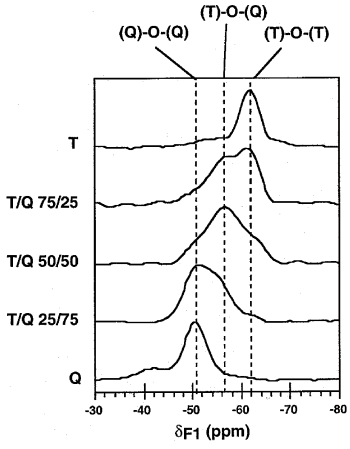

Fig. 9. Isotropic total projections of ^{17}O 3Q MAS spectra for organically modified silica gels prepared from MTES and TEOS in various molar ratios. The experiments have been recorded on a DSX300 Bruker spectrometer using the shifted echo sequence [53].

Abstract

Hydroboration reactions of dichloroborane-, monochloroborane- and borane-dimethylsulfide with dichloromethylvinylsilane and trichlorovinylsilane were investigated. The proposed structures of the produced organochlorosilylboranes **1**–**4** were verified by NMR spectroscopic measurements and in the case of [α-(dichloromethylsilyl)ethyl]dichloroborane-dimethylsulfide (**4**) the molecular structure was determined by single-crystal X-ray diffraction (L.M. Ruwisch, R. Riedel, U. Klingebiel, M. Noltemeyer, Z. Naturforsch., Teil B 54 (1999) 624). Following the Markovnikov rule, the first addition appears strictly regioselective in the α-position to silicon, producing one chiral methine group between silicon and dichloroborane in compound **4**. The second addition of borane- or monochloroborane-dimethylsulfide at the vinyl groups of dichloromethylvinylsilane and trichlorovinylsilane also takes place in the α-position to silicon, forming a second chiral methine group. In the case of borane-dimethylsulfide the third addition occurs in the β-position (anti-Markovnikov) owing to steric hindrance to boron in tris[(dichloromethylsilyl)ethyl]borane (**1**). A stepwise substitution of chlorine bonded at boron in compounds **2** and **3** using hexamethyldisilazane produces bis[α-(dichloromethylsilyl)ethyl]boryl-trimethylsilylamine (**5**) and bis[α-(trichlorosilyl)ethyl]boryl-trimethylsilylamine (**6**), respectively, under release of chlorotrimethylsilane. The remaining trimethylsilylamine group in **6** can be replaced by further reaction with **3** forming tetrakis[α-(trichlorosilyl)ethyl]diborylamine (**7**). This reaction resembles a selective amino condensation at boron. In a similar condensation reaction of **4** with equivalent amounts of hexamethyldisilazane, tris[α-(dichloromethylsilyl)ethyl]borazine (**8**) can be obtained. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The synthesis of monomeric molecular precursors is one of the major steps in the construction of polymers with definable structural composition as starting materials for the production of novel ceramics with unique properties such as ultra high temperature stability or extraordinary hardness. Depending on the different synthetic pathways applied, the elemental composition of the polymers varies from binary to ternary to quaternary or multinary systems. Nitrogen and/or carbon in addition to main group elements (E = B, P, O, Al, Si) are utilized for the synthesis of a wide range of preceramic polymers with different elemental compositions [1]. Currently, new ceramic materials in the quaternary Si–B–C–N system derived from polymers with outstanding thermal stability in combination with improved crystallization resistance are under investigation by different authors [2,3]. Boron plays an important but still little understood role in enhancing the high temperature characteristics of these boron modified polyorganosilazane derived materials. One first step towards interpretation of the influence of boron is to vary the amount of boron by varying the silicon to boron ratio or to modify the boron environment within the precursors.

Silyl substituted organoboranes produced by hydroboration reactions are generally suitable compounds for the synthesis of polyorganoborosilanes, polyorganosiloxanes [4] and polyorganosilazanes [2,5]. Owing to the functional chlorine attached to silane it is possible to transform the monomeric units into molecules, oligomers and polymers by substitution reactions. Therefore, condensation reactions such as hydrolysis, ammonolysis or aminolysis, and salt elimination such as Wurtz analogue reactions are utilized. The resulting monomers, oligomers, and polymers are defined by the structure and composition of the monomeric building units. Also the silicon to boron ratio of the precursors from which the ceramics will be prepared can be controlled. Nevertheless, owing to the restrictions on the use of BH_3

complexes in hydroboration reactions, the resulting Si:B ratios of monomers currently do not change. Only the cocondensation of derived monomers with additional chlorosilanes or the subsequent modification with boranes or boron compounds can be used to adjust higher or lower Si:B ratios in the final polymer. Depending on the different production pathways applied, the elemental compositions of the polymers vary by the amount of secondary modification.

We are currently exploring the Si–B–C–N system in order to develop a precursor concept for ultra high temperature ceramics with extraordinary thermal stability up to 1700°C and above [6]. In this paper we report on the synthesis and characterization of the aforementioned monomolecular species via hydroboration. The selective condensation of the resultant chloro functional boranes with hexamethyldisilazane will be discussed also. Our work is basically focused on the systematic construction of molecules with various Si and B ratios with the aim of studying the influence of the Si:B ratio on the pyrolytic behaviour of the derived polymers and on the high temperature thermal stability of the resulting silicoboron carbonitride ceramics.

2. Experimental

2.1. General

All syntheses were performed under dry (P_4O_{10}) inert atmosphere (argon). The utilized glassware was stored in a drying oven for several hours at 120°C. Toluene was dried with a sodium-benzophenone mixture under reflux. Dichloromethane was dried and stored over pure water-free calcium dichloride. All solvents and chemicals were handled using Schlenk techniques. The commercially available silanes were distilled before use and the boranes were stored at 4°C and used as received by syringe.

^{1}H, ^{13}C, ^{11}B, and ^{29}Si NMR spectroscopy was performed in C_6D_6 or $CDCl_3$ with a Bruker WM 300 spectrometer. Tetramethylsilane was used as an internal standard and trifluoroborane-diethyl ether was used as external standard for ^{11}B NMR. The ^{13}C and ^{29}Si data of compounds **1**–**4** are given in Table 1, and all ^{11}B NMR data are given in Table 2. The mass spectroscopy was performed with a Balzers 429 mass spectrometer. Purification of the reaction products by distil-

lation was avoided because of the thermal instability of the obtained boranes.

2.2. Tris[(dichloromethylsilyl)ethyl]borane (1) [2]

Into a precooled solution of 100 ml (108.5 g, 0.76 mol) dichloromethylvinylsilane dissolved in 50 ml toluene, a mixture of 23.6 ml (19.0 g, 0.25 mol) of borane-dimethylsulfide and 50 ml toluene was added. During the addition of borane and for the first 6 h the temperature should not exceed 10°C. After 30 h of stirring at room temperature the released dimethylsulfide and toluene were removed under reduced pressure (0.02 Torr) at 60°C, and 107 g (98%) of the colourless liquid product were obtained.

Anal. Found: C, 24.3; H, 4.8; Cl, 49.2; Si, 18.1; B, 2.2. Calc.: C, 24.7; H, 4.8; Cl, 48.6; Si, 19.2; B, 2.5%. $\Sigma = 98.6\%$.

Mass spectra (rel. int., %): $C_9H_{21}Cl_6Si_3B$ ($M = 437.1$); 293 (90) $[M–(C_2H_4–SiCl_2CH_3)]^+$.

FT-IR spectra (thin film, KBr, cm^{-1}): ν 3000–2835 (CH_x); 1466 (CH_x); 1261 (Si–CH_x); 1171 (B–C_x); 790 (Si–CH_3); 560, 480 (Si–Cl_2).

NMR (C_6D_6, ppm): ^{1}H δ 0.47, 0.47, 0.48, 0.49, 0.51, 0.55 ($SiCH_3$), 0.86–1.48 (CH_2–CH_2), 1.09–1.13 (CH_3), 1.58–2.03 (CH); ^{11}B δ 80 ($h_{1/2} = 1650$ Hz); ^{13}C and ^{29}Si see Table 1.

2.3. Bis[(α-dichloromethylsilyl)ethyl]chloroborane (2)

A solution of 36 ml (38.1 g, 0.345 mol) chloroborane-dimethylsulfide and 50 ml toluene was added dropwise into a precooled mixture of 90.6 g (98.3 g, 0.70 mol) dichloromethylvinylsilane and 50 ml toluene. The reaction mixture was held below 10°C over 6 h and subsequently warmed to room temperature. After 20 h stirring the side products dimethylsulfide and toluene were removed under vacuum (0.02 Torr) and at 60°C. 110 g (97%) of the colourless liquid **2** were obtained.

Anal. Found: C, 21.5; H, 4.5; Cl, 53.1; Si, 17.7; B, 3.0. Calc.: C, 21.9; H, 4.2; Cl, 55.2; Si, 17.0; B, 3.3%. $\Sigma = 99.8\%$.

Mass spectrum (rel. int., %): $C_6H_{14}Cl_5Si_2B$ ($M = 330.5$); 328 (50) $[M]^+$.

FT-IR spectra (thin film, KBr, cm^{-1}): ν 3000–2840 (CH_x); 1466 (CH_x); 1269 (Si–CH_x); 1179 (B–C_x); 1040 (B–Cl); 802 (Si–CH_3); 560, 480 (Si–Cl_2).

NMR (C_6D_6, ppm): ^{1}H δ 0.48 ($SiCH_3$, 6H), 0.57 ($SiCH_3$, 6H), 1.17 (CH_3, 6H), 1.18 (CH_3, 6H), 1.74 (CH, 2H), 1.97 (CH, 2H); ^{11}B δ 69.4 ($h_{1/2} = 629$ Hz); ^{13}C and ^{29}Si see Table 1.

2.4. Bis[(α-trichlorosilyl)ethyl]chloroborane (3)

The synthesis of **3** was carried out under the same reaction conditions as used for **2**. Into a solution of 87.8 ml (111.5 g, 0.70 mol) trichlorovinylsilane and 50 ml toluene, 36 ml (38.1 g, 0.345 mol) chloroborane-dimethylsulfide were added. After completion of the reaction the solvent toluene and dimethylsulfide were removed under vacuum (0.02 Torr) and 84.5 g (98%) of **3** were obtained as a colourless liquid.

Mass spectrum (rel. int., %): $C_4H_8Cl_7Si_2B$ ($M = 371.3$); 333 (20) $[M–Cl]^+$.

FT-IR spectra (thin film, KBr, cm^{-1}): ν 3000–2875 (CH_x); 1458 (CH_x); 1278 (Si–CH_x); 1161 (B–C_x); 1040 (B–Cl); 625–570, 535–450 (Si–Cl_3).

NMR (C_6D_6, ppm): ^{1}H δ 1.14 (CH_3, 6H), 1.21 (CH_3, 6H), 1.85 (CH, 2H), 2.08 (CH, 2H); ^{11}B δ 68.5 ($h_{1/2} = 495$ Hz); ^{13}C and ^{29}Si see Table 1.

2.5. [(α-Dichloromethylsilyl)ethyl]dichloroborane-dimethylsulfide (4)

Into a solution of 22.5 ml (24.5 g, 0.17 mol) dichloromethylvinylsilane in 50 ml dichloromethane, a homogeneous mixture of 20 ml (25.1 g, 0.17 mol) dichloroborane-dimethylsulfide dissolved in dichloromethane was added. After 6 h stirring at room temperature the reaction mixture was held under reflux for 2 h. Excess solvent was removed under vacuum and 44.9 g (93%) of colourless liquid **4** were obtained.

Mass spectrum (rel. int., %): $C_5H_{13}Cl_4SiBS$ ($M = 285.9$); 222 (60) $[M–S(CH_3)_2]^+$.

FT-IR spectra (thin film, KBr, cm^{-1}): ν 2980–2850 (CH_x); 1460 (CH_x); 1250 (Si–CH_x); 1156 (B–C_x); 1035, 985 (B–Cl_2); 789 (Si–CH_3); 630, 590 ($S(CH_3)_2$); 560, 465 (Si–Cl_2).

NMR (C_6D_6, ppm): ^{1}H δ 0.93 ($SiCH_3$, 3H), 1.25 (CH_3, 3H), 1.57 ($S(CH_3)_2$/CH, 7H); ^{11}B δ 5.8 ($h_{1/2} = 64$ Hz); ^{13}C, ^{29}Si see Table 1.

2.6. Bis[(α-dichloromethylsilyl)ethyl]boryl-trimethylsilylamine (5)

Into 10 ml (12.7 g, 37.8 mmol) of precooled compound **2**, equivalent amounts (8.0 ml, 6.15 g, 38 mmol) of HMDS were added. The reaction mixture was constantly stirred for 2 h at 0°C and the chlorotrimethylsilane produced was removed at 30°C under vacuum (0.02 Torr). Compound **5** was isolated in 14.5 g (98%) yield as a colourless liquid.

Anal. Found: C, 28.0; H, 6.1; Cl, 36.6; Si, 21.5; B, 2.7; N, 3.7. Calc.: C, 28.3; H, 6.3; Cl, 36.7; Si, 22.0; B, 2.9; N, 3.7%. $\Sigma = 98.6\%$.

Mass spectrum (rel. int., %): $C_9H_{24}Cl_4Si_3BN$ ($M = 383.2$); 310 (50) $[M–Si(CH_3)_3]^+$.

NMR ($CDCl_3$, ppm): ^{1}H δ 0.21–0.24 ($Si(CH_3)_3$), 0.75–0.78 ($SiCH_3$, 6H), 1.20–1.25 (CH_3, 6H), 1.34–1.36 (CH, 2H), 4.1 (NH, 1H); ^{11}B δ 45.1 ($h_{1/2} = 792$ Hz); ^{13}C δ 1.54, 1.92 ($Si(CH_3)_3$), 5.7, 5.9 ($SiCH_3$), 9.9, 11.3 (CH_3), 18.1, 23.2 (CH); ^{29}Si δ 5.5 ($Si(CH_3)_3$), 32.3, 33.4 ($SiCl_2CH_3$).

2.7. Bis[(α-trichlorosilyl)ethyl]boryl-trimethylsilylamine (6)

Under the same reaction conditions as described for the synthesis of **5**, 8.0 ml (6.15 g, 38 mmol) HMDS were added

dropwise into 10 ml (13.9 g, 37.7 mmol) of compound **3**. After extraction of chlorotrimethylsilane 15.9 g (99%) of colourless liquid compound **6** were obtained.

Mass spectrum (rel. int., %): $C_7H_{18}Cl_6Si_3BN$ (M = 424.0); 406 (15) $[M–CH_3]^+$.

FT-IR spectra (thin film, KBr, cm^{-1}): ν 3368 (N–H); 2965–2875 (C–H_x); 1617 (N–H); 1456 (C–H_x); 1420–1380 (B–N); 1260 (Si–CH_x); 1155 (B–C_x); 624–575, 500 (Si–Cl_3).

NMR ($CDCl_3$, ppm): ^{1}H δ 0.24–0.27 ($Si(CH_3)_3$), 1.28–1.37 (CH_3, 6H), 1.55–1.63 (CH, 2H), 4.2–4.3 (NH, 1H); ^{11}B δ 43.6 ($h_{1/2}$ = 633 Hz); ^{13}C δ 1.76, 1.86 ($Si(CH_3)_3$), 10.0, 11.6 (CH_3), 21.3, 26.0 (CH); ^{29}Si δ 6.7 ($Si(CH_3)_3$), 11.9, 12.4 ($SiCl_3$).

2.8. Tetrakis[(α-trichlorosilyl)ethyl]-diborylamine (7)

10 ml (13.9 g, 37.7 mmol) of **3** were precooled at 0°C. After addition of 3.9 ml (3.0 g, 18.8 mmol) HMDS the mixture was heated to reflux. The chlorotrimethylsilane formed was removed under vacuum (0.02 Torr) and 12.7 g (99%) of **7** were obtained as a colourless liquid.

Anal. Found: C, 16.5; H, 3.3; N, 2.0; Cl, 58.4; Si, 16.8; B, 2.7. Calc.: C, 16.4; H, 2.5; N, 2.0; Cl, 61.7; Si, 16.3; B, 3.2%. Σ = 99.7%.

3. Discussion

The main focus of our work was to alter the silicon to boron ratio within the molecular precursor in a directed way. For this we investigated the hydroboration reactions of borane-, monochloroborane- and dichloroborane-dimethylsulfide adducts with vinylsilanes. The reaction can be categorized according to the number of hydrogen atoms bonded to boron. Therefore the discussion will progress with respect to the borane, i.e. BH_3, $BClH_2$ and BCl_2H.

The appointed ^{13}C and ^{29}Si NMR data of the compounds prepared by these hydroboration reactions are summarized in Table 1, and the ^{11}B NMR shifts of all synthesized molecules are given in Table 2.

3.1. Hydroboration with BH_3

The reaction of borane dimethylsulfide with dichloromethylvinylsilane in toluene results in the formation of tris[(dichloromethylsilyl)ethyl]borane (**1**) (Fig. 1). The respective compound **1** was first prepared by Mikhailev in 1969 [7]. Later Jones et al. investigated several hydroboration reactions of chloromethylsilylalkenes with diborane dissolved in THF, in order to analyse stereochemical effects of primarily generated silyl substituted boranes on further additions of different chlorine functionalized alkenylsilanes [8,9]. The chlorosilylorganoboranes obtained by Jones et al. were not isolated but instead were transformed directly into organosilylboranes, using methylmagnesiumbromide, and subsequently were oxidized smoothly with hydrogen peroxide. The resulting silyl substituted alcohols were analysed by GLC and IR spectroscopy and an isomeric ratio of 90% of 1-silylethanol and 10% of 2-silylethanol was found in the case of compound **1**.

Our investigations on the reaction of 3 equiv. dichloromethylvinylsilane with borane-dimethylsulfide revealed that the first two hydroboration additions take place in the α-position forming dichloromethylvinylsilane. These additions are controlled by a partial negative charge on the α-C atom, resulting from an electron withdrawing effect of silyl chlorine induced by a $(p–\sigma)_\pi$ conjugation of the β-vinylcarbon in $C{=}C–SiCl_2(CH_3)$ [10]. Therefore the reaction of the strong electrophilic Lewis acid borane with vinylsilanes leads to an addition of boron at the α-positioned carbon atom next to silicon. This is in good agreement with results from stereochemical investigations reported by Soderquist et al. [11,12] obtained from similar reactions of borane-dimethylsulfide with 2 equiv. of alkenylsilanes. They describe only α-addition, producing two chiral methine groups between silicon and boron under preservation of the remaining B–H bond.

The third addition is dominated by a steric hindrance caused by the previously added two [α-(dichloromethylsilyl)ethyl] groups. Consequently, the remaining B–H bond reacts in β-addition to silicon, independent of the negative

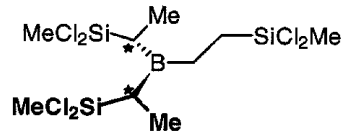

Fig. 1. Structure of **1**.

partial charge at the α-carbon of the silyl substituted vinyl group as mentioned above. This is consistent with analogous results of Soderquist et al. [12] obtained from hydroboration reactions of 9-borabicyclo[3.3.1]nonane and vinylsilanes, which ascertain a high β-regioselectivity of about 99% for dialkylboranes in hydroboration reactions with vinylsilanes.

We were able to confirm the two additions in α-position forming two chiral methine groups and the third hydroboration in β-position producing one ethylene group between boron and silicon by NMR spectroscopic investigations of compound **1**.

Owing to the two chiral methine centres, each connected to silicon, boron, carbon, and hydrogen, four constitutional isomers are formed, one pair of enantiomers (*RR*+*SS*) and the corresponding mesomers (*S*,*R* and *R*,*S*). Thus an A,B,C_2 spectrum should be expected in the ^{1}H, ^{13}C and ^{29}Si NMR. The spectrum is further complicated because of the rotating β-(dichloromethylsilyl)ethyl group. With respect to the planar environment of the central boron atom in **1** this group can be located above (*cis*) or below (*trans*) the *meso* conformations (Fig. 2). This produces an unsymmetrical signal splitting of the *meso* isomers in the ^{29}Si NMR and the corresponding ^{13}C and ^{1}H NMR spectra. In the enantiomeric *RR* and *SS* form the third addition does result in a similar pattern, owing to the resultant symmetrical environment at boron. Therefore, the β-addition produces an A,B,C,C′ spectrum (d+l, *meso*-above and *meso*-below) in the ^{1}H, ^{13}C and ^{29}Si NMR spectra of tris[(dichloromethylsilyl)ethyl]borane (**1**). The determined ^{29}Si NMR resonance of the α-hydroborated silanes are in the range from 28 to 30 ppm. The nearby location of boron effects a shift to high field of α-positioned silicon compared to a hydrogen substituted ethyl group [13]. The β-positioned dichloromethylsilylethyl group produces three ^{29}Si NMR signals between 32 and 34 ppm, according to symmetrical operations at the 1-boryl-2-silyl-substituted ethane. An intensity ratio of 2:1 was found for the α- and β-silicon in the ^{29}Si NMR spectrum. Considering the low ^{29}Si isotope abundance it will be necessary to verify the observed peak intensities by further measurements.

The same intensity ratio of 2:1 is found for the 1,1-ethyl and 1,2-ethylene protons in the ^{1}H NMR spectrum, after normalization by the observed methylsilyl-proton intensities. The appearance of six silyl bonded methyl groups supports the expected peak splitting for three isomers multiplied by two for α and β bonded silyl groups in tris[(dichloromethylsilyl)ethyl]borane (**1**). This finding coincides with ^{13}C (DEPT)-NMR data, which showed six methylene carbon in the shift range from 13 to 19 ppm. Three signals produced by C-bonded methyl groups at 10 ppm and three broad methine signals between 27 and 34 ppm ascertain the expected A,B,C,C′ isomer splitting in compound **1**. The observed peak broadening of the methine carbon originates from the magnetic quadrupole nucleus boron in direct contact to carbon. In ^{11}B NMR measurements the central boron appears at 80 ppm with a peak broadening of $h_{1/2}=1650$ Hz, which can also be caused by the isomer alteration.

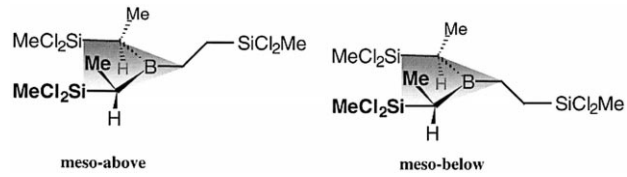

Fig. 2. Enantiomeric forms of **1**.

3.2. Hydroboration with BH_2Cl

In a similar hydroboration reaction of dichloromethylvinylsilane or trichlorovinylsilane with monochloroborane-dimethylsulfide, two organosilyl substituted boranes are formed, bis[(α-dichloromethylsilyl)ethyl]chloroborane (**2**) and bis[(α-trichlorosilyl)ethyl]chloroborane (**3**). Reactions of alkenes with monochloroborane-dimethylsulfide published by Brown et al. [14] resulted in a characteristic high α-regioselectivity of monochloroboranes for silyl substituted alkenes. Comparable investigations of Soderquist et al. [11] on the reaction of borane-dimethylsulfide with different vinylsilanes exhibited the same exclusive α-addition of borane next to silicon. Therefore it is evident that two chiral α-carbon centres are formed via this addition process and an A,B spectrum is expected, the enantiomeric isomers (*RR*+*SS*) and the *meso* form respectively. The ^{29}Si NMR data exhibit the typical C_2SiCl_2 (27.6, 27.2 ppm) **2** and $CSiCl_3$ (6.8, 6.2 ppm) **3** [15] shifts and confirm the A,B-splitting of the chiral methine groups. In ^{13}C-(DEPT) NMR data two broad peaks of the methine C-atoms bonded to boron and silicon are found at 28 and 33 ppm. The corresponding methyl groups appear at 9.4 and 9.5 ppm for bis[(α-dichloromethylsilyl)ethyl]chloroborane (**2**). This is in full agreement with the methine and methyl groups in compound **1**. In the ^{13}C NMR spectra of compound **3** we also found two broad signals at 33 and 35 ppm reflecting the methine groups. The corresponding methyl groups appear at ∼11 ppm. Owing to the exchange of carbon by chlorine, in comparison to compound **1** the boron resonances are shifted to 69.4 ppm in **2** and 68.5 ppm in **3**. From ^{1}H NMR a $^{3}J_{H-H}$ coupling of 6.7 and 6.8 Hz between methine and methyl protons was found in both molecules **2** and **3**. Only the chemical shifts differ in accordance with the silyl substituents. It can be concluded from our investigations that the first two additions of B–H take place strictly in α-position to silicon and are unaffected by the silicon or boron substituents.

3.3. Hydroboration with $BHCl_2$

In contrast to the previously described synthesis of compounds **1**, **2** and **3** in toluene, dichloroborane-dimethylsulfide added to a solution of dichloromethylvinylsilane dissolved in toluene does not lead to the presumed hydroboration forming [(α-dichloromethylsilyl)ethyl]dichloroborane (**4**). The decreased reactivity of dichloroborane-dimethylsulfide compared to borane- and monochloroborane-dimethylsulfide can be attributed to the stronger Lewis acidity of the $HBCl_2$ group. Consequently, dissociation of the dimethylsulfide adduct in

toluene is hampered [16]. Performing the reaction in methylene dichloride as solvent supports the dissociation of dichloroborane and dimethylsulfide and leads to a higher quantity of uncomplexed $HBCl_2$ [17] which can react directly with dichloromethylvinylsilane. During extraction of excess methylene dichloride [(α-dichloromethylsilyl)-ethyl]dichloroborane (**4**) and dimethylsulfide reassemble to form a stable 1:1 adduct with dimethylsulfide bonded to boron. The formed complex precipitates after 1 day at 7°C. From the crystals obtained the structure of **4** was determined by means of single-crystal X-ray diffraction [18]. Corresponding to the discussed regioselectivity the hydroboration of dichloroborane appears only in the α-position to silicon. Owing to the formation of the chiral methine groups, optical isomers *R* and *S* have to be considered. The NMR data again prove the exclusive formation of [(α-dichloromethylsilyl)ethyl]dichloroborane-dimethylsulfide (**4**). ^{13}C-DEPT NMR studies show the α-C atom of the original vinyl group bonded to boron with a signal at 20.83 ppm. The ^{1}H NMR spectrum exhibits a coupling constant of $^{3}J_{H-H} = 7.3$ Hz of the methine proton at 1.25 ppm, appearing as a quartet, and the methyl proton (doublet, superimposed by the peaks of the dimethylsulfide protons) at ~1.57 ppm. The high field shift of the related dimethylsulfide at $\delta = 1.57$ ppm compared to free dissolved dimethylsulfide ($\delta \geq 1.7$ ppm) and a peak broadening verifies the presence of an adduct.

The presented hydroboration reactions are summarized in the scheme given in Fig. 3. It clearly demonstrates the influence of the amount of chlorine in the borane on the composition of the resulting organosilylborane. As can be seen, the Si:B ratio adopts values from 3:1 to 1:1 depending on the borane used. The novel organosilylboranes allow the desired Si:B ratio to be adjusted for further transformations into polymers and ceramics with predefined compositions and properties.

3.4. Stepwise substitution with hexamethyldisilazane (HMDS)

In a second reaction step it is possible to replace selectively chlorine bonded to boron of the previously synthesized chloroboranes **2**, **3** and **4** by trimethylsilylamine using HMDS. Reactions of halogeno boranes with hexamethyldisilazane were investigated by Kulijian [19], and are a source for continued work of Barlos and Noeth [20]. Baldus and Jansen substituted the trimethylsilyl group in trimethyltrichlorodisilazane (TTDS, [21]) by trichloroborane to form trichlorosilylaminodichloroborane (TADB) [3]. Based on this reaction, they synthesized new types of polyborosilazanes as ceramic precursors in the non-oxide systems Si–B–N and Si–B–(C)–N. In an analogous substitution reaction we reacted compounds **2** and **3** with equivalent amounts of HMDS to give bis[(α-dichloromethylsilyl)ethyl]boryl-trimethylsilylamine (**5**) and bis[(α-trichlorosilyl)ethyl]boryl-trimethylsilylamine (**6**) (Fig. 4). The side product chlorotrimethylsilane was removed from the reaction mixture

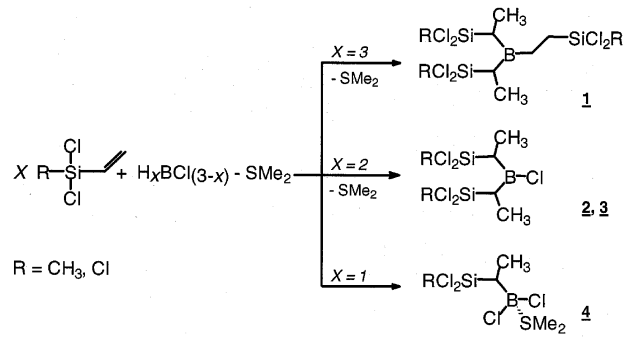

Fig. 3. Summarized reaction scheme for the reaction of chlorovinylsilanes with boranes and chloroboranes (see Section 3).

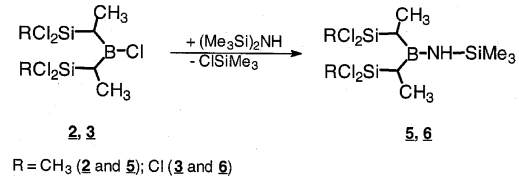

Fig. 4. Substitution reactions of HMDS at **2** and **3**.

by distillation under reduced pressure. Spectroscopic data (NMR, MS and FT-IR) of **5** and **6** reveal the systematic substitution of chlorine bonded to boron by $NH–SiMe_3$. The methine groups of the starting molecules are shifted to higher fields (^{13}C NMR, $\Delta\delta = -10$ to -15 ppm), whereas the connected silyl groups appear shifted slightly to lower magnetic fields compared to compounds **2** and **3** (^{29}Si NMR, $\Delta\delta = 5$ to 7 ppm). These changes are effected by the altered electronic properties of boron in **5** and **6**, compared to **2** and **3**, due to the introduced trimethylsilylamine group. The substitution of chlorine attached to silicon by HMDS was not found. The observed chemical shifts of boron to higher magnetic field in compounds **5** ($\delta = 45.1$ ppm) and **6** ($\delta = 43.6$ ppm) also reflect the exchange of chlorine by trimethylsilylamine and coincide with already published ^{11}B NMR data of $R_2B–NR_2$ (R = alkyl, H) [22].

Similar to the previously discussed substitution of Cl using HMDS to give **6**, bis[(α-trichlorosilyl)ethyl]boryl-trimethylsilylamine (**6**) itself can substitute Cl in bis[(α-trichlorosilyl)ethyl]chloroborane (**3**) leading to the formation of tetrakis[(α-trichlorosilyl)ethyl]diborylamine (**7**) (Fig. 5). The obtained molecule **7** can be described as a symmetrically silyl substituted diborylamine, corresponding to a regioselective condensation of bis[(α-trichlorosilyl)ethyl]chloroborane (**3**) with ammonia. This reaction allows for a selective step by step polymerization of silyl substituted chloroboranes, under prevention of well defined molecular units, and leads to a predictable elemental arrangement in the corresponding polymers. Except for the disappearance of the tri-

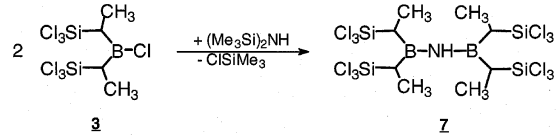

Fig. 5. Synthesis of tetrakis[(α-trichlorosilyl)ethyl]diborylamine (**7**).

methylsilyl group, compared to **6** the peak shifts in ^{11}B, ^{13}C and ^{29}Si NMR measurements were not significantly affected by the second substitution reaction forming compound **7**. The relative peak intensities of the amine protons at 4.1 ppm compared to the ethyl protons change from 1:8 (**6**) to 1:16 (**7**). The FT-IR spectra of compounds **6** and **7** reveal a typical resonance at 1628 cm^{-1}, due to a conjugated >B–NH group system as discussed earlier by Noeth et al. [23]. Independent of the second NH substituents (boron or silicon) the electron lone pair of the amine is part of a fluctuating back-bonding system between boron and nitrogen.

The reaction of [(α-dichloromethylsilyl)ethyl]dichloroborane-dimethylsulfide (**4**) with equivalent quantities of HMDS leads to a complete substitution of the chlorine bonded to boron forming tris[(α-dichloromethylsilyl)-ethyl]borazine (**8**) (Fig. 6). This finding can be explained by the formation of the intermediate [(α-dichloromethylsilyl)ethyl]chloroboryl-trimethylsilylamine which reacts further under intramolecular and/or intermolecular elimination of chlorotrimethylsilane. The silyl-substituted aminochloroborane formed as an intermediate cannot be isolated, although similar organosilylamino-chloroboranes are stable under these conditions for several days [24]. Depending on the B-substituent four-, six- and eight-membered B–N ring systems can be formed, besides minor amounts (< 5%) of polymeric chains [25]. A HCl elimination, described by Nöth and Spargue [26] was not observed. The reaction product **8** was characterized by NMR, and mass spectroscopy. Considering the three chiral methine groups connected to boron, four borazine isomers are formed, respectively two pairs of enantiomers (*RRR*/*SSS*) and (*RSS*/*SRR*). ^{29}Si NMR data show two peaks at 32.7 and 33.3 ppm, confirming the expected peak splitting for the two diastereometric isomers. We also found two separated peaks for the methine groups at 31.7 and 34.1 ppm and the methyl groups bonded to silicon at 4.5 and 5.4 ppm in the ^{13}C NMR spectra. The ^{11}B NMR data reflect the formation of alkyl(silyl) substituted borazine. Obviously the chiral substituents at boron give rise to a slight overlap forming a peak shoulder at 25 ppm, apart from the main peak at 30 ppm.

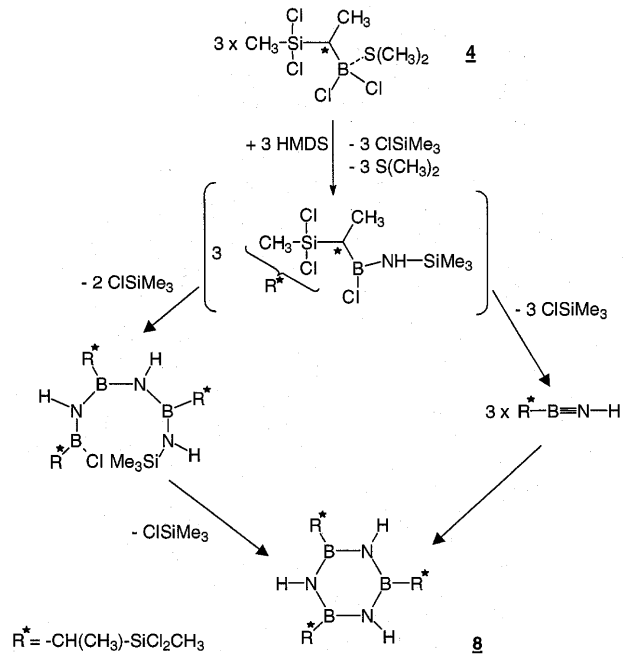

Fig. 6. Intramolecular and intermolecular condensation of **4**.

4. Conclusions and outlook

The hydroboration reaction of unsaturated organosilanes is a promising method for the synthesis of a wide range of single source precursors suitable for the production of preceramic polymers. It was shown that the hydroboration of vinylsilanes with chloroboranes gives access to molecular precursors with Si:B ratios ranging from 3:1 to 1:1. The stepwise substitution of silyl substituted dichloroboranes or monochloroboranes using HMDS or HMDS derivatives can be utilised for further adjustment of the Si:B ratios within these precursors.

The various molecular precursors can be transformed into polyborocarbosilazanes with predefined Si to B ratios by reaction with NH_3 or amines. After a crosslinking step around 300–400°C and pyrolysis at 1000°C, black amorphous ceramics with an unaltered Si:B ratio are obtained which reveal remarkable thermomechanical properties. The materials obtained from **1** and **2** by ammonolysis and subsequent pyrolysis show no further weight loss upon heating to 2000°C [2]. Moreover, a reduced tendency towards crystallization is observed, i.e. the ceramics remain amorphous up to about 1600°C. Other very promising properties are the high stability under oxidizing atmospheres and the very high resistance to creep [27]. Such properties make them potential candidates for applications as fibres and composite materials or as oxidation protective coatings. Interestingly a dependence of the mentioned properties on the elemental ratios as well as the structure of the molecular precursor was found. For example the ceramic prepared from compound **4** is quite unstable compared to that obtained from **1** and **2**. The SiBCN ceramic obtained from **4** exhibits a significant weight loss at $T > 1350$°C [28]. Such different behaviour is the reason for the necessity to prepare molecular precursor with defined elemental ratios. These precursors and the various ceramics prepared therefrom help us to clarify the processes involved during ceramic formation and especially the reasons for different high temperature stabilities of such compounds. In particular, the influence of boron in terms of content and chemical environment on the thermomechanical stability of the ceramics is presently under investigation.

Abstract

The preparation and derivatization of a series of surface functionalized ~30 Å cadmium sulfide nanoclusters possessing surfaces of varied electron demand, tethered covalently to an electroactive fluorescent ruthenium polypyridyl complex, are described. Electrochemical analyses of these nanoclusters bearing ruthenium moieties yield a monotonic relationship between the Ru(II/III) oxidation potential and the electron withdrawing nature of the cluster surface, indicating that the electron density at the electroactive ruthenium center is indeed influenced by remote electropositive and electronegative substituents attached to the nanocluster. Further evidence of cluster mediated electronic interactions between remote surface moieties presents itself in the form of a dependence of the integrated ruthenium based MLCT emission intensity on the mole per cent of attached thiolate capping agent possessing an electron withdrawing substituent in the position *para* to the point of cluster attachment. ©2000 Elsevier Science Ltd. 1. Introduction

Within the past two decades there have appeared numerous examples of experimental and theoretical investigations focused on semiconductor nanoclusters [2–7]. Many of these studies have been predicated on the future application of these interesting nanoscaled materials to molecular electronic devices [8–10]. The unique optical and electronic properties exhibited by semiconductor nanoclusters arise from the quantum size effect, which results from the splitting of the bulk semiconductor band structure into discrete, albeit closely spaced, electronic energy levels and a concurrent widening of the band gap [7]. This phenomenon becomes manifest when the size of the cluster approaches that of the exciton of the semiconductor, and can be thought of as a shift in the behavior of the conduction electrons from Bloch wave mechanics to particle-in-a-sphere wave mechanics. To date, one fundamental question crucial to the eventual development of such proposed devices (i.e. tunnel, negative resistance and coulomb blockade devices, and single electron diodes and transistors) [11–13] still remains unanswered: will the quantum size effect lead to a loss of ability of the semiconductor to mediate electronic communication between surface groups?

Previously, we demonstrated that the electronic and physical properties of thiolate-capped CdS nanoclusters are influenced significantly by the characteristics of substituents in the position *para* to the point of attachment to the cluster on an aromatic thiolate capping agent [14–17], and we presented evidence for facile surface–core communication of conduction carriers [1]. In this contribution we present the preparation of a ruthenium polypyridyl complex which, when attached covalently to mixed surface nanoclusters via previously reported esterification methods [16], serves as an effective electrochemical and fluorescent probe of cluster

mediated electronic communication between remote surface moieties.

2. Experimental

2.1. Chemicals

Water was purified by passage through a Sybron-Barnstead D8902 mixed-bed ion exchange column followed by a Sybron-Barnstead D8204 activated charcoal filter. Reagent grade dimethylformamide (DMF), acetonitrile and methanol were purchased from Caledon Laboratories (Georgetown, Ont., Canada). DMF was dried over 4 Å molecular sieves for 12 h and filtered prior to use, while acetonitrile and methanol were used as received. All deuterated solvents used for ^{1}H NMR spectroscopy were purchased from Cambridge Isotope Laboratories (Andover, MA) in sealed ampules and used immediately upon opening. $RuCl_3 \cdot xH_2O$, sodium sulfide nonahydrate, isatin (2,3-indolinedione), 2-acetylpyridine, and sucrose were purchased from Sigma-Aldrich and used as received. Cadmium acetate (Aldrich reagent grade) was recrystallized with concurrent dehydration from glacial acetic acid and dried at 100°C in vacuo for 24 h. 4-Hydroxythiophenol was obtained reagent grade from Sigma-Aldrich and distilled at reduced pressure immediately prior to use. 4-Nitrothiophenol and 2,2′-bipyridine were obtained reagent grade from Sigma-Aldrich, recrystallized from absolute ethanol and stored in a nitrogen atmosphere at 5°C until required. Phenolic surface CdS nanoclusters (**1**) were prepared using the kinetic trapping method as described previously [16].

2.2. Mixed surface X%NO_2/Y%OH quantum dot synthesis (**2a–2f**)

The synthesis of **2c** (16% NO_2) will be discussed as a representative sample for all mixed surface 'nitro-phenolic' CdS nanoclusters (**2a**–**2f**). Two solutions were prepared in a 1:1:2 MeOH:MeCN:H_2O (v:v:v) solvent mixture. A 20 ml cadmium acetate solution (1.7 g, 7.4 mmol) was prepared and degassed thoroughly with N_2. A second solution (20 ml) of sodium sulfide nonahydrate (0.7 g, 2.9 mmol), 4-nitrothiophenol (0.2 g, 1.3 mmol) and 4-hydroxythiophenol (1.2 g, 9.5 mmol) was degassed and added to the cadmium acetate solution yielding a yellow precipitate. The precipitate was repeatedly sonicated in water and recovered by centrifugation. The precipitate was then suspended in acetonitrile, reprecipitated upon addition of water, recovered by centrifugation, and dried in vacuo for 12 h.

Yield 0.8 g. ^{1}H NMR (DMSO, ppm): δ 8.6–9.02 (m, 1H), 5.9–7.8 (m, aromatic 5H). FT-IR (KBr, cm^{-1}): 3288 (s, v br, O–H stretch), 1654 (s), 1920, 1750 (w, 1,4-disub-ϕ overtone), 1613 (m), 1576 (m), 1489 (vs, NO_2 asymmetric stretch), 1432 (s, ring C=C), 1331 (vs, NO_2 symmetric stretch), 1090 (s), 822 (m), 745 (m, ϕ C–H out-of-plane), 635 (m). UV–Vis (DMF, nm): 404.

2.3. Preparation of 2-(2-pyridyl)-4-carboxyquinoline sodium salt (**3**)

2-(2-Pyridyl)-4-carboxyquinoline was prepared using a modification of the literature preparation described by Bass and Morgan [18]. 18 g (0.12 mol) of isatin (2,3-indolinedione) and 15 g (0.12 mol) of 2-acetylpyridine were combined and stirred for 30 min. The reaction mixture was subsequently cooled to 5°C and 60 ml of 33% aqueous NaOH was added with stirring. The ensuing reaction mixture was warmed to ~60°C. The addition of 60 ml of ice water yielded a purple–red slurry, which was recovered by filtration and washed with water. The crude product was dissolved in a minimum of hot water and decolorized using NORIT activated carbon pellets. Upon cooling, light purple shiny crystals of the sodium salt were obtained and dried in vacuo.

Yield 18.43 g (67%). M.p. >340°C (literature >300°C).

2.4. Preparation of 2-(2-pyridyl)-4-carboxyquinoline (**4**)

17.3 g of **3** were dissolved in 300 ml of water and titrated, with stirring, to pH 7 using 10% HCl. Off-white crystals were recovered by filtration and dried in vacuo.

Yield 13.71 g. M.p. >300°C (literature >300°C). ^{1}H NMR (DMSO, ppm): δ 8.99 (s, 1H), 8.78 (d, 1H), 8.76 (d, 1H), 8.62 (t, 1H), 8.21 (d, 1H), 8.05 (t, 1H), 7.75 (t, 1H), 7.56 (t, 1H). EI-MS (m/z): 250, 206.

2.5. Preparation of cis-[Ru(bpy)$_2$]Cl$_2$ (**5**)

cis-Ru(bpy)$_2$Cl$_2$ was prepared using a modified literature preparation as outlined by Meyer and coworkers [19]. 2.54 g of $RuCl_3 \cdot xH_2O$, 3.78 g (24.20 mmol) of 2,2′-bipyridine and 6.7 g (0.15 mol) of LiCl were refluxed in DMF (40 ml) under a nitrogen atmosphere for 8 h with vigorous stirring. The reaction mixture was allowed to cool to room temperature and then 200 ml of acetone was added. After standing for 18 h at 4°C, a dark solid was recovered, washed three times with 30 ml portions of water and dried in vacuo. The recovered product was subsequently Soxhlet extracted with methylene chloride for a period of 4 days. The purple methylene chloride solution was concentrated to half its original volume and the resultant shiny dark purple crystals were recovered and dried in vacuo.

Yield 1.61 g, 3.3 mmol, (14%). M.p. >300°C. ^{1}H NMR (DMSO-d_6, ppm): δ 10.00 (d, 2H), 8.30 (d, 2H), 8.13 (d, 2H), 7.91 (dd, 2H), 7.51 (dd, 2H), 7.49 (d, 2H), 6.93 (dd, 2H). UV–Vis (methanol, nm): 364, 524.

2.6. Preparation of [Ru(bpy)$_2$(2-PCQH)]Cl$_2$ (**6a**)

cis-Ru(bpy)$_2$Cl$_2$ (0.25 g, 0.52 mmol) was dissolved in 10 ml of methanol and a methanol solution (10 ml) containing $AgNO_3$ (0.241 g, 1.04 mmol) was added. The reaction mixture was stirred for 2 h yielding an orange solution and white precipitate. The precipitate was removed by filtration and

0.13 g (0.55 mmol) of **4** was added. The reaction mixture was refluxed for 16 h under a N_2 atmosphere. The solvent was removed in vacuo, and the orange–red residue was purified by column chromatography on alumina using a 1:1 methanol:chloroform eluent.

Yield 0.31 g, 0.42 mmol (81%). M.p. 280–282°C (dec.). ^{1}H NMR (DMSO-d_6): δ 8.9 (d, 1H), 8.8 (m, 2H), 8.7 (s, 1H), 8.6 (d, 1H), 8.5 (d, 1H), 8.4 (d, 1H), 8.15 (m, 6H), 8.0 (t, 1H), 7.8 (d, 1H), 7.7 (d, 1H), 7.6 (m, 8H), 7.3 (t, 1H). FT-IR (KBr, cm^{-1}): 3410 (m, br, OH stretch), 3070 (m, br, aromatic C–H stretch), 1610 (s, sharp, C=O stretch). UV–Vis (methanol, nm): 450, 482 shoulder. ES-MS (m/z): 334.0, 333.5, 333.0, 332.5, 332.0, 331.5, 331.0, 330.5, 330.0, 329.5, 329.0.

2.7. Preparation of $[Ru(bpy)_2(2\text{-}PCQH)](PF_6)_2$ (**6b**)

0.2 g (0.27 mmol) of **6a** was dissolved in water and the addition of an aqueous solution of excess of NH_4PF_6 resulted in the precipitation of an orange solid. The precipitate was isolated by centrifugation and washed three times with water.

Yield 0.19 g. M.p. 244–246°C (dec.). ^{1}H NMR (DMSO-d_6): δ 9.0 (d, 1H), 8.9 (m, 2H), 8.7 (m, 4H), 8.2 (m, 5H), 8.0 (m, 2H), 7.6 (m, 11H), 7.3 (t, 1H). ES-MS (m/z): 334.0, 333.5, 333.0, 332.5, 332.0, 331.5, 331.0, 330.5, 330.0, 329.5, 329.0.

2.8. Covalent attachment of **6b** to **1**, **2a–2f** via esterification (**7**, **8a–8f**)

The preparation of **7** will be presented as a representative example of the derivatization of CdS nanoclusters with polypyridyl ruthenium probe through an ester linkage. 30 mg of **6b** were refluxed in $SOCl_2$ (10 ml) under a dry N_2 atmosphere for 3 h to yield a purple solution. The excess solvent was removed in vacuo, and 100 mg of imidazole in 10 ml of toluene were added to the purple residue and refluxed for 1.5 h. The toluene was removed and the residue was heated at 60°C in vacuo to sublime excess imidazole from the reaction flask. All procedures involving nanoclusters were carried out under subdued light. 300 mg of **1** were suspended in 10 ml of DMF with sonication. The DMF suspension was added to the reaction flask containing the imidazole derivative of **6b** and stirred for 1 h. The reaction mixture was quenched with water and the resulting orange solid was isolated by centrifugation and purified through repeated sonication/centrifugation cycles in water, methanol and diethyl ether. The solid was dried in vacuo for 12 h.

Yield 105 mg. ^{1}H NMR (DMSO-d_6, ppm): δ 6.0–9.2 (br M, aromatic and OH protons). FT-IR (KBr, cm^{-1}): 3265 (s, v br, OH stretch) 1874 (w, 1,4-disub-ϕ overtone), 1652 (m), 1582 (m), 1488 (s), 1431 (m), 1383 (w), 1256 (s), 1170 (m), 1092 (w), 821 (m), 763 (w), 635 (w). UV–Vis (DMF, nm): 310 (shoulder), 430, 505.

2.9. Electrochemical analysis of **7**, **8a–8f**

2.9.1. Electrode preparation

A homogeneous conductive carbon paste was prepared by thoroughly mixing 1.2 g of graphite powder with 200 μl of heavy paraffin oil. Electrodes were subsequently constructed by thoroughly mixing 100 mg of the standard paste matrix with 20 mg of the nanocluster to be studied, in subdued light, until a homogeneous mixture was obtained. A $\sim$2 mm thick pellet of the paste was formed in the tip of a 1 ml glass syringe (diameter $\sim$2 mm) and electrical contact was achieved via the compression of a silver powder layer which was in turn addressed with a copper wire.

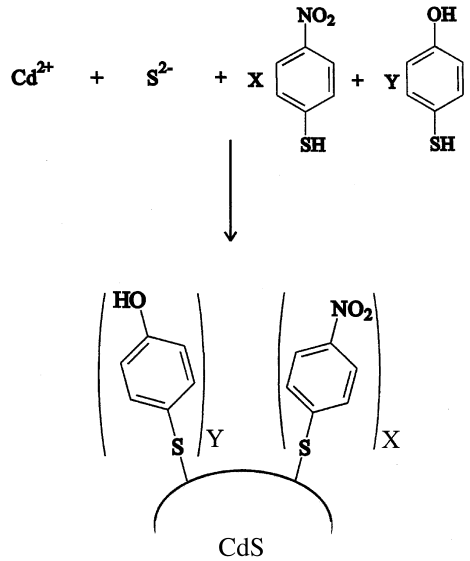
2.9.2. Differential pulse polarography of **7**, **8a–8f**

Differential pulse polarography was carried out using a Cypress Inc. computer controlled potentiostat system in a 0.1 M $TBAPF_6$ acetonitrile solution with a graphite paste working electrode, platinum wire counter electrode and platinum wire pseudo-reference electrode. All electrochemical measurements were calibrated using an internal ferrocene standard. The pulse height, pulse width, and sample time for all differential pulse polarography measurements were 50 mV, 40.0 ms, and 35.0 ms, respectively. Prior to analysis, all electrolyte solutions were thoroughly degassed with argon and all experiments were carried out in an argon atmosphere.

2.10. Voltammetric analysis of **6a**, **6b**

Cyclic voltammetry was performed with a Princeton Applied Technologies PAR 263 potentiostat/galvanostat using an electrode system which consisted of a platinum disk working electrode (diameter 0.5 mm), a platinum wire counter electrode and platinum wire pseudo-reference electrode which were separated from the bulk solution by a polished graphite frit. Samples were prepared in a stock 0.1 M $TBAPF_6$ solution in electrochemical grade dimethylformamide and degassed with dry argon prior to analysis. All measurements were done at a scan rate of 100 mV s^{-1} and potentials were standardized using an internal ferrocene standard.

2.11. Spectroscopic analyses



IR spectra were recorded as KBr pellets with a Mattson 3000 Fourier transform IR spectrometer. ^{1}H NMR spectra were performed on a Brucker ARX 400 MHz nuclear magnetic resonance spectrometer. ^{1}H NMR samples were sonicated in DMSO-d_6 and centrifuged prior to analysis. Electronic spectra were performed in 1 cm quartz cuvettes using a Hewlett-Packard 8452 diode array spectrometer. Solutions for fluorescence studies were thoroughly deoxygenated with argon and measurements were made using a Shimadzu RF-551 spectrofluorometric detector driven by PC-551 software.

2.12. Transmission electron microscopy

Transmission electron microscopy (TEM) was performed using a Phillips EM-301 transmission electron microscope. Nanocluster samples were prepared by placing a few drops of freshly sonicated and centrifuged DMF suspension of the desired cluster (2.5 mg of nanocluster in 3 ml of solvent) onto J.B.EM Services (Pointe Claire, Dorval, Que.) JBS-183 300 mesh carbon coated copper grids (cleaned in acetone, chloroform and again in acetone followed by air drying). The excess solvent was drawn off with a piece of filter paper while holding the grid in non-capillary forceps, leaving aggregates as well as individual nanoclusters adhering to the grid surface. Grids were then air dried at room temperature. Size calibration was performed using a precision silicon grid of 21600 lines cm^{-1}.

3. Results and discussion

The covalent attachment of an electroactive transition metal fluorophore to the surface of a semiconductor nanocluster offers an opportunity to probe the electronic interactions between remote surface moieties as mediated by the quantum dot core. All 'parent' CdS nanoclusters were prepared using a modification of the kinetic trapping method (Scheme 1) thus providing control of the cluster size and surface composition while facilitating the introduction of chemically active moieties [1,14–17,20]. We have successfully controlled the electron withdrawing/donating properties of nanocluster organic surface layers through careful consideration of the surface capping agent composition employed in the initial reaction mixture. By incorporating predetermined mole percentages of an electronegative surface moiety (4-nitrothiophenolate) and an electron donating surface moiety (4-hydroxythiophenolate), we have prepared a series of CdS quantum dots (**2a**–**2f**) with varied surface electronic properties as well as surface moieties which are easily derivatized via well established esterification methods [16].

2a) X=0.06, Y=0.94
2b) X=0.07, Y=0.93
2c) X=0.16, Y=0.84
2e) X= 0.51, Y= 0.49
2f) X= 0.97, Y=0.03

Scheme 1.

Proton NMR analyses of **2a**–**2f** show characteristic homogeneous peak broadening with superimposed structure similar to that discussed for other CdS nanocluster systems indicative of the multiple chemical shift environments and slow cluster tumbling on the NMR timescale [1,14,15,21]. Regions of the ^{1}H NMR spectra of **2a**–**2f** can be assigned to aromatic (~6–8 ppm) and phenolic protons (8.5–9.95 ppm). The integration of these broadened regions provides a suitable determination of the relative percentages of 4-hydroxythiophenolate and 4-nitrothiophenolate actually incorporated as surface caps. The ^{1}H NMR spectrum of **2a**, corresponding to 6 mol% 4-nitrothiophenolate, is shown in Fig. 1. For all mixed surface nanoclusters (**2a**–**2f**), ^{1}H NMR integration ratios indicate that the fraction of 4-nitrothiophenolate surface caps is somewhat greater than that defined by the relative solution mercaptan concentrations during cluster synthesis; this is expected considering the relative acidities of 4-nitrothiophenol ($pK_{a(SH)} = 4.5$) [22] and 4-hydroxythiophenol ($pK_{a(SH)} = 6.75$) [23]. A summary of the ^{1}H NMR spectra and surface compositions for **2a**–**2f** are included in Tables 1 and 2, respectively.

All mixed surface nanoclusters prepared in this work (**2a**–**2f**) lie in a 20–30 Å size regime. The diameters of nanoclusters with low percentages of surface tethered ϕ-NO_2 (**2a**) may be determined by applying tight binding band theory analysis to data obtained from electronic spectroscopy as previously described, and are in good agreement with measurements obtained by TEM and X-ray analysis [14–17,24–26]. Unfortunately, the diameters of clusters with surface mole percentages of the 4-nitrothiophenolate exceeding

about 7% (**2b**–**2f**) cannot be evaluated reliably using electronic spectroscopy as the excitonic absorption of the CdS cluster is obscured by the intense $n \rightarrow \pi^*$ transition of the ϕ-NO_2 chromophore. For these systems, TEM analysis alone was performed to evaluate cluster dimensions. A summary of spectroscopic and TEM determined diameters for **2a**–**2f** may be found in Table 3.

FT-IR spectra of KBr pellets of **2a**–**2f** show absorptions characteristic of the pendant surface groups. As expected, broad absorptions indicative of phenolic functionalities appear at ca. 3300 cm^{-1} for **2a**–**2f**, while the spectra lack the characteristic –SH stretch at 2580 cm^{-1}, thus confirming exclusive thiolate binding of surface moieties. A complete summary of the FT-IR spectra for **2a**–**2f** appears in Table 4.

Polypyridyl complexes of ruthenium have been widely studied [27], and are well known for their stability, long lived charge transfer excited states, intense phosphorescence and well characterized electrochemical properties. Numerous examples of correlations between metal centered electrochemical potentials and electronic properties of chemical moieties on substituents on ligands exist in the literature. The

strong dependence of the metal centered oxidation potential upon electron donating and withdrawing properties of substituted fragments affords a means to probe the effectiveness of a ligand (or nanocluster) to mediate the electronic influence of a remote functionality on a metal center. Indeed, Meyer and coworkers [28–31], as well as others [32–35], have demonstrated that a [*cis*-$Ru(bpy)_2$] fragment serves as an effective probe for the electron interaction of a third ligand with the ruthenium metal center.

Although ruthenium polypyridyl species have previously been attached to TiO_2 nanoparticles by Meyer and coworkers [36,37], and although these materials exhibited interesting properties of solar energy conversion with monochromatic efficiencies of 0.30, no detailed discussion of the electrochemical analysis nor the affects of remote substituents on the ruthenium(II/III) oxidation potential was offered. Hence, we endeavored to link covalently an electroactive polypyridyl ruthenium fluorophore to the surface of quantum sized cadmium sulfide where it serves to probe the extent to which the semiconductor core mediates electron demand between surface groups. To facilitate the covalent attachment of a polypyridyl ruthenium complex to a phenolic surface CdS nanocluster, it was necessary to replace a single bipyridine ligand of $[Ru(bpy)_3]^{2+}$ with a polypyridyl analog bearing a carboxylic acid moiety. 2-(2′-Pyridyl)-4-carboxyquinoline (**4**) offers a carboxylic acid group suitable for esterification and was prepared using the coupling reaction of 4-acetylpyridine and isatin (2,3-indolinedione) as described by Bass and Morgan [18].

The 2D-COSY analysis of **4** shows numerous aromatic signals, the most striking of which is a singlet appearing at 9.0 ppm assigned to the proton in the 3 position. The electron impact mass spectrum of **4** shows a parent peak at $m/z = 250$ corresponding to the loss of a proton and a fragmentation pattern including an intense peak at $m/z = 206$ arising from the loss of $–CO_2$. Scheme 2 illustrates the reaction of **4** with

Scheme 2.

cis-Ru(bpy)$_2$Cl$_2$ yielding ruthenium polypyridyl complex (**6a**) bearing a carboxylic acid functionality which may be exploited as a point of covalent attachment to CdS nanoclusters. The ^{1}H NMR of **6a** is illustrated in Fig. 2, and shows a series of multiplet signals in the aromatic region of the spectrum ($\sim$7.0–10.0 ppm), all of which have been assigned with the aid of 2D NMR. The most striking feature of the ^{1}H NMR spectrum of **6a** is a singlet appearing at 8.67 ppm arising from the unique proton in the 3 position of the 2-2′-pyridylcarboxyquinoline ligand. Peak assignments, chemical shifts, integration ratios and coupling constants for the 2D-COSY spectrum of **6a** are reported in Table 5.

Electrochemical analysis of **6a** shows a well defined reversible Ru(II/III) oxidation process at 1.27 V versus SCE as well as a reversible 2-2′-pyridylcarboxyquinoline reduction at −1.26 V and two reversible bipyridine reductions at −1.57 and −1.93 V versus SCE. In addition, an irreversible chloride oxidation is also observed at 1.18 V versus SCE and will preclude any accurate measurement of changes in the Ru(II/III) oxidation potential of probes tethered to functionalized nanoclusters. Thus, **6a** was converted to the corresponding hexafluorophosphate salt (**6b**) by treatment with excess aqueous NH_4PF_6. The electrochemical analysis of **6b** shows a reversible Ru(II/III) oxidation at 1.27 V versus SCE and three reversible ligand reductions at −1.26, −1.57 and −1.93 V versus SCE, with the chloride oxidation absent.

Electronic and emission spectroscopy of **6a** and **6b** shows the expected MLCT absorptions (450 nm and 482 nm shoulder) and MLCT emission maxima (652 nm), respectively (Fig. 3).

The ^{1}H NMR spectra of all [Ru(bpy)$_2$(PCQ)]$^{2+}$ functionalized CdS nanoclusters (**7**, **8a**–**8f**, Scheme 3) in this

Scheme 3.

work show homogeneously broadened peaks similar to those observed for all nanoclusters discussed previously (**4a**–**4e**), indicating that the cluster core remained intact throughout the derivatization process. The most striking change noted when comparing the ^{1}H NMR spectrum of the ruthenium derivatized CdS functionalized nanoclusters to that of the parent quantum dots is a loss of definition (Fig. 4(b)) between the phenolic and aromatic signal regions previously reported for the corresponding parent nanocluster counterparts (Fig. 4(a)). The increased complexity in the ^{1}H NMR suggests that, as expected, the derivatization process caused an increase in the number of proton environments on the cluster surface. Table 1 summarizes the ^{1}H NMR spectroscopy of **7**, **8a**–**8f**.

FT-IR assignments of KBr pellets of **7** and **8a**–**8f** are summarized in Table 2 The appearance of an absorbance at ~1650 cm^{-1} not present in similar spectra of **1** and **2a**–**2f** confirms the formation of an ester linkage between the phenolic surface functionalities and $[Ru(bpy)_2(PCQ)]^{2+}$. Another significant observation is the appearance of a sharp absorption at 3381 cm^{-1}, characteristic of a non-hydrogen bonded –OH, in the FT-IR spectrum of **8f**, confirming a loss of interaction between surface –OH moieties. Fig. 5 shows the FT-IR spectrum of a KBr pellet of **8f**.

The electronic spectra of CdS quantum dots derivatized with **6b** and bearing low molar percentages of 4-nitrothiophenolate surface caps (**8a**) show the characteristic excitonic shoulder arising from the semiconductor core, while the MLCT absorptions of the pendant ruthenium polypyridyl center are masked by the presence of a weak absorption shoulder arising from the $n \rightarrow \pi^*$ transition of the $-NO_2$. For clusters with greater than about 7 mol% 4-nitrothiophenolate caps, both the excitonic shoulder of the cluster core and the MLCT absorptions of the pendant $[Ru(bpy)_2(PCQ)]^{2+}$ are hidden by the intense absorption attributed to the $n \rightarrow \pi^*$ transition of the $-NO_2$ functionality. The electronic spectrum of **7** is shown in Fig. 6 as a representative example of clusters having surfaces without $-NO_2$ moieties.

For clusters showing excitonic absorptions, **7** and **8a**, it is possible to approximate the core diameter using a tight binding band approach as previously described [24–26]. All of the presented clusters have been found to lie in a size regime of ca. 27 Å. Good agreement was found between tight binding band theory approximations and TEM analyses for clusters **2a**, **7**, and **8a**. A summary of cluster dimensions for **7** and **8a**–**8f** may be found in Table 3.

The properties of the covalently attached ruthenium moieties on **7** and **8a**–**8f** offer two independent methods for the investigation of the electronic processes mediated by the semiconductor core, emission spectroscopy and electrochemistry. All of the presented ruthenium functionalized nanoclusters (**7** and **8a**–**8f**) exhibit MLCT emission characteristic of the tethered ruthenium moiety (**6b**) at ca. 652 nm as shown in Fig. 7. Variation of the mole percentage of 4-nitrothiophenolate surface cap results in a unique relationship between the mole percentage of 4-nitrothiophenolate surface functionality and the integrated fluorescence intensity (Fig. 8(a)). There is an observed rapid decrease in integrated

~50 and ~97%. From this analysis, it is evident that the MLCT emission characteristics are effectively quenched by only a few caps bearing remote electron withdrawing substituents, indicating that electronic communication mediated by the semiconductor core is indeed occurring. Interestingly, electrochemical studies of the same series of ruthenium derivatized nanoclusters exhibit a similar relationship (Fig. 8(b)). Differential pulse polarography of a graphite mull of **7** and **8a**–**8f** shows a broad reversible oxidation process arising from the pendant ruthenium center which shifts between 0.497 and 0.747 V versus SCE with increased mole percentage of 4-nitrothiophenolate surface.

These phenomena may be explained on the basis of a core-mediated electronic inductive effect. The valence and conduction band edges of bulk CdS are 1.36 V and −1.18 V, respectively, relative to an SCE reference [38]. The quantum size effect symmetrically widens the observed band gap of bulk CdS ($E_g = 2.54$ eV) to 3.65 eV for ~30 Å diameter CdS nanoclusters, providing a valence band edge of 1.92 V versus SCE and a conduction band edge at −1.74 V versus SCE at the core interior. However, we have previously shown that changes in the electronic properties of the cluster capping agent, as predicted by the Hammett σ_p parameter, result in an ultimate change in the electronegativity of the cluster surface [1], consequently shifting the positions of the conduction and valence band edges at the cluster core/cap interface, relative to the respective levels in the core interior.

If one considers an electron rich surface (**7**), the valence and conduction bands bend up, rendering the surface relatively electropositive (Fig. 9(a)), which in turn increases the electron density at a pendant ruthenium center via a cluster mediated inductive mechanism, and shifts the Ru(II/III) oxidation potential of the pendant $Ru(bpy)_2(PCQ)$ moiety (1.27 V versus SCE for the free complex; 0.497 V versus SCE for **7**). This dramatic change in Ru(II/III) oxidation potential for cadmium sulfide nanocluster tethered ruthenium polypyridyl probes is comparable to that observed for functionalized TiO_2 clusters [36,37] and is in good agreement with the value of 0.59 V versus SCE determined using the literature analysis of ruthenium based MLCT absorptions as described by Lever and Dodsworth [35].

We report here that as the mole ratio of 4-nitrothiophenolate cap increases from 0 to 0.97, the oxidation potential of the pendant $[Ru(bpy)_2(PCQ)]^{2+}$ moiety increases from

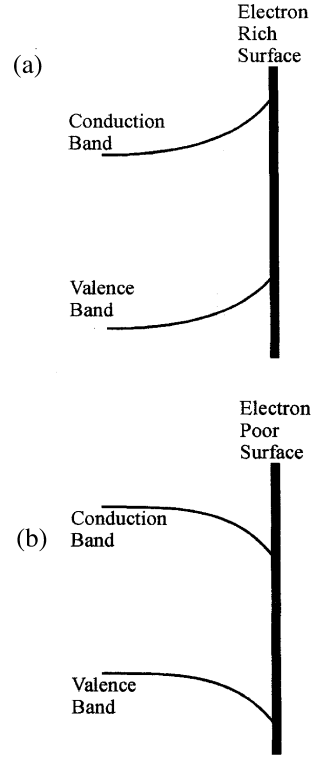

Fig. 9. (a) Electron donating surface caps on Ru-tagged CdS nanoclusters (**7**, **8a**–**8f**) result in an upward bending of the valence and conduction bands, decreasing the cluster surface electronegativity, which in turn results in an increase of electron density at the ruthenium center lowering the Ru(II/III) oxidation potential. (b) Electron withdrawing surface caps cause the conduction and valence bands to bend downward, consequently increasing the cluster surface electronegativity and increasing the Ru(II/III) oxidation potential.

0.497 to 0.747 V versus SCE. Applying the inductive model described above, as the nanocluster surface becomes more electronegative, the valence and conduction bands bend down and the electron density will be depleted at the ruthenium center (Fig. 9(b)), shifting the Ru(II/III) redox couple to higher potentials.

The core-mediated inductive model is also consistent with the observed quenching of the Ru based MLCT emission. In the case of an electron rich surface (**7**), the conduction band edge is bent up above the PCQ π^* level, and the excited π^* electron of $[Ru(bpy)_2(PCQ)]^*$ remains localized within the ligand orbital, ultimately relaxing via MLCT emission. Conversely, for a relatively electronegative surface, the conduction band edge bends below the PCQ π^* level, resulting in electron capture and concurrent fluorescence quenching.

4. Conclusions

We have presented the synthesis and characterization of a series of CdS nanoclusters having controlled surface electron demand, and bearing an electroactive ruthenium polypyridyl fluorophore. Electrochemical and emission studies of these interesting materials have yielded conclusive evidence that electronic communication can indeed be mediated by CdS nanoclusters via a core-mediated inductive mechanism. These results further suggest the possibility that surface functionalized semiconductor nanoclusters may possess device activity.

POLYHEDRON

Photolithographic deposition of conducting gold films from thin amorphous films of $AuPR_3X$ ($X = NO_3$, RCO_2) on silicon surfaces

J. Pablo Bravo-Vasquez, Ross H. Hill *

Received 2 May 1999; accepted 30 July 1999

Abstract

The photochemical reactions of amorphous films of $AuPR_3X$ ($X = NO_3$, RCO_2) on silicon surfaces are presented. In each case these precursors could be used to form amorphous thin films on silicon substrates by spin coating. The photolysis of these films was monitored by FTIR spectroscopy and the products analyzed by Auger electron spectroscopy. The photolysis with 254 nm light led to the loss of the anionic ligand from the film. The phosphine ligand also diffused from the film although far less efficiently. The purity of the contaminated films could be improved by a heat treatment at 150°C. The films following this heat treatment were approximately 90 at.% gold. This process was then used to lithograph gold patterns on silicon surfaces. A feature size of 1.2 μm was demonstrated. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

In this paper we outline a method for the deposition of patterned gold films from gold complexes by photochemical metalorganic deposition (PMOD). Gold has properties such as oxidation resistance and high conductivity which make it desirable for use in microelectronics [1]. As the minimum feature size in electronic devices decreases, there is an increasing pressure to use higher conductivity metals as interconnects in the semiconductor industry. This has necessitated the recent change from aluminum to copper for some applications [2]. Gold, like copper, has a higher conductivity than aluminum and its use may be advantageous in some applications.

Metal complexes have been used as precursors to generate thin films of metals and metal oxides by both chemical and photochemical vapor deposition pathways [3–11]. For the production of patterned films, however, photo induced processing is desirable. For gold, considerable work has been done on laser processing by laser induced CVD [12–14]. The laser processing has the disadvantage of high local temperatures during the processing. A photochemical approach has also been taken in processing films consisting of polymers containing metal complexes or particles [15,16]. A related method relies on photolithographed SAMs to transfer the image via metallization yielding patterned gold [17]. The photochemical pathway has the advantage that photolysis through a mask can result in a patterned deposition process. In our research we have utilized thin films of inorganic and organometallic complexes as precursors to metal and metal oxide films [18–27]. In these studies, films of the precursor complexes are converted photochemically in the solid state to thin films of a metal [18,19] or metal oxide [20–27].

Previously we have demonstrated the fabrication of metal and metal oxide structures via photolysis of amorphous films of inorganic precursor through a lithography mask [18–23,25–27]. The amorphous film is formed by spin coating the substrate with a solution of the precursor molecule. This is followed by the irradiation of the surface film through a lithography mask to produce the patterned structures. Generally we find that the product of this reaction in air is the metal oxide. Normally the metal, liberated photochemically, reacts with atmospheric oxygen to yield the metal oxide. In vacuum or an inert atmosphere the metal may be formed directly. Gold presents an opportunity for the direct formation of a metal in air.

2. Results

2.1. Spectroscopic data for the complexes

All the complexes studied here could be cast from methylene chloride solvent as optical quality thin film on both

PII S0277-5387(99)00364-2

silicon chips and CaF_2 optical flats. The FTIR spectral data described in this section were obtained as transmission spectra on CaF_2 substrate. The FTIR spectra of the relevant complexes as thin films are summarized in Table 1.

The nitrate complex $AuPPh_3NO_3$ is characterized by nitrate bands at 1499, 1279 and 979 cm^{-1}. It is worth noting that these bands are not significantly shifted from the energies of 1500, 1270 and 980 cm^{-1} reported for the complex in Nujol mull [28,29]. In this region there are other bands associated with the phosphine ligand at 1437 and 1480 cm^{-1}. The triethylphosphine derivative, $AuPEt_3NO_3$, exhibited absorption bands in the same region characteristic of the nitrate ligand. In addition, to these bands, the CH stretching vibrations of the ethyl groups in the region of 2900 cm^{-1} were also observed.

The FTIR spectra of films formed from the carboxylato complexes are also included in Table 1. The complex $AuPPh_3(OOCCH_3)$ exhibited intense bands characteristic of the symmetric and antisymmetric bands of the coordinated acetate group at 1626 and 1306 cm^{-1}. These bands are consistent with those reported for this complex in a Nujol mull [29] at 1632 and 1310 cm^{-1} and have been interpreted as being associated with a unidentate acetate group. In addition to these bands there are additional absorption bands at 1590 and 1369 cm^{-1}. These weaker bands may be indicative of other coordination modes being present in the amorphous film.

The spectrum of $AuPEt_3(OOCCH_3)$ was very similar to that of the triphenylphosphine derivative. The most intense bands were associated with the symmetric and antisymmetric carboxylate stretches at 1626 and 1310 cm^{-1}. In addition to these, a second pair at 1597 and 1369 cm^{-1} were observed. The only substantial difference was that the stretches associated with the alkyl CH bonds of the triethylphosphine ligand were apparent near 2900 cm^{-1}.

The complex $AuPPh_3(OOCCH(OH)CH_3)$ displayed antisymmetric and symmetric carboxylate stretching modes at 1628 and 1314 cm^{-1}. For this complex the hydroxyl stretch of the lactate ligand was observed at 3443, shifted significantly from the literature value of 3390 cm^{-1} [30]. The triethylphosphine complex exhibited a similar FTIR spectrum. The hydroxyl stretch for this complex was observed at 3455 cm^{-1}. As with the other triethylphosphine complexes, additional bands associated with the CH stretches of the ligand were observed in the region of 2900 cm^{-1}.

Electronic absorption spectra for amorphous films of the pure compounds were obtained from thin films on CaF_2 and the results are summarized in Table 2. The complex $AuPPh_3NO_3$ is characterized by the presence of absorption bands at 200 and 249 nm. Presumably these are associated with charge transfer transitions between the phosphine and nitrate ligands and gold. The intensities of these transitions relative to the FTIR transitions are also given in Table 2. The calibration of the absolute intensities was hampered by problems with partial decomposition of solutions of the gold com-

plexes. As we will see, these complexes are both light and heat sensitive.

The remaining complexes also have absorptions in this spectral region and the absorption bands are summarized in Table 2. In each case there are intense bands in the UV spectrum near 254 nm. In the following photochemical study of the films we will use 254 nm light to initiate the photochemistry.

2.2. Photochemistry of $AuPPh_3NO_3$ and $AuPEt_3NO_3$

In order to study the photochemistry, an amorphous film of $AuPPh_3NO_3$ was cast on a silicon chip. The initial FTIR spectrum of the complex was obtained as a transmission spectrum through the band gap of silicon. The spectroscopic changes resultant from the photolysis of a thin film of $AuPPh_3NO_3$ were then obtained and are shown in Fig. 1. The bands associated with the nitrate at 1497, 1267 and 979 cm^{-1} all decrease in intensity. This decrease appears to be accompanied by the growth of bands associated with triphenylphosphine oxide at 1200 and 1121 cm^{-1}. The overlap between the bands associated with triphenylphosphine and its oxide do not allow us to determine whether all of the triphenylphosphine is oxidized. The bands associated with the aryl groups bound to phosphorus at 1480 and 1437 cm^{-1} decrease at a much slower rate. Following prolonged photolysis no bands associated with the nitrate ligand are observed within the film. This indicates the loss of all starting material. Bands associated with the aryl groups bound to phosphorus and the phosphine oxide continued to decay although at a much slower rate. Presumably this is associated with the diffusion of the triphenylphosphine out of the film. It is important to note that there must be some interaction between the triphenylphosphine and its oxide and the gold during this process, however, no absorption bands associated with the formation of intermediate gold complexes were observed during the photochemical reaction. This is consistent with the overall photoreaction shown in Eq. (1).

$$AuPPh_3NO_3 \xrightarrow{h\nu} Au + NO_3 + PPh_3 \quad (1)$$

It is notable that in Eq. (1) we depict the photoreaction as

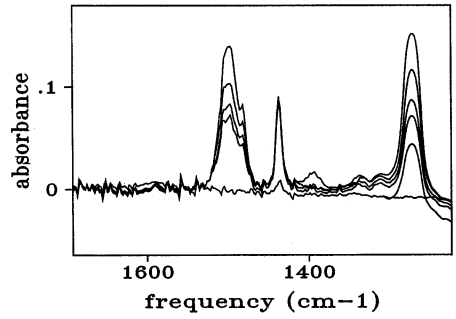

Fig. 1. FTIR spectra associated with the photolysis of an amorphous film of $AuPPh_3NO_3$ for 0, 5, 44, 94, and 200 min followed by thermolysis at 150°C for 1 min.

generating triphenylphosphine directly. The oxidation to the phosphine oxide we believe occurs in a separate unrelated step. Our evidence for this is that the exposure of films of triphenylphosphine in air to the photolytic conditions results in their conversion to the phosphine oxide. This does not rule out other processes also contributing to the formation of the phosphine oxide, but does establish that the proposed mechanism is plausible.

FTIR spectroscopic data following photolysis of the compound indicate loss of all starting material. In order to measure the residual ligand remaining within the films, the resultant films were analyzed by Auger electron spectroscopy. The analysis of films produced from $AuPPh_3NO_3$ is consistent with the loss of NO_3 and some PPh_3 from the film leaving a film composed primarily of gold, phosphorus and carbon (Table 3). The surface layer was removed by sputtering and the composition of the interior of the film is also indicative of the retention of some PPh_3. There is no evidence for oxygen, indicative of triphenylphospine oxide, within the film. The ratio of carbon to phosphorus is higher than expected although this may be indicative of problems associated with some charging of the film during data collection. The key result here is that most of the phosphine is lost from the film. This can be taken as an indication that the photochemistry results in the formation of gold rather than a molecular complex. The gold however retains some phosphine

Table 3
Properties of the films: composition of initial films by FTIR, thickness of the initial films and composition of the final films by Auger analysis

impurity. The results of both the IR and Auger experiments suggest the production of metallic gold as the product film.

Similar experiments were conducted with the triethylphosphine complex $AuPEt_3NO_3$. The results were consistent with the findings for the triphenylphosphine complex. Irradiation resulted in the loss of the ligands from the coordination sphere and the observation of no new IR active products. Once again the bands associated with the nitrate ligand were observed to decay much faster than those associated with the phosphine ligand. In this case the spectra did not provide evidence for the formation of triethylphosphine oxide although it appears reasonable to assume that at least some of the triethylphosphine would oxidize in air. Auger results are indicative of the loss of all the nitrate from the film and some loss of the phosphine ligand. Once again significant organic contamination remained in the film. In this case the amount of carbon and oxygen is suggestive of some external contaminants contributing to the impurity. However, the Auger results indicate that the photochemistry produces an impure gold film rather than a molecular complex. The result of the experiments are all consistent with the photochemistry being that shown in Eq. (2).

$$AuPEt_3NO_3 \xrightarrow{h\nu} Au + NO_3 + PEt_3 \quad (2)$$

2.3. Photochemistry of $AuPPh_3(O_2CCH_3)$, $AuPEt_3(O_2CCH_3)$, $AuPPh_3(O_2CCH(OH)CH_3)$ and $AuPEt_3(O_2CCH(OH)CH_3)$

The spectral changes resulting from the photolysis of an amorphous thin film of $AuPPh_3(O_2CCH_3)$ are summarized in Fig. 2. Photolysis resulted in the loss of absorbance associated with the coordinated carboxylate group at 1626, 1597, 1366 and 1306 cm^{-1}. During the photolysis the relative ratio of these bands remained constant, indicating that no thermally stable intermediate was formed in the photoreaction. The absorption bands associated with the phosphine ligand at 1481 and 1435 cm^{-1} did not change at a proportionate rate but at a much slower rate. These bands are presumably related to the presence of either phosphine or gold phosphine complexes in the film. Also evident from the times given in the caption to Fig. 2 is a slowing of the rate of the photoreaction with time. This decrease in decay rate is at least in part associated with the lessening absorbance of the starting material as the reaction progresses. This effect is expected to be significant since the initial stages of the reaction are occurring under conditions where the starting material absorbs 100% of the incoming light. As the reaction progresses this percentage decreases as a result of the decrease in the amount of starting material remaining and also as a result of competitive absorption (or reflection) by the photoproducts. This effect is expected to be extreme when a gold mirror is on the surface. In order to complete this reaction the surface was heated to 150°C. The result of this heating was the loss of all absorption bands in the FTIR spectrum. For thinner films exhaustive photolysis resulted in the loss of all carboxylate absorption bands.

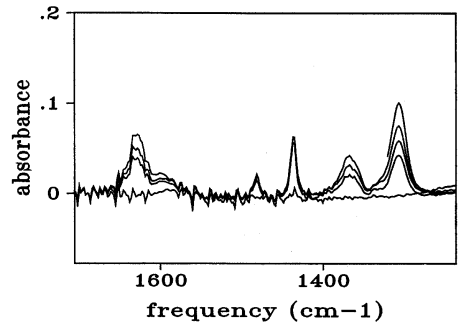

Fig. 2. FTIR spectra associated with the photolysis of an amorphous film of $AuPPh_3(OOCCH_3)$ for 0, 60, 430, and 880 min followed by thermolysis at 150°C for 1 min.

The film produced by the photolytic reaction was examined by Auger electron spectroscopy and the results are summarized in Table 3 (the film used for this study was not subjected to the heat treatment used on the sample of Fig. 2). Clearly the photolysis resulted in the loss of the carboxylate ligand from the film. This is indicated by the lack of oxygen in the film as observed after sputtering. The film has some remaining phosphorus indicative of some triphenylphosphine remaining in the film. The ratio of phosphorus to carbon in the film is consistent with triphenylphosphine being the sole source of carbon contamination. The experimental data are all consistent with the reaction shown in Eq. (3). The detailed analysis of the reaction will be deferred to Section 3.

$$AuPPh_3(O_2CCH_3) \xrightarrow{h\nu} Au + CO_2 + \cdot CH_3 + PPh_3 \quad (3)$$

Similar results were obtained with the triethylphosphine complex $AuPEt_3(O_2CCH_3)$. Photolysis of an amorphous film consisting of this complex resulted in the loss of FTIR bands associated with the starting complex and the formation of a gold film. Once again bands associated with the carboxylate ligand decayed at a much faster rate than those associated with phosphine. The resultant film was subjected to Auger analysis. As can be seen from Table 3 there is a much higher retention of carbon than can be explained on the bases of the phosphine being the sole source of organic impurity. In this sample significant other impurity must be present.

The photochemistry of amorphous thin films of the lactate phosphine complexes was also examined. In all cases the results were similar to those above. Photolysis led to the loss of the carboxylate ligand at a greater rate than the phosphine ligand. Spectroscopic evidence suggested that in the case of $AuPPh_3(O_2CCH(OH)CH_3)$ some of the photoproduced triphenylphosphine was oxidized to the phosphine oxide. Consistent with these results, the Auger was indicative of substantial phosphine or phosphine oxide retention within the product film. In the case of the triethylphosphine containing precursor, only a quarter of the phosphine remained in the film while in the case of the triphenylphosphine containing precursor there was no evidence for loss of the phosphine

from the film. This latter result is however in question as charging made the examination of the surface after sputtering unreliable. The photoreactions of all the carboxylate complexes are summarized in Eq. (4).

$$AuPR_3(O_2CR') \xrightarrow{h\nu} Au + CO_2 + \cdot R' + PR_3 \quad (4)$$

2.4. Thermal chemistry of $AuPR_3(NO_3)$ and $AuPR_3(O_2CR)$

While is was apparent that the chemistry initiated with light could be used to pattern surfaces, the Auger spectroscopy indicated that the films all retained significant impurities. In this section we explore the use of thermal treatment to improve the purity of the surfaces. A brief study of the thermal chemistry of the amorphous films was conducted. A film of $AuPPh_3(NO_3)$ was cast onto a silicon chip and the FTIR spectrum obtained. The sample was heated to 150°C and the FTIR spectrum obtained again. No thermal products were apparent from the spectrum and all bands attributable to the starting material were lost, including those associated with the phosphine ligand. Auger analysis indicated that the film consisted of 90% gold with some remaining phosphorus (1%) and carbon (9%). The resulting film was conductive and a four-point probe measurement yielded a sheet resistance of 40 μΩ cm. This value is significantly higher than the bulk value of 2.8 μΩ cm [1]. One reason for this discrepancy may be the poor signal to noise of our measurement. At high enough current density for measurement the electrodes used were glowing and a deposition of some sort appeared on the surface of the film.

The above results were general and appeared to be insensitive to the phosphine ligand combination chosen. In addition, complexes photolyzed then subjected to thermal treatment gave similar results.

2.5. Lithography

This surface photochemistry is compatible with lithography allowing us to pattern surfaces. This was demonstrated by irradiation of a surface film of $AuPPh_3(O_2CCH_3)$ through a lithography mask. The mask was set up in contact with the surface negating the need for optics. The films were exposed with 254 nm light for 2 h through the mask. The resultant latent image was formed and the surface developed with a methylene chloride rinse. The resultant image is shown in Fig. 3. Clear formation of lines 1.2 μm by 50 μm is visible. Similar results were found for films constructed of the other complexes.

3. Discussion

The complexes studied here all provide useful staring materials for the deposition of gold films. These compounds all spin coat well to yield optical quality amorphous films.

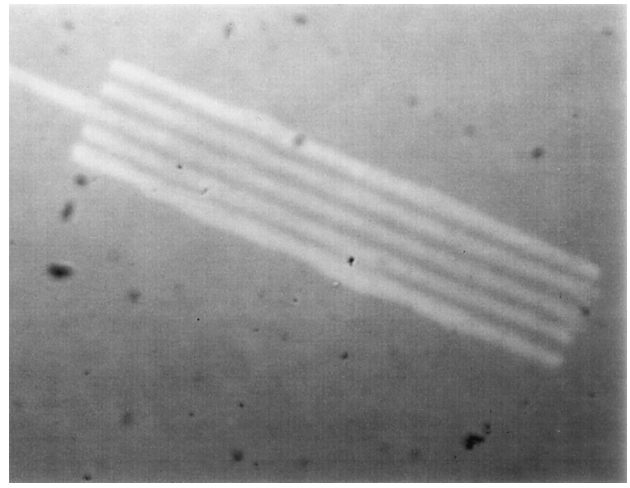

Fig. 3. Optical micrograph of surface obtained by the photolithography of $AuPPh_3(O_2CCH_3)$ on a silicon surface. An internal scale is provided by the 50 μm length of the lines.

The complexes with the films provide FTIR spectral data consistent with their formulation as monomeric complexes within the film entirely analogous to the structure in a mull or in solution.

The photochemical reactions all appear to follow a charge transfer transition. In the case of $AuPPh_3(NO_3)$ this would result in the formation of gold(0) and the nitrate radical. The nitrate radical would then be lost from the film, leaving gold phosphine clusters. Such clusters have been proposed as intermediates in the thermal reactions of gold compounds [30]. These are evidently unstable in the film and gold metal is formed.

The reactions of the carboxylate complexes can be rationalized in a similar fashion. Charge transfer transitions result in the extrusion of carbon dioxide from the carboxylate and the resulting formation of a gold(0) phosphine and an organic radical. The radicals can combine in the film yielding volatile organic fragments. The gold(0) phosphine decomposes to yield an impure gold film. The purity of the film may be enhanced by heating the films following the photochemistry.

The lithographic images presented establish that this process can be used to pattern gold films. This were done by simple contact printing on a laboratory bench and is not meant to imply that we have established limits on the feature size available by this process. The quality of the image does however establish that the optical quality of the film is retained throughout the deposition process. This presumably is the result of self healing of the film during the photoreaction. Surface diffusion of molecules of the precursor from areas of high surface energy to areas of lower surface energy results in the self healing of the film. The quality of the films produced indicates that the rates of surface diffusion of these precursors are acceptable for this surface healing to occur.

4. Conclusions

The studies described here establish that conducting gold films can be deposited by photochemical metal organic dep-

osition. The photoreactions are dependent upon the anionic ligand. For $AuPR_3(OOCR')$ the initial charge transfer transition results in the loss of CO_2 and the formation of an organic radical and $AuPR_3$. Photolysis of $AuPR_3NO_3$ results in the expulsion of the nitrate ligand and the production of $AuPR_3$. In each case the gold containing product is not stable and loses phosphine yielding gold films.

The use of this process for lithographic deposition of gold has been illustrated. The most practical way to achieve lithography in these complexes is with the combination of the thermal and photochemical routes.

5. Experimental

The silicon wafers were obtained from Wafernet. The Si(111) surface was used in these studies and the wafers were p-type silicon cut to the approximate dimensions of 1 cm × 1.5 cm in house. The CaF_2 crystals were obtained from Wilmad Glass Co. Inc.

The FTIR spectra were obtained with 4 cm^{-1} resolution using a Bomem Michelson 120 FTIR spectrophotometer. Electronic absorption spectra were obtained with a HP 8452A diode array spectrometer. The photolysis was conducted with the 254 nm output of a low pressure mercury lamp. Auger spectra were obtained using a PHI double pass CMA at 0.85 eV resolution at the Surface Physics Laboratory, Department of Physics, Simon Fraser University. Optical microscopy was conducted with a Leitz Laborlux 12 MES optical microscope. The chromium plated quartz lithography mask was kindly donated by IBM.

The complexes $AuPPh_3(O_2CCH_3)$ and $AuPPh_3(O_2CCH(OH)CH_3)$ were prepared by literature procedures [29,30]. The remaining complexes, $AuPEt_3NO_3$, $AuPEt_3(O_2CCH_3)$ and $AuPEt_3(O_2CCH(OH)CH_3)$ were prepared by routes analogous to the literature preparations of the PPh_3 complexes [28–30].

5.1. Calibration of absorption on the surface

A solution of $AuPPh_3NO_3$, in methylenechloride was used to spin coat a silicon chip. The resultant sample was mounted in the FTIR spectrometer and the spectrum determined. The spectrum is summarized in Table 1. A similar procedure was used to obtain the spectra of all the complexes studied here.

The electronic absorption spectra were obtained by spin coating samples onto CaF_2 plates. The energies of the electronic transitions are obtained directly while the extinction coefficients were obtained relative to the intensities of the IR transitions. Energies and relative extinction coefficients for all the compounds are reported in Table 2.

5.2. Photolysis of complexes as films on silicon surfaces

An amorphous film of $AuPPh_3(NO_3)$ on a silicon surface was prepared by dispensing a CH_2Cl_2 solution containing the gold complex onto a spinning silicon chip. This resulted in the formation of a uniform, amorphous coating on the chip. The FTIR spectrum of the film deposited on the chip was obtained. The sample was then irradiated for 5 min and another FTIR spectrum was obtained. This procedure was repeated for the following (accumulated) photolysis times: 44, 94 and 200 min. The spectra are presented in Fig. 1.

A sample prepared in a similar fashion was investigated in the scanning Auger microprobe for elemental analysis of the surface. The results are presented in Table 3.

A similar procedure was used to monitor the photoreactions of all the complexes studied here.

5.3. Lithography

A film containing $AuPPh_3(O_2CCH_3)$ was spin coated onto a silicon chip, as described above. This sample was then photolyzed through a mask in contact with the surface. The film was then rinsed with methylene chloride to yield the image shown in Fig. 3.

Abstract

MOCVD is a promising technique for the deposition of the pyroelectric oxide lead scandium tantalate, $Pb(Sc_{0.5}Ta_{0.5})O_3$. In order to exploit the full potential of the method, it is important to identify the optimum combination of precursors so that process parameters and film properties are optimised. In this paper, issues involved in the selection of suitable Pb, Sc and Ta precursors are discussed and the molecular design of new Ta and Sc sources is described. It is shown how the use of carefully matched precursors allows the growth of $Pb(Sc_{0.5}Ta_{0.5})O_3$ in the required perovskite phase at low substrate temperatures. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Metal–organic chemical vapour deposition; Precursors; Lead scandium tantalate; Ferroelectric oxides

1. Introduction

Thin films of the ferroelectric oxides $Pb(Zr,Ti)O_3$, $Pb(Mg,Nb)O_3$ and $Pb(Sc_{0.5}Ta_{0.5})O_3$ have important applications in pyroelectric [1], and piezoelectric devices [2]. Various techniques have been used for the deposition of such oxides, including reactive sputtering [3], sol–gel deposition [4,5] and metal–organic chemical vapour deposition (MOCVD) [6–8]. Of these techniques, MOCVD offers the most flexible approach, having the advantages of large area deposition capability, good composition control and film uniformity, high film densities and deposition rates, and excellent conformal step coverage at device dimensions less than 2 μm, which is particularly important in microelectronics applications.

An essential requirement for successful MOCVD is the availability of suitable precursors with the appropriate physical properties for transport and reactivity for deposition. There must be an adequate temperature window between precursor vaporisation and decomposition, and for most electronics applications oxide deposition is limited to temperatures in the region of 500°C, to prevent degradation of the underlying silicon circuitry and metal interconnects.

The most accessible and widely used precursors for ferroelectric oxide MOCVD are metal alkoxides and β-diketonates [9], which generally have quite low equilibrium vapour pressures, typically in the order of 1 Torr at 200°C. In order to overcome this inherent involatility, liquid injection MOCVD, in which a solution of the precursor is injected into a heated evaporator, is now widely used [10,11]. This approach minimises thermal degradation of precursors, but leads to the added requirements that the precursor must be stable for long periods in solution, and must not react with other precursors in the solution. Precursor solutions should also evaporate at a common temperature without decomposition, otherwise blockages will eventually occur in the evaporator. Ideally, the separate precursors should also decompose to deposit oxide film in a similar temperature regime in order to optimise film uniformity. Although acceptable MOCVD performance and high quality ferroelectric films can often be obtained using existing precursors, in the case of more complex oxides it is sometimes necessary to 'tailor' the precursor to improve compatibility with other precursors and to optimise process parameters such as precursor evaporation temperature and oxide deposition temperature. In this paper we discuss one approach to the selection

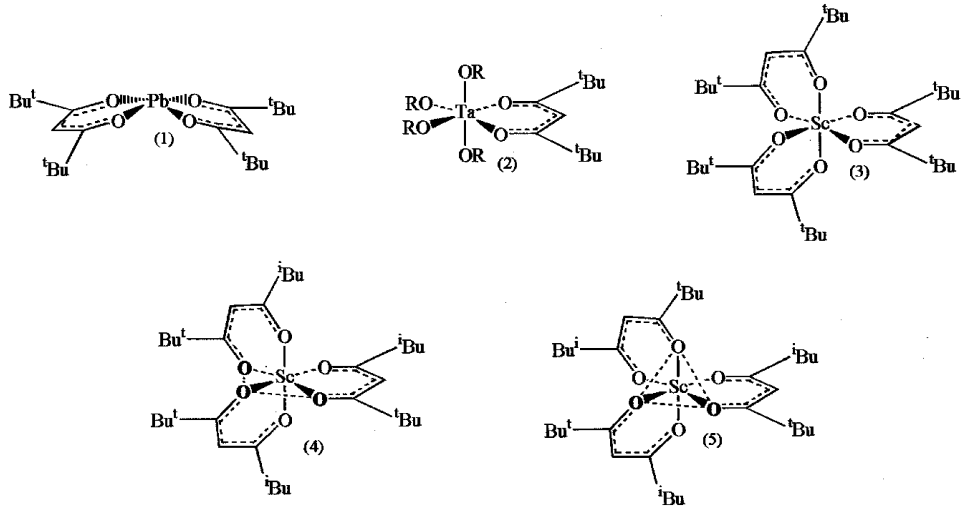

Fig. 1. Molecular structures of some lead, scandium and tantalum compounds used in this study. (1) $Pb(thd)_2$, (2) $Ta(OR)_4(thd)$, (3) $Sc(thd)_3$, (4,5) $Sc(tmod)_3$. In the solid state $Sc(tmod)_3$ exists as a mixture of meridional and facial isomers (4) and (5). In solution the statistically preferred facial isomer predominates.

and design of precursors for the deposition of $Pb(Sc_{0.5}Ta_{0.5})O_3$ by liquid injection MOCVD. $Pb(Sc_{0.5}Ta_{0.5})O_3$ is a sensitive pyroelectric oxide with a high figure of merit which has applications in uncooled thermal imaging, including night sight technologies and fire detection [12].

2. Precursor selection

2.1. Pb precursors

Although PbO and $Pb(Zr,Ti)O_3$ can be deposited using lead alkyls or alkoxides such as tetraethyllead, $PbEt_4$, lead *tert*-butoxide, $Pb(OBu^t)_2$, and triethyllead neopentoxide, $Et_3Pb(OCH_2C(CH)_3)$, their high toxicity and reactivity, coupled with their high volatility, make them difficult to handle and extremely hazardous to use in liquid injection MOCVD.

In contrast, lead β-diketonates are less toxic and have lower vapour pressures, which minimises the toxic release hazard. Therefore the following precursors have all been used in MOCVD: $Pb(thd)_2$ (thd = 2,2,6,6-tetramethyl-3,5-heptanedionate), Pb(acetylacetonate)$_2$, Pb(hexafluoroacetylacetonate)$_2$, $Pb(fod)_2$ (fod = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionate) [6]. The fluorine-containing compounds $Pb(hfac)_2$ and $Pb(fod)_2$ can lead to high levels of fluorine contamination in the oxide films, decomposing above 300°C to form a PbF_2 phase [6]. Consequently, the most volatile of the non-fluorine containing precursors $Pb(thd)_2$ is at present the precursor of choice for the MOCVD of lead oxide based ferroelectrics $Pb(Zr,Ti)O_3$ and $Pb(Sc_{0.5}Ta_{0.5})O_3$.

$Pb(thd)_2$ is a monomeric molecule [13], see Fig. 1, which gives it a reasonably high vapour pressure for a β-diketonate compound of 0.1 Torr at 128°C. In liquid injection MOCVD [11], an evaporator temperature of 200°C is sufficient to give acceptable PbO growth rates at substrate temperatures above 400°C, with maximum growth rates occurring in the region 450–500°C [11]. However, at evaporator temperatures greater than 250°C, $Pb(thd)_2$ begins to decompose to deposit an oxide residue, and at substrate temperatures greater than 500°C desorption of PbO from the substrate occurs. Therefore, for the growth of $Pb(Sc_{0.5}Ta_{0.5})O_3$ with good uniformity, it is necessary to identify the Sc and Ta sources which most closely match the evaporation and deposition characteristics of $Pb(thd)_2$.

2.2. Sc precursors

The choice of Sc precursor is more limited than that of Pb, with the available Sc sources being restricted to β-diketonates such as $Sc(thd)_3$. This molecule is monomeric [14] with octahedral coordination at the metal atoms, see Fig. 1, and it deposits oxide films over a conveniently wide temperature regime of 450 to at least 600°C (see Fig. 2), showing reasonable overlap with the $Pb(thd)_2$ oxide deposition zone (450–500°C) [15]. However, $Sc(thd)_3$ is significantly less

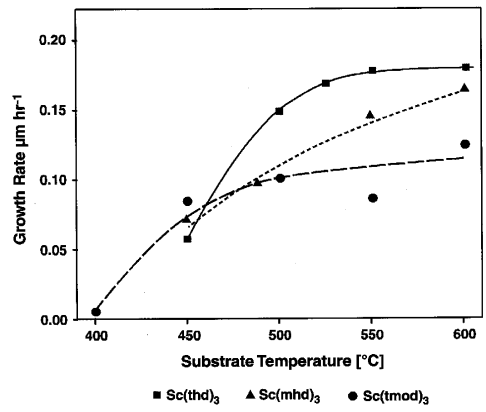

Fig. 2. Variation in oxide growth rate with substrate temperature for $Sc(thd)_3$, $Sc(tmod)_3$ and $Sc(mhd)_3$.

volatile than $Pb(thd)_2$, and consequently the evaporator temperature must be approximately 300°C to obtain adequate Sc_2O_3 growth rates. This can lead to decomposition of the $Pb(thd)_2$ and the Ta alkoxide precursors, and so a more volatile Sc oxide source than $Sc(thd)_3$ would be very desirable.

Asymmetric β-diketonate ligands R′C(O)CHC(O)R″, containing two different R groups, such as tmod (2,2,7-trimethyloctane-3,5-dionate) and mhd (6-methylheptane-2,4-dionate) (see Fig. 3) have been shown to influence significantly the volatility of yttrium β-diketonates [16]. The lack of symmetry and increased disorder associated with the tmod and mhd ligands can be expected to disrupt the molecular packing of the metal β-diketonates, thereby increasing the precursor vapour pressure [16]. We have therefore investigated the sterically hindered scandium β-diketonates $Sc(tmod)_3$ and $Sc(mhd)_3$ as alternatives to $Sc(thd)_3$, and a schematic of the $Sc(tmod)_3$ structure is shown in Fig. 1. TGA data for the various Sc β-diketonates, shown in Fig. 4, indicate that $Sc(tmod)_3$ and $Sc(mhd)_3$ both evaporate at lower temperature than $Sc(thd)_3$. The residues of between 5 and 10 wt.% remaining after the evaporation of $Sc(tmod)_3$ and $Sc(mhd)_3$ are not intrinsic features, and arise from slight sample decomposition due to the presence of trace oxygen and moisture during analysis of very small samples (ca. 10 mg).

Both $Sc(tmod)_3$ and $Sc(mhd)_3$ were shown to deposit oxide over a wide temperature range (Fig. 2), fully compatible with the oxide deposition temperature from $Pb(thd)_2$. In particular, the new $Sc(tmod)_3$ source looks to be ideally suited to the MOCVD of $Pb(Sc_{0.5}Ta_{0.5})O_3$, however the tmodH ligand is significantly more expensive than thdH which may somewhat limit the utility of $Sc(tmod)_3$ as an alternative to $Sc(thd)_3$.

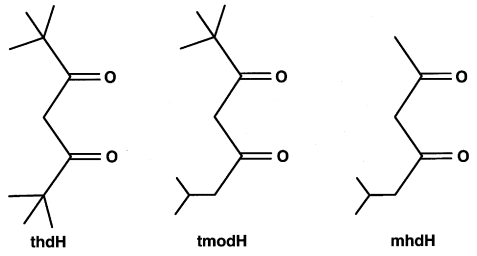

Fig. 3. β-diketone ligands used to influence the volatility of Sc(β-diketonate)$_3$ complexes.

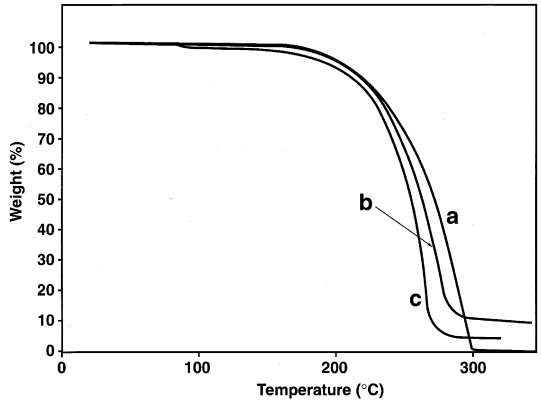

Fig. 4. Typical TGA data for some *tris*-β-diketonates of scandium: (a) [$Sc(thd)_3$], (b) [$Sc(mhd)_3$], (c) [$Sc(tmod)_3$]. Sample weight ca. 10 mg, Pt cell, argon atmosphere, heating rate 20°C min^{-1}.

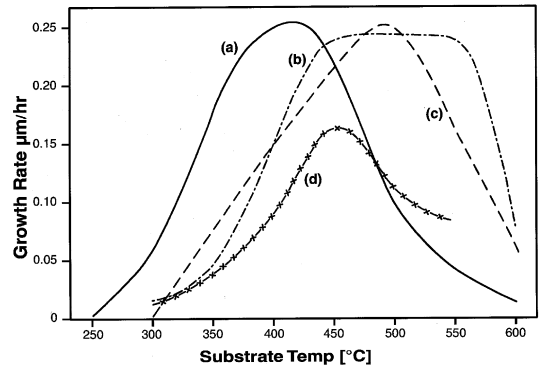

Fig. 5. Variation in growth rate with substrate temperature for Ta alkoxides: (a) $Ta(OEt)_5$, (b) $Ta(OMe)_4(thd)$, (c) $Ta(OEt)_4(thd)$, (d) $Ta(OPr^i)_4(thd)$.

2.3. Ta precursors

The selection of a suitable Ta source presents a major challenge in the MOCVD of $Pb(Sc_{0.5}Ta_{0.5})O_3$. There are no tantalum β-diketonates available, and the simple alkoxide precursor $Ta(OEt)_5$ has a significantly lower thermal stability than $Sc(thd)_3$, which leads to oxide deposition in a different temperature regime, and also gives rise to decomposition of $Ta(OEt)_5$ in the evaporator and reactor inlet pipes at the temperatures used to evaporate $Sc(thd)_3$.

However, the thermal stability of tantalum alkoxide precursors can be increased by the insertion of β-diketonate groups, or by altering the alkoxide group. For instance, the oxide deposition temperature is higher for $Ta(OEt)_4(thd)$ than for $Ta(OEt)_5$ and increases in the order $Ta(OPr^i)_4(thd) < Ta(OEt)_4(thd) < Ta(OMe)_4(thd)$ [17], as shown by the growth rate data in Fig. 5. These precursors are monomeric (Fig. 1) and are less air sensitive than the parent alkoxides. It has also been shown that $Ta(OR)_4(thd)$ compounds undergo significantly less decomposition than $Ta(OEt)_5$ in the evaporator at temperatures greater than 200°C [17]. Therefore $Ta(OEt)_4(thd)$ and $Ta(OMe)_4(thd)$ can be selected as most compatible with $Sc(thd)_3$ and $Pb(thd)_2$ for $Pb(Sc_{0.5}Ta_{0.5})O_3$ growth.

3. MOCVD of $Pb(Sc_{0.5}Ta_{0.5})O_3$

The application of $Pb(Sc_{0.5}Ta_{0.5})O_3$ in pyroelectric devices has been restricted by the high temperatures (>1000°C) usually required to synthesise the desired perovskite phase and to eliminate the pyrochlore phase, with its poor dielectric properties, which tends to form at low temperature. Although $Pb(Sc_{0.5}Ta_{0.5})O_3$ in the perovskite phase has been grown at low temperature by sol-gel techniques

[18,19], there have been relatively few reports of successful MOCVD studies. Early studies [20] reported that a processing temperature of 800°C and a post growth anneal were required to obtain the perovskite phase. More recent studies [21] have shown that $Pb(Sc_{0.5}Ta_{0.5})O_3$ in the perovskite phase can be grown in one step at temperatures as low as 600°C. However, in both of these studies conventional MOCVD was employed, in which the Pb, Sc and Ta precursors were held in bubblers at relatively high source temperatures, leading to the possibility of source decomposition with time.

In order to avoid source decomposition we have employed liquid injection MOCVD, and $Pb(Sc_{0.5}Ta_{0.5})O_3$ films have been successfully grown at substrate temperatures of between 400 and 600°C using a single solution of $Pb(thd)_2$, $Sc(thd)_3$ and $Ta(OEt)_4(thd)$, dissolved in tetrahydrofuran (THF) [22]. This precursor combination was selected initially as the best compromise between precursor availability and cost and MOCVD performance.

At substrate temperatures of 500°C and below the material was found to be a mixture of the perovskite and pyrochlore phases. Increasing the substrate temperature led to increasing amounts of the perovskite phase, and at 600°C the perovskite phase was found to be predominant (see Fig. 6). These low growth temperatures are fully compatible with device fabrication requirements, indicating that the use of liquid injection MOCVD techniques, together with the use of carefully selected precursors, should lead to increased exploitation of this important technology.

4. Conclusions

Careful selection and molecular design of the Pb, Sc and Ta precursors have allowed us to match more closely the physical properties of each precursor, and to achieve oxide growth in a similar temperature regime. The use of the precursor combination $Pb(thd)_2$, $Sc(thd)_3$ and $Ta(OEt)_4(thd)$ has allowed the growth of $Pb(Sc_{0.5}Ta_{0.5})O_3$ in the required perovskite phase at substrate temperatures as low as 600°C.

5. Experimental

5.1. Precursor synthesis

The β-diketones thdH, tmodH and mhdH used in this study were purchased from Lancaster synthesis. $Pb(thd)_2$ was synthesised by the addition of Na(thd) to $PbCl_2$ in aqueous methanol [13]. The Sc β-diketonates $Sc(thd)_3$, $Sc(tmod)_3$ and $Sc(mhd)_3$ were synthesised by the reaction of $Sc(NO_3)_3(H_2O)_x$ with the sodium salts of the respective β-diketonates (3 mol equivalents, prepared in situ by reaction of NaOH with the β-diketone in aqueous methanol) [23]. After isolation of the solid products by filtration, the Sc β-diketonates were dried overnight and then purified by vacuum

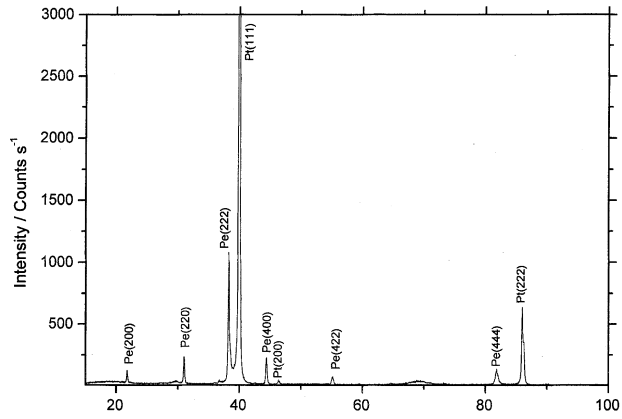

Fig. 6. X ray diffraction data for $Pb(Sc_{0.5}Ta_{0.5})O_3$ grown at 600°C using $Pb(thd)_2$, $Sc(thd)_3$ and $Ta(OEt)_4(thd)$. Pe diffraction peaks from perovskite phase, Pt diffraction peaks from platinum substrate.

sublimation. Each compound was fully characterised by ^1H NMR, $^{13}C\{^1H\}$ NMR, mass spectroscopy, and microanalysis, and full details are given elsewhere [14].

$Ta(OR)_4(thd)$ compounds were prepared from the reaction between $Ta(OR)_5$ and 1 mol equivalent of thdH in *n*-hexane solvent. After removal of the solvent and volatiles in vacuo, the $Ta(OR)_4(thd)$ products were purified by vacuum distillation. The synthesis and characterisation of $Ta(OR)_4(thd)$ compounds are described more fully elsewhere [24].

5.2. Growth of single oxide films

PbO, Sc_2O_3 and Ta_2O_5 films were deposited on Si(100) substrates at 1000mbar, using a liquid injection MOCVD reactor described elsewhere [11]. The films were grown from individual solutions of the Pb, Sc and Ta oxide precursors dissolved in THF. The growth conditions are summarised in Table 1.

5.3. Growth of $Pb(Sc_{0.5}Ta_{0.5})O_3$ films

Thin films of $Pb(Sc_{0.5}Ta_{0.5})O_3$ were deposited onto Pt(111) substrates by the evaporation of a single solution of precursors in THF using an MOCVD reactor described in detail elsewhere [11]. An evaporator temperature of 300°C

Table 1

POLYHEDRON

Compartmental control of mineral formation: adaptation of a biomineralization strategy for biomedical use

William L. Murphy [1], Phillip B. Messersmith *

Northwestern University, Division of Biological Materials, Departments of Physical Medicine and Rehabilitation, and Biomedical Engineering, 311 East Chicago Avenue, Chicago, IL 60611, USA

Received 8 June 1999; accepted 1 October 1999

Abstract

A common biomineralization strategy is the use of lipid vesicle compartments to sequester ions, control ion transport, and to control the shape and size of inorganic mineral particles deposited within developing tissues. In this paper, we describe an adaptation of this bioinspired strategy for inducing rapid formation of calcium phosphates for potential medical and dental use. Calcium and inorganic phosphate salts were separately loaded into temperature-sensitive liposomes composed of 90% 1,2-bis(palmitoyl)-*sn*-glycero-3-phosphocholine and 10% 1,2-bis(myristoyl)-*sn*-glycero-3-phosphocholine. Leakage of calcium and inorganic phosphate from liposomes stored at room temperature was negligible over a period of several weeks. Calcium-loaded liposomes released entrapped calcium when heated to 36–37°C, while phosphate-loaded liposomes released entrapped inorganic phosphate (P_i) at slightly lower temperatures (33–34°C). Release of entrapped ions at this temperature was due to increased permeability of phospholipid bilayers at the lipid chain melting temperature. Aqueous suspensions containing mixtures of calcium and P_i-loaded liposomes formed calcium phosphate mineral when heated to 37°C, as indicated by a rapid drop in suspension pH from 7 to approximately 5. This result was consistent with diffusion of both calcium and phosphate ions out of the liposomes and their reaction to form calcium phosphate mineral. Such a strategy could be used in medical and dental procedures to induce rapid inorganic mineral formation from an injectable liposome-containing fluid. This was illustrated by applying a liposome suspension to warm human dentin and enamel surfaces, which resulted in deposition of calcium phosphate minerals onto the tissue substrates. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Calcium phosphates; Biomimetics; Biomineralization; Liposomes

1. Introduction

A ubiquitous biological strategy during mineralized tissue formation is the use of lipid vesicle compartments to sequester ions, control ion transport, and to control the shape and size of inorganic mineral particles deposited within developing tissues [1]. Both lower and higher organisms utilize the compartment of lipid vesicles to exert control over the size, shape, and even orientation of biological inorganic crystals. For example, in the cytoplasm of magnetotactic bacteria, a string of nanosized magnetic iron oxide particles is deposited within pre-existing lipid vesicles [2–4]. The individual magnetite particles (typically 100 nm diameter) are organized with their magnetic axes aligned in the same direction, and the entire construct is believed to be used by the organism to navigate according to the magnetic field of the earth [2–4]. The complex-shaped calcium carbonate exoskeletons (coccoliths) of some marine algae are also believed to be the result of mineralization within a lipid vesicle [1,5–7]. Each coccolith is itself composed of several anvil-shaped subunits, each of which acts as a single crystal (by diffraction) and is formed within an intracellular lipid vesicle [5–7].

Like many of the non-collagenous proteins that are important contributors to mineralized tissue formation [8], phospholipids appear to play an important role in both developing and mature bone, dentin, and enamel (the following reviews and references cited therein discuss the role of phospholipids in mineralization [9,10]). It has been shown that certain phospholipids can only be extracted after acidic decalcification of bone and dentine [11–13]. Ennever and Vogel also observed that demineralized dental calculus and bone matrix did not recalcify in the absence of its lipid components [14,15]. In the form of so-called matrix vesicles, phospholipids may also play a role in ion transport, reagent seques-

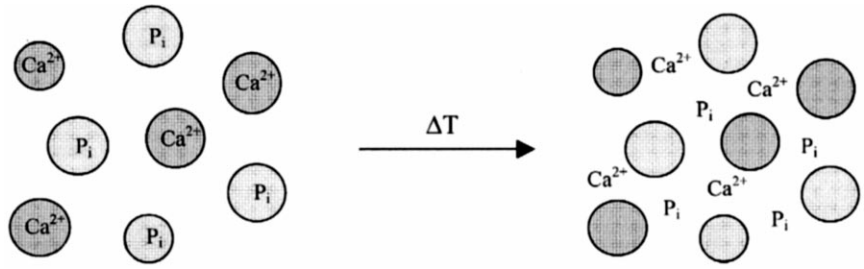

Fig. 1. Schematic illustration of thermally triggered release of Ca^{2+} and P_i from temperature-sensitive liposomes.

tering, and the nucleation of calcium phosphate crystals during the development of dentin and certain types of bone [16–23]. Matrix vesicles are non-cellular lipid vesicles believed to form as a result of budding from plasma membranes, which migrate in the extracellular matrix and accumulate at the calcification front (growth plate) of long bones [16]. It was reported in the late 1960s by Bonucci and Anderson that initial mineral formation during growth plate mineralization occurs within or on the surface of extracellular matrix vesicles [17,18].

Eanes and coworkers utilized synthetic liposomes as tools to model the mineral precipitation sequence believed to occur during matrix vesicle calcification [19–23]. Phosphate-loaded liposomes of size similar to matrix vesicles were prepared by encapsulating aqueous inorganic phosphate (P_i) solutions within liposomes constructed from phosphatidylcholine, dicetyl phosphate, and cholesterol [20,21]. The lipid bilayer, which serves as a barrier to ion transport, isolated extraliposomal Ca^{2+} from entrapped P_i and prevented mineral formation. However, when these liposomes were made permeable to external Ca^{2+} using a calcium ionophore, apatite mineral readily formed inside the liposomes. Mineral also formed outside of vesicles when intraliposomally formed apatite crystals penetrated the surrounding lipid bilayer membrane and seeded crystallization in the external medium. This model system was used to investigate the role of acidic phospholipids such as phosphatidylserine, phosphatidic acid, and phosphatidylinositol in calcium phosphate crystal nucleation and growth [22,23].

Several investigators have utilized lipid vesicles as components for the formation of nanometer-sized inorganic particles [24–30]. Typically, ions encapsulated within the vesicles are allowed to react with suitable ions of opposite charge permeating at a controlled rate through the vesicle membrane. In these studies, the vesicles are used to provide nucleation sites, control reaction kinetics and the size, geometry, and aggregation properties of the products. Nanoscale particles of oxides [25,26,29], hydroxides [27,28], and semiconductor particles [25,26] have been synthesized using this technique.

In our laboratory we recently began to explore the use of vesicles and other three-dimensional assemblies of phospholipids to mediate in situ formation of biomaterials [31–33]. We developed a strategy whereby the protective nature of phospholipid vesicles is exploited to isolate intravesicular Ca^{2+} from extravesicular P_i [31,32]. Using appropriate mixtures of saturated phospholipids, thermally sensitive Ca-loaded liposomes were designed which released entrapped calcium at physiologic temperature (37°C), resulting in rapid mineral formation as a result of reaction with extraliposomal phosphate ions.

In this paper, we extend this strategy to include the use of both Ca- and P_i-loaded vesicles, as depicted in Fig. 1. When heated to physiologic temperature, both Ca- and P_i-loaded liposomes release their contents into the extravesicular aqueous phase, where the ions react to form hydroxyapatite mineral. We also demonstrate how this approach can be used to deposit mineral onto enamel and dentin surfaces.

2. Experimental

2.1. Materials

1,2-bis(palmitoyl)-*sn*-glycero-3-phosphocholine (DPPC, >99%) and 1,2-bis(myristoyl)-*sn*-glycero-3-phosphocholine (DMPC, >99%) were obtained from Avanti Polar Lipids and used as received. Reagent grade $CaCl_2 \cdot 2H_2O$, Na_2HPO_4, ammonium molybdate ($(NH_4)_6Mo_7O_{24} \cdot 4H_2O$), sulfuric acid, citric acid, arsenazo III (AIII) dye, and all other chemicals were obtained from Aldrich Chemical Co. and used as received.

2.2. Preparation and characterization of calcium-loaded liposomes

All liposomes were prepared using the interdigitation-fusion method [34]. Ca^{2+} loaded liposomes were prepared using aqueous $CaCl_2$ (0.2 M, pH 7) from a mixture of DPPC (90 mol%) and DMPC (10 mol%) as described previously [32]. Unentrapped Ca^{2+} was removed from the liposome suspension by washing with aqueous NaCl (0.285 M, pH 7), centrifuging at 20000*g*, and decanting the supernatant. This process was repeated a minimum of five times or until Ca^{2+} could not be detected in the supernatant, using a standard spectrophotometric method [35]. The amount of Ca^{2+} contained in the liposome suspension was then determined by atomic absorption spectroscopy as described previously [31]. Calcium encapsulation efficiency ranged from 60–75% of available calcium.

Temperature-dependent release of Ca^{2+} from liposomes was detected using the Ca^{2+}-sensitive dye AIII, which undergoes a color change from purple to blue upon complexation with Ca^{2+} [35]. Following removal of unencapsulated Ca^{2+}, a 10 μl aliquot of the vesicle suspension was transferred to 4 ml of an AIII solution (0.4 mM AIII in 0.285 M NaCl) buffered to pH 7.4 with HEPES (10 mM). A circulating water bath and a jacketed quartz cuvette were used to heat the suspension at a rate of 1°C min^{-1} during measurement. Release of Ca^{2+} from the liposomes was followed by measuring the absorption intensity of the 650 nm band as a function of temperature. The amount of Ca^{2+} released, expressed as a percentage of total encapsulated Ca^{2+} ($\%Ca_{rel}$), was calculated from:

$$\%Ca_{rel} = \frac{A}{A_{100\%} - A_{0\%}} \times 100 \quad (1)$$

where $A_{100\%}$ and $A_{0\%}$ correspond to the final and initial absorbance at 650 nm, respectively. $A_{100\%}$ was determined by adding a lipid surfactant (20 μl of a 20% solution of Triton X-100) to the suspension following collection of data.

2.3. Preparation and characterization of phosphate-loaded liposomes

P_i loaded liposomes were prepared from 90% DPPC and 10% DMPC using the interdigitation-fusion method by substituting Na_2HPO_4 (0.23 M, pH 9) in place of $CaCl_2$ in the above protocol. Removal of unencapsulated P_i was accomplished as described above by washing with aqueous NaCl (0.285 M), and the amount of entrapped P_i determined using a phosphomolybdate assay [36]. Briefly, a 60 μl aliquot of the liposome suspension was diluted to within the linear range of the UV–Vis instrument and added to a solution containing 2 vol. acetone, 1 vol. sulfuric acid (5N), and 1 vol. ammonium molybdate (10 mM). Immediately following the formation of the phosphomolybdate complex, a small amount of 1.0 M citric acid was added to the solution to stop the reaction and thus avoid interference from acid-labile organic phosphates in the lipid membranes. A calibration curve for absorbance (400 nm) versus [P_i] was obtained using standard solutions of known P_i concentration. Inorganic phosphate encapsulation efficiency ranged from approximately 75–85% of available P_i.

Leakage of P_i from liposomes at room temperature was determined by dispersing 1 ml P_i-loaded liposomes in 14 ml aqueous NaCl (0.285 M, pH 7.4) and storing at room temperature for several weeks. At selected intervals, the suspension was vortexed and a 500 μl aliquot removed from the solution. The aliquot was transferred into a microcentrifuge tube and spun for 3 min at 20 000×g. The amount of P_i in the supernatant was then determined using the phosphomolybdate assay as described above.

Thermally triggered release of P_i from liposomes was detected using a modification of the phosphomolybdate assay described above [36]. Briefly, 20 μl liposomes, 3.2 ml ammonium molybdate (10 mM), and 400 μl sulfuric acid (5N) were combined and immediately transferred to a water-jacketed quartz cuvette. A circulating water bath was used to heat the suspension at a rate of 1°C min^{-1} during measurement. Release of P_i from the liposomes resulted in formation of the phosphomolybdate complex, detected by an increase in absorbance at 400 nm. Absorbance values were converted to percentage P_i release as described above. Control experiments performed using this method indicated that only minimal P_i leakage occurred during the first hour at ambient temperature.

2.4. Thermally triggered mineral formation

Temperature-activated mineral formation in unbuffered liposome suspensions was detected by measuring time-dependent pH changes of suspensions containing Ca^{2+}- and P_i-loaded liposomes held isothermally at various temperatures [32]. In a thin-walled glass tube, one part each of Ca-loaded liposomes, P_i-loaded liposomes, and 0.285 M NaCl were incubated at 20°C for 30 min. Initial pH values of the metastable liposome suspension ranged from 6.8 to 7.0. The liposome suspension was then transferred to a water bath thermostated at 25, 30, 34, or 37°C. A computerized data acquisition system was used to monitor simultaneously the voltage output from a pH electrode, sample temperature, and bath temperature prior to and during immersion. pH values were corrected for temperature changes as described previously [32].

2.5. Mineralization of dentin and enamel

Mineralization of dentin and enamel slabs was investigated as follows. 1 mm thick slabs of human dentin and enamel were cut from non-carious third molars using a diamond cutting wheel. The smear layer was removed by etching in 10% H_3PO_4 for 20 s to expose the tissue surface, after which the slabs were washed in distilled water and stored at room temperature in HEPES (10 mM, pH 7.4). An aluminum cylinder of dimension 2 cm diameter by 3 cm height was immersed in a thermostated water bath to a depth of 2.8 cm. Onto the top surface of the cylinder, which was not submerged, was placed a dentin or enamel slab and the tip of a thermocouple probe was affixed in direct contact with the top surface of the slab. By using a thermal controller to modulate power input to the water bath, the temperature of the slab was maintained at 37°C via heat transfer through the aluminum cylinder. After equilibration at the temperature indicated, 200 μl of a suspension of Ca^{2+}- and P_i-loaded liposomes ([Ca] = [P] = 5–60 mM) suspended in 0.285 M NaCl was pipetted onto the surface of the slab and left unstirred for 20 min. Following this, the slab was removed and washed in room temperature distilled water to remove the liposome suspension. Treated samples were then air dried for 1 h and dried in vacuo for an additional 24 h.

2.6. Electron microscopy

Treated dentin/enamel slabs were mounted on specimen stubs using colloidal graphite and sputter coated with Au/Pd. The surfaces of the treated dentin/enamel slabs were imaged in secondary electron mode using a Cambridge Scanning Electron Microscope (SEM) operating at an accelerating voltage of 25 kV.

3. Results and discussion

The interdigitation-fusion method was used to encapsulate Ca^{2+} and P_i because it results in large unilamellar liposomes with a high encapsulation efficiency [34]. This method takes advantage of the formation of a lamellar interdigitated phase in the presence of low molecular weight alcohols to form large unilamellar vesicles, and was easily adapted for entrapment of Ca^{2+} and P_i. After removal of unentrapped Ca^{2+}, the measured Ca^{2+} concentration of the Ca-loaded liposome suspension was 120 mM. Likewise, the P_i concentration of the P_i-loaded liposomes was 180 mM. Both Ca and P_i-loaded liposomes were stable and highly resistant to leakage when stored at room temperature for several weeks. For example, P_i-loaded liposomes lost less than 2% of entrapped P_i during room temperature storage for 6 weeks (Fig. 2).

The liposomes used in this study were formulated to release their entrapped contents when heated to body temperature, which was accomplished by utilizing a mixture of DPPC (90%) and DMPC (10%) phospholipids. In a previous study, liposomes constructed from this mixture were found to release Ca^{2+} rapidly at 37°C [32]. Thermally triggered release from both Ca-loaded and P_i-loaded liposomes was determined using a spectrophotometric method in which release of liposome-entrapped species was detected photometrically by either a Ca^{2+} sensitive dye [35] or the formation of a phosphomolybdate complex [36]. As shown in Fig. 3, Ca^{2+} was rapidly released from 90% DPPC/10% DMPC liposomes beginning at approximately 36–37°C, which is in agreement with our previous results [32]. Surprisingly, as shown in Fig. 4, P_i release from liposomes of identical composition (90% DPPC/10% DMPC) began at a slightly lower temperature (approximately 33°C). Although the reason for the observed difference in release temperature is not known, it is possible that the low pH conditions ($pH < 2$) necessary to detect photometrically the phosphomolybdate complex [36] may have altered the release behavior of the P_i-loaded liposomes.

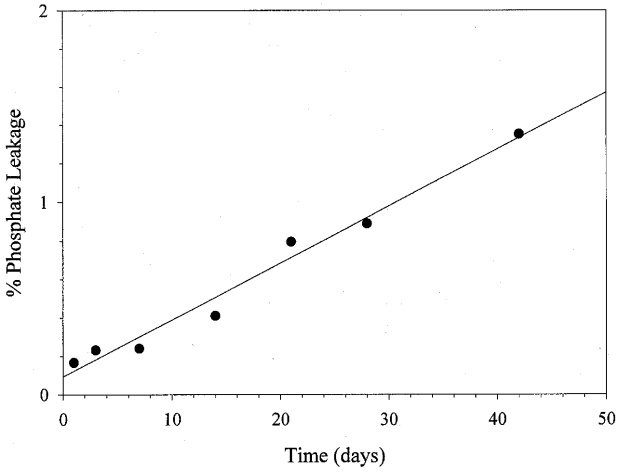

Fig. 2. Time-dependent release of P_i from liposomes during storage at room temperature. Raw absorbance data were converted to percentage P_i release as described in the text.

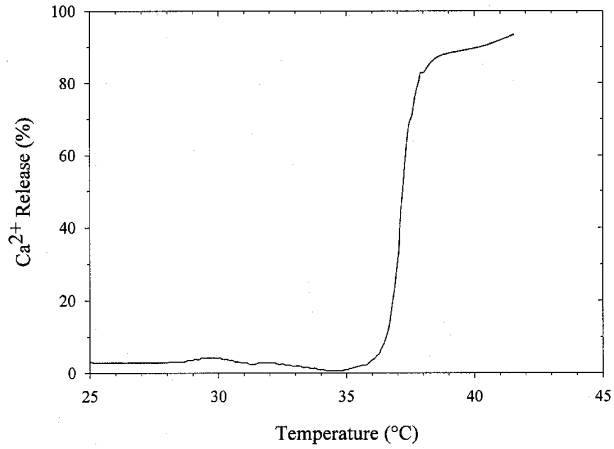

Fig. 3. Detection of thermally triggered release of Ca^{2+} from liposomes. Liposomes were suspended in *iso*-osmotic AIII solution and heated at 1°C min^{-1} while monitoring absorbance of the solution. Raw absorbance data were converted to percentage Ca release as described in the text.

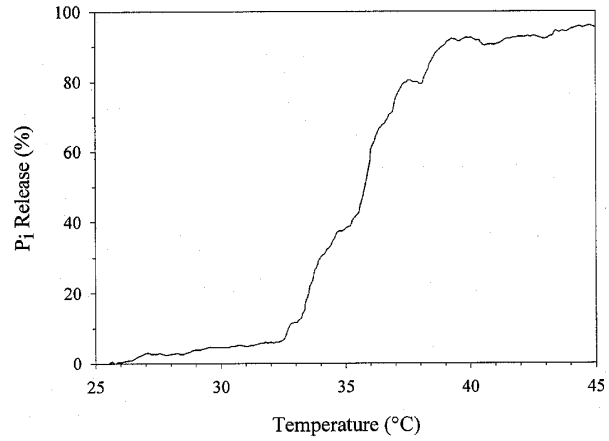

Fig. 4. Detection of thermally triggered release of P_i from liposomes. Liposomes were suspended in ammonium molybdate solution and heated at 1°C min^{-1} while monitoring absorbance of the solution. Raw absorbance data were converted to percentage P_i release as described in the text.

Because of the sequestering of Ca^{2+} and P_i within separate vesicle compartments, liposome suspensions containing very high concentrations of Ca^{2+} and P_i could be made by combining Ca-loaded liposomes with P_i-loaded liposomes. As described previously [32], we used pH as an indicator of the extent of mineral formation in the liposome suspensions, since upon release from the liposomes the Ca^{2+} and P_i ions react to form apatite-like and/or brushite calcium phosphates according to the idealized reactions

$$5CaCl_2 + 3Na_2HPO_4 + H_2O \rightarrow Ca_5(PO_4)_3OH + 6NaCl + 4HCl \quad (2)$$

$$CaCl_2 + NaH_2PO_4 + 2H_2O \rightarrow CaHPO_4 \cdot 2H_2O + NaCl + HCl \quad (3)$$

Mixtures of Ca-loaded liposomes and P_i-loaded liposomes maintained stable neutral pH values for several hours after combining (data not shown). However, rapid pH changes were observed when these suspensions were heated to temperatures above ambient (Fig. 5). For example, when a liposome suspension of concentration $[Ca^{2+}] = [P_i] = 40$ mM was held isothermally at 30°C, there was a slight increase of approximately 0.1 pH unit during the first 2 min, after which the pH remained stable. When the same suspension was heated to 34°C, a slightly larger increase (0.4 pH units) was observed in the first few minutes but again the pH did not change significantly within 30 min. However, when the suspension was heated at 37°C, there was an initial rise in pH after which the pH dropped rapidly to approximately pH 5.

The temperature-dependent behavior of the liposome suspensions can be explained by taking into consideration the differences in temperature release characteristics of the Ca-loaded and P_i-loaded liposomes. The data in Figs. 3 and 4 clearly show that the P_i-loaded liposomes released P_i at a temperature 2–3°C below that of the Ca-loaded liposomes. At 30°C there may have been slow leakage from the P_i-loaded liposomes, and since the pH of the P_i solution was basic (pH 9), there was a slight increase in measured pH of the suspension. At 34°C P_i leakage was more pronounced, leading to a larger pH rise as shown in Fig. 5. Finally, at 37°C both P_i and Ca^{2+} were released from the liposomes. This gave rise to an initial increase in pH due to the basicity of the P_i solution, after which the solution rapidly became highly supersaturated with respect to both apatite and brushite and mineral formation occurred as indicated by the rapid drop in pH as shown in Fig. 5.

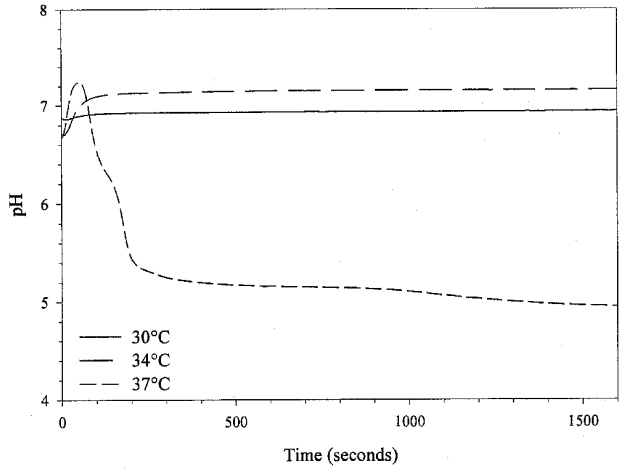

Fig. 5. pH vs. time of liposome suspensions isothermally held at 30, 34, and 37°C. Thin-walled glass tubes containing the liposome suspensions ($[Ca] = 40$ mM; $[P_i] = 60$ mM) were immersed in a thermostated water bath at time 0.

The pH of the reaction medium is likely to have a strong influence on the calcium phosphate phases formed in the liposome suspensions. For example, it is well known that apatitic calcium phosphate forms at neutral to basic pH values, whereas brushite forms under acidic conditions [37]. In the present case, the initial pH of the suspension undergoing mineralization at 37°C was slightly acidic, increased slightly as a result of phosphate release, and then rapidly dropped to approximately 5. Because of this pH fluctuation, it is likely that a combination of both apatite and brushite mineral formed during thermally triggered mineralization. It is also possible that apatite mineral formed during the initial stages of the reaction (at neutral pH), subsequently dissolved as the pH dropped, and reprecipitated as brushite.

The use of thermally triggered mineral formation to deposit mineral onto the surfaces of dentin and enamel tissue was explored by applying liposome suspension (buffered to pH 7.4) to dentin/enamel slabs equilibrated at specific temperatures (Fig. 6), and examining the treated surfaces to detect mineral deposition. As shown in Figs. 7 and 8, treatment of dentin and enamel in this manner at 20°C did not result in detectable mineral formation. However, treatment of dentin/enamel with liposome mineralizing suspension at 37°C resulted in the deposition of mineral particles on both dentin and enamel surfaces. Although the composition of these particles was not determined, the experimental conditions (pH 7.4 and high Ca, P_i concentration) are favorable for the formation of amorphous calcium phosphates, which may gradually transform into poorly crystalline apatite. The appearance of the mineral deposits is consistent with this interpretation.

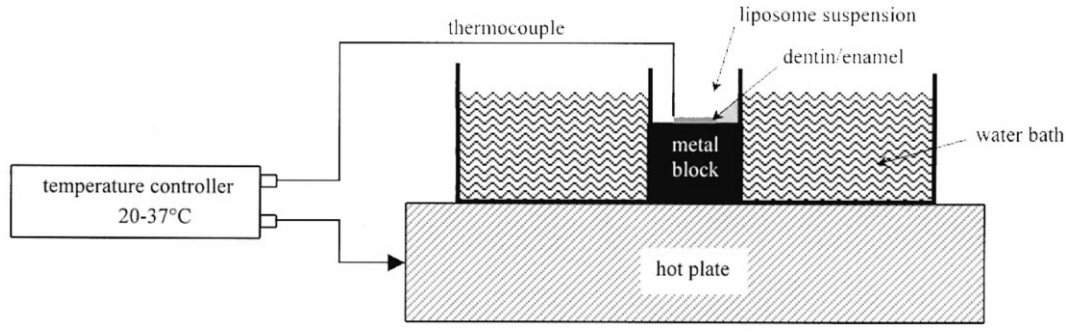

Fig. 6. Experimental apparatus used to control enamel/dentin slab temperature during treatment with liposome suspension.

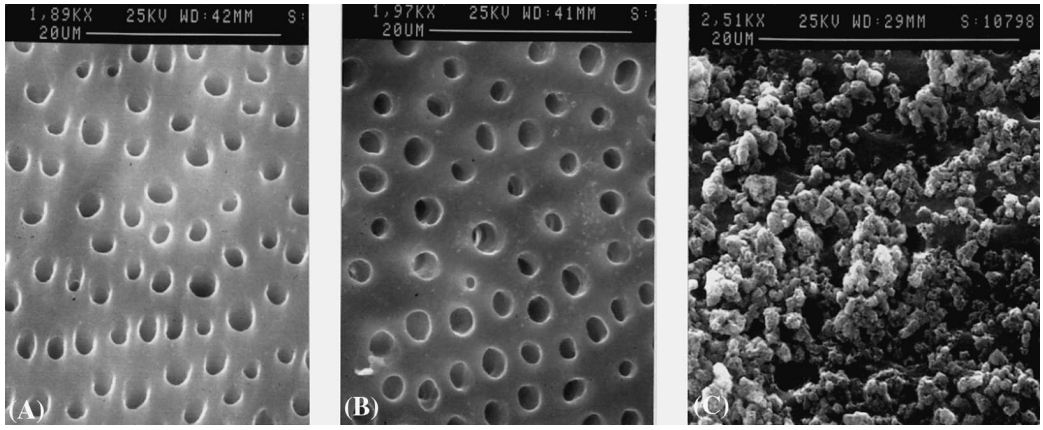

Fig. 7. Scanning electron micrographs of acid etched human dentin surfaces following treatment with liposome suspension ([Ca] = [P] = 40 mM). Dentin slabs were untreated (A) or treated with liposome suspension for 20 min at either 20°C (B) or 37°C (C).

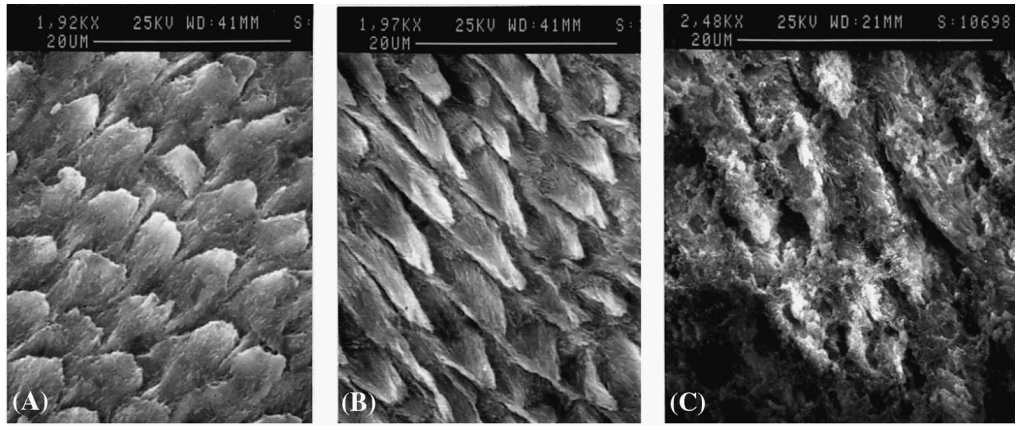

Fig. 8. Scanning electron micrographs of acid etched human enamel surfaces following treatment with liposome suspension ([Ca] = [P] = 40 mM). Enamel slabs were untreated (A) or treated with liposome suspension for 20 min at either 20°C (B) or 37°C (C).

In summary, we have used the biomimetic strategy of compartmentalization to isolate reactive precursors for calcium phosphate mineral formation. Interdigitation-fusion processing yielded liposomes containing highly concentrated solutions of either calcium or phosphate. Leakage of ions from these vesicles was slow when stored at room temperature for a period of several weeks, in spite of the high concentration gradient existing across the liposome membrane. Liposomes were constructed from a mixture of dipalmitoyl and dimyristoyl phosphatidylcholines, which rendered the vesicles permeable to calcium and phosphate ions when heated to body temperature. At this temperature, entrapped calcium and phosphate rapidly diffused out of the liposomes into the aqueous medium where they reacted to form calcium phosphate. This strategy is designed to take advantage of the difference between ambient and body temperature and could be useful for minimally invasive repair or reconstruction of human skeletal tissue. To illustrate this, a room temperature liposome suspension was applied to warm dentin and enamel slabs, and mineral was found to be deposited onto the surface. Potential dental and medical applications of this technology include the remineralization of incipient caries, treatment of hypersensitive dentin, and as a bone substitute material.

Abstract

Using a heterogeneous route, the precursor silylating agent 3-mercaptopropyltrimethoxysilane (mts) was first grafted onto silica gel and then condensed to one molecule of ethylenimine (etn). In the homogeneous route, mts reacted with etn to yield 3-trimethoxypropylthioethylamine (mptt), which was covalently anchored onto silica gel. In both cases, the new silylating agent displayed a chelating moiety containing nitrogen and sulfur basic centres. The amount of nitrogen immobilized was 1.73 and 1.74 mmol g^{-1} silica for the heterogeneous and homogeneous methods, respectively. In both routes of synthesis ν(N–H) stretching bands appeared at 3361 and 3284 cm^{-1} with the absence of a ν(S–H) stretching band. ^{13}C NMR of the new silylating agent, $(CH_3O)_3SiCH_2CH_2CH_2SCH_2CH_2CH_2NH_2$, showed chemical shifts for methoxy groups at 50.0 ppm and signals at 8.4, 23.0, 34.4, 36.1 and 41.2 ppm for the sequence of carbons from the silicon atom to the NH_2 group at the end of the organic chain. The ^1H NMR spectrum presented a singlet peak which was attributed to methoxy groups at 3.52 ppm; a triplet at 2.76, quintet at 1.64 ppm, multiplet at 2.49 and triplet at 0.65 ppm were assigned to hydrogen atoms bonded to carbons in the same sequence as above. A broad amidic proton peak appeared at 1.08 ppm. ^{13}C NMR–CPMAS (cross-polarization magic-angle spinning) of the immobilized surface gave a series of peaks similar to those of the free silylating agent. Thermal and elemental analyses confirmed the covalent attachment of the organic species onto the silica gel surface. The chelating moiety formed by basic centre atoms of the pendant groups on the silica surface have a pronounced ability to extract divalent copper from aqueous solution. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Ethylenimine; Immobilization; 3-Mercaptopropyltrimethoxysilane; Silica gels

1. Introduction

Work on the immobilization of molecules on inorganic supports has been intensively revived in the last three decades [1,2], with much attention given to the establishment of a new covalent bond on the desired surface [3,4]. These investigations depend on the substitution reactions between the modifiers and accessible silanol groups distributed on such surfaces. In exploring the advantages of the covalent bond formed, a series of porous adsorbents, such as silica gel [5–12], porous glass [13,14], porous polymers [15,16], alumina [17], titania and zirconia [18], have been investigated as supports.

The systematic application of immobilization has been directed mainly at silica gel, because its surface has been investigated from both physical and chemical aspects and it offers many advantages over organic surfaces: (1) a large variety of silylating agents can be used [1,3,19], allowing a myriad of pendant functional groups to be immobilized on the support; (2) functional groups immobilized on silica gel react more easily than those on an organic support because this matrix has a large number of crosslinking bonds which may require hours to reach equilibrium; (3) silica, as well as other inorganic supports, are unreactive to organic solvents and have a high thermal resistance [20].

Conventional modifiers have been used to establish a link between the molecule and the inorganic support through mono-, di- and trifunctional chlorosilanes or by employing methoxy or ethoxysilane derivatives. Normally, these silylating agents are reacted with the silanol of the surface in a one-step procedure, allowing the function of the organic chain to be explored for various uses. However, for other purposes, agents are synthesized before anchoring, or a simple immobilized molecule reacts in a heterogeneous medium

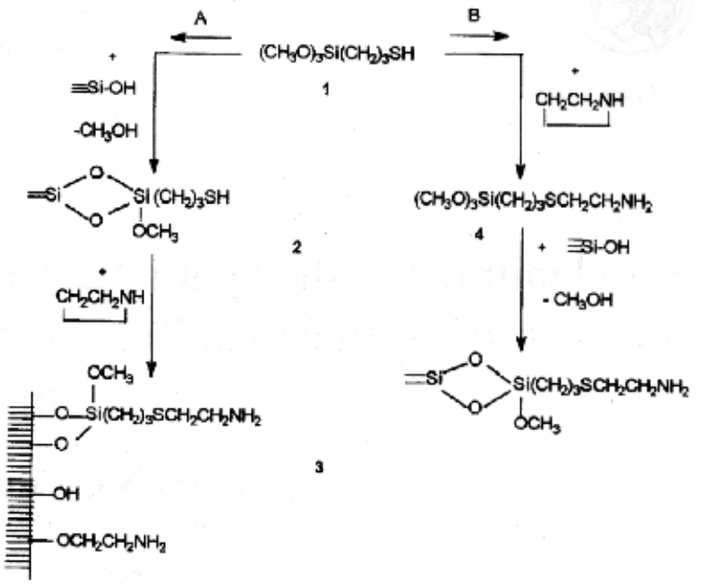
PII S0277-5387(99)00347-2

in order to increase the chain to include a variety of organic functions. In coordination chemistry, these agents can be enriched by a diversity of functional groups, which can act as chelating agents, for example, to remove cations from a complex mixture. These anchored supports can also be used in analytical investigations for which a high selectivity is desirable [15,21,22], as well as in several applications, such as chemically bonded phases in chromatography [23–28], extraction of cations from aqueous or non-aqueous solvents [10–12,29,30], in catalytic [1,3,22,31–33] or ion-exchange [3,29,34–36] reactions and also in some biotechnological processes [37–40].

This present paper focuses on the immobilization of the three-member cyclic ethylenimine molecule on the surface of silica gel, using homogeneous and heterogeneous routes as previously proposed [8,9], in order to elucidate and characterize the products of reactions. This new and unusual anchored compound contains sulfur and nitrogen as heteroatoms in the organic chain, and has the ability to extract cations from solution. This synthetic silylating agent was first obtained through a homogeneous method, before immobilization on the silica gel surface. The nitrogen content was established as a good criterion to distinguish the effectiveness of both routes of immobilization.

2. Experimental

2.1. Materials



The silylating agent 3-mercaptopropyltrimethoxysilane (mpts) (Aldrich) was used without previous purification. Silica gel (Aldrich), with particle size 70–230 mesh, medium diameter 60 Å and pore volume 0.75 $m^3 g^{-1}$, was stirred with H_2SO_4–HNO_3 (2.0 mol dm^{-3}) in 9:1 proportion. The suspension was left standing for 24 h and the supernatant then decanted. The solid was added to the same acidic solution and the same procedure was repeated. Then, the solid was filtered and extensively washed with bidistilled water until the filtrate had the same pH as water. After this treatment, the silica was activated by heating at 423 K for 8–10 h in vacuo under nitrogen atmosphere. Ethylenimine was synthesized following a described procedure, by reacting 2-amino-hydrogen sulfate (Aldrich) in hot alkali medium [41]. Xylene was firstly treated with metallic sodium and distilled just before use. A solution of divalent copper nitrate was prepared in bidistilled water from reagent grade materials.

2.2. Immobilization of ethylenimine

2.2.1. Reaction with the precursor

Ethylenimine was covalently bonded to the precursor mpts through two distinct routes: heterogeneous (A) or homogeneous (B) [8,9]. Scheme 1 outlines the different procedures.

2.2.1.1. Heterogeneous method. First, 40.0 g of activated silica gel was suspended in 150.0 cm^3 of dry xylene and 15.0

Scheme 1. Distinct routes of immobilizing ethylenimine on a silica gel surface: heterogeneous (A); homogeneous (B).

cm^3 (84.0 mmol) of mpts was slowly added to this suspension. The mixture was mechanically stirred under solvent reflux, in an inert dry nitrogen atmosphere for 72 h [29]. After cooling, the solid was filtered, washed with xylene and acetone until the filtered solution did not test positive for thiol groups [42]. The obtained product, denominated ≡Sil–SH, was dried in vacuo for 8 h at 373 K. In the next stage, 5.0 g of the modified silica was suspended in 30.0 cm^3 of several amounts of xylene. The suspension was maintained under solvent reflux with mechanical stirring; 2.0 cm^3 (38.77 mmol) of liquid etn was added under nitrogen atmosphere and the reflux continued for another 24 h. After cooling, the solid was filtered off, washed with xylene and anhydrous acetone, and dried in vacuo for 12 h.

2.2.1.2. Homogeneous method. A 5.5 cm^3 volume (29.0 mmol) of mpts was reacted with 6.0 cm^3 (116.0 mmol) of etn under reflux at 323 K, with magnetic stirring, under inert dry nitrogen atmosphere for 24 h. Excess etn was eliminated from the cooled solution in vacuo. The resulting compound, 3-trimethoxypropylthioethylamine (mptt), was allowed to react with 5.0 g of activated silica in dry xylene at 343 K and the mixture was mechanically stirred for 72 h. Then, the solid was washed and dried as in the heterogeneous method, to obtain the final product.

2.2.2. Direct immobilization of ethylenimine

An 5.0 g amount of silica was suspended in 50.0 cm^3 of dry toluene and 10.0 cm^3 (193.5 mmol) of ethylenimine in a sealed tube closed under low pressure. The mixture was heated at 353 K for 48 h and was periodically shaken at least three times a day. The solid was filtered and washed with toluene, water and finally ethanol and dried in vacuo for 8 h at room temperature.

The degree of functionalization of the silica that contained an attached amino group or etn molecule was based on nitrogen analyses using the Kjeldhal method. Sulfur elemental

analysis was carried out for the precursor thiol silica ≡Sil–SH (compound **2**; Scheme 1).

2.3. Capacity of modified silicas to adsorb copper

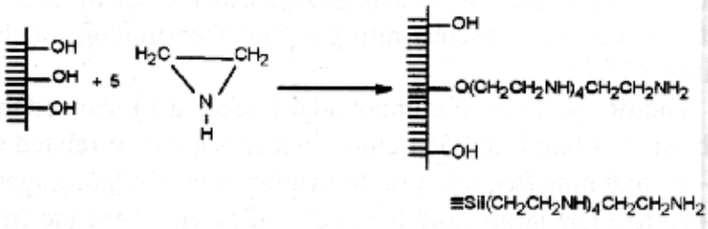
The capacity of the modified silica to extract metal ions from aqueous solution was determined in duplicate using a batchwise process with copper(II) nitrate as follows: about 50.0 mg of the modified silica was suspended in 20.0 cm^3 of an aqueous solution of $Cu(NO_3)_2$ with concentrations varying from 1.0 to 40.0 mmol dm^{-3}. The suspensions were mechanically stirred for 3 h at 298 ± 1 K and separated by centrifugation at 3000 rpm for 10 min [9]. Aliquots of the supernatant solution were pipetted and the cation was determined by EDTA complexometric titration. From these values the adsorption capacities were calculated.

2.4. Physical measurements

Activated silica gel and functionalized silicas were characterized by determination of the surface area using the BET method [43] in a Flowsorb II 2300 Micrometrics apparatus.

Carbon, nitrogen, sulfur and hydrogen contents were determined using a Perkin-Elmer microelemental Model PE 2400 analyser.

Thermogravimetric curves were produced using DuPont model 1090 B apparatus coupled with a thermobalance 951, by heating the samples from room temperature to 1273 K at a heating rate of 0.17 K s^{-1} under argon flow of 1.67 cm^3 s^{-1}, with the sample varying in weight from 15.0 to 30.0 mg.



IR spectra of all compounds were obtained with a Fourier transform IR spectrophotometer (MB-Bomem). Liquid samples were obtained using the thin film technique between windows of sodium chloride; solid samples were obtained from KBr pellets.

NMR spectra were obtained on Gemini-300 Varian and AC 300/P Bruker spectrometers. The liquid samples were prepared in carbon tetrachloride for hydrogen and carbon signals. The parameters used for ^1H spectra were: frequency 300 MHz with pulse width 30°, pulse delay 1 s, acquisition time 2.35 s; 64 scans were used. For ^{13}C spectra of liquid samples, frequency at 75.47 MHz, pulse width 45°, pulse delay at 2 s, acquisition time of 0.88 s and 256 scans were used. For solid samples, the carbon signal was obtained on an AC/300P Bruker spectrometer with cross-polarization and magic-angle spinning (CPMAS) at a frequency of 75.47 MHz with acquisition time 0.156 s, pulse delay at 4 s, contact time 1 ms and in the range of 13 663–25 600 scans.

3. Results and discussion

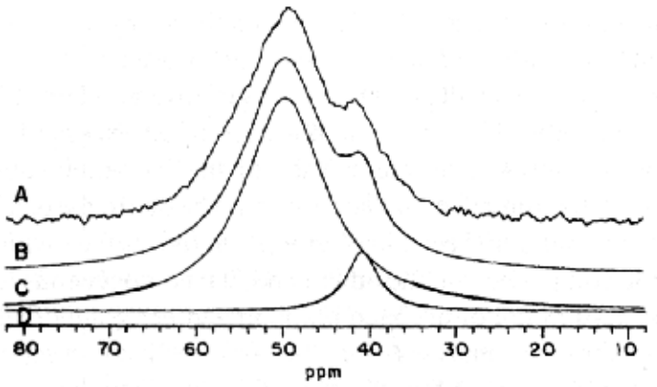
The condensation of ethylenimine molecules on the active sulfur sites of the silica gel surface embracing the derivative precursor ≡Sil–SH gave, by elemental analyses, 2.5% of this element, which corresponds to 0.78 mmol of thiol groups per gram of support. The value found for nitrogen by the Kjeldhal method was 1.73 mmol g^{-1} silica [8,9]. Based on this value, it is supposed that all precursor thiol groups should react with etn molecules. However, the presence of an excess of 0.95 mmol of nitrogen on the surface of the inorganic support beyond the equivalent molar ratio could be due to the reaction of the remaining free silanol groups on the surface with the cyclic compound. On the other hand, the homogeneous route gave 1.74 mmol of nitrogen immobilized per gram of silica. The nitrogen analyses for the immobilized compound obtained from the direct reaction of the cyclic molecule with silica surface gave 3.40 mmol g^{-1} silica. This large value clearly demonstrates the great ability of this cyclic molecule to interact with free silanol groups on the silica gel surface. Thus, this molecule develops a remarkable role in reacting with almost all disposed active acidic centres, as shown in the heterogeneous route. However, the effectiveness of the etn molecule in interacting with the unmodified surface is elucidated by considering the accepted number of free silanol groups, which is proposed to be 4–5 mmol g^{-1} silica [42,44]. Based on the present results it is inferred that this cyclic molecule succeeded in nearly completely covering the available silanol groups.

The immobilization of the cyclic etn molecule on the support was performed by the two proposed routes shown in Scheme 1. In route A, the precursor silylating agent mpts was first immobilized; subsequently, the cyclic molecule was incorporated to increase the original carbonic chain. Based on the determined amount of nitrogen bonded to the organic chains, the result inferred that a parallel reaction occurred between etn molecules and the remaining silanol groups, after anchoring the pendant groups on the silica surface. In attempting to elucidate this fact, a direct reaction of etn molecules with the activated silica gel was made to yield the new modified surface, represented by $\equiv Sil(CH_2CH_2NH)_4CH_2CH_2NH_2$, as shown in reaction 1:

(1)

The main contribution to the knowledge of the distribution of these pendant groups on the silica surface was obtained through ^{13}C NMR in solid state. The spectrum showed an intense peak at 49.2 ppm and a small one at 41.5 ppm, as illustrated in Fig. 1. These peaks in A were deconvoluted using a computer simulation, giving spectrum B, and the correspondent areas gave a 9:1 ratio in C and D. Peak C was assigned to a set of nine non-resolved carbon atoms and peak D to the methylene group bonded to the amine function, in a normal chain of this new immobilized molecule.

The reaction of ethylenimine with mpts in route B was carried out without catalyst or solvent during a reaction period



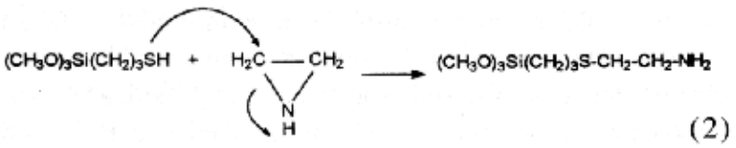


Fig. 1. ^{13}CNMR–CPMAS spectra for $\equiv Sil(CH_2CH_2NH)_4CH_2CH_2NH_2$ (A), computer simulation (B) and the deconvoluted signals (C, D).

of 24 h at 323 K to avoid the possible polymerization of the monomer of the reagent. The proposed mechanism of the reaction process can be illustrated by reaction 2:

(2)

After the synthesis and characterization of the desired compound **4** (Scheme 1), it was grafted onto activated silica to form the same anchored silica as obtained in the preceding route A. However, a better yield on functionalization can be obtained from route B. This procedure has the advantage that the precursor compound can be easily characterized. However, route A is the most useful method due to its operational simplicity [8,9].

The determination of the specific surface area, S_{BET} [43], based on the adsorption of gaseous nitrogen at several pressures at 77 K, gave values of 484, 345, 285 and 21 $m^2\ g^{-1}$ for activated silica, ≡Sil–SH (compound **2**), ≡Sil–SN (compound **3**) and $\equiv Sil(CH_2CH_2NH)_4CH_2CH_2NH_2$, respectively. This decrease in surface area after functionalization is due to the presence of pendant groups which block the access of molecules of gaseous nitrogen into the structure of the silica [43,45].

The IR spectrum of compound **4** (Scheme 1) showed the absence of bands at 2564 cm^{-1}, which should be related to S–H stretching frequency of the original mpts silylating agent [45,46]. The large band located at 3239 cm^{-1} for the free etn molecule, which was attributed to NH stretching vibrational mode of the secondary amine, disappeared after reacting. On the other hand, the appearance of two other new bands at 3361 and 3284 cm^{-1}, characteristic of NH stretching vibrational modes of the primary amine formed during the reaction, were detected. All these features are in agreement with the success of the immobilization, and the IR spectra of the silylating agent (A), the ligand ethylenimine (B) and the formed compound **4** (C) are shown in Fig. 2.

The ^{13}C NMR spectrum of 3-trimethoxypropylthioethylamine, compound **4**, whose formula is shown below, showed a chemical shift for methoxy groups (C-6) at 50.0 ppm [45,46].

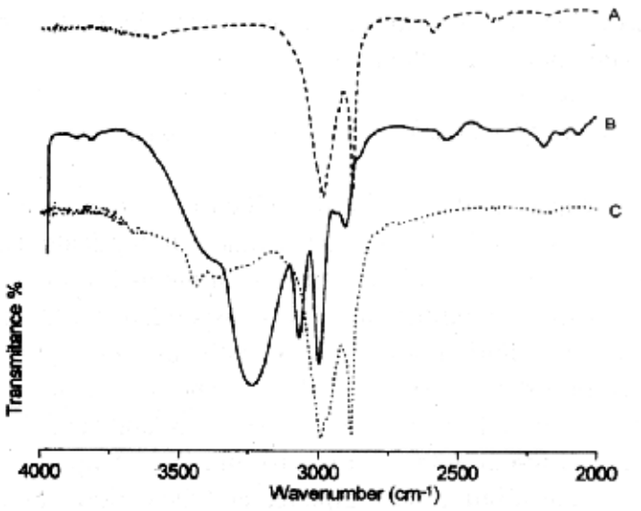

Fig. 2. IR spectra of 3-mercaptopropyltrimethoxysilane (A), ethylenimine (B) and 3-trimethoxypropylthioethylamine (C).

$$(CH_3O)_3Si\ CH_2\ CH_2\ CH_2\ S\ CH_2\ CH_2\ NH_2$$
$$6 \qquad 5 \quad 4 \quad 3 \qquad 2 \quad 1$$

The chemical shifts at 41.2, 36.1, 34.4, 23.0 and 8.4 ppm refer to carbons labelled 1, 2, 3, 4 and 5, respectively, in the above formula; the chemical shift at 96.0 ppm is due to the solvent CCl_4 [8], as shown in Fig. 3. The corresponding signals for protons for this compound can be summarized as follows: methylenes 1 and 5 appeared as triplets at 2.78 and 0.65 ppm, respectively, while protons of carbons 2 and 3 presented a multiplet at 2.48 ppm; the methylene 4 appeared at 1.64 ppm as a quintet; the amidic proton showed a broad peak at 1.08 ppm. Finally, an intense singlet peak at 3.52 ppm is attributed to the presence of the methoxy groups.

The IR spectrum in Fig. 4 showed a large and broad band near 3600 cm^{-1} for the activated silica (A), which corresponds to O–H stretching vibration. Some additional bands are incorporated, as illustrated after anchoring the silylating agent mpts (B) and the subsequent reaction with etn molecule (C). Identical IR spectra of immobilized compound **3**, shown in Fig. 4(C), were obtained by both routes and are

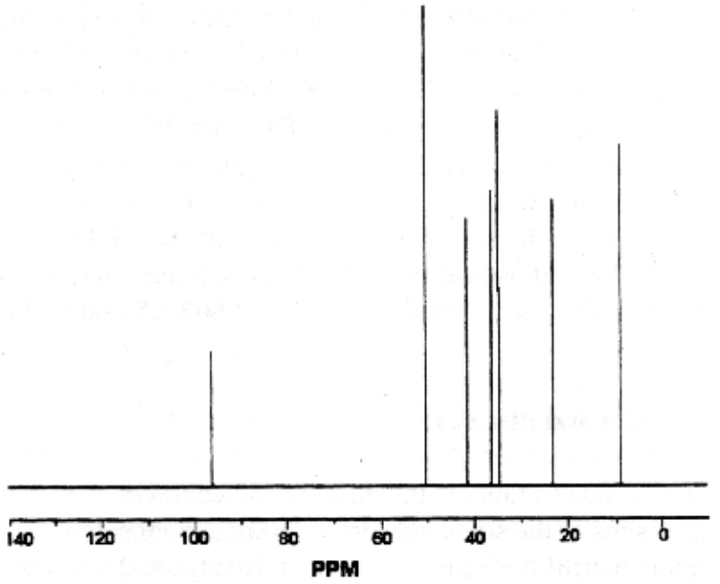

Fig. 3. ^{13}C NMR spectrum of 3-trimethoxypropylthioethylamine.

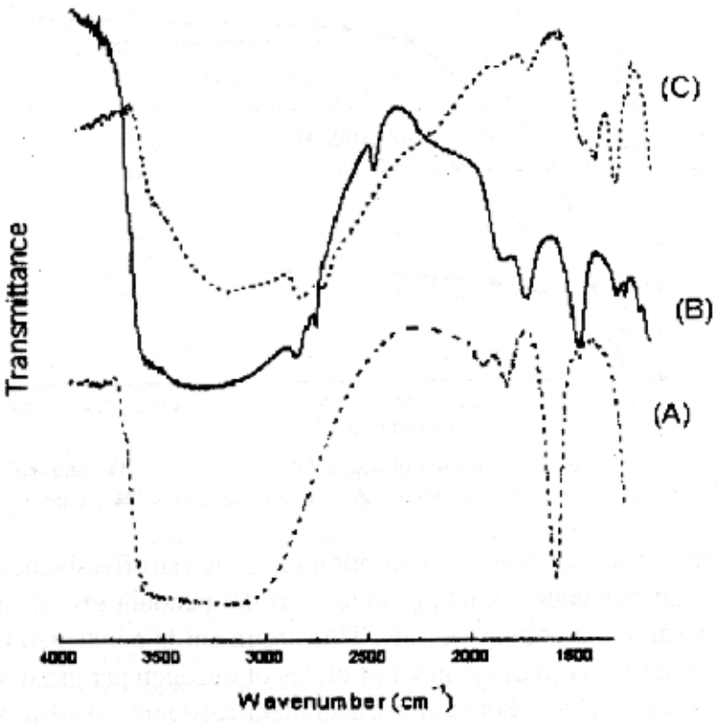

Fig. 4. IR spectra of silica gel (A), ≡Sil–SH (B) and ≡Sil–SN (C).

characterized by the disappearance of the band at 2564 cm^{-1}, which is attributed to S–H stretching vibrational group. This band is clearly observed for the precursor compound, as illustrated in Fig. 4(B). Compounds B and C presented two bands in the range 2950–2850 cm^{-1}, characteristic of CH stretching vibration mode. The CN stretching band belonging to compound 4C is well defined at 1600 cm^{-1}. However, the organofunctionalized surface $\equiv Sil(CH_2CH_2NH)_4CH_2CH_2NH_2$ showed two well-defined bands at 2949 and 2838 cm^{-1} that were attributed to C–H stretching vibration modes [45,46].

The solid state carbon NMR spectrum of the final immobilized surface gave a series of peaks, in the same sequence as observed for the free molecule in liquid phase. Thus, for compound synthesized by homogeneous methods, a weak signal was observed at 50.7 ppm, relative to methoxy carbon groups, and the chemical shift at 13.2; 24.0; 35.8 and 42.1 ppm are attributed to carbons 5, to the equivalent carbons 2 and 3, 4 and 1, respectively, as illustrated in Fig. 5(a). The compound synthesized by the heterogeneous process has a sharp and strong peak at 50.0 ppm, attributed to methoxy carbon groups. This is due to the parallel reaction of the free silanol groups on the silica surface with etn. This molecule is anchored by forming a new oxygen carbon bond, whose chemical shift is the same as those of the methoxy groups. The sequence of peaks is exactly the same as observed in the homogeneous process, with the following chemical shifts: 12.7; 24.3; 35.8 and 42.2 ppm, respectively, as shown in Fig. 5(b).

The thermogravimetric curve of the activated silica gel is shown in Fig. 6(A). An initial 1.0% weight loss at 298–473 K is attributed to the water physically adsorbed water on the surface. The following loss of mass of 2.60% reached at 1170 K is related to the condensation of free silanol groups on the

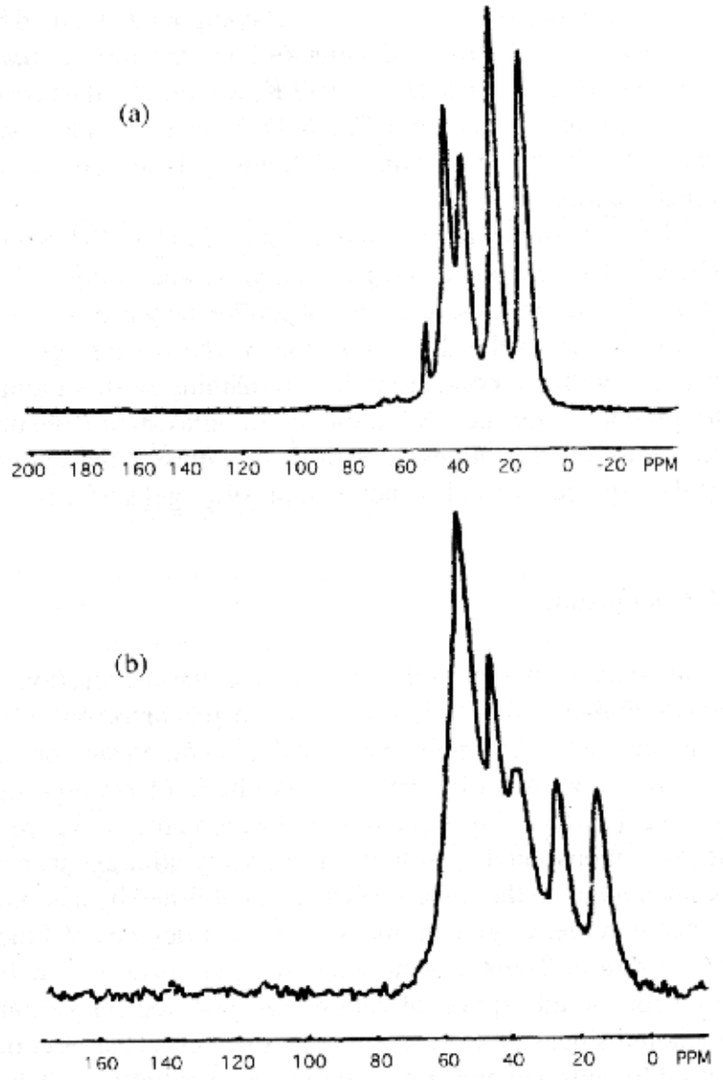

Fig. 5. ^{13}C NMR–CPMAS spectra of ≡Sil–SN obtained by homogeneous (a) and heterogeneous (b) routes.

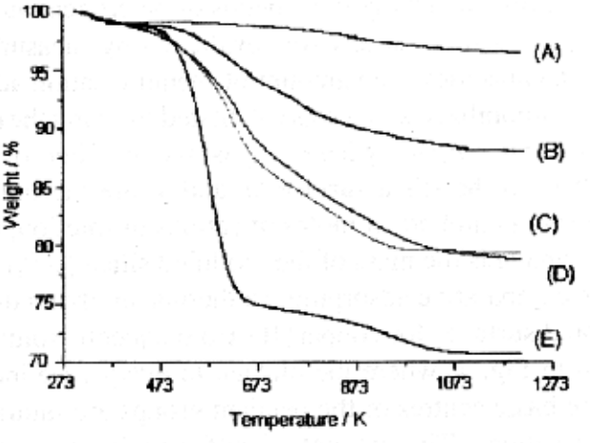

Fig. 6. Thermogravimetric data for silica gel (A), ≡Sil–SH (B) and ≡Sil–SN obtained by the heterogeneous (C) and homogeneous routes (D), and $\equiv Sil(CH_2CH_2NH)_4CH_2CH_2NH_2$ (E).

surface to form siloxane groups [47]. For compound **2** in Scheme 1, referring to the ≡Sil–SH immobilized surface as represented in Fig. 6(B), a first loss of mass of 1.11% between 298 and 473 K, is due to physically adsorbed water. The second loss of mass corresponding to 11.0% at 525–1075 K is due to decomposition of the organic groups covalently bonded on the silica surface. In considering both thermogravimetric data of compound **3**, only one loss of mass is

observed in both cases. Thus, for the compound obtained by the heterogeneous method (Fig. 6(C)), the loss of mass corresponded to 18.0% at 495–973 K, whereas by the homogeneous route (as shown in Fig. 6(D)) the loss of mass was equal to 20.0%, indicating a slightly higher degree of functionalization.

The thermogravimetric curve of the ≡Sil$(CH_2CH_2NH)_4$-$CH_2CH_2NH_2$ anchored surface, as represented in Fig. 6(E), showed a second loss of mass of 24.2% between 493 and 1040 K, due to the decomposition of the organic groups together with the condensation of remaining silanol groups to produce siloxane. All these thermogravimetric results showed a direct relationship of the loss of mass to the amount of the organic molecules anchored on silica gel surfaces.

4. Conclusions

In conclusion, the results demonstrate that the reaction of ethylenimine with a thiol-immobilized precursor on silica was successful in forming a new stable modified support, as was well confirmed by the direct synthesis of etn onto the silica gel surface. The same immobilization process was perfectly demonstrated by isolating the new silylating agent prior to anchorage on the same surface, as established by a homogeneous route, to give surfaces of distinct degrees of functionalization. These organofunctionalized surfaces can be used for the adsorption of cations, as observed for various anchored silicas. In the present case, two basic centres composed by nitrogen and sulfur atoms are potentially available as chelating moieties to complex cations.

The ability of the anchored silicas, ≡Sil–SH and ≡Sil–SN, the latter obtained by homogeneous or heterogeneous methods, in extracting cations was evaluated by measuring the sorption capacities. The amount of metallic cation adsorbed on the immobilized silica was calculated by using the expression $n_{fix} = n_i - n_s/m$, where n_{fix} is the number of moles adsorbed on the silica surface, n_i and n_s are the initial and equilibrium numbers of moles of cations in solution, respectively, and m is the mass of the modified silica [8,9,11].

The comparative adsorption isotherms involving the three anchored surfaces for copper(II) from aqueous solution are shown in Fig. 7, where the plateau in every case indicated that the basic centres of the pendant groups are saturated by copper cations. The amount of sulfur basic centre of 0.78 mmol g^{-1} on precursor ≡Sil–SH extracted 0.40 mmol g^{-1} of cation. However, this value contrasted with 1.50 and 1.60 mmol g^{-1} for the anchored surfaces obtained from heterogeneous and homogeneous methods, respectively. The proximity of the maximum adsorption capacities should be associated with the bidentate chelate centres composed by sulfur and nitrogen atoms. Therefore, a coherence was obtained with the largest values for these last immobilized surfaces, which reflected the elemental analysis of the number of nitrogens bonded in the pendant groups, indicating a slight increase for the surface synthesized by the homogeneous

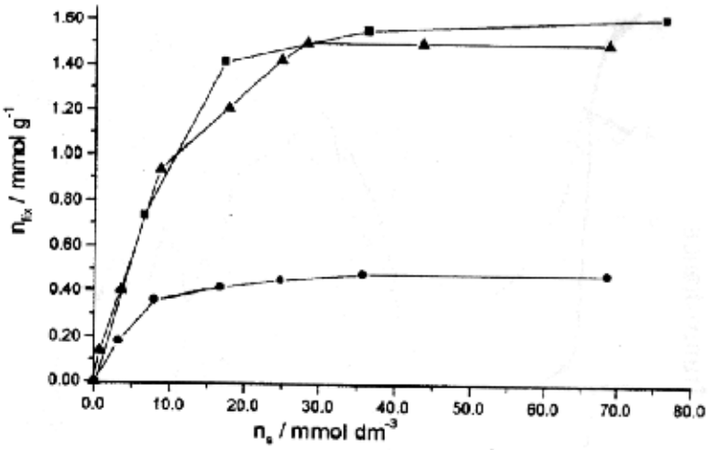

Fig. 7. Isotherms of adsorption of copper(II) by ≡Sil–SH (●) and ≡Sil–SN obtained by the heterogeneous (▲) and homogeneous (■) routes.

route. The increment in adsorption suggested an effectiveness of the bidentate chelating moiety on the pendant groups in coordinating copper cations. This argument is connected to the similarity in the number of moles of nitrogen per gram of silica gel, which should give a near identical degree of adsorption. However, the organofunctionalized surface obtained by the heterogeneous method is also embodied by the amine groups derived from the reaction of the cyclic ethylenimine molecules bonded to silanol groups on the surface, which should be involved in the coordination process [3,4], but in an expected less effective fashion.

These synthetic methods have elucidated the importance of designing appropriate molecules to embrace chelate centres to coordinate cations from aqueous solution through distinct routes, which makes clear the efficiency of the preparative methods.

Abstract

From the reactions between the diols *S*(−)-1,1-diphenyl-1,2-propanediol, *S*(−)-1,1,2-triphenyl-1,2-ethanediol and (1*R*, 2*R*)-(−)-1,2-dicyclohexyldiol and each of $Mo_2(O^tBu)_6$ and $Mo_2(NMe_2)_6$, the compounds $Mo_2(O_2C_{15}H_{15})_3$ (**1**), $Mo_2(O_2C_{20}H_{17})_3$ (**2**) and $Mo_2(O_2C_{14}H_{25})_4$ (**3**) have been isolated and characterized. In the reactions leading to the formation of **1** and **2**, kinetic control leads to highly sterically congested products having six phenyl groups at one end of the Mo–Mo axis. Three methyl groups in compound **1** and three phenyl groups in compound **2** are at the other Mo centers. In compound **3**, four equivalents of the diol are taken up by the Mo_2^{6+} center, two straddle the Mo–Mo triple bond and one chelates at each Mo center. Inspection of the Mo–O and O···O distances in compound **3** reveals the presence of OH groups such that the compound may be considered an alcoholate $Mo_2(O\sim\sim O)_2(O\sim\sim OH)_2$. These results are discussed in terms of crystals engineering an infinite chain of Mo_2 units with parallel Mo–Mo axes wherein a chiral ligand framework imposes a C_3 screw axis.

1. Introduction

The field of crystal engineering rests on a fundamental understanding of intermolecular forces and their use in ordering molecules or aggregates in the solid state [1]. In general it is the weak forces of molecular recognition, such as hydrogen bonding, π–π stacking of aromatic hydrocarbons or dipolar interactions, that are involved in this ordering. The problem of control of architecture in the solid state is, however, complicated by the variety of ways in which such weak forces may act in concert as well as in the molecular design of the subunits to be assembled. Multiple bonds between metal atoms in dinuclear complexes, M_2L_n, are known to have large diamagnetic anisotropies [2,3] and, more recently, have been shown to have large hyperpolarizabilities leading to large third-order non-linear optical responses [4,5]. The measurements of the latter have been made in solution or in the solid state from microcrystalline powders. These measurements of γ represent an isotropic or averaged value and if any application of this phenomenon is to be forthcoming it would be useful to know the value of γ parallel and perpendicular to the M–M axes. From our studies of the liquid crystalline phases of $Mo_2(O_2CR)_4$ compounds, we know that the largest component of the index of refraction for the mesophase is coincident with the columnar axis, which in turn is coincident with the M–M quadruple bond axis, i.e. the mesophase is an optically positive uniaxial material [6]. While we have learnt how to orientate the mesophase in an applied field, it is still simpler in principle to align the M–M axes in the solid state by taking advantage of weak intermolecular peaking forces as in $W_2(O^cC_6H_{11})_6$ or by weak intermolecular metal–ligand interactions as in $W_2(O_2C_2Me_4)_3$, where $O_2C_2Me_4$ is pinacolate [7]. These two structures are shown in Figs. 1 and 2, respectively. In the $W_2(O^cC_6H_{11})_6$ structure the W≡W bonds are aligned in a parallel manner but the shortest intermolecular W to W non-bonding distance is >6 Å, whereas in $W_2(O_2C_2Me_4)_3$, where there are weak

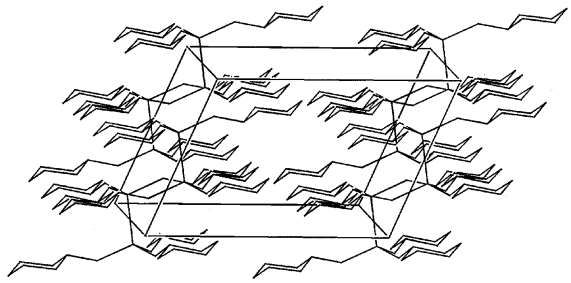

Fig. 1. Drawing depicting the packing of the $W_2(OCy)_6$ molecule. The cyclohexyl rings cause the alignment of the W–W axes without any $\sim W_2\cdots O\cdots W_2\cdots O$ intermolecular bonding.

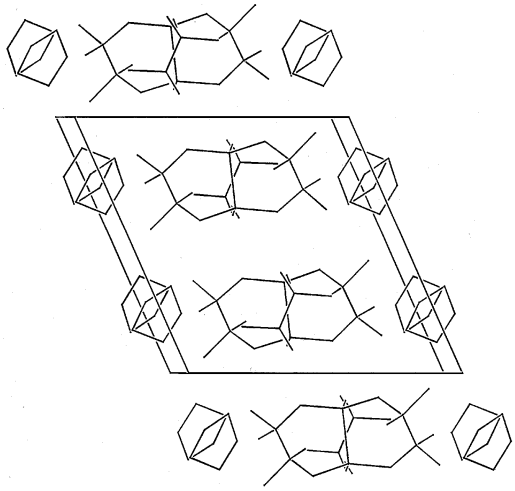

Fig. 2. Drawing of the unit cell of $W_2(O_2C_2Me_4)_6$ THF showing the alignment of the Mo–Mo triple bonds as a result of the weak intermolecular $W_2\cdots O\cdots W_2\cdots O$ interactions. The THF solvate is disordered and not bonded to the W_2 units but is found between the columnar stacks of $[W_2(O_2C_2Me_4)_3]_\infty$.

$(W_2\cdots O\cdots W_2–O–)_\infty$ chains the W to W non-bonded distances are $\sim$3.0 Å. Compounds of this type, wherein the M–M axes are all parallel and are at a unique angle with respect to the crystal growth axis *c*, are ideal for single crystal spectroscopic studies. It seemed plausible that the use of a chiral diolate ligand could impart a helical pitch to the infinite chains in a structure of the type shown in Fig. 2. It was with this in mind that we carried out the present study.

2. Results and discussion

2.1. Synthesis

2.1.1. $[Mo_2(O_2C_{15}H_{15})_3]_2\cdot 2THF$ (1)

The reaction between either $Mo_2(O^tBu)_6$ [8] or $Mo_2(NMe_2)_6$ [9] and (*S*)-(−)-1,1-diphenyl-1,2-propanediol in benzene gave the yellow crystalline compound **1**. The molecular structure of this compound is shown in Fig. 3. It involves two dinuclear units weakly bonded to each other by $Mo_2\cdots O$ interactions of the type seen in Fig. 2 for $W_2(O_2C_2Me_4)_3$. Each terminal Mo is also very weakly ligated by tetrahydrofuran (THF) molecules with Mo–O equal to 2.9 and 3.0 Å. However, it is not these molecules that terminate chain propagation in the solid state but rather that the mechanism of diolate substitution at the M_2^{6+} center leads to an unfavorable steric disposition of ligands. Specifically six phenyl groups are crowded at one Mo center while the three methyl groups are at the other. The dimer of M_2^{6+} units is favored over chain propagation by the linking of the sterically unencumbered Mo atoms through the weak Mo···O bonds, 2.6 and 2.7 Å. The weaker (as evidenced by longer Mo···oxygen THF bonds) are formed at the terminus. Selected bond distances and angles are given in Table 1. Fig. 4 shows a view looking down the M–M axis.

2.1.2. $Mo_2(O_2C_{20}H_{17})_3$ (2)

From a similar reaction between $Mo_2(O^tBu)_6$ [8] or $Mo_2(NMe_2)_6$ [9] and (*S*)-(−)-1,1,2-triphenyl-1,2-propanediol a yellow crystalline product (**2**) was obtained. The ^1H NMR spectrum of this complex implicated a similar substitution pattern, namely six phenyl groups at one Mo end and three at the other (see below). Suitable crystals were not obtained for a single crystal X-ray diffraction study.

2.1.3. $Mo_2(O_2C_{14}H_{24})_2(O_2C_{14}H_{25})_2$ (3)

The reaction between $Mo_2(O^tBu)_6$ [8] and (1*R*, 2*R*)-(−)-1,2-dicyclohexyl-1,2-ethanediol was carried out in benzene with the formation of compound **3**. Cooperative substitution at the Mo_2 center was observed so that no $Mo_2(O_2C_{14}H_{24})_3$ could be obtained. The molecular structure of this compound is shown in Fig. 5. Selected bond distances and angles are given in Table 2. From Fig. 5 one can see that there are two bridging and two chelating diolate ligands. From an inspection of the Mo–O distances one can see two long distances of 2.21 Å, involving the chelate ligands, one at each Mo atom (Mo(1)–O(35) and Mo(2)–O(54)), implying the presence of two OH groups. Inspection of the O···O distances

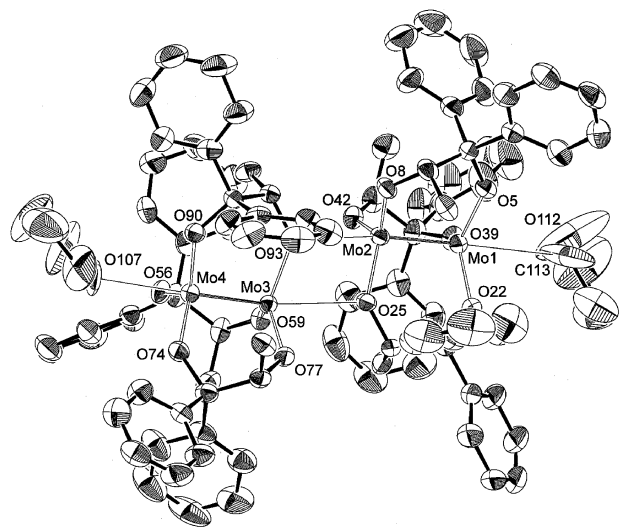

Fig. 3. Molecular structure of the dimeric $(1\cdot THF)_2$ found in the solid state, showing the atom numbering scheme. One THF denoted by C113 and O112 is disordered such that the O and C atoms cannot be distinguished. The $Mo_2\cdots THF$ interactions are extremely weak.

O(74)–Mo(4)–O(90)	117.9(1)

reveals that O(54)···O(38) = 2.50 Å and O(35)···O(51) = 2.51 Å, suggestive of OH···O bonding across the Mo–Mo bond (see Table 2).

2.2. ^{1}H NMR characterization

The ^{1}H NMR spectra of compounds **1** and **2** in toluene-d_8 are entirely consistent with that observed for the substitution pattern as seen for compound **1** in Fig. 3. Thus for compound **1**, aside from the phenyl proton resonances, we observe one Me doublet at δ 0.1 and a quartet for the methine proton signal at δ 5.84. The upfield position of the Me signal and the downfield shift of the methine ^{1}H signal can be attributed to the magnetic anisotropy of the Mo≡Mo bond and the phenyl groups.

For compound **2** only a single methine signal is observed at $\delta \sim 5.2$, consistent with three equivalent methine groups at one end of the molecule.

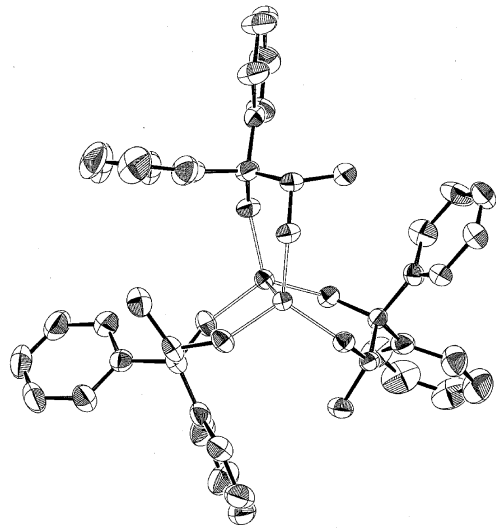

Fig. 4. View looking down the Mo–Mo axis of compound **1** showing the near eclipsed geometry of the Mo_2O_6 skeleton. The O–Mo–Mo–O torsion angles are 9°. The ground state configuration is Δ ($\lambda\lambda\lambda$).

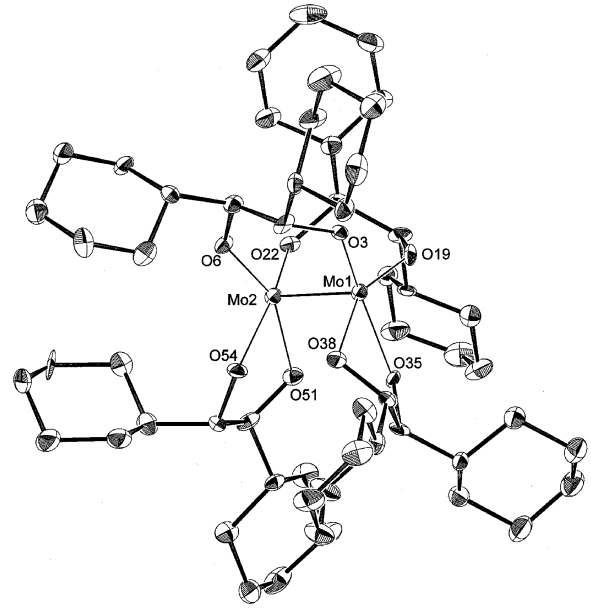

Fig. 5. Drawing of molecule **3** showing the presence of two bridging and two chelating diolate ligands. The Mo–O distances indicate that O(35) and O(54) are protonated and from the O···O distances that they are hydrogen-bonded O(35)–H···O(51) and O(54)–H···O(38).

For compound **3**, which has virtual C_2 symmetry with two chelating and two bridging diolates, we observe three methine signals at $\delta \sim 4.9$, 4.0 and 3.4 in the integral ratio 2:1:1. The most plausible explanation for this would seem to be that the most downfield C*H*O signal arises from the μ-$O_2C_2H_2Cy_2$ ligand because of accidental degeneracy, whereas for the chelate $O_2C_2H_2Cy$ ligands the methine protons are in markedly different orientations with respect to the Mo≡Mo bond, one being proximal and the other distal. The hydroxyl proton is observed at $\delta \sim 4.7$ in toluene-d_8 at 25°C as a somewhat broadened signal. On the ^{1}H NMR time-scale rapid OH···O

transfer clearly makes the chelating diolates oxygen atoms and their attendant methine protons equivalent.

2.3. Isomerization of compound *1* to compound *4*

When a toluene solution of compound **1** is heated in the presence of pyridine, an isomerization occurs to give a compound (**4**) with a much more complex ^{1}H NMR spectrum. However, in the C*Me* region there are simply three sets of doublets of equal intensity and for the C*H* methine signals we observe two resonances of equal integral intensity at δ 4.9 and 4.3, each appearing as quartets (J_{HH} = 6 Hz). The region from δ 6 to 8.8 contains many aromatic resonances and within this region there is concealed the third methine quartet as determined by a COSY spectrum.

There are two possible isomers of compound **1**, namely a $Mo_2(\mu\text{-}O\sim\sim O)(\eta^2\text{-}O\sim\sim O)_2$ complex and a $Mo_2(\mu\text{-}O\sim\sim O)_3$ complex wherein one of the μ-O$\sim\sim$O ligands has 'turned around'. In the latter isomer, one Mo has two OCHMe groups and one $OCPh_2$ and the other two $OCPh_2$ and one OCHMe. In both the chelate and bridged isomers of compound **1** there would be three inequivalent C*Me* and C*H* groups and thus NMR spectroscopy cannot unequivocally distinguish between these isomers. However, from the construction of models we are disinclined to favor the bis-chelate structure because of strain within the five-membered MO_2C_2 rings. Also for the tris-bridged compound we note that one C*H* group is disposed toward the center of the Mo–Mo triple bond. This would cause a significant deshielding [10], resulting in its movement to lower field and as such would explain why it likely appears below 6 ppm.

3. Concluding remarks

The present findings reveal how subtle substitutional preferences at the Mo_2^{6+} center have thwarted our attempts at the 'molecular engineering' of chiral chains of aligned Mo_2 units in the solid state. The kinetic preference for the formation of isomer **1** relative to **4** reveals that substitution at the Mo_2 center is influenced in a cooperative manner. The intermediate $Mo_2(\mu\text{-}OCHMeCPh_2O)(O^tBu)_4$ is preferentially attacked by the next diol at the least sterically hindered Mo atom by the MeHC*OH* moiety and this is again repeated for $Mo_2(\mu\text{-}OCHMeCPh_2O)_2(O^tBu)_2$. Thus ring closure occurs across the Mo≡Mo bond, leading to the most sterically congested isomer having six Ph groups near one Mo atom but only three Me at the other. As in previous studies, such ethane-like isomers are thermally stable and only in the presence of the donor ligand pyridine do we observe the isomerization of compound **1** to compound **4** [11].

4. Experimental

All syntheses were carried out employing thoroughly dried and degassed solvents under a purified N_2 atmosphere. Samples were stored and handled in a Vacuum Atmospheres DriLab system under N_2. The preparation of $Mo_2(NMe_2)_6$ [8] and $Mo_2(O^tBu)_6$ [9] was according to literature methods. The chiral diols employed in this work were obtained from Aldrich and were degassed and stored over 4 Å molecular sieves prior to use.

^{1}H NMR spectra were recorded on a Varian Gemini 300 in benzene-d_6 or toluene-d_8.

4.1. Synthesis of $Mo_2(O_2C_{15}H_{15})_3$ (*1*)

4.1.1. From $Mo_2(O^tBu)_6$

To a solution of $Mo_2(O^tBu)_6$ (0.41 g, 1.8 mmol) dissolved in benzene (10 cm^3) at 25°C was added (*S*)-(−)-1,1-diphenyl-1,2-propanediol (0.40 g, 0.63 mmol) dissolved in benzene (20 cm^3). (The latter required heating for 1 h.) The solution was stirred with the aid of a magnetic stir-bar for 20 h at room temperature. The color gradually darkened from yellow to brown. The solvent and volatile organic components were removed under a dynamic vacuum at room temperature to leave crude $Mo_2(O_2C_{15}H_{15})_3$ (**1**) as a yellow solid. Recrystallization of this solid from benzene–hexane

gave a pale yellow microcrystalline solid (0.39 g, yield 71%). ^{1}H NMR (C_6D_6, 25°C, 30 MHz): δ 7.76 (m, 6H), 6.9–7.3 (m, 24H), 5.85 (d, 3H), 0.10 (d, 9H), with J_{HH} = 6 Hz.

Crystals suitable for single crystal X-ray study were obtained by dispersing hexane in a concentrated solution of compound **1** dissolved in THF. This gave $[Mo_2(O_2C_{15}H_{15})_3]_2 \cdot 2THF$ with the structure shown in Fig. 3.

4.1.2. From $Mo_2(NMe_2)_6$

To a solution of $Mo_2(NMe_2)_6$ (0.4 g, 0.88 mmol) dissolved in benzene (15 cm^3) at room temperature was added (*S*)-(−)-1,1-diphenyl-1,2-propanediol (0.56 g, 2.46 mmol) dissolved in benzene (25 cm^3). (The latter required heating for 1 h to obtain complete dissolution of the diol.) The solution was stirred with the aid of a magnetic follower for 24 h at room temperature. The color changed from yellow to orange–red. The solvent and organic components were removed under a dynamic vacuum at room temperature to yield a yellow powder. Recrystallization from hexane–benzene gave compound **1** as a microcrystalline yellow solid (0.50 g, yield 65%). The ^{1}H NMR data were identical to those reported above.

Compound **1** is air-sensitive and soluble in common hydrocarbon solvents and ethers. It is thermally stable at 100°C for several hours.

4.2. Isomerization of compound *1*

Pure crystalline compound **1** (60 mg) was dissolved in dry and deoxygenated pyridine and heated to 80°C for 15 min. The color changed from yellow to maroon. The pyridine was removed under a dynamic vacuum at room temperature to yield a maroon powder. The ^{1}H NMR spectrum was more complex than that reported above, indicating a lower symmetry. The CH_3 resonance were split into three sets of equal intensity in benzene-d_6: δ 1.95, 1.72 and 1.45, each doublets of equal integral intensity with J_{HH} = 6 Hz. Methine ^{1}H NMR: δ 4.36, 4.94 and 6.18, each quartets of equal integral intensity, J_{HH} = 6 Hz.

4.3. Synthesis of $Mo_2(O_2C_{20}H_{17})_3$ (*2*)

4.3.1. From $Mo_2(O^tBu)_6$

To a Schlenk flask (150 ml), $Mo_2(O^tBu)_6$ (0.80 g, 1.27 mmol) and (*S*)-(−)-1,2,3-triphenyl-1,2-ethanediol were added followed by benzene (3 cm^3). The resultant solution was stirred for 12 h at room temperature and solvent was then removed under a dynamic vacuum to give a yellow microcrystalline powder. The pure compound $Mo_2(O_2C_{20}H_{17})_2$ (**2**) was obtained by recrystallization from a benzene–hexane solution (1.35 g, 67% yield).

^{1}H NMR data (benzene-d_6, 25°C, 300 MHz): δ 7.83 (d, 6H), 6.8–7.2 (m, 39H), 5.15 (s, 3H).

4.3.2. From $Mo_2(NMe_2)_6$

A similar reaction procedure involving $Mo_2(NMe_2)_6$ and the diol (as described in the preparation of compound **1**) yielded compound **2** in 65% yield.

4.4. Synthesis of $Mo_2(O_2C_{14}H_{25})_4$ (*3*)

To a solution of $Mo_2(O^tBu)_6$ (0.25 g, 0.4 mmol) dissolved in benzene (10 cm^3) at room temperature was added (1*R*, 2*R*)-(−)-1,2-dicyclohexyl-1,2-ethanediol (0.35 g, 1.55 mmol) dissolved in benzene (20 cm^{-3}). (The latter required heating to 60°C for 1 h.) The solution was stirred with the aid of a magnetic follower for 24 h at room temperature. The solution darkened from yellow to brown. The solvent was removed under a dynamic vacuum to leave $Mo_2(O_2C_{14}H_{25})_4$ (**3**) as a pale yellow powder. Slow recrystallization of this product from benzene yielded the benzene solvate, $Mo_2(O_2C_{14}H_{25})_4 \cdot 2C_6H_6$ (**3**$\cdot 2C_6H_6$), which was used in the crystallographic study.

Reactions employing $Mo_2(O^tBu)_6$ and 2.5 equivalents of this diol still led to the formation of compound **3** along with unreacted $Mo_2(O^tBu)_6$. Attempts to remove one equivalent of diol from $Mo_2(O_2C_{14}H_{25})_4$ by heating compound **3** under a dynamic vacuum at 55, 70, 85 and 95°C failed, yielding only compound **3**. Above 120°C compound **3** undergoes thermal decomposition.

4.5. Single crystal X-ray studies

General operating procedures have been published previously [12]. A summary of the crystal data is given in Table 3.

Table 3
Summary of crystal data

Abstract

The reaction of 3-*tert*-butylpyrazole with dibromomethane under phase-transfer catalytic conditions afforded a new ligand, bis(3-*tert*-butylpyrazol-1-yl)methane [CH_2(3-Bu^{t}Pz)$_2$]. However, the reaction of 3-isopropylpyrazole with dibromomethane under the same conditions yielded three isomers: bis(5-isopropylpyrazol-1-yl)methane [CH_2(5-iPrPz)$_2$], (3-isopropylpyrazol-1-yl-5′-isopropylpyrazol-1-yl)methane [CH_2(3-iPrPz-5′-iPrPz)] and bis(3-isopropylpyrazol-1-yl)methane [CH_2(3-iPrPz)$_2$]. Although CH_2(5-iPrPz)$_2$ suffered the greatest degree of steric hindrance, this ligand was obtained in highest yield. Upon treating the isomeric mixture with diorganotin halides in petroleum ether (60–90°C), the isomers were isolated in the form of diorganotin derivatives of bis(pyrazol-1-yl)methanes. The crystal structures of CH_2(3-iPrPz-5′-iPrPz)$SnPh_2Br_2$ and CH_2(5-iPrPz)$_2SnPh_2Br_2$ determined by X-ray crystallography indicated that the isopropyl group in the 3-position of the pyrazole ring decreased the coordination ability of CH_2(3-iPrPz-5′-iPrPz), and the average Sn–N distance in CH_2(3-iPrPz-5′-iPrPz)$SnPh_2Br_2$ (2.52 Å) was longer than that in CH_2(5-iPrPz)$_2SnPh_2Br_2$ (2.435 Å). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Organotin(IV); Poly(pyrazol-1-yl)alkanes; X-ray structure

1. Introduction

Diorganotin complexes containing nitrogen donor ligands have attracted considerable attention in recent years due to their potential antitumor activity against P388 leukemia [1,2]. Many complexes of the type R_2SnX_2(N–N) have been synthesized and tested [3], in which the N–N ligands are symmetric *N*,*N*-chelating agents such as bipyridine-type ligands [4] or asymmetric ones such as 8-aminoquinoline [5]. We have successfully prepared a variety of pentacoordinate organotin(IV) complexes in which the metal was coordinated with tridentate ligands containing nitrogen and oxygen. We find that the Schiff bases of amino acids [6,7], substituted hydrazones [8], semicarbazones and thiosemicarbazones [9] exhibit good coordination activity for organotin(IV) complexes.

Recently, poly(pyrazol-1-yl)alkanes, especially bis(pyrazol-1-yl)alkanes, have also been found to act as good donors to organotin compounds. Pettinari and co-workers have extensively studied the interactions between bis(pyrazol-1-yl)alkanes and tin(IV) and organotin(IV) acceptors [10–13]. The donating ability can be easily controlled by varying the substituents of the pyrazole ring [14]. A survey of the larger number of tin(IV) and organotin(IV) derivatives of poly(pyrazol-1-yl)alkanes showed that poly(pyrazol-1-yl)alkanes in these derivatives are completely symmetric, and no tin(IV) and organotin(IV) derivatives with asymmetric poly(pyrazol-1-yl)alkanes have been reported. An important reason may be that it is difficult to obtain pure asymmetric poly(pyrazol-1-yl)alkane ligands.

In the present work, we report a simple method to obtain organotin(IV) derivatives containing asymmetric poly(pyrazol-1-yl)alkanes and the first determination of their crystal structures. In order to explain the different steric and electronic features of isopropyl and *tert*-butyl groups,

organotin(IV) derivatives of bis(3-*tert*-butylpyrazol-1-yl)methane have also been synthesized and characterized.

2. Experimental

Melting points were measured with a PHMK melting-point apparatus and were uncorrected. Elemental analyses were carried out on a Perkin-Elmer 240C analyser. The ^{1}H NMR spectra were obtained with a Bruker AC-P 200MHz spectrometer and the ^{119}Sn NMR spectra were recorded on a Bruker AC-P 200MHz spectrometer at 74.63 MHz, using $CDCl_3$ as solvent unless otherwise noted. The chemical shifts were reported in ppm with respect to the references (internal $SiMe_4$ for ^{1}H NMR, external $SnMe_4$ for ^{119}Sn NMR). IR spectral data were obtained from a Nicolet 170SX spectrometer using KBr discs. The conductivity in solution was measured with a DDS-11A conductimeter at room temperature. 3-*tert*-Butylpyrazole [15] and 3-isopropylpyrazole [16] were prepared by published methods. The solvents were dried by standard methods, and all reactions related to Ph_2SnX_2 (X = Cl, Br) were carried out under moisture-free conditions.

*2.1. Bis(3-tert-butylpyrazol-1-yl)methane (**1**)*

3-*tert*-Butylpyrazole (12.4 g, 100 mmol), CH_2Br_2 (8.7 g, 50 mmol), 25 ml of 40% aqueous sodium hydroxide and tetrabutylammonium bromide (1.0 g, 3.1 mmol) were added to benzene (50 ml). The mixture was vigorously stirred and refluxed for 48 h. After cooling, the two layers were separated and the aqueous layer was extracted with benzene (2×30 ml). The organic phases were combined and dried over anhydrous magnesium sulfate. The solvent was removed in vacuo to give an oil. The oil was redissolved in minimum petroleum ether (60–90°C) and cooled to −20°C to yield the crude product, which was recrystallized from petroleum ether to yield colorless plates of CH_2(3-Bu^{t}Pz)$_2$ (**1**) (5.98 g, 46%), m.p. 99–101°C. ν_{max} (cm^{-1}) (pyrazole ring) 1520.2 s. δ_H 1.27 (18H, s, C(CH_3)$_3$), 6.10 (2H, d, H^4), 6.18 (2H, s, CH_2) and 7.45 (2H, d, H^5). *Anal*. Calc. for $C_{15}H_{24}N_4$: C, 69.23; H, 9.23; N, 21.54. Found: C, 69.30; H, 9.39; N, 21.42%.

*2.2. Bis(5-isopropylpyrazol-1-yl)methane (**2**), (3-isopropylpyrazol-1-yl-5′-isopropylpyrazol-1-yl)methane (**3**) and bis(3-isopropylpyrazol-1-yl)methane (**4**)*

3-Isopropylpyrazole (13 g, 118 mmol), CH_2Br_2 (10.3 g, 59 mmol), 40 ml of 40% aqueous sodium hydroxide and tetrabutylammonium bromide (1.1 g, 3.5 mmol) were added to benzene (60 ml). The mixture was vigorously stirred and refluxed for 48 h. After cooling, the two layers were separated and the aqueous layer was extracted with dichloromethane (2×30 ml). The organic phases were combined and dried over anhydrous magnesium sulfate. The solvent was removed in vacuo to yield an oil. Upon treatment of the oil with 30 ml of petroleum ether (60–90°C), a white solid precipitated out. The precipitate was filtered off and discarded. Evaporating the filtrate again yielded a colorless oil. The oil was kept under 1 mmHg at 100°C for several hours to remove all volatile materials to give the mixture of compounds **2**, **3** and **4** (7.4 g, 54%, total yield). The relative amounts were 54% (**2**), 33% (**3**) and 13% (**4**), calculated from ^{1}H NMR of the mixture. δ_H 1.17 (d, CH(CH_3)$_2$ in compound **4**), 1.18 (d, CH(CH_3)$_2$ in compound **2**), 1.20 (d, CH(CH_3)$_2$ in compound **3**), 1.22 (d, CH(CH_3)$_2$ in compound **3**), 2.98 (m, CH(CH$_3$)$_2$ in componds **3** and **4**), 3.33 (septet, CH(CH$_3$)$_2$ in compound **3**), 3.46 (septet, CH(CH$_3$)$_3$ in compound **2**), 6.01 (m, H^4 in compounds **2**, **3** and **4**), 6.04 (s, CH_2 in compound **3**), 6.13 (s, CH_2 in compound **2**), 6.20 (s, CH_2 in compound **4**), 7.26 (d, H^5 in compound **4**), 7.45 (dd, H^3 or H$^{5'}$ in compound **3**), 7.48 (d, H^3 in compound **2**). The assignment was achieved by analyzing the ^{1}H NMR and crystal structures of adducts with Ph_2SnBr_2.

*2.3. Bis(3-tert-butylpyrazol-1-yl)methane diphenyltin(IV) dibromide (**5**)*

A solution of compound **1** (0.26 g, 1 mmol) dissolved in 5 ml of diethyl ether was added dropwise to a stirred diethyl ether solution (15 ml) of Ph_2SnBr_2 (0.433 g, 1 mmol) by syringe. After the mixture was stirred for 2 h at room temperature, the solvent was removed under reduced pressure. The residual was washed with petroleum ether (60–90°C) and dried in vacuo to afford a white powder of CH_2(3-Bu^{t}Pz)$_2$SnPh$_2$Br$_2$ (**5**) (0.52 g, 75%), m.p. 63–65°C. ν_{max} (cm^{-1}) 1523.3 s (pyrazole ring) and 452.1 m (Sn–C). δ_H 1.28 (18H, s, C(CH_3)$_3$), 6.10 (2H, d, H^4), 6.17 (2H, s, CH_2), 7.49 (8H, m, H^5 and C$_6$H$_5$), 7.66 (4H, m, C$_6$H$_5$). ^{119}Sn NMR ($CDCl_3$): δ −157.4. *Anal*. Calc. for $C_{27}H_{34}Br_2N_4Sn$: C, 46.75; H, 4.91; N, 8.08. Found: C, 46.40; H, 4.90; N, 7.80%.

*2.4. Bis(3-tert-butylpyrazol-1-yl)methane diphenyltin(IV) dichloride (**6**)*

This complex was prepared similarly to complex **5**, yielding 0.48 g of a white solid (80%), m.p. 73–75°C. ν_{max} (cm^{-1}) 1523.3 s (pyrazole ring) and 453.9 m (Sn–C). δ_H 1.28 (18H, s, C(CH_3)$_3$), 6.11 (2H, d, H^4), 6.19 (2H, s, CH_2), 7.46 (2H, d, H^3), 7.52 (6H, m, C$_6$H$_5$), 7.69 (4H, m, C$_6$H$_5$). *Anal*. Calc. for $C_{27}H_{34}Cl_2N_4Sn$: C, 53.64; H, 5.63; N, 9.27. Found: C, 53.49; H, 5.56; N, 9.43.%.

*2.5. Bis(5-isopropylpyrazol-1-yl)methane diphenyltin(IV) dibromide (**7**) and (3-isopropylpyrazol-1-yl-5′-isopropylpyrazol-1-yl)methane diphenyltin(IV) dibromide (**8**)*

A mixture of isomers **2**, **3** and **4** (0.232 g, 1 mmol) was added dropwise to a stirred petroleum ether (60–90°C) solution (30 ml) of Ph_2SnBr_2 (0.433 g, 1 mmol) by syringe. The reaction mixture was stirred continuously for 2 h at room

temperature, during which time a white precipitate was gradually formed. The precipitate was filtered off, washed with petroleum ether and recrystallized from dichloromethane–hexane at −20°C to yield colorless crystals of CH_2(5-iPrPz)$_2SnPh_2Br_2$ (**7**) (0.28 g, 78%, based on the ratios **2**:**3**:**4** = 54:33:13), which was identified by X-ray crystallography, m.p. 140–142°C. ν_{max} (cm^{-1}) 1527.8 m (pyrazole ring) and 460.1 s (Sn–C). δ_H 1.15 (12H, d, CH(CH_3)$_2$), 3.51 (2H, septet, CH(CH_3)$_2$), 6.08 (2H, d, H^4), 6.43 (2H, s, CH_2), 7.45 (2H, d, H^3), 7.50 (6H, m, C_6H_5), 7.65 (4H, m, C_6H_5). ^{119}Sn NMR ($CDCl_3$): δ −83.4. *Anal*. Calc. for $C_{25}H_{30}Br_2N_4Sn$: C, 45.11; H, 4.51; N, 8.42. Found: C, 44.95; H, 4.08; N, 8.56%. The mother liquor was concentrated to 5 ml to afford a white solid, which was filtered off, washed with cooled petroleum ether (25 ml) and dried in vacuo to yield a white powder of CH_2(3-iPrPz-5′-iPrPz)$SnPh_2Br_2$ (**8**) (0.12 g, 65%), which was identified by X-ray crystallography, m.p. 96–98°C. ν_{max} (cm^{-1}) 1528.3 m (pyrazole ring) and 456.9 s (Sn–C). δ_H 1.19 (12H, dd, 3- and 5′-CH(CH_3)$_2$), 2.98 (1H, septet, 3- or 5′-CH(CH_3)$_2$), 3.32 (1H, septet, 3- or 5′-CH(CH_3)$_2$), 6.05 (2H, dd, H^4 and $H^{4'}$); 6.22 (2H, s, CH_2), 7.49 (8H, m, H^3 or $H^{5'}$ and C_6H_5), 7.65 (4H, m, C_6H_5). ^{119}Sn NMR ($CDCl_3$): δ −85.0. *Anal*. Calc. for $C_{25}H_{30}Br_2N_4Sn$: C, 45.11; H, 4.51; N, 8.42. Found: C, 44.75; H, 4.34; N, 8.28%.

*2.6. Bis(5-isopropylpyrazol-1-yl)methane diphenyltin(IV) dichloride (**9**) and (3-isopropylpyrazol-1-yl-5′-isopropylpyrazol-1-yl)methane diphenyltin(IV) dichloride (**10**)*

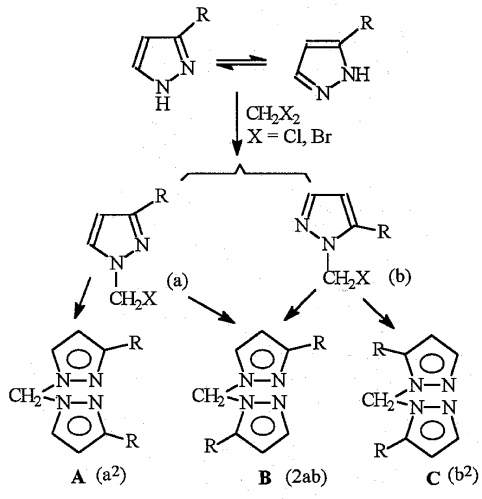
A mixture of isomers **2**, **3** and **4** (0.232 g, 1 mmol) was added dropwise to a stirred petroleum ether (60–90°C) solution (30 ml) of Ph_2SnCl_2 (0.344 g, 1 mmol) by syringe. A white precipitate was formed immediately. The reaction mixture was stirred continuously for 2 h at room temperature to complete the reaction. The precipitate was filtered off, washed with petroleum ether and recrystallized from dichloromethane–hexane at −20°C to yield colorless crystals of CH_2(5-iPrPz)$_2SnPh_2Cl_2$ (**9**) (0.25 g, 81%,), identified by comparing the ^{1}H NMR spectrum with that of complex **7**, m.p. 137–139°C. ν_{max} (cm^{-1}) 1527.4 m (pyrazole ring) and 458.2 s (Sn–C). δ_H 1.25 (12H, d, CH(CH_3)$_2$), 2.98 (2H, septet, CH(CH_3)$_2$), 6.10 (2H, d, H^4), 6.25 (2H, s, CH_2), 7.45 (8H, m, H^3 and C_6H_5), 7.67 (4H, m, C_6H_5). *Anal*. Calc. for $C_{25}H_{30}Cl_2N_4Sn$: C, 52.08; H, 5.21; N, 9.72. Found: C, 51.82; H, 5.44; N, 9.70%. The mother liquor was concentrated to 5 ml to afford a white solid, which was filtered off, washed with cooled petroleum ether (25 ml) and dried in vacuo to yield a white powder of CH_2(3-iPrPz-5′-iPrPz)$SnPh_2Cl_2$ (**10**) (0.11 g, 62%), identified by comparing its ^{1}H NMR with that of complex **8**, m.p. 101–103°C. ν_{max} (cm^{-1}) 1527.6 m (pyrazole ring) and 458.4 s (Sn–C). δ_H 1.19 (12H, dd, 3 and 5′-CH(CH_3)$_2$), 2.94 (1H, septet, 3 or 5′-CH(CH_3)$_2$), 3.31 (1H, septet, 3 or 5′-CH(CH_3)$_2$), 6.04 (2H, dd, H^4 and $H^{4'}$), 6.21 (2H, s, CH_2), 7.50 (2H, dd, H^3 and $H^{5'}$), 7.52 (6H, m, C_6H_5), 7.66 (4H, m, C_6H_5). *Anal*. Calc. for $C_{25}H_{30}Cl_2N_4Sn$: C, 52.08; H, 5.21; N, 9.72. Found: C, 52.41; H, 5.36; N, 10.12%.

2.7. X-ray crystallography

Crystals of compound **7** suitable for crystallographic investigation were grown from slow vaporization of a dichloromethane–hexane solution at room temperature. Intensity data were collected on a CAD4 diffractometer with graphite-monochromated Mo Kα radiation (0.71073 Å) at 299 K using the $\omega/2\theta$ scan technique in the range of $2° \leq \theta \leq 23°$. Correction for empirical absorption (DIFABS) [17] was applied, and the stucture was solved by direct methods [18] and refined by full-matrix least-squares. All non-hydrogen atoms were refined anisotropically. The calculations were performed on a PDP 11/44 computer with the SDP-PLUS program package [19].

Crystals of compound **8** suitable for X-ray analysis were obtained from a dichloromethane–hexane solution at 4°C. The data were collected on a Rigaku AFC7R diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71069 Å) at 20°C using the $\omega/2\theta$ scan technique to a maximun 2θ value of 50°. An empirical absorption correction was applied, and the structure was solved by direct methods [20] and expanded using Fourier techniques [21]. The non-hydrogen atoms were refined anisotropically. All calculations were performed using the teXsan [22] crystallographic software package. The crystallographic data and data collection parameters for complexes **7** and **8** are summarized in Table 1.

3. Results and discussion



3.1. Synthesis of ligands

Since asymmetric pyrazoles such as 3(5)-methylpyrazole and 3(5)-aminopyrazole can exist in two tautomeric structures in solution, the reaction of asymmetric pyrazoles with alkylation agents such as methylene chloride or methylene bromide in phase-transfer catalytic conditions yields three isomers **A**, **B** and **C** (Scheme 1), in which R is a methyl or amino group. It is of interest that the relative amounts of isomeric bis(pyrazol-1-yl)methanes (**A**:**B**:**C**) correspond to $(a+b)^2$ [23,24]. Recent investigation shows that the reaction of 3-(2-pyridyl)pyrazole with CH_2Br_2 under phase-transfer conditions affords only two isomers **A** and **B**, where R is a 3-(2-pyridyl) group, and the third isomer **C** is not formed [25].

In this work, we find that the reaction of 3-*tert*-butylpyrazole with CH_2Br_2 in analogous conditions gives only isomer **A** (R = Bu^t), which is the result of the strong steric hindrance of *tert*-butyl group. However, when R is an isopropyl group, the reaction of 3-isopropylpyrazole with CH_2Br_2 under the same conditions gives three isomers. It is notable that the relative amount of isomer **C** (R = iPr) with the strongest

Scheme 1. Compound **1**: **A**, R = C(CH$_3$)$_3$; compound **2**: **C**, R = CH(CH$_3$)$_2$; compound **3**: **B**, R = CH(CH$_3$)$_2$; compound **4**: **A**, R = CH(CH$_3$)$_2$.

steric hindrance is highest (54%), which reflects the characteristics of the isopropyl group [16]. The assignment of ^{1}H NMR spectra of the mixture is achieved by comparision with the ^{1}H NMR spectra of their adducts with $SnPh_2X_2$ (X = Cl, Br) and the crystal structures of their adducts.

3.2. Complexes with diphenyltin(IV) dihalides

Although ligand **1** has a bulky substituent in the 3-position of the pyrazole ring, its reaction with an equimolar amount of Ph_2SnX_2 (X = Cl, Br) in ether afforded 1:1 adducts compounds **5** and **6**. The two complexes were slightly soluble in petroleum ether, and soluble in polar organic solvents such as CH_2Cl_2 and acetone.

The pure isomers **A**, **B** and **C** were obtained by chromatography as described in the literature [23,24], which was time-consuming and resulted in some losses. In our work, the isomers **A**, **B** and **C**, where R = iPr, were easy isolated by taking advantage of the different solubility of their adducts with $SnPh_2X_2$ (X = Cl, Br) in petroleum ether (60–90°C). The reaction of the isomeric mixture with $SnPh_2Br_2$ in petroleum ether precipitated out the adduct of isomer **C** (complex **7**), while the adduct of isomer **B** (complex **8**) and the adduct of isomer **A** remained in solution. The pure complex **8** could be obtained from recrystallizing the mixture of complex **8** and the adduct of isomer **A** with $SnPh_2Br_2$ from dichloromethane–hexane. However, we could not obtain the pure adduct of isomer **A** by recrystallization due to its low yield and its similar solubility to that of complex **7**.

The ^{1}H NMR spectra of complexes **5**, **6**, **7** and **9** indicated that the two methylene protons are equivalent, as are the corresponding pyrazole protons. It may be possible that a fluxional behavior of rapid boat inversion through Sn–N bond breaking [12] could exist, owing to weak interactions between ligands and organotin(IV) (see Section 3.3). Since the pyrazole protons and isopropyl protons in complexes **8** and **10** are non-equivalent, two sets of signals for the pyrazole and isopropyl protons were observed. The ^{119}Sn NMR chemical shifts for complexes **5**, **7** and **8** occurred at −157.4, −83.4 and −85.0 ppm in $CDCl_3$, respectively. These data are comparable with those of related organotin derivatives of poly(pyrazol-1-yl)alkanes [10] and $SnPh_2Br_2$ (−72.9 ppm) determined under the same conditions, which showed that these complexes are also extensively dissociated in chloroform solution. The molar conductances of these complexes (Table 2) were found to be in the range of 4–8 Ω^{-1} cm^2 mol^{-1} in acetone, indicating that they are not electrolytic in acetone. However, all complexes are partly ionized in dimeth-

Table 2

3.3. Crystal structures of complexes *7* and *8*

Selected distances and angles for complexes **7** and **8** are listed in Tables 3 and 4, respectively. The crystal structure of complex **7** is shown in Fig. 1 and that of complex **8** in Fig. 2; it is clear that the two isopropyl groups in complex **7** are in the 5- and 5′-positions of pyrazole rings, whereas in complex **8** one isopropyl group is in the 3-position of the pyrazole ring and the other in the 5′-position. The tin atoms in complexes **7** and **8** are six-coordinate with a distorted octahedral geometry, a *cis* arrangement of the bromine atoms and a *trans* arrangement of the phenyl groups. The six-membered Sn–N–N–C–N–N metallacycle in complex **7** adopts a slightly distorted boat conformation, which is similar to that in complex **8**.

It is of interest that the two phenyl groups in complexes **7** and **8** bend towards bis(pyrazol-1-yl)methane ligands owing to the repulsion between phenyl groups, bromine atoms and bis(pyrazol-1-yl)methane, and the stronger repulsion of bromine atoms than that of bis(pyrazol-1-yl)methane ligand. The two phenyl planes form a dihedral angle of 104.4° in complex **7** and 91.6° in complex **8**.

Although the angles ∠N–Sn–N and ∠C–Sn–C in complex **7** [∠N(1)–Sn(1)–N(3) = 77.6(3)° and ∠C(21)–Sn(1)–C(11) = 168.2(5)°, respectively] are similar to those in complex **8** [∠N1–Sn–N3 = 77.9(10)°, ∠C14–Sn–C20 = 165.8(2)°], the angles ∠Br–Sn–Br and ∠N1–Sn–Br2 are quite different. The angle ∠Br–Sn–Br in complex **7** (100.3(10)°) is larger than that in complex **8** [94.68(2)°] and the angle ∠N1–Sn–Br2 in complex **7** [168.6(7)°] is smaller than that in complex **8** [175.57(9)°]. It seems that the isopropyl group in the 3-position of the pyrazole ring is responsible for these. The isopropyl group increases the repulsion of phenyl groups in complex **8** and ligand **3** so that the phenyl group (composed of C20, C21, C22, C23, C24, C25) is pushed out to Br2, which leads to increased repulsion between the phenyl group and Br2, making Br2 bend towards Br1. Thus, the angle ∠Br–Sn–Br in complex **8** decreases and the angle ∠N1–Sn–Br2 increases, compared with those in complex **7**. The Sn–C distances are 2.158(16) and 2.143(16) Å in complex **7** and 2.144(4) and 2.137(4) Å in complex **8**, which are within the normal range for such bonds [10]. The average Sn–N distance in complex **7** (2.435 Å) is similar to that in $CH_2(4\text{-MePz})_2SnMe_2Cl_2$ (2.436 Å) [10]. However, the average Sn–N distance in complex **8** is 2.52 Å and con-

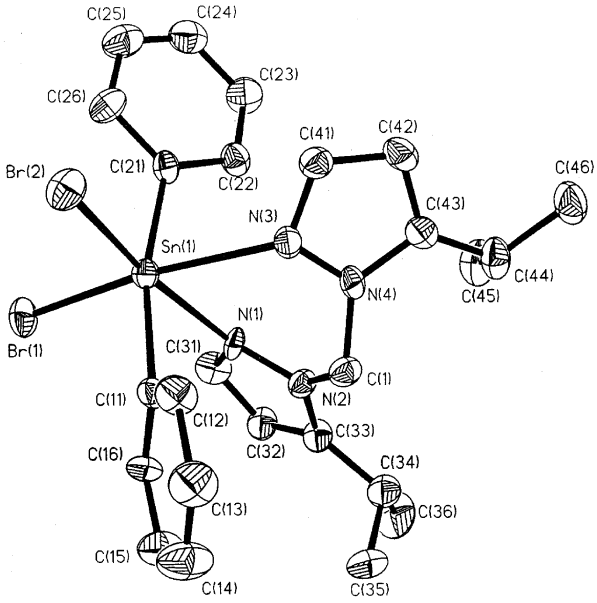

Fig. 1. The molecular structure of compound **7**.

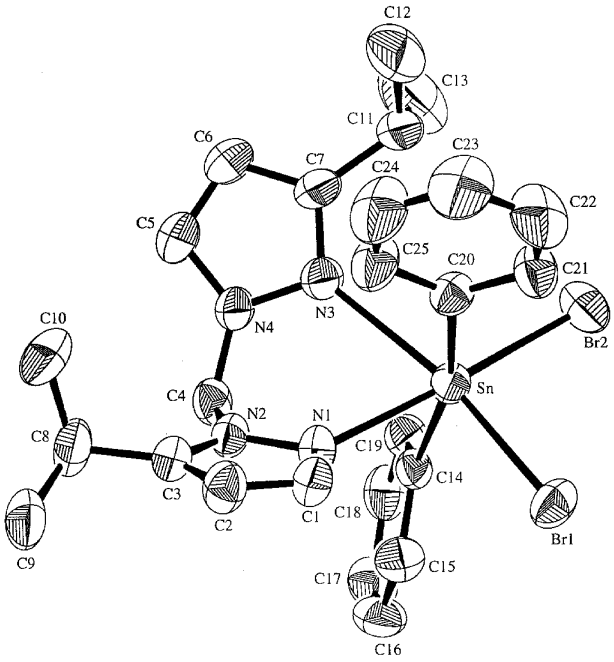

Fig. 2. The molecular structure of compound **8**.

siderably longer than that in complex **7** due to the isopropyl group in the 3-position of the pyrazole ring weakening the interactions between ligand **3** and organotin acceptors.

In conclusion, the bulky substituents in the 3- or 5-position of the pyrazole ring significantly affect the structures of organotin derivatives of poly(pyrazol-1-yl)alkanes. The steric hindrance of substituents reduces the interactions of poly(pyrazol-1-yl)alkanes with organotin acceptors. The Sn–N bonds in complexes **7** and **8** are found to be remarkably longer than the values in the antitumor active compounds [10].

Supplementary data

Atomic coordinates, thermal parameters and bond lengths and angles for complexes **7** and **8** have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Any request to the CCDC for this material should quote the full literature citation and the reference numbers CCDC 114184 and CCDC 114185.

POLYHEDRON

The electronic structure of planar phosphazene rings

Martin Breza *

Department of Physical Chemistry, Slovak Technical University, SK-812 37 Bratislava, Slovakia

Received 2 August 1999; accepted 22 November 1999

Dedicated to Professor Peter Pelikán on the occasion of his 60th birthday.

Abstract

Using a standard ab initio method, the electronic structure and optimal geometries of cyclo-$(NPX_2)_n$ ($n=2$, 3, 4 and X = H, F, Cl) have been investigated using the DZP basis set. The out-of-plane π bonds as well as the in-plane π' bonds in phosphazenes are dominated by p orbitals, although the bonding interaction between p orbitals on N atoms and d orbitals on P atoms is symmetrically forbidden in rings of D_{nh} symmetry with odd n only. In-plane π' and σ bonds in cyclic planar phosphazenes can be distinguished using Mulliken population analysis of cylindrical atomic orbitals. The d functions on P atoms do not correspond to their d orbitals and can be explained as polarization functions only. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Ab initio methods; Cyclic phosphazenes; Electronic structures; Group theory

1. Introduction

The phosphazene backbone formally consists of alternating single and double P–N bonds. The electronic structure of phosphazenes has been the subject of much controversy, but the generally accepted 'island model' [1] supposes that the σ bonds in the phosphazenes are formed by sp^3 hybrid orbitals of phosphorus. Out-of-plane π bonds are formed by the nitrogen p_z orbital, the adjacent phosphorus d_{xz} and d_{yz} orbitals being combined into sets of three-centre π molecular orbitals (MOs) which overlap only weakly with one another. The break in conjugation at each phosphorus atom implies that adjacent three-centre π bonds need not be coplanar and that the cyclic phosphazenes are not aromatic. A second set of delocalized electrons that occupy MOs symmetric to reflection in the molecular plane (d_{xy} and $d_{x^2-y^2}$ orbitals on P atoms, p_x and p_y orbitals on N atoms), but which are otherwise generally similar to the MO concerned in π delocalization, is referred to as in-plane π' bonding [2].

The importance of the d orbitals of the central atoms of the main group for bonding in hypervalent tetracoordinate species [3] has been questioned and makes the above model doubtful. Moreover, claims of dsp^3 or d^2sp^3 hybridization in such species are misleading. The d orbitals on the central atom play only a secondary role in π bonding, which occurs mainly through negative hyperconjugation. Using energy criteria (a correlation extra energy per valence shell electron pair) it has been shown [4] that the d functions of the main group elements act as polarizing and correlating functions only.

The above statements cannot assume that the d functions are unnecessary. Many authors have shown their importance for the exact description of the geometry and electronic structure of phosphazenes using various semi-empirical and ab initio treatments [5–18]. It can be concluded that the d orbital must be described using d functions, but that not all d functions describe d orbitals. In the latter sense they improve the flexibility of the incomplete s and p basis sets only.

The most common subjects of theoretical studies are small cyclic phosphazenes (Fig. 1) with planar phosphazene rings of D_{nh} symmetry (despite the fact that IR spectra in vapour and in solution [19] indicate non-vanishing deviations from ring planarity for $n>3$). Ab initio methods [13–18] using good basis sets are able to reproduce the experimental structure data [20–24] satisfactorily (Table 1). The charge distribution is best described as a zwitterionic form because there is a significant amount of charge accumulation on the ring nitrogen. An experimental electron density map was in agreement with the classical 'island' model [25]. Contrary to out-

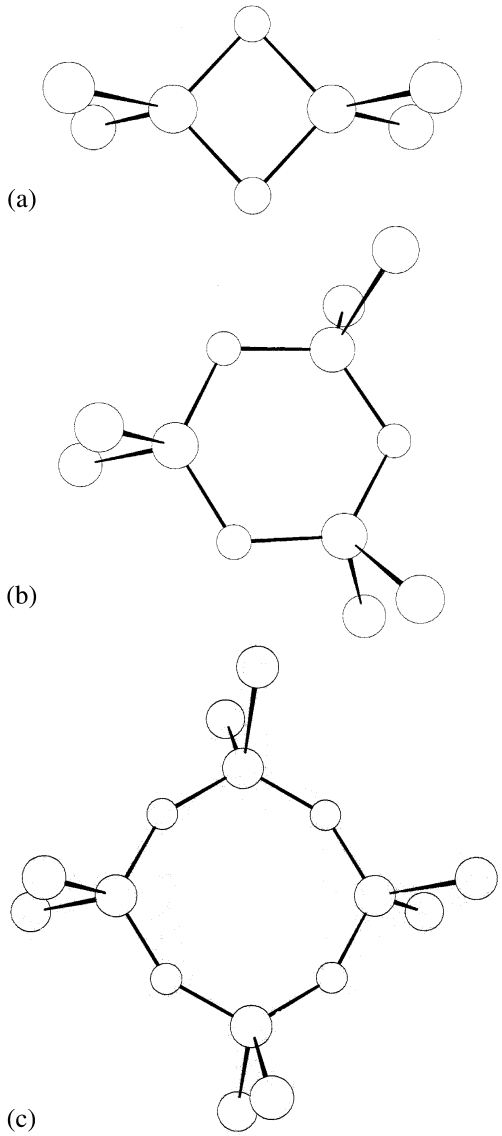

Fig. 1. Molecular structure of planar cyclo-$(NPX_2)_2$ (a), cyclo-$(NPX_2)_3$ (b) and cyclo-$(NPX_2)_4$ (c).

of-plane π bonds (antisymmetric to the ring plane), group theoretical treatment cannot distinguish between in-plane π′ and σ bonds. An attempt to estimate the π′ bond order was based on the d electron population on P atoms [17].

The aim of our present study was a critical reinvestigation of the classical picture of the bonding of phosphazenes in the light of recent ideas of the role of d functions. Using more complex group theoretical analysis accompanied by ab initio calculations, we have attempted to distinguish between in-plane π′ and σ bonds.

2. Group theoretical analysis

The geometry of planar cyclic phosphazenes (Fig. 1) is described by D_{nh} symmetry point groups. The plane of the phosphazene ring is usually denoted as a σ_{xy} or σ_h mirror

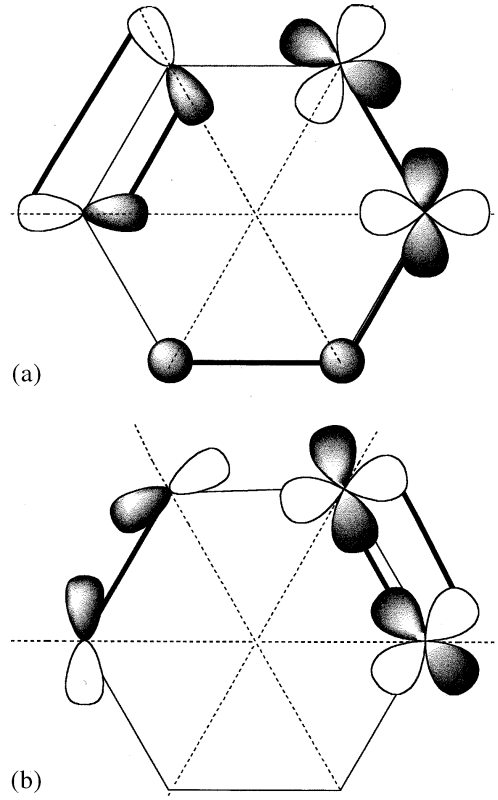

Fig. 2. In-plane bonding in six-membered rings: (a) (from bottom clockwise) σ bonding s–s, non-bonding s–p_r, in-plane π′ bonding p_r–p_r, non–bonding p_r–d_{hr}, σ bonding d_{hr}–d_{hr} and σ bonding d_{hr}–s interactions; (b) σ bonding p_τ–p_τ, non-bonding p_τ–$d_{h\tau}$ and in-plane π′ bonding $d_{h\tau}$–$d_{h\tau}$ interactions.

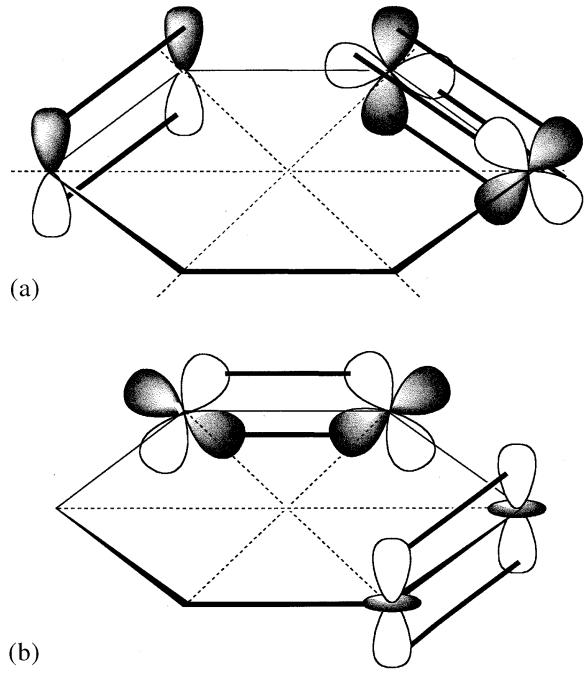

Fig. 3. Out-of-plane π bonding in six-membered rings: (a) bonding p_z–p_z, non-bonding p_z–d_{zr} and bonding d_{zr}–d_{zr} interactions; (b) bonding $d_{z\tau}$–$d_{z\tau}$, non-bonding d_{zt}–d_{z^2} and bonding $d_{z^2-z^2}$ interactions.

plane. The principal symmetry axis and couples of opposite P and/or N atoms define *n* vertical σ_v planes (perpendicular to σ_h planes). In order to describe the bonding ability of individual atomic orbitals (AOs), we have introduced a non-planar tangential τ surface that contains all the ring atoms and is perpendicular to the σ_h and all σ_v mirror planes. This surface shape is something between a cylindrical and *n*-gonal prismatic one; in the atom areas it is tangential to the σ_v planes and between them corresponds to the symmetry plane (perpendicular to σ_h) of the P–N bond. It can be thought of simply as a prismatic surface with (infinitesimally) rounded edges.

For our purposes, it is advantageous to use the cylindrical coordinate system with an origin at the centre of the ring instead of the Cartesian system. As the *z*-axis is equivalent to the principal axis, the AOs of s, p_z and d_{z^2} types are the same in both coordinate systems. Using simple coordinate transformations, the couples of p_x and p_y orbitals are converted into radial p_r and tangential p_τ AOs (see Fig. 2) in the σ_h mirror plane. Analogously, the $d_{x^2-y^2}$ and d_{xy} orbitals in the σ_h plane are transformed into radial d_{hr} and tangential $d_{h\tau}$ orbitals. The remaining d_{xz} and d_{yz} orbitals perpendicular to σ_h are converted into radial d_{zr} and tangential $d_{z\tau}$ orbitals (Fig. 3).

In the linear combination of AOs treatment, the MOs are constructed as symmetry-adapted linear combinations of individual AOs. According to the group theoretical rules, only orbitals with the same symmetry species can contribute to chemical bonding [26]. This means that all AOs in the same MO must be either symmmetric or antisymmetric under the same symmetry operation.

The symmetry properties relating to σ_h and τ elements are crucial for ring P–N bonding. The AOs on the adjacent atoms must be of the same symmetry defined by these elements, otherwise the bonding interactions cannot be formed. Consequently, these orbitals can be grouped as follows (see Table 2 and Figs. 2 and 3):

Table 1

Table 2
Symmetry description of cylindrical atomic orbitals (see Figs. 2 and 3)

Atomic orbital	Character value			Cartesian analogs	Specification
	τ	σ_h	$n\sigma_v$		
S	+1	+1	+1	s	
P_r	−1	+1	+1	(p_x, p_y)	principal axis in σ_v, nodal plane $\equiv\tau$
p_τ	+1	+1	−1	(p_x, p_y)	nodal plane $\equiv\sigma_v$, principal axis in τ
P_z	+1	−1	+1	p_z	
d_{hr}	+1	+1	+1	($d_{x^2-y^2}$, d_{xy})	two lobes in σ_v, two lobes in τ
$d_{h\tau}$	−1	+1	−1	($d_{x^2-y^2}$, d_{xy})	one nodal plane $\equiv\sigma_v$, one nodal plane $\equiv\tau$
d_{zr}	−1	−1	+1	(d_{xz}, d_{yz})	four lobes in σ_v, one nodal plane $\equiv\tau$
$d_{z\tau}$	+1	−1	−1	(d_{xz}, d_{yz})	one nodal plane $\equiv\sigma_v$, four lobes in τ
d_{z^2}	+1	+1	+1	d_{z^2}	

1. Bonds can be formed by s, p_τ and/or d_{hr} orbitals that are both σ_h and τ symmetric. They are situated in the σ_h plane, contrary to d_{z^2} orbitals which might contribute to the out-of-plane π interactions only (in-plane s–d_{z^2} bonds vanish due to the ring-shaped nodal surface of the d_{z^2} orbitals).
2. In-plane π' bonds can be formed by p_r and/or $d_{h\tau}$ orbitals which are σ_h symmetric and τ antisymmetric.
3. Out-of-plane π bonds can be formed by p_z and/or $d_{z\tau}$ orbitals that are σ_h antisymmetric and τ symmetric.
4. Another set of out-of-plane π bonds might be formed by d_{zr} orbitals that are both σ_h and τ antisymmetric.

As no d orbitals on N atoms are assumed, further simplifications can be concluded:

1. Simple σ bonds can originate in s(P)–s(N), s(P)–p_τ(N), p_τ(P)–s(N), p_τ(P)–p_τ(N), d_{hr}(P)–s(N) and d_{hr}(P)–p_τ(N) orbital interactions only.
2. In-plane π' bonds can originate in p_r(P)–p_r(N) and $d_{h\tau}$(P)–p_r(N) orbital interactions only.
3. Out-of-plane π bonds can originate in p_z(P)–p_z(N) and $d_{z\tau}$(P)–p_z(N) orbital interactions only.

In phosphazene rings of D_{nh} symmetry with odd n, the opposite P and N atoms are situated in the same σ_v mirror planes. Because all atoms of the same type are equivalent, the AOs located on the neighbouring atoms must be either σ_v symmetric or antisymmetric to form the bond. This additional condition (Table 2) causes further reduction of bonding patterns.

Possible N–P bonding interactions in the phosphazene ring may be exclusively of s(P)–s(N), p_τ(P)–p_τ(N) and s(N)–d_{hr}(P) of σ type, p_z(P)–p_z(N) of out-of-plane π type and p_r(P)–p_r(N) of in-plane π' type. These results indicate that the π and the π' bonding between p orbitals on N atoms and d orbitals on P atoms is symmetry forbidden in D_{nh} phosphazene rings with odd n. This statement can also be generalized to all non-phosphazene rings of D_{nh} symmetry with odd n.

The analogous statement on the π or π' bonding between p orbitals on N atoms and d orbitals on P atoms for D_{nh} phosphazene rings with even n cannot be deduced by symmetry arguments. We can verify it only by numerical calculations (see Section 4).

3. Method of calculation

Ab initio molecular orbital calculations of planar cyclo-$(NPX_2)_n$ molecules with $n = 2$, 3, 4 and X = H, F, Cl were performed using a standard HONDO-type [27] computer program within the standard DZP basis set from the HONDO library [27]. For H atoms, a single p function with exponent of 1.0 has been added to the contracted (4s)/[2s] basis set. Single d functions with exponents equal to 0.8 and 0.9 were added to the contracted (9s5p)/[3s2p] basis sets for N and F atoms, respectively. Similarly, the exponents equal to 0.5 and 0.65 were used for additional d functions to the contracted (11s7p)/[6s4p] basis sets for P and Cl atoms, respectively [27].

The geometries of all the systems were optimized within D_{nh} symmetry (see Table 1 and Fig. 1). Electronic structure was evaluated in terms of Mulliken population analysis (MPA; gross or net atomic charges for atoms and overlap populations for bonds) as well as in terms of Roby–Davidson–Heinzmann–Ahlrichs population analysis based on occupation numbers (PABON; atomic charges with multicentre corrections for atoms and shared electron numbers for bonds) [28,29].

4. Results and discussion

The influence of ligand variation on the properties of phosphazenes has been the subject of several theoretical studies [5–18]. Comparison of our results (Tables 1 and 3–5) with optimal geometries calculated using DZ basis sets confirms the necessity of using polarization functions. Neglecting them causes deviations from the experimental data in bond lengths up to 10^{-11} m and in bond angles up to 5°. Use of DZP basis sets gives discrepancies one order lower (Table 1). Inclusion of diffuse functions may slightly change the results for very electronegative atoms. The basis set effect has been studied elsewhere [18]. Nevertheless, it must be mentioned that the symmetry of the experimental structures [20–24] is lower than D_{nh} due to solid state effects (deviations of ca. 10^{-12}

m). Moreover, both forms of cyclo-$(NPCl_2)_4$ exhibit significant deviations from planarity (up to 0.4×10^{-10} m) that might be of intrinsic origin [19,23,24]. However, the planarity of model systems is necessary for group theoretical analysis of π bonding. According to our results for the series of planar cyclo-$(NPX_2)_n$ molecules, the P–N bond length decreases with increasing *n* (due to a decrease in ring strain) compared with the nearly constant P–X bond lengths and X–P–X bond angles. These trends are in agreement with experimental data [20–24].

Electronic structure data such as charges on X and P atoms or P–X bond strength are ordered according to the electronegativity of the X ligands (Tables 3–5). The values of the remaining parameters are complex functions of the size (or

[a] Numbers in parentheses correspond to net Mulliken populations.

proton number) and the electronegativity of these ligands (cf. [11]). Only P atoms possess non-vanishing formal d electron populations. Intra-ring P–P and N–N interactions are vanishing or antibonding (as implied by MPA).

Group theoretical analysis shows that there is no bonding between d orbitals on P atoms and p orbitals on N atoms in cyclic phosphazenes of D_{nh} symmetry with odd n. Consequently, in-plane π' bond order cannot be estimated using the formal d electron population on P atoms as in Ref. [17]. The possibility to extend these conclusions to all D_{nh} rings is tested by ab initio calculations and the results are compared in Tables 6–8 ($n=2$, 3 and 4). Our results show that d_{hr} functions are always included in the same MOs as the s and p_r functions. The same holds for $d_{h\tau}$ and p_τ as well as for d_{zr} and p_z. As these polarization d functions do not describe d orbitals, they might be understood as flexibility complements to corresponding s and/or p orbitals. Moreover, the out-of-plane π bonding between p_z(N) and d_{zr}(P) AOs is forbidden due to their different symmetry to the τ surface. The same holds for in-plane bonding between p_r(N) and d_{hr}(P) as well as p_τ(N) and $d_{h\tau}$(P) AOs (Table 9). Analogously, a polarization d_{z^2} function might represent the out-of-plane flexibility complement to σ bonds as its symmetry does not allow any bonding interactions within phosphazene rings. The problem of interpretation arises for a $d_{z\tau}$ function without any symmetry counterpart among s and p orbitals of P atoms.

The analysis of phosphazene MOs by bonding type is based on the symmetry properties of individual AOs (deduced from gross orbital populations of MPA). As N atoms are bonded only to P atoms, the difference between gross and net orbital populations on nitrogens (proportional to P–N overlap population) may be helpful to deduce the relative strength of in-plane π' and σ bonds within MOs of the same symmetry.

In cyclo-$(NPX_2)_2$ molecules of D_{2h} symmetry (Table 6), the fully symmetric a_g MO includes AOs that enable σ bonding s(N)–s(P) (with possibly s(N)–d_{hr}(P) also) and in-plane π' bonding p_r(N)–p_r(P) interaction as well. As the gross population on s(N) is equal to or lower than the net population (i.e. no bonding or antibonding character), this MO corresponds exclusively to in-plane π' bonding. MOs of b_{1g} and b_{2u} types describe σ bonds mediated by p_τ(N)–p_τ(P) and p_τ(N)–s(P) (with allowed p_τ(N)–d_{hr}(P)) bonding interactions, respectively. An MO of b_{3u} symmetry corresponds to σ bonding s(N)–p_τ(P) interaction, whereas possible in-plane π' bonding via p_r(N)–$d_{h\tau}$(P) interaction does not occur (also due to a negative difference between the gross and net p(N) population). Possible out-of-plane π bonding via p_z(N)–$d_{z\tau}$(P) interaction of b_{2g} type is questionable not only because of the purely polarizing character of d orbitals

[a] Numbers in parentheses correspond to net Mulliken populations.

but also because of the discrepancy between MPA and PABON description (weakly bonding or antibonding? — see Table 3). The absence of electron density on N atoms implies the P–N non-bonding character of b_{3g} MO. Thus, only b_{1u} MO forms an out-of-plane π bond via p_z(N)–p_z(P) interaction. According to our results, the in-plane π' bond is comparable with the out-of-plane π bond and its strength corresponds to about one-fifth of the total bond strength in cyclic diphosphazenes.

In cyclo-$(NPX_2)_3$ molecules of D_{3h} symmetry (Table 7), the fully symmetric a_1' MO enables analogous σ and in-plane π' bonding such as the a_g MO of cyclic diphosphazenes. Similarly, a_2' and a_2'' MOs are analogues of the b_{1g} and b_{1u} MOs in cyclic dimers, respectively. The degenerate e′ MO has two components. The first includes bonding similar to that of the a_1' MO except that comparison of gross and net orbital populations on s(N) and p(N) AOs indicates σ rather than in-plane π' bonds. The second e′ component is analogous to a σ bonding a_2' MO. The first component of degenerate e″ MO exhibits an out-of-plane π bond like an a_2'' MO, whereas the second component is non-bonding (only $d_{z\tau}$(P) polarizing functions). There is no bonding between p_z(N) and $d_{z\tau}$(P) AOs because they are included in MOs of different symmetries. The same holds for p_τ(N) and d_{hr}(P) as well as for p_r(N) and $d_{h\tau}$(P) AOs. Our results indicate that out-of-plane π bond strength corresponds to about one-fifth of the total bond strength and the in-plane π' bond is about two times weaker than the π bond in cyclic triphosphazenes.

In cyclo-$(NPX_2)_4$ molecules of D_{4h} symmetry (Table 8), the a_{1g} and a_{2g} MOs are completely analogous to a_g and b_{1g} of cyclic diphosphazenes, respectively. In b_{1g} MO, p_τ(N)–s(P) bonding interaction of σ type exists. MOs of b_{2g} and e_u symmetries are analogous to b_{3u} MO in cyclic dimer and e′ MO in cyclic trimer (with the exception of comparable σ and

Table 9
Summary of bonding schemes in planar phosphazene rings

Bonds	Interactions		Ring symmetry		
	bonding	non-bonding	D_{2h}	D_{3h}	D_{4h}
	In-plane:

σ			b_{1g}	a_2', e'	a_{2g}, e_u
σ			b_{2u}	-	b_{1g}
$\sigma + \pi'$			b_{3u}	-	b_{2g}
	Out-of-plane:				
π			b_{2g}	-	b_{1u}
π			b_{1u}	a_2'', e''	e_g, a_{2u}

in-plane π' bond strengths), respectively. Similarly, e_g and a_{2u} MOs are completely analogous to e″ MO in cyclic trimer and b_{1u} MO in cyclic dimer, respectively. A possible out-of-plane π bond of b_{1u} MO is questionable (Table 5) in the same way as for b_{2g} MO of diphosphazene. The lack of electron density on N atoms causes the P–N non-bonding character of b_{2u} MO. According to our results, the in-plane π' bond strength corresponds to about one-quarter of the total bond strength and the out-of-plane π bond is somewhat weaker in cyclic phosphazene tetramers.

It is evident that there are only some bonding patterns in planar phosphazene rings (Table 9) that would be preserved in larger cyclic systems. We have shown that in-plane π' and σ bonds in cyclic phosphazenes can be distinguished using MPA and group theory treatment. Although d_π–p_π bonding is symmetry forbidden in cyclic phosphazenes of D_{nh} symmetry with odd n only, it also does not play any significant role in cyclic phosphazenes of D_{nh} symmetry with even n. Both π bonding and π' bonding is dominated by p atomic orbitals. This is in agreement with the idea that the d functions on P atoms do not correspond to their d orbitals but cause increased flexibility of the basis set used. Nevertheless, neglecting them causes non-vanishing discrepancies in electronic structure and geometry.

Abstract

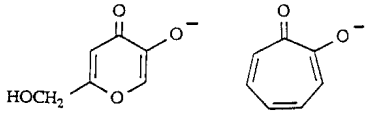
The structures of solvates of the bis-ethylmaltolatodichloro-metal(IV) complexes $M(etma)_2Cl_2$, with M = Sn and Ti, and of trichloro(1-methyl-2-ethyl-3-hydroxy-4*H*-pyridin-4-onato)aquatin(IV), $Sn(mepp)Cl_3(H_2O)$, have been established by single crystal X-ray diffraction methods. $Sn(etma)_2Cl_2$ crystallised with one molecule of dichloromethane, $Ti(etma)_2Cl_2$ with one molecule of tetrahydrofuran, and $Sn(mepp)Cl_3(H_2O)$ with one molecule of acetone, from their respective recrystallisation media. Both ethylmaltol complexes $M(etma)_2Cl_2$ are *cis*-octahedral. The coordination around the tin atom in $Sn(mepp)Cl_3(H_2O)$ approximates to octahedral, with the three chloride ligands in *fac* geometry. The tin(IV)–water bond distance in this pyridinone complex is discussed in relation to this distance in other aquatin(IV) complexes. The effects of coordinating tin(IV) on the geometry of the coordinated pyridinone are considered. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; 2-Ethyl-3-hydroxy-4-pyranonate; Ethylmaltol; 1-Methyl-2-ethyl-3-hydroxy-4-pyridinonate; Tin(IV); Titanium(IV)

1. Introduction

Pyranone and pyridinone ligands and complexes are currently of considerable interest in view of their actual and potential usefulness in clinical diagnosis and chemotherapy, and as agents for controlling metal levels in the body [1,2]. A number of iron(III) complexes have been tested for administration for the amelioration of anaemia [3–5], and, complementarily, a number of these ligands have been tested as orally administrable agents for the control of iron [6] and aluminium [7,8] overload. ^{67,68}Ga and ^{111}In derivatives [9] have been assessed for imaging and chemotherapy. These ligands also form complexes with metal(IV) centres of the type $M(LL)_2X_2$, where X = halide or alkoxide [10–14]. In view of the promise of complexes of this general type, particularly of budotitane, $Ti(bzac)_2(OEt)_2$ [12,13], as antitumour agents, we have been interested in synthesising a series of complexes $M(LL)_2X_2$, where LLH is a 3-hydroxy-4-pyranone such as maltol (maH) or ethylmaltol (etmaH) (**1**) with R = Me or Et, respectively, or a 3-hydroxy-4-pyridinone (**2**). Ethylmaltolate complexes currently appear particularly attractive [14], so we have synthesised a series of complexes $M(etma)_2Cl_2$, where M = Si, Ge, Zr, Hf, V and Mo. These complement our earlier syntheses of series of titanium [15] and tin [16] complexes $M(LL)_2Cl_2$, where LLH is ethylmaltol, several 3-hydroxy-4-pyridinones, or related ligands. Our attempts to synthesise an analogous complex from tin tetrachloride and 1-methyl-2-ethyl-3-hydroxy-4-pyridinone (mepp, **3**) resulted in the isolation of $Sn(mepp)Cl_3(H_2O)$, whose structure combines the interest of the effect of coordination of tin(IV) on bond distances in the coordinated mepp ligand with a tin(IV)–water bond, a fairly uncommon species.

1 **2** **3**



Structures have been reported for several 3-hydroxy-4-pyranones and 3-hydroxy-4-pyridinones [17–20], and for

PII S0277-5387(99)00371-X

several of their tris-ligand–metal(III) complexes [21–25]. The coordination of M^{3+} to ligands of this type has small but significant effects on bond distances, especially those that form part of the chelate rings in the complexes [26] — a topic most fully documented for closely related hydroxamato-iron(III) and -gallium(III) complexes [27]. A number of ternary complexes of the type $M^{IV}(LL)_2X_2$ (X = halide or alkoxide) containing these ligands bonded to metals in oxidation state 4+ have been prepared and characterised, but only a very few crystal structure determinations (e.g. that of $Sn(ma)_2Cl_2$ [11,28]) of such a compounds have been published. However, structures have been determined for a number of related complexes of the type $M^{IV}(LL)_2X_2$, including $Sn(acac)_2Cl_2$ [29], $Sn(bzac)_2Cl_2$ [30], $Sn(kojate)_2Me_2$ {as MeOH solvate; kojate = **4**} [31], and $Sn(trop)_2Me_2$ {trop = **5**} [31,32]. In the present paper we report the results of X-ray diffraction determinations of the crystal structures of $Ti(etma)_2Cl_2$ (**I**), $Sn(etma)_2Cl_2$ (**II**) and Sn(mepp)-$Cl_3(H_2O)$ (**III**). We discuss and compare structures for compounds of the type $M^{IV}(LL)_2X_2$, and examine the effects of coordinating Sn^{IV} ion on bond distances in coordinated 1-methyl-2-ethyl-3-hydroxy-pyridin-4-one.

2. Experimental

2.1. Materials

Bis-ethylmaltoldichloro-titanium(IV) and -tin(IV) were obtained from the respective tetrachlorides. Ethylmaltol (2.8 g, 20 mmol) was stirred in 30 ml of anhydrous tetrahydrofuran (THF) at room temperature. Titanium tetrachloride (1.9 g, 10 mmol) was added dropwise to the solution, giving an orange precipitate. The mixture was stirred at room temperature for 30 min, then filtered. The product was washed with anhydrous diethyl ether, and recrystallised from 50/50 dichloromethane/40–60 petroleum ether. The yield of dark orange crystals was 3.8 g (95%). Slow recrystallisation of a portion of product from THF gave crystals suitable for structure determination. The preparation of $Sn(etma)_2Cl_2$ was similar, i.e. reaction of 1.4 g (10 mmol) of ethylmaltol and 1.3 g (5 mmol) of tin tetrachloride giving 2.05 g (87% yield) of pale yellow product. Crystals suitable for X-ray structure determination were obtained by slow evaporation of a dichloromethane solution of this complex. Trichloro(1-methyl-2-ethyl-3-hydroxy-4*H*-pyridin-4-onato)aquatin(IV) was obtained from the reaction of 0.154 g (1 mmol) of the pyridinone, prepared from ethylmaltol as described elsewhere [33], with 0.26 g (1 mmol) of tin tetrachloride in wet acetone; 0.14 g (36%) of product was obtained, in the form of white crystals, upon slow crystallisation of the reaction mixture. The products gave satisfactory CH(N) analyses, and ^1H and ^{13}C NMR spectra were identical with previously characterised samples {for the $M(etma)_2Cl_2$ compounds}.

2.2. X-ray crystallography

Crystals of compounds **I**, **II** and **III** suitable for X-ray crystallographic analysis were obtained as detailed in Section 2.1. Crystal data, and a summary of the data collection and structure refinement parameters, are given in Table 1. Data for compounds **I**, **II** and **III** were measured at 290 K using graphite monochromated Mo Kα radiation ($\lambda = 0.7107$ Å) using omega (ω) scans. Crystals were glued onto glass fibres. Unit cell dimensions for compounds **I** and **II** were determined by least-squares refinement of ω values for different layers, and for compound **III** by least-squares refinement of optimised setting angles. The data were corrected for Lorentz and polarisation effects; analytical absorption corrections were applied to compounds **II** and **III**. The structures were solved by Patterson methods (SHELX86), and refined by full-matrix least-squares using SHELXL96. Hydrogen atoms were included in calculated positions (C–H = 0.96 Å) with the exception of those of the coordinated water molecule in compound **III** which were located from a difference Fourier map. All hydrogen atoms had isotropic displacement parameters fixed at 1.2 U_{eq} of the bonded atom. All non-hydrogen atoms except the THF solvent of compound **I** were refined with anisotropic displacement parameters.

3. Results and discussion

All three complexes are basically octahedral, but with significant distortions of angles at the central metal atom from the ideal 90° and 180°, presumably arising from the impossibility of the two oxygens of the coordinating hydroxypyranone or hydroxypyridinone ligands subtending angles as large as 90° at the metals. The structures of the three complexes are shown in Figs. 1–3; selected bond distances and bond angles are given in Tables 2–4.

The complexes $M(etma)_2Cl_2$ (**6**) are octahedral, with the chlorides in *cis* positions, the hydroxy-oxygens *trans* to each other and the keto-oxygens *cis* to each other. The ethylmaltolate ligand bite angles (∠O–M–O) at 79.0 and 79.8° for the tin compound are slightly smaller than the value of 78.4° (both ligand molecules) for the titanium compound. This is not consistent with the slightly smaller steric constraint imposed by the larger tin atom; ionic radii for Sn^{4+} and Ti^{4+} are 0.71, 0.68 Å [34,35] and 0.83, 0.75 Å [36,37], respectively (differences that are compatible with differences in appropriate pairs of M–O bond distances in Table 2). There is a reasonably good correlation between ∠O–M–O and ionic radii for M^{2+} and M^{3+} complexes with this type of ligand [38], but Sn^{4+} and Ti^{4+} apparently do not fit this pattern. We are unable to offer an explanation for this exceptional

behaviour, especially as bond distances in the coordinated ligands cannot here provide clues (see Section 3.5).

Despite the difference in ethylmaltolate ligand bite angles, the Cl–M–Cl angles in $Sn(etma)_2Cl_2$ and $Ti(etma)_2Cl_2$ are identical. The Cl–Sn–Cl angle in $Sn(etma)_2Cl_2$ is exactly the same as in $Sn(bzac)_2Cl_2$, slightly smaller than in $Sn(acac)_2Cl_2$ (96.8°). The ligand bite angles in $Sn(etma)_2Cl_2$ are intermediate between those of $Sn(acac)_2Cl_2$ and $Sn(bzac)_2Cl_2$ (87.0, 87.3 and 86.2, 86.4°) on the one hand and $Sn(kojate)_2Me_2$ and $Sn(trop)_2Me_2$ (71.4, 72.5 and 72.5, 73.2°) on the other.

The coordination environment of the tin in trichloro(1-methyl-2-ethyl-3-hydroxy-4*H*-pyridin-4-onato)aquatin(IV), $Sn(mepp)Cl_3(H_2O)$, is also approximately octahedral, as shown in structure **7**. Angles between pairs of *cis* donor atoms range from 79.3° {the two pyridinone-oxygen donors; the

bite here is the same as the mean for $Sn(etma)_2Cl_2$} to 101.5° (two of the chlorides). The three chlorides are mutually *fac*, as in a number of similar compounds, although the Cl–Sn–Cl angles are all considerably greater than 90°. The aqua ligand is *trans* to one of the chlorides, although the angle O–Sn–Cl of 169.3° indicates the marked deviation from collinearity of these *trans* ligands.

6 **7**

3.1. Tin–chlorine distances

The tin–chlorine distances in all the ternary complexes listed in Table 5, and also in $Sn(mepp)Cl_3(H_2O)$, are shorter than tin–chlorine in the hexachlorostannate(IV) anion [39]. The Sn–Cl bond distances appear to decrease as the affinity of the bidentate two-oxygen donor ligands for the metal increases. Thus the shortest Sn–Cl distance is in the bis-acetylacetonate complex, and the Sn–Cl distances of 2.342 and 2.345 Å in the 3-hydroxy-4-pyridinonate complex $Sn(mepp)Cl_3(H_2O)$ are significantly shorter than the Sn–Cl distances in the ethylmaltolate and maltolate complexes shown in Table 5. However, Sn–Cl distances in $Sn(mepp)Cl_3(H_2O)$ actually span 2.34–2.38 Å, and thus the average is very close to the mean Sn–Cl bond distances in the two maltol complexes.

3.2. Tin–water distances

The tin(IV) to water-oxygen distance in $Sn(mepp)Cl_3(H_2O)$ of 2.132 Å is comparable to analogous distances in other tin(IV) complexes containing coordinated water (Table 6) [40–45]. There is little evidence for simple Sn^{4+} aq, either in crystal hydrates or in aqueous solution [46], apart from some rather unconvincing ^1H and ^{119}Sn NMR evidence for a hydration number of six [47], even though

[c] i.e. $SnCl_4\cdot 5H_2O$.

$[Sn(OH)_6]^{2-}$ seems to be long established in the solid state [48]. The tin(II) to water-oxygen distance is 2.21–2.34 Å in Sn^{2+} aq [46].

3.3. Tin to pyranone-oxygen distances

Differences between Sn–O distances in the various complexes $Sn(LL)_2Cl_2$ (see Table 5) are generally too small to merit detailed discussion. However, it is apparent that these Sn–O distances are markedly shorter than in the methyl analogues $Sn(LL)_2Me_2$, and that the differences between tin to carbonyl-oxygen and tin to hydroxyl-oxygen distances (Δ in Table 5) are considerably smaller for the two *cis*-Sn(maltolate)$_2$L$_2$ compounds than for *trans*-$Sn(kojate)_2Me_2$, reflecting the strong *trans* influence of the methyl groups. Elsewhere such differences between metal to carbonyl-oxygen and to hydroxyl-oxygen distances have proved useful in assessing relative extents of delocalisation in chelate rings of hydroxy-pyranonate and hydroxy-pyridinonate complexes, but here the small but significant differences between the two metal–oxygen distances even to symmetrical bidentate ligands ($acac^-$, $trop^-$ and $bzbz^-$) precludes a meaningful assessment of chelate ring delocalisation in these unsymmetrical ternary *cis* complexes by this means.

3.4. Titanium to chlorine and oxygen distances

Similar comments apply to the metal–ligand bond distances in $Ti(etma)_2Cl_2$ as to those in $Sn(etma)_2Cl_2$. The Ti–Cl distance is significantly less than in $TiCl_6^{2-}$ [49–52], but similar to those in the β-diketonate analogues $Ti(\beta\text{-dik})_2Cl_2$ (β-dik = dibenzoylmethane, bzbz [53], or dipivaloylmethane, dpm [54]) and $[Ti(acac)Cl_3]_2$ [55]. All the Ti–Cl distances in octahedral species are markedly longer than in tetrahedral $TiCl_4$, where Ti–Cl = 2.18 Å (electron diffraction [56]; an X-ray examination of solid $TiCl_4$ [57] established lattice constants but not bond distances); Ti–Cl = 2.18 Å in

the Et_4N^+ salt of square-pyramidal $TiOCl_4^{2-}$, where the four chlorides are all equatorial [58].

The Ti–O bond distances in $Ti(etma)_2Cl_2$ are similar to those in the β-diketonate analogues $Ti(\beta\text{-dik})_2Cl_2$ [53,54], in $Ti(acac)_3^+$ [59] and in $Ti(OCH_2CH_2O)_3^{2-}$ [60]. They are slightly shorter than the equivalent Ti–O distances in $Ti(acac)_2$(2,6-diisopropylphenoxide)$_2$ [61] and those in $Cs_4[TiO(ox)_2]_2\,3H_2O$ [62]. All the Ti–O bond distances to chelating O,O′ ligands are longer than those in rutile (1.94, 1.99 Å [63]), in tetrahedral TiO_4^{4-} (1.79–1.84 Å [64,65]) and the axial Ti–O bond in the square-pyramidal $TiOCl_4^{2-}$ [58]. Comparison with Ti–O in Ti^{4+} aq is hardly possible in view of the lack of any firm evidence for the existence of this species, or indeed of the often-invoked TiO^{2+} aq [66], but comparison may be made with Ti–O = 2.01 Å in the organometallic aqua ion $[(\eta^5\text{-}C_5H_5)_2Ti(H_2O)_2]^{2+}$ [67] or, perhaps better, with Ti–O = 2.10, 2.11 Å in the cation $[(tmtaa)Ti(H_2O)_2]^{2+}$, where the macrocyclic ligand tmtaa is a tetra-azatetradecine derivative [68]. Further Ti–O bond distances may be traced through references cited elsewhere [60]; they may be compared with the 'expected distance' of 1.81 Å claimed for a single titanium(IV)–oxygen bond [62].

3.5. Coordinated ligand geometry

Comparison of bond distances in the chelate ring of a complex with analogous bond distances in the free ligand can sometimes give insight into the extent of delocalisation in the chelate ring. Unfortunately we cannot reach any conclusions with regard to the $M(etma)_2Cl_2$ complexes in the present study since the bond distances in the free ligand vary too much between the three polymorphs so far characterised by X-ray diffraction [69].

Bond distances in the chelate ring of $Sn(mepp)Cl_3(H_2O)$ are compared in Fig. 4 with those in the free mepp ligand [19], and with mean values for the three non-identical rings in $Al(mepp)_3$ [70]; other bond distances in the ligand are not significantly affected on coordination to aluminium or tin. It is noteworthy that the C–C distance in the chelate ring is not significantly changed on coordination to tin(IV), since for a number of metal(III) complexes this bond has been found to be significantly shortened on chelation. This C–C distance in the closely related ligand 1,2-dimethyl-3-hydroxy-4*H*-pyridin-4-one (compound **3** with R = R′ = Me; variously called L1, CP20, or deferiprone) is 1.435 Å [17], but in the tris-chelate complexes $[Fe(L1)_3]$ [23] and $[Co(L1)_3]$ [71] has decreased to 1.408 and 1.412 Å, respectively. The difference between the two C–O bond distances is probably the best measure of delocalisation in chelate rings in this type of complex. The C–O distances are significantly affected by coordination to the tin, reflecting delocalisation in the chelate ring. The difference between the two C–O distances is 0.075 Å in the free ligand and 0.026 Å in the complex. The analogous difference for $Al(mepp)_3$ is 0.032 Å. It is tempting to point out the slightly smaller effect for coordination to aluminium(III) than to tin(IV), but the uncertainties in the two values involved do not permit this conclusion to be drawn safely.

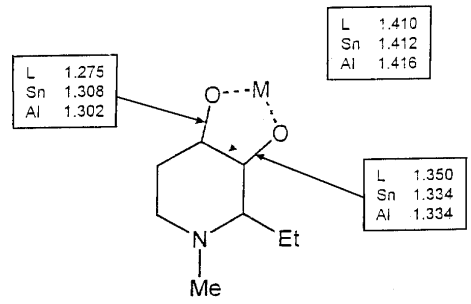

Fig. 4. Comparison of intraligand bond distances in the chelate rings of 3-hydroxy-1-methyl-2-ethyl-4-pyridinonate (mepp) complexes of tin and of aluminium with analogous distances in tris–ligand metal(III) and in the free ligand. L represents free ligand, Sn represents $Sn(mepp)Cl_3(H_2O)$, Al represents $Al(mepp)_3$.

One significant difference between the tin and titanium compounds $M(etma)_2Cl_2$ lies in the shape of the chelate rings. In the tin compound the chelate rings are essentially planar, with a mean deviation from the plane of only 0.005 Å, but the chelate rings in the titanium analogue are puckered, with a mean deviation from the plane of 0.64 Å.

3.6. Solvent of crystallisation

All three compounds crystallised as 1:1 solvates, with dichloromethane, THF and acetone, respectively. In both of the $M(etma)_2Cl_2$ compounds the solvent of crystallisation occupies spaces in the structure and does not interact strongly with surrounding molecules of complex. The dichloromethane in $Sn(etma)_2Cl_2\cdot CH_2Cl_2$ is in sites defined by orthogonal pyran rings in adjacent complex molecules. The tetrahydrofuran in $Ti(etma)_2Cl_2\cdot$THF is end-to-end disordered, and occupies sites in the lattice such that THF-oxygen to titanium distances are well over the limit for significant bonding interaction. By way of contrast, the acetone in $Sn(mepp)Cl_3(H_2O)\cdot C_3H_6O$ is hydrogen-bonded to the coordinated water. The acetone-oxygen to water-oxygen (O_3–O_4) distance is 2.633(4) Å, the H_1 to O_4 distance is 1.856 Å, and the O···H–O angle is 156.4°, all signifying relatively strong hydrogen bonding. It is interesting that it is the water, the very minor component in the solvent medium, that coordinates to the tin, rather than the major component, acetone. However, such strong preferential hydration of a metal centre is normal for metal cations M^{n+} in acetone–water mixtures [72]. It should be added that the methanol of crystallisation in $Sn(kojate)_2Me_2\cdot$MeOH is hydrogen-bonded to coordinated kojate ligands [31].

4. Supplementary data

All other crystallographic data can be obtained from the Cambridge Crystallographic Data Centre, where CIF files have been deposited (deposition numbers 132461 for compound **I**, 132462 for compound **II**, and 132463 for compound

III). Copies of this information can be obtained from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.uk).

Abstract

The immediate environment about tellurium in $Ph_2Te[S_2POCMe_2CMe_2O]_2$ (**1**) and $2Ph_2Te[S_2POCH_2CMe_2CH_2O]_2 \cdot 2Ph_2TeCl_2 \cdot CS_2$ (**2**) is essentially that of a saw-horse structure in which the lone-pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid. However, when the second sulfur atom of the unsymmetrical bidentate ligand is included in the coordination sphere, the arrangement about tellurium in compound **1** is better described as distorted octahedral and that in $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ as distorted pentagonal pyramidal. An intermolecular association involving a chlorine atom of Ph_2TeCl_2 results in a pentagonal bipyramidal arrangement. Sulfur and chlorine bridges between the Te atoms of $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ and Ph_2TeCl_2 indicate pseudo dimers or Te_2S_2Cl cages. The isolation of this mixed species rather than $Ph_2TeCl[S_2POCH_2CMe_2CH_2O]$ was most unexpected. There is no indication of hydrogen bonding in $HS_2POCMe_2CMe_2O$ (**3**) and $HS_2POCH_2CMe_2CH_2O$ (**4**); even the shortest S–S internuclear distance, which is in compound **3**, is 3.556(2) Å. In both acids, the P–SH bond is significantly longer than the P=S terminal bond. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: *O*,*O*-Alkylene dithiophosphate acids and ligands; Organotellurium(IV)

1. Introduction

Diphenyltellurium(IV) *O*,*O*-alkylene dithiophosphates of the type $Ph_2Te[S_2POGO]_2$ (where G = –CMe_2CMe_2–, –CHMeCHMe–, –$CH_2CMe_2CH_2$–, –$CH_2CEt_2CH_2$– and –$CHMeCH_2CMe_2$–) have been reported in the literature [1]. A report of the corresponding dimethyltellurium(IV) compounds of the type $Me_2Te[S_2POGO]_2$ includes the crystal structures of $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ [2]. In the course of attempting to prepare fully substituted GeL_4 compounds, where L = $S_2POCMe_2CMe_2O$ and $S_2POCH_2CMe_2CH_2O$, X-ray quality crystals of $HS_2POCMe_2CMe_2O$ and $HS_2POCH_2CMe_2CH_2O$ were obtained, presumably as a result of hydrolysis. This provides an opportunity to report on the structures of these acids along with the corresponding diphenyltellurium derivatives of these cyclic dithiophosphates, $Ph_2Te[S_2POCMe_2CMe_2O]_2$ and $2Ph_2Te[S_2POCH_2CMe_2CH_2O]_2 \cdot 2Ph_2TeCl_2CS_2$. The latter was formed fortuitously while attempting the synthesis of halo derivatives of the type $Ph_2TeCl[S_2POGO]$. Comparisons are made with the related dimethyltellurium(IV)dithio derivatives [2], which generally show greater stability than their diphenyl counterparts as well as less tendency to undergo reductive elimination to the diligand and diorganotellurium(II) [3].

2. Experimental

$TeCl_4$ and Ph_4Sn were obtained from Aldrich. Ph_2TeCl_2 was prepared by the reaction of $TeCl_4$ and Ph_4Sn in toluene at 60°C under reflux [4]. Sodium/ammonium salts of alkylene dithiophosphates were prepared by literature methods [5]. $Ph_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ (**1**) was synthesized on the basis of the method given earlier [1] by the reaction of Ph_2TeCl_2 with a greater than two-fold excess of $NH_4[S_2\overline{POCMe_2CMe_2O}]$. Reactions with equimolar amounts of Ph_2TeCl_2 and $NH_4[S_2\overline{POCMe_2CMe_2O}]$ or $NH_4[S_2\overline{POCH_2CMe_2CH_2O}]$ were carried out in carbon disulfide to attempt the preparation of the partially substituted derivatives, $Ph_2TeCl[S_2\overline{POCMe_2CMe_2O}]$ and $Ph_2TeCl[S_2\overline{POCH_2CMe_2CH_2O}]$, but the only crystals that were isolated were those of $2Ph_2Te[S_2\overline{POCH_2CMe_2CH_2O}]_2 \cdot 2Ph_2TeCl_2CS_2$. The acids were originally formed by the fortuitous in situ hydrolysis of GeL_4, where $L = S_2\overline{POCMe_2CMe_2O}$ or $S_2\overline{POCH_2CMe_2CH_2O}$, but can of course also be obtained by more conventional methods.

2.1. Crystal structure determination

The procedures for data collection, structure solution and refinement were as described previously [6] and relevant information is in Table 1.

The structures were solved by direct methods [7]. The non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in their idealized positions with C–H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. For compounds **3** and **4**, the H atom attached to S was located from difference maps and treated isotropically, with positional parameters fixed at the observed values from the penultimate least-squares cycle to ensure convergence. All calculations were performed using the TEXSAN [8] crystallographic software package of Molecular Structure Corp.

3. Results and discussion

$Ph_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ (**1**) crystallizes in the space group $P2_1/n$ and $2Ph_2Te[S_2\overline{POCH_2CMe_2CH_2O}]_2 \cdot 2Ph_2TeCl_2 \cdot CS_2$ (**2**) in the space group $C2/c$. The ORTEP diagrams (Fig. 1) illustrate that, for both dithiophosphate derivatives, as well as for Ph_2TeCl_2, the immediate environment about tellurium can be described as the saw-horse structure typical of tellurium(IV) compounds in which the lone-pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid, approximately in the position of the Te labels. For the two phenyl groups occupying the other two equatorial positions in $Ph_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ and $Ph_2Te[S_2\overline{POCH_2CMe_2CH_2O}]_2$, the average Te–C bond lengths

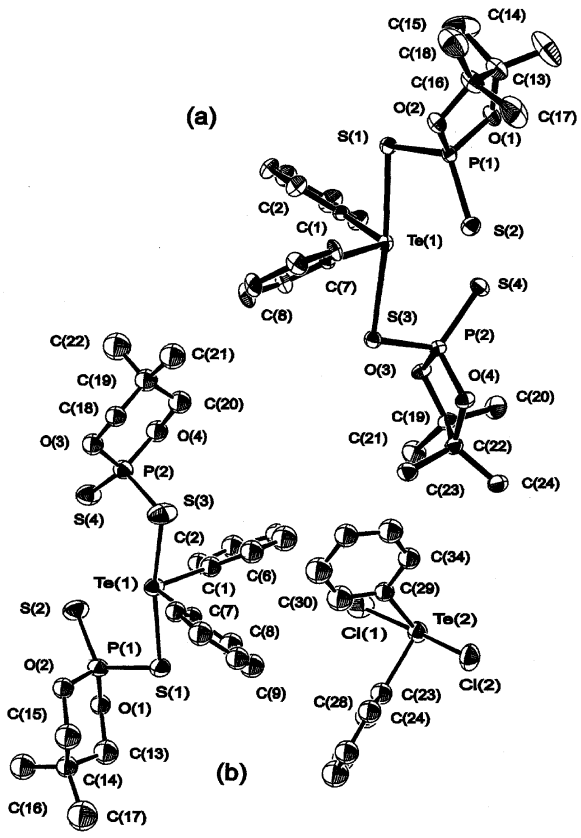

Fig. 1. ORTEP plots of the molecules (a) $Ph_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ (**1**) and (b) $2Ph_2Te[S_2\overline{POCH_2CMe_2CH_2O}]_2 \cdot 2Ph_2TeCl_2 \cdot CS_2$ (**2**). Atoms are drawn with 30% probability ellipsoids and spheres, with hydrogen atoms and CS2 omitted for clarity.

2.130(4) and 2.135(21) Å, respectively, are marginally longer than those in $Me_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ and $Me_2Te[S_2\overline{POCH_2CEt_2CH_2O}]_2$ (2.121(7) Å) [2], and longer than that in Ph_2TeCl_2 (2.095(7) Å) in the asymmetric unit of compound **2** (Table 2).

In $Ph_2Te[S_2\overline{POCMe_2CMe_2O}]_2$, as was found in the analogous non-cyclic dithiophosphate derivatives $Ph_2Te[S_2P(OMe)_2]_2$ [9] and $Ph_2Te[S_2P(OEt)_2]_2$ [10], both Te–S bonds in the axial positions (S–Te–S bond angle of 173.78(7)°) are of similar length, the average value of 2.630(9) Å being close to the overall average for most bisdithio derivatives R_2TeL_2. By contrast, in $Ph_2Te[S_2\overline{POCH_2CMe_2CH_2O}]_2$, one of the Te–S bonds is significantly longer than the other (2.657(6) and 2.615(6) Å), as was also found for $Me_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ and $Me_2Te[S_2\overline{POCH_2CEt_2CH_2O}]_2$ [2]. However, there are no obvious Te–S intermolecular interactions involving S(1) or S(3) in compound **2** to rationalize this difference.

As was found for the other dithiophosphates [2,9,10], the terminal sulfur atoms are oriented towards the tellurium atom at distances of 3.323(3) and 3.402(3) Å in compound **1** and 3.637(7) and 3.479(7) Å in compound **2**; such distances are significantly shorter than the sum of the van der Waals radii of Te and S [11]. The inclusion of the second sulfur atom of these anisobidentate ligands in the coordination sphere of tellurium results in a bi-capped trigonal bipyramid for $Ph_2Te[S_2P(OEt)_2]_2$ [10] and a distorted octahedron for $Me_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ and $Me_2Te[S_2\overline{POCH_2CEt_2CH_2O}]_2$ [2]. The description of a distorted octahedron is also apt for compound **1** (Fig. 2a), but a distorted pentagonal pyramid is more appropriate for the dithiophosphate in compound **2** (Fig. 2b). Thus in compound **1**, C(1), Te(1), S(1) and S(2) are approximately coplanar (mean deviation from plane is 0.123 Å) with the second phenyl carbon atom attached to tellurium, C(7), out of the plane by 2.13(1) Å. Similarly, C(7), Te(1), S(3) and S(4) are approximately coplanar (mean deviation of 0.137 Å) with the C(1) out of the plane by 2.12(1) Å. The dihedral angle between the planes Te(1), S(1), S(2) and Te(1), S(3), S(4) is 71.5(2)° with the aniso-bonded atoms *cis* to one another. The dihedral angle is similar to that in $Me_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ (77.0(2)°). By contrast, in compound **2**, Te(1), S(1), S(2), S(3), S(4) and C(7) are approximately coplanar (mean deviation from plane is 0.157 Å) with the second phenyl carbon atom attached to tellurium, C(1), out of this plane by 2.14(1) Å. The difference in the orientation of the ligands is emphasized by noting that the dihedral angle between the planes Te(1), S(1), S(2) and

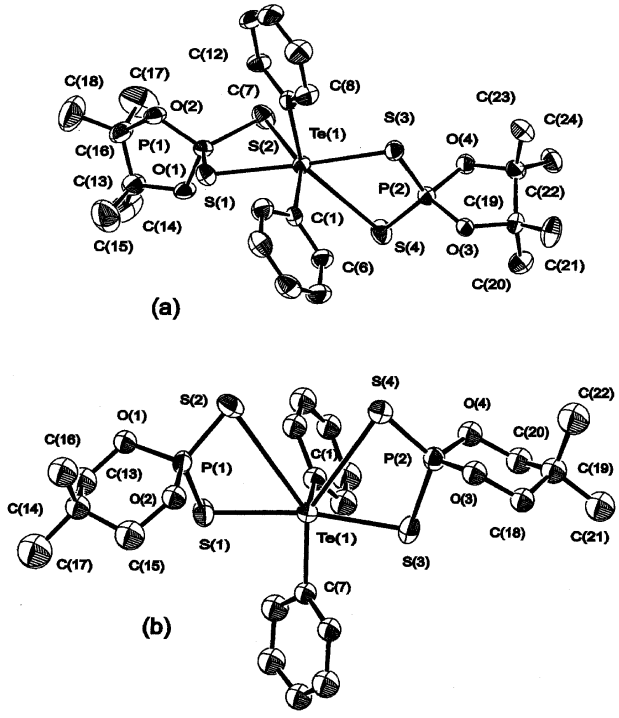

Fig. 2. ORTEP plots of the molecules showing the stereochemistry about tellurium when the intramolecular interactions leading to unsymmetrical bidentate ligands are included for $Ph_2Te[S_2POCMe_2CMe_2O]_2$ (**1**) and (b) $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ (**2**). The atoms are drawn with 30% probability ellipsoids and spheres. Hydrogen atoms are omitted for clarity.

Te(1), S(3), S(4) is now 172.5(2)°. There is also an intermolecular interaction in compound **2** involving a chlorine atom of Ph_2TeCl_2 which results in a Te(1)···Cl(2)′ distance of 3.531(7) Å and a C(1)–Te(1)···Cl(2)′ angle of 175.0(6)°. Thus the complete extended environment about tellurium is a seven-coordinate distorted pentagonal bipyramid.

The bite angles of 67.22(7) and 66.27(6)° in compound **1** and 62.4(2) and 65.1(2)° in compound **2**, and bite lengths of 3.348(3) and 3.358(3) Å in compound **1** and 3.368(9) and 3.36(1) Å in compound **2**, reflect the slightly longer Te(1)–S(2) and Te(1)–S(4) distances in compound **2**, which in turn could arise from additional intermolecular associations in compound **2**, as discussed below.

The TeS–P bonds, which average 2.051(6) Å in compound **1** and 2.043(13) Å in compound **2**, are longer than the terminal or aniso-bonded P=S bonds, which average 1.93(1) Å in compound **1** and 1.912(13) Å in compound **2**. These distances are comparable to those reported for $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ and the related non-cyclic derivatives, as are the S–P–S bond angles that average 114.8(6)° in compound **1** and 116.6(4)° in compound **2**. The O–P–O bond angles average 97.0(2)° in compound **1** and 103.9(6)° in compound **2**, which are essentially identical to those in the five- and six-membered rings of $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ [2]. However, the comparable angles in the two derivatives containing the non-cyclic dimethoxy and diethoxy dithiophosphates [9,10] range from 93.6(5) to 96.2(5)°, indicating that the larger O–P–O angle is related to the constraints imposed by the ring systems. The bond lengths and angles within the ring systems are as expected and essentially as observed and described in detail for $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ [2].

The bond lengths and angles around Te in Ph_2TeCl_2 in compound **2** (Table 3) are essentially the same as in the pure orthorhombic compound [12]. One Te–Cl bond is longer than the other, 2.515(7) and 2.466(6) Å in compound **2** and 2.529(2) and 2.482(2) Å in orthorhombic Ph_2TeCl_2, and the Cl–Te–Cl angles are 174.9(2) and 175.5(1)°, respectively. In orthorhombic Ph_2TeCl_2, the longer Te–Cl bond is associated with the only secondary interaction with a Te atom of an adjacent Ph_2TeCl_2 molecule. In compound **2** the longer Te–Cl bond in Ph_2TeCl_2 is associated with the tellurium atom of the closest $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ molecule, as mentioned above. The Te···Cl′ partial bond (3.677(2) Å) in orthorhombic Ph_2TeCl_2 is essentially *trans* to a C–Te bond (Cl′···Te–C = 164.1(2)°), resulting in a distorted octahedral arrangement about Te with the position *trans* to the second Te–C bond being vacant [12]. In compound **2**, this interaction is replaced by the Te(2)···S(2)′ partial bond (3.641(8) Å) *trans* to the C(29)–Te(2) bond (S(2)′···Te(2)–C(29) = 157.3(5)°). There is also a weak interaction with the second pendant (or aniso) atom of $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ with Te(2)···S(4)′ (3.783(7) Å) *trans* to the C(23)–Te(2) bond (S(4)′···Te(2)–C(23) = 162.1(5)°). Thus the extended environment about Te(2) is distorted octahedral and the additional intermolecular interactions in compound **2** are consistent with the longer Te···S intramolecular interactions in compound **2** relative to compound **1**. $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$ and Ph_2TeCl_2 can also be considered as pseudo dimers in a Te_2S_2Cl cluster. The core atoms around each tellurium atom are shown in Fig. 3. The two aniso sulfur atoms and one of the chlorine atoms form bridges between the two tellurium atoms to give a Te(1)···Te(2)′ distance of 4.340(2) Å.

$HS_2POCMe_2CMe_2O$ (**3**) crystallizes in the space group $P2_1/n$ and $HS_2POCH_2CMe_2CH_2O$ (**4**) in the space group $C2/c$, the same space groups as the corresponding tellurium derivatives just reported. The ORTEP diagrams are shown in Fig. 4. The S–H bond lengths and H–S–P angles of 1.12 Å and 90.9° in compound **3** and 1.21 Å and 90.5° in compound **4** (Table 4) compare well with the gas phase structure of H_2S of 1.33 Å and 92° (for H–S–H). There is no evidence of hydrogen bonding in compound **3** or compound **4**.

The HS–P bonds, 2.052(2) Å in compound **3** and 2.082(2) Å in compound **4** are longer than the terminal P=S bonds, 1.923(2) Å in compound **3** and 1.908(2) Å in compound **4**. These distances are very similar to those reported above for $Ph_2Te[S_2POCMe_2CMe_2O]_2$ and $Ph_2Te[S_2POCH_2CMe_2CH_2O]_2$, as are the S–P–S bond angles 112.78(8)° in compound **3** and 115.64(8)° in compound **4**,

compound **3** and compound **4**, the hydrogen atom attached to sulfur is not in the S_2P plane. The dihedral angles defined by H(1), S(1), P(1) and H(1), S(2), P(1) are essentially identical (157 and 156°, respectively, for compound **3** and compound **4**) but very different from the corresponding angles involving Te, S, P planes in compounds **1** and **2**, which is to be expected because of the secondary interactions involved in the tellurium derivatives. However, the structural features of the dithiophosphate ring systems in the acids and tellurium derivatives are similar. The O–P–O bond angle is smaller, 97.6(2)°, in the five-membered ring of compound **3** than in the six-membered ring, 105.1(1)° of compound **4**. The twist in the five-membered ring in compound **3** is the same as in compound **1** as is demonstrated by the fact that the two carbon atoms in the ring are above and below the P(1), O(1), O(2) plane, with C(1) 0.33 Å above and C(4) 0.24 Å below. Also, as in compound **1**, a view down the C(1)–C(4) bond shows that the four methyl groups are in the staggered configuration so that two methyl groups are oriented above and below the approximate plane of the distorted five-membered ring at an average distance of 3.28(2) Å from P. The second pair of methyl groups are oriented away from phosphorus, at an average distance of 3.78(1) Å. In compound **4**, as with compound **2**, the six-membered ring has the chair conformation as demonstrated by P(1) and C(2) being 0.59 and 0.69 Å above and below the O(1), O(2), C(1), C(5) plane. The orientation within the ring again results in one of the methyl groups being oriented away from phosphorus and the other towards it to give two very different distances; 3.656(5) and 4.449(5) Å for P(1)–C(3) and P(1)–C(4), respectively.

The isolation of the mixed species compound **2**, rather than $Ph_2TeCl[S_2POCH_2CMe_2CH_2O]$, was most unexpected in view of the number of halo-dimethyl and -diphenyl derivatives whose structures have been reported by us, including $Me_2TeI[(SPPh_2)_2N]$, $Me_2TeBr[S_2CN(CH_2)_3CH_2]$, $Me_2TeCl[S_2COEt]$ [13–15], $Ph_2TeBr[S_2CNEt_2]$ [16] and most recently $Me_2TeCl[S_2POCMe_2CMe_2O]$ [17].

Supplementary data

Additional material available from the Cambridge Data Centre comprises the final atomic coordinates of the non-hydrogen atoms, hydrogen-atom coordinates, thermal parameters and all of the bond lengths and angles. Crystal structure codes are as follows: $Ph_2Te[S_2POCMe_2CMe_2O]_2$ (132699), $2Ph_2Te[S_2POCH_2CMe_2CH_2O]_2 \cdot 2Ph_2TeCl_2CS_2$ (132700), $HS_2POCMe_2CMe_2O$ (132701) and $HS_2POCH_2CMe_2CH_2O$ (132702). Structure factors tables are available from the authors.

Abstract

The crystal structure of *N*-tosylimido-*meso*-tetraphenylporphyrinatozinc(II), Zn(N-NTs-tpp), was determined. The zinc is tetracoordinated with the nitrogen atoms of only three pyrrole bases and with an extra nitrogen atom of the nitrene fragment. The porphyrin ring is severely distorted, the pyrrole ring bonded to the NTs ligand making a large dihedral angle of 29.1° with the plane containing the three pyrrole nitrogens bonded to the zinc (i.e. the (3N) plane) and the other pyrroles making smaller angles of 13.8, 7.6 and 5.9°. The zinc atom lies out of the (3N) plane by 0.39 Å and the extra nitrogen N(4) by 1.54 Å on the same side as the zinc. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Bridged structures; Crystal structures; Heteronuclear multiple bond coherence; *N*-Tosyl ligands; Zinc porphyrin complexes

1. Introduction

Metalloporphyrins with a bridged structure between the central metal and one of the four pyrrole nitrogens have drawn much attention recently. Bridged metalloporphyrins with a metal–N–N linkage (metal = Zn, Ni, Fe, Hg) [1–6] have been reported. Callot et al. [1] described X-ray structure investigations of the metallation of *N*-tosylamido-*meso*-tetraphenylporphyrin [N-NHTs-Htpp] (NHTs = tosylamido, tpp = di-anion of *meso*-tetraphenylporphyrin, Ts = tosyl) [7] leading to mononuclear complexes of *N*-tosylimido-*meso*-tetraphenylporphyrinatonickel(II) [Ni(N-NTs-tpp)] (NTs = tosylimido) [1]. The nickel in Ni(N-NTs-tpp) is tetracoordinated with nitrogen atoms of only three pyrrole bases and with the extra nitrogen atom of the nitrene fragment. The title compound, *N*-tosylimido-*meso*-tetraphenylporphyrinatozinc(II), Zn(N-NTs-tpp), is a homolog of Ni(N-NTs-tpp). Zn(N-NTs-tpp) is also a four-coordinate zinc(II) porphyrin complex. It is noted that the ionic radius increases from 0.69 Å for Ni^{2+} in Ni(N-NTs-tpp) to 0.74 Å for Zn^{2+} in Zn(N-NTs-tpp) [8]. In addition, the ^{13}C chemical shifts of β-pyrrole carbon (C_β) provide a complementary method to investigate the distortion of the *N*-pyrrole ring via the insertion of the nitrene moiety into the Zn(1)···N bond in Zn(N-NTs-tpp).

However, until now there were no X-ray structural data available for Zn(N-NTs-tpp). In this paper we report (1) the X-ray structure determination of Zn(N-NTs-tpp), which establishes definitively the Zn^{II}-NTs-N structure, and (2) the ^{13}C chemical shifts of the C_β, to investigate the distortion in the porphyrin macrocycle for Zn(N-NTs-tpp).

2. Experimental

2.1. Preparation of Zn(N-NTs-tpp)

The title compound was prepared as described elsewhere [1]. Crystals were grown by diffusion of ether vapor into a CH_2Cl_2 solution. The complex was dissolved in $CDCl_3$ (99.8%; from Aldrich) at 24°C for the ^1H and ^{13}C NMR measurements. ^1H NMR (400.13 MHz; Fig. 1b): 9.00 (d, $^3J_{H-H} = 4.7$ Hz, $H_\beta(4,15)$), where $H_\beta(a,b)$ represents the two equivalent β-pyrrole protons attached to carbons a and b, respectively; 8.90 (d, $^3J_{H-H} = 4.7$ Hz, $H_\beta(5,14)$); 8.82 (s, $H_\beta(9,10)$); 7.40 (s, $H_\beta(19,20)$); 8.47 (d, $^3J_{H-H} = 7.3$ Hz),

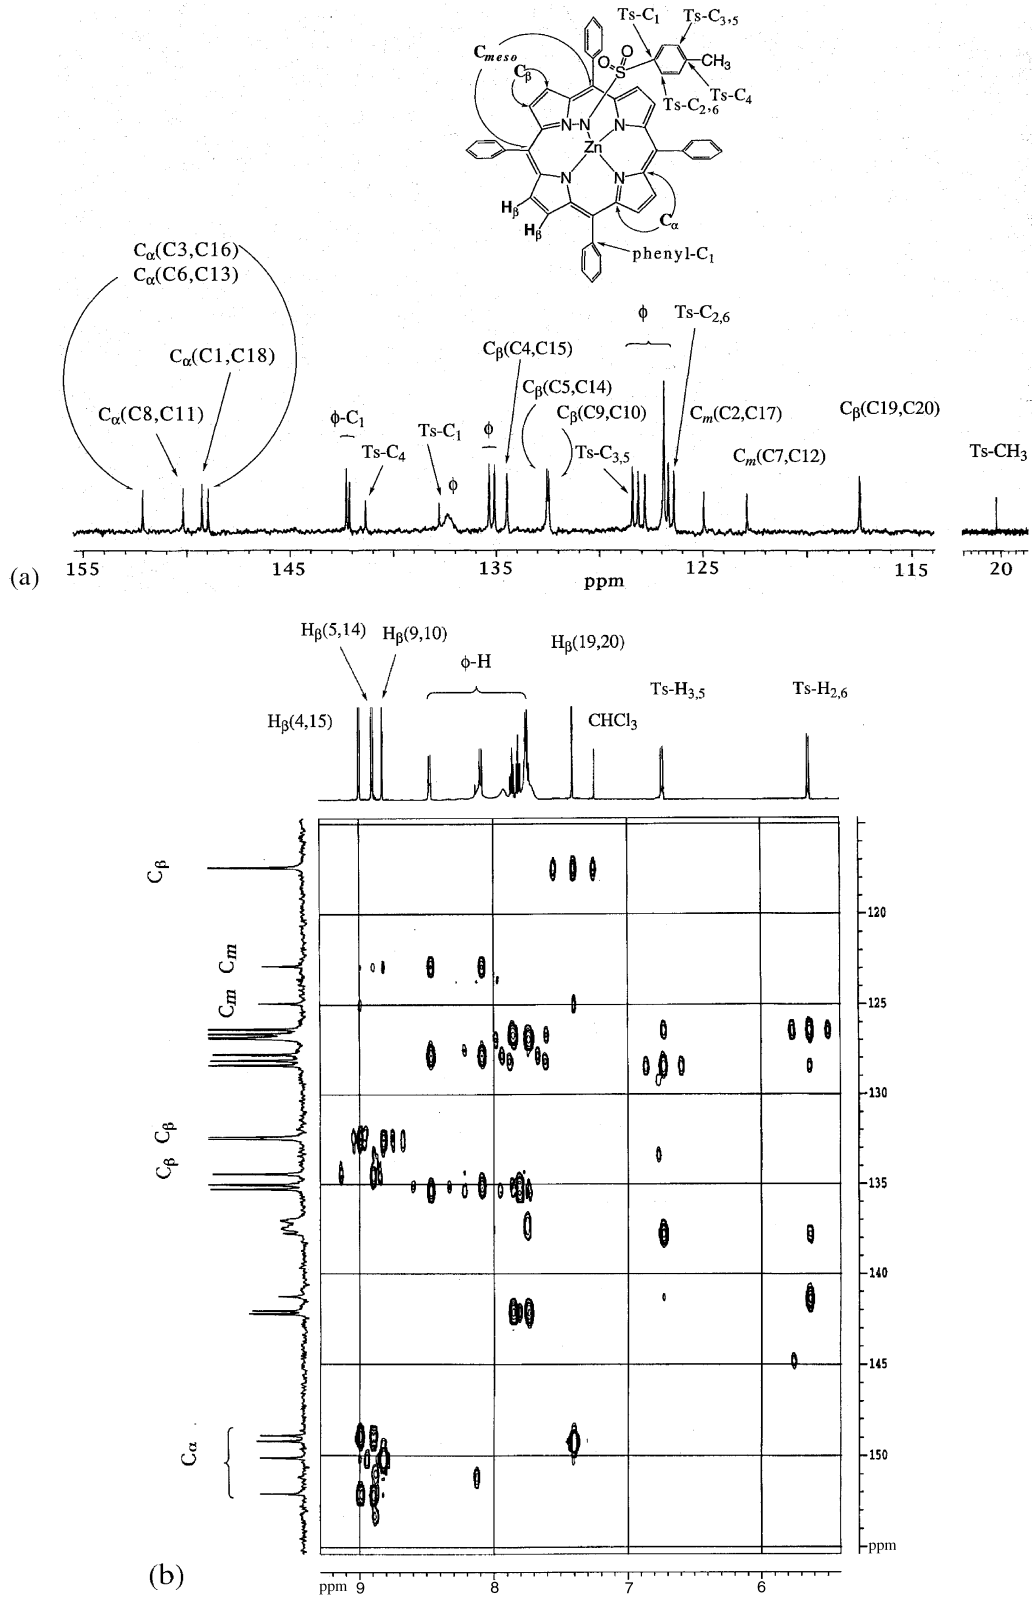

Fig. 1. (a) ^{13}C broad-band (50.33 MHz) and (b) HMBC [600.16 MHz (^{1}H), 150.92 (^{13}C)] NMR spectra for Zn(N-NTs-tpp) in $CDCl_3$ at 24°C, where ϕ-C_1 represents the phenyl-C_1 carbons, ϕ represents the phenyl-$C_{2,6}$, $C_{3,5}$ and C_4 carbons, and ϕ-H represents the phenyl protons.

8.09 (d, $^{3}J_{H-H} = 7.4$ Hz) and 7.72–7.85 (m) for *ortho*-, *meta*- and *para*-phenyl protons (*o*-, *m*-, *p*-H); 6.73 (d, $^{3}J_{H-H} = 8.0$ Hz, tosyl-$H_{3,5}$); 5.64 (d, $^{3}J_{H-H} = 8.1$ Hz, tosyl-$H_{2,6}$); 2.23 (s, tosyl-CH_3). ^{13}C NMR (100.61 MHz; Fig. 1a): 152.2 (s, C_α(C6, C13)); 149.0 (s, C_α(C3, C16)); 149.3 (s, C_α(C1, C18)); 150.2(s, C_α(C8, C11)); 142.3 (s) and 142.1 (s) for

phenyl-C_1(C33, C27) and phenyl-C_1(C39, C21)); 117.5 (s, C_β(C19, C20)); 132.4 (s, C_β(C9, C10)); 132.5 (s, $C_{\beta?}$(C5, C14)); 134.5 (s, C_β(C4, C15)); 125.0 (s, C_m(C2, C17)); 122.9 (s, C_m(C7, C12)); 141.3 (s, tosyl-C_4); 137.8 (s, tosyl-C_1); 128.4 (s, tosyl-$C_{3,5}$); 126.4 (s, tosyl-$C_{2,6}$); 21.2 (s, tosyl-CH_3); 135.3 (s), 135.1 (s), 128.2 (s), 127.8 (s), 126.9 (s) and 126.7 (s) for phenyl-$C_{2,6}$, $C_{3,5}$, C_4.

2.2. Spectroscopy

Proton and ^{13}C NMR spectra in $CDCl_3$ (99.8%; from Aldrich) were recorded at 400.13 (or 600.16) and 100.61 (or 150.92) MHz, respectively, on a Bruker AM-400 (or Bruker DMX-600) spectrometer locked on solvent deuterium, and referenced to the solvent peak. ^1H and ^{13}C NMR are relative to $CDCl_3$ at 7.24 and the central line of $CDCl_3$ at 77.0, respectively. ^1H–^{13}C correlation spectroscopy was used to correlate protons and carbon through one-bond coupling and heteronuclear multiple-bond coherence (HMBC) for two- and three-bond proton–carbon coupling.

2.3. Crystallography

Table 1 presents the crystal data and other information for Zn(N-NTs-tpp). Measurements were taken on a Siemens SMART CCD diffractometer using monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Empirical absorption corrections were applied. The structures were solved by direct methods (SHELXTL PLUS) and refined by full-matrix least-squares. All non-hydrogen atoms were refined with anisotropic thermal parameters, whereas all hydrogen atom positions were calculated using a riding model and included in the structure factor calculation. Table 2 lists selected bond distances and angles.

3. Results and discussion

3.1. Molecular structures of Zn(N-NTs-tpp)

Fig. 2 illustrates the skeletal framework of the complex Zn(N-NTs-tpp). This structure has a four-coordinate zinc with three nitrogen atoms of the porphyrins and the extra nitrogen atom (N(4)) from the nitrene fragment. Zn(N-NTs-tpp) appears as the *N*-tosyl moiety being inserted into a Zn–N bond of *meso*-tetraphenylporphyrinatozinc(II), Zn(tpp). The most interesting distances and angles from Zn(II) atoms to the ligand are summarized in Table 2.

The pyrrole nitrogen N(5) is no longer bonded to the zinc as shown by the large Zn(1)···N(5) distance of 2.588(2) Å. Consequently, the Zn(1)–N(2) bond *trans* to the N(4) position is somewhat shorter than the other two Zn(1)–N distances [1.929(2) Å for Zn(1)–N(2) versus 2.044(2) Å for Zn(1)–N(1) and 2.049(2) Å for Zn(1)–N(3)]. Fig. 3 shows the porphyrin skeleton departures from the mean plane containing the three pyrrole nitrogens N(1), N(2) and N(3)

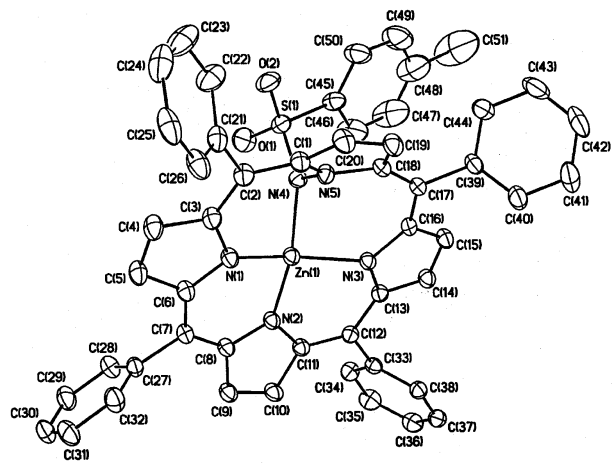

Fig. 2. Molecular configuration and atom-labeling scheme for Zn(N-NTs-tpp), with ellipsoids drawn at 30% probability. Hydrogen atoms are omitted for clarity.

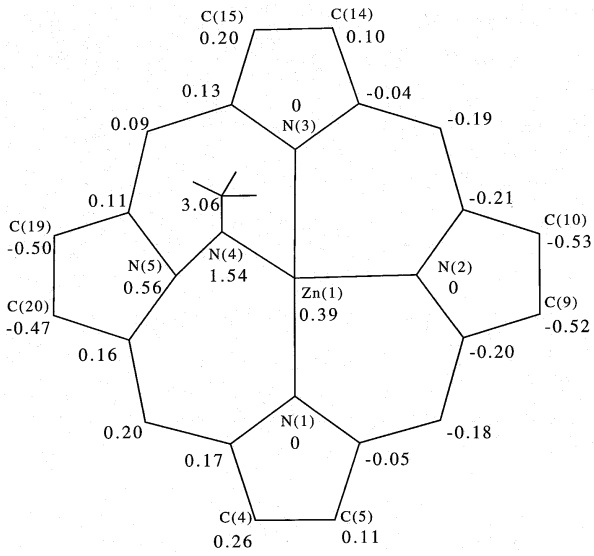

Fig. 3. Diagram of the porphyrinato core ($C_{20}N_4$, Zn and NTs) of Zn(N-NTs-tpp) showing the displacement (in Å) of the atoms from the mean plane of 3N [i.e. N(1), N(2) and N(3)].

bonded to the zinc (i.e. the (3N) plane). The tosyl nitrogen N(4) is considerably removed from the (3N) plane; its displacement of 1.54 Å is in the same direction as that of the zinc atom itself displaced by 0.39 Å (Fig. 3). The porphyrin macrocycle is severely distorted as a result of the *N*-tosyl group. Thus, the pyrrole N(5) bearing the *N*-tosyl group deviates most from the (3N) plane, making a dihedral angle of 29.1°, whereas small angles of 7.6, 13.8 and 5.9° occur with pyrrole N(1), N(2) and N(3). The extent of this large deviation from planarity for pyrrole N(5) is observed from the upfield shift of approx. −15.6 ppm for C_β (C19, C20) at 117.5 ppm relative to 134.5 ppm for C_β (C4, C15), 132.5 ppm for C_β (C5, C14) and 132.4 ppm for C_β (C9, C10). The distortion for Zn(N-NTs-tpp) is, however, less important than that present in the Ni(N-NTs-tpp) complex in which the dihedral angle between the mean plane of one pyrrole ring and mean plane of the four pyrrole nitrogens (4N) is as large as 40.5° [1]. The plane (P) defined by Zn(1), N(4), N(5) and the sulfur atom S(1) is almost perpendicular to the (3N) plane (87.8°). The tosyl group (T) defined by C(45)–C(50) is bound to N(4) such that it lies above the macrocycle making a dihedral angle of 18.9° with the (3N) plane. The dihedral angles between the mean plane of the skeleton (3N) and the planes of the phenyl group are 58.9° (C(27)), 52.1° (C(33)), 61.1° (C(39)) and 63.3° (C(21)).

In comparing the four-coordinate structure of Ni(N-NTs-tpp) [1], we adopt the mean plane of the four pyrrole nitrogens N(1), N(2), N(3) and N(5) as a reference plane (i.e. the (4N) plane). Because the larger size of the Zn^{2+}, Zn and N(4) lie 0.29 Å and 1.23 Å further above the (4N) plane in Zn(N-NTs-tpp) [cf. the corresponding displacement of 0.21 Å for Ni and 0.94 Å for the nitrogen atom of the nitrene fragment in Ni(N-NTs-tpp)] [1].

3.2. ^1H and ^{13}C NMR for Zn(N-NTs-tpp) in $CDCl_3$

Zn(N-NTs-tpp) was characterized by ^1H and ^{13}C NMR spectroscopy. In solution, where the phenyl and *N*-tosyl groups are free to rotate, the molecule has effective C_s symmetry with the mirror plane running through the N(2)–Zn(1)–N(4)–N(5) unit. In this case there are four distinct β-pyrrole protons, H_β, four β-pyrrole carbons C_β, four α-pyrrole carbons C_α, two different *meso* carbons C_{meso} and two phenyl-C_1 carbons. ^1H NMR reveals that the aromatic protons of the tosyl group appear as doublets at 6.73 (tosyl-$H_{3,5}$) and 5.64 ppm (tosyl-$H_{2,6}$) for Zn(N-NTs-tpp). All tosylimido protons are shifted upfield compared to those of free NHTs, presumably due to the porphyrin ring current effect. The ^1H NMR showed four different chemical shifts of H_β: the doublet at 9.00 ppm is assigned as H_β(4, 15), the doublet again at 8.90 ppm is assigned as H_β(5,14), the singlet at 8.82 ppm is assigned as H_β(9, 10) and the singlet again at 7.40 ppm is assigned as H_β(19, 20). The distinction of the two doublets is via HMBC. As shown in the HMBC of Zn(N-NTs-tpp) (Fig. 1), the correlation between C_m(C7, C12) (122.9 ppm) and H_β at 8.90 ppm, and between C_m(C2, C17) (125.0 ppm) and H_β at 9.00 ppm supports our assignment of the 8.90 ppm as H_β(5, 14) and 9.00 ppm as H_β(4, 15).

Zn(N-NTs-tpp) is the second X-ray structure of the metal M^{II}-NTs-N linkage in the porphyrin complex with four coordinate geometry. Disregarding the phenyl protons and carbons, the unambiguous assignment of ^1H and ^{13}C NMR data for Zn(N-NTs-tpp) in $CDCl_3$ is reported in this work.

Abstract

Cr(VI) and Cr(V) interaction with D-ribose 5′-monophosphate (R5P), adenosine 5′-monophosphate (AMP), cytidine 5′-monophosphate (CMP) and 2′-deoxythymidine 5′-monophosphate (dTMP) was studied by electron paramagnetic resonance (EPR) spectroscopy (Cr(V)) and potentiometry (Cr(VI)) in aqueous solutions. The EPR spectra showed a narrow but composed signal. The Cr(V) signals showed experimental g_{iso} and ^{53}Cr A_{iso} values that are typical of five-coordinate oxochromate(V) complexes. Potentiometric studies of CMP and AMP in the presence and absence of potassium dichromate allow us to suggest the presence of three species of S–Cr(VI), differing in their degree of protonation. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Carcinogenic; Chromium; Nucleotides

1. Introduction

The carcinogenicity and mutagenicity of chromium(VI) has been established in many different compounds [1–6]. Chromate causes a variety of damage to DNA, such as single-strand breaks (SSB), induction of apurinic/apyrimidinic sites (AP-sites), alkali-labile sites and DNA–protein cross-links both in vivo and in cultured cells [7]. The observation that both lesions (induction of AP-sites and SSB in isolated DNA) are formed with equal probability and follow a similar time course suggests that they might arise from attack by a reactive species at C4′ of the DNA sugar moiety [8].

Although well-established as carcinogens, the way in which Cr(VI) compounds exert their carcinogenic, mutagenic and DNA-damaging potential remains obscure [9], but this oxidation state is not considered to be responsible for the DNA lesions associated with the observed carcinogenic activity [10]. Reduction of Cr(V) to lower oxidation states by cellular reductants is an important step [11] and has been observed with a wide variety of naturally occurring cellular reductants such as ascorbate, cysteine and glutathione (GSH). The chromium oxidation state that is responsible for producing a particular DNA lesion and the mechanism by which the lesion is produced are not unknown. However, there is a general belief that Cr(V) and Cr(IV), acting either directly or through reactive oxygen species produced from molecular oxygen or hydrogen peroxide, are responsible for much of the oxidative stress and DNA damage observed in biological systems [10,12]. Relatively long-lived Cr(V) intermediates have been detected in the reduction of Cr(VI) both in vitro and in vivo [10]. Farrell et al. initially postulated that direct binding of Cr(V) to DNA led to oxidation and DNA strand breakage [13], and, recently, studies of the genotoxicity of Cr(V) complexes in mammalian cells supported other evidence that Cr(V) may be important in Cr-induced cancers [14]. This intermediate oxidation state is frequently stabilized by the formation of complexes with ligands that possess two oxygen atoms able to form five-member chelate rings about the metal atom, such as 1,2-diols and α-hydroxy-acids [15]. For this reason, sugars and their derivatives may play an important role in the chemistry of Cr(VI) [16]. Although studies have been performed about Cr(V) species with small molecular weight reductants (ascorbate, GSH, etc.) [7,9], few of them related to nucleotides [10,15]. Nucleosides and nucleotides have, in their sugar moiety,

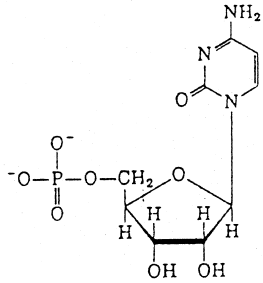
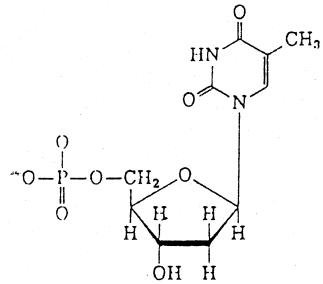
hydroxyl groups with the correct geometry for stabilizing Cr(V) [15].

As most of the known Cr(V) compounds are EPR-active at room temperature due to their d^1 electronic configuration, EPR spectroscopy has become the most powerful technique for studying Cr(V) chemistry [17].



In previous work, we found several Cr(V)–sugar species formed during the Cr(VI) reduction by aldoses (D-mannose [18], D-ribose [19]), deoxyaldoses (L-rhamnose [18], 2-deoxy-D-glucose (2DG) [20,21], 2-deoxy-D-ribose (2DR) [19]) and aldonic acids [22,23]. The previous data have been employed to understand the interaction of Cr(VI) and/or Cr(V) with D-ribose 5′-monophosphate (R5P), adenosine 5′-monophosphate (AMP), cytidine 5′-monophosphate (CMP) and 2′-deoxythymidine 5′-monophosphate (dTMP) in vitro as simple bioinorganic models. Potentiometric studies of the chromic esters of nucleotides provided the stoichiometric relationship between Cr(VI) and ligand, and EPR spectroscopy of the ligand-exchange reaction of the substrates with $[Cr(ehba)_2O]^-$ (**I**) allowed the characterization of Cr(V) intermediates in these systems.



R5P (1)

AMP (2)

CMP (3)

dTMP (4)

2. Experimental

Caution: Cr(VI) compounds are human carcinogens and the Cr(V) complexes are mutagenic and potential carcinogens [1–6]. Appropriate precautions should be taken to avoid skin contact and inhalation of Cr(VI) and Cr(V) solutions and dusts.

2.1. Reagents

Potassium dichromate (from BDH), AMP, CMP, dTMP and D-ribose 5-phosphate sodium salt (Sigma) were used as received. $Na[Cr(ehba)_2O]\cdot H_2O$ (ehba = 2-ethyl-2-hydroxybutyric acid) was synthesized from 2-ethyl-2-hydroxybutanoic acid (Aldrich; 99%) and sodium dichromate in acetone [24].

2.2. EPR spectroscopy

X-band EPR spectra were recorded as the first derivative of absorption on a Bruker spectrometer operating at room temperature. Spectral parameters were: 100 kHz field modulation, 0.25–5.0 G modulation amplitude, ≈9.78 GHz microwave frequency, 1×10^5 receiver gain, centre field = 3525 G. Measurements were done on samples of ≈0.1 ml, drawn into a capillary tube that was sealed at one end with high-vacuum grease. Typically 1024 points were accumulated per spectrum. The complexes of Cr(V) with R5P, AMP, CMP and dTMP were generated: (1) in situ by mixing stock solutions of $K_2Cr_2O_7$ and each substrate; (2) by dissolving $Na[Cr(O)(ehba)_2]$ (typically 1 mmol dm^{-3}) in aqueous solutions of each substrate.

In all these cases the mole ratio [S]/[Cr(V)] was ≥100/1; the excess of organic substrate shifted the equilibrium toward the ligand-exchange products. The reactions and spectra were made at room temperature. The stock solutions of both aqueous reagents were kept at 5°C before mixing, in order to minimize the redox reaction.

2.3. Potentiometric measurements

Potentiometric studies of CMP and AMP, in the absence and presence of Cr(VI) (as potassium dichromate), were carried out with a Corning 350 pH meter equipped with glass combination electrodes calibrated with HCl to read $-\log[H^+]$ = pH. The temperature was maintained at 25.0°C and the experimental solutions, adjusted to 0.10 M ionic strength (μ) by addition of KCl, were titrated with 0.100 M standard CO_2-free NaOH.

Potentiometric studies were carried out on 50.00 ml of experimental solution in a thermostated cell, purged with CO_2-free nitrogen; 30–40 points were acquired per pH profile, providing in general at least ten pairs of data (volume base, pH) per neutralization equivalent. All stability constants and the standard deviations in the refined constant were determined using procedures outlined in detail in the literature, with the aid of BEST [25] and random error analysis in the determination of equilibrium constants [26]. Log K_w for the system, defined in terms of $\log([H^+][OH^-])$, was maintained fixed at −13.78 during the refinements [25]. For the determinations of species distributions, the program SPE was used [25]. Different relationships [S]/[Cr(VI)] were tried. These experiments were done only with AMP and CMP, because no redox reaction took place between the nucleotide and Cr(VI) during the time of performing the potentiometric measurements.

2.4. ^{31}P NMR

$^{31}P\{^{1}H\}$ NMR measurements were recorded on a Bruker WM-250 spectrometer at 20°C. Spectra of 0.03 M aqueous solution of the substrates R5P, AMP, CMP and dTMP and of the reaction mixtures S–Cr(VI) at molar ratio [S]/[Cr(VI)] = 3/1 and S–**I** at molar ratio [S]/[CrV)] = 30/1 were recorded at $t = 3$ min after mixing ($[Cr(VI)]_o = 0.01$ M and $[Cr(V)]_o = 0.001$ M). Typical data acquisition conditions were as follows: sweep width 300 (±150) and 30 (±15) ppm, with 85% orthophosphoric acid as external reference, with complete proton decoupling; acquisition time for the spectrum was 100 s. The reagents were stored at 4°C before the reactions were initiated in order to decrease the oxidation rate.

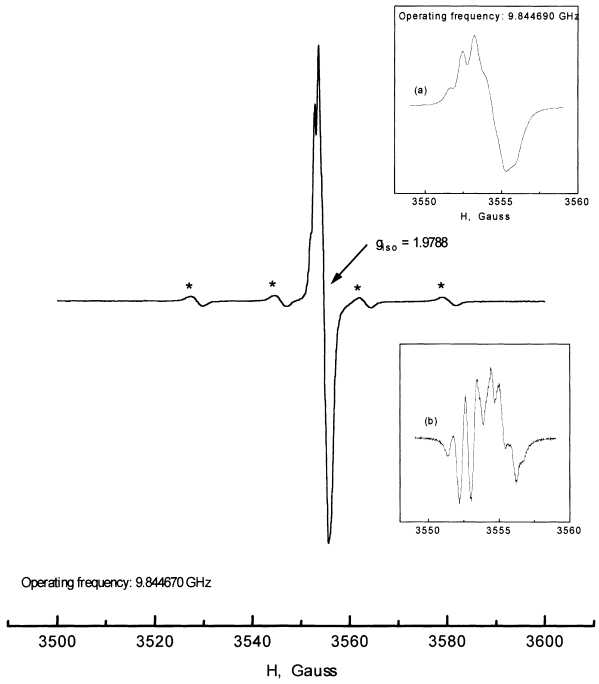


Fig. 1. X-band EPR spectrum of the Cr(V) species generated in the reaction of potassium dichromate with R5P; reaction time 6 h. * ^{53}Cr hyperfine coupling. Other conditions as in Table 1. (a) Details of the shf structure; modulation amplitude 0.25 G. (b) Second-derivative plot of (a), filtered.

Table 1
Isotropic spin hamiltonian parameters for the Cr(V) species generated in the systems Cr(VI)–substrate [a]

Substrate	g_{iso}	$\Delta H_{p\text{-}p}$ (G)	A_{iso} ^{53}Cr (G)
R5P	1.9788	2.03	17.42
AMP	1.9789	1.87	17.37
CMP	1.9789	1.81	17.35
dTMP	1.9790	2.00	ND [b]

[a] Room temperature, pH 7.5, reaction time 5–6 h, $[substrate]_o = 0.37$ M, $[Cr(VI)]_o = 0.037$ M.
[b] ND, not determined. The ^{53}Cr hyperfine signals were too weak to allow accurate determination of A_{iso} values.

2.5. Geometry optimizations

Geometry optimizations were carried out with HYPERCHEM modelling software using a personal computer.

3. Results and discussion

3.1. EPR determination of Cr(V) complexes on R5P/Cr(VI) and nucleotide/Cr(VI) systems

EPR spectra of aqueous solution of R5P/Cr(VI) (mole ratio 10:1), pH 7.5, at room temperature were acquired 5–6 h after mixing. The spectrum was dominated by a sharp signal ($\Delta H_{p\text{-}p} = 2.03$ G) with a g_{iso} mean value of 1.9788 (Fig. 1), with four ^{53}Cr (9.55% abundance, $I = 3/2$) hyperfine coupling lines (Table 1).

The spectra of the nucleotide/Cr(VI) systems showed a similar pattern to that observed for R5P, dominated by a narrow signal with a g_{iso} value of ≈1.979 and the minor peaks that arise from the ^{53}Cr hyperfine coupling (Fig. 2). Signals were detected more than 1 h after mixing AMP or CMP with Cr(VI).

EPR spectra of the Cr(V)–AMP species showed the same pattern of Cr(V)–adenosine EPR spectra. This experience

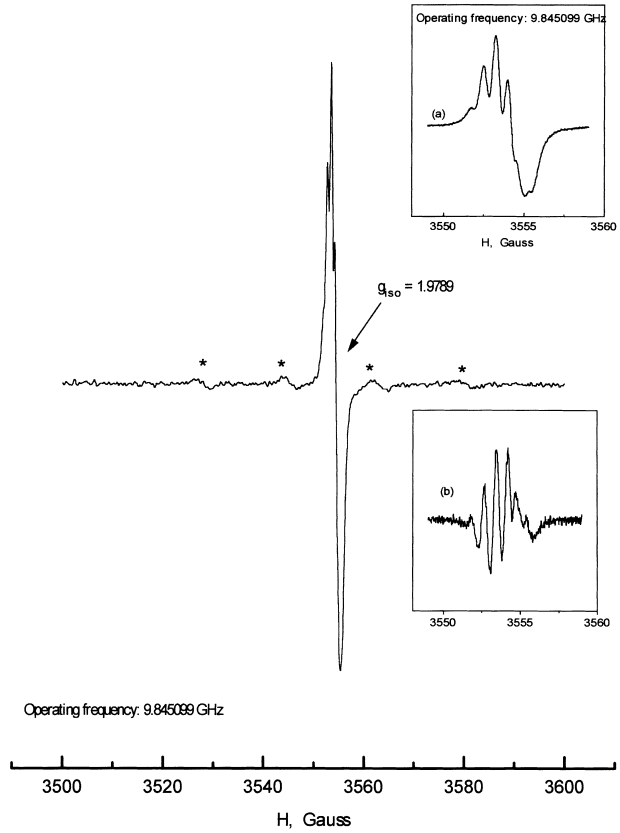

Fig. 2. X-band EPR spectrum of the Cr(V) species generated in the reaction of potassium dichromate with AMP; reaction time 6 h. * ^{53}Cr hyperfine coupling. Other conditions as in Table 1. (a) Details of the shf structure; modulation amplitude 0.25 G. (b) Second-derivative plot of (a), filtered.

was made in order to compare substrates with and without phosphate group [27].

Table 1 summarizes the experimentally observed isotropic values for g and A ^{53}Cr for the Cr(V) species in the systems R5P/Cr(VI) and nucleotides/Cr(VI) at room temperature and pH 7.5.

3.2. Ligand-exchange reactions of $[Cr(O)(ehba)_2]^-$ (I) with R5P and with nucleotides

Cr(V) may undergo rapid ligand exchange reactions in the presence of suitable reductants; hence, it may be possible to use pre-existing Cr(V) complexes as starting materials in the generation of new complexes. Normally, these reactions are rapid compared to the subsequent reduction of Cr(V) by organic substrates, or disproportionation of Cr(V) to Cr(VI) and Cr(III) [28]. The relatively stable Cr(V) complex $Na[Cr(O)(ehba)_2]$(I) was used for ligand exchange reactions in the presence of large excess of the substrates ($[S]/[I] \geq 100/1$), in aqueous solutions.

The splitting of the ^{53}Cr hyperfine coupling bands 2 min after mixing compound **I** with R5P (Fig. 3b), suggested that more than one species of Cr(V) was present, which might imply that the exchange of the ehba ligands was taking place. Such splitting was not observed in the EPR spectrum of $[Cr(O)(ehba)_2]^-$ under the experimental conditions employed in this work (Fig. 3a)) The observed superhyperfine (shf) pattern of the ligand-exchange reaction between compound **I** and R5P changed through time (Fig. 4), and it

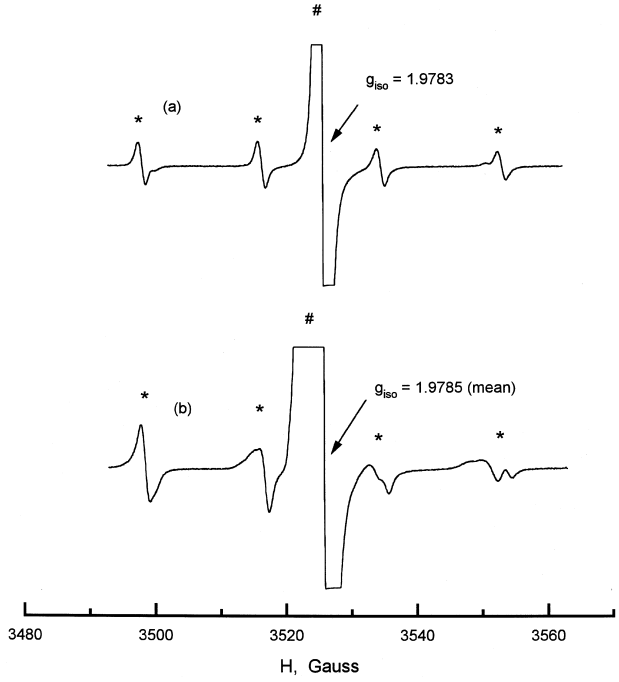

Fig. 3. X-band spectrum of compound **I** (a) and of the ligand-exchange reaction of compound **I** with R5P (b) 2 min after mixing. $T = 25$°C, $[\mathbf{I}] = 1$ mM, $[R5P] = 0.28$ M, pH 10. Assignment of peaks: # ^{52}Cr, $I = 0$; * ^{53}Cr, $I = 3/2$ hyperfine coupling, showing a different pattern in (a) than in (b). Modulation amplitude 1.603 G. Receiver gain 5e+004. Operating frequencies (GHz): (a) 9.779522; (b) 9.780355.

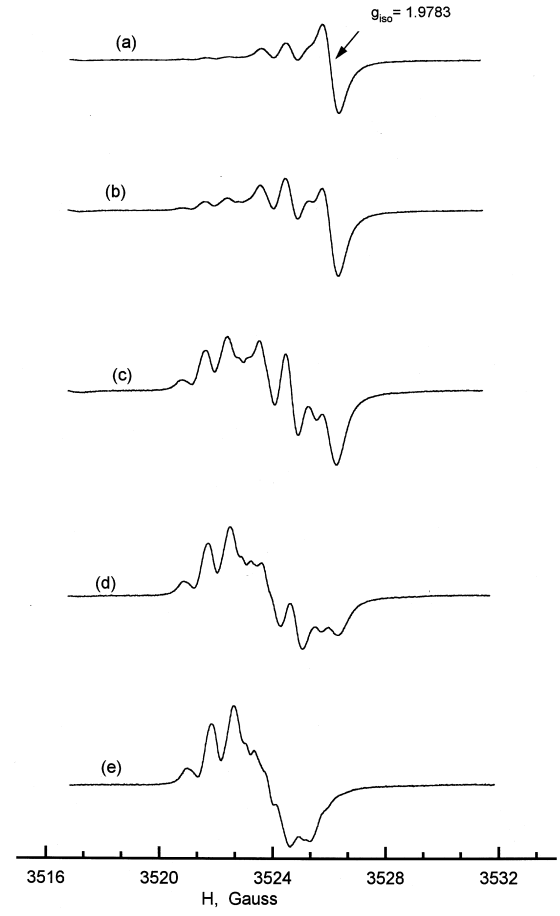

Fig. 4. X-band spectra of the ligand-exchange reaction of compound **I** with R5P. $T = 25$°C, $[\mathbf{I}] = 1$ mM, $[R5P] = 0.28$ M, pH 10; modulation amplitude 0.285 G. Operating frequencies (GHz) and times of reaction: (a) 9.780661, 2 min; (b) 9.780681, 3 min; (c) 9.780170, 5 min; (d) 9.780748, 7 min; (e) 9.780658, 14 min.

showed a very different pattern when the ehba ligand began to be exchanged and when the exchange was practically finished. The single peak due to compound **I** ($g_{iso} = 1.9783$) [29], which dominated the spectrum at $t = 2$ min, decreased in intensity with a simultaneous increase of signals of the complex species Cr(V)–R5P. After 14 min the spectrum look similar to that observed for a mixed solution of R5P–Cr(VI) (Fig. 1a). In the system Cr(V)–D-ribose, the EPR pattern observed was not so complex compared with the that of the system Cr(V)–R5P (Fig. 5). In general, the EPR spectra in the systems **I**–nucleotide (Fig. 6) and **I**–dTMP (a deoxynucleotide, Fig. 7) retained the same pattern as those with R5P. The second derivative plots of the spectra of central Cr signal (Figs. 1b, 2b, 6e and 7d) were unsymmetric, which suggests the presence of more than one species.

3.3. Structure of the Cr(V)–S complexes

All the A_{iso} ^{53}Cr and all the g_{iso} (mean) values experimentally observed were assignable to five-coordinate complexes with all oxygen donors [17]. As the g_{iso} and A_{iso} values are not consistent with a six-coordinate geometry [17,30], hence

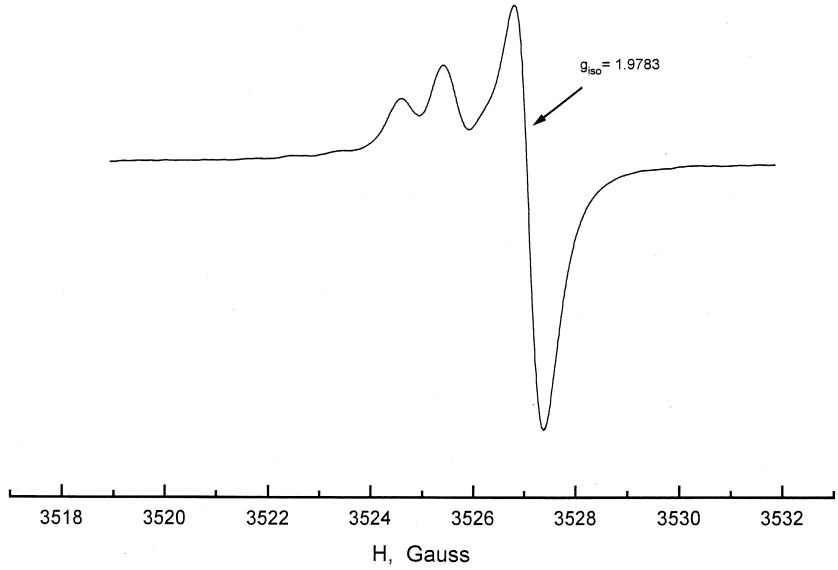

Fig. 5. Observed X-band EPR spectrum of the Cr(V) species generated in the ligand-exchange reaction of $[Cr(O)(ehba)_2]^-$ with D-ribose. $[Cr(O)(ehba)_2]^-$ concentration = 1 mM, [D-ribose] = 120 mM, pH 5.5, t = 15 min, T = 25°C, modulation amplitude = 0.285 G, operating frequency = 9.781895 GHz.

EPR spectral results need to be rationalized in the context of a five-coordinate geometry; thus, the structures of these complexes are most likely to be square-pyramidal $[Cr{=}O]^{3+}$ species [30]. Neither superhyperfine coupling due to two phosphorus atoms nor to nitrogen atoms nor hyperfine coupling of ^{53}Cr with N donors [31–33] were observed.

The g_{iso} values of $\approx$1.980 observed for all central Cr signals let us suggest species of $(CrO)^{3+}$ coordinated with four RO^- groups [17], at C2′ and C3′ of the ribose unit of two nucleotide moieties [15]. The second derivative plots of the spectra were more complicated when the ligand was R5P than with nucleotides. Possibly, R5P acts as a tridentate ligand [17] bound to Cr(V) at the hydroxyl groups of C1, C2 and C3, or C1, C2 and the phosphate group, or C2, C3 and the phosphate group. All of these coordination modes are possible according to the molecular mechanics force field method Hyperchem. Besides the other species to be considered are mono- or bis-chelates with donor sites at the hydroxyl groups of C1 and C2, and C2 and C3.

Additionally, $^{31}P\{^1H\}$ NMR spectra were recorded in aqueous solution of the substrates and in the reaction mixtures S–Cr(VI) and S–**I**. Employing molar ratios of [S]/[Cr(VI)] = 3/1 ([Cr(VI)] = 0.01 M) and [S]/[Cr(V)] = 30/1 ([Cr(V)] = 0.001 M), at t = 3–4 min after mixing, all these systems showed little change in ^{31}P chemical shift relative to the free substrates [34], indicating a weak interaction with the phosphate group [35,36].

The presence of phosphate modifies sterically and electronically the donor ability of the polyalkoxide moiety of the sugar. Phosphate itself affords an additional binding site [37].

The result is a different and more complex EPR pattern with a larger number of signals, which means a mixture of species with very close g values. A simpler EPR pattern was observed for nucleotides, as a consequence of a lower number of linkage isomers involving only three coordination sites — phosphate group, C2′OH and C3′OH — compared with four binding sites available in a ligand such as R5P.

Table 2
Log values of protonation constants of Cr(VI), AMP (L) and CMP (L), and their binding constants with chromate (Cr) at 25.0°C, μ = 0.10 M (KCl)

[a] Smith and Martell [40].
[b] Obtained as mean values from potentiometric determinations in the systems AMP–Cr(VI) and CMP–Cr(VI) with the following concentrations: [Cr(VI)] = 0.00196 M; [AMP] = 0.00135, 0.00293, 0.00593 M; [CMP] = 0.00182, 0.00357, 0.00708 M.

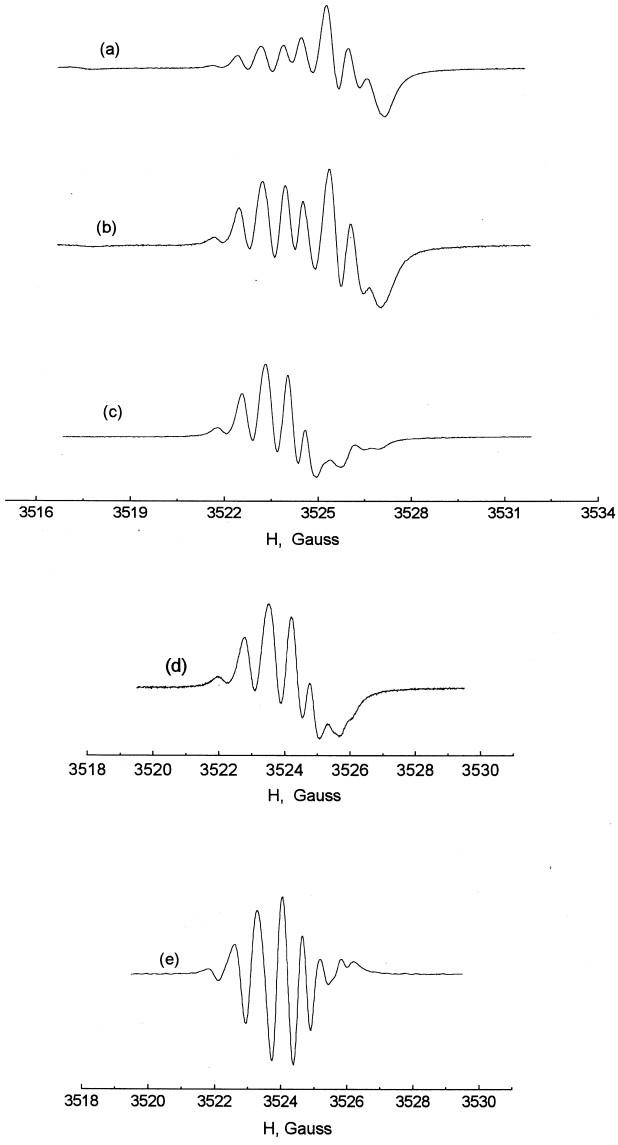

Fig. 6. X-band spectra of the ligand-exchange reaction of compound **I** with CMP (a–c). $T = 25°C$, aqueous solution, [**I**] = 1 mM, [CMP] = 0.096 M. Operating frequencies (GHz) and time of reaction: (a) 9.782007, 2 min; (b) 9.782016, 3 min; (c) 9.782028, 10 min. (d) X-band spectrum of the Cr(V) species generated in the reaction of potassium dichromate with CMP. Operating frequency 9.782746 GHz, time of reaction 2 h. (e) Second-derivative plot of (d), filtered.

It is very difficult to ascertain the number and structures of the species present in solution due to the overlapping of shf coupling ^{31}P ($I = 1/2$) [17,38] and ^{1}H, even with simulation software [39]. Work is in progress to elucidate the species present in these systems.

3.4. Potentiometric studies

The protonation constants of chromate, AMP and CMP and the formation constant of dichromate were calculated from titration data under the present experimental conditions. The potentiometric titration curve for a mixture of CMP and potassium dichromate in a molar ratio [CMP]/[Cr(VI)] = 1/1 is shown in Fig. 8, together with the curve of CMP. The curves were analyzed, and species with stoichiometry LM, HLM and H_2LM were found, where L is the deprotonated nucleotide ($H_2L = [C_{10}O_7N_5PH_{12}]^{2-}$ for AMP and $[C_9O_8N_3PH_{12}]^{2-}$ for CMP) [40] and M represents chromate. Similar curves were obtained for the system AMP–potassium dichromate. The values of the equilibrium constants obtained at different relationship [S]/[Cr(VI)] are reported in Table 2, and Fig. 9 shows the species distribution for the system Cr(VI)–CMP. Similar curves were obtained for the system AMP–potassium dichromate. In all cases the σ_{fit} values [25] were less than 0.030, and the analysis of random error [26] gave a very satisfactory result for each constant.

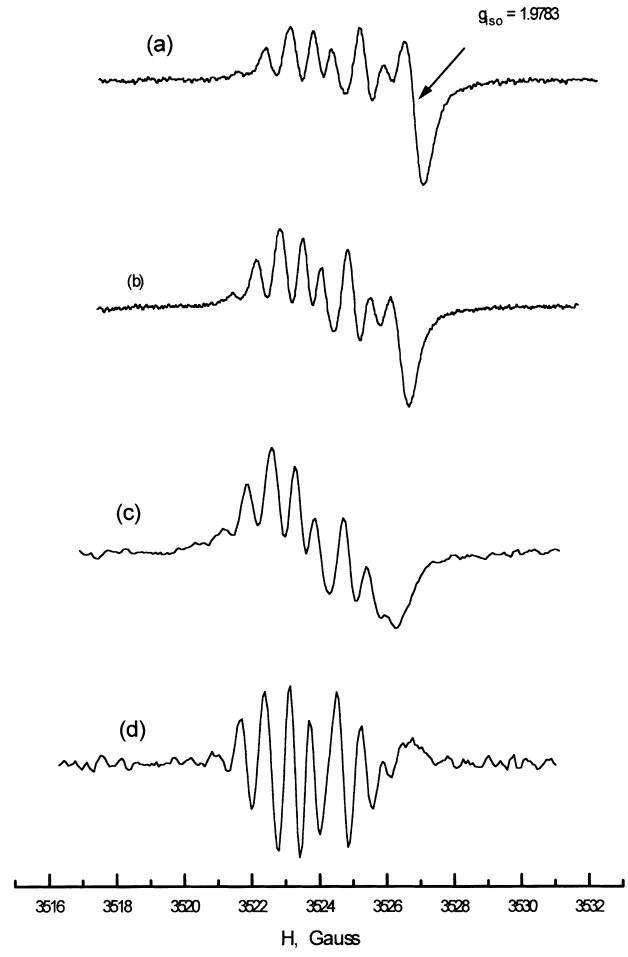

Fig. 7. X-band spectra of the ligand-exchange reaction of compound **I** with dTMP. $T = 25°C$, pH 10, [**I**] = 1 mM, [dTMP] = 0.1 M. Operating frequencies (GHz) and times of reaction: (a) 9.780587, 3 min; (b) 9.780598, 4 min; (c) 9.780617, 11 min. (d) Second-derivative plot of (c), filtered.

Although three species could be found between each nucleotide (AMP or CMP) and chromate, with different degrees of protonation, the concentration of di- and monoprotonated species decreased with the decrease of pH. In all relationships [S]/[Cr(VI)] the non-protonated species, LM, reached the maximum percentage. Thus, the nucleotide diprotonated would not form a stable complex with chromate. These results seem to indicate that the first step leading to the electron

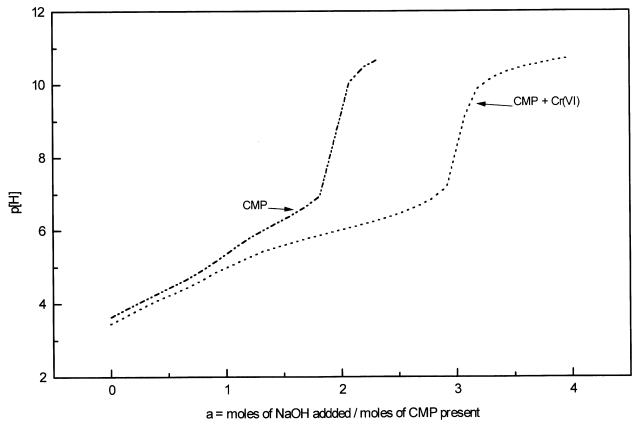

Fig. 8. Potentiometric tritration curves of CMP with and without potassium dichromate. [CMP] = 1.8 mM, [Cr(VI)] = 1.96 mM, [NaOH] = 0.1245 M, T = 25°C, μ = 0.1 M (KCl).

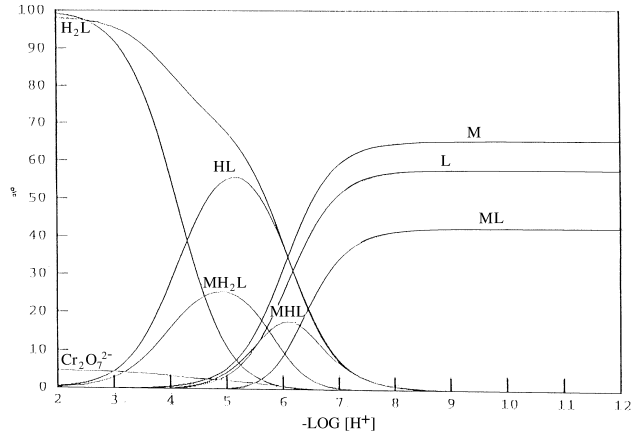

Fig. 9. Species distribution curves of a 1:1 molar ratio CMP–Cr(VI) as a function of $-\log[H^+]$ for a solution initially containing CMP 1.82 mM and chromate 1.96 mM. μ = 0.1 M (KCl), T = 25°C. L, CMP; M, chromate.

transfer reaction should be the chromate monochelate formed with the deprotonate nucleotide.

POLYHEDRON

Electrochemistry and strong near-IR absorption of the $[Ni(dphdt)_2]^n$ complexes ($n = -1, 0$; dphdt = 5,6-diphenyl-1,4-dithiin-2,3-dithiolate); X-ray crystal structure of $(Ph_4P)[Ni(dphdt)_2](CH_2Cl_2)$

Ha-Jin Lee, Dong-Youn Noh *

Received 17 March 1999; accepted 6 December 1999

Abstract

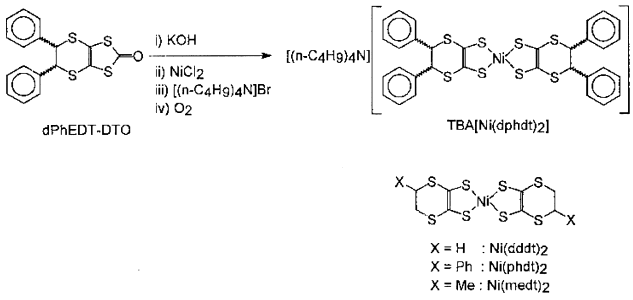
Nickel bisdithiolene complexes $C_x[Ni(dphdt)_2]$ ($x = 1$ or 0.1, C = tetrabutylammonium (n-Bu_4N^+); $x = 1$, C = tetraphenylphosphonium (Ph_4P^+); dphdt = 5,6-diphenyl-1,4-dithiin-2,3-dithiolate) have been synthesized and characterized. The molecular structure of $(Ph_4P)[Ni(dphdt)_2](CH_2Cl_2)$ was determined by X-ray analysis. $Ni(S_2C_2S_2)_2$ core is planar and stacking along the *c*-axis and the shortest intra-stack S···S distance is 4.529 Å. According to the cyclic voltammetry of (n-Bu_4N)$[Ni(dphdt)_2]$, two phenyl groups on the dphdt ligand decrease the electron density on the $Ni(S_2C_2S_2)_2$ core and increase the oxidation potentials compared to those of the (n-Bu_4N)$[Ni(dddt)_2]$ complex (dddt = 5,6-dihydro-1,4-dithiin-2,3-dithiolate). Near-IR spectra of the complexes show that phenyl substitution on the ligand does not give rise to the evident change in transition energy due to the lack of coplanarity with the $Ni(S_2C_2S_2)_2$ core. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; Cyclic voltammetry; Nickel bisdithiolenes; Strong near-IR absorption

1. Introduction

Metal bisdithiolene complexes have received considerable attention in the area of developing new materials due to their versatile properties such as electrical conductivity, strong near-IR absorption, molecular magnetism and catalytic behaviour [1–3]. In order to obtain better properties, many new ligands have been designed, prepared and utilized in preparing metal complexes [4–15]. Recently, we have been intensively involved in developing new dithiolene ligands and their metal complexes with those properties [4–13]. One of those ligands is diphenyl-containing dphdt (5,6-diphenyl-1,4-dithiin-2,3-dithiolate) as shown in Scheme 1, which was prepared by [2 + 4] cycloaddition reaction followed by oxo transformation using $Hg(OAc)_2$ [9]. $Ni(dphdt)_2$ complex in which dPhEDT-DTO (4,5-diphenylethylenedithio-1,3-dithiole-2-one) is used as a ligand precursor, is one of the analogues of $Ni(dddt)_2$ complex (dddt = 5,6-dihydro-1,4-dithiin-2,3-dithiolate) [16–18] which is regarded as a promising metal dithiolene because its molecular structure is closely similar to that of ET (bis(ethylenedithio)tetrathiafulvalene). Other analogues include $Ni(phdt)_2$ (phdt = 5-phenyl-6-hydro-1,4-dithiin-2,3-dithiolate) [7,14] and $Ni(medt)_2$ (medt = 5-methyl-6-hydro-1,4-dithiin-2,3-dithiolate) [15] which contain one phenyl and one methyl substituent per ligand, respectively. Compared to the phdt ligand containing one phenyl substituent, dphdt contains two symmetrically substituted phenyls.

In this paper, we describe the molecular structure and crystal packing of $(Ph_4P)[Ni(dphdt)_2](CH_2Cl_2)$. The strong near-IR absorption and electrochemical behaviour of the $Ni(dphdt)_2$ complexes are also explained and compared with those of $Ni(dddt)_2$ and $Ni(phdt)_2$ complexes.



2. Experimental

2.1. Synthesis

All reactions were carried out under nitrogen atmosphere. Ligand precursors (dPhEDT-DTO and PhEDT-DTO) were prepared by the [2 + 4] cycloaddition reaction as fully explained in the previous report [9]. The nickel complexes prepared in this study were recrystallized from CH_2Cl_2–ethyl acetate, the synthesis of which [7] is outlined in Scheme 1.

Scheme 1.

2.1.1. (n-Bu$_4$N)[Ni(dphdt)$_2$]

To a methanol solution of dPhEDT-DTO (0.5 mmol) treated with KOH (1 mmol) were added $NiCl_2$ (0.25 mmol) and n-$Bu_4N\cdot Br$ (0.5 mmol) successively in the presence of air. Elemental analysis data for (n-Bu_4N)[Ni(dphdt)$_2$]-(CH_2Cl_2)$_{0.5}$: Calc.: C, 57.84; S, 25.42. Found: C, 57.59; S, 25.73%. FT-IR (KBr, cm^{-1}): 1489.1, 1452.5 (C=C), 1369.5, 1179.8 (C–S).

2.1.2. (Ph$_4$P)[Ni(dphdt)$_2$]

This complex was synthesized by mixing (n-Bu_4N)-[Ni(dphdt)$_2$] and excess $Ph_4P\cdot Br$ in CH_3CN. Elemental analysis data for (Ph_4P)[Ni(dphdt)$_2$](CH_2Cl_2): Calc.: C, 59.74; S, 22.34. Found: C, 59.96; S, 21.82%. FT-IR (KBr, cm^{-1}): 1489.4, 1436.3 (C=C), 1364.6, 1182.2 (C–S).

2.1.3. (n-Bu$_4$N)$_{0.1}$[Ni(dphdt)$_2$]

This complex was prepared by the reaction of (n-Bu_4N)-[Ni(dphdt)$_2$] and excess iodine in CH_3CN. Elemental analysis data for (n-Bu_4N)$_{0.1}$[Ni(dphdt)$_2$](CH_2Cl_2): Calc.: C, 52.22; S, 32.17. Found: C, 51.65; S, 31.98%. FT-IR (KBr, cm^{-1}): 1226.7 (br).

2.1.4. (n-Bu$_4$N)[Ni(phdt)$_2$], (Ph$_4$P)[Ni(phdt)$_2$], [Ni(phdt)$_2$]

Ni(phdt)$_2$ complexes were prepared using the PhEDT-DTO ligand precursor following the method for Ni(dphdt)$_2$ complexes, and fully analyzed as reported previously [7].

2.2. General methods

Infrared spectra were measured by the KBr method on a MIDAC FT-IR spectrometer and UV–Vis–Near-IR spectra in CH_2Cl_2 on a Shimadzu UV-3100 instrument. Cyclic voltammetry was measured at room temperature on a BAS CW50W system in tetrahydrofuran (THF; 2 ml) containing 0.1 M n-$Bu_4N\cdot BF_4$ as a supporting electrolyte, Ag/Ag^+ as a reference electrode, glassy carbon working electrode, and platinum wire as a counter electrode ($E_{1/2}=0.2$ V for the Fc/Fc^+ couple).

2.3. X-ray structure determination

X-ray crystallographic data of (Ph_4P)[Ni(dphdt)$_2$]-(CH_2Cl_2) were collected on an Enraf-Nonius CAD-4 automatic diffractometer with graphite-monochromated Mo Kα radiation ($\lambda=0.71073$ Å) at 293(2) K. Intensities of 3827 ($R_{int}=0.0275$) independent reflections within the θ range 1.23–23.96° were measured using $\omega/2\theta$ scan mode for the range $0\le h\le 11$, $0\le k\le 26$, $-26\le l\le 26$. A total of 3462 reflections were considered [$I>2\sigma(I)$] and used in calculations performed on an IBM PC using SHELXS-86 and SHELXL-93 [19,20]; atomic scattering factors for all non-hydrogen atoms were supplied by the SHELXS-86 system. Crystal parameters and procedural information corresponding to data collection are given in Table 1.

3. Results and discussion

3.1. X-ray crystal structure

The molecular structure of (Ph_4P)[Ni(dphdt)$_2$] grown in CH_2Cl_2–CH_3OH solvent pair by slow diffusion was solved by X-ray single crystal analysis. The structure of [Ni(dphdt)$_2$]$^{1-}$ with the atom numbering scheme is shown in Fig. 1, and the selected bond distances and angles are listed in Table 2. The bond distances of C1–C2 and C17–C18 are within 1.33–1.34 Å, corresponding to the typical distance of a C=C bond in alkene [21], and very close to those of [Ni(dddt)$_2$]$^{1-}$ (1.339 Å) [18] as shown in Table 3. They are, however, quite different from those of [Ni(phdt)$_2$]$^{1-}$ (1.384 Å) [14] which corresponds to a C···C bond distance in benzene (1.39 Å) [21]. This could be attributed to the inductive effect together with the structural effect based upon

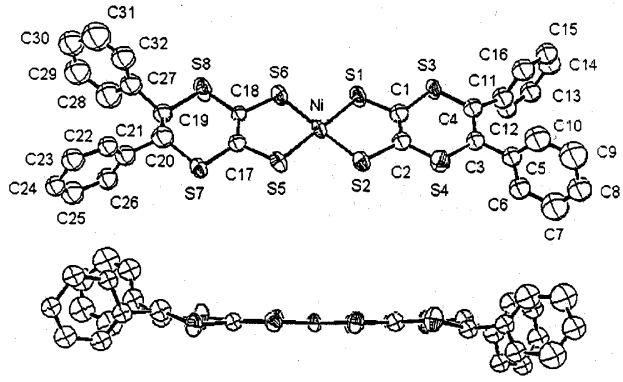

Fig. 1. ORTEP view of $[Ni(dphdt)_2]^{1-}$ with atom numbering scheme: top view (top) and side view (bottom). Hydrogen atoms are omitted for clarity.

[a] Tetraphenylphosphonium salt.
[b] Tetrabutylammonium salt.

the fact that dphdt and dddt ligands have two identical substituents (two phenyls and two hydrogens, respectively) symmetrically linked to the peripheral sp^3 carbons, whereas

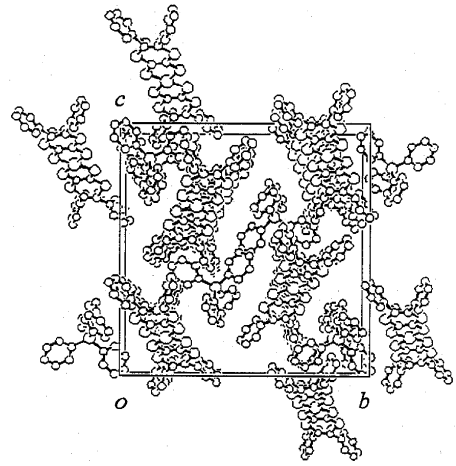

Fig. 2. Crystal structure of $(Ph_4P)[Ni(dphdt)_2]$ viewed along the *a*-axis.

phdt ligand has two different substituents (one phenyl and one hydrogen) (Scheme 1). The similarity in bond distances between $[Ni(dphdt)_2]^{1-}$ and $[Ni(dddt)_2]^{1-}$ can also be observed in the Ni–S and S–C bonds as shown in Table 3.

The $[NiS_4]$ core yields complete square-planar geometry with four S–Ni–S angles adding up to 360° (Table 2). The $S_2C{=}CS_2$ units in dphdt ligand are also planar as the sum of three angles around C1, C2, C17 and C18 are 360°, respectively. Therefore, the $Ni(S_2C_2S_2)_2$ unit is planar and, moreover, external (Ph)CH–CH(Ph) units are not bent so much from the central $Ni(S_2C_2C_2)_2$ plane as can be seen in the molecular side view (Fig. 1). This planar geometry of metal–bisdithiolene complex is one of the requirements for intermolecular close contact and is thus of high electrical conductivity [2,3]. Owing to the planar geometry, $[Ni(dphdt)_2]^{1-}$ units can be stacked along the *a*-axis and make columns which are separated from one another by tetraphenylphosphonium cation (Ph_4P^+) as shown in Fig. 2. The shortest intermolecular S···S interaction occurs within a stacking column with the distance of 4.529 Å between S4 and S7, which is much longer than the sum of van der Waals radii of sulfur atoms (3.7 Å) [22]. This is not surprising if we consider the geometry of $[Ni(dphdt)_2]^{1-}$ units: four phenyl groups connected to the periphery of the ligand are nearly perpendicular to the central $Ni(S_2C_2C_2)_2$ plane (Fig. 1) and would prohibit the close contact of molecules.

3.2. Cyclic voltammetry

Cyclic voltammograms of microcrystalline $(n\text{-}Bu_4N)[Ni(dphdt)_2]$, $(n\text{-}Bu_4N)[Ni(phdt)_2]$ and $(n\text{-}Bu_4N)[Ni(dddt)_2]$ complexes were measured in THF and compared in order to verify the effect of substituted phenyl groups on the redox properties of nickel complexes. Three voltammograms are quite similar in overall shape and redox potentials, implying that the redox processes are not so different for the three complexes.

Upon scanning from about −0.4 V (denoted by an asterisk in Fig. 3), $Ni(dphdt)_2$ complex exhibits two reversible waves

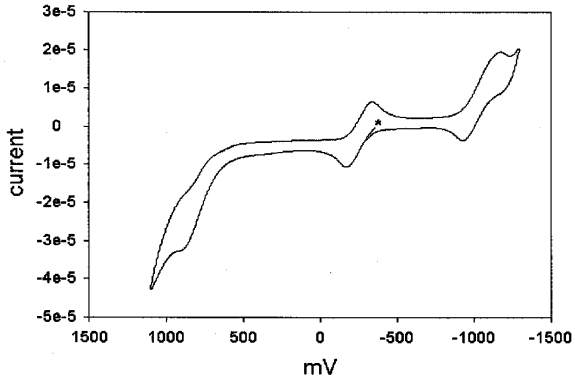

Fig. 3. Cyclic voltammogram recorded at a glassy carbon electrode on a THF solution containing $(n\text{-}Bu_4N)[Ni(dphdt)_2]$ (0.01 mol dm^{-3}) and $n\text{-}Bu_4N\cdot BF_4$ as supporting electrolyte. Scan rate 0.05 V s^{-1}. * Starting potential value.

with the half-wave potentials ($E_{1/2}$) of -0.25 and -1.05 V, respectively, along with the irreversible oxidation peak at around 0.9 V. Based on the redox process of $(n\text{-}Bu_4N)[Ni(dddt)_2]$ reported [16], the wave centred at -1.05 V is undoubtedly due to the $[Ni(dphdt)_2]^{2-} \rightleftharpoons [Ni(dphdt)_2]^{1-}$ process and the wave centred at -0.25 V can be attributed to the formation of neutral complex from $[Ni(dphdt)_2]^{1-}$. It is noteworthy that these potentials are almost the same as those of the $Ni(phdt)_2$ complex (-0.26 and -1.05 V) but comparatively different from those of the $Ni(dddt)_2$ complex (-0.29 and -1.07 V). The potential difference between $Ni(dddt)_2$ and $Ni(dphdt)_2$ complexes can be explained by the acceptor property of phenyl substituents [14]: the stronger the acceptor property of substituent is (phenyl is a stronger acceptor than H), the less electron density is expected on the $Ni(S_2C_2S_2)_2$ core. In consequence, the oxidation potential of the complex becomes higher due to the introduction of phenyl groups. The multielectron irreversible oxidation peak at the higher potential (0.9 V) can be assigned to the formation of cationic complex $[Ni(dphdt)_2]^0 \rightarrow [Ni(dphdt)_2]^{\delta+}$, if we suppose that the redox behaviour of $Ni(dphdt)_2$ and $Ni(dddt)_2$ complexes is not so very different [16].

3.3. Near-IR spectra

The characteristic strong near-IR absorption bands are found in the electronic spectra of nickel complexes prepared in this study. The absorbance and absorption maxima of the complexes are collected in Table 4. Monoanionic $Ni(dphdt)_2$ complexes show absorption maxima at 1158 nm ($\varepsilon \approx 13\,000$ M^{-1} cm^{-1}), which is not so very different from those of $[Ni(phdt)_2]^{1-}$ and $[Ni(dddt)_2]^{1-}$ (20 nm or 14 cm^{-1}) in energy even though the influence of solvent is not ruled out completely. In the simple MO diagram of Ni–dithiolene [1] the frontier orbitals are shifted in energy by the presence of the electron acceptor/donor substituted on the Ni–dithiolene core. Therefore, the highest occupied molecular orbital (HOMO) level ($2b_{1u}$) is expected to be stabilized by the electron-accepting substituent and thereby the transition

Table 4
Near-IR spectral data of the nickel complexes

Complex	λ_{max} (nm)	ε (M^{-1} cm^{-1})	Solvent	Ref.
$(n\text{-}Bu_4N)[Ni(dphdt)_2]$	1158	12 900	CH_2Cl_2	this work
$(Ph_4P)[Ni(dphdt)_2]$	1158	13 100	CH_2Cl_2	this work
$(n\text{-}Bu_4N)_{0.1}[Ni(dphdt)_2]$	1029	24 600	CH_2Cl_2	this work
$(n\text{-}Bu_4N)[Ni(phdt)_2]$	1178	11 300	CH_2Cl_2	this work
	1172	15 000	CH_3CN	[14]
$(Ph_4P)[Ni(phdt)_2]$	1157	9 400	CH_2Cl_2	this work
$[Ni(phdt)_2]$	1012	68 700	CH_2Cl_2	this work
	1028	43 000	C_6H_6	[14]
$(n\text{-}Bu_4N)[Ni(dddt)_2]$	1175	15 600	CH_3CN	[14]

energy (ΔE_{NIR}) between HOMO ($2b_{1u}$) and lowest unoccupied molecular orbital (LUMO) ($3b_{2g}$) levels will increase. In our complex, however, the phenyl substituents are not effectively conjugated with the $Ni(S_2C_2S_2)_2$ core due to the lack of coplanarity, as can be seen in its molecular structure (Fig. 1), and that the substituent effect is not evident. This is comparable to the phenyl-substituted bis[1,2-ethylenedithiolato(2−)-S,S′]nickel complexes in which the phenyl substituents are almost coplanar to the Ni–dithiolene core [23]: bis[1-phenylethene-1,2-dithiolato(2−)-S,S′]-nickel (810 nm) and bis[1,2-diphenylethene-1,2-dithiolato(2−)-S,S′]nickel (865 nm) complexes show an electronic transition energy difference of 55 nm (785 cm^{-1}), which is much bigger than our case (14 cm^{-1}).

Solution near-IR spectrum of $(n\text{-}Bu_4N)[Ni(dphdt)_2]$ is demonstrated in Fig. 4 together with that of $(n\text{-}Bu_4N)_{0.1}[Ni(dphdt)_2]$. While the monocationic complex shows broad absorption ($\lambda_{max} = 1158$ nm) with a shoulder at the high energy region, the partially oxidized complex gives a relatively narrow absorption band at a higher energy region ($\lambda_{max} = 1029$ nm) with more intense absorbance ($\varepsilon = 24\,600$ M^{-1} cm^{-1}) than that of the monocationic one ($\varepsilon \approx 13\,000$ M^{-1} cm^{-1}). This behaviour is also observed in the spectra of $Ni(phdt)_2$ complexes along with the solvent dependency

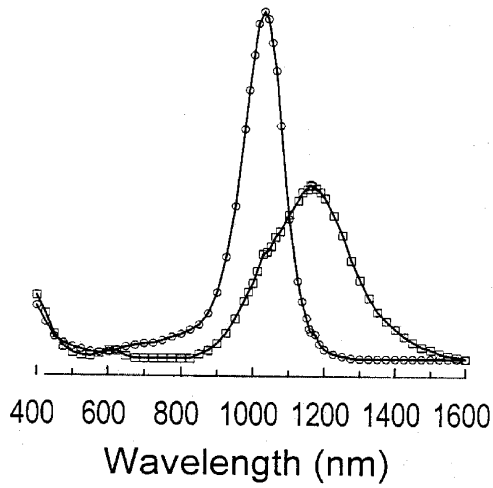

Fig. 4. Near-IR absorption spectra of $(n\text{-}Bu_4N)[Ni(dphdt)_2]$ (□) and $(n\text{-}Bu_4N)_{0.1}[Ni(dphdt)_2]$ (○).

of absorption maxima (Table 4). It can be rationalized by the fact that oxidation of monocationic complex can change HOMO from b_{1u} to b_{3g} of Ni–dithiolene core, for example, and therefore increase the electronic transition energy (ΔE_{NIR}). Consequently, a hypsochromic shift of 129 nm (108 cm^{-1}) results from the oxidation of (n-Bu_4N)-[Ni(dphdt)$_2$] with more intense absorbance.

4. Conclusions

The crystal structure of (Ph_4P)[Ni(dphdt)$_2$](CH_2Cl_2) was solved by X-ray structural analysis. The selected bond distances in this complex such as Ni–S, S–C and C=C are quite close to those of (n-Bu_4N)[Ni(dddt)$_2$] but quite different from those of (n-Bu_4N)[Ni(phdt)$_2$] because of the substituent effect on the ligand: dddt and dphdt ligands are symmetric but phdt is not. Due to the electron-withdrawing effect of substituted phenyl groups, higher oxidation potentials in the cyclic voltammogram are observed in $[Ni(dphdt)_2]^{1-}$ and $[Ni(phdt)_2]^{1-}$ complexes. However, the electronic transition energy of (n-Bu_4N)[Ni(dphdt)$_2$] in the near-IR range (ΔE_{NIR}) is not so very different from that of the (n-Bu_4N)[Ni(phdt)$_2$] complex.

Supplementary data

Full crystallographic details have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, on request, quoting the deposition number 116572.

Received 19 July 1999; accepted 14 December 1999

Abstract

The potential octadentate ligand, 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (**L**), gives iron(II) and cobalt(II) complexes of general formula $[M\mathbf{L}](ClO_4)_2 \cdot nH_2O$ ($n = 1$ or 0.5). The crystal and molecular structures of the complexes have been determined by single-crystal X-ray analysis. The complex $[Fe\mathbf{L}](ClO_4)_2 \cdot H_2O$ can be considered as octacoordinated with two semicoordinated bonds. The complex $[Co\mathbf{L}](ClO_4)_4 \cdot 0.5H_2O$ is six-coordinated with approximate octahedral geometry. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The coordination properties toward metal ions of macrocyclic ligands bearing pendant donor groups have recently attracted much interest, mainly because the study of such systems may provide a basis for a better understanding of the metal environment in some metalloenzymes and metalloproteins [1,2]. A number of derivatives of tetraazamacrocycles (cyclen and cyclam) have been prepared by substituting the hydrogen on the amine group with alkyl substituents having pendant arms containing functional groups such as carboxylic acids, alcohols, pyridyl and other donor groups [3–5]. 1,4,7,10-Tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (**L**) (Chart 1), a potential octadentate ligand, can bond to transition metals to form a variety of stable complexes utilizing all eight donor atoms or fewer donor atoms to form binuclear and mononuclear complexes. In previous publications, we reported 1,4,7,10-tetraazacyclododecane (cyclen) with four pyridyl groups connected to the macrocycle through methylene chains, and the nickel(II), copper(II), zinc(II) and lanthanide complexes [6–9]. The metal ion is always bound to the four nitrogen atoms of the macrocycle, whose central cavity is too small to accommodate cations, and its coordination sphere is completed by two to four additional nitrogen atoms from the pendant groups.

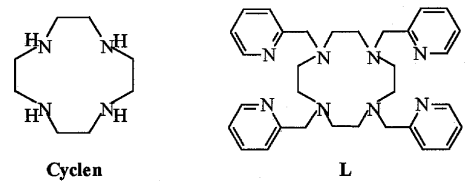

Chart 1

We report here the synthesis, characterization and crystal structure of the iron(II) and cobalt(II) complexes with 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (**L**). One of the title complexes, $[Fe(\mathbf{L})](ClO_4)_2 \cdot H_2O$ (**1**), is an encapsulated complex. The study of such systems may also provide a basis for a better understanding of the environment in some metalloenzymes and metalloproteins [2].

2. Experimental

2.1. Materials and methods

All reagents were of reagent grade; the intermediate compound 1,4,7,10-tetraazacyclododecane (cyclen) was prepared according to a literature method [10], 2-(chloromethyl)pyridine hydrochloride was purchased from Aldrich and used without further purification, and 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (**L**) was prepared by a literature method [7]. Hydrated metal perchlorates were prepared by standard methods.

IR spectra were recorded on a 170SX (Nicolet) IR spectrometer in the range 4000–400 cm^{-1} using KBr pellets. UV–Vis spectra were recorded on a Shimadzu UV-240 spectrometer. Magnetic susceptibilities were measured on a Faraday balance at room temperature and Mohr's salt was used for calibration. Variable temperature magnetic susceptibilities were measured on a vibrating sample model CF-1 magnetometer. The effective magnetic moment was calculated using the equation $\mu_{eff} = 2.828(\chi_m T)^{1/2}$, where χ_m is the magnetic susceptibility corrected for diamagnetism of the constituting atoms using Pascal's constants. Elemental analysis was performed on a P-E 240C analyzer.

2.2. Synthesis of the complexes

2.2.1. [Fe**L**](ClO4)2·H2O (**1**)

The ligand **L** (107 mg, 0.2 mmol) in acetonitrile (10 ml) and an aqueous solution (10 ml) of $FeCl_2 \cdot 4H_2O$ (40 mg, 0.2 mmol) in 1:1 molar ratio was mixed at room temperature for 0.5 h. The reaction mixture was filtered to remove small solids and the filtrate treated with a solid sample of $NaClO_4 \cdot H_2O$ (100 mg). The colorless crystalline product suitable for X-ray analysis was obtained from the solution. Yield: 80 mg (49%). *Anal*. Calc. for $C_{32}H_{42}Cl_2N_8O_9Fe$: C, 47.3; H, 5.2; N, 13.8. Found: C, 47.0, H, 4.9, N, 13.4%. Selected IR (cm^{-1}): 2859 (CH_2), 1607, 1571 (py ring), 1090, 623 (ClO_4^-).

2.2.2. [Co**L**](ClO4)2·0.5H2O (**2**)

The above-mentioned procedure was repeated using $Co(ClO_4)_2 \cdot 6H_2O$ (73.2 mg, 0.2 mmol) as starting material. Pink crystals were obtained from the pink reaction solution. Yield: 84 mg (52%). *Anal*. Calc. for $C_{32}H_{41}Cl_2N_8O_{8.5}Co$: C, 47.8; H, 5.1; N, 13.9. Found: C, 47.3, H, 4.9, N, 13.6%. Selected IR (cm^{-1}): 2874 (CH_2), 1608, 1594, 1571 (py ring), 1091, 623 (ClO_4^-).

2.3. Crystallography

Crystal data were measured on an Enraf-Nonius CAD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). The intensities of reflections were measured in the $\omega/2\theta$ scan mode at room temperature with $\theta \leq 25°$ for the Fe(II) complex and $\theta \leq 23°$ for the Co(II) complex. All data were corrected for empirical absorption. The structure was solved by MolEN or SHELXS-86. The final refinement by full-matrix least-squares method with anisotropic thermal parameters for non-hydrogen atoms converged with unweighted and weighted (unit weights for all observed reflections) agreement factors of 0.0624 and 0.0678 for the Fe complex and 0.0594 and 0.0639 for the Co complex.

Table 1 contains the crystal data and further details of the X-ray structural determinations. Selected bond distances and angles are listed in Tables 2 and 3.

3. Results and discussion

3.1. Synthesis of the complexes

The reaction of the octadentate ligand **L** with Fe(II) or Co(II) salt in equimolar ratios gave crystalline compounds having the general formula $[ML](ClO_4)_2 \cdot nH_2O$ ($n = 1$ or 0.5). The electronic spectra of the complexes were recorded in methanol solution. Absorption maxima in the 200–800 nm region are listed in Table 4 together with the values of magnetic moment. The spectrum of the iron complex exhibited two strong absorption bands in the 200–300 nm region, which can be assigned to the $\pi \rightarrow \pi^*$ intraligand transitions, and two absorptions at 363 and 350 nm, which correspond to the charge transitions between ligand and metal. The spectrum of the colorless iron(II) complex is essentially featureless in the range 400–800 nm, and d–d transitions are hardly observable. The visible spectrum of the cobalt(II) complex is indicative of a MN_6 coordination sphere, giving two bands at 479 and 565 nm which correspond to the transitions $^4T_{1g(F)} \rightarrow {}^4T_{1g(P)}$ and $^4T_{1g(F)} \rightarrow {}^4A_{2g(F)}$ [11].

3.2. Structure of $[FeL](ClO_4)_2 \cdot H_2O$

The crystal structure consists of a packing of discrete $[FeL]^+$ cations, ClO_4^- anions and H_2O molecules, as illustrated in Fig. 1. The iron(II) ion in the cation is in an eight-coordinate environment (FeN_6N_2'), being coordinated by all eight nitrogen atoms (N(1), N(2), N(3), N(4) and N(11), N(22), N(33), N(44)) of the ligand **L**. The four nitrogen atoms (N(1), N(2), N(3), N(4)) of the macrocyclic ring and the four pyridyl nitrogens (N(11), N(22), N(33), N(44)) of the ligand **L** are arranged at the corners of a square prism with the basal faces rotated about the pseudo-fourfold axis. These nitrogen atoms thus fully encapsulate the Fe(II) ion which lies 1.135 and 1.620 Å from the basal planes in the above order; the two planes form an angle of 2.75° with each other.

Such a high coordination number is achieved at the expense of two long Fe–N(pyridyl) distances (Fe–N(11) = 3.108(5) Å and Fe–N(33) = 2.998(5) Å), which can be considered as semicoordinate. In addition, the four Fe–N(macrocyclic ring) (2.302(5)–2.344(5) Å) and two Fe–N(pyridine pendants in non-adjacent positions) (2.226(4) and 2.233(6) Å) are normal Fe–N bonds. If both semi-bonds are ignored, the coordination stereochemistry of the remaining FeN_6 can be considered as distorted octahedral. The nitrogen atoms (N(22) and N(44)) of coordinated pyridyl groups in non-adjacent positions are in *cis*-positions.

In the unit cell, the two perchlorate ions are linked together by the water molecule through hydrogen bonding.

3.3. Crystal structure of $[CoL](ClO_4)_2 \cdot 0.5H_2O$

The structure of the cobalt(II) complex consists of $[CoL]^{2+}$, ClO_4^- anions and H_2O molecules. The cobalt atom is six-coordinated, with approximate octahedral geometry, by the four nitrogen atoms of the macrocyclic ring and two pyridyl nitrogens (N(11), N(13)) belonging to non-adjacent arms of the ligand (Fig. 2). In the cation, the cobalt atom is constrained to lie on the least-squares plane defined by atoms N(1), N(3), N(13) and N(11), which deviate by ≤ 0.03 Å from that plane, but it is highly displaced, by ca. 1.067 Å, from the four basal nitrogens (of cyclen) of the macrocyclic ligand.

The Co–N distances formed by the pyridyl nitrogens are shorter than those formed by the amine nitrogens, in agreement with what is generally observed [7]. The bond distances Co–N(1) and Co–N(3) are slightly shorter than the distances Co–N(2) and Co–N(4), indicating weaker coordination of

Table 4

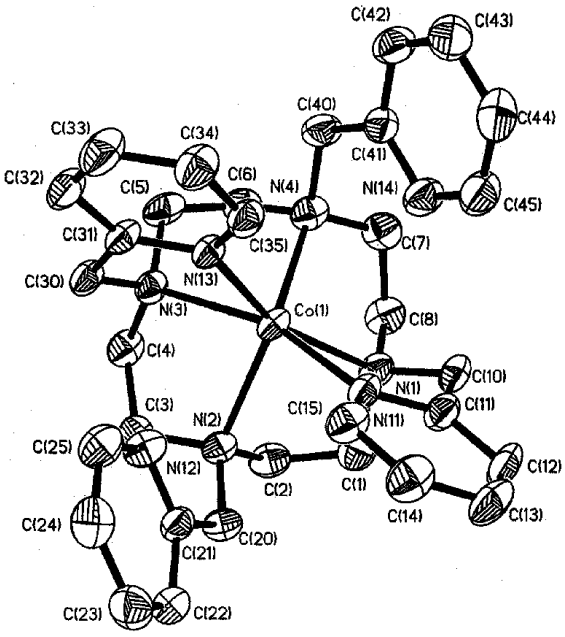

Fig. 2. Perspective view of the cationic entity of the complex $[Co\mathbf{L}]^{2+}$.

the macrocyclic nitrogens connected to the uncoordinated methylpyridines, possibly for relieving steric strain within the macrocycle and minimizing repulsion among the coordinated methylpyridine groups. It is worth noting that the N atoms of uncoordinated methylpyridines are oriented such that they make close contact to Co(II) at Co···N(12) = 3.206 Å and Co···N(14) = 3.157 Å. The presence of Co···N (N(12) and N(14)) contacts of such lengths can be considered to indicate a weak reaction between the central metal atom and the N atoms.

The unit cell contains two molecular units, and hydrogen bonds are not formed between the H_2O molecule and other atoms.

The structures of **1** and **2** may be compared with that of the corresponding Ni(II) complex [7]. The ability of the ligand to adapt to such changes in the dimensions of the cage about the metal ion for a given coordination geometry, as well as its ability to yield six- to eight-coordinate complexes, are indicative of considerable flexibility. In these complexes, the macrocycle takes a *trans*-I configuration in which all the lone pairs in the four basal nitrogens are oriented on the same side of the macrocyclic plane [12] and the 12-membered ring is folded by the coordination of the metal atom; the degrees of folding from the Fe complex to the Ni complex are presented by an increase in the N(2)–M–N(4) angles and a decrease in the N(1)–M–N(3) angles (Table 5). All metal ions are high above the mean plane formed by the four basal macrocyclic nitrogens by ca. 0.900 Å for Ni^{2+}, 1.067 Å for Co^{2+} and 1.135 Å for Fe^{2+}. Four nitrogen atoms of the macrocyclic ring and a pair of nitrogen atoms of coordinated pyridyl groups in non-adjacent positions are bonded to metal ions in normal coordination, and the other nitrogens of pyridyl groups in non-adjacent positions are in uncoordination or semicoordination. The distances between uncoordinated or semicoordinated nitrogen of the pyridine group and M(II) are in the order Fe(II) < Co(II) < Ni(II) in these complexes. The structure of the Co complex is similar to that of the Fe complex, while it is notably different from the Ni complex with respect to the bond angles involving the metal and nitrogens of the macrocyclic ring and the M···N distances formed by the uncoordinated or semicoordinated pyridyl nitrogens (Table 5).

3.4. Magnetic properties of the complexes

The effective magnetic moments of $[Fe\mathbf{L}](ClO_4)_2 \cdot H_2O$ and $[Co\mathbf{L}](ClO_4)_2 \cdot 0.5H_2O$ are 5.46 and 5.31 BM (293 K), corresponding to an $S = 2$ and an $S = 3/2$ state with an appreciable orbital contribution. A variable-temperature (4.2–300 K) study of the magnetic susceptibility was undertaken for **1**. The magnetic properties of **1** are shown in Fig. 3 in the form of effective magnetic moment versus temperature plot. The magnetic moment of 5.37 BM at 298 K decreases steadily with decreasing temperature, reaching a value of 5.06 BM at 21 K, and then it starts to decrease very rapidly, reaching a value of 3.33 BM at 4.5 K. The rapid decrease in the magnetic moment below 21 K may be attributed to an intermolecular antiferromagnetic interaction and/or a zero-field splitting of the iron(II) ion. It was also found that within the temperature range from 21 to 300 K, the susceptibilities may be approximated by the Curie–Weiss law: $\chi_m = C/(T-\theta)$, where $\theta = -6.4$ K.

3.5. Mössbauer studies of [Fe**L**](ClO)$_2$·H$_2$O

The Mössbauer spectrum of solid complex **1** at room temperature is a symmetrical doublet and yields an isomer shift $\delta = 1.007$ mm s^{-1} and quadrupole splitting $\Delta E = 3.20$ mm s^{-1}, corresponding to typical high-spin Fe(II) ($S = 2$) [13]. The values of the isomer shifts indicate a pronounced difference for $FeCl_2$ ($\Delta\delta = -0.1081$ mm s^{-1}, $\Delta(\Delta E) = 0.5$ mm s^{-1}). In addition, there is a small peak in the spectrum indicating the presence of a small amount of Fe(III) impurity in the sample of the Fe(II) complex.

Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition numbers 127379 and 127380.

POLYHEDRON

Tetrahedral chalcogeno thiocyanate cluster complexes $[Re_4Q_4(SCN)_{12}]^{4-}$ (Q = S, Se, Te): synthesis and crystal structures

Yuri V. Mironov [1] *

Lehstuhl für Analytische Chemie, Ruhr-Universität Bochum, D-44780 Bochum, Germany

Received 21 July 1999; accepted 9 December 1999

Abstract

The $[Re_4Q_4(SCN)_{12}]^{4-}$ (Q = S, Se, Te) anions were obtained by the reactions of neutral molecular clusters $Re_4Q_4Cl_8(TeCl_2)_4$, Q = S, Se, Te, with melting KSCN. Crystal structures were determined for the isostructural compounds $(Ph_4P)_4Re_4S_4(SCN)_{12}$ (**1**), $(Ph_4P)_4Re_4Se_4(SCN)_{12}$ (**2**) and $(Ph_4As)_4Re_4Te_4(SCN)_{12}$ (**3**). Each contains an Re_4Q_4 cubane-like cluster core with Re–Re distances in the ranges 2.762(3)–2.768(2) Å (**1**), 2.799(2)–2.803(2) Å (**2**) and 2.864(2)–2.877(2) Å (**3**). The faces of the Re_4 units are symmetrically capped by triply bridging chalcogenide ligands Q^{2-} (Q = S, Se, Te). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Rhenium; Metal clusters; Sulfur; Selenium; Tellurium; Crystal structures

1. Introduction

Re_4 tetrahedral cluster compounds have been studied intensively in recent years. At the present time a number of well characterized chalcogeno halide clusters are known: $Re_4Q_4Te_4X_{16}$ (Q = S, Se, Te; X = Cl, Br) [1,2] and $(Pr_4N)_2Re_4Q_4(CH_3CONH)_2Cl_8$ (Q = S, Se) [3], chalcogeno cyanide clusters $[Re_4Q_4(CN)_{12}]^{4-}$ [4–6], the mixed rhenium thiotelluride $Re_4S_4Te_4$ [7] and thio complexes $[Re_4S_4(\mu\text{-}S_3)_6]^{4-}$ [8,9]. We have now successfully extended this work to allow the isolation of the first such rhenium clusters with thiocyanate ligands, which display the ionic structures $(Ph_4P)_4Re_4Q_4(SCN)_{12}$, Q = S, Se, and $(Ph_4As)_4Re_4Te_4(SCN)_{12}$.

2. Experimental

All manipulations were performed under air. $Re_4Q_4Te_4Cl_{16}$ (Q = S, Se, Te) was prepared as described previously [1]. IR spectra were recorded as KBr discs on a Perkin-Elmer 1760X spectrometer. Elemental analyses were performed on an elemental analyzer system Vario E1.

2.1. Synthesis of $(Ph_4P)_4Re_4S_4(SCN)_{12}$ (1)

$Re_4S_4Te_4Cl_{16}$ (50 mg, 0.026 mmol) and KSCN (200 mg, 2.06 mmol) were heated up to the melting point of KSCN, left at this temperature for 5 min and then cooled down. The solid product was dissolved in 10 ml of water and PPh_4Cl (100 mg, 0.267 mmol) was added to this solution. The resulting precipitate was filtered off, dried and recrystallized from the solvent mixture CH_3CN–$(C_2H_5)_2O$ to afford dark red crystals of $(Ph_4P)_4Re_4S_4(SCN)_{12}$; yield 35 mg (46%). *Anal*. Found: C, 43.9; H, 2.6; N, 5.6; S, 17.1. Calc. for $C_{108}H_{80}N_{12}P_4Re_4S_{16}$: C, 44.3; H, 2.75; N, 5.7; S, 17.5%. IR (cm^{-1}): 2085 ν(CN) (cationic bands are omitted).

2.2. Synthesis of $(Ph_4P)_4Re_4Se_4(SCN)_{12}$ (2)

50 mg of $(Ph_4P)_4Re_4Se_4(SCN)_{12}$ were obtained from $Re_4Se_4Te_4Cl_{16}$ (50 mg, 0.023 mmol) and KSCN (200 mg, 2.06 mmol) by a procedure similar to that described for **1**. Yield 69%. *Anal*. Found: C, 41.0; H, 2.65; S, 11.9. Calc. for $C_{108}H_{80}N_{12}P_4Re_4S_{12}Se_4$: C, 41.6; H, 2.59; S, 12.3%. IR (cm^{-1}): 2089 ν(CN) (cationic bands are omitted).

2.3. Synthesis of $(Ph_4As)_4Re_4Te_4(SCN)_{12}$ (3)

48 mg of $(Ph_4As)_4Re_4Te_4(SCN)_{12}$ were obtained from $Re_4Te_8Cl_{16}$ (60 mg, 0.026 mmol) and KSCN (200 mg, 2.06 mmol) in a manner as described for **1**, using Ph_4AsCl instead

2.4. X-ray structural analyses

Crystals used in the crystallographic study were mounted on glass fibres. Intensity data were collected at room temperature on a Siemens P4 diffractometer. Graphite-monochromated Mo Kα radiation ($\lambda=0.71073$ Å) was utilized. SHELXS-86 [10] was employed for structure solution by direct methods and SHELXL-93 [11] for refinement by full-matrix least-squares. DIFABS [12] (compound **1**) and semi-empirical absorption corrections based on ψ scan data (compounds **2** and **3**) were applied to the intensity data. Hydrogen atoms were included at calculated positions [13]. Crystal data for compounds **1**, **2** and **3** are given in Table 1, selected bond distances are given in Table 2.

3. Result and discussion

Treatment of molecular clusters $Re_4Q_4Cl_8(TeCl_2)_4$, Q = S, Se, with molten KSCN leads to the formation of chalcogeno thiocyanate complexes with tetra anions $Re_4Q_4(SCN)_{12}^{4-}$, Q = S, Se, Te. During the reaction, exchange of all terminal ligands, Cl^- and $TeCl_2$, by thiocyanate ligands is observed. The final products may be obtained as salts with different tetraalkylammonium counter cations, such as Me_4N^+, Et_4N^+, Pr_4N^+ or with Ph_4X^+ (X = P, As). Although all of these compounds were tested for suitability, only the Ph_4X^+ (X = P, As) forms were found to be of adequate though poor scattering power for X-ray analysis. Their mediocre quality may be gauged by the relatively low number of reflections with $I>2\sigma(I)$ which varies between 36.5% (for **1**) and 39.3% (for **3**). As a result the reliability indices R_1 and wR_2 in Table 1 are rather high and with the exception of the bond distances to Re, metrical aspects of the structures will not, therefore, be discussed in detail.

The structures of all three compounds $(Ph_4P)_2Re_4S_4(SCN)_{12}$ (**1**), $(Ph_4P)_2Re_4Se_4(SCN)_{12}$ (**2**) and $(Ph_4P)_2Re_4Te_4(SCN)_{12}$ (**3**) were determined by single-

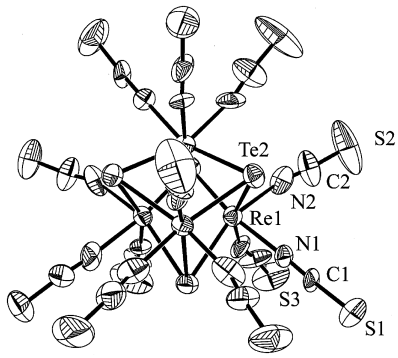

Fig. 1. The crystal structure of the anion $Re_4Te_4(SCN)_{12}^{4-}$.

crystal X-ray analysis. A view of the cluster anion is shown in Fig. 1. Compounds **1**, **2** and **3** are isostructural and possess crystallographic S_4 symmetry. Each contains an Re_4Q_4 cubane-like core formed from a nearly regular Re_4 tetrahedron with Re–Re distances in the range 2.762(3)–2.768(2) Å for **1**, 2.799(2)–2.803(2) Å for **2** and 2.864(2)–2.877(2) Å for **3**. Each triangular face of the Re_4 tetrahedron is capped symmetrically by triply bridging chalcogenide ions with Re–Q distances of respectively 2.353(8)–2.378(7) Å (**1**), 2.443(3)–2.448(3) Å (**2**), and 2.626(2)–2.628(2) Å (**3**). These values are in good agreement with those reported for other Re_4 cluster compounds [1]. Each Re atom is ligated by the N atoms of three terminal SCN^- ligands with Re–N distances lying in the ranges 2.07(3)–2.14(2) Å for **1**, 2.07(3)–2.18(2) Å for **2**, and 2.09(2)–2.14(2) Å for **3**. This type of coordination mode was also observed for the SCN^- ligand in previously characterized cluster complexes of Mo and W [13–15].

The most interesting feature of this reaction lies in the preservation of the cluster units $[Re_4Q_4]$ (Q = Se, Te) in the presence of KSCN, as a potential source of sulfur atoms. This state of affairs is in accordance with a high kinetic stability of these fragments under the chosen reaction conditions. Treatment of Re with S and Te at high temperature leads to the formation of $[Re_4S_4]Te_4$ [7], indicating that $[Re_4S_4]$ clusters are thermodynamically more stable than those of the heavier Group 16 congener. It was also previously found for W and Nb, that the reactions of selenium-rich cluster complexes with molten KSCN under similar conditions always lead to exchange of Se by S atoms from the thiocyanate source [16]. The only known selenothiocyanate cluster $(Me_2NH_2)_6[(SCN)_9W_3Se_4SnCl_3]\cdot 0.5H_2O$ was obtained by the reaction of $[W_3Se_4(H_2O)_9]^{4+}$ in aqueous HCl solution with $SnCl_2\cdot 2H_2O$ in the presence of Me_2NH_2Cl and NaSCN [17].

$[Re_4Te_4(SCN)_{12}]^{4-}$ is the first example of a tellurothiocyanate cluster anion.

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.uk) on request, quoting the deposition numbers CCDC 132396 (**1**), 132397 (**2**) and 132398 (**3**).

Abstract

New copper complexes have been prepared from benzilbisthiosemicarbazone (L^1H_6) and from the cyclic 6-methoxi-1,6-diphenyl-4-thio-3,4,5,6-tetrahydro-2,3,5-triazine (L^2H_2). The complexes were characterized by mass spectrometry, IR, electronic and electron paramagnetic resonance spectra. Complexes from L^1H_6 (**1**–**5**) present 1:1 stoichiometry and show different characteristics with a variable grade of deprotonation in the ligand, depending on the salt used (chloride, nitrate or sulfate) and the presence of acid in the medium. A macrocyclic Schiff base, 3,4,9,10-tetraphenyl-1,2,5,6,8,11-hexaazacyclododeca-7,12-dithione-3,4,9,10-tetraene (L^3H_2), containing thiosemicarbazone moieties is readily prepared and characterized for the first time, with fairly good yield, from the mesocycle (L^2H_2) in methanol with copper chloride as template. Near quantitative synthesis of the precursor, L^2H_2, which is a potential chemotherapeutic agent against cancer, has been achieved by reacting benzil and thiosemicarbazide in the absence of metal salt and using a high dilution technique. Macrocyclic complexes **6** and **7** containing thiosemicarbazone moieties were obtained from L^2H_2 and copper nitrate and sulfate. Direct reaction between the copper salt and the macrocyclic thiosemicarbazone (L^3H_2) gave similar complexes but with a lower grade of purity. Macrocyclic complexes **6** and **7** present metal–ligand ratios of 1:2 and 1:1 and the ligand is in a deprotonated form. The redox behaviour was explored by cyclic voltammetry. L^1H_6 complexes show Cu(II)/Cu(I) couples and quasireversible waves associated with the Cu(III)/Cu(II) process. The reduction/oxidation potential depends on the structure and conformation of the central atom in the coordination compounds. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Thiosemicarbazones; Macrocyclic ligands; Electrochemistry; Copper complexes; Dithio-Schiff base complexes

1. Introduction

Schiff base macrocyclic ligands based on thiosemicarbazones and their complexes have received considerable attention since, because of their pharmacological properties, they have numerous applications, for example as antibacterial and anticancer agents [1–3]. They can yield mono- or polynuclear complexes, some of which are biologically relevant [4–7]; for example, some copper complexes can serve as models for enzymes such as galactose oxidase and may be used as effective oxidant and redox catalysts [8,9]. Furthermore, they allow selective complexation and extraction of metallic cations and anions of biochemical and environmental importance [10–13]. The number and relative position of donor atoms and the cavity size in the macrocyclic compounds give these molecules special reactivity. For a particular dicarbonyl and diamine as precursors, control of the reaction conditions allows the condensation product formed to be determined: [1+1], [1+2] and [2+2] condensation products, with open chain and cyclic structures. Alternatively, the high dilution technique is a good method to obtain macrocyclic Schiff bases [14]. The most important factors are the solvent, pH, temperature and the presence of metal ions. Metal salts have been used as templating agents to yield macrocyclic Schiff bases from diamine and dicarbonyl as precursors [15,16], but transition metals such as copper and nickel, which have been used in the preparation of aza crowns, are surprisingly absent [17]. If the metal is present, the size, charge and favourable geometries of the metal have to be considered.

Biological activities may be related to the redox properties of complexes. For some copper(II) compounds a lower reduction potential seems to be related to an increased anti-

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(99)00383-6

fungal activity [1,3]. Some copper complexes exhibit the abilities of superoxide dismutase (SOD) and chemical nucleases [18,19]. Moreover, copper is also toxic in elevated concentration so many investigations have attempted to develop sensors to determine its presence with high selectivity. Potentiometric measurements with copper ion-selective electrodes (ISE) allow the free ion concentration to be determined directly in water samples. The possible biomimetic activity and the potential application as sensors for copper complexes can be evaluated from the electrochemical behaviour and visible and EPR spectra.

The redox properties include oxidation and reduction of the central metal ion, various oxidation and reduction reactions of the ligand, and processes which involve both the central atom and the ligand [20]. The redox potentials of the Cu(III)/Cu(II) and Cu(II)/Cu(I) couples have been shown to be markedly affected by the nature of the solvent, background electrolyte and by the structure of the chelating ligand and of the complex as a whole. Redox potentials of Cu(II)–Cu(I) systems depend on the relative thermodynamic stabilities of the two oxidation states in a given ligand environment. The factors influencing the metal-located redox properties of the copper systems have been extensively studied. The influence of various structural features has been gauged, including ring size, degree and arrangement of unsaturation and alkyl substitution [21–23].

In previous work, we obtained different condensation products from the reaction of benzil and thiosemicarbazide depending on the reaction conditions: open chain molecule, benzilbisthiosemicarbazone L^1H_6, and a cyclic [1+1] molecule L^2H_2. Both compounds were obtained in the absence of metal salts (nickel, copper or iron), because in the presence of these salts the product isolated was always a thiosemicarbazide complex, even when working with high dilution conditions [24]. However, the reaction between the open chain molecule and iron chloride in methanol and in the presence of lithium hydroxide gave an iron complex of a macrocyclic species, but it is not possible to obtain the free macrocycle from this complex [25]. We have prepared metal complexes from L^1H_6 with several metal salts [24,26]. Redox properties of cobalt(II) and nickel(II) complexes have been explored [26]. Some copper derivatives have shown that the changes in the coordination sphere are connected with the halfwave potential values for the Cu(II)/Cu(I) redox couple, and these results and the spectral data on solution agree with the superoxide dismutase (SOD) mimetic activity [27]. Moreover, carbon paste ion selective electrodes based on thiohydrazone and thiosemicarbazone complexes exhibit rapid response, adequate sensitivity and selectivity for copper ions [28].

As a part of our work involving the preparation of free iminomacrocyclic compounds and their metal complexes, we are interested in obtaining the free [2+2] condensation product from benzil and thiosemicarbazide. The aim of our work is to compare the reactivity of different macroligands containing the same functional group, but with variable number and different structure, with a particular metal ion. In addition, we are trying to determine the best conditions to control the nature of copper complexes, since the different structures can improve their potential applications. Therefore, we report the reactions of an open chain ligand, benzilbisthiosemicarbazone L^1H_6, a cyclic molecule 6-methoxi-1,6-diphenyl-4-thio-3,4,5,6-tetrahydro-2,3,5-triazine L^2H_2 (Fig. 1) with copper(II) chloride, nitrate and sulfate in variable work conditions. Since a new free macrocycle 3,4,9,10-tetraphenyl-1,2,5,6,8,11-hexaazacyclododeca-7,12-dithione-3,4,9,10-tetraene L^3H_2 (Fig. 1) has been obtained from the reaction of L^2H_2 with copper chloride, we have studied its interactions with copper nitrate and sulfate. We have studied the electrochemical behaviour of complexes by cyclic voltammetry, because their applications as SOD mimetic complexes and as copper sensors are related to the redox properties.

2. Experimental

2.1. Reagents

Copper salts were commercial products of highest chemical grade (Fluka). Solvents were purified according to standard procedures.

2.2. Synthesis of the organic molecules

Benzilbisthiosemicarbazone, L^1H_6, was prepared following the procedure previously reported [24].

L^2H_2 was prepared by modifying the published procedure [25]. A solution of thiosemicarbazide (1.14 g, 12.5 mmol) in methanol (150 cm^3), a solution of hydrochloric acid (25 cm^3, 2 M), 1 cm^3 of HCl (12 M) and a solution of benzil (2.63 g, 12.5 mmol) in methanol (100 cm^3) were added alternately dropwise and slowly with strong stirring to 75 cm^3 of methanol. After completion of the addition of all reactants, the mixture was heated for 8 h. Overnight a crystalline solid was formed, which was filtered off, washed and dried in vacuo (yield 95%).

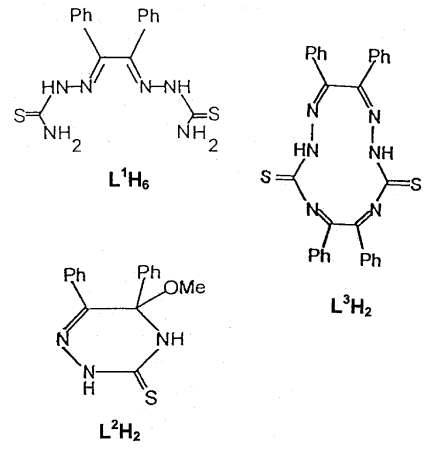

Fig. 1. Structures proposed for the organic molecules.

A solution of copper chloride dihydrate (0.23 g, 1.40 mmol) in methanol (50 cm^3) was added to a solution of L^2H_2 (0.41 g, 1.40 mmol) in methanol (50 cm^3). The mixture was stirred for 2 h at room temperature. The cream solid L^3H_2 formed was filtered off, washed several times with methanol and dried in vacuo (yield 79%), m.p. 205°C. *Anal*. Calc. for $C_{30}H_{22}N_6S_2$: C, 67.92; H, 4.15; N, 15.85; S, 12.07. Found: C, 67.82; H, 4.28; N, 15.75; S, 12.13%. Selected spectroscopic data: *m/z* (FAB) 529.1 ($C_{30}H_{21}N_6S_2$, 100%). ^{13}C NMR (DMSO, 300 MHz): 166.90 (CS), 156.57, 155.97 (CN), 134.89, 134.54, 131.31, 129.79, 129.47, 128.67, 128.57 (Ph).

2.3. Synthesis of the complexes from L^1H_6 and copper(II) chloride dihydrate

To L^1H_6 (0.20 g, 0.56 mmol) in methanol (25 cm^3) was added a solution of copper(II) chloride dihydrate (0.10 g, 0.56 mmol) in methanol (40 cm^3). The mixture was stirred for 5 h at room temperature, heated under reflux for 5 h or heated under reflux for 5 h in the presence of LiOH. In all cases a brown solid **1** was formed, which was filtered off, washed with methanol and dried in vacuo (yield 40%).

To L^1H_6 (0.20 g, 0.56 mmol) in methanol (25 cm^3) was added a solution of copper(II) chloride dihydrate (0.05 g, 0.28 mmol) in methanol (20 cm^3). The mixture was stirred for 12 h at room temperature. The reddish solid **2** formed was filtered off, washed with methanol and dried in vacuo (yield 20%).

A solution of copper(II) chloride dihydrate (0.24 g, 1.40 mmol) and hydrochloric acid (50 cm^3, 12 M) in methanol (50 cm^3), was added to L^1H_6 (0.50 g, 1.40 mmol) in methanol (100 cm^3). The mixture was refluxed for 3 h with stirring. The green solid **3** formed was filtered off, washed with methanol and dried in vacuo (yield 85%).

The same solid was obtained if the acid (2 M) was added dropwise.

A suspension of L^1H_6 (0.75 g, 2.10 mmol) in dichloromethane (25 cm^3) was mixed with a suspension of copper(II) chloride dihydrate (0.36 g, 2.10 mmol) in the same solvent (20 cm^3). The mixture was refluxed for 2 h with stirring. The green solid formed was filtered under nitrogen and dried in vacuo. The solid decomposes very quickly in the presence of air.

The reaction was carried out using toluene and cyclohexane as solvent with the same results described above.

A solution of copper(II) chloride dihydrate (0.10 g, 0.58 mmol) in methanol (50 cm^3) was added to a suspension of L^1H_6 (0.20 g, 0.58 mmol) and benzil (0.12 g, 0.58 mmol) in methanol (60 cm^3). The mixture was refluxed for 4 h with stirring. The brown solid formed was filtered off, washed with methanol and dried in vacuo (yield 45%).

2.4. Synthesis of complexes from L^1H_6 and copper(II) nitrate trihydrate

A solution of copper(II) nitrate trihydrate (0.36 g, 1.50 mmol) in methanol (20 cm^3) was added to L^1H_6 (0.53 g, 1.50 mmol) in methanol (20 cm^3). The mixture was stirred for 3 h at room temperature. The brown solid **4** formed was filtered off, washed with methanol and dried in vacuo (yield 65%).

A solution of copper(II) nitrate trihydrate (0.36 g, 1.50 mmol) in methanol (20 cm^3) and 50 cm^3 of nitric acid (15 M) was added to L^1H_6 (0.53 g, 1.50 mmol) in methanol (20 cm^3). The mixture was stirred for 2 h at room temperature. The green oil formed was concentrated in a rotary evaporator to half the initial volume and then the solvent was evaporated slowly at room temperature. Finally needle shaped yellow crystals were separated.

Identical results were obtained adding the acid (2 M) dropwise.

2.5. Synthesis of complexes from L^1H_6 and copper(II) sulfate pentahydrate

To a suspension of L^1H_6 (0.10 g, 0.30 mmol) in methanol (40 cm^3) was added a solution of copper(II) sulfate pentahydrate (0.06 g, 0.28 mmol) in methanol (40 cm^3). The mixture was stirred for 6 h at room temperature. The reddish solid formed was filtered off, washed with methanol and dried in vacuo (yield 20%).

To a suspension of L^1H_6 (0.10 g, 0.30 mmol) in methanol (40 cm^3) were added three drops of sulfuric acid (18 M) and then a solution of copper(II) sulfate pentahydrate (0.07 g, 0.28 mmol) in methanol (40 cm^3). The mixture was stirred for 12 h at room temperature. On slow diffusion of ether through the dark blue oil formed, a crystalline dark blue solid **5** was obtained. The solid was filtered off, washed with ether and dried in vacuo (yield 51%).

2.6. Synthesis of complexes derived from L^2H_2

A solution of copper(II) nitrate trihydrate (0.15 g, 0.63 mmol) in methanol (20 cm^3) was added to a suspension of L^2H_2 (0.37 g, 1.26 mmol) in methanol (20 cm^3). The mixture was stirred for 12 h at room temperature. The brown solid **6** formed was filtered off, washed with methanol and dried in vacuo (yield 27%).

A solution of copper(II) sulfate pentahydrate (0.10 g, 0.40 mmol) in methanol (20 cm^3) was added to a suspension of L^2H_2 (0.24 g, 0.80 mmol) in methanol (20 cm^3). The mixture was stirred for 12 h at room temperature. The orange–brown solid **7** formed was filtered off, washed with methanol and dried in vacuo (yield 37%).

2.7. Synthesis of complexes from L^3H_2

A solution of copper(II) chloride dihydrate (0.02 g, 0.23 mmol) in dried methanol (10 cm^3) was added to a suspension of L^3H_2 (0.11 g, 0.23 mmol) in dried methanol (10 cm^3). The mixture was heated under reflux with stirring for 2 h. The red solid **8** formed was filtered off, washed with methanol and dried in vacuo (yield 27%).

A solution of copper(II) nitrate trihydrate (0.02 g, 0.90 mmol) in methanol (20 cm^3) was added to a suspension of L^3H_2 (0.05 g, 0.90 mmol) in methanol (20 cm^3). The mixture was heated under reflux with stirring for 2 h. The clear brown solid **9** formed was filtered off, washed with methanol and dried in vacuo (yield 47%).

2.8. Physical measurements

Microanalyses were carried out using a Perkin-Elmer 2400 II CHNS/O elemental analyser. Copper was analysed on a Hitachi Z-8200 atomic absorption spectrophotometer.

IR spectra in the 4000–400 cm^{-1} range were recorded as KBr pellets on a Bomen-100 spectrophotometer and in the range 550–200 cm^{-1} on a Bruker IFS 66V spectrophotometer. UV–Vis spectra in solution were registered on an Ati-Unicam UV2 spectrophotometer and the solid reflectance spectra on a Pye-Unicam SP-8-100 spectrophotometer. Conductivity data were measured using freshly prepared DMF solutions (ca. 10^{-3} M) at 25°C with a Metrohm Herisau model E-518 instrument. ^1H and ^{13}C NMR spectra were recorded on a Bruker AMX-300 spectrophotometer using dimethylsulfoxide-d_6 as solvent and TMS as internal reference. EPR spectra in the solid state were run on a Bruker ER 200D X-band spectrophotometer.

Fast atom bombardment mass spectra were recorded on a VG Auto Spec instrument using Cs as the fast atom and *m*-nitrobenzylalcohol (*m*NBA) as the matrix.

Electrochemical measurements were performed with a BAS CV 27 voltammograph and a BAS A-4 XY register using a glassy carbon (ϕ 5 mm) working electrode, a platinum wire as auxiliary, and a double junction, with porous ceramic wick, Ag/AgCl reference electrode, standardized for the redox couple ferricinium/ferrocene ($E_{1/2} = +0.400$ V, $\Delta E_p = 60$ mV). Cyclic voltammetry studies of ligands and complexes were carried out on 0.01 M solutions in dimethylsulfoxide (L^1H_6 complexes) and dichloromethane (L^2H_2 derivatives) containing 0.1 M $[NBu_4][PF_6]$ as supporting electrolyte. The range of potential studied was between +1 and −1.5 V. All solutions were purged with nitrogen steam for 5 min before measurement and the working electrode was polished before each experiment with diamond paste. The procedure was performed at room temperature and a nitrogen atmosphere was maintained over the solution during the measurements.

3. Results and discussion

The reaction of L^2H_2 with copper chloride in methanol at room temperature yields a cream solid. The analytical data show the modification of the reactant. The mass spectrum shows a peak at 529 amu corresponding to the macrocyclic species $[C_{30}H_{21}N_6S_2]^+$. The ^1H NMR spectrum in DMSO confirms the absence of methanol inserted or as a crystallization molecule. The ^{13}C NMR spectrum shows signals corresponding to one thio group, seven phenyl carbons and two imine carbons, confirming the proposed structure. The absorption bands observed in the IR spectrum are consistent with the functional groups present in the molecule.

The reaction of compound L^2H_2 with copper chloride, under the described conditions, is the first direct procedure to isolate a free macrocycle L^3H_2 containing thiosemicarbazone moieties. The copper chloride acts as a selective template in the reaction from the mesocycle. This effect is original because the template usually acts from diamine and dicarbonyl as precursors, but with benzil and thiosemicarbazide the condensation reaction does not work [24].

The direct reaction, using the high dilution technique, improves the yield of the cyclic ligand L^2H_2, which could be useful in the future since this molecule is a potential anticancer agent and it is being currently tested against the full panel of 60 human tumours (NSC no. 711635-Y) by the National Cancer Institute (USA).

The complexes characterized are stable to air and moisture. The analytical data of complexes are consistent with the stoichiometries proposed which are summarized in Table 1.

3.1. L^1H_6 complexes

Complexes from L^1H_6 present different formulae and variable grades of deprotonation depending on the halide and/or the working conditions, in particular the presence of protons.

From the copper chloride reactions, three type of complexes with the same stoichiometry are obtained. In methanol as solvent, complexes **1**, **2** and **3** are isolated; the last compound appears only in the presence of hydrochloric acid. Working in a molar ratio 1:2, the complex **2** is obtained. This product had been obtained previously in ethanol under reflux [24]. The reaction in the presence of benzil yields complex **1**.

The reactions with nitrate give only the complex **4** because by working in the presence of nitric acid only a ligand breakdown product is obtained. However, with sulfate two different complexes are obtained, **5** and **2**, depending on whether or not protons are present in the medium.

The analytical data of complexes are in agreement with the ligand acting as a monoanion in complexes **1** and **4**, a dianion in complex **2** and a neutral molecule in complexes **3** and **5**. The mass spectra of complexes show a peak at 418 amu corresponding to $[C_{16}H_{15}N_6S_2Cu]^+ + 1$ and in addition for complex **4** the spectrum exhibits the peak corresponding to the molecular mass.

The conductivity data in DMF indicate that the complexes are non-electrolyte compounds, but complex **5** is a 1:1 electrolyte [29]. Therefore chloride and nitrate are bonded to the copper ion, while the sulfate ion is outside the metal coordination sphere.

3.1.1. IR spectra

The most significant IR bands, useful for determining the ligand mode of coordination, are listed in Table 2. The most important bands of the ligand were assigned according to published data [24].

The absence of any bands in the 2600–2800 cm^{-1} region of the IR spectra of L^1H_6 and its complexes suggests the absence of any thiol tautomer in the solid state [30].

The spectrum of complex **2** shows three bands in the 3500–3000 cm^{-1} region, which indicate the total deprotonation of the ligand. Spectra of complexes **3** and **5** exhibit a larger number of bands in the amine stretching region, which confirms that the neutral form of the ligand is bonded in these complexes. Spectra of complexes **1** and **4** show an intermediate situation, more bands than complex **2** and less than complex **3**, which agrees with a partial loss of the acidic hydrogens present in L^1H_6. These conclusions are according to the analytical data of complexes and the mass spectrum of complex **4**.

The IR spectra of the complexes, except complex **5**, show the band assigned to the azomethine nitrogen shifted to lower wavenumber [31]. Coordination of these nitrogens is confirmed with the presence of new bands assignable to ν(Cu–NC) in the spectra of complexes (Table 2) [32].

In the spectra of complexes **3** and **5**, in which the ligand acts in its neutral form, the band assigned to $\delta(NH_2)$ remains in the same position as in the free ligand, so the primary amines are not bonded to the copper ion. In addition, coordination via the sulfur atoms is indicated by a decrease in the frequency of the thioamide band. The presence of a new band assignable to ν(CuS) confirms that the sulfur atoms are involved in the coordination.

The spectrum of complex **4** shows bands corresponding to the nitrate anion coordinated to the copper. Except for these bands, this spectrum is very similar to the spectra of **1** and **2** in the 1700–700 cm^{-1} region so the ligand coordination modes must be the same. The three spectra show a band at 1634 cm^{-1}, which could be related to the $\delta(NH_2)$ shifted because of bonding to copper or the new CN group since the ligand is deprotonated. The new bands appearing below 500 cm^{-1} confirm that the primary amines are bonded to the metal ion. Therefore L^1H_6 acts as a tetradentate ligand through four nitrogen atoms.

From the IR spectra data, one can deduce that the coordinative behaviour of L^1H_6 depends on whether it is deprotonated or acts in its neutral form. In complexes **1**, **2**, and **4**, which contain the ligand in deprotonated form, it is bonded to the copper through four nitrogen atoms (provided by the imine and the primary amine groups). However, in complexes **3** and **5**, in which L^1H_6 acts as a neutral molecule, the sulfur atoms participate in the coordination. The copper coordination sphere is completed by the anions present in complexes **1**, **3** and **4**.

3.1.2. Electronic and EPR spectra

The significant electronic absorption bands in the spectra of complexes recorded in solution and in solid state are presented in Table 3.

The reflectance spectra of complexes **3**, **4** and **5** present bands in the same region, so the copper will have the same environment, with a distorted octahedral geometry around

the metal ion [33]. Therefore, the nitrate ion acts as a bidentate ligand in complex **4**. The spectrum of complex **2** agrees with a quasiplanar disposition for the copper ion. The spectrum of complex **1** is different from the others, the number and positions of the absorption bands suggest a pentacoordinated geometry.

Structures for each coordination number are illustrated in Fig. 2, where we have plotted the output of the calculation carried out using the Hyperchem program (semiempirical method, ZINDO/1).

The solution spectra of all complexes in DMSO, DMF and methanol present the same absorption bands (solutions are red), so the solvent molecules partially replace the anion in the coordination sphere of copper, giving a quasiplanar environment in all complexes. The spectrum of complex **2** does not change in solution because the disposition in the solid state was already quasiplanar.

For complexes **3** and **5** the spectra in DMF were registered after the addition of hydrochloric acid (2 M). An important change was observed: the solution colour changes to green and the position of the band indicates a significant modification in the copper coordination sphere giving a pseudo-octahedral geometry for the copper ion as in the complexes in the solid state (Fig. 3) [33].

We studied the variation of UV–Vis spectra of 10^{-3} M copper(II) chloride dihydrate solution in DMSO after successive additions of 10^{-3} M L^1H_6 solution in the same solvent with the total volume constant and in the presence of $[NBu_4][PF_6]$ to maintain the ionic force. The visible spectra were recorded and the absorbance variations represented versus the molar fraction of ligand added/Cu (Fig. 4).

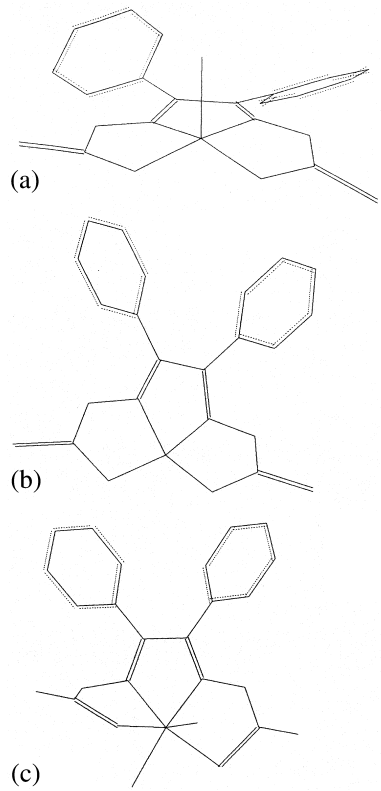

Fig. 2. Possible structures for L^1H_6 complexes: (a) complex **1**, (b) complex **2**, (c) complex **3**.

From the first addition, a new band appears at 448 nm in the visible spectrum whose absorbance increases lineally until a 2 molar fraction; after that the value is constant.

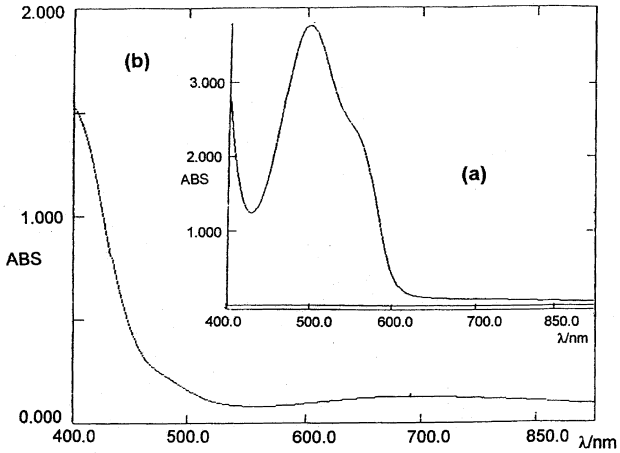

Fig. 3. UV–Vis spectra of complex **3** [$CuL^1H_6Cl_2$]: (a) DMF solution; (b) DMF + HCl (2 M).

The spectra were registered after 2 days, and the position of the band is shifted to 500 nm (identical position to that in the isolated complexes in DMSO solutions). The absorbance increases until a 1.5 molar fraction and then is constant (Fig. 4). Therefore, in DMSO a 1:1 molar ratio complex is formed but in this solvent an excess of the ligand is necessary.

The EPR parameters observed for complexes in the solid state (300 K) are presented in Table 3. In Fig. 5 the spectrum of complex **1** is shown.

The EPR spectra, which do not show hyperfine coupling, confirm the copper oxidation state and the mononuclear nature for the complexes. Complexes **1**, **2**, **3** and **4** give typical axial spectra, but complex **5** has a slightly axial isotropic spectrum. Values of $g_\parallel$ and $g_\perp$ are in the range for this kind of complexes. In all of the complexes, $g_\parallel > g_\perp > 2$ values are consistent with a $d_{x^2-y^2}$ state. Complex **2** presents a lower $g_\parallel$

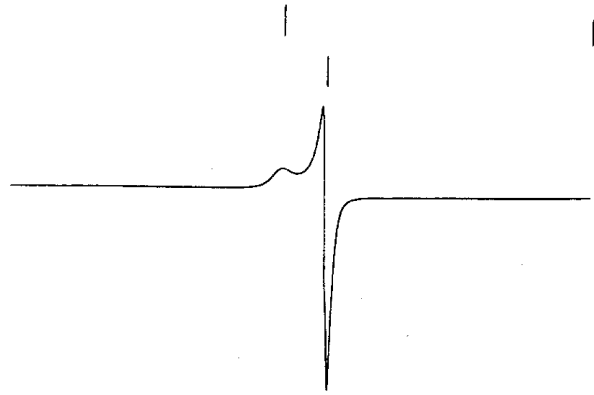

Fig. 5. Solid state EPR spectrum of complex **1**.

value, which agrees with the L^1H_6 being tetradentate dianion and pseudo-planar, while the higher value is presented for complex **3** in which the ligand is neutral and the copper is hexacoordinated [8,30,34].

3.2. Complexes derived from L^2H_2

Reactions of the mesocyclic ligand L^2H_2 with copper(II) nitrate and sulfate hydrate give stable solids in air and moisture. The colour, melting point and analytical data are included in Table 1. The formulae of complexes depend on the metal salt used.

Reaction with nitrate gives complex **6**, whose analytical data and mass spectra indicate that the complex contains the deprotonated macrocyclic ligand L^3H. The mass spectrum shows a peak at 529 amu corresponding to the macrocycle molecular mass $[C_{30}H_{21}N_6S_2]^+$ and a peak corresponding to the fragment $[CuC_{30}H_{21}N_6S_2CH_3OH]^+$. From the reaction with sulfate the complex **7** was obtained. Its analytical

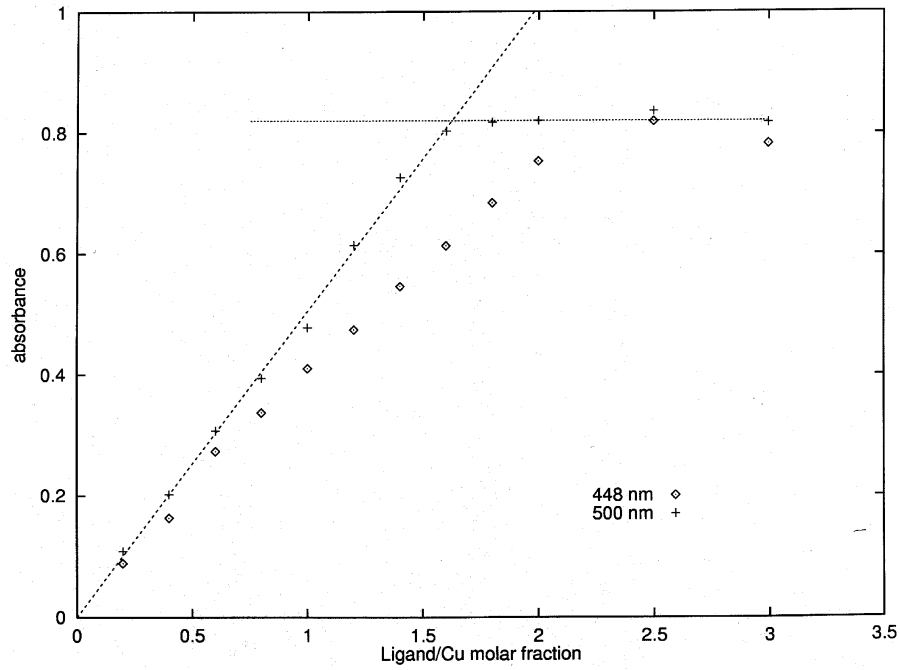

Fig. 4. Absorbance evolution of the L^1H_6 copper complex, in DMSO solution, versus ligand/Cu molar fraction; (◇) direct measurements; (+) after 24 h.

Table 4
Relevant IR spectral data and assignment of L^2H_2 complexes (cm^{-1})

	ν(N–H)	ν(C=N)	Thioamide I	Thioamide IV	ν(Cu–N)/ν(Cu–S)
L^2H_2	3184, 3131	1608	1550	846	
$L^3H_2C_{30}H_{22}N_6S_2$	3057	1599, 1581	1480	866	
$Cu(C_{30}H_{21}N_6S_2)_2CH_3OH$ (**6**)	3053	1601, 1583, 1575, 1550	1485	865	439
$CuC_{30}H_{20}N_6S_2$ (**7**)	3053	1600, 1582, 1575, 1550	1488	878, 866	436

data suggest a 1:1 deprotonated ligand:copper ratio. The mass spectrum confirms the macrocyclation of the ligand. In addition, in both reactions L^3H_2 is isolated from the reaction liquor. Therefore, the macrocyclic ligand is formed in all reactions where the copper ion acts as template. The characteristics of the final product depend on the salt used. A free macrocycle is obtained in the reaction with copper chloride, while complexes were isolated from the reaction with nitrate and sulfate.

3.2.1. IR spectra

The IR spectrum of complex **6** shows only a band assignable to ν(NH), the thioamide I slightly shifted to higher frequencies and four bands in the region of stretching vibration of the imine group (Table 4). These modifications suggest that the L^3H_2 ligands are partially deprotonated and two equivalent imine groups of each ligand are bonded to the copper ion.

The spectrum of complex **7** exhibits the presence of water and the deprotonation of the ligand. The bands are slightly shifted with respect to the L^3H_2, indicating that the ligand is bonded to the copper ion through four nitrogen atoms.

3.2.2. Electronic spectra

The electronic spectra of complexes in the solid state are very similar. Both of them show a band at a position which agrees with a pentacoordination for the copper, so the solvent molecules are bonded to the copper ion.

3.3. Complexes derived from L^3H_2

Direct reactions of the macrocyclic ligand with copper chloride and nitrate give complexes **8** and **9**, respectively. The analytical and spectroscopic data indicate that they are adulterated with the ligand, although it was necessary to work under stronger conditions than with the mesocyclic ligand L^2H_2, probably owing to its inherent rigidity.

3.4. Cyclic voltammetry

The study of the electrochemical behaviour of the complexes was carried out in the range from +1 to −1.5 V. In the positive range, +1 to 0 V, the oxidation processes Cu(III)/Cu(II) can be observed. Cyclic scanning between 0 and −1.5 V permits study of the copper reduction centred processes and the ligand reductions; the potential reduction of the Cu(II)/Cu(I) process is related to the potential SOD mimetic activity. Both ranges of potentials were studied independently. The electrochemical response in the total range studied (Figs. 6–8) showed a pattern that can be considered as the sum of the individual responses.

The cyclic voltammogram of L^1H_6 in DMSO shows irreversible reduction waves in the more negative region (Fig. 9(b)) [26,35].

The voltammetric response of all L^1H_6 complexes exhibits oxidation and reduction metal centred processes, as for complexes previously published [27]. Cyclic voltammograms between +1 and 0.0 V show a redox couple associated with the Cu(III)/Cu(II) process (Table 5). In addition, in the range 0.0 to −1.5 V, peaks which can be assigned to Cu(II)/Cu(I) and Cu(I)/Cu(0) processes appear [1].

Cyclic scanning of complex **1** (Fig. 6(a)) between +1 and 0 V shows in the cathodic scan a peak at +0.625 V. In the forward scan a poorly defined wave at +0.410 V can be observed and an anodic peak at +0.680 V associated with

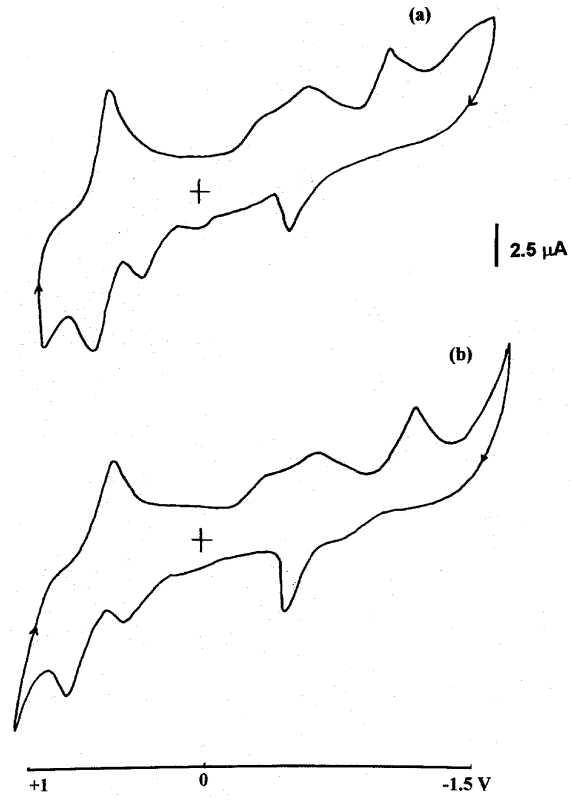

Fig. 6. Cyclic voltammograms for complexes: (a) complex **1**, $[CuL^1H_5Cl]$; (b) complex **3**, $[CuL^1H_6Cl_2]$; $\nu = 100$ mV s^{-1}.

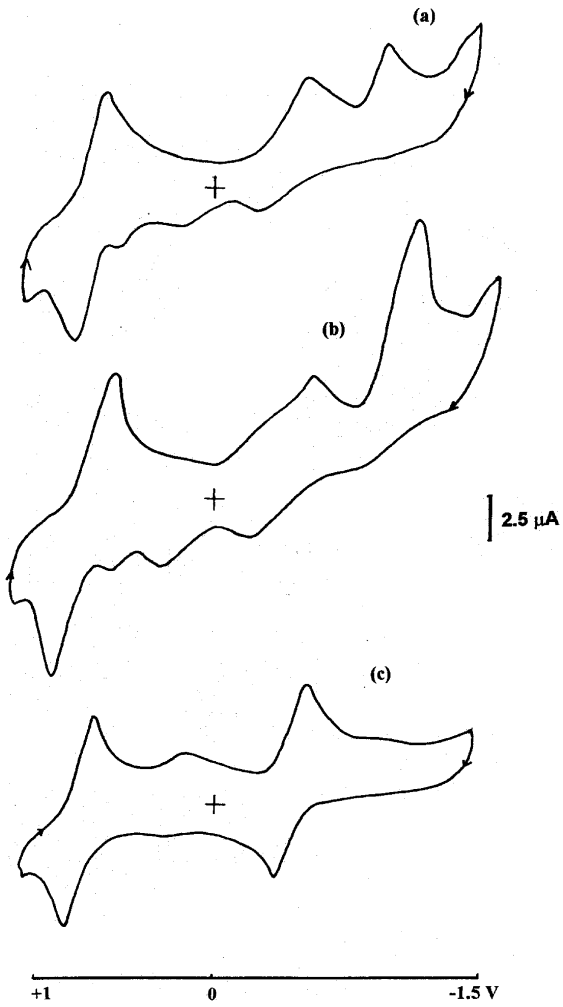

Fig. 7. Cyclic voltammograms for (a) complex **4**, $[CuL^1H_5NO_3]$, (b) complex **5**, $[CuL^1H_6CH_3OH]SO_4$, (c) complex **2**, $[CuL^1H_4]$, $\nu = 100$ mV s^{-1}.

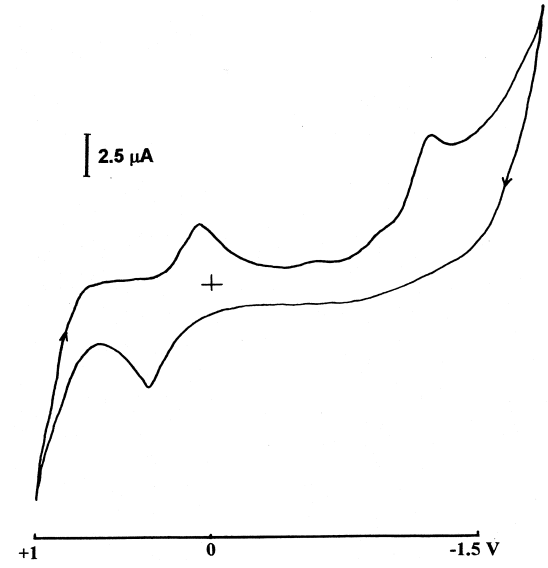

Fig. 8. Cyclic voltammogram of complex **3**, $[CuL^1H_6Cl_2]$, in DMSO after the addition of HCl (2 M), $\nu = 100$ mV s^{-1}.

the cathodic peak at +0.625 V. The ΔE_p values fall in the range 50–70 mV, when the scan rate is varied between 100–800 mV s^{-1}, with peak current ratio constant (0.8). Also the ratio between the cathodic peak current and the square root of the scan rate ($I_{pc}/\nu^{1/2}$) is practically constant. All of these data are diagnostic of a quasireversible one-electron transfer controlled by diffusion following the equation

$$[Cu(III)L] + e^- \Leftrightarrow [Cu(II)L]$$

Cyclic scans of **1** in the range 0 to −1.5 V reveal peaks at −0.470 and −0.930 V in the cathodic scan and in the forward scan a peak at −0.390 V associated with the more negative cathodic peak. These peaks can be assigned to successive Cu(II) reduction processes.

The voltammogram of complex **3** (Fig. 6(b)) is very similar to that of complex **1**. The cyclic voltammogram of **3** shows, between +1.5 and 0 V, a cathodic peak at +0.680 V and an anodic peak at +0.740 V associated with the cathodic peak. The ΔE_p and the current peak ratio of this couple of peaks are as expected for a quasireversible Cu(III)/Cu(II) process.

In the cathodic scan, in the range 0 to −1.5 V, peaks at −0.400 V and −1.030 V are observed. In the anodic scan there is a peak at −0.380 V, associated with the more negative cathodic peak. The first wave is attributed to Cu(II)/Cu(I) reduction and the other peaks correspond to the Cu(II)/Cu(0) reduction processes.

Cyclic voltammograms of complexes **4** and **5** (Fig. 6(a,b)) are very similar. The electrochemical response of complex **4** in the cathodic scan shows a peak at +0.600 V and in the reverse scan an anodic peak at +0.675 V associated with the cathodic peak. The variation of the redox parameters of the redox couple is indicated in Table 6, so it is associated with a quasireversible Cu(III)/Cu(II) process. The voltammogram between 0 and −1.5 V shows peaks at −0.520 V and −0.960 V, which can be attributed to the reductions Cu(II)/Cu(I) and Cu(I)/Cu(0), respectively. The electrochemical parameters for complex **5** are included in Table 6.

The cyclic voltammogram of complex **2** (Fig. 7(c)) shows a different electrochemical response and it is close to that published previously [27]. The most important characteristic is the quasireversible waves associated with the Cu(II)/Cu(I) process (Table 6).

For all complexes, redox processes associated with oxidation to Cu(III) are observed, probably because the L^1H_6 is

Table 5

1	0.625	0.680	0.055	0.800	−0.470	−0.390	−0.930
2	0.620	0.670	0.050	0.860	−0.600	−0.500	
3	0.680	0.740	0.060	1.000	−0.400	−0.380	−1.030
4	0.600	0.675	0.075	0.980	−0.520		−0.960
5	0.610	0.670	0.060	0.820	−0.510		−0.990

[a] Redox potential (V) at 298 K, scan rate 100 mV s^{-1}. Cyclic voltammograms registered in the range from +1 to −1.5 V.
[b] Scan rate in the range 100–800 mV s^{-1}.

an open chain ligand and in its complexes the oxidation of copper is favoured since this ligand can adopt a different conformation to fit the small copper(III). The change from the Cu(II) to the Cu(III) state (d^8 low spin) involves a drastic reduction of the metal ion radius. In addition, this process does not involve changes in the geometries of the copper(II) complexes in DMSO solution. The oxidation values in Table 5 agree with that, because more positive values and more difficulty in stabilizing the copper(III) oxidation state are observed for complexes **1** and **3** [36,37].

On the other hand, the values of the reduction potential fall in the range −0.400 to −0.520 V, indicating difficulty in reducing the copper(II) ion in these complexes. This fact can be interpreted in terms of less favourable fitting of the Cu(II)/Cu(I) ion, because this reduction is related to the level of tetrahedral distortion in the complexes and in our

case in solution they seem to be almost planar. In accordance with these reduction potentials and the electronic spectra of L^1H_6 complexes, they do not seem to be suitable SOD mimetics.

The electrochemical response of complexes **1** and **3** with successive additions of hydrochloric acid (2 M) was also studied. The voltammogram changes immediately with the first addition, the more positive potential peaks are modified and a new peak couple arises. These changes increase with the successive additions of acid or with time until 1 cm^3 is added. The voltammogram (Fig. 8) now shows two peaks at $+0.280$ and -1.00 V in the cathodic scan and an anodic peak at $+0.360$ V associated with $+0.280$ V, indicating a significant change in the complex structure under these conditions. These results agree with those from the visible spectra in the same solvent described in the previous section.

Reaction of copper(II) chloride with L^1H_6 in DMSO was studied by cyclic voltammetry. Cyclic voltammograms of $CuCl_2 \cdot 2H_2O$ solutions in DMSO, in which L^1H_6 was added gradually until a 1:3 molar ratio was reached, were recorded (Fig. 9(a,b)). Changes in the colour and in the electrochemical response were shown from the first addition. The changes increase when the ligand proportions increase (Fig. 9(c,d)), but the cyclic voltammogram does not reproduce the cyclic voltammogram of isolated complex until a 1:2.5 molar ratio. These results indicate that the complexation reaction is slow. The donor character of the solvent may be the reason for that, owing to the difficult substitution by the ligand as was shown for the visible spectra of complexes.

Cyclic voltammograms of macrocyclic complexes **6** and **7** are very different to those of the open chain complexes. They do not show waves corresponding to a Cu(III)/Cu(II) process; this agrees with the behaviour of similar copper macrocyclic complexes [27]. The voltammograms only exhibit reduction waves at negative potentials which could be related to the reduction process of the copper ion and the unsaturation of the ligand [38].

Abstract

$LnCl_3$ reacted with $K_2C_8H_8$ in THF in the ratio 1:1 at room temperature and formed $(C_8H_8)LnCl\cdot n$THF, which was then treated with RCpK–THF ($RCp = MeOCH_2CH_2C_5H_4$ or $C_4H_7OCH_2C_5H_4$) to yield the title complexes $(\eta^5\text{-RCp})Ln(\eta^8\text{-}C_8H_8)(THF)$ (Ln = Nd (**1**) and Sm (**2**), $RCp = MeOCH_2CH_2C_5H_4$; Ln = La (**3**), Nd (**4**) and Sm (**5**), $RCp = C_4H_7OCH_2C_5H_4$). The crystal structures of complexes **1** and **3** were determined by X-ray diffraction and revealed that the oxygen atoms of the ether group on the cyclopentadienyl ring is coordinated to the central metal atom. The central lanthanum atom is in a distorted tetrahedral geometry. The average bond distances Nd–C(η^8) and Nd–C(η^5) are 2.697(2) and 2.749(2) Å, respectively, while the Nd–O(THF) and Nd–O(η^1) distances are 2.580(1) and 2.619(1) Å, respectively. The average bond lengths La–C(η^5) and La–C(η^8) are 2.842(7) and 2.740(8) Å, respectively. The La–O(THF) and La–O(η^1) distances are 2.607(4) and 2.633(4) Å. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Organolanthanide complexes; Ether-side chain cyclopentadienyl; Cyclooctatetraenyl; Crystal structures

1. Introduction

Cyclooctatetrene and its derivatives are important backbones for the construction of organolanthanide sandwich complexes [1–4]. Hayes and Thomas initially synthesized cyclooctatetraenyl complexes [5], and Jamerson et al. reported the synthesis of $(\eta^5\text{-}C_5H_5)Sm(\eta^8\text{-}C_8H_8)(THF)$, leading to the wide use of cyclooctatetraenyl (COT) as a ligand in organolanthanide chemistry [6]. In 1989, Schumann and coworkers reported a series of cyclopentadienyl and cyclooctatetraenyl lanthanide complexes such as $(\eta^5\text{-}C_5Me_5)Lu(\eta^8\text{-}C_8H_8)$ and $(\eta^5\text{-}C_5(CH_2Ph)_5)Lu(\eta^8\text{-}C_8H_8)$ [7,8]. Furthermore, Chen and coworkers reported the crystal structures of $(\eta^5\text{-}C_5H_5)Pr(\eta^8\text{-}C_8H_8)(THF)_2$ and $(\eta^5\text{-}C_9H_7)Pr(\eta^8\text{-}C_8H_8)(THF)$ [9], $(\eta^5\text{-}2,4\text{-}Me_2C_5H_3)Sm(\eta^8\text{-}C_8H_8)$ and a trinuclear $[(\eta^8\text{-}C_8H_8)_3(\eta^5\text{-}C_6H_5CH_2C_5H_4)\text{-}Nd_2K(THF)_3]$ [10,11].

Recently, Porema et al. reported the synthesis of silylated cyclooctatetraenyl lanthanide complexes [12]. Chen and coworkers reported acyclic pentadienyl and cyclooctatetraenyl lanthanide complexes [13]. Cyclopentadiene ligands with ether side chains have been widely used as ligands to synthesize organolanthanocene complexes [14,15], so we are interested in investigating the synthesis of lanthanide complexes with both cyclooctatetraenyl and substituted cyclopentadienyl as ligands. In this paper we wish to report our recent progress: the synthesis and crystal structure of the title complexes.

2. Experimental

All manipulations were carried out under dry argon using Schlenk techniques. The solvents were dried with sodium

wires and distilled from sodium benzophenone ketyl before use. Anhydrous $LnCl_3$ was prepared by Taylor's method [16]. Potassium methoxyethyl cyclopentadienide and tetrahydrofurfuryl cyclopentadienide were prepared as previously reported [14]. The mass spectra were obtained on a HP 5989A mass spectrometer using EI method (70 eV). The elemental analyses were performed at the micro-analytical laboratory, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences.

*2.1. Synthesis of (η^5-$MeOCH_2CH_2Cp$)Nd(η^8-C_8H_8)(THF) (**1**)*

Complex **1** was synthesized as follows. To a well mixed suspension of $NdCl_3$ (1.94 g, 7.74 mmol) in THF (40 cm^3), $K_2C_8H_8$ (8.20 mmol) in THF (13 cm^3) was added with stirring. The mixture turned to pale green initially, then to pale yellow and finally to blue–green. The suspension was stirred for a further 24 h and $MeOCH_2CH_2CpK$ (7.74 mmol) in THF (13 cm^3) was added with a color change to brown, and the reaction was continued for a further 24 h. After centrifugation, the residual was washed twice with THF (2×20 cm^3); the combined solution was concentrated to dryness to give a green crystalline solid which was recrystallized in THF to form violet–green prism crystals (1.41 g, 41%), m.p. 138°C (dec.). *Anal.* Calc. for $C_{20}H_{27}NdO_2$: C, 54.14; H, 6.13. Found: C, 53.85; H, 6.06%. EI-MS: 369 (M^+–THF, 7.80%), 246 (Nd(COT), 1.6%), 267 (Nd($MeOCH_2CH_2Cp$), 1.9%), 104 (C_8H_8, 13%), 91 ($C_5H_4CH_2CH_2^+$, 100%).

*2.2. Synthesis of (η^5-$MeOCH_2CH_2Cp$)Sm(η^8-C_8H_8)(THF) (**2**)*

This complex was prepared from $SmCl_3$ (1.61 g, 6.27 mmol), $K_2C_8H_8$ (6.27 mmol) and $MeOCH_2CH_2CpK$ (6.27 mmol) in THF (40 cm^3) using the procedure above. Purple–brown crystals were obtained (1.31 g, 46.5%), m.p. 110°C (dec.). *Anal.* Calc. for $C_{20}H_{27}SmO_2$: C, 53.40; H, 6.05. Found: C, 53.26; H, 6.21%. EI-MS: 379 (M^+–THF, 5.5%), 275 (($MeOCH_2CH_2Cp$)–Sm, 16.4%), 256 (Sm(COT), 0.55%), 104 (C_8H_8, 17.3%), 92 ($CpCH_2CH_2^+$, 53.4%).

*2.3. Synthesis of (η^5-$C_4H_7OCH_2C_5H_4$)La(η^8-C_8H_8)(THF) (**3**)*

This complex was prepared from $LaCl_3$ (1.83 g, 7.46 mmol) in THF (40 ml), and $K_2C_8H_8$ (7.5 mmol) in THF (12 ml). The pale blue reaction mixture was stirred for 24 h with the color changing to pale yellow. Then a 6.8 ml THF solution of potassium tetrahydrofurfuryl cyclopentadienide $C_4H_7OCH_2C_5H_4K$ (7.44 mmol) was added and the resulting suspension was stirred for 3 days. After work-up, the resulting pale yellow crystalline solid was dissolved in THF and set in a refrigerator to obtain yellow prism crystals (2.08 g, 60.2%), m.p. 164°C (dec.). *Anal.* Found: C, 57.03; H, 6.27. Calc. for $C_{22}H_{29}LaO_2$: C, 56.90; H, 6.29%. EI-MS: 392 (M^+–THF, 100%), 288 (La($C_4H_7OCH_2C_5H_4$), 16%), 243 (La(COT), 23%).

*2.4. Synthesis of (η^5-$C_4H_7OCH_2C_5H_4$)Nd(η^8-C_8H_8)(THF) (**4**)*

Complex **4** was prepared analogously to **3** from $NdCl_3$ (1.13 g, 4.51 mmol), and $K_2C_8H_8$ (4.51 mmol in 7 ml THF) in 30 ml THF, which was then reacted with $C_4H_7OCH_2C_5H_4K$ (4.51 mmol in 4.0 ml THF). Blue–green crystals were obtained (0.891 g, 42.0%), m.p. 148°C (dec.). *Anal.* Found: C, 55.91; H, 6.05. Calc. for $C_{22}H_{29}NdO_2$: C, 56.27; H, 6.22%. EI-MS: 466 (M^+, 10%), 394 (M^+–THF, 88.8%), 291 (Nd($C_4H_7OCH_2C_5H_4$), 24.7%), 246 (Nd(C_8H_8), 22.5%), 150 ($C_4H_7OCH_2C_5H_4$, 11%), 104 (C_8H_8, 9.7%).

*2.5. Synthesis of (η^5-$C_4H_7OCH_2C_5H_4$)Sm(η^8-C_8H_8)(THF) (**5**)*

Complex **5** was prepared analogously to **3** from $SmCl_3$ (1.20 g, 4.67 mmol), and $K_2C_8H_8$ (4.66 mmol in 7.5 ml THF) in 30 ml THF, which was then reacted with $C_4H_7OCH_2C_5H_4K$ (4.97 mmol in 4.5 ml THF). Purple–black crystals were obtained (1.05 g, 47.2%), m.p. 135°C (dec.). *Anal.* Found: C, 55.11; H, 5.99. Calc. for $C_{22}H_{29}O_2Sm$: C, 55.55; H, 6.14%. EI-MS: 404 (M^+, 23.6%), 301 (Sm($C_4H_7OCH_2C_5H_4$), 100%), 257 (Sm(C_8H_8), 5.5%), 149 ($C_4H_7OCH_2C_5H_4$, 4.7%), 104 (C_8H_8, 11.2%).

*2.6. Structure determination of (η^5-$MeOCH_2CH_2Cp$)Nd(η^8-C_8H_8)(THF) (**1**) and (η^5-$C_4H_7OCH_2Cp$)La(η^8-C_8H_8)(THF) (**3**)*

Blue–green crystals of **1** and yellow prismatic crystals of **3** were sealed and mounted on a Siemens P4 four-circle diffractometer (for **3**, Rigaku AFC7R diffractometer). Crystal data were collected at ambient temperature using Mo Kα radiation ($\lambda = 0.71069$ Å for **1** and $\lambda = 0.71073$ Å for **3**). The data were corrected for Lorentz and polarization and empirical absorption. The structure was solved by heavy-atom Patterson methods and expanded Fourier techniques. The structure was refined by full-matrix least-squares. All of the hydrogen atoms were found from difference Fourier maps connecting analysis of geometric positions. All coordination parameters for atoms were refined, anisotropic thermal parameters for non-hydrogen atoms and isotropic parameters for hydrogen atoms. The molecular structures of **1** and **3** are shown in Figs. 1 and 2. Crystal data, selected bond lengths and angles for complexes **1** and **3** are given in Tables 1–3, respectively.

3. Results and discussion

Using well established ester-substituted cyclopentadienyl ligands, one can synthesize a series of lanthanocene com-

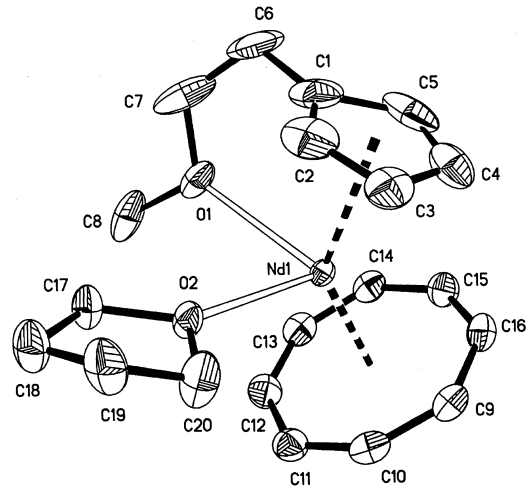

Fig. 1. Molecular structure of $(\eta^5\text{-MeOCH}_2\text{CH}_2\text{Cp})\text{Nd}(\eta^8\text{-C}_8\text{H}_8)(\text{THF})$ (**1**).

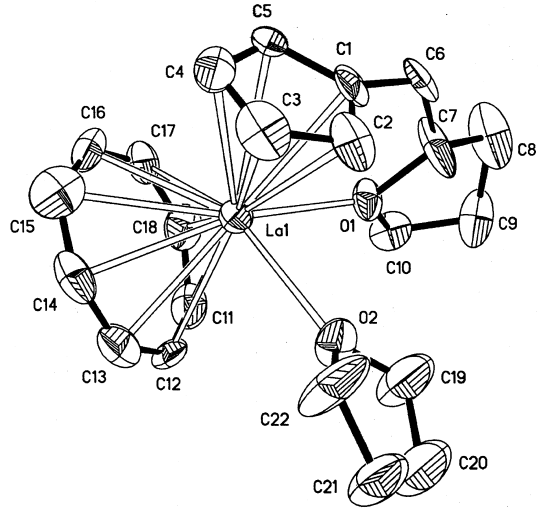

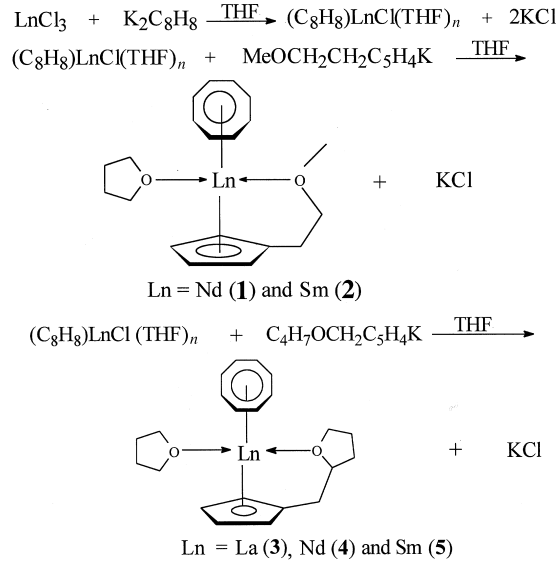

Fig. 2. Molecular structure of $(\eta^5\text{-C}_4\text{H}_7\text{OCH}_2\text{Cp})\text{La}(\eta^8\text{-C}_8\text{H}_8)(\text{THF})$ (**3**).

plexes [15,17,18]. The crystal structures determined for these complexes indicate that the oxygen atoms of the ligands can have intramolecular coordination to lanthanide metal ions, and can also satisfy the coordination requirement of the lanthanide centers even in the cases of early lanthanocene halide complexes. Anhydrous $LnCl_3$ was reacted with potassium salt of cyclooctatetraenyl, and then treated with the potassium salt of methoxyethyl cyclopentadienide or tetrahydrofurfuryl cyclopentadienide in THF. This led to isolation of the title complexes **1**–**5**. They may have one THF fragment in the crystals. However, the THF fragments were not observed in MS spectra of complexes **1**–**5**. This indicates that coordination between the lanthanide center and solvent THF of **1** and **5** is weak, which can be further proved by drying the above complexes under reduced pressure for more than 1 h with the loss of THF. Elemental analyses and mass spectra suggested that the title complexes were successfully synthesized, and X-ray determination confirmed the molecular structures. These results can be indicated as follows:

Single crystal X-ray determinations of **1** and **3** gave further evidence (Figs. 1 and 2). In these complexes, the central atom is bonded to a substituted cyclopentadienyl ring, a cyclooctatetraenyl ring and two oxygens (from the substituted Cp ring and THF) to form a distorted tetrahedron and the coordination number of the central atom is 9.

In complex **1**, the bond lengths Nd–C(η^8) range from 2.679(2) to 2.717(2) Å and the average Nd(1)–C(η^8) length is 2.697(2) Å which is similar to the bond lengths of $[(\eta^8\text{-C}_8\text{H}_8)_3(\eta^5\text{-C}_6\text{H}_5\text{CH}_2\text{C}_5\text{H}_4)\text{Nd}_2\text{K}(\text{THF})_3]$ (2.690(4) and 2.737(4) Å) [11], $[(\eta^8\text{-C}_8\text{H}_8)\text{Nd}(\text{THF})_2][(\eta^8\text{-C}_8\text{H}_8)_2\text{Nd}]$ (2.68(1) and 2.79(4) Å) and $(\eta^8\text{-C}_8\text{H}_8)\text{-Nd}(\eta^5\text{-2,4-C}_7\text{H}_{11})(\text{THF})$ (2.65(7) Å) [13]; the bond

lengths Nd–C(η^5) range from 2.743(2) to 2.759(2) Å and the average length is 2.749(2) Å which is shorter than the relative value in $(MeOCH_2CH_2Cp)_3Nd$ (2.807 Å) [17] and in $[(\eta^8\text{-}C_8H_8)_3(\eta^5\text{-}C_6H_5CH_2C_5H_4)Nd_2K(THF)_3]$ (2.838(4) Å) [13] because of the steric effect of cyclooctatetraenyl and the ether group on the side chain. The bond length Nd–O(THF) is 2.580(1) Å, similar to that of $(\eta^8\text{-}C_8H_8)Nd(\eta^5\text{-}2,4\text{-}C_7H_{11})(THF)$ (2.55(9) Å) [13], and the Nd–O(η^1) distance is 2.619(1) Å, slightly shorter than that of $(MeOCH_2CH_2Cp)_3Nd$ (2.782 Å) [17].

In complex **3**, the La–C(η^5) bond distances range from 2.827(7) to 2.867(7) Å, the average La–C(η^5) distance is 2.842(7) Å, similar to those of $(MeOCH_2CH_2Cp)_3La$ (2.860 Å) [17] and $[(MeOCH_2CH_2Cp)_2LaCl]_2$ (2.836 Å) [18]. However, it is longer than the La–C(η^5) distance of $(C_8H_8)La(C_5Me_4H)(THF)_2$ (2.573(2) Å) [19]. The La–COT(η^8) bond distances range from 2.691(8) to 2.774(8) Å, and the average La–C(η^8) distance is 2.740(8) Å, which is longer than that of $(C_8H_8)La(C_5Me_4H)(THF)_2$ (2.094(3) Å). While La–O(THF) is 2.607(4) Å, comparable to those of $La(C_5H_5)_3(THF)$ (2.47 Å) and La–O(η^1) (2.633(4) Å) in itself and La–O of $(\eta^8\text{-}C_8H_8)La(C_5Me_4H)(THF)_2$ (2.681(3) Å), it is shorter than the relative La–O average distances in $[(MeOCH_2CH_2Cp)_2LaCl]_2$ (2.720(2) Å) [18] and $(MeOCH_2CH_2Cp)_3La$ (2.806(6) Å) [17]. The bond angle O(1)–La–O(2) is 76.1(1)°.

The average bond distances Nd–C(η^8) (2.697(2) Å) and Nd–C(η^5) (2.749(2) Å) in complex **1** are slightly shorter than those of La–C(η^8) (2.842(7) Å) and La–C(η^5) (2.740(8) Å) in complex **3**, which can be considered as the result of the different radii of the central ions.

Supplementary data

All of the parameters for atomic coordinates, isotropic thermal parameters, bond lengths and angles have been deposited at CCDC (CCDC numbers 108612 for **1** and 112642 for **3**).

Comparison of theophyllinato Cu(II) complexes of ethanolamine and diethanolamine
Part 2. Structure and thermal study of the dimeric complex with diethanolamine[1]

Abstract

There is now much evidence that anticancer drugs exert biological action by preferred binding of a transition metal to the N7 sites of the guanine residues of DNA. In our series of theophyllinato copper(II) complexes containing amine ligands, the structural effect of changing from ethanolamine to diethanolamine is examined. A new mixed ligand copper(II) complex, bis(μ-2-(2-hydroxyethyl)aminoethanolato-*O,N,O′*)bis(theophyllinato-N7)dicopper(II) ($C_{22}H_{34}N_{10}O_8Cu_2$) (**1**) has been synthesized as model compound from aqueous solutions of $CuSO_4$, theophylline, and diethanolamine (dea). Its distinct $Me_2L_2L'_2$ structure has been determined by single crystal X-ray diffraction. The centrosymmetric binuclear complex contains two strongly distorted square pyramidally (or pseudo-octahedrally) coordinated copper ions bound together by two alkoxo-bridges. The bridging O is a deprotonated oxygen of the monoalcoholate formed from diethanolamine. Both of the theophyllinate anions take part in N7/O6 chelation in the complex **1**, while only one of the theophyllinate anions is able to perform it in the mononuclear complex (SPY-5-12)-(2-aminoethanol-N)(2-aminoethanol-*N,O*)bis(theophyllinato-N7)copper(II) dihydrate (**2**). The two copper(II) centres in **1** are found to be antiferromagnetically coupled. The combined thermogravimetric and evolved gas detection shows that the tridentate alcoholate anions are fragmented and evolved between 125 and 275°C, whilst the degradation of theophyllinate anions begins at 350°C. Structural, spectroscopic and thermal comparison to the previously published analogous monoethanolamine Cu(II) complex (**2**) is presented. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Dialkoxo-bridged binuclear Cu(II) complexes; Model of metal–guanine interaction; Single crystal structures; Thermal decomposition; Theophylline; Diethanolamine(2,2′-iminodiethanol)

1. Introduction

The synthesis and structural study of transition metal complexes containing theophylline still draw considerable attention because of the potential antitumour activity of these complexes [2–4]. They are used as models of direct interactions and associations between various transition metal ions and the chain-bonded guanine base of oligonucleotides and DNA [5], especially to model binding of the antitumour drug *cis*-platin (*cis*-$Pt(NH_3)_2Cl_2$), through its *cis*-diammineplatinum(2+) form to the N7 site of guanine residues of DNA [3,4].

Metal complexes isolated from non-alkaline medium bind theophylline as a neutral ligand, while other complexes which are obtained from alkaline solutions show the presence of theophyllinate anions [6,7]. Single crystal data prove that theophylline moieties are regularly bound to the metal centre through the N7 nitrogen atom [8].

Special theophyllinato metal complexes can be prepared using aqueous solutions of ammonia, various amines or aminoalcohols, also incorporating these amine type molecules as ligands [9–11]. Nevertheless, the structures of such complexes depend on the type of transition metal and amine as well. There are a few single crystal data reported on complexes chelated with diamines or triamines. Ethylenediaminebis(theophyllinato)zinc(II) [12] has tetrahedral coordination, while bis(theophyllinato)diethylenetriaminecopper(II) dihydrate [13] is found to be pentacoordi-

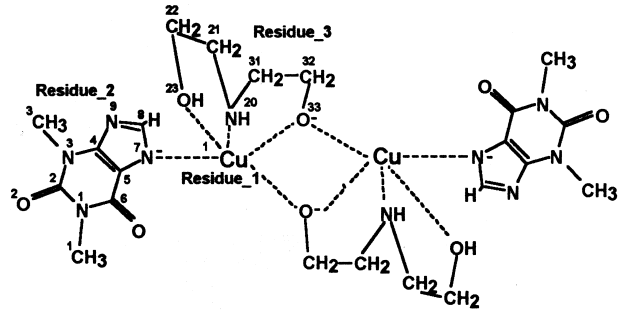
PII S0277-5387(99)00386-1

nated, whilst theophyllinatochlorobis(ethylenediamine)-cobalt(III) salts have basically octahedral arrangements [14,15].

Recently we have found that there are two distinguishable ethanolamine molecules in bis(ethanolamine)bis(theophyllinato)copper(II) dihydrate [1]. One behaves as a monodentate, while the other behaves as a bidentate ligand within the same square pyramidal structure. Furthermore, a secondary interaction between the copper cation and one of the theophylline carbonyl oxygens (O6) occurs. Such an interaction had been postulated earlier to be an advantageous structural feature for potential antitumour activity. In addition, a strong correlation has been observed between the binding strength and the thermal escape sequence of the variably bonded ligands of this complex [1].

As a part of our ongoing research on the binding interactions in theophyllinato complexes incorporating various amines or aminoalcohols [16], we report here the synthesis, single crystal structure and thermal decomposition scheme of a new theophyllinato copper complex containing diethanolamine (2,2′-iminodiethanol). The structural and thermal features of the obtained bis(μ-2-(2-hydroxyethyl)aminoethanolato)bis(theophyllinato)dicopper(II) (**1**) are compared to those of the (SPY-5-12)-(2-aminoethanol-N)-(2-aminoethanol-*N,O*)bis(theophyllinato-N7)copper(II) dihydrate (**2**) building up from neutral monoethanolamine (2-aminoethanol) [1] (Fig. 1). Characterization of **1** was completed with FTIR spectroscopy, powder X-ray diffraction (XRD), electron spin resonance (ESR) and magnetic susceptibility measurements.



2. Experimental

2.1. Synthesis of *1*

A clear solution was obtained from $CuSO_4 \cdot 5H_2O$ (0.25 g, 1.00 mmol) in 20 cm^3 of water with 2 cm^3 (17.3 mmol) of diethanolamine. It was added to 20 cm^3 of aqueous solution of theophylline (0.40 g, 2.02 mmol) dissolved also by the addition of 1 cm^3 (8.7 mmol) of diethanolamine. The reaction mixture was heated in a water bath for 2 h. The blue precipitate was allowed to crystallize in its mother liquor. After slow cooling it was placed in a refrigerator at 4°C for 2 weeks. Finally, the blue columns of single crystals were filtered (yield 90% based on $CuSO_4 \cdot 5H_2O$).

2.2. Elemental analysis

C, H, and N analysis of the crystals of **1** was carried out by the Microanalytical Laboratory, Roland Eötvös University of Budapest, Hungary. Found: C, 38.1; H, 4.9; N, 19.7%. Calc. for $Cu_2(C_7H_7N_4O_2)_2(C_4H_{10}NO_2)_2$ (**1**): C, 38.1; H, 4.9; N, 20.2%.

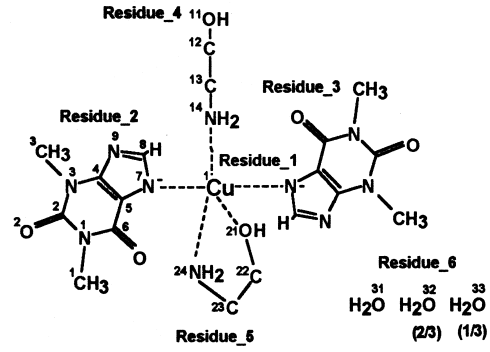


Fig. 1. Formulae diagrams of bis(μ-2-(2-hydroxyethyl)aminoethanolato)bis(theophyllinato)dicopper(II), $[Cu_2(dea)_2(th)_2]$ (**1**) and (SPY-5-12)-(2-aminoethanol-N)(2-aminoethanol-*N,O*)bis(theophyllinato-N7)-copper(II) dihydrate (**2**).

2.3. Thermal and FTIR studies

Thermal behaviour of **1** was studied by a DuPont 990 instrument equipped with model 951 thermobalance. A sample size of 5–6 mg and heating rate of 10°C min^{-1} were used. The measurements were carried out in dynamic air atmosphere at a flow rate of 10 l h^{-1}.

Evolved gas detection (EGD) study was carried out with a DuPont 916 thermal evolution analyzer. For measurement of organic volatile products a hydrogen flame ionization detector was applied in this instrument. Samples of 4–6 mg were heated in a nitrogen flow of 1.8 l h^{-1} up to 350°C at a heating rate of 8°C min^{-1}.

FTIR spectroscopy was used to study **1** and the solid intermediates during its decomposition. The FTIR spectra were obtained in the range 400–4000 cm^{-1} with a Perkin Elmer IR 2000 instrument in KBr pellets.

2.4. X-ray diffraction

Determination of the unit cell parameters and collection of reflections of **1** were performed on an Enraf-Nonius CAD4 single crystal diffractometer using graphite-monochromated Cu Kα radiation (1.54184 Å) at 293(2) K. A blue needle-like single crystal with size $0.30 \times 0.14 \times 0.08$ mm was mounted on a glass fibre. The unit cell dimensions of the monoclinic crystal ($a = 12.847(2)$, $b = 7.288(1)$, $c = 14.865(2)$ Å; $\beta = 95.12(3)°$) were calculated using 25

reflections observed in the θ range from 36.97 to 39.76°. $Cu_2(C_7H_7N_4O_2)_2(C_4H_{10}NO_2)_2$ (**1**) crystallizes in the space group $P2_1/n$, $Z=2$. The calculated density is 1.662 g cm^{-3}. 3073 reflections were collected between 4.36 and 74.85° θ angles within the index ranges $0 \le h \le 16$, $0 \le k \le 9$, $-18 \le l \le 18$. 2838 intensity data were found to be independent ($R_{int} = 0.0091$). Data reduction was carried out using the program XCAD4 [17], while the empirical absorption correction (ψ-scan method) was carried out using MolEN [18]. The maximum and minimum transmissions were 1.000 and 0.863, respectively. The initial structure model was found by direct methods (SHELXS86 [19]), while the structure refinement was done by SHELXL93 [20]. Anisotropic displacement parameters were refined for all of the non-hydrogen atoms. All non-carbon hydrogen atoms and H82 were located on the difference Fourier map. CH_3 hydrogen atoms were introduced into calculated positions and refined riding on the respective carbon atoms.

The full-matrix least-squares refinement on F^2 with 2740/199 data/parameter ratio resulted in R values ($I > 2\sigma(I)$) of $R_{obs} = 0.0300$, $R_w = 0.0918$ and $R_{wtot} = 0.0954$. The goodness of fit was 1.079. The largest diffraction peak and hole in the final difference map were 0.590 e Å^{-3} and -0.477 e Å^{-3}, respectively. Neutral atomic scattering factors were taken from the International Tables for X-ray Crystallography, vol. C [21].

X-ray powder patterns for the complex **1** and the decomposition products were recorded by an FPM HZG4 and a Philips PW 3710 powder diffractometer using Cu Kα radiation (Ni filter and graphite monochromator were used, respectively).

3. Results and discussion

*3.1. FTIR analysis of **1**: indication of anionic ligands*

The FTIR spectrum of **1** shows two carbonyl stretching absorption bands at 1691 cm^{-1} for O2 and 1657 cm^{-1} for O6. These are at lower wavenumbers than those observed in the spectra of pure theophylline (1716 and 1667 cm^{-1}) or in complexes of neutral theophylline ligands (in the range 1702–1715 and 1662–1681 cm^{-1}) [6]. (The corresponding bands of **2** containing monoethanolamine occur at 1691 cm^{-1} for O2 and 1643 cm^{-1} for O6 [1].) These wavenumber shifts are due to deprotonation and coordination of the theophylline moiety at the N7 nitrogen. We can suppose that the larger is the shift observed towards lower wavenumbers, the stronger is the secondary interaction of the O6 oxygen atom with the metal.

The very sharp and intense band at 3272 cm^{-1} corresponds to the ν_{NH} stretching vibration of the metal-bonded secondary amine group of diethanolamine, while a weak sharp band at 1582 cm^{-1} is an NH deformation frequency of the same amine. Broad bands centred at 3421 and 3152 cm^{-1} are probably due to weaker and stronger H-bonded OH stretching vibrations. An unusual splitting of CH stretching absorption bands observed in the 2800–3000 cm^{-1} region and even the occurrence of one branch of them at 2855 cm^{-1} indicates the presence of the alcoholate/ethanolate functional group, which can belong to a partially deprotonated diethanolamine.

*3.2. Thermal analysis of **1**: indication of the dimeric structure*

The thermogravimetric curve of **1** measured in an air stream (Fig. 2) is found to be completely different from that of **2** [1]. The first thermal change of **1** between 125 and 275°C (mass loss 31%) seems to be a rather complex change. It consists of several slow continuous processes and a rapid but overlapping mass loss process, whilst in the case of **2** two well separated and stoichiometric releases of mono- and bidentate neutral ethanolamine ligands were observed [1]. The final step of the air decomposition of **1** (350–400°C) corresponds to the rapid oxidative degradation of the theophyllinato moieties, causing local heat evolution in the surroundings of the sample. The thermocouple indicates this is a strong exothermic process. The recorded temperature overtakes the programmed temperature value and cools only later. Meanwhile a rapid change in the mass also takes place. If the rate of mass change (time derivative of the recorded mass curve TG) is redrawn as a function of recorded temperature (DTG curve), a curiously skewed peak corresponds to the sudden exothermic decomposition, which in this case leads to the formation of CuO. The residue was checked by powder XRD (JCPDS card No. 41-254, CuO). The percentage of

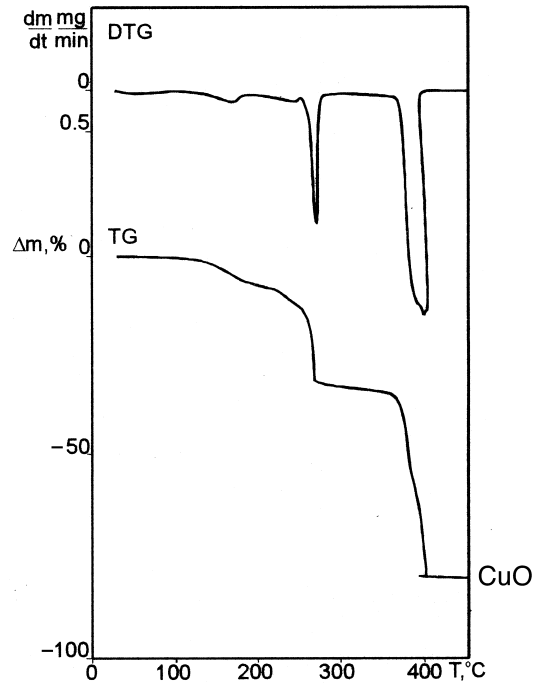

Fig. 2. TG (Δm vs. T) and DTG ($d(\Delta m)/dt$ vs. T) curves of $[Cu_2(dea)_2(th)_2]$ (**1**) in air flow of 10 l h^{-1}, at a heating rate of 10°C min^{-1}; initial weight is 5.78 mg.

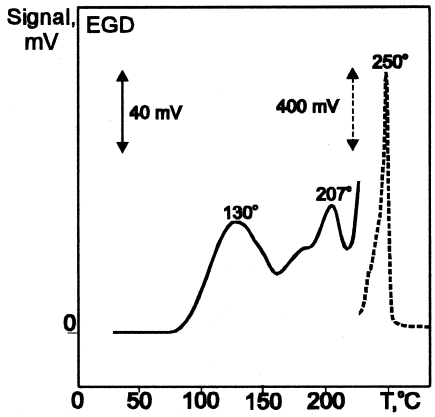

Fig. 3. Evolution rate of organic volatile substances from $[Cu_2(dea)_2(th)_2]$ (**1**) in nitrogen flow of 1.8 l h^{-1}, at a heating rate of 8°C min^{-1}; an initial weight of 5.03 mg was used during the evolved gas detection (EGD).

CuO residue (22%) was found to be about twice as large as that of the corresponding value for **2** (ca. 11%).

This high copper content was the first indication of a possible binuclear structure of **1**. A dimeric composition requires all of the ligands to be in deprotonated anionic form in order to compensate for the four positive charges of two copper(II) cations. The participation of two 2-(2-hydroxyethyl)-aminoethanolates (monoalcoholate of diethanolamine) and two theophyllinate anions in the dimeric composition of **1** has been found to be in good agreement with data obtained from both elemental analysis and air decomposition in the thermal balance.

The following explanation of the TG process of **1** can be given. First the monoalcoholate anions are degraded and evolved thermally (the theoretical mass loss is 30.31%). The complexity of chemical degradation of the alcoholate ligands may explain the overlapping mass changes up to 275°C. The rate of evolved organic gaseous species observed by hydrogen flame ionization detector (Fig. 3) shows also that organic volatile fragments are released parallel to the mass loss (Fig. 2, DTG curve). Above 300°C the more stable theophyllinate anion also begins to decompose. The process is accelerated above 360°C and it is accompanied by oxidative processes of the decomposition products in air.

3.3. Single crystal X-ray structure

The asymmetric unit contains half of the dialkoxo-bridged copper complex (Fig. 4). An inversion centre is located between the two Cu^{2+} ions. The bridging oxygen atoms and the copper atoms form a centrosymmetric planar Cu_2O_2 core (Fig. 5). The relevant bond distances and angles are listed in Tables 1 and 2. The N72, N203, O233 and O62 atoms deviate by −0.6423(3), 0.213(2), 2.310(2) and −2.7895(1) Å from the Cu_2O_2 plane. The Cu1···Cu1a distance of 3.004(1) Å agrees well with the distances found in other dimeric alkoxo-bridged Cu(II) complexes [22,23]. The Cu_2O_2 core and the theophylline frame has a dihedral angle of 56.70(4)°.

Two nitrogen atoms, one from the theophyllinato anion (N72···Cu1 1.973(2) Å) and the other from diethanolamine (N203···Cu1 2.023(2) Å), and the deprotonated oxygen atom from the anion of diethanolamine (O333···Cu1 1.926(2) Å) with its symmetry related pair (O33a···Cu1 1.932(2) Å) form a distorted square planar coordination geometry around the copper ion. The planes O333···Cu1···O33a and N72···Cu1···N203 are at an angle of 19.2(2)°. The inner coordination sphere of the copper cation is completed to a square pyramid with the hydroxyl oxygen atom of the tridentate diethanolamine anion (O233···Cu1 2.457(1) Å).

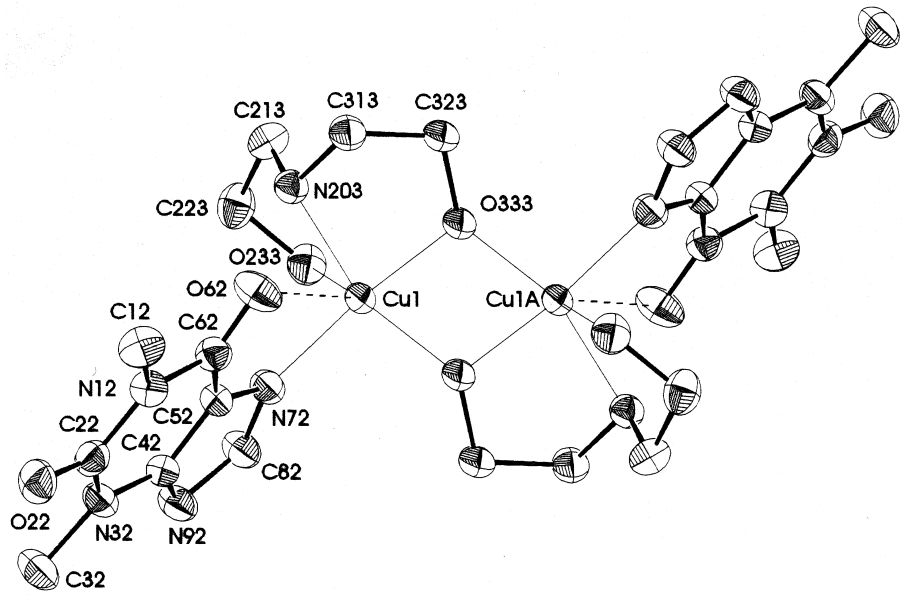

Fig. 4. ZORTEP [27] diagram of the molecule $[Cu_2(dea)_2(th)_2]$ (**1**) showing atomic displacement parameters at 50% probability level and atomic numbering. The asymmetric unit contains half of the complex molecule. The inversion centre is placed between the two Cu^{2+} ions. The symmetry operator to generate equivalent atoms is $-x+1, -y, -z+1$.

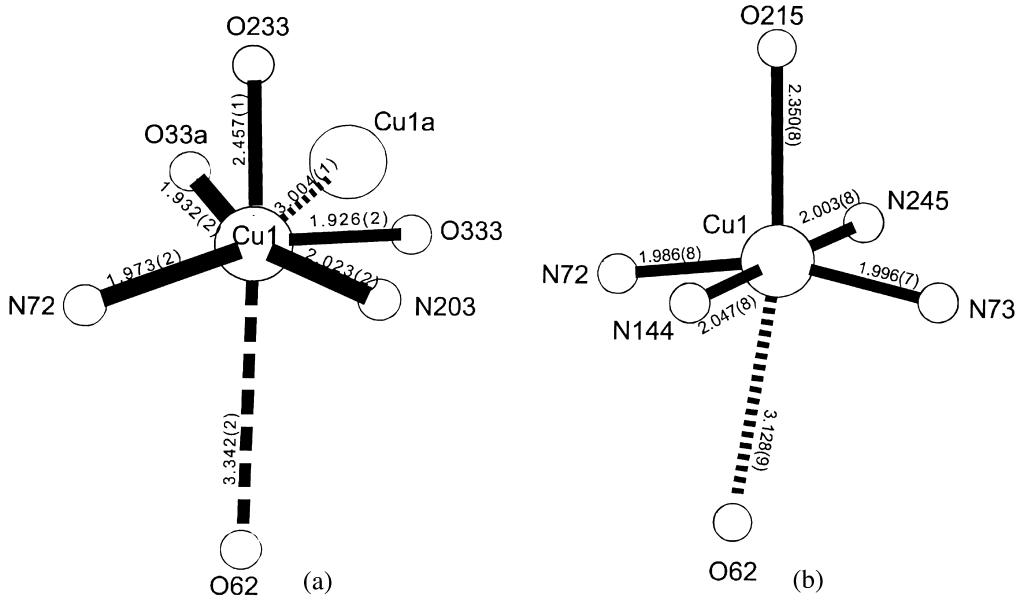

Fig. 5. Square pyramidal or pseudooctahedral coordination around Cu^{2+} in (a) $[Cu_2(dea)_2(th)_2]$ (**1**) and (b) $[Cu(ea)_2(th)_2 \cdot 2H_2O]$ (**2**). The inversion centre organizes the atoms denoted by 'a' in **1**. The octahedron is repeated around Cu1a upside-down.

[a] Ref. [1].

The copper ions can increase their coordination by association with oxygen anions forming dimeric, tetrameric or infinite chain species [23]. Dimeric complex formation is realized in **1** because of the presence of the hydroxide group in the diethanolamine ligand (O233···Cu1 2.457(1) Å) and the exocyclic oxygen atom of the theophyllinato anion (O62···Cu1 3.342(2) Å) near to the open apical position of the primer pyramidal coordination sphere. This O62···Cu1 distance is longer than bonds formed usually by oxygen atoms in an inner coordination sphere but it is shorter than the average Cu···O6 distance (3.75 Å) [8] in related structures, where the carbonyl O6 is involved in a hydrogen bond to a neighbouring ligand. No hydrogen bond of O6 is found in the crystal structure of **1**. Considering potential antitumour activity, an opportunity for N7/O6 chelation to the metal centre is postulated to be useful, whilst competitive interligand interactions to O6 in the form of, for example, hydrogen bonds is suggested to be injurious [8].

The crystal structure of (SPY-5-12)-(2-aminoethanol-N)-(2-aminoethanol-*N*,*O*)bis(theophyllinato-N7)copper(II) dihydrate (**2**) [1] gives the opportunity to compare the copper coordination sphere (Fig. 5, Tables 1 and 2, see also Fig. 1). Two theophyllinato anions, one 2-ethanolamine as bidentate and one 2-ethanolamine as monodentate ligand, form the square pyramidal arrangement of Cu^{2+} in the mononuclear **2**. One of the theophyllinato ligands has an exocyclic oxygen atom closer to the copper in **2** (O62···Cu1 3.128(9) Å) than in **1** (O62···Cu1 3.342(2) Å) at the open apical direction in the sixth coordination site. This means that only one of the theophyllinate anions can take part in N7/O6 chelation in the mononuclear complex **2**, whilst both of the theophyllinate anions form a similar, but weaker, N7/O6 chelation in the complex **1**.

The slightly distorted square pyramidal arrangement around the copper cation in **2** becomes a more distorted arrangement in **1**. An apical elongation can be observed, while three of the four bonds in the square plane are shortened because of the more favourable dialkoxo-bridging binuclear complexation. The fourth coordination bond becomes longer in **1**, as N203 also takes part in an interligand hydrogen bond. The bond angles in the pentahedron also characterize the distortion: the angles in the square plane of **1** are strongly different from 90°, nevertheless their sum is 360.3°. The exocyclic O62 of the theophyllinato ligand is also farther and in a more deviating position in **1** compared to **2**. These distor-

tions make possible the spatial adjustment of the two symmetry related pseudo-octahedra around Cu1 and Cu1a. The well-defined coordination of the bidentate theophylline and tridentate diethanolamine ligands yields low thermal motion.

The dimeric molecules of **1** are ordered into columns along the crystallographic *a* axis (Fig. 6). The theophylline rings in the column are 3.41(1) Å apart showing π···π stacking interaction between their purine rings. Intermolecular hydrogen bonds of N203···O22 (2.897(5) Å) in the column and N92···O233 (2.787(4) Å) between the columns stabilize the crystal.

3.4. Magnetic and ESR measurements

A sharp electron spin resonance signal proves the presence of unpaired electrons of the copper(II) centres, while the magnetic susceptibility is very small and measured with great standard deviation at various temperatures. In the literature various hydroxy and alkoxy bridged copper Cu_2O_2 type dimers have been studied, in order to find correlations between their structural and magnetic features [24,25]. Crawford et al. [26] have found a rather strong linear relationship between the Cu–O–Cu bridge angle and the magnetic exchange parameter 2*J* for a series of μ-hydroxo bridged planar dimers. In the same series, plots of the 2*J* values versus copper–copper distance were also found to be linear. Our planar compound does not seem to be a member of this series, for rather different $2J = -360\ cm^{-1}$ ($\phi_{Cu-O-Cu} = 102.3(1)°$) and $2J = -510\ cm^{-1}$ ($d_{Cu-Cu} = 3.004(1)$ Å) values of the exchange parameter could be estimated from the two correlation lines given there. Although we were not able to deduce the experimental 2*J* value, the above estimates indicate the antiferromagnetic nature of **1**. Antiferromagnetic behaviour was also reported for several structurally closely related dialkoxo bridged Cu dimeric compounds [22,23].

4. Summary

Bis(μ-2-(2-hydroxyethyl)aminoethanolato-*O,N,O′*)bis-(theophyllinato-N7)dicopper(II) (**1**) has been synthesized from aqueous solutions of $CuSO_4$, theophylline and excess diethanolamine in order to examine the structural effect of changing one of the ligands from ethanolamine to diethanolamine in theophyllinato copper complexes. The FTIR spectrum showed the presence of both anionic ligands (theophyllinate and aminoalcoholate). The thermal decomposition of the crystalline material indicated a composition for **1** consisting of one to one ratio of both anions to the copper cation. Single crystal studies proved that **1** has a dialkoxo-bridged binuclear structure with planar Cu_2O_2 core. The bridging O is the deprotonated oxygen of the monoalcoholato ligand formed from diethanolamine. The 2-(2-hydroxyethyl)aminoethanolate anion is found to be a tridentate ligand. It is bonded to one of the copper cations through its amino, hydroxo and alcoholate group. The theophyllinato ligand is bonded to the copper atom through the N7 nitrogen atom, while its O6 oxygen also has a weak secondary interaction with the centre. Such a coordination predicts only potentially medium antitumour activity. According to the ESR and magnetic measurements the two copper atoms are antiferromagnetically coupled.

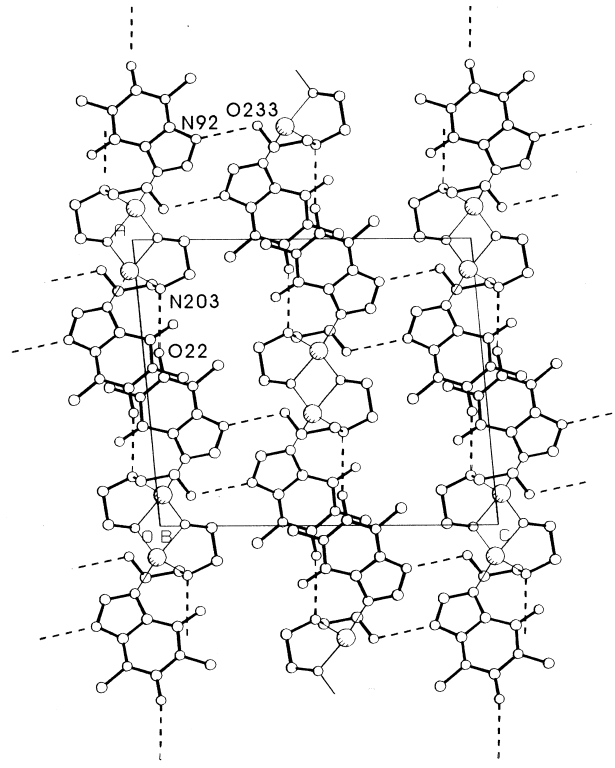

Fig. 6. The packing motif in the unit cell of $[Cu_2(dea)_2(th)_2]$ (**1**) shows the parallel arrangement of the columns of complexes and their hydrogen-bonding interligand interactions viewed from the direction of the crystallographic *b* axis.

Supplementary data

Crystallographic data (final atomic coordinates with anisotropic displacement parameters, full list of interatomic distances, interbond angles, torsion angles together with least square plane data, and F_o/F_c values, excluding structure factors) for the structure in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary data deposition no. CCDC 127826. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk). Measured and calculated powder diffraction patterns are available from the authors.

Acknowledgements

The authors thank Mr Csaba Kertész, Dr László Korecz and Dr Imre Labádi for the measurement of the single crystal X-ray, ESR and magnetic data, respectively. Many thanks to

Dr Vladislav Izvekov for the valuable discussion on the IR spectra. This work was supported by the National Scientific Research Foundation of Hungary (OTKA, Grant No. F 025664). Dr Edit Forizs is also thanked for her inspiration on this work.

POLYHEDRON

Chiral macrocyclic Nd(III) and Tm(III) complexes

Jerzy Lisowski *, Przemysław Starynowicz

Department of Chemistry, University of Wrocław, 14 F. Joliot-Curie, 50-383 Wrocław, Poland

Received 21 July 1999; accepted 15 December 1999

Abstract

The two new chiral macrocyclic complexes obtained in a template condensation of *R,R*-1,2-diaminocyclohexane and 2,6-diformylpyridine, $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$, have been synthesized and their X-ray crystal structures have been determined. The lanthanide(III) ions in both complexes are coordinated by a helically twisted hexadentate macrocycle and two bidentate nitrate anions. The $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$ complexes have been studied also by ^1H and ^{13}C NMR spectroscopy. The signal assignment was based on COSY, NOESY and HMQC measurements. The spectra of the investigated compounds in methanol–chloroform solution confirm the D_2-symmetrical helical conformation of the ligand. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Macrocycles; Lanthanide complexes; Chiral complexes; NMR of paramagnetic compounds

1. Introduction

The Schiff bases obtained in a template 2 + 2 condensation of diamines and 2,6-diformylpyridine or 2,6-diacetylpyridine are particularly suitable for the coordination of relatively large metal ions [1]. The complexes of these hexaazamacrocyles with lanthanide(III) ions have attracted a lot of attention owing to their unique properties. For instance, they have been shown to be efficient catalysts for cleavage of the phosphate ester bond [2–4]. The Gd(III) complexes have been studied also as potential MRI contrast agents [5].

When the chiral precursor *R,R*-1,2-diaminocyclohexane is used in the above template reaction, chiral lanthanide(III) complexes $[LnL](NO_3)_3 \cdot nH_2O$ (where Ln is the lanthanide(III) ion and L = 4(*R*),9(*R*),19(*R*),24(*R*)-3,10,18,25,31,35-hexaazapentacyclo[25.3.1.1^{12,24}.0^{4,9}.0^{19,24}]-dotriaconta-1(31),2,10,12,14,16(32),17,25,27,29-decaene, Fig. 1) are formed [6,7]. The coordination of the lanthanide(III) ion in a chiral macrocyclic environment leads to interesting properties of these compounds. Thus the $[TbL](NO_3)_3$ and $[EuL](NO_3)_3$ complexes have been shown to exhibit circularly polarized luminescence [6] and the paramagnetic $[EuL](NO_3)_3$ and $[YbL](NO_3)_3$ complexes have been shown to form diastereoisomeric complexes with D- and L-amino acids [7].

^1H NMR and ^{13}C NMR study of the La(III), Ce(III), Eu(III) and Yb(III) complexes has indicated a D_2-symmetrical helical conformation of the ligand in solution [7]. In contrast, the solid state X-ray crystal structure of related racemic $[GdL(H_2O)_3]Cl_3 \cdot 3H_2O$ shows lower symmetry of the complex with the twist-bent conformation of the ligand and unsymmetrical coordination of the axial water molecules [8]. In this report we show that the two new members of this

family of complexes, $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$, also maintain the symmetrical structure of the ligand in the solid state.

2. Experimental

2.1. Synthesis

The $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$ complexes have been prepared in the same way as earlier complexes [6,7]. Thus, 1 mmol (114.2 mg) of *R,R*-1,2-diaminocyclohexane, 1 mmol (135.1 mg) of 2,6-diformylpyridine, and 0.5 mmol of appropriate lanthanide nitrate hydrate were refluxed for 3 h in 15 ml of methanol. The white precipitates were filtered, recrystallized from methanol and dried in vacuo to give $[NdL](NO_3)_3$ or $[TmL](NO_3)_3$ in 48 and 65% yields, respectively. Both compounds gave satisfactory C, H, N analyses.

2.2. Methods

The NMR spectra were taken on a Bruker AMX 300 spectrometer. The chemical shifts were referenced to the residual solvent signal or TMS. The magnitude COSY spectra were acquired using 512 data points in both dimensions. The data were processed using a square sine bell window in both dimensions and zero filled to a $1K \times 1K$ matrix. The phase-sensitive (TPPI) NOESY spectra were recorded using mixing times varying from 15 to 400 ms and shifted square sine function. HMQC spectra were recorded using BIRD preparation period and 512×512 data points. A square sine function was used for apodization in both dimensions. T_2 relaxation times were evaluated from the linewidths. Elemental analyses were obtained from the elemental analysis facility in this department.

2.3. X-ray data collection

Crystals of both $[NdL](NO_3)_3 \cdot CH_3OH$ and $[TmL](NO_3)_3 \cdot CH_3OH$ were grown by slow evaporation of chloroform–methanol solutions of $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$. The obtained crystalline compounds lose solvent molecules and decompose when exposed to vacuum. Crystals of approximate size $0.4 \times 0.4 \times 0.2$ mm for $[NdL](NO_3)_3 \cdot CH_3OH$ and $0.5 \times 0.4 \times 0.2$ mm for $[TmL](NO_3)_3 \cdot CH_3OH$ were mounted on a Kuma KM4 diffractometer equipped with a CCD counter and an Oxford Cryosystem low-temperature appliance. The measurement was performed at 100 K. The structure was solved with direct

methods with SHELXS-97 [9] and refined with SHELXL-97 [10]. The absorption corrections were applied with a locally written program [11]. Since the two compounds are isomorphic, the parameters obtained for $[NdL](NO_3)_3 \cdot CH_3OH$ were used as the starting values for the refinement of the $[TmL](NO_3)_3 \cdot CH_3OH$ structure. The positions of C-bonded hydrogen atoms, with the exception of the CH_3 group of the methanol molecule, were placed geometrically, and their positions were constrained to the relevant C atoms, while their temperature factors were set at 1.2 times the trace of the C atoms. No attempt to localize the methanol hydrogens was made. The enantiomorph was selected on the basis of the value of Flack parameter. Details of the data collection and the refinement are presented in Table 1.

3. Results and discussion

3.1. X-ray crystal structures

The two structures are isomorphous and are composed of relevant macrocyclic complexes, nitrate anions and methanol molecules of solvation. The metal cations are decacoordinate; their coordination environments are composed of four nitrate oxygen atoms, and six nitrogen atoms belonging to the macrocyle: two from pyridine and four from the Schiff base fragments. The distances are unexceptional (see Table 2). The planes of the coordinated nitrate anions (N10, O11, O12, O13 and N20, O21, O22, O32) are twisted at angles of 72.2 and 72.8° in the case of the $[NdL](NO_3)_3 \cdot CH_3OH$ and $[TmL](NO_3)_3 \cdot CH_3OH$, respectively. Generally, the macrocyclic ligand is more twisted in the case of the Tm(III) complex: the angle between the least-squares mean planes of the cyclohexyl fragments (C7, C8, C9, C10, C11, C12 and C20, C21, C22, C23, C24, C25) is 75.2°, whereas the analogous angle is 64.6° for the Nd compound. The angles between the pyridine rings (C1, C2 C3, C4, C5, N1 and C14, C15, C16, C17, C18, N4) are 23.8 and 28.0° for the Nd(III) and Tm(III) compounds, respectively. The Cremer and Pople ring puckering parameters [12], calculated with the PUCK2 program [13], for the cyclohexyl rings C7, C8, C9, C10, C11, C12 are $Q = 0.558(10)$ Å, $\theta = 4.3(10)°$ for $[NdL](NO_3)_3 \cdot CH_3OH$ and $Q = 0.573(10)$ Å, $\theta = 8.7(10)°$ for $[TmL](NO_3)_3 \cdot CH_3OH$. The parameters for the C20, C21, C22, C23, C24, C25 rings are the following: $Q = 0.575(11)$ Å, $\theta = 4.2(11)°$ for the Nd compound and $Q = 0.609(12)$ Å, $\theta = 9.0(11)°$ for the Tm compound (the ϕ angle, which is rather meaningless for the case of low θ values, is omitted). Thus all the rings display fairly good chair conformations. The structure is held together by van der Waals interactions and hydrogen O···O bonds. An ORTEP [14] view of the complexed macrocycle is presented in Fig. 2.

The X-ray molecular structures of both $[NdL](NO_3)_3 \cdot CH_3OH$ and $[TmL](NO_3)_3 \cdot CH_3OH$ confirm the conclusion reached on the basis of solution NMR study [7], that the macrocycle L in $[LnL](NO_3)_3$ complexes adopts a helical structure of D_2 symmetry. In contrast, the X-ray crystal structure of the related racemic compound $[GdL(H_2O)_3]Cl_3 \cdot 3H_2O$ shows lower symmetry of the complex with the twist-bent conformation of the ligand and unsymmetrical coordination of the axial water molecules [8]. Thus the different axial ligation of lanthanide(III) ions complexed by the ligand L brings about a rather profound change of conformation of this macrocycle. In fact the bent structure observed for $[GdL(H_2O)_3]Cl_3 \cdot 3H_2O$ is characteristic [1] for complexes of hexaazatetraimine macrocycles, e.g. that of ligand L^1, and is observed also for the La(III) complex [15] of L^2 (a saturated tetraamine analogue of L). On the other hand, the helical structure is observed in the case of Zn(II) and Cd(II) complexes of the related tetraamine ligands L^2 and L^3 [15–17]. In these complexes, however, the twisting of the macrocyclic ligand is much more pronounced, as compared with that observed for $[LnL](NO_3)_3$ complexes. The extent of helical twisting of the discussed macrocyclic ligands can be measured by the dihedral angle between the N_3 donor sets derived from the two pyridine fragments. This angle is equal to 22.1° for $[NdL](NO_3)_3 \cdot CH_3OH$ and is slightly larger (27.7°) for $[TmL](NO_3)_3 \cdot CH_3OH$, as expected for

Table 2
Selected bond lengths (Å)

	Ln = Nd	Ln = Tm
Ln–O(11)	2.536(9)	2.393(10)

the smaller lanthanide(III) ion. Both values are considerably smaller than that observed [15] for $[ZnL^1]^{2+}$ (103.4°) and $[CdL^1]^{2+}$ (69.0°). In this way the $[NdL](NO_3)_3 \cdot CH_3OH$ and $[TmL](NO_3)_3 \cdot CH_3OH$ complexes constitute examples of relatively planar, moderately twisted hexaazamacrocyclic complexes.

3.2. NMR spectroscopy

The investigated compounds give rise to eight signals in their ^{1}H NMR spectra and seven signals in ^{13}C spectra (Fig. 3), which is consistent with the presence of diastereotopic cyclohexane protons and indicates the effective D_2 symmetry of the $[LnL](NO_3)_3$ complexes in the investigated solutions. This symmetry is in accord with the helical twist conformation of the macrocyclic ligand, similar to observations in the case of analogous La(III), Ce(III), Eu(III) and Yb(III) complexes [7].

The signals of both complexes are strongly affected by the additional shift, called the isotropic shift δ_{iso}, that arises from the interaction of the nuclear and electronic spins (for NMR of paramagnetic complexes, see refs. [18–22]). The magnitude of this shift is difficult to predict and prevents assignment of spectra based on the values of chemical shifts.

In the case of the solution of the $[NdL](NO_3)_3$ complex in CD_3OD–$CDCl_3$ 1:2 v/v the signal **a** at 11.84 ppm (see the labelling scheme, Fig. 3) can be easily found on the basis of integration (intensity 2H, in contrast to signals of intensity 4H of other positions). This signal shows both COSY and NOESY cross peaks to the pyridine signal **b** at 12.95 ppm. The HMQC spectrum (Fig. 3) shows a pair of geminal protons of the cyclohexane ring at 3.08 and 2.69 ppm and another pair at 3.08 and 1.59 ppm, each pair correlated to one carbon signal. The integration of the signal at 3.08 ppm confirms that it corresponds to two overlapped resonances. As expected, these three signals at 3.08, 2.69 and 1.59 ppm are correlated to each other in COSY and NOESY spectra. Additionally, the signal at 2.69 ppm is COSY correlated to another signal at 3.54 ppm. This latter signal must then correspond to the remaining cyclohexane proton **d**. It follows that the pair of signals at 2.69 and 3.08 ppm belongs to the protons **e′** and **e**, while the pair of signals at 3.08 and 1.59 ppm belongs to the geminal protons **f** and **f′**. The remaining signal at 25.64 ppm has to correspond to the imino proton **c**.

The assignment of the ^{1}H NMR spectrum of $[Tm](NO_3)_3$ was based on analysis of the linewidths. In the case of a dominant dipolar and/or Curie relaxation mechanism, the relaxation times of protons in a paramagnetic metal complex should be proportional to the sixth power of proton–metal ion distances [9]. The ratio of relaxation times equal to 39.9:17.0:4.3:1:11.4:11.9:61.8:24.1 for the positions **a**, **b**, **c**, **d**, $\mathbf{e_{eq}}$, $\mathbf{e_{ax}}$, $\mathbf{f_{eq}}$, $\mathbf{f_{ax}}$, respectively, can be calculated on the basis of proton–lanthanide(III) ion distances. Since linewidths are inversely proportional to the T_2 relaxation times, it is clear that the linewidths of the $[LnL](NO_3)_3$ complexes should increase in the following order: **f**, **f′**, **a** < **b**, **e**, **e′** < **c** < **d**. This information, together with identification of pairs of geminal signals **e**, **e′** and **f**, **f′** on the basis of HMQC correlations as well as the integration of signal a to 2H, allows for the assignment of protons **a**, **b**, **c**, **d**, **e**, **e′**, **f**, **f′** to the signals at −8.86, −13.03, −16.69, 38.27, 7.81, 6.02, 8.10 and 5.70 ppm, respectively.

The HMQC spectra allow for the assignment of ^{13}C NMR spectra of $[NdL](NO_3)_3$ and $[TmL](NO_3)_3$ complexes on

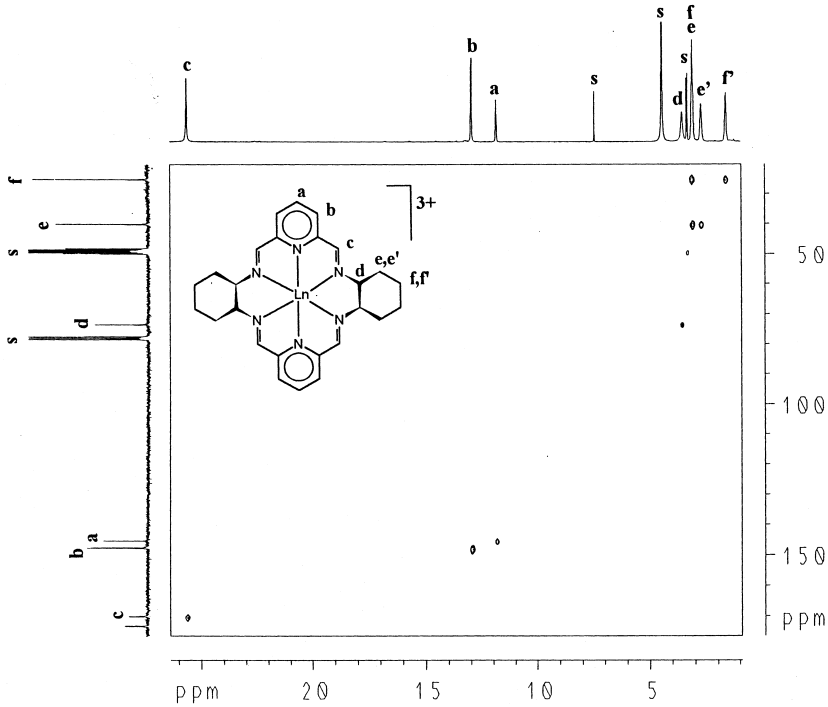

Fig. 3. The HMQC spectrum and labelling scheme of $[NdL](NO_3)_3$ (CD_3OD–$CDCl_3$ 1:2 v/v solution, 294 K); s solvent and HDO signals.

the basis of ^{1}H NMR assignments. The carbon atoms **a**, **b**, **c**, **d**, **e**, f, and the quaternary carbon **q** give rise to signals at 145.36, 147.70, 170.13, 73.36, 40.01, 25.22 and 173.32 ppm, respectively, in the case of the $[NdL](NO_3)_3$ complex, and to signals at 116.63, 89.56, 109.50, 41.41, 33.28, 30.04 and 81.22 ppm, respectively, in the case of the $[TmL](NO_3)_3$ complex.

In summary, we have shown that the $[LnL](NO_3)_3$ complexes exhibit symmetrical helical structure both in solution and in the solid state. The influence of different axial ligands on the symmetry of the macrocycle L complexed to lanthanide(III) ions is presently under investigation.

Supplementary data

Supplementary data for $[NdL](NO_3)_3 \cdot CH_3OH$ and $[TmL](NO_3)_3 \cdot CH_3OH$ structures are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.uk) on request, quoting the deposition numbers CCDC 130630 and CCDC 130631, respectively.

POLYHEDRON

Synthesis and characterization of 1-aza-allyl complexes of aluminum, gallium and bismuth

Chunming Cui, Haijun Hao, Mathias Noltemeyer, Hans-Georg Schmidt, Herbert W. Roesky *

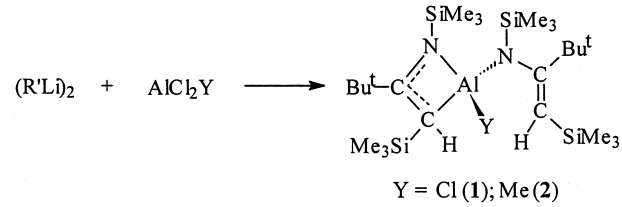
Institut für Anorganische Chemie der Universität Göttingen, Tammannstrasse 4, D-37077 Göttingen, Germany

Received 13 August 1999; accepted 16 December 1999

Abstract

Bis(1-aza-allyl) aluminum compounds of formula R'_2AlY (Y = Cl (**1**), Me (**2**); R′ = $N(SiMe_3)C(Bu^t)CH(SiMe_3)$) were obtained in good yields by the reaction of $(LiR')_2$ with equivalent amounts of $AlCl_3$ and $AlMeCl_2$, respectively, in diethyl ether. The reaction of compound **1** with one equivalent of $AlCl_3$ in toluene afforded the ionic species $[R'_2Al][AlCl_4]$ (**3**). Treatment of RLi·THF ($R = N(SiMe_3)C(Ph)C(SiMe_3)_2$) with $GaCl_3$ and $BiBr_3$ yielded mono(1-aza-allyl) complexes $RGaCl_2$ (**4**) and $RBiBr_2$ (**5**), respectively. Complexes **1**, **2**, **4** and **5** have been characterized by multinuclear NMR spectroscopy, mass spectroscopy and elemental analysis. The characterization of compound **3** is based on multinuclear NMR spectroscopy and physical properties, whereas single crystal X-ray diffraction data are provided for compound **1**. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Aluminum complexes; 1-Aza-allyl; Bismuth complexes; Crystal structures; Gallium complexes



1. Introduction

1-Aza-allyl lithium salts RLi·THF ($R = N(SiMe_3)C(Ph)C(SiMe_3)_2$) and $(R'Li)_2$ ($R' = N(SiMe_3)C(Bu^t)CH(SiMe_3)$), first prepared by Lappert and co-workers [1–3], have been successfully used as ligand transfer reagents for preparing a variety of transition metal and main group element complexes [4]. One of the most interesting features of these ligands is their diversified bonding modes, including η^3 chelating, η^2 bridging, and η^1 enamido, depending greatly on the metal centers, substituents on the ligand backbone and the other ligands on the metal atom. It seems that this type of ligand is suitable for fundamental studies of the relationship between ligand structure and metal coordination geometry due to the variation of the substituents on the ligand backbone. The known 1-aza-allyl complexes include a few main group elements (K, Li, Na, Pb, Sn) [1–3,5] and transition metal (Cu, Hg, Zr, Sm, Yb, Th) [6–11] compounds. Recently we reported on a general route for preparing mono(1-aza-allyl) aluminum compounds of formula $RAlX_2$ (X = halogen, alkyl; $R = N(SiMe_3)C(Ph)C(SiMe_3)_2$) [12]. Here we describe bis(1-aza-allyl) aluminum derivatives and the related gallium and bismuth compounds.

2. Results and Discussion

*2.1. Syntheses of the bis(1-aza-allyl) aluminum complexes **1**, **2** and **3***

Reaction of the 1-aza-allyl lithium salt $(R'Li)_2$ ($R' = N(SiMe_3)C(Bu^t)CH(SiMe_3)$) with $AlCl_3$ or $AlMeCl_2$ in diethyl ether afforded the bis(1-aza-allyl) aluminum complex R'_2AlCl (**1**) or R'_2AlMe (**2**) in good yield (Scheme 1). Compounds **1** and **2** were fully characterized by ^1H, ^{13}C and ^{29}Si NMR, mass spectroscopy and elemental analyses. Spectroscopic data for compound **1** indicate that two ligands are coordinated to the aluminum center in different bonding modes: one is η^3 chelating and the other is η^1 amido. NMR spectra for compound **2** are rather complicated due to rapid exchange of ligands in solution compared to compound **1** with a more polarized Al–Cl bond. Mass spectra indicate that both compounds **1** and **2** are monomers in the

PII S0277-5387(99)00390-3

gas phase. Initial efforts to examine reactivities of the two compounds showed that compound **2** does not react with the fluorinating reagent Me_3SnF in CH_2Cl_2 or toluene to give the corresponding fluoride, and that compound **1** cannot be reduced by alkali metals (Na and K) in hydrocarbon solvents even at elevated temperatures as indicated by recovery of 70–80% of compound **1** after refluxing for 24 h in n-hexane. Treatment of compound **1** with the Lewis acid $AlCl_3$ in toluene afforded a yellow oil that deposited from the solvent. Obviously a liquid clathrate (an oil containing compound **3** and solvent) is formed like many of the aluminum ionic compounds which exhibit two-phase liquid behavior in aromatic solvents [13,14]. A white solid of compound **3** can be obtained after treating the crude product with pentane. The solid is extremely air-sensitive and unstable in tetrahydrofuran (THF) and CH_2Cl_2. Crystallization of the solid from THF or CH_2Cl_2 leads to the formation of $AlCl_3(THF)_2$ [15,16] and compound **1** or decompostion of compound **3** into $AlCl_3$ and compound **1**. The formation of $AlCl_3(THF)_2$ from compound **3** in THF is particularly noteworthy since the direct interaction of aluminum chloride (Al_2Cl_6) and THF has been shown to give the ionic compound $[AlCl_2(THF)_4][AlCl_4]$ [17,18]. The mechanism might involve the initial interaction of the cation R'_2Al^+ with THF, which is in contrast to the related cation $[(2\text{-}C(SiMe_3)_2Py)_2Al]^+$, which could be crystallized from THF [19,20]. The different stabilities may be due to the flexibility of the 1-aza-allyl ligand. Compound **3** can be dissolved in CD_2Cl_2, and the solution is stable for a few days, which allows easy characterization of the product by NMR spectroscopy. The ^1H NMR spectrum of compound **3** contains four singlets (δ 0.30, 0.42, 1.39, 3.03 ppm) which are assigned to $NSiMe_3$, $SiMe_3$, Bu^t and CH, respectively. The chemical shift for CH indicates that the ligand is coordinated to the aluminum atom in an η^3 fashion due to the high field signal, compared with those found for the protons of normal C=C double bonds. Further evidence for the formation of cationic species was provided by the ^{27}Al NMR spectrum, in which two signals are observed: one at 103 ppm is typical for $AlCl_4^-$ [21]; the second (111 ppm) is assigned to R_2Al^+, which is in the typical range for a four-coordinated aluminum center.

Attempts to synthesize bis(1-aza-allyl) aluminum compounds containing the more bulky ligand R (R= $N(SiMe_3)C(Ph)C(SiMe_3)_2$) in solvents such as diethyl ether, n-hexane, THF and toluene were unsuccessful, even under reflux conditions.

2.2. Synthesis and characterization of complexes *4* and *5*

Reaction of RLi·THF with $GaCl_3$ and $BiBr_3$ in toluene–n-hexane afforded the corresponding mono(1-aza-allyl) gallium dichloride $RGaCl_2$ (**4**) and bismuth dibromide $RBiBr_2$ (**5**), respectively (Scheme 2). The two compounds have been characterized by MS, multinuclear NMR and elemental analysis. Mass spectra of compounds **4** and **5** indicate that the two compounds are monomers. The ^1H and ^{29}Si NMR

M = Ga, X=Cl (**4**); M = Bi, X=Br (**5**)

Scheme 2.

spectra of compounds **4** and **5** contain only one singlet for $SiMe_3$ (see Section 3), indicating that R is coordinated to the central atom in an η^3 chelating mode. It should be mentioned that $RAlCl_2$ has been characterized by X-ray single-crystal diffraction analysis, in which R is coordinated to Al in an η^3 chelating mode [12]. Compounds **4** and **5** have similar NMR patterns comparable to $RAlCl_2$. Compound **4** is soluble in hydrocarbon solvents while compound **5** has only a very limited solubility in n-hexane and is soluble in aromatic solvents. Compound **5** is not stable in solution, and slowly decomposes even under an inert atmosphere. Reduction of compound **5** with potassium in toluene afforded a slightly yellow oil, which we were not able to characterize completely. Compounds **4** and **5** represent the first known 1-aza-allyl compounds of gallium and bismuth. Further investigation of the chemistry of 1-aza-allyl gallium and bismuth compounds is in progress.

2.3. Molecular structure of compound *1*

Single crystals of **1** were obtained from n-hexane solution at −30°C. Selected bond lengths and angles are given in Table 1. The structure of compound **1** with the atom labeling scheme is shown in Fig. 1. Compound **1** adopts a distorted tetrahedral structure with aluminum bonded to C(3), Cl(1), N(1) and N(4); thus one ligand R is coordinated to the aluminum atom in an η^3 chelating fashion with the acute core angle N(1)–Al(1)–C(3) (71.44(6)°). The other ligand acts as amide ligand only, with the N(4) being coordinated to the aluminum atom. The different bonding modes of the ligand can be further realized when selected bond parameters are compared to each other. The Al(1)–N(1) distance (1.9701(15) Å) is longer than the Al(1)–N(4) distance (1.8194(15) Å); moreover the C(2)–C(3) bond length (1.478(2)Å) is longer than the C(5)–C(6) bond length (1.349(2) Å) while the N(1)–C(2) bond length (1.321(2) Å) is shorter than the N(4)–C(5) bond length (1.450(2)

Table 1
Selected bond lengths (Å) and angles (°) for compound **1**

Al(1)–N(1)	1.9701(15)	Al(1)–N(4)	1.8194(15)
Al(1)–C(3)	2.003(2)	Al(1)–Cl(1)	2.1504(8)
C(2)–C(3)	1.478(2)	C(5)–C(6)	1.349(2)
N(1)–C(2)	1.321(2)	N(4)–C(5)	1.450(2)
N(1)–Al(1)–C(3)	71.44(6)	N(1)–Al(1)–N(4)	115.59(7)
N(4)–Al(1)–C(3)	119.93(7)	N(1)–C(2)–C(3)	111.82(14)
N(4)–Al(1)–Cl(1)	108.81(5)	N(1)–Al(1)–Cl(1)	116.66(5)
N(4)–Al(1)–C(2)	116.87(6)	C(6)–C(5)–N(4)	119.2(2)

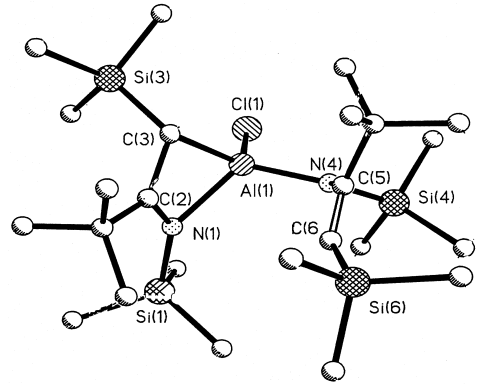

Fig. 1. Molecular structure of compound **1** in the crystal; hydrogen atoms have been omitted for clarity.

Å) due to electron delocalization in the η^3 ligand backbone. The bond angle C(3)–C(2)–N(1) (111.82(14)°) reflects an sp^3 hybrid of C(2) while the angle N(4)–C(5)–(C(6) (119.2(2)°) indicates an sp^2 hybrid of C(5). These data are in agreement with the different bonding modes of the ligand. The ^{1}H NMR spectrum of compound **1** clearly shows two sets of signals for the R′ group, indicating that the solid-state structure is maintained in C_6D_6 solution at room temperature. The singlets (δ 2.33 and 4.94 ppm) in the ^{1}H NMR spectrum also demonstrate different bonding modes of the ligand and can be used to identify the bonding interactions in the compounds incorporating this ligand.

3. Experimental

3.1. General

All manipulations were carried out under a purified nitrogen atmosphere using standard Schlenk techniques. Solvents were distilled from drying agents and degassed prior to use. The ^{1}H NMR (250.130 MHz), ^{13}C NMR (100.600 MHz), ^{29}Si NMR (79.460 MHz) and ^{27}Al NMR spectra (104.245 MHz) were recorded using Bruker AM 200 and Bruker AM 250 spectrometers. The chemical shifts were externally referenced to $SiMe_4$ (^{1}H, ^{13}C, ^{29}Si NMR) and $AlCl_3$ (^{27}Al NMR). EI (70 eV) mass spectra were measured on a Finnigan MAT 8230 or a Varian MAT CH5 instrument. Elemental analysis was performed by the analytical laboratory of the Institute of Inorganic Chemistry at the University of Göttingen. Melting points were measured in sealed glass tubes and were not corrected.

3.2. Preparations

3.2.1. [{N(SiMe$_3$)C(Bu^t)CH(SiMe$_3$)}$_2$AlCl] (1)

(LiR′)$_2$ (0.75 g, 1.5 mmol) in diethyl ether (20 ml) was added to a suspension of $AlCl_3$ (0.40 g, 1.5 mmol) in diethyl ether (10 ml) at −78°C. The reaction mixture was allowed to warm to room temperature and then stirred for 18 h. The volatiles were removed in vacuo and the residual was extracted with pentane (3×20 ml). The extract was concentrated and stored at −30°C overnight to afford colorless crystals of compound **1** (0.72 g, 88%). M.p.: 136–137°C. MS: *m/z* (%): 531 [M−Me]$^+$ (8%), 489 [M−Bu^t]$^+$ (81%), 304 [M−R′]$^+$ (100%). ^{1}H NMR (C_6D_6): δ 0.25, 0.29 (s, 9H, NSiMe$_3$), 0.36, 0.47 (s, 9H, SiMe$_3$), 1.07, 1.30 (s, 9H, Bu^t), 2.33, 4.94 (s, 1H, CH). ^{13}C NMR (C_6D_6): δ 1.99, 2.93 (s, NSiMe$_3$), 3.51, 4.12 (s, SiMe$_3$), 29.04, 31.83 (s, Bu^t), 39.22, 42.38 (s, Bu^t), 119.1, 47.4 (s, CH), 172.8, 222.0 (s, CN). ^{29}Si NMR (C_6D_6): δ −14.6, 0.81 (s, SiMe$_3$), 3.20, 3.49 (s, NSiMe$_3$). *Anal*. Found: C, 52.40; H, 10.17; N, 5.05%. Calc. for $C_{24}H_{56}AlClN_2Si_4$: C, 52.65; H, 10.31; N, 5.11%.

3.2.2. [{N(SiMe$_3$)C(Bu^t)CH(SiMe$_3$)}$_2$AlMe] (2)

This compound was prepared using (LiR′)$_2$ (2.00 g, 4 mmol) and $AlMeCl_2$ (3 ml, 1 M in n-hexane, 4 mmol) as described for compound **1**. After work-up, colorless crystals (1.90 g, 90%) were obtained. M.p.: 115–116°C. MS: *m/z* (%) 526 M$^+$ (5%), 511 [M−Me]$^+$ (20%), 469 [M−Bu^t]$^+$ (56%), 284 [M−R′]$^+$ (100%). ^{1}H NMR (C_6D_6, 295 K): δ −0.12 (s, 3 H, AlMe), 0.25–0.37 (m, SiMe$_3$), 1.07–1.29 (m, Bu^t), 2.32, 4.95(s, CH). ^{13}C NMR (C_6D_6, 300 K): δ −3.57 (s, AlMe), 1.37, 2.01, 2.25, 2.95, 3.53, 3.72, 4.13 (s, NSiMe$_3$ and SiMe$_3$), 29.25, 31.04 (s, Bu^t), 45.88, 42.39, 45.88 (s, Bu^t), 116.64 (s, CH), 174.4, 222.0 (s, CN). *Anal*. Found: C, 56.16; H, 11.44; N, 5.46%. Calc. for $C_{25}H_{59}AlN_2Si_4$: C, 56.95; H, 11.29; N, 5.32%.

3.2.3. [({N(SiMe$_3$)C(Bu^t)CH(SiMe$_3$)}$_2$Al)][AlCl$_4$] (3)

A mixture of compound **1** (0.55 g, 1 mmol) and $AlCl_3$ (0.13 g, 1.0 mmol) in toluene (10 ml) was stirred at room temperature for 2 h. Two phases (a yellowish oil deposited) were formed with the complete consumption of $AlCl_3$. The volatiles were removed to leave a semi-solid product, which was washed with pentane (2×5 ml) to give compound **3** as a white solid (0.47 g, 69%). ^{1}H NMR (CD_2Cl_2): δ 0.30 (s, 18H, NSiMe$_3$), 0.42 (s, 18H, SiMe$_3$), 1.39 (s, 18H, Bu^t), 3.03 (s, 2H, CH). ^{27}Al NMR (CD_2Cl_2): δ 103.0 (s, $AlCl_4^-$), 111.8 (br, R′$_2$Al$^+$).

3.2.4. [{N(SiMe$_3$)C(Ph)C(SiMe$_3$)$_2$}GaCl$_2$] (4)

A solution of RLi·THF (0.83 g, 2 mmol) in toluene (15 ml) was added to a stirred suspension of $GaCl_3$ (0.35 g, 2 mmol) in n-hexane (10 ml) at −78°C. The mixture was allowed to warm to room temperature and stirred for 15 h and then filtered. The filtrate was concentrated and stored at −30°C for 2 days to afford colorless crystals (0.62 g, 65%). M.p.: 165°C. MS: *m/z* (%) 475 M$^+$ (90%), 460 [M−Me]$^+$ (100%). ^{1}H NMR (C_6D_6): δ −0.01 (s, 9H, NSiMe$_3$), 0.24 (s, 18H, SiMe$_3$), 6.82–7.00 (m, 5H, Ph). ^{13}C NMR (C_6D_6): δ 0.69 (s, NSiMe$_3$), 2.55 (s, SiMe$_3$), 63.6 (s, CSi$_2$), 126.4, 128.7, 130.8 (s, Ph), 139.3 (s, *ipso*-C), 207.3 (s, CN). ^{29}Si NMR (C_6D_6): δ −0.42 (s, SiMe$_3$), 9.73 (s, NSiMe$_3$). *Anal*. Found: C, 42.69; H, 6.48; N, 2.98%. Calc. for $C_{17}H_{32}Cl_2GaNSi_3$: C, 42.90; H, 6.78; N, 2.94%.

*3.2.5. [{N(SiMe$_3$)C(Ph)C(SiMe$_3$)$_2$}BiBr$_2$] (**5**)*

A solution of RLi·THF (0.83 g, 2 mmol) in toluene (20 ml) was added to a suspension of $BiBr_3$ (0.90 g, 2.0 mmol) in n-hexane (10 ml) at −78°C. The mixture was allowed to warm to room temperature, stirred for 20 h and then filtered. The filtrate was concentrated and stored at −30°C overnight to give orange crystals (0.97 g, 69%). M.p.: 90°C(dec.). MS: *m/z* (%) 703 M^+ (4%), 624 $[M-Br]^+$ (90%), 73 $[SiMe_3]^+$ (100%). ^{1}H NMR (C_6D_6): δ −0.08 (s, 9H, $SiMe_3$), 0.33 (s, 18H, $SiMe_3$), 6.82–7.00 (m, 5H, Ph). ^{29}Si NMR (C_6D_6): δ −2.17 (s, $SiMe_3$), 4.00 (s, $NSiMe_3$). *Anal.* Found: C, 29.81; H, 4.88; N, 2.33%. Calc. for $C_{17}H_{32}BiBr_2NSi_3$: C, 29.03; H, 4.59; N, 1.99%.

3.3. X-ray structure determination and refinement

Data for crystal structure of compound **1** were collected on a Stoe-Siemens four circle diffractometer using Mo Kα radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-96) [22] and refined against F^2 using SHELXL-97 [23]. All heavy atoms were refined anisotropically. Hydrogen atoms were included using the riding model with U_{iso} tied to the U_{iso} of the parent atom. Crystal data, data collection details and refinement are summarized in Table 2.

Table 2
Crystallographic data for compound **1**

Formula	$C_{24}H_{56}AlClN_2Si_4$

POLYHEDRON

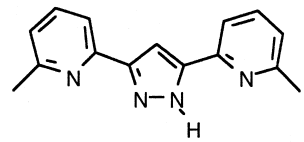
Synthesis and X-ray crystal structures of several dinuclear ruthenium cymene complexes based on the tetradentate ligand, 2,2′-(1*H*-pyrazole-3,5-diyl)bis(6-methylpyridine) (Me_2DppzH)

Vincent J. Catalano *, Tegan J. Craig

Department of Chemistry, University of Nevada, Reno, NV 89557, USA

Received 12 July 1999; accepted 6 December 1999

Abstract



The complexes $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2Cl_2]^+$ (**1**), $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(NO_3)_2]^+$ (**2**), $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(OH_2)_2]^{3+}$ (**3**), $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(NO_2)_2]^+$ (**4**), $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(CH_3CN)_2]^{3+}$ (**5**) and $[Ru_2(NO_2\text{-}6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2Cl_2]^+$ (**6**), where 6,6′-Me_2dppzH is 2,2′-(1*H*-pyrazole-3,5-diyl)-bis(6-methylpyridine) and NO_2-6,6′-Me_2dppzH is 2,2′-(1*H*-4-nitropyrazole-3,5-diyl)bis(6-methylpyridine), were synthesized and characterized by ^{1}H NMR and UV–Vis spectroscopy, X-ray crystallography and elemental analysis. Compounds **2** and **4** were additionally characterized by IR spectroscopy. Reaction of compound **1** with an aqueous silver ion produces the corresponding aquo complex **3**. Complex **3** can be isolated or further reacted with $NaNO_2$ to form the N-bound nitrite complex **4**. Complex **1** can also be reacted with an acetonitrile solution of HPF_6 to produce the acetonitrile species (**5**). Reaction of compound **1** with an excess of $NOBF_4$ produces the corresponding chloro complex with nitration at the pyrazole carbon atom. Attempts to isomerize the geometry of complex **1** from the 'anti-facial' geometry to the 'syn' geometry were unsuccessful using either chemical or photochemical means. All efforts to convert the bound nitro group to the nitrosyl were futile, resulting in either ligand substitution or alteration of the ligand backbone. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Cymene; Nitration; Pyrazolyl; Ruthenium; Structure; Synthesis

1. Introduction

Mononuclear ruthenium polypyridyl complexes are known to perform a variety of inorganic [1–4] and organic transformations [5,6]. Their ease of synthesis, high catalytic performance under relatively mild reaction conditions, high selectivity and easily modified ligand systems make these complexes particularly well suited for this purpose. For example, the terpyridine-containing complex $[Ru(trpy)(bpy)(NO_2)]^+$ (where trpy is 2,2′:6′,2″-terpyridine and bpy is 2,2′-bipyridine) is capable of interconverting a bound nitrite ligand to a nitrosyl moiety using simple acid–base chemistry, and further to an ammonia ligand by electrochemical methods [7]. Further, the closely related Ru(IV)=O complexes, $[Ru(trpy)(diimine)O]^{2+}$, are used extensively as catalysts for the oxidation of organic substrates [5,6,8–14].

It has been postulated that this catalytic behavior could be enhanced by coupling two adjacent metals, thus allowing for strong communication between the metals and perhaps a cooperative catalytic or redox behavior [15,16]. Meyer et al. have reported a dinuclear ruthenium oxo-bridged catalyst that homogeneously transforms water into dioxygen. This dimer is also capable of many other substrate oxidations [17–19]. Although the reactivity of the dimeric form is high, instability renders the complex less effective as a catalyst. However, incorporation of a multidentate ligand as a chelating backbone can alleviate this problem by stabilizing the dimeric form [15,20–24].

6,6′-Me_2dppzH

The dipyridylpyrazolate ligand (6,6′-dppzH) is one such candidate. Deprotonation of this ligand provides an open coordination pocket that allows for dimetallic complex formation, forcing the two ruthenium centers into close proximity. This arrangement allows a halide or small molecule to

PII S0277-5387(99)00391-5

bridge between the metals [25] and allows both metals to influence the reactivity of the bridging molecule. Further, methyl groups in the 6 and 6′ positions add moderate steric congestion to the complex, directing incoming substrate molecules towards the center of the complex. Herein is reported the synthesis, characterization and reactivity of a series of new dimetallic ruthenium compounds based on the dipyridylpyrazolate ligand.

2. Results

2.1. Synthesis

The synthesis of the 2,2′-(1*H*-pyrazole-3,5-diyl)bis(6-methylpyridine) (6,6′-Me_2dppzH) ligand was modified from the literature procedure [25–27], and $Ru_2Cl_4(\eta^6$-*p*-cymene$)_2$ was prepared according to a literature procedure [28]. Reaction of the 6,6′-Me_2dppzH ligand with one equivalent of $Ru_2Cl_4(\eta^6$-*p*-cymene$)_2$ produced complex **1** as a bright orange, microcrystalline solid in 90% yield (Eq. (1)).

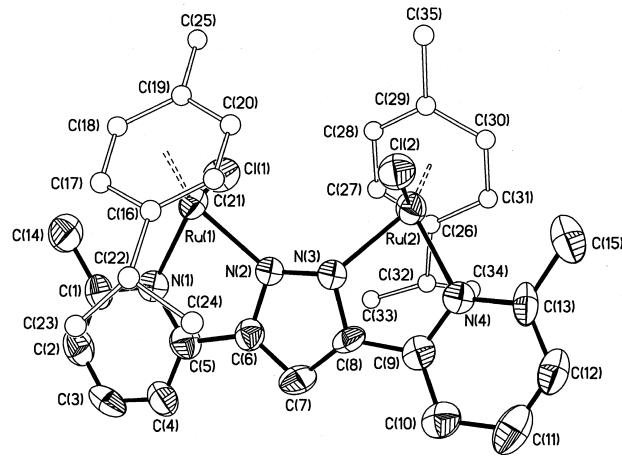
$$6,6'\text{-Me}_2\text{dppzH} + \text{Ru}_2\text{Cl}_4(\eta^6\text{-}p\text{-cymene})_2 \rightarrow [\text{Ru}_2(6,6'\text{-Me}_2\text{dppz})(\eta^6\text{-}p\text{-cymene})_2\text{Cl}_2]\text{Cl} + \text{HCl} \quad (1)$$

As shown in Fig. 1, the crystal structure (see below) of complex **1** has an 'anti-facial' geometry in which the cymene ligands are directed away from one another. This geometry likely results from a minimization of the steric hindrance caused by the bulky arene ligands. The reaction to form complex **1** also produced a minor product (less than 10%), which might be an isomer of complex **1**. This impurity could not be removed by recrystallization or chromatographic techniques.

According to Scheme 1, complex **1** can be treated with excess $AgNO_3$ in acetone–H_2O to produce the monodentate nitrate species (**2**) as a yellow solid. Complex **1** can also be reacted with $NOBF_4$ dissolved in CH_2Cl_2 to form complex **6**, in which the ligand backbone has been nitrated. Reaction of complex **1** in acetone with an aqueous solution of $AgBF_4$ or $AgClO_4$ produces the aquo species (**3**). This can be isolated or further reacted with $NaNO_2$ to form species **4** as a yellow solid. The IR spectrum (KBr pellet) of compound **4** displays two stretches at 1367 and 1311 cm^{-1} along with a bending mode at 845 cm^{-1}, consistent with an N-bound nitro group [29]. Dissolution of complex **4** in acetonitrile and further treatment with HPF_6 produces the solvato species (**5**). Substitution chemistry of complex **1** to form complexes **2**, **3** and **5** eliminates the aforementioned impurity. All of the complexes reported here have been studied by X-ray diffraction and have analogous structures with the 'anti-facial' geometry and non-bridging small molecule ligands.

2.2. NMR spectroscopy studies

General ^{1}H NMR assignments were made for each of the complexes, and the chemical shift data are presented in Section 5. Analyses of the 1D and 2D ^{1}H NMR and ^{13}C{^{1}H} NMR experiments provide for nearly complete assignment of protons for complex **5,** while 1D experiments were used for the remaining complexes. The ^{1}H NMR spectra for complexes **1**–**6** further support the geometry of the complexes. The pyrazole proton resonances for each of the complexes appears between 7.65 and 7.89 ppm and are not significantly influenced by changes in ligation at the metal centers. Each complex also shows the appropriate aromatic resonances for the ligand backbone between 8.11 and 7.57 ppm, again with little shift upon ligand substitution. The cymene ring protons are also unaffected by substitution at the ruthenium centers,



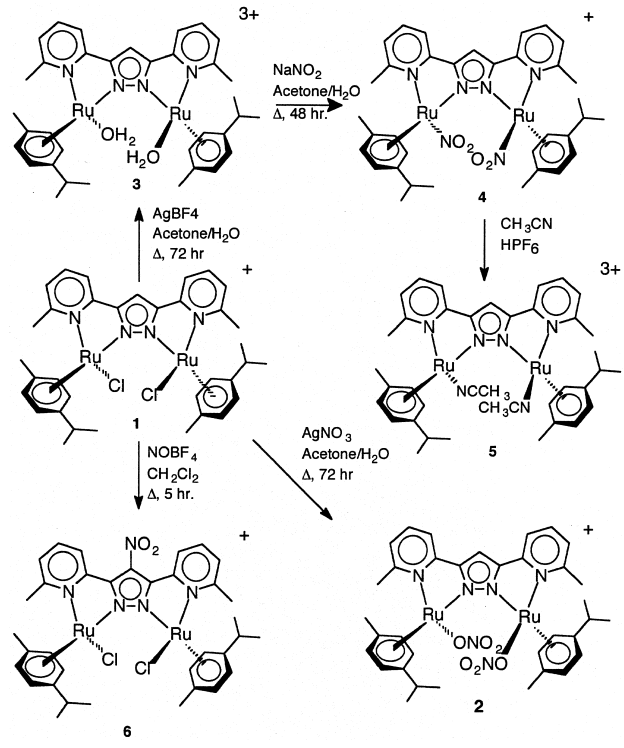


Fig. 1. Crystal structure drawing for the cation of $[Ru_2(6,6'\text{-Me}_2\text{dppz})(\eta^6\text{-}p\text{-cymene})_2Cl_2](PF_6)$ (**1**) with 40% probability ellipsoids. Cymene carbon atoms are shown as arbitrarily sized circles and hydrogen atoms are removed for clarity.

Scheme 1.

giving rise to four resonances in the aromatic region of the spectra between 6.64 and 5.67 ppm. The methyl groups in the 6 and 6′ positions provide a distinct spectroscopic handle in the ^{1}H NMR spectra. The characteristic 6,6′-Me_2dppz methyl resonance for complex **1** appears at 3.26 ppm. Substitution of the chloride for NO_3^- shifts the resonance downfield to 3.41 ppm. This resonance moves upfield to 3.10 and 3.11 ppm for NO_2^- and CH_3CN, respectively. For complex **6** the resonance appears at 3.31 ppm, and for the aquo species (in D_2O) the resonance appears at 3.28 ppm. The aliphatic portions of the cymene ligands are resolved and appear between 2.71 and 0.57 ppm, as expected.

2.3. Electronic absorption spectra

The electronic absorption spectra of compounds **1**–**6** (CH_3OH) are similar. All six complexes show intense $\pi-\pi^*$ absorptions in the UV portion of the spectrum. For compound **1** this band appears at 327 nm. Substitution in complexes **2**–**6** shifts the band to slightly higher energy to 319, 322, 326, 320 and 317 (shoulder) nm, respectively. Complex **6** also exhibits a shoulder at 302 nm. Each complex also exhibits a broad band in the visible region of the spectrum. This band can be assigned to a metal-to-ligand charge transfer (MLCT) process and appears at 430 nm for compound **1**. The MLCT band shifts slightly upon substitution of the chloride for nitrate to 425 nm for compound **2**. For compounds **3** and **5** this band shifts to higher energy, to 407 and 400 nm, as expected for the substitution of an anionic ligand for a neutral species. The poor donor property of the monodentate nitrate moiety in compound **4** is exemplified with a MLCT band shift at 398 nm. Upon nitration of the ligand backbone the MLCT band appears at 407 nm for compound **6**. As expected, this energy is higher than that of compound **1**.

3. Structural analyses

3.1. Structure of [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2Cl_2$](PF_6)·0.5CH_3OH (**1**)

The asymmetric unit of complex **1** contains the cation, one disordered hexafluorophosphate counterion, and one-half of a molecule of methanol. There are no unusual contacts between these moieties. A view of the cation is presented in Fig. 1. Selected bond distances and angles are given in Table 1, and atomic coordinates and complete crystallographic details are provided in the section on supplementary data. The structure of compound **1** shows each Ru atom in a roughly octahedral environment with the η^6-*p*-cymene ligand coordinated in a facial fashion. The 6,6′-Me_2dppz ligand is bound in a chelate fashion to both ruthenium centers. The chloride atom is positioned in a manner as to prohibit bridging between the two ruthenium centers. The ruthenium atoms are on opposite sides of the bridging ligand backbone, and the η^6-*p*-cymene ligands are directed away from one another in an 'anti-facial' geometry. The cymene methyl groups are directed on the same side as the chloro ligands with the cymene isopropyl groups pointing opposite to the chloro groups, possibly to remove any steric hindrance from the large chloride ligand. The steric encumbrance of the 6,6′-Me_2dppz methyl groups is manifested in the Ru–N separations. The Ru(1)–N(1) and Ru(2)–N(4) distances of 2.129(12) and 2.160(12) Å are longer than the Ru(1)–N(2) and Ru(2)–N(3) distances of 2.090(10) and 2.089(11) Å, respectively. The distance between the two metal centers is long at 4.445 Å. The average Ru–C bond distance is normal [30–32] at 2.20 Å with the average Ru–$C_{centroid}$ length of 1.691 Å, while both Ru(1)–Cl(1) and Ru(2)–Cl(2) distances of 2.402(5) and 2.386(4) Å are typical for a ruthenium(II)–chloro complex [5,32,33]

3.2. Structure of [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$-(NO_3)$_2$](PF_6)·0.5(CH_3)$_2$CO (**2**)

The structure of compound **2** is analogous to that of compound **1**. The asymmetric unit of compound **2** contains the cation, one disordered hexafluorophosphate counterion and one-half of an acetone solvate molecule, with no unusual contacts between any of these species. A drawing of the cation is shown in Fig. 2, and selected bond distances and angles are given in Table 2. Complete crystallographic data are provided in the section on supplementary data. The structure of

compound **2** is similar to that of compound **1**. As seen in compound **1**, the ruthenium centers of compound **2** lie on opposite faces of the 6,6′-Me_2dppz ligand backbone. Again, the cymene methyl groups are directed towards the monodentate nitrate ligand. The Ru(1)–O(1)–N(5) and Ru(2)–O(4)–N(6) angles are larger than the ideal 120°, at 140.8(11) and 128.7(8)°, respectively. The O(1)–N(5)–O(2) and O(4)–N(6)–O(5) angles are 107.5(16) and 120.0(12)°, while the O(1)–N(5)–O(3), O(2)–N(5)–O(3), O(4)–N(6)–O(6) and O(5)–N(6)–O(6) angles are 139.5(17), 107.3(18), 121.0(13) and 119.0(13)°. Again, the steric encumbrance of the methyl groups of the Me_2dppz ligand forces the metal–pyridine bond to elongate relative to that of the metal–pyrazole; the Ru(1)–N(1) and Ru(2)–N(4) distances are 2.151(10) and 2.139(9) Å, compared with the Ru(1)–N(2) and Ru(2)–N(3) distances of 2.071(8) and 2.100(8) Å, respectively. The Ru···Ru separation of 4.420 Å and the average $Ru–C_{centroid}$ bond distance of 1.695 Å are similar to those of compound **1**. The average Ru–O distance is 2.091 Å.

*3.3. Structure of $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(H_2O)_2](ClO_4)_3\cdot 2CH_3CH_2COCH_3$ (**3**)*

The structure of complex **3** contains the cation, three-disordered perchlorate counterions and two molecules of disordered 2-butanone solvent in the asymmetric unit. There are no unusual contacts between any of these moieties. A view of the cation is given in Fig. 3. Selected bond distances and angles are given in Table 3, while complete crystallographic details are provided in the section on supplementary data. The 'anti-facial' geometry is again present in complex **3**, with the methyl groups of the cymene ligands pointed in the same direction as the coordinated water molecule. The Ru(1)–N(1) distance of 2.170(6) Å is longer than the Ru(1)–N(2) distance of 2.091(5) Å. Similar to the above compounds, the Ru···Ru separation is 4.456 Å, and the average $Ru–C_{centroid}$ bond distance is 1.679 Å. The Ru(1)–O(1) bond distance is

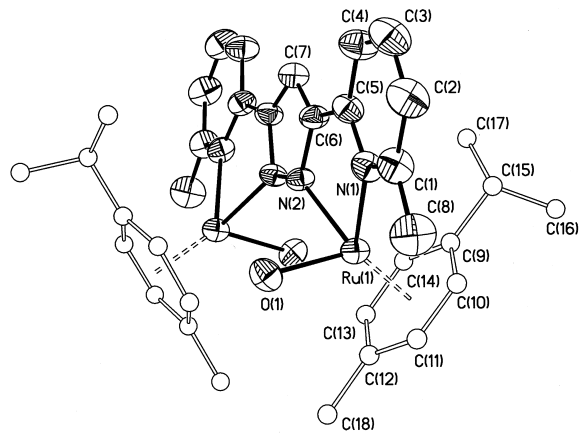

Fig. 3. Crystal structure drawing for the cation of $[Ru_2(6,6'\text{-}Me_2dppz)(\eta^6\text{-}p\text{-cymene})_2(H_2O)_2](BF_4)_3$ (**3**) with 40% probability ellipsoids. Cymene carbon atoms are shown as arbitrarily sized circles and hydrogen atoms are removed for clarity.

2.153(5) Å, which is a typical length for ruthenium(II) aquo complexes [34].

*3.4. Structure of [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$-(NO_2)$_2$](ClO_4)·0.5(CH_3)$_2$CO (**4**)*

The solid-state structure of complex **4** contains the cation, one disordered perchlorate counterion and one-half of an acetone solvate molecule in the asymmetric unit. There are no unusual contacts between these species. A drawing of the cation is presented in Fig. 4. The complete crystallographic data are provided in the section on supplementary data, and selected bond distances and angles are given in Table 2. Complex **4** also maintains the 'anti-facial' geometry, with the cymene methyl groups pointed in a similar direction as the nitrite ligands. The solid state structure confirms the N-bound geometry of the nitrite group with the Ru(1)–N(5) and Ru(2)–N(6) separations of 2.155(5) and 2.091(6) Å, respectively. The average Ru–N–O angle is 119.0°, and the O(1)–N(5)–O(2) and O(3)–N(6)–O(4) angles are 120.2(5) and 119.7(7)°. These angles are typical of ruthenium(II)–nitrite complexes [35]. As above, the Ru(1)–N(1) and Ru(2)–N(4) distances of 2.144(5) and 2.130(6) Å are longer than the Ru(1)–N(2) and Ru(2)–N(3) distances of 2.089(5) and 2.085(5) Å, respectively. The Ru···Ru separation is 4.468 Å, and the Ru–$C_{centroid}$ distances are 1.717 and 1.731 Å, slightly longer than those of compound **1**. The average Ru–C bond distance is 2.226 Å for compound **4**.

*3.5. Structure of [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$-(CH_3CN)$_2$](PF_6)$_2$(BF_4)·0.5(CH_3)$_2$CO (**5**)*

The asymmetric unit of compound **5** contains the cation, two hexafluorophosphate counterions (one of which is slightly disordered), one tetrafluoroborate counterion and one-half of a molecule of acetone solvent. There are no unusual contacts between any of these species. Fig. 5 displays the structure of the cation. Selected bond distances and angles are given in Table 3, and complete crystallographic data are provided in the section on supplementary data. Like the above structures, the geometry of complex **5** is 'anti-facial', with

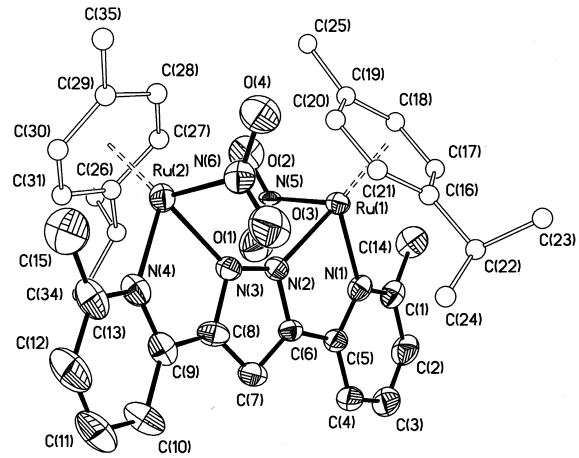

Fig. 4. Thermal ellipsoid plot (40% probability) for the cation of [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$(NO_2)$_2$](PF_6) (**4**). Cymene carbon atoms are shown as arbitrarily sized circles and hydrogen atoms are removed for clarity.

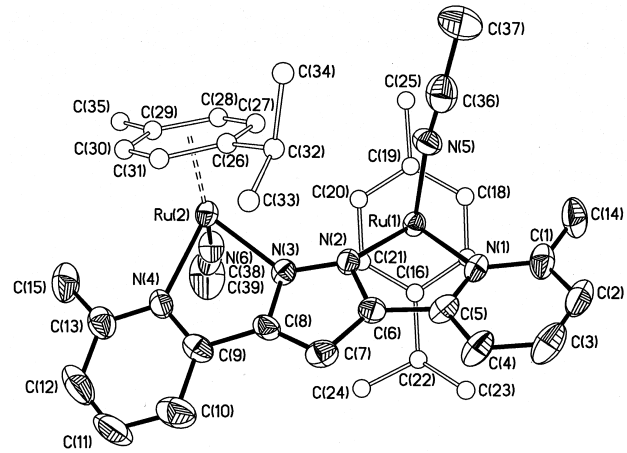

Fig. 5. Crystal structure drawing for the cation of [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$(CH_3CN)$_2$](BF_4)$_3$ (**5**) with 40% probability ellipsoids. Cymene carbon atoms are shown as arbitrarily sized circles and hydrogen atoms are removed for clarity.

the cymene methyl groups pointed in the same direction as the coordinated acetonitrile molecules. In agreement with complex **1**, the Ru(1)–N(1) and Ru(2)–N(4) bond distances are 2.156(7) and 2.134(8) Å, and the Ru(1)–N(2) and Ru(2)–N(3) distances are 2.076(7) and 2.092(7) Å, respectively. Similar to compound **1**, the Ru···Ru distance is 4.482 Å and the average Ru–$C_{centroid}$ bond distance is 1.702 Å. The Ru(1)–N(5) and Ru(2)–N(6) distances are 2.071(9) and 2.050(8) Å, typical for this type of complex [5,36].

*3.6. Structure of [Ru_2(NO_2-6,6′-Me_2dppz)(η^6-p-cymene)$_2$-Cl_2](PF_6)·0.25CH_2Cl_2 (**6**)*

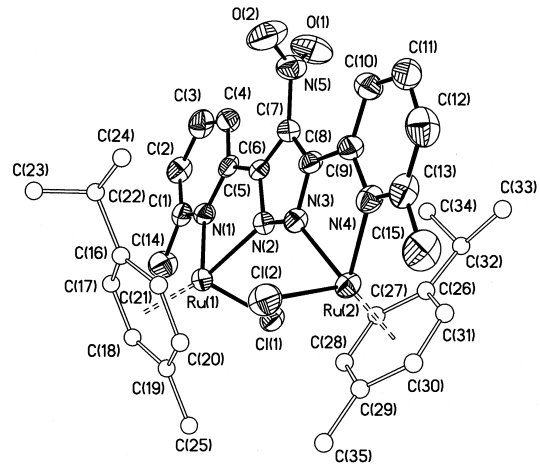
The asymmetric unit of complex **6** contains the cation, one disordered hexafluorophosphate counterion and one-quarter of a dichloromethane solvate molecule, with no unusual contacts between these species. A view of the cation is presented in Fig. 6. Selected bond distances and angles are given in Table 1, while atomic coordinates and complete crystallographic details are provided in the section on supplementary data. As seen in all the above structures, complex **6** has an 'anti-facial' geometry. The cation of complex **6** resembles that of compound **1** with many similar bond distances and angles. The Ru(1)–N(1) and Ru(2)–N(4) bond distances are 2.132(8) and 2.161(8) Å, and the Ru(1)–N(2) and Ru(2)–N(3) distances are 2.101(7) and 2.098(7) Å, respectively. Similar to compound **1**, the Ru···Ru distance is 4.418 Å, the average Ru–C bond distance is 1.700 Å and the average Ru–Cl distance is 2.400 Å. The striking feature of this structure is the nitrated pyrazole group. The nitro group is significantly canted with respect to the pyrazole ring, with a dihedral angle defined by the nitro group and the pyrazole ring of 117.6°. The O(1)–N(5)–O(2) angle is 124.4(11)°, while the N(5)–O(1) and N(5)–O(2) separations are 1.169(11) and 1.243(12) Å and the C(7)–N(5) distance is 1.459(13) Å.

3.7. Electrochemistry

In acetonitrile, complex **1** exhibits a reversible oxidation at 1.5 V and an irreversible reduction past −1.3 V relative to Ag/AgCl. Nitration of the ligand backbone in compound **6** shifts the potential anodically with a reversible oxidation at 1.6 V and a quasi reversible reduction at −0.9 V. Given the strong electronic coupling expected between the two metals, these are likely one-electron processes. Compounds **2**, **3** (in H_2O), **4** and **5** did not exhibit reversible electrochemical behavior in the range of +1.8 to −1.8 V.

4. Discussion

All of the complexes described here possess the 'anti-facial' geometry with respect to the 6,6′-Me_2dppz ligand backbone. The preference for this arrangement is likely



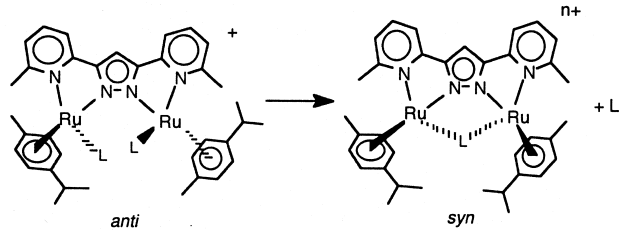


Fig. 6. Thermal ellipsoid plot (40% probability) for the cation of [Ru_2(NO_2-6,6′-Me_2dppz)(η^6-*p*-cymene)$_2Cl_2$](PF_6) (**6**). Cymene carbon atoms are shown as arbitrarily sized circles and hydrogen atoms are removed for clarity.

related to the large steric bulk of the coordinated arene. Interestingly, the analogous benzene derivative of compound **1** shows the same 'anti-facial' arrangement, indicating that the [Ru(arene)]$^{n+}$ fragment is sufficiently large to block one side of the 6,6′-Me_2dppz ligand, preventing the second metal center from entering 'syn' to the first group [37]. The lack of bridging in this arrangement precludes concerted chemistry at the small molecule site, and much effort was therefore directed at isomerizing these complexes to the 'syn' isomer (Eq. (2)):

(2)

Simple thermal isomerization of compounds **1**, **3** or **5** proved unfruitful, as did an attempted photochemical isomerization of compound **5**. Reactions to induce isomerization of compound **1** by introducing a bridging group (as in compound **2** or **4**) produced the 'anti' geometry as the only product. Further, the reactions of compound **1** with other bridging groups, including CO_3^{2-}, oxalate and N_3^-, showed either no reaction or resulted in decomposition. Alternatively, substitution reactions of the arene were also unfruitful. Unlike many Ru(II)–cymene complexes, compound **1** did not react with phosphines, pyridine or dimethylsulfoxide (DMSO) under forcing conditions and extended reaction times. Instead, only starting materials were recovered.

This lack of reactivity is in part attributed to the presence of the Me_2dppz ligand whose strong sigma donor properties stabilize the Ru–cymene bonding. The competition for π-bonding between the cymene and the Me_2dppz further explains the sluggish substitution chemistry observed for displacement of the anionic, π-basic chloride ligand in com-

pound **1**. The highly anodic Ru(III)/Ru(II) couples further reflect this property. For comparison, the loosely related $[Ru(cymene)Cl(PPh_2R)(NCCH_3)]^+$ (R = allyl or vinyl) complexes have Ru(III)/Ru(II) couples between 1.46 and 1.63 V [38]. With their good σ-donating phosphines these complexes are expected to be more electron-rich.

Another manifestation of the electron-poor nature of complexes **1**–**6** resides in their inability to form a stable nitrosyl complex. Polypyridine Ru(II)–NO_2 complexes are well known to undergo nitrite to nitrosyl conversion effectively upon protonation (Eq. (3)).

$$[Ru-NO_2]^{n+} \underset{-H^+,\ +H_2O}{\overset{+2H^+,\ -H_2O}{\rightleftharpoons}} [Ru-NO]^{n+2} \quad (3)$$

However, replacement of the polypyridine groups with the π-acidic cymene ligand likely prevents the effective backbonding necessary to stabilize a nitrosyl ligand. For example, treatment of compound **4** with HCl regenerated the chloro species (**1**), while reaction of compound **4** with aqueous $HClO_4$ produced compound **3**, and reaction of compound **4** with an acetonitrile solution of HPF_6 formed compound **5**. In each case the nitrosyl may have formed but was ultimately displaced by better donor molecules present in solution. Similarly, direct reaction of the aquo species (**3**) with NO(g) also did not produce a bound NO ligand. Lastly, reaction of compound **1** with $NOBF_4$ did not produce the anticipated nitrosyl complex, but it nitrated the 4 position of the pyrazole ring instead, leaving the metal unchanged to form compound **6**. A control reaction between Me_2dppz and $NOBF_4$ produced no reaction, indicating that the formation of compound **6** must be metal-assisted. There is precedence for formation of Ru(II)–nitrosoarene complexes [39]; however, since the corresponding Ru–nitrosyl complex could not be formed in our system, the mechanism likely resembles an electrophilic aromatic substitution by NO^+ followed by oxidation to the nitro species [40].

4.1. Conclusion

The complexes reported here show a remarkable preference for the 'anti' geometry with respect to the Me_2dppz ligand and are remarkably resistant to both isomerization and to arene substitution. Furthermore, unlike many Ru(II) complexes, conversion of the nitro ligand to nitrosyl was not achieved, nor was the attempted introduction of a NO ligand from NO(g) or NO^+.

5. Experimental

5.1. Materials

Silver tetrafluoroborate (99%) and 60% hexafluorophosphoric acid were from Acros; nitrosonium tetrafluoroborate was from Aldrich; 97.6% sodium nitrite was from Fisher; 50% *R*-(−)-α-phellandrene was from Fluka Chemika; silver nitrate was from Mallinckrodt; $RuCl_3 \cdot 3H_2O$, 99.5% ammonium hexafluorophosphate, 98% sodium tetrafluoroborate and 99% silver perchlorate monohydrate were from Strem Chemical. All chemicals were used without further purification.

^{1}H NMR spectra were obtained on a Varian Unity Plus 500 MHz spectrometer, and all spectra were referenced to tetramethyl silane. UV–Vis spectra were recorded using a HP845 diode array instrument with Teflon-stoppered quartz cells having a 1.0-cm path length. IR spectra were obtained using a Perkin-Elmer FT-IR spectrometer. Elemental analyses were carried out by Desert Analytics, Tucson, AZ. The irradiation study was carried out using a 300-W Xe lamp.

All electrochemical experiments were performed with a Bioanalytical Systems (BAS) model CV50-W electrochemical analyzer. Cyclic voltammetry (CV) was performed at 20 ± 3°C with a normal three-electrode configuration consisting of a highly polished glassy-carbon working electrode and an AgCl/Ag reference electrode containing 1.0 M KCl. The working compartment of the electrochemical cell was separated from the reference compartment by a modified Luggin capillary. All three compartments contained a 0.1 M solution of supporting electrolyte. Acetonitrile (Burdick and Jackson) was distilled from CaH_2 before use. Tetrabutylammonium hexafluorophosphate ($TBA^+PF_6^-$, from Southwest Analytical) was used as received.

5.2. Preparations

$Ru_2Cl_4(\eta^6$-*p*-cymene$)_2$ [28] and 2,2′-(1*H*-pyrazole-3,5-diyl)bis(6-methylpyridine) (6,6′-Me_2dppzH) [25–27] were synthesized according to literature procedures.

Caution: perchlorate salts are potentially explosive and should be handled with proper precautions.

*5.2.1. [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2Cl_2$](PF_6) (1)*

$Ru_2Cl_4(\eta^6$-*p*-cymene$)_2$ (0.245 g, 0.400 mmol) and 2-Me_2dppz (0.100 g, 0.400 mmol) were refluxed under a nitrogen atmosphere with magnetic stirring for 60 h in 50 ml of 95% ethanol. The solvent was removed by rotary evaporation. The orange residue was dissolved in 20 ml of absolute ethanol, added to 10 equivalents of 99.5% NH_4PF_6 (0.655 g, 4.000 mmol), and stirred for 30 min. The mixture was cooled in an ice bath, and the orange microcrystalline precipitate was collected on a sintered-glass funnel. The solid was washed with 2-propanol and dried with diethyl ether. Recrystallization was accomplished by slowly cooling a hot acetone–2-propanol solution of the compound. Yield: 0.337 g, 90%. ^{1}H NMR [$(CD_3)_2CO$]: δ = 8.03 (apparent t, $^3J_{(HH)}$ = $^3J_{(HH)}$ = 7.5 Hz, 2H, H2), 7.89 (unresolved dd, $^3J_{(HH)}$ = 7.5 Hz, 2H, H1), 7.75 (s, 1H, H4), 7.57 (unresolved dd, $^3J_{(HH)}$ = 7.5 Hz, 2H, H3), 6.64 (unresolved dd, $^3J_{(HH)}$ = 6.0 Hz, 2H, cymene ring H), 6.20 (unresolved dd, $^3J_{(HH)}$ = 6.0 Hz, 2H, cymene ring H), 6.12 (unresolved dd, $^3J_{(HH)}$ = 6.0 Hz, 2H, cymene ring H), 5.80 (unresolved dd, $^3J_{(HH)}$ = 6.0

Hz, 2H, cymene ring H), 3.26 (s, 6H, H5), 2.64 (s, 6H, H11), 1.96 (apparent septet, $^3J_{(HH)} = {}^3J_{(HH)} = 7.0$ Hz, 2H, H6), 0.69 (d, $^3J_{(HH)} = 7.0$ Hz, 6H, cymene isopropyl H), 0.59 (d, $^3J_{(HH)} = 7.0$ Hz, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} cm^{-1})] (in CH_3OH): 430 (2.2×10^3), 327 (2.3×10^4). $C_{35}H_{41}Cl_2F_6N_4PRu_2\cdot 0.5C_8H_{18}O$ (1007.85): Calc. C, 46.77; H, 5.05; N, 5.60. Found: C, 47.01; H, 4.97; N, 6.02%.

*5.2.2. [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$(NO_3)$_2$](PF_6) (**2**)*

[Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2Cl_2$](PF_6) (0.100 g, 0.107 mmol) and 10 equivalents of $AgNO_3$ (0.364 g, 2.140 mmol) were refluxed under a nitrogen atmosphere with magnetic stirring for 72 h in 50 ml of acetone–water (4:1, v/v). The yellow–gray solution was filtered over Celite, and the filtrate was evaporated to dryness. The yellow residue was dissolved in dichloromethane and filtered over Celite to remove insoluble materials. The filtrate was evaporated to dryness. The residue was dissolved in 10 ml of methanol and added to 10 equivalents of 99.5% NH_4PF_6 (0.175 g, 1.070 mmol). The methanol was removed by rotary evaporation, the residue was dissolved in dichloromethane, and the mixture was filtered. To the filtrate was added 20 ml of 2-propanol, and the solution was reduced in volume to remove the dichloromethane. The mixture was cooled in an ice bath. The yellow precipitate was collected on a sintered-glass funnel, washed with cold 2-propanol, and dried with diethyl ether. Yield: 0.0836 g, 79%. ^{1}H NMR [$(CD_3)_2CO$]: $\delta = 8.09$ (apparent t, $^3J_{(HH)} = {}^3J_{(HH)} = 7.5$ Hz, 2H, H2), 7.94 (unresolved dd, $^3J_{(HH)} = 7.5$ Hz, 2H, H1), 7.81 (s, 1H, H4), 7.66 (dd, $^3J_{(HH)} = 7.5$ Hz, 2H, H3), 6.45 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 6.28 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 6.17 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 6.10 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 3.41 (s, 6H, H5), 2.51 (unresolved dq, 6H, H11), 0.78 (unresolved d, 6H, cymene isopropyl H), 0.66 (unresolved d, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} m^{-1})] (in CH_3OH): 425 (1.8×10^3), 319 (2.2×10^4). IR [29] (KBr): $\nu_{as}(NO_2) = 1484$ cm^{-1} (s), $\nu_s(NO_2) = 1271$ cm^{-1} (vs), $\nu(NO) = 842$ cm^{-1} (vs) (m). $C_{38}H_{46}F_6N_6O_7Cl_5PRu_2\cdot(CH_3)_2CO\cdot CHCl_3\cdot CH_2Cl_2$ (1223.18): Calc.: C, 37.3; H, 3.8; N, 6.9. Found: C, 37.07; H, 4.25; N, 6.33%.

*5.2.3. [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$(H_2O)$_2$](BF_4)$_3$ (**3**)*

This complex was prepared by the analogous procedure of Gerli et al. [6]. [Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$-$(Cl)_2$](PF_6) (0.100 g, 0.107 mmol) and 10 equivalents of 99% $AgBF_4$ (0.421 g, 2.140 mmol) were refluxed under a nitrogen atmosphere with magnetic stirring for 72 h in 50 ml of acetone–water (4:1, v/v). The gray solution was filtered over Celite, and the solvent was removed by rotary evaporation at 30°C. The yellow–gray residue was dissolved in 20 ml of methanol, added to 10-fold excess of 98% $NaBF_4$ (0.360 g, 3.210 mmol) and evaporated to dryness. The residue was dissolved in CH_2Cl_2 and filtered over Celite to remove insoluble materials. The filtrate was added to 20 ml of 2-propanol, and the solution was reduced in volume to remove the CH_2Cl_2. To the mixture was added 30 ml of diethyl ether, and the flask was stored at 0°C for 30 min. The light yellow solid was collected on a sintered-glass funnel and dried with diethyl ether. Yield: 0.0912 g, 84%. ^{1}H NMR (D_2O): $\delta = 8.09$ (apparent t, $^3J_{(HH)} = {}^3J_{(HH)} = 8.0$ Hz, 2H, H2), 7.91 (unresolved dd, $^3J_{(HH)} = 8.0$ Hz, 2H, pyridyl H), 7.68 (unresolved dd, $^3J_{(HH)} = 8.0$ Hz, 2H, pyridyl H), 7.65 (s, 1H, H4), 6.29 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 6.18 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 6.15 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 5.67 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, cymene ring H), 3.28 (s, 6H, H5), 2.63 (s, 6H, H11), 1.80 (unresolved dq, 2H, H6), 0.73 (unresolved d, 6H, cymene isopropyl H), 0.60 (unresolved d, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} cm^{-1})] (in CH_3OH): 407 (2.6×10^3), 322 (2.0×10^4). $C_{35}H_{45}Cl_3N_4O_{14}Ru_2$ (1054.25): Calc.: C, 39.87; H, 4.30; N, 5.31. Found: C, 39.98; H, 4.75; N, 5.20%. The above compound as a perchlorate salt has also been prepared by an analogous procedure with $AgClO_4\cdot H_2O$.

*5.2.4. [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$(NO_2)$_2$](PF_6) (**4**)*

[Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2Cl_2$](PF_6) (0.100 g, 0.107 mmol) and 10 equivalents of 99% $AgBF_4$ (0.421 g, 2.140 mmol) were refluxed under a nitrogen atmosphere with magnetic stirring for 72 h in 50 ml of acetone–water (4:1, v/v). The yellow–brown solution was filtered over Celite, and the solvent was removed by rotary evaporation at 30°C. The yellow–gray residue was dissolved in 40 ml of acetone and filtered over Celite to remove insoluble materials. The yellow solution was added to 10 equivalents of $NaNO_2$ (0.151 g, 2.14 mmol) dissolved in 10 ml of water. The solution was refluxed under a nitrogen atmosphere with magnetic stirring for 48 h. The yellow–gray solution was filtered over Celite, and the solvent was removed by rotary evaporation. The yellow residue was dissolved in dichloromethane and filtered over Celite to remove insoluble materials. The filtrate was evaporated to dryness, and the residue was dissolved in methanol and added to 10 equivalents of 99.5% NH_4PF_6 (0.175 g, 1.070 mmol). The methanol was removed by rotary evaporation. The residue was dissolved in dichloromethane and filtered. To the filtrate was added 20 ml of 2-propanol, and the dichloromethane was removed by rotary evaporation. The yellow precipitate was collected on a sintered-glass funnel. The solid was washed with cold 2-propanol and dried with diethyl ether. Yield: 0.0879 g, 86%. ^{1}H NMR [$(CD_3)_2CO$]: $\delta = 8.07$ (apparent t, $^3J_{(HH)} = {}^3J_{(HH)} = 8.0$ Hz, 2H, H2), 7.98 (dd, $^3J_{(HH)} = 8.0$ Hz, $^4J_{(HH)} = 1.0$ Hz, 2H, H1), 7.89 (s, 1H, H4), 7.60 (dd, $^3J_{(HH)} = 8.0$ Hz, $^4J_{(HH)} = 1.0$ Hz, 2H, H3), 6.34 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, H9′), 6.16 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, H10), 6.12 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, H10′), 6.03 (unresolved dd, $^3J_{(HH)} = 6.0$ Hz, 2H, H9), 3.10 (s, 6H, H5), 2.71 (s, 6H, H11), 1.85 (unresolved dq, 2H, H6), 0.67 (unre-

solved d, 6H, cymene isopropyl H), 0.57 (unresolved d, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} cm^{-1})] (in CH_3OH): 398 (2.2×10^3), 326 (2.5×10^4). IR [29] (KBr): $\nu_{as}(NO_2)=1367$ cm^{-1} (s), $\nu_s(NO_2)=1311$ cm^{-1} (s), $\delta(ONO)=845$ cm^{-1} (s). $C_{35}H_{41}F_6N_6O_4PRu_2$ (956.85): Calc.: C, 43.93; H, 4.32; N, 8.78. Found: C, 43.88; H, 4.47; N, 8.61%. The above compound as a perchlorate salt has also been prepared by an analogous procedure with $AgClO_4\cdot H_2O$.

*5.2.5. [Ru_2(6,6′-Me_2dppz)(η^6-p-cymene)$_2$(CH_3CN)$_2$](BF_4)$_3$ (**5**)*

[Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$(NO_2)$_2$](PF_6) (0.100 g, 0.105 mmol) was dissolved in 5 ml CH_3CN and 1 ml 60% HPF_6 was added to the solution dropwise. The solution was stirred for 5 min with gentle heating, cooled in an ice bath, and poured into 100 ml of diethyl ether. The precipitate was collected, redissolved in acetone and filtered. The filtrate was evaporated to dryness, and the residue was dissolved in a 5 ml CH_3CN. Diethyl ether was added to the filtrate to precipitate a light-yellow solid. The solid was filtered and washed with diethyl ether. Yield: 0.0699 g, 63%. ^{1}H NMR [$(CD_3)_2CO$]: $\delta=8.06$ (apparent t, $^3J_{(HH)}=$ $^3J_{(HH)}=7.8$ Hz, 2H, H2), 7.97 (dd, $^3J_{(HH)}=7.8$ Hz, $^4J_{(HH)}=1.1$ Hz, 2H, H1), 7.86 (s, 1H, H4), 7.59 (dd, $^3J_{(HH)}=7.8$ Hz, $^4J_{(HH)}=1.1$ Hz, 2H, H3), 6.31 (unresolved dd, $^3J_{(HH)}=6.0$ Hz, 2H, H9′), 6.17 (unresolved dd, $^3J_{(HH)}=6.3$ Hz, 2H, H10), 6.09 (unresolved dd, $^3J_{(HH)}=6.0$ Hz, 2H, H10′), 6.05 (unresolved dd, $^3J_{(HH)}=6.3$ Hz, 2H, H9), 3.11 (s, 6H, H5), 2.72 (s, 6H, H11), 1.91 (unresolved dq, 2H, H6), 0.70 (unresolved d, 6H, cymene isopropyl H), 0.64 (unresolved d, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} cm^{-1})] (in CH_3OH): 400 (2.3×10^3) and 320(2.1×10^4). $C_{39}H_{47}F_{18}N_6P_3Ru_2\cdot CHCl_3$ (1355.97): Calc.: C, 35.39; H, 3.58; N, 6.19. Found: C, 34.96; H, 3.79; N, 6.83%.

*5.2.6. [Ru_2(NO_2-6,6′-Me_2dppz)(η^6-p-cymene)$_2$$Cl_2$]($PF_6$) (**6**)*

[Ru_2(6,6′-Me_2dppz)(η^6-*p*-cymene)$_2$$Cl_2$]($PF_6$) (0.100 g, 0.107 mmol) and 3 equivalents of $NOBF_4$ (0.075 g, 0.642 mmol) were refluxed under a nitrogen atmosphere with magnetic stirring for 5 h in 20 ml of dichloromethane. The yellow solution was rotavapped to dryness, and the residue was dissolved in methanol and added to 10 equivalents of 99.5% NH_4PF_6 (0.175 g, 1.070 mmol). The solution was evaporated to dryness. The residue was dissolved in CH_2Cl_2–acetone and filtered. To the filtrate was added 15 ml of 2-propanol, and the CH_2Cl_2 was removed by rotary evaporation. The solution was cooled and the yellow precipitate was filtered and washed with diethyl ether. Yield: 0.0652 g, 62%. ^{1}H NMR [$(CD_3)_2CO$]: $\delta=8.13$ (apparent t, $^3J_{(HH)}=$ $^3J_{(HH)}=8.0$ Hz, 2H, H2), 7.83 (unresolved dd, $^3J_{(HH)}=8.0$ Hz, $^4J_{(HH)}=1.0$ Hz, 2H, pyridyl H), 7.77 (dd, $^3J_{(HH)}=8.0$ Hz, $^4J_{(HH)}=1.0$ Hz, 2H, pyridyl H), 6.48 (unresolved dd, $^3J_{(HH)}=6.0$ Hz, $^4J_{(HH)}=1.3$ Hz, 2H, cymene ring H), 6.43 (unresolved dd, $^3J_{(HH)}=6.0$ Hz, $^4J_{(HH)}=1.3$ Hz, 2H, cymene ring H), 6.26 (unresolved dd, $^3J_{(HH)}=6.0$ Hz, $^4J_{(HH)}=1.3$ Hz, 2H, cymene ring H), 5.83 (dd, $^3J_{(HH)}=6.0$ Hz, $^4J_{(HH)}=1.3$ Hz, 2H, cymene ring H), 3.32 (s, 6H, H5), 2.85 (singlet, 6H, H11), 2.12 (apparent septet, $^3J_{(HH)}=$ $^3J_{(HH)}=7.0$ Hz, 2H, H6), 0.79 (d, $^3J_{(HH)}=7.0$ Hz, 6H, cymene isopropyl H), 0.66 (d, $^3J_{(HH)}=7.0$ Hz, 6H, cymene isopropyl H). UV–Vis [λ_{max} (nm), ε_{max} (dm^3 mol^{-1} cm^{-1})] (in CH_3OH): 407 shoulder (4.5×10^3), 317 shoulder (1.5×10^4), 302 (1.9×10^4). $C_{38}H_{46}Cl_2F_6N_5O_3PRu_2\cdot0.5C_3H_6O$ (1019.77): Calc.: C, 43.90; H, 4.47; N, 6.73. Found: C, 44.38; H, 4.30; N, 7.29%.

5.3. X-ray structure and solution

Crystals were grown by slow diffusion of di-n-butyl ether into an acetone solution of compound **1**, **2** or **5**, a 2-butanone solution of compound **3** or **4** or a dichloromethane solution of compound **6**. Suitable crystals were coated with epoxy cement, mounted on a glass fiber and placed on the goniometer of a Siemens P4 diffractometer. Unit cell parameters were determined by least-squares analysis of 40 reflections with $5.15°<\theta<12.45°$ for compound **1**, 42 reflections with $4.8°<\theta<12.5°$ for compound **2**, 28 reflections with $4.83°<\theta<12.54°$ for compound **3**, 27 reflections with $5.33°<\theta<12.47°$ for compound **4**, 47 reflections with $4.83°<\theta<12.5°$ for compound **5** and 28 reflections with $4.83°<\theta<12.54°$ for compound **6**. A total of 6268 reflections were collected between $3.5°<2\theta<45°$ yielding 5054 unique reflections ($R_{int}=0.0603$) for compound **1**, while for compound **2** 6999 reflections were collected with $3.5°<2\theta<45.0°$, producing 5729 ($R_{int}=0.0327$) unique data. For compound **3**, 5497 reflections were collected with $3.5°<2\theta<45.0°$, yielding 4568 unique reflections ($R_{int}=0.0384$), and for compound **4** 8095 reflections were collected, generating 6873 unique ($R_{int}=0.0438$) reflections with $3.5°<2\theta<50.0°$. A total 10 538 data were collected for compound **5** with $3.5°<2\theta<50.0°$, producing 8784 unique data ($R_{int}=0.0571$), and 6365 data were collected with $3.5°<2\theta<45.0°$ for compound **6**, yielding 5167 unique data ($R_{int}=0.0343$).

The data were corrected for Lorentz and polarization effects. Crystal data are given in Table 4. Scattering factors and corrections for anomalous dispersion were taken from a standard source [41].

Calculations were performed using Siemens SHELXTL PLUS, version 5.03, system of programs refining on F^2. The structures were solved by direct methods. Each complex contained a positionally disordered counterion typical of room temperature structures. Simple models of all of this disorder provided satisfactory refinements. Each structure contains a solvent of crystallization. Complex **1** contains one-half of a methanol solvate, while complexes **2**, **4** and **5** each contain one-half of an acetone molecule. Complex **3** contains a methyl ethyl ketone solvate. Complex **6** contains one-quarter of a dichloromethane solvate. An absorption correction was applied using an empirical model derived from ψ scans.

Abstract

The *cis*-[Rh(CO)$_2$(2-picoline)$_2$](PF$_6$) complex is active for the catalytic reduction of nitrobenzene to aniline in aqueous 2-picoline solution under water gas shift reaction conditions. The catalytic activities for this system were studied as functions of the reaction parameters (P(CO), [Rh]$_{tot}$, and T). The nitrobenzene reduction rate displays a first-order dependence on CO pressure, P(CO), over the range 0–1.9 atm at 80, 100 and 120°C. The kinetics behavior with respect to P(CO) leads to the proposal that addition of CO to the catalytic species precedes the rate-limiting step. The catalytic activity proved to be non-linear in total rhodium concentration, [Rh]$_{tot}$, over the range 5–60 mM. This observation was interpreted in terms of the presence of active mononuclear and polynuclear rhodium species in the system, the mononuclear species being the more active for nitrobenzene reduction. In situ FT-IR spectroscopic study confirms the presence of rhodium species with terminal and bridging carbonyls. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Nitrobenzene catalytic reduction; Rhodium complexes; 2-picoline; Water gas shift reaction

1. Introduction

The reduction of nitroarenes catalyzed by transition metal complexes under CO/H$_2$O (Eq. (1)) has been reported in the literature [1–14]. This reaction has been proposed to proceed via a multi-step catalytic scheme [15]. However, a detailed kinetics study has not yet been carried out.

$$\text{R-NO}_2 + 3\text{CO} + \text{H}_2\text{O} \rightarrow \text{R-NH}_2 + 3\text{CO}_2 \quad (1)$$

The rhodium(I) complexes of *cis*-[Rh(CO)$_2$(amine)$_2$](PF$_6$) (amine = 4-picoline, 2-picoline, pyridine, or 2,6-lutidine) in aqueous amine, 2/8, v/v, [Rh] = 10 mM, and P(CO) = 0.9 atm at 100°C catalyzed the water gas shift reaction [16] (WGSR, Eq. (2)). Proposed mechanisms for these systems involve the formation of rhodium hydride intermediates (Rh-H), which were confirmed by in situ ^{1}H NMR spectroscopic studies. So, it should be possible to intercept this Rh-H species by reaction with nitrobenzene to generate rhodium nitrobenzene intermediates. Under WGSR conditions, the latter would expect to react further to give aniline.

$$\text{CO} + \text{H}_2\text{O} \rightleftarrows \text{CO}_2 + \text{H}_2 \quad (2)$$

Furthermore, research in our group [14] demonstrated the selective reduction of nitrobenzene to aniline by rhodium(I) complexes, *cis*-[Rh(CO)$_2$(amine)$_2$](PF$_6$) (amine = 4-picoline, 3-picoline, 2-picoline, pyridine, 3,5-lutidine or 2,6-lutidine), dissolved in aqueous amine, under WGSR conditions. In addition, the role of amine was examined and the formation of aniline (yield in mmol, after 3 h) followed the order 2-picoline (0.52) > 2,6-lutidine (0.46) > 3,5-lutidine (0.44) > 3-picoline (0.35) > 4-picoline (0.13) > pyridine (0.08). Reaction conditions were as follows: 10 ml of amine/H$_2$O, 2/8, v/v, 0.26 ml of nitrobenzene (2.5×10^{-3} mol), [Rh] = 10 mM, and P(CO) = 0.9 atm at 100°C.

In this report, quantitative studies are described on the effect of variation of the carbon monoxide pressure $P(CO)$, rhodium concentration [Rh], and temperature T on the reduction of nitrobenzene to aniline catalyzed by *cis*-$[Rh(CO)_2(2\text{-picoline})_2](PF_6)$ dissolved in aqueous 2-picoline under water gas shift reaction conditions. Also, these data are discussed in terms of a possible mechanism.

2. Experimental

2.1. Materials

2-Picoline (2-pic) was obtained from Aldrich and distilled from KOH. Nitrobenzene (RNO_2) was distilled in H_2SO_4 (1 M) and redistilled in $CaCl_2$ before use. Double distilled water was used for the preparation of solutions. The gas mixtures CO/CH_4 (95.8/4.2%, v/v), He/H_2 (91.4/8.6%) and $CO/CH_4/CO_2/H_2$ (84.8/5.1/5.3/4.8%, v/v) were purchased from BOC Gases. *Cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ was prepared by the method reported by Denise and Pannetier [17].

2.2. Instrumentation

Infrared spectra were recorded on a Perkin-Elmer 1760X-FT spectrophotometer. Analyses of gas samples from kinetics runs were performed as described previously [18] on a Hewlett-Packard 5890 series II programmable (ChemStation) gas chromatograph (GC) fitted with a thermal conductivity detector. The column used was Carbosieve-B (80-100) mesh obtained from Hewlett-Packard. The column temperature was programmed from 60–175°C at a flow rate of 50 $ml \cdot min^{-1}$ using a He/H_2 mixture as the carrier gas. Calibration curves were prepared periodically for H_2, CO, CO_2, and CH_4. The individual analyses were found to be accurate and reproducible to within less than 10%.

Liquid phase reaction products were analyzed using a Hewlett-Packard 5890 series II programmable gas chromatograph fitted with 3% OV-10N Supelcoport (mesh 80-100) column and flame ionization detector using *ortho*-xylene as an internal standard, and identified by co-injection on a Hewlett-Packard 5890 series II programmable gas chromatograph-mass spectrometer fitted with Pona capillary column (50 m).

2.3. Batch reactor procedures

Kinetics runs were conducted in an all-glass reactor vessel described in detail in a previous publication [18]. In a typical kinetics experiment, a given amount (typically 0.1 mmol) of *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ and 10 ml of 80% aqueous 2-picoline were added to the glass reactor vessel, then the solution was degassed by three freeze–pump–thaw cycles. The reaction vessel was charged with CO/CH_4 mixture at the desired CO partial pressure (typically 0.9 atm), then suspended in a circulating thermostated glycerol oil bath set at a desired temperature (typically 100°C). The specified reaction temperatures were maintained at ± 0.5°C by continuous stirring of the oil bath and the reaction mixture which was provided with a Teflon-coated magnetic stirring bar.

After reaching a constant WGSR activity [16], a given amount (typically 0.26 ml, 2.4×10^{-3} mol) of nitrobenzene was added to the reaction vessel. Subsequent to addition of nitrobenzene, the glass reactor vessel was charged with CO/CH_4 at the desired CO pressure and placed in the heated oil bath for a given time and at a given temperature. At the end of the desired reaction time, gas samples (1.0 ml) were removed from the reactor vessel in a manner similar to that described previously for the WGSR catalytic test [16] and analyzed by GC. Also, liquid samples were removed and analyzed by GC and GC-MS. The CH_4 was used as internal standard to allow calculation of absolute quantities of CO consumed and CO_2 produced, during a time interval. In addition, calibration curves were prepared periodically for CO, CH_4, H_2, and CO_2, and their validities were checked by analyzing known gas mixtures.

3. Results and discussion

3.1. Catalysis study of the nitrobenzene reduction

The rhodium(I) complex *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ in 80% aqueous 2-picoline generates a system that shows higher catalytic activity for nitrobenzene reduction than those found for the other ligand and solvent systems studied (pyridine, 4-picoline, 3-picoline, 2,6-lutidine or 3,5-lutidine) under the same reaction conditions. Also, the effect of varying the ratio $[RNO_2]/[Rh]$ was examined in the range 2500 to 25 at $P(CO) = 0.9$ atm and $T = 100$°C and the reaction rate was found to be almost independent of the initial concentration of nitrobenzene within this range [14]. Furthermore, aniline formation (the only organic product detected by analyzing the catalysis liquid phase) and CO_2 formation (the only gas product detected by analyzing the catalysis gas phase) were equal stoichiometrically (within experimental uncertainty) as required by Eq. (1) [14]. For example, analyses of liquid samples using *ortho*-xylene as internal standard were carried out to check the consistency of these results and showed that there was no statistically significant difference between both GC methods for a confidence level of 95% [19].

Control experiments show catalytic inactivity toward both WGSR and nitrobenzene reduction when 10 ml of 80% aqueous 2-picoline solution under $P(CO) = 0.9$ atm at 100°C for 3 h is tested in the absence of the *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ complex. Also, this Rh/2-pic catalytic system exhibits no WGSR activity (i.e. no molecular hydrogen is formed) in the presence of nitrobenzene. Fig. 1 shows a plot of turnover number (moles aniline/moles Rh) versus reaction time for $[Rh] = 10$ mM and $P(CO) = 0.9$ atm at 100°C.

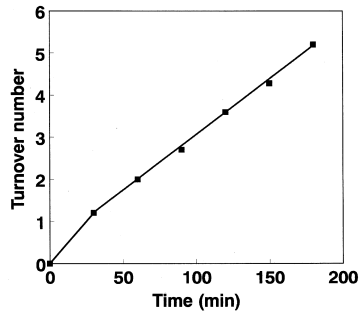

Fig. 1. Plot of turnover number (mol aniline formed/mol Rh) vs. reaction time. Reaction conditions: 0.26 ml of nitrobenzene, [Rh] = 10 mM, [nitrobenzene]/[Rh] = 25, $P(CO) = 0.9$ atm, at 100°C and 10 ml of 2-picoline/water, 8/2, v/v. (Line drawn for illustrative purposes only).

The total turnover as a function of time increased from 1.2 (5% conversion) at 30 min to 5.2 (20% conversion) at 3 h.

3.2. FT-IR characterization

The FT-IR spectrum of an active Rh/2-pic catalyst solution ([Rh] = 100 mM), in the presence of nitrobenzene, after being exposed to CO (0.9 atm) and heated at 100°C for 1 h, displays six bands in the ν_{CO} region at 2083(m), 2009(s), 1998(s), 1990(vs), 1964(m, sh), 1932(m) cm^{-1} characteristic of CO coordinated terminally to Rh, and one band at 1813(s) cm^{-1} characteristic of bridging CO.

Furthermore, the IR spectrum, both in pyridine solution and in the solid state, of the well characterized polynuclear anionic rhodium(−I), $[Rh_5(CO)_{13}(py)_2]^-$ complex shows five bands in the CO stretching region at 2040(m), 2011(m), 1980(vs) 1818(m), and 1756(m) cm^{-1}. The X-ray structure of this compound shows five Rh atoms at the vertices of a trigonal bipyramid, seven terminal and six edge-bridging carbonyls and two coordinated pyridine molecules to one Rh [20]. In addition, Fachinetti et al. [21] demonstrated that this complex was accumulated during catalysis of the WGSR by *cis*-$[Rh(CO)_2(py)_2](PF_6)$ or $RhCl_3 \cdot 3H_2O$/80% aqueous pyridine systems.

On the other hand, the solid state IR spectrum of mononuclear cationic rhodium(I), *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ complex presents two bands in the CO stretching region at 2080(s) and 2010(s) cm^{-1} characteristic of CO coordinated terminally to Rh(I) [17]. Also, the solid state IR spectrum of rhodium(I), $[Rh(CO)(py)_3](PF_6)$ complex presents one band in the CO stretching region at 1993 cm^{-1} characteristic of a CO coordinated terminally to Rh(I) [20].

Thus, based on analysis of the number as well as the position of the CO stretching bands of the Rh/2-pic catalytic active solution, we suggest the presence of mononuclear cationic *cis*-$[Rh(CO)_2(2\text{-pic})_2]^+$ (bands at 2083 and 2009 cm^{-1}), $[Rh(CO)(2\text{-pic})_3]^+$ (band at 1998 cm^{-1}) and polynuclear anionic rhodium(−I) complexes of the type $[Rh_5(CO)_x(2\text{-pic})_y]^-$ (bands at 1990, 1964, 1932, and 1814 cm^{-1}) with bridging carbonyls as reaction intermediates. These assignments are consistent with the reported results of Fachinetti et al. [20,21] and Denise and Pannetier [17].

3.3. Kinetics study of the nitrobenzene reduction

For this highly active Rh/2-pic system the effects of varying the carbon monoxide pressure $P(CO)$, the rhodium concentration [Rh], and the temperature T on the nitrobenzene reduction were explored. Owing to simplicity and speed of analysis of gaseous samples, TF(aniline) kinetics data reported in Tables 1 and 2 and Figs. 2–4 are based on CO_2 production. These were confirmed periodically by analyzing the liquid phase. The results of Table 1 represent the average value of duplicate runs performed under identical experimental conditions. The calculated kinetics activity defined as TF(aniline) (TF(aniline) = mol aniline (mol Rh 24 h)$^{-1}$) was reproducible to within less than 10% for a series of experimental runs. In addition, the TF(aniline) for the kinetics runs were determined for short periods (3 h or less) where $P(CO)$, $[H_2O]$ and [nitrobenzene] were essentially constant, diminishing by less than 20% overall. Hence, possible shifts in $P(CO)$-, $[H_2O]$- and [nitrobenzene]-dependent equilibria among the catalyst component during a run were minimized owing to the near constancy of $P(CO)$, $[H_2O]$ and [nitrobenzene]. On the other hand, the highest value

[b] Yield of CO_2 formed after 3 h or less of continuous heating in order to keep the conversion less than 20%.
[c] Selectivity > 99%. Based on CO_2 formed.
[d] TF(aniline) = mol aniline (mol Rh 24 h)$^{-1}$. Experimental uncertainty < 10%.
[e] $P(CO) = 1.9$ atm.

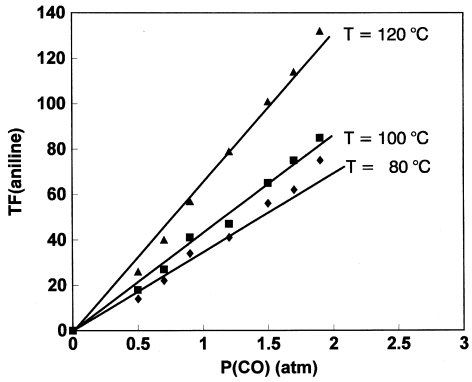

Fig. 2. Effect of carbon monoxide pressure. Reaction conditions: 0.26 ml of nitrobenzene, [Rh] = 10 mM, [nitrobenzene]/[Rh] = 25, at T = 80, 100 and 120°C and 10 ml of 2-picoline/water, 8/2, v/v. (Lines drawn for illustrative purposes only).

TF(aniline) = 200 day^{-1} (89% conversion) was achieved under optimal conditions, e.g. [Rh] = 5 mM, $P(CO) = 1.9$ atm at 130°C for 3 h (Table 2).

3.3.1. Effect of carbon monoxide pressure

Fig. 2 is a plot of TF(aniline) versus $P(CO)$ for [Rh] = 10 mM at 80, 100 and 120°C (Table 1). A linear dependence of TF(aniline) on $P(CO)$ variation in the range of the study was noted, indicating that the reaction is first order in [CO]. In addition, this was confirmed by plotting log TF(aniline) versus log $P(CO)$ in which slopes with values of 1.2, 1.1 and 1.2 were observed at 80, 100 and 120°C, respectively. This clearly establishes a first-order dependence on $P(CO)$ in the range 0–1.9 atm. Similar first-order [CO] behavior was reported in the catalysis of the WGSR by Baker et al. [22] and by Pardey and Ford [16].

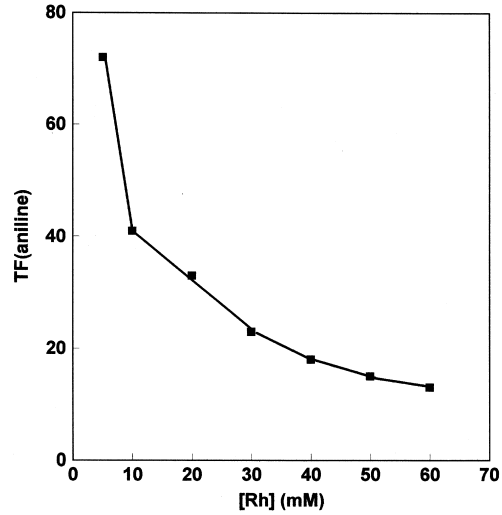

Fig. 3. Effect of rhodium concentration. Reaction conditions: 0.13–1.56 ml of nitrobenzene, [nitrobenzene]/[Rh] = 25, $P(CO) = 0.9$ atm at 100°C and 10 ml of 2-picoline/water, 8/2, v/v. (Line drawn for illustrative purposes only).

Based on the first order in [CO] we suggest a possible mechanism in that the rate-limiting step (k_2) is preceded by coordination of CO, e.g.

$$[RNO_2\text{-Rh}]^+ + CO \overset{k_1}{\rightarrow} [RNO_2\text{-Rh-CO}]^+ \overset{k_2}{\rightarrow} [Rh]^+ + \text{products} \quad (3)$$

The rate law ($r_{aniline}$) for such behavior would be:

$$r_{aniline} = k_1 k_2 P(CO)[Rh]_{tot} \quad (4)$$

where $[Rh]_{tot} = [RNO_2\text{-Rh}]^+ + [RNO_2\text{-Rh-CO}]^+$ and k_1

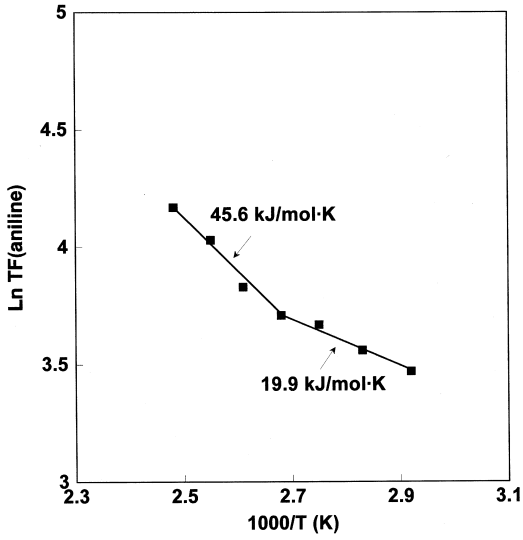

Fig. 4. Arrhenius plot for nitrobenzene reduction. Reaction conditions: 0.26 ml of nitrobenzene, [Rh] = 10 mM, [nitrobenzene]/[Rh] = 25, $P(CO) = 0.9$ atm and 10 ml of 2-picoline/water, 8/2, v/v.

includes $[RNO_2]$ and the solubility of CO in the medium. The above expression (Eq. (4)) can be reduced to:

$$TF(\text{aniline}) = k_1 k_2 P(CO) \quad (5)$$

For this kinetics model, plots of *TF*(aniline) versus $P(CO)$ should be linear with slopes of k_1k_2 and zero intercept. Indeed, these plots are linear at 80, 100 and 120°C with nearly zero intercept value as predicted by Eq. (5).

3.3.2. Effect of rhodium concentration

Runs were carried out for a series of different rhodium concentrations over the range 5–60 mM. The amount of nitrobenzene was varied from 0.13 at [Rh] = 5 mM to 1.56 ml at [Rh] = 60 mM in order to keep the ratio [nitrobenzene]/[Rh] = 25 in all runs (Table 2).

A typical kinetics run involved determining the reaction rate defined as turnover frequency *TF*(aniline) as a function of [Rh] under $P(CO) = 0.9$ atm at 100°C. Fig. 3 is a plot of the *TF*(aniline) values versus [Rh]. An increase in [Rh] from 5 to 40 mM resulted in a decrease in *TF*(aniline), followed by nearly constant values at higher [Rh]. The results indicate that the reaction rate is not first order in the [Rh] range 5–60 mM, and suggest that the active species may be present in several forms having different nuclearities (mononuclear and polynuclear) with mononuclear species being the more active. This suggestion is strongly supported by the in situ FT-IR data discussed above and by similar results reported for the homogeneous WGSR catalysts *cis*-$[Rh(CO)_2(4\text{-pic})_2](PF_6)$ and $RhCl_3 \cdot 3H_2O$ both dissolved in aqueous 4-picoline. The dependence of the rates on [Rh] complex in both batch [16] and continuous flow reactors [23] suggested the presence of at least two different active species in solution; in situ ^{13}C NMR and IR spectral analyses were consistent with this explanation. Based on their results, Ford and co-workers concluded that the active species were mononuclear and polynuclear in equilibrium, where the mononuclear species showed a higher activity. Furthermore, Fachinetti et al. in their study of WGSR catalysis by *cis*-$[Rh(CO)_2(py)_2](PF_6)$ and $RhCl_3 \cdot 3H_2O$, both dissolved in aqueous pyridine, proposed a catalytic cycle where the mononuclear *cis*-$[Rh(CO)_2(py)_2]^+$ and the polynuclear $[Rh_5(CO)_{13}(py)_2]^-$ are the active species [21].

3.3.3. Effect of temperature

In order to determine the activation parameters for the reduction of nitrobenzene catalyzed by *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ in 80% aqueous 2-picoline, *TF*(aniline) values were measured at various temperatures (Table 2). Fig. 4 displays a plot of ln *TF*(aniline) versus $1/T$ for [Rh] = 10 mM at $P(CO) = 0.9$ atm. This Arrhenius plot is concave in the 70–130°C range and can be fitted with two curves. A lower activation energy ($E_{a1} = 19.9$ kJ mol^{-1} K^{-1}) was calculated at temperatures below 100°C; temperatures greater than 100°C gave a higher energy ($E_{a2} = 45.6$ kJ mol^{-1} K^{-1}). Arrhenius plots which are concave upwards suggest a change in the rate-limiting step between two competitive reaction pathways, with the reaction path with the higher activation energy being favored at high temperatures and the reaction path with the lower activation energy being predominant at low temperatures [24].

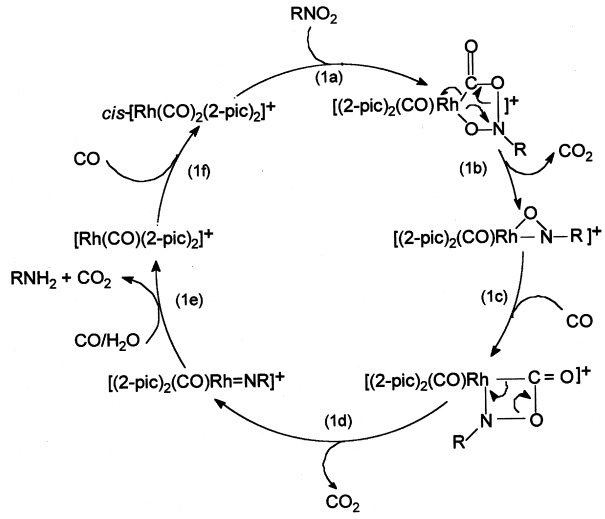
It was suggested from the rhodium concentration studies that an equilibrium between the two kinds of rhodium active species, mononuclear and polynuclear, was established under the reaction conditions. It can also be envisioned that upwards segmentation of the Arrhenius plot could result when the nitrobenzene reduction is catalyzed by both mononuclear and polynuclear rhodium species with different activation energy pathways, as observed in the present study. If the polynuclear species are favored at low temperatures, a possible explanation is that E_{a1} represents the catalytic pathway with these species at low temperatures.

Non-linear Arrhenius plots similar to that reported here have previously been observed for the WGSR catalyzed by $RhCl_3 \cdot 3H_2O$ in 80% aqueous 4-picoline [20]. Recently Ford and co-workers [25] reported the hydrogenation and hydroformylation of alkenes catalyzed by polymer-anchored rhodium complexes under WGSR conditions. The temperature dependence also follows a segmented Arrhenius plot.

Furthermore, other factors such as variation in the oxidation state of these rhodium complexes may be responsible for curvatures in the Arrhenius plot. For example, the rate-limiting step of catalysis between these two competitive cationic mononuclear Rh and anionic polynuclear Rh complexes may not be the same owing to the different charge of these complexes [26].

3.4. Mechanistic consideration

The evaluation of the mechanism for aniline formation by solutions prepared from *cis*-$[Rh(CO)_2(2\text{-pic})_2](PF_6)$ in 80% aqueous 2-picoline and nitrobenzene in CO shows some



key features. First, aniline was the only organic product detected. Second, IR spectroscopy studies of the catalytic solution point to the presence of both cationic mononuclear and anionic polynuclear rhodium complexes as the predominant species. Third, kinetics study indicates that the reaction is first order in [CO] and pseudo-first order in [RNO_2]. Fourth, the rhodium concentration and temperature studies suggest a mononuclear–polynuclear equilibrium between active rhodium species, under nitrobenzene reduction conditions. Fifth, catalytic schemes for the reduction of nitrobenzene to aniline have been proposed in which nitrobenzene cycloaddition to a metal carbonyl complex is an important first step [15]. In addition, kinetics study related to the reaction between nitroarenes and [Ru(dppe)$(CO)_3$] where dppe = 1,2-bis(diphenylphosphino)ethane show a first-order reaction on each reagent. An intermediate identified as [Ru(dppe)$(CO)_2(\eta^2$-ONR)] was reported [27]. Given the above, the reaction mechanism depicted in Scheme 1 is proposed for the reduction of nitrobenzene to aniline catalyzed by the most active mononuclear Rh species.

In Scheme 1, the cycloaddition (1a) of the nitro group to the Rh–CO bond followed by elimination of CO_2 leads to the formation of rhodium nitrosobenzene [Rh(CO)$(2\text{-pic})_2(\eta^2$-ONR)]$^+$ complex (1b) [27]. Insertion of one CO molecule to the Rh–O bond (1c) forms the [Rh(CO)$(2\text{-pic})_2(\eta^2$-O(CO)NR)]$^+$ complex.

The formation of [Rh(CO)$(2\text{-pic})_2(\eta^2$-O(CO)NR)]$^+$ specie as the rate-limiting step (1c) would rationalize the first-order dependence of *TF*(aniline) on *P*(CO). Decarboxylation of the rhodium [Rh(CO)$(2\text{-pic})_2(\eta^2$-O(CO)-NR)]$^+$ (1d) generates a rhodium-nitrene complex [Rh(CO)$(2\text{-pic})_2$(NR)]$^+$ and CO_2. Hydrogenation (1e) of this rhodium-nitrene species, probably by the Rh-H species formed under conditions similar to the WGSR, affords aniline, CO_2 and the coordinatively unsaturated [Rh(CO)$(2\text{-pic})_2$]$^+$ complex. Coordination of CO to the latter would give the *cis*-[Rh$(CO)_2(2\text{-pic})_2$]$^+$ complex to close the catalytic cycle (1f). An analogous cycle may be proposed for the polynuclear Rh complexes.

4. Conclusions

The following conclusions have been drawn from catalytic studies of the reduction of nitrobenzene by *cis*-[Rh$(CO)_2(2\text{-pic})_2$](PF_6) dissolved in aqueous 2-picoline under conditions analogous to those for the WGSR. The FT-IR and kinetics study of the Rh/(2-pic) system suggest the presence of rhodium carbonyl compounds with different nuclearities and different oxidation state numbers as reaction intermediates. The Rh/(2-pic) system shows a first-order dependence of the rate on *P*(CO) and non-linear dependence of the rate on Rh concentration. Finally the effect of variation of Rh concentration and temperature on catalytic activity can be explained on the basis of the presence of at least two kinds of rhodium species with different nuclearities and oxidation states.

POLYHEDRON

A new synthesis of a potentially versatile ligand 2,2′-bi-(1,10-phenanthroline): crystal structure and complexation chemistry

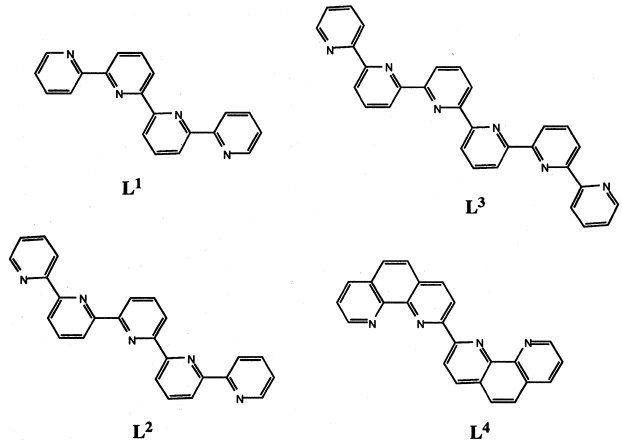
Craig R. Rice *, Kirsty M. Anderson

School of Chemistry, University of Bristol, Cantock's Close, Bristol BS8 1TS, UK

Received 13 September 1999; accepted 3 January 1999

Abstract

Coupling of 2-chloro-1,10-phenanthroline with a source of Ni(0) affords the tetradentate ligand 2,2′-bi-(1,10-phenanthroline). This ligand and a resulting Ni(II) complex were characterised by X-ray crystallography. ©2000 Elsevier Science Ltd All rights reserved.



Keywords: Crystal structures; Complexation chemistry; 1,10-Phenanthroline

1. Introduction

The chemistry of 2,2′:6′2″:6″,2‴-quaterpyridine (**L**^{1}) and its higher analogues such as 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (**L**^{2}) and 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′-sexipyridine (**L**^{3}) have been extensively studied [1]. Unlike their smaller 2,2′-bipyridine and 2,2′:6′,2″-terpyridine [2,3] analogues which form mainly mononuclear complexes, ligands **L**^{1}–**L**^{3} can, under the right conditions, form polynuclear helical complexes [4–8]. Examples of such complexes, which have been examined crystallographically, include $[Cu^{I}_{2}(L^{1})_{2}]$ [9], $[Ag^{I}_{2}(L^{1})_{2}]$ [9], $[Cu^{I}_{2}L^{2}]$ [4–8], $[Ni^{II}Cu^{I}(L^{2})_{2}]$ [10], $[Ni^{II}_{2}(L^{2})_{2}]$ [11] and $[Co^{II}Ag^{I}(L^{2})_{2}]$ [12]. However, one related class of ligand that has been largely ignored is the poly-phenanthrolines. In this paper we describe the synthesis and solid state structure of 2,2′-bi-(1,10-phenathroline) (**L**^{4}) as the free ligand and as a nickel(II) complex.

2. Results and discussion

2,2′-Bi-(1,10-phenanthroline) was first reported by Case in 1964 [13] and was prepared by Ullman coupling of 2-chloro-phenanthroline with copper, although surprisingly no further reports have appeared in the literature. 2,2′-Bi-(1,10-phenanthroline) is a desirable ligand owing to its rigidity and extended π-system and also once formed, the ligand can undergo further reactivity by oxidation of the inter-pyridine ethylene bridge. Herein we describe the preparation of 2,2′-bi-(1,10-phenanthroline) (**L**^{4}) directly from phenanthroline

in four steps (Scheme 1), the final step requiring coupling of 2-chloro-1,10-phenanthroline employing the method of Iyoda et al. [14].

Thus reaction of the chloro derivative (**4**) with a catalytic amount of nickel(0), generated in situ by reaction of $[NiCl_{2}(PPh_{3})_{2}]$ with excess Zn in thf yielded, after refluxing for 24 h, 2,2′-bi-(1,10-phenanthroline) (**L**^{4}) as a crude material which was purified by recrystallisation from chloroform. It is important to note that the final step of coupling 2-chloro-1,10-phenanthroline is highly dependent upon the purity of the chloro-substituted precursor (**4**) and before coupling was attempted, great care had to be taken to remove any remaining halogenated solvent. Furthermore, as long as this purification

PII S0277-5387(00)00292-8

procedure is adhered to, this preparation has proven to be, at least in our hands, more robust than that reported by Case.

The crystal structure of **L⁴** (Fig. 1) as a chloroform solvate shows that the structure is almost planar with an angle of 10.0(2)° between the least-square planes of the two phenanthroline units, thereby maximising the π-bonding. Nitrogens N(2) and N(3) exhibit *transoid* geometries similar to those found in the other polypyridines such as bipyridine [15–17] and quaterpyridine [18]. This conformation is observed as it minimises the nitrogen lone pair–lone pair interactions. However, owing to the constraints of the phenanthroline geometry, nitrogens N(1)–N(2) and N(3)–N(4) necessarily lie mutually *cis* to one another. No π-stacking is observed in the crystal, unlike in quaterpyridine [18], presumably owing to the presence of three chloroform molecules of crystallisation.

Reaction of **L⁴** with 1 equiv. of $NiCl_2 \cdot 6H_2O$, in methanol gave a complex characterised as $[Ni(\mathbf{L^4})Cl(H_2O)]Cl \cdot H_2O$ by X-ray crystallography (Fig. 2). The ligand (**L⁴**) acts in a tetradentate manner with all four nitrogens virtually co-planar (with an angle of 5.6(1)° between the least-square planes of the two phenanthroline units), with the remaining two sites (mutually *trans*) occupied by the chlorine and the water molecules (Ni–Cl 2.419(1) and Ni–O 2.066(3) Å with the Cl–Ni–O angle close to linearity at 172.09(8)°). The internal coordinating site of **L⁴** (N(2)–Ni–N(3) 75.9(1)°, N(2)–Ni 2.026(3), N(3)–Ni 2.020(3) Å) is comparable with that found in the related quaterpyridine compound $[Ni(NCMe)_2(L^1)]^{2+}$ [18] (N(1)–Ni–N(1A) 77.6(2)°, N(1)–Ni

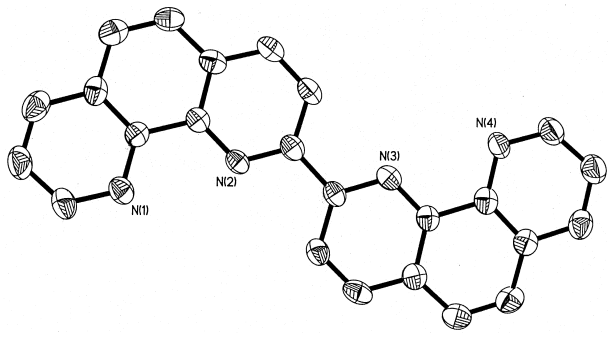

Fig. 1. Molecular structure of **L⁴** (ellipsoids shown at 50% probability).

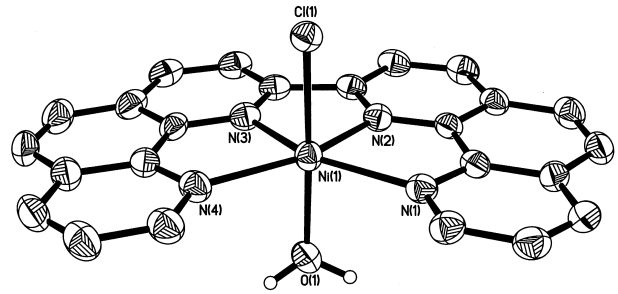

Fig. 2. Molecular structure of the cation $[Ni(\mathbf{L^4})Cl(H_2O)]$ (ellipsoids shown at 50% probability). Selected bond lengths and angles: Ni(1)–N(1) 2.200(3), Ni(1)–N(2) 2.026(3), Ni(1)–N(3) 2.020(3), Ni(1)–N4 2.172(3), Ni(1)–O(1) 2.066(3) and Ni(1)–Cl(1) 2.419(1) Å; N(1)–Ni(1)–N(4) 128.0(1), O(1)–Ni(1)–Cl(1) 172.09(8), N(2)–Ni(1)–N(3) 75.9(1), N(1)–Ni–N(2) 77.4(1), N(3)–Ni(1)–N(4) 78.3(1), N(2)–Ni(1)–N(4) 154.0(1) and N(1)–Ni(1)–N(3) 153.1(1)°.

2.004(3) Å). The two outermost coordination sites N(1) and N(4) have longer Ni–N bonds (N(1)–Ni 2.200(3), N(4)–Ni 2.172(3) Å; c.f. Ni(L^1), N(2)–Ni 2.106(4) Å), similar to that observed for **L¹**, although for **L⁴** the geometry is constrained, unlike that of **L¹** which can, at least in theory, rotate away from the metal centre.

One of the main objectives of the synthesis of 2,2′-bi-(1,10-phenanthroline) was to produce polynuclear helical species as found for the polypyridyls, although all such attempts have so far been fruitless. The inability to form such dinuclear complexes may be a result of the constrained terminal pyridine groups found in **L⁴**, unlike that of **L¹** in which all the pyridine groups can rotate freely. However, molecular modelling [19] of $[Ag_2(\mathbf{L^4})_2]^{2+}$ shows that the corresponding helical complex is only slightly more strained than that of the analogous quaterpyridine helicate $[Ag_2(L^1)_2]^{2+}$, thus indicating that helical complexes of **L⁴** are, at least in principle, feasible.

Further work will focus upon formation of polynuclear helical complexes and derivatising 2,2′-bi-(1,10-phenanthroline) by oxidation of the inter-pyridine ethylene bridge.

3. Experimental

^{1}H NMR spectra were recorded on a JEOL Λ-300 MHz spectrometer. Mass spectra were obtained on a VG-Autospec instrument (EI) and on a VG-Quattro mass spectrometer (ESI). Starting materials were obtained from either Aldrich or Lancaster Synthesis and used without further purification, apart from thf which was distilled from sodium wire under an atmosphere of nitrogen.

3.1. Synthesis

N-methyl-1,10-phenanthrolinium iodide (**2**) [20]. M.p. 209–211°C (lit. 210–213°C [20]). *Anal*. Found: C, 48.9; H, 3.5; N, 9.0. $C_{13}H_{11}N_2I$ requires: C, 48.5; H, 3.4; N, 8.7%. ^{1}H NMR (300 MHz, $(CD_3)_2SO$): δ 9.57 (H^2, dd, 1H, $J^{2,3}=5.9$, $J^{2,4}=1.0$ Hz), 9.38 (H^4, dd, 1H, $J^{4,3}=8.2$, $J^{4,2}=1.0$ Hz),

9.30 (H^9, dd, 1H, $J^{9,8}=4.4$, $J^{9,7}=0.8$ Hz), 8.78 (H^7, dd, 1H, $J^{7,8}=8.2$, $J^{7,9}=0.8$ Hz), 8.42 (H^3, dd, 1H, $J^{3,4}=8.2$, $J^{3,2}=5.9$ Hz), 8.41 (H^5, d, 1H, $J^{5,6}=8.8$ Hz), 8.37 (H^6, d, 1H, $J^{6,5}=8.8$ Hz), 8.04 (H^8, dd, 1H, $J^{8,7}=8.2$, $J^{8,9}=4.4$ Hz), 5.26 (CH_3, s, 3H).

N-Methyl-1,10-phenanthrolin-2(1H)-one (**3**) [20]. To a vigorously stirred solution of $K_3[Fe(CN)_6]$ (7.0 g, 21.2 mmol) in water, solutions of saturated NaOH and *N*-methyl-1,10-phenanthrolinium iodide (2.9 g, 9.0 mmol) in water (10 cm^3) were added dropwise, adding approximately three times the amount of alkali to phenanthroline. It was important to make sure that the *N*-methyl-1,10-phenanthrolinium iodide solution was completely dissolved, which required periodic heating. After addition was complete, the solution was allowed to stir for 45 min after which extraction with CH_2Cl_2 (3×50 cm^3), drying ($MgSO_4$) and solvent removal by vacuum afforded crude *N*-methyl-1,10-phenanthrolin-2(1H)-one as a brown oil. This oil was then dissolved in the minimum amount of hot toluene, treated with decolorising charcoal, filtered and cooled to give pure *N*-methyl-1,10-phenanthrolin-2(1H)-one as yellow crystals. Yield 1.4 g, 74%. M.p. 123–124°C (lit. 120–121°C [20]). *Anal*. Found: C, 74.0; H, 4.4; N, 13.1. $C_{13}H_{10}N_2O$ requires: C, 74.3; H, 4.8; N, 13.3%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.92 (H^9, dd, 1H, $J^{9,8}=4.2$, $J^{9,7}=1.8$ Hz), 8.16 (H^7, dd, 1H, $J^{7,8}=8.3$, $J^{7,9}=1.8$ Hz), 7.75 (H^3, d, 1H, $J^{3,4}=9.1$ Hz), 7.55 (H^5, d, 1H, $J^{5,6}=8.4$ Hz), 7.51 (H^6, d, 1H, $J^{6,5}=8.4$ Hz), 7.48 (H^8, dd, 1H, $J^{8,7}=8.3$, $J^{8,9}=4.2$ Hz), 6.89 (H^4, d, 1H, $J^{4,3}=9.1$ Hz), 4.46 (N–CH_3, s, 3H). Mass spectrum: *m/z* 210 (M^+ 79%).

2-Chloro-1,10-phenanthroline (**4**) [20]. To a suspension of *N*-methyl-1,10-phenanthrolin-2(1H)-one (6.0 g, 28.0 mmol) in $POCl_3$ (54 cm^3), PCl_5 (7.2 g, 34.0 mmol) was added and the reaction refluxed for 8 h. The solvent was then removed by vacuum and ice added carefully and the resulting solution poured onto ammonia solution (0.88 sp.gr., 150 cm^3). Upon addition, a precipitate formed which was isolated by filtration and washed with water (4×10 cm^3). The precipitate was then redissolved in CH_2Cl_2 (30 cm^3) washed with water (2×10 cm^3) and dried ($MgSO_4$). Removal of all the volatiles by vacuum afforded a solid which was then dissolved in the minimum amount of hot toluene, treated with decolorising charcoal, filtered and cooled to give pure title compound as pale yellow crystals. Further purification was achieved by dissolving in the minimum amount of $CHCl_3$ from which large colourless crystals were deposited over a period of a few days. Yield 4.1 g, 68%. M.p. 127–128°C (lit. 129–130°C [20]). *Anal*. Found: C, 67.4; H, 3.3; N, 13.2. $C_{12}H_7N_2Cl$ requires: C, 67.1; H, 3.3; N, 13.0%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 9.26 (H^9, dd, 1H, $J^{9,8}=4.4$, $J^{9,7}=1.7$ Hz), 8.31 (H^7, dd, 1H, $J^{7,8}=8.1$, $J^{7,9}=1.7$ Hz), 8.22 (H^4, d, 1H, $J^{4,3}=8.3$ Hz), 7.85 (H^5, d, 1H, $J^{5,6}=8.8$ Hz), 7.81 (H^6, d, 1H, $J^{6,5}=8.8$ Hz), 7.70 (H^8, dd, 1H, $J^{8,7}=8.1$, $J^{8,9}=4.4$ Hz), 7.65 (H^3, d, 1H, $J^{3,4}=8.3$ Hz). Mass spectrum: *m/z* 214 (M^+ 90%, correct isotope pattern).

2,2′-Bi-(1,10-phenanthroline) (**L^4**). To a round-bottomed flask charged with $[NiCl_2(PPh_3)_2]$ (0.22 g, 0.33 mmol), $[Et_4N]I$ (0.84 g, 3.3 mmol) and zinc dust (0.32 g, 4.9 mmol) under an atmosphere of argon, thf (20 cm^3) was added and the reaction stirred until a dark brown colour had formed (approximately 45 min). To this reaction mixture a solution of 2-chloro-1,10-phenanthroline (0.70 g, 3.3 mmol) in thf (10 cm^3) was then added and the reaction refluxed for 12 h. After this time the solvent was removed by vacuum and ammonia solution (0.88 sp.gr., 100 cm^3) added and the reaction stirred for a further 12 h. After this time the suspension was extracted with CH_2Cl_2 (3×75 cm^3) and dried ($MgSO_4$). Removal of all the volatiles by vacuum afforded a yellow oil, which was suspended in Et_2O and the resulting solid isolated by filtration. Dissolving in the minimum amount of chloroform and cooling gave pure 2,2′-bi-(1,10-phenanthroline) as yellow crystals, which lost solvent rapidly. Yield 0.18 g, 30%. M.p. $<$300°C (lit. 365–366°C [13]). *Anal*. Found: C, 63.7; H, 3.1; N, 11.0. $C_{24}H_{14}N_4\cdot CHCl_3$ requires: C, 62.8; H, 3.2; N, 11.7%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 9.50 (H^4, d, 1H, $J^{4,3}=8.4$ Hz), 9.34 (H^9, dd, 1H, $J^{9,8}=4.4$, $J^{9,7}=1.6$ Hz), 8.51 (H^3, d, 1H, $J^{3,4}=8.4$ Hz), 8.34 (H^7, dd, 1H, $J^{7,8}=8.1$, $J^{7,9}=1.6$ Hz), 7.94 (H^5, d, 1H, $J^{5,6}=8.8$ Hz), 7.85 (H^6, d, 1H, $J^{6,5}=8.8$ Hz), 7.70 (H^8, dd, 1H, $J^{8,7}=8.1$, $J^{8,9}=4.4$ Hz). Mass spectrum: *m/z* 358 (M^+ 100%). HRMS: $C_{24}H_{14}N_4$ requires 358.12184, found 358.12184.

$[Ni(\mathbf{L^4})Cl(H_2O)]Cl\cdot H_2O$. To a solution of $NiCl_2\cdot6H_2O$ (0.010 g, 0.04 mmol) in MeOH (1 cm^3) a suspension of 2,2′-bi-(1,10-phenanthroline) (0.015 g, 0.04 mmol) in MeOH (1 cm^3) was added and the solution filtered. Cooling at -29°C for several days gave a brown precipitate which was collected by filtration and washed with Et_2O (1 cm^3) and dried in vacuo. Yield 0.015 g, 71%. *Anal*. Found: C, 55.9; H, 2.6; N, 10.4. $C_{24}H_{14}N_4NiCl_2\cdot2H_2O$ requires: C, 55.0; H, 3.5; N, 10.7%. ESI mass spectrum: *m/z* 451 ($[C_{24}H_{14}N_4NiCl]^+$, 10%).

3.2. Crystallography

The structures were solved by direct methods and refined by least-squares on F^2 values for all reflections. All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. All hydrogen atoms (excepting those on the water molecules of $[Ni(\mathbf{L^4})Cl(H_2O)Cl\cdot H_2O$, H(1–6), which were located in the electron density difference map, assigned isotropic displacement parameters and refined without positional constraints) were constrained to ideal geometries and refined with fixed isotropic displacement parameters. Absorption correction was carried out using the SADABS [21] absorption correction software (Table 1).

Within $[Ni(\mathbf{L^4})Cl(H_2O)]Cl\cdot H_2O$ the cation is ordered, with a hydrogen bond between H(6) and Cl(1) (H(6)···Cl(1) 2.247(24) Å). However, the chloride counterion Cl(2) is disordered over two sites. The major site Cl(2) has an occupancy of 0.879(3) and contains a free

POLYHEDRON

The preparation and characterisation of platinum and palladium phosphine thiocarbonate complexes $M(PR_3)_2(CS_3)$ and $Pt(PR_3)_2(CSeS_2)$

Steven A. Aucott, Alexandra M.Z. Slawin, J. Derek Woollins *

Department of Chemistry, University of St Andrews, St Andrews, Fife KY16 9ST, UK

Received 15 October 1999; accepted 4 January 2000

Abstract

Reaction of CS_2 with NH_3(liq) gives the $(CS_3)^{2-}$ dianion which undergoes in situ reaction with $MCl_2(PR_3)_2$ to give $M(PR_3)_2(CS_3)$. X-ray analysis of four examples (M = Pt, PR_3 = PMe_3, PMe_2Ph, PPh_3, dppp) reveals square planar coordination with the $[CS_3]^{2-}$ dianion being effectively in the same plane as the coordination sphere. The first example of a $[CSeS_2]^{2-}$ complex is also reported. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Platinum; Palladium; Phosphine thiocarbonates

1. Introduction

Sulfur donor ligands have been investigated by a number of groups for both academic and industrial reasons including their use in lubricant additives [1], metal specific coordination [2] and bioinorganic chemistry [3]. Although there is a wide range of organosulfur systems [4], and more recently S–P–N–P–S systems [5–8], there is surprisingly little information [9–12] on perhaps the simplest anionic sulfur chelate, $[CS_3]^{2-}$. We have been interested in the incorporation of sulfur-rich ligands into complexes for a number of reasons [13,14], and the thiocarbonate ligand has the attraction of giving complexes with exocyclic sulfur atoms which could be important in the formation of molecular metals as a result of weak interactions to other species in the solid state [15]. There was a recent report on the synthesis of (diphosphine)platinum(II) carbonate complexes [16] and this has prompted us to describe our work on the related thiocarbonate compounds. In this work we describe a facile synthesis of $[CS_3]^{2-}$ together with the formation of a range of $M(PR_3)_2(CS_3)$ (M = Pd, Pt) complexes. The complexes have been characterised by NMR and vibrational spectroscopy; in addition, the X-ray structures of selected examples are reported.

2. Experimental

2.1. General

Diethyl ether, petroleum ether (60–80°C) and tetrahydrofuran were purified by reflux over sodium and distillation under nitrogen. Dichloromethane was heated to reflux over powdered calcium hydride and distilled under nitrogen. Chemicals were purchased from Aldrich and Lancaster and were used as received. The compounds $[PdCl_2cod]$ and $[PtCl_2cod]$ [17] were prepared using literature procedures.

Infrared spectra were recorded from KBr discs on a Perkin-Elmer system 2000 spectrometer; ^{31}P NMR spectra were recorded on a Jeol FX90Q operating at 36.21 MHz; ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded on Bruker instruments operating at 250, 62.9 and 101.3 MHz, respectively. Fast atom bombardment mass spectra were obtained by the Swansea Mass Spectrometer service.

2.2. Synthesis of *1–8*

Carbon disulfide (5–10 ml) was placed into a Schlenk tube and cooled to −78°C. NH_3 was bubbled into the cooled CS_2 until two distinct layers were formed (ca. 10 min), a clear bottom layer and a blood red top layer containing the CS_3^{2-} anion. MCl_2(bis-phosphine), M = Pd, Pt (100–130 mg) was added as a solid and the mixture was stirred magnetically for

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(00)00295-3

2 h at −78°C and then slowly warmed to room temperature with continual stirring until the excess NH_3 had evaporated. The resulting bright orange residue was placed under vacuum for 1 h then extracted with 3×20 ml portions of dichloromethane. The combined extracts were reduced in volume to approximately 10 ml, and 60–80 petroleum ether (ca. 40 ml) was added slowly to the stirred solution to precipitate the product. The bright yellow solid was collected by suction filtration, washed with a small amount of methanol (5 ml) and diethyl ether (1 ml), and dried overnight in vacuo. Yield 70–90% based on metal used.

2.3. Synthesis of **9** and **10**

Tetrabutylammonium borohydride (0.144 g, 0.560 mmol) and elemental selenium (0.022 g, 0.279 mmol) were heated to 40°C under a nitrogen atmosphere in dry thf (50 cm^3) for 4 h or until the reaction mixture was colourless. The mixture was then cooled to −78°C (cardice/acetone) and 11.9 cm^3 of a 1.78×10^{-3} M solution of CS_2 in thf (0.021 g, 0.276 mmol) was added and the solution stirred for 30 min, resulting in a bright red coloured solution. To this was added solid $PtCl_2(PMe_2Ph)_2$ (0.151 g, 0.278 mmol) and the mixture was stirred for 1 h at −78°C and 1 h at room temperature, giving a bright orange solution containing a light colourless precipitate. The precipitate was removed by filtration through celite and the filtrate was evaporated to dryness leaving an oily dark orange residue. The crude product was taken up into a small volume of dichloromethane (1.5–2 cm^3) and diethyl ether (40 cm^3) was added with stirring to give an orange precipitate. The product was collected by suction filtration, washed with ice cold methanol (2 cm^3) followed by diethyl ether (2×5 cm^3) and dried in vacuo. Yield 0.091 g, 52%.

2.4. X-ray crystallography
