Details of the structure determination of **1**–**5** are given in Table 1. X-ray diffraction measurements were made with graphite-monochromated Mo Kα X-radiation ($\lambda=0.71073$ Å) using a Siemens SMART diffractometer or with Cu Kα radiation and a Rigaku AFC7S serial diffractometer. For the SMART data, intensity data were collected using 0.3° or 0.15° width ω steps accumulating area detector frames spanning a hemisphere of reciprocal space for all structures (data were integrated using the SAINT [18] program) and for the Rigaku AFC7S data were collected by ω scans over a single quadrant of reciprocal space. All data were corrected for Lorentz, polarisation and long-term intensity fluctuations. Absorption effects were corrected on the basis of multiple equivalent reflections or by empirical methods. Structures were solved by direct methods and refined by full-matrix least-squares against F (teXsan) or F^2 (SHELXTL) for all data with $I>3\sigma(I)$ with weights w set equal to $(\sigma_c^2(F_o^2)+(aP)^2+bP]^{-1}$, where $P=[\max(F_o^2,0)+2F_c^2]/3$. The parameter x, of the form $k[1+0.001xF_c^2\lambda^3/\sin(2q)]^{0.25}$ was refined for the SMART/SHELXTL [19] structures; the weighting scheme for the Rigaku/teXsan [20] was as previously reported [21]. All hydrogen atoms were assigned isotropic displacement parameters and were constrained to idealised geometries. Refinements converged to residuals given in Table 1. High electron densities in the final difference maps were located close to the heavy metal centre in all the determinations. In **10** the S/Se disorder of the metal bonded sites in the $[CSeS_2]^{2-}$ was refined using 50% occupancy, using anisotropic refinements with the sulfur and selenium atoms on each site sharing common coordinates. There was no indication of any contribution from a selenium occupancy for the terminal sulfur atom. All calculations were made with SHELXTL [19] or teXsan [20].

3. Results and discussion

The $(CS_3)^{2-}$ dianion is well established but not particularly well investigated. Typically the dianion is prepared by reaction of a base such as KOH with CS_2 in an inert solvent such as dimethylformamide [9]. We have found liquid ammonia to be a very useful solvent for a range of reactions [22]. Here we report a simple reaction for the preparation of $(NH_4)_2(CS_3)$ as well as for a range of $M(PR_3)_2(CS_3)$ complexes (M = Pd, Pt). Furthermore, we have determined the X-ray crystal structures of four $Pt(PR_3)_2(CS_3)_2$ complexes for comparison with the $(CO_3)^{2-}$ complex which was recently reported [16].

The new $[CS_3]^{2-}$ complexes were obtained by reaction of CS_2 with excess NH_3(liq) followed by the appropriate $MCl_2(PR_3)_2$ species. All of the compounds gave satisfactory microanalyses and FAB mass spectra (with the expected isotopomer distributions, Table 2). In **1**–**8** (Tables 3 and 4) the ν(C=S) vibrations were observed at ca. 1050, and the ν(M–S) all lie close to 337 cm^{-1} which is in accord with previous observations for related systems [10]. In the ^{31}P NMR spectra the platinum complexes have δ values which are ca. 8 ppm to higher frequency than the analogous carbonate complexes [16].

The $^1J(^{31}P–^{195}Pt)$ coupling constants observed for the $Pt(PR_3)_2(CS_3)$ complexes lie in the range 2590–3145 Hz for the dppm and PPh_3 complexes, respectively and as such are generally ca. 500 Hz smaller in magnitude than those observed for the analogous carbonate complexes. The values observed here are relatively high for sulfur donor systems though there are few dianionic examples that are directly comparable.

X-ray analysis of four $Pt(PR_3)_2(CS_3)$ complexes reveals (Table 5, Fig. 1) the expected square planar geometry at platinum. The Pt–S distances appear independent of the *trans* phosphine (range 2.336(3)–2.358(2) Å), though as expected the Pt–P distances vary with the nature of the phosphine, with the PPh_3 complex having the longest Pt–P bond length. Interestingly, in Pt(dppp)(CS_3) (**5**) the Pt–P bond lengths (2.263(3), 2.266(3) Å) are substantially longer than those [16] in Pt(dppp)(CO_3) (2.216(5), 2.2149(5) Å).

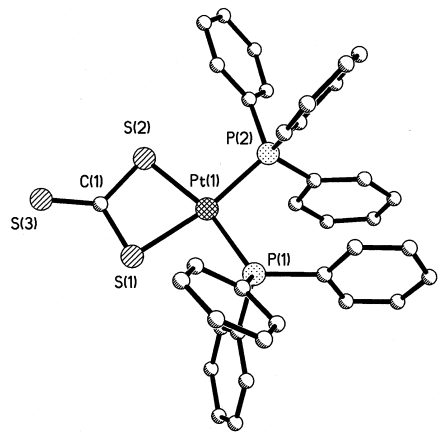

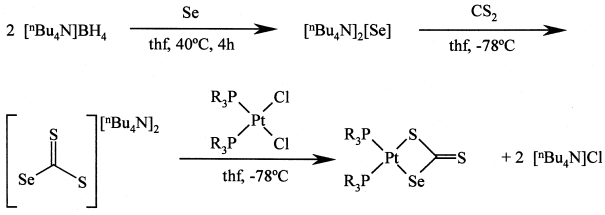

Fig. 1. The X-ray structure of $Pt(PPh_3)_2(CS_3)$ (**4**).

This is presumably a consequence of the greater electronegativity of the carbonate ligand that enables the dppp to behave as a better σ donor; the same effect would also explain the difference in the $^1J(^{31}P–^{195}Pt)$ coupling constants. The S–Pt–S angle in **5** (73.6(1)°) is significantly less strained than the O–Pt–O angle (65.3(5)°) in the carbonate complex [16]. The C–S bond lengths in the $[CS_3]^{2-}$ ligand are longer for the coordinated sulfur atoms than for the exocyclic sulfur which is as anticipated. Within the PtS_2C rings the Pt–S–C and S–C–S angles are in the range 87.6(5)–89.7(3)° and 107.5(4)–110.5(7)°, respectively, reflecting the ability that sulfur has to adapt to greater angular distortion. In all of the structures the $(CS_3)^{2-}$ ligand is effectively coplanar with the coordination plane (maximum deviation for S(3) 0.29 Å in **4**). There are no significant intermolecular interactions in the solid state for any of the structures.

We have also developed a synthesis of the previously unknown $[CS_2Se]^{2-}$ dianion according to Scheme 1. We made no attempt to isolate the $[Bu_4N]_2[CS_2Se]$ but used it in situ to form complexes **9** and **10**. The NMR of **9** and **10** are the expected AB type with $^1J(^{31}P–^{195}Pt)$ couplings which are appropriate for the *trans* coordination of sulfur or selenium. Although very similar, the δ values can be assigned to phosphorus *trans* to sulfur and selenium by comparison with the δ values/coupling constants in complexes **3** and **5**. The X-ray diffraction studies on **10** clearly indicate the presence of a 50% disordered $[CS_2Se]^{2-}$ group with the selenium being bound to the platinum; however, no meaningful bond lengths and angles can be derived because of the disorder.

Supplementary data

Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk. Organometallic chemistry at the interface with materials science

Jeffrey Schwartz *, Ellen S. Gawalt, Gang Lu, Delia J. Milliron, Kathleen L. Purvis, Steven J. Woodson, Steven L. Bernasek, Andrew B. Bocarsly, Susan K. VanderKam

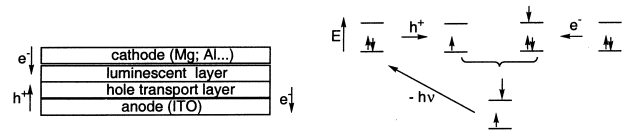
Abstract

Surface hydroxyl groups of indium tin oxide (ITO) react with zirconium or tin alkoxides to give surface metal alkoxide complexes, which can be converted to surface metallic complexes of carboxylates or phenoxides. These latter surface complexes can be used to modify electrode properties of the ITO. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Indium tin oxide; Surface modification; Alkoxides; Interfaces

Organometallic materials play an important role as essential components of modern optoelectronic devices, for example of organic light emitting diodes (OLEDs). In one OLED process, 'holes' are injected from an inorganic anode into an organic 'hole transport layer (HTL)' material; typically, the anode is a mixed oxide of indium and tin (ITO), and the HTL is an aromatic hydrocarbon derivative (Fig. 1) [1–3]. 'Hole injection' into (oxidation of) the HTL is often inefficient, perhaps owing to poor molecular contact at the interface between the hydrophilic ITO and the hydrophobic HTL; this inefficiency results in device failure after only short utilization times [1,4,5]. Until the surface chemistry of ITO is better understood, it is unlikely that precisely designed interfaces can be developed for applications in microelectronic devices. Fortunately, surface hydroxyl groups can provide a chemical 'handle' with which to accomplish ITO surface modification in a well controlled, systematic way, and because they react with surface OH groups, organometallic species seem perfectly set up to enhance, on the molecular level, the interface between an oxide-based inorganic electrode and an organic overlayer.

Metal alkoxides react with OH groups of metal oxides to give surface organometallic complexes by protolytic loss of one or more alkoxide ligands [6–10]. Alkoxide ligands remaining in the coordination sphere of the metal following 'chemisorption' can react by ligand metathesis to give families of new surface-bound complexes from a common precursor [11–16]. Tetra(*tert*-butoxy)zirconium (**1**) is a particularly useful 'linker' to interface metal oxide surfaces with organic materials. Reaction of **1** with ITO/glass was accomplished both in ultrahigh vacuum (UHV) and under 'normal' laboratory conditions (10^{-2}–10^{-4} Torr). Products were determined in UHV using reflectance–absorbance IR spectroscopy (FT-RAIRS), X-ray photoelectron spectroscopy (XPS), and thermally programmed desorption mass spectrometry (TDS), all of which indicated the presence of *tert*-butoxy ligation. Chemisorption involves protolytic loss primarily of one *tert*-butoxide ligand to give **2**; a small amount of **2′**, formed by a second protonolysis step, may also be present at room temperature. A similar deposition stoichiometry is to be expected for reaction of **1** with ITO/glass under 'normal' laboratory conditions (Scheme 1).



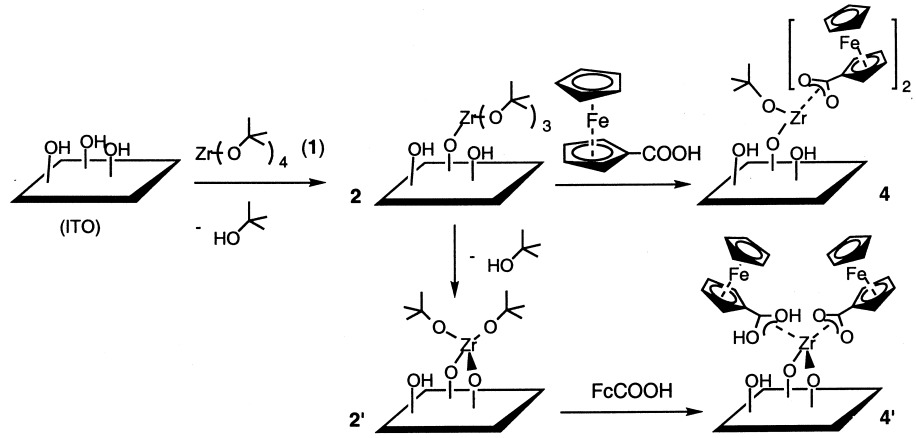


Fig. 1. Schematic diagram of a simple OLED.

Ligand metathesis of **2**/**2′** with simple carboxylic acids [16] was modeled in UHV using Al-bound Zr alkoxide complexes [11]. Carboxylate-for-alkoxide exchange was accomplished by repetitive dosing of the substrate with butanoic acid at 170 K, followed by heating to 300 K. FT-RAIRS analysis after one cycle of treatment of **1** with 0.6×10^{-6} Torr-sec. of butanoic acid showed both alkoxide and carboxylate ligands. Even after eleven further 'dose–desorb' cycles, FT-RAIRS showed only two *tert*-butoxy ligands had been exchanged for butanoate ligands, to give butanoate com-

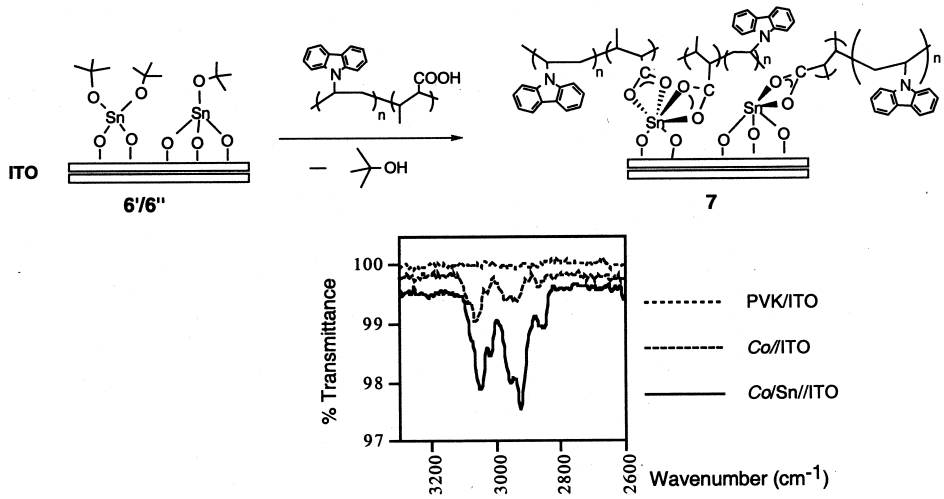

Scheme 1. Synthesis of surface organometallic complexes on ITO.

plexes **3**/**3**′. Reaction of **3**′ with a third equivalent of carboxylic acid may be sterically unfavorable.

Surface hydroxylated ITO/glass was treated with vapor of **1** to give **2**/**2**′; slides were then sprayed with an aerosol of a 1 mM solution of ferrocenecarboxylic acid (FcCOOH) in ether, dried, washed, and dried again, to give **4** and **4**′ [15]. ITO/glass electrodes coated with **4**/**4**′ were rinsed thoroughly and subjected to electrochemical analysis. The cyclic voltammogram of the **4**/**4**′-modified ITO electrode showed a redox peak at $E_{1/2} = 0.55$ V versus SCE, which is reasonable for a surface bound carboxyferrocene derivative [17,18]. The loading density of surface-bound ferrocene carboxylate ligands of **4**/**4**′ onto ITO was determined by chronocoulometry [19] to be 1.01×10^{-10} mol cm^{-2}. Assuming that there are two ferrocenecarboxylate ligands in **4**/**4**′, then the amount of **4**/**4**′ on the surface per nominal unit area is ca. 5×10^{-11} mol cm^{-2}, comparable to the amount reported by 'self-assembly' of elaborated ferrocenyl derivatives on ITO [18,20–22]. Importantly, our studies show that the redox properties of the FcCOOH-derived reagent have not been changed significantly by its incorporation into a surface organometallic complex: The surface complex does not constitute an insulating barrier.

Tin interfaces are attractive for ITO surface modification, in that their use does not entail introduction of a new metallic species, such as Zr. UHV stoichiometric determination for reaction products of ITO/glass and tetra(*tert*-butoxy)tin (**5**) indicated a mixture of tin analogs of **2**/**2**′ (**6**/**6**′/**6**″), similar to that found for deposition of **5** onto hydroxylated Ti [10]. It is interesting that both on ITO and on oxidized metals, Sn alkoxides are more reactive toward multiple chemisorption than are Zr analogs [7]. Polyvinylcarbazole (PVK) is an HTL material of significance for polymer-based OLEDs [23], but PVK does not adhere well to untreated ITO. We prepared a co-polymer of polyvinylcarbazole and crotonic acid, which incorporates a low level of the acidic component, by polymerizing a large excess of vinylcarbazole (relative to crotonic acid) using AIBN initiation [24]. The co-polymer adhered [14] better to ITO than did PVK, but it adhered even better in the presence of **6**′/**6**″, which gives **7** (see Scheme 2). Using typical spin-coating techniques, we were able to prepare a simple OLED with **7**. Analysis of current versus voltage for this simple device indicated much higher carrier mobility compared with a device prepared simply by spin-coating a solution of PVK onto untreated ITO.

Scheme 2. Preparation of PVK co-polymer/ITO via an Sn interface.

An interesting model to facilitate 'hole injection' from ITO into an HTL material involves the organization of a dipole at the surface of the ITO [3,25]. Phenols are acidic compared to *tert*-butanol, and we find that **2**/**2′** react with phenols from the gas phase to give products of ligand metathesis in which *tert*-butoxy ligands are replaced by phenoxides [13]. A series of substituted phenolic compounds was reacted with **2**/**2′** to give a family of similar phenoxyzirconium complex surface materials. An analogous series was made using **6′**/**6″**. Surface phenoxides were structurally elucidated though a combination of FT-RAIRS, XPS and TPD measurements. Functional studies of Zr and Sn phenoxides on ITO are now underway.

In conclusion, we have shown that covalently binding a metallic complex interface to the surface of ITO can enhance interactions between generally hydrophobic organic materials and the hydrophilic oxide substrate surface. In conventional cases, the interaction between such organic materials and the oxide surface would depend on either hydrogen bonding effects or Lewis acid/Lewis base interactions. However, for an oxide such as ITO which is not heavily hydroxylated, and for tertiary amines such as are present in PVK, hydrogen bonding and Lewis acid/Lewis base interactions will likely be weak. In marked contrast, using the metallic interface, strong covalent bonding can be effected irreversibly between the substrate and the organic material.

Abstract

The heteronuclear complexes $[(CO)_4Fe(\mu\text{-}PPh_2)Pd(\mu\text{-}Cl)_2]_2$, $[Et_4N][FeCo_3(CO)_{12}]$ and $Rh_2Co_2(CO)_{12}$ were physically entrapped in SiO_2–sol–gel matrices. The doped materials, so formed, were utilized as recyclable catalysts for (a) selective isomerization of 1-octene, (b) selective dimerization of norbornadiene to 'binor-S', and (c) hydrogenation and hydrogenolysis of styrene, nitrobenzene and 1-chloronaphthalene, respectively. During the hydrogenation of the nitrobenzene and of chloronaphthalene, the dodecacarbonylbis(cobalt)dirhodium was converted into sol–gel entrapped carbonyl-free nanoparticles that efficiently catalyze the reduction of the aromatic C–C bonds.

1. Introduction

Recent studies on heterogenizing of homogeneous transition metal catalysts revealed that physical entrapment of a wide range of mono- and homobimetallic complexes in SiO_2–sol–gel matrices does not only permit facile recycling of the encapsulated catalysts, but often also increases their stability and improves their catalytic properties [1]. In recent years, heteropolynuclear catalysts have become of particular interest. Synergistic effects that may exist in such compounds are responsible for their unusually high catalytic potency and/or their ability to promote unique organic processes [2]. However, under homogeneous conditions, many mixed-metal complexes tend to dissociate or to disproportionate and to yield either mononuclear or homopolynuclear species. With the objective of overcoming this discrepancy, we have now investigated the immobilization of three model heterobimetallic complexes by their entrapment in sol–gel glasses, and studied some of the catalytic properties of the resulting hybrid materials.

2. Experimental: entrapment of mixed-metal complexes in sol–gel matrices

2.1. (2Fe–Pd)octacarbonyl[μ-(di-μ-chlorodipalladio)-bis(μ-diphenylphosphino)]diiron

A Schlenk tube was charged under Ar atmosphere with 30 mg of $[(CO)_4Fe(\mu\text{-}PPh_2)Pd(\mu\text{-}Cl)]_2$ [3] in 4 ml of dry THF. To the clear stirred solution were injected 3.2 ml of degassed *tert*-BuOH and 2.0 ml of $SiCl_4$. Stirring was continued until gelling occurred (4 h). The gel was left for aging for 24 h and dried at 1 mm for 24 h. The sol–gel material was treated under exclusion of air for 1 h with 20 ml of boiling CH_2Cl_2, sonicated in the same solvent at room temperature, and dried at 1 mm to constant weight (3 h).

2.2. Tetraethylamminium(3Co–Co)(3Co–Fe)tricarbonyl-(tri-μ-carbonylhexacarbonyltricobaltate)ferrate(1−)

A flask was charged under N_2 with 1.2 ml of HCl solution of pH 1.9, 2.5 ml of $Si(OMe)_4$ and 3.5 ml of MeOH. The mixture was stirred magnetically for 20 min and the pH was raised by addition of 0.44 ml of 0.1 N aqueous NH_3. To the mixture was added at once a solution of 30 mg of $[Et_4N][FeCo_3(CO)_{12}]$ [4] in 4 ml of dry THF. Stirring was continued until complete gelation (4–5 h). The gel was left

PII S0277-5387(99)00396-4

for aging for 2 days, dried at 1 mm, washed thoroughly with 20 ml of CH_2Cl_2 and sonicated for 30 min in the same solvent. Finally, the glass was dried to constant weight.

2.3. (Co–Co)(4Co–Rh)(Rh–Rh)tri-μ-carbonyltetracarbonyl(pentacarbonyldicobalt)dirhodium

To a stirred solution of 19.8 mg of $Rh_2Co_2(CO)_{12}$ [5] in 1 ml of benzene was added under N_2 2.5 ml of MeOH. After a further 5 min, 2.4 ml of water were added. The mixture was then treated with 3.5 ml of $Si(OMe)_4$ and the stirring was continued until gelation occurred (usually 2–3 h). The sol–gel material, so formed, was dried at 0.1 mm for 20 h, washed and sonicated twice with 20 ml of benzene and dried again for 2 h at 0.1 mm.

3. Results and discussion

Each of the three mixed metal complexes was entrapped in a sol–gel matrix in a different way. The water sensitive isomerization catalyst $[(CO)_4Fe(\mu\text{-}PPh_2)Pd(\mu\text{-}Cl)]_2$ [6] was immobilized by a non-hydrolytic process in which the complex was added to a polycondensation reaction mixture of $SiCl_4$ and *tert*-BuOH in THF. Although the interaction of *tert*-butanol and silicon halides is a known procedure for the preparation of sol–gel materials [7], to the best of our knowledge it has not yet been used for molecular entrapment of metallic complexes. FT-IR measurements indicated that during the entrapment all eight CO groups were eliminated. Continuous Soxhlet extraction of the heterogenized complex with CH_2Cl_2 (48 h) gave a paramagnetic mixture whose FAB mass spectrum consisted of the molecular ions of the starting material less 8-CO ($m/z = 762$–768) as well as of THF adducts (up to $m/z \sim 1340$). When a mixture of the entrapped complex and 1-octene (catalyst:substrate molar ratio 1:330) was heated under N_2 at 90°C for 6.5 h most of the alkene was converted into *cis*- and *trans*-2-octene.

$$CH_3(CH_2)_5CH{=}CH_2 \rightarrow$$

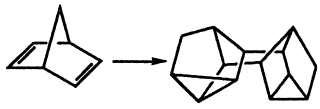
$$cis + trans\text{-}CH_3(CH_2)_4CH{=}CHCH_3$$

The seven isomeric octenes could be separated on a 25 m × 0.25 mm CP-Sil 5 capillary column between 50 and 150°C, programmed for a temperature increase of 2°C min^{-1}. Although the heterogenized catalyst was shown to be leach proof and recyclable, its selectivity decreased in the second run owing to clogging of some pore entrances [8]. Reopening of the pores was accomplished by initial sonication with CH_2Cl_2 (30 min) followed by treatment with hot water (80°C, 30 min) and drying. After such treatment the activity and selectivity of the catalyst did not change further. A representative set of experiments of the [Fe–Pd]-catalyzed isomerization of 1-octene is summarized in Table 1. Unlike the isomerization by the homogeneous complex [9], the heterogenized catalyst did not require the presence of MeOH.

It is remarkable that after the entrapment of the bimetallic catalyst it became insensitive to water. Under 40 atm of CO at 100°C and a catalyst:substrate ratio of 1:50 it even promoted the hydration of acetylenes in aqueous dioxane containing 10% of H_2O:

$$C_6H_5C{\equiv}CH + H_2O \xrightarrow[63\%]{10\ h} C_6H_5COCH_3$$

The entrapment of the norbornadiene dimerization catalyst $[Et_4N][FeCo_3(CO)_{12}]$ [10] in a sol–gel matrix was best accomplished by a two-step process, in which $Si(OMe)_4$ was first hydrolyzed at low pH to polysilicic acids which in turn were treated with aqueous NH_3 and a THF solution of the mixed metal complex [11].



FT-IR studies revealed that upon this encapsulation of the cluster in the sol–gel matrix, no considerable structural changes in the complex took place. The homogeneous and the entrapped catalyst, before and after application (vide infra), showed *the same* C–O stretching vibrations (KBr pellets) at 2061, 2010, 1992, 1965, 1924 and 1815 cm^{-1} (cf. [4]). When a mixture of norbornadiene (2.97 mmol), $BF_3 \cdot OEt$ (0.49 mmol), the encapsulated catalyst (containing 0.1 mmol of the Fe–Co complex) and 2 ml of acetone was heated for 1 h at 48°C, a quantitative yield of dodecahydro-1,2,4:5,6,8-dimetheno-*s*-indecene ('binor-S') free of any other norbornadiene dimer was isolated. Under the same conditions a quantitative yield of 'binor-S' was obtained also in the second run, but the catalysis slowed down in the third and

Isomerization of 1-octene by the sol–gel entrapped [Fe–Pd] catalyst [a]

Run	Composition of reaction mixture after 6.5 h (%)				
	1-octene	*cis*-2-octene	*trans*-2-octene	*trans*-3-octene	*trans*-4-octene
1	1	17	48	27	7
2 [b]	10	17	38	25	10
3	8	19	49	18	6
4	8	19	49	18	6
5	8	19	49	18	6

[a] Reaction conditions: 9.9 mmol of 1-octene, 3×10^{-2} mmol catalyst, 90°C.
[b] After the second run the catalyst was treated with water at 80°C.

fourth runs (conversions after 1 h were 93 and 88%, respectively) owing to partial pore clogging in the hybrid catalyst.

The complex $Rh_2Co_2(CO)_{12}$ [5] could be entrapped in sol–gel matrices by the conventional method in which a benzene solution of the tetranuclearic cluster was added to a reaction mixture of $Si(OMe)_4$, H_2O and MeOH during the 'one-step' polycondensation process [11]. Unlike the homogeneous complex which tends to disproportionate in various media into rhodium and cobalt carbonyls [12,13], the sol–gel entrapped version seems to preserve its original structure. Thus, the C–O bonds of the non-entrapped compounds (in pentane) at 1855, 1871, 1885, 1910, 1920, 2038, 2059, 2064 and 2074 cm^{-1} [5] were shifted only slightly (KBr pellets) to 1857, 1869, 1888, 1908, 1919, 1941, 2040, 2055 and 2069 cm^{-1}. When the immobilized catalyst was employed in the hydrogenation of styrene (1.7 mmol substrate, 0.015 mmol catalyst, 3.4 atm H_2, 10 ml hexane, 30°C, 22 h) a quantitative yield of ethylbenzene was obtained.

$$C_6H_5CH{=}CH_2 + H_2 \rightarrow C_6H_5CH_2CH_3$$

During the next five runs the results did not change but the metal carbonyl peaks gradually became weaker. The reaction could be enhanced by increasing the temperature to 60°C. (Under the same conditions at 30°C the non-encaged cluster yielded only 62% of ethylbenzene.) Nitrobenzene reacted with hydrogen only above 60°C. The mixture of products in the first four runs consisted, after 22 h, of the following respective amounts of aniline and of aminocyclohexane: first run 96 and 4%; second run 64 and 36%; third run 16 and 84%; fourth run 2 and 98%.

$$C_6H_5NO_2 + H_2 \rightarrow C_6H_5NH_2 + C_6H_{11}NH_2$$

A similar change in product distribution was observed during the hydrogenation of 1-chloronaphthalene. Under the above conditions the chloroarene was transferred in the first three runs of 22 h to 5-chlorotetralin, *cis*-decaline and *trans*-decaline in the following respective amounts: first run 29, 58 and 8%; second run 11, 72 and 12%; third run 6, 82 and 12%.

$$1\text{-}ClC_{10}H_7 + H_2 \rightarrow 5\text{-}ClC_{10}H_{11} + \textit{cis}\text{-}C_{10}H_{12} + \textit{trans}\text{-}C_{10}H_{12}$$

High resolution transition electron microscopy (TEM) studies of the hybrid catalyst before and after the hydrogenation processes revealed that during the catalyses of nitrobenzene and 1-chloronaphthane (but not during the reaction of styrene), metallic nanoparticles of 2–3 nm diameter are formed (see Fig. 1). Energy dispersive X-ray microanalysis (EDX), which was used in conjunction with TEM, failed to indicate the presence of metal lattices in the particles, which suggests that the particles are composed of a Rh–Co alloy [14].

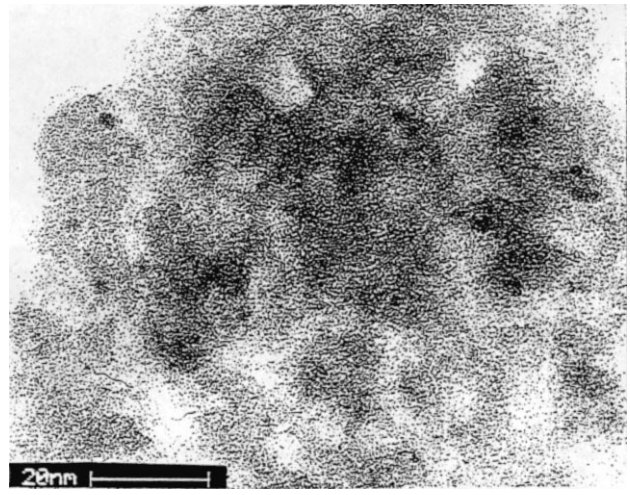

Fig. 1. Transmission electron micrograph of sol–gel entrapped $Rh_2Co_2(CO)_{12}$ after its use as catalyst for hydrogenation of nitrobenzene (fourth run).

While the sol–gel entrapped nanoparticles catalyze the hydrogenation of aromatic C–C bonds in nitroarenes and chloroarenes, they fail to promote the reduction of the aromatic ring in styrene. In fact, the presence of styrene during the hydrogenation of nitrobenzene leads only to the formation of aniline. However, after the consumption of the styrene in a hydrogenation process, the used catalyst promotes the transformation of nitrobenzene to aminocyclohexane. Phenylacetylene, like styrene, is reduced (at 60°C) to ethylbenzene rather than to ethylcyclohexane.

4. Conclusions

The results of this study show that sol–gel entrapped heteronuclear clusters preserve the unique catalytic properties of the homogeneous compounds. The encaging process can be accomplished under hydrolytic or non-hydrolytic conditions and may be associated with extrusion of CO ligands. Further transformation of the encaged mixed-metal carbonyl complexes to catalytically active nanoparticles occurs during ring hydrogenation of nitroarenes and chloroarenes.

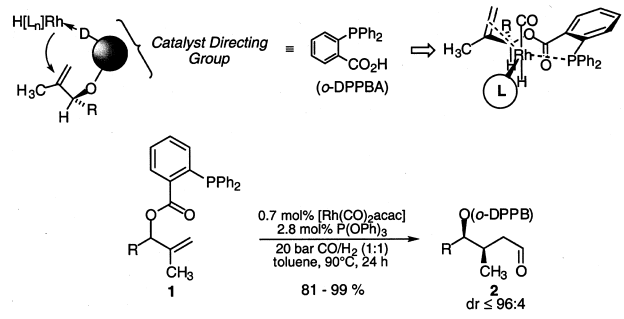
POLYHEDRON

Stereoselective hydroformylation, cuprate addition and domino reactions with the aid of a catalyst directing group

Bernhard Breit *, Stephan K. Zahn

Organisch-Chemisches Institut, Ruprecht-Karls-Universität Heidelberg, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany

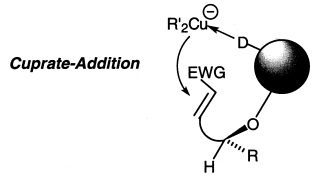
Received 4 October 1999; accepted 1 November 1999



Abstract

Stereoselective hydroformylation and stereoselective conjugate addition to enoates has been achieved in a synthetic sequence employing a substrate-bound catalyst directing the *o*-DPPB group (*o*-DPPB = *ortho*-diphenylphosphanyl benzoate). Furthermore, a stereoselective domino process combining hydroformylation, Wittig olefination and a transition metal catalyzed hydrogenation is described. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Hydroformylation; Organocopper reagents; Catalysis; Asymmetric synthesis; Domino reactions

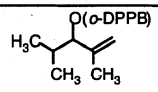


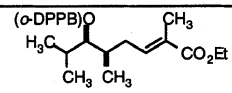
Hydroformylation of olefins is an industrially important homogenously catalyzed C–C bond forming process; for recent reviews, see Refs. [1–4]. However, this important reaction has not found many applications in organic synthesis (for exceptions see Refs. [5–8]). This may be due to the difficulty in controlling stereoselectivity in the course of this reaction; for reviews see Refs. [9–11]. Although some recently developed chiral rhodium catalysts allow for enantioselective and diastereoselective hydroformylation of certain specific classes of alkenes [12–18], only very little is known on the diastereoselective hydroformylation of acyclic olefins (for substrate directed diastereoselective hydroformylation of cyclic systems, see Refs. [19–21]).

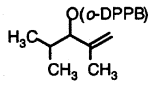
We recently devised a solution to this problem making efficient use of substrate direction employing a substrate bound catalyst directing group (CDG) [22–24]. The principles which guided the design of an efficient CDG were as follows: (i) reversible coordination of the catalytically active transition metal center under hydroformylation conditions, (ii) ease of introduction into and removal from the substrate, and (iii) correct geometry to pass a cyclic transition state for the stereochemistry defining step.

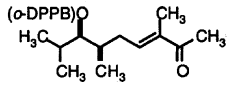
A system which proved to be in accord with these criteria is the *ortho*-diphenylbenzoyl group (*o*-DPPB). Introduction of this CDG enabled a stereoselective hydroformylation of methallylic and homomethallylic alcohol derivatives, with high levels of acyclic stereocontrol (**1**→**2**) [22–26].

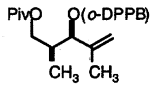
In order to optimize the CDG concept, it was decided to employ the specifically introduced *o*-DPPB group in a second step, again as a stereochemistry control unit. In this context, the conjugate addition of cuprates to acyclic enoates became of interest.

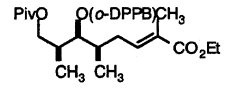


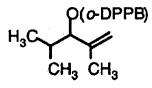


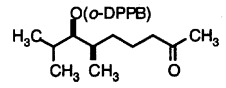


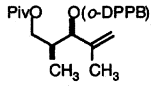


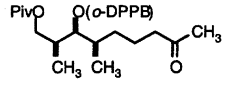


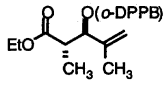


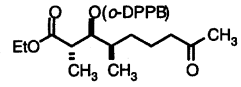


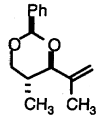


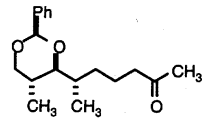


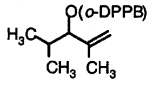


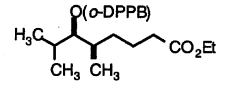


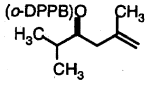


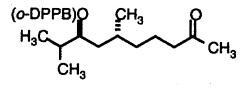












Starting from methallylic *o*-DPPB esters **1**, *o*-DPPB directed hydroformylation (→**2**), HWE olefination (→**3**),

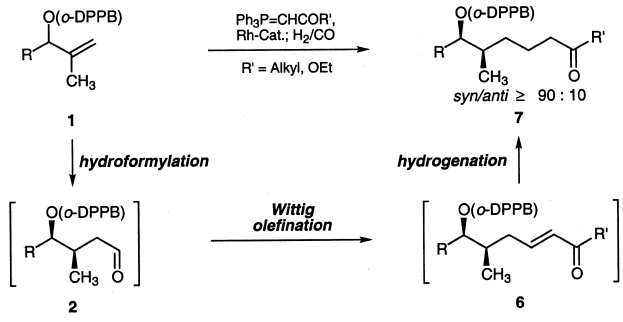
followed by an *o*-DPPB directed cuprate addition gave the corresponding *anti*-conjugate adducts **4** in good yield and diastereoselectivity. Control experiments indicated that the *o*-DPPB group controls both the reactivity and diastereoselectivity [27].



Combining, *o*-DPPB directed hydroformylation, HWE olefination, and *o*-DPPB directed cuprate addition gave access to building blocks with up to four stereogenic centers.

In order to improve the synthetic efficiency of an *o*-DPPB directed hydroformylation reaction, one may want to employ this reaction as a part of sequential transformations. In this regard the hydroformylation should be ideally suited, since a synthetically most valuable aldehyde functionality is generated under mild reaction conditions. This aldehyde may be reacted with carbon nucleophiles to allow for further skeleton extending processes in a one-pot operation. Thus, hydroformylation of methallylic *o*-DPPB esters **1** in the presence of disubstituted Wittig-ylids furnished the trisubstituted alkenes **5** in good yield and diastereoselectivity. These are the first examples of a domino-hydroformylation-Wittig reaction (see Table 1) [28–31].

Interestingly, when using mono-substituted Wittig-ylids the saturated derivatives **7** were obtained (see Table 1). These compounds result from three sequential reactions: step 1 is the hydroformylation reaction to give the aldehyde **2** which is olefinated in step 2 with the Wittig-ylid present ($\rightarrow$**6**); finally, a transition metal catalyzed hydrogenation of the alkene finishes the sequence of reactions and provides the saturated products **7** in good yield and diastereoselectivity.

Since the hydroformylation is the stereochemistry defining step, one could make use of both 1,2- and 1,3-asymmetric induction employing the CDG concept (entries 1–6, 8, 9, Table 1). Alternatively, one could employ substrate control via conformational constraints to give an all-*anti* stereotriad building block (entry 7).

As a result of its mild nature, this domino process may allow the coupling of any two given complex building blocks within the context of a convergent synthesis strategy.

POLYHEDRON

The Heck reaction: mechanistic insights and novel ligands

Michael Casey *, John Lawless, Colette Shirran

Chemistry Department, University College Dublin, Belfield, Dublin 4, Ireland

Received 4 October 1999; accepted 6 December 1999

Abstract

The kinetics of the Heck reaction of aryl iodides with methyl acrylate using phosphane ligands were studied. Triphenylphosphane strongly inhibited the reaction when used in excess over the Pd(0) precatalyst. The rate of reaction was found to be weakly dependent on the concentrations of both the aryl iodide and the alkene. The results indicate that the migratory insertion step is turnover limiting, with the oxidative addition to the aryl iodide being faster but not negligible. Phosphane sulfane hemilabile ligands were found to give good yields and good catalyst stability in Heck reactions. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Heck reactions; Palladium; Phosphane; Sulfane; Ligands; Mechanism

1. Introduction

The Heck reaction has developed into an extremely important synthetic method [1–4]. Nevertheless, there is scope for further improvement, for example in developing catalysts which give greater reactivity or enantioselectivity. We were interested in studying ligands containing sulfur donors because, despite their extensive coordination chemistry [5,6], such ligands have not often been applied in transition metal catalysis [7–13]. Phosphane ligands are frequently employed in the Heck reaction, so we decided initially to carry out a semiquantitative kinetic comparison of our new ligands with triphenylphosphane. Surprisingly, although the individual steps of the catalytic cycle have been studied in detail [14–17], very few studies of the kinetics of the Heck reaction using phosphorus ligands have been reported [18–20]. We now report our preliminary observations on the kinetics of Heck reactions of aryl iodides.

2. Experimental

Kinetics runs were carried out by adding a freshly prepared solution of $Pd_2dba_3 \cdot CHCl_3$ or $Pddba_2$ (0.02–0.05 mmol) in DMF (1 ml) to the reaction mixture consisting of iodobenzene (1 mmol), methyl acrylate (1.2 equiv.), ligand (0.02–0.08 equiv.), DIPEA (5 equiv.) and pentamethylbenzene (internal standard for GC analysis), in dry DMF (5–20 ml), at room temperature. After stirring for 10 min, the mixture was heated to the required temperature. All steps were performed under an atmosphere of nitrogen. Samples were withdrawn periodically and analysed by GC. All kinetics experiments were carried out at least twice.

3. Results and discussion

The model Heck reaction studied was the addition of iodobenzene to methyl acrylate to give methyl cinnamate (Fig. 1). Use of $Pd_2dba_3 \cdot CHCl_3$ and $Pddba_2$ as precatalysts gave essentially identical results. Early runs at 50°C, using 4% Pd and 8% ligand, revealed an induction period, during which the rate was negligible. During this phase the reaction mixtures remained pale yellow in colour, but they darkened quickly once product formation had begun, to give wine coloured solutions. When the reactions got underway the decay of iodobenzene and the formation of methyl cinnamate appeared to be roughly exponential, but the rates decreased substantially towards the end. All of the PhI was consumed, but only ca. 65% yields of product were obtained.

The length of the induction period correlated strongly with the initial ratio of PPh_3 to Pd, varying from ca. 700 min for a 4:1 ratio to ca. 30 min for a 1.1:1 ratio. Addition of CuI, which is known to bind to PPh_3 [21], caused a significant reduction in the induction period. When $Pd(OAc)_2/2PPh_3$ was the catalyst precursor, only a short induction period was observed (ca. 30 min). Presumably, 1 equiv. of PPh_3 was

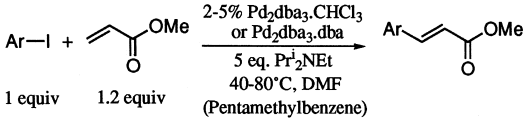

Fig. 1. The model Heck reaction.

consumed in reducing the $Pd(OAc)_2$ [22], so that the initial PPh_3:Pd(0) ratio was 1:1. When an additional 0.5 equiv. of PPh_3 relative to Pd was added to a reaction mixture after ca. 40% product formation, the reaction stopped completely for 155 min, after which it continued to completion, albeit at a slower rate. These experiments showed that when the PPh_3:Pd ratio exceeds 1:1 the reaction is *strongly* inhibited. With higher initial ratios, the PPh_3 is slowly oxidised by traces of air, until most of the excess is destroyed, and the overall rate then increases dramatically. We thought that catalyst decomposition might be responsible for the observed curvature of the graphs of product concentration against time. The amount of Pd was therefore increased from 4% to 10%, only 11% of PPh_3 was employed to keep the induction period to a minimum, and the temperature was reduced to 40°C. GC analysis produced straight line graphs of product concentration versus time, with tailing at the end (Fig. 2). Virtually no induction period was observed, but again only ca. 60% yield of methyl cinnamate was obtained. The results suggested that the reaction was proceeding with pseudo zero order kinetics (constant [Pd]). The reactions of 4-iodotrifluoromethylbenzene and 4-fluoroiodobenzene with methyl acrylate, and the reaction of iodobenzene with styrene, which were slower than the model reaction, also showed linear behaviour.

A series of experiments was performed using 10% Pd and 11% PPh_3 at 40°C, varying the initial concentrations of substrates. The rate of reaction in the initial linear phase was calculated in each case, but we were unable to obtain quantitatively reproducible rates. To minimise sources of error, the reactions were then carried out in batches of three, prepared by dividing one solution of catalyst, ligand, base and one substrate in three, and adding different quantities of the second substrate. The three reactions were then treated identically. Although the rate constants still showed some variability, the trends observed within these series of triple

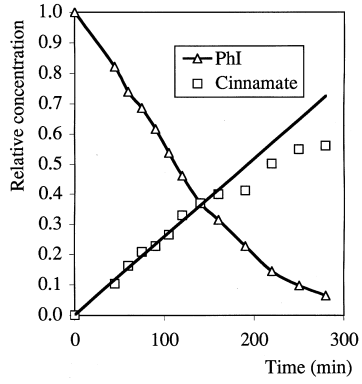

Fig. 2. Product concentration vs. time.

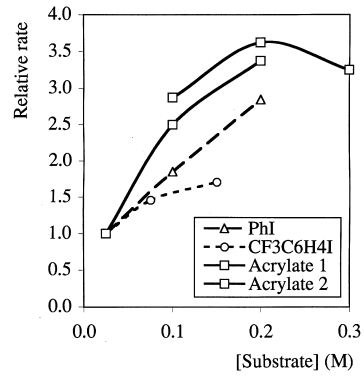

Fig. 3. Relative rate of the reaction vs. substrate concentration.

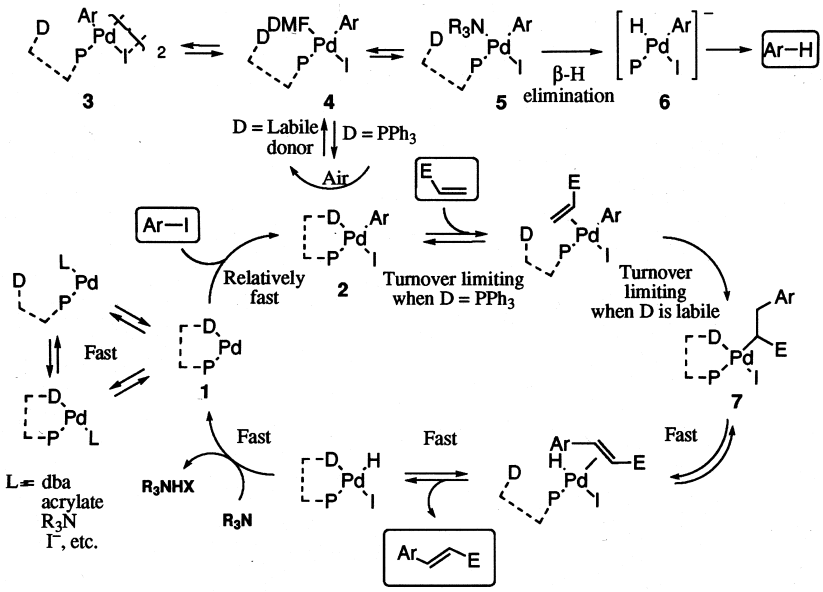
experiments were reproducible (Fig. 3). The initial rate was found to be weakly dependent on the concentration of iodobenzene, with a ca. three-fold rate increase on an eight-fold increase in [PhI]. A weaker dependence of rate on aryl iodide concentration was observed for the reaction of 4-iodotrifluoromethylbenzene with methyl acrylate at 75°C. The initial rate increased by a factor of ca. 2 on increasing [acrylate] by a factor of eight and the dependence was suggestive of saturation behaviour. The weak dependence on substrate concentration is consistent with the approximate straight line kinetics depicted in Fig. 2, with curvature at high conversions.

In these model reactions only ca. 60% yields of methyl cinnamate were obtained even though virtually all the iodobenzene had been consumed. Benzene seemed a likely by-product as there are reports of reduction of aryl halides under Heck conditions [23,24]. Indeed, GC showed that benzene was formed and ^{19}F NMR analysis of a 4-fluoroiodobenzene reaction showed that fluorobenzene was the only significant by-product. The reduction can be accounted for by coordination of DIPEA to the PhPdI oxidative addition complex, and β-H elimination of the amine [25,26], thus forming a hydridopalladium(II) species such as **6**, which gives benzene by reductive elimination (Fig. 4). To confirm the proposal, bases which cannot undergo β-elimination were tested. With 2,2,6,6-tetramethylpiperidine, DABCO [27] or quinuclidine, reaction continued to only ca. 30% conversion but the yields of methyl cinnamate based on iodobenzene consumed were excellent.

Based on these results, we propose a mechanism for the model Heck reaction that focuses on the ligation of the oxidative addition product (Fig. 4). Initially, the Pd(0) bistriphenylphosphane complex **1** is formed from the $Pd(dba)_2$ [28]. This species is in equilibrium with other Pd(0) complexes formed by coordination of other ligands such as dba [28], acrylate, trialkylamine [29] and iodide [30]. Reaction with iodoarene then gives bisphosphane complex **2** ($P=D=PPh_3$) [28] and the alkene coordination step is unfavourable and turnover limiting due to the difficulty of displacing PPh_3. The reaction proceeds, if at all at these low temperatures, by a slow catalytic cycle. When the phosphane to Pd ratio is reduced to <2:1 by air oxidation, the oxidative addition products may be substitutionally labile *mono*phos-



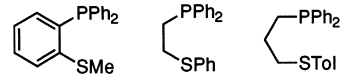


Fig. 4. Proposed mechanism for the model Heck reaction.

phane complexes such as **3**, **4**, and **5** [19,31] in which one phosphane is replaced by more weakly coordinating ligands. Alkene coordination is now fast and the equilibrium favours the alkene complex **7**. The approximate pseudo zero order kinetics are consistent with this, and prove also that oxidative addition is a relatively fast step (although it seems to be sufficiently slow to influence the rate weakly). Any of the other steps may be turnover limiting, but the migratory insertion is likely to be the slowest of these. As the reaction nears completion, continued phosphane oxidation and catalyst decomposition may be contributing to the departure from linearity. To our knowledge, this is the first detailed study of the kinetics of this prototypical Heck reaction using phosphane ligands at atmospheric pressure. *It indicates that for aryl iodides, alkene coordination is turnover limiting with ≥2 equiv. of PPh_3, whereas migratory insertion is turnover limiting with 1 equiv. of phosphane.* The mechanistic proposal is consistent with previous work, especially with its emphasis on the need for a weak ligand/vacant site to facilitate alkene coordination [14,19]. An induction period in the Heck reaction [23] and inhibition by phosphane have been reported [20,32,33]. A fast reaction cycle involving monoligated complexes has also been invoked in a very recent paper by van Leeuwen and co-workers [19], but with their very bulky phosphorus amidite ligand the reaction was first order with respect to alkene (styrene).

We also studied the kinetics of reactions using tri-*o*-tolylphosphane, which Heck showed to be the ligand of choice in many cases [34]. The use of 1–4 equiv. of $P(o\text{-Tol})_3$ with both iodobenzene (40°C) and 4-iodotrifluoromethylbenzene (70°C) gave high conversion, with no more than a brief induction period, and pseudo zero order kinetics up to 60% conversion. The contrast with PPh_3 is striking and the results suggest that $Pd[P(o\text{-Tol})_3]_2$ forms sterically hindered oxidative addition complexes (**2**, $P=D=P(o\text{-Tol})_3$) in which one phosphane is readily displaced by other ligands including alkene [31,34].

8 **9** **10**

With these mechanistic insights, we decided to study a series of heterobidentate phosphane/sulfane ligands **8**–**10**. We hoped that these hemilabile ligands [35] would form active catalysts, as alkene coordination could take place by displacement of a weakly coordinating sulfane rather than a strongly coordinating phosphane. Ligand **8** was tested using a 1:1 Pd:ligand ratio at 80°C. Product formation clearly followed pseudo zero order kinetics until the conversion reached ca. 75% and the yield was ca. 100%. Ligand **9** gave very similar results under the same conditions (Fig. 5), although an induction period of ca. 95 min was observed. Ligand **10** gave much faster reaction, but the yield of cinnamate was only ca. 65%.

Clearly PS ligands are viable in the Heck reaction. The reactions were relatively fast, high conversions were achieved and yields of methyl cinnamate were high, except for ligand

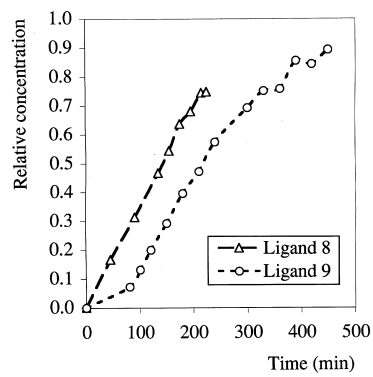

Fig. 5. Product concentration vs. time for the ligands **8** and **9**.

10 with the propane backbone. When the catalyst is a palladium complex containing PS ligands, the sulfur donor atom of the oxidative addition product (**2**, PD = chelating phosphanosulfane) is easily displaced by the alkene. The ligands give better catalyst stability and higher yields than PPh_3, presumably because the dissociated S moiety of the hemilabile ligand can recoordinate to stabilise the other complexes in the cycle, and to prevent competitive coordination of the amine. Ligand **10** gives faster reactions and lower yields than ligands **8** and **9**, presumably because it gives a less stable six-membered chelate. Reactions using these ligands are not as fast as those using 1 equiv. PPh_3 or $P(o\text{-Tol})_3$, where the concentration of the Pd-alkene complex should be the highest. To our knowledge, the use of hemilabile ligands in the Heck reaction has not been reported, although they have been used in related reactions involving insertion of alkenes [36,37]. Ligand **9** seemed to give the best results so it was investigated further. The reaction of styrene, in the presence of ligand **9**, was performed at 90°C. An induction period of ca. 90 min was observed, the reaction rate was slow (ca. 1000 min to reach completion) and excellent pseudo zero order kinetics were observed. High conversion was obtained (ca. 95%) but the yield was relatively low (ca. 70%), albeit much higher than using PPh_3. Bromobenzene was reacted with methyl acrylate employing **9** as ligand (2.4 equiv.) at the higher temperature of 110°C. The reaction was slow (ca. 20 h at 110°C), it ceased at 40% consumption of PhI, and the yield of methyl cinnamate was only 35%. Although these preliminary results are not as impressive as others reported recently [19], we believe that PS ligands offer considerable potential and deserve further investigation.

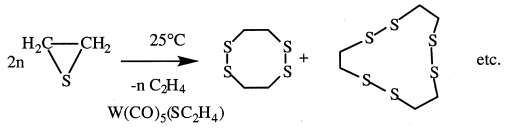
POLYHEDRON

The catalytic transformation of thiiranes to cyclic disulfides by tungsten carbonyl complexes

Richard D. Adams *, Joseph L. Perrin

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, USA

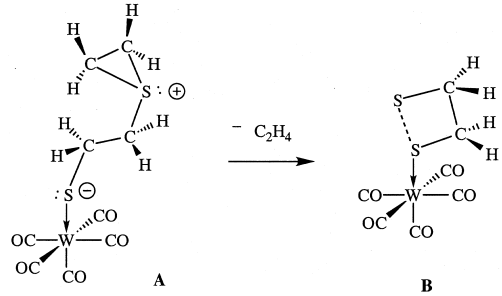


Received 4 October 1999; accepted 8 November 1999

Abstract

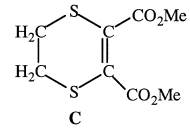
This report reviews our recent studies of the catalytic transformations of thiiranes and vinylthiiranes by tungsten pentacarbonyl complexes. Whereas the thiranes yield only macrocyclic polydisulfides, the latter reactions yield only the cyclic monodisulfides known as 3,6-dihydro-1,2-dithiins. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Thiiranes; Dihydrodithiins; Tungsten carbonyls



In recent studies we have discovered novel transformations of thiiranes into macrocyclic polydisulfides by carbonyl complexes of tungsten, Eq. (1) [1,2].

(1)

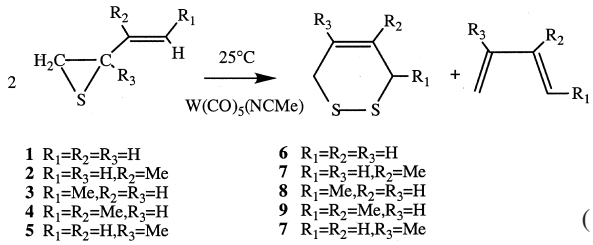


Two equivalents of thiirane are consumed in the formation of each disulfide group. One equivalent of alkene is also formed. The thiirane molecule is activated by coordination of its sulfur atom to the tungsten atom. In one case, a thiirane-tungsten complex, $W(CO)_5$(*cis*-SCHMeCHMe)), was isolated and characterized structurally by single crystal X-ray diffraction methods [1,2]. The sulfur atom from a second molecule of thiirane is then added to one of the carbon atoms of the thiirane ligand of the complex in a ring opening step. This leads to the formation of a zwitterionic intermediate **A** containing a thiiranium-thiolate ligand that subsequently eliminates an olefin from the thiiranium group to yield a reactive alkene disulfide containing tungsten species **B**, Scheme 1.

The nature of the bond between the sulfur atoms in **B** has not been established. The alkene disulfide ligand in **B**, also known as 1,2-dithietane, has not yet been synthesized and isolated as a free molecule by any procedures. The dithietane ligands from two or more molecules then combine to form the cyclic polydisulfides and regenerate catalytically active

Scheme 1.

'$W(CO)_5$' groupings. Evidence for the existence of the dithietane ligand in **B** was obtained by trapping experiments using dimethylacetylene dicarboxylate (DMAD) which yielded the product 1,4-dithia-2,3-bis(methoxycarbonyl)-cyclohexene (**C**). Compound **C** is not formed from mixtures of the macrocyclic polydisulfides and DMAD.



C

$W(CO)_5$(NCMe) is as good a catalyst precursor for these reactions, but $W(CO)_6$, which has no labile ligands, is not catalytically active.

We have also found that vinylthiirane (**1**) and the methyl-substituted vinylthiiranes **2**–**5** can be effectively transformed into 3,6-dihydro-1,2-dithiin (**6**) and a series of new methyl-substituted 3,6-dihydro-1,2-dithiins **7**–**9** by tungsten carbonyl compounds such as $W(CO)_5$(NCMe), Eq. (2) [3,4].

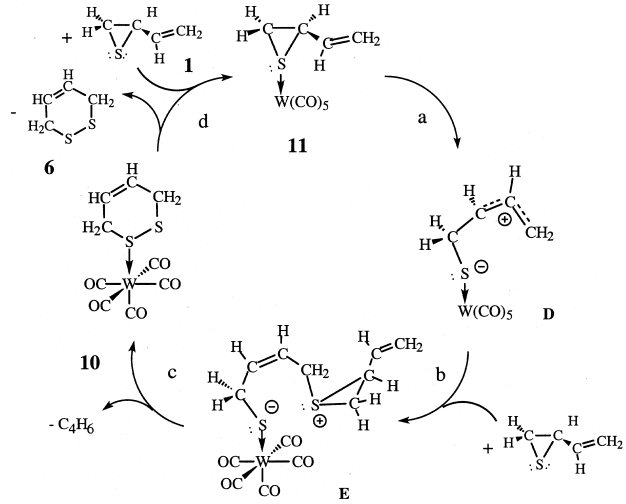
(2)

These reactions are accompanied by the formation of the corresponding butadiene and essentially 100% conversion is obtained when they are performed at 25°C. Turnover frequencies (TOFs) range from a low of 2 h^{-1} to a high of 29 h^{-1}, see Table 1. The reaction is inhibited by methyl groups on the thiirane ring, but is accelerated when methyl groups are placed on the vinyl group. The reaction is insensitive to the atmosphere over it and similar turnover frequencies were obtained when the reactions were performed under nitrogen, in air and even under CO.

The tungsten complex $W(CO)_5(\overline{SSCH_2CH{=}{=}CHCH_2})$ (**10**) was isolated from the vinylthiirane reaction and was structurally characterized [3,4]. The molecule contains a dihydrodithiin ligand coordinated to the tungsten atom through one of the sulfur atoms. This complex was shown to be a component in the catalytic cycle, see Scheme 2.

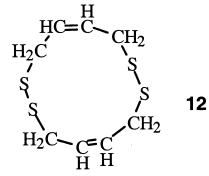


$W(CO)_5(NCMe)$ is a good catalyst precursor, but is not a component in the catalytic cycle. ^{13}C NMR studies of catalytically active solutions showed that **10** is converted to vinylthiirane containing tungsten complexes **11** (two isomers which differ depending on which of the two lone pairs of electrons on the sulfur atom is coordinated) in the course of the catalysis. Unlike the reactions of the simple thiiranes, it was proposed that the thiirane ring opening occurs spontaneously in the complexes **11** (Scheme 2, step a), to give an allylium-thiolate intermediate **D**. This could explain the enhancement of the reaction by methyl substituents on the vinyl group. Intermediate **D** then rapidly adds a second equivalent of vinylthiirane, step b, to yield a thiiranium-thiolate species **E** that eliminates butadiene, step c, to yield the stable dihydrodithiin complex **10**. Vinylthiirane is capable of displacing the dihydrodithiin ligand to release the six-membered ring product **6** and also to complete the catalytic cycle, step d.

Interestingly, it has been shown that the catalysis is significantly increased when a phosphine ligand is substituted for

Table 1
Results of catalytic transformations of vinylthiiranes to dihydrodithiins by $W(CO)_5(NCMe)$ [3,4]

Reagent	Product	Yield (%) [a]	TON (24 h)	TOF (h^{-1})
1	**6**	86	212	15
2	**7**	84	141	29
3	**8**	86	149	24
4	**9**	80	146	19
5	**7**	34	53	2



[a] Isolated yields after 24 h.

Scheme 2.

CO on the tungsten atom. For example, the turnover frequency for the catalytic formation of **6** from **1** by $W(CO)_4(PPh_3)(NCMe)$ is 47 h^{-1}, nearly three times the rate of that of $W(CO)_5(NCMe)$. The increase can be attributed to steric crowding effects that promote the spontaneous ring opening step, Scheme 2, step a.

Since the monodisulfides **6**–**9** contain relatively stable six-membered rings, few if any macrocyclic polydisulfides are formed in these reactions. However, these disulfides do possess some torsional ring strain at the S–S bond [5] and concentrated solutions of them will yield polymers in the presence of stimulation by light. Interestingly, the macrocyclic 12-membered bis-disulfide 1,2,7,8-tetrathiacyclododeca-4,10-diene (**12**) (a dimer of **6**) can be isolated from solutions of **6** during the course of these polymerizations [3,4]. Compound **6** reacts with $Os_3(CO)_{10}(NCMe)_2$ by insertion into the S–S bond to yield a series of osmium cluster complexes containing the butadienedithiolate ligand [6].

12

Dihydrodithiins have been prepared by other methods, most notably the addition of S_2 to butadienes [7–9], but the catalytic procedure described above appears to be superior by far.

Abstract

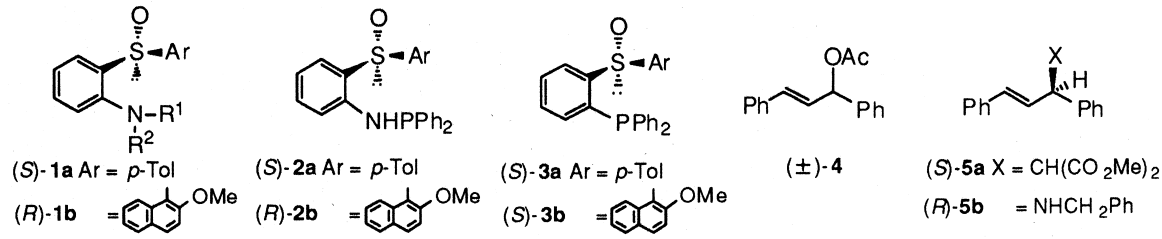
Participation of chiral sulfinyl functionality in palladium-catalyzed asymmetric reactions is demonstrated by using chiral sulfoxides as chiral ligands or chiral substrates. New chiral ligands, *o*-(phosphinoamino)phenyl and *o*-phosphinophenyl sulfoxides, have been developed. The structure of an intermediary palladium complex was determined by X-ray crystallographic analysis. The palladium-catalyzed asymmetric 1,3-rearrangements of (1,3-butadienyl)cyclopropanes bearing chiral sulfinyl groups to cyclopentenes are described. The participation of the chiral sulfinyl group to the palladium catalyst is described. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Asymmetric alkylation; Asymmetric rearrangements; Chiral ligands; Chiral sulfoxides; Palladium catalysts

The organosulfur functionality has been widely used in organic synthesis as a stereo- and enantiocontrollable element, and the high efficiency of the selectivity, especially the enantioselectivity by chiral sulfinyl groups, has received much attention in recent years. We wish to demonstrate here the usefulness of chiral sulfinyl functionality as a ligand or a chiral source in the substrate in palladium-catalyzed asymmetric reactions such as nucleophilic substitutions of chiral π-allylpalladium complexes and 1,3-rearrangements in olefinic cyclopropanes bearing chiral sulfinyl groups.

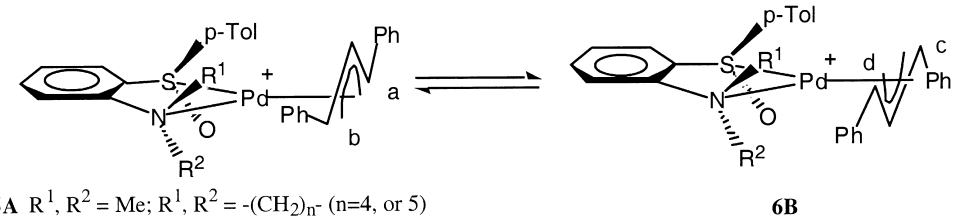
There have been published some issues related to asymmetric synthesis using chiral ligands involving organosulfur functions; however, few reports have appeared concerning asymmetric synthesis with chiral ligands bearing chiral organosulfur groups [1–7] such as sulfinyl [8–10] and sulfoximine [11] functions as the sole chiral source. Hitherto, we have studied asymmetric synthesis using chiral sulfoxide ligands as the sole chiral source.

A chiral sulfinyl group forms a chiral chelate of palladium by coordination of the sulfinyl sulfur atom. The design and development of chiral efficient ligands along this line provided new ligands bearing chiral sulfinyl groups as sole chiral sources, and other coordinatable heteroatoms such as nitrogen and phosphorus (Scheme 1).



Use of chiral *o*-aminophenyl *p*-tolyl sulfoxides (*S*)-**1** [12,13] as ligands in the palladium-catalyzed reaction of compound **4** with sodium malonate provided compound (*S*)-**5a** with moderate enantiomeric excess (e.e.). The reactions proceed via chiral π-allylpalladium chelate **6** (Scheme 2). Chelate **6B** would be sterically preferred to chelate **6A** because of the existence of steric hindrance between the *p*-tolyl and the phenyl group in the allylic systems in compound **6A**. Therefore, the nucleophile (malonate sodium enolate) would attack the allylic site (c) in compound **6B** from the back side of the palladium to produce compound (*S*)-**5a**.

Use of chiral *o*-(phosphinoamino)phenyl sulfoxides as ligands improved the enantioselectivity. The palladium-catalyzed reactions of compound (±)-**4** with sodium malonate using compound (*R*)-**2b** produced compound (*R*)-**5a** with 97% e.e. Thus, the existence of vicinal phosphinoamino groups in the chiral sulfinyl ligands was essential for the improvement of the enantioselectivity. This high enantioselectivity presumably arises from the formation of a sterically controllable six-membered transition state [14].



The phosphorus and sulfur atoms in the chiral ligands (*S*)-**2a** have rather strong coordination ability to palladium catalysts, forming six-membered π-allylpalladium intermediates (**7**) (Scheme 3). The nucleophile (malonate carbanion) would preferentially attack the allylic site *trans* to the phosphorus group in the conformationally most preferred π-allylpalladium complex (**7Ba**), producing compound (*S*)-**5a**.

Scheme 1.

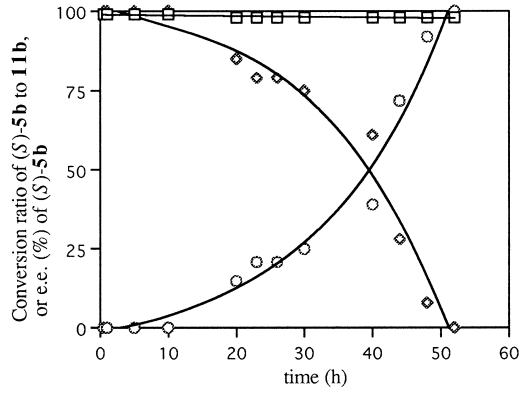
Scheme 2.

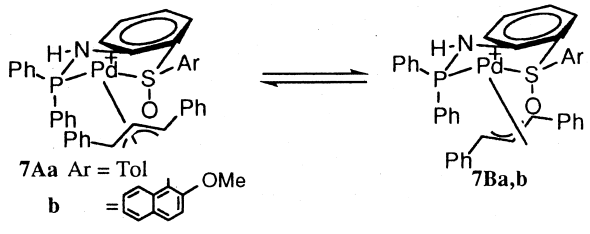
With compound (*R*)-**2b** as a ligand, the nucleophile would attack the allyl terminus *syn* to the phosphorus group because of steric interference by the bulky naphthyl substituent in complex **7Bb**.

In contrast to (*R*)-2-(diphenylphosphino)ethyl *p*-tolyl sulfoxide, chiral *o*-phosphinophenyl sulfoxides were obtained with retention of the chirality on the sulfonyl functions.

The chiral sulfoxide (*S*)-**3b** was concluded to be very stable in tetrahydrofuran (THF) at room temperature, with complete retention of the chirality without conversion into the phosphine oxide. However, upon heating in refluxing THF, a more rapid irreversible transformation of compound (*S*)-**3b** into compound **8** was observed with almost complete retention (>96% e.e.) of the chirality (Scheme 4). This is shown in Fig. 1, which was plotted from HPLC analysis with Chiralpak AD in relation to the elapse of the reaction time [15].

A chiral sulfinyl compound, (*S*)-**3b**, with a bulky substituent was demonstrated to serve as a highly efficient chiral ligand in the palladium-catalyzed reactions, providing an extremely high degree of asymmetric induction. The reactions of compound (±)-**4** with sodium malonate were carried out in THF at −20°C in the presence of $PdCl_2(CH_3CN)_2$ (0.03 equiv.) and compound (*S*)-**3b** (0.06 equiv.) to afford compound (*S*)-**5a** in good yields with 82% e.e.





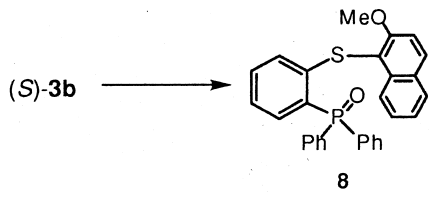


Fig. 1. The conversion ratio of compound **3b** to compound **8**, showing enantiomeric excess (e.e.) (%) of compounds (*S*)-**3b** (□), (*S*)-**3b** (◇) and **8** (○).

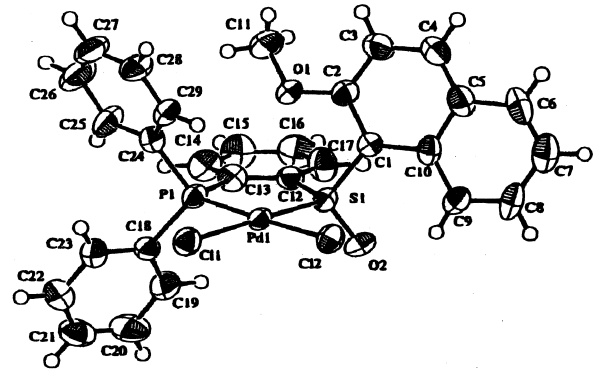
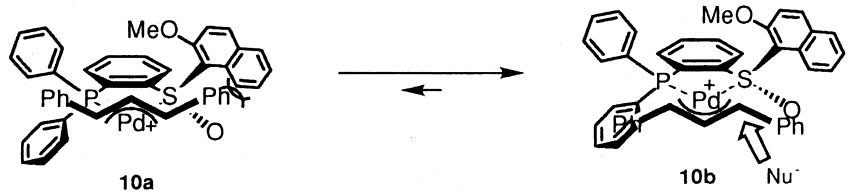
Scheme 3.

Scheme 4.





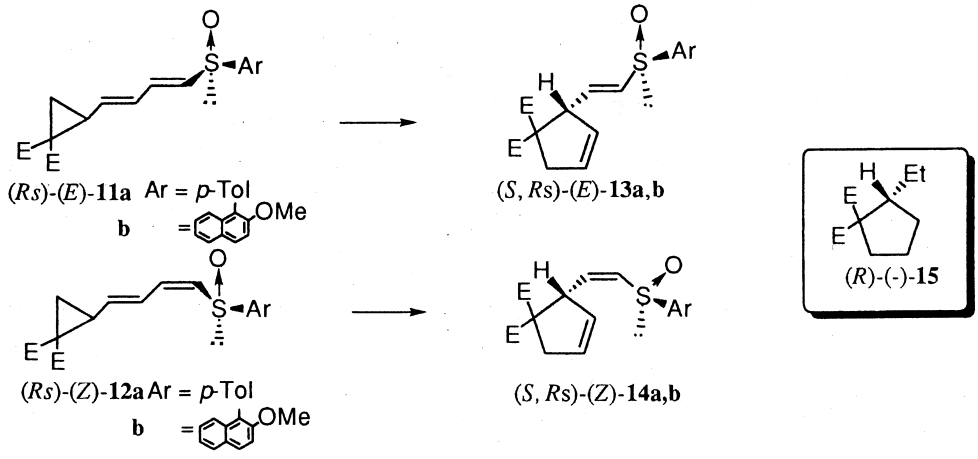


Fig. 2. Molecular structure (ORTEP drawing) of compound **9**. Selected bond distances (Å) and angles (°) are: Pd(1)–S(1) 2.221(2), Pd(1)–P(1) 2.229(2), Pd(1)–Cl(1) 2.313(2), Pd(1)–Cl(2) 2.356(2), S(1)–Pd(1)–P(1) 88.88(8), S(1)–Pd(1)–Cl(2) 89.13(8), P(1)–Pd(1)–Cl(1) 87.85(8).

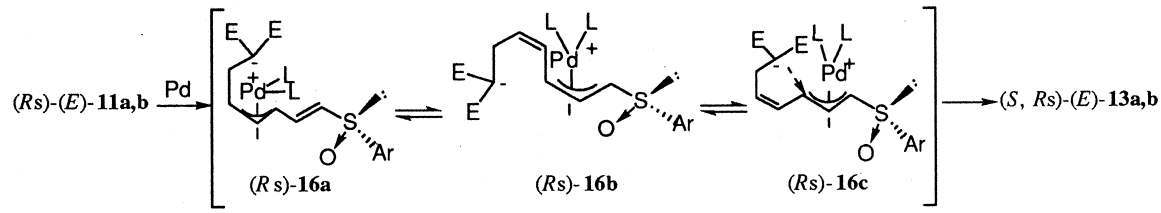
Scheme 5.

Scheme 6.

The intermediary palladium complex derived from compound (*S*)-**3b** and $PdCl_2(CH_3CN)_2$ was isolated by recrystallization from CH_2Cl_2–Et_2O. The structure as determined by X-ray crystallographic analysis is shown in Fig. 2. The palladium-catalyzed reactions of compound (±)-**4** with sodium malonate using the isolated palladium complex **9** as a catalyst gave the same result as that obtained under the normal reaction conditions.

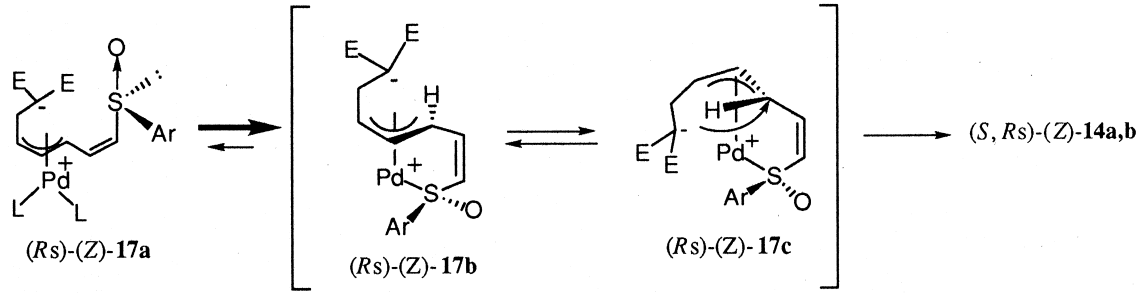
As the crystallographic data clearly show, a five-membered chelated palladium complex is formed by coordination of the phosphino group and the sulfinyl sulfur function to palladium. In the conformational equilibrium (Scheme 5), the conformer **10b** would be preferred to compound **10a** because of the existence of steric interference between the large substituent (*p*-tolyl or 2-methoxy-1-naphthyl) on the chiral sulfoxide and the phenyl group in the allyl terminus in compound **10a**. Therefore, the nucleophile (sodium malonate or benzylamine) attacks preferentially the allyl terminus in compound **10b** *trans* to the better π-acceptor, which is the phosphine group in the current case, despite the steric effect by the bulky substituent (2-methoxy-1-naphthyl), affording compounds (*S*)-**5a** and (*R*)-**5b** in a highly enantioselective fashion.

The unequivocal participation of the chiral sulfinyl functionality was observed in palladium-catalyzed 1,3-rearrangements of 1,3-butandienylcyclopropanes bearing chiral sulfinyl groups [16].



The palladium-catalyzed reaction of compound (*R*s)-(*E*)-**11a,b** was carried out in toluene at room temperature for 18 h in the presence of $Pd_2(dba)_3 \cdot CHCl_3$ (0.1 equiv.) and phosphine ligands (0.2 equiv.) to give compound (*S*,*R*s)-(*E*)-**13a,b** with high diastereomeric excess (d.e.) (90–94%) (Scheme 6). A similar reaction of compound (*R*s)-(*Z*)-**12a,b** was carried out under the same reaction conditions to produce compound (*S*,*R*s)-(*Z*)-**14a,b** with high d.e., with unexpected retention of the (*Z*)-geometry of the starting olefin.

The absolute configuration of the newly asymmetric carbon center was determined to be the (*S*)-configuration by chemical correlation to compound **15**.



The mechanism for the asymmetric induction in these palladium-catalyzed rearrangements is rationalized on the basis of the stereochemical outcome observed.

The initially formed π-allylpalladium complex (*R*s)-**16a** derived from complex (*R*s)-(*E*)-**11a,b** would be equilibrated into the more stable π-allyl system (*R*s)-**16b,c**; in the most preferred π-allyl system, (*R*s)-**16c**, with the *syn* arylsufinyl group at C1 and the *syn* substituent at C3, the palladium–phosphine moiety is orientated at the sterically less crowded upper side (the lone pair side of the sulfinyl group) in the electronically most advantageous conformation with the sulfinyl sulfur–oxygen bond coplanar to the π-allyl system, as designated in compound **16c**. The intramolecular substitution of the carbanion in compound (*R*s)-**16c** occurs at the C3 allyl site from the opposite side of the palladium in a highly stereoselective fashion to afford compound (*S*,*R*s)-(*E*)-**13a,b** with high d.e. (Scheme 7).

In the case of compound (*R*s)-(*Z*)-**12a,b**, the direct participation of the chiral sulfinyl group to the palladium should be crucial for the rationalization of the stereochemical results; the initially formed π-allylpalladium complex (*R*s)-(*Z*)-**17a** would be stabilized by the coordination of the sulfinyl group to the palladium. It is certainly assumed that the formation of the conformationally more stable π-allylpalladium complex

Scheme 7.

Scheme 8.

(*Rs*)-(*Z*)-**17c** with the retained (*Z*)-configuration of the olefin, presumably by the coordination of the sulfinyl sulfur atom to the palladium, followed by intramolecular nucleophilic substitution from the opposite side of the palladium, provided compound (*S*,*Rs*)-(*Z*)-**14a,b** in a highly stereoselective fashion (Scheme 8).

Abstract

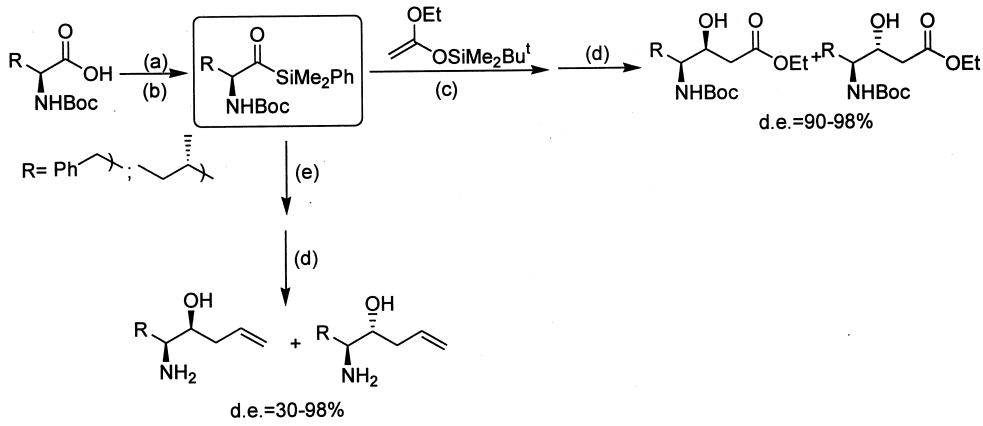
Several new *N*-Boc-protected α-aminoacylsilanes from L-phenylalanine and L-isoleucine are synthesized via silylcupration of the corresponding imidazolides. The addition reaction of nucleophiles to the carbonyl moiety gives satisfactory yields of highly functionalized β-amino alcohols and statine analogues. The diastereoselectivity ranges from 30 to 98% and depends upon the nature of the C-nucleophile, on the structure of the starting amino acid as well as on the chelating properties of the Lewis acid employed. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: α-Aminoacylsilanes; β-Amino alcohols; Lewis acid; Silylcupration; Statine analogues

1. Introduction

The synthesis of enantiopure β-amino alcohols is currently the subject of enormous interest, mainly due to their applications as peptidomimetics, as building blocks for pharmaceuticals and also as ligands for asymmetric catalysis. Diastereoselective addition to α-amino aldehydes [1,2] has emerged as one of the most efficient and versatile methods available for preparing functionalized β-amino alcohols [3,4]. However, it is well known that most of the nitrogen-protected α-amino aldehydes are relatively unstable both chemically and configurationally and they must be used immediately after their preparation. Another problem is the low degree of stereoselectivity often encountered in the addition step.

Homochiral α-aminoacylsilanes [5,6], obtained from natural α-amino acids, can be used as stable synthetic equivalents of α-amino aldehydes for the diastereoselective synthesis of optically active β-amino alcohols. This approach is based on the possibility of replacing the silyl group stereospecifically with a proton in the α-hydroxysilanes initially formed. Moreover, the use of acylsilanes as synthetic equivalents of the corresponding aldehydes has the advantage of increasing the degree of stereoselectivity in the addition of nucleophiles, due to the bulkiness of the silyl group.



2. Results and discussion

We have previously reported that the allylation reaction under Hosomy–Sakurai conditions of *N*-Pht- and *NH*-Ts-protected α-aminoacylsilanes derived from L-phenylalanine occurs with good chemical yields and high diastereoselectivity [5,6]. The degree of diastereoselectivity during the nucleophilic addition depends on both the nitrogen protecting group and the reagents. Diastereomeric excess (de) values ranging between 96 and 98% were obtained in the $TiCl_4$-promoted allylation of the *N*-Pht-aminoacylsilanes and of the *NH*-Ts-aminoacylsilane with allyltrimethylsilane. Lower de values were obtained in the $Sc(OTf)_3$-catalysed allylation with tetra-allyltin.

In the formation of the homoallylic alcohols the harsh reaction conditions required for deprotection–desylilation made these steps problematic. This led us to consider as more suitable candidates for these reactions *NH*-Boc aminoacylsilanes in which the Boc group could be removed under much milder conditions. To this end *NH*-Boc L-phenylalanine and *NH*-Boc L-isoleucine were converted in good yields into the corresponding α-aminoacylsilanes by reaction with carbon-

yldiimidazole, followed by treatment of the acylimidazolides with $(Me_2PhSi)_2CuCNLi_2$ (Scheme 1).

A systematic three-carbon and two-carbon stereoselective elongation of the carbon skeleton of the two α-aminoacylsilanes was performed via allylation and aldol reactions, respectively.

Since the allylation under Hosomi–Sakurai conditions led to extensive decomposition of the starting materials because of the incompatibility of $TiCl_4$ with the *NH*-Boc moiety, and to avoid racemization at C-2 induced by more basic allylic metals, $Sc(OTf)_3$-catalysed allylation [7] with tetra-allyltin and In-mediated [8] allylation with allyl bromide under Barbier conditions were employed. Both these reactions afforded the expected homoallylic alcohols in satisfactory to good yields and with de values ranging between 30 and 98%.

The α-hydroxysilanes thus formed were then subjected to stereospecific protiodesilylation with TBAF to give the enantiopure β-amino alcohols, and the subsequent deprotection of the *NH*-Boc group took place under normal conditions affording the isomerically pure free amino alcohols in high yields.

The significant differences in diastereoselectivities appear to be related to the structure of the starting amino acid. The observation that, under the same allylation conditions only the isoleucine leads to very high *syn* selectivity, suggests that factors other than chelation are likely to play a major role in determining the stereochemical outcome.

Stereoselective two-carbon elongation of the carbon skeleton of the two α-aminoacylsilanes was performed by introducing an acetic acid moiety. The aldol reaction of *O*-ethyl-*O*-*tert*-butyldimethylsilyl ketene acetal proceeded smoothly in the presence of $BF_3 \cdot Et_2O$ to give the expected addition products in good yields and with high diastereoselectivity in favour of the *syn* adduct. The stereochemistry of the adducts was determined after desilylation of the compounds with TBAF by comparing the spectroscopic data with those reported in the literature. A set of important biologically active statine analogues with natural configurations [9] (3*S*,4*S*) can thus be prepared by this four-step highly *syn*-diastereoselective sequence. In summary, the methodology outlined here, based on three-carbon and two-carbon elongation of the carbon chain of several new *N*-Boc-protected α-aminoacylsilanes via nucleophilic addition to the carbonyl moiety, constitutes a convenient and reliable means for the stereoselective synthesis of functionalized β-amino alcohols.

3. Experimental

3.1. Silylcupration: general procedure

Phenyldimethylsilyl lithium [10] 0.85 M (35.5 ml, 30.17 mmol) was added to a suspension of CuCN (1.25 g, 15.07 mmol) in tetrahydrofuran (THF) (70 ml) at 0°C. The reaction mixture was stirred for 20 min under argon and then slowly transferred by cannula to a suspension of (2*S*)-2-[*N*-(*tert*-butoxycarbonyl)amino]-1-imidazol-1-yl-3-phenylpropan-1-one (4.31 g, 13.7 mmol) in THF (90 ml) at −78°C. Stirring was continued at this temperature for a further 30 min. A saturated solution of NH_4Cl was then added and the mixture was allowed to warm to room temperature; it was then extracted three times with diethyl ether (3×30 ml). The organic extracts were separated and dried on Na_2SO_4. After removal of the solvent in vacuo the crude extract was purified by column chromatography on silica gel (light petroleum–Et_2O, 4:1), affording 2.62 g (50%) of pure (2*S*)-3-phenyl-2-[*N*-(*tert*-butoxycarbonyl)amino]-propanoyl-dimethylphenylsilane as a light yellow oil. $[\alpha]_D^{24}$ +19.3 (*c* 2.00, $CHCl_3$). IR (cm^{-1}): 3420, 1715, 1650, 1240. MS (EI): *m/z* 383 (M^+), 298, 221, 164, 135, 91, 57. ^1H NMR (200 MHz): δ 0.55 (s, 6H), 1.40 (s, 9H), 2.50 (dd, 1H, *J* = 14.0 , 7.4 Hz), 2.95 (dd, 1H, *J* = 14.0 , 5.8 Hz), 4.70 (bq, 1H, *J* = 7.6 Hz), 4.95 (d, 1H, *J* = 9.9 Hz), 6.80–6.95 (m, 2H), 7.20–7.80 (m, 8H). ^{13}C NMR (50.3 MHz): δ

−4.6, −4.4, 28.2, 35.6, 64.2, 79.5, 126.5, 128.3, 128.3, 129.3, 130.1, 134.0, 134.1, 136.0, 154.8, 241.6. *Anal*. Calc. for $C_{22}H_{29}NO_3Si$: C, 68.90; H, 7.63; N, 3.65. Found: C, 68.82; H, 7.58; N, 3.61%.

(2*S*,3*S*)-3-Methyl-2-[*N*-(*tert*-butoxycarbonyl)amino]-pentanoyl-dimethylphenylsilane was prepared following the above procedure, using (2*S*,3*S*)-2-[*N*-(*tert*-butoxycarbonyl)amino]-1-imidazol-1-yl-3-methyl-pentan-1-one (4.2 g, 15.0 mmol) and 16.5 mmol of bis-dimethylphenylsilyl lithium cyanocuprate. Silica gel chromatography (light petroleum–Et_2O, 6:1) gave 2.88 g (55%) of (2*S*,3*S*)-3-methyl-2-[*N*-(*tert*-butoxycarbonyl)amino]-pentanoyl-dimethylphenylsilane as a pale yellow oil. $[\alpha]_D^{24}$ +62.6 (*c* 2.00, $CHCl_3$). IR (cm^{-1}): 3440, 1730, 1650, 1240. Abstract

The addition of vinyl, aryl and alkynyl Grignard reagents to propargyl alcohols for the direct synthesis of dihydroxydienes (**7**), furans (**9**), butenolides (**10**) and enediyne alcohols (**11**) from a one-pot reaction involving a putative magnesium chelate intermediate (**3**) is described. Treatment of 5-bromo-1,3-pentadiene with indium metal in the presence of carbonyl compounds resulted in γ-pentadienylation to generate 1,4-dienes (**30**). Dehydration afforded cross-conjugated trienes (**31**) for tandem Diels–Alder reactions, while the alcohol product (**34**) from an unsaturated aldehyde after oxy-Cope rearrangement afforded the 1,4-diene product (**35**) and ultimately hydrindane (**36**). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Cycloadditions; Dienes; Indium; Magnesium; Trienes

Our interest in the synthesis of taxoids required the development of diverse organometallic reagents and protocols for the preparation of key intermediates and building blocks [1–3]. This included routes to stereodefined dienes by the direct addition of vinyl Grignard reagents to propargyl alcohols (**1**) [4–14]. Thus generation of the magnesium chelate (**3**) (or a closely related species) provides a direct synthesis of the family illustrated in Scheme 1. This includes the halodienes (**3**, **4**) [15], plus diene-diols (**7**), furans (**9**), 2(5*H*)-furanones (butenolides) (**10**) and enediynes (**11**) [16,17].

Direct condensation of the diene unit with carbonyl compounds was more efficient in cyclohexane due to the increased nucleophilicity of the Grignard complex in a less polar solvent. Table 1 lists representative examples for the preparation of compound **7**. It is of interest that the presence of the silyl ether is sufficient to inhibit the reaction of compound **14** (Table 1, entry e).

Furans comprise an important class of oxygen heterocycles for which new preparative routes continue to be developed [18–21]. Following the protocol developed above, substituted furans (**9**) can be synthesized directly upon reaction of (**3**) with dimethylformamide (DMF) followed by acidification. Alternatively, reaction with aryl nitriles provides C-2 substitution. The vinyl furan systems contain useful functionality for the construction of more complex skeletons

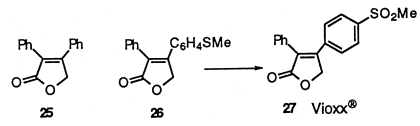
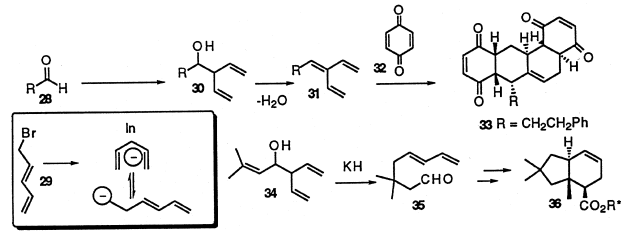
via a double Diels–Alder strategy and also may be used as monomers. The versatility and scope of this furan synthesis was extended by in situ generation of the intermediate chelate compound **3** via lithium–magnesium transmetallation, as illustrated in Scheme 2. Thus, modification of the standard protocol permitted the control of the substitution pattern at all the ring positions. Various examples are listed, including the bis-furanyl system (**23**). Thus, depending upon the substrate–reagent–reactant combination selected, a large number of substituted furans can be prepared in a straightforward manner.



The study and synthesis of enyne and enediyne chromophores are of current interest because of their challenging structures and biological activity as antibiotics and antitumor agents [22–24]. An additional application of the synthetic utility of this carbometallation method is the facile preparation of these building blocks [25–28]. Thus the enediyne alcohol (**11**) [29] was prepared easily with trimethylsilylacetylene magnesium chloride.

Early examples of dialkyl butenolides from the condensation of species related to compound **3** with carbon dioxide have been reported [30,31], and other methods are available [32,33]. However, there is medicinal interest in preparing 3,4-diaryl-2(5*H*)-furanones. Thus, phenylpropargyl alcohol plus phenylmagnesium chloride or 4-thiomethylphenylmagnesium chloride followed by carbon dioxide afforded lactones **25** and **26** (Scheme 3). Oxidation of the sulfide with *m*-chloroperoxybenzoic acid gave the new Merck anti-inflammatory drug Vioxx® (**27**) in quantitative yield.



Li and Chan [34] have demonstrated the utility of allylindium species for addition to carbonyl compounds where the tin and zinc reagents failed [35–37]. For many metal pentadienyl systems condensation is not regioselective, and the delocalized anion may react at either the α or γ position (Scheme 4). However, the reagent generated from 5-bromo-1,3-pentadiene [38] and indium metal adds in a regioselective manner to give non-conjugated compounds of type **30** [39]. During our investigations, Araki and co-workers [40] reported related studies. Recently, Chan and Yang [41] have established that allylindium additions to ketones proceed via

Scheme 2. Synthesis of furans.

Scheme 3. Butenolide products.

Scheme 4. Pentadienyl indium addition and [4+2] cycloadditions.

the formation of an indium(I) species rather than indium(III). A parallel process involving metal surface-mediated allyl radical anions is also possible. In view of the close structural similarity between pentadienyl and allylindium species, the mechanisms are probably closely related.

Dehydration of these diene products (**30**) under Mitsunobu-type conditions (Ph_3P, diethylazodicarboxylate (DEAD), C_6H_6, 80°C) generated the corresponding trienes (**31**). These trienes facilitate diene-transmissive tandem Diels–Alder reactions [42] such as the reaction with compound **32** to give compound **33**. The alcohol product (**34**) from an unsaturated aldehyde is a surrogate for the Michael addition product. Thus oxy-Cope rearrangement afforded the 1,4-diene product (**35**). Subsequent cycloaddition with the Oppolzer chiral auxiliary [43,44] completed an enantioselective route to the hydrindane (**36**) [45].

In summary, the carbometallation protocols described above provide direct access to a number of useful unsaturated systems that can be employed for a variety of synthetic objectives. In addition, the organoindium reagent derived from 5-bromo-1,3-pentadiene and indium metal reacts with excellent regioselectivity and after further manipulation affords rapid entry to complex multicyclic skeletons from various [4+2] cycloadditions.

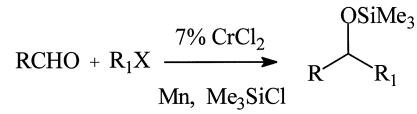
POLYHEDRON

The first catalytic enantioselective Nozaki–Hiyama–Kishi reaction

Marco Bandini, Pier Giorgio Cozzi* [1], Achille Umani-Ronchi* [2]

Dipartimento di Chimica G. Ciamician, Università di Bologna, Via Selmi 2, 40126 Bologna, Italy

Received 4 October 1999; accepted 4 January 2000



Abstract

Herein we report the first example of a catalytic enantioselective Nozaki–Hiyama–Kishi reaction performed with a catalytic amount of chiral chromium complex. A large variety of non-stereogenic and stereogenic reactive halides can be added to aldehydes to afford the corresponding alcohols with excellent stereoselectivity using a catalytic amount of chiral chromium complex ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Chromium; Salen; Manganese; Catalysis; Enantioselection; Nozaki–Hiyama–Kishi reaction

In recent years catalytic redox reactions have become increasingly important in organic synthesis as processes which are environmentally friendly. Titanium [1], samarium [2], vanadium [3] and chromium [4] catalytic redox processes have recently been applied in C–C bond forming reactions. Among these, the Nozaki–Hiyama–Kishi (NHK) reaction [5] reported by Fürstner and Shi [6], with catalytic amounts of chromium, is of considerable interest (Scheme 1). In fact, Cr(II) or Cr(II)/Ni(II) mediated reactions are unique in scope and chemoselectivity.

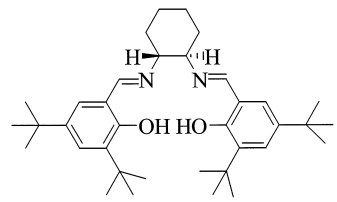
The wide compatibility with different functional groups in both reaction partners and the low basicity make the organochromium complexes the best reagents for the synthesis of sensitive and polyfunctional compounds. The driving force of the chromium reaction arises from the formation of stable O–Cr(III) bonds. For this reason stoichiometric NHK reactions require almost 2 mol of Cr(II) per 1 mol of organic halide. The key features of Fürstner's modification are based on the addition of an oxophilic additive such as trimethyl silyl chloride as the scavenger and driving force for the chemical catalytic reaction [7], and on the use of Mn which reduces the Cr(III) to Cr(II). In fact, the main advantage is that the Mn is not capable of reacting with the substrates in the reaction mixture, and the Mn(II) salt obtained is a weak Lewis acid. We have carried out the first catalytic enantioselective Nozaki–Hiyama–Kishi reaction, catalytic both in chromium and in ligand. Our enantioselective process requires the use

Scheme 1. Carbon–carbon bond forming redox processes promoted by a catalytic amount of $CrCl_2$.

of the inexpensive and commercially available chiral Salen ligand (Fig. 1).

Chiral chromium(III)–Salen complexes were reported to mediate interesting transformations [8,9]. The chiral Cr–Salen complex was prepared in situ according to Jacobsen and co-workers by adding anhydrous $CrCl_2$ to a THF solution of Salen. The further addition of allyl bromide affords the organometallic allylchromium reagent which was used in a catalytic amount (10%) in the presence of manganese, TMSCl, and benzaldehyde at room temperature (Scheme 2). However, under these conditions the desired silylated homoallylic alcohol was only obtained in low yields (15%, 21% enantiomeric excess), with the main product being the pinacol.

We optimized the reaction conditions for the preparation of the Cr–Salen complex by adding a base (20%) capable of



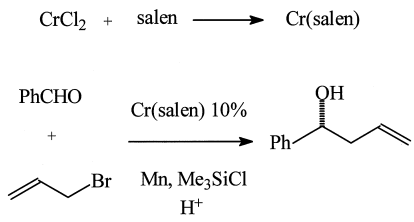


Fig. 1. (*R*,*R*)-(−)-Salen = (*R*,*R*)-(−)-*N*,*N*′-bis(3,5-di-*tert*-butyl-salicylidene)-1,2-cyclohexane-diamine.

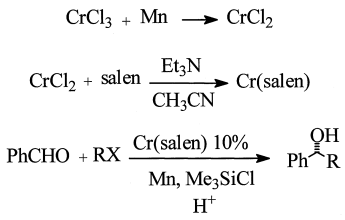
Scheme 2. Allylation reaction of the PhCHO promoted by Cr(Salen) complex in THF.



deprotonating the Salen ligand in acetonitrile, where the pinacol coupling was minimized. The procedure was improved further on avoiding the manipulation of the highly sensitive Cr(II) salt by the reduction in situ of anhydrous $CrCl_3$ with Mn in CH_3CN. The Cr(II) salt was complexed to the Salen ligand by the addition of Et_3N (20 mol%). The resulting Cr(II)–Salen, used in catalytic amount (10%), promoted the addition of several allyl, propargyl, and benzyl halides to benzaldehyde in the presence of Me_3SiCl (Scheme 3).

As summarized in Table 1 a large variety of reactive halides can be used, however a high enantiomeric excess was only obtained with allyl chloride (Table 1, entry 1). Vinyl or aryl halides, where the presence of a catalytic amount of nickel salt in the NHK reaction is necessary, are under investigation.

As reported in Table 2, the results obtained with several aliphatic and aromatic aldehydes show the generality of the method. Different silylating agents do not exhibit any significant influence on the asymmetric induction of the reaction, while the dependence on the enantioselection of the chromium salts and halides employed was observed [10].

Unfortunately in all cases, by-products derived from the pinacol coupling (20–40%) or derived from the reduction of the aldehyde (with aliphatic aldehydes) were isolated.

Several Schiff bases were synthesized to improve the enantiomeric excess of the homoallylic alcohols. However, all the

new Schiff bases screened in allylation reaction performed with the standard protocol have shown lower enantioselectivity than Salen. Stereogenic allylhalides were also employed with our method. After several attempts, we discovered that the amount of ligand is crucial for achieving good results. In fact, high diastereoisomeric and enantiomeric excesses were obtained with the addition of crotyl bromide to aromatic aldehydes, when the reaction was performed with an excess of Salen ligand (Scheme 4). The addition of crotyl chromium reagent to aromatic aldehydes shows a *syn* simple diastereoselection. This is an important result which indicates the possibility of modifying selectively the diastereoselection of organometallic reactions when macrocyclic ligands are involved.

The reaction performed in the presence of the Salen ligand is unique because normally reactions of aldehydes with stereogenic allylchromium reagents afford homoallylic alcohols with an excellent degree of *anti* selectivity. This selectivity is thought to be due to a cyclic Zimmermann–Traxler transition state. In fact, using the catalytic conditions described by Fürstner for the addition of crotylbromide to aromatic

aldehydes, the *anti* diastereoisomer was always obtained in larger amount [6]. This intriguing result may suggest a mechanism for the Cr–Salen mediated NHK reactions in which two molecules of Cr–Salen complexes are involved in the transition state (Fig. 2) [11].

In conclusion, the catalytic enantioselective NHK reaction described here represents the first example of an effective enantioselective reaction mediated by a catalytic amount of Cr salt, opening the way to rational design of new redox catalytic enantioselective reactions. Work on this project is currently under investigation in our laboratory.

1. Typical experimental procedure

$CrCl_3$ (16 mg, 0.1 mmol) and Mn (166 mg, 3 mmol) were added to anhydrous CH_3CN (5 ml) and the mixture was kept for about 5–10 min, then the reaction mixture was stirred until a green–white precipitate was observed. The Salen ligand (54 mg, 0.1 mmol) was introduced followed by dried triethylamine (30 μl, 0.2 mmol) and the resulting brown solution was stirred at room temperature for 1 h. The solution was treated with allylchloride (116 μl, 1.5 mmol) and the resulting red solution was stirred for 1 h at room temperature. Finally, PhCHO (100 μl, 1 mmol) and Me_3SiCl (190 μl, 1.5 mmol) were added and the mixture was stirred until complete consumption of the aldehyde. After quenching with a saturated solution of $NaHCO_3$, the reaction mixture was filtered on a celite© bed, and the CH_3CN was evaporated under reduced pressure. The residue was extracted with Et_2O and the organic phases were collected and evaporated under reduced pressure. The oil obtained was dissolved in THF (3 ml) and treated with 1 ml of HCl 1 N. The mixture was stirred to complete desilylation (checked by TLC). After evaporation of THF, the residue was extracted with Et_2O. The organic phases were collected, dried over Na_2SO_4 and concentrated in vacuo to give a brown residue purified by flash chromatography (silica gel, cyclohexane/Et_2O 4/1, $R_f = 0.3$). The (*R*)-1-phenyl-3-buten-1-ol was isolated as a light yellow oil (100 mg, 67% yield) in 84% enantiomeric excess.

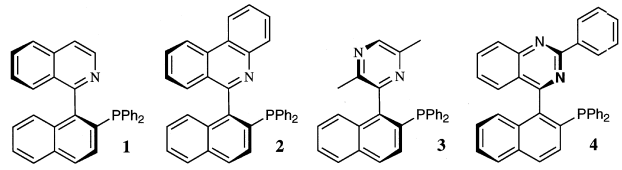
POLYHEDRON

A new quinazoline-containing axially chiral ligand for asymmetric catalysis

Mary McCarthy, Patrick J. Guiry *

Department of Chemistry, University College Dublin, Belfield, Dublin 4, Ireland



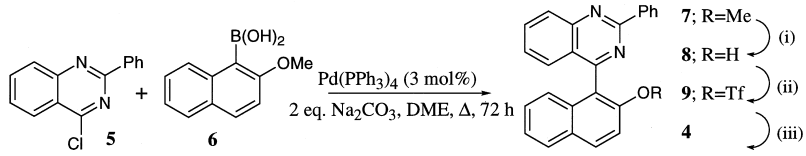
Received 4 October 1999; accepted 8 November 1999

Abstract

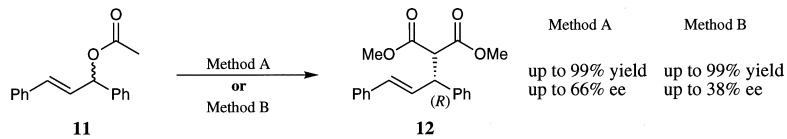
The rationale behind the design of an axially chiral quinazoline-containing phosphinamine ligand, 2-phenyl-Quinazolinap, is described. Its synthesis had two metal-catalysed couplings as the key steps. Enantiopure ligand was obtained after resolution and afforded up to 66% enantiomeric excess (ee) in Pd-catalysed allylic alkylation. η^3-Allyl Pd complexes were investigated by ^{1}H NMR in an attempt to explain the sense of enantioselection observed, which was opposite to that of related ligands. Rhodium-catalysed enantioselective hydroboration of a variety of substituted styrenes was achieved with excellent conversions, good regioselectivities and ee values of up to 91% with 2-phenyl-Quinazolinap as the ligand. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Allylic alkylation; Axially chiral phosphinamine; Hydroboration; Quinazolines

Recently, interest in non-C_2-symmetric axially chiral phosphinamine bidentate ligands has increased [1–4]. The first axially chiral phosphinamine to be reported was Quinap (**1**) and it was applied in Rh-catalysed hydroboration and Pd-catalysed allylic substitution [5–7]. Mechanistic studies suggested that the 3H of the isoquinoline unit takes up a region in space leading to steric interactions that are important for asymmetric induction [7]. This observation was the design principle behind the vaulted analogue Phenap (**2**), which in turn gave high enantioselectivities in Rh-catalysed hydroboration [8] and Pd-catalysed allylic substitution [9]. In a recent study we prepared and resolved 1-(3,6-dimethylpyrazin-2-yl)(2-naphthyl)diphenylphosphine (**3**), but this was found to racemise at room temperature [10]. As an extension to these studies we designed diphenyl[1-(2-phenylquinazolin-4-yl)(2-naphthyl)]phosphine (**4**), which has the acronym 2-phenyl-Quinazolinap. (We have prepared a series of substituted diphenyl[1-quinazolin-4-yl)(2-naphthyl)]phosphines and we find this acronym useful as it follows directly from the Binap, Quinap and Phenap acronyms [11].) The 2-phenylquinazoline unit was chosen as we predicted that the naphthalene–quinazoline pivot would be essentially inert to racemisation and, once resolved, we could investigate the effect on enantioselection relative to compounds **1** and **3** of the increased steric bulk at the 2-position of compound **4** (equivalent to the 3-position of compound **1**). In this communication the synthesis and resolution of ligand **4** and its preliminary application in asymmetric catalysis is described.



The synthesis of compound **4**, similar to that previously reported for ligands **1**–**3**, has the metal-catalysed reactions of biaryl coupling and formation of the naphthyl–phosphorus bond as the two key steps. The electrophilic component of the Pd-catalysed cross-coupling was 4-chloro-2-phenylquinazoline (**5**), while the nucleophilic component was 2-methoxy-1-naphthylboronic acid (**6**) Scheme 1. This gave 2-methoxy-1-(2-phenylquinazolin-4-yl)naphthalene (**7**) in 53% yield. The next two steps involved the conversion of the methyl ether into 1-(2-phenylquinazolin-4-yl)-2-naphthyl(trifluoromethyl)sulfonate (**9**) by demethylation and triflation of the resultant alcohol (**8**) in 81 and 46% yields, respectively. Nickel(II)-catalysed coupling of compound **9** with diphenylphosphine gave 2-phenyl-Quinazolinap (**4**) as a racemate in 74% yield.



Ligand **4** was successfully resolved by the separation of diastereomeric complexes derived from compound **4** and (+)-di-μ-chlorobis{(*R*)-dimethyl[1-(1-naphthyl)ethyl]-

aminato-C_2,*N*}dipalladium(II) (**10**), a resolving agent that has been successful in the resolution of a wide range of phosphorus-containing ligands [12–14].

The initial precipitate from the reaction in MeOH was the (*R*,*R*)-diastereomer; the (*S*,*R*)-diastereomer was isolated from the filtrate [15]. Enantiopure ligand was generated after decomplexation of the appropriate diastereomer by the addition of dppe. The enantiopurity was tested by recomplexing with (*R*)-**10** and observing only one diastereomer by ^1H and ^{31}P NMR. We then wished to test its metal complexes in asymmetric catalysis.

Pd-catalysed allylic alkylation is an asymmetric transformation that has proved to be a useful testing ground for new ligands and for gaining mechanistic insights into organopalladium chemistry [16–19]. The standard test reaction in allylic substitution is between 1,3-diphenylpropenyl acetate (**11**) and the soft nucleophile derived from dimethyl malonate. The results of our preliminary investigations using (*R*)-**4** are summarised in Scheme 2. The key points are that the conversions are good (up to 99% yield) but the enantioselectivities are moderate (optimised to 66%) and show the *opposite* sense of asymmetric induction compared to ligands **1** and **2**; i.e. (*R*)-**1** and (*R*)-**2** afford an excess of (*S*)-**12** whereas (*R*)-**4** gives (*R*)-**12** in excess.

As the major structural difference between compounds **1**, **2** and **4** is the presence of the 2-phenyl substituent on the quinazoline, this substituent must cause steric interactions which lead to lowered and opposite asymmetric induction. From ^1H NMR solution studies of cationic 1,1,3-triphenylallyl palladium complexes of ligand **4** it was determined that the CPh_2 group was *trans* to nitrogen in the major diastereomer [20]. Inspection of molecular models is also useful in coming to the same conclusion to explain the formation of the (*R*)-enantiomer in excess. Unambiguous NOE (nuclear Overhauser effect) assignments were not possible for complexes **13** and **14**, but we infer attack *trans* to phosphorus at the *endo* isomer (**13**) being disfavoured due to the 2-phenyl substituent inhibiting the required rolling of the allyl [21] (Scheme 3). Attack *trans* to phosphorus at the *exo* isomer (**14**) gives *R* product in a favoured process as now the rolling alleviates potential steric interactions between the phenyl groups. There is, therefore, a mismatch between the *R* axial chirality and the presence of a bulky 2-substituent and in this case the latter steric interaction predominates.

Scheme 3.

Axially chiral diphosphine [22] and phosphinamine ligands have also been applied in the Rh-catalysed hydroboration of alkenes [7,8,23]. A summary of the preliminary Rh-catalysed hydroboration results that we have obtained using ligand **4** with a range of variously substituted styrenes (**15**–**19**) is given in Table 1.

Our reactions were carried out with catecholborane in tetrahydrofuran (THF) using 1 mol% of a catalyst prepared in situ from adding trimethylsilsyl (TMS) triflate to a solution of (1,5-cyclooctadiene)(2,4-pentanedionato)rhodium(I) and compound **4**. These results demonstrate that we have an extremely enantioselective catalyst system which affords high enantioselectivities for substituted styrenes and stilbenes. This is in marked contrast to Rh complexes of BINAP where (*Z*)-**19** gave only 16% enantiomeric excess (ee) [22]. We explain these results by inferring that the increased steric demand of the olefin is more easily accommodated by our less sterically demanding ligand **4**.

In conclusion, this communication reports a new quinazoline-containing axially chiral ligand and its preliminary applications in asymmetric catalysis.

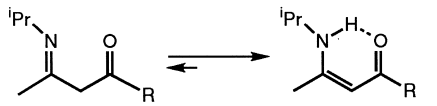
Abstract

The reactions of enamines (ROC)HC=CMe(NH^{i}Pr) with η^3-allenyl/propargyl complexes $[M(PPh_3)_2(\eta^3\text{-}C_3H_3)]^+$ (M = Pd, Pt) result in the formation of pyrrole derivatives. Such reactions involve the intermediates of central-carbon-substituted η^3-allyl complexes $\{M(PPh_3)_2(\eta^3\text{-}CH_2C[C(COR)=CMe(NH^iPr)]CH_2)\}^+$ which are formed by hydroalkenylation to the C_3H_3 moiety. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Enamine; Alkenylation; Pyrrole

1. Introduction



The addition of an olefinic C–H bond across an unsaturated carbon–carbon bond is highly interesting from the viewpoint of synthetic methodology [1]. The involvement of transition metal complexes in such processes is often crucial, particularly for the development of novel ways of C–C bond formation [2]. We and other groups have discovered that cationic η^3-allenyl/propargyl complexes generally behave as good carbon electrophiles and are subject to the addition with a wide variety of nucleophiles containing O, S, Se, N, P or C donor [3–7]. Meanwhile, such complexes exhibit keen chemical selectivity. For instance, tertiary amine such as Et_3N can be added to $[Pt(PPh_3)_2(\eta^3\text{-}C_3H_3)]^+$ (**3**) via C–N bond formation to give a platinacyclobutene adduct [8]. In contrast, compound **3** activates a phenyl C–H bond in NMe_2Ph to allow arylation, yielding an arylallyl complex [9].

We have chosen to use enamines that are known to contain both active N–H as well as C–H bonds to react with η^3-allenyl/propargyl complexes. Our studies lead to the discovery of the first examples of hydroalkenylation of metal complexes of allenyl/propargyl. The insertion of η^3-C_3H_3 to an enamine C–H bond affords a diene 'skeleton' which allows incorporation of an amino functionality to form the pyrrole derivatives.

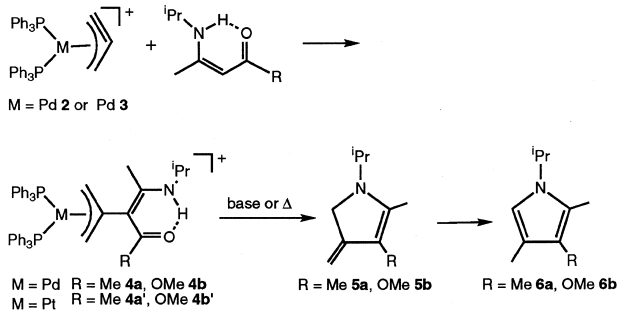
2. Results and discussion



The enamines Me(NH^{i}Pr)C=CHR [R = COMe (**1a**), CO_2Me (**1b**)] have been prepared by the reactions of α,γ-diketone or ketoester methane, respectively, with ^{i}PrNH$_2$ [10]. The NMR data for compounds **1a** and **1b** indicate that tautomerization overwhelmingly inclines to the enamine form, which is presumably stabilized by hydrogen bonding between N–H and the keto group:

R = Me **1a**, OMe **1b** (1)

Previous studies have shown that amines and amino derivatives with active hydrogen are prone to undergo regioselective hydroamination to $[M(PPh_3)_2(\eta^3\text{-}C_3H_3)]^+$ [M = Pd (**2**), Pt (**3**)], yielding azatrimethylenemethane (N-TMM) complexes and their derivatives (N-TMM represents the azatrimethylenemethane complexes $M[CH_2C(NR)CH_2]$) [11]. However, heating a mixture of compounds **2** and **1b** at 50°C was found to generate the pyrrole derivatives. Further investigation shows that reactions of equimolar amounts of compound **2** and enamine at 25°C undergo unprecedented hydroalkenylation. The regioselective C–C coupling takes place between the central carbon of the C_3H_3 and the β-olefinic carbon of the enamine, and results in enamine–allyl complexes of the formula of $Pd(PPh_3)_2\{\eta^3\text{-}CH_2C$-

Scheme 1.

$[C(COR)CMe(NH^iPr)]CH_2\}^+$ [R = Me (**4a**), OMe (**4b**)] with yields of over 75%. Complexes **4a** and **4b** were characterized mainly by NMR techniques and elemental analysis. By heating the reaction solutions of complexes **4a** and **4b** to 50°C, or treating them with base, yielded the pyrrole derivatives **6a** and **6b**, respectively (Scheme 1).

The analogous reactions of $[Pt(PPh_3)_2(\eta^3\text{-}C_3H_3)](BF_4)$ (**3**) with compound **1a** or **1b** produced $\{Pt(PPh_3)_2(\eta^3\text{-}CH_2C[C(COR)=CMe(NH^iPr)]CH_2)\}(BF_4)$ [R = Me (**4a′**), OMe (**4b′**)], also in very good yields. The enamine–allyl platinum complexes could alternatively be formed from the reactions of *trans*-$Pt(Br)(PPh_3)_2(\eta^1\text{-}CHCCH_2)$ and enamine at 25°C, but with longer reaction time. Single-crystal X-ray crystallography provides the authentic molecular structure of **4b′**. Fig. 1 shows its ORTEP drawing. The length of C2–C4 is 1.46(2) Å, a typical C_{sp^2}–C_{sp^2} single bond. The dihedral angle between the C1–C2–C3 and C1–Pt–C2 planes is 68(1)° and ∠C1–C2–C3 is 113(1)°, which is consistent with the η^3-allyl characteristic and somewhat approaches that of the η^3-trimethylenemethane species [7,12]. This indicates that there is significant electronic delocalization in the planar N–C5–C4–C10–O1 moiety of enamine. The distance between N and O1 atoms is 2.52 Å, which is suitable for hydrogen bonding in the vicinity. However, the generated amino hydrogen points out of the enamine plane with ∠O1–H–N = 116(7)°. The single crystals of compound **4b′** were obtained by recrystallization in CH_2Cl_2–Et_2O solution. Crystal data: orthorhombic $P2_12_12_1$ $a = 11.100(5)$ Å, $b = 17.764(4)$ Å, $c = 21.951(4)$ Å, $V = 4328(2)$ Å^3, Mo Kα radiation $\lambda = 0.7107$ Å, $Z = 4$, $\mu = 3.398$ mm^{-1}, 5490 total reflections, 3032 observed reflections ($I > 2.0\sigma(I)$), $R = 0.044$, $R_w = 0.036$.

Ring closure in compounds **4a** and **4b** could be accomplished by heating or treating with base as well, except that cyclization of compound **4b** first generates a dihydropyrrole derivative (**5b**). Upon chromatographing on a silica gel column, **5b** would isomerize to the stable pyrrole product (**6b**). Such a reaction is mechanistically comparable to furan formation from an enolate–allyl complex [13].

3. Conclusions

The regioselective addition of enamine to η^3-allenyl/propargyl complexes demonstrates a new type of 'alkene–alkyne' coupling which affords new enamine–allyl complexes and leads to the formation of pyrrole derivatives.

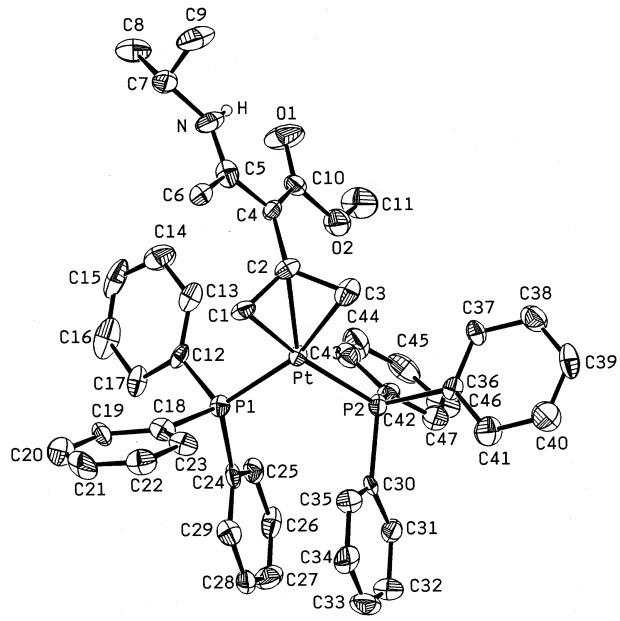

Fig. 1. ORTEP drawing of $\{Pt(PPh_3)_2(\eta^3\text{-}CH_2C[C(CO_2Me)\text{-}CMe(NH^iPr)]CH_2)\}(BF_4)$ (**4b′**) with 50% probability ellipsoids. All hydrogen atoms except the N-bound one are omitted for clarity. Selected bond distances (Å) and angles (°): Pt–P1 2.298(4), Pt–P2 2.300(3), Pt–C1 2.17(1), Pt–C2 2.24(1), Pt–C3 2.19(1), C1–C2 1.40(2), C2–C3 1.45(2), C2–C4 1.46(2), C4–C5 1.44(2), C4–C10 1.41(2), C5–N 1.32(2), C10–O1 1.22(2); ∠P1–Pt–P2 100.3(1), ∠C1–Pt–C3 66.2(5), ∠C1–C2–C3 113(1), ∠C1–C2–C4 122(1), ∠C3–C2–C4 125(1), ∠C5–C4–C10 116(1), ∠C5–C4–C2 118(1), ∠C2–C4–C10 126(1), ∠C4–C5–N 120(1), ∠C4–C10–O1 130(1).

4. Experimental

4.1. General

Commercially available reagents were purchased and used without purification unless necessary. Solvents were dried using standard procedures. All reactions and other manipulations were carried out under a nitrogen atmosphere, using standard Schlenk techniques. The IR spectra were recorded on a Bio-Rad FTS-40 spectrophotometer. The NMR spectra were run on either a Bruker AC-200 or ACE-300 spectrometer. For the ^{31}P NMR spectra, the spectrometer frequency at 81.015 or 121.49 MHz was employed, and the chemical shifts are given in ppm (δ) relative to 85% H_3PO_4 in $CDCl_3$. Values upfield of the standard are defined as negative. The corresponding frequencies for ^{13}C NMR spectra were at 75.47 MHz, respectively. Mass spectrometric (MS) data were collected on a JEOL SX-102A spectrometer. Elemental analyses were done on a Perkin-Elmer 2400 CHN analyzer.

4.2. Synthesis and characterization

4.2.1. $\{Pd(PPh_3)_2(\eta^3\text{-}CH_2C[C(COMe)=CMe(NH^iPr)]\text{-}CH_2)\}(BF_4)$ (**4a**)

The reaction of compound **2** (300 mg, 0.39 mmol) and (MeOC)HC=CMe(NH^iPr) (**1a**) (55 μl, 0.039 mmol) was

carried out in 20 ml of predried CH_2Cl_2 at −30°C. After stirring for 90 min, the solution was concentrated to 2 ml. Addition of 20 ml of dried Et_2O gave a yellow solid product. Recrystallization resulted in compound **4a** in 76% isolated yield (260 mg). ^{31}P NMR ($CDCl_3$, 300 MHz): δ 23.8. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.21, 1.24 (3H, 3H, s, s, CH_3), 2.00 (6H, d, J_{HH} = 6.9 Hz, CH(CH_3)$_2$), 3.50 (2H, m, br, H_{anti}), 3.69 (1H, m, CH(CH$_3$)$_2$), 4.12 (2H, br, H_{syn}), 7.02–7.73 (30H, m, phenyl H), 12.6 (1H, d, J_{HH} = 2.2 Hz, NH). ^{13}C NMR (CD_3CN, 300 MHz): δ 18.4, 23.7 (*C*H$_3$), 30.5 (*C*H$_2$), 46.2 (CO*C*H$_3$), 80.1 (t with virtual coupling, J_{CP} = 15.4 Hz, C_t), 104.2 (C_γ), 129–134 (phosphino phenyl C), 146.1 (C_c), 165.0 (N*C*=C), 193.7 (*C*OMe). MS (FAB, *m*/*z*): 810 ($M^+ - BF_4$). *Anal*. Calc. for $PdC_{47}H_{48}NOP_2BF_4$: C, 62.86; H, 5.38; N, 1.56. Found: C, 62.30; H, 5.04; N, 1.25%.

*4.2.2. {Pd(PPh$_3$)$_2$(η^3-CH$_2$C[C(CO$_2$Me)=CMe(NH^{i}Pr)]-CH$_2$)}(PF$_6$) (**4b**)*

Refer to compound **4a** for the procedure. The reaction of compounds **2** (100 mg, 0.12 mmol) and **1b** (20 mg, 0.15 mmol) gave a yellow solid product in 76% isolated yield (90 mg). IR (KBr) (cm^{-1}): ν_{CO} 1638. ^{31}P NMR ($CDCl_3$, 300 MHz): δ 24.53. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.15 (6H, d, J_{HH} = 6.4 Hz, CH(CH_3)$_2$), 2.04 (3H, CH_3), 3.14 (3H, s, OCH_3), 3.68 (5H, m, br, CH_2(allyl), CH(CH$_3$)$_2$), 6.82–7.64 (30H, m, phenyl H), 10.09 (1H, d, J_{HH} = 2.0 Hz, NH). ^{13}C NMR ($CDCl_3$, 300 MHz): δ 17.7 (*C*H$_3$), 23.5 (s, (*C*H$_3$)$_2$CH), 45.3 ((CH$_3$)$_2$*C*H), 50.9 (O*C*H$_3$), 78.5 (t, J_{CP} = 15.7 Hz, C_t), 91.2 (MeC=*C*), 128.7, 128.9, 130.1, 130.7, 131.1, 133.7 (phosphino phenyl C), 141.5 (C_c), 164.0 (Me*C*=C), 168.8 (*C*O$_2$Me). MS (FAB, *m*/*z*): 826 ($M^+ - PF_6$). *Anal*. Calc. for $PdC_{47}H_{48}NO_2P_3F_6.CH_2Cl_2$: C, 55.43; H, 4.75; N, 1.35. Found: C, 54.01; H, 4.63; N, 1.11%.

*4.2.3. {Pt(PPh$_3$)$_2$(η^3-CH$_2$C[C(COMe)=CMe(NH^{i}Pr)]-CH$_2$)}(PF$_6$) (**4a′**)*

The reaction of compound **3** (240 mg, 0.28 mmol) and an equimolar amount of compound **1a** produced compound **4a′** in 82% yield (220 mg). ^{31}P NMR ($CDCl_3$, 300 MHz): δ 18.1 (J_{PPt} = 3828 Hz). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 2.00 (6H, d, J_{HH} = 6.9 Hz, CH(CH_3)$_2$), 2.13, 2.15 (3H, 3H, s, s, CH_3), 3.33 (2H, br, H_{syn}), 3.45 (2H, dd, J_{HP} = 8 Hz, J_{HPt} = 40.8 Hz, H_{anti}), 3.77 (1H, m, CH(CH$_3$)$_2$), 7.03–7.76 (30H, m, phenyl H), 12.5 (1H, d, J_{HH} = 2.2 Hz, NH). ^{13}C NMR ($CDCl_3$, 300 MHz): δ 15.2, 23.4 (*C*H$_3$), 30.6 (*C*H$_2$), 45.4 (CO*C*H$_3$), 69.6 (d, J_{CP} = 34 Hz, J_{CPt} = 105 Hz, C_t), 103.7 (J_{CPt} = 30 Hz, C_γ), 128.0–133.9 (phosphino phenyl C), 143.5 (t, J_{CP} = 4 Hz, J_{CPt} = 20.2 Hz, C_c), 165.1 (N*C*=C), 192.4 (*C*OMe). MS (FAB, *m*/*z*): 899 ($M^+ - BF_4$). *Anal*. Calc. for $PtC_{47}H_{48}NOP_2BF_4$: C, 57.20; H, 4.90; N, 1.42. Found: C, 56.78; H, 4.04; N, 1.20%.

*4.2.4. {Pt(PPh$_3$)$_2$(η^3-CH$_2$C[C(CO$_2$Me)=CMe(NH^{i}Pr)]-CH$_2$)}(BF$_4$) (**4b′**)*

Complex **3** was first prepared from *trans*-Pt(Br)(PPh$_3$)$_2$(η^3-CHCCH$_2$) (300 mg, 0.36 mmol) and $AgBF_4$ (69 mg, 0.36 mmol) in situ. The reaction of compounds **3** and **1b** (0.36 mmol) basically followed the procedure used for the preparation of compound **4a** and produced **4b′** in 77% isolated yields (272 mg). Colourless single crystals were obtained by recrystallization from CH_2CH_2–benzene. IR (KBr) (cm^{-1}): ν_{CO} 1634, $\nu_{C=C}$ 1580. ^{31}P NMR ($CDCl_3$, 300 MHz) δ 19.6 (J_{PPt} = 3845 Hz,). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.24 (6H, d, J_{HH} = 6.3 Hz, CH(CH_3)$_2$), 2.20 (3H, J_{HPt} = 7.2 Hz, CH_3), 3.10 (2H, d, J_{HH} = 8.6 Hz, J_{HPt} = 42 Hz, H_{anti}), 3.20 (3H, s, OCH_3), 3.63 (2H, br, H_{syn}), 3.77 (1H, dhep, J_{HH} = 6.3, 8.0 Hz, CH(CH$_3$)$_2$), 7.0–7.6 (30H, m, phenyl H), 10.4 (1H, d, J_{HH} = 8.0 Hz, NH). ^{13}C NMR ($CDCl_3$, 300 MHz): δ 15.1 (*C*H$_3$), 22.6 (s, (*C*H$_3$)$_2$CH), 45.4 (dd, J_{CP} = 5.8, 14.2 Hz, (CH$_3$)$_2$*C*H), 50.9 (O*C*H$_3$), 67.6 (d, J_{CP} = 32 Hz, J_{CPt} = 100 Hz, C_t), 91.6 (J_{CPt} = 27 Hz, MeC=*C*), 128.4–133.4 (phosphino phenyl C), 140.6 (t, J_{CP} = 2.9 Hz, J_{CPt} = 18.4 Hz, C_c), 165.0 (J_{CPt} = 19.0 Hz, Me*C*=C), 169.1 (J_{CPt} = 11 Hz, *C*O$_2$Me). *Anal*. Calc. for $PtC_{47}H_{48}NO_2P_2BF_4$: C, 56.29; H, 4.83; N, 1.40. Found: C, 55.74; H, 4.91; N, 1.12%.

*4.2.5. 3-Carboxymethyl-2-methyl-4-methylene-N-isopropyldihydropyrrole (**5b**)*

^{1}H NMR (C_6D_6, 200 MHz): δ 1.13 (6H, d, J_{HH} = 6.5 Hz, CH_3), 2.31 (3H, s, CH_3), 3.61 (3H, s, OCH_3), 4.01 (1H, m, J_{HH} = 6.5 Hz, CH), 4.18 (2H, t, J_{HH} = 3.4 Hz, CH_2), 4.52, 5.10 (1H, 1H, dt, J_{HH} = 1.5, 3.4 Hz, =CH_2).

*4.2.6. 3-Acetyl-2,4-dimethyl-N-isopropyldihydropyrrole (**6a**)*

A solution that contained compound **4a** (30 mg) in 2 ml of chloroform was heated at 50°C for 24 h. The solution was then chromatographed on alumina and eluted with Et_2O. Compound **6a** was obtained in 75% yield. ^{1}H NMR ($CDCl_3$, 200 MHz): δ 1.34 (6H, d, J_{HH} = 6.6 Hz, CH(CH_3)$_2$), 2.38, 2.47 (3H, s, s, CH_3), 4.28 (1H, m, J_{HH} = 6.6 Hz, CH(CH$_3$)$_2$), 6.38 (1H, s, =CH).

^{1}H NMR ($CDCl_3$, 200 MHz): δ 1.34 (6H, d, J_{HH} = 6.6 Hz, CH_3), 2.19 (3H, s, CH_3), 2.48 (3H, s, CH_3), 3.76 (3H, s, OCH_3), 4.27 (1H, m, J_{HH} = 6.6 Hz, CH_2), 6.38 (1H, s, =CH). ^{13}C NMR ($CDCl_3$, 300 Hz): 11.1, 12.8, 23.2, 46.6, 50.3, 114.0, 120.4, 128.4, 132.0, 166.9. HRMS: calc. for $C_{11}H_{17}NO_2$ (M^+) 194.1181; found 194.1180.

4.3. X-ray crystallographic analysis

Diffraction data were measured at 298 K on a Nonius CAD-4 diffractometer with graphite-monochromatized Mo Kα radiation. Cell parameters were determined by a least-squares fit on 25 reflections. Intensity data were corrected for absorption on the basis of an experimental ψ rotation curve. The refinement procedure was by a full-matrix least-squares

method including all the non-hydrogenic atoms anisotropically. Hydrogen atoms were fixed at the ideal geometry and the C–H distance of 1.0 Å; their isotropic thermal parameters were fixed to the values of the attached carbon atoms at the convergence of the isotropic refinement. Atomic scattering factors were taken from international tables [14]. Computing programs are from the NRCC SDP VAX package [15]. Detailed data of compound **4b′**are supplied in the supplementary material.

Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), on request, quoting deposition number 135924.

Abstract

Allylic chlorides are efficient reagents in the indium-mediated Barbier-type allylation reaction with various aldehydes and ketones in pure water under sonication or in a 1:1 mixture of H_2O and t-BuOH. Also indium is effective in bisallylation reactions of the 2-pyridyl esters with allyl halides in pure water. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Allylation; Aqueous reactions; Esters; Indium; Indium compounds; Pyridines

Recently, organic reactions that can be carried out in aqueous media or water have become one of the most challenging areas in organic synthesis due to environmental benefits and favorable effects of water on organic transformations [1]. In particular, reactions mediated by indium in aqueous media are of current interest because of its exceptional stability to air and water compared to other metals and considerable applications in organic synthesis [2,3]. Since indium has special properties in water, the application of indium for other chemical transformation will be of great interest. Here we report the indium-mediated allylation reaction of carbonyl compounds with allylic chlorides and bisallylation of 2-pyridyl carboxylate with allyl halides.

The allylation reaction of carbonyl compounds with allylic halides to afford the homoallylic alcohols is probably the most widely used of the many indium-mediated reactions in organic synthesis [4]. Allylic bromide and iodide have been used effectively in this reaction, but allylic chloride, a cheaper and more stable reagent, has rarely been used because of low yields, even in other metal-mediated reactions [5,6]. We report here that allylic chlorides are efficient reagents in indium-mediated Barbier-type allylation reactions in aqueous media [7].

A variety of aldehydes and ketones can be sucessfully allylated with allylic chlorides using indium metal in pure water under sonication or in a 1:1 mixture of H_2O and t-BuOH to afford the corresponding homoallylic alcohols in good to excellent yields. The results are summarized in Table 1. A mixture of carbonyl compounds (1 mmol), allyl chloride (2 mmol) and indium powder (1 mmol) was stirred at room temperature in water (2 ml) (method A), under sonication (method B) or in a 1:1 mixture of H_2O and t-BuOH (method C). Using method A, the reaction required a longer reaction time and gave poorer yields in most cases. The reactions with the addition of NH_4Cl or using a mixed solvent of water and THF were unsatisfactory too. As can be seen in Table 1, the reaction using method B or method C gave good yield irrespective of the substituents on aromatic aldehydes; in particular, the yield of 4-carboxybenzaldehyde increased dramatically when method C was used, probably due to its solubility (entry 12). The reaction of crotyl chloride using method B was γ-regioselective (entries 5, 6) and gave a diastereomeric mixture in the raio of 2.8:1 in moderate yield, whereas β-substitution did not affect the yield (entry 7). Even low boiling aliphatic aldehydes can be effectively allylated in these conditions (entry 13). In the case of ketone, acetophenone and β-keto ester were reacted in method C to give moderate and excellent yields, respectively (entries 16, 17).

Although the indium-mediated allylation of carbonyl compounds such as aldehydes and ketones has been explored

extensively, the reaction with carboxylic ester compounds has never been reported. Among the indium-mediated reactions with carboxylic acid derivatives, only the indium-mediated allylations of cyclic acid anhydrides in DMF [7] and acyloyl-imidazoles and pyrazoles in water [8] have been reported. Our continuous efforts in the area of indium [9,10]

lead us to determine that indium is effective in bisallylation of the 2-pyridyl carboxylate with allyl halides.

Various 2-pyridyl esters were reacted with indium metal and allylic halides in water at 10°C to give the corresponding bisallylated alcohols in moderate to good yields together with a small amount of homoallyl ketones, as shown in Table 2. The reactions with allyl bromides and iodides were all successful and the ester hydrolysis was increased at higher temperature or with a longer reaction time. In these bisallylation reactions the optimized ratio of ester, allyl halide and indium was 1:1:3 in spite of various trials for increasing the yields by changing the ratio of reactants. In the case of γ-methyl-substituted crotyl bromide (entry 7), the reaction was γ-regioselective and the major product was the homoallyl ketone due to the steric bulkiness. More bulky cinnamyl bromide afforded exclusively the corresponding ketone in a good yield (entry 9). Interestingly, 3-pyridyl or 4-pyridyl carboxylates did not react under these conditions.

A typical procedure is as follows. To a mixture of 2-pyridyl benzoate (0.5 mmol) and allyl bromide (0.5 mmol) in 2 ml of water was added indium powder (1.5 mmol) in one portion. The reaction mixture was stirred vigorously for 10 h in an ice-bath while the progress of the reaction was monitored by TLC. The reaction was stopped by the addition of 1 N HCl, and then the mixture was extracted with ethyl acetate (3×10 ml). The combined organic phase was washed with brine, dried over magnesium sulfate and concentrated in vacuo. The bisallylated alcohol was obtained in 86% yield after purification by flash column chromatography on silica gel using a 10:1 mixture of hexane and ethyl acetate as eluent.

In conclusion, allylic chlorides have been successfully employed in indium-mediated Barbier-type allylation reactions with various carbonyl compounds in aqueous media to afford the homoallylic alcohols in good to excellent yields. Also we have demonstrated that the 2-pyridyl ester compounds can be converted to bisallylated alcohols mediated by indium with allyl halides in pure water.

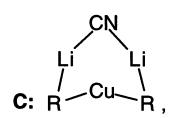
Structure and reactivity of cyanocuprates containing the monoanionic C,N-chelating aminoaryl ligand $[C_6H_4CH_2NMe_2\text{-}2]^-$

Claudia M.P. Kronenburg, Johann T.B. H. Jastrzebski, Gerard van Koten *

Debye Institute, Department of Metal-Mediated Synthesis, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands

Received 4 October 1999; accepted 6 December 1999



Abstract

The 2:1 cyanocuprate $[Ar_2Cu(CN)Li_2(THF)_4]_\infty$ (**1**, Ar = $[C_6H_4CH_2NMe_2\text{-}2]^-$) is obtained as the only product in the reaction of two equivalents of ArLi with one equivalent of CuCN in tetrahydrofuran (THF) at −78°C. The X-ray crystal structure reveals an ionic polymeric chain consisting of consecutive $[Ar_2Cu]^-$ and $[(THF)_2LiCNLi(THF)_2]^+$ units. Its composition in THF solution has been investigated.

Keywords: Cryoscopy; Cyanocuprates; Ionic; Reactivity; Structures

The application of cyanocuprates of general formula $[R_nCu(CN)Li_n]$ ($n = 1$ or 2) to organic synthesis by Lipshutz et al. [1] in 1981 led to a lively discussion on their possible structure in the solid state and in solution in the following years. Depending on the stoichiometry of the reaction of alkyl- or aryllithiums (one or two molar equivalents) with copper(I) cyanide, two types of cyanocuprates can be formed: the so-called 1:1 cyanocuprates of type $[RCu(CN)Li]$, or the 2:1 cyanocuprates with formula $[R_2Cu(CN)Li_2]$. According to the initial proposal by Lipshutz, the high reactivity of the latter type of cyanocuprates is due to bond formation between the cyano anion and the copper(I) center, thereby forming a dianionic species of type $[R_2Cu(CN)]^{2-}$ (**A**) [2]. In addition to this proposal, three other structures were also postulated: a monoanionic copper species (**B**) [3,4], a neutral monomeric copper species (**C**) [5,6] and a 'cyano-Gilman' cuprate (**D**) [7].

A: $[R_2Cu(CN)]^{2-}$ $2[Li]^+$, **B:** $[R_2Cu]^-$ $[Li_2(CN)]^+$,

C: , **D:** $R_2CuLi + LiCN$

The discussion on the structural aspects of 2:1 cyanocuprates has mainly been focused on proposals **C** and **D**, although arguments were put forward to support each of the four structures [8]. Moreover, recent spectroscopic studies (EXAFS [9–11] and NMR [12–14]) and molecular weight determinations [15] seemed also to support the structural proposals **C** and **D**.

Unambiguous proof of the structure of the thermodynamically most stable form of 2:1 cyanocuprates in the solid state has been obtained by crystal structure determinations. In 1998 both our group [15] and the group of Boche [16] reported the crystal structure of a 2:1 cyanocuprate. Remarkably, both structures, one alkyl- and one arylcyanocuprate, support proposal **B**. We reported on the synthesis, isolation and structural characterization of the bisarylcyanocuprate $[Ar_2CuLi_2(CN)(THF)_4]_\infty$ (**1**, Ar = $[C_6H_4CH_2NMe_2\text{-}2]^-$) (see Fig. 1). The solid state structure of this 2:1 cyanocuprate comprises a linear polymeric chain, consisting of alternating $[ArCu]^-$ anionic units and $[Li_2CN(THF)_4]^+$ cationic units. These are linked via intermolecular coordination by the nitrogen donor atom of the aryl ligand. The CN^- acts as a bridging C,N-coordinating ligand for two Li^+ to form a very stable $[Li_2CN]^+$ with a linear LiNCLi arrangement. Furthermore, the X-ray structure determinations of [t-BuCu(CN)Li] [16] and $[Li(THF)_2\{Cu(CN)C_6H_3\text{-}2,6\text{-}Trip_2\}]_2$ (Trip = C_6H_2-2,4,6-iPr_3) have been reported [17].

To study the aggregation behaviour of cuprates in solution we measured the molecular weights by cryoscopy of various cuprates in tetrahydrofuran (THF) in collaboration with the group of Professor Krause (Table 1) [6]. Although for an anion/cation pair a calculated value of the aggregation state

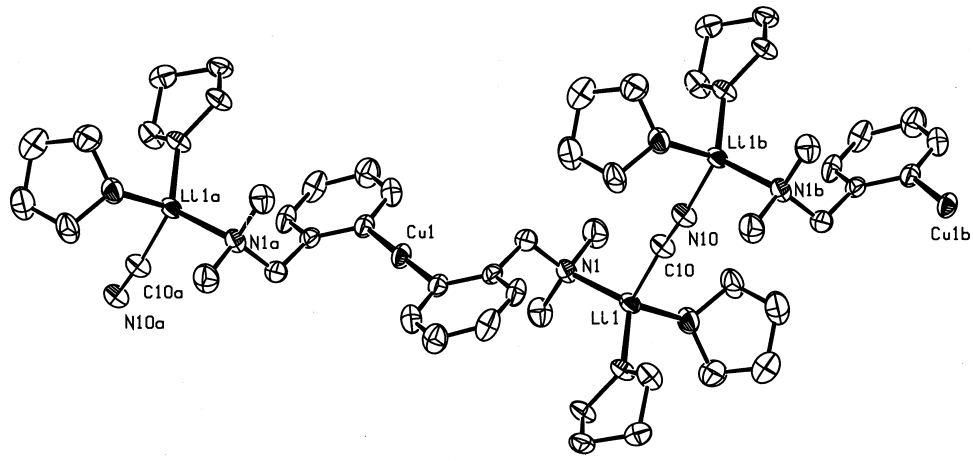

Fig. 1. ORTEP drawing (50% probability level) of $[Ar_2Cu(CN)Li_2(THF)_4]_\infty$ (**1**). C(1a)–Cu–C(1) 180°; Li(1)–C(10)–N(10) 175.6(3)°, C(10)–N(10) 1.156 Å. For X-ray structural data and tables of fractional coordinates, thermal parameters, bond distances and angles see [15].

Table 1
Cryoscopic data for cuprate compounds in THF

Entry	Cuprate	C_{nom} (mmolal)	$n = C_{nom}/C_{exp}$
1	$[Me_2CuLi_2(CN)]_n$	35.2–72.9	1.1–1.2
2	$[t\text{-}Bu_2CuLi_2(CN)]_n$	46.0–75.7	0.7–0.8
3	$[t\text{-}BuCu(CN)Li]_n$	70.4	1.1
4	$[Ph_2CuLi_2(CN)]_n$	25.5	1.2
5	$[PhCu(CN)Li]_n$	88.2	2.0
6	$[Ar_2CuLi_2(CN)]_n$	14.8–73.6	0.7–0.9
7	$[ArCu(CN)Li]_n$	79.9–147.2	0.9–1.4
8	$[Ar_2CuLi]_n$	24.8–84.2	2.0–1.7

of 0.5 is expected, the measured values for the 2:1 cyanocuprates (entries 2 and 6) range from $n = 0.7$ to 0.9. This suggests the presence of a trinuclear $CuLi_2$ species, structure **C**, which can be regarded as a neutral cuprate complex comprising an anionic $[R_2Cu]^-$ and a cationic $[Li_2CN]^+$ unit. However, for the other cuprates described in Table 1, discrete monomeric or dimeric species are found.

It is noted that cryoscopic results may be deceptive, as association of anionic and cationic species to higher aggregates (ion-pair formation) [18] might occur. As a result of such association, a virtual aggregation state of almost 1 could be calculated.

The higher reactivity of the 2:1 cyanocuprates in most of the substitution reactions was ascribed to the fact that the CN^- was bound to copper. [The idea of using a CN group as a 'non-transferable' ligand was first introduced by Gorlier et al. [19].] In order to further test the hypothesis that the active species contains $[R_2Cu]^-$ in solution, we studied the influence of the nature of the various cuprate reagents on the outcome of a substitution reaction of a primary halide with such cuprate reagents (Table 2). These preliminary results (see Table 2) show that in the given reaction time (1 h) the 2:1 cyanocuprates (entries 1 and 2) transfer 50% of the R groups to the substrate, while the other Cu^I species tested are not reactive (entries 3–5).

[b] van Koten and Noltes [20].
[c] van Koten et al. [21].

The fact that only 50% of the R groups of the 2:1 cyanocuprate (see entries 1 and 2) is transferred suggests that the remaining cyanocuprate species, after transfer of the R group, assembles into a stable, and unreactive, 1:1 cyanocuprate (entry 3).

In conclusion, it can be stated that the solid-state structure of a 2:1 cyanocuprate of type $[Ar_2CuLi_2CN]_\infty$ has revealed the presence of ionic structural motifs. In addition, more insight into the apparent structure of some specific cyanocuprates in solution has been provided by cryoscopic measurements in THF.

Supplementary data

X-ray structural data for compound **1** are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number SITYEZ.

Acknowledgements

We thank Professor N. Krause and Dr A. Gerold for the collaboration in the field of the cryoscopic measurements and helpful discussions.

POLYHEDRON

Iridium complex-catalyzed allylic alkylation

Ryo Takeuchi *

Department of Environmental Science, Faculty of Science, Yokohama City University, 22-2 Seto, Kanazawa-ku, Yokohama 236-0027, Japan

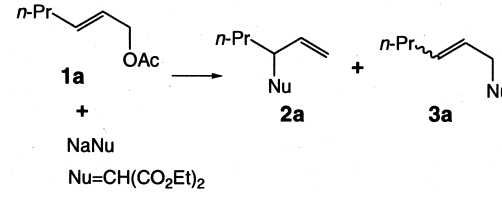
Received 4 October 1999; accepted 9 November 1999

Abstract

An iridium complex was found to be an efficient catalyst for allylic alkylation of allylic acetates with a stabilized carbon nucleophile. Two unique features of iridium complex catalysis are found. (1) Regioselective alkylation at the substituted allylic terminus: the reaction of (*E*)-2-alkenyl acetates or 1-substituted 2-propenyl acetates with sodium salt of diethyl malonate in the presence of a catalytic amount of $[Ir(COD)Cl]_2/P(OPh)_3$ ($P/Ir = 1–2$) gave products alkylated at the substituted allylic terminus with 95–99% selectivities. ^{31}P NMR and ^{13}C NMR revealed that a catalytically active species is $Ir(COD)(P(OPh)_3)Cl$. The π-acceptor property of $P(OPh)_3$ promotes a carbonium ion character at the substituted allylic terminus. Therefore, the nucleophile is directed to this position. (2) Retention of *Z* geometry in the allylic alkylation of (*Z*)-2-alkenyl acetates; the reaction of (*Z*)-2-alkenyl acetates gave a product alkylated at the unsubstituted allylic terminus with the retention of *Z* geometry predominantly. Retention of *Z* geometry in allylic alkylation is also possible by iridium catalysis. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: π-Allyl complexes; Allylic substitutions; Iridium; Regioselectivity; Stereoselectivity; Phosphites

1. Introduction



The use of iridium complexes for organic synthesis is relatively unexplored. Since Crabtree reported that a cationic iridium complex is a highly active catalyst for hydrogenation of alkenes [1], iridium complexes have received much attention as efficient hydrogenation catalysts. In contrast to its utility in hydrogenation, the iridium complex-catalyzed carbon–carbon bond forming reaction was not developed until the 1990s. Recently, synthetically useful carbon–carbon bond forming reactions have been reported [2–5].

One of the most important carbon–carbon bond forming reactions catalyzed by transition metal complexes is allylic alkylation, which is widely used for constructing complex organic molecules. The control of regioselectivity in allylic alkylation is important. When the π-allyl intermediate is terminally monosubstituted, palladium complexes generally lead to a preferential alkylation at the unsubstituted allylic terminus [6–8]. On the other hand, molybdenum [9,10], tungsten [11], ruthenium [12] and platinum [13–15] complexes tend to lead to a preferential alkylation at the substituted allylic terminus. Complete regiocontrol of alkylation at the substituted allylic terminus is a challenging problem. A new catalyst is required for the realization of such selectivity. We have found an iridium complex that is a new and efficient catalyst for allylic alkylation [16,17]. Based on our results, iridium complex-catalyzed asymmetric allylic alkylation has been reported [18,19].

2. Results

2.1. Regioselective allylic alkylation at the substituted allylic terminus

The reaction of (*E*)-2-hexenyl acetate (**1a**) with sodium salt of diethyl malonate in the presence of a catalytic amount of $[Ir(COD)Cl]_2$ and ligand gave compounds **2a**, (*E*)-**3a** and (*Z*)-**3a** (Eq. (1)).

(1)

Added phosphorus ligand had a substantial effect on the selectivity and yield of the products. Results are summarized in Table 1. $P(OPh)_3$ was found to be the most efficient ligand. The reactions using 1 or 2 equivalents of $P(OPh)_3$ to Ir

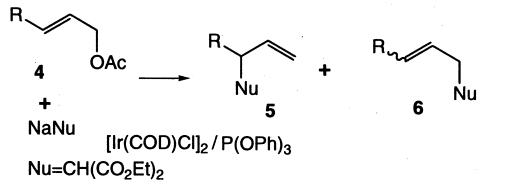
Effect of ligand on allylic alkylation of compound **1a** with sodium salt of diethyl malonate [a]

Entry	Ligand	P/Ir	Conditions	Yield (%) [b]	Ratio [c] **2a**:**3a** (*E*/*Z*)
1	$P(OPh)_3$	1	room temperature, 3 h	90	96:4 (78/22)
2	$P(OPh)_3$	2	room temperature, 3 h	89	96:4 (81/19)
3	$P(O4\text{-}MeC_6H_4)_3$	2	room temperature, 8 h	81	95:5 (73/27)
4	$P(O4\text{-}FC_6H_4)_3$	2	room temperature, 23 h	55	94:6 (94/6)
5	$P(OEt)_3$	2	reflux 3 h	81	59:41 (90/10)
6	PPh_3	2	reflux 16 h	6	24:76 (63/37)
7	dppe	2	reflux 16 h	18	39:61 (94/6)

[a] A mixture of compound **1a** (2 mmol), $NaCH(CO_2Et)_2$ (4 mmol), $[Ir(COD)Cl]_2$ (0.04 mmol), ligand and THF (10 ml) was stirred under argon.
[b] Isolated yield.
[c] Determined by GLC.

proceeded at room temperature to give an excellent yield of products (entries 1 and 2). The selectivity of compound **2a** was 96%. The use of $P(O4\text{-}MeC_6H_4)_3$ and $P(O4\text{-}FC_6H_4)_3$ as a ligand gave an excellent selectivity for compound **2a**, but the reactions required a longer reaction time compared to that using $P(OPh)_3$ (entries 3 and 4). With $P(OEt)_3$, the reaction gave compound **2a** in a much decreased selectivity (entry 5). Reaction using a more electron-donating phosphorus ligand such as PPh_3 and dppe gave products in poor yields (entries 6 and 7).

Reaction of compound **1a** with various stabilized carbon nucleophiles was examined (Eq. (2)).

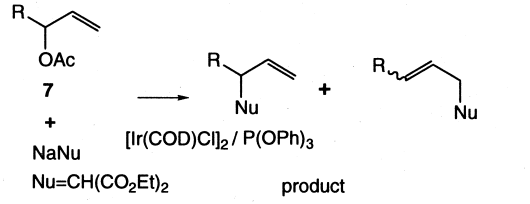


(2)

b	$Nu=CH(CO_2Me)_2$	room temp. 3 h	90%	97 : 3 (E/Z=79/21)
c	$Nu=CHAcCO_2Et$	THF reflux 7 h	85%	93 : 7 (E/Z=80/20)
d	$Nu=CMe(CO_2Et)_2$	THF reflux 1 h	87%	29 : 71 (E/Z=90/10)

The reaction of compound **1a** with various stabilized carbon nucleophiles gave product **2a**–**c** in 93–97% selectivities. Increasing the steric bulk of carbon nucleophile reversed the regioselectivity. The reaction with sodium salt of diethyl ethyl malonate gave product **3d** in 71% selectivity.

We examined the reaction of a series of acyclic allylic acetates (**4**) with sodium salt of diethyl malonate in the presence of a catalytic amount of $[Ir(COD)_2Cl]_2/P(OPh)_3$ (P/Ir=2) (Eq. (3)).

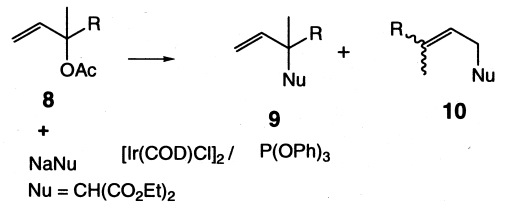


(3)

a	R= Me	room temp. 2 h	77%	97 : 3
b	R= Ph	room temp. 3 h	98%	99 : 1 (E/Z=100/0)
c	R= *n*-Hex	room temp. 5 h	99%	95 : 5 (E/Z=66/34)
d	R= *n*-Oct	room temp. 5 h	95%	95 : 5 (E/Z=69/31)

Highly regioselective alkylation at the substituted allylic terminus was achieved. All reactions proceeded at room temperature to give compound **5** in 95–97% selectivities.

Regioisomeric acetate **7** was used as a substrate (Eq. (4)).



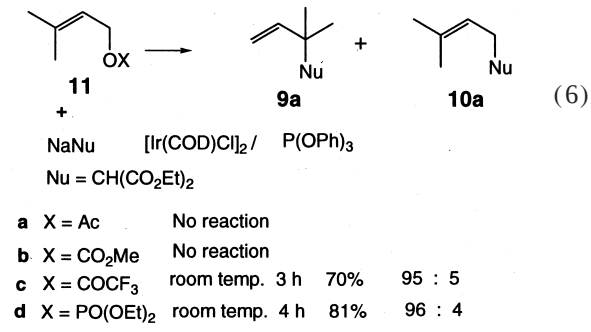
(4)

product

a R= *n*-Pr	room temp. 3 h	86%	**2a: 3a**	95 : 5	(E/Z=78/22)
b R= Ph	room temp. 3 h	91%	**5b: 6b**	99 : 1	(E/Z=79/21)
d R= *n*-Oct	room temp. 3 h	95%	**5d: 6d**	95 : 5	(E/Z=78/22)

Reactions with sodium salt of diethyl malonate gave the same product distribution to that of compounds **1a**, **4b** and **4d**. The result strongly suggests the intermediacy of a π-allyl iridium complex.

The most unique feature of iridium complex catalysis was demonstrated for the reaction of compound **8**. The reactions occurred with perfect regioselectivity at the tertiary allylic terminus to give a product (**9**) bearing a quaternary carbon center exclusively (Eq. (5)).

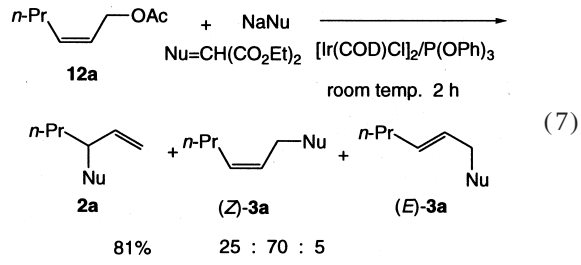


(5)

a	R= Me	room temp. 2 h	80%	100 : 0
b	R= *n*-Bu	room temp. 16 h	80%	100 : 0
c	R= $CH_2CH_2C=Me_2$	room temp. 5 h	85%	100 : 0

Iridium complex-catalyzed allylic alkylation provides an efficient method for the construction of a quaternary carbon center which is a feature of broad range of natural products. Several transition metal complex-catalyzed reaction of compound **8** have been reported [20]. Iridium complex only led to the exclusive formation of a product bearing a quaternary carbon center.

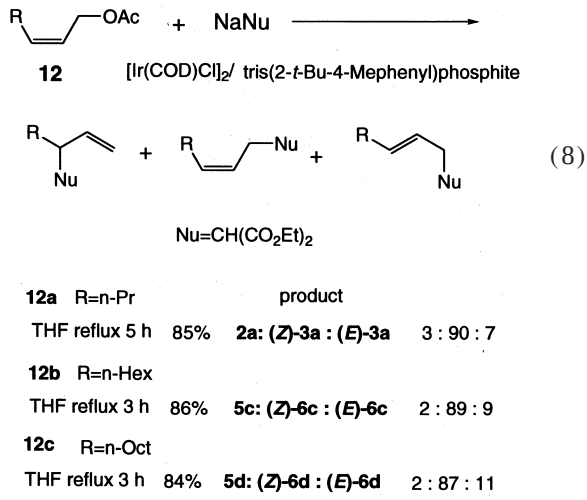
3-Methyl-2-butenyl acetate (**11**) failed to react with sodium salt of diethyl malonate under refluxing dioxane for 24 h. The corresponding product was not obtained at all. 3-Substituted 2-alkenyl acetate was much less reactive than that of 2-alkenyl acetate. Changing the leaving group enhanced the reactivity of the substrate (Eq. (6)).



(6)

The reaction of compounds **11c** and **11d** with sodium salt of diethyl malonate proceeded at room temperature to give compound **9a** in 96 and 95% selectivity, respectively.

2.2. Retention of Z geometry in the allylic alkylation



The geometry of the carbon–carbon double bond in the allyl system affected the regiochemistry of the allylic alkylation. The reaction of compound **12a** with sodium salt of diethyl malonate at room temperature gave products in 81% yield (Eq. (7)).

(7)

The major product was (*Z*)-**3a**, resulting from the alkylation at the unsubstituted allylic terminus. Regioselectivity was opposite to that of compound **1a**. This result showed that the alkylation occurred prior to *syn–anti* isomerization and the regioselectivity of alkylation to the *syn* π-allyl iridium complex was different from that to the *anti* π-allyl iridium complex.

Palladium complex-catalyzed allylic alkylation of (*Z*)-2-alkenyl acetate resulted in a loss of *Z* geometry [21], because the *anti* π-allyl palladium complex easily isomerized to the thermodynamically more stable *syn* π-allyl palladium complex [22]. The reaction of compound **12a** with sodium salt of diethyl malonate gave compound (*Z*)-**3a** as a major product. The ratio (*Z*)-**3a**/(*E*)-**3a** was 93/7. *Syn–anti* isomerization of a terminally monosubstituted π-allyl iridium complex is quite slow compared to that of a terminally monosubstituted π-allyl palladium complex. Iridium catalysis provides a possibility of (*Z*)-selective allylic alkylation. However, in the reaction of (*Z*)-2-alkenyl acetate, the regioselectivity of alkylation at the unsubstituted allylic terminus is not satisfactory. To improve the selectivity of (*Z*)-alkene, alkylation must be directed to the unsubstituted allylic terminus. A bulky phosphite ligand is expected to increase such regioselectivity. We examined the reaction of (*Z*)-2-alkenyl ester with sodium salt of diethyl malonate using a bulky phosphite ligand (Eq. (8)).

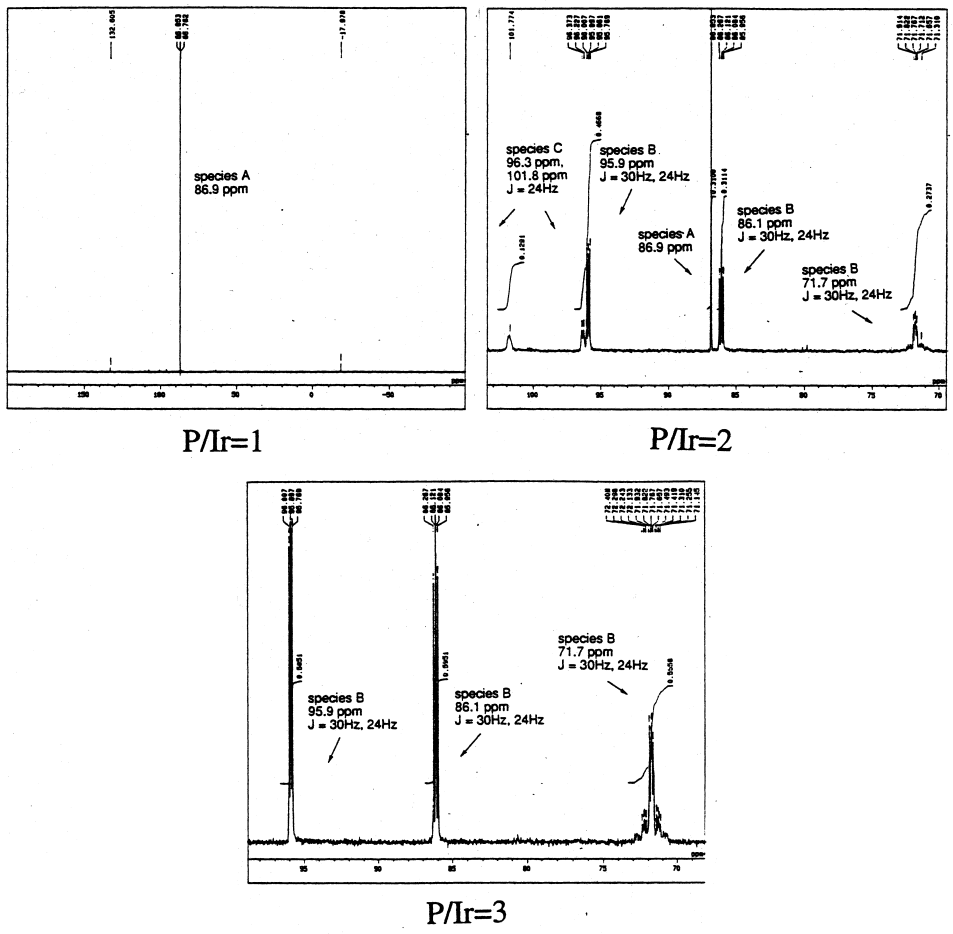
(8)

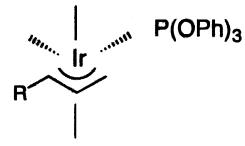
The reaction using 1 equivalent of tris(2-*tert*-butyl-4-methylphenyl)phosphite to iridium under refluxing THF for 3 h gave the product in 85% yield (entry 2). The selectivity of compound (*Z*)-**3a** was increased to 90%. The reaction of compounds **12b** and **12c** with sodium salt of diethyl malonate gave compounds (*Z*)-**6c** and (*Z*)-**6d** in 89 and 87% selectivity, respectively.

3. Discussion

As mentioned above, triphenylphosphite is an essential ligand for regioselective alkylation at the substituted allylic terminus. To clarify the catalytically active species, we monitored the reaction of $[Ir(COD)Cl]_2$ with $P(OPh)_3$ in THF-d_8 by ^{31}P NMR. The spectra are shown in Fig. 1. The spectrum at $P/Ir = 1$ showed a singlet (δ 86.9). No free $P(OPh)_3$ was detected. It indicated the formation of a monophosphite species (species A). The ^{13}C NMR spectra of species A showed two sets of doublets (δ 54.7, $J = 2.4$ Hz; 106.4 $J = 19.5$ Hz). Species A was identified as $IrCl(COD)(P(OPh)_3)$ by comparing these chemical shifts values and their coupling constants with those in the literature [23].

Increasing the amount of $P(OPh)_3$ led to the appearance of a new set of signals. The reaction of $[Ir(COD)Cl]_2$ with 2 equivalents of $P(OPh)_3$ formed three species (species A, B and C). The spectrum at $P/Ir = 2$ showed a singlet (δ 86.9; species A), three sets of doublets (δ 71.7, 86.1 and 95.9, $J = 30$, 24 Hz; species B) and two sets of doublets (δ 96.3 and 101.8, $J = 24$ Hz; species C) in the ratio 42:42:16. The





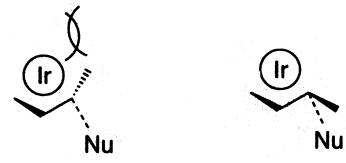


Fig. 1. ^{31}P NMR spectra of the reaction of $[Ir(COD)Cl]_2$ with $P(OPh)_3$.

spectra at $P/Ir = 3$ showed three sets of doublets (δ 71.7, 86.1 and 95.9, $J = 30$, 24 Hz; species B). Signals of species A and C disappeared. The allylic alkylation was highly regioselective at the ratios $P/Ir = 1$ and 2 (Table 1; entries 1 and 2). It is clear that a catalytically active species is species A. Triphenylphosphite coordinates with the metal *trans* to the substituted allylic terminus to avoid steric repulsion. Since $P(OPh)_3$ is a better π-acceptor, it promotes a carbonium ion character at the substituted allylic terminus and directs the nucleophilic attack to this position (Scheme 1). In agreement with this, when a ligand with weaker acceptor properties was used, such as $P(OEt)_3$, the reaction was much less selective (Table 1; entry 5).

The regioselectivity of the reaction of (*Z*)-2-alkenyl acetate is different from that of (*E*)-2-alkenyl acetate. The difference is explained as follows. Nucleophilic attack at the substituted allylic terminus in *anti* π-allyl iridium intermediate would bring the *anti* substituent close to the iridium moiety. The steric interaction gives an unfavorable transition state. On the other hand, such steric interaction does not occur in the alkylation at the substituted allylic terminus of the *syn* π-allyl iridium intermediate. Thus, alkylation at the unsubstituted allylic terminus is favored in the case of (*Z*)-2-alkenyl acetate (Scheme 2).

Scheme 1.

Scheme 2.

In conclusion, iridium complex was found to be a new and efficient catalyst for allylic alkylation. The selectivities described here complement palladium complex catalysis. These unique features will make iridium complexes a useful tool for the carbon–carbon bond forming reaction.

Abstract

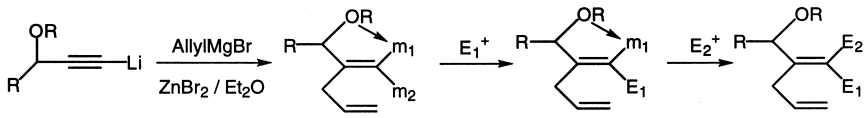
The first straightforward synthesis of tris-metallated olefins and functionalized metallated alkynes is reported via the use of low-valent titanium derivatives. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Alkynes; Functionalized metalloalkynes; Olefins; Polymetallated olefins; Titanium

The development of new strategies in organic syntheses with a minimum of chemical steps is becoming increasingly necessary for the efficient assembly of complex molecular structures [1], and then the combination of multiple reactions in a single operation represents a particularly efficient approach. Among different strategies [2], the synthesis and reactivity of geminated organobismetallics is becoming increasingly useful for the synthesis of molecules with complex architecture [3].

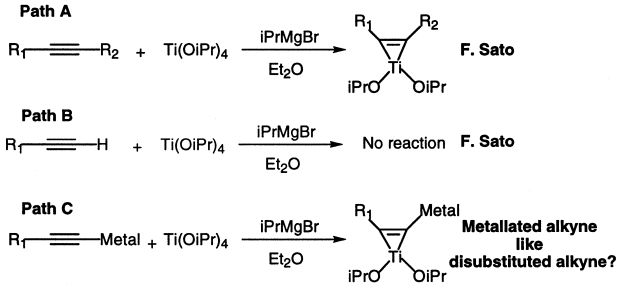
One particular example is the preparation of polysubstituted olefins in a single-pot operation from polymetallated olefins. Indeed, several 1,1-dimetalloalkenes with a large variety of metals (dilithium [4], aluminum and titanium [5,6], aluminum and zirconium [5,6], zinc and zirconium [7,8], zinc and boron [9], copper and boron [9], copper and zirconium [7,8], lithium and boron [10,11] and boron and zirconium [12–14]) have been used as a source of polysubstituted carbon–carbon double bonds with variable stereochemical purities. In this context, we have already reported that the allylmetallation of alkynyl metals [15–18] leads to sp^2 1,1-bis-metallic derivatives in good overall yield [19,20]. These geminated bis-anions react selectively with two different electrophiles and can be a source of chiral α,α'-disubstituted alkynes [19–21] (Scheme 1).

However, the major drawback of this strategy is the necessary incorporation of the allyl moiety on the carbon skeleton. Also we needed a more general preparation of sp^2 polymetallated derivatives allowing the access to a wide variety of carbon skeletons. To answer this requirement, we thought that some organometallic derivatives might behave, to a certain extent, like a carbon atom. If this assumption is correct, it should then be possible to prepare an organometallic derivative on an already metallated carbon center. In order to test this new concept, we used the pioneering work of Sato and co-workers [22], who demonstrated that various disubstituted alkynes react with diisopropoxy(η^2-propene)-titanium (**1**), readily generated by the reaction of $Ti(OiPr)_4$ with 2 equivalents of iPrMgX, to give the corresponding titanacyclopropene derivatives as described in Scheme 2, path A.



As terminal alkynes failed to participate in the present reaction (path B versus path A), the Sato reagent was ideal for testing this new concept: can a metallated alkyne behave like a disubstituted alkyne (path C identical to path A) and so an organometallic moiety like a carbon atom?

Our initial attempts were to add alkynyl metal derivatives to the preformed Ti(II) complex (**1**) as described in Scheme 3.



The metallated titanacyclopropenes were effectively obtained with moderate chemical yield for $MX_{n-1}=$

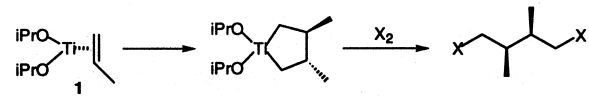
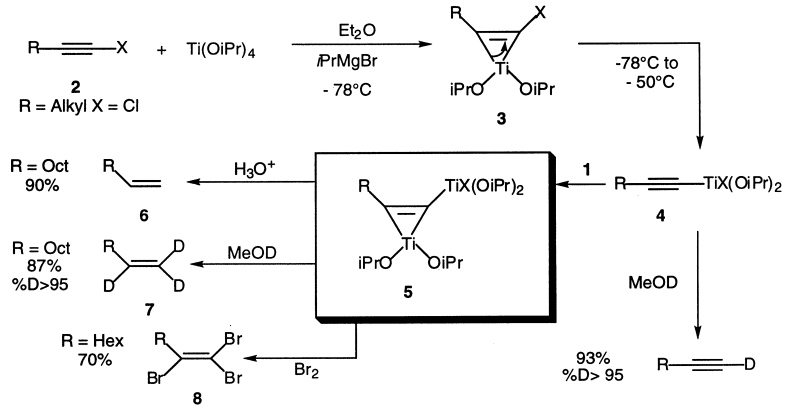
Scheme 1.



Scheme 2.

Scheme 3.



$Ti(OiPr)_3$, ZnBr or ZnBu. However, it was very difficult, in our hands, to get reproducible results (for example, the yield of the alkynylzinc bromide varied from 25 to 70%). These fluctuations were attributed to the possible instability of the preformed low-valent titanium alkoxide (**1**) in these Grignard experimental conditions [Grignard conditions (formation of the organometallic derivative and then introduction of the electrophile) as compared to Barbier conditions (formation of the organometallic derivative in the presence of the electrophile)], and also to the rearrangement of compound **1** into the corresponding cyclic product (*meso*/*dl* = 99/1) (Scheme 4).

Scheme 4.

In order to overcome these chemical yield fluctuations, it was then necessary to prepare compound **1** in the presence of the alkyne (Barbier conditions, see above). However, the addition of iPrMgBr to the mixture of alkynylzinc bromide and $Ti(OiPr)_4$ in ether at low temperature in Barbier conditions did not give the expected product, but more probably the alkynyldiisopropyl zincate. So, the transmetallation between iPrMgBr and the alkynylzinc bromide was faster than the reaction between the same Grignard and the titanium(IV). Finally, we found that treatment of chloroalkyne (**2**) with 2.5 equivalents of the combination $Ti(OiPr)_4$–2iPrMgBr in Et_2O gives, in a single-pot operation at $-50°C$, the desired titanotitanacyclopropene (**5**) in high chemical yield as described in Scheme 5.

Then, the in situ formed diisopropoxy(η^2-propene)-titanium (**1**) reacts with the chloroalkyne (**2**) to give as unstable intermediate, the chlorotitanacyclopropene (**3**). This latter undergoes a fast β-elimination at low temperature to give the alkynyltitanium derivative (**4**). The second equivalent of compound **1** present in the reaction mixture reacts with compound **4** to give the metallated titanacyclopropene (**5**). After hydrolysis, the alkene (**6**) is obtained in high chemical yield. The presence of three carbon–metal bonds was proven by the reaction of compound **5** with MeOD or with Br_2 to give, respectively, the trideuterated olefin (**7**) in 87% yield (D > 95%) or the tribromo derivative in 70%

Scheme 5.

Table 1
Generalization for the synthesis of metallated titanacyclopropenes

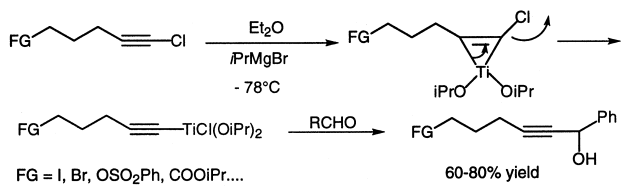
yield. The scope of this reaction is broad, as described in Table 1, since alkyl as well as aromatic groups on the alkyne give the polymetallated olefins whatever the nature of the leaving group (compare entries 1, 2 and 3).



The reactivity of zirconocenes [23] and titanocenes [24] was also studied in this process and we found that only the combination zirconocenes/aromatic halogenoalkynes gave good results (Scheme 6).

In a parallel study, we have also investigated the reactivity of tribromo olefins such as compound **8** (see Scheme 5) and found that this compound can undergo specific coupling reaction with various organometallics in the presence of a catalytic amount of transition metal [25].

We finally turned our attention to the new preparation of metalloalkyne (**4**) (Scheme 5) via diisopropoxy(η^2-propene)titanium (**1**). Indeed, it is known that triisopropoxyalkynyl titanium derivatives react chemoselectively with carbonyl compounds to give the corresponding carbinols in high yield [26]. However, and to the best of our knowledge, these metallated alkynes were always prepared by transmetallation between alkynyl lithium and $ClTi(OiPr)_3$, which precludes the presence of sensitive moieties on the carbon skeleton [27]. It then appeared to us that this new methodology established for the synthesis of **4** could be an interesting alternative for the formation of chlorodiisopropoxyalkynyl titanium possessing sensitive groups [28]. This was effectively the case, as described in Scheme 7.

Scheme 6.

Scheme 7.

The metallated alkyne (**14**) shows a remarkable functional group tolerance, and several classical functional organic moieties can be present during the formation of the chlorodiisopropoxyalkynyl titanium derivatives.

In conclusion, this new concept (organometallic derivative can behave like a carbon atom) enabled us to describe the first and straightforward preparation of tris-metallated olefins in high chemical yield. Moreover, during the preparation of the latter, we found a new preparation of metallated alkynes possessing functional groups.

Stereodivergent hydrosilylation of 1-alkynes catalyzed by $RhI(PPh_3)_3$ leading to (*E*)- and (*Z*)-alkenylsilanes and the application to polymer synthesis

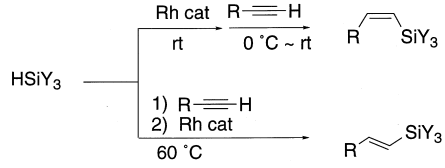
Atsunori Mori *, Eisuke Takahisa, Hiroshi Kajiro, Yasushi Nishihara, Tamejiro Hiyama

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Yokohama 226-8503, Japan

Received 4 October 1999; accepted 15 November 1999

Abstract

Hydrosilylation of 1-alkynes catalyzed by $RhI(PPh_3)_3$ gives (*E*)- and (*Z*)-alkenylsilanes in a stereodivergent manner by switching the reaction conditions and the order of the addition of the reagents. The reaction is also applied to the synthesis of silicon-containing polymers with (*E*) and (*Z*) main-chain structures via polyaddition. ©2000 Elsevier Science Ltd All rights reserved.



Keywords: Alkenylsilanes; Hydrosilylation; $RhI(PPh_3)_3$; Polyaddition; Stereodivergent

Hydrosilylation serves as one of the most fundamental reactions in organosilicon chemistry. The reaction proceeds by the catalysis of a variety of transition metals, and the control of the reactivity and the selectivity in the hydrosilylation have been of major concern in synthetic organic chemistry as well as in organometallic chemistry [1,2]. The hydrosilylation of a terminal alkyne with a hydrosilane, for example, would form regio- and stereochemical isomers.

We found that the use of $RhI(PPh_3)_3$ as a catalyst for the hydrosilylation of a terminal alkyne furnishes *E*- and *Z*-alkenylsilanes in stereochemically divergent manners by switching the order of the addition of the reagents and reaction conditions [3,4].

The process is illustrated in Scheme 1. When an alkyne was added to a pretreated mixture of a hydrosilane and the rhodium catalyst at room temperature for 2 h, (*Z*)-alkenylsilane was obtained in a good yield (>99%) with an excellent stereoselectivity (>99:1). On the other hand, reaction of the mixture of a hydrosilane, an alkyne and the catalyst at 60°C lead to the (*E*)-product (>99% yield, >99% selectivity).

The results on the stereodivergent hydrosilylation leading to *E*- and *Z*-alkenylsilanes are summarized in Table 1. The hydrosilylation is effective for a variety of hydrosilanes, namely those with heteroatom substituent(s) such as a siloxy or an alkoxy group. This is in contrast to most of the previous rhodium-catalyzed hydrosilylations which have been examined with the use of triethylsilane [1].

Scheme 2.

The obtained alkenylsilanes were successfully subjected to transformation reactions of the carbon–silicon bond to a carbon–carbon bond via palladium-catalyzed cross-coupling reaction with retention of the stereochemistry [5].

Then the stereodivergent hydrosilylation was applied to bis-alkynes with bis-hydrosilanes via polyaddition to afford the poly[(phenylene)-((*E*), or (Z)-vinylene)-(silylene)]s. The reactions proceeded in a highly stereospecific manner as shown in Scheme 2, with the ratios higher than 90%. The molecular weights and the molecular weight distributions were estimated by SEC analyses in the range 6000–20000 and 2.4–5.5, respectively. UV absorption and emission spectra of the polymers were also measured [6].

X-ray crystallographic proof of regioselectivity in a nitrosobenzene cycloaddition, and development of a novel in situ heterocycloaddition trap for use during decomplexation of tricarbonyliron diene complexes in hippeastrine synthesis

Christopher E. Anson [1], Sascha Hartmann, Richard D. Kelsey, G. Richard Stephenson *

School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, UK

Received 4 October 1999; accepted 18 November 1999

Abstract

The heterocycloaddition reaction between nitrosobenzene and 2-methylcyclohexa-1,3-diene preferentially affords the regioisomer with the N–Ph group next to the methyl substituent, and this product has been characterised by X-ray crystallography. As a model study for a tricarbonyliron mediated route to the alkaloid hippeastrine, a 2-methyl-6-phenylcyclohexadiene analogue has been prepared from tricarbonyl(η^5-3-methylcyclohexadienyl)iron(1+) hexafluorophosphate(1−) and has been examined in the heterocycloaddition reaction. A novel in situ heterocycloaddition trapping procedure has been developed based on this chemistry. Tricarbonyl(η^4-2-methyl-6-phenylcyclohexadiene)iron(0) can be converted directly into the cycloadduct in this way by reaction with trimethylamine *N*-oxide in the presence of nitrosobenzene. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Nitrosobenzene cycloaddition; Regioselectivity; Organoiron compounds; Decomplexation; Heterocycloaddition trap; Alkaloid synthesis

Our investigation of the use of tricarbonyliron complexes as electrophilic intermediates in alkaloid synthesis aims to demonstrate the intrinsic flexibility of this approach, by addressing synthetic targets with common structural features that are arranged differently around a central portion of the molecule. In the case of the *Amaryllidaceae* alkaloids [1] lycoramine and hippeastrine, this central feature contains an aromatic and saturated (or partially-saturated) six-membered ring, joined at a chiral centre. Because of their shared biogenesis from tyrosine, these alkaloids also contain a two-carbon alkylamine (CH_2–CH_2–X) side-chain, but this appears at the chiral centre in the aryl-substituted ring junction in lycoramine, and opposite the point of arene attachment in hippeastrine. Tricarbonyliron complexes used in these syntheses serve as powerful electrophiles and give complete stereocontrol in reactions with nucleophiles, and our general approach is based on the concept of a central 'C_{12} building block' [2] comprising an aryl-substituted chiral cyclohexadienyliron complex. We have reported [3] a formal total synthesis of lycoramine based on this approach and employing a sequence of two organoiron-mediated nucleophile addition steps at the same carbon atom. Analysis of the requirements for regiocontrol [4] (Fig. 1) in the manipulation of the tricarbonyliron complexes shows this to be a '1,1' pattern, because both of the nucleophile addition steps occur at the same carbon atom. This is achieved by developing an OMe leaving group at the C-1 position in the electrophile, the centre at which the first nucleophile adds. For hippeastrine, a '1,2' regiocontrol pattern is needed, and for this the leaving group needs to be located at C-6. We have demonstrated that in this way, a sequence of nucleophile addition, reactivation by extraction of the leaving group, and an intramolecular second nucleophile addition step can form the ABC ring system of the hippeastrine target [5], and since both nucleophiles react under control of the iron centre, *cis* relative stereochemistry at the BC ring junction is assured in this approach. We have also shown that biotechnology can afford from arenes a simple enantioselective entry to suitably substituted chiral diene complexes equipped with correctly placed leaving groups [6].

In this communication, we present results that relate to the CD ring section of hippeastrine, where our objective is to use

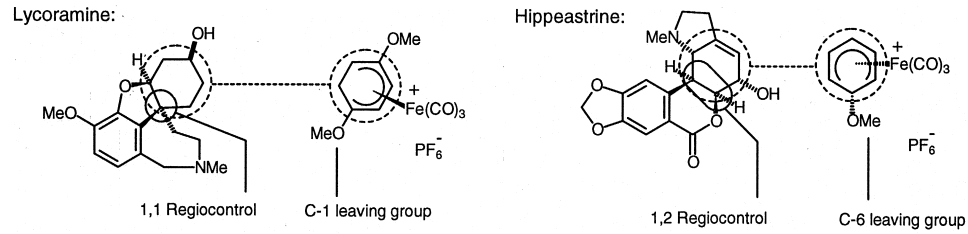

Fig. 1. Identification of 1,1 and 1,2 regiocontrol patterns needed for syntheses of *Amaryllidaceae* alkaloids such as lycoramine and hippeastrine, using alkoxy-substituted cyclohexadienyliron complexes.

aryl, acyl, or α-chloroalkylnitroso compounds as heterodienophiles to trap the diene at the decomplexation step in the iron-mediated synthesis. Intermediates for hippeastrine that combine a 1,3-diene in ring C with the lactone in ring B are prone to aromatisation by opening of the lactone [7], but we have developed a novel in situ procedure for heterocycloaddition in the presence of reagents for the oxidative detachment of the tricarbonyliron group. This should offer good prospects for use with sensitive intermediates in our synthetic route.

The cycloaddition chemistry of nitroso complexes has been studied in detail and has the advantage of proceeding at low temperature (room temperature, or even below [8]), but regiocontrol with unsymmetrical dienes [9–11] has not been so extensively defined as is the case with classic Diels–Alder cycloadditions. For our purpose, we require the nitrogen atom of the nitroso reagent to add to the carbon adjacent to the 'CH_2–CH_2–X' alkyl substituent on the cyclohexadiene, so that the D ring can ultimately be formed by cyclisation of CH_2–X to the nitrogen introduced in the dienophile. This is known [11] to be the preferred regioselectivity of reaction of nitrosobenzene with 2-methylbutadiene. We began by preparation of the known [12] 2-methylcyclohexa-1,3-diene (**1**) and an examination of its reaction with commercially available nitrosobenzene. An excess of the nitroso compound was mixed with the diene and stored at −20°C for 1 week. After chromatography, the major product **2** was recrystallised from ethanol–water, and we were able to prove by X-ray crystallography [13] (Fig. 2) that the correct regioisomer had been formed. The substituted end of the heterodienophile adds to the more hindered end of the diene, suggesting that the reaction is initiated by approach of the oxygen terminus of the Ph–N=O unit to the most accessible site for reaction.

A substrate for use in a model study of in situ trapping of the diene was easily prepared from tricarbonyl(η^5-3-methylcyclohexadienyl)iron hexafluorophosphate (**3**). Excellent results were obtained by reaction with Ph_2CuLi in THF. The *exo*-substituted product **4** was obtained in 91% yield. This complex has the same relative position of alkyl and aryl components as the proposed 'C_{12} + CH_2–CH_2–X' [2] building block for our route to hippeastrine. Attempted direct reaction of the tricarbonyliron complex with an excess of nitrosobenzene resulted only in recovery of the starting material, but by pre-mixing the complex and nitrosobenzene in DMA at 0°C, then adding trimethylamine *N*-oxide and allowing the mixture to warm to room temperature, the cycloadduct **5** was obtained in 68% yield. The same cycloadduct could be formed by a conventional stepwise procedure, detaching the metal first with trimethylamine *N*-oxide, and taking the crude diene (ca. 50% yield, mixed with products from aromatisation) on into the cycloaddition step (Scheme 1). TLC analysis of the products of the cycloaddition reaction using a

Scheme 1.

phosphomolybdic acid stain produces characteristic purple spots, and in this way it was demonstrated that although several cycloaddition products are formed in this reaction, one predominates to a large extent. Minor reaction pathways to alternative stereo- and regioisomers can account for this observation, but at this stage only the major diastereoisomer has been isolated and characterised (HRMS, ^{1}H NMR, COSY, ^{13}C NMR, DEPT). To date, attempts to obtain crystals to confirm the relative stereochemistry by X-ray crystallography have been unsuccessful, but the NMR data are consistent with the expected product, which corresponds to the approach of the heterodienophile to the unsubstituted face of the diene, and the structure is provisionally assigned on that basis.

In summary, we have developed a novel low temperature trapping procedure to intercept sensitive substituted diene products during the metal removal step, which when applied in our organoiron-mediated approach to hippeastrine shows promise as a convenient and efficient method to introduce the C–N and C–O substituents on the C ring. Cycloaddition ensures that these two features are *cis* to one another, and approach of the dienophile to the open face of the structure, and with the unsubstituted end of the nitroso compound bonding preferentially to the less hindered end of the diene, would lead to the formation of the required regio- and stereoisomer as the major product. By the in situ trapping method, the decomplexation reaction becomes a 'working step' [14] in the synthesis, and the metal-mediated construction of the 'C_{12}' aryl-substituted cyclohexadiene complex described here is suitable to allow easy preparation of more representative model structures containing the methylenedioxy and CH_2–CH_2–X features that will figure in the natural product synthesis itself. The scope of the in situ trapping method with more highly substituted dienes and with heterodienophiles that can easily be converted into NMe substituents by reduction of the N–O bond [15] in the cycloaddition product, is currently under investigation.

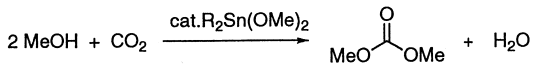
Synthesis of dimethyl carbonate from carbon dioxide: catalysis and mechanism

Toshiyasu Sakakura *, Jun-Chul Choi, Yuko Saito, Takeshi Sako

National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki 305-8565, Japan

Received 4 October 1999; accepted 7 December 1999

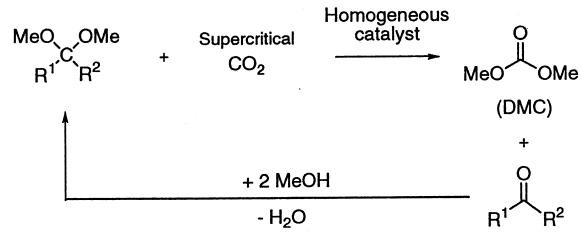
Abstract



The turnover number of the catalytic production of dimethyl carbonate from CO_2 and methanol is restricted by thermodynamics as well as catalyst decomposition. The catalytic efficiency is remarkably improved using an acetal as the starting material in methanol. The catalytic activity and selectivity also depend strongly on the CO_2 pressure. A possible catalytic cycle involving transformation of CO_2 to dimethyl carbonate is postulated based on mechanistic studies at a molecular level. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Carbon dioxide; Dimethyl carbonate; Homogeneous catalysis; Mechanism; Supercritical conditions

1. Introduction



There is no need to discuss the importance of carbon dioxide as a C_1 feedstock (for recent reports of CO_2 conversion by homogeneous catalysis, see Refs. [1–6]). In particular, the utilization of supercritical carbon dioxide has recently attracted much interest from the viewpoint of Green Chemistry [7] for the following reasons. (i) The environmentally friendly nature of CO_2 (non-toxic and inflammable) is attractive for solvent-free processes and as a substitute for toxic chemicals such as phosgene and CO. (ii) Physical properties such as polarity, solubility etc. can be varied by changing the pressure and temperature. (iii) The reactivity of CO_2 itself is often improved dramatically under supercritical conditions [8,9]. (iv) Separation from the reaction mixture is easy.

One of the most interesting synthetic targets starting from CO_2 is dimethyl carbonate (DMC) [10–12]. The possible organotin-catalyzed formation of DMC from CO_2 was first proposed by Japanese groups (Eq. (1)) [13,14]. Kizlink et al. have paid much attention to improving the catalytic activities of this reaction although the turnover number (TON) is still far from satisfactory [15–18].

(1)

Previously, we reported the organotin-catalyzed synthesis of DMC from orthoesters and CO_2 [19–21]. However, this procedure has the disadvantages of high cost of the starting material and the co-production of methyl ester. This article discloses an improved procedure, the synthesis of DMC from acetals and CO_2 (Eq. (2)) [22,23]. Since the co-produced carbonyl compounds are easily recycable, the process can be regarded as a formal DMC synthesis from methanol and CO_2.

(2)

2. Results and discussion

2.1. Catalytic reaction

As for the synthesis of DMC from methanol and CO_2 only (Eq. (1)), there are two factors that restrict the amount of DMC: (i) thermodynamics and (ii) deactivation of the catalyst by water. Although both factors are important, the former is more notable. Indeed, the yield of DMC does not depend significantly on the amount of catalyst (Fig. 1). In other words, the turnover number decreases sharply with increasing amount of catalyst (Fig. 2).

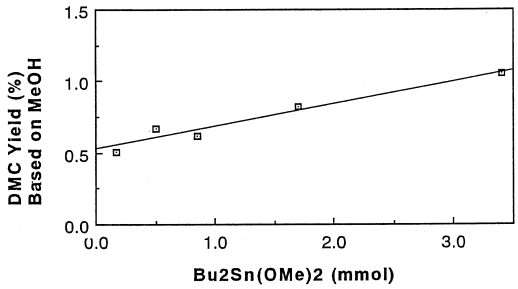

Fig. 1. Effect of amount of catalyst on the yield of DMC. Reaction conditions: $Bu_2Sn(OMe)_2$, MeOH (8.1 cm^3), 180°C, 300 atm, 24 h.

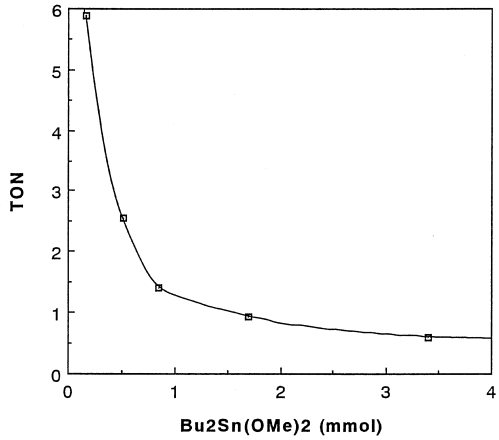

Fig. 2. Effect of amount of Sn on catalyst efficiency. Reaction conditions: $Bu_2Sn(OMe)_2$, MeOH (8.1 cm^3), 180°C, 300 atm, 24 h.

Owing to the limitations stated above, the amount of DMC becomes constant during the initial stage of the reaction of Eq. (1) (black squares in Fig. 3). On the other hand, we have found that the DMC yield increased steadily with a longer reaction time in the presence of dimethyl acetals (white squares). Namely, the addition of acetals is an effective way to overcome the thermodynamic limitation.

Another important factor in achieving high DMC yields is the CO_2 pressure. Higher DMC yields were obtained by applying a higher CO_2 pressure [22,23]. Interestingly, the

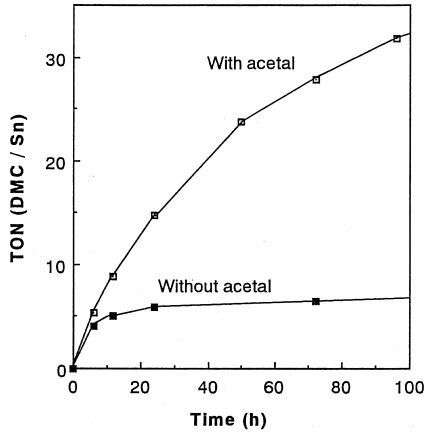

Fig. 3. Time dependence of DMC synthesis. Reaction conditions: 2,2-dimethoxypropane (10 mmol or 0 mmol), $Bu_2Sn(OMe)_2$ (0.17 mmol), MeOH (8.1 cm^3), 180°C, 300 atm.

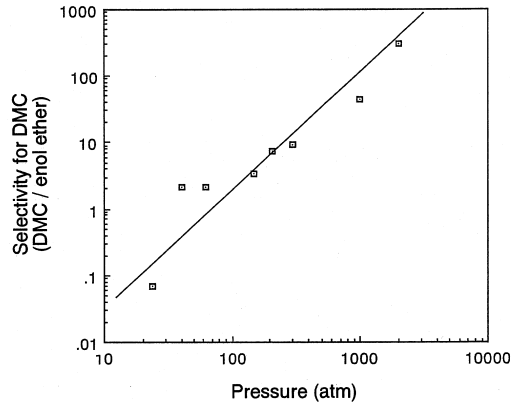

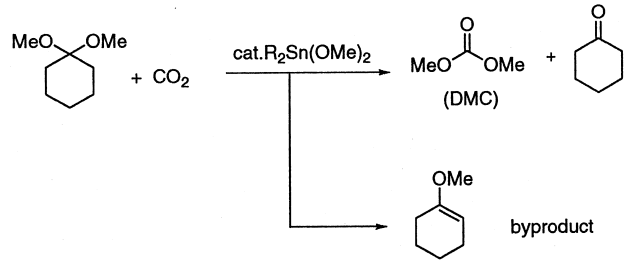

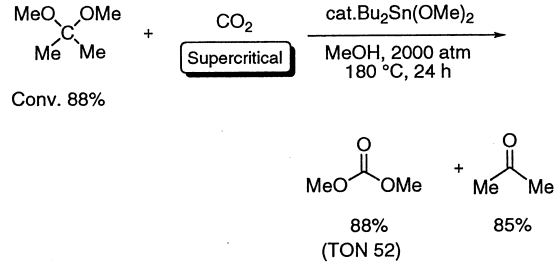

Fig. 4. Effect of pressure on the selectivity. Reaction conditions: 1,1-dimethoxycyclohexane (10 mmol), $Bu_2Sn(OMe)_2$ (0.17 mmol), MeOH (8.1 cm^3), 180°C, 24 h. Selectivity: DMC/enol ether.

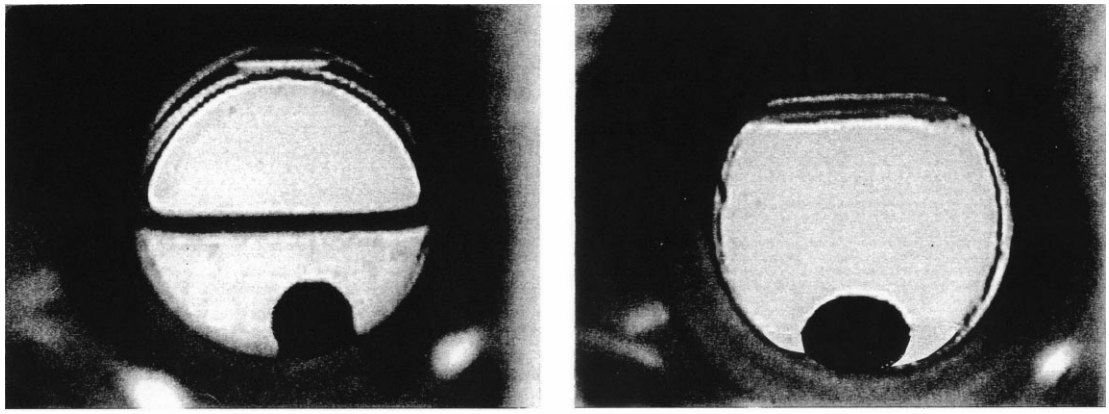
selectivity, DMC/(enol ether) ratio, is also improved under higher CO_2 pressure (Eq. (3), Fig. 4).

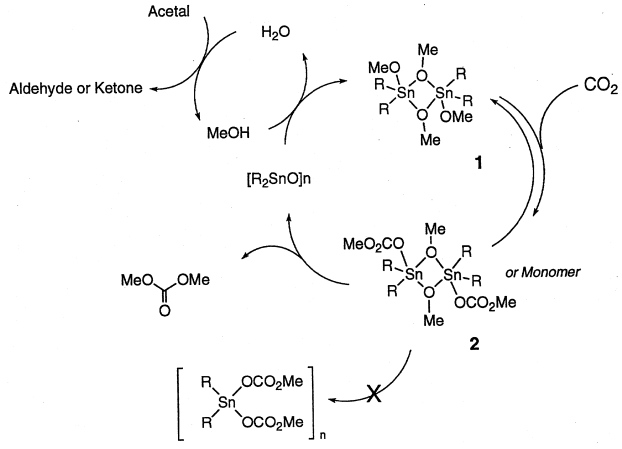
(3)

After rough optimization, a nearly 90% yield and 100% selectivity were realized by carrying out the reaction at 2000 atm using 2,2-dimethoxypropane as the substrate (Eq. (4)).

(4)

The phase behavior of the reaction mixture was studied using an autoclave with sapphire windows. Two phases were observed at a low CO_2 pressure such as 25 atm. The gas phase became smaller as the CO_2 pressure increased, and finally vanished around 150 atm (Fig. 5). The reaction mixture was completely homogeneous above 300 atm. The phase behavior and the enhancement of the DMC yield at high pressures [22,23] are presumably attributable to the increase in CO_2 density. The densities of pure CO_2 at 180°C are calculated to be 0.200, 0.417, and 1.025 g cm^{-3} under 150, 300, and 2000 atm, respectively (CO_2 densities were calculated according to the literature method, see Ref. [24]).





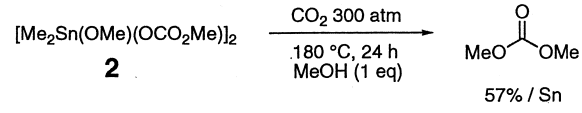


Fig. 5. Phase behavior of $Bu_2Sn(OMe)_2$-catalyzed synthesis of DMC from CO_2 and acetal. The black bar at the bottom is a stirring magnet. Reaction conditions: 1,1-dimethoxycyclohexane (10 mmol), $Bu_2Sn(OMe)_2$ (0.17 mmol), MeOH (8.1 cm^3), 180°C, 24 h.

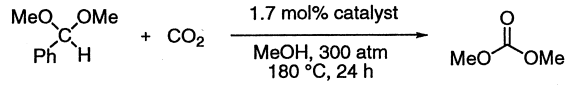
2.2. Possible mechanism

A possible catalytic cycle of the tin-based system is shown in Scheme 1. $R_2Sn(OMe)_2$ (**1**) has a methoxo-bridged dinuclear structure. Carbon dioxide inserts only into the non-bridging methoxo groups of **1** to give a dinuclear carbonato complex (**2**) [25](see also Ref. [13]). The second CO_2 insertion into **2** did not occur even at a high CO_2 pressure (60 atm), as confirmed by ^1H, ^{13}C, and ^{119}Sn NMR studies [26]. The thermolysis of **2** resulted in the formation of DMC in a reasonable yield (Eq. (5)). On the other hand, the carbonato complex **2** readily loses CO_2 under an N_2 atmosphere even at room temperature to regenerate **1**. In addition, the equilibrium between **1** and **2** should shift in the direction of CO_2 release at higher temperatures. Hence, at the reaction temperature (180°C), a high pressure would be required to generate **2** in a fair concentration. This may be one reason for the remarkable acceleration of Eq. (2) under high CO_2 pressure. The role of acetals in realizing high turnover numbers is presumably as H_2O scavengers rather than as reactants in the catalytic cycle.



Scheme 1. Possible catalytic cycle.

(5)

Dialkyltin oxide (or its oligomer) is a key intermediate in Scheme 1. Hence, the catalytic activity of $Bu_2Sn{=}O$ was examined using dimethoxyphenylmethane as a substrate. As expected, $Bu_2Sn{=}O$ exhibited almost the same catalytic activity as $Bu_2Sn(OMe)_2$ (Eq. (6)). Although $Bu_2Sn{=}O$ was insoluble in the reaction mixture at room temperature, a clear solution was obtained at 180°C. Thus, each step of Scheme 1 seems plausible.

Catalyst	Yield (%)
$Bu_2Sn{=}O$	14
$Bu_2Sn(OMe)_2$	14
none	0

(6)

In summary, we have achieved formal DMC synthesis from CO_2 and methanol catalyzed by organotin complexes. This work demonstrates the promising prospect of using carbon dioxide, especially under supercritical conditions, as a non-toxic and cheap C_1 building block in molecular catalysis.

3. Experimental

Moisture sensitive complexes were handled using Schlenk and/or glovebox techniques under argon or carbon dioxide. 2,2-Dimethoxypropane, 1,1-dimethoxycyclohexane, dimethoxyphenylmethane, dibutyltin dimethoxide, dibutyltin oxide, and carbon dioxide (purity over 99.9%, water content less than 0.01%) were all commercially available. Dimethyltin dimethoxide was synthesized according to the litera-

ture [27]. Reaction products were analyzed by GC using capillary columns and further characterized by GC-MS.

A typical high pressure reaction was carried out as follows. In a stainless steel autoclave (20 cm^3 inner volume), carbon dioxide (liquid, 65 atm) was added to a mixture of dimethyl acetal (10 mmol), a tin complex (0.17 mmol), and methanol (8.1 cm^3) at room temperature. The autoclave was then heated in an oil bath and the initial pressure was adjusted to 300 atm at 180°C. After cooling, 1,3,5-trimethylbenzene (50 μl) was added to the reaction mixture as the internal standard for the GC analysis.

Caution. All high-pressure experiments need sufficient safety considerations although CO_2 itself is non-toxic.

Role of halide ions in palladium(II) catalyzed nucleophile alkyne-α,β-unsaturated carbonyl coupling reactions

Xiyan Lu *, Zhong Wang

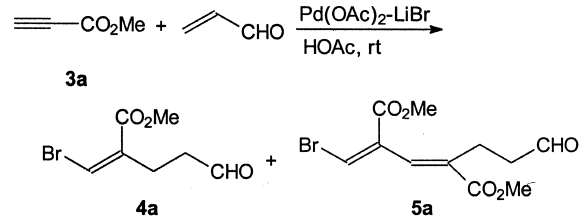
Abstract

The integral role of halide ions as a ligand in divalent palladium catalyzed nucleophile alkyne-α,β-unsaturated carbonyl coupling reactions as well as in the stoichiometric reaction of arylpalladium reagents with acrolein was studied. Excess of halide ions can effectively inhibit the β-hydride elimination of a (2-oxoalkyl)palladium intermediate, giving preferentially the protonolysis product in acidic media. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Palladium catalyzed reactions; Halide ions; Coupling reactions; Protonolysis

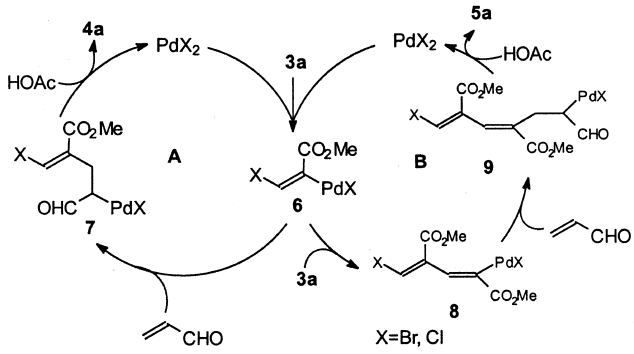
In our ongoing studies of divalent palladium catalyzed reactions, we have established a series of efficient methods for synthesizing α-alkylidene-γ-butyrolactone derivatives using halopalladation–cyclization–deheteropalladation as the key step [1–3]. While studying the scope and synthetic application of this protocol, we discovered serendipitously an intramolecular Pd-catalyzed conjugate addition reaction, which was applied to the formal synthesis of (+)-pilocarpine [4]. In this reaction, an aldehydic enyne ester **1** was cyclized under the catalysis of Pd(II) to give the aldehydic γ-lactones **2**.



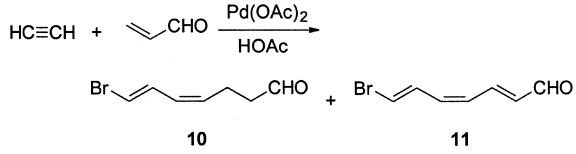
1 **2**

Based on this intramolecular version, we developed the tandem halopalladation-conjugate addition [5] and tandem oxypalladation-conjugate addition reactions [6] which allow efficient and highly stereoselective synthesis of multifunctional carbonyl compounds.

1. Tandem halopalladation-conjugate addition to γ,δ-unsaturated carbonyls [5]



When methyl propynoate **3a** (1.0 mmol) was treated with acrolein (5.0 mmol) in the presence of $Pd(OAc)_2$ (0.02 mmol) and LiBr (4.0 mmol) in acetic acid, two products **4a** and **5a** were isolated.



Compound **4a** was the 1:1 codimerization product and **5a** was the 2:1 cotrimerization product. The formation of these two products was rationalized by the mechanism shown in the following. Vinylpalladium intermediate **6** was first formed by *trans*-halopalladation of **3a** in HOAc, followed by acrolein insertion (path A) or subsequent alkyne and acrolein insertion (path B). The competing alkyne insertion may be ascribed to the higher reactivity of acetylenes than olefins. Both reaction paths involved the protonolysis of the carbon–palladium bond to regenerate the catalytic Pd(II) species, giving **4a** and **5a**, respectively.

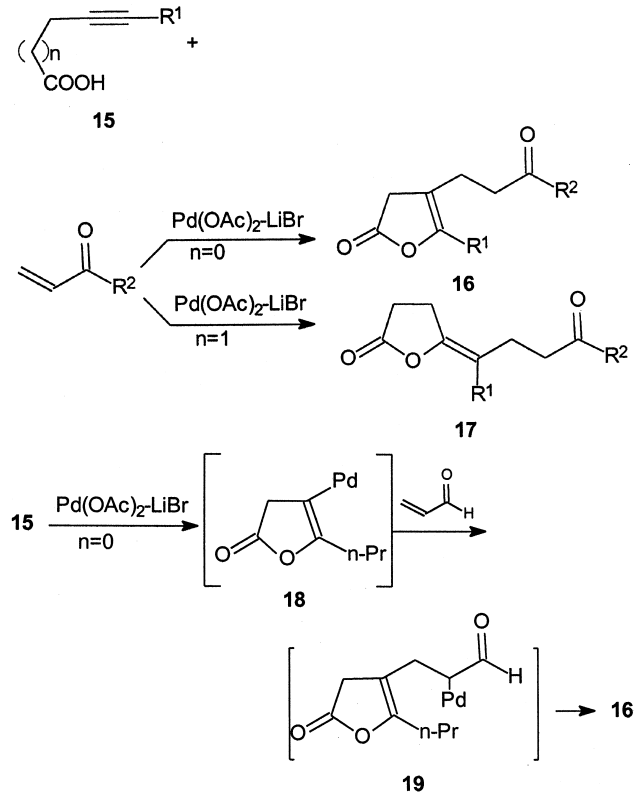
PII S0277-5387(99)00412-X

The reaction of acetylene with α,β-unsaturated electron-deficient alkenes in the presence of a palladium catalyst was attempted to explore the possibility of developing new methods for (*E,Z*)-diene synthesis [7]. The reaction afforded the expected dienal **10** together with the α,β-unsaturated trienal **11** in 220 and 80% yield, respectively (yields are calculated on the basis of $Pd(OAc)_2$). Compound **10** could be purified carefully by column chromatography and its NMR data show unambiguously the (*E,Z*)-configuration of the molecule.

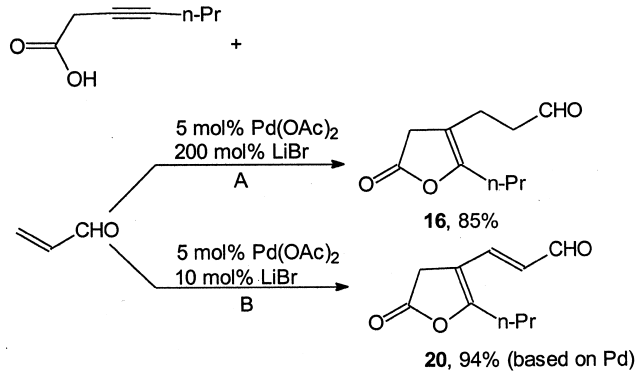


The formation of **10** and **11** could be explained with the following mechanism which also rationalizes the stereoselectivity:

Preliminary results showed that polar solvents, high acetylene concentration, high halide concentration and low temperature favor the formation of **10**.

2. Nucleophile alkyne-α,β-unsaturated carbonyl coupling [6]

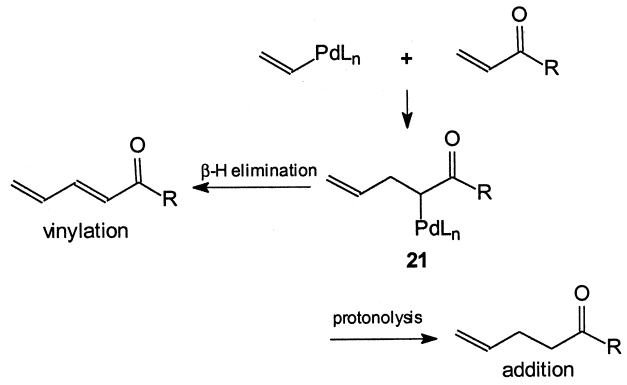
Using $Pd(OAc)_2$ as the catalyst, 4-substituted 3-butynoic acid (**15**, $n=0$) and 5 equiv. of acrolein in the presence of excess LiBr (2 equiv.) in HOAc gave the cyclized acrolein coupling products **16** in high yield [6]. The reaction of 4-alkynoic acids (**15**, $n=1$) with acrolein afforded γ-alkylidene-γ-butyrolactone derivatives **17** in good yield and stereoselectivity.



3. Role of halide ions

The key step to form the products and regenerate the Pd(II) catalytic species in the above reactions is the protonolysis of the carbon–palladium bond in **7**, **9**, **14** and **19**. Vinylpalladium species usually react with α,β-unsaturated carbonyls to give vinylation products through β-hydride elimination of the insertion intermediate rather than addition products through protonolysis. There are a few reports concerning the quenching of carbon–palladium bonds by acid hydrolysis [8,9], but the formation of addition products was influenced by many factors [10].

Inhibition of the normal β-hydride elimination pathway was achieved by addition of excess phosphine, but this inhibited the insertion step as well. In the reaction of preparation of (*E,Z*)-dienes, while pure **10** could be obtained in high concentration of LiBr, the reaction afforded the expected dienal **10** together with the trienal **11** in 220 and 80% yield (based on Pd), respectively, with a low concentration of LiBr. We found that the LiBr:Pd ratio has a great impact on the reaction: when the LiBr:Pd ratio was increased from 10:1 to 200:1, the catalyst activity was enhanced dramatically and the reaction yield went up from 550 to 3980% (based on Pd),



respectively. This can be accounted for by the predominant complexation of halide ions on palladium which favors protonolysis over β-H elimination.

While a high yield of lactone **16** was obtained by the oxypalladation procedure in a high concentration of LiBr, in the presence of less LiBr **20** was produced by β-hydride elimination and obtained in 94% yield (based on Pd) together with precipitated palladium black [6]. This, again, demonstrated the significant role of halide in the present reaction.

In order to explore the mechanism of protonolysis, a stoichiometric reaction of a palladium complex with acrolein in the absence or presence of the halide ion was studied as a model reaction of the role of halide ions. The reaction shows that with no extra anionic ligand or with ClO_4^- or OAc^- only the β-H elimination product is formed, while reactions with Cl^-, Br^- or I^- afford exclusively the protonolysis product. This indicates that the anions play a critical role in determining the reaction outcome.

It is significant that by simply applying metal halides, the reaction pathway of an alkylpalladium intermediate can be cleanly switched from the normal β-H elimination (Heck-type reaction) to heterolytic C–Pd bond cleavage processes, i.e. protonolysis, when the forming carbanion is stabilized by an electron-withdrawing group.

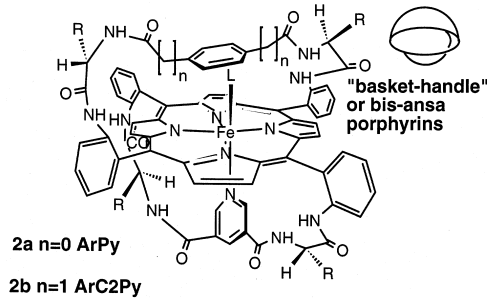
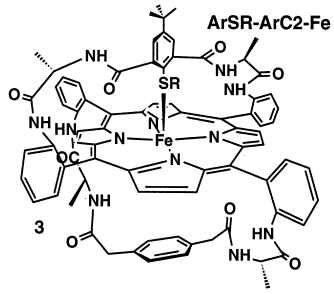
Abstract



Porphyrins, with two chiral binaphthyl handles, efficiently catalyze the epoxidation of terminal olefins to give epoxides with high enantiomeric excess and turnover number. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Porphyrins; Hemoprotein models; Chiral catalysts; Epoxidation; Olefins

Porphyrins play an important role in a bewildering array of proteins [1]. Their functions include O_2 storage (myoglobin Mb), O_2 transport (hemoglobin Hb), oxidation of unactivated carbon–hydrogen bonds (cytochrome P_{450}), and oxygen reduction (cytochrome *c* oxidase.) In the case of Mb and Hb, the axial ligand is the nitrogen atom of a histidine residue, whilst in the case of cytochrome P_{450}, the axial ligand is the sulfur atom of a cysteinate. The diversity of functions of these natural hemoproteins is mainly dictated by the number and the nature of the axial ligands, the spin and the oxidation state of the metal center, the nature of the polypeptide chain, and the geometry of the porphyrin ring.



In the presence of O_2, synthetic iron(II) porphyrins, which are not protected on both faces, tend to be oxidized irreversibly and give μ-oxo Fe(III) dimers [2]. To avoid this, several models with protected faces have been developed [3–5]. For instance, we have prepared 'gyroscope' porphyrins **1** [4,6], which have two different handles: one pyridinic handle which is able to coordinate the iron atom of the porphyrin and one terephthalic handle which protects the active site. We have also prepared 'basket handle' porphyrins **2**, with the same handles or with a homologated terephthalic handle. It is worth noting that **2b** discriminates carbon monoxide and oxygen in a similar way to Mb and Hb [7,8]. Indeed, we observed a partition coefficient $M = 105$ (M is the ratio between O_2 and CO affinity), which is similar to the values described in the case of natural hemoproteins. Similarly, we prepared cytochrome P_{450} models **3** [4] and **4** [9] bearing handles or pickets which contain sulfur derivatives.

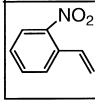
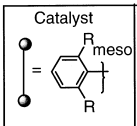
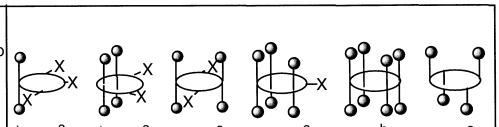
R=-NH-C(O)-C*(OMe)(CF_3)(C_6H_5)

More recently, we prepared an octa nitrophenyl porphyrin **5a** by condensing pyrrole with 2,6-dinitro-4-*tert*-butylbenzaldehyde and correspondingly the octa aminophenyl porphyrin **5b**. Condensation of acryloyl chloride with **5b** gave the octa-Michael acceptor **6** which reacts with cyclen to give a porphyrin that we called a 'barrel' porphyrin **7** [9].



In parallel, we developed a new class of catalysts for asymmetric epoxidation of olefins based on cytochrome P_{450} models. Indeed, it is well known that by using a strong oxidant, it is possible to oxidize the iron atom to a high oxidation state able to epoxidize olefins [10]. We undertook the mixed condensation of pyrrole with two aldehydes, namely pentafluorobenzaldehyde and 2,6-dinitro-4-*tert*-butylbenzaldehyde [11]. The first aldehyde was used to obtain catalysts with robust pentafluoro phenyl groups while the *tert*-butylbenzaldehyde was selected in order to increase the solubility of the catalyst. Thus, we obtained porphyrins **14**, **15** and **17** with two, four and six nitro or amino groups respectively ($R = NO_2$, NH_2), Table 2. Condensation of different chiral acylchlorides with the amino-porphyrins allowed us to prepare porphyrins **15** and **17** (R = –NH–C(O)–C*(CF_3)-(C_6H_5)(OMe)) [11]. Unfortunately, epoxidations conducted with porphyrins bearing Mosher pickets only gave low enantiomeric excess, Table 2.





Other chiral porphyrins have been obtained by condensing a chiral binap diacid chloride with aminophenyl porphyrin. The iron-porphyrin **8** called a 'seat' porphyrin, was used to epoxidize different terminal olefins in the presence of iodosylbenzene. We respectively obtained 59% and 85% enantiomeric excesses for styrene and pentafluorostyrene [18].

These results can be compared with those obtained using a similar catalyst **9** which is prepared by condensing the same binap diacylchloride with the $\alpha^2\beta^2$ atropoisomer of tetrakis-2-aminophenylporphyrin. This atropoisomer is obtained in 92% yield by heating the statistical mixture ($\alpha\beta\alpha\beta/\alpha\alpha\alpha\alpha/\alpha^2\beta^2/\alpha^3\beta = 1/1/2/4$) of tetrakis-2-nitrophenyl Zn porphyrin atropoisomers in naphthalene [19]. Interestingly, with the bis-binaphthylporphyrin **9**, we obtained 83% and 88% enantiomeric excess for the epoxidation of styrene and pentafluorostyrene [20]. The best enantiomeric excess yet ever observed with our porphyrin catalyst was obtained in the case of *tert*-butylethylene with a 92% enantiomeric excess. Surprisingly, we observed an increase of the enantiomeric excess during the initial period of the styrene epoxidation using **9**. Indeed, enantiomeric excess values raised from 65% at 10 turnovers to 83% at 200 turnovers. From 100 to 2000 turnovers, the reaction maintains 83% enantiomeric excess. The complex catalyzes the epoxidation at a rate of 2400 turnovers per hour if iodosylbenzene is added portionwise to the reaction mixture. Indeed, after 5000 turnovers the enantiomeric excess is still about 75%. We believe that oxidative demethylation of the binap strap occurs during the initial reaction corresponding to the transformation to a quinone-like structure. Probably, the quinone-type catalyst is less hindered than the original methoxy catalyst, allowing easier access of the olefin to the active site with a good facial discrimination.

Table 3
Type III system: double-faced protected ansa porphyrins. Summary of percentages of enantiomeric excess obtained with catalysts **20**–**23**, **8** and **9** and styrene and *ortho*-nitrostyrene

[d] Refs. [37–41].
[e] This work.
[f] Refs. [18,20].

At this stage, we can compare the properties of the different catalysts described in the literature (Tables 1–3). A classification of the catalysts into three structure-types can be proposed:

type I systems correspond to single-faced protected ansa porphyrins,
type II systems are bis-faced picket porphyrins,
type III systems are bis-faced protected ansa porphyrins.

In the case of type I porphyrins, enantiomeric excess can reach 58% with catalyst **10** [21,22] for the epoxidation of indene with PhIO in the presence of different imidazoles as blocking ligands (Fig. 1). When the handle of the catalyst **12** is too far from the metal center, a low 13% enantiomeric excess is obtained for the epoxidation of styrene [24,25]. Using Mn-'threitol' porphyrins with a small strap **13c**, the enantiomeric excess can reach 74% with *ortho*-nitrostyrene. However, the numbers of turnovers remain low when the unhindered face of the porphyrin is blocked with a bulky imidazole ligand, (Table 1, Fig. 1) [23,26].

In the case of type II catalysts, the Mn catalyst **18b** shows 76% enantiomeric excess for the epoxidation of *cis*-β-methylstyrene [13]. Catalysts **18c**, **18d** give 70% enantiomeric excess of the R epoxide of styrene [14]. In the particular cases of catalysts **19a**–**19c**, low turnovers and enantiomeric excess are obtained. With the catalyst **19d**, the turnover is good but not the enantiomeric excess [27]. An improvement has been described by Marchon and co-workers using Mn

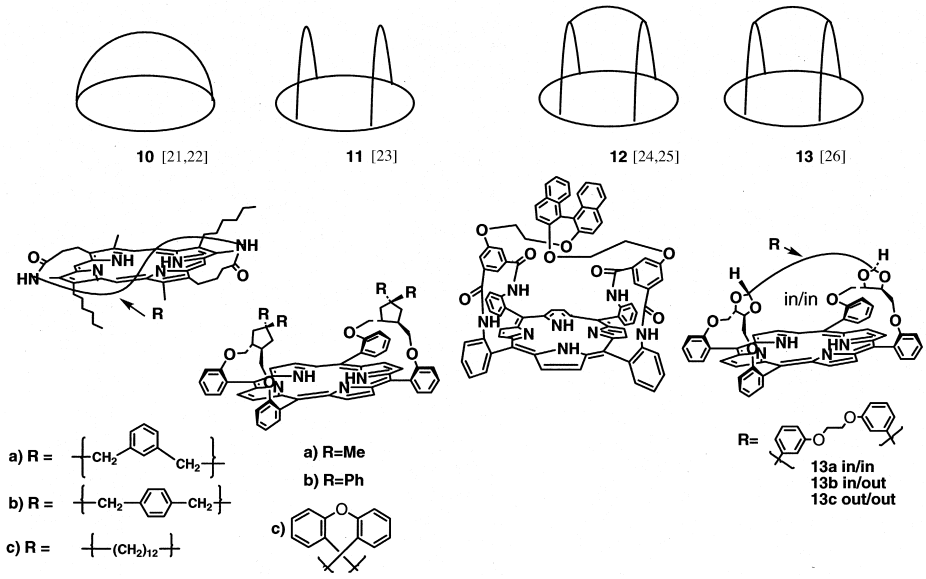

Fig. 1. Type I system: single-faced protected ansa porphyrins.

chiroporphyrins **19f** [31–33]. Indeed, they obtained 86% enantiomeric excess with the bulky porphyrin **19f** for the epoxidation of 1,2-dihydronaphthalene (Fig. 2, Table 2) [31].

With type III catalysts, the enantiomeric excess can reach 72% for the epoxidation of *cis*-β-methylstyrene with the bis-ansa derivative **20c**, but the turnover barely reaches 300 [36] and is only 2 in the case of catalyst **20b** [34]. The enantiomeric excess can be improved using staggered and eclipsed catalysts **22** and **23** (twin-coronet porphyrins) [37–40]; an enantiomeric excess of up to 54% in the case of styrene (Fig. 3, Table 3) [37–41] can be obtained but yields for the preparation of the catalysts are low. However, the enantiomeric excess can reach 96% for the epoxidation of the electron-deficient 3,5-dinitrostyrene [37–40].

In conclusion, we have prepared chiral bis-handle porphyrins that are good models of Mb in terms of discriminating between CO and O_2. We have also prepared *C*2-symmetric chiral porphyrins bearing binaphthyl handles. These are efficient catalysts for olefin epoxidation giving high enantiomeric excess and turnover numbers. In particular, catalyst **9** gives the highest enantiomeric excess ever obtained for the

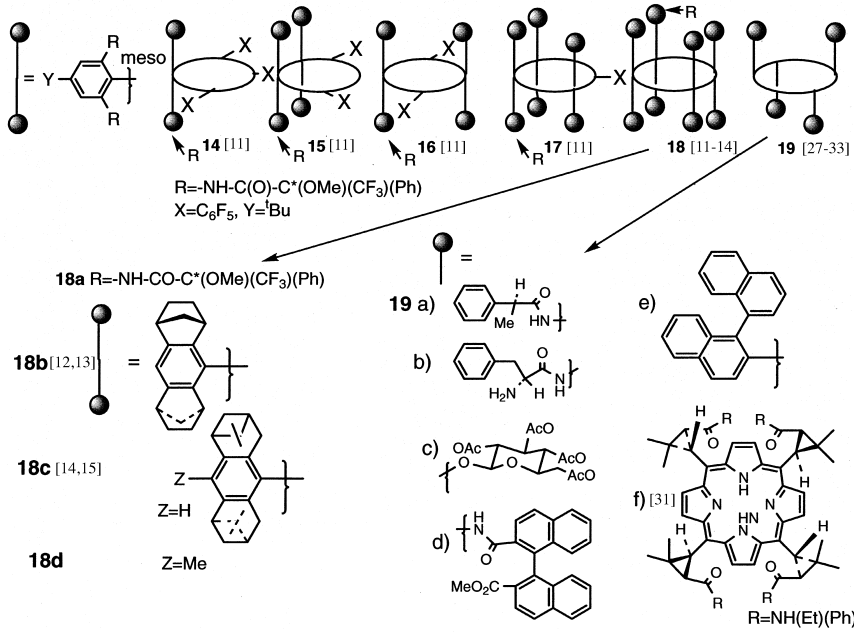

Fig. 2. Type II system: double-faced protected picket porphyrins.

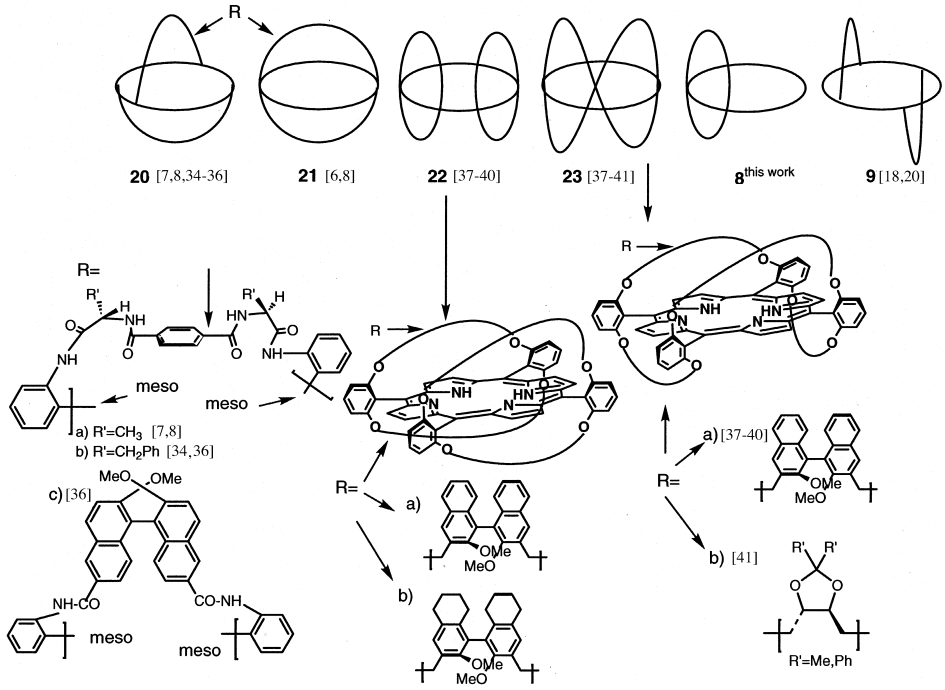

Fig. 3. Type III system: double-faced protected ansa porphyrins.

epoxidation of aliphatic olefins, 92% enantiomeric excess for the epoxidation of *tert*-butylethylene, and the turnovers are unexpectedly high!

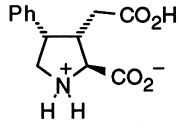
Abstract



Attempts to synthesize kainic acid and analogous kainoids via asymmetric boronic ester chemistry are described. Problems involving functional group and steric interactions have been encountered, and most have been solved. The way to completion now appears clear.
©2000 Elsevier Science Ltd All rights reserved.

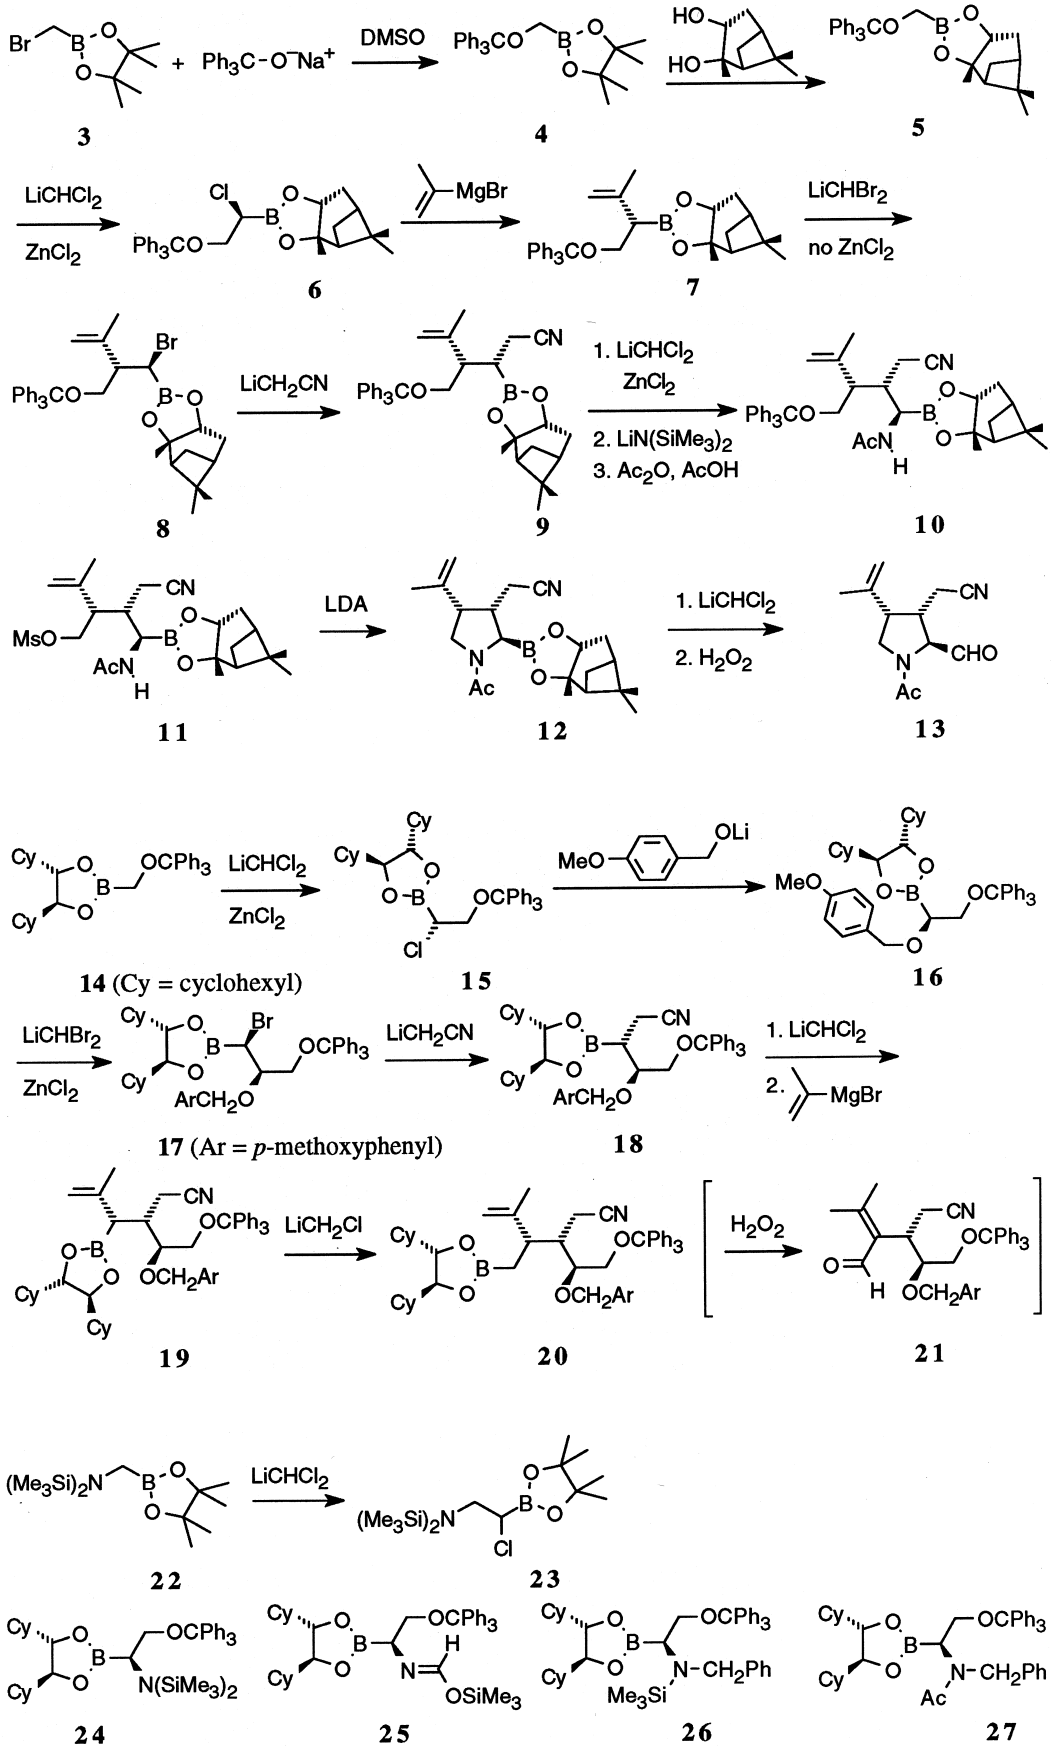
Keywords: Kainoids; Boronic esters; Asymmetric synthesis; Pyrrolidine

Kainic acid (**1**) and related compounds such as the phenyl analog **2** are of interest as agonists at glutamate receptor sites in the brain [1].

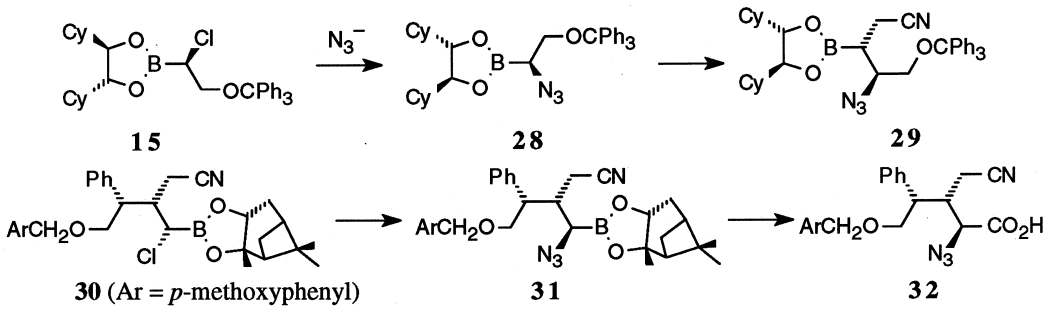
1

2

The relative stereochemistry of these trisubstituted pyrrolidines is the same as that produced by successive chain extensions of boronic esters with (dichloromethyl)lithium, but the polar functional groups involved impose new problems for this method of asymmetric synthesis [2].



Several attempts to complete syntheses of **1** or **2** have fallen short. Our first approach began with the unusual reaction of sodium trityl oxide with bromomethyl boronic ester **3** to form trityloxy boronic ester **4**, which was converted to the pinanediol ester **5** prior to asymmetric reaction with (dichloromethyl)lithium to generate **6** [3]. Isopropenylation of **6** to **7** was routine [4]. Chain extension of **7**, done without the usual zinc chloride promoter in order to avoid allylic isomerization, yielded crystalline bromo intermediate **8** plus ~10% diastereomer. Conversion of **8** to cyano compound **9**, chain extension to acetamido boronic ester **10**, and further conversions to **11** and **12** followed. This sequence eventually foundered because the reaction of the very polar amido boronic ester **12** with (dichloromethyl)lithium proved inefficient, and insufficient amounts of the pyrrolidine aldehyde **13** were obtained to allow further progress toward **1** [4].



We also tried approaching the molecule from the opposite direction starting from **14**, which utilizes (*R*,*R*)-1,2-dicyclohexylethane-1,2-diol as the chiral director [5]. Possible precursor **20**, which contains all of the stereocenters corresponding to kainic acid (**1**) but only oxygen and carbon linked substituents, was easily synthesized via intermediates **15**–**19**. A single attempt at deboronation of **20** to the alcohol resulted in an oxidative rearrangement to α,β-unsaturated aldehyde **21**, but replacement of the boron in a useful manner could no doubt be achieved with further study. Completion of this route would require cleavage of the trityl ether of **20** and oxidation of the hydroxymethyl group to carboxyl, as well as replacement of the *p*-methoxybenzyl protected hydroxyl group of **20** by an amine, accompanied by some means of double inversion to achieve the correct diastereomer.

Because of the inherent number of steps required for any possible route from **20** to kainic acid (**1**), we have attempted to revise this synthesis to incorporate the carbon–nitrogen bond from the start. Initially encouraged by the successful chain extension of [bis(trimethylsilyl)aminomethyl]-boronic ester **22** to α-chloro boronic ester **23**, we made **24**–**27** from **15** and tested their reactions with (dichloromethyl)lithium [6]. NMR evidence indicated that yields of up to 30–50% of chain extended α-chloro boronic esters were obtained from **24** and **25**, but efficient conversions were never achieved. Intermediates **26** and **27** did not yield any detectable chain extension products, although based on proton NMR spectra it appeared that **27** did form the expected borate complex with (dichloromethyl)lithium.

In work in progress, we have investigated the use of azido boronic esters as intermediates for the synthesis of **1** or **2** [7]. The first problem was to find satisfactory conditions to convert α-chloro boronic esters such as **15** to the corresponding azides. These details will be published later. Azido boronic ester **28** was prepared and converted to **29** in the usual manner. Attempts to carry out chain extension of **29** with (dichloromethyl)lithium or (dibromomethyl)lithium yielded erratic results.

Our most nearly completed synthesis, in progress as this is written, closely resembles the route from **3** to **10**, but with *p*-methoxybenzyl in place of trityl, phenyl in place of isopropenyl, and conversion of chloro boronic ester **30** to the azido derivative **31**. Chain extension of **31** to azido acid **32** was carried out by the same method as that used in our published amino acid synthesis [8]. Further conventional transformations of **32** have brought us to within one or two steps of our objective.

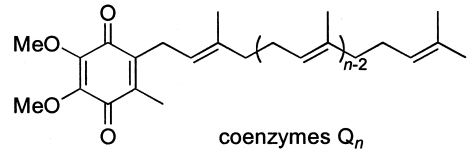
POLYHEDRON

A general method for the synthesis of *E* and/or *Z* oligoisoprenoids based on Pd-catalyzed homoallyl-alkenyl and homopropargyl-alkenyl cross coupling and Zr-catalyzed carboalumination

Ei-ichi Negishi *, Show-Yee Liou, Caiding Xu, Shouquan Huo

Department of Chemistry, Purdue University, West Lafayette, IN 47907, USA

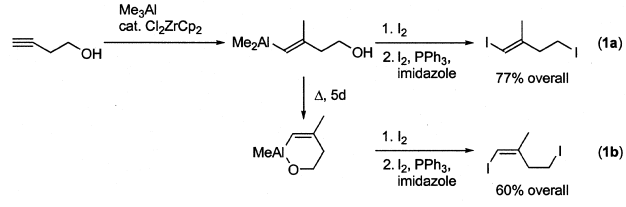
Received 4 October 1999; accepted 15 November 1999



Abstract

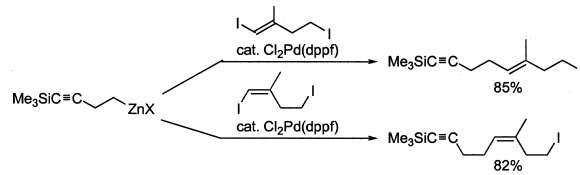
A truly general, versatile, and highly regioselective and stereoselective methodology for the synthesis of terpenoids containing 1,5-diene units of *E* and/or *Z* geometry critically involves (a) Pd-catalyzed homoallyl-alkenyl and homopropargyl-alkenyl coupling and (b) Zr-catalyzed carboalumination of alkynes. In each introduction of an *E* or *Z* trisubstituted C_5 alkene unit, the yield is excellent, and the regioselectivity and stereoselectivity level is >98%. As such, this appears to represent the first general synthetic method accommodating *Z* alkene units in >95% regioselectivity and stereoselectivity. Its application to some representative terpenoids of both natural and unnatural geometries is discussed. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: 1,5-diene; Cross coupling; Terpenoids; Carboalumination; Palladium



Herein reported is an unprecedentedly general, efficient, and selective methodology for the synthesis of geometrically defined 1,5-dienes and 1,5-oligoenes, especially of terpenoid origins. This methodology is based on (i) carbometallation [1,2] of hetero-substituted alkynes [3] for the preparation of **1a**, (ii) chelation-promoted synthesis of **1b** [4], (iii) exceedingly clean, high-yielding, and selective lithiation of primary alkyl iodides [5] applicable to lithiation of homoallyl iodides, and (iv) Pd-catalyzed homoallyl-alkenyl and homopropargyl-alkenyl cross coupling involving homoallylzinc and homopropargylzinc derivatives [6–8] (Schemes 1–3).

Elongation of 1,5-diene containing isoprenoids by an (*E*)- or (*Z*)-C_5 unit as shown in Schemes 2 and 3 can be achieved in one pot in ≥98% stereoselectivity, and these processes can be used both iteratively and convergently. In these manners, various natural and/or unnatural isomers of farnesol, geranylgeraniol, and coenzymes Q_n have been synthesized. Capping the tail end of isoprenoids in the form of allylic alcohols can be achieved by Zr-catalyzed carboalumination-hydroxymethylation for the *E* isomer [9] and by Sato's Ti-catalyzed hydromagnesiation-methylation of propargylic alcohols for the *Z* isomer [10].



coenzymes Q_n

The details of these transformations are discussed orally. To the best of our knowledge, a recently reported multistep homologation of isoprenoids requiring several steps in up to 90% stereoselectivity [11] represented the state of the art for the synthesis of isoprenoids containing (*Z*)-trisubstituted

Scheme 3.

alkene units in the middle of an isoprenoid chain. In contrast, the present methodology permits one-pot homologation in $\geq 98\%$ stereoselectivity, either *E* and/or *Z*, in both iterative and convergent manners.

POLYHEDRON

Synthesis of carbocycles and heterocycles by the titanocene(II)-promoted reactions of thioacetals

Takeshi Takeda *, Md. Abdur Rahim, Mayumi Takamori, Kenjirou Yanai, Tooru Fujiwara

Department of Applied Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184-8588, Japan

Received 4 October 1999; accepted 14 December 1999

Abstract

The preparation of carbocyclic and heterocyclic compounds by the low-valent titanium species-promoted intramolecular reactions of thioacetals was studied. The cyclization of thioacetals having an olefin moiety proceeded with the loss of terminal olefin carbon to produce the corresponding five-, six-, and seven-membered cycloalkenes when they were treated with the low-valent titanium species $Cp_2Ti[P(OEt)_3]_2$. This method has been successfully applied to the syntheses of cyclic unsaturated amines and ethers. When *S*-[3,3-bis(phenylthio)propyl] thioalkanoates were treated with the low-valent titanium species, the intramolecular carbonyl olefination proceeded to produce 5-substituted 2,3-dihydrothiophenes. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Thioacetal; Titanocene(II); Ring-closing metathesis; Intramolecular carbonyl olefination; Cycloalkenes; Heterocyclic compounds

1. Introduction

Recently we found the first practical method for the preparation of organotitanium species which serve as carbene complexes by the desulfurization of thioacetals with the low-valent titanium complex $Cp_2Ti[P(OEt)_3]_2$ (**1**). Since thioacetals are easily prepared from carbonyl compounds or through alkylation, this method enables us to utilize various types of titanium-carbene complexes in organic synthesis. We found that these organotitanium compounds react with organic molecules having a carbon–oxygen [1–5] or carbon–carbon multiple bond [6–8]. It was also found that the organotitanium species formed by the reaction of *gem*-dichlorides with **1** are useful for the Wittig-like olefination of carbonyl compounds [9,10].

The construction of cyclic molecules is of fundamental importance in organic synthesis, and many carbon–carbon bond forming reactions have been employed for this purpose. Because a variety of functionalized thioacetals are easily available, we have studied the preparation of carbocyclic and heterocyclic compounds by titanocene(II)-promoted intramolecular reactions.

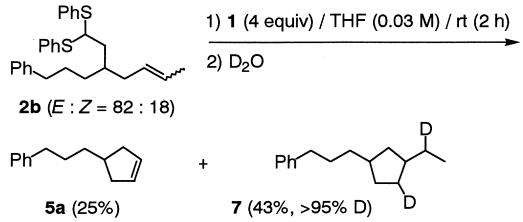
2. Ring-closing metathesis of thioacetals having a carbon–carbon double bond

The transition metal catalyzed ring-closing metathesis (RCM) of dienes is a useful method for the preparation of cyclic compounds [11,12]. Ruthenium, molybdenum, and tungsten carbene complexes have been employed as catalysts for such transformations. Nicolaou et al. recently reported the preparation of cyclic ethers from unsaturated esters by the successive carbonyl methylenation and RCM using the Tebbe or Petasis reagent. An alkylidenetitanocene is suggested to serve as an intermediate in this reaction [13].

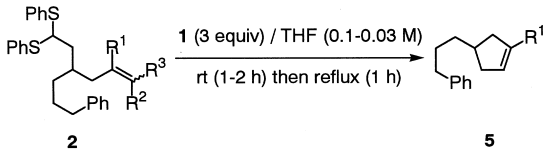
Since the titanocene(II)-promoted reaction of thioacetals with trialkylallylsilanes afforded the metathesis products, γ-substituted allylsilanes [8], we expected that thioacetals could be employed as starting materials for RCM. We then studied the preparation of cycloalkenes **5** from thioacetals **2** having a carbon–carbon double bond via the formation of titanium-carbene complexes **3** as shown in Scheme 1.

First the thioacetal **2b** was treated with the low valent titanium species prepared from Cp_2TiCl_2 (4 equiv.), magnesium turnings (4.4 equiv.), and $P(OEt)_3$ (8 equiv.) at room temperature, and then the reaction was quenched with D_2O (Scheme 2). The formation of the dideuterio compound **7** suggests that this reaction proceeds via the titanacyclobutane intermediate **4**. The RCM product **5a** was obtained in

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(99)00388-5



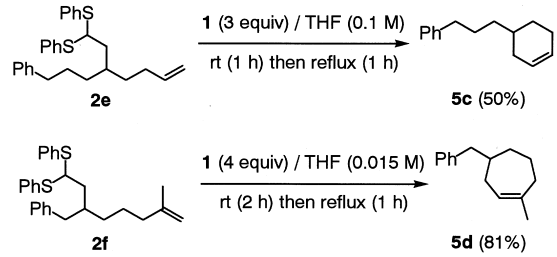
Scheme 1.



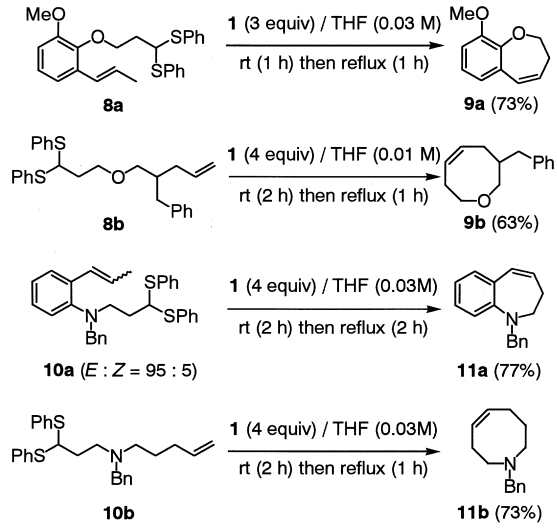
good yield when the reaction mixture was refluxed after the treatment of **2b** with **1** at room temperature. The reaction of thioacetal **2a** having a terminal olefin also produced the cyclopentene **5a** in comparable yield. In contrast to these results, only a small amount of cyclopentene **5a** was produced from the thioacetal **2c** having two methyl groups at a terminal sp2 carbon atom. In the case that a trisubstituted olefin was formed, metathesis proceeded smoothly to produce the methyl group substituted cyclopentene **5b** in high yield (Scheme 3, Table 1). These substituent effects are explained well by the extent of the formation of the titanacyclobutane intermediate **4** and the extent of the retrograde reaction between the RCM product **5** and the alkylidenetitanocene **6**.

Under similar conditions, the reactions of various thioacetals **2** were performed, and the six- and seven-membered cycloalkenes were obtained in good yields [14]. Some representative examples are provided in Scheme 4.

This RCM can be employed for the synthesis of various heterocyclic compounds (Scheme 5). The cyclic ethers **9** were produced by the simple treatment of the acyclic ethers **8** having a thioacetal and an olefin moiety. Using the unsaturated amines **10** as starting materials, the cyclic amines **11** were obtained [15]. Monocyclic seven- and eight-membered amines, the formation of which would be a conformationally less favorable process than the formation of a cyclic amine fused with a benzene ring, are produced in good yields by this reaction. In the case of the preparation of eight-membered rings, the slow addition of thioacetals to a THF solution of **1** over 3 h increased the yields of RCM products.

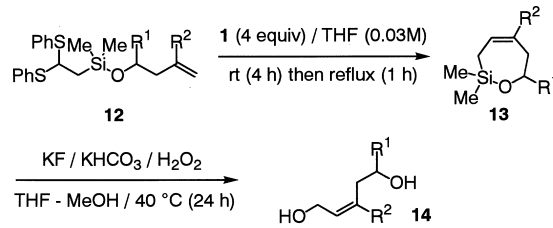


Scheme 2.



Scheme 3.

Table 1
Preparation of cyclopentenes **5**



Thioacetal **2**	**5**	Yield (%)
2a: $R^1=H$, $R^2=H$, $R^3=H$	**5a**	71
2b: $R^1=H$, $R^2=H$, $R^3=Me$	**5a**	67
2c: $R^1=H$, $R^2=Me$, $R^3=Me$	**5a**	8
2d: $R^1=Me$, $R^2=H$, $R^3=H$	**5b**	87

Scheme 4.

Scheme 5.

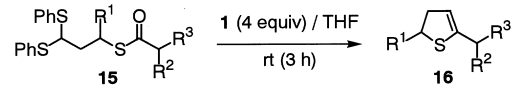
Scheme 6.

Table 2
Preparation of *Z*-olefinic diols **14**

Silyl ether **12**	Overall yield **12**→**14** (%)
12a: $R^1=Ph$, $R^2=H$	68
12b: $R^1=Ph(CH_2)_2$, $R^2=H$	54
12c: $R^1=Ph(CH_2)_2$, $R^2=Me$	61
12d: $R^1=Me(CH_2)_8$, $R^2=H$	51

An interesting application of RCM using thioacetal is the preparation of unsaturated diols **14**. When the silyl ethers **12** were treated with the low-valent titanium species **1** at room temperature and then at the reflux temperature, the cyclic allylsilanes **13** were obtained. The oxidation of **13** under the conditions developed by Tamao et al. [16] produced the *Z*-diols **14** in good overall yields (Scheme 6, Table 2) [17].

The stereoselective preparation of *Z*-olefinic dihydroxy compounds by the transition metal-alkylidene catalyzed RCM of silicon-connected dienes followed by oxidative ring cleavage was reported by Chang and Grubbs [18]. Similar preparations of silicon-containing oxygen heterocycles were also reported [19,20]. It should be noted that the present method provides an alternative synthetic route to the olefinic diols.



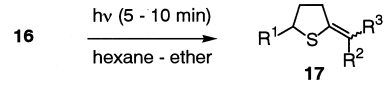
3. Intramolecular carbonyl olefination

Another useful application of titanocene(II)-promoted reaction of thioacetals to the synthesis of heterocyclic compounds is the intramolecular carbonyl olefination of carboxylic acid derivatives. This idea was substantiated when *S*-[3,3-bis(phenylthio)propyl] thioalkanoates **15** were treated with 4 equiv. of the low-valent titanium species **1** in THF at room temperature giving the intramolecular olefination products, 5-substituted 2,3-dihydrothiophenes **16** in good yields (Scheme 7, Table 3) [21].

2,3-Dihydrothiophene is one of the most fundamental sulfur-containing heterocycles and several methods have been developed for its preparation [22–28]. Paquette et al. reported the synthesis of 5-hydroxymethyl-2,3-dihydrothiophenes by the reaction of 5-lithio-2,3-dihydrothiophene with aldehydes [29], and the improved procedure using 5-tributylstannyl-2,3-dihydrothiophene was reported by O'Neil et al. [30]. The chemistry of 5-substituted 2,3-dihydrothiophenes, however, has not been fully explored yet. During this study, we found an interesting isomerization reaction. 5-Substituted 2,3-dihydrothiophenes **16** obtained by this reaction were susceptible to sunlight, and easily isomerized to exocyclic olefins **17** by a brief irradiation with a high pressure mercury lamp under air (Scheme 8, Table 4) [21].

4. Conclusions

We have developed the intramolecular reactions of titanium carbene complexes formed from thioacetals with carbon–carbon or carbon–oxygen double bonds. The results described above indicate that these reactions are useful for the construction of a variety of carbocyclic and heterocyclic compounds. Recently we found that the treatment of titanium-alkylidenes with trialkylsilanes or related Group 14 metal hydrides affords the corresponding Group 14 organometallic compounds [31], and the vinylcarbene complexes react with *tert*-alkyl halides to form terminal olefins [32].



Scheme 7.

Table 3
Preparation of 2,3-dihydrothiophenes **16** [a]

Thiol ester **15**	Product	Yield (%)
15a: R^1 = H, R^2 = H, R^3 = $Me(CH_2)_6$	**16a**, **17a**	57 [b]
15b: R^1 = H, R^2 = Et, R^3 = Bu	**16b**	68
15c: R^1 = H, R^2 = $PhCH_2$, R^3 = $PhCH_2$	**16c**	55
15d: R^1 = Me, R^2 = R^3 = $(CH_2)_5$	**16d**	62

[a] The thioacetal was added slowly to a THF solution of **1** over 20 min.
[b] **16a**:**17a** = 95:5.

Scheme 8.

Table 4
Isomerization of 2,3-dihydrothiophenes **16** by photoirradiation

2,3-Dihydrothiophene **16**	Thiophene recovered (%)	**17**:**16**
16a	62	74:26
16b	71	94:6
16c	69	>99:<1
16d	71	80:20

These results suggest that the organotitanium species would be reactive toward various organic molecules in addition to olefins and carbonyls. Further study of the reactions of organotitanium species formed from thioacetals and their application to the synthesis of cyclic compounds is now in progress.

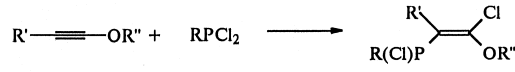
POLYHEDRON

Catalyzed and non-catalyzed addition reactions to the triple bond

I.P. Beletskaya *, M.A. Kazankova

Moscow State University, Moscow 119899, Russia

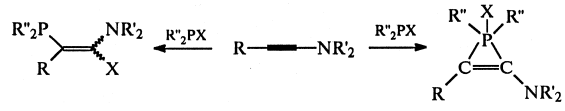
Received 4 October 1999; accepted 1 December 1999



Abstract

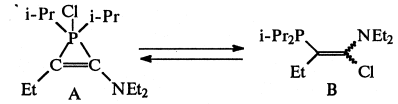
New addition reactions of the E–Hal bond (E = Hg, P(III), P(V), Si, Ge, Sn) to electron-enriched alkynes leading to trisubstituted and tetrasubstituted alkenes with carbon–heteroatom bonds are considered. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Alkoxyalkynes; Aminoalkynes; Addition reactions; Organophosphorus halides; Organosilane halides; Organogermane halides; Pd-catalyzed cross-coupling reactions



In recent years our laboratory in Moscow State University has studied different types of addition reactions to alkynes. These reactions include the following. (1) Electrophilic addition reactions of the E–Hal bond to alkoxyalkynes and aminoalkynes to give functionalized trisubstituted or tetrasubstituted olefines with nucleophilic and electrophilic centers. (2) Nucleophilic addition reactions catalyzed by Pd(II) and, more unusually, by Pt(IV) complexes. The reaction of terminal alkynes in the system I^-–I_2–MeOH catalyzed by $Na_2PtCl_6 \cdot 6H_2O$ leads to *trans*,*trans*-1,4-diiododienes ICH=C(R)–C(R)=CHI [1]. The intermediate Pt(IV) complex was isolated and characterized by X-ray analysis [2] and the diene was introduced in a variety of cross-coupling reactions. (3) Reactions of E–H addition (E = Si) to cyclopropylacetylenes and dicyclopropylacetylenes catalyzed by Rh(I) and Pd(0) complexes leading to disubstituted and trisubstituted olefines [3,4], and silaformylation of alkynes catalyzed by a very efficient Rh(I) complex $[(C_4H_6)_2RhCl]_2$ [5]. (4) The addition of $HP(O)(OR)_2$ to various terminal alkynes using a modified Tanaka procedure [6,7] and further asymmetric hydrogenation of vinylphosphonates formed [7]. (5) The addition of Ph_2PH or Ph_2PSiMe_3 to alkynes catalyzed by Pd(0) or Ni(0) complexes [8].

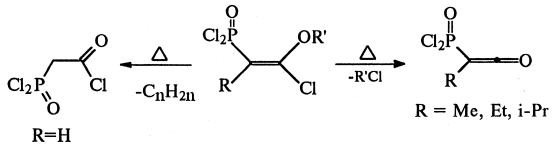
In this report we concentrate on reactions of the first type. These are less known in spite of the fact that they proceed very easily and lead to interesting and useful olefines. The example of this reaction is the addition of $HgCl_2$ to terminal or internal alkoxyacetylenes with the formation of anti-addition products in quantitative yield. The addition of P–Cl bond of PCl_3 and $RPCl_2$ proceeds in the same manner to give in the case of $R^1 = EMe_3$ tetrasubstituted olefines with C–E and C–P bonds at the same carbon center.



R=Cl, Alk; R'=Alk, Me_3Si, Me_3Ge, R"=Alk

The addition of dialkyl(aryl)chlorophosphines to internal alkoxyacetylenes revealed the formation of cyclic phosphacyclopropene-phosphirene as a stable compound. In the same reaction with aminoacetylenes both products, stable phosphirenium halides and non-cyclic addition product, can be formed depending on the nature of R, R′, R″, Hal, and solvent employed.

The tautomeric equilibrium with 1:1 ratio between these two forms in benzene is shifted to the cyclic form in dichloromethane and to the open form in hexane, as observed for the first time [9].



hexane A : B = 10 : 90 benzene A : B = 53 : 47 CH_2Cl_2 A 100%

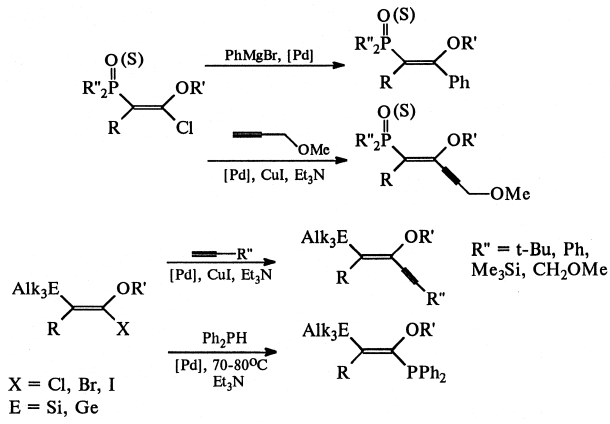
The products of the addition of phosphorus pentachloride to alkoxyalkynes or aminoalkynes were transformed into many useful compounds, for example $(R_2N)_2P(O)C(R)=C(NEt_2)(NR_2)$ [10]. 2-Alkoxy-2-chloroalkenyldichlorophosphonate under heating was converted to phosphorylated ketene for R = Alk and to α-phosphorylated acid chloride for R = H.



The addition of $EHal_4$ (E = Si, Ge, Sn; Hal = Cl, Br) to alkoxyacetylenes proceeds very smoothly with terminal and internal alkoxyalkynes and in the case of element containing alkoxyacetylene gives tetrasubstituted olefines with two C–E bonds at the same carbon center. Treating these compounds with RMgX leads to dielement substituted ketenes.

Alk_3EHal (E = Si, Ge; Hal = Br, I) can also be added to alkoxyacetylenes but in the case of bulky substituents in acetylene the reaction affords element substituted ketenes, probably owing to rearrangement.

Owing to the high lability of the halogen (even chlorine) atom in the α-position to alkoxy or dialkylamino groups, all compounds obtained can be easily introduced in different types of Pd-catalyzed cross-coupling reactions. We illustrate this here by several examples [11,12].

Received 2 June 1999; accepted 29 November 1999

Abstract

Copper(I) salts form with pyrazine carboxamide (pyza) complexes of the type $Cu(pyza)_2X$ for X = Cl, Br, I, NO_3 and ClO_4, $Cu_2(pyza)_3X_2$ for X = Cl and Br, Cu(pyza)X for X = Cl, Br and I, and $Cu(pyza)I \cdot H_2O$. The complexes were characterized by elemental analysis and infrared, Raman and electron spectroscopy. The overall physical measurements suggest that pyza behaves as a monodentate ligand in all complexes, except the 1:1 bromide which contains *N*-, and *N*,*O*-pyza molecules, whereas the halide, nitrate and perchlorate complexes behave as bridging ligands giving rise to polymeric structures. The structural determination of $Cu(pyza)_2I$ reveals that the Cu and I atoms are arranged alternately to form a polymeric zigzag chain with an approximately tetrahedral copper(I) environment. These chains are connected via hydrogen bonds of the type N–H···O between two pyza molecules to form two-dimensional systems. The bromide and iodide complexes of all types display visible emission in the 640–675 nm region when irradiated in the UV, whereas the other complexes do not fluoresce at room temperature. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Hoskins and Robson [1] have proposed that infinite-ordered frameworks may be formed by linking together tetrahedral or octahedral metal centres through rod-like connecting ligands, such as pyrazine. These coordination polymers [1–4] present potential utility in host–guest chemistry, ion exchange and heterogeneous catalysis. Thus, numerous examples of pyrazine-bridged derivatives of copper(II) complexes have been prepared and structurally characterized in order to study the ability of the pyrazine bridge to mediate interactions in novel one- [5,6] and two-dimensional [7,8] materials. Pyrazine carboxamide (otherwise known as pyrazine amide (**I**), hereafter abbreviated as pyza), while keeping the rod-like nature of pyrazine, adds two coordination centres (namely –CO and $–NH_2$ groups), thereby increasing the coordination ability of pyza as a ligand. It has been pointed out [9] that pyza acts as a bidentate ligand with coordination via the O atom and N α-hetero atom of the ring in $M(OAc)_2(pyza)_2$ (M = Mn or Ni), whereas it acts as a monodentate ligand with coordination through the N β-hetero atom and carbonyl O atom in the corresponding Cu and Hg complexes, respectively. Complexes of pyza with many transition metal ions, including Ni(II), Co(II) [10], Fe(II), Cu(II), Zn(II), Cd(II), Hg(II) and Pd(II) [11,12], as well as with Ti(IV) and Zr(IV) [13], have been studied. Variable-temperature magnetic susceptibility studies of $CuX_2(pyza)_2$ suggested a one-dimensional chain structure for these complexes [14]. Crystal structures have been determined for $ZnCl_2(pyza)_2$ [15] and $Cu(pyza)_2(ClO_4)_2$ [16]. The zinc centre is tetrahedrally coordinated in $ZnCl_2(pyza)_2$, whereas the copper centre, which is chelated by the amide O atom and α-N atom of two ligand molecules, is weakly bonded to other N atoms of the pyrazine rings of two neighbouring complex molecules in $Cu(pyza)_2(ClO_4)_2$ [16]. To the best of our knowledge no copper(I) complex of pyza has been reported in the literature. In the present paper we report the synthesis and characterization of such copper(I) complexes, together with the X-ray structure determination of the title iodide complex, the first to have been reported.

2. Experimental

Pyrazine carboxamide (pyza) was purchased from Aldrich; other chemicals are of analytical grade quality.

2.1. Preparation of complexes

2.1.1. $Cu(pyza)_2X$ ($X = Cl, Br, I$)

L-(+)-Ascorbic acid was added to an aqueous solution mixture of $Cu(NO_3)_2 \cdot 3H_2O$ (0.48 g, 2 mmol) and NaX (in 1:1 molar ratio with respect to copper). A saturated solution of NaX was then added dropwise until a clear solution was obtained. Upon addition of an ethanol solution of pyza (0.83 g, 6 mmol) and boiling, a clear yellow solution was produced. The final mixture was allowed to stand for several days to yield red crystals of the complexes.

2.1.2. $Cu_2(pyza)_3X_2$ ($X = Cl, Br$)

These complexes were prepared according to the above method except that the amount of pyza added was in a molar ratio of 2:1 to copper.

2.1.3. $Cu(pyza)I \cdot H_2O$

This complex was prepared as above except that the molar ratio of pyza to copper was 1:1. The final mixture was allowed to stand in the open air for several days to yield the complex.

2.1.4. $Cu(pyza)X$ ($X = Cl, Br, I$)

These complexes were prepared by mixing a suspension of CuX (2 mmol) in water with a boiled aqueous solution of pyza (0.27 g, 2 mmol). The complexes were deposited as powder samples after several minutes.

2.1.5. $Cu(pyza)_2X$ ($X = NO_3$ or ClO_4)

These complexes were prepared by the addition of L-(+)-ascorbic acid to a mixture of $Cu(NO_3)_2 \cdot 3H_2O$ or $Cu(ClO_4)_2 \cdot 6H_2O$ and pyza in a molar ratio of 1:2.5, in aqueous ethanol medium. The final mixture was boiled, cooled and allowed to stand for several hours.

2.2. Elemental analysis

Elemental analysis results and some physical properties of the isolated complexes are listed in Table 1.

2.3. Spectral measurements

The IR and Raman spectral data for some complexes are given in Table 2. The experimental procedures and instruments used for different physical measurements are as described previously [17].

2.4. X-ray structural analyses

$[Cu(pyza)_2I]_n$, $C_{10}H_{10}IN_6O_2$, fw = 436.68, monoclinic, space group $P2_1/m$ (no. 11), $a = 4.1192(13)$, $b = 26.493(7)$, $c = 6.177(2)$ Å, $\beta = 97.16(2)°$, $V = 668.9(3)$ Å^3, $Z = 2$; $d_c = 2.168$ Mg m^{-3}. The X-ray single crystal data were collected on a modified STOE four circle diffractometer. Crystal size: $0.11 \times 0.08 \times 0.05$ mm. Graphite-monochromatized

Mo Kα radiation ($\lambda = 0.71069$ Å) with the ω-scan technique was used to collect the data set. The accurate unit-cell parameters were determined from automatic centering of 47 reflections ($3.7° < \theta < 15.6°$) and refined by least-squares methods; 2040 reflections (1480 independent reflections, $R_{int} = 0.0306$) were collected in the range $3.08° < \theta < 26.97°$. Corrections were applied for Lorentz polarization effects, and for absorption using the DIFABS [18] computer program (range of normalized transmission coefficients 0.340–1.000). The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 (i.e. squared), using the SHELXTL/PC V 5.03 [19] program package. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were assigned isotropic displacement factors and included in the final refinements cycles by use of geometrical restraints. The final R indices are 0.0454 (R_1) and 0.1083 (wR_2) [$I > 2\sigma(I)$]. Goodness-of-fit on F^2 is 1.193. Number of refined parameters is 102. Maximum and minimum peaks in the final difference Fourier synthesis were 1.253 [in vicinity of I(1)] and −1.288 e Å^{-3}. Selected bond parameters are given in Table 3.

3. Results and discussion

The reactions between pyza and copper(I) halide, nitrate and perchlorate or the reduction of copper(II)–pyrazine carboxamide complex in the presence of these anions afforded the complexes given in Table 1. All the complexes are coloured and stable against air oxidation when well-dried. The copper(I) halide, nitrate and perchlorate complexes are insoluble in many non-polar solvents (e.g. benzene, carbontetrachloride, toluene) and polar solvents (e.g. water, alcohols, acetone), which is an indication of their polymeric nature.

3.1. IR and Raman spectra

The IR and Raman (R) spectral results for pyrazine carboxamide and some of its copper(I) complexes are given in Table 2. The assignments given are in accordance with those reported previously [17] for the parent ligand. The spectra of these complexes show a very strong band around 1700 cm^{-1} (IR) and 1670 cm^{-1} (R), suggesting that the carbonyl group does not participate in the coordination bond with copper(I). In case of the yellow 1:1 bromide complex two bands are observed at 1706 and 1662 cm^{-1} (IR), suggesting the existence of two types of pyza molecules; in one of them the carbonyl group coordinates the metal atom whereas it does not in the other. The small shift of the carbonyl band from 1714 cm^{-1} in the spectrum of free ligand may be due to hydrogen bonding. The bands due to the amino group in the 3400–2800 cm^{-1} region and around 1610 cm^{-1} are little influenced by coordination, and this again may be due to N–H···O hydrogen bonding. The spectrum of complex **8** shows a broad band of medium to strong intensity around 3450 cm^{-1} due to the hydrogen-bonded water molecule. A broad band of medium intensity appears in the IR spectra of all complexes, except in the region 800–815 cm^{-1} for complex **7** and at 805 cm^{-1} in free pyza, which exists as dimers formed by hydrogen bonds between carboxamide groups. This band is assigned to the OH out-of-plane deformation of the system, similar to that reported for dimers formed by hydrogen bonds between carboxylic groups [20]. In the 1600–400 cm^{-1} region (pyrazine nucleus vibrations) the bands at 1581, 1054, 787 cm^{-1} (IR) and at 1576, 1051, 867, 805, 616 cm^{-1} (R) are slightly shifted; those at 619, 432 cm^{-1} (IR) and at 412 and 379 cm^{-1} (R) experience substantial shifts to higher frequencies, whereas the other bands are not affected or are slightly shifted to lower wave numbers upon complexation. Similar results have been reported for other metal complexes of pyrazine [21]. These results suggest that pyza may act as a *N*-monodentate ligand in all but one of the isolated copper(I) complexes. In the yellow 1:1 bromide complex one pyza acts as a *N*-monodentate whereas the other acts as a *N*,*O*-bidentate ligand. Further evidence for the presence of two different pyza molecules in the above complex comes from the splitting and appearance of a large number of peaks (Table 2). In the far IR region we could not locate any absorption band due to νCu–Cl or Cu–Br above 200 cm^{-1}, the region where these vibrations are expected [22]. This suggests that the halide atoms act as bridging ligand in these complexes. The spectra of the 1:2 copper(I) perchlorate complex show three peaks at 1144, 1112 and 1087 cm^{-1} and two peaks at 636 and 628 cm^{-1} (IR), and at 1096, 1068 and 1037 cm^{-1} and at 673, 658 and 620 cm^{-1} (R), due to ν_3 and ν_1 modes of the perchlorate, a result which indicates a bridging bidentate perchlorate group [22]. Likewise the appearance of strong bands at 1313 and 1436 cm^{-1} due to ν_5 and ν_1 (IR), respectively, of the NO_3^- group is suggestive of a bridging bidentate nitrate group in the respective complex. The above conclusions are confirmed by crystal structure determination of the 1:2 copper(I), bromide (**3**) and iodide (**4**) complexes.

3.2. Structure of $[Cu(pyza)_2I]_n$

The structural determination of $[Cu(pyza)_2I]_n$ confirms the presence of pyza dimers as inferred by the IR spectral results given above. Cu^+ and I^- occupy special positions on mirror planes with multiplicity 2; thus the asymmetric unit (Fig. 1) corresponds exactly to 2:1 pyza–CuI stoichiometry. The copper and iodide ions are arranged alternately to form a polymeric zigzag chain [I–Cu–I = 99.49(5)°, Cu–I–Cu = 99.49(5)°] extending along the *a*-axis. The almost planar hydrogen-bonded pyza dimeric unit [mean deviation from planarity = 0.034 Å; torsion angle C(5D)–O(1D)···N(3)–C(5) = −2.7°] is diagonally linked, through the nitrogen atoms, N(1), to two metal centres belonging to adjacent $(CuI)_n$ chains (Fig. 2). The coordination geometry about the copper(I) atom is thus approximately tetrahedral (Table 3), and the resulting crystal structure comprises layers parallel to the *ab* set of planes.

The present structure is very similar to that of the previously reported $CuCl(HNA)_2$ complex (HNA is nicotinic acid) [23], having tetrahedral copper(I) atoms and zigzag $(CuCl)_n$ chains. While the measured Cu–N bond distances (Table 3) lie within the range of 2.00–2.05 Å for copper(I) complexes with pyridine and substituted pyridine ligands [24], the Cu–I bonds are longer than those found [2.475(4), 2.611(4) Å] in the structure of $[Cu(s\text{-collidine})I]_n$ containing trigonal planar copper(I) [25]. Complexes of stoichiometry L_2CuX, where L = pyridine or substituted pyridine and X = halogen, commonly exist as bis(μ-halo)-bridged $[L_2CuX]_2$ dimers with a cyclic Cu_2X_2 core [26–28]. When steric crowding of the ligand prevents dimerization, a mononuclear, pseudo-trigonal planar L_2CuX complexes are produced, as found in the structures of $(2,6\text{-}Me_2py)_2 \cdot CuX$, X = Cl, Br [29] or I [27]. The present structure is an example of the rare polymeric structure of L_2CuX stoichiometry, the existence of which may be ascribed to the stabilizing influence of the hydrogen-bonded pyrazine carboxamide.

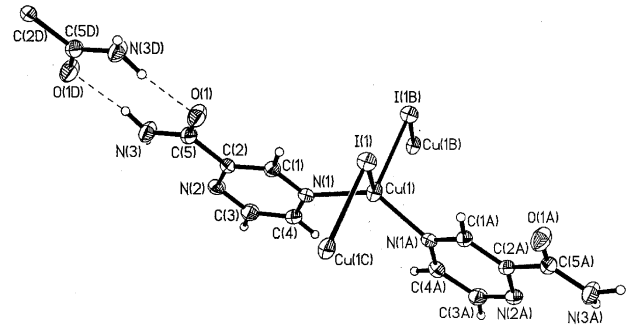

Fig. 1. Molecular geometry and atom labelling scheme of $[Cu(pyza)_2I]_n$. Symmetry codes are according to Table 3. Hydrogen bonds are indicated as broken lines.

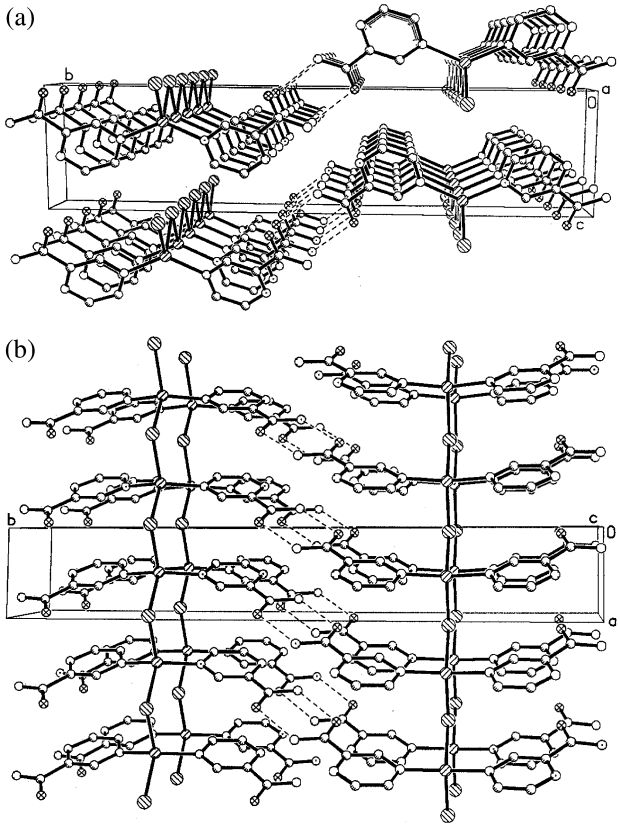

Fig. 2. Packing view of $[Cu(pyza)_2I]_n$ (a) along the *a*-axis and (b) along the *c*-axis of the unit cell.

3.3. Electronic spectra

The electronic spectra (Table 4, Fig. 3) of the solid copper(I) complexes mulled in Nujol exhibit strong absorption bands in the visible region, which are due to metal-to-ligand charge transfer (MLCT) from Cu^I d^{10} to an empty π^* orbital on the pyza molecule. The brown to black complexes (**2**–**6**, **10**), however, show two such MLCT bands. A similar situation occurs in the copper(I)–pyrazinic acid complexes [30], in the bis(arylazo-oximates) of copper(I) [31,32] and in bis[(2-phenylazo)-pyridine]copper(I) complexes [33], except that the two bands appear at 700–780 nm and 550–580 nm, in the latter two cases, respectively. In a tetrahedral molecular environment, the metal valence d orbitals split into two sublevels, t_2 and e. If the two MLCT bands observed in the spectra of some of the present complexes are due to t_2–π^* (516–618 nm) and e–π^* (400–428 nm), the energy gap between them lies in the range 7100–6500 cm^{-1}. This difference is comparable to that observed for the above pyrazinic acid complexes, but much greater than that for arylazo-oximate or phenylazopyridine–copper(I) complexes. Copper(I) complexes of bipyridine and related ligands exhibit the lowest energy charge-transfer band near 450 nm [34,35], whereas those of pyridine and related ligands show an MLCT band around 300–500 nm [36–38]. In grossly planar and unsaturated macrocyclic environments for copper(I), an allowed transition is documented [39,40] near 700 nm.

3.4. Emission spectra

The results of the room temperature emission spectra of the solid copper(I) complexes are given in Table 4. The bromide and iodide complexes display emission spectra at room temperature with λ_{max} in the range 640–675 nm, whereas the chlorides of all types, the nitrate and the perchlorate complexes do not emit. The spectrum of each of the emitting compounds consists of a single slightly asymmetric band, as seen in Fig. 4. The luminescence spectra of all of the emitting compounds proved to be independent of the exci-

Table 4
Electronic [a] and emission [b] spectral data

Complex	λ_{max} (nm)	
	MLCT [c]	Emission
$Cu(pyza)_2Cl$	300–540	no emission

tation wavelength, and their excitation spectra are very similar.

The emission spectra of copper(I) halide complexes of pyridine and pyridine derivatives have been extensively studied [41–47] and found to display high-energy (HE; 430–540 nm) and low-energy (LE; 620–698 nm) bands. The HE band was attributed to MLCT or halide-to-metal charge transfer (XMCT) [47], and the LE band to the metal centre in the Cu_4X_4 core with Cu···Cu distances less than 2.8 Å [46]. It is clear from Table 4 that the λ_{max} changes from 671 for the 1:2 bromide to 660 nm for the corresponding iodide, a result that is consistent with what has been observed previously [48], namely that the emission bands for the chloride clusters occur at lower energy than the HE bands of the respective iodide clusters. As these complexes do not possess the Cu_4X_4 core structure, the LE bands are not expected, and therefore the emitting state in the present copper(I) halide complexes of pyza would be triplet MLCT or XLCT excited states. The results given in Table 4 suggest that the emission spectra of the complexes of pyza experience a substantial shift to lower energies when compared with corresponding complexes of pyridine [46–50], which reflects the influence of the substituent in the skeleton of the aromatic ring itself.

Supplementary data

Supplementary data are available from CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), on request, quoting deposition number CCDC 123608.

POLYHEDRON

Synthesis and characterization of a series of copper(II) complexes with azo-linked salicylaldimine Schiff base ligands. Crystal structure of Cu5PHAZOSALTN·$CHCl_3$

A.A. Khandar *, K. Nejati

Department of Inorganic Chemistry, Faculty of Chemistry, Tabriz University, Tabriz, Iran

Received 5 August 1999; accepted 6 December 1999

Abstract

Complexes of copper (II) with Schiff bases obtained by condensation of 5-phenylazo salicylaldehyde with di-or tri-amines have been synthesized and characterized by their infrared spectra and elemental analysis. The copper(II) chelates investigated are [bis(5-phenylazo salicylaldehyde)ethylene diiminato]copper(II) (Cu5PHAZOSALEN) **(I)**, [bis(5-phenylazo salicylaldehyde)*O*-phenylene diiminato]-copper(II) (Cu5PHAZOSALOPHEN) **(II)**, [bis(5-phenylazo salicylaldehyde)trimethylen diiminato]copper(II) (Cu5PHAZOSALTN) (**III**) and [bis(5-phenylazo salicylaldehyde)diethylene triiminato]copper(II) (Cu5PHAZOSALDETA) (**IV**). The single-crystal X-ray diffraction is reported for Cu5PHAZOSALTN·$CHCl_3$. The copper atom lies in a near square-planar coordination with Cu–N bond lengths of 1.962(7) and 1.949(7) Å and Cu–O lengths of 1.903(5) and 1.931(6) Å. Cyclic voltammetry indicates that copper complexes **III** and **IV** have a quasi-reversible redox behaviour and complexes **I** and **II** undergo irreversible and reversible reduction (at a scan rate 0.05 V s^{-1}), respectively, under the experimental conditions. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Schiff bases; Copper complexes; X-ray structure; 5-Phenylazosalicylaldehyde; Cyclic voltammetry

1. Introduction

Schiff base complexes containing different central metal atoms such as Cu, Ni, Co and Pd have been studied in great detail for their various crystallographic features, enzymatic reactions, steric effects [1–4], structure–redox relationships [5], mesogenic characteristics [6–9], catalysis, magnetic properties [10,11] and their important role in the understanding of the coordination chemistry of transition metal ions [12]. CuN_2O_2 coordination is very common in copper chemistry and the redox behaviour of a wide series of mononuclear copper(II) Schiff base complexes was reviewed some years ago in relation to their structural changes [5]. We report here the synthesis, characterization and cyclic voltammetry of copper(II) complexes of a series of Schiff base ligands derived from condensation of 5-phenylazo salicylaldehyde with di-or tri-amines (Scheme 1). We also report the crystal structure of [bis(5-phenylazo salicylaldehyde)trimethylen diiminato]-copper(II) (Cu5PHAZOSALTN) (**III**) as determined by single-crystal X-ray diffraction.

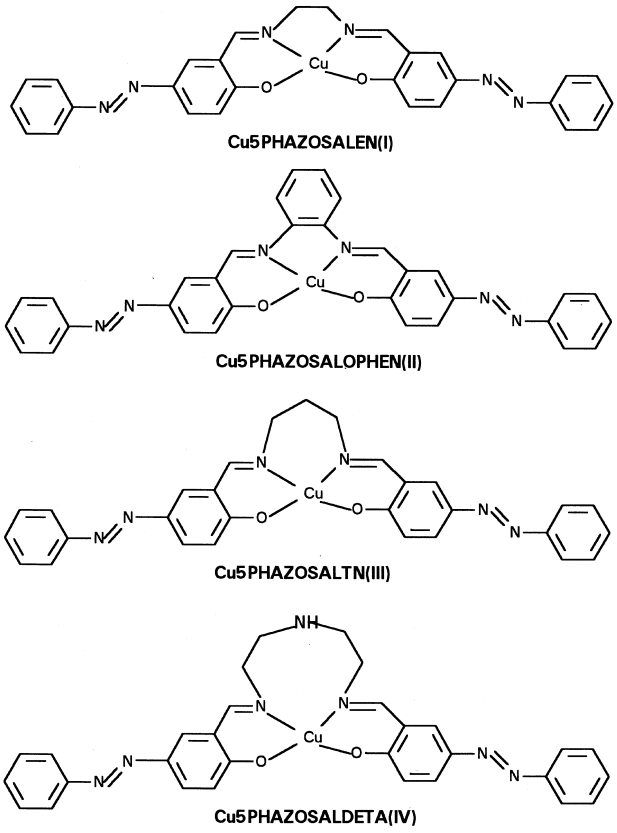
2. Experimental

2.1. Reagents



All reagents and solvents were used as supplied by Merck.

2.2. Physical measurements

Elemental (C, H and N) analyses were made on a Perkin-Elmer Model 240B automatic analyser. Electron impact (70 eV) mass spectra were recorded on a Finnigan-mat GC-MS-DS spectrometer Model 8430. Infrared (IR) spectra were recorded on an IR-408 Shimadzu 568. The redox properties of the complexes were studied by cyclic voltammetry. The voltammetric experiments were carried out in deaerated (with purged nitrogen) dimethylformamide (DMF) solutions of the complexes containing 0.1 M tetrabutylammonium perchlorate (TBAP) as supporting electrolyte. Spectroscopic grade DMF was distilled and dried on 0.4-nm molecular sieves. TBAP was dried in an oven and used without further purification.

Cyclic voltammograms were performed using an AMEL Instruments Model 2053 as potentiostat connected with a

function generator (AMEL Model 568).When an iR drop (ohmic drop) was compensated a multipurpose instrument from EG&G was used, comprising potentiostat/galvanostat Model 273 coupled with an IBM personal computer connected to an Epson Model FX-850 printer. In all electrochemical experiments, an aqueous saturated calomel electrode (SCE) was used as reference electrode and all potential cited are given versus SCE. A platinum wire was used as counter electrode and a glassy carbon disc with a diameter of 3 mm was used as working electrode. The ferricinium/ferrocene (Fc^+/Fc) couple was used as an internal standard; the ferrocene solution concentration was 1 mM. All experiments were carried out at room temperature. NMR spectra were measured in $CDCl_3$ on a Brucker ACE-300 NMR spectrometer, 300.133 MHz. All chemical shifts are reported in δ units downfield from Me_4Si.

2.2.1. X-ray crystallography

Crystallographic data for complex **III** are given in Table 1 as a typical example. Single crystals of complex were acquired by slow evaporation from a chloroform–ethanol (5:1) solution at room temperature and mounted in sealed glass capillaries. Diffraction data were collected on a Siemens P3/PC diffractometer (four-circle geometry) at 293 K. Intensity data were obtained using Mo Kα radiation (0.7107 Å) monochromatized from graphite; the ω–2θ scan mode was used to a maximum 2θ value of 47.97. The data were reduced and the structure was solved by direct methods using the program SHELXTL Plus, version 5, and refined by the full-matrix least-squares method. In subsequent refinements, the function $\Sigma w(|F_o|-|F_c|)^2$ was minimized, where F_o and F_c are the observed and calculated structure factor amplitudes. The agreement indices $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|)^2]^{1/2}$ were used to evaluate the results. Atomic scattering factors are from the international tables for X-ray crystallography. Hydrogen atoms were introduced at theoretical positions with a C–H distance of 0.95 Å for the aromatic H atoms and 0.99 Å for methylene groups.

2.3. Materials [1]

2.3.1. 5-Phenylazo salicylaldehyde

5-Phenylazo salicylaldehyde was obtained as described elsewhere [13].

2.3.2. Ligands

All ligands were prepared in a similar manner. First, 0.013 mole of related amine and 0.026 mole of 5-phenylazo salicylaldehyde were condensed by refluxing in 80 ml of absolute ethanol for 1 h. The solution was left at room temperature. Bis(5-phenylazo salicylaldehyde)ethylene diimine (5PHAZOSALEN) and bis(5-phenylazo salicylaldehyde)trimethylen diimine (5PHAZOSALTN) were obtained as yellow microcrystals, and bis(5-phenylazo salicylaldehyde)*O*-phenylene diimine (5PHAZOSALOPHEN) and

bis(5-phenylazo salicylaldehyde)diethylene triimine (5PHAZOSALTEDA) were obtained as red microcrystals; the microcrystals were filtered off, washed with 10 ml of absolute ethanol and then recrystallized from ethanol–chloroform (1:3, v/v).

2.3.3. Complexes

All complexes were prepared in a similar manner. A solution of 0.004 mole of $Cu(CH_3COO)_2 \cdot 4H_2O$ in 10 ml of ethanol was added to an ethanol–chloroform (1:1, v/v) solution containing 0.004 mole of ligand and refluxed for 1 h. The obtained brown solution was left at room temperature and brown microcrystals were collected by filtration, washed with 15 ml of ethanol and then recrystallized from ethanol–chloroform (2:1, v/v).

3. Results and discussion

3.1. Syntheses

The 5-phenylazo salicylaldehyde (pre-ligand), Schiff base ligands and related copper complexes were obtained in good yield and purity. The pre-ligand and Schiff base ligands were characterized by ^{1}H NMR and IR and mass spectroscopy.

Copper complexes were characterized by elemental analysis and IR spectroscopy. All physical and characterization data for the ligands and complexes are given in Tables 2 and 3, respectively. In the mass spectra of 5-phenylazo salicylaldehyde and the related Schiff base (5PHAZOSALOPHEN), $[M+1]$, M and $[M-C_6H_5N_2]$ for aldehyde and $[M-2{*}C_6H_5N_2]$ for Schiff base were observed. For the IR spectra of the four title complexes, ν(C=N) shifted to a lower wavenumber by 10–30 cm^{-1} upon coordination. On the other hand, the disappearance of the OH band of free ligands in copper(II) complexes indicates that the OH group has been deprotonated and bonded to the metal ions as $-O^-$.

On the basis of these results it can be deduced that in complexes **I**, **II** and **III** the Schiff bases are coordinated to copper atom as tetradentate ONNO ligands. The IR spectra of complex **IV** shows no shift for N–H bond in comparison to the IR spectra of the ligand. Therefore complex **IV** is also four-coordinate via ONNO of the ligand atoms.

*3.2. Crystal structure of [bis(5-phenylazo salicylaldehyde)-trimethylen diiminato]copper(II) (Cu5PHAZOSALTN) (**III**)*

The crystal structure and unit cell diagram of complex **III** are illustrated in Figs. 1 and 2, respectively. The selected bond distances and angles are given in Table 4.

The coordination geometry around copper can be described as a near square-planar. The Cu–O(1) and Cu–O(1′) distances of 1.903(5) and 1.931(6) Å are similar to the corresponding value [Cu–O(2), 1.915(7) Å] in *N*,*N*′-trimethylene bis(salicylaldehyde imine)copper(II), Cu(sal$_2$tn), as reported by Xiong et al. [12], and the differences are not significant, but the differences between Cu–O(1) and Cu–O(1′) with Cu–O(1) [1.840(9)Å] in Cu(sal$_2$tn) are probably just significant.

The Cu–N(1) and Cu–N(1′) distances are 1.949(7) and 1.962(7) Å. The corresponding values of complex Cu(sal$_2$tn) are 1.954(7) and 1.995(8) Å.

The bond angles O(1′)–Cu–O(1), N(1′)–Cu–N(1), N(1)–Cu–O(1′) and N(1′)–Cu–O(1) are 79.8(2), 95.7(3), 171.9(3) and 171.8(3)°, respectively. The two former bond angles are similar to the values in Cu(sal$_2$tn) [79.8(4) and 95.5(4)°], but on the basis of the two latter bond angles [(171.9(3) and 171.8(3)°] we can conclude that the coordination geometry around copper in the title complex is near to square-planar in comparison to Cu(sal$_2$tn), which has corresponding values of 159.7(4) and 158.2(4)°, respectively. The central carbon atom in the trimethylene diamine chelate ring (labelled C(1) and C(1′); see Fig. 1) is disordered over two positions, one of which is above and another below the coordination plane. The disorder is quite common and is observed, for example, in some of the transition metal complexes with Schiff base ligands [14].

Complex **III** has been prepared and recrystallized in ethanol solution. The elemental analysis confirms the formulation of the complex. Recrystallization of complex **III** for preparing a single crystal was carried out in ethanol–chloroform. The crystal structure shows the presence of a $CHCl_3$

3.3. Cyclic voltammetry

The cyclic voltammograms recorded (without iR compensation) for complexes **I–IV** are shown in Fig. 3 and the corresponding characteristic data are given in Table 5. Note that the free ligands are electroinactive in the working potential region.

On the basis of the cyclic voltammograms in Fig. 3, complex **I** undergoes an irreversible reduction process under the experimental condition (Fig. 3a). The peak separations ΔE ($=E_{pa}-E_{pc}$) for complexes **II**, **III** and **IV** were 82, 103 and 227 mV, respectively, at a scan rate of 0.05 V s^{-1}, and decreased to 62, 78 and 204 mV when the iR drop was compensated by the cyclic voltammetry set-up; thus the redox process for complex **II** is reversible and quasi-reversible for complexes **III** and **IV** [15]. Note that when a similar iR compensation is applied to the cell, the ferrocene behaved ideally and the peak separation for the ferricinium/ferrocene couple was at 60 mV, which can be used as a criterion for electrochemical reversibility in the present experimental conditions.

As seen in Table 5, the peak:current ratio decreases with increasing scan rate, indicating a weak adsorption of the reactants on the electrode [16]. For N_2O_2 Schiff base complexes of copper the redox potential is correlated with the degree of

tetrahedral distortion of the copper coordination environment [17,18]. The more tetrahedral geometries correspond to less negative redox potential for Cu(II)/Cu(I) couples, whereas more planar geometries give rise to more negative potentials.

Complexes **I** and **II** can be assumed to be planar complexes [5]. The angles N(1′)–Cu–O(1) 171.8° and N(1)–Cu–O(1′) 171.9 in complex **III** indicate that the copper coordination environment is near square-planar; therefore the redox potential of this complex is less negative than the planar analogue. On the basis of the redox potential, we conclude that complex **IV** has a structure deviating from square-planar with N_2O_2 and not N_3O_2 coordination [5,19].

Supplementary data

Supplementary crystallographic data are available from the CCDC, 12, Union Road, Cambridge CB2 1EZ, UK (fax. +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number CCDC 120858.

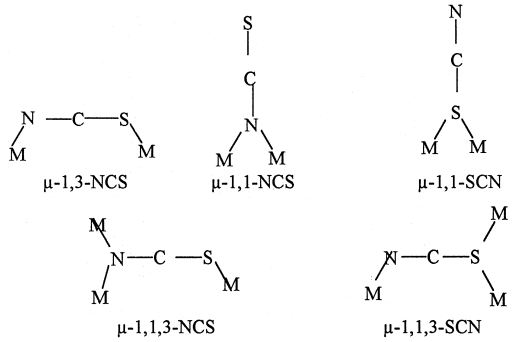
Received 17 June 1999; accepted 10 December 1999



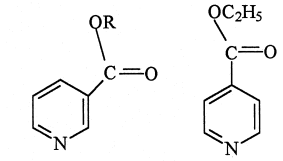
Abstract

Three new copper(I) thiocyanato complexes $[Cu(NCS)L]_n$ (L = methyl nicotinate **1**, ethyl nicotinate **2**), and $[HL][Cu(NCS)_2]$ (HL = H-ethyl isonicotinate **3**), have been prepared and characterized by spectroscopic and crystallographic methods. All three complexes display MLCT transitions in the visible region, as well as visible solid state emission spectra at room temperature. Their IR spectra are measured and discussed. In the structure of **1** each copper atom links two S atoms from two μ-S,S,N thiocyanato ligands and two nitrogen atoms from a pyridine nucleus and from a third μ-S,S,N thiocyanate group; the two S atoms bind another copper atom forming a Cu_2S_2 cyclic unit. The ladder propagates along the *a* axis of the unit cell. The structure of **2** features CuS_2N_2 coordination with approximate tetrahedral environment, μ-S,S,N bridging thiocyanate groups giving rise to corrugated layers at $y = 1/4$. Complex **3** consists of an N-protonated ethyl isonicotinate cation and a polymeric $[Cu(NCS)_2]^-$ anion. Each trigonal planar copper atom in the anion is coordinated by two S atoms from a μ-S,N thiocyanate bridge and a terminal S-thiocyanate group, and the third site is occupied by the end nitrogen of a μ-S,N thiocyanate bridge. The terminal NCS group forms a hydrogen bond of the type N–H···N with an N–H group of the $[HL]^+$ cation. The planar ribbon which runs in the *a* direction is further stabilized by N–H···O hydrogen bonds. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Copper(I) thiocyanate complexes; Methyl nicotinates; Ethyl nicotinates; Ethyl isonicotinate complexes; Crystal structures; Trigonal planar anions

1. Introduction

The pseudohalide NCS^- is known to coordinate to metals in both terminal and bridging modes. As bridging ligand the thiocyanate can link a pair of metal centers in either an end-on (μ-1,1-NCS, μ-1,1-SCN) or end-to-end (μ-1,3-NCS) configuration. The thiocyanate ion may link a third metal atom giving rise to a μ-1,1-3 (μ-N,N,S or μ-S,S,N) mode:



Binuclear, and polynuclear copper thiocyanate systems are of considerable interest owing to the broad range of their structural and magnetic properties [1,2]. However, the vast majority of studies have focused on copper(II) thiocyanate complexes [3,4]. On the other hand, reports on copper(I) thiocyanate complexes are relatively few. For example, only two structures, namely that of $[Cu_2L(\mu\text{-}1,1\text{-}SCN)_2]$ (L = macrocyclic Schiff base) [5] and $[Cu_2(\mu\text{-}Ph_2Ppypz)_2(\mu\text{-}1,1\text{-}SCN)][ClO_4]$ (Ph_2Ppypz = 2-(diphenylphosphino)-6-(pyrazol-1-yl)pyridine] [6] which exhibit μ-1,1-SCN bridges have been established.

Previously we have shown that when a mixture of CuNCS and 2-benzoylpyridine stands in an ethanol medium for about 2 weeks in contact with air, the intramolecular oxidative cyclization of 2-benzoylpyridine occurs with the formation of [9-oxo-indolo[1,2-*a*]pyridinium]$^+$[$Cu(NCS)_2$]$^-$, whereas CuCN and 2-benzoylpyridine under the same conditions lead to the formation of a polymeric 1:1 copper(I) complex [7]. Also, we have shown that copper(I) azide dissolved in excess NaN_3 interacts with pyrazinecarboxamide

in ethanol giving a novel polymeric copper(I) complex containing an unusual μ-1,1,3-N_3 bridge, and we have established that such methodology is a potentially versatile approach to the construction of uncharged inorganic coordination networks [8]. We have used this approach for the preparation of the copper(I) thiocyanato complexes of methyl nicotinate and ethyl nicotinate (**I**) and ethyl isonicotinate (**II**). In the present paper we describe the synthesis and characterization of the title complexes as elucidated by spectroscopic and crystallographic methods.

2. Experimental

Methyl nicotinate, ethyl nicotinate and ethyl isonicotinate were obtained from Aldrich; the other chemicals were of analytical grade quality.

2.1. Preparation of the complexes

2.1.1. Polymeric [CuNCS(methyl nicotinate)]$_n$ (*1*)

This complex was prepared by mixing aqueous solutions of $Cu(NO_3)_2 \cdot 3H_2O$ (0.48 g, 2 mmol) and NaNCS (0.164 g, 2 mmol) in the presence of excess L(+) ascorbic acid. To the precipitated CuSCN obtained by decantation of the aqueous layer, a concentrated aqueous solution of NaSCN was added until complete dissolution, and any impurities filtered off. An ethanol solution of methyl nicotinate (0.548 g, 4 mmol) was added to the clear solution, and the final mixture allowed to stand in an open beaker over several days until pale yellow needle-like crystals of the complex deposited. Yield 20% (with respect to copper). *Anal*. Found: C, 37.0; H, 2.8; N, 10.9; S, 12.1; Cu, 24.7. Calc. for $C_8H_7CuN_2O_2S$: C, 37.13; H, 2.73; N, 10.82; S, 12.37; Cu, 24.55%.

2.1.2. Polymeric [CuNCS(ethyl nicotinate)]$_n$ (*2*)

This complex was prepared according to the above procedure except that an ethanol solution of ethyl nicotinate was added to the clear aqueous solution of CuNCS dissolved in concentrated solution of NaNCS. The final mixture was allowed to stand over several days to produce yellow crystals of the complex. Yield 25% (with respect to copper). *Anal*. Found: C, 39.8; H, 2.4; N, 10.1, S, 11.6; Cu, 23.4. Calc. for $C_9H_9CuN_2O_2S$: C, 39.62; H, 3.73; N, 10.26; S, 11.73; Cu, 23.29%.

2.1.3. [(Ethyl isonicotinate)H][Cu(NCS)$_2$] (*3*)

A concentrated aqueous solution of NaNCS was added to a suspension of CuSCN (3 mmol) until complete dissolution, followed by addition of an ethanol solution of ethyl isonicotinate (3 mmol), upon which the solution turned yellow.

This clear solution mixture was allowed to stand in open air over 2–3 weeks to yield yellow crystals of the complex. *Anal*. Found: C, 36.3; H, 3.2; N, 12.4; S, 19.1; Cu, 19.3. Calc. for $C_{10}H_{10}CuN_3O_2S_2$: C, 36.19; H, 3.04; N, 12.65; S, 19.28; Cu, 19.15%.

2.2. Physical measurements

The experimental procedures and instruments used for different physical measurements are as described previously [9].

2.3. X-ray crystallography

Information concerning crystallographic data and structure refinement of the three complexes is summarized in Table 1. Data collection was performed on a Siemens R3m/V diffractometer in the variable ω-scan mode [10] using Mo Kα radiation ($\lambda = 0.71073$ Å). Unit cell parameters were calculated from least-squares fitting of 2θ angles. The raw data were processed with a learnt-profile procedure [11], and empirical absorption corrections based on ω-scan data were also applied.

All calculations were performed on a PC 486 computer with the SHELXTL/PC program package [12]. Each crystal structure was solved with the Patterson superposition method. The non-hydrogen atoms were refined anisotropically. All hydrogen atoms were generated geometrically, assigned fixed isotropic thermal parameters and included in the structure factor calculations. Analytical expressions of neutral-atom scattering factors were employed [13], and anomalous dispersion corrections were incorporated.

3. Results and discussion

The reactions between aqueous copper(I) thiocyanate dissolved in excess sodium thiocyanate with the esters of nicotinic and isonicotinic acids in ethanol afforded copper(I) complexes of the type Cu(NCS)L for L = methyl nicotinate and ethyl nicotinate and an ionic complex [LH][Cu(NCS)$_2$] when L is ethyl isonicotinate. Using this procedure allowed us to avoid the isolation of any Cu^{II} impurities, and single crystals of the above complexes were obtained. The three complexes are yellow, diamagnetic and sufficiently stable against air-oxidation when well dried. They are insoluble or slightly soluble in many common non-polar and polar solvents, e.g. benzene, toluene, water, methanol, ethanol, acetone, etc.

3.1. Structures

3.1.1. [Cu(NCS)(methyl nicotinate)]$_n$ (1)

Fig. 1 illustrates the principle structural features of complex **1**, along with the atom numbering scheme; bond lengths and bond angles are given in Table 2. Each copper atom, Cu(1), coordinates two nitrogen atoms, from a methyl nicotinate and a thiocyanato ligand. The other two coordination sites are occupied by two sulfur atoms from two thiocyanato ligands, giving rise to an approximate tetrahedral environment around the copper atom. The two sulfur atoms further link a second copper atom, Cu(1A), forming a Cu_2S_2 cyclic unit. Thus the thiocyanate groups function as tridentate μ-S,S,N bridges connecting three different metal centers, resulting in a ladder extended along the *a* axis of the unit cell (Fig. 2). The Cu–N(L) bond length of 2.013(2) Å is within the range of 2.00–2.05 Å found for copper(I) complexes with pyridine and substituted pyridines [14,15]. While the Cu–N(NCS) of 1.944(2) Å match very well, the Cu–S distances are significantly longer than corresponding distances found in the structure of polymeric [$Cu_2(NCS)_2$(pyrazine)]$_n$ (Cu–N = 1.940(4) and Cu–S = 2.249(2), 2.338(2) Å) [16]. The pyrazine complex, however, contains μ-N,S thiocyanate bridges.

3.1.2. [Cu(NCS)(ethyl nicotinate)]$_n$ (2)

The most relevant feature of the structure of complex **2** is the disposition of Cu(I) ions in a two-dimensional lattice. Within each layer the metal ions are bridged by two sulfur atoms from two thiocyanate bridges and two nitrogen atoms from a thiocyanate bridge and from an ethyl nicotinate ligand. Thus each copper atom is tetra-coordinated, giving rise to a CuS_2N_2 chromophore. A view of the chromophore along with the atom labeling scheme is given in Fig. 3, while selected bond lengths and bond angles are listed in Table 2. Within the coordination polyhedron the Cu–N(L) of 2.033(4) Å is slightly longer than the corresponding distance, whereas the Cu–N(NCS) and Cu–S distances are within the ranges found in complex **1**. As seen from Fig. 4, each thiocyanate group functions in the μ-1,1,3-SCN mode as found in the structure of complex **1**. The structure of complex **2**, however, differs from that of **1**. In complex **1** two sulfur atoms from two thiocyanate groups link the same two copper atoms giving rise to a cyclic Cu_2S_2 unit, but in complex **2** the sulfur atoms of two thiocyanate ligands bind three different metal centers, giving rise to corrugated layers at $z = 1/2$, and hence the structure does not contain the Cu_2S_2 cyclic units.

3.1.3. [(Ethyl isonicotinate)H][Cu(NCS)$_2$] (3)

The principle structural features of complex **3** are illustrated in Fig. 5; bond lengths and bond angles are given in

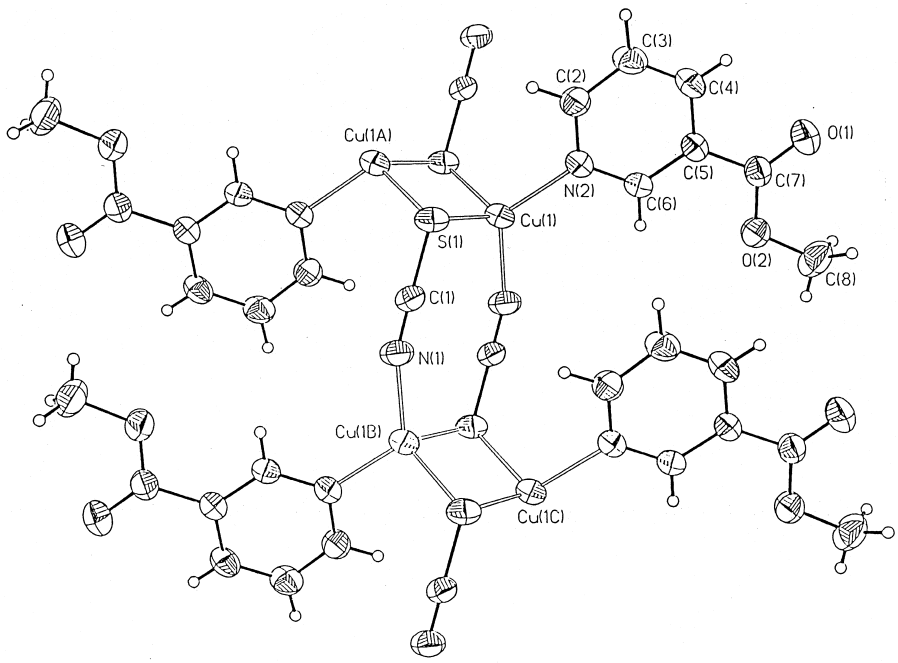

Fig. 1. Atom labeling and principle structural features of polymeric [Cu(SCN)(methyl nicotinate)]$_n$ (**1**).

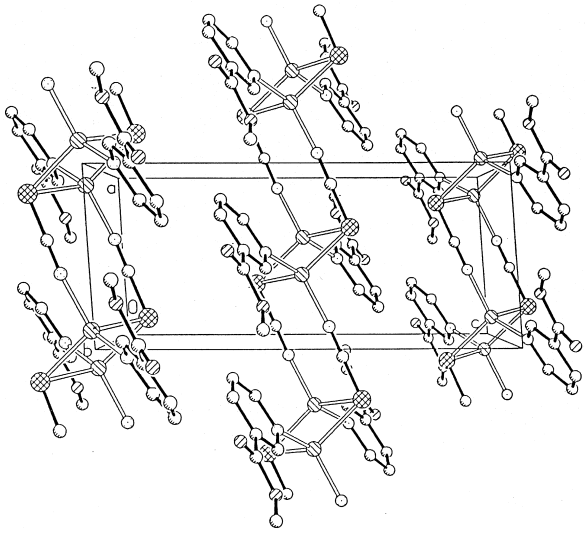

Fig. 2. Stereoview of the crystal structure of polymeric [Cu(SCN)(methyl nicotinate)]$_n$ (**1**).

Table 2. The structure of this complex consists of a packing of N-protonated ethyl isonicotinate cations and polymeric $[Cu(NCS)_2]^-$ species. Ethyl isonicotinate thus differs from methyl nicotinate, or ethyl nicotinate in that its nitrogen atom is protonated and does not enter in the coordination sphere of the copper atom. In the polymeric $[Cu(NCS)_2]^-$ species, each copper atom is coordinated by two sulfur atoms (Cu–S = 2.2587(9) and 2.2640(9) Å) and one nitrogen atom (Cu–N = 1.893(3) Å) from three different thiocyanate ligands, giving rise to approximate trigonal planar geometry around the copper centers. It is clear from Fig. 5 that one independent thiocyanato group S(1)–C(1)–N(1) functions as a μ-1,3-NCS bridging bidentate ligand, giving rise to a planar ribbon at $y = 1/4$ running in the *a* direction of the unit cell. The other independent thiocyanate group acts as a monodentate ligand with S(2) linked to a copper atom; S-coordinated ligands of this type protrude on both sides of each layer and serve as partitions for adjacent heterocyclic cations arranged in rows parallel to the *c* axis. The nitrogen atom, N(2), of the monodentate thiocyanate ligand forms a hydrogen bond of the type N–H···N with the N–H group of the N-protonated ethyl isonicotinate molecule. The structure of the compound is further consolidated by another hydrogen bond of the type C–H···O between the C(7)–H and oxygen atom, O(1), of two adjacent protonated ethyl isonicotinate molecules. Both thiocyanate groups are linear (angles 179.1(3) and 179.7(3)°) within experimental error.

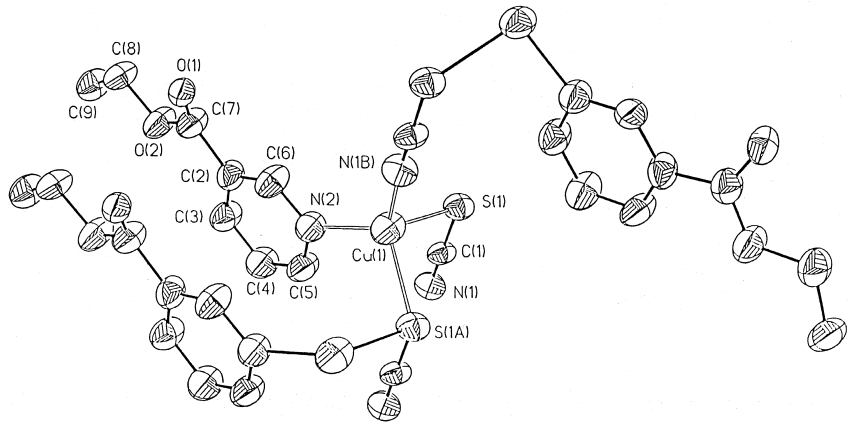

Fig. 3. Atom labeling and principle structural features of polymeric [Cu(SCN)(ethyl nicotinate)]$_n$ (**2**).

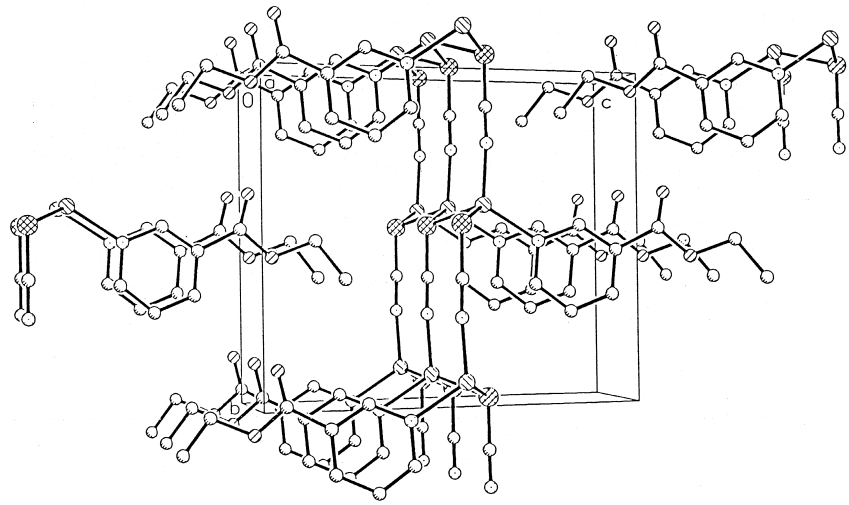

Fig. 4. Stereoview of the crystal structure of polymeric [Cu(SCN)(ethyl nicotinate)]$_n$ (**2**).

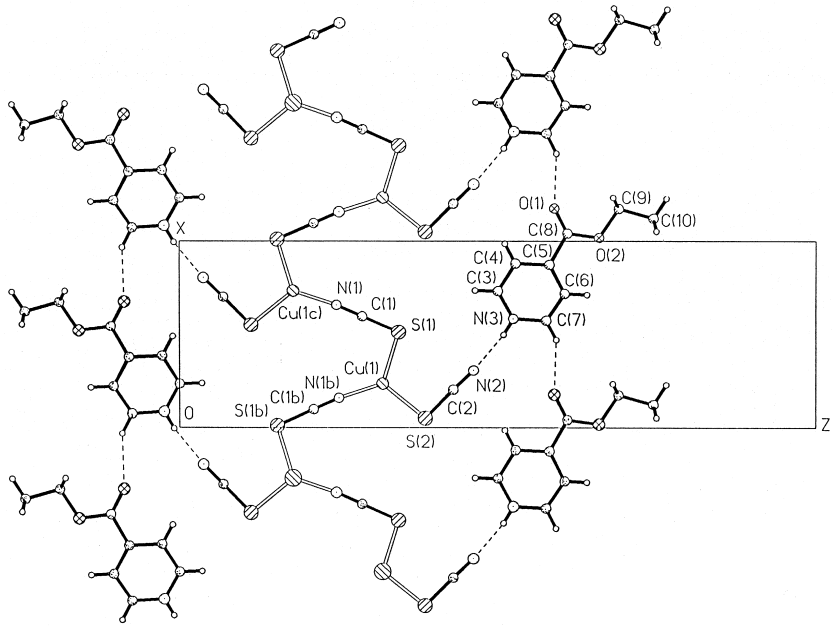

Fig. 5. The coordination environment of the copper(I) atom and the cation in the complex [(ethyl isonicotinate)H][$Cu(SCN)_2$] (**3**). Hydrogen bonds are represented by broken lines.

The structure of the present $[Cu(NCS)_2]^-$ species differs from that of the corresponding species found in the structure of [9-oxo-indolo[1,2-*a*]pyridinium]$^+[Cu(NCS)_2]^-$, although both are polymeric. In the latter species, each copper atom is tetrahedrally coordinated by two nitrogen atoms (Cu–N(av) = 1.947 Å) and two sulfur atoms (Cu–S = 2.373(2) and 2.471(2) Å). This species contains an independent μ-1,1,3-SCN bridging tridentate ligand in which the sulfur atom links two different copper atoms, whereas the nitrogen atom binds a third copper center, giving rise to a puckered layer; the other thiocyanate group acts as an N-monodentate ligand [7].

3.2. Electronic and IR spectra

The electronic spectra of solid samples of the three copper(I) complexes exhibit strong broad absorption bands over the range 300–450 nm (Table 3) due to MLCT transitions in complexes **1** and **2**. For complex **3**, however, L is protonated rather than coordinated, and the charge transfer therefore could not be of the above type. It is possible that the charge transfer in this case is due to XLCT (X = anion).

Table 3
Electronic, IR and emission spectral data

	1	**2**	**3**
Electronic spectra [a]			
λ_{max} (MLCT) (nm)	300–380s	300–400s	300–450s
IR (cm^{-1})			
ν(CN)	2111vs, 2070m	2119vs, 2085m	2117vs, 2076ms
ν(CS)	756m, 696m	755m, 694wm	757m, 689wm
ν(C=O)	1728vs	1722vs	1723vs
ν(N–H···H+)			3420m,br
ν(C–H···O)			3097, 2990m
Emission spectra [b]			
λ_{max} (nm)	499	498	575

[a] Samples measured as solids mulled in Nujol.
[b] Excitation wavelength 358 nm.

The IR spectra (Table 3) of complexes **1**–**3** show two strong absorption peaks above and below 2100 cm^{-1}, associated with the ν(CN) mode of the thiocyanato ligands, in addition to two weak to medium bands due to the ν(CS) mode. These results, while suggesting bridging thiocyanato ligands, cannot distinguish between μ-1,3 and μ-1,1,3 thiocyanate bridges. This result, however, is not uncommon. For example, the IR spectrum of [9-oxo-indolo[1,2-*a*]-[pyridinium][$Cu(NCS)_2$], which contains μ-1,1,3-SCN and terminal NCS groups also exhibits two ν(CN) peaks at 2105 and 2075 cm^{-1} [7]. Bands due to hydrogen bonds are observed in the region 3450–2800 cm^{-1}, in the spectrum of complex **3** only. The small shift of the ν(C=O) band in the spectrum of complex **3** to a lower frequency compared with that of free ligand (1735 cm^{-1}) is due to hydrogen bonding, N–H···O formation with the N–H group of an adjacent molecule. The N-protonation of ethyl isonicotinate manifests itself in a large shift [17] of the vibration bands related to the pyridine ring to higher frequencies (1633, 1605, 1557 cm^{-1}) when compared with those of free ligand (1600, 1570 cm^{-1}) or with other copper(I) complexes of the same ligand [18].

3.3. Emission spectra

The results of the emission spectra of complexes **1**–**3** in the solid state at room temperature are given in Table 3 and Fig. 6. The three compounds fluoresce in the solid state and their emission spectra exhibit a single band, slightly asym-

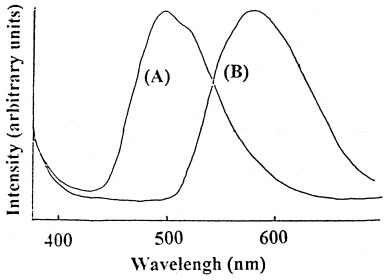

Fig. 6. Emission spectra of solid complexes at room temperature: (A) [Cu(SCN)(methyl nicotinate)]$_n$ (**1**); (B) [(ethyl isonicotinate)H]-[Cu(SCN)$_2$] (**3**).

metric for complex **3**, but with a pronounced shoulder on the lower energy side for both complexes **1** and **2**. While the λ_{max} of the main band appears at 498 and 499 nm for **1** and **2**, respectively, complex **3** shows λ_{max} at 575 nm. The luminescence spectra of these complexes proved independent of the excitation wavelength at room temperature. Previous studies [19–22] of the emission spectra of copper(I) halides of pyridine and pyridine derivatives have shown that these complexes display a high energy (HE) band (430–540 nm) attributed to metal-to-ligand charge transfer (MLCT) or XLCT, and a low energy (LE) band (620–698 nm) related to the metal center in complexes with Cu···Cu distance of less than 2.8 Å. The energies of the former band are quite sensitive to the substituent on the pyridine; the electron-withdrawing substituent shifts these bands to lower energy values. The results given in Table 3 suggest that the emission observed in the present complexes **1** and **2** is attributed to the MLCT transition states. In the case of complex **3**, the emission is substantially due to XLCT (X = anion) transition since the ligand L is protonated and not coordinated to the copper atom. That the λ_{max} of the emission band observed for complex **3** is shifted to lower energy compared to those for **1** and **2**, which reflects the difference between the source of the emission in both cases, is also consistent with what has been observed previously [23,24], and suggests that the HE emission band (MLCT) is not only sensitive to the nature of the substituent group, but is also sensitive to its position in the pyridine ring.

Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers; CCDC 121740, 121741 and 121744, for **1**, **2** and **3**, respectively.

POLYHEDRON

Crystal structure of a copper stabilized hydrate of di-2-pyridyl ketone

O. Jerry Parker *, Sheryl L. Aubol, Gary L. Breneman

Department of Chemistry and Biochemistry, Eastern Washington University, Cheney, WA 99004, USA

Received 14 May 1999; accepted 6 December 1999

Abstract

The addition of a yellow ethanolic solution of di-2-pyridyl ketone to a blue–green aqueous solution of copper(II) bromide produces an exothermic reaction and a brilliant purple solution. Brilliant purple single crystals were obtained from the solution by solvent evaporation and were subjected to a crystal structure determination. The structure of the isolated *gem*-diol compound stabilized by a transition metal contains two di(2-pyridyl)methanediol ligands bonded to the central copper atom in a distorted octahedral arrangement providing four nitrogen atoms at relatively short bond distances and two oxygen atoms at longer bond distances. In the solid state, both oxygen atoms on each of the *gem*-diol ligands are protonated. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Copper; *gem*-Diol,di-2-pyridyl ketone; Di(2-pyridyl)methanediol; Crystal structures

1. Introduction

The reversible addition of water to carbonyl compounds yielding hydrates (*gem*-diol compounds) has been a subject of considerable interest [1–7]. The hydration reaction has been extensively studied as the mechanistic prototype for many reactions at carbonyl centers. Most *gem*-diol compounds are too unstable or too labile to isolate for determination of the crystal or molecular structure. Predominant examples of stable hydrated ketones are polyhaloginated ketones and cyclic compounds such as chloral hydrate and the hydrate of cyclopropanone. The fluorinated alcohol hexafluoropropane-2,2-diol, $(CF_3)_2C(OH)_2$, forms *gem*-diol complexes with many metals such as Cu^{2+}, Ni^{2+}, Co^{3+}, Mn^{2+} and Pt^{2+} in a variety of structures with at least three different modes of coordination [8–10]. Recent interest in di-2-pyridyl ketone as a ligand has shown that several different types of structures are possible. Di-2-pyridyl ketone can function as a bidentate ligand with bonding through the two nitrogens or as a tridentate ligand with bonding through the oxygen and two nitrogen atoms [11]. Mononuclear and polynuclear transition metal complexes with ligands of di-2-pyridyl ketone that has undergone hydrolysis and alcoholysis have been reported [12–17]. The title compound is a copper(II) complex that has two stable *gem*-diol ligands in the solid state and presumably in the aqueous solution from which it was prepared. The stability of the crystalline state is enhanced by a system of hydrogen bonding involving both hydroxy groups of the hydrated di-2-pyridyl ketone ligands through water molecules. The hydrated di-2-pyridyl ketone ligands are stabilized by modifying the angles about the carbon to the normal tetrahedral angles while preserving a square planar configuration about the copper. The complex has a molecular composition represented by $[Cu(dpydiol)_2]$-$Br_2 \cdot 4H_2O$, where dpydiol = di(2-pyridyl)methanediol, and an empirical formula of $[Cu(C_{11}H_{10}N_2O_2)_2]Br_2 \cdot 4H_2O$. The presence of two bromide anions for each $[Cu(dpydiol)_2]^{2+}$ cation shows that both oxygen atoms on each di(2-pyridyl)methanediol ligand are protonated in the solid state. The dimensions of the ligand and the tetrahedral angle about the *gem*-diol carbon requires that the six-membered ring formed by this carbon, two additional carbons and two nitrogens from each pyridyl ring, and the center copper atom be stable in either a chair or boat type configuration. The observed boat configuration places one of the oxygen atoms on the *gem*-diol carbon close to the fifth position of an octahedral stereochemistry about the copper atom. The second di(2-pyridyl)menthanediol ligand furnishes two of the nitrogen atoms and an oxygen atom from one of the two hydroxy groups on the *gem*-diol to complete the distorted octahedral arrangement around the central copper atom.

2. Results and discussion

2.1. Crystal and molecular structure of $[Cu(dpydiol)_2]Br_2 \cdot 4H_2O$

A summary of the crystal data is given in Table 1. Selected bond distances and bond angles are presented in Table 2. A thermal ellipsoid plot of the structure and atom numbering scheme with hydrogen atoms omitted is shown in Fig. 1. Fig. 2 shows the hydrogen bonding network between molecules. Fig. 3 shows a unit cell packing diagram.

The X-ray structure of the complex (Fig. 1) contains a copper atom positioned at a center of inversion. The nitrogens from the two di(2-pyridyl)methanediol ligands surround the copper atom in a square planar arrangement with Cu–N1 and Cu–N2 bond distances of 2.011(4) Å and an N1–Cu–N2 angle of 87.8(1)°. The crystallographic symmetry demands that the N1–Cu–N1′ angle be 180°. The fifth and sixth positions which form a distorted octahedral arrangement about the copper atom are occupied by an oxygen atom of one of the two hydroxy groups on each di(2-pyridyl)methanediol ligand. The Cu–O2 distance is 2.464(3) Å with O2–Cu–N1 and O2–Cu–N2 angles of 74.9(1) and 73.6(1)° respectively. The bond distances are very similar to those reported for $[Cu\{C_{11}H_8N_2(OH)_2\}_2](ClO_4)_2$ with Cu–N1 of 2.009(2) Å and Cu–N2 of 2.010(2) Å and the Cu1–O1 distance is 2.454(3) Å [17]. The structure and bond distances are very similar to those reported for $[Cu\{C_{11}H_8N_2(OH)_2\}_2]$-$Cl_2 \cdot 4H_2O$, with Cu–N1 of 2.006(5) Å and Cu–N2 of 1.994(5) Å and the Cu–O1 distance is 2.465(5) Å, and for the compound $Cu\{C_{11}H_8N_2(OH)_2\}_2](NO_3)_2 \cdot 2H_2O$ with Cu–N1 of 1.990(5) Å and Cu–N2 of 2.036(5) Å and the Cu–O1 distance is 2.464(4) Å [12].

The Cu–O distance of 2.464(3) Å is very similar to the long Cu–O distance of 2.43 Å in $Cu(DMG)_2$, where DMG = dimethylglyoxime [18], and 2.397(8) Å for anhydrous copper(II) formate [19]. The O1 atom of the hydroxy group that does not occupy an octahedral position about the copper atom is slightly distorted from the expected tetrahedral angles about the C6 atom as seen in Table 1. Both hydroxy groups on each di(2-pyridyl)methanediol ligand are hydro-

gen bonded through two water molecules to the crystallographically related hydroxy groups on a di(2-pyridyl)-methanediol ligand of a neighboring $[Cu(dpydiol)_2]^{2+}$ cation. Two additional water molecules are associated through hydrogen bonding to the two bromide counter ions present in the crystal packing.

3. Experimental

3.1. Preparation

The reaction of copper(II) bromide (0.447 g, 2 mmol) in water with di-2-pyridyl ketone (0.737 g, 4 mmol) in ethyl alcohol resulted in an exothermic reaction which produced a brilliant purple solution. Deep purple crystals were obtained by the evaporation of solvent for the structural determination. The compound and crystals were stable at room temperature.

3.2. Single-crystal X-ray determination

$[Cu(dpydiol)_2]Br_2 \cdot 4H_2O$. A summary of crystal data is given in Table 1. All data were collected on an Enraf Nonius CAD4 diffractometer using monochromated Mo Kα radiation. Diffraction symmetry ($2/m$) and systematic extinctions (hkl, $h+k$ odd; $h0l$, l odd) indicated monoclinic Cc or $C2/c$ as the choices for the space group. Successful solution and refinement in $C2/c$ proved this to be the correct space group. An approximately $0.15 \times 0.20 \times 0.70$ mm crystal was mounted in a glass capillary for data collection on the CAD4 diffractometer using a 1.6° θ–2θ scan. Cell dimensions were determined by least-squares refinement of 25 reflections in the range $19.9 < \theta < 22.4°$. One standard reflection was monitored periodically and showed no systematic variation. Psi scan absorption corrections were made. The structure was solved using direct methods and subsequent cycles of structure-factor calculations and difference synthesis. Non-hydrogen atoms were refined anisotropically. H atom positions were calculated and left riding the non-hydrogen atoms during refinement to $R = 0.038$ and $wR = 0.056$ using $w^{-1} = \sigma^2(F_o) + 0.0004|F_o|^2$, $\sum w(|F_o| - |F_c|)^2$ minimized. All data reduction was executed using MolEN [20] on a VAX 6410 computer. Structure solution and graphics were done using SHELXTL/PC [21] on a Pentium based PC.

Supplementary data

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 135311. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

Direct synthesis of oxonium derivatives of the dodecahydro-*closo*-dodecaborate anion is described and the reaction mechanism is discussed. Various derivatives of the $[B_{12}H_{12}]^{2-}$ anion containing hydroxyl, amine, acid, and amino acid functions were prepared by ring opening reactions of the tetramethylene oxonium derivative $[B_{12}H_{11}O(CH_2)_4]^-$ with different nucleophiles. This approach is suitable for the development of compounds to be used in tumour selective boron neutron capture therapy (BNCT) and as linkers for the attachment of radioactive halogen labels for radioimmunodetection and radioimmunotherapy. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: *closo*-Dodecaborate; Oxonium derivatives; Functional derivatives; Amino acids; Boron neutron capture therapy

1. Introduction

Water-soluble functionalised derivatives of the dodecahydro-*closo*-dodecaborate anion $[B_{12}H_{12}]^{2-}$ are promising candidates for boron neutron capture therapy (BNCT) for cancer [1]. The traditional approach for the functionalisation of the $[B_{12}H_{12}]^{2-}$ anion consists of the introduction of a primary substituent (reactive centre) such as an amino [2–4], mercapto [5–7], or hydroxy [8–10] group into the boron cage, followed by the attachment of a side chain containing a functional group.

Here, we describe the direct synthesis of various oxonium derivatives of the dodecahydro-*closo*-dodecaborate anion and the use of one of these, the tetramethyleneoxonium derivative $[B_{12}H_{11}O(CH_2)_4]^-$, as a convenient precursor for the synthesis of various functional derivatives of the $[B_{12}H_{12}]^{2-}$ anion for BNCT, namely the $[B_{12}H_{11}O(CH_2)_4Z]^{2-}$ (Z = OH, NH_2, C(O)H, COOH, $CH(NH_2)COOH$) derivatives. The key step in the synthesis of these derivatives is a nucleophilic ring opening reaction.

2. Experimental

2.1. General

The ^1H, ^{11}B, and ^{13}C NMR spectra were collected using a Bruker ACP-200, a Varian Gemini 200 or a Varian Unity 400 spectrometer with TMS as internal or $BF_3 \times OEt_2$ as external standard. Infrared spectra were obtained on a Perkin Elmer 1760 FTIR spectrometer. Elemental analyses were performed in the Laboratory of Microanalysis of the Institute of Organo-Element Compounds (Moscow).

2.1.1. $(Me_4N)[B_{12}H_{11}OEt_2]$

2.70 g (1.2 mmol) *p*-nitrobenzoyl chloride dissolved in 10 ml diethyl ether were added slowly during 2 h at room temperature to a solution of 1.90 g (10.0 mmol) $Na_2[B_{12}H_{12}]$ in 20 ml acetone, and the reaction mixture was stirred for 1 h. The reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was treated with 70 ml water and stirred in air for 12 h. Then the solution was filtered and the filtrate was treated with 2.18 g (20.0 mmol) Me_4NCl dissolved in 30 ml water. The precipitate formed was filtered

off, washed with a few small portions of cold water and with ether and dried in air, giving 2.68 g (92%) of the product. ^{1}H NMR (MeCN-d_3, ppm): 4.48 (4H, q, –OCH_2CH$_3$), 3.09 (12H, s, N–CH_3), 1.39 (6H, t, –OCH$_2$CH_3). ^{13}C NMR (MeCN-d_3, ppm): 78.2 (–OCH$_2$CH$_3$), 56.2 (t, Me_4N^+), 13.4 (–OCH$_2$CH$_3$). ^{11}B NMR (MeCN-d_3, ppm): 8.3 (1B, s), −16.3 (5B, d), −16.8 (5B, d), −19.3 (1B, d). *Anal.* Calc. for $C_8H_{33}B_{12}NO$: C, 33.21; H, 11.51; N, 4.84. Found: C, 33.04; H, 11.26; N, 4.88%.

2.1.2. (Me$_4$N)[B$_{12}$H$_{11}$O(CH$_2$)$_4$]

0.7 ml (0.78 g, 5.5 mmol) $BF_3\times Et_2O$ was added to a stirred solution of 0.95 g (5.0 mmol) $Na_2[B_{12}H_{12}]$ in 25 ml of dry tetrahydrofuran and the reaction mixture was stirred at room temperature for 12 h. The reaction mixture was filtered and the solvent was distilled off from the filtrate. The residue was dissolved in 70 ml water and treated with a solution of 1.54 g (10.0 mmol) Me_4NBr in 30 ml water. The precipitate formed was filtered and dried in air, giving 1.25 g (86%) of the product. ^{1}H NMR (MeCN-d_3, ppm): 4.38 (4H, t, –O(CH_2CH$_2$)$_2$), 3.09 (12H, s, N–CH_3), 2.07 (4H, t, –O(CH$_2$CH_2)$_2$). ^{13}C NMR (MeCN-d_3, ppm): 81.6 (–O(CH_2CH$_2$)$_2$), 56.3 (Me_4N^+), 25.7 (–O(CH$_2$CH_2)$_2$). ^{11}B NMR (MeCN-d_3, ppm): 7.2 (1B, s), −16.6 (10B, d, J_{B-H} = 131.0 Hz), −19.4 (1B, d, J_{B-H} = 131.0 Hz). *Anal.* Calc. for $C_8H_{31}B_{12}NO$: C, 33.44; H, 10.88; N, 4.88. Found: C, 32.95; H, 10.76; N, 4.78%.

2.1.3. (Bu$_4$N)[B$_{12}$H$_{11}$O(CH$_2$)$_4$]

In another experiment the aqueous solution of crude Na[$B_{12}H_{11}O(CH_2)_4$] prepared as described above was treated with a solution of Bu_4NBr in water. The precipitate formed was filtered off, dried in air and recrystallised from methanol, giving the crystalline product in 88% yield. ^{1}H NMR ($CDCl_3$, ppm): 4.52 (4H, dt, –O(CH_2CH$_2$)$_2$), 3.21 (8H, m, Bu_4N^+), 2.15 (4H, dt, –O(CH$_2$CH_2)$_2$), 1.62 (8H, m, Bu_4N^+), 1.44 (8H, q, Bu_4N^+), 0.98 (12H, t, Bu_4N^+).

2.1.4. (Ph$_3$PMe)[B$_{12}$H$_{11}$O(CH$_2$CH$_2$)$_2$O]

0.7 ml (0.78 g, 5.5 mmol) $BF_3\times Et_2O$ was added to a stirred solution of 0.95 g (5.0 mmol) $Na_2[B_{12}H_{12}]$ in 70 ml 1,4-dioxane and the reaction mixture was stirred at room temperature for 1 week. The reaction mixture was filtered and the solvent was distilled off from the filtrate. The residue was dissolved in 70 ml water and treated with 4.05 g (10.0 mmol) Ph_3PMeI dissolved in 130 ml water. The precipitate formed was filtered, washed with water, and dried, giving 0.98 g (38%) of the product. ^{1}H NMR (MeCN-d_3, ppm): 7.7 (15H, t, *Ph*$_3$PMe$^+$), 4.47 (4H, t, –O(CH_2CH$_2$)$_2$O), 3.83 (4H, t, –O(CH$_2$CH_2)$_2$O), 2.8 (3H, d, Ph$_3$P*Me*$^+$). ^{13}C NMR (MeCN-d_3, ppm): 136.1 (d, *Ph*$_3$PMe$^+$), 134.2 (d, *Ph*$_3$PMe$^+$), 131.2 (d, *Ph*$_3$PMe$^+$), 120.0 (d, *Ph*$_3$PMe$^+$), 82.0 (–O(*C*H$_2$CH$_2$)$_2$O), 65.8 (–O(CH$_2$*C*H$_2$)$_2$O), 8.3 (d, Ph$_3$P*Me*$^+$). ^{11}B NMR (MeCN-d_3, ppm): 6.0 (1B, s), −16.7 (5B, d), −17.9 (5B, d), −22.7 (1B, d). *Anal.* Calc. for $C_{23}H_{37}B_{12}O_2P$: C, 54.52; H, 7.37. Found: C, 53.71; H, 7.75%.

2.1.5. Cs$_2$[B$_{12}$H$_{11}$OBu]

0.28 ml (0.31 g, 2.2 mmol) $BF_3\times Et_2O$ was added to a stirred suspension of 1.25 g (2.0 mmol) $(Bu_4N)_2[B_{12}H_{12}]$ in 100 ml tetrahydrofuran and the reaction mixture was refluxed overnight. The solution formed was evaporated to dryness. The residue was treated with 20 ml 1 M aqueous solution Na_2CO_3 and extracted with 100 ml dichloromethane. The residue was redissolved in 30 ml methanol and treated with 0.36 g (2.4 mmol) CsF in 10 ml methanol. The precipitate formed was filtered, washed with methanol and dichloromethane and dried in air, giving 0.75 g (78%) of the product. ^{1}H NMR (DMSO-d_6, ppm): 3.22 (2H, m, –OCH_2CH$_2$CH$_2$CH$_3$), 1.40–1.10 (4H, m, –OCH$_2$-CH_2CH_2CH$_3$), 0.82 (3H, t, –OCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR (DMSO-d_6, ppm): 68.0 (–O*C*H$_2$CH$_2$CH$_2$CH$_3$), 34.0 (–OCH$_2$*C*H$_2$CH$_2$CH$_3$), 19.1 (–OCH$_2$CH$_2$*C*H$_2$CH$_3$), 14.3 (–OCH$_2$CH$_2$CH$_2$*C*H$_3$).

2.1.6. (Ph$_4$P)$_2$[B$_{12}$H$_{11}$O(CH$_2$)$_4$OMe]

0.29 g (1.0 mmol) $(Me_4N)[B_{12}H_{11}O(CH_2)_4]$ was stirred in 200 ml 2 M NaOH solution in aqueous methanol (3:1) overnight. The solution formed was neutralised with 2 M HCl, concentrated to 70 ml and treated with 0.90 g (2.4 mmol) Ph_4PCl in 20 ml water. The precipitate formed was filtered, washed with water and dried in vacuo, giving 0.80 g (87%) of the product. ^{1}H NMR (DMSO-d_6, ppm): 8.0–7.6 (40H, m, Ph_4P^+), 3.20 (4H, m, –OCH_2CH$_2$CH$_2$CH_2OCH$_3$), 3.13 (3H, s, –OCH$_2$CH$_2$CH$_2$CH$_2$OCH_3), 1.33 (4H, m, –OCH$_2$CH_2CH_2CH$_2$OCH$_3$). ^{13}C NMR (DMSO-d_6, ppm): 135.5 (d, Ph_4P^+), 135.1 (d, Ph_4P^+), 130.6 (d, Ph_4P^+), 117.7 (d, Ph_4P^+), 72.4, 67.8, 57.7, 28.5, 26.1.

2.1.7. (Ph$_4$P)$_2$[B$_{12}$H$_{11}$O(CH$_2$)$_4$OH]

0.29 g (1.0 mmol) $(Me_4N)[B_{12}H_{11}O(CH_2)_4]$ in 70 ml 2 M aqueous NaOH was stirred with heating to 60°C for 4 h. The solution formed was neutralised with 2 M HCl and treated with 0.90 g (2.4 mmol) Ph_4PCl in 20 ml water. The precipitate formed was filtered, washed with water and dried in vacuo, giving 0.88 g (97%) of the product. ^{1}H NMR (DMSO-d_6, ppm): 8.0–7.6 (40H, m, Ph_4P^+), 4.57 (1H, t, –OCH$_2$CH$_2$CH$_2$CH$_2$O*H*), 3.4–3.1 (4H, m, –OCH_2-CH$_2$CH$_2$CH_2OH), 1.32 (4H, m, –OCH$_2$CH_2CH_2CH$_2$OH). ^{13}C NMR (DMSO-d_6, ppm): 135.4 (d, Ph_4P^+), 134.6 (d, Ph_4P^+), 130.5 (d, Ph_4P^+), 117.7 (d, Ph_4P^+), 68.1, 61.2, 30.3, 29.0. ^{11}B NMR (DMSO-d_6, ppm): 6.4 (1B, s), −16.8 (5B, d), −18.3 (5B, d), −23.2 (1B, d). IR (Nujol, cm^{-1}): 3519 (ν_{OH}), 2472 (ν_{BH}).

2.1.8. (Me$_4$N)$_2$[B$_{12}$H$_{11}$O(CH$_2$)$_4$N(CO)$_2$C$_6$H$_4$]

0.22 g (1.2 mmol) potassium phthalimide was added to a solution of 0.46 g (1.0 mmol) $(Bu_4N)[B_{12}H_{11}O(CH_2)_4]$ in 40 ml dimethylformamide and the reaction mixture was stirred overnight. The solvent was distilled off in vacuo and the residue was dissolved in 30 ml methanol. The solution was filtered and added to a solution 0.24 g (2.2 mmol) Me_4NCl in 10 ml methanol. The precipitate formed was fil-

tered, washed with methanol and dichloromethane and dried in air, giving 0.39 g (77%) of the product. ^{1}H NMR (DMSO-d_6, ppm): 7.83 (4H, m, C_6H_4), 3.52 (2H, t), 3.21 (2H, t), 3.08 (24H, s, Me_4N^+), 1.50 (2H, m), 1.30 (2H, m). ^{13}C NMR (DMSO-d_6, ppm): 168.0, 134.3, 131.6, 123.0, 67.5, 54.4 (t, Me_4N^+), 37.8, 29.5, 25.3.

2.1.9. $(Bu_4N)[B_{12}H_{11}O(CH_2)_4NH_3]$

1.0 ml hydrazine hydrate was added to a solution of 0.25 g (0.5 mmol) $(Me_4N)_2[B_{12}H_{11}O(CH_2)_4N(CO)_2C_6H_4]$ in 50 ml water and the reaction mixture was heated under reflux overnight. The reaction mixture was allowed to cool to room temperature and a solution of 0.64 g (2.0 mmol) Bu_4NBr in 20 ml water was added. The solution was then concentrated to 30 ml under vacuum at room temperature. The precipitate formed was filtered, washed with water and dried in air, giving 0.15 g (65%) of the crystalline product. ^{1}H NMR (DMSO-d_6, ppm): 7.67 (3H, s, $-OCH_2CH_2CH_2CH_2NH_3$), 3.29 (2H, t, $-OCH_2CH_2CH_2CH_2NH_3$), 3.15 (8H, m, Bu_4N^+), 2.69 (2H, t, $-OCH_2CH_2CH_2CH_2NH_3$), 1.56 (12H, m, $-OCH_2CH_2CH_2CH_2NH_3 + Bu_4N^+$), 1.29 (8H, q, Bu_4N^+), 0.92 (12H, t, Bu_4N^+). ^{13}C NMR (DMSO-d_6, ppm): 67.7, 57.5 (Bu_4N^+), 30.1, 26.8, 23.1 (Bu_4N^+), 19.7 (Bu_4N^+), 13.5 (Bu_4N^+). ^{11}B NMR (DMSO-d_6, ppm): 5.5 (1B, s), −16.9 (5B, d), −17.8 (5B, d), −22.3 (1B, d). IR ($CHCl_3$, cm^{-1}): 3179 (ν_{NH}), 2479 (ν_{BH}), 1621 (δ_{NH}). *Anal*. Calc. for $C_{20}H_{58}B_{12}N_2O$: C, 50.85; H, 12.37; B, 27.46; N, 5.93. Found: C, 50.97; H, 12.0; B, 27.28; N, 5.93%.

2.1.10. $Cs_2[B_{12}H_{11}O(CH_2)_4CHS_2(CH_2)_3]$

0.6 ml (1.5 mmol) 2.5 M solution of *n*-butyllithium in hexane was added at −30°C to a stirred solution of 0.10 g (0.8 mmol) 1,3-dithiane in 50 ml tetrahydrofuran and the solution was stirred at −30°C for 2 h. 0.23 g (0.5 mmol) $(Bu_4N)[B_{12}H_{11}O(CH_2)_4]$ was added and the reaction mixture was stirred at −30°C for 1 h and then at room temperature overnight. The solvent was distilled off in vacuo and the residue was dissolved in 30 ml methanol. The solution was filtered and treated with 0.18 g (1.2 mmol) CsF in 10 ml methanol. The precipitate formed was filtered, washed with methanol, dried in air, and dissolved in 10 ml water. The solution was then filtered, evaporated to half its volume, and treated with 70 ml methanol. The precipitate was collected by filtration, washed with methanol and ether, giving 0.22 g (73%) of the product. ^{1}H NMR (DMSO-d_6, ppm): 4.08 (1H, t, $-O(CH_2)_4CHS_2(CH_2)_3$), 3.18 (2H, m, $-OCH_2CH_2CH_2CH_2CHS_2(CH_2)_3$), 2.95–2.65 (4H, m, $-O(CH_2)_4CHS_2(CH_2)_2CH_2$), 2.10–1.60 (2H, m, $-O(CH_2)_4CHS_2(CH_2)_2CH_2$), 1.60–1.25 (6H, m, $-OCH_2CH_2CH_2CH_2CHS_2(CH_2)_3$). ^{13}C NMR (DMSO-$d_6$, ppm): 69.0 ($-OCH_2CH_2CH_2CH_2CHS_2(CH_2)_3$), 47.5 ($-O(CH_2)_4CHS_2(CH_2)_3$), 35.9 ($-OCH_2CH_2CH_2CH_2CHS_2(CH_2)_3$), 31.6 ($-OCH_2CH_2CH_2CH_2CHS_2(CH_2)_3$), 30.3 ($-O(CH_2)_4CHS_2(CH_2)_2CH_2$), 26.4, 23.7.

2.1.11. $(Bu_4N)_2[B_{12}H_{11}O(CH_2)_4CN]$

A solution of 0.23 g (0.5 mmol) $(Bu_4N)[B_{12}H_{11}O(CH_2)_4]$ and 0.16 g (0.5 mmol) tetrabutylammonium bromide in 50 ml dichloromethane was added to a solution of 0.05 g (1.0 mmol) sodium cyanide in 25 ml 1 M aqueous sodium hydroxide and the reaction mixture was stirred vigorously at room temperature overnight. The organic layer was separated, washed with water, dried over anhydrous $MgSO_4$, and evaporated to dryness, giving 0.35 g (97%) of the product. ^{1}H NMR ($CDCl_3$, ppm): 3.70 (2H, t, $-OCH_2CH_2CH_2CH_2CN$), 3.25 (16H, m, Bu_4N^+), 2.44 (2H, t, $-OCH_2CH_2CH_2CH_2CN$), 1.60 (20H, m, $-OCH_2CH_2CH_2CH_2CN + Bu_4N^+$), 1.43 (16H, q, Bu_4N^+), 0.97 (24H, t, Bu_4N^+). ^{13}C NMR ($CDCl_3$, ppm): 121.1 ($-OCH_2CH_2CH_2CH_2CN$), 67.6 ($-OCH_2CH_2CH_2CH_2CN$), 58.8 (Bu_4N^+), 30.0, 24.1 (Bu_4N^+), 22.6, 19.7 (Bu_4N^+), 16.7, 13.7 (Bu_4N^+). ^{11}B NMR ($CDCl_3$, ppm): 6.3 (1B, s), −16.3 (5B, d), −17.7 (5B, d), −22.3 (1B, d). IR ($CHCl_3$, cm^{-1}): 2470 (ν_{BH}), 2246 (ν_{CN}).

2.1.12. $(Bu_4N)_2[B_{12}H_{11}O(CH_2)_4COOH]$

A solution of 10.0 g potassium hydroxide in 25 ml water was added to a solution of 0.29 g (0.4 mmol) $(Bu_4N)_2[B_{12}H_{11}O(CH_2)_4CN]$ in 50 ml methanol and the reaction mixture was refluxed overnight. The solution was cooled to room temperature and adjusted to pH 3 by addition of hydrochloric acid. The reaction mixture was evaporated to dryness. The residue was treated with 200 ml of water and extracted twice with 200 ml of dichloromethane. The organic layer was dried over $MgSO_4$ and the solvent was distilled off, giving 0.26 g (88%) of the product. ^{1}H NMR ($CDCl_3$, ppm): 3.76 (2H, t, $-OCH_2CH_2CH_2CH_2COOH$), 3.24 (16H, m, Bu_4N^+), 2.63 (2H, t, $-OCH_2CH_2CH_2CH_2COOH$), 1.60 (20H, m, $-OCH_2CH_2CH_2CH_2COOH + Bu_4N^+$), 1.43 (16H, q, Bu_4N^+), 0.97 (24H, t, Bu_4N^+). ^{13}C NMR ($CDCl_3$, ppm): 177.2 ($-OCH_2CH_2CH_2CH_2COOH$), 69.7 ($-OCH_2CH_2CH_2CH_2COOH$), 58.7 (Bu_4N^+), 34.8, 27.6, 25.5, 24.1 (Bu_4N^+), 19.7 (Bu_4N^+), 13.7 (Bu_4N^+). ^{11}B NMR ($CDCl_3$, ppm): 5.7 (1B, s), −16.4 (5B, d), −17.6 (5B, d), −22.1 (1B, d). IR ($CHCl_3$, cm^{-1}): 2475 (ν_{BH}), 1717 (ν_{CO}).

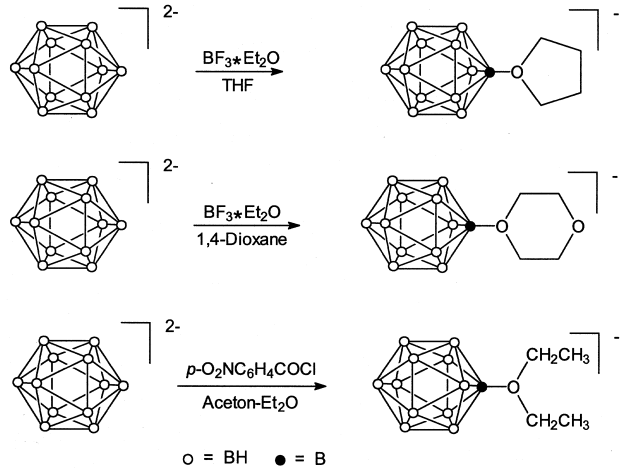
2.1.13. $Cs_2[B_{12}H_{11}O(CH_2)_4C(COOEt)_2NHCOMe]$

0.26 g (1.2 mmol) diethyl acetamidomalonate, 0.46 g (1.0 mmol) $(Bu_4N)[B_{12}H_{11}O(CH_2)_4]$, 0.32 g (1.0 mmol) Bu_4NBr, and 0.70 g (5.0 mmol) K_2CO_3 in 50 ml acetonitrile was refluxed overnight. The reaction mixture was cooled and filtered. The solvent was distilled off in vacuo, the residue was dissolved in 15 ml methanol and treated with 0.36 g (2.4 mmol) CsF in 10 ml methanol. The precipitate formed was filtered, washed with methanol and ether, giving 0.55 g (79%) of yellowish product. ^{1}H NMR (DMSO-d_6, ppm): 8.23 (1H, s, $NHCOCH_3$), 4.11 (4H, q, $COOCH_2CH_3$), 3.39 (2H, t, $-OCH_2CH_2CH_2CH_2C(NHCOMe)(COOEt)_2$), 2.00 (2H, t, $-OCH_2CH_2CH_2CH_2C(NHCOMe)(COOEt)_2$), 1.24 (4H, m, $-OCH_2CH_2CH_2CH_2C(NHCOMe)(COOEt)_2$),

1.13 (6H, t, $COOCH_2CH_3$). IR (Nujol, cm^{-1}): 3379 (ν_{NH}), 2477 (ν_{BH}), 1735 ($\nu_{CO(ester)}$), 1665 ($\nu_{CO(amide)}$).

2.1.14. Cs[$B_{12}H_{11}O(CH_2)_4CH(NH_3)COOH$]

0.21 g (0.3 mmol) was dissolved in 40 ml 2 M hydrochloric acid and the solution was refluxed overnight. The solvent was distilled off to dryness in vacuo and the residue was washed with methanol giving 0.08 g (63%) of the product. ^1H NMR (D_2O, ppm): 3.87 (1H, t, $–OCH_2(CH_2)_3CH(NH_3)COOH$), 3.52 (2H, t, $–OCH_2(CH_2)_3CH(NH_3)COOH$), 1.82 (2H, m), 1.71 (2H, m), 1.45 (2H, m). ^1H NMR (DMSO-d_6, ppm): 8.30 (3H, s, $–OCH_2(CH_2)_3CH(NH_3)COOH$), 3.87 (1H, t, $–OCH_2(CH_2)_3CH(NH_3)COOH$), 3.63 (2H, t, $–OCH_2(CH_2)_3CH(NH_3)COOH$), 1.74 (4H, m), 1.4 (2H, m). ^{11}B NMR (DMSO-d_6, ppm): 3.3 (1B, s), −16.4 (5B, d), −17.5 (5B, d), −22.3 (1B, d). IR (Nujol, cm^{-1}): 3218 (ν_{NH}), 2494 (ν_{BH}), 1730 (ν_{CO}), 1620 (δ_{NH}).



3. Results and discussion

The formation of stable oxonium charge-compensated derivatives seems to be one of the characteristic features of the chemistry of polyhedral boron hydrides. At present, a number of such compounds with side and cage-bridging oxonium atoms have been described, such as $[B_{12}H_{11}O(CH_2)_5]^-$ [8], [8-O(CH_2CH_2)$_2$O-3,3′-Co(1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)] [11], [8-X-8′-O(CH_2CH_2)$_2$O-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] (X = Br, I) [12,13], [3-(CO)$_2$-3-(η^3-C_3H_5)-8-Et_2O-3,1,2-$MoC_2B_9H_{10}$], [1,2-Me_2-3-(CO)$_2$-3-(η^3-C_3H_5)-8-Et_2O-3,1,2-$MC_2B_9H_8$] (M = Mo, W), [1,2-Me_2-3-(CO)$_2$-(η^3-C_3H_5)-8-O(CH_2)$_4$-3,1,2-$MoC_2B_9H_8$] [14], [3-(CO)$_3$-8-O(CH_2)$_4$-3,1,2-$MnC_2B_9H_{10}$] [15], ($Et_2C_2B_4H_4$)Co($Et_4C_4B_8H_7O(CH_2)_4$) [16], [1,1′-(μ-H)-2,2′-(μ-OR)-($B_{10}H_8$)$_2$]$^{2-}$ (R = Et, $O(CH_2)_4OMe$, $O(CH_2)_4O(CH_2)_2CHMe_2$) [17,18], [8,8′-(μ-OR)-3,3′-Co(1,2-$C_2B_9H_{10}$)$_2$] (R = Me, Et) [19], and [6,6′-μ-MeO-2,2′-Co(1,7-$C_2B_9H_{10}$)$_2$] [20].

In the literature until now, the only known oxonium derivative of the dodecahydro-*closo*-dodecaborate anion, $[B_{12}H_{11}O(CH_2)_5]^-$, has been obtained by alkylation of $[B_{12}H_{11}OH]^{2-}$ with 1,5-dibromopentane [8]. The formation of this oxonium derivative was supposed to favour the six-membered ring closing and no oxonium derivatives form in alkylation of $[B_{12}H_{11}OH]^{2-}$ with other alkyl halides [8,10].

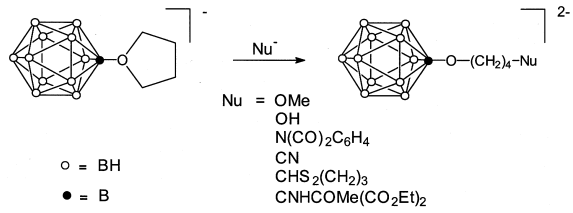
Most known oxonium derivatives of polyhedral boron hydrides have not been prepared by the alkylation reaction, but by the solvent molecule addition.

We here report that oxonium derivatives of the $[B_{12}H_{12}]^{2-}$ anion can also be obtained by the 'solvent addition' reaction. The reaction of $Na_2[B_{12}H_{12}]$ with boron trifluoride etherate in tetrahydrofuran at room temperature results in the formation of tetramethyleneoxonium derivative in high yield (Scheme 1).

Scheme 1.

We suppose that boron trifluoride in this reaction acts as a Lewis acid and abstracts hydride ion from the $[B_{12}H_{12}]^{2-}$ anion, giving $[HBF_3]^-$ [21] and $[B_{12}H_{11}]^-$ intermediates which react with the solvent molecule.

$$[B_{12}H_{12}]^{2-} \xrightarrow[-HBF_3^-]{BF_3*Et_2O} [B_{12}H_{11}]^- \xrightarrow{THF} [B_{12}H_{11}O(CH_2)_4]^-$$



The possibility of formation of the $[B_{12}H_{11}]^-$ intermediate was mentioned earlier by Knoth et al. [22], and its formation in acid-assisted substitution reactions from the $[B_{12}H_{12}]^{2-}$ anion is supported by calculations [23]. This mechanism is close to the 'electrophile-induced nucleophilic substitution' (EINS) mechanism [24], which is characterised by the following processes: (i) the electrophile removes the terminal hydrogen from the B–H vertex; (ii) the transient vacancy at this B-vertex is then filled by the best nucleophile or by the most abundant nucleophile present in the reaction medium.

The reaction of $(Bu_4N)_2[B_{12}H_{12}]$ with $BF_3 \times Et_2O$ in refluxing tetrahydrofuran did not give the tetramethyleneoxonium derivative, but the butoxy derivative. Formation of the butoxy derivative could be due to the initial formation of the tetramethyleneoxonium derivative followed by attack with $[HBF_3]^-$ at high temperature.

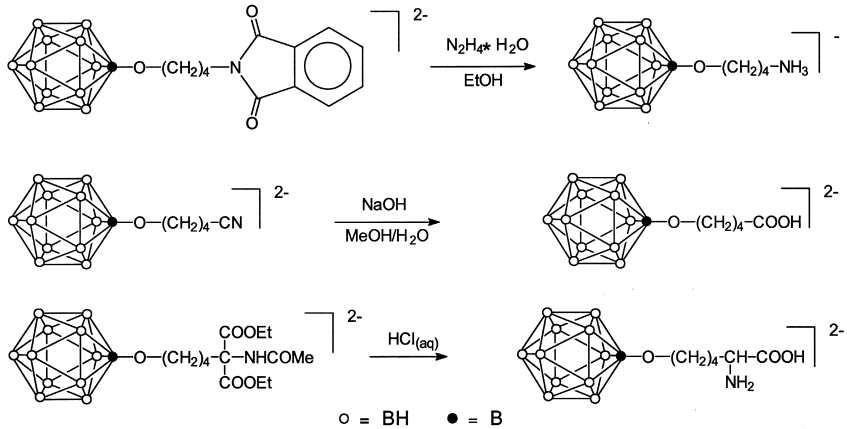
The reaction of $Na_2[B_{12}H_{12}]$ with $BF_3 \times Et_2O$ in 1,4-dioxane also leads to the corresponding oxonium derivative $[B_{12}H_{11}O(CH_2CH_2)_2O]^-$, but its yield is much lower because of the cluster decomposition during the reaction (Scheme 1).

The diethyloxonium derivative $[B_{12}H_{11}OEt_2]^-$ was prepared by reaction of $Na_2[B_{12}H_{12}]$ with *p*-nitrobenzoylchloride in acetone–diethyl ether mixture (Scheme 1). A possible reaction mechanism includes electrophilic attack of $[B_{12}H_{12}]^{2-}$ with *p*-$NO_2C_6H_4CO^+$ which results in the formation of $[B_{12}H_{11}]^-$ and the corresponding aldehyde and subsequent reaction of $[B_{12}H_{11}]^-$ with the solvent molecule. It was shown earlier that in the absence of diethyl ether the main product of the reaction is $[B_{12}H_{11}C(O)R]^{2-}$ [25].

Little is known about the reactivity of oxonium derivatives of polyhedral boranes. It has been shown that the treatment

Scheme 2.

of $[1,2\text{-}Me_2\text{-}3\text{-}(CO)_2\text{-}3\text{-}(\eta^3\text{-}C_3H_5)\text{-}8\text{-}Et_2O\text{-}3,1,2\text{-}MC_2B_9H_8]$ (M = Mo, W) with K-Selectride in dichloromethane results in the loss of one ethyl group with formation of the corresponding ethoxy derivatives [14]. The ring openings in $[B_{12}H_{11}O(CH_2)_5]^-$ under nucleophilic attack with hydroxide and fluoride ions [26], in $[8\text{-}I\text{-}8'\text{-}O(CH_2CH_2)_2O\text{-}3,3'\text{-}Co(1,2\text{-}C_2B_9H_{10})_2]$ under treatment with $C_5H_{11}ONa$ [13], in $[1,2\text{-}Me_2\text{-}3\text{-}(CO)_2\text{-}(\eta^3\text{-}C_3H_5)\text{-}8\text{-}O(CH_2)_4\text{-}3,1,2\text{-}MoC_2B_9H_8]$ with fluoride ions [14], and in $[3\text{-}(CO)_3\text{-}8\text{-}O(CH_2)_4\text{-}3,1,2\text{-}MnC_2B_9H_{10}]$ under treatment with Lewis bases (PPh_3, NEt_3, 4-MePy) and iodide ions [15], have been reported. Considering $[B_{12}H_{11}O(CH_2)_4]^-$ as a possible synthon for the synthesis of various derivatives of the *closo*-dodecaborate anion via ring opening, we investigated its reactions with different nucleophiles. We found that attack of strong nucleophilic agents results in the ring opening reaction, giving $[B_{12}H_{11}O(CH_2)_4Nu]^{2-}$ derivatives, where $Nu^- = OMe^-$, OH^-, $N(CO)_2C_6H_4^-$, $(CH_2)_3S_2CH^-$, CN^-, $C(COOEt)_2NHCOMe^-$ (Scheme 2).



It should be noted that treatment of $[B_{12}H_{11}O(CH_2)_4]^-$ with 2-lithio-1,3-dithiane in tetrahydrofuran at room temperature does not give the desired product and that 95% of the starting material was recovered. Refluxing of the reaction mixture gives the desired ring-opened product in less than 20% yield. However, the reaction of $[B_{12}H_{11}O(CH_2)_4]^-$ with 2,2-dilithio-1,3-dithiane proceeds smoothly at room temperature, giving the corresponding protected aldehyde in high yield. It is known that the lithium atom in 2-lithio-1,3-dithiane occupies the equatorial postion (the preference for the equatorial conformer is largely thermodynamically controlled) [27,28] and the unshared electron pairs of the sulfur atoms can prevent attack with sterically hindered electrophiles such as $[B_{12}H_{11}O(CH_2)_4]^-$. Heating increases the amount of the more reactive axial conformer, but at the same time results in destruction of the organolithium compound. Use of the dilithium derivative of 1,3-dithiane overcomes these sterical restrictions and results in the desired product in high yield.

An initial attempt at ring opening with cyanide in dimethylsulfoxide at 90°C [29] failed; however, the reaction under phase transfer conditions (method used earlier to open 1,2-epoxides [30]) using sodium cyanide and an equimolar amount of tetrabutylammonium bromide at room temperature was successful and gave the nitrile required, which can be readily converted to the coresponding acid by alkaline hydrolysis (Scheme 3).

Deprotection of $[B_{12}H_{11}O(CH_2)_4N(CO)_2C_6H_4]^{2-}$ with hydrazine hydrate gave unexpectedly the protonated amino derivative $[B_{12}H_{11}O(CH_2)_4NH_3]^-$ isolated at pH 8 (Scheme 3). The protonated form obtained can be considered as an inner salt stabilised by formation of the intramolecular hydrogen bond between the ammonium proton and the oxygen atom or the intramolecular B–H···H–N dihydrogen bond similar to the corresponding dihydrogen bonds found in ammonium salts of the dodecahydro-*closo*-dodecaborate anion [31,32].

The first amino acid derived from the *closo*-dodecaborate anion was prepared by the ring-opening reaction with diethyl acetamidomalonate (glycine anion equivalent for amino acid synthesis) in acetonitrile in the presence of potassium carbonate, a variation of the classical Sörensen synthesis of amino acids, followed by acidic hydrolysis and decarboxylation.

The synthesis described here of the tetramethylene oxonium derivative of the *closo*-dodecaborate $[B_{12}H_{11}\text{-}O(CH_2)_4]^-$ anion followed by ring opening under nucleophilic attack is a powerful instrument for the synthesis of various functional derivatives and synthetic building blocks on the basis of the $[B_{12}H_{12}]^{2-}$ anion. The compounds prepared can be used not only for boron neutron capture therapy, but also as carriers of radioactive halogen labels for radioimmunodetection and for radioimmunotherapy [33–35].

Abstract

In the NMR and ESR time-scale of this experiment, an attempt was made to prepare the copper sitting-atop (SAT) species $[Cu(H_2tptp)]^{2+}$ by the reaction of $Cu(CF_3SO_3)_2$ with *meso-p*-tolyl-porphyrin (H_2tptp) in $CDCl_3$; however, this led to the formation of *meso-p*-tolyl-porphyrinatocopper(II) Cu(tptp) and the protonated porphyrin $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (**2a**). Previous researchers might have misinterpreted the SAT $[Cu(H_2tpp)]^{2+}$ complex as being a single component instead of a mixture of $[H_4tpp]^{2+}[CF_3SO_3]_2^-$ (**1**) and Cu(tpp) for a similar reaction between 5,10,15,20-tetraphenylporphyrin H_2tpp and $Cu(CF_3SO_3)_2$ in CH_3CN. This work determines the crystal structure of Cu(tptp) and its hyperfine constants $a_{Cu} = 94.0$ G and $a_N = 15.8$ G using ESR. The crystal structure of $[H_4tptp]^{2+}[CH_3SO_3]_2^-$ (**3**) is reported and employed to simulate the groupings of $[H_4tptp]^{2+}$ and $CF_3SO_3^-$ in the di-cation ion-pair complex **2a**. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Previously, Inada et al. [1,2] reported on the formation of the 'sitting-atop' (SAT) complex $[Cu(H_2tpp)]^{2+}$ via the reaction of $Cu(CF_3SO_3)_2$ with 5,10,15,20-tetraphenylporphyrin (H_2tpp) in acetonitrile under a dry nitrogen atmosphere. We have not been successful in synthesizing the complex $[Cu(H_2tpp)]^{2+}$ by repeating the previous work [1] using the same solvent acetonitrile. According to their suggestion, the reaction of $Cu(CF_3SO_3)_2$ with H_2tpp in $CHCl_3$ in the absence of a strong base should be easily arrested at the formation of the SAT complex because of the low donor number (DN) of $CHCl_3$. It is known that the donor number of chloroform (DN = −) is less than that of acetonitrile (DN = 14.1) [3]. Hence, we did not investigate the reaction in the same solvent, i.e. chloroform. However, the SAT complex $[Cu(H_2tpp)]^{2+}$ is not detected in the reaction of $Cu(CF_3SO_3)_2$ with H_2tpp in $CDCl_3$ under a dry N_2 atmosphere; instead, a mixture (A) consisting of Cu(tpp) and $[H_4tpp]^{2+}[CF_3SO_3]_2^-$ (**1**) is observed. The proton NMR spectrum (^{1}H NMR) for the Cu(tpp) in mixture A in $CDCl_3$ shows a broad multiplet at 7.50 ppm for *meta*-hydrogens and at 7.64 ppm for *para*-hydrogens (see Fig. 1 and Table 1). The ^{1}H NMR values are quite close to those of 7.48 ppm (*meta*-H) and 7.62 ppm (*para*-H) for the compound Cu(tpp) reported by Godziela and Goff [4]. The ^{1}H NMR data for **1** in mixture A in $CDCl_3$ at 24°C (see Fig. 1 and Table 1) showed a singlet at 8.73 ppm (8H) for β-pyrrole protons, a doublet at 8.61 ppm (8H) for *ortho*- protons and a multiplet at 8.00 ppm (12H) for *meta*- and *para*- protons, and a singlet at −1.84 ppm (with 4H) for the N-H protons. Our interpretation of these data differs from that of Inada et al. [1,2]. Inada et al. [1,2] might have misinterpreted the mixture A as the SAT complex $[Cu(H_2tpp)]^{2+}$. The ^{1}H NMR data for their SAT complex in CD_3CN at room temperature (see Table 1) showed a singlet at 8.77 ppm (4H)

[a] ^3J(H–H) coupling constant.
[b] Compound **3** was obtained by protonation of H_2tptp with CH_3SO_3H.
[c] Compound **2b** (or **1**) was obtained by protonation of H_2tptp (or H_2tpp) with CF_3SO_3H.
[d] Mixture B = **2a** + Cu(tptp).
[e] Mixture A = **1** + Cu(tpp).
[f] m = multiplet.

for the coordinating β-pyrrole protons, a doublet at 8.66 ppm (4H) for the uncoordinating β-pyrrole protons, one multiplet at 8.10–8.12 ppm for *ortho*-phenyl protons and another multiplet at 7.31–7.50 ppm for the *meta*- and *para*-phenyl protons, and a singlet at −2.05 ppm (2H) for pyrrole N-H [1,2]. If the doublet centered at 8.61 ppm is due to the long-range

coupling of β-protons with a nitrogen-bonded proton of the same pyrrole ring, the ^4J(H–H) coupling constant should be less than 4 Hz [5,6]. However, the coupling constant of 6.9 Hz is reasonably assigned to adjacent ^{1}H–^{1}H coupling, ^3J(H–H). Furthermore, the doublet at 8.61 ppm remains unchanged on irradiating the NH proton at δ −1.84 ppm. In addition, the doublet for the *ortho*- protons becomes a singlet on irradiating the *meta*- and *para*-phenyl protons at 8.00 ppm. Thus the ^{1}H NMR spectral data support the composition of mixture A proposed by us and disagree with the SAT complex reported previously [1,2].

When the porphyrin group (tpp) was substituted using *meso-p*-tolyl-porphyrin (tptp), a mixture B consisting of *meso-p*-tolyl-porphyrinatocopper(II) Cu(tptp) and the protonated porphyrin $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (**2a**) was formed via the reaction of $Cu(CF_3SO_3)_2$ with H_2tptp in $CDCl_3$. Cu(tptp) was crystallized out in mixture B and its X-ray structure is reported here. Both Cu(tptp) and **2a** in mixture B were characterized using ESR, ^{1}H, ^{13}C and ^{19}F NMR methods.

2. Experimental

2.1. Preparation of mixture B consisting of Cu(tptp) and $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (2a)

H_2tptp (0.5 mmol) and $Cu(CF_3SO_3)_2$ (1 mmol, from TCI) were dissolved in $CDCl_3$ (15 cm^3, 99.8% from Aldrich) under a nitrogen atmosphere and the mixture was stirred at room temperature for 12 h. After the removal of unreacted $Cu(CF_3SO_3)_2$ through filtration, the filtrate consisting of Cu(tptp) and **2a** (i.e. the mixture B) was studied using NMR (Fig. 2) and ESR (Fig. 3) spectroscopy. Meanwhile, a blue–purple crystal of Cu(tptp) was grown by slow evaporation of $CDCl_3$ from the solution of mixture B.

2.2. Preparation of $[H_4tptp]^{2+}[CH_3SO_3]_2^-$ (3) and $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (2b)

Compound **3** (or **2b**) was obtained by protonation of H_2tptp (1 mmol) with 3 mmol of CH_3SO_3H (or CF_3SO_3H) in $CHCl_3$. Compound **3** was dissolved in $CHCl_3$ and layered with benzene. After 2 weeks, blue–green and equant shape crystals of complex **3** were obtained for single-crystal X-ray analysis. ^{1}H (or ^{13}C, or ^{19}F) NMR data for **2b** and **3** are shown in Table 1 (or Table 2), respectively.

2.3. NMR spectra

^{1}H and ^{13}C NMR spectra in $CDCl_3$ were recorded at 400.13 and 100.61 MHz, respectively, on a Bruker AM-400 spectrometer. The ^{19}F NMR spectra were measured in $CDCl_3$ at 376.76 or 282.40 MHz, on a Varian Mercury-400 or Bruker MSL-300 spectrometer. The reference peaks in ^{1}H NMR and ^{13}C NMR are relative to $CHCl_3$ at 7.24 ppm and the center line of $CDCl_3$ at 77.0 ppm, respectively. ^{19}F data are externally relative to $CFCl_3$.

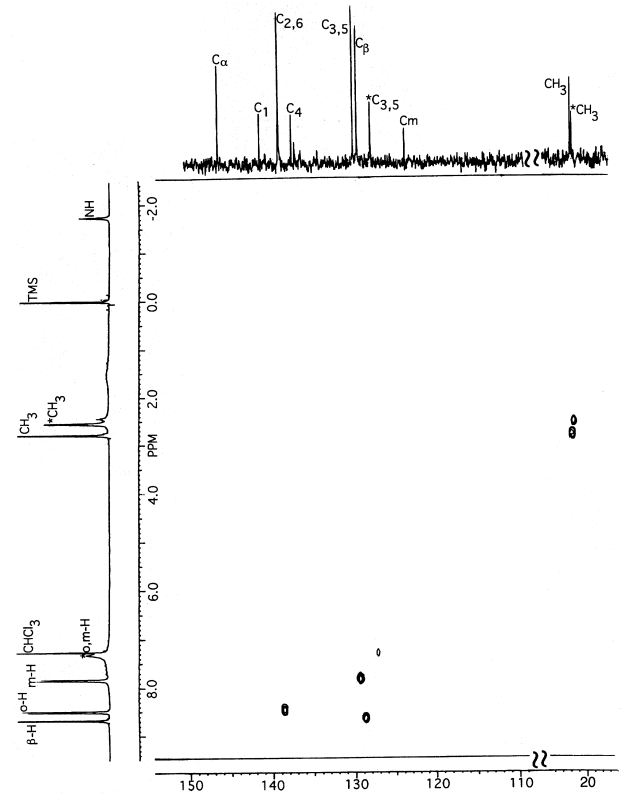

Fig. 2. The C-H COSY spectrum for the mixture B consists of Cu(tptp) and complex **2a** in $CDCl_3$ at 24°C. Resonances due to Cu(tptp) are labeled with an asterisk (*).

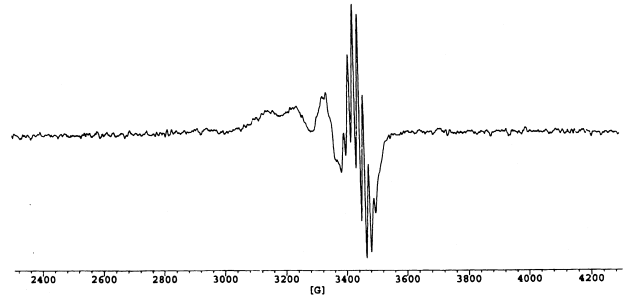

Fig. 3. The first derivative ESR spectrum for Cu(tptp) of mixture B in $CDCl_3$ at 24°C.

2.4. ESR spectra

ESR spectra were obtained with a Bruker EMX-10 X-band spectrometer system operating at 9.726 GHz with 100 kHz field modulation.

2.5. Crystallography

Table 3 presents crystal data and other information for Cu(tptp) and $[H_4tptp]^{2+}[CH_3SO_3]_2^- \cdot 2CHCl_3$ (**3**·2$CHCl_3$). Measurements were taken on a Siemens SMART CCD diffractometer using monochromatic Mo Kα radiation

3. Results and discussion

3.1. Molecular structure of Cu(tptp)

Crystals of Cu(tptp) were obtained by slow evaporation of $CDCl_3$ from the mixture B. Fig. 4(a) illustrates the skeletal framework of complex Cu(tptp), with $P2_1/n$ symmetry. This

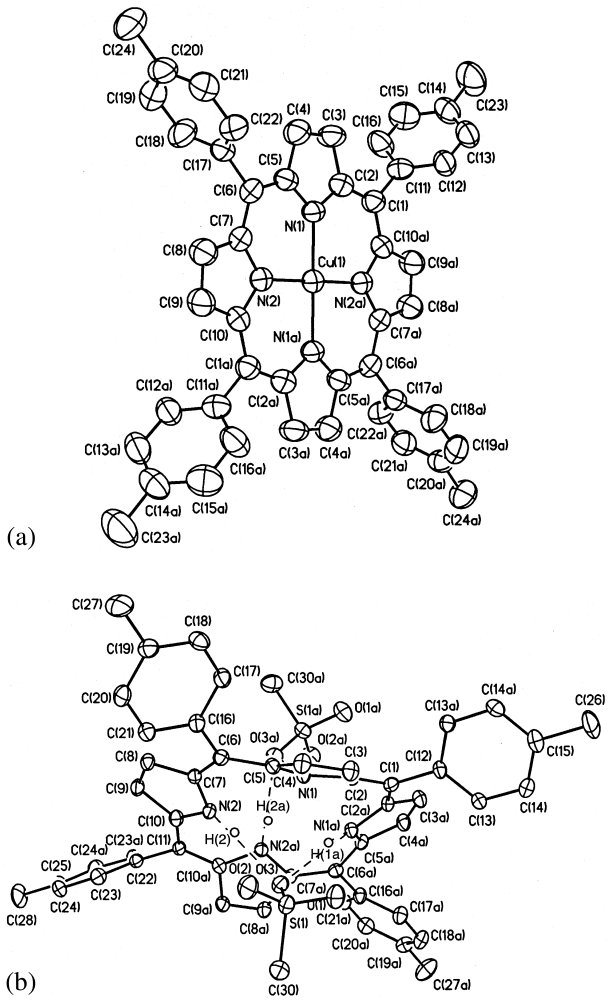

Fig. 4. Molecular configuration and atom-labeling scheme for (a) Cu(tptp) and (b) $\mathbf{3}\cdot 2CHCl_3$, with ellipsoids drawn at 20% probability. The refined positions of the hydrogen atoms bonded to the pyrrole nitrogens are shown for $\mathbf{3}\cdot 2CHCl_3$; all other hydrogen atoms for both compounds and solvents C(29)H(29a)Cl(1)Cl(2)Cl(3) for $\mathbf{3}\cdot 2CHCl_3$ are omitted for clarity.

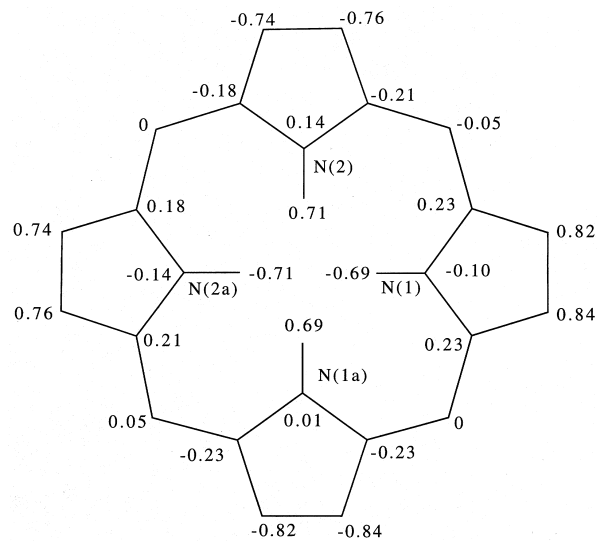
structure has a four-coordinate copper with four nitrogen atoms of the porphyrinato group. Bond distances are Cu(1)–N(1) = 2.000(4) and Cu(1)–N(2) = 1.994(4) Å. The $C_{20}N_4$ core is essentially planar. The Cu(1) sits at the inversion center, so the angles N(1)–Cu(1)–N(1a) and N(2)–Cu(1)–N(2a) are 180.0(1)°. The dihedral angles between the mean plane of the skeleton ($C_{20}N_4$) and the planes of the phenyl groups are 68.4° (C(14)) and 87.5° (C(20)).

The radius of the central hole ($C_{t'}\cdots N$, the distance from the geometrical center $C_{t'}$ of the mean plane of the 24-atom core to the porphyrinato-core N atoms) is 1.997 Å (or ~2.00 Å) which is similar to the value of ~2.01 Å suggested by Collins and Hoard [7]. Hence, the copper(II) atom is bonded and centered in a porphyrinato core ($C_{20}N_4$) with 'radial strain' being minimized. The average distance of 1.997 Å in Cu(tptp) is comparable with the observed Cu–N distances of 1.981 Å in Cu(tpp) [8], 1.998 Å in Cu(oep) (H_2oep = octaethylporphyrin) [9], 1.997 Å in Cu(oetpp) (H_2oetpp = octaethyltetraphenylporphyrin) [10], 1.984 Å in CutTEtpp (H_2tTEtpp = 2,3,12,13-tetraethyl-5,10,15,20-tetraphenylporphyrin), 1.975 Å in CucTEtpp (H_2cTEtpp = 2,3,7,8-tetraethyl-5,10,15,20-tetraphenylporphyrin) and 1.980 Å in CuHEtpp (H_2HEtpp = 2,3,7,8,12,13-hexaethyl-5,10,15,20-tetraphenylporphyrin) [11]. Interestingly, the structure of Cu(tptp) is also isomorphic to that of *meso-p*-tolyl-porphyrinatozinc(II) Zn(tptp) [12].

3.2. The crystal structure of $[H_4tptp]^{2+}[CH_3SO_3]_2^-\cdot 2CHCl_3$ ($\mathbf{3}\cdot 2CHCl_3$)

Each porphyrin nucleus is associated with two complex anions $CH_3SO_3^-$ (Fig. 4(b)). First, the contacts between the porphyrin nitrogen atoms N(2) (or N(1a)) and O(3) of the anion are 2.866 (or 2.927 Å), and these are short enough to permit hydrogen bonding of the type N–H···O. The mean N···O distance in these types of hydrogen bonds is calculated as 2.90 Å. Second, the H···O distances (based on the refined hydrogen atom positions) are 1.94 Å for O(3)···H(2) and 1.98 Å for O(3)···H(la). The mean H···O distance in hydrogen bonds is calculated as 2.60 Å. Third, the values of N–H···O angles are close to linear values with 171.5° for N(2)–H(2)···O(3) and 163.2° for N(la)–H(1a)···O(3). All these results indicate that two triflate anions are hydrogen bonded to the pyrrole hydrogens in a monodentate bridging fashion, with one O(3) (or O(3a)) bonded to two opposite N-H protons, i.e. H(2) and H(la) (or H(1) and H(2a)), on the same face of the porphyrin [13]. The four phenyl group–porphyrin dihedral angles in $\mathbf{3}\cdot 2CHCl_3$ are 35.4° (C(15)), and 31.4° (C(19a)), 40.0° (C(25)) and 31.4° (C(l9)). These dihedral angles are quite acute, averaging only 34.6°. They are slightly larger than the average 27° in $[H_2tpp][ClO_4]_2$ but smaller than 63° (or 75°) in $[H_4tmp][ClO_4]_2$ [14]. The distortion ($C_{20}N_4$) of $\mathbf{3}\cdot 2CHCl_3$ is saddle shaped. Fig. 5 depicts the displacement (in Å) of each atom of the



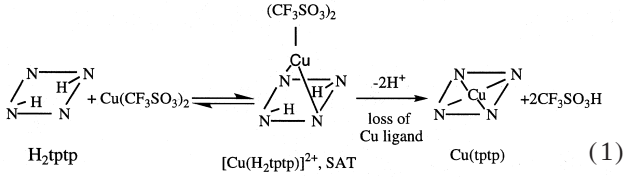


Fig. 5. Schematic diagram of the porphyrin core ($C_{20}N_4$) and four inner hydrogen atoms of $\mathbf{3}\cdot 2CHCl_3$ in which each atom symbol is replaced by a number showing the displacement (in Å) of that atom from the mean plane of the porphyrin ($C_{20}N_4$) with a typical esd of 0.003 Å.

porphyrin from the porphyrin mean plane ($C_{20}N_4$) as well as displacements of the four central hydrogen atoms. The pyrrole NH protons are alternately displaced above and below the 24-atom mean plane by −0.69 Å for H(1), 0.71 Å for H(2), −0.71 Å for H(2a), and 0.69 Å for H(1a). The out-of-plane displacements of the inner hydrogen atoms help to relieve steric strain [15]. The groupings of $[H_4tptp]^{2+}$ and $CH_3SO_3^-$ of **3** in $CDCl_3$ retain their basic properties when bonded together by hydrogen bonds called an ion-pair. Although the structures of Cu(tpp) [8], Cu(oep) [9], Cu(oetpp) [10], CutTEtpp [11], CucTEtpp [11], CuHEtpp [11] and the di-cation of tetraarylporphyrin species $[H_4por](ClO_4)_2$ [14], $[H_4por](TFA)_2$ (TFA = trifluoroacetate) [15], and $[H_4por](OAc)_{3/2}(TFA)_{1/2}$ [15] (por = tpp, oep, oetpp) have already been published, Cu(tptp) and **3** are two new crystal structures with different porphyrin (tptp) and counter ion ($CH_3SO_3^-$).

*3.3. NMR spectra of Cu(tptp) and $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (**2a**) in mixture B*

The net reaction of $Cu(CF_3SO_3)_2$ with H_2tptp in $CDCl_3$ is known by Eqs. (1) and (2), where **2a** is a di-cation ion-pair complex [16].

(1)

$$H_2tptp + 2CF_3SO_3H \rightarrow [H_4tptp]^{2+}[CF_3SO_3]_2^- \quad (2)$$
(**2a**)

The SAT complex $[Cu(H_2tptp)]^{2+}$ has been proposed as an intermediate. Loss of the N-H protons and $CF_3SO_3^-$ ligand produces Cu(tptp) and CF_3SO_3H. Finally, protonation of the remaining H_2tptp produces the ion-pair complex **2a** between the *meso*-*p*-tolyl-porphyrin di-cation $[H_4tptp]^{2+}$ and triflate ($CF_3SO_3^-$). Only Cu(tptp) and complex **2a** are observed by ^1H NMR in our system. The ^1H NMR spectrum for Cu(tptp) in mixture B in $CDCl_3$ (see Table 1 and Fig. 2) shows *m*-phenyl signals at 7.30 ppm and methyl protons at 2.53 ppm. These values are quite close to the corresponding signals at 7.30 ppm for the *m*-phenyl protons and 2.52 ppm for the methyl protons in complex Cu(tptp) reported by Godziela and Goff [4]. The N-H signals are downfield shifted by ~1.03 ppm from −2.79 (for H_2tptp) to −1.76 ppm for complex **2a** by protonation. The similar downfield shift due to protonation is also reflected by observing a 4.2–4.7 ppm downfield shift of N-H at −2.588 and −2.672 ppm for H_2Cttp (**4**) (2-aza-21-carba-5,10,15,20-tetra-*p*-tolylporphyrin), compared to 2.034, 1.877 and 1.612 ppm for $[\mathbf{4}\text{-}H_2]^{2+}$ [17]. In complex **2a**, the integrated peak areas are 8:8:8:4 for the β-pyrrole:*o*-phenyl:*m*-phenyl:N-H protons, respectively. Owing to the paramagnetic copper(II) ion in Cu(tptp), the ^{13}C NMR spectrum of Cu(tptp) (see Fig. 2 and Table 2) shows only two peaks at 127.1 ($C_{3,5}$) and 21.4 ppm (*p*-CH_3). The ^{13}C, ^{19}F and ^1H NMR data for **2a** in mixture B shown in Tables 1 and 2 are consistent with those of $[H_4tptp]^{2+}[CF_3SO_3]_2^-$ (**2b**) obtained by protonation of H_2tptp using CF_3SO_3H. Notably, these consistencies suggest that complex **2a** is **2b**. Furthermore, the ^{13}C (or ^{19}F) resonance of $CF_3SO_3^-$ for compound **2a** at $\delta = 116.2$ ppm with ^1J(C–F) coupling constant 318 Hz (or −81.2 ppm) is different from that of free ionic $CF_3SO_3^-$, i.e. $Bu_4N^+CF_3SO_3^-$, with $\delta = 121.0$ and ^1J(C–F) = 321 Hz (or −78.7 ppm) at room temperature [18,19]. Hence, the mutual geometric arrangement of the $[H_4tptp]^{2+}$, $CF_3SO_3^-$ and the solvent $CDCl_3$ in complex **2a** is explained as ion pairs. The intramolecular electric fields in the ion-pair complex **2a** cause considerable upfield shifts of −4.8 ppm (from 121.0 to 116.2 ppm) for the triflate carbon and about −2.5 ppm (from −78.7 to −81.2 ppm) for the ^{19}F resonance in the same complex [20]. When the CF_3^- of **2a** was replaced by a CH_3^- group, the complex **2a** became $[H_4tptp]^{2+}[CH_3SO_3]_2^-$ (**3**). In the absence of the crystal structure of **2a**, the close resemblance of ^{13}C and ^1H data (shown in Tables 1 and 2) for the di-cation $[H_4tptp]^{2+}$ of **2b** and **3** indicates a similar structure for these two complexes. Two $CH_3SO_3^-$ anions axial and hydrogen-bonded to the pyrrole hydrogen in **3** (shown in Fig. 4(b)) suggest that two $CF_3SO_3^-$ might be located on the axial position of the porphyrin ring ($C_{20}N_4$) of **2a**. The upfield shift of about −3.3 ppm (from 41.3 (obtained from free $CH_3SO_3^-$, i.e. $Cs^+CH_3SO_3^-$) [19] to 38.0 ppm) for carbon of CH_3SO_3 in **3** is due to the same electric field as in complex **2a**. Nevertheless, the ^1H chemical shift of CH_3SO_3 in **3** experienced an upfield shift of −0.15 ppm from 2.8 (obtained from free $CH_3SO_3^-$) [19] to 2.65 ppm, being controlled by the ring current effect.

3.4. ESR spectra for Cu(tptp) in mixture B

Cu(tptp) are paramagnetic because of the d^9 configuration of Cu(II). The unpaired electron resides in the $d_{x^2-y^2}$ orbital, which leads to characteristic EPR spectra for Cu(tptp): four peaks due to the nuclear spin ($I = 3/2$) of the Cu and super-hyperfine interaction with the four nitrogens ($I = 1$) of the porphyrin. Cu(tptp) in $CDCl_3$ exhibits a typical Cu(II) porphyrin EPR spectrum as shown in Fig. 3. The experimental spectrum yields $a_{Cu} = 94.0$ G and four nitrogens with $a_N = 15.8$ G. These data are similar to those reported, $a_{Cu} = 90.5$ G and $a_N = 15.8$ G for Cu(tpp) [21], $a_{Cu} = 90$ G and $a_N = 15$ G for Cu(oep) [9], or $a_{Cu} = 86.5$ G and $a_N = 14.4$ G for Cu(oetpp) [10].

4. Conclusions

Inada postulated that in the reaction of Cu(II) with H_2tpp in CH_3CN, an intermediate complex species forms,

$[Cu(H_2tpp)]^{2+}$, in which the metal stays above the tetra-aza plane. We have repeated the reaction using a slightly different porphyrin (H_2tptp) in less basic solvent $CDCl_3$, and have crystallized from the solution the Cu(tptp) and the doubly protonated ligand $[H_4tptp]^{2+}[CF_3SO_3]^-$ (**2a**), which demonstrates that the H_2tptp acts simultaneously as Cu^{2+} complexation and as a proton receptor.

Amine-oxide-mediated oxidative methanolysis of metal–metal bonds in $[MM'(CO)_{10}]$ (M = Mn, Re; M′ = Re) and $[Os_3(CO)_{12}]$: crystal structure of *fac*-$[Re\{OC(O)OMe\}(CO)_3(\eta^2\text{-dppf})]$

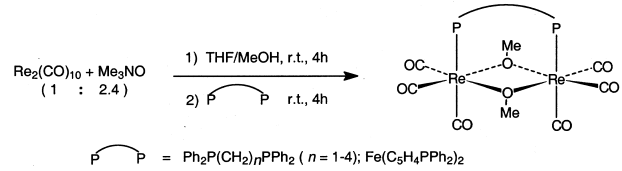
Abstract



The reaction of 1,1′-bis(diphenylphosphino)ferrocene (dppf) with a mixture of $[MnRe(CO)_{10}]$, MeOH and Me_3NO afforded the complexes *fac*-$[MnH(CO)_3(\eta^2\text{-dppf})]$ and $[Re_2(\mu\text{-OMe})_2(\mu\text{-dppf})(CO)_6]$. In the one-pot reaction of $[Re_2(CO)_{10}]$ with Me_3NO, MeOH and dppf, the major mononuclear Re species isolated was the CO_2-inserted complex *fac*-$[Re\{OC(O)OMe\}(CO)_3(\eta^2\text{-dppf})]$, the crystal structure of which was determined. The coordination sphere of the rhenium atom is roughly octahedral, consisting of an oxygen atom from the methyl carbonate ligand, two phosphorus atoms from a chelating dppf ligand, and three carbon atoms from a facial arrangement of three terminally bonded carbonyls. Analogous Me_3NO-mediated methoxylation reactions involving $[Os_3(CO)_{12}]$ were also investigated. With a $[Me_3NO]:[Os_3(CO)_{12}]$ ratio of 2:1, the major product is $[Os_3(CO)_{10}(\mu\text{-H})(\mu\text{-OMe})]$. With three molar equivalents of Me_3NO, significant quantities of $[Os_3(CO)_{10}(\mu\text{-OMe})_2]$ are also obtained. ©2000 Elsevier Science Ltd All rights reserved.

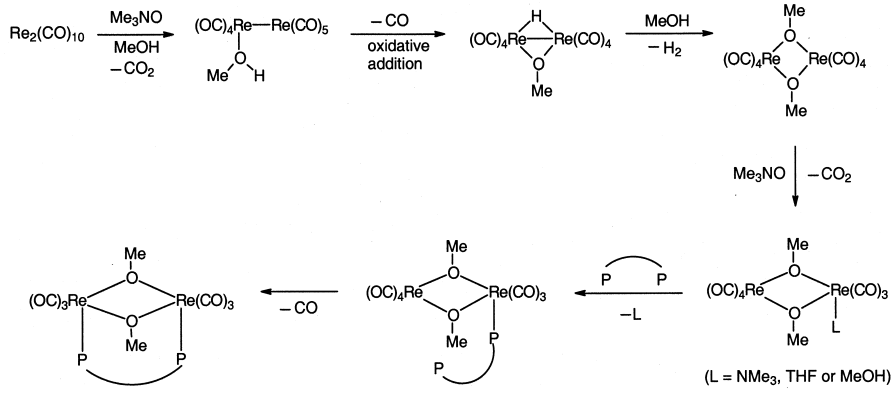
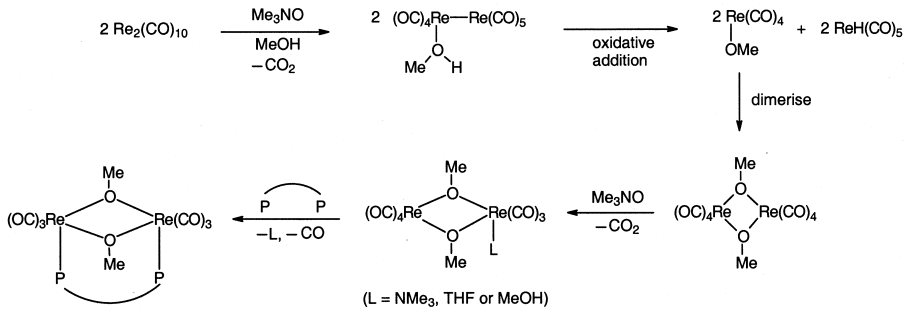
1. Introduction

Transition-metal carbonyl hydroxides and alkoxides have been proposed as intermediates in a number of important reactions, such as metal-catalysed hydrogenation of CO [1], the water-gas shift reaction [2], and carboalkoxylation of olefins [3]. They are also molecular models of silica-anchored $M(CO)_n$ species, the only structural difference between alkoxy and surfaced anchored complexes being that the –OR group is replaced by an –OSi≡ group [4].

We have reported the facile synthesis of a series of dimethoxo-bridged complexes $[Re_2(\mu\text{-OMe})_2(\mu\text{-PP})(CO)_6]$ (PP = dppf (1,1′-bis(diphenylphosphino)ferrocene) or $Ph_2P(CH_2)_nPPh_2$, $n = 1$–4) by the addition of diphosphines to a mixture obtained from the reaction of $[Re_2(CO)_{10}]$ with Me_3NO in THF–MeOH mixture at room temperature (Scheme 1) [5,6]. The facile rupture of the Re–Re bond under such mild conditions is in sharp contrast to the general observation that metal–metal bonds are quite resistant to thermal cleavage [7,8] and that Re–Re bond alcoholysis requires rather drastic conditions, such as refluxing in methanolic KOH [9].



Scheme 1.



At first, a mechanism for the Me_3NO-aided oxidative methoxylation reaction in which the originally bonded Re atoms in $[Re_2(CO)_{10}]$ remain paired in the same molecule of the product $[Re_2(\mu\text{-OMe})_2(\mu\text{-PP})(CO)_6]$ (Scheme 2) seemed plausible [10]. We then extended our investigations to the reaction of $[Re_2(CO)_{10}]$ with Me_3NO and phenol, which yielded the complexes $[Re_3(\mu\text{-H})(CO)_{14}]$ and $[Re_2(\mu\text{-OPh})_3(CO)_6]^-$ [11]. This suggested a mechanism involving the separation of the Re atoms of $[Re_2(CO)_{10}]$ into mononuclear hydrido and phenoxo species, followed by dimerisation of the phenoxo species to form the bis(phenoxo)-bridged intermediate $[Re_2(\mu\text{-OPh})_2(CO)_8]$ [11]. It seemed probable that the oxidative methoxylation reaction also follows a similar pathway involving Re–Re

Scheme 2.

Scheme 3.

bond heterolysis, but we have not been able to observe any rhenium hydrido species in this reaction. The reaction of $[Re_2(CO)_{10}]$ with Me_3NO and methanol (without diphosphine) yields $[Me_3NH]^+[Re_3(\mu_3\text{-}OMe)(\mu\text{-}OMe)(\mu\text{-}OH)_2(CO)_9]^-$ as the only isolable product [11].

In an effort to throw more light onto the mechanism of Me_3NO-aided oxidative methoxylation, we studied the reaction of dppf with the mixture of $[MnRe(CO)_{10}]$, MeOH and Me_3NO. The products of this reaction should indicate whether the Re and Mn atoms are separated during the reaction. Formation of the homometallic complexes $[Re_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ and/or $[Mn_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ would support the M–M bond heterolysis mechanism. The results of this study are reported in this paper. We also report a similar amine-oxide mediated methoxylation of Os–Os bonds in the cluster $[Os_3(CO)_{12}]$ to form $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(CO)_{10}]$ and $[Os_3(\mu\text{-}OMe)_2(CO)_{10}]$. These methoxo clusters were first reported in 1968 [12], but to date no convenient one-pot synthesis giving high yields of these clusters from $[Os_3(CO)_{12}]$ has been reported [4,13–16].

2. Results and discussion

2.1. Reaction of dppf with $MnRe(CO)_{10}$, MeOH and Me_3NO

The reaction of dppf with the mixture of $[MnRe(CO)_{10}]$, MeOH and Me_3NO afforded the complexes *fac*-$[MnH(CO)_3(\eta^2\text{-dppf})]$ (8%), $[Re_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ (26%) and a trace amount of *fac*-$[ReCl(CO)_3(\eta^2\text{-dppf})]$. These results confirm the occurrence of metal–metal bond cleavage and the formation of metal hydride intermediates in the reaction. The mechanism for the formation of $[Re_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ from the reaction of dppf with $[Re_2(CO)_{10}]$, MeOH and Me_3NO is therefore proposed as shown in Scheme 3.

Interestingly, the complexes $[Mn_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ and $[ReH(CO)_3(\eta^2\text{-dppf})]$ are not observed as products of the reaction, probably because these complexes are unstable under the conditions of the reaction and isolation of products. The complex $[ReCl(CO)_3(\eta^2\text{-dppf})]$ is likely to be produced from the reaction of initially formed $[ReH(CO)_3(\eta^2\text{-dppf})]$ with CH_2Cl_2 used during the isolation of products by TLC [17]. We have also not been able to synthesise $[Mn_2(\mu\text{-}OMe)_2(\mu\text{-dppf})(CO)_6]$ via the reaction of dppf with the mixture of $[Mn_2(CO)_{10}]$, Me_3NO and MeOH.

2.2. One-pot reaction of $[Re_2(CO)_{10}]$ with Me_3NO, MeOH and dppf

In an attempt to trap the $[Re(OMe)(CO)_4]$ intermediate in the reaction of $[Re_2(CO)_{10}]$ with Me_3NO and MeOH, the one-pot reaction of $[Re_2(CO)_{10}]$ with Me_3NO, MeOH and dppf has been carried out [11]. The major mononuclear Re complex formed in this reaction (**1**) was mistakenly identified as the terminal methoxo complex *fac*-$[Re(OMe)(CO)_3(\eta^2\text{-dppf})]$ in Ref. [11]. We have subsequently determined the crystal structure of **1** (see below), and iden-

tified it as the methyl carbonate complex *fac*-[Re{OC(O)OMe}(CO)$_3$(η^2-dppf)].

Complex **1** is most probably formed by the insertion of CO_2 into the intermediate complex *fac*-[Re(OMe)(CO)$_3$(η^2-dppf)] resulting from the reaction of dppf with [Re(OMe)(CO)$_4$]. The CO_2 needed for the insertion reaction is probably produced by the decarbonylation of [Re_2(CO)$_{10}$] by Me_3NO. The facile CO_2-insertion reactions of the complexes *fac*-[Re(OR)(CO)$_3$(η^2-PP)] (R = Me, Et, CF_3CH_2; PP = 1,2-bis(diphenylphosphino)ethane (dppe), 1,3-bis(diphenylphosphino)propane) with atmospheric CO_2 has been reported [18].

2.3. Crystal structure of fac-[Re{OC(O)OMe}(CO)$_3$(η^2-dppf)] (1)

The crystal structure of **1** (Fig. 1) is similar to that of *fac*-[Mn{OC(O)OMe}(CO)$_3$(η^2-dppe)] [18]. The coordination sphere of the rhenium atom is roughly octahedral, consisting of an oxygen atom from the methyl carbonate ligand (taken to occupy an axial position), two phosphorus atoms from a chelating dppf ligand, and three carbon atoms from a facial arrangement of three terminally bound carbonyls. The P–Re–P angle in **1** (Table 1) is larger than the P–Mn–P angle in *fac*-[Mn{OC(O)OMe}(CO)$_3$(η^2-dppe)] (84.1(1)°), probably owing to the greater steric demand of dppf compared to dppe. The Re–CO(eq) distances (average 1.943(7) Å) are longer than the Re–CO(ax) distance (1.890(7) Å). Correspondingly, the C–O bond length of the axial carbonyl (1.154(8) Å) is longer than the lengths of 1.131(7) and 1.138(7) Å observed for the equatorial carbonyls. This can be attributed to the greater extent of M → CO backbonding experienced by the axial carbonyl, which is *trans* to the π-donating methyl carbonate ligand. The Re–O(1) bond to the methyl carbonate ligand has a length of 2.150(4) Å, which is comparable to the Re–O bond lengths of 2.150(4) Å in *fac*-[Re(OPh)(CO)$_3$(η^2-dppe)] [19], 2.162(6) Å (average) in [Re_2(μ-OMe)$_2$(μ-dppf)(CO)$_6$] [5], and 2.143(8) Å (average) in [Re_2(μ-OMe)$_2$(μ-dppm)(CO)$_6$] [6].

2.4. Reactions of [Os$_3$(CO)$_{12}$] with Me$_3$NO and MeOH

Reaction of [Os_3(CO)$_{12}$] with Me_3NO (1.2 molar equivalents) in refluxing THF–methanol (7:1) mixture for 4 h gave the complex [Os_3(μ-H)(μ-OMe)(CO)$_{10}$] (**2**) in 71% yield. Increasing the amount of amine oxide (2.4 molar equivalents) and methanol (THF:MeOH 4:1) did not significantly increase the yield of **2** (73%). The same cluster has been prepared in 10% yield by direct reaction of [Os_3(CO)$_{12}$] with methanol at 170°C for 38 h in vacuo in a steel-lined autoclave [13]. It can also be prepared via multi-step processes involving [Os_3(CO)$_{10}$(cyclohexa-1,3-diene)] [14], [Os_3(CO)$_{10}$(cyclooctene)$_2$] [15], [Os_3(CO)$_{10}$(CH_3CN)$_2$] [15], or [Os_3(μ-H)(μ-NCHNMe_2)(CO)$_{10}$] [16] as intermediates. However, since three or four steps are required starting from [Os_3(CO)$_{12}$], overall yields are never more than 50%. More recently, the reaction of methanol with the silica-anchored cluster [Os_3(μ-H)(μ-OSi≡)(CO)$_{10}$] (prepared by refluxing an *n*-octane solution of [Os_3(CO)$_{12}$] with silica for 10 h) was reported to give complex **2** in 52% yield (starting from [Os_3(CO)$_{12}$]) [4]. An alternative route involving the reaction of methanol with [Os_3(μ-H)(μ-OH)(CO)$_{10}$] (prepared by heating a suspension of [Os_3(μ-H)(μ-OSi≡)(CO)$_{10}$] in a water–toluene mixture at 95°C for 5 h) gives complex **2** in 82% overall yield from [Os_3(CO)$_{12}$] [4]. Compared with the reported syntheses of **2**, the present method is much more attractive since it is a high-yield one-pot synthesis over 4 h, starting directly from [Os_3(CO)$_{12}$], under relatively mild conditions.

When the molar ratio of Me_3NO to [Os_3(CO)$_{12}$] is increased to 3.3:1, the bis(methoxo) cluster [Os_3(μ-OMe)$_2$(CO)$_{10}$] (**3**) is obtained in 11% yield, while complex **2** is obtained in 33% yield. The yield of **3** is increased to 17% when 4.3 molar equivalents of amine oxide are used, while the yield of **2** remains essentially unchanged. As far as we are aware, the highest-yield synthesis for **3** reported thus far involves direct reaction of [Os_3(CO)$_{12}$] with methanol at 170°C for 38 h in vacuo in a steel-lined autoclave, which

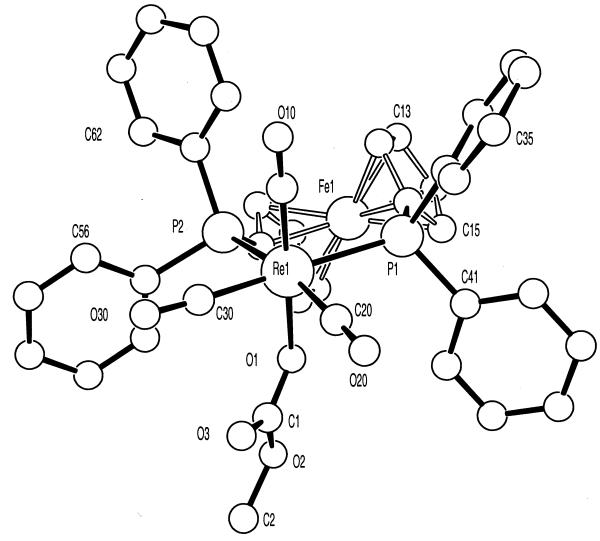

Fig. 1. Crystal structure of *fac*-[Re{OC(O)OMe}(CO)$_3$(η^2-dppf)] (**1**). Hydrogen atoms are omitted for clarity.

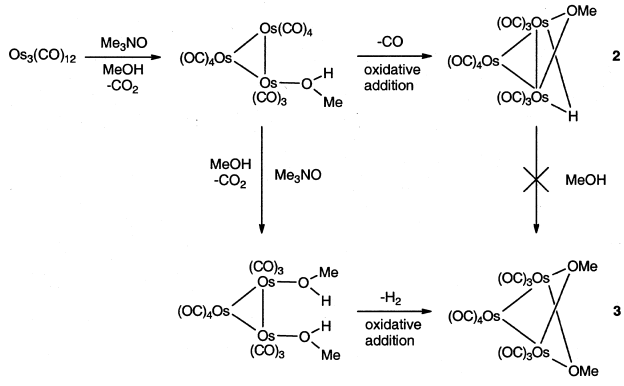
gives **3** in 13% yield and **2** in 10% yield (see above) [13]. The present one-pot synthesis for **3** is comparatively more convenient and gives a similar yield of the cluster.



*2.5. Proposed mechanism for the formation of clusters **2** and **3***

A plausible mechanism for the formation of clusters **2** and **3** is given in Scheme 4. As in the proposed mechanism for the formation of $[Re_2(\mu\text{-}OMe)_2(\mu\text{-}dppf)(CO)_6]$ from $[Re_2(CO)_{10}]$, the first step involves Me_3NO-assisted substitution of a CO ligand by methanol. Oxidative addition of MeO–H across the M–M bond does not, however, result in the formation of two separate mononuclear species $[OsH(CO)_3]$ and $[Os(OMe)(CO)_3]$, since the two $[Os(CO)_3]$ fragments are still bonded to the third osmium atom, which keeps them in close proximity. The oxidative addition reaction therefore results preferentially in the hydrido- and methoxo-bridged cluster $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(CO)_{10}]$ (**2**), with three Os–Os bonds. The loss of the second CO ligand which accompanies the oxidative addition presumably does not require Me_3NO, since there is no significant difference in the yield of **2** whether 1.2 or 2.4 molar equivalents of amine oxide is used.

The cluster $[Os_3(\mu\text{-}OMe)_2(CO)_{10}]$ (**3**) is probably formed by the oxidative addition of methanol and elimination of H_2 from the disubstituted intermediate $[Os_3(CO)_{10}(MeOH)_2]$. The formation of $[Os_3(CO)_{10}(MeOH)_2]$ from $[Os_3(CO)_{11}(MeOH)]$ probably requires Me_3NO and is slow compared to the conversion of $[Os_3(CO)_{11}(MeOH)]$ to $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(CO)_{10}]$. Hence cluster **3** is only formed in significant quantities when excess amine oxide is used. The higher concentration of Me_3NO probably increases the rate of formation of $[Os_3(CO)_{10}(MeOH)_2]$, enabling this process to compete more effectively against the formation of $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(CO)_{10}]$. Cluster **3** is unlikely to be formed from the secondary reaction of **2** with excess methanol since **2** remains unchanged when refluxed in methanol for 4 h.

Interestingly, Deeming et al. reported that $[Ru_3(CO)_{12}]$ reacts with $Me_3NO\cdot 2H_2O$ (5.8 molar equivalents) in the presence of (*R*)-BINAP (2,2′-bis(diphenylphosphino)-1,1′-binaphthyl) to give an 80% yield of the dihydroxo complex $[Ru_3(\mu\text{-}OH)_2(CO)_8\{\mu\text{-}(R)\text{-}BINAP\}]$ [20]. Although the authors identified $Me_3NO\cdot 2H_2O$ as the probable source of the hydroxo ligands, they did not propose any mechanism for the formation of $[Ru_3(\mu\text{-}OH)_2(CO)_8\{\mu\text{-}(R)\text{-}BINAP\}]$. We believe that the mechanism is similar to that proposed above for the formation of $[Os_3(\mu\text{-}OMe)_2(CO)_{10}]$. The complex $[Ru_3(\mu\text{-}OH)_2(CO)_{10}]$ is probably formed, and is further decarbonylated by the excess Me_3NO present to give an unsaturated intermediate which reacts with BINAP to form $[Ru_3(\mu\text{-}OH)_2(CO)_8\{\mu\text{-}(R)\text{-}BINAP\}]$. It is noteworthy that when dppm (bis(diphenylphosphino)methane) was added to the mixture resulting from the reaction of $[Os_3(CO)_{12}]$ with 4.3 molar equivalents of Me_3NO in THF–MeOH, a product tentatively identified as $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(\mu\text{-}dppm)(CO)_8]$ could be isolated.

So far, we have not observed products where two or more Os–Os bonds have been methoxylated.

Scheme 4.

3. Summary and conclusions

The reaction of dppf with the mixture of $MnRe(CO)_{10}$, MeOH and Me_3NO gives the complexes *fac*-$[MnH(CO)_3(\eta^2\text{-}dppf)]$ and $[Re_2(\mu\text{-}OMe)_2(\mu\text{-}dppf)(CO)_6]$, confirming that mononuclear alkoxo and hydrido intermediates are formed during the reaction. Reaction of $[Os_3(CO)_{12}]$ with Me_3NO (1–2 molar equivalents) and methanol gives $[Os_3(\mu\text{-}H)(\mu\text{-}OMe)(CO)_{10}]$ in good yield. With 3 molar equivalents of Me_3NO, significant quantities of $[Os_3(\mu\text{-}OMe)_2(CO)_{10}]$ are also obtained. No further methoxylation of Os–Os bonds occurs when the $[Me_3NO]$:$[Os_3(CO)_{12}]$ ratio is increased to 4:1.

4. Experimental

All reactions were performed under pure dry argon using standard Schlenk techniques. Solvents used were of reagent grade and were dried by published procedures and freshly distilled under argon before use. Unless otherwise stated, all reagents and starting materials used were of AR grade and were obtained from commercial sources and used as supplied. Precoated silica plates of layer thickness 0.25 mm were obtained from Merck. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded at ca. 300 K on a Bruker ACF 300 MHz spectrometer. ^1H and ^{31}P chemical shifts are quoted in ppm downfield of tetramethylsilane and external 80% H_3PO_4, respectively. Infrared spectra were recorded on either a Perkin Elmer 1600 or a Bio-Rad FTS165 FT-IR spectrophotometer. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, National University of Singapore.

4.1. Preparation of $[MnRe(CO)_{10}]$

The reported method [21,22] for the preparation of $[MnRe(CO)_{10}]$ was used with slight modification. A

degassed solution of $[Mn_2(CO)_{10}]$ (0.235 g, 0.60 mmol) in freshly dried THF (10 cm^3) was transferred into a Schlenk flask (cooled in an ice bath) containing sodium amalgam (3% Na by weight) ($\sim$1 g). The resultant suspension was stirred under argon at 0°C for 1 h, then at room temperature for another 1 h. The solution was then filtered under argon into a flask containing a stirred solution of $[ReBr(CO)_5]$ (0.406 g, 1.0 mmol) in THF (10 cm^3). Reaction was continued at room temperature under argon for 4 h. Solvent was removed under reduced pressure and the resultant residue was exposed in air for 1 week to oxidise any unreacted $[Mn_2(CO)_{10}]$. The orange solid obtained was then sublimed at 55°C, 0.3 mmHg. The compound $[MnRe(CO)_{10}]$ was obtained as an orange solid with a yield of 0.40 g (77% based on Re).

The purity of the $[MnRe(CO)_{10}]$ obtained was ascertained by IR spectroscopy and elemental analysis. ν_{max}(CO): 2054s, 2017 vs,1978s cm^{-1} (cyclohexane) (none of the IR absorption peaks of $[Mn_2(CO)_{10}]$ and $[Re_2(CO)_{10}]$ were detected). *Anal*. $C_{10}MnO_{10}Re$ requires: C, 23.0. Found: C, 23.4%.

4.2. Reaction of dppf with [MnRe(CO)$_{10}$], MeOH and TMNO

The solution of $Me_3NO\cdot 2H_2O$ (0.062 g, 0.56 mmol) in THF–MeOH (1:1, 20 cm^3) was transferred into a Schlenk flask containing a stirred solution of $[MnRe(CO)_{10}]$ (0.120 g, 0.23 mmol) in THF (10 cm^3) at room temperature. This solution was stirred in vacuo for 4 h at room temperature. Solid dppf (0.128 g, 0.23 mmol) was added and the orange solution so formed was stirred in vacuo for 1 h. It was then evaporated to half its volume and stirred for 3 h. The solvent was then removed and the residue was redissolved in a minimum amount of CH_2Cl_2 and chromatographed on silica TLC plates (CH_2Cl_2:hexane 2:3). From the main bands the complexes *fac*-$[MnH(CO)_3(\eta^2\text{-dppf})]$ ($R_f = 0.57$) and $[Re_2(\mu\text{-OMe})_2(\mu\text{-dppf})(CO)_6]$ ($R_f = 0.47$) were isolated with yields of 0.012 g (8%) and 0.035 g (26%), respectively. A trace amount of *fac*-$[ReCl(CO)_3(\eta^2\text{-dppf})]$ ($R_f = 0.13$) was also isolated.

The complex *fac*-$[MnH(CO)_3(\eta^2\text{-dppf})]$ was recrystallised from CH_2Cl_2–MeOH mixture at 0°C. *Anal*. Found: C, 63.5; H, 4.3; P, 8.8. $C_{37}H_{29}O_3P_2FeMn$ (FW 694) requires: C, 64.0; H, 4.2; P, 8.9%. ν_{max}(CO): 1998s, 1920m(sh), 1903m ($CHCl_3$); 1996s, 1917m(sh), 1903m (CH_2Cl_2); 1997s, 1922m(sh), 1906m cm^{-1} (THF). δ_H ($CDCl_3$) 7.7–7.4 (m) (20H, Ph), 4.38 (s, 2H, CpH), 4.29 (s, 2H, CpH), 4.18 (s, 2H, CpH), 4.08 (s, 2H, CpH), -6.18 (t, 1H, hydride), $J_{(P-Mn-H)}$ 50 Hz; δ_p ($CDCl_3$) 64.8. The complexes $[Re_2(\mu\text{-OMe})_2(\mu\text{-dppf})(CO)_6]$ and *fac*-$[ReCl(CO)_3(\eta^2\text{-dppf})]$ were identified by IR, ^1H and ^{31}P NMR spectroscopy [5,23].

4.3. Preparation of fac-[Re{OC(O)OMe}(CO)$_3$(η^2-dppf)] (1)

A solution of $Re_2(CO)_{10}$ (0.151 g, 0.23 mmol) in THF (20 cm^3) was transferred into a stirred solution of $Me_3NO\cdot 2H_2O$ (0.062 g, 0.56 mmol) and dppf (0.128 g, 0.23 mmol) in a mixture of MeOH (10 cm^3) and THF (20 cm^3). The resultant solution was stirred under partial vacuum at room temperature for 4 h. The solvent was removed under reduced pressure and the residue was redissolved in a minimum amount of THF and chromatographed on silica TLC plates (acetone:hexane 1:4). The complex *fac*-$[Re\{OC(O)OMe\}(CO)_3(\eta^2\text{-dppf})]$ (**1**) was isolated from the chrome-yellow band at $R_f = 0.23$. Air-stable orange prismatic crystals of **1** were obtained by cooling a solution of **1** in benzene–hexane–MeOH mixture to -10°C. Yield 0.016 g (4%). The crystals have the composition $[Re\{OC(O)OMe\}(CO)_3(\eta^2\text{-dppf})](C_6H_6)_{0.5}$. *Anal*. $C_{42}H_{34}FeO_6P_2Re$ (FW 938.7) requires: C, 53.7; H, 3.6; P, 6.5. Found: C, 53.8; H, 3.7; P, 6.4%. ν_{max}(CO) 2037vs, 1948m, 1899s (C_6H_6); 2033vs, 1951s, 1900s (acetone); 2029s, 1947s, 1895s cm^{-1} (KBr); ν(C=O methyl carbonate ligand) 1678m cm^{-1} (KBr). δ_H (C_6D_6) 7.94–7.82 (m), 7.17–7.02 (m) (20H, C_6H_5), 5.06 (s, 2H, CpH), 4.32 (s, 2H, CpH), 3.90 (s, 2H, CpH), 3.81 (s, 2H, CpH), 3.59 (s, 3H, OCH_3); δ_P (C_6D_6) 7.23 (s).

4.4. Reaction of [Os$_3$(CO)$_{12}$] with MeOH and one molar equivalent of Me$_3$NO

Tetrahydrofuran (60 cm^3) and $[Os_3(CO)_{12}]$ (0.0365 g, 0.040 mmol) were placed in a 250 ml three-neck round-bottom flask fitted with a reflux condenser, an argon inlet, and a 100 ml pressure-equalising dropping funnel. The reaction mixture was stirred and heated to reflux (oil bath temperature maintained at 80°C). A solution of $Me_3NO\cdot 2H_2O$ (0.0052 g, 0.047 mmol) in THF–methanol (1:1) mixture (20 cm^3) was then added dropwise over an hour. The resultant solution was refluxed for a further 3 h. The yellow solution obtained was then cooled to room temperature and filtered through silica. The silica was washed with THF until the washings were colourless. The combined filtrate and washings was rotary evaporated to obtain an oily residue. The residue was redissolved in a minimum amount of CH_2Cl_2 and chromatographed on silica TLC plates, eluting with CH_2Cl_2–hexane (5:95) mixture. A major yellow band ($R_f = 0.72$) was obtained and extracted with CH_2Cl_2 to give $[Os_3(\mu\text{-H})(\mu\text{-OMe})(CO)_{10}]$ (**2**). Yield 0.0251 g (71%). The identity of this compound was confirmed by IR and ^1H NMR spectroscopy [12].

4.5. Reaction of [Os$_3$(CO)$_{12}$] with MeOH and two molar equivalents of Me$_3$NO

The procedure adopted was similar to that for the reaction with one molar equivalent of Me_3NO except for the relative

amounts of reagents used: $[Os_3(CO)_{12}]$ 0.0352 g, 0.039 mmol; $Me_3NO \cdot 2H_2O$ 0.0103 g, 0.093 mmol; dissolved in THF–methanol (1:1) mixture (40 cm^3). Yield of **2** was 0.0249 g (73%).

4.6. Reaction of $[Os_3(CO)_{12}]$ with MeOH and three molar equivalents of Me_3NO

The amounts of reagents used were as follows: $[Os_3(CO)_{12}]$ 0.0356 g, 0.039 mmol; $Me_3NO \cdot 2H_2O$ 0.0143 g, 0.129 mmol; dissolved in THF–methanol (1:1) mixture (60 cm^3). TLC on silica plates (CH_2Cl_2:hexane 1:9) gave two main yellow bands: **2** ($R_f = 0.87$, 0.0173 g, 49%) and **3** $[Os_3(\mu\text{-OMe})_2(CO)_{10}]$ ($R_f = 0.71$, 0.0039 g, 11%). The identity of compound **3** was confirmed by IR and ^1H NMR spectroscopy [12].

4.7. Reaction of $[Os_3(CO)_{12}]$ with MeOH and four molar equivalents of Me_3NO

The amounts of reagents used were as follows: $[Os_3(CO)_{12}]$ 0.0335 g, 0.037 mmol; $Me_3NO \cdot 2H_2O$ 0.0178 g, 0.160 mmol; dissolved in THF–methanol (1:1) mixture (80 cm^3). Yields: **2** (0.0103 g, 32%); **3** (0.0056 g, 17%).

4.8. Reaction of $[Os_3(CO)_{12}]$ with MeOH, four molar equivalents of Me_3NO, and one equivalent of bis(diphenylphosphino)methane (dppm)

The compounds $[Os_3(CO)_{12}]$ (0.0556 g, 0.061 mmol), $Me_3NO \cdot 2H_2O$ (0.0294 g, 0.265 mmol, dissolved in THF–methanol (1:1) mixture (80 cm^3)) were allowed to react as above. After 4 h, dppm (0.0243 g, 0.093 mmol) was added. The solution was stirred for another 30 min, during which the colour of the solution darkened somewhat. The solution was filtered through silica and the filtrate was rotary evaporated to obtain an oily residue. The residue was dissolved in CH_2Cl_2 and loaded onto a silica column. Elution with CH_2Cl_2–hexane mixture (1:4) yielded a major yellow band which gave IR and ^1H NMR spectra consistent with the formulation $[Os_3(\mu\text{-H})(\mu\text{-OMe})(\mu\text{-dppm})(CO)_8]$. $\nu_{max}(CO)$ 2086vw, 2074m, 2048w, 2038vw, 2003vs, 1990sh, 1941m cm^{-1} (hexane). δ_H ($CDCl_3$) 7.3–7.5 (m) (20H, Ph), 3.4 (s) (3H, OCH_3), 3.1 (dt) (1H, CH_2), 2.9 (dt) (1H, CH_2), −11.2 (t) (1H, hydride), $J_{(H-P)}$ 12 Hz; δ_P ($CDCl_3$) −8.4 (s).

4.9. X-ray crystallography of fac-[Re{OC(O)OMe}-$(CO)_3(\eta^2\text{-dppf})$] (**1**)

Data were collected on a crystal of dimensions $0.17 \times 0.30 \times 0.40$ mm using a Siemens P4 diffractometer in the θ–2θ mode, with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystal data: $C_{39}H_{31}FeO_6P_2Re \cdot 0.5(C_6H_6)$, monoclinic, $P2_1/n$, a = 9.670(2), b = 18.983(4), c = 20.823(5) Å, β = 92.58(1)°, V = 3819(2) $Å^3$, Z = 4. Data were collected at 297 K to a maximum 2θ value of 55.0°. A total of 9993 reflections were measured, of which 8004 were unique ($R_{int} = 0.034$). The number of data used for structure solution and refinement was 5303 ($I > 2.0\sigma(I)$). Empirical ψ corrections were made; the minimum and maximum transmission factors were 0.7130 and 0.9560 respectively. The structure was solved by direct methods. All non-hydrogen atoms (except those of the disordered solvate molecule) were refined anisotropically by the full-matrix least-squares method (on F^2). Hydrogen atoms were introduced in calculated positions and refined isotropically (riding model) in the final cycles of least-squares refinement. The disordered benzene solvate is located about a crystallographic inversion centre. The unique half of the benzene molecule was modelled isotropically in terms of two overlapping C_3 fragments of half occupancy each (C(100)–C(300)) and (C(101)–C(301)), with the constraint C–C = 1.390 ± 0.002 Å. The C(100)···C(300) and C(101)···C(301) distances were constrained to be 2.400 ± 0.002 Å to fix the C–C–C angles at 120°. The last least-squares cycle was calculated with 466 parameters and 7950 reflections (all of the unique reflections except very negative ones), and converged with R_1 = 0.040 and $wR_2 = 0.080$ (for reflections with $I > 2.0\sigma(I)$) ($R_1 = \sum||F_o| - |F_c||/\sum|F_o|$, $wR_2 = [\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$). The weighting function used was $w^{-1} = \sigma^2(F_o^2) + (0.0400P)^2$, where $P = (F_o^2 + 2F_c^2)/3$. In the last difference map the deepest hole was −0.605 e $Å^{-3}$, and the highest peak was 0.677 e $Å^{-3}$. Computations were carried out on a Pentium PC using the SHELXTL PLUS software package [24].

Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), CCDC no. 135934.

Abstract

Two lead compounds containing the aspartate ligand are described, with compositions Pb(aspH)NO_3 and Pb(asp). The crystal structure of the first shows it is a three-dimensional polymer in which each lead atom is coordinated to six oxygen atoms, five from carboxyl groups and one from a nitrate ion. For Pb(asp), spectroscopic data suggest the presence of Pb–NH_2 interaction. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Lead(II); Aspartate; Structures

1. Introduction

Knowledge of the toxicity of lead goes back to ancient times. Recent clinical studies have established that it affects several organs such as the kidneys and the brain, and also that it interferes with many steps in the biosynthesis of heme [1–3]. However, the critical interactions of this metal with specific biomolecules have not yet been elucidated. For instance, it is known that it binds strongly to sulfhydryl groups, acting as a soft acid, but also that it accumulates in the oxygen rich sites of bone, where it replaces calcium, a typical hard acid, and that its toxic effects are more serious for patients who are calcium deficient [4,5]. Recent studies strongly suggest that Pb(II) finds its way into the organism by binding to a calcium transport protein known as ICBP or calbindine [6]. The amino acid sequence of this protein has been determined and it is known that the calcium binding site is rich in aspartic and glutamic residues. This fact, together with the lack of studies of interactions of lead with simple biomolecules, motivated the present work, in which two different lead complexes with aspartate were obtained, Pb(aspH)(NO_3) (**I**) and Pb(asp) (**II**). Since lead can present a wide variety of coordination numbers and geometries [7] and since the crystal structures of several metal complexes with aspartate [8–12] show the coordination versatility of this ligand, the structural analysis of this pair of complexes proved to be interesting in itself.

2. Experimental

Lead nitrate and lead oxide (litharge) were purchased from Merck, L-aspartic acid and L-aspartic acid monosodium salt hydrate were from Sigma Chemical Co., and all were used without further purification. Elemental analyses were carried out by Desert Analytics, Tucson, AZ. IR spectra were recorded in the 4000–400 cm^{-1} region using both KBr pellets and HCBD suspension in a Nicolet 540 spectrophotometer. The far IR spectra were recorded in a Nicolet 740 FTIR in the 700–70 cm^{-1} region using polyethylene pellets. Amino group protons were interchanged by deuterium by soaking samples in D_2O for 24 h.

The ^{13}C CP-MAS spectra were recorded on a Varian Unity-plus 300 MHz spectrometer operating at 75.429 MHz, and 30° pulse was used. A 7 mm diameter silicon nitride rotor

0277-5387/00/$ - see front matter ©2000 Elsevier Science Ltd All rights reserved.
PII S0277-5387(00)00299-0

with kel-F caps was used. The rotor spin rate was kept between 3.5 and 4.5 kHz for all experiments, with a delay time of 7 s, and between 128 and 516 transients accumulated. Adamantane was used as external reference.

2.1. Preparation of Pb(aspH)(NO_3) (I)

3.31 g (10 mmol) of lead nitrate were dissolved in 50 ml water and combined with 1.55 g (10 mmol) of monosodium aspartate hydrate also in 50 ml of water. The pH was adjusted to 4.0 with 0.1 M NaOH and the solution left to crystallise. Colourless needles were collected the next day. *Anal*. Calc. for Pb($C_4H_6O_4N$)(NO_3): C, 11.97; H, 1.49; N, 6.98. Found: C, 12.11, H, 1.55, N, 6.84%.

2.2. Preparation of Pb(asp) (II)

1.33 g (10 mmol) aspartic acid were dissolved in 300 ml water. To this solution, 2.23 g PbO powder (litharge) were added. The reaction vessel was placed in an ultrasound bath for 15 min during which the yellow powder dissolved and a white precipitate formed. *Anal*. Calc. for Pb($C_4H_5O_4N$): C, 14.20, H, 1.47, N, 4.1. Found: C, 14.10; H, 1.42, N, 3.98%.

2.3. Crystallography

Pertinent crystal data are collected in Table 1, and complete crystallographic information is deposited as a CIF file. The structure was solved and refined using standard procedures [13–15]. On the final difference map, a maximum peak of 1.81 e $Å^{-3}$ close to the heavy atom was attributed to the fact that the crystal was larger than the X-ray beam and to the difficulty in applying a suitable absorption correction. H atoms were omitted because of their small contribution to the structure factors.

Table 1
Crystal data

Empirical formula	$C_4H_6N_2O_7Pb$

[a] R_{int}, R_1, wR_2 and S are defined as follows:

$$R_{int}=\frac{\sum|F_o^2-\langle F_o^2\rangle|}{\sum F_o^2},\quad R_1=\frac{\sum||F_o|-|F_c||}{\sum|F_o|},$$

$$wR_2=\sqrt{\frac{\sum w(F_o^2-F_c^2)^2}{\sum w(F_o^2)^2}},\quad S=\sqrt{\frac{\sum w(F_o^2-F_c^2)^2}{m-n}}.$$

3. Results and discussion

3.1. Spectroscopic results

3.1.1. IR spectra

For the free ligand, in its monosodium salt form, asymmetric and symmetric stretching absorptions of the carboxylate group appear at 1582 and 1415 cm^{-1} respectively, while for the lead complex **I**, the first absorption shifts to 1560 cm^{-1} and the second is obscured by the nitrate ion absorption, which displays a quite intense band at 1385 cm^{-1}. Even though the crystal structure shows each lead atom has a nitrate ion coordinated in unidentate mode, the IR spectrum displays the characteristic band of free nitrate, which appears practically at the same wavenumber in Pb(NO_3)$_2$, suggesting a rather weak interaction, mainly of electrostatic nature. To rule out the possibility that coordination of nitrate to lead had been broken during the fabrication of the KBr pellet, the spectrum was recorded in HCBD, which is transparent in the 1565–1170 cm^{-1} region, and showed no difference. In the N–H region, three weak bands in the 2920–3150 cm^{-1} interval are consistent with the presence of the –NH_3^+ group.

The IR spectrum for complex **II**, however, is very different in the latter region. It has two very well defined bands with moderate intensity at 3301 and 3233 cm^{-1}, indicative of a coordinated –NH_2 group [16,17]. The assignment of these two bands was confirmed by deuterium exchange upon which they shift towards 2464 and 2379 cm^{-1} respectively.

The asymmetric stretching absorption of the carboxylate in this complex is located at 1532 cm^{-1}, 28 cm^{-1} lower than for the Pb(aspH)NO_3 complex. The symmetric stretching absorption can be observed in complex **II** at 1347 cm^{-1}. The difference ($\Delta\nu$) between ν_a and ν_s is 185 cm^{-1}, which is very close to the $\Delta\nu$ of the free amino acid or its sodium salt (vide supra, 167 cm^{-1}), and this is in agreement with a bridging carboxylate [16,17].

3.1.2. Far IR spectra

Pb(asp) has an important band at 325 cm^{-1}, not present in the far IR spectrum of Pb(aspH)NO_3. Since it shifts to 313 cm^{-1} in the deuterated sample, it could be indicative of a Pb–NH_2 vibration.

3.1.3. NMR spectra

Table 2 shows chemical shifts in ^{13}C solid state NMR for both the reported complexes as well as for the acid and monobasic forms of the ligand. While δ (ppm) values for aliphatic carbon atoms in both lead complexes are very sim-

Table 2
^{13}C NMR chemical shifts (ppm)

Nucleus	$AspH_2$	NaAspH	Pb(AspH)NO_3	Pb(Asp)

ilar, those for the carboxylate groups of Pb(asp) are significatively shifted to lower fields, suggesting a qualitatively different interaction with lead atoms.

Further experiments were carried out to measure ^1H relaxation times by observing the change in signal intensity for cross-polarisation ^{13}C solid state spectra, as a function of time [18,19] (Fig. 1(a,b)). For Pb(AspH)NO_3 a value of 3.60 ± 0.16 s was obtained, whereas for Pb(asp) the value was 12.37 ± 0.68 s. Since these values are a measure of the rigidity of the molecules, the latter is consistent with the chelate formation suggested by the IR spectrum. For both forms of the ligand, relaxation times are assumed to be less than 1 s, which is the minimum waiting time allowed by the apparatus, since signal intensity was constant at all times measured up to 70 s.

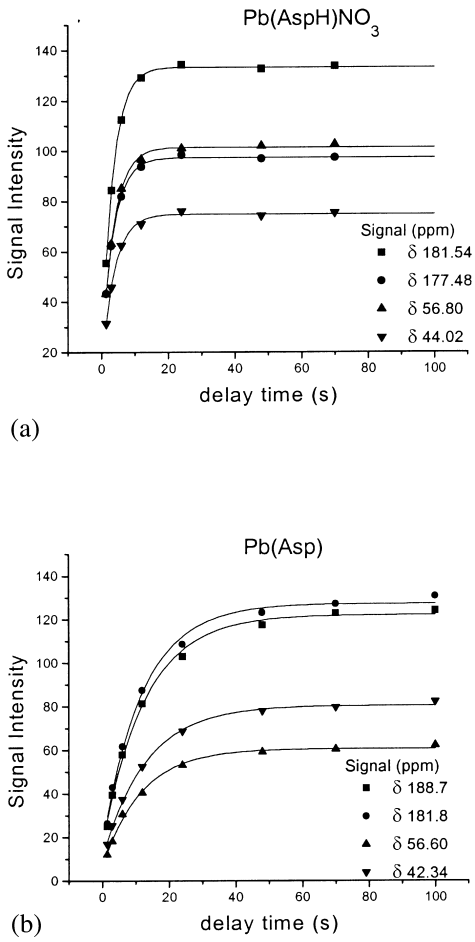

Fig. 1. Determination of ^1H relaxation times for (a) Pb(aspH)(NO_3) and (b) Pb(asp).

3.2. Crystal structure

The crystal structure shows this compound forms a three-dimensional network, owing to the nature of the aspartate ligand which can coordinate to two different lead atoms through each carboxylate, together with the fact that a single oxygen atom in a carboxylate can bridge two metal atoms. The three-dimensional network has chains running along the three axes of the orthorhombic cell. A remarkable feature is the formation of 18-membered rings containing three Pb ions and three ligand molecules with weak metal–metal interactions: Pb···Pb 4.589 and 4.706 Å (Fig. 2).

The overall geometry around each Pb can be considered a distorted square pyramid, with the apex occupied by the two oxygen atoms from the chelating β-carboxylic group (Fig. 3) with a bite angle O1–Pb–O2 = 49.8° and with bond lengths C1–O1 = 1.264(19) and C1–O2 = 1.24(2) Å. The difference in the two Pb–O distances for this group, Pb–O1 = 2.706(12) and Pb–O2 = 2.500(11) Å, is consistent with the

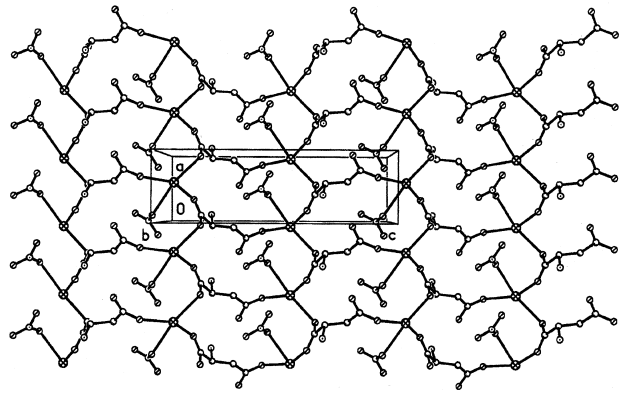

Fig. 2. 18-membered rings containing three Pb ions and three ligand molecules.

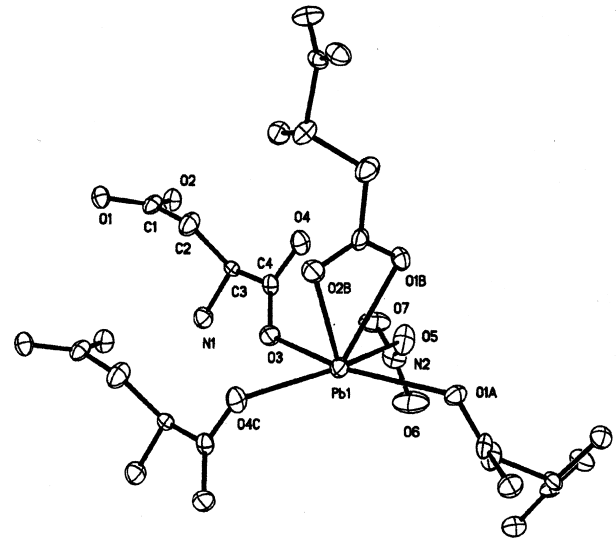

Fig. 3. The coordination environment of lead atoms in Pb(aspH)(NO_3) with the labelling scheme. Symmetry codes used to generate equivalent atoms are the following: A $-x-1/2$, $-y+2$, $z+1/2$; B $-x-1$, $y-1/2$, $-z+3/2$; C $x+1$, y, z. Thermal ellipsoids are at 30% probability level. H atoms were not included in the refinement.

bridging role of O1 between two symmetry related Pb ions (Table 3).

The lead atom lies 0.13 Å above the base of the pyramid, which is defined by four oxygen atoms from four different ligand moieties. Two of these oxygen atoms are from α-carboxylates in two symmetry related ligands, with similar distances, Pb–O3 = 2.493(12) and Pb–O4′ = 2.563(12) Å.

The third position in the base of the pyramid is occupied by the oxgen atom O1A, which forms part of a β-carboxylate that chelates a neighbouring Pb atom. An oxygen atom from the nitrate anion is coordinated at the fourth position in the base of this pyramid in unidentate mode, with the expected distance Pb1–O5 = 2.730(17) Å, only slightly shorter than the Pb–O distance in lead nitrate (2.81 Å [20]), which is in agreement with the apparent ionic behaviour of this nitrate observed in the IR spectrum.

The α-carboxylic groups are disymmetric, as noted from bond lengths C4–O3 = 1.20(2) and C4–O4 = 1.257(19) Å, in line with a localisation of the negative charge on O3. This is confirmed by the fact that Pb–O3 is the shortest coordination distance (2.493(12) Å).

This geometry leaves a wide space below the base of the pyramid containing the lead atom, which can be thought of as occupied by the 'inert pair' of electrons on Pb(II).

The possible stereochemical activity of the lone pair in divalent lead compounds has recently been discussed by Shimoni-Livny et al. based on a thorough review of crystal data available in the Cambridge Structural Database (CSD) [7]. They classify lead complex coordination as holodirected or hemidirected. Holodirected refers to complexes in which the bonds to ligand atoms are directed throughout the surface of an encompassing sphere, while hemidirected refers to those cases in which the bonds to ligand atoms are directed throughout only part of the coordination sphere, leaving a void or gap in the distribution of bonds to the ligand. The latter, present in all Pb(II) compounds with coordination numbers 2 to 5, is quite common in Pb(II) complexes with coordination numbers 6, 7 and 8, and does not exist in lead complexes with higher coordination numbers, where holodirected geometry is the rule. For the structure described here, coordination around the lead atoms is hemidirected with a significant void *trans* to the chelating β-carboxylate, quite similar to what Clegg et al. found for lead crotonate [21].

The coordination chemistry of Pb(II) in aqueous media has not yet been widely explored, but at the present time both solution equilibria and structural studies suggest a low affinity of lead for nitrogen donors, particularly aliphatic amines. In most cases, pH values needed to deprotonate these donors promote metal hydrolysis and precipitation of $Pb(OH)_2$, which is why the compound Pb(asp) described in this work cannot be found in aqueous solution. This suggests that under physiological conditions, amine residues in proteins or

Abstract

The oxidative chemistry of three Ni(II) complexes with Schiff base ligands derived from salicylaldehyde and diamines with different steric demands, *N*,*N*′-2-methylpropane-2,3-diyl-bis(salicylideneiminate)nickel(II) (**1**), *N*,*N*′-1,2-cyclohexyl-1,2-dyil-bis(salicylideneiminate)-nickel(II) (**2**) and *N*,*N*′-2,3-dimethylbutane-2,3-diyl-bis(salicylideneiminate)nickel(II) (**3**), was studied by cyclic voltammetry and chronoamperometry in *N*,*N*′-dimethylformamide and $(CH_3)_2SO$. The electrogenerated species were characterised by EPR spectroscopy. All three complexes exhibited metal-centred oxidised processes and the oxidised products were low-spin six-coordinate Ni(III) species (d_{z^2} ground state) with two solvent molecules axially coordinate. Addition of pyridine resulted in the replacement of solvent molecules with no changes in the ground state. The crystal structures of compounds **1** and **3** were determined from single crystal X-ray diffraction data, and the crystal packing for any of the complexes did not show any systematic parallel orientation of any part of the molecules. X-ray structural data for the Ni(II) complexes provided a rationale for the $E_{1/2}$ values obtained in the oxidation processes and for the relative energy of the low-lying excited duplets of the electrogenerated Ni(III) species. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Nickel(II) complexes with N_2O_2 Schiff base ligands derived from salicylaldehyde have long been used as homogeneous catalysts [1–3]. More recently, the ease of preparation of metal salen-based modified electrodes by oxidative electropolymerisation of metal complexes in poor coordinating solvents has prompted their use in heterogeneous electrocatalysis [4]. Knowledge of the role played by structural/electronic effects to control the redox chemistry of these metal complexes may prove to be critical in the design of new catalysts.

We have been studying the oxidative chemistry of Ni(II) complexes with N_2O_2 Schiff base ligands in solvents with different coordinating strength and have found the oxidation products to be solvent dependent [5–15]. Nickel(II) complexes with salicylaldehyde-based ligands (L) are oxidised in dimethylformamide (DMF) and $(CH_3)_2SO$ by a one-electron metal-centred process to six-coordinate Ni(III) species, formulated as $[Ni^{III}L(solv)_2]^+$ (where solv stands for a solvent molecule) [5–9]. However, in CH_3CN the complexes are oxidatively polymerised at the electrode surface to generate electroactive films [10–15], for which the oxidative behaviour has been shown to be associated with a ligand-centred process of the surface redox couple [11–13]. The complexes [Ni(salen)] and [Ni(saltMe)] (see Scheme 1 for an explanation of the abbreviations used) exhibit in strong coordinating solvents (DMF and $(CH_3)_2SO$) a quasi-reversible diffusion-controlled one-electron transfer process [8], in which the value of $E_{1/2}$ of [Ni(salen)] is less positive (approximately 0.07 V in DMF and 0.09 V in $(CH_3)_2SO$) than that of [Ni(saltMe)], a behaviour suggested to arise

Scheme 1.

from steric repulsions imposed on axial binding by the axially oriented methyl groups of the imine bridge [8].

In CH_3CN the electrogenerated polymers exhibit, in the oxidative redox switching, quite different properties in terms of stabilisation; poly[Ni(saltMe)] reveals high stability/durability, and conductivity in CH_3CN (even for very thick polymers) and for a wide potential window [11], a behaviour to be contrasted with that of poly[Ni(salen)], a poor conducting polymer with very low stability [10]. Since these two nickel complexes differ in four methyl substituents of the ethylenimine bridge, we decided to investigate the effect of a smooth increase in the bulkiness of the imine bridge substituents on the solution redox properties of salen-based Ni(II) complexes in $(CH_3)_2SO$ and DMF, and on the redox properties of their electrogenerated polymers in CH_3CN.

The work presented here describes the redox characterisation of [Ni(saldMe)] (**1**) and of [Ni(salhd)] (**2**) in CH_3SO and DMF; the results in CH_3CN will be published elsewhere. The ligand, H_2saldMe, has only two methyl groups in the imine bridge, albeit on the same carbon atom, and the ligand H_2salhd, has the nitrogen atoms bound to two consecutive carbons of a cyclohexane (Scheme 1). These ligands provide intermediate situations between those of H_2salen and H_2saltMe. Cyclic voltammetry and chronoamperometry were used to characterise electrochemically the complexes; chronoamperometric data are also included for [Ni(saltMe)] (**3**). The molecular and crystal structures of [Ni(saldMe)] and [Ni(saltMe)] have been solved and are reported here. Cyclic voltammetric data for [Ni(saltMe)] have been published elsewhere [8], but a brief description of the key features are included to provide a complete and coherent framework for the overall study reported here.

2. Experimental

2.1. Reagents, solvents, ligands and complexes

The solvents for syntheses were of reagent grade and those for electrochemical studies were of analytical grade; all were used as received. All reagents (nickel acetate tetrahydrate, salicylaldehyde, 2-methyl-2,3-propanediamine, 1,2-cyclohexanediamine) were obtained from Aldrich and used as received. Tetraethylammonium perchlorate (TEAP; Fluka, puriss) was kept in an oven at 60°C prior to use. **Caution**: perchlorates are hazards and may explode.

The ligands H_2saldMe, *N*,*N*′-2-methylpropane-2,3-dyil-bis(salicylideneimine), and H_2salhd, *N*,*N*′-1,2-cyclohexyl-1,2-dyil-bis(salicylideneimine), and the respective Ni(II) complexes were prepared by standard methods [16]; in H_2salhd the cyclohexane in the imine bridge exists as a mixture of the *cis* and the *trans* isomers. The synthesis, spectroscopic and cyclic voltammetric studies in DMF and $(CH_3)_2SO$ of the Ni(II) complex with *N*,*N*′-2,3-dimethylbutane-2,3-diyl-bis(salicylideneiminate), [Ni(saltMe)], have been published previously [8]. X-ray quality crystals of [Ni(saldMe)] and [Ni(saltMe)] were obtained by slow evaporation of solutions of the corresponding complexes in CH_3CN–CH_3Cl.

[Ni(saldMe)], $C_{18}H_{18}N_2O_2Ni$. *Anal*. Calc.: C, 61.2; H, 5.1; N, 7.9. Found: C, 61.6; H, 5.2; N, 7.8%. ^{1}H NMR ($CDCl_3$, 298 K, δ): 7.41 (2H, =CH), 7.27–7.01 (6H, aromatic H), 6.59–6.50 (2H, aromatic H), 3.26 (2H, –CH_2), 1.50 (6H, –C(CH_3)$_2$. Electronic spectra (800–250 nm), λ_{max} (ε, mol^{-1} dm^3 cm^{-1}): in $(CH_3)_2SO$, 558 (133), 444 (2460), 410 (5900), 388 (3318), 342 (7146), 321 (7482); in DMF, 559 (137), 444 (3317), 411 (6545), 386 (3614), 344 (7911), 324 (8455).

[Ni(salhd)], $C_{20}H_{20}N_2O_2Ni$. *Anal*. Calc.: C, 63.3; H, 5.3; N, 7.4. Found: C, 63.3; H, 5.2; N, 7.4%. ^{1}H NMR (DMSO-d_6, 298 K, δ): 7.71 (2H, =CH), 7.38–7.34 (2H, aromatic H), 7.20–7.11 (2H, aromatic H), 6.70–6.66 (2H, aromatic H), 6.53–6.50 (2H, aromatic H), 3.11 (4H, –C_6H_{10}), 1.77 (2H, –C_6H_{10}), 1.25 (4H, –C_6H_{10}). Electronic spectra (700–250 nm), λ_{max} (ε, mol^{-1} dm^3 cm^{-1}): in $(CH_3)_2SO$, 557 (133), 443 (3227), 410 (6588), 390 (4152), 345 (7410), 324 (7914); in DMF, 557 (127), 444 (2509), 412 (5717), 392 (3264), 345 (6528), 322 (7443).

Details on the electrosynthesis of Ni(III) complexes and the preparation of their pyridine adducts have been described elsewhere [5,8].

2.2. Physical measurements

Elemental analyses (C, H and N) were performed at the Departamento de Química, Universidade de Aveiro, Portugal. ^{1}H NMR spectra were recorded with a Bruker AC 200 spectrometer at 25°C, using $SiMe_4$ as internal reference. Electronic spectra of Ni(II) complexes were recorded with a Unicam UV2 spectrophotometer at room temperature, in a standard 1-cm quartz cuvette, using solutions of the ligands (1×10^{-5} mol dm^{-3}) or of the metal complexes (1×10^{-3} and 1×10^{-5} mol dm^{-3}) in DMF and $(CH_3)_2SO$. EPR spectra were obtained with a Bruker ESP 300 spectrometer (X-band) at 120 K; the magnetic field was calibrated by using Mn^{2+} in MgO and diphenylpicrylhydrazyl was used as internal reference (dpph; $g=2.0037$). The reported EPR parameters were obtained by spectral simulation using the program WinEPR Simfonia (Bruker) and assuming rhombic

spin hamiltonians; line widths were typically in the range 0.05–0.20 mT.

Electrochemical measurements were performed using an Autolab PGSTAT20 potentiostat/galvanostat. The electrochemical cell used in cyclic voltammetry and in double potential step chronoamperometry was a closed standard three-electrode cell connected to a solution reservoir through a Teflon tube. A Pt disk electrode with an area of 0.0314 cm^2 was used as the working electrode, a Pt gauze electrode as the counter electrode and an Ag/AgCl (1 mol dm^{-3} NaCl) as reference electrode. The ferrocene/ferrocinium (Fc/Fc) redox couple was used as internal standard: under the experimental conditions used, $E_{1/2}$ for the Fc/Fc^+ couple was 0.48 and 0.45 V in DMF and $(CH_3)_2SO$, respectively. Prior to use, the Pt working electrode was polished with an aqueous suspension of 0.05-μm alumina (Buehler) on a Master-Tex (Buehler) polishing pad, then rinsed with water and acetone and dried in an oven. All solutions were de-areated and delivered to the cell by a stream of argon. For cyclic voltammetry, scan rates in the interval 0.005–1.0 V s^{-1} were used, and the potential limits were 0.0 and 1.3 V. For chronoamperometry the potential was stepped from 0.0 V to E_1 and back to 0.0 V. After each step the potential was held for 20 s. The applied potentials E_1 were the same for all complexes in DMF and equal to 1.0 V; in $(CH_3)_2SO$ they were 0.93, 0.90 and 1.0 V for [Ni(saldMe)], [Ni(salhd)] and [Ni(saltMe)], respectively.

Electrolysis were carried out at controlled potential, at a value 0.1 V higher than the anodic peak potential. A three-electrode cell was used, with a Pt gauze as the working electrode, a Pt foil as counter electrode and an Ag/AgCl (1 mol dm^{-3} NaCl) as reference electrode.

2.3. Crystallography

Data were collected at room temperature for [Ni(saldMe)] on an Enraf Nonius TURBOCAD4 diffractometer with a copper rotating anode and for [Ni(saltMe)] on an Enraf Nonius MACH3 diffractometer with Mo graphite monochromatised radiation. Data reduction, Lorentz, polarisation and empirical absorption corrections were made using the CAD4 software package.

For both complexes the positions of the nickel atoms were obtained from a three-dimensional Patterson synthesis. Three molecules were found in the asymmetric unit of compound [Ni(saltMe)], while only one molecule was refined in complex [Ni(saldMe)]. All the non-hydrogen atoms were located in subsequent difference Fourier maps, and were refined, on F^2, with anisotropic thermal motion parameters. The hydrogen atoms were inserted in calculated positions and refined isotropically riding with the parent carbon atom. Details for data collection and for structure refinement are presented in Table 1.

Structure solution and refinement were done with SHELXS-86 [17] and SHELX-97 [18], and all molecular diagrams were drawn with the program ORTEP III [19]. Atomic scattering factors and anomalous scattering terms

3. Results and discussion

3.1. Spectroscopic characterisation

Ni(II) complexes with the ligands H_2saldMe and H_2salhd show electronic spectra in DMF and $(CH_3)_2SO$ that are very similar to those of [Ni(saltMe)] and of other Ni(II) Schiff base complexes derived from salicylaldehyde, both in solution and in solid. They are characteristic of square planar low-spin Ni(II) complexes [21]; typically the spectra exhibit a low-intensity broad brand at $\lambda_{max} \approx 550$–560 nm ($\varepsilon \approx 125$–135 mol^{-1} dm^3 cm^{-1}) assigned to transitions from the four low-lying orbitals, which is superimposed on a group of high-intensity charge transfer bands at higher energies ($\lambda <$ 440 nm, $\varepsilon \approx 2500$–500 mol^{-1} dm^3 cm^{-1}). The similarity between the spectra in both solvents and in the solid indicates that no effective coordination of solvent molecules took place in any of the solvents.

3.2. Molecular structure

Molecular structure of complexes [Ni(saldMe)] and [Ni(saltMe)] are depicted in Figs. 1 and 2; relevant bond lengths and bond angles and the most relevant torsion angles are listed in Table 2. The same numbering scheme was used for the three independent molecules of [Ni(saltMe)].

In both compounds the coordination geometry around the nickel atom is roughly square planar, with the ligands bound through two nitrogen and two oxygen atoms in a *cis* configuration, but with the four N_2O_2 atoms distorted in a tetrahedral fashion.

The maximum deviation from planarity of the coordinated atoms in [Ni(saltMe)] are 0.074(2), 0.084(2) and 0.099(2) Å for molecules A, B and C, respectively, while the nickel atom is 0.018(2) Å out of that plane for molecule A, and 0.016(2) Å for molecules B and C. In [Ni(saldMe)], the coordination atoms are more distorted towards a tetrahedron, with a maximum deviation from planarity of 0.124(1) Å and with the nickel atom 0.013(1) Å out of the plane. The values of maximum deviation from planarity compare with those found for the two independent molecules of [Ni(1*R*,2*R*(-)salhd)] [22], which are 0.057 Å for molecule 1 and 0.088 Å for molecule 2; however, in this molecule the nickel atom lies practically within the coordination plane (−0.0096 and −0.0042 Å, respectively). The values of maximum deviation from planarity also compare with those found for *N*,*N*′-1,2-*cis*-cyclohexane-1,2-diyl-bis(2-hydroxyacetophenonylidene-iminate)nickel(II), [Ni(α,α′-Me_2-salhd)], for which the deviation is 0.076 Å and the nickel atom is 0.018 Å out of the plane [7]. It must be pointed that [Ni(salhd)] exists in solution as a mixture of isomers and it is to be expected that they present a comparable deviation

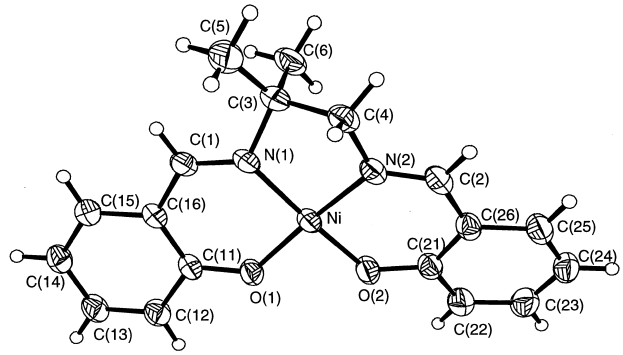

Fig. 1. Molecular diagram with atomic labelling scheme for [Ni(saldMe)]. Ellipsoids at 40% probability level [19,38].

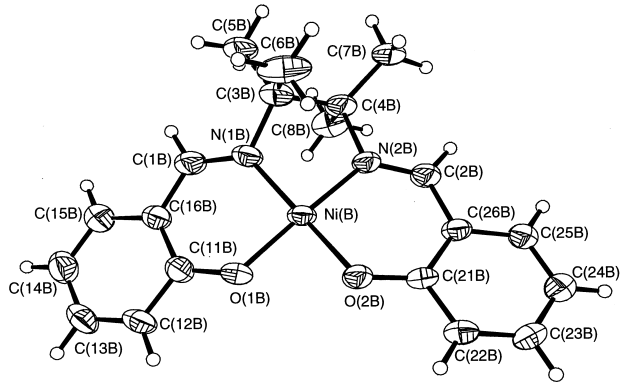

Fig. 2. Molecular diagram with atomic labelling scheme for molecule B of [Ni(saltMe)]. Ellipsoids at 40% probability level [19,38].

from planarity. In contrast, the structure of the compound with no substituents in the imine bridge, [Ni(salen)], is almost planar; maximum deviation from planarity of 0.023 Å and with the nickel atom 0.0056 Å out of the plane [23].

The configuration of the three independent molecules of [Ni(saltMe)] is asymmetric umbrella, with NCCN torsion angles of 20(1)° for molecule A, −43.9(6)° for molecule B and −46.7(5)° for molecule C; the conformations of the imine bridge are thus *cis*, *gauche* and *gauche*, respectively. Deviations of the imine bridge atoms, C3 and C4, from the NiN_2O_2 plane are −0.02(1) and −0.19(1) Å (molecule A), −0.619(8) and 0.097(7) Å (molecule B) and −0.300(7) and 0.507(7)° (molecule C). The values of the torsion angle for molecules B and C are of the same order of magnitude as those observed in the homologous ligand derived from naphthaldehyde, [Ni(naptMe)], for which the value is 47.5(5)° [6].

The configuration of the [Ni(saldMe)] molecules is an asymmetric umbrella but with the two aldehyde moieties twisted. The NCCN torsion angle is 39.6(5)°, smaller than those found in the two crystallographic independent molecules in the similar complex *N*,*N*′-2-methylpropane-2,3-diyl-bis(3-hydroxysalicylideneiminate)nickel(II), [Ni(3-HO-saldMe)], [24], which are 44(1) and 45(1)°. The two carbon atoms, C3 and C4, in [Ni(saldMe)] are below and above the NiO_2N_2 coordination plane with a quasi-symmetric displacement, −0.365(5) and +0.341(5) Å, respectively.

The maximum deviation from planarity of the coordinated atoms (and the distance of the nickel atom to the equatorial plane) in similar molecules which have ethylene-based bridges without substituents or aromatic bridges are 0.033 Å (0.0073 Å) in [Ni(α,α′-Me_2salen)] [7], 0.023 Å (0.0056 Å) in [Ni(salen)] [23], 0.013 Å in [Ni(saloph)] [25], 0.039 Å (0.0078 Å) in [Ni(3,5-Cl_2salophen)] [7] and 0.01 Å in [Ni(napen)] [26]. We can conclude, when comparing the above values with those of [Ni(saldMe)], [Ni(1*R*,2*R*-(-)salhd)] and [Ni(saltMe)], that the observed distortions are mainly due to the bulkiness of the substituents in the imine bridge. The presence of these bulky substituents imposes severe steric requirements due to interactions between the hydrogen atoms, and consequently the three molecules [Ni(saldMe)], [Ni(saltMe)] and [Ni(salhd)] are quite distorted.

Another key result that emerged from the molecular structures is that one methyl group in [Ni(saldMe)] is oriented perpendicular to the equatorial plane, and that two methyl groups in [Ni(saltMe)] are oriented perpendicular to the

equatorial plane and in opposite directions. No crystal structure is known for [Ni(salhd)] with the cyclohexane in the *cis* form, but recalling that of [Ni(α,α′-Me_2salhd)] it is to be expected the ring to be also axially oriented.

Regarding the Ni–O and Ni–N bonding distances (Table 2), they are comparable to those observed in Schiff base complexes with identical coordination spheres [6,7,23–29] and are within the average values found in a Cambridge Structural Database search [28,29] for compounds having two carbon atoms in the imine bridge. The relative values of Ni–O and Ni–N bond lengths do not follow any pattern and no trend could be established between their values and any of the parameters used to characterise molecular distortion.

3.3. Crystal packing

The packing of both [Ni(saldMe)] and [Ni(saltMe)] do not show any Ni···Ni intermolecular distance below 3.5 Å. In the packing of [Ni(saldMe)] the shorter Ni···Ni interaction is 4.463 Å, and for [Ni(saltMe)] the existence of three independent molecules with such different orientations in the asymmetric unit prevents shorter interactions in the crystal packing. The shorter ones, 5.561 and 6.471Å, are between the nickel atom of molecule A and the nickel atoms of molecules B and C. Actually, the close intermolecular interactions between molecule A and the surrounding molecules in the unit cell explain the different conformation found for this molecule.

3.4. Cyclic voltammetry

3.4.1. Ligands

The three ligands, H_2saldMe, H_2salhd and H_2saltMe, are irreversibly oxidised in both solvents; the respective anodic peak potentials (scan rate 0.01 V s^{-1}) are approximately 1.22, 1.26 and 0.88 V in DMF, and 1.17, 1.15 and 0.84 V in $(CH_3)_2SO$. With increasing scan rates all ligands show a positive peak potential shift, as well as an increase in current intensity. Although no comparison between the potential peak values of the three ligands can be made due to the irreversible nature of charge transfer, it should be noted that the peak potential pattern for H_2saltMe is quite different from that of the other ligands.

3.4.2. Nickel complexes

Cyclic voltammetric data are summarised in Table 3. The results for [Ni(saltMe)] have been published elsewhere [8], and this complex shows in both solvents a quasi-reversible oxidation of Ni(II) to Ni(III). The cyclic voltammograms of [Ni(saldMe)] and [Ni(salhd)] are solvent dependent; in DMF in the potential range used they exhibit one anodic peak and the corresponding cathodic peak. The values of $E_{1/2}$ (vs. Ag/AgCl) are very similar and the anodic–cathodic peak potential separations, for the lowest scan rates used, are comparable to that of Fc^+/Fc couple, but somewhat higher for fast sweep rates. The ratio i_{pc}:i_{pa} was found to decrease with increasing scan rates.

The behaviour of [Ni(saldMe)] and [Ni(salhd)] in $(CH_3)_2SO$ is more intricate, since the voltammograms are dependent on scan rate. At low scan rates (0.005–0.02 V s^{-1}), two anodic waves, E_{pa}(I) and E_{pa}(II), but only one cathodic wave, which is related to the first anodic process (E_{pc}(I)), could be detected (Fig. 3 and Table 3). As the scan rate increases, a positive shift in E_{pa}(I) and E_{pa}(II) (larger for the latter process) and an increase in peak current (smaller for the latter process) are observed; furthermore, for scan rates faster than 0.05 V s^{-1} only the first anodic wave and the corresponding cathodic wave could be observed, as shown in Fig. 3. The ratio i_{pc}:i_{pa} (Table 3) for the first process is somewhat larger than 1 for low scan rates, but smaller than 1 for the highest scan rates.

For [Ni(saldMe)] and [Ni(salhd)] in the two solvents, the dependence of i_p with $\nu^{1/2}$ was found to be linear at low scan rates, but to deviate from linearity with increasing sweep rate. By coupling these results with the observations that, with increasing scan rate, the ratios i_{pc}:i_{pa} become smaller than 1 and the anodic–cathodic peak potential separation (ΔE) becomes larger than the values for Fc^+/Fc, it becomes clear that the rate of the electron transfer, relative to that of the mass transport, is insufficient to maintain the nernstian

Table 3
Cyclic voltammetric data for Ni(II) complexes in DMF and $(CH_3)_2SO$ (0.1 mol dm^{-3} TEAP) [a]

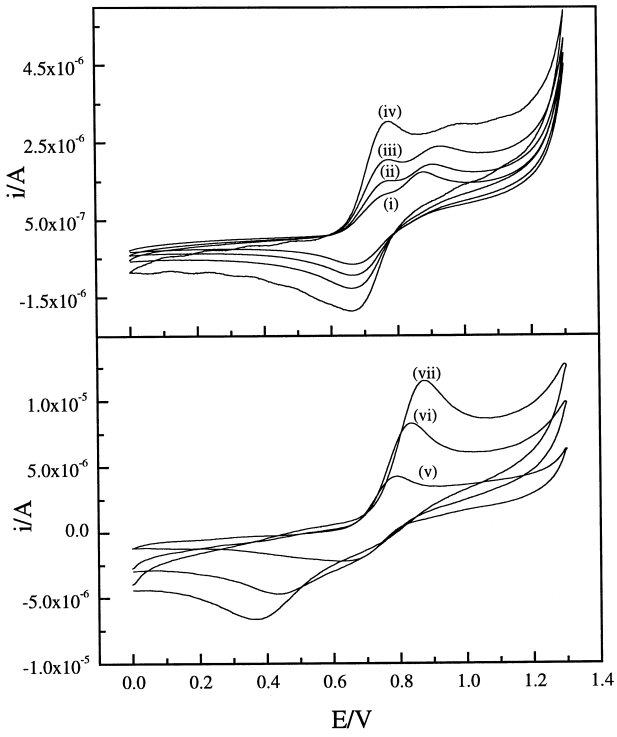

Fig. 3. Cyclic voltammograms of [Ni(salhd)] in 0.1 mol dm^{-3} TEAP–$(CH_3)_2SO$ between 0.00 and 1.30 V at different scan rates: (i) 0.005, (ii) 0.010, (iii) 0.020, (iv) 0.050, (v) 0.100, (vi) 0.500, (vii) 1.00 V s^{-1}.

equilibrium at the electrode surface. The one-electron charge transfer process is thus reversible and diffusion controlled at low scan rates, whereas at high scan rates a transition to a quasi-reversible mixed (kinetic and diffusion) controlled process must take place [30].

The oxidation of several N_2O_2 salicylaldehyde-derived Schiff base Ni(II) complexes has been shown to occur with a concomitant axial coordination of solvent molecules, and this step proved to be decisive in the overall charge transfer process, as it controls the final oxidised products and the $E_{1/2}$ values [5–15]. A similar solvent dependence is also operative in the oxidation process of [Ni(salhd)] and [Ni(saldMe)], as can be gathered by noting that their $E_{1/2}$ values are less positive in $(CH_3)_2SO$, the strong coordinating solvent used.

The $E_{1/2}$ values for [Ni(salhd)] and [Ni(saldMe)] in each solvent are similar, albeit slightly more positive than that of [Ni(salen)] [$E_{1/2}$ (DMF) = 0.81 V and $E_{1/2}$ ($(CH_3)_2SO$) = 0.70 V; scan rate 0.01 V s^{-1}] and less positive than that of [Ni(saltMe)]. To account for this behaviour, it must be pointed out that introduction of substituents in the imine bridge not only affects the electronic properties of the complex, but also may impose steric constraints on axial coordination. Electron-donating substituents (methyl groups and the cyclohexyl) are expected to decrease the values of $E_{1/2}$, and as such their $E_{1/2}$ values would be expected to be less positive than those of [Ni(salen)]. However, the values obtained were more positive, an indication that steric constraints play a more important role than electronic effects in the solution stability of the electrogenerated Ni(III) species. The X-ray structure of [Ni(saldMe)] shows one methyl group oriented towards one axial position which thus will interact directly with one axially bound solvent molecule in the oxidised species, weakening the bond to the metal with the consequent destabilisation of Ni(III) complexes. This explanation also holds for [Ni(saltMe)], for which two methyl groups of the imine bridge are directed towards two opposite axial positions thus weakening axial coordination of the two solvent molecules in the Ni(III) complexes. Therefore [Ni(saltMe)] exhibits, as expected, the more positive $E_{1/2}$ values for the series of complexes studied. Although no crystal structure for the *cis* isomer of [Ni(salhd)] is known, the preceding discussion suggests that in this isomer the cyclohexane ring must hinder axial coordination and must influence markedly its electrochemical responses.

A caveat to the above discussion is that structural data were obtained in the solid state. In solution, where solid states effects are absent, it is not possible to rule out the existence of other conformations of [Ni(saldMe)] and [Ni(salhd)], and thus the two anodic processes observed at low scan rates in $(CH_3)_2SO$ may be due to the oxidation of complexes in different conformations, one of which does not allow stabilisation of Ni(III) species.

3.5. Chronoamperometry

In both solvents the current–time responses in chronoamperometric experiments for [Ni(saldMe)], [Ni(salhd)] and [Ni(saltMe)], depicted as i versus $t^{-1/2}$ (Cottrell representation [30]), are straight lines that exhibit small deviations from linearity for long periods, particularly in the reduction step (typically longer than 6 s for the oxidation and 2 s for the reverse step). These deviations from linearity suggest a change from a diffusion-controlled process to a mixed controlled process [30], as has been inferred from cyclic voltammetry in $(CH_3)_2SO$. By using the linear region of the Cottrell equation, the diffusion coefficients for oxidation ($D_{CA}{}^{oxi}$) and the reverse step ($D_{CA}{}^{red}$) were calculated and are summarised in Table 4. The values for $D_{CA}{}^{oxi}$ are of the same magnitude as those obtained for the oxidation of [Ni(salen)] and [Co(salen)] using the Randles–Sevcik equation [31].

Table 4
Values of D_{CA} obtained using the Cottrell equation

Complex	$(CH_3)_2SO$		DMF	
	Step (V)	$10^6 D_{CA}$ (cm^2 s^{-1})	Step (V)	$10^6 D_{CA}$ (cm^2 s^{-1})

	1.0→0.0	2.65	1.0→0.0	7.35

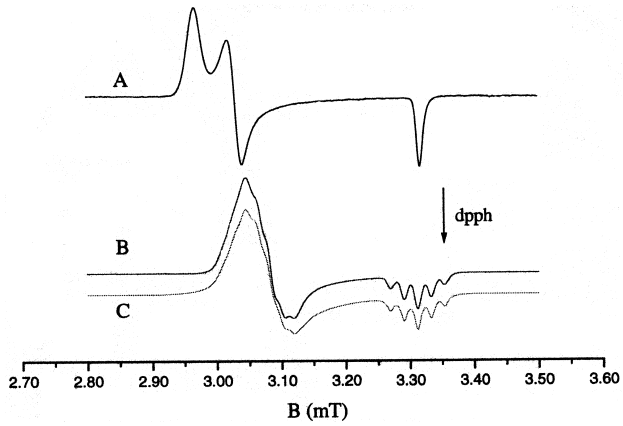

Fig. 4. Frozen-solution X-band EPR spectra at −140°C of (A) an electrochemically oxidised solution of [Ni(saldMe)] in DMF, (B) the corresponding pyridine adduct, and its simulation (C).

Analysis of D_{CA} shows that: (1) the values in DMF are higher than those obtained in $(CH_3)_2SO$, and (2) the values decrease in both solvents in the order [Ni(saldMe)] > [Ni(salhd)] > [Ni(saltMe)]. Solvent dependence can easily be accounted for by differences in solvent viscosity [30,31]: the complexes have smaller D_{CA} values in the solvent with higher viscosity, $(CH_3)_2SO$. No straightforward explanation can be invoked for the differences in D_{CA} for the complexes; we note, however, that the smallest value is obtained for the complex with the longest axial bonds ($[Ni(saltMe)(solv)_2]^+$ (see EPR section, below), and that the average size of the Ni(III) complexes may be the key factor in controlling diffusion.

3.6. Electrolysis and EPR characterisation of the oxidised solutions

Electrochemical oxidation of [Ni(saldMe)] and [Ni(salhd)] in DMF and $(CH_3)_2SO$ proceeds as that of [Ni(saltMe)] and [Ni(salen)] [8], with a solution colour change from reddish to dark brown. Frozen-solution EPR spectra of electrolytically generated nickel complexes are similar in both solvents, and show the rhombic symmetry and the large *g* tensor anisotropy typically associated with metal-centred oxidised species (Fig. 4A). The spectra exhibit no hyperfine splittings and are similar to those of oxidised solutions of [Ni(saltMe)], [Ni(salen)] [8] and other electrogenerated Ni(III) Schiff base complexes derived from salicylaldehyde [5–7]. The oxidised complexes can thus be formulated as six-coordinate, with two solvent molecules bound axially, $[Ni(L)(solv)_2]^+$, and with the metal centre in a low-spin $^2A_1$ (d_{z^2}) ground state. In the absence of EPR crystal data for the Ni(III) complexes studied, the observed similarity between their *g* features and those of analogous Ni(III) compounds [5–9] can be extended to support the following orientation scheme for the tensor axes of the nickel complexes: $g_1 = g_x$, $g_2 = g_y$, $g_3 = g_z$, where g_1 an g_3 refer to the lowest and highest magnetic field *g* values, respectively. EPR data for Ni(III) species in DMF and $(CH_3)_2SO$ are summarised in Table 5; for comparison the values for $[Ni(salen)(X)_2]^+$ and $[Ni(saltMe)(X)_2]^+$ are also included.

In order to obtain more information on the effect of the imine bridge substituents on the electronic properties of six-coordinate Ni(III) species, the EPR characterisation was extended to compounds with axially bound pyridine molecules. Upon addition of pyridine to freshly prepared solutions of electrogenerated Ni(III) complexes in DMF at temperatures just above the softening point of the frozen glass, new Ni(III) species are formed, as can be inferred from their frozen-solution EPR spectra (Fig. 4B). These are of rhombic type, although with less rhombicity than the parent complexes, have smaller values of g_{av} (2.140–2.144) and exhibit hyperfine couplings in all *g* regions. The existence of one

well-resolved quintuplet ($A=2.15$–2.13 mT) in the region of higher magnetic field and of two non-resolved quintuplets in the other g regions, implies that solvent molecules have been substituted by two pyridines (^{14}N; $I=1$) and that the resulting Ni(III) complexes have unequivocally a low-spin $^2A_1$ (d_{z^2}) ground state. The similarity between the g pattern of these species with those of the parent complex supports the same orientation scheme for the g tensor of the pyridine adducts.

No EPR signals were detected in fluid solutions of pyridine–DMF or in frozen solution of pyridine adducts in $(CH_3)_2SO$, as has also been observed for the homologous complexes with H_2salen and H_2saltMe ligands, a consequence of the very fast decomposition rate of the pyridine adducts in fluid solutions [5,8,9,32]. EPR parameters for $[Ni(L)py_2]^+$ are summarised in Tables 5 and 6; values for similar complexes with salen and saltMe are also included.

3.7. Electronic structure of the Ni(III) species

Analysis of the EPR parameters using the model developed by McGarvey for d^7 systems with an $^2A_1$ (d_{z^2}) ground state [33], in conjunction with the approximation suggested by Labause and Raynor [34,35], can provide information on the electronic structure of Ni(III) species. A full description of this analysis is described elsewhere [5,8,9] and its application allows an estimate of the energy of excited doublet states $\Delta(^2B_1)$ and $\Delta(^2A_2)$ and the average energy of the quartet states ΔQ, provided the values of complex spin orbit coupling constants (ξ) are known. We have used the ξ values of $[Ni(saltMe)((CH_3)_2SO)_2]^+$ and $[Ni(salen)((CH_3)_2SO)_2]^+$, which were found to be 55% of the free ion [8,36]. In Table 5 are included the values for $\Delta(^2B_1)$, $\Delta(^2A_2)$ and ΔQ for $[Ni(L)(DMF)_2]^+$, $[Ni(L)((CH_3)_2SO)_2]^+$ and $[Ni(L)(py)_2]^+$.

Analysis of data in Table 6 failed to reveal any correlation between the energy of the excited quartets and axial ligation. The energy of the doublet states does not change significantly when the solvent is varied from DMF to $(CH_3)_2SO$, but the axial coordination of pyridine induces a significant increase in the energy of the doublets, as a result of the strong interaction of the pyridine lone pair with the d_{z^2} orbital. This increase lowers the value of the McGarvey coefficients, C_2 and C_1, and using the g factor equations neglecting second-order terms, $g_x=2.0023+6C_2$ and $g_y=2.0023+6C_1$ [5,8,9], a decrease in g_x and g_y is predicted, as was actually observed.

Analysis of data in Table 5 reveals also that for the same axial coordinate molecule (X = DMF, $(CH_3)_2SO$ and py), the energy of the excited doublets decreases in the order $[Ni(salen)(X)_2]^+ > [Ni(salhd)(X)_2]^+ \geq [Ni(saldMe)(X)_2]^+ > [Ni(saltMe)(X)_2]^+$. This ordering reflects the strength of the axial ligation/axial bond length and thus we can deduce that axial bond lengths in the Ni(III) complexes with saltMe are the weakest (longest), and that those of salen complexes are the strongest (shortest), with the other complexes exhibiting intermediate and similar bond lengths. These observations correlate with the sequence of $E_{1/2}$ values, and reflects mainly, as mentioned above, steric interactions of the imine bridge substituents with the axially bound molecules in Ni(III) complexes.

3.7.1. Nitrogen hyperfine tensor and spin density on nitrogen atoms of axial bound pyridines

The 2s and 2p spin densities, the ratio p:s ($\lambda^2=C^2_{2p}/C^2_{2s}$) and the total spin density delocalised onto the axially bounded pyridine have been calculated by procedures described elsewhere [5,8,9,37] and are reported in Table 6. The values of C^2_{2s} are practically insensitive to changes in the equatorial ligand, whereas those of C^2_{2p} show larger variations. Thus changes in total spin density and in λ^2 reflect primarily changes in values of C^2_{2p}. The two new complexes exhibit values for the latter quantities that are in the range observed for pyridine adducts of Ni(III) complexes with ligands derived from salicylaldehyde and aliphatic diamines, but no correlation with the bulkiness of the aliphatic imine bridge could be extracted from the data, probably due to the limited number of complexes studied.

4. Concluding remarks

The oxidation of [Ni(saldMe)] and [Ni(salhd)] in DMF and $(CH_3)_2SO$ (strong donor solvents) was shown to proceed through oxidation of the metal centre and with concomitant axial coordination of solvent molecules, as has been observed for [Ni(salen)] and [Ni(saltMe)], giving Ni(III) complexes formulated as $[Ni(L)(solv)_2]^+$, where L is a Schiff base and solv a solvent molecule.

X-ray structure of the complexes revealed that in [Ni(saltMe)] two methyl groups of the imine bridge are perpendicular to the equatorial plane and directed towards the two axial coordination positions, whereas in [Ni(saldMe)] only one methyl group is directed towards one axial position. It is to be expected also that in the *cis* isomer of [Ni(salhd)] the cyclohexane group is directed towards one of the axial positions. Thus the required axial coordination of solvent molecules in these electrogenerated Ni(III) species is hindered sterically when compared with [Ni(salen)] and the main result is that the sequence observed for the $E_{1/2}$ values, [Ni(salen)] < [Ni(salhd)] ≤ [Ni(saldMe)] < [Ni(saltMe)], parallels the hindrance on axial coordination. Thus, bulky substituents in the imine bridge tend to render less accessible the +3 oxidation state in Ni(II) complexes with the N_2O_2 Schiff base ligands.

Supplementary data

Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC 133149 {[Ni(saldMe)]} and CCDC 133150 {[Ni(saltMe)]}. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, (fax: +44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Abstract

The two new bis-alkylpyridyl substituted dmit ligands, 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione (bpmdmit) and 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione (bpedmit), and some of their transition metal complexes have been prepared. Two basic structural types for the complexes MX_2L (M = Ni, Co, Cu, Pd; L = bpmdmit or bpedmit; X = Cl or Br) were determined by X-ray crystallography. The cobalt(II) and the nickel(II) complexes $CoBr_2$(bpmdmit) and $NiCl_2$(bpmdmit) show octahedral geometries around the metal ions with coordination to the metal ions by the pyridyl nitrogen atoms and the thioether sulfur atoms of the ligand and *cis* coordination of the halide ions. By contrast, only the pyridyl nitrogen atom of the ligands in the copper(II) and the palladium(II) complexes, $CuCl_2$(bpedmit) and $PdCl_2$(bpedmit), are coordinated to the metal ions to give essentially square planar metal environments. The copper complex was isolated as both green and purple crystals. However, the X-ray structures of both forms are similar, and show a dimeric arrangement with bis-μ-chloride bridges between the copper ions in the dimeric units. The green crystals contain two molecules of acetonitrile in the unit cell, however these do not interact with the metal ions. The geometry of the copper ions in the green form deviates most from centrosymmetric square planar geometry and this is consistent with the observed colour. Apart from the colour, the solids can be distinguished in the solid state by EPR spectroscopy since they give different rhombic signals. UV–Vis and EPR spectroscopy show that in solution the structures of the purple and green forms of $CuCl_2$(bpedmit) are identical, as expected. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Copper; Cobalt; Nickel; Palladium; dmit; 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione; 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione

1. Introduction

4,5-Disulfanyl-1,3-dithiole-2-thionate ($dmit^{2-}$) has been used extensively for the preparation of mononuclear bis-dmit and tris-dmit complexes of transition and main group metals [1–3]. These sulfur-rich molecules have the potential for novel electronic properties owing to the extensive π overlap of the sulfur and metal-based d orbitals. Several examples of thiolate functionalized dmit compounds have been reported [4] but to our knowledge none of these have been used as ligands for metal ions. The work reported here describes the attachment of alkylpyridyl moieties to the thiolate sulfur atoms of $dmit^{2-}$, to give chelating groups containing thioether and pyridyl donor groups (Chart 1). The thioether groups are not expected to be strong donors to other than soft metal ions; however, as part of a chelating system thioether groups are known to coordinate to metal ions [5–9]. In this study complexation reactions with various metal(II) salts were investigated. Only reactions with chloride salts gave tractable products and the structures of these have been determined.

trometer. FAB mass spectra were recorded on a Kratos MS50TC. Electron spin resonance (ESR) measurements at X-band frequencies were obtained using a Bruker ESP-380E FT-EPR spectrometer. Cyclic voltammograms were measured using a locally constructed three-electrode potentiostat using acetonitrile solutions containing $^{n}Bu_4NPF_6$ (0.1 M) and a scan rate of 0.100 V s^{-1}. The working electrode was a BAS platinum electrode, with an Ag/AgCl electrode as reference electrode and a counter electrode of platinum. $^{n}Bu_4PF_6$ was used as electrolyte ($\approx$0.1 M). In this set-up ferrocene was used as an internal standard for which a halfwave potential at 105 mV was recorded. Elemental analyses were carried out at the microanalytical laboratory of the H.C. Ørsted Institute, Copenhagen. TLC was carried out on Merck Silicagel 60 F_{254} coated aluminium foil; the same type of silica was used for columns. Where necessary, solvents were dried according to standard literature methods [10]. $(Et_4N)_2$-$(Zn(dmit)_2)$ [11] and 4,5-bis(benzoylsulfanyl)-1,3-dithiole-2-thione [12] were prepared by literature methods.

2.1. Syntheses

2.1.1. 4,5-Bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione (bpmdmit)

4,5-Bis(benzoylsulfanyl)-1,3-dithiole-2-thione (3.173 g, 7.80 mmol) was suspended in 80 cm^3 anhydrous methanol and purged with nitrogen for 25 min. Sodium (0.73 g, 31.75 mmol) dissolved in anhydrous methanol (50 cm^3) was added over a period of 30 min. After the addition the suspension was stirred for a further 15 min, by which time it became a deep red colour and all of the thione dissolved. 2-Picolylchloride hydrochloride (2.56 g, 15.61 mmol) was added over a period of 90 min and the solution stirred overnight. The resulting red solution was concentrated in vacuo and the residue dissolved in EtOAc. A small amount of precipitate was removed by filtration. The filtrate was concentrated and purified by column chromatography using EtOAc as eluent. The product was obtained as a TLC- and NMR-pure dark brown oil. Raw yield, 1.771 g (60%). The oil was dissolved in boiling hexane (50 cm^3) and a yellow powder obtained by scratching the glass vessel while cooling. Yield, 0.569 g (19%); m.p. 52–53°C (hexane). *Anal*. Found: C, 47.83; H, 3.27; N, 6.94. Calc. for $C_{15}H_{12}N_2S_5$: C, 47.34; H, 3.18; N, 7.36%. ^{1}H NMR (250 MHz, $CDCl_3$): δ 4.13 (s, 4H, CH_2), 7.18–7.24 (m, 4H, Py-H4,5), 7.63 (dt, J=2/8 Hz, 2H, Py-H3), 8.55–8.57 (d, J=5 Hz, 2H, Py-H6). ^{13}C NMR (62.5 MHz, $CDCl_3$): δ 42.38 (CH_2), 122.60 (Py-C3/5), 123.09 (Py-C3/5), 136.72 (Py-C4), 137.26 (C=C), 149.74 (Py-C6), 155.68 (Py-C2) and 211.22 (C=S). IR (KBr): 1060, 1435, 1475, 1568, 1594 cm^{-1}. UV–Vis (CH_3OH): λ_{max} (log ε) 266 (4.05), 377 nm (4.06).

2.1.2. 4,5-Bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione (bpedmit)

$(Et_4N)_2(Zn(dmit)_2)$ (10.619 g, 14.79 mmol) and 2-vinylpyridine (9.774 g, 93 mmol) were mixed in $CHCl_3$/AcOH (3:1, 200 cm^3) and heated under reflux overnight. The solution was filtered and washed with water (200 cm^3), sat. aq. $NaHCO_3$ (2×200 cm^3) (caution!), sat. aq. NaCl (200 cm^3), water (200 cm^3), dried ($MgSO_4$) and concentrated in vacuo. The residue was dissolved in acetone and a small amount of sticky precipitate was discarded. The solution was concentrated and purified by column chromatography with EtOAc/hexane (2:1) as eluent. The product was recovered as an oil, R_f=0.24 (EtOAc/hexane, 2:1). After 3 h in an open flask the oil solidified. The solid was pulverized and dried. Yield, 6.956 g (58%); m.p. 37–38.5°C. *Anal*. Found: C, 49.95, H, 3.94, N, 6.88. Calc. for $C_{17}H_{16}N_2S_5$: C, 49.97; H, 3.95; N, 6.86%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.15 (t, J=7 Hz, 4H, SCH_2), 3.34 (t, J=7 Hz, 4H, CH_2Py), 7.15–7.20 (m, 4H, Py-H4,5), 7.63 (dt, J=2/8 Hz, 2H, Py-H3), 8.55 (d, J=4 Hz, 2H, Py-H6). ^{13}C NMR (75 MHz, $CDCl_3$): δ35.71 (SCH_2), 38.01 (CH_2Py), 121.89 (Py-C3/5), 123.42 (Py-C3/5), 136.55 (Py-C4), 136.61 (C=C), 149.64 (Py-C6), 158.43 (Py-C2), 211.39 (C=S). IR (KBr): 1062, 1435, 1473, 1569, 1592 cm^{-1}. UV–Vis (CH_3OH): λ_{max} (log ε) 263 (4.18), 381 nm (4.13).

2.1.3. 4,5-Bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione cobalt(II) bromide, $CoBr_2$(bpmdmit) (**1**)

Bpmdmit (35.7 mg, 0.094 mmol) and cobalt(II) bromide hexahydrate (31.4 mg, 0.096 mmol) were dissolved in CH_3CN (20 cm^3) to give a blue–green solution. After 2 h red/green pleochroic crystals began to precipitate. Yield, 39 mg (69%). *Anal*. Found: C, 30.06; H, 2.02; N, 4.67. Calc. for $C_{15}H_{12}Br_2CoN_2S_5$: C, 30.49; H, 1.87; N, 4.82%. FABMS: *m/z* 598 (M^+), 519 ([M−Br]$^+$), 381 ([ligand+H]$^+$). IR (KBr): 1072, 1438, 1482, 1568, 1601 cm^{-1}. UV–Vis (CH_3OH): λ_{max} (log ε): 267 (4.24), 377 nm (4.16).

2.1.4. 4,5-Bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione nickel(II) chloride, $NiCl_2$(bpmdmit) (**2**)

Bpmdmit (43.6 mg, 0.115 mmol) and nickel(II) chloride hexahydrate (33.6 mg, 0.141 mmol) were mixed in CH_3CN:H_2O (25:1, 25 cm^3) to give a green solution. Green crystals deposited after 24 h. Yield, 35 mg (60%). *Anal*. Found: C, 34.08, 34.16; H, 2.34, 2.36; N, 5.32, 5.37. Calc. for $C_{15}H_{12}Cl_2N_2NiS_5 \cdot H_2O$: C, 34.11; H, 2.67; N, 5.30%. FABMS: *m/z* 551 ([ligand+NiCl+DMSO]$^+$), 473 ([ligand+NiCl]$^+$), 438 ([ligand+Ni]$^+$), 381 ([ligand+H]$^+$). IR (KBr): 1072, 1439, 1482, 1568, 1601 cm^{-1}. UV–Vis (CH_3OH): λ_{max} (log ε): 266 (5.09), 377 nm (5.08).

2.1.5. 4,5-Bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione copper(II) chloride, $CuCl_2$(bpedmit)·$2CH_3CN$ (**3a**)

Bpedmit (58.8 mg, 0.144 mmol) and copper(II) chloride dihydrate (25.2 mg, 0.15 mmol) were dissolved in CH_3CN (5 cm^3) to give a green solution. On standing, **3a** as green needles and a small amount of **3b** as purple needles precipitated from the solution. Combined yield, 70.2 mg (79–92%). The crystals were separated manually to obtain the elemental

analysis and spectroscopic data for **3a** and the crystal used for X-ray crystallography. *Anal*. Found: C, 40.16; H, 3.48; N, 8.64. Calc. for $C_{17}H_{16}Cl_2CuN_2S_5 \cdot 2CH_3CN$: C, 40.35; H, 3.55; N, 8.96%. IR (KBr): 1062, 1440, 1485, 1570, 1605, 2244 cm^{-1}. FABMS: *m/z* 541 ($[ligand + CuCl_2]^+$), 506 ($[ligand + CuCl]^+$), 471 ($[ligand + Cu]^+$), 409 ($[ligand + H]^+$). UV–Vis (CH_3OH): λ_{max} (log ε): 263 (4.78), 380 (4.64), 611 nm (2.81). UV–Vis (CH_3CN): λ_{max} (log ε) 263 (4.09), 384 nm (4.06).

*2.1.6. 4,5-Bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione copper(II) chloride, $CuCl_2$(bpedmit) (**3b**)*

4,5-Bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione (bpedmit) (98.6 mg, 0.241 mmol) dissolved in ethanol (15 cm^3) and copper(II) chloride dihydrate (51.2 mg, 0.300 mmol) dissolved in ethanol (10 cm^3) were mixed, effecting an immediate colour change from yellow to green. The product precipitated as purple block like crystals. Yield, 120 mg (92%). *Anal*. Found: C, 37.70, 37.80; H, 2.88, 2.89; N, 5.13, 5.18. Calc. for $C_{17}H_{16}Cl_2CuN_2S_5$: C, 37.60; H, 2.97; N, 5.16%. IR (KBr): 1064, 1439, 1485, 1570, 1605 cm^{-1}. FABMS: *m/z* 541 ($[ligand + CuCl_2]^+$), 506 ($[ligand + CuCl]^+$), 471 ($[ligand + Cu]^+$), 409 ($[ligand + H]^+$). UV–Vis (CH_3OH): λ_{max} (log ε): 263 (3.55), 381 (3.47), 606 nm (2.44). UV–Vis (CH_3CN): λ_{max} (log ε): 263 (4.00), 383 (3.99).

*2.1.7. 4,5-Bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione palladium(II) chloride, $PdCl_2$(bpedmit) (**4**)*

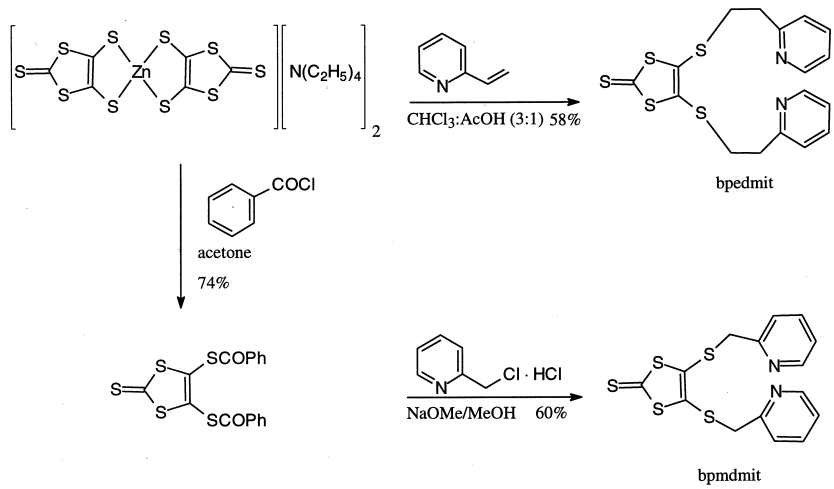
Bpedmit (89.0 mg, 0.218 mmol) and $Pd(CH_3CN)_2Cl_2$ (63.5 mg, 0.245 mmol) dissolved in CH_3CN (45 cm^3) were mixed to give a turbid yellow solution. The solution was filtered and red crystals deposited. Yield, 51.0 mg (40%). *Anal*. Found: C, 35.14; H, 2.53; N, 5.41. Calc. for $C_{17}H_{16}Cl_2N_2PdS_5$: C, 34.85; H, 2.75; N, 4.78%. ^1H NMR (250 MHz, $(CD_3)_2SO$): δ 3.59–3.66 (m, 4H, SCH_2), 4.27–4.34 (4H, m, CH_2Py), 7.45–7.50 (m, 4H, Py-H4,5), 7.98 (dt, 2H, Py-H3), 9.04 (d, 2H, Py-H6). IR (KBr): 1064, 1445, 1488, 1569, 1604, 2249 cm^{-1}. UV–Vis (CH_3OH): λ_{max} (log ε): 264 (3.71), 371 nm (3.10).

2.2. X-ray crystal structure determinations

The structures of complexes **1** and **3a** were determined with data measured using a four-circle diffractometer. Cell dimensions were determined from the setting angles of selected reflections measured at $\pm 2\theta$. Intensity data were corrected for background, Lorentz and polarization effects using the programs in the KRYSTAL system [13]. The structures of complexes **2**, **3b** and **4** were determined with data measured using an area detector [14]; data were processed using SAINT [14] and SADABS [15]. The structures were determined using SIR92 [16] and refined using the local modification [13] of ORFLS [17]. Non-hydrogen atoms were refined with anisotropic displacement parameters, hydrogen atoms were kept fixed in calculated positions (C#H = 0.95 Å) except for those of the acetonitrile molecules of **3a** where the hydrogen atom coordinates were refined. Hydrogen atoms were given isotropic displacement parameters 20% larger than those of the atoms to which they were attached. Atomic scattering factors were taken from Ref. [18]. Crystal data and details of the structure determinations are given in Table 1.

3. Results and discussion

3.1. Synthesis



Two potentially tetradentate ligands containing dmit and pyridyl units 4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione (bpmdmit) and 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione (bpedmit), Chart 1, have been prepared using the zinc salt of $dmit^{2-}$, $[Et_4N]_2[Zn(dmit)_2]$, as starting material, as depicted in Scheme 1. Bpedmit was obtained by the direct reaction of $[Et_4N]_2[Zn(dmit)_2]$ with 2-vinylpyridine in chloroform:acetic acid (3:1). Bpmdmit was obtained by a two-step synthesis; first $[Et_4N]_2[Zn(dmit)_2]$ was reacted with benzoyl chloride in acetone to obtain the benzoyl protected dmit which was subsequently deprotected using sodium methoxide. The resulting dithiolate was alkylated using picolyl chloride.

Reaction of bpmdmit and bpedmit with the halide salts of the divalent metal ions Co^{2+}, Ni^{2+}, Cu^{2+} and Pd^{2+} has given a series of five complexes, all of which have been characterized by X-ray crystallography. Reactions of bpmdmit or bpedmit with non-halide salts of the same metal ions did not lead to solid products. Two basic structural types for complexes with the MLX_2 (L = bpmdmit or bpedmit; X = Cl or Br) formulation have been found. (i) Complexes in which the metal coordination geometry is octahedral and the thioether sulfur atoms and the pyridyl nitrogen atoms are coordinated leaving two *cis* oriented coordination sites. (ii) Square planar complexes in which only the pyridyl nitrogen atoms are used as *trans*-orientated donor atoms and halide ions complete the coordinations sphere of the metal. The complexes of the ligand with the pyridylmethyl arms (bpmdmit) show the octahedral coordination geometry, while the complexes of the homologous ligand, bpedmit, are the square planar complexes. Whether or not the coordination geometries observed are controlled by the choice of ligand or of metal ion has not been established, however, the geometries observed are those expected for the respective metal ions. Attempted preparations of bpedmit complexes of Ni^{2+} and Co^{2+} and bpmdmit complexes of Cu^{2+} and Pd^{2+} did not lead to tractable products.

The crystal structures of the cobalt(II) and nickel(II) of bpmdmit complexes **1** and **2** are depicted in Figs. 1 and 2. Complex **1** crystallizes with two almost identical molecules in the asymmetric unit (Fig. 1). Both molecules have approximate two-fold symmetry with the cobalt atom coordinated to two *cis* bromide atoms (Co1–Br 2.514(1), 2.496(1) Å;

Co2–Br 2.509(1), 2.488(1) Å), two *trans* pyridyl nitrogen atoms (Co1–N 2.195(5), 2.169(5) Å; Co2–N 2.168(5), 2.171(5) Å), and to the two sulfanyl sulfur atoms (Co1–S 2.596(2), 2.522(2) Å; Co2–S 2.543(2), 2.551(2) Å). The dmit unit is coplanar with the $CoBr_2$ moiety. Complex **2** crystallizes with only one molecule in the asymmetric unit, and the coordination geometry is similar to that of complex **1** with the nickel atom coordinated to two chloride atoms

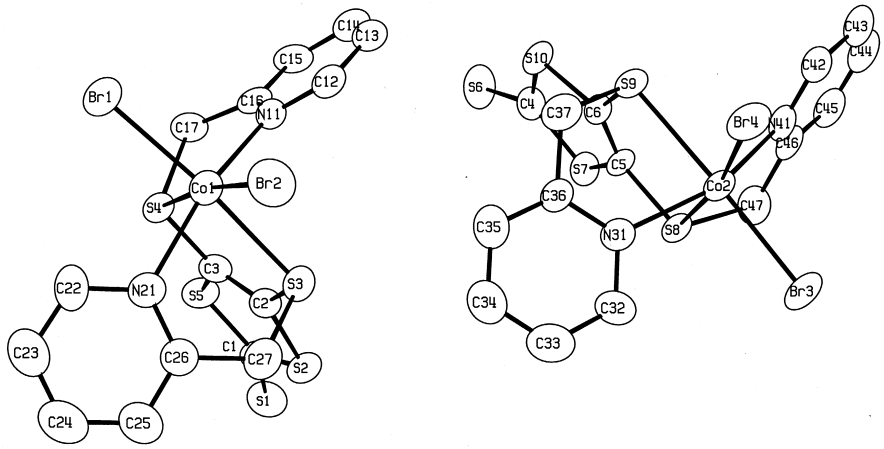

Fig. 1. The atomic arrangement for the two molecules of $CoBr_2$(bpmdmit) (**1**) together with the numbering scheme. Ellipsoids are drawn at the 50% probability level.

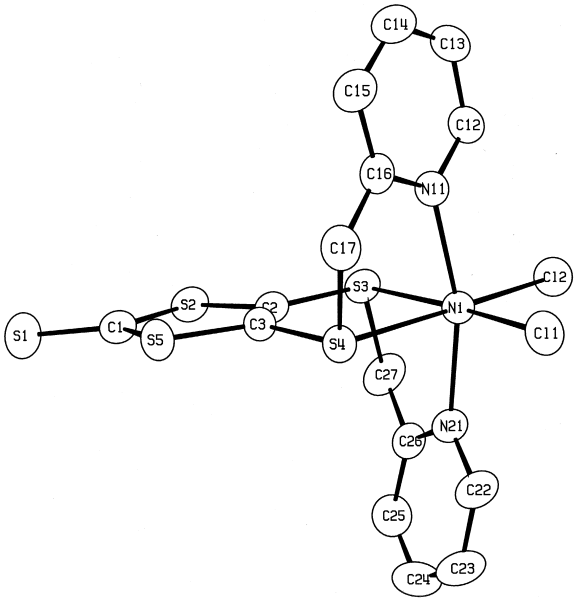

Fig. 2. The atomic arrangement for $NiCl_2$(bpmdmit) (**2**) together with the numbering scheme. Ellipsoids are drawn at the 50% probability level.

(Ni–Cl 2.3435(5), 2.3683(4) Å), two pyridyl nitrogen atoms (Ni–N 2.103(1), 2.106(1) Å), and to the two sulfanyl sulfur atoms (Ni–S 2.4620(4), 2.4763(4) Å). Selected bond distances and angles for complexes **1**, **2**, **3a**, **3b** and **4** are listed in Tables 2 and 3, respectively.

The complex obtained from the reaction of copper chloride with bpedmit gives two distinct crystalline products: green needles (**3a**) and dark purple crystals (**3b**) from acetonitrile solutions, and dark purple crystals (**3b**) only from ethanol solutions. On no occasion was **3a** isolated from acetonitrile solution free of **3b**. The colour difference prompted solid state studies of both crystalline types, however, the structures are similar with no solvent coordination. Both complexes are bis(μ-chloro)-bridged dimers. The structure of **3a** is shown in Fig. 3. In contrast to the Co and Ni complexes described above, the thioether sulfur atoms are not coordinated to the metal ions in either of these complexes. The coordination geometries around the copper atom in these complexes are approximately square pyramidal with the two pyridine nitrogen atoms (Cu–N 2.040(2), 2.041(2) Å) and two chloride ions (Cu–Cl 2.324(1), 2.226(1) Å) in the square plane. A long bond to the chloride ion bound to an adjacent copper atom forms the apical bond. The Cu–N and Cu–Cl distances are significantly shorter than the corresponding distances found for the octahedral Ni and Co complexes. The ligand is folded sharply at the thioether sulfur atoms and there are no Cu···S interactions shorter than 5 Å. The structure of complex **3a** shows approximate mirror symmetry. Pairs of centrosymmetrically related complexes are linked by weak Cu···Cl interactions, Cu···Cl1 2.858(1) Å, to form dimers with a Cu···Cu distance of 3.864(1) Å. The Cu–Cl bond of the

chloride bridge is 0.058 Å longer than that to the terminal Cl. The acetonitrile molecules are not involved in bonding to the complex. The purple form of complex **3b** crystallizes without lattice acetonitrile and the structure is similar to that of **3a**, with Cu–N 2.016(3), 2.022(3) Å and Cu–Cl 2.238(1), 2.274(1) Å. However the apical Cu···Cl interactions (Cu···Cl1 3.178(1) Å) are weaker and consequently the copper–copper separation (Cu···Cu 4.178(1) Å) of the dimer is longer. The crystal structures show that the square plane of the metal ion of the green form (**3a**) has a slight tetrahedral distortion with N–Cu–N_A 177.71(7)° and Cl1–Cu–Cl2 159.87(3)°. The crystal structure of the purple form **3b** is closer to square planar with differences in the metal ligand bonds in the *xy* plane less than those for **3a** and its four strong bonds quite close to planar with N–Cu–N_A 171.5(1)° and Cl1–Cu–Cl2 176.02(7)°. As well, there is a significantly shorter apical Cu···Cl interaction for **3a** compared to **3b**, further distorting the Cu environment in **3a**. This is consistent with the observed colour differences: deviation from the centrosymmetric square planar geometry allows a forbidden transition to occur, with the consequence that yellow is mixed with the blue giving the observed green colour. A similar dimeric arrangement was observed in the the structures of the blue Cu(2-methylpyridine)$_2$Cl$_2$ [19]. The bond lengths in Cu(2-methylpyridine)$_2$Cl$_2$ are Cu–Cl 2.21, 2.26 Å and Cu–N 1.98, 2.02 Å, an apical Cu···Cl distance of 3.37 Å and a Cu···Cu distance in the dimer of 4.41 Å. For the Cu–Cl bonds, one bond is longer than the other and the Cu···Cl distance is significantly longer. The distance between the two metal ions in Cu(2-methylpyridine)$_2$Cl$_2$ is longer than in **3a** and **3b**, owing to the longer apical Cu···Cl bonds, and is consistent with the colour variation in the series of compounds, **3a** (green), **3b** (purple) and Cu(2-methylpyridine)$_2$Cl$_2$ (blue) [19].

The structural arrangement in the palladium complex **4** is similar to that found for the copper complexes with a square planar geometry about the palladium ion with Pd–N 2.038(2) Å and Pd–Cl 2.299(1), 2.317(1) Å (Fig. 4). However, by contrast to the copper complexes the complex is monomeric in the solid state. There are no significant metal···sulfur interactions. Complex **4** crystallizes with the molecule across a crystallographic mirror plane so that the molecule itself has exact mirror symmetry.

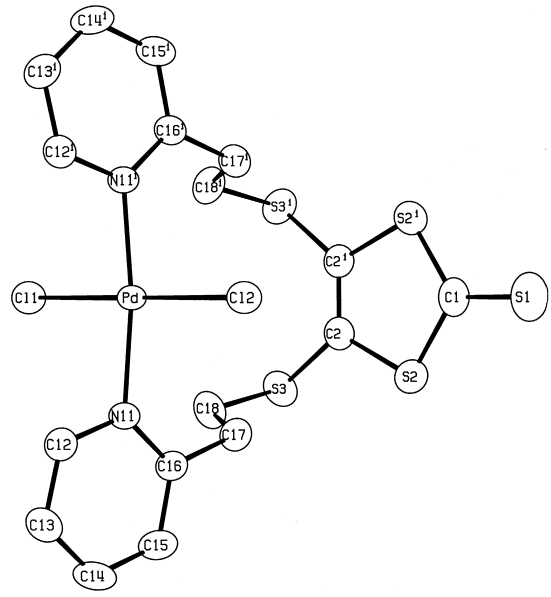

Fig. 4. The atomic arrangement for $PdCl_2$(bpedmit) (**4**) together with the numbering scheme. The symmetry code is $x, 1/2-y, z$. Ellipsoids are drawn at the 50% probability level.

3.2. ESR spectroscopy

ESR spectra of the copper complexes **3a** and **3b** were recorded in powder form (room temperature) and in frozen glass solution (methanol/DMF,100 K). The two solid state forms of $CuCl_2$(bpedmit) **3a** and **3b** can be distinguished by the observation of slightly different rhombic signals; for **3a** with $g_x = 2.034$, $g_y = 2.066$ and $g_z = 2.249$ and for **3b** with $g_x = 2.034$, $g_y = 2.056$ and $g_z = 2.223$. The solution ESR spectra of **3a** and **3b** are identical as expected, giving an axial signal with $g_\perp = 2.074$, $g_{||} = 2.398$ and $A_{||} = 121$ G. This is corroborated by identical solution UV–Vis spectra for **3a** and **3b** in methanol.

3.3. Cyclic voltammetry

Irreversible oxidation peaks at 1.017 and 1.252 V for the free ligands bpmdmit and bpedmit were obtained respectively. These peaks originate from the dmit moieties of the ligands since an irreversible peak is observed for the simpler dimethyl derivatized dmit (4,5-bis(methylsulfanyl)-1,3-dithiole-2-thione, i.e. there are no pyridyl groups) at 871 mV. The peaks are absent in the voltammograms of the complexes, thus irreversible ligand oxidation is, not unexpectedly, suppressed by complexation to a dipositive metal ion. The cobalt complex **1** was the only complex to give an electrochemical response in the range available. For **1** a reversible peak assigned to a Co(II)/(III) process with a halfwave potential at 576 mV versus Ag/AgCl was recorded.

4. Conclusions

This work describes the first reported transition metal complexes of the thiolate-functionalized dmit-containing ligands

4,5-bis(2-pyridylmethylsulfanyl)-1,3-dithiole-2-thione (bpmdmit) and 4,5-bis(2-pyridylethylsulfanyl)-1,3-dithiole-2-thione (bpedmit). Complexes with the formulation MX_2L (M = Ni, Co, Cu, Pd; L = bpmdmit or bpedmit; X = Cl or Br) have been crystallographically characterized. The thioether sulfur atoms are coordinated to the metal ions in the octahedral Ni and Co complexes but not in the square planar Cu and Pd complexes. Oxidation of the dmit units of the ligands is suppressed by coordination to the metal ions in these complexes.

Supplementary data

Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC 136158, CCDC 136159, CCDC 136160, CCDC 136161, CCDC 136162. Fractional atomic coordinates for **1**, **2**, **3a**, **3b**, **4** (STables 1–5); complete listing of bond distances, angles and selected torsion angles (STables 6–10). Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

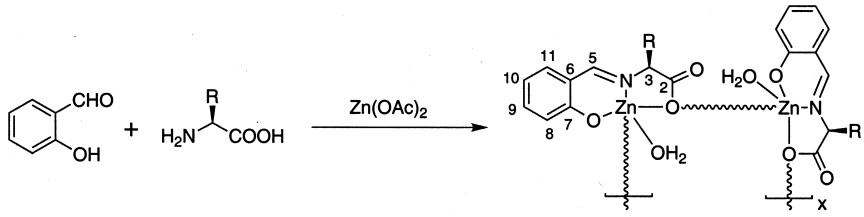
The synthesis in aqueous ethanol solution of eight Zn(II) compounds of salicylaldehyde-amino acid Schiff bases together with their spectral characterisation is reported. Two of the complexes, [(*N*-salicylidene-L-alaninato)(aqua)zinc(II)]·0.25H_2O (**1**) and [(*N*-salicylidene-L-valinato)(aqua)zinc(II)] (**2**), have been obtained in the form of crystals suitable for X-ray crystallography. The coordination geometry about the zinc in both structures is between distorted trigonal bipyramidal and distorted square pyramidal with the iminic nitrogen N(4) (**1** = 2.020(3) and **2** = 2.015(7) Å), the phenolic O(8) (**1** = 1.991(2) and **2** = 1.997(6) Å) and the carboxylic O(1) (**1** = 2.160(2) and **2** = 2.156(5) Å) of the *N*-salicylidene-aminoacidato base ligand. Another carboxylic O(1)* of an adjacent unit (**1** = 2.033(2) and **2** = 2.033(5) Å), curiously shorter than the bond from the ligand itself, and a water molecule (**1** = 2.006(3) and **2** = 1.999(6) Å) comprise the fourth and fifth coordination positions. The crystals are constituted by polymeric [(*N*-salicylidene-L-aminoacidato)zinc(II)] moieties forming helical arrays about three-fold screw axes. To our knowledge these are the first two structures of binary complexes of the type [(*N*-salicylidene-L-aminoacidato)Zn(II)]. The NMR studies, in DMSO, agree with a general *endo* disposition between the side chain of the amino acid and the aromatic ring of the salicylidene moiety. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Schiff base complexes; *N*-Salicylidene derivatives; X-ray structures; Zn(II) complexes

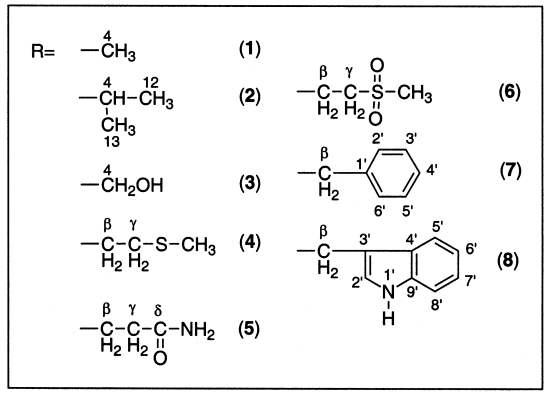
1. Introduction

Transition metal complexes of salicylaldehyde-amino acid Schiff bases are non-enzymatic models for pyridoxal-amino acid systems which are of considerable importance as key intermediates in many metabolic reactions of amino acids catalysed by enzymes which require pyridoxal as a cofactor [1–6]. Considerable effort has been devoted to the preparation and structural characterisation of Schiff base Cu(II) complexes derived from salicylaldehyde and amino acids such as Gly [7–9], β-Ala [10], Val [11,12], Ser [13], Thr [14], Met [15], Glu [16,17], Phe [18,19], Tyr [20], Trp [21] and α-aminoisobutyrato [22] and reduced salicylidene amino acids [23]. Although the syntheses of several *N*-salicylideneaminoacidato zinc(II) complexes have been reported in the literature [24–26], most of them have been carried out in solution [25,27–30] and single-crystal X-ray diffraction studies on *N*-salicylidene-aminoacidato Zn(II) complexes are very limited [31–34].

As part of a continuing study of complexes formed by metal(II) ions and Schiff base amino acids [13,21], we have synthesised and characterised spectroscopically eight new zinc(II) complexes with *N*-salicylidene amino acids (Scheme 1). Moreover, the first X-ray structures of binary Zn(II) *N*-salicylidenealaninato and valinato, Zn(Sal-L-ala) and Zn(Sal-L-val), are described.



2. Experimental



2.1. Analysis and physical measurements

IR spectra were measured in the solid state (KBr pellets) on a PE 683 with an IR data station PE 1600 and the electronic spectra were registered on a PE 552 spectrophotometer. Ther-

Scheme 1.

mogravimetric data in the temperature range from 30 to 700°C were recordered in a flowing nitrogen atmosphere (heating rate 10°C min^{-1}) on a PE TGA-2 thermobalance. 1D and 2D ^1H and ^{13}C NMR spectra were recorded on a Bruker AMX 300. Proton and carbon chemical shifts in DMSO-d_6 were referenced to DMSO-d_6 (^1H NMR, $\delta_{(DMSO)} = 2.60$ ppm; ^{13}C NMR, $\delta_{(DMSO)} = 43.5$ ppm). Unequivocal assignments were made by 2D NMR experiments, HMQC [35] and HMBC [36], or by comparison of spectra of other related products. Satisfactory C, H and N analyses were obtained for all compounds and carried out with a Carlo Erba model 1106 microanalyser. NOE studies were performed by 2D NMR experiments (ROESY) [37]. The 2D spectra were processed using commercial Bruker software and experimental characteristics presented below.

^1H-Detected heteronuclear multiple quantum coherence spectroscopy (HMQC). The one-bond ^1H–^{13}C shift correlation spectra resulted from a 502×2048 data matrix with 48 scans (preceded by 16 dummy scans) per t_1 value. Pre-delay was 1.0 s and a 10.3 μs, 90° ^{13}C pulse width was used. A sine bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

^1H-Detected multiple-bond heteronuclear multiple quantum coherence spectroscopy (HMBC). The multiple-bond ^1H–^{13}C shift correlation spectra resulted from a 246×2048 data matrix with 128 scans (preceded by 8 or 16 dummy scans) per t_1 value. Pre-delay was 1.0 s and a 10.3 μs, 90° ^{13}C pulse width was used. The delay between the first and the second 90° ^{13}C pulses was 75 ms. A sine bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

Rotating frame Overhauser effect spectroscopy (ROESY). The ^1H–^1H shift correlation spectra resulted from a 250×2048 data matrix with 64 scans (preceded by 8 or 16 dummy scans) per t_1 value. Pre-delay was 2.0 s and a 5.1 μs, 90° ^1H pulse width and 2.3 kHz (23 dB) of ^1H r.f. power and 107.5 μs, 90° ^1H pulse width were used. Mixing time was 500–600 ms. A sine bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

Salicylaldehyde, amino acids and zinc(II) acetate monohydrate were purchased from Aldrich and used without further purification.

2.2. Crystallographic studies

Crystals were selected and mounted on an Enraf-Nonius CAD-4 four-circle diffractometer with graphite-monochromated Mo Kα radiation at room temperature. Unit cell parameters were determined from the automatic centring of 25 reflections (in the ranges $12 < \theta < 31°$ and $10 < \theta < 32°$ for **1** and **2**, respectively) and refined by least-squares methods. In both cases, intensities were collected using the ω–2θ scan technique. Three standard reflections were measured every hour as intensity controls during data collections; no significant intensity decay was observed in any case. Lorentz polarization and Ψ-scan absorption corrections (maximum and minimum transmissions factors for **1** and **2**: $T_{max} = 0.998$, $T_{min} = 0.906$ and $T_{max} = 0.999$, $T_{min} = 0.967$) were applied using the MolEN package [38]. Additional crystallographic data are presented in Table 1. The structures were solved by direct methods with the SHELXS-86 [39] computer program and refined by full-matrix least-squares methods using the SHELXL-93 [40] computer program. Thermal motions of non-hydrogen atoms were refined anisotropically. H-atoms were positioned at calculated positions and refined with two global isotropic thermal factors in each case. The refinement processes converged at $R_1 = 0.046$ and 0.038 and $wR_2 = 0.083$ and 0.080 ($I > 2\sigma(I)$) for **1** and **2**, respectively. In both cases

Table 1

R indices (all data)	R_1 = 0.0834, wR_2 = 0.0859	R_1 = 0.1261, wR_2 = 0.0933
Largest difference peak (e Å^{-3})	0.346	0.231
Largest difference hole (e Å^{-3})	−0.521	−0.275

the minimised function was $\sum w(|F_o|^2 - |F_c|^2)$, with respectively $w = [\sigma^2(|F_o|^2) + (0.0574P)^2]^{-1}$ and $w = [\sigma^2(|F_o|^2) + (0.0393P)^2]^{-1}$, $P = [(|F_o|^2 + 2|F_c|^2)/3]$. Scattering factors were taken from International Tables for X-ray Crystallography [41] except for those of the H-atoms [42]. A summary of the refinements is shown in Table 1. Selected bond distances and angles for **1** and **2** are listed in Table 2.

2.3. Preparation of the complexes: general procedure

To a warm solution (60–70°C) of the corresponding amino acid (**1**–**8**) (5 mmol) (Scheme 1) in 10 ml of water (or ethanol for compound **8**), 5 mmol (0.61 g) of salicylaldehyde in 10 ml of ethanol were added. The resulting solution was stirred for 0.5 h. A solution of zinc(II) acetate monohydrate (5 mmol, 1.00 g) dissolved in a minimum quantity of water was added dropwise. During the addition, the pH was adjusted to 7 by addition of 0.5 M KOH. The solution was stirred for 1 h and the yellowish precipitate obtained was filtered, washed with water and air dried. The resulting solid was crystallised from either methanol or DMSO.

2.3.1. [(N-Salicylidene-L-alaninato)(aqua)zinc(II)]·0.25H_2O (*1*)

47% yield. White crystals from MeOH. Exhibits a mass decrease (found 6.66; calc. 6.56) between 142 and 200°C corresponding to the loss of one water molecule per formula unit. *Anal*. Found: C, 43.04; H, 3.95; N, 5.02. Calc. for $C_{10}H_{11}NO_4Zn \cdot 0.25H_2O$: C, 43.03; H, 4.12; N, 5.02%. IR (cm^{-1}): 3301m, 2975m, 2934m, 1647s, 1607s, 1542s, 1470s, 1448s, 1381m, 1362s, 1338s, 1290s, 1260m, 1193m, 1157m, 1135m, 1115m, 1062w, 1041w, 987w, 937w, 913m, 873w, 859w, 799m, 763s, 746m, 681w, 648w, 601w, 540m, 508w, 487w, 437w, 403w, 340w. UV–Vis (DMSO): λ 370 (ε 6.5×10^3), 258 nm (9.1×10^3 dm^3 mol^{-1} cm^{-1}). ^{1}H NMR (DMSO-d_6, 293 K): δ 8.45s (1H, H(5)), 7.25d+t (2H, H(11)+H(9)), 6.80bd (1H, H(8)), 6.57t (1H, H(10), *J* = 7.1 Hz), 3.81q (1H, H(3), *J* = 7.1 Hz), 1.41d (1H, CH_3, *J* = 7.1 Hz). ^{13}C-NMR (DMSO-d_6, 293K): δ 180.3 (C(2)), 173.0 (C(7)), 171.8 (C(5)), 139.0 (C(11)), 137.3 (C(9)), 126.5 (C(8)), 123.4 (C(6)), 117.7 (C(10)), 66.7 (C(3)), 25.1 (CH_3). Λ_M (Ω^{-1} cm^2 mol^{-1}) (10^{-3} mol dm^{-3} in DMSO, 23.5°C) 3.0.

2.3.2. [(N-Salicylidene-L-valinato)(aqua)zinc(II)] (*2*)

84% yield. White crystals from DMSO. Exhibits a mass decrease (found 6.11; calc. 5.95) between 128 and 160°C (−0.5H_2O) and 232 and 265°C (−0.5H_2O) corresponding to the loss of one water molecule per formula unit. *Anal*. Found: C, 47.67; H, 5.07; N, 4.64. Calc. for $C_{12}H_{17}NO_5Zn$: C, 47.62; H, 4.96; N, 4.63%. IR (cm^{-1}): 3302m, 2966m, 1632s, 1605s, 1542s, 1471s, 1449s, 1414w, 1338s, 1313m, 1279w, 1253w, 1193m, 1157m, 1134w, 1099w, 1066w, 1039w, 996w, 978w, 966w, 942w, 924w, 902w, 871m, 857w, 846w, 831w, 804m, 787w, 761m, 746m, 694w, 635w, 603w, 546m, 507w, 462w, 425w, 406w, 339w, 282w, 251w, 231w. UV–Vis (DMSO): λ 371 (ε 8.8×10^3), 258 nm (1.5×10^4 dm^3 mol^{-1} cm^{-1}). ^{1}H NMR (DMSO-d_6, 325 K): δ 8.36s (1H, H(5)), 7.27d+t (2H, H(11)+H(9)), 6.87bd (1H, H(8), $J_{estimated}$ = 7.7 Hz), 6.60t (1H, H(10), *J* = 7.2 Hz), 3.49d (1H, H(3), *J* = 5.0 Hz), 2.14dhp (1H, H(4), *J* = 5.0 and 6.9 Hz), 1.10d (3H, CH_3, *J* = 6.9 Hz), 0.98d (1H, CH_3, *J* = 6.9 Hz). ^{13}C NMR (DMSO-d_6, 325 K): δ 178.8 (C(2)), 172.3 (C(5)), 172.1 (C(7)), 139.0 (C(11)), 137.3 (C(9)), 126.5 (C(8)), 123.6 (C(6)), 118.7 (C(10)), 78.8

3. Results and discussion

3.1. Crystal structures

The ORTEP drawings of the structural units of **1** and **2** are shown in Figs. 1 and 2. The coordination geometry about the zinc in both structures **1** and **2** is between distorted trigonal bipyramid and distorted square pyramidal with the iminic nitrogen N(4) (**1** = 2.020(3) and **2** = 2.015(7) Å), the phenolic O(8) (**1** = 1.991(2) and **2** = 1.997(6) Å) and the carboxylic O(1) (**1** = 2.160(2) and **2** = 2.156(5)) of *N*-salicylidene-aminoacidato base ligand, another O(1)* carboxylic of other unit (**1** = 2.033(2) and **2** = 2.033(5) Å) and a water molecule (**1** = 2.006(3) and **2** = 1.999(6)) occupying the five coordination positions. The Zn–N(4) and Zn–O(8) distances are similar to that corresponding to [(methoxysalicylidene-L-aminoacidato)(pyridine)$_2$zinc(II)], where the amino acid is methionine [31], valine [32] or serine [33] (2.030–2.035 and 1.992–2.010 Å, respectively) but the Zn–O(1) varies significantly (2.087–2.133 Å). Moreover, the [(*N*-salicylidene-ethanolaminato)zinc(II)] [34] presents slightly shorter Zn–N(4) (2.007 Å) and clearly shorter Zn–O(8) (1.938 Å) distances. The polymeric structure results from the repetition of [Zn**–O(1)–Zn–O(1)*]$_n$ (Zn**–O(1) and Zn–O(1)*, **1** = 2.033(2) and **2** = 2.033(5) Å; Zn–O(1), **1** = 2.160(2) and **2** = 2.156(5) Å). The crystals are constituted by polymeric [(*N*-salicylidene-L-aminoacidato)zinc(II)] moieties forming helical arrays about three-fold screw axes (Fig. 3).

To our knowledge these are the first structures of binary complexes of the type [(*N*-salicylidene-L-aminoacidato)-zinc(II)]. Only the pyridine complexes of [*N*-methoxysalicylidene-L-(methioninato, valinato or serinato)(pyridine)$_2$zinc(II)] [31–33] and the binary complex of [(*N*-salicylidene-ethanolaminato)zinc(II)] [34] have been described until now.

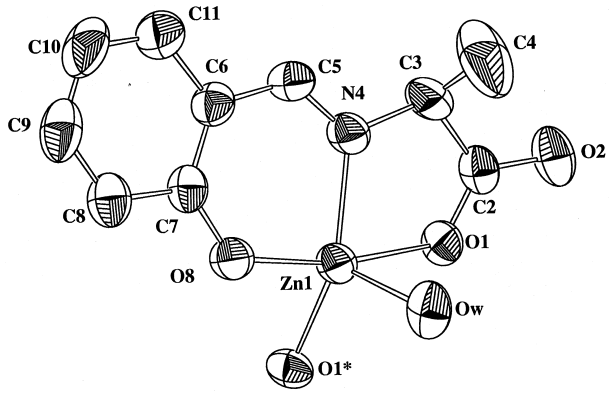

Fig. 1. ORTEP drawing of [(*N*-salicylidene-L-alaninato)(aqua)-zinc(II)]·0.25H_2O (**1**).

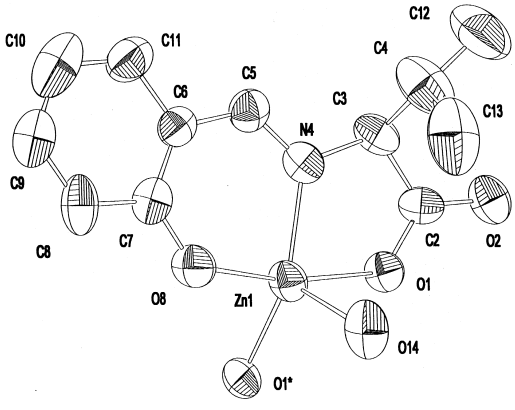

Fig. 2. ORTEP drawing of [(*N*-salicylidene-L-valinato)(aqua)zinc(II)] (**2**).

3.2. Infrared spectra

The Schiff base structure of the salicylidene-aminoacidato moiety of the obtained compounds is confirmed by the presence of strong imine ν(C=N) bands occurring in the range 1624–1647 cm^{-1} of the IR spectra [13,43,44]. The strong band at 1660 cm^{-1} in **5** is assigned to the carbonyl group of the glutamine lateral chain [45].

The ν_{as}(COO) is related to the strong band appearing in the spectra of the complexes between 1577 and 1608 cm^{-1}, whereas the ν_s(COO) is attributed to the medium–strong peaks appearing in the 1339–1392 cm^{-1} region. This gives rise to a $\Delta\nu$ (ν_{as}(COO) − ν_s(COO)) of 196–266 cm^{-1} characteristic of monodentate coordination of the carboxylate group [46]. According to X-ray structural analysis in com-

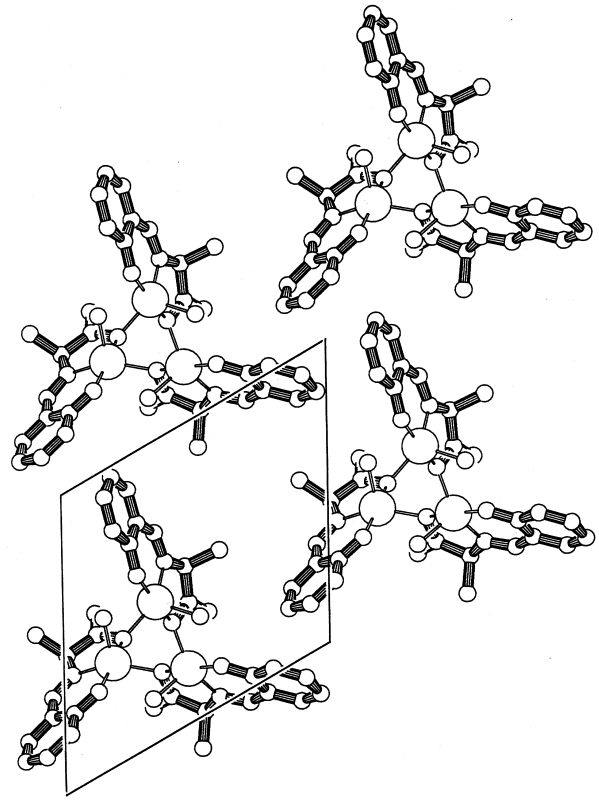

Fig. 3. View of the crystal structure of [(*N*-salicylidene-L-alaninato)-(aqua)zinc(II)]·0.25H_2O (**1**) showing the helical arrays about three-fold screw axes. (The view is through the C3 axis and the apparent trimers are really polymeric pillars.)

plexes **1** and **2**, the bridging carboxylate group is bound 'via only one oxygen' to two Zn(II) ions. This coordination mode has been described and discussed in other $RCOO^-$ anions and similar systems, i.e. NO_2^- [47] but has not been discussed in the extensive IR studies performed on metal complexes of carboxylic acids [46]. The shape, intensity and frequency of the two ν(COO) bands in complexes **3** and **5** are very similar to those of **1** and **2**, the $\Delta\nu$ values being very close to 240 cm^{-1} which could be indicative of the same type of carboxylate bridge although the presence of the terminal donor groups of the lateral chain in **3** and **5** can change the coordination sphere of the Zn(II) and the way in which the monomeric units are linked.

3.3. NMR spectra

^{1}H NMR and ^{13}C NMR were unequivocally assigned via bidimensional techniques (HMQC and HMBC) and by comparison with other similar spectra (Table 3). As can be seen, in **7** and **8**, a relative *endo* disposition between the two aro-

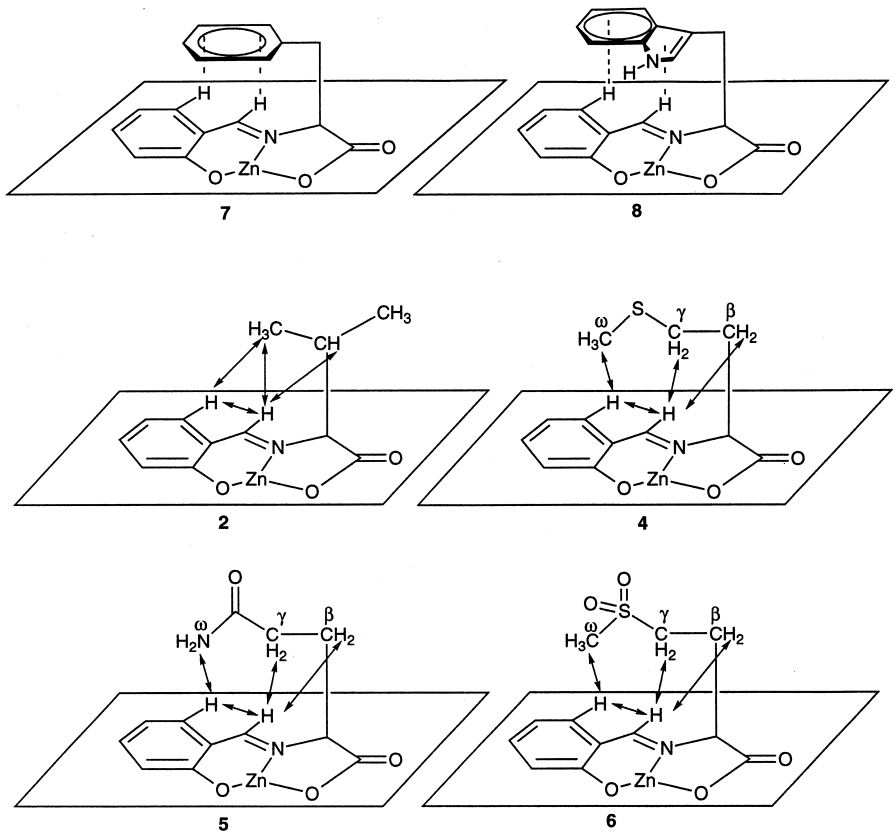

Fig. 4. Relative disposition of the lateral chain of different Schiff bases in DMSO solution (selected NOEs).

matic systems of the complex is necessary in order to explain the observed downfield shift in ^{1}H NMR for C(5)–H (standard value for non-aromatic amino acids is 8.40 ± 0.05 versus 7.60 ppm) and C(11)–H (standard value for non-aromatic amino acids is 7.27 ± 0.02 versus 6.78 ± 0.03) that can be assigned to the anisotropic behaviour of the aromatic rings of the lateral chain of these two amino acids towards methylene and *ortho* carbons of the Schiff base. On the other hand, NOEs presented in the ROESY between the *ortho* C(11)–H and the ω-Hs and between the iminic C(5)–H and the γ-Hs of the lateral chain of the amino acids show, if aggregates do not exist in solution, a general tendency for the *endo* disposition. Fig. 4 shows the NOEs presented in **2**–**8**. Moreover, ROESY results obtained for compound **2** indicate that the disposition of the lateral chain in DMSO solution is not the same as that in the crystal structure (see Figs. 2 and 4). This characteristic could be presumably extended to the remaining Zn(II) complexes since these compounds are probably monomers in solution, whereas in the crystal they are present as polymeric structures. On the other hand, the Λ_M (10^{-3} mol dm^{-3}) values in DMSO at 23–26°C (between 2.0 and 3.0 Ω^{-1} cm^2 mol^{-1}) imply the presence of non-electrolyte species [48].

Supplementary data

Supplementary data are available from Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers 136497 (**1**) and 136496 (**2**).

POLYHEDRON

^{13}C NMR and FT-IR spectra of thiocyanogen, $S_2(CN)_2$, selenocyanogen, $Se_2(CN)_2$, and related compounds

F. Cataldo *

Progega snc, Via Casilina 1626/A, 00133 Rome, Italy

Received 9 November 1999; accepted 13 January 2000

Abstract

The pseudohalogens thiocyanogen [$(SCN)_2$], sulfur dicyanide [$S(CN)_2$], selenocyanogen [$(SeCN)_2$], selenium dicyanide [$Se(CN)_2$] and selenium diselenocyanate [$Se(SeCN)_2$] have been prepared and studied by ^{13}C NMR spectroscopy for the first time. The ^{13}C NMR results confirm the structure previously assigned to these compounds on the basis of vibrational spectroscopy. Thiocyanogen, sulfur dicyanide, selenocyanogen and selenium dicyanide have been also studied as liquid film on KBr plate in the solid state (KBr pellet) by FT-IR spectroscopy and the data collected have been compared and discussed with previous results recorded on solutions in organic solvents. Good agreement with early results has been obtained. It has been confirmed by solid state ^{13}C NMR–MAS that under mild conditions selenocyanogen disproportionates into selenium dicyanide and selenium diselenocyanate. By heating selenocyanogen above 180°C it polymerizes irreversibly into a brown polymer known as paraselenocyanogen whose FT-IR spectrum is surprisingly very similar to that of parathiocyanogen or polythiocyanogen, the product of self-polymerization of thiocyanogen. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Pseudohalogens; Selenocyanogen; Thiocyanogen

1. Introduction

The chemistry of pseudohalogens has always been a fascinating and rather briefly treated subject in textbooks of inorganic chemistry [1–4]. Thiocyanogen [$S_2(CN)_2$] was discovered by Soderback 81 years ago [1,5], whereas selenocyanogen [$Se_2(CN)_2$] was prepared in pure form only in 1925 [1,6,7].

Infrared (IR) and Raman spectra of thiocyanogen [8–10] strongly suggest structure **1**, which has a disulfide bridge, NC–S–S–CN, rather than structure **2**, which has the isothiocyanate form S=C=N–N=C=S, even though, according to certain authors [9], on the basis of the position of the IR band due to a –SCN or –NCS group, structure **2** is favoured in polar solvents such as ether while structure **1** is largely predominant in non-polar aprotic solvents. This consideration is not negligible because the addition of thiocyanogen to ethylenic double bonds of organic substrates involves the addition of both –SCN and –NCS groups [11]:

$$R–CH=CH–R + S_2(CN)_2 \rightarrow$$

$$NC–S–C(R)–C(R)–S–CN \ (\mathbf{3})$$

$$+ NC–S–C(R)–C(R)–N=C=S \ (\mathbf{4})$$

However, in contrast to the above suggestion, the product with structure **4** can be formed in both polar and non-polar solvents [11,12]. Recently, the matter has been rationalized [12], and it has been shown that the IR band shift of thiocyanogen observed previously in ether could reasonably be due to a charge-transfer interaction of thiocyanogen with solvent rather than to the presence of isomer **2**.

Moreover, it has been pointed out [12] that the heat of formation of thiocyanogen found experimentally coincides with the value theoretically calculated for isomer **1** rather than compound **2** [13], and similar conclusions were obtained from the gas-phase UV spectrum of thiocyanogen, in agreement with theoretical calculations [14].

Thus, to explain the different addition behaviour which leads simultaneously to structures **3** and **4**, it is possible that the thiocyanogen radical derived from S–S homolysis has a bifunctional behaviour, as has been previously postulated [11,15–17]:

•S–CN (**5**) ↔ •N=C=S (**6**)

Bhatnagar et al. [18] have shown by magnetic susceptibility measurements that freshly prepared solutions of thiocyanogen in carbon disulfide and other solvents are diamagnetic but that on standing they become paramagnetic. In certain solvents such as cyclohexane, thiocyanogen is less stable and paramagnetism is observed also in freshly prepared solutions. The paramagnetism can be attributed to the formation of thiocyanogen radicals due to homolysis of S–S bonds during solution ageing. Probably these radicals induce the irreversible self-polymerization of thiocyanogen to a brick-red solid known as parathiocyanogen or polythiocyanogen whose structure seems to be very peculiar [15–17,19].

Selenocyanogen [$Se_2(CN)_2$] was isolated for the first time in 1925 thanks to the work of Birkenback and Kellermann ([6,7]). Fundamental studies of the structure of selenocyanogen and related compounds have already been published [20,21] and are based on IR spectroscopy; some short reviews on selenocyanogen and related compounds are also available [22–24]. Selenocyanogen and related compounds belong to the class of pseudohalides and are the selenium analogues of the thiocyanogen family of compounds. In comparison to thiocyanogen, selenocyanogen and its homologues have received much less attention by investigators, but the available data show that the selenocyanogen family has the same chemical structure as the thiocyanogen family of compounds.

Some unexpected differences between thiocyanogen and selenocyanogen can be immediately outlined here. While thiocyanogen is unstable and cannot be isolated in the pure state unless special conditions at low temperatures are adopted, selenocyanogen is rather more stable and can be isolated at room temperature as a yellow powder; it can also be re-crystallized from CH_2Cl_2 solutions and remains unchanged for months if stored in a closed flask at $+5$°C in the absence of humidity or solvent impurities. Thiocyanogen heated above 0°C or isolated by solvent evaporation at room temperature quickly turns into a brick-red solid [17]; however, selenocyanogen when heated in solution with carbon disulfide undergoes a unique disproportionation reaction as follows [21–24]:

$$2Se_2(CN)_2 \rightarrow Se(CN)_2 + Se_3(CN)_2 \quad (1)$$

When heated at higher temperatures, selenocyanogen liberates a sublimate (see below) and is polymerized into a brownish material. Practically nothing is known about the selenocyanogen polymerization products or about the strong sensitivity of selenocyanogen to certain molecules and solvents which cause its polymerization to a deep-red solid [25].

The difference in stability between thiocyanogen and selenocyanogen is quite striking notwithstanding that the two molecules should have the same geometrical structure, and in general it is expected that the S–S bond strength is comparable to that of the Se–Se bond strength. However, the dissociation energy of a Se–Se bond in diselenides is about 73 kcal mol^{-1} [24], which is larger than that for a S–S bond, which requires 63 kcal mol^{-1} [26]; in any case, these data should be considered only as approximations. Taking into account the rich organic chemistry of selenium [23,24], the C–Se bond should be as stable as the C–S bond; moreover, the Pauling electronegativity of selenium is slightly lower than that of sulfur [24], thus the C–Se bond should have at least the same degree of covalency as the C–S bond.

2. Experimental

^{13}C NMR spectra in $CDCl_3$ solution were performed with a Bruker AMX-600 spectrometer operating at 150.9 MHz; 7 s relaxation delay with 0.7 s of acquisition time and 90° pulse angle were applied. Spectra were obtained with 64 000 words. All reagents and solvents used were from Aldrich or Fluka.

Solid state ^{13}C MAS–NMR spectra were recorded at room temperature on a Bruker AC-200 spectrometer, equipped with an HP amplifier, ^1H 200 MHz, 120 W continuous wave and a pulse amplifier M3205. Samples were packed into 4-mm zirconia rotors and sealed with Kel-F caps. The spin rate was 8 kHz. Spectra were obtained with 512 words in the time domain, zero-filled and Fourier-transformed with a size of 1024 words; 20 000 scans were performed.

FT-IR spectra were recorded on a Perkin-Elmer 1710 spectrometer. Samples were studied embedded in KBr pellets. All reagents and solvents were from Aldrich or Fluka and were used as received.

2.1. Lead thiocyanate preparation

Lead thiocyanate was prepared by adding ammonium thiocyanate solution to an aqueous solution of lead(II) nitrate in stoichiometric amounts. The white precipitate was collected by filtration, washed with water and dried in an oven at 105°C.

2.2. Silver cyanide preparation

Similarly, silver cyanide was prepared by precipitation from silver nitrate and sodium cyanide in stoichiometric amounts. The white precipitate was collected by filtration, protected totally from light and dried in a desiccator under dynamic vacuum.

2.3. Thiocyanogen preparation

Thiocyanogen [$S_2(CN)_2$] was prepared as previously reported [17], by suspending 6.8 g of dry lead(II) thiocyanate in 50 ml of $CDCl_3$ (deuterated chloroform) by magnetic stirring and adding dropwise 3.36 g of bromine. The freshly prepared thiocyanogen solution was decanted and immediately used to record the ^{13}C NMR spectrum. On standing the

solution polymerized to the insoluble and brick-red solid polythiocyanogen [15–17].

2.4. Sulfur dicyanide preparation

Sulfur dicyanide [$S(CN)_2$] was prepared by suspending 4.5 g of silver cyanide in 50 ml of $CDCl_3$ by vigorous stirring and by adding dropwise 1.0 ml of sulfur dichloride (SCl_2). The mixture was stirred for 30 min at room temperature and then the silver chloride formed was separated by decantation. The $CDCl_3$ solution of $S(CN)_2$ was used to record the ^{13}C NMR spectrum.

2.5. Preparation of silver selenocyanate

Silver selenocyanate was prepared by adding a solution of potassium selenocyanate to a solution of silver nitrate in stoichiometric amounts. The precipitate formed was collected by filtration, washed with water and dried into a desiccator under dynamic vacuum. Care should be taken to avoid exposure to light.

2.6. Preparation of selenocyanogen

Selenocyanogen was prepared by suspending 13.5 g of silver selenocyanate [Ag(SeCN)] in 100 ml of dichloromethane with vigorous stirring. Then an iodine solution in dichloromethane was added (6.0 g of iodine per 160 ml of dichloromethane). Very rapid discolouration of the iodine was observed. The mixture was stirred for 2 h at +13°C and then it was decanted. The silver iodide collected was yellow while the $Se_2(CN)_2$ solution was orange. Dichloromethane was then distilled off under reduced pressure in a water-bath to leave a canary-yellow powder. Yield: 2.77 g (55.9% over iodine used).

Selenocyanogen was dissolved in $CDCl_3$ to record the ^{13}C NMR spectrum in solution immediately after preparation. The solid-state ^{13}C NMR spectrum was recorded 3 weeks after preparation.

2.7. Stability of selenocyanogen

Selenocyanogen is rather stable when stored in closed flasks in the dark at +5°C. When stored in this way no decomposition can be observed (visually and by IR spectroscopy) even after months. However, humidity, heat and certain solvents greatly accelerate the decomposition and polymerization of selenocyanogen [10].

2.8. Preparation of selenium dicyanide and paraselenocyanogen

Selenocyanogen (0.217 g) was mixed with 15 ml of decalin and heated in a oil-bath for 2 h at 210°C and 1 h at 180°C. The initially yellow decalin solution quickly became orange and then during heating turbid and brown. In the refrigerator, a discrete crystalline sublimate was deposited; this was collected and identified as selenium dicyanide by its IR spectrum. The dark-brown precipitate formed in the flask was easily separated from decalin by settling and decantation. The collected precipitate was washed several times with dichloromethane and then dried in air. The precipitate was paraselenocyanogen or polyselenocyanogen.

2.9. Stability of selenium dicyanide

The white and tabular crystals of selenium dicyanide are stable for months when stored in a tightly closed flask at room temperature. Exposure to light causes the formation of an orange colour. Also moisture and certain solvents cause a change in colour.

3. Results and discussion

In previous work we have concentrated our efforts on the study of the structure of parathiocyanogen or polythiocyanogen [$(SCN)_x$], the inorganic polymer resulting from spontaneous polymerization of thiocyanogen [15–17]. In these studies we reported evidence about the peculiar and probably linear structure of parathiocyanogen. With FT-IR and electronic spectroscopy we have also studied thiocyanogen [$(SCN)_2$] with the aim of understanding some aspects of its spontaneous polymerization [17].

3.1. ^{13}C NMR spectrum of thiocyanogen

The ^{13}C NMR spectrum of freshly prepared thiocyanogen (see Table 1) is characterized by a sharp singlet at 107.36 ppm. The thiocyanate ion of potassium thiocyanate is reported to show a ^{13}C NMR signal at about 133.3 ppm [27,28], but alkyl thiocyanates such as methyl-, ethyl- and butylthiocyanate give an NMR signal at higher fields, namely at 113.5, 112.1 and 112.1 ppm, respectively [27]. On the other hand, organic isothiocyanates are detected at 128–136 ppm [27,28], in the same range where the inorganic thiocyanate ion of KSCN gives an NMR signal, hence at considerably lower fields than organic thiocyanates (see Table 1).

Based on these data, it can be concluded that thiocyanogen has structure **1**, with a disulfide bridge connecting the two cyanide groups because its NMR signal is comparable to that of alkylthiocyanates. In fact, for isomer **2** of 'isothiocyanogen' we should expect a singlet NMR signal at 128–132 ppm, while for isomer **7** of 'thiocyanogen–isothiocyanogen' (NC–S–N=C=S) we would expect two different signals, one due to the thiocyanate group at about 107 ppm and the other due to the isothiocyanate group at 128–132 ppm. Since we observe a unique signal at 107.36 ppm we can conclude that structure **1** is the correct structure of thiocyanogen.

Additionally, our NMR spectrum does not show any evidence for the presence of thiocyanate (**5**) and isothiocyanate

Table 1
^{13}C NMR synopsis

Compound name	Structure (see text)	NMR signal (ppm)	Reference
Thiocyanogen	**1**	107, 36 (singlet, in $CDCl_3$)	this work
Sulfur dicyanide	**8**	126 (singlet, in $CDCl_3$)	this work
Selenocyanogen	**10**	89, 92 (singlet, in $CDCl_3$)	this work
Selenium dicyanide	see Eq. (2)	130 (broad, solid-state MAS–NMR)	this work
Selenium diselenocyanate	see Eq. (2)	98,3 (broad, solid-state MAS–NMR)	this work
Potassium thiocyanate	KSCN	133.3	[27,28]
Methyl thiocyanate	Me–SCN	113.5	[27]
Ethyl thiocyanate	Et–SCN	112.1	[27]
Potassium cyanide	KCN	168.5	[28]
Alkyl nitrile	R–CN	112–126	[28]
Alkyl isonitrile	R–N=C	157–167	[27,28]
Alkyl isothiocyanate	R–N=C=S	128–136	[27,28]

(**6**) radicals, which means that these radicals are only present at very low concentrations in our system.

Ageing of thiocyanogen solution in $CDCl_3$ causes the formation of an orange-coloured solution, and also a brick-red precipitate starts to appear in suspension and at the bottom of the solution. As mentioned in Section 1, Bhatnagar et al. [18] have shown that freshly prepared thiocyanogen solutions are diamagnetic but become paramagnetic upon ageing due to free radical formation. The ^{13}C NMR spectrum of aged thiocyanogen solution still shows the signal at 107 ppm due to thiocyanogen but a new feature at 169.6 ppm starts to appear. We have already shown [17] that thiocyanogen polymer (polythiocyanogen) has a unique feature at 186 ppm in dimethylformamide (DMF) solution, where it has some degree of solubility; however, polythiocyanogen is not soluble in chloroform. Thus the signal at 169.6 ppm (in $CDCl_3$) could be due to a low molecular weight and soluble oligomer of thiocyanogen.

Other possible interpretations involve the presence of isothiocyanate ion, which we suppose should absorb in this field from the observation that isocyanides give NMR signals at 157–165 ppm (see Table 1). If the assignment of the feature at 169.6 ppm to the isothiocyanate group is correct, we have the first direct indication that thiocyanogen undergoes the scission of its S–S bond followed by a rearrangement to an isothiocyanate group. This could explain the simultaneous N and S addition to the double bonds of organic substrates (see structures **3** and **4**). However, a simpler and more convincing explanation exists for the feature at 169.6 ppm. In fact, cyanide ion absorbs at 168.5 ppm (see Table 1); hence, instead of scission of the S–S bond, we have evidence of scission of the C–S bond which leads to the cyanide group. Scission of the C–S bond of thiocyanogen would imply the formation of thiocyanate ion and free sulfur. Unfortunately, there is no evidence of the presence of free thiocyanate in our NMR spectrum because no signal at 113.5 ppm was observed. Thus, the NMR spectroscopy data suggest that the degradation of thiocyanogen in chloroform involves the formation of cyanide ions and free sulfur.

3.2. ^{13}C NMR spectrum of sulfur dicyanide

We have also studied by ^{13}C NMR spectroscopy the lower thiocyanogen homologue sulfur dicyanide, which has the structure NC–S–CN (**8**) (V-shaped, not linear), which was assigned on the basis of vibrational spectroscopy and X-ray studies [22,23], rather than NC–N=C=S (**9**) or other possible structures.

Freshly prepared sulfur dicyanide shows a unique and sharp singlet at about 126 ppm (see Table 1) in $CDCl_3$ solution. Even if the ^{13}C NMR signal of this molecule appears at lower fields than that observed for thiocyanogen, we can immediately exclude structure **9**, which requires two different signals at lower fields, namely one at least at 157 ppm [27,28] for the isocyanide group, which was not observed, and the other above 130 ppm for the isothiocyanide group [27,28]. Since only one signal was detected we can conclude that structure **8** is the correct structure of sulfur dicyanide. To explain why the signal of sulfur dicyanide appears at 126 ppm and that of thiocyanogen at 107 ppm we must assume that some conjugation between the triple bonds of the two cyano groups occurs through the sulfur bridge in the case of sulfur cyanide, while this is absent in the case of thiocyanogen, which has two sulfur atoms per bridge. Therefore, conjugation causes an NMR signal closer to the thiocyanate ion in the case of sulfur dicyanide (133.3 ppm for thiocyanate versus 126 ppm for sulfur dicyanide), while for thiocyanogen the NMR signal at 107 ppm is comparable to that of organic alkyl thiocyanates which in fact absorb in that region [20,21]. The general observation that sulfur dicyanide is more stable than thiocyanogen could be ascribed to the fact that the former is stabilized also by conjugation while the latter is not. In fact, sulfur dicyanide can be isolated in the form of crystals by sublimation [22], whereas thiocyanogen can be isolated in crystal form only under more complex conditions at $-50°C$ [10] and at temperatures above 0°C shows a certain stability only in solution. When thiocyanogen in solution is concentrated by evaporating the solvent at room temperature under reduced pressure, it polymerizes very quickly [17], sometimes with detonation [17]. Upon prolonged ageing in solu-

tion at room temperature, sulfur dicyanide begins self-polymerization. The ^{13}C NMR spectrum shows a resonance at 129 ppm, but also a new line appears at 124 ppm and complicated resonances are observed in the 147–165 ppm region with the main peak at 155.5 ppm. Additional features are observed in the 171–182 ppm region. These aged spectra will be interpreted and discussed elsewhere [25].

3.3. ^{13}C NMR spectra of selenocyanogen and selenium dicyanide

As reported in Table 1, the ^{13}C NMR spectrum of freshly prepared selenocyanogen [$Se_2(CN)_2$] in $CDCl_3$ solution shows a sharp singlet at 89.92 ppm. The presence of a unique singlet is in complete agreement with the fact that the correct structure of selenocyanogen is analogous to that assigned to thiocyanogen, NC–Se–Se–CN (**10**).

All other possible structures involving isoselenocyanide, Se=C=N–N=C=Se (**11**), and selenocyanide isoselenocyanide, Se=C=N–Se–CN (**12**), can be excluded completely. What is somewhat surprising is that the resonance of selenocyanogen appears at higher fields than that of thiocyanogen (89.92 ppm for the former versus 107.36 ppm for the latter), notwithstanding that these two compounds have the same general structure and that selenium and sulfur are very close in their chemical properties. At present we have no clear explanation for this difference, but it may be that if the Se–Se–C angle is different from the S–S–C angle this difference could affect the electronic shielding of the carbon nucleus leading to a difference in chemical shift.

As mentioned in Section 1, selenocyanogen is relatively stable at room temperature and we have tried to record also its solid-state ^{13}C NMR spectrum. This spectrum (see Table 1), was recorded only 3 weeks after selenocyanogen preparation. It is characterized by two main resonance peaks, one lying at 98.3 ppm and a doublet at about 130 ppm. Since only one resonance was detected in freshly prepared selenocyanogen solution, it is likely that some disproportionation or decomposition occurred in the solid during the 3 weeks after the preparation so that the solid-state spectrum now shows at least two resonance peaks. Since the well-known disproportionation reaction of selenocyanogen described in the literature [22–24] involves the reaction (Eq. (1)) showing that selenocyanogen is transformed into selenium dicyanide and selenium diselenocyanate in mild conditions, we tentatively assign the resonance due to selenium diselenocyanate the peak at 98.3 ppm, while the peak at about 130 ppm is assigned to selenium dicyanide by observing that sulfur dicyanide has a ^{13}C NMR signal (in solution) at 126 ppm.

3.4. FT-IR spectra of thiocyanogen and sulfur dicyanide

As shown in Table 2, the strong thiocyanogen band due to antisymmetric stretching of the –CN group has been observed

in the range 2171–2177 cm^{-1} by various authors when the pseudohalogen was dissolved in organic solvents. By leaving some drops of thiocyanogen solution in CH_2Cl_2 to evaporate onto a KBr disk, it is possible to record the spectrum of almost 'dry' and still not polymerized thiocyanogen [17]. Under these special conditions, the strong band due to antisymmetric stretching appears at 2162 cm^{-1} while the band presumably due to symmetric stretching is detected at 2073 cm^{-1}. This is at a significantly higher frequency than the value detected in CCl_4 solution (1990 cm^{-1}) and in ether solution (2030 cm^{-1}) reported by other authors [9,10]. This suggests that this band is very sensitive to the nature of the solvent in which the molecule is dissolved [12]. The intense band at about 670 cm^{-1} is due to a C–S stretching band, confirming structure **1**.

An alternative and reasonable interpretation suggests that the band at 2073 cm^{-1} could be assigned to cyanide ion. In fact, sodium cyanide shows an IR band at 2060 cm^{-1} [15]. This assignment seems to confirm the NMR interpretation we have given in the preceding section about the decomposition of thiocyanogen in chloroform.

Table 2 shows also that the FT-IR spectrum of sulfur dicyanide is in reasonable agreement with previously published spectra. In particular, only one nitrile stretching band is observed at 2180 cm^{-1} in the solid state (KBr pellet). Thermodynamic calculations using the group increment method [29] give for thiocyanogen $\Delta G_f^o = 63.7$ kcal mol^{-1} and $\Delta H_f^o = 69.8$ kcal mol^{-1} (literature experimental data: $\Delta H_f^o = 74.3$ kcal mol^{-1}). Sulfur dicyanide is a slightly less endothermic compound, with $\Delta G_f^o = 61.4$ kcal mol^{-1} and $\Delta H_f^o = 64.0$ kcal mol^{-1}.

3.5. FT-IR spectra of selenocyanogen and selenium dicyanide

The IR spectrum of selenocyanogen in solution has been studied by several authors [20,21,23]. In this work we have recorded for the first time the FT-IR spectrum of selenocyanogen in KBr pellet. As shown in Table 3, there is generally good agreement between the main bands of $Se_2(CN)_2$ measured in solution and in the solid state. The nitrile stretching band of selenocyanogen was reported at 2152 cm^{-1} when measured in organic solvents [20], while it is shifted to 2143 cm^{-1} in KBr pellet followed by a weaker band at 1992 cm^{-1}. If the former stronger band is assigned to nitrile antisymmetric stretching then the weaker band at lower frequency is assignable to nitrile symmetric stretching. There are no indications about the presence of an isoselenocyanate group, since it is characterized by out-of-phase stretching at 2182 cm^{-1} and in-phase stretching mode at 983 cm^{-1} [30], which are completely absent from our spectra. The symmetric Se–C(N) stretching is reported as a strong band at 521 cm^{-1} in organic solvents whereas in KBr pellet it appears at 505 cm^{-1}; in the solid state we observe also another band at 580 cm^{-1} which could be due to antisymmetric Se–C(N) stretching. In the solid state we were able to observe also Se–CN bending at 436 cm^{-1}. Additionally, we have recorded other intense bands in the FT-IR spectrum of selenocyanogen in KBr. These bands were never reported previously because the spectra were recorded in organic solvents so that some spectral regions were buried by the intense absorption of the solvent, or at the time of the early measurements certain spectral regions were not accessible to the spectrophotometers or were not considered by the researchers. In fact, we observe additional bands at 3650, 3540 and 3434 cm^{-1}; these bands are strong and may be are only overtones or combination bands, but additionally we observe other two bands at 1640 and 1610 cm^{-1} which, however, remain unassigned. There are several other weak and very weak infrared bands (see Table 1) which were detected for the first time but which could also be due to impurities.

Also for selenium dicyanide (see Table 1), for the IR spectrum (in KBr) recorded on the sublimate formed by thermal decomposition of selenocyanogen there is a good general agreement between early reported spectra and the FT-IR reported here. The nitrile stretching appears in KBr pellet as a sharp peak at 2181 cm^{-1}, hence at higher frequency than selenocyanogen, in agreement with previous values reported at 2171 and 2183 cm^{-1} [20,21]. In agreement with previous measurements [20,21] we observe the antisymmetric C–Se stretching at 605 cm^{-1} and the symmetric C–Se stretching at 507 cm^{-1}. At 462 and 436 cm^{-1} we observe the C–Se bending mode. Again also in the case of selenium dicyanide we observe new IR bands never reported before, namely at 3649, 3589, 3581, 3453, 2922, 2851 cm^{-1} and at 1638, 1612 cm^{-1}. These bands remain unassigned; some of them could be due to impurities.

3.6. FT-IR spectrum of paraselenocyanogen

Concerning paraselenocyanogen or polyselenocyanogen there are no precise data available in the literature. In Section 2 we have shown that selenocyanogen undergoes a thermal decomposition reaction when heated at high temperature with liberation of a sublimate which was identified as selenium dicyanide by IR spectroscopy as just discussed, and the formation of a dark-brown insoluble product which is paraselenocyanogen and can be described by the general formula of $[Se_y(CN)_2]_x$ with $0 < y < 3$ and x very large. We will examine in more detail the paraselenocyanogen formation mechanism and its structural aspects elsewhere [25]. However, here we would like to report that the IR spectrum of paraselenocyanogen is very peculiar and is very similar to the spectrum of parathiocyanogen [17].

In fact, the spectrum of paraselenocyanogen is characterized by a very intense and broad band at 1200 cm^{-1} with a shoulder at 1263 cm^{-1}, two medium bands at 1444 and 1412 cm^{-1} and medium-weak bands at 1619 and 881 cm^{-1}. Weak bands are detectable at 801, 638, 609, 525 cm^{-1} as well as at 2262, 2184 and 2148 cm^{-1}. Since selenium diselenocyanate $[Se_3(CN)_2]$ has only three main IR lines (see Table 3) which do not coincide at all with the spectrum of para-

selenocyanogen, we can conclude that the disproportionation reaction (Eq. (1)) happens under very mild conditions, while under strong heating the decomposition reaction of selenocyanogen is as follows:

$$2x\mathrm{Se}_2(\mathrm{CN})_2 \rightarrow x\mathrm{Se}(\mathrm{CN})_2 + [\mathrm{Se}_y(\mathrm{CN})_2]_x + x\mathrm{Se} \quad (2)$$

(with $0<y<3$)

The coincidence between the FT-IR spectra of paraselenocyanogen and parathiocyanogen shows only that selenocyanogen polymerizes like thiocyanogen by forming a polymer which should have the same structure of parathiocyanogen. Since we have proposed [15–17] that parathiocyanogen could have a linear structure rather than a triazine-based structure, we can conclude that paraselenocyanogen also has a linear structure because its spectrum is impressively similar to that of parathiocyanogen.

Received 26 October 1999; accepted 18 January 2000

Abstract

From the reaction between Cu(II) and Ni(II) salts and the Schiff base 6-amino-5-formyl-1,3-dimethyluracil-benzoylhydrazone (H_2BEZDO), in dimethylformamide (DMF)–water and ammonia media, the complexes Ni(BEZDO)·H_2O·NH_3, Cu(BEZDO)·H_2O·NH_3 and [Cu(BEZDO)(H_2O)]·H_2O containing the dianionic organic ligand have been obtained. These compounds have been studied by IR, electronic and EPR spectroscopy and magnetic measurements. The structure of [Cu(BEZDO)(H_2O)]·H_2O has been solved by means of X-ray diffraction methods. The coordination environment around the Cu(II) may be described as a square-plane structure in which the Schiff base acts as tridentate ligand through the N(6), N(51) and O(52) atoms, making two five- and six-membered chelate rings. The coordination sphere is completed with the oxygen atom of a water molecule; any additional interactions with potential donor atoms in the axial direction have not been found. The crystal structure is formed by infinite hydrogen-bonded monodimensional chains, in which the nearest metal centres are at distances of 4.511 and 3.585 Å. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Biological activity of complexes derived from hydrazones has been widely studied and contrasted, acting in processes such as antibacterial, antitumoral, antiviral, antimalarial and antituberculosis effects [1]. The antitumoral and antiviral activities of a lot of complexes derived from hydrazones such as thiosemicarbazones have also been reported [2–5]. Often, these compounds show an N,N,S-coordinating pattern; however, there is very little information about O,N,O- or N,N,O-coordinated hydrazone compounds in the literature. We are studying the structure of several complexes with hydrazones derived from uracil, in which O,N,O- [6] and N,N,O-chelating systems [7–9] are present.

This paper focuses on the structural study of three new Ni(II) and Cu(II) complexes with the dianion of 6-amino-5-formyl-1,3-dimethyluracil-benzoylhydrazone, which seems to possess some important structural features related to the thiosemicarbazone complexes with biological activity. Thus, the molecular structure displays a global planar character with a local square plane around the metal ion and a N,N,O-tridentate system which may allow coordination of metal ions with a stronger acid character than the N,N,S-thiosemicarbazone chelating systems [10].

2. Experimental

2.1. Synthesis

2.1.1. Preparation of the ligand

The Schiff base ligand 6-amino-5-formyl-1,3-dimethyluracil-benzoylhydrazone (H_2BEZDO) was prepared by con-

densation, in EtOH medium containing a few drops of glacial acetic acid, of equimolar amounts of 6-amino-5-formyl-1,3-dimethyluracil with benzoylhydrazine. Yield 85%. *Anal.* Found: C, 55.7; H, 5.1; N, 23.3%. Calc. for $C_{14}H_{15}N_5O_3$: C, 55.8; H, 5.1; N, 23.2%. IR (cm^{-1}): 3311, 3243, ν(N–H); 1705, 1646, ν(C=O); 1615, ν(C=N) + ν(C=C); 1456, 1289, ν(C=C) + ν(C–N); 1554, *Amide II*; 927, ν(N–N).

*2.1.2. Preparation of Ni(BEZDO)·H_2O·NH_3 (**1**)*

Equimolar amounts (0.5 mmol) of the ligand and the corresponding nitrate salt were mixed in 100 ml of concentrated aqueous ammonia. The resulting suspension was stirred and strongly heated for several hours; an orange powdery material was obtained, which was filtered off, washed with ethanol and diethyl ether and air dried. Yield 72%. *Anal.* Found: C, 42.8; H, 4.6; N, 21.3; $NH_3 + H_2O$, 9.4%. Calc. for $C_{14}H_{18}N_6O_4Ni$: C, 42.8; H, 4.6; N, 21.4; $NH_3 + H_2O$, 8.9%; loss of water and ammonia between 50 and 320°C (DSC peaks at 82 and 263°C). IR (cm^{-1}): 3455, 3405, ν(N–H); 1690, ν(C=O); 1615, 1592, ν(C=N) + ν(C=C); 1473, 1311, ν(C=C) + ν(C–N); 1555, *Amide II*; 971, ν(N–N); 435, ν(Ni–N). $\Lambda_M = 4$ ohm^{-1} cm^2 mol^{-1}.

*2.1.3. Preparation of Cu(BEZDO)·H_2O·NH_3 (**2**)*

The same procedure as that for complex **1** was used. Yield 60%. *Anal.* Found: C, 42.2; H, 4.4; N, 21.0; $NH_3 + H_2O$, 9.1%. Calc. for $C_{14}H_{18}N_6O_4Cu$: C, 42.3; H, 4.5; N, 21.1; $NH_3 + H_2O$, 9.0%; loss of water and ammonia between 50 and 300°C (DSC peaks at 97 and 235°C). IR (cm^{-1}): 3326, 3171, ν(N–H); 1693, ν(C=O); 1616, 1592, ν(C=N) + ν(C=C); 1474, 1301, ν(C=C) + ν(C–N); 1546, *Amide II*; 964, ν(N–N); 431, ν(Cu–N). $\Lambda_M = 2$ ohm^{-1} cm^2 mol^{-1}.

*2.1.4. Preparation of [Cu(BEZDO)(H_2O)]·H_2O (**3**)*

The synthesis of this complex was carried out by mixing equimolar amounts (0.5 mmol) of the ligand and $Cu(NO_3)_2 \cdot 3H_2O$ in 30 ml of DMF–water (1:1). The resulting solution was stirred and strongly heated for several hours; then, in order to make the solvent evaporate very slowly, the flask was covered with a plastic layer containing small holes. Some days later, a small amount of crystals suitable for X-ray diffraction studies was obtained; these crystals were filtered off, washed with ethanol and diethyl ether and air dried. Yield 65%. *Anal.* Found: C, 42.1; H, 4.3; N, 17.8; H_2O, 9.2%. Calc. for $C_{14}H_{17}N_5O_5Cu$: C, 42.2; H, 4.3; N, 17.6; H_2O, 9.0%; loss of water between 50 and 260°C (DSC peaks at 132 and 198°C). IR (cm^{-1}): 3436, 3387, ν(N–H); 1698, ν(C=O); 1621, 1598, ν(C=N) + ν(C=C); 1313, ν(C=C) + ν(C–N); 1559, *Amide II*; 970, ν(N–N); 434, ν(Cu–N). $\Lambda_M = 2$ ohm^{-1} cm^2 mol^{-1}.

2.2. Crystallographic studies

Crystal data: $C_{14}H_{17}N_5O_5Cu$; $M = 398.88$; monoclinic; $P2_1/c$; $a = 7.708(1)$, $b = 28.080(1)$, $c = 8.004(1)$ Å, $\beta = 115.812(1)°$, $V = 1559.6(5)$ Å^3 (from 25 random reflections); $T = 293$ K; graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å); $Z = 4$; $D_c = 1.699$ Mg m^{-3}; $F(000) = 820$; black cube ($0.1 \times 0.1 \times 0.1$ mm); $\mu = 14.971$ mm^{-1}; KappaCCD diffractometer, ω scans, data range $3.00 < \theta < 27.12°$, $0 \le h \le 8$, $0 \le k \le 36$, $-10 \le l \le 9$, 3530 reflections were measured, 2130 with $I > 3\sigma(I)$ were used in the refinement. Non-hydrogen atoms were located in successive difference Fourier maps and refined anisotropically by full-matrix least-squares on *F*. All the hydrogen atoms were located from ΔF series, but were not refined. The weighting scheme was $1/[\sigma^2(F_o) + 0.03F_o]$. The final *wR* [$I > 3\sigma(I)$] was 0.047 for 297 parameters, goodness-of-fit was 1.542, maximum and minimum residuals in the ΔF map were +0.35 and −0.57 e Å^{-3}. All calculations were made with the MaXus system (MacScience, Japan) and drawings were performed using the PLUTON 94 system.

2.3. Physical measurements

Microanalyses of C, H and N were performed on a Fisons EA1108 apparatus. The loss of water and ammonia was determined from the TG and DSC plots (Shimadzu TGA-50). Conductivity measurements were carried out using 10^{-3} M freshly prepared DMF solutions on a Hanna HI8820 instrument. IR were measured on a Perkin-Elmer FT-IR 1760-X (KBr pellets, 4000–400 cm^{-1}) and FT-IR Bruker Vector-22 spectrophotometers (polyethylene pellets, 600–220 cm^{-1}). Reflectance diffuse spectra (240–1500 nm) were recorded on a Perkin-Elmer UV–Vis–near-IR Lambda-19 machine using a $BaSO_4$ pellet as reference. The EPR spectra were obtained in the X-band at room temperature on a Bruker ESP 300E apparatus, with a microwave frequency of 9.79 GHz and a modulation frequency of 100 kHz. Magnetic measurements (77–290 K) were carried out on a Manics DSM-8 system.

3. Results and discussion

3.1. Description of the structure

In Fig. 1 a view of the molecular structure of the complex [Cu(BEZDO)(H_2O)]·H_2O (**1**) is depicted. The bond

length and angles around the metal centre are given in Table 1. The coordination sphere around the metal displays a square-based geometry with the tridentate ligand $BEZDO^{2-}$ coordinated through the N(6), N(51) and O(52) atoms and an oxygen atom of a water molecule, at distances of between 1.9 and 2.0 Å. The assignment of the N(6) as metal-binding site, instead of its pseudo-related O(4) atom (through the pseudo-two-fold axis passing through O(2)–C(2)–C(5)–C(51)), was carried out on the basis of two facts: (1) the location of one hydrogen, H(6), attached to the N(6) donor atom; and (2) the larger C(6)–N(6) distance (1.310(6) Å) compared with the C(4)–O(4) distance (1.261(5) Å) [6–9]. The remaining water molecule is joined to the structure through three hydrogen bonds. There is no other potential donor atom above or below the coordination plane, which allows us to suggest a coordination number bigger than four.

The molecular unit rings are virtually planar, with average torsion angles from 0.9 (benzene ring) to 4.2° (uracil ring). The uracil ring is almost coplanar with both chelates, with dihedral angles near to 4°. However, the benzene ring is angled by 10.4° with the uracil ring, and this angle is smaller than that of the free ligand (38.2°) . Thus, the molecular unit is formed by three adjacent rings, the two chelates and the uracil ring, almost coplanar with each other, which must contribute to the stability of the structure.

Geometrical details of the hydrogen bonding are given in Table 2. The establishment of hydrogen bonds makes chains that are monodimensionally extended through the 101 direction (Fig. 2). The molecules are joined through the hydrogen bonds O(W1)–H···O(W2), O(W1)–H···O4 and O(W2)–H···N(52); these bonds make a chain in which the coordination planes are roughly perpendicular to the $10\bar{1}$ direction. Each chain is paired with an analogous one through two hydrogen bonds O(W2)–H···O(4), in such a way that the molecular units are mutually related by symmetry centres. In the structure, the shorter distances between two copper atoms are Cu–Cu $(1-x, -y, 1-z)$ 4.511 Å and Cu–Cu $(1-x, -y, 2-z)$ 3.585 Å.

In order to analyse the possible different tautomeric forms of the ligand $HBEZDO^{2-}$ in this complex, the bond distances near the donor atoms have been compared (see Table 3) with those in the free ligand structure and in other complexes in which this ligand appears undeprotonated [6] and monodeprotonated [8,11]. The possible forms in which the negative charges lie near to the donor atoms, i.e. N(6), N(51) and O(52), are given in Fig. 3. In forms I–III, the negative charge of the N(6) atom moves near the donor atoms. The forms

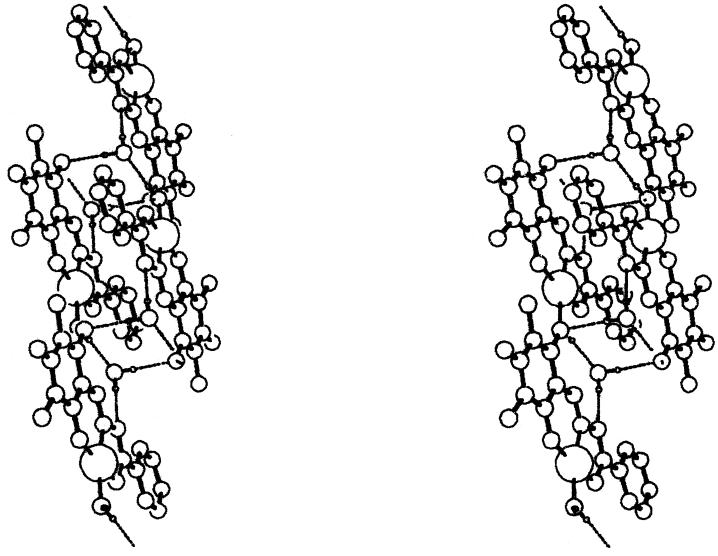

Fig. 2. Stereoview of the hydrogen-bonded chains in the crystal structure of $[Cu(BEZDO)(H_2O)]\cdot H_2O$. The chain grows following the [101] direction and the coordination planes are roughly perpendicular to the $10\bar{1}$ direction.

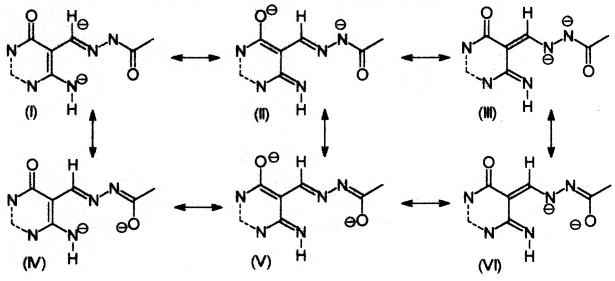

Fig. 3. Structure of the possible tautomeric forms for the dianion $BEZDO^{2-}$.

IV–VI may be explained by the ceto-imine equilibrium which displaces the negative charge from the N(52) atom to the O(52) atom.

The C(52)–O(52) bond distance is clearly longer in the dianion than in the others. This indicates that there is an important contribution of any of forms IV–VI. The C(4)–O(4) bond distance becomes longer due to involvement of the oxygen atom in the hydrogen bonds. The C(6)–N(6) and C(5)–C(51) bond distances become shorter, as in the monoanionic form of the ligand. C(51)–N(51) becomes a little longer than in the monoanion, and N(51)–N(52) and N(52)–C(52) become longer and shorter, respectively, with respect to their lengths in the monoanionic form. Therefore, it may be suggested there is a main contribution to the structure of the dianion by forms III and VI. The proximity of the two negative charges in form III may explain the lengthening of the N(51)–N(52) bond (1.405 Å), whereas the double bond N(52)=C(52), present in form VI, could justify the shortening of this distance (1.310 Å) compared with the monoanion (≈1.33 Å). Finally, the C(52)–O(52) bond is double in form III and single in form VI, which is in accordance with the intermediate bond distance experimentally found (1.311 Å). However, some contribution of form IV must be taken into account in order to explain the intermediate single–double character of the C(6)–N(6) bond (1.310 Å).

3.2. Spectral and magnetic properties

The comparative study of the infrared spectra of the complexes and the free ligand is very difficult because of the large number of bands, and only general remarks can be made. A general displacement is observed due to the coordination and deprotonation processes. These shifts agree with those found in the literature for similar compounds [12–16]. In all cases, as observed in other related complexes, the band assigned to the ν(N–N) mode is shifted to a higher wavenumber, which could be explained by the more electronic delocalization due to the O52 coordination to the metal. Also, the far-IR spectra show a band at around 430 cm^{-1} assignable to the ν(M–N) mode [17].

The Ni(II) complex (**1**) is diamagnetic, although when diamagnetic corrections were done $\mu_{eff} \approx 0.5$ BM was found, which is in accordance, together with the orange colour of the compound, with a square-plane structure. Magnetic susceptibility measurements at different temperatures in the two Cu(II) complexes have been successfully fitted to the Curie–Weiss law ($1/\chi_m = (T-\theta)/C$) (**2**, $C = 0.299(5)$ ucgs K mol^{-1}, $\theta = 16(5)$ K, $r = 0.9969$, $\mu_{eff} = 1.85(5)$ BM; **3**, $C = 0.325(6)$ ucgs K mol^{-1}, $\theta = 16(6)$ K, $r = 0.9960$, $\mu_{eff} = 1.91(5)$ BM) and the effective magnetic moments are in accordance with diluted monomeric units.

The X-band EPR spectrum on polycrystalline samples of the two Cu(II) complexes looks like an axial doublet with $g_\perp = 2.03$ and $g_\parallel = 2.19$ (**1**), $g_\perp = 2.05$ and $g_\parallel = 2.21$ (**2**). The observed pattern $g_\parallel > g_\perp > 2.0$ is indicative of a copper(II) $d_{x^2-y^2}$ orbital ground state in agreement with the square-plane environment of the copper.

The electronic spectra show bands assignable to tetragonally surrounded Ni(II) and Cu(II) ions. Thus, in the spectrum of the Ni(II) complex, only a single absorption is observed at 20900 cm^{-1}, as a consequence of the eight electrons of Ni(II) paired in the four low-lying d orbitals; these orbitals are often so close together in energy that individual transitions therefrom to the upper d level cannot be distinguished [18]. The copper complexes display a broad and poorly defined band centred at 17600 (**2**) and 16600 cm^{-1} (**3**); the bathochromic shift of the maximum is in accordance with the existence of a coordinated ammonia and a water molecule, respectively.

From these data, a similar structure to that found for complex **3** can be proposed for complexes **1** and **2**, but in these compounds the square-planar coordination around the metals must be completed with an ammonia molecule, instead of a water molecule as in compound **3**.

Abstract

Metathesis of the monochloro metal(II) complexes [MCl(dien)]Cl (M = Pd or Pt; dien = diethylenetriamine) with $K[Ph_2P(O)NP(E)Ph_2]$ (E = S or Se) or $K[Ph_2P(O)NPPh_2]$ (prepared in situ from $Ph_2P(O)NHPPh_2/KOBu^t$) in methanol gave the cationic, mononuclear compounds $[M\{Ph_2P(O)NP(E)Ph_2\text{-}E\}(dien)]^+$ or $[M\{Ph_2P(O)NPPh_2\text{-}P\}(dien)]^+$, isolated as their hexafluorophosphate salts. Ligand substitution reactions of the dichlorometal(II) precursors $[MCl_2(N\sim N)]$ (M = Pd or Pt; N∼N = ethane-1,2-diamine, 1,2-diaminocyclohexane) with $K[Ph_2P(O)NP(E)Ph_2]$ or $K[Ph_2P(O)NPPh_2]$ gave the neutral bis substituted compounds $[M\{Ph_2P(O)NP(E)Ph_2\text{-}E\}_2(N\sim N)]$ or $[M\{Ph_2P(O)NPPh_2\text{-}P\}_2(N\sim N)]$ in high yields (63–89%). Reaction of the unsymmetrical palladium(II) compound $[PdCl_2(ampy)]$ (ampy = 2-aminomethylpyridine) with $K[Ph_2P(O)NP(E)Ph_2]$ gave $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}E\}_2(ampy)]$, analogous to the recently described compound $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}E\}_2(en)]$, in which both $[Ph_2P(O)NP(E)Ph_2]^-$ ligands are exclusively *E*-monodentate bound. In contrast, transmetallation of $K[Ph_2P(O)NP(E)Ph_2]$ with $[PdCl_2(tmeda)]$ (tmeda = *N,N,N′,N′*-tetramethylethylenediamine) gave only the *O,E*-chelate monocationic complexes $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(tmeda)]PF_6$ and not $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}E\}_2(tmeda)]$. Under similar reaction conditions the symmetrical anions $[Ph_2P(E)NP(E)Ph_2]^-$ (E = S or Se) gave, without exception, the known bis homoleptic complexes $[M\{Ph_2P(E)NP(E)Ph_2\text{-}E,E'\}_2]$ (M = Pd or Pt) with displacement of all chloride and amine ligands. All new compounds have been characterised by a combination of multinuclear NMR (^1H, $^{31}P\{^1H\}$, $^{195}Pt\{^1H\}$), IR spectroscopy and elemental analyses. Furthermore, the X-ray crystal structures of five compounds have been determined and reveal a range of intermolecular and intramolecular hydrogen bonding contacts. There is also evidence for π-delocalisation within the E–P–N–P–O and P–N–P–O backbones of the *E*-ligating or *O,E*-chelating ligand. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The coordination chemistry of phosphorus containing ligands with inorganic backbones, for example R_2PNHPR_2 [1–4], $[R_2PNPR_2]^-$ [5,6], $R_2P(E)NHPR_2$ [7,8], $[R_2P(E)NPR_2]^-$ [7,8] and $[R_2P(E)NP(E)R_2]^-$ (E = O, S or Se) [9–17], has been the topic of much interest especially over the last three years. Specifically $[Ph_2P(E)NP(E)Ph_2]^-$, which coincidentally is closely related to $acac^-$ (acetylacetonate), is an excellent ligand for complexing numerous metal ions and furthermore has found important uses as selective metal extractants [18], NMR shift reagents [19] and more recently in catalysis [20]. This class of ligand displays a wide range of ligation modes reminiscent to that of $acac^-$ and its derivatives [21]. In contrast, the coordinating ability of the unsymmetrical ligands $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S or Se), bearing a mismatch in donor atoms, has been remarkably poorly studied, especially towards transition-metal ions [22–26]. Furthermore, sparse examples of compounds with $[Ph_2P(O)NP(E)Ph_2]^-$ and a central s- [27] or p-block [28–30] element have only recently been reported. Of those examples documented, the *O,E*-chelating mode of binding (**I**) is most prevalent [22,25,26,28–30]. One very unusual example is the complex *cis*-$[Pd\{Ph_2P(O)NP(Se)Ph_2\text{-}O,Se\}_2]$ in which both six-membered Pd–O–P–N–P–Se rings adopt distinctly different ring geometries (X-ray evidence) [26]. Silvestru and coworkers recently described the synthesis and X-ray crystal structure of the dimeric compound $[Na\{Ph_2P(O)NP(S)Ph_2\}\cdot 2C_4H_8O]_2$ in which each $[Ph_2P(O)NP(S)Ph_2]^-$ behaves simultaneously as an *O,S*-chelating and *O*-bridging ligand (**II**) [27]. In

PII S0277-5387(00)00311-9

contrast the 'soft' *E*-donor of $[Ph_2P(O)NP(E)Ph_2]^-$ can bridge two late transition-metal centres (**III**), as observed in $[\{Pd(\eta^3\text{-}C_3H_5)[\mu\text{-}Ph_2P(O)NP(Se)Ph_2\text{-}Se]\}_2]$, forming a central Pd_2Se_2 core with two pendant $-P(O)Ph_2$ groups [23]. The $[Ph_2P(O)NP(E)Ph_2]^-$ can also behave as a non-coordinating anion (**IV**) as exemplified by the unusual salt $[Pt(Ph_2PC_6H_4NH_2\text{-}P,N)(Ph_2PC_6H_4NH\text{-}P,N)][Ph_2P(O)\text{-}NP(E)Ph_2]$ (E = S or Se) [22]. We described in a recent preliminary communication [24] the synthesis and characterisation of $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}E\}_2(en)]$ and $[Au\{Ph_2P(O)NP(E)Ph_2\text{-}E\}\{Ph_2P(O)NHPPh_2\text{-}P\}]$ which are the first reported examples in which $[Ph_2P(O)NP\text{-}(E)Ph_2]^-$ adopts an *E*-monodentate coordination mode (**V**). This mode of ligation is especially noteworthy since $[Ph_2P(O)NP(E)Ph_2]^-$ are ambidentate ligands capable of binding through either O or E donor atoms depending on whether the metal centre is 'soft' or 'hard' in character. Furthermore in these rare examples there is a strong propensity for hydrogen bonding between the 'dangling' $-P(O)Ph_2$ group and the ancillary amine ligand [en, $Ph_2P(O)NHPPh_2$] in the metal coordination sphere.

An understanding of the binding capabilities of these extremely versatile, readily synthesised, ligands towards precious metals and their subsequent reactivity is important given that complexes of acac are useful in several metal complex catalysed reactions. Furthermore, there is considerable interest in *cis*-$[PtCl_2(amine)_2]$ for their cytotoxic activity and their reactivity with various sulfur containing ligands. To elucidate further the complexing properties of $[Ph_2P(O)NP(E)Ph_2]^-$ (E = S or Se), their reactions with selected metal(II) amine complexes have been investigated. We present here our work regarding the synthesis and characterisation of a series of square-planar palladium(II) and platinum(II) complexes with didentate and tridentate amine and monodentate *E*-bound $[Ph_2P(O)NP(E)Ph_2]^-$ ligands. For comparison we have extended the scope of these reactions to the preparation of related complexes with *P*-bound $[Ph_2P(O)NPPh_2]^-$ ligands. The new compounds have been characterised by multinuclear NMR (^1H, $^{31}P\{^1H\}$, $^{195}Pt\{^1H\}$), IR spectroscopy and elemental analyses. Moreover, the molecular structures of five compounds are reported and confirm, in three cases, that $[Ph_2P(O)NP(E)Ph_2]^-$ adopts an *E*-unidentate mode of bonding and also a range of intramolecular and intermolecular hydrogen bonding motifs.

2. Experimental

2.1. General

Unless otherwise stated manipulations were carried out in air with no special precaution taken regarding the use of dry/distilled solvents. The potassium salts $K[Ph_2P(O)\text{-}NP(E)Ph_2]$ (E = S or Se) [26] and $K[Ph_2P(E)NP(E)Ph_2]$ (E = S or Se) [8,31] were prepared according to known procedures whilst $K[Ph_2P(O)NPPh_2]$ was prepared in situ from $Ph_2P(O)NHPPh_2$/KOBu^t. The compounds $[PdCl_2\text{-}(en)]$, $[PdCl_2(tmeda)]$, $[PtCl_2(C_6H_{14}N_2)]$ ($C_6H_{14}N_2$ = 1,2-diaminocyclohexane), $[PtCl_2(py)_2]$, $[NH_4][PF_6]$ and KOBu^t were purchased from Aldrich Chemical Co. and used without further purification. [MCl(dien)]Cl (M = Pd or Pt) and $[PdCl_2(ampy)]$ were prepared by previous reported methods [32–34].

Infrared spectra were recorded as KBr pellets in the range 4000–220 cm^{-1} on a Perkin-Elmer system 2000 Fourier-transform spectrometer. ^1H NMR spectra (250 MHz) were recorded on a Bruker AC250 FT spectrometer with chemical shifts δ in ppm to high frequency of $Si(CH_3)_4$ and coupling constants *J* in Hz; $^{31}P\{^1H\}$ NMR spectra (36.2 MHz) were recorded on a JEOL FX90Q spectrometer with chemical shifts δ in ppm to high frequency of 85% H_3PO_4 and coupling constants *J* in Hz; $^{195}Pt\{^1H\}$ NMR spectra (53.7 MHz) were recorded on a Bruker AC250 FT NMR spectrometer with δ referenced to external H_2PtCl_6 (in D_2O/HCl). All spectra were measured in $CDCl_3$ unless otherwise stated. Elemental analyses (Perkin-Elmer 2400 CHN elemental analyser) were performed by the Loughborough University Analytical Service within the Department of Chemistry.

Precious metal salts were provided on loan by Johnson Matthey plc.

2.2. Preparations

2.2.1. Preparation of $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}S\}(dien)]PF_6$ (1)

To the solids [PdCl(dien)]Cl (0.029 g, 0.103 mmol) and $K[Ph_2P(O)NP(S)Ph_2]$ (0.051 g, 0.108 mmol) was added CH_3OH (1 cm^3). After stirring at ambient temperature for ca. 2 h, the yellow solution was filtered to remove trace amounts of solid, and a methanolic solution (ca. 0.5 cm^3) of $[NH_4][PF_6]$ (0.041 g, 0.252 mmol) was added. The solution was stirred for 15 min and distilled water was added dropwise to afford a yellow precipitate. The mixture was stirred for an additional 20 min and the solid **1** isolated by suction filtration and dried in vacuo. Yield 0.071 g, 88%. FAB^+ MS: *m/z* 641 $(M\text{–}PF_6)^+$. IR: 3641 (ν_{OH}), 3319, 3268, 3202, 3112 (ν_{NH}), 1243 (ν_{PNP}), 562 (ν_{PS}). ^1H NMR (CD_3OD): 7.99–7.29 (arom. H), 2.89–2.54 (dien). In a similar manner the following complexes were prepared: $[Pd\{Ph_2P(O)NP(Se)\text{-}Ph_2\text{-}Se\}(dien)]PF_6$ (**2**) (85%). FAB^+ MS: *m/z* 689 $(M-PF_6)^+$. IR: 3639 (ν_{OH}), 3316, 3268, 3203, 3115 (ν_{NH}), 1236 (ν_{PNP}), 558 (ν_{PSe}). ^1H NMR (CD_3OD): 7.96–7.34

(arom. H), 2.90–2.55 (dien). [Pt{$Ph_2P(O)NP(S)Ph_2$-*S*}(dien)]PF_6 (**3**) (83%). FAB^+ MS: *m/z* 730 ($M-PF_6$). IR: 3640 (ν_{OH}), 3306, 3214 (ν_{NH}), 1223 (ν_{PNP}), 559 (ν_{PS}). ^1H NMR (CD_3OD): 7.95–7.35 (arom. H), 3.06–2.48 (dien). [Pt{$Ph_2P(O)NP(Se)Ph_2$-*Se*}(dien)]PF_6 (**4**) (85%). FAB^+ MS: *m/z* 777 $(M-PF_6)^+$. IR: 3651, 3636 (ν_{OH}), 3303, 3204, 3113 (ν_{NH}), 1239 (ν_{PNP}), 558 (ν_{PSe}). ^1H NMR (CD_3OD): 7.97–7.36 (arom. H), 3.18–2.46 (dien). [Pd{$Ph_2P(O)NPPh_2$-*P*}(dien)]PF_6 (**5**) (71%). FAB^+ MS: *m/z* 609 $(M-PF_6)^+$. IR: 3334, 3280, 3193 (ν_{NH}), 1165, 1155 (ν_{PNP}). ^1H NMR (CD_3OD): 8.03–7.38 (arom. H), 3.08–2.63 (dien).

Crystals of **1** and **2** suitable for X-ray crystallography were grown by slow diffusion of Et_2O into a CH_3OH solution over ca. 4 days.

Reaction of [MCl(dien)]Cl (M = Pd or Pt) with K[$Ph_2P(E)NP(E)Ph_2$] (E = S or Se, 1:1 or 1:2 molar ratio) under analogous conditions to those described above gave the known homoleptic complexes [M{$Ph_2P(E)NP(E)Ph_2$-*E,E′*}$_2$] [42]. The ^{31}P NMR shifts were identical to those previously reported.

2.2.2. Preparation of [Pd{$Ph_2P(O)NPPh_2$-*P*}$_2$(en)] (*6*)

To the solids [$PdCl_2$(en)] (0.024 g, 0.101 mmol) and $Ph_2P(O)NHPPh_2$ (0.084 g, 0.209 mmol) was added CH_3OH (1.5 cm^3). To this slurry was added $KOBu^t$ (0.025 g, 0.223 mmol) and the mixture was stirred for ca. 4 h. The solid was filtered under reduced pressure, washed with CH_3OH (ca. 0.5 cm^3) and dried in vacuo. Yield 0.062 g, 63%. FAB^+ MS: *m/z* 967 (M^+). IR: 3650 (ν_{OH}), 3313, 3294, 3194 (ν_{NH}), 1188, 1173 (ν_{PNP}). ^1H NMR: 8.18–6.90 (arom. H), 2.80, 1.76 (CH_2, NH_2).

Crystals of **6** suitable for X-ray crystallography were grown by slow evaporation of a $CDCl_3/Et_2O$ solution over ca. 30 days.

2.2.3. Preparation of [Pt{$Ph_2P(O)NP(S)Ph_2$-*S*}$_2$($C_6H_{14}N_2$)] (*7*)

A slurry of [$PtCl_2(C_6H_{14}N_2)$] (0.020 g, 0.0526 mmol) and K[$Ph_2P(O)NP(S)Ph_2$] (0.050 g, 0.106 mmol) in CH_3OH (10 cm^3) was refluxed, under a nitrogen atmosphere, for 5 h. The yellow solution was evaporated to dryness under reduced pressure, the residue taken up in CH_2Cl_2 (5 cm^3) and passed through a Celite pad. The volume was reduced to ca. 1 cm^3 and petroleum ether (b.p. 60–80°C, 10 cm^3) added to precipitate the product **7** which was collected by suction filtration and dried in vacuo. Yield 0.050 g, 81%. FAB^+ MS: *m/z* 1175 (M^+). IR: 3287, 3262, 3201 (ν_{NH}), 1282, 1249, 1235 (ν_{PNP}), 560 (ν_{PS}). ^1H NMR: 7.89–7.24 (arom. H), 5.46, 4.40, 1.80–0.80 ($C_6H_{14}N_2$). In a similar manner [Pt{$Ph_2P(O)NP(Se)Ph_2$-*Se*}$_2$($C_6H_{14}N_2$)] (**8**) was prepared in 89% yield. FAB^+ MS: *m/z* 1269 (M^+). IR: 3293, 3266, 3205 (ν_{NH}), 1243 (ν_{PNP}), 545 (ν_{PSe}). ^1H NMR: 7.91–7.26 (arom. H), 5.35, 4.40, 1.81–0.86 ($C_6H_{14}N_2$). Attempts to prepare [Pt{$Ph_2P(O)NP(E)Ph_2$-*E*}$_2$($py)_2$] under similar conditions gave several phosphorus containing species (^{31}P NMR evidence).

2.2.4. Preparation of [Pd{$Ph_2P(O)NP(S)Ph_2$-*S*}$_2$(ampy)] (*9*)

To the solids [$PdCl_2$(ampy)] (0.017 g, 0.070 mmol) and K[$Ph_2P(O)NP(S)Ph_2$] (0.070 g, 0.148 mmol) was added CH_3OH (1 cm^3). The solids dissolved slowly within ca. 10 min whereupon product **9** deposited. The mixture was stirred for a further 2 h and the solid collected by suction filtration and dried in vacuo. Yield 0.058 g, 77%. FAB^+ MS: *m/z* 1079 (M^+). IR: 3227, 3176 (ν_{NH}), 1287, 1266, 1232 (ν_{PNP}), 564 (ν_{PS}). ^1H NMR: 8.90–6.76 (arom. H), 5.21, 3.78 (NH_2, CH_2). In a similar manner [Pd{$Ph_2P(O)NP(Se)Ph_2$-*Se*}$_2$(ampy)] (**10**) was prepared in 87% yield. FAB^+ MS: *m/z* 1174 (M^+). IR: 3231, 3189 (ν_{NH}), 1283, 1259, 1225 (ν_{PNP}), 560, 549, 540 (ν_{PSe}). ^1H NMR: 9.23–6.87 (arom. H), 4.83, 3.75 (NH_2, CH_2). The solids **9** and **10** could be recrystallised from CH_2Cl_2/OEt_2.

Crystals of **9** suitable for X-ray crystallography were grown by slow diffusion of petroleum ether (b.p. 60–80°C) into a $CDCl_3$ solution over the course of ca. 4 days.

Reaction of [$PdCl_2$(ampy)] with 2 equiv. of K[$Ph_2P(E)NP(E)Ph_2$] (E = S or Se) gave [Pd{$Ph_2P(E)NP(E)Ph_2$-*E,E′*}$_2$] in 87% (E = S) and 63% (E = Se) yields respectively.

2.2.5. Preparation of [Pd{$Ph_2P(O)NP(S)Ph_2$-*O,S*}(tmeda)]PF_6 (*11*)

To the solids [$PdCl_2$(tmeda)] (0.029 g, 0.099 mmol) and K[$Ph_2P(O)NP(S)Ph_2$] (0.049 g, 0.104 mmol) was added CH_3OH (1 cm^3). After stirring for 2 h, the solution was filtered and a methanolic (ca. 0.5 cm^3) solution of [NH_4][PF_6] (0.040 g) was added to afford a yellow precipitate. The product was collected by suction filtration and dried in vacuo. Yield 0.073 g, 92%. FAB^+ MS: *m/z* 654 $(M-PF_6)^+$. IR: 1230 (ν_{PNP}), 581 (ν_{PS}). ^1H NMR: 7.90–7.38 (arom. H), 2.76 (CH_2), 2.63, 2.39 [$N(CH_3)_2$]. In a similar manner [Pd{$Ph_2P(O)NP(Se)Ph_2$-*O,Se*}(tmeda)]PF_6 (**12**) was prepared (95%). FAB^+ MS: *m/z* 702 $(M-PF_6)^+$. IR: 1230 (ν_{PNP}), 539 (ν_{PSe}). ^1H NMR: 7.92–7.38 (arom. H), 2.76 (CH_2), 2.60, 2.46 [$N(CH_3)_2$].

Crystals of **11** suitable for X-ray crystallography were grown by slow diffusion of diethyl ether into a CH_3OH/CH_2Cl_2 solution over the course of ca. 3 days.

Microanalytical and spectroscopic data are given in Tables 1 and 2.

2.3. X-ray crystallography

The crystal structures of complexes **1**, **2**, **6**, **9** and **11** were determined using either a Rigaku AFC7S serial diffractometer with graphite-monochromated (Cu Kα) radiation (λ = 1.541 78 Å) and ω-scans or a Bruker SMART diffractometer with graphite-monochromated (Mo Kα) radiation (λ = 0.710 37 Å). Details of the crystal data collections and

refinements are given in Table 3. For the SMART data, intensities were collected using 0.3° or 0.15° width ω steps accumulating area detector frames spanning a hemisphere of reciprocal space for all structures (data were integrated using the SAINT [35] program) and for the Rigaku AFC7S data collections by ω scans over a single quadrant of reciprocal space. All data were corrected for Lorentz, polarisation and long-term intensity fluctuations. Absorption effects were corrected on the basis of multiple equivalent reflections or by empirical methods [36].

Structures were solved by direct methods and refined by full-matrix least-squares against F (TEXSAN [37]) or F^2 (SHELXTL [38]) for all data with $I > 2\sigma(I)$. Standard SHELXTL weighting scheme was used for **2**, **6**, **9** and **11** whilst in the case of **1** the weighting scheme for the Rigaku/TEXSAN structure was as previously reported [26]. For **1** the O–H hydrogen atoms on both the H_2O and CH_3OH solvent molecules were located from ΔF maps. In compound **2** the N(3)–H hydrogen atom was not located. For **6** the hydro-

[a] Two independent molecules.

gen atoms on the H_2O solvent molecule were located from ΔF maps with these hydrogen atoms and those on N(49) and N(50) refined isotropically. One mole of H_2O for each independent molecule of **9** (two H_2O molecules in the asymmetric unit) was located and all O–H hydrogen atoms found. In all structures the remaining hydrogen atoms (including those on the solvent molecules in **1** and **2**) were assigned isotropic displacement parameters and were constrained to idealised geometries. The chirality of **2** was tested by a Flack parameter refinement which refined to −0.007(13) indicating the correct absolute stereochemistry. Refinements converged to residuals given in Table 3. All calculations were made with programs of the TEXSAN [37] or SHELXTL [38] systems.

3. Results and discussion

The cationic compounds [MCl(dien)]Cl (M = Pd, Pt) are useful precursors in which the tridentate dien ligand leaves a single vacant coordination site for ligand exchange reactions as illustrated by the recent synthesis of [Pt(O_2CCH_2SMe-*S*)(dien)]Cl (**A**) [39]. Hence metathesis of [MCl(dien)]-Cl with 1 equiv. of K[$Ph_2P(O)NP(E)Ph_2$] (E = S **B**; E = Se **C**) in CH_3OH, followed by addition of methanolic [NH_4][PF_6] and precipitation with water, gave the following series of metal(II) complexes (Scheme 1): [M{Ph_2P-(O)NP(E)Ph_2-*E*}(dien)]PF_6 (M = Pd, E = S **1**; M = Pd, E = Se **2**; M = Pt, E = S **3**; M = Pt, E = Se **4**). Compounds **1**–**4** were isolated in good yields (83–88%) as air-stable, yellow (**1** and **2**) or white (**3** and **4**) solids, insoluble in hydrocarbons (e.g. toluene) and water but appreciably soluble in CH_2Cl_2 and CH_3OH. The pertinent spectroscopic and microanalytical data for these compounds are given in Tables 1 and 2 and Section 2. Particularly informative was $^{31}P\{^1H\}$ NMR which showed single metal complexes as inferred by resonances at $\delta(P_S)$ 29.1 (for **1**) and 26.4 ppm (for **3**) and $\delta(P_{Se})$ 14.6 (for **2**) and 11.5 ppm (for **4**). In the case of **3** (and **4**) the P_S and P_{Se} resonances were flanked by ^{195}Pt satellites (^1J(PtP) coupling constant of ca. 100 Hz). Furthermore $\delta(P_O)$ was observed at ca. 17 ppm and implied that the phosphoryl group was not involved in coordination with the metal(II) centre. These observations are consistent with **B** and **C** adopting an *E*-monodentate mode of binding through either the 'soft' S or Se donor atom. Pasini and coworkers recently described a series of related complexes of formula [Pt(L-*S*)(dien)]$^+$ (L = methylsulfanyl- and methylsulfinyl-acetate, benzoate and phenolate ligands) and confirmed by NMR and IR the absence of any carboxylate interaction with the metal centre [39,40]. The $^{195}Pt\{^1H\}$ NMR spectra of **3** (and **4**) appeared as broad, poorly resolved signals at ca. δ(Pt) −3100 ppm and in the range anticipated for complexes with a PtN_3S core [40,41]. The ^1H NMR spectra for **1**–**4** (recorded in CD_3OD) have chemical shifts that lie in a very similar range, indicating congruous structures. Treatment of **1** in $CDCl_3/CH_3OH$ with concentrated HCl resulted in smooth conversion to the parent acid $Ph_2P(O)NHP$-(S)Ph_2 and [PdCl(dien)]Cl ($^{31}P\{^1H\}$ NMR evidence). The corresponding reaction with the symmetrical ligands K[$Ph_2P(E)NP(E)Ph_2$] (E = S or Se) gave only the known neutral metal(II) complexes [M{$Ph_2P(E)NP(E)Ph_2$-*E*,*E*′}$_2$] [42]. The compound [Pd{$Ph_2P(O)NPPh_2$-*P*}-(dien)]PF_6 (**5**) was likewise prepared from [PdCl-(dien)]Cl and K[$Ph_2P(O)NPPh_2$] in 71% yield and the spectroscopic data are in full agreement with the structure proposed. The $^{31}P\{^1H\}$ NMR spectrum showed a pair of doublets centred at 32.1 and 21.7 ppm ($^2J(PP_O)$ 19.8 Hz)

Scheme 1. (i) [MCl(dien)]Cl, [NH_4][PF_6], (ii) [MCl_2(N~N)], (iii) [$PdCl_2$(ampy)], (iv) [$PdCl_2$(tmeda)], [NH_4][PF_6].

indicating two non-equivalent phosphorus environments. Attempts to prepare the platinum(II) compound [Pt{$Ph_2P(O)NPPh_2$-*P*}(dien)]PF_6 from [PtCl(dien)]Cl have so far proved unsuccessful.

The crystal structure of **1** (Fig. 1, Table 4) reveals an approximate square planar environment around the palladium(II) metal centre (N(3)–Pd(1)–N(4) 85.0(5), N(2)–Pd(1)–N(3) 85.3(5), S(1)–Pd(1)–N(4) 94.5(3), S(1)–Pd(1)–N(2) 95.0(4)°, molecule 1; N(33)–Pd(31)–N(34) 84.5(5), N(32)–Pd(31)–N(33) 84.9(5), S(31)–Pd(31)–N(32) 94.8(3), S(31)–Pd(31)–N(34) 95.8(3)°, molecule 2) with the Pd lying 0.08 (molecule 1) and 0.05 Å (molecule 2) out of the plane of its four donor centres. The ligand adopts an *E*-monodentate coordination mode with long P–S and short P–N bonds consistent with some degree of delocalisation. There is extensive hydrogen bonding in **1**, consisting of (i) intramolecular PO···HN hydrogen bonding (O(2)···N(2) 3.04, O(2)···H(2A) 2.30 Å, O(2)···H(2A)–N(2) 139°, molecule 1; O(32)···N(32) 2.84, O(32)···H(32A) 1.81 Å, O(32)···H(32A)–N(32) 175°, molecule 2), (ii) intermolecular hydrogen bonding to CH_3OH and H_2O solvate molecules (O(2)···O(60) 2.70, O(2)···H(60) 1.64 Å, O(2)···H(60)–O(60) 157°, N(3)···O(60*) 2.84, O(60*)···H(3) 1.87 Å, O(60*)···H(3)–N(3) 146°, N(4)···O(33) 2.95, N(4)···H(33A) 2.11 Å, N(4)···H(33A)–O(33) 164°, molecule 1; O(32)···O(36) 2.68, O(32)···H(36A) 1.89 Å, O(32)···H(36A)–O(36) 122°, O(36)···N(33) 2.82, O(36)···H(33) 1.82 Å, O(36)···H(33)–N(33) 143°, molecule 2).

The X-ray structure of **2** (Fig. 2, Table 4) shows the palladium metal centre to be roughly square planar (N(3)–Pd(1)–N(4) 83.5(2), N(2)–Pd(1)–N(3) 84.2(2), N(2)–Pd(1)–Se(1) 90.67(14), N(4)–Pd(1)–Se(1) 102.16(14)°). The PdN_3Se core embraces a tridentate dien ligand and an Se-bound [$Ph_2P(O)NP(Se)Ph_2$]$^-$ ligand with the palladium lying approximately in the plane of its four

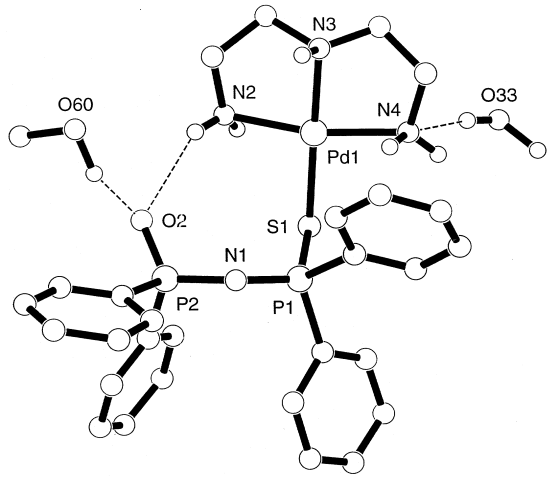

Fig. 1. Crystal structure of [Pd{$Ph_2P(O)NP(S)Ph_2$-*S*}(dien)]PF_6·H_2O·0.5CH_3OH showing one of the independent cations (PF_6^- anion and CH protons omitted for clarity). Hydrogen bonding is indicated by thin dashed lines.

Table 4
Selected bond distances (Å) and angles (°) for compounds **1** and **2**

	1 (E = S) [a]	**2** (E = Se)

E(1)–Pd(1)–N(3)	178.1(4) [179.7(4)]	172.6(2)
E(1)–Pd(1)–N(4)	94.5(3) [95.8(3)]	102.16(14)
N(2)–Pd(1)–N(3)	85.3(5) [84.9(5)]	84.2(2)
N(2)–Pd(1)–N(4)	168.2(4) [168.1(4)]	165.6(2)
N(3)–Pd(1)–N(4)	85.0(5) [84.5(5)]	83.5(2)

[a] Equivalent parameters for the second molecule are given in square brackets.

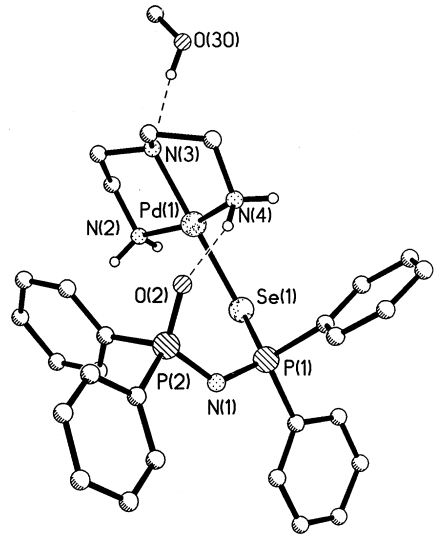

Fig. 2. Crystal structure of [Pd{$Ph_2P(O)NP(Se)Ph_2$-*Se*}(dien)]PF_6·CH_3OH (PF_6^- anion and CH protons omitted for clarity). Hydrogen bonding is indicated by thin dashed lines.

N_3Se-donor atoms. The Pd(1)–Se(1) distance of 2.4475(7) Å is similar to that observed in other complexes with [$Ph_2P(O)NP(Se)Ph_2$]$^-$, e.g. [{Pd(η^3-C_3H_5)[μ-Ph_2P-(O)NP(Se)Ph_2-*Se*]}]$_2$ (Pd–Se 2.477(2), 2.475(2) Å) [23] but longer than that observed in *cis*-[Pd{Ph_2P-(O)NP(Se)Ph_2-*O*,*Se*}$_2$] (Pd–Se 2.381(7), 2.383(8) Å) [26]. A comparison of bond distances and angles within the Se(1)–P(1)–N(1)–P(2)–O(2) backbone is especially noteworthy. The Se(1)–P(1), P(1)–N(1) and N(1)–P(2) bond lengths indicate some degree of delocalisation within the [$Ph_2P(O)NP(Se)Ph_2$]$^-$ ligand and are similar to those reported for [{Pd(η^3-C_3H_5)[μ-$Ph_2P(O)NP(Se)Ph_2$-*Se*]}]$_2$ [23], [Pd{$Ph_2P(O)NP(Se)Ph_2$-*Se*}$_2$(en)] [24] and

cis-[Pd{$Ph_2P(O)NP(Se)Ph_2$-*O*,*Se*}$_2$] [26], whilst the P–N–P angle (129.8(3)°) is smaller in magnitude compared with **1** (137.9(9)° for molecule 1; 137.6(8)° for molecule 2). The P(2)–O(2) bond length (1.515(5) Å) in **2** is similar to that observed for $Ph_2P(O)NHP(S)Ph_2$ (average P–O 1.503(4) Å) which exists in the solid state as a hydrogen-bonded polymeric chain [27]. There is a CH_3OH solvate which displays a close contact with N(3) of the coordinated dien ligand (N(3)···O(30) 2.93, N(3)···H(30) 2.22 Å, N(3)···H(30)–O(30) 144°). There is also an intramolecular hydrogen bond between the PO functionality and N(4)–H(4b) (N(4)···O(2) 2.85, H(4b)···O(2) 1.99 Å, N(4)–H(4b)···O(2) 160°) and an intermolecular N(2)–H(2b)···O(2*) hydrogen bond (N(2)···O(2*) 2.84, H(2b)···O(2*) 1.96 Å, N(2)–H(2b)···O(2*) 166°).

We recently described the preparation and characterisation of [Pd{$Ph_2P(O)NP(E)Ph_2$-*E*}$_2$(en)] [24] containing two *E*-monodentate bound [$Ph_2P(O)NP(E)Ph_2$]$^-$ ligands. Using this metathetical procedure we have synthesised the complex [Pd{$Ph_2P(O)NPPh_2$-*P*}$_2$(en)] (**6**) from [$PdCl_2$(en)] and 2 equiv. of K[$Ph_2P(O)NPPh_2$] in methanol. The $\delta(P_O)$ chemical shift for **6** is similar to that for **5** and the previously reported values for the mixed P^{III}/P^{V} ligand $Ph_2P(O)NHPPh_2$ ($\delta(P_O)$ 21.4 ppm) and $Ph_2P(O)NHP(O)Ph_2$ ($\delta(P_O)$ 20.7 ppm), suggesting no phosphoryl interaction with the Pd^{II} metal centre [43].

In the X-ray structure of **6** (Table 5, Fig. 3) the palladium centre is bound by two terminal [$Ph_2P(O)NPPh_2$]$^-$ ligands and a didentate $H_2NCH_2CH_2NH_2$ ligand in a slightly distorted square planar geometry with coordination angles in the range 81.11(8)–98.19(2) and 170.47(6)–172.39(6)°. The Pd–P distances in **6** (2.264(1) and 2.272(1) Å) are at the higher end of the range found in the corresponding complexes [Pd(*o*-$C_6H_4CH_2NMe_2$-*C*,*N*)-{$Ph_2P(O)NPPh_2$-*P*,*O*}]·CH_3OH (2.242(1) Å) and [PdCl{$Ph_2P(O)NPPh_2$-*P*,*O*}(Ph_2POCH_3)]·0.5CH_2Cl_2 (2.255(3) Å) [44] but shorter than that found in [{Pd(η^3-C_3H_5)[μ-$Ph_2P(O)NPPh_2$-*P*,*O*]}$_2$] (2.293(1) Å) [45]. The P–N bond lengths in **6** (P(1)–N(1) 1.601(2), N(1)–P(2) 1.604(2), P(3)–N(3) 1.593(2), N(3)–P(4) 1.599(2) Å) are similar to those described previously for metal complexes with [$Ph_2P(O)NPPh_2$]$^-$ and indicate some degree of delocalisation within the P–N–P backbone. The P(1)–O(1) and P(3)–O(3) bond lengths (1.492(2) and 1.499(2) Å) are similar in magnitude to that observed for $Ph_2P(O)NHPPh_2$ (1.508(2) Å) which exists in the solid state as a hydrogen-bonded dimer pair [43]. Both [$Ph_2P(O)NPPh_2$]$^-$ ligands are involved in intramolecular N–H···OP hydrogen bonding with $H_2NCH_2CH_2NH_2$ (N(49)···O(1) 2.85, H(49A)···O(1) 1.92 Å and N(49)–H(49A)···O(1) 158°; N(50)···O(3) 2.80, H(50B)···O(3) 1.85 Å and N(50)–H(50B)···O(3) 162°). This leads to a spirocyclic arrangement composed of two seven-membered rings about a central palladium(II) metal centre. An intermolecular O–H···O hydrogen bond is observed between O(3) and H(60A) of a water molecule (O(3)···O(60) 2.77, O(3)···H(60A) 1.79 Å and O(3)···H(60A)–O(60) 176°).

P(2)–Pd(1)–P(4)	98.19(2)

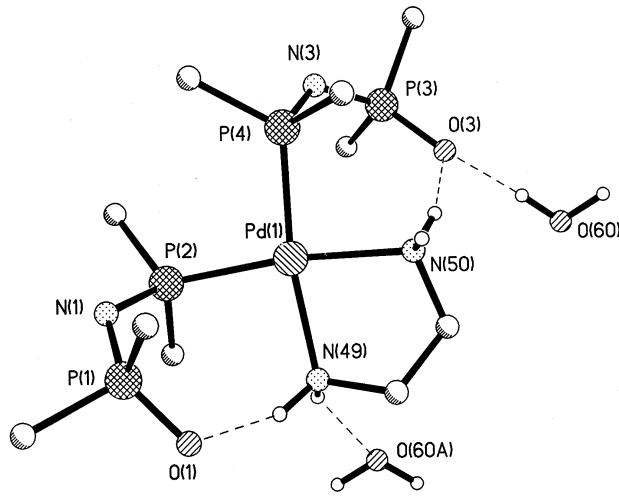

Fig. 3. Crystal structure of [Pd{$Ph_2P(O)NPPh_2$-*P*}$_2$(en)]·H_2O (only the *ipso* and methylene carbons and solvent are shown for clarity). Hydrogen bonding is indicated by thin dashed lines.

A second intermolecular N–H···O hydrogen bond is also observed between H(49B) and an adjacent water molecule (N(49)···O(60A) 3.15, H(49B)···O(60A) 2.29 Å and N(49)–H(49B)···O(60A) 146°).

Using more forcing conditions (reflux, 5 h) we were able to prepare the platinum(II) complexes [Pt{$Ph_2P(O)NP(E)Ph_2$-*E*}$_2$($C_6H_{14}N_2$)] (E = S **7**; E = Se **8**) [3] whereas attempts to obtain analogues with [$Ph_2P(E)NP(E)Ph_2$]$^-$ gave only [M{$Ph_2P(E)NP(E)Ph_2$-*E*,*E*′}$_2$]. Reaction of **B** with [$PtCl_2(py)_2$] (2:1 molar ratio) in refluxing CH_3OH

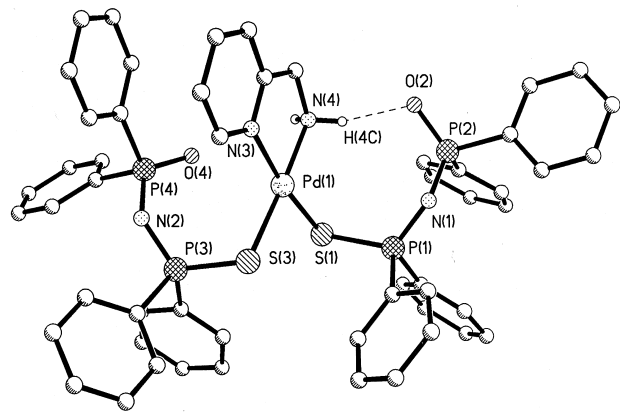
[3] Crystals of **7** have also been isolated but refinement of the X-ray data only resulted in a value of $R = 13.2\%$. Nevertheless the refinement again indicated an *S*-bound arrangement of the [$Ph_2P(O)NP(S)Ph_2$]$^-$ ligands.

gave, after solvent evaporation, a solid whose $^{31}P\{^{1}H\}$ NMR spectrum clearly showed a mixture of phosphorus containing species. Two major compounds identified were $[Pt\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}_2(py)_2]$ ($\delta(P_S)$ 25.7 ppm, $^{1}J(PtP)$ 88 Hz; $\delta(P_O)$ 11.3 ppm, $^{2}J(P_SP_O)$ 5 Hz) and $Ph_2P(O)NHP(S)Ph_2$, but attempts to isolate the platinum(II) complex by recrystallisation have so far proved unyielding.

The reaction of $[PdCl_2(ampy)]$ with **B** (and **C**) was of particular interest since it has previously been shown that, depending on the choice of $[PdCl_2(amine)_2]$, different products were obtained. Hence when $[PdCl_2(bipy)]$ was employed the *O,E*-chelate complexes $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}(bipy)]PF_6$ were isolated in high yields, but in contrast $[PdCl_2(en)]$ gave $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}_2(en)]$ with *E*-monodentate ligands [24,25]. Transmetallation of **B** (or **C**) with $[PdCl_2(ampy)]$ in methanol gave the neutral compounds $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}_2(ampy)]$ (E = S **9**; E = Se **10**) and hence the reactivity seen here resembles that of $[PdCl_2(en)]$. Four ^{31}P resonances were observed in the $^{31}P\{^{1}H\}$ NMR spectra of **9** (and **10**) consistent with four unique phosphorus environments (i.e. two *E*-monodentate $[Ph_2P(O)NP(E)Ph_2]^-$ ligands *trans* to the divergent nitrogen donor atoms of ampy). Furthermore $\delta(P_O)$ was indicative of a 'dangling' PO functionality (Table 2).

The X-ray structure of **9** (Fig. 4, Table 6) reveals two independent molecules and shows the palladium metal centres to be roughly square planar (N(3)–Pd(1)–N(4) 82.2(3), N(4)–Pd(1)–S(1) 90.7(2), S(1)–Pd(1)–S(3) 91.74(8), N(3)–Pd(1)–S(3) 95.5(2)°, molecule 1; N(63)–Pd(2)–N(64) 82.1(3), N(64)–Pd(2)–S(61) 90.1(2), S(61)–Pd(2)–S(63) 92.85(8), N(63)–Pd(2)–S(63) 94.9(2)°, molecule 2). The PdN_2S_2 core is composed of a didentate 2-aminomethylpyridine ligand and two *S*-bound $[Ph_2P(O)NP(S)Ph_2]^-$ ligands with the palladium lying essentially in the plane of its four constituents (for both independent molecules). The Pd(1)–N(3) distance (2.070(7) for molecule 1; 2.071(7) Å for molecule 2) is longer than that reported for $[Pd(cbdca)(ampy)]\cdot 2H_2O$ (1.989(12) Å) (cbdca = cyclobutane-1,1-dicarboxylate) whereas the Pd(1)–N(4) bond length (2.030(6) for molecule 1; 2.048(6) Å for molecule 2) is similar to that in $[Pd(cbdca)(ampy)]\cdot 2H_2O$ (2.024(12) Å) [34]. The Pd–S distances of 2.304(2) and 2.324(2) Å (molecule 1) and 2.299(2) and 2.314(2) Å (molecule 2) are similar to those in **1** (2.315(4), molecule 1; 2.334(4), molecule 2) and **11** (2.3315(8) Å). Within the S–P–N–P–O backbone there is evidence for some electron delocalisation with long S–P and short P–N/N–P bonds. The P–O bond lengths (1.494(5), 1.485(5) Å, molecule 1; 1.499(5), 1.495(5) Å, molecule 2) are similar to that observed in $Ph_2P(O)NHP(S)Ph_2$ [27]. One of the $[Ph_2P(O)NP(S)Ph_2]^-$ ligands is involved in intramolecular hydrogen bonding with $H_2NCH_2C_5H_3N$ (N(4)···O(2) 2.85, H(4C)···O(2) 1.97 Å, N(4)–H(4C)···O(2) 164°, molecule 1; N(64)···O(62) 2.85, H(64C)···O(62) 1.96 Å, N(64)–H(64C)···O(62) 166°, molecule 2) forming a pseudo eight-membered ring. This may account for the enlarged P(3)–N(2)–P(4) (137.2(4), molecule 1; 138.4(4)°, molecule 2) angle with respect to P(1)–N(1)–P(2) (132.6(5), molecule 1; 135.7(5)°, molecule 2). There is also additional intermolecular hydrogen bonding with a water solvent molecule (N(4)···O(71) 3.06, H(4B)···O(71) 2.21 Å, N(4)–H(4B)···O(71) 156°, molecule 1; N(64)···O(72) 3.03, H(64B)···O(72) 2.15 Å, N(64)–H(64B)···O(72) 166°, molecule 2).

We have also attempted to prepare *E*-monodentate analogues of $[PdCl_2(tmeda)]$ but were only able to isolate the *O,E*-chelate complexes $[Pd\{Ph_2P(O)NP(E)Ph_2\text{-}O,E\}$-



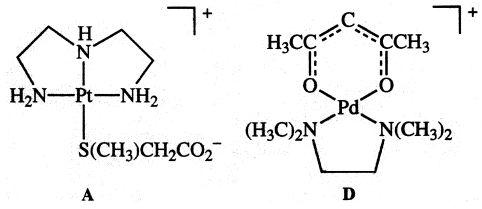


Fig. 4. Crystal structure of $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}S\}_2(ampy)]\cdot H_2O$ showing one of the independent molecules (solvent and CH protons omitted for clarity). Hydrogen bonding is indicated by thin dashed lines.

Table 6
Selected bond distances (Å) and angles (°) for compound **9** [a]

Pd(1)–S(1)	2.304(2) [2.299(2)]
Pd(1)–S(3)	2.324(2) [2.314(2)]
S(1)–P(1)	2.039(3) [2.028(3)]
S(3)–P(3)	2.042(3) [2.032(3)]
P(1)–N(1)	1.590(6) [1.579(6)]

N(3)–Pd(1)–S(3)	95.5(2) [94.9(2)]
N(4)–Pd(1)–S(1)	90.7(2) [90.1(2)]
N(4)–Pd(1)–S(3)	177.2(2) [176.9(2)]
S(1)–Pd(1)–S(3)	91.74(8) [92.85(8)]

[a] Equivalent parameters for the second molecule are given in square brackets.

(tmeda)]PF_6 (E = S **11**; E = Se **12**) in high yields (>90%). López and coworkers recently described the synthesis of the cationic complex $[Pd(acac)(tmeda)]^+$ (**D**) from the hydroxo palladium dimer $[\{Pd(\mu\text{-}OH)(tmeda)\}_2]^{2+}$ and the protic acid Hacac [46]. The $^{31}P\{^1H\}$ NMR spectra of **11** and **12** showed that $\delta(P_O)$ was shifted downfield by ca. 20 ppm with respect to **1**–**4**, **7**–**10**, suggesting an *O,E*-chelation mode of binding. This was further corroborated by ^1H NMR which showed two well resolved $N(CH_3)_2$ resonances at 2.63, 2.39 (for **11**) and 2.60, 2.46 ppm (for **12**). Furthermore, the IR spectra of **11** and **12** showed the absence of ν_{PdCl} (326 cm^{-1}) for $[PdCl_2(tmeda)]$, consistent with metathesis of both Pd–Cl ligands by an *O,E*-chelating $[Ph_2P(O)NP(E)Ph_2]^-$ anion. The reaction of $[PdCl_2$-(tmeda)] with 2 equiv. of **B** in CH_3OH was monitored by $^{31}P\{^1H\}$ NMR spectroscopy and showed that both **11** and unreacted **B** were present with no evidence for a neutral complex such as $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}S\}_2(tmeda)]$. This difference in reactivity may be ascribed to the use of a more sterically hindered diamine, the absence of suitable centres for hydrogen bonding or a combination of both factors. Attempts to prepare a corresponding complex from $[PdCl_2(tmeda)]$ and $K[Ph_2P(O)NPPh_2]$ (1:1 molar ratio) gave instead the known bis homoleptic compound *cis*-$[Pd\{Ph_2P(O)NPPh_2\text{-}P,O\}_2]$ [43].

The X-ray structure of **11** (Fig. 5, Table 7) shows the palladium metal centre to be surrounded by a chelating $Me_2NCH_2CH_2NMe_2$ and $[Ph_2P(O)NP(S)Ph_2]^-$ ligand in a slightly distorted square planar geometry with coordination angles in the range 85.89(12)–96.05(7) and 171.52(7)–172.09(12)°. The palladium lies 0.05 Å out of the plane of its four N_2OS donor constituents. The Pd(1)–N bond lengths reflect the nature of the *trans* donor atom (Pd(1)–N(25) 2.055(3), P *trans* to O; Pd(1)–N(26) 2.104(3) Å, P *trans* to S). Furthermore Pd(1)–N(25) is at the lower end of the range previously reported for the aryl- and alkoxide complexes *cis*-$[Pd(CH_3)(OR)(tmeda)]$ (2.060(5) (R = *p*-$C_6H_4NO_2$) to 2.080(2) Å (R = $CH(CF_3)_2$)) [47]. The six-membered Pd–O–P–N–P–S ring conformation in **11** can be most readily described as pseudo-boat with S(1) at the prow (0.88 Å above the plane) and P(2) at the stern (0.21 Å above the plane) of the 'boat'. In **11** the Pd(1)/P(1)/N(1)/O(2) atoms are approximately coplanar (maximum deviation from the mean plane 0.2 Å for N(1)). Within the $PdOP_2NS$ metallacycle the bond lengths are consistent with a fair degree of delocalisation.

We have shown that new complexes of palladium(II) and platinum(II) with *E*-monodentate $[Ph_2P(O)NP(E)Ph_2]^-$ ligands are readily accessible via transmetallation reactions. In contrast the use of symmetrical anions $[Ph_2P(E)$-$NP(E)Ph_2]^-$ leads exclusively to the formation of $[M\{Ph_2P(E)NP(E)Ph_2\text{-}E,E'\}_2]$ with displacement of all chloride and amine ligands. This disparity can presumably be traced to the dissimilar donor properties of the asymmetrical ligands. In this context the rare coordination mode displayed by $[Ph_2P(O)NP(E)Ph_2]^-$ may well mean that these ligands have a role in catalysis and in the synthesis of heterobimetallic compounds.

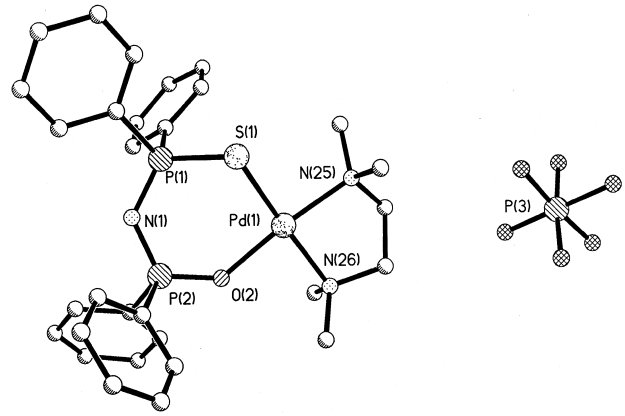

Fig. 5. Crystal structure of $[Pd\{Ph_2P(O)NP(S)Ph_2\text{-}O,S\}(tmeda)]PF_6$ (CH protons omitted for clarity).

Abstract

The electrochemical synthesis of $Sc(OMe)_3$ (**1**), $Sc(OEt)_3$ (**2**) and $Sc_5O(OPr^i)_{13}$ (**3**) was carried out via anodic oxidation of scandium metal in aliphatic alcohols. X-ray single crystal study showed **3** to be analogous to the known isopropoxides of Y, Er, Yb and In. The interaction of **3** with excess ROH (R = Me, Et, Bu^n, Bu^s, Bu^t) gives non-volatile amorphous **1**, **2** and $Sc(OBu^n)_3$ (**4**), and volatile $Sc_5O(OBu^s)_{13}$ (**5**) and $Sc_5O(OPr^i)_8(OBu^t)_5$ (**6**). Oxoalkoxides $Sc_5O(OPr^i)_8(OR)_5$ (R = Bu^n **7**, Me **8**) were obtained on reaction of **3** with n-ROH in 1:5 ratio. The mass spectral study shows **5** is an individual compound, whereas **6**–**8** in the gas phase consist of a number of aggregates with different extents of substitution for OPr^i groups, $Sc_5O(OR)_n(OPr^i)_{13-n}$: for R = Bu^t $n \leq 5$, for R = Bu^n $n \leq 8$, and for R = Me $n \leq 12$. The maximal intensity in the spectrum of **6** is observed for $Sc_5O(OPr^i)_{10}(OBu^t)_2^+$, and in the spectra of **7** and **8** for $Sc_5O(OPr^i)_{12-n}(OBu^n)_n^+$, $n = 4$, 5, and $Sc_5O(OPr^i)_9(OMe)_3^+$ respectively. The presence of the $Sc_5O(OMe)_{12}^+$ ion in the spectrum of **8** indicates the possibility of replacing all the OPr^i in the pentanuclear core and demonstrates the existence of a 'volatile scandium methoxide' in the gas phase. Study of the complex formation of $Sc(OR)_3$ with $Al(OR)_3$ has shown that **2** and **4** form volatile $Sc[Al(OR)_4]_3$, R = Et **9**, Bu^n **10**, while **3** does not react under these conditions. $Sc[Al(OPr^i)_4]_3$ (**11**) can be obtained only on exchange reaction of $ScCl_3$ with $KAl(OPr^i)_4$. The results obtained indicate rather high stability of the $[Sc_5O(OR)_8]$ core for primary and secondary R. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Scandium; Alkoxides; Crystal structures; Volatility

1. Introduction

The scandium alkoxides are the least studied among the analogous derivatives of the rare earth elements. The methoxide **1**, ethoxide **2** [1,2], isopropoxide **3** [2–4], n- **4** and *tert*-butoxides [1,2] have been described, and also a volatile derivative of a fluorinated alcohol $\{Sc[OCH(CF_3)_2]_3\}_2$, its solvate $\{Sc[OCH(CF_3)_2]_3(NH_3)_2\}_2$-*trans* [5], and a sterically overcrowded phenoxide $Sc(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)_3$ [6].

The aliphatic derivatives are formed by an exchange reaction of $ScCl_3$ with alcohols in the presence of ammonia [1] or with NaOR [3,4], and also, according to patent data, on interaction of $Sc(RCOO)_3$ with the corresponding alkoxides of Li, Na or K [2]. The described reactions (as well as other syntheses of this kind) are complicated by the formation of rather stable intermediate alkoxide halides or carboxylates. The preparation of **3** was achieved via alcoholysis of $Sc[N(SiMe_3)_2]_3$, and also by interaction of metal with alcohol in the presence of mercury salts as catalysts [3,4]. The disadvantages of this method include a very low reaction rate and the possibility of partial thermolysis in the presence of $HgCl_2$ [7]. The direct electrochemical synthesis of **3** appeared therefore rather more simple and efficient [4].

According to the literature, **1** is an insoluble polymer, and **4** is a viscous oil that crystallizes slowly on storage [1]. Bradley et al. [3] have shown using mass spectral and ^1H NMR data that **3** has a molecular structure analogous to that of indium and ytterbium isopropoxides, i.e. $M_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu\text{-}OPr^i)_4(OPr^i)_5$. The molecules of the latter are $[M_5]$ tetragonal pyramids, centered by a μ_5-oxoatom and supported by four μ_3-OR groups situated over the side faces and by four μ-OR groups over the edges of the basal plane. Crystalline **3** can be sublimed in vacuo (150 and 220°C, 10^{-2} Torr [3,4]), its thermal decomposition begins at about 300°C.

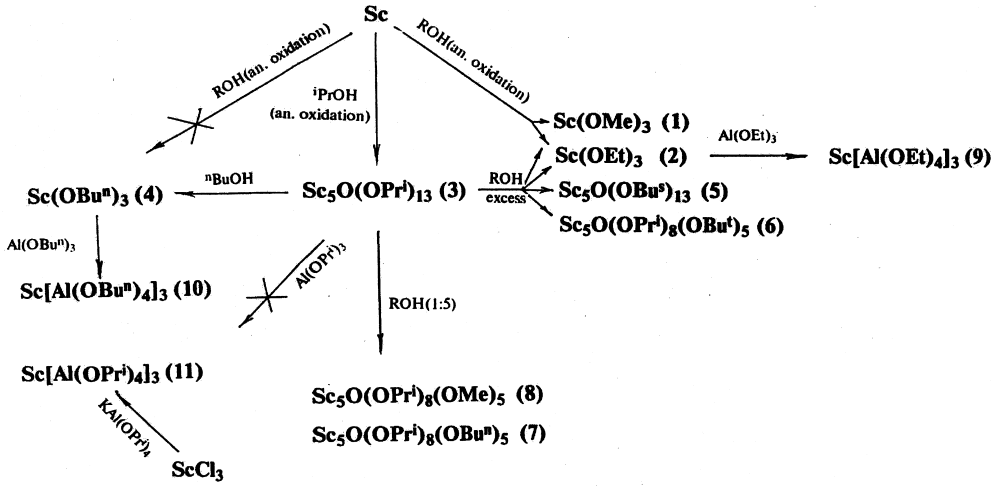
The present work is devoted to the development of the electrochemical synthesis of different $Sc(OR)_3$ homologs and the study of reactions of alcohol interchange for **3** and also the complex formation of scandium and aluminum alkoxides.

2. Results and discussion

2.1. Conditions for the formation of scandium alkoxides



Scandium alkoxides have been prepared using two methods.

(a) The anodic oxidation of metal, which at present is a common route for the preparation of III–VIII group alkoxides [8]. The electrolysis in MeOH occurred with a high rate and was accompanied by precipitation of **1**. The synthesis of **2** was complicated by a continuous decrease in current and extinguishing of the process. The isolated soluble product contained residual amounts of chlorine. The conditions used for the preparation of **3** in the present work did not differ substantially from those described earlier [4], however the more accessible LiCl was used instead of $[Bu_4N]Br$. The rate of anodic dissolution in n-, s- and t-BuOH was so low, even at rather high concentrations of electrolyte (>0.1 M), that it became impossible to use it for the preparation of butoxides. The electrochemical method therefore was attractive in the case of insoluble **1** and in that of **3**, which crystallizes from solution at room temperature.

(b) Alcohol interchange reactions starting from the isopropoxide The alcohol interchange reactions starting from the isopropoxide have been used for the preparation of numerous homologs of different rare-earth metals. Taking into account the fact that scandium isopropoxide is an oxoderivative, it appeared to be of interest to determine the nature of other homologs formed via alcohol interchange reactions starting from it. Relationships between products, described in the present work, are summarized in Scheme 1.

The action of considerable excess of ROH (R = Me, Et, Bu^n, Bu^s, Bu^t) on solution of **3** in toluene only led instantly to precipitation in the case of R = Me, while the reaction products were soluble in other cases. Isolated from solutions (see Section 3) they were solids (R = Et, Bu^t) or liquids ($R = Bu^n$, Bu^s). The microanalysis data indicate that only $Sc(OMe)_3$ (**1**) does not contain oxoligands. $Sc(OEt)_3$ (**2**) and $Sc(OBu^n)_3$ (**4**) did possess a lower oxocontent than the initial **3**. The derivatives of n-alcohols, **1**, **2** and **4**, were not volatile, while the products formed by the action of different ramified ROH were transferred into the gas phase under the conditions of the mass-spectral experiment. The products of alcohol interchange with ^{s}BuOH and ^{t}BuOH turned out to be $Sc_5O(OBu^s)_{13}$ (**5**) and $Sc_5O(OPr^i)_8(OBu^t)_5$ (**6**), according to mass spectral and microanalysis data. Both **3** and **5**, the derivatives of the secondary alcohols, appear therefore to have the same composition and structure. Only 5 out of 13 OPr^i groups in **6** could be substituted. It might be supposed that these groups are terminal in the molecule of **3** (taking into account its structure).

We then tried to replace five OPr^i groups in **3** with other radicals on the action of ROH (R = Me, Bu^n) on **3** in a 5:1 molar ratio. Thus the soluble products of composition $Sc_5O(OPr^i)_8(OR)_5$ ($R = Bu^n$ **7** or R = Me **8**) were obtained. In the mass spectra of the partial substitution products **6**–**8**, in contrast to the individual complexes **3** and **5**, the series of ions (Fig. 1) of composition $Sc_5O(OPr^i)_{12-n}(OR)_n^+$ were observed. The number of substituted OPr^i groups *n* varied from 1 to 5 for $R = Bu^t$, from 1 to 8 for $R = Bu^n$, and from 2 to 12 for R = Me. The depth of substitution is higher when a smaller ligand is applied. The maximal intensity was observed for the ions with $n = 2$ for $R = Bu^t$, $n = 4$, 5 for $R = Bu^n$ and $n = 3$ for R = Me. The observed series of ions could not result from the fragmentation under electron impact. Ions differed in *m/z* by 14 ($R = Bu^n$, Bu^t) or 28 (R = Me), which corresponds to CH_2 and C_2H_4 groups. The loss of CH_2 groups by an OBu^n ligand or C_2H_4 groups by an OPr^i ligand appears to have a low probability. The results

Scheme 1.

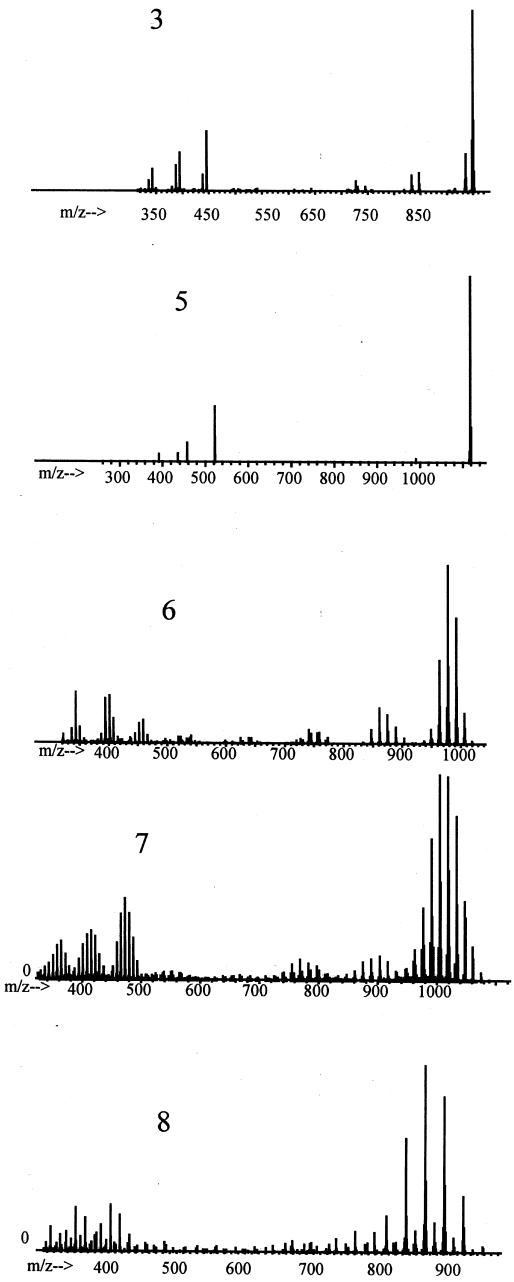


Fig. 1. Mass spectra: $Sc_5O(OPr^i)_{13}$ (**3**), $Sc_5O(OBu^s)_{13}$ (**5**), $Sc_5O(OPr^i)_8(OBu^t)_5$ (**6**), $Sc_5O(OPr^i)_8(OBu^n)_5$ (**7**), $Sc_5O(OPr^i)_8(OMe)_5$ (**8**).

obtained indicate that $Sc_5O(O^iPr)_{13-n}(OR)_n$ molecules, with different extents of substitution for OPr^i groups, exist not only in the gas but even in the condensed phase.

In the mass spectra of **5**–**8**, as well as in that of **3** (Fig. 2), the first ions correspond to the loss of one alkoxide group with the formation of $Sc_5O(OR)_{12}^+$ ($R = Pr^i$, Bu^s) or $Sc_5O(O^iPr)_{12-n}(OR)_n^+$ ($R = Bu^t$, Bu^n, Me). Then they all undergo (except **8**) the elimination of ethers R_2O ($R = Pr^i$,Bu^s) and ^iPrOR ($R = Bu^n$, Bu^t) with the formation of $Sc_5O_2(O^iPr)_{10-n}(OR)_n^+$.

The mass spectral data indicate thus that the introduction of 5 equiv. of alcohol (which is supposed to affect only the terminal groups) affects actually also the ligands that belong

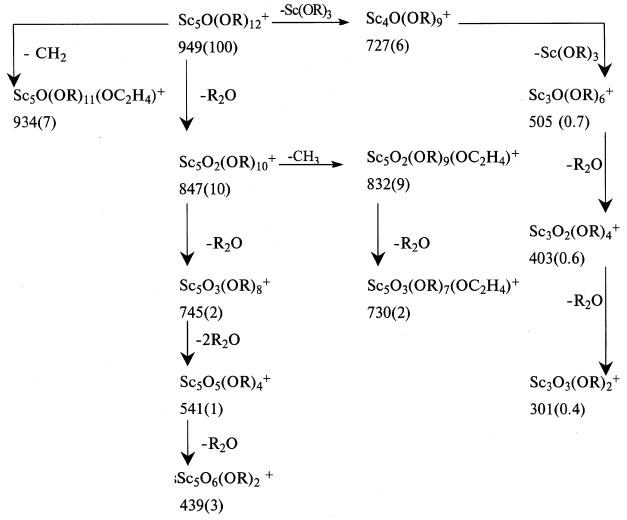

Fig. 2. Fragmentation scheme for $Sc_5O(OPr^i)_{13}$ (**3**).

to the 'core', up to three bridging OR groups in the case of ^{n}BuOH and seven in the case of MeOH. The presence of the mixed-ligand species in the mass spectra of **7** and **8** (up to $Sc_5O(OMe)_{12}^+$, which can be considered as the fragmentation product of the 'volatile' methoxide) is of special interest. As was noted, the action of the considerable excess of n-ROH in the course of the preparation of $Sc(OR^n)_3$ leads to destruction of the pentanuclear core of **3** and the formation of polymeric, non-volatile products. The prepared complexes **6**–**8** are the first mixed-ligand complexes of rare earth elements containing different alkoxide groups.

In conclusion we can identify two types of reaction of **3** with alcohols: (1) complete or partial substitution of the terminal and bridging groups with conservation of the $[Sc_5O(OR)_8]$ core, which keeps the products volatile **6**–**8**; (2) decomposition of the pentanuclear core on action of the most acidic and least sterically demanding n-ROH with the formation of disordered aggregated structures of '$Sc(OR)_3$' **1**, **2**, **4**. It should be taken into account that the alcohol interchange products of **3** (as well as those of the other rare earth isopropoxides) do contain oxoligands. Therefore the data on the possibility of preparation of various homologs of the $Ln(OR)_3$ [9–12] series using this route should be questioned. This method can be used successfully for the preparation of homoleptic alkoxides only in cases where the product formed is insoluble (as for **1**) or crystallizes easily from the reaction mixture (as, for example, for $[Y(OC_2H_4OMe)_3]_{10}$ or $\{Y[OCH(CF_3)_2]_3Thf_3\}$ [13,14]). In both latter cases the complexes containing a higher number of oxogroups than the initial isopropoxides remain in the parent solution. The reaction products obtained on complete evacuation of the solvent (as for samples **2** and **4**), should undoubtedly contain an amount of oxogroups equal to or surpassing that in the initial isopropoxide.

2.2. Crystal structure

The X-ray single crystal study of **3** (the selected bond distances and angles are given in Table 1) shows that its

structure is analogous to those of the known Yb [5], In [5], Y [15] and Er [16] isopropoxides (Fig. 3).

2.3. Complexation with $Al(OPr^i)_3$

The problem of stability of the $[Ln_5O(OPr^i)_8]$ core has been discussed repeatedly in the literature, and is exemplified by the reaction of complex formation of 'isopropoxides' with $Al(OPr^i)_3$. The compounds of the general formula $M[Al(OPr^i)_4]_3$, (where M = Sc, Y, Ln) were synthesized and investigated by Mehrotra et al. [17,18]. The majority of these volatile complexes, including $Sc[Al(OPr^i)_4]_3$, were obtained by an exchange reaction of the corresponding metal chlorides with $K[AlOPr^i]_4$.

According to Hubert-Pfalzgraf and coworkers, no interaction was observed on prolonged reflux of the solutions prepared from $Al(OPr^i)_3$ and the crystalline $[Y_5O(OPr^i)_{13}]$ or $[Nd_5O(OPr^i)_8(^iPrOH)_2]$. At the same time, the reaction of $Al(OPr^i)_3$ with the sample of '$Y(OPr^i)_3$', obtained by reaction of metal with alcohol or with rather unstable $[Nd(OPr^i)_3(^iPrOH)]_4$, led to the formation of volatile $Ln[Al(OPr^i)_4]_3$ [9,19]. However, Westin et al. [16] observed the formation of $Ln[Al(OPr^i)_4]_3$, (Ln = Er, Y), using crystalline $[M_5O(OPr^i)_{13}]$ as reactants. We have studied the complex formation with three scandium alkoxides, **2**, **4** and **3**. Crystalline **3** as well as its yttrium analog [15] did not react with $Al(OPr^i)_3$ on prolonged heating. It was **3** that crystallized from the reaction mixture on heating and the mass spectrum of the residue after evacuation contained only the fragmentation patterns of the components. At the same time the reaction products of **2** or **4** with corresponding $Al(OR)_3$

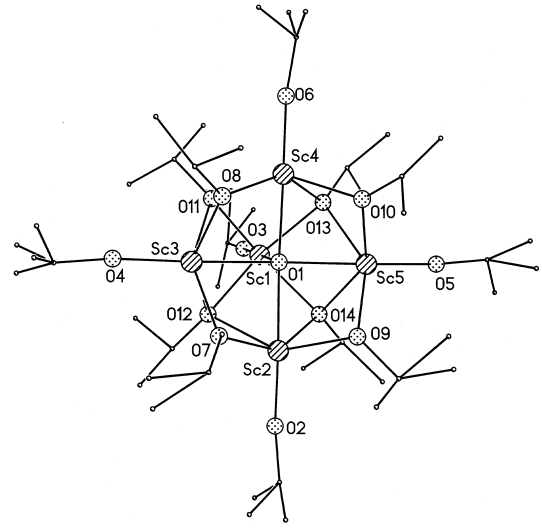

Fig. 3. Stereoscopic ORTEP drawing of non-hydrogen atoms in **3**, showing atom labeling of inner coordination sphere. Unlabeled atoms are carbon.

were the $ScAl_3(OR)_{12}$ bimetallic species, R = Et **9** (amorphous solid), Bu^n **10** (vax). The most intensive peaks in their mass spectra corresponded to $[ScAl_3(OR)_{11}]^+$, which decomposed further under electron impact mainly via elimination of ethers (Fig. 4). $Sc[Al(OPr^i)_4]_3$ (**11**) could be prepared only using the method proposed by Mehrotra et al. [17]. These results indicate the high stability and low reactivity of $[M_5O(OPr^i)_{13}]$ molecules (existing not only in the crystal structure but also in the gas phase). Samples of **2** and **4**, incorporating oxogroups in particles of different size and structure, react easily with the aluminum alkoxides and form rather stable scandium alkoxoaluminates. The possibility of preparation of **11** by an exchange reaction of $ScCl_3$ with $KAl(OPr^i)_4$ is presumably due to the fact that **3** is not formed as an intermediate in this reaction. The fragmentation patterns in the spectra of **9**–**11** correspond to that described for $La[Al(OPr^i)_4]_3$ [20]. The mass spectrum of **10** contains in combination with the ions of the complex itself (their intensity is considerably lower than for the corresponding ones in the spectra of **8** and **11**) the ions corresponding to the fragmentation of the components. This fact can indicate either the lower stability of **10**, or the incompleteness of the complexation in case of n-butoxides.

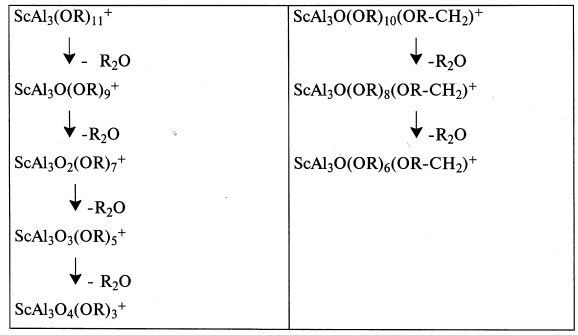

Fig. 4. Fragmentation scheme for $Sc[Al(OR)_4]_3$ (**9**–**11**).

3. Experimental

All compounds described in this work are sensitive to moisture and therefore all operations were carried out using a dry-box. Dehydration of alcohols used was performed by boiling them under reflux over magnesium (MeOH, ^{n}BuOH, ^{s}BuOH), calcium (EtOH), aluminum (^{i}PrOH) alkoxides and zeolite (^{t}BuOH) with subsequent distillation. Toluene and hexane were refluxed with sodium and then distilled over $LiAlH_4$. The carbon and hydrogen contents of the samples were determined using the conventional combustion technique. The scandium content was determined from the incombustible residue.

Infrared spectra were registered with a UR-20 for Nujol or hexachlorobutadiene mulls. Crystalline solids were identified using powder diffractometry (DRON 3M). Mass spectra were measured with a MI 1201 spectrometer (direct insertion of substance, 70 eV, 250°C).

$Al(OPr^i)_3$ was obtained by dissolution of metal in ^{i}PrOH on reflux and purified by distillation. $Al(OR)_3$ ($R = Et, Bu^n$) were obtained from $Al(OPr^i)_3$ by alcohol interchange [21].

3.1. Synthesis and isolation of the products obtained

The anodic oxidation of Sc in different alcohols was carried out in a standard cell with an undivided cathodic and anodic space, supplied with water cooling [4]. A Sc cylinder was used as an anode, a stainless steel plate was used as a cathode. Solutions of LiCl in MeOH (0.001 M) and EtOH, ^{i}PrOH (0.05 M) were used as electrolytes. (LiCl was previously dried in vacuo at 80–100°C.) The process was performed under direct current ($V = 110$ V, $I = 0.4$–1 A) [4].

3.2. $Sc(OMe)_3$ (1)

(a) The anodic dissolution in MeOH occurred much faster than in other alcohols. The current remained constant during the whole reaction time. Some minutes after the start of the electrolysis, a white sediment began to precipitate, continuing in the course of the process. When the synthesis was finished (after 2 h) the sediment was separated by centrifugation, washed twice with MeOH and dried in vacuo. White powder. Yield 2.3 g, 98% (in relation to metal dissolved). *Anal*. Found: C, 25.4; H, 7.3; Sc, 31.8. Calc. for $C_3H_9O_3Sc$: C, 26.1; H, 6.5; Sc, 32.6%. IR (cm^{-1}): 1170 m, 1070 s, 1040 sh, 465 s(br).

(b) MeOH (3.95 g, 123 mmol) was added to the solution of **3** (0.5 g, 0.5 mmol) in 10 ml of toluene. The precipitate formed was separated from the solution (the latter still contained a certain amount of alkoxide). 10 ml of MeOH were added to the precipitate and the mixture was subjected to reflux for 15 min. The solution was then removed and a new portion of MeOH was added. The procedure was repeated twice and the residual solid was dried in vacuo. Its composition was found to be $Sc(OMe)_{2.9}(OPr^i)_{0.1}$. Yield 0.24 g (70%). *Anal*. Found: C, 27.7; H, 6.7; Sc, 31.4. Calc. for $C_{3.2}H_{9.4}O_3Sc$: C, 27.2; H, 6.7; Sc, 31.9%.

3.3. $Sc(OEt)_3$ (2)

(a) The electrochemical synthesis was carried out during 12–15 h. In order to separate the product, the electrolyte was evacuated and hexane was added to the white solid residue. Its major part dissolved with formation of a yellow solution. Evaporation of the hexane extract gave a white powder that contained about 3% Cl. On addition of EtOH, in order to purify it by recrystallization, there occurred initially a complete dissolution of the solid and then a slow precipitation of a snow-white powder, which was then separated and dried in vacuo. It also contained a chlorine admixture (1.99%). Yield 1.5 g (51%). *Anal*. Found: C, 39.5; H, 8.6; Sc, 24.6. Calc. for $C_6H_{15}O_3Sc$: C, 40.0; H, 8.3; Sc, 25.0%.

(b) EtOH (3.95 g, 86 mmol) was added to the solution of **3** (0.5 g, 0.5 mmol) in 10 ml of toluene and then the mixture was evacuated. When the volume of the solution diminished to a few milliliters the procedure was repeated. Once the operation had been carried out 3–4 times the solvent was evacuated completely. The composition of the white powder obtained corresponded to $ScO_{0.1}(OEt)_{2.8}$. Yield 0.43 g (100%). *Anal*. Found: C, 38.9; H, 7.3; Sc, 25.8. Calc. for $C_{5.6}H_{14}O_{2.9}Sc$: C, 38.9; H, 8.1; Sc. 26.1%. IR (cm^{-1}): 1170 vs, 1110 s, 1070 vs, 900 m, 525 s, 515 vs.

3.4. $Sc_5O(OPr^i)_{13}$ (3)

(a) The current remained constant (1 A) in the course of the synthesis. The crystals precipitating on cooling of the parent solution were separated and recrystallized twice from ^{i}PrOH and dried in vacuo. Colorless crystals. Yield 0.95 g (95%). *Anal*. Found: C, 46.5; H, 9.26; Sc, 21.9. Calc. for $C_{39}H_{91}O_{14}Sc_5$: C, 46.4; H, 9.0; Sc, 22.3%. IR (cm^{-1}): 1175 vs, 1158 sh, 1130 s, 1060 m, 1022 s, 985 m, 955 m, 899 vw, 847 w, 730 w, 565 s, 520 s, 490 m, 465 vw, 455 m, 428 m. 3.11. $ScAl_3(OBu^n)_{12}$ (10)

$Sc(OBu^n)_3$ (0.5 g, 1.9 mmol) and $Al(OBu^n)_3$ (1.40 g, 5.7 mmol) were dissolved in 10 ml ^{n}BuOH, refluxed for 30 min and dried in vacuo. White powder. Yield 1.89 g (100%). *Anal*. Found: C, 56.6; H, 9.7; $Al_2O_3+Sc_2O_3$, 20.8. Calc. for $Al_3C_{48}H_{108}O_{12}Sc$: C, 57.5; H, 10.8; $Al_2O_3+Sc_2O_3$, 22.1%. IR (cm^{-1}): 1080 s, 1010 w, 975 vw, 910 vw, 880 vw, 840 vw, 675 m, 640 m, 575 m, 475 w. EI-mass spectrum, *m/z*: 929 (13, M^+–OR), 799 (6.5, M^+–OR–R_2O), 669 (1, M^+–OR–$2R_2O$), 540 (0.3, M^+–OR–$3R_2O$), 901 (2.5, M^+–OR–CH_2), 785 (4.8, M^+–OR–CH_2–R_2O), 655 (0.4, M^+–OR–CH_2–$2R_2O$).

3.12. $ScAl_3(OPr^i)_{12}$ (11)

$Al(OPr^i)_3$ (3.07 g, 15 mmol) was dissolved in 50 ml ^{i}PrOH and K metal (0.58 g, 15 mmol) was added. An $ScCl_3$ (0.76 g, 5 mmol) solution in 20 ml of ^{i}PrOH was added dropwise to the $K[Al(OPr^i)_4]$ solution obtained. The viscous liquid obtained by evacuation of the solution after the removal of KCl solidified at 0°C on storage. Yield 4.18 g (100%). White powder. *Anal*. Found: C, 51.2; H, 10.7; $Al_2O_3+Sc_2O_3$, 26.1. Calc. for $Al_3C_{36}H_{84}O_{12}Sc$: C, 51.8; H, 10.1; $Al_2O_3+Sc_2O_3$, 26.6%. IR (cm^{-1}): 1470 s, 1380 s, 1180 vs, 1140 s, 1080 s, 1030 s, 970 s, 900 w, 850 s, 675 s, 595 s. EI-mass spectrum, *m/z*: 775 (100, M^+–OR), 673 (45, M^+–OR–R_2O), 571 (18, M^+–OR–$2R_2O$), 469 (27, M^+–OR–$3R_2O$), 367 (34, M^+–OR–$4R_2O$), 761 (45, M^+–OR–CH_2), 659 (9, M^+–OR–CH_2–R_2O), 557 (2, M^+–OR–CH_2–$2R_2O$).

3.13. Crystallography

X-ray quality crystals of **3** were grown in ^{i}PrOH at −10°C. The crystals were placed in glass capillaries, and sealed under an inert atmosphere. Complex **3**, $C_{39}H_{91}O_{14}Sc_5$, $M=1008.92$, monoclinic, space group $P2_1/n$, $a=12.537(6)$, $b=21.253(12)$, $c=20.720(11)$ Å, $\beta=90.35(4)°$, $V=5547(5)$ Å^3, $Z=4$, $D_c=1.208$ g cm^{-3}, $F(000)=2168$, $\mu=6.32$ cm^{-1}, crystal size $0.6\times0.5\times0.3$ mm.

3.14. Crystal structure determination

The X-ray crystal data were collected at 143 K using a Siemens P3/PC diffractometer equipped with graphite-monochromated Mo Kα radiation, ($\lambda=0.71073$ Å), θ–2θ scan mode (θ range 1.4–22.5°). The total of 6187 reflections were averaged to produce 5199 unique data. The structure was solved by direct methods and refined by full-matrix least-squares in the anisotropic approximation for non-hydrogen atoms with the exception of the carbon atoms of some dis-

ordered ^{i}Pr groups. The H atoms were placed geometrically and included in the refined rigid model approximation. The refinement converged to $wR_2 = 0.2467$ (on F_{hkl}^2 for all 5110 reflections, 480 variables) with $R_1 = 0.0807$ (on F_{hkl} for 2835 reflections with $I > 2\sigma(I)$). The highest peak in the final difference Fourier map had a height of 0.58 e Å^{-3}. The maximum negative peak in the final difference electron density synthesis was -0.37 e Å^{-3}. All calculations were performed on an IBM PC using the SHELXTL PLUS 5 program package [22].

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number 117908.

Abstract

The reaction of $(\mu\text{-S}_2)Fe_2(CO)_6$ with $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ gives the anionic complexes $[(\mu\text{-RSe})(\mu\text{-S})\{Fe_2(CO)_6\}_2(\mu_4\text{-S})]^-$ (**1**). Reactions of **1** with electrophiles such as alkyl halides, acid chlorides and PhN_2BF_4 form neutral complexes $(\mu\text{-RSe})(\mu\text{-R'S})[Fe_2(CO)_6]_2(\mu_4\text{-S})$ (R = Ph, R' = Me **2a**; R = Ph, R' = $PhCH_2$ **2b**; R = Et, R' = Me **2c**; R = Ph, R' = $CH_3C(O)$ **3a**; R = Ph, R' = PhC(O) **3b**; R = Et, R' = PhC(O) **3c**; R = R' = Ph **4**). Treatment of **1** with $Cp(CO)_2FeI$ affords pentanuclear iron complexes $(\mu\text{-RSe})[\mu\text{-Cp}(CO)_2FeS][Fe_2(CO)_6]_2(\mu_4\text{-S})$ (R = Ph **5a**; R = Et **5b**). From the reaction mixture of **1** (R = Ph) and $Cp(CO)_2FeI$, $(\mu_3\text{-S})_2Fe_3(CO)_8[Se(Ph)Fe(CO)_2Cp]$ (**6**) was also obtained. The structure of complex **6** was determined by single-crystal X-ray analysis.

1. Introduction

The chemical reactivities of $[(\mu\text{-RS})(\mu\text{-CO})Fe_2(CO)_6]^-$ and $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ have been studied extensively [1–17]. However, most studies concentrated mainly on reactions with organic reagents. Studies of the reactivities toward organometallic compounds, especially cluster complexes, are relatively rare. Available examples include the reactions with organomercury [3–5], organogold [15], organoiridium [16], organorhenium and organomanganese [17] compounds. Recently we reported the reaction of $[(\mu\text{-RS})(\mu\text{-CO})Fe_2(CO)_6]^-$ with $(\mu\text{-S}_2)Fe_2(CO)_6$, yielding anionic complexes $[(\mu\text{-RS})(\mu\text{-S})\{Fe_2(CO)_6\}_2(\mu_4\text{-S})]^-$ (see Eq. (1)) [18], which reacted readily with electrophiles to form neutral complexes of the type $(\mu\text{-RS})(\mu\text{-R'S})[Fe_2(CO)_6]_2(\mu_4\text{-S})$. To compare the reactivity of $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ with that of $[(\mu\text{-RS})(\mu\text{-CO})Fe_2(CO)_6]^-$, we have investigated the reaction of $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ with $(\mu\text{-S}_2)Fe_2(CO)_6$, and the reactivity of the resulting complexes $[(\mu\text{-RSe})(\mu\text{-S})\{Fe_2(CO)_6\}_2(\mu_4\text{-S})]^-$ toward electrophiles. Herein we report the results.

(1)

2. Experimental

All reactions were carried out under nitrogen using standard Schlenk techniques. Tetrahydrofuran (THF) and diethyl ether were distilled from sodium benzophenone ketyl. PhSeH [19], PhN_2BF_4 [20], $Fe_3(CO)_{12}$ [21], $Cp(CO)_2FeI$ [22] and $(\mu\text{-S}_2)Fe_2(CO)_6$ [23] were prepared by published procedures. The solution of $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ (R = Ph, Et) was prepared by the method described in the literature [8,14]. The progress of all reactions was monitored by thin-layer chromatography. Infrared spectra (KBr disk) were obtained using a VECTOR22 spectrometer. ^1H NMR spectra were recorded on either a Varian EM360L or a JEOL FX-90Q spectrometer. Elemental analyses were performed with a 240C analyzer.

2.1. Preparation of (μ-PhSe)(μ-R^1S)[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**2a**, R^1 = Me; **2b**, R^1 = $PhCH_2$)

A solution of the triethylammonium salt of [(μ-PhSe)(μ-CO)$Fe_2(CO)_6$]$^-$ was generated by reacting 0.65 g (1.29 mmol) of $Fe_3(CO)_{12}$, 0.14 ml (1.32 mmol) of PhSeH and 0.19 ml (1.36 mmol) of Et_3N in 30 ml of THF at room temperature under nitrogen. The solution was cooled to −78°C, and 0.27 g (0.78 mmol) of (μ-S_2)$Fe_2(CO)_6$ was added with stirring for 30 min at −78°C. Subsequently 0.12 ml (1.93 mmol) of iodomethane was syringed. The mixture was warmed to room temperature and stirred overnight. The solvent was removed at reduced pressure and the residue extracted with petroleum ether. After removal of the solvent, the material remaining was subjected to filtration chromatography (silica gel) using petroleum ether as eluent. The first band gave 0.10 g (26% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$ as dark purple crystals. The second band gave 0.02 g (5% based on $Fe_3(CO)_{12}$) of dark red crystalline (μ-PhSe)$_2$$Fe_2(CO)_6$ and the third main band afforded 0.16 g (26% based on (μ-S_2)$Fe_2(CO)_6$) of red crystalline **2a**, m.p. 142–144°C. *Anal*. Found: C, 28.50; H, 0.89. Calc. for $C_{19}H_8Fe_4O_{12}S_2Se$: C, 28.72; H, 1.01%. ^{1}H NMR (CCl_4): δ (ppm) 2.20 (s, 3H, Me), 7.26 (s, 5H, Ph). IR: ν (cm^{-1}) 2083m, 2056s, 2031vs, 1993s, 1973s (Fe–CO).

A similar reaction was carried out, in which 1.30 mmol of benzyl chloride was added to a solution of anion **1** prepared from 1.43 mmol of $Fe_3(CO)_{12}$, 1.51 mmol of PhSeH and 1.50 mmol of Et_3N followed by addition of 1.28 mmol of (μ-S_2)$Fe_2(CO)_6$ giving, after similar work-up, 0.08 g (13% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$, 0.19 g (25% based on $Fe_3(CO)_{12}$) of (μ-PhSe)$_2$$Fe_2(CO)_6$ and 0.14 g (13% based on (μ-S_2)$Fe_2(CO)_6$) of dark red crystals of **2b**, m.p. 110°C (dec.). *Anal*. Found: C, 34.33; H, 1.13. Calc. for $C_{25}H_{12}Fe_4O_{12}S_2Se$: C, 34.48; H, 1.39%. ^{1}H NMR (CCl_4): δ (ppm) 3.60 (s, 2H, CH_2), 7.03–7.23 (m, 10H, Ph). IR: ν (cm^{-1}) 2082m, 2054vs, 2036vs, 2010s, 1999vs, 1990vs (Fe–CO).

2.2. Preparation of (μ-EtSe)(μ-MeS)[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**2c**)

A Schlenk tube was charged with 0.16 g (2.03 mmol) of selenium powder, 30 ml of THF and 2.00 mmol of EtMgBr in Et_2O. The mixture was stirred at room temperature for 20 min. To the solution was added 0.90 g (1.78 mmol) of $Fe_3(CO)_{12}$ and stirring was continued for 20 min, resulting in a brown–red solution of [MgBr][(μ-EtSe)(μ-CO)-$Fe_2(CO)_6$]. The solution was cooled to −78°C, and 0.55 g (1.60 mmol) of (μ-S_2)$Fe_2(CO)_6$ was added with stirring for 30 min at −78°C. Subsequently 0.20 ml (3.21 mmol) of iodomethane was syringed. The mixture was warmed to room temperature and stirred for 3 h. Work-up as described in Section 2.1 gave 0.11 g (14% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$ and 0.13 g (11% based on (μ-S_2)-$Fe_2(CO)_6$) of red crystalline complex **2c**, m.p. 143–146°C. *Anal*. Found: C, 24.41; H, 1.32. Calc. for $C_{15}H_8Fe_4O_{12}S_2Se$: C, 24.13; H, 1.08%. ^{1}H NMR (CCl_4): δ (ppm) 1.50 (t, J = 7 Hz, 3H, Me), 2.16 (s, 3H, Me), 2.67 (q, J = 7.5 Hz, 2H, CH_2). IR: ν (cm^{-1}) 2083m, 2057s, 2035vs, 2006s, 1992s, 1969s (Fe–CO).

2.3. Preparation of (μ-PhSe)[μ-R^2C(O)S]-[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**3a**, R^2 = Me; **3b**, R^2 = Ph)

To a cooled solution of [Et_3NH][(μ-PhSe)(μ-CO)-$Fe_2(CO)_6$] generated from 0.82 g (1.61 mmol) of $Fe_3(CO)_{12}$, 0.18 ml (1.70 mmol) of PhSeH and 0.24 ml (1.71 mmol) of Et_3N in about 30 ml of THF was added 0.44 g (1.28 mmol) of (μ-S_2)$Fe_2(CO)_6$ with stirring for 30 min at −78°C. Subsequently 0.20 ml (1.82 mmol) of acetyl chloride was syringed. The mixture was warmed to room temperature and stirred overnight. Work-up as described in Section 2.1 gave 0.08 g (13% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$, 0.22 g (46% based on $Fe_3(CO)_{12}$) of (μ-PhSe)$_2$$Fe_2(CO)_6$ and 0.08 g (8% based on (μ-S_2)-$Fe_2(CO)_6$) of **3a** as red crystals, m.p. 130°C (dec.). *Anal*. Found: C, 29.38; H, 1.12. Calc. for $C_{20}H_8Fe_4O_{13}S_2Se$: C, 29.20; H, 0.98%. ^{1}H NMR (CCl_4): δ (ppm) 2.54 (s, 3H, Me), 7.20 (s, 5H, Ph). IR: ν (cm^{-1}) 2085m, 2054s, 2036vs, 1999s, 1988s, 1976s (Fe–CO); 1732w (MeCO).

A similar reaction, in which 0.16 ml (1.38 mmol) of benzoyl chloride was added to a cooled solution of anion **1** (prepared from 1.57 mmol of $Fe_3(CO)_{12}$, 1.61 mmol of PhSeH and 1.64 mmol of Et_3N and then 1.37 mmol of (μ-S_2)$Fe_2(CO)_6$), gave 0.11 g (16% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$, 0.08 g (17% based on $Fe_3(CO)_{12}$) of (μ-PhSe)$_2$$Fe_2(CO)_6$ and 0.26 g (21% based on (μ-S_2)$Fe_2(CO)_6$) of red crystals of **3b**, m.p. 140°C (dec.). *Anal*. Found: C, 34.06; H, 1.29. Calc. for $C_{25}H_{10}Fe_4O_{13}S_2Se$: C, 33.94; H, 1.14%. ^{1}H NMR ($CDCl_3$): δ (ppm) 7.18 (s, 5H, Ph), 7.34–7.46 (m, 3H, Ph), 7.97–8.09 (m, 2H, Ph). IR: ν (cm^{-1}) 2085m, 2052s, 2039vs, 2000s (Fe–CO); 1681m (PhCO).

2.4. Preparation of (μ-EtSe)[μ-Ph C(O)S]-[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**3c**)

The solution of [MgBr][(μ-EtSe)(μ-S){$Fe_2(CO)_6$}$_2$-(μ$_4$-S)] was prepared according to the same procedure and scale as described in Section 2.2. To the cooled solution was added 0.19 ml (1.64 mmol) of benzoyl chloride. The mixture was warmed to room temperature and stirred overnight. Work-up as described in Section 2.1 gave 0.07 g (9% based on (μ-S_2)$Fe_2(CO)_6$) of (μ$_3$-S)$_2$$Fe_3(CO)_9$ and 0.14 g (10% based on (μ-S_2)$Fe_2(CO)_6$) of red crystalline **3c**, m.p. 140°C (dec.). *Anal*. Found: C, 30.41; H, 1.38. Calc. for $C_{21}H_{10}Fe_4O_{13}S_2Se$: C, 30.14; H, 1.20%. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.53 (t, J = 7 Hz, 3H, Me), 2.70 (q, J = 7 Hz, 2H, CH_2), 7.30–7.70 (m, 3H, Ph), 7.90–8.25 (m, 2H, Ph). IR: ν (cm^{-1}) 2085m, 2057s, 2036vs, 2000s, 1989vs (Fe–CO); 1681w (PhCO).

2.5. Preparation of (μ-PhSe)(μ-PhS)[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**4**)

To a cooled solution of [Et_3NH][(μ-PhSe)(μ-CO)-$Fe_2(CO)_6$] generated from 0.78 g (1.53 mmol) of $Fe_3(CO)_{12}$, 0.17 ml (1.61 mmol) of PhSeH and 0.23 ml (1.64 mmol) of Et_3N in about 30 ml of THF was added 0.42 g (1.22 mmol) of (μ-S_2)$Fe_2(CO)_6$ and the mixture was stirred for 30 min at −78°C. Subsequently 0.24 g (1.25 mmol) of PhN_2BF_4 was added. The mixture was warmed to room temperature and stirred overnight. Work-up as described in Section 2.1 gave 0.08 g (14% based on (μ-S_2)$Fe_2(CO)_6$) of (μ_3-S)$_2Fe_3(CO)_9$, 0.23 g (50% based on $Fe_3(CO)_{12}$) of (μ-PhSe)$_2Fe_2(CO)_6$ and 0.07 g (7% based on (μ-S_2)$Fe_2(CO)_6$) of red crystals of **4**, m.p. 175°C (dec.). *Anal*. Found: C, 33.35; H, 1.35. Calc. for $C_{24}H_{10}Fe_4O_{12}S_2Se$: C, 33.64; H, 1.18%. ^{1}H NMR (CCl_4): δ (ppm) 7.22–7.62 (m, 10H, Ph). IR: ν (cm^{-1}) 2081m, 2057s, 2037vs, 1996s, 1976m (Fe–CO).

2.6. Preparation of (μ-PhS)[μ-Cp(CO)$_2$FeS]-[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**5a**) and (μ_3-S)$_2Fe_3(CO)_8$-[PhSeFe(CO)$_2$Cp] (**6**)

To a cooled solution of [Et_3NH][(μ-PhSe)(μ-CO)-$Fe_2(CO)_6$] generated from 0.86 g (1.69 mmol) of $Fe_3(CO)_{12}$, 0.19 ml (1.80 mmol) of PhSeH and 0.25 ml (1.79 mmol) of Et_3N in 30 ml of THF was added 0.46 g (1.34 mmol) of (μ-S_2)$Fe_2(CO)_6$ and the mixture was stirred for 30 min at −78°C. Subsequently 0.41 g (1.35 mmol) of Cp(CO)$_2$FeI was added. The reaction mixture was warmed to room temperature and stirred overnight. Solvent was removed at reduced pressure and the residue extracted with CH_2Cl_2:petroleum ether (1:9 v/v). After removal of the solvent, the material remaining was subjected to filtration chromatography (silica gel). Petroleum ether eluted a purple band which gave 0.05 g (8% based on (μ-S_2)$Fe_2(CO)_6$) of (μ_3-S)$_2Fe_3(CO)_9$. The second band gave 0.05 g (10% based on $Fe_3(CO)_{12}$) of (μ-PhSe)$_2Fe_2(CO)_6$. Further elution with 2:8 v/v CH_2Cl_2:petroleum ether gave 0.19 g (15% based on (μ-S_2)$Fe_2(CO)_6$) of complex **5a** as black crystals and 0.10 g (9% based on (μ-S_2)$Fe_2(CO)_6$) of black crystalline complex **6**. **5a**: m.p. 150°C (dec.). *Anal*. Found: C, 31.38; H, 1.32. Calc. for $C_{25}H_{10}Fe_5O_{14}S_2Se$: C, 31.39; H, 1.05%. ^{1}H NMR ($CDCl_3$): δ (ppm) 5.08 (s, 5H, Cp), 7.20 (s, 5H, Ph). IR: ν (cm^{-1}) 2076m, 2051s, 2027vs, 1973s (Fe–CO). **6**: m.p. 87–88°C. *Anal*. Found: C, 31.63; H, 1.24. Calc. for $C_{21}H_{10}Fe_4O_{10}S_2Se$: C, 31.98; H, 1.28%. ^{1}H NMR ($CDCl_3$): δ (ppm) 4.90 (s, 5H, Cp), 7.20 (s, 5H, Ph). IR: ν (cm^{-1}) 2066s, 2039s, 2017vs, 1997vs, 1954m, 1947m (Fe–CO).

2.7. Preparation of (μ-EtS)[μ-Cp(CO)$_2$FeS]-[$Fe_2(CO)_6$]$_2$(μ$_4$-S) (**5b**)

The solution of [MgBr][(μ-EtSe)(μ-S){$Fe_2(CO)_6$}$_2$-(μ$_4$-S)] was prepared according to the same procedure and scale as described in Section 2.2. To the solution was added 0.50 g (1.64 mmol) of Cp(CO)$_2$FeI at −78°C with stirring. The mixture was warmed to room temperature and stirred overnight. Solvent was removed at reduced pressure and the residue extracted with CH_2Cl_2:petroleum ether (1:9 v/v). After removal of the solvent, the material remaining was subjected to filtration chromatography (silica gel). Petroleum ether eluted a purple band which gave 0.09 g (12% based on (μ-S_2)$Fe_2(CO)_6$) of (μ_3-S)$_2Fe_3(CO)_9$. Further elution with 2:8 v/v CH_2Cl_2:petroleum ether gave 0.13 g (9% based on (μ-S_2)$Fe_2(CO)_6$) of complex **5b** as black crystals, m.p. 142°C (dec.). *Anal*. Found: C, 28.27; H, 1.37. Calc. for $C_{21}H_{10}Fe_5O_{14}S_2Se$: C, 27.76; H, 1.11%. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.50 (t, J = 7.5 Hz, 3H, Me), 2.53 (q, J = 7.5 Hz, 2H, CH_2), 5.10 (s, 5H, Ph). IR: ν (cm^{-1}) 2074m, 2050s, 2026vs, 1996s, 1982s, 1967vs (Fe–CO).

2.8. Crystal data and structure determination of complex **6**

Black crystals of complex **6** were grown from a petroleum ether–CH_2Cl_2 solution at 0°C. Data were collected on a Siemens P4 four-circle diffractometer using graphite-monochromated Mo Kα radiation. Absorption correction was applied using SADABS. The structure was solved by the direct method and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for non-hydrogen atoms on a PC using SHELXS-86 and SHELXL-97 software packages, respectively [24,25]. A summary of crystal data and refinement parameters is given in Table 1. Selected bond distances and angles are listed in Table 2.

Table 1
Crystal data and refinement parameters for complex **6**

Formula	$C_{21}H_{10}Fe_4O_{10}S_2Se$
M	788.77
Crystal system	triclinic
Space group	$P\bar{1}$ (no. 2)

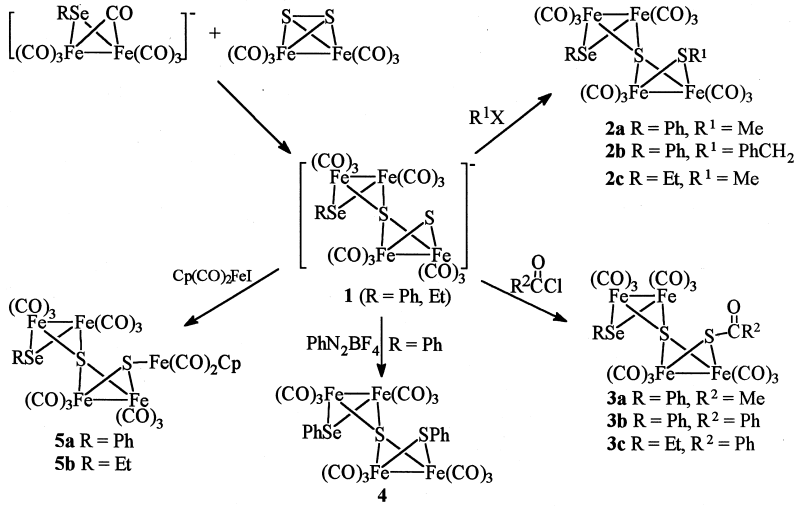
[a] Cent is the centroid of the Cp ring composed of carbon atoms C(11)–C(15).

3. Results and discussion

The synthesis and reactions of $[(\mu\text{-RSe})(\mu\text{-S})\{Fe_2(CO)_6\}_2(\mu_4\text{-S})]^-$ are summarized in Scheme 1. Both $[Et_3NH][(\mu\text{-PhSe})(\mu\text{-CO})Fe_2(CO)_6]$ and $[MgBr][(\mu\text{-EtSe})(\mu\text{-CO})Fe_2(CO)_6]$ were prepared by reported methods [12,14] and reacted readily with $(\mu\text{-S}_2)Fe_2(CO)_6$ at −78°C, as indicated by gas evolution. Treatment of the reaction mixture with electrophiles such as alkyl halides, acid chlorides and PhN_2BF_4 gave neutral complexes of the type $(\mu\text{-RSe})(\mu\text{-R}'\text{S})[Fe_2(CO)_6]_2(\mu_4\text{-S})$ (R′ = alkyl, acyl or phenyl). Thus the expected anions **1** were formed. Similarly to the reaction between $[(\mu\text{-RS})(\mu\text{-CO})Fe_2(CO)_6]^-$ and $(\mu\text{-S}_2)Fe_2(CO)_6$, the sulfur–sulfur bond of $(\mu\text{-S}_2)Fe_2(CO)_6$ is cleaved by the iron-centered anions and the μ-CO ligand of $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ is replaced by one of the sulfur atoms of $(\mu\text{-S}_2)Fe_2(CO)_6$. It is noteworthy that the yields of $(\mu\text{-RSe})(\mu\text{-R}'\text{S})[Fe_2(CO)_6]_2(\mu_4\text{-S})$ were low and, for R = Ph, the oxidation product $(\mu\text{-PhSe})_2Fe_2(CO)_6$ was formed in low to moderate yield. In addition, $(\mu_3\text{-S})_2Fe_3(CO)_9$ was also obtained in each reaction. Treatment of the reaction mixture of $[(\mu\text{-RSe})(\mu\text{-CO})Fe_2(CO)_6]^-$ and $(\mu\text{-S}_2)Fe_2(CO)_6$ with $Cp(CO)_2FeI$ afforded pentanuclear complexes **5a** and **5b**. For R = Ph, an unexpected product, $(\mu_3\text{-S})_2Fe_3(CO)_8[Se(Ph)Fe(CO)_2Cp]$ (**6**), was also isolated. The formation of complex **6** may arise from the reaction of $(\mu_3\text{-S})_2Fe_3(CO)_9$ with $PhSeFe(CO)_2Cp$ produced from $Cp(CO)_2FeI$ and excess $Et_3NH^+SePh^-$ (Scheme 2).

$$Et_3NH^+SePh^- + Cp(CO)_2FeI \longrightarrow Cp(CO)_2FeSePh$$

$(\mu_3\text{-S})_2Fe_3(CO)_9$ →



6

Scheme 2.

Both complexes $(\mu_3\text{-S})_2Fe_3(CO)_9$ and $(\mu\text{-PhSe})_2Fe_2(CO)_6$ are known and were identified by elemental analyses and by comparison of their melting points, IR and ^1H NMR (for the latter) spectra with those of authentic samples [26,27].

Complexes **2**–**4** are red solids and **5a** and **5b** are black solids. They are air stable in the solid state, but slightly air sensitive in solution. The new complexes **2**–**5** were characterized by elemental analyses, IR and ^1H NMR spectra. Their IR spectra showed four to six terminal carbonyl absorption bands in the range 2085–1969 cm^{-1}. For complexes **3a**–**3c** the absorption bands of thiocarboxylato groups were also observed. Their ^1H NMR spectra all exhibited respective organic group resonance signals. It is worthy of note that complexes **2**–**5** can exist as only one isomer in which the two substituents are bonded to the bridged Se and S atoms with an equatorial type of bond. This is because the μ_4-S atom of **2**–**5** utilizes two axial bonds to attach both (μ-RSe)-

Scheme 1.

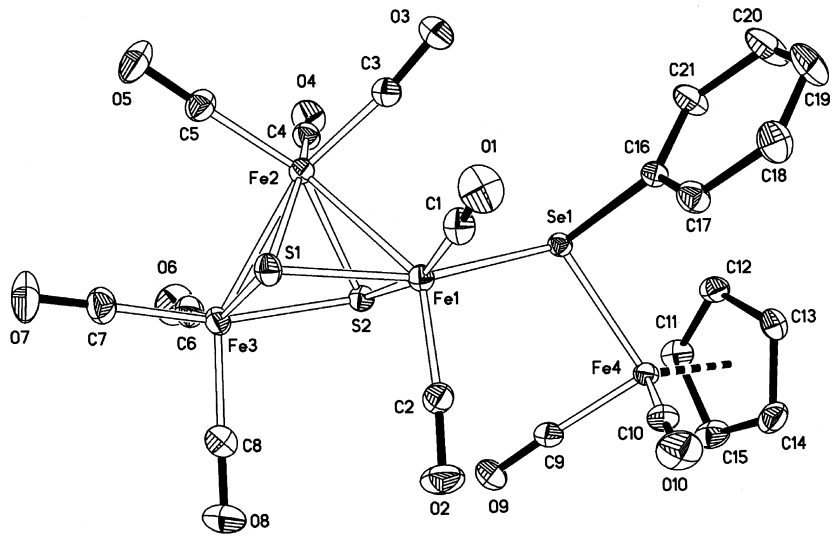


Fig. 1. ORTEP representation of the molecular structure of complex **6**. The thermal ellipsoids are drawn at the 20% probability level.

$Fe_2(CO)_6$ and $(\mu\text{-}R'S)Fe_2(CO)_6$ units, respectively, and because there are larger non-bonded repulsions between the axial R (or R′) group and axial $Fe(CO)_3$ group [28]. This deduction can be verified by some of the ^1H NMR spectra. For example, the ^1H NMR spectrum of **2c** showed one quartet at δ 2.67 ppm for $SeCH_2$ [29] and one singlet at δ 2.16 ppm for SCH_3 [28]; the $CH_3C(O)$ group of **3a** showed one singlet at δ 2.54 ppm [30] and the CH_2Se group of **3c** showed one quartet at δ 2.70 ppm [29].

Complex **6** was isolated as a black solid. Its IR spectrum exhibited terminal carbonyl absorption bands and the ^1H NMR spectrum showed the presence of phenyl and cyclopentadienyl groups. The C/H analytical data agree closely with the calculated values for complex **5**. From these analytical results it seems as if complex **6** was an isomer of complex **5**. However, the chemical shift of the ^1H NMR spectrum for the Cp group (δ 4.90 ppm) was close to that of an axial $Fe(CO)_2Cp$ [31]. This would involve considerable non-bonded repulsion between two axial groups. For this reason, a single-crystal X-ray diffraction study was undertaken. The result showed that complex **6** is a mono-substituted product of $(\mu_3\text{-}S)_2Fe_3(CO)_9$ by $Se(Ph)Fe(CO)_2Cp$ (Fig. 1). The skeletal structure is very similar to that of $(\mu_3\text{-}S)_2Fe_3(CO)_9$ [32], i.e. it consists of an open triangle of iron atoms (Fe(1)Fe(2)Fe(3)) capped on each side by the two sulfur ligands, and S_2Fe_3 is a distorted square pyramid.

$Se(Ph)Fe(CO)_2Cp$ replaces the carbonyl at the basal position and the orientation of $Se(Ph)Fe(CO)_2Cp$ is axial. This is consistent with $(\mu_3\text{-}S)_2Fe_3(CO)_8[P(OMe)_3]$ [33] and $(\mu_3\text{-}S)_2Fe_3(CO)_8[P(SPh)_3]$ [34]. The bond lengths Fe–Fe and Fe–S are comparable with the corresponding values in $(\mu_3\text{-}S)_2Fe_3(CO)_8[P(OMe)_3]$ [33] and $(\mu_3\text{-}S)_2Fe_3(CO)_8[P(SPh)_3]$ [34]. The Se–Fe bond length (2.4433(3) and 2.4134(4) Å, respectively) is close to those found in $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}Se)$ (average 2.428 Å) [35], but a little longer than those in $(\mu\text{-}PhSe)(\mu\text{-}PhCH_2SC{=}S)\text{-}Fe_2(CO)_6$ (average 2.374 Å) [8] and $(\mu\text{-}Se_2)Fe_2(CO)_6$ (average 2.364 Å) [36].

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number CCDC 134795.

Synthesis and properties of $[CuLCl_2]$ and $[CuL(N_3)(OClO_3)]\cdot H_2O$ (L = α,α′-bis(pyrazolyl)-*m*-xylene): X-ray structure of $[CuLCl_2]_2$

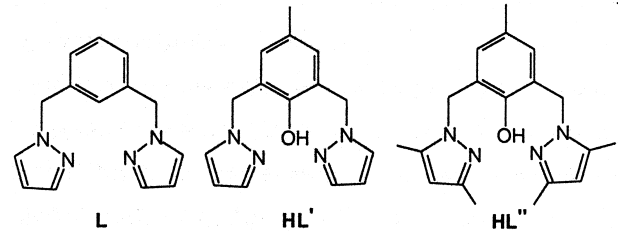
Abstract



Using an *m*-xylyl based dinucleating ligand α,α′-bis(pyrazolyl)-*m*-xylene (L), providing only one pyrazole nitrogen coordination to each copper(II) centre, two copper(II) complexes $[CuLCl_2]$ (**1**) and $[CuL(N_3)(OClO_3)]\cdot H_2O$ (**2**) have been synthesized. Complex **1** has been structurally characterized, revealing that the coordination sphere of each copper(II) ion is distorted square pyramidal. Two pyrazole nitrogens from two different ligands and two chloride ions form the equatorial plane and an additional weak bonding interaction by a chloride ion from an adjacent layer provide axial coordination. The dimeric repeat unit $[CuLCl_2]_2$ having a Cu_2Cl_2 bridging unit gives rise to an extended network. Based on physicochemical studies, a similar structure has been proposed for **2**; however, in **2** one azide ion and a coordinating perchlorate ion are in the equatorial plane. Magnetic susceptibility measurements (25–300 K) reveal that the two copper(II) centres in each 'pseudo dicopper(II) unit' are weakly antiferromagnetically coupled, with the relevant 2*J* values of $\approx -10\ cm^{-1}$ for **1** and $\approx -9\ cm^{-1}$ for **2**. The square pyramidal stereochemistry of the copper(II) centres is revealed by absorption and EPR spectral properties. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

During the past few years we have investigated [1–13] the coordination chemistry of pyrazole-based chelating ligands. Recently, we have initiated a programme [14–16] to investigate the reactivity properties of binuclear Cu(I) complexes with dioxygen and pinpoint the effect of ligand topology on arene hydroxylation, using *m*-xylyl based ligands capable of providing only two N-coordination to each copper site. As part of this activity, using 4-methyl-2,6-bis(pyrazol-1-ylmethyl)phenol (HL′) and its 3,5-dimethyl pyrazole derivative (HL′′), we have synthesized and characterized two diphenoxo-bridged copper(II) complexes $[Cu_2(L'/L'')_2(OClO_3)_2]$ and the complex $[Cu_2(L')_2(OClO_3)_2]$ has been structurally characterized. The copper(II) centres in these complexes are strongly antiferromagnetically coupled [17].

With the aim of synthesizing and studying the magnetic properties of dichloro- and diazido-bridged copper(II) complexes, similar to diphenoxo-bridged copper(II) complexes $[Cu_2(L'/L'')_2(OClO_3)_2]$, we have investigated the reaction between $CuCl_2\cdot 2H_2O$ and $Cu(ClO_4)_2\cdot 6H_2O/NaN_3$ and L. Here we present the properties of two dimeric copper(II) complexes $[Cu^{II}LCl_2]_2$ (**1**) and $[Cu^{II}_2(L)_2(N_3)_2(OClO_3)_2]\cdot 2H_2O$ (**2**). We also present the molecular structure of **1** and comparative spectroscopic and temperature-dependent magnetic properties of **1** and **2**.

2. Experimental

2.1. Materials

All chemicals and reagents were obtained from commercial sources and used as received, unless otherwise stated. Purification of methanol was achieved by distillation from $Mg(OMe)_2$. DMF was stored over BaO and distilled under

PII S0277-5387(00)00318-1

inert atmosphere. Dichloromethane was washed thoroughly with aqueous solution of Na_2CO_3 followed by distilled water before final reflux and distillation over anhydrous $CaCl_2$. 2,6-bis(1-bromomethyl)benzene was prepared following a reported procedure [18].

2.2. Synthesis of ligand α,α′-bis(pyrazolyl)-m-xylene (L)

The methodology followed to prepare this ligand (which does not require phase-transfer catalysed conditions such as that reported [19]) is adapted from Sorrell et al. [20].

Pyrazole (0.26 g, 3.8 mmol) was added to a suspension of sodium hydride (0.24 g, 10.0 mmol) in DMF (7 cm^3), under a dry dinitrogen atmosphere. The mixture was then stirred for 1 h. To this was added 2,6-bis(1-bromomethyl)benzene in DMF (4 cm^3) dropwise, anaerobically. The resulting mixture was stirred magnetically for 4 days at 298 K. Addition of water (5 cm^3) followed by solvent evaporation under reduced pressure afforded a slurry, to which was added 10% sodium hydroxide solution (5 cm^3). The ligand was extracted with CH_2Cl_2 and the organic layer washed with water, followed by drying over anhydrous Na_2SO_4. Solvent removal under reduced pressure afforded a thick yellowish-brown oil (yield ca. 90%). ^{1}H NMR (80 MHz, $CDCl_3$): δ 7.5 (2H, s, aromatic protons), 7.3 (2H, d, aromatic protons), 7.10–6.73 (4H, m, aromatic protons), 6.30 (2H, t, aromatic protons), 5.30 (4H, s, $PhCH_2$) [19].

2.3. Synthesis of [$Cu^{II}LCl_2$]

A methanolic solution (8 cm^3) of L (0.1 g, 0.42 mmol) was added to a solution of $CuCl_2 \cdot 2H_2O$ (0.072 g, 0.42 mmol) in methanol (4 cm^3), under magnetic stirring at 298 K and a green mixture resulted. After 2 h, the solution was filtered to remove some yellow precipitate. On concentration of the filtrate a dark green crystalline material precipitated out. The crystalline product was collected by filtration, washed with methanol and dried in vacuo (yield ca. 64%). Single crystals suitable for X-ray diffraction studies were obtained from the filtrate within a day. *Anal*. Found: C, 45.4; H, 3.7; N, 15.3; Cl, 19.3. Calc. for $C_{14}H_{14}N_4Cl_2Cu$: C, 45.1; H, 3.8; N, 15.0, Cl 19.1%. Absorption spectrum (DMF solution): λ_{max} (nm) (ε ($dm^3\ mol^{-1}\ cm^{-1}$)) 434 (560), 945 (160).

2.4. Synthesis of [$Cu^{II}(L)(N_3)(OClO_3)] \cdot H_2O$

A methanolic solution (8 cm^3) of L (0.1 g, 0.42 mmol) was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.156 g, 0.42 mmol) in methanol (4 cm^3), followed by solid NaN_3 (0.027 g, 0.42 mmol). The resulting brownish-green mixture was stirred for 2 h at 298 K. The diethyl ether was added to the filtrate, resulting in the formation of a dark green crystalline material. The product was collected by filtration, washed with methanol and dried in vacuo. Recrystallization from MeCN–$(C_2H_5)_2O$ afforded microcrystalline solid (yield ca. 77%). *Anal*. Found: C, 36.6; H, 3.4; N, 20.6. Calc. for $C_{14}H_{16}N_7O_5ClCu$: C, 36.4; H, 3.5; N, 21.3%. IR (KBr, cm^{-1}, selected peaks): 2080 ($\nu[N_3^-]$); 1100, 1060, 630, 625 ($\nu[ClO_4^-]$). Absorption spectrum (DMF solution): λ_{max} (nm) (ε ($dm^3\ mol^{-1}\ cm^{-1}$)) 417 (2200), 655 (290).

2.5. Measurements

Elemental analysis was obtained from the Indian Association for the Cultivation of Science, Calcutta. Solution electrical conductivity measurements were carried out with an Elico (Hyderabad, India) type CM-82 T conductivity bridge. Spectroscopic data were obtained using the following instruments: IR spectra, Perkin-Elmer M-1320; electronic spectra, Perkin-Elmer Lambda 2; X-band EPR spectra, Varian E-109 C; ^{1}H NMR spectra, Bruker WP-80 (80 MHz) NMR spectrometer. Variable-temperature (25–300 K) solid-state magnetic susceptibility measurements were recorded by the Faraday technique using a locally built magnetometer. The setup [21,22] consists of an electromagnet with constant gradient pole caps (Polytronic Corporation, Mumbai, India), Sartorius M25-D/S balance (Germany), a closed cycle refrigerator and a Lake Shore temperature controller (Cryo Industries, USA). All measurements were made at a fixed main field strength of $\approx$10 kG. Susceptibility was corrected for diamagnetic contribution using Pascal constants [23].

2.6. Structure determination and refinement

A green crystal of [$CuLCl_2$] (dimensions $0.2 \times 0.1 \times 0.05$ mm) was used for data collection. Diffracted intensities were collected on an Enraf Nonius CAD4-Mach diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.710\ 73$ Å). The data were collected at 298 K using θ–2θ scan techniques to a maximum 2θ value of 45.0°. 5810 reflections were measured of which 2614 were unique and 1376 reflections with $I > 3\sigma(I)$ were used in the structure refinement. The cell parameters were obtained from least-squares analyses of 25 machine-centred reflections in the range $16.02 \leq 2\theta \leq 27.18°$. Three standard reflections were measured at every hour to monitor instrument and crystal stability.

2.6.1. Crystal data

$C_{14}H_{14}N_4Cl_2Cu$, $M = 372.55$, monoclinic, space group $P2_1/c$, $a = 7.797(1)$, $b = 22.328(7)$, $c = 8.699(9)$ Å, $\beta = 101.77(5)°$, $V = 1482.8(2)$ Å^3, $Z = 4$, $D_c = 1.670$ g cm^{-3}, $\mu = 18.3\ cm^{-1}$, $F(000) = 756$.

Intensity data were corrected for Lorentz and polarization effects; analytical absorption corrections were applied. The structures were solved by the direct method and successive difference Fourier syntheses. All non-H atoms were refined anisotropically and H atoms were included at their calculated positions but not refined. All non-hydrogen atoms were refined with anisotropic thermal parameters. All refinements were performed by full-matrix least-squares procedures on F where the function minimized was $\sum w(F_o - F_c)^2$ where

Table 1
Selected bond distances (Å) and angles (°) for $[CuLCl_2]_2$

Cu–N(2)	2.003(6)	N(2)–Cu–N(3)	162.8(2)
Cu–N(3)	1.987(7)	Cl(1)–Cu–Cl(2)	178.8(1)
Cu–Cl(1)	2.281(2)	Cl(1)–Cu–N(2)	89.5(2)

$w = 1/\sigma(F)$. The final cycle of refinement included 190 variable parameters and converged with $R = 0.046$, $R_w = 0.036$ ($I > 3\sigma(I)$), $S = 1.892$, final difference Fourier synthesis: $-0.92 \le \Delta\rho \le 0.88$ e Å^{-3}. All calculations were performed using the XTAL3.2 crystallographic software package [24]. Selected bond lengths and angles are given in Table 1.

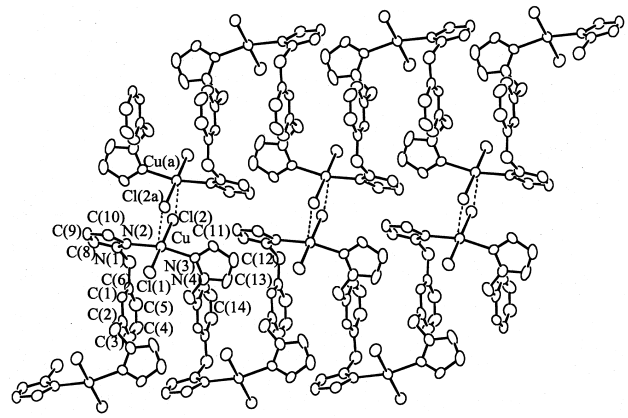

Fig. 1. View of the repeat unit of $[CuLCl_2]_2$. Hydrogen atoms are omitted for clarity. Unlabelled atoms are related to labelled atoms by the crystallographic centre of inversion.

3. Results and discussion

3.1. Synthesis

The ligand L was prepared from the reaction between 2,6-bis(1-bromomethyl)benzene and sodium pyrazolate in DMF. A straightforward reaction between L and $CuCl_2 \cdot 2H_2O$ (1:1 mole ratio) in methanol afforded a dark green complex of composition $[CuLCl_2]$. A single-crystal structural analysis (vide infra) revealed its dimeric nature $[CuLCl_2]_2$ (**1**). A similar reaction using $Cu(ClO_4)_2 \cdot 6H_2O$, L and NaN_3 (1:1:1 mole ratio) afforded a brownish-green solid of composition $[Cu(L)(N_3)(OClO_3)] \cdot H_2O$. The IR spectrum of this complex clearly demonstrated the presence of azide ion [25], coordinated perchlorate ion [17] and water of crystallization. The electrical conductivity data of complex **1** in DMF ($\Lambda_M = 50\ \Omega^{-1}\ cm^2\ mol^{-1}$) revealed that it behaves as a 1:1 electrolyte (expected range for a 1:1 electrolyte: 65–90 Ω^{-1} cm^2 mol^{-1} [26]), implying that the chloride ions are partially dissociated in solution, i.e. in solution the copper(II) centre is bound by only one chloride ion with additional DMF coordination (vide infra). Complex **2** behaves almost as a 1:2 electrolyte in DMF ($\Lambda_M = 130\ \Omega^{-1}\ cm^2\ mol^{-1}$; expected range 130–170 Ω^{-1} cm^2 mol^{-1} [26]), implying that both the anions are dissociated in solution. Based on physicochemical properties (vide infra) the azido complex has been proposed to be a dimer $[Cu(L)(N_3)(OClO_3)]_2 \cdot 2H_2O$ (**2**). Microanalytical, IR (for **2**), and absorption spectral behaviour (vide infra) are in conformity with the suggested formulations for **1** and **2**.

3.2. Description of the structure of $[CuLCl_2]_2$

Fig. 1 provides a perspective view of **1**. The dimeric unit sits on a crystallographically imposed inversion centre. Each copper(II) centre is coordinated by two pyrazole nitrogens from two L and two chloride ions. Interestingly, an additional bonding interaction exists at 2.778 Å, provided by a Cl atom of an adjacent layer (Cl(2a)). However, from each CuN_2Cl_2 moiety only one chloride ion is engaged in this type of interaction. Hence each copper(II) ion is present in a five-coordinate environment. The Cu···Cu separation between the two successive layers (Cu–Cu(a)) is 3.798(2) Å and within a layer (Cu–Cu′) is 8.112(3) Å. The separation between Cl(2) and Cl(2a) is 3.20(6) Å. The angles Cu–Cl(2)–Cu(a) and Cu–Cl(2a)–Cu(a) are 86.78(4) and 75.29(3)°, respectively. The average Cu–N(pyrazole) distance of 1.995 Å is in line with the metric parameters of copper(II) complexes of pyrazole-based chelating ligands [1]. The average Cu–Cl distance in the equatorial plane is 2.303 Å. The N(2)–Cu–N(3) angle is 162.8(2)°, which is appreciably smaller than the expected 180° for a linear arrangement of two pyrazole nitrogens to a copper centre having a perfect square planar geometry. However, the Cl(1)–Cu–Cl(2) angle (178.77(8)°) is close to 180°. From this equatorial plane the Cu(II) ion is displaced towards a chloride ion of an adjacent layer by 0.1357 Å. The Addison structural distortion index parameter τ [27] is 0.266. Therefore the coordination environment for each copper(II) centre is best described as distorted square pyramidal.

3.3. Electronic properties

3.3.1. Absorption spectroscopy

In the solid state (dispersed in mineral oil) compound **1** exhibits a peak at ~680 nm along with a low energy shoulder at ~950 nm, typical of square pyramidal geometry around the copper(II) centre [28]. However, in going from solid to solution (DMF), a red shift of the main absorption band was observed, which is known to occur as a result of increased coordination around the metal centre (tetragonal geometry) [13]. Thus this complex exhibits a d–d transition at 945 nm with an additional band at 434 nm. The latter band could be due to $Cl^- \rightarrow Cu(II)$ charge transfer. In the solid state, complex **2** also shows a low energy band centred at 705 nm; however, a blue shift has been observed in the DMF solution (655 nm). This result implies that for **2** in the solid state a

'pseudo dimeric structure' exists [13], due to weak coordination of one azide ion of a Cu(II) centre to a nearby Cu(II) centre. We note that the extent of DMF coordination is more in **1** than in **2**. For **2** the band at 417 nm could be assigned as $N_3^- \rightarrow Cu(II)$ charge-transfer transition.

3.3.2. EPR spectroscopy

In the polycrystalline state (77 K), the complex **1** exhibits an axial EPR spectrum with $g_\parallel = 2.171$, $g_\perp = 2.066$ and $A_\parallel = 105$ G. The position of the high-field signal ($g > 2.04$) is consistent with a $d_{x^2-y^2}$ ground state [28]. In frozen DMF solution, superhyperfine interaction with chlorine atoms on the $g_\perp$ component is clearly observable; however, the resolution is not sufficient to extract any meaningful information. Otherwise, the spectral parameters remain almost unaltered with slightly diminished signal intensity. Complex **2** is EPR silent in the solid state both at 300 K and at 77 K. This could be due to concentration broadening caused by magnetic dipolar interaction. However, in frozen DMF solution it exhibits a typical axial spectrum with $g_\parallel = 2.396$, $g_\perp = 2.077$ and $A_\parallel = 120$ G.

3.4. Magnetic properties

To study (i) whether any magnetic exchange interaction exists between two copper(II) centres in **1** and (ii) to substantiate the proposed structure of **2** (unsymmetrical azide bridging), we investigated the temperature-dependent (25–300 K) magnetic susceptibility behaviour. The μ_{eff}/Cu values at 300 K and at 25 K vary from 1.83 to 1.60 μ_B for **1** and 1.85 to 1.68 μ_B for **2**. The magnetic behaviour (Fig. 2) is typical of a very weak antiferromagnetic interaction. If we assume that the observed magnetic curve is intrinsic to the binuclear entity then χ_M may be expressed as [15–17]

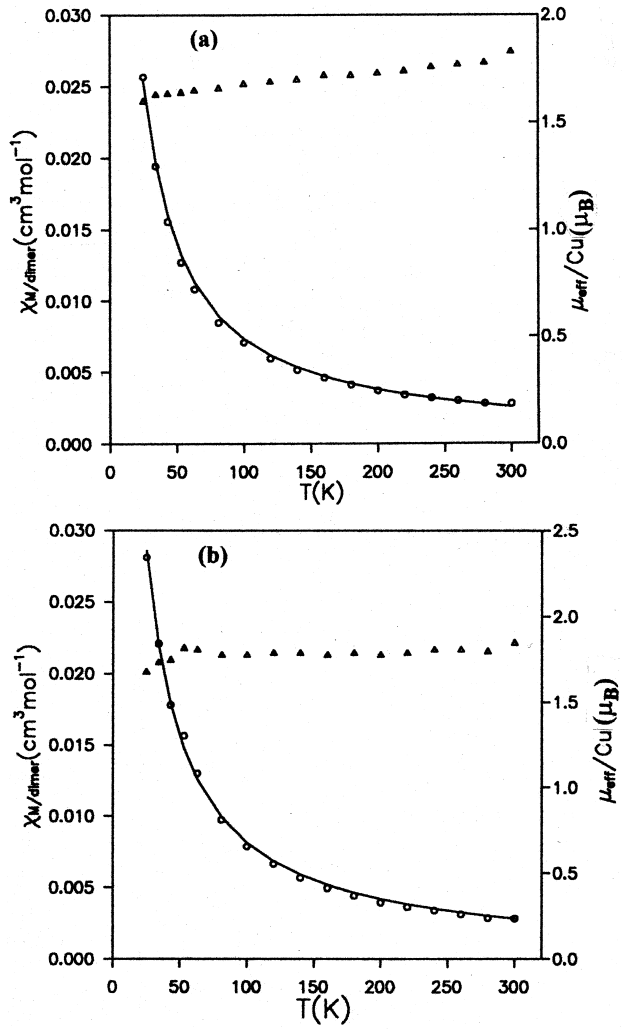
$$\chi_M = \frac{2N\beta^2 g^2}{kT}[3+\exp(-2J/kT)]^{-1} + 2N_\alpha \qquad (1)$$

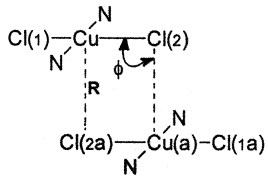
where the symbols have their usual meanings. Keeping the temperature-independent paramagnetism ($2N_\alpha$) fixed at 120×10^{-6} cm^3 mol^{-1}, the parameters J (the singlet–triplet energy gap is expressed in terms of $2J$) and g were determined by looking for the minimum of $R = \Sigma(\chi_M^{obsd} - \chi_M^{calc})^2/\Sigma(\chi_M^{obsd})^2$. Non-linear regression analysis of the data using Eq. (1) gave good data fits (Fig. 2): $J = -4.9$ cm^{-1}, $g = 2.00$, $R = 1.45\times10^{-6}$ for **1** and $J = -4.4$ cm^{-1}, $g = 2.103$, $R = 1.60\times10^{-6}$ for **2**. Inclusion of a corrective term for non-coupled copper(II) impurity gave no improvement in the fit.

Incorporation of a corrective term (θ) for interdimer interactions [29] in **1** and hence using Eq. (2),

$$\chi_M = \frac{2N\beta^2 g^2}{k(T-\theta)}[3+\exp(-2J/kT)]^{-1} + 2N_\alpha \qquad (2)$$

a similar data analysis gave rise to the following parameters: $J = -4.67$ cm^{-1}, $g = 1.977$ ($2N_\alpha = 120\times10^{-6}$ cm^3 mol^{-1}, fixed), $\theta = -0.055$ K, and R is then equal to 9.37×10^{-7}, which corresponds to an excellent agreement between observed and calculated magnetic data. The very small θ value, however, indicates that intermolecular exchange effects are essentially non-existent. The observed behaviour is again pointing towards the weak nature of antiferromagnetic coupling betwen two copper centres.





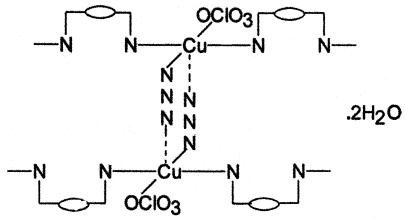


Fig. 2. Plot of magnetic susceptibility (left scale) per dimer and effective magnetic moment (right scale) per metal vs. temperature for polycrystalline samples of (a) $[CuLCl_2]_2$ (**1**) and (b) $[CuL(N_3)(OClO_3)]_2\cdot2H_2O$ (**2**). The solid line represents theoretical fits using Eq. (1), as described in the text.

In the solid state of compound **1** (Fig. 1) one Cl atom at each Cu site occupies the fifth coordination of the Cu centre of an adjacent layer, resulting in a long intermolecular Cu···Cl contact. However, the optimized $2J$ parameter for this compound does not follow the empirical Hodgson correlation between structural parameter ϕ/R and the coupling constant J [30,31]. Here ϕ is the Cu–Cl(2)–Cu(a) bridging angle and R is the longer Cu–Cl(2a) separation. The dihedral angle between the planes Cu–Cl(2)–Cu(a) and Cu–Cl(2a)–Cu(a) is 87.92°, revealing that the four-membered ring Cu–

Cl(2)–Cu(a)–Cl(2a) is non-planar. This could be the reason behind its deviation from this empirical correlation.

With asymmetric end-to-end azido bridges, with a short and a long Cu–N(azide) bond, it is well documented that the magnetic interaction is negligible when the geometry around the copper(II) ion is square pyramidal [32,33]. The observed magnetic behaviour of **2** is in line with this bonding interaction. In fact, in **2** the geometry around the copper centre is square-based pyramidal (vide absorption spectra). Two nitrogen atoms from two ligands are bonded to the Cu(II) ion; one oxygen atom from a perchlorate ion and a bridging azide ion are coordinated in the basal plane. The two copper(II) atoms are linked via one end-to-end bridging azide. The situation is very similar to what we have observed in **1**. Thus the structure of compound **2** can be proposed as shown below.

4. Conclusions

Using an *m*-xylyl based pyrazole ligand L two dimeric copper(II) complexes $[CuLCl_2]_2$ and $[CuL(N_3)(OClO_3)]_2 \cdot 2H_2O$ have been synthesized. The presence of a dimeric structure containing a $\{Cu_2Cl_2\}^{2+}$ structural unit, with an interacting Cl^- ion from an adjacent layer affording a network structure, is clearly established by a crystal structural analysis of one such complex **1**. The structure reveals that two L ligands are not capable of accommodating two copper centres at a distance capable of providing a discrete $Cu_2L_2Cl_2$ bridged structure. The X-ray structure of the dicopper(I) complex of the 3,5-dimethylpyrazole derivative of L behaved similarly (each copper(I) centre had two pyrazole coordination from two ligands with a Cu···Cu separation of 6.350 Å) [34]. Temperature-dependent magnetic measurements reveal very similar structures for **1** and **2**, exhibiting weak antiferromagnetic exchange coupling.

Supplementary data

Full tables of bond lengths and angles, tables of non-hydrogen and hydrogen atomic coordinates, anisotropic thermal parameters for non-hydrogen atoms as well as hydrogen atom parameters are available as supplementary material from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), on request (CCDC deposition number 129652).

Received 24 November 1999; accepted 28 January 2000

Abstract

New benzolamide (H_2bz, 5-phenylsulfonamide-1,3,4-thiadiazole-2-sulfonamide) zinc(II) and copper(II) complexes with diethylenetriamine were synthesized and characterized. The crystal structures of the [M(Hbz)$_2$(dien)] (M = Cu(II), Zn(II); dien = diethylenetriamine) complexes were determined. The metal centre adopts a near regular square pyramidal geometry. The benzolamidate anion acts as a monodentate ligand through the thiadiazole N atom contiguous to the deprotonated sulfonamido group. Spectroscopic properties are in good agreement with the crystal structures. The EPR and electronic spectroscopic studies showed that the copper(II) species doped into the zinc(II) complex adopts a near square planar geometry. The energy and composition of the SOMO of [Cu(Hbz)$_2$(dien)] and of copper substituted [Zn(Hbz)$_2$(dien)] were studied. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Divalent metals; Zinc; Copper; Benzolamide; Diethylenetriamine; Ternary complexes

1. Introduction

There are many areas of considerable potential interest for sulfonamide coordination chemistry. Metal complexes of 2-sulfanilamidopyrimidine (sulfadiazine) have been used to prevent bacterial infections of burns, and many of these complexes have been structurally characterized [1,2]. A tungsten complex of the bis-sulfonamide of 2,6-bis(aminomethyl)-pyridine catalyses cleavage of N–N bonds and is therefore of interest as a model for fixation of nitrogen [3]. More recently, a chiral zinc-sulfonamide complex has been demonstrated to be a relevant catalyst in enantioselective cyclopropanations [4]. Moreover, aromatic and heteroaromatic sulfonamides are well known as inhibitors of carbonic anhydrase (CA) and they have been extremely useful in the study of molecular properties and of the catalytic mechanisms of zinc-containing carbonic anhydrases [5].

A part of our investigation is focused on the study of these heteroaromatic sulfonamides as ligands. Neutral sulfonamides are expected to be poor ligands because of the withdrawal of the electron density from the nitrogen atom onto the electronegative oxygen atoms. However, if the sulfonamide N atom bears a dissociable hydrogen atom, this same electron-withdrawing effect increases its acidity and in the deprotonated form sulfonamide anions are effective sigma-donor ligands. Our previous studies on the interaction of sulfonamides with metal ions (Zn(II), Co(II), Ni(II) and Cu(II)) have shown that these can bind in several ways and not only as unidentate anions through the sulfonamide N atom [6–11]. Recently, as a continuation of our investigation, we initiated the study of the coordination behaviour of benzolamide (H_2bz, 5-phenylsulfonamide-1,3,4-thiadiazole-2-sulfonamide). Benzolamide (Fig. 1) contains two dissociable protons and affords potentially chelating thiadiazole and sulfonamide N donor binding sites, hence different coordination possibilities can be expected.

We have reported ternary zinc and copper benzolamide complexes with amines (ammomia, diethylenetriamine (dien), dipropylenetriamine (dpt) and tris(2-benzimidazolyl-methylamine) (L)) [12,13]. In these complexes the coordination behaviour of the benzolamide was different. Thus, in Cu(bz)(NH$_3$)$_4$, Cu(bz)(dien)·H_2O and Cu(bz)(dpt)·H_2O the dideprotonated sulfonamide coordinates the metal ion through the N atom of the free sulfonamido

group, whereas in the polymer $\{[Zn_2(bz)_2(NH_3)_4]\cdot 2H_2O\}_\infty$ the dinegative benzolamide anion acts as a bridge, linking two metal centres through the N atom of the free sulfonamido group and the thiadiazole N closest to the substituted sulfonamido moiety. In the $[Zn(Hbz)L]ClO_4\cdot H_2O$ compound the monodeprotonated benzolamide interacts via thiadiazole N contiguous to the substituted sulfonamido moiety [13]. In this paper, as a part of our continuing interest in the coordination behaviour of benzolamide, we report the synthesis, structure and spectroscopic properties of the new benzolamide $M(Hbz)_2(dien)$ (M = Cu(II) and Zn(II)) complexes in which the sulfonamide in its monodeprotonated form interacts through one of the thiadiazole N atoms.

2. Experimental

2.1. Materials

Benzolamide (H_2bz, 5-phenylsulfonamide-1,3,4-thiadiazole-2-sulfonamide) was provided by Professor C.T. Supuran (University of Florence, Italy). All reagents were of the highest grade commercially available and used without further purification.

2.2. Methods

IR spectra were recorded on a Perkin-Elmer 843 instrument. Samples were prepared using the KBr technique. Electronic spectra were registered on a Shimadzu UV 2101PC spectrophotometer. EPR spectra were carried out with a Bruker ER 200 D spectrometer. Magnetic susceptibility measurements at room temperature were taken with a fully automated AZTEC DSM8 pendulum-type susceptometer. Mercury tetrakis(thiocyanato)cobaltate(II) was used as a susceptibility standard. Corrections for diamagnetism were estimated from Pascal's constants.

2.3. Synthesis

2.3.1. Cu(Hbz)$_2$(dien)

0.25 mmol of diethylenetriamine was added with continuous stirring to 40 ml of an ethanolic solution containing 0.25 mmol of $Cu(NO_3)_2\cdot 3H_2O$ and 0.5 mmol of benzolamide. Immediately, a little amount of a blue solid was formed. It was separated by filtration and the filtrate was left to stand at 4°C. After a few days prismatic blue crystals suitable for X-ray measurements were obtained. The crystals were filtered, washed with cooled ethanol and dried under vacuum. Yield 40%. *Anal*. Found: C, 29.45; H, 3.28; N, 19.23. Calc. for $C_{20}H_{27}CuN_{11}O_8S_6$: C, 29.83; H, 3.35; N, 19.14%.

2.3.2. Zn(Hbz)$_2$(dien)

The synthesis procedure is similar to that described above but $Zn(ClO_4)_2\cdot 6H_2O$ was used and no solid was obtained after the addition of diethylenetriamine. After 3–4 days prismatic colourless crystals were obtained from the resulting solution at room temperature. Yield 30%. *Anal*. Found: C, 29.57; H, 3.31; N, 19.32. Calc. for $C_{20}H_{27}ZnN_{11}O_8S_6$: C, 29.76; H, 3.34; N, 19.10%.

2.3.3. Doped Zn,Cu(Hbz)(dien)

0.25 mmol of dien was added to 40 ml of an ethanolic solution containing 0.225 mmol of $Zn(ClO_4)_2\cdot 6H_2O$ and 0.025 of $Cu(ClO_4)_2\cdot 6H_2O$ under stirring. The solution turned dark blue and then 0.5 mmol of benzolamide was added. It was stirred for about half an hour and then was left to stand at room temperature. Slow evaporation of the solvent gives a violet precipitate. Yield 65%.

2.4. Crystal data and structure refinement

A well-shaped blue crystal of $[Cu(Hbz)_2(dien)]$ ($0.22\times0.25\times0.27$ mm) and a colourless crystal of $[Zn(Hbz)_2(dien)]$ ($0.17\times0.18\times0.18$ mm) were mounted on a Siemens P4 four circle diffractometer coupled to Mo Kα radiation. The unit cell dimensions were determined from the angular settings of 25 reflections with $1.88<\theta<22.5°$ for the Cu(II) compound and $1.87<\theta<22.5°$ for the Zn(II) complex. A total of 4376 and 4415 reflections were measured for $[Cu(Hbz)_2(dien)]$ and $[Zn(Hbz)_2(dien)]$, respectively, of which 4130 ($R_{int}=0.0248$) and 4161 ($R_{int}=0.0452$) were unique ($0\le h\le 12$, $-12\le k\le 11$, $-14\le l\le 14$). Semi-empirical absorption corrections from ψ scans were applied for $[Zn(Hbz)_2(dien)]$ and no absorption corrections were applied for $[Cu(Hbz)_2(dien)]$. Each structure was solved by direct methods [14] and refined by full-matrix least-squared analysis on F^2. Largest peak and hole in the final difference map were $+0.767$ and -0.664 e Å^{-3} (Cu(II) compound) and 0.415 and -0.563 e Å^{-3} (Zn(II) complex). Other relevant parameters of crystal structure determination are collected in Table 1.

2.5. EHMO calculations

All calculations were performed using the Package of Programs for Molecular Orbital Analysis by Mealli and Proserpio [15] based on CDNT (atom Cartesian coordinate calculations), ICON (extended Hückel method with the weighted *Hij* formula) and FMO (fragment molecular orbital), including the drawing program CACAO (computer aided composition of atomic orbitals).

The extended Hückel parameters are as follows. *Hij*: Cu 4s, −11.40 eV; Cu 4p, −6.06 eV; Cu 3d, −14.00 eV; Zn 4s, −12.41 eV; Zn 4p, −6.53 eV; N 2s, −26.00 eV; N 2p, −13.40 eV; S 3s, −20.00 eV; S 3p, −13.30 eV; O 2s, −32.30 eV; O 2p, −14.80 eV; C 2s, −21.40 eV; C 2p, −11.40 eV; H 1s, −13.60 eV. Orbital exponents (contraction coefficients in double-ξ expansion given in parentheses): Cu 4s, 4p, 2.200; Cu 3d, 5.950 (0.5933), 2.300 (0.5744); Zn 4s, 2.010; Zn 4p, 1.700; N 2s, 2p, 1.950; S 3s, 3p, 1.817; O 2s, 2p, 2.275; C 2s, 2p, 1.625; H 1s, 1.300.

3. Results and discussion

3.1. Synthesis of the complexes

The ternary complexes [M(Hbz)$_2$(dien)] were obtained by reaction of the metal salt, the triamine and benzolamide in a molar ratio 1:1:2. The ratio of reagents is important to obtain the compounds described here since the addition of an equimolecular amount of triamine and benzolamide leads to the formation of the previously reported [M(bz)(dien)]·H_2O compounds in which the benzolamide is present in its dideprotonated form [12].

3.2. Description of the crystal structures

A drawing of [Cu(Hbz)$_2$(dien)] including the atomic numbering scheme is shown in Fig. 2. Interatomic distances and angles relevant to the coordination sphere for the [Cu(Hbz)$_2$(dien)] and [Zn(Hbz)$_2$(dien)] complexes are given in Table 2.

The metal ion is pentacoordinated by five N atoms, the structure being best described as a regular square pyramid. The three N atoms (N(5), N(6) and N(7)) of the dien ligand occupy equatorial positions. The remaining two M(II) square pyramidal coordination sites are occupied by two benzolamidate anions that interact through the thiadiazole N atom contiguous to the deprotonated sulfonamido group (N(3), N(9)). The Cu–N(dien) bond distances are in the narrow range from 2.014(5) to 2.035(5) Å and the Zn–N(dien) lengths range from 2.082(7) to 2.202(7) Å. As expected from the ionic radii of the divalent metal ions, the average of these Zn–N bond distances is considerably longer than those involving Cu. Both MN_5 chromophores are essentially square pyramidal but with significant differences in the local molecular stereochemistry. In particular, in the Zn complex the Zn–N(6) (2.202(7) Å) is the longest bond distance while in the Cu compound the Cu–N(6) (2.035(5) Å) distance is one of the shorter distances. Moreover, the equatorial Cu–N(thiadiazole) (Cu–N(3), 2.070(5) Å) is markedly shorter than the axial Cu–N(thiadiazole) distance (Cu–N(9), 2.233(5) Å) but the equatorial Zn–N(thiadiazole) (Zn–N(3), 2.188(7) Å) is longer than the axial Zn–N(thiadiazole) distance (Zn–N(9), 2.042(7) Å). The equatorial Cu–N(thiadiazole) is found to be comparable to the corresponding bond in Cu(II) complexes with related sulfonamides [7,9] and the equatorial Zn–N(thiadiazole) is comparable to the same distance in the [Zn(Hbz)L]ClO_4·H_2O compound (L = tris(2-benzimidazolyl-methylamine)) [13]. The axial Cu–N(thiadiazole) length is ca. 0.23 Å shorter than that of the Cu(Hacm)$_2$(en)$_2$ complex (H_2acm = acetazolamide, en = ethylenediamine) [8]. The

N(3)–Cu(1)–N(9)	102.8(2)	N(3)–Zn(1)–N(9)	107.0(3)

Cu–N(dien) bond distances are similar to those in other Cu(II) complexes with dien [16–19].

The in-plane angular distortions described by the ratio τ represent a percentage trigonal distortion of a square pyramidal geometry (1 for perfect trigonal bipyramidal, 0 for perfect square pyramidal). The calculated τ value from bond angles of 0.02 for the Cu(II) compound and of 0.06 for the Zn(II) complex clearly indicates a quasi regular pyramidal geometry [20]. For the two structures the major changes in the angles subtended at the metal centre are found in N(5)–M–N(7) and N(6)–M–N(3) which expand from 149.8(3) and 153.4(3)° [$Zn(Hbz)_2(dien)$] to 163.4(2) and 162.3(2)° [$Cu(Hbz)_2(dien)$]. The *cis* equatorial N–M–N bond angles differ from 90° owing to the presence of a chelate ring that produces rhombic in-plane effects [21].

In the copper compound the atoms that constitute the equatorial plane deviate 0.050 Å from planarity and those of the zinc complex deviate 0.006 Å. The copper atom is displaced 0.2543 Å from the equatorial plane towards the apical position and the zinc ion is situated at 0.4876 Å from this plane.

It is also interesting to note that the copper compound presents a square pyramidal geometry since of the dien complexes structurally characterized, very few contain dien and a monodentate ligand [17] and these adopt six-coordinate tetragonally elongated octahedral geometries, with both ligands located equatorially and anions weakly bound axially [17]. Square pyramidal geometries are found only in copper dien complexes with bidentate ligands [22]. This geometry is also exhibited by Cu(II) compounds with pentamethyldiethylenetriamine and a monodentate ligand, but in these cases a third ligand (either solvent or anion) binds in the axial position [23–25].

The uninegative benzolamidate anions behave as monodentate ligand through the thiadiazole N atom (N(3), N(9)) contiguous to the deprotonated sulfonamido group. This coordination behaviour is also exhibited by the monodeprotonated benzolamide in the $[Zn(Hbz)L]ClO_4 \cdot H_2O$ compound (L = tris(2-benzimidazolyl-methylamine)) [13]. In these complexes the coordination mode of the benzolamide is determined by the fact that the deprotonation takes place on the substituted sulfonamido moiety. This makes the thiadiazole N closest to this sulfonamido group the best donor atom. However, it differs from that found in $[Cu(bz)(NH_3)_4]$ [12] where the dideprotonated benzolamide acting as monodentate ligand binds the metal ion through the free sulfonamide N atom. Although it is difficult to rationalize the coordination behaviour of benzolamide, our investigation of its coordination properties has demonstrated that in the monodeprotonated form it behaves as a monodentate ligand coordinating the metal through the thiadiazole N atom closest to the substituted sulfonamido group. When dideprotonated it shows a more variable coordination behaviour, acting as a bridge through the thiadiazole and free sulfonamido N atoms [13] or as monodentate via free sulfonamido N atom [12].

It is interesting to compare the coordination behaviour of benzolamide and the structurally related acetazolamide (H_2acm, 5-acetamido-1,3,4-thiadiazole-2-sulfonamide) when both are monodeprotonated. Although both sulfonamides offer the same donor sites, a N thiadiazole atom and a N sulfonamido, the coordination behaviour of acetazolamide in the previously reported $[Cu(Hacm)(dien)] \cdot H_2O$ and $[Cu(Hacm)(dpt)] \cdot H_2O$ compounds [26] contrasts with that of benzolamide. Acetazolamide in these complexes acts as a monodentate ligand through the N sulfonamido atom.

3.3. IR spectra

In Table 3 are collected the most significant IR data for the complexes reported here. For comparison the IR data for related compounds are also included.

The modifications of the characteristic bands of the benzolamide ligand give some information about its coordination and/or its deprotonation. It is found that the changes in the asymmetric and symmetric stretching modes of the SO_2 group afford some evidence of the deprotonated nature of the benzolamide. When monodeprotonated, two bands are associated with each vibration, whereas when dideprotonated, one band for each vibration is observed. These bands show some splitting in the $[Zn(Hbz)_2(dien)]$ complex that probably arises from hydrogen bonding or crystal packing effects. Moreover, it is noteworthy that in all the complexes, the ν(C=N) vibration is strongly modified. Since the changes occur in the complexes where the benzolamide is monodeprotonated and in the complexes where the benzolamide is

dideprotonated, this fact could be attributed to the modifications that take place on the thiadiazole π-system upon deprotonation of the substituted sulfonamido group.

3.4. Magnetic susceptibility, electronic and EPR spectra

The [Cu(Hbz)$_2$(dien)] compound exhibits a normal value of magnetic moment for an orbitally non-degenerate ground state, 1.76 BM.

The solid electronic spectrum of [Cu(Hbz)$_2$(dien)] is in agreement with the crystallographic data. It presents a single broad ligand field absorption with a maximum at 630 nm as expected for copper(II) complexes having a square pyramidal geometry [27].

At room temperature the solid-state EPR spectrum of [Cu(Hbz)$_2$(dien)] is axial with the parallel component poorly resolved. The calculated EPR parameters are $g_\parallel \approx 2.30$ and $g_\perp = 2.13$. The EPR of the copper doped into its zinc counterpart is also axial in nature. The low-field region shows the quartet hyperfine structure from Cu ($I = 3/2$). The ground state parameters extracted from the experimental spectrum by simulation [28] are $g_\parallel = 2.21$, $g_\perp = 2.05$ and $A_\parallel = 191 \times 10^{-4}$ cm^{-1}. This $A_\parallel$ value of the complex diluted in the isomorphous zinc lattice is larger than the values expected for a five-coordinated geometry. It is well known that Cu(II) square planar and octahedral complexes with tetragonal elongation lead to a large parallel Cu hyperfine coupling. Further, the quotient $g_\parallel/A_\parallel$ lies in the range 105–135 cm, supporting a square planar geometry [29]. So, it seems that the Cu(II) assumes a stereochemistry much more close to that of a planar CuN_4 chromophore [30]. This change in the geometry is supported by the mull spectrum of the copper(II) complex doped in the corresponding zinc complex that exhibits a shift from 630 nm in the pure copper to 575 nm.

In acetonitrile the EPR spectrum of the [Cu(Hbz)$_2$(dien)] displayed axial anisotropy with some rhombic perturbation. The EPR features obtained from simulation are $g_\parallel \approx 2.29$, $g_\perp = 2.13$ and $A_\parallel = 185 \times 10^{-4}$ cm^{-1}. They are indicative of a square planar based structure. The UV–Vis spectrum shows a d–d band at ca. 600 nm ($\varepsilon = 130$ mol^{-1} cm^{-1}) which agrees well with a square planar arrangement around the copper ion. Apart from the d–d transition, the spectrum displays an intense absorption at 300 nm ($\varepsilon = 29120$ mol^{-1} cm^{-1}) and a less intense absorption at 245 nm ($\varepsilon = 16990$ mol^{-1} cm^{-1}) associated with ligand π–π* transitions. Both EPR and electronic spectra indicate that the geometry of the copper ion in solution is, like in the doped compound, nearer to square planar with weak apical interactions.

3.5. Extended Hückel molecular orbitals calculations

The crystal structures of the isomorphous [Cu(Hbz)$_2$(dien)] and [Zn(Hbz)$_2$(dien)] complexes have shown that both compounds present some differences in their local molecular stereochemistry. The most significant differences are found in the M–N(9) (2.233(5) (Cu) and 2.045(7) Å (Zn)), in the M–N(6) (2.035(5) (Cu) and 2.202(7) Å (Zn)) bond lengths and in the *trans* angles N(5)–M–N(7) and N(6)–M–N(3), which expand from 149.8(3) and 153.4(3)° [Zn(Hbz)$_2$(dien)] to 163.4(2) and 162.3(2)° [Cu(Hbz)$_2$(dien)]. Moreover, the [Cu(Hbz)$_2$(dien)] complex presents electronic properties (see Section 3.4) different to those of the copper doped compound that suggests that when the Cu(II) substitutes the Zn(II) ion does not adopt the geometry observed in the pure copper compound. In order to understand how these structural differences can affect the energy and composition of the relevant molecular orbitals of the complexes we have undertaken extended Hückel molecular orbital (EHMO) calculations by means of the CACAO program [15]. These calculations have been performed using the crystallographic coordinates derived from the crystal structures of the [Cu(Hbz)$_2$(dien)] compound and [Zn(Hbz)$_2$(dien)] in which the Zn(II) has been replaced by Cu(II) as a 'model' of the copper doped compound.

The SOMO of the [Cu(Hbz)$_2$(dien)] presents an energy of −11.049 eV (Fig. 3). The contribution of metal d orbitals to the SOMO is 39% ($d_{x^2-y^2}$ (28%), d_{xz} (8%), d_{xy} (2%) and d_{z^2} (1%)). The atomic orbitals of the ligands that participate in SOMO formation are the three N atoms of the dien (N(5), px 12%, py 2%; N(6), py 18%; N(7), px 10%, pz 3%) and one N thiadiazole atom (N(3), py 9%) from one of the benzolamidate ligands.

When these calculations are performed on the 'model' copper doped compound, a SOMO with an energy of −11.649 eV is obtained (Fig. 4). The overall contribution of the copper d atomic orbitals to this MO is 34% ($d_{x^2-y^2}$ (25%), d_{xz} (7%) d_{xy} (1%) and d_{yz} (1%)), although the ligand orbitals involved are the same as in Cu(Hbz)$_2$(dien) their contribution is slightly different (N(5), px 12%; N(6), py 21%; N(7), px 7%, pz 5%; N(3), py 9%).

The electronic and EPR spectra of the [Cu(Hbz)$_2$(dien)] and of the copper doped compound suggest a change of geometry for the Cu(II) ion when it replaces the Zn(II) ion in the [Zn(Hbz)$_2$(dien)] complex. The EHMO calculations have

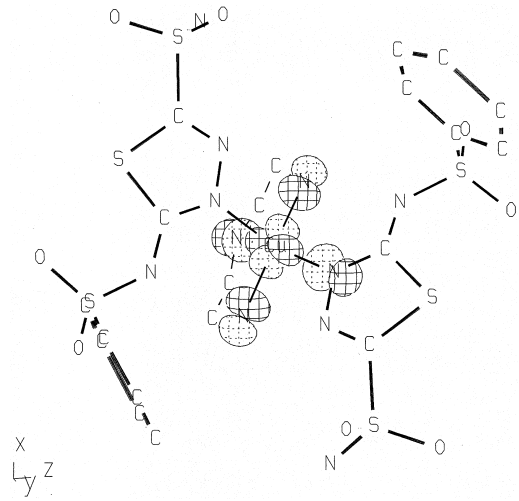

Fig. 3. SOMO of the [Cu(Hbz)$_2$(dien)] complex.

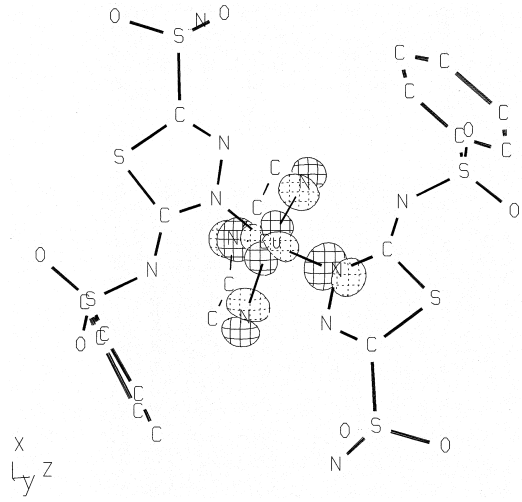

Fig. 4. SOMO of the copper substituted [Zn(Hbz)$_2$(dien)] complex.

shown that the energy difference between the SOMOs of both compounds, 0.6 eV (ca. 5000 cm^{-1}), could explain the variances found in their electronic properties.

Supplementary data

Supplementary crystallographic data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, deposition numbers CCDC 132907/CCDC 132908.

Abstract

The reaction of $Mo_3OS_3(dtp)_4(H_2O)$ ($dtp = S_2P(OC_2H_5)_2$) with CuI yielded the new trimolybdenum cluster $[Mo_3(\mu_3\text{-}X)(\mu_2\text{-}S_2)_3(dtp)_3I_3]$ (X = 58%O + 42%S). Crystal structure analysis showed that the compound has a $[Mo_3X(S_2)_3]^{4+}$ cluster core, and the I_3^- group functions as a two-way coordinated ligand which links the three out-of-$\{Mo_3\}$ plane S atoms in the cluster core at one end (I–S ~ 3.3 Å) and two adjacent trinuclear clusters at the other (I···S ~ 3.6 Å), thus forming a $[Mo_3X(S_2)_3]$ cluster layer. The bonding features of the cluster characteristic of a semiconductor are demonstrated by energy band and density functional calculations. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Mo–S clusters; Crystal structures; Electronic structures; Layer-like packing

1. Introduction

Cluster compounds with a $[Mo_3S_7]^{4+}$ core have been widely studied in the last two decades owing to their potential applications in biological inorganic chemistry and new materials research. For example, $(NH_4)_2[Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3(S_2)_3]$ may be used as a good hydrodesulfurition catalyst [1]. Many clusters with different ligands and anions have been synthesized using a variety of methods, including the reduction of some Mo(V) complexes, and the oxidation of some Mo(III) compounds in solution or by solid state reaction [2–6]. Since 1980 we have obtained a series of M_2-type clusters [7–10] of the general formula $[Mo_3X(S_2)_3L_3Y]$ (X = O, S; $L = S_2P(OC_2H_5)_2^-$ (dtp), $S_2CN(C_2H_5)_2^-$, $S_2CNC_4H_8^-$, $S_2P(OC_3H_7)_2^-$, $S_2C_6H_3CH_3^{2-}$, Cl; Y = Cl, I, $S_2P(OC_3H_7)_2^-$). However, a cluster of this type containing the I_3^- anion has not yet been reported. Herein, the synthesis and crystal structure of the cluster $[Mo_3X(S_2)_3(dtp)_3(I_3)]$ (X = 58%O + 42%S) are described together with a discussion of the formation mechanism and bonding features.

2. Experimental

All the reactions and manipulations were carried out under the atmosphere with CP or AR grade reagents. CuI was used as purchased, and the compound $[Mo_3OS_3(dtp)_4(H_2O)]$ was prepared according to the literature procedure [11].

2.1. Preparation of the title compound

A mixture of 0.1 g (0.09 mmol) $Mo_3OS_3(dtp)_4(H_2O)$ and 0.02 g (0.1 mmol) CuI was dissolved in 25 ml CH_3COOEt with stirring, and then 0.2 ml DMF was added to the resulting solution. The solution was stirred for 2 h at room temperature and filtered. The filtrate was evaporated in air. Well shaped black crystals (0.03 g) were obtained after 1 month. The crystals were isolated, washed with EtOH and petroleum ether, and then dried in air (yield 23%).

2.2. X-ray structural characterization

Information concerning crystallographic data and structure refinement is summarized in Table 1.

Intensity data were collected using a crystal of dimensions 0.4 × 0.4 × 0.1 mm on a Rigaku AFC5R diffractometer with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). The structure was solved by direct methods, and all non-hydrogen atoms were refined with anisotropic thermal parameters except for the carbon atoms and X atom. The hydrogen atoms were placed in idealized geometries and their contributions were added to the structure factor calculations. Full-

R indices (all data)	$R_1=0.0774$, $wR_2=0.1168$
Largest difference peak, hole (e Å^{-3})	1.804 (close to X atom), −1.088
Max. shift $(\Delta/\sigma)_{max}$ in final cycle	−0.002

[a] $R=\sum||F_o|-|F_c||/\sum|F_o|$, $wR=[\sum w(F_o^2-F_c^2)^2/\sum w(F_o^4)]^{1/2}$, $w=[\sigma^2(F_o^2)+(aP)^2+bP]^{-1}$, $P=(2F_c^2+F_o^2)/3$.

matrix least-squares refinement was based on F^2 with the SHELXTL-5 program [12].

Selected bond lengths and angles are listed in Table 2.

3. Results and discussion

3.1. Description of the molecular structure

An ORTEP drawing of the molecular structure of $[Mo_3X(S_2)_3(dtp)_3I_3]$ is shown in Fig. 1, and a packing diagram is shown in Fig. 2.

Fig. 1 shows that the title compound has a typical M_2 type structure, in which three Mo atoms form an approximately equilateral triangle with Mo–Mo bond distances of 2.657(1), 2.663(1) and 2.663(1) Å. The average Mo–Mo bond distance (2.661 Å) is between those of the clusters $[Mo_3S_7(dtp)_3I]$ and $[Mo_3OS_6(dtp)_3I]$, whose average Mo–Mo bond distances are 2.723 and 2.626 Å, respectively [9]. The μ_3-X atom with O/S statistical distribution (X=58%O+42%S) is above the $\{Mo_3\}$ triangle. Each pair of Mo atoms is bridged by a (S_2) group, and each Mo atom is coordinated further by a terminal dtp ligand; thus a pentagonal bipyramidal coordinated geometry of the Mo atom is formed by six S atoms and a μ_3-X atom. The most specific feature of this structure is that three out-of-plane S atoms are connected with the I_3^- anion at S–I bond distances of 3.270(2), 3.307(2) and 3.364(3) Å (average 3.314 Å), which are much shorter than the corresponding van der Waals

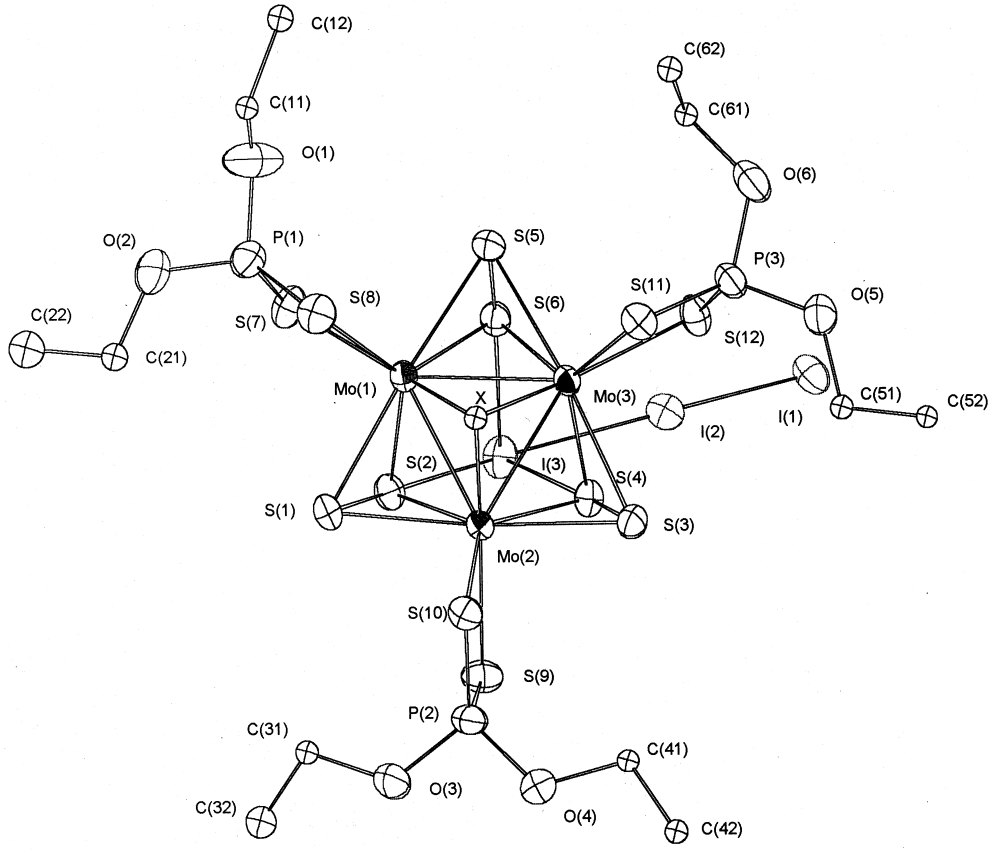

Fig. 1. Structure of the cluster $[Mo_3X(S_2)_3(dtp)_3(I_3)]$ (X = O, S).

contact ($\sim$4.00 Å) [13], showing weak bonding interaction between the S and I atoms. The I–I bond lengths of the I_3^- anion are 2.824(1) and 3.040(1) Å, which are comparable with the corresponding values found in the dinuclear cluster $[Mo_2(NTO)_2(dtp)_2S(O_2CMe)(SI_3)]_n$ reported by Jun et al. [14]. Another important feature lies in the packing structure. As shown in Fig. 2, the other terminal atom of I_3^- connects with the S(1), S(3) and S(10) atoms of two adjacent cluster molecules at S···I distances of 3.530(2), 3.641(2) and 3.648(2) Å, respectively. Thus three cluster molecules are joined together through the I_3^- anion, and a layer-like structure corresponding approximately to the (101) plane is formed in the unit cell. This is the first example of such M_2 type clusters.

3.2. About the formation mechanism

The title compound is an unexpected product according to the following reaction scheme:

$$Mo_3OS_3(dtp)_4\cdot H_2O + CuI \xrightarrow{\text{EtOAc, DMF, air}} Mo_3(X)(S_2)_3(dtp)_3\cdot I_3$$

In this sulfur-addition reaction, the source of the S atoms may come from the disruption of parts of the starting cluster $[Mo_3OS_3(dtp)_4\cdot H_2O]$, and the $(S_2)^{2-}$ groups are formed by the oxidative dimerization $2S^{2-} \rightarrow (S_2)^{2-}$ in air. Such reactions have been observed previously in our reaction system [15]. The I_3^- group may originate from the oxidation of CuI in air. Some capping O atoms were also substituted by S atoms during the reaction. As a result, two kinds of molecules, i.e. $Mo_3OS_6(dtp)_3(I_3)$ and $Mo_3S_7(dtp)_3(I_3)$ were cocrystallized at 58 and 42% occupancies, respectively.

3.3. Energy band structure

In order to study the electronic structure of the cluster with layer-like packing structure, we used the tight-binding method within the extended Hückel scheme [16,17] to calculate the energy band, which is shown in Fig. 3. Analysis of the composition of the bands shows that the bands around E_f consist mainly of the contributions of I, Mo and S atoms. There are many bands near E_f, and the band gap is very narrow; furthermore, there is a band crossing through several bands while bending to E_f, which shows that the crystal is a typically anisotropic semiconductor. The main compositions of this band are the components of I and S atoms, indicating that it is the I···S interaction that causes the charge transfer between the clusters.

3.4. Density functional calculation

DFT calculations have been performed on this cluster compound using the Amsterdam Density Functional package

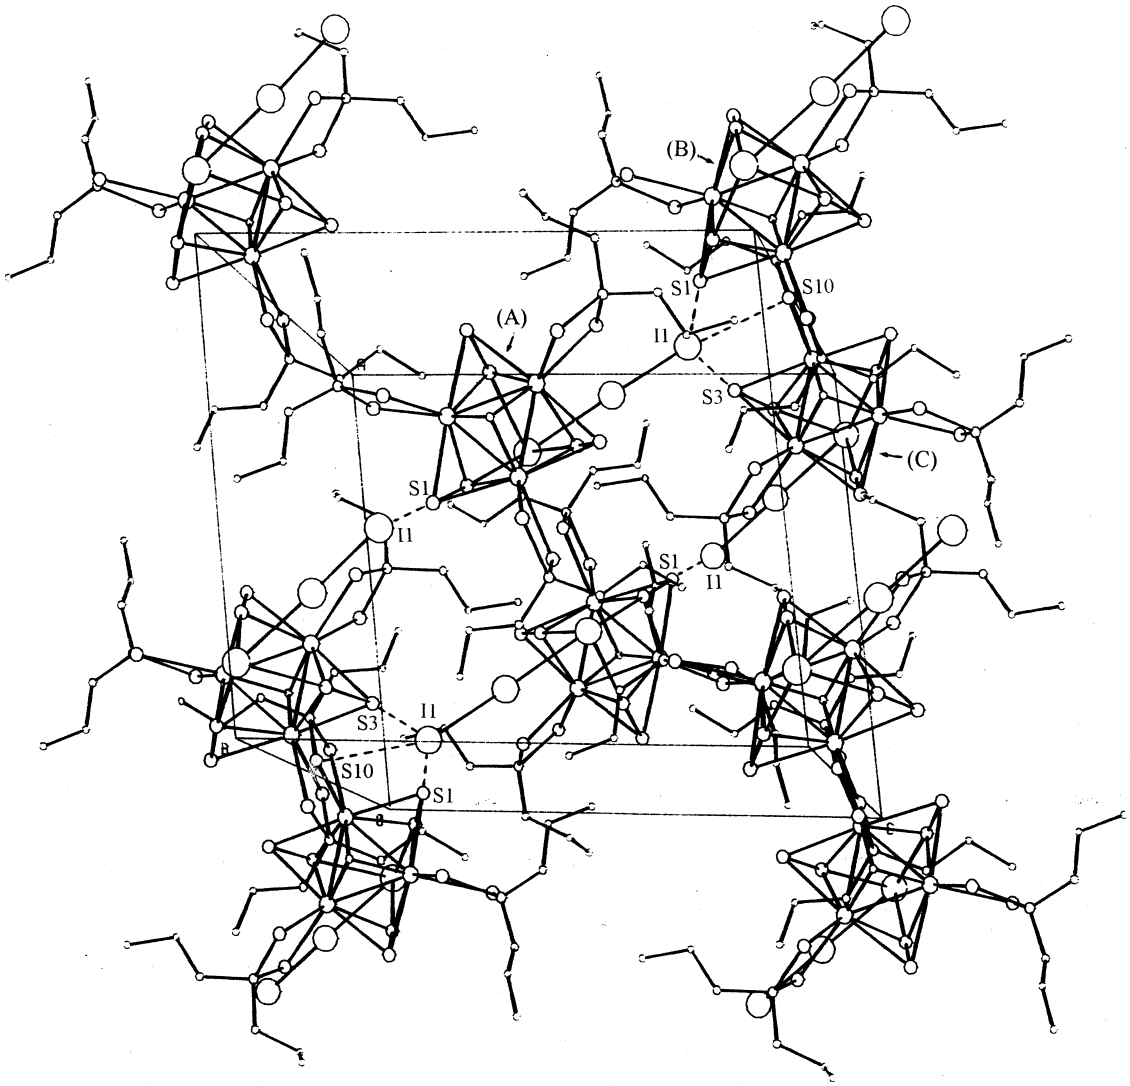

Fig. 2. Packing diagram of $[Mo_3X(S_2)_3(dtp)_3(I_3)]$.

(ADF) developed by Baerends et al. [18]. An uncontracted double-ξ STO basis set has been used for 5s, 5p, and 4d orbitals of molybdenum atoms, for 5s, 5p orbitals of iodine atoms, and for ns, np of S, P, O, C atoms. The calculations have been performed on the LSD level, and the VWN [19] approximation with Becke [20] and Perdew's [21] non-local corrections has been used.

The electronic structures of $[Mo_3S_7]^{4+}$ and $[Mo_3S_7(dtc)_3]^{+}$ have been carefully studied using ADF by Mayor-Lopez et al. [22]. In their work the electronic structure of $[Mo_3OS_6]^{4+}$ which is very similar to those of $[Mo_3S_7]^{4+}$ and $[Mo_3S_7(dtc)_3]^{+}$ was calculated, and so we do not describe it here but will focus on the interaction between I_3 and the cluster. As the oxygen component is the major component of the μ_3-X atom in the cluster $[Mo_3X(S_2)_3(dtp)_3I_3]$, we use $[Mo_3O(S_2)_3(dtp)_3I_3]$ in the study of the electronic structure.

From the crystal cell packing diagram of the cluster we can see that each I_3^- connects with three cluster molecules A, B and C in different ways. I(3) connects with molecule A by three intramolecular I–S_{ax} distances at 3.270(2), 3.307(2) and 3.364(2) Å. I(1) connects with two adjacent cluster molecules: one by I(1)···S(1) with molecule B at 3.530(2) Å, and the other by I(1)···S(3) and I(1)···S(10) with molecule C at 3.641(2) and 3.648(2) Å. Thus we calculated four structures: I_3^- with molecule A, I_3^- with molecule B, I_3^- with molecule C, and the cluster core $[Mo_3O(S_2)_3]$ itself. In order to reduce the computing time, we substituted $O(CH_3)_2$ for the group $O(CH_2CH_3)_2$, which is not expected to influence the electronic structure of the I_3^- and $[Mo_3OS_6]$ moieties significantly.

The calculated total binding energies (E_b) between I_3 and clusters are listed in Table 3 ($E_b = E(\text{cluster and } I_3) - E(\text{cluster}) - E(I_3)$).

From Table 3 we can see that the binding energy between I_3 and molecule A is much larger than that of a common hydrogen bond (about 10–20 kcal mol^{-1}) and the binding energy between I_3 and molecule B (or C), but is less than a

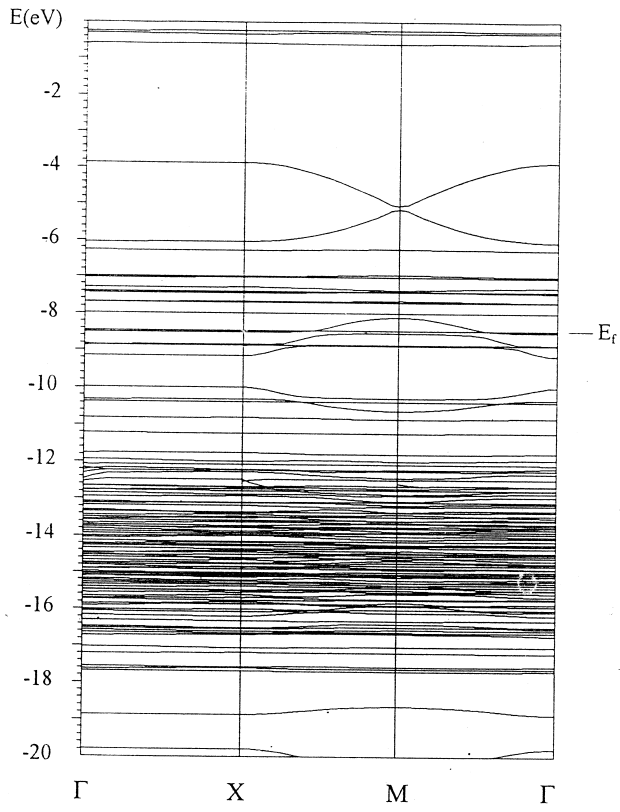

Fig. 3. Band structure of $[Mo_3X(S_2)_3(dtp)_3(I_3)]$.

normal covalent bond. The interactions between I_3 and molecule B, I_3 and molecule C are also stronger than the hydrogen bond. Thus we believe that there exist relatively strong interactions between I_3 and its adjacent molecules, and the cluster cores are connected to form a layer-like structure through I_3. The order of the binding energies between I_3 and the three molecules is the same as that of the distances between I_3 and the adjacent S atoms among the clusters.

Table 3
Binding energies between I_3 and the cluster molecules

	Molecule A and I_3	Molecule B and I_3	Molecule C and I_3
E_b (kcal mol^{-1})	55.690	45.682	40.47
HOMO–LUMO gap (eV)	0.915	0.139	0.029

Now we describe the electronic structure of the clusters. The main constitution of the frontier orbitals of the calculated structures is displayed in Tables 4–6. The frontier occupied orbitals are mainly from I and S, and the unoccupied orbitals are from Mo and S. Here the S atoms denote those in $[Mo_3OS_6]$, while the S atoms of the ligand contribute little to the frontier orbitals. By a more detailed analysis we find that the occupied orbitals are p–π* (p orbital of I with π* of Mo_3OS_6), p–σ* (p orbital of I with σ* of Mo_3OS_6) and σ bonds within I_3, while the unoccupied orbitals are all from Mo_3OS_6. The overlap between the orbitals of I_3 and molecule A is much larger than those between the orbitals of I_3 and molecule B (or C). The HOMO–LUMO gaps of the three calculated complexes are very narrow (see Table 3), and the orbitals of S and I overlap each other, just like the results of EHT calculation. The DFT calculation also supports the conclusion that the crystal may be a semiconductor (conduction by I–S charge transfer).

4. Conclusions

The reaction of $Mo_3OS_3(dtp)_4 \cdot H_2O$ with CuI yielded a novel cluster $[Mo_3X(S_2)_3(dtp)_3(I_3)]$ (X = O, S) in which I_3^- can be viewed as an intermediary of the trinuclear unit aggregation. The energy band and density functional calcu-

Abstract

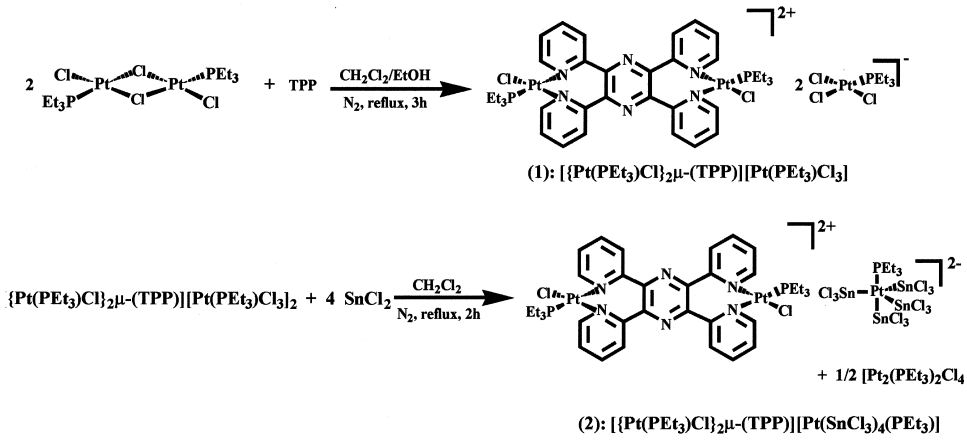
Reaction between 2,3,5,6-tetrakis(α-pyridyl)pyrazine (TPP) and the dimer $[Pt_2(PEt_3)_2Cl_4]$ yielded an ionic complex of formula $[\{Pt(PEt_3)Cl\}_2\mu\text{-}(TPP)][Pt(PEt_3)Cl_3]_2$ (**1**), in which TPP behaves as a bis(bidentate) ligand between the two Pt atoms of the cation. Insertion of $SnCl_2$ into the Pt–Cl bonds of this compound led to an unusual rearranged product, $[\{Pt(PEt_3)Cl\}_2\mu\text{-}(TPP)][Pt(SnCl_3)_4(PEt_3)]$ (**2**), with a rare example of a pentacoordinate Pt(II) species in the anionic moiety, where Pt is at the centre of a trigonal bipyramid, in addition to two other square planar Pt atoms in the cationic moiety. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Insertion reactions; Platinum(II) complexes; Platinum–tin bimetallics; 2,3,5,6-Tetrakis(α-pyridyl)pyrazine

1. Introduction

Platinum(II) complexes containing trichlorostannyl groups are widely studied due to their ability to behave as homogeneous catalysts in olefin hydroformylation, hydrogenation and carbonylation, especially when the Sn:Pt ratio is large [1–4]. $SnCl_3^-$ groups are also important in the stabilization of a few unusual pentacoordinate Pt compounds [5–8], such as $[Pt(SnCl_3)_5]^{3-}$, $[Pt(SnCl_3)_4H]^{3-}$ and $[Pt(SnCl_3)_3L_2]^-$, where L = PEt_3 or $AsEt_3$.

The ligand 2,3,5,6-tetrakis(α-pyridyl)pyrazine (TPP) has been used as a bridge to prepare several bimetallic complexes, in which TPP is bis-tridentate [9–14]. However, there is no example of a bis-bidentate coordination mode for this ligand. Reaction between the $[Pt(PEt_3)Cl_2]_2$ bridging dimer and TPP led to the isolation of $[\{Pt(PEt_3)Cl\}_2\mu\text{-}(TPP)]$-$[Pt(PEt_3)Cl_3]_2$. $SnCl_2$ insertion was performed on this complex, for the following reasons: in addition to having a large cation, which is an essential requisite for stabilizing large anionic complexes, our precursor complex provided a means of having different kinds of Pt–Cl bonds into which $SnCl_2$ insertion might be attempted. Only the anionic part was attacked, however, leading to a change in coordination number and the formation of a pentacoordinate anionic cluster, $[Pt(SnCl_3)_4(PEt_3)]^{2-}$, which was stabilized by the $[\{Pt(PEt_3)Cl\}_2\mu\text{-}(TPP)]^{2+}$ cation.



The present study allowed a series of correlations to be undertaken, namely between the molecular structure of the final product, on the one hand, and multinuclear NMR ($^{31}P\{^1H\}$, ^{119}Sn and ^{195}Pt) studies of both this complex and its precursor, on the other, which clearly established the nature of the novel heptametallic complex.

2. Experimental

All the reactions were carried out under N_2 in Schlenk glassware, with solvents purified by standard methods. 2,3,5,6-Tetrakis(α-pyridyl)pyrazine and $[Pt_2(PEt_3)_2Cl_4]$ were prepared according to the literature [15,16]. Scheme 1 shows the reactions from which the complexes **1** and **2** were prepared.

Scheme 1.

2.1. Synthesis of [{Pt(PEt$_3$)Cl}$_2$μ-(TPP)][Pt(PEt$_3$)Cl$_3$]$_2$ (1)

A 10-ml volume of a CH_2Cl_2 solution of [$Pt_2(PEt_3)_2Cl_4$] (301 mg, 0.392 mmol) was added under N_2 to 15 ml of an EtOH solution of TPP (76 mg, 0.196 mmol). The mixture was refluxed for 3 h, followed by reduction to one-quarter its original volume. Addition of n-hexane caused precipitation of a yellow product. This was filtered off and dried in vacuo. The solid was recrystallised from a 1:1 mixture of CH_2Cl_2–n-hexane. Yield 86%, m.p. 179–180°C. *Anal*. Found: C, 30.3; H, 3.9; N, 4.2; Pt, 40.5. Calc. for $C_{48}H_{76}N_6P_4Cl_8Pt_4$: C, 30.0; H, 4.0; N, 4.4; Pt, 40.5%.

2.2. Synthesis of [{Pt(PEt$_3$)Cl}$_2$μ-(TPP)][Pt(SnCl$_3$)$_4$(PEt$_3$)] (2)

Solid $SnCl_2$ (118 mg, 0.622 mmol) was added under N_2 to 11 ml of a CH_2Cl_2 solution of [{Pt(PEt_3)Cl}$_2$μ-(TPP)][Pt(PEt_3)Cl_3]$_2$ (299 mg, 0.156 mmol). After a 2 h reflux, during which the solution changed colour from yellow to brick, reduction to one-quarter of the initial volume, followed by addition of n-hexane, a red precipitate was formed. This was filtered off, washed with tetrahydrofuran (THF) and dried in vacuo. Attempts to obtain single crystals at this stage led to decomposition of the complex. Good crystals were later fortuitously obtained from the CD_3NO_2 solution used in the $^{31}P\{^1H\}$ NMR experiment. Yield 78%, m.p. 200°C (dec.). *Anal*. Found: C, 21.6; H, 2.3; N, 3.5; Pt, 26.0; Sn, 21.0. Calc. for $C_{42}H_{61}N_6P_3Cl_{14}Pt_3Sn_4$: C, 21.9; H, 2.7; N, 3.7; Pt, 25.5; Sn, 20.7%.

$^{31}P\{^1H\}$, ^{195}Pt and ^{119}Sn NMR spectra were obtained in different solvents using a DRX400 Bruker Avance instrument, with 85% H_3PO_4, K_2PtCl_4 and Me_4Sn, respectively, as external references. The pertinent NMR data are shown in Table 1. Red prismatic single crystals of [{Pt(PEt_3)Cl}$_2$μ-(TPP)][Pt($SnCl_3$)$_4$(PEt_3)] were collected from a CD_3NO_2 solution previously used in NMR studies, and the crystallographic data collection was performed on a Siemens P4 diffractometer equipped with graphite monochromator Mo Kα radiation ($\lambda = 0.71073$ Å), using XSCANS software [17]. Several well-formed red crystals were selected by optical analyses in a polarized light microscope and mounted on glass fibre using epoxy glue. The crystals were optically centred in the X-ray beam and rotation photographics and peak profiles of representative reflections were used to choose the best crystal, which was then used in subsequent data collection. The molecular structure of [{Pt(PEt_3)Cl}$_2$μ-(TPP)]-[Pt($SnCl_3$)$_4$(PEt_3)] is shown in Fig. 1.

Crystal data: $C_{42}H_{61}N_6P_3Cl_{14}Pt_3Sn_4$, $M = 2299.21$, triclinic space group $P\bar{1}$, $a = 9.994(2)$, $b = 18.839(3)$, $c = 20.772(3)$ Å; $\alpha = 66.02(1)$, $\beta = 85.62(1)$, $\gamma = 78.90(1)°$; $V = 3506.5(10)$ Å^3; $Z = 2$; $D_c = 2.178$ Mg m^{-3}; $\mu = 7.997$ mm^{-1}. The structure of the crystal ($0.15 \times 0.15 \times 0.20$ mm) was solved by direct methods and analysis of Fourier difference map. Hydrogen atoms were placed in calculated positions. Full-matrix least-squares methods were employed in

3. Results and discussion

A complex formulated as $(Et_4N)_2[Pt(SnCl_3)_4(PEt_3)]$ has been described in the literature; its structure was suggested on the basis of an NMR study [19]. In our case, both the molecular structure and NMR analysis are presented. The present case also differs from previous examples in the literature in that we have a complex anion of a complex bimetallic cation.

Table 1 shows the NMR data for compounds **1** and **2**. Complex **1** shows two $^{31}P\{^1H\}$ signals at δ 5.42 and 4.25, with two sets of satellites, corresponding to $^1J_{PtP}$ values of 3350 and 3707 Hz, respectively. The former was assigned to the less shielded phosphorus *trans* to nitrogen in the cationic moiety of compound **1**, whereas the latter was associated with phosphorus *trans* to chloride in the anionic species. The $^1J_{PtP}$ values are consistent with this assignment [20], since the Pt–N bond is stronger than the Pt–Cl bond, implying less PtP coupling in the cationic moiety compared with the anionic part of complex **1**. Complex **2** also shows two P signals, at δ 5.95 and 7.82, with $^1J_{PtP}$ values of 3299 and 2377 Hz, respectively. The cationic part hardly changed in both chemical shift and $^1J_{PtP}$, whereas the anionic species became more shielded and underwent a considerable decrease in its $^1J_{PtP}$, which can be accounted for by its being *trans* to the very strong $SnCl_3^-$ π acceptor.

Table 1 also shows the ^{195}Pt NMR data for compounds **1** and **2**. Complex **1** presents two doublets at δ –3448 and –3522, with $^1J_{PtP}$ values of 3368 and 3702 Hz, respectively. The first of these absorptions corresponds to the cation Pt atoms, with the signals somewhat broadened as a result of the fact that the Pt atoms are bound to N atoms, which exhibit a quadrupolar nuclear effect. The PtP couplings are the same, within experimental error, as those observed in the $^{31}P\{^1H\}$ NMR measurements.

Complex **2** also shows two doublets, relative to two types of Pt atoms in totally different chemical environments. The doublet centred at δ −3459, with $^1J_{PtP} = 3299$ Hz, was assigned to the tetracoordinate cationic Pt atoms, whereas the doublet at δ −5560, with $^1J_{PtP} = 2378$ Hz, was assigned to the pentacoordinate anionic Pt atom. One can see that for the tetracoordinate Pt atoms the values of both δ and $^1J_{PtP}$ remained very similar to those of complex **1**, as expected. It is important to note how the presence of the strong $SnCl_3^-$ π-acceptor groups affects $^1J_{PtP}$ of the pentacoordinate moiety, dramatically lowering its value (from 3702 to 2378 Hz), compared to that of complex **1**. The great downward change in chemical shift between the ^{195}Pt signals shown by the anionic parts of complexes **1** and **2** reflects the much enhanced shielding shown by the Pt nucleus in the latter. It was not possible here to observe the ^{119}Sn satellites in the ^{195}Pt NMR spectrum, even after the temperature was lowered to −50°C, and the coupling between Pt and Sn could only be observed in the ^{119}Sn spectrum.

The ^{119}Sn NMR spectrum of complex **2** was obtained at −90°C, and allowed us to distinguish two types of Sn atoms in a 3:1 ratio. The signal at δ −84.7 presents $^2J_{SnP} = 230$ Hz, and ^{195}Pt satellites with $^1J_{PtSn} = 19328$ Hz; this was assigned to the equatorial Sn atoms. In contrast, the signal at δ −173.6,

with $^2J_{SnP} = 2439$ Hz and $^1J_{PtSn} = 5967$ Hz, was assigned to the axial Sn atom. Of course, equatorial $SnCl_3^-$ groups will produce much greater SnPt coupling constants than axial groups, taking into account the enhanced Pt–Sn back-donation in the former compared to the latter. As expected also, $^2J_{SnP}$ values follow an inverse order; that is, the equatorial Sn atoms, which are approximately at a 90° angle to the P atom, show lower $^2J_{SnP}$ values than the axial Sn atom, which is at an angle of approximately 180° to the P atom. Finally, the ^{119}Sn NMR spectrum also gives the $^2J_{SnSn}$ couplings; as the data in Table 1 show, two equatorial Sn atoms present a much higher $^2J_{SnSn}$ value (15800 Hz) than an equatorial and the apical Sn atom (1330 Hz).

Fig. 1 shows the molecular structure of complex **2**, and Table 2 gives a selected number of bond distances and angles. One can see that there is an excellent agreement between the NMR results and the crystallographic data; that is, the complex retains its solid-state structure when dissolved. The Pt(1) and Pt(2) sites in the cationic part of the complex are joined by the TPP ligand and coordinated in a bidentate mode to the pyridine nitrogens in a slightly distorted square planar geometry. It is interesting to note in the cationic part of the complex that the Pt(1)–N(3) and Pt(2)–N(5) bond distances are significantly longer than Pt(1)–N(4) and Pt(2)–N(6), respectively, as a result of the more efficient Pt–P bonding as compared to Pt–Cl. As a consequence, the bonds *trans* to the phosphorus atoms will be weakened, hence their longer distances.

The structure of the cationic moiety also shows that the two PEt_3 groups are in a *sym–trans* configuration, probably due to steric requirements in the solid state.

The anionic site presents a distorted trigonal bipyramidal geometry, in which the phosphine occupies an axial position *trans* to Sn(1). The Sn(2), Sn(3) and Sn(4) atoms lie on the equatorial plane, from which Pt(3) is 0.169 Å away, towards P(3). In spite of this position of Pt(3), on the average, the Pt(3)–Sn_{eq} bonds are longer than Pt(3)–Sn(1). This is in accordance with the expectation that in d^8 TBP transition metal complexes the metal–axial ligand bonds ought to be shorter than the metal–equatorial ligand bonds [21]. In addition, the fact that any Pt(3)–Sn bond is significantly shorter than the sum of the covalent radii (≈ 2.80 Å) suggests some degree of multiple bonding in Pt–Sn, including a considerable π Pt → Sn back-bonding [22–24]. This is corroborated by the greater Pt(3)–P(3) bond distance compared to Pt(1)–P(1) and Pt(2)–P(2), consistent with the strong *trans* influence provided by the $SnCl_3^-$ group (and also shown in the respective $^1J_{PtP}$ coupling constants).

Supplementary data

Crystallographic data have been deposited at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk). The deposition number for this compound is CCDC 12390.

Abstract

Reaction of L^1 ($L^1 = Ph_2P(CH_2)_2O(CH_2)_2O(CH_2)_2PPh_2$) with $[Cu(MeCN)_4]PF_6$ or $AgBF_4$ in CH_2Cl_2 solution yields the complexes $[Cu(L^1)]PF_6$ and $[Ag(L^1)]BF_4$ respectively as white solids. Spectroscopic measurements are consistent with coordination via the P-donors and the crystal structure of $[Ag(L^1)]BF_4$ confirms that L^1 acts as a *trans*-chelate giving an unusual example of approximately linear P_2-coordination at Ag(I) ($\angle$P–Ag–P = 164.66(4)°) and, despite the availability and proximity of the ether O atoms, these remain essentially uncoordinated (Ag···O = 2.95 Å), thus reflecting the low affinity of the soft Ag(I) ion for hard O-donor ligands. $[AuCl(tht)]$, L^1 and $TlPF_6$ react in a 1:1:1 molar ratio in MeCN solution to yield the analogous Au(I) species $[Au(L^1)]PF_6$, the structure of which also shows linear P_2-coordination and once again the O-donors are non-coordinating, at a distance of ca. 3.16 Å from Au(I). The neutral dinuclear species $[(AuCl)_2(L^1)]$ is readily formed by reaction of $[AuCl(tht)]$ with L^1 in a 2:1 molar ratio in MeCN. Confirmation of the coordinated Cl ligands comes from IR spectroscopy, ν(Au–Cl) = 324 cm^{-1}, and $\delta(^{31}P)$ which is indicative of a PCl donor set at Au(I). This arrangement is confirmed in the solid state from the crystal structure. The related phosphathia complex $[(AuBr)_2(L^2)]$ ($L^2 = Ph_2P(CH_2)_2S(o\text{-}C_6H_4)S(CH_2)_2PPh_2$) is prepared similarly from $[AuBr(tht)]$ and L^2 in MeCN solution and its structure reveals the AuBr units each coordinated to one P-donor and directed to the same side as the *o*-C_6H_4 unit. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Our interest in multidentate mixed P/S-, P/N- and P/O-donor ligands, in which the phosphine functions are located at the termini, stems mainly from the fact that complexes of these ligands offer a wide structural diversity, and incorporation of two different donor types within a single ligand may lead to unusual properties. Phosphine ligation may enhance the binding properties of the poorer thioether functions or of the hard amine or ether functions or, alternatively, these functions may simply act as spacers between the phosphines. To date, our work has mainly focused on the phosphathia ligands and we have shown, for example, that $Ph_2P(CH_2)_2S(CH_2)_2S(CH_2)_2PPh_2$ (L^3) coordinates to Pt(II) and Pt(IV) via both the P and the S donor atoms in $[Pt(L^3)]^{2+}$ and $[PtX_2(L^3)]^{2+}$, generating square planar and octahedral species respectively [1]. In contrast, in the Au(I) species $[Au(L^3)]PF_6$ we observe primary P_2-coordination, with weak interactions to the thioether donors at ca. 3.0 Å. L^3 can also act as a bridging ligand, e.g. in $[Au_2(L^3)_2]Cl_2$, which adopts a helical metallocyclic cavity which hosts one of the Cl^- anions [2–4]. In view of the unusual structures adopted by these phosphathia ligand complexes we were interested to investigate the effect of substituting the thioether functions for the much harder ether functions, since the combination of hard and soft donors may lead to other unusual characteristics. A variety of transition metal complexes of the mixed P/O-donor ligand $Ph_2P(CH_2)_2O(CH_2)_2O(CH_2)_2PPh_2$ (L^1) are known, including *cis*- and *trans*-$[MX_2(L^1)]$ (M = Ni, Pd or Pt, X = Cl, Br or I) [5–7], and the Rh(I) species $[Rh(L^1)(EtOH)(CO)]PF_6$ [8]. Gray and co-workers have also investigated metallocyclic species containing the related P_2O_n-donor ligands L ($L = Ph_2P\{(CH_2)_2O\}_n(CH_2)_2PPh_2$, n = 3–5), e.g. *cis*-$[Mo(CO)_4(L)]$ [9], which involve bidentate P_2-coordination with the O-donors non-coordinating. The Pt(II) species $[PtX_2(L)]$ also show P_2-coordination and treatment of these species with a halide abstractor affords the species $[Pt(H_2O)(L)]^{2+}$, which involve coordination of L

PII S0277-5387(00)00291-6

to Pt(II) via both P-donor atoms and one ether O-donor [10]. The closely related metallocrown ether complex $[PdX_2\{Ph_2P(CH_2CH_2O)_4CH_2CH_2PPh_2\text{–}P,P'\}]_n$ (X = Cl or I) shows a unique and reversible mode of molecular recognition in which PdX_2 units are incorporated into the metallocrown ether ring via a ring-expansion [11].

We describe herein the preparation and characterisation of a series of transition metal complexes incorporating the mixed P/O-donor ligand L^1, including the crystal structures of $[Ag(L^1)]BF_4$, $[Au(L^1)]PF_6$ and $[(AuCl)_2(L^1)]$. The crystal structure of the phosphathia ligand complex $[(AuBr)_2(L^2)]$ is also included.

2. Results and discussion

The ligand L^1 was prepared using a modification of the literature procedure [6]. $LiPPh_2$ was generated in situ by reaction of Li metal with PPh_3 in thf solution. The LiPh byproduct was then destroyed by addition of ^tBuCl and $Cl(CH_2)_2O(CH_2)_2O(CH_2)_2Cl$ was added. The resulting mixture was refluxed for 1 h. After work-up and recrystallisation of the product from CH_2Cl_2/hexane, L^1 was obtained in good yield. When the reaction was attempted without refluxing, $^{31}P\{^1H\}$ NMR studies showed considerable amounts of starting material, along with some mono-substituted product and traces of L^1.

Treatment of $[Cu(MeCN)_4]PF_6$ with one molar equivalent of L^1 in CH_2Cl_2 solution, followed by precipitation with Et_2O, yields a white solid. Electrospray mass spectrometry shows peaks at 549 and 551 indicative of $[^{63/65}Cu(L^1)]^+$, with no significant peaks at higher *m/z*. The IR spectrum shows no evidence for any remaining coordinated MeCN, but peaks corresponding to coordinated L^1 and free PF_6^- are clearly evident. ^1H NMR spectroscopy and microanalyses are consistent with the formulation $[Cu(L^1)]PF_6$ for the product. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at −16.2 ppm (broadened owing to direct bonding to quadrupolar $^{63/65}Cu$) arising owing to the coordinated L^1 and a septet due to the PF_6^- anion centred at −146 ppm. The NMR spectra were recorded using thoroughly degassed solvents, since upon the introduction of air to the solution the $^{31}P\{^1H\}$ NMR spectrum also shows a resonance at +29.5 due to oxidised phosphine. These data indicate the formulation $[Cu(L^1)]PF_6$ for the product, and suggest that coordination to Cu(I) is via the P-donors.

The corresponding Ag(I) species, $[Ag(L^1)]BF_4$, was obtained as a white, light-sensitive solid by reaction of $AgBF_4$ with L^1 in MeCN in a foil-wrapped flask, followed by concentration of the solution and addition of Et_2O. The IR spectrum shows peaks indicative of coordinated L^1 as well as peaks at ca. 1053 and 525 cm^{-1}, corresponding to free BF_4^- anion. The APCI mass spectrum shows peaks at *m/z* 593 and 595, corresponding to $[^{107/109}Ag(P_2O_2)]^+$. These data, together with ^1H NMR spectroscopic and microanalytical data, indicate the formulation $[Ag(L^1)]BF_4$ for the product. The $^{31}P\{^1H\}$ NMR spectrum of this species shows (Fig. 1) two doublets at −3.4 ppm with $^1J(^{109}Ag\text{–}P) = 601$ Hz and $^1J(^{107}Ag\text{–}P) = 523$ Hz. These data are consistent with coordination of L^1 to Ag(I) via the two P-donor atoms [12]. The coupling constants for this species are larger than those observed for the phosphathia ligand analogues, e.g. $[Ag\{Ph_2P(CH_2)_2S(CH_2)_2S(CH_2)_2PPh_2\}]^+$ which gave $^1J(^{109}Ag\text{–}P) = 510$ Hz and $^1J(^{107}Ag\text{–}P) = 445$ Hz [2–4], although the $^1J(^{107}Ag\text{–}P)$:$^1J(^{109}Ag\text{–}P)$ ratio of 0.87 is the same, and this is consistent with the ratio expected from the respective nuclear magnetic moments of the two nuclei. $^1J(^{107}Ag\text{–}P)$ for the two-coordinate species $[Ag\{P(tol)_3\}]_2PF_6$ and $[Ag(P^tBu_3)_2]BF_4$ are reported as 496 and 444 Hz respectively [12,13], while the crystallographically authenticated two-coordinate $[Ag\{P(NMe_2)_3\}_2]$-BPh_4 shows $^1J(^{107}Ag\text{–}P) = 610$ Hz [14].

In order to confirm the 1:1 Ag:L^1 stoichiometry and to establish unequivocally the coordination mode of L^1 to Ag(I), a single crystal structure determination was undertaken. The crystal structure of $[Ag(L^1)]BF_4$ confirms (Fig. 2, Table 1) that L^1 functions essentially as a *trans*-chelating ligand, giving an approximately linear arrangement at Ag(I) with $d(Ag\text{–}P) = 2.402(1)$ Å, and with a P–Ag–P angle of 164.66(4)°. The Ag···O distances of ca. 2.95 Å are possibly indicative of very weak interactions, but are probably simply a consequence of the bite angle of the diphosphine unit in L^1. Both the large P–Ag–P angle and the observation that the P, O and Ag atoms are approximately co-planar, provide strong evidence that the O-donor atoms are not coordinating. L^1 is expected to be sufficiently flexible to accommodate a distortion towards the tetrahedral geometry usually favoured by four coordinate Ag(I). Both the cation and the BF_4^- anion have crystallographic two-fold symmetry, with the Ag and B atoms sitting on two-fold axes. Although Ag(I) has a much greater affinity for soft donor atoms such as phosphines rather

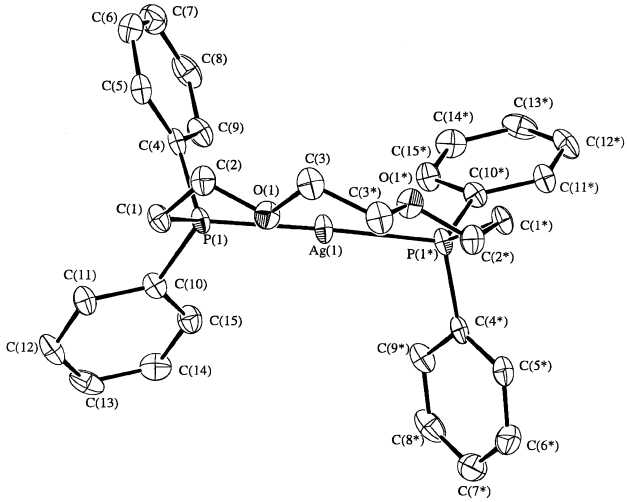

Fig. 2. View of the structure of $[Ag(L^1)]^+$ with the numbering scheme adopted. Atoms marked * are related by a crystallographic two-fold axis. Ellipsoids are drawn at the 40% probability level and H atoms are omitted for clarity.

Table 1
Selected bond lengths (Å) and angles (°) for $[Ag(L^1)]BF_4$

Ag(1)–P(1)	2.402(1)
P(1)–Ag(1)–P(1*)	164.66(4)
Ag(1)–P(1)–C(1)	113.9(1)
Ag(1)–P(1)–C(4)	109.0(1)
Ag(1)–P(1)–C(10)	116.8(1)

than hard ether functions, significant Ag–O(ether) interactions have been observed, for example, in the mixed thia/oxa macrocyclic species $[Ag_n([15]aneS_2O_3)_n](PF_6)_n$ ([15]aneS_2O_3 = 1,4,7-trioxa-10,13-dithiacyclopentadecane) (Ag–O = 2.492(4)–2.690(4) Å) [15] and $\{[Ag_2([18]aneS_2O_4)_2]_2\}(PF_6)_4$ ([18]aneS_2O_4 = 1,4,7,10-tetraoxa-13,16-dithiacyclohexadecane) (Ag–O = 2.458(7)–2.661(6) Å) [16], hence there is no inherent reason for the O-donors not interacting with the Ag(I) ion. Only two mononuclear Ag(I) complexes involving genuine P_2-coordination have been structurally characterised previously, [Ag(trimesitylphosphine)$_2$]PF_6 (P–Ag–P = 179.4(5)°, Ag–P = 2.461(6) Å) [17,18] and $[Ag\{P(NMe_2)_3\}_2]BPh_4$ (P–Ag–P = 166.9(1)°, Ag–P = 2.395(2), 2.393(2) Å) [14]. Several bis(phosphine)–silver(I) species involving ClO_4^- or NO_3^- are known, although these also involve coordination via the O-donors of the anions and this results in a much smaller P–Ag–P angle, e.g. $[Ag\{PPh_2(C_5H_9)\}_2]ClO_4$, Ag–P = 2.397(2)–2.432(2) Å, Ag···O = 2.662(5), 2.709(5) Å, ∠P–Ag–P = 145.1(1), 153.0(1)° [19], $[Ag(PCy_3)_2(NO_3)]$, Ag–P = 2.440(3), 2.445(3) Å, Ag–O = 2.45(1), 2.73(1) Å, ∠P–Ag–P = 139.04(9)° [20], $[Ag(PCy_3)_2]ClO_4$, Ag–P = 2.429(1), 2.432(1) Å, Ag···O = 2.720(7) Å, ∠P–Ag–P = 147.34(3)° [20].

Reaction of L^1 with [AuCl(tht)] in a 2:1 molar ratio in MeCN gave the neutral dinuclear species $[(AuCl)_2(L^1)]$ which was isolated by precipitation with Et_2O from a concentrated solution. The IR spectrum confirms the presence of L^1 and a peak at 327 cm^{-1} is attributed to ν(Au–Cl). This compares with 324 cm^{-1} for $[(AuCl)_2(L^2)]$ [2–4]. The APCI mass spectrum shows peaks with the correct isotopic distribution at *m/z* 915, corresponding to $[Au_2(L^1)Cl]^+$. Further peaks at lower *m/z* correspond to loss of Cl or Au from the complex. The $^{31}P\{^1H\}$ NMR spectrum shows a single resonance at +23.3 ppm, which is comparable with $\delta(^{31}P)$ for the previously synthesised $[(AuCl)_2(L^2)]$ (25.3 ppm) [2–4].

The crystal structure of $[(AuCl)_2(L^1)]$ shows (Fig. 3, Table 2) each gold atom coordinated to one P-donor from L^1 and one Cl ligand, giving essentially linear coordination, with no interaction between the Au centres and the O-donor atoms. The Cl–Au–P angles are 174.2(2) and 174.1(3)°. The L^1 backbone adopts a twisted conformation with the AuCl units pointing in the same direction.

We have reported previously the preparation and spectroscopic characterisation of the species $[(AuCl)_2(L)]$ ($L = L^2$, L^3 or L^4) ($L^4 = Ph_2P(CH_2)_2S(CH_2)_3S(CH_2)_2PPh_2$) although their structures were not authenticated crystallographically [2–4]. In order to provide a comparison with

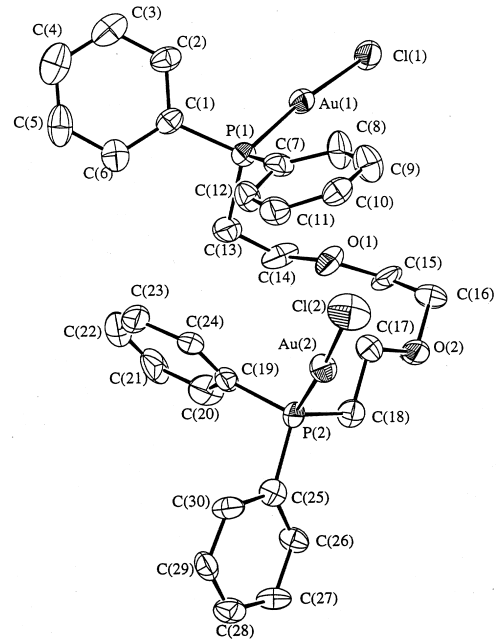

Fig. 3. View of the structure of $[(AuCl)_2(L^1)]$ with numbering scheme adopted. Ellipsoids are drawn at 40% probability and H atoms are omitted for clarity.

Table 2
Selected bond lengths (Å) and angles (°) for $[(AuCl)_2(L^1)]$

Au(1)–Cl(1)	2.295(5)	Au(1)–P(1)	2.231(5)
Au(2)–Cl(2)	2.279(5)	Au(2)–P(2)	2.219(5)
Cl(1)–Au(1)–P(1)	174.2(2)	Cl(2)–Au(2)–P(2)	174.1(3)

Au(2)–P(2)–C(25)	115.5(6)		

$[(AuCl)_2(L^1)]$ above, we have prepared the species $[(AuBr)_2(L^2)]$ similarly from L^2 and [AuBr(tht)] in MeCN. The Au–Br stretching vibration occurs at 315 cm^{-1} for this species and $\delta(^{31}P)$ occurs as a singlet at 28.0 ppm, consistent with coordination of an AuBr fragment to each P-donor of L^2. A single crystal X-ray structure determination was also undertaken on a weakly diffracting crystal of $[(AuBr)_2(L^2)]$. The structure shows (Fig. 4) a dinuclear molecule with each Au(I) ion coordinated linearly to one P-donor from L^2 and one Br atom, with the S-donor atoms remaining non-coordinating. The molecule has crystallographic C_2 symmetry and the Au–P distances of 2.16(1) Å are slightly shorter than those in $[(AuCl)_2(L^1)]$ above, although since the structure quality is rather poor, geometric parameters should be treated with caution. The P–Au–Br angle is 177.5(4)°. The L^2 backbone adopts an approximately planar arrangement and the AuBr units lie on the same side of the backbone as the *o*-phenylene unit.

The 1:1 Au:L^1 complex, $[Au(L^1)]PF_6$ was prepared readily by treatment of [AuCl(tht)] with one molar equivalent of L^1 and $TlPF_6$ in MeCN to give a white precipitate (TlCl) and a colourless solution. Following removal of the TlCl by filtration through Celite, concentration of the solution and addition of Et_2O, a white precipitate was obtained. The IR spectrum of this product provides evidence for the presence of L^1 and PF_6^- (840, 555 cm^{-1}), and there is no evidence for an Au–Cl stretching vibration. The highest mass peak in the APCI mass spectrum appears at *m/z* 683, corresponding to $[Au(L^1)]^+$. These data, together with ^1H NMR spectroscopic and microanalytical data, suggest the formulation $[Au(L^1)]PF_6$ for the product. The $^{31}P\{^1H\}$ NMR resonance due to the coordinated L^1 occurs at 32.5 ppm, i.e. a higher frequency than that for $[(AuCl)_2(L^1)]$, and is indicative of a P_2-donor set at Au(I). The septet due to the PF_6^- anion occurs at −146.0 ppm.

This crystal structure of $[Au(L^1)]PF_6$ shows (Fig. 5, Table 3) L^1 acting as a *trans*-chelating ligand, bonded to Au(I) by the two P-donors (Au–P = 2.308(2), 2.311(2) Å), with the Au···O distances ca. 3.15 Å indicating no interaction, and demonstrating the indifference of Au(I) towards the hard O-donor atoms. Thus, this geometry is similar to that observed for $[Ag(L^1)]^+$ above. The Au–P distances in this cation are slightly shorter than the Ag–P distances in $[Ag(L^1)]^+$ and the P–Au–P angle of 171.85(9)° is larger than the corresponding P–Ag–P angle in the analogous Ag(I) species. Schmidbaur and co-workers have previously demonstrated that for the isomorphous species [Ag(trimesitylphosphine)$_2$]BF_4 and [Au(trimesitylphosphine)$_2$]BF_4, d(Ag–P) > d(Au–P) by almost 0.1 Å [18]; a similar trend is observed here. The structure of the analogous phosphathia complex $[Au(L^2)]PF_6$ shows similar primary Au–P interactions of 2.284(7) and 2.302(7) Å, although in this case long-range, weak Au···S interactions of ca. 3.0 Å are also observed in the solid state [2–4].

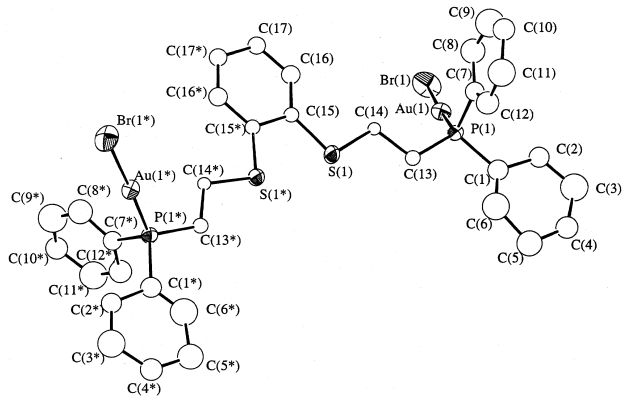

Fig. 4. View of the structure of $[(AuBr)_2(L^2)]$ with numbering scheme adopted. Ellipsoids are drawn at 40% probability. Atoms marked * are related by a crystallographic two-fold axis and H atoms are omitted for clarity. Au(1)–P(1) = 2.16(1) Å, ∠P(1)–Au(1)–Br(1) = 177.5(4)°.

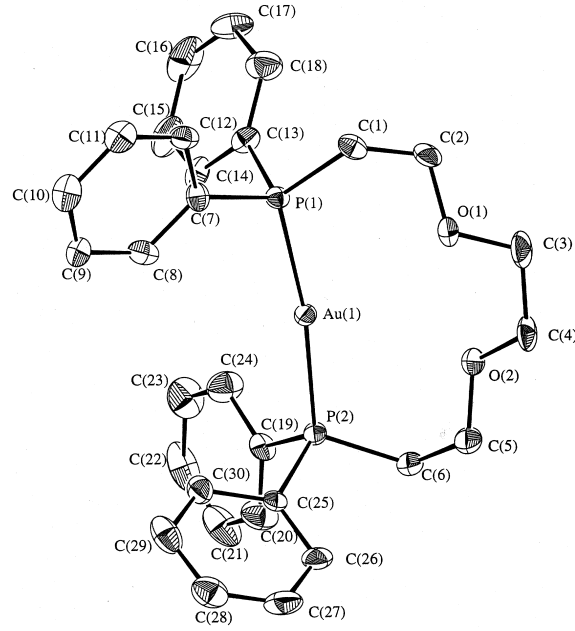

Fig. 5. View of the structure of $[Au(L^1)]^+$ with numbering scheme adopted. Ellipsoids are drawn at 40% probability and H atoms are omitted for clarity.

Table 3
Selected bond lengths (Å) and angles (°) for $[Au(L^1)]PF_6$

Au(1)–P(1)	2.308(2)	Au(1)–P(2)	2.311(2)
P(1)–Au(1)–P(2)	171.85(9)	Au(1)–P(1)–C(1)	117.4(3)

Au(1)–P(2)–C(25)	109.2(3)		

3. Experimental

Infrared spectra were recorded as KBr or CsI disks using a Perkin-Elmer 983 spectrometer over the range 4000–200 cm^{-1}. Mass spectra were run by positive electrospray or by APCI (atmospheric pressure chemical ionisation) in MeCN solution using a VG Biotech platform. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded in $CDCl_3$ using a Bruker AM300 spec-

trometer. $^{31}P\{^{1}H\}$ NMR spectra were recorded in CH_2Cl_2 containing ca. 10–15% $CDCl_3$ using a Bruker AM360 spectrometer operating at 145.8 MHz and are referenced to 85% H_3PO_4. Microanalyses were performed by the University of Strathclyde microanalytical service. L^2 was prepared according to the literature procedure [6].

3.1. Preparations

L^1: PPh_3 (30 g, 114 mmol) was dissolved in dry, degassed thf (300 cm^3) and freshly crushed Li (3 g, 432 mmol) was added in small pieces at room temperature. This reaction mixture was stirred for 12 h, before the remaining pieces of lithium were filtered off. ^{t}BuCl (9.9 cm^3, 91 mmol) was added dropwise and the mixture was stirred for 1 h at room temperature. $Cl((CH_2)_2O)_2(CH_2)_2Cl$ (7.5 cm^3, 0.4 equiv., 46 mmol) was added slowly and the mixture was heated to reflux for 1 h until it decolourised and a white precipitate formed. After cooling, degassed water (30 cm^3) was added dropwise. The organic layer was separated, the aqueous layer was washed with Et_2O and the combined organic extracts were dried over $MgSO_4$. The $MgSO_4$ was filtered off under nitrogen and the solvent was removed in vacuo. The residue was taken up in a small amount of CH_2Cl_2, then hexane was added. The mixture was stirred for a few minutes and subsequent cooling yielded a white precipitate which was filtered and dried in vacuo. Yield 10.7 g, 39%. *Anal*. Calc. for $C_{30}H_{32}O_2P_2$: C, 74.1; H, 6.6. Found: C, 73.7; H, 6.9%. ^{1}H NMR: δ 7.41–7.52 (m, 20H, Ph), 3.58 (m, 4H, OCH_2), 3.51 (s, 4H, OCH_2), 2.40 (m, 4H, CH_2P) ppm. $^{13}C\{^{1}H\}$ NMR: δ 28.9 (CH_2P), 68.7 (*C*H_2CH$_2$P), 70.2 (OCH_2CH_2O), 128.6 (*para*-C), 128.8 (*meta*-C), 132.8 (*ortho*-C), 138.5 (*ipso*-C) ppm. $^{31}P\{^{1}H\}$ NMR: δ −21.3.

$[Cu(L^1)]PF_6$: L^1 (0.100 g, 0.206 mmol) was dissolved in CH_2Cl_2 (30 cm^3) and $[Cu(CH_3CN)_4]PF_6$ (0.077 g, 0.206 mmol) was added in one portion. The mixture was stirred for 1 h and the volume was reduced to ca. 2 cm^3 in vacuo. Et_2O was then added to afford a white solid which was collected by filtration and dried in vacuo. Yield 0.085 g, 60%. *Anal*. Calc. for $C_{30}H_{32}O_2P_3F_6Cu$: C, 51.8; H, 4.6. Found: C, 52.4; H, 4.6%. ^{1}H NMR: δ 7.17–7.49 (m, 20H, Ph), 3.62–3.77 (m, 8H, CH_2), 2.59 (m, 4H, CH_2) ppm. $^{31}P\{^{1}H\}$ NMR: δ −16.2 (s, L^1), −146.2 (spt, PF_6^-) ppm. APCI mass spectrum: found *m/z* 551, 549, 487; calc. for $[^{65}Cu(L^1)]^+$ *m/z* 551, $[^{63}Cu(L^1)]^+$ 549, $[L^1]^+$ 486. IR spectrum (CsI disk): 3058w, 2985w, 2922w, 2873w, 1574w, 1485m, 1438s, 1403w 1360m, 1310w, 1161m, 1133s, 1101s, 999m, 841vs, 744s, 696s, 558m, 508m, 478m cm^{-1}.

$[Ag(L^1)]BF_4$: To a degassed solution of L^1 (0.100 g, 0.206 mmol) in MeCN (20 cm^3) at 0°C was added $AgBF_4$ (0.040 g, 0.206 mmol) and the resulting mixture was stirred for 1 h at room temperature in a foil-wrapped flask. The solution was then concentrated in vacuo to ca. 5 cm^3 and Et_2O was added to afford a white solid which was filtered, washed with Et_2O and dried in vacuo. Yield 0.096 g, 69%. *Anal*. Calc. for $[C_{30}H_{32}AgBF_4O_2P_2]$: C, 52.9; H, 4.7. Found: C, 52.6; H, 4.4%. Electrospray mass spectrum (MeCN): found *m/z* 595, 593, 487; calc. for $[^{109}Ag(L^1)]^+$ *m/z* 595, $[^{107}Ag(L^1)]^+$ 593, $[L^1]^+$ 486. ^{1}H NMR: δ 7.4–7.7 (m, Ph, 20H), 3.7 (m, CH_2O, 8H), 2.8 (m, CH_2P, 4H). $^{31}P\{^{1}H\}$ NMR: δ –3.4 (d, $^1J^{109}(Ag–^{31}P) = 601$ Hz, d, $^1J^{107}(Ag–^{31}P) = 523$ Hz). IR spectrum (CsI disk): 3055w, 2960w, 2917w, 2869w, 1572w, 1481m, 1461w, 1434m, 1410w, 1365m, 1350m, 1309w, 1284w, 1099s, 1053s, 1005s, 998s, 976w, 885m, 856m, 790w, 760s, 746s, 712m, 698s, 692s, 673w, 525m cm^{-1}.

$[Au(L^1)]PF_6$: To a solution of L^1 (0.100 g, 0.206 mmol) in degassed MeCN (20 cm^3) was added [AuCl(tht)] (0.066 g, 0.206 mmol). After stirring this mixture for 15 min, $TlPF_6$ (0.072 g, 0.206 mmol) was added and the reaction mixture was stirred for ca. 12 h. The resulting white precipitate (TlCl) was removed by filtration and the filtrate was concentrated in vacuo. Addition of Et_2O gave a white precipitate which was filtered, washed with Et_2O and dried in vacuo. Yield 0.054 g, 32%. *Anal*. Calc. for $[C_{30}H_{32}AuF_6O_2P_3]$: C, 43.5; H, 3.9. Found: C, 43.5; H, 3.6%. Electrospray mass spectrum (MeCN): found *m/z* 683, 487; calc. for $[Au(L^1)]^+$ *m/z* 683, $[L^1]^+$ 486. ^{1}H NMR: δ 7.5–7.8 (m, Ph, 20H), 3.8 (m, CH_2O, 4H), 3.6 (s, CH_2O, 4H), 2.9 (m, CH_2P, 4H). $^{31}P\{^{1}H\}$ NMR: δ 32.5 (s, L^1), −146.0 (spt, PF_6^-). IR spectrum (CsI disk): 3061w, 2980w, 2925w, 2866w, 1560w, 1482m, 1458w, 1435s, 1406w, 1362m, 1227w, 1186w, 1134s, 1114m, 1104s, 1063m, 1012m, 836vs, 789m, 744m, 713s, 696s, 690s, 558s, 529m, 509m 463m, 438w cm^{-1}.

$[(AuCl)_2(L^1)]$: To a solution of L^1 (0.100 g, 0.206 mmol) in degassed MeCN (30 cm^3) was added [AuCl(tht)] (0.130 g, 0.411 mmol). The mixture was stirred for 1 h before being concentrated in vacuo. Et_2O was then added to yield a white solid which was filtered, washed with Et_2O and dried in vacuo. Yield 0.060 g, 31%. *Anal*. Calc. for $[C_{30}H_{32}Au_2Cl_2O_2P_2]$: C, 37.9; H, 3.4. Found: C, 38.0; H, 3.4%. Electrospray mass spectrum (MeCN): found *m/z* 915, 683, 487; calc. for $[Au_2{}^{35}Cl(L^1)]^+$ *m/z* 915, $[Au(L^1)]^+$ 683, $[L^1]^+$ 486. ^{1}H NMR: δ 7.4–7.8 (m, Ph, 20H), 3.8 (m, CH_2O, 4H), 3.5 (s, CH_2O, 4H), 2.8 (m, CH_2P, 4H). $^{31}P\{^{1}H\}$ NMR: δ +23.3 (s, L^1). IR spectrum (CsI disk): 3049w, 2945w, 2911w, 2857w, 1560w, 1482m, 1433s, 1395w, 1368m, 1351m, 1289w, 1158w, 1129s, 1100s, 1009m, 998w, 980m, 905w, 864w, 763m, 744s, 698s, 690s, 544m, 525m, 487m, 476w, 327m cm^{-1}.

$[(AuBr)_2(L^2)]$: To a solution of L^2 (0.08 g, 0.0141 mmol) in degassed MeCN (30 cm^3) was added [AuBr(tht)] (0.103 g, 0.242 mmol). The resulting mixture was stirred for 1 h. The reaction volume was concentrated to 2 cm^3 in vacuo and Et_2O was added to give a white solid. Yield 0.115 g, 73%. *Anal*. Calc. for $[C_{34}H_{32}Au_2Br_2P_2S_2]\cdot Et_2O$: C, 38.1; H, 3.3. Found: C, 37.8; H, 3.0%. Electrospray mass spectrum (MeCN): found *m/z* 763, 566; calc. for $[Au(L^2)]^+$ *m/z* 763, $[L^2]^+$ 566. ^{1}H NMR: δ 7.1–7.7 (m, aromatic H, 24H), 2.6–3.2 (m, CH_2S, 8H). $^{31}P\{^{1}H\}$ NMR: δ 28.0 (s, L^1). IR spectrum (Nujol mull): 315 cm^{-1}.

3.2. X-Ray crystallography

Details of the crystallographic data collection and refinement parameters are given in Table 4. The crystals were grown by vapour diffusion of diethyl ether onto solutions of the complexes in CH_2Cl_2 at ca. −15°C or by slow evaporation from a solution of the complex in CH_2Cl_2/EtOH ($[Ag(L^1)]BF_4$). Data collection used a Rigaku AFC7S four-circle diffractometer equipped with an Oxford Systems open-flow cryostat operating at 150 K, using graphite-monochromated Mo Kα X-radiation ($\lambda = 0.71073$ Å). The structures were solved by heavy atom methods [21] and developed by iterative cycles of full-matrix least-squares and difference Fourier synthesis [22]. The weighting scheme $w^{-1} = \sigma^2(F)$ gave satisfactory agreement analyses.

$[Ag(L^1)]BF_4$: During data collection an 8.2% decrease in the intensity of the standard reflections was observed and hence a linear decay correction was applied. The initial cell was triclinic, and was solved to reveal one $[Ag(L^1)]^+$ cation and one BF_4^- anion occupying general positions. However, further analysis suggested a C-centred monoclinic cell, which was solved to reveal a half $[Ag(L^1)]^+$ cation and half BF_4^- anion, both with crystallographic two-fold symmetry. Although the final residuals for the monoclinic version are slightly higher ($R = 0.053$ versus 0.045) than for the triclinic solution, it does appear that the correct solution is as monoclinic C-centred. All non-H atoms were refined anisotropically while H-atoms were placed in fixed, calculated positions. Selected bond lengths and angles are given in Table 1.

$[Au(L^1)]PF_6$: All non-H atoms were refined anisotropically while H-atoms were placed in fixed, calculated positions. Selected bond lengths and angles are given in Table 3.

$[(AuCl)_2(L^1)]$: All non-H atoms were refined anisotropically and H atoms were included in fixed, calculated positions. Selected bond lengths and angles are given in Table 2.

$[(AuBr)_2(L^2)]\cdot 2CH_2Cl_2$: The data were collected from a weakly diffracting crystal, hence the structure quality is not as high as normal. The molecule possesses crystallographic C_2 symmetry and hence only half the molecule is present in the asymmetric unit. A CH_2Cl_2 solvent molecule was also identified in the asymmetric unit. At isotropic convergence a DIFABS [23] absorption correction was applied. In view of the weak data, only the Au, Br, S and P atoms were refined anisotropically. The H atoms were included in fixed, calculated positions.

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers 134142–134145.

Acknowledgements

We thank the EPSRC and the University of Southampton for support and Johnson Matthey plc for generous loans of gold salts. We also thank the crystallographic referee for suggesting the higher symmetry cell for $[Ag(L^1)]BF_4$.

POLYHEDRON

The reactions of $[M(dppe)_2]$ (M = Pd, Pt) with elemental selenium or tellurium: preparation and structure of the platinum polyselenide $[PtSe_4(dppe)]$

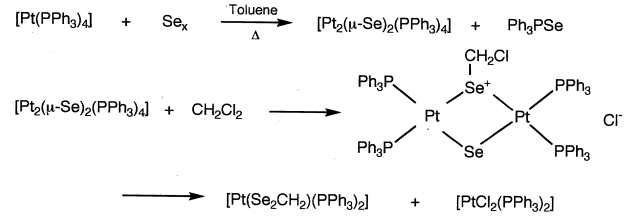
Abstract

Reaction of $[Pt(dppe)_2]$ (dppe = 1,2-bis(diphenylphosphino)ethane) with elemental selenium in toluene under reflux, or of $[PtCl_2(dppe)]$ with lithium polyselenide in tetrahydrofuran, leads in good yield to the complex $[PtSe_4(dppe)]$ whose structure has been determined by X-ray crystallography. Reaction of $[Pt(dppe)_2]$ with elemental tellurium, followed by treatment with dichloromethane, leads to isolation of the salt $[Pt_3(\mu_3\text{-}Te)_2(dppe)_3]Cl_2$. $[Pd(dppe)_2]$ reacts with elemental selenium to give $[Pd_2(\mu\text{-}Se)_2(dppe)_2]$ or $[Pd_3(\mu_3\text{-}Se)_2(dppe)_3]Cl_2$, depending on the conditions. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Palladium; Platinum; Selenium; Tellurium

1. Introduction

Investigations of the reactions of low-valent transition metal compounds with elemental selenium or tellurium are rare [1,2]. We are interested in the use of such reactions for the preparation of metal polychalcogenides, and the reactivity of the products towards activated alkynes to yield diselenolenes or ditellurolenes. These are the selenium and tellurium analogues of dithiolenes, which already have a variety of applications in materials chemistry [3]. The incorporation of heavier chalcogen atoms is an attractive synthetic target since this should lead to a smaller HOMO–LUMO gap, and an increase in the strength of intermolecular interactions in the solid state.



The platinum(0) and palladium(0) complexes $[M(PPh_3)_4]$ and $[M(dppe)_2]$ react with sulfur at room temperature, to yield both tetrasulfides $[MS_4L_2]$ and dinuclear disulfides $[M_2S_2L_4]$, depending on the conditions (Eq. 1) [4,5].

$$[Pt(PPh_3)_4] + S_8 \xrightarrow[RT]{\text{Benzene}} [Pt_2(\mu\text{-}S)_2(PPh_3)_4] + [PtS_4(PPh_3)_2] \quad (1)$$

Further treatment of $[PtS_4(PPh_3)_2]$ with dimethylacetylene dicarboxylate leads to the dithiolene $[Pt\{S_2C_2(CO_2Me)_2\}(PPh_3)_2]$ (Eq. 2) [6].

$$[PtS_4(PPh_3)_2] + MeO_2CC{\equiv}CCO_2Me \xrightarrow[\Delta]{CH_2Cl_2} [Pt\{S_2C_2(CO_2Me)_2\}(PPh_3)_2] \quad (2)$$

We have previously reported the results of the reactions of $[M(PPh_3)_4]$ with selenium. Whilst only decomposition was observed for M = Pd, when M = Pt the product is the dinuclear diselenide $[Pt_2(\mu\text{-}Se)_2(PPh_3)_4]$ [7], which reacts further with dichloromethane to yield a novel methanediselenolate complex (Eq. 3) [8]. No reaction was observed between $[M(PPh_3)_4]$ (M = Pd, Pt) and tellurium.

(3)

We have now studied the analogous reactions of $[M(dppe)_2]$ (M = Pd, Pt) and find significant differences from our work with $[M(PPh_3)_4]$.

2. Results and discussion

Heating a toluene solution containing $[Pd(dppe)_2]$ with an excess of powdered vitreous selenium to reflux overnight leads to dissolution of some of the selenium, and formation of a brown–black precipitate. This may be isolated by filtration and purified by treatment with triphenylphosphine, which reacts with any selenium still present. The residue is insoluble in all common organic solvents, but, on the basis of microanalysis, infrared and visible spectroscopy may be identified as $[Pd_2(\mu\text{-}Se)_2(dppe)_2]$ (**1a**), or a polymeric form thereof (Eq. 4a). It is notable that compound **1a**, unlike the analogous compound containing platinum and triphenylphosphine (see above), does not appear to react with dichloromethane.

Carrying out the reaction of $[Pd(dppe)_2]$ with selenium at lower temperature (85°C) leads to a different product. Filtration of the reaction mixture and extraction of the residue with dichloromethane leads to the isolation of compound **1b**, which has been identified as the salt $[Pd_3(\mu_3\text{-}Se)_2(dppe)_3]Cl_2$ (Eq. 4b).

$$[Pd(dppe)_2] + Se_x \xrightarrow[\Delta]{\text{Toluene}} \underset{\mathbf{1a}}{[Pd_2(\mu\text{-}Se)_2(dppe)_2]} + dppeSe_2 \qquad (4a)$$

(4b)

Sulfido species of the type $[M_3(\mu_3\text{-}S)_2(PR_3)_6]^{2+}$ have been reported for: M = Ni, $R_3 = Et_3$ [9]; M = Pd, $R_3 = Me_3$ or $MePh_2$ [10]; M = Pt, $R_3 = Me_2Ph$ [4,11]. Analogous selenides are known only for M = Ni [12,13]. They are usually prepared, either directly or indirectly, via nucleophilic attack of the bridging chalcogenide ligands in $[M_2(\mu\text{-}E)_2(PR_3)_4]$ (E = S or Se) on *cis*-$[MCl_2(PR_3)_2]$. In the case of compound **1b**, the mechanism is presumably similar, with the $[PdCl_2(dppe)]$ being generated in situ by the action of dichloromethane on an unidentified intermediate.

Compound **1b** has been characterised by microanalysis, NMR, UV–Vis and IR spectroscopy, and by mass spectrometry. It is a brown microcrystalline air-stable solid, readily soluble in polar organic solvents. An intense cluster of peaks is observed in the FAB mass spectrum, corresponding to the ion $[Pd_3(\mu_3\text{-}Se)_2(dppe)_3Cl]^+$. The ^{77}Se resonance is at unusually high field (−41 ppm), but chemical shifts for triply bridging selenides are known to cover a wide range, i.e. from 796 ppm for $[CoFe_2(\mu_3\text{-}Se)(\eta\text{-}C_5H_5)(CO)_6]$ [14] to −483 ppm for $[Fe_2Pt(\mu_3\text{-}Se)(CO)_6(PPh_3)_2]$ [15]. Coupling to ^{31}P could not be resolved. Compound **1b** behaves as a 1:2 electrolyte in dichloromethane solution.

The platinum compound $[Pt(dppe)_2]$ reacts with vitreous selenium in a visually similar manner. The product isolated after extraction of the residue with dichloromethane is, however, in this case the polyselenide $[PtSe_4(dppe)]$ (**2**) (Eq. 5).

$$[Pt(dppe)_2] + Se_x \xrightarrow[\Delta]{\text{Toluene}} \underset{\mathbf{2}}{[PtSe_4(dppe)]} + dppeSe_2 \qquad (5)$$

The crystal structure of compound **2** has been determined by X-ray diffraction (Fig. 1). One molecule of the recrystallisation solvent (dichloromethane) was incorporated per four formula units. Selected bond lengths and angles are listed in Table 1. The platinum atom is approximately square planar coordinated. There is, however, a significant distortion of the coordination geometry towards tetrahedral, as indicated by the deviations of the donor atoms from the least-squares plane through the $PtSe_2P_2$ unit: Se(1), −0.04 Å; Se(4), +0.04 Å; P(1), +0.30 Å; P(2), −0.27 Å. This is presumably in part brought about by the need to accommodate the obtuse angle subtended by the polyselenide ligand at the Pt atom, Se(1)–Pt–Se(2) (98.1°), the bite angle of the chelating diphosphine being relatively fixed. A similar distortion has been noted in $[Pt(Se_4)_2]^{2-}$ [16]. Preliminary extended Hückel calculations indicate that electronic factors (relating to the bonding in the Se_4^{2-} fragment) are also important in determining the observed geometry. The Pt–Se and Pt–P bond lengths are similar to those reported previously: e.g.

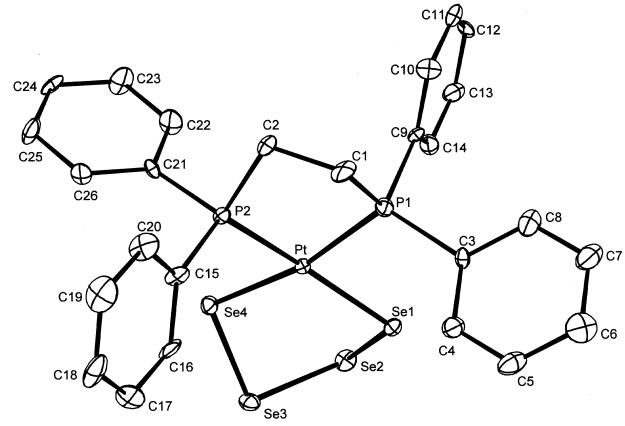

Fig. 1. Molecular stucture of compound **2** in $[PtSe_4(dppe)]\cdot 0.25CH_2Cl_2$.

Table 1
Selected bond lengths (Å) and angles (°) for $[PtSe_4(dppe)]\cdot 0.25CH_2Cl_2$

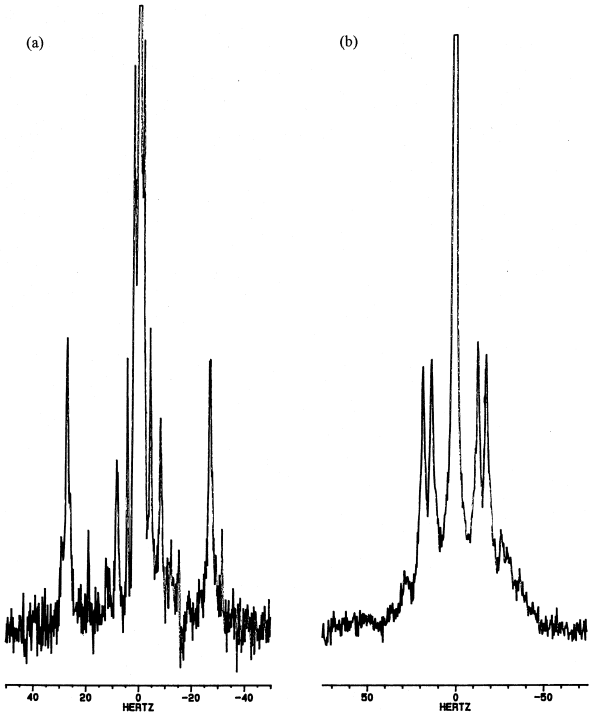
Pt–P(1)	2.246(5)	Pt–P(2)	2.242(5)
Pt–Se(1)	2.445(3)	Pt–Se(4)	2.448(2)
Se(1)–Se(2)	2.352(3)	Se(2)–Se(3)	2.303(4)
Se(3)–Se(4)	2.338(4)		
P(1)–Pt–Se(1)	89.19(16)	Se(1)–Pt–Se(4)	98.09(8)
Se(4)–Pt–P(2)	87.69(15)	P(2)–Pt–P(1)	86.31(20)
Pt–Se(1)–Se(2)	105.93(10)	Se(1)–Se(2)–Se(3)	97.13(12)
Se(2)–Se(3)–Se(4)	97.50(13)	Se(3)–Se(4)–Pt	104.34(11)

2.426 (av.) Å and 2.282 (av.) Å, respectively, in $[Pt(Se_2CH_2)(PPh_3)_2]$ [8]. There is an alternation amongst the Se–Se distances in the polyselenide ligand, with Se(2)–Se(3) being the shortest (by about 0.04 Å). This is a common feature in the structures of tetraselenide complexes [17].

Compound **2** is a red crystalline, air-stable solid, soluble in a wide range of organic solvents. It has been further characterised by microanalysis, NMR, UV–Vis and IR spectroscopy, and by mass spectrometry. The colour of compound **2** is associated with the tail of an intense UV absorption ($\lambda_{max} = 260$ nm) which has significant intensity up to a wavelength of approximately 470 nm.

Only a single broad resonance at 640 ppm is observed in the ^{77}Se NMR spectrum. This is surprising, as α-Se and β-Se generally have quite different chemical shifts in tetraselenide complexes. For example, the ^{77}Se NMR spectrum of $[Pt(Se_4)_2]^{2-}$ has peaks at 680 and 790 ppm [16]. It may be that the resonance for the metal-bound selenium atoms in compound **2** is not observed as a result of the broadening due to coupling to ^{31}P and ^{195}Pt. The satellite structure of the ^{31}P resonance for compound **2** is shown in Fig. 2(a). The inner lines are due to coupling to ^{13}C. It has not been possible to analyse this spectrum completely, as too few of the eight lines expected for each AA′X pattern have been observed, but the presence of coupling to at least one ^{77}Se is clear.

Compound **2** may also be prepared by the action of a polyselenide solution on $[PtCl_2(dppe)]$ (Eq. 6). This method avoids the formation of dppe diselenide, which must be separated from the product in the reaction of $[Pt(dppe)_2]$ with selenium, and proceeds in comparable yield. A tetrafuran (THF) solution of lithium polyselenide does not, however, react with $[PdCl_2(dppe)]$ under the same conditions, the starting material being recovered largely unchanged in this case.



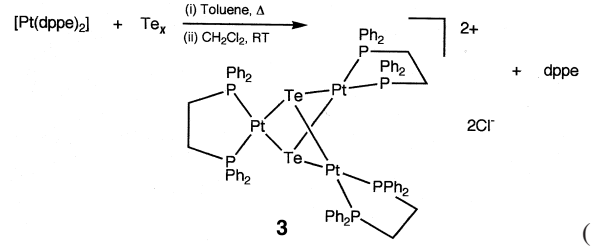


Fig. 2. Satellite structure of ^{31}P resonance for compounds **2** (a) and **3** (b).

$$[PtCl_2(dppe)] + Li_2Se_x \xrightarrow[\Delta]{THF} \underset{\mathbf{2}}{[PtSe_4(dppe)]} + LiCl \qquad (6)$$

Tellurium is not as reactive as selenium in this system. No change is observed on heating a mixture of $[Pd(dppe)_2]$ and tellurium powder for a prolonged period in toluene under reflux. $[Pt(dppe)_2]$ does react with tellurium, but a tetratelluride analogous to compound **2** is not formed. Treatment of a toluene solution of $[Pt(dppe)_2]$ with an excess of powdered tellurium leads to the eventual precipitation of a yellow solid. Filtration of the reaction mixture and extraction of the residue with dichloromethane yields compound **3**, identified as $[Pt_3(\mu_3\text{-}Te)_2(dppe)_3]Cl_2$ (Eq. 7).

(7)

Compound **3** is analogous to the triethylphosphine derivative $[Pt_3(\mu_3\text{-}Te)_2(PEt_3)_6][PF_6]_2$, previously reported by Dahl and co-workers [18]. It is presumably formed by the same mechanism as the tripalladium diselenide (**1b**) via $[Pt_2(\mu\text{-}Te)_2(dppe)_2]$ and $[PtCl_2(dppe)]$. Compound **3** is a yellow microcrystalline solid, readily soluble in polar organic solvents. It has been characterised by microanalysis, NMR, UV–Vis and IR spectroscopy, and by mass spectrometry. The electronic spectrum of compound **3** is similar to that of compound **2** in having three absorption maxima in the ultraviolet region; the difference in colour arises because absorption attenuates more rapidly at higher wavelengths. An intense cluster of peaks is observed in the FAB mass spectrum, corresponding to the ion $[Pt_3(\mu_3\text{-}Te)_2(dppe)_3Cl]^+$, and, like compound **1b**, it behaves as a 2:1 electrolyte in dichloromethane solution. In contrast to the selenium-containing compound, however, compound **3** is prone to decomposition in solution, depositing tellurium after a few hours at room temperature or above.

The satellite structure of the ^{31}P resonance for compound **3** is shown in Fig. 2(b). Coupling to ^{125}Te is clearly visible. The spectrum is, however, deceptively simple. This is the A and A′ part of an $A_3A'_3X$ system: simulation using estimated values for the coupling constants (based on data for comparable compounds) shows that it consists of a total of 46 lines. The ^{31}P resonance is significantly further upfield ($\delta = 41.4$ ppm), and the platinum–phosphorus coupling constant (3147 Hz) much greater than those for the mononuclear tetrachalcogenides $[PtE_4(dppe)]$ (E = S: $\delta = 49.6$ ppm, $^1J(^{195}Pt–^{31}P) = 2809$ Hz; E = Se (**2**): $\delta = 47.1$ ppm,

$^1J(^{195}Pt–^{31}P) = 2805$ Hz). The same trend is also evident from a comparison of the chemical shifts of the tripalladium diselenide (**1b**) (50.9 ppm) and [PdS_4(dppe)] (57.2 ppm). The magnitude of $^1J(^{195}Pt–^{31}P)$ for compound **3** is similar to that observed in the analogous complexes [$Pt_3(\mu_3$-$Te)_2(PEt_3)_6][PF_6]_2$ (3238 Hz) [18] and [$Pt_3(\mu_3$-$S)_2$-$(PMe_2Ph)_6][BF_4]_2$ (3202 Hz) [11].

The reactions of the polyselenide (**2**) with activated alkynes to yield diselenolenes are currently under study and the results will be reported separately [19].

3. Experimental

All reactions were performed using standard Schlenk techniques and pre-dried solvents under an atmosphere of dinitrogen. ^1H and ^{13}C NMR spectra: Bruker AC400, tetramethylsilane as internal standard. ^{31}P and ^{77}Se NMR spectra: Bruker WM250, 85% phosphoric acid or dimethyl selenide as external standard. IR spectra: Perkin-Elmer 1725X. UV–Vis spectra: Perkin-Elmer Lambda 9. Mass spectra were recorded by the EPSRC Mass Spectrometry Centre, using fast atom bombardment (FAB). Values of m/z quoted are for isotopomers containing ^{35}Cl, ^{80}Se, ^{106}Pd, or ^{195}Pt as appropriate; expected isotope distribution patterns were observed. Elemental analyses were performed by the Analytical Service of the University of Wales, Cardiff.

Bis[bis(diphenylphosphino)ethane]palladium [20,21] and -platinum [22] and [bis(diphenylphosphino)ethane]-dichloroplatinum [23] were prepared by literature procedures.

3.1. Bis[bis(diphenylphosphino)ethane]di-μ_2-selenidodipalladium (*1a*)

A mixture of [Pd(dppe)$_2$] (0.45 g, 0.5 mmol) and powdered vitreous selenium (0.40 g, 5.0 mmol) in toluene (50 cm^3) was heated under reflux for 18 h. After this time a microcrystalline brown–black solid had been formed. This was collected by filtration and purified by treatment with triphenylphosphine (13.1 g, 50 mmol) in toluene under reflux for 2 days. The product was a brown–black solid, insoluble in all common solvents.

Yield 0.24 g, 82%. M.p. 300°C (dec.). *Anal*. Found: C, 51.9; H, 4.11. $C_{52}H_{48}P_4Pd_2Se_2$ requires: C, 53.5; H, 4.14%. Vis (diffuse reflectance), absorption across the whole of the visible region apart from 435–450, 480–495 and 585–700 nm. IR (KBr disk) (cm^{-1}): ν 3044m, 2963m, 2920s, 2851m, 1637m, 1436m, 1401w, 1385m, 1262w, 1188s, 1102vs, 1052m, 879w, 818m, 694m, 569w, 531s, 490w.

3.2. Tris[bis(diphenylphosphino)ethane]di-μ_3-selenidotripalladium dichloride (*1b*)

A mixture of [Pd(dppe)$_2$] (0.09 g, 0.1 mmol) and powdered vitreous selenium (0.79 g, 1.0 mmol) in toluene (50 cm^3) was heated to 85°C for 18 h. The product was collected by filtration, washed with toluene and extracted into dichloromethane. Removal of the solvent by evaporation under reduced pressure left a crystalline brown solid.

Yield: 0.03 g, 52%. M.p. 342°C. *Anal*. Found: C, 50.7; H 4.21. $C_{78}H_{72}Cl_2P_6Pd_3Se_2$ requires: C, 53.7; H, 4.16%. ^1H NMR: δ 7.34 (m, 36H), 7.07 (m, 24H), 2.49 (m, 12H). ^{13}C NMR: δ 132.9 [$J(^{13}C–^{31}P)$ not resolved], 131.7, 129.6 [average $J(^{13}C–^{31}P)$ 23 Hz], 128.9 [$J(^{13}C–^{31}P)$ not resolved], 26.6 [$J(^{13}C–^{31}P)$ not resolved]. ^{31}P NMR: δ 50.9. ^{77}Se NMR: δ −41 [$J(^{77}Se–^{31}P)$ not resolved]. UV–Vis (CH_2Cl_2), λ_{max} (ε, $dm^3\ cm^{-1}\ mol^{-1}$): 230 (55000), 280 (35000), 300 (31000), 360 (20000), 370 (16000), 470 (1500) nm. IR (KBr disk) (cm^{-1}): ν 3056s, 2960m, 2928s, 1620m, 1482m, 1434vs, 1307w, 1186w, 1101s, 1026m, 998m, 876m, 820m, 746m, 705s, 691vs, 531vs, 480s. MS: *m/z* 1707 [{M − Cl}$^+$].

3.3. Bis(diphenylphosphino)ethane(tetraselenido-Se, Se)-platinum (*2*)

(a) A mixture of [Pt(dppe)$_2$] (0.25 g, 0.25 mmol) and powdered vitreous selenium (0.20 g, 2.5 mmol) in toluene (50 cm^3) was heated under reflux for 5 h. After cooling overnight, the product was collected by filtration, washed with toluene and extracted into dichloromethane. Removal of the solvent by evaporation under reduced pressure left a crystalline red solid. Yield: 0.16 g (70%).

(b) A mixture of $LiBEt_3H$ (3.0 cm^3 of a 1 M solution in THF, 3.0 mmol) and powdered vitreous selenium (0.43 g, 5.4 mmol) in THF (150 cm^3) was heated under reflux for 1 h. A hot suspension of [$PtCl_2$(dppe)] (0.66 g, 1.0 mmol) in THF (150 cm^3) was added to the purple solution of Li_2Se_x thus formed, and the mixture was heated under reflux for a further 2 h. The solvent was removed by evaporation under reduced pressure. The black residue was Soxhlet extracted with dichloromethane to yield an orange solution. Removal of the solvent in vacuo left a red crystalline solid, which was washed with cold toluene and dried. Yield: 0.64 g (70%).

M.p. 207°C (dec.). *Anal*. Found: C, 34.1; H, 2.83. $C_{26}H_{24}P_2PtSe_4$ requires: C, 34.3; H, 2.66%. ^1H NMR: δ 7.71 (m, 8H), 7.43 (m, 12H), 2.41 (m, 4H). ^{13}C NMR: δ 133.2 [average $J(^{13}C–^{31}P)$ 6 Hz], 131.7, 129.9 [average $J(^{13}C–^{31}P)$ 31 Hz], 128.8 [average $J(^{13}C–^{31}P)$ 6 Hz], 29.0 [eight peaks]. ^{31}P NMR: δ 47.1 [$J(^{195}Pt–^{31}P)$ 2805 Hz]. ^{77}Se NMR: δ 640 [$J(^{77}Se–^{31}P)$ not resolved]. IR (KBr disk) (cm^{-1}): ν 3050m, 2963m, 2927m, 1639m, 1618m, 1483m, 1435s, 1408m, 1385m, 1308w, 1262m, 1187w, 1160w, 1103s, 1027m, 998w, 879w, 820m, 749m, 715m, 706m, 691s, 657w, 617w, 533vs, 484m, 405w. UV–Vis (CH_2Cl_2), λ_{max} (ε, $dm^3\ cm^{-1}\ mol^{-1}$) 230 (36000), 250 (7500), 260 (7000) nm. MS: *m/z* 913 [M$^+$].

3.4. Tris[bis(diphenylphosphino)ethane]di-μ_3-telluridotriplatinum dichloride (*3*)

A mixture of [Pt(dppe)$_2$] (0.25 g, 0.25 mmol) and tellurium powder (0.32 g, 2.5 mmol) in toluene (50 cm^3) was

heated under reflux for 3 h. The solution became deep red in colour and some of the tellurium gradually dissolved. After cooling overnight, a yellow solid had been deposited. The product was collected by filtration, washed with toluene and extracted into dichloromethane to yield an orange solution. Removal of the solvent by evaporation under reduced pressure left a yellow oily solid, which could be further purified by passage of a dichloromethane solution through a bed of Celite. The product was unstable in solution and decomposed after a few hours at room temperature with the deposition of tellurium.

Yield: 0.09 g, 51%. M.p. 168°C (dec.). *Anal*. Found: C, 53.4; H 3.11. $C_{78}H_{72}Cl_2P_6Pt_3Te_2$ requires: C, 44.5; H, 3.44%. ^{1}H NMR: δ 7.43 (m, 12H), 7.35 (m, 24H), 7.18 (m, 24H), 2.54 (m, 12H). ^{13}C NMR: δ 132.8 [average $J(^{13}C–^{31}P)$ 5 Hz], 131.8, *ipso*-C not observed, 128.8 [average $J(^{13}C–^{31}P)$ 5 Hz], 27.7 [average $J(^{13}C–^{31}P)$ 20 Hz]. ^{31}P NMR: δ 41.4 [$J(^{195}Pt–^{31}P)$ 3147 Hz]. UV–Vis (CH_2Cl_2), λ_{max} (ε, dm^3 cm^{-1} mol^{-1}): 230 (21000), 250 (13000), 260 (11000) nm. IR (KBr disk) (cm^{-1}): ν3056s, 2960m, 2928s, 1637vs, 1619vs, 1435m, 1385m, 1262w, 1103s, 803w, 749m, 692vs, 669s, 618s, 534vs, 483vs. MS: m/z 2071 [$\{M-Cl\}^+$].

3.5. X-ray crystallography

Details of the crystal structure determination of compound **2** are given in Table 2. Measurements were carried out at room temperature with an Enraf-Nonius CAD4 diffractometer, using graphite-monochromated Mo Kα radiation. Crystals diffracted poorly; the sample used for the final data collection was cut from a bigger piece. Lattice parameters were determined from the settings of 24 reflections at $12 \le \theta \le 14$. No decay of intensities was observed at data collection time. An empirical correction for absorption was applied to the data, with DIFABS [24] (correction factors range 0.677–1.419). Structure solution was by direct methods with SIR97 [25], and Fourier cycles with SHELXL-93 [26], which was also used for structure refinements. The final refinement cycles were performed against F^2 with all non-hydrogen atoms anisotropic and with hydrogen atoms in calculated positions. Phenyl rings were treated as rigid groups with idealized geometry; refinement of the light atoms parameters suffered from the poor quality of the data (probably caused in part by disordered solvent) and from the presence of heavy atoms. The presence of dichloromethane solvate molecules disorderly arranged about a 2-fold axis was suggested by difference Fouriers. The occupancy factor of the site was assigned based on the results of refinements in which the solvent molecule, geometrically constrained throughout, was applied an overall temperature factor.

Table 2
Crystallographic data for $[PtSe_4(dppe)]\cdot 0.25CH_2Cl_2$ (**2**)

Formula	$C_{26.25}H_{24.50}Cl_{0.50}P_2PtSe_4$

Abstract

Heterobi- and tri-metallic compounds containing a $Cp_2Ti(IV)$ unit linked via nicotinate, thiophenoxyacetate or diphenylphosphinoacetate ligands to Pd, Pt, Cu, Ag or Au centres have been isolated. They are of the types $[Cp_2Ti\{\mu\text{-}OC(O)R\}_2MCl_2]$ (M = Pd, R = *m*-C_5H_4N, CH_2SPh and CH_2PPh_2; M = Pt, R = *m*-C_5H_4N or CH_2PPh_2), $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2(M'Cl)_2]$ (M′ = Cu or Au) and $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2AgCl]$. The diphenylphosphinoacetate products arise both from methane elimination reactions of $[Cp_2TiMe_2]$ with either $[MCl_2(Ph_2PCH_2CO_2H)_2]$ or $[M'Cl(Ph_2PCH_2CO_2H)]$ and from reactions of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ with metal complexes containing labile ligands. Crystal structures of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ and $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2PdCl_2]$ are discussed. The latter compound contains diphenylphosphinoacetate groups which are O-unidentate with respect to titanium and P-unidentate with respect to palladium, the result being the formation of a ten-atom heterobimetallic ring system. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Bis(η-cyclopentadienyl)titanium(IV); Crystal structures; Diphenylphosphinoacetate; Heterometallics; Nicotinate; Thiophenoxyacetate

1. Introduction

Compounds containing $Cp_2Ti(IV)$ units linked to late transition metal centres are representatives of a broad class of heterometallic species, interest in which has been stimulated by, for example, their potential catalytic [1], biological [2,3] or medicinal [4] applications. The combination of an oxophilic early transition metal centre with electron-rich late transition metal centres may lead to products with properties considerably different than bimetallic species containing identical or closely related metals. This topic has been comprehensively reviewed by Stephan [5,6], whose group has made major advances in the application of early transition metal complexes functionalised to act as metalloligands for late transition metals.

Bridging ligands that have been employed to link the $Cp_2Ti(IV)$ fragment to late transition metals include μ-η^1:η^2-carbonyl [7] and anions such as phosphino [8], thiolato [9], selenolato [10] and η^1,η^6-benzoate [11]. Crystallographic results and extended Hückel or Fenske–Hall molecular orbital calculations are consistent with the presence of direct early–late transition metal interactions in a number of such compounds, for example, in $[Cp_2Ti(SCH_2CH_2SCH_2)_2CH_2Cu][PF_6]$ [12] and $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Ni]$ [13].

Of particular relevance to the results reported here, is a recent communication [14] reporting the self-assembly of two heterobimetallic early–late metallomacrocycles from the iso-nicotinate $[Cp_2Ti\{OC(O)C_5H_4N\text{-}p\}_2]$ [15] and the Pt(II) triflate complexes *cis*-$[Pt(OSO_2CF_3)_2L_2]$ [L = PEt_3 or $0.5Ph_2P(CH_2)_3PPh_2$]. The products, $[Cp_2Ti\{\mu\text{-}OC(O)C_5H_4N\text{-}p\}_2PtL_2]_2[CF_3SO_3]_4$, were held to be cationic and tetranuclear with a 28-atom ring based on NMR and, for the PEt_3 complex, liquid SIMS evidence. No X-ray crystal-

lographic evidence was available but molecular modelling was used to illustrate the shape of the complex and its cavity based on square planar platinum and distorted tetrahedral titanium as corner units.

We report here on a wider variety of related heterometallic compounds containing $Cp_2Ti(IV)$ carboxylate units linked to late transition metals synthesised by employing functionalised carboxylates containing additional nitrogen (nicotinate, *m*-$C_5H_4NCO_2^-$ [16]), sulfur (thiophenoxyacetate, $PhSCH_2CO_2^-$) or phosphorus (diphenylphosphinoacetate, $Ph_2PCH_2CO_2^-$) donor sites. Unlike the cationic, tetranuclear iso-nicotinate complexes [14], the products are non-ionic and either binuclear macrocycles involving a $Cp_2Ti(IV)$ unit assembled with one group 10 (Pd or Pt) or group 11 (Ag) metal, or trinuclear acyclic complexes in which the $Cp_2Ti(IV)$ unit is linked to two group 11 (Cu or Au) metals. The majority of the investigation has employed diphenylphosphinoacetate as the bridging carboxylate and it has been shown that most of the products can be prepared equally well either from methane elimination reactions of $[Cp_2TiMe_2]$ with our recently reported [17] complexes $[MCl_2(Ph_2PCH_2CO_2H)_2]$ (M = Pd or Pt) and $[M'Cl(Ph_2PCH_2CO_2H)]$ (M = Cu or Au) or from reactions which employ the new O-unidentate carboxylate $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ as a metalloligand in reactions with late transition metal complexes containing labile ligands. An X-ray crystallographic structure determination shows one of the products, $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2PdCl_2]$, to contain a ten-atom heterobimetallocyclic ring.

2. Experimental

Diphenylphosphinoacetic acid was prepared and characterised as before [17], nicotinic and thiophenoxyacetic acids being used as supplied (Aldrich). The compound $[Cp_2TiMe_2]$ was prepared from the chloride (Aldrich) and methyllithium in diethyl ether. Bis(benzonitrile)Pd(II) or Pt(II) dichlorides were obtained by dissolving the metal chlorides in hot benzonitrile and isolating the crystalline products by filtration of the cooled solutions. Solvents were dried by distillation from appropriate reagents (sodium–benzophenone, calcium hydride or molecular sieves) before use and all reactions and manipulations were carried out under dry nitrogen.

Microanalyses were carried out using a Carlo-Erba microanalysis system. JEOL GX 270 and EX 400 spectrometers were used to obtain ^1H, ^{13}C and ^{31}P NMR spectra. Infrared spectra were recorded as Nujol or hexachlorobutadiene mulls (NaCl or CsI windows) using Nicolet 510P or Perkin-Elmer 597 spectrophotometers. Only selected bands are reported here. Positive and negative ion FAB mass spectra were recorded in 3-nitrobenzyl alcohol matrices using a VG Autospec instrument. The *m*/*z* values reported are based on ^{35}Cl, ^{48}Ti, ^{63}Cu and ^{197}Au isotopes and intensities are expressed relative to the strongest metal-containing fragment.

2.1. Bis(cyclopentadienyl)bis(O-nicotinato)titanium(IV) (1)

Sodium nicotinate (1.00 g, 6.9 mmol), prepared by reaction of the acid with sodium ethoxide in absolute alcohol, and $[Cp_2TiCl_2]$ (0.50 g, 2.0 mmol) were reacted in refluxing tetrahydrofuran (25 cm^3) under nitrogen for 1 h. After cooling, sodium salts were removed by filtration and the orange filtrate was treated with hexane to produce orange crystals on standing in an ice-bath (0.125 g, 15%). *Anal*. Found (calc. for $C_{22}H_{18}N_2O_4Ti$): C, 62.9 (62.6); H, 4.30 (4.30); N, 6.66 (6.63)%. IR (cm^{-1}): 3106s, 3049w (Cp), 1634vs (ν_{asym} CO_2), 1423m (Cp), 1350vs, 1306vs (ν_{sym} CO_2), 1028m (Cp), 824s (Cp). ^1H NMR ($CDCl_3$): δ 6.66 (s, 5H, Cp), 7.42 (dd, 1H, pyridyl), 8.28 (dt, 1H, pyridyl), 8.76 (dd, 1H, pyridyl), 9.21 (d, 1H, pyridyl). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 118.8 (Cp), 123.2, 129.2, 137.2, 151.0, 152.0 (pyridyl), 170.1 (CO_2). FAB-MS (*m*/*z*): 344 (50% $[M-C_5H_4N]^+$), 300 (100% $[M-C_5H_4NCO_2]^+$).

2.2. Bis(cyclopentadienyl)bis(O-thiophenoxyacetato)-titanium(IV) (2)

A solution of $[Cp_2TiMe_2]$ (0.44 g, 2.1 mmol) in tetrahydrofuran (3 cm^3) was added dropwise to a suspension of thiophenoxyacetic acid (0.71 g, 4.2 mmol) in tetrahydrofuran (12 cm^3) resulting in a vigorous evolution of methane. After stirring for 1 h, removal of the solvent gave the required product, recrystallised from tetrahydrofuran–hexane as bright red cubes (1.00 g, 93%). *Anal*. Found (calc. for $C_{26}H_{24}O_4S_2Ti$): C, 60.6 (60.9); H, 4.73 (4.72)%. IR (cm^{-1}): 3108m (Cp), 1661s, 1632vs (ν_{asym} CO_2), 1437sh (Cp), 1337s, 1302vs (ν_{sym} CO_2), 1022m (Cp), 824s (Cp). ^1H NMR ($CDCl_3$): δ 3.61 (s, 2H, CH_2), 6.27 (s, 5H, Cp), 7.09 (m, 1H, Ph), 7.22 (m, 2H, Ph), 7.35 (m, 2H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 37.8 (CH_2), 118.5 (Cp), 125.8, 128.1, 128.8, 136.4 (Ph), 174.1 (CO_2). FAB-MS (*m*/*z*): 447 (7% $[M-Cp]^+$), 345 (100% $[M-PhSCH_2CO_2]^+$), 178 (16% $[Cp_2Ti]^+$).

2.3. Bis(cyclopentadienyl)bis(O-diphenylphosphino-acetato)titanium(IV) (3)

A solution of $[Cp_2TiMe_2]$ (0.33 g, 1.6 mmol) in dichloromethane (6 cm^3) was added dropwise to a solution of diphenylphosphinoacetic acid (0.77 g, 3.2 mmol) in dichloromethane (4 cm^3). After evolution of methane, the mixture was stirred for 6 h, then the solvent was removed to produce a solid which was recrystallised from dichloromethane layered with hexane to give bright orange cubes suitable for an X-ray crystal structure determination (1.01 g, 95%). *Anal*. Found (calc. for $C_{38}H_{34}O_4P_2Ti$): C, 67.6 (67.7); H, 5.13 (5.17)%. IR (cm^{-1}): 3100w, 3056vw (Cp), 1649m, 1618s (ν_{asym} CO_2), 1433w (Cp), 1325s, 1285s (ν_{sym} CO_2), 1019w (Cp), 824m (Cp). ^1H NMR ($CDCl_3$): δ 2.96 (s, 2H, CH_2), 6.01 (s, 5H, Cp), 7.10 (m, 6H, Ph), 7.29 (m, 4H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 37.6 (d, $^1J_{C,P}$ = 17.6 Hz,

CH_2), 118.2 (s, Cp), 128.3 (d, $^2J_{C,P}$ = 6.6 Hz, C_{meta}), 128.6 (s, C_{para}), 132.6 (d, $^1J_{C,P}$ = 19.8, C_{ipso}), 138.4 (d, $^2J_{C,P}$ = 15.4 Hz, C_{ortho}), 175.4 (d, $^2J_{C,P}$ = 8.8 Hz, CO_2). $^{31}P\{^1H\}$ ($CDCl_3$): δ −17.6. FAB-MS (m/z): 599 (5% $[M-Cp]^+$), 522 (9%, $[M-Cp-Ph]^+$), 421 (100%, $[M-Ph_2PCH_2CO_2]^+$), 344 (29%, $[M-Ph_2PCH_2CO_2-Ph]^+$).

2.4. Adduct of compound **1** with $PdCl_2$

A solution of $[PdCl_2(NCPh)_2]$ (0.045 g, 0.12 mmol) in tetrahydrofuran (5 cm^3) was added dropwise with stirring to a solution of compound **1** (0.050 g, 0.12 mmol) in tetrahydrofuran (10 cm^3) to give an orange precipitate. After stirring for 24 h the product was obtained by filtration and washed with tetrahydrofuran (0.099 g, 69%). *Anal*. Found (calc. for $C_{22}H_{18}Cl_2N_2O_4PdTi$): C, 44.0 (44.1); H, 3.41 (3.03); N, 4.57 (4.67)%. IR (cm^{-1}): 3108w (Cp), 1642vs (ν_{asym} CO_2), 1462m (Cp), 1319vs (ν_{sym} CO_2), 1019w (Cp), 828s (Cp), 358m (ν PdCl).

2.5. Adduct of compound **1** with $PtCl_2$

This compound was prepared in a similar manner to the above palladium complex using $[PtCl_2(NCPh)_2]$ (0.034 g, 0.07 mmol) and compound **1** (0.030 g, 0.07 mmol) in dichloromethane (5 cm^3). Yield: 0.018 g, 37%. *Anal*. Found (calc. for $C_{22}H_{18}Cl_2N_2O_4PtTi$): C, 37.0 (38.4); H, 2.79 (2.64); N, 4.40 (4.07)%.

2.6. Adduct of compound **2** with $PdCl_2$

A similar method to that above using $[PdCl_2(NCPh)_2]$ (0.070 g, 0.18 mmol) dissolved in dichloromethane (5 cm^3) and compound **2** (0.089 g, 0.18 mmol) in dichloromethane (3 cm^3) gave a bright orange precipitate which was filtered and washed with dichloromethane before drying in vacuo. Yield: 0.090 g, 72%. *Anal*. Found (calc. for $C_{26}H_{24}Cl_2O_4PdS_2Ti$): C, 44.2 (45.3); H, 3.46 (3.51)%. IR (cm^{-1}): 3112m (Cp), 1626vs (ν_{asym} CO_2), 1443s (Cp), 1319vs (ν_{sym} CO_2), 1024m (Cp), 828s (Cp), 358w, 324m (ν PdCl).

2.7. Adduct of compound **3** with $PdCl_2$

2.7.1. Method A

Complex **3** was generated in situ from $[Cp_2TiMe_2]$ (0.19 g, 0.90 mmol) and diphenylphosphinoacetic acid (0.44 g, 1.80 mmol) in dichloromethane (6 cm^3). Addition of a solution of $[PdCl_2(NCPh)_2]$ (0.35 g, 0.90 mmol) in dichloromethane (2 cm^3) gave a red solution which, on standing, deposited large red crystals which were collected by filtration (0.43 g, 43%).

2.7.2. Method B

A solution of $[Cp_2TiMe_2]$ (0.034 g, 0.17 mmol) in dichloromethane (2 cm^3) was added to a suspension of *trans*-$[PdCl_2(Ph_2PCH_2CO_2H)_2]$ [17] (0.11 g, 0.17 mmol) in dichloromethane (2 cm^3). Slow evolution of methane was observed. After 2 h the solvent was removed to give an orange solid. *Anal*. Found (calc. for $C_{38}H_{34}Cl_2O_4P_2PdTi$): C, 52.1 (54.2); H, 3.90 (4.07)%. IR (cm^{-1}): 3087w (Cp), 1651vs (ν_{asym} CO_2), 1435s (Cp), 1312vs (ν_{sym} CO_2), 1019m (Cp), 818s (Cp), 339m, 307m (ν PdCl). ^1H NMR ($CDCl_3$): δ 3.53 (t, 2H, J = 4.4 Hz, CH_2), 6.30 (s, 5H, Cp), 7.22 (m, 6H, Ph), 7.59 (m, 4H, Ph). $^{31}P\{^1H\}$ ($CDCl_3$): δ +13.8.

2.8. Adduct of compound **3** with $PtCl_2$

2.8.1. Method A

The desired compound was prepared as for the palladium analogue using $[Cp_2TiMe_2]$ (0.05 g, 0.24 mmol), $Ph_2PCH_2CO_2H$ (0.117 g, 0.48 mmol) and $[PtCl_2(NCPh)_2]$ (0.12 g, 0.24 mmol) in dichloromethane (3 cm^3).

2.8.2. Method B

A solution of $[Cp_2TiMe_2]$ (0.052 g, 0.25 mmol) in dichloromethane (0.5 cm^3) was added to a suspension of *cis*-$[PtCl_2(Ph_2PCH_2CO_2H)_2]$ [17] (0.166 g, 0.25 mmol) in toluene–dichloromethane (5:1, 6 cm^3). A further 0.5 cm^3 of dichloromethane was added and the mixture stirred for 24 h. The orange precipitate was filtered and washed with dichloromethane (0.071 g, 23%). A further crop of orange crystals was obtained by concentration of the filtrate (0.123 g, 40%). *Anal*. Found (calc. for $C_{38}H_{34}Cl_2O_4P_2PtTi$): C, 48.6 (49.1); H, 3.60 (3.68)%. IR (cm^{-1}): 3088w (Cp), 1647s, 1593s (ν_{asym} CO_2), 1439s (Cp), 1312s (ν_{sym} CO_2), 1028w (Cp), 822w (Cp), 322m, 310m (ν PtCl).

2.9. Adduct of compound **3** with 2CuCl

2.9.1. Method A

Cu(I) chloride (0.10 g, 1.00 mmol) and complex **3** (0.34 g, 0.50 mmol) were stirred in dichloromethane (5 cm^3) for 72 h to give a dark red solution. Filtration followed by concentration of the filtrate in vacuo gave an orange powder (0.40 g, 93%).

2.9.2. Method B

A solution of $[Cp_2TiMe_2]$ (0.061 g, 0.29 mmol) in dichloromethane (2 cm^3) was added with stirring to a suspension of $[\{CuCl(Ph_2PCH_2CO_2H)\}_4]$ [17] in dichloromethane (2 cm^3). Evolution of methane was observed. After standing for 72 h, concentration of the solution gave an orange solid (0.17 g, 68%). *Anal*. Found (calc. for $C_{38}H_{34}Cl_2Cu_2O_4P_2Ti$): C, 52.4 (52.9); H, 3.93 (3.97)%. IR (cm^{-1}): 3050w (Cp), 1634s (ν_{asym} CO_2), 1435s (Cp), 1310s (ν_{sym} CO_2), 1017w (Cp), 828s (Cp). ^1H NMR ($CDCl_3$): δ 3.48 (br s, 2H, CH_2), 6.23 (s, 5H, Cp), 7.40 (m, 6H, Ph), 7.68 (m, 4H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 37.3 (s, CH_2), 118.9 (s, Cp), 128.9 (s, Ph), 130.3 (s, Ph), 132.3 (d, J = 15.5 Hz, Ph), 132.7 (t, J = 7.7, Ph), 172.5 (s, CO_2). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −12.4 (s). FAB-MS (m/z) 827

(16% $[M-Cl]^+$), 762 (21% $[M-CuCl]^+$), 727 (100% $[762-Cl]^+$), 662 (74% $[727-Cp]^+$).

2.10. Adduct of compound **3** with AgCl

2.10.1. Method A

Compound **3** (0.050 g, 0.08 mmol) and silver chloride (0.011 g, 0.08 mmol) were stirred in dichloromethane (4 cm^3) for 72 h. Filtration followed by concentration of the filtrate gave a bright orange solid. The same product resulted from similar reactions employing two or four molar equivalents of AgCl, but in these cases an excess of AgCl had to be removed by filtration.

2.10.2. Method B

Silver(I) diphenylphosphinoacetate (0.60 g, 1.70 mmol), prepared from $AgNO_3$ and $Ph_2PCH_2CO_2Na$, and $[Cp_2TiCl_2]$ (0.21 g, 0.85 mmol) were stirred in dichloromethane (10 cm^3) for 24 h. Filtration removed AgCl and the orange filtrate was evaporated and the solid product crystallised from dichloromethane to give an orange crystalline solid (0.53 g, 77%). *Anal*. Found (calc. for $C_{38}H_{34}AgClO_4P_2Ti$): C, 55.3 (56.5), H, 4.49 (4.24)%. IR (cm^{-1}): 3050w (Cp), 1642vs (ν_{asym} CO_2), 1435s, (Cp), 1310sh, 1273vs (ν_{sym} CO_2), 1017m (Cp), 828s (Cp). ^1H NMR ($CDCl_3$): δ 3.51 (s, 2H, CH_2), 6.10 (s, 5H, Cp), 7.37 (m, 6H, Ph), 7.66 (m, 4H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 37.9 (d, $^1J_{C,P}=8.3$ Hz, CH_2), 118.9 (s, Cp), 129.0 (d, $^2J_{C,P}=5.0$ Hz, C_{meta}), 130.5 (s, C_{para}), 131.9 (d, $^1J_{C,P}=12.9$ Hz, C_{ipso}), 132.8 (d, $^2J_{C,P}=8.3$ Hz, C_{ortho}), 171.7 (s, CO_2). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −1.84 ($^1J^{107}$Ag, $^{31}P=439.3$ Hz; $^1J^{109}$Ag, $^{31}P=506.4$ Hz). FAB-MS (m/z): 773 (100% $[M-Cl]^+$), 709 (77% $[M-Cl-Cp]^+$).

2.11. Adduct of compound **3** with 2AuCl

A solution of $[Cp_2TiMe_2]$ (0.050 g, 0.24 mmol) in dichloromethane (1 cm^3) was added slowly with stirring to a suspension of $[AuCl(Ph_2PCH_2CO_2H)]$ [17] (0.23 g, 0.48 mmol) in dichloromethane (2 cm^3). After stirring overnight, concentration of the solution in vacuo gave an orange–yellow solid (0.22 g, 81%). *Anal*. Found (calc. for $C_{38}H_{34}Au_2Cl_2O_4P_2Ti$): C, 40.1 (40.4); H, 2.92 (3.03)%. IR (cm^{-1}): 3058w (Cp), 1634vs (ν_{asym} CO_2), 1439s (Cp), 1325s, 1292vs (ν_{sym} CO_2), 1017m (Cp), 824s (Cp), 335ms (ν AuCl). ^1H NMR ($CDCl_3$): δ 4.11 (d, 2H, $^2J_{P,H}=13.4$ Hz, CH_2), 6.24 (s, 5H, Cp), 7.49 (m, 6H, Ph), 7.84 (m, 4H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 37.8 (d, $^1J_{C,P}=33.1$ Hz, CH_2), 119.0 (s, Cp), 129.1 (d, $^2J_{C,P}=11.0$ Hz, Ph), 129.9 (s, Ph), 131.9 (s, Ph), 133.3 (d, $^1J_{C,P}=14.4$ Hz, Ph), 170.6 (d, $^2J_{C,P}=2.2$ Hz, CO_2). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ +24.9 (s). FAB-MS (m/z) 1129 (3% $[M]^+$), 1093 (13% $[M-Cl]^+$), 1028 (13% $[M-Cl-Cp]^+$), 917 (14% $[Au_2Cl(Ph_2PCH_2CO_2H)_2]^+$), 441 (100% $[Au(Ph_2PCH_2CO_2H)]^+$).

2.12. X-ray crystallography

Crystal data, collection and refinement details for $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ (crystals from dichloromethane solution layered with hexane) and for $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2PdCl_2]\cdot 3CH_2Cl_2$ (crystals from dichloromethane solution; method A above) are given in Table 1.

Selected bond lengths and angles are reported in Tables 2 and 3, respectively. Diagrams of the molecular structures produced using ORTEX [18] are shown in Figs. 1 and 2.

Data were collected using an Enraf-Nonius CAD4 diffractometer using graphite-monochromated Mo Kα 0.71069 Å radiation. Data for both compounds were corrected for Lorentz and polarisation effects and those for the $PdCl_2$ adduct also corrected for absorption. The structures were solved using SHELX 86 and refined using SHELX 93 [19,20]. For $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$, in the final least-squares cycles all atoms were allowed to vibrate anisotropically. Hydrogen atoms were included at calculated positions. Data for $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2PdCl_2]\cdot 3CH_2Cl_2$ were collected at 170(2) K, the crystals not being of a very high quality and crystal mounting was not without difficulty due to solvent loss. As a result, satisfactory anisotropic refinement of all atoms was not achieved. In the final least-squares cycles, atoms O(3), C(13), C(29) and C(37) were treated isotropically whereas all other atoms were allowed to vibrate anisotropically. Hydrogen atoms were included at calculated positions.

3. Results and discussion

Two new bis(η-cyclopentadienyl)titanium(IV) bis(*O*-carboxylates), $[Cp_2Ti\{OC(O)R\}_2]$ with $R=CH_2SPh$ (thiophenoxyacetate) and CH_2PPh_2 (diphenylphosphinoacetate) and the previously known [16] analogue with $R=C_5H_4N$-*m* (nicotinate) have been shown to act as S-, P- or N-donor metalloligands to various transition metal centres. Products contain Ti(IV) linked to either group 10 d^8 (Pd or Pt) or group 11 d^{10} (Cu, Ag or Au) metal chlorides via bridging carboxylate moities which are O-unidentate with respect to titanium and S-, P- or N-unidentate with respect to the group 10 or group 11 metal. Most of the work reported here focuses on the use of the diphenylphosphinoacetate in this manner.

The carboxylates have been prepared from $[Cp_2TiCl_2]$ and sodium nicotinate or from $[Cp_2TiMe_2]$ and thiophenoxyacetic or diphenylphosphinoacetic acids, the latter reactions proceeding with the smooth elimination of methane. Analytical, NMR (^1H, ^{13}C and ^{31}P), partial IR and mass spectrometric data for the three compounds are given in Section 2 and, being unexceptional, are not discussed further except to note that in the mass spectra the most abundant fragment in each case is that of the parent ion having lost one carboxylate group.

To provide a comparison with one of the metal halide adducts, an X-ray single-crystal structure determination of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ has been carried out (Fig. 1). This confirms the presence of a distorted tetrahedral environment around the metal with two O-unidentate carboxylate groups [Ti–O 1.972(4) and 1.925(5) Å] in accord with the large IR [$\nu_{asym}-\nu_{sym}$ CO_2] difference of 333 cm^{-1}. Taking the centroids of the cyclopentadienyl rings as Z, the distortion from regular geometry is evident from the Z–Ti–Z angle of 132.4° and the O(1)–Ti–O(3) angle of 91.5(2)°. The two carboxylate oxygens, O(2) and O(4), not bonded to the titanium, are more than 3 Å from the metal, and the two phosphorus atoms, which could potentially donate, are more than 5 Å from the titanium with the phosphine units so arranged that the lone pairs are directed away from each other. Unidentate carboxylate coordination is also indicated by the significant differences in C–O bond lengths depending on whether the oxygen is coordinated to titanium [1.282(8), 1.300(7) Å] or not [1.216(8), 1.189(8) Å]. The two diphenylphoshinoacetate groups are bonded to the titanium in a somewhat inequivalent manner, one carboxylate having a longer Ti–O (difference 0.047 Å), a smaller Ti–O–C angle

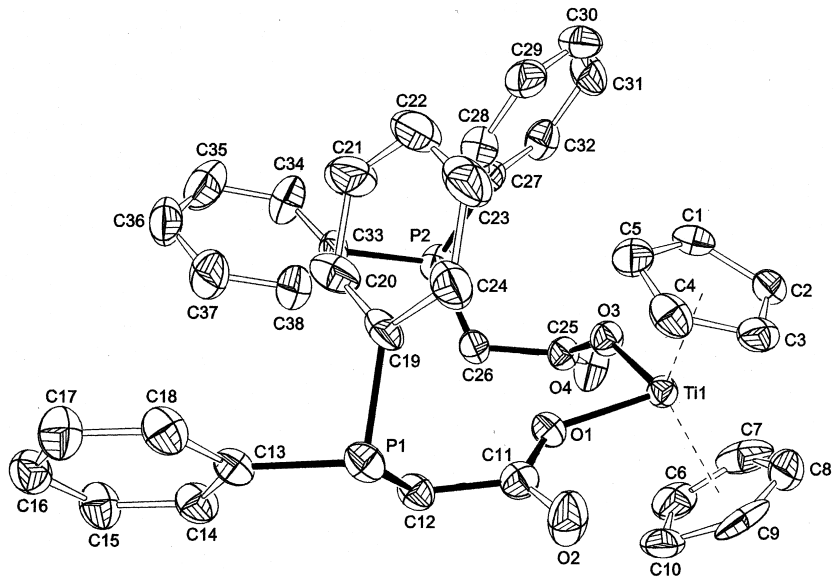

Fig. 1. ORTEX plot of the molecular structure of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ (**3**) showing the labelling scheme. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are at the 30% probability level.

(difference 7.3°) and a shorter C–O bond length (difference 0.018 Å) than the other. This may imply the presence of a differing extent of Ti–O π interaction supporting the primary σ bonding for the two carboxylate ligands. Such differences have been noted previously, for example in the orthorhombic form of $[Cp_2Ti\{OC(O)Ph\}_2]$ [21,22], which shows Ti–O, Ti–O–C and C–O differences between the two benzoates of 0.101 Å, 33.5° and 0.025 Å, respectively. This has been ascribed to the presence of a strong Ti–O π bond supplementing the Ti–O σ bond for one of the benzoates, thus giving an effective 18-electron count rather than a formal 16-electron count for the valence electrons. However, structure determinations of some other $[Cp_2Ti\{OC(O)R\}_2]$ compounds show very near equivalence of the carboxylate groups, e.g. R = H [23] or CH_2CN [24], presumably resulting from some additional Ti–O π bonding for both carboxylate groups, as indicated by EHMO calculations on the formate [25]. The average Ti–C and C–C bond lengths and C–C–C angles of the cyclopentadienyl groups agree well with such values from structure determinations of other $[Cp_2TiX_2]$ compounds [25]. Finally, it is noted that the present structure determination appears to be the first in which the diphenylphosphinoacetate anion acts solely as a unidentate ligand, the usual coordination mode being O,P-chelating as in, for example, *cis*-$[Pd\{OC(O)CH_2PPh_2\}_2]$ [26].

The compound $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ has been used both as a P-donor chelate metalloligand to assemble neutral bimetallic macrocyclic complexes in which the two phosphorus atoms bond to one group 10 (Pd or Pt) or group 11 (Ag) metal centre and as a P-donor bridging metalloligand

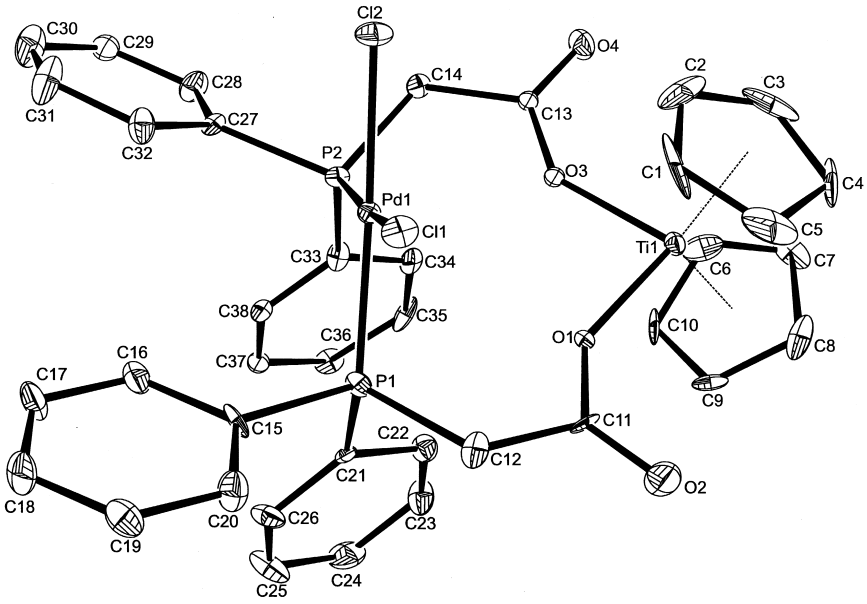

Fig. 2. ORTEX plot of the molecular structure of the 1:1 adduct of compound **3** and $PdCl_2$ solvated with $3CH_2Cl_2$ showing the labelling scheme. The dichloromethane molecules and hydrogen atoms are omitted for clarity. Thermal ellipsoids are at the 30% probability level.

forming neutral trimetallic acyclic complexes by bonding to two group 11 (Cu or Au) metal centres. In each case, the diphenylphosphinoacetate ligands remain O-unidentate with respect to the titanium. These products are therefore related to, but quite distinct in type from, the cationic tetranuclear $[Cp_2Ti\{\mu\text{-}OC(O)C_5H_4N\text{-}p\}_2PtL_2]_2[CF_3SO_3]_4$ complexes (L = PEt_3 or 0.5 dppp) isolated by Stang and Persky [14] from *cis*-$[PtL_2(OSO_2CF_3)_2]$ and $[Cp_2Ti(\text{iso-nicotinate})_2]$. The binuclear complexes $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2MCl_2]$ (M = Pd or Pt) have been prepared from $[MCl_2(NCPh)_2]$ and the trinuculear $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2(CuCl)_2]$ directly from Cu(I) chloride. One significant feature concerning the syntheses of these compounds is that they can be prepared at least equally well, and often better, from methane elimination reactions of $[Cp_2TiMe_2]$ with the neutral P-donor diphenylphosphinoacetic acid complexes $[MCl_2(Ph_2PCH_2CO_2H)_2]$ (M = Pd or Pt) and $[M'Cl(Ph_2PCH_2CO_2H)]$ (M′ = Cu or Au) that we have reported previously [17]. For the complexes involving group 11 metals, the silver complex has a 1:1 Ti:Ag stoichiometry whereas the copper and gold products both have 1:2 Ti:M′ stoichiometries. The silver complex $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2AgCl]$ has been prepared both from the direct reaction of AgCl with $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ and from the reaction of silver diphenylphosphinoacetate with $[Cp_2TiCl_2]$.

The silver complex has a large IR ($\nu_{asym} - \nu_{sym}\ CO_2$) separation of around 370 cm^{-1}, indicative of the expected O-unidentate bonding of the carboxylates to Ti(IV). The single ^{31}P NMR resonance and the magnitude of the ^{107}Ag–^{31}P and ^{109}Ag–^{31}P coupling constants are reasonable for a silver–bisphosphine complex [27]. These results coupled with the mass spectrometric data, which show no significant fragments of mass above that of $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2Ag]^+$, suggest that the complex is a bimetallocyclic three-coordinate silver species. For the copper and gold complexes $[Cp_2Ti\{\mu\text{-}OC(O)PPh_2\}_2(M'Cl)_2]$, the gold product certainly contains linear two-coordinate PAuCl moieties with both an IR ν(AuCl) and a ^{31}P NMR chemical shift almost identical to those of the structurally characterised [17] $[AuCl(Ph_2PCH_2CO_2H)]$ (IR ν(AuCl) 335 cm^{-1}; ^{31}P NMR δ +25 ppm). The mass spectrum contains a parent ion supporting this proposal, other fragments involving loss of chloride and/or cyclopentadienyl units. On the other hand, the copper complex is unlikely to contain two-coordinate Cu(I). If it did, an IR ν(CuCl) at around 400 cm^{-1} may be expected but no such band could be assigned. The ^{31}P NMR δ of −12.4 ppm is very similar to that of $[CuCl(Ph_2PCH_2CO_2H)]$ (δ of −13.3 ppm) which was suggested [17] to be tetrameric with a cubane or step structure. The present complex could be similar. The ^{31}P NMR δ values of the group 11 metal complexes are all downfield of that of the parent $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ as a result of the additional bonding from phosphorus. The coordination shifts, $\Delta\delta$, increase significantly on progressing from copper through to gold ($\Delta\delta$ values of 5.2, 15.8 and 42.5 ppm for the copper, silver and gold complexes, respectively).

The square planar palladium and platinum complexes $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2MCl_2]$ have been isolated from both preparative routes but are less soluble than the group 11 metal complexes, the very low solubility of the platinum complex in suitable solvents precluding the acquisition of NMR data. For the palladium complex, the ^{31}P NMR chemical shift is close to that of $[PdCl_2(Ph_2PCH_2CO_2H)_2]$ [17]. These two complexes, as confirmed by the X-ray crystal structure determination of the palladium complex, involve *cis*-$[MCl_2P_2]$ geometry with ten-atom $\overline{TiOCCPMPCCO}$ rings. The precursor $[PdCl_2(Ph_2PCH_2CO_2H)_2]$ has [17] a

trans square planar geometry when crystallised from aqueous ethanol so that in its reaction with $[Cp_2TiMe_2]$ to produce $[Cp_2Ti\{\mu\text{-}OC(O)CH_2PPh_2\}_2PdCl_2]$ a rearrangement of the ClPdCl and PPdP arrays from *trans* to *cis* must occur. Large IR ($\nu_{asym} - \nu_{sym}$ CO_2) differences for both complexes confirm the expected O-unidentate coordination of the carboxylates to titanium and the detection of two IR (νMCl) stretches supports the presence of *cis*-$[MCl_2P_2]$ arrangements.

A crystal structure determination of the palladium complex, as a tris(dichloromethane) solvate, confirms that the titanium has a distorted tetrahedral environment comprising two cyclopentadienyl and two O-unidentate carboxylate ligands (Fig. 2). The distortion can be assessed by considering the centroids, Z, of the cyclopentadienyl rings, the Z–Ti–Z angle being 131.6° and the O(1)–Ti–O(3) angle 89.4(3)°. The carboxylates are also P-bonded to the palladium to produce the ten-atom ring mentioned above. The Ti···Pd distance across the ten-atom ring is 4.18 Å indicating the absence of direct metal–metal interaction, unlike, for example, the square planar Rh(I) complex $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Rh][BF_4]$ in which the Ti···Rh distance is only 3.127(2) Å [28]. The *cis*-$[PdCl_2P_2]$ square planar arrangement is distorted, the P–Pd–P angle opening to 103.93(13)° and the Cl–Pd–P angles closing to 83.12(13) and 84.63(13)°. The Pd–P bond lengths [2.259(4), 2.277(4) Å] are slightly shorter than those found [17] for the three independent molecules in *trans*-$[PdCl_2(Ph_2PCH_2CO_2H)_2]\cdot 0.33H_2O\cdot 0.33EtOH$ [2.326(1), 2.309(1), 2.337(2) Å]. Conversely, the Pd–Cl bond lengths are longer [2.348(4), 2.339(4) Å] when compared to those of the above solvated diphenylphosphinoacetic acid complex [2.305(1), 2.303(1), 2.295(1) Å]. Some comparisons and contrasts with the structure of the parent $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$ are instructive. The markedly inequivalent diphenylphosphinoacetate ligands of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$, as illustrated by Ti–O and C–O bond length and Ti–O–C bond angle differences, become essentially equivalent in the palladium complex with respect to the titanium centre, the Ti–O and C–O bond length differences being 0.01 Å or less and the Ti–O–C angles showing only a difference of 0.7°. The average Ti–C (ring) distances of 2.35(2) and 2.37(2) Å are in good agreement with those of $[Cp_2Ti\{OC(O)CH_2PPh_2\}_2]$, [2.372(7), 2.360(8) Å], and many other bis(cyclopentadienyl)Ti(IV) compounds [25].

Finally, we have illustrated the versatility of this type of reaction by using the potentially N- and S-donor carboxylates, nicotinate and thiophenoxyacetate, in place of the P-bonding diphenylphosphinoacetate but in a more restricted range of examples. In this manner, analogous $[Cp_2Ti\{\mu\text{-}OC(O)C_5H_4N\text{-}m\}_2MCl_2]$ (M = Pd and Pt) and $[Cp_2Ti\{\mu\text{-}OC(O)CH_2SPh\}_2PdCl_2]$ complexes have been isolated as orange, rather insoluble, solids from reactions of the appropriate $[Cp_2Ti\{OC(O)R\}_2]$ with $[MCl_2(NCPh)_2]$. These products will similarly possess ten-atom TiOCCEMECCO rings (E = N or S).

Supplementary data

Crystallographic data are available from CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), on request, quoting the deposition numbers CCDC 136188 and CCDC136189.

Abstract

We report the use of layered copper phosphonate materials for the oxidative polymerization of aniline. The use of copper carboxyethylphosphonate results in the formation of the perinigraniline form of polyaniline in the interlayer region of the host structure, giving rise to an increase in the interlayer spacing by 10.2 Å. For copper phenylphosphonate, the emeraldine form of polyaniline is generated, although there is no evidence for intercalation within the interlayer region of the host material. Copper methylphosphonate is destroyed during the process of polymerization of aniline, yielding bulk copper metal as the only solid product. The results demonstrate the diversity of behaviour that may result from the use of structurally related, although chemically different, host materials for the polymerization of aniline. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Aniline polymerization; Copper phosphonates; Intercalation compounds

1. Introduction

Polyaniline (PANI) has been much studied as a conducting polymer [1–6], and may be described by the general formula $\{[-(C_6H_4)-NH-(C_6H_4)-NH-]_{1-x}[-(C_6H_4)-N=(C_6H_4)=N-]_x\}_n$, where the value of x ($0 \leq x \leq 1$) defines the oxidation state of the polymer [7]. The forms with $x \neq 0$ have the capacity to be protonated by non-oxidizing acids, with protonation occurring on the imine (–N=) nitrogen atoms [8]. The formation of polyaniline chains separated (insulated) from each other by microporous dielectric host materials has received considerable attention in recent years [9–13]. As a result of such confinement of the polymer chains, the polymer may display quantum-size effects in its electrical and optical properties [14]. As a consequence, formation and confinement of a given polymer in different host materials may allow the physical properties to be controlled and optimized for specific applications of the material.

A number of layered host materials have been reported [9,10,15–21] to catalyse the polymerization of aniline, including montmorillonite, vanadium pentoxide, iron oxychloride, copper-exchanged α-zirconium phosphate, zirconium phosphonates and copper-containing layered double hydroxide materials. Previous reports [9,10,19–21] of the formation of PANI using layered copper-containing materials indicate that the polymer can be formed either in the interlayer region or on the external surfaces of the material [9,10]. In general, in these preparations, the PANI is produced in the emeraldine base form (with $x = 0.5$). The presence of Cu(II) is thought to enhance the oxidation of aniline by ambient O_2, as a consequence of the accessible Cu(I) oxidation state [9]. In a number of these systems, however, complete reduction to produce bulk copper metal has been observed.

This paper reports the use of layered copper phosphonate materials to bring about the polycondensation of aniline. Copper phosphonates, $Cu(O_3PR)\cdot H_2O$, are layered materials in which layers of five-coordinate copper atoms are linked via $-PO_3$ pyramids. The phosphorus atom is tetrahedrally coordinated, and the fourth vertex is occupied by an organic functional group R [22]. As a variety of groups R can be used, there is considerable scope for fine-tuning both the structural and chemical properties of these materials. In particular, chemical reactions in which the interlayer region is accessed by the reactant molecules may be influenced significantly by the nature of the host material. For copper phosphonates, the presence of a redox active metal leads to the possibility of electron transfer between the intercalated guest species and the host material, with potentially important implications concerning electronic conductivity. The copper phosphonate materials chosen for this study were copper methylphosphonate ($R = CH_3$), copper phenylphosphonate ($R = C_6H_5$) and copper carboxyethylphosphonate ($R = CH_2CH_2CO_2H$).

2. Experimental

2.1. Synthetic aspects

Copper carboxyethylphosphonate (abbreviated CuCEP) was synthesized following the method of Drumel et al. [23]. Copper nitrate hydrate and 2-carboxyethylphosphonic acid (molar ratio 1:1) were placed in a solution of 5% deionized water in acetone, which was then kept at 60°C for 5 days. The solid was recovered by centrifugation, washed with deionized water and dried in air at 60°C.

Copper phenylphosphonate (abbreviated CuPhP) was synthesized using the method of Hayashi and Hudson [24]. Basic copper nitrate was prepared by adding copper oxide (8.0 g, 0.1 mol) to an aqueous solution of copper nitrate (100 cm^3, 2.4 mol dm^{-3}) with vigorous stirring at ambient temperature. After 16 h, the dark green solid was filtered off, washed with deionized water and ethanol, and then dried in air at 60°C. This solid (1 g) was then suspended in an aqueous solution of phenylphosphonic acid (160 cm^3, 0.1 mol dm^{-3}) and the pH adjusted to 6 by addition of NaOH solution (1 mol dm^{-3}). The suspension was maintained at 65°C and stirred for 16 h. Copper phenylphosphonate was recovered by filtration, washed with deionized water, and then dried in air at 60°C.

Copper methylphosphonate (abbreviated CuMeP) was prepared following a synthetic method that we have published previously [25]. Copper hydroxide and methylphosphonic acid were mixed in a 1:1 molar ratio. This mixture was placed in a sealed glass tube and heated at 100°C for 48 h. After cooling, the product was washed with deionized water and dried in air at 60°C.

2.2. Polymerization of aniline

A quantity (typically 0.5 g) of the copper phosphonate materials was placed in a flask with 50 cm^3 of pure aniline, and the mixture was refluxed overnight (at 184°C). The resulting solutions were black in colour. The solid residues were recovered from these solutions by filtration, and washed with acetone prior to drying in air at ambient temperature. The black colour of the solutions is probably due to colloidal copper (perhaps with some contribution from any oligomers of PANI present in the solution), although here we focus on the solid products recovered by filtration rather than the remaining liquid (colloidal) phase.

2.3. Characterization

Powder X-ray diffraction patterns were recorded using Cu $K\alpha_1$ radiation on a Siemens D5000 diffractometer, operating in transmission mode with a primary beam Ge monochromator. Fourier transform IR (FTIR) spectra were recorded on a Perkin Elmer Paragon 1000 FTIR spectrometer at a spectral resolution of 2 cm^{-1}; the samples were prepared as KBr pellets (containing approximately 1% sample). Thermogravimetric analysis (TGA) was carried out on a TA Instruments SDT 2960 simultaneous DTA-TGA thermogravimetric analyser. Samples were heated (at a rate of 10°C min^{-1}) in an alumina crucible to a maximum temperature of 1200°C in an atmosphere of flowing oxygen (100 ml min^{-1}). Recalcined alumina was used as the reference material. For the materials containing PANI (CuPhP–PANI and CuCEP–PANI, see Section 3.1), the copper content was measured using a Philips PU9400X atomic absorption spectrometer. The solutions for analysis were prepared by digesting the samples in concentrated HNO_3 (Analar). The solutions were gently warmed to aid dissolution; after cooling, the solutions were made up to the required volume with distilled water. Standards of 5.0 ppm, 2.5 ppm and 0.5 ppm were prepared by dilution of a commercial copper solution standard.

3. Results and discussion

3.1. General observations

Refluxing the copper phosphonate materials in aniline resulted in the formation of viscous black solutions in which solid products were suspended. This colour change is indicative of polymerization of aniline in each of the reactions carried out. In each case, the solid products were separated by filtration, and we focus here on characterization of these materials. The nature of the recovered solids was different for each of the copper phosphonates considered. For the preparation involving CuMeP, the only crystalline solid recovered (as identified from powder X-ray diffraction) was bulk copper metal. Any other solid residues are presumably either amorphous (and not directly evident from powder X-ray diffraction) or have particle sizes sufficiently small that they are not collected in the filtration procedure. The solid (denoted CuCEP–PANI) recovered from the preparation involving CuCEP was violet in colour. The solid (denoted CuPhP–PANI) recovered from the preparation involving CuPhP was dark green in colour.

The colour of the solid products gives some indication of the oxidation state of the PANI, and the reported [26] colours of different forms of PANI are given together with their classical names in Table 1. The most frequently reported form of PANI resulting from reactions of this type [9,10] is the emeraldine base, which is dark blue in colour and becomes green on protonation.

The dark green colour of CuPhP–PANI suggests that the protonated emeraldine form of polyaniline has been formed. Indeed, this assignment is supported by the fact that, on subsequently suspending the material in a dilute solution of NaOH, a colour change from green to blue is observed (corresponding to deprotonation).

The CuCEP–PANI sample is particularly interesting, as the violet colour suggests that the PANI is produced in the fully oxidized perinigraniline form (note that the colour of this form does not change on protonation). Further reaction

Table 1
Colours and nomenclature for different forms of PANI; in each case the colour of the protonated form is given in brackets

	Colour	Name
$\{-(C_6H_4)-NH-(C_6H_4)-NH-\}_n$	yellow	leucoemeraldine base
$\{[-(C_6H_4)-NH-(C_6H_4)-NH-]_{0.75}[-(C_6H_4)-N=(C_6H_4)=N-]_{0.25}\}_n$	blue (light green)	protoemeraldine base
$\{[-(C_6H_4)-NH-(C_6H_4)-NH-]_{0.5}[-(C_6H_4)-N=(C_6H_4)=N-]_{0.5}\}_n$	dark blue (green)	emeraldine base
$\{[-(C_6H_4)-NH-(C_6H_4)-NH-]_{0.25}[-(C_6H_4)-N=(C_6H_4)=N-]_{0.75}\}_n$	blue–black (blue)	nigraniline base
$\{-(C_6H_4)-N=(C_6H_4)=N-\}_n$	violet (violet)	perinigraniline base

of CuCEP–PANI with dilute hydrochloric acid and dilute NaOH did not result in any colour change. As discussed below, we believe that the PANI is in the interlayer region in CuCEP–PANI, which probably renders it inaccessible to external reagents. To our knowledge, the perinigraniline form of PANI has not been reported previously to be obtained from a reaction of this type.

3.2. Sample analyses

For CuCEP–PANI, on the initial assumption that the sample contains only CuCEP and PANI, the CHN analysis (Table 2) leads to the composition $[Cu(O_3PCH_2CH_2CO_2H)] \cdot [C_6H_4N]_{0.95}$. However, while this accounts for the relative values of the percentages of C, H and N, it does not account for the absolute values of these percentages. Furthermore, this stoichiometry suggests that the residue ($Cu_2P_2O_7$) in the TGA experiments should represent 50.0% of the original mass (whereas the actual residue is 64.7% of the original mass), and suggests that the copper content is 16.4% (whereas the actual copper content found from analysis is 40.0%). These discrepancies are due to the presence of bulk copper metal (as evident from powder X-ray diffraction) in addition to CuCEP and PANI. During the TGA experiment, the bulk copper metal is oxidized to CuO, accounting for a mass increase centred around 550°C. On this basis, the residue from the TGA experiment (after heating to 1200°C) comprises $Cu_2P_2O_7$ (from the CuCEP) and CuO (from the bulk copper metal). In summary, the overall stoichiometry of the recovered product is $[Cu(O_3PCH_2CH_2CO_2H)] \cdot [C_6H_4N]_{0.95}[Cu]_{1.3}$.

For CuPhP–PANI, similar analysis (Table 2) leads to the following overall stoichiometry of the recovered product: $[Cu(O_3PC_6H_5)] \cdot [C_6H_4N]_{1.1}[Cu]_{0.1}$. In this case, the amount of bulk copper metal within the sample is substantially smaller than for the CuCEP–PANI sample discussed above. The presence of some bulk copper metal in CuPhP–PANI is again evident from powder X-ray diffraction, although this amount is apparently not sufficient to give an observable mass increase in the TGA experiment.

The TGA trace for CuPhP–PANI shows two major mass losses centred at 185 and 385°C, implying that the organic material in CuPhP–PANI is lost in two steps. These mass losses may be attributed to the loss of PANI (see also Section 3.3) and the organic part of CuPhP respectively. On the other hand, the TGA trace for CuCEP–PANI shows only one major mass loss centred at 378°C, suggesting that all the organic material (PANI and the organic part of CuCEP) is lost in one step. In both cases, there is a further mass loss at ca. 640°C, arising from the final oxidation to yield $Cu_2P_2O_7$.

3.3. Powder X-ray diffraction

The powder X-ray diffraction patterns for all the solid materials contain peaks characteristic of bulk copper metal. For the experiment involving CuMeP, bulk copper metal is the only crystalline product, whereas for the experiments involving CuCEP and CuPhP, bulk copper metal is not the major product. The powder X-ray diffraction patterns for CuCEP–PANI and CuPhP–PANI have an intense series of $(00l)$ peaks, suggesting that the layered nature of the host materials is retained during the formation of PANI. However, as now discussed, significant changes in the positions of these peaks indicate changes in the interlayer spacing. For CuCEP–PANI, no peaks with $h \neq 0$ or $k \neq 0$ are discernible above the noise level in the powder X-ray diffraction pattern, whereas for CuPhP–PANI, only very few peaks with $h \neq 0$ or $k \neq 0$ are discernible.

Table 2
Results of analyses of CuPhP–PANI and CuCEP–PANI; the experimental errors are ca. 0.3% in the CHN analysis and ca. 0.5% in the Cu analysis; the TGA residue represents $Cu_2P_2O_7 + CuO$

	CuPhP–PANI	CuCEP–PANI
C (%)	46.7	26.9
H (%)	4.2	2.3
N (%)	4.8	3.4
Cu (%)	23.7	40.0
TGA residue (theoretical)	42.9 (48.5%)	64.7 (66.5%)
Composition	$[Cu(O_3PC_6H_5)] \cdot [C_6H_4N]_{1.1}[Cu]_{0.1}$	$[Cu(O_3PC_2H_4CO_2H)] \cdot [C_6H_4N]_{0.95}[Cu]_{1.3}$

For CuCEP–PANI, powder X-ray diffraction (Fig. 1) shows that the formation of PANI is associated with an increase in the interlayer spacing of the CuCEP host material, providing direct evidence that the PANI is located within the interlayer region. The increase in the interlayer spacing is 10.2 Å. It is reported that inclusion of PANI within layered host materials leads to an increase in the interlayer spacing of ca. 4.2 Å if the phenyl rings are oriented parallel to the host layers [9] and ca. 8.6 Å if the phenyl rings are oriented perpendicular to the host layers [10]. On this basis, we deduce that the PANI included within CuCEP has a perpendicular orientation of the rings with respect to the layers of the host material.

In contrast, powder X-ray diffraction (Fig. 2) for CuPhP–PANI shows no evidence for an increase in the interlayer spacing, but instead a slight decrease from 14.5 to 12.7 Å is observed (note that powder X-ray diffraction patterns recorded at lower diffraction angles (higher *d*-spacing) than those shown in Fig. 2 confirm that no new peaks appear at very low diffraction angle (such peaks would indicate an increase in the interlayer spacing)). The slight decrease in the interlayer spacing in CuPhP–PANI suggests that some

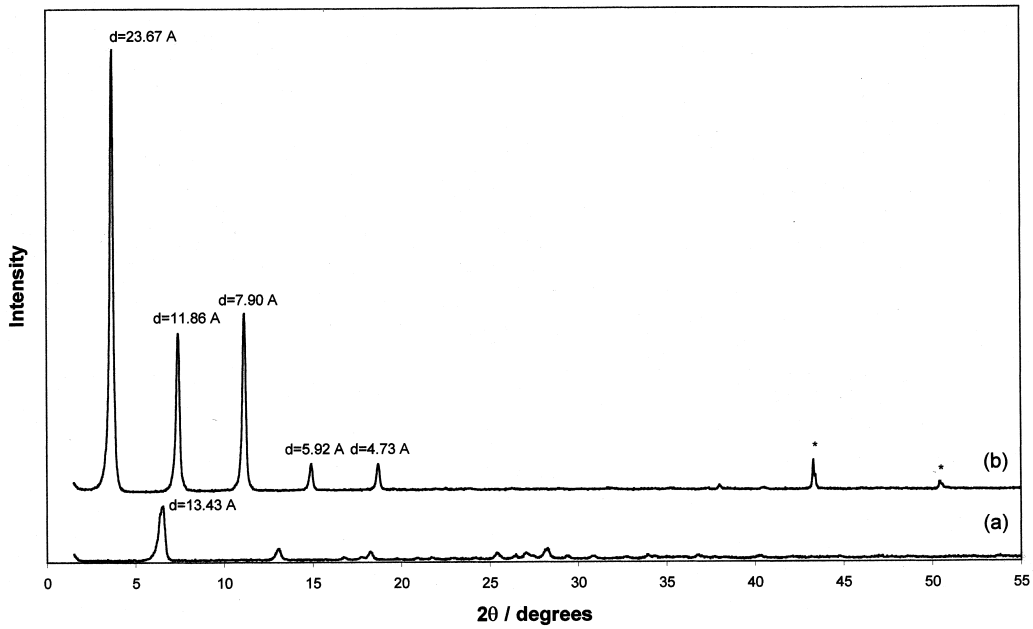

Fig. 1. Powder X-ray diffraction patterns (Cu Kα_1 radiation) for (a) CuCEP and (b) CuCEP–PANI. The *d*-spacings for selected (00*l*) peaks due to the layered metal phosphonate material are indicated. Peaks marked with an asterisk are due to bulk copper metal.

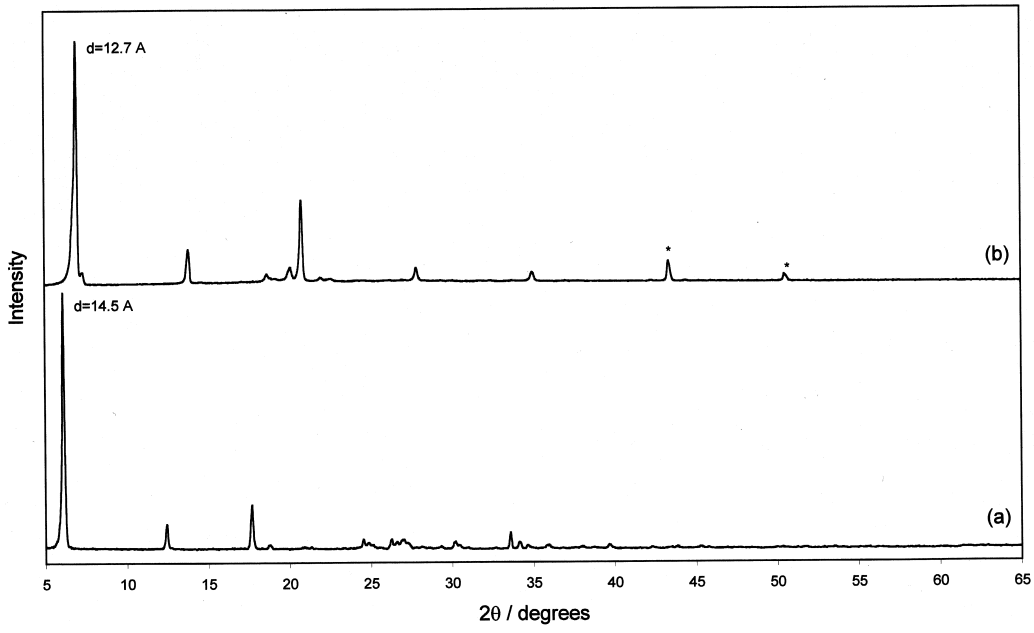

Fig. 2. Powder X-ray diffraction patterns (Cu Kα_1 radiation) for (a) CuPhP and (b) CuPhP–PANI. The *d*-spacings for selected (00*l*) peaks due to the layered metal phosphonate material are indicated. Peaks marked with an asterisk are due to bulk copper metal.

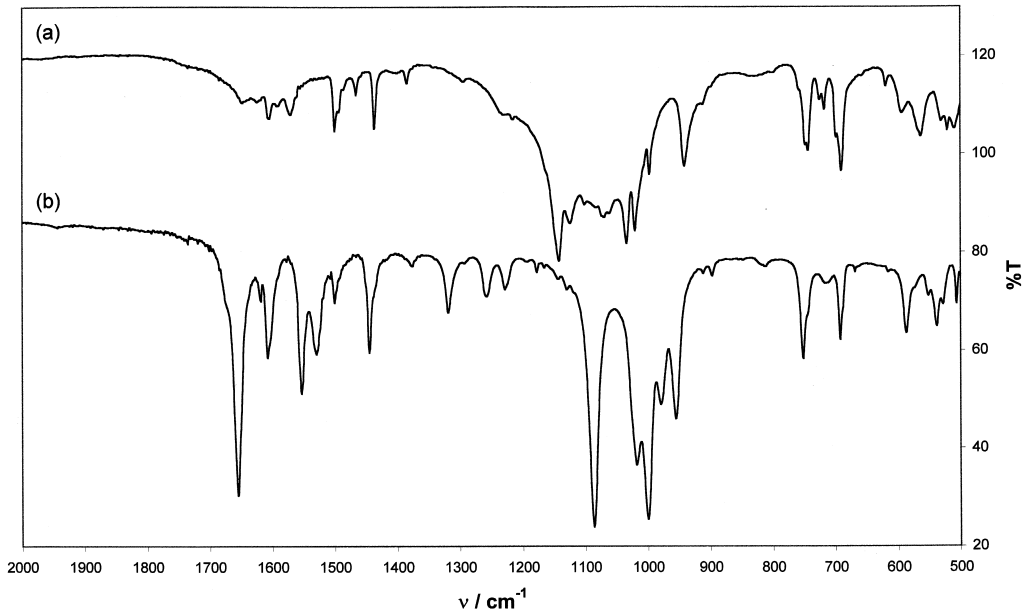

Fig. 3. FTIR spectra for (a) CuPhP–PANI and (b) CuCEP–PANI.

structural rearrangement of the parent host material (perhaps resulting from loss of water) is associated with the polymerization reaction. Our observations suggest that the formation of PANI in this system does not actually involve intercalation of PANI within the interlayer region, but may instead occur on the external surface of the CuPhP particles. Presumably some amount of PANI may be retained on the external surfaces of the CuPhP particles (giving rise to the colour of the solid product). However, the relative amount of PANI in the CuPhP–PANI sample recovered (see Section 3.2) implicates the presence of an additional phase of PANI (i.e. in addition to PANI on the external surfaces of the CuPhP particles). As there is no evidence from powder X-ray diffraction for any crystalline phase other than CuPhP, we may conclude that the excess PANI is present as an amorphous phase.

3.4. Infrared spectroscopy

Infrared spectroscopy has been used previously [8,10] to assign the oxidation state of PANI. The assignment relies on the relative intensities of peaks at ca. 1500 and 1600 cm^{-1}, which are associated with phenyl and quinoid ring vibrations respectively. The IR spectrum of the fully reduced form (leucoemeraldine) of PANI exhibits only a very weak peak at ca. 1600 cm^{-1}, and this peak becomes apparent as the level of oxidation of PANI increases (i.e. as the proportion of quinoid units increases). For CuPhP–PANI and CuCEP–PANI, peaks are observed in both regions ca. 1500 and ca. 1600 cm^{-1} (Fig. 3, Table 3). Other bands characteristic of the formation of PANI are at ca. 1290 cm^{-1} (medium) and ca. 820 cm^{-1} (weak), and are assigned as ring breathing and out-of-plane CH bending respectively. In addition, two sharp peaks observed in the ranges 770–730 cm^{-1} and 710–630 cm^{-1} are characteristic of five adjacent ring hydrogens (representing the chain end of the polymer). The fact that these bands are observed may indicate that the PANI is present as short oligomers. No bands characteristic of aniline or protonated aniline are observed for either CuPhP–PANI or CuCEP–PANI.

Table 3
Diagnostic vibration frequencies observed in FTIR spectra of CuPhP–PANI and CuCEP–PANI

CuPhP–PANI	CuCEP–PANI	Assignment
	1654	C=O carboxylic acid
1603	1607	ring mode (quinoid)
1499	1499	ring mode (phenyl)
1033	1085	ν(P–O) XPO_3 stretching mode
1019	1017	ν(P–O) XPO_3 stretching mode
996	998	ν(P–O) XPO_3 stretching mode
745	751	δ(C–H) out-of-plane 5 adjacent H atoms
690	692	δ(C–H) out-of-plane 5 adjacent H atoms
592	585	aromatic ring deformation
508	506	aromatic ring deformation

Bands associated with the layered copper phosphonate host materials are also observed in the region 1150–990 cm^{-1}, representing P–O stretching modes of the phosphonate group. The peak at 1654 cm^{-1} in the spectrum of CuCEP–PANI arises from the C=O group of the carboxylic acid. This frequency is slightly lower than that expected for a free carboxylic acid (ca. 1700 cm^{-1}) and may constitute evidence for an interaction between the carboxylic acid group and PANI in the interlayer region.

4. Conclusions

In summary, all three copper phosphonate materials used in this work give rise to polymerization of aniline. It is thought

that copper aids the oxidation of aniline by atmospheric oxygen, but in doing so, the copper phosphonate material is itself destroyed in the process. Reduction of Cu(II) to bulk copper metal is evident in the powder X-ray diffraction patterns of all the samples recovered. For CuMeP, bulk copper metal is the only crystalline product isolated following the polymerization reaction. For CuCEP and CuPhP, PANI is formed with retention (at least partially) of the layered copper phosphonate host material. For CuPhP–PANI, the emeraldine form of PANI is produced, but formation on the surfaces of the CuPhP particles (rather than within the interlayer region) is implicated. As such there is little change in the powder X-ray diffraction pattern of the layered copper phosphonate host material, and, as shown by the analyses, a relatively small quantity of bulk copper metal is produced. For CuCEP–PANI, the PANI is present as the perinigraniline form, and powder X-ray diffraction provides direct evidence that the PANI is retained within the layered copper phosphonate host material. The higher oxidation state of the PANI is reflected by the larger quantity of bulk copper metal produced (with the implication that the reduction of copper is associated with oxidation of PANI). In conclusion, the results reported here provide new insights concerning preparative aspects of PANI through reactions in constrained solid state environments, and demonstrate the diversity of behaviour that may result from the use of structurally related, although chemically different, host materials for this reaction. Ultimately, the observed differences in the course of the reactions in the three different copper phosphonate materials reflect, inter alia, the differing relative stabilities of these materials as well as the differing relative accessibilities of the metal centres to the aniline guest molecules. Clearly a future programme of experimental research, including the use of both in situ and ex situ probes of the structural and chemical evolution of the system as a function of reaction progress, should shed further light on mechanistic aspects of the reactions to produce PANI as well as the concomitant structural degradation of the copper phosphonate materials.

POLYHEDRON

Optical spectroscopy of neodymium(III) complexes with diethylenetriaminepentaacetic acid in solution and in $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ single crystal

Anna Mondry *, Przemysław Starynowicz

Faculty of Chemistry, University of Wrocław, Joliot-Curie 14, 50-383 Wrocław, Poland

Received 8 November 1999; accepted 3 January 2000

Abstract

The crystal structure of $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ (H_5dtpa = diethylenetriaminepentaacetic acid) has been determined. Electronic absorption spectra of a single crystal of the $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ compound were measured at room and liquid helium temperatures. In order to investigate the formation and structure of Nd^{III}–dtpa species occurring in solution, the spectral results for the crystal were compared with those of the Nd^{III}–dtpa (1:1) complex in solution. The analysis of spectral properties of this system may be applied for solutions of coordination chemistry problems encountered in lanthanide polyaminopolycarboxylates. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Contrast agents; Crystal structures; Diethylenetriaminepentaacetate; Lanthanides; Neodymium

1. Introduction

Our previous studies based on electronic absorption spectroscopy of lanthanide complexes with multidonor ligands in solution and single crystals have proved the usefulness of this method in the elucidation of such problems as the structure of complexes, the coordination environment of the Ln^{III} ion and the role of ligand polarizability [1–3]. Among lanthanide chelates with acyclic polyaminopolycarboxylates, the coordination chemistry of the Ln^{III} complexes with diethylenetriaminepentaacetic acid (H_5dtpa) is well recognized both in solution [4–25] and in the solid state [25–30]. The majority of investigations concern, however, the Gd^{III}–dtpa complex [19–27,31,32]. This compound has for many years been approved clinically as a contrast enhancing agent in magnetic resonance imaging (MRI).

Studies of Ln^{III} ion complexation in solution with the dtpa ligand were carried using various NMR techniques [13–24]. However, the application of those techniques may sometimes be problematic, particularly in cases when two or more species with different coordination modes are in equilibrium. To ascertain how the coordination properties of the Ln^{III}–dtpa system determined by different physical methods will influence its optical behaviour, we decided to study the Nd^{III}–dtpa complex using electron absorption spectroscopy both in the single crystal and in solution.

The aim of this paper is to report the solid-state X-ray structure and UV–Vis absorption spectroscopic results of the $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ crystal in order to compare its spectral properties with those of the Nd^{III}–dtpa (1:1) system in solution.

2. Experimental

2.1. Materials and sample preparation

A stock solution of neodymium perchlorate was prepared from Nd_2O_3 (99.9%; Merck). The Nd^{III} ion concentration was determined complexometrically using xylenol orange as indicator. The stock solution of H_5dtpa (98%; Aldrich) was prepared by half-neutralization with NaOH. The NaOH solution was also used to adjust the pH of investigated solutions. All measured solutions were prepared with the same ionic strength (0.5 M $NaClO_4$).

Crystals of $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ were prepared by a slightly changed method described by Ruloff

et al. [27]. The molar ratio of Nd_2O_3, H_5dtpa and $[C(NH_2)_3]_2CO_3$ was 1:2:2. After dissolution of the substrates, the solution was alkalized with $[C(NH_2)_3]_2CO_3$ to the final pH 5 and left to crystallization. Large well-formed violet crystals were obtained. The Nd^{III} ion concentration in these crystals was determined by inductively coupled plasma atomic emission spectroscopy (2.185 M). *Anal*. Found: C, 24.6; H, 6.2; N, 16.1; Nd, 19.1. Calc. for $[C(NH_2)_3]_2$-$[Nd(dtpa)(H_2O)]\cdot 7H_2O$: C, 24.1; H, 5.8; N, 15.8; Nd, 18.1%.

The refractive index (n) of the crystal was assumed to be 1.50 and that of the measured solutions − 1.33.

2.2. Crystallography

A suitable crystal was cut from a larger one, placed in a capillary and mounted on a Kuma KM4 diffractometer with κ geometry and a graphite monochromator. The unit cell parameters were determined from angular settings of 37 reflections with 2θ between 18 and 23°. The stability of data collection was monitored with three control reflections remeasured every 100 intensities. The data were corrected for Lorentz and polarization factors, but not for extinction. The position of the neodymium ion was found from a Patterson map; other atoms were found from subsequent difference Fourier syntheses. The C- and N-bonded hydrogen atoms were placed from geometry, and some of the water hydrogen atoms were found from a difference Fourier synthesis. The absorption corrections were calculated with the locally modified ABSORB program [33]. The structure was refined with the full-matrix least-squares method with all non-hydrogen atoms anisotropic and hydrogen atoms isotropic with common temperature factors (separately for C-, N- and O-bonded atoms). The positions of the hydrogen atoms were geometrically constrained (the C- and N-bonded ones) or restrained (the O-bonded ones). The calculations were performed with SHELXS-97 [34] and SHELXL-97 [35] programs with commonly used atom scattering factors and anomalous dispersion corrections [36]. Other details of data collection and the structure refinement are given in Table 1.

2.3. Spectroscopic measurements and calculations

All absorption spectra were recorded on a Cary 5 UV–Vis–near-IR spectrophotometer which was equipped with an Oxford CF 1204 continuous flow helium cryostat for single crystal measurements in the 293–4 K temperature range. The intensities of the 4f–4f transitions (P) and values of the Ω_λ parameters were calculated from the Judd–Ofelt [37,38] relation:

$$P=\chi\,\frac{8\pi^2 mc\sigma}{3h(2J+1)}\sum_{\lambda=2,4,6}\Omega_\lambda(f^n\psi J\|U^{(\lambda)}\|f^n\psi' J')^2 \qquad (1)$$

where P denotes the oscillator strength, $\chi=(n^2+2)^2/9n$, n is the refractive index, J is the total quantum number of the ground state, $(f^n\psi J\|U^{(\lambda)}\|f^n\psi' J')$ is the reduced matrix element of the unit tensor operator $U^{(\lambda)}$ tabulated by Carnall et al. [39] and Ω_λ are empirical least-squares fitted parameters.

3. Results and discussion

3.1. Crystal structure

The geometry of the first coordination sphere of the Nd^{III} ion is presented in Table 2. The structure consists of the complex anion, guanidinium cations and water of hydration. The Nd^{III} ion is nine-coordinate. Its environment consists of three nitrogen, five carboxylate oxygen atoms and a water molecule. The shortest Nd···Nd distance is 8.720(5) Å. The coordination figure of the lanthanide cation may be defined as a distorted capped square antiprism (CSA). In the best fitted figure the non-capped base is spanned by N(1), N(2), N(3) and O(9), whereas O(3), O(1), O(5) and O(7) form the capped one, and OW(1) is the cap. The parameter Δ (defined as $\Sigma d_i^2/9$, i=1–9, where d_i is the distance between ith atom and the relevant vertex of the ideal least-squares fitted polyhedron [40]) was 0.123 Å^2. On the other hand, none of the fitted tricapped trigonal prisms had Δ less than

0.3 Å^2. An ORTEP [41] view of the complex anion is presented in Fig. 1. There are two independent guanidinium cations in the structure. One of them forms hydrogen bonds with five water molecules and only one hydrogen bond to a carboxylate oxygen atom, O(4), from the complex anion. The other guanidinium cation links two symmetry related complex anions with two pairs of hydrogen bonds, and also forms bonds with two water molecules. In general, the structure is held together by a network of O···O and N···O hydrogen bonds.

It may be mentioned that in the case of crystals with bulky anions the countercations can markedly influence structural geometries around the metal ion because of their role in the formation of hydrogen bond network. Thus, comparing the crystal structures of the $[Nd(dtpa)(H_2O)]^{2-}$ anion in the barium [28] and in guanidinium salt, one can notice that for the first one, the Nd^{III}–$O(H_2O)$ distance is equal to 2.616 Å and is situated between the Nd^{III}–$O(COO^-)$ and Nd^{III}–N distances. For the $[C(NH_2)_3][Nd(dtpa)(H_2O)]\cdot 7H_2O$ compound this distance is equal to 2.449 Å and is comparable with Nd^{III}–$O(COO^-)$ bond lengths. The average Nd^{III}–dtpa distances for these crystals are 2.566 and 2.540 Å, respectively.

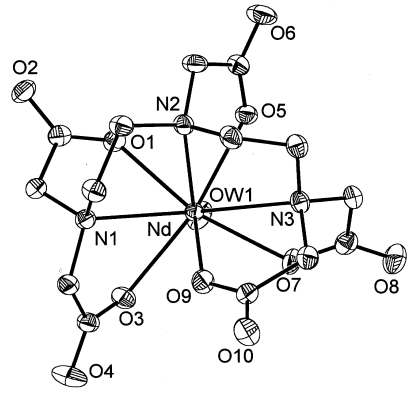

Fig. 1. An ORTEP view of the complex anion, together with the atom numbering scheme. The thermal ellipsoids are drawn at 30% probability. The labels of carbon atoms have been omitted for the sake of clarity. The OW(1) atom is eclipsed by Nd.

3.2. Spectral results

Absorption spectra of the Nd^{III}–dtpa (1:1) system were examined in aqueous solution over a wide pH range (1.5–13) at room temperature and for the $[C(NH_2)_3]_2$-$[Nd(dtpa)(H_2O)]\cdot 7H_2O$ single crystal at 293 and 4 K.

The assignment of the f–f transitions of the investigated complexes in the 300–2000 nm region is shown in Fig. 2. One can observe a good correspondence between the absorption spectra for these two phases. The number of Stark components of the excited states observed in the 4 K spectra for the crystal is in agreement with the expected splitting of levels predicted by the group theory for a single Nd^{III} ion site with the C_1 symmetry. The appearance of a single, sharp peak of the $^4I_{9/2}\rightarrow{}^2P_{1/2}$ transition at 23283 cm^{-1} with a half-width of 5 cm^{-1}, as well as a splitting of the $^2H_{11/2}$ into six optical lines (16071, 16029, 16000, 15962, 15928, 15914 cm^{-1}), the $^4F_{9/2}$ into five lines (14874, 14846, 14798, 14744, 14717 cm^{-1}) and the $^4F_{3/2}$ into two lines (11549, 11459 cm^{-1}) is indicative of a single Nd^{III} site, consistent with the X-ray analysis.

In order to compare the spectral properties of the single crystal with those in solution, the influence of pH on the UV–Vis spectra of 1:1 Nd^{III}–dtpa solutions was studied. The effect of pH on the shape of the two most characteristic transitions of the Nd^{III} ion, namely the $^4I_{9/2}\rightarrow{}^2P_{1/2}$ and the $^4I_{9/2}\rightarrow{}^4G_{5/2}$, $^2G_{7/2}$ for a 1:1 Nd^{III}–dtpa solution, is shown in Fig. 3. The shape and intensity of the absorption bands of the f–f transitions, especially of these two mentioned above, change up to a pH of about 3. A further increase of pH gives no changes in the absorption spectra. It indicates that even at pH ≈ 3 (which is lower than the third pK_a value of the H_5dtpa acid [42]), the inner coordination sphere of Nd^{3+} is not affected by protonation. It may suggest that the proton is attached to a non-coordinated atom of the carboxylate group.

The $^4I_{9/2}\rightarrow{}^2P_{1/2}$ transition can indicate the number of species of different coordination geometry around the Nd^{III} ion existing in equilibrium in solution, because the excited $^2P_{1/2}$ state is a Kramer's doublet and does not split in the ligand field of any symmetry. At low pH, around 2, two well-resolved peaks of this transition are observed. The energy of the first component corresponds to that observed for the aquoion (23406 cm^{-1}) and disappears when the pH of the investigated solutions increases, whereas the position of the second peak at 23276 cm^{-1} remains constant in all examined solutions. With the pH increases up to 3 it becomes only

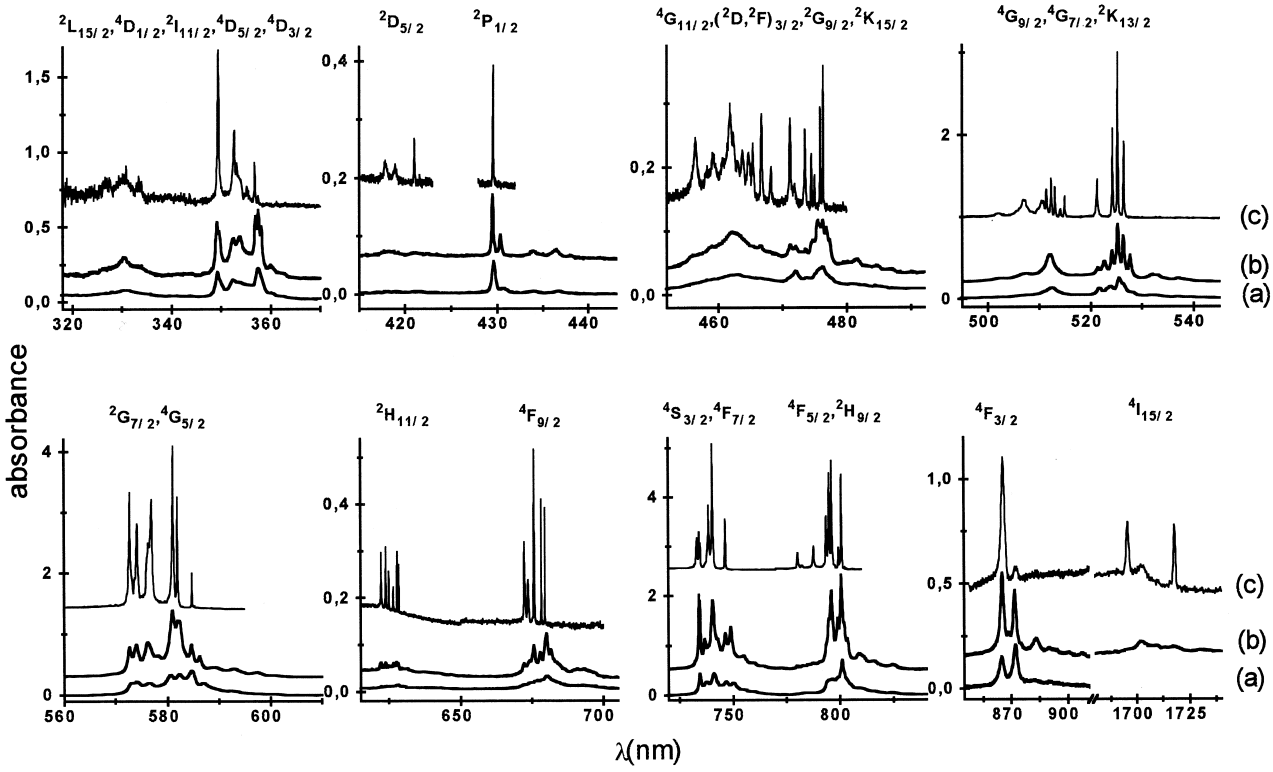

Fig. 2. Absorption spectra of Nd^{III}–dtpa complexes in solution (a) and for the crystal of $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ at 293 K (b) and 4 K (c). For solution: $c_{Nd}=1.827\times10^{-2}$ M, $c_{dtpa}=2.403\times10^{-2}$ M, pH = 8.61, $d=2$ cm. For crystal: $c_{Nd}=2.185$ M, $d=0.053$ cm.

narrower and more intense. Its width at the half-height is equal to 33 and 24 cm^{-1} at pH 1.85 and at pH ≥ 3, respectively, while the half-width of the relevant peak of the $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ crystal at 23283 cm^{-1} is equal to 13 cm^{-1} at 293 K.

Since the excited $^2P_{1/2}$ state is a Kramer's doublet, we were able to deduce the energies of the components of the $^4I_{9/2}$ ground multiplet, which amount: 0, 60, 235, 378 cm^{-1} for solutions at pH above 3 (the fifth level was not identified) and 0, 47 (45), 240 (239), 372 (374), 453 (459) cm^{-1} for the crystal. The values of the energy sublevels given in parentheses were found from the splitting of the $^4I_{9/2}\rightarrow{}^4F_{3/2}$ transition.

The hypersensitive $^4I_{9/2}\rightarrow{}^4G_{5/2}$, $^2G_{7/2}$ transition shows among all f–f transitions the strongest intensity variations depending on the changes of the nearest surrounding of the Nd^{III} ion. It has to be pointed out that when the equilibrium between species is reached (pH ≈ 3), the intensity and shape of the band does not change any more. Absorption spectra of this transition for the aquoion and the $[C(NH_2)_3]_2$-$[Nd(dtpa)(H_2O)]\cdot 7H_2O$ crystal are for comparison purposes also presented in Fig. 3b. A good agreement between the crystal field energies, but not between intensities of particular crystal field components, in the hypersensitive transition of these two phases is observed. This may indicate that the similarity between the coordination polyhedra of species found for the crystal and those existing in solution is not satisfied.

Analysing the $^4I_{9/2}\rightarrow{}^2P_{1/2}$ transition spectra shown in Fig. 3a, one may observe that even in the solution with a very low pH value (≈2), for which exists the equilibrium between the aquoion and hydrated species of the Nd^{III}–dtpa complex, the arrangements of donor atoms around the Nd^{III} ion are very similar to that of the fully deprotonated Nd^{III}–dtpa chelate. Probably in the case when the dtpa is still highly protonated, the number of water molecules is about three, as was shown from the luminescence decay lifetime measurements for the Tb^{III}–dtpa complex [12]. Nevertheless, the characteristic peak energy of the Nd^{III}–dtpa complex is unchangeable as well for the hydrated protonated species as for the deprotonated species. This means that this large polyaminopolycarboxylate molecule imposes the coordination environment around the Nd^{III} ion even at very low pH values, by encapsulating hydrated species of the Nd^{III} ion. When the carboxylate groups become deprotonated, the coordinated water molecules are substituted.

The appreciable broadening of the peak of the $^4I_{9/2}\rightarrow{}^2P_{1/2}$ transition at 23276 cm^{-1} in the solution spectra as compared to that in the crystal may be a result of stronger vibronic interactions in the solution and/or of the presence of species which differ very slightly from each other. It seems likely that it can be caused by the mutual interconversion of two species which occur in the middle O_2CCH_2N branch of the dtpa ligand [18].

It should be pointed out that the energy of the highest peak in the $^4I_{9/2}\rightarrow{}^2P_{1/2}$ transition is shifted to the UV region in

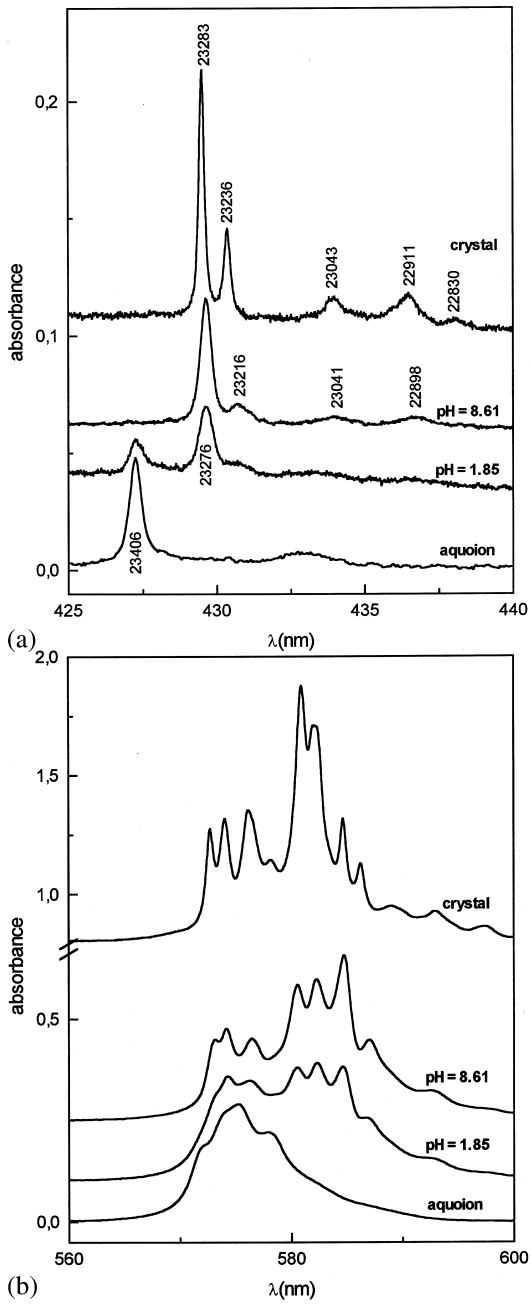

Fig. 3. Absorption spectra of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ (a) and $^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$ (b) transitions of the aquoion and Nd^{III}–dtpa systems. For solution: $c_{Nd} = 1.827 \times 10^{-2}$ M, $c_{dtpa} = 2.403 \times 10^{-2}$ M, $d = 2$ cm. For crystal: $c_{Nd} = 2.185$ M, $d = 0.053$ cm.

the spectrum of the crystal compared to that in solution. However, one should notice that the energy of this transition in the crystal spectra may depend on the size and electrostatic properties of the used counter-cations. As has been shown by the X-ray investigations of the barium [28] and guanidinium salts, these counter-cations form a different hydrogen bond network with the hydration water molecules and the oxygen atoms from the ligand molecules. The rigid hydrogen bond network in the solid state, contrary to that in the solution, to some degree may affect the geometry around the Ln^{III} ion, which influences the position of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition.

It is interesting to compare the spectral intensities of all f–f transitions as well as the Ω_λ parameters for the studied Nd^{III}–dtpa complexes in solutions and in the single crystal. These results together with that for the aquoion are presented in Table 3. A large decrease in intensity of almost all transitions in the single crystal is observed when the temperature is lowered from 293 to 4 K. Because of the high J manifolds of the Nd^{III} ion in the ground and excited states it is difficult to establish which part of the intensity changes is related to 'hot' transitions from the ground state and which to the vibronic transitions.

The oscillator strength values of the f–f transitions of the $[Nd(dtpa)(H_2O)]^{2-}$ complex in the crystal at 293 K resemble much more those of the aquoion than those calculated for solutions. This is especially well seen for the most intense transitions of the Nd^{III} ion like the $^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$ hypersensitive transition, the $^4I_{9/2} \rightarrow {}^4F_{7/2}$, $^4S_{3/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$ transitions, which play a significant role in the Judd-Ofelt intensity analysis.

According to Mason [43], the ligand polarization mechanism is important mainly for hypersensitive transitions and influences the Ω_2 parameter values, while the crystal field mechanism contributes mostly to the Ω_6 values. In the case of Nd^{III} compounds, the Ω_6 parameters depend particularly on intensities of the $^4I_{9/2} \rightarrow {}^4F_{7/2}$, $^4S_{3/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$ transitions for which the $U^{(6)}$ matrix elements have the highest values [39]. In the Nd^{III}–dtpa solution spectrum, the values of the oscillator strengths of these transitions, the hypersensitive one as well as the Ω_λ parameters have higher values than those for the crystal spectrum. This may indicate that in solution various species differing in both symmetry and total polarizability of ligands are present.

A similar phenomenon, connected with much higher oscillator strength values of the $^4I_{9/2} \rightarrow {}^4F_{7/2}$, $^4S_{3/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$ transitions for solution as compared to the crystal, was earlier reported for the $[Nd(dpa)_3]^{3-}$ complex [1], where dpa^{2-} is a dipicolinate anion. This distinct intensity increase was explained to be caused by a high structural dynamics between $[Nd(N_3O_6)]^{3-}$ species, which in solution exist as a racemic mixture [44,45].

It is noteworthy that, in the solid state, the oscillator strengths of the $^4I_{9/2} \rightarrow {}^4F_{7/2}$, $^4S_{3/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$ transitions, which are higher than those of the aquoion but similar to those observed for Nd^{III}–dtpa (1:1) and $[Nd(dpa)_3]^{3-}$ complexes in solution, were obtained for a dimeric crystal of the Nd^{III} complex with triethylenetetraaminehexaacetic acid [3]. In this crystal both Nd^{III} centres are very similar, though not strictly equivalent. This confirms a significant contribution of the crystal field mechanism on the Ω_6 parameter value.

The presented results establish a certain parallelism to earlier investigations of lanthanide polyaminocarboxylates, and therefore will be of use while studying similar systems for which other methods are difficult to apply.

Table 3
Oscillator strength (P) and Ω_λ parameters for Nd^{III} complexes with dtpa in solution at 293 K and for the $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ crystal at 293 and 4 K [a]

Supplementary data

The X-ray crystallographic data for the structure of the $[C(NH_2)_3]_2[Nd(dtpa)(H_2O)]\cdot 7H_2O$ compound have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) as supplementary publication no. CCDC 136710.

Acknowledgements

The authors would like to thank Professor K. Bukietyńska for valuable discussions and Dr L.B. Jerzykiewicz for help in performing the X-ray measurement. This work was supported by the Polish Committee of Scientific Research.

Abstract

Solid complexes of lanthanide picrates with 2,2′-[1,2-phenylenebis(oxy)]bis(*N*,*N*-diphenylacetamide) (PBD) have been prepared in ethanol. These complexes have been characterized by elemental analysis, conductivity measurements, IR, electronic and ^{1}H NMR spectroscopies. The crystal and molecular structures of $[Y(pic)_3(PBD)]\cdot 3.8CH_3CN$ have been determined. The crystal structure shows that the Y(III) ion is coordinated to four oxygen atoms of PBD, four oxygen atoms of one bidentate and two unidentate picrates. The coordination number of yttrium is eight. The structure reveals that PBD acts as a tetradentate ligand, forming a ring-like coordination structure similar to those of crown compounds. The Eu(III) complex shows strong emission when excited with 260 nm radiation in the solid state. The intensity ratio $^5D_0$–$^7F_2$/$^5D_0$–$^7F_1$ is 21.5. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Lanthanide picrates; PBD; Fluorescence; Crystal structures

1. Introduction

Acyclic polyethers offer many advantages over the use of crown ethers in the extraction and analysis (ion-selective electrodes) of rare earths [1–6]. Ding et al. have reported that *N*,*N*,*N*′,*N*′-tetraphenyl-3,6-dioxaoctanedimide (TDD) has the largest separation factor of five derivatives of glycol-*O*,*O*′-diacetamide, and both the separation factor and distribution ratio of lighter lanthanide ions for TDD are larger than those for dicyclohexyl-18-crown-6, if the picrate is used as accompanying ion [4]. In order to further investigate the affect of the variety of skeleton on the properties and structures of compounds, the group $–CH_2–CH_2–$ of TDD was changed to phenylene, i.e. 2,2′-[1,2-phenylenebis(oxy)]-bis(*N*,*N*-diphenylacetamide) (PBD). PBD has been used as a neutral carrier of sodium ion-selective electrodes [7], however solid complexes with PBD have rarely been investigated. We report here the synthesis, characterization and structure of complexes of lanthanide picrates with PBD.

2,2'-[1,2-phenylenebis(oxy)]bis(*N*,*N*-diphenylacetamide) (PBD)

2. Experimental

2.1. Materials

Lanthanide picrates [8] and PBD [7] were prepared according to the literature methods. All commercially available chemicals were reagent grade and were used without further purification.

2.2. General preparation of the complexes

A solution of lanthanide picrate (0.1 mmol) in 15 ml of anhydrous ethanol was added dropwise to a solution of PBD

(0.1 mmol) in 10 ml of anhydrous ethanol. The mixture was stirred at room temperature for 2 h. The precipitated solid complex was filtered, washed with ethanol and dried in vacuo over P_4O_{10} for 48 h. All the complexes are yellow powders and stable in air. Single crystals of the yttrium complex were grown and recrystallized from MeCN with slow evaporation in a desiccator over $CaCl_2$ at room temperature. After ca. 3 weeks, transparent yellow crystals were formed from the solution.

2.3. Chemical and physical measurement

The lanthanide(III) ion was determined by EDTA titration using xylenol orange as an indicator. C, H, N were determined using a vario-EL elemental analyzer. Conductivity was determined using a conductivity bridge with 10^{-3} mol dm^{-3} in CH_3COCH_3 at 25°C. Thermal analyses (TG and DTA) were performed on a Beijing Optical Instrument Factory PCT-2 precision thermobalance analyzer in air at a heating rate of 5°C min^{-1}. The IR spectra were recorded on a Nicolet 170 SX FT-IR instrument using KBr disks in the 220–4000 cm^{-1} region. ^{1}H NMR spectra were recorded on a Bruker AC 80 spectrometer in CD_3COCD_3 solution, with TMS as internal standard. Electronic spectra were recorded with a UV-260 Shimadzu spectrophotometer in acetonitrile solution. Fluorescence spectra were obtained on a Hitachi M-850 fluorescence spectrophotometer.

2.4. X-ray crystallography

For the yttrium complex, X-ray measurements were performed on a P4 four-circle diffractometer with graphite-monochromatized Mo Kα radiation at 295 ± 2 K. A summary of crystallographic data and details of the structure refinements are listed in Table 1. The structure was solved by direct methods and refined by full-matrix least-squares techniques with all non-hydrogen atoms treated anisotropically. Theoretical models fixed the hydrogen atoms of the compounds. All calculations were performed on an Eclipse S/140 computer with the program package SHELXTL.

3. Results and disscussion

Analytical data for the complexes (presented in Table 2) conform to a 1:3:1 metal-to-picrate-to-PBD stoichiometry, Ln(pic)$_3$(PBD), together with 1 mol C_2H_5OH and 1 mol H_2O. All the complexes are soluble in polar organic solvents, DMSO, acetone, methanol and MeCN etc., and are slightly soluble in ethanol and AcOEt. They are sparingly soluble in benzene, Et_2O and cyclohexane. The molar conductance values of the complexes in acetone (Table 2) indicate the presence of a non-electrolyte [9].

DTA analyses of the complexes of Sm(III) and Y(III) show that they lose one ethanol molecule at 71 and 80°C and lose one water molecule at 148 and 154°C respectively, corresponding to endothermic peaks. The weight losses of these complexes are in agreement with the calculated values.

Table 2
Analytical data and molar conductance values for [Ln(pic)$_3$(PBD)]·C_2H_5OH·H_2O (Ln = La, Nd, Sm, Eu, Er, Y)

Complex	C (%) found (calc.)	H (%) found (calc.)	N (%) found (calc.)	Ln (%) found (calc.)	Λ_m (S cm^2 mol^{-1})
[La(pic)$_3$(PBD)]·C_2H_5OH·H_2O	45.24 (45.80)	3.02 (2.99)	10.79 (10.88)	9.54 (9.81)	22.16
[Nd(pic)$_3$(PBD)]·C_2H_5OH·H_2O	45.61 (45.63)	2.77 (2.98)	10.62 (10.84)	9.89 (10.15)	25.69
[Sm(pic)$_3$(PBD)]·C_2H_5OH·H_2O	45.56 (45.44)	2.96 (2.97)	10.56 (10.80)	10.41 (10.54)	21.83
[Eu(pic)$_3$(PBD)]·C_2H_5OH·H_2O	45.40 (45.38)	2.97 (2.96)	10.57 (10.78)	10.35 (10.64)	20.23
[Er(pic)$_3$(PBD)]·C_2H_5OH·H_2O	44.74 (44.90)	2.67 (2.93)	10.58 (10.67)	11.21 (11.58)	19.12
[Y(pic)$_3$(PBD)]·C_2H_5OH·H_2O	47.96 (47.48)	3.06 (3.10)	10.97 (11.28)	6.74 (6.51)	20.98

3.1. IR spectra

The IR spectrum of free PBD shows bands at 1677 and 1078 cm^{-1} assigned to ν(C=O) and ν(C–O–C). In the complexes of La, Sm and Y, the bonds shift by ca. 60 and 50 cm^{-1} towards lower wave numbers, thus indicating that the C=O and ether O-atoms take part in coordination to the metal ions. The large shifts for ν(C=O) in the spectra of the complexes suggest that the Ln–O(carbonyl) bond is stronger than the Ln–O(ether) bond.

The OH out-of-plane bending vibration of the free Hpic at 1151 cm^{-1} disappears in the spectra of the complexes, indicating that the H-atom of the OH group is replaced by Ln(III). The vibration ν(C–O) at 1265 cm^{-1} is shifted toward higher frequency by ca. 5 cm^{-1} in the complexes. This is due to the following two effects. First, the hydrogen atom of the OH group is replaced by Ln(III), increasing the π-bond character in the C–O bond. Secondly, coordination of the oxygen atom of PBD to Ln(III) causes the π-character to weaken. The free Hpic has $\nu_{as}(NO_2)$ and $\nu_s(NO_2)$ at 1555 and 1342 cm^{-1} respectively, which split into two bands at ca. 1581, 1542 cm^{-1} and ca. 1331, 1361 cm^{-1}, respectively, in the complexes. This indicates that some nitronyl O-atoms take part in coordination [10].

3.2. ^{1}H NMR spectra

The ^{1}H NMR spectra of the free ligand PBD and its lanthanum and yttrium complexes were determined in CD_3COCD_3. The spectrum of PBD exhibits two unsolved multiplets at ca. 7.41 and 6.66 ppm and a singlet at 4.62 ppm, assigned to $-C_6H_5-$, $-C_6H_4-$, $-C(O)-CH_2-$ respectively. Upon coordination, the signals of $-C(O)CH_2-$ are shifted by 0.3 ppm and those of $-C_6H_4-$ protons by only 0.03 ppm. This is probably due to the inductive effect of Ln–O(PBD) bands and a change in the conformation of the ligand in the complexes. The larger shift for $-C(O)-CH_2-$ protons than for $-C_6H_4-$ protons indicates that the Ln–O(C=O) bond is stronger than the Ln–O(C–O–C) bond [11].

The ^{1}H signal of the OH group in free Hpic disappears in the complexes, indicating that the H-atom of the OH group is replaced by Ln(III).The benzene ring protons of the free Hpic exhibit a singlet at 9.12 ppm. Upon coordination, the signal moves to higher field. Only one singlet is observed for the benzene ring protons of the three coordination picrate groups, indicating fast exchange among the groups in solution [12].

In addition, the spectra of these complexes also exhibit a triplet at ca. 3.5 ppm and a quadruplet at ca. 1.2 ppm assigned to $-CH_2-$ and $-CH_3$ of CH_3CH_2OH. There is a singlet at ca. 3 ppm assigned to H_2O which disappeared after D_2O was added.

3.3. Electronic spectra

The electronic spectra in the visible region of the Nd(III) and Er(III) complexes exhibit alternations in intensity and shifts in position of the absorption bands relative to the corresponding Ln(III) aquo ions. The shift has been attributed by Jørgensen to the effect on the crystal field of interelectronic repulsion between the 4f electrons, and is related to the covalent character of the metal–ligand bond, assessed by Sinha's parameter (δ), the nephelauxetic ratio (β) and the bonding parameter ($b^{1/2}$) [13–15]. The relative energies and J level assignments are given in Table 3; the values of covalent parameters are also presented.

The values of β, which are less than unity, and positive values of δ and $b^{1/2}$ support the existence of partial covalent bonding between metal and ligand [16]. The comparatively small magnitude of $b^{1/2}$ values also shows the involvement of the 4f orbital metal–ligand bond to be very small. Moreover, the magnitudes of covalency and bonding parameters increase from Nd(III) to Er(III), indicating that the extent of covalent character of the metal–ligand bond increases with atomic number (in agreement with the lanthanide contraction).

3.4. Electronic fluorescence

Only the Eu(III) complex shows strong emission when excited with 260 nm radiation in the solid state at room temperature. Excitation around 260 nm causes a strong emission of the Eu(III) complex, in which the luminescence band of the ligand does not appear, suggesting that energy transfer from ligand-centered to metal-centered levels takes place [17]. The most intense band at 616 nm is assigned to a $^5D_0$–$^7F_2$ transition, while the two relatively weak bands at 592 and 699 nm are assigned to $^5D_0$–$^7F_1$ and $^5D_0$–$^7F_4$ transitions,

Table 3
Electronic spectral data and covalent parameters

Complex	Frequency (cm^{-1})	Assignment	Covalent parameters
Nd(pic)$_3$(PBD)	11473	$^4I_{7/2}$–$^4F_{3/2}$	$\beta = 0.9992$
	12497	–$^4F_{5/2}$	$\delta = 0.0801$
	13426	–$^4F_{7/2}$	$b^{1/2} = 0.0200$
	13624	–$^4S_{3/2}$	
	14758	–$^4F_{9/2}$	
	16015	–$^2H_{11/2}$	
	17212	–$^4G_{5/2}$	
	19040	–$^2K_{13/2}$	
	19577	–$^4G_{9/2}$	
Er(pic)$_3$(PBD)	15291	$^4I_{15/2}$–$^4F_{9/2}$	$\beta = 0.9991$
	18450	–$^4S_{3/2}$	$\delta = 0.0901$
	19172	–$^2H_{11/2}$	$b^{1/2} = 0.0212$

Table 4
Electronic fluorescence spectral data for the solid Eu complex

Electron transition	Peak (nm)	Relative intensity
$^5D_0$–$^7F_1$	592	0.65
$^5D_0$–$^7F_2$	616	14.05
$^5D_0$–$^7F_4$	699	0.89

respectively (Table 4). The exceptionally high value for the intensity ratio η ($^5D_0$–$^7F_2$/$^5D_0$–$^7F_1$) of 21.5 indicates that the central Eu(III) ion does not lie in a centrosymmetric coordination site [18], in agreement with the crystal structure analysis.

3.5. X-ray crystal structure

Fig. 1 shows the structure and the atomic numbering schemes for the yttrium complex, and Fig. 2 shows the molecular packing arrangement in the unit cell. Selected bond lengths and angles are given in Table 5.

The crystal structure is composed of [Y(pic)$_3$(PBD)] and 3.8CH_3CN linked by van der Waals' force. The Y(III) ion is eight-coordinated by four oxygen atoms of PBD and four oxygen atoms of one bidentate and two unidentate picrates. The coordination polyhedron is a distorted dodecahedron. The PBD molecule wraps around the metal ion with its oxygen atoms and forms a ring-like coordination structure together with the yttrium atom. The four oxygen atoms of PBD (O(1), O(2), O(3), O(4)) are not quite coplanar, their deviation from the mean plane being in the range 0.021–0.064 Å. The mean absolute deviation is 0.051 Å from the mean plane. The yttrium atom lies out of this plane by 0.096 Å.

The average distance between the yttrium atom and the coordinated oxygen atoms is 2.347 Å, where the Y–O(19) distance is the shortest, owing probably to the higher electron density on the oxygen anion of the picrate. The Y–O(C=O) distances (mean 2.283 Å) are significantly shorter than the Y–O(C–O–C) distances (mean 2.460 Å). This suggests that the Er–O(C=O) bond is stronger than the Y–O(C–O–O) bond, in agreement with the ^{1}H NMR and IR spectral data.

Compared with crystallographic data of Y(pic)$_3$TDD [19], the average Y–O(C=O) bond length of the present

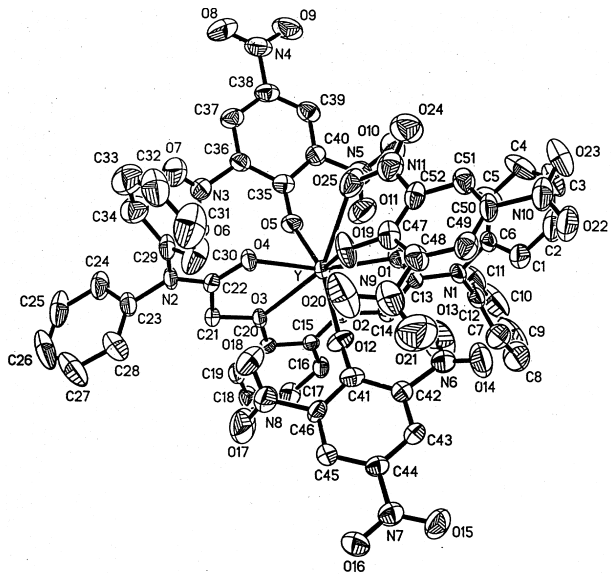

Fig. 1. Molecular structure of [Y(pic)$_3$(PBD)] · 3.8CH_3CN.

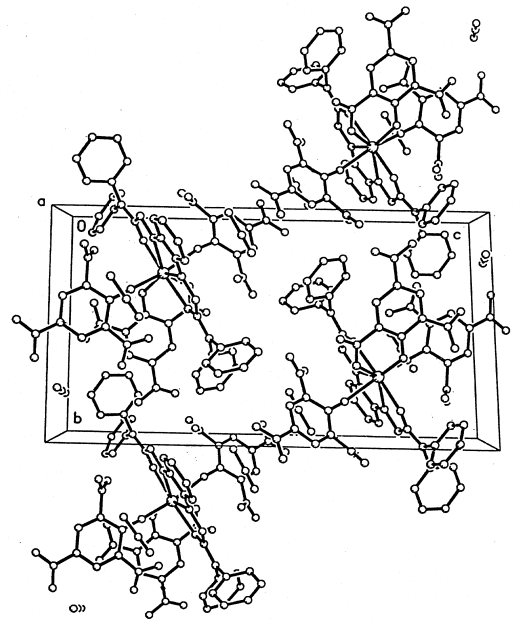

Fig. 2. The molecular packing arrangement in the unit cell.

complex is a little shorter than that of Y(pic)$_3$TDD, but the Y–O(C–O–C) bond length is longer than that of Y(pic)$_3$ TDD. The existence of phenylene in the PBD skeleton causes a noticeable difference in the conformations of these two crystal structures. The relevant torsion angle is O_2–C_{15}–C_{20}–$O_3 = 0.5(4)°$, which is smaller than that of Y(pic)$_3$TDD (O_2–C_{15}–C_{16}–$O_3 = -53.0(8)°$).

In conclusion, the PBD molecule acts as a multidentate ligand forming a ring-like coordination structure. Because of

its flexibility, PBD exhibits a stable conformation that provides a cavity. The internal cavity formed by the coordination oxygen atoms is suited for the uptake of a cation. Because of its rigid structure, it has a relatively fixed cavity. This enables PBD to be more sensitive to the variation of radius of the lanthanide ion. So it is expected to have a better selectivity than TDD.

Supplementary data

Abstract

1-Trifluoromethyl-3-[2.2]metacyclophanyl-1,3-propanedione (HtfacacMCP) which has a non-planar conjugated π system and 1-trifluoromethyl-3-(*p*-tolyl)-1,3-propanedione (*p*-tolutfacacH) as the referential ligand were prepared. Complexation of these ligands with europium(III) chloride in the presence of bipyridine (bpy) gave (tfacacMCP)$_3$(bpy)Eu(III) and piperidinium[(*p*-tolutfacac)$_4$Eu(III)] complexes respectively. The X-ray crystal structure of (tfacacMCP)$_3$(bpy)Eu(III) revealed an eight-coordinate configuration with two N atoms of bpy and six O atoms of HtfacacMCP. On the other hand, piperidinium[(*p*-tolutfacac)$_4$Eu(III)] was found to be an eight-coordinate complex surrounded by eight O atoms of *p*-tolutfacacH. The former contains bpy, but the latter contains no bpy. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; Europium(III) complexes; Non-planar conjugated ligands; Fluorescence spectra

1. Introduction

Europium(III) complexes of β-diketone type give a narrow-band emission from the europium ion under near-UV excitation, and some of these complexes exhibit laser action when dissolved in organic solvents [1,2]. The absorbed pump energy is transferred intramolecularly to the europium ion via a triplet state (by intersystem crossing). Since this intramolecular energy transfer from the triplet state to the resonance level of an europium ion is of a spin-forbidden type, the energy is transferred by the resonant exchange interaction in which the role of the triplet state is very important. It has been concluded by many researchers that the excitation energy could not be transferred from the ligand to the europium ion if the triplet state of the ligand was below the resonance level of the europium ion [3]. On the other hand, the through-space interaction in small-sized metacyclophane (MCP) compounds has attracted great interest by organic and organophysical chemists [4–7]. The spectral properties of these MCP compounds are particularly interesting because there is transannular interaction between the π electrons of two aromatic rings and the non-planar π conjugated system formed [8]. In the past, experimental and theoretical studies of the fluorescence behavior of these MCP compounds were scarcely investigated because of difficulties in synthesizing MCPs in a large amount and calculation of the energy level of the non-planar π conjugated system in the MCPs. In this paper, we report the preparation of [2.2]MCP having a β-diketone moiety as a ligand and its complexation with an europium ion in the presence of bipyridine and piperidine. Furthermore, the europium(III) complex with 1-trifluoromethyl-3-(*p*-tolyl)-1,3-propanedione (*p*-tolutfacacH) was prepared under the same conditions. Structures of these complexes were analyzed by X-ray structure analyses. ^{1}H NMR, FT-IR, UV and fluorescence spectra of the complexes were recorded in order to determine the relationship between the π electron systems in the ligands and the spectral properties.

2. Experimental

2.1. Materials and methods

All chemicals were of reagent grade and were used without further purification. All solvents except for ethanol were used without further purification. Absolute ethanol was used in the complexation reaction. Reactions were carried out in an apparent flask under argon atmosphere. 8,16-Dimethyl-[2.2]MCP and *p*-tolutfacacH were prepared according to the literature [9,10].

All melting points were recorded on a Yanako hot-stage microscope apparatus and are uncorrected. FT-IR spectra in the region 400–4000 cm^{-1} were taken on a Nippon Bunko JASCO IR-700 spectrophotometer at room temperature. The KBr technique was employed. Ultraviolet and visible spectra covering the 14000–37000 cm^{-1} range were recorded on a Shimadzu UV-200S double beam spectrophotometer for chloroform solutions at room temperature. ^1H NMR measurement were taken on a Nippon Densi α-500 spectrometer operating in Fourier transform mode. The NMR spectra were run in $CDCl_3$ and chemical shifts are given in ppm relative to tetramethylsilane as an internal reference standard. Mass spectra were recorded with a Nippon Densi JMS-SX102A spectrometer using a direct inlet system for EI measurement and in a glycerin matrix for FAB measurement. Elemental analyses were determined with a Yanaco CHN corder MT-3.

2.2. Synthesis of 5-acetyl-8,16-dimethyl[2.2]MCP

To a solution of 8,16-dimethyl[2.2]MCP (4.0 g, 17 mmol) in CS_2 (200 ml) were added acetic anhydride (300 mg, 5.6 mmol) and $TiCl_4$ (3.8 ml), and then the mixture was stirred for 3 h at room temperature. The reaction mixture was poured into water and the organic layer was washed with water and dried over anhydrous magnesium sulfate. Solvents were removed under reduced pressure and the residue was chromatographed on a silica gel column with toluene–chloroform (1:1 vol/vol) as an eluent to give 5-acetylMCP as colorless needles (1.98 g, 42%). M.p. 134–135°C (hexane). *Anal.* Calc. for $C_{20}H_{22}O$: C, 86.29; H, 7.97. Found: C, 86.33; H, 7.91%. ^1H NMR ($CDCl_3$, 500 MHz): 0.49 (s, 3H), 0.53 (s, 3H), 2.56 (s, 3H), 2.70–3.05 (m, 8H), 6.93 (t, 1H, $J=7.32$ Hz), 7.13 (d, 2H, $J=7.32$ Hz), 7.75 (s, 2H). IR (KBr, cm^{-1}): 2569(m), 1672(s), 1585(m), 1353(m), 1282(s), 1184(m), 775(w), 728(w). MS (EI): 278 (M^+).

2.3. Synthesis of 1-trifluoromethyl-3-[2.2]metacyclophanyl-1,3-propanedione (HtfacacMCP)

To a solution of 5-acetyl-8,16-dimethyl[2.2]MCP (1.01 g, 3.6 mmol) in THF (350 ml) was added sodium methoxide (1.06 g, 19.6 mmol) and the mixture was stirred for several minutes at room temperature. Then, methanol (5 ml) and ethyltrifluoroacetate (1.2 ml, 6.02 mmol) were added to the mixture which was stirred for a further 18 h under reflux. Solvents were removed under reduced pressure and the resulting residue was dissolved in chloroform. The solution was washed with water and dried with anhydrous sodium sulfate. Solvents were removed by diminished pressure and the residue was chromatographed on a silica gel column with toluene–chloroform (1:1 vol/vol) as an eluent to give HtfacacMCP as pale-yellow prisms (600 mg, 45%). M.p. 147–149°C (hexane). *Anal.* Calc. for $C_{22}H_{21}O_2F_3$: C, 70.58; H, 5.65. Found: C, 70.48; H, 5.65%. ^1H NMR ($CDCl_3$, 500 MHz): 0.57 (s, 3H), 0.68 (s, 3H), 2.75–3.10 (m, 8H), 6.54 (s, 1H), 6.96 (t, 1H, $J=7.32$ Hz), 7.14 (d, 2H, $J=7.32$ Hz), 7.75 (s, 2H), 15.70 (br s, 1H). IR (KBr, cm^{-1}): 2932(m), 1617(br s), 1585(m), 1452(s), 1286(br s), 1140(s), 799(m), 727(m). MS (EI): 374 (M^+).

2.4. Synthesis of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2

To a solution of HtfacacMCP (1.0 g, 2.68 mmol) and bipyridine (280 mg, 19.6 mmol) in absolute ethanol (350 ml) was added a solution of $EuCl_3 \cdot 6H_2O$ (200 mg, 0.55 mmol) in absolute ethanol (20 ml) and piperidine (2.0 ml), and then the solution was stirred for 24 h at room temperature. Solvent was condensed in vacuo and a pale-yellow solid precipitated. The solid was filtered, washed with absolute ethanol and then dried under reduced pressure. Recrystallization from dichloromethane–hexane gave the complex (490 mg, 92%). M.p. 295–297°C. *Anal.* Calc. for $EuC_{76}H_{68}N_2O_6F_9$: C, 63.91; H, 4.80; N, 1.96. Found: C, 63.78; H, 4.97; N, 2.07%. ^1H NMR ($CDCl_3$, 500 MHz): −0.10 (s, 9H), 0.89 (s, 9H), 2.50–3.10 (m, 24H), 2.75 (3H, br s), 5.25 (s, 2H), 6.75 (br s, 6H), 6.84 (t, 3H, $J=7.30$ Hz), 7.06 (d, 6H, $J=7.30$ Hz), 7.10–7.25 (m, 8H). IR (KBr, cm^{-1}): 2935(m), 1611(s), 1585(m), 1583(s), 1299(s), 1183(s), 1134(s), 790(m), 761(m). MS (POS-FAB): 1055 ([$M-$(tfacacMCP)]$^+$).

2.5. Synthesis of piperidinium(t-tolutfacac)$_4$Eu(III)

To a solution of *p*-tolutfacacH (100 mg, 0.27 mmol) and bipyridine (50 mg, 0.32 mmol) in absolute ethanol (100 ml) were added a solution of $EuCl_3 \cdot 6H_2O$ (35 mg, 0.10 mmol) in absolute ethanol (20 ml) and piperidine (2.0 ml), and then the reaction solution was stirred for 24 h at room temperature. Solvent was condensed in vacuo and a pale-yellow solid precipitated. The solid was filtered, washed with absolute ethanol and then dried under reduced pressure. Recrystallization from dichloromethane–hexane gave the complex (106 mg, 92%). M.p. 229–232°C. *Anal.* Calc. for $EuC_{76}H_{68}N_1O_8F_{12}$: C, 50.96; H, 3.84; N, 1.21. Found: C, 50.53; H, 3.80; N, 1.38%. ^1H NMR ($CDCl_3$, 500 MHz): 2.70 (s, 12H), 2.15 (s, 4H), 3.39 (br s, 2H), 4.05 (br s, 4H), 4.87 (br s, 4H), 7.22 (d, 8H, $J=7.94$ Hz), 7.99 (d, 8H, $J=7.94$ Hz), 8.00 (br s, 2H). IR (KBr, cm^{-1}): 2945(m), 1615(s), 1568(m), 1536(s), 1316(s), 1186(s), 1146(s), 783(m), 691(m). MS (POS-FAB): 1055 ([$M-$(*p*-tolutfacac)]$^+$).

2.6. X-ray crystal structure determination of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and piperidinium-[(p-toluacac)$_4$Eu(III)]

Crystals of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and piperidinium[(*p*-tolutfacac)$_4$Eu(III)] suitable for X-ray work were obtained from a mixed solution of dichloromethane and hexane. X-ray data were collected with a Rigaku AFC7R diffractometer using Cu Kα radiation at 298 K for (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and with a Rigaku RAXIS-IV diffractometer using Mo Kα radiation at 298 K for piperidinium[(*p*-tolutfacac)$_4$Eu(III)]. Cell parameters and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections. Crystallographic data for these complexes are summarized in Table 1. The intensities of three standard reflections of each sample were recorded every 3 h upon X-ray exposure and showed no systematic change. All calculations were carried out with a teXsan crystallographic software package of Molecular Structure Corporation. The intensity data were corrected for Lorentz and polarization effects and empirical absorption corrections (DI-FABS) were also applied. The structures were solved by a combination of Patterson and difference Fourier methods for (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and SHELXS86 and difference Fourier methods for piperidinium[(*p*-tolutfacac)$_4$Eu(III)], and refined by full-matrix least-squares methods. All non-hydrogen atoms were refined anisotropically. The positions and isotropic B factors of hydrogen atoms were refined during least-squares calculation. The final cycle of refinement on *F* converged to the agreement indexes given in Table 1.

3. Results and discussion

3.1. Synthesis and characterization of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and piperidinium-[(p-tolutfacac)$_4$Eu(III)]

8,16-Dimethyl[2.2]MCP (**1**) [9] was reacted with acetic anhydride in the presence of $TiCl_4$ as a Lewis acid catalyst to give 5-acetyl-8,16-dimethyl[2.2]MCP (**2**) in 68% yield. Reaction of compound **2** with ethyltrifluoroacetate led to compound **3** (48%) (Scheme 1). *p*-TolutfacacH can be prepared from 4′-methylacetophenone in the same manner. Both compound **2** and *p*-tolutfacacH exist in the enol form according to ^{1}H NMR data which are described in Table 2. Complexation of compound **3** with Eu(III)Cl_3·$6H_2O$ in methanol in the presence of bipyridine [10] and piperidine afforded (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 (**3**) in 92% yield. On the other hand, complexation of *p*-tolutfacacH with

[a] Chemical shifts are given in ppm for TMS. Measured in $CDCl_3$. The multiplicity of a proton signal is given in parentheses after the δ value: s singlet; d doublet; m multiplet.

Scheme 1.

Scheme 2.

Eu(III)$Cl_3 \cdot 6H_2O$ was treated under the same conditions, however, piperidinium[(*p*-tolutfacac)$_4$Eu(III)] was obtained (Scheme 2). In this complex, bipyridine did not coordinate but a piperidinium ion ($C_5H_{12}N$) exists as a counter cation. This result can be explained by the bulkiness of HtfacacMCP.

In order to confirm the structures of their complexes some physical measurements were carried out. Selected ^{1}H NMR spectral data of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and piperidinium[(*p*-tolutfacac)$_4$Eu(III)] are summarized in Table 2. The signals of some protons in the tfacacMCP and the *p*-tolutfacac ligands are extremely upfield shifted because of the paramagnetic effect of the europium ion.

Elemental analyses of these complexes are summarized in Section 2. Found values of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 were different from calculated values because a molecule of dichloromethane was lost. On the other hand, piperidinium[(*p*-tolutfacac)$_4$Eu(III)] showed good agreement with the expected composition. The europium complexes indicate clusters of ions corresponding to $[M-(\text{tfacacMCP})]^+$ and $[M-(p\text{-tolutfacac})]^+$, respectively, which are the base peak in FAB mass spectra. When the complexes are analyzed with a FAB method, the molecular ions are not obtained.

3.2. Crystal structure of the complexes

The perspective views of the molecular units of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 and piperidinium[(*p*-tolutfacac)$_4$Eu(III)] are shown in Figs. 1 and 2, respectively. The selected bond lengths and bond angles are also given in Tables 3 and 4, respectively. Fig. 1 shows that the structure unit of (tfacacMCP)$_3$(bpy)Eu(III)·CH_2Cl_2 consists of one complex molecule and one dichloromethane molecule. The europium(III) is coordinated through six O atoms of

tfacacMCP and two N atoms of bpy. The average bond lengths Eu–O and Eu–N are 2.366(6) and 2.60(1) Å, respectively. The longest bond length Eu–O is 2.400(10) Å and the shortest length is 2.330(9) Å. The longest bond length Eu–N is 2.61(1) Å and the shortest length is 2.58(1) Å. On the other hand, Fig. 2 shows that the structure unit of piperidinium[(*p*-tolutfacac)$_4$Eu(III)] is composed of one complex molecule and a piperidinium ion. In the complex, the Eu(III) is coordinated through eight O atoms of *p*-tolutfacac ligands. The average bond length Eu–O for piperidinium[(*p*-tolutfacac)$_4$Eu(III)] is 2.390 Å. The longest bond length Eu–O is 2.441(4) Å and the shortest length is 2.366(3) Å, respectively.

3.3. Absorption spectra

The absorption spectral data of the ligands and their Eu(III) complexes are shown in Table 5. These absorption properties are characteristic of β-diketone type compounds, but the maximum absorption of HtfacacMCP shows ca. 34 nm longer shifts than that of *p*-tolutfacacH. This can be explained by the enhanced π system existing between two aromatic rings of an MCP moiety. Maximum absorption of $[(tfacacMCP)_3(bpy)Eu(III)]\cdot CH_2Cl_2$ indicates ca. 28 nm longer shifts than that of piperidinium[(*p*-tolutfacac)$_4$Eu(III)]. This tendency can also be explained by the effect described above.

3.4. Fluorescence spectra

Emission spectral data and charts of these two complexes in solution are given in Table 5, and Fig. 3 for $(tfacacMCP)_3(bpy)Eu(III)\cdot CH_2Cl_2$ and in Fig. 4 for piperidinium[(*p*-tolutfacac)$_4$Eu(III)], respectively. In piperidinium[(*p*-tolutfacac)$_4$Eu(III)], the strong metal-centered emission was observed at 615 nm but the emission from ligands was not observed when the excitation wavelength was 366 nm. This strong emission can be assigned to a $^5D_0$–$^7F_2$ energy level transition of the 4f orbital on the europium ion. Furthermore, another weak emission ($^5D_0$–^7F_n, $n=1,4$) was observed. The corrected excitation spectrum of piperi-

Piperidinium[(*p*-tolutfacac)Eu]	328 (70800)	451 (1.02), 615 (0.09) [c]

[a] In $CHCl_3$.
[b] $\lambda_{EX}=366$ nm.
[c] $\lambda_{EX}=366$ nm.

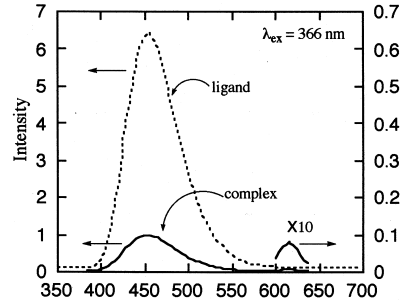

Fig. 3. Emission spectral chart of tfacacMCP and $(tfacacMCP)_3(bpy)Eu(III)$ in $CHCl_3$ at room temperature.

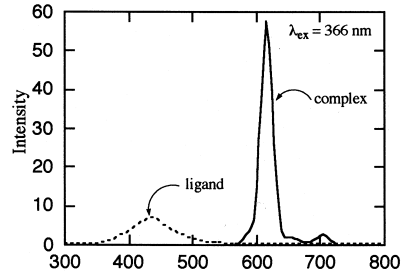

Fig. 4. Emission spectral chart of *p*-tolutfacac and piperidinium(*p*-tolutfacac)$_4$Eu(III) in $CHCl_3$ at room temperature.

dinium[(*p*-tolutfacac)$_4$Eu(III)] (λ_{EM} = 615 nm) shows exactly the same pattern as its absorption spectrum. This means that light absorption in the ligands is followed by energy transfer to the emitting $^5D_0$ excited state of the europium ion. In [(tfacacMCP)$_3$(bpy)Eu(III)]·CH_2Cl_2, the intensity of the metal-centered emission was much weaker than that of the ligand emission from the MCPtfacac moiety. Although the corrected excitation spectrum of [(tfacacMCP)$_3$(bpy)Eu(III)]·CH_2Cl_2 (λ_{EM} = 615 nm) shows exactly the same pattern as its absorption spectrum, the excited energy almost seems to be relaxed on the MCP ligand. That is to say, a part of the excited energy is transferred from the ligands to the europium ion. This phenomenon is perhaps due to the excited energy level of the triplet state in the MCP skeleton existing in the vicinity of the $^5D_0$ energy level of the 4f orbital on the europium ion.

Supplementary data

Further details of crystal structure determinations can be ordered from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers 116595 for [(tfacacMCP)$_3$-(bpy)Eu(III)]·CH_2Cl_2 and 116030 for piperidinium[(*p*-tolutfacac)$_4$Eu(III)], respectively.

POLYHEDRON

Stereochemistry of chiral, substituted η^3-butadienyl molybdenum(II) complexes

Annabelle G.W. Hodson *, Rupinder K. Thind

Faculty of Applied Sciences, University of the West of England, Bristol BS16 1QY, UK

Received 1 November 1999; accepted 25 January 2000

Abstract

Chiral complexes of general type $[MoCl(CO)_2(\eta^3\text{-}CH_2C(COX)C{=}CH_2)(phen)]$ (phen = 1,10-phenanthroline) containing optically active substituents X have been prepared by reaction of the chlorocarbonyl (**1**) with esters of L-valine, L-alanine, L-phenylalanine, L-cysteine, L- and DL-serine or with amino alcohols (*S*)-(+)-1-amino-2-propanol and (*S*)-(+)-2-amino-1-propanol, and their diastereomers have been investigated by ^{1}H NMR spectroscopy. Reaction of compound **1** with diamines containing one (L-lysine) or two (L-cystine) stereogenic centres gives rise to dimeric complexes containing dibutadienyl bridging ligands, and these have been identified by a combination of synthetic and computer modelling methods. The probable spectra and structures of the corresponding poly-L-lysine derivatives are discussed.

Keywords: Bridging ligands; Butadienyl; Chiral substituents; Molybdenum

1. Introduction

The synthesis and reactivity of η^3-allyl transition metal complexes have been widely investigated, both experimentally and theoretically, in part because of their relevance to allylic alkylation and coupling reactions of commercial importance [1,2]. By comparison, the chemistry of related η^3-butadienyl complexes has received limited attention. During the past decade several synthetic routes have been discovered which provide access to these complexes containing a range of substituents at C1, C2 or C3 positions of the C1C2C3=C4 unit [3–5], and the organic fragment has been examined crystallographically [6,7]. However, theoretical and mechanistic studies of η^3-butadienyl transition metal complexes are rare, and their reactivity has not been systematically explored. In addition, whilst there are many known examples of complexes containing the allyl unit acting as a bridging ligand between metal centres [8], only a very limited number of bridging butadienyl systems have been described [9–11]. In an attempt to explore some of these issues, the authors and others have been investigating the formation and reactivity of complexes of the general type $[MCl(CO)_2(\eta^3\text{-}CH_2C(COX)C{=}CH_2)(L_2)]$ (M = Mo,W; L_2 = 2,2′-bipyridyl, 1,10-phenanthroline) containing various substituents X at C2. The ester, amide and thioester (X = OR, NRR′, SR) complexes have been characterised by spectroscopic and crystallographic methods, and mechanisms of formation for the chlorocarbonyl (X=Cl) and ester substituted complexes have been discussed [12–14]. The asymmetry of the metal-bound substituted butadienyl unit leads to an expectation that isomers of this type of complex should be accessible; however, to date they have not been observed in either solution or solid states. In this study, a series of mono- and diamines containing one or more stereogenic centres has been used to explore the stereochemistry of chiral mono- and dimeric η^3-butadienyl complexes and to predict the structures of long-chain polymeric systems.

2. Experimental

2.1. Materials and physical methods

All chemicals were purchased from Sigma-Aldrich and used without further purification. Solvents and liquid reagents were dried with molecular sieves and degassed with dinitrogen prior to use. All reactions were carried out under an atmosphere of this gas at room temperature unless specified otherwise. The starting material (**1**) was freshly prepared from 1,4-dichloro-2-butyne and $Ph_4P[MoCl(CO)_3(phen)]$

PII S0277-5387(00)00315-6

by the published method [12] and recrystallised from dichloromethane–petrol mixtures. Infrared spectra were recorded on a Perkin-Elmer 781 spectrometer using samples prepared as Nujol mulls on sodium chloride discs. The ^{1}H NMR spectra were obtained for solutions in dichloromethane-d_2 or dimethylsulfoxide-d_6 (DMSO-d_6) and referenced to tetramethylsilane (TMS) as internal standard. Molecular modelling was carried out using Hyperchem software (HyperChem™ version 5.1 uses molecular mechanics computations to predict new structures based on X-ray diffraction data of known complexes), and the structure of [Mo($O_2CC_3F_7$)(CO)$_2$(η^3-CH_2C(CONHMe)C=CH_2)-(2,2′-bipyridine)] was accessed from the Cambridge Crystallographic Database, UK.

2.2. Preparation of the complexes

2.2.1. Synthesis of monomeric complexes (2–6, 9, 10)

A solution of glycine ethyl ester hydrochloride or the methyl ester hydrochlorides of L-serine, L-valine, L-alanine, L-phenylalanine, L-cysteine (5.0 mmol) or L-lysine (1.0 mmol) in 2-propanol (50 cm^3) was stirred with excess potassium hydrogen carbonate (6.0 mmol, 0.600 g) for 1 h. To this was added triethylamine (1.0 mmol, 0.14 cm^3) and freshly prepared complex **1** (1.0 mmol, 0.483 g), and the mixture was stirred for a further 2 h. The solvent was removed under vacuum, the residue was extracted three times with aqueous dichloromethane (15 cm^3, 35%, v/v) and the organic phase finally dried over sodium sulfate. Chromatography on silica gel (60–120 mesh) using 5%, v/v methanolic dichloromethane, followed by addition of petrol and storage at low temperature yielded the products as orange powders, which were recrystallised from dichloromethane–petrol mixtures with yields of 30–55%.

2.2.2. Synthesis of aminopropanol derivatives (7, 8)

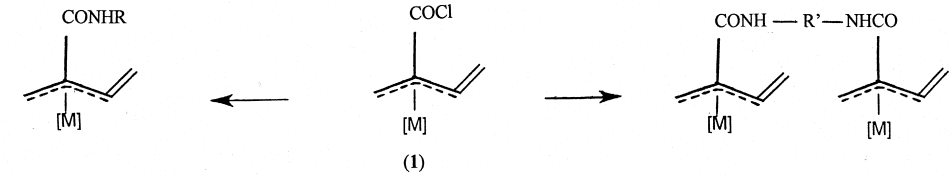
A solution of compound **1** (0.5 mmol, 0.2415 g) in dichloromethane (25 cm^3) was stirred with excess triethylamine (0.5 cm^3). To this was added dropwise (*S*)-(+)-2-amino-1-propanol or (*S*)-(+)-1-amino-2-propanol (0.5 mmol) and the mixture stirred for 2 h. The filtered solution was mixed with petrol and stored at low temperature. The crude solid which precipitated was recrystallised as described above, and gave the products as bright orange, microcrystalline powders in yields of 57 and 76%.

2.2.3. Synthesis of N(α)-acetyl-L-lysine product (11)

N(α)-Acetyl-L-lysine methyl ester hydrochloride (0.46 mmol, 0.108 g) was stirred with excess potassium hydrogen carbonate (1.0 mmol) in 2-propanol (20 cm^3) and then reacted with compound **1** (0.46 mmol, 0.222 g) and triethylamine (0.14 cm^3) as described in Section 2.2.1. Yield: 60%.

2.2.4. Synthesis of dimeric complexes (12, 13)

A suspension of excess potassium hydrogen carbonate (3.0 mmol, 0.300 g) in 2-propanol (20 cm^3) was stirred with the dimethyl ester dihydrochloride of L-cystine or methyl ester hydrochloride of L-lysine (0.5 mmol) for 1 h, and this mixture was then combined with triethylamine (1.0 mmol, 0.14 cm^3) and complex **1** (1.0 mmol, 0.483 g). After stirring for 2 h, the mixture was treated as described in Section 2.2.1, and the dried dichloromethane solution (15 cm^3) was chromatographed on silica gel (60–120 mesh) using dichloromethane followed by 5%, v/v methanol–dichloromethane as eluant. The alcoholic solution was collected, the solvent removed by vacuum and the residue recrystallised from dichloromethane–petrol. Yields: 20%, 31%.



2.2.5. Synthesis of poly-L-lysine derivative (14)

Poly-L-lysine hydrobromide of approximate molecular weight 1000 (0.1 mmol, 0.100 g) was stirred with potassium hydrogen carbonate (0.7 mmol, 0.707 g) in 2-propanol (20 cm^3) for 60 min, and this was added to a stirred mixture of excess triethylamine (0.5 cm^3) and compound **1** (0.5 mmol, 0.2415 g). Filtration after 2 h gave a dark orange–brown residue, which was washed with dichloromethane to remove unreacted compound **1**, and dried in vacuo. Yield: 10%.

3. Results and discussion

3.1. Synthesis and structure of monomeric complexes

Reaction of compound **1** with a series of L-amino esters or L-aminopropanols under basic conditions gave rise to substi-

Scheme 1.

tuted 2-amido η^3-butadienyl complexes (Scheme 1, **2**–**10**), and these were characterised by IR and NMR spectroscopy and by elemental analysis (Tables 1 and 2). The ^{1}H NMR spectra of complexes **3**–**6**, produced from methyl esters of L-alanine, L-phenylalanine, L-valine and L-serine, and of complexes **7** and **8**, obtained from (*S*)-(+)-2-amino-1-propanol and (*S*)-(+)-1-amino-2-propanol, respectively, all showed evidence of diastereomers in solution; however, that of complex **2**, derived from glycine ethyl ester, did not. This can be understood by considering the probable structures of the chlorocarbonyl precursor **1** and its amide derivatives. These can be predicted with some confidence based upon the ^{1}H NMR evidence, the existing X-ray data obtained by the authors and others for [Mo($O_2CC_3F_7$)(CO)$_2$(η^3-CH_2C(CONHMe)-C=CH_2)(2,2′-bipyridine)] [15] and the use of molecular modelling methods. Crystallographic analysis of the bipyridyl complex did not locate the amide hydrogen atom, and during refinement this was placed at an idealised position which approximated to sp^3 hybridisation at nitrogen. The structure revealed a *trans* arrangement of CO and NH and an essentially planar CO–NC unit. This is in accord with a high degree of double bond character between the carbonyl carbon and nitrogen atom of the amide, and predicts a high barrier to rotation about this bond. The double bond terminus of the η^3-butadienyl unit was orientated away from the carbonyl of the amide, and a similar structural unit in this part of the molecule in the new complexes **2**–**10** can be expected. A mechanism has been proposed for reaction of Ph_4P-[MoCl(CO)$_3$(phen)] and 1,4-dichloro-2-butyne in dichloromethane which is consistent with the production of compound **1** as an enantiomeric pair (Fig. 1, A and B). These give rise to a single set of proton NMR resonances due to the highly symmetrical nature of the (CO)$_2$Mo(phen) unit and to the magnetically equivalent environments of the two butadienyl groups. On reaction with an achiral amine such as glycine, the amide-substituted analogues of each isomer are formed. These are indistinguishable from their ^{1}H NMR spectra, because the butadienyl, NH and ester substituent for each isomer continue to exist in magnetically equivalent environments. For a chiral amine, however, reaction with the two isomers of compound **1** gives rise to a pair of diastereomers with amide substituents in inequivalent magnetic fields, and these can be differentiated from their ^{1}H NMR spectra as described below.

Spectra for complexes **3**–**7** all exhibited two sets of signals which could be assigned to a diasteromeric pair. However, pairs of resonances for the 1-amino-2-propanol derivative (**8**) were all superimposed with the exception of H''_{syn} of the butadienyl terminal double bond and the methyl group at C_α of the substituent. Thus increasing distance between the metal-bound phenanthroline moiety and $C_\alpha H$ of the chiral amine decreases the observable magnetic inequivalence of the diastereomeric pair. There was no evidence for the formation of dimeric complexes arising from reaction of compound **1** at hydroxyl groups of serine ester or the amino alcohols during production of compounds **6**–**8**, the more basic amine reacted preferentially in each case. Both L-serine (**6**) and DL-serine methyl ester products (DL-**6**) were prepared from compound **1**, and their ^{1}H NMR spectra were compared. Both complexes produced two sets of resonances, and almost identical peak positions and $^3J_{NH-CH}$ coupling constants were observed for compounds **6** and DL-**6**. This arises because the pair of diastereomers for L-**6** shows an enantiomeric relationship to a diastereomeric pair for D-**6**. Consider the pairs C/F and D/E shown in Fig. 2, which represent the pairs of diastereomers arising from L-serine and D-serine products, respectively. The symmetrical nature of the (CO)$_2$Mo(phen) unit gives rise to a similar magnetic environment for the $C_\alpha H$

group and substituent R in the pair C/D, and thus this enantiomeric pair gives rise to one set of resonances. Similarly, the magnetic environments of these groups in the pair E/F are equivalent, and this pair also produces a single set of resonances. Thus the spectra of L-, D- and racemic DL-serine products are all expected to show two sets of very similar resonances, and this was confirmed by experiment. (Data for the L-serine derivative are given in Table 2.)

The relative positions of ester, $C_\alpha H$ and R groups within the (η^3-$CH_2C(CONHC_\alpha H(R)CO_2Me)C{=}CH_2$) unit in complexes **3**–**6** can be predicted using both a comparison of ^1H NMR resonances for the free and reacted amino acid ester and the Karplus relationship for vicinal protons based on $^3J_{NH-CH}$ coupling constants [16]. Singlets arising from the methyl ester in the metal complexes were found close to the free amino ester positions of approx. 3.5 ppm, and these two resonances for any pair of diastereomers were separated by less than 0.07 ppm. In contrast, resonances due to the R group at $C_\alpha H$ in the complexes were shifted significantly upfield compared to the free positions, and signals for a particular component of R in one complex differed by up to 1.08 ppm between the two diastereomers. For example, the two diastereomers of the L-alanine complex **3** gave rise to two singlets at 3.62 and 3.65 ppm due to the methyl ester and two doublets at −0.15 and 0.93 ppm due to the C_α methyl group. This implies that for both isomers the ester is distant from, and unaffected by, the anisotropic ring system, and that the C_α substituents have differing, but greater proximity to phenanthroline. Using the Karplus relationship, the $^3J_{NH-CH}$ value of 5.22 Hz for both isomers of compound **3** was found to be consistent with torsion angles of approximately 27 or 123°. The probable structure of compound **3** was modelled, based upon the known structure of [$Mo(O_2CC_3F_7)(CO)_2$(η^3-$CH_2C(CONHMe)C{=}CH_2$)(2,2′-bipyridine)], by replacing the heptafluorobutyrate with a chlorine atom, changing bipyridyl to phenanthroline and substituting the amide methyl group by L-alanine methyl ester. Geometry optimisation was carried out using a molecular mechanics programme, and gave a minimum energy conformation whose dihedral angles were consistent with the observed NMR coupling constants. Viewed along the HN–C_α bond, the two isomers may be represented by G and H in Fig. 3, in which the two methyl groups at C_α are orientated towards different regions of the phenanthroline ring system. Similar arguments pertain to the structures of the diastereomers of L-serine derivative **6**; however, the $^3J_{NH-CH}$ constants are noticeably different for this pair at 6.59 and 7.51 Hz. Construction of molecular models of compound **6** shows that hydrogen bonding between NH and the C_α hydroxyl controls the NH–CH torsion angle, and the resultant approach of OH to phenanthroline accounts for the large upfield shift of the hydroxyl signal, from a broad peak at 8.6 ppm in the free amine to a pair of triplets at 4.70 and 4.77 ppm in the two isomers of the complex. As discussed above, the proton NMR spectra of DL-serine and L-serine derivatives are identical, and by analogy the spectrum of (*S*)-(+)-aminopropanol derivative (**7**) should be magnetically equivalent to the (*R*)-(−) derivative. This permits direct comparison of spectra for compounds **6** and **7**, which both contain CH_2OH groups at C_α of the butadienyl substituent. The two spectra exhibited similar resonance positions for methine, methylene and hydroxyl groups at the C_α substituent, and $^3J_{NH-CH}$ constants were comparable. However, whilst the signal due to the methyl ester in compound **6** was almost identical to that for free serine ester, the C_α methyl group of (*S*)-(+)-aminopropanol shifted resonance position from 1.00 for the free amine to 0.38 and −0.41 ppm in the two isomers of complex **7**. It is likely, therefore, that the structures of compounds **6** and **7** are related, but that the absence of a carboxy group in compound **7** results in the C_α methyl moving within the sphere of influence of the phen system.

The cysteine product (**9**) was identified by the position of the amide carbonyl stretching frequency and SH absorption

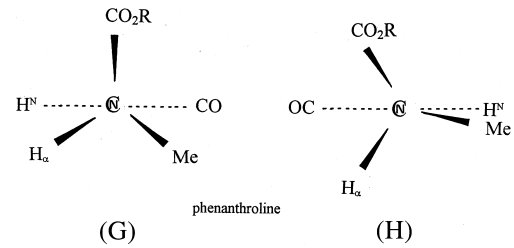

Fig. 3. Relative positions of amide substituents in compound **3**.

in the IR spectrum. This product proved to be unstable in solution over several days (oxidation of the thiol group by traces of atmospheric O_2 leads to formation of the dimeric disulfide, probably by way of thioxy radicals or sulfenic acid derivatives), and this led to non-repeating elemental analyses. In addition, the ^{1}H NMR spectrum of compound **9** was very broad, and signals attributable to the dimeric cystine derivative (**12**) were identified by comparison (see Section 3.2).

Combination of L-lysine ester, which contains two primary amine groups of pK_a 9.2 and 10.8, with compound **1** in a 1:1 mole ratio may result in the acyl chloride reacting at either C_α or C_ε positions only to give a monomeric complex, or the reaction may occur at both positions leading to a dimeric product and unreacted amino ester. Only one set of ^{1}H NMR signals for the phen ring system, the termini of the butadienyl unit and the amino ester substituent in the resultant complex (**10**) was observed. Comparison of the integrals for signals due to the lysine unit and the butadienyl termini revealed the presence of a monomeric species only, and this was supported by the elemental analysis results. Synthesis of the *N*(α)-acetyl-L-lysine ester derivative (**11**) for comparison was informative. This complex gave rise to one set of signals in its ^{1}H NMR solution spectrum, in accord with a diastereomeric pair having C_α distal from the metal–phen unit. Two signals attributable to NH could be identified at 3.61 and 6.07 ppm. The latter is within the range of 5.61–6.04 ppm found for complexes **3**–**6** and can be assigned to $CON_\varepsilon H$, which is adjacent to the butadienyl group. The ^{1}H NMR spectrum of lysine monomer **10** also showed a single set of signals, and comparison of integrals for phen and the $N_\varepsilon H(CH_2)_4$-$C(H)N_\alpha H$ unit confirmed a preferential reaction of the acyl chloride at $N_\varepsilon H$, the amine of higher pK_a.

3.2. Synthesis and structure of polymeric complexes

Mixing compound **1** with L-cystine dimethyl ester in 2:1 mole ratio under basic conditions gave rise to complex **12**, which was identified from elemental analysis and IR and NMR evidence as a dimeric species having two metal-bound η^3-butadienyl units bridged by the bis-amido disulfide unit. The ^{1}H NMR spectrum of compound **12** showed only two sets of broad signals despite the presence of two stereogenic centres, suggesting that the magnetic environments of the possible diastereomers are not sufficiently dissimilar to differentiate all the possible forms. Some peaks attributable to compound **12** could be identified in the spectrum of compound **9**, and refluxing compound **12** with 2-mercaptoethanol gave compound **9** by cleavage of the disulfide bond. Attempts to separate the isomers of compound **12** by fractional crystallisation or chromatography were not successful.

Reaction of L-lysine methyl ester and compound **1** in 1:2 mole ratio yielded complex **13**, whose ^{1}H NMR spectrum was highly complex. It has been demonstrated that two sets of signals due to diastereomers may be observed when $C_\alpha H$ is adjacent to the butadienyl amide substituent and that increasing distance of $C_\alpha H$ from the butadienyl amide group leads to overlapping of these signals. Thus if both the amine at $C_\alpha H$ ($N_\alpha H$) and the terminal amine ($N_\varepsilon H$) have reacted with the chlorocarbonyl group to give a dimeric complex, then the two diastereomers of compound **13** should give rise to a total of three magnetically distinct sets of signals, integrating in the ratio 1:1:2. Whilst this was observed for the butadienyl terminal protons, detailed interpretation was not possible, since the three peaks for the amide and those of the ester were each broad and overlapping and the multiplets due to aromatic and methylene protons gave rise to highly complex patterns. By comparison of the integrals for multiplet peaks arising from the phenanthroline unit, the methyl ester and for NH with those due to the $(CH_2)_4$ chain it was possible to support a dimeric formulation for compound **13**, and this was confirmed by the elemental analyses. Reaction of long-chain polyamines and excess compound **1** would give increasingly complex spectra; however, some general observations can be made on their probable structure. Poly-L-amino acids can exist naturally in either α-helix or β-pleated sheet forms, and the preferred construction is dependent upon the degree and extent of inter- and intra-molecular hydrogen bonding. Under laboratory conditions of pH 12 and above the α-helix stucture is adopted, and thus mixing a basic solution of excess compound **1** and poly-L-lysine (approximate molecular weight 1000) may be predicted to give rise to a short helical chain having butadienyl groups at some or all of the peripheral $N_\varepsilon H$ groups and/or at the $N_\alpha H$ terminus. Whilst the IR spectrum of this product (**14**) confirmed the presence of metal–carbonyl, C=O amide and NH groups, the low solubility of the solid in common organic solvents resulted in poor elemental analyses and also prevented investigation by NMR solution spectroscopy. This was unfortunate, since the small size of $^3J_{HN-C\alpha H}$ coupling constants can be used as a hallmark characteristic of α-helix secondary structure [17], and torsion angle constraints can be calculated from their associated empirical Karplus relations [18,19]. An average degree of polymerisation for the polylysine of six might be used as a model system. It has been shown that compound **10** gives rise to one set of NMR signals due to attachment of the butadienyl at $N_\varepsilon H$ only, and that compound **13** gives a complex pattern in which signals due to three diastereomers may be identified. The spectra and elemental analysis of compound **13** suggest that, in the presence of excess compound **1**, terminal and pendant amino groups of polylysine will all react, and a total of six pendant and one terminal butadienyl group will be present in the product **14**. The resultant ^{1}H NMR spectrum can be expected to be highly complex, although some simplification may occur if magnetic equivalence of pendant butadienyl groups is present.

3.3. Infrared spectroscopy

All complexes gave rise to a pair of strong absorptions between 1980 and 1890 cm^{-1}, and these can be assigned to the stretching modes of a *cis*-metal–dicarbonyl unit. A band

of medium intensity near 1735 cm^{-1} resulted from the carbonyl of the alkyl ester functionality in complexes **2**–**6** and **9**–**13**, and weak absorptions at about 1675 cm^{-1} due to the vinylic double bond could be identified for some complexes. Signals due to NH were found in the region 3425–3303 cm^{-1}, and, with the exception of spectra for compounds **2**, **4** and **9** which each exhibited a single sharp peak, these absorptions were broad and weak. For the poly-L-lysine derivative **14**, the terminal carboxylic acid group gave rise to a broad peak centred at 1700 cm^{-1} (carbonyl), and signals due to OH, NH(amide) and NH (primary amine) were combined in a very wide, shallow band across the range 3650–3300 cm^{-1}. It has been demonstrated [12] that the position of the carbonyl absorption due to ester, amide and thioester substitutents in the butadienyl unit of $[WCl(CO)_2(\eta^3\text{-}CH_2C(COX)C{=}CH_2)(phen)]$ (X = OMe, NEt_2, SBu) reflects the differing electronegativities of the group X. In accord with these observations, a carbonyl stretching absorption for the amide appeared near 1645 cm^{-1} for all the complexes, and supported reaction at the more basic amine rather than the hydroxyl in 1-amino-2-propanol and 2-amino-1-propanol. A weak absorption near 2600 cm^{-1} for SH of the freshly prepared cysteine complex **9** was absent from the cystine complex **12**.

3.4. ^1H NMR spectroscopy

The poor solubilities of the complexes in common organic solvents precluded measurement of ^{13}C NMR spectra, however proton NMR spectra of complexes in dichloromethane-d_2 and DMSO-d_6 were recorded where possible, and pertinent data are presented in Table 2. The glycine derivative (**2**) gave rise to a pair of doublets (coupling constants ca. 2.2 Hz) at 5.80 ppm (H_{anti}) and 6.31 ppm (H_{syn}) due to the vinylic protons of the butadienyl and to singlets at 2.04 ppm (H_{anti}) and 3.84 ppm (H_{syn}) arising from the allylic protons. This is in accord with previous observations for a transoid butadienyl in which the uncoordinated carbon–carbon bond is unconjugated with respect to the π-delocalisation of the η^3-allyl unit [12]. Peaks assigned to the alkyl groups of the ethyl ester were shifted slightly upfield compared to the free amine due to the anisotropic effect of the phenanthroline ring system. The methylene protons adjacent to NH produced two multiplets due to their differing magnetic environments, and coupling of NH to the two protons was dissimilar. The hydrogen at higher field can be expected to be closer to the phenanthroline ligand, and this gives rise to a smaller coupling constant (4.22 Hz) than for the lower field signal (5.67 Hz). There were no minor peaks present in the spectrum to suggest isomers were present, and there was no alteration of the spectrum in the temperature range −50 to +25°C to indicate dynamic behaviour in solution.

Spectra for complexes derived from the esters of alanine, phenylalanine, valine, serine (**3**–**6**) and from 2-amino-1-propanol and 1-amino-2-propanol (**7**, **8**) all showed doubling of peaks across the whole ppm range, although some overlapping of signals was observed for the latter complex. The relative intensities of these pairs were dependent upon the length of time between completion of reaction of compound **1** with the amine and filtration of the precipitated product after addition of petrol, implying fractional crystallisation of two diastereomers was occurring. For example, the spectrum of the L-phenylalanine derivative (**4**) filtered after 24 h was dominated by one set of peaks which was shadowed by a second set as a 5% component (by integration). On filtration after 7 days the intensity of the minor set had increased to almost equal that of the second set of peaks. The two sets of signals could be assigned to two independent isomeric forms. Fig. 4 shows illustrative regions of this spectrum. The vinylic protons of the butadienyl gave rise to four doublets between 5.6 and 6.2 ppm with two pairs of coupling constants of 2.13 and 2.20 Hz. Comparison of integrals showed the total sum of the lower field pair was equivalent to the higher field pair, and each pair of minor or major doublets were of equal integration. An obscured pair of doublets due to the NH proton occurred near 5.64 ppm. The two sets of signals for vinylic protons and the NH both integrated in the ratio 2:2:2, and indicated the presence of two diastereoisomers of compound **4** in solution. The allylic protons occurred as two pairs of singlets near 2.04 and 3.88 ppm, and the methyl ester signal appeared as a pair of singlets near 3.40 ppm. For each isomer, the methylene group of the α-carbon substituent gave rise to two AB quartets, which were centred near 1.67 and 2.57 ppm. Signals due to phenanthroline were unexceptional and appeared as distinct sets for the two isomers. Inequivalence of the protons of the benzyl ring was apparent, with four multiplets centred at 6.67, 6.79, 7.16 and 7.24 ppm integrating in the ratio 1:1:4:4, and was in accord with two diastereoisomers, each having one *ortho* proton of the ring directed towards the anisotropic phen ligand.

Both the lysine derivative (**10**) and its *N*(α)-acetyl model (**11**) gave one set of ^1H NMR signals only in accord with $C_\alpha H$ being distant from the butadienyl amide substituent. Attachment of the butadienyl unit to $N_\varepsilon H$ in both complexes was supported by peak positions of 6.15 and 6.07 ppm, respectively, and the free $N_\alpha H$ signal at 7.78 ppm for compound **10** appeared slightly upfield from the free lysine ester position of 8.40 ppm due to the proximity of phen in the complex. Although the spectra for cystine and lysine deriv-

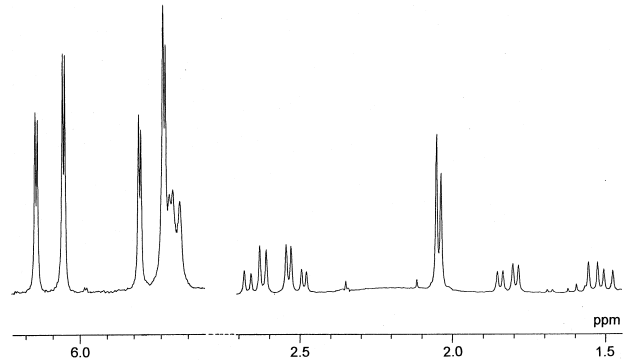

Fig. 4. Part of the ^1H NMR spectrum of compound **4**.

atives **13** and **14** were broad, individual peaks due to the terminal protons of the butadienyl could be identified, and for the latter complex these appeared in the ratio 1:1:2, as predicted for a dimeric species. Comparison of integration of peaks across the full spectral width supported dimeric formulae in each case.

4. Conclusions

Reaction of chiral L-amino esters or (*S*)-(+)-amino alcohols with [$MoCl(CO)_2(\eta^3$-$CH_2C(COCl)C{=}CH_2)(phen)$] yields monomeric complexes containing an amide substituent, and these optical isomers can be identified by ^1H spectroscopy. Both dibasic L-cystine and L-lysine may react with the chlorocarbonyl substituent to give dimeric complexes containing two metal centres bridged by linked butadienyl groups. However, equimolar reactions of L-lysine and the chlorocarbonyl complex result in reaction at the amine of higher pK_a preferentially. The chemistry of these complexes is currently under investigation.

Acknowledgements

Elemental analyses were carried out by the Analysis Centre, University of Kent; NMR spectra were recorded by the University of Portsmouth.

Abstract

The reactions of ammonium salts of dialkyldithiophosphate ligands, $(RO)_2PS_2^-NH_4^+$ (R = Me/Et), with $Ru^{III}Cl_3 \cdot 3H_2O$ in methanol solvent and under N_2 atmosphere result in one-electron paramagnetic tris complexes $\{(RO)_2PS_2\}_3Ru^{III}$ (**1**) in the solid state. The molecular structures of both complexes were determined by single-crystal X-ray diffraction. This shows the expected pseudo-octahedral geometry with reasonable strain due to the presence of a four-membered chelate ring. The reflectance spectra of the solid complexes display two bands in the range 596–476 nm and in the solid state the complexes exhibit one isotropic EPR signal at 77 K. Although the complexes **1** are stable in the solid state, in solution the complexes are transformed selectively into the diamagnetic and electrically non-conducting sulfur-bridged dimetallic species $[\{(RO)_2PS_2\}_2Ru^{IV}(\mu\text{-}S)_2Ru^{IV}\{S_2P(OR)_2\}_2]$. The formation of dimeric species in the solution state is authenticated by the electrospray mass spectrum of one representative complex where R = Et (**1b**). In dichloromethane solution the complexes show two moderately strong sulfur to ruthenium charge-transfer transitions in the range 514–419 nm, and two strong ligand based transitions in the UV region. The complexes exhibit two successive reversible reductions in the ranges $1.01 \rightarrow 0.91$ V and $-0.44 \rightarrow -0.49$ V versus SCE corresponding to Ru^{IV}–Ru^{IV}/Ru^{III}–Ru^{III} and Ru^{III}–Ru^{III}/Ru^{II}–Ru^{II} couples respectively. Electrochemically or chemically generated first step reduced complexes $[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-}$ display two ligand to metal charge-transfer transitions in the visible region and in the complexes the two one-electron paramagnetic metal centers (low-spin Ru^{III}, t_{2g}^5, $S = 1/2$) are antiferromagnetically coupled. The second step reduced species $[\{(RO)_2PS_2\}_2Ru^{II}(\mu\text{-}S)_2Ru^{II}\{S_2P(OR)_2\}_2]^{4-}$ are observed to be very unstable. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Ruthenium; Phosphates; X-ray crystal structures

1. Introduction

Although the ruthenium chemistry of dithioacid based ligands such as dithiocarbamate and dithiocarbonate has been the subject of continuous study [1–24], the corresponding ruthenium dithiophosphate chemistry has not been developed much [25–29]. The versatile bonding, structural features as well as fascinating chemical and electrochemical reactivities of ruthenium dithiocarbamate and dithiocarbonate complexes have prompted us to make a systematic study of ruthenium dialkyldithiophosphate complexes. The present study indicates that the reactions of ammonium salts of dialkyldithiophosphates, $(RO)_2P(S)S^-NH_4^+$, with $RuCl_3 \cdot 3H_2O$ result in tris complexes $\{(RO)_2PS_2\}_3Ru^{III}$ (**1**) in the solid state, whereas in solution the complexes **1** exist predominantly in the dimeric form of type $[\{(RO)_2PS_2\}_2Ru^{IV}(\mu\text{-}S)_2\text{-}Ru^{IV}\{S_2P(OR)_2\}_2]$. Herein we report the solid state characterization of the tris complexes **1**, including the single-crystal X-ray structure and the solution spectroscopic and electron-transfer properties of the complexes.

2. Experimental

2.1. Materials

Commercial ruthenium trichloride (S.D. Fine Chemicals, Bombay, India) was converted into $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. The ligands NH_4L^{1-2} were synthesized according to the reported method [30]. Other chemicals and solvents were

PII S0277-5387(00)00316-8

reagent grade and were used as received. Silica gel (60–120 mesh) used for chromatography was of BDH quality. For spectroscopic and electrochemical studies, HPLC grade solvents were used. Commercial tetraethyl ammonium bromide was converted into pure tetraethyl ammonium perchlorate by following an available procedure [31].

2.2. Physical measurements

UV–Vis spectra were recorded using a Shimadzu-160 spectrophotometer. FT-IR spectra were taken on a Nicolet spectrophotometer with samples prepared as KBr pellets. Solution electrical conductivity was checked using a Systronic 305 conductivity bridge. Magnetic susceptibility was checked with a PAR vibrating sample magnetometer. NMR spectra were obtained with a 300 MHz Varian Fourier transform spectrometer. Cyclic voltammetric, differential pulse voltammetric and coulometric measurements were carried out using a PAR model 273A electrochemistry system. Platinum wire working and auxiliary electrodes and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. The supporting electrolyte was $[NEt_4]ClO_4$ and the solute concentration was 10^{-3} M. The half-wave potential E^0_{298} was set equal to $0.5(E_{pa}+E_{pc})$, where E_{pa} and E_{pc} are the anodic and cathodic cyclic voltammetric peak potentials respectively. A platinum wire-gauze working electrode was used in coulometric experiments. All experiments were carried out under a dinitrogen atmosphere and were uncorrected for junction potentials. The electrospray mass spectra were recorded on a Micromass Quattro II triple quadrupole mass spectrometer. The elemental analyses were carried out with a Carlo Erba (Italy) elemental analyzer. The EPR measurements were made with a Varian model 109C E-line X-band spectrometer fitted with a quartz Dewar for measurements at 77 K (liquid nitrogen). The spectra were calibrated using tetracyanoethylene (tcne) ($g=2.0023$).

2.3. Preparation of complexes

The complexes (**1a** and **1b**) were synthesized by following a general procedure. Details are given for the complex **1a**. Yields vary in the range 70–75%.

2.3.1. Tris(dimethyldithiophosphate)ruthenium(III) (*1a*)

$RuCl_3\cdot 3H_2O$ (100 mg, 0.38 mmol) was dissolved in 15 ml of methanol solvent and a stream of nitrogen gas was flushed through the solution for a period of 15 min. The ligand NH_4L^1, 266 mg (1.52 mmol), was added and the reaction mixture was stirred magnetically under nitrogen atmosphere for 12 h. The solvent was removed under reduced pressure and the solid product thus obtained was purified using a silica gel column. On elution with benzene one pink colored band was separated out, leaving behind a dark mass at the top of the column which did not move even on using methanol. On removal of benzene under reduced pressure, dark crystalline solid complex **1a** was obtained in the pure state. Yield 190 mg (72%).

2.4. X-ray structure determination

Single crystals of complexes **1a** and **1b** were grown by slow diffusion of dichloromethane solution of the complexes into hexane followed by slow evaporation.

Cell parameters were determined by least-squares fit of 25 ($2\theta=10$–$17°$) and 30 ($2\theta=15$–$30°$) machine centered reflections for **1a** and **1b** respectively. Data were collected by the ω-scan technique in the ranges $4\le 2\theta\le 50°$ and $3\le 2\theta\le 48°$ on a Nonius MACH 3 and Siemens R3m/V four-circle diffractometer for **1a** and **1b** respectively with graphite-monochromated Mo Kα radiation ($\lambda=0.71073$ Å) at 293 K. Significant crystal data and data collection parameters are listed in Table 1. The check reflections were measured after every 100 reflections during data collection to monitor crystal stability. No significant intensity reduction was observed during exposure to X-ray radiation. Absorption correction was done by performing psi-scan measurements for **1a** and for **1b** all data were corrected for Lorentz polarization effects and empirical absorption corrections were done on the basis of azimuthal scans of six reflections [32]. For **1a**, data reduction was done using MAXUS and structure solution and refinement were done using the programs SHELXS-97 and SHELXL-97 respectively [33,34]. For **1b**, all calculations for data reduction, structure solution and refinement were done using the program SHELXTL Version 5.03 [33,34]. The metal atom was located from the Patterson map and the other non-hydrogen atoms emerged from successive Fourier synthesis and the structure was refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions. The numbers of variable parameters were 198 and

3. Results and discussion

3.1. Synthesis

Two dialkyldithiophosphate ligands were used for the present study and are abbreviated as NH_4L^1 and NH_4L^2.

R= Me, NH_4L^1
R= Et, NH_4L^2

The reaction of NH_4L with $RuCl_3 \cdot 3H_2O$ in methanol solvent under N_2 atmosphere at room temperature for 12 h results in a dark solution. Chromatographic purification of the dark solution on silica gel column, using benzene as eluant, yields pure tris complexes, $Ru^{III}\{S_2P(OR)_2\}_3$ (**1**) (R = Me **1a**, R = Et **1b**) in the solid state, Eq. (1).

$$Ru^{III}Cl_3 \cdot 3H_2O + (RO)_2PS_2NH_4 \rightarrow Ru^{III}\{S_2P(OR)_2\}_3 + NH_4Cl + H_2O \quad (1)$$

3.2. Solid state characterization

The complexes **1a** and **1b** are stable in the solid state. Microanalytical data of the complexes are in good agreement with the calculated values (Table 2). The complexes are one-electron paramagnets (Table 2), as expected for low-spin Ru^{III} complexes (low spin d^5, $S = 1/2$) [35].

The molecular structures of both the complexes were determined by single-crystal X-ray diffraction. The crystal structures are shown in Figs. 1 and 2. Selected bond lengths and angles are listed in Table 3. The complexes are monomeric and the lattice consists of one type of molecule where the

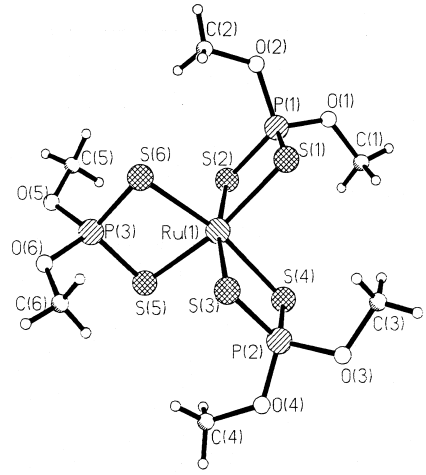

Fig. 1. An ORTEP plot for complex **1a**.

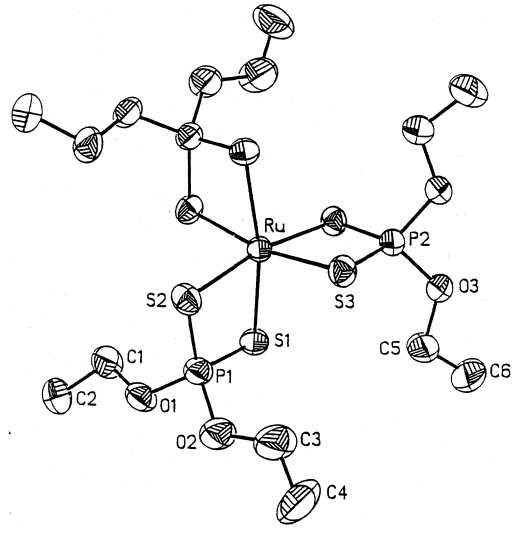

Fig. 2. An ORTEP plot for complex **1b**.

dialkyldithiophosphate ligands are in bidentate *S,S* mode. For **1b**, Ru and P_2 atoms are in special positions and a mirror plane passes through them (Fig. 2). The RuS_6 coordination sphere is distorted octahedral as can be seen from the angles subtended at the metal (Table 3). The observed distortion from the perfect octahedral symmetry originates from the constraints due to the four-membered chelate rings in which the average S–Ru–S bite angles are 81.54(8)° and 81.84(6)° for **1a** and **1b** respectively (Table 3). A similar effect of ring

constraints on the molecular geometry has been also observed earlier [36–39].

The Ru–S distances are unequal, the longer and shorter distances are respectively 2.452(3) and 2.395(3) Å for **1a** and 2.425(14) and 2.401(13) Å for **1b**. The Ru^{III}–S distances in the present complexes are reasonably longer than the corresponding Ru^{III}–S distances, 2.376(4) and 2.383(6) Å (mean Ru^{III}–S distances) in the tris-ruthenium dithiocarbamate complexes $Ru^{III}(S_2CNEt_2)_3$ and $Ru^{III}\{S_2C(CN)(CH_2)_4O\}_3$ respectively [40,41] (the only two other structurally characterized tris-ruthenium(III) dithioacid complexes).

The distances within the dithiophosphate ligands agree well with those found in structurally characterized dithiophosphate complexes of other metal ions [42–44].

It may be noted that the present work demonstrates the first crystal structure of a ruthenium complex incorporating the dithiophosphate ligand.

The reflectance spectra of the solid complexes **1** exhibit two broad bands in the visible region (Fig. 3, Table 2). The band profiles look similar for both complexes, but the lowest energy band maxima are observed to be sensitive to the nature of the R groups.

Consistent with the low-spin configuration, the complexes $[Ru^{III}L_3]$ (low-spin d^5 Ru^{III}, $S=1/2$) display one isotropic

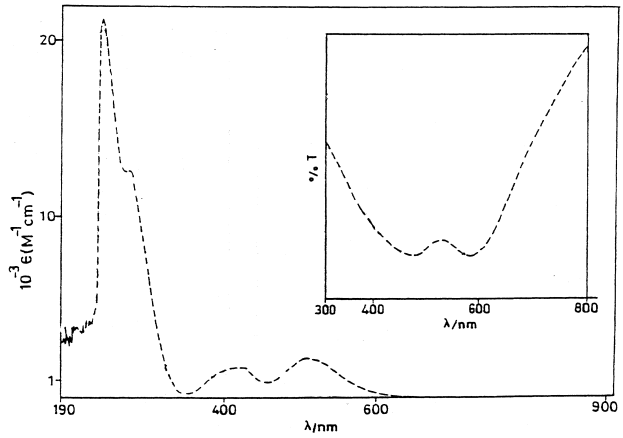

Fig. 3. Electronic spectrum of **1a** in dichloromethane. The inset shows the reflectance spectrum of **1a**.

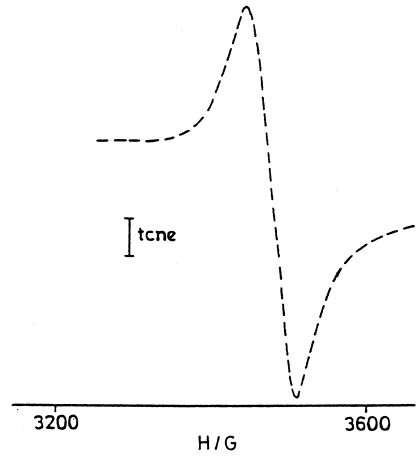

Fig. 4. X-band EPR spectrum of **1b** in the solid state at 77 K.

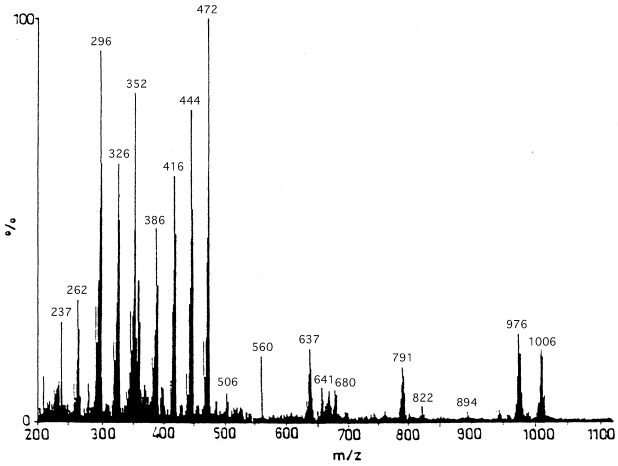
broad EPR signal (Table 2, Fig. 4) [45,46]. No anisotropic pattern has been observed even at liquid N_2 temperature (77 K).

3.3. Solution properties of the complexes

The solid complexes **1** are fairly soluble in non-polar solvents such as dichloromethane, chloroform and benzene, but are sparingly soluble in polar solvents such as acetonitrile, *N*,*N*-dimethylformamide and dimethylsulfoxide. In dichloromethane and acetonitrile the complexes **1** are non-conducting, diamagnetic and consequently EPR silent even at chloroform–toluene glass temperature (77 K, liquid N_2). The change in magnetic behavior of the complexes while moving from the solid to solution state implies that the one-electron paramagnetic solid complexes **1** undergo molecular reorganization in the solution state which eventually leads to the formation of diamagnetic complexes.

The electrospray mass spectrum of a representative complex (**1b**) was recorded in dichloromethane solvent. The maximum molecular peak is observed at *m/z* 1006 (Fig. 5) which corresponds to the molecular ion $[\{(EtO)_2PS_2)\}_2Ru^{IV}(\mu\text{-}S)_2Ru^{IV}\{S_2P(OEt)_2\}_2]$ (calculated molecular



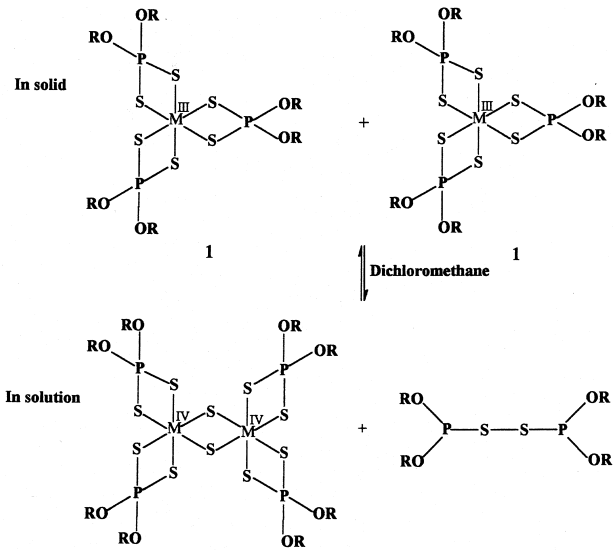


Fig. 5. Electrospray mass spectrum of $[\{(EtO)_2PS_2\}_2Ru^{IV}(\mu\text{-}S)_2\text{-}Ru^{IV}\{S_2P(OEt)_2\}_2]$ (**1b**) in dichloromethane.

weight 1006.2). Thus the tris complexes **1** in the solid state have been transformed into the sulfur bridged dinuclear species as shown in Scheme 1. The conversion of solid tris complexes **1** to the dimeric complexes in the solution state can account for the change in magnetic behavior (one-electron paramagnetic in the solid state and diamagnetic in the solution state) and overall electron balancing.

It may be noted that the tris dithiophosphate cobalt complex $Co^{III}(L)_3$ is also known to liberate one L^- from the tris core in the solution state and the liberated L^- subsequently dimerizes to the disulfide species [47].

^{1}H NMR spectra of the ligands NH_4L^{1-2} and the complexes were recorded in D_2O and $CDCl_3$ respectively. The representative spectra are shown in Fig. 6. The ^{1}H NMR spectrum of NH_4L^1 exhibits two singlets at 3.663 and 3.615 ppm due to two inequivalent $-OCH_3$ groups and similarly NH_4L^2 exhibits two quartets (3.93 and 3.76 ppm) and two triplets (1.17 and 1.12 ppm) due to two inequivalent $-OC_2H_5$ groups. The ^{1}H NMR spectrum of the $R = CH_3$ complex exhibits one

Scheme 1.

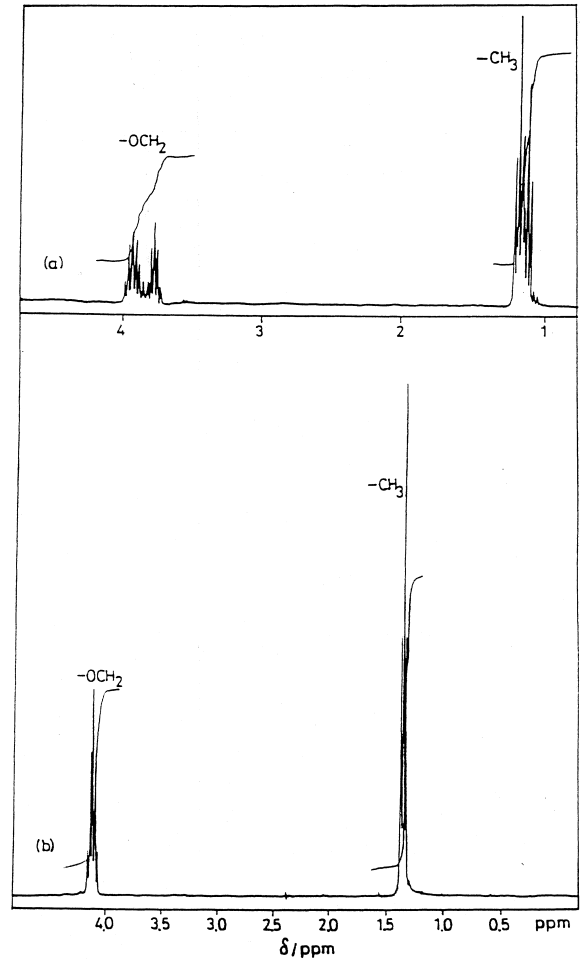

Fig. 6. ^{1}H NMR spectra of (a) NH_4L^2 in D_2O and (b) **1b** in $CDCl_3$.

singlet corresponding to $-OCH_3$ groups at 3.70 ppm and for the $R = C_2H_5$ complex one quartet at 4.18 and one triplet at 1.28 ppm due to $-OC_2H_5$ groups as internal symmetry makes all the ligands equivalent.

Although the decoupled ^{31}P NMR spectra of the ligands (NH_4L^{1-2}) in D_2O exhibit one signal as expected, the complexes in $CDCl_3$ solvent display two signals near 85 and 100 ppm having an intensity ratio of approximately 1:2 due to the presence of more than one type of phosphorus center in the solution state. This may provide support in favor of the presence of disulfide species along with the dimeric complex as proposed in Scheme 1.

In dichloromethane the violet colored complexes exhibit multiple transitions in the UV–Vis region. In the visible region the complexes display two moderately intense bands and the higher energy band is associated with a shoulder at a further higher energy part of the spectra (Table 4, Fig. 3). Since the ruthenium ion is in the +4 oxidation state in the complexes, the bands may therefore be assigned as ligand to metal charge-transfer transitions from sulfur to the metal ion [48–52]. The direct comparisons of the solid state reflectance spectra of **1** with the solution absorption spectra (Fig. 3, Tables 2 and 4) reveal that the bands have been reasonably blue shifted while moving from the solid to solution state.

[a] In dichloromethane at 298 K.
[b] Conditions: solvent, dichloromethane; supporting electrolyte, NEt_4ClO_4; reference electrode, SCE; solute concentration, 10^{-3} M; working electrode, platinum. Cyclic voltammetric data: scan rate, 50 mV s^{-1}; $E^0_{298} = 0.5(E_{pc} + E_{pa})$ where E_{pc} and E_{pa} are the cathodic and anodic peak potentials respectively.
[c] $n = Q/Q'$ where Q' is the calculated Coulomb count for a two-electron transfer and Q that found after exhaustive electrolysis of $\sim 10^{-2}$ mol of solute.

The observed shift in band maxima on switching from solid to solution state supports the existence of different species in the solution state as shown in Scheme 1.

The strong bands in the UV region (Fig. 3) may be due to ligand centered transitions as the free ligands also exhibit a strong band in the same region (NH_4L^1, 236 nm and NH_4L^2, 237 nm in H_2O).

Electron-transfer properties of the complexes were studied in dichloromethane solvent by cyclic voltammetry using a platinum working electrode in the range ± 2.0 V versus a saturated calomel electrode (SCE) (tetraethyl ammonium perchlorate as electrolyte, 298 K). Representative voltammograms are shown in Fig. 7 and the reduction potentials are given in Table 4. The complexes display two reversible reductive couples and the separation between the two $E_{1/2}$ values is found to be ~ 1.4 V (Fig. 7, Table 4). The two-electron nature of the first couple (Fig. 7, couple I) is confirmed with the help of constant-potential coulometry (Table 4). The two-electron nature of the second couple (Fig. 7, couple II) at the negative side of SCE is determined by direct comparison of its differential pulse voltammogram peak height with that of the previous two-electron process (confirmed by coulometric experiment). The reduction potentials are observed to be lower for the complex having the ethoxy group (**1b**) as compared to the methoxy complex (**1a**).

The responses at positive and negative potentials are respectively assigned to ruthenium(IV)–ruthenium(III) and ruthenium(III)–ruthenium(II) couples as in Eqs. (2) and (3).

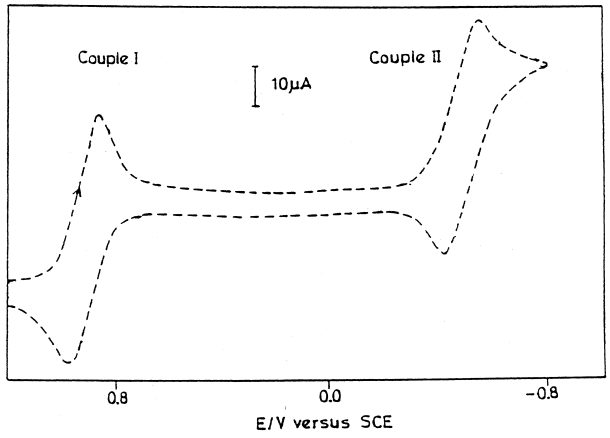

Fig. 7. Cyclic voltammograms of **1b** in dichloromethane at 298 K.

$$[\{(RO)_2PS_2\}_2Ru^{IV}(\mu\text{-}S)_2Ru^{IV}\{S_2P(OR)_2\}_2] + 2e^- \rightleftharpoons [\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-} \quad (2)$$

$$[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-} + 2e^- \rightleftharpoons [\{(RO)_2PS_2\}_2Ru^{II}(\mu\text{-}S)_2Ru^{II}\{S_2P(OR)_2\}_2]^{4-} \quad (3)$$

It may be noted that the free ligands (NH_4L^{1-2}) do not show any redox activities within the specified potential range. Here the difference in potential between the two successive reduction processes is found to be ~ 1.4 V (Table 4) which is in good agreement with the earlier observed potential differences (1.3–1.4 V) between the two successive reduction processes $Ru^{IV/III}$–$Ru^{III/II}$ in other complexes [53–55].

Electrochemical reductions (constant-potential coulometry) of the complexes at 0.5 V versus SCE in dichloromethane solvent using a platinum gauze working electrode under a dinitrogen atmosphere result in a sharp color change from pink to greenish yellow. The observed Coulomb counts correspond to two-electron transfer (Table 4). The resulting reduced $[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-}$ species display voltammograms which are superposable on those of the corresponding starting complexes, which imply that the reductions here may be stereoretentive in nature [56]. When the same reduced solutions are reoxidized coulometrically at a potential 100 mV positive to the corresponding E_{pa} of the M^{III}/M^{IV} couple, the starting violet colored tetravalent complexes are formed quantitatively. The reduced species are not stable enough to be isolated in the solid state even at 273 K, however, we have managed to check the EPR spectra of the reduced complexes at 77 K and to record the qualitative electronic spectra. Since the reduced complexes are observed to be EPR silent even at 77 K, it may therefore be assumed that the two ruthenium(III) centers in the complexes are antiferromagnetically coupled [57]. In dichloromethane solvent, the complexes display two sulfur to metal charge transfer transitions in the visible region (Fig. 8, Table 4) and one ligand based transition in the UV region (Table 4).

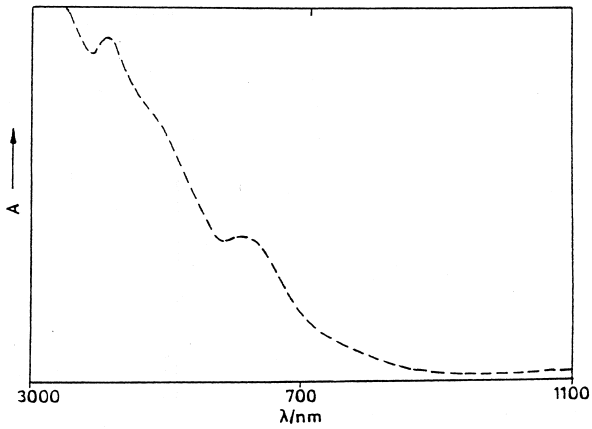

Fig. 8. Electronic spectrum of coulometrically reduced complex of $[\{(MeO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OMe)_2\}_2]^{2-}$ (**1a**$^{2-}$) in dichloromethane.

Coulometric reductions of the ruthenium complexes at −0.7 V versus SCE result in light blue colored reduced species. The resulting reduced complexes $[\{(RO)_2PS_2\}_2Ru^{II}(\mu\text{-}S)_2\,Ru^{II}\{S_2P(OR)_2\}_2]^{4-}$ are very unstable. On contact with a small amount of air, the complexes are oxidized immediately to the trivalent species, therefore no further study was made in this direction. The low $Ru^{III/II}$ potentials (~ -0.5 V) and the tetraanionic nature of the second reduced species might be responsible for their spontaneous aerial oxidation to the higher congeners.

The complexes can also be reduced chemically to the trivalent congeners by hydrazine hydrate. Although the greenish-yellow colored first step reduced species $[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-}$ are stable on the coulometric time scale and can even be generated by chemical means, all our attempts to isolate the first step reduced species in the pure solid state have failed. Further investigations are in progress in the direction of developing the first step reduced species, $[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(OR)_2\}_2]^{2-}$, particularly in the absence of any disulfide product in order to obtain direct evidence in favor of dimer formation.

4. Conclusions

We have observed that the reactions of dialkyldithiophosphate ligands with $RuCl_3\cdot 3H_2O$ result in paramagnetic tris ruthenium complexes $\{(RO)_2PS_2\}_3Ru^{III}$ (**1**) in the solid state, however, in solution the complexes exist predominantly in the dimeric form, $[\{(RO)_2PS_2\}_2Ru^{IV}(\mu\text{-}S)_2Ru^{IV}\{S_2P(RO)_2\}_2]$. The tetravalent dinuclear complexes are susceptible to facile stereoretentive electrochemical reductions to the corresponding trivalent and bivalent dinuclear congeners $[\{(RO)_2PS_2\}_2Ru^{III}(\mu\text{-}S)_2Ru^{III}\{S_2P(RO)_2\}_2]^{2-}$ and $[\{(RO)_2PS_2\}_2Ru^{II}(\mu\text{-}S)_2Ru^{II}\{S_2P(RO)_2\}_2]^{4-}$ respectively. The bivalent species are found to be unstable whereas the trivalent complexes are stable on the coulometric time scale but isolation in the pure solid state has not been successful.

Supplementary data

Supplementary data are available from the Cambridge Crystallography Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers 136793 and 136794 for compounds **1a** and **1b** respectively.

Acknowledgements

Financial support received from the Department of Science and Technology, New Delhi, India, is gratefully acknowledged. The X-ray structural studies of **1a** and **1b** were carried out at the National Single Crystal Diffractometer Facilities, Indian Institute of Technology, Bombay and Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta, India respectively. Special acknowledgement is made to the Regional Sophisticated Instrumental Center, RSIC, Indian Institute of Technology, Bombay for providing NMR and EPR facilities.

POLYHEDRON

Synthesis and characterisation of platinum(II) complexes containing heterobidentate *S*,*N*-chelating ligands: X-ray crystal structure of *cis*-[Pt{SPPh$_2$N=C(Me)NH-*S*,*N*}(PMe$_2$Ph)$_2$]Cl

Abstract

Deprotonation of the terminal amino group in the *N*-thiophosphoryl compounds Me$_2$P(S)N=C(NH$_2$)$_2$ (HL^1), Ph$_2$P(S)N=C(Me)NH$_2$ (HL^2) or Ph$_2$P(S)N=C(NH$_2$)$_2$ (HL^3) using potassium *tert* butoxide in thf, followed by treatment with *cis*-[PtCl$_2$(PR$_3$)$_2$] (PR$_3$ = PMe$_2$Ph or $\frac{1}{2}$dppe) generates monocationic complexes *cis*-[Pt(L^n-*S*,*N*)(PR$_3$)$_2$]Cl (**1**–**6**), which have been characterised by ^{31}P{^{1}H} NMR, IR and FAB$^+$ mass spectroscopies, and for *cis*-[Pt(L^2-*S*,*N*)(PMe$_2$Ph)$_2$]Cl (**2**) by single crystal X-ray diffraction. The molecular structure of **2** reveals bidentate coordination of the platinum(II) centre by a bidentate *S*,*N*-chelating [Ph$_2$P(S)N=C(Me)NH]$^-$ anion, giving a six-membered platinacycle, which adopts a chaise-longue conformation, with a strong hydrogen-bonding interaction between the chloride counterion and the nitrogen-bound proton. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Thiophosphoryl guanidines; Platinum complexes; Crystal structures

1. Introduction

Ourselves [1,2] and others [3–8] have studied the coordination chemistry of imidodiphosphinate anions [R$_2$P(E)NP(E′)R′$_2$]$^-$ (R, R′ = alkyl, aryl or alkoxy; E, E′ = oxygen, sulfur or selenium), generated from the weak acids HN(R$_2$PE)(R′$_2$PE′), regarded as 'inorganic' analogues of the more ubiquitous β-diketonates such as acetylacetonate. Bidentate *E*,*E*′ chelation of imidodiphosphinate ligands at d- and p-block metal centres produces hexa-atomic metallacycles; crystallographic analyses of several such metal complexes indicate substantial flexibility within the E–P–N–P–E′ backbone which enables the adoption of a variety of chelate ring conformations in the solid state, although planarity is rarely observed. The facile construction of imidodiphosphinate ligands, generally by the base-catalysed clipping together of R$_2$P(E)NH$_2$ and R′$_2$P(E′)Cl precursors or via oxidation of the parent diphosphine R$_2$PNHPR′$_2$ using elemental chalcogen or hydrogen peroxide, has led to applications for such ligands as metal extraction agents, NMR shift reagents and recently in a catalytic function in the aerobic co-oxidation of alkenes and aldehydes [7–10].

As a class of potentially chelating bidentate ligands, the phosphorus(V) derivatised guanidines and amidines R$_2$P(E)N=C(X)NH$_2$ (R = alkyl or aryl; E = oxygen or sulfur; X = NH$_2$ or alkyl) have been known for some time, but their coordination chemistry does not appear to have been well explored [11–16]. The presence in these molecules of an ionisable nitrogen-bound proton coupled with the potential for delocalisation of the resulting uninegative charge through the π-system of the anion suggests a high degree of similarity with both imidodiphosphinate and β-diketonate ligands. The combination of chalcogen and nitrogen donor atoms offered by these molecules is, however, rarely encountered in their P–N–P or carbon-backboned counterparts.

Here, we describe our studies on the coordination chemistry of the monoanions derived from Me$_2$P(S)N=C(NH$_2$)$_2$ (HL^1) and Ph$_2$P(S)N=C(X)NH$_2$ (X = Me (HL^2) or NH$_2$ (HL^3)) at platinum(II) centres, including one representative crystal structure.

2. Results and discussion

Deprotonation of the amine nitrogen atom in HN(R$_2$PE)(R′$_2$PE) gives π-delocalised imidodiphosphinate anions [R$_2$P(E)NP(E′)R′$_2$]$^-$ which have great propen-

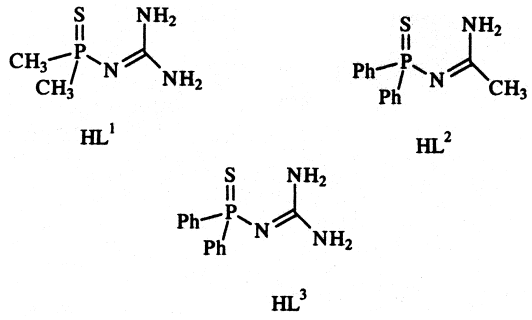

Fig. 1. Structures of the ligands $HL^{1–3}$.

sity towards bidentate *E,E′* chelation at metal centres [1–6]. We believed that the *N*-thiophosphoryl amidine (HL^2) and guanidines ($HL^{1,3}$) (Fig. 1) could in a similar way function as monobasic acids and undergo coordination to metal ions, to give chelates using a heterobidentate *S,N* donor array. To test our hypothesis we attempted to prepare platinum(II) complexes using the anions derived from $HL^{1–3}$.

Treatment of thf solutions of $HL^{1–3}$ with potassium *tert*-butoxide followed by a stoichiometric quantity of *cis*-$[PtCl_2(PR_3)_2]$ ($PR_3 = PMe_2Ph$ or $\frac{1}{2}$dppe) proceeds smoothly at reflux with displacement of the chloro ligands from the metal coordination sphere and chelation of the $(L^n)^-$ anion to give cationic complexes *cis*-$[Pt(L^n\text{-}S,N)(PR_3)_2]Cl$ (**1**–**6**) isolable in moderate yields (39–65%) from dichloromethane–diethyl ether, Eq. (1).

$$cis\text{-}[PtCl_2(PR_3)_2] + KL^n \rightarrow cis\text{-}[Pt(L^n\text{-}S,N)(PR_3)_2]Cl + KCl \quad (1)$$

The platinum(II) complexes **1**–**6** are colourless (**1**, **2**) or pale yellow (**3**–**6**) solids, tolerant to air and moisture, and are highly soluble in chlorinated solvents and thf. In their FAB^+ mass spectra all of the complexes give intense peaks which correspond to an ion of composition $[PtL(PR_3)_2]^+$. The $^{31}P\{^1H\}$ NMR spectra for **1**–**6** (Table 1) contain extensive information on ^{195}Pt–^{31}P and ^{31}P–^{31}P coupling constants and are in accord with their structures; the complexes exhibit first-order AMX spin systems with platinum-195 satellites. The ^1J(Pt–P) coupling constants for the phosphine co-ligands P(2), P(3) lie in the ranges 2917–3004 Hz (P(3) *trans* sulfur) and 3234–3371 Hz (P(2) *trans* nitrogen) in accord with the weaker *trans* influence of N versus S. A similar variation in ^1J(Pt–P) values as a function of the *trans* donor atom has been observed in *cis*-$[Pt(S_2N_2)(PR_3)_2]$ and *cis*-$[Pt(S_2N_2H)(PR_3)_2]^+$, in which the sulfur–nitrogen anions are *S,N*-bidentate at platinum(II) [17,18]. The ^2J(Pt–P) couplings for the phosphorus(V) atom P(1) of the chelate in **1**–**6** (85–102 Hz) are somewhat larger than the values we have reported in the dithio-imidodiphosphinate complexes *cis*-$[Pt\{(SPPh_2)_2N\}(PR_3)_2]Cl$ (60–64 Hz for monodentate phosphines, 79 Hz for dppe) which contain *S,S′*-chelating $[(SPPh_2)_2N]^-$ anions [19]. The *cis* $^2J(P^{III}\text{–}Pt\text{–}P^{III})$ couplings for the $PhMe_2P$ complexes **1**–**3** (20–25 Hz) are larger in magnitude compared with the dppe complexes (5–10 Hz), in which there is an additional ^3J(P–P) component through the ligand backbone of opposite sign. Each of the *cis* or *trans* $^3J(P^{III}\text{–}Pt\text{–}S\text{–}P^{V})$ couplings for **1**–**6** have comparable magnitudes, being between 4 and 11 Hz. Upon deprotonation and chelation the phosphorus atom P(1) of the chelate experiences modest shielding, moving ca. 15 ppm to low frequency from the free ligand value (δ_P 48.3 and 42.2 for HL^1 and HL^2 (*d*-chloroform), 42.5 for HL^3 (d_4-methanol)). Formation of the *S,N* chelate is exclusive in these instances; there is no evidence from $^{31}P\{^1H\}$ NMR spectroscopy for the formation of isomeric complexes of $(L^1)^-$ or $(L^3)^-$ in which the $[R_2P(S)NC(NH_2)NH]^-$ anion functions as an *N,N′* bidentate chelate to platinum(II) by the amino groups at the imine carbon.

In their IR spectra **1**–**6** exhibit several strong bands in the region 1400–1700 cm^{-1}; the ν_{NH} vibrations (broad bands of medium intensity between 3400–3100 cm^{-1}) and the ν_{PS} bands (ca. 562 cm^{-1} for **1** and **4**, ca. 588 cm^{-1} for **2**, **3**, **5** and **6**) are shifted only marginally from the values in the uncomplexed molecules $HL^{1–3}$ (HL^1 3377, 3142 (ν_{NH}) and 558 (ν_{PS}); HL^2 3361, 3285, 3230 (ν_{NH}) and 575 (ν_{PS}); HL^3 3437, 3350, 3299, 3201 (ν_{NH}) and 586 (ν_{PS})).

The molecular structure of *cis*-$[Pt\{SPPh_2N{=}C(Me)NH\text{-}S,N\}(PMe_2Ph)_2]Cl$ (**2**) has been determined by single crystal X-ray diffraction, Fig. 2. The coordination sphere at the metal atom Pt(1) comprises two mutually *cis* dimethylphenylphosphine ligands, bound through P(2) and P(3), and $(L^2)^-$ ligand bound via the terminal sulfur and nitrogen atoms S(1) and N(14) to form a six-membered Pt(1)–

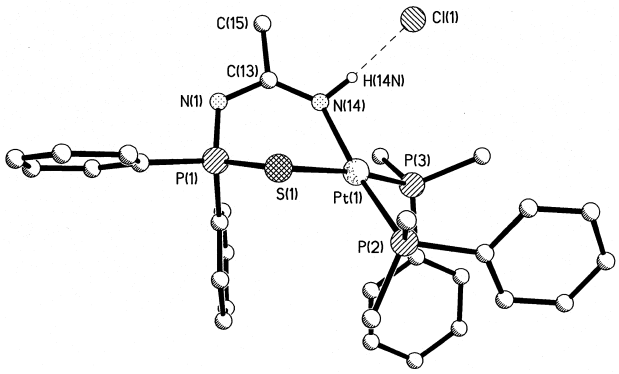

Fig. 2. X-ray crystal structure of *cis*-[Pt{SPPh$_2$N=C(Me)NH-*S*,*N*}-(PMe$_2$Ph)$_2$]Cl (**2**) (hydrogen atoms bound to carbon omitted for clarity). Selected bond lengths (Å) and angles (°): Pt(1)–S(1) 2.403(2), Pt(1)–P(2) 2.284(2), Pt(1)–P(3) 2.289(2), Pt(1)–N(14) 2.060(8), P(1)–S(1) 2.036(4), P(1)–N(1) 1.604(8), N(1)–C(13) 1.335(12), C(13)–N(14) 1.314(12); P(3)–Pt–P(2) 96.17(9), P(2)–Pt(1)–S(1) 85.57(9), S(1)–Pt(1)–N(14) 90.8(3), N(14)–Pt(1)–P(3) 89.1(3), Pt(1)–S(1)–P(1) 91.75(12), P(1)–N(1)–C(13) 121.5(7), S(1)–P(1)–N(1) 115.3(3), N(1)–C(13)–N(14) 127.5(9), C(13)–N(14)–Pt(1) 134.5(7).

S(1)–P(1)–N(1)–C(13)–N(14) platinacycle. There is a hydrogen-bonding interaction between the chloride counterion Cl(1) and the remaining amine proton H(14n) at N(14) (H(14n)···Cl(1) 2.34 Å, N(14)–H(14n)···Cl(1) 164°). Within the chelate ring, the atoms of the Pt(1)–N(14)–C(13)–N(1)–P(1) chain are coplanar, S(1) being displaced by 1.27 Å from this plane. There are deviations from square planarity at the metal centre; the angles between *cis* atoms are in the range 85.6–96.2°, moreover the P(2)–Pt(1)–P(3) and N(14)–Pt(1)–S(1) planes are twisted by 13° relative to each other. The Pt–P and Pt–N distances in **2** (Pt(1)–P(2) 2.284(2), Pt(1)–P(3) 2.289(2) and Pt(1)–N(14) 2.060(8) Å) correspond closely with the parameters for [Pt(S$_2$N$_2$)(PMe$_2$Ph)$_2$] (Pt–P 2.271(4) and 2.265(3) Å, Pt–N 2.081(8) Å) although the Pt–S distance is somewhat longer in the $(L^2)^-$ complex (Pt–S 2.403(2) Å in **2**, c.f. 2.270(5) Å for the $(S_2N_2)^{2-}$ complex) [17].

In summary *S*,*N* bidentate chelates can be readily formed at platinum(II) by *N*-thiophosphoryl derivatives of guanidines and amidines upon prior deprotonation using potassium *tert*-butoxide. Efforts are underway to extend the range of metal complexes which can be obtained using the anions derived from HL[1–3].

3. Experimental

Complexation reactions were performed under an atmosphere of oxygen-free nitrogen; subsequent work-up and recrystallisations were in air. Dichloromethane and thf were dried and distilled from calcium hydride and sodium respectively, *cis*-[PtCl$_2$(PR$_3$)$_2$] (PR$_3$ = PMe$_2$Ph or $\frac{1}{2}$dppe) was prepared by the addition of stoichiometric quantities of PR$_3$ to *cis*-[PtCl$_2$(cycloocta-1,5-diene)] in dichloromethane, potassium *tert*-butoxide (Aldrich) and other solvents employed were unpurified. ^{31}P{^{1}H} NMR (36.2 MHz, referenced to external 85% phosphoric acid (δ 0)) and IR spectra (pressed KBr discs) were recorded on JEOL FX90Q NMR and Perkin-Elmer System 2000 NIR FT-Raman spectrometers respectively. Elemental analyses (PE 2400 CHN elemental analyser) were performed by the University of Loughborough Analytical Service, FAB mass spectra (positive ionisation mode, 3-nitrobenzyl alcohol matrix) were carried out by the EPSRC National Mass Spectrometry Service Centre, Swansea.

The platinum(II) complexes *cis*-[Pt(L^n-*S*,*N*)(PR$_3$)$_2$]Cl (**1**–**6**) were prepared by the same general procedure.

To a solution of the ligand HL^n (0.2 mmol) and potassium *tert*-butoxide (0.25 mmol) in thf (5 cm^3) was added *cis*-[PtCl$_2$(PR$_3$)$_2$] (0.2 mmol) as a solid in one portion. The resulting yellow mixture was heated at reflux for 2 h and then cooled to room temperature. The solvent was removed in vacuo, the crude product was extracted in dichloromethane (5 cm^3) and the solution filtered through a plug of glass wool-Celite. The dichloromethane filtrate was concentrated under reduced pressure to ca. 2 cm^3; vapour diffusion of diethyl ether into the solution over several days gave the complexes *cis*-[Pt(L^n-*S*,*N*)(PR$_3$)$_2$]Cl (**1**–**6**) as either colourless (**1**, **2**) or pale yellow (**3**–**6**) solids. Conversion is quantitative by ^{31}P{^{1}H} NMR spectroscopy, isolated yields of the complexes were typically 39–65% based on Pt.

3.1. X-ray crystallography

X-ray diffraction studies on crystals of *cis*-[Pt(L^2-*S*,*N*)(PMe$_2$Ph)$_2$]Cl (**2**) grown from dichloromethane–hexane by solvent diffusion, were performed using a Bruker SMART diffractometer with graphite-monochromated Mo

Kα radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods, the non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms bound to carbon were idealised and fixed (C–H 0.95 Å); the NH proton H(14n) associated with N(14) was located by a ΔF map and allowed to refine anisotropically. Structural refinements were by the full-matrix least-squares method on F^2 using the program SHELXTL-PC [20]. $C_{30}H_{36}N_2P_3ClPtS$, colourless needles, $0.08 \times 0.12 \times 0.15$ mm, $M = 780.12$, monoclinic, $a = 9.9790(2)$, $b = 29.4825(4)$, $c = 10.9449(2)$ Å, $\beta = 90.835(1)°$, $U = 3219.7(1)$ Å^3, $T = 293$ K, space group $P2_1/n$, $Z = 4$, μ(Mo Kα) = 4.677 mm^{-1}. Of 13959 measured data 4587 were unique reflections ($R_{int} = 0.0421$) to give $R_1 = 0.0414$ ($I > 2\sigma(I)$, 3680 observed) and $wR_2 = 0.0881$.

Supplementary data

Full lists of structure refinement data, atomic coordinates, bond lengths and angles, anisotropic displacement parameters and hydrogen atom parameters have been deposited as supplementary material, no. 137216, at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

Acknowledgements

We are grateful to the EPSRC for funding (P.B.), Johnson Matthey plc for the loan of platinum salts and to Professor Alfred Schmidpeter, University of Munich, for the generous gift of samples of HL[1–3].

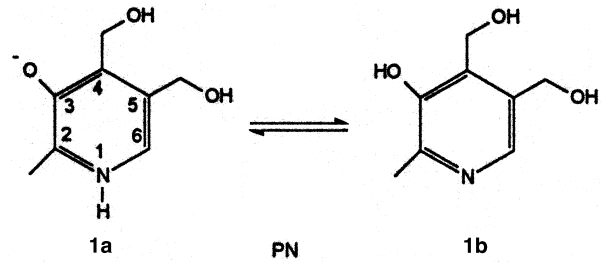
Abstract



The reaction of the diethyltin(IV) cation with pyridoxine (PN, vitamin B_6) in 80:20 (v/v) ethanol–water mixtures containing NO_3^- and Cl^-, NO_3^- and AcO^- or Cl^- and AcO^- ions in various molar ratios was investigated. The compounds $[SnEt_2(PN–H)]Cl$ (**1**), $[SnEt_2(PN–H)](NO_3)\cdot 2H_2O$ (**2**) and $[SnEt_2(PN–2H)]$ (**3**) were isolated. These compounds were characterized by IR, Raman and Mössbauer spectroscopy and EI and FAB mass spectrometry. The structure of compound **1**, determined by X-ray diffraction, consists of dimeric $[SnEt_2(PN–H)]_2^{2+}$ units (in which two bridging-chelating hydrogen pyridoxinate anions link Sn atoms with coordination number five) and hydrogen-bonded Cl^- ions. The behaviour of these compounds in DMSO-d_6 and DMF-d_7 was studied by NMR spectroscopy. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; Diethyltin; Pyridoxine

1. Introduction

The wide range of industrial applications of organotin compounds [1] has led to increasing concern about their presence in the environment and, as a consequence, to an increase in research aimed at determining the species generated by their hydrolysis [2–5]. Also, biological considerations such as the possible use of organotin compounds as antitumour agents [6] have led to increased study of the interactions of their cations with ligands of biological significance in water or mixtures of water and organic solvents [7–13]. Although most work on the hydrolysis and thermodynamics of organotin has concerned the dimethyltin(IV) cation [2–5,7–13], recent studies have used the diethyl and dibutyl cations [14–17], finding that for a given ligand the stability of the species present in solution depends on the nature of R in SnR_2^{2+}.

As part of our work on the interactions of diorganotin compounds with vitamins in aqueous or organo-aqueous media [18,19], we have previously studied [20] the interaction of the dimethyltin(IV) cation with pyridoxine (2-methyl-3-hydroxy-4,5-bis(hydroxymethyl)pyridine, PN), one of the recognized forms of vitamin B_6 [21], in ethanol–water containing NO_3^- and Cl^-, NO_3^- and AcO^- or Cl^- and AcO^- in various molar ratios; the presence of these anions enabled us to prepare complexes of $SnMe_2^{2+}$ with both di- and mono-deprotonated pyridoxine, Cl^- and NO_3^- acting as counterions in the latter case. We now report the results of an analogous study using the diethyltin(IV) cation, and describe the crystal structure of one of the compounds isolated, $[SnEt_2(PN–H)]Cl$.

2. Experimental

2.1. Material and methods

Pyridoxine hydrochloride (Aldrich), pyridoxine (Aldrich), diethyltin dichloride (Aldrich), silver nitrate (Merck) and silver acetate (Probus) were used as received. Elemental analysis was performed with a Fisons 1108 microanalyser. Melting points were determined with a Büchi apparatus. Mass spectra were recorded on a Kratos MS50TC spectrometer connected to a DS90 system and operating under EI conditions (direct insertion probe, 70 eV, 250°C) and FAB (*m*-nitrobenzyl alcohol, Xe, 8 eV; ca. 1.28×10^{-15} J); ions were identified by DS90 software and values for the metallated peaks were calculated using the isotope ^{120}Sn. IR spectra (KBr pellets or Nujol mulls) and Raman spectra (polycrystalline samples) were recorded on a Bruker IFS66V FT-IR spectrometer equipped with an FRA-106 Raman accessory and are reported in Section 2.2 using the following abbreviations: vs very strong, s strong, m medium, w weak, sh shoulder, br broad. ^{1}H NMR spectra in DMSO-d_6 or DMF-d_7 were recorded at room temperature on a Bruker AMX 300 operating at 300.14 MHz, using 5 mm o.d. tubes; chemical shifts are reported relative to TMS. ^{119}Sn NMR spectra in DMSO-d_6 were run on a Bruker AMX 500 instrument using 5 mm o.d. tubes, and referred to external neat tetramethyltin. The conductivities of 10^{-3} M solutions were measured in a Crison MicroCM2202 conductivity meter. Mössbauer spectra were recorded at 80.0 K in a Harwell cryostat; the $Ca^{119m}SnO_3$ source (15 mCi, NEN) was kept at room temperature and moved with a triangular velocity wave form; suitable computer programs were employed to fit Lorentzian lineshapes to the experimental data.

2.2. Synthesis of the compounds

2.2.1. [$SnEt_2$(PN–H)]Cl (**1**)

Solid NaOH (0.40 g, 10 mmol) was added to a solution of PN·HCl (2.06 g, 10 mmol) in ethanol–water (80:20 v/v, 50 ml) (solution A). Solid Ag(AcO) (1.67 g, 10 mmol) was added to a solution of $SnEt_2Cl_2$ (1.23 g, 5 mmol) in the same solvent (25 ml), and the AgCl formed upon stirring was filtered out to leave solution B. Solution B was added with stirring to solution A, and stirring was continued for 1 day (final pH 5.5). After 12 h standing, the appearance of well formed crystals was observed. *Anal*. Found: C, 38.0; N, 3.7; H, 5.2. Calc. for [$SnEt_2$(PN–H)]Cl: C, 37.8; N, 3.7; H, 5.2%. M.p. 218°C. Yield (first batch) 65%. The main metallated signals in the EI spectrum are at *m/e* (ion, intensity): 327 ([$SnEt_2$(PN–2H–OH)], 60.95); 268 ([$SnEt_2$-(PN–2H–2CH_2OH–CH_3)], 73.8); 240 ([SnEt(PN–H–2CH_2OH–CH_3)], 35.7); 195 ([$SnEt_2$OH], 12.5); 149 ([SnEt], 27.1), 120 ([Sn], 29.8). The FAB spectrum shows a signal at 344 ([$SnEt_2$(PN–2H)], 100). Infrared (Raman) cm^{-1}: 1622w (1622w, 1607w), 1530vs (1538w), 1455m (1456m), ν(ring); 1020vs, 1012vs, ν(CO); 528m (524w), ν_{asym}(Sn–C); 478sh (482vs), ν_{sym}(Sn–C). Mössbauer: δ 1.61, ΔE_Q 3.83, Γ 1.04, $A_{2/1}$ 1.02. Λ_M (DMF, 10^{-3} M solution), 23.8 S cm^2 mol^{-1}.

The same product was obtained in media with Cl^- and AcO^- in 3:1 molar ratio, with Cl^- and NO_3^- in 3:1 molar ratio, and with Cl^- alone (see Table 1).

2.2.2. [$SnEt_2$(PN–H)](NO_3)·2H_2O (**2**)

To a solution of PN·HCl (2.06 g, 10 mmol) in ethanol–water (80:20 v/v, 50 ml) were added solid NaOH (0.40 g, 10 mmol) and solid $AgNO_3$ (1.70 g, 10 mmol). The AgCl formed upon stirring was filtered out, a solution of $SnEt_2Cl_2$ (1.23 g, 5 mmol) in the same solvent (25 ml) was added with stirring, and stirring was continued for 1 day (final pH 5.5). Slow concentration of the solution afforded a crystalline solid. *Anal*. Found: C, 31.6; N; 6.2; H, 5.5. Calc. for [$SnEt_2$(PN–H)](NO_3)·2H_2O: C, 32.5; N, 6.3; H; 5.4%. M.p. 220°C. Yield (first batch) 51%. The main metallated signals in the EI spectrum are at *m/e* (ion, intensity): 327 ([$SnEt_2$(PN–2H–OH)], 57.4); 298 ([$SnEt_2$(PN–H–CH_2OH–OH)], 12.89); 268 ([$SnEt_2$(PN–2H–2CH_2OH–CH_3)], 68.1); 240 ([SnEt(PN–H–2CH_2OH–CH_3)], 39.7); 195 ([$SnEt_2$OH], 11.8); 149 ([SnEt], 33.4), 120 ([Sn], 48.1). The FAB spectrum has a signal at 344 ([$SnEt_2$(PN–2H)], 100). Infrared (Raman), cm^{-1}: 1630w (1641w, 1625w), 1527vs, 1474m ν(ring); 1026m, 995vs, ν(CO); 1383vs, ν_{asym}(NO_3^-); 1040sh (1046vs), ν_{sym}(NO_3^-);

539m (537w), ν_{asym}(Sn–C); 482sh (485vs), ν_{sym}(Sn–C). Mössbauer: δ 1.63, ΔE_Q 3.90, Γ 0.93, $A_{2/1}$ 1.08. Λ_M (DMF, 10^{-3} M solution), 39.8 S cm^2 mol^{-1}.

The same product was obtained in media with NO_3^- and Cl^- in 3:1 molar ratio, with NO_3^- and AcO^- in 3:1 molar ratio, and with NO_3^- alone (see Table 1).

*2.2.3. [$SnEt_2$(PN–2H)] (**3**)*

To a solution of PN·HCl (2.06 g, 10 mmol) in ethanol–water (80:20 v/v, 50 ml) were added solid NaOH (0.40 g, 10 mmol) and $AgNO_3$ (1.70 g, 10 mmol), and the AgCl formed after stirring was filtered out to leave solution A. To a solution of $SnEt_2Cl_2$ (1.23 g, 5 mmol) in the same solvent (25 ml) was added solid Ag(OAc) (1.67g, 10 mmol) and the AgCl formed after stirring was filtered out to leave solution B. Solution B was added with stirring to solution A and stirring was continued for 1 day (final pH 5). After standing for 2 days, crystals of **3** were observed. *Anal*. Found: C, 41.6; N, 4.2; H, 5.5. Calc. for [$SnEt_2$(PN–2H)]: C, 41.8; N, 4.1; H, 5.5%. M.p. 275°C. Yield (first batch) 68%. The main metallated signals in the EI spectrum are at *m/e* (ion, intensity): 327 ([$SnEt_2$(PN–2H–OH)], 41.3); 268 ([$SnEt_2$-(PN–2H–2CH_2OH–CH_3)], 55.7); 240 ([SnEt(PN–H–2CH_2OH–CH_3)], 27.5); 195 ([$SnEt_2$OH], 9.5); 149 ([SnEt], 28.7) and 120 ([Sn], 50.4). The FAB spectrum has signals at 344 ([$SnEt_2$(PN–2H)], 100) and 688 ([{$SnEt_2$(PN–2H)}$_2$], 23). Infrared (Raman), cm^{-1}: 1556m (1557w), 1463sh (1454w), 1404m, ν(ring); 1018s (1022w), 982s, ν(CO); 517m (525w), ν_{asym}(Sn–C); 490sh (488,476vs), ν_{sym}(Sn–C). Mössbauer: δ 1.44, ΔE_Q 3.07, Γ 0.96, $A_{2/1}$ 1.01.

2.3. Crystal structure determination

2.3.1. X-ray data collection and reduction

A colourless prismatic crystal of **1** was mounted on a glass fibre for data collection in an Enraf-Nonius MACH3 automatic diffractometer [22]. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data for 25 reflections in the range $10.63 < \theta < 18.12°$. Data were collected at 293 K using Mo Kα radiation ($\lambda = 0.71073$ Å) and the ω scan technique, and were corrected for Lorentz and polarization effects [23]. An empirical absorption correction (DIFABS) [24] was also made.

2.3.2. Structure solution and refinement

The structure was solved by direct methods [25] and subsequent Fourier maps, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [26]. All hydrogen atoms were located from difference Fourier maps and were refined isotropically. Atomic scattering factors were taken from International Tables for X-ray Crystallography [27]. Molecular graphics were generated with PLATON98 [28]. The crystal data, experimental details and refinement results are summarized in Table 2.

Table 2
Crystal data, data collection and structure refinement parameters

Compound	[$SnEt_2$(PN–H)]Cl (**1**)
Empirical formula	$C_{24}H_{40}Cl_2N_2O_6Sn_2$
Formula weight	760.86
Temperature (K)	293(2)
Wavelength (Å)	0.71073
Crystal system	monoclinic
Space group	$P2_1/c$ (no. 14)
Unit cell dimensions

Z	2
D_c (Mg m^{-3})	1.666
F(000)	760
μ (mm^{-1})	1.861
Crystal size (mm)	0.55×0.15×0.15
θ Range for data collection (°)	2.27 to 26.28
Index ranges	$-11 \le h \le 0$
	$-0 \le k \le 15$
	$-16 \le l \le 16$
Reflections collected	3264
Unique reflections	3075 ($R_{int} = 0.0180$)
Absorption correction	DIFABS
Maximum, minimum transmission	0.7677, 0.4276
Data, restraints, parameters	3075, 0, 244
Goodness of fit on F^2	1.053
Final R indices ($I > 2\sigma(I)$)	$R_1 = 0.0212$, $wR_2 = 0.0540$
R indices (all data)	$R_1 = 0.0306$, $wR_2 = 0.0570$
Largest difference peak, hole (e Å^{-3})	0.420, −0.309

3. Results and discussion

3.1. Synthesis

The crystal of **1** used for X-ray diffraction studies was synthesized as described in Section 2. Additionally, compound **1** and other compounds were prepared using other quantities of $AgNO_3$ and/or Ag(OAc) in solutions A and B so as to procure other relative amounts of NO_3^-, Cl^- and AcO^- in the reaction mixture; as previously [20], PN was used in excess to promote its deprotonation. Table 1 lists the reactions affording products that were characterized successfully by chemical analysis and by IR and ^{1}H NMR spectrometry. In each case, after the first batch of solid was separated from the mother liquor, further concentration led to the formation of impure solids.

As in the case of the methyl derivatives [20], the solids isolated from asymmetric NO_3^-/Cl^- systems contain the major anion of the solution; and whereas the 2:2 Cl^-/AcO^- solutions afforded a solid with monodeprotonated pyridoxine, the ligand was dideprotonated in the solid obtained with 2:2 NO_3^-/AcO^- solution. However, when the NO_3^-:Cl^- molar ratio was 2:2 the nitrate was obtained, whereas the methyl derivative obtained under the same conditions contained random amounts of Cl^- and NO_3^- [20].

3.2. Structure of [$SnEt_2$(PN–H)]Cl (**1**)

The crystal is composed of chloride ions and dimeric $[Sn_2Et_4(PN–H)_2]^{2+}$ units in which the Sn atoms are linked as shown in Fig. 1 by two bridging-chelating hydrogen pyridoxinate anions derived from **Ia** (see Section 1) by deprotonation of the C(4)–CH_2OH group. Selected bond distances and angles are listed in Tables 3 and 4. In each dimeric unit, each tin atom coordinates to two ethyl C atoms (the unremarkable Sn–C bond distances are close to those found in other diethyltin(IV) complexes [29]), to the O(2) of a deprotonated phenolic hydroxyl group, to the O(1) of a deprotonated C(4)–CH_2OH group and to the similarly deprotonated O(1)[a] of the other pyridoxinate anion, leading to a coordination polyhedron that is closer to a square pyramid than a trigonal bipyramid [30]. No other atoms lie nearer the tin atom than 3.70 Å, the sum of the van der Waals radii of tin and oxygen [31].

Like $[SnMe_2(PN–H)](NO_3)\cdot 2H_2O$ and $[SnMe_2(H_2O)(PN–H)]Cl\cdot H_2O$, the two previously characterized diorganotin complexes of monodeprotonated pyridoxine [20], $[SnEt_2(PN–H)]Cl$ contains dimeric $[SnR_2(PN–H)]_2^{2+}$ units. The following similarities and differences deserve comment.

In $[SnEt_2(PN–H)]Cl$ the tin atom is pentacoordinated, whereas in the methyl compounds it is hexacoordinated, the sixth position being occupied by one of the C(5)–CH_2OH oxygens of a neighbouring unit in the nitrate and by the oxygen of an H_2O molecule in the chloride. Nevertheless, the difference in coordination environment does not significantly change the structural parameters of either the planar Sn_2O_2 ring (in which distances and angles are very close to those found in the dimethyltinpyridoxinatenitrate) or the SnR_2 unit (the C–Sn–C angle, 152.77(13)°, is only slightly narrower than the angle of 159.9(1)° found in the methyltin chloride derivative, in which the tin atom has distorted octahedral coordination).

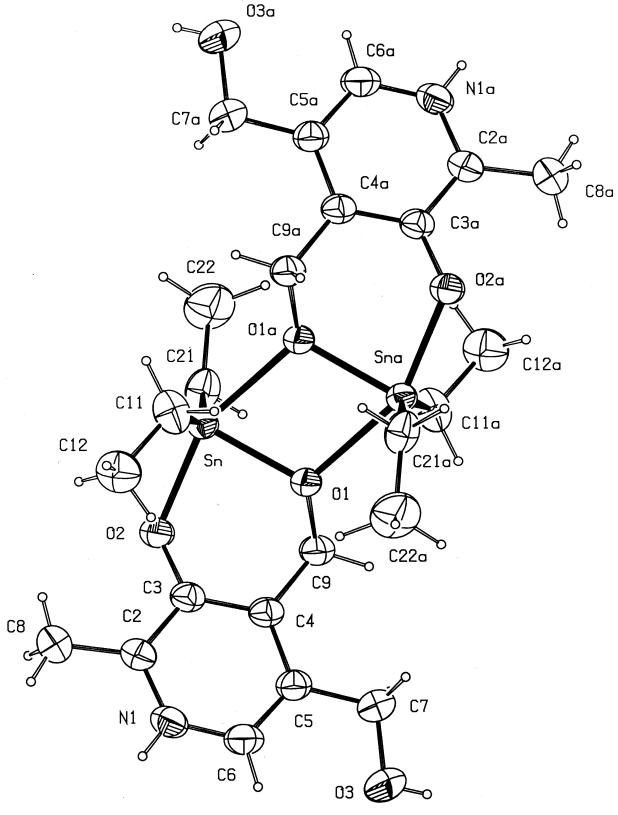

Fig. 1. The crystal structure of $[SnEt_2(PN–H)]Cl$ (**1**), showing the numbering scheme (chloride ions have been omitted).

O(3)–H(30)···Cl#3	0.77(5)	2.39(5)	3.143(3)	164(5)

[a] Symmetry operations: #2 $-x, y-1/2, -z+1/2$; #3 $x, -y-1/2, z+1/2$.

The main geometrical features of the (PN–H) ligand are similar to those found previously in the methyl derivatives; for example, the C(2)–N(1)–C(6) angle (124.9(2)°) is in all three compounds practically identical to that found in PN·HCl [32] (124.7(2)°). Nevertheless, C(8), O(2),

C(9) and C(7) lie somewhat farther from the plane of the pyridine ring than in the methyl derivatives (O(2), for example, is 0.093 Å from the plane, as against 0.05 Å in the methyltin nitrate). The conformation of the C(5)–CH_2OH group, with O(3) near C(6) (the torsion angle C(4)–C(5)–C(7)–O(3) is $-170.3(3)°$), resembles that found in the methyltin chloride compound, whereas O(3) is closer to C(9) in the methyltin nitrate.

The absence of water from the lattice of the ethyl derivative makes its hydrogen bond system simpler than in the methyl derivatives, the only such bonds being those of the N–H and C(5)–CH_2OH groups with the Cl^- ions (Tables 3 and 4).

3.3. Vibrational spectra

Besides the bands indicated in Section 2, the IR spectra of compounds **1** and **2** exhibit medium-strong bands at 3346 and 3404 cm^{-1} respectively (the latter contributed to by ν(OH) of the lattice water), and also a set of medium-strong bands centred on 2900 cm^{-1} (2981, 2970, 2952, 2918, 2866 and 2811 cm^{-1} in the case of [$SnEt_2$(PN–H)]Cl) and attributed to ν(C–H), ν(O–H) of the C(5)–CH_2OH group and ν(N–H) of the N–H group. In the spectrum of **3** the latter region shows only three bands, at 2957, 2925 and 2871 cm^{-1}. The range 1650–1450 cm^{-1} shows the pyridine ring bands and, in the spectra of the compounds with protonated N(py), the expected [33] strong IR band at about 1530 cm^{-1} (probably contributed to by ν(C–O) of the coordinated phenolato group) and two weak Raman bands near 1600 cm^{-1}. In the spectra of **3** these two bands do not appear and the IR band at 1530 cm^{-1} is only a shoulder. The strong bands close to 1000 cm^{-1} have been attributed [34] to ν(C–O) of the C(5)–CH_2OH group, and the other bands near this position may be produced jointly by the coordinated C(4)–CH_2O^- group and the pyridine ring. The non-linearity of the C–Sn–C fragment is shown by the presence of ν_{asym}(Sn–C) and ν_{sym}(Sn–C) in the IR and Raman spectra of all three compounds.

3.4. Mössbauer spectra

All the Mössbauer spectra consist of well resolved, slightly asymmetric doublets with isomer shift and quadrupole splitting values that reflect the coordination geometries around the tin centres and the charges of the ligand. The isomer shift is larger for compounds **1** and **2**, in which the ligand is monoanionic, than for compound **3**, in which it is a dianion; since δ is positively correlated with the electron density on the tin centre, this may be attributed to the metal drawing more charge from the monoanion than from the dianion.

Owing to the pronounced deviation of **1** from ideal trigonal bipyramidal geometry, only the contribution of the covalently bonded organic groups has been taken into account in using the point charge model to calculate ΔE_Q. The simplified formula [35]:

$$\Delta E_Q = -4[R]\left(1-\tfrac{3}{4}\sin^2\theta\right)^{1/2} \quad (1)$$

together with the experimental C–Sn–C bond angle, 152.77°, yields a ΔE_Q value of 3.45 or 4.16 mm s^{-1} depending on whether the p.q.s. used is appropriate for organic moieties in tba positions (0.94 mm s^{-1}) or tbe positions (-1.13 mm s^{-1}). Although both these ΔE_Q values are within the usually accepted margin of error, a value of 3.81 mm s^{-1} in much better agreement with the experimental 3.83 mm s^{-1} is obtained if the p.q.s. is -1.03 mm s^{-1}, half way between the tba and tbe values, in consonance with the C–Sn–C bond angle being half way between those of the apical and equatorial positions (180 and 120°, respectively).

The parameters of compound **2** are very close to those of compound **1** and so the same coordination structure can be proposed. This supports the hypothesis that the water in **2** is occluded in the lattice, not coordinated to tin atoms.

3.5. Studies in solution

In DMSO, the PN signal that is most affected by deprotonation and complexation is that of H(6), which shifts to higher field in the complexes of both dimethyltin(IV) [20] and diethyltin(IV) derivatives (Table 5). This shift seems to be increased by di-deprotonation and the formation of PN–2H derivatives in which N(1) is deprotonated as well as O(2) being deprotonated and coordinated. The other PN protons are at most only slightly shielded when [SnR_2(PN–H)]$^+$ forms in the presence of Cl^-, but are slightly or significantly deshielded in the presence of NO_3^-. Note that the nature of the counterion also affected the synthesis of the complexes. The coordination of O(1) in compounds **2** and **3** is confirmed by the singlet associated with C(9)H_2 being flanked by two satellites due to the coupling of these protons with the tin atom. Like the organometallic methyl protons of the dimethyltin(IV) derivatives [20] (and like H(6)), the ethyl methylene protons of the $(CH_3CH_2)_2Sn^{2+}$ complexes are more shielded with the dideprotonated than with the monodeprotonated ligand. The same effect seems also to be shown, though less strongly, by the protons of the methyl group, the $^3J(^1H–^{119}Sn)$ coupling constant decreasing with increasing shielding like $^2J(^1H–^{119}Sn)$ does in the dimethyltin(IV) derivatives [20] ($^2J(^1H–^{119}Sn)$ could not be calculated for the diethyltin(IV) complexes).

There are significant differences between the ligand regions of the spectra of the diethyltin(IV) and dimethyltin(IV) derivatives of PN–$2H^{2-}$. The signals of [$SnEt_2$(PN–2H)] appear at higher field, the H(6) proton being shielded by ca. 0.6 ppm relative to the free ligand, as it is in the dibutyltin(IV) complex [36].

These differences may be due to the presence of an additional ligand (a water molecule) in the coordination sphere of the dimethyltin(IV) cation in [$SnMe_2$(PN–2H)(H_2O)] [20], but other structural and/or coordination factors cannot be ruled out since the coordination kernel observed in the solid state may be modified upon solution in DMSO.

[a] Chemical shifts in ppm (δ); J in Hz; s singlet; b broad; t triplet; d doublet. In parentheses, relative numbers of protons calculated by integration.

Table 5 also lists the ^{1}H NMR data for PN and its complexes in DMF-d_7. In this solvent the signal corresponding to H(O3) disappears, probably owing to fast exchange of this proton with the deuterated solvent. In [SnEt$_2$(PN–H)]Cl the ligand protons are hardly shielded at all relative to PN, while in the nitrate complex most are deshielded. Only in [SnEt$_2$(PN–2H)] do the proton signals clearly lie at higher field than in the spectrum of pyridoxine.

Finally, ^{119}Sn chemical shifts in DMSO-d_6 are also listed in Table 5. Though also influenced by other factors [37], these shifts depend largely on the coordination number of the tin atom. The values obtained for our compounds are in the range −90 to −330 reported [38] for pentacoordinated tin compounds, but are nevertheless sufficiently negative for it not to be possible to rule out the possibility of a DMSO molecule bringing the coordination number up to six, especially in the case of the nitrate complex.

Supplementary data

Crystallographic data have been deposited at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), deposition number CCDC 135673.

Abstract

$[Zn(dmit)_2]^{2-}$ dianions in $[Q]_2[Zn(dmit)_2]$ complexes (**2**: Q = 1,4-Me_2-pyridinium ($C_7H_{10}N$) or NEt_4), and $[PPh_4]_2[Zn(dmit)_2]\cdot DMSO$ ((**2**: Q = PPh_4)·DMSO) have distorted tetrahedral geometries, as a result of the 94.49(3) to 95.27(3)° range of the bite angle of the dmit ligands; H_2-dmit = 4,5-dimercapto-1,3-dithiole-2-thione, $H_2C_3S_5$. The Zn–S bond lengths are in the range from 2.3285(8) to 2.3520(9) Å. In (**2**: Q = $C_7H_{10}N$) and (**2**: Q = NEt_4), both the cations and the dianions are found in alternating layers, which form columns and sheets. Whereas in (**2**: Q = $C_7H_{10}N$), there are no S···S contacts less than the sum of the van der Waals radii, 3.70 Å, S···S contacts at 3.5792(13) and 3.6605(12) Å, within dianion layers, are found in (**2**: Q = NEt_4). In ((**2**: Q = PPh_4)·DMSO), the steric bulk of the $[PPh_4]^+$ cations is such that the dianions cannot be distributed in well-defined sheets: no S···S contacts less than 4.0 Å are found in ((**2**: Q = PPh_4)·DMSO). The structures are compared with those reported for other $[Q]_2[Zn(dmit)_2]$ compounds. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: 1,3-dithiole-2-thione-4,5-dithiolates; dmit complexes; Zinc dmit compounds; Zincates

1. Introduction

Derivatives of 4,5-dimercapto-1,3-dithiole-2-thione (H_2-dmit **1**) have been extensively studied as heterocyclic compounds [1], coordination compounds [2–4], precursors of tetrathiafulvalene derivatives [1,5–8] and electronic conducting materials [9]. Both transition and main group metal–dmit coordination compounds have attracted considerable attention in recent times [2–4]. Of the main group metal complexes, $[Zn(dmit)_2]^{2-}$ salts have a pivotal role as stable dmit precursors for use with other metals and in the syntheses of heterocyclic compounds [1–4].

Dmit derivatives have a tendency to associate in the solid state, particularly via S···S contacts, at distances less than the sum of the van der Waals radii of two sulfur atoms, 3.70 Å [10]. This is illustrated generally in the dmit compounds listed in the Cambridge Crystallographic Data Base [11,12]. The nature and extent of the intermolecular S···S contacts, and the arrays generated, depend on the dmit compound. For example, the inter-dianionic S···S interactions in $[Q]_2[Sn(dmit)_3]$ compounds vary with the cation Q; the connectivity is three-dimensional for the smallest cations Q = 1,4-dimethylpyridinium and NMe_4, in chains for the somewhat larger cation NEt_4, and is absent for the still larger

PPh_4 cation [13]. Variable S···S contacts are also indicated in three reported structures of $[Q]_2[Zn(dmit)_2]$ (**2**) compounds, namely $[NEt_4]_2[Zn(dmit)_2]\cdot MeOH$ ((**2**: $Q = NEt_4)\cdot MeOH$) [14], [(ferrocenylmethyl)trimethyl)-ammonium]$_2[Zn(dmit)_2]$ (**2**: $Q = FcCH_2NMe_3$) [14], and $[NBu_4]_2[Zn(dmit)_2]$ (**2**: $Q = NBu_4$) [15]. To investigate further the effect of the cation on inter-dianionic interactions of $[Zn(dmit)_2]^{2-}$ salts, the crystal structures of unsolvated $[NEt_4]_2[Zn(dmit)_2]$ (**2**: $Q = NEt_4$) and [1,4-Me_2-pyridinium]$_2[Zn(dmit)_2]$ (**2**: $Q = C_7H_{10}N$) as well as the solvated salt $[PPh_4]_2[Zn(dmit)_2]\cdot DMSO$ ((**2**: $Q = PPh_4)\cdot DMSO$) have been determined and are now reported.

2. Results and discussion

The cations in the three $[Zn(dmit)_2]^{2-}$ salts have their usual geometries and are not futher discussed.

2.1. Dianion structures

Atom arrangements for the dianions in (**2**: $Q = C_7H_{10}N$ or NEt_4) and ((**2**: $Q = PPh_4)\cdot DMSO$) are shown in Fig. 1; Zn–S bond lengths and S–Zn–S angles are listed in Tables 1–3. The dmit bite angles, between 94.49(3) and 95.27(3)°, lead to distorted tetrahedral zinc geometries. These angles are similar to those previously reported for (**2**: $Q = NBu_4$) [15], NEt_4 [14] and $FcCH_2NMe_3$ [14], see Table 4. While the Zn–S bond lengths (Table 4) and geometric parameters within each dmit ligand (Table 5) of all six $[Q]_2[Zn(dmit)_2]$ salts vary little, there is a noticeable difference between the interplanar dmit angle in ((**2**: $Q = NEt_4)\cdot MeOH$) of 69.9(5)° [14] and those of the other compounds, which are between 79.53(3) and 84.72(2)°; the dianion in ((**2**: $Q = NEt_4)\cdot MeOH$) is thus somewhat flattened compared to the other complexes. The reference dmit plane is taken as the plane through the central C=C bond and the attached S atoms. The thione atoms, C=S, and the metal atom, M, in metal–dmit complexes, e.g. the $[Sn(dmit)_s]^{2-}$ complexes, are frequently out of this reference plane, providing either boat or chair shaped MSCSCSCS eight-membered rings, see Fig. 2. However, in only three of the ten distinct $[Zn(dmit)_2]^{2-}$ fragments in the six $[Q]_2[Zn(dmit)_2]$ complexes are the Zn atoms appreciably out (i.e. > 0.1 Å) of the dmit reference plane, see Table 4; these three $[Zn(dmit)_2]^{2-}$ fragments are present, one in each of the two independent dianions in (**2**: $Q = NEt_4$) and in the dianion of (**2**: $Q = PPh_4$). The thione S atoms, in these three cases, are just out of the reference dmit plane, by between 0.0961(17) and 0.1381(15) Å, on the same side as the Zn atoms. These fragments, thus, have flattened boat conformations; all others have near planar conformations. There are no apparent correlations between the conformations and other geometric parameters, including the asymmetry in the Zn–S bond lengths to each dmit ligand.

2.2. Dianion packing

In (**2**: Q = $C_7H_{10}N$) and (**2**: Q = NEt_4), both the cations and the dianions are found in distinct layers which alternate throughout the structures, see Figs. 3 and 4. In (**2**: Q = $C_7H_{10}N$), the layers are perpendicular to [102]. They are extended in the direction of *b* (perpendicular to the plane of the drawing in Fig. 3) purely by cell translations thus forming columns. For the dianions, these columns are related to one another by crystallographic centres of symmetry thus forming sheets. Within a single dianionic sheet, all the dianions are identical in geometry and orientation. Adjacent dianion sheets are related by crystallographic centres of symmetry (and the *c*-glide plane), thus producing inversion of the atomic arrangement from one sheet to the next. This last general arrangement applies also to the sheets of cations but here there is the additional complication that two crystallographically distinct type of cations are present.

While this general description is also applicable to (**2**: Q = NEt_4), the detailed description is very different. First of all, the sheets are now perpendicular to $[\bar{1}02]$, see Fig. 4. Two crystallographically distinct dianions are present in the asymmetric unit and the operation of a 2_1 axis together with cell translations transforms each of these into a dianionic column. Since the individual dianions are crystallographically distinct (discounting the strong pseudosymmetry of the structure discussed further below) so too are the columns which they form. The cationic sheets are also more complex because no fewer than four crystallographically distinct species are present.

In the final stages of the structure refinement of (**2**: Q = NEt_4) in the preferred space group, $P2_1$, the refinement

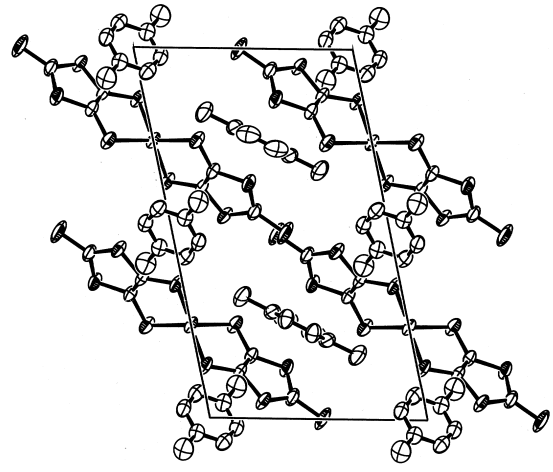

Fig. 3. The cell of (**2**: Q = $C_7H_{10}N$) projected on 010 with *a* across and *b* down into the page. Non-H atoms are shown as 50% ellipsoids and H atoms have been omitted for clarity.

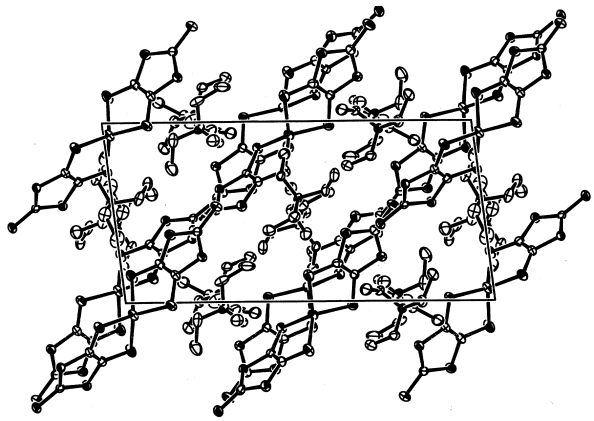

Fig. 4. The cell of (**2**: Q = NEt_4) projected on 010 with *c* across and *b* up out of the page. Non-H atoms are shown as 50% ellipsoids and H atoms have been omitted for clarity.

program (SHELXL97) indicated twin refinement. In response to this, the introduction of the TWIN and BASF instructions resulted in the refined value of the Flack *x* parameter, representing the fraction of the minor twin component, of 0.306(7). The absolute structure of this compound is therefore to this extent indeterminate. The success of the twin refinement of the structure of (**2**: Q = NEt_4) prompts the question how and why is it twinned? It is evident from the unit cell contents of (**2**: Q = $C_7H_{10}N$) and (**2**: Q = NEt_4), see Figs. 3 and 4, that the two structures almost verge on the isostructural, despite the differences in their unit cells and space groups. The cell content of (**2**: Q = $C_7H_{10}N$), with $b = 8.8467(7)$ Å, can be thought of as a single layer, which is replicated purely by cell translation in the direction of *b* to complete the structure. For (**2**: Q = NEt_4), with $b = 17.8699(2)$ Å, the cell content consists of two layers, which are related by the operation of a crystallographic twofold screw axis. As a direct consequence, the dianion layers in (**2**: Q = NEt_4) are more buckled than they are in (**2**: Q = $C_7H_{10}N$), owing to the greater bulk of the NEt_4 cation compared to the 1,4-Me_2-pyridinium cation.

As noted above, adjacent dianion layers of (**2**: Q = $C_7H_{10}N$), parallel to *b*, are related to one another by a crystallographic centre of symmetry. In the space group $P2_1$, this is not precisely possible for the dianion layers of (**2**: Q = NEt_4), but if it were approximately true, this would account for the pseudosymmetry detected by ADDSYM. Further, if in the structure of (**2**: Q = NEt_4) the occasional (roughly 1 in 3) dianion layer was incorporated in the inverted configuration, this would account for the success of the twin refinement. Note that if the structure of (**2**: Q = NEt_4) were truly in the centrosymmetric space group $P2_1/c$, half of the NEt_4 cations would have to lie on centres of symmetry and would be highly disordered. It is concluded therefore that it is ordering the NEt_4 cations which reduces the space group symmetry to $P2_1$ and disorder in the dianionic layers, which is responsible for the twinning.

In ((**2**: Q = PPh_4) · DMSO), the phosphorus atoms in the cations are associated more or less in planes perpendicular to

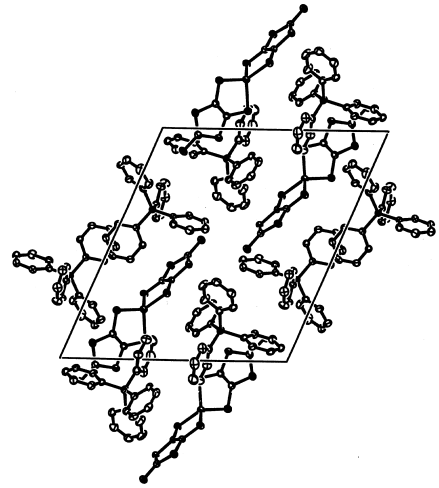

Fig. 5. The cell of ((**2**: Q = PPh_4) · DMSO) viewed down *a* with *b** across the (landscape) page. Non-H atoms are shown as 50% ellipsoids. H-atoms and DMSO solvate atoms have been omitted for clarity.

$[0\bar{1}1]$. However, the bulk of the phenyl groups is such that the dianions cannot be distributed in well-defined sheets, see Fig. 5.

2.3. Interanion S···S contacts in (2: Q = $C_7H_{10}N$ or NEt_4) and ((2: Q = PPh_4) · DMSO)

In (**2**: Q = $C_7H_{10}N$), there are no S···S contacts less than the sum of the van der Waals radii; the closest contacts involve (a) S4···S4′ (symmetry operation: $-x-1$, y, $-z+1/2$; S(ring)···S(ring), between adjacent dianionic sheets) at 3.876(2) Å and (b) S4···S5′ (symmetry operation: $-x-1$, $-y$, $-z+1$; S(ring)···S(thione), within a dianionic sheet) at 3.876(2) Å.

Short S···S contacts are present in (**2**: Q = NEt_4). With the notation that the ligands on Zn1 are ligand A (S1, S5 etc.) and ligand B (S6, S10 etc.) and ligands on Zn2 are ligand C (S11, S15 etc.) and ligand D (S16, S20 etc.), then contacts involve SB(ring)···SC(thione) (S8···S15′ = 3.5792(13) Å (symmetry operation: $x+1$, y, z)) and SB(thione)··· SD(ring) (S10···S19′ = 3.6605(12) Å (symmetry operation: $-x+1, y-1/2, -z+1$)). No sulfur atoms of ligand A are involved in any of these contacts: the shortest contacts are S3···S20′ (SA(ring)···SD(thione)) at 3.8236(12) Å and S5···S13′ (SA(thione)···SC(ring)) at 3.8324(12) Å. All of the contacts are within a dianion layer. There are no contacts between adjacent dianion layers.

There are no S···S contacts in ((**2**: Q = PPh_4) · DMSO) less than 4.0 Å.

2.4. Comparison with other $[Q]_2[Zn(dmit)_2]$ salts

Distinction between the structures of the $[Q]_2$-$[Zn(dmit)_2]$ salts (Q = $C_7H_{10}N$, NEt_4, NBu_4, $FcCH_2NMe_3$ and PPh_4) can be made on the basis of the cation size, and the effect that this has on the layering of the dianions.

The structures of the salts with the smallest cations, $C_7H_{10}N$ and NEt_4 (**2**: Q = $C_7H_{10}N$ or NEt_4) and ((**2**: Q = NEt_4)·MeOH) [14], are in the form of well-defined and alternating cation and dianion layers. While the layers are aligned differently in the three compounds (parallel to 102, $\bar{1}02$ and 001, respectively), the dianion layers are similar and can be described in terms of dianions stacked end to end in rows and side by side in columns. Adjacent columns are staggered with respect to one another and interpenetrate to differing extents; Fig. 6 illustrates the situation with ((**2**: Q = NEt_4)·MeOH) [14], in which the interpenetration of the columns is greatest. Interestingly, this complex also contains the anomalously flattened dianions. The MeOH solvate molecules occupy sites within the dianion layers. The interpenetration of columns is least in (**2**: Q = $C_7H_{10}N$), where the thione S atoms are more or less aligned.

Layers of dianions are also discernable in (**2**: Q = $FcCH_2NMe_3$) [14], but here the dianions are tilted with respect to the direction of propagation of the rows, see Fig. 7(a), and the layers themselves are also markedly corrugated, see Fig. 7(b). Some corrugation, but to a much smaller extent, occurs in (**2**: Q = NEt_4) also. The corrugation in (**2**: Q = $FcCH_2NMe_3$) is particularly apparent when viewed along the length of the rows of dianions and cations, Fig. 7(b): interanionic S3···S3′ contacts of 3.519(2) Å form chains running diagonally through the dianion layers, while the S4···S4′ contacts of 3.696(2) Å interconnect these layers. A striking feature of the structure of (**2**: Q = $FcCH_2NMe_3$) is the pairs of cation rows lying in channels defined by six rows of dianions, see Fig. 7(b).

In (**2**: Q = NBu_4) [15], the physical bulk of the cations prevents the formation of layers of dianions. Here instead the dianions are found stacked side by side in columns parallel to *b* but separated by the cell translation (8.954 Å) and therefore essentially unassociated.

With the still bulkier tetraphenylphosphonium cation in (**2**: Q = PPh_4), there is still less association of the dianions, which exist in loosely associated pairs in cavities between the cations (Fig. 5). Other cavities are occupied by dimethyl sulfoxide solvate molecules.

3. Experimental

Compounds $[Q]_2[Zn(dmit)_2]$ (**2**: Q = NEt_4, 1,4-Me_2-pyridinium or PPh_4) were obtained by a general procedure, from Na, CS_2 and [Q]X ([Q]X = [NEt_4]Br, [1,4-Me_2-pyridinium]I or [PPh_4]Cl) [14]. The ^{1}H NMR spectrum in Me_2CO-d_6 of the sample of (**2**: Q = PPh_4), grown from DMSO solution and with m.p. 198–201°C, indicated the presence of approximately 1 mol of DMSO per mole of (**2**: Q = PPh_4); elemental analytical data were in between those expected for unsolvated and mono-solvated species. *Anal.* Found: C, 55.8; H, 3.7. Calc. for $C_{54}H_{40}P_2S_{10}Zn$ ($C_{56}H_{46}OP_2S_{11}Zn$): C, 57.0 (55.3); H, 3.5 (3.8)%. Conformation of the DMSO solvate came from the X-ray studies, see later. The analytical analyses for (**2**: Q = NEt_4), m.p. 186–188°C, and (**2**: Q = $C_7H_{10}N$), m.p. 232–233°C (both obtained from Me_2CO/isopropanol solutions), were as expected for unsolvated species.

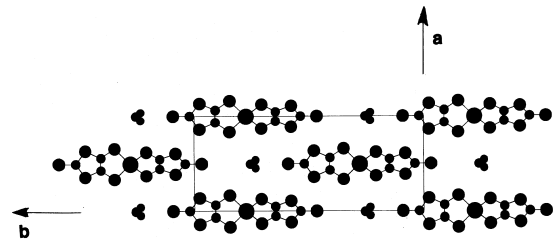

Fig. 6. A portion of the dianion layer of ((**2**: Q = NEt_4)·MeOH) projected on 001. The atoms, with $-0.125 < z < 0.125$ are shown as spheres of arbitrary radius. Atoms of incomplete dianions have not been drawn. The disordered MeOH solvate molecules are also indicated.

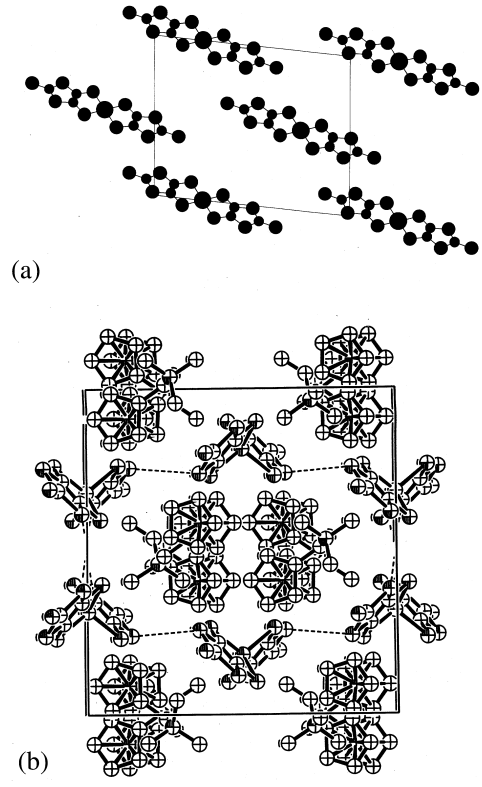

Fig. 7. (a) A portion of the dianion layer of (**2**: Q = $FcCH_2NMe_3$) projected on 010, with *a* vertically up the page. Atoms have *z* coordinates in the range $0 < z < 0.5$. Atoms are shown as spheres of arbitrary radius and atoms of incomplete dianions have not been drawn. (b) The cell of (**2**: Q = $FcCH_2NMe_3$) viewed down *c*, i.e. showing the rows of dianions and cations end-on. The reciprocal *b** axis is across the (landscape) page. Non-H atoms are shown as 50% ellipsoids and H atoms have been omitted for clarity.

3.1. Crystal structure determinations

3.1.1. Compounds ((2: Q = PPh_4)·DMSO) and (2: Q = NEt_4)

Data for (**2**: Q = NEt_4) and ((**2**: Q = PPh_4)·DMSO) were obtained at 150 K, at the National Data Collection Centre of the EPSRC at Southampton on an Enraf Nonius KappaCCD area detector with an Enraf Nonius FR591 rotating anode as

X-ray source. The ϕ–ω scan mode, filling the Ewald sphere, was employed. Data collection, and cell refinement and data reduction were accomplished with COLLECT [16] and DENZO [17]. An empirical correction for absorption was applied by means of SORTAV [18,19]. The structure was solved by direct methods, SHELXS-97 [20], and completed and refined with SHELXL-97 [21]. All non-H atoms were refined anisotropically and H atoms were placed in calculated positions and refined with a riding model.

In (**2**: Q = NEt_4) the asymmetric unit consists of two complete dianions and no fewer than four complete cations. In this case the ADDSYM component of the checkcif facility of the IUCr is at pains to point out the possible existence of an additonal symmetry element (which turns out to be a putative *c*-glide) and, as a result, a crystallographic centre of symmetry. A careful re-examination of this structure in the space group $P2_1/c$ does indeed provide some sort of a solution for the structure but attempted refinement of this alternative model resulted in an extremely high final *R*-factor and very poor estimates of bond lengths and angles and in addition provoked an extreme degree of disorder in one of the cations. It is concluded that the extra symmetry is merely an accidental approximation and not crystallographic in nature and may be neglected.

In ((**2**: Q = PPh_4)·DMSO), the phosphorus atoms in the cations are associated more or less in planes perpendicular to $[0\bar{1}1]$. However, the bulk of the phenyl groups is such that the dianions cannot be distributed in well-defined sheets. In the later stages of refinement, several quite large features (C*n*S, *n* = 1 to 7) were found in a difference map and included in the refinement simply as C atoms with SOF = 1 and refined isotropically. These 'atoms', and the bonds and angles which they provide, were commented out of the final cif at which point the PLATON element of checkcif indicated the presence in the structure of solvent accessible voids of 264 $Å^3$. The additional electron density, which is found (in subsequent calculations) to be equivalent to ca. $28e^-$ summed over the seven C*n*S atoms and to ca. $38e^-$ when other small peaks $>1e^-$ are included, is considered to arise from the presence of a highly disordered DMSO solvent molecule. These molecules, one per Zn atom, occur as centrosymmetrically related pairs in the voids revealed by PLATON.

*3.1.2. Compound (**2**: Q = $C_7H_{10}N$)*

Data were obtained at 293 K on a Siemens SMART automated CCD diffractometer (graphite-monochromated Mo Kα radiation). Preliminary scans indicated a primitive monoclinic unit cell. Raw frame data were collected in narrow-slice ω-scan mode. Data collection and cell refinement, and data reduction utilised the programs, SMART and SAINT [22]. Duplicate data, collected at the end of the experiment, indicated that no significant crystal decay or movement had occurred. An absorption correction was applied with SADABS [23] on the basis of multiple and symmetry-equivalent reflections. The structure was solved by direct methods, SHELXS-97 [20], and completed and refined with SHELXL-97 [21]. All non-H atoms were refined anisotropically and H atoms were placed in calculated positions and refined with a riding model.

Every ion sits on a crystallographic symmetry element. The zinc atom of the dianion lies on a crystallographic two-fold axis and therefore, in addition to Zn, only a single but complete dmit ligand (S1–S5 and C1–C3) is present in the asymmetric unit. The centroid of one of the cations (C4, C5/N1, C6 and C7) coincides with a crystallographic centre of symmetry. The other cation (C8, C9/N2, C10 and C11) lies on a crystallographic two-fold axis passing through the midpoints of the C8–C8′ and C10–C10′ bonds (symmetry operation: $-x-1, y, -z+3/2$). Thus for both of these cations, only one half is present in the asymmetric unit. Furthermore, the atom pairs C5/N1 and C9/N2 must be completely disordered to comply fully with the crystallographic symmetry. It is for these reasons that they have been refined in pairs with SOF values fixed at 0.5 and coordinates and thermal vibration parameters constrained to be exactly equal within the pair.

Diagrams were obtained with ORTEP-3 for Windows [24] and ATOMSV4.1 [25]. Crystal data and structure refinement details are listed in Table 6.

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers CCDC 137189 to 137191 for (**2**: Q = $C_7H_{10}N$), (**2**: Q = NEt_4) and ((**2**: Q = PPh_4)·DMSO), respectively.

Acknowledgements

The authors thank the EPSRC Crystallography Service, based at the University of Southampton, UK for data collection for the compounds (**2**: Q = NEt_4) and ((**2**: Q = PPh_4)·DMSO). The agencies CAPES, CNPq and Fapemig, are thanked for their support.

POLYHEDRON

Liquid-mediated metathetical synthesis of binary and ternary transition-metal pnictides

Claire J. Carmalt, Daniel E. Morrison, Ivan P. Parkin *

Department of Chemistry, Christopher Ingold Laboratories, University College London, 20 Gordon Street, London WC1H 0AJ, UK

Received 30 November 1999; accepted 28 January 2000

Abstract

Nickel and cobalt pnictides have been synthesised using a liquid-mediated metathetical reaction of transition-metal dihalides with the appropriate sodium pnictide Na_3E (E = P, As, Sb) in refluxing toluene for 48 h. Binary and ternary compounds have been prepared. Products were analysed by powder X-ray diffraction, scanning electron microscopy, energy dispersive analysis by X-rays, FT-IR, Raman and vibrating sample magnetometry. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Antimonides; Arsenides; Metathesis; Phosphides

1. Introduction

Nickel and cobalt phosphides, arsenides and antimonides have various uses and characteristics as advanced materials. However, few synthetic methods for these materials can be found in the literature.

Amorphous NiP shows anomalous magnetisation temperature characteristics [1]. NiP has been evaluated as a catalyst for oxidative dehydrogenation of ethylbenzene [2] and as an underlayer for magnetic recording media and computer hard drives. There has been an extensive effort into understanding its magnetic properties [3] and crystallisation behaviour [4]. NiP/Sn multilayers have been investigated because of their unique properties [5]. NiP is used as an interlayer between particles and matrix in aluminium-matrix composites [6]. Nickel and cobalt phosphides have been synthesised as thin films by plasma arc spraying [7], ion implantation [8,9], galvanic and electrodeposition [10,11]. NiP, NiAs and NiSb have been synthesised by electroplating [12]. CoP and CoAs have been synthesised by single- and dual-source chemical vapour deposition [13] and molecular organic chemical vapour deposition [14]. Bulk transition-metal phosphides, arsenides and antimonides have been synthesised by the high-temperature hydrogen reduction of phosphates, arsenates and antimonates [15], by direct combination of the elements, typically at 1000°C and by solid state metathesis reactions at 550°C in sealed ampoules [16].

Phosphorus was thought to form a metal phosphide with all metals in the periodic table with the exception of antimony and bismuth [17]. However, recent work has suggested the existence of BiP and SbP [18]. A wide range of stoichiometries are known for metal phosphides, from M_4P to MP_{15}. For nickel, eight stoichiometric phosphide phases are known and have been cystallographically characterised: Ni_3P, Ni_5P_2, $Ni_{12}P_5$, NiP_2, Ni_5P_4, NiP, NiP_2 and NiP_3. The corresponding nickel and cobalt arsenide and antimonide chemistry is also extremely rich with a multitude of well characterised phases [17].

We report here the low temperature synthesis of amorphous and crystalline cobalt and nickel phosphides, arsenides and antimonides via a convenient liquid-mediated metathetical route.

2. Experimental

All manipulations were performed under an inert N_2 atmosphere using either Schlenk techniques or a Saffron Scientific inert atmosphere glove box. Toluene was dried over sodium and distilled from sodium under nitrogen prior to use. Distilled water was degassed with nitrogen prior to use and absolute ethanol (Aldrich, 99.5%) was dried over 3 Å molecular sieves. $NiBr_2$ (98%), $NiCl_2$ (98%) and $CoCl_2$ (98%) were purchased from Aldrich Chemicals and used as received. Na_3P, Na_3As and Na_3Sb were prepared by a modification of the literature procedure [19,20] from the reaction of sodium

metal with the appropriate chalcogenide in refluxing toluene under an inert atmosphere for 48 h. Precursor identity was verified by powder X-ray diffraction. Thermolysis studies were performed in a Lenton Thermal Designs tubular furnace, the samples were sealed in evacuated glass ampoules and annealed at 500°C for 48 h. Some selected samples were annealed at 800°C in evacuated silica ampoules. Powder X-ray diffraction measurements were recorded on a Siemens D5000 transmission diffractometer using germanium monochromated Cu $K\alpha_1$ radiation ($\lambda = 1.5406$ Å). Samples were mounted between two pieces of adhesive tape. Scanning electron microscope (SEM) micrographs were taken and energy dispersive analysis by X-rays (EDAX) was performed on an Hitachi S570 scanning electron microscope with a Link Analytical EDAX detector attachment. The EDAX system had an elemental detection limit of 0.2 atom% and a quantitative accuracy of 2 atom%. Polished elemental samples were used to calibrate the system. The EDAX excitation volume was typically of the order of 1 μm^3, sufficiently small that individual grains of the product could, in most cases, be investigated. Vibrating sample magnetometry (VSM) was performed on an Aerosonic 3001 magnetometer at room temperature. IR spectra were recorded on a PE 205 grating spectrometer from 4000 to 250 cm^{-1} and Raman spectra on a Dilor XY spectrometer.

2.1. Liquid-mediated metathesis reactions of MX_2 and Na_3E ($M = Ni, Co$; $E = P, As, Sb$; $X = Br$ for all reactions save $NiCl_2 + Na_3P$)

MX_2 (3.00 mmol) and Na_3E (2.00 mmol) were separately ground in a mortar and pestle. Na_3E was placed in a Schlenk flask to which 20 ml of dried, degassed toluene was added. MX_2 was added to the Schlenk flask with stirring and the resultant mixture was heated and allowed to reflux under stirring for 48 h. The resulting slurry was allowed to settle and the toluene was syringed off. The solid was washed with ethanol (2×20 ml), followed by distilled water (3×20 ml) and ethanol (2×20 ml). The remaining powder was dried in vacuo (yield 75%). The resulting powders were analysed by X-ray powder diffraction (Table 1), SEM, EDAX and VSM. Selected samples were analysed by Raman, IR and UV measurements.

3. Results

The reaction of a stirred suspension of sodium pnictide and metal(II) halide in refluxing toluene for 48 h results, after trituration with ethanol and distilled water, in the formation of amorphous metal pnictides (Eq. (1)). Powders obtained from evaporation of the water and ethanol washings showed them to be sodium halide by X-ray diffraction.

$$3MX_2 + 2Na_3E \rightarrow 2ME + 6NaX + M \quad (1)$$

(M = Ni, Co; E = P, As, Sb; X = Cl, Br)

Neither starting material had any detectable solubility in refluxing toluene. However, a fine suspension of the reactants did form. A slow colour change of the suspended solids was observed during the course of the reaction. The colours of the two individual precursors were seen to become less and less distinct as the reaction proceeded and a fine black powder product became more apparent.

The powder X-ray diffraction patterns of all the as-formed triturated samples revealed them to be X-ray amorphous. Analysis of the evaporated washings by X-ray powder diffraction showed crystalline NaBr or NaCl. The amorphous triturated pnictide powders were annealed at 500°C for 48 h. The annealing results are summarised in Table 1 and the unit cell dimensions of the samples that crystallised are collected in Table 2, and in the case of NiAs represented in Fig. 1.

Vibrating sample magnetometry shows either no response or a very weak ferromagnetic signal on the as-formed pnictides. This indicates that the as-formed pnictide powders did not contain any significant quantity of free metal. SEM analysis of these powders showed ca. 2–5 μm amorphous particles (Fig. 2). Spot EDAX analysis using an approximately 1-μm^3 excitation volume shows consistent metal to pnictide ratios over a number of spots with no evidence of sodium, chlorine or bromine (ca. 0.2% detection limit). These data taken together indicate that an amorphous, but, on the 1-μm scale, a chemically homogeneous powder is formed. This

powder contains little if any free metal. It should be noted that this is counter-intuitive to that speculated in Eq. (1) and is commented upon in the discussion below.

IR spectroscopy of the unannealed products showed spectra consistent with the formation of transition-metal phosphides, arsenides and antimonides with broad IR signals between 250 and 600 cm^{-1}. The Raman spectrum shown in Fig. 3 is that from the reaction of $CoCl_2$ and Na_3P. The spectrum obtained is different from that of free phosphorus and cobalt metal. To our knowledge CoP has no reported Raman spectra.

4. Discussion

Nickel and cobalt pnictides are known to have a large number of phases with different stoichiometries, the majority of which are thermodynamically stable at room temperature. In this work all of the reactions were salt balanced such that all of the sodium and halide in the starting materials can be eliminated as sodium halide. This necessitates that the formally expected phase in all the reactions would be M_3E_2. However, in the reactions involving nickel(II) bromide and sodium antimonide and sodium arsenide the products were invariably the NiE (E = As, Sb) phase with no evidence for the formation of free nickel metal in the product by magnetometry, X-ray powder diffraction or SEM/EDAX analysis. It is anticipated that in this case the excess free nickel metal indicated by Eq. (1) is removed in the washing stage of the reaction, possibly as a soluble hydroxide. Nickel was detected by chemical analysis in the washings from the reaction, but was not quantified, but was of the appropriate magnitude. In reactions involving cobalt halides and sodium pnictides the products after trituration showed a stoichiometry of Co_3E_2 by EDAX.

The as-formed products in all of the reactions were shown to be X-ray amorphous. The products were inferred to be

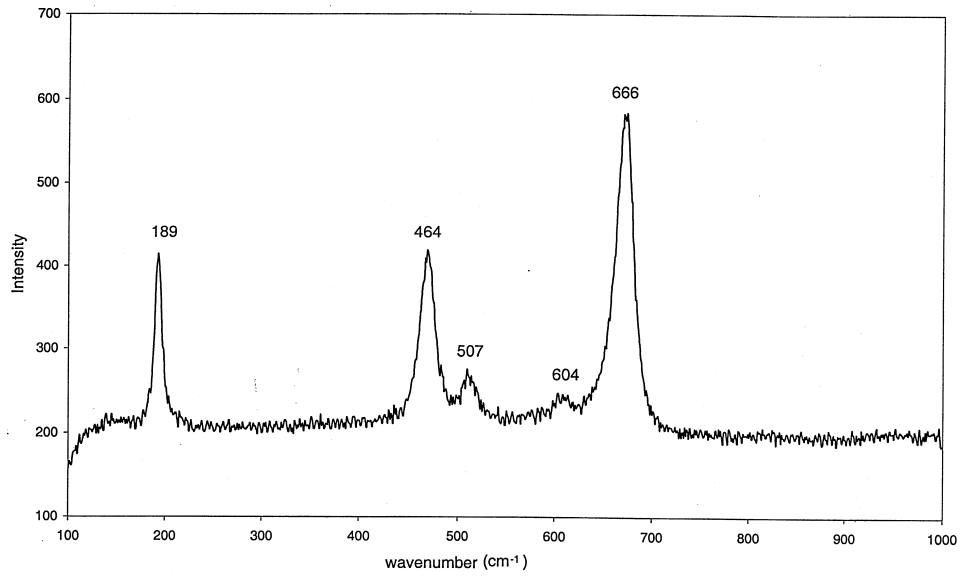

Fig. 3. Raman spectrum for product of the reaction of $CoCl_2$ and Na_3P in refluxing toluene for 48 h, as prepared.

amorphous metal pnictides by the consistent spot EDAX analysis across the samples, the absence of any free metal as evidence by the VSM signature and the formation of sodium halide. Further, the products in all reactions were black, fine grained powders with IR and Raman signatures corresponding to the formation of amorphous metal pnictides.

Annealing the amorphous metal pnictide powders at 500°C for 24 h induced crystallinity for both the nickel and cobalt arsenide and antimonides. The crystalline phases obtained were the binary ME phases (Table 2). These materials indexed well and gave lattice parameters within error limits of those reported in the literature [21]. No X-ray powder diffraction, EDAX or VSM evidence was seen for the presence of free metal in the annealed samples.

Ternary $NiAs_{0.5}Sb_{0.5}$ and $NiAs_{0.25}Sb_{0.75}$ phase could be readily made by reacting the appropriate ratios of sodium arsenide and sodium antimonide with nickel bromide. These phases were found to contain the appropriate elemental ratios by EDAX both before and after annealing over a number of spots. However, it was found difficult to initiate crystallisation in the ternary compounds. Even at higher temperatures (800°C or 1000°C) for prolonged periods, only amorphous X-ray powder diffraction patterns were obtained. EDAX data, the presence of sodium halide in the water washings (Eq. (1)) and the lack of crystalline binary compounds observed in the X-ray powder diffraction pattern suggest that the ternary compounds were obtained.

The reaction of $NiBr_2$ with Na_3P gave a product which by EDAX showed a 2:1 Ni:P atomic ratio over a number of spots. The X-ray powder diffraction pattern of the as-prepared sample showed it to be X-ray amorphous. After annealing at 500°C for 72 h a low-intensity X-ray powder diffraction pattern was observed which corresponded to that of Ni_2P. SEM/EDAX data on the annealed material showed two distinct forms: rounded particles with a corresponding 2:1 Ni:P atomic ratio and angular block-shaped particles corresponding to a 1:1 Ni:P atomic ratio. Thus, the reaction of nickel chloride with sodium phosphide is unlike the corresponding arsenide and antimonide reactions in that the as-formed product has a higher nickel content. Annealing of the sample produces a mixture of Ni_2P and NiP, this probably means that no nickel is lost in this particular case during the initial washing stage. Annealing of the nickel phosphide sample in vacuo at 800°C shows an X-ray powder diffraction pattern corresponding to Ni_3P. It has been observed previously that heating Ni_2P and NiP at 800°C under vacuum eliminates phosphorus producing Ni_3P [19,20].

The reaction of $CoCl_2$ with Na_3P gave a product which by EDAX showed a 3:2 elemental ratio of Co:P, the initial starting ratio. After annealing at 550°C the atomic ratio was still found to be 3:2 by EDAX and X-ray amorphous. The reaction of Na_3As and Na_3Sb with $CoBr_2$ gave a product that analysed as Co_3E_2 by EDAX both before and after annealing. However, X-ray powder diffraction showed only a single crystalline phase after annealing that indexed as CoE. This presents a problem in explaining the difference between the EDAX and X-ray powder diffraction analyses. This can be accounted for by the product being a biphasic mixture of CoE and E (E = As, Sb). If this is the case, the scale of intermixing would have to be submicrometre, the free pnictide be X-ray amorphous, and no preferential sublimation was observed under the annealing conditions employed.

The 1:1 ratio found for the reactions with nickel of Ni:E as compared to the 3:2 ratio of Co:E deserves noting. The cobalt products reflect more accurately the 3:2 elemental ratio of the reactants, while NiAs and NiSb are found solely in a 1:1 ratio. This may be because the NiE forms have a particularly high thermodynamic stability and do not readily incorporate excess nickel into these structures. In the phosphide case the surplus nickel (Eq. (1)) is being incorporated into an amorphous Ni_2P structure. VSM data strongly suggests that there is appreciably less free nickel than Eq. (1) would

suggest, since free nickel would give a much stronger ferromagnetic response than was observed. This is also supported by EDAX data which shows a 2:1 Ni:P ratio in the as-synthesised product as well as in the product annealed at 500°C. Annealing causes some separation of the amorphous as-prepared product into a Ni_2P phase and an amorphous NiP phase.

Liquid phase metathesis routes have been reported previously by Kehr and Wells for the formation of a range of gallium and indium pnictides [22]. In a number of these reactions the as-formed pnictides were nanocrystalline with particle sizes ranging from 3 to 36 nm. These materials gave typically broadened X-ray diffraction spectra. No evidence was seen in the nickel and cobalt reactions reported here for the formation of nanocrystalline products. Despite this, the solution phase metathesis is important in determining the phase of product isolated. The refluxing toluene solution acts as a heat sink in the reaction. The corresponding solid state metathesis reaction, in the absence of a solvent produces temperatures ranging from 1000 to 1400°C. This has a direct effect on the phase of material isolated. For example, the reaction of $NiCl_2$ and Na_3As produces a mixture of crystalline $Ni_{11}As_8$ and Ni_5As_2 by solid state metathesis. Similarly, the corresponding solid state metathesis reaction of $CoCl_2$ and Na_3As produces crystalline mixture of CoAs and Co_2As. The solvent-mediated metathesis reactions have a vast excess of toluene solvent which can absorb reaction enthalpy, lower the reaction temperature to the boiling point of the solvent and enable isolation of amorphous pnictides. The corresponding solid state metathesis reactions are self-sustaining, proceed with a thermal flash, complete in 1–2 s and produce products that are invariably crystalline and fused. The phase differences observed between the solid-state and solvent-mediated routes are a consequence of the temperatures reached in the reactions. If the solvent-mediated metathesis products are heated to 1400°C it is likely that the same (thermodynamic phases) would be formed. The role of the refluxing solvent is also crucial, as it enables large surface areas of the insoluble powders to react. By refluxing and stirring the suspension, fresh reactants are continually brought together thus helping to alleviate the solid state diffusion barrier. The solvent-mediated reactions are completed over a longer time scale than the equivalent solid state metathesis reaction but do enable the isolation of significantly different phases. The surprising feature of this chemistry is that the reactions can be made to proceed at significantly lower temperatures (110°C) than that required to initiate the corresponding solid-state reactions (550–800°C).

5. Conclusions

Binary and ternary nickel and cobalt pnictides have been synthesised successfully using the liquid-mediated metathetical reaction of the transition-metal dihalide with the appropriate sodium pnictide, Na_3E, in refluxing toluene for 48 h. The nickel products form NiE (E = As, Sb) and a mixture of NiP and Ni_2P while cobalt forms Co_2E_3 (E = P, As, Sb). The solution phase metathesis reactions form amorphous products that in certain cases can be readily annealed to form crystalline ME (M = Co, Ni; E = As, Sb). Solvent-mediated metathesis reactions allow access to phases unaccessable from the equivalent solid state metathesis reactions.

Abstract

The condensation reaction of 2-pyridinecarboxaldehyde N-oxide with ethylenediamine yields the tetradentate ligand L^1 = poxen. Hydrogenation then produces tetrahydropoxen, $L^2 = H_4$-poxen, which has been isolated in a free form. Several metal complexes of the formula $[M(H_4\text{-poxen})](ClO_4)_2\cdot nH_2O$ have been prepared (M = Mn, Cu and Zn) and investigated. The X-ray structure of $[Cu(H_4\text{-poxen})H_2O](ClO_4)_2\cdot H_2O$ shows that the copper atom is pentacoordinate, the poxen ligand forming a base of the tetragonal pyramid; the aqua ligand is situated in the apical position inside the cavity formed by the ligand arms. In contrast, in the case of $[Co(poxen)H_2O](ClO_4)_2$, the apical aqua ligand is situated outside the 'cavity' formed by the dehydrogenated ligand arms. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The condensation of (substituted) salicylaldehyde with ethylenediamine is a Schiff reaction which results in the well known salen, and its derivatives. The coordination chemistry of this class of tetradentate, Schiff-base ligands with transition metal atoms is well investigated, and dozens of examples have been structurally characterized.

Of recent interest are the hydrogenated derivatives of the salen-type ligands, H_4-salen, and their complexes with transition metal ions [1–6]; among these, an X-ray structure of $[Ni(H_4\text{-Bu}^t\text{-salen})]$ has been reported [7].

The Schiff condensation, however, is not restricted to salicylaldehyde derivatives. It proceeds on other aromatic aldehydes, exemplified for instance by 2-pyridinecarboxaldehyde N-oxide. The condensation results in the ligand L^1 abbreviated as poxen (Scheme 1).

The principal difference between salen and poxen lies in the fact that $[M^{II}(salen)]$ complexes are electroneutral whereas $[M^{II}(poxen)]^{2+}$ complexes require the presence of counter anions.

Scheme 1. Sketch of L^1 = poxen (left) and $L^2 = H_4$-poxen (right).

Although the isolation of the free ligand L^1 has not been reported so far, several complexes of the general formula $[M(L^1)]X_2$ have been prepared and structurally characterized [8,9], for example $[Ni(L^1)(H_2O)_2](ClO_4)_2$ and $[Cu(L^1)(H_2O)](ClO_4)_2$ in which the L^1 ligand is tetradentate. In the tetranuclear complex $[ZnCl_4][Cu(L^1)]_2[ZnCl_4]$ the ligand L^1 is pentadentate owing to its bridging functionality [10].

Reports on the hydrogenated analogues of poxen-type ligands are, to our knowledge, absent in the literature. Therefore we focused our attempt to prepare and isolate the free ligand L^2 first. Then a series of metal complexes of formula $[M(L^2)]X_2$ was prepared. Finally the X-ray structure of $[Cu(H_4\text{-poxen})H_2O](ClO_4)_2\cdot H_2O$ was determined and compared with that of $[Co(poxen)H_2O](ClO_4)_2$.

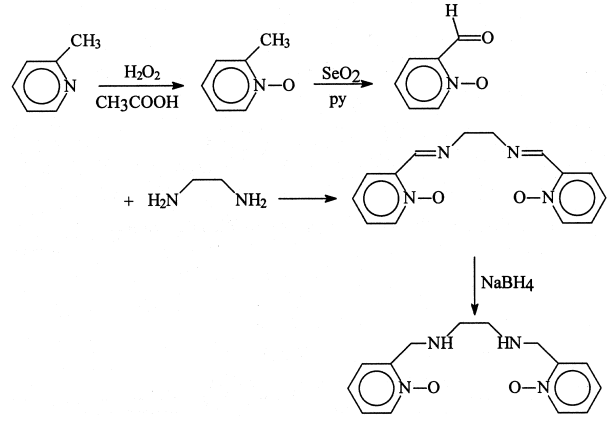
2. Experimental

2.1. Ligands

The ligand poxen and its hydrogenated product were synthesized according to Scheme 2.

17.7 g (144 mmol) of 2-pyridinecarboxaldehyde N-oxide in 200 cm^3 of methanol were combined with 3 cm^3 (44.8 mmol) of freshly distilled 1,2-diaminoethane in 10 cm^3 of methanol. The mixture was boiled for 5 min and left to cool. A yellow product was filtered off, washed by ethanol and left to dry. The final product, L^1, was recrystallized from methanol. Yield 14.3 g (74%).



7.6 g (28.1 mmol) of L^1 in 200 cm^3 of methanol were boiled in a water bath and slowly (within 45 min) 3.2 g (84.6 mmol) of $NaBH_4$ were added. The pH of the mixture was then reduced from 11 to 1 by adding conc. HCl and subsequently raised to 10 by adding conc. NaOH. The product was extracted into chloroform (three times 150 cm^3). The extract was dried over Na_2SO_4 and $CHCl_3$ was distilled under reduced pressure. The final product, L^2, was liberated in the form of cream–yellow crystals. Yield 5.6 g (74%). *Anal*. Found: C, 59.9; H, 6.5; N, 19.8. Calc. for $C_{14}H_{18}N_4O_2 \cdot H_2O$: C, 59.3, H, 6.7; N, 19.8%. Melting point 125°C.

The presence of the water molecules as a monohydrate was confirmed by IR spectra (broad stretching bands at 3450 and 3540 cm^{-1}; deformation bands at 1685 and 1655 cm^{-1}). Stretching N–O vibration at 1210 cm^{-1} confirms the presence of the pyridine N-oxide unit.

2.2. Complexes

Complexes of the type $[CuL^2](ClO_4)_2 \cdot nH_2O$ with a variable amount of water were obtained for different conditions of complexation.

1. A blue anhydrous product $[CuL^2](ClO_4)_2$ precipitates when the ethanol solution of L^2 is added slowly to the ethanol solution of $Cu(ClO_4)_2 \cdot 6H_2O$ in the molar ratio $x(L^2{:}Cu) = 1{:}1$. *Anal*. Found: C, 31.3, H, 3.4; N, 10.4; Cu, 12.2; Cl, 13.2. Calc. for $C_{14}H_{18}N_4O_{10}CuCl_2$: C, 31.3; H, 3.4; N, 10.4; Cu, 11.8; Cl, 13.2%.
2. An ethanol solution of $Zn(ClO_4)_2 \cdot 6H_2O$ was added slowly to the ethanol solution of L^2; then the ethanol solution of $CuCl_2 \cdot 2H_2O$ was added so that $x(L^2{:}Zn{:}Cu) = 1{:}1{:}2$. A blue hemihydrate $[CuL^2](ClO_4)_2 \cdot 0.5H_2O$ crystallizes within a week from the blue solution. *Anal*. Found: C, 31.1; H, 3.6; N, 10.2. Calc. for $C_{14}H_{18}N_4O_{10}CuCl_2 \cdot 0.5H_2O$: C, 30.8; H, 3.5; N, 10.3%.
3. An ethanol solution of $Cu(ClO_4)_2 \cdot 6H_2O$ was added slowly to the ethanol solution of L^2; then the ethanol solution of $ZnCl_2 \cdot 2H_2O$ was added so that $x(L^2{:}Zn{:}Cu) = 1{:}2{:}1$. A blue dihydrate $[CuL^2](ClO_4)_2 \cdot 2H_2O$ crystallizes within a week from the blue solution. *Anal*. Found: C, 29.2; H, 3.7; N, 9.6; Cu, 11.5. Calc. for $C_{14}H_{18}N_4O_{10}CuCl_2 \cdot 2H_2O$: C, 29.4; H, 3.9; N, 9.8; Cu, 11.1%.

Scheme 2. Synthetic route for poxen and H_4-poxen.

Complexes of the formula $[ML^2](ClO_4)_2 \cdot nH_2O$ for M = Mn (yellow–green) and M = Zn (pale yellow) were synthesized by adding the ethanol solution of L^2 to the ethanol solution of $M(ClO_4)_2 \cdot 6H_2O$ in the molar ratio $x(L^2{:}M) = 1{:}1$. Elemental analysis confirms the composition of these complexes. *Anal*. Found: C, 31.7; H, 4.0; N, 10.4. Calc. for $C_{14}H_{18}N_4O_{10}MnCl_2 \cdot 0.5H_2O$: C, 31.3; H, 3.6; N, 10.4%. Found: C, 29.5; H, 3.9; N, 9.6. Calc. for $C_{14}H_{18}N_4O_{10}ZnCl_2 \cdot 2H_2O$: C, 29.3; H, 3.9; N, 9.7%.

Attempts to prepare $[ML^2](ClO_4)_2 \cdot nH_2O$ for M = Fe, Co and Ni failed; no acceptable elemental analyses were achieved, probably owing to air sensitivity.

The $[Co(poxen)H_2O](ClO_4)_2$ complex precipitated as a Bordeaux–brown powder from the 1:1 mixture of the ethanol solution of the ligand and the ethanol solution of the cobalt(II) perchlorate. *Anal*. Found: C, 30.0, H, 3.2; N, 9.9. Calc. for $C_{14}H_{14}N_4O_{10}CoCl_2 \cdot H_2O$: C, 30.8; H, 3.0; N, 10.3%.

2.3. X-ray structure determination

Suitable single crystals were mounted on an Enraf-Nonius CAD-4 diffractometer. The cell parameters were determined on the basis of 25 reflections by applying the least-squares method. The intensities were determined by the ω–2θ scan, using Mo Kα radiation with a graphite monochromator. The experimental data are collected in Table 1. The intensities were corrected for Lorentz polarization and an empirical correction for absorption was applied via the ψ-scan technique.

The structure was solved by direct methods [11] allowing determination of the positions of all non-hydrogen atoms. The structure was refined by full-matrix least-squares on F^2 [12]. The hydrogen atoms were situated in the calculated positions except those belonging to water. These were determined from the difference Fourier map and refined. The function minimized for the refinement was $\Sigma w(|F_o| - |F_c|)^2$; the weights were determined using the formulae $w = 1/[\sigma^2(F_o^2) + (0.0868P)^2 + 1.72P]$ for **1** and $w = 1/[\sigma^2(F_o^2) + (0.0807)^2 + 2.95P]$ for **2**, where $P = (F_o^2 + 2F_c^2)/3$.

3. Results and discussion

The structure of $[Cu(H_4\text{-poxen})H_2O](ClO_4)_2\cdot H_2O$ (**1**) consists of isolated mononuclear dications, perchlorate anions and a molecule of crystal water. The copper(II) atom is pentacoordinate: four donor atoms of the ligand form a tetragonal base above which at 0.30 Å the central atom is situated. The distances within the *cis*-{CuN_2O_2O'} chromophore are Cu–N2 = 2.003 and Cu–O1 = 1.950 Å towards the basal atoms and Cu–O′ = 2.176 Å for the apical aqua ligand (Table 2).

[a] Symmetry transformations used to generate equivalent atoms: #1 x, $-y+1/2$, z.

A few fragments of the structure are noticeable (Fig. 1): (i) the oxygen atoms of the crystal water and the aqua ligand occupy special positions; (ii) the perchlorate group is disordered; (iii) the ethylene bridge is disordered since for the carbon atoms two equivalent positions exist.

The ligand as a whole is far from the planar arrangement. The planes of the pyridine N-oxide make an angle of 44°;

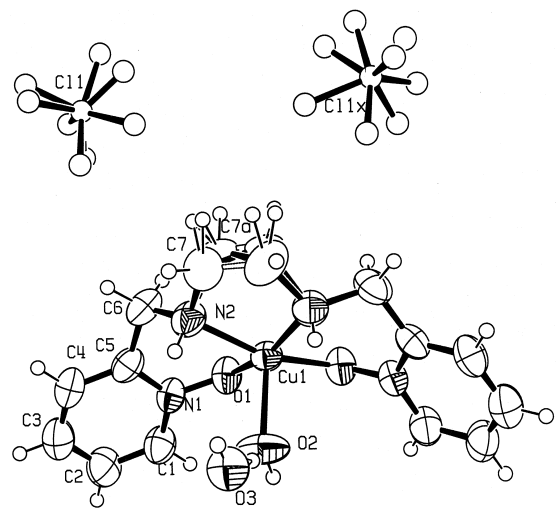

Fig. 1. ORTEP plot for **1**.

their dihedral angles with respect to the basal plane N_2O_2 are 34°. The butterfly-like arms form a cavity inside which the aqua ligand is situated. The bond length Cu–O2 = 2.176 Å is anomalously short compared, for instance, with Cu–O2 = 2.519 Å in the dehydrogenated analogue $[Cu(poxen)H_2O](ClO_4)_2 \cdot H_2O$ [9]. The dihedral angle of the pyridine N-oxide planes in the latter compound is only 16° and, moreover, the apical aqua ligand is situated outside the 'cavity'.

The crystal water molecule forms a hydrogen bond towards the aqua ligand: O2–O3 = 2.778 Å (and angle O2–H2B–O3 = 158°). The perchlorate groups do not show any hydrogen bonding.

The structure of $[Co(poxen)H_2O](ClO_4)_2$ (**2**), shows some similarities to the corresponding salen-type complexes (Fig. 2). The cobalt(II) atom is pentacoordinate: the central atom is situated only 0.05 Å above a tetragonal base formed of four donor atoms. The distances within the *cis*-$\{CoN_2O_2O'\}$ chromophore are Co–N = 1.934 and 1.936 Å and Co–O = 1.925 and 1.932 Å. The apical aqua ligand is situated at Co–O3 = 2.489 Å (Table 2).

The ligand arms are only slightly bent (the angle of the pyridine rings is 29°); the dihedral angles with respect to the basal plane N_2O_2 are 11 and 19°, respectively. The apical aqua ligand is situated outside the 'cavity' formed by the ligand arms. In this respect the structure of $[Co(poxen)H_2O](ClO_4)_2$ is quite similar to that of $[Cu(poxen)H_2O](ClO_4)_2 \cdot H_2O$ [9]. One perchlorate group shows a static disorder.

The copper(II) complex of the H_4-poxen ligand is stable against oxygen both in the solid state and in solution. This property is analogous to Cu(salen)- and Cu(poxen)-type complexes. In all these cases the unpaired electron occupies the in-plane molecular orbital, predominantly of d_{xy} character (*x*-axis bisecting the angle O–M–O). This orbital is well screened against attack from the molecular oxygen. In contrast, in planar Co(II) complexes the unpaired electron occupies an out-of-plane orbital (predominanly of either d_{yz} or d_{z^2} character) which has been confirmed by ESR spectroscopy [13]. Therefore effective interaction with the attacking dioxygen is possible and this leads to the formation of the end-on superoxo-like adduct $Co(III)-(O_2^-)$ [14]. The dioxygen activated in this way potentially acts as a strong oxidation agent able to subtract $H^{\bullet}$ radicals from organic substrates. In the hydrogenated ligands, like H_4-salen and H_4-poxen, there are some hydrogen atoms just sterically available owing to the distorted structure of the corresponding complex; they can be removed by the activated dioxygen and therefore the $[Co(H_4\text{-salen})]$ and $[Co(H_4\text{-poxen})]$ type complexes are air unstable.

In order to support these predictions a molecular-orbital model was calculated. The geometry of the $[Co(poxen)]^{2+}$ complex was optimized first using the ZINDO/1-UHF method [15]. Figs. 3 and 4 show drawings of the spin density in the corresponding complexes (contours of 0.015 e). It can be seen that in $[Cu(poxen)]^{2+}$ the spin density is situated in-plane and delocalized over the donor set. On the contrary, in $[Co(poxen)]^{2+}$ the spin density is situated out-of-plane and highly localized. These data support the hypothesis that the in-plane spin density in $[Cu(H_4\text{-poxen})]^{2+}$ prevents appreciable interaction with the oxygen molecule and thus secures its air stability.

Abstract

The multidentate ligand, 2,6-diacetylpyridine bis(3-hexamethyleneiminylthiosemicarbazone) monohydrate, $H_2$2,6Achexim·H_2O, crystallizes with one thiosemicarbazone moiety in an intramolecular hydrogen bonded, bifurcated *E′* form. The other thiosemicarbazone moiety is *E* and is not involved in intramolecular hydrogen bonding, but is involved in hydrogen bonding with the hydrate water molecule. The dianion (loss of N3a and N3b hydrogens) of $H_2$2,6Achexim acts as a pentadentate ligand, 2,6Achexim, in a planar conformation to a central tin(IV) ion, and as a bridging tetradentate ligand with the two thiosemicarbazone moieties of 2,6Achexim coordinating to different zinc atoms. The tin(IV) is heptacoordinate in a distorted pentagonal dipyramidal configuration, with the five SNNNS donor atoms of 2,6Achexim in the pentagonal plane and the two *n*-butyl groups in the axial positions. The binuclear zinc complex has two equivalent tetrahedral zinc centers, with the pyridyl nitrogens of the two ligands not coordinated. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Heterocyclic bis(thiosemicarbazone); Heptacoordinate complexes; Organotin(IV) complexes; Binuclear zinc complexes

1. Introduction

Considerable interest has been shown in 2,6-diacetylpyridine bis(thiosemicarbazone), and its metal complexes [1]. Crystal structures have been reported for three different zinc complexes, and two are binuclear [2]. Of the two binuclear complexes, one features distorted octahedral zinc atoms that are nearly equivalent, and the second binuclear complex contains a distorted octahedral and a tetrahedral zinc center. More recently, the former of these binuclear complexes has been prepared under different conditions and a new crystal structure reported [3]. De Sousa et al. reported the crystal structures of heptacoordinate tin(IV) complexes, namely [MeSnCl(H2,6Ac4DH)]Cl·MeOH [4] and [Ph_2Sn(H2,6-Ac4DH)]Cl [5], where $H_2$2,6Ac4DH = 2,6-diacetylpyridine bis(thiosemicarbazone). Other reports on $H_2$2,6Ac4DH complexes include the following: a third tin(IV) heptacoordinate complex [Ph_2Sn(2,6Ac4DH)]·2DMF [6], the structure of a manganese(II) complex [7], and the structures of several indium(III) complexes [8]. Although spectral and biological studies have been carried out on metal complexes of 2,6-diacetylpyridine bis(N(4)-substituted thiosemicarbazones) [9,10], no structural information has been provided even though the N(4)-substituent in other types of thiosemicarbazones, including bis(thiosemicarbazones), has been shown to affect their biological activity [11].

X-ray studies [12–14] have previously shown that 2-formyl-, 2-acetyl- and 2-benzoylpyridine N(4)-substituted thiosemicarbazones exist in the solid state in at least four different

structural modifications: *E* isomers without hydrogen bonding by N3H to the pyridine nitrogen, two forms of hydrogen bonding *Z* isomers, and as a bifurcated hydrogen bonded *E′* isomer. The four modifications are shown in Fig. 1 and can be described as follows: (a) *E* with respect to the imine function of the thiosemicarbazone [12] without hydrogen bonding to the pyridyl nitrogen; (b) hydrogen bonding to the pyridyl nitrogen by N3H, *Z* with respect to the imine function of the thiosemicarbazone and *Z* with respect to the N3–C8 bond [12–14]; (c) hydrogen bonding to the pyridyl nitrogen by the N3H, *Z* with respect to the imine function of the thiosemicarbazone, but *E* with respect to the N3–C8 bond [13]; (d) the bifurcated *E′* tautomer in which the N3 hydrogen has shifted to the imine nitrogen, N2, and is hydrogen bonding to both the pyridyl nitrogen and sulfur of the thiosemicarbazone moiety [12,15]. A representation of $H_2$2,6Achexim showing that one thiosemicarbazone moiety is *E* and the other is *E′* is included in Fig. 1.

Since tin(IV) [16] and zinc(II) complexes [1,17] have significant pharmacological activity and little research has been done on N-heterocyclic bis(thiosemicarbazones), we report in this work the X-ray crystal structures of $H_2$2,6Achexim·H_2O, [Bu_2Sn(2,6Achexim)], and [Zn(2,6-Achexim)]$_2$.

(a) A representation of an *E* isomer of 2-acetylpyridine N(4)-ethylthiosemicarbazone, HAc4E; (b) a representation of a *ZZ* isomer of 2-benzoylpyridine 3-piperidylthiosemicarbazone, HBzpip; (c) a representation of a *ZE* isomer of 2-benzoylpyridine 3-hexamethyleneiminylthiosemicarbazone, HBzhexim; (d) a representation of an *E′* isomer of 2-acetylpyridine 3-hexamethylene-iminylthiosemicarbazone, HAchexim; (e) 2,6-diacetylpyridine bis(3-hexamethyleneimylthiosemicarbazone), $H_2$2,6Achexim.

2. Experimental

2.1. Materials

Solvents were purified and dried according to standard procedures. 2,6-Diacetylpyridine (Aldrich), di-*n*-butyltin(IV)dichloride (Aldrich) and zinc acetate were used without further purification. IR spectra were recorded on a Nicolet 5ZDX-FT spectrophotometer in the 4000–400 cm^{-1} range using KBr pellets. NMR spectra were obtained with a Varian 300 MHz Gemini spectrometer using [$^2H_6$]DMSO or $CDCl_3$ as the solvents with chemical shifts reported in parts per million downfield from Me_4Si.

2.2. Preparation of $H_2$2,6Achexim·H_2O, [Bu_2Sn(2,6Achexim)] and [Zn(2,6Achexim)]$_2$

The bright yellow bis(thiosemicarbazone), $H_2$2,6-Achexim·H_2O, was prepared by refluxing a 2:1 molar mixture of hexamethyleneiminylthiosemicarbazide (1.73 g, 10 mmol) [18] with 2,6-diacetylpyridine (0.82 g, 5 mmol) in absolute EtOH (50 ml). The tin(IV) complex was obtained by mixing $H_2$2,6Achexim·H_2O (0.10 g, 0.20 mmol) and the acid n-Bu_2SnCl_2 (0.15 g, 0.21 mmol) in 15 ml of EtOH, and slow evaporation of the solvent led to the appearance of a crystalline product suitable for X-ray structure analysis. The zinc complex was prepared by refluxing zinc acetate dihydrate (0.22 g, 1 mmol) and $H_2$2,6Achexim·H_2O (0.5 g, 1 mmol) in 40 ml of EtOH for 2 h. The resulting orange solid was filtered, washed with anhydrous Et_2O and dried on a warm plate. $H_2$2,6Achexim·H_2O, yield 60%; m.p. = 167–169°C. *Anal.* Found: C, 55.4; H, 7.5; N, 19.4. Calc.: C, 55.6; H, 7.4; N, 19.6%. [Bu_2Sn(2,6Achexim)], yield 74%; m.p. = 261–264°C. *Anal.* Found: C, 52.7; H, 7.3; N, 13.9. Calc.: C, 52.6; H, 7.1; N, 13.7%. [Zn(2,6Achexim)]$_2$, yield, 67%, m.p. = 266–268°C (dec.).

2.3. X-ray crystallography

Crystals of $H_2$2,6Achexim·H_2O, [Bu_2Sn(2,6Achexim)] and [Zn(2,6Achexim)]$_2$ were grown by evaporation of EtOH solutions and mounted on glass fibers. The structures were solved with direct methods and missing atoms were found by difference-Fourier synthesis. All non-hydrogen atoms were refined with anisotropic temperature factors, and all hydrogens were found on the difference Fourier map. The

H atoms attached to carbons were allowed to ride on the C atoms and assigned a fixed isotropic temperature factor, $U = 0.06$ Å^2 ($U = 0.08$ Å^2 for [Bu_2Sn(2,6Achexim)]). Only the coordinates of the H atoms attached to nitrogens and oxygen were refined. Both seven-membered rings of $H_2$2,6Achexim·H_2O display conformational disorder such that atoms C13A and C11B split into two alternative positions with complementary occupancy factors (0.65 and 0.35).

Owing to the site symmetry of [Bu_2Sn(2,6Achexim)] the atoms N1, C4, Sn and the carbon atoms of the *n*-butyl groups are located in special crystallographic positions, with $y/b = 0.25$ and site multiplicity 0.50. One of the *n*-butyl groups is apparently disordered (C31–C34) while the other group (C41–C44) does not show any sign of disorder. The C32 atom is split between two positions related by the mirror plane, and the C31, C33 and C34 atoms show largely elongated displacement ellipsoids perpendicular to the mirror plane also indicating disorder. Attempts to refine C32 with the two positions did not cause any decrease in R values, however. The alternative structure solution involving the space group $Pn2_1$[a], one maximal non-isomorphic subgroup of *Pmna*, was also possible and all non-hydrogen atoms were found by subsequent Fourier difference synthesis and refined isotropically. However, the molecule with site symmetry 1 shows one *n*-butyl group (C31–C34) that is chemically incorrect. The crystallographic experimental details are given in Table 1 and selected bond lengths and angles for $H_2$2,6Achexim·H_2O and the complexes are reported in Tables 2 and 3, respectively.

[a] The two thiosemicarbazone moieties of [Bu_2Sn(2,6Achexim)] are equivalent.

3. Results and discussion

3.1. Molecular structure of $H_2$2,6Achexim·H_2O

The molecular structure of $H_2$2,6Achexim·H_2O is shown in Fig. 2. Much of $H_2$2,6Achexim·H_2O is planar, except for the hexamethyleneimine rings, which are tilted in opposite directions from the plane of the molecule and make dihedral angles of 8.2(1) and 8.0(1)° with the pyridine ring (Fig. 3 is a stereoview of $H_2$2,6Achexim·H_2O). $H_2$2,6Achexim·H_2O, like its tin(IV) complex [Bu_2Sn(2,6Achexim)], crystallizes in the orthorhombic system, in contrast to 2-acetylpyridine 3-hexamethyleneiminylthiosemicarbazone, HAchexim [12], which is monoclinic. However, both ligands possess the bifurcated *E′* structure with the N1 atom of the pyridyl ring and the S1 atom of the moiety hydrogen bonded intramolecularly to the N2a hydrogen (Fig. 1(d,e)). Intermolecular hydrogen bonds between the H_2O molecule and the N3b hydrogen and S2 atoms helps to cause differences in bond distances and angles between the two thiosemicarbazone moieties of $H_2$2,6Achexim·H_2O (Tables 2 and 3).

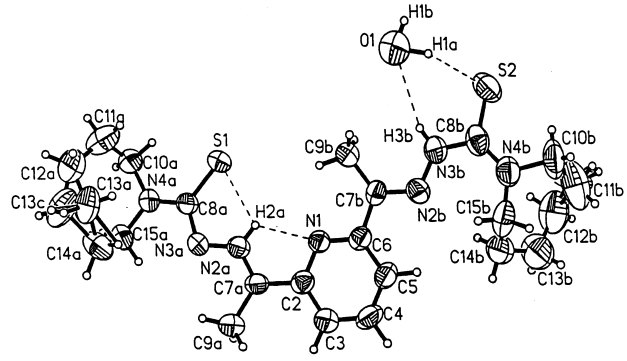

Fig. 2. Perspective view of $H_2$2,6Achexim·H_2O showing the atom numbering scheme.

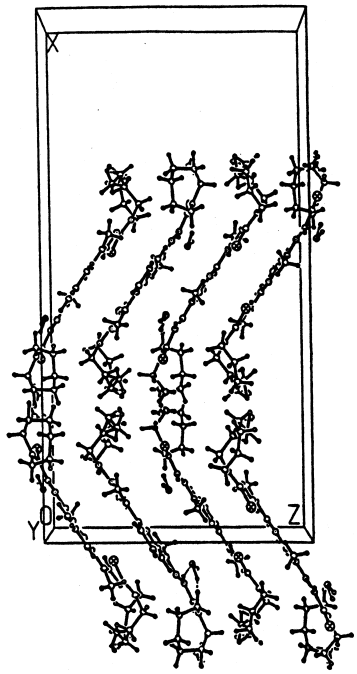

Fig. 3. Stereoview of the unit cell packing of $H_2$2,6Achexim·H_2O.

The *E* arm has a S2–C8b distance of 1.689(7) Å and is intermediate between typical C–S single- and double-bond lengths [5]. This agrees well with the N3b–C8b (1.359(7) Å) and N4b–C8b (1.337(9) Å) bond distances, which indicate partial double-bond character for both bonds. The N2b–C7b bond, 1.313(7) Å, is significantly shorter than a N–C single bond, as expected for a thiosemicarbazone. The *E′* arm S1–C8a distance, 1.716(6) Å, is longer than S2–C8b of the *E* arm, 1.689(7) Å, which is consistent with its involvement in the bifurcated hydrogen bonding resulting in a formal single C–S bond, and similar to that found for HAchexim, 1.70(1) Å [12]. Other bonds in the *E′* thiosemicarbazone moiety of $H_2$2,6Achexim·H_2O and HAchexim are as follows: N2a–C7a, 1.291(6) and 1.29(1) Å; N2a–N3a, 1.347(6) and 1.37(1) Å; N3a–C8a, 1.364(7) and 1.36(2) Å; N4a–C8a, 1.346(7) and 1.36(1) Å. The similarity in bond distances of the two *E′* forms of the two compounds is also true for their bond angles. In summary, the bonding in $H_2$2,6Ahexim·H_2O has considerable delocalization of the electron density along both moieties, and although conventional bonding theory makes the two thiosemicarbazone moieties appear different, the bond distances between the two do not differ greatly. Far greater differences occur in the bond angles with the greatest differences being N2a–N3a–C8a, 112.4(4) and N2b–N3b–C8b, 126.6(5)°; N3a–C8a–S1, 124.1(4) and N3b–C8b–S2, 115.1(5)°; N3a–N2a–C7a, 123.0(4) and N3b–N2b and C7b, 117.1(5)°. This difference in bond angles may be due to the requirements of the thiolato/thione sulfur's difference in hydrogen bonding interactions; the intramolecular H2a···S1 has a distance of 2.38(6) Å and the hydrogen bond involving the water molecule, H1a···S2, has a distance of 2.29(6) Å (Fig. 2).

3.2. Molecular structure of [Bu_2Sn(2,6Achexim)]

The heptacoordinate neutral complex, [Bu_2Sn(2,6-Achexim)], has approximately pentagonal dipyramid stereochemistry, with the bis(thiosemicarbazone) ligand lying in the equatorial plane as shown in Fig. 4. As a result of chelation to the metal center, both five-membered rings and therefore also their symmetry related counterparts, are almost planar Sn–S1–C8–N3–N2 (RMS plane deviation 0.093 Å) and Sn–N2–C7–C2–N1 (RMS plane deviation 0.0548 Å), respectively. As a consequence, the sums of the respective internal angles, 537.4 and 538.4°, are in good agreement with the ideal value of 540°. The observed angle of 8.0(6)° between these rings and the angle between the ring Sn–N2′–C7′–C2′–N1′ and its symmetry related ring Sn–N2′–C7′–C2′–N1′ of 6.14(16) underline the planarity of the pentagonal ring S–N2–N1–N2′–S′ (RMS deviation 0.0751 Å) from which the tin(IV) ion is moved away by 0.008(3)°.

Owing to the geometric requirements of the thiosemicarbazonato moieties, the pentagon is not regular; the angle subtended at tin(IV) by the two sulfur atoms is significantly enlarged to 83.31(7)° from that in an idealized pentagonal bipyramid (72°), while the other equatorial angles range from 66.86(11) to 71.65(11)°. The axial butyl groups also contribute to the observed distortion since they have a C–Sn–C angle of 171.6(4)°. The bond distances Sn–S1 2.6921(17), Sn–N2a 2.436(5), Sn–N1 2.417(6), Sn–C31 2.145(11), and Sn–C41 2.171(8) Å are in good agreement with the bond distances Sn–S 2.593(1) and 2.603(1), Sn–N(imine) 2.427(4) and 2.421(4), Sn–N(py) 2.368(3), and Sn–C 2.178(4) and 2.179(4) Å, found in [Ph_2Sn(2,6-Ac4DH)]·2DMF (2,6Ac4DH is the dianion of 2,6-diacetylpyridine bis(thiosemicarbazone)), another heptacoordinated pentagonal dipyramidal diorganotin(IV) deriva-

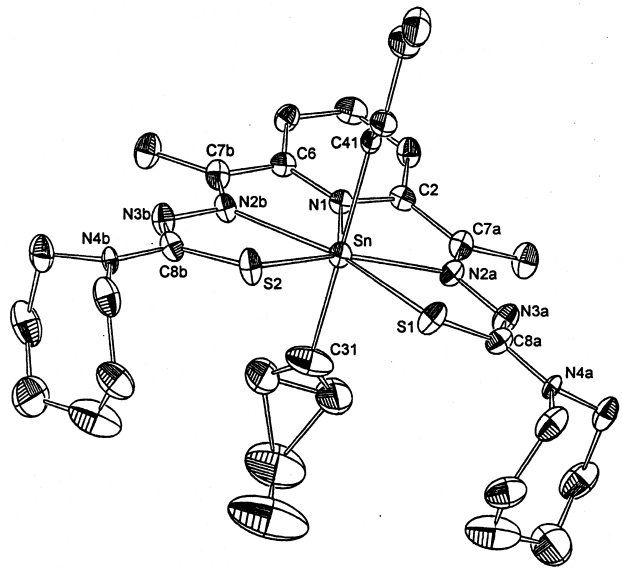

Fig. 4. ORTEP plot with atom-labeling scheme of [Bu_2Sn(2,6Achexim)], displacement ellipsoids at the 30% probability level. Atoms labeled with a and b are related by the symmetry operation $x, -y+1/2, z$.

tive containing a quinquedentate thiosemicarbazone ligand in the pentagonal girdle [6]. Coordination to the tin(IV) center by the imine nitrogen and the thiolato sulfur lengthens N2a–C7a and N2b–C7b to 1.331(7) Å, as well as S1–C8a and S2–C8b to 1.746(7) Å, from an average of 1.302(7) and 1.703(7) Å, respectively, in $H_2$2,6Achexim·H_2O. Therefore, as a result of their coordination, both bonds lose substantial π-character. The bond angles of the entire thiosemicarbazone moiety, which lose the amide hydrogen on coordination, show substantial changes compared to the angles in $H_2$2,6Achexim·H_2O, and the changes are greater for [Bu_2Sn(2,6Achexim)] than for [Zn(2,6Achexim)$]_2$, Table 3. The butyl group bonded to Sn by C31 shows considerable disorder and contributes to the relatively high *R* value for [Bu_2Sn(2,6Achexim)].

3.3. Molecular structure of [Zn(2,6Achexim)$]_2$

The bonding in [Zn(2,6Achexim)$]_2$, Fig. 5, is best described as distorted tetrahedral stereochemistry about the two zinc centers, which are equivalent. As expected, the Zn–S bonds, 2.352(2) and 2.363(2) Å, are longer than the Zn–N2a (and Zn–N2b) bonds, 2.053(5) and 2.050(6) Å. In the octahedral-tetrahedral binuclear zinc complex of 2,6-diacetylpyridine bis(thiosemicarbazone), $H_2$2,6Ac4DH, the tetrahedral Zn center has Zn–S bond distances of 2.317(3) and 2.327(4) Å, shorter than in [Zn(2,6Achexim)$]_2$, and both Zn–N bond distances of 2.07(1) Å [2]. The longer Zn–S bond distances, which likely contribute to the shorter Zn–N distances for [Zn(2,6Achexim)$]_2$, probably result from the bulkiness of the hexamethyleneiminyl rings.

The distortion from tetrahedral symmetry is substantial; the largest bond angle is N(imine)–Zn–N(imine), 159.2(2)°, the S–Zn–S angle with the two largest donor atoms is 114.6(1)°, and the smallest is a chelating S–Zn–N(imine), 82.9(2)°. The smallness of the latter angle is due to the requirements of the chelating thiosemicarbazonato moiety. For the octahedral-tetrahedral binuclear complex [Zn(2,6Ac4DH)$]_2$, the angles around the tetrahedral zinc center are as follows: N(imine)–Zn–N(imine), 140.8(4)°, the S–Zn–S angle is 118.3(2)° and the smallest is a chelating S–Zn–N(imine), 83.8(4)°. The chelating S–Zn–N(imine) angles are essentially the same, but the other two angles show significant differences. Differences are not surprising since in [Zn(2,6Ac4DH)$]_2$ the two arms are from different 2,6Ac4DH ligands, as is the case for 2,6Achexim, but both ligands in [Zn(2,6Ac4DH)$]_2$ coordinate their pyridyl nitrogens to the octahedral zinc center while the pyridyl nitrogens are uncoordinated in [Zn(2,6Achexim)$]_2$.

3.4. IR spectra

The most significant difference which emerges from a comparison of the vibrational spectra of $H_2$2,6Achexim·H_2O and its complexes is the disappearance of the band ν(N–H) at 3221 cm^{-1} as a consequence of the dianionic nature it assumes upon coordination. Assignment of ν(C=N) is complicated by the differences in the thiosemicarbazone moieties (i.e. the bifurcated *E′* and the *E* arm, which is involved in hydrogen bonding to the hydrate water molecule), as well as the partial double bond character possessed by all of the C–N bonds of the molecule. In the bifurcated *E′* arm N3a–C8a is formally a double bond and the bond distances C8a–N4a and C8b–N4b suggest considerable double bond character. The spectrum of $H_2$2,6Achexim·H_2O has bands at 1574 and 1561 cm^{-1} that are likely due to ν(C=N). When two bands are present in the spectra of coordinated anionic thiosemicarbazones that are assignable to ν(C=N), one is usually at lower energy, e.g. C7=N2, and one at higher energy, e.g. N3=C8, compared to ν(C=N) of the uncoordinated neutral thiosemicarbazone [12–15]. The spectrum of [Zn(2,6-Achexim)$]_2$ has bands at 1591 and 1564 cm^{-1} that we suggest are due to ν(C=N) for N3=C8 and C7=N2, respectively. Although the bands at ca. 1272, 1100 and 836 cm^{-1} in the spectrum of $H_2$2,6Achexim·H_2O have a significant contribution from ν(C=S), only the first absorption is shifted to lower frequency (1213 cm^{-1}) in the spectrum of [Bu_2Sn(2,6Achexim)] and the third absorption to lower frequency (739 cm^{-1}) in the spectrum of [Zn(2,6Achexim)$]_2$.

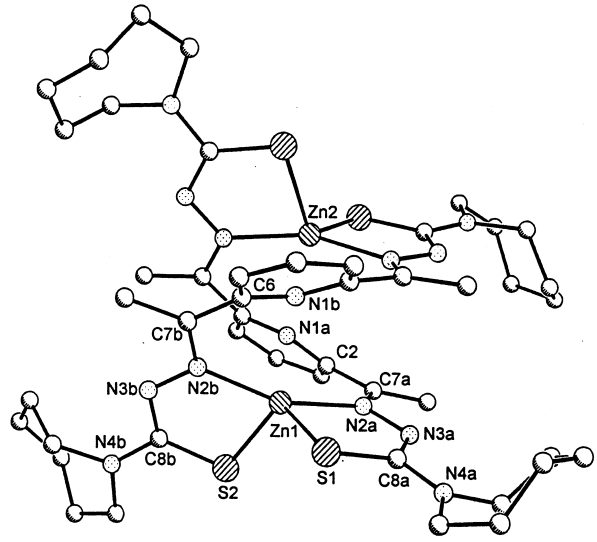

Fig. 5. Perspective view of [Zn(2,6Achexim)$]_2$ showing the atom numbering scheme.

3.5. NMR spectra

The ^{1}H NMR spectrum ($CDCl_3$) of $H_2$2,6Achexim·H_2O shows the two different thiosemicarbazone arms with the *E′* arm having NH3a at 15.18 ppm and NH3b for the *E* arm at 8.52 ppm. Its ^{13}C NMR spectrum shows two peaks for thione carbons, C8a and C8b, at 184.3 and 180.9 ppm, and for imine carbons, C7a and C7b, 147.6 and 147.4 ppm, but we are not able to assign these to a specific carbon atom with certainty. The ^{1}H NMR spectrum ($CDCl_3$) of [Bu_2Sn(2,6Achexim)] shows no peaks assignable to N3aH (or N3bH), but shows a triplet at 8.17 and a doublet at 7.85 ppm for pyridyl protons,

two singlets for N=C–CH_3 protons at 2.83 and 2.57 ppm, two doublets at 3.86, 1.54 ppm and a singlet at 1.79 ppm for the magnetically non-equivalent hexamethyleneiminyl protons. The Sn–CH_2–CH_2–CH_2– protons appear as a complicated multiplet centered at about 0.99 ppm, while the n-bu–CH_3 protons appear as a triplet at 0.60 ppm. In $CDCl_3$ [Zn(2,6Achexim)]$_2$ shows a triplet centered at 7.93 ppm and a doublet at 7.30 ppm for the pyridyl protons, a singlet at 2.53 ppm for N=C–CH_3, and a multiplet centered at 3.69 ppm and broads singlets at 1.85 and 1.59 ppm for the hexametheneiminyl protons.

3.6. Biological activity

Although other bis(thiosemicarbazones) derived from 2-acetylpyridine have shown antitumor activity when tested by the National Cancer Institute, $H_2$2,6Achexim·H_2O showed insufficient activity against 60 tumor lines and showed no activity in the HIV test. In antifungal tests $H_2$2,6-Achexim·H_2O shows no activity against *Aspergillus niger* and modest activity at a concentration of 10^3 mg ml^{-1} against *Paecilomyces variotii*.

Supplementary data

Crystallographic data (excluding structure factors), a complete listing of the atomic positions, bond distances, bond angles and anisotropic thermal parameters, for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication CCDC 118877. Copies of available material can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

The bismuth(III) halides BiX_3 (X = Cl, Br) react readily with the tridentate thioether $MeSi(CH_2SMe)_3$ to give complexes of composition $Bi_2\{MeSi(CH_2SMe)_3\}_2X_6$, which have been characterized analytically, spectroscopically and, for the chloro derivative, by single-crystal X-ray diffraction. In contrast to the mononuclear derivatives formed in the reactions of $BiCl_3$ with crown thioethers, $Bi_2\{MeSi(CH_2SMe)_3\}_2Cl_6$ exhibits in the solid state an extended chain structure with bridging unidentate/bidentate thioether ligands. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Bismuth; Thioether; Coordination polymers; Crystal structures; Electrospray

1. Introduction

We recently reported the synthesis of the new tridentate thioether $MeSi(CH_2SMe)_3$ (Chart 1) and prepared and structurally characterized its group 6 metal carbonyl derivatives $\{MeSi(CH_2SMe)_3\}M(CO)_3$ (M = Cr, Mo, W) [1] as well as a number of polymeric copper(I) complexes, including $Cu_3L_2X_3$ (X = Cl, Br) and $[LCu(NCMe)]PF_6$ [2].

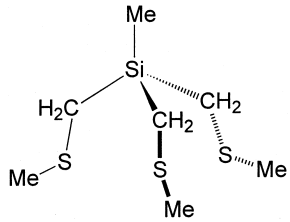

Chart 1

Seeking to extend our survey of the coordination chemistry of this ligand to the main group metals, we set out to explore its reactivity towards bismuth(III) halides. Bi(III), a 'borderline' metal ion according to Pearson's HSAB Principle [3,4] forms coordination complexes with both 'hard' (N, O) and 'soft' (S) Lewis bases [5,6]. While a variety of sulfur ligands, including thioureas $[(R_2N)_2CS]$, thiolates (RS^-), xanthates ($ROCS_2^-$), and dithiocarbamates ($R_2NCS_2^-$), have been extensively used in the context of bismuth chemistry, thioether derivatives are surprisingly uncommon. In this regard, other than a handful of macrocyclic or 'crown' thioether complexes such as (15S5)$BiCl_3$ and (18S6)$BiCl_3$ [7–9], only the dinuclear anion $[Bi_2I_8(SMe_2)_2]^{2-}$ [10] and a polymeric compound of stoichiometry $Bi_4\{MeS(CH_2)_3SMe\}_4Cl_{12}$ [11] have been reported. It is also interesting to note that compounds of bismuth, the heaviest non-radioactive element in the periodic table, have a fascinating array of applications, ranging from organic synthesis [12] to biology and medicine [13–16]. The synthesis and complete characterization of two new thioether complexes of bismuth(III) are described in this paper.

2. Results and discussion

The reaction of equimolar amounts of the bismuth(III) halides BiX_3 (X = Cl, Br) and $MeSi(CH_2SMe)_3$ in dichloromethane or acetonitrile affords yellow (X = Cl) or yellow–orange (X = Br) complexes of elemental composition $Bi\{MeSi(CH_2SMe)_3\}X_3$, isolated in 60–80% yield after appropriate work-up (Eq. (1)).

$$BiCl_3 + MeSi(CH_2SMe)_3 \rightarrow Bi\{MeSi(CH_2SMe)_3\}Cl_3 \quad (1)$$

The products are diamagnetic, slightly air-sensitive solids, soluble in polar solvents such as acetonitrile, dimethylsulf-

PII S0277-5387(00)00328-4

oxide (DMSO), or tetrahydrofuran (THF) but insoluble in aliphatic, aromatic, or chlorinated hydrocarbons.

The new complexes were characterized by a combination of analytical and spectroscopic techniques. Their ^{1}H NMR spectra (in CD_3CN) are very similar and display three singlet resonances in the ratio 3:2:1, assigned to the methylthio, methylene, and methylsilyl protons, respectively, all of which are only slightly downfield shifted (ca. 0.1–0.2 ppm) relative to the free ligand in the same solvent. These observations are consistent with the presence in acetonitrile solution of a fairly symmetrical complex bearing a tridentate thioether ligand (e.g. $LBiX_3$) or, alternatively, the existence of two or more highly fluxional species that are rapidly equilibrated in the NMR time scale (e.g. L_2BiX_3). Similarly, the ^{13}C NMR spectra of both compounds consist of only three signals, with approximate chemical shifts δ 21.2, 18.7, and -4.8 ppm, corresponding to the MeS, CH_2, and MeSi groups, respectively.

Electrospray ionization mass spectrometry (ESI-MS) [17,18] was used to investigate the nature of the new complexes in solution. The positive ion mass spectra of dilute acetonitrile solutions of both complexes (Fig. 1) exhibit peaks corresponding to the $[LBiX_2]^+$ (X = Cl, m/z = 505; X = Br, m/z = 595) and $[L_2BiX_2]^+$ (X = Cl, m/z = 731; X = Br, m/z = 821) fragments, all of which show the correct isotopic distributions. It is worth noting that loss of a halide is the most common ionization pathway for transition metal coordination complexes containing halide ligands [19]. This observation is in agreement with the formation of cationic complexes derived from both $LBiX_3$ and L_2BiX_3, and provides indirect evidence for the existence of a fast equilibrium of at least these two species in acetonitrile solution. In addition, a set of peaks centered at m/z = 517, tentatively assigned to the $[LBi(NCMe)_2]^+$ species, was also observed for the chloro complex. Interestingly, both spectra show an intense peak corresponding to the BiS^+ ion (m/z = 241), a species previously observed in the electron ionization (EI) and atmospheric pressure chemical ionization (APCI) mass spectra of some dithiabismuth(III) heterocyclic compounds [20] and an indication of significant thermal decomposition of the thioether complexes during ionization.

Single crystals suitable for an X-ray diffraction study of the chloro derivative were obtained by slow evaporation at room temperature of a saturated acetonitrile solution of $Bi\{MeSi(CH_2SMe)_3\}Cl_3$ (Fig. 2). Selected bond lengths and angles given in Table 1. The compound exhibits in the solid state with an extended chain structure, with each asymmetric unit consisting of a dinuclear Bi_2Cl_6 group and two bridging unidentate/bidentate (μ-η^1:η^2) thioether ligands. We have also observed this binding mode of $MeSi(CH_2SMe)_3$ in the aforementioned Cu(I) coordination polymers [2], a phenomenon that underscores the enhanced flexibility of our thioether ligand relative to that of related crown thioethers such as 9S3 (1,4,7-trithiacyclononane). The two six-coordinate bismuth centers are linked by a single chloro ligand so that the complex could also be envisioned as a

dinuclear derivative of stoichiometry $Bi_2\{MeSi(CH_2SMe)_3\}_2Cl_6$. It is noteworthy that complexes containing neutral Bi_2Cl_6 groups supported exclusively by additional donor ligands are extremely rare. The bipyridine derivative $Cl_2(bipy)_2Bi(\mu\text{-}Cl)Bi(bipy)Cl_3$ [21], which exhibits both hexa- and heptacoordinate metal centers, appears to be the only other such complex to have been structurally characterized. Both bismuth atoms in $Bi_2\{MeSi(CH_2SMe)_3\}_2Cl_6$ display distorted octahedral geometries, with 'trans' Cl(S)–Bi–Cl(S) angles in the range 162.5 to 175.8°. There are two distinctive coordination environments for the bismuth centers: (i) BiS_3X_3, with one arm of a thioether ligand and two from another bonded to a $BiCl_3$ center, as for Bi(1), and (ii) BiS_2X_4, with two arms of a thioether ligand and the bridging Cl atom attached to the other $BiCl_3$ moiety, as in Bi(2).

Four of the five terminal Bi–Cl bonds (Bi(1)–Cl(1), Bi(1)–Cl(2), Bi(2)–Cl(5), and Bi(2)–Cl(6)) are almost identical in length (ca. 2.56 Å) and are similar to those

observed in other bismuth chloride derivatives. For example, the mean terminal Bi–Cl bond length for compounds contained in the Cambridge Structural Database [22] is 2.616 Å. In contrast, the terminal Bi(2)–Cl(4) bond length (2.810(2) Å) is closer to the mean value for bridging Bi–μ-Cl bond lengths (2.936 Å) found in the same database. While the asymmetry of the bridging Bi–Cl–Bi group (Bi(1)–Cl(3) = 2.980(3) Å, Bi(2)–Cl(3) = 2.729(3) Å) could be ascribed to the contribution of a charge-separated complex $[Bi(S)_3Cl_2]^+[Bi(S)_2Cl_4]^-$ (S = thioether donor group) to the overall bonding scheme, we also note that its geometry is similar to that observed for such bridging units in other polynuclear bismuth complexes, including $[Bi_2Cl_{10}]^{4-}$ [23,24], Ph_2BiCl [25], $PhBi(THF)Cl_2$ [26], $[Bi_2Cl_8(THF)_2]^{2-}$ [27], and $Bi_2(bipy)_3Cl_6$ [20]. The Bi–S bond lengths vary between 2.872(2) and 3.180(2) Å and are within the range of values reported for other bismuth(III) thioether complexes (Table 2). While the observed Bi–S distances exceed the sum of covalent radii of bismuth and sulfur (2.56 Å) [28], they are significantly shorter than the sum of their van der Waals radii (4.25 Å) [28]. All the remaining interatomic distances (i.e. S–C and Si–C bond lengths) appear to be normal [29].

3. Conclusions

In contrast to the mononuclear seven-, eight- or nine-coordinate complexes obtained from $BiCl_3$ and crown thioethers, the corresponding reaction with $MeSi(CH_2SMe)_3$ results in the formation of a polymeric product with hexacoordinate bismuth centers. $Bi_2\{MeSi(CH_2SMe)_3\}_2Cl_6$ is only the second coordination polymer of Bi(III) to be structurally characterized, a reflection of the enhanced coordinative flexibility of $MeSi(CH_2SMe)_3$, at least relative to that of crown thioethers. ESI-MS studies revealed that the mono- and bis(thioether) complexes $[LBiX_2]^+$ and $[L_2BiX_2]^+$ are the two main species present in acetonitrile solutions of $Bi_2\{MeSi(CH_2SMe)_3\}_2X_6$ and that bismuth(III) sulfide or perhaps the sulfohalides Bi(S)X readily form upon thermal decomposition of these complexes. Finally, it is interesting to note that all the thioether complexes of bismuth that have

been isolated and structurally characterized to date are adducts of BiX_3 (X = Cl, I), an observation that has stimulated our current interest in the preparation of thioether derivatives of some organobismuth compounds.

4. Experimental

4.1. General considerations

All reactions were performed under dry oxygen-free nitrogen in an Innovative Technology System One-M-DC glove box or under argon using a combination of high-vacuum and Schlenk techniques [30–32]. Solvents were purified and degassed by standard procedures and all commercially available reagents were used as received. $MeSi(CH_2SMe)_3$ was prepared as reported [1].

^1H and ^{13}C NMR spectra were obtained on General Electric QE 300 or Varian Gemini (300 MHz) FT spectrometers. Chemical shifts (δ) are reported in parts per million relative to $SiMe_4$ ($\delta = 0$ ppm) and were referenced internally with respect to the residual protio or ^{13}C solvent resonances (δ 1.94 for CD_2HCN, δ 1.39 for CD_3CN); coupling constants are given in hertz (Hz). IR spectra were recorded as KBr pellets on a Midac Collegian FT spectrophotometer and are reported in cm^{-1}; relative intensities of the absorptions are indicated in parentheses (vs very strong, s strong, m medium, w weak). Electrospray ionization mass spectra were obtained on a PerSeptive Biosystems Mariner ESI-TOF mass spectrometer by direct infusion using acetonitrile solutions and a flow rate of 10 μl min^{-1}. Elemental analyses were determined by Desert Analytics (Tucson, AZ).

4.2. Synthesis of $Bi\{MeSi(CH_2SMe)_3\}Cl_3$

A stirred suspension of $BiCl_3$ (1.00 g, 3.17 mmol) in dichloromethane (20 ml) was treated with $MeSi(CH_2SMe)_3$ (0.64 ml, 3.22 mmol), resulting in an immediate color change from off-white to yellow. After stirring for 2 h at room temperature, the suspension was concentrated under reduced pressure to ca. 5 ml, and pentane (15 ml) was added. The yellow microcrystalline product was isolated by filtration, washed with pentane (2 × 10 ml), and dried in vacuo for 1 h (1.03 g, 60%). NMR data in CD_3CN: ^1H δ 0.21 (s, 3H, CH_3Si), 1.98 (s, 6H, CH_2), 2.18 (s, 9H, SCH_3); ^{13}C δ −4.8 (q, $^1J_{C–H} = 121$, 1C, CH_3Si), 18.5 (t, $^1J_{C–H} = 132$, 3C, CH_2), 20.9 (q, $^1J_{C–H} = 140$, 3C, SCH_3). IR data: 2964 (w), 2911 (w), 2878 (w), 2825 (w), 1420 (m), 1381 (w), 1314 (w), 1254 (m), 1141 (w), 961 (m), 813 (vs). *Anal*. Calc. for $C_7H_{18}BiCl_3S_3Si$: C, 15.5; H, 3.4. Found: C, 15.4; H, 3.1%.

4.3. Synthesis of $Bi\{MeSi(CH_2SMe)_3\}Br_3$

A stirred suspension of $BiBr_3$ (1.00 g, 2.23 mmol) in dichloromethane (30 ml) was treated with $MeSi(CH_2SMe)_3$ (0.48 ml, 2.42 mmol), resulting in an immediate color change from yellow to yellow–orange. After stirring for 1 h at room temperature, the suspension was concentrated under reduced pressure to ca. 10 ml, and pentane (40 ml) was added. The yellow–orange microcrystalline product was isolated by filtration, washed with pentane (3 × 30 ml), and dried in vacuo for 1 h (1.20 g, 80%). NMR data in CD_3CN: ^1H δ 0.25 (s, 3H, CH_3Si), 2.11 (s, 6H, CH_2), 2.31 (s, 9H, SCH_3); ^{13}C δ −4.7 (q, $^1J_{C–H} = 121$, 1C, CH_3Si), 18.8 (t, $^1J_{C–H} = 132$, 3C, CH_2), 21.6 (q, $^1J_{C–H} = 140$, 3C, SCH_3). IR data: 2956 (w), 2911 (w), 2876 (w), 1414 (m), 1374 (m), 1256 (m), 1143 (m), 961 (s), 811 (vs). *Anal*. Calc. for $C_7H_{18}BiBr_3S_3Si$: C, 12.5; H, 2.7. Found: C, 12.1; H, 2.6%.

4.4. X-ray structure determination

Crystal data collection and refinement parameters are given in Table 3. A crystal suitable for data collection was selected and mounted in a nitrogen-flushed, thin-walled capillary. Data were collected on a Siemens P4 diffractometer equipped with a SMART/CCD detector using Mo Kα radiation ($\lambda = 0.71073$ Å). The systematic absences in the diffraction data were uniquely consistent with the reported space group. The structure was solved using direct methods, completed by subsequent difference Fourier synthesis, and refined by full-matrix least-squares procedures. An empirical absorption correction was applied to the data set using DIFABS [33]. All non-hydrogen atoms were refined with anisotropic displacement coefficients and all hydrogen atoms were treated as idealized contributions. All software and sources of the scattering factors are contained in the SHELXTL (version 5.10) program library [34].

Supplementary data

Crystallographic data (excluding structure factors) for $Bi_2\{MeSi(CH_2SMe)_3\}_2Cl_6$ have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road,

Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk), CCDC No. 134940.

Received 3 October 1999; accepted 3 January 2000

Abstract

The synthesis of the new pyrazole-derived ligands 3-phenyl-5-(2-pyridyl) pyrazole (HL^0) and 3-phenyl-5-(6-methyl-(2-pyridyl))pyrazole (HL^1) and their Co(II) complexes is reported. Elemental analyses, conductivity measurements and IR and UV–Vis spectroscopies defined all complexes. ^1H and ^{13}C NMR spectroscopies were also used in the characterization of ligands. The crystal and molecular structures of $[Co(HL^0)_2Cl(H_2O)]Cl\cdot H_2O$, consisting of discrete ions and water molecules linked by hydrogen bonds, are also reported. The hexacoordinated metal atom is bonded to two pyridinic nitrogens, two pyrazolic nitrogens (one of each nitrogen belonging to two different ligands), one chlorine atom and one water molecule, forming a distorted octahedral environment. The ligands are not exactly planar and the arrangement of ligands is *cis*, with a dihedral angle between the two mean planes of ligands of 89.21(6)°. The degree of distortion from regular octahedral geometry is compared to that of closely related structures. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Since the first review of pyrazole-derived ligands appeared in 1972 [1], the coordination chemistry of pyrazole and its derivatives has strongly evolved over the last two decades [2]. La Monica and Ardizzoia published an extensive review in 1997, which covers the years 1985–1995, and updates the work of Trofimenko [3]. Recent studies have shown the high catalytic activity, under mild conditions, of some polynuclear heterobridged pyrazolate complexes, thus encouraging the exploration of the unusual and specific features of the pyrazolate ligands [1,2]. Some authors have suggested that the nucleophilicity of N2 (sp^2) and the acid character of pyrazole may be modified by introducing appropriate substituents at the positions 3, 4 or 5 of the heterocyclic ring [4,5]. We have described the preparation of the ligands 3,5-bis(2-pyridyl)pyrazole (HL), 2-(6-methyl)pyridyl-2-pyridyl-3,5-pyrazole (HL′) and 3,5-bis-2-(6-methylpyridyl)pyrazole (HL″), where the pyrazole ring is attached to nitrogen heterocycles at the positions 3 and 5. We elsewhere [6,7] have also studied a series of HL complexes with the divalent metal ions Ni(II), Co(II), Zn(II) and Cu(II) [6–9]. Structural data on the Ni(II) [6] and Cu(II) [8] complexes have shown that this tetradentate nitrogen donor has a marked preference for the formation of dinuclear complexes, in which the ligand (itself) exhibits a strictly planar bridging mode with the axial coordination sites of the metal ions occupied by additional solvent molecules. In 1995 Munakata et al. [10] reported three HL complexes, two of Ag(I), and one of Cu(II).

Here, following the research on 3,5-disubstituted pyrazole ligands, we report the synthesis of the new pyrazole ligands 3-phenyl-5-(2-pyridyl)pyrazole (HL^0) and 3-phenyl-5-(6-methyl-(2-pyridyl))pyrazole (HL^1) (Fig. 1) and of some Co(II) complexes of formula $Co(HL^0)_2X_2$ (X = NO_3 (**1**), Cl (**2**), Br (**3**)), $Co(HL^1)_2X_2$ (X = NO_3 (**4**), Cl (**5**), Br (**6**)), $Co(HL^0)Cl_2$ (**7**), $Co(HL^1)X_2$ (X = Cl (**8**), Br (**9**),

and $Co(HL^0)Cl(OH)$ (**10**). The crystal structure of $[Co(HL^0)_2Cl(H_2O)]Cl\cdot H_2O\cdot 0.2CH_3CN$ (**2**) is described and compared to those of closely related structures.

2. Experimental

2.1. General methods

Preparations were performed using usual Schlenk techniques. All reagents were commercial grade materials and were used without further purification. All solvents (ethanol, tetrahydrofurane THF) were dried and distilled by standard methods and previously deoxygenated in a vacuum line.

Analyses (C, N, H) were performed in our analytical laboratory on a Perkin-Elmer 240-B instrument. Conductivity measurements were performed at room temperature in 10^{-3} M methanolic solutions employing a Radiometer CDM-3 conductimeter. Infrared spectra were recorded from KBr discs or Nujol films on a Perkin-Elmer 2000 spectrometer in the region 4000–100 cm^{-1}. The ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained in $CDCl_3$ or acetone-d_6 solutions on a Bruker AC-250 MHz instrument and referenced to TMS. In all cases chemical shifts (δ) are given in ppm. Mass spectra were obtained on a HP 5989A apparatus. Electronic spectra in solution were run on a Kontron-Uvikon 860 in different solvents and in solid state (KBr pellets, diffuse reflectance) were obtained on a Kontron-Tegimenta, Rotkreuz, Switzerland.

2.2. Materials

Methyl 2-picolinate and methyl 6-methyl-2-picolinate were prepared by previously reported procedures [11,12].

2.3. Synthesis of the ligands

2.3.1. Preparation of 1-phenyl-3-(2-pyridyl)-1,3-propanodione

Under a dinitrogen atmosphere, a 250 ml Schlenk flask was charged with sodium (0.68 g, 29.6 mmol). Deoxygenated absolute ethanol (20 ml) was added and the mixture was stirred until all the sodium was consumed. The ethanol was eliminated in vacuo to yield a white solid. Dry toluene (25 ml), methyl-2-picolinate (4.05 g, 32.4 mmol) and acetophenone (4.83 g, 45.0 mmol) were added in this order, slowly, to the white residue of sodium ethanolate. Upon stirring the mixture overnight, a pale orange compound precipitated, which was filtered and dried. The resulting solid was slowly added to a vigorously stirred solution of acetic acid (30 ml), water (30 ml) and ice (100 g), yielding a white solid, which was filtered and dried in vacuo. Yield: 6.2 g, 85.0%. Melting point: 85–86°C. IR (KBr, cm^{-1}): $\nu(C–H)_{ar}$ 3098, $\nu(C=O)$, $\nu(C=C)$ 1602, $\nu(C=N)$ 1549, $\delta(C–H)_{OOP}$ 775. ^1H NMR (250 MHz, acetone-d_6, ppm): δ 4.84 (s, 1H, $H_2C(C=O)_2$), 7.5–7.7 (m, 4H, H–ph, H–py), 8.0–8.2 (m, 4H, H–ph, H–py), 8.75 (d, 1, H–py). ^{13}C NMR: (62.75 MHz, acetone-d_6, ppm): δ 49.7 (H_2C), 94.5 (C–py), 120.0, 128.0, 129.1, 130.0, 131.2, 135.5, 136.0, 137.3, 152.0 (C–py, C–ph), 153.6 (C–py), 185, 186.0 (C=O). MS (CI, CH_4) *m/z*: 225 (MH^+, 95), 105 ($PhCO^+$, 97), 78 (py, 79), 77 (ph, 83), 51 ($C_4H_4^+$, 100). *Anal*. Found: C, 74.6; H, 5.1; N, 6.2. Calc. for $C_{14}H_{11}NO_2$: C, 74.6, H, 4.9; N, 6.2%.

2.3.2. Preparation of 3-phenyl-5-(2-pyridyl) pyrazole (HL^0)

A 100 cm^3 Schlenk flask connected to a Dean-Stark apparatus was charged with 1-phenyl-3-(2-pyridyl)-1,3-propanodione (1 g, 4.4 mmol) and hydrazine (0.27 g, 5.4 mmol). Dry toluene (20 ml) was added, and the mixture was refluxed for 18 h, allowed to cool to room temperature and then filtered. Yield: 0.50 g, 51%. Melting point: 167–168°C. IR (KBr, cm^{-1}): ν(N–H) 3244, $\nu(C–H)_{ar}$ 3062, ν(C=C), ν(C=N) 1598–1565, $\delta(C–H)_{OOP}$ 759. ^1H NMR (250 MHz, $CDCl_3$, ppm): δ 7.2–7.4 (m, 5H, H–ph, H–py), 7.8–7.9 (m, 4H, H–ph, H–py), 8.57 (d, 1H, H–py), 11.0 (b, 1H, H–N(pz)). ^{13}C NMR (62.75 MHz, $CDCl_3$, ppm): δ 100.3 (C–pz), 120.1, 124.0, 126.0, 128.2, 129.3, 132.6, 137.0, 144.6, 148.0, 149.1, 152.0 (C–py, C–ph), 207.4 (C–pz). MS (CI, CH_4) *m/z*: 221 (MH^+,100), 192 ($MH^+–N_2H$, 64), 78 (py, 37), 77 (ph, 31), 51 ($C_4H_4^+$). *Anal*. Found: C, 74.3; H, 5.1; N, 18.6. Calc. for $C_{14}H_{11}N_3\cdot 1/4H_2O$: C, 74.5, H, 5.1, N, 18.6%.

2.3.3. Preparation of 1-phenyl-3-(6-methyl-(2-pyridyl))-1,3-propanodione

Under a dinitrogen atmosphere, a 250 ml Schlenk flash was charged with sodium (0.68 g, 29.0 mmol). Ethanol (20 ml) was added and the mixture was stirred until all the sodium was consumed. The ethanol was eliminated in vacuo. Dry toluene (25 ml), methyl-6-methyl-2-picolinate (4.05 g, 27.0 mmol) and acetophenone (4.83 g, 45.0 mmol) were added in this order, slowly, to the white residue of sodium ethanolate. The mixture was stirred until a yellowish precipitate appeared (ca. 1 h), then it was gently warmed for 12 h until the sodium salt of the β-diketone was formed. The salt was filtered and dried. The resulting solid was slowly added to a vigorously stirred solution of acetic acid (30 ml), water (30 ml) and ice (100 g), yielding a solid, which was filtered off and dried in vacuo. Yield: 4.90 g, 76.4%. Melting point: 50–52°C. IR (KBr, cm^{-1}): $\nu(C–H)_{ar}$ 3095, ν(C=O), ν(C=C) 1601, ν(C=N) 1561, $\delta(CH_3)$ 1448, $\delta(C–H)_{OOP}$ 773. ^1H NMR (250 MHz, $CDCl_3$, ppm): δ 2.70 (s, 3H, CH_3–py), 4.74 (s, 1H, $H_2C(C=O)_2$), 7.4–7.6 (m, 5H, H–ph), 7.66 (t, 1H, H–py), 7.91 (d, 1H, H–py), 8.03 (d, 1, H–py). ^{13}C

NMR (62.75 MHz, $CDCl_3$, ppm): δ 24.2 (CH_3–py), 48.2 (H_2C), 93.3, 118.9 (C–py), 124.0, 125,2, 126.0, 132.2, 137.0 (C–py, C–ph), 151.6 (C–py), 183.8, 185.8 (C–pz), 195.0, 196.0 (C=O). MS (CI, CH_4) *m/z*: 239 (MH^+, 62), 162 (MH^+–Ph, 18), 105 ($PhCO^+$, 100), 93 (2-Mepy, 97), 77 ($PhCO^+$–CO, 84). *Anal*. Found: C, 75.1; H, 5.7; N, 5.8. Calc. for $C_{15}H_{13}NO_2$: C, 75.3; H, 5.8; N, 5.5%.

2.3.4. Preparation of 3-phenyl-5-(6-methyl-(2-pyridyl))-pyrazole (HL^1)

A 100 cm^3 Schlenk flask connected to a Dean-Stark apparatus was charged with 1-phenyl-3-(6-methyl-2-(pyridyl)-1,3-propanodione (1 g, 4.2 mmol) and hydrazine (0.27 g, 5.4 mmol). Toluene (20 ml) was added, then the mixture was refluxed for 18 h, allowed to cool to room temperature and then filtered. Yield: 0.99 g, 50%. Melting point: 158–160°C. IR (KBr, cm^{-1}): ν(N–H) 3283, $\nu(C–H)_{ar}$ 3058, ν(C=C), ν(C=N) 1598–1564, $\delta(C–H)_{OOP}$ 789. ^1H NMR (250 MHz, $CDCl_3$, ppm): δ 2.30 (s, 3H, CH_3–py), 7.03 (s, 1H, H–pz), 7.04 (d, 1H, H–ph), 7.3–7.6 (m, 6H, H–py, H–ph), 7.84 (d, 1H, H–py), 9.8 (b, 1H, H–N(pz)). ^{13}C NMR (62.75 MHz, $CDCl_3$, ppm): δ 24.4 (CH_3–py), 100.2 (C–pz), 117.1, 122.5, 128.7, 132.8, 137.1, 144.7, 151.6, 158.4 (C–py, C–ph), 200.0 (C–pz). MS (CI, CH_4) *m/z*: 235 (MH^+, 100), 207 (MH^+–N_2, 10), 206 (MH^+– N_2H, 36), 92 (2-Mepy, 5), 65 (C_5H_5, 10). *Anal*. Found: C, 76.2; H, 5.5; N, 17.8. Calc. for $C_{15}H_{13}N_3$: C, 76.6; H, 5.6; N, 17.9%.

2.4. Synthesis of the metal complexes

2.4.1. Complexes $Co(HL)_2(NO_3)_2 \cdot xH_2O$ with $HL = HL^0$ (1), HL^1 (4)

The reactions were carried out under anaerobic conditions. The appropriate ligand (HL^0, HL^1) (0.45 mmol: HL^0, 0.10 g; HL^1, 0.11 g) was added to a solution of the $Co(NO_3)_2 \cdot 6H_2O$ (0.06 g, 0.21 mmol) in THF (10 ml). Upon addition no appreciable change in colour was observed, but after 24 h crystalline solids were obtained, which were filtered off and dried in vacuo.

1: IR (KBr, cm^{-1}): ν(N–H) 3122, $\nu(C–H)_{ar}$ 3068, ν(C=C), ν(C=N) 1612, 1574, $\nu(NO_3)$ 1385, $\delta(C–H)_{OOP}$ 763, ν(Co–N) 414, ν(Co–O) 284, ν(Co–N) 256. IR (Nujol, cm^{-1}): $\nu(NO_3)$ 1769, 1741. UV–Vis (methanol 1.23×10^{-3} M, nm): λ (ε) 614 (6), 471 (57). Solid state (KBr, nm): λ 706, 506.

4: IR (KBr, cm^{-1}): ν(N–H) 3143, $\nu(C–H)_{ar}$ 3063, ν(C=C), ν(C=N) 1614, 1571, $\nu(NO_3)$ 1387, $\delta(C–H)_{OOP}$ 766, ν(Co–N) 374, ν(Co–O) 274. IR (Nujol, cm^{-1}): $\nu(NO_3)$ 1767. UV–Vis (methanol 2.27×10^{-3} M, nm): λ (ε) 1606 (40), 489 (49). Solid state (KBr, nm): λ 698, 591, 518.

2.4.2. Complexes $Co(HL)_2X_2 \cdot xH_2O$ with HL^0 and X = Cl (2), and X = Br (3), or HL^1 and X = Cl (5), and X = Br (6)

0.25 mmol of the appropriate metal salt ($CoCl_2 \cdot 6H_2O$, 0.059 g; $CoBr_2 \cdot 6H_2O$, 0.082 g) was added to a solution of 0.45 mmol of the ligand (HL^0, 0.10 g; HL^1, 0.11 g) in ethanol (99%, 40 ml). The mixture was heated with stirring for 20 h, concentrated until a crystalline precipitate appeared, which was filtered off, washed with ethanol (5 ml) and diethyl ether (5 ml) and vacuum dried.

2: IR (KBr, cm^{-1}): ν(N–H) 3183, $\nu(C–H)_{ar}$ 3058, ν(C=C), ν(C=N) 1609, 1573, $\delta(C–H)_{OOP}$ 764, ν(Co–N) 410, ν(Co–Cl) 280. UV–Vis (methanol 1.16×10^{-3} M, nm): λ (ε) 614 (8), 477 (40). (CH_3CN 1.00×10^{-3} M, nm): λ (ε) 685 (119), 589 (95). Solid state (KBr, nm): λ 712, 506.

3: IR (KBr, cm^{-1}): ν(N–H) 3178, $\nu(C–H)_{ar}$ 3081, ν(C=C), ν(C=N) 1609, 1572, $\delta(C–H)_{OOP}$ 763, ν(Co–N) 412, ν(Co–Br) 278, ν(Co–N) 238. UV–Vis (methanol 1.20×10^{-3} M, nm): λ (ε) 614 (6), 464 (112). (CH_3CN 0.98×10^{-3} M, nm): λ (ε) 697 (134), 618 (105). Solid state (KBr, nm): λ 698, 498.

5: IR (KBr, cm^{-1}): ν(N–H) 3112, $\nu(C–H)_{ar}$ 3059, ν(C=C), ν(C=N) 1612, 1570, $\delta(C–H)_{OOP}$ 765, ν(Co–N) 372, ν(Co–Cl) 296, ν(Co–N) 258. UV–Vis (methanol 3.86×10^{-3} M, nm): λ (ε) 1612 (23), 640 (5), 500 (29). (CH_3CN 0.29×10^{-3} M, nm): λ (ε) 664 (530), 570 (363). Solid state (KBr, nm): λ 666, 590, 518.

6: IR (KBr, nm): ν(N–H) 3201, $\nu(C–H)_{ar}$ 3058, ν(C=C), ν(C=N) 1612, 1569, $\delta(C–H)_{OOP}$ 765, ν(Co–N) 372, ν(Co–Br) 280, 260. UV–Vis (methanol 3.67×10^{-3} M, nm): λ (ε) 1612 (19), 497 (28). (CH_3CN 0.29×10^{-3} M, nm): λ (ε) 664 (370), 590 (199). Solid state (KBr, nm): λ 666, 591, 518.

2.4.3. Complexes $Co(HL)X_2 \cdot xH_2O$ with HL^0 and X = Cl (7) or HL^1 and X = Cl (8), and X = Br (9)

The reactions were carried out under a dinitrogen atmosphere. To a Schlenk flask containing deoxygenated warm THF (20 ml) was added, in this order, 3-phenyl-5(2-pyridyl)pyrazole (0.10 g, 0.45 mmol), and $CoX_2 \cdot 6H_2O$ (0.45 mmol). The resulting solution was stirred at room temperature for 24 h and concentrated on a vacuum line to one-fifth of the initial volume. After standing at room temperature for a few hours, crystalline solids were obtained, which were filtered off and dried in vacuo, washed with THF and vacuum dried.

7: IR (KBr, cm^{-1}): ν(N–H) 3192, $\nu(C–H)_{ar}$ 3061, ν(C=C), ν(C=N) 1611, 1572, $\delta(C–H)_{OOP}$ 765, ν(Co–N) 412, ν(Co–Cl) 296, ν(Co–N) 236. UV–Vis (methanol 1.55×10^{-3} M, nm): λ (ε) 614 (5), 493 (26). (CH_3CN 1.30×10^{-3} M, nm): λ (ε) 684 (341), 588 (263). Solid state (KBr, nm): λ 700, 641.

8: IR (KBr, nm): ν(N–H) 3158, $\nu(C–H)_{ar}$ 3066, ν(C=C), ν(C=N) 1615, 1566, $\delta(C–H)_{OOP}$ 764, ν(Co–N) 372, ν(Co–Cl) 280, 268. UV–Vis (methanol 4.44×10^{-3} M, nm): λ (ε) 1608 (28), 494 (87). (CH_3CN 0.90×10^{-3} M, nm): λ (ε) 668 (256), 572 (129). Solid state (KBr, nm): λ 662, 591.

9: IR (KBr, nm): ν(N–H) 3162, $\nu(C–H)_{ar}$ 3065, ν(C=C), ν(C=N) 1615, 1565, $\delta(C–H)_{OOP}$ 763, ν(Co–N)

2.4.4. Complex $Co(HL^0)(OH)Br\cdot H_2O$ (**10**)

The procedure was the same as given above (using bromide salt instead of chloride) but concentration of the reagent mixture almost to dryness was necessary in order to obtain crystalline solid. This was filtered off, washed with THF, and dried in vacuo.

10: IR (KBr, nm): ν(N–H) 3194, ν(C–H)$_{ar}$ 3065, ν(C=C), ν(C=N) 1610, 1572, δ(C–H)$_{OOP}$ 764, ν(Co–N) 414, ν(Co–Br) 282, 271. UV–Vis (methanol 1.52×10^{-3} M, nm): λ (ε) 614 (7), 478 (30). (CH_3CN 1.26×10^{-3} M, nm): λ (ε) 696 (205), 617 (136). Solid state (KBr, nm): λ 725, 702, 665.

Table 1 shows the analytical and physical data for all complexes.

2.5. X-ray crystal structure analysis

Suitable crystals for X-ray diffraction experiments of the compound $[Co(HL^0)_2Cl(H_2O)]Cl\cdot H_2O$ were obtained by crystallization from acetonitrile. One crystal was mounted on an Enraf-Nonius CAD4 diffractometer. Intensities were collected using the ω–2θ scan mode to $2\theta_{max}=50°$. Graphite-monochromated Mo Kα radiation was used. The structure was solved by direct methods (SHELXS-86) [13] and refined by full-matrix least-squares methods on F^2 for all reflections (SHELXL-97) [14]. The final $R(F)$ and $R_w(F^2)$ values as well as the number of parameters refined and other details concerning the refinement of the crystal structure are presented in Table 2. The weight was $w^{-1}=\sigma^2(F_o^2)+(0.064P)^2+0.1183P$ where $P=(F_o^2+2F_c^2)/3$.

Table 2
Crystal data and structure refinement

Compound	$[Co(HL^0)_2ClH_2O]Cl\cdot H_2O\cdot 0.2CH_3CN$
Empirical formula	$C_{28.4}H_{26.6}Cl_2CoN_{6.2}O_2$
Formula weight	616.59
Temperature (K)	293(2)
Wavelength	0.71069
Crystal system, space group	triclinic, $P\bar{1}$ (no. 2)

Absorption coefficient (mm^{-1})	0.841
Crystal size (mm)	$0.50\times0.40\times0.36$
Unique data/restraints/parameters	4936/8/376
Goodness-of-fit on F^2	1.062
Final R indices ($I>2\sigma(I)$)	$R(F)=0.0337$, $R_w(F^2)=0.0939$
R indices (all data)	$R(F)=0.0418$, $R_w(F^2)=0.0954$
Largest difference peak and hole (e Å^{-3})	0.269 and −0.602

3. Results and discussion

3.1. The synthesis and spectroscopic properties of the complexes

The β-diketone compounds 1-phenyl-3-(2-pyridyl)-1,3-propanodione and 1-phenyl-3-(6-methyl-(2-pyridyl))-1,3-propanodione have been synthesized following a Claisen condensation of the appropriate ketones and esters. Further treatment of these β-diketone compounds with hydrazine in toluene yielded the expected pyrazole-derived ligands 3-phenyl-5-(2-pyridyl)pyrazole and 3-phenyl-5-(6-methyl-(2-pyridyl))pyrazole (Fig. 2).

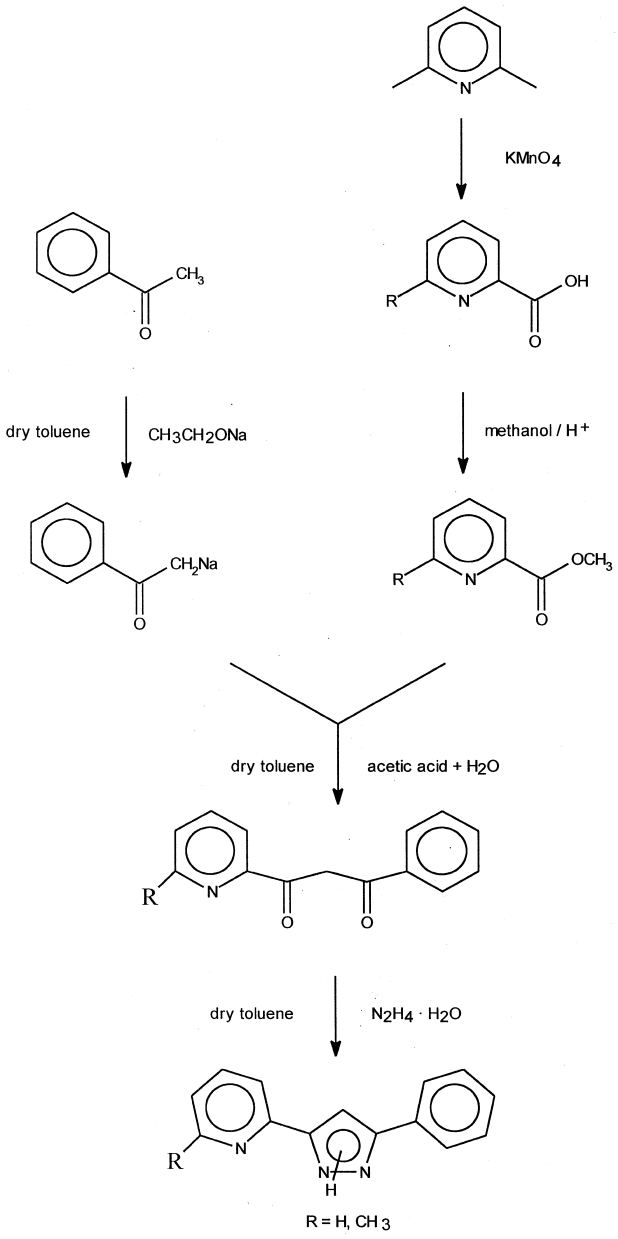

Fig. 2. Scheme of synthesis of the ligands.

In chloroform, the β-diketones here described are in equilibrium with the corresponding ketoenol forms, in the ratio 5% β-diketone to 95% ketoenol (quantified by NMR).

The complexes $Co(HL)X_2$ and $Co(HL)_2X_2$ were obtained by reacting the appropiate metal salt with the corresponding pyrazole ligand in an M:L ratio of 1:1 and 1:2, respectively.

The conductivity of the complexes was measured (Table 1). The values of the nitrate complexes are high enough to assess the non-coordinated nature of the nitrate anion. As for the complexes of formula $Co(HL)X_2$, $Co(HL)_2X_2$ and Co(HL)(OH)Br, different values were found, depending on the solvent. The conductivity in methanol was 90–150 Ω^{-1} cm^2 mol^{-1} (consistent with 1:1 electrolyte) whereas that in acetonitrile was 20–150 Ω^{-1} cm^2 mol^{-1} (in agreement with the non-electrolytic nature of the complexes). The reported values for 1:1 and 1:2 electrolytes in methanol are 80–115 and 160–220 Ω^{-1} cm^2 mol^{-1}, respectively and, in acetonitrile, the values are 120–160 and 220–300 Ω^{-1} cm^2 mol^{-1}, respectively [15,16].

The IR spectra of the nitrate containing complexes are a valuable tool in elucidation of their stereochemistry. Such studies are frequently based on the behaviour of the $\nu_3(E', D_{3h})$ band, which is very sensitive to the coordination mode of the nitrate group. Several bands are attributable to the organic ligands in the N–O stretching mode region, which hinders the analysis of the ν_3 band. Lever and Montovani [17] have shown that the $\nu_1 + \nu_3(E', D_{3h})$ combination band is useful for structural purposes. This band, near 1750 cm^{-1}, is generally not overlapped by other ligand bands. The results of the analysis of the IR absorptions in the $(\nu_1 + \nu_3)$ combination band region of the complexes synthesized were as follows: the complex $Co(HL^0)_2(NO_3)_2$ (**1**) exhibits the typical two bands (1769, 1741 cm^{-1}) of a monodentate nitrate group [18,19]. However, in spite of the band at 1769 cm^{-1}, other ionic nitrate groups cannot be ruled out. In addition, the compound exhibits two bands in the N–O stretching mode region at 1448 and 1284 cm^{-1}, as in monodentate nitrate groups [20].

The complex $Co(HL^1)_2(NO_3)_2$ (**4**) shows one single band at 1767 cm^{-1}, which is consistent with the ionic behaviour of the nitrate group.

The IR spectra of halide complexes in the region 400–100 cm^{-1} were also studied. The complexes $Co(HL)Cl_2$ (**7**, **8**) and $Co(HL)_2Cl_2$ (**2**, **5**) display two well-defined ν(Co–Cl) bands each at 326, 268 cm^{-1} and 296, 258 cm^{-1}, respectively. The bromide derivatives $Co(HL)Br_2$ (**9**) and $Co(HL)_2Br_2$ (**3**, **6**) show two bands ν(Co–Br), at 288 and 260 cm^{-1}, respectively. ν(Co–N(pz)) bands are in the range 414–220 cm^{-1} [21,22]. For the complex $Co(HL^0)(OH)Br$ (**10**) no bands are attributable to OH.

Electronic spectra for the synthesized complexes were measured in methanol, in acetonitrile, and in KBr pellets (reflectance diffuse).

The spectra of Co(II) compounds in methanolic solution show one band in the visible region between 580 and 450 nm (ε = 25–112 mol^{-1} cm^{-1} l), as in octahedral Co(II) complexes [23–25]. The Co(II)-halide complexes in acetonitrile show two bands between 700–660 nm (ε = 120–530 mol^{-1} cm^{-1} l) and 620–550 nm (ε = 95–363 $mol^{-1}cm^{-1}$ l), respectively. The position and intensity of the bands between 700–660 nm are indicative of the $^4A_2 \rightarrow {}^4T_1(P)$ transition of the d^7 ion in a tetrahedral field [26,27], while the bands at 620–550 nm agree with of the transition of the d^7 ion in an octahedral field $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ [7,28]. The presence of two types of absorption is consistent with the coexistence of tetrahedral and octahedral species in solution[24]. The Co(II)-nitrate compounds are insoluble in acetonitrile.

The spectra of the Co(II) complexes were also measured following diffuse reflectance methods. The complexes $Co(HL)X_2$ show one broad band from 750 to 575 nm, in the visible region, which can be assigned to the $^4A_2 \rightarrow {}^4T_1(P)$

transition of the d^7 ion in a tetrahedral field [24,25,29]. The compounds $Co(HL)_2X_2$ show two bands: one weak band between 712 and 690 nm and a broad intense band between 506 and 498 nm. This spectrum suggests that the complexes have a distorted octahedral geometry [24,25,29].

3.2. Crystal structure of $[Co(HL^0)_2Cl(H_2O)]Cl \cdot H_2O \cdot 0.2CH_3CN$ (2)

The molecular structure of the complex (Fig. 3) consists of discrete $[Co(HL^0)_2Cl(H_2O)]^+$ cations, Cl^- anions and solvent molecules (H_2O, MeCN). The cation complex is mononuclear. Table 3 lists selected bond distances and angles.

In the cation, the metal atom, with a distorted octahedral geometry, is coordinated to one Cl atom, one H_2O molecule and two pairs of nitrogen atoms, which correspond to two HL^0 ligands. Each ligand uses only two of its three nitrogen atoms, the pyridinic nitrogen and one of the two pyrazolic nitrogens, acting as a bidentate ligand and forming a five-membered metallocycle.

Three structures with a $Co(II)N_4ClO$ core have been described, two with Cl and O in *cis* arrangement [30,31] and one with Cl and O in *trans* arrangement [32].

The Co–Cl distance, in compound **2** is in the range observed for the *cis* structures (2.400–2.379 Å), and is significantly shorter than the distance found in the *trans* structure (2.617 Å). Likewise, the Co–O bond length is similar to those found in the *cis* complexes (2.319–2.084 Å) and shorter than that found in the *trans* compound (2.341 Å). The O–Co–Cl angle 94.20(6)° is also in the range observed for the reported structures (90–103°). The Co–Npy bond distances (0.06 Å average) are clearly longer than those of Co–Npz. The Co–Npy bond distances are consistent with described values (1.927–2.343 Å) [33].

Twelve structures with Co(II) containing pyrazol ligands have been described. The most common coordination for Co(II) in these structures is tetrahedral, except in four cases, where the coordination is octahedral [34–37]. The Co–Npz bond distances of compound **2** are similar to those found in these four structures.

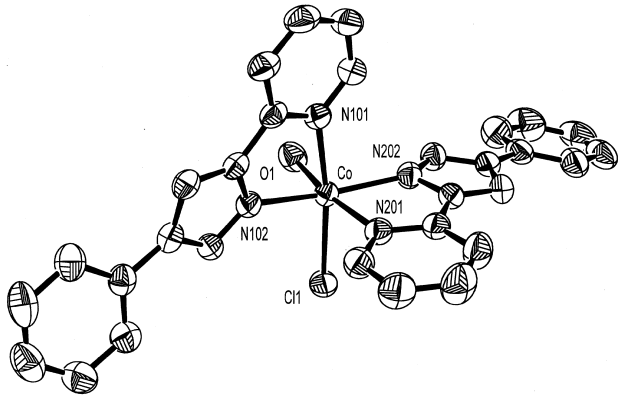

Fig. 3. An ORTEP view of the structure of $[Co(HL^0)_2Cl(H_2O)]^+$. The thermal ellipsoids enclose 50% probability.

The N(102)–Co–N(101) and N(202)–Co–N(201) bite angles, 75.51(8) and 75.31(7)° respectively, are similar to those found in dinuclear nickel(II) and copper(II) compounds with the related ligand 3,5-bis(2-pyridyl) pyrazole (hereafter abbreviated as Hbpypz): 77.8(1)° in $[Ni_2(bpypz)_2(MeOH)_4]Cl_2 \cdot 2H_2O$ (**4**), 79.8(2)° in $[Cu_4(bpypz)_4(H_2O)_4](NO_3)_4 \cdot 4H_2O$ [8], 80.3(2)° in $[Cu_4(bpypz)_4(ClO_4)_4] \cdot 2H_2O$ [10] and in a mononuclear Ag(I) compound 70.7(4)° [10].

The ligand HL^0 is not completely planar. The pyridyl and phenyl groups are slightly twisted with respect to the pyrazole ring with different dihedral angles for the two ligands: in ligand 1, the py–pz angle is 3.87(9)°, the ph–pz angle is 18.60(9)° and the py–ph angle is 14.92(9)°; while in ligand 2, the py–pz angle is 9.18(8)°, the ph–pz angle is 7.50(9)° and the py–ph angle is 16.48(8)°. The dihedral angle between ligand mean planes is 89.21(6)° and 94.88(9)° between pz1 and pz2. The phenyl rings are on opposite sites of the coordination sphere.

Two cations, related by an inversion centre, are linked by two NH–Cl hydrogen bonds and OH–OH–Cl additional hydrogen bonds involving two non-coordinated water molecules. These dimers and two non-coordinating Cl ions are also bonded by hydrogen bonds, yielding infinite chains parallel to the crystallographic vector *a* (Table 4, Fig. 4).

4. Conclusions

The study of the coordination of 3-phenyl-5-(2-pyridyl)pyrazole (HL^0) and 3-phenyl-5-(6-methyl-(2-pyridyl)pyrazole (HL^1) to Co(II) has revealed the formation of $Co(HL)X_2$ and $Co(HL)_2X_2$ compounds.

The conductivity measurements and spectroscopic data of the complexes are consistent with mononuclear structures where neutral HL pyrazole ligands coordinate the metal centre in a bidentate form. The electronic spectra of the compounds in methanol suggest that the geometry of the complexes is octahedral, whereas experiments in acetonitrile agree with the coexistence of tetrahedral and octahedral species in solution. Diffuse reflectance spectra have shown that $Co(HL)X_2$ complexes are tetrahedral and that $Co(HL)_2X_2$ are octahedral in the solid state. The X-ray structure of the compound $[Co(HL^0)_2Cl(H_2O)]Cl$ indicates that the coordination of metal in $Co(HL)_2X_2$ complexes is octahedral and that the anions which can be replaced by solvent molecules in the coordination sphere of Co(II) are labile, in agreement with the conductivity results. These results reveal that the ligands HL^0 and HL^1 are appropriate candidates for studies on the coordination of Zn^{2+} centres in order to provide models of zinc metalloenzymes. The geometry of Zn^{2+} in biological systems has proved to be crucial for its biological activity [38].

Supplementary data

Additional material, consisting of fractional atomic coordinates, displacement parameters, observed and calculated structure factors and complete lists of bond distances and bond angles are available from the CCDC, deposition number 134331. Copies of the data can be obtained free of charge on application to Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

Abstract

$Yb(H_2PO_2)_3$ crystallizes in space group $C2/m$. Planar rectangular arrays of Yb^{3+} ions are doubly bridged by hypophosphite ions in the *b* direction and singly bridged in the *c* direction, giving rise to a stacking of corrugated layers in the crystal structure. The YbO_6 site symmetry is C_{2h}, but not far from D_{4h}. The vibrational spectra of the hypophosphite anion have been interpreted in detail using unit cell group analysis and are shown to be consistent with the crystallographic data. The 10 K electronic absorption spectrum confirms the presence of two non-equivalent Yb^{3+} ions situated at centrosymmetric sites in the unit cell. For the first time, the two-centre transitions in the vibronic sidebands have been assigned to the excitation of individual unit cell group modes, showing a one-to-one correspondence with the vibrational spectra. The importance of moiety mode–hypophosphite mode couplings, and of Yb^{3+}–hypophosphite interactions of the type quadrupole–dipole, or higher, is indicated in the interpretation of the intensities of the cooperative vibronic transitions. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

We have recently reported the syntheses, crystal structures and spectroscopic behaviour of anhydrous and hydrated lanthanide hypophosphite complexes $Ln(H_2PO_2)_3$ (Ln = La, Pr, Nd) and $Ln(H_2PO_2)_3 \cdot H_2O$ (Ln = La, Pr) [1,2]. In both series of compounds, the lanthanide ion is eight-coordinate and hypophosphite ions bridge adjacent metal ions to give infinite chains, with additional one-oxygen atom bridges linking the chains in the former series. The structures of the hydrated Ln = La, Eu complexes have in fact been reported some time ago [3,4]. More recently, Seddon et al. [5,6] found that the reactions between $Ln(NO_3)_3$ and NaH_2PO_2 give, with controlled oxidation, the formation of $[Ln(H_2PO_2)(HPO_3)(H_2O)_n] \cdot nH_2O$. These authors reported two distinct types of anhydrous lanthanide hypophosphite: $Pr(H_2PO_2)_3$ type [5], with the lanthanide ion exhibiting eight-coordination as in $La(H_2PO_2)_3$; $Dy(H_2PO_2)_3$ type [6], with six-coordination for the smaller Ln^{3+} ion. Although the space group of $Dy(H_2PO_2)_3$ was equivalent to that previously reported for $Er(H_2PO_2)_3$ [7], there were important differences between the two determinations, such as large disparities between the Er(1)–O axial and equatorial bond distances (2.32 and 2.08 Å), as opposed to fairly similar Dy(1)–O bond distances (2.243 and 2.246 Å). We therefore decided to investigate the structure of the anhydrous lanthanide hypophosphite at the end of the series, which is expected to have the smallest Ln–O bond distances, $Yb(H_2PO_2)_3$ (hereafter, $Yb(hyp)_3$), in order to attempt to resolve these discrepancies. In addition, the spectral characteristics expected for the structural type $Yb(hyp)_3$, which are different from those of earlier members of $Ln(H_2PO_2)_3$ (Ln = La, Nd, Pr [2]), were of particular interest to us. The vibrational and electronic spectra of $Pr(H_2PO_2)_3$ have been assigned in detail [2], and both the different coordination geometry and the presence of non-equivalent Yb^{3+} ions in the unit cell of $Yb(hyp)_3$ would be expected to provide spectral manifestations. $Pr(H_2PO_2)_3$ was not found to be a suitable system for the investigation of vibronic transitions in the electronic spectra of lanthanide ions [2] because of overlapping electronic transitions, and the presence of obscuring impurity bands due to Nd^{3+}. The simple energy level structure of Yb^{3+}, together

PII S0277-5387(00)00333-8

with the ability to obtain large single crystals of $Yb(hyp)_3$, enabled a more detailed study to be undertaken herein of two-centre vibronic transitions.

2. Experimental

2.1. Synthesis of $Yb(hyp)_3$

$Yb(hyp)_3$ was prepared by dissolving 1 g (0.0025 mol) Yb_2O_3 (Strem Chemicals, 99.9%) in 9 cm^3 of 37% hydrochloric acid (Riedel-de Haën, RG) with heating and stirring in a 100 cm^3 beaker. After complete dissolution, 10 cm^3 of 50% hypophosphorous acid (Riedel-de Haën, RG) was added into the solution. The solution was then placed inside a desiccator for crystallization to occur at room temperature. Large crystals, up to several centimetres in length, and small needles were obtained from different preparations, and both were shown to be the same compound by X-ray examination.

2.2. Analytical results

Qualitative analysis of a single crystal of $Yb(hyp)_3$ by a Jeol T300 scanning electron microscope using electron microprobe analysis, showed only the presence of the elements Yb and P. Elemental analyses for Yb and P were carried out, after dissolution of the crystals in dilute nitric acid, using a Perkin-Elmer Plasma 1000 inductively coupled plasma atomic emission spectrometer. H was determined by a Leco 900 CHN-analyser. Fluorolube mull IR spectra showed the compound to be anhydrous.

Anal. Calc. for $Yb(hyp)_3$: Yb, 47.02; P, 25.25; H, 1.64. Found: Yb, 49.0 ± 0.8; P, 23.2 ± 0.4; H, 1.61 ± 0.03.

2.3. Spectroscopic measurements

Infrared Nujol and fluorolube mull spectra (resolution 2 cm^{-1}) were recorded at 90 and 295 K over the range 400–4000 cm^{-1} using Bomem MB120 and Perkin-Elmer PE1600 spectrometers. Raman spectra were recorded at 295 K by a Spex 1403DM system using <20 mW of 514.5 nm argon ion radiation. Electronic absorption spectra in the mid- and near-IR regions (4000–13500 cm^{-1}) were recorded as previously described [8] by a Biorad FTS65A wide-range spectrometer equipped with PbSe and Si detectors, at temperatures down to 10 K, at the resolution 2 cm^{-1}. A Glann-Taylor polarizer was employed to select polarizations parallel and perpendicular to the *b* crystal axis. The crystal was oriented according to the locations of the faces determined by X-ray methods on a smaller crystal.

2.4. X-ray analyses

The details of the crystal parameters, data collection and structure refinement are given in Table 1. The structure was solved by the direct method and refined by full-matrix least-squares on F^2 using the Siemens SHELXTL-93 (PC Version) package of crystallographic software [9]. All non-hydrogen atoms were refined with anisotropic thermal parameters. A distance restraint, which refined to 1.468(5) Å, was applied to all P–H bonds with respect to the coordinates of the hydrogen atoms.

Table 1
Crystal data and structure refinement for $Yb(hyp)_3$

Formula	$Yb(H_2PO_2)_3$
Crystal habit	colourless needle
Crystal size (mm)	$0.03 \times 0.04 \times 0.40$
Formula weight	368.00
Temperature (K)	293(2)
Wavelength (Å)	0.71073

Theta range for data collection (°)	2.86–42.50
Limiting indices	$0 \le h \le 27,\ -10 \le k \le 0,\ -22 \le l \le 19$
Reflections collected/unique	3237/3149 ($R_{int} = 0.0185$)
Completeness to $\theta = 42.50°$ (%)	99.7
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	3149/5/70
Goodness-of-fit on F^2	1.039
Final R indices ($I > 2\sigma(I)$)	$R_1 = 0.0350$, $wR_2 = 0.0943$
R indices (all data)	$R_1 = 0.0584$, $wR_2 = 0.1076$
Extinction coefficient	0.0072(4)
Max. and min. shift	0.003 and 0.000
Largest difference peak and hole (e Å^{-3})	1.609 and -2.544

3. Results

3.1. Crystal structure of $Yb(hyp)_3$

The atomic coordinates and thermal parameters are listed as supplementary data. Bond lengths and bond angles are given in Table 2.

The crystal structure of $Yb(hyp)_3$ contains two independent ytterbium ions and three independent hypophosphite anions. The Yb(1) and Yb(2) atoms occupy different special positions of site symmetry $2/m = C_{2h}$. All three $H_2PO_2^-$ groups are located in mirror planes (Fig. 1). However, two $H_2PO_2^-$ groups (those centred at P(1) and P(2) and designated as such for subsequent discussion) each have the PH_2 fragment lying in the crystallographic mirror plane (and hence the O–P–O bond angle is bisected by this plane),

Table 2

[a] Symmetry transformations used to generate equivalent atoms: #1 $x, -y, z$; #2 $x, -y+1, z$; #3 $x, -y-1, z$.

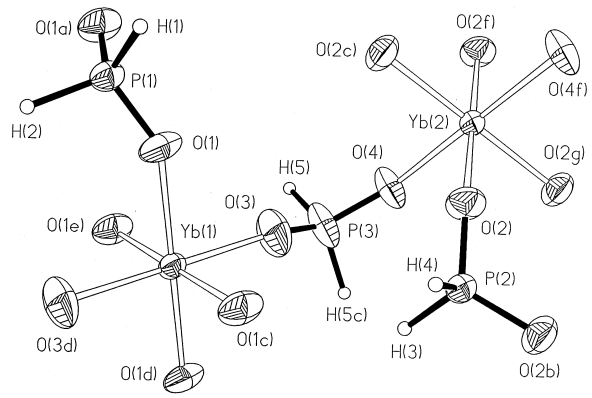

Fig. 1. Three independent hypophosphite groups and coordination environment about the ytterbium ions with atom labelling scheme. The non-hydrogen atoms are represented by thermal ellipsoids at the 50% probability level. Symmetry transformations: a $x, 1-y, z$; b $x, -1-y, z$; c $x, -y, z$; d $1-x, -y, -z$; e $1-x, y, -z$; f $1-x, -y, 1-z$; g $1-x, y, 1-z$.

whereas the third (designated as P(3)) has the PO_2 fragment lying in the crystallographic mirror plane. As seen from Fig. 2, the $H_2PO_2^-$ groups of type P(1) form double bridges between adjacent ytterbium atoms of type Yb(1) to form an infinite chain running parallel to the *b* axis. In an analogous manner, another chain is constructed from $H_2PO_2^-$ groups of type P(2) and ytterbium atoms of type Yb(2). These two kinds of chain are arranged alternately and cross-linked by $H_2PO_2^-$ groups of type P(3) to generate a corrugated layer as illustrated in Fig. 2. The crystal structure is composed of a stacking of such layers, whose mean planes correspond to the (200) family of planes, as shown in Fig. 3.

The coordination geometries of Yb(1) and Yb(2) are of distorted D_{4h} symmetry, each with two sets of Yb–O bond distances. The O–Yb–O angles are between 89.2 and 90.6°. These results are consistent with the study of Seddon et al. on $Dy(H_2PO_2)_3$ [6], but not with that of Aslanov et al. on $Er(H_2PO_2)_3$ [7]. From interpolation of the plot of Ln–O bond distance against ionic radius of Ln^{3+} (Ln = Dy, Yb), the mean Er–O bond distance is expected to be 2.22 Å, close to the average value 2.29 Å from [7]. However, the precision of measurement of individual Er–O bond distances in [7] is poor. The P(1)–O(1) and P(2)–O(2) bond distances in $Yb(hyp)_3$ are each about 0.4% shorter than the corresponding distances in $Dy(H_2PO_2)_3$, whereas the hypophosphite ion P(3) which bridges the non-equivalent Ln^{3+} ions has slightly longer ($<0.4\%$) P–O bond distances in $Yb(hyp)_3$.

The comparison of the mean Yb–O bond distance with those for other hypophosphite complexes of the six-coordinate group I cation Na^+ [10], group IIA cation Ca^{2+} [11] and group IIB cation Zn^{2+} [12] shows the trend of shorter M–O distances with decreasing ionic radius of M^{n+}. Each of these systems exhibits a range of P–O bond distances [10–

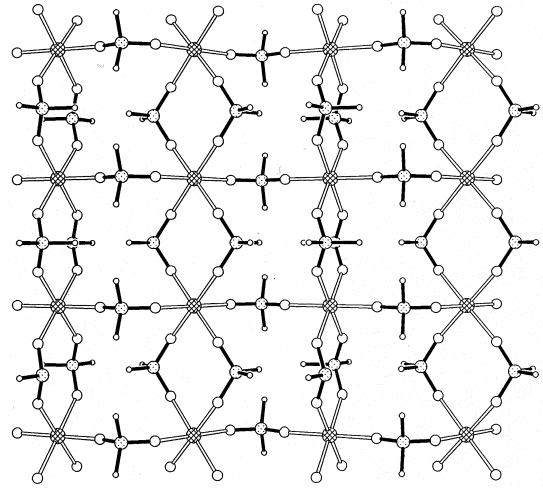

Fig. 2. A corrugated layer in the crystal structure of $Yb(H_2PO_2)_3$. The *b* axis is vertical, the *c* axis runs from left to right, and the mean plane of the layer is normal to the *a** axis. Starting from the left side of this figure, the structural motifs repeat in the following order: infinite chain built of Yb(1) and P(1), bridging P(3) groups, and infinite chain built of Yb(2) and P(2).

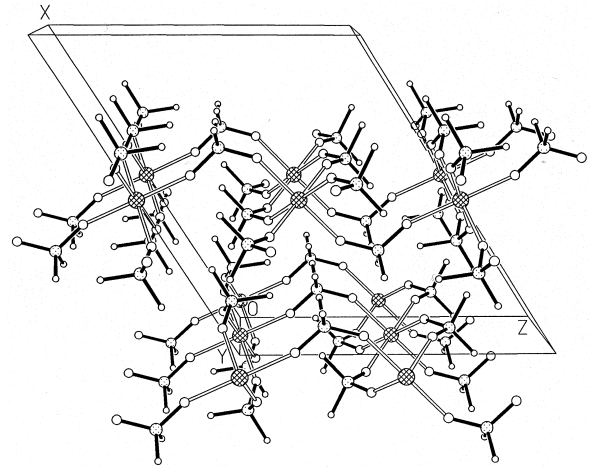

Fig. 3. Packing of adjacent corrugated layers in the crystal structure of $Yb(H_2PO_2)_3$. The origin of the unit cell lies in the lower left corner, with *a* pointing upward at a slant, *b* toward the reader, and *c* from left to right.

12], with values between 1.482–1.513 Å. The P(1)–O(1) and P(2)–O(2) distances in $Yb(hyp)_3$ fall within this range. However, the P(3)–(O) distances for the hypophosphite ion bridging the Yb(1) and Yb(2) chains are much shorter, in agreement with those reported for $Dy(H_2PO_2)_3$, and explicable by the longer O(hyp)–Ln distances in these cases. The Yb–O distances in $Yb(hyp)_3$ (ca. 2.2 Å) are much shorter than the Ln–O distances in the eight-coordinate earlier members of the series Ln = La, Pr (Ln–O between 2.4–2.6 Å).

3.2. Vibrational spectra of $Yb(hyp)_3$

Deuteration studies [13–15], the use of polarized radiation [16,17] and normal coordinate analyses [14,15,18] have enabled firm assignments to be made for the nine normal modes of vibration of the hypophosphite ion. The presence of three non-equivalent hypophosphite ions in the Bravais cell, and the lowering of free hypophosphite ion symmetry from C_{2v} to the $m = C_s$ site symmetry, give rise to multiplicity of bands and changes in intensity in the IR and Raman spectra. The unit cell group (UCG) analyses for the hypophosphite anions, presented in Table 3, show that the vibrations of the ions P(1) and P(2) transform similarly, giving rise to one IR active and one Raman active UCG mode for each parent ion vibration. The a_1 and a_2 mode irreps of P(3) transform similarly to those of P(1) and P(2), but b_1 and b_2 mode irreps transform differently. Mixing of UCG modes of the same symmetry species may occur, and thus each parent ion mode may lead to the appearance of three IR and three Raman bands.

Under low resolution, the IR spectrum of $Yb(hyp)_3$ is similar to that given by Seddon et al. for type C anhydrous lanthanide hypophosphites [6]. However, more detail is resolved under higher resolution, and a general assignment of the room temperature IR bands, together with those in the Raman spectrum, is given in Table 4. Since no more than three IR and three Raman bands are observed for each hypophosphite mode, the results are consistent with the UCG analysis. However, the complexity of the spectrum, together with overlapping of bands, does not enable more detailed assignments to be made.

The IR spectra are more clearly resolved at lower temperatures, and patterns of three bands for each parent $H_2PO_2^-$ mode are more readily apparent. For example, Fig. 4 shows the P–H stretch region of the IR spectrum at 90 K. The lowest

7	4790	R2390 + IR2400 = 4790; R2380 + IR2409 = 4789
8	4796	R2380 + IR2415 = 4795; R2398 + IR2400 = 4798
9	4804	R2390 + IR2415 = 4805
10	4810	R2380 + IR2427 = 4807; R2412 + IR2400 = 4812
11	4817	R2426 + IR2390 = 4816; R2390 + IR2427 = 4817
12	4821	R2412 + IR2409 = 4821; R2426 + IR2395 = 4821
13	4828	R2426 + IR2400 = 4826; R2412 + IR2415 = 4827
14	4832	R2417 + IR2415 = 4832
15	4849	R2426 + IR2427 = 4853

[a] The energies (in cm^{-1}) of the fundamental modes are taken from the 90 K IR (2390, 2395, 2400, (2409?), 2415, 2427) and 80 K Raman (R) (2380, 2390, 2398, 2412, 2417, 2426) spectra. Alternative assignments are possible, but not presented, in many cases. As in other hypophosphite systems [2], Fermi-resonance enhanced combination bands are observed to low energy of the fundamental P–H stretching modes. These weak bands are at 2373 and 2348 cm^{-1} (IR) and 2298 cm^{-1} (R) at low temperatures.

energy bands (lines 1, 2: 2348, 2373 cm^{-1}) are assigned to Fermi-resonance enhanced combination bands, whereas the remaining bands (lines 3–7) between 2390 and 2427 cm^{-1} correspond to the UCG modes derived from ν_s(P–H) and ν_{as}(P–H). One exception to the three-band pattern in the IR spectrum is observed: four bands are clearly resolved in the ν_7 region. In this case, the lowest energy band (801 cm^{-1}) is again assigned to a Fermi-resonance, this time involving $\nu_4 + \nu_s$(Yb–O).

The first harmonic region of the P–H stretch was studied at 10 K using an oriented single crystal (Fig. 5), in order to confirm the assignments of the P–H stretch UCG modes. In all cases, the observed features can be assigned to the combination of one gerade and one ungerade UCG mode (Table 5). In addition, the polarization behaviour is in general agreement with the analysis given in Table 3, since combination/overtone modes of b_u (a_u) symmetry are expected in the perpendicular (parallel) spectrum. Whereas the transformation behaviour from the free ion to the UCG is the same for ν_1 ν_s(P–H) at all three of the hypophosphite sites, that of ν_6 ν_{as}(P–H) differs for site P(3), compared with P(1) and P(2). Thus, for example, the highest energy band (line 15), which must correspond to the overtone of the symmetric P–H stretching mode, is expected to be of $a_g + b_u = b_u$ symmetry. The overtone band $2\nu_6$ ν_{as}(P–H) (line 6) is also of b_u symmetry, being a combination of either $a_g + b_u$ or $a_u + b_g$ modes. However the combination bands $\nu_6 + \nu_1$ (lines 7–10) are of mixed polarization, since they may correspond to a_u and b_u symmetry. The temperature shifts from room temperature to 10 K are appreciable for bands in this region, being up to 50 cm^{-1} (for the $2\nu_1$ ν_s(P–H) band located at 4799 cm^{-1} at 295 K).

3.3. Electronic absorption spectrum of Yb(hyp)$_3$: pure electronic transitions

The electronic energy level scheme of the f^{13} ion Yb^{3+} is simple, consisting of two LSJ terms $^2F_{7/2}$ (ground state term) and $^2F_{5/2}$ separated by ca. 10000 cm^{-1}. The coordination

[a] The electronic ground state is the Kramers doublet corresponding to $\Gamma_6(O_h)$ in all cases.

Table 7
Electronic energy level schemes of Yb^{3+} in octahedral ($Cs_2NaYbCl_6$) and distorted octahedral ($Yb(hyp)_3$) symmetry environments at 10 K

SLJ term manifold	O_h irrep	Experimental energy (cm^{-1})	
		$Cs_2NaYbCl_6$ [19]	$Yb(hyp)_3$
$^2F_{7/2}$	Γ_6	0	0
	Γ_8	206	210, (331)
	Γ_7	572	
$^2F_{5/2}$	Γ_8	10248	site 1: 10296 (IA); site 2: 10302 (IB) (II) 10397
	Γ_7	10718	(III) 10938

geometry of this ion in $Yb(hyp)_3$ is that of a distorted octahedron, and the energy level scheme deduced in this study from the analysis of the 10 K single crystal absorption spectrum (Fig. 6, Table 6) is presented in Table 7. In octahedral symmetry, the transition to the lowest $^2F_{5/2}$ level, Γ_8, from the electronic ground state Γ_6, is magnetic dipole (and electric-quadrupole) allowed, whilst that to the further excited state, Γ_7, is electric-quadrupole allowed. For the two non-equivalent Yb^{3+} ions at C_{2h} sites in the unit cell of $Yb(hyp)_3$, there are several modifications, including the splitting of the Γ_8 Kramers quartet state into two Kramers doublets (these states are simply labelled I and II herein). In addition, the presence of two Yb^{3+} sites leads to a doubling of bands throughout the spectrum. This splitting is only resolved for the lowest energy transitions, to the Kramers doublets labelled IA, IB (split by 6 cm^{-1}). From the room temperature spectrum, hot bands are located at 175 cm^{-1} (and, less certainly, at 339 cm^{-1}) to high energy of the pure electronic transitions. At 120 K, these bands shift to 210 and 331 cm^{-1}, respectively, to high energy of the pure electronic transitions.

Owing to the orthogonal orientations of the Yb^{3+} ions at sites I and II, little additional information was available from polarized electronic absorption spectra. However, the transition to state III is relatively stronger in the polarization perpendicular, rather than parallel, to the *b* crystal axis. All of the pure electronic transitions in the absorption spectrum are electric-dipole forbidden since the Yb^{3+} ions are situated at centrosymmetric sites. The transition to the parent $\Gamma_7(O_h)$ state III acquires magnetic dipole intensity at the C_{2h} site. The total oscillator strength of the transitions IA, IB and II is 3.5×10^{-8}. This value may be compared with the calculated magnetic dipole oscillator strength of the parent ($^2F_{7/2}$) $\Gamma_6\rightarrow\Gamma_8$ ($^2F_{5/2}$) transition in octahedral $Cs_2NaYbCl_6$, 2.1×10^{-7}.

3.4. Electronic absorption spectrum of Yb(hyp)$_3$: vibronic structure

The remaining (vibronic) structure in the absorption spectrum is enabled by the electric dipole vibronic mechanism. By analogy with the spectra of octahedrally coordinated

Yb^{3+} in $Cs_2NaYbCl_6$, the most prominent bands are expected to involve one quantum of the YbO_6 odd-parity moiety modes. These vibrations are near (in cm^{-1}) 257 (ν_3), 108 (ν_4) and 86 (ν_6) for the $YbCl_6^{3-}$ anion [20].The vibronic structure built upon IA, IB is overlapped by the intense transition to II, but a clearer comparison is available for the sideband of the transition to III. Prominent bands are located at 83, 113, 137, 233 and 261–289 cm^{-1} above the zero phonon lines which are assigned to the C_{2h} components of t_{2u}, t_{1u} and t_{1u} (O_h) modes respectively. The features between 261–289 cm^{-1} clearly correspond to ν_{as}(Yb–O) modes, and are located at similar energy in the IR spectrum (Table 4).

Many other weaker features are apparent in Fig. 6, and these correspond to two-centre vibronic transitions involving Yb^{3+} and the hypophosphite ions. The conventional theory for the interpretation of two-centre vibronic transitions has been given by Stavola et al. (for example [21–23]), with comparisons and further discussion by Dexpert-Ghys and Auzel [24]. Following the latter authors, the electric dipole strength for the qth polarized component of the transition in which the Yb^{3+} ion (A) undergoes an intraconfigurational $4f^1$ transition, $A_1 \rightarrow A_2$, and one quantum of vibration is simultaneously excited at the hypophosphite centre (B: i.e. $B_1 \rightarrow B_2$), is:

$$P^q_{A_1B_1,A_2B_2} = |\langle A_1B_1|M^q_A + M^q_B|A_2B_2\rangle|^2 \quad (1)$$

where M_A and M_B operate over the coordinates of A and B respectively. Dropping the superscript q in the following, assuming that A_1 and B_1 refer to ground states with reference energy zero, and denoting intermediate states by the subscript u, the matrix element in Eq. (1) is expanded, with rounded kets denoting zeroth-order states [2]:

$$\langle A_1B_1|M_A+M_B|A_2B_2\rangle = (A_1B_1|M_A+M_B|A_2B_2) \quad (2a)$$

$$-\sum_{u\neq 1}(A_u|M_A|A_2)(A_1B_1|H_{AB}|A_uB_2)\times(E_{A_u}+E_{B_2})^{-1} \quad (2b)$$

$$-\sum_{u\neq 2}(B_u|M_B|B_2)(A_1B_1|H_{AB}|A_2B_u)\times(E_{A_2}+E_{B_u})^{-1} \quad (2c)$$

$$-\sum_{u\neq 2}(A_1|M_A|A_u)(A_uB_1|H_{AB}|A_2B_2)\times(E_{A_2}+E_{B_2}-E_{A_u})^{-1} \quad (2d)$$

$$-\sum_{u\neq 1}(B_1|M_B|B_u)(A_1B_u|H_{AB}|A_2B_2)\times(E_{A_2}+E_{B_2}-E_{B_u})^{-1} \quad (2e)$$

The first term (Eq. (2a)) is non-zero in the presence of odd crystal field terms (but zero in the present case for Yb^{3+} at the C_{2h} site) but was omitted by Stavola and Dexter [22]. Following several assumptions, such as the neglect of Eqs. (2c) and (2e), and of interference effects when squaring matrix elements, and the restriction of H_{AB} to dipole–dipole coupling interactions; and approximations such as the averaging over polarization directions and over LSJ-multiplet states of A, a simple expression for the dipole strength of the cooperative absorption $A_1B_1 \rightarrow A_2B_2$ was derived [22]:

$$P_{A_1B_1,A_2B_2} = (10e^4/3\kappa^2R^6)(2J+1)^{-1} \times \Xi^2(1,2)|(B_1|D_B|B_2)|^2|(A_1|U^{(2)}|A_2)|^2 \quad (3)$$

where the symbols are defined in [22], and it is sufficient for our purposes to note that D_B is the electric dipole operator, so that the squared matrix element involving this operator is proportional to the intensity of the relevant IR bands.

The vibronic bands involving two-centre transitions are assigned in detail in Table 6, and the following conclusions can be drawn.

(i) The two-centre vibronic structure can be assigned in terms of the UCG modes observed in the IR spectrum, with no more than three UCG modes being observed for each parent hypophosphite ion mode. In most cases, since the gerade–ungerade UCG splittings are small, the assignments could equally apply to Raman modes, except for several vibronic bands where the corresponding Raman features are not clearly observed.

(ii) The two-centre vibronic structure is stronger on IA, IB than on II. However, some of the structure based on III is the most intense. The relative intensities of the vibronic bands thus do not parallel the relative intensities of the zero phonon lines. This shows the importance of Ln^{3+}–hyp interaction mechanisms other than dipole–dipole interaction. In particular, both of the transitions of Yb^{3+} in octahedral symmetry, $(^2F_{7/2})\Gamma_6 \rightarrow \Gamma_8$, Γ_7, are electric-quadrupole allowed, so that the quadrupole–dipole terms in Eqs. (2c) and (2e) are important, and may not be neglected in this case.

(iii) The relative intensities within groups of UCG modes do not parallel those observed in the IR or Raman spectra; furthermore, the relative intensities of structure involving different vibrational modes do not parallel those observed in the IR or Raman spectra.

(iv) The comparison of the relative intensities of P–O and P–H modes in the vibronic sidebands does not provide clear conclusions. The PH_2 rocking and twisting modes are generally weak, but the P–H stretching modes are clearly observed. The PO_2 symmetric stretch is generally prominent, together with another higher energy band which has been assigned to the PH_2 scissor. If this assignment is correct, then the PO_2 antisymmetric stretch, which is the strongest IR band, is only observed weakly in the vibronic sidebands. However, the mixing of the vibrational modes between 1050–1170 cm^{-1} is appreciable so that assignment to single parent ion modes may not be meaningful. Since the Yb–O and O–P bonds are adjacent, mixing of the symmetry coordinates of the lower energy $H_2PO_2^-$ modes (notably ν_4) with the YbO_6 moiety modes may be appreciable, leading to vibronic intensity via the one-phonon mechanism [20,25].

The consequence of the importance of Eqs. (2c) and (2e), which involve the (virtual) excited states of the ligand, is that *gerade* vibrations are involved. These processes are distinguished from that of Eq. (2a), in which totally symmetric Franck–Condon replicas appear in an electric dipole transition enabled at a non-centrosymmetric site. The gerade–ungerade classification does not apply to the *parent* hypophosphite modes, but the strongest features in the P–O and P–H stretching regions of the vibronic sidebands appear to be parent ion symmetric rather than antisymmetric modes.

4. Summary and conclusions

$Yb(hyp)_3$ differs from that of the earlier members of the lanthanide series $Ln(hyp)_3$ (Ln = La, Pr, Nd) in that the coordination number of Ln^{3+} is six and not eight. The structure consists of a stacking of corrugated layers, each comprising a planar rectangular grid of Yb^{3+} ions that are doubly bridged by hypophosphite ions in the *b* direction and singly bridged in the *c* direction. The $Er(hyp)_3$ structure reported in [7] is not entirely incorrect, but the bond lengths and angles are of low precision. The unit cell dimensions also require confirmation. Our $Yb(hyp)_3$ structure is isostructural with the $Dy(hyp)_3$ structure reported in [6], but the Ln–O bonds are significantly shorter (by about 0.03 Å) for Ln = Yb, and the coordination octahedra are more regular.

The vibrational spectra have been rationalized using unit cell group theory. The low temperature electronic absorption spectra show that two independent Yb^{3+} ions are situated at centrosymmetric sites in the unit cell of $Yb(hyp)_3$. Furthermore, rich two-centre vibronic structure is observed at up to 2430 cm^{-1} above the zero phonon line energies. As far as we are aware, this is the first conclusive report of the observation of the same vibrational unit cell group modes in the electronic and vibronic spectra. We have simulated the relative intensities of the two-centre vibronic bands under a model which employs Eqs. (2b) and (2d), and the agreement is poor. Some of the reasons have been highlighted: the Yb^{3+}–hyp interaction terms of the type quadrupole–dipole are important, and mixing of YbO_6 internal modes with the lower energy hypophosphite modes occurs. We are presently investigating a quantitative description of the results.

Supplementary data

Further details of the crystal structure determination can be ordered from Fachinformationszentrum Karlsruhe, 76344, Eggenstein-Leopoldshafen, under the depository number CSD-410976.

Abstract

The complexes [*triangulo*-Hg_3(μ-dppm)$_3X_n$]$^{(4-n)+}$ (X = Cl, Br and I, n = 1, 2) are formed in a small extent upon addition of halides to the cationic subvalent cluster [*triangulo*-Hg_3(μ-dppm)$_3$]$^{4+}$, whereas $SeCN^-$ and CN^- cause quantitative fragmentation. The cluster [*triangulo*-Hg_3(μ-dppm)$_3$(SCN)$_2$]$^{2+}$ is produced either by the reaction of [*triangulo*-Hg_3(μ-dppm)$_3$]$^{4+}$ with thiocyanate or via reduction of a mixture of Hg(SCN)$_2$, [Hg(Me_2SO)$_6$](O_3SCF_3)$_2$ and 3 mequiv. of dppm with elemental mercury. The X-ray structure of [Hg_3(μ-dppm)$_3$(SCN)$_2$](O_3SCF_3)$_2$ shows a Hg_3 triangle (Hg–Hg distances 286.60(14), 279.32(12) and 281.2(2) pm) spanned by three dppm ligands. The thiocyanate ions are positioned nearly parallel to the Hg_3 plane in the two cavities formed by the Hg_3 group at the bottom and the phenyl groups of the dppm ligands as the walls (Hg1–S1 277.5(6) and Hg3–S2 278.4(6) pm). Phosphorus-31 solution NMR indicates a rapid rotation of the SCN^- ligands about the Hg_3 triangle within the cavity. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Mercury; Clusters; Thiocyanate; Host–guest chemistry

1. Introduction

The subvalent mercury cluster $[Hg_2]^{2+}$ tends to disproportionate into elemental Hg and Hg^{2+} in the presence of strong Lewis bases. The driving force for this disproportionation has been suggested to be the population of antibonding orbitals by ligand donated electrons. The subvalent cyclic $[Hg_3]^{4+}$ cluster with the oxidation number of +4/3 accommodates strong Lewis bases as is demonstrated by the existence of the phosphine complex [*triangulo*-Hg_3(μ-dppm)$_3$]$^{4+}$ with six phosphorus donor atoms [1]. This cluster has been reported with the weakly coordinating anions SO_4^{2-}, SiF_6^{2-}, PF_6^-, $O_3SCF_3^-$ or $O_3SCH_3^-$ [1,2]. The [Hg_3(μ-dppm)$_3$]$^{4+}$ clusters are bifunctional recognition hosts and two anions of all these clusters are found inside the two cavities formed by the 12 phenyl groups of the dppm ligands and the Hg_3 triangle [2]. We were interested in the stability of [*triangulo*-Hg_3(μ-dppm)$_3$]$^{4+}$ towards stronger Lewis bases and report in this paper on the reactions with halides and pseudohalides. The feasibility of the coordination of additional strong donors was nurtured by the existence of [*triangulo*-Hg_3(μ-dmpm)$_4$]$^{4+}$ (dmpm = bis(dimetylphosphino)methane) in which eight strong donor atoms are coordinated to the $[Hg_3]^{4+}$ system [3]. Chloride coordinated to a $[Hg_3]^{4+}$ system is present in the mineral terlinguaite, an insoluble coordination polymer [4].

Halide capped M_3(μ-dppm)$_3$ complexes are quite common and the presence of the halides has been reported to organize M_3(μ-dppm)$_3$ systems [5,6].

2. Results and discussion

2.1. Reaction of [triangulo-Hg_3(μ-dppm)$_3$]$^{4+}$ with halides

Halide adducts [*triangulo*-Hg_3(μ-dppm)$_3$X]$^{3+}$ or [*triangulo*-Hg_3(μ-dppm)$_3X_2$]$^{2+}$ (X = Cl, Br, I) are formed in a small extent in addition to Hg(II)–dppm–halide complexes and elemental mercury upon addition of tetraalkylammonium halides to [*triangulo*-Hg_3(μ-dppm)$_3$]$^{4+}$, or upon reaction of HgX_2, [Hg(Me_2SO)$_6$](O_3SCF_3)$_2$ and 3 mequiv. of dppm

PII S0277-5387(00)00335-1

with elemental mercury. This is indicated by ^{31}P solution NMR spectroscopy showing two signals attributable to the complexes containing one or two halide ions, respectively, in a shift region at higher frequencies compared with Hg(II)–dppm–halide complexes. The concentrations were too low to observe ^{199}Hg NMR spectra or ^{31}P NMR signals of isotopomers containing ^{199}Hg nuclei. All attempts to isolate the halide adducts in the solid state produced dinuclear mercury(II) complexes of the type $[Hg_2(\mu\text{-dppm})_2(\mu\text{-X})X_2]^+$. The crystal structure of $[Hg_2(\mu\text{-dppm})_2(\mu\text{-Br})Br_2](O_3SCF_3)$ is shown in Fig. 1 and is closely related to the corresponding chloride which was previously obtained by the reaction of $Pd(dppm)_2Cl_2$ with elemental mercury [7].

The low equilibrium concentrations of the halide adducts $[triangulo\text{-}Hg_3(\mu\text{-dppm})_3X]^{3+}$ and $[triangulo\text{-}Hg_3(\mu\text{-dppm})_3X_2]^{2+}$ are probably controlled by the rates of decomposition and formation of the $[Hg_3]^{4+}$ system as indicated in Scheme 1: intermediate displacements of dppm-phosphorus atoms by halide ions might produce species with monodentate dppm ligands. The stability of the $[Hg_3]^{4+}$ system in solution seems to be tied to the presence of at least three bridging dppm or related ligands. All attempts to stabilize the cluster by monodentate phosphines or mixtures of dppm and monodentate phosphines failed and hence the intermediates containing monodentate dppm are likely to fragmentate into Hg(II) complexes and elemental mercury.

2.2. Reaction of [triangulo-$Hg_3(\mu$-dppm)$_3$]$^{4+}$ with thiocyanate

2.2.1. Synthesis and NMR spectroscopy

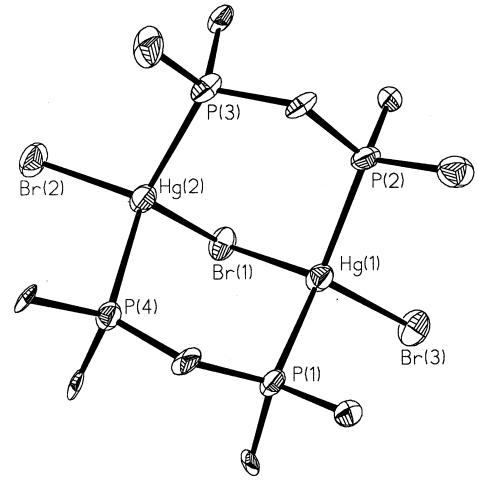
Treatment of $[triangulo\text{-}Hg_3(\mu\text{-dppm})_3](O_3SCF_3)_4$ with 2 mequiv. of KSCN gives $[triangulo\text{-}Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2$ (Eq. (1)), which was isolated as pale yellow crystals with good yield.

$$[Hg_3(\mu\text{-dppm})_3]^{4+} + 2SCN^- \rightleftharpoons [Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+} \quad (1)$$

This cluster is also formed via reduction of a mixture of $Hg(SCN)_2$, $[Hg(Me_2SO)_6](O_3SCF_3)_2$ and 3 mequiv. of dppm with elemental mercury according to Eq. (2).

$$[Hg(Me_2SO)_6](O_3SCF_3)_2 + Hg(SCN)_2 + 3dppm + Hg \rightleftharpoons [Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2 + 6Me_2SO \quad (2)$$

The coordination of the SCN^- ligands according to Eq. (1) is associated with a decrease in the ^{31}P chemical shift of ca. 10 ppm. Phosphorus-31 NMR spectroscopy shows the equivalence of all dppm phosphorus atoms in solution, demonstrating that, in contrast to the solid state structure (see below), the SCN^- ligands are not coordinated to individual Hg atoms on the NMR timescale, but are fluxional and undergo rapid intramolecular or intermolecular exchange between Hg atoms.



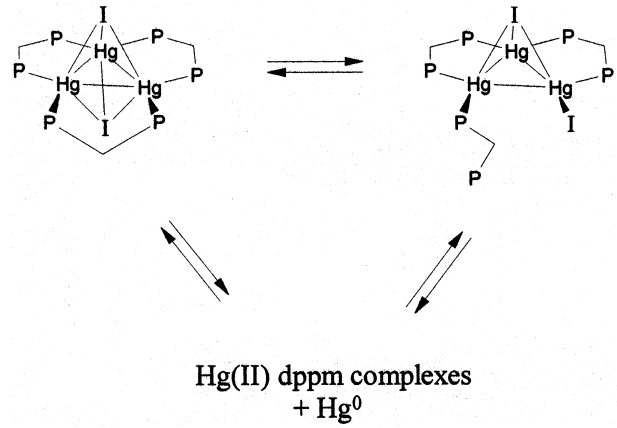


Fig. 1. Structure of $[Hg_2(\mu\text{-dppm})_2(\mu\text{-Br})Br_2]^+$. Selected interatomic distances (pm) and angles (°): Hg(1)–Br(1) 271.5(2), Hg(1)–Br(3) 260.2(2), Hg(2)–Br(1) 273.8(2), Hg(2)–Br(2) 259.1(2), Hg–P 247.6(4)–249.9(4), P(1)–Hg(1)–P(2) 122.48(12), P(1)–Hg(1)–Br(3) 107.85(10), P(2)–Hg(1)–Br(3) 108.45(10), P(1)–Hg(1)–Br(1) 109.66(9), P(2)–Hg(1)–Br(1) 105.29(10), Br(3)–Hg(1)–Br(1) 101.04(5), P(3)–Hg(2)–P(4) 124.49(12), P(3)–Hg(2)–Br(2) 110.05(10), P(4)–Hg(2)–Br(2) 107.31(9), P(3)–Hg(2)–Br(1) 107.97(10), P(4)–Hg(2)–Br(1) 104.15(10), Br(2)–Hg(2)–Br(1) 100.03(5), Hg(1)–Br(1)–Hg(2) 81.94(4).

Scheme 1.

The species containing one SCN^- ligand is present in solution in an equilibrium with $[Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+}$ and $[Hg_3(\mu\text{-dppm})_3]^{4+}$ according to Eq. (3): a low temperature (233 K) ^{31}P NMR spectrum of a solution of SCN^- and $[triangulo\text{-}Hg_3(\mu\text{-dppm})_3]^{4+}$ in the ratio of 1/1 consists of three signals at 54.0, 49.5 and 44.2 ppm, which are attributed to the species without, with one and with two SCN^- ligands.

$$2[Hg_3(\mu\text{-dppm})_3(SCN)]^{3+} \rightleftharpoons [Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+} + [Hg_3(\mu\text{-dppm})_3]^{4+} \quad (3)$$

The existence of only one ^{31}P NMR signal per species

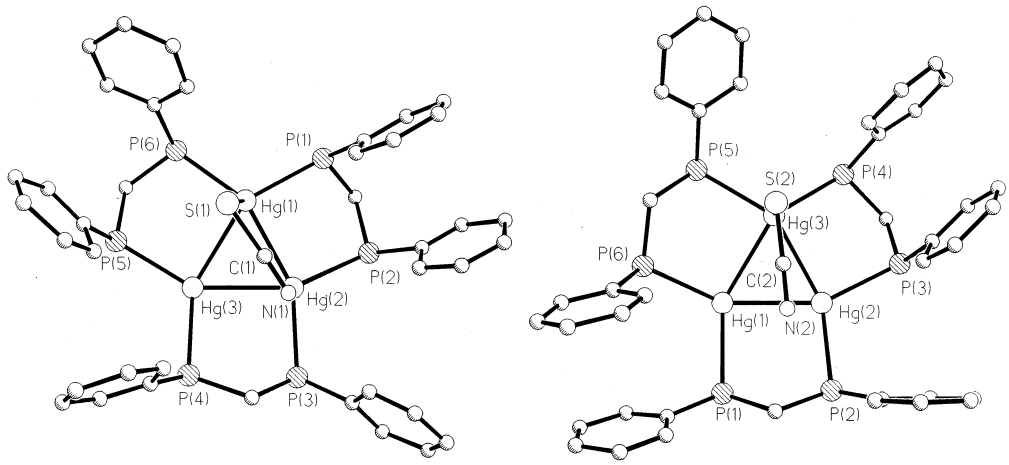

Fig. 2. Structure of $[Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+}$. Two projections show the position of the two SCN^- ligands within the cavities formed by the Hg_3 group at the bottom and the phenyl groups of the dppm ligands as the walls.

shows again the equivalence of the P atoms, but in this case an intermolecular exchange can be ruled out and the fluxionality must be caused by a rapid rotation of the SCN^- ligand about the Hg_3 triangle. At ambient temperature one broad signal indicates intermolecular SCN^- exchange between the species involved in the equilibrium Eq. (3). The species with one SCN^- ligand could not be isolated in the solid state.

2.2.2. Crystallography

The solid state structure of [*triangulo*-$Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2$ has been determined by X-ray diffraction. Fig. 2 shows the structure of the cluster cation. Selected distances and angles are presented in Table 1. The $O_3SCF_3^-$ counterions have no contacts to the cation within the van der Waals estimates. The three Hg atoms form a triangle, each side of which is spanned by a bridging dppm ligand to form a roughly planar $[Hg_3P_6]$ core. Two essentially linear SCN^- ligands are located inside the two cavities formed by the Hg_3 group at the bottom and the phenyl groups of the dppm ligands as the walls.

The Hg–Hg distances are 286.60(14), 279.32(12) and 281.2(2) pm resulting in a mean of 282.4 compared with a range of 271.7(2)–286.49(13) pm for the [*triangulo*-$Hg_3(\mu\text{-dppm})_3]^{4+}$ cluster with the anions SO_4^{2-}, SiF_6^{2-}, PF_6^-, $O_3SCF_3^-$ or $O_3SCH_3^-$ [1,2], 270.3 pm for the mineral terlinguaite, $Hg_4Cl_2O_2$ [4], and 266.2–269.6 pm for $Hg_9As_4O_{16}$ [8], which both possess Hg_3 moieties. The Hg–Hg distances in $[Hg\text{–}Hg]^{2+}$ complexes centre around 250 pm [9]; the clusters $[Hg_n]^{2+}$ ($n=3$, 4) and $[Hg_{3-\delta}]^+$ involve values of 255–270 pm [10–19]. In crystalline elemental mercury each atom has six nearest neighbours at 299 pm. Whereas the distances between Hg1–Hg2 and Hg2–Hg3 in [*triangulo*-$Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2$ are close together, the bond between Hg2 and Hg3, i.e. the mercury atoms coordinated by the SCN^- ligands, is distinctly longer. This is in keeping with [*triangulo*-$Hg_3(\mu\text{-dmpm})_4](O_3SCF_3)_4$, in which one edge of the Hg_3 triangle is doubly bridged by dmpm ligands and is significantly longer (295.53(14) pm) compared with the other two singly bridged edges [3]. In contrast, the M–M distances in [*triangulo*-$M_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ (M = Pd, Pt) are virtually unchanged upon addition of ligands. This indicates that an additional ligand binds to [*triangulo*-$M_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ using empty $6p_z$ orbitals of the metal atoms rather than empty σ* orbitals of the cluster [20].

The two SCN^- ligands are coordinated to different Hg atoms via the sulfur atoms. The distances between Hg and S of the SCN^- ligands are 277.5(6) and 278.4(6) pm, indicating a rather weak interaction when compared with other Hg–SCN complexes (236–273 pm) present in the Cambridge Crystallographic Data Base. For example, Hg–S distances of 256.6 and 257.4 pm have been reported for $Hg(PPh_3)_2(SCN)_2$ [21]. The coordination geometry of the SCN^- ligands is sketched in Fig. 3, showing the SCN^- groups to be nearly parallel to the Hg_3 plane. The orientation of the nitrogen atoms relative to the Hg_3 triangle is depicted in Fig. 2: the nitrogen atom N1 points to Hg2, i.e. the sole Hg atom which is not coordinated by sulfur donor atoms of the SCN^- ligands. The Hg2–N1 contact distance is 291 pm compared to the van der Waals sum of 296 or 319 pm when

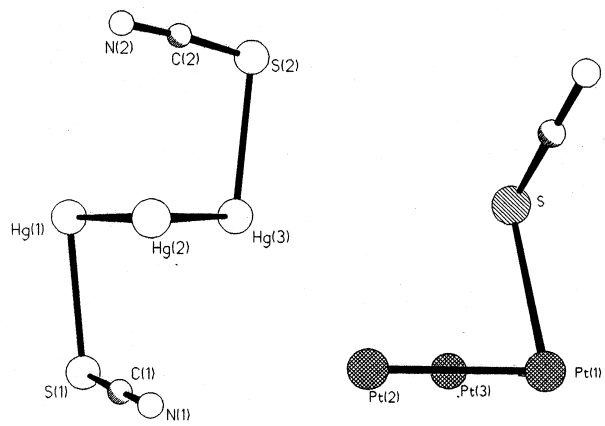

Fig. 3. The different coordination geometries of the SCN^- ligands relative to the M_3 triangles in $[Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+}$ and for the related cluster $[Pt_3(\mu_3\text{-CO})(SCN)(\mu\text{-dppm})_3]^+$. The dppm ligands and CO are omitted for clarity.

using a Hg radius of 150 or 173 pm [22]. N2 is located in between Hg1 and Hg3 and has Hg–N distances of 360 and 329 pm.

The Hg1–S1–C1 angle is 87.9(8)° which is somewhat smaller than Hg3–S2–C2 of 92.4(9)°, both showing values different from the Hg–S–C angle of ca. 100° found in most other Hg–SCN complexes in the Cambridge Crystallographic Data Base.

An essentially different coordination geometry of the SCN^- ligand relative to the M_3 triangle was observed for the related cluster $[Pt_3(\mu_3\text{-CO})(SCN)(\mu\text{-dppm})_3]^+$ which is also depicted in Fig. 3 [23]. This may be rationalized by the smaller size of the cavity caused by the smaller M–M and M–P distances for M = Pt compared with Hg: the tunnel spanned by the dppm phenyl groups in $[Pt_3(\mu_3\text{-CO})(SCN)(\mu\text{-dppm})_3]^+$ seems to be too small to allow a similar coordination geometry of SCN^- as in $[Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+}$.

The C–S bond lengths in [*triangulo*-$Hg_3(\mu\text{-dppm})_3(SCN)_2]^{2+}$ (159(3) and 167(2) pm) are in the range of non-coordinating SCN^- anions (160–170 pm).

The P atoms lie approximately in the plane defined by the Hg atoms. The Hg-Hg-P-C-P rings adopt envelope conformations with the methylene carbon at the flap. Two methylene groups lie above the Hg_3 plane and one below, causing four equatorial plus two axial and two equatorial plus four axial phenyl groups respectively positioned above the opposite faces of the Hg_3 triangle. The Hg–P distances do not show any peculiarities.

2.2.3. Mass spectrometry

FAB MS has been successfully applied for the characterization of the non-volatile, high molecular weight [*triangulo*-$M_3(\mu\text{-dppm})_3$] type clusters, e.g. [*triangulo*-$Ni_3(\mu_3\text{-L})(\mu_3\text{-I})(\mu\text{-dppm})_3]^{n+}$, {[*triangulo*-$Ni_3(\mu_3\text{-I})(\mu\text{-dppm})_3]_2(\mu_3,\mu_3,\eta^1,\eta^{1\prime}\text{-CN-R-NC})\}^{2+}$ [24] and [*triangulo*-$Hg_3(\mu\text{-dmpm})_4]^{4+}$ [3].

The FAB mass spectrum of [*triangulo*-$Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2$ showed a methanol solvate of the molecular ion at *m/z* 2200.1 with an isotopic distribution which agrees with the calculated envelope, and the formation of dppm at *m/z* 384 as base peak. The fragmentation patterns are dominated by multiple loss of anions, dppm or Hg. Fragments containing three Hg atoms are $Hg_3(dppm)_3(SCN)(O_3SCF_3)_2$, $Hg_3(dppm)_3(SCN)_2(O_3SCF_3)$, $Hg_3(dppm)_3(O_3SCF_3)_2$ and $Hg_3(dppm)_2(O_3SCF_3)_2$.

Interestingly, electrospray mass spectrometry turned out not to be suitable although it is a softer technique than FAB.

2.3. Reaction of [triangulo-$Hg_3(\mu\text{-dppm})_3]^{4+}$ with selenocyanate and cyanide

Treatment of [*triangulo*-$Hg_3(\mu\text{-dppm})_3]^{4+}$ with KSeCN results in a complete degradation of the subvalent Hg cluster and the mercury(II) complex $[Hg(dppmSe)_2]^{2+}$ [25] is identified as the main product. This is thought to be the result of a selenium transfer from selenocyanate to dppm producing dppm-selenides which do not stabilize the $[Hg_3]^{4+}$ cluster. Not surprisingly, cyanide also causes an immediate and complete redox disproportionation of the [*triangulo*-$Hg_3(\mu\text{-dppm})_3]^{4+}$ cluster.

3. Experimental

3.1. Instrumentation

The ^{31}P NMR spectra were recorded on a Bruker AC 200 spectrometer at 81.015 MHz and are referenced against external 85% H_3PO_4. Mass spectra were recorded on a Finnigan

MAT 95 instrument with the fast atom bombardment technique. Microanalyses were obtained from the Mikroanalytisches Laboratorium, Institut für Physikalische Chemie, Universität Wien.

3.2. Crystallography

Crystal data and details of structure solution and refinement are summarized in Table 2. For [*triangulo*-$Hg_3(\mu\text{-dppm})_3(SCN)_2](O_3SCF_3)_2\cdot 4CH_3OH$ only Hg, P, S, N and the O and F atoms of one trifluoromethanesulfonate anion were refined anisotropically owing to the poor crystal quality. The other trifluoromethanesulfonate anion is disordered over two positions (S3A, F1–3A, C3A, O1–3A and S3B, F1–3B, C3B, O1–3B) with an occupancy of 2/1. Two methanol molecules are disordered over two positions (C91, O91A–B and C92, O92A–B) with occupancies of 1/1 respectively, and one methanol molecule over three positions (C93A–C, O93A–C) with an occupancy of 1/1/1. One phenyl group of one dppm ligand is disordered over two positions (C41, C42–46A, C41, C42–46B) with an occupancy of 1/1.

3.3. Syntheses

The cluster [*triangulo*-$Hg_3(\mu\text{-dppm})_3](O_3SCF_3)_4$ and $[Hg(Me_2SO)_6](O_3SCF_3)_2$ were prepared as described previously [1,26].

3.3.1. Synthesis of [triangulo-$Hg_3(\mu$-dppm$)_3(SCN)_2$]-$(O_3SCF_3)_2$

A solution of KSCN (9.7 mg, 0.1 mmol) in 0.4 ml of CH_3OH is added in 50 μl steps to a stirred solution of [*triangulo*-$Hg_3(\mu\text{-dppm})_3](O_3SCF_3)_4$ (117.6 mg, 0.05 mmol) in 0.5 ml of CH_3OH. First, the colour changes from a pale to a more intense yellow, then the product precipitates as a pale yellow powder, which is dissolved by dropwise addition of CH_2Cl_2 and crystallized at −19°C as yellow prisms. Yield 65.4 mg (60%); m.p. 139–142°C (dec.). ^{31}P NMR (CH_2Cl_2/CH_3OH, 298 K): 44.8 ppm. *Anal*. Found: C, 44.07;

POLYHEDRON

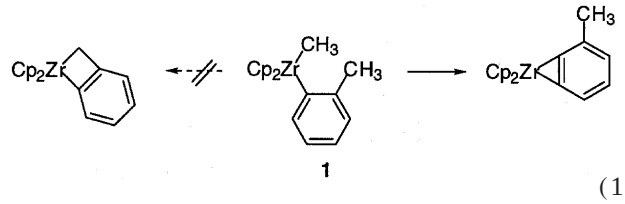
Regioselectivity of metallacycle formation via intramolecular CH activation

Kenneth M. Doxsee *, Jerrick J.J. Juliette

Department of Chemistry, University of Oregon, Eugene, OR 97403, USA

Received 6 July 1999; accepted 26 January 2000

Abstract



Carbometalation of alkynes by dimethyltitanocene affords vinyl complexes which serve as intermediates for the formation of titanacyclic products through subsequent hydrogen abstraction/methane elimination. Although multiple sites for hydrogen abstraction are present in the intermediate vinyl complexes, the hydrogen abstraction step is in most cases highly regioselective, leading to the formation of either titanacyclobutenes (via γ-H abstraction) or titanacyclopropanes (via β-H abstraction). Rotational isomerization, restricted in the case of larger vinyl group substituents, provides a simple and consistent explanation for the observed regioselectivities, and this effect is sufficiently pronounced to lead to preferential γ-aliphatic CH activation even in the presence of γ-aromatic hydrogens. The titanacyclopropanes may be alternatively formulated as allene complexes of titanocene. An independently prepared trimethylphosphine-ligated analog of 3-methyl-1,2-butadiene, representing the first titanocene allene complex to be reported, undergoes reductive coupling reactions with excess 3-methyl-1,2-butadiene and with alkynes. ©2000 Elsevier Science Ltd All rights reserved.

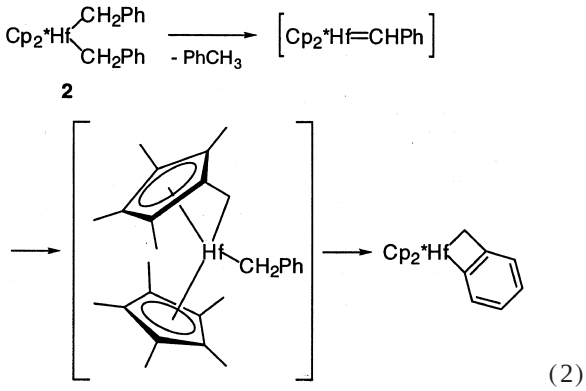
1. Introduction

Reactions involving the insertion of transition metals into carbon–hydrogen bonds continue to receive considerable attention, at least in part given their potential for the activation of hydrocarbons toward catalytic functionalization [1]. Numerous examples of both intermolecular and intramolecular CH bond activation have been reported, including the well known α- and β-hydride elimination processes [2,3] and related cyclometalation reactions of heteroatom-containing ligands [4–6]. Longer-range intramolecular CH activation reactions have also been documented. Thus, orthometalation reactions of arylphosphine [4–7] and arylsilane [8] complexes represent γ-elimination processes, and thermolysis of a Ta(V) aryloxide complex is reported to proceed via sequential *ε*-elimination processes [9,10]. For recent examples of δ- and *ε*-activation processes in aniline, benzylamine and phenethylamine complexes of palladium, see [11,12]. These longer-range activation reactions, however, remain uncommon in comparison with the seemingly ubiquitous α- and β-hydride elimination processes.

A sufficient body of information regarding intramolecular CH-activation reactions has been amassed to allow some generalizations to be drawn. Aromatic CH bonds appear to be more reactive toward such processes than aliphatic CH bonds, despite the higher bond strength of the aromatic CH bond. Thus, for example, (*o*-tolyl)(methyl)zirconocene (**1**) undergoes aromatic β-CH bond activation to produce an aryne complex rather than the isomeric benzometallacyclobutene which would be formed through activation of a benzylic γ-CH bond (Eq. (1)) [13]. Dibenzylhafnocene



1

(1)

complex **2** undergoes kinetic α-elimination, while the resulting 'tucked in' benzyl complex then reacts through activation of an aromatic γ-CH bond, forming a benzohafnacyclobutene (Eq. (2)) [14]. Similarly, Petasis and Bzowej have noted apparent α-elimination reactions of dibenzyltitanocene and related derivatives [15,16].

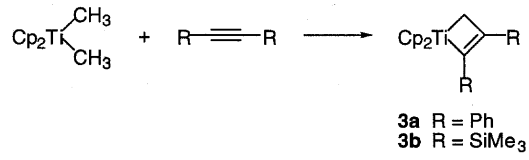
(2)

Teuben and co-workers have reported selective α-, β-, and δ-hydrogen elimination reactions of paramagnetic vanadium(III) dialkyls [17] (e.g., Eq. (3)) and several α- and

(3)

β-hydrogen elimination reactions of permethyltitanocene alkyls [18] (Eq. (4)). However, information is scarce

(4)

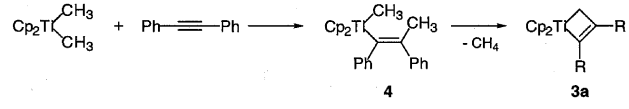


regarding the regiochemical preferences of intramolecular CH activation processes in which there is a less defined chemical difference between two (or more) potentially reactive sites, with the selective γ-elimination reactions of neopentyl platinum complexes providing perhaps the best known examples [19,20]. Interestingly, whereas the neopentyl platinum complexes undergo selective γ-elimination, tetraneopentyltitanium has recently been shown to undergo selective α-elimination [21].

In the course of our studies of the carbometalation reactions of dimethyltitanocene [22], which contrast with an early account reporting no thermal reaction between dimethyltitanocene and alkynes [23], we were afforded the opportunity to examine the intramolecular competition between two alternative sites for allylic CH activation, one representing a β-activation process and the other a γ-activation process [24]. Herein we present further studies of these competing allylic CH activation processes as well as an unusual example wherein allylic γ-CH activation is strongly favored over aromatic γ-CH activation.

2. Results and discussion

2.1. Selective γ-activation processes

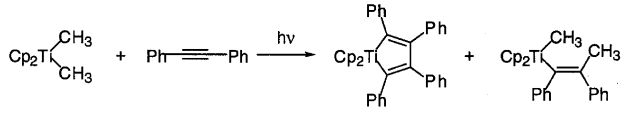


Diphenylacetylene and bis(trimethylsilyl)acetylene react cleanly with dimethyltitanocene in dry, deoxygenated benzene at moderate temperatures (65–80°C, 14–30 h) to produce the corresponding titanacyclobutenes (**3a**, R = Ph; **3b**, R = $SiMe_3$) in high yield (Eq. (5)) [22,25]. Although these

(5)

metallacycles may also be prepared through the addition of the alkynes to $Cp_2TiCH_2 \cdot Al(CH_3)_2Cl$ (Tebbe's reagent) [26], removal of the aluminum-containing byproducts can be problematic, reducing isolated yields of pure metallacycles. In contrast, the dimethyltitanocene route allows isolation of pure metallacycles in near-quantitative yield after a simple recrystallization while also avoiding the requirement for use of the highly air- and moisture-sensitive Tebbe's reagent. (In marked contrast, dimethyltitanocene may be isolated through standard bench top techniques, requiring no exclusion of air or moisture.)

Shorter reaction times in the diphenylacetylene reaction lead to formation of carbometalation product **4**, together with a small amount of the titanacyclobutene (Eq. (6)). Complex



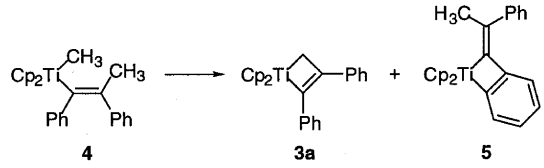
(6)

4, which may be isolated as a pure solid by crystallization at −20°C, serves as a precursor to titanacyclobutene **3a**, with thermolysis at ca. 80°C resulting in clean conversion to the metallacycle.

The allylic methyl group resonance appears at 1.48 ppm in the ^1H NMR spectrum of **4**, while the Ti–CH_3 group appears at −0.42 ppm. Similar upfield shifts are seen for other methyltitanocene complexes and may be attributed to an agostic interaction with a vacant titanium wedge plane orbital [27,28]. In the ^{13}C NMR spectrum of **4**, the allylic methyl resonance appears at 25.7 ppm and the Ti–CH_3 group at 50.3 ppm. High resolution mass spectral and elemental analytical data provide final confirmation of the proposed structure.

Both the carbometalation reaction and the subsequent methane elimination process are noteworthy. Carbometalation reactions of group 4 metallocene alkyl complexes are often sluggish, with formation of cationic alkyls typically used to accelerate the reactions [29,30]. Insertion reactions of dimethyltitanocene have scarcely been examined, although CO_2 and SO_2 insertions have been reported [31,32], and NO insertion reactions of dimethylzirconocene have also been noted [33]. The carbometalation of diphenylacetylene by dimethyltitanocene to form **4** is quite rapid. The reasons for the facility of this reaction are not clear, but may be rooted in the propensity of methyltitanocene derivatives to undergo Ti–CH_3 bond homolysis [34], with addition of CH_3• to the alkyne, followed by addition of the resulting vinyl radical to titanium providing a convenient pathway to the observed product.

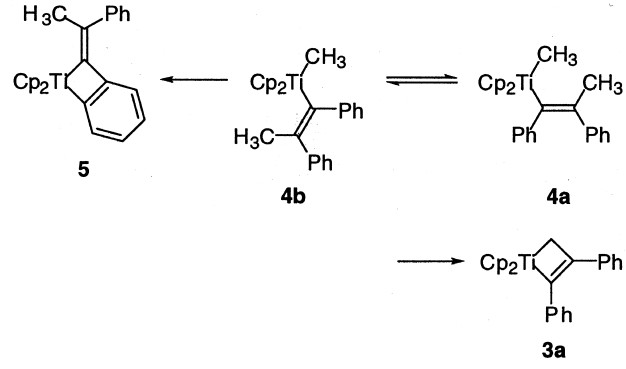
Vinyl complex **4** was previously reported as the minor byproduct in the photochemical reaction between dimethyltitanocene and diphenylacetylene, the major product of which was a titanacyclopentadiene formed through the reductive coupling of 2 equiv. of the alkyne by transiently generated titanocene (Eq. (7)) [35–37]. Formation of **4** in this reaction



(7)

perhaps provides circumstantial support for the radical pathway for its formation, given the likelihood of generation of methyl radicals under photolytic conditions, although direct thermal insertion via σ-bond metathesis [38] is not ruled out.

Given the generally preferred reactivity of aromatic CH bonds relative to aliphatic CH bonds, the formation of the titanacyclobutene from **4** is intriguing, especially since preferential activation of the γ-aliphatic position occurs in the presence of a γ-aromatic CH bond. This may point toward a radical mechanism for the CH activation process, with initial Ti–CH_3 bond homolysis followed by preferential abstraction of an allylic hydrogen by the resulting methyl radical and subsequent collapse to the metallacyclobutene.

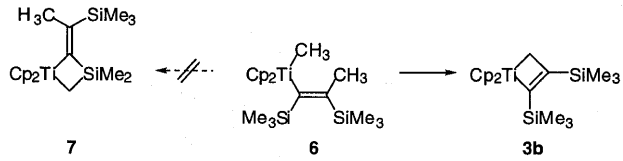


Formation of the titanacyclobutene could conceivably be initiated by the thermal extrusion of diphenylacetylene from **4**, regenerating dimethyltitanocene. Thermal decomposition of dimethyltitanocene can serve to generate $Cp_2Ti{=}CH_2$ [39,40], although this decomposition reaction is appreciably more complex than that of the permethyltitanocene analog [41], and this methylidene complex, based on the known chemistry of Tebbe's reagent and of titanacyclobutanes [26,42], would be expected to react with diphenylacetylene to form the titanacyclobutene. In order to address this possibility, vinyl complex **4** was thermolyzed at 90°C in the presence of an excess of bis(4-chlorophenyl)acetylene. Complex **4** is cleanly converted to diphenyltitanacyclobutene **3a**, providing support for the γ-CH activation process, although the alternate mechanism cannot be unequivocally ruled out by this result, given the possibility of slow exchange of bis(4-chlorophenyl)acetylene into the coordination sphere of the metal center. Further information regarding these mechanistic possibilities is provided in the discussion of the reactions of 2-butyne and 3-hexyne with dimethyltitanocene (vide infra).

Higher reaction temperatures in the thermolysis of **4** do lead to the formation of the isomeric titanacyclobutene (**5**) resulting from the less favorable aromatic CH activation step, although this metallacycle is formed in only low yield (up to ca. 25% at 110°C), with the allylic activation product still the major product of the reaction (Eq. (8)).

(8)

Given the anticipated steric preference of the vinyl group to lie in the wedge plane, two rotamers of **4** might be anticipated, one (**4a**) placing the γ-methyl group in close proximity to the departing Ti–CH_3 group and the other (**4b**) placing the aromatic γ-CH in this position (Eq. (9)). With

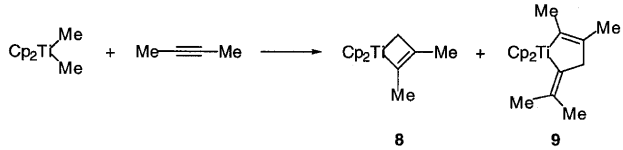


(9)

either concerted methane elimination or with Ti–CH_3 bond homolysis followed by hydrogen abstraction, rotamer **4a** would be expected to lead to formation of the titanacyclobutene (**3a**) and rotamer **4b** to the benzotitanacyclobutene (**5**). Restricted rotation of vinyl groups in permethyltitanocene chloride derivatives has been previously noted [43]. Although steric effects can be less pronounced in simple titanocenes than in the permethyl analogs, they are nonetheless often profound. For example, steric effects play an extreme role in the nitrile and aldehyde insertion reactions of titanacylobutenes [44,45]. It seems likely that the initial carbometalation step in the reaction of dimethyltitanocene with diphenylacetylene affords a single rotamer (**4a**), presenting a γ-H poised for abstraction and leading to the diphenyltitanacyclobutene. Thermolysis at higher temperatures facilitates rotational equilibration of **4a** with **4b**, leading to the formation of observable quantities of benzotitanacyclobutene **5**. Consistent with this hypothesis is the recent report of γ-elimination from (*Z*)-CpNi(CPh=CPh–CH_3), which deliv-

ers the γ-hydrogen close to the nickel center, but not from the (*E*) isomer, which maintains a longer distance between the nickel center and the γ-hydrogens [46].

The reaction between dimethyltitanocene and bis(trimethylsilyl)acetylene (Eq. (5), R = $SiMe_3$) affords no spectrally observable intermediates, even when carried out at comparatively low temperature (35°C), but presumably proceeds via an initial carbometalation step, affording vinyl complex **6** (Eq. (10)). An allylic CH activation process



7 **6** **3b**

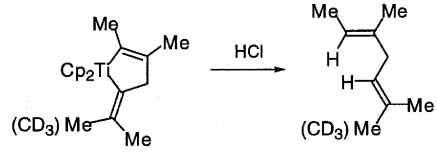
(10)

analogous to that seen for the diphenyl analog would then close up the titanacyclobutene ring. Again, a high degree of regiocontrol is apparent in this CH activation process. The isomeric metallacycle (**7**) which would result from activation of a silyl methyl group (Eq. (10)) is not observed, even though such reactivity of a silyl methyl group is well precedented for the later transition metals [47–49] and has been reported for a bis(trimethylsilyl)amide complex of titanocene as well [50]. As in the case of the diphenyl derivative, this is consistent with initial formation of a single reactive rotamer of the intermediate vinyl complex which displays significant steric inhibition of bond rotation. In contrast to the diphenyl case, in which formation of the anticipated isomeric titanacycle (**5**) is observed at higher reaction temperatures, rotation of the vinyl group in the bis(trimethylsilyl) derivative (**6**) is sufficiently hindered to preclude formation of detectable quantities of the silatitanacyclobutane (**7**) even at the highest temperatures examined (ca. 120°C, in toluene-d_8 in a sealed NMR tube).

2.2. Competitive β- and γ-activation processes

2-Butyne is partially polymerized in the presence of dimethyltitanocene at 65°C, and use of only 1 equiv. of this alkyne thus leads to rather intractable mixtures of organic and organometallic products as well as unreacted dimethyltitanocene. Use of two or more equivalents of 2-butyne, however, leads to much cleaner reaction chemistry. Unexpectedly, the dominant product (> 90%) of this reaction is not the titanacyclobutene (**8**), but rather a new metallacyclic complex (**9**) incorporating 2 equiv. of 2-butyne (Eq. (11)).

8 **9**



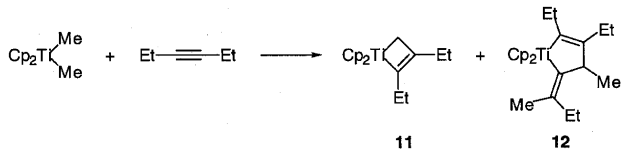
(11)

The new complex is easily purified through recrystallization from hexanes at −30°C. ^1H and ^{13}C NMR spectra provide unambiguous proof of the structure of complex **9**, and mass spectral and elemental analytical data are also supportive of this structure. Particularly revealing are two ^{13}C resonances in the downfield region of 180–195 ppm, highly characteristic of vinylic carbons attached to titanium [51].

In order to provide additional information about the formation of **9**, the reaction of 2-butyne with $Cp_2Ti(CD_3)_2$ was examined. The ^1H and ^{13}C NMR spectra of **9**-d_3 are virtually identical to those of **9**, with the exception of the loss of the highest field ^1H methyl resonance (0.8 ppm) and lowest field ^{13}C methyl resonance (24.8 ppm). (Loss of ^{13}C signal intensity for CD_3 groups due to spin–spin splitting is well known [52–54].) These chemical shifts unambiguously define the labeled methyl group as the isopropylidene methyl *cis* to the titanocene fragment [55]. An agostic interaction between this methyl group and the empty titanium wedge plane orbital seems likely, with the opposing shifts of the ^1H and ^{13}C resonances consistent with other reports of such agostic interactions [27,28].

In addition to allowing for the assignment of the outlying NMR resonances to this *cis*-methyl group, the deuterium labeling study also provides compelling information regarding the mechanism of formation of **9**. Thermal elimination of methane from dimethyltitanocene, generating $Cp_2Ti{=}CH_2$, may be virtually unequivocally ruled out as a mechanistic step, since neither a CD_2 group nor a CD_2H group, which might potentially be formed from a CD_2-containing intermediate, is found in **9**-d_3.

Given the mechanistic significance of the formation of **9**, its structure was further verified through protonolysis and analysis of the resulting diene **10** (Eq. (12)). (*E*)-2,5-di-



9 **10**

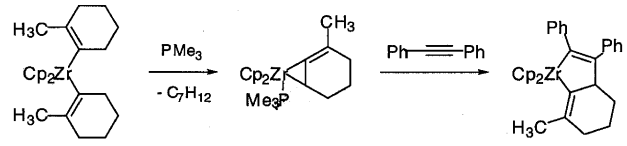
(12)

methylhepta-2,5-diene is formed with no loss of stereochemistry, being obtained as the sole volatile component of the protonolysis reaction (as demonstrated by gas chromatographic and NMR spectral analysis). Although two methyl resonances are degenerate in the ^1H NMR spectrum, all nine carbons in **10** are unambiguously resolved in the ^{13}C NMR spectrum. As in the ^{13}C NMR spectrum of its titanacyclic precursor, one of the methyl resonances is rather downfield (25.9 ppm) from the others. In this case, simple correlation tables point to the assignment of this resonance to the (*E*)-methyl of the isopropylidene group, shifted to lower field than the (*Z*)-methyl group due to the γ effect [56,57]. Protonolysis of the deuterated titanacycle, **9**-d_3, affords diene **10**-d_3, displaying ^1H and ^{13}C NMR spectral properties completely consistent with the location of the CD_3 group anticipated from the proposed structure of its titanacyclic precursor.

Dimethyltitanocene displays analogous reactivity toward 3-hexyne, but the titanacyclobutene is formed in appreciably

higher yield in this reaction than in that of 2-butyne. Again, methane is formed as a byproduct and two metallacyclic complexes, one incorporating a second equivalent of 3-hexyne, are obtained (Eq. (13)).

(13)

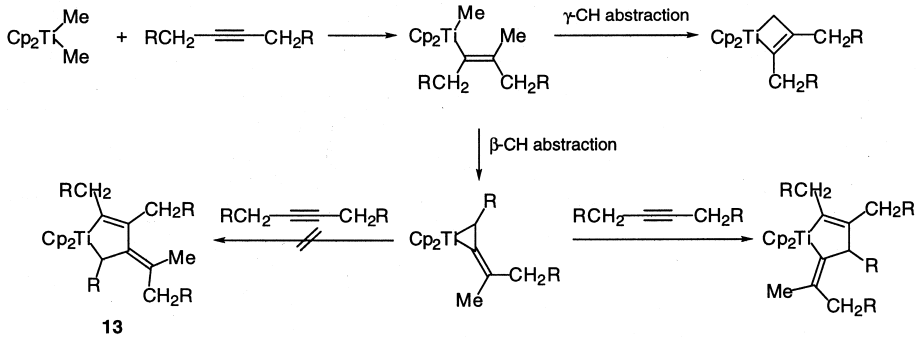


The most characteristic ^{1}H NMR spectral features of titanacyclopentene **12** are a methine quartet at 2.83 ppm coupled to a methyl doublet (1.16 ppm, $^3J_{HH} = 6$ Hz), a high-field methyl singlet (0.65 ppm), and two cyclopentadienyl resonances, clearly indicating the lack of a plane of symmetry in the complex. The ^{13}C NMR spectrum of **12** displays similar features to that of 2-butyne-derived complex **9**, most notably two downfield singlets (192.6, 193.0 ppm) for the sp^2-carbons attached to the titanium center, with the other vinyl carbons appearing near 132 ppm; assignment of resonances was facilitated by use of the DEPT (distortionless enhancement by polarization transfer) technique [58]. The methine carbon appears as a doublet ($^1J_{CH} = 125$ Hz) at 41.6 ppm.

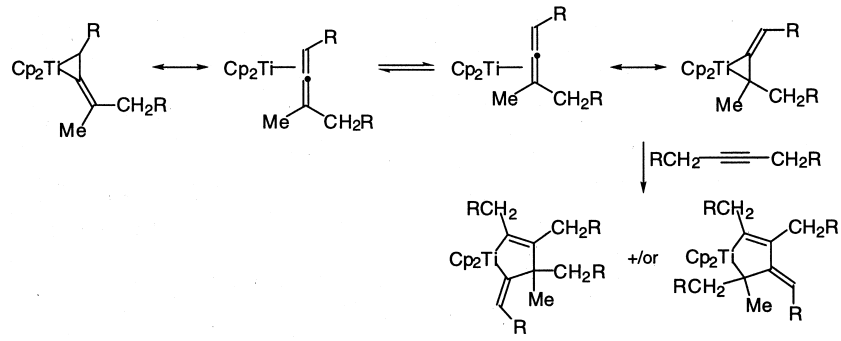
Formation of both titanacyclobutenes and titanacyclopentenes in the reaction of dimethyltitanocene with alkynes is conveniently rationalized by initial alkyne carbometalation, followed by competitive allylic γ-CH activation, affording the titanacyclobutene, and β-CH activation, affording a titanacyclopropane (Scheme 1). Rotamer isomerization, affording access to elimination from the β-allylic position, is more facile in these cases than in the more hindered phenyl and trimethylsilyl derivatives. The product of this β-activation becomes dominant in the case of the 2-butyne reaction, while the increased steric bulk of the 3-hexyne derived intermediate allows for appreciable formation of the γ-activation product. Whereas the titanacyclobutenes are comparatively unreactive toward alkynes, the titanacyclopropanes undergo facile alkyne insertion, with steric issues directing the incoming alkyne to the observed insertion site rather than to the more crowded site, which would form unobserved isomer **13** (Scheme 1).

2.3. Metallacyclopropane (allene complex) intermediates

The titanacyclopropane intermediate may be represented in an alternative resonance form as an allene complex of titanocene [59,60]. Significantly, an intermediate is observed by NMR spectroscopy in both the 2-butyne and 3-hexyne reactions which displays a cyclopentadienyl ^{1}H resonance at ca. 4.7 ppm, a chemical shift similar to that displayed by isolable titanocene(II) derivatives, including $Cp_2Ti(PMe_3)_2$ (4.51 ppm) [61] and $Cp_2Ti(CO)_2$ (4.58 ppm) [62], and a cyclopentadienyl ^{13}C resonance at 98 ppm ($^1J_{CH} = 168$ Hz), in range with that reported for $Cp_2Ti(PMe_3)_2$ (91.2 ppm). Observation of these NMR resonances is consistent with intermediate formation of a titanocene(II) complex. While this observation does not unequivocally point to the allene complex as the observed intermediate, given the possibility of generation of other titanocene(II) species under the reaction conditions, the close resemblance of these spectral features to those of an independently prepared allene complex (vide infra) is noteworthy.



While this work was in progress, Jones and co-workers reported related chemistry in the zirconocene series [63]. Thermolysis of bis(methylcyclohexenyl)zirconocene in the presence of trimethylphosphine affords a 1,2-cyclohexadiene complex of zirconocene through a β-activation process (Eq. (14)). No evidence was reported for the formation of the

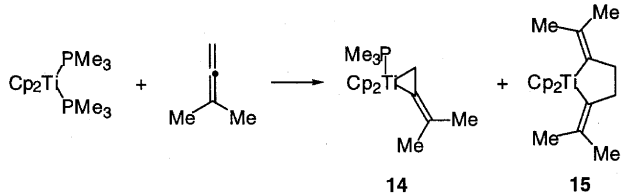


(14)

isomeric zirconacyclobutene which would arise from competitive γ-activation. The allene complex reacts with unsaturated substrates (e.g. diphenylacetylene) to afford zirconacyclic complexes analogous to **9** and **12**.

Given the likelihood of the intermediacy of allene complexes in the reactions of dimethyltitanocene with 2-butyne and 3-hexyne, the possibility of additional isomeric products is raised by the ability of allene complexes to undergo coordination isomerization [64] (for discussions of related issues for ketene complexes see Ref. [65]), as suggested in Scheme 2. In each case, however, the isomeric allene complex would

Scheme 1.

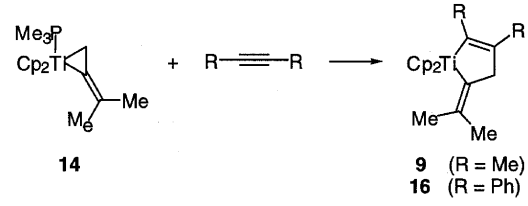


Scheme 2.

be expected to be sterically destabilized due to additional interactions between the cyclopentadienyl rings and the allene substituents.

The possibility that titanacyclopentene **9** arises from a follow-up reaction of titanacyclobutene **8** was ruled out by examining the reactivity of independently prepared dimethyltitanacyclobutene [26,66,67] toward 2-butyne. No spectral evidence was obtained for the formation of **9**, and the only noticeable reaction after 24 h at 70°C was the partial decomposition of the titanacyclobutene. The appearance of broad peaks in the allyl region of the ^{1}H NMR spectrum is suggestive of the polymerization of 2-butyne by the titanacyclobutene, supportive of earlier proposals regarding the possible intermediacy of metallacyclobutenes in certain catalytic alkyne polymerization mechanisms [68].

In order to establish more firmly the titanacyclopropane (allene complex) intermediate, the reaction between $Cp_2Ti(PMe_3)_2$ and 3-methyl-1,2-butadiene was examined. Two metallocene products are obtained, the allene complex **14** and titanacyclopentane **15**, incorporating 2 equiv. of the allene (Eq. (15)).



14 **15**

(15)

When the reaction is carried out in the presence of an excess of trimethylphosphine, complex **14**, apparently representing the first example of a titanocene allene complex (the first and, prior to our report, only preparation of a group 4 allene complex was that by Jones and co-workers [63]), is obtained cleanly and may be isolated in analytically pure form by simple evaporation of solvent and excess phosphine at ca. −5°C. In contrast to vinyl complex **4** and metallacycles **9** and **12**, for which NMR analysis suggests an agostic interaction between a proximal methyl group and the titanocene center, the methyl ^{1}H (2.02 and 2.41 ppm) and ^{13}C (24.2 and 29.7 ppm) resonances of complex **14** appear at rather typical chemical shifts. Clearly, the trimethylphosphine ligand in **14** overrides the weaker agostic interaction present in **4**, **9**, and **12**.

Attempted isolation of **14** through removal of solvent at higher temperature (25°C instead of −5°C) results in its partial conversion to the metallacyclopentane **15**. Treatment of $Cp_2Ti(PMe_3)_2$ with 2 equiv. of 3-methyl-1,2-butadiene permits the preparation of **15** in pure form. An agostic interaction between the methyl groups *cis* to the titanium center appears likely given the appearance of one methyl resonance in the ^{1}H NMR spectrum of **15** at appreciably higher field (0.75 ppm) than the other (1.48 ppm). Reductive coupling of allenes by zirconocene(II) has been noted previously [69,70], and a simple titanium(II) complex, $(iPrO)_2Ti$(1-propene), has very recently been reported to effect analogous allene coupling [71]. Allenes have also recently been incorporated successfully as reactants in the Pauson–Khand reaction [72]; although mechanistically unrelated, also noteworthy is the reductive coupling of allenes and alkynes mediated by hydrozirconation [73].

Importantly, allene complex **14** reacts readily with 2-butyne (1 h at 65°C) to form titanacyclopentene **9** (R = CH_3) (Eq. (16)), providing circumstantial evidence for the intermediacy of an allene complex in the reaction between 2-butyne and dimethyltitanocene. Diphenylacetylene also couples efficiently with allene complex **14** to form titanacyclopentene **16** (R = Ph) (Eq. (16)), suggesting potential synthetic applications in the form of cross couplings of unsaturated substrates [71].

14 **9** (R = Me) **16** (R = Ph)

(16)

2.4. Reaction kinetics

Kinetic analysis of the 2-butyne and 3-hexyne reactions is complicated by non-linearity at longer reaction times, at least in part due to the thermal decomposition of the titanacyclobutenes, but nonetheless qualitatively reveals some significant features of the reactions. First order consumption of dimethyltitanocene is observed at all temperatures examined

(ranging from 41 to 120°C). Interestingly, the rate of disappearance of dimethyltitanocene is significantly greater in the 2-butyne reaction than in the 3-hexyne reaction (a five-fold difference at 63°C), providing further circumstantial evidence against rate-determining formation of $Cp_2Ti{=}CH_2$ as a mechanistic step.

In contrast with the reaction of 2-butyne with dimethyltitanocene, which affords low yields of titanacyclobutene **8** together with titanacyclopentene **9** (Eq. (11)), the reaction with $Cp_2Ti(CD_3)_2$ affords only the titanacyclopentene at all temperatures examined. This suggests a substantial kinetic isotope effect, slowing the γ-CH(D) activation process, consistent with rate-determining CH(D) activation. A firm number for the isotope effect cannot be obtained due to the complete disappearance of the titanacyclobutene product in the $Cp_2Ti(CD_3)_2$ reaction. However, given the assumption that formation of $>2\%$ of the titanacyclobutene product would be detectable by ^{1}H NMR and ignoring any secondary isotope effects, a lower limit of $k_{\gamma\text{-H}}/k_{\gamma\text{-D}} = 3.2$ may be calculated. Interestingly, Janssens et al. have recently noted a similar dramatic change in reaction pathway for neopentyl groups on Pt(111) surfaces, with exclusive α-elimination seen for the protio derivative and exclusive γ-elimination for the α,α-d_2 derivative [74].

Formation of the titanacyclopentene product in the 2-butyne reaction was studied over a 50°C temperature range. An Eyring plot provides values for $\Delta H^{\ddagger} = 12.9$ kcal mol^{-1} and $\Delta S^{\ddagger} = -28$ eu, with the relatively large and negative entropy of activation consistent with a fairly ordered transition state. This could point toward a concerted methane elimination, requiring the proper alignment of Ti–CH_3 and β-H groups, but may also arise from rapid Ti–CH_3 bond homolysis, followed by rate-determining β-hydride abstraction.

The 3-hexyne reaction affords a unique opportunity to examine the competition between β- and γ-CH activation, since products arising from both processes are obtained at all reaction temperatures studied. An Eyring analysis of the product ratio as a function of temperature allows determination of $\Delta\Delta H^{\ddagger}_{\beta/\gamma} = 9.6$ kcal mol^{-1} and $\Delta\Delta S^{\ddagger}_{\beta/\gamma} = -8$ eu. The positive $\Delta\Delta H^{\ddagger}_{\beta/\gamma}$ is consistent with the formation of a more highly strained titanacyclopropane via β-hydride activation versus a less strained titanacyclobutene via γ-hydride activation. The small but negative $\Delta\Delta S^{\ddagger}_{\beta/\gamma}$ is in accord with a more organized transition state to bring the ethyl group bearing the β-hydrogen into proper alignment for elimination than is required to align the sterically less demanding methyl group bearing the γ-hydrogen.

3. Summary and conclusions

Alkynes undergo carbometalation by dimethyltitanocene, affording vinyl complexes which serve as intermediates for the formation of titanacyclic products through the elimination of methane. Rotational isomerization, restricted in the case of larger substituents, provides a simple and consistent explanation for the observed regioselectivity in the subsequent hydrogen abstraction/methane elimination step. Intermediates bearing vinyl groups able to undergo rotation favor formation of titanacyclopropanes through a β-activation process, while those unable to undergo rotation undergo a γ-activation process, leading to titanacyclobutenes. This selectivity is observed both for intermediate vinyl complexes presenting chemically very similar β- and γ-hydrogens (the 2-butyne and 3-hexyne reactions) and for those in which the competing sites for hydrogen abstraction are inequivalent (the diphenylacetylene and bis(trimethylsilyl)acetylene reactions) and appears to override the frequently observed preference for aromatic over aliphatic CH abstraction. Alternative formation of titanacyclobutenes through thermal decomposition of dimethyltitanocene, affording $Cp_2Ti{=}CH_2$, appears inconsistent with labeling and kinetic studies at moderate reaction temperatures, although it may appear as a competitive side reaction at very high temperatures.

The titanacyclopropanes may be alternatively formulated as allene complexes of titanocene. An independently prepared trimethylphosphine-ligated analog of 3-methyl-1,2-butadiene, representing the first titanocene allene complex to be reported, undergoes reductive coupling reactions with excess 3-methyl-1,2-butadiene and with alkynes.

4. Experimental

4.1. General

After purification and drying, all solids and solvents were stored under nitrogen in a Vacuum Atmospheres glove box equipped with a Dri-Train MO 40-1 inert gas purifier unit, RGF-1 regeneration flow unit, Pedatrol pressure control unit, DK-3E Dri-Kool refrigeration unit and Dri-Cold freezer. Unless otherwise noted, all operations were carried out under an atmosphere of argon and nitrogen, purified by passage first through activated BASF catalyst, then through activated molecular sieves.

4.2. Materials

Titanocene dichloride was purchased from Boulder Scientific and used without purification. Diphenylacetylene, bis(trimethylsilyl)acetylene, 3-hexyne, MeLi (1.4 M in diethyl ether), and CD_3Li (1.5 M in diethyl ether) were used as received from Aldrich. 2-Butyne was obtained from Farchan and used as received. Benzene-d_6 was purchased from MSD and distilled under a pre-purified nitrogen atmosphere from Na/K alloy and benzophenone. Toluene, benzene, THF and diethyl ether were distilled from Na/K alloy and benzophenone under a pre-purified nitrogen atmosphere. Alkanes (pentane and hexane) were washed with concentrated H_2SO_4, then with aqueous $NaHCO_3$, dried over calcium hydride, and distilled from Na/K alloy and benzophenone under a pre-purified nitrogen atmosphere. Trimethylphos-

phine (Aldrich) was stored in the glove box freezer and used without purification. Bis(trimethylphosphine)titanocene was prepared as described [61].

4.3. Instrumentation

Nuclear magnetic resonance (NMR) spectra of all samples were obtained on a GE QE-300 (300.152 MHz, ^{1}H; 75.481 MHz, ^{13}C). The following notation is used in reporting NMR data: (1) chemical shifts are reported in parts per million (ppm); (2) multiplicity of signal where s = singlet, d = doublet, t = triplet, m = multiplet, br = broad, dt = doublet of triplets, br s = broad singlet, etc; (3) coupling constants are reported in Hertz (Hz). Chemical shifts are referenced to residual solvent signals in benzene-d_6 (δ 7.150, ^{1}H; δ 128.00, ^{13}C), chloroform-d (δ 7.26, ^{1}H; δ 77.0, ^{13}C) and toluene-d_8 (δ 2.09, ^{1}H; δ 21.4, ^{13}C). Gas chromatographic analyses were performed on a Shimadzu GC-9A with He as the carrier gas with a flow rate of 50 ml min^{-1}, using an FID detector and an injection port temperature of 225°C. Mass spectroscopy was performed at the University of Oregon Mass Spectrometry Facility.

4.4. Preparation of dimethyltitanocene [39,40]

A Schlenk flask was charged with titanocene dichloride (5.0 g, 20.1 mmol) and diethyl ether. To the red suspension, cooled to −40°C, was added dropwise 32.0 ml of a 1.4 M solution of MeLi in diethyl ether (44.8 mmol, 2.23 equiv.). The mixture was stirred for 80 min while slowly warming to ca. 0°C, affording an orange solution. After cooling to −40°C, 40 ml of water was cautiously added. The organic phase was washed with water (2×25 ml) and brine (1×25 ml) and dried over $MgSO_4$. Removal of the solvent on a rotary evaporator afforded the crude product as an orange solid (3.9 g, 95%). Recrystallization from ca. 15 ml of pentane at −30°C afforded crystalline product (3.5 g, 85%). ^{1}H NMR (C_6D_6): δ 0.05 (s, 6H, CH_3), 5.68 (s, 10H, Cp). ^{13}C NMR: δ 45.9 (q, $^1J_{CH}$ = 124 Hz, CH_3), 113.2 (dm, $^1J_{CH}$ = 173 Hz, Cp). Dimethyltitanocene-d_6 was prepared analogously, using MeLi-d_3 in place of MeLi.

4.5. Reaction of dimethyltitanocene with diphenylacetylene: formation of vinyl intermediate **4**

To a Schlenk flask containing a solution of Cp_2TiMe_2 (1.00 g, 4.80 mmol) in toluene (25 ml) was added diphenylacetylene (1.71 g, 9.59 mmol, 2 equiv.). The flask was wrapped in aluminum foil to exclude light and heated at 72°C for 5 h. The solution underwent a color change from orange to deep-red. The solvent was then removed in vacuo, affording a brownish solid. This solid was mixed with 10 ml of hexanes and cooled at −20°C for 2 days, resulting in the precipitation of vinyl complex **4**, which was isolated as a reddish-brown solid by filtration (400 mg, 22%). (This product appears identical to the minor product obtained by Rausch and coworkers in the photochemical reaction between dimethyltitanocene and diphenylacetylene [35–37].) ^{1}H NMR (C_6D_6): δ −0.42 (s, 3H, Ti–CH_3), 1.45 (s, 3H, CH_3), 5.84 (s, 10H, Cp), 6.72 (d, 2H, $^3J_{HH}$ = 7.5 Hz, ArH), 6.82–6.87 (m, 4H, ArH), 6.91–7.01 (m, 4H, ArH). ^{13}C{^{1}H} NMR (C_6D_6): δ 25.7 (CH_3), 50.3 (Ti–CH_3), 112.5 (Cp), 123.7 (Ar), 123.9 (Ar), 124.9 (Ar), 127.3 (Ar), 127.5 (Ar), 128.3 (Ar), 135.5 (Ti–C=*C*), 146.4 (Ar), 147.2 (Ar), 189.6 (Ti–*C*=C). ^{13}C NMR (C_6D_6): δ 25.7 (q, $^1J_{CH}$ = 125 Hz, CH_3), 50.3 (q, $^1J_{CH}$ = 126 Hz, Ti–CH_3), 112.5 (d, $^1J_{CH}$ = 174 Hz, Cp), 123.7 (d, $^1J_{CH}$ = 160 Hz, Ar), 123.9 (m, Ar), 124.9 (d, $^1J_{CH}$ = 163 Hz, Ar), 127.3 (d, $^1J_{CH}$ = 161 Hz, Ar), 127.5 (d, $^1J_{CH}$ = 158 Hz, Ar), 128.3 (d, $^1J_{CH}$ = 161 Hz, Ar), 135.5 (s, Ti–C=*C*), 146.4 (s, Ar), 147.2 (s, Ar), 189.6 (s, Ti–*C*=C). HRMS. Calc. for $C_{26}H_{26}Ti$: 386.1514. Found: 386.1508. *Anal*. Calc. for $C_{26}H_{26}Ti$: C, 80.82; H, 6.78. Found: C, 80.67; H, 6.86%.

4.6. Thermolysis of **4**

Thermolysis of solutions of vinyl complex **4** in benzene-d_6 or toluene-d_8 at 70°C for 3 days resulted in the formation of methane (^{1}H NMR (C_6D_6): δ 0.15) and clean conversion to deep-red solutions of the titanacyclobutene (**3a**). Removal of solvent in vacuo afforded the titanacyclobutene in quantitative yield, with spectral properties identical to those previously reported [26,66,67]. ^{1}H NMR (C_6D_6): δ 3.45 (s, 2H, CH_2), 5.67 (s, 10H, Cp), 6.91–7.14 (m, 8H, ArH), 7.31–7.33 (d, 2H, ArH). ^{13}C{^{1}H} NMR (C_6D_6): δ 73.4 (CH_2), 100.6 (Ti–C=*C*), 112.4 (Cp), 124.5 (Ar), 125.9 (Ar), 126.2 (Ar), 129.5 (Ar), 129.6 (Ar), 138.7 (Ar), 147.6 (Ar), 210.9 (Ti–*C*=C).

Prolonged thermolysis of vinyl complex **4** at higher temperatures (28 h at 80–85°C) leads to the formation of a new product in up to a ca. 1:4 ratio to the titanacyclobutene. Although this complex has not been isolated in pure form, its ^{1}H NMR spectrum is consistent with the benzotitanacyclobutene **5**. ^{1}H NMR (C_6D_6): δ 0.70 (s, 3H, CH_3), 5.57 (s, 10H, Cp), 6.8–7.2 (m, ArH). Control experiments indicate that complex **5** is not formed via thermolysis of the titanacyclobutene.

4.7. Direct preparation of titanacyclobutene **3a** from dimethyltitanocene

Titanacyclobutene **3a** may also be prepared without isolation of the intermediate vinyl complex. Thus, Cp_2TiMe_2 (0.998 mg, 4.79 mmol) reacted with 0.902 g of diphenylacetylene (5.06 mmol, 1.06 equiv.) in 10 ml of toluene to afford, after heating for 16 h at 65–68°C and removal of solvent in vacuo, a dark-purple solid (1.815 g, 98%) composed of titanacyclobutene **3a** (ca. 80%) and vinyl complex **4** (ca. 20%). This material was redissolved in 10 ml of toluene and heated for 12–14 h at 80–85°C. Removal of solvent in vacuo quantitatively afforded the crude metallacycle. Crystallization of the crude product twice from hexanes afforded

the pure titanacyclobutene as a nicely crystalline, purple solid (60%).

4.8. Preparation of bis(trimethylsilyl)titanacyclobutene (**3b**) [26,66,67,75,76]

To a solution of 1.05 g of Cp_2TiMe_2 (5.0 mmol) in 30 ml of toluene in a 100 ml Schlenk flask was added 0.83 g of bis(trimethylsilyl)acetylene (1 equiv.). The flask was wrapped in aluminum foil and heated in an oil bath at 80°C for 14 h, at which point ^{1}H NMR analysis of an aliquot showed clean conversion to the titanacyclobutene. Solvent was removed in vacuo, yielding the product in a satisfactory state of purity as an oil in quantitative yield. Crystallization from hexanes at −30°C afforded a dark-red solid (1.46 g, 80%). ^{1}H NMR (C_6D_6): δ 0.21 (s, 9H, $Si(CH_3)_3$), 0.32 (s, 9H, $Si(CH_3)_3$), 4.67 (s, 2H, CH_2), 5.22 (s, 10H, Cp). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 1.49 (CH_3), 2.80 (CH_3), 107.6 (Cp), 108.8 (CH_2).

4.9. Preparation of titanacyclopentene **9**

A side-arm round bottom flask was charged with 50 ml of dry toluene and 1.38 g of dimethyltitanocene (6.62 mmol). To this solution was added 2-butyne (1.04 ml, 717 mg, 2 equiv.). The flask was wrapped in foil and heated in an oil bath at 70°C for 12 h. ^{1}H NMR analysis of the reaction mixture at this point revealed conversion to a mixture of titanacyclopentene **9** and titanacyclobutene **8**, which displays identical spectral properties to those of an authentic sample [26,66,67,75,76]. The solvent was removed in vacuo and the residue was extracted with 25 ml of hexanes. The resulting solution was cooled to −30°C, then filtered. The pure product was isolated in ca. 35% yield by evaporation of the filtrand in vacuo. ^{1}H NMR (C_6D_6): δ 0.82 (s, 3H, CH_3), 1.17 (s, 3H, CH_3), 1.39 (s, 3H, CH_3), 1.52 (s, 3H, CH_3), 2.57 (br s, 2H, CH_2), 5.94 (s, 10H, Cp). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 18.4 (CH_3), 20.4 (CH_3), 20.9 (CH_3), 24.8 (CH_3), 42.0 (CH_2), 113.8 (Cp), 119.6 (Ti–C=*C*), 125.1 (Ti–C=*C*), 185.6 (Ti–*C*=C), 188.1 (Ti–*C*=C). ^{13}C NMR (C_6D_6): δ 18.4 (q, $^1J_{CH}$ = 124 Hz, CH_3), 20.4 (q of t, $^1J_{CH}$ = 124 Hz, $^3J_{CH}$ = 4 Hz, CH_3), 20.9 (q, $^1J_{CH}$ = 124 Hz, CH_3), 24.8 (q of q, $^1J_{CH}$ = 123 Hz, $^3J_{CH}$ = 6 Hz, CH_3), 42.0 (t of q, $^1J_{CH}$ = 121 Hz, $^3J_{CH}$ = 4 Hz, CH_2), 113.8 (m, Cp), 119.6 (hextet, $^3J_{CH}$ = 6.5 Hz, Ti–C=*C*), 125.1 (heptet, $^3J_{CH}$ = 5.8 Hz, Ti–C=*C*), 185.6 (s, Ti–*C*=C), 188.1 (s, Ti–*C*=C). MS: *m/z* = 300 (M^+, 24%), 232 (M–C_5H_8, 14%), 218 (28%), 192 (17%), 178 (Cp_2Ti, 100%), 152 (26%), 128 (18%), 113 (CpTi, 76%). HRMS. Calc. for $C_{19}H_{24}Ti$: 300.1357. Found: 300.1370. *Anal*. Calc. for $C_{19}H_{24}Ti$: C, 75.99; H, 8.06. Found: C, 75.83; H, 8.12%.

4.10. Preparation of titanacyclopentene **9**-d_3

This complex was prepared analogously, using 400 mg of $Cp_2Ti(CD_3)_2$ (1.88 mmol) and 0.292 ml of 2-butyne (2 equiv.) and heating at 70°C for 24 h, then stirring at room temperature for an additional 12 h. ^{1}H NMR (C_6D_6): δ 1.17 (s, 3H, CH_3), 1.36 (s, 3H, CH_3), 1.49 (s, 3H, CH_3), 2.54 (br s, 2H, CH_2), 5.94 (s, 10H, Cp). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 18.4 (CH_3), 20.3 (CH_3), 20.9 (CH_3), 42.0 (CH_2), 113.8 (Cp), 119.7 (Ti–C=*C*), 125.0 (Ti–C=*C*), 185.5 (Ti–*C*=C), 188.0 (Ti–*C*=C). *Anal*. Calc. for $C_{19}H_{24}Ti$: C, 75.99; H, 8.06. Found: C, 75.88; H, 8.17%.

4.11. Protonolysis of titanacyclopentene **9**

A side-arm round bottom flask was charged with titanacycle **9** (500 mg, 2.77 mmol) and 0.75 ml of C_6D_6. Excess dry HCl gas was gently introduced to the solution over the course of 5 min, then the volatile portion of the reaction mixture was isolated by vacuum transfer. Gas chromatographic analysis on a 30 m × 0.25 mm Carbowax column, 50–210°C at 10°C min^{-1}, revealed only a single component (retention time 5.2 min) in addition to the solvent. (*E*)-2,5-dimethylhepta-2,5-diene: ^{1}H NMR (C_6D_6): δ 1.54 (s, 3H, CH_3), 1.56 (s, 6H, 2 × CH_3), 1.66 (s, 3H, CH_3), 2.71 (d, 2H, J = 7.2 Hz, CH_2), 5.23–5.33 (m, 2H, 2 × =CH). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 13.5 (CH_3), 15.9 (CH_3), 17.6 (CH_3), 25.8 (CH_3), 38.6 (CH_2), 118.5 (=CH), 123.3 (=CH), 132.2 (=*C*(CH_3)$_2$), 135.3 (=*C*(CH_3)CH_2). ^{13}C NMR (C_6D_6): δ 13.5 (q of d, $^1J_{CH}$ = 126 Hz, $^3J_{CH}$ = 4.5 Hz, CH_3), 15.9 (q, $^1J_{CH}$ = 125 Hz, $^3J_{CH}$ ~ 4 Hz, CH_3), 17.6 (m, $^1J_{CH}$ = 125 Hz, $^3J_{CH}$ ~ 4 Hz, CH_3), 25.8 (m, $^1J_{CH}$ = 125 Hz, $^3J_{CH}$ ~ 3.7 Hz, CH_3), 38.6 (t, $^1J_{CH}$ = 124 Hz, CH_2), 118.5 (m, $^1J_{CH}$ = 152 Hz, $^3J_{CH}$ ~ 6 Hz, =CH), 123.3 (m, $^1J_{CH}$ = 151 Hz, $^3J_{CH}$ ~ 5 Hz, =CH), 132.2 (heptet, $^3J_{CH}$ ~ 6 Hz, =*C*(CH_3)$_2$), 135.3 (s, =*C*(CH_3)CH_2). MS (70 eV): *m/z* = 97 (M–C_2H_3, 7%), 79 (10%), 69 (12%), 67 (15%), 65 (10%), 63 (10%), 56 (C_4H_8, 31%), 55 (23%), 54 (C_4H_6, 43%), 53 (18%), 51 (29%), 50 (19%), 44 (18%), 43 (65%), 42 (22%), 41 (C_3H_5, 100%), 40 (11%).

4.12. Protonolysis of titanacyclopentene **9**-d_3

Treatment of **9**-d_3 with excess dry HCl, as above, afforded the corresponding diene, (*E,E*)-1,1,1-d_3-2,5-dimethylhepta-2,5-diene, as the sole volatile product. ^{1}H NMR (C_6D_6): δ 1.54 (s, 3H, CH_3), 1.56 (s, 6H, 2 × CH_3), 2.70 (d, 2H, J = 7.5 Hz, CH_2), 5.25 (t, 1H, J = 7.5 Hz, =C*H*–CH_2), 5.28–5.34 (m, 1H, =CH). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 13.5 (CH_3), 15.9 (CH_3), 17.6 (CH_3), 24.7 (m, $^1J_{CD}$ ~ 18 Hz, CD_3), 38.6 (CH_2), 118.5 (=CH), 123.3 (=CH), 132.1 (=*C*(CH_3)$_2$), 135.3 (=*C*(CH_3)CH_2). MS (70 eV): *m/z* = 127 (M^+, 5%), 109 (M–CD_3, 6%), 100 (M–C_2H_3, 7%), 95 (11%), 79 (11%), 73 (25%), 69 (14%), 67 (22%), 65 (12%), 63 (12%), 60 (10%), 59 (27%), 58 (16%), 57 (30%), 56 (C_4H_8, 57%), 55 (46%), 54 (C_4H_6, 56%), 53 (46%), 51 (46%), 50 (46%), 47 (43%), 46 (46%), 45 (46%), 44 (46%), 43 (94%), 42 (59%), 41 (C_3H_5, 100%), 40 (33%).

4.13. Reaction of dimethyltitanocene with 3-hexyne

An NMR tube was charged with 0.5 ml of C_6D_6, 42 mg of dimethyltitanocene (0.2 mmol), and 23 μl of 3-hexyne (1 equiv.). The tube was wrapped in foil and heated in an oil bath at 60°C for 12 h, with periodic ^{1}H NMR monitoring of the progress of the reaction. Upon complete consumption of the dimethyltitanocene, a 58:42 mixture (based on integration of the cyclopentadienyl resonances) of titanacyclopentene **12** and titanacyclobutene **11** was obtained. The titanacyclobutene displays spectral properties identical to those reported previously [51]. Titanacyclobutene **11**: ^{1}H NMR (C_6D_6): δ 0.92 (t, 3H, $^3J_{HH}$ = 7.5 Hz, CH_3), 1.04 (t, 3H, $^3J_{HH}$ = 7.5 Hz, CH_3), 1.95 (q, 2H, $^3J_{HH}$ = 7.5 Hz, CH_2), 2.53 (q, 2H, $^3J_{HH}$ = 7.5 Hz, CH_2), 3.30 (s, 2H, Ti–CH_2), 5.53 (s, 10H, Cp). ^{13}C{^{1}H} NMR (C_6D_6): δ 12.4 (CH_3), 15.8 (CH_3), 22.4 (CH_2), 29.3 (CH_2), 77.6 (Ti–CH_2), 92.5 (Ti–C=*C*), 110.0 (Cp), 221.0 (Ti–*C*=C). ^{13}C NMR (C_6D_6): δ 12.4 (q, $^1J_{CH}$ = 126 Hz, CH_3), 15.8 (q, $^1J_{CH}$ = 125 Hz, CH_3), 22.4 (t, $^1J_{CH}$ = 127 Hz, CH_2), 29.3 (t, $^1J_{CH}$ = 124 Hz, CH_2), 77.6 (t, Ti–CH_2), 92.5 (s, Ti–C=*C*), 110.0 (dm, $^1J_{CH}$ = 172 Hz, Cp), 221.0 (s, Ti–*C*=C). Titanacyclopentene **12**: ^{1}H NMR (C_6D_6): δ 0.65 (s, 3H, CH_3), 1.16 (d, 3H, $^3J_{HH}$ = 6 Hz, C*H*$_3$–CH), 2.83 (q, 1H, $^3J_{HH}$ = 6 Hz, CH_3–C*H*), 5.96 (s, 5H, Cp), 6.05 (s, 5H, Cp). (The remaining aliphatic resonances appear as a set of complex multiplets, partially obscured by the resonances of the titanacyclobutene, between 0.8–2.6 ppm.) ^{13}C{^{1}H} NMR (C_6D_6): δ 12.8 (CH_3), 13.2 (CH_3), 14.8 (CH_3), 21.1 (CH_3), 22.3 (CH_3), 22.9 (CH_2), 27.1 (CH_2), 27.6 (CH_2), 41.6 (*C*H–CH_3), 113.4 (Cp), 114.7 (Cp), 131.3 (Ti–C=*C*), 132.7 (Ti–C=*C*), 192.6 (Ti–*C*=C), 193.0 (Ti–*C*=C). ^{13}C NMR (C_6D_6): δ 12.8 (q, $^1J_{CH}$ ~ 127 Hz, CH_3), 13.2 (q, $^1J_{CH}$ ~ 123 Hz, CH_3), 14.8 (q, $^1J_{CH}$ ~ 120 Hz, CH_3), 21.1 (q, $^1J_{CH}$ ~ 123 Hz, CH_3), 22.3 (q, $^1J_{CH}$ ~ 126 Hz, CH_3), 22.9 (CH_2), 27.1 (CH_2), 27.6 (CH_2), 41.6 (d, $^1J_{CH}$ ~ 122 Hz, *C*H–CH_3), 113.4 (dm, $^1J_{CH}$ = 173 Hz, Cp), 114.7 (dm, $^1J_{CH}$ = 173 Hz, Cp), 131.3 (Ti–C=*C*), 132.7 (Ti–C=*C*), 192.6 (Ti–*C*=C), 193.0 (Ti–*C*=C). (Resonances for which no multiplicity information is provided were of insufficient intensity to permit such a determination.)

*4.14. Protonolysis of titanacyclopentene **12***

Treatment of **12** with excess dry HCl, as above, afforded the corresponding diene, (*Z*,*E*)-6-ethyl-3,5-dimethyl-3,6-nonadiene. ^{1}H NMR (C_6D_6): δ 0.87–0.99 (m, 9H, C*H*$_3$–CH_2), 1.18–1.29 (m, 3H, C*H*$_3$–CH), 1.39 (m, 1H, C*H*–CH_3), 1.65 (d, 2H, *J* = 0.6 Hz, CH_3–C=), 1.90–1.97 (m, 6H, C*H*$_2$CH$_3$), 4.81 (d, 1H, *J* = 5.1 Hz, =C*H*–CH(CH_3)), 5.15 (t, 1H, *J* = 7.2 Hz, =C*H*–CH_2CH_3).

*4.15. Preparation of (trimethylphosphine)(3-methyl-1,2-butadiene)titanocene (**14**)*

To a stirred solution of 100 mg of $Cp_2Ti(PMe_3)_2$ (0.303 mmol) in 2 ml of C_6D_6 was added 100 μl of trimethylphosphine and 30 μl of 3-methyl-1,2-butadiene (1 equiv.). The mixture was stirred at room temperature for 1 h, then frozen in a −5°C bath. Volatiles were removed from the frozen sample in vacuo, yielding **14** in analytically pure form as a greenish-brown solid (0.079 g, 81%), m.p. 120°C. ^{1}H NMR (C_6D_6): δ 0.29 (br s, 2H, CH_2), 0.83 (br s, 9H, PMe_3), 2.02 (s, 3H, CH_3), 2.41 (s, 3H, CH_3), 4.82 (s, 10H, Cp). ^{13}C{^{1}H} NMR (C_6D_6): δ 7.2 (PMe_3), 24.2 (CH_3), 29.7 (CH_3), 99.6 (Cp), 113.7 (Ti–CH_2), 118.5 (=*C*(CH_3)$_2$), 172.0 (Ti–*C*=C(CH_3)$_2$). ^{13}C NMR (C_6D_6): δ 7.2 (m, J_{app} = 150 Hz, PMe_3), 24.2 (q, $^1J_{CH}$ = 123 Hz, CH_3), 29.7 (q, $^1J_{CH}$ = 127 Hz, CH_3), 99.6 (d, $^1J_{CH}$ = 174 Hz, Cp), 113.7 (m, J_{app} = 3 Hz, Ti–CH_2), 118.5 (s, =*C*(CH_3)$_2$), 172.0 (s, Ti–*C*=C(CH_3)$_2$). *Anal*. Calc. for $C_{18}H_{27}PTi$: C, 67.08; H, 8.44; P, 9.61. Found: C, 67.12; H, 8.33; P, 9.50%.

4.16. Reaction of (trimethylphosphine)(3-methyl-1,2-butadiene)titanocene with 2-butyne

To a solution of 20 mg of allene complex **14** (0.062 mmol) in 0.5 ml of C_6D_6 in an NMR tube was added 9.5 μl of 2-butyne (2 equiv.). The tube was sealed, then heated at 65°C for 1.5 h, at which time spectral analysis revealed complete conversion of **14** to titanacyclopentene **9** (ca. 97%) and a trace of the product of reductive coupling of two equivalents of the allene (**15**, vide infra).

4.17. Reaction of (trimethylphosphine)(3-methyl-1,2-butadiene)titanocene with diphenylacetylene

Treatment of allene complex **14** with 1 equiv. of diphenylacetylene as described above afforded a ca. 9:1 mixture of titanacyclopentene **16** (R = Ph) and reductive coupling product **15** (vide infra). ^{1}H NMR (C_6D_6): δ 0.8 (s, 3H, CH_3), 1.52 (s, 3H, CH_3), 3.16 (s, 2H, CH_2), 6.02 (s, 10H, Cp), 6.8–7.4 (m, 10H, Ph).

4.18. Reductive coupling of 3-methyl-1,2-butadiene by $Cp_2Ti(PMe_3)_2$

To a solution of 250 mg of $Cp_2Ti(PMe_3)_2$ (0.758 mmol) in 8 ml of diethyl ether was added 100 μl of trimethylphosphine and 148 μl of 3-methyl-1,2-butadiene (2 equiv.). The mixture was kept at room temperature, with periodic monitoring of aliquots by ^{1}H NMR. After the reaction appeared complete (ca. 24 h), removal of all volatiles in vacuo afforded an orange solid. This crude product was extracted into pentane and the resulting solution was filtered to remove insoluble residues and evaporated, affording the titanacyclopentane **15** as a bright-orange solid (186 mg, 78%). ^{1}H NMR (C_6D_6): δ 0.75 (s, 6H, CH_3), 1.48 (s, 6H, 2×CH_3), 2.23 (s, 4H, CH_2), 6.05 (s, 10H, Cp). ^{13}C{^{1}H} NMR (C_6D_6): δ 21.4 (CH_3), 25.9 (CH_3), 31.3 (CH_2), 114.2 (Cp), 124.5 (Ti–C=*C*), 186.7 (Ti–*C*=C). MS (70 eV): *m/z* = 314 (M^+), 312, 310, 296, 272, 243, 192, 178 (Cp_2Ti), 113 (CpTi). HRMS. Calc. for $C_{20}H_{26}Ti$: 314.1514. Found:

314.1529. *Anal*. Calc. for $C_{20}H_{26}Ti$: C, 76.42; H, 8.34. Found: C, 76.34; H, 8.41%.

4.19. Kinetic studies

Reaction mixtures comprised 0.288 mM Cp_2TiMe_2 in C_6D_6, 2–10 equiv. of the alkyne, and 10 mol% of ferrocene as an internal standard were sealed under dry nitrogen in 5 mm NMR tubes. Reactions at $>70°C$ were carried out directly in the NMR probe ($\pm 0.5°C$), while reactions at lower temperatures were carried out in thermostatted oil baths, with the tubes wrapped in aluminum foil to preclude possible photochemical reactions. Reaction progress was monitored using the cyclopentadienyl resonances of the products, which were all clearly resolved.

Abstract

Two new mixed-valence tetranuclear copper(I,II) α,β-unsaturated carboxylate complexes $Cu^{I}_{2}Cu^{II}_{2}A_{6}(PPh_3)_4(CH_3OH)_2$ (**1**, $A = CH_2{=}CH{-}COO^-$; **2**, $A = CH_2{=}C(CH_3){-}COO^-$) have been synthesized by partial reduction of $Cu_2A_4(H_2O)_2$ by triphenylphosphine in methanol solution, and characterized by elemental analyses, IR, ESR, electronic reflectance spectroscopies as well as magnetic susceptibility measurements. In complex **2** two copper(II) atoms in a molecule are linked by four carboxylate groups forming a dimeric unit $Cu^{II}_{2}A_4$, and each copper(II) atom coordinates with a copper(I) moiety through a μ_2-O,O′ carboxylate group. The electronic reflectance spectra in the solid state suggest a square pyramidal coordination environment around the copper(II) atoms. Bond valence calculations further confirm the presence of the mixed-valence system and the oxidation state of the copper atoms. Room temperature X-band ESR spectra of powdered samples and variable-temperature magnetic susceptibility studies indicate the presence of strong antiferromagnetic exchange interactions between two copper(II) atoms, with $2J = -310\ cm^{-1}$ for complex **1** and $2J = -288\ cm^{-1}$ for complex **2**. The formation mechanism of the title complexes and the structural interconversion among related mixed-valence copper(I,II) carboxylate complexes are also discussed.

Keywords: Copper(I,II) complexes; α,β-Unsaturated carboxylates; Triphenylphosphine; Magnetic properties; Crystal structures

1. Introduction

Electron transfer between copper(I) and copper(II) remains a subject of intense interest [1–4]. Copper(I) and copper(II) polymers play an important role in copper-catalyzed substrate oxygenation in biochemical processes [5–8]. The crystal structure of mixed-valence copper(I,II) complexes has received a great deal of attention for what they may reveal about structural changes accompanying oxidation and reduction of copper in metalloenzymes [9]. Indeed, only a few structurally characterized mixed-valence copper(I,II) complexes containing carboxylate and phosphine ligands have been reported. Specifically, Beddoes et al. [10] and Connor et al. [11] characterized a one-dimensional chain of repeating $Cu^{II}_{2}Cu^{I}$ units (A) by partial reduction of copper(II) with triethylphosphine, and a tetrameric complex with triphenylphosphine (B) was synthesized and character-

ized by Valigura et al. [12,13], as depicted in structural formulas, A and B.

Two mixed-valence copper(I,II) complexes, $Cu^{I}_{2}Cu^{II}_{2}(CH_2{=}CH{-}COO)_6(PPh_3)_4(CH_3OH)_2$ (**1**) and $Cu^{I}_{2}Cu^{II}_{2}[CH_2{=}C(CH_3){-}COO]_6(PPh_3)_4(CH_3OH)_2$ (**2**) synthesized here were characterized by elemental analyses, IR, ESR, electronic reflectance spectroscopies as well as magnetic susceptibility measurements. The crystal structure of complex **2** was determined by X-ray diffraction, and the oxidation states of the copper atoms have also been calculated with bond valence theory.

Both complexes **1** and **2** have a tetranuclear structure, in which two Cu(II) atoms are linked by four μ_2-O,O′ α-methacrylate groups forming a cage structural unit. It is interesting that the solvent molecule MeOH coordinates with the Cu(I) atom and completes its tetrahedral coordination environment along with two triphenylphosphine molecules and a μ-O,O′ α-methacrylate group. The Cu(I) moiety is linked with the Cu(II) atom through a μ-O,O′ α-methacrylate group. The formation mechanism of complexes **1** and **2** and the structural interconversion among the three related structures (A, B and the complex reported here) are discussed in this paper.

2. Experimental

2.1. Syntheses

All chemicals were purchased commercially and used as received. $Cu_2(CH_2{=}CH{-}COO)_4(H_2O)_2$ and $Cu_2[CH_2{=}C(CH_3){-}COO]_4(H_2O)_2$ were prepared as previously reported [14].

$Cu^{I}_{2}Cu^{II}_{2}(CH_2{=}CH{-}COO)_6(PPh_3)_4(CH_3OH)_2$ (**1**): a methanol solution (10 ml) of PPh_3 (2.68 g, 10.0 mmol) was added to a solution of $Cu_2(CH_2{=}CH{-}COO)_4(H_2O)_2$ (1.00 g, 2.24 mmol) in methanol (30 ml). The mixture was boiled for 2 h and filtered under warm conditions in a nitrogen atmosphere. Upon standing at room temperature for several days in vacuo, pale-green crystals were obtained. *Anal*. Calc. for $C_{92}H_{86}Cu_4P_4O_{14}$: C, 61.60; H, 4.83; Cu, 14.17. Found: C, 61.40; H, 4.92; Cu, 14.33%.

$Cu^{I}_{2}Cu^{II}_{2}[CH_2{=}C(CH_3){-}COO]_6(PPh_3)_4(CH_3OH)_2$ (**2**): this was prepared according to the same procedure as for complex **1**, using $Cu_2[CH_2{=}C(CH_3){-}COO]_4(H_2O)_2$ (1.13 g, 2.24 mmol) instead of $Cu_2(CH_2{=}CH{-}COO)_4(H_2O)_2$. *Anal*. Calc. for $C_{98}H_{98}Cu_4O_{14}P_4$: C, 62.60; H, 5.22; Cu, 13.53. Found: C, 62.73; H, 5.35; Cu, 13.45%.

2.2. Crystallography

A pale-green crystal of complex **2** with approximate dimensions 0.28×0.22×0.20 mm was mounted on a Siemens P4 diffractometer, using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The data were collected with the ω–2θ scan technique ($2.03 \le \theta \le 23.99°$) by the XSCANS program. A total of 6163 reflections were collected (5874 independent reflections, $R_{int} = 0.0395$). Lp corrections and absorption correction were applied (transmission factors: 0.8071 and 0.7105). The structure was solved by direct methods and refined with full-matrix least-squares technique. The hydrogen atoms were generated in idealized positions. All calculations were performed on a IBM 486/PC using the Siemens SHELXTL-PC program. A summary of the crystallographic data collection is presented in Table 1.

2.3. Physical measurements

Elemental analyses were determined with a Perkin-Elmer model 240C automatic instrument. IR spectra were recorded on KBr pellets with a Nicolet 170SX FT-IR spectrometer. Electronic reflectance spectra were recorded on a Perkin-Elmer 40P spectrophotometer. ESR spectra were recorded on powder samples at X-band frequency of about 9.77 GHz with a Bruker ER200-D-SRC10/12 automatic spectrometer. Variable-temperature (77–300 K) magnetic susceptibility measurements were carried out on a CAHN-2000 Faraday balance with $Ni(en)_3S_2O_3$ as a standard at 5 T magnetic field. The diamagnetic corrections were evaluated from Pascal's constants [15]. The effective magnetic moments were calculated from the expression:

$$\mu_{eff} = 2.83\sqrt{\chi^{Cu}_{M}T} \quad (1)$$

3. Results and discussion

3.1. IR spectra

The IR spectra show strong bands corresponding to $\nu_{as}(COO)$ and $\nu_s(COO)$ at 1575 and 1430 cm^{-1} for complex **1**, and 1579 and 1421 cm^{-1} for complex **2**. The $\Delta\nu$ values of the two complexes are 145 and 158 cm^{-1}, respectively, which are close to the corresponding values of CH_2=CH–COONa (134 cm^{-1}) and CH_2=C(CH_3)–COONa (150 cm^{-1}), indicating that the α,β-unsaturated carboxylate group behaves as a bridging bidentate ligand between two Cu atoms [16,17], and complex **1** is likely to have a structure similar to that of complex **2**.

3.2. Crystal structure of $Cu^I_2Cu^{II}_2[CH_2=C(CH_3)–COO]_6(PPh_3)_4(CH_3OH)_2$ (2)

The selected bond lengths and angles for complex **2** are listed in Table 2. The ORTEP drawing of complex **2** is shown in Fig. 1. The molecule is centrosymmetric, with its pair of Cu(II) atoms bridged by four α-methacrylate groups forming a dimeric cage structural unit $Cu^{II}_2[CH_2=C(CH_3)–COO]_4$, which is connected at each end by a $Cu^I[CH_2=C(CH_3)–$

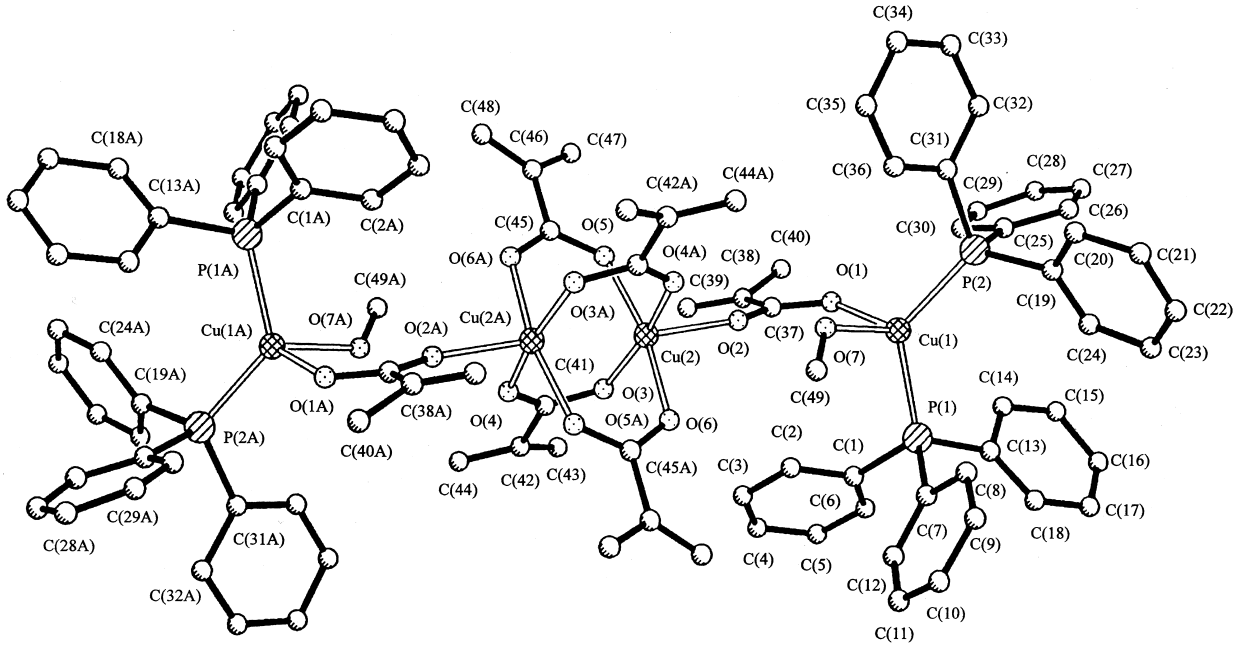

Fig. 1. ORTEP drawing of $Cu^I_2Cu^{II}_2[CH_2=C(CH_3)–COO]_6(PPh_3)_4(CH_3OH)_2$ (**2**).

COO](PPh$_3$)$_2$(CH$_3$OH) unit via an axial μ-O,O′ α-methacrylate group to form a tetranuclear structure.

The configuration of each Cu(II) atom is a square pyramid, in which the basal plane (average deviation: 0.0069 Å, plane 1) is composed of O(3), O(4A), O(5) and O(6) from four μ_2-O,O′ α-methacrylate groups of the $Cu^{II}_2[CH_2{=}C(CH_3){-}COO]_4$ unit. The Cu(II) atom is displaced from the basal plane towards the apical oxygen atom O(2) by 0.2204 Å, which is slightly larger than the corresponding value of 0.211 Å in $Cu^{I}_2Cu^{II}_2(CH_3{-}COO)_6(PPh_3)_4$ [12] owing to the influence of carboxylate and apical ligands. The average distance Cu(2)–O in the dimeric unit is 1.963 Å, shorter than the apical Cu(2)–O(2) distance of 2.130(2) Å. The O(2)–Cu(2)–O(basal) angles are in the range 89.64(9)–102.87(9)° with average value 96.44°. The atoms O(2), Cu(2) and Cu(2A) are not co-linear, with O(2)–Cu(2)–Cu(2A) = 171.15(8)°, which is slightly smaller in comparison with the values for dimeric copper(II) complexes such as 175.82° in $Cu_2(CH_2{=}CH{-}COO)_4(H_2O)_2$ [18], 178.69° in $Cu_2[CH_2{=}C(CH)_3{-}COO]_4(benzimH)_2$ [19] and 176.4° in $Cu_2(CH_2{=}CH{-}COO)_4(urea)_2$ [14]. The Cu(2)···Cu(2A) separation of 2.6465(10) Å is close to that in the dimer $Cu_2(CH_3{-}COO)_4(H_2O)_2$ (2.64 Å) [17,20], indicating the presence of strong interactions between two Cu(II) atoms, which is confirmed by the magnetic susceptibility studies. The Cu(II)···Cu(II) separation reported here is close to that in the complex $Cu^{I}_2Cu^{II}_2(CH_3{-}COO)_6(PPh_3)_4$ (2.642 Å) [12], but somewhat longer than that in the polymeric complex $[Cu^{I}Cu^{II}_2(CH_3{-}COO)_5\{P(OEt)_3\}_2]$ (2.56 Å) [10].

The Cu(I) atom in the $Cu^{I}[CH_2{=}C(CH_3){-}COO](PPh_3)_2(CH_3OH)$ moiety has a tetrahedral coordination environment, being surrounded by O(1) from a μ-O,O′ α-methacrylate group, O(7) of a methanol molecule and P(1), P(2) from two triphenylphosphine ligands. The angles O(1)–Cu(1)–O(7), O(1)–Cu(1)–P(1), O(1)–Cu(1)–P(2), O(7)–Cu(1)–P(2), O(7)–Cu(1)–P(1) and P(1)–Cu(1)–P(2) are 93.56(8), 105.71(8), 109.69(8), 111.40(8), 106.10(8) and 125.57(4)°, respectively. The bond distances Cu(1)–P(1) and Cu(1)–P(2) are 2.2396(13) and 2.2280(13) Å, respectively, close to the corresponding values in $[Cu^{I}Cu^{II}_2(CH_3{-}COO)_5\{P(OEt)_3\}_2]$ (2.21 and 2.22 Å) [10] and in $Cu^{I}_2Cu^{II}_2(CH_3{-}COO)_6(PPh_3)_4$ (2.249 and 2.225 Å) [12]. The distances Cu(1)–O(1) and Cu(1)–O(7) are 2.052(2) and 2.176(2) Å, longer than the corresponding values of Cu(2)–O(basal) and Cu(2)–O(apical), suggesting that the oxidation state is +2 for Cu(2) and Cu(2A), as well as +1 for Cu(1) and Cu(1A).

Table 3
Bond valence sums [a] for the Cu atoms in complex **2**

	R_i (Å)	S_i	ΣS_M
Cu(1)			1.05
Cu(1)–O(1)	2.052	0.26	
Cu(1)–O(7)	2.176	0.18	
Cu(1)–P(1)	2.2396	0.30	
Cu(1)–P(2)	2.2280	0.31	
Cu(2)			2.15
Cu(2)–O(2)	2.130	0.30	
Cu(2)–O(3)	1.943	0.49	
Cu(2)–O(4A)	1.967	0.46	
Cu(2)–O(5)	1.962	0.46	
Cu(2)–O(6)	1.980	0.44	

[a] Valence sums are calculated with the formula $S_i = \exp[(R_0 - R_i)/B]$ where S_i is the bond valence of bond '*i*', R_0 is a constant dependent on the bonded elements, R_i is the bond length of bond '*i*', $B = 0.37$. ΣS_M is the bond valence sum for the metal. R_0[Cu(II)–O] = 1.679, R_0[Cu(I)–O] = 1.55, and R_0[Cu(I)–P] = 1.79.

Atoms Cu(2), O(5), C(45), O(6A) and Cu(2A) lie on one plane (average deviation: 0.0132 Å, plane 2), and Cu(2), O(3), C(41), O(4) and Cu(2A) on another plane (average deviation: 0.00174 Å, plane 3). Plane 2 and plane 3 are nearly orthogonal with a dihedral angle of 90.8°.

3.3. Bond valence calculation

Bond valence calculations [21,22] were employed to quantify the charge distribution around each copper atom, and the results are summarized in Table 3. The calculated bond valence sum is 1.04 for Cu(1) and Cu(1A), and 2.14 for Cu(2) and Cu(2A).

3.4. Electronic reflectance spectra

The solid state spectra of **1** and **2** recorded in the range 200–1100 nm exhibit three absorptions, and the data are listed in Table 4. The intense reflectance bands (band III) at higher frequencies are assigned to the intraligand transitions [23,24] in the complexes. The absorptions at 26316 cm^{-1} for complex **1** and 27174 cm^{-1} for complex **2** are assigned as carboxylate-to-copper charge-transfer bands (LMCT) [25,26]. The visible reflectance spectra also contain bands at 13514 with a shoulder at 9765 cm^{-1} for complex **1** and 14286 with

Table 4
Electronic reflectance spectral data of the complexes

Complex	ν_{max} (cm^{-1})		
	Band I	Band II	Band III
$Cu^{I}_2Cu^{II}_2(CH_2{=}CH{-}COO)_6(PPh_3)_4(CH_3OH)_2$ (**1**)	13514, 9765	26316	47620, 37879
$Cu^{I}_2Cu^{II}_2[CH_2{=}C(CH_3){-}COO]_6(PPh_3)_4(CH_3OH)_2$ (**2**)	14286, 9687	27174	44643, 36765

a shoulder at 9687 cm^{-1} for complex **2**, which are characteristic of the Cu(II) $d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$ ($^2B_1 \rightarrow {}^2E$) transition in a tetragonal ligand field [27,28]. The shoulders are characteristic of a bridging system with antiferromagnetic interactions [29,30]. The electronic reflectance spectra show that both complexes **1** and **2** contain a binuclear cage structural unit, in which the coordination environment of the Cu(II) atom is a distorted square pyramid.

3.5. ESR spectra

The X-band ESR spectra obtained for the powdered samples of the complexes at room temperature are shown in Fig. 2. The spectra show absorptions at low and high fields H_{z1} and H_{z2} with asymmetrical absorptions H_{xy2}, where $H_{z1}=214$, $H_{z2}=6237$ and $H_{xy2}=4934$ Gs for complex **1**, $H_{z1}=224$, $H_{z2}=6171$ and $H_{xy2}=4934$ Gs for complex **2**. The H_{xy1} absorptions of the two complexes are missing because $|D| > h\nu$ at the X-band frequency used. The spectra can be interpreted using a spin Hamiltonian for axial symmetry,

$$\boldsymbol{H}=g_{\parallel}\beta\boldsymbol{H}_z\hat{\boldsymbol{S}}_z+g_{\perp}(\beta\boldsymbol{H}_x\hat{\boldsymbol{S}}_x+\boldsymbol{H}_y\hat{\boldsymbol{S}}_y)+\boldsymbol{D}(\hat{\boldsymbol{S}}_z^2+2/3)$$

where $S=1$ for the thermally accessible triplet state, and the other symbols have their usual meanings. The calculated ESR parameters are $g_{\parallel}=2.318$, $g_{\perp}=1.998$, $g_{av}=2.105$ and $D=0.3488\ cm^{-1}$ for complex **1**, and $g_{\parallel}=2.348$, $g_{\perp}=2.008$, $g_{av}=2.121$ and $D=0.3399\ cm^{-1}$ for complex **2**, where $g_{av}=(1/3)(g_{\parallel}+2g_{\perp})$. The values are comparable to those found in dimeric copper(II) α,β-unsaturated carboxylates [29,30], indicating the presence of the dimeric unit in the complexes.

3.6. Magnetic susceptibility

Magnetic susceptibilities in the temperature range 77–300 K were determined by the Faraday method and the corrected molar magnetic susceptibility data (χ_M) and effective magnetic moments (μ_{eff}) are listed in Table 5. The fact that χ_M or μ_{eff} decreases gradually with lowering of the temperature reveals the presence of antiferromagnetic coupling interactions through an effective O–C–O (bridging carboxylate) exchange pathway [31,32] for both complexes. The data were fitted to the Bleaney–Bowers equation, Eq. (2), allowing for the presence of paramagnetic impurity [33], where P is the mole fraction of the non-coupled copper(II) impurity, g_i is the average g factor for the impurity, and the other symbols have their usual meanings.

$$\chi_M=\frac{2Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}(1-P)+\frac{2Ng_i^2\beta^2}{4kT}P \quad (2)$$

The g values are obtained from the ESR spectra. The experimental and theoretical curves of χ_M of the two complexes

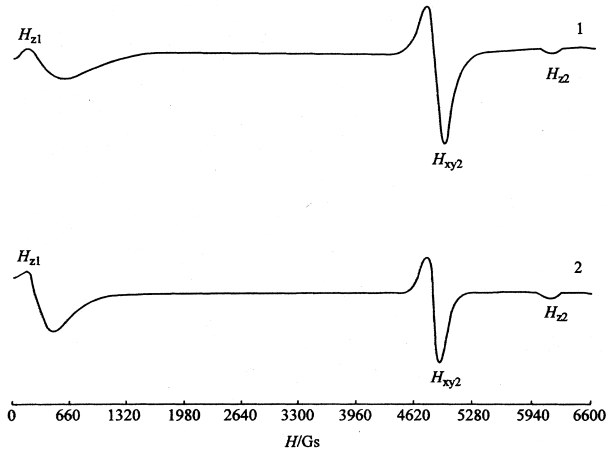

Fig. 2. Solid-state ESR spectra of $Cu_2^ICu_2^{II}(CH_2{=}CH{-}COO)_6(PPh_3)_4(CH_3OH)_2$ (**1**) and $Cu_2^ICu_2^{II}[CH_2{=}C(CH_3){-}COO]_6(PPh_3)_4(CH_3OH)_2$ (**2**).

are shown in Fig. 3, and the estimated parameters $2J$, g_i and P are listed in Table 6.

The energy of the singlet–triplet separation $2J$ values are $-310\ cm^{-1}$ for complex **1** and $-288\ cm^{-1}$ for complex **2**. The effective magnetic moments at room temperature are 1.34 BM for complex **1** and 1.41 BM for complex **2**, which are lower than that of an unpaired single electron (1.73 BM), indicating that strong antiferromagnetic exchange interactions exist between two Cu(II) atoms. The antiferromagnetic interaction in complex **2** is slightly weaker than that of complex **1** in terms of the $2J$ values. The $2J$ values obtained here are comparable with $2J=-270\ cm^{-1}$ for $Cu_2^ICu_2^{II}(CH_3{-}COO)_6(PPh_3)_4$ [12] and $2J=-248\ cm^{-1}$ for $[Cu^ICu_2^{II}(CH_3{-}COO)_5\{P(OEt)_3\}_2]$ [10].

3.7. Formation and structural interconversion

In the study of the chain type complex $[Cu^ICu_2^{II}(CH_3{-}COO)_5\{P(OR)_3\}_2]$ (structure A), Beddoes et al. [10] found that the NMR spectra in alcohol solution showed the presence of two types of acetate methyl proton resonance in the ratio of 3:2. This was explained in terms of a structure which contains three *syn–syn* acetate ligands bridging two copper(II) atoms and two unidentate acetate ligands linking each copper(II) with a four-coordinate copper(I). It was also proposed that the terminal copper(I) atom is coordinated by one or more alcohol solvent molecules, but it has not been demonstrated experimentally. In this work, it is notable that methanol solvent molecules coordinate with Cu(I) in the solid-state complex with structure D (Scheme 1). The formation and structural interconversion among three mixed-valence copper(I,II) carboxylate complexes with phosphine ligands D, E and G is suggested as shown in Scheme 1.

In alcohol solution, phosphine molecules partially reduce the dimer $Cu_2^{II}(R{-}COO)_4(H_2O)_2$ (A) and also act as ligands coordinating with Cu(I) of structure B [10]. The solvent molecules further disrupt the dimeric structure B forming a mononuclear Cu(I) moiety with tetrahedral configuration as

Scheme 1. Formation and structural interconversion of complexes (P = phosphine ligand; L = solvent).

in structure C [34]. Subsequent reaction then follows two alternative routes. In the first one, when a pair of Cu(I) moieties (C) substitute for two terminal aqua of structure A, the mixed-valence complex D is produced, the same as that synthesized in this work. In a reversible step, the loss of solvate molecules L from structure D results in another mixed-valence complex of structure E, which is similar to that reported by Valigura et al. [12,13]. In the second route, the coordination mode of the carboxylate group changes from monodentate to bidentate along with the loss of solvate molecule L from C, giving rise to structure F [10]. The Cu(I) moiety (F) substitutes for a terminal aqua of A, along with breakage of one Cu(I)–O(carboxyl) bond and linkage of Cu(I) to an O atom of a μ-O,O′ bridging carboxylate ligand, forming a mixed-valence chain complex with structure G similar to $[Cu^{I}Cu^{II}_{2}(CH_3–COO)_5\{P(OR)_3\}_2]$ [10].

Supplementary data

Additional material containing non-hydrogen and hydrogen atomic coordinates, thermal parameters, and the remaining bond lengths and angles are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number 114065.

Abstract

A series of platinum(II) complexes of stoichiometry *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(L-L)] were obtained from the reactions of platinum tetrachloride with pyridine-2-thione (C_5H_5NS) in the presence of Et_3N base in an ethanol–benzene mixture followed by the addition of bis(tertiary phosphines), viz. {Ph_2P–X–PPh_2}, or phosphine chalcogenides {Ph_2P–CH_2–P(E)Ph_2} {X(L-L) = $(CH_2)_2$(dppe) (**1**), CH=CH(dppen) (**2**), $(CH_2)_3$(dppp) (**3**), $(CH_2)_4$(dppb) (**4**), E = S, dppmPS (**5**), E = Se, dppmPSe (**6**)}. Palladium(II) complexes, viz. [Pd(η^1-*S*-$C_5H_4NS)_2$(L-L)] {L-L = dppm (X = CH_2) (**7**), dppe (**8**), dppp (**9**), dppmPS (**10**), dppmPSe (**11**)}, were prepared by reacting [$PdCl_2$(diphosphines)] suspended in ethanol with C_5H_5NS in the presence of aqueous NaOH. All these compounds have been characterised with the help of analytical data [IR, far-IR, NMR (^1H, ^{13}C, ^{31}P) spectroscopy] and X-ray crystallography (for compounds **1**, **2** and **8**). The geometry about each metal centre is distorted square planar with *trans* bond angles of: compound **1**, P–Pt–S, 170.31(11), 173.18(10)°; compound **2**, P–Pt–S, 168.97(5), 171.43(5)°; compound **8**, P–Pd–S, 170.78(8), 171.83(8)°. The bite angles P(1)–M–P(2) and angles *trans* to bite angles, S(1)–M–S(2), are, respectively: compound **1**, 85.68(11), 82.69(11)°; compound **2**, 86.65(5), 84.01(6)°; compound **8**, 85.19(8), 83.90(7)°. The dppe complexes (**1** and **8**) are isomorphous, monoclinic with space group *C*2/*c*, whereas the dppen complex is triclinic.These compounds represent the first examples of an interesting series of *cis*-platinum(II) and -palladium(II) derivatives of pyridine-2-thione containing chelating diphosphines and pendant pyridyl groups. ©2000 Elsevier Science Ltd All rights reserved.

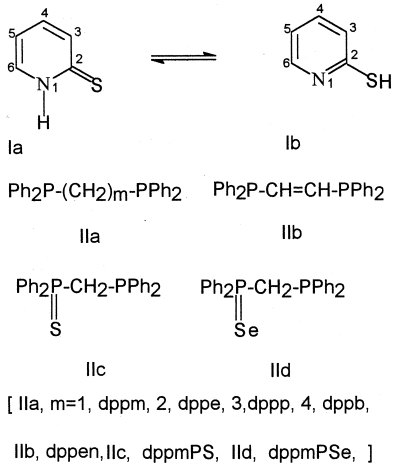
1. Introduction



The interaction of heterocyclic thiones with metals has been the subject of several investigations as these ligands contain chemically active groups [–N(H)–C(=S)– ↔ –N=C(–SH)–] and are useful model compounds for sulfur-containing analogues of purine and pyrimidine bases. Heterocylic 2-thiones bind to a metal in several ways, leading to the formation of monomeric or polymeric complexes [1–4]. For example, the simplest prototype of heterocylic 2-thiones, i.e. pyridine-2-thione (hereafter C_5H_5NS, I), has several ways of binding, notably terminal S-bonding and S-bridging (in neutral form), whereas in anionic form the modes are terminal S-bonding, S-bridging, N,S-chelating, N,S-bridging, N,S-chelation-cum-S-bridging, N,S-bridging-cum-S-bridging [1–32].

The interactions of heavy metals such as platinum, gold with N,S-donor atoms have been recognised for their anticarcinogenic properties with the potential to develop metal-based drugs [1–4,33–36]. These drugs probably exert their therapeutic action via interaction with DNA [33,34]. Recently, some papers involving platinum(II or IV) and gold(I) complexes with tertiary phosphines as co-ligands have been published [37–42]. Using pyridine-2-thione (C_5H_5NS), only a few compounds of platinum(II) and

PII S0277-5387(00)00329-6

palladium(II) with tertiary phosphines (R_3P) have been reported: namely, monomeric $[Pt(\eta^2\text{-}N,S\text{-}C_5H_4NS)(PPh_3)_2]PF_6$ [43], *trans*-$[Pt(\eta^1\text{-}S\text{-}C_5H_4NS)_2(PPh_3)_2]$ [21], $[PdCl(\eta^2\text{-}N,S\text{-}C_5H_4NS)(PPh_3)]$ [44] and dimeric $[PdCl(\eta^2\text{-}N,S\text{-}C_5H_4NS)(PMe_3)]_2$ [45]. There is no report of these metals containing bis-tertiary phosphines and pyridine-2-thione (C_5H_5NS). Among the metals under discussion, *trans*-$[Pt(\eta^1\text{-}S\text{-}C_5H_4NS)_2(PPh_3)_2]$ [21] was the first compound reported, by Lobana et al. [21], containing a pendant pyridyl group in the *trans* position. In this paper, we report first examples of platinum(II) and palladium(II) complexes containing chelating bisphosphines(II) and pendant pyridyl groups in the *cis* position; these compounds may act as potential precursors for polymeric complexes [46].

2. Experimental

2.1. General materials

Platinum tetrachloride was procured from M/s Central Drug House Pvt. (Bombay). *cis*-1,2-Bis(diphenylphosphino)ethene ($Ph_2PCH{=}CHPPh_2$, dppen), bis(diphenylphosphino)methane ($Ph_2PCH_2PPh_2$, dppm) and bis(diphenylphosphino)propane $\{Ph_2P(CH_2)_3PPh_2$, dppp$\}$ were procured from Aldrich. 1,2-Bis(diphenylphosphino)ethane $\{Ph_2P(CH_2)_2PPh_2$, dppe$\}$ and 1,4-bis(diphenylphosphino)-butane $\{Ph_2P(CH_2)_4PPh_2$, dppb$\}$ were prepared by lithiation of PPh_3 in dry tetrahydrofuran followed by reaction with 1,2-dichloroethane or 1,4-dihalobutane as reported earlier [15]. 2-Hydroxypyridine was procured from M/s Sisco Laboratories (Bombay), and pyridine-2-thione was then prepared from it by treatment with P_4S_5 at 140–145°C, as reported earlier [5]. The monosulfide (or selenide) of dppm was prepared by reacting dppm with sulfur powder (or selenium metal) in 1:1 ratio in dry benzene [6]. The starting materials, $PdCl_2$(L-L), were prepared by reacting $PdCl_2$ solutions in CH_3CN with suitable bisphosphines [7].

2.2. Platinum complexes

2.2.1. *cis*-$[Pt(\eta^1\text{-}S\text{-}C_5H_4NS)_2(dppe)]$ (1)

To a solution of C_5H_5NS (0.07 g, 0.60 mmol) in 20 ml of benzene containing 2 ml of Et_3N base was added dropwise a solution of $PtCl_4$ (0.100 g, 0.30 mmol) in 20 ml of dry ethanol under magnetic stirring, followed by the addition of solid dppm (0.120 g, 0.30 mmol) when a clear solution formed, and was stirred overnight (24 h). The white salt of $Et_3NH^+Cl^-$ formed was separated by filtration and slow evaporation of the filtrate gave a light yellow complex. Yield, 80%; m.p., 219–220°C. *Anal*. Found: C, 52.8; H, 3.90; N, 3.24. Required for $C_{36}H_{32}N_2S_2P_2Pt$: C, 53.1; H, 3.93; N, 3.44%. IR (KBr, cm^{-1}): 1550s, 1445s, 1415s, 1120s (νC–S), 1095sh (νP–C), 1110s, 820s, 720s, 698vs, 540s, 405w (νPt–P), 360w (νPt–S). 2.4. Elemental analyses and spectroscopic techniques

C, H and N determinations were performed by the microanalytical laboratory of the Regional Sophisticated Instrumentation Centre (RSIC) of Panjab University, Chandigarh. Infrared (IR) spectra were recorded as KBr pellets in the range 4000–200 cm^{-1} on a Philips Analytical SP3-300 spectrophotometer. ^{1}H NMR spectra were recorded on a Bruker AC-200 spectrometer operating at a frequency of 200 MHz. $CDCl_3$ was used as a solvent with TMS (tetramethylsilane) as the internal reference. ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer operating at a frequency of 50 MHz using $CDCl_3$ as solvent and TMS as the internal

reference. ^{31}P NMR spectra were recorded on a Bruker ACP-300 spectrometer operating at a frequency of 121.4 MHz with 85% phosphoric acid as the external reference (δP 32.5 ppm).

2.5. Crystal structure determinations

The suitable light yellow prismatic crystals of compounds **1**, **2** and **8** were mounted on glass fibres and used for data collection. Cell constants and orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the θ range of 8–20° for compounds **1** and **2** with XSCANS (Siemens Analytical X-Ray Instruments) and $7.567 < \theta < 11.889$° for compound **8**. No detectable decompositon of the crystals occurred during data collection. For compounds **1** and **2**, data were collected on a Siemens P4 diffractometer and for compound **8** on an Enraf-Nonius Mach 3 automatic diffractometer [47]. The data were collected using Mo Kα radiation ($\lambda = 0.71073$ Å) and ω–2θ scan technique, and corrected for Lorentz and polarisation effects [48]. A semi-empirical absorption correction (psi scan) was made [49]. The structure was solved by direct methods and refined by a full-matrix least-squares method based on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were fixed geometrically and were not refined for compounds **1** and **2**, but were refined for compound **8** using a riding model. Atomic scattering factors were used from International Tables for Crystallography [50]. Data reduction, structure solution, refinement and molecular graphics were performed using SHELXTL-PC [51–54]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

3. Results and discussion

3.1. Synthesis and IR spectroscopy

In a recent study, it was found that reaction of N,S-bridged dimeric $Pt(C_5H_4NS)_2$ {obtained from $PtCl_2$ with $Na^+C_5H_4NS^-$} in CH_3CN with PPh_3 formed *trans*-[$Pt(\eta^1$-*S*-$C_5H_4NS)_2(PPh_3)_2$] with pendant pyridyl groups in the *trans* position [21]. The *cis*-[$Pt(\eta^1$-*S*-$C_5H_4NS)_2$(L-L)] compounds [L-L = dppe, dppen, etc. (**1**–**6**)] were obtained by the reactions of $PtCl_4$ (soluble in ethanol, unlike $PtCl_2$) with neutral C_5H_5NS in benzene in the presence of Et_3N,

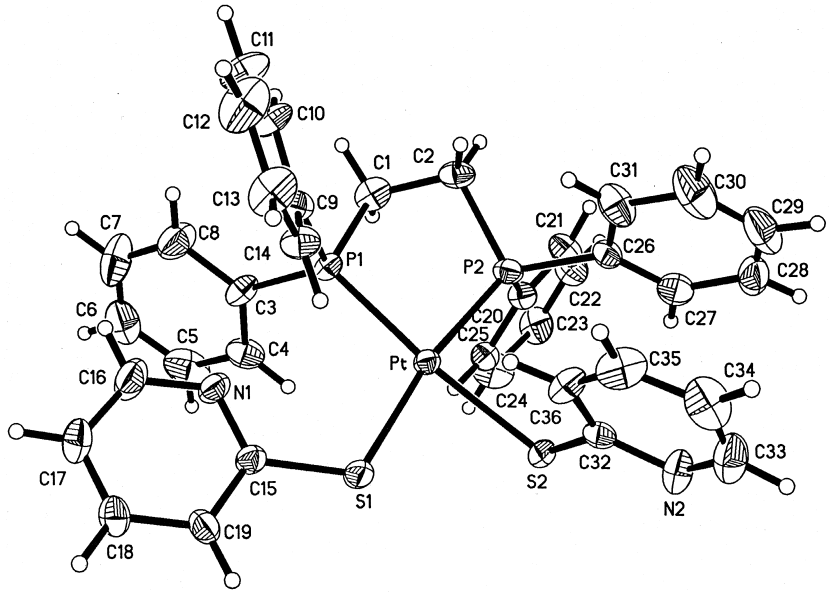

Fig. 1. Structure of monomeric *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppe)] (**1**) showing the numbering scheme.

followed by addition of diphosphines or phosphine chalcogenides. Palladium(II) complexes were prepared by reacting $PdCl_2$ (diphosphines) with C_5H_5NS in the presence of aqueous NaOH.

The IR spectra of the complexes show various characteristic peaks of $C_5H_4NS^-$, diphosphines (see Section 2). The neutral C_5H_5NS shows ν(N–H) at 3162 cm^{-1}, and its absence in the complexes shows deprotonation of the pyridine-2-thione ligand (also confirmed by NMR data, see below). The coordination to Pt^{II}/Pd^{II} via S-donor atom is shown by the characteristic low-energy shift of ν(C–S) in the region 1110–1130 cm^{-1} occurring as a weak to strong peak. The ν(P=S) and ν(P=Se) peaks also undergo low-energy shifts, confirming coordination via P,S/P,Se-donor atoms of dppmPS and dppmPSe. Other tentative assignments due to ν(M–P) and ν(M–S) in the regions 400–420 cm^{-1} and 350–380 cm^{-1}, respectively, have been made.

3.2. Crystal and molecular structures

The atomic numbering schemes of *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppe)] (**1**), *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppen)] (**2**) and *cis*-[Pd(η^1-*S*-$C_5H_4NS)_2$(dppe)] (**8**) are shown in Figs. 1–3, respectively; the packing arrangements for compounds **1** and **2** are shown in Figs. 4 and 5, respectively. The basic monomer unit of compound **1** shows weak intermolecular interaction (4.036 Å) via phenyl groups of two different Ph_2P moieties (Fig. 4). However, no such interaction was visible in compound **2** (Fig. 5), as the closest distance between phenyl groups of two different molecules was 4.672 Å. In compound **1**, intramolecular interaction (3.663 Å) is observed between a pyridyl and a phenyl group of the same molecule (Fig. 4).

In complexes **1** and **2**, two P atoms of diphosphines and two S atoms of $C_5H_4NS^-$ groups coordinate to the Pt atom

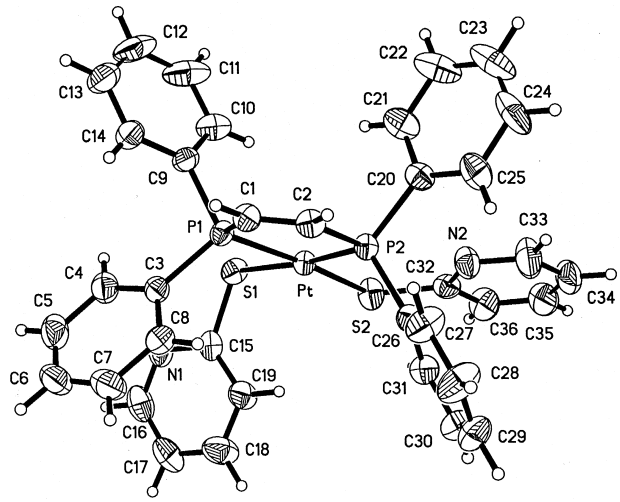

Fig. 2. Structure of monomeric *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppen)] (**2**) showing the numbering scheme.

and the geometry about Pt centres is distorted square planar with *trans* P–Pt–S angles of 173.18(10), 170.31(11)° for compound **1** and 171.43(5), 168.97(5)° for compound **2** (Table 2). There is a small difference in the bite angles of both diphosphines [P(1)–Pt–P(2), 85.68° for compound **1** and 86.65(5)° for compound **2**] as well as in angles *trans* to these bite angles [S(1)–Pt–S(2), 82.69(11) and 84.01(6)° for compounds **1** and **2**, respectively]. Of the *cis* angles about Pt, only one is obtuse [P–Pt–S, 103.99(11)° for compound **1** and 104.38(5)° for compound **2**]; all the others are acute (Table 2). Significantly, an analogous complex, *trans*-[Pt(η^1-*S*-$C_5H_4NS)_2(PPh_3)_2$] (**A**) containing *trans* pendant pyridyl groups [21], showed *trans* bond angles (P–Pt–P* and S–Pt–S*) of exactly 180° and two acute (85.24°) and two obtuse (94.76°) angles about Pt. In a related diphosphine dimeric Pt complex [39], [(dppm)Pt(μ_2-*N*,*S*-TT)$_2$Pt-(dppm)] {**B**, dppm = $Ph_2PCH_2PPh_2$, H_2TT = 8-thiotheo-

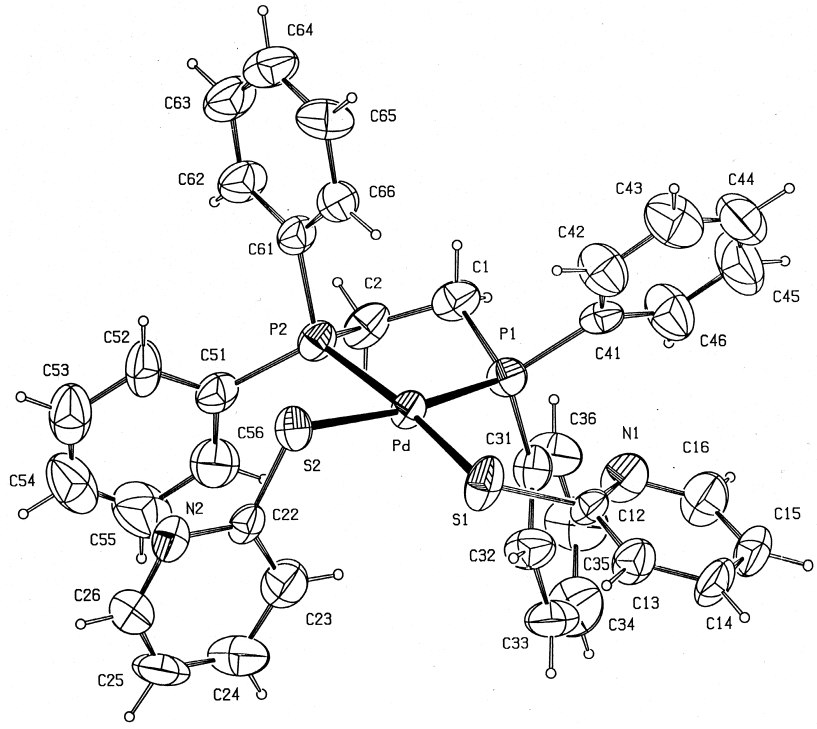

Fig. 3. Structure of monomeric *cis*-[Pd(η^1-*S*-$C_5H_4NS)_2$(dppe)] (**8**) showing the numbering scheme.

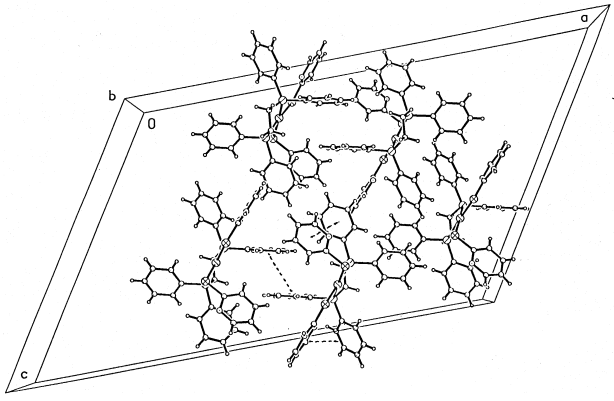

Fig. 4. Molecular packing arrangement of *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppe)] (**1**).

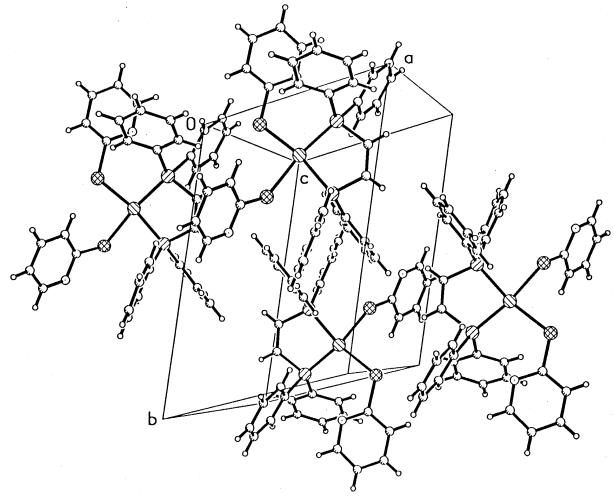

Fig. 5. Molecular packing arrangement of *cis*-[Pt(η^1-*S*-$C_5H_4NS)_2$(dppen)] (**2**).

phylline-N,S}, the diphosphine bite angle (P–Pt–P) was 73.35(12)° and *trans* P–Pt–S and P–Pt–N bond angles were 168.91(11) and 171.80(3)°, respectively; other *cis* angles about Pt were obtuse.

The Pt–P and Pt–S distances are similar in all four cases under discussion (Pt–P (Å): for compound **1**, 2.270(3), 2.256(3); compound **2**, 2.241(2), 2.268(1); compound **A**, 2.315 [21]; compound **B**, 2.270(3), 2.235(3) [6]. Pt–S (Å): compound **1**, 2.327(3), 2.389(3); compound **2**, 2.370(1), 2.332(2); compound **A**, 2.343(2) [21]; compound **B**, 2.356(3) [39]). There are small differences in P–C_{Ph} and P–$C_{alkane/alkene}$ bond lengths in compounds **1** and **2**. The S(1)–C(15) and S(2)–C(32) bond distances are slightly longer in compounds **1**, **2** and **B** compared with that in **A** (average: compound **1**, 1.7645(11); compound **2**, 1.753(6); compound **A**, 1.739(6); compound **B**, 1.751(12) Å). In compounds **1** and **2**, the bite angles of S(1)–C(15)–N(1) and S(2)–C(32)–N(2) are different: compound **1**, 119.8(1), 114.7(9)°; compound **2**, 113.4(5), 120.1(4)°, respectively. However, these bite angles (113–120°) are characteristic of an S-bonded monodentate $C_5H_4NS^-$ moiety [21,55]. Other characteristic bond angles, Pt–S(1)–C(15) and Pt–S(2)–C(32), are also different in the two cases: compound **1**, 116.9(4), 106.1(4)°; compound **2**, 109.1(2), 115.8(2)°.

Complexes **1** and **8** are isomorphous and their bond angles and distances are similar. Considering different planes for the complexes, the plane in compound **1** defined by the atoms $S^1S^2P^1P^2Pt$ makes an angle of 89.68° with the plane defined

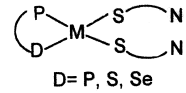
[a] Symmetry transformations were used to generate equivalent atoms.

by the atoms $C^{32–36}$, N^2, and the angle is 5.98° with the second pyridyl group defined by atoms $C^{15–19}$, N^1. The corresponding angles are 12.19° for compound **3** and 74.94° for complex **2**. The orientation of pyridyl groups in compound **8** is similar to that of complex **2**, the corresponding angles being 7.36 and 84.10°. A further significant observation is the small angle of 13.07° between the planes defined by $C^{32–36}$, N^2 and $C^{26–31}$ for compound **1**; this explains the closest contact between a pyridyl group and a phenyl group as described earlier. It shows π-interactions between the two rings. In summary, the change in alkane moiety connecting Ph_2P groups from $–CH_2–CH_2–$ to –CH=CH– affects the orientation of the planes of Ph and py groups, in addition to inducing variations in bond distances and angles as discussed above.



3.3. NMR spectroscopy

The observed ^1H and ^{13}C NMR resonances for all the complexes are given in Section 2. Deprotonation of C_5H_5NS in the complexes is evident from the absence of an NH proton signal (δ_{N-H}, 13.4 ppm (b) for free C_5H_5NS) and it shows platinum(II)–$C_5H_4NS^-$ bonding in complexes via S- or N,S-donor atoms [18–20]. The diagnostic H(6) proton signal of a pyridyl group in the vicinity of N atoms generally undergoes a shift to the low field in the complexes relative to neutral C_5H_5NS; other proton signals H(3), H(4) and H(5), all move upfield in the complexes. This behaviour of $C_5H_4NS^-$ is similar to that in *trans*-[Pt(η^1-*S*-$C_5H_4NS)_2(PPh_3)_2$] [21] and shows increased aromaticity of pyridyl groups in the complexes [55]. The $–(CH_2)_n–$, –CH=CH– and $C_6H_5–$ protons of diphosphine ligands show small low-field shifts.

The ^{13}C NMR spectra provide more convincing information about the uni- or bi-dentate behaviour of the $C_5H_4NS^-$ moiety [15–21,56]. The C(2) carbon signal of the pyridyl group moves upfield in the complexes (relative to free C_5H_5NS) and is characteristic of an S-bonded unidentate $C_5H_4NS^-$ moiety as a N,S-chelating moiety shows a low-field shift in the C(2) signal. Further C(3) and C(6) signals move downfield, while C(4) and C(5) signals move upfield, the latter carbon showing more pronounced shifts [15–21,56]. Finally, the $–CH_2–$ signals of diphosphine ligands show significant low-field shifts. The *ipso*-carbon of the $C_6H_5–$ group of free ligands moves upfield in all the complexes. The *meta*- and *para*-carbon signals either appear as separate or overlap; however, the *ortho*-carbon signal is almost unaffected. The –CH=CH– carbon signal of dppen appears as a triplet at δ 146.6t (J_{C-P}, 7.5 Hz) which shifts to a higher field at δ 145.4 ppm as an unresolved singlet in compound **2**. Thus NMR shows that, in all the complexes, pyridine-2-thiolate is coordinating to metals via an S-donor atom with pendant pyridyl groups in *cis* positions.

The ^{31}P NMR spectrum of compound **2** shows two ^{31}P NMR signals with corresponding pairs of satellites due to coupling from ^{195}Pt ($I = 1/2$), whereas compound **1** shows one ^{31}P signal with a pair of satellites. The presence of two sets of ^{31}P signals could be due to the non-equivalent pyridyl groups facing P atoms and this non-equivalence is probably not resolved in the dppe complex (**1**). While the J_{P-Pt} constants are similar in magnitude in the two cases (compound **1**, 2968.2 Hz; compound **2**, 2958.5, 2969.4 Hz), the coordination shifts ($\Delta\delta P$) are different (compound **1**, 58.2 ppm; compound **2**, 77.1 ppm). Thus, dppen is coordinating more strongly to the Pt centre than dppe is. The difference is attributed to the unsaturation in the –CH=CH– moiety of dppen, which could favour increased charge delocalisation in the Pt–dppen moiety.

In conclusion, *cis*-[M(η^1-*S*-$C_5H_4NS)_2$(diphosphines)]-(III) represent an interesting series of first examples with the potential to act as precursors to develop further polymetallic chemistry.

POLYHEDRON

Molybdenum(VI) equilibria at high perchloric acid concentration

J.J. Cruywagen *, J.B.B. Heyns

Department of Chemistry, University of Stellenbosch, Stellenbosch 7600, South Africa

Received 15 November 1999; accepted 7 February 2000

Abstract

Equilibria involving the protonation and dimerization of $MoO_2(OH)(H_2O)_3^+$ at high perchloric acid concentration have been investigated. A value for the protonation constant has been determined, $\log K = -2.23 \pm 0.09$. Values for the enthalpy and entropy changes for the reaction are $\Delta H = -21.4 \pm 1.8$ kJ mol^{-1} and $\Delta S = -90 \pm 6$ J mol^{-1} K^{-1} in 6.29 M $HClO_4$. For the dimerization reaction the values pertaining to 3.0 M Na(H)ClO_4 are $\Delta H = -30 \pm 5$ kJ mol^{-1} and $\Delta S = -63 \pm 10$ J mol^{-1} K^{-1} as determined by enthalpimetric titrations. Thermodynamic quantities for the conversion of $[MoO_4]^{2-}$ to the various mono- and dinuclear cationic species are reported. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Equilibrium constants; Molybenum(VI) cations; Thermodynamic quantities

1. Introduction

The successive protonation equilibria of $[MoO_4]^{2-}$ up to the formation of the cationic species, $MoO_2(OH)(H_2O)_3^+$, are well characterized, and equilibrium constants have been determined for different ionic media by various authors [1–9]. The total molybdate concentration must be lower than 10^{-4} M (mol dm^{-3}) for the species to be predominantly mononuclear in aqueous solution. A perchloric acid concentration of at least 1 M is required to have about 90% of molybdate protonated to $MoO_2(OH)(H_2O)_3^+$ [3]. There are indications that further protonation to a doubly charged cation occurs at higher acid concentration (>3 M) but the reaction has not been investigated in detail [3–5]. At high acid concentration, characterization of the equilibrium at constant ionic medium is problematic, whereas the tendency of molybdenum(VI) to form dinuclear cations [10–16] even at very low concentration must also be taken into account.

In this paper we report the results of a spectrophotometric study of these reactions in perchloric acid medium up to a concentration of 8 M. By introducing the hydrogen ion activity a quite satisfactory description of the equilibria can be obtained under these extreme conditions. The equilibrium constants can therefore be used to calculate relative concentrations of the species. It is shown to what extent dimerization is promoted by an increase in perchloric acid concentration at a given molybdate concentration.

The protonation of $MoO_2(OH)(H_2O)_3^+$ has been found to be an exothermic reaction. Thermodynamic quantities for the formation of the dimeric species have also been determined.

2. Experimental

Analytical grade chemicals (Merck, p.a.) were used and solutions were prepared with water purified with a Millipore Milli-Q system. A sodium molybdate stock solution of known concentration was prepared by weighing out an appropriate amount of $Na_2MoO_4 \cdot 2H_2O$. A stock solution of sodium perchlorate was prepared from recrystallized $NaClO_4$. These solutions were standardized by evaporating known volumes to dryness and heating at 160°C to constant weight. Perchloric acid was standardized indirectly against potassium hydrogen phthalate by titration with sodium hydroxide.

A GBC 920 UV–Vis double-beam spectrophotometer equipped with a Peltier thermocell was used for the absorption measurements. The temperature was kept constant at 25°C. Absorption spectra of molybdate(VI) solutions at two different concentrations (2.5×10^{-5} and 2.5×10^{-3} M) were recorded in the range 211–301 nm at intervals of 2 nm. Quartz cuvettes of path length 1.00 and 0.20 cm were used for measurements at the low and high concentrations, respectively. In each case a series of solutions (and corresponding blank solutions) were prepared of varying perchloric acid concentration in the range 0.40–8.0 M.

An isothermal calorimeter, Tronac Model 1250, was used for the enthalpy measurements. Perchloric acid solutions (20.0 or 25.0 cm^3) of four different concentrations (0.50, 1.00, 2.00 and 3.00 M) were titrated with either 0.05 or 0.50 M sodium molybdate solution from a precision microburette (2.50 cm^3). The total heat measured for the titrations with 0.05 and 0.50 M molybdate was about 4.5 and 45 J, respectively. Some of the titrations were done in duplicate. All solutions were made 3.0 M with respect to perchlorate ions by addition of the appropriate amount of $NaClO_4$. Blank titrations of 3.0 M sodium perchlorate into solutions of perchloric acid and sodium perchlorate were done to correct for the heat of dilution (endothermic). This heat varied from $\sim$0.15 to 0.12 kJ mol^{-1} for $NaClO_4$ added to 3.0 M $HClO_4$, but was negligible in the case of 0.50 M $HClO_4$.

3. Results and discussion

3.1. Mononuclear species

The equilibria involved can be represented as follows:

$$MoO_3(H_2O)_3 + H^+ \leftrightharpoons MoO_2(OH)(H_2O)_3^+ \quad (1)$$

$$MoO_2(OH)(H_2O)_3^+ + H^+ \leftrightharpoons MoO_2(H_2O)_4^{2+} \quad (2)$$

There is little to choose between the alternative formulations for the uncharged mononuclear molybdic acid, i.e. $MoO_3(H_2O)_3$ and $MoO_2(OH)_2(H_2O)_2$. Slight preference is given to the former as discussed in a previous paper [17].

Although the focus is on the characterization of reaction (2), overlap of the equilibria necessitates the inclusion of reaction (1) in the description of the system. In the range of acid concentrations investigated, the maximum percentage concentration of $MoO_3(H_2O)_3$ is about 20%. To prevent the formation of dimeric cations the measurements had to be carried out at a very low molybdenum concentration (2.5×10^{-5} M). At this concentration the absorption in the UV is just high enough to yield results of sufficient accuracy for quantitative treatment. The change in absorption with change in perchloric acid concentration is shown in Fig. 1.

At varying ionic strength the protonation constants must be expressed in terms of the activities of the species; for example, for reaction (2) the constant is given by:

$$K_2 = \frac{[MoO_2(H_2O)_4^{2+}]y_2}{[MoO_2(OH)(H_2O)_3^+]y_1 a_{H^+}} \quad (3)$$

where y_2 and y_1 are the molar activity coefficients of the doubly and singly charged ions respectively and a_{H^+} is the molar activity of the hydrogen ion.

The activity of the hydrogen ion in perchloric acid is known [18,19] and can be substituted for the hydrogen ion concentration in the calculations. A reasonable approximation at high acid concentration is to assume that the activity coefficients of the molybdenum species vary roughly in the same manner, i.e. y_2/y_1 remains approximately constant. A value

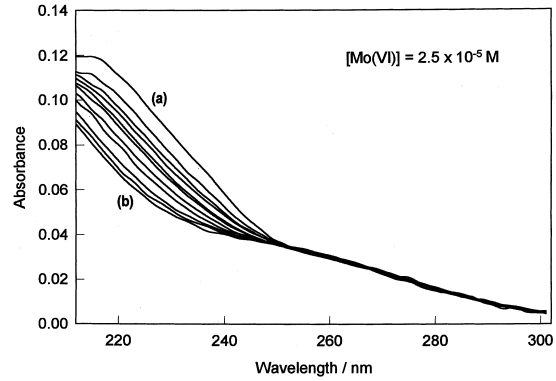

Fig. 1. Change in absorption spectra with change in perchloric acid concentration from 0.408 (a) to 8.15 M (b) of a 2.5×10^{-5} M molybdenum(VI) solution measured in a 1.00-cm cuvette.

for the protonation constant can therefore be determined from the change in the absorption with change in perchloric acid concentration.

By following this procedure and using the program EQUISPEC [20] to treat absorption data in the wavelength range 217–241 nm, where the greatest change in absorption occurs on protonation, a satisfactory fit between calculated and experimental points was obtained. The spectrum of the uncharged molybdic acid is known from previous work [3] so that the molar absorptivities at the wavelengths in question could be supplied to the program. The values calculated for the overall protonation constants were $\log \beta_1 = 0.95 \pm 0.01$ and $\log \beta_2 = -1.18 \pm 0.09$, where $\beta_1 = K_1$ and $\beta_2 = K_1K_2$.

The value for $\log \beta_1$ can be compared with the values 0.90 and 1.06 previously determined in 1.0 and 3.0 M Na(H)ClO_4 medium, respectively [3]. The calculated absorption spectra of the species are shown in Fig. 2. The spectrum of the singly charged cation agrees well with that previously reported, showing that the methodology followed provides an acceptable description of the behaviour of mononuclear molybdate at high acid concentration. From the distribution of the species with variation of perchloric acid concentration shown in Fig. 3 it is seen that a perchloric acid concentration higher than 6 M is required to obtain more than 50% protonation to the doubly charged cation.

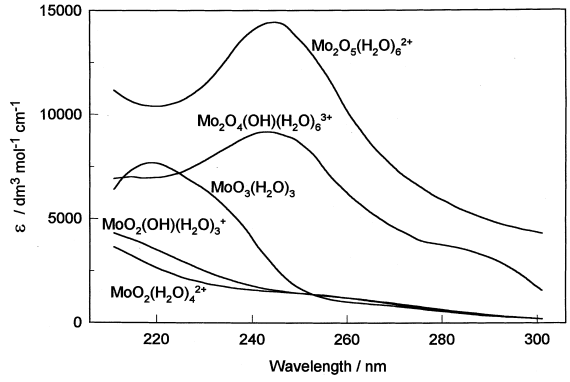

Fig. 2. Calculated absorption spectra of the various mono- and dinuclear species of molybdenum(VI).

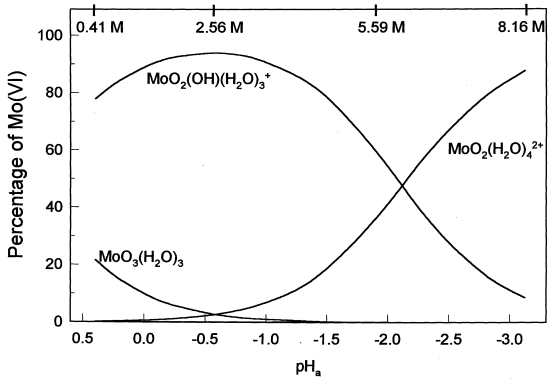

Fig. 3. Distribution of species as a function of pH_a ($-\log a_{H^+}$). The perchloric acid concentration corresponding to pH_a is shown on the upper axis.

The values $\log \beta_1 = -1.16$ and $\log \beta_2 = -3.98$ for the above reactions have been reported, by way of example, in the discussion of a program capable of calculating thermodynamic constants by correcting for variations in activity coefficients applying either Debye–Hückel, specific interaction or the modified Bromley theory [21]. However, as no information about the experimental conditions or the distribution of the species was given, a comparison with the results of the present work is not possible.

The enthalpy change for the protonation of $MoO_2(OH)(H_2O)_3^+$ has been determined from the variation in the equilibrium constant with temperature following a procedure analogous to that previously described [3]. The constant at a particular temperature can be calculated using Eq. (4):

$$K' = \frac{(\varepsilon_1 - \varepsilon)}{(\varepsilon - \varepsilon_2)[H^+]} \quad (4)$$

where ε_1, ε_2 and ε are the molar absorption coefficients of $MoO_2(OH)(H_2O)_3^+$, $MoO_2(H_2O)_4^{2+}$ and the sample solution, respectively. At the hydrogen ion concentration chosen for the measurements (6.29 M), the ratio of the concentration of the two cations is about 1 and $(\varepsilon_1 - \varepsilon)/(\varepsilon - \varepsilon_2) \sim 1$, which is the most suitable for the determination of the constant. Any shift in the equilibrium position due to a change in the temperature will result in the largest possible change in ε, while uncertainties in the values of $(\varepsilon_1 - \varepsilon)$ and $(\varepsilon - \varepsilon_2)$ will have the least effect on the calculated values of K'. This constant represents a concentration quotient and should also be regarded as a conditional protonation constant valid only for this particular medium, i.e. 6.29 M $HClO_4$. Perchloric acid is completely ionized up to about 6 M [22].

Assuming ΔH remains constant over the temperature range 16–36°C, the protonation constant is related to the enthalpy and entropy changes by the equation:

$$\log K' = \frac{(\Delta S - \Delta H/T)}{2.303R} \quad (5)$$

The average values of $\log K'$, calculated from absorbance measurements at the four wavelengths 217, 219, 221 and 223 nm plotted against $1/T$ are shown in Fig. 4. From the slope and intercept of the best straight line, obtained by a least-squares fit, the following values were calculated: $\Delta H = -21.4 \pm 1.8$ kJ mol^{-1}, $\Delta S = -90 \pm 6$ J mol^{-1} K^{-1}.

When compared with the small positive enthalpy change (6.0 kJ mol^{-1}) for the protonation of $MoO_3(H_2O)_3$ in 3.0 M $NaClO_4$ [3], the quite favourable enthalpy change for the protonation of $MoO_2(OH)(H_2O)_3^+$ appears to reflect the unusual medium in which the latter reaction occurs. However, ΔH values reported for the protonation of the ions $Hg(OH)^+$, $Fe(OH)^{2+}$ and $Cd(OH)^+$ (-30.1, -46 and -54.8 kJ mol^{-1}, respectively) are also favourable [23]. By considering the enthalpy involved in the formation of a water molecule (-54 kJ mol^{-1}) the trend has been explained in terms of a decrease in the metal–oxygen bond strengths in the order Hg > Fe > Cd. According to this reasoning, a favourable enthalpy change for the protonation of $MoO_2(OH)(H_2O)_3^+$ is to be expected compared with that of the protonation of $MoO_3(H_2O)_3$, where a double-bonded oxygen must accept the proton.

3.2. Equilibria involving dimeric cations

Depending on both the molybdenum and acid concentration the following three dimeric cations, $Mo_2O_5(OH)(H_2O)_5^+$, $Mo_2O_5(H_2O)_6^{2+}$ and $Mo_2O_4(OH)(H_2O)_6^{3+}$, have been found to exist in solution [10–13]. The formulations are based on a structure with a single oxo-bridge formed by elimination of one water molecule during dimerization. The presence of four terminal oxygens and a single bridging oxygen has been indicated by Raman spectroscopy [15] and an analysis of XANES (X-ray absorption near edge structure) and EXAFS (extended X-ray absorption fine structure) measurements [24]; an angle of $\sim 125°$ was suggested for the Mo–O–Mo bridge. Equilibrium constants for these cations have been determined in 3.0 M $Na(H)ClO_4$ medium and a satisfactory description of the system has been obtained despite the considerable changes in ionic medium necessitated by the high acid concentration [13].

The presence of these dimeric cations is indicated by a strong absorption band at ~ 246 nm. The increase in concentration of dimers with increase in perchloric acid concentration is seen from the experimental spectra of a series of

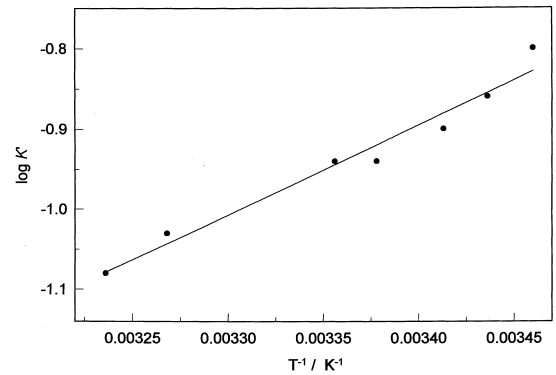

Fig. 4. Log K' as a function of the reciprocal of the Kelvin temperature.

molybdate solutions (2.5×10^{-3} M) measured in the concentration range 0.8–7.7 M (Fig. 5). Initially, there is a decrease in absorption at wavelengths lower than ~240 nm due to the formation of the monomeric cation, while a peak typical of dimeric cations develops at ~246 nm. These spectra (up to 6.29 M $HClO_4$) were used to obtain a rough estimate of the relative concentrations of the various monomers and dimers at high perchloric acid concentrations. Under these conditions, the singly charged dimer would be practically absent and only the following two equilibria have to be considered in addition to those involving the monomers:

$$2MoO_2(OH)(H_2O)_3^{+} \overset{K_D}{\leftrightarrow} Mo_2O_5(H_2O)_6^{2+} + H_2O) \quad (6)$$

$$2MoO_2(OH)(H_2O)_3^{+} + H^{+} \overset{K_{DI}}{\leftrightarrow} Mo_2O_4(OH)(H_2O)_6^{3+} + H_2O \quad (7)$$

Applying the same assumptions regarding the variation in activity coefficients as in the case of the mononuclear species and introducing the activity of the hydrogen ion as well as that of water [25], the spectrophotometric data (211–301 nm) were treated with the program EQUISPEC. To account for the presence of the mononuclear species their now-known absorption spectra and equilibrium constants were supplied to the program. In view of the approximations, the extraction of too many unknown parameters from the data would not be justified. The previously determined spectrum of $Mo_2O_5(H_2O)_6^{2+}$ [13] was therefore supplied to the program while the spectrum of the triply charged dimer was regarded as unknown to allow a comparison with the previous results. A quite reasonable fit (cf. error limits) of calculated to experimental absorption values was obtained, in particular at wavelengths in the region of the absorption band of the dimers. The shape of the spectrum obtained for the $Mo_2O_4(OH)(H_2O)_6^{3+}$ species (Fig. 2) agrees with that previously calculated from data pertaining to 3.0 M $Na(H)ClO_4$ medium [13] but lies higher. The difference most likely reflects the imperfections of the assumptions regarding the variation in activity coefficients of the species which in this case would have a greater effect than in the case of the protonation reactions described in the previous section, because the concentration of the mononuclear cation is now squared in the equilibrium expression. The values obtained for the two dimerization constants (3σ error limits), $\log K_D = 1.83\pm0.03$ and $\log K_{D1} = 1.14\pm0.21$ were used together with $\log \beta_1$ and $\log \beta_2$ to calculate the relative concentrations of the species in the perchloric acid concentration range 0.6–6.3 M (Fig. 6). The distribution curves, although approximate, illustrate the importance of the dimeric cations at high acid concentration even at this rather low molybdenum(VI) concentration (2.5×10^{-3} M).

3.3. Thermodynamic quantities for the dimerization reaction

The heat involved in the dimerization reaction was investigated by titrating a molybdate solution at constant ionic

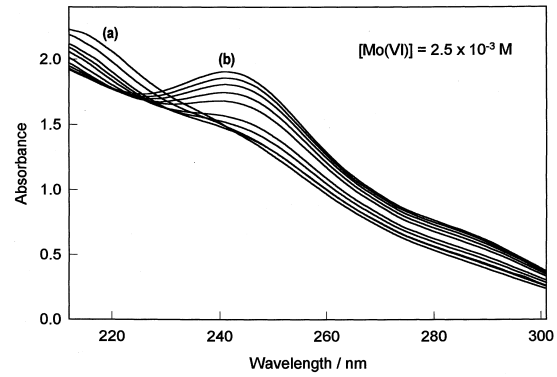

Fig. 5. Change in absorption spectra with change in perchloric acid concentration from 0.815 M (a) to 7.66 M (b) of a 2.5×10^{-3} M molybdenum(VI) solution measured in a 0.2-cm cuvette.

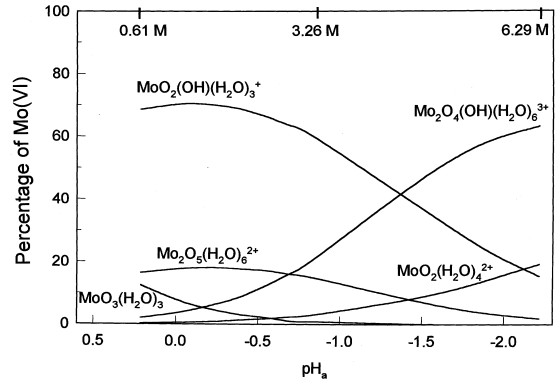

Fig. 6. Distribution of species as a function of pH_a ($-\log a_{H^+}$). The perchloric acid concentration corresponding to pH_a is shown on the upper axis.

medium (3.0 M $Na(H)ClO_4$) into perchloric acid at four different concentrations (0.50, 1.00, 2.00 and 3.00 M). Under these conditions, the formation of the two monomers $MoO_3(H_2O)_3$ and $MoO_2(OH)(H_2O)_3^{+}$ as well as that of the three dimeric cations contribute to the measured heat.

In principle the molar enthalpy change, ΔH_{pq}, of a particular species can be calculated from the measured heat, Q, by solving a set of linear equations of the form:

$$Q = \Sigma m_{pq} \cdot \Delta H_{pq}$$

where m_{pq} is the number of moles of a particular species and ΔH_{pq} the molar enthalpy change for its formation from $[MoO_4]^{2-}$ at 25°C in ionic medium 3.0 M $Na(H)ClO_4$. The subscripts p and q identify the species in terms of the stoichiometric coefficients of molybdate and hydrogen ions in the formation reaction.

The data were treated with the program SIRKO [26] using literature values for the formation constants of the various species [3,6,7,13]. The results are summarized in Table 1. The error limits given are estimated and are greater than those calculated by the program. The maximum concentration of $MoO_3(H_2O)_3$ is rather small (<10%) under the most favourable conditions and also changes very little during the titration. For this reason as well as some correlation with the concentration of $Mo_2O_5(OH)(H_2O)_5^{+}$, the enthalpy change for $MoO_3(H_2O)_3$ could not be calculated from the data. A

Table 1
Values for the thermodynamic quantities of molybdenum(VI) species formed from $[MoO_4]^{2-}$ in 3.0 M $Na(H)ClO_4$ medium

	Log K	ΔH (kJ mol^{-1})	ΔS (J mol^{-1} K^{-1})
$MoO_3(H_2O)_3$	7.75	$[-38\pm5]$ [a]	
$MoO_2(OH)(H_2O)_3^+$	8.81	-33.5 ± 1.0	56 ± 2
$Mo_2O_5(OH)(H_2O)_5^+$	18.93	-95 ± 5	44 ± 3
$Mo_2O_5(H_2O)_6^{2+}$	19.60	-97 ± 3	50 ± 3
$Mo_2O_4(OH)(H_2O)_6^{3+}$	18.98	-69 ± 5	132 ± 10
Dimerization (Eq. (6))	1.99	-30 ± 5	-63 ± 10

[a] See text.

fixed value (-38 ± 5 kJ mol^{-1}) based on the enthalpy change now obtained for the monomeric cation and its enthalpy change for ionization (-6.0 ± 1.2 kJ mol^{-1}) previously determined for this ionic medium [3] was supplied to the program after some preliminary runs. The best fit changed very little as long as the fixed value was kept within the limits given above, while the values for the other parameters remained well within the error limits given in Table 1. The fixed value(s) also seems very reasonable when compared with the enthalpy change determined spectrophotometrically for ionic medium 0.1 M NaCl, from the variation in the protonation constant with temperature (-29 ± 3 kJ mol^{-1}) [17].

From the results it can be seen that the dimerization reaction (6) is enthalpy-driven (-30 kJ mol^{-1}) coupled with an unfavourable entropy change; the favourable enthalpy change emanates mainly from the formation of a free water molecule and the unfavourable entropy change from the restriction placed on the system. Values have been reported at three different temperatures for a conditional dimerization constant pertaining to 0.50 M $HClO_4$ in 1.0 M $LiClO_4$ medium [16]. From these values one can estimate an enthalpy change of -23 ± 4 kJ mol^{-1}, which would be consistent with the present results.

In view of the discussion above (Section 3.1), the substantially more unfavourable enthalpy change for the protonation of the doubly charged dimer, $Mo_2O_5(H_2O)_6^{2+}$ (28 kJ mol^{-1}), compared with that of the singly charged dimer, $Mo_2O_5(OH)(H_2O)_5^+$ (-2 kJ mol^{-1}), is to be expected since protonation of any one of the double-bonded oxygen atoms of $Mo_2O_5(H_2O)_6^{2+}$ would be more difficult than protonation of the hydroxyl group of $Mo_2O_5(OH)(H_2O)_5^+$.

Received 8 December 1999; accepted 11 February 2000

Abstract

Several novel binuclear Pd^{II}, Pt^{II}, and Pt^{IV} complexes of *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) or *cis*,*trans*,*cis*-1,2,3,4-tetrakis(diphenylphosphino)cyclobutane (dppcb) have been prepared and characterized by X-ray diffraction methods, $^{195}Pt\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectroscopy, FAB mass spectrometry, IR spectroscopy, elemental analyses and melting points. The X-ray structure and NMR parameters of $[Pt_2I_4(trans\text{-dppen})_2]$ (**1**) confirm that homobimetallic complexes of the type $[M_2L_4(trans\text{-dppen})_2]$ ($M = Ni, Pd, Pt$; $L = Cl^-, I^-, CN^-$) contain two square planar coordination units joined by two *trans*-dppen bridges in the solid as well as in the solution state. An analogous structure type is retained in the Pt^{IV} compound $[Pt_2Cl_8(trans\text{-dppen})_2]$ (**2**). In contrast to the corresponding Pt^{II} complex of the new tetradentate phosphine dppcb, the X-ray structure of $[Pd_2Cl_4(dppcb)]$ (**3**) reveals only one conformation. This can be explained by the longer Pd–P bonds compared with the Pt–P bonds and the weaker square planar stabilization energy in **3**. In **3** dppcb acts as a binuclear tetraligate single-bridging ligand combining two square planar coordination centres. The reaction of $Pd(CN)_2$ with dppcb leads to $[Pd_2(CN)_4(dppcb)]$ (**4**). The removal of the coordinated chlorides in **3** by $AgBF_4$ followed by subsequent treatment with $NaNO_2$ produces $[Pd_2(NO_2)_4(dppcb)]$ (**5**). In an analogous reaction with 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy), $[Pd_2(dppcb)(phen)_2](BF_4)_4$ (**6**) and $[Pd_2(dppcb)(bipy)_2](BF_4)_4$ (**7**) are formed. The complexes **4**–**7** show structure types corresponding to the X-ray structure of **3**. The same is true for the treatment of **3** with $PMePh_2$ or PMe_2Ph, where $[Pd_2(dppcb)(PMePh_2)_4](BF_4)_2Cl_2$ (**8**) and $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_4$ (**9**) are obtained. However, the X-ray structure of **8** reveals that the chlorides are coordinated in the solid state, and the crystal structure consists of *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**). The flexibility and stereochemical demands of dppcb in the compounds **3**–**10** and related species are discussed in view of the possible application of Pd^{II} complexes containing bidentate tertiary phosphine ligands as catalysts for the alternating copolymerization of ethene and carbon monoxide. In this respect dppcb can be regarded as a combination of two bidentate phosphines, where the cyclobutane ring corresponds to a relatively rigid ligand backbone. This produces strain in the five-membered rings of **3**–**10** which is released by 'envelope'-folding in the X-ray structures of **3** and **10**. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Trans-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) is a diphosphine-like 1,2-bis(diphenylphosphino)acetylene (dppa), in which the rigidity of the unsaturated carbon backbone forces two phosphorus atoms to remain too far apart for them both to bond to a single metal atom [1–3]. Furthermore, *trans*-dppen bridges preclude the possibility of a bridging halogen atom between the metal centres in bimetallic species, where the number of *trans*-dppen bridges varies from one to four [4–6]. In this work the structure of homobimetallic complexes of the type $[M_2L_4(trans\text{-dppen})_2]$ ($M = Ni, Pd, Pt$; $L = Cl^-, I^-, CN^-$) [7,8] is confirmed by the X-ray structure of the novel compound $[Pt_2I_4(trans\text{-dppen})_2]$ (**1**) corresponding to structure type (a) in Scheme 1. The NMR

Scheme 1. Structure types observed in compounds **1**–**10**. Structure (a) occurs in $[Pt_2I_4(trans\text{-dppen})_2]$ (**1**), structure (b) in $[Pt_2Cl_8(trans\text{-dppen})_2]$ (**2**), structure (c) in $[Pd_2L_4(dppcb)]$ ($L=Cl^-$ (**3**), $L=CN^-$ (**4**), $L=NO_2^-$ (**5**)), structure (d) in $[Pd_2(dppcb)(phen)_2](BF_4)_4$ (**6**) and analogous to it in $[Pd_2(dppcb)(bipy)_2](BF_4)_4$ (**7**), structure (e) in $[Pd_2(dppcb)(PMePh_2)_4](BF_4)_2Cl_2$ (**8**) and $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_4$ (**9**), and structure (f) in *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**).

parameters of **1** indicate that the same structure is retained in solution. The Pt^{IV} complex $[Pt_2Cl_8(trans\text{-dppen})_2]$ (**2**) shows the analogous structure type (b) in Scheme 1.

Only recently, *trans*-dppen together with Pt^{II} as a template have been used to produce the new tetradentate phosphine *cis,trans,cis*-1,2,3,4-tetrakis(diphenylphosphino)cyclobutane (dppcb) [7]. Comparable to the tetratertiary phosphine 2,3-bis[(diphenylphosphino)methyl]-1,4-bis(diphenylphosphino)butane, dppcb coordinates in a bis(bidentate) manner to two metals and favours homobimetallic complexes [9]. However, the rigidity of the cyclobutane ring in dppcb prevents the coordination of all four phosphorus atoms to one metal. Pd^{II} complexes containing bidentate tertiary phosphine ligands show high catalyst activity and yield for alternating CO/ethene copolymerization and opened the way for efficient synthesis of polyketone [10], where dppcb can be regarded as a combination of two bidentate phosphines. Since also Pd^{II} complexes of nitrogen-containing bidentate ligands are very active precatalysts in the copolymerization of styrene with carbon monoxide, an investigation of the structural possibilities of bimetallic Pd^{II} complexes with dppcb is interesting [11]. Therefore, the novel compounds $[Pd_2L_4(dppcb)]$ ($L=Cl^-$ (**3**), CN^- (**4**), NO_2^- (**5**)), $[Pd_2(dppcb)(phen)_2](BF_4)_4$ (**6**) and $[Pd_2(dppcb)(bipy)_2](BF_4)_4$ (**7**), where phen and bipy are 1,10-phenanthroline and 2,2′-bipyridine, respectively, have been prepared. They belong to structure types (c) and (d) in Scheme 1, where **7** is analogous to **6**, and have been confirmed by the X-ray structure of **3**.

Furthermore, in order to extend the type of potentially catalytic active compound for oligomerization and polymerization of olefins, Pd^{II} complexes of the type $[PdCl(diphosphine)(monophosphine)]^+$ have been synthesized [12]. The corresponding new complexes containing dppcb $[Pd_2(dppcb)(PMePh_2)_4](BF_4)_2Cl_2$ (**8**), $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_4$ (**9**), and *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**) show structure types (e) and (f) in Scheme 1. Upon crystallization of **8**, the chloride anions coordinate to Pd^{II} and **10** is formed. **10** is fully characterized by an X-ray structure analysis.

2. Experimental

2.1. Reagents and chemicals

Reagent grade chemicals were used as received unless stated otherwise. *Trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) was purchased from Aldrich. $PMePh_2$ and PMe_2Ph were obtained from Strem. All other reagents and solvents were received from Fluka. Solvents used for NMR measurements and crystallization purposes were of purissimum grade quality. $PdCl_2$ and $Na_2PtCl_4\cdot 4H_2O$ were also obtained from Fluka.

2.2. Instrumentation

Fourier-mode $^{195}Pt\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were obtained using Bruker AC-200 and DPX-300 spectrometers (internal deuterium lock) and were recorded at 43.02 (64.50) and 80.96 (121.44) MHz, respectively. Positive chemical shifts are downfield from the standards, where 1.0 M Na_2PtCl_6 and 85% H_3PO_4 were used as standards, respectively.

2.3. Syntheses of Pd^{II}, Pt^{II}, and Pt^{IV} complexes

A Schlenk apparatus and oxygen-free, dry Ar were used in the syntheses of all complexes. Solvents were degassed by several freeze–pump–thaw cycles prior to use. All reactions were carried out at room temperature unless stated otherwise. [Pt_2Cl_4(*trans*-dppen)$_2$] and dppcb were prepared as described earlier [7].

2.3.1. [Pt_2I_4(*trans*-dppen)$_2$] (**1**)

[Pt_2Cl_4(*trans*-dppen)$_2$] (0.075 mmol, 0.100 g) was dissolved in CH_2Cl_2/DMF (v/v = 2:1, 5 cm^3) and LiI (0.30 mmol, 0.040 g) was added with vigorous stirring and prevention of light. The reaction mixture was stirred at 45°C for 48 h. Then the solvent was completely removed, the yellow residue was filtered off in H_2O, washed with H_2O and dried in vacuo. An ochre-yellow powder was recrystallized from CH_2Cl_2/Et_2O. Yield 0.100 g (79%); m.p. > 310°C. *Anal*. Found: C, 36.8; H, 2.7. Calc. for $C_{52}H_{44}I_4P_4Pt_2$: C, 36.9; H, 2.6%. A sample for X-ray diffraction with the composition $C_{52}H_{44}I_4P_4Pt_2 \cdot 0.75$DMF was crystallized from $CHCl_3$/DMF with prevention of light.

2.3.2. [Pt_2Cl_8(*trans*-dppen)$_2$] (**2**)

Chlorine was bubbled through a solution of [Pt_2Cl_4(*trans*-dppen)$_2$] (0.075 mmol, 0.100 g) in DMF (10 cm^3) for 10 min with prevention of light. The volume of the solvent was reduced and a yellow precipitate formed. Then Et_2O was added, the precipitate was filtered off and dried in vacuo. A yellow powder was recrystallized from DMF. Yield 0.079 g (72%); m.p. 192–194°C. *Anal*. Found: C, 42.4; H, 3.1. Calc. for $C_{52}H_{44}Cl_8P_4Pt_2$: C, 42.6; H, 3.0%.

2.3.3. [Pd_2Cl_4(dppcb)] (**3**)

$PdCl_2$ (0.50 mmol, 0.089 g) was suspended in DMF (7 cm^3). Then dppcb (0.25 mmol, 0.198 g) was added with vigorous stirring. The reaction mixture was stirred at 55°C for 6 h and a white precipitate formed. The solvent was completely removed, the white residue was filtered off in CH_2Cl_2, washed with CH_2Cl_2 and dried in vacuo. A white powder was recrystallized from DMF. Yield 0.328 g (91%); m.p. > 320°C. *Anal*. Found: C, 53.2; H, 5.1; N, 3.8. Calc. for $C_{52}H_{44}Cl_4P_4Pd_2 \cdot 4$DMF: C, 53.4; H, 5.0; N, 3.9%. A sample for X-ray diffraction with the composition $C_{52}H_{44}Cl_4P_4Pd_2 \cdot 4$DMF was crystallized from DMF.

2.3.4. [$Pd_2(CN)_4$(dppcb)] (**4**)

Compound **4** was prepared in an analogous manner to **3**, where $Pd(CN)_2$ (0.50 mmol, 0.079 g) was used. A white powder was recrystallized from DMF. Yield 0.227 g (82%); m.p. 304°C. IR (KBr, cm^{-1}) CN: 2135 ν. *Anal*. Found: C, 60.4; H, 4.2; N, 4.8. Calc. for $C_{56}H_{44}N_4P_4Pd_2$: C, 60.6; H, 4.0; N, 5.0%.

2.3.5. [$Pd_2(NO_2)_4$(dppcb)] (**5**)

Compound **3** (0.060 mmol, 0.069 g) was suspended in DMF (6 cm^3). Then $AgBF_4$ (0.24 mmol, 0.047 g) was added with stirring. The reaction mixture was stirred for 2 h, the formed AgCl was filtered off and the solvent completely removed. The residue was dissolved in CH_2Cl_2/DMF (v/v = 10:1, 5 cm^3) and $NaNO_2$ (0.24 mmol, 0.017 g) was added slowly with vigorous stirring. After 5 h the solvent was completely removed, the yellowish residue was filtered off in H_2O, washed with H_2O and dried in vacuo. A yellowish powder was recrystallized from DMF. Yield 0.060 g (84%); m.p. 270–272°C dec. IR (KBr, cm^{-1}) NO_2: 1370 ν_a, 1318 ν_s, 814 δ. *Anal*. Found: C, 52.4; H, 3.7; N, 4.5. Calc. for $C_{52}H_{44}N_4O_8P_4Pd_2$: C, 52.5; H, 3.7; N, 4.7%.

2.3.6. [Pd_2(dppcb)(phen)$_2$](BF_4)$_4$ (**6**)

Compound **3** (0.060 mmol, 0.069 g) was suspended in DMF (6 cm^3). Then $AgBF_4$ (0.24 mmol, 0.047 g) was added with stirring. The reaction mixture was stirred for 2 h, the formed AgCl was filtered off and the solvent completely removed. The residue was dissolved in CH_2Cl_2 (5 cm^3) and 1,10-phenanthroline · H_2O (0.12 mmol, 0.024 g) was added slowly with vigorous stirring. A white precipitate immediately formed. After 5 h the precipitate was filtered off, washed with CH_2Cl_2 and dried in vacuo. A white powder was recrystallized from DMF. Yield 0.084 g (82%); m.p. > 320°C. *Anal*. Found: C, 53.3; H, 3.8; N, 3.2. Calc. for $C_{76}H_{60}B_4F_{16}N_4P_4Pd_2$: C, 53.3; H, 3.5; N, 3.3%.

2.3.7. [Pd_2(dppcb)(bipy)$_2$](BF_4)$_4$ (**7**)

Compound **7** was prepared in an analogous manner to **6**, where 2,2′-bipyridine (0.12 mmol, 0.019 g) was used. A white powder was recrystallized from DMF. Yield 0.062 g (62%); m.p. > 320°C. *Anal*. Found: C, 51.7; H, 3.7; N, 3.3. Calc. for $C_{72}H_{60}B_4F_{16}N_4P_4Pd_2$: C, 51.9; H, 3.6; N, 3.4%.

2.3.8. [Pd_2(dppcb)($PMePh_2$)$_4$](BF_4)$_2Cl_2$ (**8**) and trans-[Pd_2Cl_2(dppcb)($PMePh_2$)$_2$](BF_4)$_2$ (**10**)

Compound **3** (0.090 mmol, 0.104 g) was suspended in CH_2Cl_2/DMF (v/v = 7:1, 10 cm^3). Then $AgBF_4$ (0.18 mmol, 0.035 g) was added with stirring. The reaction mixture was stirred for 8 h, the formed AgCl was filtered off and the solvent completely removed. The residue was dissolved in CH_2Cl_2 (8 cm^3) and $PMePh_2$ (0.36 mmol, 0.072 g) was added via a syringe with vigorous stirring. The solution was stirred for 5 h. The ^{31}P ^1H NMR parameters of this solution correspond to **8**. The solvent was completely removed, the yellow residue was filtered off in EtOH, washed with EtOH

and dried in vacuo. A yellow powder was recrystallized from CH_2Cl_2. Yield 0.120 g (73%); m.p. 220–221°C. FAB mass spectrum: *m/z* 1528.3 $[Pd_2Cl(dppcb)(PMePh_2)_2](BF_4)^+$, 1127.9 $[Pd_2Cl(dppcb)](BF_4)^+$. *Anal.* Found: C, 52.6; H, 4.2. Calc. for $C_{78}H_{70}B_2Cl_2F_8P_6Pd_2 \cdot 2CH_2Cl_2$ corresponding to **10**$\cdot 2CH_2Cl_2$: C, 52.8; H, 4.1%. A sample for X-ray diffraction with the composition $C_{78}H_{70}B_2Cl_2F_8P_6Pd_2 \cdot 2CH_2Cl_2$ was crystallized from CH_2Cl_2.

*2.3.9. $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_4$ (**9**)*

Compound **3** (0.060 mmol, 0.069 g) was suspended in DMF (6 cm^3). Then $AgBF_4$ (0.24 mmol, 0.047 g) was added with stirring. The reaction mixture was stirred for 2 h, the formed AgCl was filtered off and the solvent completely removed. The residue was dissolved in CH_2Cl_2/DMF (v/v = 5:1, 5 cm^3) and PMe_2Ph (0.24 mmol, 0.033 g) was added via a syringe with vigorous stirring. After 10 min a yellowish precipitate slowly formed. The slurry was stirred for 5 h. The solvent was completely removed, the yellow residue was filtered off in CH_2Cl_2, washed with CH_2Cl_2 and dried in vacuo. A yellow powder was recrystallized from DMF. Yield 0.053 g (46%); m.p. 208–210°C. FAB mass spectrum: *m/z* 1818.6 $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_3^+$, 1593.7 $[Pd_2(dppcb)(PMe_2Ph)_3](BF_4)_2^+$. *Anal.* Found: C, 52.8; H, 4.8. Calc. for $C_{84}H_{88}B_4F_{16}P_8Pd_2$: C, 53.0; H, 4.7%.

2.4. X-ray data collection, structure determination and refinement

Details of the crystal and data collection are summarized in Table 1. The empirical absorption corrections were based on ψ-scans of nine reflections, respectively ($\chi = 78$–$102°$, 360° scans in 10° steps in ψ) [13]. All structure determination calculations were carried out using SHELXTL NT 5.10 including SHELXS-97 [14] and SHELXL-97 [15]. Final refinement on F^2 was carried out with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were included using a riding model with isotropic *U* values depending on U_{eq} of the adjacent carbon atoms.

3. Results

*3.1. Crystal structure of $[Pt_2I_4(trans\text{-}dppen)_2]$ (**1**)*

In order to characterize definitely $[Pt_2I_4(trans\text{-}dppen)_2]$ (**1**), its solid state structure was determined by X-ray crystallography. It is a further novel example showing that homobimetallic complexes of *trans*-dppen with d^8 metals are of the type $[M_2L_4(trans\text{-}dppen)_2]$ (M = Ni, Pd, Pt; L = Cl^-, I^-, CN^-) [7,8] corresponding to structure type (a) in Scheme 1. The crystal structure of **1** contains one discrete $[Pt_2I_4(trans\text{-}dppen)_2]$ molecule and a DMF molecule with a site occupation factor of 0.75 per asymmetric unit. Views of **1** are given in Fig. 1; Table 2 contains selected bond distances and bond angles of **1**.

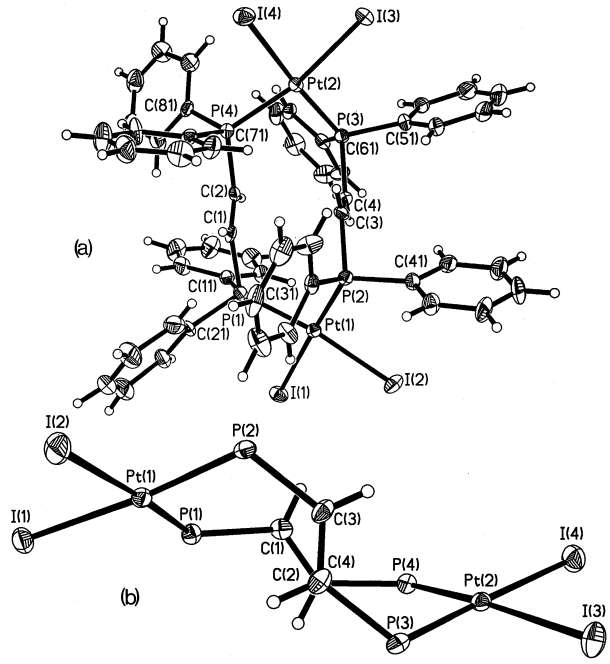

Fig. 1. (a) View of $[Pt_2I_4(trans\text{-}dppen)_2]$ (**1**), showing the atom labelling scheme; (b) C(2)···C(4) projection of $[Pt_2I_4(trans\text{-}dppen)_2]$ (**1**). Phenyl rings omitted for clarity.

The square planar coordinations in **1** are distorted, where the deviations from least-squares planes through the two coordination units are very different: Pt(1) −0.056, I(1) 0.032, I(2) −0.007, P(1) −0.007, P(2) 0.037 Å; Pt(2) −0.070, I(3) 0.109, I(4) −0.082, P(3) −0.079, P(4) 0.121 Å. This is in contrast to $[Pt_2Cl_4(trans\text{-}dppen)_2]$ (**11**) showing a largest deviation of only 0.059 Å for Pt(2) [7]. The difference can be explained by the stronger *trans* influence of I^- versus Cl^- [16,17], producing a longer mean Pt–P bond length of 2.273(5) Å in **1** than of 2.248(3) Å in **11**. Like in the case of other polyphosphines [18], the steric demands of two bridging *trans*-dppen ligands in a *cis* position (see Fig. 1(a)) lead to a 'steric pressure', which is opposed by the electronic demands of Pt(II). The weaker Pt–P bonds in **1** compared with **11** allow a release of the steric strain by larger deviations from ideal square planar coordinations in **1** than in **11**.

Owing to these differences, the angle between the coordination planes of 43.1° in **1** is larger than the corresponding parameter of 39.7° in **11**. This produces a significantly smaller Pt···Pt separation of 6.757(1) Å in **1** compared with 6.800(1) Å in **11**. The P–Pt–P angles of 96.15(11) and 96.65(10)° in **1** are significantly larger than the P–Pt–P angles of 94.77(14) and 95.08(14)° in **11**. This is a further consequence of the weaker Pt–P bonds in **1** than in **11**. This opening of the P–Pt–P angles in **1** leads to longer C(1)···C(3) and C(2)···C(4) distances of 3.093 and 3.076 Å, respectively, compared with the corresponding values of 2.837 and 2.858 Å in **11**. The C(2)···C(4) projection angle between the aliphatic double bonds (Fig. 1(b)) of 37.3° in **1** is very similar to the corresponding value of 37.6° in

$[Pd_2Cl_4(trans\text{-dppen})_2]$ [7], but different from the value of 34.8° in **11**. Comparable differences in the orientations of diphosphine-bridges have been observed in the X-ray structures of a series of dimers containing dppa [1–3]. All Pt–I bond lengths in **1** (see Table 2) are located within the typical range also found in $[Pt_2I_4(dppa)_2]$ [2]. Owing to the large P–Pt–P angles in **1**, the I–Pt–I angles of 87.62(5) and 85.81(4)° are significantly reduced to values below 90°, where the same effect is present in $[Pt_2I_4(dppa)_2]$. The X-ray structure of **1** reveals that replacement of Cl^- in **11** by I^- in **1** leads to a fine tuning of the actual structure also with respect to the orientations of the aliphatic double bonds. Since the intramolecular [2+2] photocycloaddition of these double bonds in **11** produces the new tetradentate phosphine dppcb [7], the observed fine tuning is important for the development of further Pt(II) templates, which will be used for the production of other new ligands.

3.2. Crystal structure of $[Pd_2Cl_4(dppcb)]$ (3)

The two conformations of $[Pt_2Cl_4(dppcb)]$ (**12**) seen in its X-ray structure [7] reveal the amount by which this molecular structure varies in the solution phase as the local solvent field varies with time, if we assume as a first approximation that the forces on the molecule in solution are of the same order as those in the solid [19]. Since this flexibility could influence the catalytic properties of homobimetallic complexes of dppcb, the solid state structure of **3** was also determined by X-ray crystallography. It confirms that compounds of the type $[Pd_2L_4(dppcb)]$, where L is Cl^-, CN^- or NO_2^- (**3–5**), $[Pd_2(dppcb)(phen)_2](BF_4)_4$ (**6**), and $[Pd_2(dppcb)(bipy)_2](BF_4)_4$ (**7**) correspond to structure types (c) and (d) in Scheme 1. The crystal structure of **3** consists of two discrete $[Pd_2Cl_4(dppcb)]$ molecules and eight molecules of DMF per unit cell. $[Pd_2Cl_4(dppcb)]$ is located on a centre of symmetry. Views of **3** are given in Fig. 2; Table 3 contains selected bond distances and bond angles of **3**.

As in the case of **12**, owing to crystallographic constraints produced by the centre of symmetry, the cyclobutane ring is completely planar in **3**. The mean C–C bond length of 1.557(4) Å in **3** is, within statistical significance, identical with the same parameter of 1.548(7) Å in **12** and within the usual range of 1.545–1.607 Å [20,21]. The 'envelope'-fold-

ing of 163.1° for the five-membered rings in **3** (see Fig. 2(b)) is in between the corresponding values of 153.1 and 168.3° for conformations A and B of **12**, respectively. This is reflected in the Pd(1)···Pd(1A) separation of 7.246(1) Å in **3** compared with the Pt···Pt separations of 6.952(1) and 7.327(1) Å in A and B. The same is true for the P(1)–Pd(1)–P(2) angle of 86.40(4)°, which is also in between the P–Pt–P chelate angles of 85.19(11)° in A and 89.11(10)° in B. Thus it seems likely that the effects leading to the two conformations in **12** are balanced in the solid state structure of **3**. The occurrence of two conformations in **12** has been explained by a subtle energetic balance between the preference of dppcb to release the strain of the five-membered rings by a larger 'envelope'-folding in A and the preference of Pt(II) for an ideal square planar environment in B [7]. However, the mean Pd–P bond length of 2.2372(8) Å in **3** is significantly larger than the mean Pt–P bond length of 2.222(2) Å in **12**. This reduces the strain of the five-membered rings in **3**. Furthermore, the square planar stabilization energy is smaller in **3** than in **12** [22]. Both differences lead to the occurrence of only one balanced conformation in **3**. This different flexibility in homobimetallic complexes of dppcb could be important for their catalytic application.

As a consequence of the reduced square planar stabilization energy in **3**, the Pd(1) atom deviates 0.082 Å from a least-squares plane through Cl(1), Cl(2), P(1), and P(2) (see Fig. 2(b)). Comparable large deviations of the Pd atoms in square planar complexes of tetradentate phosphines are well

known and seem to be typical for Pd(II) [9,23]. The Pd–P bond lengths of 2.2402(12) and 2.2341(12) Å in **3** are in the typical range reported previously [9,24] for square planar Pd(II) complexes containing also chelating phosphines *trans* to chlorides. The chelate angle of 86.40(4)° in **3** is comparable to the corresponding parameters of 85.82(3)° in $[Pd(CN)_2$(*cis*-dppen)] [8] and 85.4(1)° in $[Pd(SCN)_2$-(*cis*-dppen)] [25], where *cis*-dppen is *cis*-1,2-bis-(diphenylphosphino)ethene. However, in contrast to **3** and analogous to **12**, $[PdCl_2$(dppe)] shows two conformations with chelate angles of 85.82(7) and 88.3(1)°, where dppe is 1,2-bis(diphenylphosphino)ethane [24,26]. Comparable to $[PdI_2$(*cis*-dppen)]·I_2 [27], in **3** the general impression is that despite the relatively rigid ligand backbone there is little strain in the molecule. The shorter M–P distances in the Pt species **12** are consistent with the stronger Pt–P bonding relative to Pd in **3** [28] and with the 'relativistic or Lanthanide contraction' [8].

3.3. Investigation of *1*–*9* in the solution state

The $^{195}Pt\{^1H\}$ and $^{31}P\{^1H\}$ NMR parameters of compounds **1**–**9** are summarized in Table 4. The NMR data for **1** are consistent with structure (a) in Scheme 1 showing four equivalent phosphorus atoms. This means that the two different diphosphine bridges indicated in the X-ray structure of **1** (see Fig. 1) are equalized in solution at room temperature. The ^1J(Pt,P) value of 3330 Hz in **1** is reduced compared with the analogous parameter of 3550 Hz in **11** in agreement with the stronger *trans* influence of I^- versus Cl^- [16,17] and with the difference of the mean Pt–P bond lengths (see above). The simultaneous presence of this ^1J(Pt,P) value in **1** typical for *trans* iodide and of ^4J(Pt,P) of 41 Hz confirms that complexes of the type $[M_2L_4$(*trans*-dppen)$_2]$ (M = Ni, Pd, Pt; L = Cl^-, I^-, CN^-) [7,8] are also binuclear in solution.

The clean preparation of the Pt(IV) complex **2** by halogenation of the corresponding Pt(II) species **11** indicates that no drastic structural change occurs [29]. This is confirmed by the NMR data for **2**, which are consistent with structure (b) in Scheme 1 also showing four equivalent phosphorus atoms. The δ(Pt) value of −3156 in **2** is comparable with the corresponding parameter of −3226 in the analogous complex $[Pt_2Cl_8(dppa)_2]$ [2]. The same is true for the ^1J(Pt,P) value of 2093 Hz in **2** located in the typical range for a phosphine *trans* to chloride in a Pt(IV) compound [2,16,17]. This is in agreement with *cis* diphosphine bridges, where as in the case of **1** the simultaneous presence of this ^1J(Pt,P) value in **2** typical for *trans* chloride and of ^4J(Pt,P) of 34 Hz confirms the binuclear structure of **2** in solution.

The single $^{31}P\{^1H\}$ NMR resonances for **3**–**7** indicate four equivalent phosphorus atoms in all these compounds, which is consistent with structures (c) and (d) in Scheme 1. The δ(P) downfield shifts of **3**–**7** compared with **1** and **2** show the typical five-ring contribution for chelating dppcb [7,30]. Thus the solution structure of **3** appears to be the same as its solid state structure. In **4** the presence of the cyanides is clearly indicated in the IR spectrum by the C≡N stretching frequency at 2135 cm^{-1}. It is normally found for $[Pd(CN)_2$(monophosphine)$_2]$ complexes that the *cis* isomer is thermodynamically more stable than the *trans* [31], leading to higher C≡N stretching vibrations for cyanides

Table 4
$^{195}Pt\{^1H\}$ and $^{31}P\{^1H\}$ NMR data for **1**–**9** [a]

Compound	δ(Pt)	δ(P)	^1J(Pt,P)	^4J(Pt,P)	^2J(P,P)$_{trans}$
1		1.9	3330	41

3		78.0			
4		63.2			
5		58.8			
6		85.0			
7		81.0			
8		83.6d			309
		8.4d			309
9		74.0d			307
		10.0d			307

[a] *J* values in Hz. d, doublet; t, triplet. Spectra were run at 298 K. The following solvents were used: CH_2Cl_2 (**1**, **2**, **8**) and DMF (**3**–**7**, **9**).

trans to phosphines [8,32,33] than for cyanides *trans* to cyanides [34]. The stretching value in **4** is in agreement with *cis*-dicyanides. In the case of **5** the direct replacement of the chlorides of **3** by nitrites is not possible, though this transformation has been shown to occur via associative *cis* attack on chloride by nitrite [35]. For **5** the removal of the chlorides from **3** by precipitating AgCl with $AgBF_4$ was necessary for the completion of the reaction with nitrite. The δ(P) value of 77.4 for a DMF solution of the resulting cationic intermediate is consistent with $[Pd_2(dppcb)(DMF)_4](BF_4)_4$, which is analogous to the corresponding Pt(II) complex [7]. The IR spectrum of **5** shows $\nu_a(NO_2)$, $\nu_s(NO_2)$, and δ(ONO) at 1370, 1318, and 814 cm^{-1}, respectively, clearly indicating N-bonded NO_2^- leading to a unidentate nitro complex [36]. This is confirmed by the comparable vibrations in $[PtCl(NO_2)(cis\text{-dppen})]$ [32], where the unidentate N-bonded coordination of NO_2^- has been proven by an X-ray structure analysis [37]. Also for **6** and **7** the removal of the chlorides from **3** by the above procedure was necessary for the completion of the reaction with phen or bipy. The single $^{31}P\{^1H\}$ NMR signals for **6** and **7**, respectively, are consistent with structure (d) in Scheme 1 shown for the phen complex, which is confirmed by the analogous structure found in the corresponding Pt(II) compounds [7]. These complexes are further examples of the tendency for multiple five-ring formation [38].

The reaction of **3** with monophosphines strongly depends on the number of chlorides removed as AgCl. The removal of two chlorides and subsequent treatment with $PMePh_2$ leads to **8**. The $^{31}P\{^1H\}$ NMR data for **8** are in agreement with structure (e) in Scheme 1. The signal with δ(P) of 83.6 is attributed to chelating dppcb showing the typical downfield five-ring contribution [7,30] and the signal with δ(P) of 8.4 to coordinated $PMePh_2$. The $^2J(P,P)_{trans}$ value of 309 Hz is located within the typical range [8,16,23]. However, after isolation of **8** the FAB mass spectrum indicates a strong peak at *m/z* of 1528.3 consistent with $[Pd_2Cl(dppcb)(PMePh_2)_2](BF_4)^+$ and its elemental analysis is in agreement with the loss of two coordinated $PMePh_2$ groups. Since the removal of all chlorides from **3** and subsequent treatment with $PMePh_2$ led to no pure product, the solid state structure of **10** has been clarified by an X-ray structure analysis (see below). In the case of PMe_2Ph the complete replacement of the chlorides in **3** by this monophosphine leading to **9** has been successful. The $^{31}P\{^1H\}$ NMR data for **9** are consistent with structure (e) in Scheme 1. The downfield shifted signal with δ(P) of 74.0 is again attributed to chelating dppcb [7,30] and the signal with δ(P) of -10.0 to coordinated PMe_2Ph. The $^2J(P,P)_{trans}$ value of 307 Hz is nearly identical with the corresponding parameter in **8** and is also located within the typical range [8,16,23]. After isolation of **9** the FAB mass spectrum and elemental analysis are in full agreement with its formulation as $[Pd_2(dppcb)(PMe_2Ph)_4](BF_4)_4$.

The ^1H NMR resonances (CH_2Cl_2-d^2) for the aromatic protons in **1**–**9** occur at 6.5–8.2. In **1** and **2** the ^1H NMR signals of the ethene bridges are obscured by these aromatic resonances. For **3**–**9** broad ^1H NMR signals of the cyclobutane protons are observed at 4.2–4.6. In **8** and **9** the methyl group resonances of coordinated $PMePh_2$ and PMe_2Ph, respectively, occur at 2.1. For **3**–**9** the integrated intensities are in agreement with the proposed structures.

3.4. Crystal structure of trans-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (10)

In order to characterize definitely the product obtained after isolation of **8**, its solid state structure was determined by an X-ray structure analysis. It shows that this product consists of *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**) corresponding to structure type (f) in Scheme 1. The crystal structure of **10** consists of two discrete *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2]^{2+}$ cations, four $(BF_4)^-$ anions, and four molecules of CH_2Cl_2 per unit cell. *Trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2]^{2+}$ is located on a centre of symmetry. Views of the cation of **10** are given in Fig. 3; Table 5 contains selected bond distances and bond angles of **10**.

As in the cases of **3** and **12**, owing to crystallographic constraints produced by the centre of symmetry, the cyclobutane ring is completely planar in **10**. The mean C–C bond length of 1.556(3) Å in **10** is, within statistical significance, identical with the same parameters in **3** and **12** (see above)

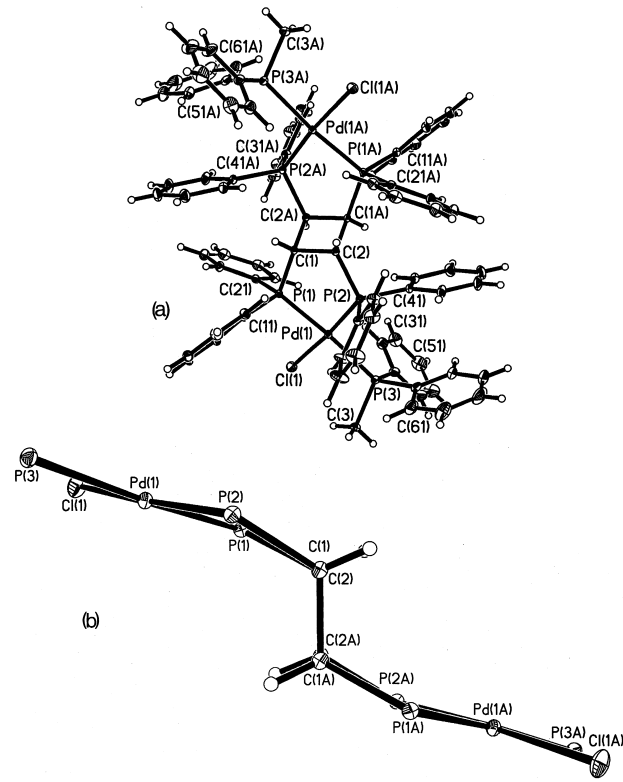

Fig. 3. (a) View of the cation of *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**), showing the atom labelling scheme; (b) view of the cation of *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**) with the cyclobutane plane perpendicular to the projection plane. Phenyl rings and methyl groups omitted for clarity.

[a] Symmetry transformations used to generate equivalent atoms: $-x+1, -y, -z$.

and also within the usual range [20,21]. However, the smaller 'envelope'-folding of 165.7° for the five-membered rings in **10** (see Fig. 3(b)) compared with the same parameter of 163.1° in **3**, already indicates strain in **10**. Though this produces a significantly larger Pd(1)···Pd(1A) separation of 7.378(1) Å in **10** than of 7.246(1) Å in **3**, the alignment of the phenyl rings containing C(61), C(41), and C(21A) in **10** (see Fig. 3(a)) is necessary to overcome unfavourable repulsive interactions. This stacking of aromatic rings has been observed in complexes of nucleobases also mediated by Pd(II) [39]. The *cis* isomer of **10** is destabilized by these interactions, since one side of the molecule becomes too crowded. A comparable preference of the *trans* isomer has been found for *trans*-[$PdCl(\mu\text{-}PPh_2)(PPh_2H)]_2$ [40]. Also the significantly smaller P(1)–Pd(1)–P(2) chelate angle of 85.94(3)° in **10** compared with 86.40(4)° in **3** is indicative of strain, presumably due to the 'steric pressure' [18] produced by the alignment of the phenyl rings.

The Pd(1)–P(1) bond length of 2.2978(8) Å is significantly larger than the Pd(1)–P(2) bond length of 2.2589(8) Å in **10**, in agreement with the stronger *trans* influence of a phosphine versus chloride [28,41,42]. This difference of Pd–P bond lengths is comparable with the corresponding parameters of 2.284(1) and 2.244(1) Å in [$PdCl(Ph_2PNPPh_2)(PEt_3)$] [12]. The same is true for the Pd–monophosphine bond lengths of 2.3753(9) Å in **10** and 2.366(1) Å in [$PdCl(Ph_2PNPPh_2)(PEt_3)$]. Like in **3** and typical for Pd(II) [9,23], the Pd(1) atom deviates 0.056 Å from a least-squares plane through Cl(1), P(1), P(2), and P(3) (see Fig. 3(b)). There is considerable steric blocking on one side of each coordination unit by the cyclobutane ring and the phenyl groups in **10** (see Fig. 3(a)). This causes an incoming fifth ligand to attach on the other side of the square plane leading to a square pyramidal coordination [43]. Together with the observed steric crowding in **10** leading to the alignment of the phenyl rings, this could initiate the loss of two $PMePh_2$ groups from **8** producing **10**.

When the crystals of **10** are redissolved in CH_2Cl_2/DMF (v/v = 1:1), the $^{31}P\{^1H\}$ NMR spectrum shows three different resonances consistent with the solid state structure of **10**. The single resonance at 81.1, showing the typical downfield five-ring contribution, is attributed to the phopshorus of dppcb *trans* to chloride. Furthermore, two doublets occur at 82.5 (dppcb) and 12.2 ($PMePh_2$), where $^2J(P,P)_{trans}$ is 430 Hz. However, several other signals are also observed in this spectrum indicating that **10** is not stable in solution.

4. Discussion

As already mentioned, some of the new complexes presented in this paper are potentially catalytic active compounds for the alternating CO/ethene copolymerization [10]. In this respect the rigidity of the cyclobutane backbone in homobimetallic complexes of dppcb with Pd(II) together with the orientations of the phenyl rings could influence the activity of these catalysts. Indeed preliminary experiments show that dppcb has beneficial effects on the copolymerization rate [44]. Obviously, like the tripodal the dppcb polyphosphine-control element is so effective that the combined bulk of the ligand–metal assembly and substrate operates to exclude alternatives so that one reaction path is specifically favoured [45]. However, the nature of the metal centre must be finely tuned, depending on the type of reaction involved.

In the case of Rh(I) the binuclear tetraligate single-bridging coordination of dppcb [46] leads to 'mechanical coupling' [47], where preliminary X-ray results show that steric interactions of the phenyl rings comparable with **10** produce

different coordination sites. For the tetradentate phosphine 1,2,4,5-tetrakis(diphenylphosphino)benzene, which is comparable with dppcb, any intramolecular electron transfer in the excited states of its dimetallic complexes also containing Pd(II) relies less on the presence of a low-lying, empty σ* orbital in the ligand than on superexchange or tunnelling interactions [48]. Homobimetallic complexes of dppcb with Ru(II) also show these interactions, since preliminary experiments indicate that their photochemical behaviour is completely different from analogous compounds containing diphosphines.

Since $[Pd(CH_3CN)_4](BF_4)_2$ has been found to catalyse the polymerization of acetylenes and olefins [49], the complex $[Pd_2(dppcb)(DMF)_4](BF_4)_4$ presented above could show comparable catalytic properties. Furthermore, Pd(II) complexes of $PhP(CH_2CH_2PPh_2)_2$ catalyse the electrochemical reduction of CO_2 to CO [18,50]. In this paper it is shown that compounds of the type $[Pd_2(dppcb)(monophosphine)_4]^{4+}$ are possible. Therefore, also $[Pd(dppcb)_2]^{2+}$ could be prepared. Similar to the chelating bis(phosphine) 3,5-bis[(diphenylphosphino)methyl]pyridine, which forms a trinuclear Pd complex, a metalloligand like $[Pd(dppcb)_2]^{2+}$ offers a straightforward approach for the generation of oligonuclear and multinuclear complexes [51]. Further work on this is in progress.

Supplementary data

Details on the structure determinations, atomic fractional coordinates and other relevant data are obtainable from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK on request (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk). The crystal structures of $[Pt_2I_4(trans\text{-}dppen)_2]$ (**1**), $[Pd_2Cl_4(dppcb)]$ (**3**), and *trans*-$[Pd_2Cl_2(dppcb)(PMePh_2)_2](BF_4)_2$ (**10**) have been allocated the deposition numbers CCDC 137542, CCDC 137543, and CCDC 137544, respectively.

Abstract

The reaction of tributylphosphine, benzoic acid and $Mo_3Te_7(S_2P(OPr^i)_2)_3I$ produced a new compound with triangular cluster skeleton $Mo_3Te_4^{4+}$, $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$ (**1**). An unexpected compound including an $Mo_3Te_3S^{4+}$ skeleton, $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$ (**2**), was obtained using aminobenzoic acid instead of benzoic acid. X-ray crystallographic analysis revealed that these complexes belong to the $Mo_3E_4^{4+}$ (E = S, Se, Te) incomplete cuboidal cluster family and are dimeric through the Te···Te interaction. ^1H and ^{31}P NMR and IR spectroscopic data were also used to characterize these compounds. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Cluster compounds; Molybdenum complexes; Tellurium-rich compounds; De-tellurium reaction; Crystal structures

1. Introduction

Intensive studies have been carried out on molybdenum/tungsten chalcogenide clusters since 1985 [1–5]. Compared with sulfides and selenides, the chemistry of tellurido complexes of molybdenum and tungsten is much less developed because many traditional reagents applicable to Mo/W–S/Se systems are not simply transferable to the Mo/W–Te system, and limited progress has been made in the exploration of effective reagents or starting materials [6]. Until recently, only a few such Mo/W–Te clusters, including the triangular cluster complex $Cs_{4.5}[Mo_3Te_7(CN)_6]I_{2.5}\cdot 3H_2O$ [7] with an $Mo_3(\mu_3\text{-}Te)(\mu\text{-}Te_2)_3^{4+}$ core, the tetrahedral clusters $K_7[Mo_4Te_4(CN)_{12}]\cdot H_2O$ and $K_6[W_4Te_4(CN)_{12}]\cdot 5H_2O$ containing the $M_4(\mu_3\text{-}Te)_4^{n+}$ ($n = 5, 6$) cuboidal core [8–10], and the octahedral cluster $[Na(Py)_6]^+[W_6Te_8(Py)_6]^-\cdot Py$ and $W_6Te_8(PiP)_6\cdot 6PiP$ with a W_6Te_8 core [11], have been reported. However, the absence of the Mo_3Te_4 type cluster, of which the sulfide and selenide analogues have been well studied, has drawn our attention to conversion of the Mo_3Te_7 cluster core to Mo_3Te_4. In comparison with those compounds containing Mo_3Te_7, Mo_4Te_4 or W_6Te_8 cores, the compound with an Mo_3Te_4 core has higher reactivity since it possesses a vacant subsite and three μ-Te ligands, making it potentially a good precursor for other tellurido cluster compounds.

A convenient route to the $M_3(\mu_3\text{-}E)(\mu\text{-}E)_3^{4+}$ (M = Mo, W; E = S, Se) cluster by reaction of $M_3(\mu_3\text{-}E)(\mu\text{-}E_2)_3^{4+}$ cluster compounds with phosphine or cyanide has been reported [12–15]. Saito and co-workers considered that the $Mo_3Te_7^{4+}$ fragment has an extraordinary stability in aqueous cyanide or in CH_3OH with PEt_3 [7]. However, our experiments showed that the $Mo_3Te_7^{4+}$ cluster core is stable in CH_2Cl_2 with PPh_3, and the reaction of $Mo_3Te_7[S_2P(OPr^i)_2]_3I$ with tributylphosphine leads to transformation of the $Mo_3Te_7^{4+}$ core to the $Mo_3Te_4^{4+}$ core. Another very interesting result in our experiments is that aromatic acids might have different effects on the transformation of the $Mo_3Te_7^{4+}$ cluster core to produce a Te-capping or S-capping triangular cluster core, which has never been observed in previous studies in this field. Herein we report the syntheses and molecular structures of two cluster compounds containing $Mo_3Te_4^{4+}$ and $Mo_3(\mu_3\text{-}S)Te_3^{4+}$ cores.

2. Experimental

All manipulations were carried out under dinitrogen atmosphere using standard Schlenk techniques. The solvents were degassed prior to use. Other materials were reagent-grade purity and used without further purification. The ^{31}P NMR

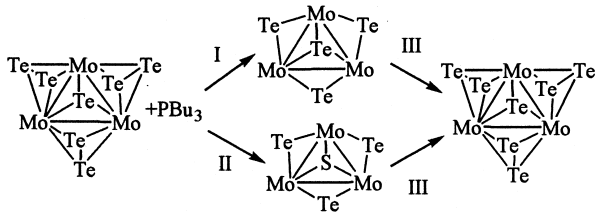
spectra were obtained on a Varian Unity-500 spectrometer in CH_2Cl_2 solutions with 80% H_3PO_4 as external standard in a $^{31}P\{^1H\}$ mode. UV–Vis spectra were recorded on a Varian Cary-2390 spectrophotometer in CH_2Cl_2 solutions. IR spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer using KBr pellets (4000–500 cm^{-1}) and CsI pellets (600–120 cm^{-1}). Element analyses were carried out by the Elemental Analysis Laboratory in our institute.

Preparation of $Mo_3Te_4S_6P_4O_8C_{37}H_{74}$ (**1**): 0.195 g (0.1 mmol) $Mo_3Te_7(S_2P(OPr^i)_2)_3I$, which was prepared according to the literature [16], 0.018 g (0.15 mmol) benzoic acid and 0.3 ml tributylphosphine were heated in 30 ml mixed-solvent of CH_2Cl_2–C_2H_5OH at 40°C for 3 h. The black crystals were isolated after the solution was allowed to stand for 4 days (0.072 g, yield 41%). *Anal*. Calc. for $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$: C, 25.23; H, 4.23. Found: C, 25.05; H, 4.29%. IR (KBr pellet, cm^{-1}): ν 1600, 1510 (CO), 716, 677 (C_6H_5). UV–Vis (CH_2Cl_2, nm): λ 370, 620. ^{31}P NMR (200 MHz, CH_2Cl_2, H_3PO_4): δ 111.7, 85.2, 22.3.

The preparation procedure of $Mo_3Te_3S_7P_4O_8C_{37}NH_{75}$ (**2**) was the same as for complex **1** except that 2-aminobenzoic acid was used instead of benzoic acid (0.053 g, yield 32%). *Anal*. Calc. for $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$: C, 26.44; H, 4.5; N, 0.83. Found: C, 26.62; H, 4.91; N, 0.88%. IR (KBr pellet, cm^{-1}): ν 1614, 1498 (CO), 3361 (NH_2), 667 (C_6H_5), 414 (Mo–(μ_3-S)). UV–Vis (CH_2Cl_2, nm): λ 337, 580. ^{31}P NMR (200 MHz, CH_2Cl_2, H_3PO_4): δ 106.0, 85.6, 17.8.



2.1. X-ray crystallography

The crystal data of complexes **1** and **2** were collected on a Siemens SMART CCD area detector diffractometer using graphite-monochromated Mo Kα radiation ($\lambda=0.71073$ Å) at 293 K, and empirical absorption correction by SADABS [17] was applied to the intensity data. Structure solution and refinement were performed on a SGI INDY workstation using the SHELXTL-5 program package [18]. The crystallographic data and refinement parameters are listed in Table 1.

3. Discussion

3.1. Synthesis

The preparation of complex **1**, $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$, using the abstraction of tellurium from an $Mo_3Te_7^{4+}$ cluster core to generate $Mo_3Te_4^{4+}$, is very similar to the preparation of the sulfide and selenide analogues, in which the bridging ligand is benzoic acid. This reaction can be completed at ambient temperature within a few hours. The preparation of complex **2**, $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$, is similar to that of **1**, except that 2-aminobenzoic acid was employed instead of benzoic acid, and the capping tellurium atom of the cluster core was substituted by sulfur in complex **2**, which might originate from the decomposition of the DTP (dialkyldithiophosphinate) ligand. It seems plausible that there is 'competition' between sulfur and tellurium to occupy the cap site in solution, and the nature of the bridging ligand might affect the structure of the final product. We found that the formation of the $Mo_3Te_3S^{4+}$ skeleton was not an incidental event since we could repeat this experiment very well. Furthermore, by using 4-aminobenzoic acid instead of 2-aminobenzoic acid, a similar product can be obtained, in which the position of 2-aminobenzoic acid was replaced by 4-aminobenzoic acid but the cluster core was still $Mo_3Te_3S^{4+}$ [19]. These compounds are mildly air sensitive, and when their solutions were exposed in air for several days, a tellurium mirror at the bottom of the receptacles was found along with some dark-brown crystals, which proved to be $Mo_3Te_7[S_2P(OPr^i)_2]_3I$ by IR spectra and X-ray diffraction experiments. The reaction scheme can be represented as shown in Scheme 1.

Scheme 1.

3.2. Structure

The structures of cluster molecules **1** and **2** are shown in Fig. 1, and selected bond distances and angles are listed in Tables 2 and 3, respectively.

In complex **1**, the three molybdenum atoms define an approximate isosceles triangle with Mo–Mo distances of 2.940(2), 2.970(2) and 2.832(2) Å, respectively, of which the shortest side is bridged by a $PhCO_2^-$ ligand. The average Mo–Mo distance of 2.914 Å is slightly longer than the value of 2.891 Å in $Cs_{4.5}[Mo_3Te_7(CN)_6]I_{2.5}\cdot 3H_2O$ [7] and 2.889 Å in $Mo_3Te_7[S_2P(OPr^i)_2]_3I$ [16]. One μ_3-Te atom and three μ-Te atoms are located above and below the Mo_3 plane, respectively, to form an incomplete cuboidal cluster skeleton. The Mo–(μ-Te) distances range from 2.597(2) to 2.649(2) Å. The average Mo–(μ_3-Te) distance of 2.650 Å is comparable to those found in $Mo_3Te_{10}I_{10}$ (2.661 Å) [20], $[Mo_3Te_7(CN)_6]^{3-}$ (2.696 Å) and $[Mo_4Te_4(CN)_{12}]^{7-}$ (2.676 Å) [8–10]. In addition to the $PhCO_2^-$ ligand that bridges two Mo atoms and one PBu_3 molecule coordinated to the third Mo atom, there is a terminal $S_2P(OPr^i)_2^-$ ligand chelating to each Mo atom. As a result, each Mo atom has a distorted octahedral coordination geometry. The Mo–P distance of 2.615(5) Å is comparable to those of other complexes containing the Mo_3S_4 cluster core and PPh_3 ligand [21,22].

In comparison, the structure of complex **2** is similar to that of complex **1** with the (μ_3-Te) and bridging $PhCO_2^-$ ligand replaced by the (μ_3-S) and 2-aminobenzoic acid group. The average Mo–Mo distance of **2** is slightly shorter (ca. 0.01–

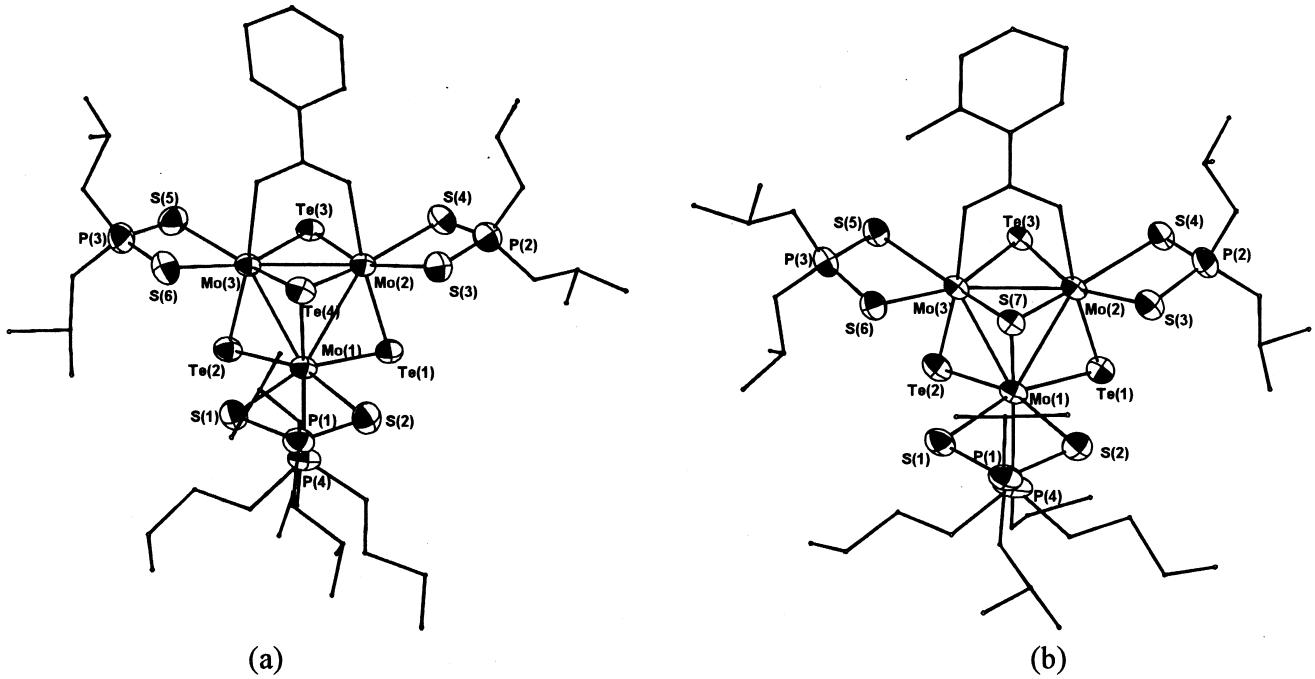

Fig. 1. Molecular drawings of (a) $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$ (**1**) and (b) $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$ (**2**). The labels for carbon and oxygen atoms have been omitted for clarity.

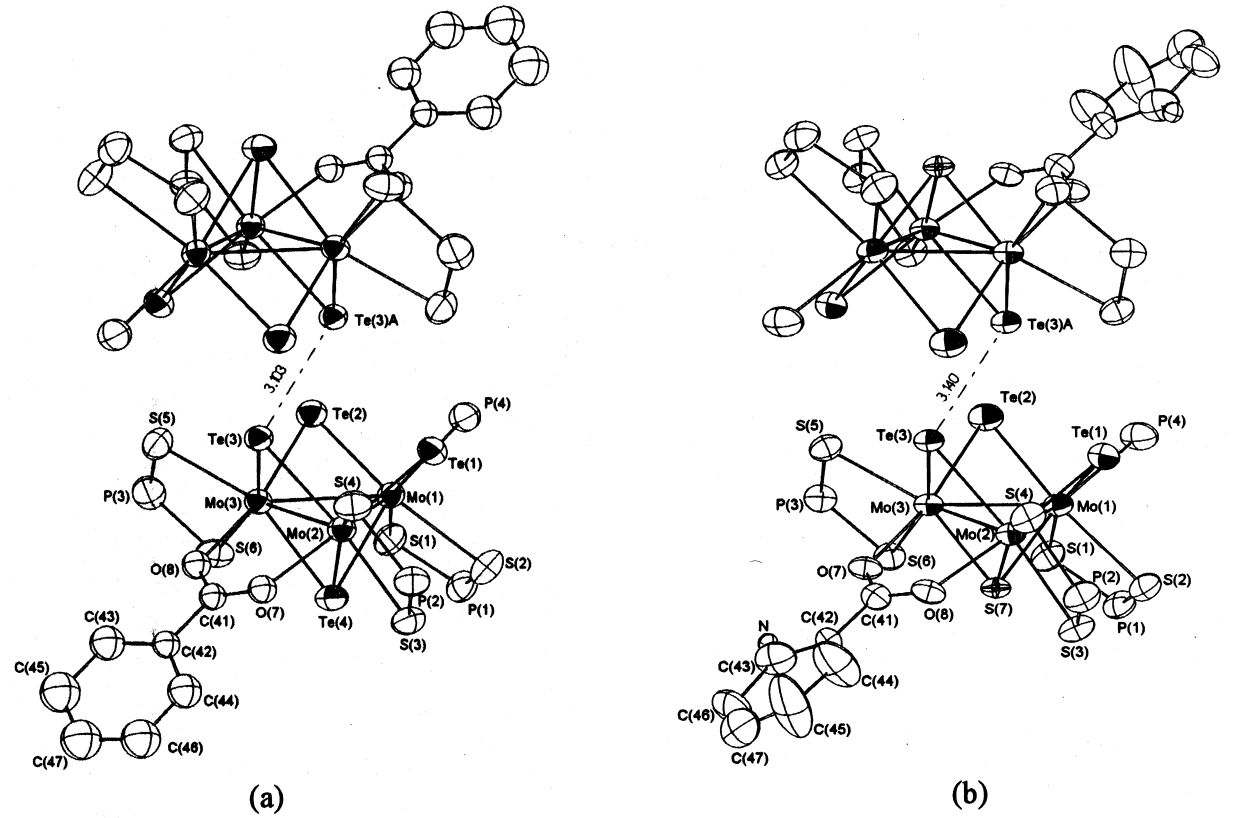

Fig. 2. ORTEP drawings of (a) $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$ (**1**) and (b) $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$ (**2**) dimers showing the atom labelling scheme at 30% probability of thermal ellipsoids. The butyl and isopropoxy groups have been omitted for clarity.

0.05 Å) than that of **1** because the capping sulfur atom has a smaller covalent radius than tellurium. On the other hand, the Mo–(μ-Te) and the Mo–P distances are significantly elongated (ca. 0.02–0.03 Å for Mo–Te and 0.06 Å for Mo–P).

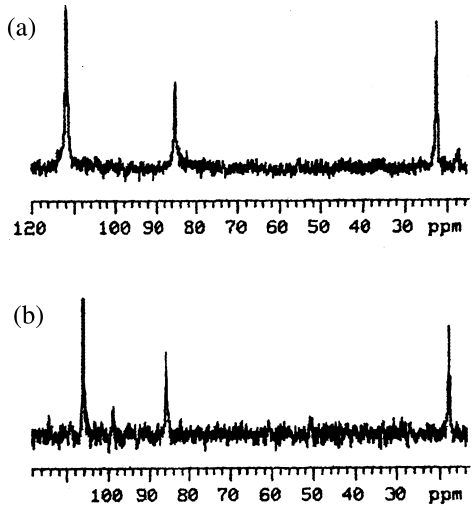

Fig. 3. ^{31}P spectra of (a) $Mo_3Te_4[S_2P(OPr^i)_2]_3(\mu\text{-}PhCO_2)PBu_3$ (**1**) and (b) $Mo_3(\mu_3\text{-}S)Te_3[S_2P(OPr^i)_2]_3(\mu\text{-}PhNH_2CO_2)PBu_3$ (**2**).

It is interesting that there is a short contact between Te(3) and Te(3A) of an adjacent molecule in both complexes (3.103(2) Å in **1** and 3.140(2) Å in **2**), leading to the formation of a dimer (Fig. 2). Consequently, the distances of Te(3) and Mo are elongated (ca. 0.03–0.05 Å) and the coordination environment of Te(3) is somewhat like that of the μ_3-Te (the distances Te(3)–Mo are comparable with Te(4)–Mo). EHMO calculation also attested that there is a weak bond between two Te(3) atoms [1] [23]. Although there are some examples of longer Te···Te interactions in existing tellurium-rich tellurides [24,25] (e.g. 3.07–3.17 Å in $LnTe_n$ ($n > 1.75$), 3.16 Å in $NaTe_3$), to our knowledge no example of dimerization of two triangular $Mo_3E_4^{4+}$ (E = S, Se) clusters through bonding interaction has been found, although the weaker dimerization through Se···Se interaction (3.415 Å) was reported in the $[M_3Se_4(CN)_9]^{5-}$ (M = Mo, W) [14] anion before.

The ^{31}P NMR spectra of complexes **1** and **2** are shown in Fig. 3. The chemical shift of P_1 of the DTP ligand is at 85.2 ppm for complex **1** (85.6 ppm for complex **2**). The peak at 111.8 ppm for complex **1** (106.0 ppm for complex **2**) with twice integration can be assigned to P_2 and P_3 of the DTP ligands, which coordinate symmetrically to Mo_2 and Mo_3, and the chemical shift of PBu_3 is at 22.3 ppm for complex **1** (17.8 ppm for complex **2**). Compared to their counterparts, δ_{P1} has no significant shift and δ_{P2}, δ_{P3} and δ_{PBu3} for complex **2** have shifted to high field. The substitution of capping-Te (in complex **1**) by capping-S (in complex **2**) in the cluster core should be mainly responsible for these shifts.

[1] Molecular orbital reduced overlap populations (MP) between Te(3) and Te(3A) are 0.052 for complex **1** and 0.027 for complex **2**. The EHMO calculations are based on the position of the atoms obtained from the X-ray structure analysis. Standard atomic parameters of the program were used. When we used a different atomic orbital parameter for tellurium (5s: −20.5, 2.57; 5p: −12.9, 2.16) [26], the MP between Te(3) and Te(3A) was 0.193 for complex **1** and 0.168 for complex **2**.

Supplementary data

Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) and are available on request quoting the deposition numbers 135939 and 135940.

Abstract

Dark coloured complexes of type VO(L)(Heg) and VO(L)(Hpd) have been synthesized in excellent yields by reacting bis(acetylacetonato)oxovanadium(IV) with H_2L in the presence of excess ethane-1,2-diol (H_2eg) and propane-1,3-diol (H_2pd), respectively in acetone. Here L^{2-} are the deprotonated forms of N-(1-hydroxyethyl)naphthaldimine (H_2L^1) and N-(1-hydroxy-2-methylpropyl)-naphthaldimine (H_2L^2). Heg^- and Hpd^- form five- and six-membered V(O,O) chelate rings, respectively. The crystal structure of $VO(L^2)(Heg)$ is reported. The ONO-coordinating tridentate $[L^2]^{2-}$ spans meridionally and consists of two planar segments mutually rotated along a C–N bond. The Heg^- ligand forms a non-planar chelate ring in which the dimethylene bridge is in *gauche* conformation. The five V–O lengths are unequal, the shortest being V–O(oxo) and the longest is V–O(alcoholic) which is subjected to the *trans* influence of the oxo oxygen atom. In the crystal lattice, the $VO(L^2)(Heg)$ molecule forms an infinite chain helical pattern via intermolecular O···O hydrogen bonding. Methylene ^1H resonances are systematically shifted to lower field compared to those of free H_2eg and H_2pd, the shift of the CH_2OV resonances being particularly large. The complex multiplet ^1H structure in $CDCl_3$ is a good indication of the rigidity of the chelate ring in solution. ^{51}V chemical shifts are found to be diagnostic of the alcohol–alkoxide chelate ring size, the shift of VO(L)(Heg) being ~25 ppm downfield from that of VO(L)(Hpd). Low V(V)/V(IV) reduction potentials (ca. −0.30 V versus SCE) are indicative of the considerable VO^{3+} stabilization due to two alkoxide coordination. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The discovery of vanadium as a cofactor in bromoperoxidase [1] and nitrogenases [2] has attracted the current attention to the reactivity and coordination chemistry of oxovanadium(V) alkoxides [3–7]. Organic vanadates have been of recent interest to inorganic and organic chemists as well as biochemists, spectroscopists and material scientists with respect to structure and reactivity [8,9]. It has been known for a long time that, like phosphorus, vanadium forms esters with alcohols in their pentavalent state [10–12]. This analogy between phosphate and vanadate is of far reaching consequence and biological processes can be modified or adjusted via the addition of vanadate which naturally influences phosphate related phenomena. A more classical and developing field of application of vanadium alkoxide and related compounds is their use as a catalyst in polymerization [13–15], as selective redox reagents [16,17] and as mimics in studies of phosphorylation [18–20], haloperoxidation [21–23] and insulin action [24,25]. The present work concerns the formation of vanadate esters incorporating ethane-1,2-diol and propane-1,3-diol. Oxovanadium(V) esters incorporating dihydroxy alcohols are in most cases polymeric [26–33]; few mononuclear species are known [34,35]. This has motivated us to search for rational ways of making mononuclear esters chelated by diols. Herein we describe the synthesis, structure and solution properties of a series of oxovanadium(V) complexes incorporating ethane-1,2-diol and propane-1,3-diol as in **1** and **2** respectively.

1 **2**

The solid and solution structures of the complexes, as well as their properties, were probed using X-ray diffraction, spectroscopic and electrochemical methods. ^{51}V chemical shifts

have been found to be diagnostic of the alcohol–alkoxide chelate ring size.

2. Results and discussion

2.1. Synthesis and characterization

In the present work, two tridentate diacidic Schiff bases H_2L^1–H_2L^2 (**3**) (written generally as H_2L) have been used as coligand so as to block three coordination positions, leaving just two positions for possible diol chelation in a six-coordinated situation.

3

The coligand Schiff bases were prepared by condensing 2-hydroxynaphthaldehyde with amino alcohols such as ethanol amine and 2-amino-2-methyl-1-propanol respectively in ethanol. The stoichiometric reaction of bis(acetylacetonato)oxovanadium(IV) with H_2L in acetone in air in the presence of excess ethane-1,2-diol (H_2eg) or propane-1,3-diol (H_2pd) afforded the dark coloured complex VO(L)(Heg) or VO(L)(Hpd) in excellent yields. The oxygen in air is believed to be the oxidant ($V^{IV}O \rightarrow V^{V}O$). Excess diol was used in the above synthesis to ensure the formation of mononuclear esters.

All the complexes are diamagnetic, suggesting vanadium is in the +5 oxidation state. The V=O stretch occurs as a sharp strong peak in the range 975–985 cm^{-1} consistent with hexacoordination [36–39]. The hydrogen bonded OH stretch occurs as a broad peak near 3450 cm^{-1}. In solution the complexes display an intense band near 375 cm^{-1} associated with a relatively weak band near 480 cm^{-1}; these are believed to be of O(alkoxide) → V LMCT origin [23,40,41]. The complexes show a quasireversible one-electron cyclic voltammetric response near −0.30 V versus SCE. The oxovanadium(V) state is thus strongly stabilized by alkoxide coordination and this facilitates spontaneous $V^{IV}O/V^{V}O$ oxidation by aerial oxygen in the synthesis. Detailed characterization data are listed in Section 3.

2.2. Crystal structure

The structure of VO(L^2)(Heg) was determined; it crystallizes in the space group $P2_1$. The asymmetric unit consists of two metrically similar but crystallographically distinct molecules. In Fig. 1 only molecule 1 is shown. The numberings of the corresponding atoms in molecules 1 and 2 are respectively n and $n+50$, e.g. V(1)–O(5) and V(51)–O(55). Selected bond distances and angles are listed in Table 1.

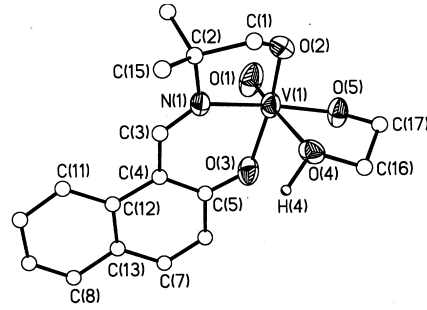

Fig. 1. Perspective view and atom labelling scheme for molecule 1 in VO(L^2)(Heg) showing the crucial hydrogen atom only.

Table 1

O(5)–V(1)–N(1)	162.1(3)	O(55)–V(51)–N(51)	161.9(3)

The VO_5N coordination sphere is distorted octahedral, the metal atom is displaced by 0.31 Å (molecule 1) and 0.30 Å (molecule 2) towards the oxo oxygen away from the equatorial plane (mean deviation 0.006 Å) defined by O(2), O(3), O(5), N(1) (molecule 1) and O(52), O(53), O(55) and N(51) (molecule 2). The $[L^2]^{2-}$ is meridionally disposed and consists (excluding the methyl groups) of two planar segments mutually rotated around an N–C bond. The segments are $OC_{10}H_6CHN$ (plane A, mean deviation < 0.07 Å) and CCH_2O (plane B), the dihedral angle being ~50°. The metal atom does not lie on either plane and is displaced respectively by 0.43 and 0.16 Å (for molecule 1) and by 0.42 and 0.15 Å (for molecule 2). The Heg^- ligand forms a non-planar five-membered chelate ring in which the dimethylene bridges are in *gauche* configuration.

The five V–O bond lengths are unequal; the shortest distance is the bond to the oxo oxygen and the longest is that to the glycolic hydroxyl oxygen. The latter is subjected to the *trans* influence of the oxo oxygen. It is logical that the weaker alcoholic oxygen donor rather than the stronger alkoxidic

donor lies *trans* to the oxo oxygen. The V–O bond lengths follow the order V–O(oxo) < V–O(alkoxide) < V–O-(phenoxide) < V–O(alcoholic). The V–O(alkoxide) length in the V(L^2) fragment is shorter than the corresponding length in the V(Heg) fragment. The variation in V–O-(alkoxide) bond is presumably due to the *trans* influence of the azomethine nitrogen, in which the alkoxide oxygen of Heg^- is placed *trans* to it. The other bond distances are as usual.

The most striking feature of the crystal structure of the complex is the helical structure formed by intermolecular O···O hydrogen bonding between the alcoholic oxygen of one molecule with the alkoxide oxygen of Heg^- of the adjacent molecule. The relevant hydrogen bonding distances are O(4)···O(55) 2.625(11), and O(54)···O(5) 2.634(11) Å. The infinite helical chain pattern is shown in Fig. 2.

Despite our best efforts, we have been unable to grow single crystals of the VO(L)(Hpd) complexes suitable for X-ray diffraction studies. However, structure determination of complexes in which $[L]^{2-}$ is substituted by O,N,O-coordinating diionized tridentate ligands are known [34,35]. Our results are indicative of a similar structure.

2.3. ^1H and ^{51}V NMR

All spectral data were recorded in $CDCl_3$. Signals were assigned on the basis of intensity, spin–spin coupling patterns and chemical shift values. In VO(L)(Heg) complexes all the methylene protons, either from L^{2-} or from Heg^-, are inequivalent in the solid state. In solution the inequivalency is clearly resolved in the case of the methylene protons of the alkoxide carbon atoms; the inequivalency is relatively large for the ligand L (Fig. 3) compared with Heg^-. VO(L)(Hpd) complexes behave similarly; here the inequivalency of the alkoxidic methylene protons in the Hpd^- fragment is not well resolved (Fig. 4).

The methylene ^1H resonances of chelated Heg^- and Hpd^- are systematically shifted to lower fields compared to those of the free H_2eg and H_2pd, the shift of the –CH_2OV resonances being particularly large. The alkoxidic CH proton of the diol ligand occurs as an isolated ^1H signal shifted downfield by 1–1.5 ppm from the alcoholic CH proton. Thus ^1H NMR can be used for easy identification of the hydrolysis of bound Heg^- and Hpd^- to the corresponding free diols in solution. The VO(L)(Hpd) complexes are much more prone to hydrolysis than VO(L)(Heg) if the solvent is slightly wet. Thus the five-membered chelate ring **1** has superior hydrolytic stability compared to the six-membered chelate **2**. The documented failure [31–33] in producing vanadate esters having propane-1,3-diol chelation in aqueous media is thus understandable. Solution experiments were done in dry solvents to prevent possible hydrolysis. The complex multiplet ^1H structure is a good indication of chelate ring rigidity in solution [34,35]. The alcoholic OH signals occur as a broad signal near 4.9 ppm which 'disappears' on shaking with D_2O.

Complexes display a sharp and single ^{51}V resonance in $CDCl_3$. For a given L ligand, VO(L)(Hpd) complexes, having a six-membered chelate ring **2**, display a signal ~25 ppm upfield from that of VO(L)(Heg) incorporating a five-membered chelate ring **1**. ^{51}V chemical shifts are thus diagnostic of the V(O,O) chelate ring size. This trend is found to

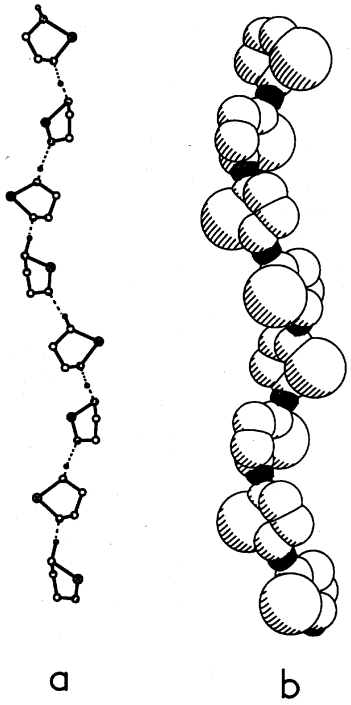

Fig. 2. (a) Perspective view and (b) space filling model of VO(L^2)(Heg) in the lattice showing the helical network formed via intermolecular O···O hydrogen bonds (for clarity only the V(Heg) fragment is shown).

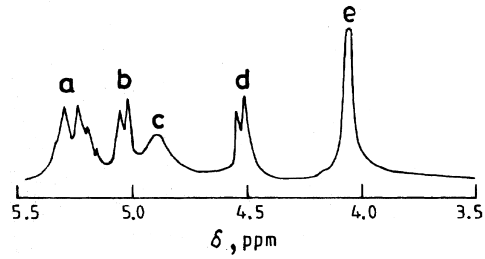

Fig. 3. Proton NMR spectrum (300 MHz, 3.5–5.5 δ) of VO(L^2)(Heg) in $CDCl_3$. Resonances *a* (for CH_2OV), *c* (for CH_2(O*H*)V) and *e* (for CH_2(OH)V) correspond to chelated Heg^- while *b* and *d* (for CH_2OV) correspond to L^2.

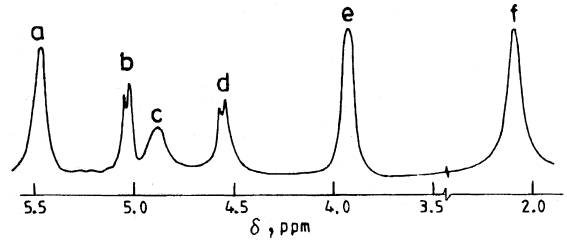

Fig. 4. Proton NMR spectrum (300 MHz) of VO(L^2)(Hpd) in $CDCl_3$ (only a selected portion is shown). Resonances *a* (for CH_2OV), *c* (for CH_2(O*H*)V), *e* (for CH_2(OH)V) and *f* (for C$H_2$$CH_2$OV) correspond to chelated Hpd^- while *b* and *d* (for CH_2OV) correspond to L^2.

be generally applicable, as observed in other cases [34,35]. Chemical shift values are listed in Section 3.

3. Experimental

3.1. Materials

Bis(acetylacetonato) oxovanadium(IV) [42] and tetraethylammonium perchlorate [43] were prepared by reported procedures. $CDCl_3$ was obtained from Sigma Chemicals. All other chemicals and solvents were of analytical grade and used as received.

3.2. Physical measurements

Proton NMR spectra were recorded on a Bruker FT 300 MHz spectrometer, IR spectra on a Perkin-Elmer 783 spectrophotometer and electronic spectra on a Hitachi 330 spectrophotometer. ^{51}V NMR spectra were drawn on a Varian spectrometer (78.8 MHz) at 25°C, externally referenced to $VOCl_3$. Electrochemical measurements were performed on a PAR model 370-4 system as described previously [44]. All potentials reported in this work are referenced to a saturated calomel electrode (SCE) and are uncorrected for junction contribution. A Perkin-Elmer elemental analyser was used to collect microanalytical data (C, H and N). For ^1H NMR, the proton numbering scheme used for the ligand L is as in Fig. 1.

3.3. Synthesis of the complexes

The VO(L)(Heg) complexes were prepared using a general procedure. Details are given below for a representative case of $VO(L^2)$(Heg). The VO(L)(Hpd) complexes were similarly prepared; here ethane-1,2-diol is replaced by propane-1,3-diol in the synthetic procedure.

$VO(L^2)$(Heg). To an acetone solution (20 cm^3) of $VO(acac)_2$ (0.10 g, 0.38 mmol) and H_2L^2 (0.92 g, 0.38 mmol) was added excess ethane-1,2-diol (1 cm^3, 17.88 mmol). The mixture was warmed on a water bath for 15 min and left to evaporate at room temperature in air. The dark coloured crystalline solid that deposited was filtered off, washed thoroughly with water and dried over P_4O_{10} in vacuo. Yield: 0.12 g (87%). *Anal.* Found: C, 55.21; H, 5.50; N, 3.72. Calc. for $C_{17}H_{20}NO_5V$: C, 55.28; H, 5.42; N, 3.79%. IR (KBr, ν_{max} (cm^{-1})): 978 (V=O); 1615 (C=N); 3420 (br, OH). UV–Vis (CH_2Cl_2, λ_{max} (nm) (ε (dm^3 mol^{-1} cm^{-1}))): 475 (1900), 375 (5580). 3.4. X-ray crystallography

Black coloured crystals of $V^VO(L^2)$(Heg) (0.3×0.4×0.3 mm) were grown by slow evaporation of the reaction mixture in acetone. Cell parameters were determined by least-squares fitting of 30 machine centred reflections (2θ, 15–30°). The crystal system was confirmed to be monoclinic by suitable checking of the Laue symmetry. Data were collected by the ω-scan technique in the 2θ range 3–48° on a Siemens R3m/V four-circle diffractometer with graphite-monochromated Mo Kα radiation (λ=0.71 073 Å). Two check reflections measured after every 98 reflections showed no intensity reduction. All data were corrected for Lorentz polarisation effects and empirical absorption corrections were done on the basis of azimuthal scan of six reflections [45].

Table 2
Crystallographic data for $VO(L^2)(Heg)$

Formula	$C_{17}H_{20}NO_5V$
M	369.28
Crystal system	monoclinic
a (Å)	9.714(8)
b (Å)	18.217(9)
c (Å)	9.720(8)
β (°)	90.04(6)
U (Å^3)	1720(2)
Space group	$P2_1$
Z	4
D_c (Mg m^{-3})	1.426
T (K)	295
μ(Mo Mα) (mm^{-1})	0.602
F(000)	768
R_1 [a], wR_2 [b] ($I>2\sigma(I)$)	0.0606, 0.1303
S [c]	1.027
No. of parameters	333
Maximum, minimum $\Delta\rho$ (e Å^{-3})	0.446, −0.273

[a] $R_1=\Sigma||F_o|-|F_c||/\Sigma|F_o|$.
[b] $wR_2=[\Sigma\{w(F_o^2-F_c^2)^2\}/\Sigma\{w(F_o^2)^2\}]^{1/2}$;
$w^{-1}=\sigma^2(F_o^2)+(ap)^2+bp$, where $p=(F_o^2+2F_c^2)/3$ and a (0.0516) and b (2.5196) are constants adjusted by the program.
[c] $S=[\Sigma\{w(F_o^2-F_c^2)^2\}/(n-p)]^{1/2}$ where n is the number of data and p the number of parameters.

All calculations for data reduction, structure solution and refinement were done using the programs of SHEXTL, version 5.03 [46]. The structure was solved by direct methods and was refined by full-matrix least-squares on F^2. Total collected reflections were 3400 of which 3153 were unique and 2366 satisfying $I>2.0\sigma(I)$ were used for structure solution. The available observed data did not permit anisotropic refinement of all atoms. All non-hydrogen atoms except C4–C13 (molecule 1) and C54–C63 (molecule 2) were made anisotropic. The remaining atoms were refined isotropically. The crucial alcoholic hydrogen along with a few other hydrogens were directly located in difference Fourier maps. The remaining hydrogen atoms were included in calculated positions (Riding model). Significant crystal data are listed in Table 2.

4. Conclusions

Mononuclear chelation of ethane-1,2-diol and propane-1,3-diol to oxovanadium(V), as in **1** and **2**, has been achieved in the form of VO(L)(Heg) and VO(L)(Hpd), respectively. Here ethane-1,2-diol forms a five-membered alcohol–alkoxide chelate whereas propane-1,3-diol forms a six-membered chelate. The ligand L^{2-} binds in tridentate meridional fashion to the metal. In the crystal lattice of $VO(L^2)(Heg)$, the molecules form an infinite chain helical structure through intermolecular O···O hydrogen bonding. The complex multiplet ^{1}H structures are good indication of the preservation of chelate ring rigidity in solution. The vanadium(V) oxidation state is strongly stabilized (low V(V)/V(IV) potentials) by two alkoxide coordination. ^{51}V chemical shifts are found to be diagnostic of chelate ring size. For a given L, the VO(L)(Heg) resonates ~25 ppm down field from VO(L)(Hpd).

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number 130243.

Abstract

The synthesis, spectroscopic and biological properties of the novel palladium(II) complexes with monoethyl (HL1) and monobutyl (HL2) esters of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid, have been prepared and studied. These potential polydentate ligands form two types of metallocyclic compounds, those with [C,N] and [N,O] five-membered chelate rings. The former are cyclopalladated chloro-bridged binuclear complexes, $[PdL(\mu\text{-}Cl)]_2$, in which the deprotonated ligand undergoes palladation at the azo nitrogen and the *ortho*-carbon, while the latter mononuclear complexes, PdL_2, contain the organophosphorus ligand bonded through the aniline nitrogen and the deprotonated phosphonic acid oxygen. The complexes were identified and characterized by elemental analysis, magnetic and conductance measurements as well as by IR, ^1H, ^{13}C and ^{31}P nuclear magnetic resonance and ESI-mass spectroscopic studies. The in vitro antitumour activity of all the complexes was evaluated against the human KB cell line as a preliminary screening for their biological activity. The coordination behaviour of monoalkyl benzeneazophosphonates as well as the spectral and biological properties of their complexes were compared with the results reported for the corresponding dialkyl phosphonates and their palladium(II) complexes. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Palladium(II) complexes; Metallocycles; Aminophosphate complexes; Spectroscopy; Antitumour activity

1. Introduction

Organopalladium chemistry is one of the most extensive and varied areas of transition metal chemistry. Special attention has been paid to metallocyclic complexes with nitrogen donor ligands, such as various alkyl and aryl substituted amines and imines, azo, hydrazo and heterocyclic compounds. The chelate ring generally possesses three to seven members, with the five-membered ring being most favoured. These compounds are used successfully in organic synthesis [1–3], homogeneous catalysis [4], asymmetric synthesis [5], photochemistry [6] and optical resolution [7,8], and are rather promising as liquid crystals [9,10] and potential biologically active materials [11–13]. Complexes with O-bonding ligands are less abundant because palladium as a soft metal has a strong preference for N-donor ligands. Monodentate ligands of this type readily undergo substitution reactions [14–16], however, the chelate effect is important in favouring the final stability of a complex and there is a well developed chemistry for chelating ligands that combine a soft and a hard donor centre. There are known cyclometallated complexes in which the ligand is bonded through the carbon, nitrogen and oxygen atoms [17,18]. Derivatives of aminocarboxylic and aminophosphonic acids as [N,O] chelate ligands are of particular interest owing to their relevance to the natural systems and promising biological activity [19–22].

Our systematic investigation has been directed to the synthesis and characterization of new biological active palladium(II) complexes with dialkyl and monoalkyl esters of phosphonic acids derived from quinoline [14–16,21–23] and aniline [13,24,25]. It was found that most of these complexes

PII S0277-5387(00)00339-9

displayed a certain in vitro antitumour activity against human and animal tumour cell lines. The greatest activity was found for complexes of dialkyl esters of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid [13]. These ligands with several donor atoms serving as potential sites for metal coordination, i.e. the anilino and azo nitrogen as well as the phosphoryl oxygen, form two types of palladium(II) halide complexes: adducts and cyclometallated derivatives. The former are square planar with *trans*-bonded ligands through the azo nitrogen, while in the latter the deprotonated ligand undergoes palladation at the azo nitrogen and the *ortho*-carbon forming the binuclear organopalladium complexes. The anilino and phosphoryl groups are not involved in metal coordination and are free to be involved in hydrogen bonding, which is known to have some importance in metal–DNA approaching and binding interactions [26]. In the present paper we describe the synthesis as well as spectroscopic analyses and biological properties of new palladium(II) complexes of monoethyl (HL1) and monobutyl (HL2) esters of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid. In the course of these investigations, the results obtained are compared with those obtained for palladium complexes of the corresponding dialkyl benzeneazophosphonates [13], and are discussed with respect to their structure–stability and structure–activity relationships. Differences in their complex-forming behaviour mainly arise from the presence of the phosphonic acid group in monoester derivatives, which enables these ligands to coordinate to the palladium ion in either their molecular or anionic form.

2. Results and discussion

2.1. Synthesis and properties

Investigations of the chelating behaviour of monoalkyl [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonates (HL1 and HL2) towards the palladium(II) ion have shown that these ligands act in a bidentate manner forming two types of metallocyclic complexes, those with [C,N] and [N,O] five-membered chelate rings (Fig. 1). The reaction of HL1 and HL2 with $PdCl_4^{2-}$ (molar ratio M:L = 1:1) in methanol affords cyclopalladated binuclear complexes with metal–metal chloro bridge, $[PdL(\mu\text{-}Cl)]_2$ (**1** and **3**), in which the deprotonated ligand undergoes palladation at the azo nitrogen and the *ortho*-carbon. In basic media the phosphonate acid group is deprotonated and, thus, the reaction of sodium salts of monoalkyl phosphonates (NaL1 and NaL2) with $PdCl_4^{2-}$ in water (M:L = 1:2) gives [N,O] chelate complexes, PdL_2 (**2** and **4**), with coordinated ligand through the aniline nitrogen and the phosphonic acid oxygen. It should be noted that in an unsymmetrically substituted azobenzene derivative, orthopalladation can occur in either benzene ring with the possibility of obtaining an isomeric mixture, but in general it has been noticed that the palladium–carbon σ-bond is formed preferentially with the benzene ring having an electron-donating group [27,28]. Our results presented here, as well as those obtained for the cyclopalladated complexes of the corresponding dialkyl phosphonates [13], are in accordance with this assumption. In both cases the palladation occurred in the anilinobenzyl-substituted aromatic ring. It may be presumed that the simplified mechanism of cyclopalladation includes the initial coordination of azo nitrogen to metal ion followed by electrophilic substitution at the *ortho*-carbon atom. It is worth noting that in the case of dialkyl phosphonates, the complexes with monodentate azo N-bonded ligands could easily be isolated, while all efforts to prepare dihalide adducts of the monoester ligands were unsuccessful.

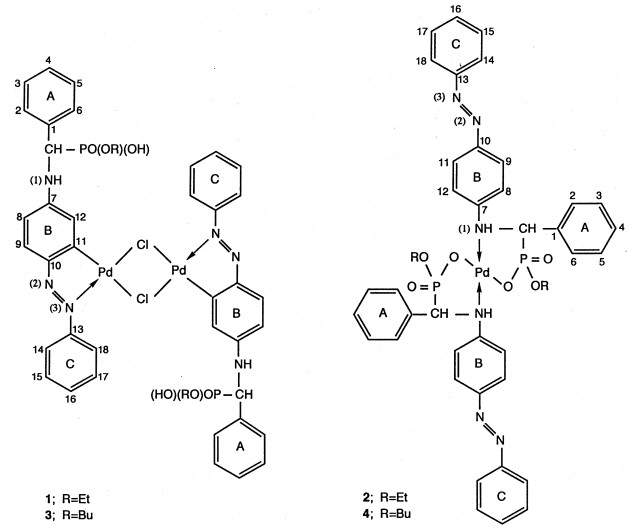

Fig. 1. Proposed chemical structures and numbering scheme of palladium complexes with monoalkyl [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonates (HL1 and HL2).

The prepared complexes are red powder like or microcrystalline compounds, stable in the solid state under normal laboratory conditions. Their diamagnetic behaviour suggests square-planar stereochemistry around the palladium(II) ion. The molar conductance values (below 15 S cm^2 mol^{-1} in DMF) correspond to those of non-electrolytes. The complexes are insoluble in water, slightly soluble or soluble in common organic solvents, and very soluble in DMF and DMSO. In general, the binuclear complexes are more soluble than the mononuclear complexes, as are complexes of butyl ester with respect to complexes of its ethyl analogue. Because of the insolubility of the prepared complexes in suitable solvents, or because of their instability, we could not grow crystals for X-ray analysis. The structure of the complexes, as well as their stability and mode of decomposition, were deduced mainly from their IR, multinuclear magnetic resonance and mass spectroscopic studies. A detailed spectroscopic analysis of the free organophosphorus ligands has also been described.

2.2. Infrared spectra

There are great differences in the IR spectra of the two types of complexes, supporting different metal–ligand inter-

actions in these compounds. Significant differences may be noticed between 1600 and 1530 cm^{-1} where the NH deformation modes along with the benzene ring stretching vibrations are found. A very strong band at 1576 cm^{-1} with a shoulder at 1555 cm^{-1} is characteristic for the cyclopalladated complexes **1** and **3** with an aryl carbon–metal σ bond, while the chelate complexes **2** and **4** in this frequency region are characterized by two very intense bands near 1600 and 1585 cm^{-1}. There are marked differences also between 1250 and 950 cm^{-1} where absorption bands appear associated with the acidic monoalkyl phosphonate group PO(OR)(OH) [29,30]. In the cyclopalladated complexes two bands at 1237 and 1198 cm^{-1} could be ascribed to the P=O stretching absorption, while the PO–H stretching vibration is superimposed on the PO–C stretching, giving broad and complex bands between 1030 and 950 cm^{-1}.

In the spectra of the mononuclear complexes **2** and **4** there is no evidence of the bands associated with P–O–H vibrations, since in these complexes the phosphonate ligands act in the anionic form. This is confirmed by the presence of the $\nu(PO_2^-)$ absorptions as medium or strong bands between 1230 and 1200 cm^{-1} for the antisymmetric and between 1070 and 1025 cm^{-1} for the symmetric mode of this vibration. In the latter frequency range the ν(PO–C) absorption is superimposed upon that of the symmetric PO_2^- vibration [31,32].

The chloro-bridged cyclopalladated complexes **1** and **3** in the far-IR region show two Pd–Cl stretching bands. The higher-frequency band at 307 cm^{-1} is attributed to the vibration of the Pd–Cl bond *trans* to the nitrogen atom, while the lower-frequency band at 255 cm^{-1} is ascribed to the vibration of the Pd–Cl bond *trans* to the σ-bonded carbon. This is a consequence of a greater *trans* influence of a σ-bonded carbon compared to that of a nitrogen atom [33].

2.3. Mass spectra

Electrospray ionization mass spectrometry (ESI-MS) is a soft ionization technique which has recently been widely used in the structural analysis of non-volatile and thermally labile species such as large biomolecules [34,35] and various coordination metal compounds, especially polynuclear complexes [36,37]. This method allows pre-existing ions in solution to be very gently transferred to the gas phase with minimal fragmentation, followed by conventional mass spectrometry. The ESI mass spectrometric investigation of monoalkyl anilinobenzylphosphonates and their palladium(II) complexes has shown that their mass fragmentation pattern is much less extensive than that obtained for the corresponding dialkyl phosphonates and their palladium complexes studied under fast atom bombardment (FAB) conditions [24,25]. In the ESI negative-ion mass spectra of the free non-coordinated organophosphorus ligands, the deprotonated molecular ion was observed as the base and the only intense peak, since the phosphonic acid group could easily be deprotonated to give an anion. In the corresponding spectra obtained in the positive-ion mode, the ligand fragmentation is more pronounced and the most abundant fragment ion is formed by cleavage of the C–P bond and complete loss of the phosphonate ester group. The abundance of the protonated molecular ion is only about 5% as is shown in Fig. 2 for HL2, as an example of the common decomposition pattern for both alkyl monoesters in positive/negative ESI mass spectra. All palladium complexes have been investigated by spectrometric measurements carried out under positive/negative-ion ESI conditions with different cone voltages, using methanol as the solvent and the mobile phase. The negative-ion mass spectra give more relevant structural information than the spectra obtained in the positive-ion mode. The molecular ion as well as the fragment ions containing palladium are identified by the presence of the characteristic clusters of isotopic peaks covering about 10 *m/z* units, due to the presence of the numerous palladium isotopes. The fragmentation pathway depends mainly on the type of complex and the major structurally informative fragments in negative-ion mass spectra are summarized in Table 1. The first point to be noted is that all complexes exhibit the deprotonated molecular ion and its relative abundance is about 3% for the cyclopalladated binuclear complexes **1** and **3** and about 1% for the mononuclear palladium complexes **2** and **4**. There are great differences in mass spectroscopic behaviour between these two types of complexes.

The fragmentation pathways of the cyclopalladated complexes, including possible structures of Pd-containing ions, proposed on the basis of the accurate mass measurements and isotopic cluster analysis are reported in Scheme 1 and Fig. 3(a). The loss of $Cl^{\bullet}$ produces the fragment ion which corresponds to binuclear monobridged species. In this respect it

could be pointed out that some monohalide-bridged binuclear palladium complexes have been isolated and characterized [38,39]. The further loss of hydrogen chloride involves structural rearrangement of the species giving a dinuclear complex in which are two cyclopalladated moieties bonded through the deprotonated phosphonic acid groups. The loss of one palladium and one ligand molecule from the parent complex ion leads to a deprotonated dichloro monopalladated complex $[PdLCl_2]^-$, which by the sequential losses of HCl and $Cl^\bullet$ leads finally to the orthometallated species $[(PdLCl)–H]^-$ and $[(PdL)–H]^{-\bullet}$, respectively. The former mono-chloropalladium fragment ion is the base peak in the spectra of these complexes. The high stability of such metallated systems is in agreement with the reported high stability of palladium(II) five-membered cyclometallated systems having nitrogen donor ligands [24,40,41]. Of the organic fragments, the most intense peak (60–80%) corresponds to the deprotonated ligand molecule.

Investigations of decomposition properties of the mononuclear complexes **2** and **4** indicate much less stability of these compounds with respect to the binuclear cyclopalladated complexes. The predominant pathway for their fragmentation is complete dissociation of the phosphonate ligand molecules (Fig. 3(b)). The deprotonated ligand ion is the major and the only intense fragment ion in the spectra of these complexes. The relative abundance of all other fragment ions is very small amounting up to 1%. The most abundant palladium containing fragment ions are the parent molecular ion $[(PdL_2)–H]^-$, and the ion containing only one [N,O] bonded organophosphorus ligand. Dimerization of the free organophosphorus ligand gives rise to $[(HL)_2–H]^-$ ions at *m/z* 798 and 845, respectively. The sodium adducts are also present.

It is worth noting that the spectra of complexes show some ions based on addition of methanol as solvent molecules as well as addition of the sodium ion either to the parent complex or to the ligand molecules or their fragments; this is in agreement with the ESI mass results obtained for various complex compounds [37,42]. Some of the most abundant adduct ions are given in Table 1.

2.4. NMR spectra

^{1}H, ^{13}C and ^{31}P NMR data of free ligands HL1 and HL2, sodium salt NaL2 and both types of palladium complexes derived from the butyl ester (complexes **3** and **4**), obtained in $CDCl_3$ solution, are summarized in Tables 2 and 3, and presented in Figs. 4–7. The numbering scheme is shown in Fig. 1. Complexes of ethyl ester are not sufficiently soluble for spectral analysis. The results obtained are compared and discussed with those reported for dialkyl [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonates and their palladium complexes [13,43]. The broadening of H/C aromatic absorptions in the free monoesters with respect to those observed in the corresponding diesters could be connected with their dimeric structure in chloroform solution [30]. The most pronounced broadening could be observed for protons H-9,11 and H-15,17, as shown in Figs. 4 and 5(a). The slight upfield shift (up to 0.25 ppm) of most of the aromatic protons with respect to those in diesters could be attributed to mutual interligand shielding between two hydrogen bonded monoester molecules lying parallel to one another. The ligand

Scheme 1. ESI negative-ion fragmentation pathway for complexes **1** and **3**.

association is ascribed to the strong intermolecular hydrogen bonding between the phosphonic acid groups, which is confirmed by the presence of a very broad absorption of the acidic OH resonance around 10 ppm. In the case of sodium salt (Fig. 5(c)) the signal broadening of the aromatic protons is not visible, as well as in the spectra of monoesters in DMSO solution (Fig. 5(b)), in which there is no ligand association. The assignment of all aromatic H/C resonances was confirmed unambiguously by two-dimensional homonuclear and heteronuclear NMR experiments. As examples, Fig. 4 shows a ^{1}H–^{1}H COSY spectrum of HL1 and Fig. 6 shows a part of the long-range ^{1}H–^{13}C HMBC spectrum of sodium salt NaL2. In addition, the signal assignment of the carbons C(1)–C(6) was supported with the long-range phosphorus–carbon couplings.

The spectra of both types of complexes are rather complex, caused either by the removal of the degeneracy of resonances due to metal coordination (complex **3**) or by the presence of more isomeric forms (complex **4**). The most pronounced chemical shift changes with respect to the uncomplexed ligand could be noticed for the atoms involved in metal binding and those in the vicinity of the ligation site. In the binuclear complex **3**, with palladation at the azo nitrogen and the *ortho*-carbon, there are significant differences in the B-phenyl and C-phenyl rings of the ligand molecule. The proton NMR spectrum shows a great broadening of all signals and an extensive overlapping of the aromatic resonances (Fig. 5(c)) due to the dimeric nature of this complex. The non-equivalence of the aromatic protons H(8) and H(12) and their upfield shifts of 0.41 and 0.19 ppm, respectively, supports

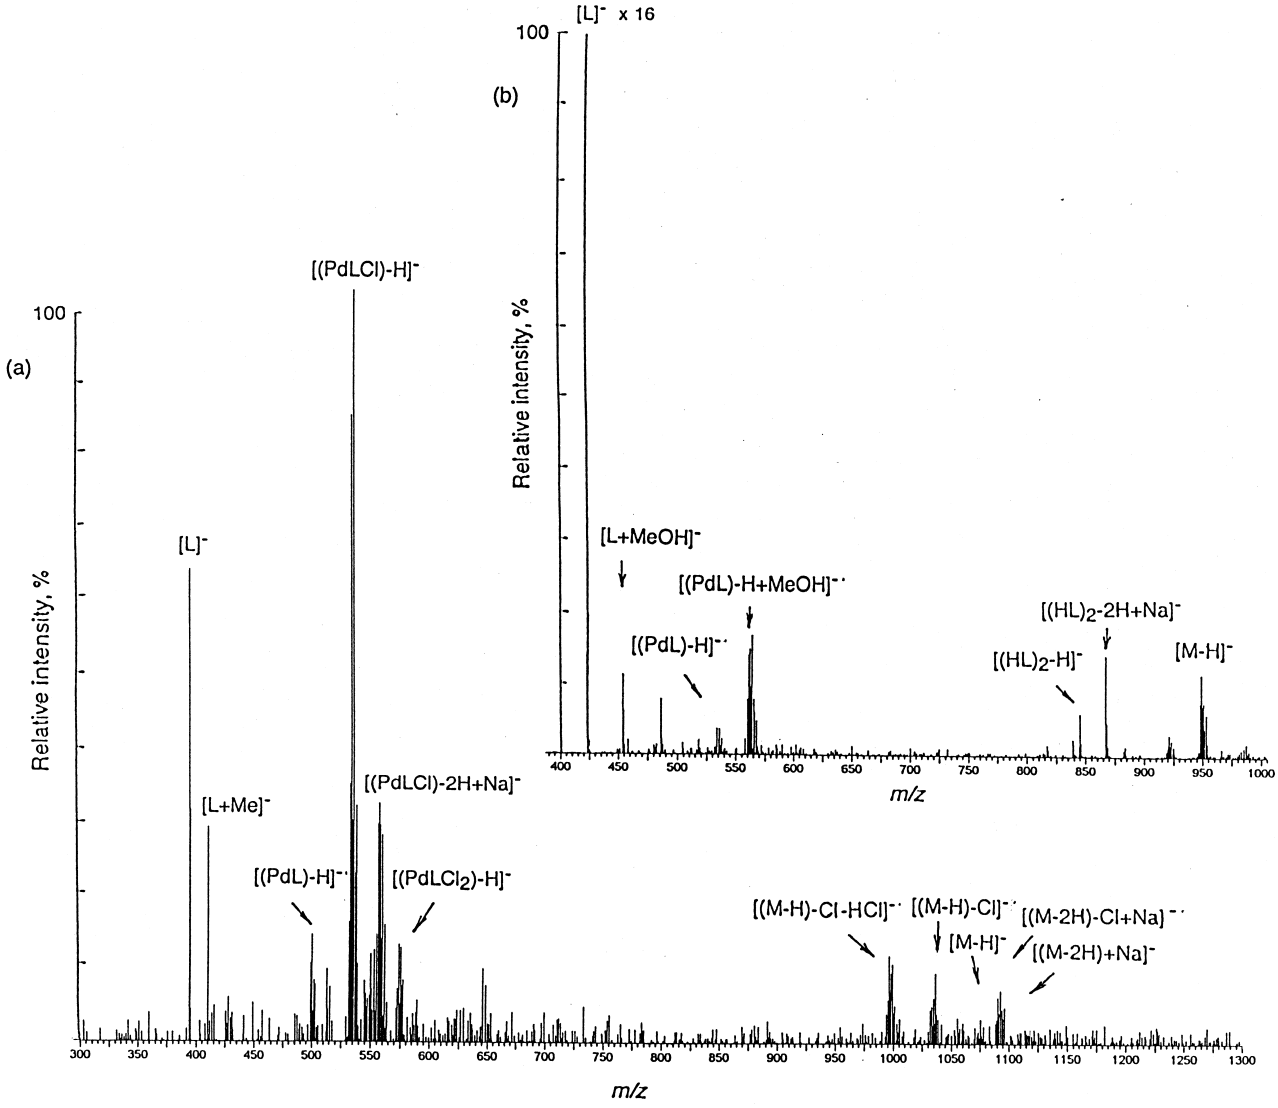

Fig. 3. Negative-ion ESI mass spectra of complexes **1** (a) and **4** (b) in methanol at a cone voltage of 50 V.

the metallation at C-11 of the B-phenyl ring. The shielding of these protons is caused by the flow of electron density from the d orbital of the palladium atom into this aromatic ring. Resonances of the other aromatic protons could not be clearly resolved owing to complex overlap of signals between 7.20 and 7.80 ppm. The ^{31}P NMR spectrum of this complex shows a broad signal at 21.88 ppm (Fig. 7(a)). The ^{13}C NMR spectrum of this complex gives much more spectral information. Comparing with the spectrum of the free ligand, the most important changes appear in resonances related to carbons C-7-C-12, as an identification of changes in the electron density of this aromatic ring due to *ortho*-metallation. For this reason none of these carbons are still equivalent. The palladium-bound C(11) is greatly shifted downfield by 31.66 ppm, C(9) and C(12) are shifted to a lesser extent by 5.87 and 2.93 ppm, respectively, while an upfield shift of 7.07 ppm for the C(8) atom, *para* to the Pd atom, clearly indicates the existence of some metal-to-ligand π-back-bonding. As expected, the overall spectral pattern of complex **3** is very similar to that of the cyclopalladated complex of dibutyl benzeneazophosphonate owing to the same palladium–ligand bonding [43].

The spectra of mononuclear complex **4** show a great complexity arising from the existence of more isomeric species in dynamic equilibrium with different magnetic environment. This can be interpreted by the presence of a new chiral centre on the nitrogen atom due to its coordination to palladium, in addition to that at the adjacent PCH asymmetric carbon and phosphorus atoms, as well as by the restricted rotation around the C–N linkage. As a consequence, the proton NMR spectrum of this complex shows a great broadening of all proton resonances (Fig. 5(d)), while its ^{13}C NMR spectrum is characterized by extensive signal splitting and multiple overlap of signals, which prevent signal assignments for almost all aromatic proton and carbon atoms. The existence of more isomeric species is visible in the ^{31}P NMR spectrum of this complex. There are few signals in the range 5–25 ppm as was shown in Fig. 7(b). The two most intense signals are at 14.46

[r] Appears as sextet with J(HH) ~ 7.4 Hz.

and 18.90 ppm. The fact that the ^{31}P NMR chemical shifts of the complex do not differ much from that observed for the free ligand and its sodium salt at 18.59 and 19.19 ppm, respectively, supports the conclusion that coordination of phosphonate to metal ion is predominantly ionic and scarcely affects the electron density of the phosphonate phosphorus [44].

The NMR spectral studies have shown that complexes retain their integrity in chloroform solution, but decompose in DMSO. This solvent with strong complexing ability initiates dissociation of the complex moiety by displacing the organophosphorus ligand. As could be expected, the decomposition process is much more pronounced in the [N,O] chelate complexes.

In conclusion, the results obtained by NMR studies are in agreement with those of mass spectrometry, indicating that the five-membered [C,N] chelate ring in the binuclear chloro-bridged complexes is much more stable than the five-membered [N,O] ring in the mononuclear chelate complexes. This behaviour is in accordance with the assumption that the chelate ring where the cyclopalladation is assisted by the coordination of a nitrogen atom has a remarkable stability.

[c] Values of dibutyl ester are related to two diastereotopic butyl groups.

Furthermore, it is known that palladium as a soft metal prefers nitrogen bonding over that of oxygen and therefore the coordination of oxygen is more easily displaced. On the other hand, it is worth noting that our recently reported investigations of the coordination of monoethyl 2-quinolylmethylphosphonate to the palladium(II) ion have shown that this monophosphonate ligand forms a very stable PdL_2 complex with a six-membered [N,O] chelate ring via the quinoline nitrogen and the phosphonic acid oxygen [14], in spite of the general belief that the six-membered ring is less favoured. The differences observed in stability between the six-membered [N,O] ring in the quinoline complex and a five-membered ring in the benzeneazoanilino phosphonate complex could be ascribed on one side to the relatively low basicity of the benzalaniline nitrogen compared with that of the quinoline nitrogen, caused by participation of its electron pair in resonance with the adjacent azobenzene π-system, and, on the other side, to the influence of steric factors. The benzeneazoaniline ligands are more bulky than the quinoline derivative. The geometric and steric requirements of the ligand containing two or more donor atoms are very important in determining the number of donor atoms that will coordinate, the final geometry, and the stability of the metallic species.

2.5. In vitro antitumour activity

The antitumour activity of the complexes was determined in vitro on the KB cell line derived from a human oral epidermoid carcinoma as a preliminary screening for their biological activity. The results obtained have shown that the concentration of the complex required to inhibit tumour cell growth by 50% was higher than 10^{-5} mol l^{-1}. There are no significant differences in response between complexes of ethyl and butyl esters, nor between the two types of complexes in spite of their differential structural properties and most probably different DNA binding and nicking ability. When comparing results of the in vitro assays related to the cyclopalladated complexes **1** and **3** with those obtained for the corresponding palladated azobenzene complexes of dialkyl phosphonates [13], it could be seen that diester complexes show about ten times higher activity ($< 5 \times 10^{-6}$ mol l^{-1}) than the monoester complexes which may be ascribed to their greater lipophilicity and solubility. In this regard it is worth noting that similar effects were observed for the antitumour activity of palladium(II) complexes with diethyl and monoethyl esters of quinolylmethylphosphonic acids [15,16,21]. The lipophilicity of the complexes increases with increasing bulkiness from monoester to diester derivatives

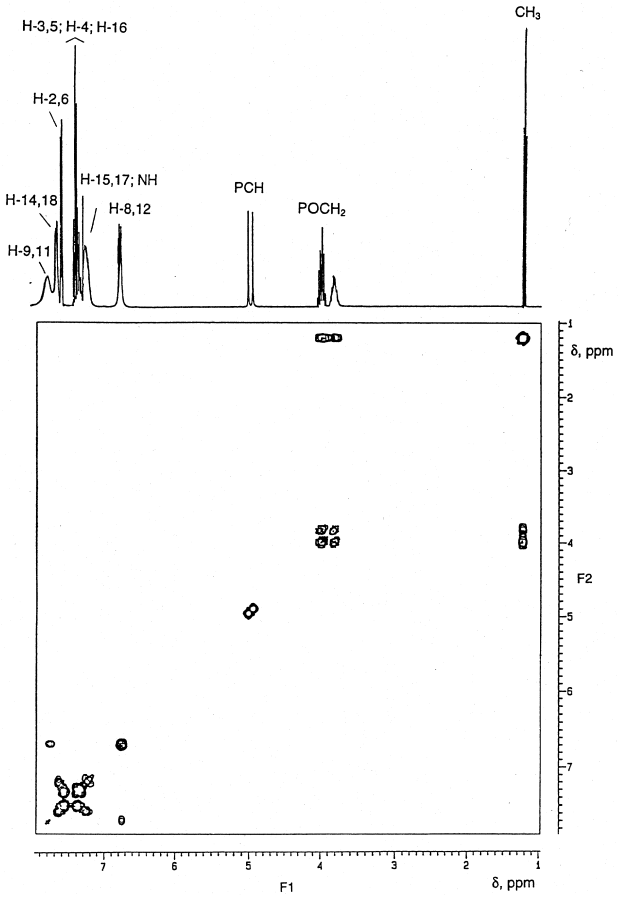

Fig. 4. ^1H–^1H COSY spectrum of HL1 in $CDCl_3$.

and may facilitate transport across the cellular membrane [45,46].

3. Experimental

3.1. Materials

Monoethyl and dibutyl [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonates (HL1 and HL2) and their sodium salts (NaL1 and NaL2), prepared as previously described [47], were purified by recrystallization from absolute ethanol prior to use. All other reagents and solvents were analytical grade products and were used without purification.

3.2. Preparation of complexes

3.2.1. $[Pd(L1)Cl]_2$ (1)

The reaction of HL1 (0.205 g, 0.52 mmol) and $Na_2[PdCl_4]$ (0.160 g, 0.54 mmol) in methanol (10 ml) at room temperature gave after stirring for 5 days a precipitate, which was separated, washed with cold methanol, and dried under vacuum. The dried complex was dissolved in hot chloroform (5 ml), and after filtering to remove some black decomposition products, the solution was evaporated to dryness yielding a dark red glassy solid which was stored overnight under vacuum. Yield 0.156 g (56%). *Anal.* Found: C, 47.13; H, 4.17; N, 8.09; Pd, 19.11. Calc. for $C_{42}H_{42}N_6O_6Pd_2P_2Cl_2$: C, 47.03; H, 3.95; N, 7.84; Pd, 19.84%. IR: ν(C=C), δ(N–H), 1576vs, 1554sh; ν(P=O), 1237w, 1198w-m; ν(PO–C), ν(P–OH), 1031s, 997m; ν(Pd–Cl), 307w, 255vw.

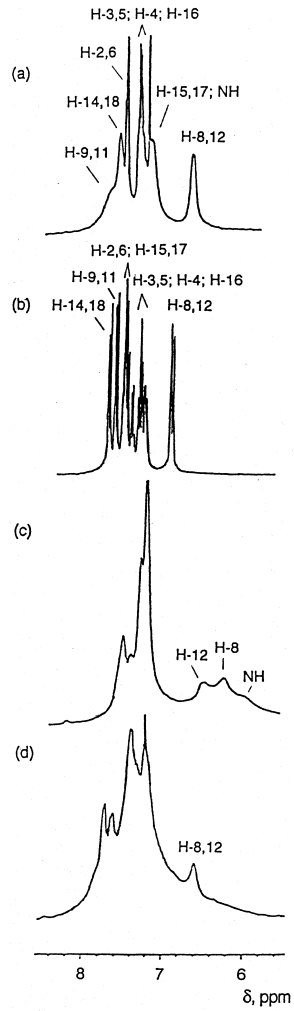

Fig. 5. Aromatic part of ^1H NMR spectra: (a) HL2 in $CDCL_3$, (b) HL2 in DMSO-d_6, (c) **3** in $CDCl_3$ and (d) **4** in $CDCl_3$.

3.2.2. $Pd(L1)_2$ (2)

A concentrated aqueous solution of $K_2[PdCl_4]$ (0.081 g, 0.25 mmol) was added dropwise to a stirred solution of NaL1 (0.203 g, 0.49 mmol) in water (10 ml). The reaction mixture was stirred continuously for 3 h at room temperature. The red precipitate formed was filtered off, washed with cold water and dried under vacuum over P_2O_5 for 24 h. Yield 0.214 g (52%). *Anal.* Found: C, 56.41; H, 4.97; N, 9.37; Pd, 12.41. Calc. for $C_{42}H_{42}N_6O_6PdP_2$: C, 56.35; H, 4.73; N, 9.40; Pd, 11.89%. IR: ν(C=C), δ(N–H), 1601vs, 1583vs; $\nu_{as}(PO_2^-)$, 1224m, 1207m; $\nu_{sym}(PO_2^-)$, ν(PO–C), 1070m, 1046s.

3.2.3. $[Pd(L2)Cl]_2$ (3)

This complex was prepared in a similar manner as complex **1** by stirring the reaction mixture of HL2 (0.204 g, 0.48

mmol) and $Na_2[PdCl_4]$ (0.145 g, 0.49 mmol) in methanol (5 ml) for 3 days. Yield 0.114 g (42%). *Anal.* Found: C, 48.65; H, 4.49; N, 7.17; Pd, 18.87. Calc. for $C_{46}H_{50}N_6O_6Pd_2P_2Cl_2$: C, 48.95; H, 4.47; N, 7.45; Pd, 18.86%. IR: ν(C=C), δ(N–H), 1576vs, 1555sh; ν(P=O), 1235w, 1198m; ν(PO–C), ν(P–OH), 1023m-s, 997m-s; ν(Pd–Cl), 306w, 255vw.

*3.2.4. Pd(L2)$_2$ (**4**)*

This complex was prepared by almost the same procedure as complex **2** by reaction of sodium salt of L2 (0.206 g, 0.46 mmol) and $K_2[PdCl_4]$ (0.081 g, 0.25 mmol) in water (5 ml). Yield 0.175 g (80%). *Anal.* Found: C, 57.96; H, 5.39; N, 8.96; Pd, 11.40. Calc. for $C_{46}H_{50}N_6O_6PdP_2$: C, 58.08; H, 5.30; N, 8.84; Pd, 11.19%. IR: ν(C=C), δ(N–H), 1598vs, 1589vs; $\nu_{as}(PO_2^-)$, 1205s br; $\nu_{sym}(PO_2^-)$, ν(PO–C), 1063s, 1025s.

3.3. Physical measurements and analyses

Melting points were determined on a hot stage microscope and are uncorrected. Infrared spectra were recorded on a Perkin Elmer 580 B spectrophotometer using KBr (4000–250 cm^{-1}) and polyethylene (400–200 cm^{-1}) pellets.

The electrospray mass spectrometric measurements were performed on a Navigator (Finnigan, San Jose, CA) instrument equipped with ESI ion source. The ligands were recorded in positive and negative ion modes using methanol or a mixture of acetonitrile and water (50:50) with 0.1% acetic acid as the solvent and the mobile phase. Complexes were recorded in methanol in both modes. The sample solution (10 μl of 10^{-5} mol l^{-1}) was introduced into the ion source, at a flow rate of 0.3 ml min^{-1}, using a Rheodyne external loop injector coupled to a Thermo Separation (San Jose, CA) spectra series HPLC pump. The measurements were performed using nitrogen as nebulizing gas, and using different cone voltages (30, 50 and 120 V). Expected natural abundance isotope clusters patterns for various ion clusters were calculated with the Isotopic Distribution Program

(IDS) contained in the FTMS 7.01 application program of the NICOS operating system using polynomial expansion based on natural abundances of the Pd and Cl isotopes.

The ^{1}H and ^{13}C one- and two-dimensional NMR spectra were performed with Varian broadband Gemini 300 and Bruker AMX 360 spectrometers, operating at 75.46 and 90.56 MHz for the ^{13}C resonance, respectively. Spectra were recorded in $CDCl_3$ or DMSO-d_6 containing $SiMe_4$ as an internal standard. Digital resolution in ^{1}H NMR spectra was 0.25 Hz, while in ^{13}C NMR it was 0.60 Hz per point. The narrower spectral regions of special interest were measured also with a smaller spectral width and greater digital resolution (down to 0.2 Hz). The following techniques were used: proton-noise decoupling, attached proton test (APT), ^{1}H–^{1}H COSY, NOESY and ^{1}H–^{13}C COSY, long-range ^{1}H–^{1}H COSY, HMQC and HMBC. The ^{1}H–^{1}H COSY spectra were obtained in the magnitude mode, while NOESY spectra were obtained in the phase-sensitive mode. All two-dimensional experiments were performed by standard pulse sequences, using Gemini Data System software Version 6.3 Revision A (for VXR-4000) and Bruker microprograms of UXNMR software Version 940501.3 [48]. For proton decoupling Waltz-16 modulation was used. ^{31}P NMR spectra were measured at 145.79 MHz on a Bruker AMX 360 spectrometer in $CDCl_3$ with external 85% H_3PO_4 in a coaxial capillary.

Conductance measurements were carried out at room temperature using a CD 7A Tacussel conductance bridge for 10^{-3} mol l^{-1} solutions in DMF. Magnetic susceptibilities in the solid state were measured at room temperature by the standard Gouy method using a Cahn-Ventron RM-2 balance and $CuSO_4 \cdot 5H_2O$ as the susceptibility standard. Elemental analyses were performed in the Ruđer Bošković Institute.

3.4. In vitro antitumour assays

Antitumour activity was assayed with the human epidermoid KB cell line [49] according to previously described methods [21,22,50]. The cells were maintained in Eagle's minimum essential medium (MEM) supplemented with glutamine, non-essential amino acids (1%) and newborn calf serum (10%). The cell population doubling time was ca. 24 h. For the cytostatic assay a cell culture in the exponential growth phase was used. The compounds were dissolved immediately before use in sterile DMSO, and these solutions were diluted with the growth medium to the desired concentrations. The final DMSO concentration in the culture medium, 0.5%, showed no cytostatic effect in preliminary tests. At least five concentrations of each compound were used and each agent was assayed on at least three separate occasions. The incubation time was 72 h. The cell growth was determined by the sulforhodamine B (SRB) method [51]. The cytostatic activity was evaluated from the inhibition of cell growth in the treated cultures with respect to the controls. The significance of the results was evaluated by use of classical Student's t test ($p < 0.01$). The activity was expressed as the concentration of the complex at which tumour cell growth showed 50% inhibition (IC_{50}), and was calculated by linear regression analysis [52]. The activity threshold was set at 10^{-5} mol l^{-1}, since this appears to be a fairly realistic cutoff point for most compounds [53].

Abstract

A series of new mononuclear and binuclear copper(II) complexes derived from *N*-salicylidenearoylhydrazines (H_2L) of the types $K_2[\{Cu(L)(OH)\}_2]\cdot nH_2O$, $[Cu(HL)Cl\cdot H_2O]\cdot nH_2O$, $[\{Cu(HL)Cl\}_2]$, $[Cu(HL)NO_2]\cdot H_2O$, $[\{Cu(HL)\}_2]\cdot 2NO_3$, $[\{Cu(HL)H_2O\}_2]\cdot 2NO_3\cdot nH_2O$ and $[Cu(HL)NCS]\cdot H_2O$ have been prepared and characterized. The X-ray crystal and molecular structure of $[Cu(HSBzh)NO_3]\cdot H_2O$, where HSBzh refers to the mononegative *N*-salicylidenebenzoylhydrazine anion, has been determined. The complex is monomeric with the copper(II) adopting a (4+1) distorted square pyramidal coordination, with the ONO aroylhydrazone tridentate anion and an oxygen atom of the unsymmetric bidentate nitrate ion occupying the basal plane. The fifth coordination site is occupied by the other oxygen of the nitrate ion. The magnetic susceptibilities of both mononuclear and binuclear complexes were measured within the temperature range 4.2–298 K. All binuclear copper(II) complexes show strong antiferromagnetic interactions, and the singlet–triplet separation ($-2J$) recorded for μ-dihydroxy bridged complexes $K_2[\{Cu(L)OH\}_2]\cdot nH_2O$ are within the range 172–276 cm^{-1}, while ($-2J$) for binuclear complexes $[\{Cu(HL)Cl\}_2]$, $[\{Cu(HL)\}_2]\cdot 2NO_3$ and $[\{Cu(HL)H_2O\}_2]\cdot 2NO_3\cdot nH_2O$ are respectively within the range 400–460, ca. 340 and ca. 390 cm^{-1}. There are no appreciable exchange interactions between copper(II) ions in the monomeric complexes $[Cu(HL)Cl\cdot H_2O]\cdot nH_2O$, $[Cu(HL)NO_2]\cdot H_2O$ and $[Cu(HL)NCS]\cdot H_2O$. The IR spectra of the prepared complexes are also discussed.

1. Introduction

N-salicylideneacylhydrazines (**1**) (H_2L) can act either as neutral, mononegative or dinegative ONO tridentate ligands [1–20]. A large number of monomeric and dimeric copper(II) complexes have been prepared and characterized [1–20]. Most recent studies have been directed towards structural studies and a number of X-ray crystal and molecular structures have been reported [16–20]. Less attention, however, has been directed towards magnetochemical studies [13–18]. In this paper we report the synthesis and characterization of some new mononuclear and dinuclear copper(II) complexes with *N*-salicylidenearoylhydrazines.

(1)

The single X-ray structure of the monomeric $[Cu(HBzh)NO_3]\cdot H_2O$ has been determined and the magnetic measurements recorded for the prepared complexes will be discussed. Hereafter, *N*-salicylidenebenzoylhydrazine

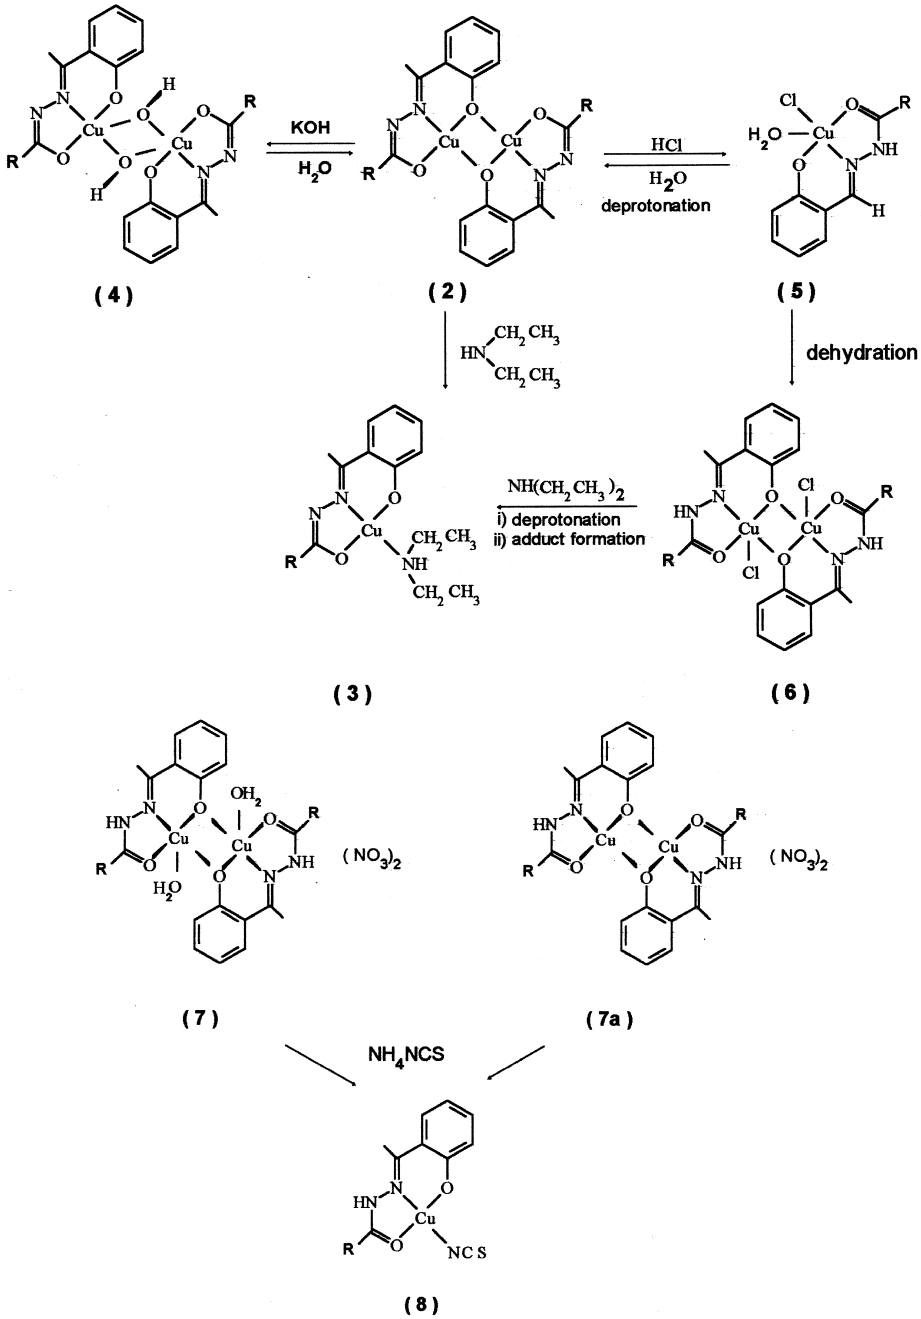
and the corresponding *p*-methyl-, *p*-methoxy- and *p*-chlorobenzoylhydrazine are abbreviated as H_2SBzh, H_2S*p*-CH_3Bzh, H_2S*p*-CH_3Obzh and H_2S*p*-ClBzh, respectively.

2. Results and discussion

2.1. Synthesis and stoichiometry

In methanol, the reaction of copper(II) acetate with *N*-salicylidenearoylhydrazines (H_2L) (**1**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) afforded the binuclear neutral copper(II) complexes [{Cu(L)}$_2$] (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4). These binuclear copper(II) complexes were insoluble in water, alcohols, halogenated aliphatic hydrocarbons and aromatic hydrocarbons but soluble in DMSO or DMF. The dissolution of these binuclear complexes proceeded with the rupture of Cu–O–Cu bridges giving the solvated monomeric species [Cu(L)S] or [Cu(L)S_2] where S refers to the solvent molecule [12]. A similar behaviour was previously reported and recrystallization of the anhydrous dimeric copper(II) complexes with the dinegative anion of 5-chloro-2-hydroxo acetophenone salicylhydrazide from DMF gave the corresponding DMF adduct of the formula [Cu(L)DMF] where L refers to the dinegative hydrazone anion [16,17]. Neutral monodentate nitrogen Lewis bases such as diethylamine [$(Et)_2$NH] can also affect the rupture of the Cu–O–Cu bridges in **2** and eventually gave the corresponding monomeric ternary complex [Cu(L)HNEt_2] (**3**, R = C_6H_5).



The reaction of the neutral dimeric copper(II) complexes [{Cu(L)}$_2$] (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$CH_3OC_6H_4$) with a large excess of KOH in dry methanol afforded the corresponding μ-hydroxo bridged copper(II) complexes of general formula K_2[{Cu(L)(OH)}$_2$] (**4**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$CH_3OC_6H_4$). The isolated hydroxo complexes are soluble in methanol, ethanol and acetonitrile. In water, these complexes are readily hydrolysed giving the parent neutral dimer (**2**). The isolated hydroxo complexes together with elemental analysis are given in Table 1.

On the other hand, treatment of a suspension of [{Cu(L)}$_2$] (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) in absolute ethanol with an equivalent amount of aqueous hydrogen chloride afforded the hydrated monochloro complex [Cu(HL)Cl·H_2O]·*n*H_2O (**5**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) (HL refers to the mononegative *N*-salicylidenearoylhydrazine anion). These

complexes were also prepared in situ from the reaction of salicylaldehyde with the corresponding aroylhydrazine (1:1 molar ratio) in the presence of copper(II) chloride in ethanol or methanol. However, direct reaction of *N*-salicylidenearoylhydrazine (**1**, R = C_6H_5 and *p*-$CH_3C_6H_4$) with 1 equiv. of copper(II) chloride in absolute ethanol afforded the anhydrous brown chloro complexes $[Cu(HL)Cl]_2$ (**6**, R = C_6H_5 and *p*-$CH_3C_6H_4$). This reaction usually gave salicylaldehyde azine ($HOC_6H_4CH{=}N{-}N{=}CHC_6H_4OH$) as a side reaction product. Meanwhile, the direct reaction of *p*-methoxy- and *p*-chlorobenzoylhydrazones (**1**, R = *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) with copper(II) chloride in ethanol or methanol gave the hydrated copper(II) complexes $[Cu(HL)Cl\cdot H_2O]$ (**5**, R = *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) and attempts to prepare the corresponding anhydrous binuclear complexes were unsuccessful. Similar to the reaction of *N*-salicylidenearoylhydrazines with copper(II) chloride, the reaction of copper(II) nitrate gave either monomeric and/or dimeric nitrate complexes. The reaction of **1** (R = *p*-$CH_3C_6H_4$) with copper(II) nitrate trihydrate in boiling absolute ethanol afforded the hydrated binuclear complex $[\{Cu(HSp\text{-}CH_3Bzh)H_2O\}_2](NO_3)_2\cdot H_2O$ (**7**, R = *p*-$CH_3C_6H_4$), while the reaction with **1** (R = C_6H_5, *p*-$CH_3OC_6H_4$) gave the corresponding anhydrous complexes $[\{Cu(HSBzh)\}_2]\cdot 2NO_3$ and $[\{Cu(HSp\text{-}CH_3OBzh)_2]\cdot 2NO_3$ (**7a**, R = C_6H_5 and *p*-$CH_3OC_6H_4$), respectively. However, the in situ preparation, using benzoylhydrazine, gave the monomeric complex $[Cu(HSBzh)(NO_3)]\cdot H_2O$. The prepared mononuclear and binuclear copper(II) chloride and nitrate complexes together with elemental analysis are included in Table 1.

The reaction of either mononuclear or binuclear copper(II) chloride and nitrate complexes with an equivalent amount of NH_4SCN in methanol afforded the corresponding thiocyanato complexes $[Cu(HL)SCN]\cdot nH_2O$ (**8**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$OCH_3C_6H_4$) and *p*-ClC_6H_4), implying the ease of displacement of either Cl^- or NO_3^- by the thiocyanate ion. However, in the presence of large excess of NH_4SCN, the reaction proceeded by the reduction of copper(II) and copper(I) thiocyanate $[CuSCN]_2$ was precipitated. On the other hand, the reaction of thiocyanate with either μ-hydroxo bridged complexes (**5**) or the neutral binuclear copper(II) complexes $[\{Cu(L)\}_2]$ (**2**) failed to give the corresponding thiocyanato complexes, suggesting that the SCN^- cannot affect the rupture of Cu–O–Cu bridges in these complexes. The isolated thiocyanato complexes $[Cu(HL)SCN]\cdot nH_2O$ together with elemental analysis are also given in Table 1.

2.2. X-ray crystal structure of [mononitratoOO′(−1)(N-salicylidenebenzoylhydrazinato)ONO′(−1)]copper(II) monohydrate complex [Cu(HSBzh)(NO$_3$)]·H$_2$O

The crystal data and structure refinement for $[Cu(HSBzh)(NO_3)]\cdot H_2O$ are collected in Table 2. The molecular structure together with the numbering scheme used are shown in Fig. 1. Some selected bond distances and bond angles are listed in Table 3. In $[Cu(HBzh)(NO_3)]\cdot H_2O$, the *N*-salicylidenebenzoylhydrazinato anion behaves as a mononegative tridentate ligand and is coordinated to the Cu(II) via the deprotonated phenolic oxygen O(1), azomethine nitrogen N(1) and the ketoamide oxygen O(2). The Cu–O(1) (1.881 Å), Cu–N(1) (1.913 Å) and Cu–O(2) (1.97 Å) bond distances are within the range reported for other copper(II) complexes derived from *N*-salicylideneacylhydrazines [10,11,18–21]. The fourth coordinate site of the basal plane is occupied by the oxygen atom O(3) of the

nitrate group. The Cu(II) lies in the ligand plane and shows a slight deviation of 0.037 Å from the least square plane. The nitrate ion in this complex behaves as a bidentate ligand, and the fifth coordinate site is weakly bonded with the O(4) of the nitrate group. This bidentate nitrate is characterized by one short Cu–O(3) (1.993 Å) distance and a second much longer Cu–O(4) (2.480 Å) with a difference of 0.487 Å which falls within the range reported for the unsymmetrically coordinated bidentate nitrate group [22–25]. The small O(3)–Cu–O(4) angle (55.5°) is also in agreement with the bidentate nature of the nitrate ion in this complex.

The coordination polyhedron around the copper(II) is better described as (4+1) distorted square pyramidal as evident from the tetragonality parameter of Addison et al. [26], $\tau=(\beta-\alpha)/60=0.033$, where α and β are the N(1)–Cu–O(3) (172.33°) and O(2)–Cu–O(1) (174.31°) angles, respectively. The uncoordinated water molecule O(6) is involved in strong hydrogen bonding with the N(2) hydrogen atom (O(6)···H(2)N) $(1-x, -0.5+y, 1.5-z)$ (1.55 Å).

2.3. Magnetic measurements

At room temperature, the binuclear copper(II) complexes $[\{Cu(L)\}_2]$ (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) show subnormal magnetic moments (1.2–1.6 μ_B) and their electronic spectra agree with a square planar configuration [1–3,27]. The magnetic susceptibility measurements within the temperature range 97–297 K showed strong antiferromagnetic interactions. The exchange coupling constant ($-2J$) of these neutral dimeric complexes were found to vary from 594 to 680 cm^{-1} [27] in agreement with the formation of dimeric copper(II) complexes with Cu–O–Cu bridges [28]. Recent X-ray studies on binuclear copper(II) complexes with *N*-salicylideneacylhydrazines show that dimerization takes place via the phenolic oxygen rather than the deprotonated enolic oxygen [18–21].

The newly prepared di-μ-hydroxo-bridged binuclear copper(II) complexes $K_2[\{Cu(L)OH)\}_2]$ (**4**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$OCH_3C_6H_4$) also show subnormal magnetic moments (1.50–1.65 μ_B) at room temperature. The variation of χ_M and μ_{eff}, recorded for $K_2[\{Cu(Sp\text{-}CH_3Bzh)OH\}_2]$ (**4**, R = *p*-$CH_3C_6H_4$), as a function of temperature (4.2–298 K) is shown in Fig. 2. The remarkable decrease in μ_{eff} (per copper atom) from 1.5 μ_B at 290 K to about 0.4 μ_B at 4.5 K suggests strong antiferromagnetic exchange interaction. Similar behaviour was also observed for the other di-μ-hydroxo-bridged copper(II) complexes (**4**, R = C_6H_5, and *p*-$CH_3OC_6H_4$). The experimental data were fitted to the modified Bleaney–Bowers equation Eq. (1),

$$\chi_M=(1-X_p)\frac{2N_L g^2\mu_\beta^2}{kT}\frac{\exp(2J/kT)}{1+3\exp(2J/kT)} + X_p\frac{2NLg^2\mu_\beta^2}{3k(T-\theta)}S(S+1)+2N_\alpha \quad (1)$$

where 2*J* is the singlet–triplet splitting or exchange integral,

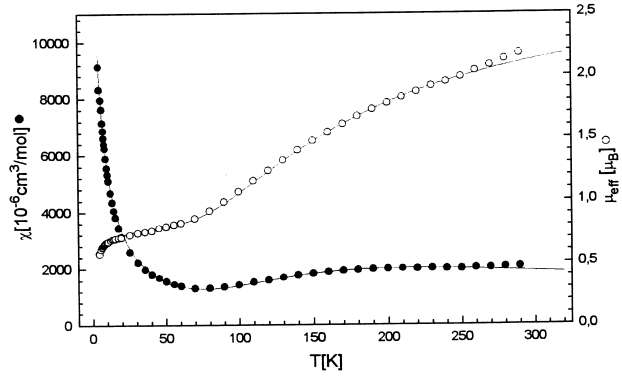

Fig. 2. Magnetic susceptibilities χ (●) and magnetic moments (o) vs. temperature for $K_2[\{Cu(Sp\text{-}CH_3Bzh)OH\}_2]\cdot 2H_2O$. Solid lines represent the best least squares fit to Eq. (1), with $J=-138$, $g=2.10$ and $X_p=4.1\%$.

X_p represents the fraction of a possible magnetically dilute copper(II) impurity ($S=1/2$), N_α is the temperature independent paramagnetism (60×10^{-6} cm^3 mol^{-1} per copper(II) ion) and the other symbols have their usual meaning and a non-linear regression analysis was carried out with *J*, *g*, and X_p as floating parameters. The obtained best fit parameters for the di-μ-hydroxo-bridged copper(II) complexes (**4**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$CH_3OC_6H_4$) are listed in Table 4. The recorded $-2J$ values are within the range reported for other bis-μ-hydroxy bridged dicopper complexes with nearly planar Cu_2O_2 [28–33] and a binuclear structure (**4**) can be proposed for these complexes.

For di-μ-hydroxo dicopper(II) complexes with almost planar Cu_2O_2, the 2*J* values were found to decrease linearly with increasing either Cu–O–Cu angle φ (°) or Cu···Cu separation r_{Cu-Cu} (Å), and least square regression analyses of the available data gave [28]:

$$2J=-77.6\varphi+7555\ cm^{-1}\ (R=-0.95) \quad (2)$$

$$2J=-46.0r_{Cu\cdots Cu}+13389\ cm^{-1}\ (R=-0.95) \quad (3)$$

Substitution of the 2*J* values, recorded for **4** (R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$OCH_3C_6H_4$), in Eq. (2) gave 99.6, 100.9 and 100.7° for the values of Cu–O–Cu angles, respectively. While 2.948, 2.971 and 2.967 Å are, respectively, the values calculated from Eq. (3) for the Cu···Cu separation.

The green hydrated chloro complexes $[Cu(HL)Cl\cdot H_2O]\cdot nH_2O$ (**5**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$, and *p*-ClC_6H_4) show normal magnetic moments (1.80–1.84 μ_B), Table 4, and the temperature dependent magnetic susceptibilities measured for these hydrated complexes, assuming Curie–Weiss behaviour, suggest a very weak antiferromagnetic coupling with θ values in the range of ca. −1.5 K. These mononuclear chloro complexes may adopt a square pyramidal coordination, the four in-plane donor atoms are provided by the tridentate ONO hydrazone and an oxygen from a coordinated water while the axial site is occupied by the chloride ion. A similar structure has been reported for $[Cu(HSAch)Cl\cdot H_2O]\cdot H_2O$, where HSAc refers to the mononegative *N*-salicylideneacetylhydrazine anion (**1**, R = CH_3) [21]. On the other hand, the brown anhydrous

chloro complexes $[\{Cu(HL)Cl\}_2]$ show, at room temperature, low lying magnetic moments within the range 1.12–1.21 μ_B. A plot of χ_M and μ_{eff}, measured for $[\{Cu(HSp\text{-}CH_3Bzh)Cl\}_2]$, as a function of temperature, Fig. 3, suggests strong antiferromagnetc interaction. Fitting the data to the Bleaney–Bowers equation gives $J=-203$ cm^{-1}, $g=2.19$, and $X_p=0.0179$. These values are comparable with those previously reported for $[\{Cu(HSBzh)Cl\}_2]$ (**6**, $R=C_6H_5$) [18]. The obtained $-2J$ values, Table 4, are within the range reported for bis-μ-aryloxo bridged dicopper complexes [18,28]. The copper(II) in these complexes has a distorted (4+1) tetragonal pyramidal coordination where the apical site is occupied by a chloride ion. Dimerization is achieved by sharing of phenoxy oxygen from each ligand through two copper atoms [18].

Similar to the chloro complexes $[\{Cu(HL)Cl\}_2]$ (**6**, $R=C_6H_5$, p-$CH_3C_6H_4$), the isolated binuclear nitrate complexes $[\{Cu(HSBzh)\}_2]\cdot 2NO_3$, $[\{Cu(HSp\text{-}CH_3Bzh)\cdot H_2O\}_2]\cdot H_2O\cdot 2NO_3$ and $[\{Cu(HSp\text{-}CH_3OBzh)\}_2]\cdot 2NO_3$ show subnormal magnetic moments (1.30–1.45 μ_B) at room temperature. A plot of the magnetic susceptibility data measured for $[\{Cu(HSBzh)_2\}]\cdot 2NO_3$ as a function of temperature (5–298 K), Fig. 4, indicates strong antiferromagnetic exchange coupling. Similar behaviour was also observed for both $[\{Cu(HSp\text{-}CH_3Bzh)\cdot H_2O\}_2]\cdot H_2O\cdot 2NO_3$ and

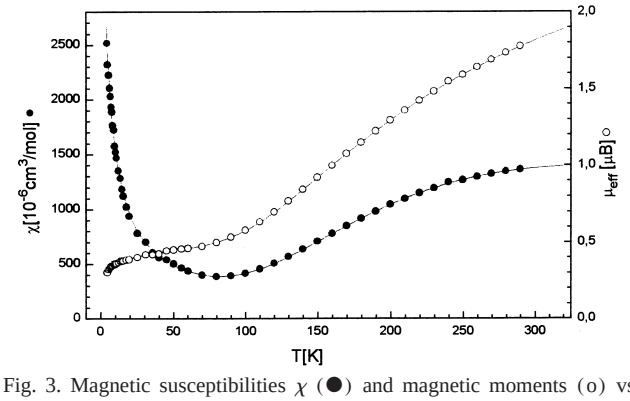

Fig. 3. Magnetic susceptibilities χ (●) and magnetic moments (o) vs. temperature for $[\{Cu(HSp\text{-}CH_3Bzh)Cl\}_2]$. Solid lines represent the best least squares fit to Eq. (1), with $J=-203$, $g=2.19$ and $X_p=1.8\%$.

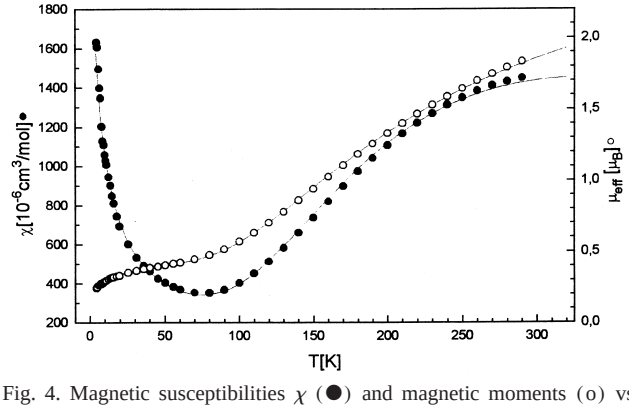

Fig. 4. Magnetic susceptibilities χ (●) and magnetic moments (o) vs. temperature for $[\{Cu(Sp\text{-}Bzh)\}_2]\cdot 2NO_3$. Solid lines represent the best least squares fit to Eq. (1), with $J=-195$, $g=2.21$ and $X_p=1.7\%$.

$[\{Cu(HSp\text{-}OCH_3Bzh)\}_2]\cdot 2NO_3$. The best fit parameters (J, g and X_p) obtained by fitting the variable temperature magnetic susceptibility data to the Bleaney–Bowers equation are listed in Table 4. The obtained $-2J$ values (338–390 cm^{-1}) suggest strong antiferromagnetic exchange interaction via bridged phenoxy oxygens [28]. Recently, the preparation and X-ray crystal and molecular structure of the analogous dinuclear complex $[\{Cu(HSAc)H_2O\}_2]\cdot 2NO_3$ have been reported [20]. This complex is a centrosymmetric (planar) dimer, the monomeric units being bridged through the phenoxy oxygen. The copper atom has a square-pyramidal geometry with the basal donor atoms coming from the ONO mononegative tridentate ligand and the symmetry related phenolate oxygen, while the fifth coordination site is occupied by water oxygen. The nitrate ions are not coordinated and act as counter ions [20]. Unfortunately, no variable-temperature magnetic data have been reported for this complex. In the present work, the room temperature magnetic moment of the dinuclear complex $[\{Cu(HSAc)H_2O\}_2]\cdot 2NO_3$ was found to be 1.29 μ_B which is more or less similar to the value reported previously by Chan et al. (1.28 μ_B) [20]. Fitting the variable temperature susceptibility data recorded for $[\{Cu(HSAc)H_2O\}_2]\cdot 2NO_3$ to a modified Bleaney–Bowers equation gives $J=-340$ cm^{-1}, $g=2.20$ and $X_p=2.2\%$. The obtained ($-2J$) is comparable to that reported for $[\{Cu(HSp\text{-}CH_3Bzh)\cdot H_2O\}_2]\cdot H_2O\cdot 2NO_3$ and a similar dimeric structure (**7**, $R=p\text{-}CH_3C_6H_4$) can be proposed for this complex, where the copper(II) is weakly bound to the oxygen of the coordinated water molecule. The anhydrous dimeric $[\{Cu(HSBzh)_2\}\cdot 2NO_3$ and $[\{Cu(HSp\text{-}OCH_3Bzh)\}_2]\cdot 2NO_3$ complexes, on the other hand, show relatively higher $-2J$ values (ca. 392 cm^{-1}) implying stronger antiferromagnetic exchange interaction between the two copper(II) centres. It seems that coordination of a water molecule in **7a** ($R=p\text{-}CH_3C_6H_4$) results in a slight distortion from planarity and decreases the strength of antiferromagnetic interactions relative to the more planar anhydrous dimers.

The thiocyanate complexes $[Cu(HL)SCN]\cdot nH_2O$, Table 1, have room temperature magnetic moments in excess of 1.8 μ_B, Table 4, suggesting that the paramagnetic centres are quite shielded by the diamagnetic matrix, and if the copper centres are spin coupled, exchange is likely to be weak. The magnetic moments of these complexes are more or less constant (ca. 1.87 μ_B) within the temperature range (35–300 K), but decrease below 35 K and drop to ca. 1.74 μ_B at 10 K, suggesting weak antiferromagnetic interactions. Assuming Curie–Weiss behaviour, plots of inverse magnetic susceptibility for **8** ($R=C_6H_5$, $p\text{-}CH_3C_6H_4$ and $p\text{-}ClC_6H_4$) versus temperature gave Curie–Weiss constants $\theta=-1.35$, -1.75 and -3.20, respectively. This magnetic behaviour can rule out the possible formation of a binuclear structure with phenoxy bridges similar to that reported for the corresponding chloride or nitrate complexes and a monomeric structure (**8**) can be proposed for these thiocyanate complexes. However, dimeric or polymeric structures with bridged thiocyanate cannot be ruled out, since no magnetic interactions between the copper(II) centres was observed in polymeric $[Cu(bheg)NCS]\cdot H_2O$ (where Hbheg is *N,N* bis(2-hydroxyethylglycine)) [34]. The actual structure of these isothiocyanate complexes must remain in doubt until complete X-ray molecular structures are available.

2.4. Infrared spectra

The IR spectra of *N*-salicylidenearoylhydrazines, Table 5, show a series of bands at ca. 3200, 1670, 1600 and 1340 cm^{-1}, respectively due to ν(N–H), ν(C=O) (amide I), ν(C=N), δ(N–H) (amide II), and ν(C–N) (amide III). The spectra of the corresponding binuclear complexes $[\{Cu(L)\}_2]$ (**2**) and $K[\{Cu(L)(OH)\}_2]\cdot nH_2O$ (**4**) lack any absorption which can be attributed to ν(N–H), ν(C=O) or δ(N–H), but show an intense absorption due to ν(C=N–N=C) as well as the amide III band, implying the deprotonation of the enolimine tautomer of the hydrazone ligand [1,2,35,36]. However, the spectra of the mononuclear complexes of the types $[Cu(HL)Cl\cdot H_2O]\cdot nH_2O$ (**5**), $[Cu(HSBzH)NO_2]\cdot H_2O$, and $[Cu(HL)NCS]\cdot nH_2O$ (**8**) as well as the binuclear complexes $[\{Cu(HL)Cl\}_2]$ (**6**), $[\{Cu(HL)H_2O\}_2](NO_3)_2\cdot nH_2O$ (**7**) $[\{Cu(HL)\}_2](NO_3)_2$ (**7a**), Table 5, show a series of bands at ca. 3180, 1615, 1600, 1540 and 1320 cm^{-1} due to ν(N–H), ν(C=O), ν(C=N), δ(N–H) and ν(C–N), respectively. The presence of ν(N–H), ν(C=O) and δ(N–H) in the IR spectra of these complexes indicate that the hydrazone molecule reacts in the ketoamine form. Moreover, the stoichiometry of these complexes as well as the pronounced shift in both ν(C=O) and ν(C=N) to lower frequencies relative to those of corresponding uncoordinated hydrazones suggest that these aroylhydrazones act as mononegative ONO tridentate ligands [1,2,35,36]. The IR spectrum of the mononuclear complex $[Cu(HSBzH)NO_2]\cdot H_2O$, Fig. 1, displays three bands at 1510, 1290 and 1000 cm^{-1}, respectively due to the ν(N=O), $\nu_{asym}(NO_2)$ and $\nu_{sym}(NO_2)$, in agreement with the unsymmetric bidentate nature of the coordinated nitrate. The spectra of the binuclear nitrate complexes $[\{Cu(HL)H_2O\}_2](NO_3)_2\cdot nH_2O$ (**7**) and $[\{Cu(HL)\}_2](NO_3)_2$ (**7a**), on the other hand, show an intense band at ca. 1380 cm^{-1} characteristic of ionic nitrate [22,37]. The spectra of the thiocyanate complexes **8** show an intense band at 2085 cm^{-1} indicating that the thiocyanate group acts as monodentate ligand, most probably through the nitrogen atom [37].

3. Experimental

3.1. Preparation of aroylhydrazines and N-salicylidene-aroylhydrazines

Aroylhydrazines were prepared, as previously described [38], by the hydrazinolysis of aromatic carboxylic methyl esters in methanol. The corresponding *N*-salicylidene aroyl-

hydrazines were prepared by the condensation of salicylaldehyde with aroylhydrazines in methanol [38–40] (H_2SBzh, m.p. = 182°C; H_2S*p*-MeBzh, m.p. = 195°C; H_2S*p*-MeOBzh, m.p. = 173°C; H_2S*p*-ClBzh, m.p. = 208°C).

3.2. Preparation of copper(II) complexes of N-salicylidenearoylhydrazines

3.2.1. Preparation of [{Cu(L)}$_2$] (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4)

To a solution of *N*-salicylidenearoylhydrazine (H_2L) (**1**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) (0.01 mol) in dry methanol (30 cm^3), an equivalent amount of $Cu(CH_3COO)_2\cdot 2H_2O$ (0.012 mol) in dry methanol (50 cm^3) was added dropwise with constant stirring. During addition a green precipitate started to appear and after complete addition of copper acetate, the reaction mixture was refluxed, with constant stirring, for ca. 30 min. On cooling the formed green complex, $[Cu(L)]_2$, was filtered, washed with hot methanol and then dried in vacuo.

3.2.2. Preparation of $K_2[\{Cu(L)OH\}_2]\cdot nH_2O$ (**4**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$OCH_3C_6H_4$)

To a suspension of [{Cu(L)}$_2$] complex (**2**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$OCH_3C_6H_4$) (0.01 mol) in hot absolute ethanol (50 cm^3), an excess amount of KOH (0.025 mol) was added and the reaction mixture was refluxed until complete dissolution of [{Cu(L)}$_2$] complex. The resulting solution was filtered and then evaporated to half its volume. On cooling the formed green complex $K_2[\{Cu(L)OH\}_2]\cdot nH_2O$, Table 1, was isolated and then dried over $CaCl_2$.

3.2.3. Preparation of [Cu(HL)Cl]·nH_2O (**5**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$OCH_3C_6H_4$ and *p*-ClC_6H_4)

A solution of $CuCl_2\cdot 2H_2O$ (0.01 mol) in ethanol (20 cm^3) was added to a solution of salicylaldehyde (0.01 mol) in

ethanol (50 cm^3). The reaction mixture was heated for a few minutes and then an equivalent amount of aroylhydrazine (0.01 mol) was added dropwise with constant stirring. The resulting mixture was then refluxed for ca. 15 min and the isolated green complex $[Cu(HL)Cl \cdot H_2O] \cdot nH_2O$ (**5**, R = C_6H_5, *p*-$CH_3C_6H_4$, *p*-$CH_3OC_6H_4$ and *p*-ClC_6H_4) which was separated on cooling, was filtered, washed with ethanol then dried in vacuo.

*3.2.4. Preparation of $[\{Cu(HL)Cl\}_2] \cdot nH_2O$ (**6**, R = C_6H_5 and p-$CH_3C_6H_4$)*

To a solution of *N*-salicylidenearoylhydrazine (H_2L) (**1**, R = C_6H_5 or *p*-$CH_3C_6H_4$) (0.01 mol) in absolute ethanol (30 cm^3), an equivalent amount of $CuCl_2 \cdot 2H_2O$ (0.01 mol) in hot absolute ethanol (20 cm^3) was added dropwise with constant stirring, then refluxed for 1 h. On cooling the precipitated copper(II) complex (2.34, R = C_6H_5 or *p*-CH_3-C_6H_4) was filtered, washed with absolute ethanol and then dried in vacuo.

3.2.5. Preparation of $[Cu(HSBz)NO_3] \cdot H_2O$

A solution of $CuNO_3 \cdot 6H_2O$ (0.01 mol) in ethanol (20 cm^3) was added to a solution of salicylaldehyde (0.01 mol) in ethanol (50 cm^3). The reaction mixture was heated for a few minutes and then an equivalent amount of aroylhydrazine (0.01 mol) was added dropwise with constant stirring. The resulting mixture was refluxed for ca. 1 h. On cooling, the separated copper(II) complex $[Cu(HL)NO_3] \cdot H_2O$ was filtered, washed with ethanol and then dried in vacuo.

*3.2.6. Preparation of $[\{Cu(HL)NO_3\}_2] \cdot nH_2O$ (**7**, R = C_6H_5, p-$CH_3C_6H_4$, and p-$CH_3OC_6H_4$)*

To a solution of *N*-salicylidenearoylhydrazine H_2L (**1**, R = C_6H_5, *p*-$CH_3C_6H_4$ and *p*-$CH_3OC_6H_4$) (0.01 mol) in absolute ethanol (30 cm^3), an equivalent amount of $Cu(NO_3)_2 \cdot 6H_2O$ (0.015 mol) in absolute ethanol (50 cm^3) was added dropwise with constant stirring. The brownish-green nitrate complex, $[Cu(HL)NO_3]_2 \cdot nH_2O$, which was formed, was filtered off, washed with ethanol and then dried in vacuo.

*3.2.7. Preparation of $[Cu(HL)SCN] \cdot nH_2O$ (**8**, R = C_6H_5, p-$CH_3C_6H_4$, p-$CH_3OC_6H_4$ and p-ClC_6H_4)*

To a suspension of either copper chloride or copper nitrate copper(II) complexes (0.01 mol) in methanol (30 cm^3), the equivalent amount of NH_4SCN (0.015 mol) as a solid or in methanol (10 cm^3) was added dropwise and the reaction mixture was stirred at room temperature or refluxed for ca. 2 h. The green precipitate, which was formed, was isolated and washed with methanol, then dried in vacuo.

3.3. Physical measurements

The IR spectra were recorded on a Perkin-Elmer 1430 data system spectrophotometer and/or Perkin-Elmer FT IR spectrometer (PARAGON 100 PC). Calibration of frequency reading was made with polystyrene film. Solid samples were examined as KBr discs. Magnetic susceptibilities of powdered dried samples were recorded on a Faraday-type magnetometer using a sensitive computer controlled D-200 Cahn RG microbalance in the temperature range 4.2–298 K. The magnetic field applied was ~1.5 T. Details of the apparatus have been described elsewhere [41,42]. Experimental susceptibility data were corrected for the underlying diamagnetism. The elemental analyses (C, H and N) were performed at the microanalytical laboratory, Faculty of Science, Alexandria University and/or at the Darmstadt Technical University, Germany. The copper(II) content of the prepared complexes was determined volumetrically by titration with EDTA using PAN as indicator and/or by atomic absorption technique.

3.4. X-ray crystal and molecular structure

Suitable crystals were sealed in a fine focus glass capillary tube and mounted on a Nonius CAD-4 [43] diffractometer. Intensity data were collected at room temperature in the ω–θ scan mode, using graphite monochromatized Mo Kα radiation. Lattice constants were determined by full-matrix least-squares refinement. The solution of the crystal structures was carried out by using both SHELXS-86 [44] and SHELXL-93 [45] programs. The SHELXL-93 program was also used for structure refinement and for the evaluation of data. The Steo-REDU4 [46] and StoeX-RED [46] programs were used for computing data reductions. The graphics plotting of the molecular and crystal structures was carried out using the PLUTON-93 [47] program as well as ORTEP [48] method. The form factors for Cu(0) were taken from the international tables [49] and those for the other atoms are included as saved values in used programs.

Supplementary data

Atomic coordinates, equivalent isotropic displacement parameters, hydrogen coordinates, isotropic displacement parameters, anisotropic displacement parameters and complete lists of bond distances and bond angles have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) and are available on request quoting no. CCDC 136950.

Received 10 December 1999; accepted 24 February 2000

Abstract

Hydrolytic reactions between various palladium(II) complexes of the type *cis*-$[Pd(L)(H_2O)_2]^{2+}$ in which L is a chelating diamine (ethylenediamine, en; 1,2-propylenediamine, 1,2-pn; *N*-methylethylenediamine, Meen; isobutylenediamine, ibn and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, Me_4en) or *S*,*N*-coordinated amino acid (*S*-methyl L-cysteine, MeS-L-HCys and L-methionine, L-HMet) and *N*-acetylated L-histidylglycine (MeCO-His-Gly), were studied by ^{1}H NMR spectroscopy. The reactions were carried out in the pH range 2.0–2.5 and at 60°C. In all these reactions, a palladium(II) complex bound to a histidine residue effects the regioselective cleavage of the amide bond involving the carboxylic group of histidine. We found that the rate of hydrolysis decreases as the steric bulk of the palladium(II) complex increases (en > 1,2-pn > Meen > MeS-L-HCys > ibn > L-HMet > Me_4en). The observed rates of hydrolytic reaction are discussed in terms of steric hindrance of the chelating diamine or sulfur-containing amino acid on the palladium(II) complexes. This study is an important step in the development of new palladium(II) complexes as artificial metallopeptidases. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Palladium(II) complexes; Catalysts; Peptides; Hydrolysis

1. Introduction

Many biological processes involve hydrolysis of peptides and proteins, but relatively little is known about the mechanism of this reaction. The extreme inertness of the amide bond makes this reaction interesting from a chemical point of view. Several proteolytic enzymes are used for cleavage [1], but application of enzymes is limited by their rather narrow requirements for temperature and pH.

Transition-metal complexes hold promise as new reagents for protein cleavage by various mechanisms. Several cobalt(III) complexes coordinate to peptides and facilitate hydrolysis, but they cleave only the *N*-terminal amino acid [2]. However, practical applications usually require cleavage of internal amide bonds. Studies with some iron-EDTA complexes that are covalently attached to amino acid side chains revealed some mechanistic features of these hydrolytic reactions, but they did not result in practical methods for analytical biochemistry [3–12]. Although in some cases the cleavage was fast, the synthetic work involved in the attachment and the additional chemicals required for cleavage limit the applicability of this method. Recently, Kostić and coworkers have shown that platinum(II) [13] and palladium(II) [14–21] aqua complexes can be promising reagents for the hydrolytic cleavage of peptides and proteins. These complexes bind to the heteroatom in the side chain of methionine [13–17] or histidine [18–21] and promote cleavage of the amide bond involving the carboxylic group of this anchoring amino acid. Palladium(II) complexes, as cleavage agents, differ from the well known complexes of other transition metals because their attachment to substrates is achieved simply by mixing, the hydrolysis reactions have half-lives as short as 15 min, and the complexes are easily removed from the cleaved substrates.

The consistent regioselectivity in the cleavage of methionine or histidine containing peptides promoted by palladium(II) aqua complexes and the mechanism of this hydrolytic reaction are not completely understood yet. A better knowledge of the coordination chemistry of histidine-containing peptides with palladium(II) complexes is necessary for understanding the regioselectivity of peptide and protein cleavage promoted by such complexes. This paper reports a ^{1}H NMR investigation of the hydrolysis reac-

tion of a model histidine-containing peptide, *N*-acetylated L-histidylglycine, catalyzed by a series of palladium(II) complex cations of the type *cis*-$[Pd(L)(H_2O)_2]^{2+}$ in which L is a chelating diamine ligand, which differ in the number of methyl groups at the nitrogen or carbon atom, or *S,N*-coordinated amino acid. The observed rates of reaction are explained in terms of steric hindrance of the chelating ligand on the palladium(II) complexes.

2. Experimental

2.1. Materials

Distilled water was demineralized and purified to a resistance greater than 10 MΩ cm. The compounds D_2O, DNO_3, NaOD, and $K_2[PdCl_4]$ were obtained from Aldrich Chemical Co. All common chemicals were of reagent grade. Dipeptide L-histidylglycine, amino acids, *S*-methyl-L-cysteine and L-methionine and all diamines were obtained from Sigma Chemical Co. The terminal amino group in His-Gly was acetylated by standard methods [14].

2.2. Synthesis of palladium(II) complexes

The palladium(II) complexes of the type *cis*-$[Pd(L)Cl_2]$ (L is ethylenediamine, en; *N*-methylethylenediamine, Meen; 1,2-propylenediamine, 1,2-pn; *S*-methyl L-cysteine, MeS-L-HCys; L-methionine, L-HMet; *N,N,N′,N′*-tetramethylethylenediamine, Me_4en; isobutylenediamine, ibn) were synthesized according to the procedures published in the literature [22–24]. K_2PdCl_4 was dissolved in water and mixed with an equimolar amount of diamine or amino acid. The pH of the solution was adjusted to ca. 3 by addition of 1 M HCl and the mixture was stirred at 80°C for 2 h. All complexes were crystallized from water at room temperature. The pure complexes were obtained by recrystallization from a small amount of water and cooling. The experimental results of the elemental analysis for C, H and N parameters for all palladium(II) complexes are in accordance with theoretical values calculated for *cis*-$[Pd(L)Cl_2]$ complexes. The chloro complexes were converted into the corresponding diaqua complexes by treatment with 2 equiv. of $AgNO_3$ at pH 2.0 according to a published method [25]. In each case, the solid AgCl was removed by filtration in the dark, and fresh stock solution of the aqua complex was used in further experiments.

2.3. Reactions of peptide with palladium(II) complexes

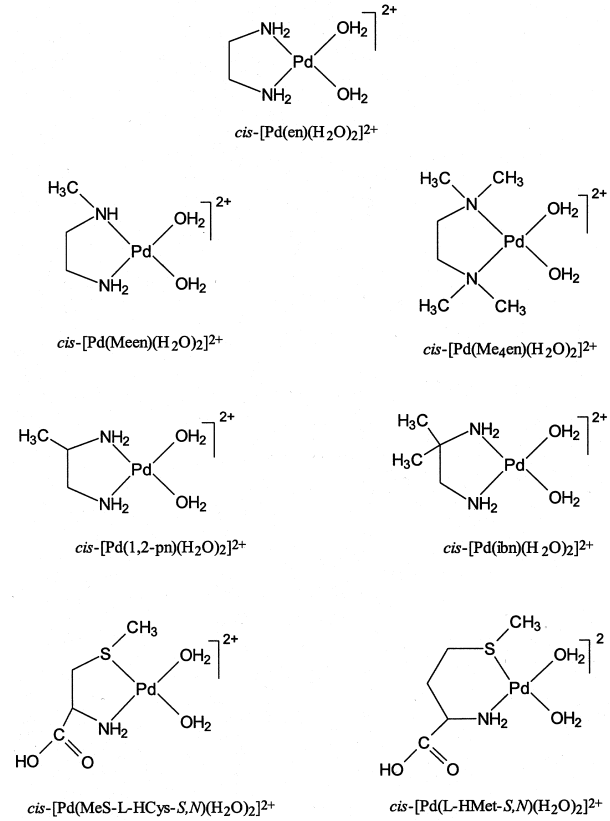
Reactions of MeCO-His-Gly with palladium(II) complexes were followed by ^{1}H NMR spectroscopy. Equimolar amounts of the palladium(II) complex and the peptide were mixed in an NMR tube. The final solution was 10 mM in each reactant. The pH was varied in the range 2.0–2.5. All reactions were carried out at 60°C.

2.4. pH Measurements

All pH measurements were made at 298 K. The pH meter (Iskra MA 5704) was calibrated with Fischer certified buffer solutions of pH 4.00 and 7.00. The results were not corrected for the deuterium isotope effect. Proton NMR spectra of D_2O solutions containing TSP (3-trimethylsilylpropane-1-sulfonate) as internal reference were recorded with Varian Gemini 200 spectrometer.

3. Results and discussion

In the present study hydrolytic reactions between various complexes of the type *cis*-$[Pd(L)(H_2O)_2]^{2+}$ (L is ethylenediamine, en; 1,2-propylenediamine, 1,2-pn; *N*-methylethylenediamine, Meen; *S*-methyl L-cysteine, MeS-L-HCys; isobutylenediamine, ibn; L-methionine, L-HMet; *N,N,N′,N′*-tetramethylethylenediamine, Me_4en) and *N*-acetylated L-histidylglycine, MeCO-His-Gly, were studied by ^{1}H NMR spectroscopy. The palladium(II) complexes are as shown in Fig. 1. The different chelate ligands (L) in these complexes are inert to substitution and are expected to remain bound to the palladium(II) atom during the reactions with the amino acids and peptides. The course of the hydrolytic reaction at pH 2.0 is shown in Scheme 1. As was shown in previous studies [18–20,26], acidic solutions are needed to suppress the formation of hydroxo-bridged oligomeric palladium(II) complexes, which are catalytically inactive.



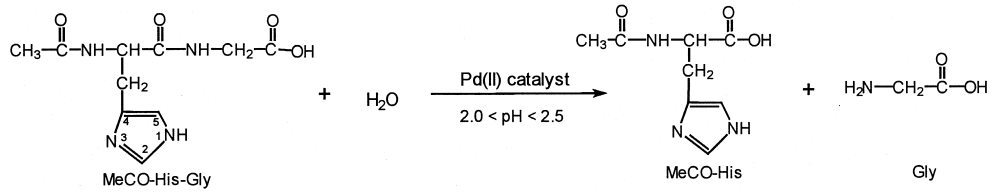


Fig. 1. Palladium(II) complexes used in the reaction with MeCO-His-Gly.

Scheme 1.

3.1. Binding of the catalysts to the substrate

The previous study with dipeptide MeCO-Gly-His and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ showed that at pH < 3 five palladium(II)-peptide products formed [18–20]. These complexes were distinguished on the basis of the chemical shifts of the two imidazole protons, H-2 and H-5. The two major complexes are linkage isomers of each other with unidentate coordination of palladium(II) via the N-3 or N-1 atom to the imidazole ring. The three minor complexes contain more than one palladium(II) atom per dipeptide or involve more than one donor atom in the dipeptide. The experiments with MeCO-His-Gly selectively methylated at the N-1 or N-3 atom of imidazole and *cis*-$[Pd(en)(H_2O)_2]^{2+}$ showed that only the palladium(II) complex with monodentate coordination to the N-3 atom of imidazole can effect the cleavage of the amide bond involving the carboxylic group of histidine (Fig. 2); none of the four other modes of coordination is effective [19]. The cleavage of the amide bond is regioselective and the reaction is completed in less than 72 h. Also, the experiments with different histidine-containing peptides and different palladium(II) complexes showed that only unidentate coordination of the peptide via the N-3 atom of the imidazole to the Pd(II) ion effects hydrolytic cleavage of the amide bond. This was explained through the fact that this coordination mode permits the necessary close approach of the palladium(II) ion and of its aqua ligand to the scissile peptide bond [18,20].

When an equimolar amount of *cis*-$[Pd(L)(H_2O)_2]^{2+}$, where L is Meen, Me_4en, or 1,2-pn, was incubated with MeCO-His-Gly at 60°C and 2.0 < pH < 2.5, five NMR-detectable complexes formed. The complexes were distinguished on the basis of the chemical shifts of imidazole protons. These complexes are identical with those for the reaction of this peptide with *cis*-$[Pd(en)(H_2O)_2]^{2+}$ [18–20]. In the reaction between *cis*-$[Pd(ibn)(H_2O)_2]^{2+}$ and MeCO-His-Gly at 2.0 < pH < 2.5, only four complexes formed. The complex with bidentate coordination of peptide via the N-3 atom of the imidazole ring and deprotonated peptide nitrogen atom was not detected in solution even after the reaction mixture stayed for 5 days at 60°C. This is in accordance with the fact that two methyl groups on the ibn ligand cause steric crowding on palladium(II) and do not allow its interaction with the peptide nitrogen atom. Mixing of *cis*-$[Pd(L)(H_2O)_2]^{2+}$, where L is MeS-L-HCys or L-HMet, with an equimolar amount of MeCO-His-Gly under the same experimental conditions resulted in a spontaneous formation of three NMR-detectable complexes. In the two complexes peptide is a unidentate ligand coordinated via the N-3 or N-1 atom of the imidazole ring to palladium(II). In the third palladium(II)-peptide complex bidentate coordination of the peptide occurs via the N-3 atom of imidazole and the deprotonated peptide nitrogen atom of the terminal amino group of histidine.

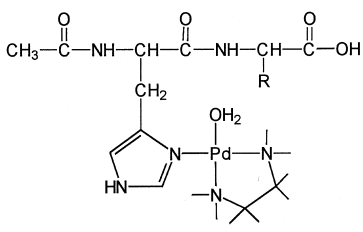

Fig. 2. Catalytically active form of the palladium(II)-peptide complex.

3.2. Regioselective cleavage of the peptide

The reactions between palladium(II) complexes of the type *cis*-$[Pd(L)(H_2O)_2]^{2+}$ and MeCO-His-Gly were carried out at 60°C and at 2.0 < pH < 2.5. The obtained results compared with those for *cis*-$[Pd(en)(H_2O)_2]^{2+}$ [18–20]. In all these reactions only the cleavage of the amide bond involving the carboxylic group of histidine was observed; see Scheme 1. In the reaction between the palladium(II) complex and MeCO-His-Gly, the ^{1}H NMR resonance at δ 3.96 ppm in the peptide decreased, while that at $\delta \sim 3.80$ ppm for free glycine increased. Upon addition of glycine to the reaction mixture its resonance is enhanced. The concentrations of the peptide and the hydrolysis products were determined from the known initial concentration of MeCO-His-Gly and from integrated resonance of the free glycine. Some of the liberated glycine reacts with the catalyst to form a small amount of the bis(bidentate) complex *cis*-$[Pd(L)(Gly\text{-}N,O)]^+$, easily detected by ^{1}H NMR spectroscopy by the resonance at δ 3.52 ppm. Indeed, the same complex is formed upon mixing of equimolar amounts of *cis*-$[Pd(L)(H_2O)_2]^{2+}$ and glycine.

3.3. Steric effects of the catalyst

The seven Pd(II) complexes in Fig. 1 differ in the chelate ligand. The palladium(II) complexes *cis*-$[Pd(Meen)(H_2O)_2]^{2+}$, *cis*-$[Pd(Me_4en)(H_2O)_2]^{2+}$, *cis*-$[Pd(1,2\text{-}pn)(H_2O)_2]^{2+}$ and *cis*-$[Pd(ibn)(H_2O)_2]^{2+}$ in relation to *cis*-$[Pd(en)(H_2O)_2]^{2+}$ have a bidentate ligand with different numbers of methyl groups at the nitrogen or carbon atom. These methyl groups contribute to the steric bulk of the palladium(II) complex. From Fig. 3 it can be concluded that the

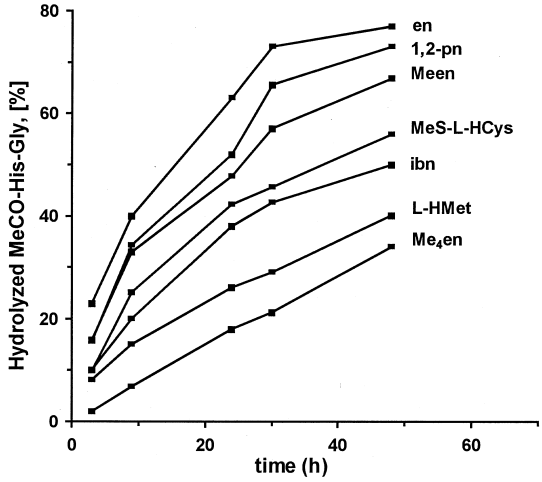

Fig. 3. Time dependence of hydrolytic reaction of MeCO-His-Gly with different palladium(II) complexes at $2.0 < pH < 2.5$ and at 60°C.

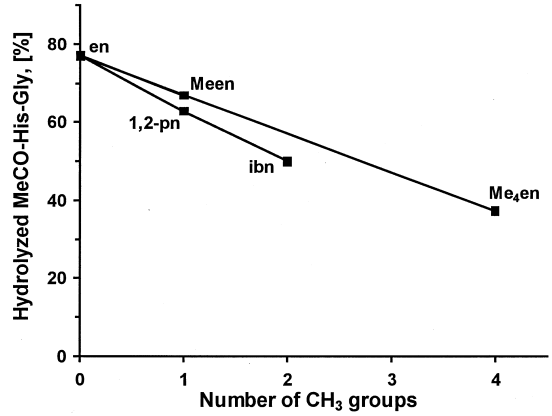

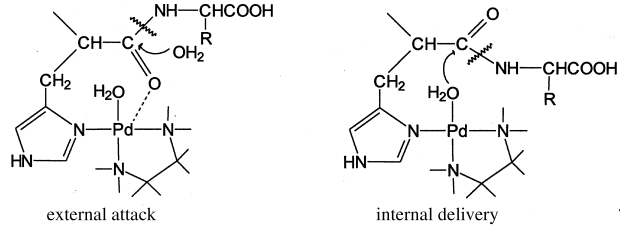

Fig. 4. Dependence of the hydrolysis rate on the steric bulk of the palladium(II). The reactions were carried out for 48 h at $2.0 < pH < 2.5$ and at 60°C.

Scheme 2.

rate of hydrolysis decreases as the steric bulk of the palladium(II) complex increases (en > 1,2-pn > Meen > MeS-L-HCys > ibn > L-HMet > Me_4en). The reaction between *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and MeCO-His-Gly after 48 h at 60°C is almost two times faster in comparison with *cis*-$[Pd(Me_4en)(H_2O)_2]^{2+}$, or one and a half times faster in relation to *cis*-$[Pd(ibn)(H_2O)_2]^{2+}$. On comparing the ligand 1,2-pn with Meen, or Me_4en with ibn, we found that the former are more sterically demanding because the methyl groups bound directly to the nitrogen atoms are closer to the metal center, hindering the approach of a nucleophile. It is very illustrative to compare the rate of reactivity of MeCO-His-Gly with en, 1,2-pn and ibn, or this peptide with en, Meen and Me_4en palladium(II) complexes, see Fig. 4. It is obvious that increasing the number of methyl groups at the nitrogen or carbon atom of the chelate ligand decreases the amount of hydrolyzed His-Gly peptide bond. For comparison, parallel work has been done with MeCO-His-Gly and *cis*-[Pd(MeS-L-HCys-*S,N*)$(H_2O)_2]^{2+}$ and *cis*-[Pd(L-HMet-*S,N*)-$(H_2O)_2]^{2+}$. These two complexes differ in the ring size of the chelate ligand. The MeS-L-HCys-palladium(II) complex with five-membered chelate ring is more reactive than L-HMet-palladium(II) with six-membered ring in the square-planar plane. This inhibition of the hydrolytic reaction can be attributed to the steric bulk of the palladium(II) complex. A similar trend to our results has emerged in a previous study of *cis*-$[Pd(en)(H_2O)_2]^{2+}$ and MeCO-His-X peptides containing different C-terminal amino acids (X is Gly, Ala, Ser, Thr, Leu, Phe, Tyr) [18]. It was found that the rate constant of the hydrolytic reaction decreases smoothly as the volume of the leaving amino acid increases.

Summing up together our results with different palladium(II) complexes and previous results with different peptides [18], we can say that inhibition of the hydrolytic reaction can be attributed to the steric bulk of the palladium(II) complex as well as to the steric bulk of the leaving amino acid. These findings can be explained in terms of two possible limiting mechanisms for hydrolytic cleavage of the peptide bond promoted by palladium(II) [18–20], see Scheme 2. In the mechanism involving external attack by water, the palladium(II) atom, as a Lewis acid, polarizes the carbonyl group in the scissile peptide bond. In the mechanism involving internal attack by water, the palladium(II) atom delivers an aqua ligand to the scissile bond. As can be seen, both mechanisms require a close approach of the pendant catalyst to the adjacent peptide bond, and in both cases the steric bulk of the leaving amino acid as well as palladium(II) complex hinder this crucial interaction.

Acknowledgements

Abstract

1,2,4-Triazolo-[1,5α]-pyrimidine (tp) was studied by gradient heteronuclear multiple-quantum correlation ^{15}N–^{1}H NMR and by cross-polarized magic angle spinning ^{13}C, ^{15}N NMR. The ^{15}N signals were unambiguously assigned. The assignments of some IR absorption bands were proposed by comparison to purine and adenine spectra. The obtained results were used for the investigation of $Zn(tp)_2X_2$-type complexes (X = Cl, Br, I, NCS), suggesting a pseudo-tetrahedral configuration around the Zn(II) ion with unidentately N(3) bonded heterocycles and halides or thiocyanates (N bonded) in terminal positions. A slight shielding effect on the N(3) nucleus upon the formation of Zn(II)–N coordination bonding was observed. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

1,2,4-Triazolo-[1,5α]-pyrimidine (tp) is a heterocycle isomeric compound with purine, its fused ring system differing from the purine skeleton in having the pyrimidine nitrogen atom in a bridge-head position (Fig. 1).

1,2,4-triazolo-[1,5α]-pyrimidine (tp) purine

Fig. 1. Tp and purine.

Tp has been the subject of many studies and its physical and chemical properties [1–3] as well as ^{1}H, ^{13}C and ^{15}N NMR spectra [4–13] have been examined. The latter spectrum was widely discussed but there was no agreement on ^{15}N assignments [9–13]. Some authors found four ^{15}N signals at analogous chemical shifts (in DMSO-d_6), but proposed different sequences for them (upfield): N(4) < N(1) < N(8) < N(3) [9], N(4) < N(1) < N(3) < N(8) [10,13], and N(1) < N(4) < N(3) < N(8) [11,12]. This problem becomes very important when ^{15}N NMR spectroscopy is used to determine the metallation sites in diamagnetic complexes. Recently, we have measured natural abundance ^{15}N NMR spectra of the following 5,7-disubstituted tp derivatives: 5,7-dimethyl-1,2,4-triazolo-[1,5α]-pyrimidine (dmtp), 5,7-diphenyl-1,2,4-triazolo-[1,5α]-pyrimidine (dptp), 5,7-di-*tert*-butyl-1,2,4-triazolo-[1,5α]-pyrimidine (dbtp) and 5,7-ditrifluoromethyl-1,2,4-triazolo-[1,5α]-pyrimidine (dftp) [14]. We have suggested, using selective decoupling techniques, the order N(1) < N(4) < N(3) < N(8) for the former three heterocycles and N(4) < N(1) < N(3) < N(8) for the latter heterocycle [14]. The lack of agreement on the ^{15}N assignment for tp has prompted us to record its ^{15}N–^{1}H NMR gradient heteronuclear multiple-quantum coherence (GHMQC) spectrum. Studies of ^{15}N–^{1}H spin–spin couplings have allowed us to make an unambiguous assignment of all the signals, settling the controversy in the literature. In order to complete the NMR spectral data for tp we have also measured its ^{13}C and ^{15}N NMR spectra in the solid state, by cross-polarized magic angle spinning

PII S0277-5387(00)00344-2

(CPMAS); to the best of our knowledge this is the first report for 1,2,4-triazolo-[1,5α]-pyrimidines.

The mass [15], electronic [16] and rotational [17] spectra of tp have already been described. However, there is only one report on the vibrational spectrum of 5- and 7-oxo analogues of tp (concerning CO stretching modes) [16] and the discussion of the two characteristic bands in the spectrum of dmtp [18]. In this paper we describe the IR spectrum of tp, based on a comparison with the purine and adenine spectra, and propose another assignment.

The new interpretation of the ^{15}N NMR and IR spectra of tp was used for structural determination of its Zn(II) halide and thiocyanate complexes of general formula $Zn(tp)_2X_2$ (X = Cl, Br, I, NCS). In addition to the known coordination compounds with other 1,2,4-triazolo-[1,5α]-pyrimidines (ZnL_2X_2, where L = dmtp, dptp, dbtp, X = Cl, Br, I, NCS) [18–22], there is only one report on $Zn(tp)_2Br_2 \cdot 0.5H_2O$ [23], where tp was N(3) bonded.

2. Experimental

2.1. Materials

Tp was purchased from Aldrich, whereas $ZnCl_2$, $ZnBr_2$, ZnI_2 of 98% purity were from POCh (Poland). $Zn(SCN)_2$ was obtained by reaction of HSCN in situ with $ZnCO_3$ [24].

2.2. Methods

^1H, ^{13}C and ^{15}N NMR spectra were recorded on a Varian GEMINI 200 XL spectrometer operating at 199.992, 50.293 and 20.270 MHz, respectively. Heteronuclear correlation (HETCOR) ^{15}N–^1H NMR spectra were detected on a Bruker DRX 500 spectrometer, using GHMQC with gradient selection, the frequency being 50.66 MHz for ^{15}N and 499.80 MHz for ^1H. The solvent was DMSO-d_6, the concentration of samples was 0.01 M for ^1H or ^{13}C and 0.1 M for ^{15}N spectroscopy, and the temperature was 295 K. The reference standard was TMS (internal) for ^1H or ^{13}C and CH_3NO_2 (external) for ^{15}N spectroscopy. The solid-state ^{13}C and ^{15}N NMR spectra were measured with the same type of spectrometer in 4 mm probeheads by CPMAS, two techniques being used: a standard technique (all C or N detected) and a short CP contact technique (protonated atoms only). The reference standard was glycine, the chemical shifts being recalculated to TMS for ^{13}C ($\delta(CH_2$ in glycine$) = +43.3$ ppm) or to nitromethane for ^{15}N ($\delta(NH_2$ in glycine$) = -347.6$ ppm). IR spectra were measured on a Perkin-Elmer spectrum 2000 FT-IR spectrometer, using KBr (400–4000 cm^{-1}) and polyethylene discs (100–400 cm^{-1}). The amounts of C, H, N in the complexes were determined by elemental semi-microanalysis, whereas that of Zn was determined by titration with EDTA (after mineralization).

2.3. Synthesis

Complexes of ZnX_2 (X = Cl, Br, I, SCN) with tp were prepared by a general procedure as follows: 5 mmol of ZnX_2 and 10 mmol of tp were dissolved in water, mixed and stirred at 90°C for 1 h. The obtained precipitate was filtered, washed with ethanol and dried in air (yield 50–75%). The elemental analyses were as follows. Calc. for $Zn(tp)_2Cl_2$, $ZnC_{10}H_8N_8Cl_2$: Zn, 17.4; C, 31.9; H, 2.1; N, 29.8. Found: Zn, 17.4; C, 32.0; H, 2.0; N, 30.1%. Calc. for $Zn(tp)_2Br_2$, $ZnC_{10}H_8N_8Br_2$: Zn, 14.0; C, 25.8; H, 1.7; N, 24.1. Found: Zn, 13.9; C, 26.0; H, 1.6; N, 23.9%. Calc. for $Zn(tp)_2I_2$, $ZnC_{10}H_8N_8I_2$: Zn, 11.7; C, 21.5; H, 1.4; N, 20.0. Found: Zn, 11.4; C, 21.7; H, 1.5; N, 20.2%. Calc. for $Zn(tp)_2(NCS)_2$, $ZnC_{12}H_8N_{10}S_2$: Zn, 15.5; C, 34.2; H, 1.9; N, 33.2. Found: Zn, 15.5; C, 34.4; H, 1.7; N, 33.1%.

3. Results and discussion

3.1. NMR spectra of tp

In the ^{15}N NMR one-dimensional spectrum of tp we have found four resonances with the following values of ^{15}N chemical shifts and ^{15}N–^1H spin–spin coupling constants (in DMSO-d_6): −102.3 ppm (doublet, $^2J_{N-H}$ 11.5 Hz), −105.2 ppm (doublet, $^2J_{N-H}$ 15.7 Hz), −149.6 ppm (doublet, $^2J_{N-H}$ 12.9 Hz), −153.6 ppm (doublet, $^2J_{N-H}$ 5.5 Hz). These results correspond well to the published data [9–13], however, they do not allow us to distinguish between N(1) and N(4) signals. The reason is that both are coupled to one proton (H(2) or H(5)) with $^2J_{NH}$ values being of the same magnitude. N(3) and N(8) resonances may be assigned properly because the value of $^2J_{NH}$ for N(3)–H(2) spin–spin interaction must be higher than that for N(8)–H(7). It is well known that ^{15}N–^1H coupling constants for pyridine-type nitrogens (possessing lone-pair electrons like N(3)) are larger than those for the pyrrole nitrogens (like N(8)) [25].

The assignment of ^{15}N signals became clear after the HETCOR ^{15}N–^1H NMR spectrum of tp was recorded by the GHMQC method (Fig. 2).

The N(4) and N(1) resonances can be easily distinguished as the former nucleus is coupled with H(5) and H(6), whereas the latter is coupled with H(2). Also, N(3) and N(8) have different coupling patterns, the former being coupled with H(2) and the latter with either H(2) or H(6) (coupling with H(7) was not registered in this experiment). These results finally prove that the order of ^{15}N signals in the tp spectrum is N(4) < N(1) < N(3) < N(8), as proposed earlier [10,13]. This sequence is consistent with the results of theoretical calculations of the absolute shielding constants, which are −40.2 for N(4), −20.3 for N(1), +22.2 for N(3) and +30.1 for N(8); the above-mentioned values were obtained by the gauge invariant atomic orbitals—coupled Hartree–Fock (GIAO-CHF) method [26].

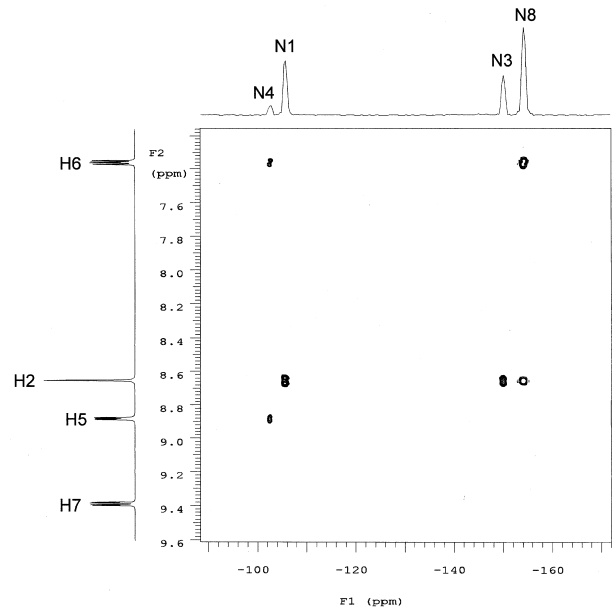

Fig. 2. ^{15}N–^{1}H HETCOR spectrum of tp.

N(8) is the only pyrrole-type nitrogen atom in the tp molecule and therefore it is more shielded than the others that are pyridine-type, which is a general rule for azoloazines [27]. However, the signal of N(3) is also detected at relatively high magnetic field compared to those of N(1) or N(4) (the difference in δ being about 45 ppm); this is probably associated with especially high electron density on this nitrogen. Earlier quantum-mechanical studies, performed by Salas et al., using the MNDO method, allowed evaluation of the electron density at N(3), N(1) and N(4) atoms as -0.240, -0.177, -0.171, respectively [28]. This fact also explains why N(3) is the preferred site in the processes of protonation and N-alkylation [5,12].

The ^{13}C CPMAS spectrum of tp exhibited signals from five carbons (including four protonated). They have been detected as follows: C(2)/C(5) 156.7/154.7, C(3a) 154.1, C(7) 138.7, C(6) 109.9 ppm. It is difficult to distinguish the C(2) and C(5) resonances, as both derive from CH carbons and have similar δ values. The signals of C(3a), C(6) and C(7) can be easily assigned because C(3a) is the only unprotonated carbon atom, whereas C(6) and C(7) have very characteristic chemical shifts, close to those reported for DMSO-d_6 solutions [8]. In the ^{15}N CPMAS spectrum of tp the two broad signals have been observed at -107.2 and -154.7 ppm. Their δ values indicate, by analogy with the measurements in DMSO-d_6, that they derive from the pairs N(1)/N(4) and N(3)/N(8). However, the coincidence of their chemical shifts does not allow us to separate them.

3.2. NMR spectra of Zn(II) complexes with tp

^{1}H and ^{13}C NMR spectra of the discussed Zn(II) complexes are nearly identical with those of tp and the observed deviations are within the limits of experimental error. This behaviour is quite different from that observed for Pd(II) chloride complexes with tp and its derivatives, where significant downfield shifts of ^{1}H resonances (maximum 0.6 ppm) and variable coordination shifts of ^{13}C signals (maximum 3.6 ppm) have been noticed [29].

The order of ^{15}N NMR resonances in the spectra of all Zn(II) complexes is the same as for tp and the chemical shifts of N(1), N(4) and N(8) are nearly identical. However, the signal of N(3) is slightly shifted upfield, 0.4–1 ppm, indicating that this atom is the coordination site (Table 1).

Similar coordination shifts of N(3) resonances (0.5–2 ppm) were observed for Zn(II) complexes with dmtp, dptp and dbtp [22]. The preference for complexation via N(3) is analogous to that via N(9) in adenine; hence, tp can be treated as a structural analogue of purine bases. It is also in accordance with the calculated highest electron density at N(3). However, in Zn(II) complexes with other N-donors possessing a similar coordination pattern, the measured shifts were usually more significant than in the case of 1,2,4-triazolo-[1,5α]-pyrimidines. For aqueous solutions of $Zn(NO_3)_2$ with imidazole or 1-methylimidazole they were in the range 10–60 ppm [30,31], whereas for adenosine complexes the shifts were between 2 and 9 ppm [32–34]. The increased shielding of the coordinated nitrogen atom is probably the result of its lone-pair electrons being engaged in Zn–N bonding. This effect seems to be analogous to that caused by protonation, N-oxidation or Pt(II) complexation of pyridine-type nitrogens in azine ring systems [25,35]. However, in the discussed Zn(II) complexes the magnitude of upfield shift is much smaller than that observed for tpH^+ (78 ppm) [12] or for $Pd(tp)_2Cl_2$ (88 ppm) [29].

Table 1
^{15}N–^{1}H HETCOR data for tp and its Zn(II) halide and thiocyanate complexes (δ coordination shifts, $\Delta\delta^{coord} = \delta^{complex} - \delta^{ligand}$, in parentheses)

Compound	N(4)	N(1)	N(3)	N(8)
tp [a]	−102.3	−105.2	−149.6	−153.6
Tp	−102.6	−105.6	−150.1	−154.2
$Zn(tp)_2Cl_2$	−102.7 (−0.1)	−105.6 (0)	−151.1 (−1.0)	−154.3 (−0.1)
$Zn(tp)_2Br_2$	−102.8 (−0.2)	−105.6 (0)	−151.1 (−1.0)	−154.2 (0)
$Zn(tp)_2I_2$	−102.7 (−0.1)	−105.7 (−0.1)	−151.1 (−1.0)	−154.3 (−0.1)
$Zn(tp)_2(NCS)_2$	−102.6 (−0.1)	−105.6 (0)	−150.5 (−0.4)	−154.1 (+0.1)

3.3. Infrared spectrum of tp

In the literature there are no IR data on tp. Some authors have described the two characteristic absorption bands (at 1634 and 1544 cm^{-1}) in the dmtp spectrum, suggesting they are derived from the stretching vibrations of the pyrimidine and imidazole ring, respectively [18]. Recently, we have observed analogous bands in the IR spectra of dptp (at 1612 and 1543 cm^{-1}) and dbtp (at 1615 and 1530 cm^{-1}) [22]. However, the spectrum of tp reveals three bands in this region (1621, 1534 and 1515 cm^{-1}). Their assignment can be based on the known and assigned spectra of purine and adenine [36–43]. The origin of the others, observed in the range 100–1500 cm^{-1}, can be proved only by studies of the ^{2}H and ^{15}N analogues of tp, supported by Raman spectroscopy and quantum-mechanical calculations.

In the purine molecule the two characteristic bands at 1618 and 1570 cm^{-1} were assigned as the vibrations of the whole purine skeleton and of the pyrimidine ring, respectively, whereas those at 1464 and 1429 cm^{-1} were assigned as the imidazole ring modes [40]. By analogy, one can suggest that in the tp spectrum the band at 1621 cm^{-1} is the triazolopyrimidine mode (ν_{tp}), whereas the two bands at 1533 and 1515 cm^{-1} are the pyrimidine ring modes (split into ν_{py1} and ν_{py2}). Consequently, one can assume that in the dmtp spectrum the absorption bands at 1637 and 1550 cm^{-1} derive from ν_{tp} and ν_{py} vibrations, respectively; this assignment differs from that previously published [18].

3.4. Infrared spectra of Zn(II) complexes with tp

The coordination of Zn(II) ions by tp molecules results in a shift of either the ν_{tp} or ν_{py} bands, most frequently towards higher frequencies, as well as in the appearance of some new bands in the far-IR region (Table 2).

An analogous increase in energy of the skeletal vibrations has already been observed for Pd(II) chloride complexes with 1,2,4-triazolo-[1,5α]-pyrimidines [29]. It may be caused by the fact that after coordination the C=N and C=C bonds in the tp ring reveal a more pronounced double-bond character, due to the π-electron localization [44]. The band shift is more profound for ν_{py1} or ν_{py2} modes than for the ν_{tp} mode, as already observed for the Zn(II) complexes with dmtp, dptp and dbtp [22]. Although the average change in ν_{tp} and ν_{py} vibration energy does not exceed 10 cm^{-1}, this tendency is evident. Hence, one can suggest that these absorption bands are taken as an indication for the complexation of 1,2,4-triazolo-[1,5α]-pyrimidines. A similar behaviour was also described for their complexes with Co(II) [21], Ru(III) [45] and Cu(II) [46].

The presence of four bands in the far-IR region suggests a monomeric structure of all the complexes and pseudo-tetrahedral configuration around the Zn(II) atom; local symmetry C_{2v} results in two Zn–Cl and two Zn–N stretching vibrations. This geometry is consistent with that found or suggested for other Zn(II) complexes with 1,2,4-triazolo-[1,5α]-pyrimidines, the frequencies of Zn–X and Zn–N stretching vibrations being in a similar range [18–23]. Analogous results were obtained for pseudo-tetrahedral Zn(II) halide and thiocyanate complexes with pyridine–$Zn(py)_2X_2$ [47,48], imidazole–$Zn(imH)_2X_2$ [49], purine–$Zn(puH)Cl_2$ [50], adenine–$Zn(adH)Cl_2$, $Zn(adH)_2Cl_2$ [51] and adenosine–$Zn(ado)_2Cl_2$, $Zn(ado)_nCl_2 \cdot xH_2O$ ($n = 1,2,3$, $x > 1$) [33,34,51].

In the spectrum of $Zn(tp)_2(NCS)_2$ the stretching vibrations of C–N and C–S are observed at 2085 cm^{-1} (strong) and 840 cm^{-1} (weak), respectively. These values are similar to those reported for Zn(II) complexes with dmtp, dptp and dbtp [20,22], being typical for thiocyanate groups terminally bonded via the nitrogen atom [52]. The deformation S–C–N vibration, expected in the range 460–480 cm^{-1} [52], is not observed, probably owing to overlapping by the tp bands at 461 and 468 cm^{-1}.

4. Conclusions

HETCOR ^{15}N–^{1}H NMR studies of tp have been the basis of an unambiguous assignment of ^{15}N signals in the tp spectrum, which settles the controversy in the literature. The observed sequence of signals is N(4) < N(1) < N(3) < N(8) (upfield). These data are completed with the results of ^{13}C and ^{15}N CPMAS measurements in the solid state. The comparison of the IR spectrum of tp with those of purine and adenine allows us to propose the assignment of the two most characteristic absorption bands for 1,2,4-triazolo-[1,5α]-pyrimidines.

Zn(II) halide and thiocyanate complexes with tp have a monomeric structure with terminally bonded halogen atoms or NCS groups (via N). The geometry around the Zn(II) ion

Table 2
The ν_{tp}, ν_{py}, Zn–Cl and Zn–N absorption bands in the IR spectra of Zn(II) halide and thiocyanate complexes with tp (ν coordination shifts, $\Delta\nu^{coord} = \nu^{complex} - \nu^{ligand}$, in parentheses)

Complex	ν_{tp} (cm^{-1})	ν_{py} (cm^{-1})	ν(Zn–X) (cm^{-1})	ν(Zn–N) (cm^{-1})
$Zn(tp)_2Cl_2$	1621 (0)	1527 (+12); 1540 (+6)	300; 276	226; 198
$Zn(tp)_2Br_2$	1617 (−4)	1521 (+6); 1537 (+3)	273; [a]	[a]; [a]
$Zn(tp)_2I_2$	1622 (+1)	1526 (+11); 1534 (0)	200; 161	228; 205
$Zn(tp)_2(NCS)_2$	1623 (+2)	1528 (+13); 1541 (+7)	310; 274	218; 206

[a] Bands overlapped in the range 180–240 cm^{-1}.

is pseudo-tetrahedral. The tp molecule behaves as a unidentate ligand and coordinates by its N(3) atom. This nitrogen is slightly shielded owing to the formation of Zn–N coordination bonding, which is expressed by a small upfield shift (0.4–1 ppm) of the respective ^{15}N NMR signal. The observed complexation mode may be regarded as representative for 1,2,4-triazolo-[1,5α]-pyrimidines and analogous to coordination via N(9) in purine bases.

Abstract

Electron spectroscopy for chemical analysis (ESCA) was performed for $[Co(NH_3)_5Cl](ClO_4)_2$, *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$, $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)](ClO_4)$ complexes. Comparison of the results for the complexes $[Co(NH_3)_5Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ shows clearly the electronic influence (+I effect) of the methylamine group on the cobalt and through this on the chlorine atom in *trans* position. Comparison of $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ with *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ shows that methylation of the four *cis*-NH_3 ligands does not produce a proportional decrease in the binding energy of the cobalt atom, while the electron density of the chloro ligand is not affected. For the complex *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)](ClO_4)$ the +I effect is almost completely compensated by the presence of the sulfato group in *trans* position. Acid dissociation constants are also reported for $[Co(NH_3)_5(OH_2)]^{3+}$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)(OH_2)]^{3+}$ ions. The implications of these results for the mechanism of the acid and base hydrolysis reactions of acidopentaaminecobalt(III) complexes are discussed. The preparation of the *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)](ClO_4)$ complex through the *trans*-$[Co(NH_3)_4(NH_2CH_3)(SO_3)]^+$ precursor is also described. ©2000 All rights reserved.

Keywords: Acidopentaaminecobalt(III) complexes; ESCA studies; ESI+ mass spectra; Acid dissociation constants

1. Introduction

Substitution reactions of octahedral cobalt(III) acidoammine complexes have been subjected to extensive and detailed investigation over recent decades [1,2]. Acid hydrolysis (or aquation) reactions of cobalt(III) complexes appear to be dissociative interchange processes, I_d, i.e. bond breaking substantially precedes bond making [3–9]. For base hydrolysis, a conjugate-base mechanism seems well defined (Eqs. (1)–(3)), although there is still some controversy on whether the process is entirely dissociative, Dcb, or whether it is partially concerted, I_dcb [10–21].

$$[Co(NH_3)_5X]^{n+} + OH^- \overset{K_a/K_w}{\rightleftarrows} [Co(NH_3)_4(NH_2)X]^{(n-1)+} + H_2O \quad (1)$$

$$[Co(NH_3)_4(NH_2)X]^{(n-1)+} \overset{k}{\rightarrow} [Co(NH_3)_4(NH_2)]^{2+} + X^{(3-n)-} \quad (2)$$

$$[Co(NH_3)_4(NH_2)]^{2+} + H_2O \overset{\text{fast}}{\rightarrow} [Co(NH_3)_5(OH)]^{2+} \quad (3)$$

Comparative studies on pentaammine and pentakis(methylamine) complexes [19,22] have been used to support these classifications. The increase in the rate for both reactions when the five ammine ligands in $[Co(NH_3)_5X]^{n+}$ are replaced by bulkier methylamine ligands is consistent with steric relief in a dissociated activated state. For example, the rate constant for aquation of $[Co(NH_2CH_3)_5Cl]^{2+}$ is 23 times that of $[Co(NH_3)_5Cl]^{2+}$, while for base hydrolysis the acceleration factor is 7.5×10^3. For *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{n+}$ ions there is only a modest rate enhancement of both aquation and base hydrolysis, when one NH_3 is substituted by a NH_2CH_3 ligand (*trans* position). Among other factors which may account for these variations

PII S0277-5387(00)00346-6

in rate, we investigated the inductive effect of the methyl substituent, making use of ESCA on $[Co(NH_3)_5Cl](ClO_4)_2$, *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$, $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)](ClO_4)$.

In the base hydrolysis reactions, if a conjugate base mechanism (Eqs. (1)–(3)) is operating, part of this acceleration could be due to an increased acidity of the N protons. Swaddle determined that $[Co(NH_2CH_3)_5(OH_2)]^{3+}$ was 6.3 times more acidic than $[Co(NH_3)_5(OH_2)]^{3+}$ [23], but the acidity of *trans*-$[Co(NH_3)_4(NH_2CH_3)(OH_2)]^{3+}$ has not yet been measured; therefore it was pertinent to accomplish this study.

2. Experimental

2.1. Preparation of compounds

$[Co(NH_3)_5Cl](ClO_4)_2$, $[Co(NH_3)_5OH_2](ClO_4)_3$, *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$, *trans*-$[Co(NH_3)_4(NH_2CH_3)OH_2](ClO_4)_3$ and $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ complexes were prepared as described in the literature [15,24,25].

trans-$[Co(NH_3)_4(NH_2CH_3)OSO_3]ClO_4$. The complex *trans*-$[Co(NH_3)_4(NH_2CH_3)(SO_3)]Cl$ [15] was dissolved (7.0 mmol) in H_2SO_4 (98%, 15 ml) saturated with Li_2SO_4 at room temperature. The resultant pink solution was poured carefully into cold methanol (0.4 l) to precipitate the *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)]HSO_4\cdot H_2O$ complex. This was collected and washed with methanol and ether. Yield 68%. Chemical characterization of the compound included elemental analysis (Calc. for $CoH_{20}N_5S_2O_9C$: C, 3.25; H, 5.42; N, 18.97; S, 17.34; Co, 16.0. Found: C, 3.37; H, 5.34; N, 18.79; S, 17.61; Co, 16.0%), electronic ($\varepsilon_{357} = 55.1\ M^{-1}\ cm^{-1}$; $\varepsilon_{520} = 65.4\ M^{-1}\ cm^{-1}$), IR ($\nu_1 = 972\ cm^{-1}$, $\nu_2 = 441\ cm^{-1}$, $\nu_3 = 1036$–1100 and 1122–$1143\ cm^{-1}$, $\nu_4 = 597$ and $626\ cm^{-1}$). The electron spray ionization (ESI^+) spectrum clearly shows the presence of $[Co(NH_3)_4(NH_2CH_3)(OSO_3)]^+$ (signal at 254 Da). The other three significant signals at 237, 220 and 203 Da correspond to consecutive loss of three NH_3 groups. For the IR measurements, the *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)]HSO_4\cdot H_2O$ complex was transformed to the bromide salt by dissolution in water and precipitation with concentrated HBr. The ESI^+ and ESCA spectra were performed on the perchlorate salt by treatment with concentrated $HClO_4$. The ESI spectra were recorded on a LC-MS Platform 1 spectrometer. The ^1H NMR spectrum (in D_6-DMSO) shows a single methyl signal (δ 1.74 ppm versus tetramethylsilane), corresponding to a methyl group *trans* to SO_4^{2-}. The salt was shown to be free of *trans*-$[Co(NH_3)_4(NH_2CH_3)(OH_2)]^{3+}$ by chromatography on Dowex 50W-X8 (Na^+ form) using 0.4 M $NaClO_4$ as eluant.

2.2. ESCA studies

The samples were studied with a VG Escalab 200iXL X-ray photoelectron spectrometer, using Al Kα radiation. The pressure during the measurements in the analyzer chamber was less than 10^{-8} mbar. The energy scale of the spectra was adjusted using the C_{1s} peak (285.0 eV) as reference. The values of the binding energies for C_{1s}, N_{1s}, $Co_{2p3/2}$, $Cl_{2p3/2}$, O_{1s} and $S_{2p3/2}$ were measured by multiplex scans.

2.3. Acid dissociation constants of aquo complexes

Potentiometric titrations of *trans*-$[Co(NH_3)_4(NH_2CH_3)(OH_2)]^{3+}$ and $[Co(NH_3)_5(OH_2)]^{3+}$ (complex concentrations between 0.987 and 2.981 mM) were carried out in the thermostated cell (25.0°C) of a Metrohm 713 Dosimat pH meter, using a glass and an Ag/AgCl (reference) electrode. Solutions made from the solid perchlorates (in the titration cell) in 20.00 ml, $NaClO_4$ 0.15 M and 2.00 ml, HCl 0.1003 M were titrated with NaOH 0.1005 M. During the course of the titrations presaturated argon (free of CO_2) was bubbled. The data were analyzed using SUPERQUAD program.

3. Results and discussion

The aquation and base hydrolysis for *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{n+}$ ions are four to eight times faster than for $[Co(NH_3)_5X]^{n+}$ complexes, while the acceleration for $[Co(NH_2CH_3)_5X]^{n+}$ ions is much more pronounced: i.e. rate increases of 30 and 10^3 for aquation and base hydrolysis respectively (when X = Cl) are observed. In the closely analogous ions studied here, the main factors which may account for the variation in rate are: (i) steric effects (steric acceleration), (ii) variations in the acidity of the protons of the amine ligands (only for the base hydrolysis reaction) and (iii) inductive effect of the methyl substituents.

The steric crowding of the $[Co(NH_2CH_3)_5Cl]^{2+}$ complex has been demonstrated by X-ray diffraction [25], while for the *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl]^{2+}$ ion this effect is less important [26]. For example, the average Cl–Co–N(*cis*) bond angle is reduced from 89.4° in the $[Co(NH_3)_5Cl]^{2+}$ ion to 88.5° in the $[Co(NH_2CH_3)_5Cl]^{2+}$ complex, while it is 89.0° in *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl]^{2+}$.

For base hydrolysis, the derivated rate law for the mechanism depicted in Eqs. (1)–(3) in Section 1 is:

$$\text{Rate} = kK_a/K_w[\text{complex}][OH^-]$$

provided K_a/K_w is small. Therefore, variations in the acidity of the protons of the coordinated amines (K_a) may produce variations in rate. The measurements of K_a for the coordinated amines is precluded in water by the low dissociation constants ($pK_a > 15$). Instead, the pK_a of the aquo complexes has been measured (Table 1). $[Co(NH_2CH_3)_5OH_2]^{3+}$ is 6.3 times more acidic than $[Co(NH_3)_5OH_2]^{3+}$ [23], but this still leaves an acceleration factor of 10^3 to be attributed to Eq. (2). On the other hand, the pK_a values of the latter complex and *trans*-$[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$ are the same. In consequence, if N-proton and O-proton acidity trends are

similar, this factor (K_a) cannot account for the observed accelerations.

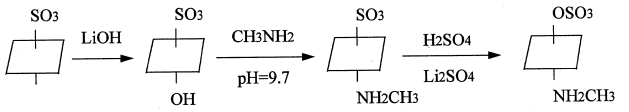
It is also possible for the amine substituent to influence the release of X by donating negative charge to cobalt, i.e. an inductive assistance of the bond breaking step may be operating. The magnitude of this effect might be gauged from the data listed in Table 2.

The comparison of results for the complexes $[Co(NH_3)_5Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ shows clearly the electronic influence (+I effect) of the methylamine group upon the cobalt and through this upon the chlorine atom in *trans* position, as the $Co_{2p3/2}$ and $Cl_{2p3/2}$ binding energies decrease 0.5 and 0.6 eV respectively; while the *cis*-NH_3 ligands are not affected (the experimental error is 0.1 eV).

For complex $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ the $Co_{2p3/2}$ binding energy decreases to 781.6 eV (0.4 eV lower than for *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$). Thus, methylation of the four *cis* ligands does not produces a proportional decrease in the binding energy of $Co_{2p3/2}$. Furthermore the $Cl_{2p3/2}$ binding energies for *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ and $[Co(NH_2CH_3)_5Cl](ClO_4)_2$ are the same, i.e. only the CH_3 group located in the ligand in *trans* position affects the electron density of the chloro atom.

We have recently been involved in the fine tuning of the spontaneous substitution reactions of neutral leaving ligands, L, on $[Co(NH_3)_5L]^{3+}$, $[Co(NH_2CH_3)_5L]^{3+}$ and *cis/trans*-$[Co(NH_3)_4(NH_2CH_3)L]^{3+}$ complexes [27]; our results indicated that the position and number of the more electron donating NH_2CH_3 ligands play a dramatic role in the dissociativeness of the processes. For example, the activation volumes for the aquation reaction of $[Co(NH_3)_5DMF]^{3+}$, *cis*-$[Co(NH_3)_4(NH_2CH_3)DMF]^{3+}$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)DMF]^{3+}$ (where DMF is dimethylformamide) were +2.0, +4.0 and +14.0 $cm^3\ mol^{-1}$, respectively, i.e. the presence of a *cis*-methylamine ligand (instead of NH_3) only slightly increases the dissociativeness of the reaction while a *trans*-methylamine ligand produces a dramatic increase. Accordingly, the supposition has been advanced that the σ donor capability of the methylamine is more important when it is located in the *trans* position, i.e. the *cis*-methylamine ligand (instead of NH_3) increases the electron density on the cobalt centre to a lesser degree. These suppositions are now supported by the present results.

trans-$[Co(NH_3)_4(NH_2CH_3)OSO_3]ClO_4$ was also investigated in order to measure the effect produced by an increased negative charge on the X ligand. Results in Table 2 indicate that the inductive effect of the *trans*-methyl group upon the cobalt atom is almost completely compensated by the presence of the sulfato ligand, i.e. the $Co_{2p3/2}$ binding energy is the same (within experimental error) of that of $[Co(NH_3)_5Cl](ClO_4)_2$.



In summary, (i) data in Table 2 clearly support the electronic inductive effect of the CH_3 substituent on the *trans* Co–Cl bond and such an effect can explain the modest acceleration observed in the rate of aquation and base hydrolysis reactions of *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{n+}$ complexes; (ii) further methylation of the four *cis*-NH_3 ligands does not produce a proportional effect. In consequence, the inductive effect of the methyl groups is a minor component of the large acceleration observed for the aquation and base hydrolysis of the pentakis(methylamine) complexes. The major contribution is the reduction of the steric strain in the transition state.

Although complexes of the type *trans*-$[Co(NH_3)_4(NH_2CH_3)L]^{n+}$ have been prepared previously with uninegative (L = Cl, Br, ONO_2, NO_2, ONO) [15,28,29], and neutral (L = OH_2, $(CH_3)_2SO$, $(CH_3)_2NCHO$) [30] substituents, no *trans*-$[Co(NH_3)_4(NH_2CH_3)L]^{+}$ ion suitable for our purpose has yet been prepared. We chose to prepare such a complex with L = OSO_3^{2-}. The only *trans*-substituted pentaamminesulfato complex obtained so far was *trans*-

Scheme 1. Realization of the complex cation *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)]^+$.

$[Co(NH_3)_4(^{15}NH_3)(OSO_3)]^+$, which was prepared from *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_2CF_3)]^{2+}$ and concentrated H_2SO_4, but this reaction produces 27% of *cis* isomer [18]. The present method of preparation of *trans*-$[Co(NH_3)_4(NH_2CH_3)(OSO_3)]^+$ follows that of the chloro complex as described earlier [10] and as modified by Balt et al. [31] (Scheme 1).

It produces an isomeric pure compound, as shown by the ^1H NMR data since the spectrum shows a single methyl signal (δ 1.74 ppm versus tetramethylsilane), corresponding to a methyl group *trans* to SO_4^{2-} [15,30].

Received 4 September 1999; accepted 15 February 2000

Abstract

A series of new platinum complexes of the type *cis*-[Pt(PIP)$_2$X] (where PIP = piperidine and X = dichloro, sulfato, oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, 1,1-cyclopropyldicarboxylato (CPDCA) or 1,1-cyclobutyldicarboxylato (CBDCA) ligand) were synthesized and characterized by elemental analysis, IR, and ^{195}Pt nuclear magnetic resonance spectroscopy. The crystal structure of *cis*-[Pt(PIP)$_2$Cl$_2$]·H$_2$O was determined by X-ray crystallography. In this complex platinum has slightly distorted square planar geometry with two adjacent corners being occupied by two nitrogen atoms of piperidine, whereas the remaining two adjacent corners are occupied by two chloride atoms. An intricate network of intermolecular hydrogen bonding holds the crystal lattice together. In these complexes, piperidine acts as non-leaving ligand, whereas the dicarboxylic acids act as leaving groups. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Platinum(II) complexes; Piperidine; Synthesis; Crystal structures

1. Introduction

Platinum complexes are now amongst the most widely used drugs for the treatment of cancers [1,2]. Among them, cisplatin is one of the most effective antitumor agents used to treat various types of human cancers [3,4]. Although it is effective against bladder tumors, testicular tumors, ovarian carcinomas and tumors of the head and neck [5–7], its clinical effectiveness has been limited by significant undesirable side effects such as dose-dependent nephrotoxicity, ototoxicity, neurotoxicity, nausea, vomiting and myelosuppression [8–10]. To overcome these limitations, efforts were directed to develop new platinum-based anticancer drugs with improved clinical effectiveness, broader spectrum of activity and reduced toxicity. Thus, much effort has been devoted to develop second-generation antitumor platinum complexes with greater activity and less toxicity [11,12]. This can be done by altering the pharmacokinetics of cisplatin by replacing the labile chloro ligands with other leaving groups and extending the stable amine ligands to a series of either cyclic or acyclic amines. As a result, the second-generation platinum drug carboplatin came into clinical use [13,14]. Like cisplatin, however, the clinical effectiveness of carboplatin is limited by undesirable side effects like nephrotoxicity, emesis and myelosuppression [15].

In recent years there has been an intense interest in developing third-generation platinum-based anticancer drugs with a broader spectrum of activity, improved clinical effectiveness, lack of cross-resistance to cisplatin and enhanced water solubility [16,17]. In the third-generation platinum complexes, the goal was the creation of an agent that overcomes resistance to cisplatin and carboplatin. As a result, several third-generation platinum complexes having 1,2-DACH as the stable amine ligand such as oxaliplatin [18], JM216 [19], LNDDP [20], and lobaplatin [21] are currently in clinical trials.

We have been developing several complexes of cisplatin analogs with 1,2-DACH and *cis*-1,4-DACH as stable amine ligands, some of which have shown promising antitumor activity [22–26]. In our continuous efforts to design and synthesize new antitumor agents, we report the synthesis and characterization of a series of platinum complexes containing piperidine as non-leaving ligand and dicarboxylate as leaving

PII S0277-5387(00)00348-X

groups. Each complex has been characterized by elemental analysis, IR and ^{195}Pt nuclear magnetic resonance (NMR) spectroscopy. We also report the X-ray crystal structure of *cis*-$[Pt(PIP)_2Cl_2]\cdot H_2O$.

2. Experimental

2.1. Chemicals

K_2PtCl_4 was purchased from Johnson Matthey, Seabrook, NH. Silver nitrate was obtained from Fisher Scientific Co., Houston, TX. Piperidine, silver sulfate, oxalic acid, malonic acid, methylmalonic acid, dimethylmalonic acid, tartronic acid, 1,1-cyclopropanedicarboxylic acid (CPDCA) and 1,1-cyclobutanedicarboxylic acid (CBDCA) were obtained from Aldrich Chemical Co., Milwaukee, WI. All chemicals obtained from commercial sources were used as supplied.

2.2. Physical measurements

Elemental analysis of the complexes was performed by Robertson Laboratory Inc., Madison, NJ. Infrared (IR) spectra in the range of 600–4000 cm^{-1} were recorded in KBr pellets and far-IR spectra in the range of 150–600 cm^{-1} were recorded in polyethylene pellets on a Perkin-Elmer 2000 spectrophotometer. ^{195}Pt NMR spectra were recorded using a Bruker 200/AF spectrometer with a 10 mm tunable probe. The ^{195}Pt spectra were recorded at 43.055 MHz and the shifts were measured relative to an external standard of 2.2 M Na_2PtCl_6 in D_2O at 0.00 ppm.

2.3. Preparation of sodium salts

Oxalic acid (0.900 g, 10 mmol) was dissolved in 100 ml of ethanol and to this a solution of NaOH (0.400 g, 20 mmol) in 20 ml of water was added. The reaction mixture was stirred for 30 min and evaporated to dryness under reduced pressure at room temperature. A colorless sticky material formed. It was dissolved in 20 ml of methanol and evaporated to dryness. To the evaporated material 10 ml of ether was added. This was evaporated to dryness, collected, and dried under vacuum.

The sodium salts of malonic acid, methylmalonic acid, dimethylmalonic acid, tartronic acid, 1,1-cyclopropyldicarboxylic acid and 1,1-cyclobutyldicarboxylic acid were prepared in a manner similar to that mentioned above.

2.4. Preparation of cis-$[Pt(PIP)_2Cl_2]\cdot H_2O$ (**1**)

K_2PtCl_4 (20.76 g, 50 mmol) was dissolved in 250 ml of deionized water and filtered. KI (83.0 g, 0.5 mol) in 100 ml of water was added to it and the reaction mixture was stirred for 10 min. Then, PIP (8.5 g, 100 mmol) was added dropwise to the reaction mixture while stirring, to obtain a yellow precipitate, *cis*-$[Pt(PIP)_2I_2]$. The stirring was continued for a further 30 min and the precipitate was then collected by filtration. This compound was dissolved in dimethylformamide and filtered. To the filtrate excess cold water was added to obtain a bright yellow precipitate, *cis*-$[Pt(PIP)_2I_2]$, which was washed with water, ethanol and acetone and dried in vacuum. *cis*-$[Pt(PIP)_2I_2]$ (12.38 g, 20 mmol) was suspended in 250 ml of an aqueous solution of silver nitrate ($AgNO_3$) (6.72 g, 39.8 mmol). The reaction mixture was stirred for 24 h at room temperature in the dark. The AgI precipitate was filtered off and a solution of NaCl was added dropwise to the filtrate with constant stirring until a yellow precipitate of *cis*-$[Pt(PIP)_2Cl_2]$ formed. The precipitate was filtered and recrystallized from dimethylformamide. The yellow crystals obtained were washed with water, acetone and dried under vacuum. These crystals were used for X-ray crystallography.

2.5. cis-$[Pt(PIP)_2(OSO_3)H_2O]$ (**2**)

To a suspension of *cis*-$[Pt(PIP)_2Cl_2]$ (2.18 g, 5 mmol) in 100 ml of deionized water, an aqueous solution of Ag_2SO_4 (1.49 g, 4.8 mmol) was added. The reaction mixture was then stirred continuously in the dark for 24 h at room temperature. The yellow precipitate of AgCl was filtered off and the filtrate was evaporated to dryness under reduced pressure at 35°C. The pale yellow solid was then dried in vacuum.

2.6. $[Pt(PIP)_2(oxalato)]\cdot H_2O$ (**3**)

cis-$[Pt(PIP)_2(OSO_3)H_2O]$ (0.958 g, 2.0 mmol) was dissolved in 100 ml of water, and an aqueous solution of sodium oxalate (0.270 g, 2.0 mmol) prepared in situ was added. The reaction mixture was then stirred continuously for 24 h at room temperature. The off-white precipitate obtained was filtered and recrystallized from hot water. A white crystalline product finally obtained was isolated by filtration and then dried in vacuum.

2.7. $[Pt(PIP)_2(malonato)]\cdot H_2O$ (**4**)

cis-$[Pt(PIP)_2(OSO_3)H_2O]$ (0.958 g, 2.0 mmol) was dissolved in 100 ml of water, an aqueous solution of sodium malonate (0.300 g, 2.0 mmol) prepared in situ was added. The reaction mixture was then stirred continuously for 24 h at room temperature. A clear solution was formed; it was filtered and evaporated to 10 ml under reduced pressure and kept at room temperature for slow evaporation. The white crystalline compound obtained was isolated by filtration and then dried in vacuum.

2.8. $[Pt(PIP)_2(methylmalonato)]$ (**5**)

cis-$[Pt(PIP)_2(OSO_3)H_2O]$ (0.958 g, 2.0 mmol) was dissolved in 100 ml of water, and an aqueous solution of sodium methylmalonate (0.85 g, 2.00 mmol) prepared in situ was added. The reaction mixture was continuously stirred for

24 h at room temperature. The clear solution obtained was filtered and evaporated to 10 ml under reduced pressure and kept aside in the refrigerator so the compound could precipitate. This precipitate was isolated by filtration and then dried in vacuum.

2.9. [Pt(PIP)$_2$(dimethylmalonato)] (6)

This complex was prepared by a method similar to that for complex **4**, by using sodium dimethylmalonate.

2.10. [Pt(PIP)$_2$(tartronato)]·H$_2$O (7)

This complex was prepared by a method similar to that for complex **5**, by using sodium tartronate.

2.11. [Pt(PIP)$_2$(CPDCA)]·2H$_2$O (8)

This complex was prepared by a method similar to that for complex **4**, by using sodium 1,1-cyclopropyldicarboxylate.

2.12. [Pt(PIP)$_2$(CBDCA)]·H$_2$O (9)

This complex was prepared by a method similar to that for complex **5**, by using sodium 1,1-cyclobutyldicarboxylate.

2.13. Crystallographic measurements

The crystal was encapsulated in a thin shell of epoxy cement and mounted on the tip of a glass fiber. Data were collected with a Bruker AXS automated CCD diffractometer using the Bruker AXS package and using Mo Kα radiation ($\lambda = 0.71069$ Å). The structure was solved by direct methods. All non-hydrogen atoms were refined with anisotropic displacement parameters, and hydrogen atoms were calculated in ideal positions (riding model). Refinement of F^2 was for ALL reflections. The weighted R-factor (R_w) and all goodness of fit (S) values were based on F^2, while conventional R-factors (R) were based on F, with F set to zero for negative F^2. The threshold expression of $F^2 > 2\sigma(F^2)$ was used only for calculating R-factor(gt) etc. and was not relevant to the choice of reflections for refinement. R-factors based on F^2 were statistically about twice as large as those based on F, and R-factors based on all of the data were even larger (Table 1). All software used is contained in the SHELXTL 5.10 [27] program library.

3. Results and discussion

3.1. Synthesis of platinum complexes

The steps involved in the synthesis of platinum complexes are shown in Scheme 1. K_2PtCl_4 was reacted with an excess

Scheme 1.

of KI to give K_2PtI_4 in solution. K_2PtI_4 was then reacted with 2 equiv. of piperidine to precipitate *cis*-$[Pt(PIP)_2I_2]$ (PIP = piperidine). The reaction of *cis*-$[Pt(PIP)_2I_2]$ with $AgNO_3$ led to the formation of *cis*-$[Pt(PIP)_2(H_2O)_2](NO_3)_2$, which was further converted to the corresponding dichloride *cis*-$[Pt(PIP)_2Cl_2]$ by treating it with an excess of NaCl. *cis*-$[Pt(PIP)_2(OSO_3)(H_2O)]$ was prepared by the reaction of *cis*-$[Pt(PIP)_2Cl_2]$ with Ag_2SO_4. Complexes of the type *cis*-$[Pt(PIP)_2X]$ (X = oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, CPDCA or CBDCA ligand) were obtained by the reaction of *cis*-$[Pt(PIP)_2(SO_4)(H_2O)]$ with the sodium salt of the corresponding dicarboxylic acid.

3.2. Characterization of Pt complexes

The complexes were characterized by elemental analysis and IR and ^{195}Pt NMR spectroscopy. The composition of each complex as determined by elemental analysis showed good agreement between the theoretical and actual values. The analytical results are summarized in Table 2. The results of characterization by IR and ^{195}Pt NMR spectroscopy are shown in Table 3.

The IR spectra (Table 3) in general showed a broad absorption between 3153 and 3193 cm^{-1}, due to the N–H stretching frequency of coordinated amino group of piperidine. The carbonyl regions for the dicarboxylate complexes show patterns characteristic of carboxylate ligands bound to the platinum metal ion. The carboxyl groups in complexes **3–9** displayed a signal in the region 1570–1675 cm^{-1} corresponding to the $\nu_a(COO^-)$ band, while the $\nu_s(COO^-)$ band normally appears in the range of 1370–1410 cm^{-1}. Complex **2** showed two intense bands at around 620 and 1120 cm^{-1} indicating the presence of an SO_4 group in these complexes. The Pt–N stretching vibrations in all the complexes were observed in the region 475–580 cm^{-1}, whereas Pt–Cl stretching vibration for complex **1** was observed at 315 cm^{-1}, respectively.

The ^{195}Pt NMR spectra (Table 3) further confirmed the structures of the platinum complexes. Complex **1** showed a signal at −2282 ppm, which is characteristic of the square planar platinum(II) complexes in which the two adjacent corners are occupied by two amino nitrogen and the other two positions by two chlorides. Complex **2** showed a signal at −1805 ppm. The ^{195}Pt NMR spectra of complexes **3–9** showed singlets in the range of −1895 to −1978 ppm. Such

Table 2
Elemental analysis of platinum(II) complexes

Complex	Complex name	Observed (calculated)			Yield (%)
		C (%)	H (%)	N (%)	
1	*cis*-$[Pt(PIP)_2Cl_2]\cdot H_2O$	26.47 (26.43)	5.36 (5.28)	6.02 (6.16)	75
2	*cis*-$[Pt(PIP)_2(OSO_3)(H_2O)]$	25.13 (25.05)	5.03 (5.01)	5.72 (5.84)	80

chemical shifts are characteristic for the square planar platinum(II) complexes having two nitrogen and two oxygen atoms as donor ligands (Fig. 1) [28].

3.3. Crystal structure

Fig. 2 shows a perspective view of the crystal structure of *cis*-[Pt(PIP)$_2$Cl$_2$]·H$_2$O (complex **1**) along with its atom labeling. Bond lengths and bond angles are given in Table 4. Significant hydrogen bond distances and angles are given in Table 5. As the data show, the platinum atom shows the usually square-planar coordination, with the two adjacent corners of the platinum plane occupied by two nitrogen of two piperidine molecules, whereas the remaining two *cis* positions are used to bind to two chloride ions. Both the piperidine rings are in chair configuration.

The coordination around the platinum atom in this complex has slightly distorted square-planar geometry. The distortion is indicated by the N(11)–Pt–Cl(1A) (178.9(2)°) and N(11A)–Pt–Cl(1) (178.9(2)°) angles, which depart from 180°. In addition, although the angle N(11)–Pt–Cl(1A) is 178.9(2)°, there is significant difference between the value of the N(11)–Pt–Cl(1) angle, 91.49(19)°, and that of the N(11)–Pt–N(11A) angle, 88.0(4)°.

The average Pt–Cl bond length of 2.315(2) Å is consistent with those found in structurally related complexes, such as

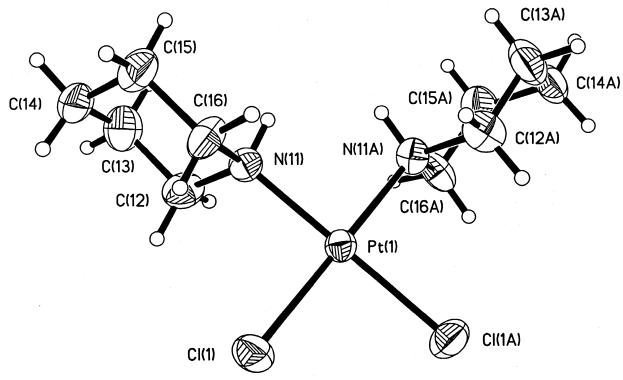

Fig. 2. ORTEP representation of the structure of a molecule of *cis*-[Pt(PIP)$_2$Cl$_2$]·H$_2$O with atom numbering scheme. The thermal ellipsoids are 50% equiprobability envelopes, with hydrogens as spheres of arbitrary diameter.

Table 5
Significant hydrogen bond distances (Å) and angles (°) for *cis*-[Pt(PIP)$_2$Cl$_2$]·H$_2$O

O(1)···Cl(1)	3.302
O(1)···Cl(1B)	3.302
O(1)···N(11)	2.999
O(1)···N(11D)	2.999
Cl(1)···O(1)···Cl(1B)	107.5
Cl(1B)···O(1)···N(11D)	129.0
Cl(1)···O(1)···N(11E)	114.3
N(11D)···O(1)···N(11E)	56.7

cis-[Pt(py)$_2$Cl$_2$] (2.296(5) Å) [29], *cis*-[Pt(pyrazole)$_2$-Cl$_2$] (2.28(3) Å) [30], *cis*-[Pt(ethyleneimine)$_2$Cl$_2$] (2.30(2) Å) [31], *cis*-[Pt(cyclohexylamine)$_2$Cl$_2$] (2.32(4) Å) [32], and *cis*-[Pt(NH$_3$)(C$_6$H$_{11}$NH$_2$)Cl$_2$] (2.30(3) Å) [33]. The average Pt–N bond length of 2.05(6) Å is comparable with the Pt–N(sp^2) average value of (2.023(12) Å) derived for *cis*-PtL$_2$Cl$_2$ compounds [34]. The average Pt–N bond distance observed in this complex is also in agreement with the other structurally related complexes, such as *cis*-[Pt(py)$_2$Cl$_2$] (2.02(1) Å) [29], *cis*-[Pt(cyclohexylamine)$_2$Cl$_2$] (2.06(1) Å) [32] and *cis*-[Pt(NH$_3$)(C$_6$H$_{11}$NH$_2$)Cl$_2$] (2.04(10) Å) [33]. The N–Pt–N and Cl–Pt–Cl bond angles are contracted and are observed as 88.0 and 89.04°, respectively, which are compensated by the expansion of N–Pt–Cl bond angles to 91.49°.

Fig. 3 shows a view of the packing diagram including hydrogen bonds to the water molecule indicated by dashed

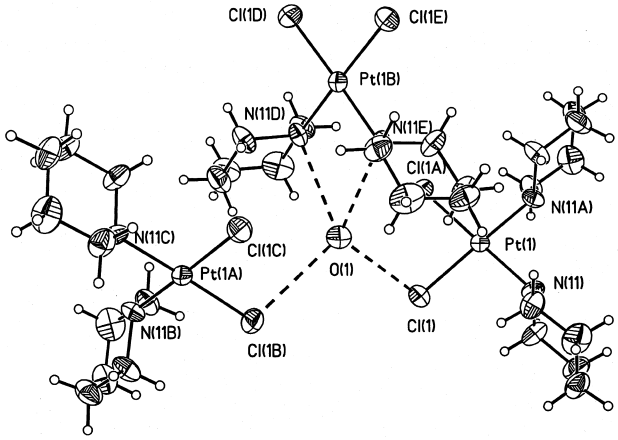

Fig. 3. A view of the packing diagram with hydrogen bonds to the water molecule indicated by dashed lines.

lines. There is an intricate network of intermolecular hydrogen bonding that holds the crystal lattice together. The interesting geometric features in the hydrogen bonding are that there are three molecules surrounding a water molecule. All the three independent molecules have virtually identical configuration. The nitrogen atoms N(11D) and N(11E) of one molecule and chloride atoms Cl(1) and Cl(1B) of the other two molecules are hydrogen bonded to the water molecule O(1). This molecular packing is clearly affected by the intermolecular hydrogen bonding occurring between O(1)···Cl(1) 3.302 Å, O(1)···Cl(1B) 3.302 Å, O(1)···N(11) 2.999 Å and O(1)···N(11D) 2.999 Å. These distances are somewhat longer compared with the known N–H···O hydrogen bond distances [35]. The angles due to hydrogen bonding are observed as Cl(1B)···O(1)···Cl(1) 107.5°, Cl(1B)···O(1)···N(11D) 129.0°, Cl(1)···O(1)···N(11E) 114.3° and N···O(1)···N 56.7°, respectively.

In summary, we have synthesized and characterized a series of new cisplatin analogs containing piperidine as nonleaving ligands and oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, CPDCA, and CBDCA as leaving groups. The X-ray crystal structure of *cis*-[$Pt(PIP)_2Cl_2$]·H_2O was determined by X-ray crystallography.

Supplementary data

Full lists of bond lengths and bond angles, atomic coordinates and equivalent isotropic displacement parameters, anisotropic displacement parameters, hydrogen coordinates and isotropic displacement parameters, and observed and calculated structure factors have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Supplementary material are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number CCDC 140100. Any request to the CCDC for this material should quote the full literature citation.

Received 11 November 1999; accepted 15 February 2000

Abstract

A series of new platinum complexes of the type [Pt(3-mepip)$_2$X] (where 3-mepip = 3-methylpiperidine, and X = dichloro, sulfato, oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, 1,1-cyclopropanedicarboxylato (CPDCA) or 1,1-cyclobutanedicarboxylato (CBDCA) ligand) were synthesized and characterized by elemental analysis, IR spectroscopy and ^{195}Pt nuclear magnetic resonance spectroscopy. The crystal structure of [Pt(3-mepip)$_2$(malonato)]·0.79H_2O was determined by single crystal X-ray diffraction. In this complex platinum has slightly distorted square planar geometry with two adjacent corners being occupied by two nitrogens of 3-methylpiperidine, whereas the remaining two adjacent corners are occupied by two oxygen atoms of the malonato group. An intricate network of intermolecular hydrogen bonds holds the crystal lattice together. In the other complexes, 3-mepip acts as non-leaving ligands, whereas the carboxylato ligands act as leaving groups. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

Cisplatin is one of the most active and effectively used antitumor agents in the treatment of various types of human cancers today [1,2], especially because of its activity against testicular, ovarian, head and neck, cervical and bladder cancers [3–5]. However, the use of cisplatin has been restricted principally because of its severe dose toxicities such as nephrotoxicity, ototoxicity, neurotoxicity, nausea, vomiting and myelosuppression [6–8]. This limitation has stimulated the synthesis and evaluation of new platinum agents with reduced toxicity and better antitumor activity [9–12]. Therefore, researchers in many laboratories around the world are actively engaged in synthesizing and studying cisplatin and its analogs, hoping to discover a better antitumor drug, with less toxicity and better activity. Consequently new platinum drugs with equal or greater antitumor activity but less toxicity have been developed by modifying the pharmacokinectics of cisplatin by replacing the labile chloro ligands with other leaving groups and extending the stable amine ligands to a series of cyclic or acyclic amines. Efforts over the past two decades have resulted in clinical trials of several platinum drugs. As a result, the second-generation platinum drug carboplatin came into clinical use [13,14]. Like cisplatin, however the clinical effectiveness of carboplatin is limited by acquired drug resistance.

In recent years, there has been an intense interest in developing third-generation platinum-based anticancer drugs with a broader spectrum of activity, improved clinical effectiveness, lack of cross-resistance to cisplatin and carboplatin [15,16]. Thus, several platinum complexes that have 1,2-diaminocyclohexane (1,2-DACH) as a carrier ligand and that retain activity against cisplatin-resistant tumors have also been developed. A number of platinum drugs such as oxaliplatin [17], JM216 [18] and LNDDP [19], which have 1,2-DACH as a carrier ligand and chloride or carboxylate as leaving groups, are now in clinical trials.

We have reported several complexes of cisplatin analogs with various isomers of 1,2-DACH as a stable amine ligand, some of which have shown promising antitumor activity [20–24]. We have also carried out work with *cis*-1,4-DACH (1,4-diaminocyclohexane) as a carrier amine group, which has

PII S0277-5387(00)00351-X

shown promising antitumor activity [25,26]. The compounds with *cis*-1,4-DACH as the carrier ligand are presently under investigation. In our continuous efforts to design new anticancer platinum drugs, we have synthesized a series of new platinum(II) complexes using 3-methylpiperidine as the carrier ligand and carboxylato ligands as leaving groups. Each complex has been characterized by elemental analysis, IR spectroscopy, and ^{195}Pt nuclear magnetic resonance (NMR) spectroscopy. The crystal structure of [Pt(3-mepip)$_2$(malonato)]·0.79H_2O was determined by single crystal X-ray diffraction.

2. Experimental

2.1. Chemicals

K_2PtCl_4 was purchased from Johnson Matthey, Seabrook, NH. Silver nitrate was obtained from Fisher Scientific Co., Houston, TX. 3-Methylpiperidine (3-mepip), silver sulfate, oxalic acid, malonic acid, methylmalonic acid, dimethylmalonic acid, tartronic acid, 1,1-cyclopropanedicarboxylic acid (CPDCA) and 1,1-cyclobutanedicarboxylic acid (CBDCA) were obtained from Aldrich Chemical Co., Milwaukee, WI. All chemicals obtained from commercial sources were used as supplied.

2.2. Physical measurements

Elemental analyses of the complexes were performed by Robertson Laboratory Inc., Madison, NJ. Infrared spectra in the range of 600–4000 cm^{-1} were recorded on KBr pellets, and far-IR spectra in the range of 150–600 cm^{-1} were recorded on polyethylene pellets on a Perkin-Elmer 2000 spectrophotometer. ^{195}Pt NMR spectra were recorded using a Bruker 200/AF spectrometer with a 10 mm tunable probe. The ^{195}Pt spectra were recorded at 43.055 MHz, and the shifts were measured relative to an external standard of 2.2 M Na_2PtCl_6 in D_2O at 0.00 ppm.

2.3. Preparation of cis-[Pt(3-mepip)$_2$Cl$_2$] (*1*)

K_2PtCl_4 (20.76 g, 50 mmol) was dissolved in 250 ml of deionized water and filtered. Then KI (83.0 g, 0.5 mol) in 100 ml of water was added to it and the reaction mixture was stirred for 10 min. To this solution, 3-methylpiperidine (9.9 g, 100 mmol) was added slowly, while stirring, to give a yellow precipitate, *cis*-[Pt(3-mepip)$_2$I$_2$], and the precipitate was collected by filtration. This compound was dissolved in dimethylformamide and filtered. To the filtrate excess cold water was added to give a bright yellow precipitate, *cis*-[Pt(3-mepip)$_2$I$_2$], which was washed with water, ethanol, acetone and ether and dried in vacuum. *cis*-[Pt(3-mepip)$_2$I$_2$] (12.94 g, 20 mmol) was suspended in 250 ml of aqueous solution of silver nitrate (6.72 g, 39.8 mmol). The reaction mixture was stirred for 24 h at room temperature in the absence of light. The AgI precipitate was filtered off, and a solution of NaCl was added dropwise to the filtrate with constant stirring until a yellow precipitate of *cis*-[Pt(3-mepip)$_2$Cl$_2$] formed. The precipitate was filtered and recrystallized from dimethylformamide. The yellow crystals obtained were washed with water and acetone and dried under vacuum.

2.4. cis-[Pt(3-mepip)$_2$(OSO$_3$)H_2O] (*2*)

To a suspension of *cis*-[Pt(3-mepip)$_2$Cl$_2$] (2.32 g, 5 mmol) in 100 ml of deionized water, an aqueous solution of Ag_2SO_4 (1.49 g, 4.8 mmol) was added. The reaction mixture was then continuously stirred in the dark for 24 h at room temperature. The AgCl precipitate was filtered off, and the filtrate was evaporated to dryness under reduced pressure at 35°C. The pale yellow solid obtained was then dried in vacuum.

2.5. [Pt(3-mepip)$_2$(oxalato)]·H_2O (*3*)

cis-[Pt(3-mepip)$_2$(OSO$_3$)H_2O] (1.01 g, 2.0 mmol) was dissolved in 100 ml of water, and an aqueous solution of sodium oxalate (0.270 g, 2.0 mmol) prepared in situ was added to it. The reaction mixture was then continuously stirred for 24 h at room temperature. The off-white precipitate obtained was filtered and recrystallized from methanol. The white crystalline product finally obtained was isolated by filtration and then dried in vacuum.

2.6. [Pt(3-mepip)$_2$(tartronato)] (*4*), [Pt(3-mepip)$_2$-(CBDCA)] (*5*)

Complexes **4** and **5** were prepared by a method similar to that used for complex **3**, with corresponding sodium salts of tartronic acid and 1,1-cyclobutanedicarboxylic acid (CBDCA), respectively.

2.7. [Pt(3-mepip)$_2$(malonato)]·0.79H_2O (*6*)

cis-[Pt(3-mepip)$_2$(OSO$_3$)H_2O] (1.01 g, 2.0 mmol) was dissolved in 100 ml of water, and an aqueous solution of sodium malonate (0.300 g, 2.0 mmol) prepared in situ was added to it. The reaction mixture was then continuously stirred for 24 h at room temperature. A clear solution obtained was filtered and evaporated to 10 ml under reduced pressure and kept at room temperature for slow evaporation. The white crystalline compound obtained was then isolated by filtration and then dried in vacuum.

The compound (100 mg) was then dissolved in 100 ml of methanol, after which the volume of the solution was reduced to 10 ml and kept aside for slow evaporation at room temperature. Within 3–4 days white crystals of [Pt(3-mepip)$_2$(malonato)]·0.79H_2O were separated from the solution, and were used for X-ray crystallography.

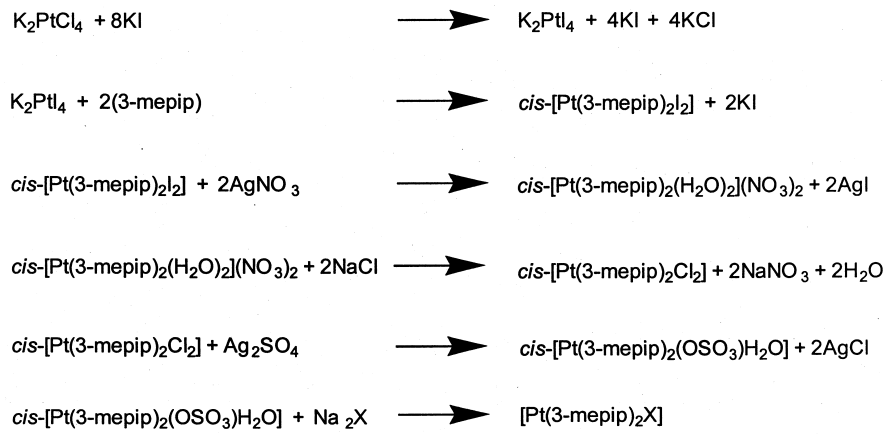
Table 1
Crystallographic data and structure refinement parameters for [Pt(3-methylpiperidine)$_2$(malonato)]·0.79H$_2$O

Empirical formula	$C_{15}H_{29.58}N_2O_{4.79}Pt$
Formula weight	509.72
Temperature (K)	298 K
Wavelength (Å)	0.71073
Crystal system	monoclinic
Space group	$C2/c$
Unit cell dimensions	
a (Å)	24.588(5)
b (Å)	15.137(3)
c (Å)	11.459(2)
α (°)	90.00
β (°)	111.07(3)
γ (°)	90.00
Volume (Å^3)	3979.9(14)
Z	8
Density (calculated) (Mg m^{-3})	1.701
Absorption coefficient	7.073
F(000) (mm^{-1})	1999
Crystal size (mm)	0.45×0.25×0.15
θ Range for data collection (°)	2.24–27.49
Index ranges	$0 \le h \le 26$, $0 \le k \le 19$, $-14 \le l \le 13$
Reflections collected	2899
Independent reflections	2798 (R_{int} = 0.0204)
Absorption correction	semi-empirical from ψ-scans
Max. and min. transmission	1.0000 and 0.6872
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	2798/0/207
Goodness-of-fit on F^2	1.037
Final R indices ($I > 2\sigma(I)$) [a]	R_1 = 0.0355, wR_2 = 0.0933
R indices (all data) [a]	R_1 = 0.0719, wR_2 = 0.1069
Largest difference peak and hole (e Å^{-3})	1.665 and −0.636

[a] $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$. $R_w = [\sum w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]^{1/2}$. $w = [\sigma^2(F_o^2) + (aP)^2 + bP]^{-1}$. $P = (F_o^2 + 2F_c^2)/3$.

2.8. [Pt(3-mepip)$_2$(methylmalonato)] (7), [Pt(3-mepip)$_2$-(dimethylmalonato)] (8), [Pt(3-mepip)$_2$(CPDCA)] (9)

Complexes **7**, **8** and **9** were prepared by a method similar to that used for complex **6**, with corresponding sodium salts of methylmalonic acid, dimethylmalonic acid, or 1,1-cyclopropanedicarboxylic acid (CPDCA) respectively, except that the compounds were recrystallized from acetone.



2.9. Crystallographic measurements

The crystal was encapsulated in a thin shell of epoxy cement and mounted on the tip of a glass fiber. Data were collected with a Rigaku AFC5-S automated four-circle diffractometer using the TEXSAN 5.0 software package [27] and were corrected for Lorentz/polarization effects and absorption (ψ-scans). Data collection and refinement parameters are summarized in Table 1. Scattering factors were taken from the literature [28]. The structure was solved using the direct methods routine of SHELXTL-PLUS software package (PC version) [29]. Refinement of F^2 for all reflections, except those with very negative F^2 values, was performed with a personal computer loaded with SHELXL-93 software [30]. Weighted R factors (R_W) and all goodness of fit (S) values were based on F^2, while conventional R factors (R) were based on F with F set to zero for negative F^2. The observed criterion of F^2 was used only for calculating R factors observed and was not relevant to the choice of reflections for refinement. R factors based on F^2 were statistically about twice as large as those based on F, and R factors based on all of the data were even larger. The weighing factor $w = [\sigma^2(F_o^2) + (xP)^2 + yP]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$, was refined for x and y. H-atom positions were refined using a riding model. The water molecules were refined to partial occupancy.

3. Results and discussion

3.1. Synthesis of platinum complexes

The steps involved in the synthesis of platinum complexes are shown in Scheme 1. *cis*-[Pt(3-mepip)$_2$Cl$_2$] (3-mepip = 3-methylpiperidine) was prepared according to Dhara's method [31]. This method was adopted because it is rapid, easy, and gives much higher yield compared to when K_2PtCl_4 is treated directly with 3-methylpiperidine. Reaction of K_2PtCl_4 with an excess of KI produced K_2PtI_4 in solution. K_2PtI_4 was then reacted with 2 equiv. of 3-methylpiperidine to precipitate *cis*-[Pt(3-mepip)$_2$I$_2$]. The reaction of *cis*-

Scheme 1.

[Pt(3-mepip)$_2$I$_2$] with $AgNO_3$ led to the formation of *cis*-[Pt(3-mepip)$_2$(H$_2$O)](NO$_3$)$_2$, which was further converted to *cis*-[Pt(3-mepip)$_2$Cl$_2$] with the treatment of excess NaCl. *cis*-[Pt(3-mepip)$_2$Cl$_2$] was then treated with Ag_2SO_4 to form *cis*-[Pt(3-mepip)$_2$(OSO$_3$)H$_2$O]. Complexes of the type [Pt(3-mepip)$_2$X] (X = oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, CPDCA or CBDCA ligand) were obtained by the reaction of *cis*-[Pt(3-mepip)$_2$-(OSO$_3$)H$_2$O] with the sodium salts of the corresponding dicarboxylic acid. These complexes are soluble in water.

3.2. Characterization of Pt complexes

The complexes were characterized by elemental analysis, IR and ^{195}Pt NMR spectroscopy. The composition of each complex as determined by elemental analysis showed good agreement between the theoretical and actual values. The analytical results are summarized in Table 2. The results of characterization by IR and ^{195}Pt NMR spectroscopy are shown in Table 3. The IR spectra in general showed a broad absorption between 3155 and 3187 cm^{-1}, due to the coordinated NH group of 3-methylpiperidine. The carbonyl regions for the dicarboxylate complexes displayed patterns characteristic of carboxylate ligands bound to the platinum metal ion. The carboxyl group in complexes **3**–**9** displayed a signal in the region 1620–1695 cm^{-1} corresponding to the $\nu_a(COO^-)$ band, while the $\nu_s(COO^-)$ band normally appears in the range of 1350–1450 cm^{-1} [32]. Complex **2** showed two intense bands at around 620 and 1120 cm^{-1}, indicating the presence of an SO_4 group in this complex [25]. The Pt–N stretching vibrations in all the complexes were observed in the range of 505–560 cm^{-1}, whereas the Pt–O stretching vibrations in complexes **2**–**9** were observed in the range of 420–470 cm^{-1}, respectively [33]. The Pt–Cl stretching vibration for complex **1** was observed at 315 cm^{-1}.

The ^{195}Pt NMR spectra further confirmed the structures of these complexes. Complex **1** showed a signal at −2275 ppm, which is characteristic of the square planar platinum(II) complexes where the two adjacent corners are occupied by two amino nitrogens and the other two positions by two chlorides. Two peaks were observed at −1758 and −1799 ppm in the spectrum of complex **2** [25]. The ^{195}Pt NMR spectra of complexes **3**–**9** showed singlets in the range of −1880 to −1970 ppm (Fig. 1). Such chemical shifts are characteristic for the square planar platinum(II) complexes having two

Table 2
Elemental analysis of platinum(II) complexes

Complex	Complex name	Observed (calculated)			Yield (%)
		C (%)	H (%)	N (%)

nitrogen and two oxygen atoms as donor ligands [34] (Fig. 2).

3.3. Crystal structure of [Pt(3-mepip)$_2$(malonato)]·0.79H$_2$O

The crystal structure and atomic numbering scheme of [Pt(3-mepip)$_2$(malonato)]·0.79H$_2$O are shown in Fig. 3. Selected bond lengths and bond angles are given in Table 4. Atomic coordinates and equivalent isotropic displacement parameters are given in Table 5. As the data show, the coordination around the platinum atom in this complex has slightly distorted square planar geometry. The distortion appears to be caused by limitation in the bite distances of the chelating ligand. The two adjacent corners of the platinum planes are occupied by two nitrogens of 3-methylpiperidine, whereas the remaining two *cis* positions are used to bind to two oxygen atoms of the malonato group. All the average Pt–N and Pt–O bond lengths are in the range normally observed for other platinum(II) complexes. The average Pt–N bond length of 2.04 Å is consistent with those found in other platinum compounds. For example, this length is 2.038 Å in [Pt(*trans-dl*-1,2-diaminocyclohexane)(*N*-methyliminodiacetato)] [35], 2.04 Å in [Pt(1*R*,2*R*-diaminocyclohexane)-(malonato)], 2.05 Å in [Pt(1*R*,2*R*-diaminocyclohexane)-(oxalato)] [36] and 2.01 Å in [Pt(*cis*-diamine)(1,1-cyclobutanedicarboxylato)] [37]. The average Pt–O bond length of 2.018 Å is also consistent with the average Pt–O bond lengths observed in [Pt(1,4-diaminocyclohexane)-(malonato)] (2.02 Å) [38], [Pt(*trans*-1,2-diaminocyclohexane)bis(acetato)] (2.01 Å) and [Pt(*cis*-diamine)-(1,1-cyclobutanedicarboxylato)] (2.029 Å) [39]. Malonato forms a six-membered chelating ring with the platinum atom. The O–Pt–O bond angle of 91.2° within the chelating ring is normal compared with the other platinum(II) carboxylato complexes for which the angles were close to 90°, for example

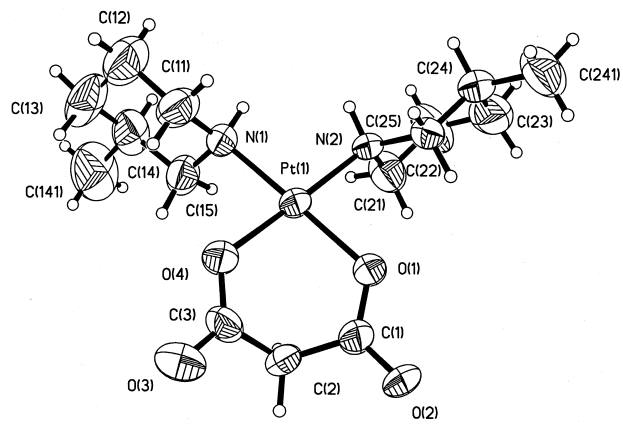

Fig. 3. ORTEP representation of the structure of the [Pt(3-methylpiperidine)$_2$(malonato)]·0.79H$_2$O molecule with atom numbering scheme. The thermal ellipsoids are 50% equiprobability envelopes, with hydrogens as spheres of arbitrary diameter.

[a] U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} tensor.

90.3° in [Pt(1,2-diaminocyclohexane)(malonato)] [36] and 90.0° in [Pt(*cis*-1,4-diaminocyclohexane)(malonato)] [38]. N–Pt–O bond angles are contracted, which is compensated by the expansion of N–Pt–N and O–Pt–O bond angles. The N–Pt–N and the average O–Pt–O bond angles are observed as 92.8 and 88.0°, respectively. Both piperidine rings are in chair configuration.

Fig. 4 shows a stereoscopic view of the molecular packing in which the molecules in this crystal are held together by a system of hydrogen bonding. This molecular packing is clearly affected by the intramolecular hydrogen bonds occuring between N(2) of 3-methylpiperidine and O(1) of malonato, and also with N(1) of 3-methylpiperidine and O(2) of malonato, N(2)–H···O(1) 2.842 Å, N(1)–H···O(2) 2.897 Å, N(2)–H···O(2) 2.874 Å. These distances compare with known N–H···O hydrogen bond distances [40]. The lattice water molecules appear to interact with themselves and with the oxygen atoms of the malonato ligand at somewhat longer distances: O(100)–H···O(3) 2.921 Å, O(100)–H···O(4) 3.373 Å, O(200)–H···O(3) 2.873 Å, O(100)–H···O(100) 3.191 and 3.434 Å.

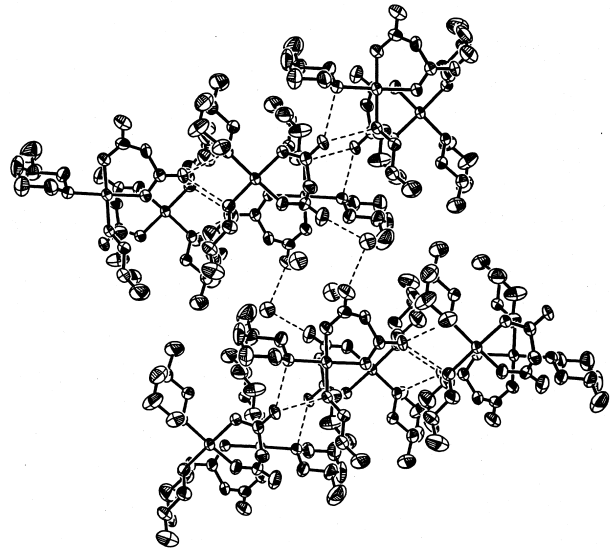

Fig. 4. A stereoscopic view of the molecular packing. Hydrogen bonds are indicated by dashed lines.

In summary, we have synthesized and characterized a series of new cisplatin analogs containing 3-methylpiperidine as non-leaving ligands and oxalato, malonato, methylmalonato, dimethylmalonato, tartronato, CPDCA, and CBDCA as leaving groups. The X-ray crystal structure of [Pt(3-mepip)$_2$(malonato)]·0.79H$_2$O was determined by X-ray crystallography. Since these complexes are highly water soluble, biological studies may reveal good antitumor activity; these are in progress and will be published in a separate paper.

Supplementary data

Full lists of bond lengths and bond angles, anisotropic displacement parameters, hydrogen coordinates and isotropic displacement parameters, and observed and calculated structure factors have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Supplementary material is available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number 136035. Any request to the CCDC for this material should quote the full literature citation.

Abstract

Hg(II), Cd(II) and Zn(II) complexes with the ligands sulfadimethoxine, sulfamethoxypyridazine, sulfadiazine, sulfamerazine, sulfadimidine and sulfamethoxazole have been prepared and characterised by spectral data. ^{1}H and ^{13}C NMR have been used to interpret the structural characteristics of the complexes in solution. The X-ray crystal structures of [Hg(sulfamethoxypyridazinato)$_2$] (**2a**), [Cd(sulfadimidinato)$_2$(H$_2$O)]·2H$_2$O (**4b**) and [Zn(sulfamethoxazolato)$_2$(py)$_2$(H$_2$O)$_2$] (**6d**) have been determined. In complex **2a** the Hg(II) ion lies on an inversion centre and exhibits linear coordination by two sulfonamidic nitrogen atoms [Hg–N(1) = 2.071(4) Å] of the two deprotonated sulfamethoxypyridazinato ligands. The polymeric Cd(II) complex (**4b**) exhibits a high distorted-octahedral geometry, involving the sulfonamidic nitrogen [Cd–N(1) = 2.328(6); Cd–N(1′) = 2.326(6) Å] and the heterocyclic N(3)/N(2′) [Cd–N(3) = 2.307(6) Å; Cd–N(2′) = 2.426(6) Å] of two bidentate sulfadimidine ligands, the terminal amino N(4′b) [Cd–N(4′b) = 2.379(7) Å] of a third sulfadimidine which is bonded to an adjacent Cd(II), and the O(3) atom of a coordinated water molecule [Cd–O(3) = 2.334(6) Å]. In complex **6d** the geometry around the Zn(II) ion can be described as a slightly distorted compressed octahedron. Two pyridine [Zn–N(16) = 2.1841(17) Å] and two isoxazole N atoms [Zn–N(2) = 2.1736(15) Å] are located in the equatorial plane and two oxygen atoms of two water molecules [Zn–O(4) = 2.0984(14) Å] are placed in the apical positions. IR and NMR spectral studies suggest a similar behaviour of the Cd(II) and Zn(II) complexes, both in solid state and solution, and different to the corresponding Hg(II) complexes. Thus ^{1}H and ^{13}C NMR spectra, in DMSO-d_6, of Cd(II) and Zn(II) compounds show coordination mainly through the heterocyclic nitrogen while the corresponding Hg(II) derivatives seem to be coordinated through the sulfonamidic nitrogen. ©2000 Elsevier Science Ltd All rights reserved.

1. Introduction

The synthesis of metal sulfanilamide compounds has received much attention due to the fact that sulfanilamides were the first effective chemotherapeutic agents to be employed for the prevention and cure of bacterial infections in humans (see Scheme 1). Although sulfamides present bacteriostatic activity [1–3] related to the inhibition of the bacterial enzyme DHPS (dihydropteroate synthetase) which catalyses the incorporation of *p*-aminobenzoic acid into the precursor of folic acid, 2-amino-4-hydroxy-6-hydroxymethyl dihydropteridine pyrophosphate (see Scheme 2) [4–7], the pharmacological activity of these types of molecules is often enhanced by complexation with metal ions [8,9]. Thus, rapid healing of skin disorders has been promoted by silver–sulfadiazine complex [10,11] in human topical burn therapy, and zinc–sulfadiazine complex [12,13] in the prevention of bacterial infection in burned animals, where the effectiveness of burn treatment seems to depend not only on the presence

Scheme 1.

of a metal ion [slow release of the Ag(I) or Zn(II)], but also crucially on the nature of the material to which the metal ion is bound [12].

Morevoer, although interesting structural results have been described in the literature (sulfadiazine: Ag(I) [10,11,14], Zn(II) [12,13], Cu(II) [15] and Hg(II) [16]; sulfathiazole: Zn(II) [9], Cu(II) [17–20]; sulfadimetoxine: Co(II) [21]; sulfacetamide: Cu(II) [22]), no general studies related to the manner with which metal–sulfonamide interactions occur have been described. For this reason, in the present paper, we report on the synthesis and spectroscopic characterisation of the Zn(II), Cd(II) and Hg(II) complexes with six sulfonamides [sulfadimethoxine (**1**), sulfamethoxypyridazine (**2**), sulfadiazine (**3**), sulfadimidine (sulfamethazine) (**4**), sulfamerazine (**5**) and sulfamethoxazole (**6**)] and the X-ray structure determination of [Hg(sulfamethoxypyridazinato)$_2$] (**2a**), [Cd(sulfadimidinato)$_2$(H$_2$O)]·2H$_2$O (**4b**) and [Zn(sulfamethoxazolato)$_2$(py)$_2$(H$_2$O)$_2$] (**6d**) in order to show the general manner with which interactions between d^{10} metal ions and these ligands take place.

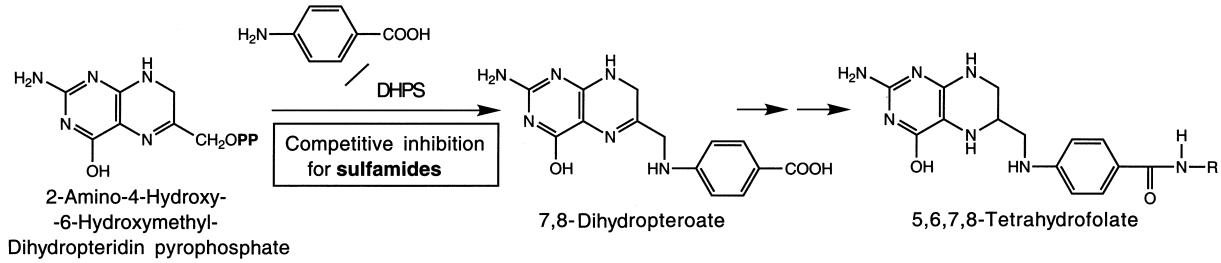
2. Experimental

2.1. Analysis and physical measurements

Satisfactory C, H, N and S analyses were obtained for all compounds and carried out using a Carlo-Erba Model 1106 microanalyser. The IR spectra in the solid state (KBr pellets) were recorded on a PE 683 spectrometer with a PE 1600 IR data station and on a Perkin-Elmer 843; electronic spectra were recorded on PE 552 and Shimadzu UV 2101PC spectrophotometers. 1D and 2D ^{1}H and ^{13}C NMR spectra were carried out on a Bruker AMX 300. Proton and carbon chemical shifts in DMSO-d_6 were referenced to DMSO-d_6 (^{1}H NMR, $\delta_{(DMSO)} = 2.60$ ppm; ^{13}C NMR, $\delta_{(DMSO)} = 43.5$ ppm). Solid state CP/MAS ^{13}C spectrum was recorded on a Varian Unity 300 spectrometer. Unequivocal C–H assignment was performed by 2D NMR experiments [HMQC [23] and HMBC [24]] or by comparison with spectra of related products. The 2D spectra were processed using commercial Bruker software and experimental characteristics are presented below.

2.1.1. ^{1}H-detected heteronuclear multiple quantum coherence spectroscopy (HMQC)

The one-bond ^{1}H–^{13}C shift correlation spectra resulted from a 502×2048 data matrix size with 48 scans (preceded by 16 dummy scans) per t_1 value. Predelay was 1.0 s, and a 10.3-μs 90° ^{13}C pulse width was used. A sine bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.



2.1.2. ^{1}H-detected multiple-bond heteronuclear multiple quantum coherence spectroscopy (HMBC)

The multiple-bond ^{1}H–^{13}C shift correlation spectra resulted from a 246×2048 matrix data size with 128 scans (preceded by 8 or 16 dummy scans) per t_1 value. Predelay was 1.0 s, and a 10.3-μs 90° ^{13}C pulse width were used. The delay between the first and the second 90° ^{13}C pulses was 75 ms. A sine bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

Sulfamides were used as received from Roig Farma. Zn(II), Cd(II) and Hg(II) acetates were supplied by Aldrich and used without purification.

2.2. Crystallographic studies

X-ray data from compounds **2a** and **4b** were collected on an Enraf-Nonius CAD4 diffractometer with Mo Kα radiation (0.71069 Å). The cell parameters and space group were determined from a least-square refinement of 25 reflections

Scheme 2.

randomly searched. Data collection employed an ω–2θ scan technique. Three reflections were measured every hour as intensity controls; an intensity decay of 1.5% (**2a**) and 7.7% (**4b**) was observed and corrected. The MOLEN [25] package was used for applying Lorentz polarization correction and ψ-scan empirical absorption corrections. The structures were solved by direct methods using the SHELXS 86 program [26] and refined by least-squares using the SHELXL 93 program [27]. Hydrogen atoms were placed in calculated positions, except for those corresponding to water molecules (for **4b**), which were located in Fourier-difference maps, and refined with an isotropic thermal factor constrained to 1.2 times U_{eq} of their bonded atom [1.5 (**2a**) or 1.3 (**4b**) times in the case of methyl groups].

X-ray data from compound **6d** were collected on an Enraf-Nonius CAD4 automatic diffractometer [28] with Cu Kα radiation ($\lambda = 1.54184$ Å). Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections. Data collection employed an ω-scan technique and were corrected for Lorentz and polarisation effects [29]. A semi-empirical absorption correction (Ψ scan) was made [30]. The structure was solved by direct methods [26] which revealed the position of all non-hydrogen atoms and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [31]. The hydrogen atoms were located from difference maps and refined isotropically. Atomic scattering factors were from International Tables for X-Ray Crystallography [32]. Molecular graphics were from ZORTEP [33].

Details of the data collection and processing are summarised in Table 1.

2.3. Preparation of Hg(II)–sulfamidato complexes

2.3.1. General procedure

Hg(II) acetate (1 mmol) in methanol (20 ml) was added dropwise to a stirred solution of the corresponding sulfamide (2 mmol) in methanol (20 ml). A white precipitate begins to form and the reaction is stirred during 18 h at room temperature. The precipitate is filtered off and air dried. Crystallisation in different mixtures of NH_4OH–H_2O or DMSO–MeOH yields white crystals.

2.3.2. Hg(sulfadimethoxynato)$_2$ (**1a**)

White solid (87% yield). Found: C, 35.00; H, 3.09; N, 13.52; S, 7.89. Calc. for $C_{24}H_{26}N_8S_2O_8Hg$: C, 35.18; H, 3.17; N, 13.68; S, 7.82%. Selected IR data (cm^{-1}): 911m, 946w, 962vw, 984w, 1009m, 1090s, 1113s, 1141vs, 1211vs, 1294s, 1362vs, 1419s, 1575vs, 1635s, 3244m, 3367s, 3454m. UV (DMSO): λ 274 nm (ε 4.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 0.7. ^{1}H NMR (DMSO-d_6): δ 7.59d [2H, H(2b)/H(6b), J = 8.2 Hz], 6.57d [2H, H(3b)/H(5b), J = 8.2 Hz], 5.83s [1H, H(5a)], 5.80bs (2H, NH_2), 3.84s [3H, $OCH_3(1)$], 3.79s [3H, $OCH_3(2)$]. ^{13}C NMR (DMSO-d_6): δ 176.2 [C(6a)], 168.0 [C(2a)], 165.8 [C(4a)], 157.2 [C(4b)], 133.7 [C(2b)/C(6b)], 128.3 [C(1b)], 116.8 [C(3b)/C(5b)], 88.6 [C(5a)], 58.8 [$OCH_3(1)$], 58.0 [$OCH_3(2)$].

2.3.3. Hg(sulfamethoxypyridazinato)$_2$ (**2a**)

White solid (94% yield). White crystals in NH_4OH–H_2O (1:1). Found: C, 34.71; H, 2.88; N, 14.70; S, 8.33. Calc. for $C_{22}H_{22}N_8S_2O_6Hg$: C, 34.80; H, 2.90; N, 14.76; S, 8.44%. Selected IR data (cm^{-1}): 952s, 1016s, 1041m, 1091s, 1125m, 1153s, 1272vs, 1318m, 1351w, 1402vs, 1460s, 1503m, 1548w, 1602s, 3209m, 3363m. UV (DMSO): λ 273 nm (ε 3.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 3.3. ^{1}H NMR (DMSO-d_6): δ 7.82d [2H, H(2b)/H(6b), J = 8.6 Hz], 7.62d [1H, H(4a), J = 9.6 Hz], 7.31d [1H, H(5a), J = 9.6 Hz], 6.68d [2H, H(3b)/H(5b), J = 8.6 Hz], 6.06bs (2H, NH_2), 4.01s (3H, OCH_3). ^{13}C NMR (DMSO-d_6): δ 165.8 [C(6a)], 158.0 [C(3a)], 156.7 [C(4b)], 133.1 [C(2b)/C(6b)], 129.9 [C(1b)], 125.5 [C(4a)], 124.4 [C(5a)], 116.7 [C(3b)/C(5b)], 58.3 (OCH_3).

2.3.4. Hg(sulfadiazinato)$_2$·2DMSO (**3a**)

Previously described [16].

2.3.5. Hg(sulfadimidinato)$_2$ (**4a**)

White solid (83% yield). Found: C, 37.91; H, 3.43; N, 14.78; S, 8.48. Calc. for $C_{24}H_{26}N_8S_2O_4Hg$: C, 38.16; H, 3.45; N, 14.84; S, 8.48%. Selected IR data (cm^{-1}): 892m, 956vw, 992m, 1086m, 1150vs, 1302s, 1343m, 1371s, 1395sh, 1434m(br), 1503m, 1555m(br), 1597s, 1629m, 3348m. UV (DMSO): λ 275 nm (ε 5.2×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 0.3. ^{1}H NMR (DMSO-d_6): δ 7.88bd [2H, H(2b)/H(6b)], 6.66d

Selected IR data (cm^{-1}): 903m, 952s, 1012m, 1061m, 1091s, 1136vs, 1288m(br), 1266s, 1296s, 1378w, 1416s, 1432s, 1472vs, 1504s, 1598s, 1613s, 1630s, 3378s, 3474m. UV (DMSO): λ 274 nm (ε 4.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 0.6. ^{1}H NMR (DMSO-d_6): δ 7.76d [2H, H(2b)/H(6b), J=8.5 Hz], 6.69d [2H, H(3b)/H(5b), J=8.5 Hz], 6.13 s[1H, H(4a)], 6.11bs (2H, NH_2), 2.38s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 174.7 [C(3a)], 165.9 [C(5a)], 157.0 [C(4b)], 133.4 [C(2b)/C(6b)], 129.2 [C(1b)], 116.7 [C(3b)/C(5b)], 99.4 [C(4a)], 16.4 (CH_3).

2.4. Preparation of Cd(II) and Zn(II)–sulfamidato complexes

2.4.1. General procedure

Cd(II) or Zn(II) acetate (1 mmol) in distilled water (20 ml) was added dropwise to a stirred solution of sodium sulfamidato (2 mmol) in distilled water (20 ml). A white precipitate begins to form and the reaction is stirred during 18 h at room temperature. The precipitate is filtered off and air dried. Crystallisation in different mixtures of NH_4OH–H_2O or DMSO–MeOH yields white crystals.

*2.4.2. Cd(sulfadimethoxynato)$_2$·1/2(NH_3)·H_2O and Cd(sulfadimethoxynato)$_2$·DMSO (**1b**)*

White solid (83% yield). White crystals in NH_4OH–H_2O (1:1). Found: C, 37.92; H, 3.84; N, 15.57; S, 8.37. Calc. for $C_{24}H_{26}N_8S_2O_8Cd \cdot 1/2(NH_3) \cdot H_2O$: C, 38.05; H, 3.89; N, 15.72; S, 8.46%. White crystals in DMSO–MeOH. Found: C, 38.41; H, 3.95; N, 13.72; S, 11.87. Calc. for $C_{24}H_{26}N_8S_2O_8Cd \cdot DMSO$: C, 38.59; H, 3.96; N, 13.85; S, 11.87%. Selected IR data (cm^{-1}): 881s, 932w, 961w, 989w, 1086s, 1145s, 1180m, 1215s, 1263s, 1363s, 1369s, 1396m, 1425s, 1461m, 1489m, 1558s, 1585vs, 1602vs, 2953m, 3337m(br), 3491m(br). UV (DMSO): λ 274 nm (ε 8.6×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 10.2. ^{1}H NMR (DMSO-d_6): δ 7.59d [2H, H(2b)/H(6b), J = 8.2 Hz], 6.57d [2H, H(3b)/H(5b), J = 8.2 Hz], 5.83s [1H, H(5a)], 5.80bs (2H, NH_2), 3.84s [3H, OCH_3(1)], 3.79s [3H, OCH_3(2)]). ^{13}C NMR (DMSO-d_6): δ 175.7 [C(6a)], 169.6 [C(2a)], 167.6 [C(4a)], 155.6 [C(4b)], 132.6 [C(2b)/C(6b)], 132.3 [C(1b)], 116.4 [C(3b)/C(5b)], 87.7 [C(5a)], 58.3 [OCH_3(1)], 57.6 [OCH_3(2)].

*2.4.3. Zn(sulfadimethoxinato)$_2$·3/4(NH_3)·3/4(H_2O) (**1c**)*

White solid (90% yield). White crystals in NH_4OH–H_2O (1:9). Found: C, 40.45; H, 3.98; N, 17.35; S, 8.91. Calc. for $C_{24}H_{26}N_8S_2O_8Zn \cdot 3/4(NH_3) \cdot 3/4(H_2O)$: C, 40.58; H, 4.19; N, 17.26; S, 9.02%. IR (cm^{-1}): 883s, 996m, 1008sh, 1058s,s 1069w, 1144s, 1181m, 1213s, 1275s, 1362s, 1369s, 1394m, 1431m, 1461w, 1488m, 1599vs, 2953m, 3168m, 3259m, 3373m(br), 3472m(br). UV (DMSO): λ 275 nm (ε 4.6×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 11.0. ^{1}H NMR (DMSO-d_6): δ 7.58d [2H, H(2b)/H(6b), J = 8.4 Hz], 6.59d [2H, H(3b)/H(5b), J = 8.6 Hz], 5.86s [H, H(5a)], 5.77bs (2H, NH_2), 3.81s [3H, OCH_3(1)], 3.73s [3H, OCH_3(2)]. ^{13}C NMR (DMSO-d_6): δ 175.4 [C(6a)], 170.1 [C(2a)], 167.6 [C(4a)], 155.7 [C(4b)], 132.8 [C(2b)/C(6b)], 132.8 [C(1b)], 116.5 [C(3b)/C(5b)], 88.4 [C(5a)], 58.2 [OCH_3(1)], 57.6 [OCH_3(2)].

*2.4.4. Cd(sulfamethoxypyridazinato)$_2$·2(H_2O) (**2b**)*

White solid (90% yield). Found: C, 37.34; H, 3.50; N, 15.71; S, 8.55. Calc. for $C_{22}H_{22}N_8S_2O_6Cd \cdot 2(H_2O)$: C, 37.37; H, 3.68; N, 15.85; S, 9.06%. Selected IR data (cm^{-1}): 836s, 971s, 1016s, 1047m, 1087s, 1138s, 1182m, 1254s, 1299s, 1367m, 1422vs, 1469s, 1503m, 1540m, 1601s, 1637m, 3264m, 3364s. UV (DMSO): λ 270 nm (ε 3.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 5.1. ^{1}H NMR (DMSO-d_6): δ 7.65 d[2H, H(2b)/H(6b), J = 8.4 Hz], 7.42 d [1H, H(4a), J = 9.6 Hz], 7.16 d [1H, H(5a), J = 9.6 Hz], 6.55 d [2H, H(3b)/H(5b), J = 8.4 Hz], 5.72 bs (2H, NH_2), 3.95 s (3H, OCH_3). ^{13}C NMR (DMSO-d_6): δ 164.1 [C(6a)], 162.3 [C(3a)], 155.4 [C(4b)], 133.9 [C(1b)], 132.6 [C(2b)/C(6b)], 125.8 [C(4a)], 124.9 [C(5a)], 116.7 [C(3b)/C(5b)], 58.1 (OCH_3).

*2.4.5. Zn(sulfamethoxypyridazinato)$_2$·2.5(H_2O) (**2c**)*

White solid (55% yield). Found: C, 39.41; H, 3.90; N, 16.61; S, 9.84. Calc. for $C_{22}H_{22}N_8S_2O_6Zn \cdot 2.5(H_2O)$: C, 39.49; H, 4.04; N, 16.76; S, 9.57%. Selected IR data (cm^{-1}): 750m, 840m, 945m, 1015s, 1091s, 1133s, 1185m, 1293s, 1417vs, 1469vs, 1503m, 1599s, 1629m, 3240m(br), 3368m, 3446m(br). UV (DMSO): λ 271 nm (ε 3.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 5.5. ^{1}H NMR (DMSO-d_6): δ 7.51d [2H, H(2b)/H(6b), J = 8.4 Hz], 7.49d [1H, H(4a), J = 9.7 Hz], 7.11d [1H, H(5a), J = 9.7 Hz], 6.51d [2H, H(3b)/H(5b), J = 8.4 Hz], 5.67bs (2H, NH_2), 3.90s (3H, OCH_3). ^{13}C NMR (DMSO-d_6): δ 163.0 [C(6a)], 162.1 [C(3a)], 155.2 [C(4b)], 134.3 [C(1b)], 132.2 [C(2b)/C(6b)], 127.6 [C(4a)], 124.6 [C(5a)], 116.5 [C(3b)/C(5b)], 58.0 (OCH_3).

*2.4.6. Cd(sulfadiazinato)$_2$·2(NH_3) (**3b**)*

White solid (80% yield). White crystals in NH_4OH–H_2O (1:1). Found: C, 37.29; H, 3.66; N, 21.56; S, 9.79. Calc. for $C_{20}H_{18}N_8S_2O_4Cd \cdot 2(NH_3)$: C, 37.24; H, 3.72; N, 21.72; S, 9.93%. Selected IR data (cm^{-1}): 725m, 785m, 806s, 846s, 964s, 980s, 1008s, 1090s, 1108m, 1262s, 1277s, 1352m, 1413vs, 1442s, 1501m, 1554s, 1584s, 1598s, 3154m, 3244m, 3315s, 3460m(br). UV (DMSO): λ 271 nm (ε 4.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 5.1. ^{1}H NMR (DMSO-d_6): δ 8.37d [2H, H(6a), J = 4.9 Hz], 7.64d [2H, H(2b)/H(6b), J = 8.6 Hz], 6.77t [1H, H(5a)], 6.53d [2H, H(3b)/H(5b), J = 8.6 Hz], 5.64s (2H, NH_2). ^{13}C NMR (DMSO-d_6): δ 166.3 [C(2a)], 162.2 [C(4a)/C(6a)], 155.0 [C(4b)], 134.1 [C(1b)], 132.9 [C(2b)/C(6b)], 116.0 [C(3b)/C5b)], 115.1 [C(5a)].

*2.4.7. Zn(sulfadiazinato)$_2$·2(NH_3) (**3c**)*

Only small quantities of the complex have been obtained using the experimental procedure previously described [12] or the general procedure described in the present paper. Under these conditions, a mixture of neutral sulfadiazine and $Zn(OH)_2$ is present [14].

Improved results have been obtained by means of the following procedure. Zn(II) nitrate (1 mmol) in NH_4OH–H_2O (1:9) (20 ml) is added dropwise to a stirred solution of sulfadiazine (2 mmol) in NH_4OH–H_2O (1:9) (20 ml). The resulting solution is heated (60°C) until a white precipitate begins to form; the solution is then filtered and crystals are obtained after cooling (24–48 h). The crystalline complex is filtered off and air dried (65% yield). Selected IR data (cm^{-1}): 836m, 978m, 994m, 1014m, 1024m, 1082s, 1102s, 1124s, 1141s, 1182m, 1230s, 1269s, 1282m, 1296m, 1363m, 1418vs, 1426vs, 1453vs, 1502m, 1554s, 1597s, 1635m, 3226m, 3340s, 3459m. ^{1}H NMR (DMSO-d_6): δ 8.30d [2H, H(6a), J = 4.5 Hz], 7.65d [2H, H(2b)/H(6b), J = 8.2 Hz], 6.73t [1H, H(5a)], 6.56d [2H, H(3b)/H(5b), J = 8.4 Hz], 5.68s (2H, NH_2). ^{13}C NMR (DMSO-d_6): δ 166.1 [C(2a)], 161.9 [C(4a)/C(6a)], 155.0 [C(4b)], 134.1 [C(1b)],

133.1 [C(2b)/C(6b)], 116.0 [C(3b)/C5b)], 115.0 [C(5a)].

*2.4.8. [Cd(sulfadimidinato)$_2$(H$_2$O)]·2H$_2$O (**4b**)*

White solid (80% yield). White crystals in NH_4OH–H_2O (3:9). Found: C, 40.09; H, 4.49; N, 15.48; S, 8.67. Calc. for $C_{24}H_{26}N_8S_2O_4Cd\cdot 3H_2O$: C, 39.98; H, 4.44; N, 15.55; S, 8.88%. Selected IR data (cm^{-1}): 885s, 982m, 1082s, 1128vs, 1144s, 1184m, 1248s, 1347m, 1380vs, 1398m, 1434s, 1499m, 1564m, 1586s, 1601s, 1641m, 3160m, 3288m, 3371m, 3465m, 3545m. UV (DMSO): λ 273 nm (ε 6.7×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 3.5. ^{1}H NMR (DMSO-d_6): δ 7.67bd [2H, H(2b)/H(6b)], 6.51bd [2H, H(3b)/H(5b)], 6.49s [1H, H(5a)], 5.62bs (2H, NH_2), 2.18s (6H, CH_3). ^{13}C NMR (DMSO-d_6): δ 171.2 [C(4a)/C(6a)], 166.1 [C(2a)], 154.9 [C(4b)], 134.2 [C(1b)], 133.5 [C(2b)/C(6b)], 115.6 [C(3b)/C5b)], 114.0 [C(5a)], 27.0 (CH_3).

*2.4.9. Zn(sulfadimidinato)$_2$·1.75(NH$_3$)·0.25(H$_2$O) (**4c**)*

White solid (71% yield). White crystals in NH_4OH–H_2O (1:9). Found: C, 43.87; H, 4.84; N, 20.90; S, 9.40. Calc. for $C_{24}H_{26}N_8S_2O_4Zn\cdot 1.75(NH_3)\cdot 0.25(H_2O)$: C, 44.06, H, 4.86; N, 20.88; S, 9.79%. Selected IR data (cm^{-1}): 886s, 984m, 1014m, 1058m, 1082s, 1128vs, 1144s, 1186m, 1274s, 1304w, 1349m, 1380s, 1400m, 1436s, 1501m, 1650m, 1588s, 1602s, 1644m, 3158m, 3281m(br), 3368m, 3456m, 3550m UV (DMSO): λ 273 nm (ε 2.1×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 2.7. ^{1}H NMR (DMSO-d_6): δ 7.68d [2H, H(2b)/H(6b), J = 7.9 Hz], 6.53d [2H, H(3b)/H(5b), J = 7.6 Hz], 6.46s [1H, H(5a)], 5.62bs (2H, NH_2), 2.18s (6H, CH_3). ^{13}C NMR (DMSO-d_6): δ 170.9 [C(4a)/C(6a)], 165.9 [C(2a)], 155.0 [C(4b)], 133.6 [C(1b)], 133.6 [C(2b)/C(6b)], 115.7 [C(3b)/C5b)], 114.3 [C(5a)], 26.8 (CH_3).

*2.4.10. Cd(sulfamerazinato)$_2$·2H$_2$O (**5b**)*

White solid (83% yield). Found: C, 39.05; H, 3.67; N, 16.40; S, 9.26. Calc. for $C_{22}H_{22}N_8S_2O_4Cd\cdot 2H_2O$: C, 39.14; H, 3.85; N, 16.60; S, 9.48%. Selected IR data (cm^{-1}): 867m, 906m, 978m, 1086m, 1104m, 1113m, 1138s, 1253s, 1328m, 1391s, 1414s, 1436s, 1460m, 1498m, 1558m, 1566m, 1581s, 1597s, 3161m, 3257m, 3292m, 3360m, 3496m, 3553m. UV (DMSO): λ 271 nm (ε 4.8×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 3.3. ^{1}H NMR (DMSO-d_6): δ 8.21bd [1H, H(6a)], 7.64d [2H, H(2b)/H(6b)], 6.63d [1H, H(5a)], 6.51bd [2H, H(3b)/H(5b)], 5.62bs (2H, NH_2), 2.18s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 171.6 [C(4a)], 166.2 [C(2a)], 161.9 [C(6a)], 154.9 [C(4b)], 134.1 [C(1b)], 133.1 [C(2b)/C(6b)], 115.8 [C(3b)/C5b)], 114.7 [C(5a)], 26.9 (CH_3).

*2.4.11. Zn(sulfamerazinato)$_2$·2H$_2$O (**5c**)*

White solid (84% yield). Found: C, 41.76; H, 4.11; N, 17.46; S, 10.29. Calc. for $C_{22}H_{22}N_8S_2O_4Zn\cdot 2H_2O$: C, 42.07; H, 4.14; N, 17.85; S, 10.20%. Selected IR data (cm^{-1}): 865m, 980m, 981m, 1014m, 1087s, 1104m, 1113m, 1138s, 1252s, 1327m, 1398s, 1419vs, 1433s, 1462s, 1499m, 1566s, 1582s, 1598vs, 1624m, 3156m, 3247m, 3286m, 3366m, 3491m, 3554m. UV (DMSO): λ 272 nm (ε 5.0×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 3.2. ^{1}H NMR (DMSO-d_6): δ 8.13s [1H, H(6a)], 7.67d [2H, H(2b)/H(6b), J = 8.2 Hz], 6.60s [1H, H(5a)], 6.54d [2H, H(3b)/H(5b), J = 8.2 Hz], 5.62bs (2H, NH_2), 2.19s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 172.3 [C(4a)], 165.8 [C(2a)], 160.9 [C(6a)], 155.2 [C(4b)], 134.2 [C(1b)], 133.5 [C(2b)/C(6b)], 116.0 [C(3b)/C5b)], 114.8 [C(5a)], 27.3 (CH_3).

*2.4.12. Cd(sulfamethoxazolato)$_2$·2(H$_2$O) (**6b**)*

White solid (89% yield). Found: C, 37.11; H, 3.69; N, 12.80; S, 9.78. Calc. for $C_{20}H_{20}S_2O_6Cd\cdot 2(H_2O)$: C, 36.78; H, 3.67; N, 12.87; S, 9.80%. Selected IR data (cm^{-1}): 792m, 835s, 930s, 942s, 1090s, 1111vs, 1174s, 1216s, 1222s, 1264m, 1302m, 1320m, 1377w, 1418s, 1445m, 1477vs, 1506m, 1604m, 1628s, 3379m, 3431m, 3476m. UV (DMSO): λ 267 nm (ε 3.4×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 12.4. ^{1}H NMR (DMSO-d_6): δ 7.58d [2H, H(2b)/H(6b), J = 8.6 Hz], 6.58d [2H, H(3b)/H(5b), J = 8.6 Hz], 5.89s [1H, H(4a)], 5.71bs (2H, NH_2), 2.26s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 172.7 [C(3a)], 168.4 [C(5a)], 155.8 [C(4b)], 133.2 [C(1b)], 133.2 [C(2b)/C(6b)], 117.0 [C(3b)/C(5b)], 100.7 [C(4a)], 16.5 (CH_3).

*2.4.13. Zn(sulfamethoxazolato)$_2$·2(H$_2$O) (**6c**)*

White solid (79% yield). Found: C, 39.52; H, 3.96; N, 13.72; S, 10.52. Calc. for $C_{20}H_{20}S_2O_6Zn\cdot 2(H_2O)$: C, 39.64; H, 3.96; N, 13.87; S, 10.57%. Selected IR data (cm^{-1}): 818s, 838s, 884sh, 920s, 951s, 1010m, 1055m, 1086s, 1131vs, 1261s, 1274s, 1305m, 1323m, 1426s, 1476s, 1504m, 1577m, 1601s, 1636s, 1661m, 3071m, 3225s, 3365s, 3496s. UV (DMSO): λ 267 nm (ε 3.3×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO, 25°C) = 10.2. ^{1}H NMR (DMSO-d_6): δ 7.60d [2H, H(2b)/H(6b), J = 8.6 Hz], 6.58d [2H, H(3b)/H(5b), J = 8.6 Hz], 5.97s [1H, H(4a)], 5.78s (2H, NH_2), 2.28s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 172.8 [C(3a)], 167.3 [C(5a)], 156.2 [C(4b)], 133.2 [C(1b)], 132.2 [C(2b)/C(6b)], 116.9 [C(3b)/C(5b)], 100.9 [C(4a)], 16.4 (CH_3).

*2.4.14. Zn(sulfamethoxazolato)$_2$(py)$_2$(H$_2$O)$_2$ (**6d**)*

A solution of $ZnCl_2$ containing 10 mmol in 50 ml H_2O–py (3:1) was added to a solution of sulfamethoxazole (5 mmol in 50 ml H_2O–py, 1:1) with continuous stirring. Immediately, a white solid was obtained. The precipitate was isolated by filtration and the filtrate was left to stand at room temperature. From the filtrate colourless prismatic crystals suitable for X-ray measurement appeared after a month. Selected IR data (cm^{-1}): 670s, 700s, 750m, 800–820m, 840m, 900m, 930s, 1000m, 1040s, 1060m, 1080s, 1130vs, 1220s, 1250s, 1270s, 1315m, 1410s, 1440s, 1460s, 1500s, 1590s, 1600s, 1630s,

3350s, 3480s. UV (solid): 258 nm. UV (DMSO): λ 273 nm (ε 4.5×10^4 dm^3 mol^{-1} cm^{-1}). Λ_M/Ω^{-1} cm^2 mol^{-1} (10^{-3} mol dm^{-3} in DMSO at 25°C) = 10.0. ^{1}H NMR (DMSO-d_6): δ 8.69dt [2H, H(o-) py, J = 4.2 and 1.7 Hz], 7.96tt [1H, H(p-) py, J = 7.7 and 1.7 Hz], 7.57m [4H, H(2b)/H(6b) + H(m-) py], 6.61d [2H, H(3b)/H(5b), J = 8.6 Hz], 6.05s [1H, H(4a)], 5.87s (2H, NH_2), 2.30s (3H, CH_3). ^{13}C NMR (DMSO-d_6): δ 172.4 [C(3a)], 167.5 [C(5a)], 155.9 [C(4b)], 153.2 [C(o-) py], 142.1 [C(p-) py], 132.7 [C(2b)/C(6b)], 132.1 [C(1b)], 128.7 [C(m-) py], 116.5 [C(3b)/C(5b)], 100.6 [C(4a)], 16.2 (CH_3). Solid ^{13}C NMR (ppm) tentative assignment: 168.2 [(C(3a)], 163.0 [C(5a)], 150.3 [C(4b) and C(o-) py], 140.1 [C(p-) py], 131.1 [C(1b)], 127.0 and 123.1 [C(2b) or C(6b) + C(m-) py and C(6b) or C(2b)], 115.3 and 111.0 [C(5b) and C(3b)], 99.3 [C(4a)], 12.0 (CH_3).

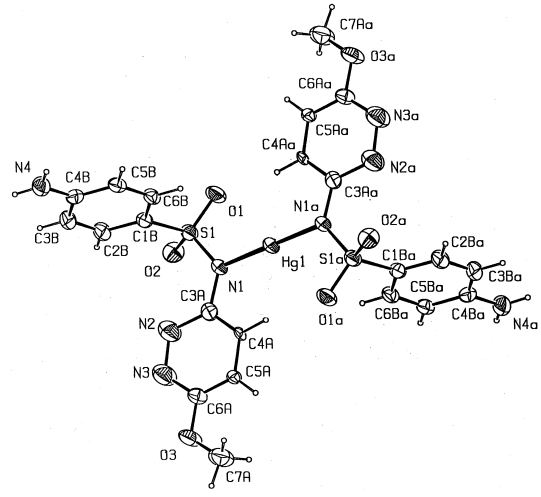

Fig. 1. ORTEP plot of [Hg(sulfamethoxypyridazinato)$_2$] (**2a**).

3. Results and discussion

3.1. Crystal structures

3.1.1. [Hg(sulfamethoxypyridazinato)$_2$] (*2a*)

The molecular structure of complex **2a** and the atom numbering scheme are shown in Fig. 1. The two sulfamethoxypyridazinato ligands are bound to the mercury atom via the sulfonamidic nitrogen N(1) in a linear arrangement. The Hg atom is at the centre of symmetry of the unit complex. The Hg–N bond distance [Hg–N(1) = 2.071(4) Å] (Table 2) is similar to previously reported distances in other Hg–N systems [16]. The bond lengths and angles of the benzene ring, the distances C(4b)–N(4b) = 1.392(7) Å, S(1)–N(1) = 1.625(4) Å, N(1)–C(3a) = 1.403(7) Å and the angle S(1)–N(1)–C(3a) conform well to those found in the free ligand. Sensitive changes in bonds and angles of the heterocyclic ring are observed by comparison with those of the free sulfamethoxypyridazine, as a consequence of a new restructuring of the ring charge. The trigonal arrangement around the sulfonamidic nitrogen is similar to those observed in the free ligand and the Hg–sulfadiazine complex [16]. The *gauche* conformation between the two rings regarding the S(1)–N(sulfonamidic) bond, the torsion angle [C(1b)–S(1)–N(sulfonamidic)–C(3a) = 74.59°] and the dihedral [O(1)–S(1)–N(sulfonamidic)–metal = 20.13°] are quite different to those observed in the Hg–sulfadiazine complex (dihedral 5.80°). The monomeric units are held through weak intermolecular hydrogen bonds between the SO_2 group and the NH_2 of an adjacent unit [N(4b)–H···OSO = 3.04°].

3.1.2. [Cd(sulfadimidinato)$_2$(H_2O)]·2H_2O (*4b*)

The molecular structure of compound **4b** and the atom numbering scheme are shown in Fig. 2. The Cd(II) ion in complex exhibits a high distorted-octahedral geometry, being coordinated to the sulfonamidic N(1) [Cd–N(1) = 2.328(6) Å; Cd–N(1′) = 2.326(6) Å] and the heterocyclic N(3)/N(2′) [Cd–N(3) = 2.307(6) Å; Cd–N(2′) = 2.426(6) Å] of two bidentate sulfadimidine ligands generating two four-membered rings. The terminal amino N(4′b) [Cd–N(4′b) = 2.379(7) Å] of a third sulfadimidine, which is bonded to an adjacent Cd(II), and the O(3) [Cd–O(3) = 2.334(6) Å] atom of a water molecule complete the coordination sphere. Although both ligands are bound in a bidentate form to the metal, only one sulfadimidine presents two equivalent Cd–N distances. The N(4)–C(4b) and N(4′)–C(4b′) distances are 1.393(11) and 1.413(9) Å, respectively, greater than the corresponding distances in the free ligand [N(4)–C(4b) = 1.384(6) Å], which is consistent with the coordination of the terminal amino group to the adjacent Cd(II). The bond lengths and angles of the benzene ring conform well to those found in the free sulfadimidine [34], whereas distances S(1)–N(1) = 1.609(7) Å, S(1′)–N(1′) = 1.578(7) Å, N(2)–C(3a) = 1.338(10) Å and N(2′)–C(3a′) = 1.348(9) Å are shorter in the Cd(II) complex. In this case the trigonal arrangement around the sulfonamidic nitrogen is similar to those observed in the Zn(II) and Cu(II)–sulfadiazine complexes [16]. The *gauche* conformation between the two rings regarding the S(1)–N(sulfonamidic) bond, with a torsion angle of [C(1b)–S(1)–N(sulfonamidic)–C(3a) = 65.51°] is similar to that of the Ag–sulfadiazine complex [10,11,14]. The packing of the complex units is governed by long chains formed by the bridging sulfadimidine ligands which are bound to Cd(1) via N(1)/N(3) and Cd(2) via NH_2 [N(4′b)–Cd = 2.379(7) Å]. Stacking interactions are present in the crystal structure involving benzene and heterocyclic rings (3.6 Å). In the complex units there are intramolecular hydrogen bonds between the NH_2 group and SO_2 of different ligands, and between SO_2 and coordinated H_2O molecules.

3.1.3. [Zn(sulfamethoxazolato)$_2$(py)$_2$(H_2O)$_2$] (*6d*)

The structure consists of centrosymmetric units of Zn(sulfamethoxazolato)$_2$·(py)$_2$(H_2O)$_2$ (Fig. 3). The geometry around the Zn(II) ion, placed at a crystallographic symmetry centre, can be described as a slightly distorted

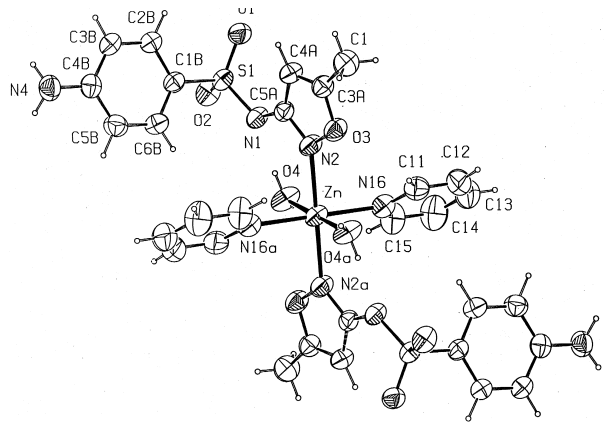

Fig. 3. ORTEP plot of [Zn(sulfamethoxazolato)$_2$(pyridine)$_2$(H_2O)$_2$] (**6d**).

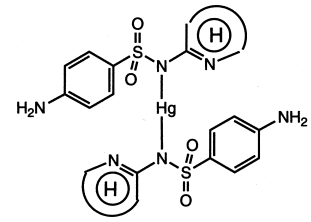
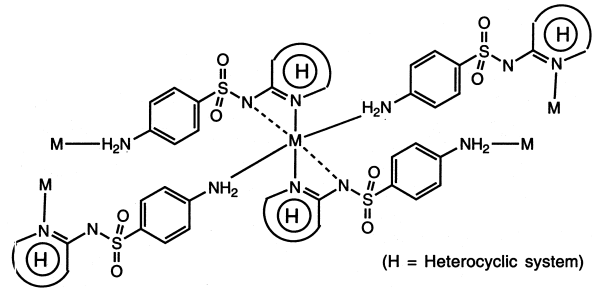
compressed octahedron. The equatorial plane is formed by two pyridine N atoms [N(16) and N(16A)] and two isoxazole N atoms [N(2) and N(2A)] from two sulfamethoxazolate anions. Two oxygen atoms of two water molecules are placed in the apical positions. The equatorial M–N distances [2.1841(17) and 2.1736(15) Å] are almost equal and markedly longer than the axial M–OW ones [2.0984(14) Å]. The coordination angles around the metal, which range from 87.50(6) to 92.50(6)°, do not deviate significantly from a regular octahedron.

It should be noted that the coordination behaviour of the sulfamethoxazolate anion contrasts with that exhibited by the related sulfathiazolate in the Zn(sulfathiazolato)$_2 \cdot H_2O$ compound [18] in spite of the structural similarity between both sulfonamides. The sulfamethoxazolate acts as monodentate through the $N_{isoxazole}$, whereas the sulfathiazolate anion behaves as a bridge linking two metal ions through the $N_{thiazole}$ and N_{amino}.



When comparing the bond lengths of the sulfamethoxazolate anion with those of the free sulfamethoxazole [35] a remarkable similarity of all bond distances is found. The most significant changes are: a small shortening of the N(1)–C(5A) distance [from 1.393(4) to 1.370(2) Å], a slight lengthening of the C(1B)–S(1) bond distance [from 1.734(3) to 1.7650(18) Å] and a marked shortening of the S(1)–N(1) length [from 1.645(3) to 1.5675(15) Å]. It must be noted that the S(1)–N(1) bond distance is very close to those of the S=N double bond (1.494–1.580 Å) [36]. Since these distances are comparable to the corresponding ones in the sulfamethoxazole sodium salt [36] and the sulfonamido group does not interact with the metal ion, these changes are ascribed to the deprotonation of this moiety. Moreover, the C(4B)–N(4) bond distance is longer than the corresponding one in the free sulfamethoxazole [1.394(3) Å in the complex, 1.358(5) Å in the ligand]. The lack of interaction of the amino N atom of the sulfamethoxazole with Zn(II) leads us to propose that this lengthening is determined by the intermolecular hydrogen bonds involving the amino group [N(4)–H···OW and N(4)···H–OW = 2.09 and 2.20 Å, respectively, N(4)–H···OSO = 2.20 Å]. The crystal structure is stabilised by an extensive network of intra- and intermolecular hydrogen bonds involving the water molecules, the sulfonamido N and O atoms and the terminal amino group. To be noticed the strong intramolecular interaction between a coordinated water molecule and the sulfonamido N(1) atom [N(1)···H–O(4) = 1.92 Å]. As found in metal complexes with other sulfonamides [18], the coordination through the heteroaromatic N atom does not significantly modify the bond lengths and bond angles of the ring. The isoxazole ring is planar and perpendicular to the benzene ring (angle between planes, 78.28°).



3.2. Infrared spectra

The infrared spectra of the complexes in the far-IR region to 200 cm^{-1} were compared with those of the free ligands. Similar modifications are observed in Zn(II)/Cd(II) complexes which are different to those in Hg(II) complexes. The bands that appear near 3500 and 3400 cm^{-1} due to $\nu_{asym}(NH_2)$ and $\nu_{sym}(NH_2)$ vibrations of the NH_2 group [16] are modified with respect to those of the free respective ligands. In general, these vibration modes appear at higher and lower wavenumbers, compared with those of the free ligand. When the amino N atom does not interact with the metal ion (this excludes the **4b** complex) these modifications are consequently due to the hydrogen bonds involving the amino group. The frequency ν(N–H) of the sulfonamido group, which in the free ligands is found at about 3125 cm^{-1}, is not present in the spectra of the complexes, confirming the deprotonation of the $–SO_2NH–$ moiety. Moreover, for the **6d** complex, in agreement with the coordination of the ligand through the isoxazole N atom, deduced from the crystal structure, the characteristic ring vibration is shifted from 1460 cm^{-1} in the free ligand to 1410 cm^{-1} in the complex. The strong band at (1370–1330 cm^{-1}) related to $\nu_{asym}(SO_2–N)$ [9,16,18] in each free ligand is also changed in frequency or split in the same way in Zn(II) and Cd(II) compounds and differently in Hg(II) derivatives. The 920–975 cm^{-1} band in the ligand is assigned to ν(S–N) [9,16] and changed to higher frequencies in all cases as a consequence of coordination to the metal. This shift to higher frequencies is in accordance with the shortening of the S–N bond lengths, which have been observed in the crystal structures of compounds **2a**, **4b** and **6d**. In complex **6d**, the bands at 1600, 1460, 1440, 1220, 760 and 700 cm^{-1} are assigned to vibrations of the pyridine rings [37,38].

All Hg(sulfamidato)$_2$ complexes (**1a–6a**) present a similar NMR pattern with two equivalent sulfamide groups. Thus, upon complexation, a downfield shift (+1.0 to +4.0 ppm) is observed for the carbon directly bonded to the sulfonamidic nitrogen [C(4a) for complex **1a**, C(3a) for complex **2a**, C(2a) for complexes **3a–5a** and C(5a) for complex **6a**]. Moreover, the downfield shift for H(2b)/H(6b) resonance (+0.14 to +0.26 ppm) could be related to the proximity of the Hg(II) which can be explained by a direct interaction, as in solid state, between the metallic ion and the sulfonamidic nitrogen (Scheme 3).

Cd(II) (**1b–6b**) and Zn(II) (**1c–6c**) complexes also show similar NMR patterns with two equivalent sulfamide groups. In these cases, important downfield shifts, higher than in the corresponding Hg(II) compounds, of the carbons directly bonded to the sulfonamidic moiety [C(4a) for complex **1a**, C(3a) for complex **2a**, C(2a) for complexes **3a–5a** and C(5a) for complex **6a** (+3.4 to +6.4 ppm) and C(1b) (+3.1 to 5.1 ppm)] together with different $\Delta\delta$ (H or C) of the resonances presented in the heterocyclic ring suggest a main metal–heterocyclic nitrogen interaction. However, secondary interaction with the sulfonamidic nitrogen cannot be completely discarded. On the other hand, the upfield shifts of the NH_2 (−0.31 to −0.47 ppm), H(3b)/H(5b) (−0.10 to −0.15 ppm) and C(4b) (−1.3 to −2.2 ppm) indicate that NH_2–metal(II) binding is also present, yielding equivalent

structures to the previously described polymeric Zn(sulfothiazolato)$_2$ [9] (Scheme 3). Similar results are obtained for compound **6d**. Moreover, the solid ^{13}C NMR spectrum shows the non-equivalence of the aromatic carbons of the bencenic moiety as can be observed in the crystal structure (Fig. 3).

The Λ_M (10^{-3} mol dm^{-3}) values in DMSO at 25°C imply the presence of non-electrolyte type species for all the complexes described in this work [39].

4. Conclusion

Spectral and X-ray data of the complexes show a general pathway for the interaction between the six sulfamides studied and the d^{10} metal ions. Thus, Cd(II) and Zn(II) compounds present coordination mainly through heterocyclic nitrogen whereas the corresponding Hg(II) derivatives seem to be coordinated through sulfonamidic nitrogen (Scheme 3).

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition numbers: 137958 (**2a**), 137959 (**4b**) and 137960 (**6d**).

Acknowledgements

Abstract

The binuclear complexes $[\{Cu(bipy)\}_2\{\mu\text{-}[(NC_5H_4)_2C(OMe)O]\}_2]X_2\cdot 1/2H_2O$, $X^- = PF_6^-$ (**1**) or ClO_4^- (**2**) and $[\{Cu(phen)\}_2\text{-}\{\mu\text{-}[(NC_5H_4)_2C(OMe)O]\}_2]X_2\cdot 2[(NC_5H_4)_2CO]$, $X^- = PF_6^-$ (**3**) or ClO_4^- (**4**) have been synthesized by the reaction of $[\{Cu(NN)\}_2\text{-}(\mu\text{-}OH)_2]X_2\cdot nH_2O$ and di-2-pyridylketone in methanol. The compounds were characterized by conductance measurements and IR and electronic spectroscopies. The X-ray crystal structure of compounds **1**, **3** and **4** show the presence of two $[(NC_5H_4)_2C(OMe)O^-]$ uninegative tridentate N,O,N-donor $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2$ ligands per dimer. The coordination sphere of Cu(II) is a very distorted octahedron. All four compounds are ferromagnetic, with a superexchange parameter $2J = 10.0$, 10.1, 16.7 and 15.8 cm^{-1} for compound **1**, **2**, **3** and **4**, respectively. Zero field splitting parameters (*D*, *E*) and *g* values have been calculated from the spin triplet state signals positions in the EPR spectra. ©2000 Elsevier Science Ltd All rights reserved.

Keywords: Crystal structures; Cu dimers; Di-(2-pyridyl)ketone; Ferromagnetic dimers; Magnetic properties; Spin triplet

1. Introduction

The magnetic aspects of dinuclear Cu(II) complexes, $[\{Cu(NN)\}_2(\mu\text{-}OH)_2]X_2$ with NN = bidentate nitrogen ligand, have been intensively studied since the magnetostructural correlations described by Hatfield and co-workers [1] for planar dimers of Cu(II) with the Cu_2O_2 group. More recently, these correlations have been extended and theoretically justified by Ruiz et al. [2,3].

In previous papers we described the interaction between the ligand PhNHpy and the dimers $[\{Cu(NN)(\mu\text{-}OH)\}_2]\text{-}X_2\cdot nH_2O$, where NN = 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen), and $X^- = PF_6^-$ [4] or ClO_4^- [5]. The corresponding magnetostructural correlations were established for the resulting dinuclear complexes.

Di-(2-pyridyl)ketone is a molecule that can exhibit different modes of coordination. As bidentate ligand may present a N,O-coordination giving a five-membered chelate ring or a N,N-coordination forming a six-membered ring [6–8]. Frequently the coordinated di-(2-pyridyl)ketone undergoes nucleophilic addition of water or an alcohol at the carbonylic carbon atom to form the diol or the corresponding hemiacetal, $(NC_5H_4)_2C(OR)(OH)$, which, deprotonated, acts as a mononegative, tridentate N,O,N-donor ligand. The three donor atoms may be coordinated to one metal atom [9–11] or to two metal atoms, bridging them, with a $\eta^1{:}\eta^2{:}\eta^1$ coordination [12–15]. In a dicubane type compound of Cu(II) the monoanion N,O$^-$,N presents a $\eta^1{:}\eta^3{:}\eta^1$ coordination between three copper atoms [16].

In this paper we describe the interaction between di-(2-pyridyl)ketone and $[\{Cu(NN)(\mu\text{-}OH)\}_2]X_2\cdot nH_2O$, where NN = 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen) and $X^- = PF_6^-$ or ClO_4^- in methanol. In all four cases the group $[(NC_5H_4)_2C(OMe)O^-]$ is formed and adopts a $\eta^1{:}\eta^2{:}\eta^1$ coordination between two copper atoms. Crystal structure and magnetic and EPR results are also decribed.

2. Experimental

2.1. Synthesis

$[\{Cu(NN)\}_2(\mu\text{-}OH)_2]X_2\cdot xH_2O$ where NN = 2,2′-bipyridyl (bipy) or 1,10-phenanthroline (phen) and

PII S0277-5387(00)00356-9

$X^- = PF_6^-$ or ClO_4^- were prepared according to Harris et al. [17].

2.1.1. [{Cu(bipy)}$_2${μ-[(NC$_5$H$_4$)$_2$C(OMe)O]}$_2$]X$_2$·1/2H$_2$O, X$^-$ = PF$_6^-$ (1) and ClO$_4^-$ (2)

A solution of di-2-pyridylketone (1 mmol) in methanol (5 ml) was added to a suspension of [{Cu(bipy)}$_2$(μ-OH)$_2$]X$_2$·nH$_2$O (0.25 mmol) in hot methanol (50 ml). By the addition the solid was dissolved and a blue solution was formed. The volume was reduced, by boiling, to 10 ml. It was cooled and filtered. By slow evaporation of the solvent green crystals were formed.

Compound **1**. Yield: 58%. Dec. 124°C. Found: Cu, 10.7; C, 45.5; H, 3.3; N, 9.6. Calc. for $Cu_2C_{44}F_{12}H_{39}N_8O_{4.5}P_2$: Cu, 10.9; C, 45.2; H, 3.4; N, 9.6%. Compound **2**. Yield: 47%. Dec.: 134°C. Found: Cu, 11.8; C, 49.3; H, 3.3; N, 10.7. Calc. for $Cu_2C_{44}Cl_2H_{39}N_8O_{12.5}$: Cu, 11.8; C, 49.0; H, 3.7; N, 10.4%.

2.1.2. [{Cu(phen)}$_2${μ-[(NC$_5$H$_4$)$_2$C(OMe)O]}$_2$]X$_2$·2[(NC$_5$H$_4$)$_2$CO], X$^-$ = PF$_6^-$ (3) and ClO$_4^-$ (4)

The same procedure as for the above compounds, using 1.5 mmol of di-2-pyridylketone per 0.25 mmol of [{Cu(phen)}$_2$(μ-OH)$_2$]X$_2$·nH$_2$O, was employed.

Compound **3**. Yield: 37%. Dec. 127°C. Found: Cu, 8.2; C, 53.2; H, 3.3; N, 10.6. Calc. for $Cu_2C_{70}F_{12}H_{54}N_{12}O_6P_2$: Cu, 8.1; C, 53.3; H, 3.5; N, 10.7%. Compound **4**. Yield: 37%. Dec.: 136°C. Found: Cu, 8.4; C, 56.5; H, 3.4; N, 11.0. Calc. for $Cu_2C_{70}Cl_2H_{54}N_{12}O_{14}$: Cu, 8.6; C, 56.6; H, 3.7; N, 11.3%.

In all four cases, when the reaction solution volume was reduced below 10 ml, blue crystals of monomers [Cu(NN)$_3$]X$_2$ were obtained. Compounds **1**, **2**, **3** and **4** are soluble in acetonitrile, methanol, ethanol, acetone, dimethylformamide, nitromethane, nitrobenzene, dimethyl sulfoxide and dichloromethane. All solutions are blue, except that of nitrobenzene, which is green.

2.2. Physical measurements

C, H and N were analysed on a Perkin-Elmer 240C elemental analyser. Copper was measured with an atomic absorption spectrophotometer (Perkin-Elmer 2380), λ = 324.8 nm. Melting points were measured on an Electrothermal 9300. Conductivity measurements were made using a Metrhom E518 conductometer. IR spectra were recorded on a Nicolet FT-IR 510 spectrometer in the range 4000–400 cm^{-1} using KBr pellets and on a Nicolet 740 in the 650–50 cm^{-1} range using nujol on a polyethylene film. Electronic spectra were recorded on a Shimadzu UV-265 FW spectrophotometer.

Magnetic measurements were carried out in the 292–4.3 K range with a magnetometer (Manics DSM8) equipped with an He continuous flow cryostat and Drusch EAF 16UE electromagnet; the magnetic field was approximately 1.5 T. The EPR spectra were recorded on a Bruker ESP 300 spectrometer with a Bruker ER 035 M gaussmeter, Oxford ITC4 cryostat and HP 5325B frequency counter.

2.3. Crystal structure determination

The X-ray diffraction data were collected, at 293 K, with a STOE STADI-4 diffractometer for compound **1**, and with a Siemens P4 diffractometer for compounds **3** and **4**, with graphite-monochromated Mo Kα radiation (λ = 0.71069 Å), operating in the $2\theta/\omega$ scanning mode. The unit cell parameters were determinated from 25 reflections for compounds **1** and **3** and from 38 reflections for compound **4**. During data collection, three standard reflections were measured every 60, 90 and 97 min, showing a decay of 6.3, 0 and 3.66%, respectively. Data were corrected for Lorentz and polarization effects. Absorption corrections with the ψ scan method were applied for compounds **1** and **3**. The crystallographic data, conditions used for the data collection and some refinement data are listed in Table 1.

The structures were solved by direct methods and refined by full-matrix least-squares on F^2, using, for each compound, the weighting scheme indicated in Table 1. Scattering factors were taken from International Tables for Crystallography [18]. For compound **1**, copper, phosphorus and non-disordered fluorine atoms have been refined anisotropically, all others isotropically. Three of the four PF_6^- groups have been disordered into two positions, restraints having been applied to some of the P–F and F–F distances in order to obtain reasonable geometries. A similar procedure was applied for the perchlorate group in compound **4**. Hydrogen atoms were introduced in their ideal positions. The program package SHELXTL-V5 [19] was used for structure solution and refinement and for drawings.

3. Results and discussion

3.1. Electrical conductivity

The molar conductivity values in acetonitrile (Table 2) correspond to a 2:1 electrolyte [20], according to the dimeric character of the cations. The application of the Onsager equation [21] confirms the dimeric character of the cations. Table 2 shows found and calculated values for the slope of the plot of ($\Lambda_o - \Lambda_e$) versus $\sqrt{c_e}$. The concordance between calculated and observed values is clear.

3.2. IR spectra

The more significant bands are considered as those due to the Cu–O and C=O bonds and to the counterions PF_6^- and ClO_4^-. The stretching ν(O–H) band, at 3600 cm^{-1}, is not observed because of the removal of the OH bridge (Table 3).

The ν_{as}(Cu–O) band shifts to higher frequency compared with the original dimers. For complexes **3** and **4**, the ν(C=O)

Table 2
Electrical conductivity results [a]

Compound	c_M (mol l^{-1})	Λ_M (Ω^{-1} cm^2 mol^{-1})	A_{found}	A_{calc} [b]
1	5.12×10^{-4}	276	681	674
2	5.25×10^{-4}	269	620	657
3	5.45×10^{-4}	290	791	674
4	5.98×10^{-4}	294	658	665

[a] A is the slope of the plot of $(\Lambda_o-\Lambda_e)$ versus $(c_e)^{1/2}$, where Λ_e is equivalent conductivity, Λ_o is limit equivalent conductivity and c_e is equivalent concentration.
[b] Calculated for the ionization: $[\{Cu(NN)\}_2\{\mu\text{-}[(NC_5H_4)_2C(OMe)\text{-}O]\}_2]X_2 \rightarrow [\{Cu(NN)\}_2\{\mu\text{-}[(NC_5H_4)_2C(OMe)O]\}_2]^{2+} + 2X^-$.

band of the non-coordinated ligand molecule is observed at the free ligand frequency, 1675 cm^{-1} [11]. For the initial dimers the ClO_4^- ν_3 band is observed as a broad band, with shoulders, characteristic of the coordinated ClO_4^-. In $[\{Cu(bipy)\}_2(\mu\text{-}OH)_2](ClO_4)_2\cdot H_2O$, two oxygen atoms of perchlorate groups are in the axial positions of the two copper atoms of the dimer, at 2.797 Å [22]. In compounds **2** and **4** the ClO_4^- ν_3 band is narrowed and the shoulders are not observed, as a consequence of the non-coordination [23].

3.3. Electronic spectra

The electronic spectra of the solutions in acetonitrile exhibit, besides the different ligands bands, the d–d band of Cu(II) at 640 nm ($\varepsilon_{max}=198$ l cm^{-1} mol^{-1}) for compound **1**, at 641 nm ($\varepsilon_{max}=197$ l cm^{-1} mol^{-1}) for compound **2**, at 671 nm ($\varepsilon_{max}=170$ l cm^{-1} mol^{-1}) for compound **3** and at 682 nm ($\varepsilon_{max}=146$ l cm^{-1} mol^{-1}) for compound **4**. In all cases a shoulder assigned to charge transfer transition is observed at 310–295 nm. In the diffuse reflectance spectra the d–d band is very broad.

chemically identical but crystallographically unequivalent dimeric units (Cu1–Cu2) (Fig. 1) and (Cu3–Cu4) (Fig. 2) are present in the asymmetric unit. Each dimer has approximately local C_2 symmetry, the corresponding twofold axis being roughly perpendicular to the average Cu_2O_2 plane.

Selected interatomic distances and bond angles of the two crystallographically unequivalent dimeric units are collected in Table 4. Each of these dimers comprises two copper atoms bridged by two anions $py_2C(OCH_3)O^-$, where $py_2C(OCH_3)OH$ represents the methanolic hemiacetal of di(2-pyridyl)ketone. Each of the nitrogen atoms of this anion is bonded to one copper atom whereas the oxygen atom of the deprotonated hydroxyl group is simultaneously linked to both metal atoms, one of the corresponding Cu–O distances being much longer than the other. The coordination sphere of each copper atom is completed by a bipyridyl chelating molecule, with one Cu–N distance significantly longer than the other (see Table 4).

The geometry around each copper atom is distorted octahedral, with the longest Cu–O and Cu–N distances *trans* to each other: Cu(1)–O(31Q) and Cu(1)N(4A); Cu(2)–O(31P) and Cu(2)–N(4B); Cu(3)–O(31S) and Cu(3)–N(4C); Cu(4)–O(31R) and Cu(4)–N(4D). In the equatorial plane, the nitrogen and oxygen atoms of one $py_2C(OCH_3)O^-$ anion are placed *trans* of, respectively, the closest N atom of bipyridyl and the N atom of the other $py_2C(OCH_3)O^-$ anion. The Cu_2O_2 group is more symmetric in the Cu(3)–Cu(4) dimer than in the Cu(1)–Cu(2) dimer. The average angle Cu–O–Cu is 93.15° for Cu(1)–Cu(2) and 92.55° for Cu(3)–Cu(4). The average value of angle τ, formed by the O–O direction and the C(3)–O(3) bond, is 48.5° for Cu(1)–Cu(2) and 49.8° for Cu(3)–Cu(4). The angle γ (Fig. 3), indicating non-planarity of the Cu_2O_2 group, is 12.85° for Cu(1)–Cu(2) and 11.15° for Cu(3)–Cu(4).

Because of the addition of methanol to the py_2CO molecule, the central carbon of $py_2C(OCH_3)O^-$ is sp^3 (see angles on C(3P), C(3Q), C(3S) and C(3R) in Table 4) and this anion is no longer plane. Its two pyridine rings form an angle of 73.6–81.1° between them. The conformation around the C(3)–OCH_3 bond is with the methyl group *gauche* to the oxygen atom linked to the copper atoms, the torsion angle C(32)–O(32)–C(3)–O(31) ranging from 42.7 to 45.1°. The bond distances C(3)–O(31) and C(3)–O(32) correspond to the simple bond C–O length, being shorter than the distance with the oxygen atom of the methoxy group.

The asymmetric unit is completed by two half-occupancy water molecules and four PF_6^- anions, three of which have been found to be disordered into two positions.

3.4.2. [(Cuphen)$_2${μ-[py$_2$C(OCH$_3$)O]}$_2$](PF$_6$)$_2$·2[py$_2$CO] (3) and [(Cuphen)$_2${μ-[py$_2$C(OCH$_3$)O]}$_2$](ClO$_4$)$_2$·2[py$_2$CO] (4)

Compounds **3** and **4** consist of $[(Cuphen)_2\{\mu\text{-}[py_2C(OCH_3)O]\}_2]^{2+}$ divalent cationic dimers, $2PF_6^-$ or $2ClO_4^-$ anions and two free molecules of py_2CO per dimer. All dimers are crystallographically equivalent. A crystallographic twofold axis relates the two halves of the cation. The coordination mode and the conformation of the $py_2COCH_3O^-$ ligand is similar to that found in compound **1**. The asymmetric unit is formed by half a dimer, an anion

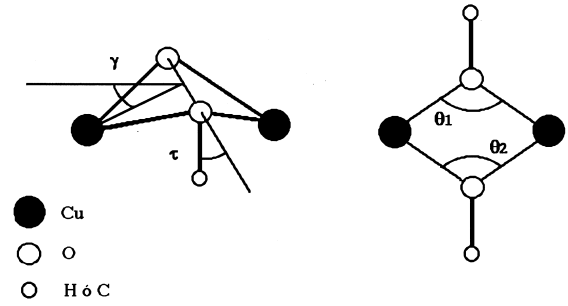

Fig. 3. θ, τ and γ angles in Cu_2O_2 group.

and a free ligand molecule (Fig. 4). Fig. 5 represents the structure of the complete dimer.

The more significant interatomic distances and angles are summarized in Table 5. As in compound **1**, each dimer comprises two copper atoms bridged by two anions

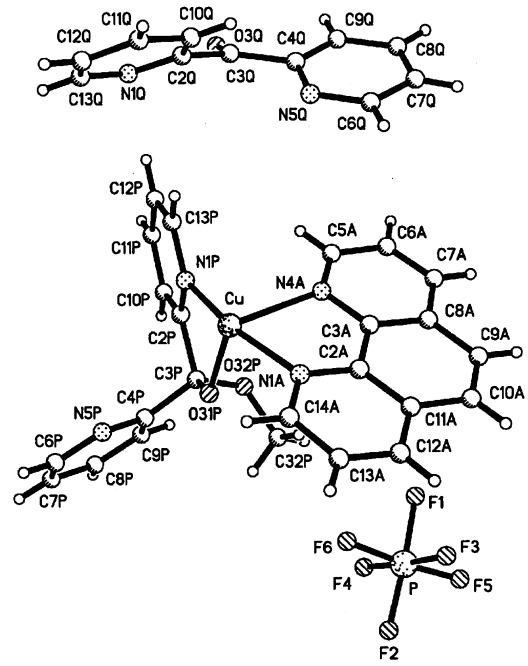

Fig. 4. Asymmetric unit of compound **3**.

[a] Symmetry transformation used to generate equivalent atoms: $-x$, y, $-z+1/2$.

$py_2C(OCH_3)O^-$, coordinated as N,O,N-donor, $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2$ ligand. Each of the nitrogen atoms of this anion is bonded to one copper atom, whereas the oxygen atom of the deprotonated hydroxyl group is simultaneously linked to both metal atoms, one of the corresponding Cu–O distances being much longer [Cu–O(31P′)] than the other [Cu–O(31P)]. The coordination sphere of each copper atom is completed by a phenanthroline chelating molecule, with one Cu–N distance significantly longer [Cu–N(4A)] than the other [Cu–N(1A)].

The Cu–O(31P)–Cu′ angles are very similar to those of compound **1**. The values of τ and γ (Fig. 3) are 43.6° and 15.4° for compound **3** and 42.8° and 15.3° for compound **4**, respectively. The non-coordinated interstitial py_2CO molecules are not planar, the angle formed by the two planar py groups being 46.6(3)° and 43.5(4)° for compounds **3** and **4**, respectively. The C(3Q)–O(3Q) bond distances agree with the double bond character, whereas C(2Q)–C(3Q), C(3Q)–C(4Q), O(31P)–C(3P), C(3P)–O(32P) and O(32P)–C(32P) bond distances correspond basically to simple bond lengths.

3.5. Magnetic results

Magnetic susceptibilities have been measured in the 4.3–292 K temperature range. The variation of the corrected molar magnetic susceptibility per Cu(II) atom, χ_M, and $\chi_M T$ versus temperature is similar for the four complexes and characteristic of a ferromagnetic intradimeric interaction. The corresponding plots for compound **3** are shown in Fig. 6. The $\chi_M T$ value is aproximately constant (0.450 $cm^3\,K\,mol^{-1}$; $\mu = 1.90$ μ_B) in the range 290–60 K. Below this temperature $\chi_M T$ increases until 0.569 cm^3 K mol^{-1} ($\mu = 2.14$ μ_B) at 4.7 K. The μ values at room and low temperature for compounds **1**–**4** are collected in Table 6.

The susceptibility data were fitted to the Bleaney–Bowers equation modified by the inclusion of the fraction of monomeric impurity [24]:

$$\chi_M = [C e^x (1-\rho)/(1+3e^x)] + C\rho/4 + N\alpha$$

where $C = Ng^2\beta^2/kT$, $x = 2J/kT$, ρ is the fraction of monomeric impurity, $N\alpha = 60\times10^{-6}$ cm^3 mol^{-1}. EPR g values were applied. The results of the best fit, shown as the solid line in Fig. 6, are collected in Table 6.

The correlation deduced by Hatfield and co-workers [1] between $2J$ and θ (bridging angle Cu–O–Cu) for di-μ-hydroxo planar copper dimers [$2J$ (cm^{-1}) $= -74.53\theta + 7270$] gives the 97.5° value as the limit between ferro- ($\theta < 97.5°$) and antiferromagnetic ($\theta > 97.5°$) character.

Ruiz et al. [2,3] studied the effect of other structural parameters for copper dimers with hydroxo and alkoxo bridges. These are, besides θ, the angle τ, formed between the O–O direction and the bond between the bridging oxygen atom and the hydrogen (carbon) atom, and the non-planarity of the Cu_2O_2 group, measured by γ (Fig. 3). High τ values are associated with lower values of θ and correspond to $2J$ more positive (ferromagnetism). For $\theta < 97.5°$ and $\tau > 40°$ a fer-

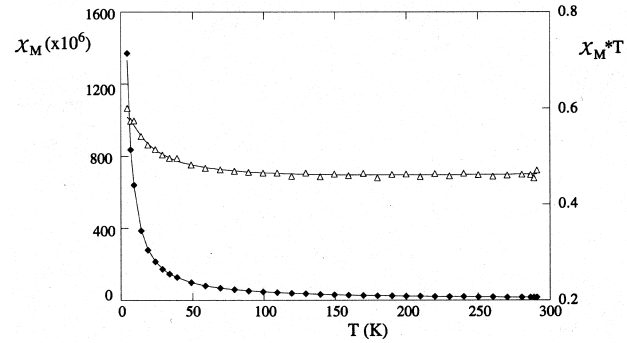

Fig. 6. Plot of of χ_M (♦) and $\chi_M T$ (△) vs. T for [{Cu(phen)}$_2${μ-[$(NC_5H_4)_2C(OMe)O$]}$_2$]$(PF_6)_2\cdot 2[(NC_5H_4)_2CO]$ (**3**).

Table 6
Magnetic results and significant structural data for compounds **1**–**4**

	1	**2**	**3**	**4**
μ (μ_B)	1.94 (290 K)	1.93 (292 K)	1.94 (291 K)	1.941 (291 K)
μ (μ_B)	2.14 (4.7 K)	2.13 (4.4 K)	2.19 (4.4 K)	2.18 (4.3 K)
g (from EPR)	2.135	2.140	2.151	2.144
$2J$ (cm^{-1})	10.0	10.1	16.7	15.8
$\rho\times10^2$ (%)	1.3	0.8	0.7	0.3
R [a]	6.80×10^{-5}	9.97×10^{-4}	1.41×10^{-5}	1.27×10^{-4}
θ (°)	92.8		92.4	92.5
τ (°)	49.1		43.6	42.8
γ (°)	12.0		15.4	15.3

[a] $R=\Sigma[(\chi_{Mi}T_i)_{exp}-(\chi_{Mi}T_i)_{calc}]^2/\Sigma[(\chi_{Mi}T_i)_{exp}]^2$.

romagnetic effect is to be expected. The non-planarity of the Cu_2O_2 group (γ) reduces the antiferromagnetic character and enhances the influence of τ.

For compounds **1**, **3** and **4**, $\theta<97.5°$ and $\tau>40°$. For compound **2** a structure similar to compound **1** may be assumed. These structural data may justify the ferromagnetic behaviour with $2J=10.0$, 10.1, 16.7 and 15.8 cm^{-1} for compounds **1**, **2**, **3** and **4**, respectively. The τ angle for the phen complexes (**3** and **4**) is lower than for the bipy complex (**1**). This fact should correspond to a more strong ferromagnetic interaction ($2J$ higher) in compounds **1** and **2** than in compounds **3** and **4**, but, at the same time, the γ angle (non-planarity of Cu_2O_2) is lower in compound **1** than in compounds **3** and **4**. According to Ruiz et al. the non-planarity of the Cu_2O_2 group enhances the ferromagnetic influence of τ, so the increase of the ferromagnetic effect in the phen complexes may be due to the stronger deviation of the planarity in the Cu_2O_2 group. All these results confirm the relation between the structural factors of the Cu_2O_2 group and the magnetic intradimer interaction.

3.6. EPR spectra

EPR spectra in the Q band at 100 K for powder samples have been recorded. In all cases the typical spectrum of the triplet state ($S=1$) for the ferromagnetic coupling in the dimer is observed. Furthermore, the six allowed $\Delta M=\pm1$ transitions, the forbidden $\Delta M=\pm2$ ($M=+1$ to $M=-1$) transition is resolved. The mononuclear impurity signal appears in the g_x zone. In Fig. 7 the spectra of compound **3** is shown.

The spectra were interpreted according to the Wasserman, Snyder and Yager equations [25,26], based on the hamiltonian: $H=gHS\beta+D[S_z^2-2/3]+E[S_x^2-S_y^2]$, with $D\neq0$ and $E\neq0$:

$$H_{x1}=(g_e/g_x)[(H_o-D'+E')(H_o+2E')]^{1/2}$$

$$H_{x2}=(g_e/g_x)[(H_o+D'-E')(H_o-2E')]^{1/2}$$

$$H_{y1}=(g_e/g_y)[(H_o-D'-E')(H_o-2E')]^{1/2}$$

$$H_{y2}=(g_e/g_y)[(H_o+D'+E')(H_o+2E')]^{1/2}$$

$$H_{z1}=(g_e/g_z)[(H_o-D')^2-E'^2]^{1/2}$$

$$H_{z2}=(g_e/g_z)[(H_o+D')^2-E'^2]^{1/2}$$

$$H_{min}=(g_e/g_{min})[(H_o^2/4)-(D'^2/3)+E'^2]^{1/2}$$

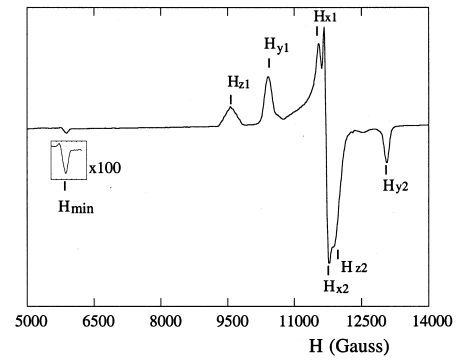

Fig. 7. EPR Q band spectra of powdered $[\{Cu(phen)\}_2\{\mu\text{-}[(NC_5H_4)_2C(OMe)O]\}_2](PF_6)_2\cdot2[(NC_5H_4)_2CO]$ (**3**), at 100 K.

Abstract

The complexes $[NiL_3](NO_2)_2 \cdot 2H_2O$ (violet, **1**) and *cis*-$[NiL_2(NO_2)_2] \cdot 0.5H_2O$ (pink, **1b**) (L = 1,2-diamino-2-methylpropane) have been synthesized from solution. The X-ray single crystal structure analysis of compound **1b** has been carried out, but the presence of a water molecule cannot be detected. Upon heating, complex **1b** undergoes dehydration followed by an endothermic phase transition to produce *trans*-$[NiL_2(NO_2)_2]$ (**1d**). The violet species (**1**) also undergoes dehydration upon heating with deamination resulting (**1d**). ©2000 Elsevier Science Ltd All rights reserved.

Keywords: *Cis–trans* isomerism; Crystal structures; 1,2-Diamino-2-methylpropane; Nickel(II) nitrite

1. Introduction

It is well known that the coordination mode of the nitrite ion, an ambidentate ligand, is influenced by the steric nature of neighbouring ligands [1–6]. This is best compared in the series of complexes of general formula Ni(diamine)$_2$-$(NO_2)_2$, formed mostly by N-substituted ethane-1,2-diamine, and it is apparent that there is a general trend for the nitrite to coordinate via nitrogen when little inter-ligand steric crowding is expected, but via oxygen when the ligands carry bulky substituents [1,7,8]. In all the cases, however, it is found that *trans*-octahedral geometry is preferred for the monodentate mode of coordination of the nitrite ion. On the contrary, reports regarding the influence of C-substituted ethane-1,2-diamine in which the substituted groups are somewhat apart from the donor nitrogen atom is scanty, although it has been found that they have considerable influence on the geometry around nickel(II) with several other counter-anions [9,10]. We report here the syntheses and characterization of $[NiL_3](NO_2)_2 \cdot 2H_2O$, *cis*- and *trans*-$[NiL_2(NO_2)_2]$ (L = 1,2-diamino-2-methylpropane) and the single crystal structure analysis of *cis*-$[NiL_2(NO_2)_2]$.

2. Experimental

2.1. Materials

1,2-Diamino-2-methylpropane (L) was purchased from Aldrich Chemical Company and used as received. Potassium hexanitronickelate(II) monohydrate was prepared using a standard method [11].

2.2. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin-Elmer 240C elemental analyser; nickel(II) content was estimated gravimetrically [12]. IR spectrum (4000–400 cm^{-1}) was taken at 27°C using a Perkin-Elmer IR 783 where KBr was used as medium. Electronic spectrum (1400–200 nm) was obtained at 27°C using an Hitachi UV–Vis–near-IR model U-3410 where Nujol was used as a medium as well as a reference. The magnetic susceptibility was measured at 27°C using an EG and G PAR

155 vibrating sample magnetometer, where [$HgCo(SCN)_4$] was used as a reference material; diamagnetic corrections were made using Pascal's constants.

2.3. Synthesis of the complexes

[NiL_3]$(NO_2)_2 \cdot 2H_2O$ (**1**) was synthesized by adding the diamine (3 mmol) in ethanol (5 cm^3) to an ethanolic suspension (10 cm^3) of potassium hexanitronickelate(II) monohydrate (1 mmol). The resulting deep-blue solution was kept in a $CaCl_2$ desiccator. After a few days, violet crystals separated out; these were filtered off, washed with ethanol and dried in the open air. Yield, 80%. Found: C, 31.8; H, 8.9; N, 24.8; Ni, 13.0%. $\mu_{eff} = 2.95\mu_M$. λ_{max} (Nujol) = 815, 525 nm. Calc. for $C_{12}H_{40}N_8O_6Ni$: C, 31.9; H, 8.9; N, 24.9; Ni, 13.0%.

cis-[$NiL_2(NO_2)_2$]$\cdot 0.5H_2O$[a] (**1b**) was synthesized in a similar way as (**1**) except that the amount of diamine (2 mmol) was different. After a few days, pink crystals separated out; these were filtered off, washed with ethanol and dried in a $CaCl_2$ desiccator. [When the compound is dried in air, a water molecule is found to be present, but on drying in a $CaCl_2$ desiccator the compound becomes *cis*-[$NiL_2(NO_2)_2$], (**1c**)]. Yield, 82%. Found: C, 29.2; H, 7.2; N, 25.7; Ni, 17.9%. $\mu_{eff} = 2.96\mu_M$. λ_{max} (Nujol) = 1148 and 718 nm. Calc. for $C_8H_{24}N_6O_4Ni$: C, 29.4; H, 7.3; N, 25.7; Ni, 18.0%.

trans-[$NiL_2(NO_2)_2$] (**1d**) was prepared pyrolytically in the solid state from compound **1** as well as from compound (**1b**). Found: C, 29.2; H, 7.3; N, 25.6; Ni, 18.0%. $\mu_{eff} = 2.99\mu_M$. λ_{max} (Nujol) = 1312, 1155 and 666 nm. Calc. for $C_8H_{24}N_6O_4Ni$: C, 29.4; H, 7.3; N, 25.7; Ni, 18.0%.

2.4. X-ray data collection and structure determination

A suitable single crystal of the title complex was mounted on a CAD4 Enraf-Nonius diffractometer. The unit cell parameters and crystal orientation matrix were determined by least-squares refinements of 25 accurately centred reflections. Intensity data were collected in the ω–2θ scan mode using graphite monochromated Mo Kα radiation. The crystal and instrument stabilities were monitored with a set of three standard reflections measured at a regular interval; in all cases no significant variations were found. The intensity data were corrected for Lorentz and polarization effects [13], and spherical absorption corrections were made. The systematic

[b] $R_1 = \sum(^0F_o - F_c^0)/\sum F_o$.
[c] $wR_2 = [\sum\{w(F_o^2 - F_c^2)^2\}/\sum\{w(F_o^2)^2\}]^{1/2}$.

absences show the space groups *C*2, *C* or *C*2/*m*. Of the three possible space groups *C*2 was confirmed by a successful structure refinement. A three-dimensional Patterson synthesis using SHELX-86 [14] showed the positions of the nickel(II) atoms at two special positions of (0, 0, 0) and (1/2, 0, 1/2). The remaining N, C and O atoms were located from the successive Fourier and difference Fourier syntheses. Full-matrix least-squares refinements on F^2 were carried out using SHELXL-93 [15] with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were constrained to ride on the respective carbon or nitrogen atoms (C–H, 0.97 Å; N–H, 0.900 Å) with an isotropic displacement parameter equal to 1.2 times the equivalent isotropic displacement parameter of the parent atom. Complex neutral atom scattering factors [16] were used throughout. All calculations were carried out using SHELXS-86, SHELXL-93, PARST [17] and ZORTEP [18] programs. Crystal data are summarized in Table 1. Selected bond lengths and bond angles are listed in Table 2.

3. Results and discussion

The composition of the complexes $NiL_3(NO_2)_2\cdot 2H_2O$ (**1**) and $NiL_2(NO_2)_2\cdot 0.5H_2O$ (**1b**) has been confirmed by elemental analyses. Both compounds **1** and **1b** possess octahedral geometry as is evident from their magnetic and electronic spectral data. In complex **1**, the IR bands due to ν_{as}, ν_s and δ of the nitrite group appear at 1329, 1264 and 827 cm^{-1}, respectively, suggesting non-coordination of the anion [19,20]. However, in compound **1b**, the above bands are observed at 1338, 1315 and 810 cm^{-1}, respectively. Shifting of both ν_{as} and ν_s to higher frequencies compared with the free nitrite ion indicates that the nitrite ion is coordinated via the N atom [7,8]. It is interesting to note that no band corresponding to a water molecule is observed in the IR spectrum of (**1b**). The X-ray single crystal analysis of compound **1b** (it also becomes dehydrated during data collection; the dehydrated species is numbered as **1c**) shows that the diamine is chelated and its IR bands for the diamines are very similar to those of complex **1**, suggesting that the diamines are also chelated in compound **1**. Electronic spectrum in the near-IR region of compound **1b** shows no splitting in the d–d band (1148 nm), indicating *cis* configuration [21,22] (Fig. 1).

Upon heating, complex **1** loses two molecules of water and transforms to compound **1a**, which on further heating yields $NiL_2(NO_2)_2$ (**1d**). On the other hand, *cis*-$NiL_2(NO_2)_2\cdot 0.5H_2O$ (**1b**) upon heating becomes dehydrated, as is evident from thermal gravimetric–differential thermal analysis (TG–

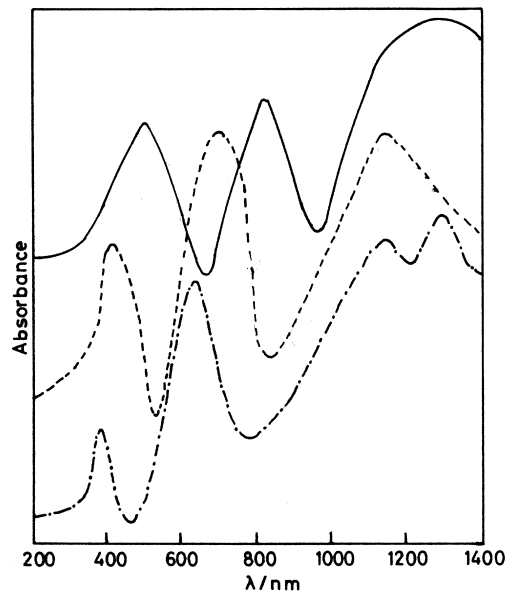

Fig. 1. Electronic spectra (Nujol) of (from top to bottom): $[NiL_3](NO_2)_2\cdot 2H_2O$ (**1**); *cis*-$[NiL_2(NO_2)_2]\cdot 0.5H_2O$ (**1b**); *trans*-$[NiL_2(NO_2)_2]$ (**1d**).

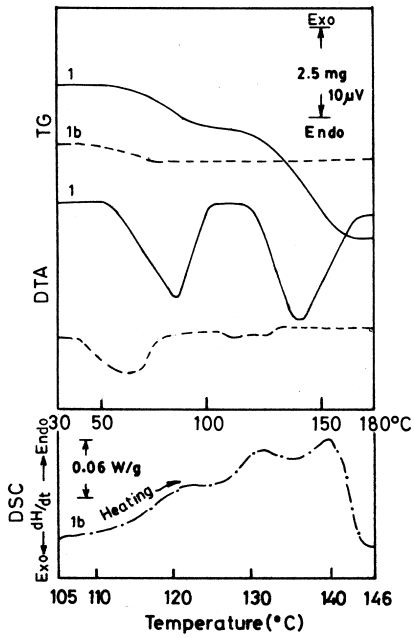
DTA) (Fig. 2), and then undergoes an irreversible endothermic phase transition ($\Delta H = 4.98$ kJ mol^{-1}) without showing any mass loss or visual colour change. The weight loss observed in the TGA curves for compounds **1** and **1b** [Found: 7.8 and 2.6%; Calc.: 8.0 and 2.7%, for compounds **1** and **1b**, respectively] corresponds to 2 and 0.5 moles of water, respectively. The species obtained from compounds **1** (after deaquation followed by deamination) and **1b** (after phase transition) are the same as they have identical X-ray diffraction powder pattern, IR and electronic spectra. The thermal reactions are summarized in Scheme 1.

Species **1d** is metastable and reverts slowly to compound **1b** as is evident from the X-ray powder diffraction pattern. It is found that the peaks characteristic of compound **1b** can be detected only after about 24 h of the isolation of compound **1d**. Gradually these peaks become dominant in the pattern and after about 10 days all the characteristic peaks of compound **1d** vanish completely. Thus it may be inferred that the metastable species **1d** remains pure for 24 h (without a detectable amount of compound **1b**) and completely transforms to compound **1b** in 10 days.

A ZORTEP view of compound **1c**, with atom numbering scheme, is shown in Fig. 3. With the metal atoms (NiA and NiB) lying at two special positions (0, 0, 0; 1/2, 0, 1/2), the crystallographic asymmetric units consist of two symmetrically independent half molecules. The coordination polyhedron of the metal atoms is best described as distorted octahedron. The angle N3A–Ni–N3A [83.0(5)° for A; 82.0(5)° for B] shows that the monodentate ligand moieties (NO_2) are coordinated in *cis* form. The angles N(amine)–Ni–N(amine) in *cis* arrangements are also close to 90°. The Ni–N bond distances are consistent with the corresponding values of other analogous octahedrally coordinated nickel(II)–amine complexes [23–27].

Relative humidity has a very interesting effect on the structure of compound **1b**. IR and crystal structure analysis of compound **1b** do not indicate the existence of a water molecule, but TG–DTA study indicates the presence of half a molecule of water per molecule of the complex. To study this effect we have used closed vessels of constant humidity (ca. 90 and 60%) [28]. At 90% humidity, complex **1b** does not lose any water molecule, but at 60% humidity and also in a $CaCl_2$ desiccator water is lost readily from compound **1b**, as is evident from the corresponding TG–DTA curves. The temperature of dehydration of compound **1b** (see below) or disappearance of a water molecule on keeping it in a desiccator suggests that the water molecule is too loosely bound. Both the hydrated and the dehydrated species upon heating show a phase transition at 103–143°C. Therefore, the presence of a water molecule in compound **1b** does not influence the phase-transition profile, which indicates that the water molecule does not alter the lattice of compound **1b**. This would have been impossible unless there exists a straight molecular sieve in the structure. This prompted us to calculate the void space in the unit cell of compound **1b** by using the program PLATON99 [29]. The calculated void space is 84 Å^3, which is sufficient to accommodate two molecules of water. It seems that the experimental conditions for IR-spectral run and X-ray data collection were not favourable for adherence of the loosely bound water molecule. The packing diagram in Fig. 4 shows channels that act as a water filter (H-bondings are shown by dashed lines). These filter-like channels contain water molecules (see below) which are lost on slight heating or low humidity (< 60%).



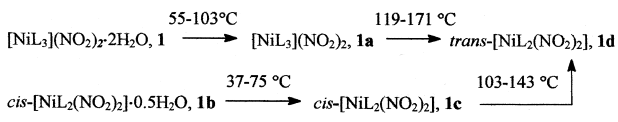


Fig. 2. Above: TG-DTA curves of $[NiL_3](NO_2)_2 \cdot 2H_2O$ (**1**) (sample mass, 12.7 mg) and *cis*-$[NiL_2(NO_2)_2] \cdot 0.5H_2O$ (**1b**) (sample mass, 12.38 mg). Below: DSC curve of $[NiL_2(NO_2)_2] \cdot 0.5H_2O$ (**1b**) (sample mass, 9.2 mg).

Several attempts were made to obtain single crystals of compound **1d**, but they revert on crystallization. As a result we examined compound **1d** by X-ray powder diffraction data. Accurate θ_{hkl} spacings (°) were obtained from the powder pattern recorded. The initial cell parameters have been determined from powder diffraction data using the program TREOR [30], and accurate lattice parameters were obtained by least-squares refinements. The results are summarized in Tables 1 and 3. Powder diffraction studies show that the unit cell volume of compound **1d** is 25.7 Å^3 larger than that of compound **1c**. The magnetic susceptibility and the electronic spectral data of compound **1d** in the solid state correspond to octahedral nickel(II). The IR bands of the nitrite group in compound **1d** at 1375, 1324 and 812 cm^{-1} correspond to ν_{as}, ν_s and δ, respectively, suggesting the coordination of nitrite ion via N atom [6,7]. X-ray single crystal structure analysis reveals that the diamine is chelated in compound **1c**. Complex **1d** possesses very similar IR bands of the diamines to those of **1c**, suggesting that the diamines are also chelated in **1d**. The appearance of two bands (1312 and 1155 nm) at the near-IR [31] region in the electronic spectrum suggests that compound **1d** is a *trans*-dinitro octahedral species.

[d] Symmetry codes: $x-1/2, y+1/2, z$.
[e] Symmetry codes: $-x+1/2+1, y+1/2, -z+1$.

The mechanism of phase transition may be explained as follows. In the *cis* species, N–H···O bonds would be expected to hinder the bond rotation of NO_2 groups and ligand moieties. These H-bonds (Table 4) are weakened upon onset of hindered rotation due to heating and thereby the *cis* molecule isomerizes to a *trans* molecule. Since X-ray diffraction studies indicate that the unit cell volume of compound **1d** is larger than that of compound **1c**, we may predict that the H-bonds and van der Waals interactions are weaker in compound **1d** than those of the *cis* species and thereby compound **1d** reverts slowly to compound **1c**.

Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting deposition number 132800.
