Abstract

Subvalent gallium can exist in aqueous solutions as Ga–Ga bonded gallium(II) species stabilised by halide ligands in the form of the complex anions $Ga_2X_6^{2-}$ (X = Cl, Br or I) whose formation and reactivity are discussed. Gallium(I) compounds and mixed valence compounds of gallium react vigorously with water, converting any Ga^+ ions into Ga(III) products. Indium(I) is more tolerant of water, so that perchlorate and other non-complexing aqueous media can support In^+ ions at concentrations up to 10^{-3} mol l^{-1} before disproportionation to In(0) and In(III) occurs. Subvalent indium concentrations of approximately 10^{-1} mol l^{-1} are attained in halogen acid solution, particularly HBr which yields red, solid InBr upon dilution. Spectroscopic data suggest the precursor is an In(II)–In(II) bromide complex (probably $In_2Br_6^{2-}$) capable of breaking up into In(I) and In(III) products.

1. Introduction

The Group 13 elements gallium, indium and thallium, the first group of the p-block, can attain the univalent state by the loss of an electron to form M^+ ions with the ns^2 configuration. The divalent state represented by M^{2+} with a single valence-shell electron is highly unstable, but when dimerised to $[M–M]^{4+}$ forms a stable nucleus which is chemically significant for gallium and, to a lesser extent, indium although practically unknown for thallium [1,2].

For gallium and indium, the subvalent states have pronounced roles. The Ga(I) and In(I) states have an important chemistry, while the M(II) state attained by virtue of direct Ga–Ga or In–In linkage also plays a part. Gallium and indium in subvalent states are liable to disproportionation and/or oxidation and hence function as reducing agents in aqueous conditions, however, the exact nature of the species remains subject to conjecture [3,4]. For thallium the Tl(I) state is usually more stable than Tl(III) and the stability of the Tl^+ ion in aqueous solution is a feature of the chemistry of this element [2].

This contribution reviews the occurrence in aqueous media of the subvalent forms of gallium and indium which can arise when these metals are attacked by acids or during electrolytic dissolution of a gallium or indium anode. Spectroscopic data are often the means of deducing the structures involved. Pertinent early work is re-examined and experiments on the indium bromide system, offering evidence of In(II) species in aqueous solution, are described and discussed.

2. Experimental

2.1. Preparative

Gallium, supplied in the form of pellets, was converted into a fine powder by melting the metal in water warmed to about 35 °C within a stoppered flask, then shaking the flask very vigorously while cooling took place. After decanting the water the powdered gallium was rinsed with acetone in order to dry it and shaken through a fine-mesh sieve to remove any larger pieces. Aqueous solutions of gallium in HCl, HBr or HI were prepared by allowing the powdered metal to dissolve in cold, concentrated acid, without stirring. Samples of the solution were withdrawn by pipette for investigation by

Raman spectroscopy. In some experiments an equal volume of diethyl ether was added to form an upper solvent layer into which gallium solute species were extracted spontaneously from the acidic aqueous phase.

Solutions of gallium in the halogen acids were also prepared by electrolytic oxidation from the anode of a simple cell. This cell consisted of gallium cast around a platinum wire which dipped into the acid phase (HCl, HBr or HI of predetermined concentration) and was connected to a platinum plate cathode through an external circuit made up of a low-voltage DC power supply with a milliammeter to monitor the current.

Indium metal was cut into thin shavings for use. Indium chloride and bromide solutions were prepared by dissolving the metal in concentrated hydrochloric or hydrobromic acid, without heating. For electrochemical experiments a short length of indium rod was attached to platinum wire and suspended in the halogen acid electrolyte as the anode of a cell similar to that for gallium.

2.2. Spectroscopy

Raman spectra of aqueous solutions and solvent extracts, contained in thin glass tubes, were obtained with a Bio-Rad Fourier Transform Raman system which employed the 1024 nm radiation of an infrared laser and hence minimised any possible photochemical decomposition.

X-ray absorption (EXAFS) data were recorded at the Stanford Synchrotron Radiation Laboratory (SSRL), using beamline 4 at 3.0 GeV and 50–60 mA. Monochromatic radiation was obtained from a Si(220) double crystal monochromator. High-order harmonics were rejected by 50% detuning. Incident and transmitted X-rays were monitored with argon-filled ion chambers. Seven scans were made for the indium sample, internally referenced by the K-edge of the corresponding metal foil to 27.924 keV. The liquid sample was contained in a cell of 2 mm thickness with Kapton film as windows. The FEFF program was employed to calculate the In–Br and In–In phase shift and amplitude functions, which were used in the non-linear, least squares fit of the new EXAFS data [5]. Final data evaluation was made by least-squares fitting [6].

2.3. Calculations

All quantum chemical calculations were performed using GAUSSIAN-98 (rev. A7) [7] ECP-based basis sets were used for indium and bromine, employing the Stuttgart-group quasi-relativistic ECP's (36 and 28 core electrons, respectively) and non-contracted valence spaces; (8s6p7d) and (5s5p1d), respectively, [8,9]. Calculations were performed at Hartree–Fock (HF) and 2nd-order Møller–Plesset perturbation theory (MP2) level.

3. Results and discussion

3.1. Subvalent gallium in halogen acid solutions

During early work [10] the Raman spectrum of a freshly prepared solution of gallium in hydrochloric acid was recorded by chance while effervescence was taking place. Despite some marring of the spectrum by reflected primary radiation, the result showed extra bands, in addition to those characteristic of the $GaCl_4^-$ complex. The tetrachlorogallate ion can be removed from the acidic aqueous phase by solvent extraction as the ion pair $[H^+(aq)][GaCl_4^-]$. A further sample was prepared by dissolving gallium into concentrated HCl in contact with an ether phase in an effort to achieve separation of the Ga(III) complex from the low-valent material within the aqueous phase; however, both species were found to transfer efficiently to the organic layer. Subsequent investigations [11,12] established that the low-valent species were gallium(II) complex anions of the type $Ga_2X_6^{2-}$ (X = Cl, Br or I). These can be prepared selectively by anodic oxidation of gallium in a medium consisting of the concentrated acid HX plus acetonitrile [13].

Experiments aimed at characterising low-valent gallium species in HCl media (aqueous solutions and solvent extracts) have revealed only $Ga_2Cl_6^{2-}$. This complex is recognised by a very strong Raman band at 233 cm^{-1} due to the coupled Ga–Ga and Ga–Cl symmetric stretching mode. The predominant species extracted from aqueous 6 mol l^{-1} HBr is also of this form, i.e. $Ga_2Br_6^{2-}$ present in the ether phase as the complex acid $H_2Ga_2Br_6$. An intense Raman band at 162 cm^{-1} characterises this complex.

The $Ga_2Cl_6^{2-}$ and $Ga_2Br_6^{2-}$ complex ions persist at ambient temperature for several hours in aqueous halogen acid media and for some days in an ether phase. Bubbles of hydrogen gas are produced during this period while slow oxidation occurs by the reaction:

$$Ga_2X_6^{2-} + 2H^+ + 2X^- \rightleftharpoons 2GaX_4^- + H_2 \quad (1)$$

The aqueous solution contains a reserve of the excess HX required. After the complex acid $H_2Ga_2Cl_6$ has been transferred to an ether phase, no longer in contact with HCl, there is a deficit of halide ligand for this reaction. Two processes have then been observed, which appear to be in competition. The major one involves co-ordination of the solvent to produce the ether adduct of $GaCl_3$:

$$Ga_2Cl_6^{2-} + 2H^+ + 2Et_2O \rightleftharpoons 2GaCl_3{\cdot}Et_2O + H_2 \quad (2)$$

Clear evidence for this process is given by the Raman spectrum, where the known Ga–Cl symmetric stretching band of $GaCl_3{\cdot}Et_2O$ at 364 cm^{-1} shows up as the reaction proceeds. The second process leads to deposition of a white solid. Only small amounts were collected

and this material has not been identified, however, a reasonable hypothesis suggests that the solid is Ga_2Cl_4, i.e. removal of two ligands from a $Ga_2Cl_6^{2-}$ anion to furnish the chloride ions required by reaction (1) leaves a Ga_2Cl_4 molecule which then disproportionates to the familiar mixed-valence form of $Ga[GaCl_4]$. Another possibility is that the solid may be a hydrolysis product of the form $Ga_2Cl_{4-n}(OH)_n$.

These preparations can be duplicated with gallium as the anode of a cell and aqueous HCl or HBr as the electrolyte, An ether layer serves to collect the products. When the cell contains 6 mol l^{-1} HBr the main product is $Ga_2Br_6^{2-}$. Subsequent changes in the Raman spectrum of the ether phase monitor the disappearance of this gallium(II) complex. Instead there are bands at 210 and 230 cm^{-1} which identify $GaBr_4^-$ and $GaBr_3{\cdot}Et_2O$, respectively, which are the obvious gallium(III) end products following oxidation.

When less concentrated HBr is employed, there is evidence of different subvalent gallium species. Thus, if 3 or 4 mol l^{-1} HBr is used, new bands appear at 173 and 186 cm^{-1}. Separate species are responsible for these, because the latter band becomes more intense when the bromide concentration is depleted, namely the pair of gallium(II) complexes, $Ga_2Br_5(Et_2O)^-$ and $Ga_2Br_4(Et_2O)_2$. The quantities have been insufficient to obtain the complete spectra by which structures might be confirmed, however, they are related to $Ga_2Br_6^{2-}$ by substitution of diethyl ether molecules for either one or two of the bromide ligands. The Raman features are assignable to the in-phase Ga–Ga plus Ga–Br stretching modes: the 173 cm^{-1} band to $Ga_2Br_5(Et_2O)^-$ and the 186 cm^{-1} band to $Ga_2Br_4(Et_2O)_2$. The latter is a molecular complex analogous to the series $Ga_2X_4L_2$ (X = Cl, Br or I; L = dioxane or other O- or N-donor) obtained by interaction of the ligand L with the halides $Ga[GaX_4]$ [14].

Dissolving powdered gallium in cold, concentrated hydriodic acid has been shown to yield $Ga_2I_6^{2-}$ alongside GaI_4^- [11]. Unfortunately the electrochemical approach fails to yield gallium complexes in HI solution because the oxidation of iodide to iodine (as I_3^-) takes over from the anodic dissolution of the metal. In consequence this system is not as well understood as those of gallium with HCl and HBr.

3.2. Subvalent indium in halogen acid solutions

Freshly prepared solutions of indium chloride, made by dissolving shavings of indium metal in concentrated (12 mol l^{-1}) hydrochloric acid, show signs of the presence of low-valent species. These acidic solutions continue to evolve hydrogen after all visible trace of the metal has disappeared, and liberate a stream of bubbles if gently stirred. The bleaching of potassium permanganate solution confirms the presence of reducing species, and warming the HCl solution causes evolution of hydrogen gas (after which the reducing property is lost).

The Raman spectrum of such an indium chloride solution is dominated by a broad band at 275 cm^{-1} arising from the In–Cl stretching modes of various chloride complexes, believed to include $InCl_4^-$ and $InCl_5^{2-}$ in their aquated forms [15]. To investigate further, this solution was diluted with water, causing indium to be regenerated in the form of a black powder and confirming the presence of low-valent species which disproportionate. Previous workers have ascribed such behaviour to the instability of indium(I) species, relative to In(III) and the metal:

$$3In(I) \rightleftharpoons 2In(0) + In(III) \quad (3)$$

Failure to detect the errant material in the Raman spectrum may be because it is simply the bare In^+ cation, or be due to masking by indium(III) chloride species whose spectra would tend to overlay those of any low-valent indium chloride complexes.

The remainder of the hydrochloric acid solution was extracted with diethyl ether. The Raman spectrum of this extract shows the strong band at 321 cm^{-1} which is characteristic of $InCl_4^-$ [15] but reveals no other indium complexes. The spectrum of the aqueous phase following extraction contains only the In–Cl band (ca. 280 cm^{-1}) due to residual indium(III) chloro-complexes.

The behaviour of indium when attacked by concentrated HBr also shows that subvalent species are implicated. Work by Dronskowsky [16] has demonstrated that the quantity of indium taken into solution is substantially more than expected by formation of In(III). In particular, experiments to measure the excess solubility of indium in the acid HX give figures of 15% for HCl, 16% for HBr, 24% for HI. The resulting solutions appeared stable in an open beaker at ambient temperature, although if heated at 50 °C and stirred, hydrogen gas was evolved. The solution in 9 mol l^{-1} HBr was estimated to contain In(III) at 2.62 mol l^{-1} along with low-valent indium at 0.90 mol l^{-1} (calculated as In(I)). Dronskowski pointed out that such a high concentration of In^+ was far beyond the levels typical reported during indium anodisation studies using aqueous media (typically less than 10^{-3} mol l^{-1}).

We have now repeated these investigations of the indium bromide system, as follows. When an equal volume of water is added to the freshly prepared, colourless solution of indium in HBr, a bright red precipitate is produced. Dronskowski showed that this material corresponds to indium monobromide [17]. Extending the investigation of this system, we find that the red solid InBr redissolves in HBr, or in a concentrated aqueous solution of NaBr, only with immediate oxidation, which is signalled by hydrogen being evolved.

Dronskowski [16] suggested that the precursor of the InBr precipitate might be an indium(I) bromide complex, proposing In_2Br^+. If so, this (or some other In(I) complex) should be regenerated on dissolution of the solid in the presence of bromide ions, which is contrary to our observations.

We investigated the aqueous solutions of indium in HBr by Raman spectroscopy. A concentrated solution of indium in 6 mol l^{-1} HBr, after heating to complete the oxidation, gives an intense ν(In–Br) band at 197 cm^{-1} due to In(III) bromide complexes, as expected [18]. However, when a freshly prepared sample was examined we obtained the Raman spectrum in Fig. 1. This spectrum contains an additional feature at 139 cm^{-1}. Initially we supposed this band might belong to an indium(I) bromide complex. Plausible In(I) complexes are $InBr_2^-$ and $InBr_3^{2-}$. The latter has a Raman spectrum [19] with ν(In–Br) bands at 149 and 177 cm^{-1} and so can be eliminated. The triatomic species $InBr_2^-$, with its smaller co-ordination number and lower charge, should exhibit In–Br stretching modes at higher

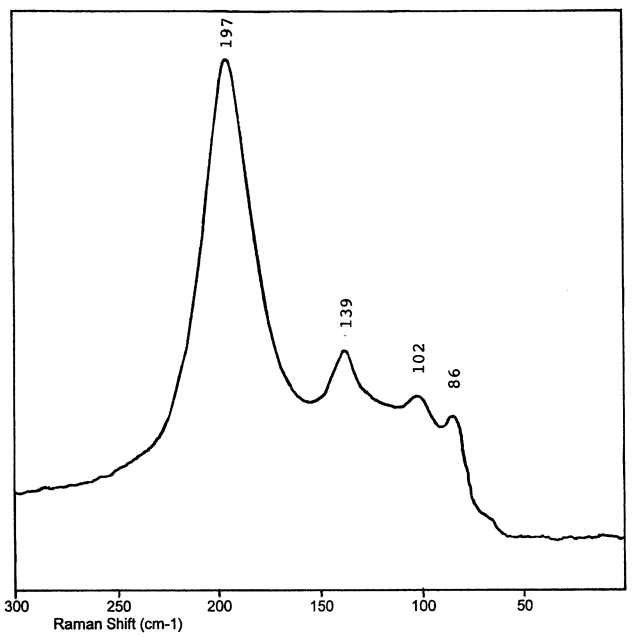

Fig. 1. Raman spectrum of a freshly prepared solution of indium in HBr with bands attributed to $InBr_4^-$ at 197 cm^{-1} and $In_2Br_6^{2-}$ at 139 cm^{-1}. The features at 86 and 102 cm^{-1} probably include bending modes.

Table 1
The calculational results for $In_2Br_6^{2-}$ of D_{3d} symmetry

Method	d_{In-Br} (Å)	d_{In-In} (Å)	Frequency (A_{1g}) (cm^{-1})
HF	2.633	2.847	136
MP2	2.614	2.808	133

The vibrational band of A_{1g} symmetry given above is dominated by stretching of the In–In bond.

frequencies than $InBr_3^{2-}$ and hence can also be discounted. Calculations made for the $InBr_2^-$ and $InBr_3^{2-}$ species indicate that the In–Br bond lengths are too long, at least 0.3 Å longer compared with $In_2Br_6^{2-}$, thus giving symmetrical In–Br stretch frequencies of potentially high Raman intensity that are about 100 cm^{-1} or less. The cation suggested earlier, namely In_2Br^+, is a possibility, although it seems unlikely that this would survive where potential ligands in the shape of bromide ions are present in large quantity.

Our alternative view is that the low-valent form co-existing with $InBr_4^-$ is an indium(II) complex of which the most probable is $In_2Br_6^{2-}$. This species, akin to $Ga_2Br_6^{2-}$, possesses an In–In bond and has been prepared and identified by Tuck who reported its vibrational spectrum [20]. The most intense Raman band (comprising the coupled In–In and In–Br symmetric stretch) appears at 139 cm^{-1} which fits the bill for the present species. Other Raman active modes of $In_2Br_6^{2-}$ are In–Br stretches at 202 and 244 cm^{-1}, however, both these are weak bands which would be hidden by those of $InBr_4^-$ at 197 and 239 cm^{-1}. The results of quantum chemical calculations given in Table 1 give good support to the proposed presence of $In_2Br_6^{2-}$. The Hessian show that the ground state configuration of $In_2Br_6^{2-}$ is the staggered (D_{3d} symmetry), whereas the eclipsed (D_{3h} symmetry) is only a transition state with respect to rotational transformation of the staggered conformer. Indium K-edge EXAFS measurements of a freshly prepared solution were also recorded. However, the results can very accurately be described in terms of tetrahedral $InBr_4^-$ complexes with an In–Br distance of 2.55 ± 0.01 Å as the only indium-containing species present. The fundamental problem is that if $In_2Br_6^{2-}$ is present as well at a reasonable but lower concentration, the very similar indium neighbourhood (three In–Br and one In–In contact at 2.6–2.8 Å) will make it extremely difficult to identify the In(II) in the presence of $InBr_4^-$. Despite this, it is possible to fit a somewhat rigid model of $In_2Br_6^{2-}$ to the EXAFS data, which is shown in Fig. 2(a) and (b). On the other hand, the EXAFS data give no indication for any significant amount of In(I) species with substantially longer In–Br distances (about 3 Å).

3.3. Mechanism of formation of InBr

It would be desirable to isolate the subvalent indium bromide complex for more complete identification, however, we were unable to prepare aqueous HBr solutions of indium, or ether extracts, other than those in which indium(III) bromide complexes are heavily predominant. We assume that the indium(II) state is stabilised in the form of $In_2Br_6^{2-}$ when bromide is in excess, but that this complex dissociates upon dilution and that the resulting product ($In_2Br_5^-$ or its solvated

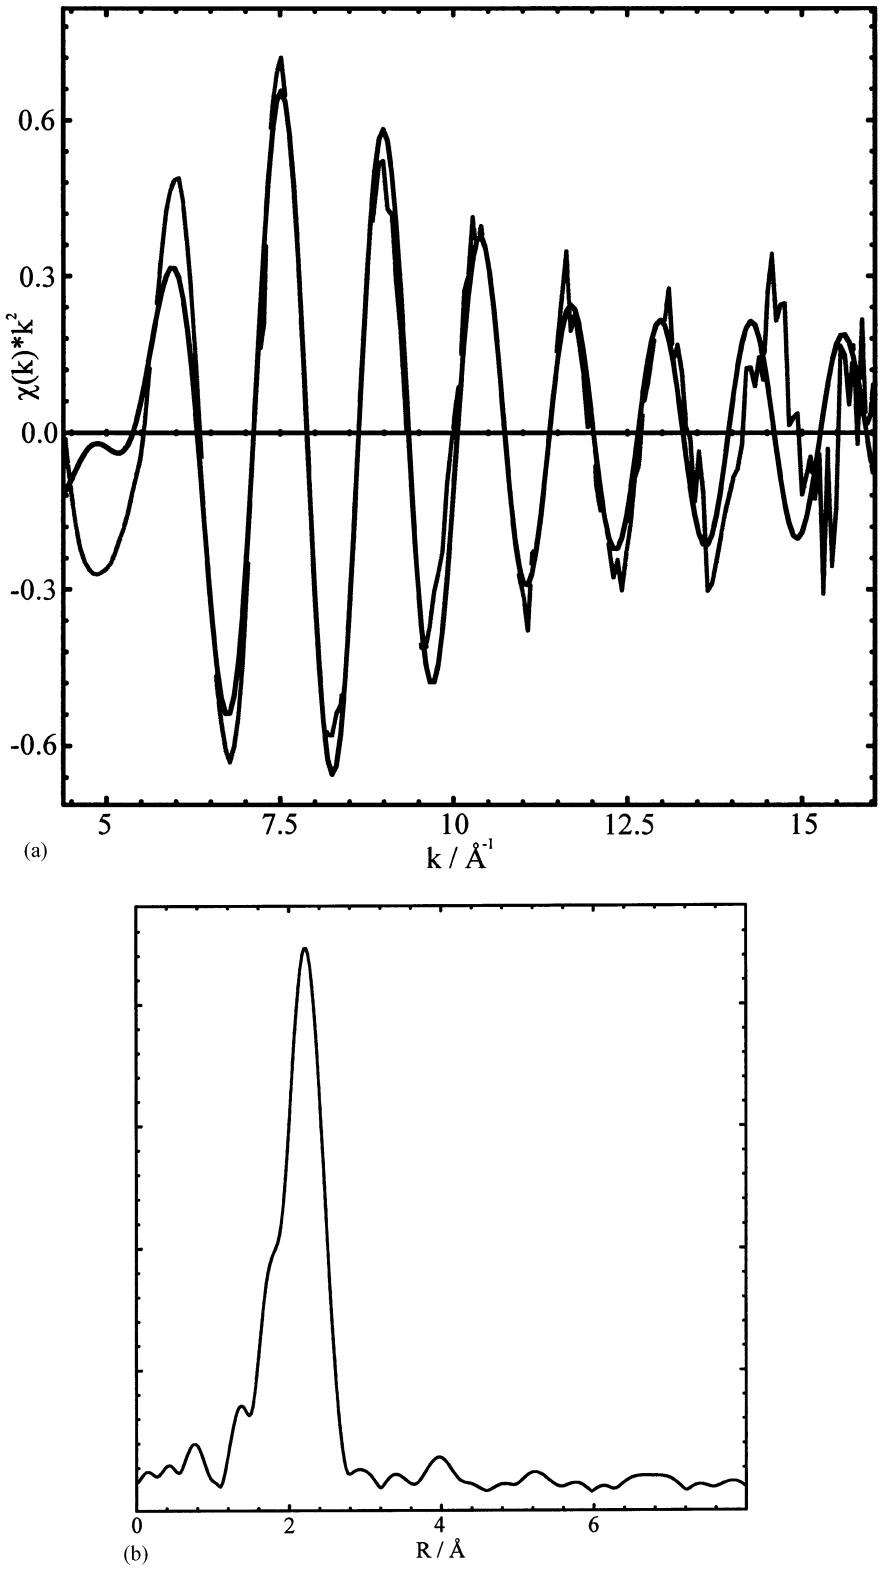

Fig. 2. (a) EXAFS data with a model of $In_2Br_6^{2-}$ included. The model has a In–In distance of 2.69 Å and a In–Br distance of 2.43 Å. (b) Fourier transform of the EXAFS data.

form $In_2Br_5(H_2O)^-$) then disproportionates to yield InBr.

$$In_2Br_6^{2-} \rightleftharpoons In_2Br_5^- + Br^- \quad (4)$$

$$In_2Br_5^- \rightleftharpoons InBr + InBr_4^- \quad (5)$$

In support of this mechanism we note that the second step parallels the reaction $In_2X_6^{2-} = InX_2^- + InX_4^-$

which has been proposed in prior studies of the stability of In–In bonded species relative to InX and InX_3 when these form an equilibrium system in suitable organic-ligand-based media [21].

The two-step mechanism proposed here accounts for the fact that InBr does not dissolve in bromide rich media (either HBr or NaBr) to regenerate a long-lived species. Instead, the solid reacts with the solution so that any indium(I) bromide complexes formed, e.g. $InBr_2^-$, will be promptly oxidised:

$$InBr_2^- + 2H^+ + 2Br^- \rightleftharpoons InBr_4^- + H_2 \quad (6)$$

Due to this reaction only a low level of indium(I) will remain in the aqueous solution.

3.4. Anodic oxidation of indium

Electrode reactions of indium provide ample evidence of the subvalent state. For indium, the value of n in the reaction $M = M^{n+} + ne^-$ (determined by measuring the weight loss of the metal anode for a given current and time) approaches unity in non-complexing media (whereas n never falls below two in the case of gallium). Thus, in acetonitrile, anodic oxidation of indium metal yields solutions with In^+ concentrations up to 0.1 mol l^{-1} [22] Similarly, anodic oxidation of indium or an indium/mercury amalgam in aqueous perchlorate media generates In^+ (presumably as the aquated cation), although the levels are much smaller than in acetonitrile, e.g. 3×10^{-4} mol l^{-1} in dilute $HClO_4$ [23]. The standard reduction potentials -0.126 V for $In^+ + e = In$ compared with -0.338 V for $In^{3+} + 3e = In$ [2] emphasise the slight stability the $+1$ state of indium relative to its $+3$ state. An aqueous solution of the hypovalent indium(I) state can be prepared as a useful reducing agent by treatment of In(Hg) with silver triflate in acetonitrile [24]. If iodide is present, a precipitate of indium monoiodide is produced during electrolysis [25] corresponding to the electrode reaction:

$$In + I^- \rightleftharpoons InI + e^- \quad (7)$$

Attempts to generate low-valent indium in HCl or HBr solutions electrolytically are beset by spontaneous disproportionation of the solute species. Such cells tend to deposit finely divided metal beneath the anode and indium(III) halide complexes dominate the resulting solution.

Reaction of $\{HC(CMeNAr)_2\}Li$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) with indium monochloride to yield the In–In bonded dimer $[\{HC(CMeNAr)_2\}InCl]_2$ and the hydroxide $[\{HC(CMeNAr)_2\}InCl(\mu\text{-}OH)]_2$

Abstract

The reaction of the sterically encumbered lithium β-diketiminate $\{HC(CMeNAr)_2\}Li$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) with InCl in THF at approximately −78 °C yielded In metal and $[\{HC(CMeNAr)_2\}InCl]_2$ (**1**) as well as minor amounts of the hydroxide $[\{HC(CMeNAr)_2\}In(Cl)(\mu\text{-}OH)]_2$, **2**. The compounds **1** and **2** were characterized by ^1H, ^{13}C NMR, IR spectroscopy and X-ray crystallography. The centrosymmetric structure of **1** features an In–In bond that is 2.8343(7) Å long which is well within the known range of In–In single bond distances. The metal β-diketiminate ring (i.e. C_3N_2In) is folded along the N···N vector and features an out of plane deviation by the indium of 0.8953 Å and a dihedral angle between the C_3N_2 and InN_2 arrays of 145.8°. This can be attributed to steric effects of the Ar groups on the β-diketiminiate ligand. The structure of the hydroxide derivative **2** is a dimer in which the indiums are bridged by hydroxides to afford a planar In_2O_2 core with an average In–O distance of 2.13(2) Å. Attempted reduction of the dihalide compounds $\{HC(CMeNAr)_2\}InX_2$ (X = Cl, I) with sodium or potassium led to the formation of metallic indium and the free β-aminoimine $(Ar)NC(Me_2)CHC(Me_2)N(Ar)H$ rather than the desired In(I) species, $\{HC(CMeNAr)_2\}In$:. © 2002 Elsevier Science Ltd. Keywords: β-Diketiminate; Low valent indium; Bulky ligands; Metal–metal bonds

1. Introduction

Recent years have witnessed an impressive revival of interest in bidentate, β-diketiminate ligands which have been known for more than four decades [1]. Much of the recent work has focused on more sterically encumbered derivatives that feature bulky substituents at the nitrogens. These ligands have proved to be very useful in a variety of rôles including the stabilization of low coordinate, low valent main Group 13 metal complexes [2–4]. Through the use of the ligand $[HC(CMeNAr)_2]^-$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) the unusual, two-coordinate, monomeric M(I) species $[HC(CMeNAr)_2]M$: (M = Al [3], Ga [4]), which are analogous to carbenes, have been stabilized. The corresponding In(I) species are unknown, although there is widespread interest in In(I) compounds as evidenced by the growing number of organometallic [5–7] and related derivatives [7,8] of In(I) that have been synthesized. Almost all of the organoindium(I) compounds are associated in the solid state. However, the trispyrazolylborate complexes $HB(pz)_3In$ (pz = 3-phenylpyrazolyl [7], 3,5-di-*tert*-butylpyrazolyl [8a], 3-*tert*-butylpyrazolyl [8b], 3,5-$(CF_3)_2$-pyrazolyl [8b,8c]), in which the In atom is coordinated by three N donors, are monomeric in the solid state. There is only one example of a monomeric, organometallic In(I) species in the literature and this species involves the bulky *m*-terphenyl group $-C_6H_3$-2,6-$Trip_2$ (Trip = $-C_6H_2$-2,4,6-*i*-Pr_3) [9]. This ligand shows a steric resemblance to the bulkyl β-diketiminate $[HC(CMeNAr)_2]^-$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) [10]. Due to the very rich chemistry already displayed by the monomeric M(I) species $[HC(CMeNAr)_2]M$: (M = Al, Ga) [11–14] it is of interest to synthesize the In ana-

logue and explore its chemistry. We now report that the reaction of $\{HC(CMeNAr)_2\}Li$ with InCl leads not to the expected monomeric $\{HC(CMeNAr)_2\}In$ analogue but to disproportionation reactions that yield the unexpected In–In bonded species $[\{HC(CMeNAr)_2\}InCl]_2$ (**1**) and the hydroxo complex $[\{HC(CMeNAr)_2\}InCl(\mu\text{-}OH)]_2$ (**2**).

2. Experimental

2.1. Synthesis

2.1.1. General procedures

All manipulations were carried out using modified Schlenk techniques under an atmosphere of N_2 or in a Vacuum Atmospheres HE-43 drybox. All solvents were distilled from Na–K alloy and degassed three times before use. The compound $\{HC(CMeNAr)_2\}H$ (Ar = C_6H_3-2,6-*i*-Pr_2) was prepared as previously described [10]. InCl (99.99%) was purchased commercially and used as received.

2.2. $[\{HC(CMeNAr)_2\}InCl]_2$ (1) and $[\{HC(CMeNAr)_2\}InCl(\mu\text{-}OH)]_2$ (2)

A solution of $\{HC(CMeNAr)_2\}Li$ in THF (generated by reaction of 1.06 g of $\{HC(CMeNAr)_2\}H$ and 1.6 ml of 1.6 M *n*-BuLi in 20 ml of THF with cooling in an ice bath) was added dropwise to a suspension of InCl (0.42 g, 2.79 mol) in THF (30 ml) with rapid stirring and cooling in a dry ice acetone bath. The reaction mixture was stirred for 2 h and then allowed to come to approximately −10 °C (ice–NaCl bath). After stirring for an additional 1 h the solvents were removed under reduced pressure. The solid residue was extracted with cold hexane (40 ml, ca. −10 °C). The solution was allowed to come to ambient temperature where the dark precipitate which had formed (indium metal and lithium chloride) was allowed to settle. The amber supernatant solution was then filtered through celite. Concentration under reduced pressure produced a low yield of large colorless needles which were collected after ca. 8 h in a ca. 4 °C refrigerator. These were identified as the hydroxide derivative **2**. Yield: 0.05 g, 0.037 mmol, 15%, melting point (decomposition) m.p. (dec.) > 100 °C. ^{1}H NMR (400 MHz, C_6D_6): δ 7.2–7.1 (m, 12H, Ph), 4.63 (s, 2H, γ-CH), 3.31 (sept, 8H, $J = 6.8$ Hz, C*H*Me$_2$), 1.48 (s, 12H, Me), 1.25 (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$), 1.10 (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$), 0.93 (s, broad, 2H, O*H*); ^{13}C NMR (C_6D_6): δ (ppm) = 159.2 (CN), 142.7, 141.3, 125.8, 123.6 (Ph), 94.2 (γ-C), 28.6 (*C*HMe$_2$), 24.4 (CH*Me*$_2$), 23.4 (CH*Me*$_2$), 20.7 (Me); IR (Nujol): ν (cm^{-1}) = 3660 (νOH). The supernatant solution was decanted and concentrated under reduced pressure to incipient crystallization (ca. 30 ml). Storage for 30 h in a ca. 4 °C refrigerator yielded the product **1** as colorless crystals. Yield: 0.23 g, 0.20 mmol, 16%, m.p. 155–157 °C. ^{1}H NMR (400 MHz, C_6D_6): δ 7.2–7.0 (m, 12H, Ph), 4.73 (s, 2H, γ-CH), 3.33 (sept, 8H, $J = 6.8$ Hz, C*H*Me$_2$), 1.58 (s, 12H, Me), 1.35 (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$), 1.21 (d, 24H, $J = 6.8$ Hz, CH*Me*$_2$); ^{13}C NMR (C_6D_6): δ (ppm) = 171.8 (CN), 144.5, 138.0, 124.8 (Ph), 98.1 (γ-C), 28.3 (*C*HMe$_2$), 25.8 (CH*Me*$_2$), 25.2 (CH*Me*$_2$), 24.6 (Me).

The attempted reduction of the dihalides $\{HC(CMeNAr)_2\}InX_2$ (X = Cl, I) with finely divided potassium in toluene resulted in the precipitation of In metal at room temperature (r.t.).

2.3. X-ray data collection

X-ray quality crystals of **1** or **2** were removed from the Schlenk tube and immediately covered with a layer of hydrocarbon oil. A suitable crystal was selected, attached to a glass fiber and placed in the cold temperature N_2-stream as previously described [15]. The data were collected near 90 K using a Bruker SMART 1000 diffractometer and Mo Kα ($\lambda = 0.71073$ Å) radiation. The SHELXTL version 5.03 program package was used for the structure solutions and refinements [16]. Absorption corrections were applied using the SADABS program [17]. The structures were solved by direct methods and refined by full matrix, least-squares procedures. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the refinement at calculated positions using a riding model included in the SHELXTL program package. Some details of the data collection and refinement are given in Table 1. Selected bond distances and angles for **1** and **2** are provided in Table 2.

3. Discussion

3.1. Synthesis

The compounds **1** and **2** were both obtained by the addition of $\{HC(CMeNAr)_2\}Li$, generated in THF, to a suspension of InCl in THF with cooling in an approximately −78 °C dry ice acetone bath. None of the expected product $\{HC(CMeNAr)_2\}In$: was isolated from the reaction under these conditions. This was to some extent surprising since the aluminum(I) and gallium(I) analogues of this putative indium species were already known [3,4]. Furthermore, the one coordinate indium derivative of the $-C_6H_3$-2,6-$Trip_2$ ($Trip = C_6H_2$-2,4,6-*i*-Pr_3) group, which bears a close steric resemblance to the $\{HC(CMeNAr)_2\}$ ligand, was already characterized [9]. Moreover 2,6-$Trip_2H_3C_6In$: was synthesized by the direct reaction of the lithiated terphenyl ligand with InCl in THF under almost identical conditions to those described in this paper. In view of the fact that indium metal, lithium chloride and free ligand were produced during the course of the attempted synthesis of $\{HC(CMeNAr)_2\}In$:, it seems probable that disproportionation and ligand redistribution reactions occur to give the observed product **1** in 16% yield. Small amounts of the hydroxo-bridged species **2** were also obtained in much lower yield. The latter species is probably the result of moisture contamination and it is possible to carry out the reaction to generate negligible amounts of **2** by using extremely strict anaerobic and anhydrous procedures. In spite of the unanticipated nature of the product **1**, it has been recently reported [18] that the reaction of the aza alkyl lithium compound $PhC\{(Me_3Si)_2C\}\{N(SiMe_3)\}Li$ with InBr afforded the In–In bonded dimer $[PhC\{C(SiMe_3)_2\}\{N(SiMe_3)_2\}InBr]_2$. This reaction is significant in that the uninegative, bidentate nature of this ligand is related to the β-diketiminate $\{HC(CMeNAr)_2\}^-$. Other examples of disproportionation reactions of various lithium amide ligands with indium(I) halides to afford In–In bonded products are also known [19,20].

3.2. Structures

The structure of **1** is illustrated in Fig. 1. Selected bond distances and angles are provided in Table 2. The structure possesses a center of symmetry at the midpoint of the In–In bond. The indiums are four-coordinate with a very distorted tetrahedral geometry at the metals. The In–In distance is 2.8334(7) Å which may be regarded as a typical one since it falls in the middle of the currently known range (2.696(2)–2.922(1) Å [21,22]) for neutral molecular In–In singly bonded species. The In–N distances, av. 2.171(2) Å, are marginally longer than the 2.111(3)–2.147(1) Å range observed in the $\{HC(CMeNAr)_2\}InX_2$ (X = Cl or I) [2], but they are shorter than the average distance of 2.197(4) Å in $\{HC(CMeNAr)_2\}InMe_2$ [2]. The variation in these distances illustrates the influence of coligands on the effective ionic radius of indium. More electronegative co-ligands contract the radius, whereas more electropositive ligands expand it; hence the longer In–N distances in $\{HC(CMeNAr)_2\}InMe_2$. The C_3N_2 ring fragment of the β-diketiminate ligand has planar geometry and the C–C and C–N distances are symmetric indicating delocalization of the negative charge. However, the C_3N_2In ring is folded along the N···N vector such that there is a dihedral angle of 145.8° between the InN_2 and C_3N_2 planes. The indium atom lies 0.895 Å from the extended C_3N_2 plane. This folding is similar to that reported in $\{HC(CMeNAr)_2\}InMe_2$ but it is higher than that seen in the halide derivatives. Another feature

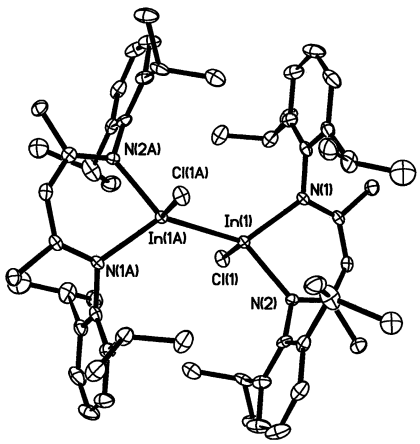

Fig. 1. Thermal ellipsoid plot (30%) of **1**. H atoms are not shown.

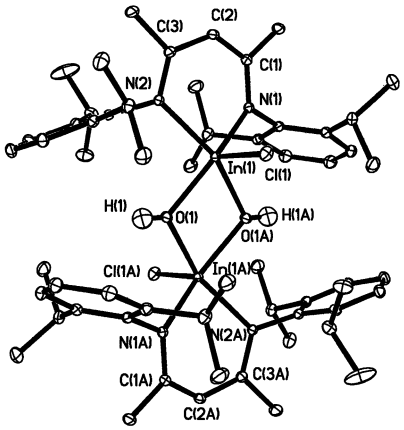

Fig. 2. Thermal ellipsoid plot (30%) of **2**. H atoms are not shown.

of the structure of **1** is the narrow N–In–N angle and this is similar to those reported for the halide and methyl derivatives [2] which all have N–In–N angles that are less than 90°. The In–Cl bond length is 2.4142(14) Å which is very similar to the 2.4174(9) Å in the tropoiminate complex $(Me_2ATI)_2InCl$ [23] and slightly longer than the average of 2.396(3) Å in $\{HC(CMeNAr)_2\}InCl_2$ [2] although the accuracy of the latter distance is reduced by the presence of bromine contaminant.

The structure of the hydroxide bridged dimer **2** is illustrated in Fig. 2. Like **1**, it is centrosymmetric with a crystallographically required planarity for the In_2O_2 core in this case. The core has diamond geometry with a difference of approximately 18° between the ring angles at indium and oxygen. The two In–O distances differ slightly and have an average value of 2.13(2) Å which is not significantly different from the average of 2.14(1) Å observed in bis(3-(2-pyridyl)pyrazolyl-1-yl)methane stabilized complex of the dimer $\{ClIn(\mu\text{-}OH)\}_2$ [24] or the average of 2.164(2) Å observed for $[\{(Me_3Si)_2CH\}_2In(\mu\text{-}OH)]_2$ [25]. The In–N bond lengths in **2** are essentially indistinguishable from those observed in **1** in spite of the increase in coordination number of the metal from four to five. As in **1**, the C_3N_2In ring is folded along the N···N vector. A dihedral angle of 150° is observed between the C_3N_2 and InN_2 planes and the indium lies 0.800 Å from the extended C_3N plane. The N–In–N angle is also less than 90° and within 0.6° of the value reported for **1**.

4. Conclusions

The attempted synthesis of $\{HC(CMeNAr)\}In$: has led to the disproportionation or hydrolysis products **1** or **2**. The reasons for the apparent lack of stability $\{HC(CMeNAr)_2\}In$: are not obvious, especially since the sterically related species $2,6\text{-}Trip_2H_3C_6In$: [9] is known to be stable. The existence of this compound and the aluminum and gallium species $\{HC(CMeNAr)\}M$: (M = Al [3] or Ga [4]) strongly suggest that $\{HC(CMeNAr)\}In$: should be obtainable under different reaction conditions.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC nos. 169219 and 169220 for compounds **1** and **2**. Copies of this information may be obtained from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Tris(pentamethylphenyl)gallium, $(Me_5C_6)_3Ga$, was prepared by reaction of pentamethylphenylmagnesium bromide with gallium(III) chloride in diethyl ether. The title compound, characterized by ^1H and ^{13}C NMR, elemental analyses, and single crystal X-ray diffraction, crystallizes in the $P\bar{1}$ (No. 2) space group with $a = 9.003(9)$ Å, $b = 10.713(1)$ Å, $c = 16.066(2)$ Å, $\alpha = 107.63\ (3)°$, $\beta = 97.63\ (3)°$, $\gamma = 90.08(3)°$, for $Z = 2$. Refinement converged at $R_1 = 0.050$, $wR_2 = 0.11$. The pentamethylphenyl ligands are configured about the gallium center in a propeller fashion at angles of 67.3°, 62.3°, and 60.9°. © 2002 Published by Elsevier Science Ltd.

Keywords: Tris(pentamethylphenyl)gallium; Pentamethylphenylmagnesium bromide; Elemental analyses; Single crystal X-ray diffraction

1. Introduction

The initial breakthrough in low-valent organogallium chemistry resulting in Ga–Ga bonds may be traced to the utilization of sterically demanding ligands [1]. Although, the phenyl ligand, $C_6H_5^-$, is not generally considered to possess significant steric bulk, it has served as the template upon which some notable sterically demanding ligands have been derived [2]. It is interesting that the methyl-saturated phenyl derivative, pentamethylphenyl, $Me_5C_6^-$, has not been examined in the organometallic chemistry of gallium (*vide infra*). Herein, we report the synthesis and molecular structure of tris(pentamethylphenyl)gallium. The title compound was isolated from reaction of the pentamethylphenylmagnesium bromide Grignard reagent with gallium(III) chloride (Eq. (1)).

2. Experimental

2.1. General comments

Standard Schlenk technique was employed in conjunction with an inert atmosphere dry-box (MBraun LabMaster 130). Diethyl ether was distilled over sodium/potassium benzophenone under an atmosphere of nitrogen prior to use. Bromopentamethylbenzene was purchased from Lancaster Synthesis, Inc. (Windham, NH) while gallium(III) chloride was obtained from Strem Chemical Co. (Newburyport, MA). All reagents were used without further purification. Pentamethylphenylmagnesium bromide was prepared by reaction of bromopentamethylbenzene with magnesium in diethyl ether. Elemental analyses were performed by E & R Microanalytical Laboratories (Parsipanny, NJ). Single crystal X-ray diffraction data were collected on a Bruker SMART™ CCD instrument.

2.2. Synthesis of $(Me_5C_6)_3Ga$

A reaction vessel was charged with diethyl ether and $GaCl_3$ (0.880 g; 5.00 mmol). Pentamethylphenylmagnesium bromide (3.86 g; 15.0 mmol) was added to this solution at -78 °C. This reaction mixture was allowed to stir overnight, slowly warming to room temperature (r.t.). The colorless solution was filtered leaving from a white precipitate (MgBrCl). Solvent reduction of the filtrate, coupled with subsequent cooling, afforded colorless, needle crystals of $(Me_5C_6)_3Ga$ (0.910 g, 31.0% yield): melting point (m.p.): 163 °C. Calc. (found) for $C_{33}H_{45}Ga$: C, 77.50 (77.42); H, 8.90 (8.67)%. ^1H NMR (400 MHz, 298 K, THF-d_8): $\delta = 1.82$ (s, 18H, m-CH_3), 1.90 (s, 9H, p-CH_3), 2.01 (s, 18H, o-CH_3); ^{13}C NMR (400 MHz, 298 K, $CDCl_8$): $\delta = 16.3$, 23.7, 25.4, 68.9, 131.8, 135.0, 137.6.

2.3. Structural solution and refinement for $(Me_5C_6)_3Ga$

A colorless needle crystal of $(Me_5C_6)_3Ga$ was mounted in a thin-walled glass capillary under an inert atmosphere of nitrogen. X-ray intensity data were measured at r.t. on a Bruker SMART™ CCD-based X-ray diffractometer system with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods using the SHELXTL-6.1 [3] system of computer programs. The non-hydrogen atoms were refined anisotropically while hydrogen atoms were placed in idealized positions with their coordinates and thermal parameters riding on the attached carbon atoms. Crystallographic Data: triclinic, space group $P\bar{1}$ (No. 2), $a = 9.003(9)$ Å, $b = 10.713(1)$ Å, $c = 16.066(2)$ Å, $\alpha = 107.63$ (3)°, $\beta = 97.63$ (3)°, $\gamma = 90.08(3)$°, for $Z = 2$. Full-matrix least-squares F^2 refinement converged at $R_1 = 0.050$, $wR_2 = 0.11$ for 10 369 collected reflections.

3. Results and discussion

The first organogallium compound, triethylgallium, was reported by Dennis and Patnode [4] almost 70 years ago. Unlike its aluminum analog, triethylgallium is a trigonal planar-based monomer as opposed to a tetrahedral-based dimer containing electron deficient Al–C_{Et}–Al bridges. Decades later the molecular structure of triphenylgallium, Ph_3Ga, [5] would confirm the gallium center residing in a virtually idealized trigonal planar environment and a mean Ga–C bond distance of 1.957 Å. Again, the trigonal planar-based monomeric nature of triphenylgallium is easily contrasted with the dimeric structure of di-μ-phenyl-bis(diphenylaluminum), Ph_6Al_2 (i.e. the triphenylaluminum dimer), with tetrahedral aluminum centers and electron deficient three center-two electron Al–C_{Ph}–Al bridges [6,7]. However, careful examination of the structure of triphenylgallium reveals subtle factors at work contributing to this observed orientation. In particular, one of the phenyl rings of Ph_3Ga is co-planar with the GaC_3 basal plane while the remaining two phenyl rings were observed with dihedral angles of 13.2 and 31.6°. Moreover, while the immediate coordination about the gallium center in Ph_3Ga is certainly trigonal planar, an examination of the unit cell packing reveals weak intermolecular interactions (3.42 Å) between a gallium atom of one Ph_3Ga molecule and the phenyl π-electrons of a neighboring Ph_3Ga molecule. Thus, when taken in a larger context, the coordination of the gallium center in triphenylgallium approaches five-coordinate trigonal bipyramidal.

Almost two decades would pass before the synthesis and molecular structure of trimesitylgallium, Mes_3Ga (Mes = 1,3,5-$Me_3C_6H_2$),[8] would be reported. The sterically demanding Mes_3Ga molecule resides about a threefold crystallographic axis with approximate D_3 symmetry. While the Ga–C bond distance of 1.968 Å and the trigonal planar coordination about the gallium center in Mes_3Ga compares with the values obtained for Ph_3Ga (Ga–C: 1.957 Å), the dihedral angle of the mesityl rings relative to the GaC_3 plane is noteworthy. Each of the aromatic rings of the mesityl ligands reside in a propeller arrangement about the gallium atom at an angle of 55.9°. The gallium center is sufficiently protected to prevent diethyl ether coordination. Indeed, the orientation of the three mesityl ligands of trimesitylgallium preclude the weak secondary interactions present in triphenylgallium and the associated secondary trigonal bipyramidal coordination of the metal center. The molecular structure of trimesitylaluminum

was shown to be very similar to that of trimesitylgallium [9].

The pentamethylphenyl ligand has received considerably less attention than the mesityl derivative in Group 13 chemistry. This is due, perhaps in large measure, to the fact that it is not immediately obvious that adding steric bulk (in the form of methyl groups) in the *meta* positions of the of a phenyl-based ligand (compared with the mesityl ligand) would effect significant changes at the metal center. In an effort to ascertain what effects, if any, would result from this ligand (compared with other $(aryl)_3Ga$ compounds) we prepared the title compound from reaction of the Grignard reagent pentamethylphenylmagnesium bromide with gallium chloride. The crystal structure of $(Me_5C_6)_3Ga$ is given in Fig. 1. The coordination of the gallium atom is almost idealized trigonal planar with a mean C–Ga–C bond angle of 120.0(1)°. Similar to Mes_3Ga, $(Me_5C_6)_3Ga$ has approximate D_3 symmetry. The mean Ga–C bond distance of 1.981(5) Å in $(Me_5C_6)_3Ga$ is considerably longer than that observed for either Ph_3Ga (1.957 Å) or Mes_3Ga (1.968 Å). This is somewhat surprising considering that the additional two methyl groups on each ligand are not in close proximity to the metal bonding site (compared with the mesityl ligand). A factor contributing to the elongated Ga–C bond distance in the title compound perhaps involves an electronic component. It is plausible that the pentamethylphenyl ligand donates more electron density (as compared with the phenyl or mesityl ligands) into a Ga–C anti-bonding orbital (thereby resulting in a longer Ga–C bond).

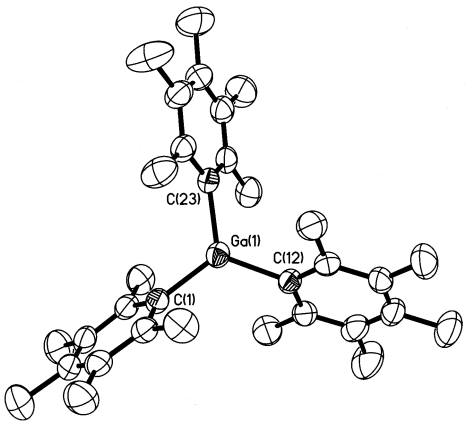

Fig. 1. A view of the $(Me_5C_6)_3Ga$ molecule showing the atom-labeling scheme. Thermal ellipsoids show 50% probability levels. Bond distances (Å): Ga–C(1): 1.974(3); Ga–C(12): 1.986(3); Ga–C(23): 1.984(3). Bond angles (°): C(1)–Ga–C(12) 121.9(1); C(1)–Ga–C(23): 120.4(1); C(12)–Ga–C(23): 117.7(1).

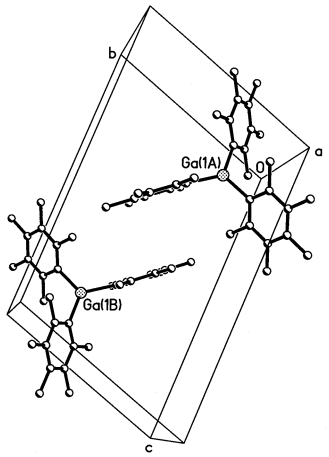

Fig. 2. A view of the unit cell of $(Me_5C_6)Ga$ showing the parallel nature of two pentamethylphenyl ligands (4.1 Å).

Also surprising about $(Me_5C_6)_3Ga$ is the dihedral angle of the pentamethylphenyl ligands with the GaC_3 basal plane. The dihedral planes were found to be 67.3°, 62.3°, and 60.9° for the C(1), C(12), and C(23) pentamethylphenyl planes, respectively. These angles are considerably greater than values obtained for Ph_3Ga (0°, 13.2° and 31.6°). Indeed, the dihedral angles observed in the title compound are significantly greater than the values obtained for Mes_3Ga (55.9°). As for possible causes for the dihedral plane angles observed in the title compound, one is drawn to the unit cell. In the unit cell of $(Me_5C_6)_3Ga$ it is shown that there is an aromatic–aromatic interaction, albeit a weak one at 4.1 Å, between parallel rings between two $(Me_5C_6)_3Ga$ molecules (Fig. 2). The only $(aryl)_3Ga$ derivative with dihedral bond angles greater that those observed for $(Me_5C_6)_3Ga$ is 2,6-dimesitylphenyldimesitylgallium, $(Mes_2C_6H_2)Mes_2Ga$, [10] with wherein the rings approach orthogonality values of 82.4°, 82.4°, and 86.3°.

Although, this laboratory has been interested in the organometallic chemistry of *m*-terphenyl-based ligands resulting in compounds containing sub-valent gallium species for some time [11–16], it is significant that simple ligands such as pentamethylphenyl can cause surprising structural effects about metal centers.

Received 8 August 2001; accepted 27 November 2001

Abstract

In analogy to the corresponding Cp*Al- and Cp*Ga-compounds two further bis(phosphine)platinum complexes [(dcpe)Pt(InCp*)$_2$] (**1(In)**) and {(dcpe)Pt[GaC(SiMe$_3$)$_3$]$_2$} (**2(Ga)**) containing monovalent Group 13 metal species as ligands are accessible by thermal activation of [(dcpe)Pt(H)(CH$_2$*t*-Bu)] (dcpe = bis(dicyclohexylphosphino)ethane) followed by the reaction with 2 equiv. of InCp* (Cp* = pentamethylcyclopentadienyl) or GaC(SiMe$_3$)$_3$. The crystal structure analysis reveals a distorted tetrahedral coordination of the platinum center for both compounds. The Pt–In distances in **1(In)** amount to 2.569(1) and 2.556(1) Å. The Pt–Ga distances in **2(Ga)** are exceptionally short and amount to 2.315(1) and 2.318(1) Å. Comparative theoretical investigations have been performed on this type of complexes and allow a deeper insight in the bonding situation. The NBO analysis reveals a significantly larger Pt → Ga π-back-donation for the model compound {(dhpe)Pt[GaC(SiH$_3$)$_3$]$_2$} (**2M(Ga)**) (0.44 e; dhpe = 1,2-diphosphinoethane) in comparison with the related model compound [(dhpe)Pt(GaCp)$_2$] (**1M(Ga)**) (0.29 e) bearing a strong π-donating organic ligand at the Ga center. A similar trend is observed for the Pt–Ga bond dissociation energies (D_e = 33.0 kcal mol^{-1} for **2M(Ga)**, D_e = 18.3 kcal mol^{-1} for **1M(Ga)**). For the model compound [(dhpe)Pt(InCp)$_2$] (**1M(In)**) a value of D_e = 19.1 kcal mol^{-1} has been calculated. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

The coordination chemistry of Group 13 elements in a low oxidation state is presently a topic of intensive research that has led to the successful synthesis of appealing new types of transition metal compounds [1]. Common synthetic routes to transition metal Group 13 metal compounds with the Group 13 metal in the formal oxidation state +I are the substitution of weakly bonded ligands like CO or olefins by ligands of the type ER (E = Al, Ga, In; R = e.g. Cp*, C(SiMe$_3$)$_3$, Si(*t*-Bu)$_3$ or sterically demanding aryl groups) as well as salt elimination and insertion reactions [2]. In a preliminary report we have shown that bis(phosphine)platinum complexes of the type [(dcpe)Pt(ECp*)$_2$] (E = Al (**1(Al)**), Ga (**1(Ga)**); dcpe = bis(dicyclohexylphosphino)ethane), carrying no additional π-acceptor ligands like CO, are readily accessible [3] by trapping the reactive intermediate [(dcpe)Pt], produced via reductive alkyl elimination from the platinum hydride compound [(dcpe)Pt(H)(CH$_2$*t*-Bu)], with the low valent aluminum and gallium species Cp*Al and Cp*Ga. Here we wish to describe two new compounds obtained by the same strategy, namely [(dcpe)Pt(InCp*)$_2$] (**1(In)**) and {(dcpe)Pt[GaC(SiMe$_3$)$_3$]$_2$} (**2(Ga)**). This latter compound is of particular interest in comparison with its close congener [(dcpe)Pt(GaCp*)$_2$] because of the ligand effects at the Ga center on the Pt–Ga bond.

2. Experimental

2.1. Reagents, solvents, and general procedures

All manipulations were carried out under purified Ar atmosphere using standard vacuum techniques. The solvents were distilled over sodium and stored over molecular sieves prior to use. Procedures described in the literature were followed for the preparation of [(dcpe)Pt(H)(CH_2t-Bu)] [4], $(InCp^*)_6$ [5] and [GaC($SiMe_3$)$_3$] [6]. Elemental analyses were performed by the Microanalytical Laboratory of the Ruhr-Universität Bochum. The NMR spectra were recorded in benzene-d_6 at 298 K using a Bruker Avance DPX-250 spectrometer (^{1}H, 250.1 MHz; ^{13}C, 62.9 MHz; ^{31}P, 101.3 MHz). Chemical shifts were referenced to the solvent resonances as internal standards and orthophosphoric acid as external standard, respectively. Infrared spectra were recorded as KBr pellets using a Perkin–Elmer 1720 X FT-IR spectrometer. Absorptions are described as follows: strong (s), medium (m), weak (w), and shoulder (sh).

2.2. Preparation of [(dcpe)Pt($InCp^*)_2$] (**1(In)**)

A sample of 100 mg (0.145 mmol) of [(dcpe)Pt(H)(CH_2t-Bu)] and 73 mg (0.048 mmol) of $(InCp^*)_6$ were combined and suspended in 0.4 ml of methylcyclohexane in an evacuated and sealed NMR tube. After the reaction mixture was heated 2 h at 60 °C the reaction was complete according to the ^{31}P NMR spectrum. The NMR tube was opened in the glove box, the content was transferred to a Schlenk tube and all volatile components were removed in vacuo, whereby the raw product could be obtained in quantitative yield. The resulting solid was recrystallized by slow evaporation of a solution of **1(In)** in toluene in the glove box to give ocre colored needle-shaped crystals. Yield of the isolated crystalline product: 106 mg (65%). The compound decomposes slowly at 108 °C. ^{1}H NMR: δ 2.40 (s, 30H, 10CH_3, Cp*), 2.00–0.95 (complex and broad superpositions, 48H, Cy_2P(CH_2)$_2$PCy_2). ^{13}C{^{1}H} NMR: δ 11.3 (10CH$_3$, Cp*), 26.8–38.0 (complex superpositions), 113.1 (10 ring C atoms, Cp*). ^{31}P NMR: δ 61.0 (s with ^{195}Pt satellites, $^1J_{(P-Pt)} = 5077$ Hz). IR: 2911 (s), 2845(s), 1443 (s), 1417 (m), 1377 (m), 1334(w), 1257 (s), 1172 (w), 1096 (s), 1022 (s), 883 (w) 847 (m), 802 (s), 733 (m), 638 (w), 587 (w), 521 (m), 459 (w). *Anal.* Calc. for $C_{46}H_{78}In_2P_2Pt$ (1117.79): C, 49.43; H, 7.03. Found: C, 49.16; H, 7.41%.

2.3. Preparation of [(dcpe)Pt{$GaC(SiMe_3)_3$}$_2$] (**2(Ga)**)

A sample of 100 mg (0.145 mmol) of [(dcpe)Pt(H)(CH_2t-Bu)] and 88 mg (0.073 mmol) of [GaC($SiMe_3$)$_3$]$_4$ were suspended in 0.4 ml of methylcyclohexane in an evacuated and sealed NMR tube. After the reaction mixture was heated 4 h at 70 °C the reaction was complete according to the ^{31}P NMR spectrum. The sample was treated following the procedure described for compound **1(In)** to give yellowish orange rhombic crystals. Yield of the isolated crystalline product: 87 mg (49%). The compound decomposes slowly at 80 °C. ^{1}H NMR: δ 0.69 (s, 54H, 18CH_3, 2C($SiMe_3$)$_3$), 2.20–0.97 (complex and broad superpositions, 48H, Cy_2P(CH_2)$_2$PCy_2). ^{13}C{^{1}H} NMR: δ 6.8 (18CH$_3$, C($SiMe_3$)$_3$), 23.3–35.8 (complex superpositions). ^{31}P NMR: δ 62.6 (s with ^{195}Pt satellites, $^1J_{(P-Pt)} = 3285$ Hz). IR: 2923 (vs), 2845 (s), 1448 (m), 1409 (w), 1342 (w), 1251 (s), 1173 (w), 1103 (m, b), 1004 (m, b), 846 (vs, b), 741 (w), 673 (m), 652 (m), 585 (m), 522 (w) 463 (w). *Anal.* Calc. for $C_{46}H_{102}Ga_2P_2PtSi_6$ (1220.30): C 45.28, H 8.42. Found: C 45.57, H 8.56%.

2.4. Crystal structure determination

Diffraction data from a ocre colored needle-shaped crystal (compound **1(In)**, crystal size $0.10 \times 0.20 \times 0.20$ mm^3) and a rhombic yellowish orange crystal (compound **2(Ga)**, crystal sizes $0.25 \times 0.20 \times 0.15$ mm^3), respectively, were collected on a Bruker-axs-SMART 1000 diffractometer (ω-scans). The structures were solved by direct methods using the SHELXS-97 program [7] and were refined by the full-matrix least square method on F^2 with the SHELXL-97 program. [8] Crystallographic data for **1(In)**: empirical formula $C_{46}H_{78}In_2P_2Pt$, $F_w = 1117.759$, monoclinic, space group $P2_1/c$, $a = 12.366(2)$, $b = 20.27(4)$, $c = 20.211(4)$ Å, $\beta = 106.629(5)°$, $V = 4796(2)$ Å^3, $Z = 4$, $\lambda = 0.71073$ Å, $T = 203$ K, reflections collected 20 642, 8424 independent reflections ($R_{int} = 0.0708$), reflections observed 6188, 460 parameters, completeness to $\theta = 25.68°$: 89.8%, final $R[I > 2\sigma(I)] = 0.0396$, $R_w[I > 2\sigma(I)] = 0.0821$, semi-empirical absorption correction, GOF = 0.958; crystallographic data for **2(Ga)**: empirical formula $C_{46}H_{102}Ga_2P_2PtSi_6$, $F_w = 1220.30$, triclinic, space group $P\bar{1}$, $a = 13.569(2)$, $b = 14.117(2)$, $c = 16.195$ Å, $\alpha = 103.872(3)$, $\beta = 94.823(3)$, $\gamma = 94.689(3)°$, $V = 2984.4(8)$ Å^3, $Z = 2$, $\lambda = 0.71073$ Å, $T = 203$ K, reflections collected 15 597, 10 398 independent reflections ($R_{int} = 0.1055$), reflections observed 7182, 572 parameters, completeness to $\theta = 25.13°$: 97.2%, final $R[I > 2\sigma(I)] = 0.0590$, $R_w[I > 2\sigma(I)] = 0.1461$, empirical absorption correction, GOF = 0.970, $R = [\Sigma(||F_o| - |F_c||)/\Sigma|F_o|]^{1/2}$, $R_w = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. Selected geometric parameters are listed in Tables 1 and 2. The trimethylsilyl groups of compound **2(Ga)** were disordered and have been calculated for two positions.

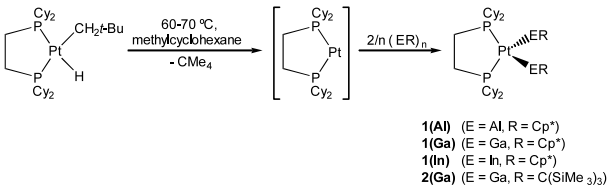
3. Results and discussion



The previously reported compounds [(dcpe)Pt(ECp*)$_2$] (E = Al (**1(Al)**), Ga (**1(Ga)**)) and the related title compounds [(dcpe)Pt(InCp*)$_2$] **1(In)** and {(dcpe)Pt[GaC(SiMe$_3$)$_3$]$_2$} **2(Ga)** were obtained by the same synthetic pathway according to Scheme 1. When a suspension of [(dcpe)Pt(H)(CH$_2$*t*-Bu)] [4] in methylcyclohexane was treated with 2 equiv. of the respective Group 13-diyl compound [5,6] and heated to 60–70 °C for several hours in an evacuated and sealed NMR tube the quantitative conversion of the starting material was observed by in situ ^{31}P NMR spectroscopy. By slow evaporation of a solution of **1(In)** or **2(Ga)** in toluene the product complexes could be gathered in the form of ocre colored needles (**1(In)**) and yellowish orange rhombic crystals (**2(Ga)**), respectively. Complexes **1(In)** and **2(Ga)** have been characterized by means of ^{1}H, ^{13}C and ^{31}P NMR, as well as IR spectroscopy, elemental analysis and single crystal X-ray diffraction.

3.1. NMR spectra

The ^{1}H and ^{13}C NMR spectra are complex and provide only little information relevant to the discussion of the Pt–E bonding. Therefor, they will not be discussed in detail here. The ^{31}P NMR spectra in benzene show characteristic singlets with ^{195}Pt-satellites at 61.0 ppm ($^1J_{(P-Pt)} = 5077$ Hz; compound **1(In)**) and 62.6 ppm ($^1J_{(P-Pt)} = 3285$ Hz; compound **2(Ga)**) indicat-

ing an analogous chemical environment of the phosphorus atoms in each compound which is in accordance with the approximate C_2 symmetry of the complexes confirmed by X-ray analyses. The values for the chemical shifts are in a range comparable to the values of 52.5 and 53.6 ppm found for the signals of the homologous complexes [(dcpe)Pt(ECp*)$_2$] (E = Al, Ga). For compounds of the type [(dcpe)Pt(ECp*)$_2$] a steady increase of the coupling constant $^1J_{(P-Pt)}$, accompanied by a shortening of the interatomic P–Pt distances following the order E = Al ($^1J_{(P-Pt)} = 3482$ Hz, $d(P-Pt)_{average} = 2.286$ Å), Ga ($^1J_{(P-Pt)} = 4625$ Hz, $d(P-Pt)_{average} = 2.259$ Å), In ($^1J_{(P-Pt)} = 5077$ Hz, $d(P-Pt)_{average} = 2.245$ Å) has been observed. In none of the cases discussed a coupling $^2J_{(P-P)}$ was observed, possibly due to dynamic conformational effects in solution. Neither ^{195}Pt nor ^{71}Ga NMR resonances have been identified yet either, most likely because of extensive quadrupolar line broadening effects caused by the Ga and In nuclei.

3.2. Molecular structures of *1(In)* and *2(Ga)*

A single crystal X-ray diffraction study was performed, the results of which confirm the structural predictions based on analytical and spectroscopic data. The molecular structure of the title compound **1(In)** is outlined in Fig. 1.

Compound **1(In)** crystallizes in the monoclinic space group $P2_1/c$ ($Z = 4$). As is has been shown for the above mentioned congeners, the platinum center of **1(In)** is coordinated in a nearly tetrahedral mode by the two phosphorus atoms of the chelating ligand dcpe and the two η^5-Cp*In units. The Pt–In distances of 2.569(1) and 2.556(1) Å are distinctly longer in comparison with the Pt–In distances of 2.441(2) Å of the homoleptic compound {Pt[InC(SiMe$_3$)$_3$]$_4$}, reported by Uhl et al. [9], but slightly shortened compared with [(dcpe)Pt(InR$_2$)(R)] (R = CH$_2$SiMe$_3$), the only further example of a structurally characterized molecular compound with a direct, unsupported Pt–In bond (2.601(0) Å) [10]. Expectedly the Pt–In bonds are somewhat shorter than estimated from covalent single bond radii (2.80–2.89 Å). The shortest Pt–In distance described for binary alloys amounts to 2.534 Å [11]. For the In(1)–Pt(1)–In(2) angle a value of 91.34(2)° has been determined, distinctly narrowed in comparison to the corresponding E–Pt–E angles of the complexes [(dcpe)Pt(ECp*)$_2$] (E = Al, Ga) with values in a range of 95.21(7)°–100.02(7)°. This feature of the solid state structure of **1(In)** is presumably caused by the smaller cone angle of the Cp*In unit (98°) within compound **1(In)** in comparison to the cone angles of the Cp*Al (107°) and Cp*Ga units (102°) within the homologous Al–Pt and Ga–Pt complexes. The small angle also explains the somewhat larger extent of the deviation of the Cp*$_{centroid}$–In–Pt vectors from linearity (169.52° and 172.75°), in comparison to the Al and Ga complexes with average values for the Cp*$_{centroid}$–E–Pt angles of 176.10° and 175.01°. The Pt–P distances of **1(In)** are nearly identical and exhibit values of 2.247(2) and 2.242(2) Å. In comparison to the compounds [(dcpe)Pt(AlCp*)$_2$] and [(dcpe)Pt(GaCp*)$_2$] with average Pt–P distances of 2.286 and 2.259 Å a shortening of the Pt–P distances following the order E = Al, Ga, In and a corresponding increase of the ^{31}P coupling constants $^1J_{(P-Pt)}$ from 3482 to 4625 and 5071 Hz, respectively, was found. For the P(1)–Pt(1)–P(2) angle a value of 93.22(6)° has been determined, similar to the respective angles in the Al and Ga compounds of around 90.50° and 92.25° (average values for the two coexisting isomers, see [3]). Within the Cp*In fragments, the η^5-bonding mode of the Cp* ring is maintained, although small deviations from ideal η^5-bonding are observed. The Cp*$_{centroid}$–In distances amount to 2.282 and 2.280 Å. These values are close to the one found for the free ligand in the gas phase (2.288(4) Å) [5]. The Cp*$_{centroid}$–E distance is regarded as an indirect measure for the polarity of the Pt–E bond (E = Group 13 metal), a subject that has already been discussed extensively in the literature [2a,2c,3,12], so that the polarity of the Pt–In bond of compound **1(In)** seems to be low compared with [(CO)$_5$Cr–InCp*], the only known metal carbonyl complex of an Cp*In ligand and Cp*$_{centroid}$–In bond distance of 2.168(4) Å [13].

The complex {(dcpe)Pt[GaC(SiMe$_3$)$_3$]$_2$} (**2(Ga)**) crystallizes in the triclinic space group $P\bar{1}$ ($Z = 2$). The molecular structure in the crystal is depicted in Fig. 2.

The platinum center is coordinated by the phosphine ligand dcpe and two $(Me_3Si)_3Ga$ units in a distorted tetrahedral mode.

The Pt(1)–Ga(1) and Pt(1)–Ga(2) distances of 2.315(1) and 2.318(1) Å represent the shortest Pt–Ga bonds known so far. The Pt–Ga distances of the related complexes $[(dcpe)Pt(GaCp^*)_2]$ (2.355(2) to 2.382(2) Å for the two coexisting isomers) and $\{(dcpe)Pt[Ga(CH_2t\text{-}Bu)_2](CH_2t\text{-}Bu)\}$ [14] (2.438(1) Å) are distinctly longer. $[Pt_2(GaCp^*)_2(\mu_2\text{-}GaCp^*)_3]$ [15], the only homoleptic Pt–Ga complex, shows terminal Pt–Ga distances that are with an average value of 2.329 Å close to the respective values for **2(Ga)**. The Ga(1)–C(3) and Ga(2)–C(4) bond lengths of 2.06(1) and 2.060(9) Å ($Cp^*_{centroid}$–Ga distances of $[(dcpe)Pt(GaCp^*)_2]$: 2.017 to 2.067 Å) correspond to the value found for the free ligand $(Me_3Si)_3Ga$ (monomer, gas phase) of 2.06(2) Å

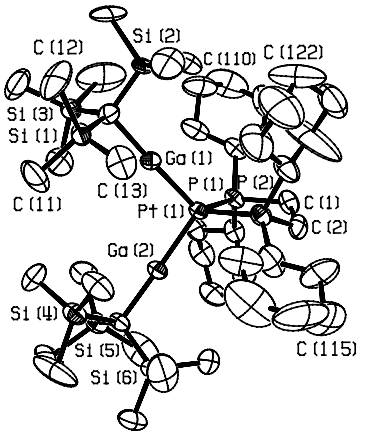

Fig. 2. Molecular structure of {(dcpe)Pt[GaC(SiMe3)3]2} (**2(Ga)**) (ORTEP plot).

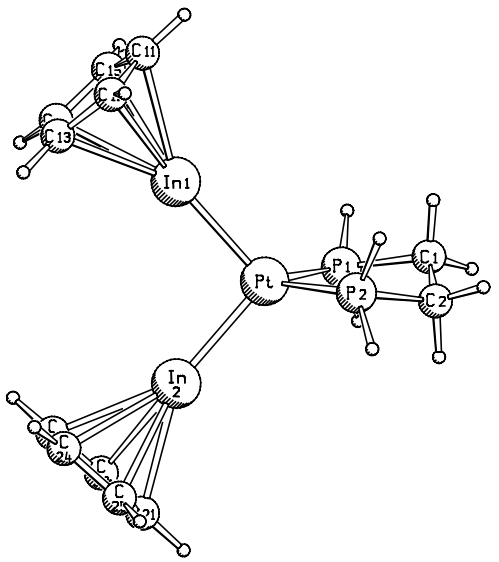

Fig. 3. Calculated structure of $[(dhpe)Pt(InCp)_2]$ (**1M(In)**) (SCHAKAL plot).

[16]. They differ clearly from the average Ga–C distances of 1.993 and 1.982 Å of the only $(Me_3Si)_3Ga$-substituted metal carbonyl complexes known so far, $\{Mn_2(CO)_8[\mu\text{-}GaC(SiMe_3)_3]_2\}$ and $\{Fe_3(CO)_9(\mu\text{-}CO)[\mu\text{-}GaC(SiMe_3)_3]_2\}$ [17], which should provide a higher polar character of the M–Ga bond. The Ga–C bond length of the only further complex with terminal coordinating $(Me_3Si)_3Ga$ units, $\{Ni[GaC(SiMe_3)_3]_4\}$ amounts to 2.014(4) Å [18]. The quantum-chemically calculated Ga–C distances of the homoleptic platinum model complex $[Pt(GaMe)_4]$ are 2.040 (BP86) and 2.028 Å (B3LYP), respectively. The Ga(1)–Pt(1)–Ga(2) angle of 100.28(4)° of compound **2(Ga)** is widened in comparison to the analogous angle of the complex $[(dcpe)Pt(GaCp^*)_2]$ with an average value of 96.14° for the two conformational isomers. The nonbonding Ga(1)···Ga(2) distance of 3.556 Å is comparable with the corresponding value in $[(dcpe)Pt(GaCp^*)_2]$ (3.510 and 3.538 Å for the two isomers). In contrast the solid state structure of tetrameric cluster compound $[(Me_3Si)_3Ga]_4$ shows Ga–Ga distances of 2.678(4) to 2.702(3) Å. The cone angle of $(Me_3Si)_3CGa$ within compound **2(Ga)** amounts to 73° (cone angle of Cp*Ga within $[(dcpe)Pt(GaCp^*)_2]$: 102°), so that steric reasons do not seem to predominate in the widening of the Ga(1)–Pt(1)–Ga(2) angle. The average Pt–P distances of compound **2(Ga)** (2.286 Å) are significantly elongated in comparison to the situation for $[(dcpe)Pt(GaCp^*)_2]$ (2.259 Å). This is presumably a consequence of a stronger Pt → Ga back-donation as predicted by quantum chemical calculations for M–ER bonds (M = transition metal, E = Group 13 element) with alkyl substituents R at the Group 13 element in contrast to the situation where R represents a π-donor ligand. This is discussed below.

4. Theoretical studies on model complexes

The structures of the model complexes $[(dhpe)Pt(InCp)_2]$ (**1M(In)**) and $\{(dhpe)Pt[GaC(SiH_3)_3]_2\}$ (**2M(Ga)**) (dhpe = 1,2-diphosphinoethane) have been optimized with the DFT functional BP86 and SVP basis sets and a relativistic pseudopotential for Pt (Figs. 3 and 4) [19–27]. The comparison of the calculated and experimental bond lengths and angles shows that the structural data of **1M(In)** and **2M(Ga)** are in good agreement with the observed values of **1(In)** and **2(Ga)** (Tables 1 and 2). The use of Cp instead of Cp* explains the somewhat longer E–C distances of the model compounds.

The calculated structures of the aluminum and gallium analogues **1M(Al)** and **1M(Ga)** of the model compound **1M(In)** have been reported by us in a previous investigation [3]. The data of **1M(Ga)** can now be compared with those of **2M(Ga).** In order to facilitate

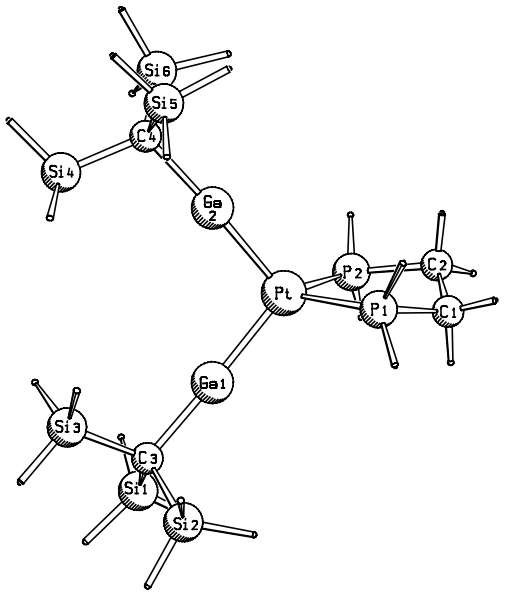

Fig. 4. Calculated structure of {(dhpe)Pt[GaC(SiH$_3$)$_3$]$_2$} (**2M(Ga)**) (SCHAKAL plot).

the comparison we give the most important bond lengths and angles in Table 1. Note that the Pt–Ga distance of **1M(Ga)** is longer than in **2M(Ga)** (Table 2) and that the latter complex has a longer Pt–P bond than the former. We analyzed the bonding situation in the model complexes with the NBO partitioning scheme [26] in order to see whether the shorter Pt–Ga bond of **2M(Ga)** correlates with stronger Pt → Ga back-donation. Tables 3 and 4 give the results of the NBO analysis of **1M(E)** (E = Al, Ga, In) and **2M(Ga)**.

The calculated atomic partial charges show that the platinum atom carries in all model compounds a negative charge between −0.2 and −0.3 e while the Group 13 elements have a large positive charge between +0.6 and +0.8. We want to point out that the atomic partial charges may be a deceptive indicator for the electrostatic forces between the atoms because they do not give information about the topographical distribution of the electronic charge. The calculated partial charges suggest that there is electrostatic attraction between the positively charged element E and the negatively charged Pt. However, the elements E in the ligands ER behave like a Lewis base because they have an electron lone pair as HOMO which donates electronic charge into the LUMO of the metal fragment. The latter species is a Lewis acid where the Pt atom is

the acceptor atom. We have recently shown in a detailed analysis of the metal–ER bonding in Group 13-diyl complexes that the *electrostatic attraction of the M–ER bond arises from the local negative charge concentration of the overall positively charged atom E with the locally charged depleted metal atom M which has an overall negative charge* [28]. The partial atomic charges give important information about the total charge flow between the atoms in a molecule but they do not tell where the charge is concentrated and where it is depleted within an atomic basin.

The ligands ECp become slightly positively charged in **1M(E)** while the ligand GaR ($R = C(SiH_3)_3$) receives a small negative charge in **2M(Ga)** (Tables 3 and 4). Note that the total charge of atom E changes only little upon formation of the Pt–ECp and Pt–GaR bonds (see the Δq(E) values in Tables 3 and 4) but the differences of the σ and π charges Δq_σ(E) and Δq_π(E) are much larger. The change in the π charges Δq_π(E) give directly the Pt → E π-back-donation. The data in Table 3 show that the Pt → E π-back-donation in **1M(E)** has the trend Al > Ga > In. The comparison of **1M(Ga)** with **2M(Ga)** shows clearly that the Pt → GaCp π-back-donation is significantly less than the Pt → GaR back-donation. This is in agreement with the results, which have been obtained for complexes $(CO)_4$Fe–ER [29]. The stronger Pt → GaR π-back-donation is in agreement with the higher bond dissociation energy (BDE) of **2M(Ga)**. The theoretically predicted BDE for dissociation of one GaR ligand is $D_e = 33.0$ kcal mol^{-1}, while the BDE of the Pt–GaCp bond of **1M(Ga)** is only $D_e = 18.3$ kcal mol^{-1}. The bond energies of the other ECp complexes are $D_e = 29.6$ kcal mol^{-1} for **1M(Al)** and $D_e = 19.1$ kcal mol^{-1} for **1M(In)**.

5. Conclusions

Recently the first examples of phosphine transition metal complexes with low valent Group 13 metal substituents, [(dcpe)Pt(ECp*)$_2$] (E = Al, Ga), have been reported by our group [3]. The row of this type of compounds has now been extended to the complexes [(dcpe)Pt(InCp*)$_2$] **1(In)** and {(dcpe)Pt[GaC(SiMe$_3$)$_3$]} **2(Ga)**, which have been fully characterized and analyzed quantum-chemically. Thus we have shown that bimetallic Pt–E (E = Al, Ga, In) compounds can be synthesized by trapping the reactive, low coordinated fragment [(dcpe)Pt] with Group 13-diyl species like ECp* (E = Al, Ga, In) or EC(SiMe$_3$)$_3$ (E = Ga). The current data suggest that the concept depicted in Scheme 1 is extendable to a variety of compounds of the type [(dcpe)Pt(ER)$_2$] which are now available with different homologues of the Group 13 metal E and organic groups R influencing the properties of the Pt–E bond. Besides, the spectator ligands at the transition metal fragment play also an important role concerning the polarity and characteristics of the Pt–E bond [3]. All complexes of the type [(dcpe)Pt(ER)$_2$] show a distorted tetrahedral coordination sphere at the platinum center. It has to be emphasized that **2(Ga)** possesses extraordinarily short Pt–Ga bonds of 2.315(1) and 2.318(1) Å. The calculated geometries of the model complexes [(dhpe)Pt(InCp)$_2$] **1M(In)** and {(dhpe)Pt-[GaC(SiH$_3$)$_3$]$_2$} **2M(Ga)** are in good agreement with the experimental values of **1(In)** and **2(Ga)**, respectively. In these bis(phosphine)platinum complexes the ER fragment functions as a two electron donor/acceptor ligand substitute in a terminal position. The NBO analysis shows that the Pt → GaC(SiH$_3$)$_3$ π-back-donation in **2M(Ga)** is significantly larger than the Pt → GaCp π-back-donation in [(dcpe)Pt(GaCp)$_2$] (**1M(Ga)**) as a result of the weaker π-donor properties of the organic ligand C(SiH$_3$)$_3$ in comparison with Cp. These accents are also reflected in the bond dissociation energies of **1M(Ga)** ($D_e = 18.3$ kcal mol^{-1}) and **2M(Ga)** ($D_e = 33.0$ kcal mol^{-1}). For **1M(In)** a value of $D_e = 19.1$ kcal mol^{-1}, comparable with the bond strength of the model compound **1M(Ga)** has been calculated.

Studies on BCl and on the exchange reaction of BCl_3 with polyboron fluorides

Jennifer A.J. Pardoe, Nicholas C. Norman, Peter L. Timms *

School of Chemistry, University of Bristol, Bristol BS8 1TS, UK

Received 16 August 2001; accepted 7 December 2001

Abstract

Gaseous BCl has been prepared at low pressure by reaction of BCl_3 with boron at 2000 °C or by decomposition of B_2Cl_4 using either an electric discharge or using flash thermolysis at 1150 °C, and then condensed at −196 °C. Reasons are discussed why each method gives BCl capable of generating $(Cl_2B)_3BCO$ when the condensate at −196 °C is treated with CO, but B_4Cl_4 is only formed from BCl prepared from B_2Cl_4. The stepwise conversion of $(F_2B)_3BCO$ to $(Cl_2B)_3BCO$ by treatment with BCl_3 has been followed by ^{11}B NMR spectroscopy. Evidence from mass spectrometry and ^{11}B NMR spectroscopy suggests that reaction of polyboron fluorides, particularly B_8F_{12} and $B_{10}F_{12}$, with BCl_3 yields a new form of B_9Cl_9 of, as yet, unknown structure which converts slowly to *closo*-B_9Cl_9 or *closo*-B_8Cl_8 depending on the solvent. © 2002 Elsevier Science Ltd. Keywords: Boron monochloride; Halogen exchange; Polyboron halides

1. Introduction

Knowledge of the chemistry of the polyboron halides has been growing for about 50 years since the original discovery of B_4Cl_4 by Schlesinger [1]. The chemistry of polyboron chlorides and bromides was reviewed in 1991 [2] and there have been some developments since [3]. An earlier review also embraced the polyboron fluorides [4]. The work reported here concentrates on two aspects of this field, on the chemistry of BCl and on halogen exchange reactions by which polyboron fluorides are converted into chlorides.

2. Experimental

All boron compounds described in this work were handled under high vacuum conditions on diffusion pumped, glass vacuum lines equipped with Teflon stopcocks, with Viton O-ring joints (J. Young) and with efficient means of separating volatiles on a low temperature vacuum distillation column [5]. Pre-dried solvents were further dried over vacuum treated 3 Å molecular sieves just before use; dry CO was obtained by collecting liquid CO from a cylinder in a liquid nitrogen cooled Schlenk tube and allowing the liquid CO to evaporate only at very low temperatures; BCl_3 (Aldrich) was pumped on to remove HCl before use; B_2Cl_4 was prepared either by reaction of excess BCl_3 with B_2F_4 in the gas phase at room temperature or by reduction of BCl_3 with copper atoms [6]; $(F_2B)_3BCO$ was prepared by reaction of CO with B_8F_{12} which had been prepared from low temperature condensation of BF [7].

A 10–1000 amu Micromass quadrupole mass spectrometer integral to the vacuum lines permitted immediate analysis of products of sufficient volatility. Less volatile samples were put in capped vials under strictly oxygen free conditions and analysed using a VG Analytical Autospec mass spectrometer. All samples for ^{11}B NMR spectroscopy were fusion sealed in 5 mm Pyrex tubes; the spectra were run at 96 MHz on a JEOL 300 MHz Eclipse spectrometer.

3. Results and discussion

3.1. Studies on BCl prepared by different methods

Boron monochloride is a well studied molecule because of its interest to spectroscopists [8,9], its importance in plasma chemistry of BCl_3 [10] and its involvement in the formation of B_2Cl_4 [11]. We have recently employed three routes to making BCl to use it as a chemical reagent. Using two procedures originally described 25 years ago [12,13], BCl has been prepared by passing the vapour of B_2Cl_4 at the rate of about 1 mmol min^{-1} and a pressure of a few mbar, either through a 2 kV, 50 Hz electrical discharge in a copper tube or through a short length of 2 mm bore quartz tubing heated to 1150 °C to allow flash thermolysis to occur. The off-gases from the discharge or flash thermolysis units were expanded into a vacuum at a pressure $< 10^{-3}$ mbar and were condensed rapidly on the liquid nitrogen cooled walls of the vacuum chamber. The discharge preparation is somewhat easier experimentally as in the flash thermolysis system there are two competing reactions shown in Eqs. (1) and (2):

$$B_2Cl_4(g) \rightarrow BCl(g) + BCl_3(g) \quad (1)$$

$$3B_2Cl_4 \rightarrow 2B(s) + 4BCl_3(g) \quad (2)$$

The reaction of Eq. (1) is less thermodynamically favoured than the reaction of Eq. (2) but the reaction of Eq. (1) can be kinetically favoured because there is a high activation energy for nucleation of solid boron in the homogeneous gas phase reaction of Eq. (2). Unfortunately, it is hard to suppress the formation of boron in a heterogeneous reaction with the tube walls and the flash thermolysis tube often blocked after only a few mmol of B_2Cl_4 had passed through.

The only molecular product of condensation of the off-gases from the discharge or flash thermolysis treatment of B_2Cl_4 was B_4Cl_4, characterised by ^{11}B NMR spectroscopy and by mass spectrometry [2]. This was formed together with a larger amount of a colourless, intractable solid. Maddren [13] was able to suppress B_4Cl_4 formation by condensation of the off-gases from the discharge with a large excess of ethyne (which gave $C_4H_4B_2Cl_2$, 1,4-diboracyclohexa-2,5-diene), showing that the B_4Cl_4 formed on the cold surface not in the discharge (or flash thermolysis) region. However, we have found that if the condensate from the discharge or flash thermolysis system is allowed to warm from −196 °C in the presence of approximately 0.5 atm pressure of CO, a new compound not found in the earlier work can be isolated in addition to B_4Cl_4. This solid was identified as $(Cl_2B)_3BCO$ from its ^{11}B NMR spectrum (peaks at 68.2 and −20.7 ppm), from its IR spectrum (showing a strong υ CO stretch at 2176 cm^{-1}) and from its crystal structure [14]. The original compound of this type, $(F_2B)_3BCO$, was prepared by reaction of CO with B_8F_{12} [7]. However, $(F_2B)_3BCO$ can also be made by reacting CO at low temperatures with $(F_2B)_2BF$, which disproportionates above −50 °C to B_8F_{12} and B_2F_4. The formation of $(Cl_2B)_3BCO$ strongly suggests that some $(Cl_2B)_2BCl$ was formed by insertion of BCl into the B–B bond or a B–Cl bond of B_2Cl_4 and that this reacted with CO as shown in Eq. (3):

$$2(Cl_2B)_2BCl + CO \rightarrow (Cl_2B)_3BCO + B_2Cl_4 \quad (3)$$

We have also recently prepared BCl by a new route, the reduction of BCl_3 by passing the gas over boron at approximately 2000 °C at low pressure. The apparatus used was similar to that previously used to prepare BF [7]. The BCl_3 was passed at a rate of 0.8 mmol min^{-1} and at pressure of < 2 mbar through a column of granular boron contained in an inductively heated graphite tube. The off-gases from the tube emerged into a vacuum at $< 10^{-4}$ mbar and passed directly to the walls of a stainless steel vessel, part immersed in liquid nitrogen. By measuring the loss of weight of boron and calculating using Eq. (4) below, about 12% of the BCl_3 seemed to be converted to BCl.

$$2B(s) + BCl_3(g) \rightarrow 3BCl(g) \quad (4)$$

On allowing the stainless steel reaction vessel to warm up, BCl_3 and B_2Cl_4 were pumped out below room temperature. With the vessel warmed to room temperature (22 °C), a mixture of green and yellow–brown solids could be pumped out slowly. Release of these solids was speeded up by warming the stainless steel vessel to approximately 40 °C. Studies of these solids by ^{11}B NMR and mass spectrometry showed the most volatile compound to be B_8Cl_8 while the less volatile solids were mainly B_9Cl_9 with some $B_{10}Cl_{10}$, $B_{11}Cl_{11}$ and $B_{12}Cl_{12}$. No B_4Cl_4 was detected. An insoluble, involatile but very air-sensitive solid was left on the walls of the reactor after exhaustive pumping to pressures $< 10^{-4}$ mbar. Repeating the experiment with addition of CO to the cold reactor after the condensate had collected, resulted in the formation of $(Cl_2B)_3BCO$, suggesting that some $(Cl_2B)_2BCl$ was among the products formed on the cold surface. The formation of $(Cl_2B)_2BCl$ and its decomposition at low temperatures may explain the formation of the observed poly-boron chlorides via the mechanism proposed by Davan and Morrison [15] in their studies of the thermal decomposition of B_2Cl_4.

The complete absence of B_4Cl_4 formation from BCl in the above experiments was a surprise but the result may give a clue as to the true mode of formation of B_4Cl_4. Earlier work has shown that B_4Cl_4 is not one of the products of decomposition of B_2Cl_4 even at temperatures up to 300 °C [15]. Apart from our work on flash thermolysis of B_2Cl_4, B_4Cl_4 has only been formed by the use of electrical discharges in BCl_3 or in B_2Cl_4. In

an electrical discharge, there is energy available to form BCl in its singlet ground state, X $^1\Sigma^+$, and also in its triplet excited state, a $^3\Pi_1$, which lies 242 kJ mol^{-1} above the ground state [9]. As suggested earlier [16], it could be that B_2Cl_4 arises from insertion of singlet BCl into the B–Cl bonds of BCl_3 while B_4Cl_4 arises from aggregation of triplet BCl. If both singlet and triplet BCl were condensed on a cold surface, polymerisation of the latter may be the source of the observed B_4Cl_4. The idea of forming a mixture of singlet and triplet forms of BCl seems less obvious in relation to the work on flash thermolysis. There would not appear to be sufficient energy available at 1150 °C to form BCl in its excited triplet state yet B_4Cl_4 is formed in amounts similar to that observed from the discharge route. The answer may lie in the mode of decomposition of B_2Cl_4 by the gas phase reaction of Eq. (1). As shown by McKee for the flash thermolysis of 1,2-$P_2B_4Cl_4$ [17], energy barriers to apparently simple modes of decomposition can be high, providing kinetic enhancement of thermodynamically less favourable pathways. So flash thermolysis of B_2Cl_4 could yield a mixture of the expected singlet BCl with some of the higher energy triplet form.

Preparing BCl at 2000 °C in a heterogeneous reaction from boron and BCl_3 is likely to be a route to the most thermodynamically favoured form, i.e. singlet, ground state BCl, and this on condensation gives no B_4Cl_4. All routes to BCl give some singlet BCl and it is believed that this is the form most suited to react efficiently with BCl_3 to give B_2Cl_4 or to react with B_2Cl_4 to give $(Cl_2B)_2BCl$ which is the precursor to $(Cl_2B)_3BCO$.

It is clear from this research that more theoretical work is needed to give a proper understanding of the mode of formation of B_4Cl_4 from BCl.

3.2. Conversion of $(F_2B)_3BCO$ to $(Cl_2B)_3BCO$ by reaction with BCl_3

The conversions of B_2F_4 to B_2Cl_4 and of B_2Cl_4 to B_2Br_4 by reaction with BCl_3 and BBr_3, respectively, have been known for many years [4]. We have found that halogen exchange also works well starting with $(F_2B)_3BCO$ and treating it with BCl_3.

Reaction of $(F_2B)_3BCO$ with BCl_3 in the vapour phase at room temperature gives a virtually quantitative conversion to $(Cl_2B)_3BCO$ in less than an hour with liberation of BF_3 [14]. This is by far the most convenient preparation of $(Cl_2B)_3BCO$ in our laboratories because $(F_2B)_3BCO$ can be made in gram quantities by allowing the products formed by condensing BF at −196 °C to warm to room temperature in the presence of CO gas. A similar reaction occurs between $(F_2B)_3BPF_3$ [18] and BCl_3 yielding $(Cl_2B)_3BPF_3$ (showing ^{11}B resonances at δ +65.9 and −17.1 ppm); no exchange of P–F for P–Cl was observed within the time scale needed to exchange B–F for B–Cl.

The stepwise nature of the above fluorine-for-chlorine exchange process was revealed by ^{11}B NMR spectroscopy. Liquid BCl_3 was allowed to interact with $(F_2B)_3BCO$ for 50 min at 0 °C, followed by cooling to −70 °C, pumping boron trihalides away and then dissolving the remaining solid in CD_2Cl_2. The ^{11}B–^{11}B COSY spectrum of the product is shown in Fig. 1. Progressive replacement of F by Cl as $(F_2B)_3BCO$ converts to $(Cl_2B)_3BCO$ can give a total of ten different compounds containing combinations of BF_2, BFCl and BCl_2 groups. The spectrum of Fig. 1 gives evidence for at least eight of these ten possible structures. Considering first the four-coordinate boron environments ranging in δ values from −50.6 ppm for $(F_2B)_3BCO$ to −20.7 ppm for $(Cl_2B)_3BCO$. There are seven different peaks corresponding to successive replacements of F by Cl in compounds of type $B_4F_{6-x}Cl_xCO$. The peaks at −45.0 and −24.4 ppm are directly assignable to $(F_2B)_2(FClB)BCO$ and to $(Cl_2B)_2(FClB)BCO$, respectively. Of the remaining three peaks, that at −29.0 ppm has an asymmetry indicating that both $(F_2B)(Cl_2B)_2BCO$ and $(Cl_2B)(FClB)_2BCO$ are present although the precise positions of their respective resonances cannot be resolved from the COSY spectrum. The COSY spectrum also suggests that both $(F_2B)(FClB)(Cl_2B)BCO$ and $(FClB)_3BCO$ and both $(F_2B)(Cl_2B)_2CO$ and $(FClB)_2(Cl_2B)BCO$ contribute to the peaks at −34.3 and −39.8 ppm, respectively. In addition, the spectrum shows three broad resonances corresponding to BF_2, BFCl and BCl_2 groups with chemical shifts at +32.4, +50.8 and +68.9 ppm, respectively. These values are similar to those previously reported for species of the type $B_2F_{4-x}Cl_x$ [19]; in pure $(BF_2)_3BCO$, the chemical shift for the BF_2 groups is +31.3. The COSY spectrum shows how the ^{11}B chemical shifts for these BF_2, BFCl and BCl_2 groups move slightly to higher field as the fluorine content of the molecules increases.

3.3. Reaction of polyboron fluorides with BCl_3

Boron trichloride has also been reacted with some of the polyboron fluorides originating from condensation of BF at −196 °C which contain eight or more boron atoms [4]. The reactions have yielded a new, unstable polyboron chloride, the detailed structure, of which can not yet be assigned from the available NMR data.

Some explanation of the nature of the starting boron fluoride materials is needed as single crystal X-ray structures have only recently been obtained for two of the polyboron fluorides, B_8F_{12} and $B_{10}F_{12}$ [20]. The structure of B_8F_{12} differs from the diborane-like structure $B_2(BF_2)_6$ proposed on the basis of its reactivity [7] mainly through the presence of a short, central B–B

bond, supported by bridging BF_2 groups and a folded rather than planar central $B_2(\mu\text{-}BF_2)_2$ unit. The existence of $B_{10}F_{12}$ was not apparent from previous studies of higher boron fluorides based largely on mass spectrometry [4], but it is now clear that this molecule with a central tetrahedral core of four boron atoms with four terminal and two bridging BF_2 groups having S_4 symmetry, is the most abundant component of the polyboron fluorides of lower volatility than B_8F_{12}.

The reaction of either B_8F_{12} or of higher polyboron fluorides rich in $B_{10}F_{12}$ with excess liquid BCl_3 follows the same pattern. Reaction begins below -30 °C with a darkening in colour, which intensifies slowly. Holding the temperature at 0 °C for several hours gives a red–brown solution and BF_3, BF_2Cl and $BFCl_2$ are formed by reaction with the BCl_3 in the vapour. If the temperature is then raised to 60 °C in the presence of BCl_3 vapour before all the highly volatile boron trihalides are pumped away, the residue is a dark brown–purple solid. Direct extraction of this solid with CD_2Cl_2 at room temperature gives a brown solution which initially exhibits a an ^{11}B NMR spectrum showing six main resonances, the chemical shifts and relative intensities of which are given in Fig. 2. Essentially the same spectrum can be obtained by heating the brown–purple solid to 40 °C and pumping out a solid by short-path distillation on to a cold finger, and dissolving the material on the cold finger in CD_2Cl_2 or C_6D_6. The colour of the sublimate can vary from run to run from almost colourless to yellow–brown. It seems likely that

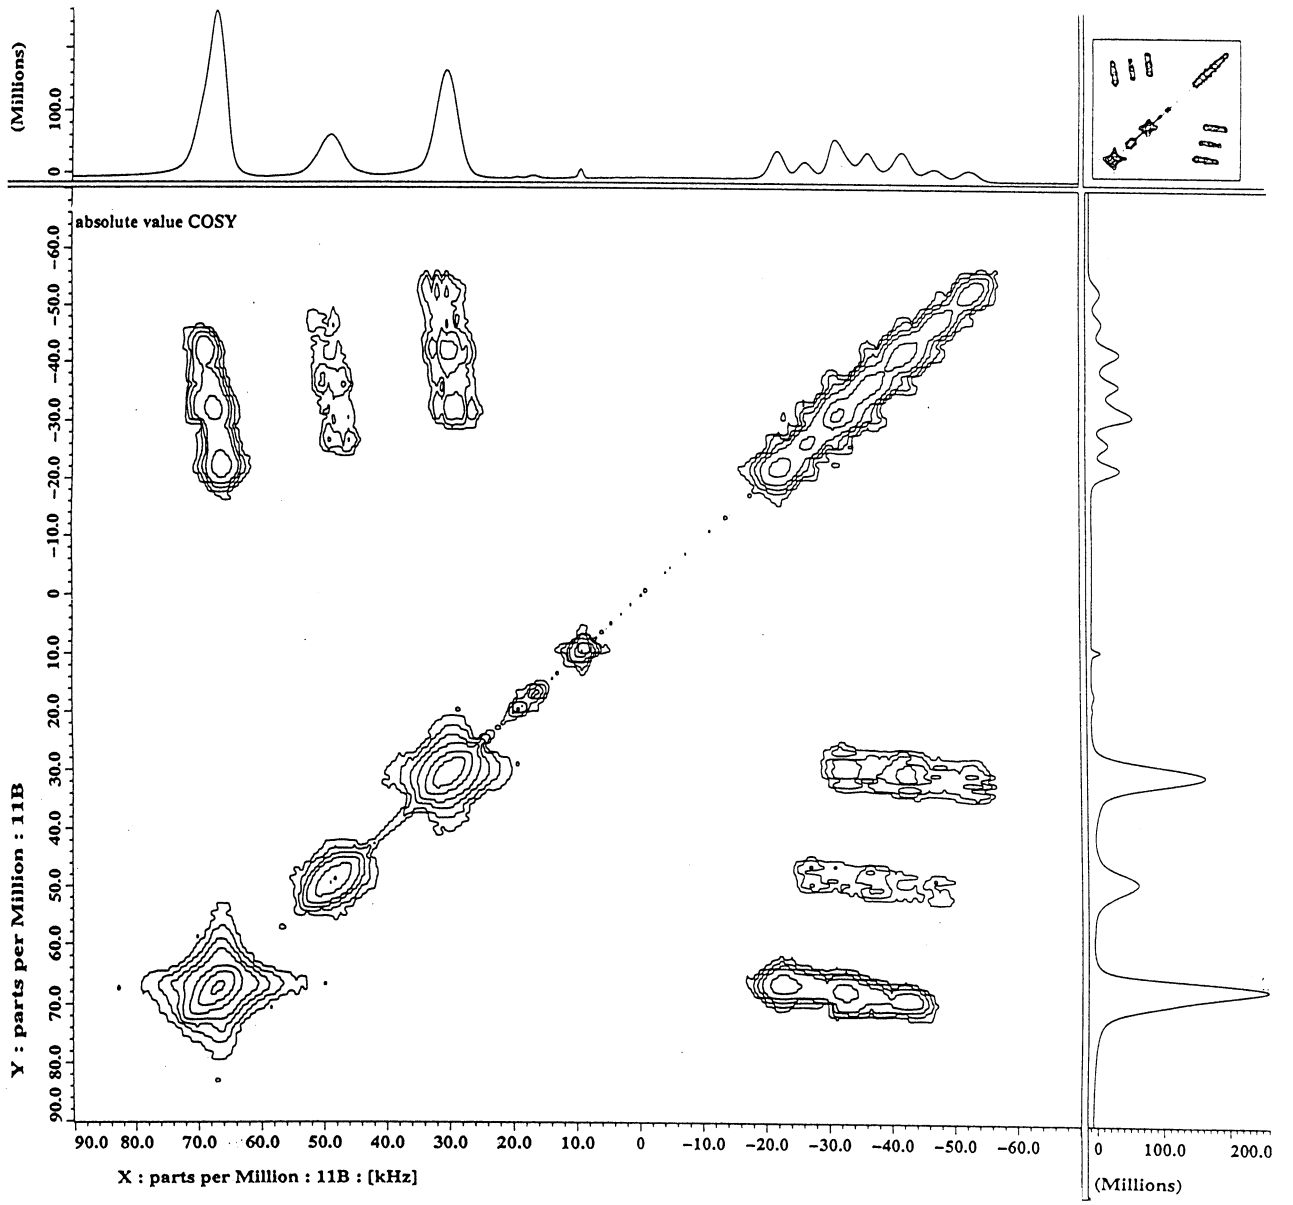

Fig. 1. ^{11}B–^{11}B COSY NMR spectrum of compounds of type $B_4F_{6-x}Cl_xCO$ prepared by reacting $(BF_2)_3BCO$ with BCl_3 (CD_2Cl_2 as solvent).

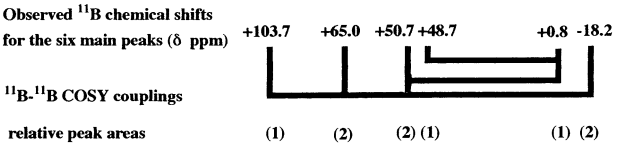

Fig. 2. ^{11}B NMR data for the dominant product formed by reacting polyboron fluorides rich in $B_{10}F_{12}$ with BCl_3 at 0 °C until chlorine for fluorine exchange was complete (CD_2Cl_2 as solvent).

the main component of the sublimate is colourless but that it is unstable and becomes contaminated to a varying extent by intensely coloured decomposition products.

The mass spectrum of the sublimate, run within a few minutes of dissolving the solid in C_6D_6, showed BCl_2^+ as the base peak, with $B_8Cl_6^+$ (m/z 293–307, centred at 299) as the dominant high mass peak, approximately 40 times more intense than the highest mass peak group at m/z 410–426, centred at 416, corresponding to $B_9Cl_9^+$. The mass spectrum of *closo*-B_9Cl_9 run under the same conditions shows a much lower ratio of the intensities of $B_8Cl_6^+$: $B_9Cl_9^+$ in line with that reported by Morrison [2]. The mass spectrum suggests that the main volatile component of the sample may have been B_9Cl_9 but an isomer of different structure to the known *closo*-B_9Cl_9, with a much greater tendency to eliminate BCl_3 to form $B_8Cl_6^+$.

In the ^{11}B NMR spectrum, the six peaks identified in Fig. 2 seem to belong to a single molecular species as they are always found in the same ratio and decline in intensity together as the sample decomposes over time. The exact position and relative intensity of the peak at +65 ppm is least certain as this region in the spectrum overlays a group of peaks associated with the *closo*-boranes and with BCl_2 groups from a variety of sources. It has been clearly demonstrated by ^{11}B and ^{19}F NMR spectra, that none of the six peaks is caused by any residual B–F containing species. The way the peaks are inter-related is shown in Fig. 2 from the ^{11}B–^{11}B COSY spectrum couplings. The peak at −18.2 ppm is coupled to peaks at +103.7, +65.0 and +50.7 ppm while the peak at +0.8 ppm is coupled to the peaks at +50.7 and +48.7 ppm. The wide range of ^{11}B chemical shifts within a single molecule points to a variety of chemical environments. The peaks at +0.8 and at −18.2 ppm may be from boron atoms without direct chlorine substituents {cf. the central boron of $(Cl_2B)_3BCO$}. The peaks at +65.0, +50.7 and +48.7 ppm are likely due to boron atoms with one or two chlorine substituents. The peak at +103.7 ppm seems to suggest a boron atom of a BCl group in a more highly strained environment than the boron atoms in B_4Cl_4 which resonate at +85.5 ppm [2].

The NMR data alone by no means proves the structure or composition of the compound giving the six resonances in the ^{11}B NMR. However, our results do strongly suggest the existence of a type of polyboron chloride never previously described. Morrison's proposals on the way in which B_2Cl_4 molecules react together to form *closo*-B_nCl_n structures with elimination of BCl_3 [2] hint at the existence of open structured intermediates but he has not reported an intermediate of this type stable enough to be sublimed. The relatively high stability of the polyboron chloride observed in our work may be due to the way it is formed from $B_{10}F_{12}$, i.e. it may not be possible to form such a species by decomposition of B_2Cl_4. Further support for the idea that the polyboron chloride giving the six ^{11}B NMR resonances may be accessible only from the reaction of BCl_3 with polyboron fluorides comes from the following observation. The product was not detected among the *closo*-B_nCl_n compounds generated under very mild conditions from the products obtained made by condensing at −196 °C, BCl made from boron and BCl_3 at 2000 °C.

The solutions obtained either by direct extraction or by sublimation followed by dissolution of the sublimate, which give the peaks at positions shown in Fig. 2, are not stable. When held at room temperature, the colour intensity increases and the ^{11}B NMR spectrum changes in a complex but fairly reproducible way. All six of the peaks of Fig. 2, decrease in intensity and become broader, but there is massive growth of one sharp resonance. For samples dissolved in C_6D_6, this occurs at δ +58.5 ppm corresponding to *closo*-B_9Cl_9. For one sample decomposing just in CD_2Cl_2, the single peak, which grew was at 65.2 ppm corresponding to *closo*-B_8Cl_8 [2]. Morrison has reported that the formation of *closo*-B_nCl_n species from B_2Cl_4 is solvent sensitive with *closo*-B_8Cl_8 favoured over B_9Cl_9 in CCl_4 as solvent [2]. In the ^{11}B NMR spectra of samples undergoing decomposition, there was some increase in the intensity of the resonance due to BCl_3, but not enough to indicate that BCl_3 was eliminated to a major extent by the transformation. If the product of reaction of BCl_3 with polyboron fluorides was left for a few days at room temperature under vacuum in the absence of a solvent and was then pumped on to remove very volatile products, the resulting intensely coloured product showed from its ^{11}B NMR and mass spectrum the presence of a mixture of the known *closo*-boranes from B_8Cl_8 to $B_{12}Cl_{12}$, with B_9Cl_9 as by far the major product.

The ^{11}B NMR spectra of the samples after treatment with BCl_3 always contain other small peaks than the six noted in Fig. 2, including a very sharp peak at +47.7 ppm due to BCl_3 which occurs in all the samples and is used as internal reference. However, the intensity ratios and chemical shifts vary appreciably from sample to sample unlike the six peaks discussed above. Their presence simply reinforces the idea that the reaction of

BCl_3 with the polyboron fluorides is an exceedingly complex process, generating a wide range of boron containing products.

The fact that the product which showed in its ^{11}B NMR spectrum the dominant six peaks of Fig. 2 could be obtained by reaction of excess BCl_3 with either B_8F_{12} or $B_{10}F_{12}$ at 0 °C can be explained by the following observation. When B_8F_{12} was treated with BCl_3 at -60 °C for a few minutes, mass spectrometry on the product showed that the B_8F_{12} had been largely converted to $B_{10}F_{12}$ and BF_3 with no evidence for chlorine-for-fluorine exchange in the polyboron fluorides. Thus, it can be assumed that conversion of B_8F_{12} to $B_{10}F_{12}$ was a rapid first step in the reaction with BCl_3 at 0 °C.

Investigations into the reaction of BCl_3 with polyboron fluorides are on-going. The primary objective will be to try to get a crystal structure of the key intermediate giving the six ^{11}B NMR resonances discussed. It may not be possible to crystallise this compound from solution because of its instability and low temperature laser techniques on the solid may also promote the transformation to a stable *closo*-B_nCl_n structure, making this a difficult problem.

Related experiments on the reaction of BBr_3 with higher boron fluorides have also been carried out. The end result is a series of known *closo*-B_nBr_n compounds but the intermediates are at least as complicated as those from the BCl_3 reaction.

4. Conclusions

The research has provided clear results relating to the synthesis of $(Cl_2B)_3BCO$ and the stepwise conversion of $(F_2B)_3BCO$ to $(Cl_2B)_3BCO$ by reaction with BCl_3. It has also provided some evidence for the existence of a new type of open-structured polyboron chloride, which can readily isomerise to the much more stable *closo*-B_nCl_n compounds. Full characterisation of this compound will be experimentally challenging. It has been shown that the formation of B_4Cl_4 from BCl is sensitive to the way the BCl is synthesised and this suggests that there is a need for theoretical work on the decomposition of B_2Cl_4 and on the mechanism by which B_4Cl_4 forms from BCl.

Acknowledgements

We thank Dr. Colin Western for helpful discussions about the electronic state of BCl and we are grateful to the Engineering and Physical Sciences Research Council for their support of this research and for a studentship to Jennifer A.J. Pardoe.

Synthesis and X-ray structure of a complex containing the trisimido borate trianion—the imido analogue of the orthoborate trianion

John C. Jeffery, Angela P. Leedham, Christopher A. Russell *

School of Chemistry, University of Bristol, Cantock's Close, Bristol, BS8 1TS, UK

Received 31 July 2001; accepted 27 November 2001

Abstract

Reaction of BCl_3 with 2-methoxyaniline (1:6 equiv.) in toluene, and subsequent metallation with ^{n}BuLi (3 equiv.) produces $\{[Li_4B(NR)_3{\cdot}THF]^+[B^nBu_4]^-{\cdot}toluene\}_2$ (R = 2-methoxyphenyl), which contains the first example of a trisimido borate trianion—the imido analogue of the orthoborate trianion, $[BO_3]^{3-}$. © 2002 Elsevier Science Ltd. Keywords: Boron; Lithium; Imido; Complexes; X-ray

1. Introduction

Recently much of our chemistry has been focussed towards the preparation of p-block element imido $\{RN^{2-}\}$ complexes. We have synthesised these anions by amination of a main group element halide followed by metallation of the amide protons with an alkyllithium reagent. The application of this approach to the group 15 elements has led to the preparation of imido analogues of the orthophosphate anion, $[PO_4]^{3-}$ [1], the phosphite anion $[HPO_3]^{2-}$ [2], and the arsenate anion, $[AsO_3]^{3-}$ [3]. Related studies into imido analogues of the group 14, heavier group 15, and 16 anions have been extensively examined by the groups of Chivers, Stalke and Wright [4–8]. These studies have partial multiple E⋯N bonding for the lighter (period 3 elements) but predominantly single bonds for the heavy p-block elements. However, no corresponding compounds of the group 13 elements have been reported to date, despite the extensive body of data concerning boron–nitrogen linkages. Recent studies by Chivers et al. into the reactions of alkyllithium reagents (RLi) with the trisaminoborane, $B\{N(H)^tBu\}_3$ (3:1 equiv.), have shown the alkyllithium compounds acting as a base to remove two amide protons and as a nucleophile to substitute the third amide group to produce dilithio boraamidinate complexes $[Li_2\{RB(N^tBu\}_2\}]_x$ (R = ^{n}Bu, $x = 2$; R = Me, $x = 3$) [9]. We reasoned that use of more elaborate amines bearing side-arm donor substituents may stabilise the cations and lead to trisimido borate ions. Herein we report the synthesis and crystal structure of a complex which contains the first example of the trisimido borate trianion $[B(NR)_3]^{3-}$, which is an imido analogue of the $[BO_3]^{3-}$ anion.

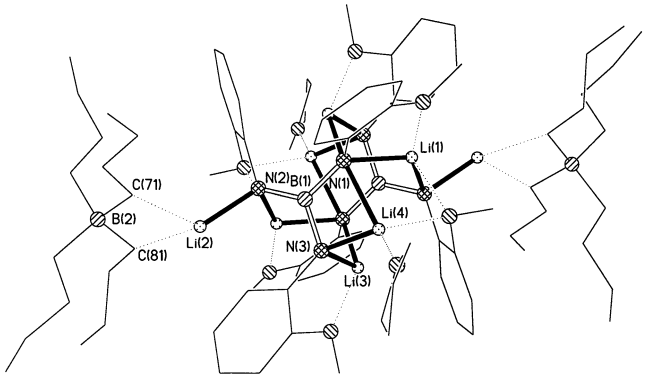

Fig. 1. Structure of $\{[Li_4B(NR)_3{\cdot}THF]^+[B^nBu_4]^-{\cdot}toluene\}_2$ (R = 2-methoxyphenyl, **1**) with the toluene molecules and all hydrogen atoms omitted for clarity. The suffix 'A' to an atom label indicates a symmetry equivalent atom.

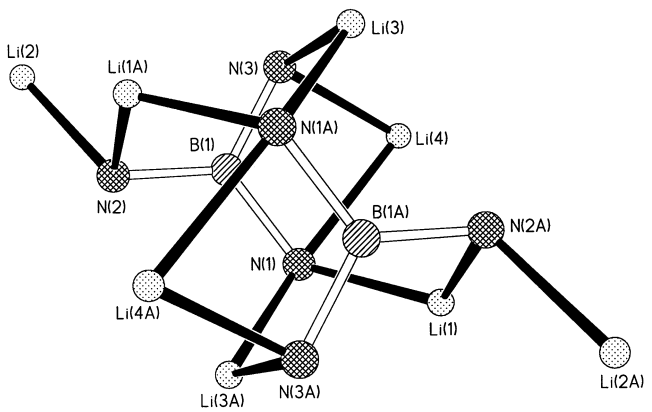

Fig. 2. Core of $[\{Li_4B(NR)_3{\cdot}THF\}_2]^{2+}$ (R = 2-methoxyphenyl) depicting just the B, N and Li centres.

2. Results and discussion

Reaction of BCl_3 with 6 equiv. of 2-methoxyaniline in toluene, followed by addition of 3 equiv. of ^{n}BuLi produces $\{[Li_4B(NR)_3{\cdot}THF]^+[B^nBu_4]^-{\cdot}toluene\}_2$ (R = 2-methoxyphenyl, **1**) in low but reproducible yield as moisture-sensitive yellow crystals. Complex **1** was characterised using ^{1}H and ^{11}B NMR spectroscopy, IR spectroscopy and elemental analyses. The lack of an N–H stretch in the IR spectrum showed that all these amido protons had been removed. The ^{11}B NMR spectrum revealed resonances at $\partial = 23.4$ (broad singlet) and -3.6 (sharp singlet), consistent with the presence of both three-coordinate and four-coordinate boron centres [10]. To confirm this assignment and to explore further features of this system we undertook a low-temperature single crystal X-ray diffraction study. This revealed that complex **1** crystallises as a dimer in the triclinic space group, $P\bar{1}$, with two $B^nBu_4^-$ anions loosely linked through Li···H and Li···C contacts to a cage that contains eight lithium cations and two trisimido borate trianions. In addition there are two molecules of toluene in the lattice for each dimeric $\{[Li_4B(NR)_3{\cdot}THF]^+[B^nBu_4]^-\}_2$ unit. The molecular structure of **1** is shown in Fig. 1 with key bond lengths and angles shown in Table 1.

The B^nBu_4 units are unremarkable, with the boron centres having distorted tetrahedral geometries {C–B–C angles range from 108.2(3)° to 110.6(3)°} and with slightly differing B–C bond distances {B–C(61) 1.652(5) Å, B–C(91) 1.642(5) Å, B–C(81) 1.676(5) Å, B–C(71) 1.679(6) Å}, presumably as a result of the contacts between two of the *n*-butyl groups and lithium centres of the central caged cation.

Within this caged cation, the core of which is illustrated in Fig. 2, two trigonal planar trisimido borate moieties are held together by four lithium centres {Li(1), Li(3), Li(1A) and Li(3A)}, with the remaining lithium centres binding on the periphery of the cage.

Of the four core lithium centres, Li(1) {and its symmetry equivalent Li(1A)} have distorted tetrahedral geometries, with contacts to a nitrogen centre from each trisimido borate moiety {Li(1)–N(1) 2.032(6), Li(1)–N(2A) 1.982(6) Å}, as well as two contacts to methoxy side arms of the 2-methoxyphenyl group moiety {Li(1)–O(1) 1.928(6), Li(1)–O(2A) 2.071(6) Å}. The remaining core lithium centres {Li(3) and the symmetry equivalent Li(3A)} have distorted pyramidal geometries, binding to an imido nitrogen centre from each trisimido borate moiety {Li(3)–N(3) 2.038(6), Li(3)–N(1A) 2.056(6) Å} with an additional contact to a methoxy side arm {Li(3)–O(3) 1.924(6) Å} from one of these imido units.

The remaining four lithium centres do not appear to play any direct role in binding the two halves of the dimer together in the solid state; Li(4) {and its symmetry equivalent Li(4A)} contact two nitrogen centres from the same trisimido borate moiety with a short contact to N(3) at 1.962(6) Å and a relatively long contact of 2.236(6) Å to N(1), in addition to being solvated by a methoxy sidearm of a methoxyphenyl group {Li(4)–O(2A) 2.114(6) Å} and a THF molecule {Li(4)–O(4) 1.887(6) Å}. By contrast, Li(2) {and its symmetry equivalent Li(2A)} contact only a single imido nitrogen centre {Li(2)–N(2) 1.977(6) Å} and has

additional Li···C and Li···H contacts to the butyl group of the $[B^nBu_4]^-$ anion {Li(2)···C(71) 2.229(6), Li(2)···C(81) 2.254(7) Å; Li(2)···H(71A) 1.910(6) Å, Li(2)···H(71B) 1.986(6) Å, Li(2)···H(81A) 1.974(6) Å, Li(2)···H(81B) 1.976(6) Å}.

Two of the nitrogen centres {N(2) and N(3)} possess distorted tetrahedral geometries, being bound to the boron centre, a carbon atom of a methoxyphenyl group and two lithium centres. The third nitrogen centre, N(1), is similarly bound to the boron centre and a carbon atom of a methoxyphenyl group but is bound to three lithium centres to give a distorted five coordinate geometry.

The pseudo trigonal planar boron atom coordinates three imido nitrogen centres (sum of NBN angles 358.8°). The B–N distances of 1.440(4), 1.448(4) and 1.492(4) Å are shorter than the commonly accepted literature values for single bonds (ca. 1.58 Å) but larger than for formal double bonds (ca. 1.40 Å) [11]. This is indicative of partial multiple bond character that would be expected as a consequence of lone pairs on the imido groups overlapping the vacant p orbital at the sp^2 boron centre. The fact that one B–N distance {B–N(1)} is considerably larger than the other two can be attributed to fact that larger coordination numbers lead to longer bonds, as has been observed in related studies of trisiimidosilanes [12,13].

Unlike the related $[E(NR)_3]^{2-}$ (E = S, Se, Te) [7,14,15], where the pyramidal trisimido chalcogenide dianions allow the formation of cages of molecular C_{2h} symmetry, which readily accommodate strong Li–N contacts in arrangements similar to those that are well known in lithium amide chemistry [16,17], the imposition of trigonal planar geometry at the boron centres in the central core of **1** does not facilitate comparable Li···N motifs. Perhaps this inability to readily accommodate the bonding requirements of the lithium centres accounts in part for the difficulty in synthesising the direct imido analogue of the orthoborate trianion.

The reaction to form **1** is evidently not as straightforward as we initially anticipated. We would suggest that the initial amination of the BCl_3 with 2-methoxyaniline is probably incomplete, leaving free BCl_3 present at the metallation step. Addition of ^{n}BuLi results in the production of LiB^nBu_4, that combines with the lithiation product of the proposed $B\{N(H)R\}_3$ intermediate to give a mixed anionic species with empirical formula $Li_4B(NR)_3B^nBu_4$ (i.e. the monomer of the observed product).

3. Conclusions

The synthesis of complex **1** illustrates that the transmetallation/metallation methodology that we have previously employed to synthesise group 15 imido anions may be employed to make corresponding group 13 imido anions. Taken with the recent results of Chivers et al. [9], it is probable that the precise nature of the product is heavily dependent on the nature of the amine used.

4. Experimental

All reagents and products were handled on a vacuum line (in an efficient fume cupboard) under dry/oxygen-free argon or dinitrogen using standard inert atmosphere techniques [18]. Toluene, THF, and hexane were dried over alumina, while a supported copper catalyst was used to remove trace oxygen from hydrocarbons prior to the reactions [19]. The products were isolated and characterised with the aid of an argon-filled Saffron Beta glove box. ^{1}H and ^{11}B NMR spectra were recorded on a JEOL Lambda 300MHz Multinuclear FT spectrometer in dry deuterated pyridine (using the solvent resonances as the internal reference standard for ^{1}H spectra and an external standard of $F_3B{\cdot}OEt_2$ for ^{11}B spectra). Infrared spectra were recorded as Nujol mulls using NaCl plates and were run on a Perkin–Elmer Spectrum One FTIR spectrophotometer. Elemental analyses were performed by first sealing the samples under argon in air-tight aluminium boats (1–2 mg) and C, H and N content was analysed using a Perkin–Elmer 240 Elemental Analyser.

4.1. Synthesis of *1*

Boron trichloride (1 ml, 1 M solution in heptane, 1 mmol) was reacted with 6 equiv. of 2-methoxyaniline (0.68 ml, 6 mmol) in toluene (20 ml). This solution was stirred for 6 h at room temperature before being filtered (porosity 3 sinter with Celite) and metallated with 3 equiv. of ^{n}BuLi (1.88 ml, 1.6 M solution in hexanes, 3 mmol). This left a yellow solution containing a small amount of residual solid that was redissolved with approximately 1 ml THF. The resulting yellow solution was left for 72 h at 5 °C, which yielded pale yellow blocks of **1**.

Yield: 0.11 g (14% based on BCl_3). IR (cm^{-1}): no distinguishing absorptions. ^{1}H NMR (+25 °C, 300 MHz, [D$_5$]-pyridine): $\delta = 7.3$–7.1 (collection of overlapping m, 17H, –NC$_6H_4$OMe and C$_6H_5$Me), 3.65 (m, 4H, THF), 3.55 (s, 9H, –OCH_3), 2.20 (s, 3H, C$_6$H$_5$CH_3), 1.98 (broad collection of m, 8H, –CH_2CH$_2$CH$_2$CH$_3$), 1.77 (broad collection of m, 8H, –CH$_2$CH$_2$CH_2CH$_3$), 1.59 (m, 4H, THF), 1.13 (t, 12H, –CH$_2$CH$_2$CH$_2$CH_3), 0.85 (broad collection of m, 8H, –CH$_2$CH_2CH$_2$CH$_3$). ^{11}B NMR (+25 °C, 96.23 MHz, [D$_5$]-pyridine): $\delta =$ 23.4 (broad singlet, $[B(NR)_3]^{3-}$), −3.6 (singlet, $[B^nBu_4]^-$). *Anal.* Found: C, 71.01; H, 8.91; N, 5.40. Calc. for $C_{74}H_{114}B_4Li_8N_6O_6{\cdot}(C_4H_8O)_2{\cdot}(C_7H_8)_2$ requires C, 71.55; H, 9.07; N, 5.22%.

4.2. X-ray crystallography

Data were collected on a Siemens SMART CCD area-detector diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å) [20] using a crystal mounted on a glass fibre in a rapidly cooled perfluoropolyether [21]. Details of the data collection, refinement and crystal data are listed below. The structure was solved by direct methods and refined by least squares on F^2 values for all reflections [22]. Absorption corrections were applied, based on multiple and symmetry equivalent measurements [23]. All hydrogen atoms were constrained to ideal geometries and refined with fixed isotropic displacement parameters.

$C_{96}H_{146}B_4Li_8N_6O_8$, $M = 1610.94$, triclinic, space group $P\bar{1}$, $a = 13.6351(19)$, $b = 13.9809(19)$, $c = 16.450(2)$ Å, $\alpha = 88.828(3)°$, $\beta = 65.990(2)°$, $\gamma = 61.734(2)°$, $V = 2464.4(6)$ Å^3, $Z = 1$, $T = 173$ K, crystal size $0.2 \times 0.2 \times 0.1$ mm. 25 719 reflections were collected of which 11 166 were independent (R_{int} 0.0767) to give $R_1[I > 2\sigma(I)] = 0.0767$, $wR_2[I > 2\sigma(I)] = 0.1969$ and R_1 (all data) $= 0.2020$, wR_2 (all data) $= 0.2513$.

5. Supplementary data

Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 167979. Copies of these data may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We gratefully acknowledge The Royal Society (University Research Fellowship for C.A.R.), The University of Bristol (Scholarship for A.P.L.) for financial support. One of the authors (J.C.J.) thanks the EPSRC for supporting diffractometer facilities. We would also like to thank Mr Jon Moore for running ^{11}B NMR experiments and Dr Nick Norman for helpful discussions during preparation of this manuscript.

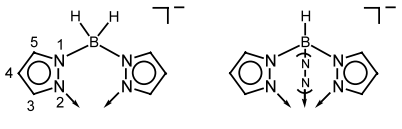
Received 2 August 2001; accepted 27 November 2001

Abstract



The structures of the thallium(I) complexes with hydrotris(pyrazolyl)borate (TpTl, **2**-Tl), and the modified Bp and Tp ligands dihydrobis(1,2,4-triazolyl)borate (**3**-Tl), hydrotris(imidazolyl)borate (**6**-Tl), dihydrobis(indazolyl)borate (**7**-Tl), and hydrotris(indazolyl)borate (**8**-Tl) are reported and discussed in terms of their (molecular) metal–ligand arrangement and their crystal packing. Compounds **2**-Tl and **7**-Tl feature molecular TpTl and Bp′Tl units with pronounced Tl···π_{azolyl} interactions between neighboring molecules. In **8**-Tl the molecular units are arranged in pairs through indazolyl π···π stacking. Complexes **3**-Tl and **6**-Tl form extended 3D and 1D structures, respectively, through the bridging action of the poly(azolyl)borate ligand between three symmetry related thallium centers. Compounds **2**-Tl, **3**-Tl, and **8**-Tl crystallize in the chiral space groups $P2_1$, $P2_12_12_1$, and $C2$, respectively.

Keywords: Thallium(I) complexes; Scorpionate ligands; Crystal packing; π-Stacking; Cation–π interaction

1. Introduction

Thallium(I) is formally a low-valence p-block metal with a closed sub-shell (s^2). Yet its structural chemistry can feature unusual patterns of aggregation in the solid state [1–8] through what could be attractive metal–metal interactions [9–13]

Poly(pyrazolyl)borate ligands (scorpionates) are versatile ligands in physio-chemical, bio-inorganic and structurally oriented coordination chemistry [14–20]. The parent compounds are dihydrobis(pyrazolyl)borate (Bp, **1**) and hydrotris(pyrazolyl)borate (Tp, **2**).

Bp, **1** Tp, **2**

-(N-N)- denotes the third pyrazolyl ring which is oriented to the rear

Thallium(I) derivatives of poly(pyrazolyl)borato ligands are important (i) as a means of isolation and characterization of new scorpionate ligands and (ii) as a mild (less reducing) and often more stable ligand transfer reagent in place of alkali metal salts of scorpionate ligands [21].

In recent years we, and others, have been interested in metal complexes with modified poly(pyrazolyl)borate ligands and in their supramolecular architecture. These modified scorpionate ligands are bis- and tris(1,2,4-triazolyl)borate (**3** and **4**) [22–27], bis(tetrazolyl)borate (**5**) [28–30], bis- and tris(imidazolyl)borate (**6**) [31–33] or bis-and tris(indazolyl)borate (**7** and **8**) [34,35]. Examples of modified poly(pyrazolyl)borate ligands studied by others are fluorinated tris(pyrazolyl)borate [36] and tris(mercaptoimidazolyl)borate [37–40].

We report here the structures of the thallium(I) complexes with **2**, **3**, **6**, **7**, and **8**, with special consideration to their supramolecular assembly. Thallium(I) complexes are also used by others to investigate supramolecular metal–ligand structures [41]. The structural investigations of **2**, **6**, and **8** have already been communicated as short notes [42,43].

2. Experimental

NMR spectra were collected on a Bruker ARX200 (200.1 MHz for ^{1}H, 50.3 MHz for ^{13}C) or ARX400 (**8**-Tl) and calibrated against the solvent signal ($CDCl_3$ ^{1}H NMR 7.26 ppm, ^{13}C NMR 77.0 ppm; d_6-DMSO ^{1}H NMR 2.53 ppm, ^{13}C NMR 39.5 ppm). Mass spectra were obtained on a Varian MAT 311A/AMD in solid-probe at an ionization energy of 70 eV. CHN analysis: Perkin–Elmer 2400 Series II CHNS/O-Analyzer and Analyzer E240 C. IR: Nicolet–Magna Spectrometer 750 or Bruker IFS 25 spectrometer, using KBr disks (only major peaks are listed).

The potassium salts of **2** [44], **3** [24], **6** [31], and **8** [34,43] were obtained as described in the literature. The synthesis of the potassium salt of **7** is given below. CH_3OH for the preparation of **7**-Tl, was dried with CaO by heating under reflux for 4 h under an inert gas, followed by distillation.

2.1. Syntheses

2.1.1. Hydrotris(pyrazolyl)boratothallium(I) (*2*-Tl)

A solution of $TlNO_3$ (530 mg, 1.99 mmol) in a mixture of 5 ml of methanol and 5 ml of water was overlayered with a solution of potassium hydrotris(pyrazolyl)borate (500 mg, 1.98 mmol) in 10 ml of methanol. Slow diffusion of the solutions together with evaporation of the solvent to half the initial volume led to crystal growth. The crystals were collected after 1 week (yield 450 mg, 54%). The melting point of 155 °C and the ^{1}H NMR and mass spectrometric characterizations agree with literature values [45]. ^{13}C NMR ($CDCl_3$): δ (ppm) = 104.11, 135.60, 139.14. IR: $\tilde{\nu}$ (cm^{-1}) = 3112w (νCH), 2443m, 2400w, 2369w (νBH), 1501m, 1422m, 1394m,1382m, 1295s, 1210s, 1185m, 1114s, 1078m, 1048s, 1038s, 970s, 774m, 754s, 737m, 722s, 665 m, 627m, 619m.

$C_9H_{10}BN_6Tl$ (417.41): Calc. C, 25.90; H, 2.41; N, 20.13; Tl, 48.96%; Found: C, 26.09; H, 1.93; N, 20.68; Tl, 48.52%. The absence of K in the crystals was confirmed by AAS.

2.1.2. Dihydrobis(1,2,4-triazolyl)boratothallium(I) (*3*-Tl)

A solution of potassium dihydrobis(triazolyl)borate (0.19 g, 1.00 mmol) in methanol (5 ml) was added to a solution of 266 mg (1.00 mmol) of $TlNO_3$ in a 1:1 mixture of H_2O–MeOH (6 ml). The cloudy solution was filtered and left to stand, partially open to air, for 3 weeks. Filtering the clear solution, now half volume, yielded large, clear crystals within 2 days, in a reproducible process (crystal yield 41 mg, 12%). IR: $\tilde{\nu}$ (cm^{-1}) = 3114w (νCH), 2405s, 2270w (νBH), 1498s (νCH), 1306w, 1264m, 1158vs, 1129s, 1016w, 966m, 874w, 669s. $C_4H_6BN_6Tl$ (353.33): Calc. C, 13.60; H, 1.71; N 23.79. Found: C, 13.60; H, 1.85; N, 23.51%.

2.1.3. Hydrotris(imidazolyl)boratothallium(I) (*6*-Tl)

A solution of $TlNO_3$ (530 mg, 1.99 mmol) in methanol (5 ml) and water (5 ml) was overlayered with a solution of potassium hydrotris(imidazolyl)borate (500 mg, 1.98 mmol) in methanol (10 ml). Slow diffusion of the solutions together with evaporation of the solvent to half of the initial volume led to crystal growth. The colorless needle-shaped crystals were collected after 1 week (yield 520 mg, 63%). Melting point (m.p.) 268–270 °C. ^{1}H NMR (d_6-DMSO): δ (ppm) = 6.80 (s, 2H, H-4 and H-5), 7.24 (s, 1H, H-2). ^{13}C NMR (d_6-DMSO): δ (ppm) = 120.60 (C-4), 127.98 (C-5), 139.65 (C-2). IR: $\tilde{\nu}$ (cm^{-1}) = 2430m, 2412m (νBH), 1477s, 1207s, 1119s, 1073s, 924s. $C_9H_{10}BN_6Tl$ (417.41): Calc. C, 25.90; H, 2.41; N, 20.13. Found: C, 25.96; H, 2.40; N, 20.07%.

2.1.4. Dihydrobis(indazolyl)boratopotassium(I) (*7*-K)

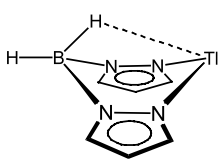
KBH_4 (2.41 g, 44.6 mmol) was added to indazole (20.75 g, 178.6 mmol) and the mixture heated for 2 h at 170 °C under nitrogen. The mixture melted, with evolution of hydrogen, and was cooled down after the theoretical amount (2.2 l by wet-test-meter) of hydrogen had evolved. The excess indazole was sublimed out (120 °C, 5×10^{-2} mbar). To ensure complete sublimation, the unsublimed residue was crushed and sublimation continued. At this stage, the product may be sufficiently pure in a yield usually above 95%. If the NMR of the unsublimed residue still indicates impurities of indazole, the impure product can be dissolved in a minimum amount of boiling toluene, filtered and cooled. Precipitation/crystallization of the product may have to be induced by overlayering with petroleum

ether (30/50). Recrystallization from toluene gives relatively pure products but results in a considerably decreased yield (30–45%). The potassium salt of **7** can also be purified by conversion to the thallium salt (see below). ^{1}H NMR (d_6-DMSO): δ (ppm) = 6.85 (dtd, 4H, H-5 and H-6), 7.15 (dt, 2H, H-4), 7.58 (dt, 2H, H-7), 7.85 (d, 2H, H-3) (see drawing **7** for the NMR labeling). IR: $\tilde{\nu}$ (cm^{-1}) = 2359m (νBH), 1615s, 1495s, 1476m, 1459s, 1258s, 1201s, 978m, 944m, 912s, 864m, 697m, 658m, 647m, 595m, 474m, 427m. Calc. for $C_{14}H_{12}BN_4K$ (286.19) C, 58.76; H, 4.23; N, 19.58. Found: C, 56.14; H, 4.25; N, 18.61%. The potassium salt of **7** is water sensitive. Dissolution in methanol and water yields indazole.

2.1.5. Dihydrobis(indazolyl)boratothallium(I) (7-Tl)

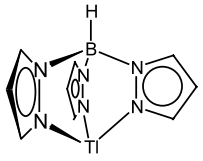
$TlNO_3$ (2.55 g, 9.57 mmol) was dissolved in dried methanol (200 ml) with heating and ultrasonication. The solution was added to **7**-K (2.74 g, 9.57 mmol) in methanol (50 ml). The product forms almost instantly upon mixing. The immediate product yield (2.51 g, 58%) can be enhanced by cooling of or slow solvent evaporation from the mother liquor. Crystals were grown by slow solvent evaporation of either the mother liquor or a methanol solution of **7**-Tl. ^{1}H NMR ($CDCl_3$): δ (ppm) = 7.06 (td, 2H, H-6), 7.38 (td, 2H, H-5), 7.63 (dt, 2H, H-4), 8.04 (d, 2H, H-3), 8.10 (dd, 2H, H-7) (see drawing **7** for the NMR labeling). IR: $\tilde{\nu}$ (cm^{-1}) = 2360m (νBH), 1614s, 1497s, 1459s, 1399m, 1337m, 1259m, 1211m, 1185m, 1132s, 1111s, 1008m, 986m, 912s, 837m, 820m, 757s, 746s, 691m, 656m, 638m, 596m, 433m. Calc. for $C_{14}H_{12}BN_4Tl$ (451.47) C, 37.25; H, 2.68; N, 12.41. Found: C, 36.63; H, 2.55; N, 13.06%.

2.1.6. Hydrotris(indazolyl)boratothallium(I) (8-Tl)



$TlNO_3$ (0.53 g, 2.0 mmol) in CH_3OH (10 ml) reacts with the potassium salt of **8** (0.80 g, 2.0 mmol), forming a white precipitate. This precipitate was filtered off and crystallized from dioxane through overlayering with petroleum ether (30/50). The product formed as colorless crystals (yield 0.67 mg, 59%). ^{1}H NMR (d_6-DMSO): δ = 7.00 (ddd, 3H, H-5, $J_{5,4}$ = 8.07 Hz, $J_{5,6}$ = 6.77 Hz, $J_{5,7}$ = 0.92 Hz), 7.26 (ddd, 3H, H-6, $J_{6,7}$ = 8.58 Hz, $J_{6,5}$ = 6.77 Hz, $J_{6,4}$ = 1.10 Hz), 7.67 ('dt', 3H, H-4, $J_{4,5}$ = 8.07 Hz, $J_{4,6}$ = 1.10 Hz, $J_{4,7}$ = 0.98 Hz), 7.89 ('dq', 3H, H-7, $J_{7,6}$ = 8.58 Hz, $J_{7,4}$ = 0.98 Hz, $J_{7,3}$ = 0.93 Hz, $J_{7,5}$ = 0.92 Hz), 8.15 (d, 3H, H-3, $J_{3,7}$ = 0.93 Hz) (see drawing **7** for the NMR labeling). MS (230 °C): 568 (26%, $[M]^+$). Calc. for $C_{21}H_{16}BN_6Tl$ (567.59) C, 44.44; H, 2.84; N, 14.81; Tl, 36.00. Found: C, 43.67; H, 2.56; N, 14.51; Tl, 35.70%.

2.2. X-ray structure determinations



Data were collected using the ω-scan method with Mo Kα radiation (λ = 0.71073) and a graphite monochromator on a Syntex $P2_1$ four-circle diffractometer (**2**-Tl) or a Bruker AXS CCD diffractometer. All crystals were colorless. Structure solution was done using direct methods (SHELXS-97 [46]); refinement was done by full-matrix least squares on F^2, again using SHELXL-97 [46]. All non-hydrogen atoms were found and refined anisotropically. The hydrogen atoms on boron were found and refined in **3**-Tl and **6**-Tl, and calculated for **2**-Tl, **8**-Tl (AFIX 13) and **7**-Tl (AFIX 23) with U(H) = 0.08. The hydrogen atoms on carbons were placed at calculated positions with bond lengths free to refine (HFIX 44 for **6**-Tl) or with d_{C-H} = 0.94 Å, using appropriate riding models (HFIX 43) and isotropic temperature factors of U(H) = 0.08 (**2**-Tl, **7**-Tl, **8**-Tl) or U(H) = 1.2 Ueq(C, N) (**3**-Tl) or U(H) = 1.5 Ueq(C, N) (**6**-Tl). The growth of good quality crystals for **2**-Tl was difficult and hence its X-ray structure is not without problems (see Table 1 and Fig. 1). Crystal data are given in Table 1. Graphics were obtained with ORTEP3 for Windows [47] with displacement ellipsoids shown at the 50% probability level and H atoms shown as spheres of arbitrary radii.

3. Results and discussion

The basic metal-ligand motif of most BpTl [4] and TpTl complexes [21] is as depicted in compound **9** and **10**, respectively. The bonding of the bidentate Bp is supplemented by a weak agostic B–H···Tl interaction [48–50].

BpTl, **9**

TpTl, **10**

Otherwise there is little variation in the bis- and tris-chelating mode of the two scorpionate ligands towards thallium. A few structures show additional Tl···Tl contacts below 4.0 Å, namely BpTl [4], $Bp^{bipy}Tl$ (bipy = 6-2,2′-bipyridine) [51], $Tp^{cyclopropyl}Tl$ [52], and $Tp^{p\text{-tolyl}}Tl$ [53]. The abbreviation Bp^{XR} and Tp^{XR} follows the suggested nomenclature by Trofimenko [14,15] to indicate a substituent R in the X position on the pyrazolyl ring.

Exceptions to the common C_3-trigonal motif for TpTl complexes only occur when the hydrogen atom on boron is replaced by a more sterically demanding group. Known compounds are $PhTp^{tBu}Tl$ [54], FcTpTl (Fc = ferrocenyl) [55], and $MeTp^{Me2}Tl$ [56]. Probably due to steric effects, one of the pyrazolyl rings rotates

around the B–N bond and either coordinates with N1 to thallium, as in PhTp^{tBu}Tl, or with N2 to a thallium atom of another molecule. The latter is the case in FcTpTl and MeTp^{Me2}Tl, which exhibit polymeric structures due to the bridging nature of the ligand.

The molecular and crystal structures of the complexes reported here will be discussed in the following. Unremarkable distances and angles are not discussed in detail but are listed in the figure captions and are summarized in Table 2. Unless otherwise noted, the Tl–N distances fall in the normal range of 2.50–2.73 Å [1,21] found for Tl–N contacts in BpTl and TpTl structures.

A notable feature of most of the structures reported here is that they crystallize in chiral space groups. This is the case for **2**-Tl ($P2_1$), **3**-Tl ($P2_12_12_1$) and **8**-Tl ($C2$). The structures of **2**-Tl and **3**-Tl were refined as pure enantiomers. For **8**-Tl the crystal structure was refined as a twin with an enantiomer ratio of 86(2) to 14(2)%

[a] Two independent molecules in the unit cell.

for the selected crystal. The crystallization of these poly(azolyl)borate thallium structures in non-centrosymmetric space groups cannot be dismissed as accidental but instead may be a more general phenomena in poly(azolyl)borate complexes with univalent metals. Unresolved chiral materials usually crystallize as a racemate and the frequency of spontaneous resolution is unusual here. A non-centrosymmetric space group ($Pna2_1$) is also found for hydrotris(1,2,4-triazolyl)boratosilver(I) [25]. In addition, the same chiral space group ($P2_12_12_1$) was determined for both dihydrobis(1,2,4-triazolyl)boratopotassium [57] and the thallium analog **3**-Tl.

The chirality is due to the solid-state packing in these structures. The ligands (or metal centers) by themselves are achiral. In **2**-Tl the chirality may be traced to the formation of 2_1-helical strands. In **3**-Tl it is due to the pyramidal or pseudo-tetrahedral coordination (taking into account the space of the presumed lone-pair) of the thallium centers by three (four) different ligands which creates the asymmetric centers. The structure of **8**-Tl features pairs of molecules where the two halves are related through a C_2 symmetry operation. Each pair represents a chiral entity.

The molecular structure of the prototypical hydrotris(pyrazolyl)thallium, **2**-Tl shows the usual pyramidal geometry of the thallium atom (Fig. 1). The packing of **2**-Tl reveals kinked, chain-type arrangements of the metal-ligand moieties (Fig. 2), with two different chain types present in the unit cell for the two crystallographically different Tl centers. The packing is most likely dictated by electrostatic interactions between the thallium and pyrazolyl π-manifolds from neighboring molecules. These non-bonded Tl···C and Tl···N distances are in the range of 3.683–3.781 Å (ring N1b·C3b) and 3.668–4.162 Å (ring C7b·C9b) for Tl1, and 3.557–3.884 Å (ring N7b·N12b) and 3.638–4.036 Å (ring N11b·C18b) for Tl2. These, along with the Tl···C/N contacts in the other structures, are included in Table 2. It can be seen that the distances in **2**-Tl are among the shortest (see also the Tl···centroid distances) and hence, are more significant. Resulting Tl···Tl′ contacts of 4.80 and 5.12 Å are too long for any metal–metal interaction. There is a Tl1–N bond length variation from 2.575(7) to 2.665(6) and 2.730(7) Å. For Tl2–N the variation is from 2.547(7) to 2.651(7) Å. The longer Tl–N bonds are to those pyrazolyl rings which are engaged in Tl···π interactions. There is a reciprocal correlation between the length of the Tl′···N contacts and the Tl–N bonds.

The building blocks of the extended 3D-structure of dihydrobis(1,2,4-triazolyl)boratothallium, **3**-Tl, are illustrated in Figs. 3 and 4. The essentially threefold nitrogen coordination in a pyramidal geometry around thallium is constructed from three different, albeit symmetry related ligands. A fourth nitrogen interaction is present at a considerably greater distance of 3.132 Å.

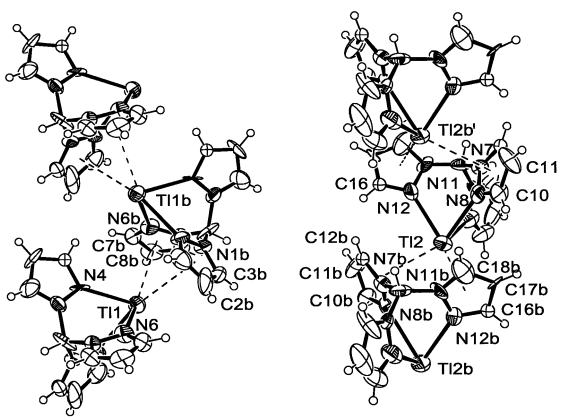

Fig. 2. Section of the strands formed in **2**-Tl. The left strand contains the Tl1-, the right strand the Tl2-molecular units. The strands run along *b*. Pyrazolyl π contacts to thallium between neighboring molecules are indicated. Shortest Tl···C/N distances (Å): Tl1···N2b 3.685, Tl1···C1b 3.683, Tl1···centroid (N1b–C3b) 3.555, Tl1···N6b 3.668, Tl1···C7b 3.817, Tl1···centroid (N5b–C8b) 3.748, Tl2···N7b 3.557, Tl2···C12b 3.654, Tl2···centroid (N7b·C12b) 3.500, Tl2···N11b 3.638, Tl2···C18b 3.760, Tl2···centroid (N11b·C18b) 3.665. Symmetry relation for Tl1: $b = -x+2,\ y+1/2,\ -z$; for Tl2: $b = -x+1,\ y+1/2,\ -z+1,\ b' = -x+1,\ y-1/2,\ -z+1$.

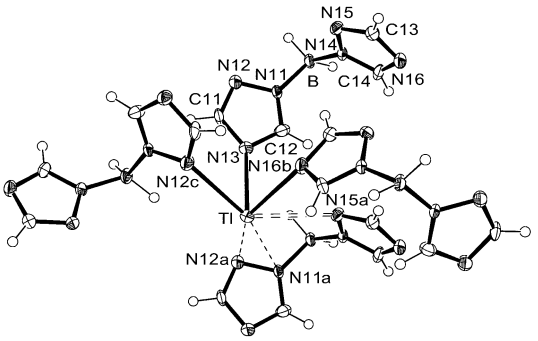

Fig. 3. Coordination environment around thallium in **3**-Tl. Selected distances (Å) and angles (°): Tl–N12c 2.767(7), Tl–N13 2.674(7), Tl–N16b 2.803(7), Tl···N15a 3.132(7), Tl···N12a 3.360(7), Tl···N11a 3.762(7), N12c–Tl–N13 76.1(2), N12–Tl–N16b 77.4(2), N13–Tl–N16b 83.7(2). Symmetry relation $a = x, y, z+1$; $b = -x+1/2, -y, z+1/2$; $c = x+1/2, -y+1/2, -z+2$.

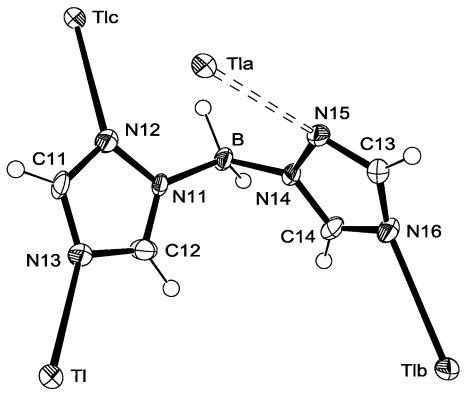

Fig. 4. Bridging action of the ligand in **3**-Tl. For distances see the caption to Fig. 3. Symmetry relation $a = x, y, z-1$; $b = -x+1/2, -y, z-1/2$; $c = x-1/2, -y+1/2, -z+2$.

There are two different donor atoms in the 1,2,4-triazolyl ring, with both the endo-(2-N) and the exo-dentate (4-N) nitrogen atoms acting as donor atoms. Thus, each ligand bridges three thallium atoms (Fig. 4), leaving one of the endo-dentate nitrogen atoms (N15) with only a weak thallium coordination. Similar bridging actions of poly(triazolyl)borate ligands between transition-metal centers have been observed previously [22,23,25,26]. In **3**-Tl, the bridging leads to an extended, three-dimensional (3D) structure (Fig. 5). Electrostatic interactions between thallium and triazolyl rings from neighboring molecules can also be seen (see Fig. 3).

Unlike **2**, the isomeric hydrotris(imidazolyl)borate ligand **6** cannot chelate a metal center but instead bridges metal ions. The formation of coordination polymers is then expected. In the structure of hydrotris(imidazolyl)boratothallium(I), **6**-Tl, each of the three imidazolyl rings coordinates to a different (albeit symmetry related) metal center, as shown in Fig. 6. Two adjacent ligands bridge two neighboring thallium ions. From this a one-dimensional (1D) ladder-like strand is formed. A two- or even three-dimensional framework, as in **3**-Tl, may be another possibility for the metal-ligand assembly. The packing of adjacent strands in **6**-Tl is probably dictated by electrostatic interactions between the thallium ion and imidazolyl π manifolds as in **2**-Tl. These non-bonding Tl···C and Tl···N interactions appear less significant than in the structures of **1**-Tl and **7**-Tl (see Table 2). Tl···centroid contacts start at 3.69 Å and Tl···C/N distances are above 3.723/3.767 Å. At the same time, the packing of neighboring strands is such that there are no close Tl···Tl distances (> 4.69 Å). The bridging action of **6** is again reminiscent of the bridge formation of the related poly(1,2,4-triazolyl)borate [22,23,25,26] and dihydrobis(tetrazolyl)borate ligand [28,30], which also possess nitrogen donors in a 1,3-position to the B–N bond.

In a first approximation the crystal structure of dihydrobis(indazolyl)boratothallium(I), **7**-Tl consists of monomeric units (Fig. 7). Yet these monomeric unit are arranged in centrosymmetric pairs, apparently through thallium–π interactions, as indicated in Fig. 8. The indazolyl moiety from N21 to C27 which is engaged in the Tl–π interaction has a longer Tl–N(22) bond [2.652(4) Å] than the other [Tl–N12, 2.565(3) Å]. The Tl–π contact may relieve the need for an agostic B–H···Tl interaction. The B···Tl and (B-)H···Tl distances are 3.52 and 3.16 Å, respectively, which is considerably greater than the B···Tl distance of 3.2–3.3 Å observed in most $Bp^{RR'}Tl$ compounds [4]. Additional packing in the crystal structure of **7**-Tl is controlled by intermolecular C–H···π interactions [34,58], as may be seen in Fig. 9. Shortest C–H···C/N contacts are between C11–H of the five-membered ring to N11d (2.81 Å), N12d (2.72 Å) and C11d (2.80 Å) of a neighboring five-membered ring (symmetry relation $d = 3/2-x, -1/2+y, 3/2-z$) The dihedral angle between these two five-membered rings is 53.3°. C–H···C contacts between the six-membered rings of the indazolyl moiety are above 2.93 Å. The shortest Tl···Tl distances of 4.156 Å in **7**-Tl are not within the Tl···π pairs but are to a neighboring molecule with symmetry relation $-x+1, -y, -z+1$.

The molecular structure of hydrotris(indazolyl)boratothallium(I), **8**-Tl, is depicted in Fig. 10. At first sight, the molecule appears to show the typical C_{3v} symmetrical metal-ligand motif. However, there is a considerable Tl–N bond length variation; from 2.584(8) Å for Tl–N12 and 2.590(9) Å for Tl–N22 to 2.747(8) Å for Tl–N32. The cause of this variation becomes apparent from the molecular packing: in the crystal structure these molecules are arranged in pairs. These pairs are obviously held together by slipped face-to-face π-stacking [59] of two indenyl moieties as shown in Fig. 11. The π-stacking is such that the two thallium centers are pointing in the same direction. The molecular units of

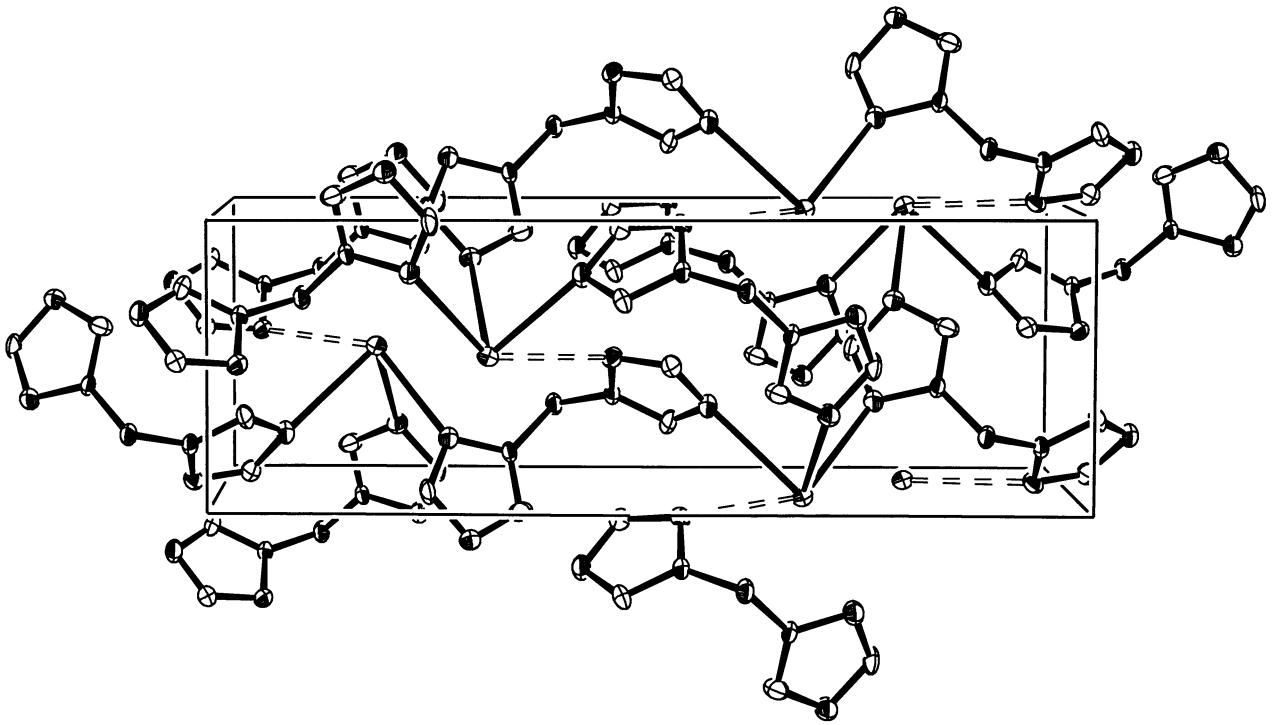

Fig. 5. Packing diagram of **3**-Tl, illustrating the extended 3D framework; view along a. Hydrogen atoms have been omitted for clarity. The weak Tl···N15 interactions are shown as dashed lines. Tl···Tl distances are 4.564 Å.

each pair are related through a C_2-symmetry operation, with no mirror plane or center of inversion. Hence each pair represents a chiral entity. As pointed out above, the single crystal did not show a 50:50 mixture of *R*- and *S*-pairs. Structure solution and refinement was only successful in the non-centrosymmetric space group *C*2. The crystal structure was refined as a (racemic) twin with an enantiomer ratio of 86(2) to 14(2)% for the selected crystal.

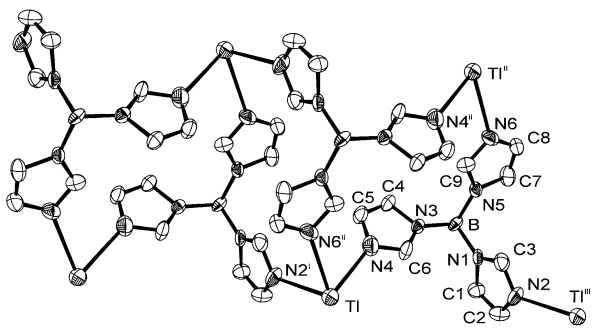

Fig. 6. Section of the one-dimensional polymeric structure of **6**-Tl. Hydrogen atoms have been omitted for clarity. The chains run along the crystallographic a direction. Selected distances (Å) and angles (°): Tl–N4 2.663(7), Tl–N2′ 2.656(6), Tl–N6″ 2.633(7), N6″–Tl–N2′ 80.8(2), N6″–Tl–N4 77.4(2), N2′–Tl–N4 86.3(2). Angles between the imidazolyl ring planes: ring N1·N2–N3·N4 89.8(5)°, ring N3·N4–N5·N6 72.4(5)°, ring N1·N2–N5·N6 79.4(5)°. Symmetry relations: $' = x-1,\ y,\ z$; $'' = 1-x,\ 1-y,\ 1-z$; $''' = x+1,\ y,\ z$.

Non-bonded Tl···C and Tl···N distances are again less significant than in the structures of **1**-Tl and **7**-Tl (see Table 2). Tl···centroid contacts start at 3.89 Å and Tl···C/N distances are above 3.968/3.672 Å, respectively. There are no close Tl···Tl distances (> 4.45 Å). Further packing interactions are dictated by C–H···π interactions between the indazolyl groups [34].

The Tl–N bond to the π-interacting indazolyl ring is longer than the other two Tl–N bonds. The solution NMR spectra of **8**-Tl shows that all three rings are equivalent due to loose or solvent-separated cation–anion contacts and to the absence of neighboring π-interactions, respectively.

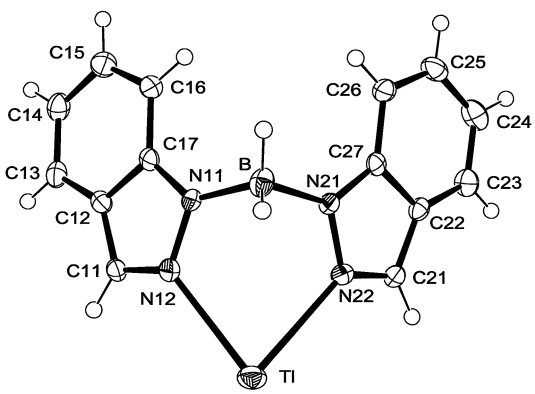

Fig. 7. Monomeric unit in **7**-Tl. Selected distances (Å) and angles (°): Tl–N12 2.565(3), Tl–N22 2.652(4), N21–Tl–N22 75.6(1).

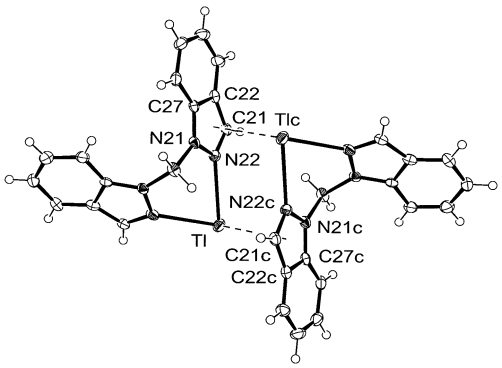

Fig. 8. Arrangement of centrosymmetric pairs in the structure of **7**-Tl. Selected Tl-π distances (Å): Tl···N21c 3.340(4), Tl···N22c 3.280(4), Tl···C21c 3.479(4), Tl···C22c 3.690(4), Tl···C27c 3.579(4), Tl···centroid (N21c·C27c) 3.267(4), Tl···Tlc 4.654(4). Symmetry relation $c = -x+1, -y+1, -z+1$.

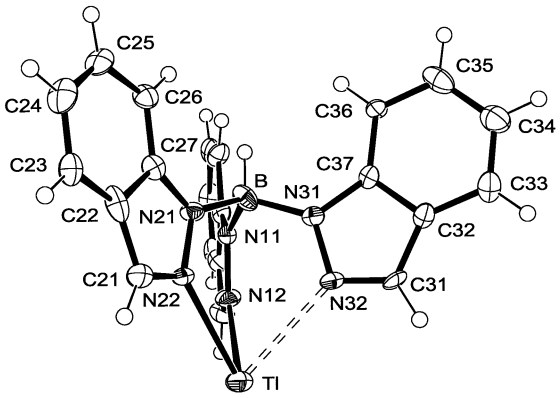

Fig. 10. Monomeric unit in **8**-Tl. The indazolyl ring with N11 and N12 could not be fully labeled for obvious reasons, yet the numbering scheme follows that of the other two rings. Selected distances (Å) and angles (°): Tl–N12 2.590(9), Tl–N22 2.584(8), Tl–N32 2.747(8), N22–Tl–N12 74.6(3), N22–Tl–N32 70.2(3), N12–Tl–N32 68.4(3).

4. Conclusions

Thallium complexes of modified poly(pyrazolyl)-borate ligands offer a great variability in their metal-ligand and crystal packing arrangement. Additional donor atoms in the azolyl ring or a 1,3- (cf. 1,2-) position of the nitrogen atoms in the ring gives rise to extended structures with bridging borate ligands. Electrostatic Tl···π_{azolyl} interactions can be quite prominent in the crystal packing of the molecular

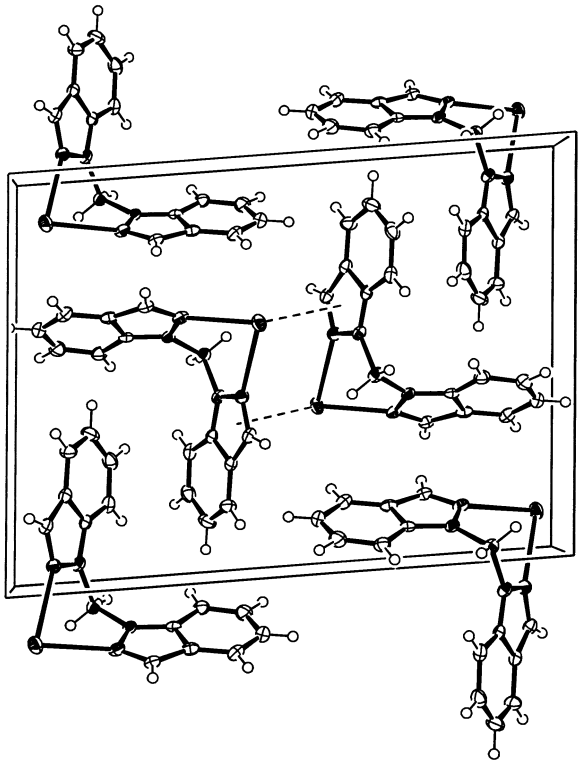

Fig. 9. Packing diagram for **7**-Tl; view along *b*.

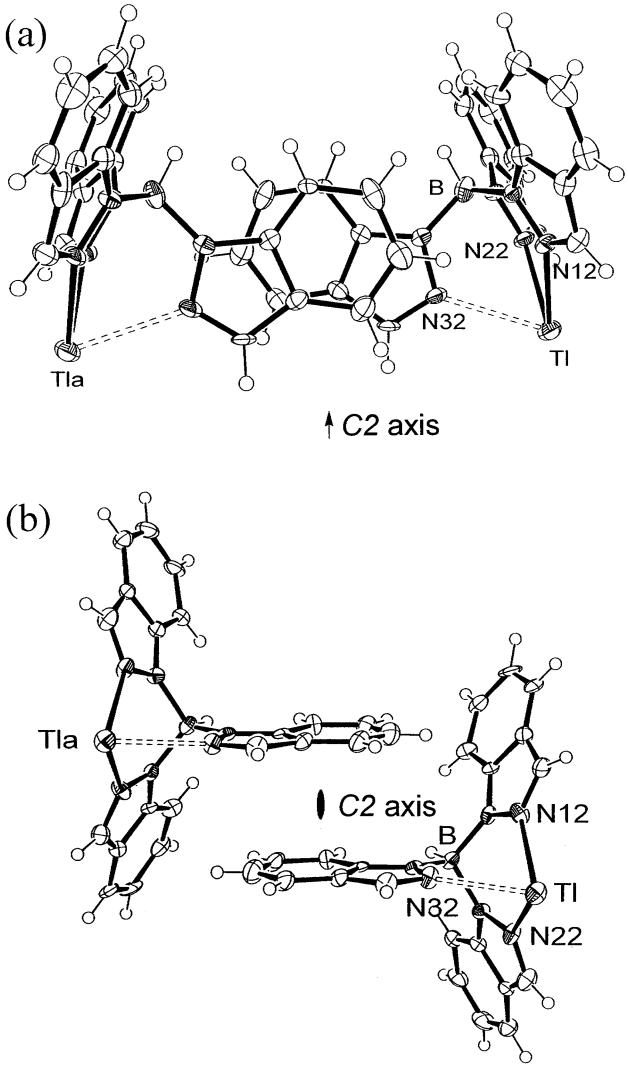

Fig. 11. π–π-stacked pairs of molecular units of **8**-Tl in the solid state, (a) top view, (b) front view. The π···π separation is 3.58 Å. Symmetry relation $a = 1-x, y, 1-z$.

thallium-ligand chelate complexes. For azolyl rings with extended π-systems, such as indazolyl, an offset $(\pi\text{–}\pi)_{\text{indazolyl}}$ stacking can also be significant. These solid-state packing effects are seen as the origin of the frequent crystallization of thallium(I) or in general metal(I) poly(azolyl)borate complexes in chiral space groups. The azolyl rings which are engaged in these type of π interactions show an increase in their Tl–N bond. There appears to be a reciprocal correlation between the strength of the π interactions and the Tl–N bonds.

5. Supplementary material

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication No. CCDC-101006 (**2**-Tl), -168036 (**3**-Tl), -135180 (**6**-Tl), -168037 (**7**-Tl), -141090 (**8**-Tl). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; email: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

An extremely hindered digermene (*E*)-Tbt(Mes)Ge=Ge(Mes)Tbt (**1**; Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl; Mes = mesityl) was synthesized. X-ray crystallographic analysis of the hexane solvated single crystal [**1**·0.5hexane] revealed that **1** has an extremely long germanium–germanium double bond [2.416(2) Å] as that of a carbon-substituted digermene. The temperature-dependent change of UV–Vis absorption of digermene **1** in solution indicated the quantitative interconversion between **1** and the corresponding germylene Tbt(Mes)Ge: (**3**). The thermodynamic parameters ($\Delta H = 14.7 \pm 0.2$ kcal mol^{-1} and $\Delta S = 42.4 \pm 0.8$ cal mol^{-1} deg^{-1}) for the dissociation of digermene **1** to germylene **3** were obtained from temperature dependence of the absorption of **1**. Since the reactivity of germylene **3** is much higher than that of digermene **1**, almost all the intermolecular reactions of **1** in solution proceeded via dissociated **3**. For instance, the reaction of **1** with oxygen in solution resulted in a non-stereospecific formation of the *cis*- and *trans*-1,3,2,4-dioxadigermetanes **11** and **7** via the initial formation of germanone **12** derived from oxygenation of the dissociated germylene **3**. In case of the oxidation in the solid state, however, digermene **1** reacted with O_2 without dissociation to give the corresponding *trans*-substituted 1,3,2,4-dioxadigermetane stereospecifically. The reaction of digermene **1** with $W(CO)_5$(THF) was also examined to give the corresponding terminal tungsten complex of the dissociated germylene **3**, i.e. Tbt(Mes)Ge=$W(CO)_5$ (**23**), as a marginally stable orange yellow paste. © 2002 Published by Elsevier Science Ltd.

1. Introduction

During the last two decades remarkable progress has been made in the chemistry of low-coordinate compounds of heavier group 14 elements, especially in those of dimetallenes and metallylenes because of their unique structures and reactivities [1]. Since the first isolation of a stable disilene by West et al. in 1981 [2], a number of stable dimetallenes (disilene [1c–e], digermene [1b,d,f], and distannene [1b,d,f]) have been synthesized and the intrinsic nature of the metal–metal double bonds in those dimetallenes has been elucidated to a considerable extent. For example, the thermal dissociation of a disilene into silylenes [3] and that of a distannene into stannylenes [4] in solution have been experimentally demonstrated on the basis of their reactivities and spectroscopic properties, and energetics for their dissociation processes have been estimated. As for digermenes, a unique 1,2-migration of the mesityl group has been reported in the thermolysis of tetramesityldigermene ($Mes_2Ge=GeMes_2$) leading to the formation of mesityl(trimesitylgermyl)germylene [5], while the thermolysis of more hindered tetraaryldigermenes (*E*)- and (*Z*)-Mes(Tip)Ge=Ge(Tip)Mes (Tip = 2,4,6-triisopropyl-

Scheme 1.

lphenyl) resulted in the rotational isomerization between these two stereoisomers [6]. Furthermore, tetrakis(2,6-diethylphenyl)digermene ($Dep_2Ge{=}GeDep_2$; Dep = 2,6-diethylphenyl) was reportedly converted into the corresponding cyclotrigermane on heating, probably via dissociation into the germylene $(Dep)_2Ge$: followed by its cyclotrimerization [1c]. Such thermal dissociation into the corresponding germylenes has also been postulated in the thermolysis of $[(Me_3Si)_2CH]_2Ge{=}Ge[CH(SiMe_3)_2]_2$ [7] and $(2\text{-}t\text{Bu-}4,5,6\text{-}Me_3C_6H)_2Ge{=}Ge(2\text{-}t\text{Bu-}4,5,6\text{-}Me_3C_6H)_2$ [8], but the evidence for the dissociation was provided only by trapping reactions of the germylenes [9]. To the best of our knowledge, no experimental estimation for the bond dissociation energy of a Ge=Ge double bond has been reported so far.

In view of these situations, we became interested in the properties of a digermene, Tbt(Mes)Ge=Ge(Mes)Tbt (**1**; Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]-phenyl [10], Mes = mesityl), the silicon analogue of which showed a quite unique structure and reactivity. Here, we present the synthesis and characterization of this extremely hindered digermene **1**, which led us to the first spectroscopic observation of an equilibrium between a digermene and germylenes. Digermene **1** provided us with a good opportunity to perform the first measurement of a bond dissociation energy for the germanium–germanium double bond.

2. Results and discussion

2.1. Synthesis and structure

Reaction of dichlorogermane [Tbt(Mes)$GeCl_2$, **2**] with lithium naphthalenide in THF at −78 °C gave a dark-brown solution. The solvent exchange from THF to hexane followed by filtration of inorganic salts and sublimation of naphthalene in vacuo afforded the corresponding (*E*)-substituted digermene **1** exclusively as orange crystals (Scheme 1). Although digermene **1** is stable at room temperature under inert atmosphere, it undergoes decomposition at 92 °C in the solid state.

The molecular structure of **1** was determined by X-ray crystallographic analysis of the hexane solvated single crystal [**1**·0.5hexane], the ORTEP drawing of which is shown in Fig. 1 along with the selected bond lengths and angles.

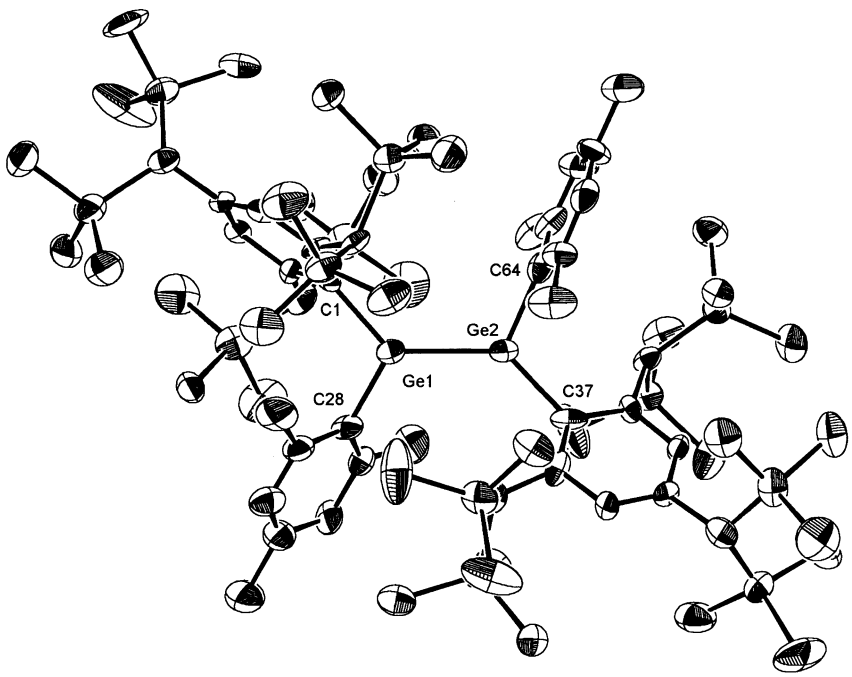

Fig. 1. ORTEP drawing of (*E*)-Tbt(Mes)Ge=Ge(Mes)Tbt·0.5hexane (**1**·0.5hexane) with thermal ellipsoid plots (30% probability). The fragment of solvated hexane is omitted for clarity. Selected bond lengths (Å) and angles (°): Ge(1)–Ge(2) 2.416(2), Ge(1)–C(1) 2.017(12), Ge(1)–C(28) 1.960(14), Ge(2)–C(37) 2.045(13), Ge(2)–C(64) 1.996(14), C(1)–Ge(1)–C(28) 108.0(5), C(1)–Ge(1)–Ge(2) 130.5(3), C(28)–Ge(1)–Ge(2) 118.1(4), C(37)–Ge(2)–C(64) 109.1(5), C(37)–Ge(2)–Ge(1) 132.7(4), C(64)–Ge(2)–Ge(1) 113.5(3).

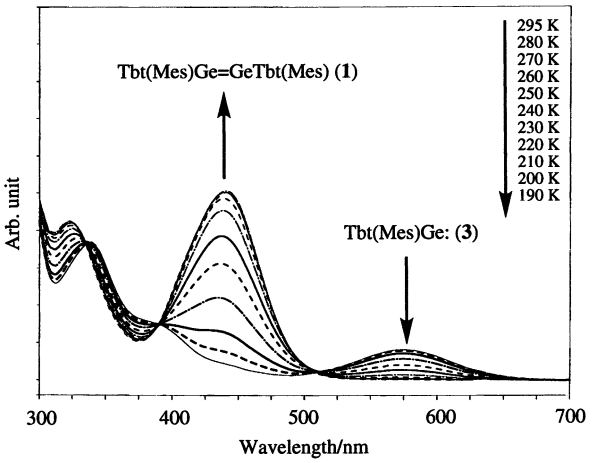

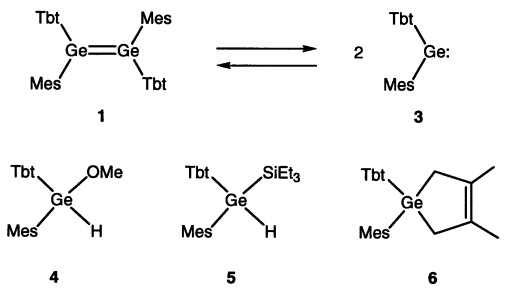

Fig. 2. Temperature-dependent UV–Vis spectra of **1** in hexane (3.7×10^{-4} M).

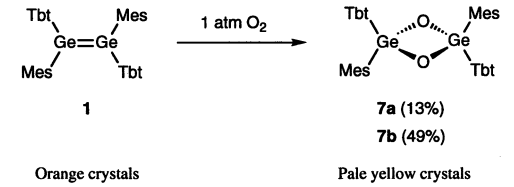
Scheme 2.

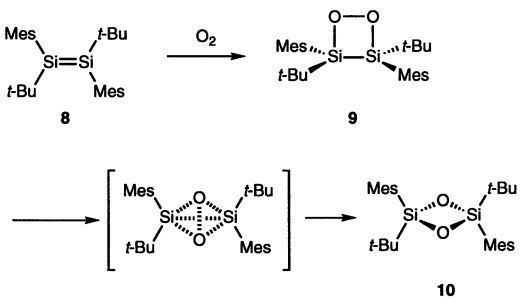
The Ge(1)–Ge(2) bond length [2.416(2) Å] of digermene **1** is remarkably longer than the germanium–germanium double bond lengths of previously reported digermenes bearing carbon substituents [2.21–2.35 Å] [6–8,11] and close to the germanium–germanium single bond length [2.465 Å in $(Ph_2Ge)_4$ or 2.463 and 2.457 Å in $(Ph_2Ge)_6$] [12], reflecting the large steric repulsion between Tbt and Mes groups. Weidenbruch et al. have already reported that strongly twisted (*E*)-1,2-diamino-1,2-disilyldigermenes having a unique skeleton have extremely elongated Ge=Ge double bonds [2.453–2.460 Å] [13]. The sums of the bond angles around Ge(1) and Ge(2) of **1** are 356.6° and 355.3°, respectively. The twist angles along the germanium–germanium bond axis are 16.5(8)° and 34.6(7)°. These structural features of **1** indicate that **1** still retains sp^2 hybridized germanium centers even though its Ge=Ge double bond is weak and elongated.

2.2. Behavior in solution



Interestingly, a hexane solution of **1** showed a reversible thermochromism; the hexane solution of **1** (3.7×10^{-4} M) was blue ($\lambda_{max} = 575$ nm) at room temperature, but it turned orange yellow ($\lambda_{max} = 439$ nm) at low temperature [14]. The change in UV–Vis absorption shown in Fig. 2 clearly indicates that **1** dissociates into the corresponding germylenes **3** at room temperature, while it does not at low temperature (Scheme 2), because tetraaryldigermenes and diarylgermylenes reportedly have their λ_{max} in the range of 408–440 nm [1f,8] and 466–581nm [15], respectively.

The absorptions observed at 190 K ($\lambda_{max} = 439$ nm, ε 2.0×10^4) and 295 K ($\lambda_{max} = 575$ nm, ε 1.6×10^3) are assignable to the π–π^* transition of digermene **1** and the n–p transition of germylene **3**, respectively. The isosbestic points observed at 335, 390 and 509 nm indicate the quantitative interconversion between **1** and **3**. The structure of digermene **1** in solution is reasonably assumed to be the (*E*)-isomer as in the solid state, since the (*Z*)-isomer has obviously much severer steric repulsion between two extremely bulky substituents (Tbt groups) facing each other.



The thermodynamic parameters ($\Delta H = 14.7 \pm 0.2$ kcal mol^{-1} and $\Delta S = 42.4 \pm 0.8$ cal mol^{-1} deg^{-1}) for the dissociation of digermene **1** to germylene **3** were obtained from the temperature dependence of the absorptions shown in Fig. 2. This bond dissociation energy (14.7 kcal mol^{-1}) of digermene **1** into germylene **3** is much smaller than the calculated value (30–45 kcal mol^{-1}) for the parent system ($H_2Ge{=}GeH_2$) [7a,16], indicating that the germanium–germanium double bond in **1** is considerably weakened due to the severe steric repulsion between the bulky substituents. In this connection, it is intriguing that Tbt(Tip)Ge: (Tip = 2,4,6-triisopropylphenyl) [15c,15d] and Tip(Mes)Ge: [6], which are more and less sterically demanding than **3**, have been shown to exist only as a monomer and a dimer, respectively, in solution. These observations point to the subtle effect of the size of substituents on the equilibrium between a digermene and germylenes. It is interesting that disilene Tbt(Mes)Si=Si(Mes)Tbt bearing the same substituents as **1** exists essentially as a dimer (i.e. disilene) [3,17]. The bis(trimethylsilyl)methyl-substituted disilene–digermene pair, $[(Me_3Si)_2CH]_2M{=}M[CH(SiMe_3)_2]_2$, (M = Si, Ge), is known to show a similar phenomenon [7,18]. In these systems, the disilene does not undergo any thermal dissociation in solution, but the digermene is reportedly isolable only in the solid state and readily dissociates in solution into the corresponding germylenes at room temperature [7,18]. It should be noted that the interconversion between **1** and **3** is the first example of an experimentally observed equilibrium between a digermene and germylenes [19].

2.3. Reactions in solution

In order to investigate the reactivity of digermene **1** having an extremely elongated Ge=Ge double bond, a solution of digermene **1** was treated at -100 °C with methanol which is known to add readily across a

Scheme 3.

Scheme 4.

Ge=Ge double bond [1f,11a], but the orange–yellow color of the solution due to **1** did not disappear after the solution was kept for 6 h at the same temperature. Upon warming up to room temperature the solution became colorless to give a methoxygermane **4** (44%), the insertion product of germylene **3** into the O–H bond of methanol (Scheme 2). These facts show that the Ge=Ge double bond in **1** is so effectively protected by the surrounding four bulky aryl groups as revealed by X-ray crystallographic analysis that **1** is incapable of reacting with methanol at low temperatures. At elevated temperatures, however, digermene **1** dissociates into the corresponding germylene **3**, which readily reacts with methanol to give the methoxygermane **4**. Germylene **3** generated by dissociation of digermene **1** also reacted with Et_3SiH and 2,3-dimethyl-1,3-butadiene at room temperature to afford the corresponding adducts **5** (70%) and **6** (62%), respectively (Scheme 2).

2.4. Oxidation reactions

Since the reaction with oxygen can be performed either in the solid state or in solution, we made a careful investigation of the oxidation reactions of the extremely hindered digermene **1** to elucidate the intrinsic reactivity.

2.4.1. Reaction of *1* with oxygen in the solid state

At first, the oxidation of digermene **1** was examined in the solid state. When a finely powdered orange sample of **1** was exposed to oxygen for 3 days in the dark, the color changed into pale yellow and two conformational isomers of *trans*-1,3,2,4-dioxadigermetanes **7a** (13%) and **7b** (49%) were obtained after usual chromatographic separation (Scheme 3).

In this reaction *cis*-1,3,2,4-dioxadigermetane was not obtained. These facts show that the reaction of the digermene with oxygen proceeds stereospecifically. Although the oxidation of disilenes is known to take place stereospecifically in solution or in the solid state [20], there have been very few reports on the stereochemistry of the oxidation of a digermene. As for the case of (*Z*)-1,2-diamino-1,2-disilyldigermene, Weidenbruch et al. have reported the stereospecific oxidation reaction with molecular oxygen leading to the formation of the corresponding *cis*-1,3,2,4-dioxadigermetane.

The mechanistic studies of the oxidation of (*E*)-Mes(*t*-Bu)Si=Si(*t*-Bu)Mes (**8**) in solution have revealed that the reaction of **8** with oxygen first gives the [2 + 2]cycloadducts, (*E*)-1,2,3,4-dioxadisiletane (**9**), stereospecifically, which then undergoes rearrangement to afford *trans*-1,3,2,4-dioxadisiletane **10** [20d]. In the solid state, (*E*)-1,2,3,4-dioxadisiletane (**9**) rearranged stereospecifically to afford *trans*-1,3,2,4-dioxadisiletane **10** (Scheme 4) [20d]. These facts suggest that the oxidation of (*E*)-digermene **1** might take place in two steps via 1,2,3,4-dioxadigermetane intermediate with retention of the stereochemistry although the observation of the intermediate was not successful in this case.

The structures of the two conformational isomers of the *trans*-1,3,2,4-dioxadigermetanes **7a** and **7b** were determined by the X-ray crystallographic analysis as shown in Figs. 3 and 4. Single crystals of *trans*-1,3,2,4-dioxadigermetane **7a** were obtained as those solvated with hexane and have been revealed to have two non-identical *trans*-1,3,2,4-dioxadigermetane molecules in the unit cell, while no solvation with hexane was observed for the conformational isomer **7b**. In Fig. 3 are shown the ORTEP drawings of [**7a**·hexane] (fragments 1 and 2, respectively). Fig. 4 shows the ORTEP drawing of another *trans*-1,3,2,4-dioxadigermetane **7b**.

Figs. 5 and 6 show the selected bond lengths and angles of the central dioxadigermetane rings of **7a** and **7b**. The dioxadigermetane rings of the fragment 1 and fragment 2 of **7a** and that of **7b** are almost planar with the sum of the interior bond angles being 360.0°, 359.9°, and 360.0°, respectively. The germanium–germanium distances of fragments 1 and 2 of **7a** and that of **7b** [2.653(2), 2.660(2), and 2.691(4) Å, respectively] are much longer than a typical Ge–Ge single bond length (2.457–2.463 Å) [12]. Dihedral angles of **7a** and **7b** formed by two O–Ge–O planes are 2.5°, 3.9°, and 1.9°, respectively, as shown in Figs. 7 and 8. There is

Fig. 3. ORTEP drawings of *trans*-1,3,2,4-dioxadigermetane [**7a**·hexane] with thermal ellipsoid plots (30% probability). (a) Fragment 1; and (b) fragment 2 for the independent molecules in the unit cell. The fragment of solvated hexane is omitted for clarity.

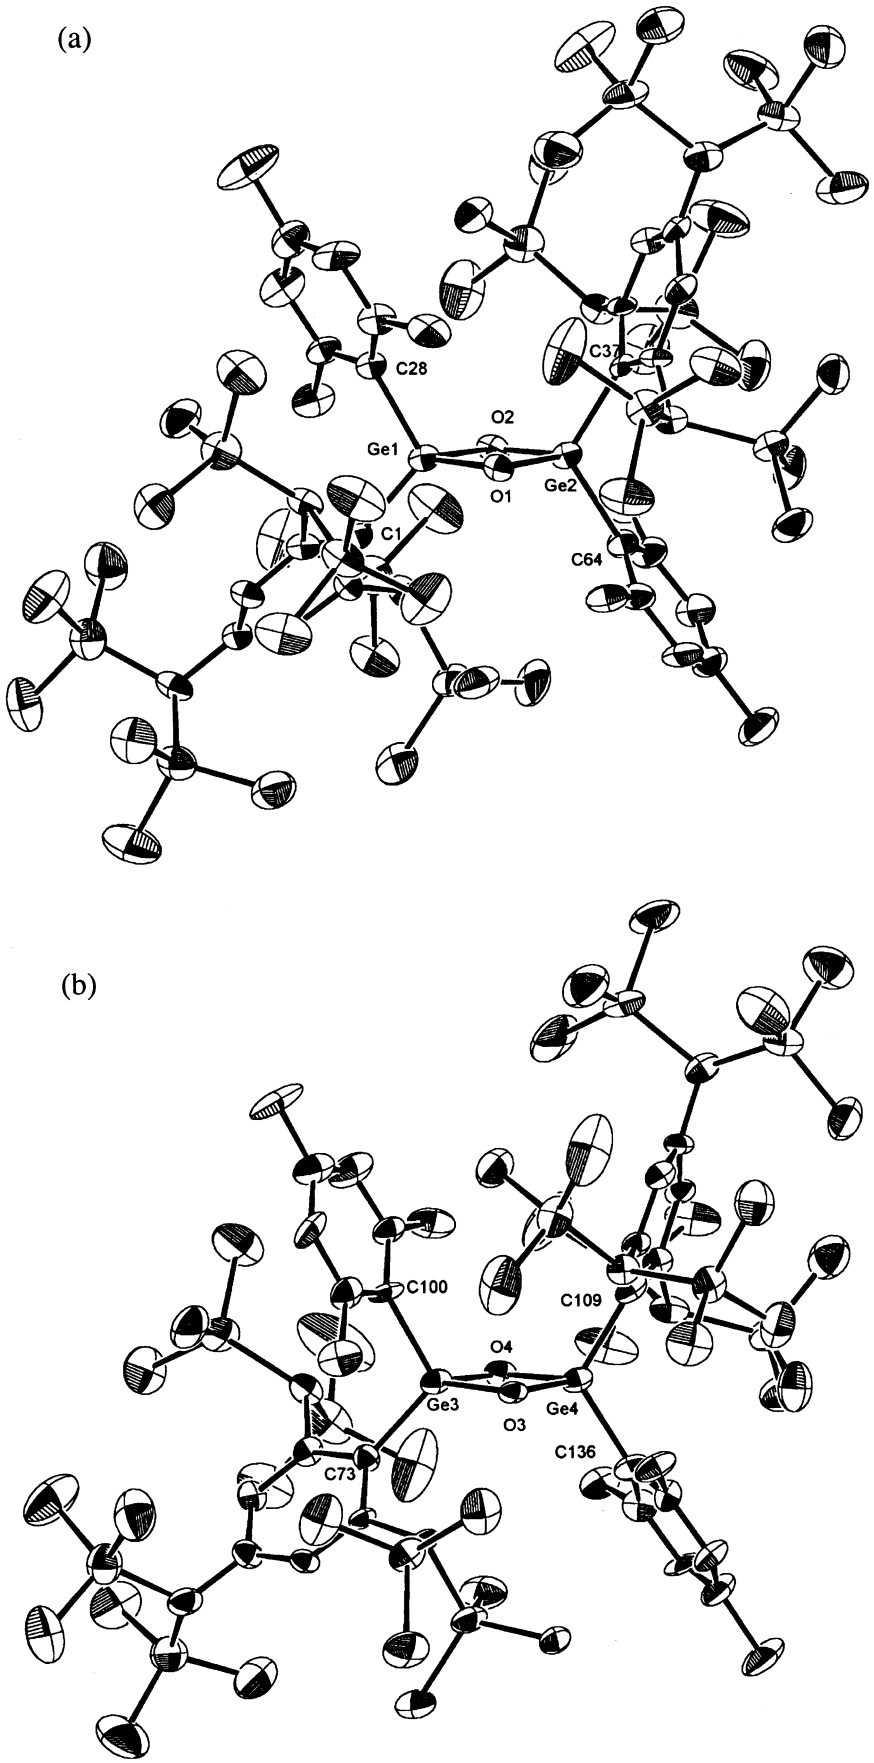


Fig. 3.

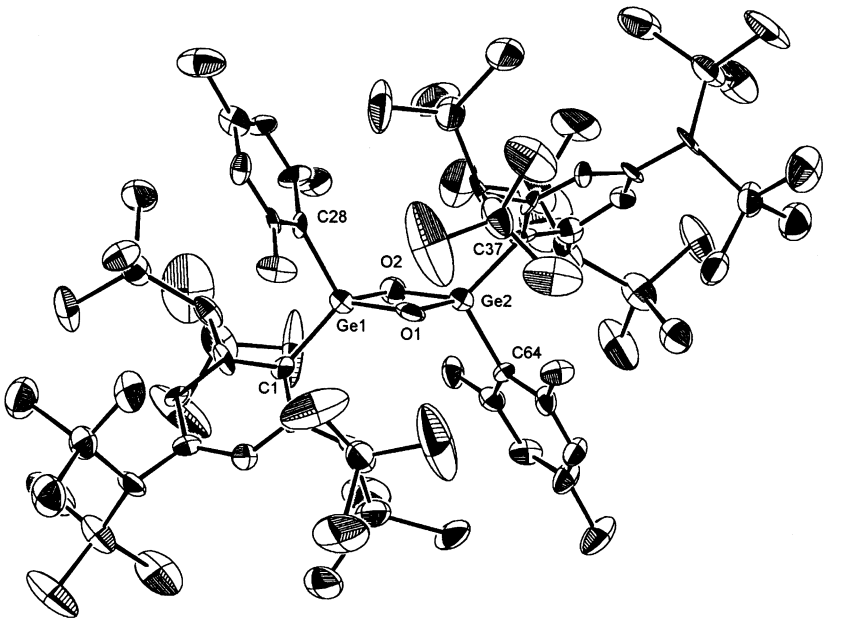

Fig. 4. ORTEP drawing of *trans*-1,3,2,4-dioxadigermetane **7b** with thermal ellipsoid plots (30% probability).

little difference in the geometries of the four-membered rings of **7a** between the two fragments as shown in Figs. 5 and 7.

The molecular structure of **7a** is different from that of **7b** in dihedral angles between the central four-membered ring and Tbt, Mes aromatic ring planes (compound **7b**: 44.8° and 41.9° for the Tbt rings and 61.0° and 61.2° for the Mes rings; fragment 1: 49.6° and 72.3° for the Tbt rings and 67.1° and 56.6° for the Mes rings; fragment 2: 48.2° and 74.6° for the Tbt rings and 68.5° and 57.4° for the Mes rings).

Although we cannot understand at present why the conformational isomers are isolated as stable compounds, it is probably due to hindered rotation of the aromatic rings with regard to the four-membered ring in the case of **7b**. Since ^{1}H NMR spectrum of **7a** shows two signals in the aromatic region, each of two Tbt and Mes groups are equivalent and hence they rotate with regard to the four-membered ring. In contrast, ^{1}H NMR spectrum of **7b** shows four signals in the aromatic region, suggesting that the Tbt and Mes groups do not rotate. Furthermore, compound **7b** exhibits a very complicated ^{1}H NMR spectrum in other regions, suggesting greater steric congestion around Tbt and Mes groups than its isomer **7a**. Consequently, the germanium–germanium distance of **7b** is slightly longer than that of **7a** and the angles of Ge–O–Ge and O–Ge–O are larger and smaller than those of **7a**, respectively.

The structures of the four-membered rings of **7a** and **7b** are similar to that of the previously reported tetrakis(2,6-diethylphenyl)-1,3,2,4-dioxadigermetane [21], although its dihedral angle between two O–Ge–O planes (8.4°) is slightly larger in **7a** and **7b**. In this connection, there have been some interesting reports on the structural properties of dioxadisiletanes. Although the 1,3,2,4-dioxadisiletane rings are generally nearly

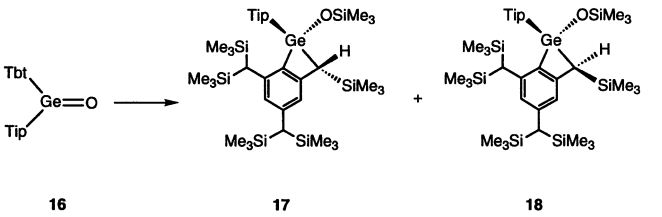


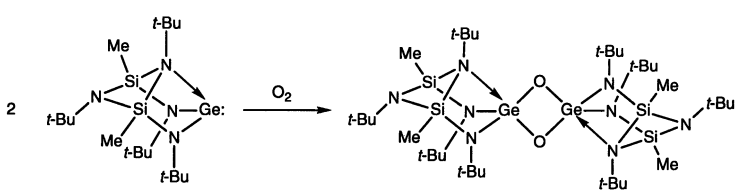
Scheme 5.

planar as in the case of the dioxadigermetane rings, the silicon–silicon distances are as long as, or even shorter than a typical Si–Si single bond lengths [22]. Two extreme qualitative explanations have been postulated for these structures (Fig. 9): (1) there is a σ bond between the two silicon atoms, and the Si–O bonds are necessarily electron deficient (structure A) and (2) the strong repulsion between the oxygen atoms causes the silicon atom to be close together, but there is no bonding between them (structure B). NMR studies confirmed the view that there is no σ bonding between the silicons [23].

The structural difference between the 1,3,2,4-dioxadisiletane and their germanium analogues is explained as follows; the Si–O bond lengths are too short to release the repulsion between the oxygen atoms. As a result, the silicon–silicon distances are close to a Si–Si single bond length, whereas the Ge–O bond lengths are

Scheme 7.

Scheme 8.



long enough to release the repulsion between the oxygen atoms.

2.4.2. Reaction of *1* with oxygen in solution

The reaction of digermene **1** with oxygen in solution gave *trans*-1,3,2,4,-dioxadigermetane **7a** (20%) and *cis*-1,3,2,4,-dioxadigermetane **11** (38%) as shown in Scheme 5, although the reaction of **1** with oxygen in the solid state gave only the *trans*-1,3,2,4-dioxadigermetanes **7a** and **7b** stereospecifically (vide supra). The most plausible reaction mechanism is that digermene **1** dissociates into the corresponding germylene **3** in solution and **3** readily reacts with molecular oxygen to give the germanium–oxygen double-bond species (germanone) **12**, which might dimerize to afford *trans*- and *cis*-1,3,2,4,-dioxadigermetanes as in the case of the previously reported germylene (Scheme 6) [24].

It is noteworthy that Tbt- and Mes-substituted metallanethiones (**14a** and **14b**) and metallaneselone **14c** derived from the dechalcogenation of 1,2,3,4,5-tetrachalcogenamatallolanes **13** dimerized to give only the *cis*-substituted 1,3,2,4-dichalcogenadimetalletanes **15** (Scheme 7) [25].

The lack of stereoselectivity in the dimerization of germanone **12** is explicable in terms of its high reactivity. It has already been reported that the germanone Tbt(Tip)Ge=O (**16**) readily underwent intramolecular C–Si insertion to give **17** and **18** in solution (Scheme 8),

Scheme 6.

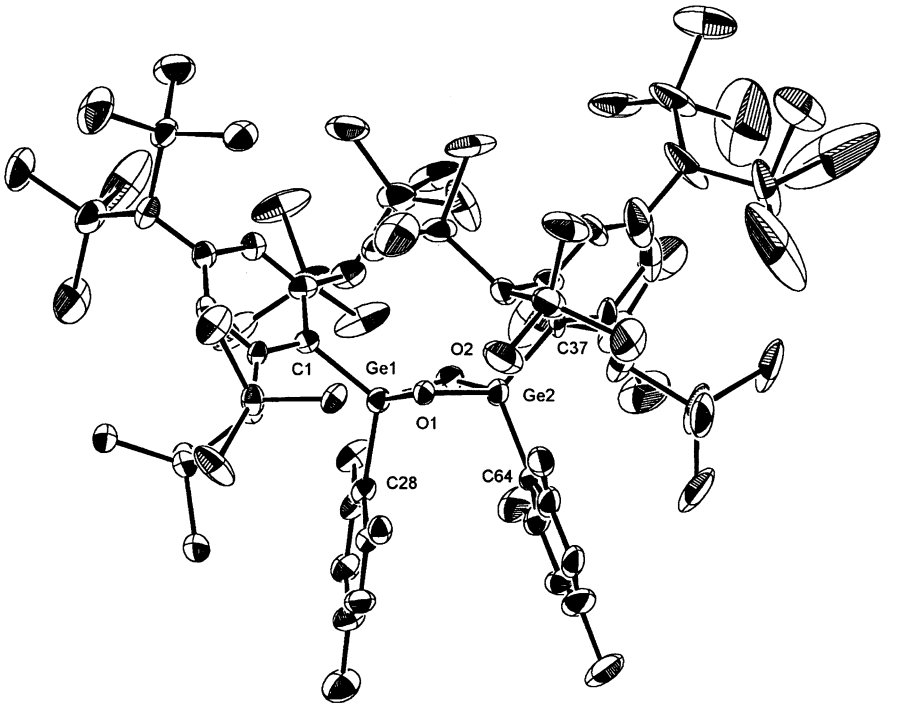


Fig. 10. ORTEP drawing of *cis*-1,3,2,4-dioxadigermetane **11** with thermal ellipsoid plots (30% probability).

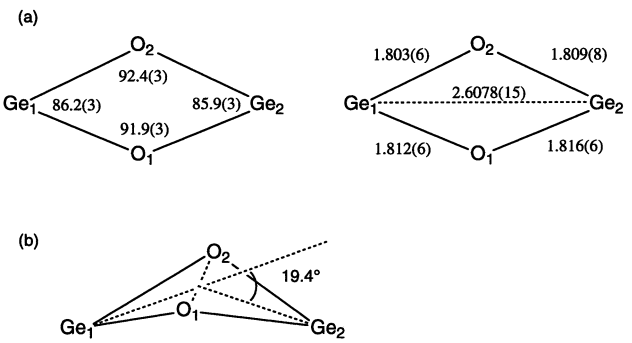
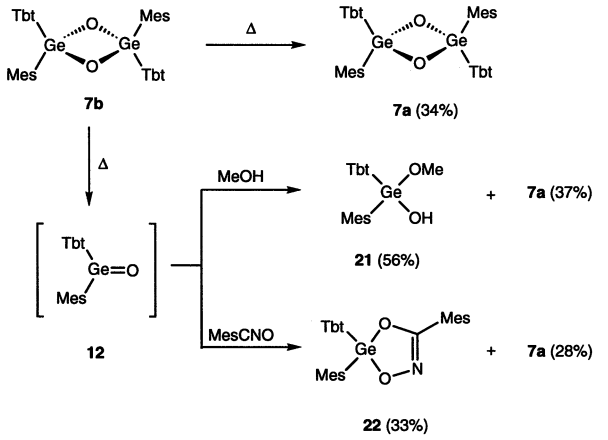
although Tbt(Tip)Ge=S (**19**) and Tbt(Tip)Ge=Se (**20**) were stable in solution [25,26]. The fact that germanone **16** shows quite a different reactivity from germanethione **19** and germaneselone **20** is probably due to the difference in the polarity of Ge=X (X = O, S, and Se) [25,26]. The high polarity of the Ge=O has been predicted by ab initio calculation for dimethylgermanone [27].

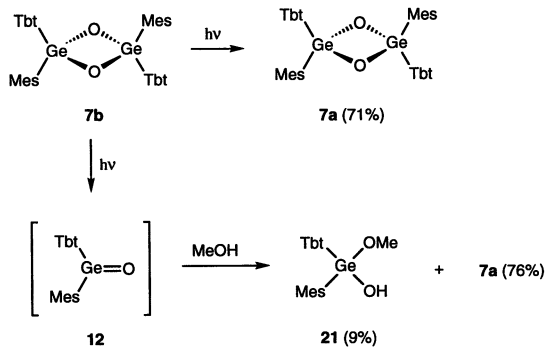
The molecular geometry of the *cis*-1,3,2,4-dioxadigermetane **11** was also determined by X-ray crystallographic analysis. In Fig. 10 is shown the ORTEP drawing of **11**, and some selected structural parameters for **11** are schematically illustrated in Fig. 11. Fig. 11(a) shows selected bond lengths and angles for the central dioxadigermetane ring in **11**. Fig. 11(b) shows that the dihedral angle formed by two O–Ge–O planes is 19.4°. In the case of *trans*-1,3,2,4-dioxadigermetanes **7a** (fragment 1 and fragment 2) and **7b**, the dihedral angles of the central ring are 2.5°, 3.9°, and 1.9°, respectively. These facts show that the steric repulsion between two Tbt groups facing each other may be released by folding the four-membered ring in the *cis*-1,3,2,4-dioxadigermetane **11**. The large folding angles have also been observed in the Tbt- and Mes-substituted *cis*-1,3,2,4-dichalcogenadimetalletane derivatives [25].

2.4.3. Stability of the oxidation products

In the oxidation of digermene **1** in the solid state, two conformational isomers (**7a** and **7b**) of a 1,3,2,4-dioxadigermetane were obtained as oxidation products. In order to investigate the possible interconversion between them, the thermolysis of **7a** and **7b** was monitored by ^{1}H NMR spectroscopy. Although no change was observed for compound **7a** at 85 °C, compound **7b** decomposed to afford the *trans*-1,3,2,4-dioxadigermetane **7a** (34%) under the same conditions (Scheme 9). When a mixture of **7b** and methanol or mesitonitrile oxide, which are useful trapping reagents for a germanone [26], was heated at 85 °C, the corresponding trapping product of germanone **12**, i.e. methoxygermanol **21** (56%) or dioxazagermole **22** (33%), was obtained together with the isomerized *trans*-1,3,2,4-dioxadigermetane **7a** (Scheme 9) [26]. On the other hand, **7a** did not give any methanolysis products in the presence of methanol under the same conditions. These







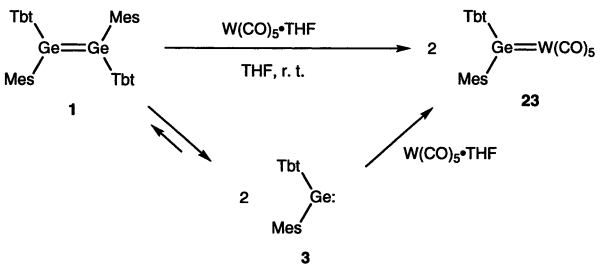


Fig. 11. (a) Selected bond lengths (Å) and angles (°) for **11**. (b) A dihedral angle between planes O(1)–Ge(1)–O(2) and O(1)–Ge(2)–O(2).

Scheme 9.

Scheme 10.

Scheme 11.

facts show that germanone **12** is generated in the thermolysis of **7b** and then **12** reacts with methanol or mesitonitrile oxide to give the methoxygermanol **21** or [3 + 2]cycloadduct **22**, respectively.

Since the 1,3,2,4-dioxadigermetane **7b** was found to dissociate thermally into the germanone **12**, we next examined the photolysis of **7a** and **7b**. Upon photolysis **7b** gave another *trans*-1,3,2,4-dioxadigermetane **7a** (71%). Dioxadigermetane **7b** was irradiated in the presence of methanol to afford **7a** (76%) and methoxygermanol **21** (9%) (Scheme 10). On the other hand, photolysis of **7a** in the presence of methanol under the same conditions did not give any photoreaction products but resulted in the complete recovery of **7a**. These results show that germanone **12** is only generated by the photolysis of the more hindered conformational isomer **7b** of the two *trans*-1,3,2,4-dioxadigermetanes.

*2.4.4. Reaction of germylene **3** derived from digermene **1** with $W(CO)_5$·THF*

In order to verify the ability of steric protection afforded by the combination of Tbt and Mes groups, we have examined the reaction of the diarylgermylene, Tbt(Mes)Ge: (**3**), generated by the dissociation of the corresponding digermene **1** in solution, with tungsten pentacarbonyl tetrahydrofuran complex.

When digermene **1** was treated with $W(CO)_5$·THF in THF at room temperature, the color of the solution changed from blue to orange suggesting the formation of the expected terminal tungsten complex of germylene, Tbt(Mes)Ge=$W(CO)_5$ (**23**) (Scheme 11). Although the tungsten complex **23** was separated from the reaction mixture by silica gel column chromatography, the further purification by GPLC resulted in the decomposition probably due to the reaction with moisture or oxygen even if toluene was used as an eluent. This marginal stability of **23** is in sharp contrast to that of the more crowded germylene–tungsten complex, Tbt(Tip)Ge=$W(CO)_5$ [15c], which is quite stable in solution or in the solid state and can be purified by GPLC and silica gel column chromatography without any decomposition. These results suggest that at least the steric protection afforded by the combination of Tbt and Tip groups is indispensable to isolate the germylene-transition metal complexes as stable compounds.

3. Conclusion

An extremely hindered digermene (*E*)-Tbt(Mes)Ge=Ge(Mes)Tbt (**1**) was synthesized, and its X-ray crystallographic analysis revealed a remarkable elongation of the Ge=Ge double bond of **1**. The temperature-dependent change in the electronic spectra of **1** indicated the quantitative interconversion between **1** and the corresponding germylene Tbt(Mes)Ge: (**3**) in solution. Since the reactivity of germylene **3** is much higher than that of digermene **1**, almost all the intermolecular reactions of **1** in solution proceeded via dissociated **3**. For example, the reaction of **1** with oxygen in solution resulted in a non-stereospecific formation of the *cis*- and *trans*-1,3,2,4-dioxadigermetanes **11** and **7** via the initial formation of germanone **12** derived from oxygenation of the dissociated germylene **3**. In case of the oxidation of **1** in the solid state, however, digermene **1** reacted with O_2 molecule as a Ge=Ge double bond compound to give the corresponding *trans*-1,3,2,4-dioxadigermetanes (**7a** and **7b**; isolable and separable conformational isomers) stereospecifically. In addition, it was revealed that an extremely

hindered tetraaryl-substituted *trans*-1,3,2,4-dioxadigermetane **7b** decomposes to generate the corresponding germanone **12** by both thermolysis and photolysis.

Further investigation of physical and chemical properties of the newly obtained, overcrowded digermene **1** and dioxadigermetanes **7** and **11** is currently in progress.

4. Experimental

All experiments were performed under argon atmosphere otherwise noted. THF was purified by distillation from sodium benzophenone ketyl before use. All solvents used in the reactions were purified by the reported method. The ^{1}H (500 MHz), ^{13}C (126 MHz) NMR spectra were measured in $CDCl_3$ and C_6D_6 with a Bruker AM-500, JEOL α-500, or JEOL AL-300 spectrometer with $CHCl_3$ and C_6D_5H as internal standard. Preparative gel permeation liquid chromatography (GPLC) was performed on LC-908 (JAI gel 1H and 2H columns) with chloroform as an eluent. Preparative thin-layer chromatography (PTLC) and dry column chromatography (DCC) were performed with Merck Kieselgel 60 PF 254 (Art. No. 7747) and ISN silica DCC 60A. Electronic spectra were recorded on a JASCO Ubest-50 UV–Vis spectrometer. All melting points (m.p.) were determined on a Yanaco micro melting point apparatus and are uncorrected. Elemental analyses were carried out at the Microanalytical Laboratory of Department of Chemistry, Faculty of Science, The University of Tokyo.

4.1. Preparation of (E)-1,2-dimesityl-1,2-bis{2,4,6-tris[bis(trimethylsilyl)methyl]phenyl}digermene (1)

To a solution of dichlorogermane **2** [28] (1.36 g, 1.67 mmol) in THF (70 ml) was added lithium naphthalenide (0.54 M, 3.6 mmol) at −78 °C, and the mixture was warmed up to room temperature (r.t.). After removal of the solvent, hexane was added to the residue to precipitate inorganic salts. The filtrate was subjected to sublimation in vacuo for 3 h at 60 °C. Then the residue was washed with hexane several times to afford digermene **1** (288 mg, 0.19 mmol, 23%).

1: Orange crystals (hexane), m.p. (dec.) 92 °C; ^{1}H NMR (500 MHz, C_6D_6, 300 K) δ 0.19 (s, 18H), 0.21 (s, 18H), 0.23 (s, 18H), 1.52 (s, 1H), 2.15 (s, 2H), 2.17 (s, 3H), 2.59 (brs, 6H), 6.55 (s, 1H), 6.67 (s, 1H), 6.77 (s, 2H).

4.2. Observation of an equilibrium between digermene 1 and germylene 3 and estimation of the thermodynamic parameters (ΔH, ΔS) for the dissociation of 1 to 3

In a quartz UV cell was placed a hexane solution (5 ml) of digermene **1** (3.2 mg). After two freeze–pump–thaw cycles, the cell was evacuated and sealed. The absorbance of the solution was observed at each temperature (Fig. 2) on a variable temperature liquid nitrogen cryostat DN1704 (Oxford Instruments Limited) and the temperature was monitored by a temperature controller model ITC (Oxford Instruments Limited) with the calibration error being ±0.2 °C.

The thermodynamic parameters (ΔH, ΔS) for dissociation of digermene **1** to germylene **3** were calculated by the equation below.

$$\ln(A_B^2/A_A) = -\Delta H/RT + (\Delta S/R - \ln(\varepsilon_A/\varepsilon_B^2)) \quad (1)$$

$$A_B = -(2\varepsilon_B/\varepsilon_A)A_A + C \quad (2)$$

A_A and ε_A are the absorbance and the molar absorption coefficient of **1**, respectively, and A_B and ε_B are that of **3**. C is a constant. The absorbances of digermene **1** and germylene **3** were obtained at 439 nm for **1** and at 575 nm for **3**. The ε_B was determined by a separate experiment for a hexane solution which was prepared by adding hexane (6 ml) to a hexane solution (3 ml) of **1** (2.0 mg, 0.0013 mmol). Their statistical errors were calculated by a standard method.

$\Delta H = 14.7 \pm 0.2$ kcal mol^{-1} and

$\Delta S = 42.4 \pm 0.8$ cal mol^{-1} K^{-1}

($\lambda_{max} = 439$ nm, ε_B 2.0×10^4)

($\lambda_{max} = 575$ nm, ε_A 1.6×10^3)

4.3. Reaction of digermene 1 with methanol

To an orange–yellow solution of **1** (65.5 mg, 0.044 mmol) in THF (5 ml) was added methanol (50 μl, 1.23 mmol) at −100 °C. The orange–yellow color due to **1** did not disappear after 6 h at same temperature, but the solution became colorless on warming up to r.t. After removal of the solvent, the reaction residue was chromatographed over GPLC and PTLC (SiO_2 with hexane) to afford methoxygermene **4** (30.2 mg, 0.039 mmol, 44%).

4: White crystals, m.p. 174–176 °C; ^{1}H NMR (500 MHz, $CDCl_3$, 300 K) δ −0.15 (s, 9H), −0.08 (s, 9H), 0.048 (s, 18H), 0.051 (s, 18H), 1.11 (s, 1H), 2.18 (s, 1H), 2.26 (s, 3H), 2.47 (s, 6H), 2.57 (s, 1H), 3.39 (s, 3H), 6.24 (s, 1H), 6.40 (s, 1H), 6.45 (s, 1H), 6.82 (s, 2H); ^{13}C NMR (126 MHz, $CDCl_3$, 300 K) δ 0.33 (q), 0.63 (q), 0.74 (q), 0.81 (q), 0.95 (q), 1.31 (q), 21.08 (q), 23.75 (q), 26.68 (d), 26.78 (d), 30.34 (d), 53.70 (q), 122.77 (d), 127.40 (d), 128.21 (s), 128.79 (d), 133.10 (s), 139.38 (s), 143.38 (s), 144.37 (s), 150.20 (s), 150.82 (s). *Anal.* Calc. for $C_{37}H_{74}OGeSi_6$: C, 57.26; H, 9.61. Found: C, 56.88; H, 9.45%.

4.4. Reaction of **1** with Et_3SiH

To a solution of **1** (63.7 mg, 0.043 mmol) in THF (3 ml) was added Et_3SiH (100 μl, 0.63 mmol) at r.t. The solution was stirred for overnight. After removal of the solvent, the reaction residue was chromatographed over GPLC and WCC (SiO_2 with hexane) to afford silylgermane **5** (51.5 mg, 0.060 mmol, 70%).

5: White crystals, m.p. (dec.) 168–170 °C; ^{1}H NMR (500 MHz, $CDCl_3$, 300 K) δ −0.20 (s, 9H), −0.14 (s, 9H), 0.02 (s, 9H), 0.03 (s, 9H), 0.09 (s, 9H), 0.10 (s, 9H), 0.77 (q, $J = 7.8$ Hz, 6H), 0.89 (t, $J = 7.8$ Hz, 9H), 1.26 (s, 1H), 1.96 (brs, 3H), 1.98 (s, 1H), 2.05 (s, 1H), 2.19 (s, 3H), 2.50 (brs, 3H), 5.09 (s, 1H), 6.29 (s, 1H), 6.41 (s, 1H), 6.63 (s, 1H), 6.78 (s, 1H); ^{13}C NMR (126 MHz, $CDCl_3$, 300 K) δ 0.91 (q), 1.01 (q), 1.05 (q), 1.17 (q), 1.68 (q), 1.78 (q), 5.21 (t), 8.12 (q), 20.96 (q), 25.48 (q), 26.52 (q), 29.10 (d), 29.55 (d), 30.13 (q), 122.78 (d), 128.04 (d), 128.46 (dx2), 133.60 (s), 136.86 (s), 137.36 (s), 141.94 (s), 142.49 (s), 143.47 (s), 149.30 (s), 149.90 (s). *Anal.* Calc. for $C_{42}H_{86}GeSi_7 \cdot H_2O$: C, 57.43; H, 10.10. Found: C, 57.79; H, 9.63%.

4.5. Reaction of **1** with 2,3-dimethyl-1,3-butadiene

To a solution of **1** (59.5 mg, 0.040 mmol) in THF (5 ml) was added 2,3-dimethyl-1,3-butadiene (90 μl, 0.80 mmol) at r.t. The solution was stirred for overnight. After removal of the solvent, the reaction residue was chromatographed over GPLC and PTLC (SiO_2 with hexane) to afford germacyclopentene **6** (40.7 mg, 0.049 mmol, 62%).

6: White crystals, m.p. (dec.) 190–192 °C; ^{1}H NMR (500 MHz, $CDCl_3$, 300 K) δ −0.08 (s, 36H), 0.02 (s, 18H), 1.24 (s, 1H), 1.69 (s, 6H), 1.90 (s, 1H), 2.01 (s, 1H), 2.03 (ABq, $J_{AB} = 16$ Hz, $\nu_{AB} = 130$ Hz, 4H), 2.20 (s, 3H), 2.35 (s, 6H), 6.24 (s, 1H), 6.36 (s, 1H), 6.75 (s, 2H); ^{13}C NMR (126 MHz, $CDCl_3$, 300 K) δ 0.83 (q), 1.04 (q), 1.28 (q), 19.31 (q), 20.79 (q), 25.68 (q), 27.48 (d), 27.61 (d), 30.05 (d), 34.56 (t), 122.54 (d), 127.71 (d), 129.01 (d), 130.76 (s), 132.32 (s), 137.67 (s), 141.13 (s), 142.35 (s), 142.73 (s), 150.40 (s), 150.64 (s). *Anal.* Calc. for $C_{42}H_{80}GeSi_6$: C, 61.06; H, 9.76. Found: C, 60.77; H, 9.48%.

4.6. Reaction of digermene **1** with oxygen in the solid state

Finely powdered orange crystals of digermene **1** (47.5 mg, 0.0319 mmol) were exposed to oxygen in the dark for 3 days, during which time the color changed into pale yellow. The crystals were chromatographed over GPLC and PTLC (SiO_2 with hexane) to give two conformational isomers of *trans*-2,4-dimesityl-2,4-bis{2,4,6-tris[bis(trimethylsilyl)methyl]phenyl}-1,3,2,4-dioxadigermetanes (**7a**) (6.3 mg, 0.0041 mmol, 13%) and **7b** (23.9 mg, 0.0199 mmol, 49%).

7a: White crystals ($CHCl_3$–EtOH), m.p. >300 °C; ^{1}H NMR (500 MHz, C_6D_6, 350 K) δ −0.04 (s, 72H), 0.00 (s, 36H), 1.51 (s, 2H), 2.13 (s, 6H), 2.85 (brs, 12H), 3.09 (s, 2H), 6.57 (s, 4H), 6.73 (s, 4H) (the peak assignable to methine protons of *o*-bis(trimethylsilyl)methyl groups of Tbt group was not observed); HRMS (FAB) m/z 1519.6611 ($[M+H]^+$), calc. for $C_{72}H_{140}O_2{}^{72}Ge^{74}GeSi_{12}$ 1519.6595. *Anal.* Calc. for $C_{72}H_{140}O_2Ge_2Si_{12}$: C, 56.88; H, 9.28. Found: C, 56.10; H, 8.76%.

7b: White crystals ($CHCl_3$–EtOH), m.p. (dec.) 153–155 °C; ^{1}H NMR (500 MHz, C_6D_6, 350 K) δ −0.07 (s, 36H), 0.19 (s, 18H), 0.23 (s, 18H), 0.32 (s, 18H), 0.48 (s, 18H), 1.53 (s, 2H), 1.87 (s, 2H), 2.16 (s, 6H), 2.26 (s, 6H), 2.94 (s, 6H), 3.40 (s, 2H), 6.63 (s, 2H), 6.69 (s, 2H), 6.74 (s, 2H), 6.78 (s, 2H); *Anal.* Calc. for $C_{72}H_{140}O_2Ge_2Si_{14}$: C, 56.88; H, 9.28. Found: C, 56.08; H, 9.01%.

4.7. Reaction of digermene **1** with oxygen in solution

To a solution of **1** (67.0 mg, 0.045 mmol) in THF (5 ml) was bubbled oxygen dried by passing through sulfuric acid and Sicapent® at r.t. The solution was stirred overnight. After removal of the solvent, the reaction residue was chromatographed over GPLC and PTLC (SiO_2 with hexane) to afford *trans*-1,3,2,4-dioxadigermetane **7a** (13.7 mg, 0.009 mmol, 20%) and *cis*-2,4-dimesityl-2,4-bis{2,4,6-tris[bis(trimethylsilyl)-methyl]phenyl}-1,3,2,4-dioxadigermetane (**11**) (25.8 mg, 0.017 mmol, 38%).

11: White crystals ($CHCl_3$–EtOH), m.p. >300 °C; ^{1}H NMR (500 MHz, C_6D_6, 350 K) δ 0.19 (s, 18H), 0.25 (s, 36H), 0.38 (s, 18H), 0.40 (s, 18H), 0.51 (s, 18H), 1.57 (s, 2H), 2.07 (s, 2H), 2.12 (s, 6H), 2.45 (s, 6H), 2.75 (brs, 6H), 3.25 (s, 2H), 6.38 (s, 2H), 6.65 (s, 4H), 6.69 (s, 2H); HRMS (FAB) m/z 1519.6611 ($[M+H]^+$), calc. for $C_{72}H_{140}O_2{}^{72}Ge^{74}GeSi_{12}$ 1519.6595. *Anal.* Calc. for $C_{72}H_{140}O_2Ge_2Si_{12}$: C, 56.88; H, 9.28. Found: C, 56.80; H, 8.99%.

4.8. Thermolysis of 1,3,2,4-dioxadigermetane **7b**

In a 5 mm NMR tube was placed a C_6D_6 solution (0.6 ml) of **7b** (12.8 mg, 0.0084 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was heated at 85 °C for 18.5 h, the ^{1}H NMR spectrum of the reaction mixture showed the absence of starting material **7b**. After removal of the solvent, the residue was separated by PTLC (SiO_2 with hexane) to afford **7a** (4.3 mg, 0.0028 mmol, 34%).

4.9. Thermolysis of 1,3,2,4-dioxadigermetane **7a**

In a 5 mm NMR tube was placed a C_6D_6 solution (0.6 ml) of **7a** (13.2 mg, 0.0087 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was heated at 85 °C for 21 h, no change was observed in the ^{1}H NMR spectrum.

4.10. Thermal reaction of **7b** with methanol

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7b** (13.0 mg, 0.0086 mmol) and methanol (50 μl, 1.24 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was heated at 85 °C for 18.5 h, the ^{1}H NMR spectrum of the reaction mixture showed the absence of starting material **7b**. After removal of the solvent the residue was separated by PTLC (SiO_2 with hexane) to afford **7a** (4.9 mg, 0.0032 mmol, 37%) and (hydroxyl)mesityl-(methoxy){2,4,6-tris[bis(trimethylsilyl)methyl]-phenyl}-germane (**21**) (7.5 mg, 0.0097 mmol, 56%).

21: ^{1}H NMR (500 MHz, $CDCl_3$, 300 K) δ −0.18 (s, 9H), −0.11 (s, 9H), 0.028 (s, 18H), 0.032 (s, 18H), 1.30 (s, 1H), 1.41 (s, 1H), 2.25 (s, 3H), 2.50 (s, 6H + 1H), 2.81 (s, 1H), 3.35 (s, 3H), 6.25 (s, 1H), 6.39 (s, 1H), 6.81 (s, 2H); ^{13}C NMR (126 MHz, $CDCl_3$, 300 K) δ 0.37 (q), 0.70 (q), 0.82 (q), 1.13 (q), 1.43 (q), 21.00 (q), 23.96 (q), 26.91 (d × 2), 30.50 (d), 50.34 (q), 122.90 (d), 127.63 (d), 129.29 (d), 129.59 (s), 131.96 (s), 139.83 (s), 143.67 (s), 145.28 (s), 150.58 (s), 150.90 (s).

4.11. Thermal reaction of **7b** with mesitonitrile oxide

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7b** (14.4 mg, 0.0093 mmol) and mesitonitrile oxide (79.8 mg, 0.50 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was heated at 85 °C for 32 h, the ^{1}H NMR spectrum of the reaction mixture showed the absence of starting material **7b**. After removal of the solvent, the residue was separated by GPLC and PTLC (SiO_2 with hexane) to afford **7a** (4.0 mg, 0.0026 mmol, 28%), and the second fraction was again separated by PTLC (SiO_2 with $CHCl_3$–hexane 1/1) to afford 2-mesityl-2-{2,4,6-tris[bis(trimethylsilyl)methyl]phenyl}-4-mesityl-1,3,5,2-dioxazagermole (**22**) (5.8 mg, 0.0063 mmol, 34%).

22: ^{1}H NMR (500 MHz, $CDCl_3$, 300 K) δ −0.07 (s, 18H), 0.00 (s, 9H), 0.03 (s, 9H), 0.05 (s, 9H), 0.06 (s, 9H), 1.38 (s, 1H), 2.07 (s, 6H), 2.10 (s, 1H), 2.22 (s, 1H), 2.23 (s, 6H), 2.52 (s, 6H), 6.36 (s, 1H), 6.49 (s, 1H), 6.775 (s, 2H), 6.782 (s, 2H); HRMS (FAB) m/z 922.4185 ($[M+H]^+$), calc. for $C_{46}H_{82}O_2N^{74}GeSi_6$ 922.4173.

4.12. Thermal reaction of **7a** with methanol

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7a** (13.0 mg, 0.0086 mmol) and methanol (50 μl, 1.24 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was heated at 85 °C for 21 h, no change was observed in the ^{1}H NMR spectrum.

4.13. Photolysis of **7b**

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7b** (12.5 mg, 0.0082 mmol). After five freeze–pump–thaw cycles, the tube was evacuated and sealed. The solution was irradiated with a 400 W high pressure Hg lamp approximately −45 °C for 14 min. After removal of the solvent, the residue was separated by PTLC (SiO_2 with hexane) to afford **7a** (8.8 mg, 0.0058 mmol, 71%).

4.14. Photolysis of **7b** in the presence of methanol

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7b** (12.5 mg, 0.0082 mmol) and methanol (50 μl, 1.2 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. When the solution was irradiated with a 400 W high-pressure Hg lamp at approximately −45 °C for 16 min. After removal of the solvent, the residue was separated by PTLC (SiO_2 with hexane) to afford **7a** (9.5 mg, 0.063 mmol, 76%) and hydroxy(methoxy)germane **21** (1.2 mg, 0.0015 mmol, 9%).

4.15. Photolysis of **7a** in the presence of methanol

In a 5 mm NMR tube was placed a $CDCl_3$ solution (0.6 ml) of **7a** (11.8 mg, 0.0078 mmol) and methanol (60 μl, 1.4 mmol). After three freeze–pump–thaw cycles, the tube was evacuated and sealed. The solution was irradiated with a 400 W high pressure Hg lamp at approximately −45 °C for 20 min. The ^{1}H NMR spectrum of the reaction mixture showed no signal of **21**.

4.16. [{2,4,6-Tris[bis(trimethylsilyl)methyl]phenyl}-(2,4,6-trimethylphenyl)germylidene]pentacarbonyltungsten(0) (**23**)

To a THF solution (2 ml) of digermene **1** (0.279 g, 0.187 mmol) was added an excess of $W(CO)_5$(THF), which was prepared by the photolysis of $W(CO)_6$ (0.173 g, 0.491 mmol) in 15 ml of THF using a 100 W high pressure mercury lamp [29]. After stirring for 12 h at r.t., the reaction mixture was evaporated to give an

orange–yellow paste. The orange–yellow paste was purified by flush column chromatography (SiO_2–hexane) to give the pentacarbonyltungsten(0) complex **23** (0.124 g, ca. 31%) as an orange solid. Complete purification of **23** was failed due to its instability in the open air. **23**: ^{1}H NMR ($CDCl_3$, 300 MHz) δ −0.04 (s, 9H), 0.04 (s, 9H), 0.05 (s, 27H), 0.10 (s, 9H), 1.37 (s, 1H), 2.21 (s, 6H), 2.24 (s, 3H), 2.45 (s, 1H), 2.48 (s, 1H), 6.37 (br s, 1H), 6.44 (br s, 1H), 6.75 (s, 2H). IR(KBr) 1943,1949, 2068 cm^{-1}. UV–Vis(CH_2Cl_2) 432 nm (ε, 14 000).

4.17. X-ray data collection for [1·0.5hexane], [7a·hexane], 7b, and 11

Single crystals of [**1**·0.5hexane], [**7a**·hexane], **7b**, and **11** were grown by the slow evaporation of the saturated solution of each compounds in hexane at r.t. All measurements were made on a Rigaku AFC7R diffractometer (for [**1**·0.5hexane], [**7a**·hexane], and **7b)** with graphite monochromated Mo Kα radiation (λ = 0.71069 Å) and a rotating anode generator and on a Rigaku/MSC Mercury CCD for **11** with graphite monochromated Mo Kα radiation (λ = 0.71070 Å). An orange prismatic crystal of [**1**·0.5hexane] was mounted in a glass capillary, while the other crystals of [**7a**·hexane], **7b**, and **11** were subjected to data collection without sealing. The structure was solved by direct methods (SHELXS-97) and refined by full-matrix least-squares procedures on F^2 for all reflections (SHELXL-97) [30]. In all cases non-hydrogen atoms were refined anisotropically, while all hydrogens except for those of solvated hexane were placed using AFIX instructions. As for the solvated hexane for [**1**·0.5hexane] and [**7a**·hexane], all non-hydrogen atoms were refined isotropically, and the intramolecular C–C bond lengths and angles are restrained to be ideal lengths using DFIX instruction.

Crystal data for [**1**·0.5hexane]: $C_{72}H_{140}Ge_2Si_{12}\cdot 0.5C_6H_{14}$, FW = 1531.19, crystal dimensions 0.30 × 0.20 × 0.15 mm, monoclinic, space group $P2_1/c$ (# 14), a = 18.779(7), b = 18.375(7), c = 28.495(16) Å, β = 96.53(4)°, V = 9769(7) Å^3, Z = 4, D_{calc} = 1.041 g cm^{-3}, μ(Mo Kα) = 7.96 cm^{-1}, $2\theta_{max}$ = 50°, T = 173(2) K, R_1 = 0.1177 [$I > 2\sigma(I)$], wR_2 = 0.2991 (all data), GOF = 0.841. The largest difference peak and hole were 0.816 and −0.605 e Å^{-3}. The final cycle of full-matrix least-squares refinement was based on 17158 reflections and 799 variable parameters with nine restraints.

Crystal data for **7a**·hexane: $C_{72}H_{140}Ge_2O_2Si_{12}\cdot C_6H_{14}$, FW = 1606.27, crystal dimensions 0.60 × 0.55 × 0.05 mm, triclinic, space group $P\bar{1}$ (# 2), a = 23.735(7), b = 30.169(11), c = 13.533(3) Å, α = 95.60(3)°, β = 90.47(2)°, γ = 88.16(3)°, V = 9639(5) Å^3, Z = 4, D_{calc} = 1.107 g cm^{-3}, μ(Mo Kα) = 8.11 cm^{-1}, $2\theta_{max}$ = 50°, T = 296(2) K, R_1 = 0.0945 [$I > 2\sigma(I)$] and wR_2 = 0.2651 (all data), GOF = 0.928. The largest difference peak and hole were 0.849 and −1.266 e Å^{-3}. The final cycle of full-matrix least-squares refinement was based on 25212 reflections and 1631 variable parameters with 20 restraints.

Crystal data for **7b**: $C_{72}H_{140}Ge_2O_2Si_{12}$, FW = 1520.10, crystal dimensions 0.20 × 0.10 × 0.05 mm, triclinic, space group $P\bar{1}$ (# 2), a = 21.28(2), b = 16.103(13), c = 16.105(14) Å, α = 84.36(7)°, β = 109.00(7)°, γ = 71.01(7)°, V = 4804(8) Å^3, Z = 2, D_{calc} = 1.051 g cm^{-3}, μ(Mo Kα) = 8.10 cm^{-1}, $2\theta_{max}$ = 45°, T = 296(2) K, R_1 = 0.1013 [$I > 2\sigma(I)$] and wR_2 = 0.1735 (all data), GOF = 0.807. The largest difference peak and hole were 0.371 and −0.664 e Å^{-3}. The final cycle of full-matrix least-squares refinement was based on 12566 reflections and 784 variable parameters with two restraints. The rigid-bond restraint to U_{ij}-values of two bonded atoms using DELU construction were applied to the *ortho*- and *para*- C–C bonds of one Tbt group (C40–C44 and C42–C45).

Crystal data for **11**: $C_{72}H_{140}Ge_2O_2Si_{12}$, FW = 1520.10, crystal dimensions 0.60 × 0.55 × 0.10 mm, orthorhombic, space group $Pna2_1$ (# 33), a = 22.135(6), b = 30.788(8), c = 13.214(4) Å, $\alpha = \beta = \gamma$ = 90°, V = 9005(4) Å^3, Z = 4, D_{calc} = 1.121 g cm^{-3}, μ(Mo Kα) = 8.64 cm^{-1}, $2\theta_{max}$ = 50°, T = 103(2) K, R_1 = 0.1049 [$I > 2\sigma(I)$] and wR_2 = 0.2495 (all data), GOF = 1.079. The largest difference peak and hole were 0.864 and −0.989 e Å^{-3}. The final cycle of full-matrix least-squares refinement was based on 14179 reflections and 793 variable parameters with eight restraints. One of the carbon atoms of the trimethylsilyl group at *para*-position of a Tbt group was restrained to be approximately isotropic (C56).

5. Supplementary material

All the crystallographic data (excluding structure factors) of [**1**·0.5hexane], [**7a**·hexane], **7b**, and **11** have already been deposited at the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC 169633, 169634, 169635, and 169636, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: +44-1233-336-033, e-mail: deposit@ccdc.cam.ac.uk).

Abstract

Substituent effects on the potential energy surface of XGeAs (X = H, Li, Na, BeH, MgH, BH_2, AlH_2, CH_3, SiH_3, NH_2, PH_2, OH, SH, F, and Cl) were investigated by using B3LYP and CCSD(T) methods. The isomers include structures with formal double (Ge=AsX) and triple (XGe≡As) bonds to germanium–arsenic, so a direct comparison of these types of species is possible. Our model calculations indicate that electropositively substituted Ge=AsX species are thermodynamically and kinetically more stable than their isomeric XGe≡As molecules. Moreover, the theoretical findings suggest that F, OH, NH_2, and CH_3 substitution prefer to shift the double bond (Ge=AsX) by forming a triple bond (XGe≡As). © 2002 Elsevier Science Ltd. Keywords: B3LYP; CCSD(T); Germanium; Arsenic

1. Introduction

The chemistry of multiple-bond compounds between Group 14 elements and heavier pnicogen atoms has continued to occupy the attention of chemists in various fields [1]. For instance, since HC≡P was characterized spectroscopically by Gier in 1961 [2], phosphorus compounds with low coordination have been studied extensively both experimentally and theoretically [3]. In comparison with this, the area of respective molecules containing multiple bonds to arsenic is rather poorly explored. Although, there have been some successful examples of arsaethene (C=As) [4], arsaethyne (C≡As) [5], and arsasilene (Si=As) [6] stabilized by taking advantage of steric protection groups, neither arsagermene (Ge=As) nor arsagermyne (Ge≡As) have been studied experimentally as yet. This is not very surprising since compounds possessing a germanium–arsenic multiple bond (such as arsagermenes and arsagermynes) are less stable than the corresponding carbon and silicon derivatives. From a synthetic point of view, while steric effects should definitely play an important role in stabilizing the germanium–arsenic multiple bonds, the contribution of electronic effects, which may be even more significant, is still unknown. Knowledge of substituent effects is of great importance in selecting new Ge–As multiple bonded molecules as possible candidates for synthesis or for understanding the nature of the germanium–arsenic bonding.

It is, therefore, worthwhile to investigate the structures and energetics of a series of substituted XGeAs species to gain some insight into the relative stability and instability among these molecules. The substituents X that were chosen from elements of the second and third rows of the periodic table, i.e. X = H, Li, Na, BeH, MgH, BH_2, AlH_2, CH_3, SiH_3, NH_2, PH_2, OH, SH, F, and Cl, exhibit a wide range of electronic properties [7,8] and make the resulting XGeAs species be isovalent. Substitution at both the germanium (X–Ge≡As) and the arsenic (Ge=As–X) ends of the multiple bonds are examined and the effect of substituents on the thermodynamic and the kinetic stability of these isomers is discussed. Our study gives the trends for the geometries, vibrational frequencies and energetics for the ground states of the XGe≡As and Ge=AsX species. All of these isomers have not yet been reported in the literature and the calculated molecular properties presented in this work should be useful when these molecules become experimentally accessible.

2. Methodology

The geometries and energetics of the stationary points on the potential energy surface of Eq. (1) (see Table 1) have been calculated with density functional theory (DFT), i.e. the B3LYP methods [9], in conjunction with the 6-311 + + G(d,p) basis set [10]. Only the singlet surface was considered throughout this work. All the stationary points have been positively identified as equilibrium structures (the number of imaginary frequency (NIMAG = 0)) or transition states (NIMAG = 1). Additionally, the vibrational zero-point energy (ZPE) corrections determined at the B3LYP/6-311 + + G(d,p) level are also included, i.e. B3LYP/6-311 + + G(d,p) + ZPE (B3LYP/6-311 + + G(d,p)) (hereafter designated B3LYP). For better energetics, single-point calculations with B3LYP/6-311 + + G(d,p) geometries were carried out at a higher level of theory: coupled cluster singles and doubles including a perturbational estimate of the triples [CCSD(T)] [11]. Unless otherwise noted, relative energies given in the text and in the figures are those determined at CCSD(T)/6-311 + + G(3df,3pd)//B3LYP/6-311 + + G(d,p) + ZPE (B3LYP/6-311 + + G(d,p)) (hereafter designed CCSD(T)). All calculations were carried out using the GAUSSIAN 98 series of program [12].

3. Results and discussion

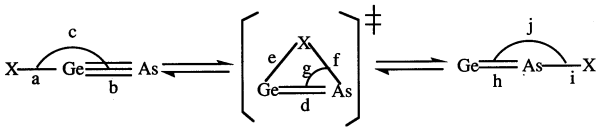

Table 1 shows molecular parameters of the XGe≡As and Ge=AsX species, calculated at the B3LYP level of theory, while their predicted vibrational frequencies, dipole moments, rotational constants, and net atomic charges are furnished in Table 2. The corresponding reaction profiles for the XGeAs intramolecular isomerizations at B3LYP and CCSD(T) levels of theory are outlined in Scheme 1.

One of the interesting structural features of the XGeAs species are the Ge≡As and Ge=As bond lengths. In the parent HGe≡As and Ge=AsH molecules, their germanium–arsenic internuclear distance is 2.111 Å (Ge≡As) and 2.251 Å (Ge=As), respectively, at B3LYP/6-311 + + G(d,p) level of theory. The data in Table 1 show that the Ge≡As bond lengths which fall in the range of 2.117–2.148 Å change quite substantially upon substitution. As expected, Ge=As double bonds are considerably longer, being in the range of 2.210–2.360 Å. It is worth noting that, based on the present study, highly electropositive substitutions at the arsenic (i.e. Ge=As–X) shortens the Ge=As bond relative to Ge=AsH (except for X = AlH_2), while electronegative substitution at arsenic causes elongation. An especially large elongation is observed in the Ge=AsPH_2 (2.360 Å). In any event, the bond-length differences between these isomers may be substantial and large enough to be observed experimentally.

The effect of the substituents on the Ge=As double bond length may be understood in terms of bond polarity. The Ge=As bond in Ge=AsH is polarized so that the germanium atom is positively charged and the arsenic is negatively charged, i.e. $Ge^{\delta+}$=$As^{\delta-}$–H. Substituents that increase this polarization and thus the degree of ionicity of the Ge=As bond are expected to

Scheme 1.

shorten this bond. Consequently, electron-donating substituents (e.g. Li and Na) increase the negative charge at arsenic (see Table 2) and, in turn, the degree of bond ionicity. As a result, the Ge=As double bond shortens. On the other hand, electronegative substituents decrease the negative charge at arsenic (see Table 2), the bond ionicity decreases, and thus the Ge=As bond lengthens. Nevertheless, in the case of XGe≡As, its Ge≡As triple bond length is always elongated relative to the parent HGe≡As, regardless of the substituents. Indeed, some electropositive substituents donate sufficient electron density to the germanium center, so that the sign of density on Ge is no longer positive. A strictly ionic contribution would then lead to repulsion and presumably bond elongation rather than shortening. However, this simple ionicity explanation cannot apply to the XGe≡As systems with electronegative substituents.

Besides these, our B3LYP calculations indicate that XGe≡As exist as stable linear species, but their Ge=AsX isomers are strongly bent in their singlet states, as shown in Table 1. Additionally, in the present study, all linear Ge=AsX molecules were found to be second-order transition structures. The reason for the double-bonded Ge=AsX species prefers a bent rather than linear structure may be due to the phenomenon of orbital nonhybridization. That is to say, the arsenic atom may be reluctant to take part in hybridization. Thus, it tends to form a nonbonding orbital acquiring mainly s-character, while the remaining p-electrons are used up to form bonds with the neighboring atom. As a result, the formation of a sp-hybrid orbital is disfavored and bent Ge=AsX (**1a**) becomes considerably more stable than its linear structure (**1b**). Of course, to obtain a better understanding of the nature of such a chemical bonding requires further computational studies, as well as experiments. Such studies, however, are beyond the scope of the present work. In any event, from our DFT calculations on the model compound Ge=AsX, it is concluded that the bent structure (**1a**) is the best representation of its conformation.

1a **1b**

From Scheme 1, it is worth noting that the B3LYP and CCSD(T) energy differences are roughly similar, suggesting that the less expensive B3LYP level can be used with some confidence for larger germanium–arsenic systems for which more elaborate calculations are not practical. Furthermore, it is clear from Scheme 1 that the electropositively substituted arsagermenes (Ge=AsX) are generally more stable than the isomeric arsagermynes (XGe≡As). That is, our best estimate (at CCSD(T)) places XGe≡As 9.2–21 kcal mol^{-1} above its more stable isomer Ge=AsX for the electropositively substituted species. On the other hand, our CCSD(T) results suggest that the highly electronegative substituents can reverse the order of the relative stabilities of the double-bonded and triple-bonded XGeAs systems, although the energy difference (ΔH) between them is quite small. For instance, FGe≡As, HOGe≡As, $H_2NGe{\equiv}As$, and $H_3CGe{\equiv}As$ are calculated to be more stable than Ge=AsF, Ge=AsOH, $Ge{=}AsNH_2$, and $Ge{=}AsCH_3$ only by 2.4, 0.26, 9.7, and 1.3 kcal mol^{-1}, respectively. This strongly implies that substituents which are more electropositive than germanium as well as arsenic increase the energy difference ΔH between XGe≡As and Ge=AsX (relative to X = H), whereas more electronegative substituents decrease this energy gap. In particular, as mentioned above, when the substituent X is highly electronegative (such as X = F and OH), the XGe≡As and Ge=AsX isomers are predicted to be nearly degenerate in energy, with an energy gap of less than 3.0 kcal mol^{-1}. In other words, our model calculations suggest that germanium and arsenic are less reluctant to form Ge=As double-bonded than Ge≡As triple-bonded molecules.

The generally higher stabilities of Ge=AsX compared with XGe≡As primarily reflect the differences in the bond energies of Ge–X versus As–X. If the Ge–X bond

is stronger than the As–X bond, then XGe≡As is expected to be more stable than Ge=AsX. According to some available experimental bond dissociation energies (in kcal mol^{-1}) [13]: Ge–F (116), As–F (98.0); Ge–O (158), As–O (115); Ge–H (≤ 76.9), As–H (65.5); and Ge–Cl (103), As–Cl (107), one may easily predict the relative stabilities of arsagermenes and arsagermynes. Thus, the preference of XGe≡As over Ge=AsX is found for X = F and OH because the Ge–F and Ge–O bonds are substantially stronger than the corresponding As–X bonds. Accordingly, the change in Ge–X and As–X bonding should be parallel to the order of the relative stabilities of XGe≡As and Ge=AsX.

However, it would seem, from a practical point of view, that the potential barrier between XGe≡As and Ge=AsX is also as important as their relative energy. The transition structures for the intramolecular isomerization reaction, (i.e. XGe≡As → Ge=AsX) were determined at the B3LYP level of theory, which were shown in Scheme 1and Tables 1 and 2. As seen in Tables 1 and 2, it is evident that those transition states, which are all at the first-order saddle point as determined by the frequency calculation at the B3LYP level, proceed in a three-center pattern involving germanium, arsenic, and substituent elements.

As one can see in Table 1, our B3LYP results indicate that the longer the Ge–As bond, the more product-like the transition state structure. For instance, the Ge–As bonds stretched in the transition structures are 5.6% (HGeAs–TS), 0.51% (LiGeAs–TS), 0.42% (NaGeAs–TS), 1.5% (HBeGeAs–TS), 0.84% (HMgGeAs–TS), 3.3% (H_2BGeAs–TS), 1.2% (H_2AlGeAs–TS), 3.5% (H_3SiGeAs–TS), 6.1% (H_3CGeAS–TS), 4.8% (H_2PGeAs–TS), 10% (H_2NGeAs–TS), 7.6% (HSGeAs–TS), 12% (HOGeAs–TS), 9.2% (ClGeAs–TS), and 13% (FGeAs–TS) which are longer than those in the corresponding XGe≡As species. According to the Hammond's postulate [14], the above data strongly imply that the XGe≡As species with electropositive substituents (e.g. Li, Na, BeH, MgH, BH_2, AlH_2 and SiH_3) should arrive at the transition state relatively early, while the arsagermynes with electronegative substituents (e.g. F, OH, NH_2 and CH_3) should reach the transition state relatively late. Thus, one may anticipate a smaller activation barrier, as well as a larger exothermicity for the former than for the latter, which is confirmed by our CCSD(T) calculations. For example, the barrier heights for the isomerization reactions of electropositive-substituted arsagermynes (i.e. $\Delta E_1^{\ddagger}$; from left to right in Eq. (1)) are within the range of 0.40–8.2 kcal mol^{-1}, which are much smaller than those for electronegative-substituted arsagermynes with activation barriers of 14–22 kcal mol^{-1}). Additionally, the reaction enthalpies (ΔH) for the isomerizations of electronegative-substituted XGe≡As fall in the range of 0.26–9.7 kcal mol^{-1}, which are larger than those for the electropositive-substituted XGe≡As (i.e. -9.2–-21 kcal mol^{-1}). Furthermore, as the reaction proceeds in the reverse direction, the intramolecular rearrangement Ge=AsX → XGe≡As is much more difficult to achieve for electropositively substituted Ge=AsX systems, with energy barriers (i.e. $\Delta E_2^{\ddagger}$) of 13–29 kcal mol^{-1}. Similarly, as seen in Scheme 1, it is apparent that electronegative-substituted Ge=AsX species are also separated from the triple-bonded XGe≡As isomer by large potential barriers (at least >12 kcal mol^{-1} at CCSD(T) for X=F, OH, NH_2, and CH_3). Again, from the above results, it is found that electropositive substitution can thermodynamically and kinetically stabilize the double-bonded Ge=AsX species relative to the isomeric XGe≡As, while electronegative substitution can cause the XGe≡As and Ge=AsX isomers to be nearly thermoneutral.

4. Conclusions

The conclusions, which may be drawn from this work, are as follows:

1. Our theoretical calculations show that the reluctance of the arsenic atom in forming GeAs triple bond in singlet ground state.
2. Although germanium and arsenic are two elements that are notoriously reluctant to form p–π multiple bonds, electronegative substitution on germanium preferentially stabilizes formal triple bonds (XGe≡As) relative to double bonds (Ge=AsX).
3. Electropositively substituted Ge=AsX molecules are thermodynamically and kinetically more stable than the isomeric XGe≡As species.
4. The second-row substituents with high electronegativity (such as F, OH, NH_2 and CH_3) can stabilize the XGe≡As triply bonded species in a kinetic sense, although germanium and arsenic are less reluctant to form Ge=As doubly bonded than Ge≡As triply bonded compounds.

As a consequence, the detection of such molecules as a monomer should be achieved in either the low-pressure gas phase (e.g. as low as 10^{-4} torr) or the low-temperature inert matrix. Moreover, the above conclusions of substituent effects on germanium–arsenic multiple bonding provide some interesting clues for designing molecules with either a Ge=As double-bond or a Ge≡As triple-bond.

We encourage experimentalists to carry out further experiments to confirm our predictions.

Acknowledgements

We would like to thank the National Center for High-Performance Computing of Taiwan for generous

amounts of computing time. We also thank the National Science Council of Taiwan for their financial support. We are grateful to the referees for their critical comments and helpful corrections of the manuscript.

Dihypersilylstannylene and dihypersilylplumbylene —two Lewis-amphoteric carbene homologues☆

K. Klinkhammer

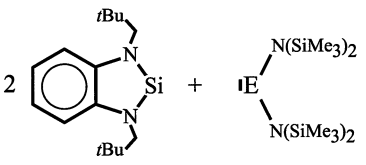
Universitat Stuttgart, Stuttgart, Germany

Received 10 August 2001; accepted 27 November 2001

Dedicated to Professor Hans Bürger on the occasion of his 65th birthday

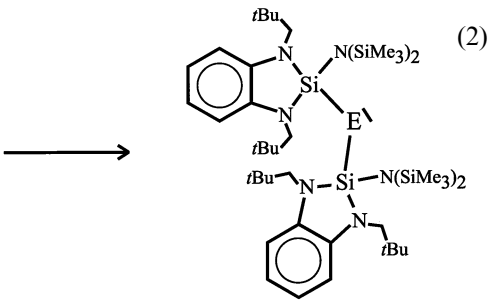
Abstract

Dihypersilylstannylene $[(Me_3Si)_3Si]_2Sn$ (**1**) and dihypersilylplumbylene $[(Me_3Si)_3Si]_2Pb$ (**2**) are Lewis-amphoteric compounds, i.e. they may behave as Lewis-acid and/or as Lewis-base. Quantum-chemical calculations indicate that their Lewis-acidity is strongly enhanced compared with their diorganyl substituted relatives by the electropositive silyl substituents present. Furthermore silyl substituents are expected to migrate more easily than organyl groups, due to relatively weak E–Si bonds formed to the heavier Group 14 congeners (tetrels) leading to different reaction patterns. Here I will give a brief report about our recent investigations on the chemical behavior of the title compounds towards other Lewis-acidic or Lewis-basic or Lewis-amphoteric species. © 2002 Elsevier Science Ltd. All rights reserved.



Keywords: Stannylenes; Plumbylenes; Distannenes; Diplumbenes; Lewis-amphoteric behavior

1. Introduction



In 1995, we reported the synthesis of the title compounds, dihypersilylstannylene (**1**) and dihypersilylplumbylene (**2**). They are obtained by simple metathesis reactions of the appropriate bis[bis(trimethylsilyl)amino]-substituted tetrylene with unsolvated alkali metal hypersilanides under homogenous conditions in inert hydrocarbon solvents at −60 °C (Eq. (1)) [1] and are easily separated from the sparingly soluble alkali metal amide by filtration at −30 °C. At this time **1** and **2** were the first bis(silyl) substituted stannylene and plumbylene ever isolated. In the meantime few further *heteroleptic* species, bearing one silyl and one aryl group could be synthesized, partially via ligand exchange reactions of **1** and **2** with other tetrylenes or aryl copper derivatives (see below) [2]. The only examples with two silyl groups other than hypersilyl

$$E[N(SiMe_3)_2]_2 + M^{I}Si(SiMe_3)_3 \quad (E = Sn, Pb;\ M^{I} = Na\cdots Cs)$$

$$\xrightarrow[-60°C]{<n\text{-pentane}>} M^{I}N(SiMe_3)_2 + E[Si(SiMe_3)_3]_2 \quad \mathbf{1, 2} \qquad (1)$$

4

(2)

3a (E = Sn), **3b** (E = Pb)

☆ Hypersilyl: tris(trimethylsilyl)silyl, $[(H_3C)_3Si]_3Si$. Since there is no common name for the elements E of Group 14 (E = C, Si, Ge, Sn and Pb), the terms tetrels—as suggested by the IUPAC—and tetrylene are used for the elements E and their divalent two-coordinate derivatives R_2E, respectively.

attached to the low valent tetrel atom were reported by Gehrhus and Lappert in 1997 [3]. These particular compounds (**3a**, **b**) were obtained by the insertion of the bisaminosilylene **4** into the Sn–N and Pb–N bonds of bis[bis(trimethylsilyl)amino]stannylene and plumbylene, respectively (Eq. (2)); other related insertion reactions involving Sn–C or Sn–N bonds led to heteroleptic species, however [2h].

In the following, we will briefly review our investigations—partially performed in fruitful cooperation with other groups—on the Lewis-acids/Lewis-base behavior of dihypersilylstannylene (**1**) and dihypersilylplumbylene (**2**). Some of the reported results are still unpublished and have been reported only during my lecture on the occasion of the Pacific Basin Conference in Honolulu (Hawaii) in December 2000.

Before going into experimental details some substantial remarks will be made concerning the electronic structures of stannylenes and plumbylenes for a better understanding of their reactivity. Stannylenes and plumbylenes as other carbene homologous species comprise both, an energetically high-lying HOMO predominantly constituted by a lone-pair on the tetrel atom of high s-character and a low-lying LUMO having high contributions of the empty valence p-orbital of the two-valent tetrel atom. Thus all stannylenes and plumbylenes are Lewis-amphoteric compounds, i.e. are expected to show both, Lewis-acidic and Lewis-basic behavior. But, in contrast to many other compounds, the amphoteric behavior is located at the *same* atom, i.e. at the two-valent tetrel center. The energy difference between the frontier orbitals is however decreasing going up Group 14 (Table 1) [4]. For most simple carbenes, finally, both orbitals are of nearly the same energy and same radial expansion such leading to a triplet ground-state or at least to a very low lying triplet state. Thus carbenes usually are extremely reactive high-energy compounds not only showing strong Lewis-acid/Lewis-base behavior, but also giving reactions typical for radicals. Dimerization of carbenes lead to alkenes as the 'natural' dimerization produc0t of two triplet species forming a σ- and a π-bond. They exhibit the typical structural, spectroscopic and chemical features attributed to doubly-bonded species. Already in the case of silylenes things markedly change. As shown by Kutzelnigg both, the difference in energy and the radial expansion of s- and p-valence orbitals strongly increase down Group 14, thus leading to a low hybridization tendency and resulting in non-radical singlet species for all heavier carbene congeners [5]. Therefore, many reactions of these species can be described in terms of simple Lewis-acid/Lewis-base reactions, not only the addition of external Lewis-acids or Lewis-bases, but also insertion reactions, and the dimerization of heavier tetrylenes to *formal* alkene homologues. The bonding within latter compounds, their structural features as well as their spectroscopic and chemical behavior was a topic of controversial discussions in the last decade, but is now well understood and widely accepted as a more or less strong double donor–acceptor bond (double dative bond) between the two constituting Lewis-amphoteric tetrylenes [4,6,7]. Going down Group 14 the energy difference between the interacting orbitals strongly increase and thus—as generally found for dative bonds—the interaction energy decreases. Due to a strong relativistic contraction of the valence s-orbital on lead the s–p gap is very large for this case (about 150 kJ mol^{-1}) resulting in no or very week double donor–acceptor bonds within plumbylene dimers (diplumbenes) and in general leading to a very weak donor ability of plumbylenes.

A simple theoretical model—the CGMT-model—which emerged during the last decade allows for a more detailed prediction of the bonding in alkene homologues and for the prediction of their structures [7]. This model addresses the relation between the HOMO–LUMO gap of the constituting tetrylene moieties (better: the singlet–triplet gap $\Sigma\Delta E_{ST}$) and the dimerization energy of the respective hypothetical triplet species: $E_{\sigma+\pi}$.

Classical double bonded systems ($\sigma+\pi$ bond; local D_{2h} symmetry) are expected if $\Sigma\Delta E_{ST} < 1/2E_{\sigma+\pi}$ (this holds for all alkenes and some disilenes). Double-dative bonds (*trans*-bent structures; local C_{2h} symmetry) are expected if $1/2E_{\sigma+\pi} < \Sigma\Delta E_{ST} < E_{\sigma+\pi}$. If $\Sigma\Delta E_{ST} > E_{\sigma+\pi}$, i.e. if the preparation energy for the triplet fragments is finally larger than the total expected E–E bond energy (see Table 1) no dimer is expected to form.

Table 1
Calculated sum of singlet–triplet gaps ($\Sigma\Delta E_{ST}$) in hydrides EH_2 (E = C–Pb), dimerization energies for the triplet species ($E_{\sigma+\pi}$) (kJ mol^{-1}) and expected structures of the dimers $H_2E{=}EH_2$ [4]

EH_2	$\Sigma\Delta E_{ST}$	$1/2E_{\sigma+\pi}$	$E_{\sigma+\pi}$	Expected structure

SnH_2	194	156	311	*trans*-bent
PbH_2	286	131	262	no dimer

2. Dihypersilyltetrylenes as Lewis-base—the formation of heteroleptic monomers and dimers

Lewis-acid–Lewis-base adducts between two same or two different stannylenes have been previously observed yielding dimers with double donor–acceptor or single donor–acceptor bonds [8], depending on the nature of the employed compounds. No such reaction, however, could be verified for plumbylenes until our own recent work, since bulky groups had been utilized

Table 2
Calculated dissociation energies (ΔE_{Diss}) of Lewis-base adducts of $Pb(CH_3)_2$ and $Pb(SiH_3)_2$ (kJ mol^{-1}) as well as bond lengths of the respective dative D→Pb bond (pm)

Method: B3LYP [19]; H, C, N, O, P, S: all electrons, cc-pvdz (Dunning) basis-sets [19]; Pb: quasirelativistic pseudopotentials (Stuttgart group) and appropriate double-zeta (d) basis [20]. No counterpoise correction.

for obtaining kinetically stable plumbylenes, which in the light of the very small expected dimerization energy prevented dimerization for sterical reasons.

Some years ago calculations by Apeloig and others indicated that electropositive substituents should generally lead to a diminished HOMO–LUMO gap for tetrylenes and therefore should enhance their tendency to form Lewis-acid–Lewis-base adducts and thus strengthen the bonds within the respective dimers [9]. Our own calculations on the simple model compounds $E(CH_3)_2$ and $E(SiH_3)_2$ and their dimers $(H_3C)_2E$=$E(CH_3)_2$ and $(H_3Si)_2E$=$E(SiH_3)_2$ on DFT (and MP2) level clearly show that the substitution of CH_3 for the more electropositive SiH_3 group dramatically increases (in the case of E = Pb more than doubles) the dimerization energies (last row in Table 2). Therefore, bis(silyl)stannylenes and bis(silyl)plumbylenes are expected to exhibit a much higher tendency to dimerize giving the respective distannenes and diplumbenes than the related diorganyl substituted species. Nevertheless cryoscopic measurements and its crystal structure showed dihypersilylplumbylene (**2**) to be strictly monomeric even in the solid state (Fig. 1). A closer inspection of the structural details revealed that an extreme sterical congestion is present in **2**: (a) the Si–Pb–Si angle with about 114° is much larger than in the bis(silyl)plumbylene **3a** and other less congested plumbylenes; (b) severe distortions from tetrahedral geometry is found around the silicon atoms of the hypersilyl ligands (Pb–Si–Si: 98.3–129.2°). Thus, inspite of a high electronic tendency to dimerize, dimerization is obviously prevented by sterical congestion. Dihypersilylstannylene (**1**) showing a monomer–dimer equilibrium already in solution—other than its lead analog **2**—does form a dimer in the solid state (Fig. 2). Although an even stronger sterical congestion is present for stannylene **1** than for the plumbylene **2**, since Sn is smaller than Pb, (Sn–Si–Si: 99.8–131.9°) the tendency to dimerize is such high that a distannene $(\mathbf{1})_2$ with a severely distorted Sn_2Si_4 skeleton is formed; a very pronounced torsion about the Sn–Sn bond of about 62.7° with respect to the expected undistorted *trans*-bent structure and a markedly elongated Sn–Sn bond of 282.5 pm is observed. The very large Si–Sn–Si angle at the two stannylene moieties of about 120.5° indicates a notable involvement of the former lone-pairs in the Sn–Sn-bond [10].

It should be noted that there is also spectroscopic evidence for a very small HOMO–LUMO gap in plumbylene **2**. The UV-spectra of diluted *n*-pentane

[a] A $MgBr_2(THF)_4$ adduct is known however with Pb–Pb 335.5 pm [2f].

solutions of **2** show two bands of low to medium intensity in the visible and near IR region which we according to CIS calculations on the model compounds $Pb(SiH_3)_2$ and $Pb[Si(SiH_3)_3]_2$ assign to the $S_0 \rightarrow S_1$ and $S_0 \rightarrow T_0$ transitions, respectively. The low energy band (putatively $S_0 \rightarrow T_0$) is experimentally found at 1056 nm, implying a ΔE_{ST}-value of 113 kJ mol^{-1} only, thus significantly lower than calculated for the parent PbH_2 (143 kJ mol^{-1}; Table 1).

From the CGMT model (see above) it can be followed that the tendency to dimerize is dependent on the *sum* of the HOMO–LUMO gaps (ΣE_{ST}) of the constituting monomers. Therefore, our simple presumption was that one could perhaps obtain stable *mixed* dimers, i.e. distannenes, stannaplumbenes or diplumbenes, by mixing the sterically congested dihypersilyltetrylenes **1** and **2**—which have high electronical tendency to dimerize (small ΔE_{ST})—with much less congested diorganyltetrylenes—which have low or even no tendency to dimerize (large ΔE_{ST}). In cooperation with the groups of Grützmacher and Weidenbruch several diaryltetrylenes R_2E' (E = Sn, Pb, R = Ar) were reacted with stannylene **1** and plumbylene **2**—and indeed quantitatively yielded *dimers* in the solid state for all investigated cases [2]. The crystal structure analyses revealed, however, that not the expected homoleptic hetero-dimers $R_2E' = EHyp_2$ (homoleptic with respect to each tetrylene moiety) were isolated, but instead a rearrangement (Eq. (3)) had taken place and homo-dimers of the heteroleptic tetrylenes were obtained: R(Hyp)E = E(Hyp)R and R(Hyp)E′ = E′(Hyp)R, respectively. In those cases where stannylenes were mixed with plumbylenes both homo-dimers were formed and could be easily separated by fractionating crystallization (the distannenes are less soluble than the diplumbenes). Despite two very bulky hypersilyl substituents present, all distannenes and diplumbenes have markedly shorter E–E bonds than the dimers of the parent tetraorganylditetrenes (Table 3) thus verifying the CGMT-model. Moreover *all* heteroleptic dimers synthesized so far exhibit an undistorted *trans*-bent structure with the expected C_i symmetry (E-isomer). Especially for E = Pb the observed Pb–Pb distance was found to be very sensitive to the organyl substituent employed. Depending on its bulkiness, its electron-withdrawing or electron-releasing power and functional groups present, the Pb–Pb distance varied from 299.0 in **5** (R = 2,4,6-^{i}Pr$_3$-C$_6$H$_2$) [2f] to 353.7 pm in **6** (R = 2,4,6-

(3)

F_3C-C_6H_2) [2a]. Very recently Weidenbruch showed that silyl groups are not mandatory for the existence of diplumbenes: a *homoleptic* aryl substituted species has been obtained using the modestly bulky 2,4,6-^{i}Pr$_3$-C_6H_2 groups [11]. Nevertheless, the Pb–Pb bond in this homoleptic diplumbene is markedly longer (305.2 pm) and putatively weaker than in the respective heteroleptic species **5**—again showing the validity of the CGMT-model.

A diplumbene with an even shorter Pb–Pb bond was formed from the reaction of dihypersilylplumbylene with mesitylcopper—one of the few reactions we investigated so far where plumbylene **2** reacts purely as a Lewis-base [2d]. The putatively formed primary

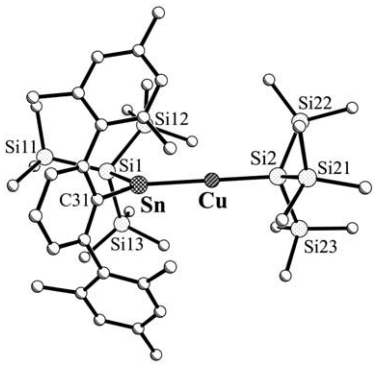

Fig. 4. Molecular structure of the hypersilyl copper adduct **10**. Selected bond lengths (pm), angles and torsion angles (°): Cu–Sn 249.92(6), Sn–Si1 259.65(12), Sn–C31 216.6(4), Cu–Si2 227.28(12), Sn–Cu–Si2 179.36(4), Si1–Cu–C31 114.51(10), Cu–Sn–Si1 116.90(3), Cu–Sn–C31 128.59(10), Si1–Sn–C31–C32 89.1, C31–Sn–Si1–Si11 18.1.

product **7a** (Scheme 1), the adduct of dihypersilylplumbylene (**2**) with mesitylcopper could neither be isolated nor could be detected spectroscopically. It immediately undergoes a rearrangement to form the adduct of the heteroleptic plumbylene Mes(Hyp)Pb with hypersilylcopper **7b** which then dissociated to finally form trimeric hypersilylcopper and the diplumbene Mes(Hyp)Pb=Pb(Hyp)Mes (**8**) with the shortest Pb=Pb bond (290.3 pm) detected so far (Fig. 3, Table 4). The respective reaction with dihypersilylstannylene (**1**) yielded the appropriate distannene **9** again comprising a very short Sn=Sn bond (270.2 pm). To date only few red (**8**) and red-lilac (**9**) crystals ($< 10\%$ yield) of these compounds could be isolated since during the time needed for crystallization (ca. 12 h) most of the initially formed products (ca. 30%) underwent subsequent reactions which could not be elucidated so far.

The reaction path postulated is very probable, however, since in co-operation with Niemeyer we could show that the extremely congested 2,6-dimesityl-phenylcopper reacts in a clean manner with stannylene **1** and plumbylene **2**, respectively, giving either the adduct of the appropriate heteroleptic stannylene with hypersilylcopper (**10**) (Fig. 4) or a mixture of the heteroleptic plumbylene (**11**) and trimeric hypersilylcopper in good yields [2d]. Thus, we finally propose a reaction scheme (Scheme 1) for reactions of copper aryls with dihypersilyltetrylenes, which must be of course still verified to have general validity. Further investigations of this reaction and of related ones with other coordinatively unsaturated metal derivatives such as diorganylzinc, diorganylmercury and triorganylboron derivatives are in our hands.

At first we were surprised about the ease with which the mentioned rearrangements of putatively formed intermediates with two hypersilyl groups still residing at the tetrel atom to the final heteroleptic products took place. The overall reactions were usually finished within a few seconds, even at −30 °C, and no intermediates could be detected by NMR-experiments so far. Preliminary ab initio calculations for the ligand exchange processes for silyl substituted distannenes $H(H_3Si)Sn{=}Sn(SiH_3)H$ and $H(H_3C)Sn{=}Sn(SiH_3)H$ revealed, however, that energetically very low lying transition-states ($E^{\#} < 40$ kJ mol^{-1}; CCSD(T) level of theory) and intermediates may be involved, which are related to the various isomers of very similar energy found on the hypersurface of the parent compound $H_2Sn{=}SnH_2$ [4,6,7]. These results imply that stannylenes and plumbylenes—at least silyl substituted ones—exhibit probably fluctional behavior in solution at ambient temperature and below, and thus allow for easy rearrangement to energetically favorable and less sterically strained products. The release of sterical strain seems to be indeed the major driving force in the formation of the rearranged products, since the angle at Sn or Pb unusually large within the tetrylenes **1** [10] and **2** is markedly less obtuse in most heteroleptic compounds. This may also be true for the rearrangements observed in other Lewis-acid–base reactions discussed in details in the next section.

3. Dihypersilyltetrylenes as Lewis-acid

The smaller HOMO–LUMO gap calculated and experimentally found for bis(silyl)stannylenes and plumbylenes compared with species bearing more electronegative substituents implies either a stronger basicity or a stronger acidity of former or both. Intuitively, one would think that the introduction of electron-re-

leasing groups such as hypersilyl groups should enhance the basicity and diminish the acidity of the divalent tetrel center. DFT calculations on several simple adducts of Lewis-bases and acids with $Pb(CH_3)_2$ on one hand and with $Pb(SiH_3)_2$ on the other hand show, however, that the opposite seems to be true. As can be seen from the calculated dissociation energies of several adducts given in Table 2, adducts of Lewis-bases with disilylplumbylene are by far more stable than respective adducts with dimethylplumbylene. Additionally, the length of the new formed dative bond is markedly shorter for adducts with $Pb(SiH_3)_2$ than for $Pb(CH_3)_2$. Even the very week donor P_4 (note that the lone-pairs on P_4 are only weakly basic, having predominantly s-character in contrast to those in phosphanes PR_3) is calculated to be substantially bonded to $Pb(SiH_3)_2$ only, but not to $Pb(CH_3)_2$.

As can be seen in the following, the dihypersilyltetrylenes **1** and **2** are indeed remarkably strong Lewis-acids compared with related species bearing more electronegative substituents.

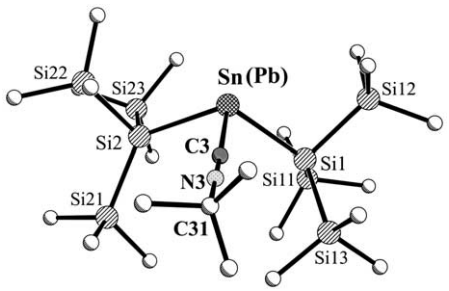

Fig. 5. Molecular structure of the *tert*-butylisonitrile adduct **12a** to dihypersilylstannylene (**1**). Selected bond lengths (pm), angles and torsion angles (°): Sn–C3 228.3(8), Sn–Si1 267.9(2), Sn–Si2 265.0(2), C3–N3 115.8(10), N3–C31 147.2(10), Si1–Sn–Si2 115.42(7), Si1–Sn–C3 91.7(2), Si2–Sn–C3 90.6(2), Si2–Sn–Si1–Si12 160.3; Si1–Sn–Si2–Si22 172.0. Selected parameters of the isostructural adduct **13a** to dihypersilylplumbylene (**2**): Pb–C3 249.5(14), Pb–Si1 275.4(3), Pb–Si2 272.8(3), C3–N3 114(2), N3–C31 147.9(14), Si1–Pb–Si2 114.00(11), Si1–Pb–C3 90.8(3), Si2–Pb–C3 89.8(3), Si2–Pb–Si1–Si12 162.3; Si1–Pb–Si2–Si22 169.9.

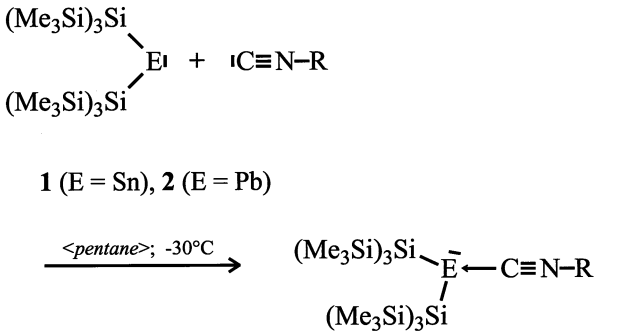
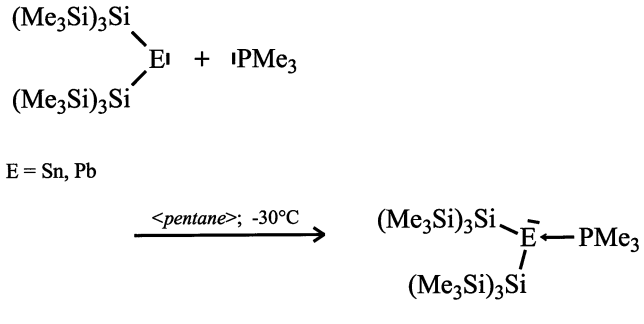
Selected bond lengths (pm), angles and torsion angles (°): Sn–C3 226.0(12), Sn–Si1 265.2(2), Sn–Si2 267.8(3), C3–N3 118.3(14), N3–C31 146.5(14), Si1–Sn–Si2 114.95(8), Si1–Sn–C3 94.6(6), Si2–Sn–C3 89.6(10), Si2–Sn–Si1–Si11 162.3; Si1–Sn–Si2–Si21 169.8.



4. Reactions with isonitriles

Both dihypersilyltetrylenes, **1** and **2**, were reacted with two different dialkylisonitriles at −30 °C: *tert*-butyl isonitrile [12] and cyclohexyl isonitrile [13]. The immediate color change from brown to yellow and blue to red, respectively, indicated a fast and complete reaction. Indeed, the expected isonitrile adducts **12a**, **b** and **13a**, **b** were obtained in nearly quantitative yields as orange–yellow and red crystalline compounds, respectively (Eq. (4)). All adducts are fairly stable in *n*-pentane solution at room temperature as far as light is excluded. The lead derivatives **13a**, **b** in solution slowly decompose cleanly to Pb, Hyp–Hyp and the appropriate isonitrile when stored under ambient light, the tin derivatives are indefinitely stable, however. In contrast to the only known isonitrile–stannylene adduct $MesN{\equiv}C \rightarrow SnAr^F_2$ **14**, prepared by Grützmacher several years ago by reaction of an diarylstannylene $SnAr^F_2$ with two strongly electron-withdrawing 2,4,6-$(F_3C)_3C_6H_2$ (Ar^F) groups [14a], there is no experimental evidence for re-dissociation of the adducts **12a**, **b** and **13a**, **b** in solution or under reduced pressure. The molecular structures of **12a**, **b** and **13a** could be determined by X-ray crystallography (Figs. 5 and 6, Table 4) and indeed show shorter C→E bonds than found for other dative C→E(II) bonds, for instant in the isonitrile adduct **14** (240 pm), or in related adduct of nucleophilic carbenes to stannylenes or plumbylenes bearing hydrocarbyl or other more electronegative ligands [15]. Recently, Weidenbruch et al. reported the molecular structure of an adduct of a heteroleptic aryl(hypersilyl)stannylene with a nucleophilic krypto-carbene [16]. Here, due to a significant double bond character of the Sn–C bond a much shorter SnC bond (203 pm) is observed as in compounds with pure donor-carbenes [17]. A significant contribution of the possible mesomeric form $RN{=}C{=}EHyp_2$ for the isonitrile adducts **12a**, **b** and **13a**, **b**, postulated by Grützmacher [14] for **14** can be ruled out by the structural data, the IR-data and from the results of NBO-analyses on model compounds. The results of X-ray diffraction showed that the NC vector is nearly perpendicular orientated to the Si–E–Si plane, thus only very weak bent σ-type interaction may be possible from the lone-pair on E to the π*(N=C)-orbital. Such interactions should however lead to a bathochromic shift of the ν(CN) band (reducing the triple-bond character of the NC bond). The opposite is true, however, the respective bands are shifted by about 30 cm^{-1} to higher energies, going from the pure isonitrile to the adducts **12a**, **b** and **13a**, **b**. Further evidence for no or at least negligible

Scheme 2.



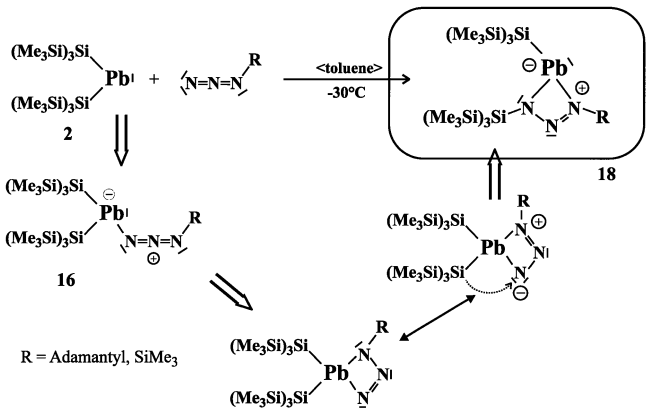
double bond character to C→E(II) bonds in isonitrile adducts was given by the detailed spectroscopic investigations by Okazaki et al. of related isonitrile adducts to a silylene, Tbt(Mes)Si←CNR (R = Tip, Tbt, Mes*; Tbt = $C_6H_2[CH(SiMe_3)_2]_3$-2,4,6; Tip = $C_6H_2^iPr_3$-2,4,6; Mes* = $C_6H_2^tBu$-2,4,6), synthesized by the reaction of the isonitriles with the appropriate sterically extremely hindered disilene Tbt(Mes)Si = Si(Mes)Tbt [14b].

(4)

5. Reaction with trimethylphosphane

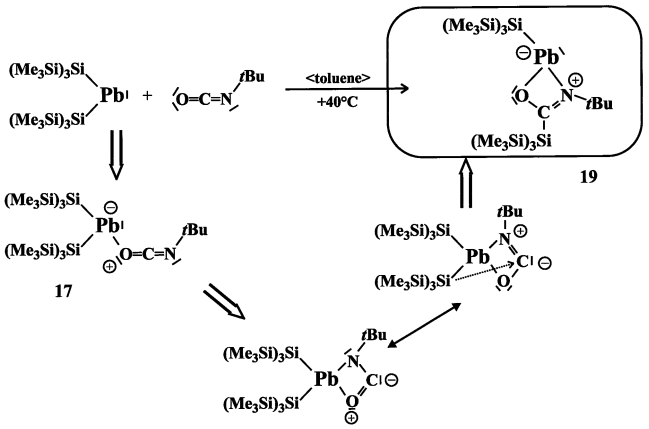
To the best of our knowledge no simple stable triorganylphosphane adduct to stannylenes or plumbylenes has ever been isolated. But, when the dihypersilyltetrylenes **1** and **2** are reacted with PMe_3 in *n*-pentane or toluene again an immediate color change is observed and stable crystalline adducts with similar colors like those of the appropriate isonitrile adducts **12**

(5)



and **13** are isolated, again in quantitative yields [13b]. Not only the stability against heat and light is virtually the same as found for the isonitrile adducts, but also no re-dissociation is detectable in solution or under reduced pressure. Unfortunately, no structural data are available to date, since all crystals obtained from *n*-pentane solution were twinned, but all NMR-spectroscopic and analytical data are in accordance with the formulated simple 1:1 adducts (Eq. (5)).

6. Reaction with white phosphorus



According to personal communication from Weidenbruch, white phosphorus does not react with several diaryl stannylenes and plumbylenes. Nevertheless, when brought in contact with dihypersilyltetrylenes **1** and **2** at −30 °C in toluene P_4 within several minutes gives a reaction, again indicated by a color change from brown or blue to violet [13b]. The reaction of plumbylene **2** is clean, i.e. giving only few products under these conditions, the ^{31}P NMR spectra of the reaction mixture showing only three dominant signals in varying ratios. The extreme low field signal at +733 pm could be unambiguously attributed to dihypersilyldiphosphene HypP=PHyp. The extreme high field signal, according to the observed high order spectrum of its ^{207}Pb satellites and its ^{1}H and ^{29}Si resonances derives from the heterocubane **16** (Scheme 2) which during the refereeing of this paper could be proofed by X-ray crystallography. Both are thermally stable at room temperature. The third compound, however, is thermally unstable, quickly decomposing at room temperature giving P_4, Pb and Hyp–Hyp. We think it to be the simple 1:4 adduct of P_4 with **2** (Scheme 2), since the ^{207}Pb satellites in the ^{31}P NMR spectrum exhibit intensities consistent with four Pb-atoms which are equivalent on the NMR time scale and show no fine structure, indicating a rapid exchange process. Further spectroscopic work has to be done, however, to verify the identity of this product. Nevertheless, a Lewis-acid–base adduct between P_4 and **2** is a very probable intermediate for all possibly following reactions, since it allows at least for a low energy approach of both reactants.

7. Reactions with ambident Lewis-bases

A second outcome of the calculations (Table 2) is worth mentioning: the harder bases H_2O and NH_3 are calculated to form stronger bonded complexes to the soft bis(silyl)tetrylenes than their heavier softer congeners H_2S and PH_3. Nevertheless, one has to keep in mind that the former species are harder, indeed, but also much stronger bases than the latter.

Scheme 3.

Scheme 4.

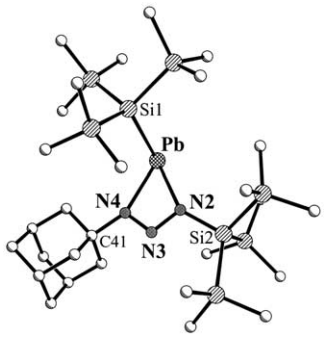


Fig. 7. Molecular structure of the hypersilylleadtriazenide **18**. Selected bond lengths (pm), angles and torsion angles (°): Pb–Si1 273.7(2), Pb–N2 237.2(6), Pb–N4 234.4(7), N2–Si2 178.0(7), N4–C41 152.4(10), Si1–Pb–N2 105.8(2), Si1–Pb–N4 100.1(2), N2–N3–N4 109.3(6), N3–N2–Si2 114.1(5), N3–N4–C41 112.6(6), N2–N3–N4–C41 −179.2, N4–N3–N2–Si2 −163.7.

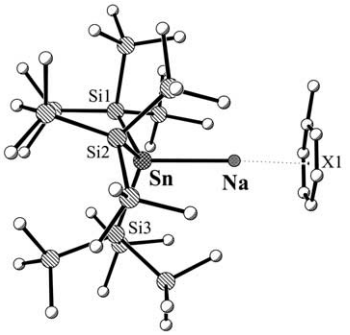
However, no simple adduct could be isolated so far with simple ethers or amines, but promisingly, (complicated) reactions take place when bubbling ammonia or wet argon through pentane solutions of **1** or **2**, thus further investigations are in our hand.

Isolable products are however obtained in good yields when ambident nitrogen/oxygen bases such as azides or isocyanates are reacted with plumbylene **2** in toluene [13a]. Again simple Lewis-adducts **16** and **17** may be formulated as initial intermediate, but for all investigated cases rearrangements took place: one hypersilyl group migrates from Pb to a heteroatom bearing a formal negative charge thus leading to a heteroleptic formal Pb(II) derivative (Schemes 3 and 4). For the reaction with adamantylazide the product could unambiguously identified by X-ray diffraction to be the red monomeric Pb(II) triazenide complex **18** with one hypersilyl and one chelating 1-adamantyl-3-hypersilylazenide present (Fig. 7, Table 4). The proposed reaction path is given in Scheme 3. We have spectroscopic evidence that trimethylsilylazide Me_3SiN_3 gives the respective violet–red 1-trimethylsilyl-3-hypersilylazenide complex, but no crystals of sufficient quality for X-ray diffraction could be obtained so far. The reaction of plumbylene **2** with *tert*-butylisocyanate produces an extraordinary air and moisture sensitive dark blue–violet compound which for its NMR and analytical data most probably is the imidato complex **19** (Scheme 4). But again no suitable crystals could be obtained and more spectroscopic work has to be done to verify this assumption. No evolution of N_2 or CO has been observed during these reaction, thus the formation of iminoplumbanes RN=PbHyp can be excluded. During attempted reactions of azides with dihypersilylstannylene (**1**), the evolution of nitrogen is observed however, but according to the ^{1}H NMR spectra of the oily residues only complex mixtures of products were obtained so far.

8. Reactions with other bases

Some attempts have been made to react lithium organyls and alkali metal silanides with the dihypersilyltetrylenes **1** and **2**. However, only few clean reactions were found so far. Thus the reaction of sodium hypersilanide with stannylene **1** quantitatively yields the yellow toluene solvate of sodium tris(hypersilyl)stannanide (**20**) (Fig. 8) [18], a very promising reagent providing an extremely bulky substituent for the synthesis of other low coordinated compounds. In contrast to this finding, plumbylene **2** is a much weaker Lewis-acid than its lighter homologue **1** and does not react with alkali



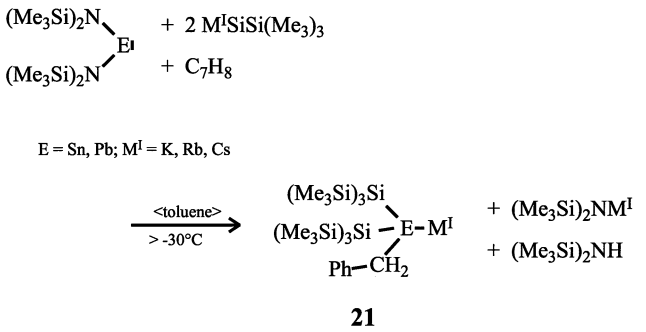


Fig. 8. Molecular structure of the sodium trihypersilylstannanide **20**. Selected bond lengths (pm) and angles (°): Na–Sn 307.0(5), Sn–Si1 270.7(3), Sn–Si2 270.2(3), Sn–Si3 270.4(3), Si1–Sn–Si2 110.14(9), Si1–Sn–Si3 110.49(9), Si2–Sn–Si3 109.15(10), Na–Sn–Si1 109.58(14), Na–Sn–Si2 108.8(2), Na–Sn–Si3 108.7(2), Na···C 282(5)–292(4), Na–X1 260. (X1: centroid of arene ring).

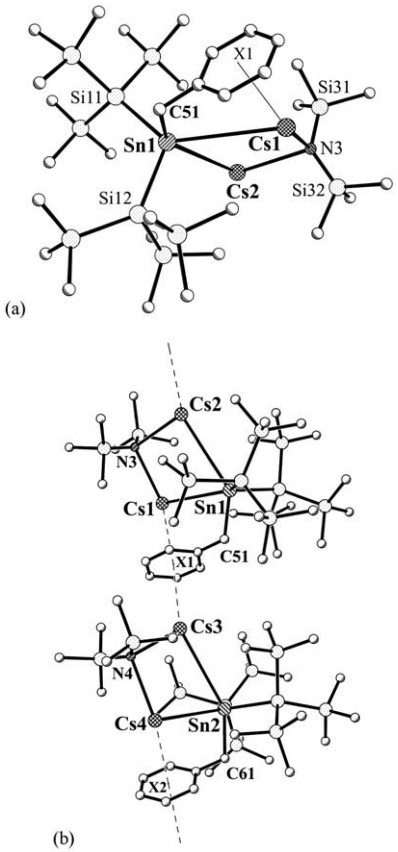
metal hypersilanides, or at least does not form any isolable product. Different very bulky stannanides and even plumbanides are formed, however, in reasonable yields when toluene instead of *n*-pentane is used as a non-innocent solvent for the (attempted) synthesis of the tetrylenes **1** and **2** with potassium, rubidium or cesium hypersilanides at temperatures above −30 °C. Virtually no tetrylene is obtained under these conditions. Instead the formal adducts of the appropriate alkali metal phenylmethanide, **21**, with **1** and **2** are isolated as orange–yellow or red crystalline materials, respectively (Eq. (6)). The molecular structure of the cesium stannanide **21a** could be determined for a mixed salt with cesium bis(trimethylsilyl)amide as the second product of the metathesis [12]. The mixed dimers found in the solid-state structure (Fig. 9(a), Table 4) are extensively linked by π-coordination of the phenyl groups of the phenylmethanide anions to the cesium cations (Fig. 9(b)).

(6)

The reactions of simple lithium organyls such as ^{n}BuLi, ^{t}BuLi or ^{i}PrLi in non-coordinating solvents did not lead to any isolable product so far, but to mixtures of mostly unidentified products (for **1**) or a rapid decomposition of the tetrylene (for **2**). In all reaction mixtures only lithium hypersilanide $LiSi(SiMe_3)_3$ could be unambiguously identified spectroscopically, thus



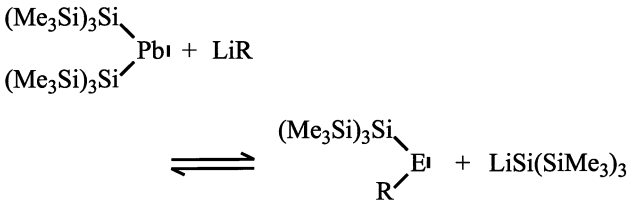


Fig. 9. Molecular structure of the cesium benzyldihypersilylstannanide **21a** (a: dimer; b: coordination polymer). Selected bond lengths (pm) and angles (°) in one of the two independent dimers: Cs1–Sn1 403.9(2), Cs2–Sn1 428.22(15), Cs1–N3 300.5(10), Cs2–N3 303(11), Sn1–Si11 268.3(4), Sn1–Si12 268.4(4), Sn1–Cs1–N3 100.2(2), Sn1–Cs2–N3 95.1(2), Cs1–Sn1–Cs2 66.05(2), Cs1–N3–Cs2 98.2(3), Si11–Sn1–Si12 114.47(13), Si11–Sn1–C51 93.7(4), Si12–Sn1–C51 97.1(4), Si31–N3–Si32 130.3(7), Cs···C (intramolecular) 344.4–367.5, Cs···C (intermolecular) 358.7.8–371.0, Cs1–X1 331, Cs3–X1 338, Cs4–X2 327, Cs2–X2′ 333. (X1; X2: centroids of arene rings)

probably again ligand exchange reactions took place yielding heteroleptic alkyl(hypersilyl) stannylenes and plumbylenes (Eq. (7)) which are not stable under these conditions. Further investigations in the absence and presence of coordinating solvents are in our hand.

(7)

9. Summary

Dihypersilylstannylene (**1**) and dihypersilylplumbylene (**2**) react as Lewis-amphoteric carbene ho-

mologues with several Lewis-acids and Lewis-bases. Their acidity seems to be higher than for other tetrylenes with more electronegative substituents as was proposed on the base of quantum chemical calculations on Lewis-base adducts of simple suitable model compounds and verified for some bases such as isonitriles, phosphanes and white phosphorous. But still the experimental evidence is scarce and must be extended in the future. All reactions where the tetrylenes act as a Lewis-base did not yield the expected adduct, but in each investigated case led to rearrangement reactions, and after migration of one hypersilyl group from Sn or Pb to a hetero atom finally giving derivatives of heteroleptic stannylenes or plumbylenes. Reactions of this particular type also led to the first plumbylene dimers (diplumbenes) with Pb–Pb distances indicating medium to weak double-dative bonds.

10. Supplementary material

All crystallographic data (excluding structure factors) for the so far unpublished structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. 173102 (**8**), 173103 (**9**), 173104 (**13a**), 173105 (**18**), 100901 (**21a**), 100905 (**12b**) and 100907 (**12a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

I would like to thank my coworkers Jan Klett, Shenglai Yao and Yun Xiong for their enthusiasm and my colleagues, Professor Hansjörg Grützmacher, Professor Manfred Weidenbruch and Dr. Konstantin Karaghiosoff for fruitful cooperations and discussions. The work has been financially supported by the 'Fonds der Chemischen Industrie'.

[10] The Si–Sn–Si angle in monomeric stannylene 1 which can not be determined directly because of the dimer formation in the solid-state, may be estimated from the respective value in its isonitrile adducts, since this value should not be influenced by a coordinated slim base. The Si–Sn–Si angle in both structurally characterized isonitrile adducts with 115.0 and 115.4° is hardly larger than the Si–Pb–Si angle in dihypersilylplumbylene 1 (113.6–114.5°) and its *tert*-butyl isonitrile adduct (114.0°). Thus the dimerization of the stannylene **1** obviously leads to rehybridization at Sn—pronounced involvement of the s-orbital in bonding—and to a larger Si–Sn–Si angle of 120.5°.

[23] Crystals had been covered with a layer of viscous hydrocarbon oil (Paratone N, Exxon). A suitable crystal was selected, attached to a glass fiber, and instantly placed in a low-temperature N_2-stream [12]. All data were collected on Siemens four-circle diffractometers ($P2_1$ or P4) at 173 K using monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å). Selected data collection parameters and other crystallographic data are summarized in Table 4. Calculations were carried out with the SHELXTL PC 5.03 program system installed on a local PC. The phase problem was solved by direct methods for all cases, and the structures were refined on F_o^2 by full-matrix least-squares refinement. Absorption corrections were applied to all data, using semiempirical ψ-scans.

$\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ electronic states of linear disilaketenylidene (SiSiO): analysis of the Renner effect in the $\tilde{A}\ ^3\Pi$ state. Comparison with the analogous multiple bonded systems SiCO, CSiO, and CCO

Abstract

Ab initio electronic structure theory has been employed to investigate systematically the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ electronic states of linear disilaketenylidene (SiSiO). The ground state displays a SiSi double bond while the excited $\tilde{A}\ ^3\Pi$ state may be assigned a SiSi bond order of 5/2. The ground ($\tilde{X}\ ^3\Sigma^-$) state of SiSiO possesses a real degenerate bending vibrational frequency, while the first excited triplet ($\tilde{A}\ ^3\Pi$) state is subject to the Renner–Teller interaction, resulting in two distinct real vibrational frequencies along the bending coordinate. The total energies and physical properties including equilibrium geometries, dipole moments, harmonic vibrational frequencies, and associated infrared (IR) intensities of the two lowest-lying triplet states were predicted using the SCF, CISD, CCSD, and CCSD(T) levels of theory with a wide range of basis sets. The $\tilde{A}\ ^3\Pi$ state was also studied using the equation-of-motion CCSD (EOM-CCSD) technique in order to avoid a possible variational collapse to the lower-lying state. With the cc-pVTZ EOM-CCSD method, the Renner parameter and average harmonic bending vibrational frequency for the $\tilde{A}\ ^3\Pi$ state were determined to be $\varepsilon = -0.078$ and $\omega_2 = 219\ \mathrm{cm}^{-1}$, respectively. With our most reliable method, cc-pVQZ CCSD(T), the $\tilde{X}$–$\tilde{A}$ splitting (T_e value) of SiSiO was predicted to be 55.7 kcal mol^{-1} (2.41 eV, 19 500 cm^{-1}) and the splitting including zero-point vibrational energy correction (T_0 value) to be 56.1 kcal mol^{-1} (2.43 eV, 19 600 cm^{-1}). The bond energy for Si–SiO was determined to be $D_e = 26.1$ ($D_0 = 25.2$) kcal mol^{-1} indicating considerable thermodynamic stability for the ground state of SiSiO against the dissociation reaction SiSiO ($\tilde{X}\ ^3\Sigma^-$) $\rightarrow$ Si (^3P_g) + SiO ($\tilde{X}\ ^1\Sigma^+$). © 2002 Published by Elsevier Science Ltd.

Keywords: Electronic states; Linear disilaketenylidene (SiSiO); Renner effect; Analogous multiple bonded systems

1. Introduction

Disilaketenylidene (SiSiO) is the fully silicon substituted analogue of the ketenylidene (CCO) molecule. While CCO has received a great deal of experimental and theoretical attention in the past (see Ref. [1]), there is only fleeting evidence for the existence of SiSiO. The first evidence of its existence was given in 1987 by van Zee, Ferrante, and Weltner [2]. They reported the electron spin resonance (ESR) spectra of the $C_2^{17}O$, $SiC^{17}O$, and $^{29}Si_2O$ molecules. Although the ESR spectra of isomers of C_2O and SiCO were reported previously [3–5], SiSiO ($\tilde{X}\ ^3\Sigma^-$) was thought to be detected for the first time, but the assignment of the spectra was made on circumstantial evidence. Based on the fact that the feature assigned to Si_2O had a doublet structure and almost all of the spin-density is on one silicon atom, the asymmetric isomer (SiSiO) was chosen as the likely molecule over the symmetric isomer (SiOSi).

Shortly after, in 1989, DeKock, Yates, and one of us attempted to answer the question as to the relative stability of the $\tilde{X}\ ^3\Sigma^-$ state of linear SiOSi to SiSiO using SCF, CISD, and CASSCF ab initio methods [6], and it was found that the SiOSi isomer was more stable by about 10 kcal mol^{-1}. In 1993 Boldyrev and Simons

PII: S0277-5387(02)00830-6

extended the search for the most stable isomer to bent isomers with singlet or triplet multiplicities in their investigation of Si_2O and Si_3O [7]. They reported structures and vibrational frequencies with MP4STDQ/6–311 + G(2df and QCISD(T)/6–311 + G(2df) methods and the bent singlet C_{2v} ($^1A_1$) Si_2O structure was found to be the global minima of the Si_2O system. The bent triplet C_{2v} ($^3B_1$) Si_2O, linear triplet ($^3\Sigma_g^-$) SiOSi, and linear triplet ($^3\Sigma^-$) SiSiO structures were predicted to lie above the global minimum C_{2v} ($^1A_1$) structure by 17.5, 20.7, and 27.0 kcal mol^{-1}, respectively, at the QCISD(T)/6–311 + G*(2df) level. Then Iraqi, Goldberg, and Schwarz sought to further confirm this conclusion from the results of their neutralization–reionization mass spectrometry experiments [8]. By subjecting the gas-phase Si_2O clusters to collisional activation with helium, they observed strong evidence that the molecule should have an Si–Si bond and, therefore, ruling out any linear SiOSi structures. In the following year (in 1994) Boldyrev, Simons, Zakrzewski, and von Niessen presented vertical and adiabatic ionization energies and electron affinities of the new Si_nC and Si_nO ($n = 1$–3) molecules [9].

While the relative stabilities of these isomers are interesting, they are not the focus of this research, for we shall concentrate on the ground and first excited state of only one of these possibilities. Recently, we

(b) 4π

Fig. 1. The 11σ and 4π molecular orbitals for the $\tilde{X}\,^3\Sigma^-$ ground state of SiSiO determined at the TZ3P(2f) SCF level of theory.

reported theoretical studies of the $\tilde{X}\,^3\Sigma^-$ and $\tilde{A}\,^3\Pi$ and states of CCO [1], SiCO [10], and CSiO [11] radicals. We have presented highly reliable CCSD(T) results for energetics, harmonic vibrational frequencies and geometric parameters for these radicals. The Renner–Teller effect [12–20] in the $\tilde{A}\,^3\Pi$ states for this series were also discussed. The $\tilde{X}\,^3\Sigma^-$ states of these three radicals posses degenerate bending vibrational frequencies, while the states $\tilde{A}\,^3\Pi$ present two distinct frequencies along the bending coordinates. The Renner parameters and average harmonic bending frequencies have been predicted for the $\tilde{A}\,^3\Pi$ states employing the equation-of-motion CCSD (EOM-CCSD) technique. The EOM-CCSD wave function does not suffer from the orbital instability problem (vide infra) because the excited-state energies are determined as higher roots of the reference CCSD wave function in the same symmetry. The present study on the SiSiO radical is a logical extension of our previous investigations on the linear ketenylidene type radicals with 14 valence electrons. The physical properties and energetics of the two lowest-lying states of linear SiSiO will be compared with those of its carbon analogues.

2. Electronic structure considerations

The ground electronic state of the linear SiSiO radical has the electronic configuration:

$$[\text{core}](8\sigma)^2(9\sigma)^2(10\sigma)^2(3\pi)^4(11\sigma)^2(4\pi_i)(4\pi_o) \quad \tilde{X}^3\Sigma^- \tag{1}$$

where [core] abbreviates the 11 core (Si:1s-, 2s-, 2p-like and O:1s-like) orbitals and π_i and π_o indicate the in-plane and out-of-plane π orbitals, which are degenerate in the ground state. The 8σ molecular orbital (MO) mainly represents the Si–O σ bond, while the 9σ MO describes the Si–Si σ bond. The 10σ and 11σ MOs are the lone pair orbitals on the O atom and the Si atom, respectively. The 3π MO components describe the Si–O π bonds, whereas the 4π MO components are attributed to the Si–Si π bond. The 11σ and $4\pi_o$ MOs for the $\tilde{X}\,^3\Sigma^-$ state of SiSiO are depicted in Fig. 1. The first excited triplet state of SiSiO corresponds to a single electron excitation

$$(11\sigma)^2(4\pi)^2 \rightarrow (11\sigma)(4\pi)^3 \tag{2}$$

and has the electronic configuration

$$[\text{core}](8\sigma)^2(9\sigma)^2(10\sigma)^2(3\pi)^4(11\sigma)(4\pi)^3 \quad \tilde{A}^3\Pi \tag{3}$$

The $\tilde{X}\,^3\Sigma^-$ state possesses a real degenerate bending vibrational frequency, whereas the $\tilde{A}\,^3\Pi$ state presents the two distinct real vibrational frequencies along the SiSiO bending coordinate. Therefore, the $\tilde{A}\,^3\Pi$ state is a type A Renner molecule as classified by Lee, Fox, Schaefer, and Pitzer for linear triatomic molecules [18].

At this point, it is useful to analyze the MO Hessian [21] of the reference self-consistent-field (SCF) wave functions. The MO Hessian is defined as the second derivatives of the SCF electronic energy with respect to MO rotations at a given geometry. For the $\tilde{X}\ ^3\Sigma^-$ state the MO Hessian possesses all positive eigenvalues at the linear equilibrium configuration, confirming that the SCF wave function for the ground state of SiSiO is *stable*. On the other hand, the $\tilde{A}\ ^3\Pi$ state of SiSiO has one zero and one negative eigenvalue of the MO Hessian. The eigenvector corresponding to the zero eigenvalue refers to the $4\pi_i$–$4\pi_o$ MO rotation, indicating that the SCF energy is not altered by such a MO rotation. The eigenvector of the negative eigenvalue is associated with the 11σ–4π MO rotation and, therefore, the SCF wave function of the $\tilde{A}\ ^3\Pi$ state of SiSiO is *unstable* with respect to a lower-lying state at this equilibrium geometry. The lower-lying state in this case is the $\tilde{X}\ ^3\Sigma^-$ state, and it may be obtained by exchanging the 11σ and 4π orbitals. Physical properties involving the 11σ–4π MO rotation should be interpreted cautiously for the $\tilde{A}\ ^3\Pi$ state of SiSiO (in this case, the ω_2^- bending frequency, see below). By the same token, the magnitudes of the eigenvalues for the MO Hessian also provide information as to the degree of stability for the SCF wave function [21–23].

3. Renner effects

Following Herzberg's exposition [15], the Renner parameter (ε) and average harmonic bending frequency (ω_2) are described in the following manner. The potential function of a linear molecule possessing a degenerate electronic state splits into two components upon bending, because in the bent conformation degeneracy no longer exists. For the Π and Δ states the 'upper' (inner) potential function is denoted V^+, while the 'lower' (outer) one V^-. The parity of the potential refers to its symmetry with respect to the plane of the bent molecule [24]. The zero-order bending potential function may be written

$$V^0 = aq^2 + bq^4 + \ldots \tag{4}$$

and the splitting of the potential function in Π, Δ, … states must also have the same form

$$V^+ - V^- = \alpha q^2 + \beta q^4 + \ldots \tag{5}$$

where a and α are quadratic force constants, b and β are quartic force constants, and q is a bending displacement coordinate. The Renner parameter (ε) is defined neglecting anharmonicity terms by

$$\varepsilon = \frac{\alpha}{2a} \tag{6}$$

It may be shown that Eq. 6 is equivalent to

$$\varepsilon = \frac{f^+ - f^-}{f^+ + f^-} = \frac{(\omega^+)^2 - (\omega^-)^2}{(\omega^+)^2 + (\omega^-)^2} \tag{7}$$

where f^+ and f^- are the force constants while ω^+ and ω^- are the harmonic vibrational frequencies associated with the 'upper' and 'lower' bending potentials. Denoting μ to be the kinetic energy contribution to the bending motion, the average harmonic bending frequency (ω_2) may be determined using the equation

$$\omega_2 = \frac{1}{2\pi c}\sqrt{\frac{a}{\mu}} = \frac{1}{2\pi c}\sqrt{\frac{f^+ + f^-}{2\mu}} \tag{8}$$

which may be rewritten as

$$\omega_2 = \sqrt{\frac{1}{2}((\omega^+)^2 + (\omega^-)^2)} \tag{9}$$

The experimentally observable values, ε and ω_2, may be compared with the corresponding theoretical values determined independently through the use of eqn. 4–9.

4. Theoretical procedures

Six triple-ζ (TZ) plus quality basis sets were employed in this research. The TZ basis set for O is obtained from Dunning's triple-ζ contraction [25] of Huzinaga's primitive Gaussian set [26] and is designated (10s6p/5s3p). The TZ basis set for Si is derived from McLean and Chandler's contraction [27] of Huzinaga's primitive Gaussian set [28] and is designated (12s9p/6s5p). The orbital exponents of the polarization functions are: $\alpha_d(O) = 1.70$ and 0.425, and $\alpha_d(Si) = 1.00$ and 0.25 for double polarization (TZ2P); and $\alpha_d(O) =$ 3.40, 0.85, 0.2125, and $\alpha_d(Si) = 2.00$, 0.50, 0.125 for triple polarization (TZ3P). The orbital exponents of the higher angular momentum functions are: $\alpha_f(O) = 1.40$, and $\alpha_f(Si) = 0.32$ for one set of higher angular momentum functions [TZ2P(f)]; and $\alpha_f(O) = 2.80$, 0.70, and $\alpha_f(Si) = 0.64$, 0.16, for two sets of higher angular momentum functions [TZ3P(2f)]. The orbital exponents of the diffuse functions are: $\alpha_p(O) = 0.05840$ and $\alpha_s(O) =$ 0.08993, and $\alpha_p(Si) = 0.02354$ and $\alpha_s(Si) = 0.02567$, for one set of diffuse functions [TZ2P + diff and TZ2P(f) + diff]. Pure angular momentum d and f functions were used throughout. The largest TZ plus basis set, TZ3P(2f), comprises 143 contracted Gaussian functions for SiSiO with a contraction scheme of O (10s6p3d2f/5s3p3d2f) and Si (12s9p3d2f/6s5p3d2f). Finally, two correlation consistent basis sets, cc-pVTZ and cc-pVQZ, developed by Dunning and coworker [29,30] have also been used. The cc-pVQZ basis set consists of 173 contracted Gaussian functions with a contraction scheme of O (12s6p3d2f1g/5s4p3d2f1g) and Si (16s11p3d2f1g/6s5p3d2f1g).

The zeroth-order descriptions for the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states of SiSiO were obtained using single-configuration SCF (restricted open-shell Hartree–Fock) wave

functions. Correlation effects were included using configuration interaction with single and double excitations (CISD), coupled cluster including singles and doubles (CCSD) [31,32], and CCSD with perturbative triples correction [CCSD(T)] [33,34] levels of theory. The EOM-CCSD wave function [35–38] was also employed for the study of the $\tilde{A}\ ^3\Pi$ state. In correlated procedures with the TZ basis sets a frozen core approximation for the 11 core (Si:1s-, 2s-, 2p-like and O:1s-like) orbitals was employed, and the three highest-lying virtual (Si,O:1s*-like) orbitals were excluded from correlation. Only the frozen core approximation was used for the correlation consistent basis sets. With the cc-pVQZ basis set, the numbers of configuration state functions (CSFs) in the CISD procedures in the Hartree–Fock interacting space [39,40] are 190 782 for the $\tilde{X}\ ^3\Sigma^-$ state of SiSiO in C_{2v} symmetry and 375 642 in C_s symmetry, 190 586 for the $\tilde{A}\ ^3\Pi$ state of SiSiO in C_{2v} symmetry and 375 151 in C_s symmetry, respectively.

The geometrical structures of the two lowest-lying triplet states of SiSiO were optimized at the SCF and CISD levels of theory using analytic derivative methods [41–43], while all coupled-cluster optimizations were performed via five point numerical differentiation of total energies [44]. Harmonic vibrational frequencies at the SCF level were evaluated analytically, while at the CISD, CCSD, EOM-CCSD, and CCSD(T) levels of theory they were obtained by finite differences of analytic gradients and/or energies [44]. All computations were carried out using the PSI 2.0.8 program package [45] except the EOM-CCSD wave functions which were performed with the ACES II package[46] on IBM RS/6000 workstations.

5. Results and discussion

5.1. Geometries

The optimized geometric parameters for the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states of SiSiO at the SCF, CISD, CCSD, and CCSD(T) levels of theory with all basis sets employed in this work are presented in Table 1. EOM-CCSD results are provided for only the $\tilde{A}\ ^3\Pi$ state since EOM-CCSD is an excited state method. Figs. 2 and 3 show optimized geometries for only the largest basis sets for each level of correlation. These representations of the theoretical predictions illustrate a number of interesting points.

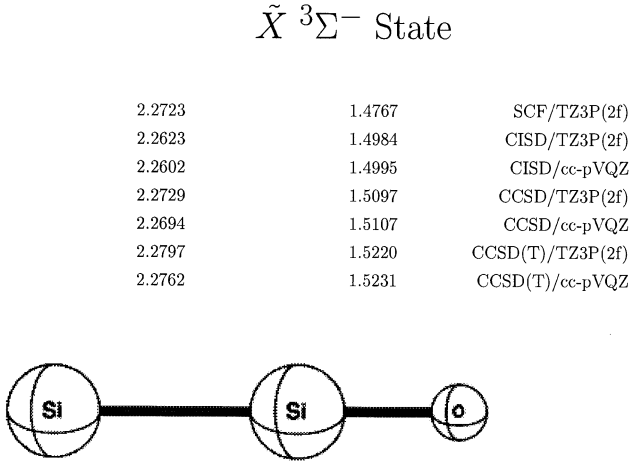

Fig. 2. Optimized geometries for $\tilde{X}\ ^3\Sigma^-$ SiSiO determined by various theoretical methods employed in this research. Bond distances are in angstroms.

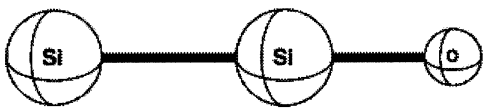

Fig. 3. Optimized geometries for $\tilde{A}\ ^3\Pi$ SiSiO determined by various theoretical methods employed in this research. Bond distances are in angstroms.

Upon excitation, the SiSi bond length significantly shortens (approximately 0.2 Å) and the SiO bond distance slightly lengthens (by approximately 0.01–0.02 Å). This can easily be explained by the nature of the MO's involved in the excitation.The 11σ MO of SiSiO in Eq. 1 (in Fig. 1(a)) is the non-bonding orbital on the Si atom, whereas the 4π MO (in Fig. 1(b)) possesses strong Si–Si π bonding and weak Si–O anti-π bonding character. Thus, a single electron excitation from the 11σ to the 4π MO distinctly shortens the Si–Si bond and marginally lengthens the Si–O bond. From Table 1, it can be seen that, as expected, the bond distances are generally contracting with basis set size, and from Figs. 2 and 3 the bond distances generally elongate with improvement of the treatment of correlation effects. Similar geometrical features have been recognized for the corresponding two triplet states of the isovalent CCO [1], SiCO [10], and CSiO [11] molecules.

It is interesting to note that, the SiO bond length changes very little upon excitation (1.5231 Å for the $\tilde{X}\ ^3\Sigma^-$ state 1.5333 Å for the $\tilde{A}\ ^3\Pi$ state at the cc-pVQZ CCSD(T) level of theory). Both of these parameters are close to the cc-pVQZ CCSD(T) equilibrium bond distance for diatomic $\tilde{X}\ ^3\Sigma^-$ SiO of 1.5201 Å. This is an implication of the strength of the SiO bond and the relatively poor ability of the Si atom to pull electrons away from the very strong SiO bond [6]. This is in contrast to CCO, where the CO bond distance is greatly affected by the addition of the terminal carbon as a consequence of the greater tendency of first-row atoms to hybridize [1,47,48]. Similar concerns will be addressed later for all of the ketenylidene analogues.

5.2. Dipole moments

The dipole moments in debye for the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states of SiSiO are given in Tables 2 and 3 along with the total energies. With the TZ3P(2f) CISD method the dipole moments of the two states of SiSiO are predicted to be $\mu_e\ (^+SiSiO^-) = 3.04$ ($\tilde{X}\ ^3\Sigma^-$) and $\mu_e\ (^+SiSiO^-) = 4.13$ ($\tilde{A}\ ^3\Pi$) debye, where the signs indicate the direction of the dipole moments. Immediately we see that the first excited triplet state is more polar than the ground state. One of the 11σ lone pair electrons on the terminal Si atom (in Fig. 1(a)) is promoted to the 4π orbital (in Fig. 1(b)), causing a shift in electron density to toward the oxygen atom, and the character of the orbitals involved in excitation may be attributed as the cause for the change in dipole moments between the two states. Given a basis set, correlation effects decrease the dipole moments of the $\tilde{X}$ and $\tilde{A}$ states. The dipole moments of the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states of CCO were predicted to be 1.42 ($\tilde{X}\ ^3\Sigma^-$) and 1.47 ($\tilde{A}\ ^3\Pi$) debye [1]. According to Pauling [49] the electronegativities for the three relevant atoms are C(2.5), Si(1.8), and O(3.5). The smaller electronegativity of Si and the larger difference in electronegativities between Si–O than between C–O may be the main reason for the larger dipole moments of SiSiO compared with those of CCO. The theoretically predicted dipole moment of the diatomic SiO ($\tilde{X}\ ^1\Sigma^+$) is $\mu_e\ (^+SiO^-) = 3.28$ debye with the TZ3P(2f) CISD method, while the experimental value is $\mu_e = 3.098$ debye [50], which once again shows the terminal Si atom interacts very little with the strong SiO bond. The dipole moment for the ground state SiSiO is close to that for the diatomic SiO ($\tilde{X}\ ^1\Sigma^+$). Since the dipole moment of SiSiO is reasonably large, microwave spectroscopic investigation may be feasible.

5.3. Harmonic vibrational frequencies

Harmonic vibrational frequencies for the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states are given in Tables 2 and 3, respectively. The Si–Si stretching (ω_3) frequency of SiSiO is significantly higher for the $\tilde{A}\ ^3\Pi$ state than for the $\tilde{X}\ ^3\Sigma^-$ state, in accordance with the shortening of the bond length of the $\tilde{A}\ ^3\Pi$ state. On the contrary, the Si–O stretching frequency (ω_1) is slightly higher for the $\tilde{X}$

$^3\Sigma^-$ state than for the $\tilde{A}\ ^3\Pi$ state. The SiO stretching frequencies of the two states generally decrease with advanced treatments of correlation effects, probably owing to elongated bond distances. Upon bending, the $^3A''$ component of the $\tilde{A}\ ^3\Pi$ state may suffer from a variational collapse to the lower lying $^3A''$ state originating from the $\tilde{X}\ ^3\Sigma^-$ state. In Table 4 the $^3A'$ component of the bending frequency is reported for the CISD, CCSD and CCSD(T) methods. The $\omega_2^-(^3A'')$ bending frequencies from the EOM-CCSD technique is more reliable in a physical and mathematical sense, since the EOM-CCSD wave function is not subjected to the variational collapse, as mentioned in Section 1. With the cc-pVQZ CCSD(T) method, the harmonic vibrational frequency of the diatomic SiO ($\tilde{X}\ ^1\Sigma^+$) is predicted to be 1235 cm^{-1}, whereas the experimental value is 1241.6 cm^{-1} [50]. The SiO stretching fundamental, 1224 cm^{-1} ($\tilde{X}\ ^3\Sigma^-$) for the ground state of SiSiO, has a slightly lower frequency than the diatomic SiO ($\tilde{X}\ ^1\Sigma^+$). The bending (ω_2) frequency is higher for the first excited state compared with that for the ground state, owing to the more contracted structure of the $\tilde{A}\ ^3\Pi$ state as mentioned above.

5.4. Infrared (IR) intensities

The IR intensities (shown in Tables 2 and 3) of the SiO stretching mode are the largest for both the $\tilde{X}\ ^3\Sigma^-$ and $\tilde{A}\ ^3\Pi$ states, due to the polar nature of the SiO bond. The SiSi stretching mode has a small vanishing IR intensity for the $\tilde{X}\ ^3\Sigma^-$ state and a marginal intensity for the $\tilde{A}\ ^3\Pi$ state. The bending modes of the two states present considerably strong intensities. It is found that the IR intensities of the SiO stretching mode of the ground and first excited triplet state of linear SiSiO are significantly larger than that of the isolated SiO ($\tilde{X}\ ^3\Sigma^+$) molecule [62.4 km mol^{-1} at the TZ3P(2f) CISD level of theory]. A similar tendency has been observed for the IR intensities of the CO stretching mode of SiCO and CO [10]. IR spectroscopic investigation of the SiSiO radical may be possible, because some of the IR intensities are relatively large.

5.5. Renner effects

Predicted Renner parameters (ε) and average harmonic bending vibrational frequencies (ω_2) for the $\tilde{A}\ ^3\Pi$ state are presented in Table 4. These values were obtained using the equations described in Section 3. Following the symmetry of the EOM-CCSD wave functions, ω^+ is assigned to the bending motion producing the $^3A'$ state and ω^- to the $^3A''$ state. The theoretical Renner parameters and ω_2 frequencies are reasonably consistent among the seven basis sets. As expected, the sign of the Renner parameter is negative, as were the cases for CCO [1], SiCO [10], and CSiO [11] indicating the potential surface corresponding to a bending motion that is antisymmetric with respect to the plane of the bent molecule lies above the symmetric, and the magnitude of ε for SiSiO is the smallest among the four ketenylidene type radicals.

5.6. Energetics

The excitation energies for the $\tilde{A}\ ^3\Pi$ state relative to the $\tilde{X}\ ^3\Sigma^-$ state are presented in Table 5. With the TZ3P(2f) basis set, the classical energy separation (T_e value) [51] is predicted to be 58.0 (SCF), 58.2 (CISD), 56.6 (EOM-CCSD), 57.1 (CCSD), and 55.9 kcal mol^{-1} [CCSD(T)], respectively. The $\tilde{X}$–$\tilde{A}$ splitting gradually decreases with the correlation level and basis set size. The upper state, with a higher silicon bond order, seems to be stabilized preferentially with the correlation effects; however, this stabilization by correlation effects for the SiSiO system appear less evident compared with that for the CCO system [1]. At the most reliable level of theory employed in this study, cc-pVQZ CCSD(T), the T_e value is predicted to be 55.7 kcal mol^{-1} (2.41 eV, 19 500 cm^{-1}). Employing the three cc-pVQZ CCSD(T) harmonic vibrational frequencies for the $\tilde{X}\ ^3\Sigma^-$ state and the two cc-pVQZ CCSD(T) harmonic stretching frequencies while doubling the TZ3P(2f) EOM-CCSD ω_2 frequency for the $\tilde{A}\ ^3\Pi$ state, the zero-point vibrational energy (ZPVE) correction is predicted to be 136 cm^{-1}. Consequently, the quantum mechanical excitation energy (T_0 value) for the $\tilde{A}\ ^3\Pi$ state is determined to be 56.1 kcal mol^{-1} (2.43 eV, 19 600 cm^{-1}).

5.7. Bond energy

The Si–SiO bond energy was evaluated from the dissociation energy of the reaction

$$SiSiO(\tilde{X}\ ^3\Sigma^-) \rightarrow Si(^3P) + SiO(\tilde{X}\ ^1\Sigma^+) \quad (10)$$

The bond dissociation energies at the SCF, CCSD, CCSD(T) levels of theory are presented in Table 6. It should be noted that these three methods are size-consistent. The dissociation energy is more sensitive to the level of correlation and basis set size than the excitation energy discussed above. The SCF dissociation energy is not reliable compared with the dissociation energies from the more sophisticated CCSD and CCSD(T) methods. At the highest level of theory, cc-pVQZ CCSD(T), the Si–SiO bond energy is predicted to be $D_e = 26.1$ kcal mol^{-1} (1.13 eV) and $D_0 = 25.2$ kcal mol^{-1} (1.09 eV). This is about 10 kcal mol^{-1} higher than DeKock et al.'s CISD/TZ + 2P result [6], but it is still the lowest of all the carbon/silicon ketenylidene analogues.

5.8. Comparisons among CCO, SiCO, CSiO, and SiSiO

In Table 7 the structural characteristics and energetics are compared for the four ketenylidene type radicals, XYO (X, Y = C, Si). It is first important to mention some discussion given by Kutzelnigg in reference to the character of first and second row atoms [47,48]. The s and p valence atomic orbitals (AOs) of first row atoms are localized in roughly the same region of space, whereas for second row atoms or higher they are much more extended into space. Consequently, single bonds between first row elements are weak and multiple bonds are strong, and vice versa for second row elements. Also, ideal hybridization is realized if the s and p valence AOs are localized in the same region of space and hence have comparable bonding and overlapping capabilities. Only the first row elements possess this property, and this is particularly the case for carbon. In second row elements or higher, the actual valence configurations are somewhere in between the ground configuration and the ideal valence, differing considerably from ideal hybridization. This argument, for our purposes, explains many of the trends that we see amongst these analogues. For instance the trend in the XY bond distance is given as

$$\mathrm{SiSiO} > \mathrm{CSiO} > \mathrm{SiCO} > \mathrm{CCO} \quad (11)$$

and it is apparent that the CO bond lengths deviate from the free diatomic bond length relative to the change in the SiO bond lengths, indicating more interaction with the terminal atom in the CO case. Also the trend in the bond dissociation energy opposes the above sequence (Eq. (11)), which is consistent with the above analysis.

Table 6

[c] From ref. [11].
[d] From this study.
[e] See text and ref. [18].
[f] Bond distances are in Å with the TZ3P(2f) CCSD(T) method.
[g] The Renner parameter is dimensionless.
[h] Dipole moments are in debye with the TZ3P(2f) CISD method. Values are given in chemists' notation where the polarity (+/−) yields a positive value.
[i] Energetics are in kcal mol^{-1} with the cc-pVQZ CCSD(T) method.

Now let us turn to the dipole moments in these analogues, for there is something very interesting that occurs upon excitation. In all cases, the electron density of the molecule shifts toward the oxygen atom upon excitation from the non-bonding lone pair σ orbital to the π orbital. This can be seen visually in Fig. 1 for the SiSiO case and is analogous for all of these molecules. The 11σ orbital extends well past the terminal Si atom and upon excitation to the 4π orbital, which is a SiSi π bonding orbital, the electron migrates closer to the O atom causing the above mentioned shift in electron density. In the case of CCO the migration is great enough to cause the polarity to change sign. A well-known and similar change in polarity is experienced in the diatomic CO molecule [52,53]. The $X\ ^1\Sigma^+$ state of CO has small dipole moment with the surprising polarity of $^-CO^+$. Excitation to the $a\ ^3\Pi$ state involves excitation from a non-bonding lone pair σ orbital from the carbon to a π orbital [54] which in turn shifts polarity to the oxygen causing a flip in the overall polarity of the molecule to $^+CO^-$. Although less pronounced in SiCO, CSiO, and SiSiO, there is definitely an electron density shift toward the oxygen atom, causing the excited state to be more polar. The percent of atomic orbital character for these MOs is presented in Table 9, and it can clearly be seen that the above analysis is correct. Therefore, the trend in this shift is

$$CCO > SiCO > CSiO > SiSiO \quad (12)$$

and the results of Table 9 provide adequate explanation for the this trend follows the p_x character contribution from the O atom to the π involved in excitations (CSiO and SiSiO have nearly the same contribution and dipole moment shift).

The polarities of the ground states of the four radicals are in order of (expressed in chemists notation where the polarity (+/−) is positive)

$$SiSiO > CSiO > SiCO > CCO \quad (13)$$

Recall that the dipole moment for the SiSiO is close to that of diatomic SiO, so this trend is once again an indication of Kutzelnigg's argument for the greater tendency of the carbon atom to hybridize. The trend in the dipole moments for the first excited triplet states follows

$$SiSiO > SiCO > CSiO > CCO \quad (14)$$

The $\tilde{A}\ ^3\Pi$ states of the four radicals are classified as type A Renner–Teller molecules. Upon the $\tilde{A} \leftarrow \tilde{X}$ excitation, the XY distances are shortened, the YO distances are elongated, and the molecular sizes (XO distances) are contracted for all four radicals.

The magnitudes of the Renner–Teller effect for the $\tilde{A}\ ^3\Pi$ states are given by the quantity $\varepsilon\omega$ [20] and are in the order of

Table 8
Orbital energy difference in hartrees between the non-bonding σ orbital and the 4π orbital of XYO

XYO (X, Y = C, Si)	Adiabatic [a]
CSiO	0.0583
CCO	0.0985
SiSiO	0.1064
SiCO	0.1494

[a] Adiabatic refers to the difference between the ground state 11σ orbital energy computed at the optimized TZ2P CISD ground state geometry and the excited state 4π orbital energy computed at the optimized TZ2P CISD excited state geometry.

$$CCO > CSiO > SiCO > SiSiO \quad (15)$$

while the trend in the absolute value of the Renner parameter, ε is

$$CSiO > CCO > SiCO > SiSiO \quad (16)$$

And the trend in the ω_2 bending frequency yields an expected ordering of

$$CCO > SiCO > CSiO > SiSiO \quad (17)$$

Since the trend in the bending frequency seems correct, it would appear that the trend in the Renner parameter is an electronic effect. This characteristic of the Renner parameter was attributed by John Brown to the tendency of the parameter to show the same proportionality to the inverse square root reduced mass of the bending coordinate ($\mu^{-1/2}$) [20]. A literature search for reported trends in the Renner–Teller splitting in a series of molecules produced only a single reference, to the work of Adachi, Kosugi, Shigemasa, and Yagishita [55]. Their work involved studying the R–T splitting in states arising from C $1s \rightarrow \pi^*$ transitions in the molecules CO_2, CSO, and CS_2. They observed the following trend:

$$CO_2 > OCS > CS_2 \quad (18)$$

Although not completely analogous, it would appear to suggest that the substitution of second-row atoms decreases the magnitude of the R–T splitting, which agrees with the trend in $\varepsilon\omega$ above.

The $\tilde{X}$–$\tilde{A}$ splittings of the four species are in the order

$$SiCO > SiSiO > CCO > CSiO \quad (19)$$

This trend can be understood by looking at the orbital energy difference in the non-bonding σ orbital from the ground state and the relaxed π orbital that is occupied after excitation. At the CISD TZ2P geometry, the orbital energy difference in these SCF reference orbitals is given in Table 8. The so-called adiabatic orbital energy difference indicates the splitting allowing for the excited state orbitals to 'relax' after excitation and follows the trend in excitation energies.

6. Concluding remarks

The ground ($\tilde{X}\ ^3\Sigma^-$) and first excited triplet ($\tilde{A}\ ^3\Pi$) electronic states of linear disilaketenylidene (SiSiO) have been studied using ab initio SCF, CISD, EOM-CCSD, CCSD, and CCSD(T) levels of theory. The $\tilde{A}\ ^3\Pi$ state of SiSiO is subject to a Renner–Teller interaction. The two distinct bending vibrational frequencies associated with the $\tilde{A}\ ^3\Pi$ state have been investigated with the EOM-CCSD technique. The $\tilde{A}\ ^3\Pi$ state of SiSiO presents the smallest Renner parameter among the four ketenylidene radicals with 14 valence electrons; however, it has the largest dipole moment. At the highest level of theory employed in this research, cc-pVQZ CCSD(T), the classical $\tilde{X}$–$\tilde{A}$ splitting is determined to be 55.7 kcal mol^{-1} (2.41 eV, 19 500) and the separation including ZPVE is 56.1 kcal mol^{-1} (2.43 eV, 19 600). The Si–SiO bond dissociation energy is predicted to be $D_e = 26.1$ kcal mol^{-1} (1.13 eV) and $D_0 =$ 25.2 kcal mol^{-1} (1.09 eV).

Table 9
Percent of atomic orbital character of selected orbitals for the $\tilde{X}\ ^3\Sigma^-$ state of the ketenylidene XYO (X, Y = C, Si) type radicals at the CISD/TZ3P(2f) optimized geometry

Molecule		X			Y			O		
		%s	%p_x	%p_z	%s	%p_x	%p_z	%s	%p_x	%p_z
CCO	7σ	45.9		10.0	8.4		5.8	1.5		2.5
	$2\pi_x$ [a]		43.7			20.5			21.9

Abstract

A mixture of $[HB(3,5\text{-}(CF_3)_2Pz)_3]Ag(\eta^2\text{-toluene})$ and $[(n\text{-}Pr)_2ATI]GeN_3$ or $[(n\text{-}Pr)_2ATI]SnN_3$ in CH_2Cl_2, rather than undergoing metathesis or nitrogen elimination or silver ion coordination to the nitrogen atoms of the azide moiety, formed 1:1 adducts $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgM(N_3)[(n\text{-}Pr)_2ATI]$ (**1**, M = Ge and **2**, M = Sn) featuring unsupported silver–germanium and silver–tin bonds (where $[HB(3,5\text{-}(CF_3)_2Pz)_3]$ = hydrotris(3,5-bis(trifluoromethyl)pyrazolyl)borate; $[(n\text{-}Pr)_2ATI]$ = N-(*n*-propyl)-2-(*n*-propylamino)troponiminate). Compounds $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ were characterized by X-ray crystallography. The Ag–Ge and Ag–Sn bond distances of **1** and **2** are 2.4146(7) and 2.5943(6) Å, respectively. The azide moieties are linear. The azide group of the germanium adduct adopts a *trans* orientation relative to the GeN_2C_7 ring system upon silver ion coordination whereas the azido moiety of the tin adduct occupies a site above the SnN_2C_7 ring (*cis*). IR spectra of **1** and **2** display $\nu_{asym}(N_3)$ bands at 2083 and 2070 cm^{-1}, respectively. The ^{119}Sn NMR spectrum of **2** shows a broad signal at 90 ppm ($^1J(^{119}Sn-^{107/109}Ag)$ = 4866 Hz). These adducts show unusually high thermal stability. © 2002 Elsevier Science Ltd. 1. Introduction

Azido derivatives of carbon represent the most widely studied group among covalent azides [1–3]. They are excellent starting materials for the preparation of a variety of organic and inorganic compounds [1,2,4–7]. Related azides of heavier group 14 members such as those of silicon(IV) and tin(IV) are also fairly well known [3,8]. Some of these are commercially available as well. In contrast, very little is known about the azide derivatives of low valent group 14 elements [9–12]. One of the difficulties in isolating such species is their tendency to decompose with the elimination of nitrogen. The lead(II) azide $Pb(N_3)_2$, for example, is widely used as a primary explosive [3,13–15]. We described the isolation of several azides of germanium(II) and tin(II) using aminotroponiminate (ATI) and diazapentadienyl (DAP) ligands (Fig. 1) [9,10]. These azides ($[(n\text{-}Pr)_2ATI]MN_3$ and $[(Mes)_2DAP]MN_3$ where M = Ge(II) or Sn(II)) show very good thermal stability.

$[(n\text{-}Pr)_2ATI]MN_3$ $[(Mes)_2DAP]MN_3$

M = Ge or Sn

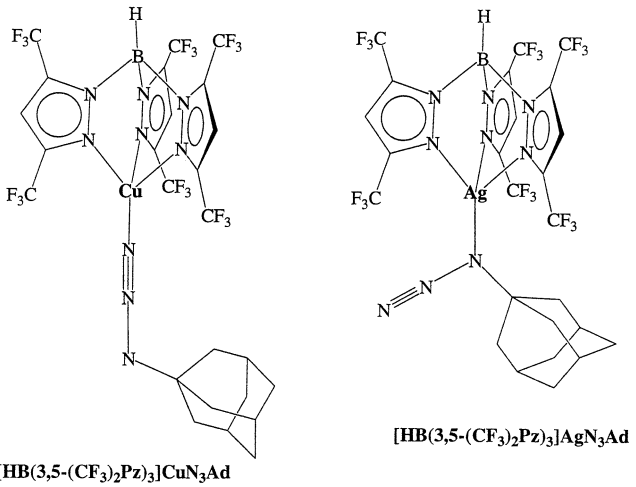

Fig. 2. Thermally stable metal organo azide complexes of copper(I) and silver(I).

There are only a very few other structurally characterized examples of this type known. Those include $Pb(N_3)_2$, $[HB(3,5\text{-}(CH_3)_2Pz)_3]GeN_3$ and $[(C_5H_5)Co\{P(O)(OEt)_2\}_3]GeN_3$ [11,12,14].

There are many transformations of organo azides mediated by transition metal ions [1,2]. It is commonly believed that such processes involve organoazido metal complexes as intermediates [16–22]. However, the isolation and characterization of such species are difficult mainly due to the rapid loss of nitrogen [17,18]. $[HB(3,5\text{-}(CF_3)_2Pz)_3]CuNNN(1\text{-}Ad)$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgN(1\text{-}Ad)NN$ (where 1-Ad = 1-adamantyl) represent two examples of organoazido metal adducts that can be isolated as thermally stable solids (Fig. 2) [23]. As illustrated in Fig. 2, they show different bonding modes, but the azido group remains linear. There are others that show significant distortions to the azido functionality upon metal coordination [19–21,24].

Overall, despite their importance, stable metal complexes containing organo azide ligands are extremely rare [23,25], and those involving divalent main group 14 elements are unknown. Therefore, it would be worthwhile to explore the chemistry between azides such as $[(n\text{-}Pr)_2ATI]MN_3$ or $[(Mes)_2DAP]MN_3$ (where M = Ge or Sn) and transition metal ions. As indicated earlier, metal ions may promote nitrogen elimination, or form isolable adducts with these azides. If adducts are formed, the site of coordination is also of interest because, in contrast to organo azides (e.g. $1\text{-}AdN_3$) where metals coordinate exclusively to azide nitrogen atoms, the azides of divalent group 14 compounds have one additional site (the group 14 lone pair) for metal ion coordination.

In this paper, we report the synthesis of the first transition metal complexes of divalent germanium and tin azides from a reaction between $[(n\text{-}Pr)_2ATI]MN_3$ (where M = Ge or Sn) and a silver(I) derivative of a fluorinated tris(pyrazolyl)borate. The solid state structural data of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ are also reported.

2. Experimental

2.1. General procedures

All manipulations were carried out under an atmosphere of purified nitrogen using either standard Schlenk techniques or in a Vacuum Atmospheres single station drybox equipped with a −25 °C refrigerator. Solvents were purchased from commercial sources and distilled from conventional drying agents prior to use. Glassware was oven-dried at 150 °C overnight. The NMR spectra were recorded at room temperature on a JEOL Eclipse 500 (^1H, 500.16 MHz; ^{19}F, 470.62 MHz; ^{13}C, 125.78 MHz; ^{119}Sn, 186.5 MHz). Proton and carbon chemical shifts are reported in parts per million versus Me_4Si. ^{19}F and ^{119}Sn NMR chemical shifts were referenced to external $CFCl_3$ and Me_4Sn standards, respectively. Melting points were obtained on a Mel-Temp II apparatus. Elemental analyses were performed at the University of Texas at Arlington using a Perkin–Elmer Model 2400 CHN analyzer. $[(n\text{-}Pr)_2ATI]GeN_3$, $[(n\text{-}Pr)_2ATI]SnN_3$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]Ag(\eta^2\text{-toluene})$ were prepared using published procedures [10,26].

2.2. $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ (1)

$[(n\text{-}Pr)_2ATI]GeN_3$ (39 mg, 0.12 mmol) and $[HB(3,5\text{-}(CF_3)_2Pz)_3]Ag(\eta^2\text{-toluene})$ (100 mg, 0.12 mmol) were mixed in dichloromethane (10 mL) at room temperature. Upon mixing, the solution turned bright yellow. After the solution was stirred for 2 h, the solvent was removed under vacuum and the resulting solid was dissolved in toluene. Filtration through Celite and removal of the toluene under vacuum gave $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ as a yellow solid (120 mg, 94%). X-ray quality crystals were grown from hexane at room temperature. M.p.: turns brown around 120 °C and melts 146–148 °C. ^1H NMR ($CDCl_3$): δ 1.04 (t, 6H, $J = 7.5$ Hz, $CH_3CH_2CH_2$), 1.82 (m, 4H, $CH_3CH_2CH_2$), 3.70 (m, 4H, $CH_3CH_2CH_2$), 6.90 (s, 3H, Pz-CH), 6.94 (t, 1H, $J = 9.5$ Hz, H_5), 6.99 (d, 2H, $J = 11.3$ Hz, $H_{3,7}$), 7.48 (m, 2H, $H_{4,6}$); ^{19}F NMR ($CDCl_3$): δ −58.6 (d, $^5J(F,H) = 2.2$ Hz), −60.7 (s); $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 11.2 ($CH_3CH_2CH_2$), 21.6 ($CH_3CH_2CH_2$), 47.3 ($CH_3CH_2CH_2$), 106.3 (CH), 116.0 (C_5), 119.3 (q, $^1J(C,F) = 271$ Hz, CF_3), 120.4 (q, $^1J(C,F) = 270$ Hz, CF_3), 125.2 ($C_{3,7}$), 138.4 ($C_{4,6}$), 140.1 (q, $^2J(C,F) = 40$ Hz, CCF_3), 143.5 (q, $^2J(C,F) = 38$ Hz, CCF_3), 159.1 ($C_{2,8}$); IR (KBr, cm^{-1}): 3338 (w), 3144

(w), 2974 (m), 2606 (w, B-H), 2083 (s, asym N_3), 1598 (m), 1558 (w), 1523 (m), 1447 (m), 1423 (m), 1397 (m), 1361 (w), 1270 (s), 1145 (s), 1082 (w), 1039 (s), 987 (m), 886 (w), 830 (m), 783 (m), 736 (m), 708 (w), 665 (w), 612 (w), 485 (w), 419 (m); *Anal.* Calc. for $C_{28}H_{23}AgBF_{18}GeN_{11}$: C, 32.13; H, 2.21; N, 14.72. Found: C, 32.04; H, 2.24; N, 14.39%.

2.3. [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[(n-Pr)$_2$ATI] (2)

[(n-Pr)$_2$ATI]SnN_3 (44 mg, 0.12 mmol) and [HB(3,5-$(CF_3)_2Pz)_3$]Ag(η^2-toluene) (100 mg, 0.12 mmol) were mixed in dichloromethane (10 mL) at room temperature. Upon mixing, the solution turned bright yellow in color. After the solution was stirred for 2 h, the solvent was removed under vacuum and the resulting solid was dissolved in toluene. Filtration through Celite and removal of the toluene under vacuum gave [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[(n-Pr)$_2$ATI] as a yellow solid (120 mg, 91%). X-ray quality crystals were grown from toluene–hexane at room temperature. M.p.: turned dark red and decomposed around 135–140 °C. ^{1}H NMR ($CDCl_3$): δ 1.09 (t, 6H, $J = 7.3$ Hz, $CH_3CH_2CH_2$), 1.97 (m, 4H, $CH_3CH_2CH_2$), 3.70 (m, 4H, $CH_3CH_2CH_2$), 6.88 (t, 1H, $J = 9.3$ Hz, H_5), 6.92 (s, 3H, Pz-CH), 6.99 (d, 2H, $J = 11.5$ Hz, $H_{3,7}$), 7.44 (m, 2H, $H_{4,6}$); ^{19}F NMR ($CDCl_3$): δ −58.7 (d, ^5J(F,H) = 3.3 Hz), −60.6 (s); ^{13}C{^{1}H} NMR ($CDCl_3$): δ 11.5 ($CH_3CH_2CH_2$), 23.6 ($CH_3CH_2CH_2$), 50.3 ($CH_3CH_2CH_2$), 106.4 (CH), 116.5 (C_5), 119.2 (q, ^1J(C,F) = 271 Hz, CF_3), 120.4 (q, ^1J(C,F) = 270 Hz, CF_3), 124.4 ($C_{3,7}$), 137.4 ($C_{4,6}$), 140.3 (q, ^2J(C,F) = 40 Hz, CCF_3), 143.5 (q, ^2J(C,F) = 38 Hz, CCF_3), 161.7 ($C_{2,8}$); ^{119}Sn-{^{1}H} NMR ($CDCl_3$): δ 90 (d, $^1J(^{119}Sn-^{109/107}Ag)$ = 4866 Hz); IR (KBr, cm^{-1}): 3138 (w), 2973 (w), 2940 (w), 2884 (w), 2632 (w, B-H), 2070 (s, asym N_3), 1597 (m), 1558 (m), 1514 (m), 1440 (w), 1421 (m), 1391 (m), 1364 (m), 1274 (s), 1248 (w), 1174 (s), 1078 (m), 1041 (s), 991 (m), 886 (w), 856 (w), 831 (m), 778 (w), 735 (m), 696 (w), 612 (w), 565 (w), 483 (w); *Anal.* Calc. for $C_{28}H_{23}AgBF_{18}N_{11}Sn$: C, 30.77; H, 2.12; N, 14.10. 2.4. X-ray structure determination

A suitable crystal covered with a layer of hydrocarbon oil was selected and attached to a glass fiber and immediately placed in the low-temperature nitrogen stream [27]. Data collections were carried out at low temperature on a Siemens P4 diffractometer equipped with a LT-2A device for low-temperature work and graphite monochromated Mo Kα radiation ($\lambda = 0.710$ 73 Å). The unit cell parameters of [HB(3,5-$(CF_3)_2Pz)_3$]-AgGe(N_3)[(n-Pr)$_2$ATI] and [HB(3,5-$(CF_3)_2Pz)_3$]AgSn-(N_3)[(n-Pr)$_2$ATI] were determined by least-squares refinement of 39 and 46 reflections, respectively. Three standard reflections were measured at every 97 data points to check for crystal deterioration and/or misalignment. No significant deterioration in intensity was observed. Data were corrected for Lorentz, polarization, and absorption (using ψ scans) effects. Structures were solved by direct methods followed by successive cycles of full-matrix least-squares refinement on F^2 and difference Fourier analysis. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms on boron were located from the difference map. The remaining hydrogen atoms were included at calculated positions. Software programs and the sources of scattering factors are contained in the Bruker SHELXTL 5.1 software package [28] provided by Bruker Analytical X-ray Instruments, Inc.

Cell dimensions and structure refinement data for [HB(3,5-$(CF_3)_2Pz)_3$]AgGe(N_3)[(n-Pr)$_2$ATI] and [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[(n-Pr)$_2$ATI] are listed in Table 1. Selected bond lengths and angles are given in Tables 2 and 3.

3. Results and discussion

Reaction of [HB(3,5-$(CF_3)_2Pz)_3$]Ag(η^2-toluene) and [(n-Pr)$_2$ATI]MN_3 (where M = Ge or Sn) in dichloromethane produces the very interesting adduct compounds [HB(3,5-$(CF_3)_2Pz)_3$]AgGe(N_3)[(n-Pr)$_2$ATI] (**1**) and [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[(n-Pr)$_2$ATI] (**2**) in high yield (Scheme 1). The essentially quantitative formation of a single product is particularly noteworthy considering the potential for several possible outcomes

from such a reactant combination. For instance, metal catalyzed decomposition reactions of [$(n$-Pr$)_2$ATI]MN_3 are possible. However, we did not observe the elimination of nitrogen gas, which is a common sign of azide decomposition. Silver halide metathesis is also a facile process [29,30]. Thus, when [HB(3,5-$(CF_3)_2Pz)_3$]Ag is treated with a pseudo-halide like [$(n$-Pr$)_2$ATI]MN_3, a metathesis process leading to [$(n$-Pr$)_2$ATI]M[HB(3,5-$(CF_3)_2Pz)_3$] adducts and AgN_3 is also a possibility. Interestingly, this did not occur either. This is not totally surprising since the chloride in [$(n$-Pr$)_2$ATI]MCl is inert to abstraction with [HB(3,5-$(CF_3)_2Pz)_3$]Ag [31]. Other possibilities include silver ion coordination to the azide moiety, via either the terminal nitrogen or the substituted nitrogen atom, or to the lone pair on the Ge(II) or Sn(II) atom.

Compounds [HB(3,5-$(CF_3)_2Pz)_3$]AgGe(N_3)[$(n$-Pr$)_2$ATI] and [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[$(n$-Pr$)_2$ATI] exhibit higher melting temperatures (>120 °C) and better air stability than their silver free counterparts [$(n$-Pr$)_2$ATI]MN_3 (where M = Ge or Sn) [10]. Indeed, [HB(3,5-$(CF_3)_2Pz)_3$]AgGe(N_3)[$(n$-Pr$)_2$ATI] and [HB(3,5-$(CF_3)_2Pz)_3$]AgSn(N_3)[$(n$-Pr$)_2$ATI] may be handled for a

Scheme 1.

longer time in air before decomposing. They show good solubility in solvents such as dichloromethane and toluene, and moderate solubility in hexanes.

IR spectra of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ in KBr display strong absorption bands at 2083 and 2070 cm^{-1}, respectively. These bands can be assigned to the N_3 asymmetric stretching vibrations [1,8]. The $\nu_{asym}(N_3)$ bands for compounds **1** and **2** both appear at a slightly higher frequency compared to those of $[(n\text{-}Pr)_2ATI]GeN_3$ (2048 cm^{-1}) and $[(n\text{-}Pr)_2ATI]SnN_3$ (2039 cm^{-1}) [10]. It is difficult to predict whether the products show any direct interaction between the silver ion and azide moiety solely on $\nu_{asym}(N_3)$ data. For example, the $\nu_{asym}(N_3)$ band does not change much upon 1-AdN_3 ($\nu_{asym}(N_3) = 2110$ cm^{-1}) coordination to silver(I) ion as in $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgN(1\text{-}Ad)NN$ ($\nu_{asym}(N_3) = 2120$ cm^{-1}) [23].

The room temperature NMR (^1H, ^{13}C, ^{19}F) spectra of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ display resonances for three equivalent pyrazolyl rings. Chemical shift values corresponding to the tris(pyrazolyl)borate moiety are very similar to those observed for various $[HB(3,5\text{-}(CF_3)_2Pz)_3]^-$ adducts [23,26,32–39]. The ^{119}Sn NMR spectroscopic data of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ clearly suggest a strong interaction between the silver ion and the tin center in solution. It shows a broad doublet centered at 90 ppm. The $^1J(^{119}Sn-^{109/107}Ag)$ of 4866 Hz ($^{109/107}Ag$ not resolved) is in the range observed for other structurally characterized compounds featuring a direct Ag–Sn bond. For example, $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(Cl)[(n\text{-}Pr)_2ATI]$ and $[(THF)Ag(\mu\text{-}SCN)Sn\{CH(SiMe_3)_2\}_2]_2$ show broad signals at 117 ppm ($^1J(^{119}Sn-^{109/107}Ag) = 5234$ Hz) and 250 ppm ($^1J(^{119}Sn-^{109}Ag) = 4632$, $^1J(^{119}Sn-^{107}Ag) = 4063$ Hz) in their ^{119}Sn NMR spectra, respectively [40,41]. The silver free $[(n\text{-}Pr)_2ATI]SnN_3$ displays a broad singlet at a higher frequency (-122 ppm) [10].

The X-ray crystallographic data for these compounds reveal a Ag–Ge bond for **1** and a Ag–Sn bond for **2** (Figs. 3 and 4). Neither compound shows bonding

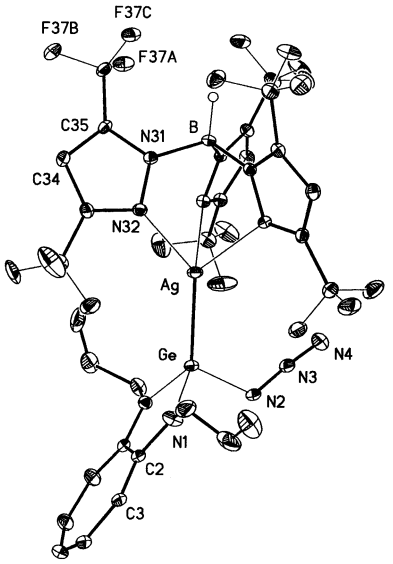

Fig. 3. Molecular structure of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ (**1**), hydrogen atoms except the one on boron have been omitted for clarity.

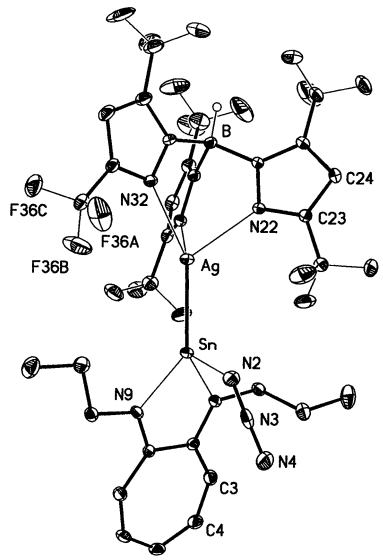

Fig. 4. Molecular structure of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ (**2**), hydrogen atoms except the one on boron have been omitted for clarity.

between one of the azide nitrogens and the silver atom, as has been observed in organoazide compounds. The lone pairs on the germanium and tin atoms appear to be more favorable for bonding with silver than the lone pairs on any of the nitrogen atoms of the azide moiety [42]. The silver–germanium bond distance of **1** is 2.4146(7) Å, while the silver–tin bond distance of **2** is 2.5943(6) Å. A longer distance for the Ag–Sn bond is expected based on the larger atomic radius of tin. Compounds **1** and **2** belong to a rare class of structurally characterized molecules with unsupported silver–germanium and silver–tin bonds [31,41,43].

The silver and germanium atoms of **1** show tetrahedral coordination geometry. The heterobicyclic C_7N_2Ge ring system is planar. The Ag–Ge distance in **1** may be compared to those of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(Cl)[(Me)_2ATI]$ (2.4215(9) Å) and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(OSO_2CF_3)[(Me)_2ATI]$ (2.4116(10) Å) [31]. The $Ge–N_{ring}$ distances are slightly shorter and $N_{ring}–Ge–N_{ring}$ angle is slightly larger in the silver adduct **1** compared to the corresponding distances and angle of the silver free species $[(n\text{-}Pr)_2ATI]GeN_3$ (Table 4) [10]. The $Ge–N_{azide}$ distance also shows a similar trend. This is probably a result of an increased *s*-character of the Ge–N bond due to silver ion coordination to the germanium atom [31,44]. An alternative explanation for the shortening of M–N is that coordination of the Lewis acid silver ion to Ge and Sn causes them to become more like M(IV) species (with increased formal positive charge) leading to a decrease in M–N bond length [45].

The azide moiety of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ is essentially linear. Interestingly, the X-ray crystal structure of $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ reveals an azide moiety turned away from the C_7N_2Ge ring plane while structural data for $[(n\text{-}Pr)_2ATI]GeN_3$ show an azide group in the *cis* orientation with the ring system. DFT calculations have shown the *trans* arrangement to be very slightly less stable by 0.2 kcal mol^{-1} for the related $[(Me)_2ATI]GeN_3$ system [10].

The azide moieties in both $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ and $[(n\text{-}Pr)_2ATI]SnN_3$ are in the *cis* arrangement. Compound **2** features a $Sn–N_{azide}$ bond distance of 2.157(4) Å that is slightly shorter than the average $Sn–N_{azide}$ bond distance of 2.242(5) Å for $[(n\text{-}Pr)_2ATI]SnN_3$ ($[(n\text{-}Pr)_2ATI]SnN_3$ crystallizes with two molecules in the asymmetric unit) [10]. Thus, coordination to the silver ion results in a shortening of the $Sn–N_{azide}$ bond. The azide moiety is linear as evident from the NNN bond angle of 177.3(5)°. The heterobicyclic C_7N_2Sn ring system is planar.

Overall, results from this study show that it is possible to isolate thermally stable transition metal adducts of divalent group 14 azides. The silver ion preferentially coordinates to the germanium and tin atom even in the presence of donor sites of the azide moiety. The theory of Hard and Soft Acids and Bases may explain this tendency [42]. Compounds $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgGe(N_3)[(n\text{-}Pr)_2ATI]$ and $[HB(3,5\text{-}(CF_3)_2Pz)_3]AgSn(N_3)[(n\text{-}Pr)_2ATI]$ also belong to a rare group of structurally characterized compounds with unsupported Ag–Ge and Ag–Sn bonds. These adducts may also be considered as models for intermediates related to the silver salt metathesis process [29–31,46,47].

Synthesis and structural characterization of the first trialkylguanidinate and hexahydropyramidopyramidinate complexes of tin

Stephen R. Foley, Glenn P.A. Yap, Darrin S. Richeson *

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received 28 June 2001; accepted 7 December 2001

Abstract

The first guanidinate complexes of tin have been prepared using *N*,*N*′,*N*″-trialkylguanidinates ($[(RN)_2C(NRH)]^-$; R = cyclohexyl; isopropyl) and 1,3,4,6,7,8-hexahydro-2*H*-pyramido[1,2-*a*]pyramidinate (hpp^-) as ligands. The direct reaction between triisopropylguanidine and $SnCl_4$ provided the complex $\{[^iPrN]_2C[NH^iPr]\}SnCl_3$ (**1**) along with concomitant formation of the guanidinium salt $\{C[NH^iPr]_3\}^+[SnCl_5(THF)]^-$ (**2**). The Sn(II) guanidinate complexes $\{(C_6H_{11}N)_2C[NH(C_6H_{11})]\}_2Sn$ (**3**) and $\{CN[N(CH_2)_3]_2\}_2Sn$ (**4**) were prepared through metathesis reactions between 0.5 equiv. $SnCl_2$ and $(C_6H_{11}N)_2C[NH(C_6H_{11})]Li$ or hppLi, respectively. Complex **4** is the first reported mononuclear complex of this ligand. In contrast, the reaction of hppLi with 1 equiv. $SnCl_2$ afforded a bridging dinuclear species, $\{CN[N(CH_2)_3]_2SnCl\}_2$ (**5**). A second mononuclear complex of the hpp^- ligand, $\{CN[N(CH_2)_3]_2\}_2SnCl_2$ (**6**), was the product obtained from the reaction of 2 equiv. of hppLi with $SnCl_4$. The full structural details of compounds **1** and **3**–**6** are reported. In the case of compounds **1** and **3** these results revealed a distinctly unsymmetrical bonding mode for the bidentate guanidinate ligand and suggest variable degrees of π delocalization with the ligand. The geometries of the Sn centers in **3**, **4** are derived from distorted trigonal bipyramidal coordination with a stereochemically active lone pair occupying one coordination site. In contrast, complex **5** displayed a geometry derived from a tetrahedral ligand array with one vertex occupied by a lone pair of electrons. Complex **6** is six coordinate and possesses 2 equiv. chelating bidentate hpp^- ligands and two *cis*-chloro groups. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Guanidinate; 1,3,4,6,7,8-Hexahydro-2*H*-pyramido[1,2-*a*]pyramidinate; Tin; Mononuclear; Dinuclear

1. Introduction

Amidinates are versatile ligands that have been used to stabilize fundamentally interesting and catalytically active complexes of tin and germanium. For example, the terminal chalcogenido complexes, $(CyNC(^tBu)NCy)_2Sn{=}S$ and $(CyNC(^tBu)NCy)_2Ge{=}E$ ($Cy = C_6H_{11}$; E = S, Se), were prepared by oxidative addition of styrene sulfide or elemental selenium to the corresponding M(II) precursors, $(CyNC(^tBu)NCy)_2M$ (M = Ge, Sn) [1,2]. An unusual cyclotetrasulfido complex, $[CyNC(Me)NCy]Sn[N(SiMe_3)_2]S_4$, was prepared with an amidinate supporting ligand [3]. Many of these complexes function as excellent catalysts for the rapid and selective cyclotrimerization of aryl isocyanates to yield isocyanurates [3,4]. Additional variation of the central N–C–N ligand framework can be achieved by employing guanidinate ligands (Chart 1). Guanidinate ligands should offer all of the coordination flexibility of amidinates and may provide added steric and electronic variability. For example, the presence of a third nitrogen center in these species allows for variation of the substitution pattern to give di-, tri-, or tetrasubstituted ligands. The main resonance contributions for

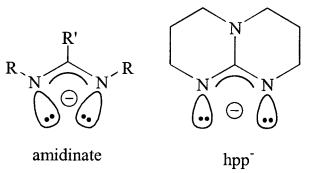
Chart 2.



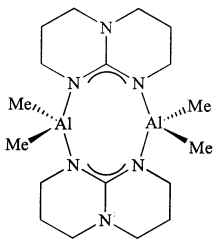


Chart 3.

N,*N*′,*N*″-trisubstituted guanidinate anions are summarized in Chart 2. The zwitterionic structure **I** does not have an analogy for amidinate ligands.

Guanidinates have received relatively limited attention as ligands in comparison with amidinates, with only three reports for main group metal complexes of *N*,*N*′,*N*″-trisubstituted guanidinate anions appearing in the literature. These consist of the lithium salts $Li_2(C(NPh)_3)$ [5], $Li_2(C(N^tBu)_3)$ [6], $Li(C(N^tBu)_2(N(H)^tBu))$ [6] and the only p-block element complex, $[(^iPrN)_2C(NH^iPr)][(^iPrN)_2C(N^iPr)]Sb$ [7].

An interesting variation on the guanidinate framework, in tetrasubstituted form, is provided by the anion of 1,3,4,6,7,8-hexahydro-2*H*-pyramido[1,2-*a*]pyramidine (hpp^-) (Chart 1). The steric bulk as well as the orientation of the N lone pairs of this heterobicyclic system is substantially restricted by the tethering of the N centers. For example, it has been suggested that the tying back of the N–R groups and the resultant projection of the σ donor orbitals in a parallel direction (Chart 3) is a critical difference between this species and the amidinate anion and is one of the reasons that hpp^- promotes the formation of bridged dinuclear transition metal complexes [8]. The restrictions of the bicyclic framework should enhance the correct orientation for π-overlap of the central C center with all three N centers and may stabilize resonance structure **I** and Y-conjugation within the ligand.

The only reported main group metal complex of hpp^- is $[(\mu\text{-hpp})AlMe_2]_2$ (**II**) [9]. As with all of the reported transition metal complexes, this aluminum complex adopts a dimeric structure in which the hpp^- ligands bridge two $AlMe_2$ moieties.

II

Given the general lack of guanidinate complexes of main group metals and of tin in particular, application of these ligands to group 14 metals is warranted and we now report the first Sn(II) and Sn(IV) complexes with guanidinate ligands employing both monoanionic *N*,*N*′,*N*″-trialkylguanidinates and the pyramidinate anion (hpp^-). These include the first examples of mononuclear complexes displaying chelating hpp^- ligand.

2. Experimental

2.1. General procedure

All manipulations were carried out in either a Vacuum Atmospheres drybox or under nitrogen using standard Schlenk-line techniques. Diethyl ether, toluene and THF were sparged with nitrogen then dried by passage through column of activated alumina using an apparatus purchased from Anhydrous Engineering. CH_2Cl_2 and $CDCl_3$ were distilled under nitrogen from CaH_2. Deuterated benzene was distilled under nitrogen from Na/K alloy. 1,3,4,6,7,8-Hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine (Hhpp), $SnCl_2$, $SnCl_4$ and MeLi (1.4 M in diethyl ether) were purchased from Aldrich and used without further purification.

NMR spectra were recorded on a Varian Gemini 200 MHz spectrometer with deuterated benzene or $CDCl_3$ as a solvent and internal standard. All elemental analyses were run on a Perkin–Elmer PE CHN 4000 elemental analysis system. All melting points were determined on a Gallenkamp Melting Point Apparatus in sealed capillary tubes.

2.2. Preparation of $\{[(CH_3)_2CHN]_2C[NHCH(CH_3)_2]\}SnCl_3$ (1) and $\{[(CH_3)_2CHNH]_3C\}SnCl_5(THF)$ (2)

To a solution of 0.500 g *N*,*N*′,*N*″-triisopropylguanidine (2.70 mmol) in toluene (50 ml) was added 1 equiv. $SnCl_4$ (0.703 g, 2.70 mmol). The reaction mixture was stirred for 12 h and then was filtered to remove complex **2** as an insoluble solid. Complex **1** was isolated by removal of the reaction solvent under vacuum. White crystals of **1** were obtained from diethyl ether at −34 °C (0.54 g, 49% yield). ^1H NMR (C_6D_6, ppm): 3.20, (br, overlapping signals CH, 3H); 3.19 (br, NH, 1H); 1.20 (d, $J_{HH} = 6.6$ Hz, CH_3, 12H); 0.62 (d, $J_{HH} = 6.0$ Hz, CH_3, 6H). ^{13}C NMR (C_6D_6, ppm): 160.1 (s, N*C*N); 48.2 (s, $C(CH_3)_2$); 46.4 (s, $C(CH_3)_2$); 23.4 (s, CH_3); 23.2 (s, CH_3). ^{119}Sn NMR (C_6D_6, ppm vs. $SnMe_4$): −356.9. *Anal.* Found: C, 29.76; H, 5.55; N, 9.81. Calc. for $C_{10}H_{22}Cl_3N_3Sn$: C, 29.34; H, 5.42; N, 10.26%. m.p. 54–56 °C.

Solid **2** that was isolated from the above filtration was washed with toluene (3 × 5 ml) and dried. White crystals of **2** were obtained from CH_2Cl_2 at −34 °C (0.46 g, 35% yield). ^{1}H NMR ($CDCl_3$, ppm): 5.18 (d, $J_{NH} = 7.8$ Hz, NH, 3H); 4.37 (br, THF, 4H); 3.88 (br, CH, 3H); 2.01 (br, THF, 4H); 1.33 (d, $J_{HH} = 6.4$ Hz, CH_3, 18H). ^{13}C NMR ($CDCl_3$, ppm): 152.1 (s, N*C*N); 45.3 (s, $C(CH_3)_2$); 22.7 (s, CH_3). *Anal.* Found: C, 30.62; H, 5.85; N, 7.51. Calc. for $C_{10}H_{24}Cl_5N_3SnTHF$: C, 30.44; H, 5.47; N, 7.61%. m.p. 133–134 °C.

2.3. Preparation of {[(C$_6$H$_{11}$)N)$_2$C[NHC(C$_6$H$_{11}$)]}$_2$Sn (3)

To a solution of 0.500 g *N*,*N*′,*N*″-tricyclohexylguanidine (1.64 mmol) in diethyl ether (40 ml) was added 1 equiv. MeLi (1.17 ml, 1.4 M, 1.64 mmol). The solution was stirred for 30 min followed by addition of 0.5 equiv. $SnCl_2$ (0.155 g, 0.82 mmol). The reaction mixture was stirred for an additional 12 h, filtered to remove the LiCl precipitate and the solvent was removed under vacuum. Crystals of **3** were obtained from diethyl ether at −34 °C (0.47 g, 78% yield). ^{1}H NMR (C_6D_6, ppm): 3.95, (br, C_6H_{11}, 2H); 3.40 (br d, $J_{NH} = 11$ Hz, NH, 2H); 3.10 (br, C_6H_{11}, 2H); 2.90 (br, C_6H_{11}, 2H); 2.19–0.74 (m, C_6H_{11}, 60H). ^{13}C NMR (C_6D_6, ppm): 148.4 (s, N*C*N); 55.0, 52.0, 49.2, 35.9, 34.7, 34.0, 26.8, 26.6, 25.9, 25.6, 25.3 (11s, C_6H_{11}, intensity ratio:1:1:1:2:2:2:1:1:1:4:2). *Anal.* Found: C, 62.29; H, 9.56; N, 11.11. Calc. for $C_{38}H_{68}N_6Sn$: C, 62.72; H, 9.42; N, 11.55%. m.p. 163–164 °C.

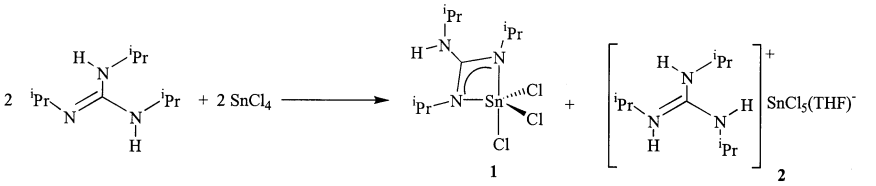
2.4. Preparation of {CN[N(CH$_2$)$_3$]$_2$}$_2$Sn (4)

To a solution of 0.300 g Hhpp (2.16 mmol) in THF (35 ml) was added 1.54 ml of MeLi (1.4 M, 2.16 mmol). Gas evolution was observed during the addition. The solution was stirred for 2 h then 0.5 equiv. $SnCl_2$ (0.204 g, 1.08 mmol) was added. The solution was stirred for an additional 24 h, filtered to remove LiCl and the solvent removed under vacuum. White crystals of **4** were obtained from THF at −34 °C (0.31 g, 73% yield). ^{1}H NMR ($CDCl_3$, ppm): 3.25, (br, CH_2, 16H); 1.85 (br, CH_2, 8H). The low solubility of **4** prevented us from obtaining a ^{13}C NMR spectrum. *Anal.* Found: C, 42.01; H, 6.10; N, 20.85. Calc. for $C_{14}H_{24}N_6Sn$: C, 42.56; H, 6.12; N, 21.27%. m.p. 154–156 °C.

2.5. Preparation of {CN[N(CH$_2$)$_3$]$_2$SnCl}$_2$ (5)



Dropwise addition of 1.54 ml of MeLi (1.4 M, 2.16 mmol) to a THF (35 ml) solution of 0.300 g Hhpp (2.16 mmol) resulted in gas evolution and formation of a pale yellow solution. This solution was stirred for 2 h then 1 equiv. $SnCl_2$ (0.408 g, 2.15 mmol) was added. The reaction mixture was stirred for an additional 24 h, filtered to remove LiCl and the solvent removed under vacuum. White crystals of **5** were obtained from CH_2Cl_2 at −34 °C (0.40 g, 63% yield). ^{1}H NMR ($CDCl_3$, ppm): 3.40, (br, CH_2, 8H); 3.20 (br, CH_2, 8H); 1.94 (br, CH_2, 8H). ^{13}C NMR ($CDCl_3$, ppm): 144.9 (s, N*C*N); 47.4 (s, CH_2); 40.9 (br, CH_2); 23.6 (br, CH_2). *Anal.* Found: C, 27.02; H, 4.23; N, 12.58. Calc. for $C_{14}H_{24}Cl_2N_6Sn_2(CH_2Cl_2)$: C, 26.91; H, 3.91; N, 12.55%. m.p. 175 °C (dec.).

2.6. Preparation of {CN[N(CH$_2$)$_3$]$_2$}$_2$SnCl$_2$ (6)

Dropwise addition of 2.56 ml of MeLi (1.4 M, 3.58 mmol) to a THF (50 ml) solution of 0.500 g Hhpp (3.59 mmol) resulted in gas evolution and formation of a pale yellow solution. This solution was stirred for 30 min then 0.5 equiv. $SnCl_4$ (0.470 g, 1.80 mmol) was added. The reaction mixture was stirred for an additional 24 h, filtered to remove LiCl and the solvent removed under vacuum. White crystals of **6** were obtained from THF at −34 °C (0.40 g, 48% yield). ^{1}H NMR ($CDCl_3$, ppm): 3.22, (br, CH_2, 8H); 3.10 (br, CH_2, 8H); 1.91 (br, CH_2, 8H). ^{13}C NMR ($CDCl_3$, ppm): 155.4 (s, N*C*N); 46.2 (s, CH_2); 40.4 (br, CH_2); 23.7 (br, CH_2). *Anal.* Found: C, 36.50; H, 5.56; N, 17.74. Calc. for $C_{14}H_{24}Cl_2N_6Sn$: C, 36.08; H, 5.19; N, 18.03%.

2.7. Structural determinations for 1, 3, 4, 5 and 6

Single crystals were mounted on thin glass fibers using viscous oil and then cooled to the data collection temperature. Crystal data and details of the measure-

Scheme 1.

ments are summarized in Tables 1 and 4. Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° ω-scans at 0°, 90°, and 180° in ϕ. Unit-cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied. The structures were solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHELXTL 5.1 program library.

3. Results and discussion

3.1. *N,N′,N″*-Trialkylguanidinate complexes of tin

The reaction of *N,N′,N″*-triisopropylguanidine with $SnCl_4$ proceeded smoothly at room temperature as depicted in Scheme 1 to give complexes **1** and **2**. In this case, we envisage the parent guanidine functioning as the base to generate the guanidinate anion bonded to **1** and the guanidinium cation of compound **2** [10]. The two products of this reaction were easily separated due to their differences in solubility and we were able to propose formula for each species on the basis of NMR spectroscopic and microanalytical characterization. The ^{1}H and ^{13}C NMR spectra of complex **1** show two sets of isopropyl resonances in a ratio of 2:1 consistent with formation of a monoanionic ligand with rapid rotation of the N(H)^{i}Pr group at room temperature. The most obvious change in the ^{13}C NMR for the guanidine upon deprotonation and coordination is a shift for the central sp^2 carbon, CN_3, from 148 to 160 ppm. This is in accord with the formulation for **1** as a monoanionic guanidinate complex [11]. Complex **1** was stable in solution at temperatures up to 125 °C.

Complex **2**, $[(^i\mathrm{PrNH})_3C^+][SnCl_5(THF)^-]$, is apparently derived from the reaction of guanidinium hydrochloride, the byproduct in the formation of **1**, with $SnCl_4$. The ^{1}H and ^{13}C NMR spectra of **2** are consistent with formation of guanidinium cation and clearly show only one set of resonances for the equivalent ^{i}Pr groups of this species [12].

Further confirmation of the connectivity of **1** comes from a single crystal X-ray diffraction study (Table 1). The resultant structure with atom labeling scheme is shown in Fig. 1 and corresponding values for bond distances and angles are given in Table 2. These results confirm the pseudotrigonal bipyramidal coordination environment for the Sn(IV) center consisting of one chelating bidentate guanidinate ligand spanning axial/equatorial sites and three chloride ligands. The pseudo-equatorial plane is defined by N(1) of the guanidinate ligand and Cl(1) and Cl(2) (Σ angles = 357°). The pseudo-axial vector defined by Cl(3)–Sn–N(2) exhibits an angle of 159.76(7)°.

While the sum of the angles around the central carbon, C(7), and N(2) of the NCN framework indicate planarity, the sum of angles around N(1) is only 349°, possibly indicating that it retains some sp^3 character. As a result, the ligand does not yield a planar four-membered ring with the Sn center. Further asymmetry is observed in the ligand with the N(1)–C(7) distance (1.361(4) Å) being slightly longer than the N(2)–C(7) distance (1.341(3) Å). The third guanidinate nitrogen, N(3), lies in the plane of the ligand (Sn–C(7)–N(3) 179.1(2)°) and the C(8)–N(3)–C(7) angle of 127.3(3)° suggests sp^2 hybridization about N(3). The short N(3)–C(7) distance of 1.339(4) Å indicates a degree of multiple bonding between these centers. For conjugation of the p orbital of an sp^2 N(3) with the π system of

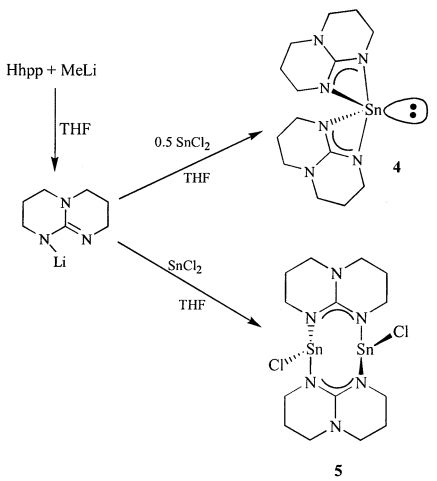
the N(1)–C(7)–N(2) group, the plane defined by C(8)–N(3)–C(7) should be coincident with the plane defined by N(1)–C(7)–N(2). The observed angle between these two planes of 32.9° allows some degree of π bonding between N(3) and C(7). On the basis of these results it appears that all three C(7)–N bonds of the guanidinate have some degree of double bond character with resonance contributors **II** and **III** being particularly important in a bonding description for **1**.

In contrast to the above reaction of $SnCl_4$, direct reaction of guanidine and $SnCl_2$ was not a successful method for generating a guanidinate complex of Sn(II). We attribute this to the reduced acidity of Sn(II) relative to Sn(IV). Therefore, an alternative metathetical route for introduction of guanidinate anions was investigated that employed the lithium salt of *N*,*N*′,*N*″-tricyclohexylguanidinate in reaction with $SnCl_2$. Following the pathway shown in Scheme 2, $[(CyN)_2C(HNCy)]_2Sn$ (**3**) ($Cy = C_6H_{11}$) was isolated in 78% yield. When the reaction is performed with an equimolar ratio of guanidinate and $SnCl_2$, in an attempt to generate a monoguanidinato tin(II) chloride species, only complex **3** and unreacted $SnCl_2$ were isolated.



The ^1H and ^{13}C NMR spectra of **3** displayed three independent cyclohexyl groups of equal intensity and are consistent with a rigid geometry derived from a trigonal bipyramid with an equatorial site occupied by a lone pair of electrons. One signal arises from a pair of unique NCy groups which occupy a pseudoequatorial position, another from the pair that resides in the pseudoaxial position, and the two noncoordinated N(H)Cy groups provide a third resonance.

In order to confirm the geometry of **3** and clarify the structural details for the guanidinate ligand, an X-ray diffraction study was performed (Table 1). From Fig. 2, it is clear that the environment about the Sn(II) center consists of two chelating bidentate guanidinate anions and that the geometry of **3** is consistent with the spectroscopic data. The two ligands are made equivalent by a crystallographic C_2 axis. Selected bond distances and angles for **3** are provided in Table 3.

The pseudoaxial vector for **3** is defined by N(1)–Sn–N(1A), with an angle of 140.4(3)° is heavily distorted from linearity due to the restricted bite angle (58.1(2)°) of the ligands. This bite angle is typical of both amidinates and guanidinates [1,11,13]. Like complex **1**, the guanidinate ligands in **3** are non-planar; while the sum of the angles around N(2) is 360°, the angles around N(1) only sum to 344°. The N(1)–C(19)

distance (1.306(9) Å) is shorter than that of N(2)–C(19) (1.344(8) Å), suggesting a degree of localization of the π bond between N(1) and C(19). While the noncoordinated guanidinate nitrogen, N(3), lies in the plane of the ligand and the C(8)–N(3)–C(7) angle of 118.3(6)° suggests sp^2 hybridization for N(3), the N(3)–C(19) distance of 1.435(9) Å indicates little π interaction between these centers. Consistent with this is the observed angle of 57.3° between the plane defined by C(18)–N(3)–C(19) and that defined by N(1)–C(19)–N(2).

3.2. Hexahydro-2H-pyramido[1,2-a]pyramidinate complexes of tin

The lithium salt of hpp$^-$ was readily prepared by reaction of Hhpp with 1 equiv. MeLi. Subsequent reaction with $SnCl_2$ follows one of two paths depending on the reaction stoichiometry (Scheme 3). Addition of 0.5 equiv. $SnCl_2$ resulted in the formation of a mononuclear complex $(hpp)_2Sn$ (**4**) in 73% yield while a stoichiometric ratio of 1:1 produced complex **5** in 63% yield.

Proton NMR spectra of **4** and **5** showed only broad signals which were of little help in assigning the structural features of this species. The presence of single quaternary signal at 144.9 ppm for the central C of the hpp$^-$ ligand in the ^{13}C NMR spectrum of **5** as well as observation of only three signals for the CH_2 groups is indicative of equivalent environments for the two ligands of **5**. In order to determine the structural details of these species, single crystals of **4** and **5** were subjected to an X-ray diffraction study (Table 4). The molecular structures of these two complexes are shown in Figs. 3 and 4 with corresponding values for selected bond distances and angles provided in Tables 5 and 6.

Contrary to all previously reported structures involving the hpp$^-$ anion, the Sn(II) complex **4** is mononuclear with two chelating bidentate ligands. The geometry of the Sn center in **4** is similar to that of **3** and can be derived from a distorted trigonal bipyramidal geometry with an equatorial site occupied by a lone pair of electrons [1]. Again, we attribute the distortion of the pseudoaxial angle (N(7)–Sn–N(17) = 129.6(3)°) to the restricted bite angle of the ligand (N(2)–Sn–N(1) = 58.1(2)°).

The sum of angles around all three nitrogen centers of the ligand varies only slightly over a range of 356–358°, suggesting sp^2 character for these atoms. The three C(central, sp^2)–N bond distances on each ligand vary from 1.30–1.37 Å. These features indicate that all three nitrogen atoms of the ligand participate to some degree in π bonding to the central carbon [C(6) or C(16)] and suggest, in comparison with **3**, that the tethering of the N centers has increased the degree of π delocalization within the ligand.

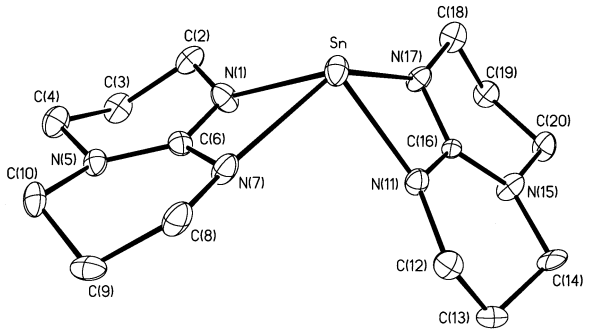

Fig. 3. Molecular structure and atom numbering scheme for $\{CN[N(CH_2)_3]_2\}_2Sn$ (**4**). Hydrogen atoms have been omitted for clarity.

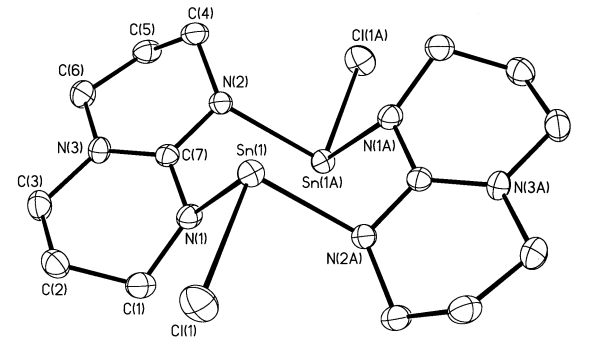

Fig. 4. Molecular structure and atom numbering scheme for one of the unique molecules of $\{CN[N(CH_2)_3]_2SnCl\}_2$ (**5**) in the unit cell. Hydrogen atoms have been omitted for clarity.

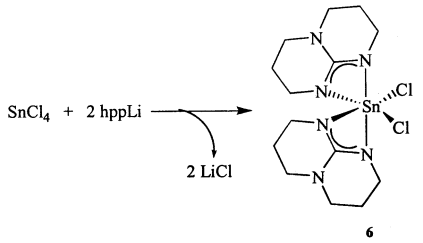
In contrast to the mononuclear complex **4**, complex **5** displayed a dinuclear structure with two hpp^- ligands bridging the two Sn atoms (Fig. 4). Two independent molecules, each lying on a crystallographic inversion center, were found in the unit cell with only marginal differences in their bond lengths and angles. Within each molecule the three N–C(central, sp^2) distances are equivalent (1.34–1.35 Å) within experimental error and correspond to a degree of NC π bonding. The Sn–N distances are equivalent at 2.21 Å. In this case the Sn(II) centers have pyramidal geometries derived from a distorted tetrahedron in which one vertex is occupied by a stereochemically active lone pair of electrons. The lone pairs on the Sn centers appear to be oriented in orthogonal directions, thus precluding any interaction between them.

A similar metathetical route can be used to prepare a Sn(IV) complex of the hpp^- ligand. Addition of 2 equiv. of in situ prepared hppLi to $SnCl_4$ in THF gave a new complex that was formulated as the mononuclear Sn(IV) complex $(hpp)_2SnCl_2$ (**6**) (Scheme 4) on the basis of what appeared to be a single ligand environment in the ^1H and ^{13}C NMR spectra and on our previous experience with similar formamidinate/amidinate complexes [13].



A single crystal X-ray diffraction analysis confirmed the structural features of **6** (Table 4). As seen in Fig. 5, complex **6** is a mononuclear Sn(IV) species with a coordination environment consisting of two chelating bidentate hpp^- ligands along with two chloride ligands. Values for selected bond distances and angles are pro-

Scheme 4.

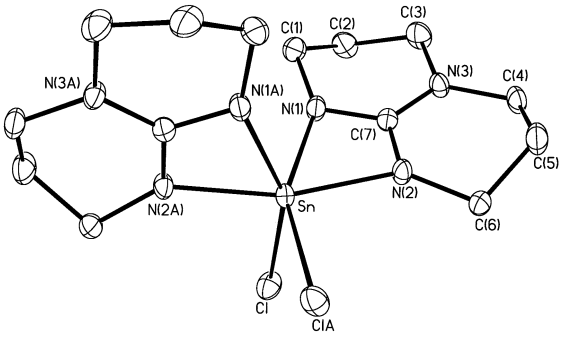

Fig. 5. Molecular structure and atom numbering scheme for $\{CN[N(CH_2)_3]_2\}_2SnCl_2$ (**6**). Hydrogen atoms have been omitted for clarity.

vided in Table 7. The geometry of **6** is based on a *cis*-dichloro distorted octahedron with a crystallographic C_2 bisecting the Cl–Sn–Cl angle making the two hpp^- ligands equivalent. Complex **6** is reminiscent of bis(amidinate) Sn(IV) dichloride species [13].

In **6** the hpp^- ligand is bonded to Sn(IV) through nitrogen atoms N(1) and N(2). The N–C(7) bond distances for N(1) and N(2) are the same at 1.326(6) Å. The sum of the angles around these two atoms is 359° and 358°, suggestive of sp^2 character. The sum of angles around N(3) is 360° and the N(3)–C(7) distance is 1.344(6) Å. As with complex **4**, this indicates that all three nitrogen atoms within the ligand participate to some degree in π bonding to C(7) and further suggests that tethering of the N centers promotes π delocalization between all three nitrogen atoms and the central carbon.

In conclusion, we have demonstrated the utility of guanidinate monoanions as ligands for complexes of tin by reporting the first examples of Sn(II) and Sn(IV) compounds of *N*,*N*′,*N*″-trialkylguanidinates ($[(RN)_2C(NRH)]^-$; R = cyclohexyl; isopropyl) and 1,3,4,6,7,8-hexahydro-2*H*-pyramido[1,2-*a*]pyramidinate (hpp^-). In the case of the trialkylguanidinate complexes, structural analysis revealed a distinctly unsymmetrical bonding mode for the bidentate ligand and suggests a degree of π localization with the ligand. We are investigating the role of this feature in the reactivity of these species. The bis(hpp) complexes of Sn(II) (**4**) and Sn(IV) (**6**) are mononuclear with chelating bidentate ligands thus representing the first reported mononuclear complexes of this ligand. Reducing the coordination number and steric bulk about tin by preparing a mono(hpp) Sn(II) complex resulted in the formation of a dinuclear species with bridging hpp^- ligands, $\{CN[N(CH_2)_3]_2SnCl\}_2$ (**5**). Structural characterization of the hpp^- complexes suggests that the tethering of the N centers may favor π delocalization within the ligand. We are further investigating the reactivity of the reported complexes and related species.

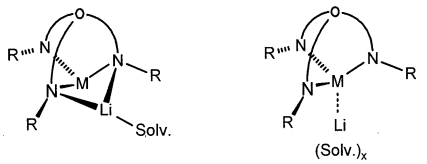
Abstract

Reaction of the trisilylmethane derivative $HC(SiMe_2Br)_3$ with three molar equivalents of (*S*)-1-(1-naphthyl)ethylamine gave the corresponding triamine $HC\{SiMe_2NH[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3$ (**1**) which in solution undergoes partial dissociation to give $HC\{SiMe_2NH((S)\text{-}1\text{-}(1\text{-naphthyl})ethyl)\}\{(SiMe_2)_2N((S)\text{-}1\text{-}(1\text{-naphthyl})ethyl)\}$ (**2**). Lithiation and subsequent reaction with $SnCl_2$ yielded the solvated lithium triamidostannate $[HC\{SiMe_2N[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3Sn\text{–}Li(thf)_3]$ (**4**). An X-ray diffraction (XRD) study established the molecular structure of the C_3-chiral triamidostannate and a direct Sn–Li contact of 3.06(2) Å. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: C_3-chiral triamidostannate; Amides; Tin; Lithium

1. Introduction



During the past 15 years a number of metallated tin compounds of the general type R_3SnM (R = alkyl, aryl, alkoxy, imido; M = alkali metal) have been structurally characterized [1,2]. In spite of their utility in synthetic organic chemistry [3], the isolated pure compounds are highly reactive and frequently thermally labile. To overcome these difficulties the use of polydentate ligand systems, which offer the stabilizing effect of chelation along with the partial shielding of the low valent metal center was found to be an efficient approach. We first employed tripodal amido ligands for the synthesis of highly rigid anionic triamidometallate cages, such as **A**, containing divalent Group 14 metals [4–8]. More recently, a related approach using tripodal amides of greater flexibility (**B**) has been published by Veith et al. [9].

A **B**

M = group 14 metal

An interesting aspect of the structural chemistry of the lithium triamidometallates in solution and in the solid state is the type of interaction between the anionic cage and the counter-cation (in most cases solvated Li^+). Both solvent-separated salts and contact ions have been found [4]. In the latter, the alkali metal ion is either attached to the amido-N atoms in a bridging coordination mode (**I**), thus breaking the overall threefold symmetry of the system or directly bound to the Group 14 metal (**II**) in what is thought to be a primarily ionic interaction.

I **II**

Apart from the stabilization by integration within a molecular cage, the use of the electronegative N-substituents at the divalent Group 14 metal centers effects their stabilization towards oxidation. The triamido metallates were thus found to be excellent anionic 'ligands' for oxidizing transition metal centers such as Ag(I) [5], Au(I–III) [6] or the tetravalent Group 4

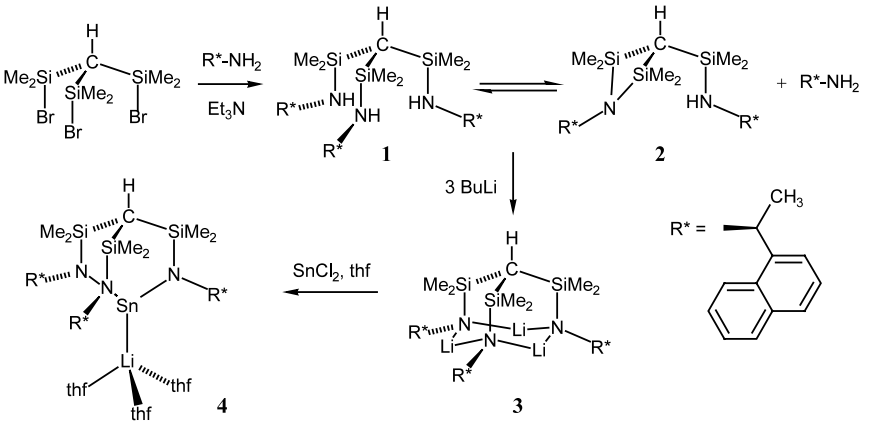
metals [7]. This capacity to act as ligands (which are isoelectronic to phosphines) has been the motivation behind the synthesis of enantiomerically pure, chiral derivatives [10]. In this paper we report the synthesis and structural characterization of such a C_3-chiral triamido metallate.

2. Results and discussion

Reaction of the previously characterized trisilylmethane derivative $HC(SiMe_2Br)_3$ [11] with three molar equivalents of (*S*)-1-(1-naphthyl)ethylamine in the presence of an excess of triethylamine as auxiliary base, after work up, cleanly gave the corresponding triamine $HC\{SiMe_2NH[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3$ (**1**) in good yield (Scheme 1). The ^1H, ^{13}C and ^{29}Si NMR spectra of **1** are consistent with a threefold molecular symmetry on the time scale of the experiment. The ^1H NMR spectroscopic shift of the apical CH proton in the trisilylmethane backbone is characteristically at high field (δ −0.76 recorded in C_6D_6). As a consequence of the chiral ligand periphery, the methyl groups of the $SiMe_2$ units are diastereotopic and their resonances are observed at δ 0.14 and 0.27.



^1H and ^{13}C NMR spectroscopy of solutions of **1** established an equilibrium between the triamine **1** and the cyclic diamine **2** which is generated by elimination of one molecule of (*S*)-1-(1-naphthyl)ethylamine (Scheme 1) [12]. We previously reported the isolation and characterization of a similar azadisilacyclobutane species, $PhC\{(SiMe_2)_2N\textit{t}\text{-}Bu\}\{SiMe_2NH\textit{t}\text{-}Bu\}$ [11].

The triamine was converted to the corresponding trilithium triamide $[HC\{SiMe_2N(Li)[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3]$ (**3**) by reaction with 3 equiv. of *n*-BuLi. It is notable that the result of this metalation is the same whether the reaction is carried out with the essentially pure tripodal amine **1** or a mixture of the triamine and the cyclic product **2** in the presence of the dissociated primary amine.

Reaction of the isolated lithium amide **3** with one molar equivalent of $SnCl_2$ at 0 °C in diethyl ether/thf gave the lithium triamidostannte $[HC\{SiMe_2N[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3Sn\text{–}Li(thf)_3]$ (**4**). Pale yellow crystals of **4** were obtained by cooling a pentane–thf (20:1) solution of the complex after separation of the lithium chloride by centrifugation. Since, the ^1H and ^{13}C NMR spectra of the compound were consistent with a threefold molecular symmetry in solution (even at 200 K) a coordination of the lithium ion to the amido N-atoms could be ruled out. In order to establish the details of the molecular structure of the compound and, in particular relate it to the previously studied triamidostannates(II) [4–7] and triamidostannanes [13], a single crystal X-ray structure analysis was carried out. The molecular structure of **4** is displayed in Fig. 1 along with the principal bond lengths and interbond angles.

As in the previously studied tripodal triamidotin compounds, the structural center piece is the [2,2,2]bicyclooctane-related cage comprising the trisilylmethane unit and the triamidotin unit. The three N-bonded 1-naphthyl groups are turned away from the Sn atom to give the C_3-symmetrical 'propeller' arrangement which is apparent in the view along the molecular threefold axis displayed in Fig. 1(b). The most interesting structural feature is the Li–Sn contact of 3.06(2) Å, which is somewhat longer than the Li–Sn bond lengths in [Ph_3Sn–Li(pmdeta)] [2.871(7) Å] reported by Wright et al. [2a] and in [$\{HC(SiMe_2NpTol)_3\}SnLi(thf)_3$] [2.93(5) Å] studied previously in our group [4b]. The lithium cation is solvated by three thf molecules, which is a structural arrangement frequently observed in solvated lithium salts [14].

Compound **4** is the second chiral triamidodistannate to be structurally characterized [10] and the first to contain an Sn–Li bonding interaction. The $<$(N–Sn–N) angles in the triamidostannate(II) **4** (94.6–95.0°) are close to 90° indicating little or no sp hybridization at the tin atoms. These angles are gener-

(b) View of **4** along the Li–Sn axis illustrating the approximate C_3-symmetry of the system.

ally increased in the Sn–M-heterobimetallics and triamidostannanes(IV) to values between 100° and 102°. The Sn–N bond lengths [Sn–N(1) 2.125(6), Sn–N(2) 2.125(7), Sn–N(3) 2.132(7) Å] lie in the usual range for divalent amido-tin compounds.

3. Conclusion

We have synthesized and structurally characterized a novel chiral triamido stannate(II) possessing a rare Li–Sn contact in its crystal structure. In view of the previously established suitability of such tripodal triamido stannates as ligands in transition metal coordination chemistry and the fact that compound **4** represents a chiral derivative with a very large cone angle, the application of such compounds in stereoselective transition metal-induced transformations is currently being studied.

4. Experimental

All manipulations were performed under an inert-gas atmosphere of dried argon in standard (Schlenk) glassware, which was flame-dried with a Bunsen burner prior to use. Solvents were dried according to standard procedures and saturated with Ar or N_2. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive 'freeze-pump-thaw' cycles and dried over 4 Å molecular sieves.

The ^1H, ^{13}C, and ^{29}Si NMR spectra were recorded on Bruker AC 200, AC 300 and AMX 400 spectrometers equipped with a B-VT-2000 variable temperature unit (at 200.13, 50.32 and 39.76 MHz, respectively) with tetramethylsilane as reference.

Elemental analyses were carried out in the microanalytical laboratories of the chemistry departments at Würzburg and Strasbourg. The compound $HC(SiMe_2Br)_3$ was prepared as reported previously [11]. All other chemicals used as starting materials were obtained commercially and used without further purification.

4.1. Preparation of the compounds

4.1.1. Preparation of $HC\{SiMe_2NH[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3$ (1)

To a stirred solution of (*S*)-1-(1-naphthyl)ethylamine (2.27 ml, 14.0 mmol) and triethylamine (2.10 ml, 15.2 mmol) in diethylether (30 ml) a solution of $HC(SiMe_2Br)_3$ (2.00 g, 4.68 mmol) in diethylether (20 ml) was added at 0 °C. After stirring for 14 h at room temperature (r.t.), the triethylammoniumbromide was separated by centrifugation and the precipitate was washed with diethylether (40 ml). The solvent of the combined ether solutions and the excess of triethylamine were removed in vacuo. Upon storing at 4 °C in diethylether for 24 h, compound **1** was obtained as a colorless, highly crystalline solid. Yield: 2.78 g, 3.98 mmol (86%). ^1H NMR (200.13 MHz, C_6D_6, 295 K): $\delta = -0.76$ (s, 1 H, $HC(Si\ldots)_3$), 0.14, 0.27 (s, 2×9 H, $Si(CH_3)_2$), 1.35 (d, 9 H, $^3J_{HH} = 6.6$ Hz, $HCCH_3$), 2.06 (d, 3 H, $^3J_{H(N)H(C)} = 9.8$ Hz, N*H*), 4.89 (dq, 3 H, $HCCH_3$), 7.22–8.07 (m, 21 H, naphthyl). $\{^1H\}^{13}C$ NMR (50.32 MHz, C_6D_6, 295 K): $\delta = 4.0$, 4.4 ($Si(CH_3)_2$), 6.2 ($HC(Si\ldots)_3$), 28.0 ($HCCH_3$), 47.9 ($HCCH_3$), 123.3, 123.5, 125.7, 125.8, 126.1, 127.6, 129.6 (C^{4-8} of 1-naphthyl), 131.2, 134.7, 145.6 ($C^{4a,8a,1}$ of 1-naphthyl); $\{^1H\}^{29}Si$ NMR (39.76 MHz, C_6D_6, 295 K): $\delta = 1.4$; $C_{43}H_{55}N_3Si_3$ (698.19): *Anal.* Calc.: C, 73.97; H, 7.94; N, 6.02. Found: C, 73.78; H, 7.93; N, 5.91.

4.1.2. Spectroscopic characterization of $HC\{SiMe_2NH\text{-}((S)\text{-}1\text{-phenylethyl})\}\{(SiMe_2)_2N((S)\text{-}1\text{-phenylethyl})\}$ (2)

Upon storing a solution of **1** in benzene for 24 h at r.t. formation of the equilibrium of **1** and

$HC\{SiMe_2NH((S)\text{-}1\text{-}(1\text{-naphthyl})ethyl)\}\{(SiMe_2)_2N\text{-}((S)\text{-}1\text{-}(1\text{-naphthyl})ethyl)\}$ (**2**) and (*S*)-1-napthylethylamine was observed. At 330 K only compound **2** and the primary amine were detected in the ^1H NMR experiment. Spectroscopic data of **2**: ^1H NMR (200.13 MHz, C_6D_6, 330 K): $\delta = -0.10$ (s, 1 H, $HC(SiMe_2)_3$), -0.02, 0.00, 0.06, 0.08, 0.10, 0.25 ($6 \times$ s, 6×3 H, $Si(CH_3)_2$), 1.44, 1.50 (d, 2×3 H, $^3J_{HH} = 6.6$ Hz, $HCCH_3$), 4.89 (m, 2 H, $HCCH_3$), 4.91 (q, 1H, $^3J_{HH} = 6.6$ Hz, $HCCH_3$), 7.22–8.20 (m, 14 H, naphthyl); $\{^1H\}^{13}C$ NMR (50.32 MHz, C_6D_6, 330 K): $\delta = 2.7$, 2.9, 3.3, 3.6, 4.7, 5.0 ($Si(CH_3)_2$), 6.8 ($HC(Si\ldots)_3$), 24.9, 28.1 ($HCCH_3$), 48.1, 49.2 ($HCCH_3$), 122.9, 123.4, 123.6, 124.2, 125.3, 125.5, 125.6, 125.7, 127.2, 127.8, 129.1, 129.2, (C^{2-8} of naphthyl), 131.0, 132.1, 134.4, 134.5, 142.6, 145.4 ($C^{4a,8a,1}$ of naphthyl); $\{^1H\}^{29}Si$ NMR (39.76 MHz, C_6D_6, 330 K): $\delta = -0.2$ ($SiMe_2N(H)(\ldots)$), 5.9, 6.0 ($(SiMe_2)_2N(\ldots)$).

4.2. Preparation of $HC\{SiMe_2NLi[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3$ (3)

To a stirred solution of **1** (3.06 g, 4.38 mmol) in *n*-pentane (40 ml) a 2.5 M solution of *n*-BuLi in *n*-hexane (5.26 ml, 13.1 mmol) was added at -78 °C. After stirring for 1 h at r.t. and concentrating to 20 ml the white precipitate was separated by centrifugation. Upon storing at 4 °C in *n*-pentane for 24 h the product was obtained as a colorless, highly crystalline solid. Yield: 2.56 g (82%). ^1H NMR (400.14 MHz, C_6D_6, 295 K): $\delta = -1.00$ (s, 1 H, $HC(Si\ldots)_3$), 0.35, 0.50 ($2 \times$ s, 2×9 H, $Si(CH_3)_2$), 0.67 (d, 9 H, $^3J_{HH} = 6.2$ Hz, $HCCH_3$), 4.71 (q, 3 H, $HCCH_3$), 6.06 (m, 3 H), 7.09 (dd, 3H, $^3J_{HH} = 7.5$ Hz), 7.25 (ddd, 3H, $^3J_{HH} = 8.2$ Hz, $^4J_{HH} = 1.0$ Hz), 7.36 (dd, 3 H, $^3J_{HH} = 7.5$ Hz), 7.49 (d, 3 H, $^3J_{HH} = 8.2$ Hz), 7.67 (dd, 3 H, $^3J_{HH} = 8.2$ Hz, $^4J_{HH} = 1.0$ Hz), 8.22, (m, 3 H, all naphthyl); $\{^1H\}^{13}C$ NMR (100.62 MHz, C_6D_6, 295 K): $\delta = 5.3$, 10.0 ($Si(CH_3)_2$), 11.9 ($HC(Si\ldots)_3$), 26.4 ($HCCH_3$), 49.7 ($HCCH_3$), 119.4, 121.8, 126.3, 126.7, 127.2, 128.4, 130.1 (C^{2-8} naphthyl), 129.0, 135.3, 149.4 ($C^{4a,8a,1}$ of naphthyl);); $\{^1H\}^{29}Si$ NMR (39.76 MHz, C_6D_6, 295 K): $\delta = -3.2$; $\{^1H\}^7Li$ NMR (155.51 MHz, C_6D_6, 295 K): $\delta = 1.4$; $C_{43}H_{52}Li_3N_3Si_3$ (715.99): *Anal.* Calc.: C, 72.13; H, 7.32; N, 5.87. Found: C, 71.86; H, 7.28; N, 5.59.

4.3. Preparation of $[HC\{SiMe_2N[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3Sn–Li(thf)_3]$ (4)

Solid $SnCl_2$ (0.29 g, 1.53 mmol) was added to a stirred solution of the lithium amide **3** (1.00 g, 1.53 mmol) in 20 ml of diethylether which was cooled at 0 °C. After warming to r.t. and stirring for 1 h the solvent was evaporated in vacuo. The solid residue was extracted with pentane (15 ml), the extract centrifugated and the organic phase concentrated to approximately 8 ml. Storing of this solution at -30 °C gave the lithium stannate **4** as a pale yellow crystalline solid. Yield 43%. ^1H NMR (400.14 MHz, C_6D_6, 295 K): $\delta = -0.72$ (s, 1 H, $HC(Si\ldots)_3$), 0.14, 0.27 ($2 \times$ s, 2×9 H, $Si(CH_3)_2$), 1.37 (d, 9 H, $^3J_{HH} = 6.6$ Hz, $HCCH_3$), 7.24–8.10 (m, 21 H, naphthyl); $\{^1H\}^{13}C$ NMR (100.62 MHz, C_6D_6, 295 K): $\delta = 3.8$, 4.2 ($Si(CH_3)_2$), 6.2 ($HC(Si\ldots)_3$), 27.8 ($HCCH_3$), 42.7 ($HCCH_3$), 123.1, 123.3, 125.6, 125.9, 126.1, 127.4, 129.4, (C^{2-8} naphthyl), 129.4, 134.6, 145.4 ($C^{4a,8a,1}$ of naphthyl); due to the instability of this compound to loss of thf a correct elemental analysis could not be obtained.

4.4. X-ray diffraction study of $[HC\{SiMe_2N[(S)\text{-}1\text{-}(1\text{-naphthyl})ethyl]\}_3Sn–Li(thf)_3]$ (4)

4.4.1. Crystal data

$C_{55}H_{76}LiN_3O_3Si_3Sn \cdot C_6H_6$, M: 1115.24, trigonal, space group: $P3_2$, $a = 14.7874(2)$, $c = 23.4637(5)$ Å, $U = 4443.4(1)$ Å^3, $Z = 3$, $D_{calc} = 1.25$ g cm^{-3}, $F(000) = 1764$, μ (Mo Kα) $= 0.537$ mm^{-1}.

4.4.2. Data collection

X-ray intensity data were collected at 173 K from a pale yellow block-shaped crystal of **4** ($0.16 \times 0.10 \times 0.08$ mm) in the θ-range 2.50–27.48° ($-19 < h < 19$, $-15 < k < 16$, $-30 < l < 20$) using an Nonius Kappa CCD diffractometer using graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). A total of 9656 independent reflections were collected with 4367 having an intensity greater than 3 $\sigma(I)$.

4.4.3. Structure solution and refinement

The structure was solved using direct methods and refined against *F*. H-Atoms were introduced as fixed contributors. The Flack parameter of $-0.03(3)$ confirmed the assignment of the absolute configuration $R_1 = 0.043$; $wR = 0.061$. For all computations, the *Enraf-Nonius* OpenMolN Package was used (OpenMolN, interactive Structure Solution, Nonius B.V., Delft, The Netherlands, 1997).

5. Supplementary material

Crystallographic data (excluding structure factors) for compound **4** have been deposited with the Cambridge Crystallographic Data Centre. Copies of this data may be obtained free of charge from The Director, 12 Union Road, Cambridge CB2 1EZ (Fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

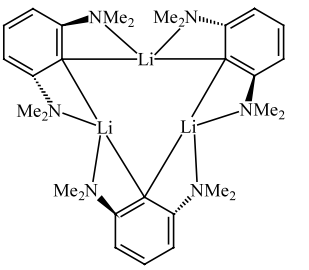
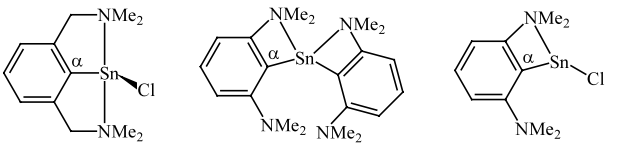
Abstract

As a continuation of our studies on the 2,6-bis(dimethylamino)phenyl ligand (R^-), we report on the synthesis and characterisation, including the X-ray structures, of HgR_2 and BCl(Ph)R. © 2002 Elsevier Science Ltd. All rights reserved.



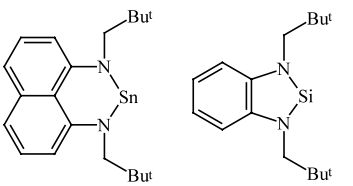
Keywords: Arylmetal complexes; Mercury(II); Boron; The 2,6-bis(dimethylamino)phenyl ligand

1. Introduction



In 1997, we drew attention to the potential of the 2,6-bis(dimethylamino)phenyl ligand $^-C_6H_3(NMe_2)_2$-2,6 (≡ R^-); it was suggested that R^- might find a useful role in organometallic chemistry by virtue of facile on/off co-ordination of a pendant NMe_2 group [1], especially in catalytic systems. The ligand R^- differs from the more widely studied $^-C_6H_3(CH_2NMe_2)_2$-2,6 (≡ R′) [2], in that in their metal complexes intramolecular N → M ligation is largely strain-free for (M–R′)-, but not (M–R)-, containing derivatives. This is clearly illustrated when comparing solid state and solution structures of Sn(Cl)R′ (**I**) [3], SnR_2 (**II**) [1] and Sn(Cl)R (**III**) [1,4]. In the crystalline complexes the angle α at the *ipso*-carbon is close to the sp^2 value in **I** [3], but in **II** it has an average value of 104° [1], while in **III** it is 112.1(4)° [4]. Furthermore, whereas in toluene-d_8 solution, ^{1}H NMR VT spectra showed that in **II** and **III** there was a rapid exchange process:

$$2\text{-}Me_2N \rightarrow Sn \rightleftharpoons 6\text{-}Me_2N \rightarrow Sn$$



at ambient temperature [1] (as also proved to be the rule for the Group 14 metal(II) complexes listed in Table 1), this was not the case for **I** [3].

We have used the ligand R^- to prepare the 12 crystalline germanium(II), tin(II) and lead(II) complexes listed in Table 1 [1,4,6–8]. For **1** [2] and eight others X-ray data are available; the principal point of interest in the present context and highlighted in Table 1 is that each R^- ligand has a single N···M intramolecular close contact in every case except in $GeR_2(BH_3)$ [6]. The germanium atom in the latter compound is four-coordinate, whereas in $SnR_2(BH_3)$ the tin atom is five-coordinate. In both, the MR_2 moiety behaves as a Lewis acid, as is also the case when SnX_2 (**IV**) [7] rather than BH_3 [6] is the electron pair acceptor. By contrast, with SnR_2 or $Sn[N(SiMe_3)_2]R$ as reagent, treatment with the thermally stable silylene **V** [abbreviated as Si(NN)] led to its product of insertion into the Sn–R or Sn–$N(SiMe_3)_2$ bond, respectively [8].

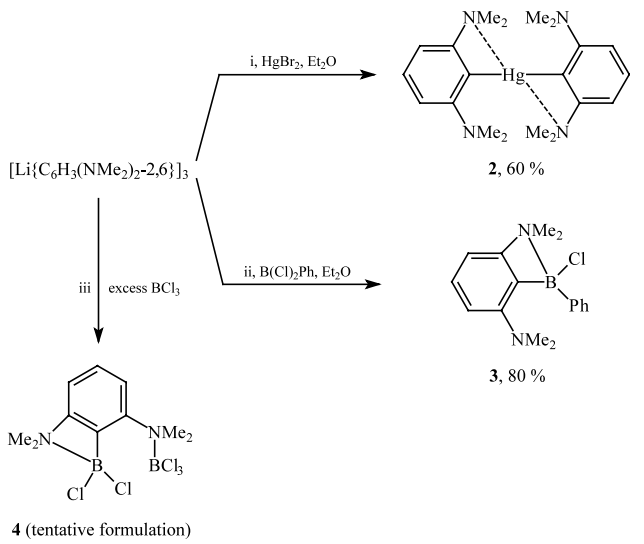
[c] Si(NN) is an abbreviation for **V**.

2. Experimental

All manipulations were carried out in flame-dried glassware under argon, using standard Schlenk techniques. Solvents were distilled from drying agents and degassed. Elemental analyses were carried out by Medac Ltd, Uxbridge. Melting points were determined in sealed capillaries under an argon atmosphere on an electrothermal apparatus and are uncorrected. The NMR spectra were recorded in benzene-d_6 at 298 K using a Bruker DPX 300 (^{1}H, 300.1; ^{13}C, 75.4 MHz) or AMX 500 (^{11}B, 160.4; ^{199}Hg, 89.1 MHz) instrument; the solvent resonances were used as internal references for ^{1}H and ^{13}C, while $^{11}BF_3(OEt_2)$ and $^{199}HgMe_2$ were the external references for the ^{11}B and ^{199}Hg NMR spectra, respectively. Electron-impact mass spectra (70 eV) were recorded using a Kratos MS 80 RF instrument. The compound $[Li(\mu\text{-}R)]_3$ (**1**) was prepared as described in the literature [2]. The other chemicals used were commercial samples (Aldrich).

2.1. Preparation of HgR_2 (2)



Solid $HgBr_2$ (0.63 g, 1.75 mmol) was added in small portions to a solution of LiR (0.60 g, 3.53 mmol) in Et_2O (30 cm^3) at room temperature. The reaction mixture was stirred for 20 h; the volatiles were then removed in vacuo. The residue was extracted with pentane (20 cm^3), the filtrate was concentrated in vacuo and stored at −25 °C, yielding compound **2** (0.55 g, 60%), as colourless plate-shaped crystals. *Anal.* Found: C, 45.6; H, 5.71; N, 10.5. Required for $C_{20}H_{30}HgN_4$: C, 45.6; H, 5.74; N, 10.6%. M.p. 63.0–64.0 °C. Mass spectrum [m/z (%)]: 528 (35, $[M+1]^+$), 163 (100, $[R]^+$), 147 (59, $[R\text{–}Me-1]^+$), 120 (24, $[R\text{–}NMe_2+1]^+$), 77 (19, $[C_6H_5]^+$). ^{1}H NMR: δ 2.71 (s, 12H, NMe_2), 6.92 (d, 2H, *m*-H in R), 7.23 (t, 1H, *p*-H in R). $^{13}C\{^1H\}$ NMR: δ 45.90 (s, NMe_2), 113.78 (s, *m*-C in R), 129.24 (s, *p*-C in R), 160.45 (s, *o*-C in R), 161.32 (s, *ipso*-C in R). $^{199}Hg\{^1H\}$ NMR: δ −642.0 (s).

2.2. Preparation of BCl(Ph)R (3)

Dichloro(phenyl)borane (1.25 cm^3, 9.63 mmol) was added dropwise at −78 °C to a stirred solution of LiR (1.61 g, 9.46 mmol) in Et_2O (75 cm^3). The resulting

2.3. Crystal data and refinement details for **2** and **3**

Suitable single crystals of HgR_2 (**2**) and BCl(Ph)R (**3**) were obtained from a concentrated diethyl ether (**2**) or THF–hexane (**3**) solution at −25 °C. Data were collected on an Enraf–Nonius CAD4 diffractometer using monochromated Mo Kα radiation, *λ* 0.71073 Å, with the crystals under a stream of cold nitrogen gas. Intensities were measured by an $\omega - 2\theta$ scan. Corrections were made for absorption using psi-scan measurements. The programs used for structure solutions and refinement (full-matrix on all F^2) were SHELXS-97 [9] and SHELXL-97 [10], respectively. Further details are in Table 2.

3. Results and discussion

The objectives of the present study were to prepare 2,6-bis(dimethylamino)phenyl–mercury(II) and –boron compounds.

The mercury(II) aryl HgR_2 (**2**) was sought as a potentially useful R^- or $R^\bullet$ transfer agent. A particular target was $^\bullet SnR_3$; crystalline, mononuclear tin(III) compounds are unknown, although earlier researches had revealed that in toluene solution $^\bullet Sn[CH(SiMe_3)_2]_3$ [11] and nitrogen analogues such as $^\bullet Sn[N(SiMe_3)_2]_3$ [11,12] were indefinitely stable at ambient temperature. In the event, there was no reaction between SnR_2 [1] and HgR_2. [Alternative strategies, based on $Sn(Br)R_3$ as a precursor, failed since this tin(IV) bromide proved to be inaccessible]. An added interest in HgR_2 was as a possible source of RHg–HgR {such mercury(I) organic compounds are unknown, an exception being XHg–HgX, X = $Si[Si(Me)_2SiMe_3]_3$ [13]}; but this also proved to be disappointing, as attempted reduction of **2** invariably yielded elemental mercury.

The compound $B(Cl)R_2$ appeared to be an attractive source of the crystalline $^\bullet BR_2$ radical or cation $[BR_2]^+$, both of which would be highly novel. However, we were unable unambiguously to displace a second chloride ion from BCl_3 using an excess of LiR, perhaps for steric reasons. An alternative strategy led us to the less hindered compound BCl(Ph)R (**3**).

Treatment of $HgBr_2$ with 2 equiv. of LiR in diethyl ether at ambient temperature yielded (step i of Scheme 1) HgR_2 (**2**) in 60% yield after crystallisation from pentane. The reaction between $B(Cl)_2Ph$ and an equivalent portion of LiR in diethyl ether at −78 °C afforded (step ii of Scheme 1) crystalline BCl(Ph)R (**3**) in high yield.

Each of the crystalline colourless **2** or cream **3** compounds was characterised by satisfactory elemental

analysis, melting point (63–64 °C, **2**; 104–106 °C, **3**), multinuclear NMR and mass (molecular ions ± 1 mass units) spectra, and single crystal X-ray diffraction (see-below). The mercury compound **2** was light-sensitive both in the solid state and in solution, a feature well documented for compounds containing Hg(II)–C bonds [14]. Substantial decomposition was significant in benzene solution only after approximately 3 weeks at ambient temperature.

The $^{199}Hg\{^1H\}$ NMR spectrum of **2** in benzene-d_6 showed a singlet at δ −642. This value is at higher frequency than the recorded values for $HgPh_2$, which range from δ −808 (acetone-d_6) to −742 (CD_2Cl_2) [15]; but is close to the δ −689 (in $CDCl_3$) reported for **VI**, for which intramolecular N···Hg interaction was inferred [16]. A further comparison is available with compound **VII**, having δ −778 in $CDCl_3$, in which such a close N···Hg contact was excluded [17].

The $^{11}B\{^1H\}$ NMR spectrum of BCl(Ph)R (**3**) in benzene-d_6 showed a singlet at δ 14.7, consistent with the solution of **3** containing a single tetrahedrally co-ordinated boron compound [18] and having a strong N→B bond [19]. This chemical shift is close to the δ 14.4 for **VIII** [19].

Attempts were made to reduce compound **3** with potassium or potassium–graphite in order to obtain either the radical $^{\bullet}$B(Ph)R or its boron–boron bonded dimer. Although in each experiment the colour of the reaction mixture changed from colourless to fluorescent green, the ^1H NMR spectra showed only signals attributable to **3**. Likewise, efforts to generate the salts $[B(Ph)R][BX_4]$, by treating **3** with $NaBPh_4$ or $[NEt_3H][B(C_6F_5)_4]$, were unsuccessful; no evidence was found for a reaction having taken place.

Treatment of BCl_3 with 2 equiv. of LiR in diethyl ether or toluene gave a white, sparingly soluble powder and unreacted LiR. This suggests that it was not possible to introduce two R^- ligands onto the boron atom, which may have a steric explanation. When an excess of boron trichloride was added to a solution of LiR, a complicated reaction mixture was obtained, from which a compound having somewhat greater solubility was eventually isolated. The $^{11}B\{^1H\}$ NMR spectrum showed two signals of approximately equal intensity at δ 11.4 and 17.5. A plausible formulation would be that shown in **4** (Scheme 1), by analogy with the crystallographically authenticated compound **IX**, for which ^{11}B spectral data were not recorded [20].

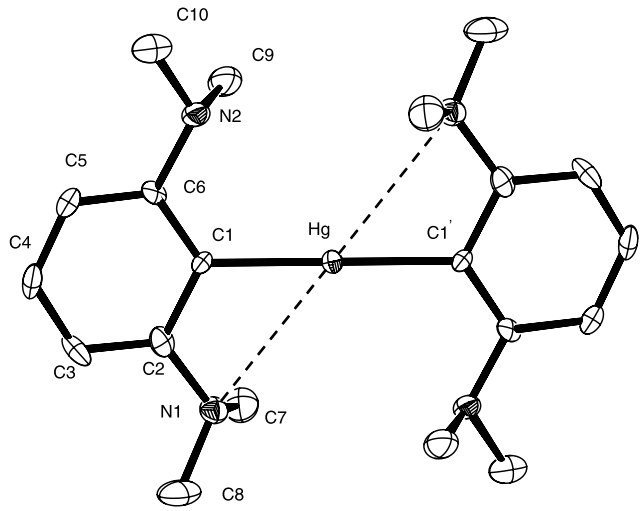

Fig. 1. The X-ray crystal structure of complex **2**.

Table 3
Selected bond distances (Å) and angles (°) for **2**

Bond distances		Bond angles	
Hg–C(1)	2.081(8)	C(1)–Hg–C(1′)	180
Hg···N(1)	3.077(8)	C(1)–C(2)–N(1)	116.7(7)
Hg···N(2)	3.247(8)	C(1)–C(6)–N(2)	117.6(7)
		Hg–C(1)–C(2)	117.0(5)
		Hg–C(1)–C(6)	123.3(6)
		Hg–C(1)···C(4)	168.7(6)

Symmetry element ′ is $-x, -y, -z$.

3.1. The molecular structure of HgR_2 (2)

The molecular structure of crystalline HgR_2 (**2**) is illustrated in Fig. 1; selected bond distances and bond angles are in Table 3.

Crystalline **2** is a centrosymmetric monomer, with a linear C(1)–Hg–C(1)′ vector. This structure is thus unexceptional. The Hg···N(1) and Hg···N(2) contacts of 3.077(8) and 3.247(8) Å are somewhat longer than those found in $Hg(C_6H_4CH_2NMe_2\text{-}2)_2$ (**X**) [2.89(1) Å] [21] or the 2-pyridylphenyl complex **VI** [2.798(7) Å] [16], but still fall well within the sum of the van der Waals radii for nitrogen (1.55 Å) [22] and a reasonable value of 1.73 Å for mercury [23]. Hence we suggest that there is a single weak Hg···N bonding interaction in **2** involving each of the R^- ligands. This is consistent with (i) the slight deviation from the sp^2 value in the angles C(1)–C(2)–N(1) and C(1)–C(6)–N(2) and (ii) magnitudes of the Hg–C(1)–C(2/6) angles which demonstrate that the fragment incorporating N(1) is slightly bent towards the mercury atom. The Hg–C(1) bond length of 2.081(8) Å in **2** is close to the 2.085(7) Å in $HgPh_2$ [24], the 2.10(2) Å in **X** [20] and the 2.098(8) Å in **VI** [16]. The mercury atom in **2** is 0.41 Å out of the C_6 aromatic mean plane, a situation similar to that in $HgPh_2$ in which, however, the deviation is only 0.1 Å [24]. The Hg–C(1)···C(4) angle in **2** is 168.7(6)°, the molecule being slightly bent at the C(1) atom. The phenyl planes are parallel to one another.

3.2. The molecular structure of BCl(Ph)R (3)

The molecular structure of crystalline BCl(Ph)R (**3**) is illustrated in Fig. 2; selected bond distances and bond angles are in Table 4.

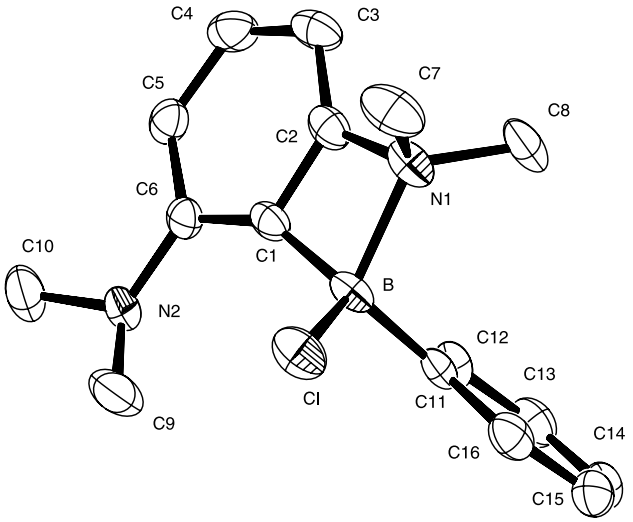

Fig. 2. The X-ray crystal structure of complex **3**.

Table 4
Selected bond distances (Å) and angles (°) for **3**

Bond distances		Bond angles	
B–C(1)	1.599(5)	C(1)–C(2)–N(1)	101.1(3)
B–C(11)	1.591(5)	B–C(1)–C(2)	92.4(3)
B–Cl	1.865(4)	C(1)–B–N(1)	82.3(2)
B···N(1)	1.740(4)	B–N(1)–C(2)	83.5(2)

Crystalline **3** is a monomer, with the boron atom in a four-coordinate, distorted tetrahedral environment. This distortion is evidently caused by the chelating R^- ligand, as reflected in the significantly narrower than the sp^2 value of the endocyclic angles at C(1) and C(2). The latter is also much narrower than in, for example, SnR_2 (**II**), 113.6(4)° [1], which is attributed to the relative sizes of the boron and tin atoms, B ≪ Sn. The B–N(1)–C(2)–C(1) ring is planar, the sum of the endocyclic bond angles being 359.3°.

The B–Cl bond in **3**, 1.865(4) Å, is significantly longer than in the three-coordinate boron chloride $B(C_6F_5)_2Cl$, 1.746(5) Å [25], but is similar to those in the four-coordinated chloroboranes $B(Cl)Ph_2(THF)$, 1.893(2) Å [26], **IX** (av. 1.86 Å) [27], and the pyridine adduct of 1-chloro-1-borafluorene **XI**, 1.898(2) Å [28].

The mean B–C distance in **3** of 1.59 Å is slightly longer than in $B(C_6F_5)_2Cl$, 1.56 Å [25], but similar to that in the four-coordinated boron chlorides **IX**, 1.60 Å [27], or **XI**, 1.61 Å [28]. The B···N(1) distance in **3** is significantly longer than in $B(Br)_2(\kappa^2\text{-}C,N\text{–}C_6H_4CH_2\text{-}NMe_2\text{-}2)$, 1.625(1) Å [29] or **IX**, 1.649(5) Å [27]. Evidently the methylene group in the latter two complexes facilitates the $R'_2N \rightarrow B$ coordination (R′ = Me or Et), whereas this effect in **3** is subject to greater strain. The B···N separation in the spiro compound $B(C_6H_4CH_2\text{-}NMe_2\text{-}2)\{\kappa^2\text{-}O,O'\text{–}OCH_2C(Ph)_2O\}$ of 1.754(4) Å [30] is similar to that in **3**.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Centre, CCDC Nos. 170829 for **2** and **3**. Copies of this information may be obtained free of charge from The Director, CCDC 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-366-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Isolated deltahedral clusters of lead in the solid state: synthesis and characterization of Rb_4Pb_9 and $Cs_{10}K_6Pb_{36}$ with Pb_9^{4-}, and $A_3A'Pb_4$ (A = Cs, Rb, K; A′ = Na, Li) with Pb_4^{4-}

Abstract

The title compounds were synthesized by direct fusion of the corresponding elements in appropriate atomic ratios at 700 °C, and the structures were determined by single-crystal X-ray diffraction. They contain isolated deltahedral clusters of lead with charge of 4−. The clusters in Rb_4Pb_9 and $Cs_{10}K_6Pb_{36}$ are Pb_9^{4-}. They are *nido* according to their charge, but their shapes do not always correspond to the classical *nido* geometry, a monocapped square antiprism. Some are differently distorted tricapped trigonal prisms. The relationship between these different geometries is discussed, and new classification for such clusters is proposed. The $A_3A'Pb_4$ compounds are isostructural and contain isolated tetrahedra of Pb_4^{4-}. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

The growing tendency for miniaturizing semiconducting devices has developed, in recent years, into research on synthesis, characterization and properties of 'quantum-size' particles, i.e. small enough particles that exhibit novel quantum effects [1,2]. Such nanoparticles consist of anywhere between a few atoms to a few hundred atoms of metals or semiconductors. The limited number of atoms in the particle leads to a physical phenomenon known as 'quantum confinement' where the properties of the system fall into the transition region between bulk material and molecules [3]. This leads to different thermodynamic properties such as melting point, phase transitions, and different electronic and optical behavior [4,5].

Large, negatively-charged deltahedral clusters of main-group elements also belong to this group. Such isolated and naked clusters are usually found in compounds containing alkali metals as countercations [6]. Recently, numbers of such species were discovered in 'neat solids' [6,7]. Many of them were previously characterized only in compounds crystallized from liquid ammonia or ethylenediamine solutions of various precursors [8,9]. Such clusters, when in solutions, can react with other molecules, can form polymers, or can oligomerize into larger nanoparticles. They are also fascinating with the aesthetics of their topologies, and better understanding of their unusual bonding will bring knowledge that is otherwise inaccessible [6].

We have undertaken a systematic and thorough search for homoatomic deltahedral clusters of the heavier elements of the carbon group in the solid state. This has resulted in the discovery of the first large deltahedral cluster of group 14, a monocapped square antiprism of Ge_9^{4-} in the binary solid Cs_4Ge_9 [10]. Similar nine-atom clusters of Si, Sn and Pb were later found in Zintl compounds with general stoichiometries A_4Tt_9 and $A_{12}Tt_{17}$ where A = alkali metal and Tt = Tetrel is an element of group 14 (except carbon) [11–14]. Some of these clusters are identical with the Zintl ions crystallized from solutions, and thus establish the relationship between Zintl phases and Zintl ions [10].

The exploration for clusters in the solid state was later extended into pseudo-binary systems with two different alkali–metal countercations. This has produced several unprecedented compounds with novel features. For example, the first isolated *arachno*-clusters of group 14, square antiprisms of Sn_8^{6-}, were discovered in two Li-containing Zintl phases with stoichiometry of $A_4Li_2Sn_8$ (A = K, Rb) [15]. Similarly, mixed alkali metals and Ge provide the largest, so far, isolated clusters of group 14, giant truncated tetrahedra of Ge_{12}^{12-} in the compound $RbLi_7Ge_8$ [16]. In addition to these compounds with isolated clusters, extended structures are also feasible. Thus, appropriate mixtures of Na/Rb or Na/Cs with Si, Ge and Sn, yielded the first stoichiometric clathrates of type II, $A_8Na_{16}Si_{136}$ and $A_8Na_{16}Ge_{136}$ (A = Rb, Cs) [17,18], the first intermetallic clathrate–III compound, $Cs_{30}Na_{(1.33x-10)}Sn_{(172-x)}$ [19], and a layered clathrate derivative $A_3Na_{10}Sn_{23}$ (A = K, Rb, Cs) with clathrate-II layers 'stuffed' with the Zintl phase A_4Sn_4 [20]. Here, we report on the extension of these studies into the heaviest homologue of the carbon group, lead, and the interesting cluster chemistry of the systems of mixed alkali metals and lead.

[a] $R_1 = [\Sigma||F_o|-|F_c||]/\Sigma|F_o|$; $wR_2 = \{[\Sigma w[(F_o)^2-(F_c)^2]^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$; $w = [\sigma^2(F_o)^2+(AP)^2+BP]^{-1}$, where $P = [(F_o)^2+2(F_c)^2]/3$.

2. Experimental

2.1. Synthesis

All manipulations were handled in an inert atmosphere glove box or under vacuum. Mixtures of the elements in appropriate atomic ratios (all from Alfa–Aesar or Acros, > 99.9% pure) were loaded in niobium containers. Details on the procedures and the containers can be found elsewhere [21]. Initially mixtures with compositions $(A_{1-x}A'_x)_4Pb_9$ were heated at 700 °C for 1 week and were then slowly cooled to room temperature at a rate of 3° h^{-1}. Phase analysis of the products was carried out with powder X-ray diffraction (Enraf–Nonius Guinier camera with Cu $K\alpha_1$ radiation). For some of them the results were quite ambiguous, and therefore, more reactions with the same atomic ratios were carried out at different temperature regimes. Nevertheless, this did not improve the phase purity of the products, which often contained traces of elemental lead. Later, reactions were loaded with a slight excess of lead intended to serve as a flux for more facile crystal growth. These were carried out at lower temperatures and for prolonged periods of time of about 4 weeks. They produced crystals of better quality that were suitable for data collection.

2.2. Structure determination

A few crystals of each sample were selected in the glove box, sealed in glass capillaries, checked for singularity on a Enraf–Nonius CAD4 single crystal diffractometer with Mo Kα radiation, and data were collected for the best of them at room temperature ($\omega-2\theta$ scans, $2\theta_{max} = 50°$). The following are more details of the data collections: (a) a quarter of a sphere of data was collected of a black, bar-like crystal of Rb_4Pb_9 with dimensions $0.18 \times 0.12 \times 0.10$ mm; (b) a hemisphere of data was collected of a black, very brittle and irregular crystal of $Cs_{10}K_6Pb_{36}$ with dimensions $0.20 \times 0.12 \times 0.10$ mm; (c) an octant of a sphere of data was collected of a dark, bar-like crystal of Cs_3NaPb_4 with dimensions $0.20 \times 0.10 \times 0.06$ mm. The data were corrected for Lorentz and polarization effects, and for absorption with the aid of the XABS program [22a]. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL V5.1 package [22b]. Further details of the data collection and structure refinements are given in Table 1. Cs_3LiPb_4, Rb_3LiPb_4 and K_3LiPb_4 are isostructural with Cs_3NaPb_4, and only their lattice parameters are reported (Table 2). Important Pb–Pb distances for Rb_4Pb_9 and $Cs_{10}K_6Pb_{36}$ are given in Tables 3 and 4, respectively.

Table 2
Lattice parameters for other lead compounds with Pb_4^{4-} tetrahedra [a]

Compound	Space group	a (Å)	b (Å)	c (Å)	V (Å^3)
Cs_3NaPb_4 [b]	*Cmcm*	7.267(1)	17.282(1)	11.074(1)	1390.7(2)
Cs_3LiPb_4	*Cmcm*	7.274(1)	16.74(1)	10.75(1)	1309(2)
Rb_3LiPb_4	*Cmcm*	7.133(1)	16.276(2)	10.534(1)	1223.0(3)
K_3LiPb_4	*Cmcm*	6.932(1)	16.09(1)	10.508(2)	1172(3)

[a] Determined from powder diffraction patterns taken at room temperature on an Enraf–Nonius Guinier camera with vacuum chamber, Cu Kα radiation ($\lambda = 1.540562$ Å) and NBS (NIST) silicon as an internal standard.
[b] Determined from 25 reflections at high θ-angles on a CAD4 single crystal diffractometer.

2.3. Magnetic measurements

The magnetizations of the compounds were measured on a Quantum Design MPMS-SQUID magnetometer at a field of 3 T in the temperature range of 10–300 K. Typically 20–40 mg of sample are packed in a special holder designed for air-sensitive compounds [21]. They all showed temperature-independent and negative magnetizations (-3.0×10^{-4}, -3.7×10^{-4}, and -7.2×10^{-4} emu for 37 mg of Rb_4Pb_9, 24 mg of $Cs_{10}K_6Pb_{36}$, and 33 mg of Cs_3NaPb_4, respectively) consistent with electronically-balanced compounds.

2.4. Electronic structure

Extended-Hückel band and MO calculations were carried out within the tight binding approximation with only the lead atoms included (H_{ii} and ζ_1 for Pb 6s: -15.70 eV and 2.35, for Pb 6p: -8.00 eV and 2.06).

3. Results and discussion

3.1. Rb_4Pb_9

This compound is isostructural with K_4Pb_9 [12]. The structure is built of isolated nine-atom clusters of lead, Pb_9^{4-}, that are surrounded by rubidium cations. There are two different clusters in the structure, clusters **A** and **B** (Fig. 1). The geometry of clusters **A** is clearly close to a monocapped square antiprism (Fig. 1(a)), while that of type **B** is closer to a tricapped trigonal prism with two elongated vertical edges (Fig. 1(b)). The way cluster **A** is shown in Fig. 1(a) is somewhat unconventional since the monocapped square antiprism is shown lying on its side. The square of atoms 2–3–4–5 is capped by 1, while square 6–7–8–9 is open. The distances within the clusters range from 3.059(4) to 3.533(5) Å for **A** and from 3.067(4) to 3.426(6) Å for **B** (Table 4). The rubidium cations cap faces, edges, and vertices with the shortest Rb–Pb distances of 3.68(1) Å. There are some relatively short intercluster contacts of 3.767(5) Å between atoms Pb7A and Pb8A of clusters **A** (Fig. 1), and suggest some intercluster interactions. This distance is even shorter in the isostructural K_4Pb_9,

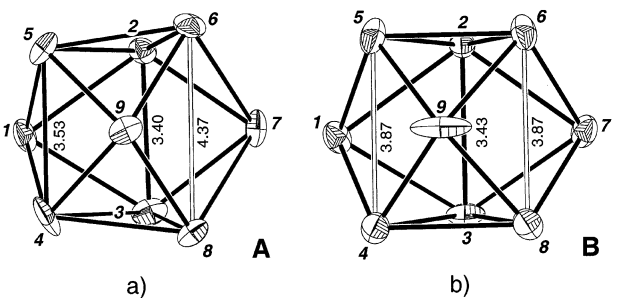

Fig. 1. The two different clusters in Rb_4Pb_9, (a) **A** and (b) **B**. Cluster **A** is a monocapped square antiprisms shown lying on its side (atom 1 caps the square face of atoms 2–3–4–5 while the square face 6–7–8–9 is open). The geometry of cluster **B** is closer to a tricapped (atoms 1, 7, 9) trigonal prism (triangular bases of atoms 2–5–6 and 3–4–8) with two elongated vertical edges (edges 4–5 and 6–8). The thermal ellipsoids are drawn at 50% probability level.

3.669(3) Å, obviously due to the larger size of the rubidium. Nonetheless, it has been proven for the potassium compound that the clusters are not bonded at all [12]. However, the 'short' intercluster contacts affect the density of states by broadening the valence *p*-band more than usual, to a width of about 5 eV. This, in turn, results in a narrow band gap of only about 0.30 eV.

3.2. $Cs_{10}K_6Pb_{36}$

This compound with mixed cations crystallizes in a novel structure type. The triclinic structure (space group *P*1), shown in Fig. 2, contains four crystallographically different clusters of Pb_9^{4-}, labeled **C**, **D**, **E** and **F** (Fig. 3). Interestingly, the corresponding binaries $K_{16}Pb_{36}$ and $Cs_{16}Pb_{36}$ are also known and both contain isolated Pb_9^{4-} [12,13], and yet the mixed cation system provides a new compound with the same overall composition $(Cs_{10}K_6)Pb_{36}$ and the same type of clusters but with a different structure. The shortest intercluster distances in this compound are very similar to those in Rb_4Pb_9, 3.70(2) Å, and similarly are not associated with any intercluster bonding interactions. The clusters are ordered in layers parallel to the (*a*, *b*)-plane (horizontal in Fig. 2). Their positions in each layer correspond to the positions of close-packed spheres, and the layers are stacked on top of each other as in hexagonal close-packed structures, i.e. they follow the order ABAB.

All four clusters in $Cs_{10}K_6Pb_{36}$ have two open square faces (Fig. 3) which clearly excludes classification as monocapped square antiprisms which have only one such face. All four geometries are somewhat closer to tricapped trigonal prisms with two elongated heights.

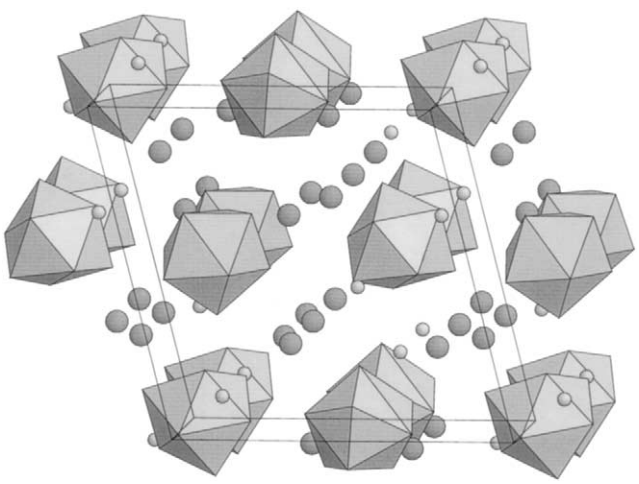

Fig. 2. A polyhedral view of the structure of $Cs_{10}K_6Pb_{36}$ along the *a* axis (*b* is horizontal) with the triclinic cell outlined. The isolated clusters of Pb_9^{4-} form nearly close-packed layers parallel to the (*a*,*b*)-plane, and these layers are stacked in a hexagonal close-packing fashion, i.e. ABAB. There are four clusters per unit cell and all are crystallographically different. The large and small isolated circles are Cs and K, respectively.

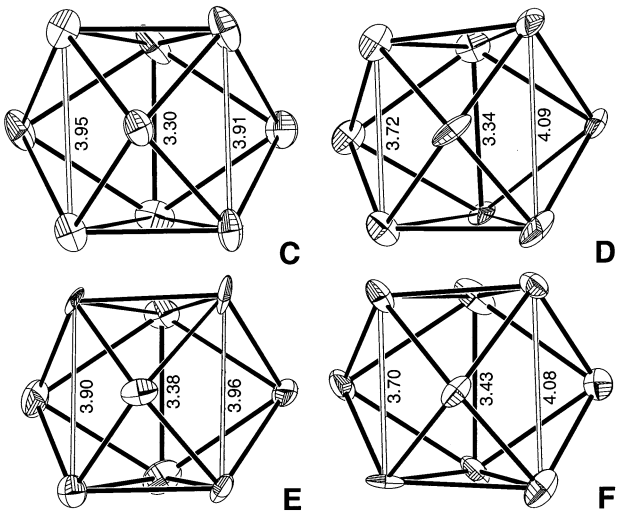

Fig. 3. The four clusters in $Cs_{10}K_6Pb_{36}$ labeled **C**, **D**, **E** and **F**. The atom numbering is the same as in Fig. 1. The thermal ellipsoids are drawn at 50% probability level.

Despite the 'deviations' from the classical *nido* shape, however, each of these clusters carries a charge typical for *nido*-clusters, 4−, according to the formula $Cs_{10}K_6(Pb_9)_4$. Thus, in this compound as well as in Rb_4Pb_9, we find clusters that do not conform to the *nido*-shape but need the same number of electrons for bonding as the *nido*-clusters. This needs more detailed investigation, and this is presented in the following section.

3.3. Nine-atom clusters

There have been quite extensive discussions in the literature about the geometry of nine-atom clusters and their classification into two classes according to their shapes, monocapped square antiprisms or tricapped trigonal prisms (usually elongated), and accordingly into *nido*- or *closo*-types, respectively [23–25]. However, this classification into two very strict classes is quite an ambiguous process since the clusters are almost never perfect, and it is impossible to draw a line between the two geometries. This is usually done based on a multitude of dihedral angles and edge ratios like those presented in Table 5. Thus, it can be seen from this table that the open square face of cluster **A** (face of atoms 6–7–8–9, Fig. 1) is perfectly planar with a 0° dihedral angle and is also nearly rectangular (Table 3) as expected for a monocapped square antiprism. Also typical for that geometry are the dihedral angles of atoms 5–9–4–1 and 2–1–3–7, 32.1(5) and 33.1(5)°, respectively. In the way the cluster is shown in Fig. 1(a), these angles are also dihedral angles within the waist of a trigonal prism of atoms 5–2–6 (upper triangular base) and 4–3–8 (bottom base) that is tricapped by atoms 1, 9, and 7. Thus, the monocapped square antiprism can be viewed as a tricapped trigonal prism

Table 5
Selected edge ratios and dihedral angles in some nine-atom lead clusters [a]

Cluster	Edge ratios		Dihedral angles			Ref.
	(6–8):(2–3)	(4–5):(2–3)	(6–7–8)/(6–8–9)	(5–9–4)/(1–4–5)	(1–2–3)/(2–3–7)

Pb_9^{4-} (E)	1.172(9)	1.154(8)	9.8(6)	12.7(6)	27.0(7)	[b]
Pb_9^{4-} (F)	1.189(9)	1.079(8)	12.2(6)	13.1(5)	24.9(5)	[b]

[a] The numbering system is from Fig. 1.
[b] This work.

with two normal edges, edges 4–5 and 3–2, and one elongated edge, the 8–6 edge. This is also indicated by the ratios between the three edges (Table 5), a number larger than one for the ratio (6–8): (2–3), 1.286(2), and a number close to one for the ratio of (5–4): (2–3), 1.040(2). The geometry with two short and one long edges is typical for a monocapped square antiprism, and is also the reason for the two large and one zero dihedral angles when considered as a tricapped trigonal prism. These dihedral angles and edge ratios of **A** also compare very well with known lead clusters that have already been 'classified' in the class of monocapped square antiprisms (Table 5).

The corresponding dihedral angles and edge ratios look quite different for the remaining five clusters, **B** through **F**. There are two small and one large deltahedral angles as well as two long and one short edges for the trigonal prism. Such clusters would be classified as distorted tricapped trigonal prisms with two elongated edges. A non-distorted prism, i.e. with three normal edges, would be expected to be a *closo*-cluster with a charge of 2− ($2n+2=20$ bonding electrons for a 9-atom cluster) according to Wade's rules [26]. However, obviously this is not the case for these clusters according to the stoichiometry of the compounds for which the clusters carry charges of 4− ($2n+4=22$ bonding electrons). This is also in agreement with the results from the extended-Hückel molecular orbital calculations performed for these clusters which show large HOMO–LUMO gaps of more than 3 eV for a total of 40 electrons (22 bonding electrons and $9\times 2=18$ lone pair electrons on 9 vertices), and correspondingly charges of 4−. Other examples of tricapped trigonal prisms distorted similarly to a different degree also carry $2n+4$ bonding electrons. Such are the cluster of Bi_9^{5+} in $BiBi_9(HfCl_6)_3$ and $Bi_9(Bi_3Cl_{14})$ [27], the heteroatomic clusters $[In_4Bi_5]^{3-}$ in (K-crypt)$_6$[In_4Bi_5]-[In_4Bi_5]·1.5en·0.5tol [28], Sn_9^{4-} in K(K-crown)$_3$[Sn_9]·en [24], and E_9^{3-} for E = Sn or Pb in (K-crypt)$_6E_9E_9$·1.5en·0.5tol where 'crypt' and 'crown' stand for 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo-[8,8,8]-hexacosane) and 1,4,7,10,13,16-hexaoxacyclooctadecane, respectively [25].

Introduced here is a new approach towards the shapes of the nine-atom deltahedral clusters. It is based on the general overall MO schemes for these clusters. In essence, it abolishes the classification into the two classes of monocapped square antiprisms and tricapped trigonal prisms, and uses only the class of the tricapped trigonal prisms but with different numbers of elongated edges. Shown in Fig. 4(a, b, c, and d) are four tricapped trigonal prisms with zero, one, two and three elongated

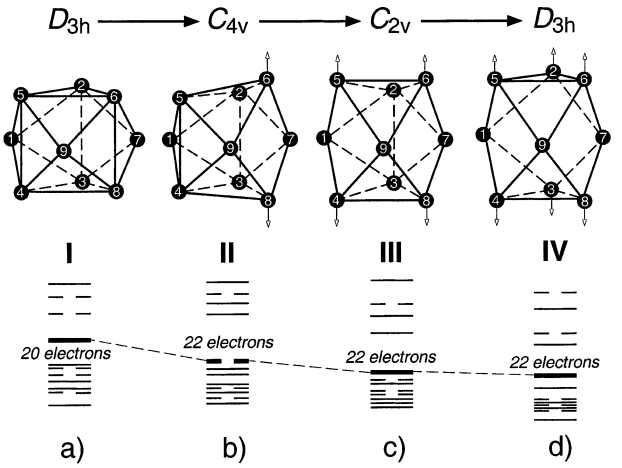

Fig. 4. A schematic representation of the consecutive opening of the three vertical edges of a tricapped trigonal prism (D_{3h}), cluster **I** in (a), along with the corresponding schematic MO diagrams. (b) The elongation of the 6–8 edge leads to a cluster, cluster **II**, with one open square face (C_{4v}) which also happens to be a monocapped square antiprism (shown lying on its side). (c) The elongation of the edge 4–5 of cluster **II** leads to cluster **III** with two open faces (C_{2v}). (d) The elongation of the edge 2–3 of cluster **III** results in an elongated tricapped trigonal prism, cluster **IV**, with three open faces (D_{3h}).

edges, respectively, and the corresponding schematic molecular orbital diagrams. Cluster **I** (Fig. 4(a)) is an ideal tricapped trigonal prism with D_{3h} symmetry and 'normal' (bonding) vertical edges (can be called 'three short' referring to the three vertical edges). The HOMO here is at $2n+2=20$ skeletal electrons but for this particular geometry there is also a relatively large gap above the LUMO a_2'' (shown with a thicker line). This would make the LUMO quite 'attractive' for additional electrons if lowered only a little more, and this can happen as a result of the distortions described below. This a_2' orbital, as it has been discussed before [29], is bonding within the triangular bases of the trigonal prism, i.e. triangles 2–5–6 and 3–4–8, but is antibonding between them (the capping atoms 1, 7, and 9, do not participate). This particular character of the orbital makes it very sensitive to changes in the heights of the prism, and this, combined with its position in the middle of a big gap (Fig. 4(a)), makes it the decisive orbital for the electron count of the cluster.

The cluster shown in Fig. 4(b), cluster **II**, is derived from cluster **I** by elongation of one vertical edge, the edge 6–8. As a result of just this relatively small distortion, the antibonding interactions in what was a_2' LUMO in cluster **I** are relieved, it drops down in energy, becomes occupied as a result of this, and now it is a part of a doubly degenerate HOMO for $2n+4$ electrons. The degeneracy is the result of the C_{4v} symmetry for this cluster which besides being a tricapped trigonal prism with one elongated edge ('two short and one long'), is also the classical monocapped square antiprism as already discussed above (compare with cluster **A** in Fig. 1(a)). This is also the classical shape for a *nido*-deltahedron, i.e. a deltahedron with one missing vertex and a charge of $4-$.

Elongation of a second edge of cluster **II**, the edge 4–5, leads to cluster **III** (Fig. 4(c)). The net character of the orbital in question is even more bonding since the antibonding interactions are reduced even more due to elongation of two instead of one edges. The HOMO–LUMO gap is still at $2n+4$ since nothing else changes significantly in the MO diagram. This cluster of C_{2v} symmetry has two long and one normal edges ('two long and one short') and, therefore, two open square faces. It resembles clusters **B** through **F** (Figs. 1 and 3). Usually the degree of elongation for each edge in a type **III** cluster with two long edges is smaller than that in a type **II** clusters with only one elongated edge. Thus, the edge 6–8 in cluster **A** (type **II**) is 4.370(4) Å while the two edges 4–5 and 6–8 in cluster **B** (type **III**) are 3.866(5) Å (Fig. 1). The same is true for the two long edges in clusters **C** through **F** which are of type **III**; they are all significantly shorter than 4.370(4) Å (Table 4).

Finally, elongation of the remaining third vertical edge of cluster **III** brings back a cluster of D_{3h} symmetry, cluster **IV** (Fig. 4(d)), which is again a tricapped trigonal prism like cluster **I** but is elongated along the threefold axis. The molecular diagram of this cluster ('three long') does not change much from that of cluster **III** and the HOMO–LUMO gap is at the same position. A well known example of this geometry is Bi_9^{5+} in $Bi[Bi_9](HfCl_6)_3$ with three long edges of 3.737 Å [27a].

As already mentioned above, the discussion of the type of a particular nine-atom cluster is often reduced to its classification as a tricapped trigonal prism or a monocapped square antiprism. Fig. 4 clearly shows that such a classification does not unambiguously define the electronic state of the cluster. Thus, clusters **I** and **IV** are both tricapped trigonal prisms but have different electronic requirements due to the relative position of the a_2' orbital. Clusters **II**, **III**, and **IV**, on the other hand, look quite different but have the same numbers of electrons. A very good illustration of this are the clusters **A** through **F**. Therefore, the usual classification of nine-atom clusters into the two classes is an oversimplification since, after all, the monocapped square antiprism is just one component of the series of distorted tricapped trigonal prisms: that with one elongated edge. Table 5 presents a good example of the difficulties when comparing edge ratios and dihedral angles since there are too many of them per cluster and it is impossible to define a cut-off line between the two categories. It is, perhaps, better to use two much more general categories such as 'normal' tricapped trigonal prism and elongated tricapped trigonal prism since these two shapes encompass all observed shapes and also differ in their electron counts. Ultimately, of course, each particular cluster can be discussed in the context of the particular stoichiometry, possible charges based on it, specifics of the shape, measured physical properties, along with careful consideration of the corresponding molecular orbital diagram.

3.4. $A_3A'Pb_4$

The four compounds Cs_3NaPb_4, Cs_3LiPb_4, Rb_3LiPb_4, and K_3LiPb_4 are isostructural with the known Cs_3LiSi_4 [30], and crystallize in the C-centered centrosymmetric space group *Cmcm*. They contain isolated tetrahedral anions of Pb_4^{4-} isoelectronic with the P_4 molecule. The four alkali metal cations provide the four extra electrons and surround the clusters in a very similar way as in the binary APb ($=A_4Pb_4$). However, the much smaller size of Na and Li and their high polarizing power and high electronegativity provide for different interactions in such compounds. For example, the structure of Cs_3NaPb_4 can also be viewed as made of isolated polymeric chains of $_\infty^1[Na(Pb)_4]^{3-}$ (Fig. 5)

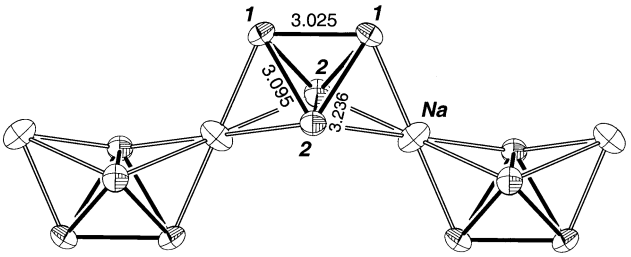

Fig. 5. The isolated polymeric chains of $_{\infty}^{1}[Na(Pb)_4]^{3-}$ running parallel to the c axis in the structure of the mixed-cation compound Cs_3NaPb_4. Lead and sodium are shown as full and crossed ellipsoids, respectively. All thermal ellipsoids are drawn at 80% probability level.

where the sodium cations act as μ_3-ligands coordinated to the staggered faces of two Pb_4^{4-} tetrahedra. The large alkali–metal cations, on the other hand, provide more complete charge transfer and simply separate and screen the chains from each other. Good evidence for the degree of covalency of the Na–Pb interactions is provided by the very different distances in the Pb_4^{4-} cluster. Thus, the edges coordinated to sodium, 1–2 and 2–2, are distinctly longer with distances of 3.095(2) and 3.236(3) Å, respectively, than the edge that is not, 1–1 with a distance of 3.025(2) Å. Furthermore, the edge that is coordinated to two sodium atoms is quite longer than the edges that are coordinated to only one such atom. Semi-covalent interactions of sodium and lithium are quite extensive in other known compounds. It should be pointed out that the 1–1 edge is not completely noncoordinated since it is capped by larger alkali–metal cations, but since the interactions there are almost purely ionic it does not experience elongation. Such combinations of very different alkali metals have been exploited extensively before and account for a large number of novel compounds with unique structures that form only with mixed cations [15–20,31].

4. Conclusions

The isolated nine-atom clusters of lead in the new compounds Rb_4Pb_9 and $Cs_{10}K_6Pb_{36}$ are best described as tricapped trigonal prisms with one or two elongated edges. They carry charges of $4-$, which is consistent with these shapes, and according to the charge they are all *nido* species with $2n+4$ bonding electrons. The commonly used classification of nine-atom clusters into two geometrical classes is not sufficient for accurate description of the electron counts for the clusters.

5. Supplementary material

A combined CIF file for the three structures has been deposited. Further details of the crystal structure determinations can be ordered from Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldsshafen, Germany (fax: +49-7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository CSD-numbers 411891 (Rb_4Pb_9), 411892 ($Cs_{10}K_6Pb_{36}$) and 411893 (Cs_3NaPb_4).

Stabilization of homonuclear Bi_5^{+} and Bi_6^{2+} polycations by cluster anions in the crystal structures of $Bi_{12-x}IrCl_{13-x}$, $Bi_{12-x}RhCl_{13-x}$ and $Bi_{12-x}RhBr_{13-x}$

Received 30 July 2001; accepted 27 November 2001

Abstract

The melting reaction of Bi with Rh or Ir and $BiCl_3$ or $BiBr_3$ yields black, metallic lustrous, air insensitive crystals of the subhalides $Bi_{12-x}MX_{13-x}$ (M = Rh, Ir; X = Cl, Br; $x < 1$). The compounds have the same structural principle as the previously reported subbromide $Bi_{34}Ir_3Br_{37}$. The structures can be subdivided in four types of complex ionic groups: cuboctahedral $[MBi_6X_{12}]^{-}$ clusters, $[MBi_6X_{13}]^{2-}$ clusters with an additional halide ion, Bi_5^{+} square pyramids and distorted Bi_6^{2+} octahedra. The range of homogeneity is due to variable contributions of the different clusters. $Bi_{12-x}IrCl_{13-x}$ is a semiconductor with an extended extrinsic regime below 200 K and a band gap of about 0.4 eV at room temperature. The subchlorides are diamagnetic at room temperature though a paramagnetic contribution appears towards lower temperature. Below 40 K, both compounds pass through a magnetic ordering that shows a hysteresis curve in the magnetization. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

The usual way to stabilize bismuth polycations in solids is the reaction of metal-rich melts of bismuth chlorides with Lewis acids like $AlCl_3$, $GaCl_3$, $HfCl_4$ or even $BiCl_3$ itself. The solids that crystallize from the melts always consist of chloro-metallate anions—$AlCl_4^{-}$ or $GaCl_4^{-}$ tetrahedra, $HfCl_6^{2-}$ octahedra or $^2_\infty[Bi_3Cl_{14}^{5-}]$ layers—combined with the objects of interest namely the well-known homonuclear bismuth polycations Bi_5^{3+} (a trigonal bipyramid [1]), Bi_8^{2+} (a square antiprism [2]), Bi_9^{5+} (a tricapped trigonal prism [3]), or the brand new heteronuclear polycation $[Bi_4Te_4]^{4+}$ (a heterocubane [4]).

Recently we introduced a new alternative for the stabilization of homonuclear bismuth polycations: the reaction of bismuth metal and bismuth halides with a moderately electron-rich transition metal (M = Rh or Ir) results in the formation of anionic $[MBi_6X_{12}]^{n-}$ clusters and polycations like Bi_5^{+} [5,6], Bi_6^{2+} [6] and $[Bi_8Si_2]^{3+}$ [7]. Here the transition metal acts as a Lewis acid by trying to achieve a favorable 16 or 18 valence electron count.

With this method a variety of ternary subhalides of bismuth have been synthesized [8]. Even within one ternary system several metal-rich compounds with diverse structural principles are formed when the reaction conditions are modified. For example, from the system Bi/Rh/Br, which comprises one of the title compounds, the subbromides $Bi_{12}Rh_3Br_2$, a slightly oxidized intermetallic phase [9], $Bi_9Rh_2Br_3$, a quasi one-dimensional metal [10] and Bi_7RhBr_8, a molecular cluster compound [11], are also accessible.

Here we present the synthesis and the crystal structures of the ternary subchlorides $Bi_{12-x}MCl_{13-x}$ (M = Rh, Ir) and of the subbromide $Bi_{12-x}RhBr_{13-x}$. In addition, the electrical conductivity and the magnetic properties of the two bismuth subclorides are described.

2. Experimental

2.1. Synthesis

Bismuth powder (chemical pure, Riedel de Haën) was reduced with hydrogen at 220 °C prior to use in synthesis. $BiCl_3$ (>98%, Alpha) and $BiBr_3$ (synthesized from the elements) were sublimed twice at 10^{-3} mbar in a temperature gradient of 200–100 °C. Rhodium powder (>99.9%, Merck) and iridium powder (>99.9%, Merck) were used without further treatment. The use of $RhCl_3$ and $RhBr_3$ in synthesis proved to be less favorable.

The starting materials were mixed together in molar relations of $Bi:BiX_3:M = 7.21:4.11:1$ (corresponding to the composition $Bi_{34}M_3X_{37}$) and sealed in evacuated quartz ampoules (inner diameter 13 mm; volume about 18 cm^3). The mixture was heated to 1000 °C in a tube furnace and subsequently cooled to room temperature (r.t.) within a period of several days. The products are fine-crystalline powders of $Bi_{12-x}MX_{13-x}$ in high yields.

Faster cooling of the melt with about 100 K h^{-1} provided single crystals suitable for X-ray structure determination. The by-products of the rapid cooling process—$BiCl_3$ (colorless) or $BiBr_3$ (yellow) and Bi_6Cl_7 or Bi_6Br_7 (needle like, black crystals)—were removed by sublimation in a temperature gradient of 300–100 °C. A slightly higher proportion of rhodium or iridium reduces the competing formation of the binary bismuth subhalides.

$Bi_{12-x}IrCl_{13-x}$, $Bi_{12-x}RhCl_{13-x}$, and $Bi_{12-x}RhBr_{13-x}$ form black, metallic lustrous crystals. The crystals have typical morphologies like steps-pyramids or u-shaped open channels. All compounds are brittle, insensitive to air and chemically resistant to diluted acids (hydrochloric acid, nitric acid, acetic acid) and to organic solvents. Upon heating the rhodium compounds decompose to Bi_4Rh [12], which is the intermetallic phase with the highest bismuth content in the Bi/Rh system, bismuth and bismuth halides.

2.2. Crystal structure determination

Powders samples and several single crystals of $Bi_{12-x}IrCl_{13-x}$, $Bi_{12-x}RhCl_{13-x}$, and $Bi_{12-x}RhBr_{13-x}$ from various preparations were characterized by X-ray diffraction methods. Precession photographs showed rhombohedral patterns for all crystals. Due to the symmetry of the low trigonal Laue group $\bar{3}$ and the absence of zonal reflection conditions the space groups $R\bar{3}$ or $R3$ were assigned. Measurements with different types of single crystal diffractometers (imaging plate system, CCD system and four-circle goniometer) confirmed these crystallographic observations; neither additional Bragg reflections nor diffuse scattering were observed. Special care was taken to avoid and correct absorption effects (Ag radiation, ψ-positions with maximum transmission [13], optimized numerical absorption correction [14,15]). The crystallographic data and experimental details of the crystal structure determinations are summarized in Tables 1 and 2.

The structures of the investigated crystals $Bi_{12-x}IrCl_{13-x}$ ($x \approx 0.77$), $Bi_{12-x}RhCl_{13-x}$ ($x \approx 0.30$) and $Bi_{12-x}RhBr_{13-x}$ ($x \approx 0.72$) have a close relationship to the previously described compound $Bi_{34}Ir_3Br_{37}$, which corresponds to $Bi_{12-x}IrBr_{13-x}$ with $x = 2/3$ [6]. The unit cell (hexagonal setting) of $Bi_{34}Ir_3Br_{37}$ contains one Bi_6^{2+} and two Bi_5^+ polycations as well as one $[IrBi_6Br_{13}]^{2-}$ and two $[IrBi_6Br_{12}]^-$ cluster anions in an ordered arrangement. Accordingly, the rhombohedral symmetry proved to only be a pseudo-symmetry with multiple twinning of triclinic structural domains [17].

Unfortunately, in the present cases it was not possible to attain fully ordered models of the crystal structures by reducing the symmetry below $R3$ because of the 'arbitrary' non-stoichiometry of the compounds and the disorder in the crystals (probably very small twin and anti-phase domains). The refinements under the symmetry of the space group $R3$ still allow to quote approximate compositions, i.e. proportions of the four cluster types, for the investigated single crystals of $Bi_{12-x}MX_{13-x}$.

2.3. Measurements of electrical conductivity and magnetic properties

The electrical resistance of a pressed pellet of $Bi_{12-x}IrCl_{13-x}$ was measured between r.t. and 12 K using the van der Pauw method. To attain low temperature a two-steps Gifford–McMahon-Refrigerator was used.

Variable-temperature susceptibility measurements (zero-field cooled) were carried out in the temperature range 1.5–300 K using an AC susceptometer (Oxford Instruments) for $Bi_{12-x}IrCl_{13-x}$ and $Bi_{12-x}RhCl_{13-x}$. Isothermal magnetization measurements were performed as a function of the external magnetic field from -1 to 1 T at 5 K. The powdered samples were introduced into a holder that consists of an inert polymer folded into a very small packet.

3. Discussion

$Bi_{12-x}IrCl_{13-x}$ and $Bi_{12-x}RhCl_{13-x}$ are the first ternary subchlorides of bismuth that not merely bismuth chloro-metallates but have the chloride ions bound to bismuth atoms in the low oxidation state +II. Like $Bi_{12-x}RhBr_{13-x}$ and the previously described $Bi_{12-x}IrBr_{13-x}$ [6] they crystallize in a unique although apparently favored structure type. The principle arrangement is similar to the CsCl type apart from

the fact that the ions are complex units, explicitly $[MBi_6X_{12}]^-$ and $[MBi_6X_{13}]^{2-}$ cluster anions along with Bi_5^+ and Bi_6^{2+} polycations Fig. 1). Allusions to the cubic symmetry of the CsCl type are the angles of the primitive rhombohedral cell, which are close to 90° (Table 1). All subhalides $Bi_{12-x}MX_{13-x}$ (M = Rh, Ir; X = Cl, Br) show a range of homogeneity ($x < 1$) that is due to changes of the relative proportions of single and double charged ions.

Within the cuboctahedral $[MBi_6X_{12}]^-$ clusters, six Bi atoms coordinate the central M atom octahedrally (Fig. 2); halide ions bridge all twelve edges of the octahedron. Whilst the short Bi–M contacts can be described as mainly covalent single bonds, the edge-lengths of the octahedra preclude any significant interaction between the Bi atoms (Table 3). Corresponding to previously reported considerations [5–8] the $[MBi_6X_{12}]^-$ cluster can be formally subdivided in a neutral $(Bi^{II}X_2)_6$ shell and an internal M atom with a −I oxidation state. Together with the six Bi–M bonds a total of 16 valence electrons on the central atom results.

The addition of a thirteenth halide ion to the $[MBi_6X_{12}]^-$ unit leads to the $[MBi_6X_{13}]^{2-}$ anion and reduces the point symmetry of the cluster from O_h to

C_3. The fact that both types of anions have at least the symmetry of a threefold rotational axis as well as their spatial arrangement in the motif of a body centered cubic packing dominate the entire crystal structure and is responsible for the rhombohedral pseudo-symmetry.

The voids in the packing are filled with squarely pyramidal Bi_5^+ and distorted octahedral Bi_6^{2+} polycations (Fig. 3). Their bond lengths and angles are known from a (fortunately) ordered triclinic crystal of

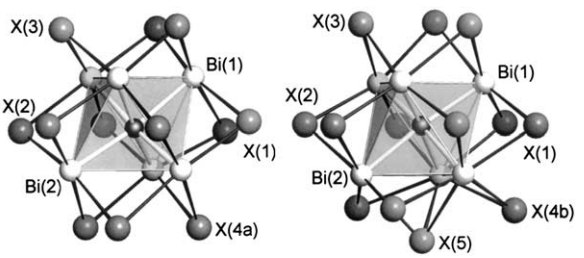

Fig. 2. $[MBi_6X_{12}]^-$ and $[MBi_6X_{13}]^{2-}$ clusters in $Bi_{12-x}MX_{13-x}$ [18].

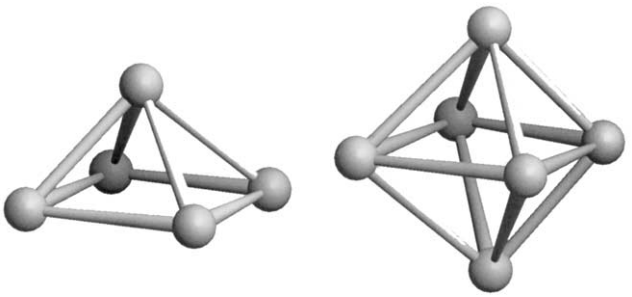

Fig. 3. The polycations Bi_5^+ (square pyramid) and Bi_6^{2+} (distorted octahedron) in $Bi_{12-x}MX_{13-x}$ [6,18].

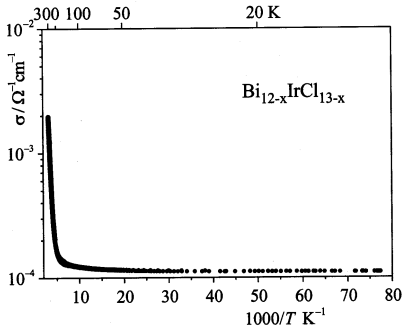

Fig. 4. Electrical conductivity of $Bi_{12-x}IrCl_{13-x}$ in the temperature range 12–310 K.

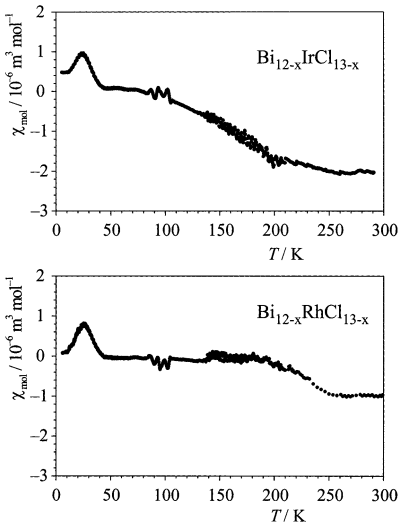

Fig. 5. Molar magnetic susceptibility of $Bi_{12-x}IrCl_{13-x}$ and $Bi_{12-x}RhCl_{13-x}$ in the temperature range 1.5–300 K (zero-field cooled).

$Bi_{34}Ir_3Br_{37}$, i.e. $Bi_{12-x}IrBr_{13-x}$ with $x = 2/3$ [6]. From the present structure determinations the precise shapes of the polycations cannot be derived because of the structural disorder and the overlying non-matching threefold pseudo-symmetry.

Whilst the square-based pyramidal Bi_5^+ cation with 14 framework electrons (only 6p electrons are counted) can easily be classified as a *nido*-cluster, with the distorted 'octahedral' Bi_6^{2+} cation things are not so simple. The seeming contradiction between the 16 framework electrons, which suggest a *nido*-cluster, and the apparently closed cage is resolved on closer examination: the shape of the Bi_6^{2+} cation deviates significantly from that of a regular octahedron so that it is as if a seventh atom has been removed from a hypothetical *closo*-cluster.

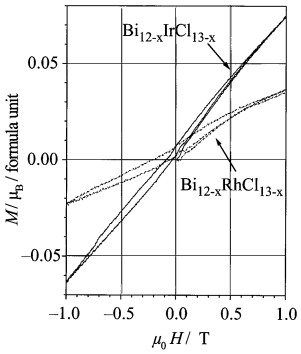

Fig. 6. Magnetization of $Bi_{12-x}IrCl_{13-x}$ and $Bi_{12-x}RhCl_{13-x}$ at 5 K in an external magnetic field from -1 to 1 T.

e.s.d. values are given in parentheses.

$Bi_{12-x}IrCl_{13-x}$, as well as the other cluster salts of the type $Bi_{12-x}MX_{13-x}$, is a semiconductor with a considerable electric resistance. The black color of the compounds indicates that the band gaps must lie below the energy of visible light. There are two regimes in the electrical conductivity (Fig. 4). Below 150 K the extrinsic conductivity that arises from the inherent impurity level in the non-stoichiometric compound is dominant, the temperature dependence is small. Above 150 K the charge carrier density is determined mainly by the thermal excitation of electrons directly from the valence to the conduction band, and therefore, the conductivity shows a strong temperature dependence. From the slope of the curve in the Arrhenius plot between 280 and 330 K the band gap at room temperature is calculated to about 0.4 eV.

Under ambient conditions the subchlorides $Bi_{12-x}IrCl_{13-x}$ and $Bi_{12-x}RhCl_{13-x}$ are very weak magnetic, diamagnetism prevails (Fig. 5). However, the molar magnetic susceptibility increases with decreasing

temperature revealing paramagnetic contributions. Probably, the paramagnetic part arises from two unpaired electrons in the HOMO (non-bonding t_{2g} orbitals of the M atom with 16 valence electrons [7]) of the cluster anion. At higher temperature the substantial diamagnetism of 1294 or 1262 electrons per formula unit $Bi_{12}IrCl_{13}$ or $Bi_{12}RhCl_{13}$ dominates.

For both compounds the susceptibility passes through a local maximum at almost the same temperature of 25 K. The hysteresis in the magnetization curves at 5 K (Fig. 6) indicate a magnetic ordering process. Whether it is only a matter of local, uncorrelated interactions of either ferromagnetic or antiferromagnetic order transformation cannot be decided at the current point of our investigations.

4. Supplementary material

Further details of the crystal structure determinations are available from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), e-mail: crysdata@fiz-karlsruhe.de, on quoting the depository numbers CSD-412014 for $Bi_{12-x}IrCl_{13-x}$ ($x = 0.77(1)$), CSD-412015 for $Bi_{12-x}RhCl_{13-x}$ ($x = 0.30(2)$) and CSD-412016 for $Bi_{12-x}RhBr_{13-x}$ ($x = 0.72(1)$).

Abstract

Reactions of an iminophosphorane bearing the Martin ligand (2,4,6-$Pr^i_3C_6H_2$)(–C_6H_4-2-$C(CF_3)_2O$–)P=NPh **1** with carbonyl compounds and phenyl isothiocyanate gave the corresponding [2 + 2]-cycloadducts, 1,3,2λ^5-oxazaphosphetidine **2a** and 1,3,2λ^5-diazaphosphetidine-4-thione **8a**, respectively, whose structures were characterized by X-ray crystallographic analyses. Thermolysis of cycloadduct **2a**, which is considered as an intermediate of the aza-Wittig reaction, showed two reactivities giving cyclic phosphinate **4** and imine **5** as well as **1** and ketone **3**, respectively. Thermolysis of **8a** afforded not only **1** and phenyl isothiocyanate **7a**, but also cyclic thiophosphinate **10** and diphenylcarbodiimide **11a**. The formation of **10** and **11a** suggests the bond recombination around phosphorus atom of **8a**. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

There has been much interest in the chemistry of four-membered ring compounds with two or more main group elements in the ring due to their characteristic structures and unique reactivities [1]. In the course of our study on the heteracyclobutanes bearing a highly coordinate main group element at the position adjacent to the heteroatom [1b,2], we have achieved the synthesis of 1,2λ^5-oxaphosphetanes [3] and 1,2λ^5-azaphosphetidines [4], i.e. the intermediates of Wittig reactions, by taking advantage of the Martin ligand [5]. On the other hand, iminophosphoranes have been explored in connection with phosphonium ylides [6], providing aza-Wittig reactions, which have been utilized as effective methods for the synthesis of nitrogen-containing heterocycles [7]. For the elucidation of the mechanism of aza-Wittig reactions, it is valuable to isolate their intermediates, i.e. 1,3,2λ^5-oxazaphosphetidines, because it can provide a direct evidence on its mechanism. Furthermore, taking into consideration the polarized electronic structure of an iminophosphorane, it is expected to be a useful building block of small-membered ring compounds. In the course of our study on the reactivities of an iminophosphorane bearing the Martin ligand, we preliminary reported the formation of 1,3,2λ^5-oxazaphosphetidine **2**, which is the first example of dioxyazaphosphorane [10-P-5(C_2O_2N)] with an 1,3,2-oxazaphosphetidine ring, by the reaction of iminophosphorane **1** with carbonyl compounds [8]. The thermolysis of the four-membered ring compound **2a** revealed the formation of the Wittig-type products and the existence of the equilibrium with the starting materials. These results encouraged us to study the synthesis and reactivities of the four-membered ring compounds derived from iminophosphorane **1**. We report here the details of the synthesis and reactions of 1,3,2λ^5-oxazaphosphetidine **2a**, which is an intermediate of the aza-Wittig reaction, as well as 1,3,2λ^5-diazaphosphetidine-4-thione. In this paper, we used the Martin ligand and

a bulky 2,4,6-triisopropylphenyl (denoted as Tip hereafter) group for the stabilization of the cycloadducts.

2. Experimental

2.1. General procedures

All reactions were performed under degassed and sealed tube unless otherwise noted. Solvents were dried by standard methods and freshly distilled prior to use. Iminophosphorane **1** was prepared according to the literature procedure [9]. The amount of **1** was estimated based on the integral of ^{19}F NMR spectra. Preparative gel permeation liquid chromatography (GPLC) was performed by LC-908 with JAIGEL 1H and 2H columns (Japan Analytical Industry) with toluene as solvent. Preparative thin layer chromatography (PTLC) was carried out with Merck Kieselgel 60 PF254. The melting point was determined on a Yanaco micro melting point apparatus and was uncorrected. ^1H (500 MHz) and ^{13}C (126 MHz) NMR spectra were recorded on a JEOL A500 spectrometer using tetramethylsilane as an internal standard. ^{19}F (254 MHz) and ^{31}P (109 MHz) NMR spectra were recorded on a JEOL EXcalibur270 spectrometer using Fleon® and 85% H_3PO_4 as external standards, respectively. Mass spectral data were recorded on a JEOL SX-102 mass spectrometer. Elemental analysis was carried out at the Microanalytical Laboratory of Department of Chemistry, Faculty of Science, The University of Tokyo.

2.2. Synthesis of 1,3,2λ^5-oxazaphosphetidine (2a)

Iminophosphorane **1** (21.9 g, 38.6 mmol) derived from hexafluorocumyl alcohol [9] in THF (200 ml) was allowed to react with hexafluoroacetone (denoted as HFA hereafter) gas **3**, which was generated by treatment of HFA·$3H_2O$ (16.2 ml, 116 mmol) with concentrated H_2SO_4 at 140 °C, in a three-necked flask at room temperature (r.t.) for 2.5 h under nitrogen atmosphere afforded 1,3,2λ^5-oxazaphosphetidine **2a** which could be purified by GPLC and recrystallization from CH_2Cl_2–ethanol giving colorless crystals (7.31 g, 26%). Compound **2a**, colorless crystals; melting point (m.p.) 178–181 °C (dec.); ^1H NMR (500 MHz, $CDCl_3$) δ 0.27 (d, $^3J_{HH} = 6.6$ Hz, 3H), 1.06 (d, $^3J_{HH} = 6.6$ Hz, 3H), 1.11 (d, $^3J_{HH} = 6.6$ Hz, 3H), 1.13 (d, $^3J_{HH} = 6.9$ Hz, 6H), 1.33 (d, $^3J_{HH} = 6.6$ Hz, 3H), 2.76 (sept, $^3J_{HH} = 6.9$ Hz, 1H), 3.54 (sept, $^3J_{HH} = 6.6$ Hz, 1H), 3.72 (sept, $^3J_{HH} = 6.6$ Hz, 1H), 6.77 (d, $^4J_{PH} = 7.2$ Hz, 1H), 7.03 (d, $^4J_{PH} = 7.2$ Hz, 1H), 7.12 (d, $^3J_{HH} = 7.6$ Hz, 2H), 7.22–7.29 (m, 3H), 7.58 (brs, 1H), 7.67 (t, $^3J_{HH} = 7.6$ Hz, 1H), 7.73 (dd, $^3J_{HH} = 7.6$ Hz, $^4J_{HP} = 9.4$ Hz, 1H), 8.52 (dd, $^3J_{HH} = 7.6$ Hz, $^3J_{HP} = 11.4$ Hz, 1H); $^{13}C\{^1H\}$ NMR (126 MHz, $CDCl_3$) δ 23.0 (s), 23.5 (s), 23.6 (s), 24.5 (s), 26.3 (s), 30.2 (d, $^3J_{CF} = 31$ Hz), 31.2 (d, $^3J_{CF} = 31$ Hz), 33.9 (s), 83.4 (sept, $^2J_{CF} = 31$ Hz), 85.3 (sept, $^2J_{CF} = 31$ Hz), 121.4 (q, $^1J_{CF} = 290$ Hz), 121.6 (q, $^1J_{CF} = 290$ Hz), 121.7 (q, $^1J_{CF} = 290$ Hz), 121.8 (q, $^1J_{CF} = 288$ Hz), 122.0 (d, $J_{CP} = 18$ Hz), 123.5 (d, $J_{CP} = 16$ Hz), 124.6 (d, $J_{CP} = 14$ Hz), 128.4 (s), 129.0 (s), 130.9 (d, $J_{CP} = 14$ Hz), 131.6 (s), 132.9 (d, $1J_{CP} = 176$ Hz), 133.4 (d, $J_{CP} = 3$ Hz), 133.7 (d, $^1J_{CP} = 147$ Hz), 134.7 (d, $J_{CP} = 3$ Hz), 136.5 (d, $J_{CP} = 12$ Hz), 137.4 (d, $J_{CP} = 22$ Hz), 148.7 (d, $J_{CP} = 21$ Hz), 150.6 (d, $J_{CP} = 4$ Hz), 150.8 (d, $J_{CP} = 12$ Hz); ^{19}F NMR (254 MHz, $CDCl_3$) δ −76.53 (q, $^4J_{FF} = 9.8$ Hz, 3F), −74.99 (q, $^4J_{FF} = 9.8$ Hz, 3F), −72.71 (q, $^4J_{FF} = 9.8$ Hz, 3F), −72.35 (q, $^4J_{FF} = 9.8$ Hz, 3F); ^{31}P NMR (109 MHz, $CDCl_3$) δ −18.6 (s); FAB MS; m/z 734 ($[M+H]^+$). *Anal.* Calc. for $C_{33}H_{32}F_{12}NO_2P$: C, 53.80; H, 4.46; N, 2.09. Found: C, 54.03; H, 4.40; N, 1.91%.

2.3. Reaction of iminophosphorane 1 with benzaldehyde

A C_6D_6 (0.8 ml) solution of iminophosphorane **1** (135 mg, 0.238 mmol) and benzaldehyde (24 μl, 0.24 mmol) in a degassed and sealed glass tube was heated at 60 °C for 16 h. Monitoring of the reaction solution by ^{19}F and ^{31}P NMR spectroscopy showed the disappearance of **1** and the formation of new peaks assignable to a mixture of two diastereomers of 1,3,2λ^5-oxazaphosphetidine **2b** (**2b**; isomer A:isomer B = 1:3 as determined by the integral of ^{19}F NMR spectrum). Separation of the crude oil involving **2b** using with GPLC and PTLC quantitatively afforded a hydrolyzed product, cyclic phosphinate **4** as a sole identifiable compound bearing the Martin ligand and a phosphorus atom because of instability of **2b**. **2b** (isomer A): ^{19}F NMR (254 MHz, C_6D_6) δ −73.39 (A_3B_3, $^4J_{FF} = 9.7$ Hz, 3F), −74.33 (A_3B_3, $^4J_{FF} = 9.7$ Hz, 3F); ^{31}P NMR (109 MHz, C_6D_6) δ −26.3. **2b** (isomer B): ^{19}F NMR (254 MHz, C_6D_6) δ −73.24 (A_3B_3, $^4J_{FF} = 9.7$ Hz, 3F), −73.36 (A_3B_3, $^4J_{FF} = 9.7$ Hz, 3F); ^{31}P NMR (109 MHz, C_6D_6) δ −27.8. **4**: colorless crystals, m.p. 136.9–139.0 °C; ^1H NMR (500 MHz, $CDCl_3$) δ 1.01 (d, $^3J_{HH} = 6.6$ Hz, 6H), 1.21 (d, $^3J_{HH} = 6.8$ Hz, 6H), 1.27 (d, $^3J_{HH} = 6.7$ Hz, 6H), 2.86 (sept, $^3J_{HH} = 6.8$ Hz, 1H), 3.60 (d, $^3J_{HH} = 6.6$ Hz, 2H), 7.08 (d, $^4J_{PH} = 6.6$ Hz, 2H), 7.72–7.76 (m, 3H), 8.14–8.19 (m, 1H); $^{13}C\{^1H\}$ NMR (126 MHz, $CDCl_3$) δ 23.4 (s), 23.5 (s), 24.5 (d, $^4J_{PC} = 4.3$ Hz), 32.4 (d, $^3J_{PC} = 5.5$ Hz), 32.4(s), 84.7 (sept, $^2J_{FC} = 33.1$ Hz, $C(CF_3)_2$), 121.1 (q, $^1J_{FC} = 286.5$ Hz, CF_3), 121.4 (q, $^1J_{FC} = 290.9$ Hz, CF_3), 122.6 (d, $^3J_{PC} = 14.0$ Hz), 124.6 (d, $^2J_{PC} = 11.5$ Hz), 125.7 (d, $^1J_{PC} = 142.0$ Hz), 130.4 (d, $^2J_{PC} = 11.6$ Hz), 131.9 (d, $^3J_{PC} = 11.9$ Hz), 133.4 (s), 134.3 (d, $^1J_{PC} = 134.0$ Hz), 134.0 (d, $^2J_{PC} = 17.6$ Hz), 151.4 (d, $^2J_{PC} = 13.0$ Hz), 153.0 (d, $^4J_{PC} = 2.8$ Hz), ^{19}F NMR (254 MHz, $CDCl_3$) δ −75.10 (q, $^4J_{FF} = 8.9$ Hz, 3F), −75.72 (q, $^4J_{FF} = 8.9$ Hz, 3F); $^{31}P\{^1H\}$ NMR (109 MHz, $CDCl_3$) δ 56.2 (s);

Anal. Calc. for $C_{24}H_{27}F_6O_2P$: C, 58.54; H, 5.53. Found: C, 58.38; H, 5.62%.

2.4. Reaction of iminophosphorane **1** with trifluoroacetophenone

Similarly, the reaction of iminophosphorane **1** (113 mg, 0.201 mmol) with trifluoroacetophenone (31 μl, 0.21 mmol) in C_6D_6 (1.2 ml) at 70 °C for 12 h gave a mixture of two diastereomers of 1,3,2λ^5-oxazaphosphetidine **2c** (**2c**; isomer A:isomer B = 1:3 as determined by the integral of ^{19}F NMR spectrum), which decomposed during separation by GPLC and PTLC due to its instability. **2c** (isomer A): ^{19}F NMR (254 MHz, C_6D_6) δ −72.22 (A_3B_3, $^4J_{FF}$ = 10.2 Hz, 3F), −72.69 (A_3B_3, $^4J_{FF}$ = 10.2 Hz, 3F), −78.37 (s); ^{31}P NMR (109 MHz, C_6D_6) δ −23.0 (s). **2c** (isomer B): ^{19}F NMR (254 MHz, C_6D_6) δ −72.69 (A_3B_3, $^4J_{FF}$ = 10.2 Hz, 3F), −73.26 (A_3B_3, $^4J_{FF}$ = 10.2 Hz, 3F), −75.66 (s); ^{31}P NMR (109 MHz, C_6D_6) δ −25.1 (s).

2.5. Thermolysis of 1,3,2λ^5-oxazaphosphetidine (**2a**)

A solution of **2a** (10 mg, 0.014 mmol) in toluene-d_8 (0.6 ml) was heated at 130 °C for 135 h in a degassed and sealed tube. Monitoring of the reaction solution by ^{1}H, ^{13}C, ^{19}F and ^{31}P NMR spectra showed the formation of cyclic phosphinate **4** (100%) and imine **5** (90%). The yields of the products were determined by the integral of ^{19}F NMR spectrum.

2.6. Thermolysis of 1,3,2λ^5-oxazaphosphetidine (**2a**) in the presence of water

Similarly, the reaction of a mixture of **2a** (10 mg, 0.014 mmol) and water (24 μl) in toluene-d_8 (0.5 ml) at 140 °C for 3 h gave HFA **3** (96%), cyclic phosphinate **4** (100%), imine **5** (4%), and aniline (89%).

2.7. Attempted hydrolysis of imine **5**

Similarly, imine **5** (0.10 ml) and water (0.10 ml) in toluene-d_8 (0.6 ml) was heated at 140 °C for 24 h. Monitoring of the reaction mixture by ^{1}H and ^{19}F NMR spectra showed no change.

2.8. Thermolysis of 1,3,2λ^5-oxazaphosphetidine (**2a**) in the presence of methanol

Similarly, the reaction of a mixture of **2a** (10 mg, 0.014 mmol) and methanol (35 μl, 1.4 mmol) in toluene-d_8 (0.5 ml) at 140 °C for 50 min gave HFA **3** (1%), cyclic phosphinate **4** (22%), imine **5** (1%), aniline, and methoxyphosphorane **6** (75%). The yields of the products were determined by the integral of ^{19}F NMR spectrum. On exposure to open air, compound **6** was hydrolyzed to give cyclic phosphinate **4**. **6**: ^{19}F NMR (254 MHz, toluene-d_8) δ −78.01 (brs, 3F), −79.32 (brs, 3F); ^{31}P NMR (109 MHz, toluene-d_8) δ −15.0 (s); FAB MS: m/z 599 (M^+).

2.9. Synthesis of 1,3,2λ^5-diazaphosphetidine-4-thione (**8**)

Similarly, the reaction of iminophosphorane **1** (455 mg, 0.800 mmol) and phenyl isothiocyanate **7a** (0.40 ml, 3.3 mmol) in benzene (5 ml) at 50 °C for 15 h gave 1,3,2λ^5-diazaphosphetidine-4-thione **8a**. Purification with GPLC and PTLC and recrystallization from hexane–CH_2Cl_2 afforded colorless crystals of **8a** (73.0 mg, 13%). **8a**: colorless crystals; m.p. 120.5–122.0 °C (dec.); ^{1}H NMR (500 MHz, $CDCl_3$) δ −0.08 (d, $^3J_{HH}$ = 6.5 Hz, 3H), −0.07 (d, $^3J_{HH}$ = 6.5 Hz, 3H), 1.21 (d, $^3J_{HH}$ = 6.5 Hz, 3H), 1.21 (d, $^3J_{HH}$ = 6.5 Hz, 3H), 1.52 (d, $^3J_{HH}$ = 7.0 Hz, 3H), 1.56 (d, $^3J_{HH}$ = 7.0 Hz, 3H), 2.58 (sept, $^3J_{HH}$ = 6.4 Hz, 1H), 2.85 (sept, $^3J_{HH}$ = 6.9 Hz, 1H), 4.75 (sept, $^3J_{HH}$ = 6.6 Hz, 1H), 6.62 (d, $^4J_{PH}$ = 8.5 Hz, 1H), 6.81 (brs, 2H), 7.20–7.30 (m, 9 H), 7.63 (brs, 1H), 7.78 (brs, 1H), 7.89 (brs, 1H), 8.85 (dd, $^3J_{HH}$ = 9.0 Hz, $^3J_{PH}$ = 12.5 Hz, 1H); ^{13}C{^{1}H} NMR (126 MHz, $CDCl_3$) δ 21.8 (s), 23.2 (s), 23.3 (s), 23.5 (s), 23.7 (s), 26.4 (s), 32.0 (d, $^3J_{CP}$ = 6 Hz), 32.2 (d, $^3J_{CP}$ = 5 Hz), 36.0 (s) 82.6 (sept, $^2J_{CF}$ = 31 Hz), 120.9 (q, $^1J_{CF}$ = 288 Hz), 121.8 (d, J_{CP} = 20 Hz), 121.9 (q, $^1J_{CP}$ = 290 Hz), 123.7 (d, J_{CP} = 15 Hz), 125.5 (d, J_{CP} = 14 Hz), 127.5 (s), 128.2 (d, J_{CP} = 3 Hz), 128.7 (s), 128.8 (d, $^1J_{CP}$ = 163 Hz), 128.9 (s), 129.3 (s), 131.1 (d, $^1J_{CP}$ = 134 Hz), 131.8 (d, J_{CP} = 13 Hz), 133.9 (d, J_{CP} = 11 Hz), 134.6 (d, J_{CP} = 3 Hz), 136.8 (s), 138.2 (d, J_{CP} = 21 Hz), 141.8 (d, J_{CP} = 4 Hz), 147.1 (d, J_{CP} = 21 Hz), 149.1 (d, J_{CP} = 10 Hz), 151.4 (d, J_{CP} = 4 Hz), 190.0 (d, J_{CP} = 6 Hz); ^{19}F NMR (254 MHz, $CDCl_3$) δ −73.17 (A_3B_3, J = 10.3 Hz, 3F), −74.78 (A_3B_3, J = 10.3 Hz, 3F); ^{31}P NMR (109 MHz, $CDCl_3$) δ −18.9 (s); FAB MS: m/z 703 ($[M+H]^+$), 568 ($[M+H–PhNCS]^+$), 194 ($[PhN{=}C{=}NPh]^+$); *Anal.* Calc. for $C_{37}H_{37}F_6N_2O$: C, 63.24; H, 5.31; N, 3.99; S, 4.56. Found: C, 63.06; H, 5.36; N, 3.99; S, 4.42%.

2.10. Reaction of cyclic phosphinate **4** with phenyl isothiocyanate

Heating of **4** (10 mg, 0.020 mmol) with phenyl isothiocyanate (2.4 μl, 0.020 mmol) in C_6D_6 (0.5 ml) at 100 °C for 1 day resulted in no change in ^{1}H, ^{19}F and ^{31}P NMR spectra.

2.11. Reaction of cyclic thiophosphinate **10** with phenyl isothiocyanate

Heating of **10** (10 mg, 0.020 mmol) with phenyl isothiocyanate (2.4 μl, 0.020 mmol) in C_6D_6 (0.5 ml) at

100 °C for 1 day resulted in no change in ^{1}H, ^{19}F and ^{31}P NMR spectra.

2.12. Thermolysis of 1,3,2λ^5-diazaphosphetidine-4-thione (8a)

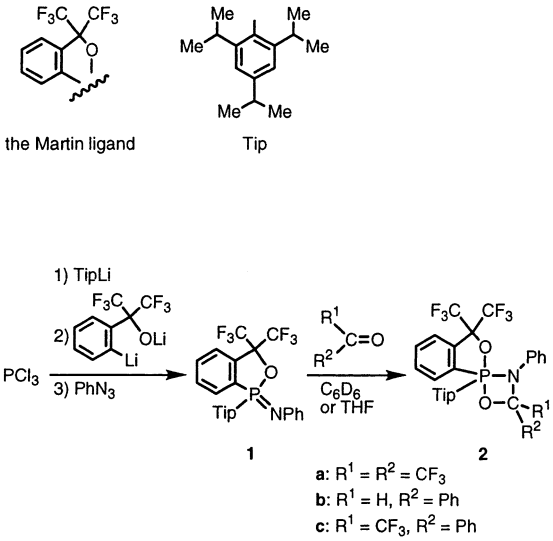
Similarly, heating of a C_6D_6 (0.6 ml) solution of **8a** (8.0 mg, 0.011 mmol) at 50 °C for 4 h gave iminophosphorane **1** (29%), cyclic phosphinate **4** (54%) and cyclic thiophosphinate **10** (17%). The yields of the products were determined by the integral of ^{19}F NMR spectra. After exposure of the reaction mixture to open air, phenyl isothiocyanate **7a**, aniline and diphenylcarbodiimide **11a** were detected by GC-MS spectra. Compound **10**: colorless crystals; m.p. 152.0–153.5 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ −0.59 (brs, 6H), 1.21 (d, $^{3}J_{HH}$ = 6.8 Hz, 6H), 1.33 (brs, 6H), 2.85 (sept, $^{3}J_{HH}$ = 6.8 Hz, 1H), 3.39 (brs, 1H), 4.34 (brs, 1H), 7.07 (brs, 2H), 7.62–7.81 (m, 3H), 8.22–8.26 (m, 1H); $^{13}C\{^{1}H\}$ NMR (126 MHz, $CDCl_3$) δ 23.5 (s), 23.6 (s), 24.2 (brs), 32.7 (brs), 34.1 (s), 85.6 (sept, $^{2}J_{CF}$ = 29.8 Hz), 121.2 (q, $^{1}J_{CF}$ = 285.6 Hz), 121.3 (q, $^{1}J_{CF}$ = 287.1 Hz), 121.4 (brs), 124.2 (d, $^{2}J_{CP}$ = 11.1 Hz), 124.3 (brs), 131.8 (d, $^{3}J_{CP}$ = 12.2 Hz), 132.0 (d, $^{1}J_{CP}$ = 113.3 Hz), 132.2 (d, $^{3}J_{CP}$ = 12.1 Hz), 132.9 (s), 133.2 (d, J = 16.5 Hz), 138.3 (d, $^{1}J_{CP}$ = 94.5 Hz), 146.7 (brs), 152.2 (d, J_{CP} = 2.8 Hz); ^{19}F NMR (254 MHz, $CDCl_3$) δ −74.65 (q, $^{4}J_{FF}$ = 9.4 Hz, 3F), −75.52 (q, $^{4}J_{FF}$ = 9.4 Hz, 3F); ^{31}P NMR (109 MHz, $CDCl_3$) δ 106.6 (s); *Anal.* Calc. for $C_{24}H_{27}F_6OPS$: C, 56.69; H, 5.35; S, 6.31. Found: C, 56.47; H, 5.35; S, 6.29%.

2.13. Reaction of iminophosphorane 1 with p-tolyl isothiocyanate

Similarly, the reaction of **1** (42 mg, 0.062 mmol) with *p*-tolyl isothiocyanate **7b** (0.10 ml, 0.74 mmol) in C_6D_6 (0.5 ml) at 60 °C for 5 h, at r.t. for 2 days, and 60 °C for 10 h gave cyclic thiophosphinate **10**, other 1,3,2λ^5-diazaphosphetidine-4-thiones **8b**, **8c**, and **8d** (**8b**:**8c**:**8d** = 1:1:1), phenyl(*p*-tolyl)carbodiimide **11b**, di(*p*-tolyl)carbodiimide **11c** (**11b**:**11c** = 6:1), and iminophosphorane **12**. The ratio of **8b**, **8c**, and **8d** was determined by the integral of ^{19}F NMR spectra. The ratio of **11b** and **11c** was determined by GC-MS spectra. After exposure of the reaction mixture to open air, it was separated by GPLC and PTLC to give **8d**, **11b**, **11c**, and a mixture of **8b** and **8c** (**8b**:**8c** = 1:1). A mixture of **8b** and **8c** could not be separated. Diastereomeric mixture of **8b** and **8c**: ^{19}F NMR (254 MHz, $CDCl_3$) δ −74.80 (q, $^{4}J_{FF}$ = 10.2 Hz), −74.62 (q, $^{4}J_{FF}$ = 10.2 Hz), −73.20 (q, $^{4}J_{FF}$ = 10.2 Hz), −73.17 (q, $^{4}J_{FF}$ = 10.2 Hz); ^{31}P NMR (109 MHz, $CDCl_3$) δ −18.73 (s), −19.23 (s). Compound **8d**: ^{19}F NMR (254 MHz, $CDCl_3$) δ −74.63 (A_3B_3, $^{4}J_{FF}$ = 10.4 Hz, 3F), −73.20 (A_3B_3, $^{4}J_{FF}$ = 10.4 Hz, 3F); ^{31}P NMR (109 MHz, $CDCl_3$) δ −19.06 (s). **12**: ^{31}P NMR (109 MHz, C_6D_6) δ −25.46 (s).

2.14. X-ray crystallographic studies of 2a and 8a

The intensity data of **2a** and **8a** were collected at 298 K using a Rigaku AFC7R diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71069 Å) and a rotating anode generator. The structure was solved by direct methods and refined by the full matrix least squares procedures on *F*. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Some details of the data collection and refinement are given in Table 1.



3. Results and discussion

3.1. Synthesis and structure of 1,3,2λ^5-oxazaphosphetidines

Iminophosphorane **1** was prepared in situ according to the literature which we previously reported [9]. Since **1** is sensitive to the moisture, it was used without further purification as such for the following reactions. Iminophosphorane **1** was allowed to react with HFA at r.t. to give the corresponding 1,3,2λ^5-oxazaphosphetidine **2a**. Compound **2a** was obtained as colorless crystals after chromatographic separation in 26% yield from hexafluorocumyl alcohol (Scheme 1). ^{31}P NMR spectra showed the quantitative conversion from **1** to **2a**. Formation of the 1,3,2λ^5-oxazaphosphetidine **2a** was confirmed by the up-field shift in ^{31}P NMR spectra of the crude products compared with **1** (from δ_P 25.6 in C_6D_6 for **1** to δ_P −18.6 for **2a** in $CDCl_3$), indicating

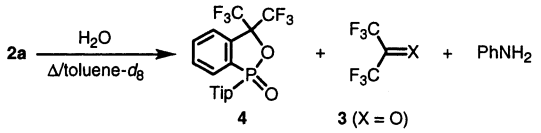
Scheme 1.

the pentacoordinate phosphorane structure of **2a** [3,4]. The molecular structure of **2a** was established by X-ray crystallographic analysis, the result of which has already been reported in a preliminary communication [8]. The crystal data and structural parameters of **2a** are shown in Tables 1 and 2, respectively. Compound **2a** was shown to have the distorted trigonal-bipyramidal (TBP) structure at phosphorus atom with two oxygen atoms at the apical positions and two carbon and nitrogen atoms at the equatorial positions. It is noteworthy that **2a** was obtained from the iminophosphorane, which was generated from the corresponding phosphine and azide as reported for the general aza-Wittig reactions. In contrast to the formation of **2a**, the previously reported 1,3,2λ^5-oxazaphosphetidines were not synthesized from the corresponding iminophosphoranes, but from the aminophosphines [10]. The reactions of iminophosphorane **1** with benzaldehyde and trifluoroacetophenone at 60 and 70 °C, respectively, also afforded 1,3,2λ^5-oxazaphosphetidines **2b** and **2c**, respectively, as the diastereomeric mixtures. Formation of **2b** and **2c** was confirmed by up-filed shifts in ^{31}P NMR spectra, (δ_P −26.3, −27.8 for **2b** and δ_P −23.0, −25.1 for **2c** in C_6D_6, respectively), compared with that (δ_P −25.6) of **1**. Unfortunately, oxazaphosphetidines **2b** and **2c** could not be purified, because they were easily hydrolysed on silica gel. Therefore, the yields of **2b** and **2c** could not be determined. On the other hand, no reaction took place upon heating of a C_6D_6 solution of **1** and benzophenone in a sealed tube even at 120 °C due to its low reactivity and steric congestion.



3.2. Reactions of a 1,3,2λ^5-oxazaphosphetidine

Oxazaphosphetidine **2a** did not dissociate into iminophosphorane **1** and HFA in $CDCl_3$ solution at r.t. in contrast to Schmidpeter's 1,3,2λ^5-oxazaphosphetidines [11]. *N*-apical pseudorotamer of **2a** was not detected by variable temperature NMR spectra between 27 and 107 °C, although *N*-equatorial pseudorotamers which violate the apicophilicity rule were observed at r.t. for azaphosphetidines [4]. This is interesting because difference in electronegativity between oxygen and nitrogen atoms for **2a** is almost same as that between carbon and nitrogen atoms for the azaphosphetidines.

Thermolysis of **2a** was performed at 140 °C in toluene-d_8. The formation of cyclic phosphinate **4** (100%) and imine **5** (90%) in the reaction mixture was confirmed by ^{1}H, ^{19}F, and ^{31}P NMR spectra (Scheme 2). The products were identified by comparing their spectral data of GC-MS and NMR spectra with those of the authentic samples. The ratio of these products was determined based on the integral of ^{19}F NMR spectra of the reaction solution. Furthermore, the oxazaphosphetidine is expected to exhibit another reactivity on the thermolysis, i.e. the formation of the iminophosphorane as in the cases of azaphosphetidines. Since this process must be reversible, thermolysis of **2a** in the presence of water was performed to offer an evidence for the existence of **1**. In fact, thermolysis of **2a** with excess amount (20 equiv.) of water at 140 °C for 3 h gave

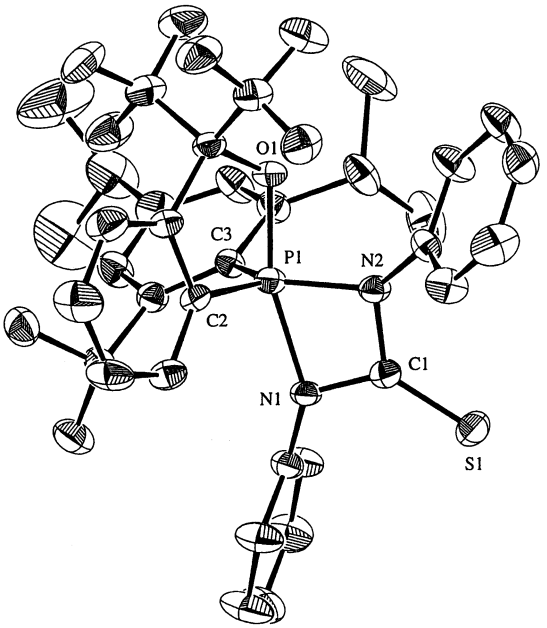
HFA **3** (96%), **4** (100%) and aniline (89%) as main products with a small amount of imine **5** (4%). It was confirmed by the control experiment that aniline is not derived from imine **5** but iminophosphorane **1**. Since aniline and **4** are hydrolysis products of **1**, thermolysis process of **2a** giving **1** and HFA was evidenced by their formation. In the experiment in the presence of water, the possible product **1** was irreversibly removed from its system by its hydrolysis. Furthermore, thermolysis of **2a** in the presence of methanol (100 equiv.) at 140 °C afforded methoxyphosphorane **6** (75%), which seems to be formed by alcoholysis of **1** formed (Scheme 3). Unfortunately, compound **6** could not be purified because of its instability to the moisture, its formation was confirmed by ^{19}F and ^{31}P NMR spectra and FAB MS spectra of the reaction solution. These results indicate two reaction pathways for the thermolysis of **2a**: one is formation of the aza-Wittig reaction products, cyclic phosphinate **4** and imine **5**, and another is regeneration of iminophosphorane **1** and HFA **3**. Since the former path is the second step of the aza-Wittig reaction, 1,3,2λ^5-oxazaphosphetidines **2a** can be regarded as an intermediate of the aza-Wittig reaction.

3.3. Synthesis and structure of a 1,3,2λ^5-diazaphosphetidine-4-thione

There has been only one report on the X-ray crystallographic analysis of a 1,3,2λ^5-thiazaphosphetidine ring to date [12]. The formation and isolation of 1,3,2λ^5-oxazaphosphetidine **2a** bearing the Martin ligand as an isolable solid encouraged us to study the cycloaddition reactions with carbon–sulfur double-bond compounds in anticipation of the formation of the 1,3,2λ^5-thiazaphosphetidines [13]. An attempted reaction of iminophosphorane **1** with thiobenzophenone resulted in

Scheme 4.

no reaction, while monitoring the reaction of **1** with carbon disulfide in C_6D_6 at 60 °C afforded the cyclic thiophosphinate **10** without an observable intermediate. On the other hand, the reaction of compound **1** with phenyl isothiocyanate **7a** in benzene at 50 °C gave the corresponding adduct **8a** (Scheme 4). Monitoring of the reaction solution by ^{31}P NMR spectra showed the appearance of a new peak at δ_P −20.7 assignable to a pentacoordinate phosphorus atom of **8a**. In the ^1H NMR spectrum of **8a**, the ortho proton of the Martin ligand resonated at low field (δ 8.85), which is a typical feature of compounds with a TBP structure bearing a polar apical bond [14]. Further heating resulted in the decrease of **8a** and the increase of cyclic thiophosphinate **10**. Compound **8a** could be easily purified by chromatographic separation and recrystallization. X-ray crystallographic study revealed that compound **8a** is not 1,3,2λ^5-thiazaphosphetidine **9a**, but 1,3,2λ^5-diazaphosphetidine-4-thione **8a**. The unit cell of the crystal of **8a** contains two almost identical molecules. One of the crystal structures of **8a** was illustrated by the thermal ellipsoid plots in Fig. 1. Selected bond lengths and angles are listed in Table 2. The sum of three equatorial bond angles around phosphorus atom [359.8°] indicates that the phosphorus atom is placed on the equatorial plane. The bond angle between two apical bonds [162.7(3)°] indicates the distortion from the linearity. Thus, it can be clearly seen that **8a** is a distorted TBP structure at P1 atom with an oxygen and a nitrogen atoms at apical positions and other three atoms at equatorial positions, respectively, (%TBP→SP, 14%) [15]. It makes contrast to the nearly square pyramidal structure of the previously reported pentacoordinate 1,2-diazaphosphetidine-4-thione [16]. The apical P1–N1 bond length of **8a** are longer than that of equatorial P1–N2 bond. Similar characteristic feature is also shown in the cases of other phosphoranes exhibiting TBP geometry [3,4]. It is interesting that the reaction of iminophosphorane **1** with phenyl isothiocyantate gave the corresponding [2 + 2]-cycloadducts, while that of the phosphorus ylide bearing the Martin ligand af-



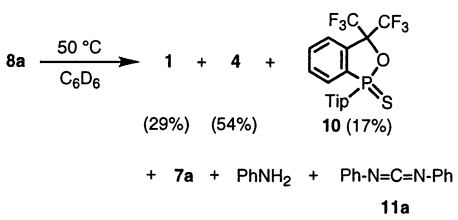


Fig. 1. ORTEP drawing of **8a** (30% probability). Hydrogen atoms are omitted for clarity.

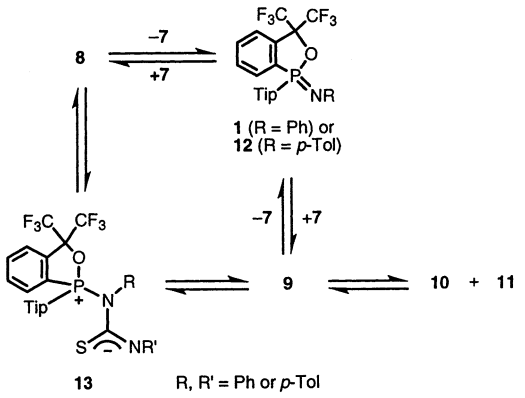
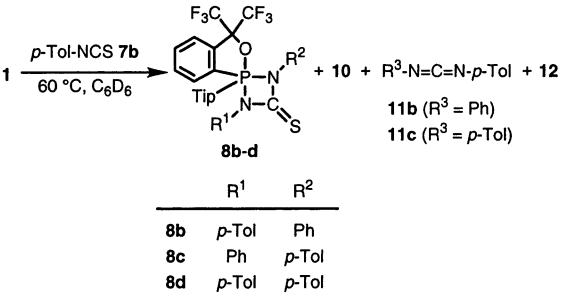


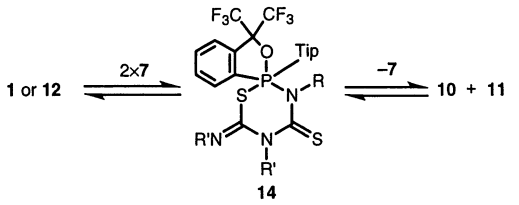
forded another type of product, a 1,2λ^5-thiaphosphetene [17]. Although compound **8a** can be handled in open air without special care in the solid state for a while, about 10% was decomposed even in the solid state after 1 week.

3.4. Reactions of 1,3,2λ^5-diazaphosphetidine-4-thiones

1,3,2λ^5-Diazaphosphetidine-4-thione **8a** was subjected to thermolysis in C_6D_6 at 50 °C (Scheme 5). Monitoring of the reaction solution by ^{19}F and ^{31}P NMR spectra revealed the disappearance of **8a** and formation of iminophosphorane **1** (29%), cyclic phosphinate **4** (54%), and cyclic thiophosphinate **10** (17%). Further heating of the reaction mixture caused no change as confirmed by NMR spectra. After exposure of the reaction mixture to open air, the formation of phenyl isothiocyanate **7a**, carbodiimide **11a**, and aniline was confirmed by GC-MS spectra. The formation of carbodiimide **11a** is most likely explained as shown in Scheme 6. Upon heating, 1,3,2λ^5-diazaphosphetidine-4-thione **8a** is firstly expected to undergo the cycloreversion giving **1** and phenyl isothiocyanate **7a**. The



Scheme 5.



Scheme 6.

sequential [2 + 2]-cycloaddition of the P=N unit of **1** with C=S unit of the isothiocyanate gives the intermediary 1,3,2λ^5-thiazaphosphetidine **9a**, which affords cyclic thiophosphinate **10** and carbodiimide **11a** due to its thermal instability. For the formation of **9a**, the P–N bond dissociation of **8a** followed by intramolecular P–S bond formation of thus obtained zwitterion **13** is also considered as another mechanism. Since four-membered ring compounds with a P–S apical bond are suspected to be labile as indicated by the study on the pentacoordinate 1,2λ^5-thiaphosphetane, bond dissociation would take place in the transient 1,3,2λ^5-thiazaphosphetidine under such reaction conditions [18]. Although compounds $ZP(MeNCH_2CH_2)_3N$ (Z = O, S) can selectively catalyze the transformation of isocyanates to carbodiimides, the control experiments revealed that neither cyclic phosphinate **4** nor thiophosphinate **10**, which were formed in the thermolysis of **8a**, catalyzes such a transformation [19].

To reveal the formation mechanism of cyclic thiophosphinate **10** and carbodiimide **11a**, reaction of **1** with excess amount of *p*-tolyl isothiocyanate **7b** was performed in C_6D_6 at 60 °C (Scheme 7). Monitoring of the reaction solution by ^{31}P NMR spectra showed the formation of two new signals at δ_P −20.6 and −21.0 assignable to two diastereomers of 1,3,2λ^5-diazaphosphetidine-4-thiones **8b** and **8c** bearing both *N*-Ph and *N*-*p*-tolyl groups after heating 5 h, and additionally new peak at δ_P −20.8 assignable to **8d** with two *N*-*p*-tolyl groups after further standing at r.t. for 2 days. The formation of cyclic thiophosphinate **10** and iminophosphorane **12** (δ_P 25.46) bearing a *p*-tolyl group instead of a phenyl group of **1** was also observed. Further heating at 60 °C for 10 h reduced the ratio of first two peaks compared with that of the new peak. Formation of three 1,3,2λ^5-diazaphosphetidines **8b**–**d**, two carbodiimides **11b** and **11c**, and cyclic thiophosphinate **10** was confirmed by GC-MS and/or ^{31}P NMR spectra after exposure of the reaction mixture to open air and successive separation with chromatography. Three 1,3,2λ^5-diazaphosphetidine-4-thiones **8b**–**d** could

Scheme 7.

Scheme 8.

not be separated from one another due to the structural similarity. The formation of **8d** is consistent with the existence of iminophosphorane **12**. Cycloreversion of 1,3,2λ^5-diazaphosphetidine-4-thiones **8b** and **8c** gives iminophosphoranes **1** and **12**, which undergo cycloaddition with *p*-tolyl isothiocyanate to give the starting mixture and **8d**, respectively. Two following mechanisms are possible for the formation of carbodiimides **11**. In the mechanism as shown in Scheme 8, each iminophosphorane **1** and **12** reacts with two molecules of an isothiocyanate to give a six-membered ring compound **14**, which undergoes ring opening to afford its carbodiimide **11** together with cyclic thiophosphinate **10** and the isothiocyanate **7**. The other mechanism involves P–N bond dissociation of **8**, formation of 1,3,2λ^5-thiazaphosphetidine **9a**, and Wittig-type ring opening reaction similarly to the thermolysis of **8a** (Scheme 6). The experimental result that phenyl(*p*-tolyl)carbodiimide **11b** was formed in higher yield than di(*p*-tolyl)carbodiimide **11c** (**11b**:**11c** = 6:1) can exclude the mechanism shown in Scheme 8, because **11c** should predominantly be formed for that mechanism. The present formation of cyclic thiophosphinate **10** and carbodiimide **11** from 1,3,2λ^5-thiazaphosphetidine **8** is considered to proceed via P–N bond dissociation in marked contrast to the reactivity of Schmidpeter's 1,3,2λ^5-diazaphosphetidine-4-thiones, which rearrange intramolecularly but do not give the corresponding P=S and carbodiimide units [20].

In summary, we have shown that the reactions of an iminophosphorane **1** bearing the Martin ligand with HFA and phenyl isothiocyanate gave the corresponding cycloadducts **2a** and **8**. It was found that 1,3,2λ^5-oxazaphosphetidine **2a** has two reactivities on its thermolysis giving imine **5** and ketone **3**, respectively. The former reactivity exhibits that **2a** is an intermediate of the aza-Wittig reaction. Thermolysis of **8** revealed two reaction pathways, that is, regeneration of **1** and the isothiocyanate **7**, and formation of cyclic thiophosphinate **10** and carbodiimide **11** via **9**. The formation of the iminophosphorane is found to be a characteristic reactivity of not only a 1,2λ^5-azaphosphetidine but also a 1,3,2λ^5-oxazaphosphetidine and a 1,3,2λ^5-diazaphosphetidine-4-thione, respectively.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 167822 and 167823 for compounds **2a** and **8a**. Copies of this information may be obtained from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The reactions of *N*-(2-chloroethyl)benzamide and *N*-[3-bromopropyl]phthalimide with $ArTe^-$ Na^+ generated in situ by borohydride reduction of Ar_2Te_2, have resulted in *N*-[2-(4-methoxyphenyltelluro)ethyl]benzamide ($\mathbf{L}^1$) and *N*-[2-(4-methoxyphenyltelluro)propyl] phthalimide ($\mathbf{L}^2$) respectively. The $\mathbf{L}^1$ and $\mathbf{L}^2$ both exhibit characteristic ^1H and ^{13}C NMR spectra. The single crystal structures of $\mathbf{L}^1$ and $\mathbf{L}^2$, the latter as a mixed crystal with $\mathbf{L}^2\mathbf{H}_2$ are determined by X-ray diffraction (XRD). The Te–C(alkyl) bond length is 2.140(8)/2.149(4) Å and longer than Te–C(aryl), 2.107(8)/2.123(5) Å. The complexes having stoichiometries $[PdCl_2(\mathbf{L}^1)]$ (**1**), $[PtCl_2(\mathbf{L}^1)]$(**2**), $[(Phen)Pd(\mathbf{L}^1)](ClO_4)_2$ (**3**), $[(DPPE)Pd(\mathbf{L}^1)](ClO_4)_2$ (**4**) and $[RuCl_2(\mathbf{L}^2)_2]$ (**5**) were synthesized and characterized by elemental analyses, conductance and molecular weight measurements, NMR (^1H and ^{13}C) and FT-IR spectra. The deshielding of CH_2Te ($\sim$0.2 ppm in ^1H NMR and up to 22 ppm in $^{13}C\{^1H\}$ NMR) and NH signals (upto 0.8 ppm in ^1H NMR) of **1**–**4**, with respect to those of free $\mathbf{L}^1$ indicates that $\mathbf{L}^1$ coordinates with Pd–Pt(II) as a (Te, N) ligand. The CH_2Te/CH_2N signals in ^1H and ^{13}C NMR spectra of **5** appear deshielded (0.8/0.14 and 20/8 ppm, respectively), when compared with those of free $\mathbf{L}^2$, indicating ligation of $\mathbf{L}^2$ via Te and N. © 2002 Elsevier Science Ltd. 1. Introduction

The current interest in the chemistry of hybrid organotellurium ligands (having other donor sites along with Te) [1–7] is due to their obvious importance in understanding further the ligation of heaviest metalloid tellurium vis a vis other well known donors. The designing of (Te_x, N_y) type of hybrid organotellurium ligands has been carried out by tellurating aliphatic amines [1,2,8,9] and pyridine derivatives [10]. However, ligand chemistry of hybrid organotellurium donor containing amide functionality is unknown so far [2–4]. Similarly the telluration of imide derivatives has been reported [4] scantly. It was, therefore, thought worthwhile to design *N*-[2-(4-methoxyphenyltelluro)ethyl]-benzamide ($\mathbf{L}^1$) and *N*-[2-(4-methoxyphenyltelluro)-propyl] phthalimide ($\mathbf{L}^2$) and investigate their ligand chemistry. The results of these investigations are reported in this paper. Both the ligands are structurally characterized. However, for $\mathbf{L}^2$, the crystal used was found to be a mixed crystal of $\mathbf{L}^2$ and $\mathbf{L}^2\mathbf{H}_2$, with

PII: S0277-5387(02)00831-8

occupancies of 40 and 60%, respectively. None of the complexes could be structurally characterized due to poor quality of their crystals. However, using their spectroscopic (NMR and IR) data it can be readily inferred that $\mathbf{L}^1$ and $\mathbf{L}^2$ both ligate as a (Te, N) donor in all the complexes **1**–**5**.

2. Experimental

The C and H analyses were carried out with a Perkin–Elmer elemental analyzer 240 C. Tellurium was estimated volumetrically [4]. The ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded on a Bruker Spectrospin DPX-300 NMR spectrometer at 300.13 and 75.47 MHz, respectively. IR spectra in the range 4000–250 cm^{-1} were recorded on a Nicolet Protége 460 FT-IR spectrometer as KBr and CsI pellets. The conductance measurements were made in acetonitrile (concentration ~ 1 mM) using an ORION conductivity meter model 162. The molecular weights (concentration ~ 5 mM) in chloroform were determined with a Knauer vapour pressure osmometer model A0280. The melting points (m.p.) determined in open capillary are reported as such. *N*-(2-Chloroethyl)benzamide and *N*-[3-bromopropyl]phthalimide obtained from Aldrich (USA) were used as received. The reported methods were used to synthesize $[(Phen)PdCl_2]$ [11,11a] and $[(DPPE)PdCl_2]$ [11b].

2.1. X-ray diffraction analysis

The Bruker P4S X-ray diffractometer was used for the data collection on $\mathbf{L}^1$, employing ω–2θ technique. The unit cell was determined from 25 randomly selected reflections using automatic search, index and least square routines. Empirical absorption correction was applied using SHELXA programme [12,12a]. The structure was solved by routine heavy atom/Fourier methods (using SHELXL 93 [12b]/SHELX 86 [12c]) and refined by full-matrix least-squares on F^2. The crystal and refinement data of $\mathbf{L}^1$ are given in Table 1. For structure determination of '$\mathbf{L}^2$' (mixed crystal of $\mathbf{L}^2$ and $\mathbf{L}^2\mathbf{H}_2$, which are colourless plates) a suitable specimen was mounted on a glass fibre and cell dimensions and intensity data were recorded on an Enraf Nonius KCCD diffractometer, with ϕ and ω scans chosen to give a complete asymmetric unit. The data collection and cell refinement [13] gave cell constants corresponding to an orthorhombic cell whose dimensions are given in Table 1 along with other experimental parameters An absorption correction was applied [14], which resulted in transmission factors ranging from 0.9650 to 0.7744. The structures were solved by direct methods [15]. All of the non-hydrogen atoms were treated anisotropically. During the course of the refinement, it was found that oxygen O(2) was split over two positions. This was interpreted as resulting from the use of a mixed crystal of $\mathbf{L}^2$ and $\mathbf{L}^2\mathbf{H}_2$. The rigidity of the phthalimide system is apparently such that all atoms are in identical positions in $\mathbf{L}^2$ and $\mathbf{L}^2\mathbf{H}_2$ with the exception of the terminal oxygen, >C(11)–O(2B) in $\mathbf{L}^2$ and the hydroxyl oxygen, >C(11)H–O(2A)H in $\mathbf{L}^2\mathbf{H}_2$. The effect is an apparent disorder of this oxygen atom

with the occupancy of O(2B):O(2A) of 0.4:0.6. Hydrogen atoms were included in idealized positions with isotropic thermal parameters set at 1.2 times that of the carbon and oxygen atom to which they were attached. The parameters for final cycle of full-matrix least-squares refinement of mixed crystal, '$\mathbf{L}^2$' [16] are also given in Table 1. The ORTEP diagram of $\mathbf{L}^2$ is displayed in Fig. 3(a) and that of $\mathbf{L}^2H_2$ in Fig. 3(b).

2.2. Synthesis of *N*-[2-(4-methoxyphenyltelluro)ethyl]benzamide ($\mathbf{L}^1$)

The solution of bis(4-methoxyphenyl)ditelluride (1.87 g, 4 mmol) made in 50 cm^3 of ethanol was refluxed under oxygen free nitrogen atmosphere. Sodium borohydride (0.5 g dissolved in 10 cm^3 of 10% aqueous NaOH) was added to it drop wise till it became colourless. *N*-(2-Chloroethyl)benzamide (1.46 g, 8 mmol) dissolved in 10 cm^3 of ethanol, was added drop wise to the refluxing colourless solution. The reaction mixture was further refluxed for 1–2 h, cooled to 25 °C and poured into ice cold water (200 cm^3). $\mathbf{L}^1$ was extracted from it into dichloromethane (100 cm^3). The extract was washed with water, dried over sodium sulfate and evaporated on a rotary evaporator, resulting in a yellowish oil, which was dissolved in a 1:2 mixture of dichloromethane and petroleum ether (40–60 °C). The solution was kept at 0–5 °C for 24 h. The fibrous white crystals of $\mathbf{L}^1$ were filtered and dried in vacuo. Yield: 70%; m.p. 68–70 °C Λ_M (Ω^{-1} cm^2 mol^{-1}) 5.3. *Anal.* Calc. for $C_{16}H_{17}O_2NTe$: C, 50.19; H, 4.44; N, 3.66; Te, 32.50. Found: C, 49.81; H, 4.58; N, 3.17; Te, 32.70%. Mol. wt.: 375 (Calc. 382). ^1H NMR ($CDCl_3$, 25 °C) (δ vs. TMS) 3.00–3.04 (t, 2H, H_1), 3.76–3.82 (m, 5H, H_2 and OMe), 6.52 (bs, 1H, NH), 6.72–6.75 (d, 2H, ArH *m* to Te), 7.35–7.49 (m, 3H, ArH *p* and *m* to CO), 7.62–7.64 (d, 2H, ArH *o* to CO), 7.69–7.72 (d, 2H, ArH *o* to Te). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 8.1 (C_1), 41.5 (C_2), 54.9 (OCH_3), 99.3 (ArC–Te), 115.2 (ArC *m* to Te), 126.8 (ArC *m* to CO), 128.2 (ArC *p* to CO), 131.7 (ArC *o* to CO), 134.1 (ArC–CO), 140.8 (ArC *o* to Te), 160.9 (ArC *p* to Te), 167.1 (CO).

2.3. Synthesis of [$PdCl_2(\mathbf{L}^1)$] (**1**)

The [$(C_6H_5CN)_2PdCl_2$] (0.49 g, 1 mmol) dissolved in 20 cm^3 of dichloromethane was mixed with a solution of ligand $\mathbf{L}^1$ (0.38 g, 1 mmol) made in 10 cm^3 of dichloromethane with vigorous stirring. The mixture was further stirred for 2 h at room temperature (r.t.), concentrated to 7–8 cm^3 on a rotary evaporator and mixed with hexane (5 cm^3). The resulting brown precipitate of **1** was filtered, washed with diethylether, recrystallized from chloroform–hexane (1:2) mixture and dried in vacuo. Yield: 85%; m.p. 84–85 °C (d) Λ_M (Ω^{-1} cm^2 mol^{-1}) 30 *Anal.* Calc. for $C_{16}H_{17}O_2NTePdCl_2$: C, 34.29; H, 3.03; N, 2.50; Te, 22.86. Found: C, 34.35; H, 3.10; N, 2.84; Te, 21.93%. Mol. wt.: 550 (Calc. 560). ^1H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 3.37 (bs, 2H, H_1), 3.77 (s, 3H, OMe), 3.87 (bs, 2H, H_2), 6.84–6.86 (d, 2H, ArH *m* to Te), 7.08 (bs, 1H, NH), 7.34–7.48 (m, 3H, ArH *p* and *m* to CO), 7.77–7.80 (d, 2H, ArH *o* to CO), 7.82–7.85 (d, 2H, ArH *o* to Te). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 22.9 (C_1), 38.1 (C_2), 55.3 (OCH_3), 105.1 (ArC–Te), 115.9 (ArC *m* to Te), 127.3 (ArC *m* to CO), 128.5 (ArC *p* to CO), 131.7 (ArC *o* to CO), 133.5 (ArC–CO), 137.8 (ArC *o* to Te), 161.5 (ArC *p* to Te), 167.8 (CO).

2.4. Synthesis of [$PtCl_2(\mathbf{L}^1)$](**2**)

To a solution of $K_2[PtCl_4]$ (0.17 g, 0.4 mmol) made in 10 cm^3 of water, ligand $\mathbf{L}^1$ (0.15 g 0.4 mmol) dissolved in 10 cm^3 of acetone was added. The resulting mixture was stirred for 1 h at r.t. and poured into 100 cm^3 of water. The complex **2** was extracted into chloroform (100 cm^3). The extract was dried over anhydrous sodium sulphate, concentrated to $\sim$10 cm^3 on a rotary evaporator and mixed with hexane (15 cm^3). The resulting precipitate of **2** was filtered, washed with hexane and recrystallized from hexane–dichloromethane (1:1) mixture. The yellow colored compound was separated, filtered and dried in vacuo. Yield: 80%; m.p. 112–113 °C (d) Λ_M (Ω^{-1} cm^2 mol^{-1}) 36. *Anal.* Calc. for $C_{16}H_{17}O_2NTePtCl_2$: C, 29.54; H, 2.61; N, 2.16 Te, 18.97. Found: C, 30.05; H, 2.84; N, 1.94; Te, 18.97%. Mol. wt.: 641 (Calc. 649.3). ^1H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 3.39 (bs, 2H, H_1), 3.74 (s, 3H, OMe), 3.86 (bs, 2H, H_2), 6.83–6.86 (d, 2H, ArH *m* to Te), 7.01 (bs, 1H, NH), 7.36–7.47 (m, 3H, ArH *p* and *m* to CO), 7.78–7.84 (m, 4H, ArH *o* to CO and *o* to Te). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 29.7 (C_1), 39.6 (C_2), 55.5(OCH_3), 104.8 (ArC–Te), 115.9 (ArC *m* to Te), 127.3 (ArC *m* to CO), 128.5 (ArC *p* to CO), 131.7 (ArC *o* to CO), 133.5 (ArC–CO), 137.8 (ArC *o* to Te), 161.5 (ArC *p* to Te), 167.8 (CO).

2.5. Synthesis of [(Phen)$Pd(\mathbf{L}^1)$]$(ClO_4)_2$ (**3**)

Solution of $AgClO_4$ (0.08 g, 0.4 mmol) made in methanol (10 cm^3) was mixed with the slurry of [(Phen)$PdCl_2$] (0.07 g, 0.2 mmol) prepared in chloroform (10 cm^3). The resulting mixture was stirred for 30 min at r.t., mixed with a solution of ligand $\mathbf{L}^1$ (1.52 g, 0.4 mmol) made in chloroform (10 cm^3) and stirred further for 2 h. The white precipitate of AgCl was filtered off. The filtrate was concentrated to 10 cm^3 on a rotary evaporator and mixed with hexane (10 cm^3). The resulting precipitate of **3** was filtered, washed with hexane–chloroform (5:1) mixture, recrystallized from acetonitrile and dried in vacuo. Yield: 68%; m.p. 114–115 °C (d) Λ_M (Ω^{-1} cm^2 mol^{-1}) 250. *Anal.* Calc. for

$C_{30}H_{25}N_3TePdCl_2O_{10}$: C, 38.66; H, 2.87; N, 4.84; Te, 14.70. Found: C, 38.88; H, 2.36; N, 4.79; Te, 14.10%. Mol. wt.: 286 (Calc. 868). ^{1}H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 3.42 (bs, 2H, H_1), 3.77–3.81 (m, 5H, H_2 and OMe), 6.66–6.62 (d, 2H, ArH *m* to Te), 6.95 (bs, 1H, NH), 7.33–7.46 (m, 3H, ArH *p* and *m* to CO), 7.62–7.80 (m, 8H, ArH *o* to CO, *o* to Te, H_a and H_b of phen), 8.46–8.49 (m, 2H, H_c of phen), 9.17–9.19 (m, 2H, H_d of phen).^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 19.3 (C_1), 39.2 (C_2), 55.1 (OCH_3), 104.0 (ArC–Te), 115.9 (ArC *m* to Te), 127–138(ArC of phen + ArC *o* to Te + ArC of benzamide), 160.5 (ArC *p* to Te), 168.1 (CO).

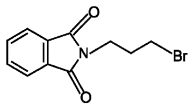
2.6. Synthesis of [(DPPE)Pd(**L**^{1})](ClO$_4$)$_2$ (**4**)

Solution of [(DPPE)$PdCl_2$] (0.12 g, 0.2 mmol) in chloroform (10 cm^3) was mixed with $AgClO_4$ (0.08 g, 0.4 mmol) dissolved in 5 cm^3 of methanol. The mixture was stirred for 30 min. The AgCl was filtered off. The $\mathbf{L}^1$ (0.76 g, 0.2 mmol) dissolved in chloroform (10 cm^3) was added to the filtrate. The mixture was stirred for 2 h at r.t., concentrated on a rotary evaporator to 10 cm^3 and mixed with hexane (20 cm^3). The resulting precipitate of **4** was filtered, recrystallized from chloroform–diethylether mixture and dried in vacuo. Yield: 70%; m.p. 96–97 °C (d) Λ_M (Ω^{-1} cm^2 mol^{-1}) 246 *Anal.* Calc. for $C_{42}H_{41}O_{10}NP_2TePdCl_2$: C, 46.34; H, 3.77; N, 1.28; Te, 11.77. Found: C, 46.04; H, 4.09; N, 1.53; Te, 11.60%. Mol. wt.: 359 (Calc. 1087.5). ^{1}H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 2.76–2.94 (m, 4H,CH_2–P), 3.55 (m, 2H, H_1), 3.67 (s, 3H, OMe), 3.81–3.83 (m, 2H, H_2), 6.49–6.52 (d, 2H, ArH *m* to Te), 7.02–7.82 (m, 28H, NH, ArH of DPPE, ArH *o* to Te, ArH of benzamide). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 16.1 (C_1), 24.0 (CH_2–P), 38.5 (C_2), 57.3 (OCH_3), 103.8 (ArC–Te), 115.4 (ArC *m* to Te), 127.3–138.0 (ArC of DPPE + ArC *o* to Te + ArC of benzamide), 161.5 (ArC *p* to Te), 167.6 (CO).

2.7. Synthesis of **L**^{2}

The solution of *N*-[3-bromopropyl]phthalimide (1.44 g, 4.2 mmol) made in 10 ml of THF was added to a refluxing colourless solution of $ArTe^-Na^+$ generated in situ by the procedure given in Section 2.2. The mixture was refluxed further for 1 h, cooled to r.t. and poured into 100 cm^3 of water. $\mathbf{L}^2$ was extracted from it into 50 cm^3 of CH_2Cl_2. The extract was dried over Na_2SO_4, concentrated to 5 cm^3 on a rotary evaporator and mixed with petroleum ether (40–60 °C). The resulting white crystalline solid $\mathbf{L}^2$ was filtered, washed with petroleum ether (40–60 °C) and dried in vacuo. The single crystals of $\mathbf{L}^2$ were grown from a mixture (8:2) of dichloromethane and petroleum ether (40–60 °C). Yield: 80%; m.p. 102–103 °C (d) Λ_M 0.8 (Ω^{-1} cm^2 mol^{-1}) *Anal.* Calc. for $C_{18}H_{17}O_3NTe$: C, 51.13; H, 4.02; N, 3.31; Te 30.18. Found: C, 50.60; H, 4.41; N, 3.53; Te, 30.77%. Mol. wt.: (Calc.). ^{1}H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 2.06–2.15 (q, 2H, H_2–C_7); 2.74–2.80 (t, 2H, H_2C–Te); 3.72–3.75 (t, 2H, H_2C–N); 3.76 (s, 3H, OCH_3); 6.73–6.76 (d, 2H, ArH *m* to Te); 7.67–7.73 (m, 4H, ArH of phthalimide ring); 7.82–7.84 (d, 2H, ArH, *o* to Te). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 4.5 (C_6), 30.6 (C_7), 39.7 (C_8), 55.1 (C_1); 100.2 (C_5), 115.2 (C_3), 123.2 (C_{11}), 132.2 (C_{10}), 133.5 (C_{12}), 141.3 (C_4), 159.8 (C_2), 168.3 (C_9).

2.8. Synthesis of [RuCl$_2$(**L**^{2})$_2$] (**5**)



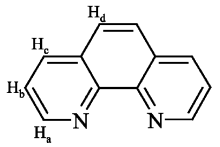
Solution of $RuCl_3 \cdot xH_2O$ (0.21 g, 1 mmol) in 20 cm^3 of methanol was mixed with $\mathbf{L}^2$ (0.86 g, 2 mmol) dissolved in 20 cm^3 of dichloromethane. The mixture was stirred for 3 h at r.t., filtered and concentrated to a solid residue on a rotary evaporator. The residue was dissolved in acetonitrile (10 cm^3) and resulting solution filtered. The filtrate was layered with 20 cm^3 of diethyl ether and kept at 0 °C for 48 h. The pale brown needle shaped crystals were separated and dried under vacuo. Yield: 55%; m.p. 168–169 °C. Λ_M 29.8 (Ω^{-1} cm^2 mol^{-1}) *Anal.* Calc. for $C_{36}H_{34}O_6N_2Te_2RuCl_2$: C, 42.49; H, 3.34; N, 2.76; Te 25.08. Found: C, 43.10; H, 2.42; N, 2.56; Te, 25.58%. Mol. wt.: 988.4 (Calc. 1017.5). ^{1}H NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 2.52–2.62 (q, 2H, H_2–C_7); 3.62–3.69 (t, 2H, H_2C–Te); 3.86–3.93 (t, 2H, H_2C–N + OCH_3); 7.03–7.06 (d, 2H, ArH *m* to Te); 7.77–7.88 (m, 4H, ArH of phthalimide ring); 8.03–8.08 (d, 2H, ArH, *o* to Te). ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) (δ vs. TMS): 25.0 (C_6), 38.3 (C_7), 47.5 (C_8), 55.6 (C_1), 115.7 (C_3), 123.5 (C_{11}), 131.9 (C_{10}), 134.2 (C_{12}), 135.0 (C_3), 162.3 (C_2), 168.3 (C_9).

3. Results and discussion

The ligands $\mathbf{L}^1$ and $\mathbf{L}^2$ and their complexes were prepared according to the reaction given in Eqs. (1)–(6)

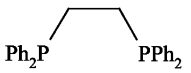
$$ArTeNa + C_6H_5CONHCH_2CH_2Cl \rightarrow \mathbf{L}^1 \text{ or } \mathbf{L}^2 + NaCl \quad (1)$$

or



$$(C_6H_5CN)_2PdCl_2 + \mathbf{L}^1 \rightarrow [PdCl_2(\mathbf{L}^1)](\mathbf{1}) + 2C_6H_5CN \quad (2)$$

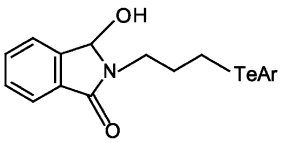
$$K_2PtCl_4 + \mathbf{L}^1 \rightarrow [PtCl_2(\mathbf{L}^1)](\mathbf{2}) + 2KCl \quad (3)$$



$$[(\text{Phen})PdCl_2] + 2AgClO_4 + \mathbf{L}^1 \rightarrow [(\text{Phen})Pd(\mathbf{L}^1)](ClO_4)_2(\mathbf{3}) + 2AgCl^- \downarrow \quad (4)$$

$$[(\text{DPPE})PdCl_2] + 2AgClO_4 + \mathbf{L}^1 \rightarrow [(\text{DPPE})Pd(\mathbf{L}^1)](ClO_4)_2(\mathbf{4}) + 2AgCl^- \downarrow \quad (5)$$

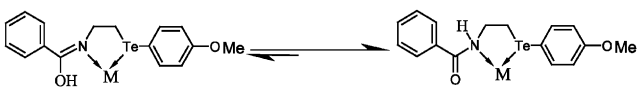
$$RuCl_3 \cdot xH_2O + 2\mathbf{L}^2 \rightarrow [RuCl_2 \cdot (\mathbf{L}^2)_2](\mathbf{5}) \quad (6)$$



Phen

DPPE

Since BH_4^- was taken in slight excess to avoid oxidation of $ArTe^-$ back to Ar_2Te_2, it probably reduced one >C=O group resulting in $\mathbf{L}^2H_2$, which formed with $\mathbf{L}^2$ a mixed crystal, '$\mathbf{L}^2$' (with occupancies 60 and 40%, respectively), selected by chance for X-ray data collection. However, the percentage of $\mathbf{L}^2H_2$ in the sample of $\mathbf{L}^2$ was below the detection limit of ^1H NMR spectra.



$\mathbf{L}^2H_2$

The ligands $\mathbf{L}^1$ and $\mathbf{L}^2$ and complexes **1**–**5** are soluble in common organic solvents. The complex **5** shows the sign of decay after 1 week even in nitrogen atmosphere. All other compounds were found stable under ambient conditions. The stoichiometries of the complexes have been authenticated by their elemental analyses. The molar conductance values (in acetonitrile at ~1 mM concentration level) and molecular weights of **3** and **4** (~one third of calculated values) suggest that they are 1:2 electrolytes [17]. For **1**, **2** and **5** the molar conductance values (Λ_M) have been found to be much lower than that of a 1:1 electrolyte [17]. Their observed molecular weights were found to be very close to the calculated ones.

3.1. Spectral data

IR spectrum of $\mathbf{L}^1$ has bands at 1641 and 3384 cm^{-1} due to CO and NH vibrations, respectively. The band appearing at 441 cm^{-1} [Te–C (aliphatic) vibrations] in IR of $\mathbf{L}^1$ shifts to ~419 cm^{-1} on the formation of **1**–**4**, indicating that $\mathbf{L}^1$ coordinates through Te. In IR spectra of **1**–**4**, NH band also shows a red shift of ~30 cm^{-1} with respect to that of free ligand $\mathbf{L}^1$, suggesting that ligation of $\mathbf{L}^1$ is through nitrogen also. However, in the spectra of **1**–**4**, the band having major contribution from CO was found almost unchanged with respect to that of $\mathbf{L}^1$, indicating that CO is not involved in coordination. In IR spectra of **3** and **4** perchlorate bands appear around 1100 (anti-symmetric stretching) and 620 cm^{-1} (anti-symmetric bending) suggesting that perchlorate ions are not coordinated. In the IR spectrum of $\mathbf{L}^2$ ν(CO) appearing at 1696 cm^{-1} remains unchanged on the formation of **5**.

In ^1H NMR spectrum of $\mathbf{L}^1$, the broad NH signal appearing at 6.52 ppm disappears with a D_2O shake. It shows a downfield shift (~0.2–0.8 ppm) in the spectra of **1**–**4** (relative to free $\mathbf{L}^1$) indicating that $\mathbf{L}^1$ ligates with Pd–Pt(II) through N. The signals of CH_2Te and aryl protons (*o* and *m* to Te) are observed deshielded (~ upto 0.2 ppm) in ^1H NMR of **1**–**4**, with respect to those of free $\mathbf{L}^1$, supporting the ligation of $\mathbf{L}^1$ through Te. However, signals of CH_2N in ^1H NMR spectra of **1**–**4** appear virtually unaffected when compared with those of free $\mathbf{L}^1$. This suggests that probably a N···Te secondary interaction exists in $\mathbf{L}^1$ and on coordination with Pd–Pt it is replaced by N→M bond. The broadness of signals of aliphatic protons in the spectra of **1**–**4** may be attributed to the coexistence of tautomers given below.

In $^{13}C\{^1H\}$ NMR spectra of **1**–**4**, the signals of C_1 and aryl C *ipso* to Te were found deshielded (upto ~22 and 6 ppm, respectively) with respect to those of free $\mathbf{L}^1$. However, signal of C_2 is found unaffected or marginally shielded (with respect to that of $\mathbf{L}^1$), supporting the existence of N···Te secondary interaction in $\mathbf{L}^1$. The signal of –CONH– is found unshifted in $^{13}C\{^1H\}$ NMR of **1**–**4**. The ^1H and $^{13}C\{^1H\}$ NMR spectra of $\mathbf{L}^2$ are characteristic and their assignments are supported by HETCOR spectrum shown in Fig. 1. In ^1H NMR spectrum of **5** the signals of CH_2Te, middle CH_2 and $N–CH_2$ appear deshielded (~0.80, 0.46 and 0.14 ppm, respectively) with respect to those of $\mathbf{L}^2$, indicating in **5** ligation of $\mathbf{L}^2$ is as a (Te, N) donor, which is corroborated by deshielding of C_6, C_7 and C_8 signals (~20, 7.5 and 8 ppm, respectively) in ^{13}C NMR spectrum of **5**, with respect to those of free $\mathbf{L}^2$. The crystals suitable for X-ray diffraction (XRD) could not be grown for **1**–**5**.

3.2. Crystal structures of $\mathbf{L}^1$ and $\mathbf{L}^2$

The molecular structure of $\mathbf{L}^1$ is shown in Fig. 2. The selected bond lengths and angles are given in Table 2. The Te–C(1) (2.107(8) Å) is shorter than Te–C(8) (2.140(8) Å), as is generally reported [18–20] for Te–C(aryl) in comparison to Te–C(alkyl). The

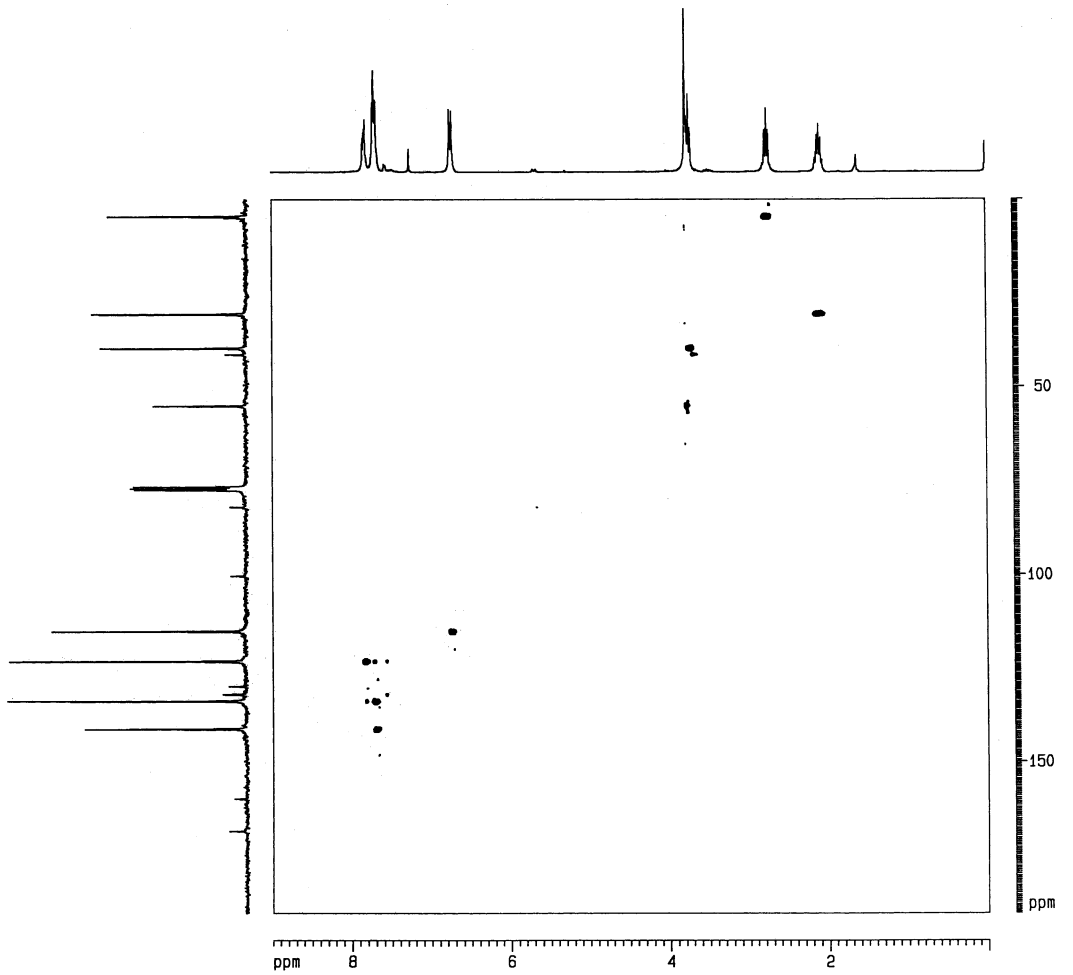


Fig. 1. HETCOR spectrum of $\mathbf{L}^2$.

C(1)–Te–C(8) angle (98.8(3)°) is consistent with the literature reports on alkyl aryl tellurides [18–20]. The C–C bond lengths and C–C–C bond angles of aryl groups are normal (average values 1.372(4)–1.377(4) Å and 119.96(1)°, respectively). The molecular structure of $\mathbf{L}^2$ is shown in Fig. 3(a) and $\mathbf{L}^2\mathbf{H}_2$ in Fig. 3(b). The selected bond lengths and angles for $\mathbf{L}^2$ are given in Table 3. The Te–C(alkyl) bond length is longer than Te–C(aryl) in this case also as observed for $\mathbf{L}^1$. The C(1)–Te(1)–C(8) angle is 94.96(14)° and consistent with the value observed for $\mathbf{L}^1$. The average C–C bond lengths and C–C–C bond angles of substituted phenyl groups are normal (1.384(1) Å and 120.0(1)°). The defining features for the two molecules $\mathbf{L}^2$ and $\mathbf{L}^2\mathbf{H}_2$ present in the mixed crystal ['$\mathbf{L}^2$'] are the angles about C(11) and the C(11)–O(2) bond distances. In spite of the site mixing at C(11)–O(2), resulting from the use of a co-crystal, the geometric parameters for C(11)–O(2) as a carbonyl in the $\mathbf{L}^2$ compound are in very good agreement with expected values. Thus, in $\mathbf{L}^2$ the C(11)=O(2B) bond length is 1.221(4) Å compared with 1.223(4) Å for C(18)=O(3) and the sum of the angles O(2B)–C(11)–N(1), O(2B)–C(11)–C(12), and N(1)–C(11)–C(12) is 356.7° compared with the sum for the corresponding angles around C(18) of 360.1°, as expected for planar sp^2 carbon. In $\mathbf{L}^2\mathbf{H}_2$, the C(11)–O(2A)H bond length is 1.298(6) Å as expected

In $\mathbf{L}^2H_2$, O(2A)–C(11) 1.298(6) Å, O(2A)–C(11)–N(1) 114.7(4)°, O(2A)–C(11)–C(12) 121.8(5)°.

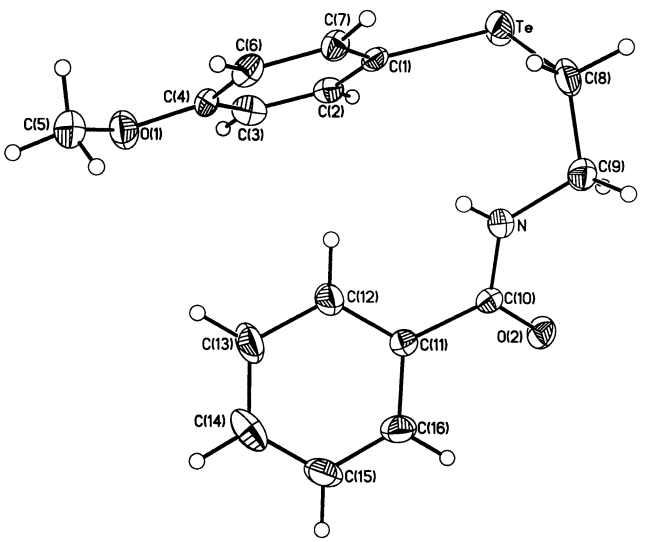

Fig. 2. Molecular structure of $\mathbf{L}^1$.

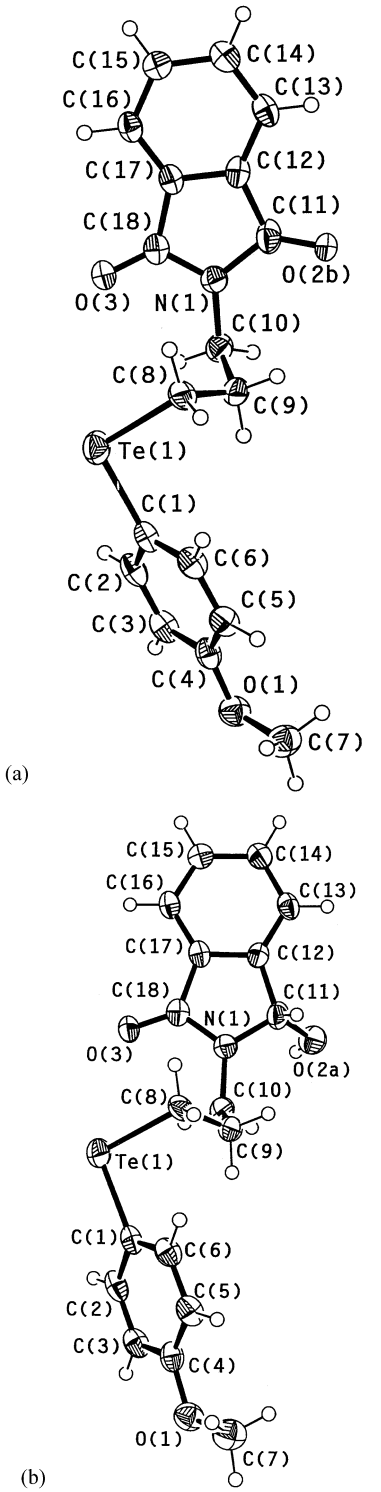

Fig. 3. (a) Molecular structure of $\mathbf{L}^2$. (b) Molecular structure of $\mathbf{L}^2H_2$.

for a C–O single bond, and the sum of the angles O(2A)–C(11)–N(1), O(2A)–C(11)–C(12), and N(1)–C(11)–C(12) is 338.8°, consistent with tetrahedral sp^3 carbon. The possibility of coordinating as a (Te, N) donor is apparent for $\mathbf{L}^1$ and $\mathbf{L}^2$ (Figs. 2 and 3). They may also act as a (Te, N, O) donor in bimetallic complexes.

4. Conclusion

Two new hybrid organotellurium ligands *N*-[2-(4-methoxyphenyltelluro)ethyl]benzamide ($\mathbf{L}^1$) and *N*-[2-(4-methoxyphenyltelluro)propyl]phthalimide($\mathbf{L}^2$) have been synthesized and characterized structurally. The

Te–C(alkyl) bond length is 2.140(8)/2.149(4) Å and longer than Te–C(aryl) 2.107(8)/2.123(5) Å. Both of them coordinate as a (Te, N) donor with Pd(II), Pt(II) or Ru(II).

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC 151396 for $\mathbf{L}^1$ and 151397 for $\mathbf{L}^2$. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Investigation of phthalocyanine crystals exposed to NO_2 ambient gas

Rudolf Słota *, Gabriela Dyrda, Witold Wacławek

Institute of Chemistry, University of Opole, ul. Oleska 48, 45-095 Opole, Poland

Received 3 August 2001; accepted 31 October 2001

Abstract

Crystals of free base phthalocyanine (H_2pc) and its unsubstituted metal derivatives Mpc (where M = Ni, Cu, Zn, Pb, and pc = $C_{32}H_{16}N_8^{2-}$ = phthalocyanine ligand) were examined after being exposed to NO_2 ambient gas. Scanning electron microscopy (SEM) supported by X-ray microprobe analysis (EDAX), UV–Vis and FTIR spectroscopy as well as X-ray powder diffractometry (XRD) were applied to study the crystals chemistry and surface morphology. The NO_2 molecules were found to penetrate the crystal unit which led to the breakdown of the phthalocyanine macrocycle. The surface of the doped crystals has been scaled and covered by a layer composed predominantly of phthalimide. Despite vacuum desorption, it has been proved some free NO_2 to be still adsorbed by the studied material. © 2002 Published by Elsevier Science Ltd.

Keywords: Phthalocyanines; Nitrogen dioxide; Scanning electron microscopy; X-ray microprobe; UV–Vis and FTIR spectroscopy; X-ray powder diffractometry

1. Introduction

Metal complexes of phthalocyanine (H_2pc) along with a number of its derivatives are considered for many electronic and opto-electronic applications, one of the most promising to be gas sensors [1,2]. High thermal stability of the molecules, semi-conductivity (or even metallic features) and interesting optical properties have placed phthalocyanine based materials among the top attractive ones for modern technologies. It is obvious, that quality demands also include a considerable durability of those materials towards chemicals and radiation, which might have affected the molecular structure and thus alter its properties. This is of particular importance when phthalocyanine based devices are designed to operate under oxidising conditions, e.g. in the presence of nitrogen oxides, halogens, air oxygen etc.

The phthalocyanines represent a family of quite well recognised macrocyclic compounds characterised by a variety of molecular structures [3]. However, regardless of the structural modification, the chemistry of these species has been dominated by the nature of the phthalocyanine ligand. This may be addressed to the strength of the overall molecular set-up, as well.

In a phthalocyanine moiety, the four coupled benzopyrole units forming the characteristic macrocycle produce a quite stable bonding system, the properties of which is determined by the conjugated π electron system of the whole molecule. This arrangement becomes more stable when a metal atom is complexed by the four inner nitrogen atoms.

Under oxidising conditions the molecules stability has proved to be considerably reduced, particularly when in solution. In the studied cases, the system was found completely chemically altered by the action of oxidants like NO_2 [4–6]. However, as far as the solid phthalocyanine material is concerned, there is some discussion in the literature as to the extent the phthalocyanine molecules are being affected. Although there is enough evidence for a structural breakdown (e.g. [6,7]) which is reflected in the reaction products of the phthalocyanine–NO_2 interaction, such as phthalimide, however, at lower concentrations of NO_2 that interaction is also considered in terms of reversible chemisorption [5,8].

It seems that the surface processes occurring at a phthalocyanine grain during the adsorption of NO_2 still need to be given a detailed research. The morphology of

[a] Sample not exposed to NO_2.

phthalocyanine thin solid films used for NO_2 detection was discussed, e.g. in [9] and [10] but merely for the non doped material. However, results of a SEM investigation presented in [11] have supplied evidence for the phthalocyanine ligand decay due to the action of NO_2. One may suppose then that most of the calibration problems reported for phthalocyanine-based gas sensors (e.g. [9,10]) may result from a molecular degradation rather than from different reasons related to physical changes only in the phthalocyanine layer exposed to the ambient gas.

The research carried out by our group was designed to supplement the existing data concerning the influence of oxidising radical chemicals upon the phthalocyanine compounds. In particular, it was focused on the chemistry of the crystal surface during and after gas doping. Unlike others, in our study we have used predominantly single crystals of the phthalocyanine material, first of all in order to minimise the effect of a large specific surface area displayed by the polycrystalline solid films or powders. Electronic absorption spectra were registered predominantly in concentrated sulfuric acid, which is believed to be the best phthalocyanine solvent and allows also to explore the UV range. Thus, we could follow not only the changes of the phthalocyanine moiety, represented by a set of bands in the Vis range but also trace the formation of the phthalocyanine decay products, which absorb exclusively in the UV range.

2. Experimental

The phthalocyanines used were synthesised and purified in our laboratory. Well developed needle-like crystals approximately 0.2 mm thick and 3–10 mm long of H_2pc and Mpc (where M = Ni, Cu, Zn) as well as the prismatic crystals of Pbpc (ca. 0.3 mm thick and 4 mm long) were obtained by vacuum sublimation. For comparison, fine polycrystalline powders of these compounds were used, as well.

Vacuum dried samples (0.005 g) of the phthtalocyanine material were exposed to NO_2 in a 2 l round-bottomed glass flask at 298 K for 10 min. Afterwards the system was evacuated at the same temperature for 1 h ($p \approx 10$ Pa) and the samples were stored in a desiccator over silica gel. Gas concentrations, expressed by the molar fraction of NO_2 in the ambient (X_{NO_2}), were approximately 1×10^{-6}, 1×10^{-5} and 5×10^{-5}. Higher temperatures (up to 473 K) as well as longer exposure and evacuation (desorption) times were also applied.

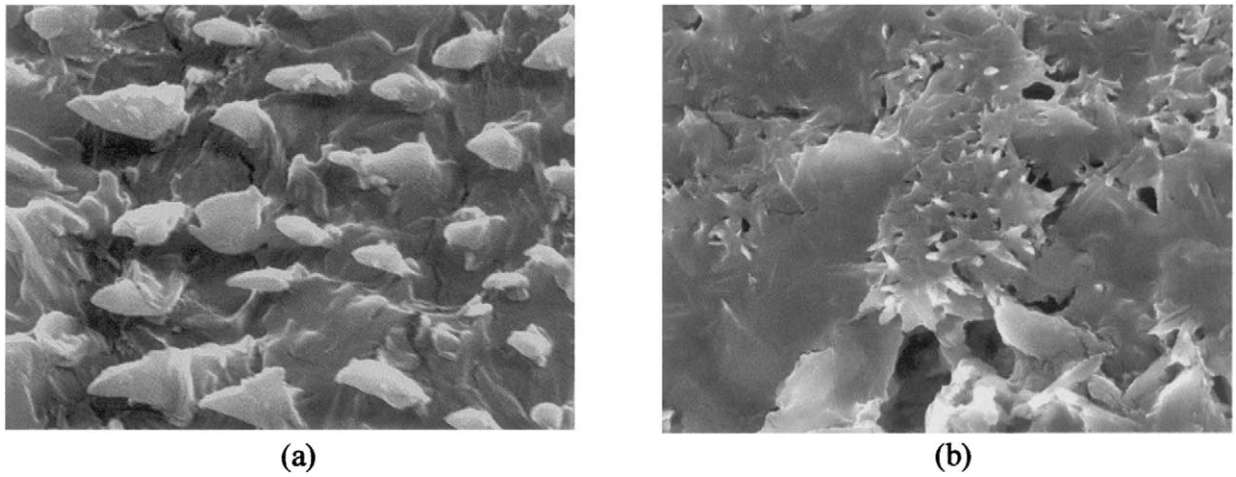

Fig. 1. SEM micrographs of the surface of phthalocyanine crystals after exposure to NO_2 at 298 K. (a) H_2pc, $X_{NO_2} \sim 10^{-6}$ (10 000 ×); (b) Cupc, $X_{NO_2} \sim 10^{-5}$ (2000 ×). A crystalline copper reaction product (centre).

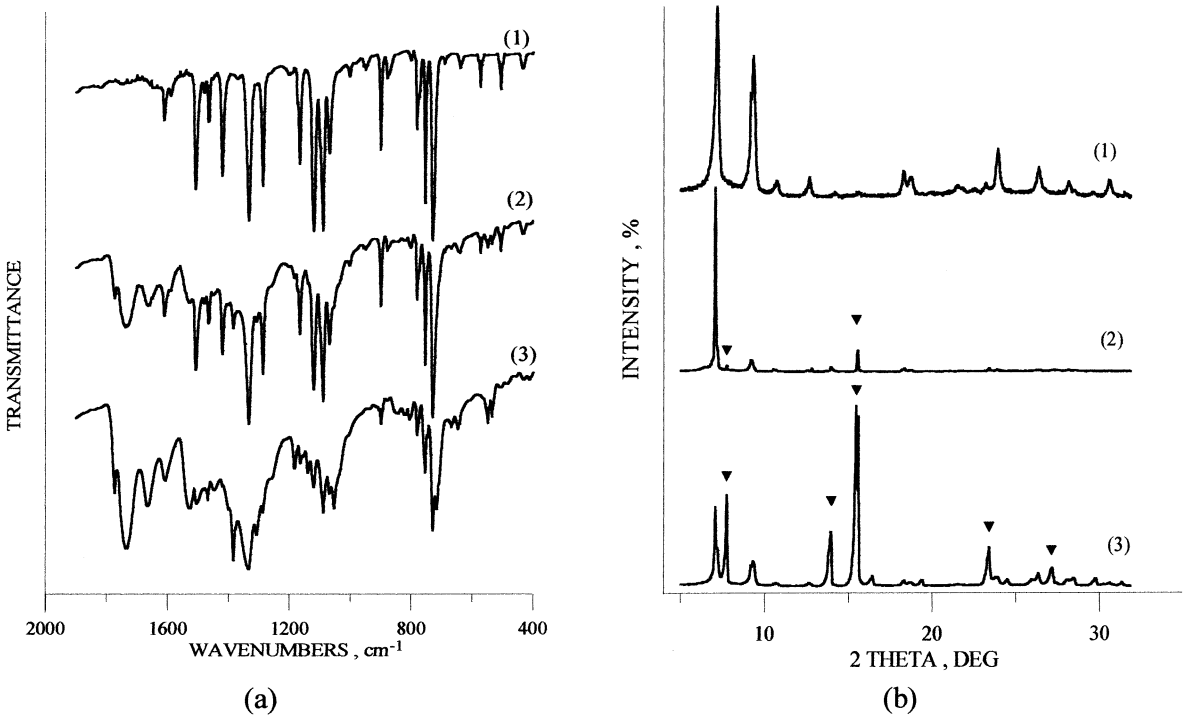

Fig. 2. Effect of NO_2 upon Cupc crystals expressed by FTIR spectra (a) and X-ray powder diffraction patterns (b). $X_{NO_2} \sim 5 \times 10^{-5}$, exposure time 10 min, desorption time 1 h. (1) Pure β-Cupc (Ref. [13]), (2) Cupc+NO_2 at 298 K, (3) Cupc+NO_2 at 473 K. ▼-phthalimide (Ref. [13]).

For the SEM investigations a JEOL JSM-5400 scanning electron microscope equipped with an energy dispersive X-ray analyser (EDAX) was used and all specimens were gold coated. The chemistry of the studied material was followed by UV–Vis (Unicam UV-300) and FTIR (Philips FTIR PU 9800) spectroscopy as well as X-ray powder diffractometry (XRD) (Philips PW 3710). Higher gas concentrations ($X_{NO_2} \approx 5 \times 10^{-5}$) were used only to emphasise the effect of NO_2 in the IR spectra and powder diffraction patterns as well as in the UV–Vis quantitative and kinetic studies.

The electronic absorption spectra were registered in concentrated sulfuric acid (95.5%) and in the case of Znpc and Pbpc also in dimethylformamide. IR spectra were collected for samples in KBr pellets.

3. Results and discussion

As it may be learned from Fig. 1, the morphology of the primarily smooth and clean phthalocyanine crystals has been dramatically changed after being exposed to NO_2. The surface is scaled and reaction products could be seen spread over it. Surface line-scans performed by the X-ray microprobe have revealed perforations of approximately 1–5 μm which indicate for a quite deep penetration of the crystal unit by NO_2 even at 298 K. Elemental EDAX analyses performed at the materials surface have shown particular high concentrations of the oxygen atoms, in contrast to the pure (undoped) phthalocyanine crystals. This confirms the reaction products to be oxidised fragments of the phthalocyanine ring. Crystalline metal compounds including both N and O elements have also been found, presumably nitrates of the complexed metals (Fig. 1(b)). IR spectroscopic studies (Fig. 2(a)) have proved the fragmentation of the macrocycle and the formation of phthalimide, featured by a characteristic set up of bands including a very strong one at 1745 cm^{-1} with a *satellite* at 1753 cm^{-1} [12]. This is also reflected in the X-ray powder diffractograms presented in Fig. 2b, registered for the doped material, which show a pattern of peaks corresponding to phthalimide [13]. At elevated temperatures the penetration of the crystals by NO_2 and thus the macrocycle degradation is yet more pronounced (Fig. 2). Similar effects one may expect not only at higher NO_2 concentrations but also at a longer exposure time, as it has been proved in our tests. The reaction progress has been noticeably increased when the phthalocyanine material used in our experiments was a powder instead of single crystals.

There is also some evidence both in the IR spectra and X-ray patterns for other intermediate and/or by-products being formed. Changes observed exclusively in the X-ray patterns of metal phthalocyanines, as shown in Fig. 2b, are similar to those reported in [14] and may suggest the formation of a phthalocyanine derivative with axially co-ordinated NO_2 ligand(s), as shown in

[15,16]. However, attempts to isolate or identify other reaction products but phthalimide have failed.

Spectra registered in the UV–VIS range also proved the cleavage of the phthalocyanine macrocycle by NO_2, reflected by a decrease in absorbance (Q band) of about 5% when and $X_{NO_2} \approx 1 \times 10-5$ and 13–15% when $X_{NO_2} \approx 5 \times 10^{-5}$ (exposure for 10 min at $T = 298$ K). Moreover, there is also a new distinct band to be seen at $\lambda = 227$ nm in the spectra registered in sulphuric acid, which we have proved to be characteristic of phthalimide. We have found no peculiar relation to the complexed metal, as far as the strength of the phthalocyanine macrocycle towards NO_2 is concerned. However, studies performed in concentrated sulphuric acid have revealed some differences in the chemistry of H_2pc and the studied metal phthalocyanines after being exposed to NO_2. Both H_2pc and Mpc' s treated with NO_2, on evacuation release the previously adsorbed gas molecules, which have not yet reacted with the solid material. Kinetic studies of such after-desorption samples dissolved in the acid have revealed a progressive decrease in the compounds concentration but only in the cases of H_2pc and Pbpc. Although it is typical for H_2pc to decompose in concentrated sulphuric acid [17], nevertheless the reaction rate has been considerably increased in comparison with samples not exposed to NO_2, as shown in Table 1. The labile Pbpc complex is being immediately converted into H_2pc when dissolved in sulphuric acid [4], thus the observed kinetic effects in the both cases were similar. Extending of the desorption time up to 24 h in the case of H_2pc resulted in a little change only in the reaction rate. Opposite to H_2pc and Pbpc, solutions of Nipc, Cupc and Znpc remained stable. However, samples which were not subject to desorption gradually decomposed in sulphuric acid solutions regardless of the complexed metal.

This observation has provided evidence that after a low pressure desorption there is some free NO_2 left in the system, still adsorbed by the material, probably under the layer of the reaction products covering the crystals surface. These gas molecules may have a little chance to escape due to difficulties in diffusion. After dissolving in sulphuric acid, due to the presence of NO_2, the oxidising potential of the obtained solution is being increased and consequently the decay of the phthalocyanine macrocycle is accelerated, as we have found for H_2pc (and Pbpc). It is not quite clear why this was not observed in the case of Nipc, Cupc and Znpc. One reason could be a less compact structure of the bulk layer of reaction products which would enhance the diffusion of NO_2 molecules out of the system during desorption. One may expect the metal nitrates (identified in the SEM studies, see Fig. 1b) to contribute in the formation of a more loose bulk structure than that of phthalimide being the only solid product formed in the case of H_2pc exposed to NO_2. Another explanation may result from the formation (besides phthalimide and metal nitrates) also of axially NO_2-substituted metal phthalocyanines of the kind shown in [15,16]. The gas molecules entrapped at the crystals surface could be used to produce such a complex, whereas in the case of the metal free phthalocyanine, H_2pc, it would not be possible. However, such a complex of Pbpc, due to the labile metal–ligand (Pb^{2+}–pc^{2-}) bond should rapidly decompose in the sulfuric acid to produce H_2pc and give off the NO_2 molecules. This may explain the different behaviour of Pbpc in comparison with the other metal phthalocyanines.

In conclusion of our work, it has to be emphasised that the cleavage of the phthalocyanine macrocycle by NO_2 is an irreversible process. Formation of phthalimide as the principal reaction product clearly indicates the attack of NO_2 molecules has been focused first of all at the bridging nitrogen atoms, thought to be the weakest site of the phthalocyanine ring [18]. Since that, it seems not possible to stabilise the macrocycle towards NO_2 neither by changing the co-ordinated metal nor axial or peripheral substitution of the phthalocyanine molecule. The extent of the macrocycle decay is strongly related to the concentration of NO_2 in the ambient and the chemistry at the surface of the doped compound. Our SEM investigations have confirmed the reaction to occur even at $X_{NO_2} \approx 10^{-6}$. Therefore, the question, if there is a possible reversible chemisorption at much lower (e.g. sub-ppm) concentrations of NO_2 seems to be still open and needs to be given a reasonable explanation.

Abstract

The interactions of Me_2SnCl_2 with *para*-substituted *meso*-tetraphenylporphyrins ($H_2T(4\text{-}X)PP$; X = OCH_3, CH_3, H and Cl) have been studied by the UV–Vis method. Equilibrium constants, K_1 and K_2, have been calculated by using UV–Vis titration spectra and data refinement was carried out with the computer SQUAD program. Adducts of composition 1:1 and 2:1 of Me_2SnCl_2 to porphyrins, [$(Me_2SnCl_2)(H_2T(4\text{-}X)PP)$] and [$(Me_2SnCl_2)_2(H_2T(4\text{-}X)PP)$], coexist in the solution. Thermodynamic parameters for adduct formation are also determined. Adduct stability constants decrease with decreasing electron donation of the free base porphyrins in the order: $H_2TpAP > H_2TpTP > H_2TPP > H_2TpCP$. © 2002 Published by Elsevier Science Ltd.

Keywords: Adduct formation; Thermodynamics; Tin compounds; Porphyrins; Equilibrium constant; Spectral method

1. Introduction

Molecular interactions of organotin(IV) halides with a variety of uni- and bidentate nitrogen donor ligands have been studied [1–4]. Organotin(IV) halides are very important because of their antitumor properties [5]. Therefore their interactions with biological systems have been the subject of a lot of investigations [6–8]. Studies of compounds of the type R_2SnX_2L, where L is a bidentate N-donor ligand showed that increasing stability is thought to reduce activity by hindering the dissociation of the ligand which is necessary for binding between tin and DNA [9]. In view of these encouraging results, this led us to investigate the solution equilibria of organotin(IV) halide complexes with a number of free base *para*-substituted *meso*-tetraphenylporphyrins. The molecular interactions of tetraarylporphyrins with π-acceptor molecules such as nitroaromatic systems [10,11], tetracyanoethylene [12] and 2,3-dichloro-5,6-dicyanobenzoquinone have been studied [13]. Here we believe that tetraarylporphyrins act as bidentate bridging ligands toward dimethyltin(IV) dichloride. This work is specified to the studies of the thermodynamics of the adduct formation of Me_2SnCl_2 with H_2TPP (*meso*-tetraphenylporphyrin), H_2TpCP (*meso-tetrakis*-(*para*-chlorophenyl)porphyrin), H_2TpTP (*meso*-tetra-*para*-tolylporphyrin) and H_2TpAP(*meso*-tetra-*para*-anisylporphyrin).

2. Experimental

2.1. Chemicals

Benzaldehyde and *para*-substituted benzaldehydes (Merck and Fluka) were used as received. Pyrrole (Fluka) was distilled before use. Propionic acid and chloroform (Merck) employed for the synthesis and the purification of free base porphyrins were used as received. Chloroform solvent for UV–Vis measurements was distilled over K_2CO_3 before use.

2.2. Instrumental

UV–Vis measurements were carried out in a JASCO V-530 UV–Vis spectrometer equipped with a LAUDA ecoline RE 104 thermostat.

2.3. Preparations

Dimethyltin(IV) dichloride was prepared by the reaction between Me_4Sn and anhydrous $SnCl_4$ and purified by sublimation [14]. H_2TPP, H_2TpCP, H_2TpTP and H_2TpAP were prepared by a general procedure for the synthesis of *meso*-tetraarylporphyrins [15], and purified by chromatography on a neutral alumina column.

2.3.1. General procedure for the synthesis of meso-tetraarylporphyrins

meso-Tetra(4-methoxyphenyl)porphyrin: 4-methoxybenzaldehyde (10 mmoles) was mixed with propionic acid (35 ml) and nitrobenzene (15 ml). Pyrrole (10 mmoles) was added and the mixture was kept at 120° C for 1 h. On cooling, the porphyrin precipitated directly from the reaction mixture and was isolated by filtration.

2.4. Spectroscopic measurements

UV–Vis measurements were carried out by the titration method at 5.0, 10.0, 15.0, 20.0, and 25.0 ± 0.1 °C. In a typical measurement, 2.5 ml solution of H_2TPP (1×10^{-5} M) in chloroform was titrated with Me_2SnCl_2 (0.0125 M). UV–Vis spectra were recorded in range 396–710 nm about 15 min after each addition. In this range of spectra about 30–40 wavelengths which had suitable variations of absorbance upon addition of Lewis acid were selected and the equilibrium constants and other thermodynamic parameters of adduct formation were calculated. Equilibrium constants were calculated by the SQUAD program [16,17].

SQUAD is a program with the capability of refining the stability constants of a general complex $M_mM_lH_kL_nL_q$, where $m,l,n,q > 0$ and k is positive for protons, negative for hydroxide ions or zero, employing a non-linear least-squares approach. The data fed to SQUAD are absorption spectra, chemical composition (total concentrations of M, M′, L, L′, and pH) and a chemical model to describe the system. The residual sum (U) is calculated from the following equation:

$$U = \sum_{\mathrm{I}}^{\mathrm{I}} \sum_{\mathrm{I}}^{\mathrm{NW}} (A_{i,k}^{\mathrm{calc}} - A_{i,k}^{\mathrm{obs}})^2$$

where the $A_{i,k}$ is the absorbance value of the ith solution at the kth wavelength, given a total of I solutions and a grand total of NW wavelengths.

3. Results and discussion

On addition of excess of Me_2SnCl_2 to a solution of free base porphyrin in chloroform its purple color changes to green, change in color is due to the interactions of Me_2SnCl_2 with free base porphyrin. By addition of *n*-hexane to these green solutions, slowly, green powdery products were obtained; attempts for further purification and recrystallization of these crude products were unsuccessful. This product can also be obtained by dissolving H_2TPP and excess Me_2SnCl_2 in $CHCl_3$ or CH_2Cl_2 followed by evaporation of the solvent at room temperature. Elemental analysis of these products (Table 1) have good agreement with adducts of composition 2:1 Me_2SnCl_2 to $H_2T(4\text{-}X)PP$. On the basis of these results we suggest that free base porphyrins as bidentate bridging ligands make a bridge between two molecules of the Lewis acid. It is probable that two neighboring nitrogen atoms of the porphyrin bound to one of the Me_2SnCl_2 molecules which is positioned above of the porphyrin plane and other two nitrogen atoms bound to the second Me_2SnCl_2 molecule from below this plane (Fig. 1). Therefore we have a structure relatively similar to that suggested by Smith et al. for XHg–TPP–HgX; $X=Cl^-$, CH_3COO^- [18]. Interactions of Me_2SnCl_2 with $H_2T(4\text{-}X)PP$ are very sensitive to temperature (Fig. 2). By increasing the temperature, the green color of the product solution changes to brown and returns to the primary color of free base porphyrin solution, eventually. Adduct forma-

$(Me_2SnCl_2)_2H_2TpAP$	51.13	4.46	4.50	53.40	4.25	4.77

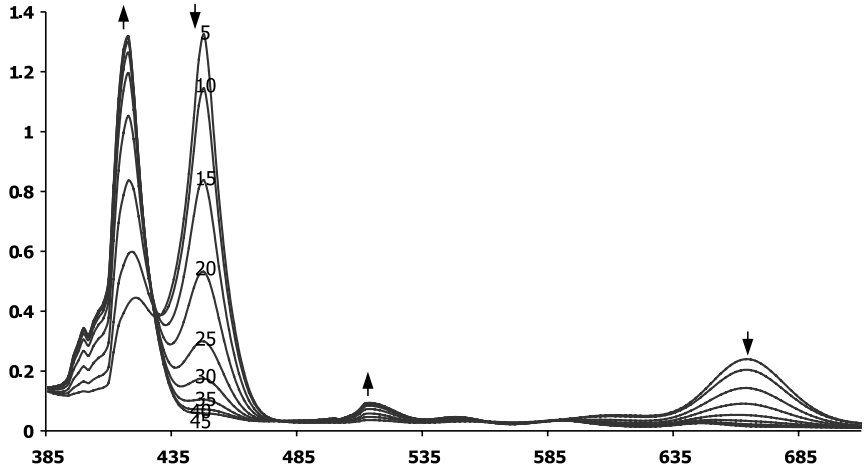

Fig. 2. Thermal dissociation spectra of Me_2SnCl_2–H_2TpCP adduct: by addition of Me_2SnCl_2 (0.0125 M, 0.5 ml) to the solution of H_2TpCP (5×10^{-6} M, 2.5 ml) in chloroform in an UV–Vis cell at 5° C, the Me_2SnCl_2–H_2TpCP adducts were recently formed. The composition of the cell remained constant and the temperature was raised to 45° C stepwise, isosbestic point at 428 nm. This spectrum is similar to that reported for acidic dissociation of the ClHg–TPP–HgCl complex, [21] in which ClHg–TPP–HgCl returned to H_2TPP and $HgCl_2$.

tions are not observed in ligating solvents such as CH_3CN and DMSO under these conditions. Interactions of dimethyltin(IV) dichloride with free base porphyrins were studied spectrometrically by the UV–Vis method.

3.1. UV–Vis analysis

By interaction of $H_2T(4\text{-X})PP$ with Me_2SnCl_2, the original peaks of free base tetraarylporphyrins slowly vanished and two new peaks appeared (Table 2). For example, by addition of Me_2SnCl_2 to H_2TpCP the original peaks (418, 514, 550, 589, 645 nm) vanished and new peaks appeared at 447 and 664 nm with a clear isosbestic point at 428 nm (Fig. 3).

3.2. Thermodynamic studies

The thermodynamic parameters are useful tools for studying these interactions and understanding the relative stability of adducts. The equilibrium constants were determined at several temperatures by analyzing the concentration and temperature dependence of UV–Vis absorptions by the SQUAD program. These absorptions were analyzed by using the following mole ratios of the acid to base as models of interaction between Me_2SnCl_2 and the typical $H_2T(4\text{-X})PP$: (1) formation of the 1:1 adduct, (2) formation of the 2:1 adduct and (3) simultaneous formation of the 1:1 and 2:1 adducts. The fit of the model to the experimental data, 15 points, is measured by the sum of the squares of the deviations of the experimental points from the point calculated by the model. For the proposed models, the simultaneous formation of 1:1 and 2:1 adducts of acid to base has the best fitting and the produced error sum of squares was between 10^{-2} and 10^{-3}. Van't Hoff plots of these formation constants, K_1 and K_2, and the overall formation constant β_2 led to the other thermodynamic parameters ΔH° and ΔS° (Tables 3–5).

Table 2
UV–Vis peaks λ ($CHCl_3$, nm) of the free base $H_2T(4\text{-X})PP$ and $H_2T(4\text{-X})PP$ adducts with Me_2SnCl_2

H_2TPP	417	514	549	589	646
H_2TPP (adduct)	445			660	
H_2TpCP	418	514	550	589	645
H_2TpCP (adduct)	447			664	
H_2TpTP	419	516	552	591	647
H_2TpTP (adduct)	448				672
H_2TpAP	421	518	555	593	650
H_2TpAP (adduct)	453				690

The data of Table 3 show that the equilibrium constant of adducts undergo a regular increase from H_2TpCP, H_2TPP, H_2TpTP, to H_2TpAP. For example, at 5° C we have the following order of formation constants:

$$Me_2SnCl_2\text{–}H_2TpCP < Me_2SnCl_2\text{–}H_2TPP < Me_2SnCl_2\text{–}H_2TpTP < Me_2SnCl_2\text{–}H_2TpAP$$

$$\log K_1 \quad 2.15 < 3.56 < 4.84 < 4.90$$

$$\log K_2 \quad 3.95 < 4.05 < 5.22 < 5.35$$

Tables 4 and 5 show the thermodynamic parameters obtained for the interactions of Me_2SnCl_2 with $H_2T(4\text{-X})PP$ in chloroform.

The results in Tables 3 and 4 show that the kind of substituent (X) on the phenyl rings of $H_2T(4\text{-X})PP$ significantly influences the interactions of the corresponding free base porphyrin with Me_2SnCl_2. Both the free energy and the enthalpies of adduct formation become more negative through the series H_2TpCP, H_2TPP, H_2TpTP to H_2TpAP, considerably, which

[b] ΔG° at 5 °C (kJ mol^{-1}).

indicates the stronger interaction along this sequence. The successive adducts $(Me_2SnCl_2)(H_2T(4\text{-X})PP)$ and $(Me_2SnCl_2)_2(H_2T(4\text{-X})PP)$ have negative values of ΔH° and ΔS°.

Our results are in agreement with the pre-equilibrium step demonstrated by previous studies on the kinetics of incorporation of some divalent metal ions into the free base porphyrins. Tanaka and coworkers [19] investigated the reaction of transition metal ions with H_2TPP in DMF. They suggested pre-complexes (M–H_2TPP, M=Cu(II), Zn(II)) with a formation constant K of 1.6×10^4 for Cu(II) and 7.2×10^2 for Zn(II). Similar results have been obtained by Robinson and Hambright [20] on the kinetics of catalyzed and uncatalyzed incorporation of Zn(II) into free base porphyrins (H_2P) in DMF. They suggested that metal ions and porphyrins formed an intermediate with composition [M–H_2P; M=Zn(II), Cd(II), Cu(II)] [18,19] in which coordination of H_2P with the metal ion causes a deformation of the porphyrin plane in such a manner that a second metal ion would more readily be able to be incorporated into this bent porphyrin structure on the opposite side. This lead to the formation of M–H_2P–Zn followed by dropping the Zn(II) ion into the porphyrin cavity [20,21]. But here dealing with stable adducts, because of our bulky Lewis acids, Me_2SnCl_2 could not drop into the free base porphyrin cavity under these conditions. We think that primarily 1:1 adduct formation, [(Me_2SnCl_2) $H_2T(4\text{-X})PP$], induces a distortion in the porphyrin plane; this deformation enhances the coordinating ability of the nitrogen lone pairs by directing them away from the central porphyrin cavity. Therefore the distorted porphyrin readily accepts the second Me_2SnCl_2 molecule on the opposite side and eventually favors the formation of the 2:1 adduct [($Me_2SnCl_2)_2$ $H_2T(4\text{-X})PP$]. Adducts have negative va-

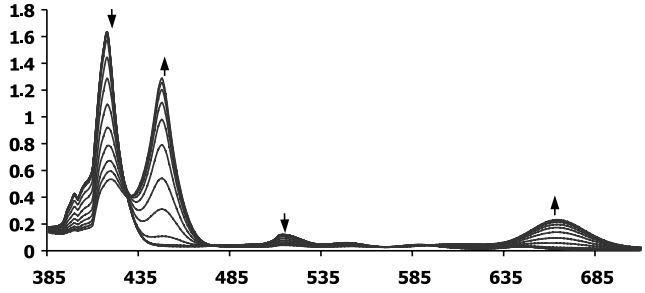

Fig. 3. Typical titration spectra for titration of H_2TpCP with Me_2SnCl_2 in chloroform. Bands appeared at 447 and 664 nm are related to the adduct, isosbestic point at 428 nm.

Table 5
The overall thermodynamic parameters ΔH°, ΔS° and ΔG° for interaction of Me_2SnCl_2 with $H_2T(4\text{-X})PP$ in chloroform [a]

	ΔH°	ΔS°	ΔG° [b]
Me_2SnCl_2–H_2TpCP	155 (±5)	−442 (±19)	−32 (±5)
Me_2SnCl_2–H_2TPP	−187 (±7)	−529 (±21)	−40 (±7)
Me_2SnCl_2–H_2TpTP	−228 (±5)	−628 (±17)	−53 (±5)
Me_2SnCl_2–H_2TpAP	−234 (±7)	−644 (±23)	−55 (±7)

[a] ΔH° (kJ mol^{-1}) and ΔS° (J K^{-1} mol^{-1}).
[b] ΔG° at 5 °C (kJ mol^{-1}).

lues of ΔH°, ΔS° and ΔG°. Generally, the negative values of ΔS° refer to association between donor and acceptor molecules. The most negative values of ΔH° and ΔG° for the Me_2SnCl_2–H_2TpAP system indicate the strongest interactions in this system relative to the other members of the series. These results show that the interactions of $H_2T(4\text{-X})PP$ toward Me_2SnCl_2 vary in the order:

$$H_2TpAP > H_2TpTP > H_2TPP > H_2TpCP$$

This trend is in accordance with the electron donation of the free base porphyrins.

Assembly via H-bonds and Ag–Ag attractions of one-dimensional silver(I) complexes of nicotinamide and nicotinic acid with sulfonate counter-anions

Cai-Hong Chen, Jiwen Cai *, Xiao-Long Feng, Xiao-Ming Chen *

School of Chemistry and Chemical Engineering & Instrumentation Analysis and Research Center, Zhongshan University, Guangzhou 510275, People's Republic of China

Received 13 August 2001; accepted 30 November 2001

Abstract

Three silver(I) complexes containing pyridine derivatives have been synthesized and structurally characterized by X-ray single crystal diffraction, in order to evaluate the effect of counter anions upon the assembly process of complex cations via intermolecular hydrogen bonds. $[Ag(nia)_2]_2(bpds)\cdot 2H_2O$ (**1**) and $[Ag(nia)_2](asa)$ (**2**) (nia = nicotinamide, bpds = 4,4′-biphenyldisulfonate, asa = aminosulfonate) contain cationic complexes comprised of two nicotinamide ligands coordinated with the pyridine nitrogen atoms to a silver(I) ion in a linear fashion. The linear unit is connected to another one by a weak Ag–Ag interaction leading to an H-shaped dimeric unit. The dimeric units are linked through hydrogen bonds formed between amide groups in a head-to-head mode, creating one-dimensional cationic ribbons. In **1**, the ribbons are extended into two-dimensional network via hydrogen bonds formed by the amide groups. The cationic complex cations in $[Ag(niac)_2]_2(1,5nds)\cdot 2H_2O$ (**3**) (niac = nicotinic acid, 1,5nds = 1,5-disulfonate) are also connected to each other through Ag–Ag interactions, leading to H-shaped dimeric units. The dimeric units are propagated via C–H···O hydrogen bonds between the aromatic hydrogen atom and the carbonyl oxygen. A database search shows that the unique Ag–Ag interaction between the discrete silver(I) coordinated linearly just by two pyridine nitrogen atoms is only observed in salts containing sulfonate or sulfate as counter anions. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Crystal engineering of metal–organic complexes represents an important and rapidly growing area of research [1]. Coordinate covalent bonds have been extensively exploited to create coordination polymers [2]. Meanwhile, the ability to design and control the assembly of coordination networks through both coordination and H-bonding interactions has been of great interest in recent years [3–5]. This strategy is realized by employing organic ligands with H-bonding functionalities combined with coordination sites for a transition metal. Yet systems sustained by soft connections, such as hydrogen bonds, π–π stacking and weak metal–metal interactions, are more flexible and sensitive to the chemical environment, and consequently are less designable and possess abundant assembly chemistry that remains to be further investigated. Especially when the building blocks are complex cations or anions, the nature of counter ions and solvent molecules play crucial roles in determining the final assembly architectures.

Due to the inherent coordination and hydrogen-bonding donor/acceptor functionalities, both nicotinamide (nia) and nicotinic acid (niac) were used in crystal engineering to construct extended frameworks sustained by both coordination and hydrogen bonds [6,7]. Herein, in order to exam the effect of counter anions upon the intermolecular interactions and assembly process of the bis(nicotinamide-*N*)silver(I) ion [6], we report the crystal and packing structures of $[Ag(nia)_2]_2(bpds)\cdot 2H_2O$ (**1**) and $[Ag(nia)_2](asa)$ (**2**) (bpds = 4,4′-biphenyldisulfonate, asa = aminosulfonate). Their nicotinic acid analogue,

$[Ag(niac)_2]_2(1,5nds)\cdot 2H_2O$ (**3**) (1,5nds = 1,5-disulfonate) was also synthesized and structurally characterized. The results show that, by changing the counter anions, the assembling architectures of the $[Ag(nia)_2]^+$ ion through non-covalent interactions can be modified dramatically and highly ordered extended networks can be constructed.

2. Experimental

2.1. Material and methods

All materials were commercially available and used as received. elemental analyses were carried out with an elementar Vario EL elemental analyzer. FTIR spectra were obtained on a Bruker EQUINOX 55 FTIR spectrometer with KBr pellets. TGA was performed using a Netzsch TG 209 analyzer in flowing nitrogen.

2.2. Syntheses and characterization

2.2.1. $[Ag(nia)_2]_2(bpds)\cdot 2H_2O$ (*1*)

An aqueous solution (20 ml) of 4,4′-biphenyldisulfonate acid (0.32 g, 1 mmol) was added to Ag_2O (0.24 g, 1 mmol) with constant stirring until all of the solids dissolved. Nicotinamide (0.25 g, 2 mmol) was added to this solution. Colorless crystals of **1** were collected after 6 days (54% yield based on Ag). $C_{36}H_{36}O_{12}N_8S_2Ag_2$ (**1**) Required: C 41.08, H 3.45, N 10.65; Found: C 41.03, H 3.34, N 10.76%. IR data (cm^{-1}, KBr): 3400s, 3308s, 3171s, 3094s, 2825m, 2787m, 1694s, 1635s, 1596s, 1574m, 1429s, 1399s, 1199s, 1129s, 1037s, 998s, 818m, 783m, 722s, 694m, 655m, 617s.

2.2.2. $[Ag(nia)_2](asa)$ (*2*)

The same procedure as that for **1** was used to obtain **2** (56% yield based on Ag). $C_{12}H_{14}O_5N_5SAg$ (**2**) Required: C 32.16, H 3.15, N 15.63; Found: C 32.15, H 2.895, N 15.92%. IR data (cm^{-1}, KBr): 3396s, 3318s, 3270s, 3173s, 3094s, 2831m, 2776m, 1695s, 1631s, 1596s, 1574m, 1428s, 1398s, 1231s, 1184s, 1121s, 1053s, 965m, 785s, 690s, 651s.

2.2.3. $[Ag(niac)_2]_2(1,5nds)\cdot 2H_2O$ (*3*)

An aqueous solution (20 ml) for hexaqua 1,5-naphthalenedisulfonic acid (0.36 g, 1 mmol) was added to Ag_2O (0.24 g, 1 mmol) with constant stirring until all of the solids dissolved. Nicotinic acid (0.25 g, 2 mmol) and acetonitrile (20 ml) were added to this solution. Colorless crystals of **3** were collected after 3 days (30% yield based on Ag). $C_{34}H_{30}O_{16}N_4S_2Ag_2$ (**3**) Required: C 39.63, H 2.93, N 5.44; Found: C 39.46, H 2.90, N 5.64%.

2.3. X-ray crystallography

Experimental details of the X-ray analyses are provided in Table 1. All diffraction data were collected on a Bruker Smart 1000 CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at room temperature using the program SMART [8] and processed by SAINT+ [9]. Absorption corrections were applied by SADABS [10]. Space groups of these compounds were determined from systematic absences and further justified by the results of refinement. In all cases, the structures were solved by direct methods and refined using full-matrix least-squares/difference Fourier techniques using SHELXTL [11,12]. All non-hydrogen atoms were refined with anisotropic displacement parameters. After that, all hydrogen atoms of the ligands were placed at idealized positions and refined as riding atoms with the relative isotropic parameters of the heavy atoms to which they are attached. Hydrogen atoms of water were located from the difference Fourier map at the finale state of refinement. Selected bond distances, angles and hydrogen bonds are shown in Tables 2–4, respectively.

3. Results and discussion

3.1. Spectral characterization and thermal analyses

The IR spectra showed that both compounds **1** and **2** have absorptions at 3000–3400 cm^{-1}, corresponding to the N–H stretching vibrations of the amide group. The C=O stretching frequency of **1** and **2** was recorded at 1694 and 1695 cm^{-1}, respectively. The aromatic C–H stretching extends through the region 2770–2840 cm^{-1}. The well-resolved frequencies of the aromatic rings span over 600–1000 cm^{-1} and 1240–1600 cm^{-1}. Those frequencies characteristic of the fundamental and split ν_3 S–O stretching modes are observed in the range 1000–1240 cm^{-1}.

TGA analyses indicated that complex **1** releases water molecules at 89.3–131.1 °C, and nicotinamide at 249.2–391.2 °C. Complex **2** is stable until release of nicotinamide at 212.9–273.5 °C.

3.2. Description of the structures

Both $[Ag(nia)_2]_2(bpds)\cdot 2H_2O$ (**1**) and $[Ag(nia)_2](asa)$ (**2**) contain cationic complexes comprised of two nicotinamide ligands coordinated through the pyridine nitrogen atoms to a silver(I) ion in a linear fashion. The amide moieties are arranged *trans* with respect to each other. The coordination geometry of the silver(I) ion, as shown in Fig. 1(a) and Fig. 2(a), is similar to that observed in the bis(nicotinamide-*N*)silver(I) triflate [6], except that in the triflate, the amide moieties are

arranged *cis* with respect to each other [6]. The Ag–N bond length and N–Ag–N bond angle are 2.174(2), 2.190(2) Å and 174.28(7)° in **1**, 2.168(2), 2.171(2) Å and 172.56(9)° in **2**, respectively. The linear unit is connected to another one, generated by an inversion center, through Ag–Ag interactions, with Ag–Ag = 3.373(6) (**1**) and 3.3776(7) Å (**2**). Consequently, H-shaped dimeric units are generated. The pyridine rings on the same side of the Ag–Ag bond are almost co-planar, forming dihedral angles of 16.5° (**1**) and 3.4° (**2**) with the distance between the two coordinated *N* atoms being 3.527 (**1**) and 3.631 Å (**2**). As shown in Fig. 1(b) and Fig. 2(b), these H-shaped cationic fragments are propagated through two head-to-head intermolecular hydrogen bonds designated as $R_2^2(8)$ [13], formed by the amide groups (N···O = 2.916(3) and 3.013(3) Å, N–H···O = 171.5° and 170.3° in **1**; N···O = 2.946 and 2.925 Å, N–H···O = 172.19° and 174.33° in **2**). The resulting ribbon-like structures sustained by hydrogen bonds are similar to that observed in the coordination polymers of silver(I) bipyridyl [14].

In **1**, the adjacent cationic ladders are further linked by $R_4^4(8)$ hydrogen bonds between another amine hydrogen and the carbonyl oxygen of a nitotinamide from an adjacent ladder (N···O = 2.960(3) Å, N–H···O = 145.9°), resulting in an infinite two-dimensional

network, as illustrated in Fig. 1(b). The bpds anions are sandwiched between two cationic sheets and anchored by hydrogen bonds formed by the SO_3^- oxygen and amino hydrogen of the amide groups. Meanwhile, water molecules are intercalated in the void space constructed by the cationic sheets and counter-anions, as illustrated in Fig. 1(c). The overall crystal packing displays alternating cationic sheets and anionic pillars. While in **2**, there are no further hydrogen bonding interactions between the adjacent cationic ladders, the anions also forms a complementary $R_2^2(8)$ motif hydrogen bonding ribbon through amino hydrogen atoms and sulfonate oxygen atoms, as shown in Fig. 2(b). The cationic chains are connected by the anionic chains through hydrogen bonds between the remaining amide hydrogen atoms and the sulfonate oxygen atoms (N···O = 3.070 Å, N–H···O = 163.10°), as shown in Fig. 2(c).

Finally, in [Ag(niac)$_2$]$_2$(1,5nds)·2H$_2$O (**3**), a near-linear cationic complex comprised of two nicotinic acid ligands coordinated through the pyridine nitrogen atoms to a silver(I) ion is present. The carboxylate moieties are arranged *trans* with respect to each other. The coordination geometry of the silver(I) ion, as shown in Fig. 3(a), is similar to that observed in **1** and **2**. The Ag–N bond length is 2.1672(16) and 2.1687(18) Å, while the N–Ag–N bond angle is 168.65(7)°. The linear unit is connected to another one through a screw axis operation (symmetric operator $-x+1, y, -z+1/2$), with Ag–Ag = 3.1978(6) Å, also resulting in a H-shaped dimeric unit. Interestingly, unlike in **1** and **2** where one-dimensional structures are constructed by strong inter-amide hydrogen bonds, in **3** the dimeric units are propagated via C–H···O hydrogen bonds between the aromatic hydrogen atom and the carbonyl oxygen (C···O = 3.178 Å, C–H···O = 133.6°), as shown in Fig. 3(a). This hydrogen bonding mode formed by two nicotinic acids is quite unusual, in comparison with the more common and stable $R_2^2(8)$ pattern we observed in another series of nicotinic acids-coordinated compounds [15]. The other two carboxylate groups are involved in strong hydrogen bonds with the water molecules, forming a pattern described as $R_4^4(12)$ (OO 2.543(2) and 2.800(3) Å, O–H···O = 172.4° and 166.7°), as illustrated in Fig. 3(b). The 1,5nds anions occupy the void space formed by the dimeric silver(I) units and water-carboxylate cluster.

3.3. Other interesting structural aspects

Due to the torsional freedom of the Ag–Ag bond, the Ag–N bond, and the C–C bond between the pyridine ring and the amide/carboxylate group, the H-shaped fragment reveals some flexibilities which can accommodate different chemical environments, as typically represented by different counter anions and water of hydration, and still retains the same double $R_2^2(8)$ intermolecular hydrogen bonding capability. There are two possible conformations for the H-shaped unit generated by the linear Ag(I) complex with the functional groups in *trans* positions, as illustrated in Scheme 1. The different orientations of the four functional groups determine the pattern of inter-units interactions.

The packing arrangements of compounds **1** and **2** do not resemble any of the reported bis(nicotinamide-*N*)silver(I) analogues with different counter anions [6]. Remarkably, the linear cationic building blocks have the same coordination environment, however, there are no Ag–Ag interactions reported for the known structures [6]. Hence, we searched the Cambridge Structure Database [16] for discrete silver(I) complexes coordinated linearly only by two pyridine nitrogen atoms (polymeric Ag(I) compounds were excluded), and identified a total of 15 entries [6,17–24]. Among them, we found two entries, namely bis(nicotinamide-*N*)silver(I) triflate [6] and bis(4-4(4-methoxystyryl)pyridinato)-silver(I) octylsulfate hemihydrate [18], containing complexes with Ag–Ag interactions (Ag–Ag = 3.307 and 3.194/3.209 Å, respectively). Most significantly, in both of these complexes and also in the three title complexes, sulfonates or sulfate are employed as counter anions. This sulfonate/sulfate-related Ag–Ag interaction is best demonstrated by the structures of bis(nicotinamide-*N*)silver(I) triflate, tetrafluoroborate and hexafluorophosphate [6]. Ag–Ag interactions are observed in the SO_3^--containing triflate but not in the last two complexes. Nevertheless, whether the Ag–Ag interaction observed in the linear pyridine-coordinated silver(I) complex is uniquely sulfonate/sulfate-promoted remains for further investigation.

The interconversion of dichlorobis(*N*-*n*-propylsalicylaldimine)zinc(II) and bis(*N*-*n*-propylsalicylaldiminato)zinc(II)

Michele A. Torzilli, Shalton Colquhoun, Danielle Doucet, Robert H. Beer *

Abstract

The interconversion of the zinc(II) complex of the neutral ligand adduct of *N*-*n*-propylsalicylaldimine $Zn(L^{pr}H)_2Cl_2$ and its salicylaldiminato counterpart $Zn(L^{pr})_2$ is investigated. The compound $Zn(L^{pr}H)_2Cl_2$ is prepared by the reaction of anhydrous $ZnCl_2$ with 2 equiv. of *N*-*n*-propylsalicylaldimine ($L^{pr}H$) in benzene. A crystallographic study of the distorted tetrahedral $Zn(L^{pr}H)_2Cl_2$ adduct reveals that the oxygen atom of the ligand is deprotonated and bound to the zinc atom while the nitrogen is protonated and non-coordinating. An infrared spectrum of $Zn(L^{pr}H)_2Cl_2$ exhibits a C=N stretch at a higher energy (1658 cm^{-1}) than the free ligand (1632 cm^{-1}) consistent with the presence of the iminium moiety. In contrast, the deprotonated ligand of the crystallographically characterized salicylaldiminato complex $Zn(L^{pr})_2$ coordinates to zinc in its prototypical bidentate monoanionic coordination mode. Deprotonation of $Zn(L^{pr}H)_2Cl_2$ with Et_3N or NaOH forms $Zn(L^{pr})_2$. The reverse reaction, protonation of $Zn(L^{pr})_2$ with anhydrous HCl, produces $Zn(L^{pr}H)_2Cl_2$. These reactions demonstrate the interrelationship between the zinc salicylaldimine adduct and its corresponding salicylaldiminato complex. © 2002 Elsevier Science Ltd. All rights reserved.

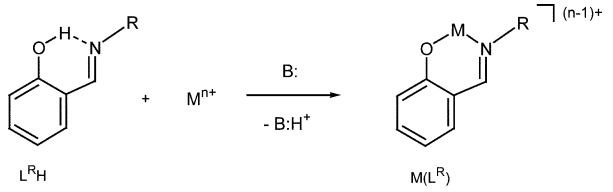
1. Introduction

The salicylaldimine ligand forms the basis of an extensive class of chelating ligands that has enjoyed popular use in the coordination chemistry of transition and main group elements [1–3]. The reaction of the neutral phenol-imine form of the salicylaldimine ligand with a suitable metal starting material in the presence of base is a simple and direct means of preparing metal salicylaldiminato complexes (Scheme 1). In these complexes, the deprotonated phenolate-imine form of the ligand acts as a bidentate monoanionic N/O donor.

Despite the frequent use of this preparative method, comparatively few of the putative precursors or intermediates involved in this reaction prior to deprotonation of the ligand have been structurally characterized [1,2,4–11] and, similarly, the precursors formed by the reverse reaction are not isolated typically [12,13]. We report here an example of the interconversion of a structurally characterized precursor and its corresponding deprotonated salicylaldiminato complex using the zinc(II) dichloride adduct of *N*-*n*-propylsalicylaldimine ($L^{pr}H$). These reactions corroborate the role of neutral salicylaldimine adducts in the formation of salicylaldiminato complexes.

2. Experimental



2.1. Materials and methods

Reagents and solvents were used as received from commercial sources. The ligand *N*-*n*-propylsalicylaldimine ($L^{pr}H$) and the protonated ligand ($L^{pr}H_2$)(CF_3SO_3) were synthesized by generally accepted methods [1,14] and $Zn(L^{pr})_2$ by modification of related literature procedures [15,16]. Infrared and electronic spectroscopic data were collected on a Mattson Satellite FTIR and Perkin–Elmer Lambda 6 instrument, respectively. The ^1H NMR spectroscopic data were obtained on a Bruker AVANCE 300 NMR spectrometer at

ambient room temperature. Chemical shifts are referenced as ppm downfield of tetramethylsilane. A conventional numbering scheme was adopted for ligand aromatic hydrogen atoms attached to carbons for ^{1}H NMR assignments in which the imine moiety was attached to ring C1, the OH to ring C2 and so on. Robertson Microlit Laboratories (Madison, NJ) and Quantitative Technologies Inc. (Whitehouse, NJ) performed the elemental analyses.

2.2. X-ray crystallographic structure determination of $Zn(L^{pr})_2$ and $Zn(LH)_2Cl_2$

Data collection, solution and refinement details are given in Table 1 and bond lengths and distances in Figs. 1 and 2 captions and Table 2. Complete crystallographic information is available as supplementary material. Rhomb-shaped single crystals of $Zn(L^{pr}H)_2Cl_2$ suitable for X-ray crystallographic studies could be obtained from slowly evaporating methanol or acetonitrile solutions in air. X-ray quality single crystals of $Zn(L^{pr})_2$ were grown by evaporating the compound dissolved in toluene over a period of 1 week. The crystals were glued to a glass fiber with epoxy and mounted on a Bruker P4 (formerly Siemens) diffractometer equipped with a SMART CCD and the data collected at low temperature under a dinitrogen cold stream.

Data collection, solution and refinement for both compounds were obtained by routine methods using SHELXTL [17] (see Table 1). A data set was collected by obtaining an initial set of cell constants calculated from reflections harvested from three sets of 20 frames. These initial sets of frames were oriented such that orthogonal wedges of reciprocal space were surveyed. The unit cell was further refined by the inclusion of reflections from the data set and the program SAINT (Bruker AXS). The structure was solved by direct methods and all non-hydrogen atoms were refined anisotropically by full-matrix least-squares on F^2. All hydrogen atom parameters, with the exception of the iminium hydrogens

H(1) and H(2) in $Zn(LH)_2Cl_2$, were placed in ideal positions and refined as riding atoms with individual (or group if appropriate) isotropic displacement. The atoms H(1) and H(2) were found in the difference map and refined to convergence with isotropic displacement parameters.

2.3. Preparation of compounds

2.3.1. N-n-Propylsalicyaldimine ($L^{pr}H$)

A solution of salicylaldehyde (6.106 g, 0.05 mol) in 50 ml of benzene was added to a 100 ml round bottom flask fitted with a Dean–Stark trap and a condenser. To this solution, 2.956 g (0.05 mmol) of *n*-propylamine was added slowly with stirring since the reaction was slightly exothermic and then refluxed for 1 h. After cooling, the reaction mixture was dried over anhydrous magnesium sulfate and gravity filtered. The filtrate was evaporated to yield 7.057 g (78%) of a yellow–brown oil that could be used without further purification. *Anal.* Found: C, 73.30; H, 8.04; N, 8.73. Calc. for $C_{10}H_{13}NO$: C, 73.59; H, 8.03; N, 8.58%. FTIR (neat) 3061(w), 2963(s), 2931(s), 2874(s), 2738(w), 2660(w), 1664(m), 1632(vs), 1582(s), 1497(s), 1461(s), 1416(m), 1382(w), 1338(w), 1279(s), 12059(m), 1150(m), 1115(w), 1054(w), 1031(w), 1013(w), 977(m), 882(m), 850(m, br), 755(s), 640, 553, 463 cm^{-1}. ^1H NMR ($CDCl_3$) δ 13.60 (1H, s br, OH),

8.23 (1H, s, NCH), 7.20 (1H, t, H5), 7.14 (1H, d, H6), 6.87 (1H, d, H3), 6.77 (1H, t, H4), 3.46 (2H, t, NCH_2), 1.63 (2H, m, NCH_2CH_2), 0.89 (3H, t, CH_3) ppm.

2.3.2. $(L^{pr}H)(CF_3SO_3)$

In a 100 ml Schlenk tube, 0.429 g (2.63 mmol) of *N-n*-propylsalicylaldimine was added to 20 ml of anhydrous diethyl ether under argon. To this solution, 0.760 ml (0.448 g, 2.99 mmol) of trifluoromethanesulfonic acid was added in drops with vigorous stirring. The resulting cloudy, slightly pink suspension was stirred for 5 min, then filtered and washed with anhydrous diethyl ether to yield 0.780 g of a white solid after drying under vacuum (95% yield). The compound could be recrystallized from hot chloroform. *Anal*. Found: C, 42.16; H, 4.46; N, 4.45; F, 18.31. Calc. for $C_{11}H_{14}F_3NOS$: C, 42.17; H, 4.50; N, 4.47; F, 18.19%. IR (KBr): 3214(s), 3140(m, br), 3006(m), 2973(m), 2885(w), 1674(m), 1611(m), 1502(w), 1459(w), 1381(w), 1360(w), 1280(vs), 1245(vs), 1223(s), 1151(m), 1061(w), 1031(s), 1000(w), 903(w), 882(w), 758(m), 645(m), 574(w), 517(w), 447(w) cm^{-1}.

2.3.3. $Zn(L^{pr}H)_2Cl_2$

In a 100 ml Schlenk tube, 1.10 g (6.74 mmol) of *N-n*-propylsalicylaldimine was dissolved in 12 ml of dry benzene (distilled over $LiAlH_4$) under Ar. A 3.3 ml solution of 1.0 M $ZnCl_2$ (3.3 mmol) in diethyl ether (Aldrich) was then added via syringe in drops forming a thick orange oil. With vigorous manual agitation the oil slowly changed to a yellow solid after approximately 0.5 h. The reaction mixture was allowed to stir for an additional 1.5 h. The solid was filtered and washed in air with 5 ml of benzene and diethyl ether (3×5 ml) to yield 1.493 g of a yellow powder after drying under vacuum (98% yield). *Anal.* Found: C, 51.57; H, 5.58; N, 6.00; Cl, 14.93. Calc. for $C_{20}H_{26}Cl_2N_2O_2Zn$: C, 51.91; H, 5.66; N, 6.05; Cl, 15.32%. m.p. 151–154 °C. Electronic spectrum ($CHCl_3$, ε M^{-1} cm^{-1}): 316 (7300), 390 (2300) nm. FTIR (KBr): 3060(m, br), 2977(sh), 2957(m), 2935(m), 2877(w), 1658 (vs), 1607(s), 1542(s), 1490(s), 1459(w), 1344(w), 1302(m), 1288(m), 1232(m), 1202(m), 1141(m), 1027(m), 989(w), 911(w), 894(w), 8649w), 787(w), 759(s), 7349(w), 583(m), 514(w), 490(w), 450(w) 434(w), 4169(w) cm^{-1}. ^1H NMR ($CDCl_3$) δ 13.6 (1H, s br, OH), 8.16 (1H, s, NCH), 7.37 (1H, t, H5), 7.23 (1H, d, H6), 7.11 (1H, d, H3), 6.74 (1H, t, H4), 3.61 (2H, t, NCH_2), 1.79 (2H, m, NCH_2CH_2), 0.99 (3H, t, CH_3) ppm.

2.3.4. $Zn(L^{pr})_2$

To a solution of 1.50 g (9.19 mmol) of *N-n*-propylsalicylaldimine in 20 ml of ethanol, 1.01 g (4.60 mmol) of $Zn(O_2CCH_3)_2 \cdot 2H_2O$ was added with stirring. A pale yellow precipitate formed after several minutes and was stirred for an additional 45 min. The precipitate was filtered and dried under vacuum to yield 0.98 g of a light yellow powder (55%). This compound could be recrystallized from acetone and water to obtain a colorless microcrystalline product. *Anal*. Found: C, 61.59; H, 6.08; N, 7.05. Calc. for $C_{20}H_{24}N_2O_2Zn$: C, 61.62; H, 6.21; N, 7.19%. 2.3.5. $Zn(L^{pr})_2$ prepared from $Zn(L^{pr}H)_2Cl_2$

In a 125 ml Erlenmeyer flask, 0.179 g (0.387 mmol) of $Zn(L^{pr}H)_2Cl_2$ was added followed by 16.8 ml (0.769 mmol) of aqueous 0.0458 M NaOH with stirring. The solution initially became a light yellow suspension followed by the formation of a white precipitate. After 2 h the product was filtered and dried under vacuum to yield 0.136 g of an off-white solid (90%). Alternatively, solid $Zn(L^{pr}H)_2Cl_2$ (0.110 g, 0.238 mmol) was dissolved in 15 ml of chloroform with stirring in a 25 ml round bottom flask. The slightly cloudy yellow solution became clear and pale yellow after 0.0485 g (0.479 mmol) of Et_3N was added by syringe. The chloroform solution was evaporated on a rotoevaporator and the resulting solid was triturated with deionized water until chloride free (by testing with $AgNO_3$(aq)). The solid was then dried under vacuum to yield 0.083 g of off-white product (89%). This material was judged to be pure based on ^1H NMR and IR spectroscopic measurements.

2.3.6. $Zn(L^{pr}H)_2Cl_2$ prepared from $Zn(L^{pr})_2$

A 2.1 ml (2.1 mmol) aliquot of a 1.0 M solution of HCl in diethyl ether (Aldrich) was added via syringe in drops to a rapidly stirring solution of 0.391 g (1 mmol) of $Zn(L^{pr})_2$ in 20 ml of benzene in a Schlenk tube under argon. The reaction mixture immediately became cloudy and yellow. After several minutes of stirring, a thick orange oil formed. Continued stirring yielded a yellow solid after 1 h. The solvent was decanted and the remaining solid was washed with 5 ml of benzene followed by 3×10 ml of diethyl ether and dried to yield 0.428 g of product (92%). Both preparations yielded material that was pure based on ^1H NMR and IR spectroscopic measurements.

3. Results and discussion

3.1. Synthesis and interconversion reactions

In accord with syntheses of zinc(II) adducts of salicylaldimine ligands [6,18], the reaction of 1 equiv. of anhydrous $ZnCl_2$ in diethyl ether with 2 equiv. of *N*-*n*-propylsalicylaldimine in benzene forms $Zn(L^{pr}H)_2Cl_2$ in a nearly quantitative 98% yield. In the presence of 2 equiv. of NaOH(aq) or Et_3N in chloroform, this compound readily forms $Zn(L^{pr})_2$ in excellent yield upon work-up (Eq. (1)). The zinc salicylaldiminato complex prepared in this manner is identical to the commonly reported method that employs $Zn(O_2CCH_3)_2\cdot 2H_2O$ with *N*-alkylsalicylaldimines [15,16,19–21]. The isolated 89–90% yield of $Zn(L^{pr})_2$ from the precursor $Zn(L^{pr}H)_2Cl_2$ is significantly greater than the 55% yield of the reaction by the more conventional preparative method, which is often problematic [22].

$$Zn(L^{pr}H)_2Cl_2 \underset{2HCl}{\overset{2Et_3N:\ or\ 2NaOH}{\rightleftarrows}} Zn(L^{pr})_2 \quad (1)$$

Conversely, the $Zn(L^{pr}H)_2Cl_2$ precursor can be prepared from $Zn(L^{pr})_2$ and 2 equiv. of HCl in benzene/diethyl ether in 92% yield indicating the ready, clean interconversion between the salicylaldimine adduct and its salicylaldiminato counterpart (Eq. (1)). Despite the presence of two nascent equivalents of HCl, this ''reverse'' reaction in the absence of base does not occur. Attempts to affect the elimination of HCl from this complex by heating the neat solid $Zn(L^{pr}H)_2Cl_2$ at 100 °C under vacuum for several days resulted in no reaction. Heating the evidently robust solid to a melt at 155 °C under vacuum or in DMSO under a N_2 purge resulted in no change after 5 h. After prolonged heating over several days, only partial decomposition to the free ligand and unidentifiable products by ^1H NMR and IR spectroscopy was observed.

3.2. Structural characterization

The X-ray crystal structures of $Zn(L^{pr}H)_2Cl_2$ and $Zn(L^{pr})_2$ allow a direct comparison between both compounds of the neutral and deprotonated *N*-*n*-propylsalicylaldimine ligand. The structure of $Zn(L^{pr}H)_2Cl_2$ shown in Fig. 1 reveals a tetrahedral zinc(II) atom bound to two chlorides and two neutral salicylaldimine ligands in their phenolate-iminium (zwitterion) form. Only the phenolate oxygen atom of the potentially bidentate mixed N/O donor ligand binds to zinc in this complex, a rare example of a mononuclear zinc complex with terminal phenolate ligands [23–25]. Notably, the imine nitrogen is non-coordinating and protonated, i.e. an iminium $\{HC{=}NH\}^+$ group. The structure is similar, overall, to the previously reported structure of zinc(II) salicylaldimine adduct $Zn(L^{ipr}H)I_2$ [26], with the exception that $Zn(L^{pr}H)Cl_2$ possesses approximate C_2 symmetry with the phenyl rings of the ligand disposed *trans* to one another rather than *cis* with respect to the normal of the X–Zn–X ($X = Cl^-$ or I^-) plane. In spite of its relative anonymity, this coordination mode has appeared in various reports of Schiff base complexes or adducts [27]. Since the coordinated salicylaldimine zwitterion was first definitively structurally characterized [28], it has appeared in novel compounds [29,30] or useful starting materials for heterobimetallic complexes of multidentate macrocyclic complexes [7–10].

The coordination mode of the monodentate zwitterion salicylaldimine in $Zn(L^{pr}H)_2Cl_2$ is in marked contrast to that of the salicylaldiminato ligand in the structure of the $Zn(L^{pr})_2$ shown in Fig. 2. In this structure, the ligand in its phenolate-imine form uses both N/O donors to bind to tetrahedral zinc(II) in its ubiquitous bidentate monoanionic coordination mode (Scheme 1). The structure of $Zn(L^{pr})_2$ is comparable to analogous bis(salicylaldiminato)zinc (II) complexes [15,16,21,26].

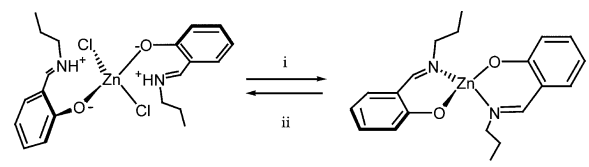
The ligands in both complexes impose a distorted tetrahedral coordination geometry with angles about the zinc atom ranging from 96.30(3)° to 116.83(3)° in $Zn(L^{pr}H)_2Cl_2$ and 95.8(1)° to 127.8(2)° in $Zn(L^{pr})_2$ (see Table 2). The Zn–O bond distances of the coordinated neutral ligand in $Zn(L^{pr}H)_2Cl_2$ (1.9535(9), 1.9742(1) Å) are slightly longer than the 1.928(2) Å distance in the corresponding salicylaldiminato complex $Zn(L^{pr})_2$, but in good agreement with the mean Zn–O distance of 1.955 Å for the reported structure of $Zn(L^{ipr}H)_2I_2$ [26]. The Zn–O–C angles (127.01(9)°, 131.69(9)°) in $Zn(L^{pr}H)_2Cl_2$ are within the range (118°–137°) of limited available data for zinc(II) complexes with terminal phenolate ligands [18,23–26,31]. The Zn–Cl bond lengths (2.2478(4), 2.2312(4) Å) of $Zn(L^{pr}H)_2Cl_2$ are comparable to related zinc dichloride adducts [18,31,32] and between those of $ZnCl_4^-$ (range 2.263–2.273 Å) [33] and $Zn(py)_2Cl_2$ (2.215, 2.228 Å) [34].

Despite the obvious difference in coordination mode, the metrical parameters of the zwitterion salicylaldimine ligand in $Zn(L^{pr}H)_2Cl_2$ are crystallographically equivalent to its bidentate anionic counterpart in $Zn(L^{pr})_2$ (see Table 2) and other coordinated salicylaldiminato ligands in general [1,2]. The C–O bond distances in both $Zn(L^{pr}H)_2Cl_2$ (1.308(2), 1.313(2) Å) and $Zn(L^{pr})_2$ (1.307(4) Å) are normal for deprotonated phenols bound to zinc [15,16,18,21–26,31]. The C–N bond distances of the protonated imine in $Zn(L^{pr}H)_2Cl_2$ (1.289(2), 1.292(2) Å) as well as the C–N–C angles (122.6(1)°, 125.8(2)°) compare favorably with the corresponding distances and angles for the imine moiety in $Zn(L^{pr})_2$ of 1.276(5) Å and 117.4(3)° consistent with a sp^2 hybridized nitrogen in a C–N double bond [35].

Of particular relevance to the interconversion of salicylaldimine and salicyclaldiminato complexes is the iminium proton in $Zn(L^{pr}H)_2Cl_2$ shown in Fig. 1. The coordinates of the hydrogen atom attached to nitrogen in the structure of $Zn(L^{pr}H)_2Cl_2$ converge upon refinement to yield N–H bond distances of 0.84(2) (N(1)–H(1)) and 0.80(2) Å (N(2)–H(2)) and positions located well within the ligand plane (the atoms in the $L^{pr}H$ fragment are co-planar with a maximum deviation of 0.05 Å). The N···O distances (2.674(2), 2.619(2) Å) and N–H···O angles (132(2), 134(2)°) in $Zn(L^{pr}H)_2Cl_2$ are consistent with an intraligand hydrogen bond between a protonated nitrogen and a phenolate oxygen [18,26,31]. In addition, the N(2)···Cl(1) distance of 3.562(2) Å and the N(2)–H(2)···Cl(1) angle of 143(2)° approach those of weak hydrogen bonds between N–H and chloride, e.g. $(CH_3NH_3)_2[ZnCl_4]$ (3.210–3.546 Å) [33]. The data suggest that H(2) participates in a three-center hydrogen bond [36] with O(2) and Cl(1).

The protonation of the iminium hydrogen in $Zn(L^{pr}H)_2Cl_2$ results from the reaction of the strong Lewis acid zinc dichloride with the oxygen atom of the phenol-imine form (Scheme 1) of the ligand. This stable hydrogen bonded form of the free ligand, seemingly, converts to the zwitterion form by intermolecular proton transfer from the metalated phenol-imine, {Zn–OH···N}, to form a hydrogen bonded phenolate-iminium species, {Zn–O···H:N}. The iminium proton participates in a moderate strength hydrogen bond [36] to the coordinated phenolate oxygen atom stabilizing this otherwise high-energy zwitterion form (in non-aqueous solvents) of the neutral ligand [2]. An alternative monodentate coordination mode, in which the zinc atom is bound to the imine and the proton resides on the phenol, e.g. {OH···Zn–N}, would lack the O–H···N hydrogen bond and is presumably less stable.

3.3. Spectroscopic characterization



The solid-state infrared spectrum of $Zn(L^{pr}H)_2Cl_2$ displays a distinctive, intense C=N stretch at 1658 cm^{-1}. The C=N stretch occurs at a considerably higher energy than the corresponding frequency in the ligand $L^{pr}H$ (1632 cm^{-1}) or the salicylaldiminato complex $Zn(L^{pr})_2$ (1626 cm^{-1}). A similar positive shift was obtained for the iminium triflate salt $L^{pr}H_2(O_3SCF_3)$ (1674 cm^{-1}) prepared from *N*-*n*-propylsalicylaldimine and trifluorosulfonic acid. This high energy stretch is a well-established characteristic of the iminium ion [14] and substantiates that the salicylaldimine ligand in $Zn(L^{pr}H)_2Cl_2$ coordinates to zinc in its zwitterion form. Infrared spectra of $Zn(L^{pr}H)_2Cl_2$ obtained in chloroform indicate the retention of the iminium C=N stretch at a slightly lower energy (1651 cm^{-1}) in solution. The electronic spectra of the complex substantiate the solution IR data. In chloroform, the lowest energy electronic absorption of $Zn(L^{pr})_2$ shifts from 369 to 390 nm in $Zn(L^{pr}H)_2Cl_2$. This absorption, assigned to a π to π* transition in *N*-alkylsalicylaldimines, is known to shift to lower energy upon formation of the iminium-phenolate form of the free ligand [37].

The iminium proton can also be observed directly as a broad exchangeable resonance at 13.6 ppm in the ^1H NMR spectrum of $Zn(L^{pr}H)_2Cl_2$ in deuterated chloroform. Previously reported NMR spectra of zinc halide salicylaldimine adducts in dimethylsulfoxide were unstable with respect to the salicylaldiminato complexes [6]. We observe, however, we observed no evidence for this in our experiments. Otherwise, the ^1H NMR spectra of $Zn(L^{pr}H)_2Cl_2$ and $Zn(L^{pr})_2$ are alike, with aromatic and propyl protons of the adduct exhibiting small discernible downfield chemical shifts.

3.4. Rationale for interconversion

The presence of the iminium proton in $Zn(L^{pr}H)_2Cl_2$ helps explain how the interconversion reaction occurs (Eq. (1) and Scheme 2). Loss of the iminium proton from $Zn(L^{pr}H)_2Cl_2$ in the form of HCl or deprotonation in the presence of comparatively weak bases to form the salicylaldiminato complex $Zn(L^{pr})_2$ is a reasonable outcome since the iminium proton is fairly acidic ($pK_a \sim 5$) [38,39]. The zwitterion form of the ligand in the adduct, furthermore, provides an explanation for why many salicylaldiminato complexes can be prepared readily from simple metal salts in the absence of base or with bases [1] which are incapable of deprotonating the salicylaldimine ligand ($pK_a \sim 10$–12) [39,40].

The reverse reaction, the protonation of $Zn(L^{pr})_2$ to $Zn(L^{pr}H)_2Cl_2$, can be considered in a similar fashion. In this reaction, the imine nitrogen of the coordinated salicyclaldiminato ligand in $Zn(L^{pr})_2$ is protonated; predictably, this nitrogen is fairly basic given that it is in resonance with the anionic nitrogen of the keto-eneamido form of the ligand [2]. Following protonation of the nitrogen, heterolytic cleavage of the zinc nitrogen bond and formation of the O···H–N hydrogen bond could occur. Under the conditions used here, addition of HCl to $Zn(L^{pr}H)_2Cl_2$, both protonation of the nitrogen and ligand substitution of chloride for imine could take place. The structure of $Zn(L^{pr}H)_2Cl_2$ (Fig. 1) hints at what the intermediate of the addition reaction might look like since it depicts the N(2)–H(2), Zn–O(2) and

i = 2 NaOH, -2 H_2O, -2NaCl or 2 Et_3N, -2 Et_3NHCl
ii = 2 HCl

Scheme 2.

Zn–Cl(1) moieties in close proximity (taking part in a three center hydrogen bond).

The formation/scission of the Zn–N bond would also affect a geometric reorganization of the complex as the ligand changes from a bidentate to a monodentate coordination mode. Examination of the structures of $Zn(L^{pr}H)_2Cl_2$ in Fig. 1 and the representations shown in Scheme 2 indicate that the zinc atom in $Zn(L^{pr})_2$ would have to move out of the same approximate plane as the ligand atoms. This could be accomplished by the rotation of the acute torsion angles in $Zn(L^{pr})_2$ (Zn–O(1)–C(11)–N(1), 16.2°) to the more obtuse corresponding angles about the C–O bond in the adduct (Zn–O(2)–C(31)–C(32), 131.4° and Zn–O(1)–C1(1)–C(12), 174.2°). Inspection of models of the complexes suggests that these rotations as well as other requisite geometric changes are feasible.

4. Supplementary material

Crystallographic data for $Zn(L^{pr}H)_2Cl_2$ and $Zn(L^{pr})_2$ have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 167224 and 167225. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Structural and ^{1}H NMR spectroscopic characterization of bis(*N*-isopropylsalicylaldiminato)iron(II)

Michele A. Torzilli, Shalton Colquhoun, Jin Kim, Robert H. Beer *

Department of Chemistry, Fordham University, Bronx, NY 10458, USA

Received 23 August 2001; accepted 3 December 2001

Abstract

Coordinatively unsaturated iron(II) species form reactive organometallic and coordination complexes and are integral to the reactivity of non-heme iron proteins and their synthetic analogues. Iron(II) Schiff base complexes have proven to be easily prepared and useful starting materials for such compounds. Here we report a detailed preparative procedure and the solid-state structure of the iron(II) complex of *N*-isopropylsalicylaldimine ($L^{ipr}H$) based on the compounds first synthesized by Larkworthy (J. Chem. Soc., A (1968) 1048). The title compound is prepared by adding 2 equiv. of salicylaldehyde (salH) to $Fe(O_2CCH_3)_2$ in $KOH–CH_3OH$ to produce a precursor formulated as $Fe(sal)_2$ which is reacted subsequently with isopropylamine in THF to form $Fe(L^{ipr})_2$ in 34% isolated yield. A single crystal X-ray crystallographic study of $Fe(L^{ipr})_2$ reveals a mononuclear complex with two bidentate salicylaldiminate ligands bound to an iron(II) atom in a tetrahedral coordination geometry. The ^{1}H NMR spectrum of $Fe(L^{ipr})_2$ in benzene-d_6 exhibits six paramagnetically shifted ligand resonances ranging from +195 to −31 ppm that are consistent with a mononuclear high spin ($S = 2$) iron(II) complex in solution. Upon exposure to air, $Fe(L^{ipr})_2$ forms the oxo-bridged dinuclear iron(III) complex $[(L^{ipr})_2Fe]_2O$ as shown by ^{1}H NMR spectroscopy. © 2002 Elsevier Science Ltd. All rights reserved.

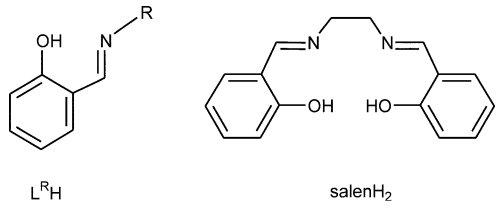
1. Introduction



The salicylaldimine ligands shown in Scheme 1 are easy to prepare and synthetically versatile and, accordingly, have been popular ligands for the synthesis of transition metal complexes [1–4]. Among metal salicylaldimine compounds, the iron complexes have been prepared extensively to investigate various aspects of their magnetic and spectroscopic properties and wide-ranging bioinorganic, organometallic, and catalytic chemistry [2,5]. A common approach to prepare these compounds takes advantage of the reactivity of an iron(II) salicylaldimine complex, notably Fe(salen), in concert with the complex being coordinatively unsaturated. By virtue of its ability to be reduced or oxidized as well as to expand its coordination number, Fe(salen) has been employed historically to introduce iron nitrosyl [6], alkyl [7], halide [7], quinone [8], and bridging oxo [9], sulfido [10], peroxo [11] and imido [12] bonds into iron salicylaldimine compounds. Similarly, widespread recent interest in iron(II) species that possess low coordination numbers has led to unusual coordination or organometallic compounds [13–25]. These compounds frequently exhibit desirable reactions with small molecules, e.g. the activation of dioxygen by non-heme iron(II) proteins and their model complexes [26–28].

Iron complexes of the L^RH and salen ligands shown in Scheme 1 figured early in studies of the magnetic, electronic and Mössbauer properties of iron(II) [5,6,29–31]. The bis(salicylaldiminato)iron(II) complexes, formulated as $Fe(L^R)_2$ (R = alkyl or aryl), were first prepared reliably by Larkworthy [6,29]. The compounds were determined to be high spin ($S = 2$), but their structure was not confirmed. In fact, a four coordinate iron(II) complex of salicylaldimine or a related Schiff base ligand with a N_2O_2 donor set has yet to be characterized by single crystal X-ray crystallography or solution NMR spectroscopy. Herein we describe explicit details of the synthesis of the iron(II) complex of *N*-isopropylsalicylaldimine ($L^{ipr}H$) based on a modifi-

cation of the general procedure by Larkworthy [29] and show that this complex is a soluble discrete mononuclear complex in the solid state and solution. We also demonstrate that Fe(L^{ipr})$_2$ reacts readily with air to form the corresponding oxo-bridged dinuclear iron(III) complex indicating that it is a useful material for synthetic strategies involving low coordinate iron(II) salicylaldimine compounds.

2. Experimental

2.1. Materials and methods

All reagents were used as received from commercial suppliers. Benzene and tetrahydrofuran were distilled under pre-purified dinitrogen from sodium benzophenone ketyl and stored under dinitrogen. Methanol was dried and distilled over activated molecular sieves under dinitrogen and stored under dinitrogen. The preparation and manipulation of bis(*N*-isopropylsalicylaldiminato)iron(II) was carried out under argon in a glove box and on a vacuum line using standard inert atmosphere methods [32]. Care must be taken to ensure all equipment is fully dried and solvents are de-gassed to successfully prepare bis(*N*-isopropylsalicylaldiminato)iron(II).

Elemental analysis of bis(*N*-isopropylsalicylaldiminato)iron(II) was performed by Desert Analytics (Tuscon, AZ). Elemental analysis of *N*-isopropylsalicyaldimine and bis(*N*-isopropylsalicylaldiminato)zinc(II) were carried out by QTI (Whitehouse, NJ). Infrared spectra were recorded on a Mattson Satellite FTIR. The NMR spectroscopic data were obtained on a Bruker AVANCE 300 spectrometer at 23 °C and are reported as positive shifts upfield of tetramethylsilane. The numbering scheme for the aromatic ring protons for the salicylaldimine anion moiety is given in Fig. 2.

2.2. X-ray crystallography of bis(*N*-isopropylsalicylaldiminato)iron(II)

Single crystals suitable for X-ray crystallographic studies were obtained by dissolving bis(*N*-isopropylsalicylaldiminato)iron(II) in tetrahydrofuran under argon in a Schlenk tube and cooling to −20 °C in a freezer for several days. The data collection, solution and refinement of bis(*N*-isopropyisalicyl-aldiminato)iron(II) summarized in Table 1 were carried out by routine methods using the SHELXTL suite of programs [33]. The ORTEP diagram and selected bond distances and angles are given in Fig. 1 and Table 2, respectively. Full crystallographic details are available as supplementary material.

A crystal of bis(*N*-isopropylsalicylaldiminato)iron(II) was attached to a glass fiber and mounted on the Siemens SMART CCD platform diffractometer system for a data collection at 173(2) K. An initial set of cell constants was calculated from reflections harvested from three sets of 20 frames. These initial sets of frames were oriented such that orthogonal wedges of reciprocal space were surveyed. This produced orientation matrices determined from 45 reflections. Final cell constants were calculated from a set of 6495 reflections from the actual

data collection. A semi-empirical absorption correction was carried out using the SHELXTL XPREP absorption routine. The space group *Pbca* was determined based on systematic absences and intensity statistics. A successful direct-methods solution was calculated which provided most non-hydrogen atoms from the E-map. Several full-matrix least-squares/difference Fourier cycles were performed which located the remainder of the non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in ideal positions and refined as riding atoms with individual (or group if appropriate) isotropic displacement parameters. A weak intermolecular hydrogen bond was observed between H(15) and O(2) equal to 2.484 Å.

2.3. Preparation of compounds

2.3.1. *N*-iso-propylsalicyaldimine ($L^{ipr}H$)

This compound was synthesized by a generally accepted method for the preparation of salicylaldimine ligands [2]. A solution of 16.69 g (0.137 mol) of salicylaldehyde in 150 ml of benzene was added to a 250 ml round bottom flask fitted with a Dean–Stark trap and condenser. To this solution, 12 ml (8.3 g, 0.14 mol) of isopropylamine was added slowly with stirring and then refluxed for 1 h. After cooling, the reaction mixture was dried over anhydrous magnesium sulfate and gravity filtered. The filtrate was rotoevaporated and dried under vacuum to yield 16.8 g (75%) of a yellow–brown oil that could be used without further purification. *Anal*. Calc. for $C_{10}H_{13}NO$: C, 73.59; H, 8.03; N, 8.58. Found: C, 73.39; H, 7.84; N, 8.44%. FTIR (neat): 3060, 2969, 2869, 1679, 1631(s), 1582, 1499, 1460, 1420, 1385, 1322, 1279, 1210, 1150, 1032, 977, 951, 905, 846, 755, 738, 632 cm^{-1}. ^1H NMR ($CDCl_3$) δ 13.72 (1H, s, OH), 8.35 (1H, s, N=CH), 7.26 (2H, m, H3, H4), 6.95 (1H, d, H6), 6.86 (1H, t, H5), 3.52 (1H, septet, $NCH(CH_3)_2$, 1.29 (6H, d, $NCH(CH_3)_2$) ppm.

2.3.2. Bis(*N*-isopropylsalicylaldiminato)iron(II) $Fe(L^{ipr})_2$

This synthetic procedure is a modification of the preparation by Larkworthy [29]. A solution of 4.21 g (34.5 mmol) of salicylaldehyde (salH) dissolved in 20 ml of a 0.14 M KOH methanol solution was added to 3.00 g (17.2 mmol) of $Fe(O_2CCH_3)_2$ (Aldrich) in 100 ml of methanol with stirring. A dark red solid formed. The solvent was decanted after 10 min. The solid product was dried to yield 2.99 g of a red-purple powder of the iron(II) salicylaldehyde compound 'Fe(sal)$_2$'. To 0.474 g (1.78 mmol) of $Fe(sal)_2$ dissolved in 50 ml of tetrahydrofuran, 0.378 g (6.40 mmol) of isopropylamine was added under argon. The opaque solution became dark orange and was allowed to stir for 3 h. The solvent was evaporated under vacuum and the crude product was dissolved in 300 ml of pentane. A small amount of product crystallized immediately as orange flakes along with a substantial amount of a red precipitate, a presumed hydrolysis product. The solution, which is extremely sensitive to moisture and dioxygen, was filtered and cooled in a freezer (−20 °C) for 2 days. The crystalline product was filtered and dried under vacuum to yield 0.23 g of orange flakes (34%). The solid product is comparatively stable when exposed briefly to air. *Anal*. Calc. for $C_{20}H_{24}N_2O_2Fe$: C, 63.17; H, 6.36; N, 7.37. Found: C, 62.97; H, 6.24; N, 7.24%. FTIR (KBr): 3447 (br), 3050, 2964, 2924, 2889, 1617, 1599 (s), 1537, 1467, 1442, 1402, 1367, 1331, 1315, 1195, 1143, 1122,

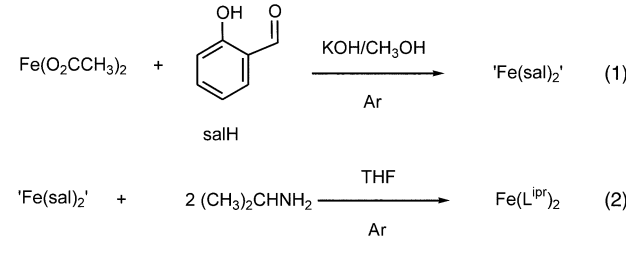
1031, 976, 919, 855, 786, 763, 756, 740, 612, 578, 493 cm^{-1}. ^1H NMR (C_6D_6, 300 MHz, 23 °C) δ 195.4 (1H, s, NCH(CH$_3$)$_2$), 67.7 (1H, s, H4), 62.0 (1H, s, H6), −15.9 (1H, s, H5), −21.8 (1H, s, H3), −30.5 (6H, s, NCH(CH$_3$)$_2$) ppm.

2.3.3. Bis(N-isopropylsalicylaldiminato)zinc(II) $Zn(L^{ipr})_2$

To a rapidly stirring suspension of 4.17 g (25.6 mmol) of *N*-isopropylsalicylaldimine in 15 ml of deionized water, 1.74 g of $ZnCl_2$ (12.8 mmol) was added slowly. A 10 ml solution of 1.02 g (24.3 mmol) of NaOH dissolved in deionized water was then added slowly to the slightly yellow solution to produce a white solid. The heterogeneous reaction mixture was stirred for an additional 10 min and filtered. The precipitate was washed with deionized water (3 × 5 ml) followed by pentane (3 × 5 ml) to remove any unreacted ligand. The product was dried under vacuum to yield 4.12 g of a white powder (83%). The product can be recrystallized from acetone–water. *Anal*. Calc. for $C_{20}H_{24}N_2O_2Zn$: C, 61.62; H, 6.21; N, 7.19. Found: C, 61.95; H, 6.10; N, 7.00%. FTIR (KBr): 3051, 2966, 2926, 2901, 1616 (s), 1537, 1466, 1445, 1408, 1333, 1316, 1191, 1145, 1123, 1032, 999, 959, 918, 857, 759, 603, 505, 449 cm^{-1}. ^1H NMR ($CDCl_3$) δ 8.35 (1H, s, N=CH), 7.29 (1H, t, H4), 7.09 (1H, d, H3), 6.85 (1H, d, H6), 6.59 (1H, t, H5), 3.63 (1H, m, NCH(CH$_3$)$_2$), 1.33 (3H, d, NCH(CH$_3$)$_2$); 1.21 (3H, d, NCH(CH$_3$)$_2$) [note: the NCH(CH$_3$)$_2$ methyl groups are diastereotopic] ppm.

3. Results and discussion

3.1. Synthesis



A general method for the reliable synthesis of bis(salicylaldiminato)iron(II) complexes has been described by Larkworthy [6,29]; these compounds had been prepared prior to this study, but because of their acute air sensitivity the complexes frequently yielded impure oxidized products. As indicated by Larkworthy [29], the optimal procedure for the preparation of bis(salicylaldiminato)iron(II) complexes was the formation of a precursor from salicylaldehyde and iron(II) acetate in the presence of a strong base followed by the addition of a primary amine in alcohol solvents [34]. No preparative details, e.g. amounts of material, yields, etc., however, are given in Larkworthy's or subsequent papers [6,12,29–31]. We have re-examined this synthetic method to render a more detailed experimental procedure for the preparation of the *N*-isopropylsalicylaldimine derivative, $Fe(L^{ipr})_2$.

The reaction of the *N*-isopropylsalicylaldimine with iron(II) acetate in tetrahydrofuran failed to produce pure product as indicated by ^1H NMR spectroscopy. We find, as previously determined, that the reaction of the primary amine with the pre-formed iron salicylaldehyde complex forms the desired pure product in an acceptable yield. Two equiv. of salicylaldehyde (salH) are deprotonated in a methanol solution of potassium hydroxide and added to 1 equiv. of iron(II) acetate as shown in Scheme 2, Eq. (1). A precipitate forms, presumed to be bis(salicyaldehydato)iron(II) 'Fe(sal)$_2$', which is dried under vacuum to yield a purple solid.

The ^1H NMR spectrum of Fe(sal)$_2$ in CD_3CN exhibits four broad markedly shifted resonances for the ligand aromatic ring protons ranging from +45 to −16 ppm. This shift range is expected since iron(II) complexes with phenolate oxygen donors ordinarily display large upfield and downfield shifts [25,35–37]. The shifts are a consequence of the alternating sign of delocalized unpaired electron spin density from partially filled iron(II) d π symmetry orbitals into ligand π orbitals [38–41]. As a result, alternating upfield and downfield ^1H NMR shifts are observed for one proton attached to a ring carbon atom to the next. On this basis and by analogy to the assignments of other iron(II) phenolate complexes, the ^1H NMR resonances of Fe(sal)$_2$ can be assigned to 6H(+44.8), 4H(+35.3), 5H(−10.4) and 3H(−16.0) in accord with the ring proton numbering scheme for salicylaldimine given in Fig. 2.

Early magnetic studies of Fe(sal)$_2$ suggest it is a high spin iron(II) ($S = 2$) complex [29], otherwise very little is known about this compound. The most closely related crystallographically characterized salicylaldehyde metal complex is the dinuclear manganese(II) compound, $Mn_2(sal)_4(CH_3OH)_2$ [42], in which phenolate oxygen atoms from two of the salicylaldehyde anions bridge the manganese centers. Our ^1H NMR studies suggest that 'Fe(sal)$_2$' is mononuclear in solution (though perhaps solvated) since only one set of ring proton resonances is observed for what we presume to be terminally coordinated salicylaldehydato ligands.

The condensation of excess isopropylamine with the coordinated aldehyde moiety in the complex 'Fe(sal)$_2$' in tetrahydrofuran produced a dark orange solution from which orange microcrystalline $Fe(L^{ipr})_2$ could be isolated in 34% yield (Eq. (2)). While solutions of $Fe(L^{ipr})_2$ are very susceptible to decomposition in air, the solid compound could be handled briefly in air. The com-

Scheme 2.

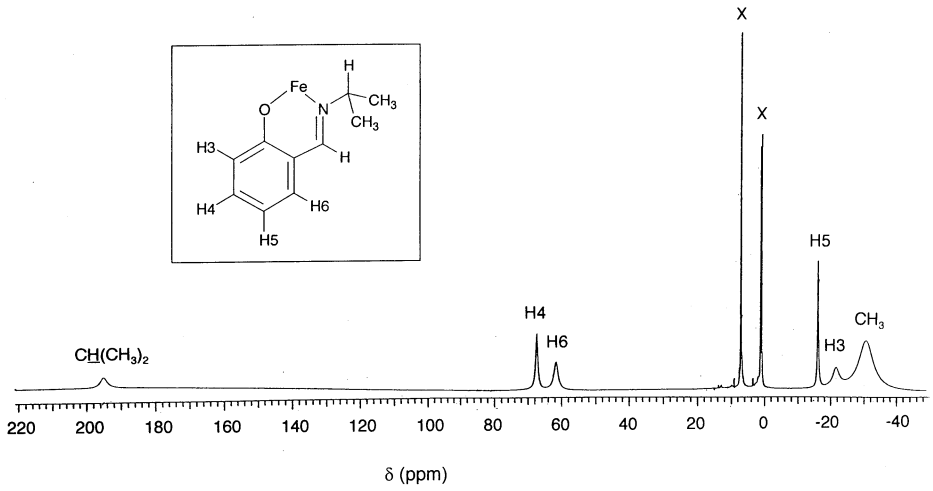


Fig. 2. The ^{1}H NMR spectrum of Fe(L^{ipr})$_2$ in benzene-d_6 at 23 °C. Chemical shift (δ) in ppm downfield of tetramethylsilane. The schematic indicates the proton assignments (inset). The symbol (×) indicates solvent or residual solvent impurity.

pound is very soluble in non-polar solvents. The solubility behavior is in marked contrast to its closest analogue, Fe(salen), which requires donor solvents to dissolve due to its assumed polymeric structure [35,43].

For comparative purposes the Zn(L^{ipr})$_2$ analog, a discrete mononuclear tetrahedral complex [45–47], was also prepared. This straightforward synthesis employed $ZnCl_2$, *N*-isopropylsalicylaldimine and sodium hydroxide, a general preparative method for zinc(II) *N*-alkylsalicylaldimines that generally gives good yields in our hands [44]. Both compounds, M(L^{irp})$_2$ (M = Fe, Zn) have very similar solubility characteristics and solid-state infrared spectra, indicative of an analogous structure. The most intense infrared stretch, assigned typically to the imine C=N bond, is found at 1599 (Fe) and 1616 (Zn) cm^{-1}. The value for the energy of the stretch in the iron complex is in excellent agreement with the C=N stretch (1603 cm^{-1}) reported for the tetrahedral iron(II) complex of the nitrogen analogue *t*-BuN=C(H)$C_6H_4NH^-$ of the salicylaldiminate ligand [18].

3.2. Structure determination by X-ray crystallography

The structure of Fe(L^{ipr})$_2$ shown in Fig. 1 displays a four coordinate iron atom coordinated to two bidentate *N*-isopropylsalicylaldimine anions. The bond distances and angles provided in Table 2 reveal relatively short Fe–O (1.912(2), 1.916(2) Å) and Fe–N (2.040(3), 2.053(3) Å) bond distances and a distorted tetrahedral coordination geometry most likely due to the acute O–Fe–N bite angles (93.4(1)°, 93.0(1)°). Metrical parameters of the ligand, also given in Table 2, indicate that the ligand is coordinated to iron in its characteristic phenolate-imine form [2]. Overall ligand geometry is very similar to generally accepted norms for salicylaldimine ligands in this coordination mode [1,2].

Though no four coordinate iron(II) salicylaldimine complex has been structurally characterized previously, the structure of Fe(L^{ipr})$_2$ and the Zn analog [46,47] are most comparable while those of the other first row d block analogs Co, Ni, and Cu deviate somewhat more significantly [48]. No simple trend is obvious and their differences are likely due to the both the nature of the metal–ligand bonding, the electronic structure of the metal atoms and the structural requirements of the ligand. The average Zn–O (1.913 Å) and Fe–O (1.914 Å) bond lengths are indistinguishable compared with the Co–O (1.905 Å), Ni–O (1.896 Å) and Cu–O (1.805 Å) bond distances. The Zn–N (2.009 Å) bond distance is only slightly shorter than the corresponding Fe–N (2.047 Å) distance while those of Co (1.992 Å), Ni (1.970 Å), and Cu (1.979 Å) are considerably shorter. The average ligand bite angles (O–M–N) for Fe (93.2°), Co (96.4°), Ni (94.4°), Cu (94.9°) and Zn (96.7°) are largely invariant due to the constraints of the ligand. Likewise, the corresponding interligand angles (N–M–O_{avg}, N–M–N, O–M–O) of the Fe complex (113.8°, 119.5°, 125.8°), Co (112.3°, 122.6°, 118.5°), Ni (112.4°, 120.9°, 125.1°), and Zn complex (112.6°, 117.2°, 122.9°) diverge only slightly, while the Cu angles (100.3°, 137.9°, 137.2°) are markedly different because of its very large distortion from tetrahedral geometry. Overall tetrahedral geometry as determined by the dihedral angle, ϕ, between the planes formed by the metal atom and corresponding ligand donor atoms, e.g. N(1)–Fe(1)–O(1), as well as a measure of the deviation of these atoms from the plane formed by ligand aromatic ring (dihedral angle θ), are most similar for the Fe (ϕ = 82.7°, θ_{avg} = 6.5°) and Zn (ϕ = 84.2°, θ_{avg} = 3.9°) complexes, whereas Co, Ni (ϕ = 94°), and Cu (ϕ = 60°) are, again, less comparable.

The most closely related structurally characterized tetrahedral iron(II) complex is that of the salicylaldi-

mine nitrogen analogue, t-BuN=C(H)$C_6H_4NH^-$ [18]. The average iron imine nitrogen distance of 2.061 Å in this complex is nearly equivalent to the corresponding distance in $Fe(L^{ipr})_2$. The remaining structural parameters of its coordination sphere, while not as similar to $Fe(L^{ipr})_2$ as $Zn(L^{ipr})_2$, are characteristic of a bidentate monoanionic ligand bound to iron(II) in a tetrahedral coordination geometry. Other similar iron nitrogen imine distances include those of tetrahedral amidinato $FeCl_2$ adducts (2.100 Å) [24] and the tropocoronand N4 macrocycle (2.020 Å) [16].

An obvious comparison, that of Fe–O bond distances of low coordinate mononuclear complexes (ranging from three to five) with terminal phenolate ligands is more problematic. The number of these complexes is limited and typically have shorter Fe–O bond distances than observed in $Fe(L^{ipr})_2$, for example, the three coordinate homoleptic phenoxide $[Fe\{O(2,4,6\text{-}t\text{-}BuC_6H_2)\}_2]_2$ (1.822 Å) [25], four coordinate trispyrazolylborate phenoxide $HB\{(3,5\text{-}i\text{pr})pz\}_3Fe(OC_6F_5)$ (1.876 Å) [49], and a five coordinate iron calixarene adduct of THF (1.895 Å) [17].

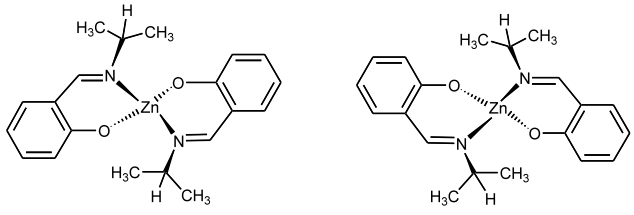
One can examine the iron ligand bond distances of the four coordinate $Fe(L^{irp})_2$ complex reported here and corresponding examples of five and six coordinate neutral high spin iron(II) salicylaldimine complexes, i.e. 'salen type' ligands with additional donors, N,N'-(3,3′-dipropylmethylamine)bis-(salicylideneimine) (a pentadentate ligand that incorporates one amine donor) [50] and 1,10-bis(5-nitrosalicylaldehyde)-1,4,7,10-tetraazadecane (a hexadentate ligand with two supplementary amines) [51]. The average iron donor bond distances (Fe–N, Fe–O) in this series from coordination number six to four are (2.127, 2.093), (2.045, 2.041), (1.953, 1.914) Å, respectively. Neglecting the differences between the ligands, the change in iron(II)-donor bond distance follows the predictable trend of decreasing bond length with decreasing coordination number.

Early studies of bis(salicylaldiminato)iron(II) or related complexes, which included electronic and Mössbauer spectroscopic measurements as well as magnetic measurements, suggested that the compound was either polymeric or monomeric with a coordination number ranging from four to six [6,29–31,52]. These conclusions are reasonable given the tendency for coordinatively unsaturated Schiff base complexes to add donors as well as undergo bridging with the oxygen atom donor portion of the ligand. For example, Fe(salen) is presumably a polymer in the solid state, but readily coordinates to good donor solvents to form soluble species or exogenous anionic ligands to form five coordinate mononuclear species in solution [35]. Likewise, a more soluble Fe(salen) analogue, Fe(acen), is dinuclear in the solid state and mononuclear in benzene [43]. Here, in contrast, we have shown that $Fe(L^{ipr})_2$ is mononuclear and tetrahedral in the solid state.

3.3. Characterization by ^1H NMR spectroscopy

The ^1H NMR spectrum of $Fe(L^{ipr})_2$ shown in Fig. 2 exhibits broad ligand resonances that experience large upfield and downfield shifts ranging from +195 to −31 ppm resulting from the paramagnetism of the complex [29]. The observed peaks and their assignment are given in Table 3. The shifts and linewidths of the peaks at 67.7, 62.0, −15.9 and −21.8 ppm in Fig. 2 are similar to those observed previously for high spin iron(II) complexes $[Fe(salen)X]^-$ (X = anion) [35] and are assigned accordingly to the aromatic ring protons H4, H6, H5, and H3. The observation of one set of ligand resonances for the ring protons in $Fe(L^{ipr})_2$ suggests that, like $Fe(sal)_2$, there is a single static ligand environment consistent with a mononuclear complex (however, we cannot exclude that a rapidly averaged environment is present in either complex).

The large peak observed at −30.5 ppm in Fig. 2 is assigned to the isopropyl methyl protons based on its 6:1 relative intensity compared with each of the aromatic ring protons. The methyl protons, which are diastereotopic in our ^1H NMR spectrum of $Zn(L^{ipr})_2$ [45,53] (see Scheme 3), are either not resolved in the spectrum of $Fe(L^{ipr})_2$ or its chirality is lost due ligand exchange or inversion through a square planar intermediate [54]. The anomalously large linewidth (700 Hz) may indicate the former explanation.



The remaining resonance at 195.4 ppm is assigned tentatively to the tertiary hydrogen of the isopropyl group. Hydrogen atoms attached to carbon atoms adjacent to tertiary amines bound to iron(II) have been observed to experience shifts greater than 100 ppm, i.e. in $[FeM(BPMP)(L)_2]^+$ (M = Fe, Zn, Ga, BPMP = 2,6-bis[[bis(2-pyridylmethylamino]methyl]-4-methylphenol anion; $L = O_2CR^-$ or $O_2P(OR)_2^-$) [37] and $(TMEDA)Fe(CH_2Ph)_2$ (TMEDA = N,N,N',N'-tetramethyl-ethylenediamine) [23]. The imine hydrogen, HC=N, resonance has not been reported previously in ^1H NMR studies of iron(II) Schiff base compounds [35,36], so its absence is predictable. Since the proton of interest is two bonds away from the iron atom in the delocalized, conjugated imine moiety of the salicylaldiminate ligand, a large proportion of electron spin density would presumably broaden this resonance beyond detection.

The observation that the linewidths (in Hz) of the ring protons H3(254), H6(200), H4(125) and H5(55) for $Fe(L^{ipr})_2$ become progressively smaller the farther the proton is from the iron center, i.e. H3(4.5 Å), H6(5.3 Å), H4(6.3 Å) and H5(6.6 Å), is consistent with their assignment. The nature of the shifts of the isopropyl protons is more difficult to discern. The fact that the proton attached to the tertiary carbon apparently shifts upfield while the methyl group attached to the same carbon shifts downfield implies a contact spin delocali-

Table 3
Tabulated ^{1}H NMR spectral data of Fe(L^{ipr})$_2$

Assignment [a]	Chemical shift [b] (δ_{obs}, ppm)	Linewidth [c] (Hz)	Integration (number of H's)	Isotropic shift [d] (δ, ppm)
H3	−21.8	254	1	−28.9
H4	67.7	125	1	60.4

Scheme 3.

zation mechanism similar to the shifts observed for methylene protons adjacent to a coordinated tertiary amine in $[Fe_2(BPMP)(O_2P(OPh)_2)_2]^+$ [37]. Since tetrahedral iron(II) has an anisotropic ground state (^{5}E), it generally experiences a significant dipolar contribution to the isotropic shift which depends on the relative orientation and distance of proton to the iron atom [39–41]. The isopropyl group protons in Fe(L^{ipr})$_2$ are likely to be very susceptible to dipolar interactions since they can experience close contacts with the iron atom (as close as 2.8 Å estimated from the X-ray structure and model building) as the isopropyl group rotates freely.

3.4. Reactivity

When a solution of Fe(L^{ipr})$_2$ in benzene-d_6 is exposed briefly to air (<1 min), the ^{1}H NMR resonances due to the iron(II) complex disappear and less shifted resonances ranging from 28.8 to 1.2 ppm are observed in the spectrum accompanied by peaks due to a small amount of free ligand ($<10\%$ by integration). The five broad resonances are consistent with the formation of the oxo-bridged dinuclear iron(III) species [Fe(L^{ipr})$_2$]$_2$O from Fe(L^{ipr})$_2$ and air (Eq. (3)). The observed ^{1}H NMR shifts found at 28.8 (very broad), 13.1, 10.1, 2.3 (overlapping), and 1.2 ppm in an approximate 1:1:1:6:1 ratio can be assigned to the (CH$_3$)$_2$C$\underline{H}$, 4H, 6H, 5H and (C$\underline{H}_3$)$_2$CH (overlapping) and 3H protons, respectively, based on comparison with published spectra of [Fe(L^R)$_2$]$_2$O [55] and Fe(salen)$_2$O [38,56] and their integration. A near identical spectrum was

$$2Fe(L^{ipr})_2 \xrightarrow[C_6D_6]{air} [Fe(L^{ipr})_2]_2O \quad (3)$$

obtained from [Fe(L^{ipr})$_2$]$_2$O prepared independently by the literature method [57]. The small exclusively upfield shifts are characteristic of oxo-bridged diiron(III) complexes with strong antiferromagnetic coupling ($J > 100$ cm^{-1}) between high-spin ($S = 5/2$) iron(III) centers mediated by an oxo bridge [38]. Since high spin iron(III) has a symmetrical electronic environment ($^6A_{1g}$), the shifts are primarily contact in origin and, therefore, proportional to the magnetic susceptibility of the complex [39–41]. The relatively small magnetic moment (~ 1.9 BM) of [Fe(L^R)$_2$]$_2$O complexes [55] results in a marked attenuation of their isotropic shift compared with Fe(L^{ipr})$_2$. With the exception of a small amount of ligand, due possibly to ligand dissociation or protonolysis, the reaction did not result in an observable precipitate or any other apparent iron species as monitored by ^{1}H NMR.

Oxo-bridged diiron(III) species have been observed previously from the reaction of air or dioxygen with mononuclear iron(II) porphyrin [58,59], salen [9], or acen [43] complexes. In contrast to Fe(salen), the reaction with Fe(L^{ipr})$_2$ can be carried out in non-polar, non-coordinating solvents in which both Fe(L^{ipr})$_2$ and [Fe(L^{ipr})$_2$]$_2$O are soluble and where Fe(L^{ipr})$_2$ is, plausibly, a discrete mononuclear species. As emphasized previously for Fe(acen) [43], these attributes are essential for studying the reactions of low coordinate iron(II) compounds. A case in point is the reaction of iron(II) porphyrins and dioxygen in toluene to detect the diiron(III) peroxo intermediate by ^{1}H NMR at low temperature [59].

In addition, tetradentate ligands like acen, salen or porphyrins enforce typically a square planar geometry about the iron center. While this allows for an often critical available coordination site, it may be of interest to probe iron(II) reactions with ligands such as L^{ipr}H that allow access to coordination geometries other than those based on square planar, e.g. as observed in the

active sites of iron(II) centers in non-heme iron proteins [28].

4. Supporting information

Full crystallographic information for $Fe(L^{ipr})_2$ is available as deposit number 168259 from the Cambridge Crystallographic Database Center (12 Union Road, Cambridge, CB2 1EZ, UK or on the web at www: http://www.ccdc.cam.ac.uk).

Abstract

The reaction of $Pt(DMB)Cl_2$ (DMB = 3,3′-dihydroxymethyl-2,2′-bipyridine) with AgF_3CSO_3 in H_2O yielded a dimeric platinum complex, $[\{Pt(DMB)(\mu\text{-}OH)\}_2](F_3CSO_3)_4\cdot 2H_2O$. X-ray structure reveals that two conformational isomers are self-assembled by different hydrogen bonding motifs in one crystal, resulting in a new type of co-crystal of monomer and its polymer. One conformer is self-assembled into the one-dimensional polymeric chain by strong hydrogen bonds, while the other conformer of which possible hydrogen bond donors/acceptors are blocked by two triflate anions exists as an isolated molecule itself. DFT calculations show that the strong hydrogen bonds and crystal packing force might compensate for the energy gap of ~ 14 kcal mol^{-1} between two conformers and the conformational energetics are dominated by the energies of the coordinated ligands rather than those of hydroxo-bridged platinum cores. © 2002 Published by Elsevier Science Ltd.

Keywords: Cocrystallization; Dinuclear platinum complexes; One-dimensional polymers

1. Introduction

Molecular self-assembly employing hydrogen bonding and its significance in crystal engineering are of considerable interest [1]. Hydrogen bonding is known to play an important role in governing the crystal packing of molecules due to its moderately strong interaction and high degree of directionality [2]. Recently, the incorporation of transition metal into supramolecular chemistry triggered the development of new molecular architecture, and several elegant examples for the combination of coordination and hydrogen bonding in self-assembly are published [3].

Some coordination or organometallic complexes which possess conformational flexibility or possible hydrogen bond donor/acceptor, could crystallize in two or more different crystal systems containing each conformational isomer or differently self-assembled molecule, respectively, by tuning crystallization conditions precisely, i.e. co-crystallization with other molecules [4] or different solvent pairs [5]. To the best of our knowledge, we are not aware, however, of any previous examples in which two differently self-assembled conformational isomers co-crystallize in one asymmetric unit.

Herein, we report a new example of the self-assembly of a platinum dinuclear complex $[\{Pt(DMB)(\mu\text{-}OH)\}_2](F_3CSO_3)_4\cdot 2H_2O$ into a co-crystal containing a dinuclear monomer and a hydrogen-bonded one-dimensional chain of the dinuclear monomer.

2. Experimental

2.1. General procedures

K_2PtCl_4 was purchased from Strem. All other reagents were purchased from Aldrich and used without further purification. Solvents were of reagent grade and

PII: S0277-5387(02)00838-0

were dried by standard methods. Pt(DMB)Cl_2 (DMB = 3,3′-dihydroxymethyl-2,2′-bipyridine) was prepared according to the published procedure [6].

^{1}H and ^{13}C{^{1}H} NMR spectra were measured on a Bruker AM 300 spectrometer and were referenced to internal solvent peaks. IR spectra were recorded in KBr discs on a Bruker Equinox 55 FT–IR spectrometer. C, H and N elemental analyses were carried out at the Seoul Branch Analytical Laboratory, Korea Basic Science Institute, on an Elementar Analysensysteme GmbH Vario EL elemental analyzer.

2.2. Synthesis of [{Pt(DMB)(μ-OH)}$_2$]$_2$-(F_3CSO_3)$_4$·2H_2O (1)

To a water solution (30 ml) of Pt(DMB)Cl_2 (190 mg, 0.40 mmol) was added a twofold amount of solid AgF_3CSO_3 (210 mg, 0.80 mmol). The reaction mixture was warmed to 55 °C and was allowed to stir for 20 h in the absence of light. The precipitated AgCl was filtered off by a membrane filter. The slow evaporation of the solvent from the yellow filtrate at room temperature gave yellow crystalline product **1**, which was collected over glass frit, washed with a small amount of cold water and dried in air (120 mg, 52%). *Anal*. Found: C, 26.85; H, 2.42; N, 4.77. Calc. for $C_{52}H_{56}F_{12}N_8O_{26}Pt_4S_4$: C, 26.63; H, 2.41; N, 4.78%. ^{1}H NMR (300 MHz, DMF-d_7, 273 K): δ 8.73 (dd, $J = 5.5$, 1.2 Hz, 4H), 8.67 (dd, $J = 8.0$, 1.2 Hz, 4H), 8.13 (dd, $J = 8.0$, 5.5 Hz, 4H), 6.00 (t, $J = 5.8$ Hz, 4H), 5.92 (s, 2H), 4.74 (d, $J = 5.8$ Hz, 8H). ^{13}C{^{1}H} NMR (75 MHz, DMF-d_7, 297 K): δ 155.0, 148.1, 143.5, 143.3, 127.2, 61.5. IR (KBr, cm^{-1}): 3425 (br m, OH stretch), 1029 (s, OH bend), 575 (m, PtO stretch).

2.3. X-ray structure determination

Yellow crystals of **1** suitable for X-ray diffraction study were grown by slow evaporation of solvent from an aqueous solution. A crystal was mounted on a glass fiber tip. Crystal data were collected on an Enraf–Nonius CAD4 diffractometer equipped with graphite monochromated Mo Kα radiation. Cell dimensions and orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 centered reflections. Intensity data were collected in the $\omega-\theta$ scan mode to a maximum 2θ of 50°. Data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied.

The structure was solved by using the SHELXS-86 system [7] and refined by full-matrix least-squares on F^2 (SHELXL-93) [8]. The non-hydrogen atoms were refined anisotropically and all hydrogen atom positions, except those of μ-OH hydrogen, were initially calculated and then refined using a riding model. Geometrical restraint was applied for four triflates using SADI in SHELXL-93. The detailed crystallographic data are listed in Table 1.

[b] $wR_2 = [\Sigma[w(F_o^2-F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$.

2.4. Computational method

The B3LYP calculations [9] were carried out with GAUSSIAN98 program [10]. Single point energy evaluations were performed using the experimental geometries. A pseudopotential was used to replace 60 core electrons while a (8s7p6d)/[6s5p3d] basis set was used to describe the valence orbitals of Pt [11]. The 6-31G** basis set was used for the other elements. The 6-31++G* and 6-311++G** basis sets were also applied for the calculation of four residues, but there was no noticeable discrepancy between energy values.

3. Results and discussion

3.1. Crystal structure of 1

ORTEP representation of **1** is shown in Fig. 1 and selected bond distances and angles are summarized in Table 2. X-ray structure determination of **1** has revealed that the asymmetric unit contains two independent conformational isomers, **1a** and **1b**, of a dinuclear $[Pt(DMB)(\mu\text{-}OH)]_2^{2+}$ unit. The crystal and molecular structures with the numbering schemes of the conformers **1a** and **1b** are shown in Figs. 2 and 3, respectively.

The conformer **1a** is a dinuclear monomer and has the expected hydroxymethyl conformation in which two hydroxymethyl substituents are oriented as far as possible to minimize steric interaction between themselves as seen in the structure of Pt(DMB)Cl_2 [6]. The

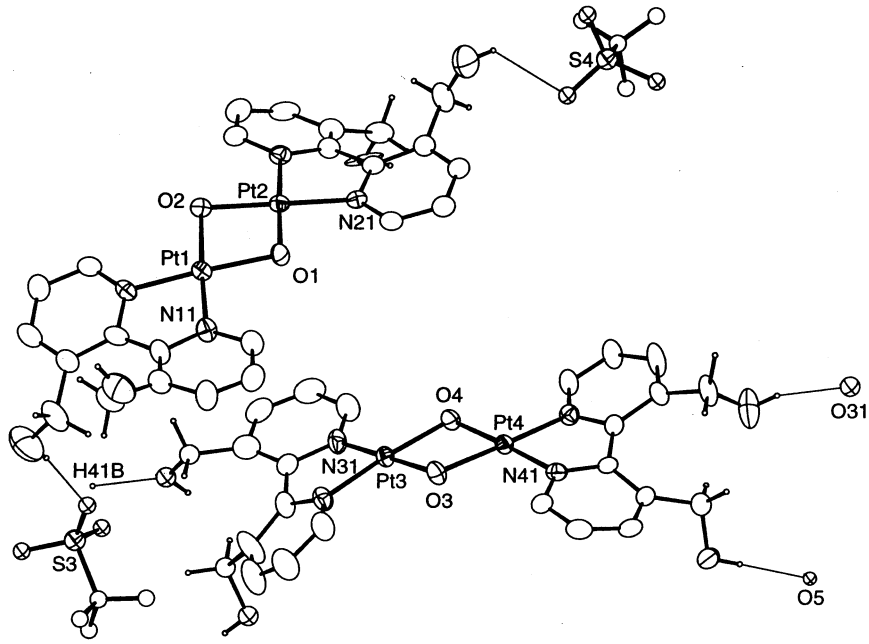

Fig. 1. ORTEP drawing of **1** showing the atom numbering scheme. Two triflates and one solvated water, which show no intermolecular interaction with two $[\{Pt(DMB)(\mu\text{-}OH)\}_2]_2$ complexes, are omitted for clarity.

two OH groups in *trans* position (relative to the plane which contains two Pt atoms and is perpendicular to the Pt_2O_2 plane) is hydrogen bonded to the oxygen atom of two triflates, which prevents the approach of other molecules for further hydrogen bonding. The O···O distances in hydrogen-bonded OH···O are 2.76 and 2.84 Å and the O–H···O angles are 167° and 108°. The

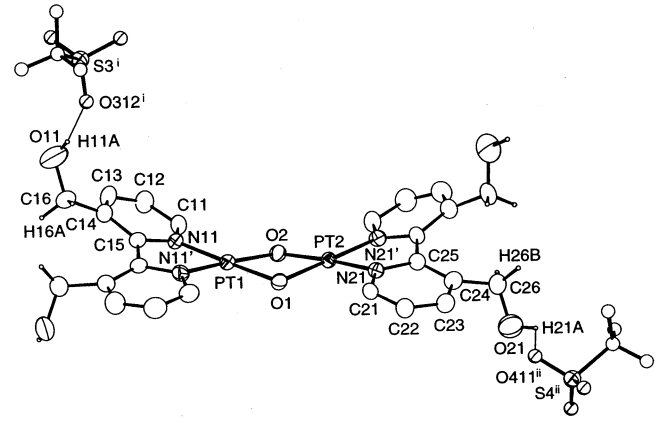

Fig. 2. Crystal and molecular structure of the conformer **1a**. Hydrogen atoms of hydroxymethyl group are only seen for clarity. Symmetry operation: (i) $x, y, -1+z$; (ii) $1-x, 1-y, 1-z$.

extreme disparity of the hydrogen bond angle from 180° may be attributed to the effect of crystal packing force [12].

In contrast to **1a**, the conformer **1b** exists as a hydrogen-bonded one-dimensional chain of the dinuclear unit and has a completely different pattern of crystal packing. The orientations of the oxygen atoms of hydroxymethyl groups are directed toward the same direction, resulting in the unfavorable interactions of C(36′)···O(31) [3.07 Å] and C(46)···O(41′) [3.08 Å]. Furthermore, the conformer **1b** self-assembles to form a one-dimensional linear polymer through the formation of intermolecular hydrogen bonding between the two hydroxymethyl OH groups of neighboring monomers. Two OH groups in **1b** involved in the connection of

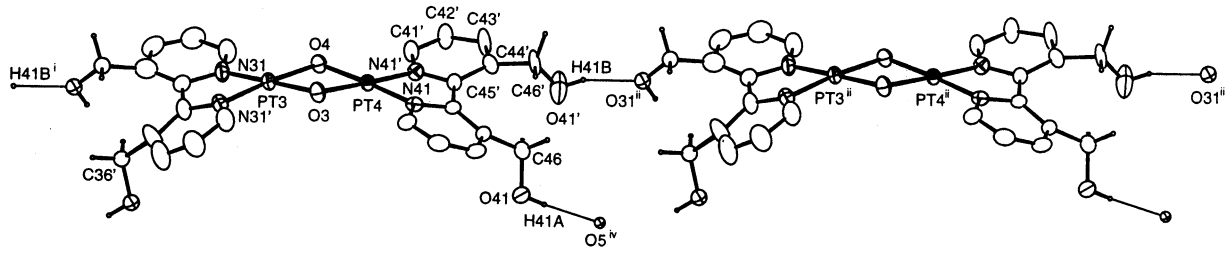

Fig. 3. Crystal and molecular structure of conformer **1b**. Hydrogen bonds are represented by thin lines. Symmetry operation: (i) $x, y, 1+z$; (ii) $x, y, -1+z$; (iii) $x, y, -2+z$; (iv) $1-x, 1-y, -z$.

building blocks are situated in *cis* position. The intermolecular O(41′)···O(31) distance of 2.69 Å and O(41′)–H(41B)···O(31) angle of 161° shows that the hydrogen bond between donor OH and acceptor O is reasonably strong [13]. One OH hydrogen atom (H41A) of the two remaining hydroxymethyl groups in **1b** is also strongly hydrogen-bonded to a crystal water [O(41)···O(5) 2.65 Å].

Perspective view of **1** clearly shows the different orientations of hydroxymethyl groups of ligands (Fig. 1). Two hydroxymethyl oxygen atoms in DMB residues of **1a** are directed to the opposite side, up and down, but those of **1b** are all oriented to the lower direction. The structures around the platinum cores of the two conformers are of close similarity. The coordination geometries of the two platinum centers are approximately square planar. Two least-squares planes of N_2PtO_2 in **1a** and **1b** are not coplanar but tilted by 15.5° and 12.2°, respectively.

3.2. Calculations

The B3LYP calculations, summarized in Table 3, indicate that the conformer **1a** is more stable than **1b**, as expected, by 13.8 kcal mol^{-1}. The stability of two conformers was further analyzed by carrying out calculations on four coordinated DMB residues using the same method. The residue *n* refers to DMB coordinated to Pt*n* ($n = 1$–4). Surprisingly, the residue 4 is more stable than the residues 1, 2 and 3 by +1.6, +2.0, and +15.6 kcal mol^{-1}, respectively. These somewhat unexpected results could be rationalized by close examination of dihedral angle between the average pyridyl planes of DMB units and torsional angles in each residue (Table 4). The dihedral angle of two least-squares pyridine planes in residue 4 is 24.1° that is smaller than 28.1° for residue 3, indicating that the residue 4 is expected to be more stable because the better π-conjugation between the two pyridyl rings can be achieved as the dihedral angle decreases [14]. The dihedral angle of 24.9° in the residue 1 is comparable with that of the residue 4 and there is no close interaction between two hydroxymethyl groups. However, torsional angles of C13–C14–C16–O11 (35.7°) and C13′–C14′–C16′–O11′ (43.7°) for the residue 1 are far from 60° of the ideal *gauche* conformation, which makes the residue 1 unstable due to torsional strain. No steric repulsion between two substituents and the favorable torsional angles of C23–C24–C26–O21 (46.8°) and C23′–C24′–C26′–O21′ (50.0°) in the residue 2 compensate less overlap of π-conjugation between the two pyridyl rings (dihedral angle: 28.2°). The energy difference of 13.6 kcal mol^{-1} [*E*(residue 3 and 4)−*E*(residue 1 and 2)] is comparable to 13.8 kcal mol^{-1} derived from intact **1a** and **1b**. This implies that the conformational energetics of **1a** and **1b** are dominated by the energies of the coordinated ligands, residue 1–4 rather than those of two hydroxo-bridged platinum cores, $N_2PtO_2PtN_2$.

Table 3
Summary of B3LYP calculations with 6-31G** basis set on the relative stability of the conformational isomers, **1a** and **1b** and DMB residues

Entries	Energy (a.u.)	Relative difference [a] (kcal mol^{-1})

4. Conclusions

Two different hydrogen bonding patterns involving *cis*- and *trans*-positioned OH groups stabilize each conformational isomer, yielding a new co-crystal of the dinuclear monomer terminated by two triflates (**1a**) and the self-assembled infinite one-dimensional polymer (**1b**). This work provides a new type of co-crystal containing two differently self-assembled conformational isomers in one crystal system. This is also a good example of the important role of hydrogen bonding in self-assembly and of the usefulness of flexible molecule in studying the nature of forces controlling the molecular structure in the crystal. The strong hydrogen bonds and crystal force seem to compensate for ~ 14 kcal mol^{-1} of energy gap between two conformers.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 166378 for compound **1**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Three complexes, namely [Cd(tren)][$Fe(CN)_5NO$] (**2**), [Cd(tren)][$Pd(CN)_4$] (**3**) and [Cd(tren)][$Pt(CN)_6$] (**4**), were prepared via direct reactions of $Na_2[Fe(CN)_5NO]$, $K_2[Pd(CN)_4]$ and $K_2[Pt(CN)_6]$, respectively, with cadmium acetate and tris(2-aminoethyl)amine (tren) in aqueous solution. X-ray structural analysis shows that **2** features a shelf-like structure formed by stacking of the quasi-square building block. Compound **3** is a battlement-like polymer constructed from cyanometalate building blocks and compound **4** represents the first example of a cyano-bridged trinuclear hexacyanoplatinate(IV) complex. © 2002 Elsevier Science Ltd. Keywords: Cyanometalate; Coordination polymers; Crystal structures; Cadmium(II) complexes

1. Introduction

Interest in the construction of multinuclear or polymeric metal cyanides has been driven by application-oriented subjects, such as design and synthesis of molecular magnets, light-emitting devices and zeolite-like materials, and also by the advantages of using cyanometalates as building blocks [1–6]. The cyanide system based on Prussian Blue and its analogs has been fully studied by the reaction of metal (especially copper and nickel) amine complexes with $[Fe(CN)_6]^{4-}$ or $[M(CN)_6]^{3-}$ (M = Fe, Mn, Co or Cr) [2]. Systematic attempts employing complementary bridging or chelating ligands have been made to modify the supramolecular architectures, in combination with octahedral, square-planar, tetrahedral and linear cyanometalate anions [3–5]. Additionally, series of crystal structures have also been reported for the organotin-cyanometalate family of coordination polymers [6].

In the binuclear or multinuclear polymeric complexes using $[M_x(CN)_y]$ as building blocks, the two most common coordination modes of the cyanide group are either the terminal C-bound mode or the linear-bridged arrangement (μ_2-κC:κN), which are based on the well-known fact that the cyanide ion owns a donor electron pair at both its C and N terminals. In our preceding communication, we reported a rare coordination mode of μ_3-κN:κN:κC in the two-dimensional (2D) coordination polymer $[Cd(tren)]_2[Fe(CN)_6]$ (**1**), where tren = tris(2-aminoethyl)amine [7]. This unusual μ_3 mode of cyanide was also observed in $[Cu(dmen)]_2[Fe(CN)_6]$, where dmen = 2-dimethylaminoethylamine [8]. As an extension to our studies on this class of cyanometalates, we report herein the results of investigations into the assembly of $[Cd(tren)]^{2+}$ with anions $[Fe(CN)_5NO]^{2-}$ (**2**), $[Pd(CN)_4]^{2-}$ (**3**), and $[Pt(CN)_6]^{2-}$ (**4**).

2. Experimental

2.1. Materials and methods

All reagents were commercially available and used as received. Elemental analysis was performed on a Perkin–Elmer 240 elemental analyzer. All infrared spectra were recorded on a Nicolet 5DX FT-IR spectrophotometer with KBr disks in the region of 4000–400 cm^{-1}.

2.2. Syntheses

2.2.1. $[Cd(tren)]_2[Fe(CN)_6]\cdot 3H_2O$ (1)

In our previous communication [7], compound **1** was obtained by diffusion in the opposite directions of a U-tube with aqueous solutions of $K_4[Fe(CN)_6]$, $Cd(NO_3)_2$ and tren ligand. Alternatively, compound **1** can be prepared by the following procedure: tren (0.668 mmol, 0.10 ml) was added to a 15 ml aqueous solution of cadmium acetate (0.668 mmol). The resulting colorless solution was added dropwise to a 10 ml aqueous solution of $K_3[Fe(CN)_6]$ (0.668 mmol) at room temperature. A brown precipitate was formed immediately and filtered out. Plate-like single crystals were obtained from the resulting brown solution after one week. Crystal structure analysis revealed that it had the same structure as the reported compound **1**.

2.2.2. $[Cd(tren)][Fe(CN)_5NO]$ (2)

Tren (0.668 mmol, 0.10 ml) was added to a 15 ml aqueous solution of cadmium acetate (0.668 mmol). The resulting colorless solution was then added dropwise to a 10 ml aqueous solution of $Na_2[Fe(CN)_5NO]$ (0.668 mmol) at 50–60 °C. Brown crystals formed immediately (ca. 76%). Prismatic crystals suitable for X-ray structural determination were obtained by recrystallization. *Anal.* Calc. for $C_{11}H_{18}CdFeN_{10}O$: C, 27.84; H, 3.82; N, 29.51. Found: C, 27.84; H, 3.89; N, 29.47%. Main IR (cm^{-1}): 3328s, 3272m, 3165m, 2164m, 2142 s, 1921vs and 1604m.

2.2.3. $[Cd(tren)][Pd(CN)_4]$ (3)

The same procedure used for **2** was performed for $Cd(Ac)_2$ (0.668 mmol), tren (0.668 mmol, 0.10 ml) and $K_2[Pd(CN)_4]$ (0.668 mmol) at 50–60 °C, affording colorless prismatic crystals by slowly diffusing diethyl ether into the DMF solution (ca. 74%). *Anal.* Calc. for $C_{10}H_{18}CdN_8Pd$: C, 25.60; H, 3.87; N, 23.89. Found: C, 25.57; H, 3.84; N, 23.85%. Main IR (cm^{-1}): 3329s, 3286s, 3253m, 3165m, 2153s, 1664m and 1596s.

2.2.4. $[Cd(tren)][Pt(CN)_6]$ (4)

The same procedure used for **2** was performed for $Cd(Ac)_2$ (0.668 mmol), tren (0.668 mmol, 0.10 ml) and $K_2[Pt(CN)_6]$ (0.668 mmol) at 50–60 °C, affording colorless prismatic crystals by recrystallization (ca. 67%). *Anal.* Calc. for $C_{12}H_{18}CdN_{10}Pt$: C, 23.64; H, 2.98; N, 22.97. Found: C, 23.65; H, 3.03; N, 22.92%. Main IR (cm^{-1}): 3352s, 3313s, 3273s, 3184m, 2218m, 2190s, 2177m, 1613m and 1586m.

2.3. X-ray crystallography

X-ray data were collected on a Bruker SMART 1000 CCD diffractometer at 293 K. Absorption correction was applied with the SADABS program [9]. The structure solution and full-matrix least-squares refinement based on F^2 were performed using SHELXTL-97 [10]. Non-hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in idealized positions. Crystallographic data for structures **2**, **3** and **4** are shown in Table 1. Selected bond distances and angles are given in Table 2.

3. Results and discussion

3.1. Synthesis

As reported previously, Cd^{2+}, $[Fe(CN)_6]^{4-}$ and tren are self-assembled from silica in a U-tube to build up a μ_3-cyano-bridged heterotrimetallic 2D coordination polymer $[Cd(tren)]_2[Fe(CN)_6]\cdot 3H_2O$ (**1**) constructed by rectangular grids [7]. Interestingly, **1** was also obtained

Symmetry codes: For **2**, #1 $x+1, y, z$; #2 $-x+1, -y, -z$; #3 $x-1, y, z$; #4 $x+1/2, -y+1/2, z+1/2$; #5 $x+1, y, z+1$. For **3**, #1 $-x+1, y-1/2, -z+1/2$; #2 $-x+1, y+1/2, -z+1/2$; #3 $x+1/2, -y+1/2, -z+1$; #4 $-x+1/2, -y+1, z+1/2$; #5 $-x, y-1/2, -z+1/2$; #6 $x, y-1, z$. For **4**, #1 $-x+1, -y+1, -z$; #2 $-x+1, -y, -z$; #3 $x, y+1, z$; #4 $-x+1, y+1/2, -z+1/2$; #5 $x+1, y, z$; #6 $-x+2, y+1/2, -z+1/2$.

from aqueous solution when $[Fe(CN)_6]^{3-}$ was used instead of $[Fe(CN)_6]^{4-}$. The reduction mechanism of the iron cation ($Fe^{3+} \rightarrow Fe^{2+}$) is not clear.

Quantitative syntheses of **2**, **3** and **4** were achieved via direct reactions of $Na_2[Fe(CN)_5NO]$, $K_2[Pd(CN)_4]$ and $K_2[Pt(CN)_6]$, respectively, with $Cd(Ac)_2$ and tren in aqueous solution. Single crystals of **2** and **4** were obtained by recrystallization, while crystals of **3** suitable for X-ray diffraction were produced by slow diffusion of diethyl ether into its DMF solution.

3.2. Crystal structure of *[Cd(tren)][Fe(CN)$_5$NO] (**2**)*

Complex **2** features a shelf-like structure formed by stacking of the quasi-square building block, namely $[Cd(tren)]_2[Fe(CN)_5NO]_2$. As illustrated in Fig. 1(a), the Cd atom is coordinated by four nitrogen atoms from two tren ligands and two nitrogen atoms from two $[Fe(CN)_5NO]^{2-}$ anions. The Cd–N (2.333(2)–2.421(2) Å) distances are consistent with that of complex **1**, and the bond lengths of Fe–C (1.933(3)–1.948(3) Å), Fe–N (1.662(3) Å), C–N (1.132(4)–1.153(4) Å) and N–O (1.126(4) Å) in the $[Fe(CN)_5NO]^{2-}$ moiety are also comparable to the reported analogs [11]. Two *cis*-$[Fe(CN)_5NO]^{2-}$ fragments and two $[Cd(tren)]^{2+}$ moieties are held together by CN^- bridges, and result in distorted square tetra-nuclear building blocks with slightly bent edges (Cd···Fe 5.345 Å, Cd···Fe# 5.351 Å; N(5)–Cd–N(6) 91.54(10)°, C(7)–Fe–C(8) 88.16(11)°, C(7#)–N(5)–Cd 159.6(3)°, C(8)–N(6)–Cd 151.6(3)°). These square moieties are linked to each other by two tren ligands to build up the shelf-like 1D column (Fig. 1(b) and (c)). The ligation mode of tren has been observed only in a few compounds [12].

Compound **2** is structurally reminiscent of the 1D 'ladder' coordination polymer with simple, linear *N*,*N*′-donor spacers such as 4,4′-bipyridine pyrazine, and other related species [13]. In the realm of molecular

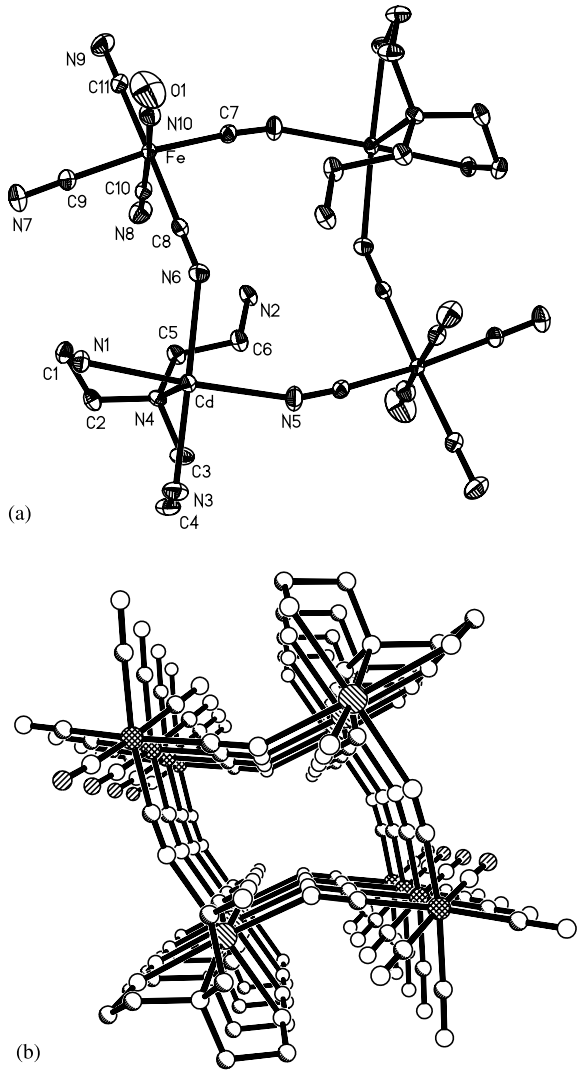

Fig. 1. (a) Perspective view of the square building block of complex **2**, with 30% probability displacement ellipsoids. Hydrogen atoms are omitted for clarity. (b) Top views showing the shelf-like column in **2**. (c) Side views showing the shelf-like column in **2**. (d) Packing diagram along *b* axis featuring the inter-column hydrogen bonds.

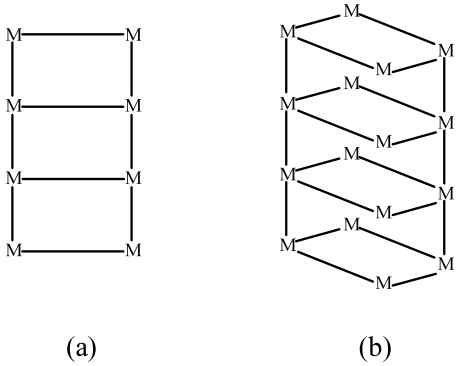

Chart 1. Comparison between two types of 1D coordination polymers: (a) molecular ladder; (b) molecular shelf.

ladders, most of inner rungs are made up of single rod-like spacers (Chart 1(a)). In contrast, square rings instead of inner rungs are assembled in **2**. Therefore, compound **2** represents a new topology of 1D coordination polymers (Chart 1(b)).

The shelf-like columns are further extended into a 3D network by inter-column hydrogen bonds (Fig. 1(d)), which are formed between the amino hydrogens of tren ligands and the N-end of terminal cyanides, with the distances of donor and acceptor ranging from 3.087(4) to 3.351(4) Å.

3.3. Crystal structure of [Cd(tren)][Pd(CN)$_4$] (**3**)

Compound **3** crystallizes in the chiral space group $P2_12_12_1$, providing a battlement-like, 1D coordination polymer as shown in Fig. 2. The infinite chain is formed by the alternate arrangement of $[Cd(tren)]^{2+}$ and $[Pd(CN)_4]^{2-}$ which are bridged by CN^- in a *cis*

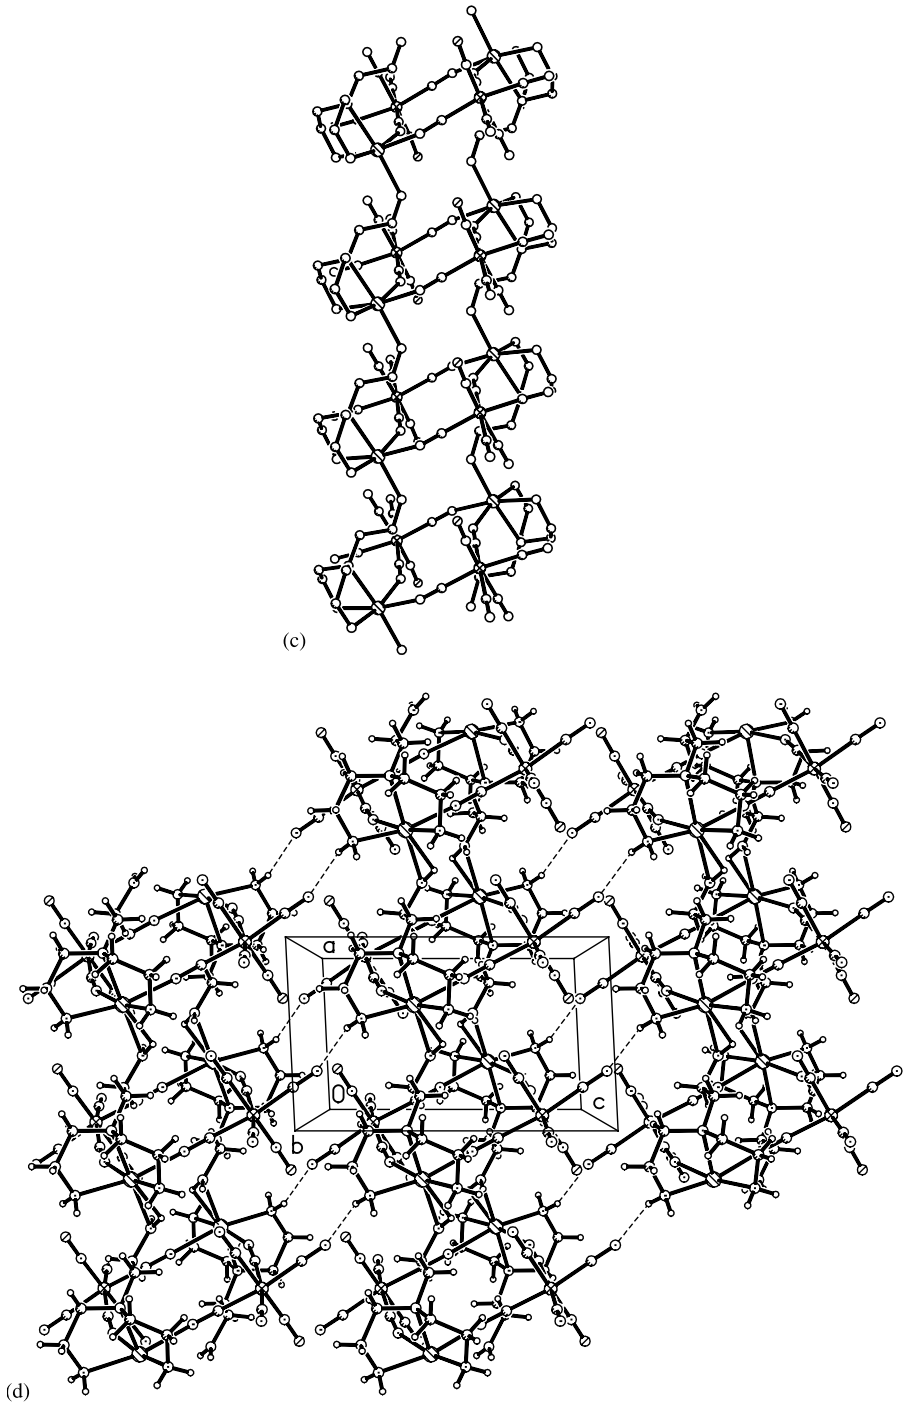

Fig. 1 (*Continued*)

fashion. The Cd atom has a distorted octahedral coordination configuration with six N atoms, four of them from one tren ligand and two from different $[Pd(CN)_4]^{2-}$ units. The Cd–N distances range from 2.299(2) to 2.493(3) Å. The $[Pd(CN)_4]^{2-}$ ion assumes four-coordination square geometry with normal Pd–C bonds (1.988(3)–2.000(3) Å) and C–N bonds (1.137(4)–1.146(4) Å), comparable to those found in the other tetracyanopalladate complexes [14]. The Cd–N(5)–C(7) and Cd#–N(6)–C(8) angles are bent significantly at the N atoms (159.7(2)° and 138.0(2)°, respectively).

In most of the cyanide-bridged species, the common theme is that cyanometallate anions, such as linear $[Ag(CN)_2]^-$, square $[Pd(CN)_4]^{2-}$, and octahedral $[Fe(CN)_6]^{3-}$ bridge metal ions in a *cis* or *trans* fashion, and create various mutinuclear 1D, 2D and 3D poly-

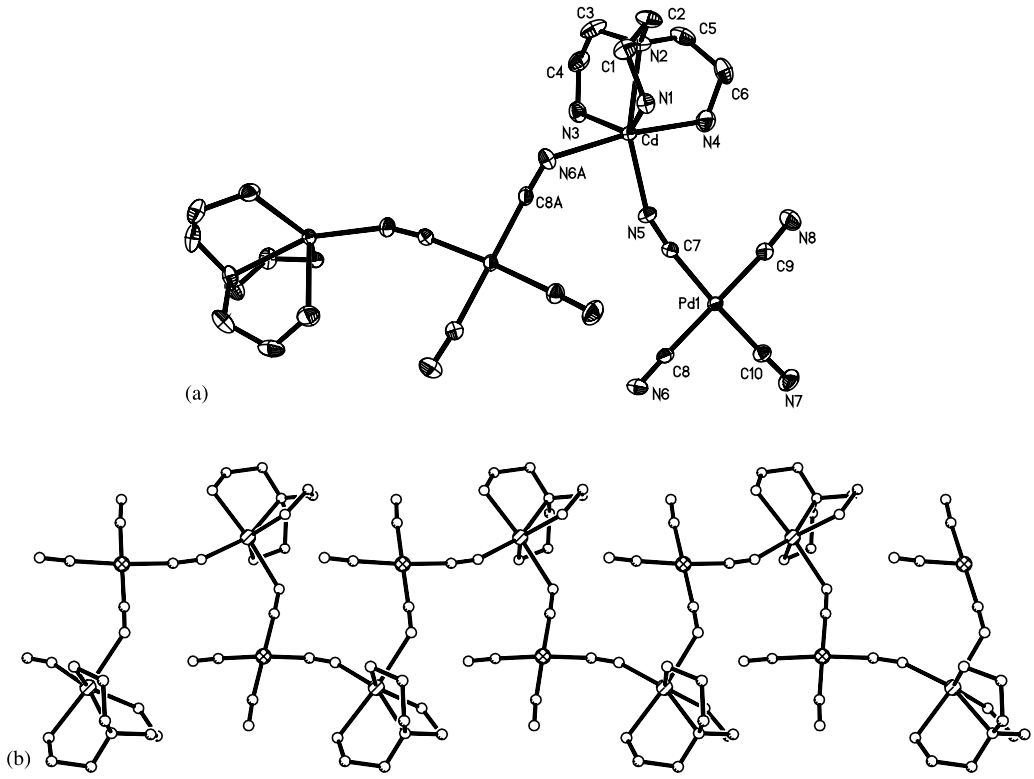

Fig. 2. (a) Perspective view of complex **3** showing the building block, with 30% probability displacement ellipsoids. (b) The 1D battlement-like string constructed in **3**. Hydrogen atoms are omitted for clarity.

meric complexes. The family of 1D cyano-bridged coordination polymers described to date is summarized in Chart 2(a)–(e) [14,15]. However, to the best of our knowledge, the battlement-like motif revealed in **3** is unprecedented (Chart 2(f)).

Hydrogen bonds are also presented in **3** between the terminal CN^- in the *cis*-$[Pd(CN)_4]^{2-}$ and the amino hydrogens of the tren ligand, with distances of D···A ranging from 3.108(3) to 3.273(4) Å. Thus the 1D coordination polymers are extended into a 3D network.

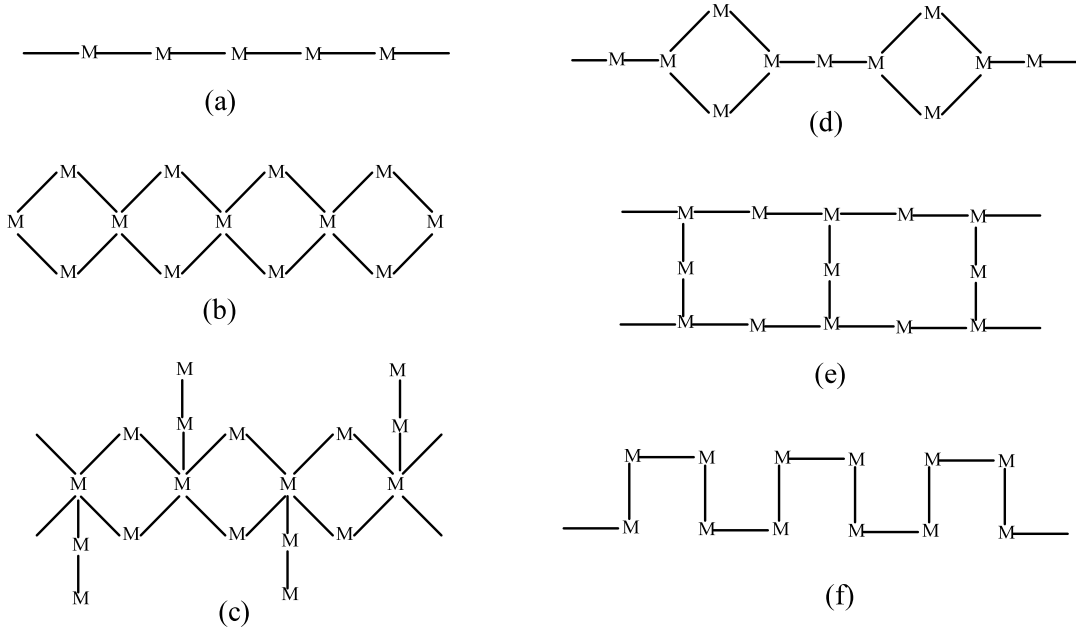

Chart 2. Possible structural types of 1D coordination polymer constructed from cyanometalate building blocks.

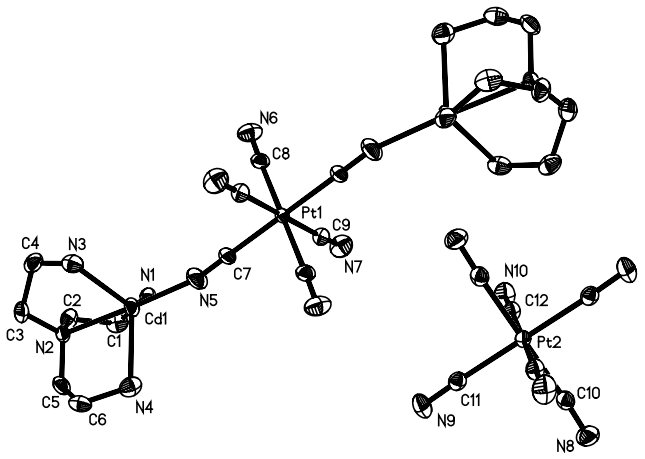

Fig. 3. Perspective view of complex **4** with 30% probability displacement ellipsoids. Hydrogen atoms are omitted for clarity.

3.4. Crystal structure of $[Cd(tren)][Pt(CN)_6]$ (4)

Different from polymeric complexes **1**, **2** and **3**, compound **4** consists of discrete trinuclear $[\{Cd(tren)\}_2Pt(CN)_6]^{2+}$ cations and $[Pt(CN)_6]^{2-}$ anions. As shown in Fig. 3, the trinuclear Cd_2Pt unit is constructed from two $[Cd(tren)]^{2+}$ complex cations spanned by an hexacyanoplatinate(IV) anion via *trans* cyanide bridges. In the discrete and bridging $[Pt(CN)_6]^{2-}$ anion, each platinum atom is bound to six cyanide ions, with Pt–C and C–N bond length ranges of 1.999(4)–2.025(4) and 1.129(5)–1.147(6) Å, respectively. In light of the Pt–C and C–N bond lengths, there is no significant difference between $[Pt(CN)_6]^{2-}$ in **4** and $[Pt(CN)_4]^{2-}$ anions in the previous cyano-bridged trinuclear complex [16]. As far as we know, no trinuclear hexacyanoplatinate(IV) complex is characterized structurally. Therefore, compound **4** represents the first structural characterization of cyano-bridged trinuclear hexacyanoplatinate(IV) complex. Additionally, a 3D hydrogen-bonding network is formed, similar to that observed in **2** and **3**.

4. Concluding remarks

Two heterometallic coordination polymers (**2** and **3**) and one trinuclear complex (**4**) containing different cyanometalate anions have been prepared and characterized. The shelf-like column of **2** represents a new topology of 1D coordination polymers. Meanwhile, compound **3** provides the first example of a battlement-like polymer constructed from cyanometalate building blocks, and compound **4** is the first case of a cyano-bridged trinuclear hexacyanoplatinate(IV) complex. It is interesting to observe the different assembly chemistry of $[Cd(tren)]^{2+}$ with the closely related complex anions of $[Fe(CN)_6]^{4-}$ (**1**), $[Fe(CN)_5NO]^{2-}$ (**2**), $[Pd(CN)_4]^{2-}$ (**3**) and $[Pt(CN)_6]^{2-}$ (**4**).

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 156516–156518 for compounds **1**–**3**, respectively. Abstract

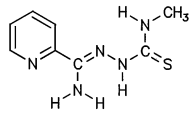
Reduction of 2-cyanopyridine by sodium in dry methanol in the presence of N(4)-methylthiosemicarbazide produces 2-pyridineformamide N(4)-methylthiosemicarbazone, HAm4M. In the crystals of $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$, $[Zn(Am4M)OAc]_2$ and $[Cd(HAm4M)Cl_2]\cdot DMSO$ the major ligand coordinates via its pyridyl nitrogen, imine nitrogen and sulfur atoms, the last of which forms a thione in the neutral ligand HAm4M and a thiolato group in $(Am4M)^-$. Both the acetato ligands in $[Zn(Am4M)OAc]_2$ are bis-monodentate bridges, which is unique among acetato-bridged binuclear complexes of thiosemicarbazones of this type. As in the complexes of other 2-pyridineformamide thiosemicarbazones, hydrogen bonds play an important role in these compounds. As well as by X-ray diffractometry, the new compounds were characterized by elemental analysis, FAB mass spectrometry and IR spectroscopy; in the case of the nickel(II) complex, by electronic spectroscopy and by molar conductivity and magnetic susceptibility measurements; and in the case of the zinc(II) and cadmium(II) complexes, by NMR spectroscopy (^1H, ^{13}C and, for Cd(II), ^{113}Cd). © 2002 Published by Elsevier Science Ltd.

Keywords: 2-Pyridineformamide; Thiosemicarbazone; Nickel(II); Zinc(II); Cadmium(II); Crystal structures

1. Introduction

The structures of a number of crystalline metal complexes of 2-pyridineformamide thiosemicarbazone (HAm4DH) have recently been studied [1–4], as have those of iron(III), cobalt(II) and nickel(II) complexes of 2-pyridineformamide N(4)-methylthiosemicarbazone, HAm4M [6] (Scheme 1). Spectra of copper(II) complexes of HAm4M have also been reported [5]. Having now obtained diffraction quality crystals of the binuclear zinc(II) complex $[Zn(Am4M)OAc]_2$, the cadmium(II) complex $[Cd(HAm4M)Cl_2]\cdot DMSO$ and the nickel(II) complex $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$, we here compare their structures with those of the analogous compounds of HAm4DH and the previously reported metal complexes of HAm4M [6].



2. Experimental

2.1. Materials and instruments

All solvents used were reagent grade. $Ni(ClO_4)\cdot 6H_2O$ (Shering-Kalbaum), $Zn(CH_3COO)_2\cdot 2H_2O$ (ABCR), $CdCl_2\cdot H_2O$ (Aldrich), 2-cyanopyridine (Aldrich) and 4-methyl-3-thiosemicarbazide (Aldrich) were used with no further purification. HAm4M was prepared from 2-cyanopyridine as described previously [6]. Elemental analyses for C, H, N and S were performed on a Carlo Erba EA model 1108 elemental analyser. Melting points were determined in open tubes with a Büchi apparatus and are uncorrected. IR spectra were obtained in the 4000–400 cm^{-1} region using KBr pellets in a Mattson Cygnus 100 spectrometer, and in the 500–100 cm^{-1} region using polyethylene-sandwiched Nujol mulls in a Bruker IFS 66V spectrometer. ^1H and ^{13}C NMR spectra in DMSO-d_6 were run in Bruker AMX 300 and WM 300 instruments, respectively, using TMS as internal refer-

ence. The ^{113}Cd NMR spectrum of the cadmium(II) complex was run on a Bruker AMX 500 apparatus in dimethylformamide with D_2O as reference and is expressed relative to 0.1 M $Cd(ClO_4)_2$. Mass spectra (FAB, 3-nitrobenzyl alcohol, Xe, 8 kV) were obtained in a Kratos MS 50 apparatus equipped with a DS-90 data acquisition system. Solid state electronic absorption (diffuse reflectance) spectra were recorded over the 900–350 nm region in a Shimadzu UV–Vis/NIR UV-3101PC spectrophotometer. Magnetic susceptibility measurements were performed at 25 °C using a Johnson Matthey Alfa MSB-MK1 Gouy balance; the data were corrected for diamagnetic susceptibilities. Molar conductivities of 10^{-3} M solutions were measured with a WTW LF-3 conductivity meter.

2.2. Synthesis and crystallization of the complexes

The complexes were prepared by the following procedure. A solution of HAm4M (0.25 g, 1.19 mmol) in ethanol (20 ml) was added to a solution of zinc(II) acetate (0.26 g, 1.19 mmol), cadmium(II) chloride (0.22 g, 1.19 mmol) or nickel(II) perchlorate (0.22 g, 0.60 mmol; **caution, perchlorates are potentially explosive and should be handled carefully**) in 20 ml of 96% ethyl alcohol, and the mixture was stirred for several days. The resulting solids were filtered off, washed thoroughly with cold ethanol and dried over $CaCl_2$.

2.2.1. $[Ni(HAm4M)_2](ClO_4)_2\cdot H_2O$

Green; 0.265 g, 63.7%; m.p. 250 °C. MS (FAB): $m/z = 477$ $[Ni(HAm4M)_2]^+$, 443 $[Ni_4(HAm4M)]^+$, 385 $[Ni_3(HAm4M)]^+$, 268 $[Ni(HAm4M)]^+$. *Anal.* Found: C, 27.90; H, 3.30; N, 19.94; S, 9.65%. Calc. for $C_{16}H_{24}Cl_2N_{10}NiO_9S_2$ (694.18): C, 27.68; H, 3.48; N, 20.07; S, 9.24%. IR (KBr, ν/cm^{-1}): 3420, 3353, 3313, 3181 (N–H); 1679, 1573, 1483 [(C=N)+(C=C)]; 1133–1089 (ν_3, ClO_4); 1030 (N–N); 940–929 (ν_4, ClO_4); 790 (C=S); 636 (py). Far-IR (Nujol, ν/cm^{-1}): 417 (py); 339 (Ni–S); 243, 225 (Ni–N). UV–Vis (ν/cm^{-1}): 28 735, 26 525, 15 611, 11 337.

2.2.2. $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$

Single crystals of $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$ suitable for analysis by X-ray diffractometry were obtained by slow evaporation of the mother liquor in air at room temperature. *Anal.* Found: C, 26.96; H, 3.77; N, 19.66; S, 8.99. Calc. for $C_{16}H_{26}Cl_2N_{10}NiO_{10}S_2$ (712.20): C, 26.98; H, 3.68; N, 19.67; S, 9.00%.

2.2.3. $[Zn(Am4M)(OAc)]_2\cdot H_2O$

Yellow; 0.336 g, 82.6%; m.p. 225 °C. MS (FAB): $m/z = 332$ $[Zn(HAm4M)(OAc)]^+$, 273 $[Zn(HAm4M)]^+$. *Anal.* Found: C, 35.18; H, 4.14; N, 20.49; S, 9.48%. Calc. for $C_{20}H_{28}N_{10}O_5S_2Zn_2$ (683.38): C, 35.15; H, 4.13; N, 20.50; S, 9.38%. IR (KBr, ν/cm^{-1}): 3432, 3314 (N–H); 1644, 1582 (ν_{as}, CO_2); 1564, 1514, 1469 [(C=N)+(C=C)]; 1385 (ν_s, CO_2); 1014 (N–N); 791 (C=S); 638 (py). Far-IR (Nujol, ν/cm^{-1}): 410 (py); 321 (Zn–S); 288 (Zn–O); 254 (Zn–N). ^1H NMR (DMSO-d_6, δ/ppm): 2.82 (s, 3H, C8H); 6.35 (s,a, 1H, N4H); 6.89 (s, 2H, N5H); 7.57, 8.06, 8.47 (4H, py). ^{13}C NMR (DMSO-d_6, δ/ppm): 29.6 (C8), 119.9 (C2), 125.3 (C4), 39.6 (C3), 144.9 (C6), 146.2 (C5), 147.1 (C1), 175.3 (C7).

2.2.4. $[Zn(Am4M)(OAc)]_2$

Single crystals of $[Zn(Am4M)(OAc)]_2$ suitable for analysis by X-ray diffractometry were obtained by slow evaporation of the mother liquor in air at room temperature. *Anal.* Found: C, 35.98; H, 3.74; N, 21.49; S, 9.68. Calc. for $C_{20}H_{26}N_{10}O_4S_2Zn_2$ (665.37): C, 36.10; H, 3.94; N, 21.06; S, 9.64%.

2.2.5. $[Cd(HAm4M)Cl_2]\cdot H_2O$

Yellow; 0.324 g, 66.3%; m.p. 234 °C. MS (FAB): $m/z = 531$ $[Cd(HAm4M)_2]^+$, 357 $[Cd(HAm4M)Cl]^+$. *Anal.* Found: C, 23.69; H, 2.86; N, 16.99; S, 8.75. Calc. for $C_8H_{13}CdCl_2N_5OS$ (410.59): C, 23.40; H, 3.19; N, 17.06; S, 7.81%. IR (KBr, ν/cm^{-1}): 3473, 3343, 3209 (N–H); 1665, 1631, 1565, 1441 [(C=N)+(C=C)]; 1016 (N–N); 794 (C=S); 640 (py). Far-IR (Nujol, ν/cm^{-1}): 404 (py); 322 (Cd–S); 252 (Cd–N); 219, 182 (Cd–Cl). ^1H NMR (DMSO-d_6, δ/ppm): 2.95 (s, 3H, C8H); 6.91 (s, 2H, N5H); 7.62 N (s,a, 1H, N4H); 7.43, 7.76, 8.44, 8.55 (4H, py); 10.06 (s, 1H, N3H). ^{13}C NMR (DMSO-d_6, δ/ppm): 30.1 (C8), 121.1 (C2), 126.4 (C4), 138.2 (C3), 140.6 (C6), 146.0 (C5), 149.0 (C1), 176.5 (C7).

2.2.6. $[Cd(HAm4M)Cl_2]\cdot DMSO$

Single crystals of $[Cd(HAm4M)Cl_2]\cdot DMSO$ suitable for analysis by X-ray diffractometry were obtained by slow evaporation of a DMSO solution in air at room temperature. *Anal.* Found: C, 25.45; H, 3.61; N, 14.85; S, 13.59. Calc. for $C_{10}H_{17}CdCl_2N_5OS_2$ (470.71): C, 25.52; H, 3.64; N, 14.88; S, 13.26%.

2.3. Crystal structure determination

Data were collected from selected crystals mounted on glass fibres. The data for $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$ were processed with SAINT [7] and corrected for absorption using SADABS (transmission factors: 1.000–0.732) [8]. For $[Zn(Am4M)OAc]_2$ and $[Cd(HAm4M)Cl_2]\cdot$DMSO, cell constants and orientation matrices for data collection were obtained by least-squares refine-

ment of the diffraction data from 25 reflections in the ranges $21.95^\circ < \theta < 45.72^\circ$ and $6.55^\circ < \theta < 10.81^\circ$, respectively, and semi-empirical absorption corrections were made (ψ-scans) [9]. The structures were solved by direct methods using the program SHELXS-97, and were refined by full-matrix least-squares techniques on F^2 using anisotropic displacement parameters [10]. Hydrogen atoms were placed at the calculated positions. Idealized H atoms were refined with isotropic displacement parameters set to 1.2 (1.5 for methyl groups) times the equivalent isotropic U values of the parent atom. Atom scattering factors were taken from the International Tables for X-ray Crystallography [11] and molecular graphics were produced using SCHAKAL [12].

3. Discussion

3.1. Synthesis and physicochemical properties

Reaction of the stated quantities of $Ni(ClO_4)\cdot 6H_2O$, $Zn(CH_3COO)_2\cdot 2H_2O$ and $CdCl_2\cdot H_2O$ with HAm4M in ethanol gave products of compositions $[Ni(HAm4M)_2](ClO_4)_2\cdot H_2O$, $[Zn(Am4M)OAc]_2\cdot H_2O$ and $[Cd(HAm4M)Cl_2]\cdot H_2O$, as shown by microanalytical. All three complexes are stable in air and are highly soluble in DMF and DMSO, less soluble in H_2O, MeOH, EtOH, MeCN and Me_2CO, and insoluble in $HCCl_3$ and toluene.

The mass spectra of the complexes all show peaks attributable to the species $[Ni(HAm4M)_2]^+$, $[Cd(HAm4M)_2]^+$ or $[Zn(Am4M)(OAc)]^+$ and, at lower m/z, to $[Ni(HAm4M)]^+$, $[Zn(Am4M)]^+$ or $[Cd(HAm4M)Cl]^+$; these species are common in the mass spectra of compounds of the form $[ML_n]X_m$ in which monovalent anions coordinate metals in oxidation states II or III [13]. The spectra also all contain peaks due to oligomeric species or ligand fragmentation (not listed), and the spectrum of the nickel compound shows peaks corresponding to multinuclear single-ligand species.

The IR spectrum of HAm4M has five strong bands in the range 4000–3000 cm^{-1}. Those at 3366 and 3234 cm^{-1} are due to the stretching modes $\nu_a(NH_2)$ and $\nu_s(NH_2)$, respectively; that at 3183 cm^{-1} to the hydrazinic NH; and the other two probably to thioamide NH stretching. The IR spectra of the nickel(II) and cadmium(II) complexes exhibit shoulders at 3420 and 3473 cm^{-1}, respectively, and broad bands at 3353–3313 and 3181 cm^{-1} (in the nickel complex) or 3343 and 3208 cm^{-1} (in the cadmium complex); all these bands probably arise from both the ν(OH) modes of the lattice water and the ν(NH) modes of the ligand. In the spectrum of the zinc(II) complex ν(NH) vibrations appear at 3431 and 3313 cm^{-1}, but there is no band corresponding to stretching of the hydrazinic NH, which is consistent with deprotonation of HAm4M. Neither does this spectrum show bands characteristic of thioamide or imino groups, which suggests that the ligand is coordinated in thiolato form, an interpretation that is further supported by the presence of a new band near 1514 cm^{-1} that seems to be due to the stretching mode of the conjugated >C=N–N=C< group (as in azines [14]) and hence implies that the sulfur is thiolic. The shift of the thiocarbonyl stretching mode from 797 cm^{-1} in HAm4M to lower frequencies in all the complexes is in keeping with coordination through sulfur [15], and the parallel shift of ν(C=N) from 1591 cm^{-1} to 1564–1578 cm^{-1} likewise corroborates coordination of the azomethine nitrogen [16]. Coordination of the pyridine nitrogen atom is less easily inferred from the pyridine bands, since the 1600–1400 cm^{-1} region is complicated by the presence of thioamide bands, but is clearly shown by the shift to higher frequencies of the deformation mode bands that appear near 625 and 405 cm^{-1} in the spectrum of HAm4M [17]. In the 400–100 cm^{-1} region the IR spectra of the complexes show bands that are not observed in that of the free ligand: a weak band in the range 340–320 cm^{-1} is attributable to ν(MS), bands in the range 260–220 cm^{-1} to ν(MN) vibrations [18], a band at 288 cm^{-1} in the spectrum of the zinc complex to ν(ZnO) [19], and two strong bands at 219 and 182 cm^{-1} in the spectrum of the cadmium complex to ν(CdCl) [20].

The molar conductivity of freshly prepared 10^{-3} M solutions of the nickel(II) compound in DMF, 166.9 S cm^2 mol^{-1}, corresponds to a 1:2 electrolyte [21]. The effective magnetic moment determined at room temperature is 3.18 MB, which is typical of high-spin octahedral complexes [22]. The diffuse reflectance spectrum is typical of hexacoordinate compounds of nickel(II) [22]. In the visible and near-IR regions, a low-energy band at 11 340 cm^{-1} can be assigned to the $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ transition (ν_1), and the band at 16610 cm^{-1} to the $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ transition (ν_2); the ν_3 band, which corresponds to the transition $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$, is masked by the high-intensity charge transfer bands at 26 525 and 28 735 cm^{-1}. The first CT band probably reflects a metal–ligand CT transition, whereas the second is probably the result of an intraligand transition.

In the ^1H NMR spectrum of the zinc complex the nonappearance of the N3H signal (at 10.03 ppm in the free ligand) shows that the ligand is deprotonated in DMSO solution. The deshielding of N4H is probably due to withdrawal of charge from N4 as the result of an increase in charge delocalization upon complexation through the thiocarbonyl sulfur atom; the shielding of the N4 methyl protons is attributable to the same mechanism. In the cadmium complex the persistence of the N3H signal shows that this proton is retained in DMSO solution; the downfield shifts of the N3H and

N4H signals are attributable to coordination through the azomethine nitrogen atom and thiocarbonyl sulfur atom, respectively, and/or to the formation of hydrogen bonds between N3H (and to a much lesser extent N4H) and solvent.

In the ^{13}C NMR spectra of the zinc and cadmium complexes the shielding of C7 and C8 is attributable to a combination of the inductive effect of the metal and the move towards the thiol form induced by deprotonation (in the zinc complex) or coordination through the sulfur atom (in the cadmium complex). The shift of the C6 signal to higher field in the cadmium complex is in consonance with coordination through the azomethine nitrogen atom, but in the zinc complex an increase in electronic delocalization in the thiosemicarbazone moiety moves this signal to lower field. Coordination through the pyridine nitrogen atom is pointed to by the shielding of the pyridine C5 signals [15].

The ^{113}Cd NMR spectrum shows a single signal at 385.5 ppm. The fact that the metal atom is less deshielded than in $CdCl_2$ in DMSO [23] is consistent with data for other complexes of cadmium(II) chloride with thiosemicarbazones, and is compatible with pentacoordination of the metal [2].

3.2. Crystal structures

Table 1 summarizes crystal data and data collection details for the complexes $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$, $[Zn(Am4M)OAc]_2$ and $[Cd(HAm4M)Cl_2]\cdot DMSO$. Selected bond lengths are listed in Table 2, and bond angles in Table 3. Perspective views of $[Ni(HAm4M)_2](ClO_4)_2$, $[Zn(Am4M)OAc]_2$ and $[Cd(HAm4M)Cl_2]$ are shown in Figs. 1–3, respectively. Intermolecular hydrogen bonding parameters are compiled in Table 4, and least-squares mean-plane data in Table 5.

3.2.1. Structure of $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$ (1)

The crystal structure of planar, tetracoordinate $[Ni(Am4M)(OAc)]\cdot H_2O$, in which HAm4M has lost its N3 hydrogen, was described previously [6]. The structure of $[Ni(HAm4DH)_2](NO_3)_2$, where HAm4DH is 2-pyridineformamide thiosemicarbazone, has also been solved, and $[Ni(HAm4DH)(Am4DH)]ClO_4$ has been synthesized by reaction of HAm4DH with nickel(II) perchlorate [3]. We are therefore able to compare the coordination of neutral HAm4M with that of anionic Am4M and with similar complexes of HAm4DH.

In $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$ the two ligands coordinate in the expected meridional conformation via the pyridine nitrogen, imine nitrogen and sulfur atoms. The N12–Ni1–N22 angle involving the imine nitrogens of the two ligands is 173.1(3)°, showing less distortion from octahedral symmetry than in $[Ni(HAm4DH)_2](NO_3)_2$, in which this angle is 169.6(2)° [3]. The other two *trans* angles, each of which involves the terminal donors of one of the tridentate ligands, are approximately 159.5°.

As in all 2-pyridyl thiosemicarbazones, the $Ni–N_{im}$, $Ni–N_{py}$ and Ni–S bonds increase in length in that order. The differences between the two ligands as regards these bond lengths are within twice their combined esds. Coordination does not significantly affect the imine C=N bond length, and the C=S bond is shortened only very slightly, from an average 1.699(5) Å to an average 1.680(9) Å (probably due to the loss of intermolecular hydrogen bonds present in HAm4M [6]). The other bonds of the coordinated thiosemicarbazone moiety are also similar in length to those found in HAm4M. The bond angles of the thiosemicarbazone moiety are altered somewhat upon coordination; the largest change affects N13–C17–S1 and N23–C27–S2, which average 122.5(2)° in $[Ni(HAm4M)_2](ClO_4)_2$ as against 120.0(4)° in HAm4M [6].

All of the coordinating bonds are, as expected, longer than in [Ni(Am4M)(OAc)] [6], which is tetracoordinate. The C17–S1 and N13–C17 bonds are significantly shorter than in [Ni(Am4M)(OAc)], but the C16–N12 bonds of the two compounds have the same length. As expected, there are significant differences between the bond angles of coordinated HAm4M and the coordinated N3-deprotonated anion [6].

The extensive hydrogen bonding in $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$ involves the perchlorate ions, the water molecules, and all the uncoordinated nitrogens (Table 4). N14–H14 binds two oxygens belonging to the same perchlorate ion (one more strongly than the other), and ligand 1 binds the O1#1 water molecule via two different NH groups (N13–H13 and N15–H15A), but ligand 2 only forms hydrogen bonds with perchlorate oxygen.

The angle between the least-squares planes of the pyridine ring and the thiosemicarbazide moiety in $[Ni(HAm4M)_2](ClO_4)_2$ averages 5.5(4)° {cf. 11.0(2)° in $[Ni(HAm4DH)_2](NO_3)_2$ [3]}. The angle between the planes of the two thiosemicarbazone moieties is 87.3(1)°, but the Ni(II) ion lies 0.058(6) Å from one plane and 0.022(7) Å from the other. The angles between the planes of the thiosemicarbazone moieties in $[Ni(HAm4DH)_2](NO_3)_2$ and $[Ni(HAm4DH)(Am4DH)]ClO_4$ are 88.6(2)° and 84.9(2)°, respectively [3].

3.2.2. Structure of $[Zn(Am4M)(OAc)]_2$ (2)

$[Zn(Am4M)(OAc)]_2$ crystallizes as a centrosymmetric binuclear molecule with the two acetato bridging ligands in a *syn–syn* arrangement and with a Zn–Zn distance of 3.6942(7) Å. By contrast, $[Zn(Am4DH)(OAc)]_2$ has two different kinds of acetato bridge: one is *syn–syn* but the other involves just a single oxygen, as in $[Zn(Ac4E)(OAc)]_2$, where Ac4E is the anion of 2-acetylpyridine N(4)-ethylthiosemicarbazone [24]. The two Zn–O distances of $[Zn(Am4M)(OAc)]_2$, which are slightly

bond lengths in the thiosemicarbazone moiety do not differ significantly from those of HAm4M. The lengths of the two C–O bonds of the acetato groups are slightly

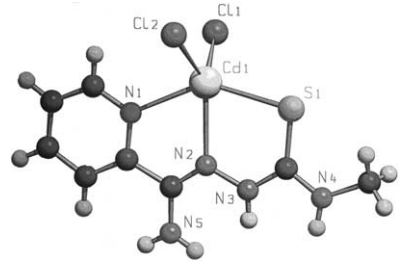

Fig. 3. Drawing of $[Cd(HAm4M)Cl_2]$.

different, in keeping with the different Zn–O distances. Compared to $[Zn(Am4DH)(OAc)]_2$, $[Zn(Am4M)(OAc)]_2$ has a significantly longer $Zn–N_{im}$ bond [2.227(2) Å as against an average 2.161(2) Å] and slightly shorter Zn–S and Zn–O distances, but the $Zn–N_{py}$ distance is the same in both compounds.

The identical ZnN_2O_2S kernels of $[Zn(Am4M)(OAc)]_2$ have N1–Zn–S angles of 156.58(6)° {cf. 150.44(5)° and 157.27(6)° for $[Zn(Am4DH)(OAc)]_2$}. With N1–Zn–S assigned as β and N1–Zn–O11′ as α, $\tau = 0.56$ [25], indicating that the arrangement about Zn is very slightly closer to a trigonal bipyramid (with N1 and S axial, and N2, O11′ and O12 equatorial) than to a square pyramid. By contrast, in $[Zn(Am4DH)(OAc)]_2$ both centres are more nearly square pyramids ($\tau = 0.20$ and 0.0), as in another recently studied binuclear zinc complex with dissimilar acetato bridges, [Zn(Ampip)-

Symmetry transformations used to generate equivalent atoms:
[a] #1: $-x+1/2$, $y+1/2$, $-z+3/2$; #2: $x-1/2$, $-y+3/2$, $z-1/2$; #3: x, y, $z-1$.
[b] #1: $-x$, y, $-z+1/2$; #2 $-x+1/2$; $y+1/2$, $-z+1/2$.
[c] #1: $-x+1$, $-y+1$, $-z+1$; #2: $-x$, $-y$, $-z+1$.

$(OAc)]_2$ (where Ampip is the anion of 2-pyridineformamide 3-piperidylthiosemicarbazone), for which $\tau = 0.04$ and 0.25 [26]. The difference between the two acetato ligands both being bis-monodentate (as in $[Zn(Am4M)(OAc)]_2$) and their one of them being bis-monodentate and the other bridging only through one oxygen (as in $[Zn(Am4DH)(OAc)]_2$ and $[Zn(Ampip)(OAc)]_2$) thus has a significant effect on the coordination polyhedra of both the zinc atoms.

There is less intermolecular hydrogen bonding in $[Zn(Am4M)(OAc)]_2$ than in other complexes of 2-pyridineformamide thiosemicarbazones because of the absence of solvate molecules. However, N4H4 interacts with a non-bonding pair of electrons on a coordinated thiolato sulfur, the N4H4···S1#1 distance and angle [3.446(3) Å and 154.3°] being similar to those found in uncomplexed N–(2-pyridyl)–N′–arylthiourea molecules [27]; and an N5 hydrogen interacts with a lone pair of electrons on a coordinated acetato oxygen atom, with a N···O distance, 2.973(3) Å, that is slightly shorter than that between an analogous nitrogen and the oxygen of a solvating water molecule in $[Zn(Am4DH)(OAc)]_2\cdot H_2O$, 3.018(3) Å [4]. As in other complexes of Am4M, the mean plane of the coordinated thiosemicarbazide moiety is just slightly inclined to that of the pyridine ring, with which it makes an angle of 3.8(2)° (Table 5).

3.2.3. Structure of $[Cd(HAm4M)Cl_2]\cdot DMSO$ (3)

A number of $[Cd(NNS)X_2]$ compounds have been reported recently (NNS being a neutral 2-pyridyl thiosemicarbazone and X being Cl, Br or I). They include $[Cd(HAm4DH)Cl_2]$ [4] and $[Cd(HAc4M)Cl_2]$ [15], where HAc4M is 2-acetylpyridine N(4)-methylthiosemicarbazone. In **3** the major ligand coordinates via its pyridine nitrogen, imine nitrogen and sulfur atoms, and the coordinating bonds between Cd and the HAm4M and chloro ligands are very similar in length to those of $[Cd(HAm4DH)Cl_2]$ [4]. The Cd–N1 and Cd–S distances are also very similar to those found in

Table 5

Table 6
Distortion from square pyramidal geometry in $[Cd(NNS)Cl_2]$ complexes

Compound	β(N1–Cd1–S1)	α(N2–Cd1–Cl)	$\beta-\alpha$	$\tau=(\beta-\alpha)/60$	Ref.
$[Cd(HAm4DH)Cl_2]$ [a]	142.8	138.4	4.4	0.07	[4]
$[Cd(HAm4M)Cl_2]$	142.4	129.2	13.2	0.22	this work
$[Cd(HAmpip)Cl_2]$ [b]	134.6	137.9	3.3	0.06	[26]
$[Cd(HAc4DH)Cl_2]$ [c]	141.5	137.7	3.8	0.06	[28]
$[Cd(HAc4M)Cl_2]$ [d]	139.8	136.7	3.1	0.05	[15]
$[Cd(HAc4DM)Cl_2]$ [e]	145.2	135.5	9.7	0.16	[29]

[a] HAm4DH = 2-pyridineformamide thiosemicarbazone.
[b] HAmpip = 2-pyridineformamide 3-piperidylthiosemicarbazone.
[c] HAc4DH = 2-acetylpyridine thiosemicarbazone.
[d] HAc4M = 2-acetylpyridine N(4)-methylthiosemicarbazone.
[e] HAc4DM = 2-acetylpyridine N(4)-dimethylthiosemicarbazone.

$[Cd(HAc4M)Cl_2]$ [15], but the Cd–N2 distance is significantly shorter than in the latter [2.365(10) Å as against 2.432(2) Å], showing that electron donation by the formamide NH_2 is significantly greater than that of the acetyl CH_3. This difference is probably responsible for the Cd–Cl bond being somewhat longer in $[Cd(HAm4M)Cl_2]$. Like all other $[Cd(NNS)Cl_2]$ compounds, $[Cd(HAm4M)Cl_2]$ has a square pyramidal coordination polyhedron, but it also exhibits greater distortion towards trigonal bipyramidal stereochemistry than any other known compound of this type (Table 6).

In the thiosemicarbazone moiety the only bond of $[Cd(HAm4M)Cl_2]$ to differ significantly in length from the corresponding bonds of $[Cd(HAm4DH)Cl_2]$ [4] and $[Cd(HAc4M)Cl_2]$ [15] is N3–C7 {1.319(13) Å in $[Cd(HAm4M)Cl_2]$, 1.358(6) Å in $[Cd(HAm4DH)Cl_2]$ and 1.370 Å in $[Cd(HAc4M)Cl_2]$}. The mean planes of the pyridine ring and the thiosemicarbazide chain make an angle of 8.6(4)° {cf. 2.0(2)° in $[Cd(HAm4DH)Cl_2]$}.

2-Pyridineformamide thiosemicarbazones have more possibilities of hydrogen bonding than 2-formyl-, 2-acetyl- and 2-benzoylpyridine thiosemicarbazones because of the presence of the formamide NH_2 group. In the present case, the four hydrogen bonds of $[Cd(HAm4M)Cl_2]\cdot DMSO$ (N3H3 and N5H5A with the oxygen of a neighbouring DMSO, N4H4 with the corresponding Cl2, and N5H5B with Cl1 of another neighbouring molecule; see Table 4) may be compared with the two of $[Cd(HAc4M)Cl_2]\cdot 2DMSO$, in which it is N3H3 and N4H4 that both interact with the same DMSO oxygen.

4. Supplementary material

Crystallographic data for the structures reported in this paper (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 168861 (for $[Ni(HAm4M)_2](ClO_4)_2\cdot 2H_2O$), 168862 (for $[Zn(Am4M)(OAc)]_2$) and 168863 (for $[Cd(HAm4M)Cl_2]\cdot DMSO$). Crystal and molecular structures of cadmium(II) nitrate complexes with triamines: 1,5-diamino-3-azapentane, 1,6-diamino-3-azahexane and 1,7-diamino-4-azaheptane

Elzbieta Bartoszak-Adamska, Romualda Bregier-Jarzebowska, Lechoslaw Lomozik *

Received 12 September 2001; accepted 5 December 2001

Abstract

The following new complexes of Cd(II) nitrate with triamines have been prepared and characterized: $[Cd(NH_2(CH_2)_2NH(CH_2)_2NH_2)_2](NO_3)_2$ (**1**), $[Cd(NH_2(CH_2)_2NH(CH_2)_3NH_2)_2](NO_3)_2$ (**2**) and $[Cd(NH_2(CH_2)_3NH(CH_2)_3NH_2)_2](NO_3)_2$ (**3**). Their structures have been determined by a single-crystal X-ray diffraction method. Because of the instability of the crystals **2** and **3** at room temperature, all complexes were examined at 100 K. In the complexes investigated all nitrogen atoms of the triamines coordinate the Cd(II) atom. All data sets showed {N6}-coordinated complexes. The stoichiometry of the complexes in the solid state is always 1:2, although the crystals were grown from solutions with different concentration ratios of the components (Cd–triamine: 1:1, 1:2 or 1:3). The Cd(II) atom of complex **1** is sandwiched between two triamines related by a twofold axis. Complexes **2** and **3** are characterized by a distorted octahedral coordination. The conclusions obtained correspond to the solution structures obtained from NMR, IR as well as equilibrium studies. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Cadmium(II) complexes; Polyamines; X-ray structures

1. Introduction

As has been observed for a number of systems, polyamines form molecular complexes with fragments of molecular acids and the metal ions present in the systems influence the character of non-covalent interactions [1–9]. Biogenic amines change the conformation of nucleic acids and directly affect the processes of genetic information transfer [10–13]. Putrescine, spermidine and spermine occur practically in all kinds of living cells and because of their high basicity in the physiological environment they are protonated and act as positive interaction centres. Often in analysis of interactions only the magnitude of the charge is taken into account, which is an oversimplification preventing the explanation of the specificity of a number of processes, and the character of interactions is also significantly affected by the structural factor. The length of the chain and the kind of chelate ring also influence the properties of coordination complexes of polyamines with metal ions. It has been recently found that Cu(II) in systems with polyamines tend to assume a coordination type {N4} or {N5}, with one or two vacant axial positions of the ML_2 type of complex [14,15]. In contrast to copper, cadmium(II) shows a tendency to bind polyamines exhausting all accessible donor atoms of the bioligand [16]. Analysis of biosystems with cadmium ions becomes a problem of particular importance in view of the established toxic influence of this metal, associated with Hg and Pb to the group of the most toxic environmental pollutants [17–20]. Recently, an increase in the concentration of the metals in living organisms has been observed [21–24]. Cadmium is accumulated in kidneys, liver and blood where it can destroy erythrocytes, also being detrimental to bones [19,20,25]. This metal competes with Zn and blocks active sites of metal–enzymes and as a relatively soft acid it can dislodge Zn(II) in cysteine-coordinated zinc compounds

or Ca(II) ions in bone cells [26,27]. This paper describes the synthesis and structure of three new complexes of Cd(II) nitrate with 1,5-diamino-3-azapentane (dien), 1,6-diamino-3-azahexane (2,3-tri) and 1,7-diamino-4-azaheptane (3,3-tri).

2. Experimental

$Cd(NO_3)_2 \cdot 4H_2O$, 99% was purchased from Merck; the polyamines: diethylenetriamine (dien), NH_2–$(CH_2)_2$–NH–$(CH_2)_2$–NH_2, 99%; 1,6-diamino-3-azahexane (2,3-tri), NH_2–$(CH_2)_2$–NH–$(CH_2)_3$–NH_2, 97% and 1,7-diamino-4-azaheptane (3,3-tri), NH_2–$(CH_2)_3$–NH–$(CH_2)_3$–NH_2, 98%, were purchased from Aldrich. The reagents were used without further purification.

2.1. Synthesis of complexes

Compounds: $Cd(dien)_2(NO_3)_2$ (**1**), $Cd(2,3\text{-tri})_2(NO_3)_2$ (**2**) and $Cd(3,3\text{-tri})_2(NO_3)_2$ (**3**) were obtained by mixing a solution containing 0.5 mM $Cd(NO_3)_2 \cdot 4H_2O$ in 2.5 cm^3 of methanol with a solution of 1.0 mM dien, 10.0 mM 2,3-tri or 1.0 mM 3,3-tri, respectively, in 2.5 cm^3 of methanol at room temperature (solutions for compounds **1** and **3** were evaporated to about three-fourth of the initial volume). Single crystals of all compounds appeared after a few days. They were filtered off, washed with methanol and diethyl ether and dried in the air. Elemental analysis of compounds **1** and **3** was performed using a Perkin Elmer CHN 2400 analyser and compound **2** on a Euro-Vector EA 3000 analyser.

Compound ***1***: Yield ~30%; *Anal*. Calc.: for $C_8H_{26}N_8O_6Cd$ ($M = 442.76$ g mol^{-1}): C, 21.70; H, 5.92; N, 25.31. Found: C, 21.82; H, 5.88; N, 25.26%; *Compound* ***2***: Yield ~35%. *Anal*. Calc. for $C_{10}H_{30}N_8O_6Cd$ ($M = 470.81$ g mol^{-1}): C, 25.51; H, 6.42; N, 23.80. Found: C, 25.85; H, 6.36; N, 23.54%. *Compound* ***3***: Yield ~30%. *Anal*. Calc. for $C_{12}H_{34}N_8O_6Cd$ ($M = 498.86$ g mol^{-1}): C, 28.90; H, 6.87; N, 22.46. Found: C, 29.06; H, 6.82; N, 22.38%.

2.2. Spectral studies

IR spectra were taken in a Brucker FT-IR spectrometer model IFS 113v and Nicolet Magna 760 instrument, in the range 4000–200 cm^{-1}, for the solid complexes in tablets with CsBr and for free polyamine in a film. NMR measurements (in D_2O) were performed using NMR Gemini-300VT Varian and NMR Varian Unity 300.

2.3. X-ray measurements

X-ray data collection at 100 K was performed in a KM4-CCD κ-geometry diffractometer equipped with an Oxford Cryosystem [28] and using graphite-monochromated Mo Kα radiation. The integrated intensities and direction cosines were obtained using the CRYSALIS program [29]. The data were corrected for Lorentz, polarization and absorption effects. Semi-empirical absorption correction was made using the raw data for absorption curve determination. The structure was solved by the heavy atom Patterson superposition method using SHELXS [30] and refined by full-matrix least-squares techniques using anisotropic displacement parameters for non-hydrogen atoms and isotropic ones for H atoms. C–H and N–H hydrogen atoms were generated geometrically and included into the refinement process. The refinement (in SHELX-97 [31]) was based on all F^2 data and included an empirical extinction parameter x, used to correct F_c according to $F_c^* = kF_c(1+0.01xF_c^2/\sin 2\theta)^{1/4}$. The highest peaks and holes in the final $\Delta\rho$ map were all located near Cd atoms (for crystals **1** and **3**) or near the N(2) atom (for crystal **2**). Crystal data and experimental details are listed in Table 1. Atomic scattering factors were taken from International Tables for X-ray Crystallography [32]. Molecular graphics were obtained using programs from XP package [33,34].

3. Results and discussion

As it has been found earlier, in complexes of cadmium with triamines $Cd(PA)_x$ in solution, a tendency has been observed to involve all donor nitrogen atoms of polyamines in the coordination [16]. Changes in all ^{13}C NMR signals assigned to carbon atoms from polyamines were observed both in Cd(PA) as well as in $Cd(PA)_2$ complexes. For example, at pH of about 10, i.e. in the range of $Cd(2,3\text{-tri})_2$ complex domination, the chemical shift values testify to participation of six nitrogen atoms of the 2,3-tri ligand in the metallation. Changes in the signals coming from C(1), C(2), C(3), C(4) and C(5) atoms (in relation to free amine) are: 0.432, 1.175, 0.157, 1.732 and 0.084 ppm, respectively (NMR signals were assigned to particular atoms on the basis of literature data [35]). Moreover, taking into consideration steric limitations, a greater difference in the stability constants for ML_1 and ML_2 complexes of triamines when compared to diamine compounds ($\log \beta_{Cd(dien)} = 7.68$, $\log \beta_{Cd(dien)_2} = 13.34$; $\log \beta_{Cd(en)} = 5.31$, $\log \beta_{Cd(en)_2} = 9.66$), also suggests the involvement of all donor atoms from each ligand in metallation. Although a comparison of the modes of coordination of analogous complexes in solid state and in solution may be risky, the results of studies in both phases are complementary. It should be added that the number of donor atoms, in particular, those more weakly bonded in the axial positions, plays an essential role in the

reactions of enzymatic catalysis involving metal complexes.

3.1. X-ray crystallography

For atomic coordinates, equivalent isotropic displacement parameters, anisotropic displacement parameters for non-hydrogen atoms, hydrogen atoms coordinates with isotropic temperature factors and full geometry of the **1**–**3** complexes see supplementary material. Table 2 lists the Cd–N distances and the geometry of compound **1** and the geometry of complexes **2** and **3**. Torsion angles of the triamines are presented in Table 3.

3.1.1. Compound *1*

The Cd^{2+} cation occupies Wyckoff position 16 e.2. in the $I4_1/acd$ space group with the origin on a centre of symmetry. An asymmetric unit cell consists of half of a Cd^{2+} cation, one triamine and one nitrate anion. The second triamine and NO_3^- anion are related by a twofold axis. Therefore, the Cd atom is coordinated by six nitrogen atoms and all N atoms of the polyamine are engaged in forming the complex. The C_2-symmetric polyhedron is presented in Fig. 1. The Cd(II) atom is sandwiched between two triamines. As a consequence of the crystallographic C_2-symmetry of the $[Cd(NH_2(CH_2)_2NH(CH_2)_2NH_2)_2]^{2+}$ complex, both triamines adopt exactly the same $g^+g^+tg^+$ conformation (Table 3(a)). The nitrogen atoms of the primary amines of the ligand form shorter Cd(1)–N distances (Cd(1)–N(1) and Cd(1)–N(3) bond lengths are 2.340(2) and 2.336(2) Å, respectively) than the N atom of the secondary amine (Cd(1)–N(2) is 2.431(2) Å). The NO_3^- anions do not play an important role in the coordination system as ligands.

3.1.2. Compound *2*

An asymmetric unit cell consists of a Cd^{2+} cation, two 2,3-triamines and two nitrate anions. The {N6}-coordinated complex is formed (Fig. 2). Conformations of the ligands bonded to the Cd(II) atom are characterized by similar torsion angles but with the opposite sign (Table 3(b)). The Cd–N distances range from 2.326(4) to 2.413(6) Å for Cd(1)–N(1') and Cd(1)–N(2), respectively. In contrast to compound **1**, the present complex does not form a sandwiched structure but it is characterized by a distorted octahedral coordination with the four equatorial nitrogen atoms (N1, N1′, N3 and N3′) and two (N2 and N2′) axial atoms (Fig. 2).

3.1.3. Compound 3

Compound **3** crystallizes in the $P2_1/c$ space group with a and b parameters very similar to the previous structure and with a longer c parameter ($\sim$0.78 Å). The isostructurality of compounds **2** and **3** is reflected in the same behaviour of the crystals and a very similar 'morphology'. At room temperature both crystals are unstable, faces are not well defined, edges are not sharp

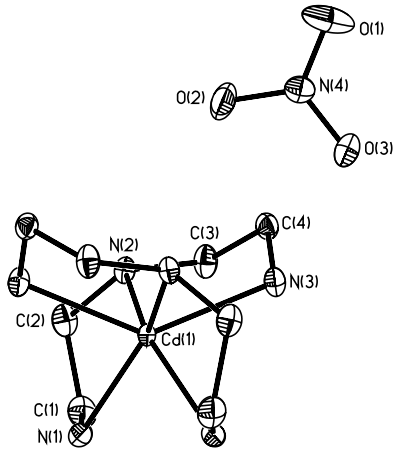

Fig. 1. Cadmium(II) nitrate complex with 1,5-diamino-3-azapentane. Twofold axis is in the plane of the drawing. Hydrogen atoms have been omitted for clarity. Ellipsoids are drawn at the 50% probability level.

and the molecular structure revealed large displacement parameters of the carbon atoms of both amines in complex **2** and one amine in complex **3**. In the present structure the unprimed amine is ordered and the primed one is affected by a disorder, especially the C(2′) and C(5′) atoms. The Cd(II) atom is coordinated by six nitrogen atoms from two polyamines (Fig. 3). Both 3,3-triamines

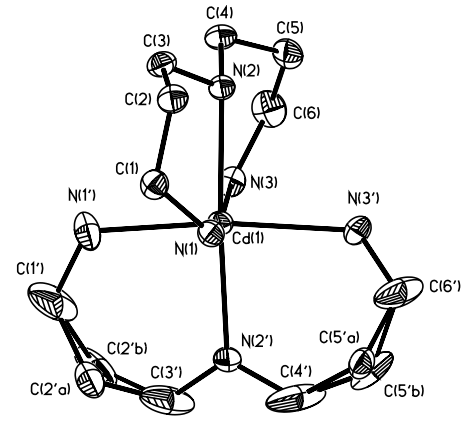

Fig. 3. Cadmium(II) nitrate complex with 1,7-diamino-4-azaheptane. Hydrogen atoms are omitted. Ellipsoids are drawn at the 50% probability level. The alternative positions A and B of the C(2′) and C(5′) atoms are shown. The split atoms positions are occupied in a 3:2 ratio (A:B).

form almost perpendicular folded sheets. The lengthening of the carbon chain causes the relief of the molecular strains and a less-distorted octahedral geometry is observed on comparing to complex **2** (Table 2(c)). The rule that nitrogen atoms of primary amines form shorter Cd–N coordination bonds than N atoms of secondary amines is fulfilled in the present structure by all equatorial (N1, N1′, N3, N3′) atoms and one axial N atom. Because of the disorder of the primed amine, the second axial N atom of the complex forms a shorter Cd–N bond than the N(2) atom of the unprimed ligand (Table 2(c)).

Results of the supplementary IR study are consistent with the conclusions of the investigations presented above. As illustrated by the data in Table 4, the metallation of triamines leads to changes in the stretching vibrations of the amine groups in the range 3400–3100 cm^{-1} and in the scissor vibrations of amine groups, occurring at about 1600 cm^{-1} in the spectra of free amines. The disappearance of a wide and intense band at $\sim$890–830 cm^{-1} (in the spectra of the complexes) assigned to deformation vibrations of $-NH_2$ groups, typical for uncoordinated amines, indicates the involvement of all nitrogen donor atoms in metallation.

The shift of the stretching vibration bands of –C–N– groups from triamines and the appearance of additional

peaks can be explained as a result of the electron drainage from the nitrogen atom on account of its coordination to the metal ion. The positions of the bands for free amines have been taken from the literature [36–39].

In the spectra of compounds **1**–**3** there are very strong high-symmetry (D_{3h}) broad bands (at about 1360 and about 830 cm^{-1}) assigned to a nitrate anions; the assignment of the bands corresponding to uncoordinated NO_3^- ions has been made on the basis of literature [40–42].

The characteristic bands appearing at about 490 cm^{-1} in the spectra of the complexes studied are a result of the formation of cadmium–nitrogen bonds in the complexes $Cd(PA)_2$. The analogous band has been observed earlier in the spectrum of a solid Cd(II) complex with dien [43].

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 168183, 169666 and 169825 for compounds **1**–**3**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The solution structures of nickel(II) and cobalt(II) mixed-ligand complexes with adenosine 5′-monophosphate and tetramines have been found. The nickel(II) ions were proved to coordinate the nitrogen atoms N(1) and N(7) from the nucleotide forming chromophore {N1} in the molecular complexes of type ML·····L′ and chromophore {N3} in the protonated complexes. In the mixed-ligand complexes with nickel(II) ions, a coordination dichotomy N1/N7 was observed. In the mixed complexes with cobalt(II) ions, the presence of a chromophore {N1,O}, with N(7) nitrogen atom and oxygen atoms from the AMP phosphate group, was found. On the other hand, in molecular complexes the non-covalent interactions between the totally protonated polyamine and nucleotide atoms of high electron density were established. The presence of interligand non-covalent interactions, additionally stabilising the complex, was discovered in the species Ni(AMP)H_2(Spm). Results of the equilibrium study for the species Ni(AMP)H_2(3,3,3-tet) indicated that only one nitrogen atom from the polyamine was involved in the coordination. © 2002 Elsevier Science Ltd. Keywords: Ni(II); Co(II); Tetramines; Adenosine 5′-monophosphate; Mixed-ligand complexes

1. Introduction

The reactions of complexation of metal ions with nucleic acids and their constituents (nucleotides, nucleosides) determine the character of many chemical processes taking place in living organisms and hence are important from biological and clinical points of view [1,2]. The results of a recent study proved the formation of molecular complexes including fragments of nucleic acids and biogenic amines (putrescine, spermidine, spermine and their analogues) present practically in all living cells [3–6]. The contents of polyamines (PA) in cells depend on the kind and age of the tissue, and according to the collected evidence, these biomolecules affect such processes as cell differentiation and proliferation, enzyme activity, DNA replication, synthesis of proteins and stabilisation of membranes [7–13]. The biogenic amines stabilise nucleic acids and prevent their thermal denaturation [14] or enzymatic degradation [15]. The interactions of polyamines are also essential for DNA packing into phage heads [16] and in condensation of native DNA [17,18]. It has been noted that such diseases as cancer, psoriasis and sickle cell anaemia are accompanied by an increase of polyamine concentration in cells [19–22]. Unfortunately, the functions of polyamines, mechanisms of their interactions and role in genetic information transfer, including development of neoplasmic diseases, have not been fully recognised yet [6,7]. The hypothesis claiming that the main factor determining the character of interactions is the charge of the protonated polyamine [23] does not explain the specificity of a number of reactions. Of course, the charge is one of the most important factors determining the character of the reaction in which a given polyamine is involved, but many data seem to indicate a significant

PII: S0277-5387(02)00849-5

role of the structural factor [3–5,8,24–26]. Investigation of the intermolecular interactions in living organisms should be performed taking into regard the fact that the reaction centres usually are the donor atoms of biomolecules which are also the sites of metal ion binding. Therefore, the metal ions should be treated as interfering agents. To gain more information on the biological significance of the reactions and the role of metal ions, studies of model systems have been undertaken. This paper reports results of investigation of model systems containing metal ions, adenosine 5′-monophosphate and polyamines.

2. Experimental

Adenosine 5′-monophosphate (AMP) (disodium salt), spermine hydrochloride (Spm·4HCl) and 1,11-diamino-4,8-diazaundecane (3,3,3-tet) were purchased from Sigma. The tetrachloride of 1,11-diamino-4,8-diazaundecane (3,3,3-tet·4HCl) was obtained by mixing one chemical equivalent of the amine suspended in methanol with four chemical equivalents of a water–methanol solution of HCl. The salt obtained was dried over P_4O_{10}. Results of the elemental analysis were consistent with the theoretical results ($\pm 0.5\%$). Nickel(II) and cobalt(II) nitrates (from POCh, Poland) were purified by twice repeated crystallisation from water solution. The concentrations of nickel and cobalt ions in parent solutions were determined by complexometry [27]. The potentiometric titration was performed using an instrument made by Methrom (713 pH Meter, 725 Dosimat, electrode 6.0233.100, after calibration [28]). All potentiometric measurements were carried out at 20 ± 1 °C, at a constant ionic strength of 0.1 M (KNO_3), in a neutral gas atmosphere (helium) and at a metal:AMP:-polyamine ratio varied from 1:2:2 to 1:3.5:3.5 (the concentrations of AMP and polyamine were varied from 0.001 to 0.003 M). The titrant was a CO_2-free solution of NaOH. The composition and stability constants of the complexes forming in the systems studied were determined on the basis of a computer analysis of the results of potentiometric titration with the use of the program SUPERQUAD [29]. The species distributions were found with the use of the program HALTAFALL [30]. Measurements of ^{13}C and ^{31}P NMR were performed in D_2O, while pD values of the solutions were corrected according to the formula pD = pH reading +0.40 [31]. The ligand concentration in the samples for NMR study varied from 0.05 to 0.1 M at a metal:ligand ratio from 1:50 to 1:90. NMR measurements were carried out on a Gemini 300 Varian and Unity 300 Varian spectrometer with dioxane as internal standard for ^{13}C NMR and H_3PO_4 as internal standard for ^{31}P NMR. The concentrations of the components in samples for VIS study (H_2O solutions) were the same as used in the potentiometric measurements. The VIS spectra were recorded on a UV 160 Shimadzu spectrometer.

3. Results and discussion

3.1. Ni(II)/AMP/Spm system

In the Ni(II)/AMP/Spm system, the presence of Ni(AMP)H_4(Spm) and Ni(AMP)H_2(Spm) mixed-ligand complexes was detected (Table 1).

The complex Ni(AMP)H_4(Spm) starts forming from a pH of about 5 and at pH 8 it binds the maximum number of nickel ions, ~80% (Fig. 1).

The composition of this compound, in which all donor nitrogen atoms are fully protonated and blocked for metallation, and the pH range of its occurrence suggest that this is a molecular complex of type ML·····L′, formed as a result of a non-covalent intermolecular interaction. This supposition is confirmed by the value of the equilibrium constant of Ni(AMP)H_4(Spm) formation ($\log K_e = 4.23$, Table 2) which is much smaller than that for the anchoring complex NiSpm ($\log K_e = 7.42$), in which metal ions are bonded by four spermine atoms. The positions of the d–d bands at pH 8 are: $\lambda_{max} = 385$ and 626 nm (Table 3), and they point to coordination of the nickel ion by one nitrogen atom (chromophore {N1}) [27].

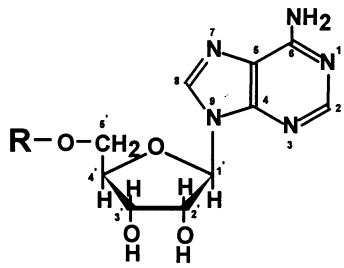
$Co(AMP) + H_4(3,3,3\text{-tet}) \rightleftharpoons Co(AMP)H_4(3,3,3\text{-tet})$	5.01



As a consequence of the interactions related to the formation of the species, in its ^{13}C NMR spectrum (pH 8) the signals assigned to the nucleotide carbon atoms neighbouring the N(1), N(7) donor atoms and phosphate group are changed [C(6), C(2), C(8), C(5) and C(5′) are shifted with respect to their positions in the free ligand spectrum by 0.055, 0.126, 0.033, 0.045 and 0.132 ppm]. Moreover, in the ^{31}P NMR spectrum at pH 8, a shift of the phosphorus atom signal by 0.182 ppm is observed. The signal assigned to C(4), the atom which does not neighbour any donor centres of the nucleotide, is shifted only by 0.014 ppm. Also the signals attributed to all carbon atoms of the polyamine C(1), C(2), C(3), C(4) and C(5) are shifted by 0.246, 0.158, 0.233, 0.416 and 0.194 ppm, respectively (numeric positions of particular atoms of the ligands are given in Scheme 1;

Table 3
Absorption spectral data for Ni(II) and Co(II) complexes with AMP and polyamines (Spm, 3,3,3-tet)

Complexes	λ_{max} (nm)	ε_{max} ($dm^3\ mol^{-1}\ cm^{-1}$)	Chromophore	pH
Ni(AMP)	386, 628	27.4	{N1}	8.0
Ni(AMP)H_4(Spm)	385, 626	24.3	{N1}	8.0
NiH_2(Spm)	377, 627	19.6	{N2}	7.0
Ni(AMP)H_2(Spm)	363, 624	18.1	{N3}	9.0
Ni(AMP)H_4(3,3,3-tet)	383, 624	22.5	{N1}	7.0
Ni(3,3,3-tet)	350, 627	16.3	{N4}	7.0
Co(AMP)	511, 820	23.7	{N1,O}	7.0
Co(AMP)H_4(Spm)	506, 822	22.3	{N1,O}	8.0
Co(AMP)H_4(3,3,3-tet)	502, 818	20.1	{N1,O}	8.0

NMR signals have been assigned on the basis of literature data [33–35]). Thus, bearing in mind the full protonation of all nitrogen atoms of the amine, the pattern of the changes indicates that the metallation and {N1} chromophore formation involve the N(1) and N(7) atoms from the purine ring (the coordination dichotomy—N1/N7) while spermine, involved in non-covalent interactions with the phosphate group of the nucleotide, remains outside the inner coordination sphere of the metal ion. The conclusions from the NMR study are in full agreement with the results of the equilibrium and VIS study, which confirm the possibility of the critical application of nuclear resonance as a supplementary method in analysis of systems with paramagnetic ions as suggested earlier [24,35–38].

Ni(AMP)H_2(Spm) starts forming from pH ~ 7.5, and is dominant in the system at pH 9, binding about 50% of nickel(II) ions (Fig. 1). The equilibrium constant of the reaction of H_2Spm binding to Ni(AMP) is log $K_e = 4.31$. This value is 0.82 log K_e units higher than that of NiH_2Spm complex formation, corresponding to the attraction of H_2Spm to Ni ions (Table 2), which suggests the presence of intramolecular nucleotide–polyamine interactions in the species Ni(AMP)H_2(Spm), additionally stabilising the complex. The positions of the d–d bands at pH 9, when the species Ni(AMP)H_2(Spm) dominates, are 363 and 624 nm, which points to the occurrence of the chromophore {N3} (Table 3) [39]. The shifts of signals in the ^{13}C NMR spectrum indicate the N(1) or N(7) (coordination dichotomy) atoms from AMP and two deprotonated nitrogen atoms of the polyamine as the coordination centres in Ni(AMP)H_2(Spm) [the shifts of the signals of C(6), C(2), C(8) and C(5) from AMP are 0.112, 0.093, 0.101 and 0.079 ppm, respectively, and the shifts for all the

AMP R = H_2PO_3

NH_2-CH_2-CH_2-CH_2-NH-CH_2-CH_2-CH_2-NH-CH_2-CH_2-CH_2-NH_2 3,3,3-tet

NH_2-CH_2-CH_2-CH_2-NH-CH_2-CH_2-CH_2-CH_2-NH-CH_2-CH_2-CH_2-NH_2 Spm

Scheme 1.

carbon atoms from spermine C(1), C(2), C(3), C(4) and C(5) are 0.193, 0.087, 0.203. 0.159 and 0.091 ppm, respectively]. The change in the positions of the C(5′) atom and P atom by 0.134 and 0.157 ppm, suggests that the phosphate group of AMP is involved in the intramolecular interaction additionally stabilising the complex. The proposed model of interactions clarifies the problems related to the mode of Ni(II) coordination in the systems containing both donor nitrogen atoms and oxygen atoms as potential reaction sites [23,40–45].

3.2. The system Co(II)/AMP/Spm

In this system a mixed complex—$Co(AMP)H_4(Spm)$ is formed in the pH range from ~5.5 to 9.5, and at pH ~8 it binds 75% of cobalt ions (Fig. 2). The same reasoning as above, based on the pH range of formation as well as stoichiometric composition of the compound, indicates that it is a molecular complex.

The equilibrium constant of $Co(AMP)H_4(Spm)$ formation is 4.65 (Table 2) and is smaller than that of CoSpm formation (log $K = 7.36$, Table 4), which confirms the molecular character of $Co(AMP)H_4(Spm)$.

The positions of the d–d absorption bands in the spectrum of Co/AMP/Spm at pH 8, where the molecular complex dominates, found at 506 and 822 nm (Table 3) are the same as for the complex CoAMP and it proves that chromophore {N1,O} is formed [27] including N(7) atom and oxygen atoms of the phosphate group (for steric reasons the chelation involving the phosphate group and N(1) atom should be excluded, as shown in Refs. [46–48]), and the fully protonated polyamine is involved in non-covalent interactions mainly with the N(1) atom from the nucleotide. This pattern of interactions is confirmed by analysis of the ^{13}C and ^{31}P NMR

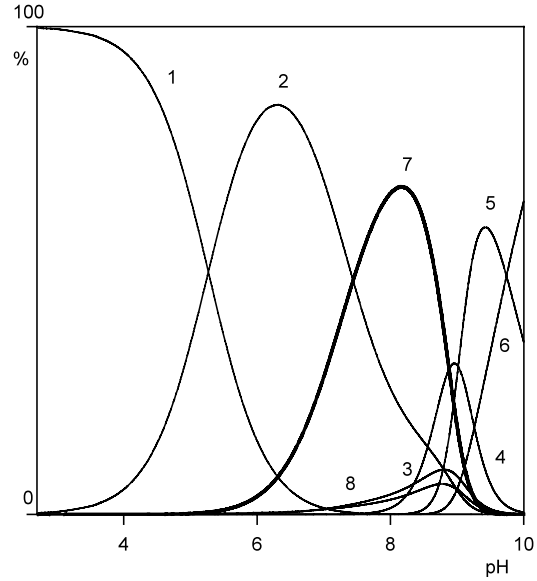


Fig. 2. Distribution diagrams for the Co(II)/AMP/Spm system: (1) $CoH_2(AMP)$; (2) CoH(AMP); (3) Co(AMP); (4) $CoH_2(Spm)$; (5) Co(Spm); (6) Co(Spm)(OH); and (7) $Co(AMP)H_4(Spm)$. $C_{AMP} = C_{Spm} = 0.001$ M; $C_{Co} = 0.0005$ M.

spectra (an explanation of application of NMR investigation of coordination mode with paramagnetic ions was discussed earlier [24]). In the $Co(AMP)H_4(Spm)$ complex at pH 8, changes in signal positions assigned to carbon atoms in the neighbourhood of N(1) and N(7) and the signal from C(5′) as well as from P atom are observed [0.073, 0.067, 0.057, 0.097, 0.063 and 0.121 ppm for C(6), C(2), C(8), C(5), C(5′) and P, respectively]. Moreover, the signals from all carbon atoms of the polyamine C(1), C(2), C(3), C(4), C(5) are shifted by 0.107, 0.131, 0.174, 0.115, 0.127 ppm, respectively.

Table 4
Overall stability constants (log β) of Co(II) complexes with AMP and polyamines (Spm and 3,3,3-tet)

Systems	Species	log β
Co(II)/AMP	CoH(AMP)	11.87(7)
	CoH_2(AMP)	17.14(9)
	Co(AMP)	2.72 (9) [a]
Co(II)/Spm	CoH_2(Spm)	25.39(11)
	Co(Spm)	7.36 (5)
	Co(Spm)(OH)	−2.38(11)
Co(II)/3,3,3-tet	Co(3,3,3-tet)	7.88(4))
Co(II)/AMP/Spm	Co(AMP)H_4(Spm)	46.04(4)
Co(II)/AMP/3,3,3-tet	Co(AMP)H_4(3,3,3-tet)	44.12(7)

[a] Ref. [27].

3.3. Ni(II)/AMP/(3,3,3-tet) system

In the system Ni(II)/AMP/(3,3,3-tet), the complex Ni(AMP)H_4(3,3,3-tet) forms starting from pH ~ 4 and it binds a maximum number of 95% of nickel ions at pH about 7.5, Fig. 3.

The equilibrium constant of its formation (log K_e = 5.41, Table 2), which is smaller than that of the NiH_2(3,3,3-tet) complex (Table 2), the stoichiometry of the compound and the pH range of its occurrence indicate that it is also a molecular complex. In the pH range of its domination the positions of the d–d bands are 383 and 624 nm (Table 3), which corresponds to the formation of the chromphore {N1} [27]. As follows from the analysis of ^{13}C and ^{31}P NMR spectra, analogously as for the species with Spm, the N(1) or N(7) atoms from AMP (coordination dichotomy) take part in the coordination, while the protonated polyamine is involved in non-covalent interactions with the phosphate group of the nucleotide remaining in the outer coordination sphere. The NMR signals assigned to the carbon atoms in the vicinity of N(1), and N(7): C(6), C(2), C(8), C(5), C(5′) are shifted by 0.087, 0.079, 0.091, 0.088, 0.107 ppm, and the signal from the P atom of the nucleotide is shifted by 0.127 ppm. The signals corresponding to the carbon atoms of the polyamine C(1), C(2), C(3), C(4) and C(5) are shifted by 0.057, 0.068, 0.097, 0.059 and 0.077 ppm, respectively.

Another mixed complex Ni(AMP)H_2(3,3,3-tet) forms together with the molecular complex and the coordination compound Ni(3,3,3-tet), which makes it impossible to obtain its spectral data (Fig. 3). The equilibrium constant of Ni(AMP)H_2(3,3,3-tet) formation is 4.50 (species Ni(AMP) is an anchoring complex), while the value of log K_e for NiH_2(3,3,3-tet), in which two deprotonated nitrogen atoms from the polyamine take part in the coordination, is 7.45 (Table 2). The lower value of log K_e for the mixed complex suggests the presence of only one nitrogen atom of the polyamine in the inner sphere of coordination (besides the donor atoms from AMP).

3.4. Co(II)/AMP/(3,3,3-tet) system

In this system the complex Co(AMP)H_4(3,3,3-tet) forms starting from pH ~ 5 and dominates from pH ~ 7.5 binding a maximum 60% of cobalt ions (Fig. 4).

As indicated by the composition of Co(AMP)-H_4(3,3,3-tet) and the pH range of its occurrence, this is a molecular complex of type ML·····L′. The d–d

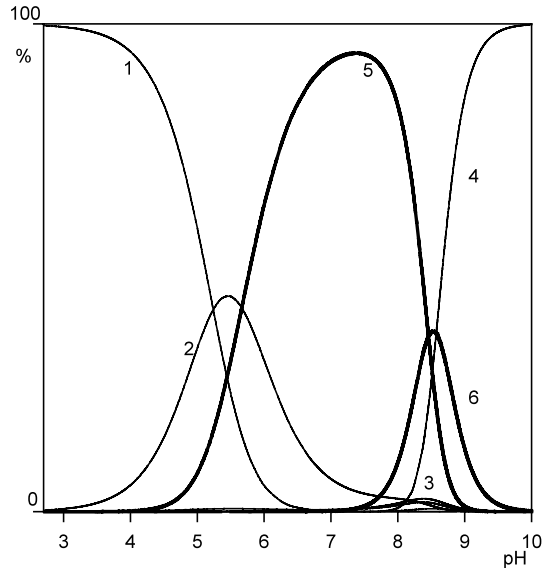

Fig. 3. Distribution diagrams for the Ni(II)/AMP/3,3,3-tet system: (1) NiH_2(AMP); (2) NiH(AMP); (3) Ni(AMP); (4) Ni(3,3,3-tet); (5) Ni(AMP)H_4(3,3,3-tet); and (6) Ni(AMP)H_2(3,3,3-tet). $C_{AMP} = C_{3,3,3tet} = 0.001$ M; $C_{Ni} = 0.0005$ M.

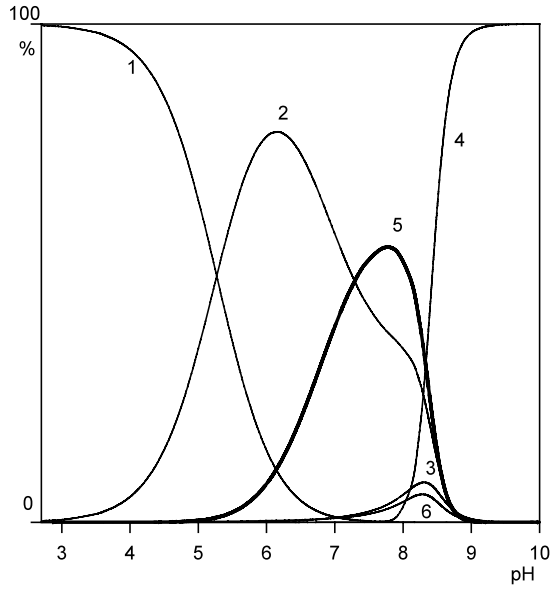

Fig. 4. Distribution diagrams for the Co(II)/AMP/3,3,3-tet system: (1) CoH_2(AMP); (2) CoH(AMP); (3) Co(AMP); (4) Co(3,3,3-tet); (5) Co(AMP)H_4(3,3,3-tet); and (6) Co^{2+}. $C_{AMP} = C_{3,3,3tet} = 0.001$ M; $C_{Co} = 0.0005$ M.

absorption bands in the conditions of Co(AMP)-H_4(3,3,3-tet) domination (pH 8) appear at 502 and 818 nm, so their positions are practically the same as for CoAMP [27]. As follows from the analysis of ^{13}C and ^{31}P NMR spectra, the N(7) atom, the phosphate group from AMP, the N(1) atom from the nucleotide as well as all the protonated nitrogen atoms from the polyamine are involved in this molecular complex formation. The signals assigned to the AMP carbon atoms C(6), C(2), C(8), C(5), C(5′) at pH 8 are shifted by 0.082, 0.099, 0.077, 0.105, 0.179 ppm, respectively, the signal ascribed to the phosphorus atom is shifted by 0.154 ppm, and the signals from the polyamine carbon atoms C(1), C(2), C(3), C(4) and C(5) are shifted by 0.081, 0.085, 0.073, 0.050, 0.073 ppm, respectively. The position of the signal assigned to the C(4) atom, which is not located close to any of the donor atoms, is changed only by 0.011 ppm. The presented pattern of changes in the spectra of the studied system proves that Co(II) in Co(AMP)H_4(3,3,3-tet) binds N(7) and the oxygen atoms from the AMP phosphate group (chromophore {N1,O}), while the fully protonated polyamine is involved in non-covalent interactions mainly with the N(1) atom and remains in the outer coordination sphere.

The above-discussed evidence proves the formation of molecular complexes of type ML$\cdots\cdots$L′, e.g. M(AMP)-H_4(PA) but with different modes of coordination in all systems considered. The nickel ions prefer the coordination with donor nitrogen atoms from AMP (coordination dichotomy was found), whereas the cobalt ions bind the N(7) atom and the phosphate group from the nucleotide. Differences also appear in the character of the non-covalent interactions between the fully protonated polyamine and the nucleotide (PA remains in the outer sphere of coordination). In the nickel(II) complexes, the main centre of non-covalent interactions is the phosphate group, while in the cobalt(II) compounds such a centre is the N(1) atom.

In the diprotonated complexes Ni(AMP)H_2(Spm) and Ni(AMP)H_2(3,3,3-tet), significant differences were found in the character of interactions of the two polyamines with the anchoring Ni(AMP) species. In Ni(AMP)H_2(Spm) two nitrogen atoms from the polyamine take part in the coordination of the nickel ion and the complex is additionally stabilised by the interaction of the two protonated nitrogen atoms from spermine with the phosphate group of the nucleotide. In Ni(AMP)H_2(3,3,3-tet), according to the results of the equilibrium study, only one nitrogen atom from the polyamine takes part in the coordination of the nickel(II) ion.

Moreover, as follows from our results, besides the charge value of protonated PA, the structure (length) of PA is also an essential factor in the types of interaction observed and the polyamine cations should not be considered as point charges as it has been sometimes suggested in the studies of model systems.

Abstract

Reaction of 2-(arylazo)pyrimidines ($R-C_6H_4-N=N-C_4H_3N_2$, abbreviated aapm; R = H (papm), *o*-Me (*o*-tapm), *m*-Me (*m*-tapm), *p*-Me (*p*-tapm), *p*-Cl (*p*-Clpapm)) with $(NH_4)_2[OsCl_6]$ in 2-methoxyethanol gives two isomers of composition $OsCl_2(aapm)_2$. They are structurally characterised by ^1H NMR spectra and established as the *cis–trans–cis* (*ctc*) and *cis–cis–cis* (*ccc*) isomer. With reference to the coordination pairs of Cl; N(pyrimidine) (N) and N(azo) (N′), the structure of *ctc*-$OsCl_2(p\text{-tapm})_2$ is confirmed by an X-ray diffraction study. The complexes exhibit multiple MLCT transitions in the visible to near-IR region. Redox studies show an Os(III)/Os(II) couple at 1.2–1.3 V and Os(IV)/Os(III) couple at ~2 V versus SCE. EHMO calculations and comparison with analogous ruthenium(II) complexes explain the spectral and redox properties of the complexes. © 2002 Published by Elsevier Science Ltd.

1. Introduction

The coordination complexes of heterocycles continues to be of attraction and their applications encompass catalysis, organic synthesis and bioinorganic chemistry [1,2]. Incorporation of an arylazo group into the heterocycle backbone gives arylazoheterocycles [3–33]. They have been used to stabilise low-valent metal redox states [3–20]; oxo-metal complexes [21–23], for the purpose of colouring and dyeing agents [24,25], metallo-chromic indicators in analytical chemistry [26–28] and some of them exhibit novel electrochemistry or non-linear optical properties [4,10,29,30]. The heterocycle moiety may be hooked to polymeric bed by an azo group and has been used in micro scale solid-phase extraction process [31,32]. Electronic property and π-acidity of arylazoheterocycles have largely been dependent on the nature and number of heteroatoms, ring size and the substituent type in the rings [34,35]. With this background, we have initiated a programme to study the chemistry of the azoimine function in the pyrimidine heterocycle [16–19]. It is chosen because of its higher π-acidity than conventional widely used pyridine bases [34,35] and its biochemical importance [1,36,37]. The ruthenium chemistry of arylazopyrimidines has already been developed by our group [17]. In this report we describe the synthesis, spectral studies, redox property and single-crystal X-ray structure of one of the isomers of osmium(II) complexes of 2-(arylazo)pyrimidines (aapm). The electronic properties of osmium(II) complexes are different from that of ruthenium(II)–arylazopyrimidine [17] complexes and have been interpreted from theoretical calculations using EHMO approximation.

2. Experimental

2.1. Materials

Osmium tetroxide was purchased from Johnson Matthey. $(NH_4)_2[OsCl_6]$ and 2-(arylazo)pyrimidine were prepared following the literature procedures [6,38]. All other chemicals, solvents, their purification process used for different measurements, etc. were described in Ref. [17].

2.2. Preparation of complexes: ctc and ccc-dichloro-bis-[2-(phenylazo)pyrimidine]osmium(II), $OsCl_2(papm)_2$ (blue–violet ctc (**2a**); red–violet ccc (**3a**))

To brown–red solution of $(NH_4)_2[OsCl_6]$ (0.5 g, 1.14 mmol) in 2-methoxyethanol (50 cm^3) nitrogen gas was bubbled continuously and refluxed on an oil-bath for 20 min. 2-(Phenylazo)pyrimidine (0.44 g, 2.4 mmol) in ethanol (10 cm^3) was added in drops to this refluxing solution over another half-an hour. The mixture was refluxed under nitrogen with magnetic stirring for 24 h. During this period, the solution turned brown–violet to blue–violet. This was concentrated to about 20 cm^3 by slow bubbling of N_2 gas. The solution was cooled to room temperature and kept in refrigerator overnight. The shining dark coloured crystalline precipitate was collected by filtration and washed with ethanol–water (1:1, v/v) and dried over P_4O_{10}. The dried product was dissolved in a small volume of CH_2Cl_2 and was chromatographed on an alumina (neutral) column. A small portion of orange–red band was eluted with benzene and rejected. Blue–violet band was eluted using 4:1 (v/v) benzene–acetonitrile. Red–violet band was eluted by acetonitrile. The solutions were collected separately and evaporated slowly in air. The crystals so obtained were dried over P_4O_{10}. The yields were of blue–violet *ctc*-$OsCl_2(papm)_2$ (**2a**), 38% and red-violet, *ccc*-$OsCl_2(papm)_2$ (**3a**), 11%.

All other complexes were prepared by following the identical procedure and the yields were varied between 30–50% for the blue–violet isomers and 10–15% for the red–violet isomers.

2.3. X-ray crystallography

Crystal that was suitable for X-ray diffraction study of *ctc*-$OsCl_2(p\text{-tapm})_2$ (**2d**) was grown by slow diffusion of hexane into a dichloromethane solution at 298 K (crystal size (mm): $0.2 \times 0.2 \times 0.1$). Data were collected on a Siemens SMART CCD diffractometer with graphite monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K. Crystal data and collection parameters are listed in Table 1. The data were corrected for absorption effects by empirical method using azimuthal scan data. Systematic absences led to the identification of space group $P\bar{1}$. Of 7753 collected reflections 3530 with $I > 2\sigma(I)$ were used for the structure solution. The structure was solved by the conventional heavy-atom method and was refined by the full-matrix least-squares method on all F_o^2 data using SHELXTL 5.03 package on silicon Graphics Indigo-R4000 computers. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters which were 1.2 aromatic (H) times the equivalent isotropic thermal parameters of their parent carbon atoms.

[a] $R = \Sigma|F_o - F_c|/\Sigma F_o$.
[b] $wR = [\Sigma w(F_o^2 - F_c^2)/\Sigma wF_o^4]^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (0.0604P)^2]$, $P = (F_o^2 + 2F_c^2)/3$.
[c] Goodness-of-fit is defined as $[w(F_o - F_c)/(n_o - n_v)]^{1/2}$ where n_o and n_v denote the number of data and variables, respectively.

3. Results and discussion

3.1. Synthesis and assignment of isomers

2-(Arylazo)pyrimidines (aapm, **1**) possess the azoimine, –N=N–C=N–, functional group and the donor centres are N(pyrimidine), N and N′. Analogues that have been used in this work are 2-(phenylazo)pyrimidine (papm, R = H, **1a**), 2-(*o*-tolylazo)pyrimidine (*o*-tapm, R = 8-Me, **1b**), 2-(*m*-tolylazo)pyrimidine (*m*-tapm, R = 9-Me, **1c**), 2-(*p*-tolylazo)pyrimidine (*p*-tapm, R = 10-Me, **1d**), 2-(*p*-chlorophenylazo)pyrimidine (*p*-Clpapm, R = 10-Cl, **1e**).

aapm

1

The reaction of aapm with $(NH_4)_2[OsCl_6]$ in 2-methoxyethanol–ethanol proceeds shortly under refluxing condition and upon concentrating dark-coloured crystals of composition $OsCl_2(aapm)_2$ (**2/3**) were isolated (Eq. (1)).

$$OsCl_6^{2-} + 2aapm \rightarrow OsCl_2(aapm)_2 + 4Cl^- \quad (1)$$

The product was purified by chromatographic separation on alumina (neutral) bed to give blue–violet (isomer A) and red–violet (isomer B) complexes. The alcoholic solvent may be responsible [6] for the reduction of Os(IV) to Os(II) in Eq. (1). Microanalytical (Table 3) data support the composition of the complexes $OsCl_2(aapm)_2$. Blue–violet and red–violet isomers are assigned to **2** and **3**, respectively. The complexes are diamagnetic in the crystalline state and are non-electrolytic in nitromethane and acetonitrile. Isomers are soluble in common organic solvents to give blue–violet (for **2**) and red–violet (for **3**) solution. The blue–violet isomer ($OsCl_2(p$-tapm$)_2$ (**2d**)) has been characterised by X-ray crystallographic method.

3.2. Structure of blue–violet $OsCl_2(p$-tapm$)_2$ (**2d**)

A view of the molecule is shown in Fig. 1. The coordination around osmium is approximately octahedral. The atomic arrangement involves sequentially *cis*-chlorine, *trans*-N(pyrimidine) and *cis*-N(azo) and is abbreviated *cis–trans–cis* (*ctc*) configuration (C_2-symmetry). Selected bond parameters are listed in Table 2.

Two atomic groups Os, Cl(1), N(22), N(27), N(2) and Os, Cl(2), N(22), N(7), N(2) constitute two planes (mean deviation < 0.04 Å) and are orthogonal (dihedral angle 91.87°). The atomic groups Os, Cl(1), Cl(2), N(7), N(27) do not constitute a good plane and is deviated by ~ 0.16 Å. The distortion from octahedral geometry is due to acute chelate bite angle 76.4(3)°. The azo nitrogens, N(7) (deviation, 0.16 Å) and N(27) (deviation, -0.15 Å) are

N(1)–N(7)	1.320(10)	N(2)–Os–Cl(2)	94.1(2)
N(21)–N(27)	1.329(11)	N(22)–Os–Cl(1)	96.1(2)
C(1)–N(2)	1.368(11)	N(27)–Os–Cl(2)	84.9(2)
C(1)–N(6)	1.328(12)	N(7)–Os–Cl(1)	86.9(2)
C(21)–N(22)	1.350(12)	N(7)–Os–Cl(2)	169.7(2)
C(21)–N(26)	1.348(13)	N(27)–Os–Cl(1)	170.2(2)
		N(27)–Os–N(2)	101.7(3)
		N(7)–Os–N(22)	101.6(3)
		N(22)–Os–Cl(2)	88.0(2)

associated with this distortion. Each chelate ring constitutes a good plane and no atom deviating by more than 0.04 Å. The dihedral angle between the chelate rings is 105.83°. The pendant *p*-tolyl ring is twisted by 36–54° from the respective chelate ring plane.

The Os–N(pyrimidine) [Os–N(2) = 2.029(7), Os–N(22) = 2.030(8) Å] bond distance is longer than Os–N(azo) [Os–N(7) = 1.974(7), Os–N(27) = 1.967(8) Å] bond distance (Table 2). The N=N distances are 1.32–1.33 Å elongated by 0.07 Å compared to free azo distance (1.26 Å) [6,39]. The coordination can lead to a decrease in the N–N bond order due to both σ-donor and π-acceptor characters of the ligand. The elongation of the N–N distance and shortening of Os–N(azo) bond length are thus an indication of the existence of considerable Os–aapm π-bonding with major involvement of the azo group.

Comparison of bond distances between ruthenium(II) [17] and osmium(II) complexes (Fig. 2) reveals that the

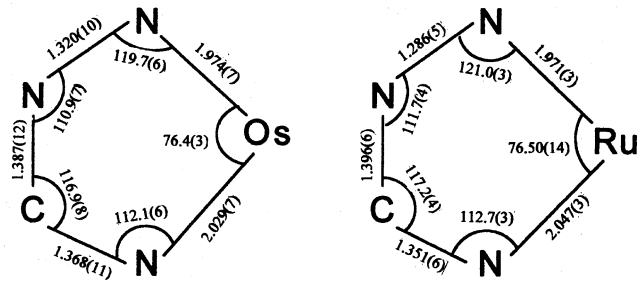

Fig. 2. Dimensions of chelate rings with e.s.d. of: (a) *ctc*-$OsCl_2$(*p*-tapm)$_2$ (**2d**) and (b) *ccc*-$OsCl_2$(*p*-tapm)$_2$ (**3d**).

N–N distance is elongated by 0.03 Å in the latter complex, the C–N distances vary only slightly. The systematic shortening of M–N(azo) distance compared to M–N(pyrimidine) distance in Ru(II) and Os(II) complexes is a further indication of the presence of stronger M–azo π-bonding. The Os–N(pyrimidine) bond distance is shortened by 0.02 Å compared to Ru–N(pyrimidine) bond distance suggesting the π-interaction order Os > Ru.

3.3. Spectral studies

The infrared spectra of the isomers differ significantly in the region 4000–200 cm^{-1}. All the complexes exhibit intense bands at 1530–1560 and 1340–1370 cm^{-1}, corresponding to C=N and N=N stretching, respectively. It is observed that endocyclic C=N is shifted to lower frequency region by 60–90 cm^{-1} and ν(N=N) is reduced by 140–150 cm^{-1} [6,17]. This supports the *N*,*N*′-chelation to osmium(II). The spectra are in agreement with the π-bonding scheme in the order Os–N(azo) > Os–N(pyrimidine) (vide supra). The N=N frequency of $OsCl_2(aapm)_2$ are systematically lowered (by 30–60 cm^{-1}) more than that of $RuCl_2(aapm)_2$ [17]. The spectra exhibit two medium intense bands at 300–310 and 320–330 cm^{-1} corresponding to two Os–Cl bonds. This supports the *cis*-$OsCl_2$ configuration in the complexes.

The vibrational spectra of isomer A, $OsCl_2(aapm)_2$ and *ctc*-$RuCl_2(aapm)_2$ are nearly superimposable in the above region [17] except for frequency shifting of N=N and C=N stretching bonds to the lower frequency region. Isomer B is similar to the spectrum of *ccc*-$RuCl_2(aapm)_2$. These observations suggest that the isomer A (blue–violet compound) has the *cis–trans–cis* (**2**) and isomer B (red–violet compound) has the *cis–cis–cis* (**3**) configuration.

The solution electronic spectra of the complexes in $CHCl_3$ exhibit multiple bands and shoulder in the region 250–1200 nm (Table 3). The absorption below 400 nm is due to intraligand charge transfer transitions ($n \rightarrow \pi^*$, $\pi \rightarrow \pi^*$) and are not considered further. High intense absorptions ($\varepsilon \sim 10^4$) are observed in the range 410–430, 510–530, 560–640 nm along with two weak shoulders ($\varepsilon \sim 10^3$) at longer wavelength region 700–730 and 900–1030 nm. Main absorption bands are assigned to $t_2 \rightarrow \pi^*$charge transfer transitions where the π*orbital has a large azo character [6,35]. The spectral comparison (Fig. 3) show that the profile pattern is comparable and the bands are blue shifted by 10–100 nm on going from *ctc*-$OsCl_2(aapm)_2$ to *ccc*-$OsCl_2(aapm)_2$ complexes. In d^6-metal complexes, multiple $t_2(Os) \rightarrow \pi^*$ charge-transfer transition [6,38] can occur from low symmetry splitting of the metal level from the presence of more than one interacting ligands (each contributing π* orbital(s)) and from mixing of singlet and triplet configuration in the excited state via spin–orbit coupling. Comparison of the electronic spectra of the present series of complexes and those of $RuCl_2(aapm)_2$ reveal that the transitions are blue shifted by 30–150 nm on going from ruthenium(II) to osmium(II) complexes. The spectral behaviour of $OsCl_2(aapm)_2$ is comparable to that of $OsCl_2(aap)_2$ [aap = 2-(arylazo)pyridine]; the absorption positions are red shifted by 20–35 nm on going from $OsCl_2(aap)_2$ to $OsCl_2(aapm)_2$. This is in agreement with the π-acidity order, arylazopyridine > arylazopyrimidine [34,35].

The ^{1}H NMR spectra of the complexes were recorded in $CDCl_3$ and were compared with the spectra of free ligands and analogous ruthenium(II) complexes. The proton-numbering patterns are shown in aapm (**1**) and are assigned on the basis of spin–spin interaction and the effect on substitution therein. Protons in two-aapm units of $OsCl_2(aapm)$ are separately assigned as H and H^1. The spectral data are summarised in Table 4. The Ar–Me signal has been particularly useful in determining isomer configuration. *ctc*-$OsCl_2(tapm)_2$ (**2b–2d**) have C_2-symmetry and are expected to exhibit a single Ar–Me signal while the *ccc*-$OsCl_2(tapm)_2$ (**3b–3d**) are C_1-symmetric and are expected to exhibit two –Me signals of equal intensities. This is indeed observed (Fig. 4). The pyrimidine protons (4–6-H) [16] appear at higher frequency region (7.4–9.3 ppm) and the signals at 6.6–7.4 ppm are due to azoaryl protons (8–12-H). The doublet at approximately 9.3 ppm refers to 4-H because of the closest position to the metal centre followed by the 6-H (ca. 8.8 ppm) and 5-H shows multiplet at approximately 7.4 ppm. Aryl protons (8–12-H) in the present complexes have been perturbed in a peculiar manner. Usually 8,12-H appears at lower frequency side compared to 9–11-H signals because of the closest position of the electron withdrawing azo group. Besides, the substitution 10-R perturbs 9 and 11-H more profoundly than 8,12-H. The electron donating substituent (–Me group in *p*-tapm) shifts 9- and 11-H to lower frequency region while the electron withdrawing group (–Cl group in *p*-Clpapm) shifts them to higher frequency side relative to phenyl-H. This has been observed in the free ligand, aapm [16] and complexes of ruthenium(II) [17] and palladium(II) [18]. It is

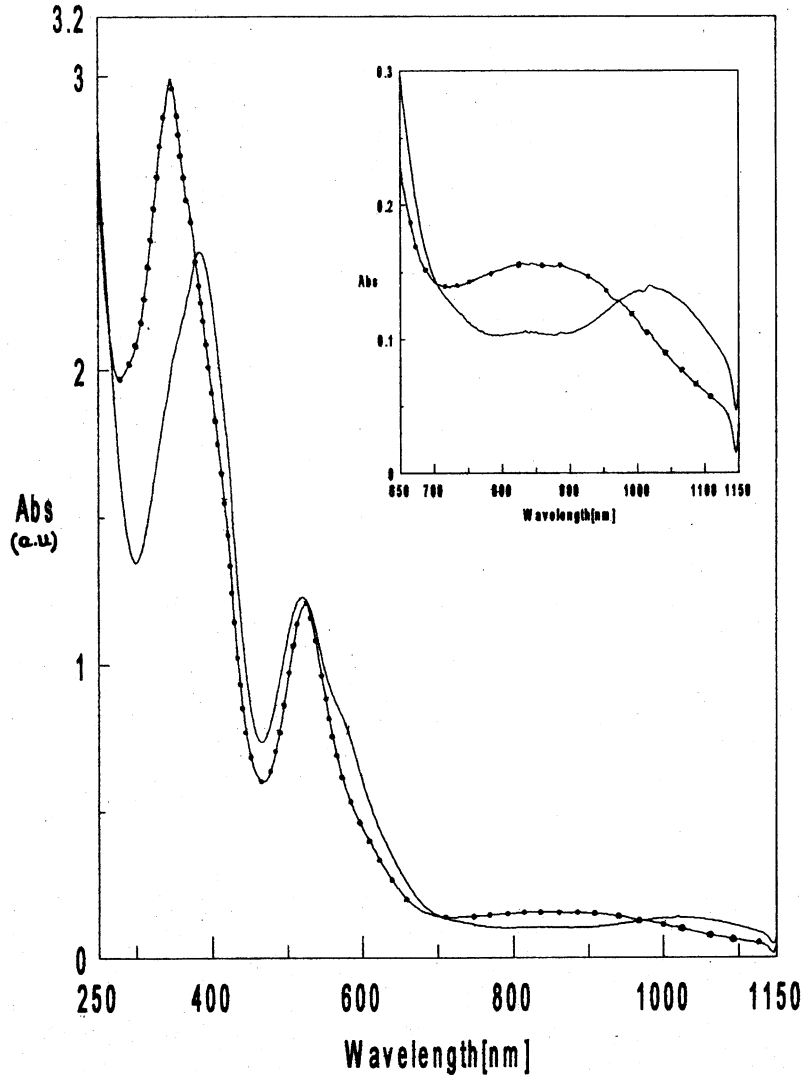

Fig. 3. Electronic spectra of *ctc*-$OsCl_2$(*p*-clpapm)$_2$ (**2e**) (—) and *ccc*-$OsCl_2$(*p*-clpapm)$_2$ (**3e**) (- - -) in $CHCl_3$ at 298 K.

observed that a doublet (2H) appears at lowest frequency side in the *ctc*-$OsCl_2$(*p*-Raapm)$_2$ (av. 6.6 ppm) which feels little perturbation on substitution at aryl ring (*p*-R) and second doublet perturbes significantly. The former doublet has been assigned to 8,12-H and the second doublet refers to the signal corresponding to 9,11-H. In $OsCl_2$(*o*-tapm)$_2$ (**2b/3b**) and $OsCl_2$(*m*-tapm)$_2$ (**2c/3c**) aryl-H are unsymmetrical. In $OsCl_2$(*m*-tapm)$_2$(**2c/3c**) a singlet (1H) resonance is observed at 6.55 ppm that is unambiguously assigned to 8-H and is followed by a doublet (6.60 ppm) for 12-H. This unusual proton movement may be concluded on considering the charge delocalisation, $t_2(Os) \rightarrow \pi^*$ orbitals. Thus, 8-H and 12-H protons are affected first and feel severe perturbation. This observation mismatches with our experience on isoelectronic ruthenium(II) complexes [17]. Because of the relativistic effect [40], 5d orbitals in Os(II) have been perturbed more effectively than that of 4d-orbitals of Ru(II) by the π acidic ligands and hence the reverse swings of charge densities.

3.4. Electrochemistry

The electrochemical properties of the complexes have been examined by cyclic volammetry on a platinum milli working electrode in super dry MeCN using $[Bu_4N][ClO_4]$ (0.1 M) as supporting electrolyte. Electrochemical data are given in Table 3 and a representative voltammogram is shown in Fig. 5. In the potential range +0.5 to +2.4 V at a scan rate 50 mV s^{-1} a nearly reversible osmium(III)–osmium(II) couple (2) is observed with peak-to-peak separation of 70–80 mV.

$$OsCl_2(aapm)_2^+ + e \rightleftharpoons OsCl_2(aapm)_2 \quad (2)$$

The formal potential, E^0_{298}, lies close to 1.2 V and is the highest potential amongst the known complexes of

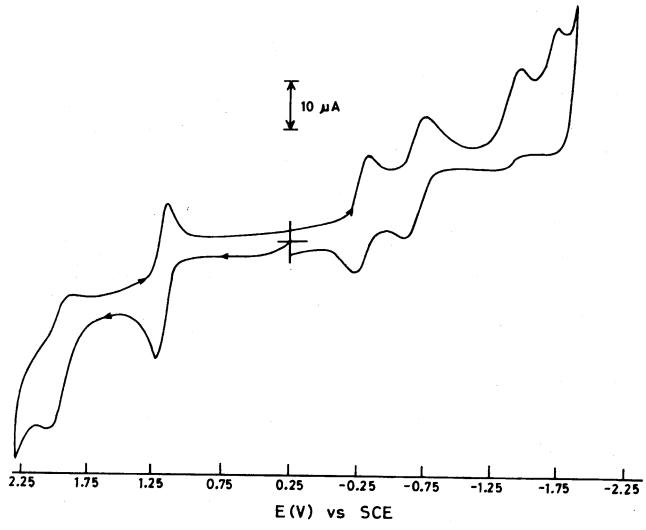

Fig. 5. Cyclic voltammogram of *ctc*-$OsCl_2(p\text{-tapm})_2$ in MeCN using Pt-disc working electrode. The solute concentration and scan rate are 10^{-3} M and 50 mV s^{-1}, respectively.

the azoimine system. A second one-electron response observed at approximately 2 V (close to solvent cutoff limit) is quasireversible ($\Delta E_p = 140$–180 mV) in nature. This is assigned to the osmium(IV)–osmium(III) redox couple [6]. The data reveal that between the two isomers the order of E^0_{298} is $tc > cc$. The one-electron stoichiometry of the first couple was established by controlled potential coulometry of one complex *ctc*-$OsCl_2(papm)_2$ at potential 1.4 V versus SCE using Pt-net working electrode. The solution colour changes from blue–violet to brown–red. Reported potentials are higher than those of osmium(II)–arylazopyridines which may be due to π-acidity order of pyrimidine > pyridine [34,35]. The azopyridine ligands thus stabilise (with respect to oxidation) osmium(II) better than the azopyridines. Reductions are observed in the potential range 0 to −2.0 V using glassy-carbon working electrode. Four successive redox couples are observed (Table 3); the first two couples are quasi-reversible ($\Delta E_p = 100$–140 mV) in nature. The remaining two responses at negative to SCE do not exhibit reasonable anodic peaks on scan reversal. These reductions are believed to be the successive electron addition into two azoimine functions [4,6,17].

3.5. EHMO calculation

Approximate composition studies of the frontier orbitals in osmium(II) complexes of 2-(arylazo)pyrimidine were performed by the extended Hückel calculation on a model complex of *ctc*-$OsCl_2(p\text{-tapm})_2$. Similar calculation has also been carried out to ruthenium(II) analogues. Since crystallographic data for *ctc*-$RuCl_2(p\text{-tapm})_2$ are not available with us; herein, we are using crystal data of *ccc*-$RuCl_2(papm)_2$ [17] for gross comparison of spectral and electrochemical properties with osmium(II) complexes. The calculated molecular orbitals, have been used in order to assess the solution spectra and redox properties of the osmium(II) complexes and their comparison with ruthenium(II) complexes. The HOMO and LUMO of the complexes are depicted in Fig. 6. In osmium(II) complex, the HOMO ($E_{HOMO} = -11.152$ eV) is constituted by 81% metal d-orbitals and the LUMO ($E_{LUMO} = -10.768$ eV) is composed of 68% ligand orbitals. The azoimine function contributes 42% to the LUMO.

In *ccc*-$RuCl_2(p\text{apm})_2$, the HOMO ($E'_{HOMO} = -11.316$ eV) is composed of 77% d(Ru) and the LUMO ($E'_{LUMO} = -10.510$ eV) is 59% ligand orbitals. In ruthenium complex the HOMO is laying 0.164 eV below than the HOMO of osmium complex and the LUMO is stabilised by 0.258 eV in osmium complex compared to ruthenium complex. Thus, the energy difference between HOMO and LUMO is higher in $RuCl_2(aapm)_2$ than $OsCl_2(aapm)_2$. This is also observed in the ordering of MLCT transitions.

The EHMO results suggest that the HOMO, HOMO-1, HOMO-2, etc. are predominantly metal character and LUMO, LUMO+1, LUMO+2 are basically π*-ligand character. So, multiple charge transfer transitions may be observed. This is indeed observed. Energy difference determines the MLCT transitions and explains the shorter wavelength absorption of osmium complexes

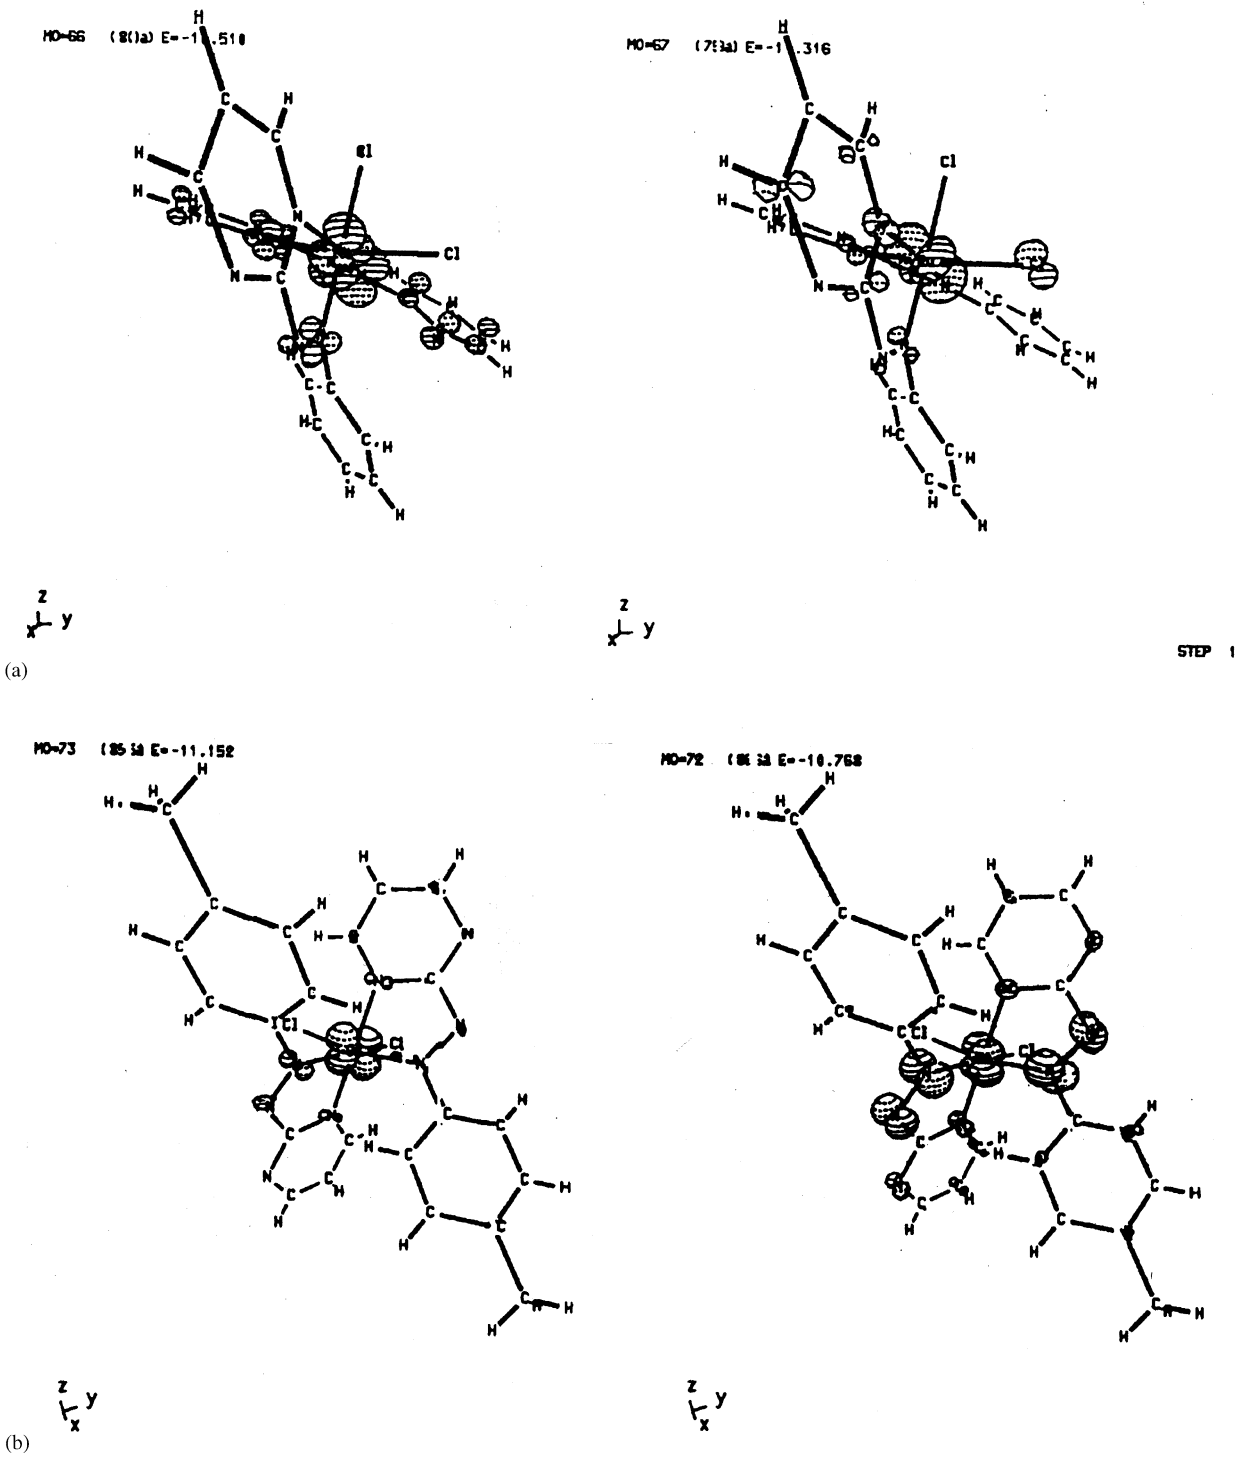

Fig. 6. Frontier orbitals, HOMO and LUMO of: (a) *ctc*-$OsCl_2(p\text{-tapm})_2$ and (b) *ccc*-$RuCl_2(p\text{-papm})_2$.

than that of ruthenium complexes. In cyclic voltammetric experiment the complexes exhibit both metal oxidations and ligand reductions. The oxidation involves electron extraction from HOMO which is metal orbital dominated and the reduction involves electron accommodation at LUMOs. Because of higher energy of HOMO of osmium complex (−11.152 eV) compared to ruthenium complex (−11.316 eV) the Os(III)/Os(II) and Os(IV)/Os(III) couples appear at higher potentials than that of Ru(III)/Ru(II) and Ru(IV)/Ru(III) complexes, respectively. The energy of LUMO of osmium complex is lower than that of ruthenium complex. Thus reduction of ligand is observed at lower potential in osmium complexes than ruthenium complexes (Table 3).

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 168654 for compound **2d**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 28 August 2001; accepted 10 December 2001

Abstract

The sodium(I) chloride and yttrium(III), lanthanum(III), samarium(III) and gadolinium(III) nitrate complexes of 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis(piperidinylcarbonyl)methylene)calix[4]arene were prepared in direct reaction of the ligand and appriopriate metal salts and characterized by spectral data (IR, UV–Vis, ^{1}H NMR, FAB MS), and elemental analysis. The transmetallation reactions of the sodium complex by the lanthanide ions was also achieved. The crystal structures of the ligand and its sodium complex were determinated by single X-ray analysis. © 2002 Published by Elsevier Science Ltd.

Keywords: *tert*-Butylcalix[4]arenes; Amide; Sodium complexes; Yttrium(III) complexes; Lanthanide(III) complexes; X-ray structures

1. Introduction

Calixarenes have been widely used in the last 15 years in supramolecular chemistry. The high preorganization and complementarity with the guests make these macrocycles hosts a rich source for molecular receptors [1–3]. Functionalization at the lower rim may lead to the design and synthesis of the ligands suitable for various metal complexation. We have recently reported on the synthesis of new series of lower rim substituted *tert*-butylcalix[4]arenes and their complexing properties in ion-selective PVC membrane electrodes [4]. In this paper we present the preparation and characterization of 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis-O(piperidinylcarbonyl)methylene)calix[4]arene (**L**) complexes with the hard cations as sodium and rare earth ions. The crystal structure of the ligand and its complex with sodium ion is also described.

2. Experimental

5,11,17,23-tetra-*tert*-Butyl-25,26,27,28-trakis(piperidinylcarbonyl)methylene)calix[4]arene (**L**) was prepared according to the procedure published earlier [4]. The hydrated yttrium and lanthanide(III) nitrates were prepared by dissolving the 99.99% oxides (Fluka) in a slight excess of nitric acid. The solutions were evaporated and precipitates recrystallized from methanol.

2.1. Preparation of the complexes

2.1.1. Sodium(I) chloride complex of *L*

To *p*-*tert*-butylcalix[4]arene (1 mmol) in 30 cm^3 of the of dried tetrahydrofuran (THF) and dimethylformamide (DMF) (5:1) 10 mmoles of sodium hydride (55% in oil) was added followed by addition of piperidide of α-

chloroacetic acid in twofold excess (8 mmol). The mixture was heated and stirred at 80 °C for 20 h. The solvent was removed by evaporation, the residue was quenched with 20 ml of water and extracted twice with methylene chloride (2 × 25 ml). The combined organic layers were washed with water, dried with $MgSO_4$ and after removing the solvent under reduced pressure the product as sodium complex was obtained with 82% yield; melting point (m.p.) 245–50 °C.

2.1.2. Crystallization

The complex Na**L**Cl (0.05 mmol) was dissolved in 10 cm^3 of refluxing methanol and left at room temperature. After 2 days crystals suitable for X-ray analysis precipitated; m.p. 248–51.

2.1.3. Na**L**Cl (**2**)

IR (cm^{-1}): 1655 s, ν(C=O), 293 m (Cl); FAB MS: $m/z = 1172.5$ $(Na\mathbf{L})^+$. ^1H NMR ($CDCl_3$, ppm): δ 1.15 (s, 36H, *t*-but), 1.67 (br, s, 24H, $(CH_2)_3$), 3.22 (br, s, 8H, NCH_2), 3.32 (d, $J = 12.5$ Hz, 4H, $ArCH_2,H_{eq}$), 3.62 (br, s, 8H, NCH_2), 4.48 (d, $J = 12.5$ Hz, 4H, $ArCH_2,H_{ax}$), 4.6 (s, 8H, $OCH_2C{=}O$), 7.12 (s, 8H, H_{arom}).

2.1.4. Yttrium(III), lanthanum(III), samarium(III) and gadolinium(III) nitrate complexes of **L**

2.1.4.1. Direct complexation reaction. All complexes were performed under similar conditions. To a solution of metal nitrate (0.005 mmol) in methanol (1 cm^3) the ligand L (0.005 mmol) in methanol (1 cm^3) was added dropwise with stirring. The reaction was carried out for 3 days. The solution volume was then reduced to 0.3 cm^3 by roto-evaporation and yellow precipitate formed on addition of a small amount of diethyl ether. This was filtered off, washed with ether, and dried in vacuo.

2.1.4.2. Transmetallation reaction. To a methanolic solution (1 cm^3) of Na**L**Cl (0.005 mmol), appropriate nitrate salt (0.005 mmol) in methanol (1 cm^3) was added dropwise with stirring. The reaction was carried out for 3–7 days until the solution turned yellow. The solvent was then partially removed by roto-evaporation. The yellow precipitate obtained by the addition of diethyl ether was collected by filtration, washed with ether, and dried in vacuo. The presence of chloride anions in the filtrate was confirmed by the reaction with $AgNO_3$.

2.1.5. $YL(NO_3)_3{\cdot}3H_2O$ ($L = C_{72}H_{100}N_4O_8$)

FAB MS: $m/z = 1512.3$ $(La\mathbf{L}(NO_3)_3{\cdot}2H_2O)^+$, 1387.4 $(La\mathbf{L}(NO_3){\cdot}2H_2O)^+$, 1412.4 $(La\mathbf{L}(NO_3)_3{\cdot}2H_2O)^+$.

2.1.7. $SmL(NO_3)_3{\cdot}7H_2O$ ($L = C_{72}H_{100}N_4O_8$)

Found: C, 53.6, H, 6.8; N, 6.1. Calc.: C, 53.6, H, 7.1, N, 6.1%; IR (cm^{-1}): 3355 m,br, ν(OH), 1648 s, ν(C=O), 1384 br, s, 810 m (NO_3); FAB MS: $m/z = 1576.0$ $(Sm\mathbf{L}(NO_3)_3{\cdot}5H_2O)^+$, 1381.0 $(Sm\mathbf{L}(NO_3){\cdot}2H_2O)^+$, 1151.2 $\mathbf{L}^+$.

2.1.8. $GdL(NO_3)_3{\cdot}2H_2O$ ($L = C_{72}H_{100}N_4O_8$)

Found: C, 57.1, H, 6.7; N, 6.5. Calc.: C, 56.6, H, 6.8, N, 6.4%; IR (cm^{-1}): 3383 m,br, ν(OH), 1655 s, ν(C=O), 1758 w, 1734 w, 1384 br, s, 815 m (NO_3); FAB MS: $m/z = 1510.24$ $(Gd\mathbf{L}(NO_3)_3{\cdot}H_2O)^+$, 1408.1 $(Gd\mathbf{L}(NO_3)_2{\cdot}2H_2O)^+$.

2.2. Measurements

IR spectra were recorded using CsI pellets in the range 4000–200 cm^{-1} on a IR Spectrometer, Magna 760, FT-Raman, Nicolet. Electronic spectra were measured on a V-550 (JASCO) spectrophotometer. ^1H NMR spectra were run in DMSO-d_6 on a Varian Gemini 300 spectrometer using TMS as an internal reference. FAB-mass spectra were obtained on a AMD-604 mass spectrometer with 3-nitrobenzyl alcohol as matrix. All data reported refer to isolated materials judged to be homogenous by thin layer chromatography performed on precoated silica gel plates (0.2 mm 60 F-254 E. Merck) and visualized by UV light.

2.3. X-ray crystal structure analysis

2.3.1. Collection of X-ray diffraction data; solution and refinement of the structures

Experimental data for **1** and **2** were collected on a KUMA KM4CCD *k*-axis diffractomiter with graphite monochromated Mo Kα radiation. The data were processed using the KUMA Diffraction (Wroclaw, Poland) program. Summaries of crystal data and details data collection together with structure refinement are given in Table 1. The available colorless transparent prism habit crystals of compound **1** have a small size and are very poorly diffracted at room temperature (r.t.). The colorless crystals of **2** were unstable under ambient conditions. These were the reasons to collect

diffraction data at low 100 K temperature for both compounds and we were able to obtain sufficient data to determine the structure details unequivocally. The fresh moist crystal of **2** was used for experiment. An initial structure models of **1** and **2** were obtained by direct methods and most of the non-hydrogen atoms were refined with anisotropic thermal parameters by full-matrix least-squares procedure based on F^2. Calculations were carried out using the SHELX-97 system of computer programs [5].

A partial occupancy dichloromethane solvent molecules were found to be disordered over three sites with 25.1, 16.3 and 9.1% probability in the structure of compound **1**. The structure of compound **2** was successfully refined with dichloromethane molecules and chlorine anions being alternate and occupied the close sites with the 50% probability. The *tert*-butyl group and methanol solvent molecules are also disordered over two (87 and 13%) and four position (0.25%), respectively, in the structure of **2**. Restraints were applied to make chemically equivalent bonds approximately equal in the disordered fragments. The carbon atoms and chlorine atoms of minor occupancy in the disordered fragments were refined isotropically.

The hydrogen atoms were placed in calculated positions and were refined as constrained to bonding atoms. All H atoms were included in model of structure with isotropic U values fixed at 1.5 times U_{eq} of C atoms for CH_3 groups and 1.2 U_{eq} for others.

3. Results and discussion

The sodium(I) chloride and yttrium(III), lanthanum(III), samarium(III) and gadolinium(III) nitrate complexes of 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis-*O*(piperidinylcarbonyl)methylene)calix[4]arene (**L**) were prepared by direct reaction of the metal salt with ligand in methanol and identified (see Experimental) by spectral data (IR, UV–Vis, ^{1}H NMR, FAB MS), and elemental analysis. The structure of the ligand and its sodium complex was established by X-ray analysis. The transmetallation reactions of the sodium complex by the yttrium(III), lanthanum(III), samarium(III) and gadolinium(III) nitrates give rise to corresponding complexes which appear to be identical with those prepared in the direct synthesis. The complexes are air stable, soluble in common organic solvents.

The infrared spectra of these complexes taken in the region 4000–200 cm^{-1} are all very similar except for anion vibrational modes and provide some information regarding the bonding in the complexes. The most significant variations between the free ligand and complexes concern the ν(C=O) vibrations. The C=O absorption band observed in the IR spectrum of **L** at 1664 cm^{-1} is shifted by 9, 15, 17, 16 and 9 cm^{-1} to lower wavennumbers upon complexation with Na(I), Y(III), La(III), Sm(III) and Gd(III) ions, respectively, as a result of the decrease in the bond order of the C=O groups, owing to a donation of electron density towards the metal cation. The rare earth ion complexes show the broad diffuse band centered at 3409–3355 cm^{-1} region due to the stretching and bending modes of lattice and coordinated water. The broadening of the bands at 1384 cm^{-1} along with medium bands at 817–810 cm^{-1} observed in the spectra of rare earth nitrate complexes suggests that the nitrate counterions are partially involved in the coordination sphere of the metal ion [6]. However, the ligand modes also fall in this region.

The electronic spectra of the ligand and its complexes in chloroform show similar features containing the intense and medium absorption bands with maxima at 233 and 276.5 nm (ligand), 230.5 nm and 275 nm (La^{3+} complex), 230.5 nm and 274.5 nm (Sm^{3+} complex), 231 nm and 274.5 nm (Gd^{3+} complex), which may be assigned to the $\pi \rightarrow \pi^*$ transitions within the ligand.

The FAB mass spectra serve an important role in confirming the formation of the complexes with ligand **L**. The observed stepwise loss of the nitrate counterions and water molecules appears to be a common route of fragmentation and supports the presence of these species in the coordination sphere of the rare earth complexes [7].

The ^{1}H NMR spectra of $CDCl_2$ solution of the sodium and diamagnetic lanthanum complexes afford further evidence for the coordination ability of the ligand **L** towards these cations. Coordination of the

oxygen atoms to metal ion is confirmed by the upfield shift of the $OCH_2C{=}O$ protons from δ 5.0 in the free ligand to 4.6 in the complexes. The multiplet at δ 3.38–3.58 assigned to the CH_2 protons adjacent to the nitrogen in the ligand piperidide moiety split to two signals in the ratio 1:1 at δ 3.2 and 3.6 in the complexes. The remaining CH_2 protons upshield from δ 1.45 to 1.7. The significant downfield shift of the aromatic protons is found in the spectra of the complexes (δ 7.1 for Na^+ complex and 7.3 for La^{3+} complex) compared with the free ligand (δ 6.8). The chemical shift of the *tert*-butyl protons (from δ 1.09 to 1.15) is, as expected, only slightly affected by coordination due to the greater distance from the donor sites. The two dublets arising from equatorial and axial protons of $ArCH_2$ groups undergo shift from δ 3.2 and 5.1 in the ligand to δ 3.3 and 4.5 in the complexes. These data suggest that the coordination influences the conformation of calixarene ligand which adopt the more rigid structure upon complexation.

It should be noted here that attempts to obtain the complexes of **L** with dioxouranium ion were unsuccessful. The remarkably high stability and selectivity for the dioxouranium(VI) demonstrated by calixarenes makes these chelators potential 'uranophiles' [8]. However, the linear geometry of UO_2^{2+} limits the coordination structure to quasi-planar equatorial one [9]. Thus, the arrangement of potential donor atoms in this lower rim substituted calix[4]arene, on the contrary to unsubstituted ones, appears to be not appropriately designed to accommodate dioxouranium(VI) ion.

In order to establish the structure of the ligand and its complex an X-ray analysis of 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis-*O*(piperidinylcarbonyl)methylene)calix[4] arene and its sodium complex was performed.

3.1. Description of the crystal structures of **L** CH_2Cl_2 (**1**) and [**L** Na](Cl)·2(CH_2Cl_2)·2(CH_3OH) (**2**)

Details for the diffraction experiments are given in Section 1 and Table 1.

The crystals of **1** have been obtained by slow crystallization from methanol–methylene chloride; suitable for X-ray study crystals of complex **2** were obtained by recrystallization from methanol. m.p. 267–270 °C

The calixarene molecular structure of **1** reveals the slightly distorted open *cone* conformation in the solid state and creates a cavity which is large enough to accommodate a solvent molecules and this is what we observe, Fig. 1a. A partial occupancy (50.5%) dichloromethane molecule disordered over three positions is enclatrate within this cavity forming the solvent inclusion complex. Apparently the position of the CH_2Cl_2 guest molecule is determined by the interplay of rather weak forces and steric fit.

The calix conformation is defined by the dihedral angles which the aromatic rings make with the plane through the carbon atoms of the methylene groups which link them, viz. 62.7(1)° (A), 62.9(1)° (B), 58.6(1)° (C), and 71.9(1)° (D), all rings being tilted so that their *tert*-butyl groups are pitched away from the open cavity, Fig. 1b. The methylene bridge carbon atoms show out-of-plane distances less than 0.008 Å. The regularity of the cone may be also characterized by a set of torsion angles, φ and χ^i [10] about the methylene bonds at the calixarene macrocycle. These are listed in Table 2. Despite the relatively regular arrangement of the aromatic rings the mutual positions of lower rim amide substitutients are essentially asymmetrical. Three amide branches on A, B and D rings have a similar conformation with the ethereal and carbonyl oxygen in the *cis*-position in respect of singular C–C bond while in the fourth on C-ring the corresponding oxygen atoms are *gauche*, Table 2.

The piperidine moiety of the amide branches on A, B and D rings forms a pseudo-cavity in which enters the piperidine moiety of the amide branches on C ring and hydrophobic binding of piperidine moieties is the reason for this. The observed conformation of calixarene molecule could be also such due to the formation of three intramolecular C–H···O hydrogen bonds between amide methylene groups and the carbonyl oxygen atoms, excluding the O(6) carbonyl oxygen atom of C-amide branch, Table 3.

The calixarene sodium complex **2**, [**L** Na](Cl)·2(CH_2Cl_2)·2(CH_3OH) in the crystal structure has fourfold symmetry and adopts a relatively open *cone* conformation with the sodium on the fourfold axis (Fig. 2). The coordination polyhedron around Na^+ is a regular square antiprism, which is formed by four ether and four carbonyl oxygen atoms from four amide subunits with Na1–O1 and Na1–O2 distances 2.503(2) and 2.470(3) Å, respectively. The position of sodium is such that it is 1.140(3) Å from the plane of the four etheral oxygen atoms and 1.180(3) Å from the plane of the four carbonyl oxygen atoms. The cavity conformation of the complexed calixarene is rather similar to that of metal free analogue in **1**. The dihedral angles made by the aromatic rings with the plane through the carbon atoms of the methylene linking groups, all 65.17(7)° and close to that found in the structure of **1,** where the average value of such dihedral angles equal 64.03°. The torsion angles, φ and χ about the methylene bonds in **1** and **2** are also similar, Table 2. In the structures of related lower rim substituted calix amide and its sodium complex [11] the same manner of Na coordination have been found but in contrast to **1** and **2** the conformation of metal free and complexed calixarene macrocycles are essentially different. So one can conclude that the ligand **L** is better preorganized for sodium complexation. The extraction studies may provide evidence for this sugges-

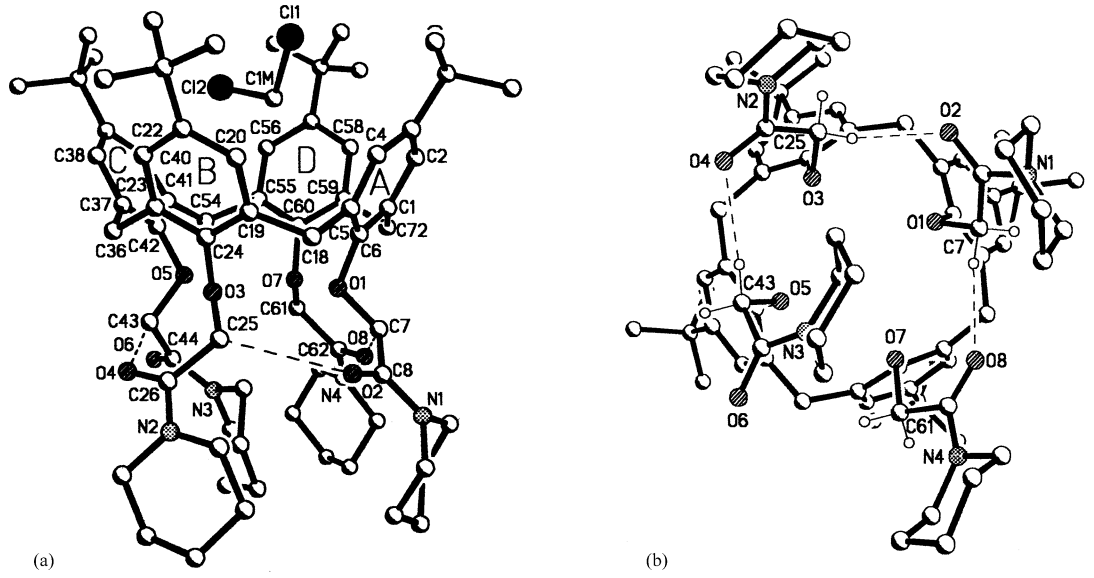

Fig. 1. (a), A general view of $\mathbf{L}\cdot CH_2CL_2$. The only highest occupancy position of disordered dichloromethane molecule is shown within the calixarene cavity. H-atoms are omitted for sake of clarity; (b), Lower rim view of the calixarene molecule illustrates the *self*-inclusion phenomena. The piperidine moiety enters a pseudo-cavity formed by three other amide branches. The hydrogen atoms involved in hydrogen bonds are shown.

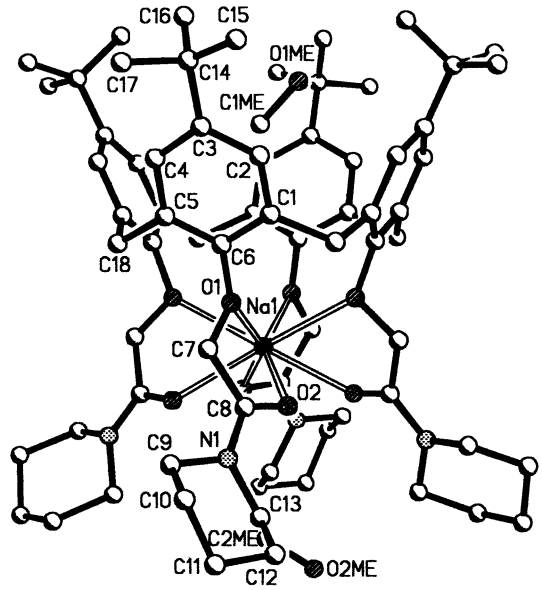

Fig. 2. A view of the Na-calixarene complex **2.** The methanol molecules (C1ME–O1ME and C1ME–O1ME) are disordered about the fourfold axis passing through C1ME, Na1 and C2ME atoms. Only one position of disordered solvent molecules and *tert*-butyl groups are shown.

tion and we are pursuing that line of investigation. Methanol molecule is enclatrated within calix cavity with the carbon atom residing on the fourfold axis and the oxygen disordered over four sites about the fourfold axis. There is also a second methanol molecule residing

on the fourfold axis like a 'saucer' of the four piperidine groups (Fig. 2). Similar to the calixarene–amide copper(II) complex [12] in the crystal structure of **2** the calixarene complexes are packing in head-to-tail manner along fourfold axis so that the methanol molecules may be involved in hydrogen bonding. The O1ME···O2ME spacing for four disordered positions are 2.68(3), 2.92(3), 3.19 (3) and 3.39(3) Å and at least two of them suitable for O–H···O hydrogen bonds. These methanol pairs enclose the calixarene cavity and a 'saucer' for the four piperidine groups, which result in total encapsulating of Na^+ cation and extend the calixarene complexes as one-dimensional chain along *c* axis of the crystal. The disordered chlorine anions reside on twofold-axes and well separated in the structure from the Na^+ cations. This feature of the crystal structures according to the principals reported in [13] is favorable for membrane electrode response, considering **L** as Na^+ ion carrier.

On the basis of available evidence it can be concluded that the sodium, yttrium and lanthanide ions, contrary to dioxouranium(VI) ion, are suitable guests for 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis-*O*(piperidinylcarbonyl)methylene)calix[4]arene host. The effectiveness of transmetallation reaction and the failure of this system to undergo the complexation reaction with dioxouranium ion reveals that the lower rim substituted *tert*-butyl calix[4]arenes may be regarded as interesting ligands towards the rare earth ions, either for extraction purposes, or for other potential application involving the biomedical diagnostics, fluorescence labels and photonic supramolecular devices.

Abstract

2-Methyl-3-(2-pyridyl)isoxazolidine (**L**) and its Pd(II), Zn(II) and Cu(II) complexes have been prepared and characterized by IR, ^{1}H, ^{13}C 1D and HMBC, NOESY 2D NMR spectroscopies. The stereochemistry of the 'free' and co-ordinated ligand has been assigned by nuclear Overhauser effect (NOE). The molecular structures of [Zn(*cis*-**L**)Cl_2]·0.5$CHCl_3$ (**2a**), [Zn(*cis*-/*trans*-**L**)Cl_2] (**2a**–**b**) and [Cu(*cis*-/*trans*-**L**)Cl_2]$_2$ (**4a**–**b**) have been established by means of X-ray crystallography. The crystal structure of **2a** consists of a racemic mixture of *cis*-**L** (3*SR*,5*RS*), while the crystal structure of **2b** comprises a racemate of *cis*- and *trans*-isomeric forms. For both complexes the zinc atoms adopt nearly tetrahedral co-ordination with two chlorine atoms and *N*,*N*-bidentate co-ordinated **L**. The crystal structure of **4a**–**b** consists of dinuclear [Cu(*cis*-/*trans*-**L**)Cl_2]$_2$ moieties with *N*,*N*-bidentate co-ordinated ligands. The square pyramidal co-ordination spheres of copper ions are completed by a bridging chloride ligand at the apex (Cu–Cl 2.79, 2.82 Å).

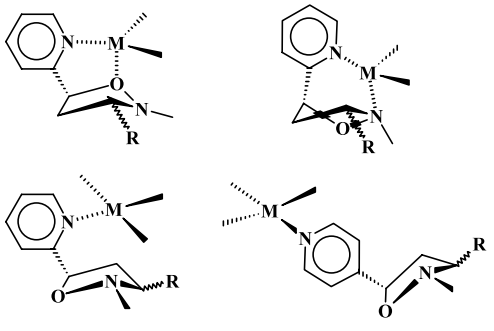
1. Introduction

Isoxazolidine systems are important in bioscience as intermediates for organic synthesis of a number of natural compounds: 1,3-aminoalcohols, alkaloids and amino sugars [1–4]. Their pharmacological properties [5–9] have stimulated interest on the control of diastereo- and enantioselectivity in 1,3-nitrone-olefine dipolar cycloaddition as the isoxazolidine preparation method. The last decade has revealed a great deal of research on improving methods for stereoselective synthesis of isoxazolidines [10–18]. Thus, nitrone-tricarbonyl(η^6-arene)chromium(0) adducts undergo cycloaddition reactions in a highly stereoselective manner yielding *cis*-3,5-disubstituted isoxazolidines [19,20]. Very recently, Cu(II)- and Zn(II)-bisoxazoline [21] as well as (BINOL)–AlMe complexes (BINOL = 2,2′-dihidroxy-1,1′-binaphthyl) [22] have been utilized as catalysts in the enantioselective synthesis of isoxazolidines through 1,3-dipolar cycloadditions of nitrones to electron-rich olefins. The stereochemistry of the products has been explained by assuming the formation of a complex between the nitrone and the catalysts.



Our interest is focused on co-ordination chemistry of the isoxazolidine systems concerning possible application of the metal complexes for the asymmetric 1,3-dipolar cycloaddition reactions between alkenes and acyclic nitrones [23,24]. Elaboration of this approach is closely related with investigation of isoxazolidine co-ordination compounds themselves because it may give significant information for understanding the importance of inherent structure of the co-ordination compounds for 1,3-dipolar cycloaddition and processes of purification and separation of isomeric isoxazolidines.

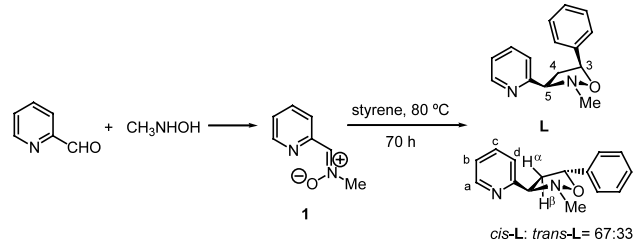
Recently, we have shown that the pyridyl substituted *N*-methyl isoxazolidines readily give co-ordination compounds with d-metal ions [23,25]. The 5-(2-pyridyl)substituted isoxazolidine core may act either as monodentate ligand through the nitrogen atom of the pyridyl substituent or as bidentate ligand (*N*,*N* for Pd, Pt; *N*,*O* for Zn). In each case, the metal co-ordinates the pyridyl nitrogen atom and one of the heteroatoms of the isoxazolidine ring (Scheme 1).



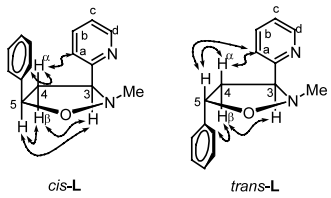
Herein we present our results on the synthesis of isomeric *cis*-/*trans*-2-methyl-3-(2-pyridyl)-5-phenylisoxazolidine (**L**) and the study of its co-ordination behavior with Pd, Zn and Cu metal ions. The presence of one co-ordinatively active substituent on the isoxazolidine ring may give rise to different co-ordination modes to the metals (Scheme 2).

Scheme 1. Co-ordination features of 5-pyridyl substituted isoxazolidines.

Scheme 2. The possible modes of chelate complexation for 2-methyl-3-(2-pyridyl)-5-phenylisoxazolidine.

Scheme 3. NOE correlations of **L**.

2. Results and discussion



2.1. Synthesis and structural identification of *L*

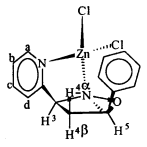
The organic ligand **L** was obtained through the [3+2] dipolar cycloaddition of *N*-methyl-*C*-(2-pyridyl)nitrone (**1**) to freshly distilled styrene in refluxing toluene–benzene (1:1, v/v) (Scheme 3). Analysis of the crude reaction showed the presence of two products in an approximate ratio 67:33 which were identified, respectively, as the *cis*- and *trans*-stereoisomers of 2-methyl-3-(2-pyridyl)-5-phenylisoxazolidine, i.e. a single regioisomer was observed. Column chromatography on silicagel (acetone–hexane 1:1) of the crude product afforded pure *cis*-/*trans*-**L** without altering the relative ratio of isomers.

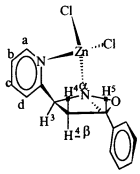
The IR spectrum of **L** is similar to the related 5-(2-pyridyl)isoxazolidine [23] and shows characteristic strong absorptions at 2990–3090 (ν(C–H) ph, py), 1490–1590 (ν(C=C) ph, py), 2780–2960, 1335–1475 cm^{-1} (ν(C–H) and δ(C–H) of the aliphatic groups).

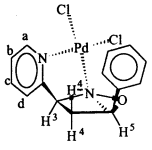
The ^{1}H NMR spectrum of **L** suggests the presence of two diastereomers. The analysis of the coupling constants in combination with nuclear Overhauser effects (NOEs) (Scheme 3) allows facile determination of both the configurations for 3,5-disubstituted isoxazolidine systems.

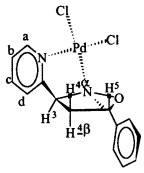
The ^{1}H NMR spectrum measured in DMSO-d_6 showed separate signals for the most significant protons of both stereoisomers (overlap occurred for the phenyl protons and H(c) of the 2-pyridyl group). The HMQC and HMBC correlation spectra allowed the straightforward assignment of the ^{1}H and ^{13}C NMR spectra. The use of $CDCl_3$ as solvent produced only minor changes in the chemical shifts of the signals (see Section 4). In principle, the relative stereochemistry of the stereogenic centers of **L** could be established from the observed coupling constants for the proton at C(5) as it has been shown for several 3,5-disubstituted isoxazolidines [26] (H(5) proton appeared as a double doublet ($^3J_{HH}$ 3–6 Hz) for the *cis* isomer, and a doublet for the *trans* derivative ($^3J_{HH}$ $\sim$5 Hz). Unfortunately, in our case both isomers produced the same multiplicity pattern for H(5), a triplet, with the same vicinal couplings ($^3J_{HH}$ 7.7 Hz), precluding to draw any stereochemical conclusion of the configuration of the isoxazolidine moiety. The 2D NOESY spectrum of the *cis*-, *trans*-**L** mixture allowed to solve the ambiguity. The major isomer is assigned the *cis* stereochemistry based on the intense correlation observed between H(3) (δ 4.19) and H(5) (δ 5.32). Additionally, the methylene proton at δ 2.46 (H(4α), dt, $^2J_{HH}$ 12.3, $^3J_{H4\alpha H3} = {}^3J_{H4\alpha H5}$ 6.9 Hz) shows the expected cross peaks with both the 2-pyridyl (δ(H^d) 7.58, see Scheme 2 for labeling) and the phenyl (δ(H^o) 7.3) substituents corresponding to their *syn* orientation. Consequently, the double triplet at δ 3.23 ($^2J_{HH}$ 12.3, $^3J_{H4\beta H3} = {}^3J_{H4\beta H5}$ 7.7 Hz) is assigned to the other methylene proton H(4β) (Scheme 4).

Scheme 4. H(α) defines the proton *syn* to the 2-pyridyl ring.









Therefore, the minor component of the mixture is the *trans* isomer. This assignment is supported by the NOE correlation between H(3) (δ 4.04, dd, $^3J_{H4\alpha H3}$ 6.5, $^3J_{H4\beta H3}$ 7.7 Hz) and the *ortho* protons (δ 7.42, m) of the phenyl ring linked to C(5) (δ 5.07, t, $^3J_{HH}$ 7.7 Hz). Again, the methylene protons are assigned from the respective correlations with H(3) and H(5) (see Section 4).

2.2. Synthesis and structural identification of complexes 2–4

Complexation of the isomeric mixture of isoxazolidines **L** with Pd(II), Zn(II) and Cu(II) metal ions was carried out by heating an alcoholic solution of the ligand with the corresponding zinc and copper chloride, or with the $Na_2[PdCl_4]$ complex for palladium. Cooling the reaction mixture to room temperature afforded a precipitate which was separated, washed with alcohol (methanol or 2-propanol) and dried, yielding the metal complexes [Zn(*cis*-/*trans*-**L**)Cl_2] (**2a**–**b**), [Pd(*cis*-/*trans*-**L**)Cl_2] (**3a**–**b**), and compound [Cu(*cis*-/*trans*-**L**)$Cl_2]_2$ (**4a**–**b**). All the compounds are air stable both as solids and in solution. They are readily soluble in acetonitrile, *N*,*N*-dimethylformamide, dimethyl sulfoxide and almost insoluble in hexane.

The ^{1}H and ^{13}C NMR data of compounds **2**–**4** acquired in DMSO-d_6 are given in Table 1. The assignment of the proton and carbon atom signals was easily made based on the analysis of the 1D (^{1}H, APT) and 2D (HMQC, HMBC) spectra. The NMR spectra of the complexes showed two sets of signals derived from the co-ordinated isomeric *cis*- and *trans*-isoxazolidines. The ratio of isomers was similar to that of the free ligand **L** (average *cis*–*trans* ratio of 65:35). As for the free ligand, the relative stereochemistry of the two carbon stereogenic centers was unambiguously deduced from the NOE correlations observed in the corresponding NOESY spectra. In all cases H(3) and H(5) exhibited a strong dipolar correlation for the *cis* isomers, while for the *trans* derivatives a correlation of low intensity was

detected between H(5) and the *ortho* protons of the phenyl substituent on C(3). The methylene protons H(4) were again assigned through their respective correlations with the vicinal protons H(3)/H(5).

The complexation of both ligands is evidenced by the variations of the proton chemical shifts compared with the free isoxazolidines. In compounds **2a**–**b**, the co-ordination of **L** to Zn(II) produce a broadening of all proton signals and a partial overlap of the aromatic protons corresponding to both stereoisomers. Clearly, for **2a**–**b** co-ordination occurred in the proximity of H(3). This is the only proton of the isoxazolidine moiety showing a significant deshielding effect due to the complexation ($\Delta\delta$H(3)^{cis} (**2a**–**L**) = 0.14 ppm; $\Delta\delta$H(3)^{trans} (**2b**–**L**) = 0.12 ppm). Variations on H(4) and H(5) are lower than 0.05 ppm. In principle, the effect on H(3) is compatible with **L** acting either as a *N*-monodentate or *N*,*N*-bidentate ligand. Co-ordination through the nitrogen of the pyridine is supported by the deshielding observed for the protons H(b) ($\Delta\delta$H(b)^{cis} (**2a**–**L**) = 0.07 ppm; $\Delta\delta$H(b)^{trans} (**2b**–**L**) = 0.05 ppm) and H(c) ($\Delta\delta$H(c)^{cis} (**2a**–**L**) = 0.16 ppm; $\Delta\delta$H(c)^{trans} (**2b**–**L**) = 0.17 ppm) of the heterocycle. On the other hand, co-ordination to the nitrogen of the isoxazolidine would prevent rapid inversion of the heteroatom, originating a new stereogenic center which relative configuration could be identified in the NOESY spectrum. Indeed, the methyl protons of *cis*-**L** in **2a**–**b** (δ 2.74) showed a dipolar correlation with H(3) and H(5), while for *trans*-**L** only the correlation of the methyl protons at δ 2.67 with H(3) was detected. These evidences indicate that in complex **2a**–**b** the ligand is bonded to the metal in a *N*,*N*-bidentate mode.

The same trends have been observed in the proton spectrum of the mixture of isomers **3a**–**b**. In this case, co-ordination of **L** to palladium produced a much stronger effect on the proton spectrum of isoxazolidine and all signals appeared deshielded compared to the free ligand. The low field shift ranged from $\Delta\delta$(**3a**–**b**–**L**) = 0.19–0.85 ppm for H(4), H(5) and the methyl protons. Even though, the shifts for H(3) exceeded 1 ppm ($\Delta\delta$H(3)^{cis} (**3**–**L**) = 1.13 ppm; $\Delta\delta$H(3)^{trans} (**3**–**L**) = 1.08 ppm). Again, the deshielding of the pyridine protons (see Table 1) and the NOEs measured for the methyl protons are consistent with **L** being doubly co-ordinated to the metal through the nitrogen atoms.

The differences in line-broadening and range of chemical shifts variations promoted by Zn versus Pd co-ordination to **L** suggest that in DMSO the solvent is competing with the ligand **L** for binding to the zinc ion and therefore, the proton spectrum of **2a**–**b** corresponds to the average situation derived from the exchange between free and complexed ligand which is rapid on the NMR time scale.

2.3. Crystal structures of [Zn(*cis*-**L**)Cl_2]·0.5$CHCl_3$ (**2a**), [Zn(*cis*-/*trans*-**L**)Cl_2] (**2a**–**b**) and [Cu(*cis*-/*trans*-**L**)Cl_2]$_2$ (**4**)

The NMR results described above indicated that compounds **2**–**4** are mixtures of stereoisomers. Recrystallization of the crude products obtained opens up different possibilities for these systems: resolution of racemic *cis*-/*trans*-isomers, self-resolution of enantiomers and co-crystallization of *cis*- and *trans*-isomers. In all cases, further insight into the structural characteristic of the co-ordination complexes could be gained through the analysis of the solid state structure (Fig. 1).

Recrystallization of **2** by slow diffusion of 2-propanol into a chloroform solution of the metal complex afforded two products suitable for X-ray analysis. One of them, [Zn(*cis*-**L**)Cl_2]·0.5$CHCl_3$ (**2a**) consists of racemic mixture of *cis*-**L** (3*SR*,5*RS*), while another one [Zn(*cis*-/*trans*-**L**)Cl_2] (**2a**–**b**) is a racemate including both *cis*- and *trans*-forms. These structures are built up from molecular [Zn(**L**)Cl_2] species, but are dramatically different in the spatial arrangement of the molecules (Figs. 2 and 3). There is a lack of strong intermolecular interactions such as co-ordination or hydrogen bonding. However, the packing pattern for the compounds is determined by stacking interactions between two aromatic functions of the ligand. Complex **2a** consists of dimers sustained by π–π, or face-to-face, stacking between pyridine groups. These weak but commonly encountered interactions contribute to crystal structures of aromatic species [27] and may be loosely regarded as a kind of 'supramolecular synthon' [28]. Two pyridine rings are parallel and the distance between their planes is approximately 3.28 Å. Two molecular complexes being paired in such a way (Py–Py) evidently generates a center of inversion in the triclinic crystal, and the lattice comprises a racemic mixture.

Stacking interactions are also present in the packing pattern of complex **2a**–**b** but between different functions, the pyridyl and phenyl groups. They also appear to be parallel with interplanar separation at approximately 3.45 Å. From this point of view, structures **2a** and **2a**–**b** may be regarded as supramolecular isomers (see Fig. 3). For complex **2a**–**b**, face-to-face stacking interactions connect the molecules into 1D chain and unsymmetric pairing results in the absence of a center of inversion. Nevertheless, the crystal also comprises both enantiomers that are related by a glide plane.

Another important feature of the structure **2a**–**b** is disordering of the C(3)–Ph fragment. This disorder has a clear chemical significance as two components correspond to *cis*- and *trans*-isomeric forms of the ligand. Refinement of partial occupancies suggested contributions of *cis*- (72%) and *trans*- (28%) isomers similar to that found in the crude product mixture (67 and 33%). Both isomers have actually the same size, shape and

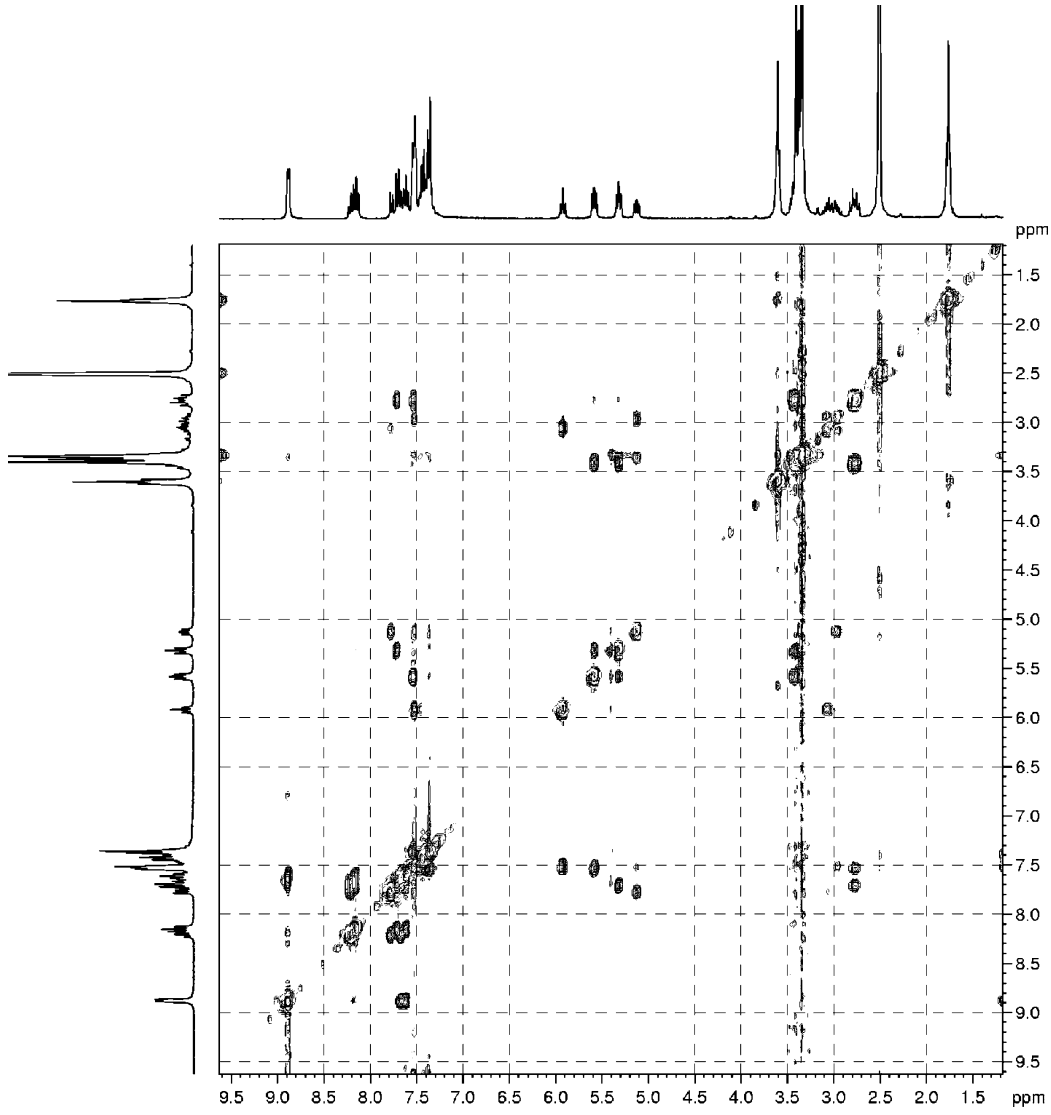

Fig. 1. The 2D NOESY spectrum of [Pd(*cis*-/*trans*-**L**)Cl_2] (300 MHz, DMSO-d_6/THF-d_8).

orientation of functional groups and (Fig. 2) therefore statistically occupy positions in the crystal. The resulting structure may be described as a solid-state solution of isomeric complexes. The existence of such phases may preclude the possibility of separation of isomeric isoxazolidines and their metal complexes by crystallization.

The zinc atoms in **2a**–**b** adopt a nearly tetrahedral co-ordination polyhedron with two chloride ligands and one *N*,*N*-bidentate co-ordinated **L**. In contrast to the X-ray data for a related structure of the palladium complex with *trans*-2-methyl-5-(2-pyridyl)-3-phenylisoxazolidine, the structure of **2a** possesses a Zn–N(1) bond (2.134(4) Å) longer than Zn–N(2) 2.049(4) Å) [23]. The five-membered chelate ring in both structures of zinc complex is almost planar. The atoms Zn(1) and N(1) deviate by −0.12 and 0.18 Å, respectively, from the mean plane of the other atoms this cycle. The isoxazolidine ring in the structures possesses an envelope conformation. In structure **2a**, the methyl group has an axial orientation to the isoxazolidine ring, while the phenyl and pyridine substituents are situated in an equatorial manner (C(6)–C(7)–C(8)–C(9) 159.5(4)°) (Table 2). In structure **2a**–**b**, the phenyl group and pyridyl ring are situated in an equatorial manner at the isoxazolidine cycle (C(10)–C(3)–C(2)–C(1) 153.7°) while the methyl group is located in an axial position (C(4)–N(1)–O(1)–C(3) −93.4°) (Table 3). The structure of copper complex **4a**–**b** (Fig. 4) consists of a neutral dimers [Cu(*cis*-/*trans*-**L**)Cl_2]$_2$. The copper atoms are co-ordinated in a distorted square pyramid comprising two nitrogen and two chlorine atoms in an equatorial plane (Cu–Cl 2.244(2)–2.262(2) Å) and an additional chloride ligand is situated in the apex (Cu–Cl 2.795(2), 2.818(2) Å). Thus two bridging chlorine atoms

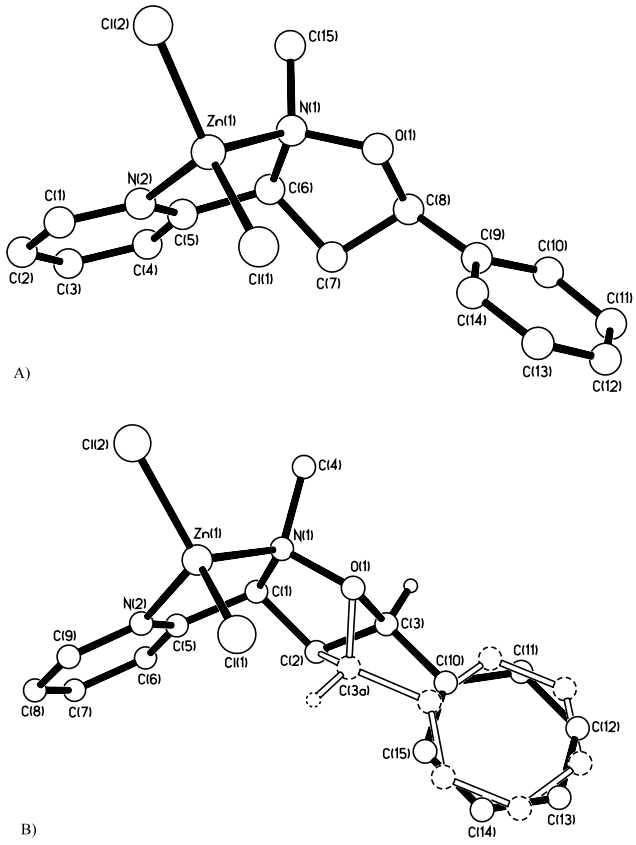

Fig. 2. Molecular structure of [Zn(**L**)Cl_2]: (A) *cis*-isomeric form of the ligand in structure **1a**. Selected bond length, Å: Zn(1)–N(2) 2.049(4); Zn(1)–N(1) 2.134(4); Zn(1)–Cl(2) 2.208(1); Zn(1)–Cl(1) 2.209(1); (B) disordering scheme for C–C_6H_5 fragment in structure **1b** suggests presence of *cis*- and *trans*-isomeric forms that possess the same shape and form mixed crystal. Selected bond length, Å: Zn(1)–N(2) 2.038(3); Zn(1)–N(1) 2.109(4); Zn(1)–Cl(1) 2.202(1); Zn(1)–Cl(2) 2.211(1).

connects molecular units [Cu(**L**)Cl_2] into the dimer (Table 4). The latter one is actually centrosymmetric, and all three pairs of isoxazolidine asymmetric atoms within the dimer frame possess opposite chirality. N-co-ordination of the isoxazolidine to the metal atom also makes impossible pyramidal inversion at the nitrogen atom, and the co-ordinated isoxazolidine core possesses three chiral centers simultaneously. Nevertheless, systematic absences suggest the chiral space group $P2_12_12_1$. The structure also shows high parameters for thermal motion of the isoxazolidine C–Ph fragment (U_{iso} 0.1–0.2 $Å^2$) that may be ascribed to co-crystallization of *cis*- and *trans*-isomeric forms, by analogy with **2a**–**b**. Both five-membered chelate rings formed are almost planar. The isoxazolidine ring has an envelope conformation and the methyl group possesses the axial position in the isoxazolidine ring (C(1A)–N(1A)–C(4A)–C(3A) 115.0°), whereas the pyridyl substituted is located in an *anticlinal* arrangement with the C(2)–C(3) bond.

3. Conclusions

2-Methyl-3-(2-pyridyl)-5-phenylisoxazolidine has been regioselectively synthetized as a 67:33 *cis*–*trans* mixture by reaction of *N*-methyl-*C*-(2-pyridyl)nitrone with styrene. The new ligand readily forms co-ordination compounds with Zn(II), Cu(II) and Pd(II) chlorides which solution structure has been assigned through 1D and 2D NMR spectroscopy. The organic ligand in the complexes is co-ordinated in a *N*,*N*-bidentate chelating mode, in contrast to isomeric 5-(2-pyridyl)substituted *N*-methyl isoxazolidine. The configuration and conformation of the isoxazolidine ring have been determined by NOE NMR experiments and confirmed by means of the X-ray diffraction data for zinc and copper chloride complexes. The crystal structure of [Zn(*cis*-/*trans*-**L**)Cl_2] (**2a**–**b**) and [Cu(*cis*-/*trans*-**L**)Cl_2] (**4a**–**b**) revealed the co-crystallization of *cis*- and *trans*-isomers of the ligand. For the zinc complex it has been also possible to isolate and characterize the co-ordination compound derived from the *cis*-isoxazolidine [Zn(*cis*-**L**)Cl_2]·0.5$CHCl_3$ (**2a**).

4. Experimental

4.1. Synthesis

All solvents were used as supplied or distilled using standard methods. The starting materials for the synthesis of organic ligands and complexes were commercial products of reagent grade (Fluka, Aldrich). The *N*-methyl-*C*-(2-pyridyl)nitrone (**1**) was prepared as previously described [24].

4.1.1. 2-Methyl-3-(2-pyridyl)-5-phenylisoxazolidine (**L**)

Freshly distilled styrene (20.2 ml, 18.36 g, 176.54 mmol) was added to a $C_6H_5CH_3$–C_6H_6 solution (1:1 v/v, 30 ml) of *N*-methyl-*C*-(2-pyridyl)nitrone (3.00 g, 22.06 mmol). The reaction mixture was stirred at reflux for 70 h and then concentrated in vacuo. Undesired side products were removed by means of column chromatography on silica gel with C_3H_6O–C_6H_{14} (1:1) as an eluent. The yield of **L** (yellow oil, mixture of *cis*–*trans* isomers in a ratio 67:33) was 3.18 g ($\sim$60%).

IR (film between KBr discs, cm^{-1}): 3085, 3065, 3035, 3010, 2990, 2960, 2960, 2915, 2875, 2850, 2780, 1670, 1590, 1570, 1495, 1475, 1450, 1440, 1400.

4.1.2. *[Zn(cis-/trans-**L**)Cl$_2$] (**2a**–**b**)*

A warm mixture 2-propanol–C_3H_6O solution (8/4 ml) of **L** (0.090 g, 0.375 mmol) was added to 2-propanol (5 ml) containing $ZnCl_2$ (0.051 g, 0.375 mmol). The red precipitate was formed immediately. After cooling to room temperature (r.t.), the precipitate of **1** was separated, washed with cold 2-propanol and dried in vacuum. Yield: 0.086 g (61%). *Anal*. Found: C, 48.4; H, 4.3; N, 7.4. Calc. for $C_{15}H_{16}Cl_2N_2OZn$: C, 47.84; H, 4.28; N, 7.44%. Recrystallization from 2-propanol–$CHCl_3$ afforded single crystals of **1a** (orange) and **1b** (white).

4.1.3. *[Pd(cis-/trans-**L**)Cl$_2$] (**3a**–**b**)*

A warm methanolic solution (5 ml) of **L** (0.156 g, 0.65 mmol) was added to a warm MeOH (5 ml) containing $Na_2[PdCl_4]$ (0.191 g, 0.65 mmol). A yellow precipitate was formed at once. The reaction mixture was cooled to r.t., the precipitate of **3a**–**b** was filtered, washed with cold MeOH and dried. Yield: 0.185 g (65%). *Anal*. Found: C, 43.2; H, 3.8; N, 6.6. Calc. for $C_{15}H_{16}Cl_2N_2OPt$: C, 43.62; H, 3.93; N, 6.60%.

4.1.4. *[Cu(cis-/trans-**L**)Cl$_2$]$_2$ (**4a**–**b**)*

A sample of **L** (0.065 g, 0.27 mmol) in warm 2-propanol (5 ml) was added to a $C_5H_{11}O$ solution (10 ml) of $CuCl_2 \cdot 2H_2O$ (0.046 g, 0.27 mmol). A light-green precipitate was formed at once. After cooling to r.t., the precipitate was separated, washed with cold 2-propanol and dried in vacuo to afford a solid 0.062 g (74%). *Anal*. Found: C, 48.0; H, 4.1; N, 7.4. Calc. for $C_{15}H_{16}Cl_2CuN_2O$: C, 47.94; H, 4.29; N, 7.46%. Crystals of the complex, green platelets, were grown by the slow liquid diffusion in next mixtures $CHCl_3$–2-propanol–C_6H_{14} and 2-propanol–DMF as well as an isothermal evaporation of $CHCl_3$ solution.

4.2. Measurements

The IR spectrum of liquid **L** was recorded on a UR-10 (Carl Zeiss, Jena) spectrometer (film between KBr discs; 400–4000 cm^{-1}).

^{1}H (300 MHz), ^{13}C (75.5 MHz) NMR spectra were recorded at r.t. on a Bruker Avance DPX300 spectrometer equipped with a 5 mm QNP-Z probe (^{1}H, ^{13}C, ^{15}N, ^{31}P). The solvents were $CDCl_3$, C_3H_6O-d_6 and DMSO-d_6–THF-d_8 mixture (internal standard—TMS). Standard Bruker software and microprograms were applied for all NMR experiments. The sweep width covered was 3000 Hz for ^{1}H, digitalized in 16 K, and 15 000 Hz for ^{13}C, digitalized in 64 K.

Crystallographic measurements were made using a Siemens SMART CCD area-detector three-circle diffractometer (KappaCCD for **2a**). Graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) was employed. The data frames were integrated using SAINT [29] and empirical absorption corrections (SADABS) [29] were employed. The essential experimental conditions and resulting crystal data are given in Table 5. All structures were solved by direct methods using the SHELXTL-PLUS set of programs [30], and refined by full-matrix least-squares methods. Positions of the hydrogen atoms were idealized.

The $CHCl_3$ of crystallization in structure **2a** have no close contacts with other atoms and fill up emptiness of the crystal. These solvate molecules are disordered over two closely situated positions with partial site occupancy factors at 0.7 and 0.3.

In structure **2a**–**b** high anisotropy of thermal motion for C(3)–C_6H_5 carbon atoms suggested that this fragment of the molecule is disordered. The disorder was resolved under constraining the standard geometry of the phenyl rings and refinement of partial occupancies led to values of 0.72 and 0.28. Refinement of the disorder proceeded smoothly and therefore it was possible to refine all atoms of the major component anisotropically, while atoms of the minor component were left isotropic and the hydrogen atoms of phenyl cycle were not included. Actually the same problem was observed for copper complex **4**. In this case, all attempts to divide the oscillatory movement of C–C_6H_5 between two positions with different partial occupancies were not successful.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 164044–164046 for compounds **2a**, **2a**–**b** and **4**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The co-ordination mode of the title ligand, HMP_zNEt_2 (synthesised for the first time and characterised by elemental analyses, mass, IR and ^1H NMR spectral parameters), is reported by solid state isolation and physico-chemical identification of cobalt(III) complexes, $[Co(MP_zNEt_2)_2]X\cdot 2H_2O$ (X = Cl, Br, ClO_4, BF_4 and NO_3). Electronic spectral features of these diamagnetic Co(III) species classify them as six co-ordinate distorted octahedral ones. IR spectra (4000–200 cm^{-1}) indicate that the Co(III) complexes have monoanionic tridentate NNS co-ordination of the title ligand through the pyrazolyl (tertiary) ring nitrogen, azomethine nitrogen and thiolato sulfur atoms. ^1H NMR data (in $CDCl_3$ at 300 MHz) for the uncomplexed ligand and those of its Co(III) complexes are commensurate with the NNS function of the monodeprotonated HMP_zNEt_2, as ascertained from downfield shift of the relevant protons adjacent to the bonding sites. X-ray crystallographic data of **I** and **II** (both $P\bar{1}$, triclinic) have authenticated a CoN_4S_2 octahedral co-ordination in both the complex ions. © 2002 Elsevier Science Ltd. 1. Introduction

Heterocyclic thiosemicarbazones (TSCs) have attracted much interest in chemistry and biology due to their antibacterial, antimalarial, antitumour and antiviral activities and represent an important series of compounds because of potentially beneficial biological activities [1,2]. In several instances, the highest in vivo activity is associated with a metal ion complex rather than the parent TSC [3]. The last decade has recorded substantial research on transition metal ion complexes of pyridyl thiosemicarbazones [4,5]. Pyrazole derivatives with potential binding sites have long been the focal point of attention [6–8] for co-ordination chemists because of their well-acclaimed pharmacological values [9]. As a part of our comprehensive effort towards establishing a correlation between the structural nature of transition metal ion complexes of pyrazolyl thiosemicarbazones and their wide spectrum therapeutic applications, and in continuation of our earlier work [10–12], the present communication reports the synthesis and spectroscopic identification of cobalt(III) complexes with 5-methyl-3-formylpyrazole-N(4)-diethylthiosemicarbazone (HMP_zNEt_2) together with X-ray crystallographic studies of $[Co(MP_zNEt_2)_2]ClO_4\cdot 2H_2O$ (**I**) and $[Co(MP_zNEt_2)_2]BF_4\cdot 2H_2O$ (**II**).

2. Experimental

All reagents were of AR grade and were obtained from commercial sources and used without further purification. Spectrograde solvents were used for spectral and conductance measurements, and $CDCl_3$ (Sigma) was used for recording ^1H NMR spectral data.

2.1. Preparation of HMP_zNEt_2

The title ligand, HMP_zNEt_2 (Fig. 1) has been synthesised for the first time by a method similar to that reported earlier [13], but appropriately modified, followed by the final transamination [14] of the *S*-methyldithiocarbazate of 5-methyl-3-formylpyrazole (HMP_zSMe) with diethylamine. The white crystallised product (from ethanol) melted at 160–162 °C. Yield ~ 60%. *Anal*. Found: C, 50.3; H, 7.1; N, 29.5. Calc. for $C_{10}H_{17}N_5S$: C, 50.2; H, 7.1; N, 29.3%. *m/z* 239 (M^+, 86%).

2.2. Preparation of the complexes $[Co(MP_zNEt_2)_2]X\cdot 2H_2O$ ($X = Cl$, Br, ClO_4, BF_4 and NO_3)

The reported Co(III) complexes have been prepared by refluxing ethanolic solution of the ligand (0.00105 mole) and corresponding hydrated Co(II) salts (0.000525 mole) in a water bath for 1 h. On slow evaporation of the dark brown solutions, the desired Co(III) complexes have been obtained. The reddish brown solids were filtered off, washed with cold ethanol, and were dried over anhydrous $CaCl_2$. The yield has been recorded to be 75–80% in each case. Dark red brown crystals of **I** and **II** were found to be suitable for X-ray diffraction.

It is pertinent to note that the ligand, HMP_zNEt_2 favours Co(II) → Co(III) transformation inducing oxidation as is known with similar ligands [15].

2.3. Physical measurements

Elemental analyses (C, H and N) were done at the Indian Association for the Cultivation of Science (IACS), Kolkata, with a Perkin–Elmer 2400 CHNS/O analyser and the cobalt contents of the complexes were determined gravimetrically as anhydrous $CoSO_4$. The molar conductances of the complexes in methanolic solution were measured with a Systronics 304 digital conductivity meter. The electronic spectra of the complexes in methanolic solution and the diffuse reflectance spectra were recorded on a Hitachi U-3501 spectrophotometer. IR spectra (4000–200 cm^{-1}) were recorded on JASCO FT/IR-420 spectrophotometer with KBr pellets at Burdwan University, West Bengal. Magnetic measurements were made in the polycrystalline state on a PAR 155 sample vibrating magnetometer at IACS, Kolkata. ^1H NMR spectra were recorded in $CDCl_3$ with Bruker AM300L (300 MHz) superconducting FT NMR. Mass spectrum of the ligand was done at Central Drug Research Institute, Lucknow, with JEOL JMS-D300 mass spectrometer.

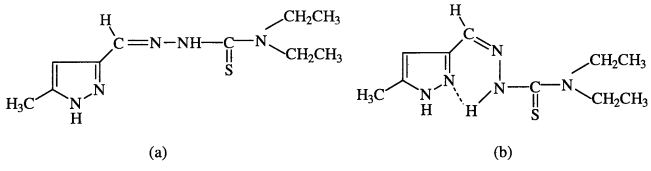

Fig. 1. Schematic diagram of HMP_zNEt_2.

2.4. Structure determination

X-ray diffraction data of the complexes were collected on a Bruker P4 diffractometer using Mo Kα radiation. The data were corrected for Lorentz and polarisation effects and for absorption by using ψ-scans.

The structures were solved by direct methods using SHELXS [16] and refined by full-matrix least-squares based on $|F_{obs}|^2$ using SHELXL [16]. The non-hydrogen atoms were refined anisotropically. The hydrogen atoms, either located from difference electron density maps or generated using idealised geometry, were made to "ride" on their parent atoms and used in the structure factor calculations. Neutral atom scattering factors were taken from Cromer and Weber [17] and anomalous dispersion effects were included in F_{calc} [18]. The crystallographic data are summarised in Table 4 and the final positional and thermal parameters are available as supplementary material.

3. Results and discussion

3.1. Spectroscopic characterisation of HMP_zNEt_2

The ligand, HMP_zNEt_2, has been characterised by elemental analyses (C, H and N), IR, ^1H NMR and mass spectra. The characteristic IR bands (cm^{-1}) at 3290–3200 (ν_{NH}), 1620 ($\nu_{CH=N}$), 1510 ($\nu_{CH=N}$), 1030 ($\nu_{N-N}P_z$), 865 ($\nu_{C=S}$), are in good agreement with the structure in Fig. 1(a). The ligand molecule has a proton adjacent to the thiocarbonyl group and consequently can exhibit thione–thiol tautomerism. The IR spectrum of the free ligand does not show any (ν_{SH}) band in the region 2600–2200 cm^{-1}, indicating that the thiol tautomer is absent in the solid state [19,20], but exhibits (ν_{NH}) bands in the region 3290–3200 cm^{-1} indicating the existence of only thioketo tautomer Fig. 1(a). The ^1H NMR spectrum of the free ligand in $CDCl_3$ gives singlets at δ 2.29 (3H), δ 6.22 (1H) assigned to C_5–CH_3 and C_4–H of the pyrazole ring, respectively. The one proton singlet at δ 7.39 is ascribed to –CH=N–. The

Analytical data and other pertinent physico-chemical properties of the complexes

Complex (colour)	Elemental analyses, Found (Calc.)				Conductivity at 30 °C in MeOH (Ω^{-1} cm^2 mol^{-1})
	%C	%H	%N	%Co	
$[Co(MP_zNEt_2)_2]Cl\cdot 2H_2O$ (red brown)	39.6 (39.6)	5.9 (5.9)	23.1 (23.1)	9.8 (9.7)	85
$[Co(MP_zNEt_2)_2]Br\cdot 2H_2O$ (red brown)	36.8 (36.9)	5.5 (5.5)	21.6 (21.5)	9.1 (9.1)	97
$[Co(MP_zNEt_2)_2]ClO_4\cdot 2H_2O$ (dark red brown)	35.7 (35.8)	5.4 (5.4)	20.9 (20.9)	8.9 (8.8)	110
$[Co(MP_zNEt_2)_2]BF_4\cdot 2H_2O$ (red brown)	36.5 (36.5)	5.5 (5.5)	21.3 (21.3)	8.9 (8.9)	105
$[Co(MP_zNEt_2)_2]NO_3\cdot 2H_2O$ (dark red brown)	37.6 (37.9)	5.7 (5.7)	24.4 (24.3)	9.4 (9.3)	92

spectrum shows a signal at δ 13.40, indicating the presence of a hydrogen-bonded proton coming from the hydrazinic hydrogen (of the thiosemicarbazone part) [21]. This is shown in Fig. 1(b) as the hydrogen-bonded stabilised form of the ligand. The thione–thiol tautomerism of the ligand in solution is also indicated by another low field signal, $\delta = 12.89$ due to the formation of the S–H bond [22]. Another singlet at $\delta = 10.71$ is due to hydrazinic proton (–NH–). The mass fragmentation data are compatible with the proposed molecular formula $C_{10}H_{17}N_5S$. The strongest molecular ion peak appears at *m/z* 239 (86%).

3.2. Characterisation of the Co(III) complexes

All these Co(III) complexes give satisfactory C, H, N and Co analyses and conform to the general composition of the complexes as $[Co(MP_zNEt_2)_2]X\cdot 2H_2O$ (X = Cl, Br, ClO_4, BF_4 and NO_3). The molar conductance values in MeOH (30 °C) classify them as 1:1 electrolytes [23] (Table 1) and the complexes are diamagnetic (at 27 °C) as expected for a low spin d^6 ion.

3.2.1. Spectroscopy

The diffuse reflectance spectra of all the reported Co(III) complexes are similar in nature and show three bands in the regions 15105–15455 cm^{-1} ($^1A_{1g} \rightarrow {}^3T_{2g}$), 21097–21645 cm^{-1} ($^1A_{1g} \rightarrow {}^1T_{1g}$), and 23364–23866 cm^{-1} ($^1A_{1g} \rightarrow {}^1T_{2g}$), consistent with an overall octahedral symmetry. Since the observed lower energy bands are not split to a large extent, the reported Co(III) complexes are indicated not to be *trans* isomers [24]. The electronic spectra of the methanolic solutions of the complexes exhibit two bands in the region 43859–44286 cm^{-1} (log $\varepsilon = 4.56$–4.59 lit cm^{-1} mol^{-1}) and 30959–31055 cm^{-1} (log $\varepsilon = 4.52$–4.55 lit cm^{-1} mol^{-1}) attributable to intraligand charge transfer bands ($\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$, respectively). The spectra also show a shoulder at 25706–26315 cm^{-1} (log $\varepsilon = 4.02$–4.07 lit cm^{-1} mol^{-1}) which may arise due to S→Co(III) charge transfer (LMCT) bands. The absence of any d→d

transition bands may be due to the masking of d→d bands by strong CT bands.

The characteristic IR bands (4000–200 cm^{-1}) for the free ligand HMP_zNEt_2 when compared with those of its Co(III) complexes provide meaningful information regarding the bonding sites of the primary ligand molecule (Table 2). A negative shift in $\nu_{(CH=N)}$ band ($\sim$1620 cm^{-1}) in the spectrum of the free ligand to lower value (1592–1598 cm^{-1}) in its complexes is consistent with co-ordination of the azomethine nitrogen to the central Co(III) ion, the IR bands at 465–475 cm^{-1} in the complexes are then assignable to $\nu_{(Co-N)}$ [23]. An intense band at 865 cm^{-1} in the free ligand spectrum, assigned to $\nu_{(C=S)}$, has been found to shift to lower frequency regions (775–797 cm^{-1}) in the complexes, indicating the co-ordination of the thiol sulfur to Co(III); moreover, the appearance of a new band in the region (355–380 cm^{-1}) in the complexes is assignable to $\nu_{(Co-S)}$ [10]. IR bands at 1510 cm^{-1} and 615 cm^{-1} in the free ligand spectrum, assignable to $\nu_{(C=N)}$ (pyrazole ring) and the in-plane deformation of the pyrazole ring, have been shifted to the higher frequency region, indicating that the tertiary ring nitrogen atom (^{2}N) is a possible bonding site [12,25,26]. The presence of bands around 272–285 cm^{-1} in the complexes are clearly assignable to $\nu_{(Co-N)}$ (pyrazole ring) [10].

^{1}H NMR spectral data of the complexes (Table 3) when compared to that of free ligand (HMP_zNEt_2), the following features are notable:

(i) The peaks $\delta = 12.89$ and 10.71 due to imino ^{2}NH (at the thiosemicarbazone part) in the free ligand disappear after complexation. The data indicate that during complexation, the ligand undergoes deproto-

nation followed by co-ordination to the Co(III) ion through the thiolato sulfur atom.

(ii) Terminal N(n-Et_2)$_2$ peaks showing slightly downfield shifts are ascribed to the co-ordination of the thiol sulfur to the Co(III) ion resulting in reduction of electron density at the terminal N-atom of N(n-Et_2)$_2$.

(iii) Azomethine CH proton peaks at $\delta = 7.39$ in the free ligand, and suffers maximum downfield shift in the complexes ($\delta = 8.20$–8.27) as expected due to the co-ordination of the azomethine nitrogen to the central Co(III) ion.

The shifting of ^{4}CH (pyrazole ring) from $\delta = 6.22$ (free ligand) to $\delta = 6.27$–6.33 in the complexes is consistent with the fact that the pyrazole ring ^{2}N(tertiary) co-ordinates to the Co(III) ion. ^{1}H NMR spectra, thus, provide support for the bonding characteristics of the primary ligand system (HMP_zNEt_2) in forming complexes with Co(III) through pyrazolyl ring nitrogen ^{2}N(tertiary), azomethine nitrogen and thiolato sulfur atom [10,21] as also envisaged by IR data.

3.3. Crystal structures of $[Co(MP_zNEt_2)_2]ClO_4 \cdot 2H_2O$ (*I*) and $[Co(MP_zNEt_2)_2]BF_4 \cdot 2H_2O$ (*II*)

Fig. 2(a) and (b) show ORTEP [27] diagrams of the complexes together with the atom numbering schemes. Cobalt(III) has a distorted octahedral co-ordination in both the complexes. In either complex, a pair of monodeprotonated ligands ($MP_zNEt_2^-$) co-ordinate to the Co(III) ion through the thiolato sulfur [S(1A), S(1B)], the pyrazolyl (tertiary) ring nitrogen [N(1A), N(1B)], and the hydrazinic chain nitrogen [N(3A), N(3B)]. The crystallographic asymmetric unit in complex **I** consists of a $[Co(MP_zNEt_2)_2]^+$ cation, a ClO_4^-

Table 6
Hydrogen bonding distances (Å) and angles (°)

D–H···A	D–H	D···A	H···A	∠ D–H···A
Complex ***I***				
N(2A)–H(11A)···O(2W)	0.860(4)	2.701(7)	1.848(6)	171.6(3)
N(2B)–H(21A)···O(1W)	0.860(4)	2.742(6)	1.929(4)	157.3(3)
O(1W)–H(1W2)···N(4A)^{i}	0.945(4)	3.008(6)	2.076(4)	168.8(3)
Complex ***II***				
N(2A)–H(2A)···O(2W)	0.874(5)	2.750(8)	1.924(7)	157.0(3)
N(2B)–H(2B)···O(1W)	0.770(5)	2.701(12)	1.943(10)	168.3(5)
O(2W)–H(2W1)···N(4B)^{ii}	0.726(7)	3.019(8)	2.305(4)	168.0 (5)

Symmetry equivalents: (i) $-x+2$, $-y+1$, $-z+1$; (ii) $-x+1$, $-y$, $-z$.

anion and two molecules of water of crystallisation. The crystallographic asymmetric unit in complex **II** is similar to that in complex **I** except that the anion is BF_4^-. The anions in both the structures are disordered.

Table 5 lists the bond distances and angles involving the Co(III) ions. In either complex, two molecules (A and B) of the tridentate 5-methyl-3-formylpyrazole-N(4)-diethylthiosemicarbazone ligand co-ordinate to the Co(III) ions to form four five-membered chelate rings [Co–S(1A)–C(6A)–N(4A)–N(3A), Co–S(1B)–C(6B)–N(4B)–N(3B), Co–N(1A)–C(4A)–C(5A)–N(3A) and Co–N(1B)–C(4B)–C(5B)–N(3B)].

The geometry about the Co(III) ions in both the complexes compare well with those reported for other similar structures [28–30]. The shortening of the Co–N distance involving the azomethine nitrogen atoms relative to that of the pyrazolyl ring nitrogen atoms may be attributed to the fact that the azomethine nitrogen is a stronger base compared to the pyrazolyl nitrogen. The two azomethine nitrogen atoms [N(3A) and N(3B)] are *trans* to each other while the pyrazolyl ring nitrogen atoms [N(1A) and N(1B)] and the thiolato sulfurs [S(1A) and S(1B)] are in the *cis* positions.

The tridentate ligands ($MP_zNEt_2^-$) in both the complexes are practically planar. In complex **I**, C(2A) and C(4A) in ligand A, and C(3B) and N(4B) in ligand B, have the largest deviations in opposite directions [C(2A): +0.060(5) Å, C(4A): −0.055(5) Å, C(3B): +0.115(4) Å, and N(4B): −0.110(4) Å] from the least-squares mean planes through Co–S(1)–C(6)–N(4)–N(3)–C(5)–C(4)–C(3)–C(2)–N(2)–N(1). The corresponding deviations in complex **II** are N(4A): +0.103(4) Å, C(3A): −0.144(5) Å, C(4B): +0.042(5) Å, and C(2B): −0.073(6) Å. In both the complexes, the co-ordinating ligands A and B are orthogonal to each other; the dihedral angle between ligand A and ligand B is 89.37(3)° in complex **I** and 89.38(3)° in complex **II**. In both the structures, the three individual rings, namely, the pyrazole and the two five-membered chelate rings, are individually almost planar with small dihedral angles between them. In complex **I**, the maximum dihedral angle of 6.0(1)° is between the pyrazole ring N(1B)–N(2B)–C(2B)–C(3B)–C(4B) and the chelate ring Co–S(1B)–C(6B)–N(4B)–N(3B); in complex **II**, the rings N(1A)–N(2A)–C(2A)–C(3A)–C(4A) and Co–S(1A)–C(6A)–N(4A)–N(3A) have the maximum dihedral angle of 6.7(2)°.

Table 6 gives the details of the hydrogen bonding contacts excluding those involving the disordered atoms.

4. Supplementary material

Crystallographic data for the structures reported here have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 150099 and 150100. Abstract

Polymeric *S*-malate nickel(II) [Δ-Ni(*S*-Hmal)$(H_2O)_2]_n \cdot nH_2O$ (**1**) was prepared from the reaction of nickel chloride and malate salt. By prolonging the reaction time and heating, the kinetic monomeric product *cis*-[Ni(*S*-H_2mal)$_2(H_2O)_2]\cdot 2H_2O$ (**2**) can be converted into the thermodynamic polymeric product **1**. The coordination polymer is linked strongly by the tetradentate malate ligand, forming an homochiral zigzag chain. It is proposed that the chiral metal center of the complex may also be involved in the enantioselective synthesis as well as the chiral ligand. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Up until now, only a few heterogeneous asymmetric catalytic systems have been investigated in some detail. One of these is the enantioselective hydrogenation of activated carbonyl compounds over an α-hydroxy acid modified Raney nickel catalyst [1]. On the basis of systematic studies it has been proposed that a modifier like tartaric acid is adsorbed and forms a binuclear Ni tartrato complex [Ni(*R*,*R*-tart)$_2$] on the surface [2]. However, the possible interactions and the resultant coordinated species between the modifier and metal are not known exactly and require further attention. Direct investigation of the interaction between the modifier and Raney nickel is not yet possible. Any indirect evidence for the adsorption mode is therefore of importance for a better understanding of reactions like malic acid on a Ni surface [3].

Complex formation between nickel and malate has been reported as a negatively charged malate complex in several nickel-accumulating plants like *Dichapetalum gelonioides* subsp. *tuberculatum* and *Psychotria douarrei* of New Caledonian species [4]. It is also found as a cationic or neutral complex in electroplating baths for various Ni alloys [5]. The role of malic acid is to complex the free metal ion thus preventing precipitation of metal hydroxide species in solution and the concomitant spontaneous decomposition of the plating solution. Moreover, the malic acid-aided process serves in the preparation of well-defined and high surface area particles at low temperature [6]. The only nickel(II) malate complex with a well-characterized crystal structure was reported as monomeric bidentated dimalato diaquonickel(II) and considered as a weak coordinated complex [7]. In the present work, the reaction behavior of malate with nickel salt and the X-ray crystal structure of chiral polymeric neutral nickel malate [Δ-Ni(*S*-Hmal)$(H_2O)_2]_n \cdot nH_2O$ (**1**) (malic acid = H_3mal), which contains the tetradentate coordinated carboxylate/hydroxy moiety, are reported.

2. Experimental

2.1. Preparation of $[\Delta$-Ni(S-Hmal)$(H_2O)_2]_n \cdot nH_2O$ (1)

In a typical reaction, nickel chloride hexahydrate (10 mmol, 2.38 g) was added to a solution of potassium hydrogen malate (0.5 M, 20 cm^3) prepared from the reaction of *S*-malic acid and potassium hydroxide (1:2). The mixture (pH 3.5) was heated in a water bath at 70 °C for 8 h. The precipitate was collected and washed with ethanol to give a light green solid **1** (1.9 g, 78%). Electronic spectrum of **1**: λ_{max} (nm, ε, M^{-1} cm^{-1}): 389 (12.9); $[\alpha]_D^{20}$ −20° (water, *c* 0.1); IR (KBr, cm^{-1}): ν_{as}(CO) 1642 s, ν_s(CO) 1429m, 1386s, 1348m. *Anal.* Calc. for $C_4H_{10}O_8Ni_1$: C, 19.6; H, 4.1. Found: C, 19.2; H, 4.2%.

2.2. Preparation of Δ/Λ-cis-$[Ni(S\text{-}H_2mal)_2(H_2O)_2]\cdot 2H_2O$ (2) [7]

The monomeric malato complex Δ/Λ-*cis*-[Ni(*S*-H_2mal)$_2$(H_2O)$_2$]·2H_2O (**2**) was prepared from the reaction of nickel chloride hexahydrate (7.5 mmol, 1.8 g), malic acid (1.0 M, 5 cm^3) and potassium dihydrogen malate (1.0 M, 10 cm^3) in a 3:2:4 ratio. The potassium dihydrogen malate was prepared from the reaction of *S*-malic acid and potassium hydroxide in an equimolar ratio [7]. The reaction mixture (pH 2.6) was reacted for 1 h and cooled in a refrigerator for several days. The resultant crystals were collected and washed with ethanol to give a light green solid **2** (1.3 g, 44%). Electronic spectrum of **2**: λ_{max} (nm, ε, M^{-1} cm^{-1}): 389 (8.6); $[\alpha]_D^{20}$ −18° (water, *c* 1.0); IR (KBr, cm^{-1}): 1716s, 1624s, ν_s(CO) 1438m, 1397s, 1332m. *Anal.* Calc. for $C_8H_{18}O_{14}Ni_1$: C, 24.2; H, 4.6. Found: C, 23.9; H, 4.6%.

2.3. Conversion of cis-$[Ni(S\text{-}H_2mal)_2(H_2O)_2]\cdot 2H_2O$ (2) to $[\Delta$-Ni(S-Hmal)$(H_2O)_2]_n \cdot nH_2O$ (1)

A solution of monomeric nickel malate **2** (1.0 g, 2.5 mmol) was heated in a water bath at 70 °C for one day. The green precipitate was separated, washed with water and ethanol and gave [Δ-Ni(*S*-Hmal)$(H_2O)_2]_n \cdot n$$H_2O$ (**1**) in 82% yield (0.5 g).

Crystals of suitable quality for the subsequent X-ray diffraction studies were obtained as transparent light green rhomboids from the heating of the reaction mixture, which is controlled by programmed-temperature apparatus. The crystals were mounted in a capillary for X-ray analysis.

2.4. Physical measurements

Electronic spectra were recorded on a Shimadzu UV 2501 spectrometer. Infrared spectra were recorded as Nujol mulls between KBr plates on a Nicolet 370 FT-IR spectrometer. Elemental analysis was performed on EA 1110 elemental analyzers.

2.5. X-ray data collection, structure solution and refinement

Crystallographic data for the polymeric malato nickel complex **1** are summarized in Table 1. Diffraction data were collected on an Enraf–Nonius CAD-4 diffractometer with graphite monochromated Mo Kα radiation at 297 K. Lp factor, anisotropic decay and empirical absorption corrections were applied. The primary structure was solved by WINGX package [8] and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all the non-hydrogen atoms. Hydrogen atoms were located from difference Fourier maps and were not refined. Final calculations were performed on a PC using MOLEN software package [9]. Selected atomic distances and bond angles are given in Table 2.

3. Results and discussion

The preparation of the malato nickel(II) complex depends mainly on the reaction temperature. The effects

of pH variation seemed not so crucial for the two neutral products. Instead of the protonated mononuclear malato nickel complex **2**, solid separation from the reaction of nickel chloride with malic acid and potassium dihydrogen malate or potassium hydrogen malate resulted only in the main product **1** after heating or prolonged standing. The polymeric product **1** is the most stable species over the pH range 2.0–5.0. This implies a special stability of the superstructure. There is no direct evidence of the other crystalline phase of the ionic malato nickel(II) complex in pH range 2.0–5.0, although solution studies have suggested the existence of cationic and anionic malato nickel species [10]. It is undoubted that two malato nickel species form neutral complexes. This is not only the result from charge balance in the complex, but also the result from measurements of the small molar electrical conductivities (3.8×10^{-3} S m^2 mol^{-1} for **1** and 2.5×10^{-3} S m^2 mol^{-1} for **2**) [11]. Further attempts to separate the other products using nickel sulfate or other nickel salts only resulted in the isolation of a mixed salt without coordination of the malate ligand.

X-ray analysis reveals that **1** possesses an infinite chain structure (Fig. 1). It is interesting that monomeric **2** can be converted easily into **1** after heating. The reaction of nickel chloride and potassium malate yields the mononuclear complex **2** after a relatively short reaction time at room temperature, whereas the coordination polymer **1** is obtained after a prolonged reaction time or heating.

$$NiCl_2 + KH_2mal \xrightarrow{\text{r.t.}} cis-[Ni(S-H_2mal)_2 \cdot 2H_2O \xrightarrow{\Delta} [Ni(S-Hmal)(H_2O)_2]_n \cdot nH_2O$$

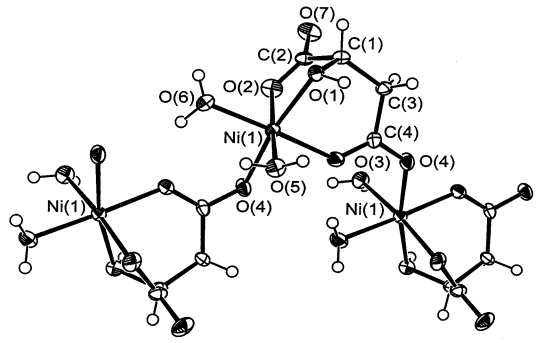

Fig. 1. Perspective view of the polymeric structure of [Δ-Ni(*S*-Hmal)$(H_2O)_2]_n \cdot nH_2O$, showing f50% thermal ellipsoids.

$$NiCl_2 + K_2Hmal \xrightarrow{\text{pH } 2-5/\Delta} [Ni(S-Hmal)(H_2O)_2]_n \cdot nH_2O$$

At high temperature one of the coordinated malates in **1** is replaced by a β-carboxylate of the other malate, inducing the formation of an infinite chain. The present results indicate that the mononuclear nickel(II) is a kinetic product formed reversibly from the components, which progressively converts into the thermodynamic product **2**. The high stability of **2** might be attributed to several factors, such as chelate effect and strain in the bound ligand and/or at the coordinate centers, hydrogen bond and enthalpic contribution.

The crystals were insoluble in most solvents and only slightly soluble in water. The structure of **1** comprises of discrete neutral chiral polymeric nickel *S*-malate and water molecules. The chiral configuration of the metal center is determined by the chiral ligand and the noncentrosymmetric space group [12]. Fig. 1 is the plot of the chiral polymeric structure of **1**, which shows nickel(II) centers bridged by *S*-malate groups. The smallest structural subunit appears to be the monomeric entity Δ-Ni(*S*-Hmal)$(H_2O)_2$. Nickel atoms are *quasi*-octahedrally coordinated by two water molecules and two different malate ligands. The malate ion acts as a tridentate ligand via its hydroxyl, α-carboxyl and β-carboxyl groups in *fac*-mode, while the β-carboxyl group further coordinates monodentately to the other nickel atom in the *trans*-position of the hydroxyl group, forming a catenarian zigzag coordination polymer. Tetradentate coordination of malate through its hydroxyl, α-carboxyl and β-carboxyl group is different from its mononuclear reactant [7]. It is a much more stable species than that of mononuclear malato nickel(II).

In some chiral coordination polymers, the chiral metal center is vague like in the *S*-lactato zinc(II) complex $[Zn(S\text{-lact})_2]_n$ for *trans*-coordination. Note that the *R*-configuration is improperly assigned in the final product [13]. As shown in Fig. 2, there are six possible diastereoisomers of the coordination polymer, which result from the geometric and asymmetric octahedral coordination environment around nickel. The

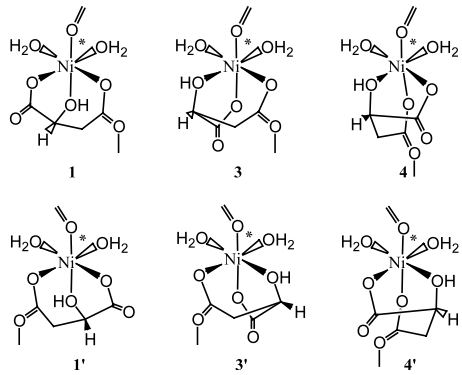

Fig. 2. Possible diastereoisomers of $[Ni(S\text{-Hmal})(H_2O)_2]_n$.

present product **1** is one of the diastereoisomers (**1** and **1′**) separated from the reaction. The bridged monodentate O(4) atom is occupied by the hydroxyl O(1) atom, which is similar to the dinuclear citrato molybdate(VI) and tungstate complex [14,15]. Usually, a chiral modifier like *S*-malic acid is involved directly in heterogeneous enantioselective catalysis [3]. It is proposed that the chiral metal center of the complex may also be involved in the enantioselective synthesis.

As shown in Table 2, the Ni–O malato nickel distances lie between 2.021(4) and 2.082(5) Å. The Ni–O (hydroxy) bonds are slightly longer [2.082(5) Å], indicating a protonated hydroxyl group in the malate anion, which is different from the alkoxy group coordination in other metal malate complexes such as vanadium, molybdenum and tungsten [16–18]. The Ni–O (water) bonds [2.049(4) and 2.059(4) Å] are slightly longer than those of Ni–O (β-carboxyl) [2.044(4) and 2.039(4) Å], and those to the α-carboxyl group are the shortest [2.021(4) Å].

Abstract

Reaction of $Mn_2(CO)_{10}$ with $R_2P(S)P(S)R_2$ (R = Me, Et, Pr^n, Bu^n) in toluene at 120 °C yields binuclear $[Mn_2(CO)_8(\mu\text{-}PR_2)_2]$ and trinuclear $[Mn(CO)_3(\mu\text{-}S{=}PR_2)]_3$ complexes. Both result from phosphorus–phosphorus bond scission, while in the former sulfur abstraction has also occurred. An X-ray diffraction study of $[Mn_2(CO)_8(\mu\text{-}PBu^n_2)_2]$ confirms that the manganese adopts a distorted octahedral geometry with local C_{2v} symmetry. © 2002 Elsevier Science Ltd. Keywords: Diphosphine disulfide; Dimanganese decacarbonyl; Phosphido; Phosphidosulfide

1. Introduction

Dimanganese decacarbonyl contrasts strongly with most other metal carbonyls in that only a relatively limited number of simple substitution derivatives have been prepared; by way of comparison, the Group VI carbonyls form literally hundreds of simple substitution products [1]. The tendency of the parent carbonyl to undergo valence disproportionation instead of substitution and the intractability of substitution products once formed are among the most important factors in the scarcity of substitution products of dimanganese decacarbonyl [2].

Since the preparation of the first tetraalkyldiphosphine disulfides complexes in 1965 [3–5], such compounds have continued to attract attention, in part because of the different possible coordination geometries which the ligand may adopt. We have recently discovered a photochemical reaction of $M(CO)_6$ (M = Mo, W) with $R_2P(S)P(S)R_2$ to give the chelate complexes $[M(CO)_4\{\mu\text{-}R_2P(S)P(S)R_2\}]$ [6], where the ligand is presumed to adopt the expected *cis*-chelate bidentate coordination. However, in certain cases, the ligand bridges between two metals affording $[M_2(CO)_{10}\{\mu\text{-}R_2P(S)P(S)R_2\}]$ [7] as secondary products.

Both product types detailed above are characterised by the tetraalkyldiphosphine disulfides remaining intact. This is not always the case and in certain reactions fragmentation has been observed. For example, the formation of, inter alia, $[Me_2PS_2]$ ions has been reported upon reaction of OH^- with $Me_2P(S)P(S)Me_2$ in the chemical ionization source of a mass spectrometer [8]. Reaction of $Co_2(CO)_8$ and $Me_2P(S)P(S)Me_2$ was first described in 1972 and two clusters were reported [9], while later the X-ray crystal structure of one of these, namely $[Co_4(CO)_9(\mu_3\text{-}S)(\mu\text{-}PMe_2)]$ confirmed that both phosphorus–sulfur and phosphorus–phosphorus scission had occurred [10].

Gelmini and Stephan [11] have reported that upon reaction with $Cp_2Ti(CO)_2$ under UV irradiation, diphosphine disulfides extrude a PR_2 unit yielding titanium(III) complexes $Cp_2Ti(\eta^2\text{-}S_2PR_2)$. We have recently shown that under similar *photochemical* conditions, $Mn_2(CO)_{10}$ also reacts with $Me_2P(S)P(S)Me_2$ to give $[Mn(CO)_4(\eta^2\text{-}S_2PMe_2)]$ as a result of PMe_2 extrusion [12]. Herein we show that the outcome of this reaction is dependent upon the conditions such that under *thermal*

conditions two different products result, namely: binuclear phosphido-bridged $[Mn_2(CO)_8(\mu\text{-}PR_2)_2]$ and trinuclear phosphido-sulfido-bridged $[Mn(CO)_3(\mu\text{-}S{=}PR_2)]_3$.

2. Experimental

2.1. General

Reactions were carried out under dry nitrogen by using Schlenk techniques. All solvents were dried and degassed prior to use. Elemental analyses were carried out using a Carlo Erba Strummentaione Model 1106 by Technical and Scientific Research Council of Turkey, Tubıtak. FTIR spectra were recorded on samples in hexane at the Ege University on a Mattson 1000 FT spectrophotometer. ^{31}P NMR spectra were recorded in $CDCl_3/CH_2Cl_2$ at UCL on a Varian VXR400 spectrometer. FAB mass spectra were recorded at UCL. $Mn_2(CO)_{10}$ (Aldrich) was used as supplied and tetraalkyldiphosphine disulfides $R_2P(S)P(S)R_2$ were prepared by literature methods [33,34].

2.2. Synthesis

Complexes, **1a**–**d** and **2a**–**d** were prepared by the thermal reactions of $Mn_2(CO)_{10}$ with $R_2P(S)P(S)R_2$ (R = Me, Et, Pr^n, Bu^n) and obtained in 20–40% yield. A typical preparation is given. $Mn_2(CO)_{10}$ (2 mmol) and $Me_2P(S)P(S)Me_2$ (2 mmol) were dissolved in toluene (20 cm^3) and the mixture refluxed under nitrogen overnight. At the end of the reaction, unreacted $Mn_2(CO)_{10}$ was not detected by FTIR. The solution was evaporated to dryness in vacuo producing a dark yellow–orange mixture. Work up procedures were performed in air. The reaction mixture was dissolved in CH_2C1_2 (2 cm^3) and preparative thin-layer chromatography (TLC) was carried out on commercial Merck plates coated with a 0.25 mm layer of silica, using light petroleum as an eluent. At the end of the chromatographic separation, two major different bands were obtained. The first band is pale yellow, **1a** (30%); the second band is dark yellow, **2a** (20%).

2.3. Crystallography

A single crystal of **1d** was mounted on a glass fibre and all geometric and intensity data were taken from this sample using an automated four-circle diffractometer (Nicolet R3mV) equipped with Mo Kα radiation ($\lambda = 0.71073$ Å). Important crystallographic parameters are summarised in Table 1. The lattice parameters were identified by application of the automatic indexing

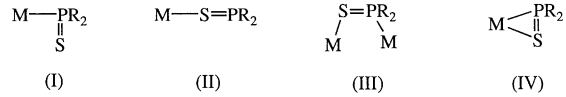
routine of the diffractometer to the positions of a number of reflections taken from a rotation photograph and centred by the diffractometer. The $\omega-2\theta$ technique was used to measure reflections in the range $5^\circ < 2\theta < 50^\circ$. Three standard reflections (remeasured every 97 scans) showed no significant loss in intensity during data collection. The data was corrected for Lorentz and polarisation effects. The unique data with $I > 2\sigma(I)$ were used to solve and refine the structure. The structure was solved by direct methods and developed by alternating cycles of least-squares refinement and difference Fourier synthesis. All non-hydrogen atoms were refined anisotropically. Hydrogens were located from difference maps but were refined isotropically with a common isotropic thermal parameter ($U = 0.08$ Å^2) Final difference Fourier maps were featureless and contained no peaks greater than 1.00 e Å^{-3}. Structure solution used the SHELXTL program on an IBM PC [35].

3. Results and discussion

Heating toluene solutions of $Mn_2(CO)_{10}$ and $R_2P(S)P(S)PR_2$ (R = Me, Et, Pr^n, Bu^n) for 18 h produced dark yellow–orange solutions from which pale yellow $[Mn_2(CO)_8(\mu\text{-}PR_2)_2]$ **1a–d** (25–30%) and dark yellow $[Mn(CO)_3(\mu\text{-}S{=}PR_2)]_3$ **2a–d** (20–25%) were isolated after chromatography. Characterisation was made on the basis of IR, NMR, mass spectral and analytical data.

R = (a) Me,(b) Et, (c) Pr^n, (d) Bu^n



Phosphido-bridged complexes $[Mn_2(CO)_8(\mu\text{-}PR_2)_2]$ **1a–d** result from loss of sulfur and phosphorus–phosphorus bond scission. Such complexes are well known [13–22] and indeed the first such complex reported (R = Ph) [13] was prepared upon phosphorus–phosphorus cleavage of Ph_2PPPh_2 when refluxed with $Mn_2(CO)_{10}$. Characterisation was straightforward, with all showing molecular ions in the mass spectra. The carbonyl region of the IR spectra show four strong bands associated with the local C_{2v}, symmetry at manganese while the equivalence of the phosphorus nuclei was shown by the observation of a singlet (δ 106.0–105.6) in the ^{31}P NMR spectra. Single crystals of $[Mn_2(CO)_8(\mu\text{-}PBu^n_2)_2]$ (**1d**) were grown upon slow evaporation of a saturated dichloromethane solution and the results of the X-ray diffraction study are shown in Table 2 and Fig. 1.

The molecule is centrosymmetric and consists of two approximately octahedral manganese centres being bridged by the butylphosphido ligands which occupy equatorial sites. The phosphorus ligands subtend an angle of 77.23(3)° at the metal centre while the Mn–P–Mn angle is 102.77(3)°. These values are within experimental error the same as those found in the dimethylphosphido-bridged complex $[Mn_2(CO)_8(\mu\text{-}PMe_2)_2]$ (**1a**) [76.9(1)°; 103.1(1)°] which is also centrosymmetric [18]. The Mn–P bond lengths [**1a**: 2.345(4), 2.348(2) Å; **1d**: 2.3949(9), 2.4017(11) Å] do differ slightly between the two structures; values in **1d** being similar to those in the diphenylphosphido-bridged complex $[Mn_2(CO)_8(\mu\text{-}PPh_2)_2]$ [Mn–P: 2.383(2)–2.394(2) Å] [19]. A number of other complexes of this type have also been crystallographically characterised and structural features do not vary significantly between them [18–22].

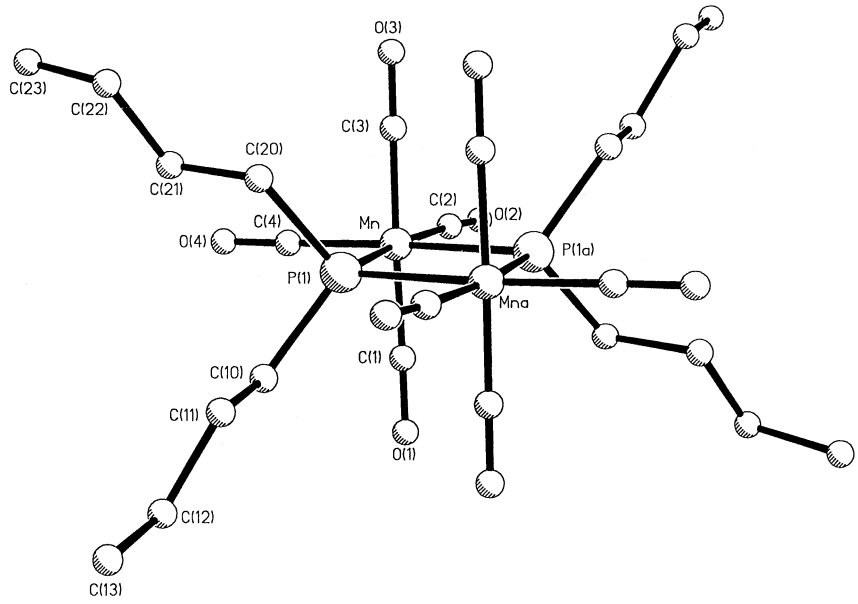
Identification of the second product as trinuclear dialkylphosphidosulfide complexes $[Mn(CO)_3(\mu\text{-}S{=}PR_2)]_3$ (**2a–d**) is based primarily on mass spectral data. Thus, while IR and analytical data are consistent with a $[Mn(CO)_3(SPR_2)]$ formulation, it is only the latter that provides insight into the nuclearity. Complexes **2b–c** both show a molecular ion in the mass spectrum consistent with a trinuclear unit, while **2d** shows the expected ion after loss of a butyl group. In the ^{31}P NMR spectrum all show a singlet, the chemical shift of which (δ 90.8–62.0 ppm) suggests that the sulfur–phosphorus bond remains intact. Phosphidosulfide ligands are known to bind to metal centres in four different ways (I–IV) as shown below [23].

(I) (II) (III) (IV)

In the absence of crystallographic data it is known that assigning specific binding modes to phosphidosulfide complexes is difficult, as spectroscopic properties depend also on both the metal centre(s) and associated other ligands [23]. Precedence strongly favours the



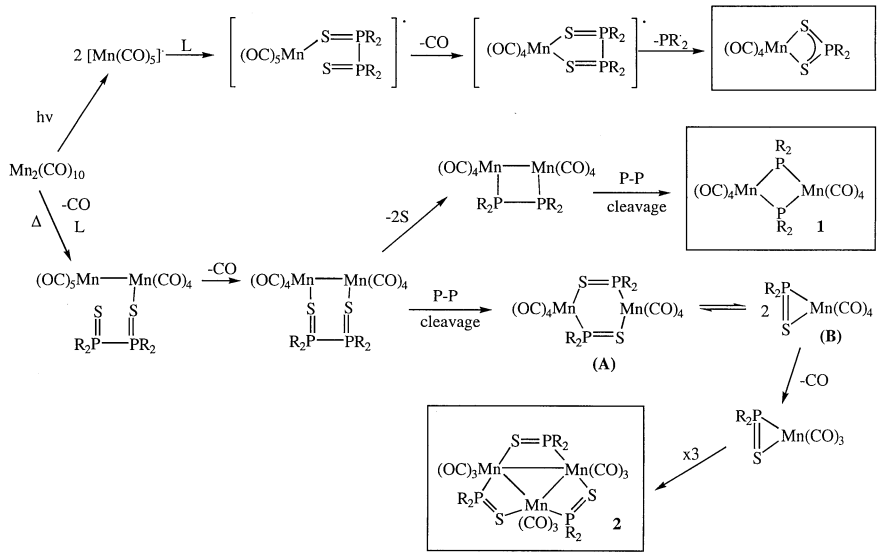


Fig. 1. Molecular structure of $[Mn_2(CO)_8(\mu\text{-}PBu^n_2)_2]$ **1d**.

doubly bridging mode (III) in **2** as, while binding mode (I) is most frequently seen, mode (III) is adopted in *all* bi- or polynuclear complexes containing this ligand reported to date [23,24]. We thus assign the structure of **2** as shown. The observation of nine bands in the carbonyl region of the IR spectrum further supports a local C_{3v} symmetric structure. As each dialkylphosphine sulfide ligand acts as a three-electron donor ligand, a total cluster electron count of 48 suggests that there are three metal–metal bonds. The observation of a single phosphorus resonance is also consistent with the proposed structure, while when in a chelate mode (IV) chemical shifts are normally upfield of H_3PO_4 (i.e. negative). We note here a report that suggests that $Fe(CO)_5$ reacts with $Me_2P(S)P(S)Me_2$ under UV irradiation to give $[Fe_2(CO)_6(\mu\text{-}SPMe_2)_2]$ as the major product, in which the ligand is bound only through sulfur (II) [25]. In light of more recent results this formulation is probably incorrect and we are currently reinvestigating this chemistry.

The condition dependence of the reaction of diphosphine disulfides with $Mn_2(CO)_{10}$ are worthy of further note and a plausible explanation and mechanistic route is shown in Scheme 1. The reactivity of $Mn_2(CO)_{10}$ is known to be condition dependent, such that photolysis favours Mn–Mn bond homolysis while under thermal conditions carbonyl loss dominates. *Photochemical* conditions leads to PR_2 extrusion [12] and probably proceeds via reaction of diphosphine disulfides with the 17-electron $[Mn(CO)_5]^\bullet$ radical. Such species are known to undergo facile substitution reactions after which PR_2 extrusion is competitive with reformation of the Mn–Mn bond. An intermediate in the process may be the 19-electron species $[(CO)_4Mn\{\eta^2\text{-}S{=}P(R_2)P(R_2){=}S)]^\cdot$, and in support of this postulation we have recently prepared analogous 18-electron molybdenum complexes [6]. *Thermal* conditions favour CO loss and formation of a bridged species $[\{Mn(CO)_4\}_2(\mu\text{-}S{=}P(R_2)P(R_2){=}S)]$ can be envisaged. Again, support for this comes from our recent preparation of the analogous dimolybdenum complexes $[\{Mo(CO)_5(\mu\text{-}S{=}P(R_2)P(R_2){=}S)]$ [7]. Cleavage of the phosphorus–phosphorus bond at this stage via oxidative-addition to the binuclear centre would afford the known complexes $[\{Mn(CO)_4(\mu\text{-}S{=}PR_2\}_2]$ (**A**) [26–29]. Such complexes are known and have been shown to be in equilibrium in solution with monomers (**B**) [30–32]. Loss of CO from the latter would result in formation of a reactive 16-electron species, trimerisation of which affords **2**. In a second pathway, disulfur extrusion from the diphosphine disulfide bridged intermediate would give diphosphine-bridged $[\{Mn(CO)_4\}_2(\mu\text{-}R_2P\text{-}PR_2)]$, oxidative addition of the phosphorus–phosphorus bond affording **1**.

4. Supplementary material

A complete list of bond lengths and angles and tables of atomic coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 173950. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

The synthesis, X-ray structure, magnetic and spectroscopic properties of new Co(II), Ni(II) and Cu(II) complexes with 1-vinyl-3-acetylamino-1,2,4-triazole (vaat) are reported. The crystal structures of $[Ni(vaat)_2(H_2O)_2](NO_3)_2$ and $[Cu(vaat)_2(H_2O)_2]Cl_2$ have been determined by X-ray diffraction. In these mononuclear complexes, the metal ion is surrounded by two water molecules in axial positions and two oxygen and two nitrogen ($N4$) atoms coming from two *trans*-oriented chelating vaat molecules. Anions are noncoordinated and are involved in a hydrogen bonding network. The complex cations of $[Cu(vaat)_2(H_2O)_2]Cl_2$ are aligned within chains. In the structure of $[Ni(vaat)_2(H_2O)_2](NO_3)_2$ the nitrate anions establish a bridge in the plane by hydrogen bonding giving a 2-D character for this compound. In addition, a colour change from pink to blue upon heating has been observed for $[Co(vaat)_2(H_2O)_2]Cl_2$, which is due to the removal of the two coordinated water molecules and the subsequent molecular reorganisation of the molecular structure. © 2002 Elsevier Science Ltd. 1. Introduction

1,2,4-Triazoles derivatives represent an interesting class of heterocycles. Their versatility as ligands is determined by the number and the arrangement of the nitrogen atoms in the aromatic cycle as well as by the nature of their substituents. Transition metal complexes with these ligands have a great interest from both theoretical and practical viewpoints since they can be subject to spin crossover or magnetic exchange studies [1–17]. Various applications in bioinorganic chemistry are well known [18,19]. They are also used as precursors of photographic materials and some of them demonstrate anticorrosion properties [20,21]. With the absence of a donor atom in the substituent, triazoles are coordinated to metal ions mainly as bridging ligands forming polynuclear complexes [1–15]. The 3-acetylamino-1,2,4-triazole (hereafter abbreviated Haat) and its derivatives are some of the most interesting ligands as they demonstrate possibilities of both chelating and bridging coordination modes and can form various types of complexes [22–28]. In addition, coordination abilities of these ligands increase with their deprotonation. Indeed, it should be mentioned, that the Haat molecule can loose acidic protons of the triazole ring and of the NH group of its substituent. Thus, variation of the synthetic conditions, i.e. the molar metal:ligand ratio, the acidity of the solution, the nature of the solvent and so forth, can result in the formation of different complex species.

Numerous papers dealing with the synthesis of Co(II), Ni(II) and Cu(II) Haat coordination compounds have been published in the last decade. Fascinating triangular trinuclear Cu(II) compounds with deprotonated forms of Haat and its 5-amino derivative, involving a pyramidal $Cu_3(\mu_3\text{-}O(H))$ core were obtained [26,29,30]. The first crystal structure of this type was found for a Cu(II)

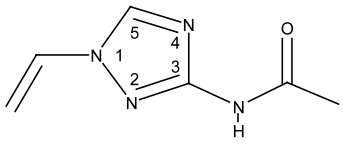
complex with 3,5-dimethyl-4-amino-1,2,4-triazole (L). Two structural formulae, namely $(H_3O)[(\mu_3\text{-}OH)(\mu,\eta^2\text{-}L)_3Cu_3Cl_6]$ and $[(\mu_3\text{-}OH)(\mu,\eta^2\text{-}L)_2(\mu_2,\eta^2\text{-}LH)Cu_3Cl_6]$, were, however, proposed for this compound as hydrogen atoms could not be properly localised [30]. Other complexes of the same type with the following composition $[Cu_3(\mu_3\text{-}OH)(aat)_3A(H_2O)_2]A\cdot nH_2O$ ($A = NO_3^-$, $CF_3SO_3^-$, ClO_4^-, $n = 0$, 2) [26] and $[Cu_3(\mu_3\text{-}OH)(aaat)_3(H_2O)_3](NO_3)_2\cdot H_2O$ [29] where aat and aaat are the deprotonated forms of 3-acetylamino-1,2,4-triazole and 3-acetylamino-5-amino-1,2,4-triazole, have also been obtained. All of them contain a triangular Cu_3 skeleton with μ_3-bridging OH-groups. The copper atoms are linked by *N*1*N*2 atoms of three peripheral bridging triazoles.



Mononuclear complexes with Haat such as $[M(Haat)_2(H_2O)_2]A\cdot nH_2O$ (M = Co(II), Ni(II), Cu(II); $A = Cl^-$, Br^-, SO_4^{2-}, NO_3^-, $n = 0$, 2, 5), $[Cu(Haat)_2(NO_3)_2]$ and two linkage isomers of $[Cu(Haat)_2(NCS)_2]$ have been synthesised and investigated [22–25,27,28]. In these compounds Haat is coordinated to the metal as a chelating ligand. Such diversity in the structure of these compounds requires further research on this topic. This is why we have synthesised complexes with a new ligand related to Haat: 1-vinyl-3-acetylamino-1,2,4-triazole, hereafter abbreviated as vaat (see Scheme 1). A vinyl group has been introduced in 1-position of the triazole ring, thus modifying the electronic distribution of the triazole ring.

This present contribution deals with the synthesis, X-ray structures, magnetic and spectroscopic properties of new coordination compounds with this ligand, i.e. $[M(vaat)_2(H_2O)_2](NO_3)_2$ (M = Co(II), Ni(II), Cu(II) (**1**, **2**, **3**)), $[M(vaat)_2(H_2O)_2]Cl_2$ (M = Co(II), Ni(II) (**4**, **5**)) and $[Cu(vaat)_2(H_2O)_2]A_2$ ($A = Cl^-$, Br^- (**6**, **7**)).

2. Experimental

2.1. General

Infrared spectra were obtained with Specord 75IR and Specord M-80 spectrophotometers in the region 200–3600 cm^{-1}. Ligand field spectra were recorded in the region 350–2200 nm on a Unicam 700A spectrophotometer by using the diffuse-reflectance technique with MgO as a reference. Thermogravimetric measurements were carried out with a "Paulik–Paulic–Erdey" apparatus in the temperature range 300–450 K with a heating rate of 2.5 K min^{-1} under ambient atmosphere. Gravimetric measurements were carried out at 420 K under ambient atmosphere according to the following technique. The sample was heated and thermostated at a certain constant temperature. Then it was cooled in a closed dessiccator over $Mg(ClO_4)_2$ and its mass was measured. X-ray powder diffraction experiments were carried out on a Philips diffractometer (Cu Kα-irradiation, Ni filter). Magnetic susceptibilities of polycrystalline samples were measured by the Faraday's method at room temperature (**1**, **2**, **4**, **5**, **7**) and in the temperature range 78–300 K for compounds **3** and **6**. Values of effective magnetic moments μ_{eff} were calculated according to the equation $\mu_{eff} = [8\chi T]^{1/2}$, where χ is the molar susceptibility corrected for diamagnetic contributions.

Scheme 1. 1-Vinyl-3-acetylamino-1,2,4-triazole.

2.2. Synthesis

Commercially available salts were used without further purification. The vaat ligand was synthesised and kindly provided by Professor L.I. Vereshchagin (Irkutsk State University).

2.2.1. $[M(vaat)_2(H_2O)_2](NO_3)_2$ (M = Co(II), Ni(II), Cu(II) (**1**, **2**, **3**))

A hot aqueous solution of vaat (3 mmol, 0.46 g) was rapidly added to a solution containing 1.5 mmol of metal salt (0.44 g $Co(NO_3)_2\cdot 6H_2O$, 0.44 g $Ni(NO_3)_2\cdot 6H_2O$, 0.36 g $Cu(NO_3)_2\cdot 3H_2O$) dissolved in 5 ml of hot water. A precipitate was obtained after evaporation and cooling of the resulting solution. It was subsequently filtered, washed with water and dried in ambient air.

$[Co(vaat)_2(H_2O)_2](NO_3)_2$: *Anal*. for $C_{12}H_{20}CoN_{10}O_{10}$: Calc. (found): C, 27.5 (26.8); H, 3.9 (4.3); N, 26.8 (27.0); Co, 11.3 (11.1). Yield: 15%.

$[Ni(vaat)_2(H_2O)_2](NO_3)_2$: *Anal*. for $C_{12}H_{20}N_{10}NiO_{10}$: Calc. (found): C, 27.6 (27.1); H, 3.9 (4.2); N, 26.8 (26.8); Ni, 11.2 (11.3). Yield: 30%.

$[Cu(vaat)_2(H_2O)_2](NO_3)_2$: *Anal*. for $C_{12}H_{20}CuN_{10}O_{10}$: Calc. (found): C, 27.3 (26.2); H, 3.8 (4.0); N, 26.5 (26.8); Cu, 12.0 (11.8). Yield: 40%.

2.2.2. $[M(vaat)_2(H_2O)_2]Cl_2$ (M = Co(II), Ni(II) (**4**, **5**))

An aqueous solution of 1.5 mmol (0.36 g) of $CoCl_2\cdot 6H_2O$ or 2 mmol (0.48 g) of $NiCl_2\cdot 6H_2O$ was mixed with a solution of vaat (3 mmol, 0.46 g (**4**) or 4 mmol, 0.61g (**5**)). Evaporation and cooling of the resulting solution led to the formation of a precipitate.

$[Co(vaat)_2(H_2O)_2]Cl_2$: *Anal*. for $C_{12}H_{20}Cl_2CoN_8O_4$: Calc. (found): C, 30.7 (30.4); H, 4.3 (5.0); N, 23.8 (23.9); Co, 12.5 (11.7). Yield: 45%.

$[Ni(vaat)_2(H_2O)_2]Cl_2$: *Anal*. for $C_{12}H_{20}Cl_2N_8NiO_4$: Calc. (found): C, 30.7 (29.9); H, 4.3 (4.6); N, 23.8 (23.5); Ni, 12.5 (12.0). Yield: 50%.

2.2.3. $[Cu(vaat)_2(H_2O)_2]A_2$ ($A = Cl^-$, Br^- (**6**, **7**))

A solution of 1.5 mmol of the corresponding metal salt (0.26 g $CuCl_2 \cdot 2H_2O$; 0.34 g $CuBr_2$) in 5 ml of water and a solution of 4.5 mmol (0.68 g) of vaat were mixed and then evaporated. The evaporation was followed by cooling the reaction mixture and by filtering the formed precipitate.

$[Cu(vaat)_2(H_2O)_2]Cl_2$: *Anal*. for $C_{12}H_{20}Cl_2CuN_8O_4$: Calc. (found): C, 30.4 (29.9); H, 4.2 (4.0); N, 23.6 (24.1); Cu, 13.4 (13.1). Yield: 30%.

$[Cu(vaat)_2(H_2O)_2]Br_2$: *Anal*. for $C_{12}H_{20}Br_2CuN_8O_4$: Calc. (found): C, 25.6 (24.7); H, 3.6 (3.6); N, 19.9 (19.5); Cu, 11.3 (11.1). Yield: 60%.

The metal content was determined by trilonometric analysis after decomposition of the samples in a mixture of $H_2SO_{4(c)}$ and $HClO_{4(c)}$. C, H and N determinations were performed by the Laboratory of Microanalysis, Novosibirsk Institute of Organic Chemistry.

Suitable crystals of $[Ni(vaat)_2(H_2O)_2](NO_3)_2$ for X-ray analysis were obtained by slow evaporation of a solution of the compound in a mixture of ethanol, DMFA and benzene (1:1:1) after 2 months. Single crystals of $[Cu(vaat)_2(H_2O)_2]Cl_2$ were obtained from an aqueous solution of this complex after 1 month.

2.3. X-ray structure determination

Crystallographic data and details of diffraction experiments are given in Table 1. Data were collected with a Siemens (Bruker) SMART platform with a CCD detector using monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å) over more than a hemisphere of reciprocal space ($2\theta < 55^\circ$) for compound **2** at room temperature. The SMART software was used for data acquisition and the SAINT software for data extraction [34a]. Absorption corrections were done using SADABS [34a], and the structure was solved and refined using the SHELXS-86 [34b] and SHELXTL program systems [34c]. Selected bond distances and angles for **2** are given in Table 2.

Compound **6** was studied by X-ray analysis at room temperature using an automatic four-cycle Enraf-Nonius CAD4 diffractometer (radiation Mo Kα, graphite monochromator, standard technique, θ–2θ scan with variable speed). The structure was solved by direct methods and refined by full-matrix least-squares methods using the SHELX97 program set [35]. Hydrogen atoms were located geometrically and refined in a rigid body approximation. Selected bond distances and angles for compound **6** are given in Table 3.

3. Results and discussion

3.1. Synthetic aspects

The coordination compounds of Co(II), Ni(II) and Cu(II) were synthesised by mixing hot aqueous solutions of the corresponding metal salts and the ligand. Precipitates were obtained after evaporation and cooling of the resulting solutions. The small yields are due to the relatively high solubility of the complexes in water. Further evaporation of mother liquors increases the yields. For the synthesis of compounds **1**–**5**, metal:ligand molar ratios of 1:1 and 1:2 were used. Complexes of the same composition were obtained by adopting such synthetic conditions. The synthesis of complexes **6** and **7** were carried out with a metal:ligand ratio of 1:3, as a metal:ligand ratio of 1:2 did not lead to the formation of compounds having a 1:2 stoichiometry. All compounds are soluble in water and organic solvents (ethanol, isopropanol, acetone, DMFA, DMSO, and in their mixtures with benzene and toluene).

Complexes **2** and **4** were recrystallised from water. The results of elemental analysis of the recrystallised phases were not different from the data of the parent compounds.

3.2. Description of the crystal structures

The molecular structure of compound **2** is shown in Fig. 1. The Ni(II) ion exhibits a slightly distorted

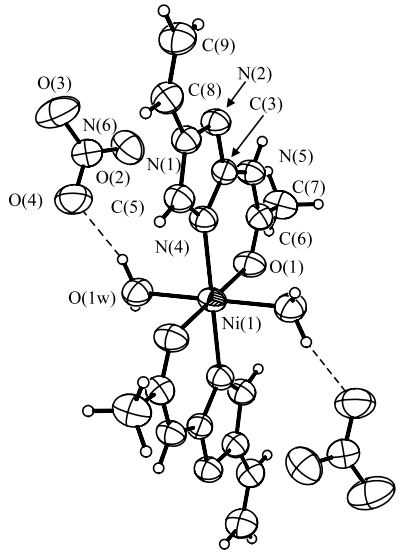

Fig. 1. View of the crystal structure of $[Ni(vaat)_2(H_2O)_2](NO_3)_2$ (**2**) (50% probability ellipsoids).

octahedral coordination geometry with two water molecules in axial positions and two nitrogen and oxygen atoms coming from two coplanar vaat ligands situated in the equatorial plane (Table 2). The nitrate anions are not involved in the coordination sphere in contrast to $[CuL_2(NO_3)_2]$ with L = 3-acetylamino-1,2,4-triazole [25]. Fig. 2 shows a view of the crystal packing on the (ab) plane. The nitrate anions appear to be involved in an extensive hydrogen bonding network involving the water molecules coordinated to the nickel ions and the amido groups attached to the triazole ligands. This

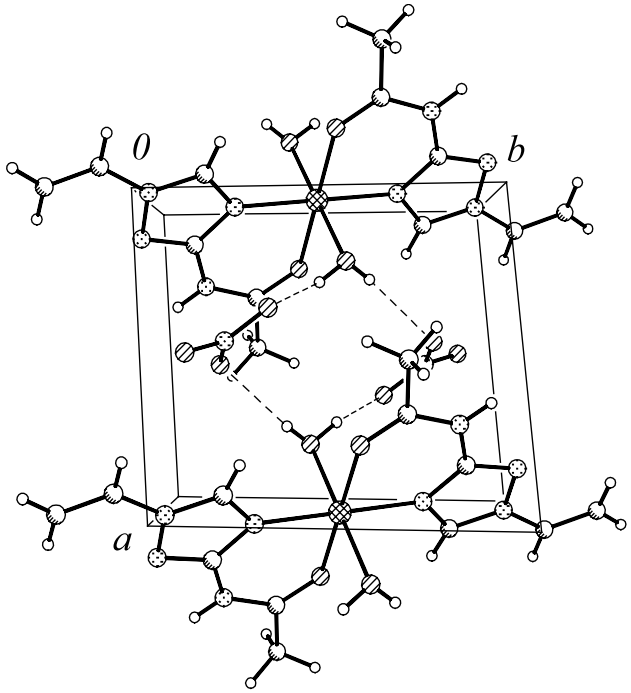

Fig. 2. View of the crystal packing of compound **2** on the (ab) plane.

allows a link to be established between the mononuclear complexes in the *a* and *b* directions, the Ni···Ni distance being equal to 7.285 Å.

The cationic unit $[Cu(vaat)_2(H_2O)_2]^{2+}$ of **6** is shown in Fig. 3. As usual in Cu(II) complexes, the coordination polyhedron of the metal ion is an elongated square bipyramid with two bidentate triazole ligands in equatorial positions and two water molecules in axial positions. The Cu–N and Cu–O bond distances have their typical values. The triazole ligand is practically planar, the deviations of N(1), N(2), C(3), N(4) and C(5) atoms from the common least-squares plane are less than 0.004 Å. The aceto-group and the copper atom also lie very close to this plane, the deviations are within 0.07 Å. This means that π–π aromatic coupling is possible in the ligand. This is also confirmed by analysis of the bond distances in the triazole ring. Indeed, the "single" bonds N(1)–N(2), N(1)–C(5) and C(3)–N(4) are only slightly longer than the "double" bonds N(2)–C(3) and N(4)–C(5) (Table 3). The crystal packing of **6** is shown in Fig. 4. There are short Cl(1)···H–N(5) and Cl(1)···H–O(1w) non-bonding contacts with Cl–N and Cl–O distances of 3.13 and 3.14 Å, respectively, which can be considered as intermolecular hydrogen bonds. In this way the chlorine anions link the complex cations into chains running along the *b* axis (Fig. 4).

Relevant interatomic distances and angles for the hydrogen bonding interactions in **2** and **6** are given in Tables 4 and 5, respectively.

3.3. Colour change of $[Co(vaat)_2(H_2O)_2]Cl_2$

Upon heating, complex **4** does show a pronounced colour change from pink to blue. Thermogravimetric analysis shows that this compound loses part of its mass in the temperature range 383–423 K. A more precise determination was obtained gravimetrically. It corresponds to the removal of (2.4 ± 0.1) water molecules per complex molecule. Additional increase of this value in comparison with the expected one (two water molecules per complex) can be due to the presence of non-

coordinating water molecules in the crystal lattice (0.4 per complex). The reversibility of the process has been checked. If the blue compound is placed in a closed dessiccator with a relative high humidity, the pink colour is recovered after 12 h. This reversible colour change has been confirmed by electronic and IR spectroscopy. Hereafter the anhydrous compound will be assigned as **4′**. A similar phenomenon was observed by us earlier for $[Co(trba\cdot HCl)]Cl_2\cdot 4H_2O$, where trba = *N*-(1,2,4-triazol-5-yl)benzamidine [31].

3.4. Spectroscopic characterisation

3.4.1. Infrared spectra

The most significant bands are summarised in Table 6. Changes observed in the spectra of the complexes (shifts of ν(CO) and ν(CN)+δ(NH) bands) with respect to the free vaat ligand show that the ligand is coordinated to M(II) through the nitrogen atom of the triazole ring and oxygen atom of the acetylamino-group in agreement with the results of the X-ray diffraction study. The ν(C=C) bands are practically not shifted in the spectra of the complexes with respect to the spectra of the free ligand. This indicates that the vinyl group of vaat is non-coordinated. The $\nu(H_2O)$ frequences were not assigned due to their possible mixing with ν(NH) bands.

Complexes were recrystallised from D_2O. It allowed us to reveal the $\nu(H_2O)$ frequencies at 3400–3000 cm^{-1}, because in the spectra of deuterated compounds these bands are displaced to lower frequencies with a coefficient of 1.34–1.38. The shifts of $\gamma(H_2O)$ and the ν(M–O) bands were also indicated by deuteration. The ν(M–N) vibrations appear at frequencies characteristic for metal complexes with triazoles and tetrazoles [32]. Thus, a comparative analysis of the spectra of the deuterated complexes with respect to their parent ones allows conclusions to be drawn about the presence of coordinated water molecules in the title compounds.

It should be pointed out that the spectrum of the blue complex **4′** changed dramatically in comparison to the one of **4** as the $\nu(H_2O)$ and $\gamma(H_2O)$ vibrations are no longer observed. This indicates that the coordination environment of Co(II) in the blue compound **4′** is changed in comparison to that of compound **4**.

3.4.2. Diffuse reflectance spectra

Table 7 lists the electronic spectra bands. The values of the maxima and the number of bands observed are in accordance with an octahedral environment for M(II) (M = Co, Ni) and allows us to propose a tetragonal geometry for the Cu(II) ion. Values of Δ (= 10 Dq) for Co(II) complexes **1** and **4**, which were calculated with the equation $\nu_1 = 0.88\Delta$ given in Ref. [33], fit with those obtained for the related mononuclear complexes $[Co(Haat)_2(H_2O)_2]Cl_2$ and $[Co(Haat)_2(H_2O)_2](NO_3)_2$, where Haat is 3-acetylamino-1,2,4-triazole [28]. For the Ni(II) complexes, **2** and **5**, the Δ parameters are larger than those of the similar complexes $[Ni(Haat)_2(H_2O)_2]Cl_2$ and $[Ni(Haat)_2(H_2O)_2](NO_3)_2\cdot 2H_2O$ [28]. One might expect that the difference is due to some change in the bonding character, but in the latter probably due to the introduction of a vinyl group in the composition of the ligand.

The spectrum of **4′** is typical for tetrahedral Co(II) complexes. An interesting feature of this spectrum,

Table 6
Selected IR bands (cm^{-1}) for vaat and its corresponding complexes

however, is the presence of relatively intense spin-forbidden bands.

3.5. Magnetic measurements

Magnetic moments (Table 7) correspond to high-spin d^7 and d^8 configurations of cobalt(II) and nickel(II) complexes, respectively, and d^9 configuration of copper(II) complexes. The magnetic moments of **3** and **6** do not show any temperature dependence (78–300 K).

4. Conclusion

In this paper we have prepared and characterised new coordination compounds containing the new 1-vinyl-3-acetylamino-1,2,4-triazole ligand. This ligand acts as a chelating ligand and leads to mononuclear complexes comparable to those reported with the non-deprotonated 3-acetylamino-1,2,4-triazole ligand [22–25,27,28]. Triazole molecules are nearly planar and π–π aromatic coupling is possible in the ligand. Thus, addition of a vinyl group in position 1 of 3-acetylamino-1,2,4-triazole does not change the coordination mode of the ligand. Furthermore, coordination of the vinyl group, which could have been expected, has not been observed. The interest of these materials resides in their ability to form an extensive hydrogen bonding network giving rise to chains for compound **6** or to a 2-D character for compound **2**. Such diversity in the structures of these compounds is indeed correlated to the nature of the counteranions. The nitrate anion for instance has three oxygen atoms which lie in the same plane and can be involved by hydrogen bonding in several directions thus establishing a link between the molecules.

Another interesting aspect of this work concerns the astonishing reversible colour change observed for $[Co(vaat)_2(H_2O)_2]Cl_2$ upon heating. It has been convincingly demonstrated on the basis of spectroscopic measurements as well as gravimetric studies that this phenomenon is actually connected to the removal and addition of water molecules giving rise to a reversible octahedron–tetrahedron transition according to the following reaction:

$$\underset{\mathbf{4}}{[Co(vaat)_2(H_2O)_2]Cl_2 \cdot 0.4H_2O} \Leftrightarrow \underset{\mathbf{4'}}{[Co(vaat)_2]Cl_2} + 2.4\ H_2O$$

The microscopic phenomenon which is present can be termed chemochromism as a chemical change at heating and cooling is involved during the above mentioned transformation.

5. Supplementary material

Crystallographic data have been deposited at the Cambridge Crystallographic Data Centre, CCDC No. 162493 for compound **2** and CCDC No. 162444 for compound **6**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 8 August 2001; accepted 19 December 2001

Abstract

Binuclear complexation between hydrated tris(1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedionato)lanthanide(III) ($Ln(tta)_3$) and tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) in benzene has been studied by a liquid–liquid distribution method and spectroscopic methods such as electronic absorption for d–d transition, IR for OH vibration of coordinated water molecules, and ^{59}Co NMR. The stability constants of a binuclear complex ($\beta_{s,1}$) across the lanthanide series were determined by both distribution and spectrophotometric methods. The $\beta_{s,1}$ values for La to Nd were close to each other and much higher than those for Er to Lu, which were almost constant. As a result, there was the large difference in $\beta_{s,1}$ between the light and the heavy Ln. The spectrochemical studies by IR and ^{59}Co NMR suggested that the binuclear complex has two different structures with inner- and outer-sphere coordination. In the former $Co(acac)_3$ displaces the coordinated water molecules in the Ln chelate and directly coordinates to the central Ln ion through the coordinating oxygen atoms of the acac ligands. In the latter hydrogen-bonding is formed between the coordinating oxygen atoms in $Co(acac)_3$ and hydrogen atoms of coordinated water molecules in the Ln chelate. Both binuclear complexes coexist in the solution of light Ln, while the outer sphere type mostly exist in heavy Ln. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Lanthanide(III) chelate; Cobalt(III) chelate; Binuclear complexes; Inner-sphere coordination; Outer-sphere coordination; Stability constant

1. Introduction

In our recent studies on the liquid–liquid distribution of tris(1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedionato)lanthanide(III) ($Ln(tta)_3$), the La, Eu and Lu chelates have been found to form binuclear complexes with inert cobalt(III) chelates such as tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) [1] and tris(8-quinolinolato)cobalt(III) ($Co(q)_3$) [2] in an organic phase. This phenomenon was explained by the reaction between $Ln(tta)_3$ as a Lewis acid and the cobalt(III) chelates as a Lewis base or a complex ligand in the organic phase.

In the above short paper dealing with $Co(acac)_3$ [1], we have pointed out the existence of two types of the binuclear complexes on the basis of the result of ^{59}Co NMR, i.e. the slow chemical-exchange species between free and complexed $Co(acac)_3$ on the NMR time scale in the La case, the fast exchange species in Lu, and both in Eu. However, the structure of the binuclear complexes and the effect of the central Ln metals could not be elucidated.

Since $Ln(tta)_3$ has residual coordinated water molecules even in the organic phase, some water molecules must be released from the inner coordination sphere of Ln when the binuclear complex is formed by the direct coordination of $Co(acac)_3$ to the Ln ion. Therefore, it is very important to study the behavior of the coordinated water molecules in the binuclear complexation.

In this paper, the stability constants of the binuclear complexes composed of $Ln(tta)_3$ and $Co(acac)_3$ are

PII: S0277-5387(02)00858-6

determined over the Ln series by both distribution method and spectrophotometry. The effect of the central Ln ions and the role of water on the stability of the binuclear complexes are clarified. Furthermore, the bonding and the structure of the binuclear complex are investigated by means of spectrochemical methods such as IR and ^{59}Co NMR spectroscopy. In particular, IR spectroscopy for the coordinated water molecules has been successfully used to differentiate the inner- and the outer-sphere coordination in the binuclear complexes.

2. Experimental

2.1. Reagents

Ln stock solutions were prepared by the same manner as in the previous paper [1]. Trioctylphosphine oxide (TOPO) was obtained from Dojindo Lab. and used without further purification. Htta, $Co(acac)_3$, and other reagents were the same as those used previously [1].

$Eu(tta)_3(H_2O)_3$ was synthesized according to the literature [3] and stored in a vacuum desiccator. Yield 53%. Melting point (m.p.) 132–140 °C. *Anal*. Calc. for $C_{24}H_{18}EuF_9S_3O_9$: C, 33.15; H, 2.17. Found: C, 33.31; H, 2.10%. The number of coordinated water molecules was also confirmed to be three by IR spectrophotometry in the benzene solution as described later.

2.2. Distribution method

The procedure for the liquid–liquid distribution of Ln was carried out in the same manner as reported previously [1]. The distribution ratio (D) of Ln was determined from the Ln concentrations in both phases.

2.3. Sample preparations and spectroscopic measurements

Sample preparations and measurements of the electronic absorption and ^{59}Co NMR were performed by the same manner reported previously [1].

The sample solutions for the IR measurements were prepared by mixing the $Ln(tta)_3$ solution obtained by the solvent extraction of 1.0×10^{-2} M Ln with 3.0×10^{-2} M Htta in benzene at pH 5.7–6.3. The concentration of the remaining Htta in the organic phase was less than 9×10^{-4} M. The water content in the sample solutions was kept constant at 2.0×10^{-2} M using anhydrous and water-saturated benzene. In the IR experiment, synthesized $Eu(tta)_3(H_2O)_3$ was also used in anhydrous benzene. IR spectra of free water and the coordinated water of 6.0×10^{-3} M $Ln(tta)_3$ in benzene were measured in the presence of varying concentrations of $Co(acac)_3$ or TOPO at 3000–4000 cm^{-1} with a Shimadzu-8200A FT IR spectrophotometer at 25 °C. A demountable liquid cell with calcium fluoride windows was used and the path length was adjusted to 1 mm.

3. Results and discussion

3.1. Determination of stability constant by the distribution method

Lanthanide(III) is extracted with Htta in nonpolar solvents as a hydrated neutral chelate, $Ln(tta)_3(H_2O)_n$. The distribution ratio (D_o) of Ln between an organic (org) and an aqueous (aq.) phase is expressed as follows:

$$D_o = \frac{[Ln(tta)_3]_{org}}{[Ln^{3+}]_{aq} + \sum[Ln(tta)_n^{(3-n)+}]_{aq}}, \quad (1)$$

where the coordinated water molecules of Ln^{3+} and $Ln(tta)_3$ were omitted to simplify. Eq. (1) can be rewritten using the equilibrium constants, $K_D\beta_3 = [Ln(tta)_3]_{org}/[Ln^{3+}]_{aq}[tta^-]_{aq}^3$, where K_D and β_3 are the distribution constant of $Ln(tta)_3$ between two phases and the stability constant of $Ln(tta)_n^{(3-n)+}$ in the aqueous phase, respectively, that is:

$$D_o = \frac{K_D\beta_3[tta^-]_{aq}^3}{1 + \sum \beta_n[tta^-]_{aq}^n} \quad (2)$$

where $[tta^-]_{aq}$ denotes the concentration of an anion of Htta in the aqueous phase. $[tta^-]_{aq}$ is readily calculated from total concentration (C_{HA}) of Htta and pH using the following equation:

$$[tta^-]_{aq} = \frac{C_{HA}}{1 + (K_{D,HA} + 1)[H^+]_{aq}/K_{HA}}, \quad (3)$$

where K_{HA} and $K_{D,HA}$ are the acid-dissociation constant of Htta in the aqueous phase and the distribution constant of Htta between two phases, respectively. In this paper, the literature values, $\log K_{HA} = -6.23$ [4] and $\log K_{D,HA} = 1.62$ [5], were adopted. The extraction of Dy, Ho, Tm, and Yb with 1.0×10^{-2} M Htta at pH 3.7–4.9 was carried out. The plots of $\log D$ versus $\log[tta^-]_{aq}$ based on Eq. (2) for those Ln indicated straight lines with a slope of 3.0 at $[tta^-] = 10^{-6.2}$–$10^{-5.0}$. Therefore, the existence of $Ln(tta)_3^{(3-n)+}$ in the aqueous phase can be neglected under the given conditions and then Eq. (2) can be rewritten as follows:

$$D_o = K_D\beta_3[tta^-]_{aq}^3 \quad (4)$$

The logarithmic values of $K_D\beta_3$ for each Ln were determined from the plots of $\log D$ versus $\log[tta^-]_{aq}$ as follows: 16.37 (Dy), 16.61 (Ho), 16.79 (Tm) and 16.96 (Yb). The $K_D\beta_3$ of La, Eu and Lu was expressed as K_e in our previous paper [1], and the logarithmic values were calculated to be 13.41 (La), 15.91 (Eu) and 16.89 (Lu) using the data shown there. The $\log K_D\beta_3$ values for

other Ln were calculated from the extraction constant reported previously on the basis of the relation of $K_{ex} = [Ln(tta)_3]_{org}[H^+]^3_{aq}/[Ln^{3+}]_{aq}[Htta]^3_{org} = K_D\beta_3 \times K^3_{HA}/K^3_{D,HA}$, and were as follows: 14.36 (Ce), 14.56 (Pr), 15.03 (Nd), 15.85 (Sm), 15.93 (Gd), 16.34 (Tb) and 16.66 (Er) [6]. Consequently, the D_o values at a certain $[tta^-]_{aq}$ can be calculated by Eq. (4).

If $Ln(tta)_3$ forms a binuclear complex with $Co(acac)_3$ in the organic phase, the distribution ratio (D) of Ln is expressed as follows:

$$D = \frac{[Ln(tta)_3]_{org} + [Ln(tta)_3(Co(acac)_3)]_{org}}{[Ln^{3+}]_{aq} + \sum[Ln(tta)_n^{(3-n)+}]_{aq}} \quad (5)$$

Since the existence of $Ln(tta)_3^{(3-n)+}$ in the aqueous phase can be neglected under the given conditions as described above, Eq. (5) can be rewritten as follows:

$$D = K_D\beta_3[tta^-]^3_{aq}(1 + \beta_{s,1}[Co(acac)_3]_{org}), \quad (6)$$

where $\beta_{s,1}$ is the stability constant of a binuclear complex and is defined by:

$$\beta_{s,1} = \frac{[Ln(tta)_3(Co(acac)_3)]_{org}}{[Ln(tta)_3]_{org}[Co(acac)_3]_{org}} \quad (7)$$

When $[tta^-]_{aq}$ in both Eqs. (4) and (6) is equal, the following equation is derived:

$$D/D_o = 1 + \beta_{s,1}[Co(acac)_3]_{org}. \quad (8)$$

Fig. 1 shows the plot of $\log(D/D_o)$ versus $\log[Co(acac)_3]_{org}$ based on Eq. (8). The plots for light Ln, for Ce to Nd, show straight lines with a slope of 1.0 over the wide concentration range of $Co(acac)_3$. For middle and heavy Ln, the plots approach to straight lines with a slope of unity in the higher concentration region of $Co(acac)_3$. These results indicate the formation of a binuclear complex in the organic phase and are in agreement with the results of La, Eu and Lu reported previously [1]. The $\beta_{s,1}$ values are determined by applying a nonlinear least-squares method to those plots based on Eq. (8), and are listed in Table 1 together with those of La, Eu and Lu.

3.2. Determination of stability constant by spectrophotometry

In a previous paper [1], it has been shown that the molar absorptivity for the d–d ($^1T_{1g} \leftarrow {}^1A_{1g}$) transition of $Co(acac)_3$ increases on complexation with $Ln(tta)_3$ (Ln:La, Eu, and Lu). A similar increase in the molar absorptivity of $Co(acac)_3$ was also observed with Pr, Nd, Sm, Gd, Tb and Er. Fig. 2 shows the relationship between the apparent molar absorptivity of $Co(acac)_3$ at 595 nm corresponding to the d–d transition and the molar ratio of $Ln(tta)_3$ to $Co(acac)_3$ in the solution. The plot of Pr or Nd well fits with two straight lines having an intersection at $[Ln(tta)_3]_{total}/[Co(acac)_3]_{total} = 1$, which corresponds to a 1:1 stoichiometry as expected

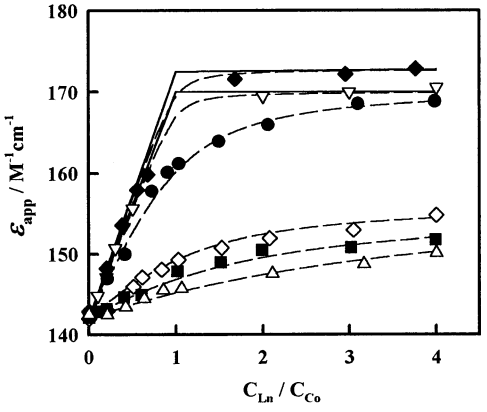

Fig. 2. Relationship between the apparent molar absorptivity of $Co(acac)_3$ at 595 nm and the molar ratio of $Ln(tta)_3$ to $Co(acac)_3$. C_{Co}, 2.0×10^{-3} M; C_{Ln}, 2.0×10^{-4}–8.0×10^{-3} M. ◆, Pr; ▽, Nd; ●,Sm; ◇,Gd; ■,Tb; △,Er.

from the result of the distribution method. To determine $\beta_{s,1}$ of the binuclear complex, the following equation was derived with respect to the apparent absorbance (A_{app}) of $Co(acac)_3$:

$$A_{app} = \varepsilon_{BNC}[Ln(tta)_3(Co(acac)_3)]_{org} + \varepsilon[Co(acac)_3]_{org}$$

$$D = (\varepsilon_{BNC} - \varepsilon)\frac{(\beta_{s,1}C_{Ln} + \beta_{s,1}C_{Co} + 1) - \sqrt{(\beta_{s,1}C_{Ln} + \beta_{s,1}C_{Co} + 1)^2 - 4\beta_{s,1}^2 C_{Ln}C_{Co}}}{2\beta_{s,1}} + \varepsilon C_{Co} \quad (9)$$

where ε_{BNC} and ε denote the molar absorptivity of complexed $Co(acac)_3$ in the binuclear complex and free $Co(acac)_3$, respectively, and C_{Co} and C_{Ln}, the total concentration of $Co(acac)_3$ and $Ln(tta)_3$, respectively. The $\beta_{s,1}$ values were calculated by a least-squares fitting for the plots in Fig. 2 on the basis of Eq. (9). The broken lines in Fig. 2 indicate the values calculated by using Eq. (9) and the $\beta_{s,1}$ values obtained, and are in good agreement with the experimental plots for all the Ln.

The $\beta_{s,1}$ values are listed in Table 1 along with those obtained by the distribution method. The values determined by both methods are reasonably consistent with each other, although, the values obtained by spectrophotometry are slightly higher than those by the distribution method. Such a little difference in $\beta_{s,1}$ is probably due to the difference in the water content of the benzene solution in both methods, i.e., 2.0×10^{-2} M H_2O in the spectrophotometry method compared with 3.1×10^{-2} M in the distribution method. In fact, it has been confirmed that the binuclear complexation between $Ln(tta)_3$ and tris(8-quinolinolato)cobalt(III) was dependent on the water content in benzene [2].

Fig. 3 shows the variation of log $\beta_{s,1}$ across the Ln series. The log $\beta_{s,1}$ values decrease with increasing the atomic number of Ln, showing a steep decrease between Nd and Sm. As a result, there are very large differences in $\beta_{s,1}$ between the light Ln (La to Nd) and the heavy Ln (Er to Lu).

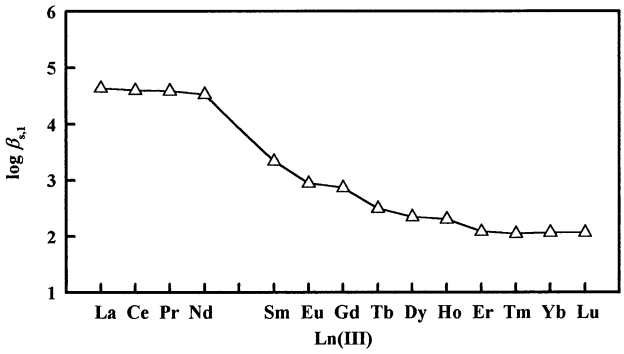

Fig. 3. Variation of the stability constant for $Ln(tta)_3(Co(acac)_3)$ across the lanthanide series.

3.3. IR spectroscopy

In an IR absorption spectrum of water in benzene, there were two intense peaks at 3600 and 3680 cm^{-1} which are assigned to the symmetric and asymmetric O–H stretching vibration of free water, respectively.

An IR absorption spectrum of $Eu(tta)_3(H_2O)_3$ in anhydrous benzene is shown in Fig. 4. The hydrated Eu chelate has two narrow absorption bands at 3552 and 3649 cm^{-1} and a broad band at 3335 cm^{-1}, which are significantly different from those of free water. To assign these absorption bands, the effect of TOPO was utilized. The absorbance of these three bands decreases with increase in the TOPO concentration in the sample solution, and alternately the two intense peaks corresponding to free water appear and gradually increase. After the addition of an equivalent quantity of TOPO to the Eu chelate, the three bands initially observed disappear, and the absorbance of free water becomes almost constant. These observations completely agree with those expected from the previous luminescence study in which the Eu–tta chelate becomes anhydrous by the formation of a 1:1 adduct of $Eu(tta)_3$TOPO [7].

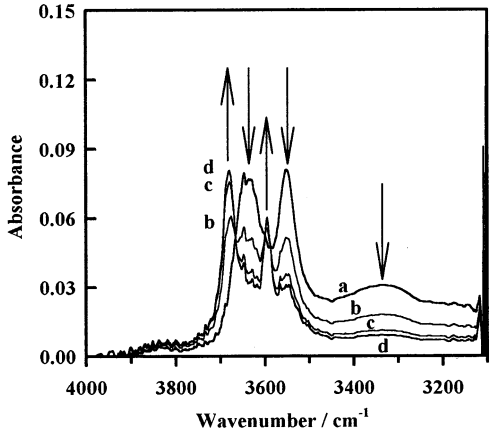

Fig. 4. IR spectra of 6.0×10^{-3} M $Eu(tta)_3(H_2O)_3$ in the presence or absence of 3.0×10^{-3}–2.3×10^{-2} M $Co(acac)_3$ in benzene. (a) Free $Eu(tta)_3(H_2O)_3$; (b) $[Co(acac)_3]_{total}/[Eu(tta)_3(H_2O)_3]_{total} = 0.5$; (c) $[Co(acac)_3]_{total}/[Eu(tta)_3(H_2O)_3]_{total} = 1.0$; (d) $[Co(acac)_3]_{total}/[Eu(tta)_3(H_2O)_3]_{total} = 3.8$.

The total number of water molecules released from the hydrated Eu chelate was determined to be 2.9 by IR spectrophotometry, which agrees with the water content in the crystal.

Therefore, the three absorption bands observed in $Eu(tta)_3(H_2O)_3$ are assigned to the O–H stretching vibration of the coordinated water molecules. The broad band in the lower wavenumber region suggests the existence of hydrogen-bonded O–H caused by the intramolecular hydrogen-bonding between hydrogen atoms of coordinated water and oxygen atoms of the ligands in the chelate. Such an hydrogen bond has been observed by IR spectra of a solid crystal of monohydrated tris(2,4-pentanedionato)RE(III) (RE: La, Pr, Nd, Sm, Gd, Dy, Ho, Er, and Y) [8].

The effect of $Co(acac)_3$ on the IR spectrum of $Eu(tta)_3(H_2O)_3$ is also shown in Fig. 4. The variation of the spectra observed by the addition of increasing concentration of $Co(acac)_3$ is similar to that in the TOPO case, i.e. the decrease in coordinated water but the increase in free water. This is indicative of the inner sphere (direct) coordination of $Co(acac)_3$ to the Eu chelate. Compared with TOPO, however, the coordinated water is not completely removed from the inner sphere of Eu even after almost all the Eu chelate becomes the binuclear complex with $Co(acac)_3$. This will be described later as a topic of the middle Ln.

The present IR method was applied to the Nd, Gd, Er, and Lu chelates which were prepared by the distribution method. The addition of TOPO gave almost the same results as in the Eu case, although, an excess of free water (2.0×10^{-2} M) existed in benzene. Fig. 5 shows the IR spectra of a hydrated Er chelate in the presence or absence of $Co(acac)_3$. Compared with Eu, the reverse trend of the variation of the broad absorption band corresponding to the hydrogen-bonded water

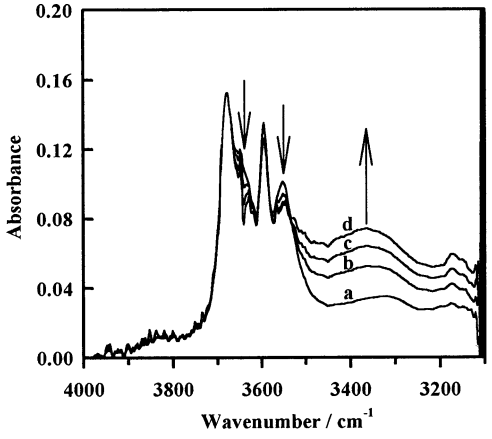

Fig. 5. IR spectra of 6.0×10^{-3} M $Er(tta)_3(H_2O)_n$ in the presence or absence of 3.0×10^{-3}–2.0×10^{-2} M $Co(acac)_3$ in benzene containing 2×10^{-2} M H_2O. (a) Hydrated $Er(tta)_3$; (b) $[Co(acac)_3]_{total}/[Er(tta)_3(H_2O)_n]_{total} = 0.5$; (c) $[Co(acac)_3]_{total}/[Er(tta)_3(H_2O)_n]_{total} = 1.0$; (d) $[Co(acac)_3]_{total}/[Er(tta)_3(H_2O)_n]_{total} = 3.3$.

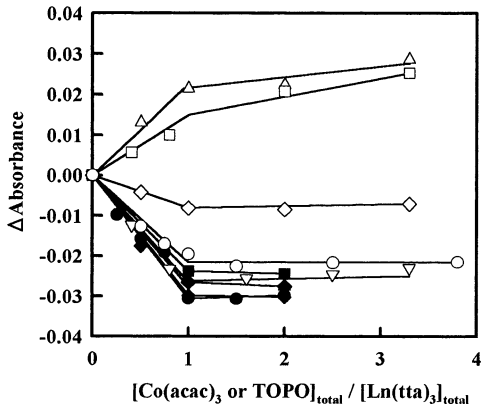

Fig. 6. Relationship between the variation of absorbance for the coordinated water of $Ln(tta)_3(H_2O)_n$ at 3320 cm^{-1} and the molar ratio of $Co(acac)_3$ or TOPO to $Ln(tta)_3$. Open symbols, $Ln(tta)_3$–$Co(acac)_3$; Closed symbols, $Ln(tta)_3$–TOPO. ▽ ▼, Nd; ○ ●, Eu; ◇ ◆, Gd; △ ▲, Er; □ ■, Lu.

is observed. The absorbance increases with increase in the $Co(acac)_3$ concentration. Furthermore, the amount of free water in benzene scarcely increases in the Er case. This fact strongly suggests the formation of hydrogen bonding between the coordinated water molecules and $Co(acac)_3$.

Relationship between the variation of the absorbance of $Ln(tta)_3$ at 3320 cm^{-1} (broad absorption band) and the molar ratio of $Co(acac)_3$ or TOPO to $Ln(tta)_3$ is shown in Fig. 6. All these plots have the intersection at $[Co(acac)_3 \text{ or } TOPO]_{total}/[Ln(tta)_3]_{total} = 1$ as expected from the results described above. The plot for the binuclear complex of Nd is very close to those of the TOPO adducts, supporting that the inner sphere coordination of $Co(acac)_3$ to the central Ln ions mainly occurs. On the other hand, the Er and the Lu complex show the increase in the absorbance, which is ascribed to the formation of hydrogen-bonding between coordinated water molecules of $Ln(tta)_3$ and $Co(acac)_3$. Consequently, the hydrogen-bonded complex or the outer-sphere binuclear complex is formed in the heavy Ln. In the middle Ln, especially Gd, however, the variation of the absorbance was much smaller than that of other Ln. This indicates that the fraction of the outer-sphere binuclear complex is higher than that of the light Ln.

3.4. ^{59}Co NMR spectroscopy

^{59}Co NMR spectra of $Co(acac)_3$ were measured in the presence or absence of $Ln(tta)_3$ (Ln: Pr, Nd, Sm, Gd, Tb and Er). When the resonance of $Co(acac)_3$ in $CDCl_3$ was set as a reference (0 ppm) on the spectra, the resonance of free $Co(acac)_3$ in benzene was observed at 112 ppm lower magnetic field. In the presence of the tta chelate of Pr, Nd and Sm, two separate resonances were observed as found in Eu [1]. Higher-field resonances appeared at

−345, −342 and −291 ppm for Pr, Nd and Sm, respectively, and were independent of the concentration of $Ln(tta)_3$. On the other hand, lower-field resonances were observed at 58, 59 and 49 ppm for Pr, Nd and Sm, respectively, at $[Ln(tta)_3]_{total}/[Co(acac)_3]_{total} = 3$ and were gradually shifted to the higher-field with increase in the $Ln(tta)_3$ concentration. Consequently, as discussed in the previous paper [1], the binuclear complex with the higher-field resonance has slow chemical exchange of $Co(acac)_3$ on the NMR time scale, while that with the lower-field resonance has rapid exchange. In the Gd, Tb and Er case, only the lower-field resonances were observed at 53, 53 and 54 ppm, respectively, and they were affected by the $Ln(tta)_3$ concentration. Therefore, there are two different kinds of binuclear complexes with slow and rapid chemical exchange of $Co(acac)_3$.

Fig. 7 shows the change in the chemical shift of ^{59}Co NMR ($\Delta\delta = \delta_{Co,BNC} - \delta_{Co}$) across the lanthanide series, where δ_{Co} and $\delta_{Co,BNC}$ express the chemical shift of free $Co(acac)_3$ and complexed $Co(acac)_3$ in the binuclear complex, respectively. The values of $\delta_{Co,BNC}$ for the rapid exchange species were corrected using the ratio of the complexed $Co(acac)_3$ and free $Co(acac)_3$, which were calculated using $\beta_{s,1}$, since the resonance appears at the averaged position. The chemical shift for the slow exchange complexes was clearly dependent on the Ln ion, whereas that for the rapid exchange complexes was almost independent of the Ln ion. The $\Delta\delta$ values observed for the slow exchange complexes of La to Eu are quite similar to those for the binuclear complexes of anhydrous tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)lanthanide(III) ($Ln(fod)_3$, Ln:La to Eu) with $Co(acac)_3$ [9].

The large difference in $\Delta\delta$ observed between the diamagnetic ions La and Lu demonstrates the strong interaction of $Co(acac)_3$ with the former but the weak interaction with the latter. On the basis of this result, the binuclear complexes of La through Eu with slow chemical exchange should be of inner-sphere coordination. The $\Delta\delta$ values of those complexes are strongly affected by the number of f-electrons of Ln, because, the proximity of the paramagnetic Ln ions to the cobalt(III) ion brings about the contact or the pseudo-contact shift. On the other hand, the rapid exchange complexes of Pr through Lu are of outer-sphere coordination since the $\Delta\delta$ values are small and almost independent of the Ln ions. The Ln–Co distance in the outer-sphere complexes is expected to be long enough to be free from the contact or pseudo-contact shift. In previous studies performed by Lindoy et al. [10–12], only inner-sphere complexes of $Eu(fod)_3$ with tris(β-diketonato)cobalt(III) were found, because, anhydrous Eu chelate was entirely used in anhydrous solvents.

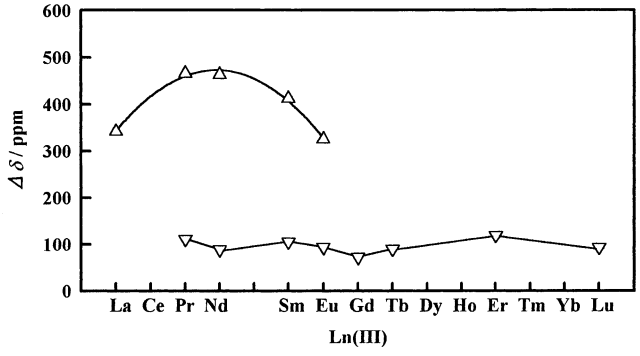

Fig. 7. Variation of the ^{59}Co NMR chemical shifts of complexed $Co(acac)_3$ in binuclear complexes across the lanthanide series. The data of La, Eu, and Lu were cited from Ref. [1]. △, slow exchange complexes; ▽, rapid exchange complexes.

4. Conclusion

Hydrated lanthanide–tta chelates form stable binuclear complexes with $Co(acac)_3$ in benzene. Since $Co(acac)_3$ has three coordinating oxygen atoms on an open octahedral face, it is expected to act as a terdentate ligand. In the light Ln of which the coordination number (CN) is usually nine in solution, the inner-sphere binuclear complex with the terdentate $Co(acac)_3$ exists along with the outer-sphere hydrogen-bonded complex as an equilibrium mixture. The inner-sphere complex has a more stable structure and an higher stability constant. In the heavy Ln which has a CN of eight and a small ionic radius, only the outer-sphere complex is formed, because, the $Co(acac)_3$ molecule cannot enter the inner-coordination sphere of $Ln(tta)_3$. The stability of the outer-sphere complex formed by the hydrogen bonding is much lower than that of the inner sphere complex.

Chiral macrocyclic La(III), Ce(III), Pr(III) and Eu(III) complexes with chloride anions

Jerzy Lisowski *, Jarosław Mazurek

Department of Chemistry, University of Wrocław, 14 F. Joliot-Curie, 50-383 Wrocław, Poland

Received 8 August 2001; accepted 20 December 2001

Abstract

The new enantiopure macrocyclic complexes $[LnL]Cl_3 \cdot nH_2O$ or their racemic mixtures $[Lnrac\,L]Cl_3 \cdot nH_2O$ ($Ln = La^{+3}$, Ce^{+3}, Pr^{+3} and Eu^{+3}) have been synthesised in a template condensation of *trans*-1,2-diaminocyclohexane and 2,6-diformylpyridine. The complexes have been studied by ^1H and ^{13}C NMR spectroscopy. The signal assignment was based on the COSY, NOESY and HMQC measurements. The X-ray crystal structure of $[Larac\,L]Cl_3$ complex has been determined. The lanthanum ion in this complex is coordinated by six nitrogen atoms of the macrocyclic ligand and three chloride anions. The macrocycle exhibits a twist–bent conformation of approximate C_2 symmetry. On the other hand, NMR spectra of the investigated compounds in methanol–chloroform solution indicate effective D_2-symmetry that results from the fast dynamic exchange of chloride anions. © 2002 Elsevier Science Ltd. 1. Introduction

The Schiff bases obtained in a template 2+2 condensation of diamines and 2,6-diformylpyridine or 2,6-diacetylpyridine are particularly suitable for the coordination of relatively large metal ions [1]. The complexes of these hexaazamacrocyles with lanthanide(III) ions have attracted attention as efficient catalysts for the cleavage of the phosphate ester bond [2]. The Gd(III) complexes have also been studied as potential MRI contrast agents [3].

When the chiral precursor *R*,*R*′-1,2-diaminocyclohexane is used in the above template reaction, chiral lanthanide(III) complexes (Fig. 1) $[LnL](NO_3)_3 \cdot nH_2O$ (where Ln is the lanthanide(III) ion and L = 4(*R*),9(*R*),19(*R*),24(*R*)-3,10,18,25,31,35-hexaazapentacyclo[25.3.1.1^{12,24}.0^{4,9}.0^{19,24}]-dotriaconta-1(31),2,10,12,14,16(32),17,25,27,29-decaene) are formed [4,5]. The coordination of the lanthanide(III) ion in a chiral macrocyclic environment leads to interesting properties of these compounds. Thus the $[TbL](NO_3)_3$ and $[EuL](NO_3)_3$ complexes have been shown to exhibit circularly polarised luminescence [4] and the paramagnetic $[EuL](NO_3)_3$ and $[YbL](NO_3)_3$ complexes have been shown to form diastereoisomeric complexes with D- and L-aminoacids [5].

Here we present the study of new lanthanide complexes of the ligand L with chloride counteranions. These complexes have been synthesised as racemic mixtures $[Lnrac\,L]Cl_3 \cdot nH_2O$ or as enatiopure compounds $[LnL]Cl_3 \cdot nH_2O$ using either racemic *trans*-1,2-diaminocyclohexane or *trans*-*R*,*R*′-1,2-diaminocyclohexane, respectively. We have previously shown that the nitrate derivatives $[LnL](NO_3)_3 \cdot nH_2O$ exhibit D_2 symmetry both in solution and in the solid state [5,6]. This symmetry arises from the presence of a helically twisted macrocycle and symmetric coordination of nitrate anions above and below the macrocycle. In contrast, the X-ray crystal structure of $[Lnrac\,L]Cl_3$, presented here, shows lower symmetry of the complex due to unsymmetrical coordination of chloride anions above and below the macrocycle plane.

2. Experimental

2.1. Synthesis

The [La*rac*L]$Cl_3\cdot 3H_2O$, [Ce*rac*L]$Cl_3\cdot 3H_2O$ and [Pr*rac*L]$Cl_3\cdot 2H_2O$ complexes have been prepared in the same way as the respective Gd(III) complex [7] in 61, 66 and 40% yields, respectively. The enantiomericaly pure complex [EuL]$Cl_3\cdot 2H_2O$ has been obtained in a similar manner in a template condensation. Thus 1 mmol (114.2 mg) of *R*,*R*-1,2-diaminocyclohexane, 1 mmol (135.1 mg) of 2,6-diformylpyridine and 0.5 mmol (167.9 mg) of europium(III) chloride hydrate were refluxed for 4 h in 15 ml of methanol. The solution was filtered and evaporated to dryness. The crude product was recrystallised from methanol–acetonitrile and dried in vacuum to give 177 mg of the desired complex in 49% yield. [PrL]$Cl_3\cdot 2H_2O$ has been synthesised similarly in 65% yield. The [PrL]$(NO_3)_3\cdot H_2O$ complex has been prepared in the same way as other nitrate derivatives [4,5]. All compounds gave satisfactory C, H and N analyses.

2.2. Methods

The NMR spectra were taken on Bruker Avance 500 and AMX 300 spectrometers. The chemical shifts were referenced to the residual solvent signal or TMS. The magnitude COSY spectra were acquired using 512 data points in both dimensions. The data were processed by using a square sine bell window in both dimensions and zero filled to $1K\times 1K$ matrix. The phase-sensitive (TPPI) NOESY spectra were recorded using mixing times varying from 25 to 600 ms and shifted square sine function. HMQC spectra were recorded using the BIRD preparation period and 512×512 data points. A square sine function was used for apodisation in both dimensions. T_2 relaxation times were evaluated from the linewidths. Elemental analyses were obtained from elemental analyses facility in this department.

2.3. X-ray data collection

The crystals of [La*rac*L]Cl_3 were grown by slow diffusion of diethyl ether into a chloroform–methanol solution of the complex. A crystal of approximate $0.4\times 0.4\times 0.3$ mm was mounted on a Kuma KM4 diffractometer equipped with an CCD counter and an Oxford Cryosystem low-temperature device. The measurement was performed at 100 K. The structure was solved with direct methods using SHELXS-97 [8] and least-squares full-matrix refinement were performed using SHELXL-97 [8]. The absorption correction was applied based on face indexing with SHELX-76 [9]. All of the hydrogen atoms were included geometrically and their positions were constrained to the relevant C atoms, while their temperature factors were set at 1.2 times the trace of C atoms. Peaks ~ 2 e $Å^{-3}$ were found in the Fourier difference map and presumably result from disordered solvent. Details of the data collection are listed in the Table 1. Publication and validation data were created using the WINGX program [10].

3. Results and discussion

3.1. X-ray crystal structure

The structure of [La*rac*L]Cl_3 is composed of a macrocyclic complex and chloride anions connected to the central lanthanum(III) cation. The lanthanum cation has a characteristic nine-coordinate geometry (Fig. 2) that is very similar to that of [Gd*rac*L$(H_2O)_3$]$Cl_3\cdot 3H_2O$ [7]—the difference is that in [La*rac*L]Cl_3 the chloride anions instead of water molecules are placed in the coordination sphere. The coordination environment is composed of six nitrogen atoms belonging to the macrocycle (La–N distances in the range 2.732(3)–2.810(4) Å) and three chloride anions (La–Cl distances equal to 2.816(2) and 2.872(2) Å). The selected bond lengths and angles are listed in Table 2. Two chloride anions are placed above and one below the mean plane of the macrocyclic ligand. The angles Cl(1)–La–Cl(2) and Cl(2)–La–Cl(2)^i are 141.5(1)° and 80.0(1)°, respectively. The macrocyclic ligand is twisted in similar range as it was observed for analogue nitrate complexes [NdL]$(NO_3)_3\cdot CH_3OH$ and [TmL]$(NO_3)_3\cdot CH_3OH$ [6]: the angle between pyridine rings (N2 C2 C3 C4 C5 C6 and N2^i, C2^i, C3^i, C4^i, C5^i, C6^i) is 24.8(1)°. The angle between the least-squares mean planes of the cyclohexyl fragments (C8, C9, C10, C11, C12, C13 and C8^i, C9^i, C10^i, C11^i, C12^i, C13^i) is 56.7°. The Cremer and Pope ring puckering parameters [11] calculated with the PARST program [12,13] are $Q = 0.578(5)$ and $\theta = 173.9(5)°$, which means that the cyclohexyl rings display a fairly good chair conformation. The crystal structure is held together by van der Waals interactions although several relatively short intermolecular distances between aromatic or imine C–H groups and the chloride anions are present.

Symmetry code: (i) $-x+1, y, -z+3/2$.

The twist–bent conformation of the ligand in the discussed complex is similar to that of [Gd*rac*L$(H_2O)_3$]$Cl_3\cdot 3H_2O$ [7]. This type of conformation is characteristic for complexes of hexaaza tetraimine macrocycles [1] and for the saturated tetraamine analogue [14] of L. The angle between two planar sections defined by nine atoms from C8 through N2 to C13^i and the symmetry related nine atoms from C8^i through N2^i to C13 is 18.0(1)°, and this is smaller than the value of 42.8° observed for [Gd*rac*L$(H_2O)_3$]$Cl_3\cdot 3H_2O$ [7]. The value of this angle for [La*rac*L]Cl_3 is similar to that for [NdL]$(NO_3)_3\cdot CH_3OH$ and [TmL]$(NO_3)_3\cdot CH_3OH$ [6].

The macrocycle in [La*rac*L]Cl_3 is considerably bent, in contrast to what is observed in the case of [NdL]$(NO_3)_3\cdot CH_3OH$ and [TmL]$(NO_3)_3\cdot CH_3OH$ complexes [6]. This bending can be measured by the angle determined by the pyridine nitrogen atoms and the lanthanide ion. This fragment is practically linear [6] in the nitrate Nd(III) complex (178.5)°, while the value of this angle is 160.0(1)° in the chloride La(III) complex. The bent conformation of the macrocycle in the [La*rac*L]Cl_3 complex can be explained by the different steric requirements of axial ligands positioned above and below the macrocycle plane. In the case of the [NdL]$(NO_3)_3\cdot CH_3OH$ and [TmL]$(NO_3)_3\cdot CH_3OH$ complexes, the symmetrical coordination of axial ligands favours a more symmetrical conformation of the macrocycle. Thus the different axial ligation of the lanthanide(III) ions brings about the change in conformation of the coordinated macrocycle L. The above observations are not obvious, since in the case of lanthanide(III) complexes of the related macrocycle L′ (Fig. 1), containing more flexible ethylene lateral chains, the bending of the macrocycle tends to increase with

decreasing metal ion radius [1] and is observed even for complexes with symmetrical axial coordination [1,15].

3.2. NMR spectroscopy

The investigated compounds give rise to eight signals in their ^{1}H NMR spectra and seven signals in ^{13}C NMR spectra, which is consistent with the presence of diastereotopic cyclohexane protons and indicates the effective D_2 symmetry of the $[LnL]Cl_3$ complexes in the investigated solutions. The same symmetry was observed for solutions of the nitrate derivatives $[LnL](NO_3)_3$ [5]. In the case of the latter complexes this symmetry is in accord with the helical twist conformation of the macrocyclic ligand observed in the solid state [6]. On the other hand the X-ray crystal structure of [Ln*rac*L]Cl_3, discussed above, shows a lower symmetry of the complex due to unsymmetrical coordination of chloride anions above and below the macrocycle plane accompanied by bending of the macrocycle. This structure, of approximately C_2 symmetry, should give rise to 15 ^{1}H NMR signals and 13 ^{13}C NMR signals. The discrepancy between the number of expected and observed signals can be explained by dynamic exchange of chloride anions, e.g. in a dissociative process depicted in Fig. 3. When such a process is fast on the NMR time scale, averaged signals are observed for respective pairs of protons that would give different signals for the static structure. For instance, the non-equivalent pyridine protons $\mathbf{b}^1$ and $\mathbf{b}^2$ give rise to an averaged signal **b** (Figs. 3 and 4). In other words the top and the bottom of the macrocycle become equivalent giving rise to effective D_2 symmetry.

The ^{1}H and ^{13}C NMR spectra of the diamagnetic [La*rac*L]Cl_3 can be assigned (Table 3) on the basis of chemical shift values as well as similarity to the spectra of the analogous nitrate complex, $[LaL](NO_3)_3$ [5]. This assignment is confirmed by COSY, HMQC and HMBC spectra. On the other hand, the values of chemical shifts of paramagnetic $[LnL]Cl_3$ complexes are difficult to predict and assignment of their spectra based on these values is not possible. The paramagnetic metal ions strongly influence the chemical shifts of the nearby protons by introducing an additional chemical shift called isotropic shift, δ_{iso}. This shift arises from interaction of the nuclear and electronic spins and can be separated into through-space (i.e. dipolar or pseudo-contact) and through bonds (i.e. contact) contributions [16–20].

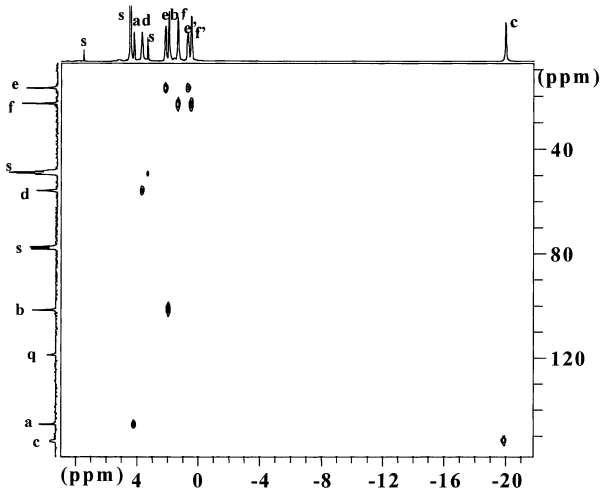

Fig. 4. The HMQC spectrum of $[EuL]Cl_3 \cdot 2H_2O$ (CD_3OD–$CDCl_3$ 1:2 v/v solution, 294 K), s-solvent and HDO signals.

The ^{1}H NMR spectra of the paramagnetic Ce(III), Pr(III) and Eu(III) complexes in question can be assigned (Table 3) using 2D NMR techniques in the following way. The HMQC spectra of the solutions of the investigated complexes in $CD_3OD/CDCl_3$ 1:2 v/v identify resonances of two pairs of geminal protons correlated to one carbon signal each (see Fig. 4 for example). As expected, the geminal protons are also COSY correlated (see Fig. 5 for example). One of the geminal protons exhibits an additional COSY crosspeak that has to correspond to a correlation between protons **d** and **e**′ (see the labelling scheme, Fig. 1). Thus the cyclohexane positions **d**, **e**, **e**′, **f** and **f**′ are identified. The COSY correlated signals of protons **a** and **b** can be easily identified on the basis of integration of signal **a** (intensity 2H, in contrast to signals of intensity 4H for other positions). The remaining signal has to correspond to the azomethine proton **c**. The above assignment is confirmed by NOESY spectra that show a sequence of NOE connectivities starting from the easily identified signal of proton **a**. Thus NOESY crosspeaks corresponding to pairs of protons **a** and **b**, **b** and **c**, **c** and **e**, **c** and **e**′, **d** and **e**, **d** and **e**′, **e** and **e**′, **e** and **f** as well as **f** and **f**′ can be observed.

The HMQC spectra of the investigated complexes allow correlation of the ^{13}C signals with the assigned

signals of the connected protons (Fig. 4). Thus the ^{13}C NMR spectra can be fully assigned (Table 3) since the molecule contains only one quaternary carbon atom that corresponds to ^{13}C NMR signal without HMQC correlation.

The NMR spectra of the investigated paramagnetic [LnL]Cl_3 complexes differ markedly from the spectra of the corresponding [LnL]$(NO_3)_3$ complexes [5], as illustrated for Pr(III) complexes in Fig. 6. Such differences can be caused by different conformations of the macrocycle, leading to different dipolar and/or contact shifts for a given position. Moreover, it was shown [5,21,22] that NMR spectra of macrocyclic lanthanide complexes can be very sensitive to axial ligation even when the conformation of the macrocycle remains essentially unchanged.

The differences of the shift values between the series of chloride and nitrate derivatives indicate that chloride anions are bound to the lanthanide(III) ions not only in the solid state, but also in the investigated chloroform–methanol solutions. As mentioned above, the X-ray crystal structure of the Gd(III) chloride derivative,

$[GdL(H_2O)_3]Cl_3 \cdot 3H_2O$, shows that the water molecules, and not chloride anions, are bound to the lanthanide(III) ion [7]. This rises the question whether chloride versus water coordination depends on the size of Ln(III) ion (and it changes along the lanthanide ions series), or is it a matter of relative amounts of water present? To answer this question, the ^1H NMR spectra of deuterated water solutions of the investigated complexes were recorded. In the case of paramagnetic complexes the spectra of water solutions were very different to those of chloroform–methanol solutions (Fig. 6, Table 3). Moreover, the NMR spectra of water solutions of nitrate and chloride complexes of the same lanthanide ion are practically identical (Table 3). This result shows that in water solution both nitrate and chloride anions dissociate and the axial positions are occupied by water molecules. Hence the difference in the coordination spheres of the La(III) and Gd(III) complexes of the ligand L, observed in the solid state, arise most likely from the different crystallisation conditions.

4. Supplementary material

Supplementary data for the $[Ln\textit{rac}L]Cl_3$ structure are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request, quoting the deposition number CCDC 165711.

Abstract

The crystal and packing structures of three racemic compounds with the formula, [Ni(tren)(DL-aminoacidato)]Cl·nH$_2$O have been investigated, aiming to compare the homochiral–heterochiral assembly process of the nickel(II) chiral complex cations with their well-studied cobalt(III) analogues. Due to the inherent hydrogen bonding donors–acceptors carried by the complex cations, infinite 1-dimensional (1-D) chains are generated by complementary inter-cationic H- bonds in both the Ni(II) and Co(III) analogues, but with different H- bond patterns. In all the Co(III) analogues studied by this group, the cations are linked together via the same pattern and strength of H- bonds which are designated as C6[$R_2^1(6)$]. They are homochiral, irrespective of the nature of the amino acidato ligands. In the Ni(II) analogues, the cations are linked by H- bonds described as $C_2^1(6)[R_2^2(12)]$. However, when the side chain of the amino acid is bulkier, the homochiral assembly of the cations becomes ambiguous due to the observed disorder of the asymmetric carbon. Additionally, it is interesting to note that the deprotonated carboxylic group of the amino acid coordinates with Ni(II) and Co(III) in different modes, as a delocalized and localized anion, respectively. © 2002 Elsevier Science Ltd. 1. Introduction

The conglomerate crystallization behavior adopted by racemic coordination compounds has been our long-term research interest [1,2]. When a racemic compound crystallizes in an enantiomorphic space group as a conglomerate, the process is one of enantioselective aggregation [3]. Species of the same chirality aggregate together during the nucleation and growth of a molecular crystal. This process is the most impressive example of chiral recognition in the solid state. Assisted by X-ray crystallography, the recognition pattern can be easily revealed by characterization of the intermolecular, or noncovalent forces involved in the supramolecular assemblies. Unfortunately, there are only a few examples of systematic investigations concerning the crystallization behavior of racemic coordination compounds [1,4–6], with helical chirality (designated as Δ and Λ) imposed by the asymmetric screw arrangement of multidentate ligands around the metal centers. The series of compounds $[M(bpy)_3](PF_6)_2$ ($M = Ni^{2+}$, Zn^{2+}, Ru^{2+}) [4] reveal that minor modification in molecular size and shape, induced by varying central metal atoms, can alter the crystallization pathway; i.e. racemic versus conglomerate, adopted by these compounds. In the structures of copper(II) complexes with $[Cu(H_2L)](ClO_4)_2$ formula (L = pentadentate Schiff-base ligands) [5], the double-faced H- bonding recognition motif carried by the Schiff-based ligand is considered as the directing force for the homochiral-assembly of the complex cations into …ΔΔΔ… and …ΛΛΛ…1-D chains. However, none of these copper(II) complexes crystallizes as a true conglomerate since the crystals contain heterochiral chains. Recently, the same research group reported the conglomerate

crystallization behavior of nickel(II) complexes with a formula $[Ni(H_3L)]X_2 \cdot MeOH$ (L = a tripod Schiff-base ligand) when $X = NO_3^-$, ClO_4^-. When $X = C_6H_5COO^-$, it crystallizes as a racemate [6]. The complex cations do not form a multidimensional network through H-bonds, and it is obvious that counter-anions play a crucial role in determining the crystallization pathway of the complex cation in this case. Finally, Bernal's group has been conducting systematically structural analyses of racemic cobalt(III) compounds with the formula $[Co(L1)_a(L2)_b]^{n+}$ (L1 = bidentate or one tetradentate amino ligands, $L2 = NO_2^-$ or $C_2O_4^{2-}$ ligands) [1]. These cobalt(III) complexes also contain the double-faced H-bonding motif carried by different ligands with H-bonding donor and acceptor functional groups. Effects of steric substitution and counter-ions were discussed. It was concluded that, in these systems, most of the conglomerates are formed by fragments which are capable of forming extended 1D chains through inter-molecular interactions, while the final aggregation of homochiral chains is effected by the so-called 'stitching agent(s)'; i.e. counter-ions and water of crystallization.

Therefore, at the moment it is not practical to rationalize the overall structural factors that will produce conglomerate crystallization, since this will raise the same issue as 'are crystal structures predictable?' [7]. In a typical molecular coordination complex, the final crystallization pathway is the result of a delicate balance between inter-molecular interactions and topological complements [4]. Thus, the structural factors controlling this supramolecular assembly process are encoded in the nature of metal atom and ligands, the coordination geometries and the counter-ions [4]. In spite of these problems, a systematic investigation of the crystallization behavior of racemic coordination compounds, especially conglomerates, is still valuable from both perspectives of chiral recognition in the solid state and in inorganic crystal engineering, a new branch of crystal engineering coined recently as a natural bridge between the two primary classes; i.e. the organic and covalent (coordination polymer) crystal engineering [8,9].

In our preceding papers, based upon our investigation about the packing arrangement of chiral $[Co(tren)(L\text{-aminoacidato})]^{2+}$ complexes, we predicted [10] and documented [2] that racemic $[Co(tren)(DL\text{-aminoacidato})]^{2+}$ complexes tend to favor conglomerate crystallization. Most significantly, in both enantiomorphic and racemic crystals, there is one dominant hydrogen bonding pattern designated as $C(6)[R_2^1(6)]$ [11], formed by the carboxylic oxygen of the amino acidato ligand and amino hydrogen atoms of the tren or amino acidato ligands. These H- bonds connect cations containing the same enantiomorphic amino acidato ligand into chiral helixes, as illustrated in Scheme 1. We refer to this pattern as the 'chiral recognition motif' of this system [2,10]. In order to compare the homo-

Scheme 1. chiral–heterochiral assembly process of the nickel(II) chiral complex cations with their cobalt(III) analogues, as well as to evaluate the role played by metal atom upon the chiral recognition process, we report herein the syntheses and crystal structures of the *trans*(*N*, *t*-*N*) isomer of $[Ni(tren)(DL\text{-valinato})]Cl \cdot 2H_2O$ (**1**), $[Ni(tren)(DL\text{-phenylalaninato})]Cl \cdot 3H_2O$ (**2**) and $[Ni(tren)(DL\text{-leucinato})]Cl \cdot 2H_2O$ (**3**) (tren = tris(2-aminoethyl)amine).

2. Experimental

2.1. Syntheses

All reagents were commercially available and used as received. Elemental analysis was carried out with a Perkin–Elmer 240 elemental analyzer.

Compounds **1**–**3** were prepared as follows, to an aqueous solution of tren (0.30 g 3 mmol), an equal molar amount of amino acid and freshly prepared 10% NaOH solution was added. An aqueous solution of $NiCl_2 \cdot 6H_2O$ (0.48 g 3 mmol) was added under stirring. The color of the solution slowly changed to blue while

the solution was kept at 60 °C for several hours in a water bath. During the heating, water was added to keep the volume constant. The solution was cooled to room temperature (r.t.) and filtered. Crystals suitable for X-ray diffraction (XRD) were obtained by slow evaporation of the result solution at ambient temperature. Compound **1**: $C_{11}H_{32}ClN_5NiO_4$ required: C, 33.66; H, 8.22; N, 17.84. Found: C, 33.26; H, 7.82; N, 17.24%. Compound **2**: $C_{15}H_{34}ClN_5NiO_5$ required: C, 39.29; H 7.47; N, 15.27. Found: C, 39.41; H, 7.07; N, 14.96%. Compound **3**: $C_{12}H_{35}ClN_5NiO_{4.5}$ required: C, 34.68; H, 8.49; N, 16.85. Found: C, 34.82; H, 8.01; N 16.66%.

2.2. X-ray crystallography

All diffraction data were collected on a Bruker SMART 1000 CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at r.t. [12]. Absorption corrections were applied with the Bruker Area Detector absorption program [13,14]. Space groups of these complexes were determined from systematic absences and further justified by the results of refinement. In all cases, structures were solved by direct methods and refined using full-matrix least-squares/difference Fourier techniques [15,16]. All non-hydrogen atoms were refined with anisotropic displacement parameters. After that, all hydrogen atoms were placed in idealized positions and refined as riding atoms with the relative isotropic parameters.

In compounds **2** and **3**, disorders of the asymmetric carbon atom of the amino acidato ligand (in **2**) and its adjacent atom (in **3**) were observed. All the disordered atoms were refined over two sites, labeled as A and B. The $|E^*E-1|$ values (0.926 and 0.931 for **2**, and **3**, respectively) unambiguously point to centrosymmetric space groups. Compound **3** was also solved and refined in space group $P1$, in order to investigate the possibility that an incorrectly assigned space group imposed the disorders. The results show that in both $P1$ and $P\bar{1}$ space group, the same magnitude of disordered was observed.

Crystal data are listed in Table 1. Selective bond lengths and distances are listed in Table 2. The coordinates, anisotropic thermal parameters, bond distances, angles and torsion angles for these complexes are submitted as supplementary materials in CIF format.

3. Results and discussion

3.1. Structural descriptions

Interestingly, in contrast with the crystal structures of [Co(tren)(aminoacidato)]X_2 which have been well-investigated [2,10,17,18], there are no crystal structures reported for either the Ni(II) tren analogues, nor any other material with the general formula $[Ni(N_4)(aminoacidato)]^+$ (N_4 = amine or ammonium ligands), according to a Cambridge Structural Database search [19,20]. As illustrated in Fig. 1, compounds **1**–**3** adopt the *trans*(*N*, *t*-*N*) geometry in which the tertiary N-atom of the tren ligand is in the *trans* position to the N-atom of the amino acidato ligand. The Ni–N bond distances are in the ranges 2.0737(12)–2.1446(13), 2.0737(12)–2.1446(13), 2.070(4)–2.169(4) Å, and those of Ni–O are 2.0742(11), 2.1027(16), 2.067(3)/2.083(3) Å in **1**, **2** and **3**, respectively. The most striking difference between the Ni(II) and Co(III) analogues resides in the deprotonated carboxylic group of the amino acidato ligands. In the Ni(II) compounds, the average distances of the two carboxylic C–O distances is 1.256 Å for the coordinated O-atoms and 1.245 Å for the unbound O-atom, indicative of conjugate bonds. In the Co(III) analogue, for instance, in [Co(tren)(DL-leucinato)]$(ClO_4)_2$ [2], the C–O distance is 1.296(6) Å for the coordinated O-atoms and 1.187(6) Å for the unbound O-atom, indicative of single and double bonds. Therefore, the carboxylic group coordinates to Ni(II) as a delocalized carboxylate anion and to Co(III) as a more localized anion. This coordination mode is valid for all the amino acidato Co(III) complexes studied by our group [2,10,17].

As shown in Fig. 1(b and c), in complexes **2** and **3**, the asymmetric carbon or/and the carbon atom next to it are disordered and were refined over two positions. Consequently, the absolute configurations of the asymmetric carbons are different in these two sites. Such disorder is indicative of the fact that D- and L-amino acids occupy the same lattice site in complexes **2** and **3**. The same phenomenon has been observed and documented previously in related Co(III) analogues [2,18]. The name conglomeratic solid was then coined [18] to describe this phenomenon since the racemic material crystallizes in an enantiomorphic space group. However, the circumstances are different here, complexes **2** and **3** crystallize in the centrosymmetric space groups $P2_1/n$ and $P\bar{1}$. In other words, they are real racemates in the crystalline lattice.

3.2. Packing descriptions

As shown in Figs. 2 and 3, the cations of **1** and **2** are assembled into 1-D chains by the same pattern of intermolecular H- bonds. The unbound carboxylic oxygen is H- bonded divergently to two amino H-atoms of the tren ligands belonging to two different adjacent cations (N···O = 3.1533(18), 3.175(2) Å and N–H···O = 142.3, 142° in **1**. N···O = 3.279(3), 3.320(3) Å and N–H···O = 129.3°, 147.6° in **2**), resulting in a ribbon-like arrangement of the cations along the *b* axis. The extended notation for the H- bond pattern can be described as $C_2^1(6)[R_2^2(12)]$ [11]. The amino H-atoms of the amino acidato ligand are not involved in any inter-

cationic H- bonds. Instead, they are so engaged by the counter anions and waters of crystallization. Interestingly in complex **1**, the cations which are H- bonded together are generated by 2_1 operations and align along the screw axis, i.e. the b axis. Therefore, they are homochiral. In contrast, cations in **2** adopt the same packing arrangement along the b axis, connected by the same pattern of H- bonds with weaker strength. The fact that D- and L- isomers occupy the equivalent lattice places makes it ambiguous to determine the chiralities of the H- bonded cations.

In **3**, there are two complex cations in the asymmetric unit. As shown in Fig. 4, the cations are also linked into 1-D chains by intermolecular H- bonds. Each complex cation forms two H- bonds with the same cation of the next unit, generating pairs of Ni–Ni and Ni′–Ni′ with the same H- bond pattern as that observed in **1** and **2** (N···O = 3.202(5), 2.919(4) Å; N–H···O = 151.4°, 164.9°), with the notation for the H- bond pattern described as $R_2^2(12)$ [11], and there is only one H- bond connecting the pairs together (N···O = 2.940(4) Å and N–H···O = 145.1°). Nevertheless, the ribbon-like arrangement of the cations is very similar to that observed in **1** and **2**. The observed disorder also suggests that the chiralities of the cations that are linked together cannot be determined.

The purpose of this investigation is to compare the inter-cationic H- bonding patterns between the Ni(II) and Co(III) analogues. Therefore, H- bonds formed by the Cl^- anion and water of hydration are not discussed in detail here. However, it should be pointed out that counter anions and water molecules play important roles in determining the overall crystallization pathway, as we concluded in our previous papers [1].

3.3. Effect of the metal atom on the inter-molecular H-bond pattern

Metal atoms play a unique role that distinguishes inorganic crystal engineering from its organic counter-

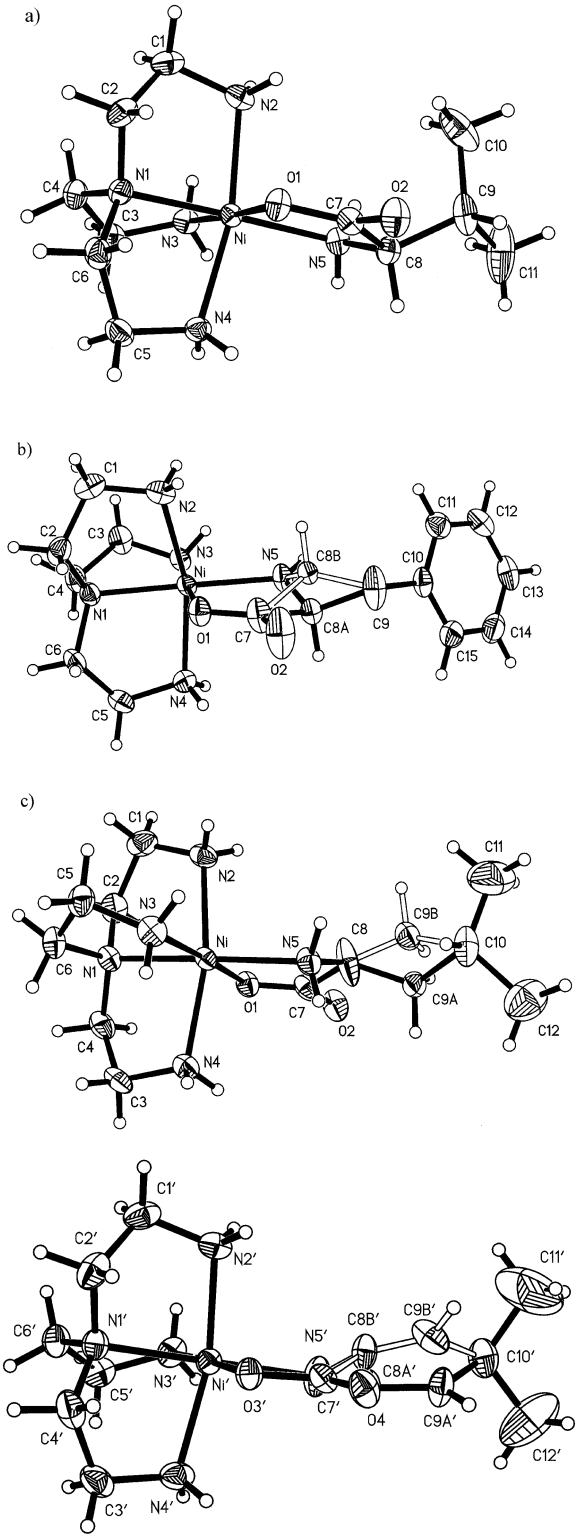

Fig. 1. (a)–(c) Atomic numbering scheme of the complex cations in **1**–**3**, respectively, with 30% probability displacement ellipsoids. Note that the asymmetric carbon atom or/and the one next to it, namely C8 **2**, C9 in **3** (cation 1), and C8′, C9′ in **3** (cation 2) are disordered and refined over two positions. These result in different absolute configurations for the two portions.

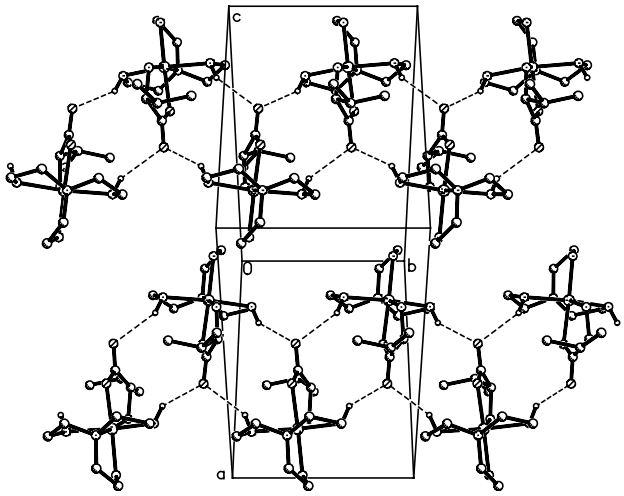

Fig. 2. Packing arrangement of the complex cations in **1.** Note that the complex cations are related to each other by the 2_1 operation and align along the *b* axis.

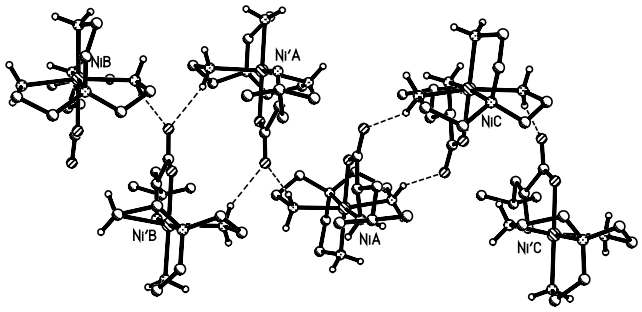
part. The properties, including crystal packing, of metal-containing materials depend on the electronic nature of the metals as well as on the characteristics of the ligands [8]. It was pointed out that in organo-metallic or coordination compounds, the metal centers are mostly situated in the molecular cores and well-shielded from neighboring molecules [9], and the peripheral portion of the molecules, i.e. the organic ligands, are crucial in



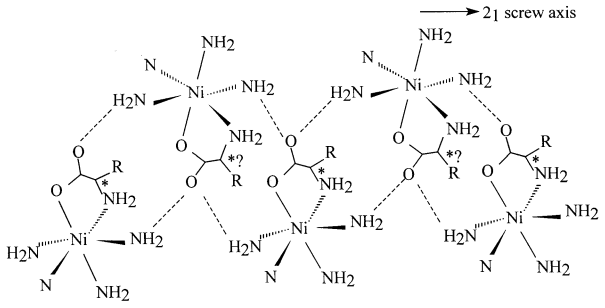


Fig. 4. Packing arrangement of the complex cations in **3**. Note that the complex cations are arranged into a 1-D chain in a similar fashion as that observed in **1** and **2**. One portion of the disordered fragments is omitted for clarity.

determining the crystal structures since they are directly involved in inter-molecular, noncovalent interactions. This is indeed what was observed for the bis(imidazolium 2,6-pyridinedicarboxylate)M(II) trihydrate complexes, where M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} or Zn^{2+} [21]. Packing in these solids is dominated by H- bonding between imidazolium cations and carboxylate anions. All of the metal complexes crystallize in the same space group with similar unit cell parameters. However, in the structure of a 14-membered polyazamacrocyclic copper(II) complex, appended by the heterocyclic melamine, it was predicted that the metal ions play a minor role in the formation of the supramolecular array [22]. Both systems share the common feature that the metal atoms are buried by the outer portion of the molecules and the metal-bonded atoms are not involved in any inter-molecular interaction. By contrast, in the series of $[M(tren)(aminoacidato)]^{n+}$ compounds, H- bonding interactions are formed directly between the complex cations which comprise the 1-D backbone [2,10]. As illustrated in Schemes 1 and 2, atoms that are involved in the inter-cationic H- bonds as donors, i.e. the amino groups, are coordinated with the metal atoms. Therefore, the nature of the metal centers adjusts the acidity of the donors. While for the acceptor, which is the carboxylic oxygen, as mentioned above the carboxylate anions coordinate in a different mode, as a delocalized

Scheme 2. Schematic representation of the homochiral–heterochiral helical chain with 2_1 symmetry generated by $[Ni(tren)(aminoacidato)]^+$ complex cations.

and localized anion to Ni(II) and Co(III), respectively. Therefore, the basicities of the free O-atoms of the carboxylic group are different in the Ni(II) and Co(III) analogues. The tuning of the acidity–basicity of the donor–acceptor in the organic ligands by the metal atoms shows a response in their H- bonding capacity, and alters the pattern and strength of inter-molecular interactions as illustrated in Schemes 1 and 2.

3.4. Intermolecular H- bonding interactions, packing forces and chiral recognition

In our previous report [2], we demonstrated that for most of the racemic $[Co(N4)(aminoacidato)]^{2+}$ complexes, inter-cationic H- bonding interactions generally exist which bring cations with the same chirality together into helical chains. The helical chain arrangement remains the same in both racemic and enantiomorphic crystals. The only difference is that in the former adjacent helices are of opposite handedness, while in the latter only one handedness of the helical array is observed. Since the H- bonding pattern observed in racemic crystals is the same as that observed in the enantiomeric form, we refer to it as the 'chiral recognition motif' of these systems. For the $[Co(tren)(aminoacidato)]^{2+}$ series, the inter-cationic H-bond pattern is characterized as $C(6)[R_2^1(6)]$ and illustrated in Scheme 1, with an average strength of N···O = 2.875/2.965 Å, N–H···O = 15···5.3/133.2°. However, the complex cations generally align along the crystallographic screw axis. This observation raises a query, i.e. is this homochiral assembly/chiral recognition process forced by the packing forces? How to evaluate the roles played by the inter-molecular interactions and the packing forces during the homochiral assembly/chiral recognition process? This doubt is resolved by the comparison of the crystal structures of Ni(II) complexes **1** and **2**. They crystallize in the same space group with similar packing arrangements. However, homochiral arrangements are observed in **1**, and cannot be determined in **2**. The fact that D- and L- isomers occupy the same crystalline lattice in **2** indicates the possibility that inter-molecular interactions in **2** are not capable of discriminating the heterochiral fragment from the homochiral one. **3** Crystallizes in a space group devoid of any screw axis operation, but the fragments are still arranged as 1-D chains connected by H- bonds. This reveals another important feature of this crystal structure, i.e. it is the double inter-molecular H- bonds, not the packing forces, that controls the assembly of the complex cations into the 1-D helix. These observations sustain our previous conclusion that the inter-molecular interactions between $[Co(N4)(aminoacidato)]^{2+}$, which combine both strength and directionality, is the 'chiral recognition motif' which drives the homochiral assembly.

4. Concluding remarks

The origin of handedness in biological molecules is one of nature's mysteries. Recently, an elegant work has been performed to demonstrate that chiroselectivity in peptide self-replication is a direct result of complementary *non-covalent interactions* that pass on both binding and stereochemical information simultaneously [23]. Herein and in our previous papers [2,10], we have illustrated a simple molecular coordination system whose chiral recognition capability is realized by non-covalent intermolecular interactions. This series of compounds can serve as a unique model to evaluate the roles played by the nature of the metal center, as well as the steric effects of the side chain of an amino acid, during the homochiral–heterochiral assembly process.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 164478–164480 for compounds **1**–**3**, respectively. Copies of this information can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http//www.ccdc.cam.ac.uk).

Abstract

A new 18-membered ligand, 2,3-dibromo-6,7,13,14,15,16,22,23-octahydro 14, 15-bis(hydroxyimino)-tribenzo [e,k,q] [1,4,10,13,7,16] diazadioxadithiacyclooctadecine (LH_4) containing three different heteroatoms (N–, O–, S–) has been prepared from 1,2-bis (2′-amino phenylsulfanylethoxy)-4,5-dibromobenzene and cyanogen di-*N*-oxide. Mononuclear $(LH_3)_2M$, where M = Ni(II), Cu(II), Co(II), Fe(II) binuclear $(LH)_2(UO_2)_2(OH)_2$ and trinuclear $(LH)_2M_3$, where M = Cu (II), Co (II) complexes of LH_4 have been obtained with a metal:ligand ratio 1:2, 2:2 and 3:2, respectively, through *N*,*N*-coordinating or N, N, S, S-coordinating in the presence of a base, as do most of the *vic*-dioximes. ^{1}H NMR, IR, UV–Vis and MS data are presented. The cyclic voltammetric (CV) measurements of the newly synthesized compounds were measured. Voltammetric results showed that oxime-containing ligands stabilize Ni(III), Fe(III), Co(III) and Cu(III). The Fe(II) complex displayed a different behavior with respect to other complexes. This indicated that both Fe(III) and Fe(I) species are stable while oxime containing ligands tend to stabilize only one of the oxidized forms of the metal center of the complexes. Differently, ligand based reduction was recorded only with the Ni(II) complex. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: *vic*-Dioxime; Nickel(II), Cobalt(II), Copper(II), Iron(II), Uranyl(IV), Electrochemistry; LH_4; $N_2O_2S_2$ macrocyle

1. Introduction

Oximes and their metal complexes are of current interest for their rich physicochemical properties, reactivity patterns and potential applications in many important chemical processes in the areas of medicine [1–4], bioorganic systems [5,6], catalysis [7,8], electrochemical and electrooptical sensors [9–12]. The high stability of the complexes prepared with *vic*-dioxime ligands has been extensively used for various purposes including model compounds for vitamin B_{12} or trace metal analysis [13,14]. The successful design and synthesis of ligands capable of forming heteronuclear complexes have been receiving world-wide attention for obtaining special effects in magnetic, optical and electrical properties [15–20]. Examples of heteronucleating ligands that could serve as polytopic receptor molecules for the binding or cobinding of metal ions and molecular substrates include molecules that contain various functionalities appended to porphyrins, phthalocyanines, salen centers and macrocyclic tetraammines [21–23]. The investigations of the redox properties of these types of complexes are also of great interest in terms of their various technological applications [24–28]

Incorporation of a *vic*-dioxime moiety on the macrocycle provides an efficient binding site for transition metal ions by formation of an MN_4 core with two additional hydrogen bridges [29]. The presence of weakly acidic hydroxyl groups and slightly basic nitrogen atoms make vicinal dioxime amphoteric ligands which form corrin-type square-planar, square-pyramidal and octahedral complexes with transition metals, such as nickel(II), copper(II), palladium(II) and cobalt(II) as central atoms [30]. When starting compounds

with macrocyclic groups were used, *vic*-dioximes incorporating macrocyclic groups capable of binding transition and alkali metal ions simultaneously have been achieved [15,29–31].

The ability of oxime-containing ligands to stabilize reduced and oxidized forms of metal ions has a vital importance in their role in the areas of technological applications. However, the literature dealing with the electrochemistry of metal-oximes especially in organic solvents is scarce [32–34]. In the present work, we have prepared a 18-membered macrocyclic *vic*-dioxime ligand, which contains two oxygen, two nitrogen and two sulfur binding sites. The mono- di- and tri-nuclear complexes of this ligand with various transition metals have been synthesized. Also, electrochemistry of the mono- and dinuclear complexes have been investigated.

2. Experimental

Routine IR spectra were recorded on a Mattison 1000 Spectrophotometer using KBr pallets, and electronic spectra on an unicam UV2 spectrophotometer. Elemental analysis was performed by the Instrument Analysis Laboratory of TUBITAK Marmara Research Centre. Proton NMR spectra were recorded on a Bruker 250 MHz spectrometer using $SiMe_4$ as reference and MS:EI on a VG Zabspec GS-MS spectrometer. The metal contents of the complexes were determined with a Hitachi 180-80 atomic absorption spectrophotometer in conc. $HClO_4$ and conc. HNO_3 solution followed by digestion in conc. HCl solution. The homogeneity of **2** and **3** were tested in each step by TLC (SiO_2, EtOH). 1,2-Di iodo-(2′-etoxyphenoxy)-4,5-dibromobenzene and *anti*-dichloroglyoxime were synthesized according to the published methods [35–40].

Cyclic voltammetric (CV) and controlled potential coulometric (CPC) measurements were carried out with an instrument (Princeton Applied Research Model 273 potentiostat controlled by an external PC, using the computer program, HEADSTRT) utilizing a three electrode configuration at 25 °C. ORIGIN 5.0 graph program was used to evaluate HEADSTRT data, to draw voltammograms and analyze them. A platinum wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and was separated from the bulk of the solution by a glass bridge. The working electrode was a platinum plate with an area of 1.0 cm^2. The surface of the working electrode was polished with a water suspension of Al_2O_3 before each run. Tetrabutylammoniumperchlorate (0.1 mol dm^{-3}) (TBAP) in extra pure DMSO was employed as the supporting electrolyte. High purity nitrogen was used for deaeration and to maintain an nitrogen blanket for at least 15 min prior to each run. For CPC studies, a Pt gauze working electrode (10.5 cm^2 surface area), a platinum wire counter electrode separated by a glass bridge, a saturated calomel reference electrode, and a model 377/12 Synchronous stirrer were used. With CPC studies of the complexes, complete electrolysis of the solution at the working electrode at constant potential (E_{pc} of redox couple) was done and as a result time integration of the electrolysis current was recorded. The electroactive species in the solution was depleted during the electrolysis and the accumulated current time integral, the charge Q at the end of electrolysis, was calculated by using the current–time response of the solution. Faraday's Law was used to calculate the number of electrons transferred for electron transfer reactions.

2.1. 1,2-Bis (2′-aminophenylsulfanylethoxy)-4,5-dibromobenzene (2)

2-Aminothiophenol (2.50 g, 20.0 mmol) was dissolved in 30.0 cm^3 ethanol under nitrogen. Then 2.00 cm^3 40% NaOH solution was added and the mixture was stirred and heated at reflux for 10 min. To this solution, 1,2-di iodo-(2′-etoxyphenoxy)-4,5-dibromobenzene (5.76 g, 10.0 mmol) in 20.0 cm^3 hot ethanol was added dropwise over a period of 1 h. After the reaction mixture had been refluxed for 2 h, the solvent was distilled off. The yellow residue was dissolved in 50.0 cm^3 diethylether and the solution was filtered. The filtrate was washed firstly with Na_2CO_3 (5%) and then with water (3×30.0 cm^3) to separate any inorganic residues, dried with sodium sulphate and finally filtered. When the hydrochloric acid gas was passed through the filtrate, white amine salt was separated. The solid was washed with diethylether and dichloromethane. The precipitate was dissolved in absolute ethanol. The pH of the solution was adjusted to 8 with 1.00 N KOH solution in methanol and free amine was separated as white crystals. It was filtered and washed with cold ethanol. Yield: 3.21 g (56.3%). This compound is soluble in chloroform, dichloromethane, diethylether, THF and slightly hot ethanol. m.p.: 96 °C. IR (KBr, cm^{-1}) ν: 3460–3350 (NH_2), 3080, 3030 (Ar-H), 2950, 2870 (Aliph-H), 1590 (w), 1515–1450 (Ar-skelt.vib.), 1270–1250 (C–O–C), 640 (C–Br). ^{1}H NMR (250 MHz, DMSO-d_6) δ:7.34 (s, 2H, Ar-H), 7.27(dd, $^3J = 7.5$ Hz, $^4J = 1.7$ Hz, 2H, Phenyl-H3), 7.01 (dt, $^3J = 7.5$ Hz, $^4J = 1.5$ Hz, 2H, Phenyl-H5), 6.67 (dt, $^3J = 7.8$ Hz, $^4J = 1.7$ Hz, 2H, Phenyl-H4), 6.50 (dd, $^3J = 7.8$ Hz, $^4J = 1.5$ Hz, 2H, Phenyl-H6), 5.38 (s, br, 4H, $-NH_2$), 4.01 (t, $^3J = 6.2$ Hz, 4H, O–CH_2CH_2) and 2.89 (t, $^3J = 6.2$ Hz, 4H, S–CH_2CH_2). MS (EI): $m/z = 570.2$ (20%) [M^+].

2.2. Synthesis of 5,6, 17,18-dibenzo-11,12-dibromobenzo, 2,3-bis(hydroxyimino)-1,4-diaza, 7, 16-dithia-10,13dioza-2,3,8,9,14,15-hexahydrocyclodecine (Diazadithiadioxa Macrocycle) (LH_4) (**3**)

Compound **1** (2.85 g, 5.00 mmol) was dissolved in 200 cm^3 dichloromethane and cooled to −20 °C with stirring. To this solution, a solution of cyanogen di N-oxide in 70.0 cm^3 dicholoromethane, which was prepared from *anti*-dichloroglyoxime (0.790 g, 5.00 mmol) and aqueous 1.00 N Na_2CO_3 solution, was added dropwise. The reaction was continued at this temperature for 6 h with stirring and then the yellow compound was separated by filtration, washed with dichloromethane, ethanol and diethylether and dried in vacuo. Yield: 0.820 g, (25.1%); m.p. 142 °C. This compound is soluble in THF, Dioxane, DMF and DMSO and slightly soluble in MeOH. IR (KBr, cm^{-1}) ν: 3350 (NH), 3220 (br, OH), 3070, 3020 (Ar-H), 2985–2850 (Aliph-H), 1640 (C=N), 1580–1420 (Ar-skel. Vib.), 1270–1230 (C–O–C), 1010 (N–O), 700, 650 (C–Br), 560. ^{1}H NMR (250 MHz, DMSO-d_6) δ: 10.72 (s, 2H, =N–OH, D-exchangeable), 8.65 (s, 2H, –NH, D-exchangeable), 7.48 (s, 2H, Ar–H), 7.23 (dd, $^3J = 7.2$ Hz, $^4J = 1.7$ Hz, 2H, Phenyl-H3), 7.04 (dt, $^3J = 7.1$ Hz, $^4J = 1.6$ Hz, 2H, Phenyl-H5), 6.73 (dt, $^3J = 7.8$ Hz, $^4J = 1.7$ Hz, 2H, Phenyl-H4), 6.50 (dd, $^3J = 7.1$ Hz, $^4J = 1.5$ Hz, 2H, Phenyl-H6), 4.24 (t, $^3J = 6.1$ Hz 4H, O–CH_2CH_2), 3.01 (t, $^3J = 6.1$ Hz 4H, S–CH_2CH_2). UV–Vis (in DMSO) λ_{max}, nm (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 320 (6100), 307 (9840) (sh), 290 (12 500), MS (positive FAB, solution in DMSO, Magnet BpI: 3582): $m/z = 655(35)$ $[M^+ + 1]$.

2.3. Mononuclear complexes

2.3.1. (LH_3)$_2$Ni (**4**)

$Ni(NO_3)_2 \cdot 6H_2O$ (0.0360 g, 0.120 mmol in 10.0 cm^3 THF) solution was slowly added with stirring to **3** (0.160 g, 0.250 mmol in 20.0 cm^3 THF). The color of the solution turned immediately into red–orange. A decrease in pH was observed. So the pH of the mixture was raised to about 7.0 by addition of $(C_2H_5)_3N$. The reaction mixture was kept at 60 °C with stirring until the precipitation was completed. Then it was brought to room temperature (r.t.) and the orange crystalline complex precipitated. The product was filtered, washed with water, ethanol, THF and diethylether and finally dried in vacuo. This compound is soluble in DMF and DMSO. Yield: 0.080 g (50%); m.p.: > 200 °C. IR (KBr, cm^{-1}): ν: 3410 (–NH), 3050 (Ar-H), 2975–2840 (Aliph-H), 1700 (O–H...O), 1620 (–CN), 1590, 1590–1460 (Ar-skel.), 1260–1240 (Ar-O-Aliph, Aliph-O-Ar), 1010 (N–O), 695, 660 (C–Br), 550. ^{1}H NMR (250 MHz, DMSO-d_6) δ:16.70 (s, 2H, O–H...O, D-exchangeable), 8.64 (s, 4H, –NH, D-exchangeable), 7.70 (s, 2H, Ar-H), 7.19 (d, $^3J = 7.8$ Hz, 4H, Phenyl-H3), 7.05 (dt, $^3J = 7.6$ Hz, $^4J = 1.7$ Hz, 4H, Phenyl-H5), 6.84 (dt, $^3J = 7.8$ Hz, $^4J = 1.5$ Hz, 4H, Phenyl-H4), 6.52 (d, $^3J = 7.2$ Hz, 4H, Phenyl-H6), 4.07 (t, $^3J = 6.2$ Hz, 8H, O–CH_2CH_2), 3.01 (t, $^3J = 6.2$ Hz, 8H, S–CH_2CH_2). UV–Vis (in DMSO) λ_{max}, nm (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 350 (6700), 321 (11 090), 303 (13030). MS (positive FAB, solution in DMSO): m/z 1365 (15%) $[M^+]$

2.3.2. (LH_3)$_2$Cu (**5**)

To a solution of **3** (0.160 g, 0.250 mmol) in 20.0 cm^3 THF, with stirring a solution of (0.0360 g, 0.120 mmol) $Cu(NO_3)_2 \cdot 6H_2O$ in 20.0 cm^3 THF was added dropwise at r.t. The color of the solution turned into dark brown. The pH of the mixture was adjusted to about 7.0 by adding $(C_2H_5)_3N$. Then the mixture was heated on a water bath until the precipitation was completed. It was brought to r.t., then the product was filtered, washed with water, ethanol, THF and diethylether and dried in vacuo. This compound is soluble in DMF, DMSO and slightly soluble in pyridine. Yield 0.07 g (41.76%). m.p.: > 200 °C. IR (KBr, cm^{-1}) ν: 3420 (NH), 3070 (Ar-H), 2950, 2845 (Aliph-H), 1710 (w), 1650 (CN), 1590 (N–H bending), 1510–1460 (Ar-skel.), 1250 (C–O–C), 1015 (N–O), 690, 640 (C–Br), 560. UV–Vis (in DMSO) λ_{max}, nm (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 348 (2240) (sh), 303 (10 500). MS (positive FAB, solution in DMSO): 1370.5 (12%) $[M^+ + 1]$.

2.3.3. (LH_3)$_2$Co (**6**)

These pale brown complexes were prepared by following the same procedure as described for the preparation of $(LH_3)_2Cu$, starting from **3** (0.160 g, 0.250 mmol) and $Co(NO_3)_2 \cdot 6H_2O$ (0.0360 g, 0.120 mmol).

Yield: 0.0640 g (37.6%); m.p.: > 200 °C. IR (KBr, cm^{-1}) ν: 3420 (NH), 3030 (Ar-H), 2920, 2860–2830 (Aliph-H), 1710, 1630 (CN), 1590, 1505–1450, 1270, 1240 (C–O–C), 1020 (N–O), 700, 650 (C–Br), 555. UV–Vis (in DMSO) λ_{max}, nm (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 350 (1550) (sh), 305 (4670).

2.3.4. (LH_3)$_2$ Fe (**7**)

To a solution of **3** (0.160 g 0.250 mmol) in 20.0 cm^3 THF, with stirring, $Fe(NO_3)_2 \cdot 9H_2O$ solution (0.041 g, 0.12 mmol in 20.0 cm^3 THF) was slowly added at r.t. When the mixture was neutralized by adding $(C_2H_5)_3N$ and heated for 2 h at 60 °C, the precipitation was completed. The reaction mixture was brought to r.t., then the product was filtrated, washed with water and ethanol and then dried in vacuo. This compound is soluble in DMF, DMSO and slightly in pyridine.

Yield: 0.0540 g (31.7%); m.p. > 200 °C. IR (KBr, cm^{-1}) ν: 3420 (NH), 3060, 3030 (Ar-H), 2930, 2840 (Aliph-H), 1700 (H–O...H), 1630 (CN), 1590 (w), 1515–1440, 1250 (C–O–C), 1020 (N–O), 680, 660 (C–Br), 550. UV–Vis (in DMSO) λ_{max}, nm (ε, $dm^3\ mol^{-1}$

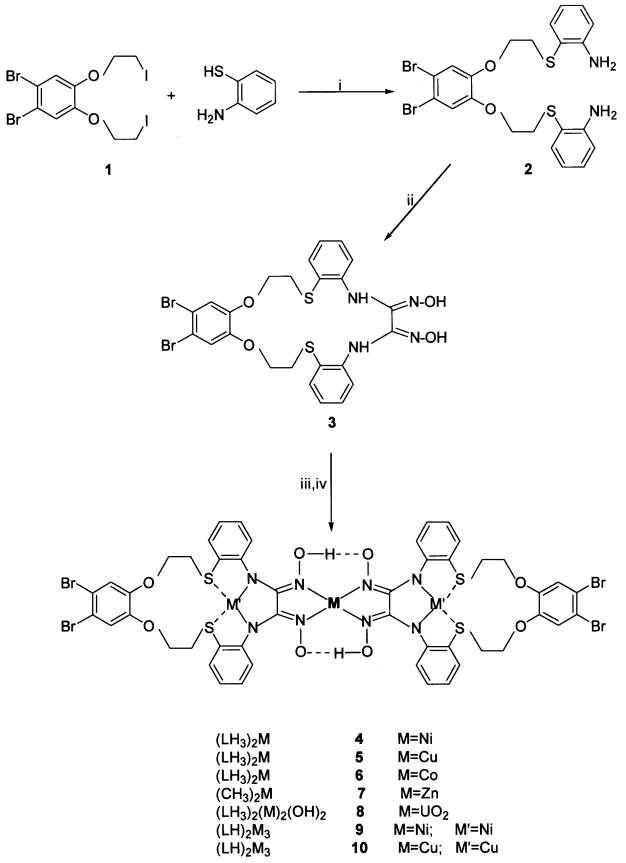
cm^{-1}): 319 (1460), 307 (9100). MS (positive FAB, solution in DMSO): 1362.5 (7%) [M^+].

2.4. Binuclear uranyl complex: $(LH)_2(UO_2)_2(NO_3)\cdot 6(OH)_2$ (**8**)

To a solution of **3** (0.160 g, 0.250 mmol in 20.0 cm^3 THF), a solution of $UO_2(NO_3)_2\cdot 6H_2O$ (0.172 g, 0.0980 mmol) in 10.0 cm^3 THF was slowly added with stirring. The pH of the mixture was adjusted to about 7.0 by adding $(C_2H_5)_3N$. The mixture was heated for 3 h at 60 °C, then it was brought to r.t. and the crystalline complex precipitated completely. The product was filtered, washed with water, ethanol and diethylether and dried in vacuo. Yield: 0.070 g (29.8%). m.p. > 200 °C. The binuclear uranyl complex is soluble in DMF and DMSO. IR (KBr, cm^{-1}): $\nu = 3370$ (N–H), 3250 (–OH), 3060, 3040 (Ar-H), 2930–2840 (CH-Aliph), 1630 (C=N), 1500–1450 (Ar-Skel.), 1260, (Ar-O–C), 1000 (N–O), 900 (O=U=O), 700, 640 (C–Br), 540. ^{1}H NMR (250 MHz, DMSO-d_6) δ:10.90 (s, 1H, N–OH, D-exchangeable), 10.45 (s, 1H, N–OH, D-exchangeable), 8.50 (s, weak, 2H, –NH, D-exchangeable), 8.30 (s, 2H, –NH, D-exchangeable), 7.60 (s, 2H, Ar-H), 7.53 (d, $^3J = 7.8$ Hz, 4H, Ar-H3), 7.45 (dt, $^3J = 7.5$ Hz, $^4J = 1.7$ Hz, 4H, Phenyl-H5), 7.08 (dt, $^3J = 7.8$ Hz, $^4J = 1.7$ Hz, 4H, Phenyl-H4), 6.73 (d, $^3J = 7.2$ Hz, 4H, Phenyl-H6), 4.28 (t, $^3J = 12.0$ Hz, 8H, O–CH_2CH_2), 2.86 (t, $^3J = 12.0$ Hz, 8H, S–CH_2CH_2). UV–Vis (in DMSO) λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1}): 405 (sh), (4350), 321(8900), 303 (11 300).

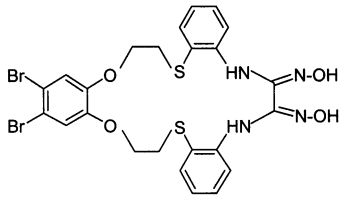
2.5. Trinuclear complexes $(LH)_2Ni_3$ (**9**) and $(LH)_2Cu_3$ (**10**)

Complex **4** (0.0500 g, 0.0360 mmol) was dissolved in 15.0 cm^3 of DMF with heating and stirring. A solution of $Ni(NO_3)_2\cdot 6H_2O$ (0.0160 g, 0.0540 mmol in 10 cm^3 of DMF) was added dropwise to the hot solution of **4** with stirring. After the mixture was stirred for 3 h at 40 °C, the pH of the solution decreased, so it was raised to 6.85 by the addition of triethylamine. After the solvent of the solution was removed under reduced pressure to nearly dryness, the precipitate was filtrated off, washed with ethanol and ether and finally dried in vacuo. This compound is slightly soluble in DMF, DMSO and pyridine.



$(LH)_2Ni_3$ (**9**): Yield: 0.02 g (18.75%), m.p. > 200 °C. IR (KBr, cm^{-1})ν: 3040 (Ar-H), 2925–2850 (Aliph-H), 1700 (w, O–H–O), 1640 (C=N), 1510–1440 (Ar-skel.), 1250(C–O–C), 990(N–O), 660, 640 (C–Br), 540. UV–Vis (in DMSO) λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1}): 375 (1940), 310 (8820). MS (positive FAB, solution in DMSO):1479.0 (10%) [M^+].

The same procedure as described for the preparation of $(LH)_2Ni_3$ (**9**) starting from **5** (0.0490 g, 0.0360 mmol) and $Cu(NO_3)_2\cdot 6H_2O$ (0.0160 g, 0.0540 mmol) was used to prepare $(LH)_2Cu_3$ (**10**).

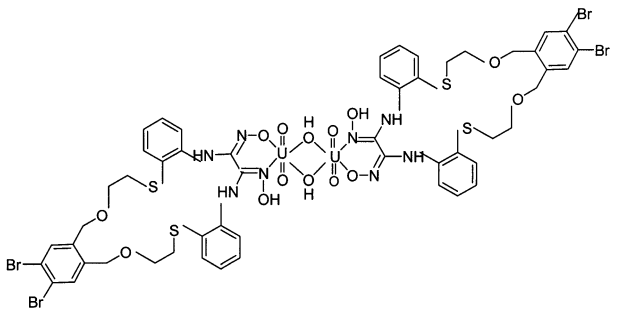


$(LH)_2Cu_3$ (**10**): Yield: 0.023 g (20.41%); m.p. > 200 °C. The complex is slightly soluble in DMF, DMSO and pyridine. IR (KBr, cm^{-1}): ν:3060, (Ar-H), 2925, 2870 (Aliph-H), 1705 (O–H...O), 1635, 1280, 1230 (Ar-O-Aliph, Aliph-O-Ar), 990 (N–O), 675, 650 (C–Br), 550. UV–Vis (in DMSO) λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1}): 390 (2400), 350 (6700), 302 (12 350). MS (positive FAB, solution in DMSO): 1493.7 (7%) [$M+1$]$^+$.

3. Results and discussion

The routes for the synthesis of **3** are given in Scheme 1. The first step is the synthesis of **2** starting from 2-aminothiophenol and 1,2-bis (2′-iodoethoxy)-4,5-dibromobenzene [35–38]. Compound **3**, shown in Fig. 1, was prepared by the reaction of **2** with dicyan di-*N*-oxide [33–35] which was prepared by treating a suspension of *anti*-dichloroglyoxime in CH_2Cl_2 with 1 N aqueous Na_2CO_3 at −20 °C.

Scheme 1. (i) 40% NaOH, EtOH (ii) Cyanogen di *N*-oxide, CH_2Cl_2, −40 °C; (iii) THF, $ML_2\,6H_2O$ (L = NO_3, M = Ni, Cu, Co, Fe, UO_2), Et_3N; (iv), dmf, $(LH_3)_2Ni$, $(LH_3)_2Cu$, $ML_2\,6H_2O$ (L = NO_3, M = Ni, Cu)Et_3N, 40 °C.



LH_4 (3)

Fig. 1. LH_4, **3**: diazadithiadioxa macrocycle.

The ligand **3** has two nitrogen, two oxygen, and two sulfur atoms in the macrocyclic ring, in addition to two oxime groups. Consequently, this *vic*-dioxime is capable of forming mono-, di- and tri-nuclear complexes [13,14,31]. While the mono and di-nuclear complexes have been synthesized from **3** with nitrates of Ni(II), Cu(II), Co(II), Fe(II) and UO_2(VI), tri-nuclear complexes have been obtained by using the relevant mononuclear complexes. Ni(II), Cu(II), Fe(II) and Co(II) mononuclear complexes have a metal:ligand ratio of 1:2 and the ligand is coordinated only by the *N*, *N*′ atoms of the *vic*-dioxime. The metal–ligand ratio was 2:2 in the dinuclear uranyl complex (**8**) having the N, O atoms of the *vic*-dioximes coordinating as shown in Fig. 2. The elemental analysis of **8** also indicated a metal:ligand ratio of 2:2. On the other hand, in trinucleating complexes (**9**, **10**), two metal ions are coordinated to the two aza and two sulfur atoms of each macrocycle, while the third metal ion is coordinated by the *N*, *N*′ atoms of each oxime group in the two ligand molecules with a ratio of 3:2. The colors and elemental analyses of **2**, **3** and the metal derivatives are listed in Table 1.

The $-NH_2$ stretching vibrations at 3460–3350 cm^{-1} and the aromatic C–Br bending vibration at 640 cm^{-1} are the most dominant ones showing the formation of **2** in the IR spectrum. In the IR spectrum of **3**, the OH stretching absorption is observed at 3220 cm^{-1} as a slightly broad band in addition to C=N, N–O and C–Br stretching absorptions at 1640, 1010 and 640 cm^{-1}, respectively. These values are in harmony with the

8 $(LH_3)_2(UO_2)_2(OH)_2$

Fig. 2. Binuclear uranyl complex: $(LH)_2(UO_2)_2(NO_3)\cdot 6(OH)_2$ **(8).**

previously reported diaminoglyoxime derivatives [15,20,31].

While weak (O–H...O) deformations of all mono- and tri-nuclear complexes are observed at around 1700 cm^{-1}, these vibrations are not involved in the IR spectra of the di-nuclear uranyl complex due to the coordination of the uranyl complex. Moreover, the vibration at 1000 cm^{-1} (N–O), 900 cm^{-1} (O=U=O) and 3370 cm^{-1} (N–H) are characteristics for **8** [15,20,31]. The –NH stretching vibrations at around 3410 and 3420 cm^{-1} observed for **4** and **5** have disappeared in the IR spectrum of **9** and **10** indicating the formation of these tri-nuclear complexes[31,40–42]. The aromatic, aliphatic, (C=N), (N–O) and (C–Br) stretching and bending vibrations of the $(LH)_2M_3$ complexes are very close to **4** and **5**. The S–C vibrations of the macrocycle in **4** and **5**, which appear as split bands at 695, 550 and 690, 560 cm^{-1}, shift to 660, 540 and 675, 550 cm^{-1}, respectively, in the IR spectra of **9** and **10** suggesting the bending of nickel or copper ions to the macrocycle sulfur atoms. The rest of the spectra of **9** and **10** are very similar to **4** and **5** with small differences in chemical shift. According to these data, in **9** and **10** the two Ni(II) or Cu(II) ions are coordinated to two aza and thia atoms of the each ligand, whereas the third Ni(II) or Cu(II) ion is coordinated by the *N*,*N*′-atoms in the complex.

In the ^{1}H NMR spectrum of **2**, the primary aromatic amine protons are observed at 5.38 ppm (s, br, 4H, NH_2, D-exchangeable) as a singlet, which is also easily identified by deuterium exchange. In addition to this resonance, there are triplets at 4.01 and 2.89 ppm, which correspond to the methylene protons. In the ^{1}H NMR spectrum of **3**, a singlet, which belongs to the NH_2 protons in **2,** disappears upon macrocyclization of **2** with cyanogens di N-oxide and a new chemical shift at 8.65 ppm is observed which can be assigned to –NH protons in the neighbourhood of the oxime groups. The deuterium-exchangeable protons of the –N–OH groups show a chemical shift at 10.72 ppm as a singlet indicating the amphi form for the oxime groups [18,23,28,29]. The signals belonging to the aromatic and methylene protons in **3** are observed at 7.48, 7.23, 7.04, 6.73, 6.50 and 4.24, 3.01 ppm, respectively. These signals indicate the (E, E) structure of the *vic*-dioxime (Scheme 1). The singlets, which belong to NH and OH, disappear after addition of D_2O. The chemical shifts of the aromatic and methylene protons of **3** are in accord with those of the macrocyclic compounds given in references [15,20,31]. The ^{1}H NMR spectrum of the diamagnetic complex **4** in DMSO-d_6 shows the disappearance of –OH at $\delta = 10.72$ ppm belonging to the neighboring oxime group. The existence of intra-molecular H-bridge protons is observed by a new signal at lower field, $\delta = 16.70$ ppm, in addition to NH protons at 8.64 ppm very near to oxime group. NH protons and

Required values are given in parentheses.

intra-molecular binding H–O. . .H protons in **4** observed at 8.64 and 16.70 ppm disappear after addition of the D_2O. The signals for methylene protons in **4** are similar with those of **3** with small differences. As expected for a d_8 configuration in a square-planar field, **4** is diamagnetic, as confirmed by the NMR spectrum. The NMR spectrum of the complex contains two peaks for N–OH protons at 10.90 and 10.45 ppm, and peaks for NH protons at 8.50 and 8.30 ppm, which can be attributed to the magnetic anisotropy of the uranyl ion, as discussed in relation to some carboxylate and amine complexes in previous works in the Bekaroğlu group [15,20,31]. It is known that uranyl ions enhance the chemical shift difference between non-equivalent protons [15,31,41,42].

The mass spectra of **2** and **3** (EI electron impact technique) show the molecular ion peaks at $m/z = 570.2$ $[M^+]$ and $m/z = 655[M^+ + 1]$ (Fig. 1) which confirm the proposed structure and obey the rules of amino and oxime compounds formed in addition to major fragments. The mass spectrometry studies by the FAB (*p*-nitrobenzylalcohol) technique on the newly synthesized metal complexes (**4**, **5**, **7**, **9** and **10**) gave molecular ion species for metal complexes. The masses of the parent molecular ions show good agreement with the calculated values for **4** ($[M^+]$ m/z:1365), **5** ($[M^+ + 1]$ m/z:1370.5), **7** ($[M^+]$ m/z:1362.5), **9** ($[M^+]$ m/z:1479) and **10** ($[M+1]^+$ m/z:1493.7) as well as various fragments with good intensities formed from these parent ions.

The UV–Vis spectral data of **3** exhibited the characteristic n–π^* absorption of the oxime group. The weak d–d transitions of all complexes could not be observed, so they do not identify the complexes. In the electronic spectrum of **8**, a strong absorption at around 400 nm, which is assigned to a charge transfer from the π orbitals of the donor atoms to the 5f and 6d orbitals of uranium, appears as reported previously for similar compounds [19,31]. The IR spectrum of **8** is also consistent with the di-nuclear structure. A strong band around 900 cm^{-1} is characteristic of ν(O=U=O) vibrations. In the UV–Vis spectra of **9**, charge-transfer bands and characteristic $n \rightarrow \pi^*$ transitions due to (C=N) groups are also observed.

The electrochemical properties of **4**–**8** were investigated using voltammetric techniques and the results are summarized in Table 2. The number of electrons transferred was determined by the CPC technique and indicated that all electron transfer processes involved one-electron except for the two-electron R-II peak of **4**.

In the CV measurements, upon scanning cathodically **4** displayed two reduction peaks at −0.350 and −1.50 V versus SCE without the corresponding anodic waves on the reverse scan (Fig. 3). The R-I peak is assigned to Ni(II)/Ni(I) processes while R-II is due to the oxime moieties, because in highly polar solvent. DMSO polarization of the hydroxy groups of the oxime moieties occurs and this causes an increase in the negative charge in the coordinated oxime moieties. Thus the ligand-based reduction in **4** occurs at more negative potentials. The variation of the R-I peak potential with scan rate ($E_p/\log v = 0.052$ V) suggests that the charge transfer step is not totally irreversible. The absence of the anodic signal should be indicative of a fast chemical reaction following the charge transfer step and instability of the electrochemically generated Ni(I) species. The oxime reduction peak is totally irreversible with the absence of an anodic wave and considerably high $E_p/\log v$ value (0.143 V). The cyclic voltammetry of the Ni(II) complex also showed an anodic redox couple, which describes a net one-electron oxidation and is clearly attributable to Ni(II)/Ni(III). The peak separation (ΔE_p) of this couple is 0.068 V at 0.010 V s^{-1} and increases with scan rate, but remains in the usual range for quasi-reversible systems ($\Delta E_p =$ 0.250 mV at 1.0 V s^{-1}). The approximately unit value of the cathodic to anodic peak current ratio ($i_{p,c}/i_{p,a}$) for this couple within the range of 0.010–1.000 V s^{-1} scan rates indicates the absence of subsequent chemical reactions and stability of the electrochemically generated Ni(III) species (Fig. 4).

Table 2

[a] $E_{1/2} = (E_{pa} + E_{pc})/2$ for redox couple; E_{pc} for irreversible peaks at 0.010 V s^{-1} scan rate.
[b] E_{pc} for reduction, E_{pa} for oxidation.
[c] $\Delta E_p = E_{pa} - E_{pc}$ at 0.010 V s^{-1} scan rate.

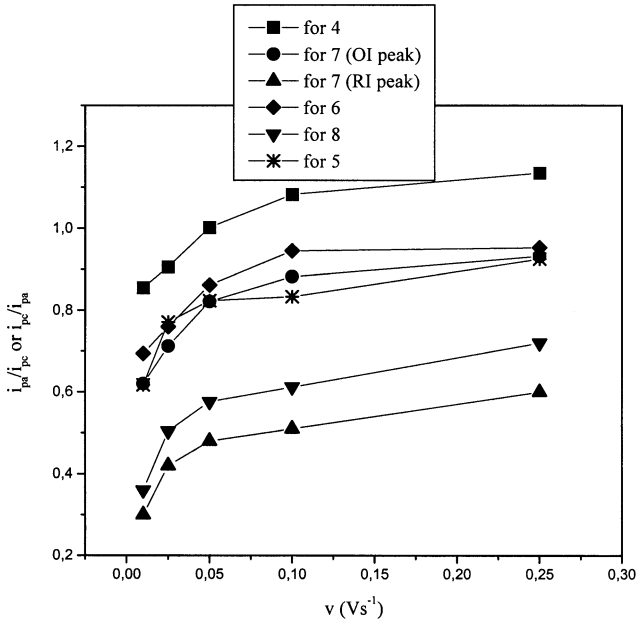

Fig. 4. Graph of peak current ratio ($i_{p,a}/i_{p,c}$ for reduction, $i_{p,c}/i_{p,a}$ for oxidation) vs. scan rate (v) for the redox couples of all complexes.

Fig. 5 represents the cyclic voltammograms of complex **6.** As shown in Fig. 5, a reduction and an oxidation couple were recorded. Analysis of the reduction peak indicated that it has a reversible peak character at very low scan rates ($\Delta E_p = 0.061$ V at 0.010 V s^{-1} scan rate) and approaches quasi-reversible behaviors with increasing scan rate. The $i_{p,a}/i_{p,c}$ values at slow scan rates are slightly lower than unity but increase towards unity with increasing scan rates. This is a characteristic response of a slow chemical reaction succeeding the electron transfer reaction [43]. The oxidation peak of **6** also has a quasi-reversible character with an ΔE_p value of 0.080 mV at 0.010 V s^{-1} scan rate and it approaches to an irreversible case at higher scan rates. Variation of $i_{p,c}/i_{p,a}$ with scan rate indicated the existence of an irreversible chemical reaction following $O-I$ electron transfer reaction of **6**.

As shown in Fig. 6, **7** gave a one-electron reduction peak without the corresponding anodic signal during the reverse scan. The absence of an anodic signal even at very high scan rates is attributed to the instability of the Co(I) species and fast chemical reaction succeeding the

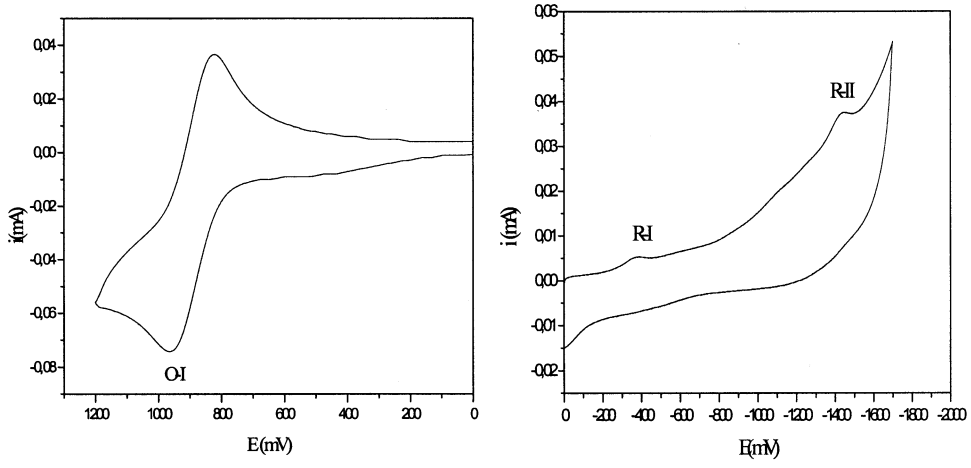

Fig. 3. Cyclic voltammogram of 1.0×10^{-4} M of **4** in DMSO/(0.1 M TBAP) at 0.100 V s^{-1} scan rate.

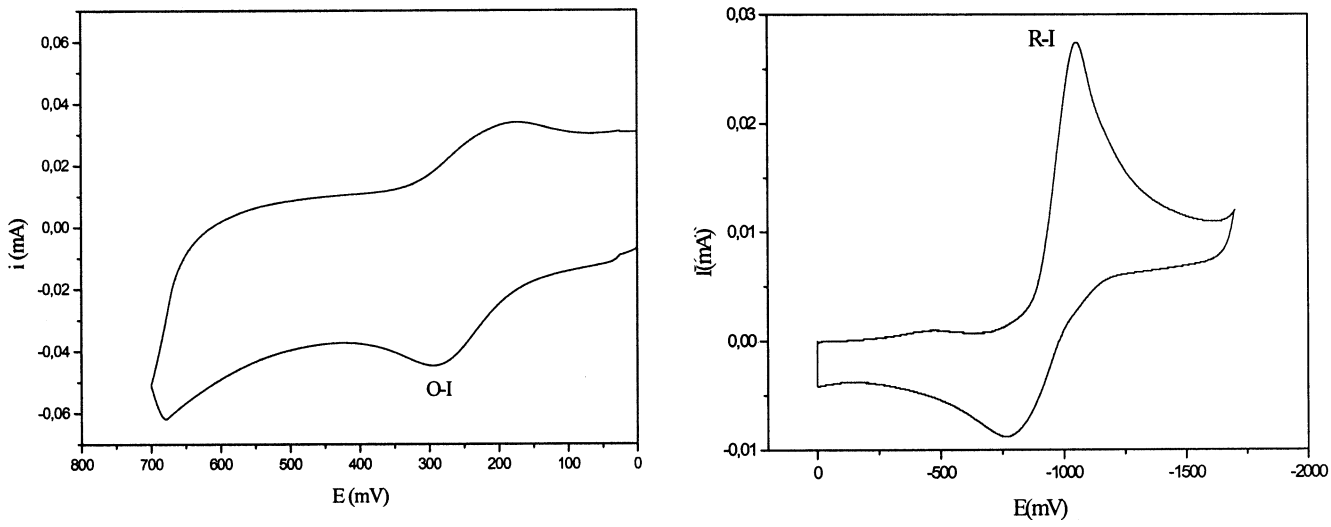

Fig. 5. Cyclic voltammogram of 1.0×10^{-4} M of **7** in DMSO/(0.1 M TBAP) at 0.100 V s^{-1} scan rate.

electrochemical reaction. The slope of $E_{p,c}$ versus log v (0.075 V) indicates the quasi-reversible character of this couple. **7** also displayed a one-electron oxidation couple, which corresponds to the Co(II)/Co(III) couple. The peak separation value of this couple is 0.061 V at 0.010 V $s^{-1}$and increases with scan rate. This behavior shows that the heterogeneous electron transfer rate is relatively slow, so that ΔE_p varies with scan rate slowly. Variation of the $i_{p,c}/i_{p,a}$ ratio with scan rate for oxidation of the Co(II) complex is also presented in Fig. 4. The shape of the curve obtained for this couple signals the existence of slow chemical reaction succeeding electrochemical reaction.

Compound **5** showed a one-electron oxidation peak with the corresponding signal during the return scan (Fig. 7). This peak corresponds to the Cu(II)/Cu(III) couple. The peak separation of this couple is approximately 0.057 V at 0.010 mV s^{-1} and changes very slowly with scan rate. This indicates the reversible characters of the redox couple. As shown in Fig. 4, the $i_{p,c}/i_{p,a}$ value indicated that this redox couple was followed by a chemical reaction. Compound **5** also gave a reduction peak without a corresponding anodic wave. The slope of $E_{p,a}$ versus log v for this peak is around 0.140 V, which indicates the irreversible nature of the peak.

Over the scan width of the voltammograms there was only one pair of peaks for **8** (Fig. 8), which can be assigned to UO_2(II)/UO_2(I). Peak separation of this couple is approximately 0.065 V at 0.010 mV s^{-1} and changes slowly with scan rate, indicating the quasi-reversible character of the redox couple. The deviation of $i_{p,a}/i_{p,c}$ from unity and the increase in this ratio with scan rate should be a consequence of the fact that the charge transfer processes for **8** is followed by slow

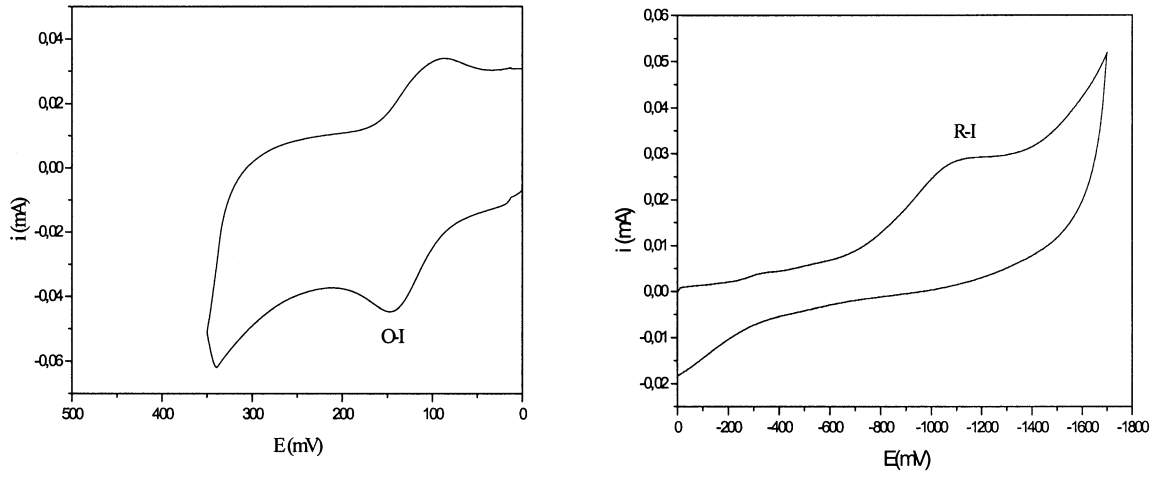

Fig. 6. Cyclic voltammogram of 1.0×10^{-4} M of **6** in DMSO/(0.1 M TBAP) at 0.100 V s^{-1} scan rate.

chemical reactions. Before and during the reverse scan electrochemically generated $U(V)O_2$ species around the electrode surface should decompose slowly.

4. Conclusion

In the present work, we have prepared and characterized a new oxime ligand in which a higher member macrocycle has been peripherally substituted. The synthesis of new hexadentate '$N_2S_2O_2$' macrocyclic oxime ligands is significant in that they provide coordination not only within but also outside the macrocycles. Therefore, complexations of both the oxime groups and the cavities of the macrocycle with transition metals, exhibiting two electron-rich centers were achieved. Mononuclear complexes have a metal:ligand ratio of 1:2 and the ligand is coordinated only by the *N*, *N′* atoms of the *vic*-dioxime. In contrast to the mononuclear complexes, in trinuclear complexes, two metal ions are coordinated to the two aza and two sulfur atoms of each macrocycle, while the third metal ion is coordinated by the *N*, *N′* atoms of each oxime group in the two ligand molecules.

This work clearly shows the prediction of the binding sites' reactivity of oximes and macrocycles and frames synthetic strategies for the preparation of interesting mixed ligand complexes. The goal of increasing electron density at the center of the macrocyles by replacing O by S donors in hexadentate diazadithiadioxa oxime ligand could be reached. This donor replacing process also increased the reactivity of complexation of the macrocyles ligand with a relatively high acidic aromatic NH near the oxime group in trinuclear complexes.

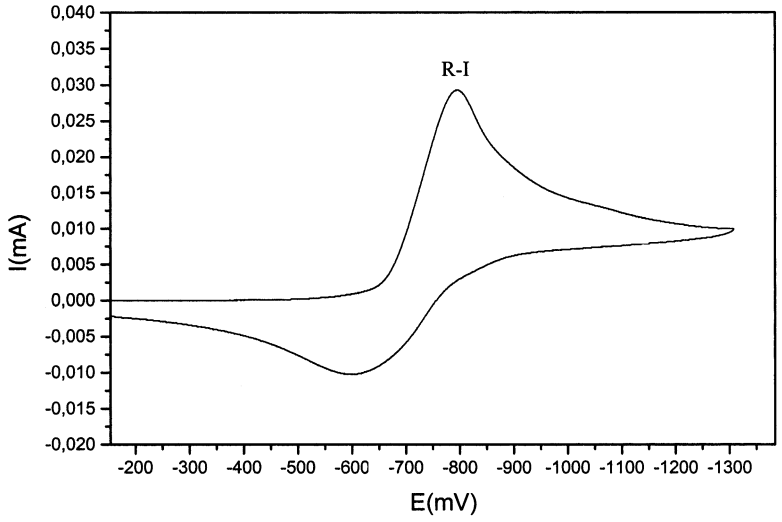

Fig. 8. Cyclic voltammogram of 1.0×10^{-4} M of **8** in DMSO/(0.1 M TBAP) at 0.100 V s^{-1} scan rate.

Voltammetric results obtained in this study showed that oxime-containing ligands stabilize Ni(III), Fe(III), Co(III) and Cu(III) since the oxidation peaks with the corresponding cathodic signals were observed for the complexes of these metals. Higher oxidation states of the complexes appeared to be accessible in systems with oximato-nitrogen donors, probably as a results of the coulombic influence of the negative charge on the HOMO [44] and of σ-donation effects [40]. Compound **7** displayed a different behavior with respect to other complexes. A reduction peak with the corresponding signal during the return scan was observed only with **7**. This indicated that both Fe(III) and Fe(I) species are stable while oxime containing ligands tend to stabilize only one of the oxidized forms of the metal center of the complexes. The stabilization of both M(I) and M(III) by the same ligand is quite uncommon. It is generally observed that a larger number of imino oxime nitrogen donors stabilize the formation of Ni(III), Fe(III), Co(III) and Cu(III) whereas thioether containing groups may stabilize Fe(I). Thus, the observed data showed that π-acceptor capability of the ligand is dominant with iron and stabilizes Fe(I) species.

Ligand based reduction was recorded with only the Ni(II) complex. In oxime containing complexes metal to ligand charge-transfer (MLCT), d(metal) to π*(N–N) and ligand to metal charge transfer (LMCT) transitions in **4** shift to less energy compared with the other complexes [45]. Metal–ligand interactions and coordination of the complexes affect the charge transfer properties of the ligand and metal. Thus both reduction and oxidation processes were recorded at a more positive potential. As a result of this, ligand based reduction was observed at the end of the solvent window (−1.50 V).

Abstract

Three metal(III)-tripodal tridentate phosphine complexes of the formula $[MCl(acac)(tdmme)]PF_6$, where M = Cr, Co or Rh; acac = pentane-2,4-dionate; tdmme = 1,1,1-tris(dimethylphosphinomethyl)ethane, were prepared and their molecular and crystal structures and spectroscopic properties examined. All the complexes crystallized in an isomorphous space group $P2_12_12_1$, which is indicative of spontaneous resolution of the enantiomeric pair. The Cr–P bond lengths in $[CrCl(acac)(tdmme)]PF_6$ (average 2.437 Å) are remarkably longer than the corresponding Co–P (average 2.201 Å) and Rh–P (average 2.252 Å) ones. The longer and therefore the weaker Cr–P bonds may explain the relatively weak *trans* influence of the $-PMe_2$ group in $[CrCl(acac)(tdmme)]PF_6$; among the three M^{III} complexes, the elongation of M–O bond lengths in $[MCl(acac)(tdmme)]PF_6$ from those in $[M(acac)_3]$ has been found to be Cr^{III} (0.016 Å) < Co^{III} (0.059 Å) < Rh^{III} (0.096 Å), indicating a much weaker *trans* influence of the $-PMe_2$ group in the Cr^{III} complex than in the Co^{III} and Rh^{III} complexes. The first d–d transition band of $[CrCl(acac)(tdmme)]^+$ was observed at 18590 cm^{-1}. This is appreciably smaller than the corresponding band of the Co^{III} complex at 20960 cm^{-1}, suggesting the ligand-field strength of tdmme is fairly weak in the Cr^{III} complex. The ligand-field strength Δ and the Racah's *B* parameters of $[CrCl(acac)(tdmme)]^+$ were also discussed. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

We have prepared various complexes of 1,1,1-tris(dimethylphosphinomethyl)ethane (tdmme) with cobalt(II or III), rhodium(III), iron(II), molybdenum(0), tungsten(0) and chromium(0 or III) [1–8]. Compared with a large number of metal complexes of 1,1,1-tris(diphenylphosphinomethyl)ethane (tdpme) [9], which is commercially available, tdmme has been used much less frequently to prepare its metal complexes [10–12], probably, because of the difficulty in synthesizing tdmme [13]. In particular, chromium(III)–tdmme complexes are rather rare [8,10,11], which is mainly due to the inherently weak coordinate bonds between Cr^{III}, a typical hard Lewis acid, and phosphines, typical soft Lewis bases, in addition to the above-mentioned difficulty. However, it is interesting to examine tdmme metal complexes more extensively since tdmme has the following advantages over tdpme in preparing various mixed-ligand complexes: (1) a lesser steric requirement around a central metal ion to incorporate with a larger ligand; (2) a higher electron density on the P atom to give a stronger σ-donicity and *trans* influence making the

PII: S0277-5387(02)00859-8

trans-positioned ligand labile; and (3) a higher solubility of the mixed-ligand complexes in polar organic solvents.

In our previous studies on cobalt(III) and rhodium(III)–phosphine complexes it has been shown that phosphine ligands, especially with dimethylphosphino donor groups, unequivocally exhibited a strong *trans* influence with significant elongation of the *trans*-positioned metal(Co^{III} or Rh^{III})–ligand bond [1,2,5,14,15]. For the chromium(III)–phosphine complexes, however, there has been no report mentioning that the phosphines induce the elongation of the *trans*-positioned Cr^{III}–ligand bond; e.g. there is no difference in the lengths between the Cr–Cl bonds *trans* to P and the mutually *trans* Cr–Cl ones in $(NPr^n_4)[CrCl_4(cis\text{-}Ph_2PCH{=}CHPPh_2)]$ [16] and *mer*-$[CrCl_3\{P(CH_2CH_2PPh_2)_3\text{-}\kappa^3P\}]$ [17]. For the better understanding of the specific interactions between Cr^{III} and phosphines, it seems essential to accumulate more examples of Cr^{III} complexes with phosphines containing dimethylphosphino donor groups which is expected to be a better σ-donor compared with the well studied diphenylphosphino ones as in tdpme.

In this study, we describe the preparation, structures and spectroscopic properties of the pentane-2,4-dionato (acac) complexes with the tdmme ligand, $[MCl(acac)(tdmme)]PF_6$ (M = Cr, Co or Rh), prepared by the ligand substitution reaction of $[MCl_3(tdmme)]$ by $acac^-$. Since it has been found that all three M^{III} complexes of $[MCl(acac)(tdmme)]PF_6$ crystallize in an isomorphous space group $P2_12_12_1$, likewise the series of $[M(acac)_3]$ complexes in $P2_1/c$ [18–20], these complexes are most suitable for a comparison of the *trans* influence of the $-PMe_2$ group by probing the M–O bond lengths.

2. Experimental

2.1. Materials and measurements

The complexes, $[MCl_3(tdmme)]$ (M = Cr [10], Co [1] and Rh [5]), were prepared by the literature methods. Lithium pentane-2,4-dionate and ammonium hexafluorophosphate were used as purchased from Aldrich Co. Ltd. and Wako Chemicals, respectively. All solvents (Wako reagent grade for preparation of complexes) were used without further purification. UV–Vis spectra in acetonitrile (DOTITE, spectrosol) were measured on a Perkin–Elmer Lambda 19 spectrophotometer at room temperature (r.t.). NMR spectra in acetonitrile-d_3 (Aldrich, 99.8 atom% D) were recorded on a JEOL EX-270 or GSX-400 spectrometer at 27 °C; chemical shifts are given in δ scale relative to TMS (^1H and ^{13}C) or 85% H_3PO_4 (^{31}P).

2.2. [CrCl(acac)(tdmme)]PF_6

To a methanol solution (100 cm^3) of $[CrCl_3(tdmme)]$ (522 mg, 1.27 mmol) was added Li(acac) (150 mg, 1.42 mmol) and the mixture was refluxed for 5 h. The red solution was cooled to r.t. and filtered. A methanol solution (10 cm^3) of NH_4PF_6 (221 mg, 1.53 mmol) was added to the filtrate and the mixture was allowed to stand in the open air for 2 days to evaporate the solvent slowly, depositing red purple columnar crystals. Yield: 379 mg (51%). *Anal*. Found: C, 32.6; H, 5.8. Calc. for $C_{16}H_{34}ClCrF_6O_2P_4$: C, 32.9; H, 5.9%. UV–Vis: 538 nm ($\varepsilon = 494$ dm^3 mol^{-1} cm^{-1}), 404 (358), 361^{sh} (2390), 338^{sh} (3960), 320 (5530), 256 (19300), 213^{sh} (17800).

2.3. [CoCl(acac)(tdmme)]PF_6 and its Rh^{III} analogue

To a suspension of $[CoCl_3(tdmme)]$ (1.00 g, 2.39 mmol) in methanol (25 cm^3) was added Li(acac) (254 mg, 2.40 mmol) with stirring, and the mixture was stirred for 1 h at r.t. The resulting red solution was evaporated to approximately 10 cm^3 under reduced pressure and a methanol solution (10 cm^3) of NH_4PF_6 (1.23 g, 7.55 mmol) was added to the concentrate to afford an orange red precipitate. The crude product was collected by filtration and recrystallized from CH_3CN–Et_2O, affording red columnar or prismatic crystals. Yield: 1.23 g (87%). *Anal*. Found: C, 32.7; H, 5.8. Calc. for $C_{16}H_{34}ClCoF_6O_2P_4$: C, 32.5; H, 5.8%. ^1H NMR (TMS): δ 1.263 (qr, $J = 3.0$ Hz, CCH_3 (tdmme), 3H); 1.346 (d, $J = 12.2$ Hz, PCH_3, 6H); 1.58–1.97 (m, PCH_3 and PCH_2C, 18H); 2.003(s, CCH_3 (acac), 6H); 5.487(s, =CH–, 1H). $^{13}C\{^1H\}$ NMR (TMS): δ 11.97(t, $J = 16$ Hz); 13.64(d, $J = 32$ Hz); 17.39(t, $J = 18$ Hz); 27.85(t, $J = 4$ Hz); 33.35(t, $J < 4$ Hz); 33.71(td, $J = 15$ and 5 Hz); 34.70(qr, $J = 11$ Hz); 38.85(s); 99.50(s); 188.91(s). UV–Vis: 646^{sh} nm ($\varepsilon = 3.5$ dm^3 mol^{-1} cm^{-1}), 477(1060), 333^{sh}(2700), 258(23600), 226(14200).

The Rh^{III} analogue, $[RhCl(acac)(tdmme)]PF_6$, was prepared similarly by mixing $[RhCl_3(tdmme)]$ and Li(acac). Colorless columnar crystals were obtained by recrystallization from CH_3CN–Et_2O. Yield: 92%. *Anal*. Found: C, 30.3; H, 5.4. Calc. for $C_{16}H_{34}ClF_6O_2P_4Rh$: C, 30.3; H, 5.4%. ^1H NMR (TMS): δ 1.291(qr, $J = 3.3$ Hz, CCH_3 (tdmme), 3H); 1.446(d, $J = 12.9$ Hz, PCH_3, 6H); 1.713(filled-in d, PCH_3, 6H); 1.79–1.85(m, PCH_3 and PCH_2C, 12H); 2.000(s, CCH_3(acac), 6H); 5.459(s, =CH–, 1H). $^{13}C\{^1H\}$ NMR (TMS): δ 12.08(t, $J = 18$ Hz); 13.60(d, $J = 37$ Hz); 16.77(t, $J = 21$ Hz); 28.28(t, $J = 4$ Hz); 32.94(t, $J < 4$ Hz); 33.56(td, $J = 20$ and 6 Hz); 35.21(qr, $J = 11$ Hz); 41.29(d, $J < 2$ Hz); 100.36(s); 188.37(s). $^{31}P\{^1H\}$ NMR (85% H_3PO_4): δ 22.50 (dd, $^1J_{Rh-P} = 102.6$ Hz, $^2J_{P-P} = 32.4$ Hz); 25.85(dt, $^1J_{Rh-P} = 104.9$ Hz). UV–Vis: 322 nm($\varepsilon = 4180$ dm^3 mol^{-1} cm^{-1}), 313(4070), 296^{sh}(3580), 218(37 500).

2.4. Crystal structure determination

The X-ray intensities were measured at 23(2) °C on a Rigaku AFC-7R four-circle diffractometer (graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), the $2\theta-\omega$ scan mode, $2\theta_{max} = 60°$, three standard reflections monitored every 150 reflections with no serious decomposition ($\leq 0.18\%$)). Final lattice parameters were determined by the least-squares treatment using setting angles of 25 reflections in the range of $25° < 2\theta < 30°$. The intensities were corrected for Lp factors and for absorption effects either by the numerical integration method [21] or by an empirical method based on a set of Ψ-scans [22]. The space group was uniquely determined by systematic absences as $P2_12_12_1$. The structures were solved by the direct method using SHELXS86 program [23] and refined by SHELXL97 program [24] (on F^2, full-matrix, complex neutral-atom scattering factors, anisotropic thermal parameters for all non-H atoms, calculated H atoms with riding models). The absolute structures were determined by the Flack's method [25]. All calculations were carried out using a TEXSAN software package [26].

Crystallographic data are summarized in Table 1 and selected structural parameters are collected in Table 2. The perspective drawings of the complex cations in $[MCl(acac)(tdmme)]PF_6$ (M = Cr, Co and Rh) are shown in Fig. 1(a–c), respectively.

3. Results and discussion

3.1. Preparation and chemical behaviors of $[MCl(acac)(tdmme)]PF_6$

The reaction of $[MCl_3(tdmme)]$ (M = Co or Rh) and Li(acac) in methanol proceeded smoothly to yield $[MCl(acac)(tdmme)]^+$, which was isolated as a PF_6^- salt in a nearly quantitative yield. However, a similar procedure afforded the corresponding Cr^{III} complex in merely a 50% yield. Such a low yield seems to be caused by the partial dissociation of tdmme from $[CrCl_3(tdmme)]$ in methanol; a characteristic odor of free phosphine was detected. However, once the acac complex is formed, it is stable in the solid state and in solution. As seen in the next section, the single-crystal X-ray analysis of $[CrCl(acac)(tdmme)]PF_6$ shows that the Cr–P bond lengths (average 2.437 Å) are shorter than those in $[CrCl_3(tdmme)]$ (average 2.456 Å [10]), indicating that the Cr–P bonds are stronger in the former complex.

The Co^{III} and Rh^{III} complexes of $[MCl(acac)(tdmme)]PF_6$ could be converted quantitatively into the acetonitrile complexes, $[M(acac)(tdmme)(CH_3CN)](PF_6)_2$, by a reaction with $AgPF_6$. The acetonitrile complexes thus produced were successfully used to prepare $[M(acac)(tdmme)L]^{2+}$-type complexes (L = pyridine or its derivatives) [3]. On the other hand, $[CrCl(acac)(tdmme)]PF_6$ did not give any characterizable products by the same procedures.

3.2. Crystal structures

The single-crystal X-ray analyses revealed that all the compounds of $[MCl(acac)(tdmme)]PF_6$ (M = Cr, Co and Rh) crystallize in an isomorphous space group $P2_12_12_1$, which is indicative of the spontaneous resolution of the enantiomeric pair. The complex cations $[MCl(acac)(tdmme)]^+$ are chiral owing to the synchronous twist of the three arms of tdmme (Fig. 2). The absolute structures of the complex cations analyzed in this study are assigned as Δ for the Cr and Λ for the Co and Rh complexes based on the twist of tdmme. The torsion angles of M–P(n)–C(2+n)–C(2) (n = 1, 2, 3) are in the range of ±21°–29° (+ for the Δ and − for the Λ isomers), which are comparable to those found in $[MCl_3(tdmme)]$ [2,5,10] or $[M(CN)_3(tdmme)]$ [2,8]. The acac plane (defined by O(1), O(2), C(13), C(14) and C(15)) is not strictly co-planar to the equatorial coordination plane defined by P(2), P(3), O(1) and O(2), as indicated by the dihedral angle between these two planes: 4.8(1)°, 9.3(3)° and 5.8(2)° for the Cr, Co and Rh complexes, respectively. This order of Cr < Rh < Co for the dihedral angle is opposite to that of the M–P(1) bond length (Cr: 2.439(2) > Rh: 2.258(2) > Co: 2.201(3) Å), suggesting that a steric interaction with the axial $-PMe_2$ group exists to some extent to bend the acac plane away from the equatorial coordination plane. Another intriguing difference between the three complex cations is the deviation of the central M atom from the least-squares equatorial coordination plane. The dis-

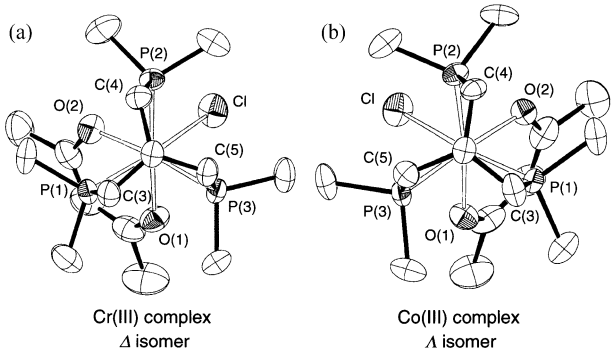

Fig. 2. Top views (along the C(1)–C(2)···M direction) of $[MCl(acac)(tdmme)]^+$ {M = Cr (a) and Co (b)}, showing the enantiomeric isomerism of the complexes.

tance, d, of the Cr atom from the equatorial coordination plane is 0.124(2) Å, while the Co or Rh atom is located on the plane (Table 2). This would result from the smaller bite angle of tdmme in [CrCl(acac)(tdmme)]PF_6 (average 84.24°) than those close to a right angle in the Co^{III} and Rh^{III} complexes.

The metrical difference between two chemically inequivalent M–P bond lengths (M–P(1) vs. M–P(2), M–P(3)) in [MCl(acac)(tdmme)]PF_6 is negligibly small for all three M^{III} complexes (Table 2). As seen in Table 3, the Co–P and Rh–P bond lengths in [MCl(acac)(tdmme)]PF_6 are comparable to those in [MCl_3(tdmme)], while the Cr–P bonds in [CrCl(acac)(tdmme)]PF_6 are shorter by approximately 0.02 Å than those in [$CrCl_3$(tdmme)]. Such a difference in the Cr^{III}–P bond lengths may be related to the higher stability of the acac complex than the trichloro complex. It should also be noted that the Cr–P bonds in Cr^{III} complexes such as [CrCl(acac)(tdmme)]PF_6, [$CrCl_3$(tdmme)] [10] and *trans*-$[CrCl_2(dmpe)_2]^+$ (dmpe = 1,2-bis(dimethylphosphino)ethane) [27] are longer by 0.2–0.25 Å than the Co–P bonds in the corresponding Co^{III} complexes [2,14], and are also longer by 0.1–0.2 Å than the Rh–P bonds in the corresponding Rh^{III} complexes [5,28]. On the other hand, the Cr–Cl bond lengths in *trans*-$[CrCl_2(dmpe)_2]^+$ and the Cr–O ones in [$Cr(acac)_3$] are longer than the corresponding Co–Cl and Co–O bond lengths, but are shorter than the corresponding Rh–Cl and Rh–O bond lengths. It seems that the ionic radii of Cr^{3+} (0.62 Å), Co^{3+} (low-spin: 0.55 Å) and Rh^{3+} (0.67 Å) [29] account satisfactorily for the differences in the M–Cl bond lengths of *trans*-$[MCl_2(dmpe)_2]^+$ and the M–O bond lengths of [$M(acac)_3$], but not for the difference in the M–P bond lengths in the phosphine complexes. Therefore, the extremely long Cr–P bonds are attributed to the inherently weak coordinate bond between Cr^{III} and P.

Table 3
Comparisons of the structural parameters (Å), (°) among Cr(III), Co(III) and Rh(III) complexes

Structural parameter complex	M		
	Cr	Co	Rh
M–P			
[MCl_3(tdmme)]	2.456[10]	2.203[2]	2.253[5]
$[MCl(acac)(tdmme)]^+$	2.437	2.201	2.252
trans-$[MCl_2(dmpe)_2]^+$	2.445[27]	2.259[14]	2.337[28]
M–Cl			
[MCl_3(tdmme)]	2.322[10]	2.323[2]	2.444[5]
$[MCl(acac)(tdmme)]^+$	2.316(2)	2.317(3)	2.430(2)
trans-$[MCl_2(dmpe)_2]^+$	2.293(4)[27]	2.260(1)[14]	2.358[28]
M–O			
$[MCl(acac)(tdmme)]^+$	1.965	1.947	2.088
[$M(acac)_3$]	1.951[18]	1.888[19]	1.992[20]
P–M–P (bite angle of tdmme)			
[MCl_3(tdmme)]	83.48[10]	89.5[2]	89.1[5]
$[MCl(acac)(tdmme)]^+$	84.24	89.64	89.17
O–M–O (bite angle of acac)			
[$M(acac)_3$]	90.1[18]	96.5[19]	95.3[20]
$[MCl(acac)(tdmme)]^+$	91.2(2)	93.7(2)	90.2(2)

The value without e.s.d. is the average one. The figures in square brackets (superscript) are the reference numbers.

It is also seen from Table 3 that the difference in the Cr–P bond lengths between *trans*-$[CrCl_2(dmpe)_2]^+$ and [CrCl(acac)(tdmme)]PF_6 is only 0.008 Å, while the mutually *trans* Co–P and Rh–P bonds in *trans*-$[MCl_2(dmpe)_2]^+$ are longer by 0.058 and 0.085 Å, respectively, than the bonds *trans* to Cl or O in $[MCl(acac)(tdmme)]^+$; i.e.

$$\Delta(\text{M–P}) = l(\text{M–P}) \text{ in } \textit{trans}\text{-}[MCl_2(dmpe)_2]^+ - l(\text{M–P}) \text{ in } \textit{trans}\text{-}[MCl(acac)(tdmme)]^+$$

$$\Delta(\text{Cr–P}) = 0.008 < \Delta(\text{Co–P}) = 0.058 < \Delta(\text{Rh–P}) = 0.085 \text{ Å} \quad (1).$$

The M–Cl bonds *trans* to the P donor in $[MCl(acac)(tdmme)]^+$ are longer than the mutually *trans* M–Cl bonds in *trans*-$[MCl_2(dmpe)_2]^+$ as follows:

$$\Delta(\text{M–Cl}) = l(\text{M–Cl}) \text{ in } \textit{trans}\text{-}[MCl(dmpe)]^+ - l(\text{M–Cl}) \text{ in } \textit{trans}\text{-}[MCl_2(dmpe)_2]^+$$

$$\Delta(\text{Cr–Cl}) = 0.023 < \Delta(\text{Co–Cl}) = 0.057 < \Delta(\text{Rh–Cl}) = 0.062 \text{ Å} \quad (2).$$

Furthermore, the elongation of the M–O bonds in $[MCl(acac)(tdmme)]^+$ from those in [$M(acac)_3$] are:

$$\Delta(\text{M–O}) = l(\text{M–O}) \text{ in } \textit{trans}\text{-}[MCl(acac)(tdmme)]^+ - l(\text{M–O}) \text{ in } [M(acac)_3]^+$$

$$\Delta(\text{Cr–O}) = 0.014 < \Delta(\text{Co–O}) = 0.057 < \Delta(\text{Rh–Cl}) = 0.096 \text{ Å} \quad (3).$$

Such elongations of the M–L (L = P, Cl and O) bond lengths may be related to the *trans* influence of the $-PMe_2$ group in tdmme (or dmpe), and the magnitude of Δ(M–L) for different M reflects the difference in the strength of the *trans* influence for specific M^{III} complexes. In particular, the comparison of M–O bond lengths in (3) would be valid, because each set of three M^{III} compounds, [MCl(acac)(tdmme)]PF_6 and [$M(acac)_3$], crystallize in an isomorphous space group and the packing effects to deviate the coordinate bond lengths would, therefore, be identical to one another. In conclusion, the strength of the *trans* influence of the $-PMe_2$ group in tdmme increases in the order of $Cr^{III} < Co^{III} < Rh^{III}$. The negligibly weak *trans* influence of $-PMe_2$ group in the Cr^{III} complex is attributed to the extremely long (and therefore weak) coordinate bonds between Cr^{III} and phosphorus.

3.3. Structures in solution and spectroscopic properties

The NMR spectra of the Co^{III} and Rh^{III} complexes of $[MCl(acac)(tdmme)]PF_6$ in CD_3CN (see Section 2) reflect the molecular C_s-symmetry of the complexes; the cations are not chiral in solution due to the fluxionality of the synchronous twist of three arms of tdmme. The $^{31}P\{^1H\}$ NMR spectrum of the Rh^{III} complex gave two resonances, a doublet-of-doublets and doublet-of-triplets with an intensity ratio of 2:1. The observed coupling constants, $^1J_{Rh-P}$ (102.6 and 104.9 Hz) and $^2J_{P-P}$ (32.4 Hz), parallel those observed for $[RhCl(tdmme)(H_2O)_2]^{2+}$ ($^1J_{Rh-P} = 106.7$ and 101.3, $^2J_{P-P} = 31.1$ Hz) [5].

In the UV–Vis absorption spectrum (Fig. 3) of the Co^{III} complex, a medium intensity band ($\varepsilon = 1060$ dm^3 mol^{-1} cm^{-1}) assignable to the first d–d ($^1A_1 \rightarrow {}^1T_1$: O_h) transition is observed at 20960 cm^{-1} (477 nm), but the explicit band-splitting expected for the lowering of the molecular symmetry is not observed. A very weak shoulder ($\varepsilon \approx 3.5$ dm^3 mol^{-1} cm^{-1}) observed around 15 500 cm^{-1} (645 nm) would be assignable to the spin-forbidden d–d transition ($^1A_1 \rightarrow {}^3T_2$: O_h) band.

In the spectrum of the Cr^{III} complex, two bands are observed at 18 590 cm^{-1} (538 nm, $\varepsilon = 494$ dm^3 mol^{-1} cm^{-1}) and 24 750 cm^{-1} (404 nm, $\varepsilon = 358$ dm^3 mol^{-1} cm^{-1}). Provided that these bands are the first ($^4A_2 \rightarrow {}^4T_2$: O_h) and the second ($^4A_2 \rightarrow {}^4T_1$: O_h) d–d transition bands, the ligand-field strength Δ and the Racah's B parameter of $[CrCl(acac)(tdmme)]^+$ are estimated as 18 590 and 513 cm^{-1}, respectively. The Δ value coincides closely with the expected value (18 610 cm^{-1}) from $\Delta_{Cl} = 13\,180$ cm^{-1}, $\Delta_{tdmme} = 20\,920$ cm^{-1} (estimated from the spectral data of $[CrCl_3(tdmme)]$ with $\Delta_{Cl} = 13\,180$ cm^{-1}) [8] and $\Delta_{acac} = 17\,860$ cm^{-1} [30]. Such a coincidence indicates that the ligand-field perturbation energies of Cl, tdmme and acac in $[CrCl(acac)(tdmme)]^+$ are almost identical to those in $[CrCl_3(tdmme)]$ and $[Cr(acac)_3]$, which is inferred from the crystallographic observation that the Cr^{III}–L bond lengths differ only slightly in these three complexes. In contrast, the B parameter of $[CrCl(acac)(tdmme)]^+$ (513 cm^{-1}) is much larger than that of $[CrCl_3(tdmme)]$ (354 cm^{-1}). In a previous paper [8], we have shown that the extremely small B value (< 360 cm^{-1}) is limited to the $[Cr(Cl\text{ or }Br)_3(tdmme)]$ complexes and the B parameters for $[CrCl_2(PMe_3)(tdmme)]^+$ (500 cm^{-1}) and $[CrCl_2(dmpp)_2]^+$ (dmpe = 1,3-bis(dimethylphosphino)-propane, 539 cm^{-1}) are large similarly to those of the di- or triamine complexes. This study also indicates that the substitution of $acac^-$ for two Cl^- induces large interelectronic repulsion by approximately 150 cm^{-1}.

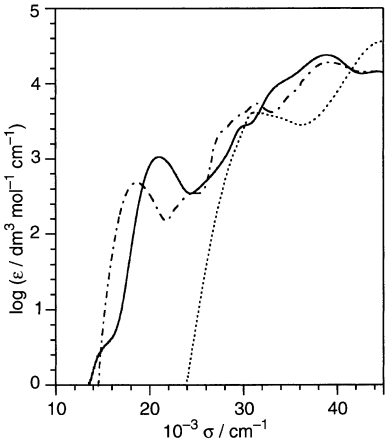

Fig. 3. UV–Vis absorption spectra of $[MCl(acac)(tdmme)]PF_6$ (M = Cr (—·—), Co (—) and Rh (·····)) in CH_3CN at room temperature.

Abstract

Four palladium(II) complexes $[PdX_2(L\text{-}N,S)]$ (X = Cl, Br; L: BzSq = benzyl 8-quinolyl sulfide, PheneSq = phenethyl 8-quinolyl sulfide) were prepared. The crystal structure of $[PdCl_2(BzSq\text{-}N,S)]$ revealed the presence of an intraligand stacking between the phenyl and quinolyl groups of BzSq. This stacking interaction was confirmed even in Me_2SO, MeCN and $MeNO_2$. On the other hand, $[PdCl_2(PheneSq\text{-}N,S)]$ did not show such an intraligand stacking both in the solid and in solutions. © 2002 Published by Elsevier Science Ltd.

Keywords: Palladium(II) complexes; Benzyl 8-quinolyl sulfide; Phenethyl 8-quinolyl; Crystal structures

1. Introduction

Aromatic interactions such as face-to-face π–π, face-to-edge π–π, and CH-π play an important role in molecular recognition [1]. Such interactions have been found in many coordination compounds. For example, there is a face-to-face interligand stacking between a phenyl group of 1,2-bis(diphenylphosphino)ethane (dppe) and an acetylacetonato (acac) ring in *cis*-$[Co(CN)_2(acac)(dppe)]$ in the solid [2]. This stacking mode is confirmed in $CHCl_3$ by its ^1H NMR spectrum. Similar π–π stacking phenomena in the solid have been reported in [Cu(bpy)(L-tyr)(ClO_4-*O*)] (bpy = 2,2′-bipyridine and L-tyr = L-tyrosine) [3], $[Pd(bpy)(L\text{-}tyr\cdot gly)]\cdot 3H_2O$ (L-tyr·gly = L-tyrosylglycine) [4], [Cu(bpy)(L-trp)]ClO_4 (L-trp = L-tryptophan) [5].

Here we report the synthesis of four palladium(II) complexes $[PdX_2(L\text{-}N,S)]$ (X = Cl, Br; L: BzSq = benzyl 8-quinolyl sulfide, PheneSq = phenethyl 8-quinolyl sulfide) and examine whether there are any intra- and/or interligand stacking interactions for these complexes both in solid and in several solvents.

2. Experimental

2.1. BzSq

An ethanol solution (30 cm^3) containing 1.0 g of 8-quinolinethiol (5.1 mmol) and 0.64 g of benzyl chloride (5.1 mmol) was refluxed for 24 h, until the initial yellow color disappeared. After cooling, white needlelike crystals were obtained by addition of 100 cm^3 of water. Yield: 1.1 g (86%). Found: C, 75.75; H, 5.24; N, 5.51%. Calc. for $C_{16}H_{13}NS$: C, 75.85; H, 5.94; N, 5.53%. NMR: δ_H (*J* (Hz), d_6-DMSO) 8.89(dd, $J_{2-3} = 4.1$, $J_{2-4} = 1.4$; 1H, H(2)), 8.35(dd, $J_{3-4} = 8.3$, $J_{2-4} = 1.4$; 1H, H(4)), 7.72(d, $J_{5-6} = 8.0$; 1H, H(5)), 7.63(d, $J_{6-7} = 7.3$; 1H, H(7)), 7.58(q, $J_{2-3} = 4.1$, $J_{3-4} = 8.3$; 1H, H(3)), 7.52(t, $J_{5-6} = 8.0$, $J_{6-7} = 7.3$; 1H, H(6)), 7.49(d, $J_{12-13} = 7.9$; 2H, H(12) and H(16)), 7.34(t, $J_{12-13} = 7.9$, $J_{13-14} = 8.1$; 2H, H(13) and H(15)), 7.29(t, $J_{13-14} = 8.1$, $J_{14-15} = 8.1$; 1H, H(14)), 4.34(s; 2H, H(21)); δ_C(d_6-DMSO) 149.2(C(2)), 144.5(C(10)), 138.2(C(9)), 137.0(C(11)), 136.3(C(4)), 128.8(C(12) and C(16)), 128.4(C(13) and

(C(15)), 127.7(C(8)), 127.0(C(14)), 126.6(C(6)), 124.0(C(7)), 123.9(C(5)), 121.9(C(3)), 34.3(C(21)).

2.2. PheneSq

To an ethanol solution (30 cm^3) containing 1.0 g of 8-quinolinethiol (5.1 mmol) and 0.71 g of 2-chloroethylbenzene (5.1 mmol) was added a solution of sodium hydroxide (0.45 g, 10.2 mmol) in 50 cm^3 of water. The mixture was refluxed for 24 h and 100 cm^3 of diethyl ether was added to it. The diethyl ether extract was evaporated to remove diethyl ether. The crude oily residue, which showed a desirable ^1H NMR spectrum, was used for the preparations without further purification. Yield: 1.1 g (82%).

3. Preparation of complexes

3.1. $[PdX_2(BzSq)]$ (X = Cl and Br)

To a solution of $Na_2[PdCl_4]\cdot H_2O$ (0.52 g, 1.7 mmol) in 50 cm^3 of ethanol was added a solution of BzSq (0.43 g, 1.7 mmol) in 50 cm^3 of ethanol. After stirring at room temperature (r.t.), the resulting orange precipitate was filtered and recrystallized from CH_2Cl_2. Yield: 0.31 g (43%). Found: C, 45.08; H, 2.95; N, 3.25%. Calc. for $[PdCl_2(BzSq)] = C_{16}H_{13}Cl_2PdNS$: C, 44.83; H, 3.06; N, 3.27%. Its NMR data is shown in Table 3. The corresponding dibromo complex was prepared from $K_2[PdBr_4]$ in a similar way. Yield: 0.18 g (88%). Found: C,36.51; H, 2.53; N, 2.47%. Calc. for $[PdBr_2(BzSq)] = C_{16}H_{13}Br_2PdNS$: C, 37.13; H, 2.53; N, 2.71%. NMR: $\delta_H(J$ (Hz), d_6-DMSO) 9.62(d, $J_{2-3} = 5.0$; 1H, H(2)), 8.75(d, $J_{3-4} = 8.3$; 1H, H(4)), 8.32(d, $J_{6-7} = 7.5$; 1H, H(7)), 8.27(d, $J_{5-6} = 7.7$; 1H, H(5)), 7.92(t, $J_{5-6} = 7.7$, $J_{6-7} = 7.5$; 1H, H(6)), 7.74(t, $J_{2-3} = 5.0$, $J_{3-4} = 8.3$; 1H, H(3)), 7.21(t, $J_{12-13} = 6.8$; 2H, H(12) and H(16)), 7.09–6.98 (m; 3H, H(13)–H(15)), 4.76(d, $J = 12.9$; 1H, H(21a)), 4.59(d, $J = 12.9$; 1H, H(21b)); $\delta_C(d_6$-DMSO) 155.8(C(2)), 130.9(C(9)), 130.6(C(12) and C(16)),

3.2. $[PdX_2(PheneSq)]$ (X = Cl and Br)

To a solution of $Na_2[PdCl_4]\cdot H_2O$ (0.24 g, 0.8 mmol) in 50 cm^3 of ethanol was added a solution of PheneSq (0.21 g, 0.8 mmol) in 50 cm^3 of ethanol. After stirring at r.t., the resulting orange precipitate was filtered and recrystallized from CH_2Cl_2. Yield: 0.30 g (85%). Found: C, 40.88; H, 3.19; N, 2.70%. Calc. for $[PdCl_2(PheneSq)] = C_{17}H_{15}Cl_2PdNS$: C, 40.97; H, 3.25; N, 2.65%. Its NMR data is shown in Table 4. The corresponding dibromo complex was prepared from $K_2[PdBr_4]$ in a similar way. Yield: 0.38 g (88%). Found: C,36.92; H, 2.77; N, 2.38%. Calc. for $[PdBr_2(PheneSq)] = C_{17}H_{15}Br_2PdNS$: C, 38.41; H, 2.84; N, 2.64%. NMR: δ_H(J (Hz), d_6-DMSO) 10.14 (d, $J_{2-3}=5.3$; 1H, H(2)), 8.48 (d, $J_{3-4}=8.2$; 1H, H(4)), 8.04(d, $J_{5-6}=7.5$, $J_{6-7}=7.2$; 2H, H(7) and H(5)), 7.76(t, $J_{5-6}=7.2$, $J_{6-7}=7.2$; 1H, H(6)), 7.67(q, $J_{2-3}=5.3$, $J_{3-4}=8.2$; 1H, H(3)), 7.07(d, $J=3.9$; 5H, H(12)–H(16)), 3.83(d, $J=11.9$; 1H, H(22)), 3.58(s; 2H, H(22)), 3.01(d, $J=11.9$; 1H, H(21b)); δ_C(d_6-DMSO) 156.9(C(2)), 150.4(C(10)),140.4(C(4)), 137.5(C(7)), 135.7(C(11)), 131.7(C(5)), 130.2(C(8)), 129.2(C(6)),

129.1(C(12) and C(16)), 128.8(C(13) and C(15)), 127.3(C(14)), 124.2(C(3)), 45.4(C(21)), 36.5(C(22)).

4. Crystallography

Single crystals of $[PdCl_2(BzSq)]$ ($0.25 \times 0.20 \times 0.12$ mm) and $[PdCl_2(PheneSq)]$ ($0.40 \times 0.25 \times 0.25$ mm) were fixed on the end of a glass fiber with epoxy resin. They were mounted on a Rigaku AFC-7R diffractometer and the diffraction data were collected at 298 K with graphite-monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) using $\omega-2\theta$ scan mode. Cell dimensions were determined by least-squares refinement of the angular positions of 25 independent reflections in the range $28 < 2\theta < 39^\circ$ for each sample. Crystallographic data and experimental details are listed in Table 1. The position of the palladium was determined by direct methods (SHELXS-86 [6]) for each complex and the remaining non-hydrogen atoms were located by subsequent Fourier syntheses. The structure was refined on F by full-matrix least-square techniques with anisotropic thermal parameters for non-hydrogen atoms. Hydrogen atoms were located at positions determined by Fourier-difference syntheses or by calculations. All calculations were carried out with the TEXAN [7] software.

5. Measurement

UV–Vis absorption spectra were recorded on an Hitachi U-3400 spectrophotometer, ^1H and ^{13}C NMR spectra with a Bruker ARX300 spectrometer. X-Ray crystal analysis was made at the X-ray Diffraction Service of the Department of Chemistry of Osaka University.

6. Results and discussion

Neutral complexes $[PdX_2(L)]$ ($X = Cl^-$ or Br^-; L = BzSq or PheneSq) were obtained in high yields by the

reaction of $[PdX_4]^{2-}$ with sulfide ligands. They were characterized by NMR spectroscopy and elemental analysis.

X-ray crystal structures were determined for [$PdCl_2$(BzSq)] and [$PdCl_2$(PheneSq)]. ORTEP [8] drawings of the present complexes are shown in Figs. 1 and 2. Selected bond distances and angles are listed in Table 2. Though there are two similar but independent molecules in [$PdCl_2$(BzSq)], we describe only the structure of Pd(1) hereafter.

The BzSq ligand coordinates bidentately through the N,S donors. The Pd–Cl bond distance *trans* to the sulfur in [$PdCl_2$(BzSq-*N*,*S*)] is 2.315(1) Å, which is longer by 0.022(1) Å than the Pd–Cl one *trans* to imine. A similar lengthening of the Pd–Cl bond [0.028(1) Å] was also observed in [$PdCl_2$(PheneSq-*N*,*S*)]. This bond weakening is known as *trans* influence [9]. The ligand bite angles [BzSq = 86.01(9)° and PheneSq = 86.33(8)°] are normal and typical values. A remarkable feature is the presence of an intraligand stacking interaction between the phenyl group and the quinolyl of BzSq (see Fig. 1(a) (left)). The angle between the phenyl plane and the quinolyl is 46.6°. The top view indicates clearly the superimposition between the phenyl group and the quinolyl (Fig. 1(b) (right)). The C(8)–S–C(10) angle of 100.3(2)° is considerably less than a tetrahedral angle of 109.5°, which is reasonably ascribed to the intraligand stacking interaction of BzSq. The dihedral angle C(8)–S–C(10)–C(11) is 43.9(4)°. The distance between C(11) and C(9) is 3.60(1) Å, which is the standard value for a π–π distance. This stacking conformation generates the repulsive interactions of Pd–Cl(2)···H–C(10) 3.41(2) Å and Pd···H–C(12) 2.99(2) Å [11]. Interligand stacking interactions between a phenyl group and another ligand (for example, bpy) in a given complex have been often reported [2–5] but intraligand stacking in the same ligand described here seems to be quite rare. There is no intermolecular stacking interaction between aromatic rings in the present complex.

On the other hand, [$PdCl_2$(PheneSq-*N*,*S*)] does not show such an intraligand stacking mode (Fig. 2(a) (left)). In general, a long alkyl chain is apt to adopt an *anti* conformation, that is, *trans* conformation, due to the repulsion between adjacent methylene protons. The C(8)-S-C(10)–C(11) dihedral angle is 56.3(4)° and the S–C(10)–C(20)–C(11) one is 173.4(3)°. The S–CH_2–CH_2–C sequence takes an *anti* conformation, so that the phenyl group becomes apart from the quinolyl. This is the reason why the PheneSq complex does not have an intraligand stacking mode. Instead there is an intermolecular stacking interaction between two quinolyl groups of adjacent molecules as shown in Fig. 2(b) (right). The distance between the quinolyl planes 3.40(1) Å is considerably shorter than the standard value (3.60 Å) for a π–π distance. Since the crystallographic inversion is located at the center of the intermolecular quinolyl stacking, the angle between two quinolyl planes becomes 0°.

The assignments of ^{1}H and ^{13}C NMR signals were carried out by proton homo-decoupling, ^{1}H-detected multiple quantum coherence (HMQC), and ^{1}H-detected multiple bondquantum coherence (HMBC) spectra. The results are listed in Tables 3 and 4.

In the ^{1}H NMR spectrum of [$PdCl_2$(BzSq-*N*,*S*)] an interesting splitting was observed: the phenyl proton signals are split into two groups, the group of H(12) and H(16) (δ 7.21) and one of H(13), H(14) and H(15) (δ 7.09–6.98), in d_6-Me_2SO as shown in Fig. 3. The free BzSq in d_6-Me_2SO shows the phenyl protons at δ7.49 (H(12) and H(16)), δ 7.34 (H(13) and H(15)), and δ 7.29 (H(14)). The changes of chemical shifts on complexation can be related to the ring current effect [10] of π-electrons of the quinolyl group by the aromatic intraligand interaction in d_6-Me_2SO. Similar changes were observed in CD_3OD (7.02 and 6.84) (Fig. 3). On the other hand, the signals of H(13), H(14), H(15) appear at relatively low magnetic field and the chemical shift separations are negligible in CD_2Cl_2 (δ 7.2) or $CDCl_3$ (δ 7.2) with low dielectric constants. This result suggests that the aromatic intraligand interaction is recognized in high dielectric solvents and does not occur in low dielectric solvents.

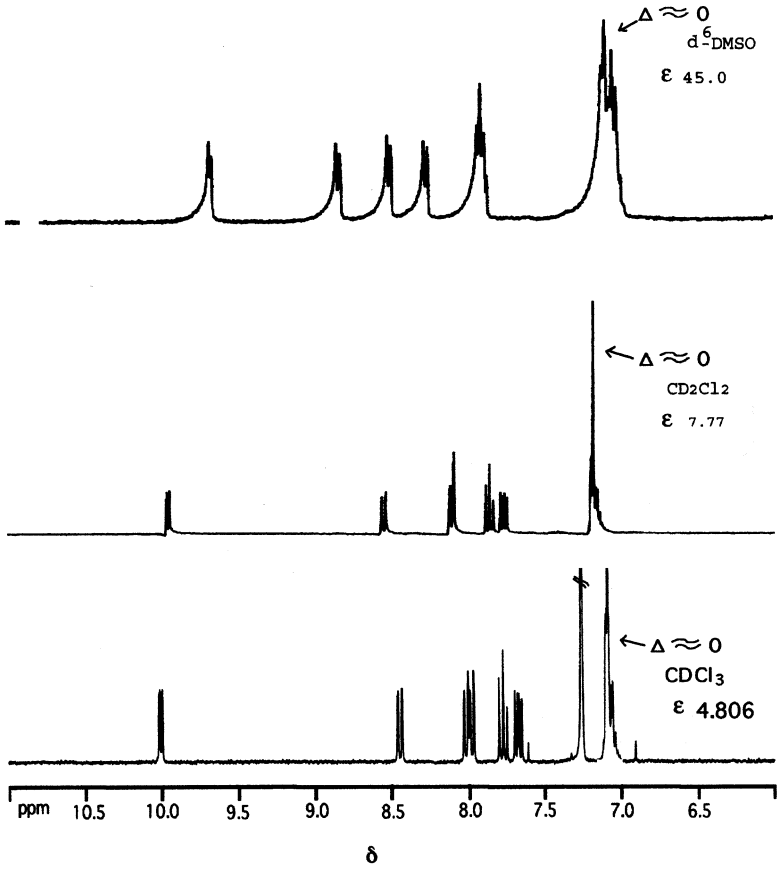

Fig. 4. Proton NMR spectra of [$PdCl_2$(PheneSq)] in several solvents. Δ is the magnitude of the splitting of phenyl protons and ε is the dielectric constant of solvent.

Similar ^{1}H NMR measurements were carried out for [$PdCl_2$(pheneSq-*N*,*S*)]. However, this complex did not show any splitting of the phenyl proton signals as shown in Fig. 4. Thus, the aromatic intraligand interaction could not be observed in the crystal and in solvents.

Each dibromo complex [$PdBr_2$(BzSq)] or [$PdBr_2$(PheneSq)] showed the same results as the corresponding dichloro complex. Hence we conclude that [$PdBr_2$(BzSq)] also has a similar noble intraligand stacking interaction as [$PdCl_2$(BzSq)] does in solid and in solvents with high dielectric constants.

7. Supplementary material

Crystallographic data have been deposited with the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-366033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) and are available on request quoting the deposition numbers 169087 for [$PdCl_2$(BzSq)] and 169088 for [$PdCl_2$(pheneSq)].

Abstract

The species [Mo{HB(3,5-Me_2pz)$_3$}(NO)Cl]$_2$(μ-NHNH) (**1**) (3,5-Me_2pz = 3,5-dimethylpyrazol-1-yl) and [Mo{HB(3,5-Me_2pz)$_3$}(NO)I]$_2$(μ-NHNH) have been synthesised. Electrochemical reduction of **1** results in a species with a near-infrared spectral band which shows no solvent dependence. Reoxidation results in the formation of another species which undergoes reversible reduction resulting in the development of another near-infrared spectral band which also is insensitive to solvent. These observations suggest that, in both cases, the mixed-valence species are class III. Additionally, **1** has been characterised structurally as a component of a solid solution also containing its chlorinated analogues; this determination shows that all components of the solution contain a near-planar Mo–NH–NH–Mo array and that Cl replacement is isomorphous. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Bimetallic complexes of redox active metal centres are of considerable interest since those containing bridging polyatomic ligands, such as pyrazine or 4,4′-bipyridyl, raise a number of theoretical challenges [1] with regard to describing the general nature of electronic interactions between metal centres. Bimetallic complexes incorporating small bridges such as O^{2-} and N_2 are clearly also of interest [2], these species often being best described by a delocalised bonding system akin to a metal–metal bond [3,4]. We have previously reported that [Mo{HB(3,5-Me_2pz)$_3$}(NO)I_2] and [W{HB(3,5-Me_2pz)$_3$}(NO)Br_2] react with various substituted hydrazines, H_2NNRR', to produce monodentate hydrazido(1-) complexes [5]. In addition, the complexes [Mo{HB(3,5-Me_2pz)$_3$}(NO)I($NHNH_2$)] and [W{HB(3,5-Me_2pz)$_3$}(NO)Br($NHNH_2$)] have been reported [5], and it is thought that these probably incorporate monodentate hydrazido(1-) ligands.

In order to further our studies of the {Mo{HB(3,5-Me_2pz)$_3$}(NO)X} (X = Cl, I) metal fragment bridged by small ligands [6–9], bimetallic species were synthesised incorporating $NHNH^{2-}$ as a bridge. [Mo{HB(3,5-Me_2pz)$_3$}(NO)I]$_2$(μ-O) has been shown to undergo a one-electron reduction, the product of which appears to be valence-trapped on the ESR timescale [10], and we were interested to establish if other bimetallic species with the metals in close proximity might display similar

properties. Furthermore, it was of interest to us to investigate the relevance of this system as a possible model for some of the chemical intermediates postulated in the past for the process of nitrogen fixation [11]. The fixation by nitrogenase is thought to occur via a process of reduction and concomitant protonation of dinitrogen coordinated to a transition metal, with one of the intermediate products in this process being a hydrazido moiety [12]. Whilst it is now thought more likely that the binding of nitrogen occurs at iron atoms [13,14], the possibility of binding occurring at molybdenum is still accepted by some [15]. Bimetallic molybdenum species are of considerable interest as reductive nitrogen-activating systems in their own right, and the Mo(III) complex $[Mo(N\{3,5\text{-}Me_2C_6H_3\}\{CCH_3(CD_3)_2\})_3]$ binds dinitrogen to form bimetallic species which can be cleaved thermally to afford the corresponding Mo(VI) nitrido-complexes [16]. Examples are known of bimetallic molybdenum complexes bridged by hydrazine [17–29], including some remarkable Fe–S–Mo clusters structurally reminiscent of the nitrogenase active site itself [28,29]. There is one example of a (μ_3-η^1,η^2-NH_2NH) ligand [30] and a few examples of bimetallic transition metal complexes containing the M-(η^1,η^1-NHNH)-M array have been structurally characterised [31], but none of these contain molybdenum. The N–N bond distances in these range from 1.23 to 1.41 Å and the nature of the bridge is thought to vary between the diazene-type [26,31–36] M–NH=NH–M for the shorter distances and the hydrazide(2-)-type [37] M–NH–NH–M for the longer. The 'side-on' bridging η^2,η^2-hydrazide ligand is also known [18].

2. Results and discussion

2.1. Synthetic studies

The compound $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$ (**1**) was obtained in 42% yield from the reaction between hydrazine hydrate and $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl_2]$ in toluene. Further reactions were carried out to investigate the formation of diastereomers, but changes in conditions failed to provide any conclusive evidence for the formation of a second isomer of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$, although a species tentatively identified as $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl(NHNH_2)]$ was isolated in low yield. $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)I]_2(\mu\text{-}NHNH)$ (**2**) was synthesised in a similar manner to $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$, but a shorter reaction time was required.

2.2. Spectroscopic studies

^1H NMR spectra were obtained for both **1** and **2**. As with [10] $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}O)$, the spectra showed that the two metals are nonequivalent. Additionally, the methyl resonances are spread over a range of 1.69 and 1.68 ppm for **1** and **2**, respectively, a consequence of ring currents due to the interleaving of pyrazole rings. This range is less than that observed [10] for $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}O)$, of 2.15 ppm, and may reflect the presence of a slightly longer bridge. AB patterns are observed for the NH protons in both bridges as a consequence of the molecular asymmetry, which persists in the solution state. The observation of sharp signals likely results from the hydrazine protons undergoing slow exchange, and because ^{14}N in a low symmetry environment will undergo very fast relaxation and so effectively decouple from the NH protons. Compounds **1** and **2** display two nitrosyl stretching frequencies at 1665 and 1635 cm^{-1} for **1** and 1670 and 1640 cm^{-1} for **2**. These frequencies are lower than those observed for $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}O)$ and are in accord with greater π-donation from the NHNH bridging system. A Raman spectrum (Fig. 1) was obtained for **1**. This spectrum is unusual in that three vibrations are very intense in comparison with the remainder of the spectrum. The intensity of these vibrations cannot be due to resonance enhancement since the electronic absorption spectrum of **1** is transparent at the energy corresponding to the laser. Such high intensities will likely only occur if the Mo–N–N–Mo bonding system is delocalised and therefore polarisable, which explanation would be in accord with the spectroelectrochemical and crystallographic studies discussed below.

2.3. Electrochemical studies

Cyclic voltammetry of **1** in dichloromethane revealed one reduction process with a half wave potential of -0.480 ± 0.005 V. Further studies of digitised data using CONDECON software [38] indicated that the electron transfer involved one electron and was slightly slower than diffusion controlled and that some decomposition of the reduced product occurred [38–40]. The mechanism for the process is EC_{irrev}. Electrochemical studies of **2** were carried out in tetrahydrofuran and in acetonitrile, and in both cases two reduction processes were observed. A reversible one-electron process was observed with $E_{1/2} = -0.420 \pm 0.005$ V ($\Delta E = 80 \pm 10$ mV) in tetrahydrofuran and $E_{1/2} = -0.395 \pm 0.005$ V ($\Delta E = 60 \pm 10$ mV) in acetonitrile. Additionally an irreversible process, with E_p values of -1.970 ± 0.010 and -2.030 ± 0.005 V in tetrahydrofuran and acetonitrile respectively, was observed. In the case of **1** the absence of a second reduction process within the ranges attainable in these solvents, and the large potential difference between the

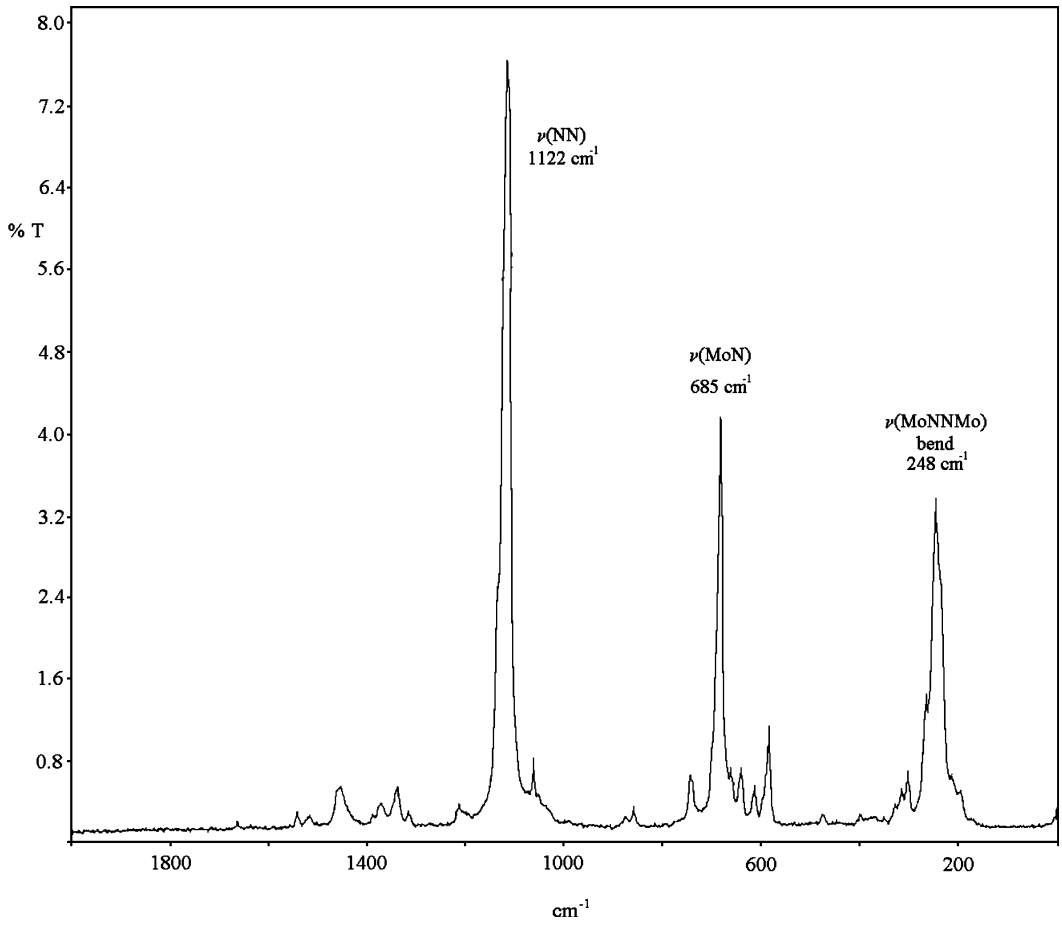

Fig. 1. Raman spectrum of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$.

first and second reduction processes in **2**, suggest that both species have strongly interacting metal centres.

2.4. Spectroelectrochemical studies

Reductive electrolysis of **1** was carried out in various solvents at 0 °C while monitoring the UV–Vis–NIR spectrum of the reaction mixture. The results are shown in Table 1. When electrolysis of **1** was carried out in chloroform, dichloromethane, or acetone the reduction process proved to be irreversible. Oxidation of the reduced product, $\mathbf{1}^-$, was also an irreversible process and afforded a compound **3** with a different absorption spectrum from that of the starting material. However, **3**

	3	8700(430)	22180(26130)		

could be reduced reversibly, the spectrum of $\mathbf{3}^-$ differing from that of $\mathbf{1}^-$.

In acetonitrile a reversible electrolytic process was observed, but the reduction product appeared to be that which was obtained upon the *second* reduction cycle of **1** (i.e. $\mathbf{3}^-$) in the other three solvents. Attempts were made to generate **3** in bulk, with a view to its chemical characterisation. Electrochemical reduction of **1** in dichloromethane followed by electrochemical or aerial reoxidation yielded a material with identical UV–Vis spectral characteristics to that of **3**. However, after passing this down a silica gel column, **1** was once again obtained, as evidenced by UV–Vis and ^{1}H NMR spectra, with recoveries of 50–80%. Attempts were made to avoid the reversion to **1** by measuring the ^{1}H NMR spectrum of the reduction–reoxidation product without chromatography. Once again the spectrum was identical to that of **1**. It is not yet clear why the transformation to **3** should occur upon oxidation of $\mathbf{1}^-$, nor why the electrochemical behaviour of **1** in acetonitrile is different. An additional bulk electrolysis was carried out upon **1** in order to generate the electrolytic product for cyclic voltammetry. The electrolysis was carried out at room temperature in CH_2Cl_2 containing 0.2 M Bu_4NBF_4 as supporting electrolyte. Following reduction of 20 mg of **1** in 10 cm^3 of solvent at -1.0 V and reoxidation at $+0.1$ V relative to a SCE, 5 cm^3 of the product solution was transferred to a nitrogen filled electrochemical cell. Cyclic voltammetry revealed a broad wave ($\Delta E_p = 230$ mV) which appeared to represent a reversible process characterised by $E_{1/2} = -0.550 \pm 0.020$ V. The broad nature of the wave probably indicates slow electron transfer which contrasts with the behaviour exhibited by **1** and the $E_{\frac{1}{2}}$ data indeed shows that **1** is 70 ± 40 mV easier to reduce than its electrolysis product **3**. The UV–Vis bands of **3** are also shown in Table 1. The similarity between the electronic spectra of the two species, and the facile transformation of **3** back into **1**, suggest that they are closely related.

It is difficult to come to any conclusion about the nature of the bands in any of the species observed. The spectra are dominated by charge transfer bands and these show varying amounts of solvent dependence. Figs. 2–4 show the progress of an experiment involving the electrolysis of, respectively, **1**–$\mathbf{1}^-$, $\mathbf{1}^-$–**3**, and **3**–$\mathbf{3}^-$ in $CHCl_3$. It should be noted that the absence of clean isosbestic points indicates the presence of more than two species in solution, which may indicate that some decomposition accompanies these redox processes.

Whereas many models describing mixed-valence behaviour are currently vying for acceptance, that developed by Hush [41] remains the easiest to apply. This model relates the energy of any intervalence charge transfer (IVCT) band, E_{op}, to spectroscopically measurable properties of the molecule under consideration and

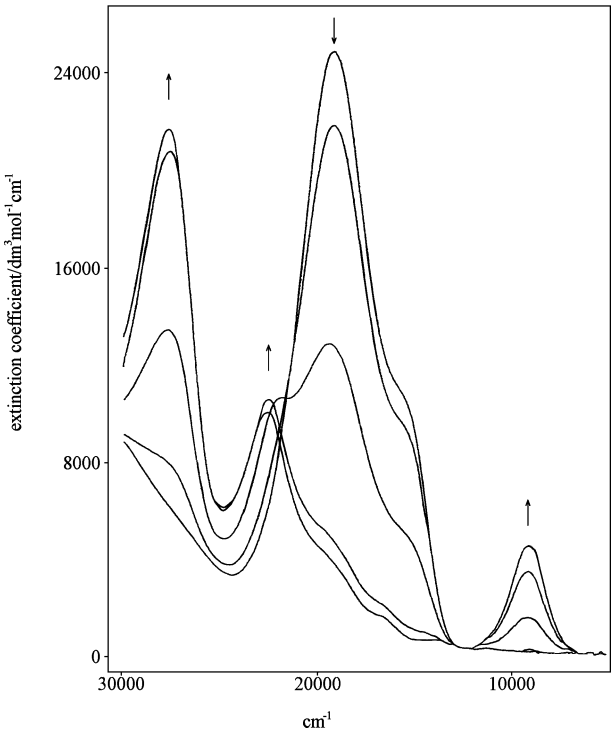

Fig. 2. Plots showing the changes in the electronic spectrum of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$ (**1**) upon electrolytic reduction to $\mathbf{1}^-$ in chloroform at 0 °C.

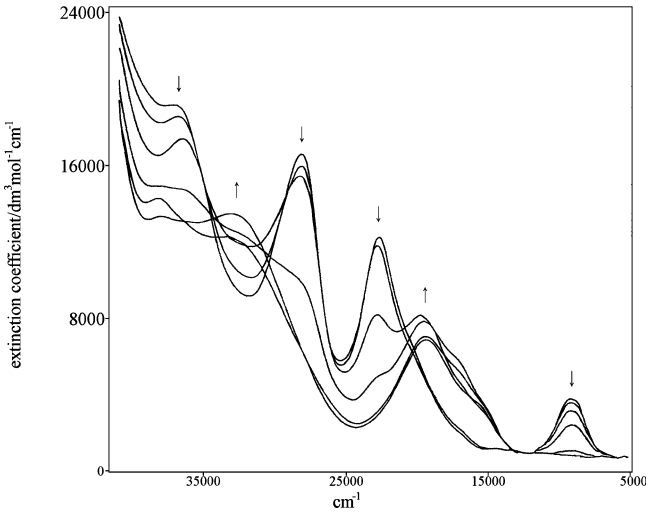

Fig. 3. Plots showing the changes in the electronic spectrum of $\mathbf{1}^-$ upon electrolytic reoxidation to **3** in chloroform at 0 °C.

to solvent properties. Amongst the many predictions of the model is that E_{op} is dependent upon $(1/D_{op} - 1/D_s)$, where D_{op} and D_s are the optical and static dielectric constants of the solvents. However, plots of E_{op} against $(1/D_{op} - 1/D_s)$ for the NIR bands observed for $\mathbf{1}^-$ show no solvent dependence; this and the comparatively high intensity of the bands suggest that $\mathbf{1}^-$ is a delocalised species.

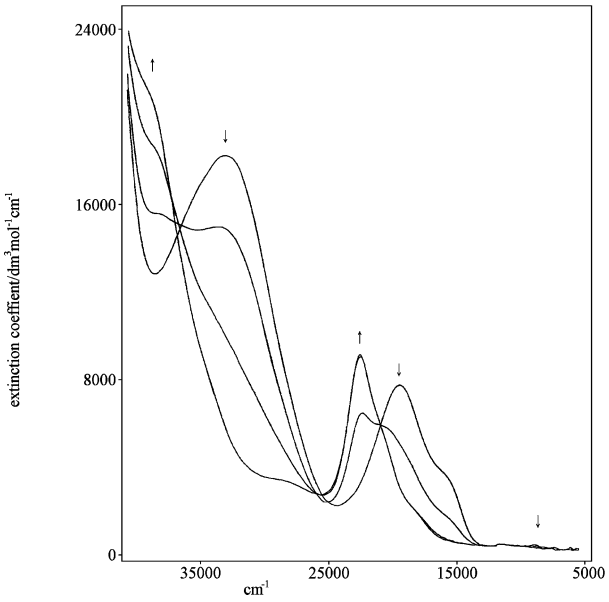

Fig. 4. Plots showing the changes in the electronic spectrum of **3** upon electrolytic reduction to $\mathbf{3}^-$ in chloroform at 0 °C.

2.5. Structural studies

Repeated attempts to grow single crystals of pure **1** suitable for analysis by X-ray diffraction failed. However, we found that crystals could be grown from a dichloromethane solution of a sample which dated from a period when, in our studies, we found it difficult to prepare the precursor [Mo{HB(3,5-Me_2pz)$_3$}(NO)Cl_2] reproducibly due to some degree of pyrazolyl ring chlorination [42]. On the basis of the ^{1}H NMR spectrum of the resulting crystalline matrix **7**, it appears to be a solid solution of four components, namely **1**, the chloro-derivative [Mo(HB(3,5-Me_2pz)$_2$(4-Cl-3,5-Me_2pz)}(NO)Cl](μ-NHNH)[Mo{HB(3,5-Me_2pz)$_3$}(NO)Cl] (two isomers, **4** and **5**), and the dichloro-derivative [Mo{HB(3,5-Me_2pz)$_2$(4-C1-3,5-Me_2pz)}(NO)Cl]$_2$(μ-NHNH) (**6**). The latter three components presumably originate from ring chlorination during the synthesis of [Mo{HB(3,5-Me_2pz)$_3$}(NO)Cl_2], rather than rearrangement or decomposition at a later stage [42]. Integrations of the signals originating from the hydrazido and pyrazolyl 4-position protons are consistent with a **1**:**4**:**5**:**6** ratio of 41.0:34.0:15.5:9.5, which corresponds to 43.5% chlorine substitution at one site and 25.0% at the other giving an overall average of 34.3% chlorine substitution in the sample as a whole.

A representation [43] of the model of **1** in **7** is shown in Fig. 5. Table 2 contains selected bond distances and angles. The structure is clearly binuclear, containing two {Mo{HB(3,5-Me_2pz)$_3$}(NO)Cl} moieties possessing different degrees of chlorine occupancy at the 4-position of the pyrazolyl ring *trans*- to the nitrosyl ligand. These two groups are linked by a (μ-NHNH) bridge. Final, refined, chlorine occupancies for the two 4-pyrazolyl

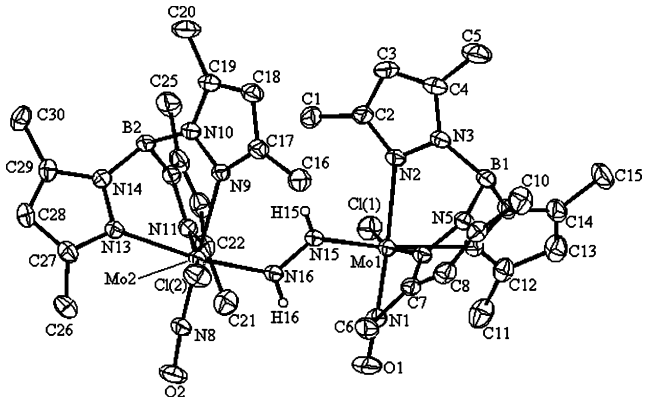

Fig. 5. A representation 43 of **1** within the matrix **7**. All hydrogens, apart from H15 and H16, have been omitted for clarity. Thermal ellipsoids are depicted at the 30% probalitity level.

Table 2
Selected bond lengths (Å) and angles (°) for **1** within the matrix **7**

Bond lengths (Å)			
Mo1–N1	1.756(3)	Mo2–N8	1.761(3)
Mo1–N2	2.241(3)	Mo2–N9	2.249(3)
Mo1–N4	2.181(3)	Mo2–N11	2.180(3)
Mo1–N6	2.200(3)	Mo2–N13	2.171(3)
Mo1–N15	1.950(3)	Mo2–N16	1.969(3)
Mo1–Cl(1)	2.400(1)	Mo2–Cl(2)	2.399(1)
N1–O1	1.198(4)	N8–O2	1.196(4)
N15–H15	0.75(4)	N16–H16	0.82(4)
N15–N16	1.362(4)		
Bond angles (°)			
N1–Mo1–N2	176.82(14)	N8–Mo2–N9	177.82(13)
N1–Mo1–N4	96.00(14)	N8–Mo2–N11	96.53(14)
N1–Mo1–N6	97.75(14)	N8–Mo2–N13	96.03(13)
N1–Mo1–N15	91.87(15)	N8–Mo2–N16	89.66(14)

N2–Mo1–N6	85.43(12)	N9–Mo2–N13	85.58(11)
N2–Mo1–N15	84.99(12)	N9–Mo2–N16	89.11(12)
N2–Mo1–Cl(1)	87.59(9)	N9–Mo2–Cl(2)	86.46(8)
N4–Mo1–N6	79.73(11)	N11–Mo2–N13	80.05(12)
N4–Mo1–N15	92.15(12)	N11–Mo2–N16	86.46(12)
N4–Mo1–Cl(1)	165.41(8)	N11–Mo2–Cl(2)	167.96(9)
N6–Mo1–N15	167.98(13)	N13–Mo2–N16	165.86(12)
N6–Mo1–Cl(1)	87.36(9)	N13–Mo2–Cl(2)	90.67(9)
N15–Mo1–Cl(1)	99.46(10)	N16–Mo2–Cl(2)	102.09(10)
O1–N1–Mo1	176.9(3)	O2–N8–Mo2	175.4(3)
H15–N15–N16	105.0(3)	H16–N16–N15	105.0(3)
H15–N15–Mo1	121.0(3)	H16–N16–Mo2	122.0(3)
N16–N15–Mo1	133.3(3)	N15–N16–Mo2	129.9(3)

positions were 48.0% for Cl(3) and 20.3% Cl(4), meaning the average chlorine 4-position occupancy, as estimated by crystallographic means, is 33.6%, which figure is in very close agreement with that obtained from NMR experiments. The two Mo centres are crystallographically distinct, as they are in solution also. Both nitrosyls point in the same direction away from the metal centres and thus the overall conformation of the molecule can be contrasted with that of [Mo{HB(3,5-

$Me_2pz)_3\}(NO)I]_2(\mu\text{-}O)$, which has nitrosyls at a relative torsion [10] of approximately 90°, or $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)I]_2(\mu\text{-}SS)$, in which the nitrosyls are inclined [6] at 180°.

The coordination environment around the Mo atoms is distorted octahedral, as is typical of complexes of this sort [42,44–50]. The trispyrazolylborate ligand, which occupies three *fac*- sites of the octahedron, is held by Mo–N bonds of average distance 2.207[1] Å. This compares with a mean distance of 2.221[2] Å ($[\ ] = \{\Sigma_{i=1}^{i=n}(\sigma_i^2)\}^{1/2}/n$) obtained from a survey of 10 other $\{Mo^{II}\{HB(3,5\text{-}Me_2pz)_3\}(NO)X\}$ (X = Cl, I)—containing structures for which bond error data is published [5,51–57]. It might be expected that the steric crowding which causes the nonequivalence of the metals might also result in greater Mo–(N)pyrazolyl distances but, on the contrary, the above comparison indicates that the trispyrazolylborate ligands are held closely to the metal. The low N–O bond order indicated by the low infrared stretching frequency of the nitrosyl ligand appears also to be detectable in the crystal structure. The N–O distances of 1.195(3) and 1.193(3) Å are significantly longer than the mean of 1.169(5) Å from the above survey group; despite the possibility that the implied electron richness of the Mo centre originates from some degree of pπ–dπ electron donation from ligand to metal, the Mo–N(hydrazido) bond distances of 1.948(2) and 1.968(2) Å do not appear to be especially short, as compared with Mo–N(amido) distances of 1.945(19) and 1.935(20) Å in $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)(NHBu)_2]$, for example [46].

The bridge is the most interesting aspect of the molecular structure. Overall, it is almost planar, deviations from the best plane through Mo1–N15–N16–Mo2 being 0.065(1), −0.073(1), −0.054(1), 0.061(1), −0.24(3) and 0.17(3) Å for Mo1, N15, N16, Mo2, H15 and H16, respectively. Mo1 and Mo2 are in mutual *trans*- positions across the planar bridge, the Mo–N–N–Mo torsion angle being 169.9(1)°. The N15–N16 bond length in the (NHNH) bridge is 1.362(3) Å and as such is only 0.05 Å shorter than that observed in $[W(\eta^5\text{-}C_5Me_4(^tBu))(CCMe_3)I](\mu\text{-NHNH})$ (1.410(9) Å) [37], but is 0.11 Å longer than that found in $[Cr(CO)_5]_2(\mu\text{-NHNH})$ [32] (1.250 Å), which would indicate that the (NHNH) bridge is more akin to the $(NH–NH)^{2-}$ hydrazido(2-) type than the (HN=NH) diazene type. The angles at the bridge nitrogens do not seem to be diagnostic of the nature of the bridge, all the (μ-NHNH) complexes which have been crystallographically characterised displaying similar M–N–N angles. In the present study the angles are 133.5(2)° and 130.2(2)°, in the case of $[W(\eta^5\text{-}C_5Me_4(^tBu))(CCMe_3)I]_2(\mu\text{-NHNH})$ the angle [37] is 131.7(5)°, whilst in $[Cr(CO)_5]_2(\mu\text{-NHNH})$ the angle is 130.5°. Additionally, the two complexes $[Ru(PPh_3)(L)]_2(\mu\text{-NHNH})$ (where H_2L is [35] $\{HS(C_6H_4\text{-}2)SCH_2\}_2$ or [36] $\{HS(C_6H_2(3,5\text{-}CMe_3)\text{-}2)SCH_2\}_2$, display N–N distances of 1.301(14) and 1.279(14) Å and Ru–N–N angles of 129.3(9)° and 131.9(8)°, respectively. An sp^2 hybridisation appears to be the norm for any N ligand attached to the $\{Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)\}$ fragment [47], and the bridge hydrogens were easily located and refined to positions consistent with this in the present study. The N–H vectors do not quite bisect the complements of the Mo–N–N angles, the hydrogens being inclined away from the Mo atoms by 5°–8°.

The variation in N–N bond length in μ-NHNH bridges suggests that a balance exists between donation of the nitrogen 2p electron density to empty metal orbitals and population of a N–N bond of π-symmetry. A qualitative bonding scheme for the M–N–N–M fragment is shown in Fig. 6, which is applicable to any of the systems discussed above. The exact nature of the NHNH bridge will be affected by the relative coefficients of the metal and nitrogen orbitals. Fig. 6 also provides an explanation for the spectral changes upon reduction of **1**. In the neutral form the 1a and 1b levels will be filled and reduction will result in an electron occupying the 2a level. The unpaired electron may then undergo low energy transitions to the 2b level.

3. Conclusion

$[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-NHNH})$ (**1**) and $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)I]_2(\mu\text{-NHNH})$ (**2**) were synthesised. Species **1** is electrochemically reducible to $\mathbf{1}^-$ which, on reoxidation, affords the structurally uncharacterised **3**, whose electrochemical behaviour is different from **1** in that it undergoes reversible reduction. All attempts to isolate **3** resulted in reversion to **1**, implying that **1** and **3** are closely related structurally. Investigation of **1** by Raman spectroscopy and of the reduction products of **1** by spectroelectrochemistry suggest that both **1** and $\mathbf{1}^-$ are electronically delocalised, and that $\mathbf{1}^-$ and $\mathbf{3}^-$ are class III mixed-valence species.

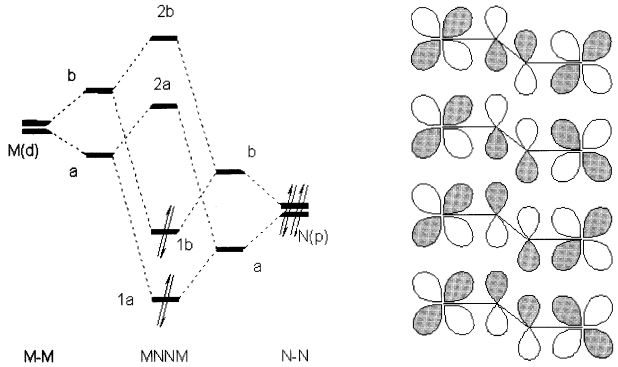

Fig. 6. Qualitative Mo diagram of an M–NH–NH–M bridge treated in C_2 symmetry, assuming sp^2 hybridisation of the nitrogens.

The molecular structure of the solid solution **7** confirms the presence of a (μ-NHNH) ligand for all its constituents. The structure also supports the suggestion that the nitrogens in the bridge are sp^2-hybridised. Consideration of other structural data in the literature suggests that the (NHNH) bridge in the present study displays some double bond character, but rather less than some similar compounds. It is appropriate, then, that the bridging ligand in $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$ be considered a hydrazide(2-) moiety, albeit with sp^2 nitrogens which allow donation of electron density into empty metal orbitals.

4. Experimental

4.1. Materials

All reactions were carried out under dry nitrogen and $C_6H_5CH_3$ was distilled from Na and benzophenone prior to use. The complexes $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)X_2]$ (X = Cl or I) were prepared as described in the literature [42,44,45]. Column chromatography was carried out using silica gel as the stationary phase (Merck 60, 70–230 mesh).

4.2. Physical measurements

Infrared, electronic, mass, 300 and 400 MHz NMR spectra were recorded respectively, on Perkin–Elmer 297, Perkin–Elmer Lambda 9, Kratos MS 90, Bruker WH300 and Bruker WH400 instruments. Raman spectra were obtained on a Perkin–Elmer FT-Raman 1700X spectrometer using a Nd:YAG laser (1064 nm) and an InGaAs detector cooled to 77 K. Spectra were obtained from solids as powders pressed into a cup sample holder. Elemental analysis was performed by the Microanalytical Laboratory, University of Birmingham. Cyclic voltammetry studies were carried out in 0.2 M Bu_4NBF_4 CH_2Cl_2 solution, the CH_2Cl_2 having been stored over K_2CO_3 and redistilled from CaH_2, in a three-electrode cell comprising a Pt bead working electrode, a Pt wire secondary electrode and a calomel reference electrode. Ferrocene (Fc) was added as an internal reference (Fc/Fc^+: $E_{\frac{1}{2}} = 0.550$ V). Initial studies were carried out using a PAR 174A potentiostat with built-in waveform generator with a Philips X–Y pen recorder. Data were also acquired using a PAR 360 potentiostat interfaced with an Amstrad PC1512 computer via an EG&G analogue–digital convertor and processed using EG&G CONDECON [38] 300 software. Spectroelectrochemistry was carried out using a Perkin–Elmer Lambda 9 spectrometer whilst samples were electrolysed in an optically transparent thin layer electrochemistry (OTTLE) cell using a Metrohm potentiostat. The temperature was held at 0 °C. Samples were dissolved in 0.4 M Bu_4NBF_4 of the requisite solvent and an Ag–AgCl reference electrode was employed. Reductive electrolysis was carried out at potentials between −1.0 and −1.3 V relative to a Ag–AgCl electrode.

4.3. Synthesis of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl]_2(\mu\text{-}NHNH)$

A solution of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)Cl_2]$ (0.50 g, 1.01 mmol) and hydrazine hydrate (0.04 g, 0.80 mmol) in $C_6H_5CH_3$ (100 cm^3) was heated to reflux for 3 days. The resulting purple solution was cooled, filtered and the filtrate was evaporated to dryness in vacuo. The solid obtained was purified by column chromatography using CH_2Cl_2 as eluant. The main purple fraction was collected. Recrystallisation from CH_2Cl_2–n-C_5H_{12} gave purple microcrystals (0.2 g, 42%). IR cm^{-1} (KBr): 3310, 3260 ν(NH), 2550 ν(BH), 1665, 1635 ν(NO). ^{1}H NMR ($CDCl_3$): δ *AB* system, $A = 14.85$, $B = 13.63$ (2H, $J_{AB} = 13.6$ Hz), 5.95 (1H, s), 5.88 (1H, s), 5.83 (1H, s), 5.81 (1H, s), 5.47 (1H, s), 5.42 (1H, s) ($C–H_{pyrazolyl}$), 2.68 (3H, s), 2.63 (3H, s), 2.54 (3H, s), 2.52 (3H, s), 2.36 (3H, s), 2.34 (6H, s), 2.33 (6H, s), 2.31 (3H, s), 1.39 (3H, s), 0.99 (3H, s) ($C–H_{methyl}$). *Anal*. Found: $C_{30}H_{46}B_2Cl_2Mo_2N_{16}O_2$: C, 42.2; H, 5.8; N, 21.6. *Anal*. Calc. C, 39.4; H, 5.1; N, 24.5%.

4.4. Synthesis of $[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)I]_2(\mu\text{-}NHNH)$

$[Mo\{HB(3,5\text{-}Me_2pz)_3\}(NO)I_2]$ (2.0 g, 2.95 mmol) was dissolved in CH_2Cl_2 (100 cm^3). Hydrazine hydrate (0.221 g, 4.43 mmol) was added to the stirred solution. The colour changed immediately to yellow. Upon stirring overnight the solution became blue. The solvent was removed in vacuo and the residue was redissolved in CH_2Cl_2 (10 cm^3). The solution was purified by column chromatography using CH_2Cl_2 as eluant. The second blue fraction was collected, the solvent removed in vacuo and the residue triturated with n-C_6H_{14}. The resulting blue product was filtered and dried (0.2 g, 10%). IR cm^{-1} (KBr): 3300, 3265 (ν_{NH}), 2545 (ν_{BH}), 1670, 1640 (ν_{NO}). ^{1}H NMR ($CDCl_3$): δ *AB* system, $A = 12.32$, $B = 11.80$ (2H, $J_{AB} = 9.0$ Hz), 5.89 (1H, s), 5.85 (1H, s), 5.80 (2H, s), 5.54 (1H, s), 5.48 (1H, s) ($C–H_{pyrazolyl}$), 2.72 (3H, s), 2.64 (3H, s), 2.57 (3H, s), 2.54 (3H, s), 2.45 (3H, s), 2.43 (3H, s), 2.38 (6H, s), 2.35 (6H, s), 1.38 (3H, s), 1.14 (3H, s) ($C–H_{methyl}$). *Anal*. Found: $C_{30}H_{46}B_2I_2Mo_2N_{16}O_2$: C, 32.2; H, 4.2; N, 19.6. Calc. C, 31.9; H, 3.9; N, 19.7%.

4.5. Crystallographic analysis of solid solution 7

$C_{30}H_{45.33}B_2Cl_{2.67}Mo_2N_{16}O_2$, $M = 970.4$, $P2_1/n$, $a = 11.3563(14)$ Å, $b = 22.3570(22)$ Å, $c = 16.5725(18)$ Å, $\beta = 97.430(11)°$, $V = 4172$ Å^3, and $Z = 4$, D_c, = 1.545 g

cm^{-3}, Mo Kα ($\lambda = 0.71069$ Å), $\mu = 0.822$ mm^{-1}, $T = 293$ K. A rhomboidal purple–black crystal of **7**, measuring approximately $0.6 \times 0.6 \times 0.2$ mm^3, was glued atop a glass fibre and mounted on an Enraf-Nonius CAD-4 diffractometer. The unit cell was determined using 14 randomly located reflections, and finally refined using 25 reflections selected from the data set. Intensities were measured with an ω–2θ bisecting geometry method using variable scan rate and angle $(1.00+0.35 \tan\theta)^\circ$. Nine thousand two hundred and sixty data were measured with $2^\circ < 2\theta < 50^\circ$, $-1 \leq h \leq 13$, $-1 \leq k \leq 26$, $-19 \leq l \leq 19$, during which two standard reflections were measured every hour, with little variation. Data were corrected for Lp and slight standard decay. Equivalent reflections were merged to give 7340 unique data. The Mo atoms were located using direct methods [58] and other non-H atoms located from subsequent difference Fourier syntheses [59]. Non-H atoms were refined [59] anisotropically, the two crystallographically distinct pyrazolyl Cl atoms being assigned individual refined site occupancies. Free positional refinement proved unstable, so the pyrazolyl Cl atoms were moved by hand, every few refinement cycles, onto theoretical positions with C–Cl distances of 1.715 Å. This resulted in satisfactory convergence. One aberrant reflection with $F_o \ll F_c$ was deleted from the dataset. Hydrogen atoms were placed in idealised positions on their parent atoms ($C–H_{pyrazolyl}$, 0.93 Å; $C–H_{methyl}$, 0.96 Å; B–H, 0.98 Å) and refined isotropically. An absorption correction [60] was applied, based on a converged model including anisotropic non-H and all hydrogen atoms. On reconvergence using the above procedure, the hydrogens' refined, type-specific isotropic thermal parameters were B–H, $C–H_{pyrazolyl}$ 0.058 $Å^2$, $C–H_{methyl}$ 0.102 $Å^2$ except for the hydrogens of the hydrazide bridge, which were successfully found and refined ($U_{iso} = 0.034$ Å). The final weighting scheme was $w^{-1} = (\sigma^2 F_o^2 + (0.0556\ P)^2 + 4.19\ P)$ where $3P = F_o^2 + 2F_c^2$. All atoms refined satisfactorily, with no indication of significant disorder, throughout the process, with the exception of Cl(4) (a pyrazolyl chlorine) whose thermal ellipsoid seems elongated roughly in the direction perpendicular to the pyrazolyl ring. Final figures of merit were $wR_2 = 11.01\%$ and equivalent $[I > 2\sigma(I)]$ $R_1 = 3.81\%$. The largest peak in the difference map was 1.70 e $Å^{-3}$, 1.07 Å from Cl(4).

5. Supplementary material

Crystallographic data for structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 170971 for compound **1**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Reduction of 2-cyanopyridine by sodium in dry methanol in the presence of 3-piperidylthiosemicarbazide produces 2-pyridineformamide 3-piperidylthiosemicarbazone, HAmpip. Complexes with nickel(II) have been prepared and characterized by magnetic susceptibility and spectroscopic techniques. The crystal structures of [Ni(Ampip)$_2$], [Ni(Ampip)OAc], and [Ni(HAmpip)Cl]Cl have been solved. Coordination of the anionic and neutral ligand is via the pyridyl nitrogen, imine nitrogen, and thiolato–thione sulfur. [Ni(Ampip)$_2$] is an approximately octahedral NiN_4S_2 center with the tridentate ligands in a meridonal arrangement. [Ni(Ampip)OAc] is essentially planar except for the acetato ligand, which is $>80^\circ$ out of the coordination plane, and the ionic [Ni(HAmpip)Cl]Cl involves the neutral thiosemicarbazone ligand. © 2002 Published by Elsevier Science Ltd.

1. Introduction

A new series of N(4)-substituted thiosemicarbazones has been prepared in which the thiosemicarbazone moiety is attached to an amide carbon rather than an aldehyde or ketone carbon in an attempt to enhance water solubility. 2-Formyl-, 2-acetyl-, and 2-benzoylpyridine N(4)-substituted thiosemicarbazones [1–3] possess substantial in vitro activity against various human tumor lines [4]. However, due to a lack of solubility in aqueous solutions, these thiosemicarbazones and their complexes show less promising in vivo activity. We have communicated our studies of metal complexes of 2-pyridineformamide thiosemicarbazone [5,6] and N(4)-methylthiosemicarbazone [7,8]. We report here spectral and structural properties of three nickel(II) complexes of 2-pyridineformamide 3-piperidylthiosemicarbazone, HAmpip, which is depicted in Fig. 1. Its structure is discussed in a communication with iron(II), cobalt(II,III), and copper(II) complexes [9].

2. Experimental

2.1. Synthetic methods

2-Cyanopyridine was purchased from Aldrich and used as received and 3-piperidylthiosemicarbazide was prepared as described by Scovill [10]. Following the literature procedure for the reduction of 2-cyanopyridine [11], sodium (0.092 g, 4 mmol) was added to 25 ml of MeOH, which had been dried over $CaSO_4$ (i.e. Drierite), and the solution stirred until complete dissolution occurred. 2-Cyanopyridine (2.6 g, 25 mmol) was then added, and the mixture stirred for 1/2 h, and 3-piperidylthiosemicarbazide (3.9 g, 25 mmol) was added in small portions over a period of 1/2 h. After addition of 15 ml of MeOH the mixture was gently refluxed for a minimum of 4 h. Slow evaporation of MeOH produced the yellow HAmpip, NMR ($CDCl_3$): N–*H* at $\delta =$

13.186; C–*H* (Py) at $\delta = 7.995$, 7.835 and 7.422; NH_2 at $\delta = 6.4$ ppm; m.p., 154–156 °C.

The nickel(II) complexes were prepared as follows, nickel(II) chloride or acetate (0.002 mol) in EtOH (30 ml) was mixed with a solution of HAmpip (0.002 or 0.004 mol for [Ni(Ampip)$_2$]) in EtOH (30 ml), and the resulting mixture was stirred under reflux for 2 h or longer. The resulting solids were filtered, washed with anhydrous ether to apparent dryness, and placed on a warm plate at 35 °C until required for characterization. %Calc.(Found) for red brown [Ni(HAmpip)Cl]Cl·EtOH: C, 38.3(38.2); H, 4.8(5.3); N, 16.0(16.0); for brown [Ni(Ampip)OAc]: C, 44.3(44.3); H, 5.2(5.1); N, 18.2(18.5); for yellow brown [Ni(Ampip)$_2$]·H_2O: C, 48.2(47.9); H, 4.8(5.7); N, 22.9(23.3). The magnetic susceptibilities are as follows: [Ni(HAmpip)Cl]Cl·EtOH, 2.6 B.M., [Ni(Ampip)OAc], 0.0 B.M. and [Ni(Ampip)$_2$]·H_2O, 3.2 B.M.

2.2. Physical and spectroscopic methods

National Chemical Consulting, Inc. of Tenafly, NJ performed partial elemental analyses for two of the complexes and a Carlos Erba 1108 microanalyser at the Universidad de Santiago de Compostela analyzed [Ni(Ampip)OAc]. The magnetic susceptibilities were measured with a Johnson Matthey magnetic susceptibility balance. NMR spectra were obtained with a Varian 300 MHz Gemini spectrometer using $CDCl_3$ as the solvent; the chemical shifts are reported in parts per million downfield from tetramethylsilane. Infrared spectra were recorded with Nicolet 5SXC and Magna 850 FT-IR spectrometers using Nujol mulls between CsI plates; electronic spectra were acquired as Nujol mulls impregnated on filter paper with a Cary 5E spectrometer.

2.3. X-ray data collection, structure solution and refinement

Crystals of [Ni(HAmpip)Cl]Cl and [Ni(Ampip)$_2$] were grown from ethanol and crystals of [Ni(Ampip)OAc]

from acetonitrile, mounted on glass fibers, and used for data collection at room temperature (r.t.) with a Nonius MACH3 diffractometer, Mo Kα, $\lambda = 0.71073$ Å. A semi-empirical absorption correction, ψ-scan, was applied. The structures were solved by direct methods [12], which revealed the position of all non-hydrogen atoms, and refined by a full-matrix least-squares procedure using anisotropic displacement parameters [13]. The C19, C110 and C111 (and C29, C210 and C211) atoms of the piperidine rings of [Ni(Ampip)$_2$] are disordered over two positions; the occupancy factor for each was refined resulting in a value of 0.793(6) for C19A, C110A and C111A. The hydrogens attached to nitrogens were located from difference Fourier maps and refined isotropically. The remaining hydrogens were located in their calculated positions (C–H 0.93–0.97 Å) and refined using a riding model. Atomic scattering factors are from 'International Tables for Crystallography' [14] and molecular graphics are from PLATON98 [15]. Relevant crystallographic information is summarized in Table 1.

3. Results and discussion

The bond distances for the nickel(II) complexes are given in Table 2 and their bond angles in Table 3. Table 4 shows the mean plane data and angles between planes and Table 5 lists the hydrogen bonding interactions. Figs. 2–4 show the ORTEP drawings of [Ni(HAmpip)Cl]Cl, [Ni(Ampip)OAc], and [Ni(Ampip)$_2$], respectively.

3.1. Crystal structure of [Ni(HAmpip)Cl]Cl

In [Ni(HAmpip)Cl]Cl, Fig. 2, coordination of tridentate HAmpip is via the pyridyl nitrogen, imine nitrogen and thione sulfur. As is most often the case with this type of NNS tridentate ligand [16–18], the imine nitrogen coordinates with a shorter Ni–N distance than the ring nitrogen and both are shorter than the Ni–S distance, Table 2. The two *trans* angles, S1–Ni1–N11 and Cl1–Ni1–N12, are $>170°$, Table 3, the *cis* angles range from 83.49(12)° to 96.82(9)° and the N11–N12–S1–Cl1 has minimal deviation from a plane, Table 4, all of which indicate an approximately square arrangement of the four donor atoms. The thiosemicarbazone moiety is nearly co-planar with the coordinate plane.

Coordination of neutral HAmpip does not cause large changes in its bond distances since the uncoordinated HAmpip is in the bifurcated *E′* form, Fig. 1, in which the hydrogen is located on the imine nitrogen [9], the same position as nickel(II) in [Ni(Ampip)Cl]Cl. For example, the S1–C17 bond distance is unchanged and C16–N12 is 1.320(4) Å compared with 1.300(3) in HAmpip. Among the other bonds of the thiosemicarbazone moiety the largest change is exhibited by C17–N14, 1.358(3) in HAmpip to 1.320(5) Å) in [Ni(Ampip)Cl]Cl. The angle N13–C17–N14 shows the largest difference on coordination, 115.2(2)° in HAmpip and 120.0(3)° in [Ni(Ampip)Cl]Cl, but all other angles except C16–N12–N13, which is unchanged, increase or decrease by as much as 3°–4°. H13A and H15B interact with a Cl2 ion (Table 5); the two N···Cl non-bonding distances and the N–H···Cl angles are similar. The

other NH_2 hydrogen, H15A, hydrogen bonds to a different Cl2 ion with similar parameters to the above two interactions.

3.2. Crystal structure of [Ni(Ampip)OAc]

The crystal structure, Fig. 3, shows Ampip coordinated in the expected NNS tridentate fashion (i.e. the thiosemicarbazone moiety becomes conjugated) and a monodentate acetato ligand, which is the same stoichiometry found for [Ni(Am4M)OAc], where Am4M is the anion of 2-pyridineformamide N(4)-methylthiosemicarbazone [8]. The Ni1–O11 bond distance in [Ni(Ampi-

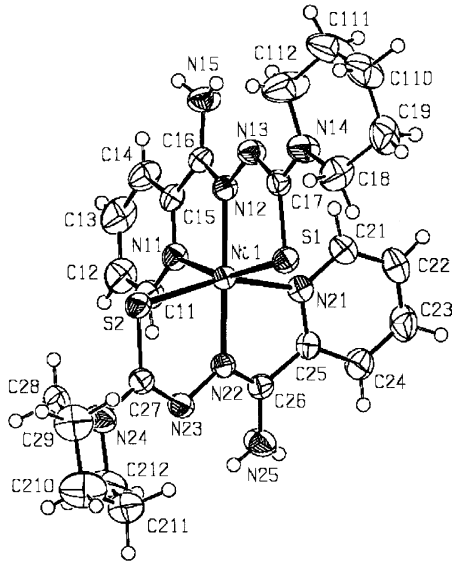

Fig. 4. ORTEP plot of [Ni(Ampip)$_2$] at 50% probability.

p)OAc], 1.871(3) Å, is marginally shorter than 1.888(3) Å for [Ni(Am4M)OAc]. The remaining metal–ligand bonds in the two complexes, as well as their thiosemicarbazone moieties, are within twice their combined e.s.d. values, and most are even more similar. Interestingly, N13–C17 is shorter than C16–N12 in [Ni(Ampip)OAc], but in [Ni(Am4M)OAc] N13–C17 is marginally longer than C16–N12. This difference is the likely cause of confusion in the thiosemicarbazone literature concerning the infrared assignment of ν(C=N) in metal complexes in which a shift to both higher and lower frequencies compared with the uncomplexed thiosemicarbazone has often been reported. Since crystal structures of a number of uncomplexed thiosemicarbazones and their metal complexes have recently been reported [19], it is now known that the C16=N12 bond distance is often somewhat longer or unchanged in the complexes. This suggests that a band in the spectrum of a complex at higher energy than in the uncomplexed thiosemicarbazone is more likely due to ν(N13=C17). Compared with HAmpip [9] [Ni(Ampip)OAc] has a longer S1–C17 bond, N13–C17 is $>0.040(6)$ Å shorter and C16–N12 is only marginally longer.

The anionic Ampip ligand in [Ni(Ampip)OAc] has a N11–Ni1–S1 *trans* angle of 168.82(14)° compared with 170.91(9)° for the neutral ligand in [Ni(HAmpip)Cl]Cl. The other angles about the nickel(II) ions in these complexes show smaller differences, but Ni1–S1–C17 and Ni1–N12–N13 are quite different for the two complexes, Table 2. A comparison of the neutral thiosemicarbazone ligand in [Ni(HAmpip)Cl]Cl to the anionic thiosemicarbazone ligand [Ni(Ampip)OAc] shows that the following angles C16–N12–N13, N12–N13–C17 and N13–C17–S1 are most different. The four donor atoms, N11–N12–S1–O11, in [Ni(Ampip)OAc] are nearly planar and nickel(II) is 0.0237(21) Å below the mean plane which is nearly twice the distance of 0.143(16) Å [Ni(Am4M)OAc] [8]. As is common for coordinated heterocyclic thiosemicarbazone ligands [1–3], the thiosemicarbazone moiety and pyridine ring are nearly co-planar with N11–N12–S1–O11, but the mean plane of the acetato ligand is 80.44(18)° out of the coordination plane. The distances and angles are listed in Table 5 for the hydrogen bonding interaction N15–H15A···N13, an intraligand hydrogen bond which is not found in HAmpip [9] or in complexes of HAmpip with other metal ions [9]. However, N15–H15A···N13 and the intermolecular N15–H15B···O12′ interaction are very similar to the interactions found for [Ni(Am4M)OAc] [8].

3.3. Crystal structure of [Ni(Ampip)$_2$]

The ORTEP plot for the approximately octahedral [Ni(Ampip)$_2$] is shown in Fig. 4. The coordination of the two ligands is meridonal due to the strong tendency toward planarity by heterocyclic thiosemicarbazones. As expected for a six-coordinate complex compared with four-coordinate complex, the donor atom bond distances to nickel(II) are all significantly longer than found for [Ni(Ampip)OAc]. The distortion from octahedral symmetry is indicated by the *trans* N11–Ni1–S1 and N21–Ni–S2 angles of approximately 158°, Table 3.

The hydrogen bonding interactions of the two ligands in [Ni(Ampip)$_2$] have similar parameters. The N15–H15B···N13 and N25–H25A···N23 intraligand interactions are identical to that discussed for [Ni(Ampip)OAc]. The other NH_2 hydrogen for each ligand has an intermolecular hydrogen bond to a thiolato sulfur of the other ligand on an adjacent molecule (Table 5). The mean planes of the coordinated thiosemicarbazones have small deviations from planarity although the imine nitrogens are substantially out of the plane. Table 4 shows deviations from planarity for the coordination

planes, N11–N12–S1–N22 and N21–N22–S2–N12, and for each plane the imine nitrogens, N22 and N12, respectively, show the greatest deviation from planarity.

3.4. Spectral and physical properties

The magnetic susceptibilities are consistent with monomeric complexes and suggest a distorted octahedral structure for [Ni(Ampip)$_2$], a planar structure for [Ni(Ampip)OAc] and a tetrahedrally distorted planar structure for [Ni(HAmpip)Cl]Cl. The latter complex could be a mixture of [Ni(HAmpip)Cl]Cl and five-coordinate [Ni(HAmpip)Cl$_2$].

The infrared bands most useful for determining the mode of coordination by HAmpip (and Ampip) are shown in Table 6. The ν(C=N) band of HAmpip at 1577 cm^{-1} undergoes shifts to lower frequencies in the spectra of the nickel complexes indicating coordination of the imine nitrogen [20]. A second band, assignable to ν(N=C) on loss of the hydrazinic hydrogen, is often observed in the 1585 cm^{-1} region of the complexes' spectra on coordination of an anionic thiosemicarbazone. Additional evidence for coordination of the imine nitrogen is the presence of ν(Ni–N) bands in the 425–455 cm^{-1} range [21]. The spectrum of HAmpip shows the thioamide IV band, which possesses considerable contribution from ν(C–S), at 823 cm^{-1}, and is found at lower energy (>60 cm^{-1}) on coordination of Ampip, but to a lesser extent for [Ni(HAmpip)Cl]Cl. The ν(Ni–S) bands are in the 355 cm^{-1} region [22]. Coordination of the pyridyl nitrogen is indicated by a 10–24 cm^{-1} shift to higher wave number for the ring in-plane deformation, ρ(py), which is at 594 cm^{-1} in the spectrum of HAmpip. The ν(M–N) bands for the pyridyl nitrogen are assigned in the 230 cm^{-1} region, ν(Ni–Cl) at 322 cm^{-1} for [Ni(HAmpip)Cl]Cl and ν(Ni–O) at 482 cm^{-1} for [Ni(Ampip)OAc].

The absorption maxima of the electronic spectra of the three nickel(II) complexes and HAmpip are shown in Table 7. The higher energy $\pi\rightarrow\pi^*$ bands are omitted because their energy is unaffected by complexation. Since HAmpip is primarily the bifurcated *E′* isomer (other isomeric forms present in small amounts are *Z* and *E* with respect to the imine bond) [9], we assign the band at 32340 cm^{-1} to $n\rightarrow\pi^*$ transitions for both the pyridine ring and imine function of the thiosemicarbazone moiety. The two lower energy bands result from $n\rightarrow\pi^*$ transitions associated with the thioamide portion of the thiosemicarbazone moiety. The broad band at 31 350 cm^{-1} in the spectrum of [Ni(HAmpip)Cl]Cl includes the Cl$\rightarrow$Ni(II) charge transfer band [23] and the thioamide $n\rightarrow\pi^*$ intraligand bands are not shifted to as high an energy on coordination of the thione sulfur. Bands in the 20 000–23 000 cm^{-1} are due to S$\rightarrow$Ni(II) charge transfer transitions and are primarily responsible for the brown color of these nickel(II) complexes. The S$\rightarrow$Ni(II) transition at 22 920 cm^{-1} in the spectrum of [Ni(Ampip)$_2$] masks the $^3A_{2g}\rightarrow{}^3T_{1g}$(P) transition.

The crystal structure of [Ni(Ampip)$_2$] shows distortion from octahedral symmetry {i.e. the angle between the imine nitrogens is 169.12(7)°}. However, calculation of ligand field parameters [24] by assigning the band at 7830 cm^{-1} to $^3A_{1g}\rightarrow{}^3T_{2g}$ and 11 330 cm^{-1} as $^3A_{1g}\rightarrow{}^3T_{1g}$(F) yields 17 640 cm^{-1} (presumably obscured by the charge transfer band at 22 920 cm^{-1}) for $^3A_{1g}\rightarrow{}^3T_{1g}$(P), Dq = 783 cm^{-1} and B = 365 cm^{-1}. The Dq and B values are higher and lower, respectively, than found for bis(ligand)nickel(II) complexes prepared with 2-formylpyridine and 2-acetylpyridine thiosemicarbazones [25]. The crystal structure of [Ni(HAmpip)Cl]Cl showed it to be a nearly planar arrangement of the four donor atoms about Ni(II), Table 4. However, the NIR spectrum shows bands below 10 000 cm^{-1}, which are not consistent with a planar structure, and suggests that this solid is a mixture of [Ni(HAmpip)Cl]Cl and five-coordinate [Ni(HAmpip)Cl$_2$]. The number of absorption

bands in the NIR region as well as the visible region is consistent with the presence of the latter.

The versatility of the heterocyclic thiosemicarbazones in forming a number of complexes having different coordination numbers and stereochemistry with the same metal ion has again been demonstrated. The present nickel(II) complexes involve coordination of the neutral HAmpip and anionic Ampip to produce five- and six-coordinate (and very likely five-coordinate) complexes.

4. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as CCDC-153294 for [Ni(HAmpip)Cl]Cl, CCDC-153295 for [Ni(Ampip)(OAc)] and CCDC-153296 for [Ni(Ampip)$_2$]. Copies of available material can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK, (fax: +44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Abstract

The synthesis of the substituted silyl cyclopentadiene ligand $(C_5H_5)Si(CH_3)_2(C_6H_5)$ ($Cp^{Si}H$) (**1**) is described. Deprotonation of (**1**) gives ($Cp^{Si}Li$) (**2**) which reacts with $CrCl_3$ to produce the chloro-bridged complex $[(\eta^5\text{-}Cp^{Si})Cr(\mu\text{-}Cl)Cl]_2$ (**3**). Single-crystal X-ray structure analysis reveals that a centrosymmetric dimer exists in the solid state. When activated with methylaluminoxane (MAO), complex (**3**) exhibits several interesting features as a catalyst for ethylene polymerization. With the help of a semi-empirical MO calculation, a cationic sandwich intermediate structure in the catalytic process was proposed. © 2002 Elsevier Science Ltd. All rights reserved.

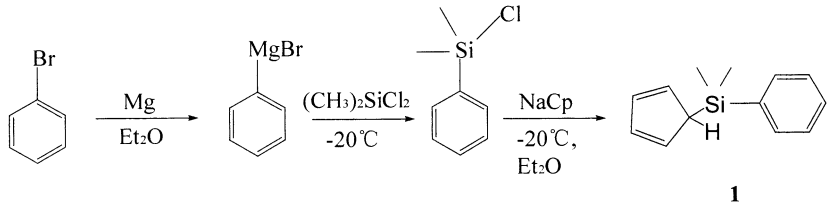
1. Introduction

The area of homogeneous metallocene-catalyzed olefin polymerization recently has received much attention, in part because ligand modification is an effective means of optimizing catalyst activity as well as polymer properties such as molecular weight, stereoregularity and microstructure, etc. [1–7]. Our most recent efforts were in this area [8,9].

Chromium has played a prominent role among the transition metals that catalyze the polymerization of olefins [10–12]. Recently, a class of chromium-based homogeneous catalysts has been synthesized [13–15], and some of them are cationic species, which are somewhat similar to the cationic Group 4 zirconocene complexes [16]. In some cationic zirconocene complexes, evidence for the coordination of a phenyl group to the zirconium center via agostic C–H–M interaction was obtained by NMR spectroscopy [17]. It is also noticeable that the active centers in homogeneous Kaminsky catalyst systems are cationic [18–20], and chromium proved easy to coordinate phenyl [21,22]. Therefore, we prepared a novel chromium-based paramagnetic homogeneous catalyst that bears a phenyl ring bound to the Cp group via a silicon bridge in the hope that the cation produced by methylaluminoxane (MAO) might give higher activity of polyethylene, which could be regarded as evidence for phenyl–chromium interactions.

2. Results and discussion



2.1. Ligand synthesis

Grignard reaction of Mg with bromobenzene in Et_2O followed by addition to $(CH_3)_2SiCl_2$ gives $(CH_3)_2SiCl(C_6H_5)$ as a light yellow oil in near quantitative yield (Scheme 1). Its isolation is possible, but not necessary since in situ addition of either NaCp or LiCp in Et_2O produces a yellow solution. This yellow solution

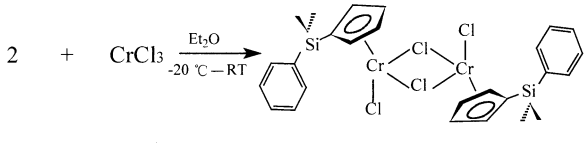
Scheme 1.

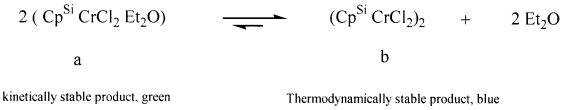
was hydrolyzed, extracted by Et_2O, and then purified by column chromatography. The major yellow oil is the desired substituted cyclopentadiene $(C_5H_5)Si(CH_3)_2(C_6H_5)$ ($Cp^{Si}H$) (**1**) as identified by ^1H NMR, IR spectra and MS (Scheme 1).



The ^1H NMR of (**1**) displays two broadened Cp ring resonances and we attribute this to rapid sigmatropic shifts of either the methine proton, the silyl group or both. Sigmatropic rearrangements are well known in related silyl substituted cyclopentadienyl systems [23,24]. Compound (**1**) is readily deprotonated by ^{n}BuLi in hexane to give the base-free lithium salt $Li(C_5H_4)Si(CH_3)_2(C_6H_5)$ (**2**) ($Cp^{Si}Li$) in good yield as an air sensitive white solid that is insoluble in aliphatic and aromatic hydrocarbons and soluble in ethers (Eq. (1)). Exposure of (**2**) to moisture produces (**1**) as observed by ^1H NMR.

(1)

2.2. Chromium complex synthesis



The reaction of 1 equiv. of (**2**) with 1 equiv. of $CrCl_3$ in Et_2O produces $[(\eta^5\text{-}Cp^{Si})Cr(\mu\text{-}Cl)Cl]_2$ (**3**) which is extracted and recrystallized in CH_2Cl_2 with high yield as an air sensitive dark blue crystal that is soluble in most common organic solvents (Eq. (2)). Complex (**3**) was identified by IR spectra, elemental analysis, MS, ESR and single-crystal X-ray analysis. Since complex (**3**) is paramagnetic, it cannot be identified by ^1H NMR.

3

(2)

In the process of the above reaction, we observed that the solution is firstly dark green, then gradually turns to green-blue, and finally becomes blue. Only this blue solution gives the dark blue crystals that can be identified as dimeric by X-ray diffraction. We also tried to isolate the green intermediate product, but it was easily lost Et_2O in vacuum so that it could not be obtained. A similar process was described by S. K. Noh [25], so we speculate that the following equilibrium may exist (Eq. (3)).

(3)

This hypothesis is further supported by the observation that if in the reaction there are other coordinatively stronger reagents such as PPh_3 or pyridine, the solution color is always green and we cannot obtain the dark blue crystals for X-ray diffraction.

2.3. Study of electron spin resonance

The ESR spectrum of (**3**) displayed in Fig. 1 shows that complex (**3**) has unpaired electrons and reveals that Cr (III) is located at a highly symmetric site.

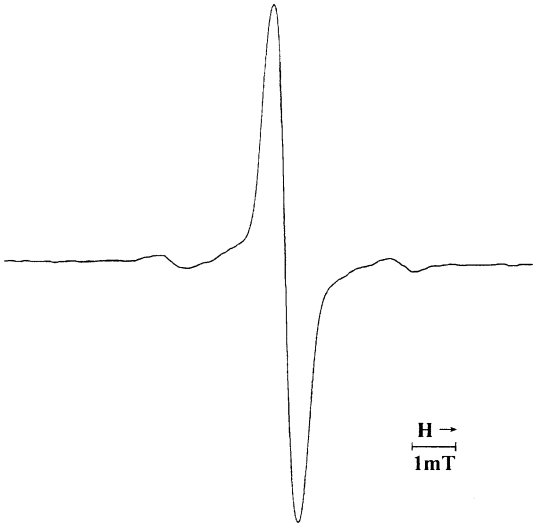


Fig. 1. ESR spectrum of complex (**3**) in toluene solution at room temperature; $g = 1.986$; microwave frequency: 9.77 GHz; microwave power: 20 dB, 2 mW; cavity: TE 104.

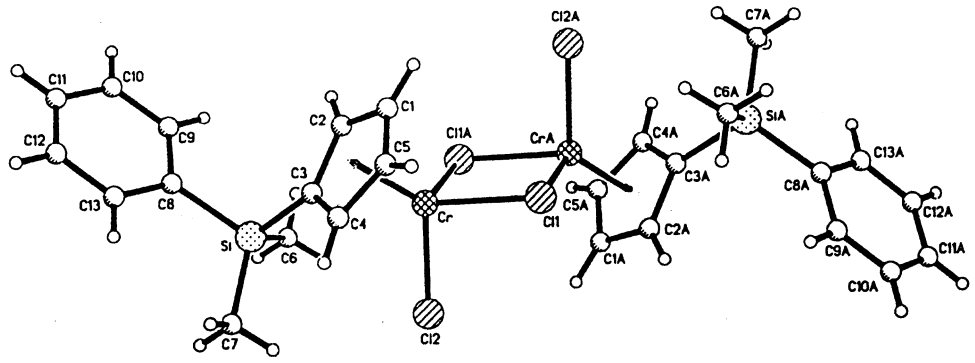

Fig. 2. Molecular structure of (**3**) with the atom-numbering scheme.

2.4. X-ray crystal structure analysis

The molecular structure of (**3**) is shown in Fig. 2. Selected bond distances and angles are given in Table 1. The complex (**3**) is a dimer located at a crystallographic inversion center. Each chromium atom is bonded to one Cp^{Si} ligand, one terminal chlorine atom and two bridging chlorine atoms, thus completing the familiar pseudooctahedral coordination environment of a three-legged piano stool. The Cp ring is bonded to the Cr atom in the η^5 manner and can be thought of as a tridentate ligand occupying one of the trigonal faces of the octahedron. This view is certainly consistent with its ESR behavior. Each chromium center has a 15-electron configuration, so it is slightly electronic unsaturated. The Cr–Cr (1A) distance of 3.336 Å is too long to form a metal–metal bond [25–27]. There are no short intermolecular contacts between dimers. The distance from the chromium to the Cp ring center is 1.861 Å. The angle between the Cp ring plane and the phenyl ring plane is 78.7°

2.5. Polymerization

In order to further our understanding of the structure of complex (**3**), it was tested for catalytic activity in ethylene polymerization. Upon activation with MAO, (**3**) shows moderate catalytic activity. The polymerization results are summarized in Table 2. As can be seen from the results, (**3**) shows several interesting features as a catalyst for ethylene polymerization. First, a low Al:Cr ratio (500:1) is needed to obtain full activity in contrast to the value of approximately 10^4:1 (Al:Zr) reported for the MAO-activated ansa-zirconocene catalysts, and this is similar to the amino-substituted cyclopentadienyl chromium catalyst [28]. Second, the catalytic activity of (**3**) does not decrease very much when the Al: Cr ratio changes from 500 to 1000. Third, the catalytic activity of (**3**) and the molecular weights of polyethylene are much higher than the reported chromium-based cationic half-sandwich catalysts [13]. It is obvious that these observed features could be explained on the basis of phenyl–chromium interactions, which could weaken the interaction between the cationic chromium center and the anionic cocatalyst and, therefore, efficiently prevent the active catalyst from bimolecular deactivation. On the other hand, this interaction could effectively lower the rate of chain termination by β-H elimination. So less MAO is required to keep the catalyst in an active state and a relatively long polyethylene chain can be formed. As a result, the catalytic activity and lifetime of the catalyst increase, and the

molecular weight of polyethylene increases correspondingly. In a word, there must be a sterically crowded environment around the metal center [8,9].

For understanding the catalytic process we calculated the cationic intermediate structure by a semi-empirical ZINDO/1 MO method. Two stable structures were obtained by geometry optimization (Fig. 3). The energy of the sandwich structure was 80.4 kcal mol^{-1} lower than that of the half-sandwich structure, which means the sandwich is so stable that it is the only possible structure in the catalytic process.

So we speculate that in the process of polymerization the dimer (**3**) first depolymerizes and then loses a chlorine to form a cationic sandwich complex in which the phenyl coordinates to the Cr(III) in the presence of MAO. This proposed structure is consistent with the experimental results. This process is illustrated in Scheme 2.

3. Experimental

3.1. General procedures and material

All reactions with moisture- and air-sensitive compounds were carried out under dry argon atmosphere (ultra-high purity) using standard Schlenk techniques. All reagents are commercially available and were used as received unless otherwise stated.

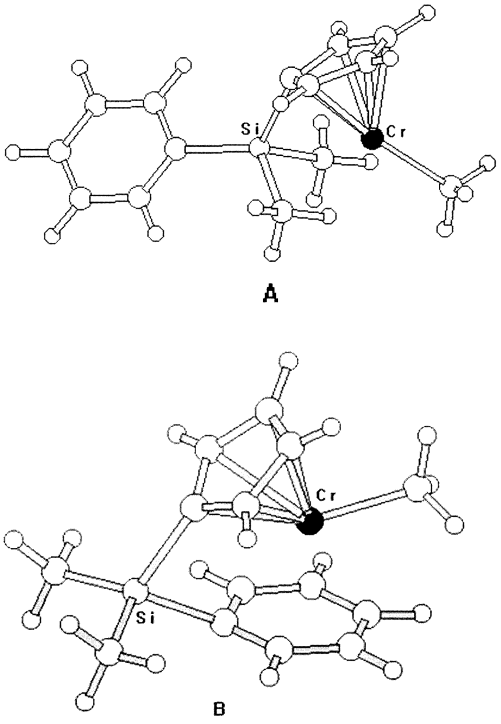

Fig. 3. Geometrically optimized structures of the cationic intermediate in the catalytic process by semi-empirical ZINDO/1 MO method. A: half-sandwich structure; B: sandwich structure.

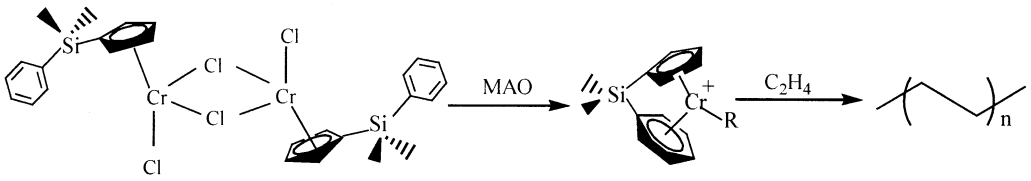

Tetrahydrofuran (THF), diethyl ether (Et_2O) and toluene were refluxed over sodium benzophenone ketyl and distilled before use under nitrogen. Hexane and dichloromethane (CH_2Cl_2) were refluxed and distilled from CaH_2 under nitrogen. $CrCl_3$ was prepared according to a published route [29,30]. Polymerization grade ethylene was further purified by passage through columns of 10 Å molecular sieves and MnO. Methylaluminoxane (MAO, 10 wt.% solution in toluene, M_n = 800 g mol^{-1}, Al = 5.3 wt.%) was purchased from Witco. ^{n}BuLi (1.6 M in hexanes) was purchased from Aldrich. Elemental analyses were performed on American PE-240 C elemental analyzer at the Center of Analysis and Test of Jilin University. The MS was obtained by Finningan GC–MS–DS MAT4510. The ESR spectrum was acquired by Bruker ER2000 EPR. NMR spectra were recorded on a Varian Unity-400 spectrometer and the X-ray structure on a Siemens P4 diffractometer. Viscosity-average molecular weights of the polyethylene were determined in decahydronaphthalene at 135 °C using a Schott Gerate model AVS/T2 Ubbelohde viscosimeter. Melting transition temperatures (T_m) of the polyethylene were determined by DSC (Du Pont 910 differential scanning calorimeter) at a heating rate of 10 °C min^{-1}.

3.2. Synthesis of $Cp^{Si}H$ (*1*)

To a solution of Me_2SiCl_2 (8ml, 66.33 mmol) in Et_2O (40 ml) was added dropwise a solution of PhMgBr (50 ml, 1.00 N, 50.03 mmol) in Et_2O (10 ml) at −50 °C and stirred for 1 h at room temperature (r.t.). Then solvent and excess Me_2SiCl_2 were removed in vacuo. The residue was redissolved in Et_2O (40 ml), and CpNa (26 ml, 1.1919 N, 49.9 mmol) in THF was added dropwise slowly to the above solution at −78 °C over 40 min, and stirred at r.t. for 5–6 h to give a pale yellow solution. The reaction was hydrolyzed and was extracted with Et_2O. The Et_2O layer was dried with $MgSO_4$. After filtration, the solvent was evaporated under vacuum and left behind a yellow oil. The product was purified by column chromatogram over silica gel (hexane-CH_2Cl_2, 3:1). Yield 83%. ^{1}H NMR ($CDCl_3$): δ 0.255 (s, 6H, Si $(CH_3)_2$); 3.135(s, 1/3H, methine); 3.676(br, 2/3H, methine); 6.580–6.696(br, 4H, Cp ring); 7.425–7.645(m, 5H, phenyl). IR (KBr): 3070.12(m), 2960.20(m), 1625.70(m), 1427.07(w), 1253.50(s), 1114.65(m), 1062.59(w), 975.80(m), 9530.85(m), 829.24(s), 802.24(s), 732.82(s), 700.03(s). 3.3. Synthesis of $Cp^{Si}Li$(*2*)

^{n}BuLi (14.5 ml) (1.6 M, 23.2 mmol) was injected slowly into a solution of $Cp^{Si}H$ (4.5043 g, 22.48 mmol)

Scheme 2.

in hexane (30 ml) at −78 °C. The reaction was allowed to warm to r.t. and left stirring for 5 h. A white precipitate was observed. The precipitate was cannula filtered, washed with 2 × 30 ml of hexane and dried under vacuum. Yield 70%.

3.4. Synthesis of $[(\eta^5\text{-}Cp^{Si})Cr(\mu\text{-}Cl)Cl]_2$ (3)

$Cp^{Si}Li$ powder (0.6367 g, 3.1 mmol), $CrCl_3$ powder (0.4946 g, 3.1 mmol) and 30 ml Et_2O was added to a dry 100 ml Schlenk flask under argon. The suspension was stirred at r.t. for 15 days. In this process the colorless solution gradually turns into green, then green–blue, and finally blue. The precipitate was filtered off and the solvent was removed in vacuo. The residue was extracted three times with CH_2Cl_2. The combined fractions were filtered and the solution was concentrated in vacuo. Recrystallization at −10 °C afforded (**3**) as a dark blue crystal. Yield 67.4%. IR: 3093.26(w), 3014.19(w), 2960.20(w), 2915.84(w), 1635.34(m), 1425.14(w), 1402.00(w), 1249.65(m), 1172.51(m), 1110.80(m), 1014.37(m), 833.10(s), 784.89(m), 736.67(m), 700.03(m). 3.5. X-ray structure determination

Data of (**3**) were collected on a Siemens P4 diffractometer with a graphite monochromator using Mo Kα radiation. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. All calculations were performed using SHELX-93 [31]. Hydrogen atoms were treated as idealized contributions. Crystallographic data and parameters are summarized in Table 3.

3.6. Polymerizations

A dry 250 ml steel reactor equipped with a magnetic stirrer was evacuated and pressurized with ethylene to 1.5 atm. Toluene and an appropriate amount of MAO were added to reactor through a septum port via syringe. After the solution was saturated with ethylene for 30 min, a solution of catalyst (1.5 μmol) in toluene was injected (total volume of the polymerization solution is 50 ml after the addition of catalyst). The vessel was repressurized to the required pressure with ethylene as soon as the catalyst was injected and the pressure was maintained by continuously feeding monomer. After the mixture was stirred for the desired reaction time, the reactor was vented and the polymerization was terminated by injecting acidified methanol [HCl (3 M)–methanol = 1:1]. The polymer was stirred in acidified methanol overnight, washed with water and methanol, dried in vacuo at 60 °C.

3.7. Semi-empirical MO calculation

The cationic intermediate structure in the catalytic process was calculated by a semi-empirical ZINDO/1 MO method of the HYPERCHEM 6.0 program [32]. The parameters are the following, Total charge: 1; spin multiplicity: 4; convergence limit: 0.01; RMS gradient of: 0.01 kcal mol^{-1}.

4. Supplementary material

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 163491. Copies of the data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Synthesis and characterization of bidentate organotin Lewis acid derivatives containing bis(pyrazol-1-yl)alkanes: X-ray crystal structure of $PhBr_2(L)SnCH_2SnPhBr_2$ (L = bis(4-chloropyrazol-1-yl)methane)

Received 31 October 2001; accepted 9 January 2002

Abstract

The reaction between bis(dibromophenylstannyl)methane, $[CH_2(SnPhBr_2)_2]$, with bis(pyrazol-1-yl)alkanes, $[(CH_2)_nPz_2]$ ($n = 1$ or 2; Pz = substituted pyrazole) in a 1:1 or 1:2 ratio yields only 1:1 adducts of $PhBr_2[(CH_2)_nPz_2]SnCH_2SnPhBr_2$, which have been confirmed by elemental analysis, ^1H NMR and IR spectroscopy. The electronic and steric characteristics of substituents on the pyrazole rings markedly influence the donating ability of bis(pyrazol-1-yl)alkanes to the bidentate organotin Lewis acid acceptor. The investigations on the reaction of the adducts with DMSO and NMR spectra of the adducts show the weak interactions between ligands and the bidentate organotin Lewis acid acceptor. X-Ray analysis of $PhBr_2(CH_2(4\text{-}ClPz)_2)SnCH_2SnPhBr_2$ showed that bis(4-chloropyrazol-1-yl)methane acts as a chelating bidentate ligand to only one tin atom. © 2002 Elsevier Science Ltd. Keywords: Bis(pyrazol-1-yl)alkane; Organotin(IV); X-ray structures

1. Introduction

The coordination behavior of organotin(IV) toward poly(pyrazol-1-yl)borate [1] ligands has been extensively investigated in recent years owing to the antitumor activity of some related organotin derivatives containing N-donor ligands. A number of organotin(IV) complexes containing poly(pyrazol-1-yl)borate ligands have been synthesized and characterized [2–8]. In these complexes, the coordinate geometry around the central tin atom depends on the steric and electronic properties of poly(pyrazol-1-yl)borate ligands, which can be easily controlled by changing the substituents on the pyrazole ring [1]. Some organotin(IV) complexes containing poly(pyrazol-1-yl)borate ligands have also shown interesting structural characteristics and reactivities [9–11]. Poly(pyrazol-1-yl)alkanes, a kind of isoelectronic and isosteric ligands with poly(pyrazol-1-yl)borate, have also been found to act as good donors to tin and organotin(IV) acceptors. The interactions between poly(pyrazol-1-yl)alkanes and tin or organotin(IV) acceptors have also been investigated in recent years [12–18]. However, in these known organotin(IV) derivatives with scorpionate ligands only one monodentate Lewis acid center acts as the acceptor.

At the present time, we have become interested in the coordination chemistry of multidentate Lewis acids, such as multidentate organotin(IV) compounds, in which Lewis acid tin centers are separated by the methylene spacer. These compounds have been found to be good acceptor molecules to heteroatom ligands [19–22]. Some different coordination behaviors have been observed in these complexes formed by multidentate organotin(IV) Lewis acids with nitrogen hetero-

PII: S0277-5387(02)00863-X

cyclic ligands, such as pyridine, pyrazole and pyridazine [23]. But, there is no report on the interactions of multidentate organotin Lewis acids with the popular multidentate scorpionate ligands. In the present paper, we report the results of the reactions between the bidentate organotin Lewis acid with bis(pyrazol-1-yl)alkanes.

2. Experimental

All solvents were dried by standard methods and distilled prior to use, and all reactions related to organotin complexes were carried out under moisture-free conditions. Melting points were measured with a PHMK melting-point apparatus and were uncorrected. NMR spectra were recorded on a Bruker AC-P-200 spectrometer. The chemical shifts were reported in ppm with respect to the references. IR spectral data were obtained from a Nicolet FT-IR 170SX spectrometer using KBr discs. Elemental analyses were carried out on a Perkin–Elmer 240C analyser. Bis(dibromophenylstannyl)methane, $CH_2(SnPhBr_2)_2$ [24], bis(pyrazol-1-yl)-methane, CH_2Pz_2 [25], bis(4-halopyrazol-1-yl)methanes, $CH_2(4\text{-}XPz)_2$ and bis(3,5-dimethyl-4-chloropyrazol-1-yl)methanes, $CH_2(3,5\text{-}Me_2\text{-}4\text{-}XPz)_2$ [26], bis(3,4,5-trimethylpyrazol-1-yl)methane, $CH_2(3,4,5\text{-}Me_3Pz)_2$ [27], bis(3,5-dimethylpyrazol-1-yl)methane, $CH_2(3,5\text{-}Me_2Pz)_2$ and bis(3,5-dimethylpyrazol-1-yl)ethane, $(CH_2)_2(3,5\text{-}Me_2Pz)_2$ [28], bis(4-nitropyrazol-1-yl)methane, $CH_2(4\text{-}NO_2Pz)_2$ [29] and 3,5-dimethyl-4-benzylpyrazole [30] were prepared according to the literature methods.

2.1. Preparation of bis(3,5-dimethyl-4-benzylpyrazole)methane, $CH_2(3,5\text{-}Me_2\text{-}4\text{-}BzPz)_2$

This ligand was obtained by the similar method used for bis(pyrazol-1-yl)methane [25]. Yield: 75%; m.p. 174–175 °C. ν_{max} (cm^{-1}): 1576.3 s (pyrazole ring). ^1H NMR ($CDCl_3$), δ: 2.08 (6H, s, CH_3), 2.35 (6H, s, CH_3), 3.67 (4H, s, $PhCH_2$), 6.19 (2H, S, CH_2Pz), 7.02–7.20 (10H, m, C_6H_5). *Anal*. Calc. for $C_{25}H_{28}N_4$: C, 78.13; H, 7.29; N, 14.58. Found: C, 78.23; H, 7.15; N, 14.65%.

2.2. Preparation of $PhBr_2(CH_2Pz_2)SnCH_2SnBr_2Ph$ (**1**)

A solution of $CH_2(SnPhBr_2)_2$ (0.2 mmol) in 10 ml ether was added to a stirred solution of CH_2Pz_2 (0.2 mmol) in 5 ml CH_2Cl_2. The reaction mixture was continuously stirred for 2 h at room temperature (r.t.), and then the solvent was removed under a reduced pressure. The residue was recrystallized in CH_2Cl_2–hexane at −18 °C to yield white crystals of **1**. Yield: 70%; m.p. 185–187 °C. ν_{max} (cm^{-1}): 1516.0 s (pyrazole ring) and 454.1 m (Sn–C). ^1H NMR (CD_3COCD_3): δ 7.93–7.90 (m, 4H, H^3 and H^5 of pyrazole), 7.51–7.38 (m, 10H, C_6H_5), 6.41 (s, 2H, H^4 of pyrazole), 6.28 (s, 2H, CH_2Pz), 3.17 (s, 2H, CH_2Sn). *Anal*. Calc. for $C_{20}H_{20}Br_4N_4Sn_2\cdot 1/2CH_2Cl_2$: C, 26.84; H, 2.29; N, 6.11. Found: C, 26.73; H, 2.45; N, 6.11%. The same product was obtained when $CH_2(SnPhBr_2)_2$ was reacted with CH_2Pz_2 in a 1: 2 ratio.

2.3. Preparation of $PhBr_2(CH_2(4\text{-}ClPz)_2)SnCH_2SnPhBr_2$ (**2**)

This compound was obtained similarly using $CH_2(SnPhBr_2)_2$ and $CH_2(4\text{-}ClPz)_2$ as described above for **1**. Yield: 62%; m.p. 133–135 °C. ν_{max} (cm^{-1}): 1571.6 s (pyrazole ring) and 452.8 m (Sn–C). ^1H NMR ($CDCl_3$): δ 7.63–7.46 (m, 14H, H^3 and H^5 of pyrazole and C_6H_5), 6.17 (s, 2H, CH_2Pz), 2.32 (s, 2H, CH_2Sn). *Anal*. Calc. for $C_{20}H_{18}Br_4Cl_2N_4Sn_2$: C, 25.45; H, 1.91; N, 5.94. Found: C, 25.14; H, 1.79; N, 5.80%.

2.4. Preparation of $PhBr_2(CH_2(4\text{-}BrPz)_2)SnCH_2SnPhBr_2$ (**3**)

This compound was obtained similarly using $CH_2(SnPhBr_2)_2$ and $CH_2(4\text{-}BrPz)_2$ as described above for **1**. Yield: 54%; m.p. 135–136 °C. ν_{max} (cm^{-1}): 1569.6 s (pyrazole ring) and 451.8 m (Sn–C). ^1H NMR ($CDCl_3$): δ 7.64, 7.49 (m, m, 6H, 8H, H^3 and H^5 of pyrazole and C_6H_5), 6.18 (s, 2H, CH_2Pz), 2.32 (s, 2H, CH_2Sn). *Anal*. Calc. for $C_{20}H_{18}Br_6N_4Sn_2$: C, 23.26; H, 1.74; N, 5.43. Found: C, 23.12; H, 1.99; N, 5.29%.

2.5. Preparation of $PhBr_2(CH_2(3,5\text{-}Me_2Pz)_2)SnCH_2SnPhBr_2$ (**4**)

This compound was obtained similarly using $CH_2(SnPhBr_2)_2$ and $CH_2(3,5\text{-}Me_2Pz)_2$ as described above for **1**. Yield: 60%; m.p. 46–48 °C. ν_{max} (cm^{-1}): 1557.7 s (pyrazole ring) and 450.3 m (Sn–C). ^1H NMR ($CDCl_3$): δ 7.65, 7.49 (m, m, 4H, 6H, C_6H_5), 6.04 (s, 2H, CH_2Pz), 5.78 (s, 2H, H^4 of pyrazole), 2.42 (s, 2H, CH_2Sn), 2.39, 2.17 (s, s, 6H, 6H, CH_3). *Anal*. Calc. for $C_{24}H_{28}Br_4N_4Sn_2$: C, 30.97; H, 3.01; N, 6.02. Found: C, 31.36; H, 2.69; N, 6.25%.

This compound was also prepared in petroleum ether (60–90 °C). A solution of $CH_2(3,5\text{-}Me_2Pz)_2$ (0.5 mmol) in 40 ml petroleum ether (60–90 °C) was added dropwise to a stirred solution of $CH_2(SnPhBr_2)_2$ (0.25 mmol) in 40 ml petroleum ether (60–90 °C). A white solid began to precipitate when half of the solution of $CH_2(3,5\text{-}Me_2Pz)_2$ was added. After the addition completed, the mixture was stirred for 2 h to complete the reaction. The white precipitate was filtered off and washed, which was confirmed to be 1:1 adduct of **4** by its ^1H NMR spectrum.

2.6. Preparation of $PhBr_2(CH_2(3,4,5\text{-}Me_3Pz)_2)SnCH_2SnPhBr_2$ (5)

A solution of $CH_2(SnPhBr_2)_2$ (0.2 mmol) in 10 ml ether was added to a stirred solution of $CH_2(3,4,5\text{-}Me_3Pz)_2$ (0.2 mmol) in 5 ml CH_2Cl_2. White solids precipitated out immediately. After continuously stirring for 2 h at r.t., the precipitate was filtered off, washed with cold ether and recrystallized in CH_2Cl_2–hexane to yield white crystals of **5**. Yield: 55%; m.p. 132–134 °C. ν_{max} (cm^{-1}): 1570.5 s (pyrazole ring) and 451.6 m (Sn–C). ^1H NMR ($CDCl_3$): δ 7.67, 7.45 (m, m, 4H, 6H, C_6H_5), 6.14 (s, 2H, CH_2Pz), 2.45 (s, 2H, CH_2Sn), 2.34, 2.12, 1.84 (s, s, s, 6H, 6H, 6H, CH_3). ^{119}Sn NMR (CD_3COCD_3): δ −210.3. *Anal*. Calc. for $C_{26}H_{32}Br_4N_4Sn_2$: C, 32.57; H, 3.34; N, 5.85. Found: C, 32.26; H, 3.41; N, 5.52%.

2.7. Preparation of $PhBr_2[(CH_2)_2(3,5\text{-}Me_2Pz)_2]SnCH_2SnPhBr_2$ (6)

This compound was obtained similarly using $CH_2(SnPhBr_2)_2$ and $(CH_2)_2(3,5\text{-}Me_2Pz)_2$ as described above for **5**. Yield: 50%; m.p. 183–185 °C. ν_{max} (cm^{-1}): 1586.0 s (pyrazole ring) and 451.4 m (Sn–C). ^1H NMR (CD_3COCD_3): δ 7.99, 7.35 (m, m, 4H, 6H, C_6H_5), 5.92 (s, 2H, H^4 of pyrazole), 4.50 (s, 4H, CH_2CH_2), 2.23 (s, 2H, CH_2Sn), 2.21, 1.91 (s, s, 6H, 6H, CH_3). *Anal*. Calc. for $C_{25}H_{30}Br_4N_4Sn_2$: C, 31.78; H, 3.18; N, 5.93. Found: C, 31.46; H, 2.96; N, 5.64%.

2.8. Reaction of $CH_2(3,5\text{-}Me_2\text{-}4\text{-}BrPz)_2$, $CH_2(3,5\text{-}Me_2\text{-}4\text{-}ClPz)_2$, $CH_2(4\text{-}NO_2Pz)_2$ or $CH_2(3,5\text{-}Me_2\text{-}4\text{-}BzPz)_2$ with $CH_2(SnPhBr_2)_2$

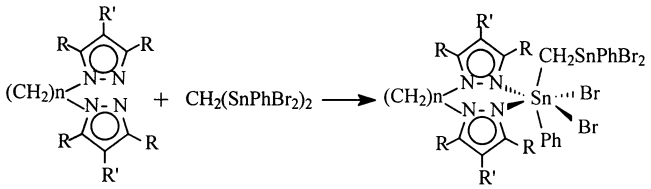
The reaction was carried out as described in the preparation of **1**. The residue was recrystallized in CH_2Cl_2–hexane to yield white crystals, which were confirmed to be the ligands by ^1H NMR spectra.

2.9. Reaction of 1 or 2 with DMSO

A twofold amount of DMSO was added to the stirred solution of **1** (0.2 mmol) or **2** dissolved in 3 ml $CHCl_3$ at r.t., a white oil appeared immediately. After 2 h, the solvent was removed under a reduced pressure, and the residue was recrystallized from CH_2Cl_2 at −20 °C to yield white crystals, which were identified to be $CH_2(SnPhBr_2)_2$.2DMSO by ^1H NMR, elemental analyses and comparison of its IR and ^1H NMR spectra with the literature data [31].

2.10. Structure determination of 2

Crystals of **2** suitable for X-ray analysis were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **2** at r.t. All intensity data were collected on an Enraf–Nonius CAD4 diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). A total of 4298 independent reflections was collected in the range of $2^\circ \leq \theta \leq 25^\circ$ with an ω–2θ scan technique. The correction for empirical absorption was applied to intensity data, and the structure was solved by direct methods and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. All calculations were performed on a PDP11/44 computer using SDP-PLUS program system. A summary of the fundamental crystal data is listed in Table 1.



3. Results and discussion

3.1. Synthesis and properties

The reaction between bis(dibromophenylstannyl)-methane with bis(pyrazol-1-yl)methane, bis(4-chloropyrazol-1-yl)methane, bis(4-bromopyrazol-1-yl)-methane, bis(3,5-dimethylpyrazol-1-yl)methane, bis-(3,4,5-trimethylpyrazol-1-yl)methane or bis(3,5-dimethylpyrazol-1-yl)ethane in a 1:1 or 1:2 ratio yielded only 1:1 adducts (Scheme 1), according to the results of elemental analyses and ^1H NMR data. However, reactions of bis(dibromophenylstannyl)methane with bis(3,5-dimethyl-4-chloropyrazol-1-yl)methane, bis(3,5-dimethyl-4-bromopyrazol-1-yl)methane, bis(4-nitropyrazol-1-yl)methane and bis(3,5-dimethyl-4-benzylpyrazol-1-yl)methane did not take place. We think that the steric and electronic characteristics of the substituents on the pyrazole rings should be responsible for this result. The methyl and benzyl groups increase the steric

Scheme 1. $n = 1$, R = R′ = H (**1**); $n = 1$, R = H, R′ = Cl (**2**); $n = 1$, R = H, R′ = Br (**3**); $n = 1$, R = CH_3, R′ = H (**4**); $n = 1$, R = R′ = CH_3 (**5**); $n = 2$ R = CH_3, R′ = H (**6**).

hindrance of these ligands, and the electron-withdrawing bromine and nitro groups decrease the donating ability of the ligands to the organotin acceptor. All new complexes are insoluble in petroleum ether, slightly soluble in ether, moderately soluble in polar organic solvents such as CH_2Cl_2 and acetone, and they are stable in air.

When **1** or **2** was treated with DMSO, the bis(pyrazol-1-yl)alkane ligand was easily substituted by DMSO, indicating that bis(pyrazol-1-yl)alkane is a weaker donor to bis(dibromophenylstannyl)methane than DMSO.

The ^{1}H NMR spectra of complexes are consistent with the formulation of 1:1 adducts, which exhibit the expected proton signals for 2 equiv. pyrazole rings. The chemical shifts of protons for the ligands in complexes are similar to those of free ligands, being only slightly shifted downfield. Although 2 nonequiv. tin atoms exist in the solid (one case shown in Fig. 1), the ^{119}Sn NMR spectrum of **5** (CD_3COCD_3) determined at r.t. shows only one ^{119}Sn signal, which occurs at −210.3 ppm. This value is comparable to those of reported monodentate organotin Lewis acid derivatives of poly(pyrazol-1-yl)alkanes [12,15], indicating that extensive dissociation of these complexes in solution may exist. In addition, fast-exchanging ligands on the NMR time scale between two tin atoms by dissociation should be responsible for the observation of only one ^{119}Sn signal.

3.2. Crystal structure of 2

Selected bond distances and angles for **2** are listed in Table 2. The molecular structure of complex **2** is shown in Fig. 1, which clearly shows that the two tin atoms are in nonequivalent environments. Bis(4-chloropyrazol-1-yl)methane acts as a chelating bidentate ligand toward the Sn(1) atom, which is six-coordinate with a distorted octahedral geometry, containing a *cis* arrangement of the bromine atoms and a *trans* arrangement of the phenyl and methylene groups, whereas Sn(2) is four-coordinate with a slightly distorted tetrahedral geometry. The six-membered Sn–N–N–C–N–N metallacycle adopts a slightly distorted boat conformation, which is similar to that in the reported monodentate organotin Lewis acid derivatives of bis(pyrazol-1-yl)alkanes [12]. The average Sn(1)–N distance in complex **2** is 2.424 Å, which is within the range for the reported organotin complexes containing scorpionate ligands [2,15]. The average Sn(1)–Br distance (2.639 Å) is considerably longer than the average Sn(2)–Br distance (2.493 Å), the higher coordinate number of Sn(1) atom being accountable for this result. The angles ∠ Br–Sn(1)–Br and ∠

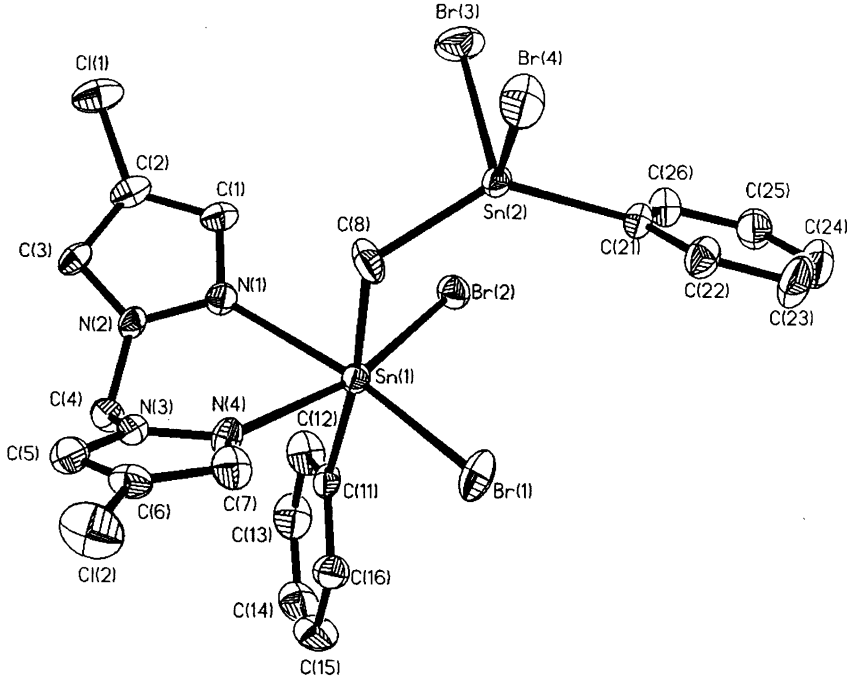

Fig. 1. Molecular structure of complex **2**. The thermal ellipsoids are drawn at the 30% probability level.

Br(3)–Sn(2)–C(8)	107.7(4)	Br(3)–Sn(2)–C(21)	106.8(3)
Br(4)–Sn(2)–C(8)	101.2(4)	Br(4)–Sn(2)–C(21)	101.4(3)

C–Sn(1)–C in complex **2** ($\angle$ Br(1)–Sn(1)–Br(2) = 105.1(1)°, $\angle$ C(11)–Sn(1)–C(8) = 172.0(5)°), are larger than those in CH_2(3-iPrPz)$_2SnPh_2Br_2$ ($\angle$ Br–Sn–Br = 100.3(1)°, $\angle$ C–Sn–C = 168.2(5)°), and CH_2(3-iPrPz-5′-iPrPz)$SnPh_2Br_2$ ($\angle$ Br–Sn–Br = 94.68(2)°, $\angle$ C–Sn–C = 165.8(2)°) [12], possibly owing to the smaller repulsion of the CH_2(4-ClPz)$_2$ ligand with the other groups around the six coordinated tin atom in **2**, originating from the absence of substituents in the 3-position of pyrazole rings. The angle $\angle$ N–Sn–N of 77.1(3)° in complex **2** is similar to that in CH_2(3-iPrPz)$_2SnPh_2Br_2$ (77.6(3)°), CH_2(3-iPrPz-5′-iPrPz)-$SnPh_2Br_2$ (77.9(10)°) and CH_2(4-MePz)$_2SnMe_2Cl_2$ (76.4(3)°) [15].

4. Conclusion

The reaction between bis(dibromophenylstannyl)methane with bis(pyrazol-1-yl)alkanes yielded only 1:1 adducts, in which the organic ligands act in a chelating bidentate mode, and four- and six-coordinate tin atoms co-exist in the solid. The electronic and steric characteristics of substituents on the pyrazole rings markedly affect the donating ability of bis(pyrazol-1-yl)alkanes to the bidentate organotin Lewis acid acceptor. The investigations on the reaction of the adducts with DMSO and the NMR spectra of the adducts show the weak interactions between the ligands and the bidentate organotin Lewis acid acceptor.

5. Supplementary material

Atomic coordinates, thermal parameters and bond lengths and angles for complex **2** have been deposited at the Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk). Any request to the CCDC for this material should quote the full literature citation and the reference numbers CCDC168634.

Abstract

We wish to report the synthesis, spectroscopic properties, and crystal structures of two Pt(II) heteroleptic complexes with triphenylphosphine (PPh_3), chloride, and the crown trithioethers 9S3 (1,4,7-trithiacyclononane) or 10S3 (1,4,7-trithiacyclodecane). Both complexes have the general formula $[Pt(L)(PPh_3)Cl](PF_6)$ (L = 9S3 or 10S3) and form similar structures in which the Pt(II) center is surrounded by a *cis* arrangement of the chloride, the P donor from the phosphine, and two sulfur atoms from the 9S3 ligand. The third sulfur in each structure forms a longer interaction with the platinum resulting in an elongated square pyramidal structure. The ^{195}Pt NMR chemical shifts for both complexes show a value near −4100 ppm, consistent with a *cis*-PtS_2PCl coordination sphere. The trithioethers in both complexes are fluxional, resulting in relatively simple ^{13}C NMR spectra for them (9S3, one line; 10S3, four lines). Although the fluxional behavior of the 9S3 ligand in platinum group metal complexes is well-documented, our NMR and structural data confirm definite fluxional behavior of the 10S3 ligand for the first time. © 2002 Elsevier Science Ltd. 1. Introduction

The past 15 years have seen remarkable activity in the study of the coordination chemistry of crown thioether ligands, such as 1,4,7-trithiacyclononane (9S3), in a number of areas including transition metal complexes, main group compounds, and organometallic complexes [2–7]. One of the most commonly studied metal ions with thioethers is platinum(II) due to the unusual properties exhibited by its complexes [8–13]. Structurally, the complexes form elongated square pyramids [S_4+S_1] coordination [8] or elongated octahedra [S_4+S_2] [10,12], a consequence of long distance Pt–S interactions involving the axial sulfur atoms present in the coordinated thioether crown. These long distance interactions result in unusual spectroscopic (d–d electronic transitions near 435 nm) and electrochemical properties (a reversible Pt(II)–Pt(III) couple observed near +0.35 V versus $Fc-Fc^+$ in cyclic voltammetry) properties [13]. The platinum–axial sulfur interactions are of considerable theoretical interest as they represent an intermediate case between bonding and non-bonding interactions [14]. Another key feature of the complexes is the fluxional behavior of the 9S3 ligand which appears to correlate with the axial interactions. Indeed, fluxional behavior of the 9S3 ligand has been observed in virtually every one of its Pd(II) or Pt(II) complexes [15–17]. In addition, Pt(II) complexes with 9S3 have been proposed as models for ligand substitution reactions which proceed by associative mechanisms in four coordinate complexes [18]. Several recent reports have focused on heteroleptic crown thioether complexes with phosphine ligands [19,20]. The current work extends that avenue of research to incorporate three different types of ligands

(thioether, phosphine, and chloride) bound to the Pt center in the complex [Pt(9S3)(PPh_3)Cl](PF_6). Few platinum(II) complexes containing these three types of ligands have been structurally characterized [22]. Lastly, we were also interested in the fluxional behavior of the related crown trithioether, 1,4,7-trithiacyclodecane, 10S3. In contrast to the 9S3 complexes, the fluxionality of this ligand had not yet been verified, so we have prepared the analogous complex, [Pt(10S3)(PPh_3)Cl]-(PF_6), for study in that regard.

2. Experimental

2.1. Materials

All solvents and reagents were purchased from Aldrich Chemical Company and used as received. The starting complex [Pt(9S3)Cl_2] was prepared by the published method [17].

2.2. Measurements

Analyses were performed by Atlantic Microlab, Inc., of Atlanta, Georgia. Fourier transform infrared spectra were obtained using a Galaxy FT-IR 5000 spectrophotometer and UV–Vis spectra were obtained on a Varian DMS 200 UV–Vis spectrophotometer. ^{13}C and proton NMR spectra were recorded on a Varian Gemini 300 NMR spectrometer using CD_3NO_2 for both the deuterium lock and reference. Carbon connectivity was confirmed via DEPT (Distortionless Enhancement by Polarization Transfer) experiments. Platinum-195 NMR spectra were recorded at 64.208 MHz using aqueous solutions of $[PtCl_6]^{2-}$ (0 ppm) as an external reference and delay time of 0.01 s. Referencing was verified versus authentic samples of $[PtCl_4]^{2-}$ which was found to have a chemical shift at −1626 ppm, in agreement with the reported value of −1624 ppm [23]. Phosphorus-31 NMR was measured at 121.470 MHz, and referencing was done using phosphoric acid (0 ppm) as an external standard.

2.3. Preparation of [Pt(9S3)(PPh_3)Cl]PF_6

A slurry of [Pt(9S3)Cl_2] (80.0 mg, 0.179 mmol) in 250 ml of 3:1 CH_3CN:CH_2Cl_2 was stirred and warmed slightly. Small portions of triphenylphosphine, PPh_3, (47.0 mg, 0.179 mmol) were added forming a clear yellow solution. Next excess NH_4PF_6 (0.300 g, 1.84 mmol) was added to form a white precipitate of NH_4Cl, and the precipitate was removed from the warm solution by filtration. The solution was then concentrated to 2/3 of its original volume, and ether was slowly added to precipitate [Pt(9S3)(PPh_3)Cl]PF_6 as yellow crystals (0.102 g, 69.6% yield). *Anal*. Calc. for $C_{25}H_{30}ClF_6NO_2P_2PtS_3$: C, 35.23; H, 3.32; S, 11.76; Cl, 4.33. Found: C, 35.00; H, 3.40; S, 11.71; Cl, 4.07%. The electronic absorption spectrum measured in acetonitrile showed a single λ_{max} at 258 nm ($\varepsilon = 23\,000$). FT-IR (KBr, cm^{-1}): 3065, 3061, 3057, 2973, 2951, 1437, 1097, 839 (s, PF_6^-), 732, 508. ^1H NMR (CD_3NO_2) δ: 7.82, 7.52 (m, PPh_3, 15 H), broad, complex multiplet centered at 3.07 (9S3, 12 H). $^{13}C\{^1H\}$ NMR(CD_3NO_2) δ: 136.1 (m, 6 C, PPh_3), 133.5 (s, 3 C, PPh_3), 130.2 (m, 6 C, PPh_3), 128.7 (d, 3 C, PPh_3, $^1J_{C-P} = 61$ Hz), 37.3 (s, 9S3, 6 C). $^{195}Pt\{^1H\}$ NMR (CD_3NO_2) δ ($\nu_{1/2}$): doublet at −4052 (70 Hz) and −4107 (70 Hz) ($^1J_{PtP} = 3399$ Hz). $^{31}P\{^1H\}$ NMR (CD_3NO_2) δ: 16.09 (s, $^1J_{PtP} = 3387$ Hz).

2.4. Preparation of [Pt(10S3)(PPh_3)Cl]PF_6

The complex is prepared by using the above procedure starting with [Pt(10S3)Cl_2] (0.0920 g, 0.200 mmol) and triphenylphosphine (0.0525 g, 0.200 mmol). These are mixed in 250 ml of 3:1 CH_3CN:CH_2Cl_2 with stirring and mild heating. Addition of excess NH_4PF_6 (0.300 g, 1.84 mmol), filtration of NH_4Cl, concentration of the solution to 2/3 of its original volume, and the slow addition of ether formed yellow crystals of [Pt(10S3)(PPh_3)Cl]PF_6 (0.130 g, 78.0% yield). *Anal.* Calc. for $C_{25}H_{29}ClF_6P_2PtS_3$: C, 36.08; H. 3.51; S, 11.56; Cl, 4.26. Found: C, 36.07; H, 3.45; S, 11.67; Cl, 4.35%. The electronic absorption spectrum measured in acetonitrile showed two λ_{max} at 260 nm ($\varepsilon = 24\,000$) and 234 nm ($\varepsilon = 35\,000$). FT-IR (KBr, cm^{-1}): 3090, 3045, 3030, 2983, 2923, 1437, 1105, 839 (s, PF_6^-), 810, 793, and 705. ^1H NMR (CD_3NO_2) δ: 7.95, 7.63 (m, PPh_3, 15 H), complex, overlapping peaks 3.35–2.75 (m, 10S3, α-methylene, 12 H), and 2.25–2.18 (m, 10S3, β-methylene, 2 H). $^{13}C\{^1H\}$ NMR(CD_3NO_2) δ: 136.3 (m, 6 C, PPh_3), 133.7 (s, 3 C, PPh_3), 130.5 (m, 6 C, PPh_3), 128.8 (d, 3 C, PPh_3, $^1J_{C-P} = 62$ Hz), 36.6, 36.2, 33.7 (s, 10S3, α-methylene, 6 C) 26.6 (s, 10S3, β-methylene, 1 C). $^{195}Pt\{^1H\}$ NMR (CD_3NO_2) δ ($\nu_{1/2}$): doublet at −4101 (73 Hz) and −4154 ppm (78 Hz) ($^1J_{PtP} = 3442$ Hz). $^{31}P\{^1H\}$ NMR (CD_3NO_2) δ: 14.20 (s, $^1J_{PtP} = 3438$ Hz).

2.5. Data collection and processing

Suitable crystals of both complexes were grown by slow diffusion of ether into a nitromethane solution. A summary of key crystallographic details for both structures is presented in Table 1. For both structures, intensity data were collected on a Siemens SMART 1K CCD diffractometer [24,25]. Both structures were solved using direct methods [24]. For the 9S3 complex, the h, k, l ranges used during its structure solution and refinement were −10/12, −25/26, −18/21. For 18 950 measured reflections 7140 were unique. The merging R-values on intensities were 0.0351. The structure was refined by a full-matrix least squares on F^2 using 7140

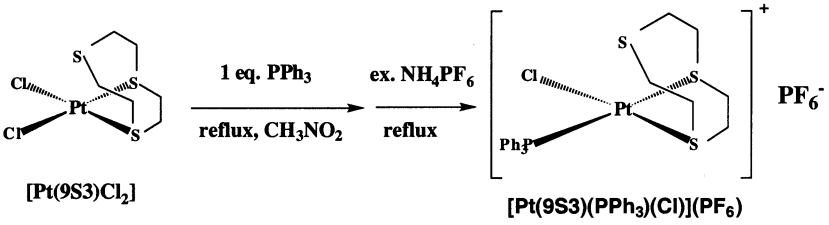
[a] $R = \Sigma||F_o| - |F_c|/\Sigma|F_o|$.
[b] $R_w = [\Sigma\ w(|F_o| - |F_c|)^2/\Sigma\ w(F_o)^2]^{1/2}$.



unique reflections and 430 parameters. The residuals were as follows, for reflections having $I > 2\sigma(I)$ $R = 0.0241$, $R_w = 0.0557$ and goodness of fit = 1.030; for all reflections $R = 0.0313$, $R_w = 0.0576$. The maximum shift/σ ratio was 0.002. In the last D-map, the deepest hole was −0.831 e Å^{-3} and the highest peak was 1.1410 e Å^{-3}. The secondary extinction coefficient was 0.00194(9) μ.

For the 10S3 complex, the h, k, l ranges used during the structure solution and refinement were −10/10, −22/20, −13/22. For 15 655 measured reflections 5223 were unique. The merging R-values on intensities were 0.0441. An absorption correction was performed using SADABS [25]. The structure was refined by a full-matrix least squares on F^2 using 5223 unique reflections and 417 parameters. The residuals were as follows: for reflections having $I > 2\sigma(I)$ $R = 0.0348$, $R_w = 0.05857$ and goodness of fit = 1.018; for all reflections $R = 0.0475$, $R_w = 0.0990$. The maximum shift/σ ratio was 0.002. In the last D-map, the deepest hole was −0.629 e Å^{-3} and the highest peak was 1.178 e Å^{-3}. The secondary extinction coefficient was 0.0072(3) microns. The structure of the 10S3 complex contains disorder in two carbons (C8, C9) of the propylene linkage within the thioether ring. The disorder model contains two orientations of this linkage in equal amounts.

3. Results and discussion

3.1. Synthesis and spectra

The two complexes are readily prepared by the reaction of the appropriate trithioether platinum dihalide salt with 1 equiv. of triphenylphosphine and isolated as the hexafluorophosphate salt as show below. Their composition is confirmed using a variety of spectroscopic techniques and elemental analysis. The proton NMR spectrum shows resonances for all phenyl and methylene protons in the appropriate ratios and splittings. In contrast to other phosphine complexes, the lower symmetry of both complexes results in a complicated pattern for the methylene protons of the thioether ligands [19,20]. In addition, ^{13}C DEPT experiments confirm all carbon connectivity in both complexes. As expected, the 9S3 ligand is fluxional in solution resulting in a single ^{13}C NMR resonance for the thioether ligand, showing all six carbon atoms to be equivalent. The fluxionality has been proposed to occur via rapid intramolecular exchanges of sulfur atoms (1,4-metallotropic shift) [15,17]. In combination with its crystal structure (see below), the ^{13}C NMR spectrum of the 10S3 ligand in $[Pt(10S3)(PPh_3)Cl](PF_6)$ does demonstrate that this ligand also undergoes an exchange process in its platinum complexes. Note that a four-line ^{13}C NMR spectrum cannot unambiguously determine if the complex is fluxional in solution since the symmetrical linkage isomer of the 10S3 would show this relatively simple spectrum. However, the linkage isomer of lower symmetry which is obtained in the crystal structure would yield a 7-line spectrum, indicating that a ligand exchange process is indeed occurring in solution. We have not been able to observe a slow trithioether exchange in the ^{13}C NMR spectrum of either complex down to −40 °C [21].

The ^{195}Pt NMR spectra for both complexes show the anticipated doublet splitting pattern centered at −4080 ppm for the 9S3 complex and −4127 ppm for the 10S3. These two values lie intermediate between the ones reported for $[Pt(9S3)Cl_2]$ at −3605 ppm and for $[Pt(9S3)(PPh_3)_2]2+$ at −4399 ppm, showing an average ligand field effect in the chemical shift [17]. The downfield shift of the platinum resonance upon the addition of the anionic chloride ligands is anticipated. The ^{31}P NMR spectra for each complex show a single resonance and a doublet of ^{195}Pt satellites. The values of $^1J(^{195}Pt-^{31}P)$ coupling constants of the two complexes occur at 3387 and 3438 Hz, respectively, and these values are relatively large compared with other thioether–phosphine complexes [1,20]. In addition, we observe the effects of coupling between the *ortho* and *meta* phenyl carbons and the phosphorus while the *para* carbon shows no coupling. We have previously observed similar coupling patterns in related thioether–phosphine complexes.

3.2. Structures

The complex $[Pt(9S3)(PPh_3)Cl](PF_6)\cdot CH_3NO_2$ crystallizes in the space group $P2_1/n$. An ORTEP perspective of the complex cation is shown in Fig. 1, and selected bond lengths are given in Table 2. A nitromethane solvent molecule is also incorporated into the crystal lattice. The complex forms an elongated square pyramidal structure which is common for heteroleptic crown thioether complexes of Pt(II) and Pd(II) [19,20]. The square plane is comprised of the Cl^- donor, the P donor from the PPh_3, and two sulfur donors from the 9S3. The third sulfur shows the elongated interaction to complete the square pyramidal structure. The Pt(II) ion is raised slightly (by 0.1172(4) Å) above the mean square plane and directed towards the axial sulfur donor. The four atoms in the equatorial plane have an average displacement of 0.0576 Å.

Table 2
Selected bond distances (Å) and angles (°) for $[Pt(9S3)(PPh_3)(Cl)]PF_6\cdot CH_3NO_2$ (**1**) and $[Pt(10S3)(PPh_3)(Cl)]PF_6$ (**2**)

	(1)	(2)
Distances (Å)		
$Pt-S_{axial}$	3.0778(8)	2.938(2)
$Pt-S_{eq}$	2.3365(8), 2.2609(9)	2.252(3), 2.350(2)
Pt–P	2.2838(8)	2.285(2)
Pt–Cl	2.3434(8)	2.332(3)
Angles (°)		
$S_{eq}-Pt-S_{eq}$	88.94(3)	87.80(9)
P–Pt–Cl	89.99(3)	88.95(9)
S(4)–Pt–Cl	86.98(1)	87.20(9)
S(7)–Pt–P	93.64(3)	95.41(9)
$S_{eq}-Pt-S_{ax}$	82.70(3), 110.55(3)	80.807(9), 94.971(9)

Of particular note is the distance between the axial sulfur donor and the platinum, as this distance is quite sensitive to the nature of the ancillary ligand(s). The structure reported here represents an intermediate case between the reported dichloro and bis(triphenylphosphine) Pt(9S3) complexes, and the three complexes follow the trend in Pt–Saxial distance: 2.638(3) Å < 3.0778(9) Å < 3.260(3) Å for the $(PPh_3)_2$, (PPh_3, Cl), (Cl_2) complexes, respectively, [17,20]. Although longer than the Pt–S bond distances, nevertheless, they are considerably shorter than 3.5 Å, the van der Waals distance for a platinum–sulfur interaction [26]. The relative π donor–acceptor characteristics of the chloride and the phosphine ligands have been proposed as being responsible for this trend. [19,20] The better π accepting phosphine ligand reduces electron density on the metal center, enhancing the positive charge and drawing the sulfur closer. In contrast, the better π donating chloride increases the electron density on the platinum, and a longer axial sulfur distance is observed. The Pt–P distance is slightly shorter than observed the one

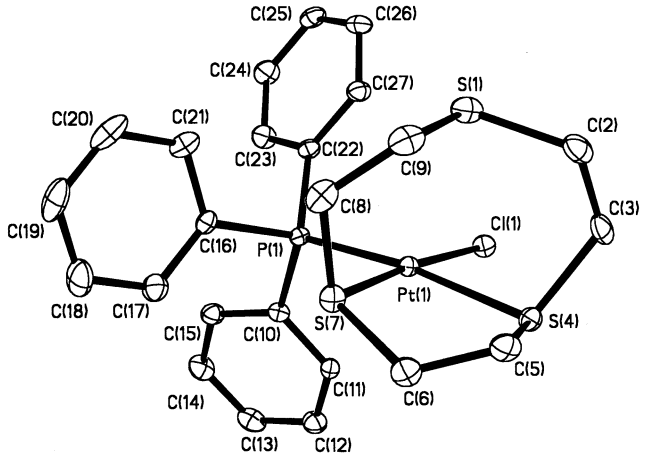


Fig. 1. ORTEP perspective of cation in $[Pt(9S3)(PPh_3)Cl](PF_6)\cdot CH_3NO_2$.

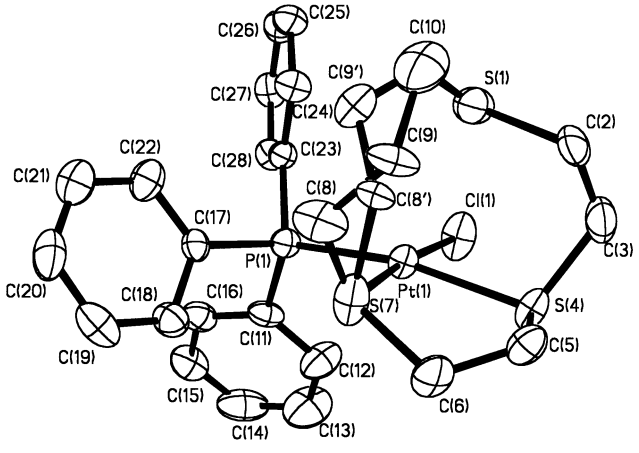

Fig. 2. ORTEP perspective of cation in $[Pt(10S3)(PPh_3)Cl](PF_6)$.

observed in $[Pt(9S3)(PPh_3)_2]^{2+}$ while the Pt–Cl distance is slightly longer than observed in $[Pt(9S3)Cl_2]$. Other structural features in the 9S3 complex including the Pt–S equatorial bond distances and the S–Pt–S bond angles lie intermediate between the values found in the two previously reported structures.

The complex $[Pt(10S3)(PPh_3)Cl](PF_6)$ crystallizes in the orthorhombic space group $P2_12_12_1$. An ORTEP perspective of the complex cation is shown in Fig. 2 and selected bond lengths are given in Table 2. This structure, too, is an elongated square pyramidal structure with the square plane comprised of the Cl^- donor, the P donor from the PPh_3, and two sulfur donors from the crown thioether. The third sulfur shows the elongated interaction with the Pt center at 2.928(9) Å to complete the square pyramidal structure. The space group is a chiral one, and the chirality arises from the single enantiomeric form of the complex that was obtained in the crystal [27]. Note that the propylene chelate ring links the axial sulfur (S1) with one of the equatorial sulfurs (S7). Its enantiomer would link S1 with the other equatorial sulfur donor, S4. The alternative *meso* diastereoisomer is the one that has this propylene chelate ring linking the two equatorial sulfur donors and would show a four line ^{13}C NMR spectrum for the 10S3 ligand. However, the exchange process of the 10S3 ligand interconverts the three stereoisomers in solution, resulting in the loss of chirality and accounting for the number of observed ^{13}C NMR signals.

As was true for the 9S3 complex, this axial Pt–S distance has shortened from those found in the dichloro analog $[Pt(10S3)Cl_2]$ (3.125(5), 3.121(5) Å) and lengthened relative to the reported value in a 10S3/diphosphine complex (2.6505(4) Å) [28,29]. In all analogous 10S3 complexes, the axial Pt–S distances are smaller than those found in the 9S3 complexes, possibly due to the greater conformational flexibility of the 10S3. In the structure the Pt(II) ion is again raised slightly (by 0.1228(12) Å) above the mean square plane and directed towards the axial sulfur donor. The four atoms in the equatorial plane have an average displacement of 0.1036 Å. In both structures, the shorter equatorial Pt–S bond lies *trans* to the Pt–Cl bond, a reflection of the relative *trans* directing strength between chloride and phosphine ligands.

4. Conclusions

One equiv. of the phosphine ligand, PPh_3, readily reacts with $[Pt(9S3)Cl_2]$ or $[Pt(10S3)Cl_2]$ forming unusual heteroleptic thioether–phosphine–chloride complexes with elongated square pyramidal structures $[S_2PCl+S_1]$ in the solid state. Increasing positive charge on the platinum center results in shorter axial Pt–S distances and an upfield ^{195}Pt NMR chemical shift. Both trithioethers are fluxional in solution, the first confirmation of fluxionality for the 10S3 ligand in platinum group complexes.

5. Supplementary material

Crystallographic data for the two structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as CCDC 172660 & 172661. Copies of the data can be obtained free of charge upon application to CCDC, 12 Union Road, Cambridge, CB2 1 EZ UK (fax: +44-1223 336 033); e-mail: deposit@ccdc.cam.ac.uk.

[21] We also have studied both complexes in CD_3CN which enables variable temperature NMR experiments to be carried out at near -40°. We still, however, cannot observe a slow exchange of the ligand in the ^{13}C NMR spectrum. This is consistent with our previous observations on Pt(II) complexes containing trithioethers such as 9S3. Bürgi (Reference [18]) notes that the observed activation free energy for the 9S3 exchange is near the lower limit of detectable NMR fluxional processes.

Abstract

The reactions of $[Os_3(CO)_{10}(MeCN)_2]$, $[Ru_3(CO)_{12}]$, $[(\mu\text{-H})Os_3(CO)_8\{Ph_2PCH_2P(Ph)C_6H_4\}]$, $[Os_3(CO)_{10}(\mu\text{-dppm})]$ and $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole are reported. The labile cluster $[Os_3(CO)_{10}(MeCN)_2]$ reacts with 2-mercapto-1-methylimidazole at 25 °C to give $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-SC=NCH=CHN(CH}_3)\}]$ (**1**) whereas the corresponding reaction of $[Ru_3(CO)_{12}]$ with the ligand at 68 °C gives $[(\mu\text{-H})Ru_3(CO)_9\{\mu_3\text{-}\eta^2\text{-SC=NCH=CHN(CH}_3)\}]$ (**2**). Both $[(\mu\text{-H})Os_3(CO)_8\{Ph_2PCH_2P(Ph)C_6H_4\}]$ and $[Os_3(CO)_{10}(\mu\text{-dppm})]$ react with 2-mercapto-1-methylimidazole at 25 and 110 °C, respectively, to give $[(\mu\text{-H})Os_3(CO)_8\{\mu\text{-SC=NCH=CHN(CH}_3)(\mu\text{-dppm})]$ (**3**). In contrast $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ reacts with 2-mercapto-1-methylimidazole at 68 °C to yield the known compound $[Ru_3(CO)_7(\mu_3\text{-CO})(\mu_3\text{-S})(\mu\text{-dppm})]$ (**4**). The structures of **1**–**3** have been determined by X-ray crystallography. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Heterocyclic thioamides; Osmium; Ruthenium; 2-Mercapto-1-methylimidazole; X-ray structures

1. Introduction

The reactions of heterocyclic thioamides with trimetallic clusters of osmium, ruthenium and iron have been investigated [1–6]. It has been demonstrated that some reactions proceed with retention of the cluster nuclearity while in other cases fragmentation into dinuclear species as well as ring opening of the ligand takes place. For example, the reaction of $[Ru_3(CO)_{12}]$ with thiomorpholine gives the triruthenium cluster $[(\mu\text{-H})Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-SCH}_2\text{CH}_2\text{NH}_2)]$ by a ring opening reaction of thiomorpholine (C_4H_9NS) followed by elimination of a C_2 fragment whereas thiazolidine (C_3H_7NS) under identical condition gives the dinuclear compound $[Ru_2(CO)_6(\mu\text{-}\eta^3\text{-SCH}_2\text{CH}_2\text{–NHCH}_2)]$ formed by cluster fragmentation and ring opening cleavage of the C–S bond of the ligand [5]. On the other hand, benzothiazoline-2-thione reacts with $[Ru_3(CO)_{12}]$ to give both tri- and dinuclear complexes $[(\mu\text{-H})Ru_3(CO)_9(C_7H_4NS_2)]$ and $[Ru_2(CO)_6(C_7H_4NS_2)]$ containing deprotonated thioamide ligand [2,3] whereas with $[Fe_3(CO)_{12}]$ it yields $[Fe_3(CO)_9S_2]$ by desulfurization of the ligand [4]. As an extension of our studies on the reactions of trimetallic clusters with N- and S-heterocyclic ligands such as 4-methylthiazole [7], thiazole [8,9], thiomorpholine [5], thiazolidine [5], benzothiazole [6] and pyrimidine-2-thione [6], we investigated the reactions of 2-mercapto-1-methylimidazole with a series of trimetallic clusters such as $[Os_3(CO)_{10}(MeCN)_2]$, $[Ru_3(CO)_{12}]$, $[(\mu$-

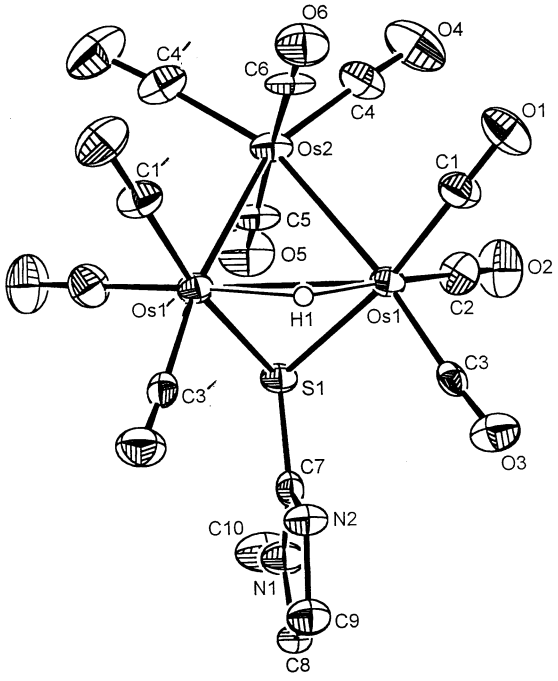
H)$Os_3(CO)_8${$Ph_2PCH_2P(Ph)C_6H_4$}], [$Os_3(CO)_{10}$(μ-dppm)] and [$Ru_3(CO)_{10}$(μ-dppm)]. The results of this study are reported herein.

2. Results and discussion

The reaction of [$Os_3(CO)_{10}(MeCN)_2$] with 2-mercapto-1-methylimidazole at 25 °C gave [(μ-H)$Os_3(CO)_{10}${μ-SC=NCH=CHN(CH_3)}] (**1**) (Scheme 1). This compound was characterised by spectroscopic data and by an X-ray structure determination. The infrared spectrum of **1** in the carbonyl stretching region is very similar to that of [(μ-H)$Os_3(CO)_{10}$(μ-dmpymt)] [10] (dmpymt = 4,6-dimethylpyrimidine-2-thiol) and [(μ-H)$Os_3(CO)_{10}$(SC=NCH_2CH_2S)] [1] indicating that they have very similar distribution of the carbonyl ligands. Besides the characteristic resonances for the heterocyclic ligand, the ^{1}H NMR contains a singlet at δ −16.76 due to the bridging hydride. The mass spectrum shows the molecular ion peak at *m*/*z* 964 and fragment ions formed by the loss of ten carbonyl ligands.

The X-ray structure of **1** is depicted in Fig. 1 and selected bond distances and angles are listed in Table 1. The molecule has a crystallographic mirror plane and consists of an isosceles triangle of osmium atoms with ten terminal carbonyl ligands, four bonded to Os(2) and three to each of Os(1) and Os(1′). The 2-mercapto-1-methylimidazole ligand symmetrically bridges the Os(1)–Os(1′) edge of the cluster via the exocyclic sulfur atom. The hydride ligand also bridges the same Os–Os edge. This doubly bridged Os–Os edge is only marginally longer than the other two edges {Os(1)–Os(1′) = 2.8569(10) Å vs. Os(1)–Os(2) = Os(2)–Os(1′) = 2.8439(8) Å}. The unique Os–S bond distance {2.415(3) Å} is similar to those found in other sulfur bridged triosmium clusters, e.g. 2.405(4) Å in [(μ-H)$Os_3(CO)_{10}$(μ-dmpymt)] [10], and 2.416(11) and 2.419(8) Å in [(μ-H)$Os_3(CO)_{10}$(μ-SC=NCH_2CH_2S)] [1]. The plane defined by Os(1), Os(1′) and S(1) is almost perpendicular to the Os_3 triangle {dihedral angle = 77.2(6)°}. The heterocyclic ligand is exactly planar and within it the exocyclic C(7)–S(1) bond at 1.75(2) Å is as expected for a single bond [11]. The C(7)–N(2) bond distance of 1.29(2) Å indicates a double bond character while the C(7)–N(1) bond at 1.37(2) Å is as expected for a C–N single bond [11].



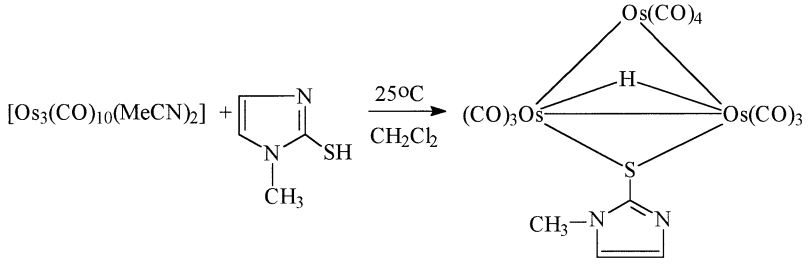


Fig. 1. X-ray structure of [(μ-H)$Os_3(CO)_{10}${μ-η^2-SC=NCH=CHN(CH_3)}] (**1**) showing the atom labelling scheme. The primed atoms, generated by the symmetry (*x*, 0.5−*y*, *z*) are related to the unprimed ones by a mirror plane. Thermal ellipsoids are drawn at 35% probability level. The ring hydrogen atoms are omitted for clarity.

In contrast, the reaction of [$Ru_3(CO)_{12}$] with 2-mercapto-1-methylimidazole at 68 °C gives [(μ-H)$Ru_3(CO)_9${μ_3-η^2-SC=NCH=CHN(CH_3)}] (**2**) (Scheme 2). The compound **2** has been characterised by spectroscopic data and single crystal X-ray diffraction studies. The infrared spectrum of **2** in the carbonyl region is similar to that of [(μ-H)$Ru_3(CO)_9${μ_3-η^2-$SN_2C_4H_3$}] [6], [(μ-H)$Ru_3(CO)_9${μ_3-η^2-$S_2NC_7H_4$}] [3] and [(μ-H)$Ru_3(CO)_9$(μ_3-η^2-pyS)] [12] in both the appearance and position of the bands indicating structural similarities. The mass spectrum shows the molecular ion peak at *m*/*z* 670 and fragment ions formed by the

[b] Approximate value.

sequential loss of nine CO groups. In addition to singlet resonances at δ 6.65, 6.57 and 3.62 for the heterocyclic ligand, the hydride region of the ^{1}H NMR spectrum of **2** at room temperature contains a broad singlet at δ −13.17 which on cooling to −60 °C resolves into two singlets at δ −13.25 and −13.05 in a relative intensity 4:1, pointing to the presence of two interconverting isomers at room temperature. This observation is consistent with the hydride ligand migration across two edges of the ruthenium triangle, which at lower temperature is frozen out giving two forms, the symmetric form (**2a**) and the asymmetric form (**2b**). Similar edge hopping of the bridging hydride ligand has been reported for the related trimetallic clusters [1].

The X-ray structure of **2** is shown in Fig. 2 and selected bond distances and angles are given in Table 2. There are two independent molecules in the asymmetric unit. Each molecule consists of a Ru_3 triangle with three different metal–metal bonds and nine terminal carbonyl ligands, three bonded to each ruthenium atom. The molecules differ in the relative location of the hydride ligand in the cluster. In molecule 1 (Fig. 2), it bridges the Ru(1)–Ru(2) edge and is consistent with the observation that this edge is significantly elongated {2.9948(1) Å} compared with the other two metal–metal bonds {Ru(1)–Ru(2) = 2.8341(10), Ru(2)–Ru(3) = 2.7041(10) Å}. However, in molecule 2 (Fig. 2) the hydride ligand bridges the Ru(2)–Ru(3) edge which is also consistent with this bond being elongated {Ru(2)–Ru(3) = 2.8376(10) Å} compared with the other two Ru–Ru distances {Ru(1)–Ru(2) = 2.8027(11), Ru(1)–Ru(3) = 2.8155(10) Å}. The overall structure of molecule 2 is symmetrical, and is similar to that reported for [(μ-H)Ru_3(CO)$_9${μ_3-η^2-$SN_2C_4H_3$)] [6] in which the hydride ligand bridges the same metal–metal edge as the exocyclic S-atom of the heterocyclic ligand. The Ru–S bond distances in both the molecules {Ru(2)–S(1) =

Scheme 2.

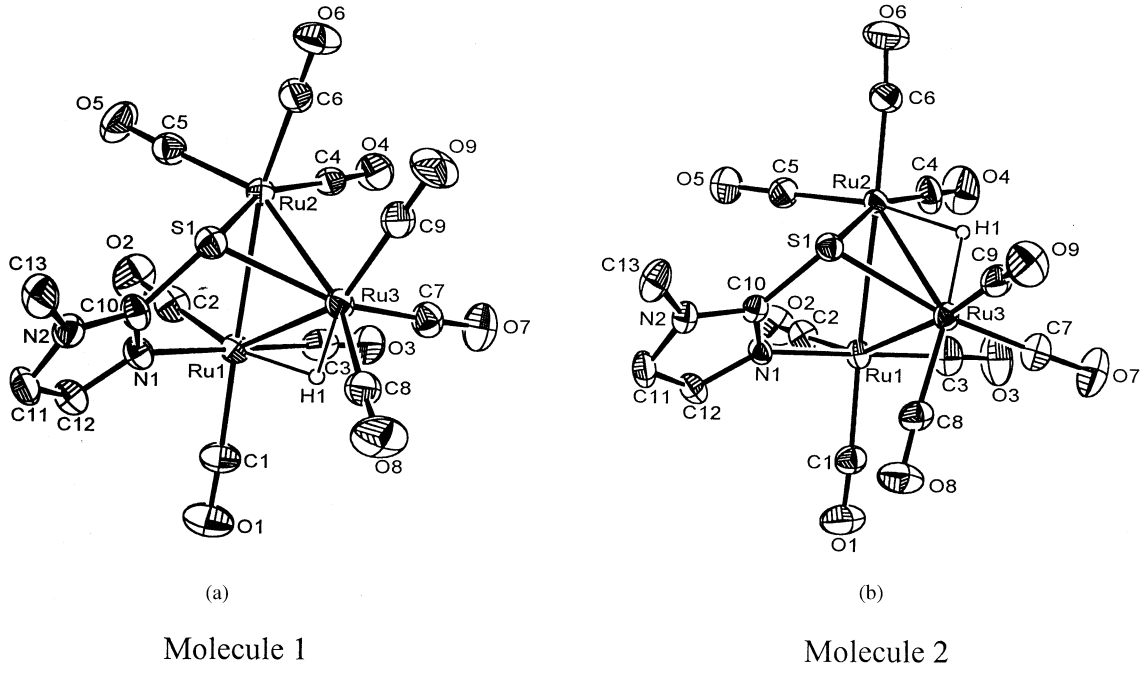

Fig. 2. X-ray structures of molecule 1 and molecule 2 of $[(\mu\text{-H})Ru_3(CO)_9\{\mu_3\text{-}\eta^2\text{-SC=NCH=CHN(CH}_3)\}]$ (**2**) showing the atom labelling scheme. Thermal ellipsoids are drawn at 35% probability level. The ring hydrogen atoms are omitted for clarity.

2.390(2), Ru(3)–S(1) = 2.422(2) Å in molecule 1 and Ru(3)–S(1) = 2.413(2), Ru(2)–S(1) = 2.422(3) Å in molecule 2} are comparable to those observed in **1** and other μ-SR triosmium and triruthenium clusters [1,6,10]. The dimensions of the 2-mercapto-1-methylimidazole ligands in both molecules are similar. Thus the S(1)–C(10), C(10)–N(1), C(10)–N(2) bond distances in molecule 1 are 1.742(9), 1.343(10) and 1.328(11) Å, respectively, while the corresponding distances in molecule 2 are 1.743(9), 1.320(10) and 1.346(10) Å, respectively.

Treatment of $[(\mu\text{-H})Os_3(CO)_8\{Ph_2PCH_2P(Ph)C_6H_4\}]$ with 2-mercapto-1-methylimidazole at room temperature yields $[(\mu\text{-H})Os_3(CO)_8\{\mu\text{-SC=NCH=CHN(CH}_3)(\mu\text{-dppm})]$ (**3**) (Scheme 3). The structure of **3** as obtained from an X-ray study, is shown in Fig. 3 and selected bond distances and bond angles are listed in Table 3. The structure consists of an Os_3 triangle with three different metal–metal bonds {Os(1)–Os(3) = 2.8453(6), Os(1)–Os(2) = 2.8661(6), Os(1)–Os(3) = 2.8581(6) Å}. The overall structural features of **3** are similar to $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-SC}_2H_5)(\mu\text{-dppm})]$ [13]. The 2-mercapto-1-methylimidazole ligand bridges Os(2) and Os(3) via the exocyclic S(1) atom. The Os(2)–Os(3) edge is also bridged by the hydride ligand. The Os–S bridge is symmetrical as indicated by the nearly equal Os–S distances {2.420(2) Å} and these values compare well those {2.402(6)–2.426(4) Å} found in $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-SC}_2H_5)(\mu\text{-dppm})]$ and other related complexes [1,6,10]. The Os–P bond lengths {average 2.33(2) Å} are comparable to those found in $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-SC}_2H_5)(\mu\text{-dppm})]$ {2.324(4) Å} [13] and $[Os_3(CO)_{10}(\mu\text{-dppm})]$ {2.331(3) Å} [14]. Within the heterocyclic ligand, the exocyclic C(9)–S(1) bond length at 1.769(7) Å is similar in length to that of a C–S single bond and the imino C(9)–N(1) bond length of 1.314(8) Å indicates appreciable double bond character while the C(9)–N(2) bond distance of 1.379(8) Å is as expected for a C–N single bond [11]. These values are also comparable with the corresponding values in **1**.

The spectroscopic data of **3** are consistent with the solid-state structure. The infrared spectrum in the carbonyl region is very similar to that of $[(\mu\text{-H})Os_3(CO)_8(\mu\text{-SC}_2H_5)(\mu\text{-dppm})]$ [13] indicating that they are structurally similar. The mass spectrum shows the molecular ion peak at *m/z* 1293 and fragment ions formed by the sequential loss of eight carbonyl groups. In addition to the well separated signals for the heterocyclic and dppm ligands, the ^1H NMR spectrum of **3** in the hydride region contains a doublet at δ −15.49 because of its coupling to one of the ^{31}P nuclei. The $^{31}P\{^1H\}$ NMR spectrum contains two doublets at δ 24.8 and 25.4 indicating non-equivalent ^{31}P nuclei.

In view of our previous studies [15] on the reactivity of $[Os_3(CO)_{10}(\mu\text{-dppm})]$ with PhSH, we believed that the reaction of $[Os_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole would lead to the S–H oxidative addition product **3**. As expected, the reaction of $[Os_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole at 110 °C gave **3** (Scheme 3).

To compare the reactivity of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with that of $[Os_3(CO)_{10}(\mu\text{-dppm})]$, we investigated the

reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole. Instead of the expected S–H oxidative addition product, the reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole at 68 °C gave $[Ru_3(\mu_3\text{-CO})(CO)_7(\mu_3\text{-S})(\mu\text{-dppm})]$ (**4**) (Scheme 4). The compound was previously reported by Bonnet et al. [16] from C–S bond cleavage reaction of $[(\mu\text{-H})Ru_3(\mu\text{-SPh})(CO)_8(\mu\text{-dppm})]$ at 95 °C. We believe that most probably compound **4** proceeds via the intermediate

formation of $[(\mu\text{-H})Ru_3(CO)_8\{\mu\text{-SC=NCH=CHN-(CH}_3\}(\mu\text{-dppm})]$, the ruthenium analogue of **3**, followed by a C–S bond cleavage reaction.

3. Experimental

All the reactions were performed out under a pre-purified nitrogen atmosphere by using standard Schlenk techniques. Reagent grade solvents were freshly distilled from appropriate drying agents. Infrared spectra were recorded on a Schimadzu FT IR 8101 spectrophotometer. NMR spectra were recorded on a Varian Unity Plus 400 spectrometer. $[Ru_3(CO)_{12}]$ was purchased from Strem Chemicals Inc. and used without further purification. $[Os_3(CO)_{10}(MeCN)_2]$ [17], $[(\mu\text{-H})Os_3(CO)_8\{Ph_2PCH_2P(Ph)C_6H_4\}]$ [18], $[Os_3(CO)_{10}(\mu\text{-dppm})]$ [18] and $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ [19] were prepared according to the known methods.

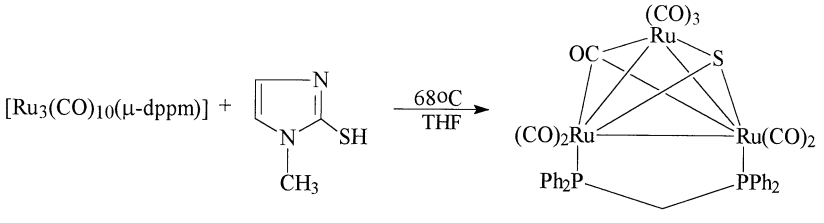
[b] Average values.

3.1. Reaction of $[Os_3(CO)_{10}(MeCN)_2]$ with 2-mercapto-1-methylimidazole



A CH_2Cl_2 solution (30 ml) of $[Os_3(CO)_{10}(MeCN)_2]$ (0.200 g, 0.214 mmol) and 2-mercapto-1-methylimidazole (0.048 g, 0.420 mmol) was stirred at room temperature (r.t.) for 50 min. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with hexane–CH_2Cl_2 (7:3; v/v) gave one major band which afforded $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-SC=N–CH=CHN(CH}_3)\}]$ (**1**) (0.149 g, 72%). Yellow crystals were obtained after recrystallisation from hexane–CH_2Cl_2 at −20 °C. IR (ν(CO), hexane): 2109m, 2074s, 2063s, 2024vs, 2014vs, 1987m, cm^{-1}; ^1H NMR ($CDCl_3$): δ 6.92 (d, 1H, $J = 0.8$ Hz), 6.90 (d, 1H, $J = 0.8$ Hz), 3.78 (s, 3H), −16.76 (s, 1H). MS (*m*/*z*): 964 (M^+). *Anal*. Calc. for $C_{14}H_6N_2O_{10}Os_3S$: C, 17.43; H, 0.63; N, 2.90. Found: C, 17.65; H, 0.82; N, 2.98%.

3.2. Reaction of $[Ru_3(CO)_{12}]$ with 2- mercapto-1-methylimidazole

A THF solution (80 ml) of $[Ru_3(CO)_{12}]$ (0.400 g, 0.626 mmol) and 2-mercapto-1-methylimidazole (0.145 g, 1.27 mmol) was heated to reflux for 3 h. The solvent was removed under reduced pressure and the residue was chromatographed by TLC on silica gel. Elution with hexane–CH_2Cl_2 (9:1, v/v) gave one major band which yielded $[(\mu\text{-H})Ru_3(CO)_9\{\mu_3\text{-}\eta^2\text{-SC=NCH=CHN(CH}_3)\}]$ (**2**) (0.126 g, 30%) as yellow crystals after recrystallisation from hexane–CH_2Cl_2 at −20 °C. IR (ν(CO) hexane): 2086m, 2053s, 2007m, 1995w, 1974w cm^{-1}; ^1H NMR ($CDCl_3$): δ 6.65 (s, 1H), 6.57 (s, 1H), 3.62 (s, 3H), −13.17 (s, 1H); MS (*m*/*z*): 670 (M^+). *Anal*. Calc. for $C_{13}H_6N_2O_9Ru_3S$: C, 23.32; H, 0.91; N, 4.18. Found: C, 23.55; H, 1.15; N, 4.28%.

3.3. Reaction of $[(\mu\text{-H})Os_3(CO)_8\{Ph_2PCH_2P(Ph)\text{-}C_6H_4\}]$ with 2-mercapto-1-methylimidazole

A CH_2Cl_2 solution (20 ml) of $[(\mu\text{-H})Os_3(CO)_8\text{-}\{Ph_2PCH_2P(Ph)C_6H_4\}]$ (0.028 g, 0.024 mmol) and 2-mercapto-1-methylimidazole (0.007 g, 0.061 mmol) was stirred at r.t. for 10 days during which time the colour changed from green to yellow. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with hexane–CH_2Cl_2 (10:3, v/v) afforded $[(\mu\text{-H})Os_3(CO)_8\{(\mu\text{-SC=NCH=CHN(CH}_3)\}(\mu\text{-dppm})]$ (**3**) (0.015 g, 48%) as yellow crystals from acetone–ethanol (0.015 g, 48%). IR (ν(CO), CH_2Cl_2): 2071vs, 2025m, 2000vs, 1990w, 1955w cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.74 (d, 1H, $J = 0.8$ Hz), 7.62 (m, 2H), 7.44 (m, 9H), 7.27 (m, 5H), 7.16 (m,

4

Scheme 4.

2H), 7.08 (m, 2H), 6.91 (d, 1H, $J = 0.8$ Hz), 5.55 (m, 1H), 4.65 (m, 1H), 3.42 (s, 3H), −15.49 (d, 1H, $J = 25.2$ Hz); $^{31}P\{^{1}H\}$ NMR ($CDCl_3$): δ 24.8 (d, $J = 41.9$ Hz), 25.4 (d, $J = 41.9$ Hz); MS (m/z): 1293 (M^+). *Anal*. Calc. for $C_{37}H_{28}N_2O_8Os_3P_2S$: C, 34.36; H, 2.19; N, 2.17. Found: C, 34.58; H, 2. 32; N, 2.28%.

3.4. Reaction of $[Os_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole

A toluene solution (15 ml) of $[Os_3(CO)_{10}(\mu\text{-dppm})]$ (0.083 g, 0.067 mmol) and 2-mercapto-1-methylimidazole (0.015 g, 0.131 mmol) was refluxed for 1 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. A similar chromatographic separation to that above gave **3** (0.028 g, 32%).

3.5. Reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with 2-mercapto-1-methylimidazole

To a THF solution (30 ml) of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (0.202 g, 0.209 mmol) was added 2-mercapto-1-methylimidazole (0.119 g, 1.04 mmol) and the reaction mixture was heated to reflux for 1 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with hexane–CH_2Cl_2 (7:3, v/v) developed two bands. The faster moving band afforded unreacted $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (0.008 g) while the second band gave $[Ru_3(CO)_7(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})]$ (**4**) (0.069 g, 35%) as orange microcrystals.

3.6. X-ray crystallography

Crystallographic data for **1** and **3** were recorded on an CAD4 diffractometer and those for **2** on a FAST TV area detector using monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å). All data sets were corrected for absorption effects by using DIFABS [20]. The structures were solved by direct methods (SHELXS-86) [21] and refined on F^2 by full-matrix least-squares (SHELXL-96) [22] using all unique data with intensities greater than 0. In all cases, the non-hydrogen atoms were anisotropic, with an ISOR = 0.01 constraint being applied for one oxygen atom [O(5)] in **1**. The bridging hydrides in all the structures were located from difference maps but not refined; all other hydrogen atoms were included in calculated positions (riding model). The crystallographic data are summarised in Table 4.

Syntheses and crystal structures of cadmium(II) coordination polymers with end-to-end dicyanamide bridges

Jun-Hua Luo, Mao-Chun Hong *, Rong Cao, Yu-Cang Liang, Ying-Jun Zhao, Rui-Hu Wang, Jia-Bao Weng

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian, 350002, People's Republic of China

Received 15 August 2001; accepted 25 January 2002

Abstract

Two new derivatives of cadmium(II) dicyanamide (dicyanamide = $[N(CN)_2]^-$, dca), $[Cd(N(CN)_2)_2(phen)]_n$ (**1**) and $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (**2**), have been synthesized and structurally characterized. The cadmium(II) centers in **1** are connected through single or double end-to-end dca bridging ligand to form a 2-D layer structure, which furthermore condense into a 3-D structure through the π–π interaction between aromatic rings of adjacent layers. In **2**, the cadmium(II) coordination sphere is a distorted octahedron, bound to four dca ligands and one chelate 2,2′-bipy ligand, and the adjacent cadmium(II) centers are bridged by the double end-to-end $\mu_{1,5}$-N≡C–N–C≡N to form an extended structure with a zigzag 1-D chain, and a 2-D layer structure results from the π–π interactions of the adjacent chains. Keywords: Cadmium complexes; Dca ligand; Double end-to-end; Zigzag chain; π–π interaction

1. Introduction

Metal-organic frameworks are widely regarded as promising materials for application in catalysis, separation and molecular recognition [1]. There have been numerous reports in which N-donor bridging ligands are used to form infinite metal-organic polymeric frameworks [2]. Dicyanamide, $[N(CN)_2]^-$, was selected due to its coordination versatility ranging from being monodentate to μ_4- coordination, and thus provides a suitable 'building block' for assembling novel inorganic/organic hybrid materials. Monodentate (terminal) coordination occurs in $[Cu(II)(o\text{-phen})_2\{N(CN)_2\}][C(CN)_3]$ [3,3a], $[Cu(II)(o\text{-phen})_2\{N(CN)_2\}_2]$ (o-phen = o-phenanthroline) [3b] and $[Zn_3(OAc)_4(4,4'\text{-bipy})_3\{N(CN)_2\}_2]$ [3c]. Bidentate coordination has often been observed and was reported for $Me_2Sn[N(CN)_2]_2$ [3d], $Me_3Sn[N(CN)_2]$ [3d], two polymorphs of $Ag[N(CN)_2]$ [3e,3f], and $Mn[N(CN)_2]_2(pyz)$ (pyz = pyrazine) [3g,3h]. Tri-coordinate μ_3-$[N(CN)_2]^-$ is observed in the rutile-type class of molecule-based magnets, $M(II)[N(CN)_2]_2$ (M = Co or Ni) [3i]. Unusual μ_4 coordination [1e] is also known and was found in the structures of $Me_2Tl[N(CN)_2]$ [3j]. Structures reported recently include $M(dca)_2L_2$ chains, (4,4) sheets, diamond-like works, interpenetrating networks, molecular tubes and self-penetrating works [4]. In these materials, σ-bond formation occurs through lone pair donation of the nitrile N atoms to an octahedral metal center. Our goal was to prepare and characterize new low-dimensional solids consisting of divalent transition metal complexes with the dicyanamide ligand. Herein, we report the syntheses, crystal structures, and vibrational properties of $[Cd(N(CN)_2)_2(phen)]_n$ (**1**) and $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (**2**), the first structurally characterized cadmium(II) dicyanamide complexes.

2. Experimental

2.1. Materials and physical measures

Elemental analyses were determined on an Elementar Vario ELIII analyzer. IR spectra were measured as KBr pellets on a Nicolet Magna 750 FT IR spectrometer in the range of 200–4000 cm^{-1}. All reagents were commercially available and used as received.

2.2. Synthesis of the complexes

2.2.1. $[Cd(N(CN)_2)_2(phen)]_n$ (1)

To an aqueous solution (20 ml) of $Cd(NO_3)_2\cdot 4H_2O$ (0.155 g, 0.5 mmol), sodium dicyanamide (0.09 g, 1 mmol) was added. After stirring the mixture for about 30 min, the dmf solution (10 ml) of phen was added into it. The above mixture was stirred and heated for 1 h, then filtered when it was still hot. Well shaped crystals of $[Cd(N(CN)_2)_2(phen)]_n$ were obtained from the mother liquor by slow evaporation at room temperature (r.t.) for several days. They were filtered off, washed with a small mount of water, and dried in air. Yield 78%. Calc. for $C_{16}H_8CdN_8$: C, 45.21; H, 1.88; N, 26.37. Found: C, 44.89; H, 2.01; N, 27.68%.

2.2.2. $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (2)

The compound was synthesized as **1** except 2,2′-bipy instead of phen. Yield 78%. Calc. for $C_{14}H_8CdN_8$: C, 41.93; H, 2.00; N, 27.95. Found: C, 41.67; H, 1.85; N, 29.21%.

2.3. X-ray crystallography

Single crystals with approximate dimensions $0.52 \times 0.48 \times 0.40$ mm for **1** and $0.42 \times 0.30 \times 0.25$ mm for **2** were selected and coated with epoxy glue. Data collections was carried out on a Siemens Smart CCD diffractometer equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 298 K. Intensities of both **1** and **2** were corrected for empirical absorption based on SADABS scan technique [5]. Their structures were solved by direct methods and all calculations were performed using the SHELXL-PC program [6]. The positions of H atoms were generated geometrically (C–H bond fixed at 0.96 Å), assigned isotropic thermal parameters. The structure was refined by full-matrix least-squares minimization of $\Sigma(F_o - F_c)^2$ with anisotropic thermal parameters for all atoms except the H atoms. Table 1 gives a structure determination summary and Table 2 and Table 3 list the selected bond lengths and angles.

3. Results and discussion

3.1. IR spectroscopic study

At room temperature, the solid state infrared spectrum depicts several ν_{CN} bands at 2301m, 2260(sh), 2216s, 2177s, 2156s cm^{-1} in complex **1** and 2303m, 2206(sh), 2229s, 2156s cm^{-1} in complex **2**, which are attributed to $\nu_{sym}+\nu_{asym}(C\equiv N)$, $\nu_{asym}(C\equiv N)$ and $\nu_{sym}(C\equiv N)$ modes, and are comparable to those of related compounds in Table 4. These bands differ significantly from those of $Na[N(CN)_2]$, which are at 2129, 2232 and 2286 cm^{-1} [7]. The bands at 1365m, 916m in **1** and 1344m, 916m in **2** are assigned to $\nu_{asym}(C–N)$ and $\nu_{sym}(C–N)$, respectively.

3.2. Crystal structure analysis

3.2.1. Crystal structure of complex *1*

Fig. 1 shows an ORTEP [8] diagram of the coordination sphere of the Cd(II) ion and atom labeling in $[Cd(N(CN)_2)_2(phen)]_n$ (**1**). Each cadmium(II) atom lies on an inversion center, and is connected to three other cadmium(II) centers through four dca ligands, one double end-to-end dca bridge to one cadmium(II) atom and two single end-to-end dca bridges to another two cadmium(II) atoms. Thus, all cadmium atoms form a 2-D layer structure through both the double end-to-end dca bridges and single end-to-end dca bridges as in Fig. 2, and furthermore generate a 3-D structure through the weak π–π interaction between aromatic rings of adjacent layers with distances 3.584 Å, as shown in Fig. 3. Each cadmium(II) center is six-coordinated and display a distorted octahedral coordination, with two terminal N atoms of two different dca ligands [Cd–N(1), 2.279(4); Cd–N(4), 2,246 Å] and two N atoms of the phen ligand [Cd–N(7), 2.342 (3); Cd–N(8), 2.322(3) Å] in the equatorial plane, while the other two N atoms of two dca ligands [Cd–N(3A), 2.291(4); Cd–N(6B), 2.481(4) Å] occupy the axial positions. Two kinds of bond angles may be found in the equatorial plane: the lower of 71.68° corresponding to the N(phen)–Cd–N(phen) bond angle and three greater N(phen)–Cd–N(dca) bond angles [N(1)–Cd–N(8), 98.04(13)°; N(4)–Cd–N(7), 94.58(14)°] and N(dca)–Cd–N(dca) bond angles [N(4)–Cd–N(1), 94.30(16)°]. The four equatorial donor atoms and the central cadmium(II) atom determine a plane with maximum deviation for Cd of −0.1628(5) Å. Approximate C_{2v} symmetry is observed for the dca ligand with C(2)–N(3), C(1)–N(1), C(4)–N(6) and C(3)–N(4) bond distances of 1.134(5), 1.143(5), 1.136(5) and 1.123(5) Å, respectively. The lack of significant electron density near the amide nitrogen N2 and N5 results in longer C(1)–N(2), C(2)–N(2), C(3)–N(5) and C(4)–N(5) bond distances, which average 1.291 Å, suggesting a small degree of π conjugation within the $[N(CN)_2]^-$ backbone [9].

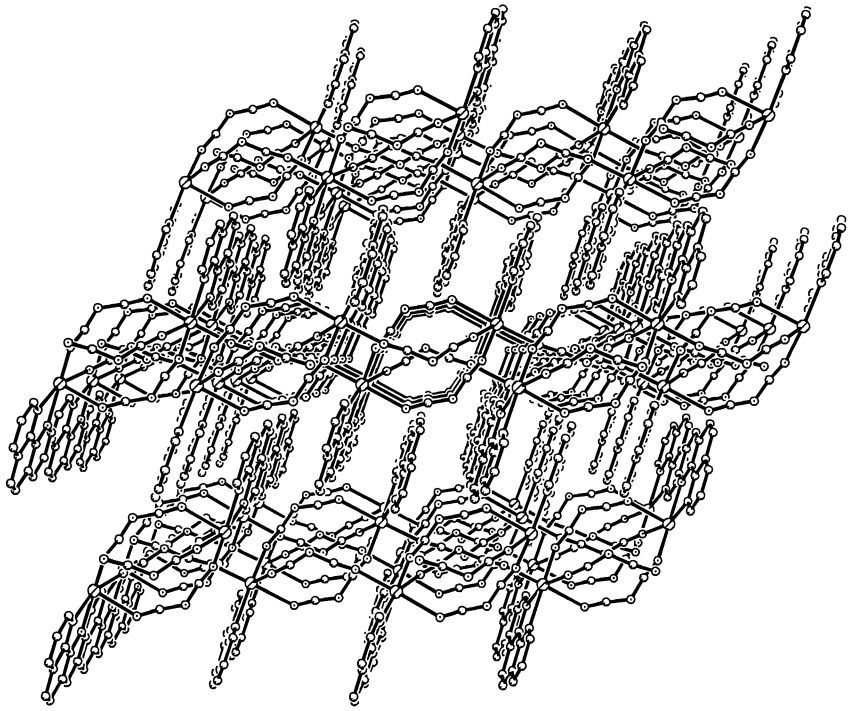

Fig. 3. The 3-D structure of $[Cd(N(CN)_2)_2(phen)]_n$ (**1**) through the weak π–π interaction between adjacent layers

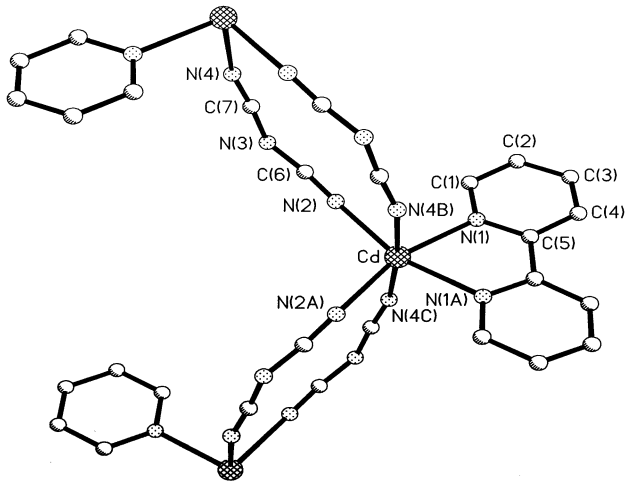

Fig. 4. An ORTEP drawing of $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (**2**) with atomic numbering scheme.

3.2.2. Crystal structure of complex *2*

In complex **2**, $[Cd(N(CN)_2)_2](2,2'\text{-bipy})]$, the adjacent cadmium(II) centers are bridged by the double end-to-end $\mu_{1,5}$-N≡C–N–C≡N to form an extended structure with a zigzag 1-D chain (Fig. 5). The cadmium(II) centers are bound to four dca ligands and one chelate 2,2′-bipy ligand (Fig. 4), the cadmium(II) coordination sphere is a distorted octahedron with two N atoms of two dca [Cd–N(2), 2.304 Å; Cd–N(2A), 2.304 Å] and two N atoms of the 2,2′-bipy ligand [Cd–N(1), 2.322(9) Å; Cd–N(1A), 2.322(9) Å] in the equatorial plane, and two N atoms of two other dca ligands [Cd–N(4B), 2.346(13) Å; Cd–N(4C), 2.346(13) Å] occupy the axial plane. The effect of the distortion is readily seen in *cis*-N–Cd–N′ bond angles, which vary from 70.4(5)° to 103.(5)° for N(1)–Cd–N(1A), N(1)–Cd–N(2) and N(2)–Cd–N(2A), respectively. $[N(CN)_2]^-$ bridging li-

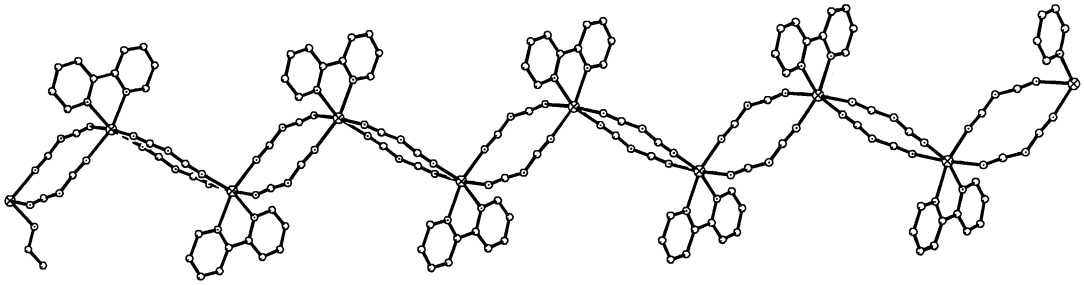

Fig. 5. The chain structure of $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (**2**).

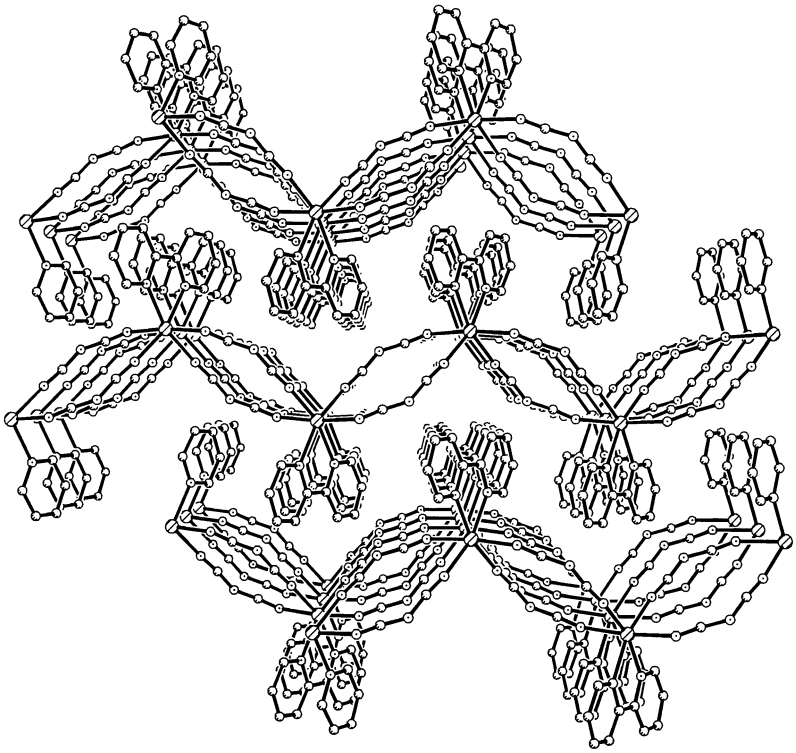

Fig. 6. The 2-D structure of $[Cd(N(CN)_2)_2(2,2'\text{-bipy})]_n$ (**2**) through the weak π–π interaction between adjacent chains.

gands retain approximate C_{2v} symmetry with C(7)–N(4) and C(6)–N(2) bond distances of 1.099(16) and 1.108(14) Å, respectively. Weak π–π interactions are evident, with the shortest distance between the pyridine rings of adjacent chains being 3.641 Å, thus forming a 2-D sheets as in Fig. 6.

4. Supplementary material

Atomic coordinates, thermal parameters and bond lengths and angles for compounds **1** and **2** have been deposited at the Cambridge Crystallographic Center (CCDC). Abstract

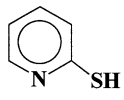
The reaction of Ru(η^2-RL)(PPh_3)$_2$(CO)Cl (**1**) with sodium pyridine-2-thiolate (Napyt) has afforded the complexes of the type Ru(η^1-RL)(PPh_3)$_2$(CO)(pyt) (**3**) in excellent yield (η^2-RL is C_6H_2O-2-CHNC_6H_4R(*p*)-3-Me-5, η^1-RL is C_6H_2OH-2-CHNC_6H_4R(*p*)-3-Me-5 and R is Me, MeO, Cl). The reaction is irreversible and is believed to proceed via *cis* attack by pyt$^-$ on an octahedral face. The type **3** species are thermodynamically more stable than the corresponding carboxylates, nitrites and nitrates. Structure determination of the solvate, **3**(R = Cl)·C_6H_6·0.5C_6H_{14} has revealed a distorted octahedral RuC_2P_2NS coordination sphere with the pairs (P, P), (C(aryl), N) and (C(carbonyl), S) defining the three *trans* directions. The η^1-ClL ligand metallated *ortho* to the phenolic oxygen occurs in the imine–phenol tautomeric form (N···O, 2.639(8) Å) which is consistent with IR and ^{1}H NMR data. The transformation **1** → **3** is associated with changes in tautomeric form, hapticity and conformation (in relation to CO) of RL. The Ru(η^1-ClL) fragment excluding the pendant C_6H_4Cl(*p*) group is nearly coplanar (dihedral angle 6.1°) with the Ru(pyt) plane. The Ru–S distance, 2.524(1) Å, is longer than usual due to steric reasons. The type **3** complexes display a quasi-reversible Ru(III)/Ru(II) couple near 0.6 V versus SCE. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Ruthenium aryls; Pyridine-2-thiolates of ruthenium; Imine–phenol function



1. Introduction

Ruthenium organometallics of type Ru(η^2-RL)(PPh_3)$_2$(CO)Cl (**1**) were discovered in this laboratory a few years ago as products of decarbonylative metallation of 4-methyl-2,6-diformylphenol by $Ru(PPh_3)_3Cl_2$ in the presence of primary amines (RNH_2) [1–3]. We are scrutinising the reactivity of these compounds. Thus alkynes have been found to undergo facile insertion into the Ru–C(aryl) bond of **1** [4–7]. The chloride ligand has been found to be susceptible to displacement by anions such as carboxylates, nitrites and nitrates affording new organometallics [8–10].

Ru(η^2-RL)(PPh_3)$_2$(CO)(Cl)

1

Hpyt

2

In the present work we have explored for the first time the feasibility of introducing a sulfur donor site into the organometallic frame via chloride displacement using pyridine-2-thiol (Hpyt), **2** as the incoming ligand. This ligand choice was based on the documented affinity of pyt$^-$ for ruthenium [11–15]. The reaction of **1** with Napyt has indeed afforded a new family of S,N-chelated organometallics, the structure and properties of which are described in this work. Changes in the coordination mode, tautomeric state and rotameric conformation of the Schiff base ligand accompany the synthetic reaction.

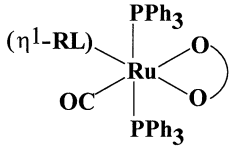
2. Results and discussion

2.1. Synthesis and characterisation

Upon treating **1** in dichloromethane–acetone solution with a sevenfold excess of aqueous Napyt, a yellow solution was afforded from which Ru(η^1-RL)$(PPh_3)_2$-(CO)(pyt) (**3**) was obtained in excellent yield. The synthetic reaction is given in Eq. (1).

The η^1-RL

Ru(η^1-RL)$(PPh_3)_2$(CO)(pyt)



3

ligand in **3** is a tautomer of the η^2-RL ligand in **1** and they bind the metal in monodentate

$$\mathbf{1} + \text{Napyt} \rightarrow \mathbf{3} + \text{NaCl} \quad (1)$$

and bidentate modes, respectively, vide infra. Three R groups have been used in this work: Me, MeO, Cl. The organometallics of type **3** are non-electrolytic in solution and are uniformly diamagnetic consistent with the metal oxidation state of +2.

A note on the thermodynamic stability of **3** compared with related systems is in order. The reaction of Eq. (1) is irreversible and addition of an excess soluble chloride like Et_4NCl into the reaction medium fails to regenerate **1**. It was demonstrated earlier that **1** reacts with carboxylates, nitrates and nitrites affording O,O-chelated species of type **4** [8,9]. This reaction is reversible and is pushed backward upon addition of excess Et_4NCl to the solution. We have now observed that **4** reacts smoothly with Napyt

4

to furnish **3** in excellent yield via displacement of the (O,O) ligand. This conversion which has been quantitated in case of the acetate, Eq. (2), is also irreversible and no

$$\text{Ru}(\eta^1\text{MeL})(PPh_3)_2(CO)(O_2CMe) + \text{Napyt} \rightarrow \mathbf{3}(\text{R=Me}) + \text{NaO}_2\text{CMe} \quad (2)$$

backward reconversion is observed upon addition of an excess acetate to the reaction medium. Thus the Ru(N,S) ring in **3** is thermodynamically much more stable than the Ru(O,O) ring in **4**.

In dichloromethane solution, the complexes display two characteristic allowed bands in the regions 400–410 and 330–350 nm, the later being more intense. The carbon monoxide stretch is seen as a sharp band near 1935 cm^{-1}.

In the ^1H NMR spectrum of **3**, the four pyt protons occur as well-resolved doublets and triplets in the region 6.1–6.7 ppm. The high field shifts of these protons is due to the ring currents of the phosphine phenyl rings. The average ring current shifts estimated from the crystallographic data (see below) and isoshielding $\rho - z$ plots [16,17] is ~0.55 ppm. The PPh_3 and Schiff base aromatic protons form a complex multiplet in the region 7.1–7.6 ppm and the azomethine singlet occurs near 8.5 ppm.

In dichloromethane solution, **3** displays a quasi-reversible one-electron cyclic voltammetric response near 0.6 V versus SCE corresponding to the Ru(III)/Ru(II) couple. As R is varied, the $E_{1/2}$ values increase in the Hammett order OMe < Me < Cl. The reduction potentials are systematically lower than those of the type **1** precursors [3] by ~100 mV indicating better stabilisation of the trivalent state in **3** compared with **1**.

2.2. Crystal structure

The X-ray structure of Ru(η^1-ClL)$(PPh_3)_2$(CO)(pyt)·C_6H_6·0.5C_6H_{14}, **3**(R = Cl)·C_6H_6·0.5C_6H_{14} has been determined authenticating the binding mode shown in **3**. A molecular view excluding solvent of crystallisation is shown in Fig. 1 and selected bond parameters are listed in Table 1. The hexane molecule lies on a crystallographic centre of inversion, ~3.44 Å away

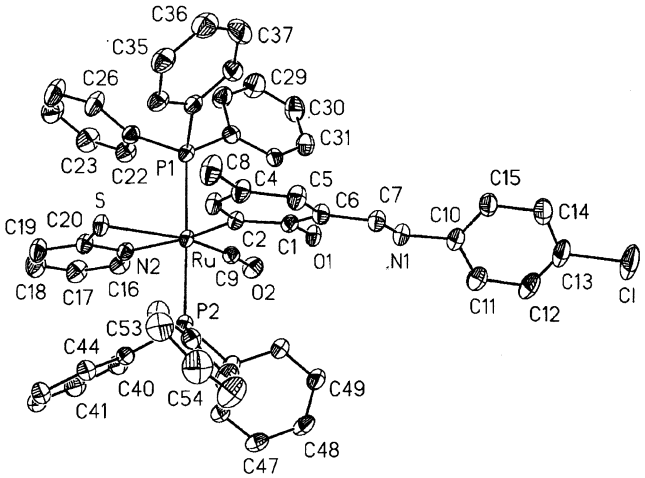


Fig. 1. ORTEP plot (30% probability ellipsoids) and atom-labelling scheme for **3**(R = Cl)·C_6H_6·0.5C_6H_{14} (excluding the solvent of crystallisation).

Table 1
Selected bond distances (Å) and angles (°) for **3**(R = Cl)·C_6H_6·0.5C_6H_{14}

Bond distances			
Ru–P1	2.394(1)	C9–O2	1.153(5)
Ru–P2	2.396(1)	C7–N1	1.280(5)
Ru–C2	2.114(4)	C1–O1	1.376(4)
Ru–C9	1.833(4)	C20–S	1.728(4)
Ru–S	2.524(1)	N1···O1	2.639(8)
Ru–N2	2.144(3)		
Bond angles			
P1–Ru–P2	174.43(4)	P2–Ru–C2	88.32(11)
P1–Ru–S	88.01(4)	Ru–C9–O2	169.9(4)

from the periphery of two PPh_3 ligands of two symmetry related molecules. The benzene of crystallisation lies in a zone near the pyt and PPh_3 aryl rings. This interesting packing situation viewed down *b* axis is highlighted in Fig. 2.

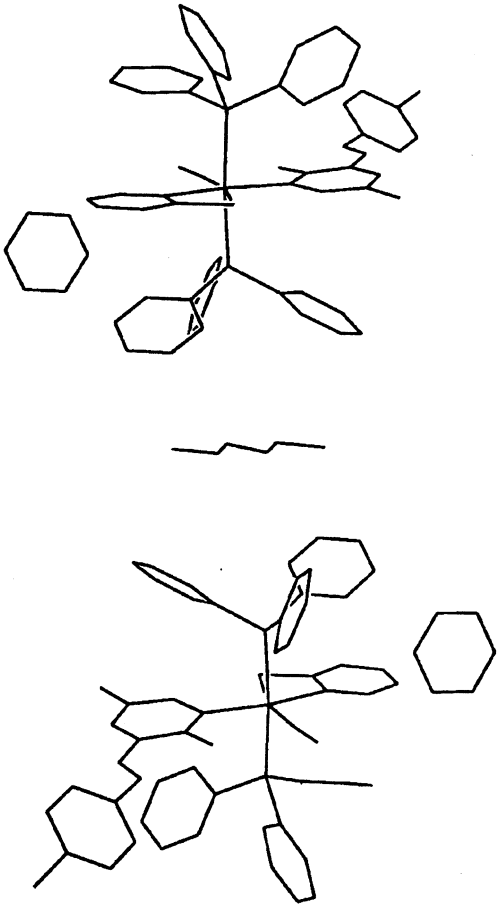

Fig. 2. Portion of packing diagram of **3**(R = Cl)·C_6H_6·0.5C_6H_{14} viewed down *b*-axis.

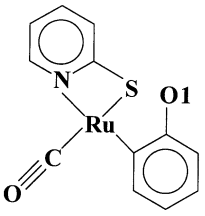
The RuC_2P_2NS coordination sphere has distorted octahedral geometry. The Ru, S, N2, C9 and C2 atoms define a good equatorial plane (mean deviation 0.019 Å) and the *trans* P1–Ru–P2 fragment is approximately linear. The η^1-ClL ligand is monodentate being coordinated to the metal only at the C2 atom. The phenolic oxygen atom (O1) is too far away for metal binding (Ru···O1, 3.439(3) Å).

The metallated aldimine ring (Ru, C1–C8, O1, N1) constitutes a satisfactory plane (plane A) of mean deviation 0.044 Å with which the pendant chlorophenyl ring makes a dihedral angle of 37.2°. The Ru(pyt) fragment along with carbon monoxide and the C2 atom also constitute a satisfactory plane of mean deviation 0.033 Å (plane B). The dihedral angle between planes A and B is 4.6°.

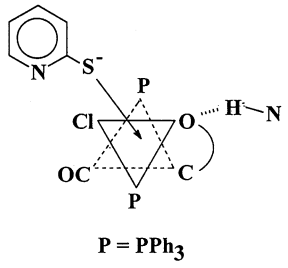


The Ru–S length, 2.524(1) Å, is significantly longer than the corresponding distances, 2.39–2.45 Å, in other structurally characterised Ru(II)(pyt) species [11–15]. This is attributed to S···C3 repulsion. The observed distance between these two non-bonded atoms is 3.420(4) Å which still falls slightly below the sum of the van der Waals radii (3.50 Å) of the carbon and sulphur atoms [18]. The interaction is thus repulsive but the repulsion would have been much more if the Ru–S bond length were shorter.

2.3. Prototropic shift and conformational change

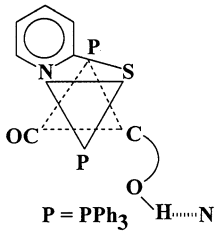
The uncoordinated salicylaldimine fragment in **3** is in the imine–phenol tautomeric form, the N···O distance in **3**(R = Cl)·C_6H_6·0.5C_6H_{14} being 2.639(8) Å. In the precursor complex **1**, the metal is coordinated to the phenolato function and the Schiff base fragment occurs in the iminium–phenolato tautometic form [1]. The reaction of Eq. (1) is thus attended with tautomerization of the salicylaldimine function, corresponding to iminium–phenolato → imine–phenol prototropic shift. The process is a distant parallel of the imine-iminium tautomerization observed in rhodopsins [19].

The observed prototropic change is consistent with certain IR and ^{1}H NMR features. Thus the C=N stretching frequency in **3** ($\sim$1580 cm^{-1}) is expectedly [19,20] lower than that in **1** ($\sim$1620 cm^{-1}) [3]. In ^{1}H NMR, the phenolic proton of **3** occurs as a relatively sharp singlet near 13 ppm. In contrast, the iminium resonance of **1** is much broadened by the quadrupole moment of nitrogen [3].



In both **1** and **3**, the carbon monoxide ligand lies *cis* to the metallated carbon atom. It is, however, located *cis* and *trans* to the phenolato oxygen in **3** and **1**, respectively.

5



Thus the Schiff base fragment rotates by $\sim 180^\circ$ around the metal–carbon bond in course of the reaction of Eq. (1). Model studies have revealed that the transformation is driven by the large steric hindrance that would otherwise arise as depicted in **5** where the estimated O1···S distance is 2.39 Å, falling far short of the sum of van der Waals radii (3.30 Å) of sulphur and oxygen atoms. After rotation as in **3**(R = Cl)·C_6H_6·0.5C_6H_{14} the O1···S distance is 5.673(6) Å.

A plausible mechanism [21,8] for the displacement of chloride in **1** consists of *cis* attack by pyt^- is shown in **6**. The anchored ligand displaces the phenolato oxygen and halide atoms achieving pyt chelation with concomitant prototropic shift and conformational reorganisation as in **7**.

3. Experimental

3.1. Materials

The starting complexes $Ru(PPh_3)_3Cl_2$ [22] and $Ru(\eta^2$-RL)$(PPh_3)_2$(CO)Cl [3] were prepared by reported methods. The purification of dichloromethane and the preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were done as described in previous work [23]. Pyridine-2-thiol was obtained from Aldrich. All other chemicals and solvents were of analytical grade and were used as received.

3.2. Physical measurements

Electronic and IR spectra were recorded with a Shimadzu UV-1601PC spectrophotometer (thermostated cell compartment) and Perkin–Elmer 783 IR Spectrophotometer. ^{1}H NMR spectra were obtained using a Bruker 300 MHz FT NMR spectrometer (tetramethylsilane internal standard). The numbering scheme used for ^{1}H NMR is the same as in crystallography. Spin–spin structures are abbreviated as: s, singlet; d, doublet; t, triplet; m, multiplet. Microanalyses (C, H, N) were done using a Perkin–Elmer 240C elemental analyser. All electrochemical measurements were performed under nitrogen atmosphere using a PAR 370-4 electrochemistry system. The reported potentials are referenced to the saturated calomel electrode (SCE) without junction correction.

3.3. Preparation of Napyt

NaOH (0.864 g, 21.6 mmol) was taken in a beaker. Then 60 ml of distilled water was added to it. The solution was then stirred and to this stirred solution 2 g (18 mmol) of pyridine-2-thiol was added slowly. The mixture was then stirred for 30 min and then evaporated to deposit the salt. It was then filtered and dried in vacuo. Yield: 1.65 g (69%).

3.4. Synthesis of the complexes

The pyridine-2-thiolato complexes $Ru(\eta^1$-RL)-$(PPh_3)_2$(CO)(pyt) were synthesised by reacting $Ru(\eta^2$-RL)$(PPh_3)_2$(CO)Cl with Napyt. Details of a representative case are given below. The other compounds were prepared analogously.

3.4.1. [$Ru(\eta^1$-MeL)$(PPh_3)_2(CO)(pyt)$] (**3**) (R = Me)

To a vigorously stirred violet solution of $Ru(\eta^2$-MeL)$(PPh_3)_2$(CO)Cl (50 mg, 0.055 mmol) in a mixture of dichloromethane (20 ml) and acetone (20 ml) was added dropwise an aqueous solution of Napyt (51 mg, 0.38 mmol). The mixture was stirred for 3 h when the original violet colour became clear yellow. The solvent was then removed under reduced pressure leaving an aqueous suspension of a yellow residue, which was isolated by filtration, washed repeatedly with water, and dried in vacuo. Yield: 45 mg (83%). *Anal*. Found: C, 69.21; H, 4.95; N, 2.87. Calc. for $C_{57}H_{48}N_2O_2SP_2Ru$: C, 69.29; H, 4.90; N, 2.84%. UV–Vis [λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1})]: 410 (3820) and 342 (14 640). IR (KBr, cm^{-1}): 1577 (ν_{CN}) and 1934 (ν_{CO}). ^{1}H NMR ($CDCl_3$, δ): 8.47 (s, 1H, H(7)), 13.06 (s, 1H, O–H), 7.12–7.56 (m, 36H, $2PPh_3$, H(3), H(5), H(11), H(12), H(14), H(15)), 2.25 and 2.31 (2s, 6H, $2CH_3$), 6.67 (d, 1H, H(16), J_{HH} 8.1), 6.17 (t, 1H, H(17), J_{HH} 6.3), 6.57 (t, 1H, H(18), J_{HH} 6.3), 6.34 (d, 1H, H(19), J_{HH} 8.4). $E_{1/2}$ (vs. SCE, CH_2Cl_2, scan rate, 50 mV s^{-1}): 0.59 V (ΔE_P = 120 mV).

3.4.2. [Ru(η¹-MeOL)(PPh₃)₂(CO)(pyt)] (3) (R = MeO)

Ru(η²-MeOL)(PPh₃)₂(CO)Cl (50 mg, 0.054 mmol) and Napyt (51 mg, 0.38 mmol) were employed. Yield: 47 mg (87%). *Anal*. Found: C, 68.22; H, 4.77; N, 2.73. Calc. for $C_{57}H_{48}N_2O_3SP_2Ru$: C, 68.18; H, 4.82; N, 2.79%. UV–Vis [λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1})]: 408 (3270) and 348 (11 250). IR (KBr, cm^{-1}): 1579 (ν_{CN}) and 1935 (ν_{CO}). ^{1}H NMR ($CDCl_3$, δ): 8.49 (s, 1H, H(7)), 13.10 (s, 1H, O–H), 7.15–7.57 (m, 36H, 2PPh$_3$, H(3), H(5), H(11), H(12), H(14), H(15)), 2.24 (s, 3H, CH_3), 3.77 (s, 3H, OCH_3), 6.68 (d, 1H, H(16), J_{HH} 8.1), 6.19 (t, 1H, H(17), J_{HH} 6.3), 6.58 (t, 1H, H(18), J_{HH} 6.1), 6.36 (d, 1H, H(19), J_{HH} 8.1). $E_{1/2}$ (vs. SCE, CH_2Cl_2, scan rate, 50 mV s^{-1}): 0.58 V ($\Delta E_P = 180$ mV).

3.4.3. [Ru(η¹-ClL)(PPh₃)₂(CO)(pyt)] (3) (R = Cl)

Ru(η²-ClL)(PPh$_3$)$_2$(CO)Cl (50 mg, 0.054 mmol) and Napyt (51 mg, 0.38 mmol) were used. Yield: 46 mg (85%). *Anal*. Found: C, 66.62; H, 4.54; N, 2.72. Calc. for $C_{56}H_{45}N_2O_2SP_2ClRu$: C, 66.69; H, 4.50; N, 2.78%. UV–Vis [λ_{max}, nm (ε, dm^3 mol^{-1} cm^{-1})]: 415 (4160) and 333 (18 640). IR (KBr, cm^{-1}): 1580 (ν_{CN}) and 1936 (ν_{CO}). ^{1}H NMR ($CDCl_3$, δ): 8.50 (s, 1H, H(7)), 13.07 (s, 1H, O–H), 7.19–7.60 (m, 36H, 2PPh$_3$, H(3), H(5), H(11), H(12), H(14), H(15)), 2.25 (1s, 3H, CH_3), 6.68 (d, 1H, H(16), J_{HH} 8.0), 6.20 (t, 1H, H(17), J_{HH} 6.0), 6.58 (t, 1H, H(18), J_{HH} 6.0), 6.35 (d, 1H, H(19), J_{HH} 8.1). $E_{1/2}$ (vs. SCE, CH_2Cl_2, scan rate, 50 mV s^{-1}): 0.67 V ($\Delta E_P = 170$ mV).

3.5. Conversion of [Ru(η¹-MeL)(PPh₃)₂(CO)(O₂CMe)] to 3 (R = Me)

To a vigorously stirred yellow solution of [Ru(η^1-MeL)(PPh$_3$)$_2$(CO)(O$_2$CMe)] (50 mg, 0.053 mmol) in dichloromethane (20 ml) and acetone (20 ml) was added dropwise an aqueous solution of Napyt (71 mg, 0.53 mmol). After further stirring for 3 h, the organic solvent was removed under reduced pressure. The yellow residue was collected by filtration, washed thoroughly with water and dried in vacuo. Yield: 78%.

3.6. X-ray crystallography

A single crystal ($0.55 \times 0.4 \times 0.4$ mm) of [Ru(η^1-ClL)(PPh$_3$)$_2$(CO)(pyt)]·C$_6$H$_6$·0.5C$_6$H$_{14}$, grown by slow diffusion of hexane into benzene solution followed by evaporation, was used. Cell parameters were determined by a least-squares fit of 30 machine-centred reflections ($2\theta = 14°$–$28°$). Data were collected with the ω-scan technique in the range $3° \le 2\theta \le 47°$ on a Siemens R3m/V four-circle diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Two check reflections measured after every 198 reflections showed no significant intensity reduction in any case. All data were corrected for Lorentz polarisation effects and an empirical absorption correction [24] was done on the basis of azimuthal scan of six reflections for the crystal.

The metal atom was located from Patterson maps and the rest of the non-hydrogen atoms emerged from successive Fourier syntheses. The structure was refined by a full-matrix least-squares procedure on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at calculated positions. Calculations were performed using the SHELXTL, Version 5.03 [25] programme package. Significant crystal data are listed in Table 2.

3.7. Computer generation of motif 5

The relative positions of CO and the pyt chelate were retained as in the structure of Ru(η^1-ClL)(PPh$_3$)$_2$(CO)-(pyt)·C$_6$H$_6$·0.5C$_6$H$_{14}$ but the phenolic oxygen (O1) (the phenolic C–O length was set at 1.363 Å) was shifted so as to correspond to the relative position in **1** (R = Me). The O1···S distance is then found to be 2.39 Å.

3.8. Computation of chemical shifts due to PPh₃ ring currents

The crystallographic data of [Ru(η^1-ClL)(PPh$_3$)$_2$-(CO)(pyt)]·C$_6$H$_6$·0.5C$_6$H$_{14}$ were used. The cylindrical coordinates (ρ and z) [26] of the protons with respect to the centroids (G) of the PPh$_3$ phenyl rings were determined from: (i) the distance of the proton from the centroid (G) of each PPh$_3$ phenyl ring and (ii) the angle between the distance vector and the normal to the plane of the ring at G. These calculated ρ and z values were expressed in units of the radius of the benzene hexagon and the shifts were estimated with the help of the available isoshielding ρ versus z plots [16]. The net shift of a proton was obtained by summing the individual contributions from all the rings.

Table 2
Crystal data for **3**(R = Cl)·C$_6$H$_6$·0.5C$_6$H$_{14}$

Formula	$C_{65}H_{58}ClN_2O_2P_2RuS$
M	1129.65
Crystal system	triclinic
Space group	$P\bar{1}$
a (Å)	11.797(2)
b (Å)	12.935(3)
c (Å)	19.241(5)
α (°)	82.24(2)
β (°)	75.14(2)
γ (°)	78.88(2)
V (Å^3)	2773.4(10)
Z	2
μ (Mo Kα) (mm^{-1})	0.473
Total reflections	8302
Independent reflections (R_{int})	8161(0.0403)
R_1, wR_2 [$I > 2\sigma(I)$] (all data)	0.0436, 0.1071; 0.0587, 0.1388

4. Conclusions

The scope of synthesis of new ruthenium aryls via chloride displacement from **1** has been augmented to sulphur donor ligands using pyridine-2-thiolate as the incoming chelator affording species of type **3**. These are found to be thermodynamically more stable than carboxylates, nitrates and nitrites.

Rational changes in tautomeric form, hapticity and conformation of RL occur in going from **1**→**3** as revealed by structural and spectroscopic data. The presence of significant crowding is reflected in both non-bonded (C···S) as well as bonded (Ru–S) distances.

5. Supplementary material

Supplementary data are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk) on request quoting the deposition number, CCDC 171587.

Professor Achim Müller awarded 2001 Sir Geoffrey Wilkinson Prize

It is a great pleasure to announce that the 2001 *Sir Geoffrey Wilkinson Prize* has been awarded to Professor Achim Müller from the University of Bielefeld, Germany.

Professor Müller is regarded as one of today's leading international scholars on the subject of soluble metal oxides and sulfides. Being an immensely creative and highly successful inorganic chemist with extremely broad interests, his work includes the synthesis of the first discrete pure metal–sulfur clusters (e.g. $Mo_3S_{13}^{2-}$) as well as of the first isopolythioanions ($W_3S_9^{2-}$); the introduction of the unusual thiometalate ligands in the field of complex chemistry; template directed organisation of metal–oxide cluster shells; new aspects of inorganic host–guest chemistry; and contributions to the development of supramolecular magneto chemistry.

One of his most remarkable achievements is the discovery of the 'Bielefeld giant wheel' polyoxomolybdate. The largest molecular cluster structurally characterised at the time, it caused a worldwide sensation. Professor Müller and his co-workers have developed novel concepts for handling highly complex molecular nanostructures, which are amongst the most fascinating problems of contemporary inorganic chemistry.

The 2001 *Sir Geoffrey Wilkinson Prize* will be presented to Professor Müller by Professor Barry Lever, on July 22nd 2002 during the XXXVth International Conference on Coordination Chemistry in Heidelberg,

0277-5387/02/$ - see front matter © 2002 Published by Elsevier Science Ltd.
PII: S0277-5387(02)00918-X

Germany. The presentation will be followed by a Prize Lecture.

The *Sir Geoffrey Wilkinson Prize*, previously designated as the *Polyhedron Prize*, was renamed after the late Professor Geoffrey Wilkinson, the Prize's first recipient in 1989. As one of Elsevier's most prestigious awards, it has been designed to pay tribute to creativity in the field of inorganic and organometallic chemistry. The winner receives from Elsevier Science a commemorative medal accompanied by a cheque for US$ 10,000. The selection committee for the 2001 Prize consisted of Professor F. Albert Cotton, Professor Akio Yamamoto and Professor Lord Jack Lewis. Past winners include: Professor Richard H. Holm (1991), Professor M. Frederick Hawthorne (1993), Professor F. Albert Cotton (1995), Professor Lord Lewis (1997) and Professor Herbert Roesky (1999).

1. Biographical sketch of Professor Achim Müller

Achim Müller studied chemistry and physics at the Georg-August University in Göttingen, where he received his PhD degree under the supervision of Oskar Glemser with a thesis about experimental thermochemistry in 1965 (his subject included theoretical physics) and only 2 years later, in 1967, his habilitation with a thesis in the field of vibrational spectroscopy.

In 1971 Achim Müller became Associate Professor at the University of Dortmund and thereafter, in 1977, accepted the Chair of Inorganic Chemistry I at the University of Bielefeld, where he has since remained although he was offered an honorable professorship at the University of Saarbrücken as successor to Professor F. Seel.

As regards research Achim Müller's interests and achievements are extremely broad and range from (synthetic) transition metal chemistry, supramolecular chemistry, through inorganic structural chemistry, electronic structure of transition metal complexes and clusters, vibrational spectroscopy (matrix isolation, band-contour analysis, resonance Raman effect), molecular physics (theory of heavy atom substitution on molecular constants), heterogeneous catalysis (desulfurization of crude oils), to bioinorganic chemistry (biological nitrogen fixation, including microbiological and biochemical investigations). Recently he even extended his knowledge to the realm of natural philosophy and public understanding of science where he has already published his first papers.

The results of his widespread chemistry investigations have been recorded in more than 700 publications and received extreme resonance in the scientific community. An exceptional aspect is that the papers were published in ca. 70 different journals specific to the above-mentioned fields. In addition, he is the author of more than 40 reviews and editor/co-editor of ten books, again dealing with all the above-mentioned fields. One of his reviews was commented by a referee as '...a beautifully idiosyncratic approach and a joy to read. Would that more chemists dared to approach their work with such panache and breadth of vision!'

Indications of the international scientific reputation of his research work can also be inferred from the fact that about 50 postdoctoral fellows and guest professors from many different countries came to Göttingen (the first in fact prior to his Habilitation), Dortmund, and Bielefeld. Documentary proof supporting this statement can be furnished by the fact that Achim Müller has for many years been one of the most cited authors in science worldwide (science citation index of ISI). In the course of his entire scientific career he has maintained a remarkable collaboration, also on an interdisciplinary level, with many groups in very different parts of the world. The scientific results were also presented in more than 60 invited, plenary (including opening), and named lectures at international conferences.

Regarding his research topics—focussed here only on inorganic chemistry—he can be considered as one of the internationally leading figures on the subject of soluble metal oxides and sulfides with many essential impulses coming from him. The following key points furnish proof for this statement: the synthesis of the first discrete pure metal–sulfur cluster (e.g. $Mo_3S_{13}^{2-}$ besides $Mo_2S_{12}^{2-}$) and the first polythioanion ($W_3S_9^{2-}$), the discovery of the most simple ferredoxin model ($[Fe_4S_4(SH)_4]^{2-}$), the introduction of unusual thiometalate ligands like MS_4^{2-} (M = Mo, W) into the field of complex chemistry in connection with the discovery of their important ability to show internal redox processes, the unprecedented use of template-directed organisation of metal–oxide cluster shells, the development of new principles of inorganic host–guest chemistry, contributions to supramolecular magneto chemistry (some of his clusters became favorable objects of investigations in magneto chemistry and in the physics of magnetism), and in more recent years the spectacular discovery of the 'Bielefeld giant wheel' polyoxomolybdate—at that time with 154 metal atoms the largest molecular cluster (his record now being 264) structurally characterized. The species was isolated from a molybdenum blue solution which chemists had been probing for more than 200 years since the time of Scheele and Berzelius. In this context Professor Achim Müller and his coworkers have developed novel concepts for handling highly complex metal oxide based molecular nanostructures to perform well defined reactions at well defined sites of structurally well defined nanoobjects/clusters, thus dealing with one of the most fascinating problems of contemporary Inorganic Chemistry. In this sense not only the discovery of chemical reactions, i.e. nucleation processes, inside the cavity of spherical and ring-shaped nanoclus-

ters but also of the possibility to link or cross-link these in distinct predefined ways even in room temperature solid state reactions (crystal-engineering) are highlights.

An important step was clearly to form and to use pentagonal building units. In agreement with the paradigm of Buckminster Fuller, this allowed the synthesis of sizable (!) spherical nanoclusters with icosahedral symmetry (inorganic fullerenes, or so-called keplerates), for instance those with 132 and 102 metal atoms. The planned (!) synthesis of a new type of supramolecular species with host–guest topology (a quantum-dot within a magneto-dot) with an encapsulated cluster (Keggin-ion), which fits exactly into an unusual spherical nanocluster (the largest molecular paramagnet with 30 Fe^{III} centers), was commented by a referee as follows: '...the readership will likely experience the same type of progression that I did upon reading it: initial surprise ('Surely this cannot be!') then curiosity, subsequent admiration, and finally lingering thought-provoking reflection'.

Achim Müller's achievements have been recognized worldwide. His work has been highlighted in *Nature*, *Science* as well as by global newspapers and magazines, not just because of the mere beauty of the molecular entities he produced, but also because of the perspectives.

On account of his extremely wide range of scientific activities and indeed his conception of science in general, he has been acknowledged with Doctor honoris causa and Honorary Professor degrees, Honorary Memberships of science institutions as well as other important awards (Alfred-Stock-Gedächtnispreis (GDCh), Prix Gay-Lussac/Humboldt of the Ministère de la Recherche, Paris). He became a member of editorial boards of many international renowned journals and is elected member of several academies (e.g. Polish Academy of Sciences, Deutsche Akademie der Naturforscher Leopoldina, and Academia Europaea, among others).

Professor Achim Müller is a most deserved winner of the 2001 *Sir Geoffrey Wilkinson Award* and we extend our congratulations to him on this important occasion.

Transition metal containing dendrimers based on cyclophosphazene units

Carlos Díaz *, M.L. Valenzuela

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Las Palmeras 3425, Casilla 653, Santiago, Chile

Received 2 April 2001; accepted 8 January 2002

Abstract

The series of complexes $[N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN\cdot MCl_n]PF_6$, $N_3P_3(OC_6H_4CH_2CN)_6\cdot(MCl_n)_6](PF_6)_6$, $[N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN\cdot MCl_{n-1}]Cl$ and $[N_3P_3(OC_6H_4CH_2CN)_6\cdot(MCl_{n-1})_6]Cl_6$, $MCl_n = MnCl_2$, $FeCl_3$, $CoCl_2$, $NiCl_2$, $CuCl_2$ have been synthesized by reaction of the corresponding cyclophosphazene ligands: $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (L_1) and $N_3P_3(OC_6H_4CH_2CN)_6$ (L_2) with the respective salts MCl_n in CH_3OH as solvent and in presence or absence of NH_4PF_6. The new compounds were characterized by elemental analysis and IR, UV–Vis and EPR spectroscopy as well as electrochemical methods. The reaction of $CuCl_2$ with the ligand L_1 affords the copper (I) complex. $[N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN\cdot Cu]PF_6$ instead the expected Cu(II) complex, which was characterized by multinuclear NMR. For comparison, the complex $[N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN\cdot ZnCl]PF_6$ was also prepared. The hexametalladendrimers of iron exhibits a six-electron reduction while that the correspondent monometalladendrimers exhibit a single one-electron reduction. Upon coordination νCN increase in a similar way to crystal field effects dependence with the metal. © 2002 Published by Elsevier Science Ltd.

Keywords: Dendrimers; Cyclophosphazene; Metal–nitrile complexes

1. Introduction

Dendrimers chemistry is a rapid developing field of research [1]. Dendrimers offer the prospect of novel material with advantageous properties allowing them to serve, as soluble catalysts [2], dendritic boxes [3], and other supramolecular dendritic arrangements. Since the initial report on this class of molecules by Vögtle in 1978, [4], and many different structural classes of dendritic macromolecules have been reported. Two main classes of dendrimers can be distinguished: the classical organic dendrimers [1] and the emergent inorganic dendrimers [5].

The incorporation of transition-metal complexes in both organic and inorganic dendrimers lead to new and interesting material with specific properties such as the capability to absorb visible light, to give luminescence and to undergo reversible multielectron redox processes [6]. Such species; in fact could find applications as component in molecular electronic and as a photochemical molecular devices for solar energy conversion and information storage [6]. Metal-containing dendrimers can be classified in to three categories, see Fig. 1:

A) Dendrimers with coordination centers at the core.
B) Dendrimers with coordination centers through all layers.
C) Dendrimers with coordination centers on the periphery.

Although dendrimers with coordination centers on the periphery have been reported [1,2,6] for those with the dendrimer, core being organic, few examples of inorganic dendrimers with metal derivatives on the surface have been reported [5–8]. This communication reports the synthesis and characterization of new inorganic dendrimers based on cyclophosphazene containing single metal complexes on the surface. We have recently reported some organometallic derivatives of partially branched cyclophosphazene derivatives [9,10].

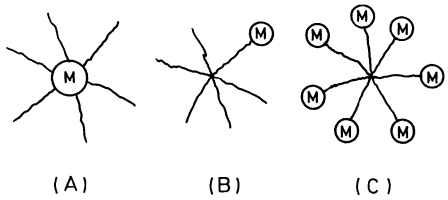

Fig. 1. Schematic representation of three classes of metallodendrimers.

2. Results and discussion

2.1. Synthesis

The synthesized complexes are showed in Table 1. As expected the synthesis of the dendrimers L_1 and L_2 was made by the divergent strategy [1], by reaction of $N_3P_3Cl_6$ with $HO–C_6H_4CH_2CN$ in acetone and in presence of the K_2CO_3 [9,10]. The metallic derivatives **1**–**17** were obtained by reaction of the respective dendrimer ligands with MCl_n in methanol as solvent (see Table 1). NH_4PF_6 as halide abstractor was used for preparation of complexes **1**–**11**. Compounds were characterized by elemental analyses, IR, UV–Vis and EPR spectroscopy as well cyclic voltammetry. The paramagnetism of the complexes precludes a NMR characterization, except diamagnetic complexes **5** and **11** which were characterized by multinuclear NMR spectroscopy. Some complexes are highly hygroscopic as revealed by its elemental analyses as well as their IR spectrum (see Section 4).

2.2. IR and crystal field correlations

The IR spectra of complexes **1**–**16** exhibit the expected bands due to ν(N=P) and ν(CN) modes of the ligand [11] as well as the $\nu(PF_6)$ band [9,10] for complexes **1**–**11**. Characteristic splitting of the ν(N=P) bands due to coordination was observed in all the series of complexes. This splitting pattern appears to be typical of metal coordination [9,10], as shown in Fig. 2, for ligand L_2 in their Fe and Zn complexes. Two intense and broad bands around 3479 and 3159 cm^{-1} corresponding to $\nu(OH_2)_{as}$ and $\nu(OH_2)_s$, respectively, as well as a medium intensity band around 1658 cm^{-1} corresponding to $\delta(OH_2)$ are consistent with the presence of a high degree of hydration for almost all the complexes. The IR spectra are collected in Table 2. Coordination of metal to ligands L_1 and L_2 produce an enhancing of the νCN band which suggest a considerable $\sigma(RCN) \rightarrow \sigma$(metal) contribution to the N···metal bond. Similar tendency has been observed for organometallic derivatives of ligands L_1 and L_2 [9,10]. The strengthening of the CN

bond upon coordination can be due to the shift of electron density from the antibonding HOMO of the cyanide ligand to the orbitals of metal. Thus we have found that the difference ν_{CN} complex $-\nu_{CN}$ ligand follow a dependence typical of crystal field stabilization energies effects (understood as covalency effects across the 3d series) [12,13].

2.3. Cyclic voltammetry studies

There are few reports of electrochemical studies on any cyclophosphazene metal complexes [8b,8c]. Cyclic voltammetry provides some insight into the origin of the very different oxidation state distribution in the complexes. Only the complexes **2**, **5**, **7** and **10** were electrochemically active. Complexes **12**–**17** were not measured owing their oily nature. Data are shown in Table 3. As observed for other [RCN][ML_n] complexes [14a] with M = Mn,Co and Ni, it shows any wave in their voltammogramm in the studied range. The cyclic voltammogram recorded for complexes **2** and **7** are shown in Fig. 3. Analysis of the cyclic voltammetric responses for these complexes with scan rate varying from 50 to 200 mV s^{-1} showed an irreversible one-electron transfer for the Fe(III)/Fe(II) couple which is located around 0.50 and 0.44 V for complexes **2** and **7**, respectively. These data are consistent with the one reduction wave at 0.47 V for the complex [$Cl_3Fe(\mu$-NC)Mn(CO)(dppm)$_2$] [14a]. $N_3P_3(OC_6H_5)_6$ and $N_3P_3Cl(OC_6H_5)_5$ does not exhibit redox process in the range of potentials $-2.0 \rightarrow +2.0$ V [8b]. Similar substituted phosphazenes with CN groups also exhibit redox reduction activity below -1.8 V [8b].

The presence of a single reduction peak (although irreversible) indicates that the six irons are reduced to the same potential which suggests that the six redox iron

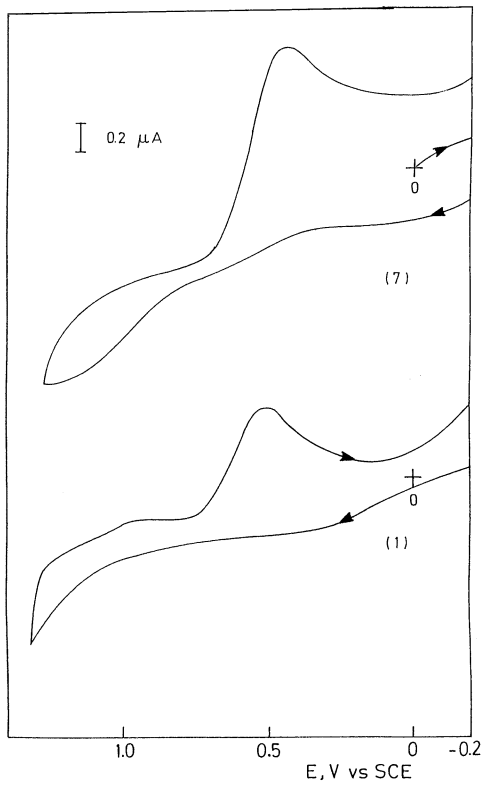

Fig. 3. Cyclic voltammogram of complexes **1** and **7**.

centers are non-interacting. Considering that the solutions have a concentration of 1.04×10^{-3} M for **2** and 7.76×10^{-4} M for **7** and assuming that the complex **2** is a monomeric unit, and the complex **7** can be considered as their polymer ($n = 6$), containing six non-interacting redox unit, then the electron number transferred in the reduction of **7** with respect to the electron transferred in **2** (one electron) can be estimated by the equation [14b]:

$$n_p = \frac{i_p/C_p}{i_m/C_m}\left[\frac{M_p}{M_m}\right]^{0.272} \quad (1)$$

where i_p and i_m are the current intensity for the polymers and the monomer, respectively, M_p and M_m are the molecular weight. Eq. (1) gives a value $n_p \approx 6$ for complex **7**.

On the other hand the cyclic voltammogram of the copper complex **10** exhibits a rather complex pattern of signals. Observed waves (see Fig. 4) can be interpreted tentatively as redox processes occurring on a copper(II) atom similar for the six position of the ligand instead of redox processes affecting each one of the Cu(II) centers. In this latter case a communication between the copper centers should cause the oxidation–reduction to occur at slightly different potentials observing several near waves [14b]. In the first cycle of the scan a single one wave at 0.28 V versus SCE was observed. Comparing with literature data for similar system [8] this wave can be tentatively assigned to the Cu(II)/Cu(III) couple.

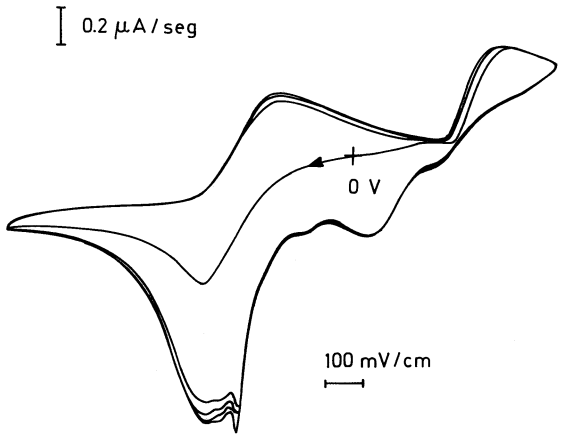

Fig. 4. Cyclic voltammogram of complex **11**.

Second and subsequent scans lead to an enhancing of the oxidation peak and the appearance of another reduction and three additional oxidation peaks. Simultaneously with this a strong characteristic stripping peak appeared which is probably due to the reoxidation of an unknown Cu(II)/Cu(III) electrodeposited planar species. According to literature data [8], the irreversible wave at 0.025, −0.05 and −0.30 V can be assigned tentatively to a Cu(I)/Cu(0), Cu(II)/Cu(0), and Cu(II)/Cu(I) processes, respectively.

2.4. UV–Vis

As found for $FeCl_3$ and other iron-chloride derivatives [13]; the UV–Vis spectra of the complexes **2** and **7** exhibit intense ligand–metal charge transfer bands around 360 and 400 nm, which obscure completely the very weak spin-forbidden d–d bands. The complexes do not exhibit absorption above 500 nm. Data are shown in Table 3. Intensity and position for the charge transfer transition are similar to those found for similar chloro–iron complexes [12,13]. The other complexes exhibit the expected d–d transition for the respective octahedral ions [12,13]. Absorption for the Mn and Co complexes are very weak; those for Cu(II) are broad probably due to a tetragonal distortion [13a].

2.5. EPR spectra

Complexes **1**, **2**, **6**, **7**, **9**, **10**, **13** and **17** exhibits intense signals both in solid as well as in dichloromethane solution. Data are displayed in Table 3. Complexes **3**, **4**, **8**, **14** and **15** are EPR silent in the measured conditions. On the other hand, the diamagnetic complexes **5** and **11** as expected, does not exhibit EPR signal. The paramagnetic complexes **2** and **7** exhibit the typical EPR signal of Fe(III) complexes [13]. The Fe(III) ion is a ground state ^6S (^6A_1g in the complexes) and is not split within an octahedral or even a lower symmetry ligand

field [15]. In addition, there can been no splitting by spin–orbital interaction. Then a single isotropic resonance line at $g = 2$ should be always observed. Hyperfine interaction of the unpaired electron with the ^{14}N nucleus ($I = 1$) of the cyanide group was not observed, although the broad, signal in solid state could contain some unresolved splitting. On the other hands, the g values (Table 3) near 2 for complexes **2** and **7** and this corresponds to high spin Fe(III) complexes, because low spin Fe(III) complexes exhibit higher g values [16–18]. The EPR spectrum of complex **10** exhibits the signal splitting typical of a tetragonal distortion of the copper complex. As observed for other similar complexes [13], compounds **3**, **4** and **8** are EPR silent.

2.6. Reaction of L_1 with $CuCl_2$ in presence of NH_4PF_6

Reaction of L_1 with $CuCl_2$ in MeOH and in presence of NH_4PF_6 affords the Cu(I) complex $[N_3P_3(O\text{-}C_6H_5)_5OC_6H_5CH_2CNCu][PF_6]$ instead of the expected Cu(II) complex. The diamagnetic white complex was characterized by elemental analysis, multinuclear NMR as well as cyclic voltammetric methods. The complex **5** exhibits the expected ^{31}P signal for the N_3P_3 ring namely a singlet at 11.64 ppm. The PF_6 anion was observed as a septuplet at −142 ppm. The ^{13}C NMR spectrum of complex exhibit among other, the typical signal of CN at 121.13 ppm. Full data are displayed in Section 4. Thus, these data compare well with the NMR multinuclear data for the diamagnetic complex $[N_3P_3(OC_6H_5)_5OC_6H_5CH_2CN\cdot ZnCl][PF_6]$ as well as with organometallic derivatives [9,10]. The single oxidation peak observed at −0.48 V can be tentatively assigned to the Cu(I)/Cu(II) processes.

2.7. Preparation of $[N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN\cdot ZnCl][PF_6]$

For comparison purpose we have also prepared the complex $[N_3P_3(OC_6H_5)_5OC_6H_5CH_2CNZnCl][PF_6]$ which was characterized by multinuclear NMR. The ^{31}P NMR spectra exhibits the N_3P_3 signal at 15.4 ppm, a value at slightly high field than the Cu(I) complex due to the most low π-back-bonding Zn→ligand with respect to that of the Cu→ligand. Consistent with this, the ^{13}C NMR signal of the CN group in the Zn complex also appears at highest field with respect to the Cu(I) complex. Other data are observed normally, see Section 4.

3. Conclusions

The dendrimers L_1 and L_2 can coordinate one and six transition atoms, respectively, at the periphery. Formations of metallodendrimers 1–17 open interesting possible applications to solubilize conventionally insoluble inorganic compounds (as MX_n salts) in organic solvents. Although the redox properties of the complexes **7** and **10** are irreversible, they are reduced or oxidized at the same potential which suggest a possible application as molecular battery. Experiments to coordinate other transition metals with possible reversible redox properties are in progress. To our knowledge complexes **2** and **7** are the first iron(III) containing cyclophosphazene dendrimers [19].

4. Experimental

Experimental procedures and IR, UV–Vis, ESR and electrochemical measurements were performed as previously reported [9,10]. The ligands $N_3P_3(O\text{-}C_6H_5)_5OC_6H_4CH_2CN$ and $N_3P_3(OC_6H_4CH_2CN)_6$ were prepared as described previously [9,10]. $MnCl_2\cdot 4H_2O$, $FeCl_3\cdot 6H_2O$, $CoCl_2\cdot 6H_2O$, $NiCl_2\cdot 6H_2O$, $CuCl_2\cdot 2H_2O$ and NH_4PF_6 were used as received. Solvents were dried and purified by standard procedures.

4.1. Preparation of the complexes

4.1.1. $[MCl_n(L_1)]PF_6$

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**1**) 0.2 g (0.27 mmol) and $MnCl_2$ 0.07 g (0.35 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.12 g (0.74 mmol), for 24 h at room temperature (r.t.). From the slight pink solution the solvent was removed by rotary evaporation. The pale pink solid was dissolved in CH_2Cl_2 and filtered through celite. The solvent was removed under vacuum and the solid was washed several times with a *n*-hexano–diethylether mixture. The resulting cream solid was vacuum dried. Analysis, Found: C 31.97; H 6.27; N 4.19. Calc. for $C_{38}H_{31}F_6O_6N_4P_4Cl_2$: $Mn\cdot CH_2Cl_2$, C 32.17; H 6.27; N 3.9%.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**2**) 0.13 g (0.1775 mmol) and $FeCl_3$ 0.0617 g (0.2282 mmol) were stirred in a Schlenk in CH_3OH (15 ml) and in presence of the NH_4PF_6 0.072 g (0.44 mmol), for 24 h at r.t. From the orange solution, the solvent was removed by rotary evaporation. The orange solid was dissolved in CH_2Cl_2 and filtered though celite. The solvent was removed under vacuum and the oily solid was broken by washing several times with a *n*-hexano–diethylether mixture. The resulting orange solid was vacuum dried. Analysis, Found: C 43.52; H 3.50; N 3.80. Calc. for $C_{38}H_{31}F_6O_6N_4P_4Cl_2Fe\cdot CH_2Cl_2$, C 42.98; H 3.03; N 5.1%.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**3**) 0.15 g (0.21 mmol) and $CoCl_2$ 0.06 g (0.25 mmol) were stirred together with NH_4PF_6 0.08 g (0.49 mmol) in CH_3OH (15 ml) at r.t. for 24 h. Similar procedure as **1** affords a

cream solid. Yield: 0.32 g, 62%. Analysis, Found: C 49.50; H 4.15; N 4.14. Calc. for $C_{38}H_{31}F_6O_6N_4P_4Cl_2Co$, C 48.35; H 3.93; N 4.02%.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**4**) 0.16 g (0.22 mmol) and $NiCl_2$ 0.07 g (0.29 mmol) were stirred in a Schlenk in CH_3OH (15 ml) and in presence of the NH_4PF_6 0.08 g (0.49 mmol), for 24 h at r.t. From the pale green solution the solvent was removed by rotary evaporation. The pale green solid was dissolved in a CH_2Cl_2–methanol mixture and filtered through celite. The solvent was removed under vacuum and the paste/oil solid was broken by washing several times with dichloromethane and vacuum dried. Undetermined amounts of water preclude good analysis.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**5**) 0.12 g (0.16 mmol) and $CuCl_2$ 0.03 g (0.18 mmol) were stirred in a Schlenk in CH_3OH (15 ml) and in presence of the NH_4PF_6 0.06 g (0.37 mmol), for 24 h at r.t. From the pale yellow solution the solvent was removed by rotary evaporation. The solid was dissolved in CH_2Cl_2 and filtered through celite. From the clear solution, the solvent was removed under vacuum and the white solid was washed several times with a *n*-hexano–diethylether mixture and vacuum dried. Yield: 0.32 g, 62%. Analysis, Found: C 51.62; H 9.23; N 4.18. Calc. for $C_{38}H_{31}F_6O_6N_4P_4ClCu\cdot CH_2Cl_2$, C 51.53; H 4.39; N 5.46%.

^{1}H NMR(CD_2Cl_2, δ ppm) 7.3–6.8(m), aromatic, 3.6(s), CH_2. ^{31}P NMR (CD_2Cl_2, δ ppm) 11.64(s) N_3P_3, −142(h) PF_6. ^{13}C NMR (CD_2Cl_2, δ ppm) 129.94, 129.68, 125.48, 116.35. 35(m) aromatic, 121.13(s) CN, 24.21(s) CH_2.

4.1.2. $[(MCl_n)_6(L_2)][PF_6]_6$

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**6**) 0.14 g (0.15 mmol) and $MnCl_2$ 0.18 g (0.91 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.3 g (1.84 mmol), for 24 h at r.t. Similar procedure as **2** affords a white solid. Yield: 0.32 g, 62%. Analysis, Found: C 24.03; H 4.41; N 4.41. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_6Mn_6$, C 24.51; H 1.53; N 5.36%.

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**7**) 0.14 g (0.15 mmol) and $FeCl_3$ 0.25 g (0.91 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.3 g (1.81 mmol), for 24 h at r.t. From the orange solution, the solvent was removed by rotary evaporation. The orange solid was dissolved in 30 ml methanol–CH_2Cl_2 (1:2) mixture and filtered through celite. The solvent was removed under vacuum and the oily solid was broken by washing several times with a 10 ml *n*-hexano–diethylether (1:2) mixture. The resulting orange solid was vacuum dried. Yield: 0.32 g, 62%. Analysis, Found: C 14.35; H 3.39; N 4.48. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_{12}Fe_6$, C 15.24; H 4.65; N 3.33%.

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**8**) 0.15 g (0.16 mmol) and $CoCl_2$ 0.23 g (0.97 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.31 g (1.90 mmol), for 24 h at r.t. From the pink solution, the solvent was removed by rotary evaporation. Similar procedure as **7** affords a blue solid. Yield: 0.32 g, 62%. Analysis, Found: C 24.05; H 4.24; N 6.33. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_6Co_6$, C 24.27; H 1.51; N 5.30%.

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**9**) 0.18 g (0.19 mmol) and $NiCl_2$ 0.28 g (1.18 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.38 g (2.33 mmol), for 24 h at r.t. Similar procedures as **8** affords a green solid. Yield: 0.32 g, 62%. Analysis, Found: C 25.71; H 4.50; N 3.59. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_6Ni_6$, C 25.35; H 1.78; N 5.21%.

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**10**) 0.16 g (0.17 mmol) and $CuCl_2$ 0.25 g (0.91 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.34 g (2.07 mmol), for 24 h at r.t. The green solution was treated similar to **9** to give a green solid. Yield: 0.32 g, 62%. Analysis, Found: C 15.65; H 3.26; N 4.71. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_6Cu_6$, C 15.99; H 3.01; N 4.41%.

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**11**) 0.1 g (0.11 mmol) and $ZnCl_2$ 0.09 g (0.66 mmol) were stirred in a Schlenk in CH_3OH (20 ml) and in presence of the NH_4PF_6 0.21 g (1.29 mmol), for 24 h at r.t. From the white solution the solvent was removed by rotary evaporation. The white solid was dissolved in 30 ml methanol–CH_2Cl_2 (1:2) mixture and filtered through celite. The solvent was removed under vacuum and the oil solid was broken by washing several times with a 10 ml *n*-hexano–diethylether (1:2) mixture. The resulting white solid was vacuum dried. Yield: 0.32 g, 62%. Analysis, Found: C 33.50; H 5.80; N 6.63. Calc. for $C_{48}H_{36}F_{36}O_6N_9P_9Cl_6Zn_6$, C 33.05; H 3.72; N 4.45%.

^{31}P NMR (CD_2Cl_2, δ ppm) 15.41(s), N_3P_3, −138(h) PF_6. ^{13}C NMR (CD_2Cl_2, δ ppm) 130.29, 128.73, 122.26(s) aromatic, 120.7(s) CN, 24.53(s) CH_2.

4.1.3. $[(MCl_{n-1})(L_1)][Cl]$

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**12**) 0.17 g (0.23 mmol) and $MnCl_2$ 0.07 g (0.35 mmol) were stirred in a Schlenk in CH_3OH (10 ml) for 24 h at r.t. From the brown solution the solvent was removed by rotary evaporation. The brown oil was dissolved in 30 ml CH_2Cl_2 and filtered through celite. The solvent was removed under vacuum and the oil was washed with a 10 ml *n*-hexano–diethylether (1:2) mixture. The resulting green oil was vacuum dried.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**13**) 0.17 g (0.23 mmol) and $FeCl_3$ 0.08 g (0.30 mmol) were stirred in a Schlenk in CH_3OH (15 ml) for 24 h at r.t. The orange solution was treated similar to **12** to give an orange oil.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**14**) 0.17 g (0.23 mmol) and $CoCl_2$ 0.08 g (0.35 mmol) were stirred

in a Schlenk in CH_3OH (10 ml) for 24 h at r.t. From the pink solution, the solvent was removed by rotary evaporation. The blue oil was dissolved in 30 ml CH_2Cl_2 and filtered through celite. The solvent was removed under vacuum and the oil solid was washed with a 10 ml *n*-hexano–diethylether (1:1) mixture. The resulting blue oil was vacuum dried. Analysis, Found: C 51.82; H 6.3; N 4.7. Calc. for $C_{38}H_{31}O_6N_4P_3Cl_2Co$, C 52.0; H 4.2; N 3.7%.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**15**) 0.10 g (0.14 mmol) and $NiCl_2$ 0.04 g (0.17 mmol) were stirred in a Schlenk in CH_3OH (10 ml) for 24 h at r.t. The green solution was treated similar to **14** to give a green oily.

The ligand $N_3P_3(OC_6H_5)_5OC_6H_4CH_2CN$ (**16**) 0.14 g (0.82 mmol) and $CuCl_2$ 0.05 g (0.29 mmol) were stirred in a Schlenk in CH_3OH (10 ml), for 24 h at r.t. From the brown solution and using a similar procedure as **15**, a brown oil was obtained. Analysis, Found: C 46.50; H 3.89; N 5.43. Calc. for $C_{38}H_{31}O_6N_4P_3Cl_2Cu$, C 46.59; H 3.39; N 3.83%.

4.1.4. $[(MCl_{n-1})_6(L_2)][Cl]_6$

The ligand $N_3P_3(OC_6H_4CH_2CN)_6$ (**17**) 0.13 g (0.14 mmol) and $FeCl_3$ 0.23 g (0.85 mmol) were stirred in a Schlenk in CH_3OH (15 ml) for 24 h at r.t. From the orange solution and using a similar procedure as **16**, an orange oil solid was obtained. Analysis, Found: C 29.66; H 4.6; N 1.87. Calc. for $C_{48}H_{36}O_6N_4P_3Cl_{18}Fe_6$, C 30.15; H 6.5; N 1.88%.

Abstract

The template reaction of a 1:1 mixture of 4,5-disubstituted(2CH_3 or 2Cl)-1,2-phenylenediamine and alkylenediamine [NH_2-$(CH_2)_n$-NH_2; $n = 2$ or 3] with 2,4-pentanedione in the presence of a nickel(II) salt gave a series of asymmetric 14-π nickel(II) complexes with disubstituted tetraazaannulene, [Ni(Me_4-X_2bzotetraaza[Y]ene)] (X = CH_3 and Cl, $Y = 14$ and 15), which were characterized by mass, infrared, ^{1}H and ^{13}C NMR spectra. The electronic effects of the disubstituent groups on the phenyl ring significantly affected the spectral properties of the complexes. The electrochemical behaviors of the nickel(II) complexes with monosubstituted benzoN_4 macrocycles, [Ni(Me_4-Xbzotetraaza[Y]ene)] (X = H, NO_3, CH_3 and Cl, $Y = 14$ and 15) exhibited cyclic voltammograms characterized by, two irreversible, one electron, waves due to oxidation of the macrocycle (Mc); $Mc \rightarrow Mc^{\bullet +}$ in the ranges of +0.06 – +0.28 V for 14-X and +0.01 – +0.29 V for 15-X, and $Mc^{\bullet +} \rightarrow Mc^{2+}$ in the ranges of +0.58 to +0.81 V for 14-X and +0.36 to +0.79 V for 15-X versus Ag/Ag^+ (0.01 M $AgNO_3$ in 0.1 M tetraethylammonium perchlorate (TEAP) acetonitrile solution). In the reduction area only one reversible wave Ni^{2+}/Ni^+ was detected at $E_{1/2} = -1.65$ to -2.65 V in DMSO. The relationships between the oxidation potentials (E_{ap}) and σ_p were linear with a slopes of 0.23 V for 14-X and 0.18 or 0.23 V for 15-X (correlation coefficients of 0.99). The catalytic reduction of dioxygen by the electropolymerized glassy carbon electrodes (GCE) occurred at about 400 mV more positive than by the bared one. The catalytic reduction using 14-X occurred at potentials somewhat more positive than using 15-X. © 2002 Published by Elsevier Science Ltd.

1. Introduction

The transition metal complexes of tetraaza[14]annulene and tetraaza[15]annulene have attracted much attention for their similarity with porphyrins and corrins in biological system or their utilities as model compounds [1–4]. The potential of these macrocyclic complexes as catalysts has also fostered some interest and is efficient [5–7]. The complexes are also efficient as electrode modifiers for anodic oxidation or cathodic reduction [8,9]. Electropolymerization is an effective way for modification of the electrode surface by deposits of redox entities such as metallic complexes. Such a modification of an electrode by symmetric nickel(II) tetraazaannulene was first investigated by Bereman and coworkers [10]. It has been shown that the electropolymerization of the nickel(II) tetraazaannulene is possible even when the ligand has a large variety of substituents on the carbon atoms of the tetraaza macrocycle as well as the two benzene rings [11]. However, most of the tetraazaannulene complexes used to study electrocatalytic reactions have a symmetric structure, such as nickel(II)-5,7,12,14-tetramethyldibenzo[b,i][1,4,8,11]tetraaza[14] annulene which could be deposited on the electrode surface by oxidative electropolymerization. The synthesis of asymmetric complexes and their

PII: S0277-5387(02)00908-7

electrochemical studies are rarely carried out. We have synthesized several asymmetric nickel(II) complexes of tetraaza[14]annulene and tetraaza[15]annulene in previous papers [12,13]. It is expected that the electrochemical characteristics of such asymmetric complexes will be similar to those of the symmetric ones.

In this paper, we attempted to monitor the electrochemical behaviors of the asymmetric nickel(II) complexes with monosubstituted monobenzotetraazaannulene and considered the electrocatalytic properties of the glassy carbon electrodes (GCEs) electropolymerized by the complexes. The GCEs modified by such a process were applied for the electrocatalytic reduction of dioxygen. We also synthesized and characterized several asymmetric nickel(II) complexes with disubstituted monobenzotetraaza[14]annulene (or monobenzotetraaza[15]annulene) for future use in order to further understand the properties and the catalytic reactions of asymmetric tetraazaannulene macrocycles.

2. Experiments

2.1. Materials and instruments

All reagents used were of analytical grade. Dimethylsulfoxide and acetonitrile as solvents were distilled according to the published method [14]. Tetraethylammonium perchlorate (TEAP) as supporting electrolyte was prepared and purified by the method described by Kolthoff and Coetzee [15].

Elemental analyses (C, H, N) of the complexes synthesized were carried out on a Carlo–Ebra, EA 1108 analyzer. Electronic spectra were recorded in chloroform solution on a JASCO V 550 UV–Vis. spectrophotometer at r.t. ^{1}H (300 MHz) and ^{13}C (75.5 MHz) NMR spectra were recorded on a Bruker instrument in $CDCl_3$ at r.t. and the chemical shifts were given in ppm relative to tetramethylsilane as an internal reference standard. EI mass spectra were measured with a JEOL MS-DX 300 gas chromatograph mass spectrometer at 70 eV using a direct inlet system. Cyclic voltammetry was performed using a Bioanalytical System (BAS) CV-50W electrochemical analyzer and C2 cell stand at 25 ± 0.2 °C. The three electrode system for the electrochemical measurements was composed of the GCE as a working electrode, Ag/Ag^{+} (0.01 M $AgNO_3$ in 0.1 M TEAP acetonitrile solution) as a reference electrode, and platinum wire as an auxiliary electrode.

2.2. Synthesis of nickel(II) complexes with disubstituted tetraazaannulene macrocycles

2,4,9,11-Tetramethyl-15,16-dimethylbenzo-1,5,8,12-tetraaza[14]cyclotetradecinato(2-)-nickel(II) (14-2Me). Under nitrogen atmosphere, 2,4-pentanedione (0.06 mol) was added to a methanol (80 cm^3) solution of nickel(II) acetate tetrahydrate (0.03 mol). 4,5-Dimethyl-1,2-phenylenediamine (0.03 mol) and ethylenediamine (0.03 mol) were added to the hot mixture. The solution was refluxed for about 3 h until precipitation of the product was complete. The hot solution was filtered, washed with methanol, and then air-dried. The product was recrystallized from dichloromethane-methanol (1:1). Yield: 65%. *Anal*. Calc. for $NiC_{20}H_{26}N_4$: C, 63.03; H, 6.68; N, 14.70. Found: C, 62.30; H, 7.23; N, 14.72%. IR (KBr disc, cm^{-1}): ν(C=C), 1,534; ν(C=N), 1473 and 1410; ν(aromatic), 737. UV–Vis: λ_{max} (nm) and ε_{max} (M^{-1} cm^{-1}) in $CHCl_3$ 377 and 551, and 24 030 and 2630. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 2.17 and 2.38 (s, MeH), 2.05 (s, ArMeH), 3.34 (s, ethyleneH), 4.98 (s, methineH), 6.95 (s, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ 20.28 23.18, 19.75, 52.60, 103.28 (methine), 121, 127.37, 120.70, 154.61, 157.49. EI MS: m/z 380 $[M]^{+}$.

2,4,9,11-Tetramethyl-15,16-dichlorobenzo-1,5,8,12-tetraaza[14]cyclotetradecinato(2-)-nickel(II) (14-2Cl) was prepared from 2,4-pentanedione (0.06 mol), nickel(II) acetate tetrahydrate (0.03 mol), 4,5-dichloro-1,2-phenylenediamine (0.03 mol) and ethylenediamine (0.03 mol) according to the procedure as described above. The product of fine dark violet was obtained by recrystallizing in chloroform. Yield: 54%. *Anal*. Calc. for $NiC_{18}H_{20}N_4Cl_2$: C, 51.23; H, 4.78; N, 13.88. Found: C, 51.26; H, 4.92; N, 14.11%. EI MS: m/z 420 $[M]^{+}$.

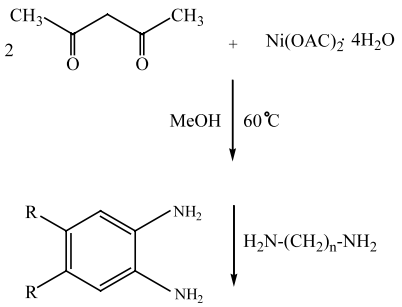
2,4,9,11-Tetramethyl-16,17-dimethylbenzo-1,5,8,12-tetraaza[15]cyclotetradecinato(2-) -nickel(II) (15-2Me) was prepared from 2,4-pentanedione (0.06 mol), nickel(II) acetate tetrahydrate (0.03 mol), 4,5-dimethyl-1,2-phenylenediamine (0.03 mol) and propylenediamine (0.03 mol), following the above-mentioned procedures. Yield: 33%. *Anal*. Calc. for $NiC_{21}H_{28}N_4$: C, 63.83; H, 7.14; N, 14.18. Found: C, 64.02; H, 7.13; N, 14.06%. IR (KBr disc, cm^{-1}): ν(C=C), 1,525; ν(C=N), 1470 and 1410; ν(aromatic), 748. UV–Vis: λ_{max} (nm) and ε_{max} (M^{-1} cm^{-1}) in $CHCl_3$ 397 and 583, and 13 380 and 1810. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 2.09 and 2.13 (s, MeH), 1.90 (s, ArMeH), 2.30 (m) and 2.79 (t) (propyleneH), 4.86 (s, methineH), 6.63 (s, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ 21.01, 21.22, 19.60, 31.90, 50.86, 103.48, 127.83 (methineC), 121.66, 160.46, 146.10, 154.61, 154.83. EI MS: m/z 394 $[M]^{+}$, 379 $[M\text{-}CH_3]^{+}$.

2,4,9,11-Tetramethyl-16,17-dichlorobenzo-1,5,8,12-tetraaza[15]cyclotetradecinato(2-)-nickel(II) (15-2Cl) was synthesized from 2,4-pentanedione (0.06 mol), nickel(II) acetate tetrahydrate (0.03 mol), 4,5-dichloro-1,2-phenylenediamine (0.03 mol) and propylenediamine (0.03 mol) by following the above procedure. Yield: 51%. *Anal*. Calc. for $NiC_{19}H_{22}N_4Cl_2$: C, 52.34; H, 5.09; N, 12.85. Found: C, 52.06; H, 5.15; N, 13.05%. IR (KBr disc, cm^{-1}): ν(C=C), 1,527; ν(C=N), 1,474 and 1,420; ν(aromatic), 748. UV–Vis: λ_{max} (nm) and ε_{max} (M^{-1} cm^{-1}) in $CHCl_3$ 388 and 565, and 19 310 and 1480. ^1H NMR ($CDCl_3$, 300 MHz): δ 1.92 and 2.07 (s, MeH), 2.34 (m) and 2.82 (s) (propyleneH), 4.91 (s, methineH), 6.84 (s, ArH). ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ 20.78, 21.45, 31.66, 50.96, 104.85 (methineC), 120.73, 121.84, 145.68, 154.40, 161.38. EI MS: *m/z* 434 $[M]^+$, 419 $[M\text{-}CH_3]^+$.

The asymmetric nickel(II) complexes with monosubstituted tetraazaannulene macrocycles, 2,4,9,11-tetramethyl-Xbenzo-1,5,8,12-tetraaza[14]cyclotetradecinato(2-)- nickel(II) and 2,4,9,11-tetramethyl-Xbenzo-1,5,8,12-tetraaza[15]cyclotetradecinato(2-)nickel(II), wherein X = H (14-H and 15-H), X = Cl (14-Cl and 15-Cl), X = CH_3 (14-Me and 15-Me) and X = NO_2 (14-NO_2 and 15-NO_2), were prepared as reported previously [12,13].

2.3. Electropolymerization of the complexes on GCE

Before GCE (GC-2OS Tokai Carbon, $\phi = 5$ mm) modification, it was polished with alumina slurry (1.0, 0.3 and 0.05 μm) on carborundum papers, washed with deionized water, and then dried. After polishing, any residual material was removed by sonication (Branson co. Model 1210) for 1 min, and then it was dried. The electrochemical behavior of the modified electrode was greatly influenced by the solvent used. The reproducibility and stability of a given GCE surface was examined using a $K_2Fe(CN)_6$ solution which was accomplished by scanning the respective CV curve, briefly stirring the solution and rescanning the CV curve. Preliminary voltammetric evaluation indicated acceptable electrode behaviors. The repeated scanning (in a dioxygen saturated solution) between +1.0 and −2.0 V versus Ag/Ag^+ (0.01 M $AgNO_3$ in 0.1 or 0.05 M TEAP acetonitrile solution) caused a relative standard deviation of only 3% of the peak currents of ferri/ferro at the scan rates 100 mV s^{-1} for ten cycles. The oxidation potential had a deviation of about 0.005 V for four to ten scans, which were within the precision of the experimental measurement. Electropolymerization of the complexes as electrode modifiers was mostly carried out by cycling the potential between +0.5 and −2.5 V at 200 mV s^{-1} in freshly distilled acetonitrile solutions containing 1×10^{-4} M complexes and 5×10^{-2} M TEAP under a nitrogen atmosphere. After ten cycles, the electrode was removed from the solution, rinsed with water and dried in air.



3. Results and discussion

The complexes 14-2Cl, 14-2Me, 15-2Cl and 15-2Me were prepared by the synthetic procedure as illustrated in Scheme 1. Template condensation of a (1:1) mixture of 4,5-disubstituted(2Cl or 2CH3)-1,2-diaminobenzene and ethylenediamine (or propylenediamine) with 2,4-pentanedione in the presence of nickel(II) ion gave the disubstituted complexes of the 14-2X and 15-2X series with a range of yields from 33% to 65%. Elemental analyses of these new complexes collected in the experimental part were consistent with their formulations.

3.1. Spectral properties of complexes with disubstituents

The EI mass spectra for 14-2Cl, 14-2Me and 15-2Me exhibited the presence of a molecular ion M^+ at *m/z* 420 (^{35}Cl, ^{58}Ni), 380 (^{58}Ni) and 394 (^{58}Ni), respectively, which are the base peaks in each mass spectrum. The 15-2Cl showed a molecular ion M^+ at *m/z* 434 (^{35}Cl, ^{58}Ni) that is not a base peak. The IR spectra of the new complexes exhibited bands at around 1530 cm^{-1} due to the vibrations of C=C and 1475 and 1410 cm^{-1} due to C=N modes but no N–H absorption at around 3200 cm^{-1}. The aromatic band occurred at around 750 cm^{-1}. These observations reflect the formation of C=N and C=C bonds, and the disappearance of N–H groups, and the formation of a conjugated six membered chelate ring in the reaction [16].

The electronic absorption spectra of these asymmetric complexes were examined over the 370–700 nm range. The bands in the near UV regions (375–390 nm) with molar absorptivities (ε_{max}) ranging from 10 000 to 25 000 M^{-1} cm^{-1} for each of the new complexes could be attributed to the $\pi \rightarrow \pi^*$ transitions of the macrocycles and are almost independent of the macrocycle rings (14- or 15-membered). The bands in the visible region had

Scheme 1.

energies between 500 and 550 nm ($\varepsilon_{max} = 2660–3220$ M^{-1} cm^{-1}) which are attributed to charge transfer (CT) transitions from the highest occupied ligand molecular orbital to the lowest empty d-orbital of the nickel. Their values of ε_{max} are much larger than those commonly assigned to ligand field transitions. This behaviour is comparable to that observed for D_{4h} nickel(II) complexes with four nitrogen donors [10,12,13]. The spectra of the 15-2X series showed shifts of λ_{max} to longer wavelengths compared with 14-2X ones. This observation is attributed to the different ring size between the 14-membered and 15-membered macrocycles, which is in agreement with other tetraazaannulene complexes [12,13]. Another feature of the electronic spectra is the variation of the band maximum according to the substituents of the phenyl ring on the macrocycle. The spectra of 14-2Me and 15-2Me with an electron-donating group showed 5 and 13 nm shifts of λ_{max} to longer wavelengths compared with 14-2H and 15-2H, respectively, while those of 14-2Cl and 15-2Cl with an electron-withdrawing group did relatively hypsochromic shifts. Such an electronic effect of the substituent group is supported by similar observations with nickel(II) tetraazaN_4 macrocycles [12,13,17,18].

The 14-2X and 15-2X complexes gave well-resolved ^1H and ^{13}C NMR spectra. The assignments of the chemical shifts were made mostly characterized by comparisons of the data with those of other nickel(II) macrocyclic complexes reported earlier [5,12,13]. The carbon sites of the diaminate framework of nickel(II)-tetraazaannulene complexes have been found to be a reactive nucleophilic centre named a methine site [13,19,20]. Thus, the resonance energies of the methine sites for the new complexes and the effects of macrocyclic rings are worth special mentioning. The methine proton peaks for 14-2Me and 15-2Me with two methyl substituents and those for 14-2Cl and 15-2Cl with two chloro substituents on the phenyl rings were equivalent and showed one singlet. The proton peaks of 14-2Me and 15-2Me, and 14-2Cl and 15-2Cl were shifted by about 0.05 and 0.02 ppm upfield, and 0.04 and 0.03 ppm downfield relative to 14-2H and 15-2H, respectively. The ^{13}C NMR peaks of 14-2Me and 15-2Me, and 14-2Cl and 15-2Cl were shifted by about 0.58 and 0.49 ppm upfield, and 0.98 and 0.88 ppm downfield relative to 14-2H and 15-2H, respectively. Such results are attributed to the shielding and deshielding effects of the substituents of the phenyl group on the macrocycle rings. The ^{13}C data was mostly in agreement with the corresponding ^1H NMR behaviour.

3.2. Electrochemical studies of complexes with a monosubstituent

Redox potentials of the monosubstituted nickel(II) complexes measured using cyclic voltammetry are given in Table 1. The cyclic voltammograms of 14-NO_2 and free base ligand, for example, are illustrated in Fig. 1 and exhibited cyclic voltammetric behaviors characterized by, two appreciably irreversible one electron waves corresponding to oxidation of the macrocycle (Mc), $Mc \rightarrow Mc^{\bullet +}$ and $Mc^{\bullet +} \rightarrow Mc^{2+}$, and only one regular and reversible wave ($Ni^{2+} \rightarrow Ni^{+}$). The number of electrons involved in each redox reaction could be determined by electrolyzing the complex relating to the more positive potential by 0.2 V more than that of each wave according to the method reported.[26] As listed in Table 1, the 1st and 2nd ligand based oxidations were detected at in the ranges of $+0.01–+0.30$ V and $+0.36–+0.81$ V versus Ag/Ag^+ (0.01 M $AgNO_3$ in 0.1 M TEAP acetonitrile solution), and the reduction of metal at $E_{1/2} = -1.65$ to -2.65 V in DMSO solution. The waves were of similar pattern to those exhibited by the symmetric nickel(II) tetraazaannulene, [10] indicating that diffusion coefficients of nickel(II) tetraazaannulene macrocycles do not appreciably differ with respect to symmetric or asymmetric complexes. The complexes, 14-X and 15-X contain macrocycles with various electron donor and withdrawing groups (X) that have different σ values [21]. As pointed out elegantly by Kadish et al. in ref. [21], the exact choice of Hammett parameters to use, i.e. σ_p, σ^+, σ^-, etc., is not clear. We have chosen σ_p ($\sigma_p = -0.17$ for CH_3, 0.00 for H, 0.23 for Cl and 0.78 for NO_3) because the correlation between redox potentials and σ_p are linear and it offers comparisons to the widest range of literature data. Totally the substituents effect on the reduction potential of the complexes was not large, but clearly appeared. The correlation between the substituent effect and the redox potentials of the complexes was examined by means of a Hammett plot. As shown in Fig. 2, the relationships between the 1st oxidation potentials (E_{ap1}) and σ_p were linear with a slopes of 0.23 V for both 14-X and 15-X series (correlation coefficients of 0.99), reflecting the similarity of structures of the 14-X and 15-X series. Interestingly, these slopes are similar to those of the oxidation potentials for metalloporphyrins with substituents located on the pyrrole residues of the porphyrin ligand [22,23].

The modification of a GCE could be carried out by scanning repeatedly in the range of a given potential and the modified electrodes were relatively stable even in air or solution. For example, the asymmetric complexes 14-H were electropolymerized by cycling from $+1.0$ to -2.0 V versus Ag/Ag^+ (0.01 M $AgNO_3$ in a 0.1 M TEAP acetonitrile solution) giving thin films on the GCE (Fig. 3). The nickel(II) complexes of tetraazaannulenes with benzoyl groups at the methine sites of the macrocycle are not electropolymerized on the GCE by cyclic voltammetry [24] supporting directly that the electropolymerization of nickel(II)-tetraazaannulene [25,26] occurs at the methine site on macrocycle. According to

Table 1
Redox potentials of 14-CH_3, 14-H, 14-Cl, 14-NO_2, 15-CH_3, 15-H, 15-Cl and 15-NO_2 vs. Ag/Ag^+ (0.01 M $AgNO_3$ in a 0.1 M TEAP [a] and in a 0.05 M TEAP [b] acetonitrile solution) at 25 °C

[d] Data from 1×10^{-3} M complexes in 0.1 M TEAP–DMSO solutions vs. Ag/Ag^+ (0.01 M) at 25 °C and sweep rates 200 mV s^{-1}.

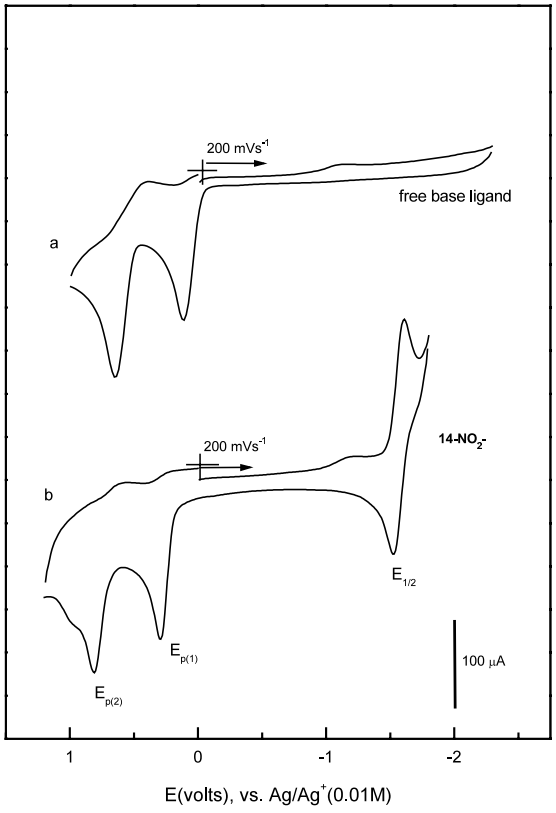

Fig. 1. Cyclic voltammograms of the free base ligand (a) and its complex, 14-NO_2 (b) in a 0.1 M TEAP acetonitrile solution at 25 °C and 200 mV s^{-1}.

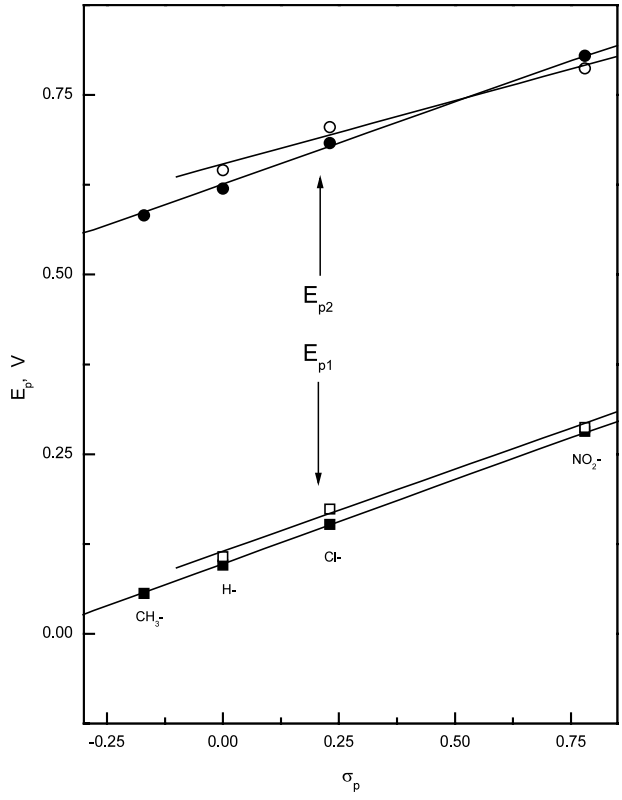

Fig. 2. Hammett plots of the first and second oxidation potentials (E_{p1} and E_{p2}) of the 14-X (■ and ●) and 15-X (□ and ○) series against the substituent constants (σ_p).

the pattern of electropolymerization and the electron number observed in each oxidation step and the results reported, we concluded that the polymer is formed at the electrode surface via a radical cation and dication. That is the mechanism for the electropolymerization of the asymmetric complex is thought to be similar to that of the symmetric one. The cyclic voltammograms of the modified electrode in neat 0.1 M TEAP acetonitrile exhibited both the $Mc/Mc^{\bullet +}$ and $Mc^{\bullet +}/Mc^{2+}$ irrever-

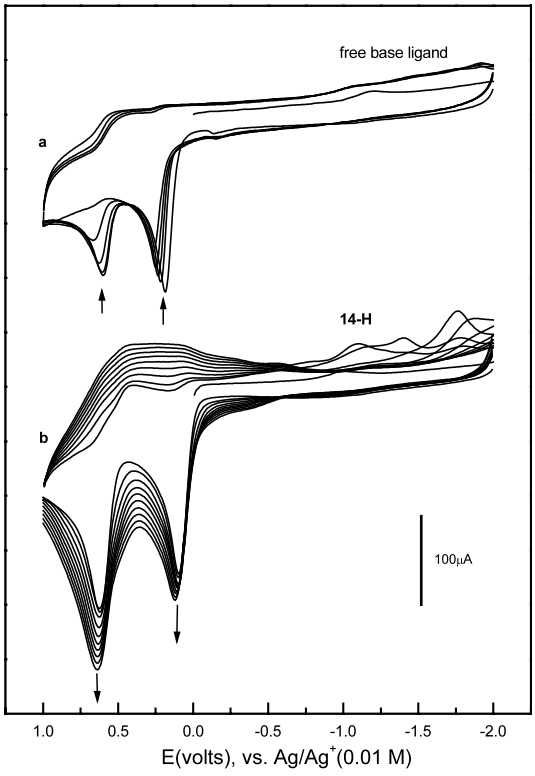

Fig. 3. Cyclic voltammetric behaviours of the free base ligand (a) and its complex, 14-H (b) cycling from +1.0 to −2.0 V vs. Ag/Ag^+ (0.01 M $AgNO_3$ in a 0.1 M TEAP acetontrile) at 25 °C and 200 mV s^{-1}.

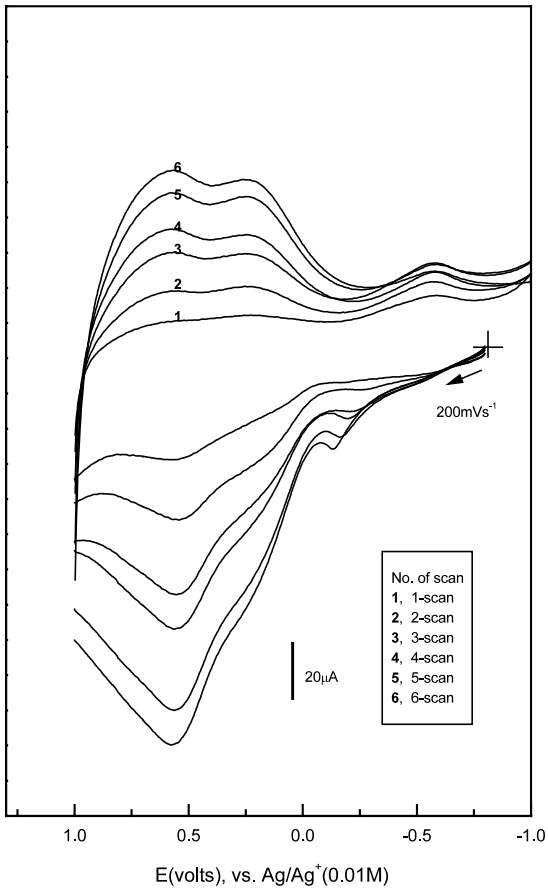

Fig. 4. Cyclic votammograms of the GCE electropolymerized by the 14-H in a neat 0.1 M TEAP acetonitrile solutions at 25 °C and 200 mV s^{-1}.

sible waves at around +0.10 and +0.60 V, respectively, as shown in Fig. 4. The first and second oxidation waves (Fig. 4) of the GCE electropolymerized by 14-H showed at almost the same potentials as those of the complex 14-H (Fig. 3), while no other chemical reaction following the electropolymerization on GCE could be found.

The applications of the GCEs modified by 14-H, 14-NO_2 and 15-NO_2 for dioxygen electroreduction were illustrated in Fig. 5. The traces a, b and c indicate the cyclic voltammograms for the GCEs electropolymerized by 14-H, 14-NO_2 and 15-NO_2 in an oxygen-saturated acetonitrile solution, respectively, while trace d is for the bare GCE in the same solution. The potential difference between the modified and bare electrodes was often used to evaluate the catalytic activity of the modifier. On comparing the voltammograms, the reduction potentials of dioxygen by the modified GCEs were reduced by about 400 mV compared with the bare one. In the case of the 14-X series, the catalytic reduction of dioxygen occurred at potentials somewhat more positive than in the 15-X series. Based upon the results herein (Fig. 5), it was shown that the electropolymerized electrodes using 14-H, 14-NO_2 and 15-NO_2 have good catalytic activities for use in electrocatalytic reduction of dioxygen. On the other hand, the same modified electrodes showed scarcely any catalytic activity in the electrooxidation of L-ascorbate [27].

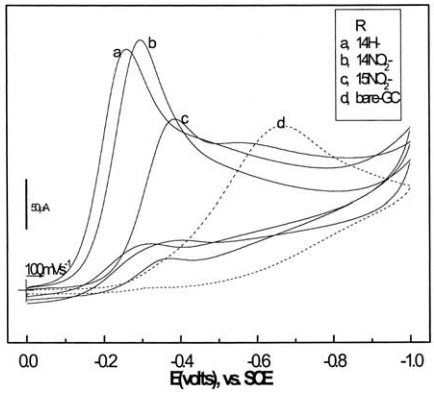

Fig. 5. Cyclic voltammograms of catalytic dioxygen reduction by the electropolymerized and bare GCEs in a 0.1 M phosphate buffer (pH 7.0) at 25 °C and 100 mV s^{-1}: (a), 14-H; (b), 14-NO_2; (c), 15- NO_2; (d), bare GCE.

Synthesis and structural characterization of complexes from the NOS ligating Schiff base of dfp: structurally different molecules in the unit cell of the manganese complex

N. Mangayarkarasi, M. Prabhakar, P.S. Zacharias *

School of Chemistry, University of Hyderabad, Hyderabad 500 046, India

Received 21 August 2001; accepted 9 January 2002

Abstract

Zinc, manganese, copper and nickel complexes (**1**–**4**) were synthesized by the template condensation of 2,6-diformyl-4-methylphenol (**dfp**) and 2-(methylmercapto)aniline with metal perchlorate salts in presence of pyrazole and triethylamine. These complexes are characterized by analytical, spectral, magnetic and electrochemical techniques. Based on these experimental data, the molecular composition of the complexes is found to be $[M_2L_2](ClO_4)_2$ instead of the pyrazole bridged binuclear complex. This is confirmed by X-ray crystal structures of zinc, **1** and manganese, **2** complexes. The geometry around the zinc atoms is pseudo octahedral with $N_2O_2S_2$ coordination. The asymmetric unit of manganese complex **2** consists of two crystallographically independent half molecules (**2A** and **2B**), two perchlorate anions and water molecules. Manganese atoms in **2A** have distorted pentagonal bipyramidal geometry and in **2B** they have irregular geometry. © 2002 Published by Elsevier Science Ltd.

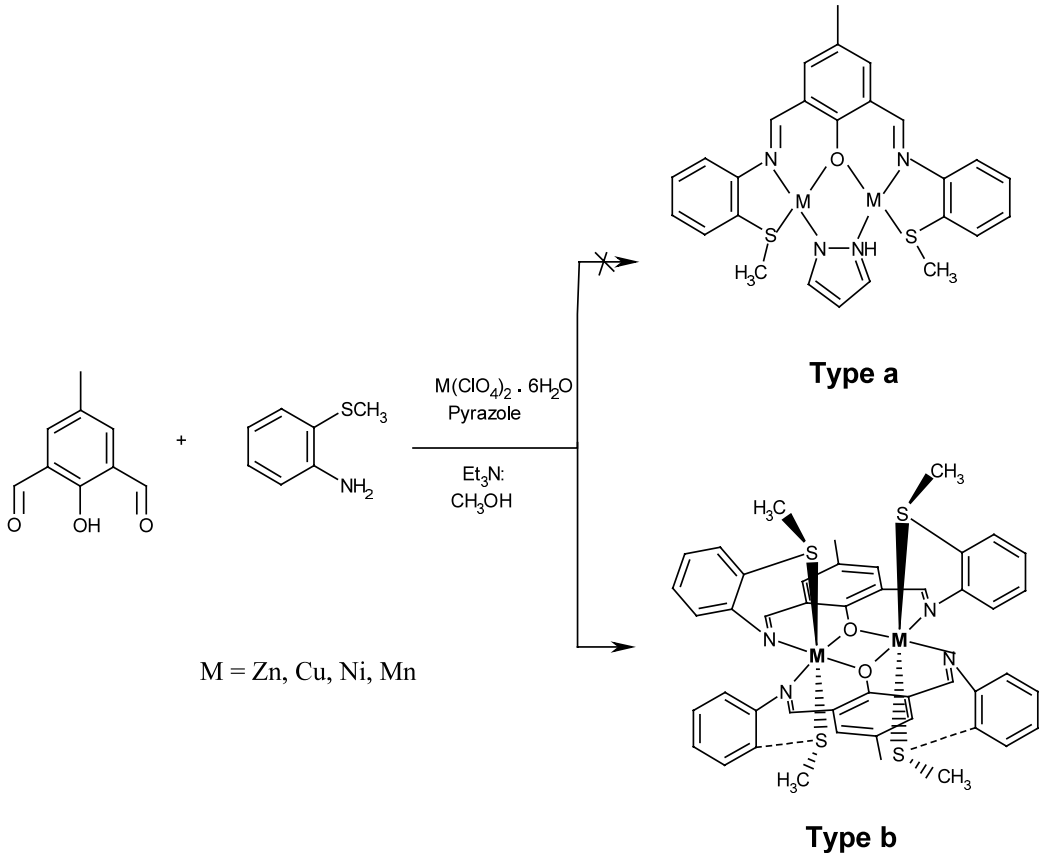
Keywords: Acyclic; Binuclear; Pyrazole bridged; Asymmetric unit; Pentagonal bipyramidal

1. Introduction

Thio ligands are employed to generate model complexes for a number of metallobiosites [1] where sulfur atoms are coordinated to iron [2], nickel [3], copper [4] and zinc [5] atoms in mono-, bi- or tridentate fashion. First row transition metal Schiff base complexes of 2,6-diformyl-4-methylphenol (**dfp**) with N_2O_2, NON and NOO coordination sites are well characterized [6]. Though many thio bridged acyclic and macrocyclic complexes of 2,6-diformyl-4-methylthiophenol (**dftp**) are known [6,7], complexes with NOS coordination from **dfp** are rare [8]. Acyclic Schiff base complexes of **dfp** either with two different bridging groups (**Type a**) or with two same bridging groups (**Type b**) can be synthesized as shown in Scheme 1. In the former case, the endogenous phenoxo bridge of **dfp** remains constant and the exogenous bridge can be formed by groups such as hydroxide, alkoxide, halide, pseudohalide, carboxylate and pyrazolate [9]. These complexes provide an opportunity to study the effect of various bridging groups on spectral, magnetic and electrochemical properties [9]. Our attempts to synthesize **Type a** complexes of sulfur ligating **dfp** derivatives with a pyrazole bridge yielded only **Type b** complexes.

This paper deals with the synthesis and structural characterization of acyclic Schiff base binuclear complexes of Zn, Mn, Cu and Ni with NOS coordination obtained by the condensation of **dfp** and 2-(methylmercapto)aniline with the respective metal perchlorate salts and triethylamine in presence of pyrazole (Hpyz). X-ray structural characterization of zinc and manganese complexes reveals interesting structural features.

2. Experimental



2.1. Chemicals and reagents

2,6-Diformyl-4-methylphenol was synthesized according to the literature procedure [10]. 2-(Methylmercapto)aniline was distilled prior to use. Other starting

Scheme 1. The schematic representation of the product formation.

materials were used without further purification. Solvents were purified and dried by the usual methods [11,12].

2.2. Physical measurements

Elemental analyses were carried out on a Perkin–Elmer 240C CHN analyzer. IR spectra were recorded on a JASCO model FT/IR-5300 spectrophotometer in the range 4000–400 cm^{-1} as KBr pellets, electronic spectra on a JASCO model 7800 UV–Vis spectrophotometer (solution concentrations 1×10^{-3} mol dm^{-3} for the visible region and 1×10^{-5} mol dm^{-3} for the UV region) and ^1H NMR spectra on a Bruker ACF-200 spectrometer at 200 MHz with TMS as internal standard. The room temperature (r.t.) magnetic susceptibility experiments were carried out on a SHERWOOD SCIENTIFIC magnetic susceptibility balance. Diamagnetic corrections were made using Pascal's constants. Cyclic voltammograms were recorded on a Cypress System model CS-1090/CS-1087 computer controlled electroanalytical system. All experiments were performed in dry solvents under dry nitrogen atmosphere. 1×10^{-3} M solutions were used with 0.1 M tetrabutylammonium perchlorate (TBAP) as supporting electrolyte, using either glassy carbon (GC) or platinum (Pt) working electrodes, Ag–AgCl as the reference electrode and platinum wire as an auxiliary electrode. The ferrocene–ferrocenium couple was used as the redox standard.

2.3. Synthesis of complexes

The complexes **1**–**4** were synthesized from **dfp**, 2-(methylmercapto)aniline, metal perchlorate salt, pyrazole and triethylamine in 1:2:2.5:1.25:1 ratio. Representative details are given for the zinc complex, **1**. **Caution**: all perchlorate salts are prone to explosion and must be handled with care.

2.3.1. $[Zn_2L_2](ClO_4)_2$, *1*

To a methanolic solution (75 ml) of 2,6-diformyl-4-methylphenol (0.164 g, 1 mmol), 2-(methylmercapto)aniline (0.280 g, 2 mmol) in methanol (25 ml) was added and stirred at r.t. for 30 min. To the orange solution, $Zn(ClO_4)_2 \cdot 6H_2O$ (0.930 g, 2.5 mmol) and pyrazole (0.085 g, 1.25 mmol) were added successively. On slow addition of triethylamine (0.100 g 1 mmol) in methanol (5 cm^3), the reddish orange solution changed into golden yellow. The resulting solution was stirred at r.t. for 6 h, then filtered and kept for crystallization. Yellow crystals suitable for X-ray structure determination were ob-

tained from the reaction mixture on slow evaporation. Yield: 90%.

2.4. Spectral and analytical data of complexes *1*–*4*

2.4.1. $[Zn_2L_2](ClO_4)_2$ (*1*)

ν_{max}/cm^{-1} 1622, 1605, 1545, 1084, 622. δ_H (200 MHz, CD_3CN) 8.77 (4H, s, H–C=N), 7.97 (4H, s, Ar–H), 7.57 (4H, d, Ar–H), 7.45 (4H, t, Ar–H), 7.30 (4H, t, Ar–H), 7.00 (4H, d, Ar–H), 2.57 (6H, s, H_3C–Ar), 2.37 (12H, s, SCH_3). Found: C, 47.99; H, 3.68; N, 4.61; Calc. for $C_{46}H_{42}N_4O_{10}S_4Cl_2Zn_2$: C, 48.43; H, 3.71; N, 4.91%. λ_{max}/nm (ε/mol^{-1} dm^3 cm^{-1}) 390 (20870).

2.4.2. $[Mn_2L_2](ClO_4)_2 \cdot 2H_2O$ (*2*)

Yield: 60%; ν_{max}/cm^{-1} 3335, 1618, 1605, 1542, 1080, 622. Found: C, 47.52; H, 4.03; N, 4.88; Calc. for $C_{46}H_{46}N_4O_{12}S_4Cl_2Mn_2$: C, 47.79; H, 4.01; N, 4.84%.

2.4.3. $[Cu_2L_2](ClO_4)_2$ (*3*)

Yield: 90%; ν_{max}/cm^{-1} 1620, 1601, 1539, 1086, 621. Found: C, 48.48; H, 3.68; N, 4.61; Calc. for $C_{46}H_{42}N_4O_{10}S_4Cl_2Cu_2$: C, 48.59; H, 3.72; N, 4.93%. λ_{max}/nm (ε/mol^{-1} dm^3 cm^{-1}) 630 (229), 441 (20816).

2.4.4. $[Ni_2L_2](ClO_4)_2$ (*4*)

Yield: 90%; ν_{max}/cm^{-1} 1626, 1603, 1535, 1087, 623. Found: C, 48.98; H, 3.58; N, 4.84; Calc. for $C_{46}H_{42}N_4O_{10}S_4Cl_2Ni_2$: C, 49.01; H, 3.76; N, 4.97%. λ_{max}/nm (ε/mol^{-1} dm^3 cm^{-1}) 479 (34636).

Due to the insolubility of the manganese complex **2**, the electronic spectrum and cyclic voltammetric studies were not done.

3. X-ray crystal structure analysis

The yellow rectangular crystals of complex **1** and the reddish orange plate like crystals of **2** were grown by slow evaporation of the methanolic solution (the reaction mixture). The crystals of **3** (green) and **4** (orange) were thin plates and due to the poor diffraction quality, the data were not collected further. The crystals of complex **1** lose the solvent molecule spontaneously on removal from the mother liquor. So, a suitable single yellow crystal of complex **1** was mounted in the glass capillary along with the mother solution. Crystal data were collected on a Nonius Enraf MACH3 diffractometer for complex **1** and on a BRUKER SMART CCD area diffractometer for complex **2** equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Twenty five carefully centered reflections were used to determine cell parameters. Using the ω scan technique, unique reflections were collected to a maximum 2θ value. The programs used for the data reduction were XTAL 3.5 [13] version and BRUKER SMART and SAINT [14] for control and integration software for complex **1** and **2**, respectively. The solution and refinement were carried out using SHELX-97 [15]. The locations of zinc and manganese atoms were determined by direct methods. The remaining non-hydrogen atoms were located through successive least-squares refinements on the difference Fourier map using SHELXL [15]. All the non-hydrogen atoms were made anisotropic. The hydrogen atoms for the molecular cations were fixed at calculated positions and were refined using the riding model and they were neither fixed nor located for the solvent molecules.

4. Results and discussion

Synthetic details of complexes **1**–**4** are given in Section 2. Pyrazole was added to promote the formation of binuclear metal complexes of **Type a** with the endogenous phenolic bridging oxygen and the exogenous pyrazole bridge as shown in Scheme 1.

The complexes show IR bands at around 1618–1626 cm^{-1} for C=N stretching vibrations. Absence of an aldehydic C=O stretch of **dfp** at 1680 cm^{-1} confirms the formation of both side condensed acyclic Schiff base complexes. The CHN analytical data of the complexes did not match with the expected molecular composition $[M_2L(pyz)](ClO_4)_2$ (**Type a**) but matched with the binuclear composition $[M_2L_2](ClO_4)_2$ (**Type b**). Since it is reported that the amount of pyrazole is an important factor governing the formation of the required complexes [16,17], the composition of substrates was also varied. Even then only binuclear complexes of **Type b** were obtained.

4.1. Binuclear zinc complex (*1*)

The zinc complex was synthesized by the procedure given in the Section 2. The IR spectrum of complex **1** shows stretching bands at around 1622 and 1545 cm^{-1} corresponding to the C=N and the oxo bridged phenolic C–O groups [18]. The bands at 1084 and 622 cm^{-1} indicate the presence of uncoordinated perchlorate ion. The ^1H NMR spectrum of the complex shows one singlet (4H) at 7.97 ppm due to the aromatic protons of **dfp** moieties in addition to a singlet (4H) at 8.77 ppm due to azomethine protons. The aromatic protons of the amine moieties appear as two doublets at 7.57 and 7.00 ppm and as two triplets at 7.45 and 7.30 ppm corresponding to four protons each. The methyl protons of **dfp** and $-SCH_3$ moieties appear at 2.57 and 2.37 ppm. No signal due to pyrazole protons is observed. The CHN analytical data agree with the binuclear composition $[Zn_2L_2](ClO_4)_2$ and confirms the presence of two perchlorate ions. The molecular structure of the complex is established by X-ray crystal structure.

The electronic spectrum of the complex in *N*,*N*-dimethylformamide (DMF) shows a band at 390 nm due to the charge transfer transitions.

4.1.1. X-ray structure determination of **1** $[Zn_2L_2](ClO_4)_2\cdot 2CO$

The zinc complex crystallizes in triclinic $P\bar{1}$ space group. The crystallographic parameters, interatomic distances and angles relevant to the coordination spheres are given in Tables 1 and 2. The asymmetric unit consists of a discrete binuclear cation $[Zn_2L_2]^{2+}$, two perchlorate anions and two methanol solvates. An ORTEP [19] diagram of the cation with the atom numbering scheme is shown in Fig. 1. The Zn(1) and Zn(2) atoms are coordinated by two azomethine nitrogen atoms, two bridging phenoxide oxygen atoms and two sulfur atoms of the thiomethyl groups of Schiff base moieties.

Each N_2O_2 coordination plane of the metal centers exhibits slight distortion from planarity. The coordination plane of Zn(1) displays the largest distortion (0.3408 Å). The plane of Zn(2) is at the normal angle of 85.01° with that of the plane of Zn(1). The in-plane distances to the phenoxide bridge Zn(1)–O(1), Zn(1)–O(2), Zn(2)–O(1), Zn(2)–O(2) are 2.001(4), 2.016(5), 2.013(5) and 2.002(4) Å.

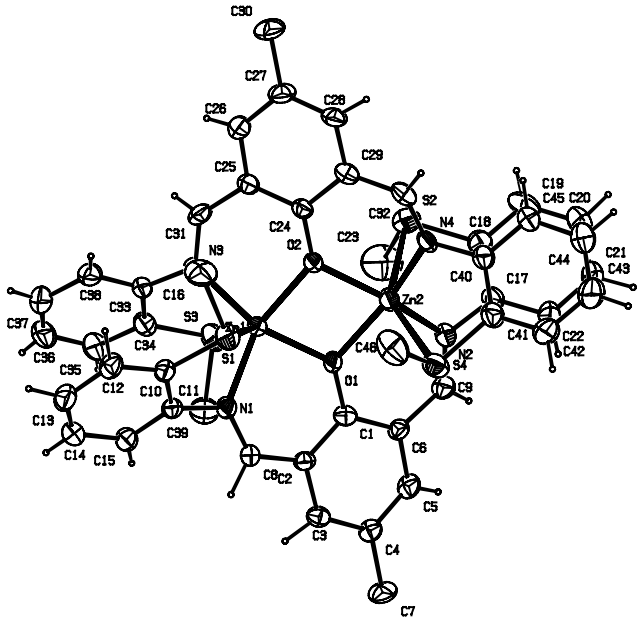

Fig. 1. ORTEP diagram of $[Zn_2L_2]^{2+}$, **1** (thermal ellipsoids at 20% probability level).

The metal-azomethine nitrogen Zn(1)–N(1), Zn(1)–N(3), Zn(2)–N(2), Zn(2)–N(4) distances are 2.033(5), 2.004(5), 2.019(5) and 2.023(6) Å, respectively. These values are similar to those of the chemically equivalent bonds in other structures [20]. However, the average distance between the zinc and axially coordinated sulfur atoms is 2.793 Å which is significantly longer than the sum of the covalent radii (2.33 Å) but shorter than the van der Waals radii (3.27 Å) indicative of weak bonding interactions. Although there are no chemically equivalent analogues of Zn–S bonds of Schiff base complexes with $-SCH_3$ groups, many Zn–S bonds with the distances in the range of 2.6–2.8 Å are reported [21].

The zinc···zinc separation is 3.137 Å. The phenoxide bridging angles Zn(1)–O(1)–Zn(2), Zn(1)–O(2)–Zn(2) are 102.81(19) and 102.68(19)°. They are larger than that of the analogous reported Schiff base complexes of **dfp** [20,22]. The geometry around the zinc atoms can be described as pseudo octahedral geometry.

The X-ray crystal structure of complex **1** confirms the formation a of binuclear complex of **type b** (Scheme 1).

4.2. Binuclear manganese complex (2)

The manganese complex was synthesized by the procedure given in Section 2. The IR spectrum of the complex shows a C=N stretching band at 1618 cm^{-1}, the characteristic bands of oxo bridged phenolic C–O groups and uncoordinated perchlorate ions at 1542, 1080 and 622 cm^{-1}. The CHN analysis of the complex supports the binuclear molecular composition, $[Mn_2L_2](ClO_4)_2\cdot 2H_2O$. The structure was confirmed by X-ray analysis. The room temperature magnetic moment value of 6.10 B.M. per manganese atom suggests the presence of high spin manganese(II) centers.

4.2.1. X-ray structure determination of 2, $[Mn_2L_2(H_2O)_2](ClO_4)_2\cdot 6.5O$

The complex crystallizes in monoclinic $C2_1/c$ space group. Due to weak diffraction intensity the refinements converged at a final $R = 10.62\%$. Crystallographic parameters are given in Table 1. The asymmetric unit consists of two crystallographically independent half molecules, two perchlorate anions and water molecules. The ORTEP diagrams of the two molecular cations (**2A** and **2B**) with atom numbering scheme are given in Figs. 2 and 3. Selected bond lengths and bond angles are given in Table 3.

In molecule **2A**, the average Mn–O(phenoxo), Mn–N(imino) bond distances are 2.131 and 2.265 Å, respectively. These distances fall within the range commonly found for bivalent manganese complexes [23] and are significantly longer than the equivalent bonds in the binuclear zinc(II) complex **1**. The Mn–O(water) bond length is 2.295(9) Å. The average Mn–S bond lengths are 2.803 Å (reported Mn–S bond distances are 2.6–2.9 Å) [24].

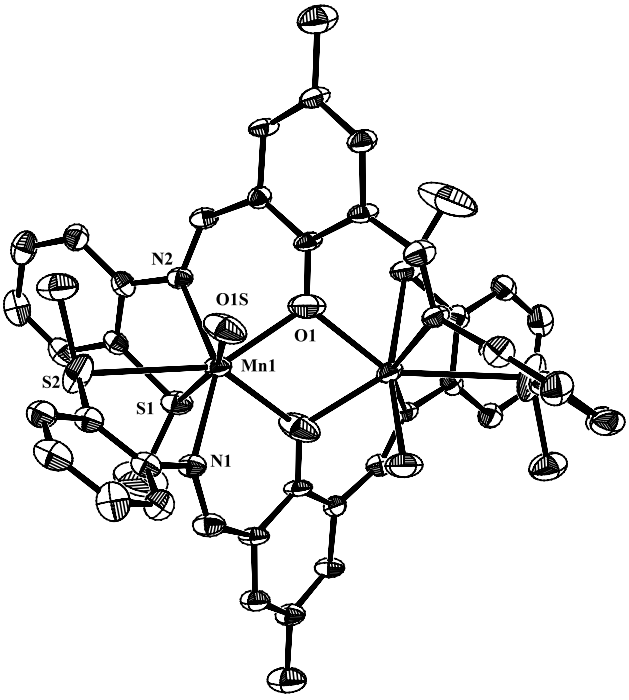

Fig. 2. ORTEP diagram of molecular cation of **2A** (thermal ellipsoids are at 30% probability level).

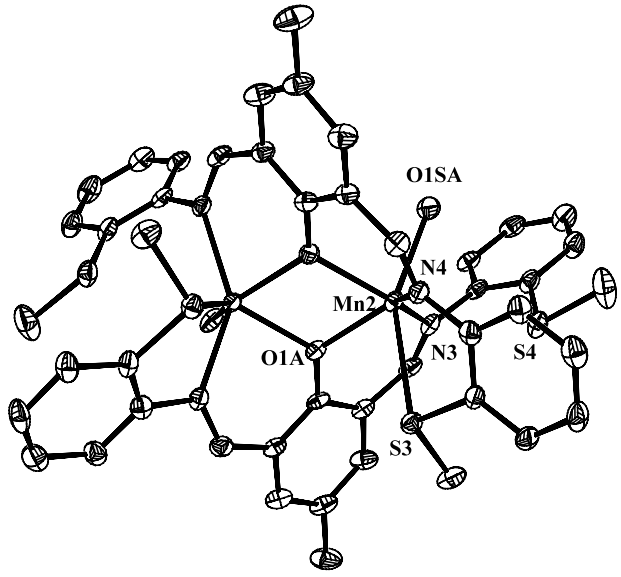

Fig. 3. ORTEP diagram of the molecular cation of **2B** (thermal ellipsoids are at 30% probability level).

The average bond angle between the metal and the axial groups O(1S)–Mn(1)–S(1) and O(1S)#1–Mn(1)#1–S(1)#1 is 165.0(4) Å. The angle between the basal pentagonal plane and the MnOS plane is 88.50°, i.e. nearly perpendicular. From the bond angles the coordination geometry around the manganese atoms

Table 3

O(1S)–Mn(1)–S(2)	80.7(4)	O(1SA)–Mn(2)–S(3)	149.34(16)
O(1)#1–Mn(1)–S(1)	114.71(17)	N(4)–Mn(2)–S(3)	69.10(16)
O(1)–Mn(1)–S(1)	77.69(16)	N(3)–Mn(2)–S(3)	96.74(16)
N(1)–Mn(1)–S(1)	96.75(16)	Mn(1)#1–O(1)–Mn(1)	106.73(19)
N(2)–Mn(1)–S(1)	69.26(14)	Mn(2)#2–O(1A)–Mn(2)	108.3(2)

can be regarded as distorted pentagonal bipyramidal with the phenoxo oxygens, imino nitrogen and one sulfur atom in the basal plane and with the other sulfur and the oxygen of the water molecule at the apices. The phenoxide bridging angle Mn–O–Mn is 106.73(19)° and the Mn_2O_2 ring is nearly planar with a mean deviation of 0.07 Å from the plane. The Mn···Mn distance is 3.421 Å and is within the range reported for acyclic binuclear manganese complexes (3.324–3.584 Å) [23]. The basal plane of Mn(1) and Mn(1)#1 displays the greatest distortion and the plane of Mn(1)#1 has a normal angle of 76.17° with that of the plane of Mn(1). The aromatic rings with $-SCH_3$ groups are inclined by 33.70° and 81.47° relative to the Mn_2O_2 mean plane, while the phenolic aromatic rings are inclined by 42.27° relative to the Mn_2O_2 mean plane. The plane of the aromatic ring of one ligand has the normal angle of 73.09° with that of the plane of the aromatic ring of the other ligand and vice versa.

In molecule **2B**, the average Mn–O(phenolic), Mn–N(imino) and Mn–O(water) bond lengths are 2.132, 2.241 and 2.183(5) Å, respectively. The Mn–O(phenolic) bond length is similar that in molecule **2A** and Mn–N(imino) bond lengths are slightly different. The Mn–O(water) bond length is shorter than in **2A** and one sulfur atom remains uncoordinated. Its bond length is 3.124 Å which is slightly shorter than the van der Waals radii of the two atoms. The phenoxide bridging angle Mn(2)#2–O(1A)–Mn(2) is 108.3(2)° which is larger than in **2A**. The Mn···Mn distance is 3.452 Å. From the bond angles the geometry around the metal atom can better be described as irregular geometry and a few manganese(II) complexes with irregular geometries are known in literature [25].

In **2B**, the aromatic rings with $-SCH_3$ are inclined more towards the Mn_2O_2 mean plane (34.16° and 88.81°) and the $-SCH_3$ moiety is away form the Mn_2O_2 plane. On the other hand the phenolic aromatic rings are inclined by 41.12° relative to the Mn_2O_2 mean plane. The plane of the aromatic ring of one ligand has the normal angle of 68.95° with that of the plane of the aromatic ring of the other ligand and vice versa. The bridging Mn–O–Mn angle is also greater than in **2A**. It is apparent that there is a subtle structural difference in the molecules **2A** and **2B**.

The delicate balance between the ligand field effects, the non-planarity and the flexibility of the ligand and the stability of the seven coordination allows the d^5 Mn(II) ion to have pentagonal bipyramidal geometry in **2A**. It is known that the d^5 ion achieves slightly greater stability with seven coordination.

4.3. Binuclear copper complex (3)

The copper complex was synthesized as described in the Section 2. The IR spectrum of the complex shows C=N stretching at 1620 cm^{-1}, the characteristic oxo bridged phenolic C–O group at 1539 cm^{-1} and the bands due to uncoordinated perchlorate ions at 1086 and 621 cm^{-1}. The CHN analysis of the complex support the binuclear molecular composition of $[Cu_2L_2](ClO_4)_2$.

The electronic spectrum of the complex in DMF exhibits a strong band at 441 nm due to the metal to ligand charge transfer transition and a broad band at 630 nm due to a *d*–*d* electronic transition. The position of the *d*–*d* band of complex **3** indicates distorted octahedral geometry at the copper(II) centers with $N_2O_2S_2$ coordination [26]. The room temperature magnetic moment of 0.98 B.M. per copper atom indicates a strong antiferromagnetic interaction between the two copper centers. Based on the experimental data and a comparison with the zinc complex **1**, a structure similar to that of complex **1** is proposed for the copper complex.

The copper complex exhibits two irreversible one electron reduction peaks of the Cu(II) centers at −0.017 and −0.119 V in DMF with a GC electrode. As the number of scans increases, the peak height decreases which indicates the adsorption of metals on the electrode. In the positive region it shows two oxidation peaks at +0.685 and +1.082 V. With a Pt electrode, the reduction peaks are at +0.260 and +0.060 V and the oxidation peaks at +0.865 and +1.165 V.

4.4. Binuclear nickel complex (4)

The synthetic procedure is given in Section 2. The IR spectrum of the complex shows C=N and oxo bridged phenolic C–O stretching bands at 1626 and 1535 cm^{-1}. The bands at 1087 and 623 cm^{-1} show the presence of uncoordinated perchlorate ions. The CHN analysis of the complex supports the binuclear composition $[Ni_2L_2](ClO_4)_2$.

The electronic spectrum of the complex in DMF in the range 250–1100 nm exhibits a very high intensity absorption band at around 479 nm corresponding to the metal to ligand charge transfer transition. No other bands are observed in the visible region. It might probably be due to the masking of the high energy *d*–*d* bands by the metal to ligand charge transfer band [27]. The magnetic moment of the complex is 2.64 B.M per nickel atom at room temperature and suggests the presence of antiferromagentism between the high spin nickel(II) centers.

The nickel(II) complex shows two stepwise one electron reduction peaks in the negative potential at −1.068 and −1.230 V in DMF with a GC electrode. A similar cyclic voltammogram is observed for a macrocyclic binuclear nickel complex [28]. The peak height of the first electron reduction is lower than the second one and indicates the stability of the reduced species. In the positive range, a quasi reversible oxidation peak at +1.135 V and an irreversible peak at +1.359 V are observed. Variation in the scan rate gave a slight shift in the peaks towards negative potentials. An increase in the number of scans did not affect the profile. With a Pt electrode two stepwise one electron reduction peaks (−1.015, −1.375) and one reversible oxidation peak at $E_{1/2}$ +1.030 ($\Delta E = 78$) are also observed. The first reduction peak is irreversible and the second one is quasi reversible in nature.

5. Conclusions

The analytical, spectral, magnetic, electrochemical properties and X-ray structure determination of the complexes show the formation of binuclear **Type b** complexes of composition $[M_2L_2](ClO_4)_2$ in contrast to the expected pyrazole bridged **Type a** complexes. In spite of the steric hindrance due to the presence of a bulky aromatic side chain containing the weak bonding –SCH_3 group in the ligand, **Type b** complexes of $N_2O_2S_2$ coordination is formed. This preference can be the result of a possible N_2O_2 coordination core in **Type b** complexes. Crystallographic identification of molecules with two different geometries in the case of the manganese complex (**2A** and **2B**) is interesting from a structural point of view.

6. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallograpahic Data Centre, CCDC no. 169459 and 169460. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit @ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 10 September 2001; accepted 24 January 2002

Abstract

Two cadmium compounds containing the aspartate ligand are described, with compositions $Cd(AspH)NO_3$ and Cd(Asp). The crystal structure of the first shows it is a two dimensional polymer in which each cadmium is coordinated to seven oxygen atoms, four from carboxylates and three from the nitrate moiety which acts both as a chelate and as a bridging ligand. For Cd(Asp), ^{111}Cd NMR studies suggests the presence of $Cd-NH_2$ interaction. © 2002 Published by Elsevier Science Ltd.

Keywords: Cadmium(II); Aspartate; Structures; ^{111}Cd NMR

1. Introduction

Though not as widely known to the general public as lead's, cadmium's toxicity is considerably larger [1]. As is the case with lead, the specific chemical interactions responsible for cadmium's toxicity are mostly unknown, although there has been some evidence that it mainly interferes in Zn^{2+} and Ca^{2+} sites and metabolism. The Cd uptake level is influenced by the calcium concentrations in the diet in a similar way as Lead, i.e. decreased by the increase of Ca intake [2]. The affinity that Cd^{2+} ion shows toward calcium binding sites, which are rich in aspartyl and glutamyl residues, has led to its use as a tool in studies of calcium binding sites in many systems as calbindin D_{9K} [3].

Similarities between cadmium and lead have been pointed out before, as one of several pairs of elements related by a knight's movement in the periodic table [4]. And just like lead's, classification of cadmium in the HSAB scheme has given problems, with some authors placing it among the soft acids, in agreement with Pearson's original papers [5] while others consider it borderline [6].

The behaviour of cadmium towards aminoacids has been studied both in solution and in the solid state. Stability constants for the 1:1 complexes are found to be consistently lower than for the corresponding lead complexes, usually for a little less than a logarithmic unit [7]. Several crystal structures of Cadmium–aminoacid complexes have been described [8]. The diversity of complexation modes is remarkable; from simple molecular structures with chelating aminoacid moieties, to polymeric structures where one or more of the donor groups are not coordinated to the metal.

In a recent paper, we reported two different lead complexes with aspartate, Pb(Asp) and $Pb(AspH)NO_3$ [9]. The X-ray structure of the latter showed it forms a three dimensional polymeric network in which each lead atom is coordinated only to oxygen atoms, from both carboxyl groups and the nitrate ion, while spectroscopic studies suggested amine group coordination in the former. Here, we present two cadmium–aspartate complexes with equivalent composition to those of lead, and discuss comparatively their structures.

2. Experimental

Cadmium nitrate tetrahydrate and cadmium oxide were purchased from Aldrich; L-aspartic acid and L-aspartic acid monosodium salt hydrate from Sigma Chemical Co. Elemental analysis were carried out by Desert Analytics, Tucson, AZ.

2.1. Preparation of Cd(AspH)(NO$_3$) (I)

To 5 mmol of $Cd(NO_3)_2 \cdot 4H_2O$ dissolved in 25 ml of water, 5 mmol of NaAspH in 25 ml of water were added and pH adjusted to 4.3 with 1 M NaOH. The solution was left to stand and colourless prismatic crystals were collected after a few weeks. *Anal*. Calc. for $Cd(C_4H_6N_2O_7)$: C, 15.68; H, 1.96; N, 9.15. Found: C, 15.63; H, 2.08; N, 8.89%.

2.2. Preparation of Cd(Asp) (II)

Five mmol $AspH_2$ were dissolved in 150 ml of warm water and to this solution 2.5 mmol finely ground CdO were added in small portions, allowing for the solid CdO to dissolve after each addition. The clear solution was evaporated with the formation of a glassy material which analysed for $Cd(Asp) \cdot 1.5H_2O$. *Anal*. Calc. for $CdC_4H_6O_{5.5}N$: C, 17.76; H, 2.96; N, 5.18. Found: C, 17.32; H, 2.81; N, 5.02%.

2.3. Crystallography

Single-crystal X-ray diffraction data for **1** were measured at 298 K on a Bruker P4 diffractometer using common procedures [10] and a correction for absorption effect was applied based on 50 ψ-scans with χ close to 90°. The structure was solved and refined using standard procedures [11], without restraints nor constraints. H atoms were placed on idealised positions and refined using a riding model with fixed isotropic U. The refinement of a Flack parameter [12] confirmed the absolute configuration of the enantiopure amino acid AspH to be C3-*S*. Pertinent crystal data are collected in Table 1 and complete crystallographic information is deposited as a CIF file.

2.4. NMR spectroscopy

The ^{111}Cd CP-MAS NMR were recorded on a VARIAN Unity-Plus 300 MHz spectrometer operating at 63.602 MHz with a 7.5 μσ pulse. A 7 mm diameter silicon nitride rotor with kel-F caps was used. The rotor spin rate was kept between 3.5 and 5 KHz for all experiments, with a delay time between 5 and 10 s and between 500 and 10 000 transients were accumulated, 1–2.5 ms of contact time for cross polarisation was used, 0.05 s of acquisition time. $CdCO_3$ was used as external reference (−30 ppm). Spectra were recorded using total side band suppression when side bands were not well removed by spinning. Processing was made using a 20–40.11 Hz of line broadening, with the exception of the compound (II) spectra, where a 530 Hz line broadening was used. ^{13}C-CP-MAS NMR were recorded on the same spectrometer operating at 75.430 MHz, acquisition time 0.05 s. Typical contact times employed were of 1.25 ms; pulse width of 8.5 μS, and delay time of 4 s. Processing was made with zero filling and a line broadening of 20.33 Hz.

Solution ^{1}H NMR was made at 299.950 MHz with a VT-Switchable broad band probe; acquisition time 2.503 s, pulse of 45° (7.5 μs). Processing was made with zero filling and a line broadening apodisation of 1 Hz. In a typical experiment 32 transients were collected. D_2O was used as a solvent and pD was fixed with either DCl or NaOD.

Table 1
Crystal data

Empirical formula	$C_4H_6CdN_2O_7$
Formula weight	306.51
Crystal system	orthorhombic
Colour, habit	colourless, regular prism
Crystal size (mm)	$0.28 \times 0.22 \times 0.14$

Symmetry transformations used to generate equivalent atoms: #1, $-x+1, y+1/2, -z+1/2$; #2, $-x, y+1/2, -z+1/2$; #3, $x-1, y, z$; #4, $-x, y-1/2, -z+1/2$.

yielding a formula similar to that of $Pb(AspH)(NO_3)$ [9]. Nevertheless, the coordination geometry and the polymeric arrangement are different when substituting Pb(II) by Cd(II). As expected from the conditions of synthesis, the aspartate moiety presents two carboxylate groups while the amine function is protonated. The metal centre is seven-coordinated, with a geometry that can be described as distorted octahedral, where the sixth position is doubly occupied by two O atoms from the bidentating nitrate ion. Remaining coordination sites are occupied by one O atom from an crystallographic equivalent nitrate ion *trans* to the first one and four O atoms from 4 equiv. aspartate ligands *cis* to the nitrate moieties, as described in Fig. 1. Coordination distances span a range common for Cd(II) complexes [13], 2.213(3)–2.600(3) Å. The distortion from an ideal octahedral geometry is obvious, for example, from *trans* angles $O1–Cd1–O2' = 171.03(9)°$, $O3–Cd1–O4 = 149.38(10)°$ and from the bite *cis* angle formed by the nitrate ligand, $O11–Cd1–O12 = 51.02(9)°$, while remaining angles are in the range 72.22(9)°–133.58(10)°.

The complex is assembled in an original bi-dimensional polymeric network composed of perpendicularly connected chains (see Fig. 2). The main chains, running along the crystallographic *b* axis, result from the bridging character of the nitrate ion: O11 bridges 2 equiv. metallic centres, O12 is coordinated to one Cd atom and O13 is coordination-free. The different behaviour of each of these O atoms is clearly reflected in the N–O bond lengths (see Table 2), which can be compared with the N–O bond length of the free nitrate ion, 1.21 Å [14]. The 2D-polymer is formed by the connection of these chains through the α and β groups of the aspartate ligands along the *a* axis of the orthorhombic cell: O1 and O2 atoms from an aspartate ligand bridge two neighbouring Cd atoms of the previously described chain (running along the *b* axis) and the O3 and O4 atoms of the same ligand bridge two neighbouring Cd atoms of an other chain. In contrast to the iso-formula Pb complex [9], C–O bond lengths of the α and β carboxylic groups in **1** fall in a small range, 1.248(4)–1.273(4) Å. An other structural difference between $Pb(AspH)(NO_3)$ and $Cd(AspH)(NO_3)$ is that the polymeric connection of first one generates 18-membered rings containing three Pb ions and three AspH ligands, while for the last one the polymer includes 14-membered rings based on two Cd ions and two AspH ligands.

Moderate to weak hydrogen bonds sustain the cohesion between the 2D layers stacked along the *c* axis. The three H atoms of the ammonium group give short contacts with the three O atoms of the nitrate anion, with N–H···O separations ranging from 2.31 to 2.64 Å and angle from 118.0° to 148.3°. The carboxylic groups also participate as donor atoms in this network, with contacts N1–H1C···O2 (2.57 Å, 128.0°) and N1–H1B···O3 (2.56 Å, 158.2°). Finally, weak contacts are directed approximately along the *c* axis, using the aliphatic groups of the asp ligand as acceptor (C2 and C3) and O atoms as donors (O1, O12 and O13). C–H···O distances and angles ranges are characteristic of weak bonds: 2.48–2.58 Å and 136.7°–171.0°. (Table 3). These interactions are illustrated in Fig. 3.

3.2. NMR spectra

3.2.1. ^{111}Cd CP-MAS NMR spectra

Usually, ^{113}Cd is preferred since it has a slightly higher receptivity, but ^{111}Cd can also be used without an appreciable receptivity loss. As there is no primary isotope effect, results obtained on both isotopes can be directly compared [15]. As a tool for elucidating the coordination environment on the cadmium atom, a general observed trend for the Cd nuclei chemical shifts has been described [16,17]: shielding on a Cd atom is: (1) decreased when it is bonded to nitrogen (low field shift); (2) increased when bonded to oxygen (high field shift), but (3) decreased when it is part of a chelate ring. In the Cd CP-MAS spectra, distortions from octahedral symmetry are sufficient to produce large chemical shift anisotropies [18].

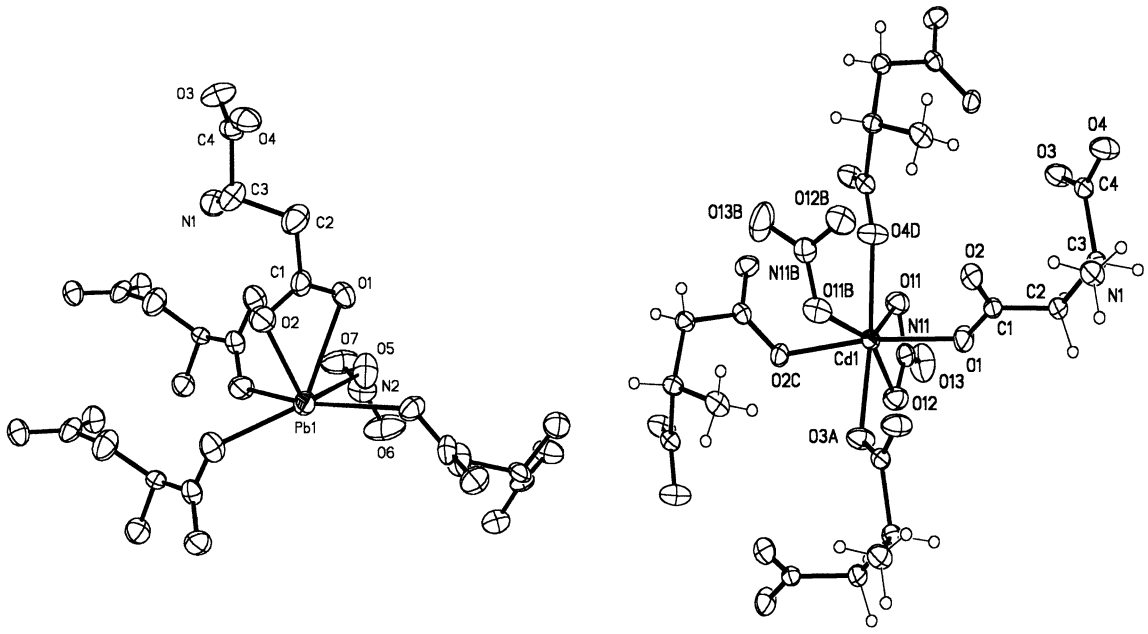

Fig. 1. The coordination environment for Cd atoms in **1** (right side) compared with the observed coordination environment in the isoformular Pb complex [9] (left side). Note that the metal centre is seven-coordinated in **1** and six-coordinated in Pb(AspH)(NO_3), leaving a large space available for a lone pair in the latter case. Thermal ellipsoids for **1** are at 50% probability level and symmetry codes used to generate equivalent atoms are the following: (A) $x-1$, y, z; (B) $-x$, $y-1/2$, $-z+1/2$, (C) $-x$, $y+1/2$, $-z+1/2$; (D) $-x+1$, $y+1/2$; $-z+1/2$.

In Cd(AspH)NO_3 (**I**), where there are seven oxygen atoms coordinated to each cadmium, an isotropic chemical shift of -78.6 ppm relative to $[Cd(H_2O)_6](ClO_4)_2$, was observed. In the latter each

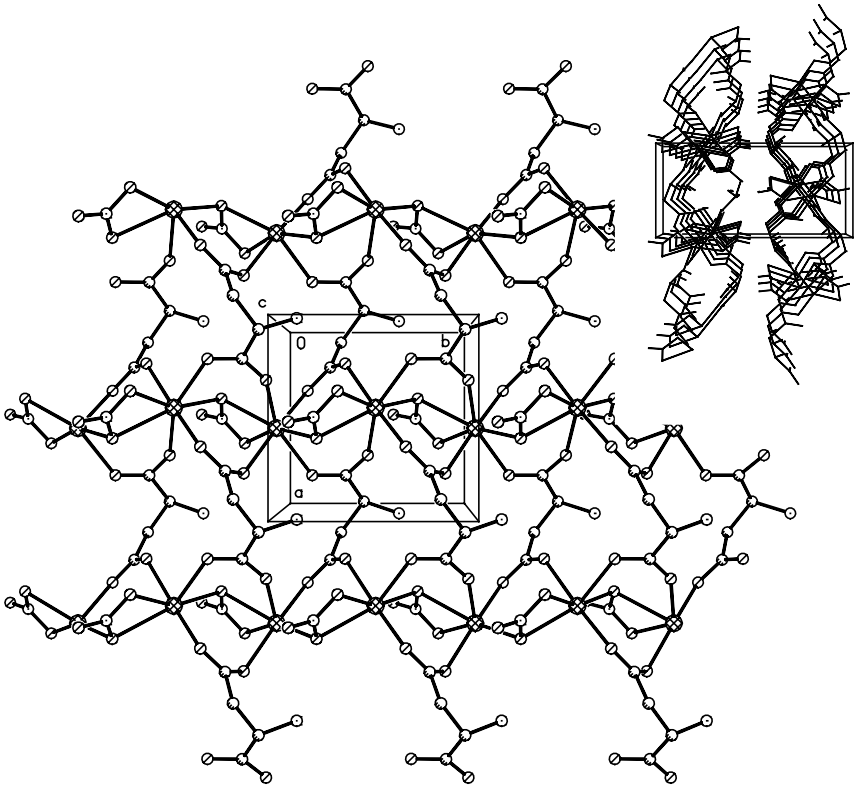

Fig. 2. The 2D polymeric layers of **1** viewed along the [001] axis. The inset shows a stick representation of two layers in a view normal to the [010] axis, i.e. as observed rotating the main figure around [100] by an angle of 90°. Note that no inter-layers contacts are observed, justifying the description of the polymer as an actual 2D framework. In both figures, H atoms are omitted for clarity.

D, donor atom; A, acceptor atom.

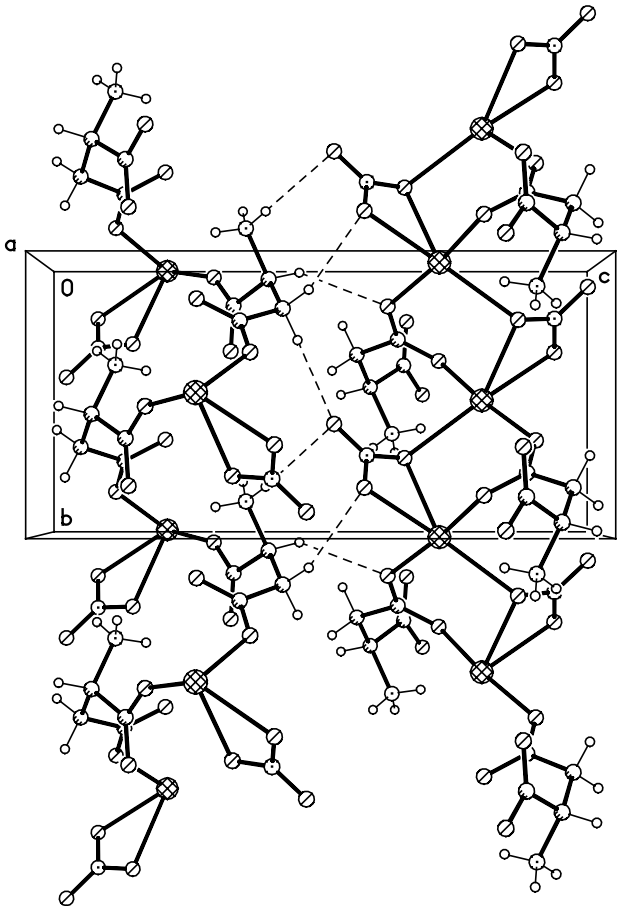

Fig. 3. Hydrogen bonding network.

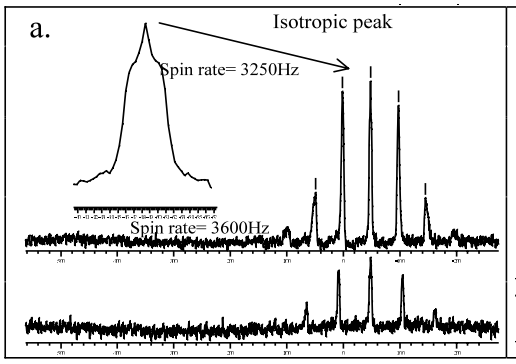
Cd atom is coordinated octahedrally to six oxygen atoms from water molecules [19,20] i.e. a high field shifting is observed, as expected from the general trends mentioned above.

Nitrate chelation may be the cause of the apparent second order coupling between ^{111}Cd and ^{14}N in complex **I** as it can be seen in Fig. 4(b), together with the deconvoluted spectrum from which it is possible to see a 1:2:1 pattern, that displays a coupling constant of 125 Hz. As far as we know, there are no reported values for this second order coupling. This splitting includes the second order coupling constant and the residual splitting due to the residual dipolar interaction between ^{111}Cd and ^{14}N [21,22].

On the other hand, the spectrum for compound **II** has a very irregular, broad signal centred on 70 ppm with the highest peak in 36 ppm. This positive chemical shift is indicative of a coordination to one or more nitrogen atoms. Unfortunately, it is not possible to observe the coupling pattern between ^{111}Cd and ^{14}N. There are examples in the literature [22–26] of Cd–N environments that do not show noticeable coupling. In these cases, the observed line widths have been greater than the coupling. In complex **II**, the cadmium atom seems to be immersed in very asymmetrical site, and therefore, in spite of the spin rate used to obtain the spectrum, anisotropy could not be removed.

3.2.2. ^{13}C CP-MAS NMR spectra



^{13}C NMR chemical shifts (ppm) are shown in Table 4. Compound **II** presents only one signal for carboxylic carbon atoms; indicating that in this compound the chemical environment for both carboxylates is quite similar. In compound **I**, however, even though both carboxylate groups are coordinated to cadmium nuclei, COOβ is involved in the strongest H-bond present in the crystal (H···O2 = 2.259 Å; N···O2 = 2.838 Å) with a H atom from the NH_3^+ group; besides, the other oxygen atom (O1) in COOβ has the strongest interaction with Cd^{2+} (shortest bond distance). Both interactions can cause a downfield shift for the COOβ carbon atom.

For compound **II**, not only the carboxylate carbon atoms show a sensible shift, but also the aliphatic ones. This could suggest the formation of a six membered chelate ring by the coordination of the amino group and the COOβ, in agreement with the observed Cd-CP-MAS data.

3.2.3. ^{1}H NMR versus pH

At a pH value close to the one used for crystallisation, the aminoacid, in presence of Cd^{2+}, develops a pattern of an ABC [27] spin system in the α-H signal (Fig. 5).

Considering the protonation state of the amine, a possible interpretation would be the formation of a chelate ring by the bonding of both carboxylate groups

c. Fit values:		
Freq(Hz)	**δ(ppm)**	**Integral**
-3210.22	-76.6	10283
-3085.50	-78.6	26435
-2960.02	-80.5	10900

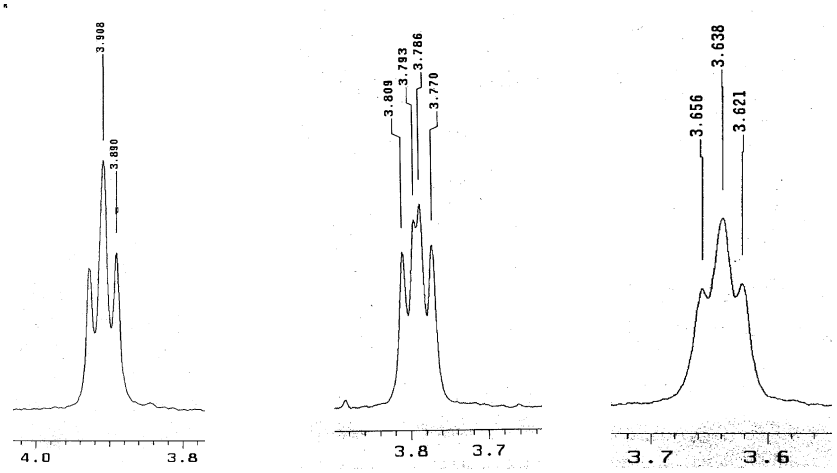
Fig. 4. ^{111}Cd NMR spectrum.

Table 4
^{13}C NMR chemical shifts (ppm)

Nucleus	$AspH_2$	NaAspH	$Cd(AspH)NO_3$ (**I**)	Cd(Asp) (**II**)
COOα	176.32	174.24	174.56	180.67
CH	54.11	48.9	55.16	52.23
CH_2	38.26	34.85	34.76	40.50
COOβ	175.25	174.24	182.75	180.67

(α and β) to cadmium. By doing so, both β hydrogen atoms would become distinguishable turning into a BC spin system rather than B_2.

When the amine group deprotonates, at a higher pH value, a different chelate ring is feasible due to the coordination of the amino group and the α carboxylate oxygen atom, releasing the β carboxylate and therefore, both hydrogen atoms on the CH_2 moiety become again indistinguishable, causing the system to return to an AB_2 pattern. As it has been discussed, the compound as is isolated near pH 4, has no chelate rings formed by the two carboxylates and formation of a 3D polymer is preferred.



The accumulation of information on structural details of cadmium aqueous coordination chemistry—which is currently scarce—will hopefully contribute to a better understanding of this metal ion's interaction with biological molecules.

4. Supplementary material

Crystallographic data have been deposited with the CCDC. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) quoting the deposition number CCDC 169070.

Abstract

The preparation, characterization and crystal structures of the mono(dpyam) copper(II)nitrato complexes $[Cu(dpyam)(O_2NO)_2]$ **(1)** and $[Cu(dpyam)(O_2NO)_2]\cdot 2H_2O$ **(2)** (dpyam = di-2-pyridylamine) have been investigated. Compound **1** consists of two crystallographically independent $[Cu(dpyam)(O_2NO)_2]$ neutral molecules. These molecules are linked into infinite chains by the bridging bidentate nitrate groups in the long-bonded tetragonal positions giving an elongated rhombic octahedral stereochemistry. The structure of **2** is composed of a couple of crystallographically independent $[Cu(dpyam)(O_2NO)_2]$ neutral molecules and four water molecules in the lattice. Each copper atom exhibits a tetrahedrally distorted square base of the N_2O_2 plane, with the second oxygen atoms of the monodentate nitrato groups weakly bound in nearly axial positions giving an extremely distorted octahedral coordination geometry. © 2002 Elsevier Science Ltd. Keywords: Crystal structures; Copper complexes; Nitrate complexes, Di-2-pyridylamine complexes

1. Introduction

The local molecular structures of the [Cu(chelate)$(OXO)_2$] or [Cu(chelate)(OXO)(OYO)] complexes, where chelate is ethylenediamine (en), *N*,*N*,*N*′,*N*′-tetramethylenediamine (tmen), 2-(2-dimethylaminoethyl)pyridine (DMAEP), 2,2′-bipyridyl (bpy) or di-2-pyridylamine (dpyam); and OXO and OYO are oxyanions, have been characterized [1–13]. Mononuclear complexes with a tetrahedrally distorted elongated octahedral geometry [2–9], dinuclear complexes with a square-pyramidal environment [8,10] and polynuclear complexes with an elongated rhombic (or tetragonal) octahedral stereochemistry [11–13], have been found by X-ray crystallography with respect to different coordinating and bridging roles of perchlorate, formate, nitrate and nitrite oxyanions. As a part of the investigation on the coordinating and bridging roles of oxyanions for this type of complexes, the compounds [Cu(dpyam)$(NO_3)_2$] **(1)** and $[Cu(dpyam)(NO_3)_2]\cdot 2H_2O$ **(2)** were prepared and their spectroscopic properties characterized. According to the differences in electronic spectra, the crystal structures of both complexes have been determined and compared with those of the above relevant complexes.

2. Experimental

All reagents were commercial grade materials and were used without further purification. Elemental analyses (C, H, N) were performed by the Microanalytical Service of Science and Technological Research Equipment Centre, Chulalongkorn University on Perkin–Elmer PE2400 CHNS/O Analyzer. Copper content was determined on atomic absorption spectrophotometer. The infrared spectra were recorded on a Biorad FTS-7/PC FTIR spectrophotometer as KBr pellets in the

4000–450 cm^{-1} region. Solid-state (diffuse reflectance) electronic spectra were recorded as polycrystalline samples on a Perkin–Elmer Lambda2S spectrophotometer over the range 8000–18 000 cm^{-1}. The X-band ESR spectra were recorded on polycrystalline samples at room temperature (r.t.) with a JEOL ESR JES-RE2X spectrometer (operating at the X-band) by the service of Scientific and Technological Research Equipment Centre, Chulalongkorn University. The complexes $[Cu(dpyam)(O_2CCH_3)_2]\cdot 2H_2O$ [6], $[Cu(dpyam)(O_2CCH_3)(NO_2)]\cdot H_2O$ [7], $[Cu(dpyam)(NO_2)_2]$ [7] and $[Cu(dpyam)(O_2CCH_2CH_3)(NO_3)]$ [13] were also prepared as the methods previously described in order to record their e.s.r. and electronic spectra for spectral comparison (Table 5).

2.1. Syntheses

2.1.1. Synthesis of [Cu(dpyam)(NO3)2] (1)

2.1.1.1. Method a. A boiling solution containing $CuCO_3\cdot Cu(OH)_2\cdot H_2O$ (0.22 g, 1.0 mmol) in water (10 ml) and 1.0 N nitric acid (2 ml) was added to a warm solution of dpyam (0.34 g, 2.0 mmol) in methanol (20 ml). The solution was stirred and solid $NaNO_3$ (0.17 g, 2.0 mmol) was added. The mixture was warmed and stirred for few minutes. On slow evaporation, green crystals of **1** (Table 5) were obtained. They were filtered off, washed with mother liquor and were dried in air. Yield approximately 84%. Found: C, 33.41; H, 2.48; Cu, 17.66; N, 19.56%. Calc. for $C_{10}H_9N_5CuO_6$: C, 33.48; H, 2.53; Cu, 17.71; N, 19.52%. IR (KBr pellet, cm^{-1}): 1380s $(\nu NO_3)_{asym}$, 1320s $(\nu NO_3)_{sym}$ and 650m (δNO_3).

2.1.1.2. Method b. Complex **1** was also prepared directly, by adding a boiling solution of $Cu(NO_3)_2\cdot 2.5H_2O$ (0.23 g, 1.0 mmol) in 20 ml acetone to a warm solution of dpyam (0.17 g, 1.0 mmol) in 10 ml methanol after which a hot solution of $CH_3COONa\cdot 3H_2O$ (0.27 g, 2.0 mmol) in 10 ml water was added. The mixture was warmed and stirred for 5 min. On slow evaporation, **1** was deposited as green crystals. Yield approximately 82%.

2.1.2. Synthesis of [Cu(dpyam)(NO3)2]·2H2O (2)

A boiling solution containing $CuCO_3\cdot Cu(OH)_2\cdot H_2O$ (0.22 g, 1.0 mmol) in water (30 ml) and 1.0 N nitric acid (2 ml) was added to a warm solution of dpyam (0.34 g, 2.0 mmol) in methanol (20 ml). The solution was stirred and solid $NaNO_3$ (0.17 g, 2.0 mmol) was added. On slow evaporation, compound **2** was obtained as greenish–blue crystals (Table 5). Yield approximately 75%. Found: C, 30.48; H, 3.28; Cu, 16.05; N, 17.70%. Calc. for $C_{10}H_{13}N_5CuO_8$: C, 30.42; H, 3.32; Cu, 16.10; N, 17.74%. IR (KBr pellet, cm^{-1}): 1380s $(\nu NO_3)_{asym}$, 1310s $(\nu NO_3)_{sym}$ and 650m (δNO_3).

2.2. Crystallography

Reflection data for complexes **1** and **2** were collected at 293 K on a 1K Bruker SMART CCD area-detector diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a detector distance of 4.5 cm and swing angle of -35°. A hemisphere of the reciprocal space was covered by combination of three sets of exposures; each set had a different ϕ angle (0, 88, 180°) and each exposure of 35 s for **1** and 15 s for **2** covered 0.3° in ω. Data reduction and cell refinements were performed using the program SAINT [14]. An empirical absorption correction by using the SADABS [15] program was applied, which resulted in transmission coefficients ranging from 0.705 to 1.000 for **1** and 0.759 to 1.000 for **2**. The structures were solved by direct methods and refined by full-matrix least-squares method on F^2_{obs} with anisotropic thermal parameters for all non-hydrogen atoms using the SHELXTL-PC V 5.03 [16] software package. All hydrogen atoms in **1** and **2** were located by difference synthesis and refined isotropically, except H(1), H(6), H(10) and H(15) in **2** which were geometrically fixed and allowed to ride on attached atoms and also two water hydrogen atoms were unable to locate. The O(3) in A; and O(10) and O(12) in B for complex **1** showed disorder with occupancies of 0.47 and 0.53; 0.58 and 0.42; and 0.50 and 0.50, respectively, for both conformers. The molecular graphics were created by using SHELXTL-PC. The crystal and refinement details for complexes **1** and **2** are listed in Table 1. Selected bond lengths and angles are given in Table 2 and Table 4. Fig. 1 illustrates the structure of **1**, Fig. 3 the structure of **2**, and the atom numbering scheme used.

3. Result and discussion

3.1. Structure of [Cu(dpyam)(O2NO)2] (1)

The asymmetric unit of **1** (Fig. 1) consists of a couple of similar and crystallographically independent $[Cu(dpyam)(O_2NO)_2]$ neutral molecules (A and B), self-assembled together by the week C–H···O intermolecular interactions involving the dpyam C–H group from A and one nitrato O atom from B and vice versa. The crystal structure is further stabilized by N–H···O hydrogen bonds. Both molecules (A and B) involve the six-coordinate $CuN_2O_2O_2'$ chromophore, with an elongated rhombic octahedral stereochemistry. The octahedra of both molecules are linked into infinite chains by the bridging bidentate nitrate group [17,18], Fig. 2(a). Two nitrogen atoms of the dpyam and two oxygen atoms of the bidentate chelate nitrate groups bond almost symmetrically in the basal CuN_2O_2 planes. The two oxygen atoms, O(4) and O(6′) in A; and O(10) and O(12′) in B, from the asymmetrically-bridging nitrate

groups occupy axial positions above and below the CuN_2O_2 planes, with Cu–O distances of 2.386(4) and 2.522(4) Å in A; and 2.422(6) and 2.510(4) Å in B. These distances are consistent with 'semi-coordination' of the bridging nitrate groups [19]. The tetragonalities (T = the mean in-plane bond length/the mean out-of-plane bond length) of molecules A and B are 0.824 and 0.817, respectively. The N–O distances involving the coordinated O atoms of the nitrate group are significantly longer compared with those of free nitrate (N–O = 1.255 Å) and non-coordinated O atoms [20]. In addition, the non-coordinated O atoms exhibit a shorter N–O bond distance than does free nitrate. Four atoms of the square-planes are essentially coplanar with a slight tetrahedral twist (dihedral angles between the CuN_2 and CuO_2 planes = 7.0(2)° in A and 3.8(2)° in B). The dihedral angles of 71.9(4)° and 87.6(4)° between two nitrate groups for each chromophore are nearly 90°. The planar pyridine rings make a dihedral angles of 10.0(2)° and 6.1(2)° with each other for A and B, respectively.

An important feature of the structure of **1** is the two-coordinate bridging coordination of the nitrate anion in the tetragonal positions, which involves an unsymmetrical bonding to the copper atom in the elongated rhombic octahedral configuration. The bond lengths and angles in **1** are comparable with those observed in the closely related complexes [Cu(dpyam)(CH_3CH_2-CO_2)(NO_3)] (**3**), $T = 0.753$ [13], [Cu(dpyam)(CH_3-CO_2)(NO_3)] (**4**), $T = 0.785$ [12] and [Cu(dpyam)(CH_3-

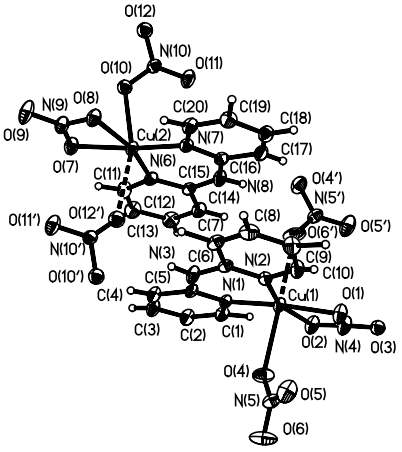

Fig. 1. The complex unit of $[Cu(dpyam)(ONO_2)_2]$ (**1**).

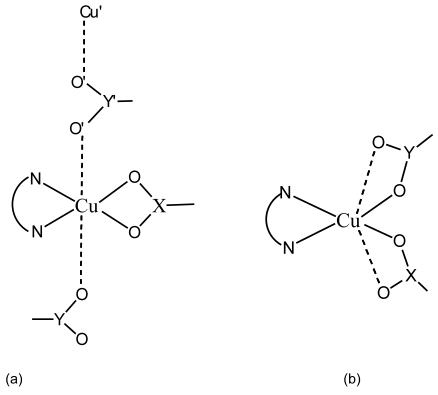

Fig. 2. Possible stereochemistries for [Cu(chelate)(OXO)(OYO)] complexes.

$CO_2)(ClO_4)]\cdot H_2O$ (**5**), $T = 0.765$ [11] but with the less elongation in the axial positions (Table 3) ($T = 0.824$ and 0.817 for A and B in **1**). Their local molecular geometries of the $CuN_2O_2O_2'$ chromophore are closely related, as in these three cases the in-plane coordinating atoms are the pyridine nitrogen atoms of the dpyam and two acetate or propionate oxygen atoms. In complex **5** the out-of-plane coordination sites are occupied by the oxygen atoms of the bridging perchlorate groups rather than the oxygen atoms of the bridging nitrate as in complexes **1**, **3** and **4**. To the best of our knowledge, complex **1** represents the first structurally characterized example of the [Cu(II)(chelate)$(OXO)_2$] derivative, exhibiting the polymeric chain with the two-coordinate bridging coordination of the nitrate anion in the tetragonal positions.

The complexes **1** and **3**–**5** are also compared with some other related complexes in Table 3. The elongated rhombic octahedral $CuN_2O_2O_2'$ chromophores of **1** and **3**–**5** are significantly different from those of the irregular rhombic octahedral CuN_4O_2 chromophore in $[Cu(bpy)_2(O_2ClO_2)](ClO_4)$ [21] or the CuN_4F_2 chromophore in $[Cu(bpy)_2(F_2BF_2)](BF_4)$ [21b] and the regular CuN_4O_2 chromophores in $[Cu(bpy)_2(S_4O_6)]$ [22] and $[Cu(bpy)_2(S_3O_6)]$ [22,23]. The in-plane CuN_4 chromophores of the remaining complexes have a marked tetrahedral distortion, with dihedral angles of approximately 37–57° (Table 3). This arises due to the steric interference of the two 2,9-hydrogen atoms of the dpyam ligand preventing these two rings from lying coplanar [21]. The unsymmetrical bonding role of the bridging nitrate group in **1** and **4** and bridging perchlorate group in **5** are comparable to that of $[Cu(bpy)_2(F_2BF_2)](BF_4)$ (Table 3) with the ΔO_{axial} of approximately 0.08–0.149 Å, but contrasts with those of the thionate complexes which involve more regular elongated rhombic octahedral chromophores. Furthermore **1** has the least out-of-plane distortion compared with those of the remaining complexes, denoted by the significantly larger tetragonalities, 0.824 and 0.817.

The one-coordinate bidentate mode of coordination is the predominating mode of the coordination of the nitrate group, involving both symmetric and asymmetric chelate nitrato coordination as in $[Cu(bpy)_2(O_2NO)](NO_3)$ [24]. The unsymmetrical bridging role of the nitrate group, which coordinates to the copper atom in the two coordinate manner as in **1**, **3** and **4** is unusual in Cu(II) chemistry. It is known to occur in an anhydrous $Cu(NO_3)_2$ [25] but with the near symmetric bridging bidentate coordination whose structure is described as distorted octahedral $(4+1+1')$. The related bpy complex $[Cu(bpy)(O_2NO)_2]$ is monomeric with an extremely distorted octahedron and both nitrate groups are bidentately bound to the copper atom [9]. In contrast, its silver analog forms a polymeric chain having the nitrate anion bridging between two Ag atoms, thereby achieving six-coordination [26].

3.2. Structure of $[Cu(dpyam)(O_2NO)_2]\cdot 2H_2O$ (**2**)

The asymmetric unit of **2** (Fig. 3) is made up of a couple of similar and crystallographically independent $[Cu(dpyam)(O_2NO)_2]$ neutral molecules (A and B) and four water molecules in the lattice. Molecules A and B are self-assembled by cooperative $O(NO_3)\cdots O(H_2O)$ in A and $O(NO_3)\cdots H(H_2O)$ in B. The crystallography structure is further stabilized by $O(NO_3)\cdots H(H_2O)$ and $N-H\cdots O(H_2O)$ hydrogen bonds via another water molecules. The Cu atoms of both molecules exhibit an irregular (4+2) coordination of the $CuN_2O_2O_2'$ chromophore. The coordination around each copper atom consists of two dpyam nitrogen atoms and two oxygen atoms from each nitrate group, forming a tetrahedral distorted square base. These equatorial planes of both molecules are markedly tetrahedrally twisted, as it is evident from the dihedral angles of 34.6(2)° and 33.0(3)°, respectively, at which the N–Cu–N and O–Cu–O planes cross. The second oxygen atoms from each nitrate group of both units then occupy the approxi-

mately tetragonal (axial) positions above and below the CuN_2O_2 basal planes at longer distances of 2.699(8) and 2.472(8) Å in A; and 2.502(9) and 2.703(7) Å in B giving the extremely distorted octahedron, Fig. 2(b). However,

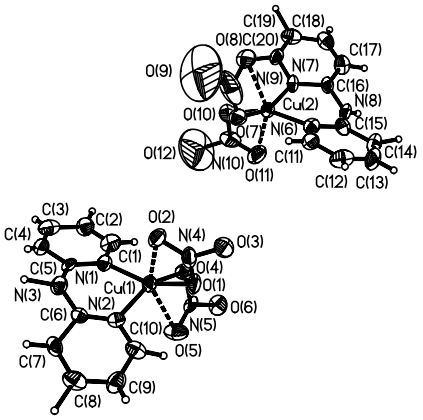

Fig. 3. The molecular structure of [Cu(dpyam)(ONO_2)$_2$]·$2H_2O$ (**2**).

both nitrate groups in A and B are bent towards the Cu atom to complete the fifth and sixth coordination sites in the axial positions with the O(2)–Cu–O(5) angle of 148.0(3)° in A and the O(8)–Cu–O(11) angle of 148.8(3)° in B which are markedly less than 180°. The dihedral angles between the individual dpyam pyridyl rings are 26.2(4)° and 25.7(4)° in A and B, respectively.

Both nitrate groups in A and B are planar and the planes of these two groups in each unit are almost perpendicular to each other [75.4(4)° in A and 72.8(6)° in B]. The coordination N–O distances [1.211(10)–1.302(8) Å in A and 1.224(11)–1.362(14) Å in B, and the subtended O–N–O angles of 124.3(7)° and 121.8(6)° in A; and 120.1(8)° and 124.0(13)° in B are consistent with an asymmetric bidentate coordination [9] compared with those of the symmetric bidentate coordination of the nitrate groups in **1** [subtended O–N–O angles = 113.2(3)° in A and 113.5(3)° in B]. However, there are some unreasonable N–O bond distances [N(4)–O(3), 1.512 Å and N(5)–O(6), 1.502 Å in A, and N(9)–O(7), 1.160 Å; N(9)–O(9), 1.730 Å and N(10)–O(12), 1.700 Å in B] with high temperature factors of some atoms [O(12), 0.192 and O(9), 0.392]. Hence, attempts were made to model and refine these

relevant atoms which were unsuccessful. There are the hydrogen bonds involved between water molecules and each of the nitrate groups in **2**. These bondings may be responsible for the evident distortion of these nitrate groups [the O–N–O angles vary from 108.6(15)° to 124.3(7)°] compared with those for the monodentate nitrate ligand (119.3°–120.6°) [10,13]. The close approach to the copper atoms of the second oxygen atoms from each nitrate group would indicate that the coordination mode of these oxygen atoms to the copper is intermediate between the purely monodentate nitrato-coordination [10,13] and the fully bidentate nitrato-coordination [27] as in **1**.

The coordination around the copper atoms of the molecules A and B is comparable to those observed in the related complexes $[Cu(bpy)(NO_2)_2]$ [4], $[Cu(bpy)(NO_3)_2]$ [9], $[Cu(tmen)(NO_3)_2]$ [2], $[Cu(DMAEP)(NO_3)_2]$ [3] and the corresponding dpyam complexes $[Cu(dpyam)(NO_2)_2]$ (**6**) [7], $[Cu(dpyam)(O_2CCH_3)(NO_2)]\cdot H_2O$ (**7**) [7], $[Cu(dpyam)(O_2CCH_3)_2]\cdot 2H_2O$ (**8**) [6], $[Cu(dpyam)(O_2CCH_3)(NO_2)]$ (**9**) [8] and $[Cu(dpyam)(O_2CCH_3)_2]\cdot H_2O$ (**10**) [5] and $[Cu(dpyam)(NO_2)_2]_2\cdot 2CH_3CN$ [8]. These complexes involve the tetrahedrally distorted elongated tetragonal-octahedral geometry with the long off-the-z-axis coordination of the second oxygen atoms from each OXO^- ligand in the axial positions. The latter complex exhibits the dinuclear complex containing both monodentate and O-bridging nitrite ligands. The most similarity in the $CuN_2O_2O'O'$ chromophore to that of **2** is observed in **8** and **10** exhibiting the similar axial distances of 2.5 and 2.7 Å and dihedral angles of 26.8° and 34.4° for both complexes, respectively, and the axial O–Cu–O angle of 148.2° for **8**. However, the coordination around the copper atoms in **2** differs from the arrangement observed in the related formato dinuclear derivative $[Cu(dpyam)(HCO_2)_2(H_2O)_{0.5}]_2\cdot H_2O$ [10], involving both monodentate and O,O′-bridging formato ligands. Each copper atom of this formate dimer is in a distorted square-pyramidal coordination environment.

3.3. Spectroscopic properties

3.3.1. ESR spectra

The polycrystalline e.s.r. spectrum of **1** is clearly axial ($g_{//} \gg g_\perp > 2.0$) with $g_{//} = 2.307$ and $g_\perp = 2.074$, suggesting a $d_{x^2-y^2}$ ground state which is consistent with an elongated rhombic-octahedral $CuN_2O_2O'_2$ chromophore of **1**. This type of polycrystalline e.s.r. spectrum is similar to that of **2** which also involves the axial type with $g_{//} = 2.225$ and $g_\perp = 2.086$, consistent with the tetrahedrally distorted elongated tetragonal-octahedral geometry with the off-the-z-axis coordination in the axial positions of **2**. The e.s.r. spectra of both **1** and **2** are compared (Table 5) with those of some relevant complexes.

3.3.2. Electronic spectra

The electronic reflectance spectrum of **1** has a broad peak centered at 14 340 cm^{-1}, with a poorly resolved shoulder to low energy at approximately 10 840 cm^{-1}, corresponding to the elongated rhombic-octahedral geometry [1,12]. This suggests the assignment [28] of the bands as the d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$ transitions, respectively, with the position of the $d_{xy} \rightarrow d_{x^2-y^2}$ transition uncertain. The electronic spectrum of **1** are comparable to those found in the related complexes $[Cu(dpyam)(O_2CCH_3)(NO_3)]$, 15 000 and approximately 10 000 (sh) cm^{-1} and $[Cu(dpyam)(O_2CCH_3)(ClO_4)]\cdot H_2O$, 15 800 and approximately 10 000 (sh) cm^{-1} (Table 5). The higher energies in electronic spectra of the latter two complexes correspond to the more elongation in the axial distances with the less tetragonalities of 0.785 and 0.765, respectively. That of **2** (tetrahedral twist, 33.80° (av.)) involves a single broad peak at a lower energy of approximately 13 580 cm^{-1}. The observed single band in **2** is comparable to that of the single band in the related complexes $[Cu(dpyam)(NO_2)_2]$ (**6**) [7] (13 890 cm^{-1}; tetrahedral twist, 31.16°), $[Cu(dpyam)(O_2CCH_3)(NO_2)]\cdot H_2O$ (**7**) [7] (13 880 cm^{-1}; tetrahedral twist, 32.69°) and $[Cu(dpyam)(O_2CCH_3)_2]\cdot 2H_2O$ (**8**) [6] (13 510 cm^{-1}; tetrahedral twist, 34.38°) (Table 5). These spectra are consistent with an elongated rhombic-octahedral stereochemistry. All four d–d transitions (d_{z^2}, d_{xy}, d_{xz} and $d_{yz} \rightarrow d_{x^2-y^2}$) are assigned to lie within the band envelope at approximately 11 000–15 500 cm^{-1} for **2** and the similar assignment can be made for the other relevant complexes. This has been found that the higher tetrahedral twist in the basal planes, the lower energies in electronic spectra. Hence, the presence of higher energies in electronic spectra of **1** and its closely related complexes compared with those of **2** and **6**–**8**, is due to the essentially square-planar arrangement in the basal planes.

3.3.3. IR spectra

The most relevant feature of the infrared spectra in **1** and **2** is the evidence for the chelating and bridging bidentate coordination of the nitrate anions. As the nitrate ion [27,29,30] has characteristic absorption frequencies at approximately 1390 (ν_3), 1050 (ν_1), 831 (ν_2) and 720 (ν_4) cm^{-1} for D_{3h} symmetry and there is no nitrate ion in these complexes; the strong bands at 1380 and 1320 cm^{-1} for **1** and 1380 and 1310 cm^{-1} for **2**, and a medium band at 650 cm^{-1} for both complexes are involved in bidentate chelating and bridging modes of coordination. It is impossible to distinguish between mono- and bidentate ligands as the nitrate ion (D_{3h}) coordination to one or two oxygen atoms lowers the symmetry to that of C_{2v}.

Received 4 October 2001; accepted 20 December 2001

Abstract

A sensitive fluorimetric method of determination of SO_2 dissolved in solvents using the steady state fluorescence of tetrasulfonated zinc(II) phthalocyanine and SO_2 in the concentration range (0.1–1.0 mM) was carried out. Effects of various solvents, pH, and salt on the interaction properties of ZnPcTs–SO_2 are determined, based on the quenchings by SO_2. Linear and non-linear Stern–Volmer plots have been analysed. Modified non-linear Stern–Volmer analysis produced best fits for a 1:2 stoichiometry. The association constant values of the ZnPcTs–SO_2 complex in various environments have been determined adopting single stage and two step equilibria processes. Stern–Volmer deviations are attributed to solvent extraplanar coordinations, a 20% DMSO–water mixture seems to produce a stability constant value higher than the other effects. A cyclic voltammogram in DMSO–water medium shows significantly suppressed redox processes of the central Zinc metal ion in ZnPcTs in the presence of SO_2 (1×10^{-3} M). Axial coordination leading to the formation of bis sulfonato ZnPcTs is envisaged. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Zinc(II)tetrasulfophthalocyanine; Sulfur dioxide; Fluorescence quenching; Association constants

1. Introduction

There has been considerable interest in the detection and control of sulphur dioxide (SO_2) gas in aquatic environments since these constitute the fundamental aspects in the global natural sulphur cycle and in various chemical transformations of corrosion inducing pollutants [1,2]. Autoxidations of SO_2 in aquated conditions are catalysed by many catalysts and among these, transition metal(II) phthalocyanine (MPc) complexes outstand in catalytic behaviour [3–5]. Cobalt(II) tetrasulfonated phthalocyanine complex is reported to catalyse the autoxidation of SO_2 in aqueous medium with a well defined kinetic and mechanistic pathway [6]. However, study of photoassisted reactions of aquated SO_2 by MPc will be required from the economical and commercial stand points [7,8].

Sulfonation of MPc renders water solubility. Zinc(II)4,4′,4″,4‴-tetra sulfophthalocyanine (ZnPcTs) is a photo active, water soluble fluorophore showing S_1–S_0 emission fluorescence around 600–700 nm upon excitation with 390 nm wavelength light [9,10]. Many organic and other compounds act as quenchers of ZnPcTs fluorescence in aqueous homogeneous and microheterogeneous media [11–14]. Presence of SO_2 in aqueous medium has been found to quench the steady state fluorescence of ZnPcTs quantitatively with the extent of quenching being proportional to the amount of SO_2 present in water. In order to investigate the interaction of SO_2 and ZnPcTs in aqueous medium, steady state fluorescence quenching experiments are carried out in view to optimise the medium effects for maximum quenching and to deduce the quantitative results on the aspects of complexation pathway through interaction constants and stoichiometry parameters. Effects of pH, salt (NaCl) and solvent media such as DMSO, DMF, THF and MeOH as aqueous mixtures on the quenching of ZnPcTS fluorescence by SO_2 are attempted.

ZnPcTs exists mostly as dimers in water at concentrations exceeding 1×10^{-7} M [15,16]. In the presence of solvents like DMSO, DMF, THF, MeOH etc, dimers of ZnPcTs exist as monomers which may be due to the solvent binding to the square-planar ZnPcTs complex at the axial sites and also by the solvent polarity effects [17]. Analysis of non-linear Stern–Volmer plots is attempted on the fluorescence quenching of ZnPcTs and a 1:2 stoichiometry of the ZnPcTs–SO_2 complex have been detected in certain cases. Solvent effect studies also show similar results as these. The association constant values of ZnPcTs–SO_2 complexes are determined for both 1:1 and 1:2 stoichiometries wherever possible. Single step and two stage equilibria pathways are proposed for the solvent, pH and electrolyte effect studies. From the best fitted modified Stern–Volmer plots, the association parameters are determined. The effectiveness of the SO_2 association process with ZnPcTs is revealed from the significant fluorescence quenching by smaller differences in the SO_2 concentrations ($\Delta c = 1 \times 10^{-4}$ M) in the DMSO–water mixture (20% w/v).

2. Experimental

2.1. Materials

ZnPcTs complex was prepared by using a modified synthesis method of Weber–Busch [18] and the solid sample was twice recrystallised from a water–ethanol mixture solvent. The sample purity was ensured by UV–Vis spectrophotometry and 99.9% pure sample was used. Hydrated SO_2 (AR grade, 99.0%) supplied by Loba-Chemi India was used as such and the concentration of SO_2 was estimated by $BaSO_4$ gravimetry as outlined in Vogel's text book [19]. Spectrosol grade solvents such as DMSO, THF, DMF and MeOH dried over 4A molecular sieves were used. Triple distilled water was always used. Various pH conditions were maintained using Tris–HCl buffer mixture. Analytical grade, Loba-Chemi NaCl salt was used.

2.2. Fluorimetric methods

Steady state fluorescence measurements were made on a Perkin–Elmer model LS-53 spectro fluorimeter fitted with 450 W Xenon arc lamp with 1 nm resolution. The fluorescence signal was detected perpendicular to the incident 390 nm excitation beam. The emission intensities are corrected for background and detector wavelength sensitivity. Electronic absorption spectra were recorded with UV–Vis Perkin–Elmer spectrometer with 1 nm resolution. Instrumental procedures are according to the manual instructions.

2.3. Cyclic voltammetry

Cyclic voltammograms were obtained from a BAS model No100A voltammetric analyser using a disk type glassy carbon working electrode (2 mm dia) (GCE) and platinum wire as the auxiliary electrode. The supporting electrolyte was tetraethyl ammonium perchlorate (TEAP) in 20% wt DMSO–water medium. The reference electrodes were silver wire dipped in 0.01 M $AgNO_3$ containing 0.1 M TEAP in 20% DMSO–water solvent and Ag/AgCl in 3 M KCl in aqueous solutions, respectively. GCE was polished with alumina, soaking in dilute nitric acid and rinsing repeatedly in water, acetone and DMSO–water solvent.

3. Results and discussion

3.1. Spectral studies

Fig. 1 represents the electronic absorption spectra of ZnPcTs in water and in various water solvent mixtures. The pronounced solvent effects are seen only in the Q band region while the S band region is unaffected. In water for ZnPcTs, the 636 nm peak corresponds to the dimer and the 673 nm peak corresponds to monomer forms [20,21]. At 1×10^{-5} M concentration, a considerable amount of dimers are present in the solution. Upon changing the solvent-nature, the monomer peak intensity seems to increase with a concomitant decrease in the dimer peak. The maximum in the monomer absorbance is seen for THF–water solvent mixture. The monomer molecules are stabilised through axial coordination of the solvent molecules to the square-planar ZnPcTs. The isosbestic point at 650 nm, detected from the solvent effect, ensures the existence of an equilibrium between the monomer and dimer species. The lowering of the band intensity also indicates the presence of lower

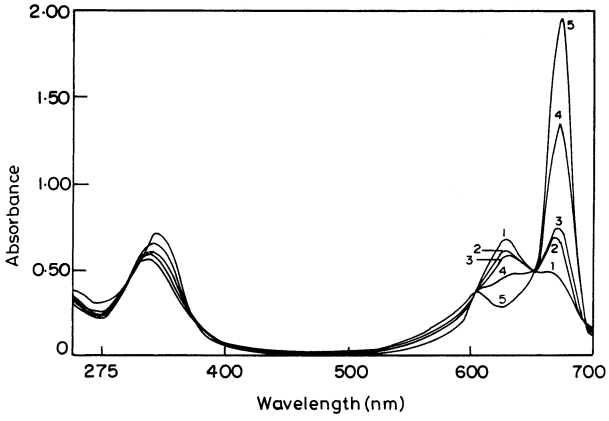

Fig. 1. Electronic absorption spectral changes on addition of various solvent–water mixtures (20% w/v), of ZnPcTs (1×10^{-5} M), (1) Water; (2) DMSO–water; (3) DMF–water; (4) MeOH–water; (5) THF–water.

amounts of dimer forms in THF. Addition of SO_2 as aqueous solution in the concentration range chosen (1×10^{-4}–1×10^{-3} M) bring in only minor changes in the visible region while almost no changes are detected in the S band region. This is possible because the sulfonate groups on the phthalocyanine do not interact with sulfur dioxide added externally. Also the absorbance spectra of metal free phthalocyanine (H_2PCTs^{4-}) taken in pyridine solvent possess strong bands at 650 and 700 nm [22,23] which are not affected by the addition of sulfur dioxide. This observation goes in hand with the reported one that tetrasulfonated phthalocyanines have satisfactory stability towards oxidation and reduction both in presence and absence of air. Alternatively, quenchings on the fluorescence spectra of ZnPcTs seem sensitive to the presence of SO_2 additions. Mostly, fluorescence intensities of ZnPcTs are lowered due to existence of dimers [24,10]. Hence, for a constant composition of ZnPcTs the fluorescence intensity is observed to be minimum in water and maximum in the presence of THF. Generally, dilution effects increase the composition of the monomer. For quenching studies involving aquated SO_2, conditions for the existence of monomeric forms are chosen. The 720–800 nm weak emission fluorescence corresponding to ZnPcTs dimers has not been considered in this study.

3.2. Fluorescence quenching studies

The fluorescence spectra of ZnPcTs show a strong florescence band in the red region (690–700 nm) when the excitation wavelength is 390 nm. The red fluorescence is mainly a radiative transition from the first excited singlet state S_1 while S_2–S_1 is a rapid process [9]. In aqueous solution even in the micromolar concentrations low intensity fluorescence exists. In DMSO solvent there is a sharp increase in the relative intensity due to ZnPcTs existing mostly as a monomer. It is thus of interest to study the fluorescence quenching of monomeric ZnPcTs, which actively interact with SO_2 in an aqueous environment and also in organic solvent such as DMSO. In Fig. 2 the stacked fluorescence quenching plots in DMSO–water (20%) are shown including other effects in solutions.

The addition of SO_2 brings about quenching of ZnPcTs fluorescence with yields $1-I_0/I$ reaching 0.5 at a quencher concentration of 9.5 mM, where I and I_0 stand for fluorescence intensity in the presence and in the absence of quencher, respectively. The corresponding conventional Stern–Volmer plot is shown in Fig. 3 [25]. The plot appears non-linear in certain systems although the quencher concentration is maintained low. The non-linearity increases towards higher quencher concentration and may be attributed to an interaction between ZnPcTs—quencher with a higher stoichiometry than 1:1. The association complex (one or more) formed

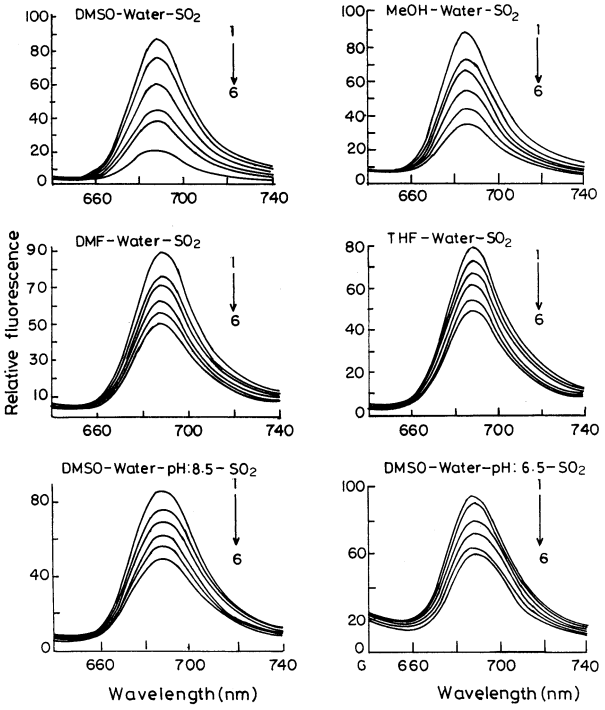

Fig. 2. Steady state fluorescence stacked spectra of ZnPcTs (1×10^{-5} M) in absence (no.1) and in presence of (nos. 2–6) $SO_2 \cdot H_2O$ [2×10^{-4}; 4×10^{-4}; 6×10^{-4}; 8×10^{-4}; 1×10^{-3}] at 25 °C and at various solvent–water mixtures and pH.

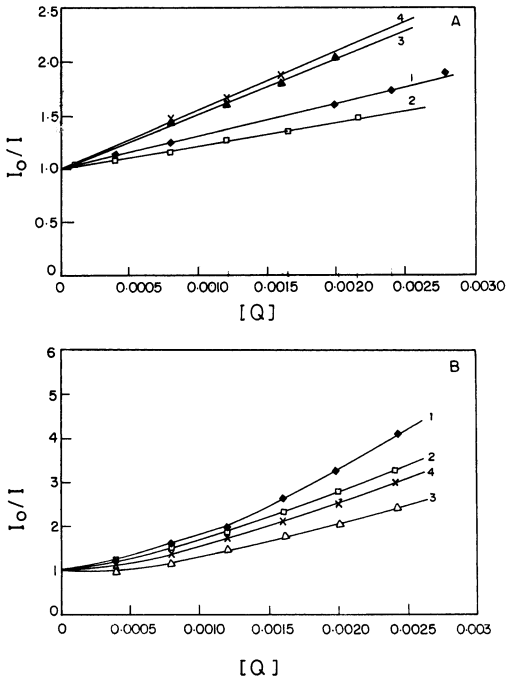

Fig. 3. Stern–Volmer plots of ZnPcTs (1×10^{-5} M) fluorescence quenching by $SO_2 \cdot H_2O$ with linear dependence (A) and non-linear dependence (B) at 25 °C. (A) (1) pH 10.5; (2) pH 8.5; (3) DMF–water (20% w/v) medium and (4) THF–water (20% w/v) medium. (B) (1) DMSO–water (20% w/v) medium; (2) MeOH–water (20% w/v) medium; (3) pH 6.5; (4) in 0.001 M NaCl.

by the quencher (ZnPcTs–nSO$_2$) are found to be non-fluorescent. There is ample evidence that SO_2 behaves as a relatively good ligand for axial site coordination to the central metal ion in ZnPcTs. Conversion of dimers to monomers seem to increase the relative fluorescence intensity in 600–700 nm region and in this region the dimer may be considered to be non-fluorescent. In the presence of various solvents like DMSO, DMF, THF and MeOH either in the pure form or in aqueous mixture, monomeric forms are increased and this is evident from the UV–Vis spectra as shown in Fig. 1. The dimer $\lambda_{max} = 630$ nm in water has been reduced considerably while there is a concomitant increase in the monomer absorbance at $\lambda_{max} = 666.5$ nm with no shifts even in presence of SO_2.

The interaction of ZnPcTs with SO_2 in aquated form is studied in presence of 20% DMSO–water mixture (when the monomeric forms show maximum absorbance due to better stability) including salt and pH effects. Also, this medium helps for carrying out selective quenching of SO_2.

In Fig. 2, stacked plots of fluorescence emission in a DMSO–water mixture with various effects are shown. From the Stern–Volmer analysis of I_0/I versus [Q] plots, it is seen that the ZnPcTs–SO_2 interaction obeys a Stern–Volmer type analysis forming 1:1 stoichiometric association in THF, and DMF-aqueous solvents at pH 10.5 and 8.5 maintained in a DMSO–water mixture, respectively. Fig. 3(A) depicts the Stern–Volmer plots based on the relation $I_0/I = 1 + K_D[Q]$, where K_D is the interaction constant for 1:1 stoichiometry. The non-linear dependances (upward deviation) of I_0/I versus [Q] are noticed in systems of DMSO and MeOH–water mixtures, in NaCl and at pH 6.5. Fig. 3(B) shows the predominate condition of the static quenching at high quencher concentration. This means that the quencher is able to bind presumably to the axial coordination sites of the central metal ion resulting in a 1:2 stoichiometry with each one of the 1:1 and 1:2 complexes formed stepwise being non-fluorescent. This observation is similar to the reported fluorescence quenching of AlPcTs [26]. In such a case, the formation of 1:2 association of ZnPcTs–SO_2 may be considered to occur via [case (i)] a stepwise equilibria as shown in Eqs. (1) and (2) or [case (ii)] in a single equilibrium step as in Eq. (3).

The products shown in Eqs. (1)–(3) are non-fluorescent

$$\mathrm{ZnPcTs} + \mathrm{SO_2} + \mathrm{S} \overset{K_1}{\rightleftharpoons} \mathrm{ZnPcTs \cdot SO_2 \cdot S} \quad (1)$$

$$\mathrm{ZnPcTs \cdot SO_2 \cdot S} + \mathrm{SO_2} \overset{K_2}{\rightleftharpoons} \mathrm{ZnPcTs(SO_2)_2} + \mathrm{S} \quad (2)$$

$$\mathrm{ZnPcTs} + 2\mathrm{SO_2} \overset{K_2}{\rightleftharpoons} \mathrm{ZnPcTs(SO_2)_2} \quad (3)$$

$\mathrm{S} = \text{Solvent molecule} \quad K_1 = K_D$

Case (i), at any instant of quenching, the total ZnPcTs concentration may be expressed as in Eq. (4) (assuming Z = ZnPcTs and Q = SO_2),

$$Z_0 = \mathrm{Ze} + \mathrm{Z \cdot Q} + \mathrm{Z \cdot Q_2} \quad (4)$$

where Z_0 and Ze are the total and free complex concentration and from Eqs. (1) and (2)

$$[\mathrm{Z \cdot Q}] = K_1[\mathrm{Z}][\mathrm{Q}] \text{ and } [\mathrm{Z \cdot Q_2}] = K_2K_1[\mathrm{Z}][\mathrm{Q}]^2$$

Substituting these in Eq. (4) and rearranging

$$[(Z_0/Z) - 1]/[\mathrm{Q}] = K_1 + K_1K_2[\mathrm{Q}] \quad (5)$$

In the above Eq. (5), $[(Z_0/Z) - 1]/[Q]$ equals $[(I_0/I) - 1]/[Q]$ where I_0 and I are the steady state fluorescence intensities observed in the absence and presence of a quencher. If linear regression analysis of Eq. (5) such as $[(I_0/I) - 1]/[Q]$ versus [Q] data shows linear plots, then the values of intercept = K_1 and slope/intercept = K_2.

Case (ii), considering single step equilibrium (Eq. (3)) to occur, then

$$K_T = [\mathrm{ZnQ_2}]/[\mathrm{Z}]\,[\mathrm{Q}]^2 \text{ and } [\mathrm{ZnQ_2}] = [Z_0] - [\mathrm{Z}]$$

Then $I_0/I = 1 + K_T[Q]^2$ and if linear regression applied on (I_0/I) versus $[Q]^2$ data shows linear plots, this produces values of slope = K_T and intercept = 1.

The fluorescence quenching measurements carried out with effects of solvents, salt and pH are subjected to Stern–Volmer (1:1 stoichiometry) and cases (i) and (ii) (1:2 stoichiometry) analyses by adopting a modified form of Stern–Volmer relation.

3.3. Solvent effect

When steady state fluorescence intensity of ZnPcTs at constant composition was measured in various percentage compositions of DMSO–water mixture, in 20% DMSO–water solvent mixture higher intensity fluorescence was detected. Hence, for comparative studies and for the use of aquated SO_2, in other studies 20% w/v of MeOH, THF and DMF–water mixtures were used. The extent of quenching at constant solvent conditions falls in the trend MeOH > DMF > DMSO > THF. In the water–solvent mixture conditions, and also at high SO_2 compositions the trend in the extent of quenching by SO_2 observed is DMSO > MeOH > DMF > THF. Higher extents of fluorescence quenchings are seen in solvents where 1:2 stoichiometry is favoured due to the higher order of association of SO_2 with ZnPcTs, and greater quenchings results. In the case of aqueous DMF and THF solvent mixtures linear Stern–Volmer plots are observed and 1:1 stoichiometry of ZnPcTs–SO_2 association complex produces best fits (Fig. 3(A)). This is because the solvent molecules concomitantly bind at the axial position of ZnPcTs. The K_1 values are 47.8 and 37.7 M^{-1} for DMF and THF, respectively. Thus, a DMF presence induces greater stability of the ZnPcTs–

SO_2 association complex than THF. Considering Stern–Volmer non-linear plots, application of case (ii) for a single step formation of the 1:2 stoichiometric association complex ZnPcTs·$(SO)_2$ produces linear fits (Fig. 3B, Fig. 4) and the K_T values of the complex are 57.14×10^4 and 35.30×10^4 M^{-1} for the DMSO and MeOH system (Table 1). The upward deviation in the Stern–Volmer plot for DMSO and MeOH may be due to the onset of 1:2 stoichiometry [27,28]. That is, the solvent effect on the ZnPcTs–SO_2 association seems peculiar and solvent specific (Fig. 5). DMSO solvent presence induces better association between ZnPcTs and SO_2, at the higher concentration range.

3.4. Salt effect

The fluorescence of a blank solution of ZnPcTs decreased slightly on addition of NaCl and with subsequent addition of SO_2 significant fluorescence quenching was noticed. In the presence of 0.001 M NaCl, SO_2 quenching measurements indicate a non-linear Stern–Volmer plot. Consideration of a stepwise, 1:2 stoichiometric [case (i)] formation of a ZnPcTs–$(SO)_2$ association complex seems to produce the best fit. The values of stepwise association constants K_1 and K_2 are found to be 1.5×10^2 and 2.00×10^3 M^{-1}, respectively. The total association constant value is: $K_T = K_1 \cdot K_2 = 30.00 \times 10^4$ M^{-2}. This indicates that 1:1 complex formation in step (i) is comparatively less stable

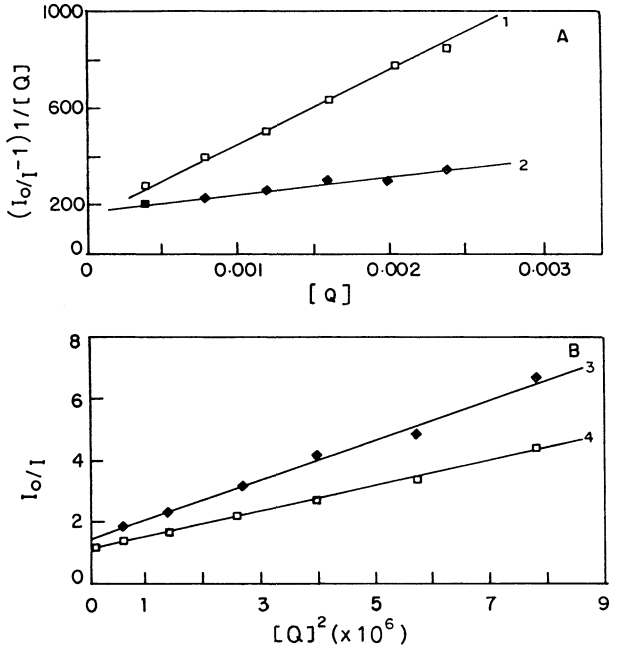

Fig. 4. Modified plots of Stern–Volmer relation on ZnPcTs fluorescence SO_2–H_2O for 1:2 stoichoimetry association via case (i)-Stepwise formations. (4-A) and case (ii)-Single step formation (4-B) at 25 °C. (A) (1) In 0.001 M NaCl; (2) in pH 6.5. (B) (3) In DMSO–water DMF–water (20% w/v) medium and (4) MeOH–water (20% w/v).

due to weak association forces that forms a driving force for the formation of a 1:2 complex with good stability which may be attributed to axial ligations. In presence of an electrolyte medium, solvation of SO_2 by water molecules are affected and due to a solvent structural effect, SO_2 coordination at the two axial positions on ZnPcTs becomes favoured [29]. This is reflected in Stern–Volmer plots corresponding to 1:2 stoichiometry (Fig. 5).

3.5. pH effects

Alkaline pH (10.5 and 8.5) conditions seem to direct the SO_2 quenching via 1:1 stoichiometry association with ZnPcTs and linear Stern–Volmer plots are obtained (Fig. 3(A)) for the two pH conditions. The K_D values are 9.10×10^2 and 3.75×10^2 M^{-1} at pH 8.5 and 10.5, respectively. The 1:1 association of ZnPcTs and SO_2 arises due to the binding of SO_2 and OH^- ions at the two axial sites instead of two SO_2 molecules binding at each axial site. Under neutral conditions linear Stern–Volmer plots corresponding to 1:1 stoichiometry and $K_D = 1.13 \times 10^2$ M^{-1} are obtained. Here SO_2 and H_2O bind as the axial ligands. At acidic pH 6.5, 1:2 stoichiometry via stepwise formation obeying case (i) pathway is observed, with K_1 and K_2 values of 1.8×10^2 and 6.94×10^2 M^{-1}, respectively and $K_T = K_1 \cdot K_2 = 12.5 \times 10^4$ M^{-2}. The values indicate more stability to the ZnPcTs$(SO)_2$ associations under acidic conditions than the 1:1 associations under basic conditions. In neutral pH weaker associations than in the acidic and basic media [30,31] are seen. The scheme presented in Fig. 5 represents the overall complexation processes involving SO_2.

3.6. Electrochemical studies

According to the scheme, sulfur dioxide coordination to the central zinc ion occurs through coordination at the axial positions and as a consequence, ring reduction through electron transfer may be possible. The electronic absorption spectral changes are negligible and hence fluorescence quenching effects are measured. Analogously Sn(IV) phthalocyanine exhibits ring reduction through electron transfer [22] and these processes are photo-assisted. Axial ligation can be monitored electrochemically in case of ZnPcTs when spectral differences are negligible [32]. The electrochemical response of ZnPcTs in the cathodic scan of the cyclic voltammogram is significant (Fig. 6) and the cathodic peak potential occurs at −0.097 V versus the silver–silver chloride reference electrode at r.t. in air and in 20% DMSO–H_2O medium containing 0.01 M tetraethyl ammonium perchlorate (TEAP) as the supporting electrolyte. Upon addition of sulfur dioxide the cathodic peak characteristic of the central metal ion completely

Table 1
Association constant and stoichiometry values of ZnPcTs–$(SO_2)_n$ complex in various solvents–aqueous (20% w/v) mixtures, pH and salt at 25 °C (S–V = Stern–Volmer plot)

Medium type	Stoichiometry	Analysis	Association constants (±0.005)
DMSO–water	1:2	S–V non-linear (single step)	$K_T = 57.14 \times 10^4\ M^{-2}$
MeOH–water	1:2	S–V non-linear (single step)	$K_T = 35.30 \times 10^4\ M^{-2}$
DMF–water	1:1	S–V linear	$K_D = 3.33 \times 10^2\ M^{-1}$
THF–water	1:1	S–V linear	$K_D = 3.00 \times 10^2\ M^{-1}$
pH 10.5	1:1	S–V linear	$K_D = 3.75 \times 10^2\ M^{-1}$
pH 8.5	1:1	S–V linear	$K_D = 9.10 \times 10^2\ M^{-1}$
pH 7.0	1:1	S–V (neutral) linear	$K_D = 1.13 \times 10^2\ M^{-1}$
pH 6.5	1:2	S–V non-linear (stepwise)	$K_1 = 1.80 \times 10^2\ M^{-1}$; $K_2 = 6.94 \times 10^2\ M^{-1}$; $K_T^{\dagger} = 12.50 \times 10^4\ M^{-2}$
0.001 M NaCl	1:2	S–V non-linear (stepwise)	$K_1 = 1.50 \times 10^2\ M^{-1}$; $K_2 = 2.00 \times 10^3\ M^{-1}$; $K_T^{\dagger} = 30.00 \times 10^4\ M^{-2}$

$K_{T\dagger}$ = total association constant = $K_1 \cdot K_2$.

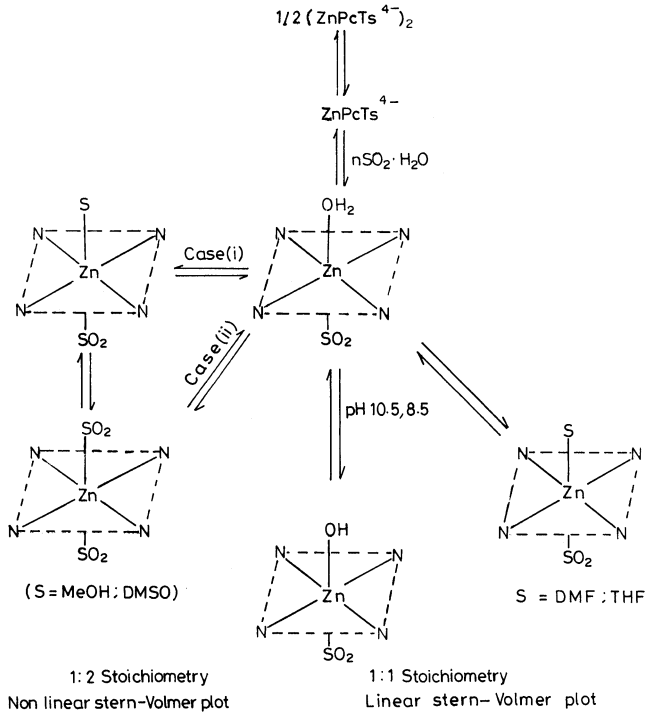

Fig. 5. Schematic representation of the proposed uni- and bi-substrate (SO_2) interaction of ZnPcTs in aqueous medium.

vanishes indicating the complete coordination at the axial sites of the square-planar ZnPcTs complex. The reducing effects of sulfur dioxide via electron transfer to the complex may be possible at the ring sites. The electrochemical evidence is a standby resource when electronic absorption spectral data prove ambiguous.

4. Conclusion

The results obtained in this work reveal that ZnPcTs can serve as an efficient fluorescent substrate to detect aquated SO_2 presence at low concentrations ($\sim 1 \times 10^{-4}$ M) in the lab and in effluent conditions. In DMSO–water (20%) solvent mixture, SO_2 association

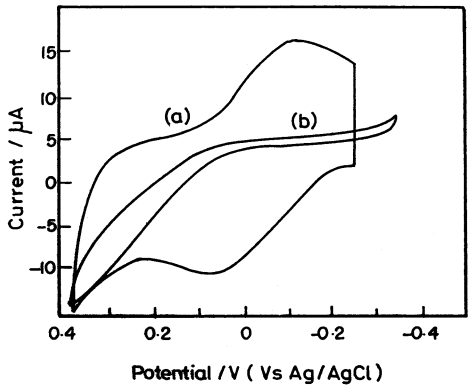

Fig. 6. Cyclic voltammograms of ZnPcTs (4×10^{-5} M) in 20% DMSO–water medium in the absence (a) and in the presence (b) of SO_2 at 25 °C in air. Supporting electrolyte is 0.1 mol dm^{-3} TEAP and scan rate 50 mV s^{-1}.

is stronger than under other conditions. Although MeOH medium shows higher extents of quenching, the DMSO–water solvent mixture (20%) is chosen since in the presence of NaCl and pH effects significant quenchings are detected. A stable 1:2 stoichiometry ZnPcTs–$(SO_2)_2$ complex has been found under acidic pH, NaCl, DMSO–water and MeOH–water conditions. The two axial ligations of sulfur dioxide at the central position of the ZnPcTs is well brought out from the CV results taken in air with and without SO_2 addition. In the oxidation reaction of SO_2 and molecular oxygen involving ZnPcTs as the catalyst, preliminary results such as these on the association characteristics at various conditions may prove vital.

Abstract

The rational synthesis of an arsenic(V) oxopolymetalate cluster from an arsenic(III) oxopolymetalate cluster has been accomplished by a redox reaction. The sandwich Mn-complex of $As^{V}W_9O_{34}^{9-}$ ($Na_9K[Mn^{II}_4(H_2O)_2(As^{V}W_9O_{34})_2]\cdot 35H_2O$ (**1**) was prepared from a tetrameric complex $[As_4W_{40}O_{140}]^{28-}$ containing $As^{III}W_9O_{33}^{9-}$ units using both Mn^{VII} and Mn^{II} salts as reagents. Structures of **1** and $Na_{27}K[As_4W_{40}O_{140}]\cdot 56H_2O$ (**2**), are reported. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

The synthesis of large and giant oxomolybdates and oxotungstates requires access to good starting materials and synthetic routes.[1,2] Specifically, a large heteroxotungstate of composition $As^{III}_{12}Ce^{III}_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$ has been reported [2] and can be described as originating from building blocks of lacunary anions such as $As^{III}W_9O_{33}^{9-}$ [2–9]. Building blocks such as $As^{V}W_9O_{34}^{9-}$ [10–12] has been used when forming oxometalates containing As in oxidation state V. In this paper we show that As^{III}–As^{V} oxometalates can be linked through redox chemistry and synthetic strategy.

The first precursor, $AsW_9O_{33}^{9-}$ was initially prepared by Tourné et al. from As_2O_3, Na_2WO_4 and HCl [6]. At this time dimeric [3,4,10], trimeric [5,6] and tetrameric structures [2,7–9] have all been reported. Tetrameric structures, containing four units of $AsW_9O_{33}^{9-}$, are linked through WO_2^{2+} groups and are also bonded to Na [2], Co [8], or Mn [9]. The sandwich anions consist of two $As^{III}W_9O_{33}^{9-}$ units linked by three metal atoms and have been reported with Cu, Mn, Co, and V [3,4]. The As^{V} sandwich compounds are linked by four metal ions, and those containing Zn, Co, Cu and Mn have been structurally characterized [10–12].

This paper describes the synthesis and structure of the mixed sodium-potassium salts of the Mn-sandwich $As^{V}W_9O_{34}^{9-}$complex ($Na_9K[Mn^{II}_4(H_2O)_2(As^{V}W_9O_{34})_2]\cdot 35H_2O$) and the tetrameric condensation product of $As^{III}W_9O_{33}^{9-}$ (Fig. 1, $Na_{27}K[As_4W_{40}O_{140}]\cdot 56H_2O$)). This work supplements structural findings [7,12] that were published while this work was in progress. More importantly, the synthetic approaches to these materials were previously limited by the starting materials heteroatom oxidation state. The concept of using a redox agent as part of the synthetic strategy is illustrated and thus allows application of a greater number of precursors for oxometalate synthesis. In this work we show by employing redox chemistry in the synthetic strategy, that an oxotungstate in the As^{III} class of compounds can be converted to an oxometalate in the As^{V} class of compounds.

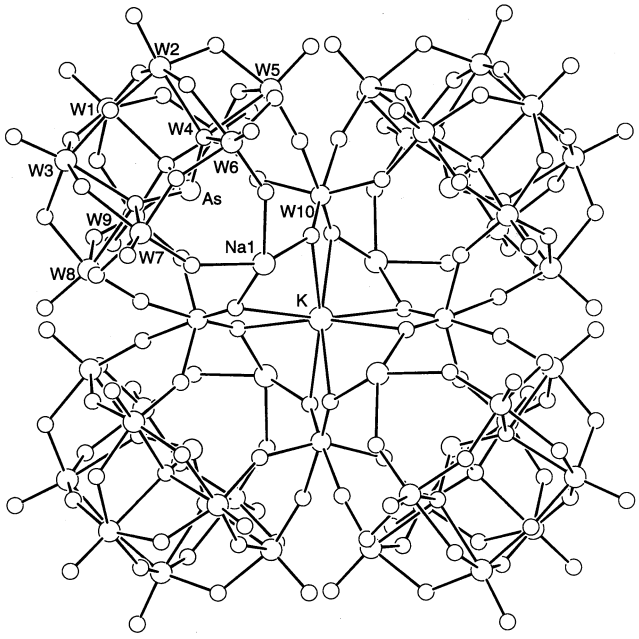

Fig. 1. The structure of the anion in $Na_{27}K[As_4W_{40}O_{140}]\cdot 56H_2O$.

2. Experimental

2.1. Reagents, solvents and procedures

The reagents were obtained from Merck and used without further purification. Elemental analyses were carried out by the microanalysis laboratories of 'Babes-Bolyai' University, Cluj-Napoca, Romania. Tungsten, manganese, sodium, potassium and arsenic were determinated by ICP. Water was determined by thermogravimetric analyses (TGA). Thermogravimetric studies (20–300 °C) were carried out with a MOM-OD 102 Paulik Erday thermoanalyser, at a heating rate of 10 °C min^{-1} and 250 mg sample.

2.2. Preparation of $Na_{27}K[As_4^{III}W_{40}O_{140}]\cdot 56H_2O$

The synthesis described in the literature was modified slightly [7]. An aqueous solution of $Na_2WO_4\cdot 2H_2O$ (33 g, 100 mmol) in 100 ml water was adjusted to pH 4.5 with glacial acetic acid and maintained at this pH for 5 min. The solution was heated to the boiling point and As_2O_3 (0.99 g, 5 mmol) in 11 M HNO_3 (1.3 ml) was added slowly under vigorous stirring. For stabilization and crystallization of the compound 0.211 g (2.68 mmol) KCl was added. The resultant clear, pale-yellow solution was heated under reflux for 1 h. In the event insoluble impurities formed, these were removed by filtration while the solution was hot. After 4–5 days of slow evaporation at ambient temperature prismatic colorless crystals were formed. The yield was 24.6 g (2.13 mmol, 85%). Recrystallization from hot water generated more uniform crystals. IR(cm^{-1}): 1640(m), 950(sh), 862(w), 750(sh), 690(m), 580(m), 510(w). ^{183}W NMR (D_2O–H_2O; Na_2WO_4 (0 ppm) −100, −110, −119, −138, −191 and −200 ppm. Elemental Analyses (%): Found: W, 63.53; As, 2.31; Na, 5.35; K, 0.35; H_2O, 8.75. Calc.: W, 63.60; As, 2.59; Na, 5.37; K, 0.34; H_2O, 8.72%.

2.3. Preparation of $Na_9K[Mn_4^{II}(H_2O)_2(As^VW_9O_{34})_2]\cdot 35H_2O$

$Na_7KAs_4W_{40}O_{140}\cdot 56H_2O$ (2.89 g, 0.251 mmol) was dissolved in 25 ml of water. Solutions of 0.143 g (0.633 mmol) of $KMnO_4$ in 5 ml of water and 0.431 g (1.76 mmol) of $Mn(OAc)_2\cdot 4H_2O$ in 5 ml of water were added drop-wise in an alternating fashion. The reaction mixture was then stirred for 30 min at 70 °C. Insoluble impurities were filtered off while the solution was hot, and the solution was left at ambient temperature. Yellow–orange crystalline plates of $Na_9K[Mn_4^{II}(H_2O)_2(As^VW_9O_{34})_2]\cdot 35H_2O$ were obtained after 10 days. The yield was 2.1 g (0.37 mmol, 74%). IR(cm^{-1}): 1642(m), 945(sh), 904(m), 858(w), 748(sh), 575(m), 510(w). Elemental Analyses(%): Found: W, 58.30; As, 2.55; Mn, 3.88; Na, 3.70; K, 0.65; H_2O, 11.75. Calc.: W, 58.27; As, 2.64; Mn, 3.87; Na, 3.64, K, 0.68; H_2O, 11.72%.

2.4. Crystal structure analyses

Data were collected by use of a Nonius CAD4 serial diffractometer. Table 1 contains a summary of crystal data and the final residuals for each compound. A more extensive table including particulars of data collection and structure refinement is provided in the supplementary material. The orientation parameters and cell dimensions were obtained from the diffractometer setting angles for 25 centered reflections. Data were corrected for absorption on the basis of azimuthal (ψ) scans. A SIR-92 E-map [13] showed all non-oxygen atoms of each polyoxoanion and many oxygen and sodium atoms. The TEXSAN program suite [14] was used in all calculations. Hydrogen atoms were not located or included in the refined model.

2.4.1. $Na_{27}K[As_4^{III}W_{40}O_{140}]\cdot 56H_2O$

A crystal of dimensions $0.11\times 0.14\times 0.25$ mm was mounted on a fiber and protected with a coating of epoxy. The $4/m$ Laue symmetry, lack of systematic absences other than those due to the I-centering, and acentric distribution of intensities indicated the space-group $I\bar{4}$. An atom clearly present at the $\bar{4}$ site at the center of the tetramer was identified as K on the basis of distances from O atoms, though its rather high refined thermal parameter may imply that the site is also partly occupied by a water molecule. Four of the seven independent Na atoms appeared to require fractional occupancy factors [Na(4–7), identified from bond lengths to oxygen]; altogether 22 Na were located per

$R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR(F^2) = [\Sigma w(|F_o|^2 - |F_c|^2)^2/\Sigma w|F_o|^4]^{1/2}$.

tetramer, it is likely that others are present but disordered. The As and W atoms and Na(1,2,3) were refined anisotropically. Anisotropic refinement of anion oxygen atoms led to many non-positive-definite ellipsoids, and the results given here are for isotropically-refined oxygens and illustrated in Fig. 1.

2.4.2. $Na_9K[Mn_4^{II}(H_2O)_2(As^VW_9O_{34})_2]\cdot 35H_2O$

A yellow plate of dimensions $0.07 \times 0.22 \times 0.41$ mm was secured by a trace of glue in a capillary containing mother-liquor. The triclinic symmetry together with the centric distribution of intensities indicated the space-group $P\bar{1}$. A total of five independent Na atoms were located, but one required a site occupancy factor of 0.5 for a satisfactory refinement. Five of the 20 independent water oxygens also appeared to be on half-occupied sites. The K atom whose presence was implied by the elemental analysis could not be located, and may be disordered over the sites of non-ligand water molecules. All atoms except oxygen atoms of water molecules were refined anisotropically.

3. Results and discussion

3.1. Synthesis of As^{III}–oxotungstate tetramer

The synthetic strategy for formation of the tetrameric condensation product illustrated in 1 was modified slightly from that reported by Leyrie and Herve [9]. The precursor sodium arsenite was replaced by As_2O_3, which was dissolved in 11 M HNO_3. Also the HCl was replaced by glacial acetic acid and HNO_3. This procedure was found to generate X-ray quality crystals directly from the reaction solution, although recrystallization from water resulted in a preparation with uniform crystal size.

$$40Na_2WO_4 + 2As_2O_3 + 52HOAc + KCl \rightarrow Na_{27}K[As_4W_{40}O_{140}] + NaCl + 52NaOAc + 26H_2O \quad (1)$$

3.2. Synthesis of As^V–oxotungstate sandwich compound

Attempts to modify the As^{III} in the tetrameric condensation product to form the As^V series compounds were explored using an oxidation reagent that is mild but yet sufficient to accomplish the oxidation. MnO_4^- is commonly used to oxidize As^{III} to As^V and was tried initially, but proved to be an unsuitable reagent. Furthermore, when treating solutions of tetramer with MnO_4^-, no change in color could be observed over several days. In the synthesis of complex oxometalates in molybdenum chemistry it is common to use reagents which involved two different oxidation states of the metal ion in order to achieve the desired redox potential in the reaction solutions. This approach was adapted in this system. Thus, the addition of both MnO_4^- and $Mn(OAc)_2$ did prove to be successful and the resulting reaction is shown in Eq. (2). The colorless solution turns violet upon addition of MnO_4^- which followed by addition of $Mn(OAc)_2$ changes the violet solution brown; the color continues to change for 5 h after which time the solution is deep orange. Although some flexibility exists with regard to the exact ratio of components, best yields were obtained when 1 equiv. of tetramer was treated with a threefold excess of MnO_4^- and a sevenfold excess of Mn^{2+} salt. When $Mn(OAc)_2$ was added to solutions of tetramer the color changed to yellow indicating a replacement of cations, however, only very small light yellow crystals were obtained. We conclude, that both redox states of the reagent were necessary to achieve the conversion of the

As^{III} oxometalate to the As^{V} oxometalate. In addition to providing an example of linking these two classes of compounds, this method significantly improves the yield of the synthesis of this type of material [7].

$$2Na_{27}K[As_4W_{40}O_{140}] + 4KMnO_4 + 14Mn(OAc)_2 + 12H_2O \rightarrow 4Na_9K[Mn_4(H_2O)_2(AsW_9O_{34})_2] + 8WO_3 + 2MnO_2 + 2KOAc + 18NaOAc + 8HOAc \quad (2)$$

3.3. Structure of $Na_{27}K[As_4^{III}W_{40}O_{140}]\cdot 56H_2O$

The tetrameric anion $[As_4W_{40}O_{140}]^{28-}$ consists of four α-B-$As^{III}W_9O_{33}$ units sharing octahedron corners with four linking WO_6 groups [W(10)]. It generally resembles the anion in $Na_{28}[(\alpha\text{-B-}AsO_3W_9O_{30})_4(WO_2)_4]\cdot 2NaCl\cdot 55H_2O$ that was reported while this work was in progress [7]. The structure differs from that of the anion in $(NH_4)_{28}Co_2As_4W_{40}O_{140}\cdot 20–22H_2O$ [8] in the following details. The point symmetry of the anion is exactly, rather than approximately $\bar{4}$. The site designated [8] S1 at the center of the tetramer is occupied by K^+ instead of by NH_4^+, bonded to the two *cis* O atoms of each bridging WO_6 group that are not involved in W–O–W linkages. The four S2 sites [8] are all occupied by Na^+ cations [Na(1)] instead of by two Co^{2+} and two NH_4^+. The four oxygens of the anion bonded to Na(1) define an approximate square which is planar to within one standard deviation (0.03 Å), and Na(1) lies 0.63(1) Å from the plane on the side away from the As atom with a possible weak bond [2.82(2) Å] to a water oxygen atom [O(43)] in an apical position. The As···Na(1) distance [3.26(1) Å] is to be contrasted with the short (2.65 Å) As···Co distance [8] in the other anion, where the Co is effectively six-coordinate. The differences from the anion in $Na_{28}[(\alpha\text{-B-}AsO_3W_9O_{30})_4(WO_2)_4]\cdot 2NaCl\cdot 55H_2O$ include the potassium, rather than sodium, central cation and the higher ($\bar{4}$) crystallographic point symmetry.

3.4. Structure of $Na_9K[Mn_4^{II}(H_2O)_2(As^{V}W_9O_{34})_2]\cdot 35H_2O$

The product of reaction (2) is $[Mn_4^{II}(H_2O)_2(As^{V}W_9O_{34})_2]^{10-}$. The assumed degree of hydration of the salt is based on the X-ray analysis. The anion lies on a crystallographic center of symmetry, with approximate point symmetry 2/*m* (C_{2h}) and contains a planar set of four Mn^{2+} ions separating two α-B-$AsW_9O_{34}^{9-}$ groups. Two Mn atoms each carry one water ligand. The anion is isostructural with the $[Co_4^{II}(H_2O)_2(P^{V}W_9O_{34})_2]^{10-}$ [15], $[Mn_4^{II}(H_2O)_2(P^{V}W_9O_{34})_2]^{10-}$ [15], and $[Co_4^{II}(H_2O)_2(As^{V}W_9O_{34})_2]^{10-}$ anions [10,11], with similar corresponding dimensions. The all-potassium salt $K_{10}[Mn_4^{II}(H_2O)_2(As^{V}W_9O_{34})_2]\cdot 18H_2O$, was reported while this work was in progress [12].

4. Supplemental material

Supplementary data are available from Fachinformationszentium Karlsruhe (FIZ) for $Na_{27}K[As_4^{III}W_{40}O_{140}]\cdot 56H_2O$ the number is 412184 and for $Na_9K[Mn_4^{II}(H_2O)_2(As^{V}W_9O_{34})_2]\cdot 35H_2O$ the number is 412183.

Received 31 October 2001; accepted 10 December 2001

Abstract

Interaction of cobalt(II) ions and sodium carbacylamidophosphates Na(L) (HL = PhC(O)NHP(O)$(NR_2)_2$; where NR_2 are morpholyl, HL^1; NMe_2, HL^2; NEt_2, HL^3) in methanol solution afforded polynuclear alkoxo complexes $[Co_4\{L^1\}_3(OCH_3)_4(OH)(H_2O)_5\cdot 3H_2O]$ **1** and $[Co_4\{L\}_4(OCH_3)_4(CH_3OH)_4]$ (L = L^2 **2**, L^3 **3**). Data of spectral and TGA studies are presented. Coordination compounds **1** and **3** have been characterized by means of X-ray diffraction. Both the structures consist of tetranuclear cubane alkoxo clusters with methoxide ions bridging three metal centers (Co–O 2.068(3)–2.093(4) Å) and phosphorylic ligands coordinated in a bidentatechelate fashion via the carbonyl oxygen atoms (Co–O **1**: 2.050(2); **3**: 2.031(4) Å) and the phosphoryl groups (2.093(2) and 2.106(4) Å). Isolation of these cubane alkoxo complexes is an important proof for close resemblance in behavior of carbacylamidophosphate systems and β-diketonates towards transition metal ions. © 2002 Elsevier Science Ltd. 1. Introduction

The cubane-like structure of tetranuclear metal complexes is a characteristic motif in coordination chemistry of different metal ions. It may dominate assembly of relatively simple compounds like thallium alkoxides [1] as well as of complicated molecular and supramolecular architectures [2]. This structural motif with close spatial alignment of metal centers is important also in the chemistry of transition metals where it may have an essential impact considering possible magnetic and catalytical properties of the compounds [3,4]. The structural and magnetochemical features of numerous Co(II) and Co(III) based cubane molecules have been reported [5–7]. Forming the complete or incomplete cubane complexes in solution is competitive for Co(II) complexes just as for Co(III).The cubane structure is also common in the realm of metal diketonates, recent examples include series of cobalt(II) and nickel (II) compounds [8–11]. We were interested in the generation of the cubane structure for new transition metal derivatives involving structural analogs of β-diketones. Such species may allow further functionalization of the metal-organic core, and phosphazo analogs of β-diketones are of special interest in this context: these *N*-acylated phosphoramides bear a close structural resemblance to the β-diketone frame, they usually act as effective chelating groups, and stoichiometry, structure and properties of coordination compounds thereof may be clearly related with known types of metal diketonates.

In this contribution we report on the engineering of a tetrameric cubane structure involving Co(II) ions and three chelating phosphoramide ligands.

2. Experimental

2.1. Preparation of $Co_4L_{4-n}(\mu_3\text{-}OCH3)_4(OH)_n \cdot mSolv$ ($Solv = H_2O$ or CH_3OH)

Dimorpholido-*N*-benzoylamidophosphate HL^1, *N*,*N*′-tetramethyl-*N*″-benzoyltriamido-phosphate HL^2 *N*,*N*′-tetraethyl-*N*″-benzoyltriamidophosphate HL^3 and their sodium salts were obtained and identified according to [12,13].

HL^1 HL^2 HL^3

Coordination compounds of cobalt(II) were synthesized reacting the metal chloride and sodium salts of the ligands in methanol solution:

$$4CoCl_2 \cdot 6H_2O + 8NaL \xrightarrow[-NaCl]{CH_3OH} Co_4L_{4-n}(\mu_3OCH_3)_4(OH)_n \cdot mSolv + 4HL$$

where $L^- = (L^1)^-, (L^2)^-, (L^3)^-$.

In a typical synthesis, $CoCl_2 \cdot 6H_2O$ (0.238 g, 1 mmol) was dissolved in methanol (15 ml) and combined with the solution of NaL^1 (0.722 g, 2 mmol) in 10 ml methanol. The mixture was allowed to stand in a vacuum desiccator over $CaCl_2$. After a while the pink-violet crystals of the complex $[Co_4\{L^1\}_3(OCH_3)_4(OH)(H_2O)_5 \cdot 3H_2O]$ **1** precipitated from the solution in the mixture along with neutral ligand HL^1. The latter was separated out by washing the product with methanol and identified according to IR spectra. Crystals of the complex were additionally washed with cool acetone, and dried over $CaCl_2$ (yield: 0.248 g, 65.6%). Complexes $[Co_4\{L\}_4(OCH_3)_4(CH_3OH)_4]$ (L = L^2 **2**, L^3 **3**) were prepared in the same manner. Single crystals of **1** and **3** were prepared by slow crystallization from acetone-methanol mixture.

The complexes are unstable in air and decompose under long-term storage. They were soluble in nonpolar aprotic solvents, less soluble in acetone, isopropanol and ethyl alcohol.

The compositions of the compounds were established on the basis of the elemental analysis. *Anal.* for **1**. Found: C 37.53, H 5.56, N 7.75. Calc. for $C_{49}H_{92}N_9Co_4O_{28}P_3$: C 38.32, H 5.8, N 8.2%. *Anal.* for **2**. Found: C 41.67, H 6.78, N 10.01. Calc. for $C_{52}H_{96}N_{12}Co_4O_{16}P_4$: C 41.40, H 6.38, N 11.16%. *Anal.* for 3. Found: C 47.01, H 8.6, N 9.3. Calc. for $C_{68}H_{128}N_{12}Co_4O_{16}P_4$: C 47.23, H 8.1, N 9.7%.

2.2. Methods

IR spectra of the compounds were recorded on an UR-10 spectrometer in the range 400–4000 cm^{-1} (samples as KBr pellets). Differential thermal analyses were carried out in the temperature range 20–500 °C using a Q-1500 'Quasi' thermoanalyzer at a heating rate of 5 °C min^{-1}. Electronic diffuse reflectance spectra were recorded on a SPECORD M-40 (Carl Zeiss, Jena) UV–Vis spectrometer.

X-ray diffraction data for **1** were collected using an Enraf-Nonius CAD-4 diffractometer. For **3** crystallographic measurements were made using a SMART CCD area-detector diffractometer (Siemens). Table 2 lists the cell parameters and details of data acquisition and structure refinement. Selected geometrical parameters of **1** and **3** are listed in Table 3. The structures were solved by direct methods and refined by full-matrix least-square methods using programs SHELXS-86 and SHELXL-93 [14,15]. All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were localized by difference Fourier techniques without further refinement.

3. Results and discussion

3.1. Spectroscopy

The IR spectra of the coordination compounds have a number of common features (Table 1). The IR bands in the region 3070–3100 cm^{-1}, observed in spectra of the neutral carbacylamidophosphates, may be ascribed to ν(NH) vibrations of the amide protons. These bands are absent in the spectra of the sodium and cobalt(II) carbacylamidophosphates **1**–**3**, which is evidence for ligand coordination in the deprotonated form. The spectra reveal significantly lower frequencies of ν(PO) as may be compared with those for the sodium salts ($\Delta\nu$(PO) = 45 and 30 cm^{-1} for compounds **2** and **3**, respectively), reflecting coordination via the phosphoryl oxygen atom [8,9]. In the case of compound **1**, the position of the ν(PO) band could not be related identically. The ν(CO) values in spectra of the complexes are shifted to lower frequencies ($\Delta\nu$(CO) = 5–60 cm^{-1}). These facts suggest a bidentate chelate coordination of the anionic ligands L^- via the oxygen atoms of phosphoryl and carbonyl groups.

UV–Vis absorption spectra reflect the octahedral environment the cobalt(II) ions in **1**–**3** [16]. The bands related to the electron transition $^4T_{1g}(P) \rightarrow {}^4T_{1g}$ are observed at 18 000, 19 000 and 21 000 cm^{-1} for **1**, **2** and **3**, respectively. The transition $^4A_{2g} \rightarrow {}^4T_{1g}$ is very weak and appears as a shoulder.

3.2. Thermogravimetry

The thermal behavior of the cobalt complexes **2** and **3** is very similar. According to the TGA data, these complexes are stable up to 100 °C. In the temperature range 100 °C–290 °C, the thermoanalytical curves indicate two endothermic effects. The first of them (115 °C) is connected with the elimination of four molecules of methanol. This relatively elevated temperature of the methanol molecule removal indirectly indicates their disposition in the internal coordination sphere of the metal ions. The other endothermic stage corresponds to the beginning of the decomposition of the complex. It takes place at the same temperature for the both compounds, namely 265 °C. Full decomposition of the complex is accompanied by its vigorous exothermic oxidation at 285 °C. It is necessary to note that a difference in the temperatures of the maximal onset of the processes is not essential and it is equal to within 20 °C. This fact shows the important role of the methanol molecules in the formation of the crystal lattice of the cobalt complexes **2** and **3**. The similar character of the decomposition of these compounds and

the same temperature interval of thermal effects may suggest a similarity of their structures.

In the case of complex **1**, the TGA results are rather different. The thermoanalytical curves also reflect two endothermic effects at 130 and 200 °C, and an exothermic one at 335 °C. The first effect is connected with the elimination of three water molecules from the external sphere of the complex. The compound decomposes at 200 °C. The fact that the further dehydration of **1** is accompanied by its decomposition is evidence of the involvement of the other five water molecules in the internal coordination sphere and their strong bonding with the central atoms. The full exothermic decomposition of the complex takes place at 335 °C.

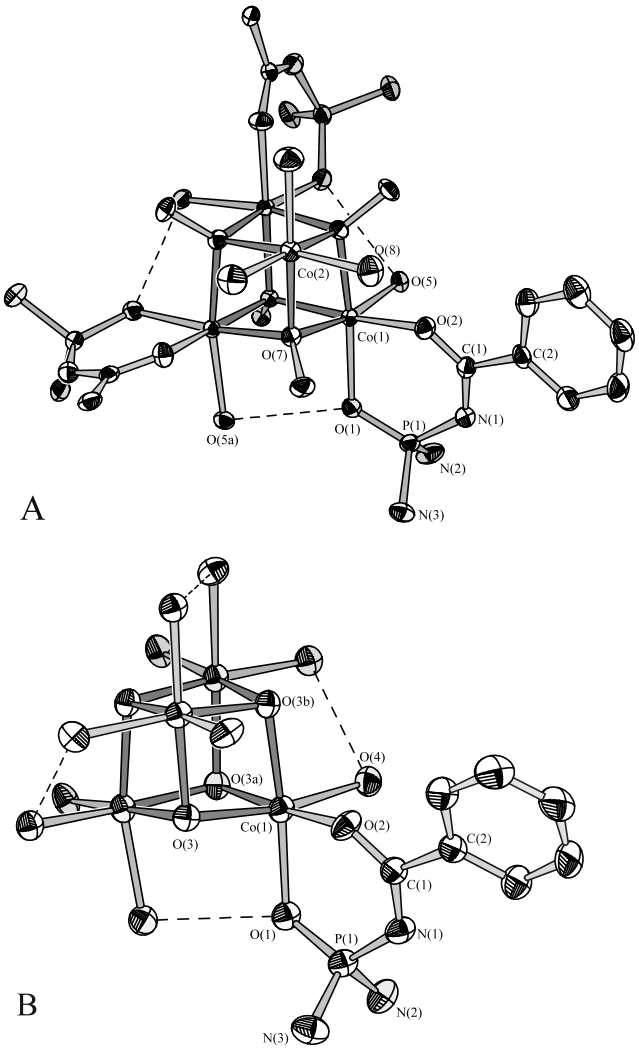
3.3. Description of the structures

We succeeded in confirming the conclusions about the structure of the obtained compounds based on IR and UV–Vis spectroscopy data by the results of full X-ray analysis of compounds **1** and **3**.

The solid-state structure of **3** contains discrete tetrameric molecules. $[Co_4\{L^3\}_4(\mu_3\text{-}OCH_3)_4(CH_3OH)_4]$, each octahedral Co(II) ion being bound to three μ_3-OMe^- ligands, one chelating carbacylphosphortriamide ligand (L^3), and one terminal MeOH ligand. Concerning the composition of the compound and the results of spectral and TGA studies, the same structure may also be ascribed for compound **2**. The molecule occupies a special position on an inversion fourfold axis and has virtual D_{2d} symmetry.

For both structures, the tetrameric skeletons are formed by four cobalt atoms and four oxygen atoms of methoxy groups. The octahedral environment for each cobalt atom in **3** and for three of four cobalt atoms in **1** comprises three oxygen atoms of methoxy groups, carbonylic and phosphoryl oxygen atoms of the chelate anionic ligands and an oxygen atom of an alcohol molecule in structure **3** (Fig. 1). The fourth cobalt atom in structure **1** is situated on a threefold axis and is connected with three oxygen atoms of methoxy groups, oxygen atoms of two water molecules and one OH^- group. These hydro and hydroxo ligands are structurally equivalent and all are related by a threefold axis.

The cubane-like frameworks in the present cases are slightly distorted, the angles O–Co–O are about 5° smaller than 90°, while the angles Co–O–Co are approximately 97°. The Co–O(2) bond with the carbonyl oxygen atom is the shortest in the cobalt environment in both structures (**1**: 2.050(2) and **3**: 2.031(4) Å). The Co–O(CH_3) bond lengths are typical for μ_2- and μ_3-OMe groups [17] and are in the range of 2.068(3)–2.093(4) Å for both structures. The distances to the phosphoryl oxygen atoms, Co–O(l) in **1** and **3**, are 2.093 (2), and 2.106(4) Å, respectively. The Co–O(4) bond with a coordinated water molecule (2.161(2) Å) for **1** and the Co–O bond with a coordinated methanol oxygen atom (2.204(4) Å) in the case of compound **3** are the longest.



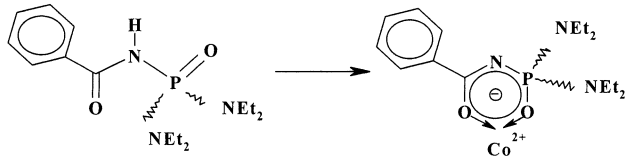


Fig. 1. Molecular structure of the cobalt cubane alkoxo complexes: A-$Co_4\{L^1\}_3(OCH_3)_4(OH)(H_2O)_5\cdot 3H_2O$ **1**, hydrogen atoms oxamethylene linkage of morpholine cycles and two of the three phenyl groups are omitted; B-$Co_4\{L^3\}_4(OCH_3)_4(CH_3OH)_4$ **3**, hydrogen atoms, ethyl and methyl fragments of the phosphorylic, metoxy and methoxo ligands are omitted for clarity, and only one of the four chelate frames is shown. Thermal ellipsoids are at 40% probability level and possible hydrogen bonding is shown as dotted lines.

The ligand deprotonation leads to the appearance of π-conjugation in the chelate ring of the compounds, which may be illustrated by the changes of the bond lengths. Thus the distances P=O (1: 1.509; 3: 1.523 Å) and C=O (1: 1.266; 3: 1.264 Å) both appeared slightly longer with respect to those for the non-coordinated molecules HL^1 and HL^3 [12,18]. The increase of the bond order for P–N and C–N caused by the increase of the π-bonding leads to the 0.05–0.09 Å shortening of these bond lengths in the complexes with respect to that observed for HL^1 and HL^3. The OPNCO chelate

fragment in both structures are planar to within 0.1 Å and the deviation of the metal atoms from these planes does not exceed 0.5 Å.

The phosphorus atoms have a distorted tetrahedral environment. The atoms forming the angles O(1)–P(1)–N(1) (118.37°, 118.7°) for both cases have the largest deviations because they are involved in the π-conjugation. All the other angles in the **3** are nearly tetrahedral.

For each type of the cubane molecules the OH and O counterparts are involved in extensive intramolecular hydrogen bonding. Thus, in **3** each MeOH hydroxy group forms an hydrogen bond with the phosphoryl oxygen atom of carbacylphosporamide ligand coordinated to a neighboring Co ion (O···O 2.78 Å). A similar pattern of intramolecular hydrogen bonding has also been observed in other alkoxides cubane complexes containing Co(II), Co(III) and Ni(II) and coordinated alcohol molecules [7,19].

4. Conclusions

Isolation of cobalt(II) tetranuclear cubane alkoxo complexes with carbacylamidophosphates is an important proof for close resemblance of behaviour of these ligand systems and β-diketonates towards transition metal ions. In the present case, the remarkable stability of $(Co\{L\})_4(OCH_3)_4$ or $(Co\{L\})_3(CoOH)(OCH_3)_4$ cores dominates the pathways of interaction in the system $M^{2+} - L^-$ and corresponding cubane molecules appear to be a most stable and common product. This effective stabilization of a cubane metal–alkoxide cluster with a carbacylamidophosphate anion may allow the preparation of novel functionalized condensed metal–alkoxide complexes.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited at the Cambridge Crystallographic Data Center, CCDC numbers CSD-142056 (**1**) and CSD-166804 (**3**). Abstract

By controlling the molar ratio of Ge(tmtaa)Cl_2 and NH_4SCN at 1:2 and 1:1 in CH_3OH (H_2tmtaa = 5,14-dihydro-6,8,15,17-tetramethyldibenzo[*b*,*i*] [1,4,8,11]tetraazacyclotetradecine), two kinds of germanium(IV) complexes, Ge(tmtaa)$(NCS)_2$ (**1**) and Ge(tmtaa)(Cl)(NCS) (**2**), were prepared and characterized by IR, UV, mass and NMR spectra as well as DSC measurements. In the IR spectrum of **1**, two C≡N stretching bands of NCS groups were observed at 2073 and 2043 cm^{-1}, while in the IR spectrum of **2**, only one C≡N stretching band of a NCS group appeared at 2110 cm^{-1}. The crystal structure of a *trans* six-coordinate tmtaa complex of germanium in the +IV oxidation state is reported. X-ray single crystal analysis of **1** reveals that it adopts a six-coordinate geometry in which two NCS groups are in *trans* positions. The bond lengths of Ge–N between the central germanium and NCS groups are 1.996(6) and 2.031(6) Å. They are longer than those between the central metal and nitrogen atoms of tmtaa (1.926 Å). © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Macrocycles; Germanium(IV) tmtaa complexes; Crystal structures; Six-coordinate geometry; *Trans*-positions

1. Introduction

The chemistry of transition metal complexes of 5,14-dihydro-6,8,15,17-tetramethyldibenzo[*b*,*i*] [1,4,8,11] tetraazacyclotetradecine (H_2tmtaa, Fig. 1) spans nearly 30 years and comprises the majority of the research activity for this ligand [1,2]. Rare earth metal complexes containing tmtaa have attracted considerable renewed attention over the last decade [3–5]. However, the chemistry of main group elements with tmtaa has not been extensively developed and only several examples of Group 13 and 14 complexes of tmtaa have been reported [6–10]. Four- and five-coordinate tmtaa complexes of germanium in the +II oxidation state were synthesized and characterized by X-ray single crystal diffraction [6,7]. Furthermore, a tmtaa complex of germanium in the +IV oxidation state was synthesized [9], but its structure was not determined.

Metal-thiocyanato chemistry has had a considerable history of investigation [11–14]. We now present the syntheses, crystal structure and spectral properties of *trans* six-coordinate di- and mono-thiocyanato tmtaa complexes containing the Group 14 element germanium in the +IV oxidation state.

2. Experimental

2.1. Reagents and physical measurements

All solvents were distilled and all chemicals were of reagent grade. Ge(tmtaa)Cl_2 was prepared according to the literature [9]. Elemental analyses were performed on a Yanaco CHN corder MT-3. IR spectra (4000–400 cm^{-1}) were recorded on a JASCO FT/IR-400 spectrophotometer in KBr pellets at room temperature (r.t.). FAB^+ mass spectra were carried out with a JEOL JMS-SX102A gas chromatograph-mass spectrometer in a 2-nitrophenyl octyl ether matrix. Ultraviolet and visible spectra were recorded on a Shimadzu UV-200S double

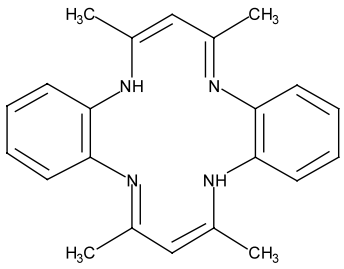

Fig. 1. Suggested structure of H_2tmtaa.

beam spectrophotometer in chloroform at r.t. DSC data were obtained using a Shimadzu DSC-50 differential calorimeter. ^{1}H NMR measurements were taken on a BRUKER AVANCE-400 in chloroform-*d* and dimethylsulfoxide (DMSO)-d_6, and chemical shifts were given in ppm relative to tetramethylsilane as an internal reference standard.

2.2. Preparation of Ge(tmtaa)(NCS)$_2$ (1)

A solution of NH_4SCN (0.045 g, 0.6 mmol) in CH_3OH (5 ml) was added dropwise to a solution of Ge(tmtaa)Cl_2 (0.146 g, 0.3 mmol) in CH_3OH (20 ml) under nitrogen atmosphere. After being heated at 50 °C for 20 h, a product precipitated as a red microcrystalline solid. The product was collected by filtration and washed with CH_3OH, and then was recrystallized from THF–acetonitrile (1:1 v/v) to give orange needles. Yield: 0.109 g (68%). *Anal*. Found: C, 54.16; H, 4.46; N, 16.01. Calc. for $C_{24}H_{22}N_6S_2Ge$: C, 54.27; H, 4.17; N, 15.83%. Melting point (m.p.) 333–336 °C (DSC). UV ($CHCl_3$, λ_{max}, nm): 378, 406, 424. IR (KBr, cm^{-1}): ν(C=C, C=N) 1581, 1541, 1470, 1412; ν(C≡N) 2073, 2043. FAB MS: $m/z = 474$ (M-NCS), 416 (M-2NCS). ^{1}H NMR ($CDCl_3$, ppm): δ 2.52 (s, 12H, CH_3), δ 5.37 (s, 2H, H (7,16-positions)), δ 7.19 (s, 8H, C_6H_4 (aromatic)).

2.3. Preparation of Ge(tmtaa)(Cl)(NCS) (2)

Changing the molar rate of NH_4SCN and Ge(tmtaa)Cl_2 from 2:1 to 1:1, the reaction was carried out in a similar method as outlined above. The orange powder was collected by filtration and washed with CH_3OH. Yield: 0.116 g (76%). *Anal*. Found: C, 53.95; H, 4.49; N, 13.69. Calc. for $C_{23}ClH_{22}N_5SGe$: C, 54.22; H, 4.36; N, 13.75%. M.p. 340–343 °C (DSC). UV ($CHCl_3$, λ_{max}, nm): 378, 408, 424. IR (KBr, cm^{-1}): ν(C=C, C=N) 1578, 1541, 1470, 1411; ν(C≡N) 2110. FAB MS: $m/z =$ 474 (M–Cl), 451 (M–NCS), 416 (M–NCS–Cl). ^{1}H NMR ($CDCl_3$, ppm): δ 2.51 (s, 12H, CH_3), δ 5.39 (s, 2H, H (7,16-positions)), δ 7.19, 7.21 (m, m, 4H, 4H, C_6H_4 (aromatic)).

3. Results and discussion

3.1. Synthesis

Due to the +IV oxidation state of germanium and a *trans* six-coordinate geometry, Ge(tmtaa)Cl_2 shows great reactivity at the axial positions. Di- and monothiocyanato tmtaa germanium(IV) complexes, **1** and **2**, were synthesized from substitution reactions of Ge(tmtaa)Cl_2 and NH_4NCS in exact 1:2 and 1:1 molar ratio under mild conditions (in a nitrogen atmosphere, 50 °C). Since **1** and **2** hardly dissolve in reaction solvent (methanol) and are air- and moisture-stable, subsequent isolation and purification procedures were carried out in air. Crystals of **1**, which were suitable for X-ray structure analysis, were grown in a THF–acetonitrile (1:1 v/v) solution at r.t. On the other hand, crystals suitable for X-ray analysis of **2** were not obtained.

3.2. IR spectrometry

The IR spectrum of **1** shows two strong peaks at 2073 and 2043 cm^{-1}, which are assigned to ν_{as} (C≡N) stretching vibrations. This suggests the presence of two thiocyanato ligands with different C≡N bond lengths and angles. **1** adopts a *trans* six-coordinate configuration and the two NCS ligands show different stretching frequencies after they coordinate to the central germanium. On the other hand, the IR spectrum of **2** gives one intense absorption band of a ν_{as} (C≡N) stretching vibration at 2110 cm^{-1}, which perhaps suggests the presence of one thiocyanato ligand. The similarity of the spectroscopic data of **1** and **2** suggests that **2** also adopts a six-coordinate geometry in which Cl and NCS groups are in *trans* positions.

3.3. Mass spectrometry

The FAB$^+$ mass spectrum of **1** shows major fragments at *m*/*z* 474 corresponding to [M-NCS]$^+$ and *m*/*z* 416 corresponding to [M-2NCS]$^+$. The FAB$^+$ mass spectrum of **2** shows the major fragments at *m*/*z* 474 corresponding to [M-Cl]$^+$, *m*/*z* 451 corresponding to [M-NCS]$^+$ and *m*/*z* 416 corresponding to [M-NCS–Cl]$^+$. No molecular ion peak was observed. These suggest **1** and **2** have the same geometry and the substituents in *trans* positions may be easily cleaved in FAB$^+$ mass measurements.

3.4. NMR spectrometry

It is well known that thiocyanato is often used in synthesizing metal polymers [15–17] and polynuclear complexes [18–21]. We had a hunch that **2** may be a polynuclear complex or a polymer. However, not only UV spectra, IR spectra, mass spectra and DSC mea-

surements, but also ^{1}H NMR spectra prove that **2** has the same *trans* six-coordinate configuration as **1**. ^{1}H NMR spectra of **1** and **2** measured in chloroform-*d* were described in Section 2. Furthermore, ^{1}H NMR spectra of **1**, **2** and Ge(tmtaa)Cl_2 measured in DMSO-d_6, are also described and compared. This proves that **2** has the same six-coordinate *trans* configuration as **1**.

Fig. 2 indicates the benzenoid ring signals of **1**, **2** and Ge(tmtaa)Cl_2 in DMSO-d_6. The DMSO solvent coordinates to the complexes and the signals split into several groups. We consider the following species to exist in solution.

Ge(tmtaa)$(NCS)_2$ (**1**, a) + DMSO
⇌Ge(tmtaa)(NCS)(DMSO) (d)
+Ge(tmtaa)$(DMSO)_2$(f)

Ge(tmtaa)(Cl)(NCS) (**2**, b) + DMSO
⇌Ge(tmtaa)(NCS)(DMSO) (d)
+Ge(tmtaa)(Cl)(DMSO) (e) + Ge(tmtaa)
× $(DMSO)_2$ (f)

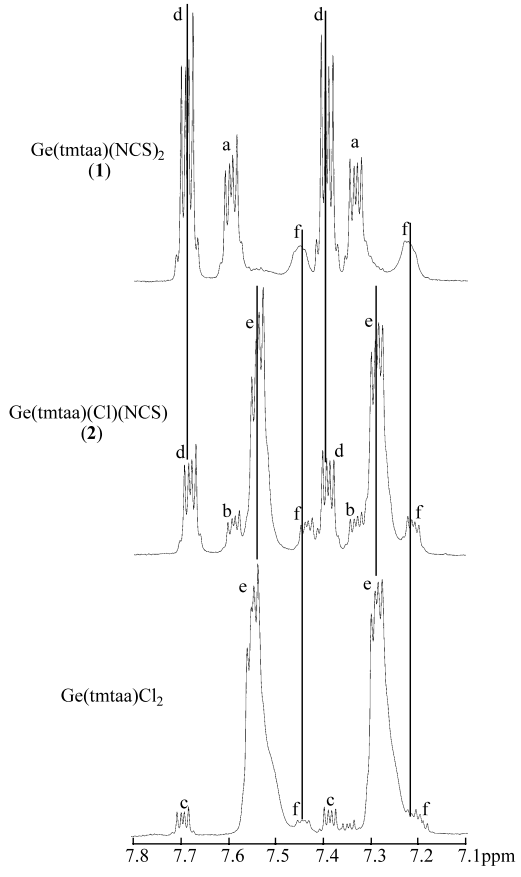

Fig. 2. NMR spectra of Ge(tmtaa)$(NCS)_2$ (**1**), Ge(tmtaa)(Cl)(NCS) (**2**) and Ge(tmtaa)Cl_2. (Section of benzenoid rings, in DMSO-d_6. (a) Ge(tmtaa)$(NCS)_2$ (**1**); (b) Ge(tmtaa)(Cl)(NCS) (**2**); (c) Ge(tmtaa)Cl_2; (d) Ge(tmtaa)(NCS)(DMSO); (e) Ge(tmtaa)(Cl)(DMSO); (f) Ge(tmtaa)$(DMSO)_2$.

Ge(tmtaa)Cl_2 (c) + DMSO
⇌Ge(tmtaa)(Cl)(DMSO) (e)
+Ge(tmtaa)$(DMSO)_2$ (f)

What signals a to f represent are stated in the next list.

a) Ge(tmtaa)$(NCS)_2$ (**1**).
b) Ge(tmtaa)(Cl)(NCS) (**2**).
c) Ge(tmtaa)Cl_2.
d) Ge(tmtaa)(NCS)(DMSO).
e) Ge(tmtaa)(Cl)(DMSO).
f) Ge(tmtaa)$(DMSO)_2$.

In Fig. 2, the signals of Ge(tmtaa)$(DMSO)_2$ (f) were observed in all three spectra. The signals of Ge(tmtaa)$(NCS)_2$ (a) and Ge(tmtaa)(NCS)(DMSO) (d) were observed in the spectrum of **1**. The signals of Ge(tmtaa)Cl_2 (c) and Ge(tmtaa)(Cl)(DMSO) (e) were observed in the spectrum of Ge(tmtaa)Cl_2. It may prove that **1** and Ge(tmtaa)Cl_2 have the same configuration. However, not only the signals of Ge(tmtaa)(Cl)(NCS) (b), but also the signals of Ge(tmtaa)(NCS)(DMSO) (d) and Ge(tmtaa)(Cl)(DMSO) (e) were observed in the spectrum of **2**. This may prove that **2** is also a six-coordinate complex with NCS and Cl groups in *trans* positions and it is not a polymer containing bridged-thiocyanato groups.

3.5. Description of the structure

An orange needle of **1** having approximate dimensions of 0.20 × 0.10 × 0.02 mm was measured at room temperature on a Rigaku AFC7R diffractometer equipped with a rotating anode generator using monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). Crystal data and details associated with the data collection are summarized in Table 1. Selected bond lengths and bond angles are listed in Table 2.

Notable features of the structural chemistry of tmtaa complexes are non-planar, saddle-shaped conformation and smaller N_4 coordination cavity 'hole size' than that of porphyrins and phthalocyanines. The ORTEP drawing of **1** is shown in Fig. 3. The structure determination of **1** reveals that it adopts a *trans* six-coordinate configuration similar to tmtaa tin(IV) complexes [9]. On the other hand, it does not behave like Group 4 (Ti, Zr or Hf) tmtaa complexes, which exhibit a *cis* six-coordinate configuration [21–25]. The saddle shape of the ligand is almost retained. The mean Ge–N bond distance in the N_4 plane is 1.926 Å. It is shorter than that of Ge–N bond of four- and five-coordinate tmtaa Ge(II) complexes (2.107 and 2.021 Å, respectively) [6,7]. The germanium atom is displaced from the N_4 plane towards the benzenoid face of the ligand by only 0.03 Å and is obviously shorter than that of the four-coordinate

		N(4)–Ge(1)–N(1)	84.7(3)

Ge(II) complex (0.909 Å) [6]. The small displacement may be a consequence of the *trans* geometry.

The two nitrogen atoms of NCS ligands and the central germanium are almost in the same line and the N(5)–Ge(1)–N(6) bond angle is 179.5(3)°. These two *trans* axial nitrogen atoms are almost vertical to the N_4 plane of the tmtaa ligand. The two NCS ligands keep their linearity. N–C–S bond angles are 177.7(7) and 176.7(7)°, whereas the Ge(1)–N(6)–C(24) and Ge(1)–N(5)–C(23) linkages are slightly bent (150.4(6) and 157.7(6)°).

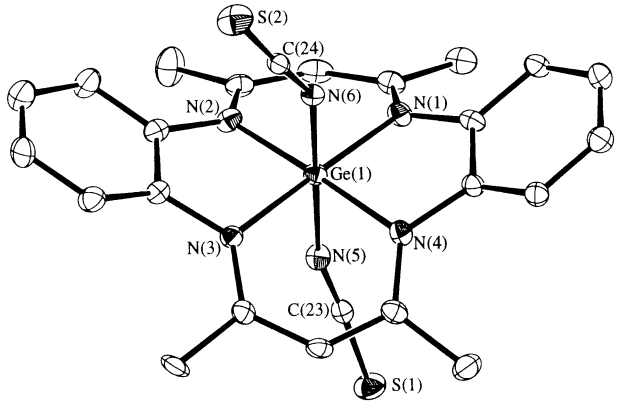

Fig. 3. ORTEP diagram of Ge(tmtaa)(NCS)$_2$ (**1**) with atom labelling scheme showing 50% probability thermal ellipsoids for all non-hydrogen atoms.

Each NCS ligand adopts the most stereochemically favorable orientation with respect to the saddle-shaped macrocycle. The bond length of N(6)–C(24) (1.164(8) Å) is about 0.012 Å shorter than that of N(5)–C(23). In addition, the bond length of Ge(1)–N(6), which is towards the benzenoid face of the ligand, is 1.996(6) Å, and the bond length of Ge(1)–N(5), which is away from the benzenoid face of the ligand, is 2.031(6) Å. It is the saddle-shaped macrocycle that leads to the structure characterization described above.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 164070 for complex **1**. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

A new series of the boron substituted cobalt bis(dicarbollide)(1-) ion (**1**) derivatives of the general formula *closo*-[(8-X-(CH_2–CH_2O)$_2$-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)-3,3′-Co]$^-$ (X = 1-O-2-CH_3O–C_6H_4 (**3**), 1-O-2-$C_6H_5CH_2$–C_6H_4 (**4**), 1-O-4-t-C_8H_{17}–C_6H_4 (**5**), –P(O)(OC_4H_9)$_2$ (**6**) and –P(O)(OC_4H_9)(OH) (**7**) was prepared by ring cleavage of 8-dioxane-**1** derivative (**2**). The compounds were synthesized with the aim to develop a new class of extraction agents effective for liquid–liquid extraction of polyvalent cations, i.e. lanthanides and actinides from high level activity nuclear waste. All compounds were characterized by a combination of ^{11}B NMR, ^{1}H high field NMR methods, mass spectrometry with electrospray ionization, HPLC and other techniques. The molecular structure of the sodium salt of anion **3** was determined by single crystal X-ray diffraction analysis. Crystallographic results proved the sodium atom is tightly coordinated to five oxygen atoms of the spacer chain, the guaiacolyl terminal group X and one water molecule, and from the opposite side of the ligand plane the short B(8′)-H–Na contact (2.26(3) Å) was found to be within bonding distance. The sodium cation is enveloped with an hydrophobic outer sphere composed of hydrophobic CH_2 and CH groups of the organic substituent and B–H groups of cobalt bis(dicarbollide)(1-) cage. The complexation ability of all new anionic ligands for target metal cations was tested by means of cyclic voltammetry at the interface between two immiscible electrolyte solutions. The measurements confirmed stoichiometry of 1:3 (cation:ligand) for the Eu^{3+} complex. Liquid–liquid extraction tests proved the extraction efficiency of anionic species for M^{3+} cations, most of them being able to extract Eu^{3+} only from slightly acidic solutions up to pH 2. The compounds allowed the use of low polar, less environmentally dangerous solvents, e.g. toluene in the liquid–liquid extraction process. Encouraging results were obtained for compound **7**, for which the extraction coefficients from 1 M HNO_3 were found to be sufficiently high even in respect of possible technological applications. © 2002 Elsevier Science Ltd. 1. Introduction

Derivatives of the cobalta bis(dicarbollide)(**1**-) ion, *closo*-[(1,2-$C_2B_9H_{11})_2$-3,3′-Co]$^-$ (**1**) [1,2] (Fig. 1), present a specific group of single-charged anionic species [1–3] particularly suitable for the extraction of ^{137}Cs from highly acidic solutions [4–11]. Based on the original Czechoslovak patent [5], a reliable, robust and efficient liquid–liquid extraction separation process for the separation of ^{137}Cs and ^{90}Sr had been developed about 25 years ago under cooperation of the I.I.C. and the Nuclear Research Institute, Řez, Czech Republic with the Radium Institute, Leningrad in the former Soviet Union. The acidic form of the hexachloroderivative of cobalt(III) bis(dicarbollide)(1-) ion *closo*-[(1,2-$C_2B_9H_8Cl_3)_2$-3,3′-Co]$^-H_3O^+$ in nitrobenzene or halogenated hydrocarbons are used as the extractant in this procedure. A slightly modified process has been recently successfully employed on an industrial scale at the Mayak complex, Ozersk, Russia for treatment of a large amount of high level activity liquid waste (HLW) [12,13].

The recent investigations were focused on a search for more powerful anion **1** based extractants for Cs^+ and Sr^{2+} with the main aim to minimize environmental risks, i.e. the extraction process had to meet the E.E.C. ecological requirements especially in respect of the solvents nocivity. A series of the new extractants for Cs^+ and Sr^{2+} based on various 8, 8′- arylene bridged and 4, 8′, 4′, 8 bis bridged (R = phenyl, tolyl, xylyl, biphenylene, tetraline, etc.) derivatives of **1** was developed and tested [14,15]. The substitution of the cluster anion with aromatic rings led to a pronounced hydrophobic behavior of the respective species and their enhanced solubility in aromatic hydrocarbons.

The main target of the current investigations is to develop an effective separation method for M(3+) lanthanides and minor actinides, i.e. long-lived nuclides from highly acidic solutions of HLW remaining after removal of Cs^+ and Sr^{2+}.

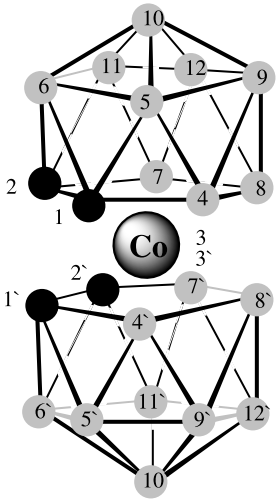

Fig. 1. Schematic structure of the parent anion [*closo*-*commo*-(1,2-$C_2B_9H_{11})_2$-3,3′-Co]$^-$ (**1**) with the cage numbering. For clarity, terminal hydrogen atoms (one on each unsubstituted skeletal vertex) are omitted.

A logical way, how to transfer the lanthanide and actinide M^{n+} cation from aqueous solution into a low polar organic phase proceeds through tight complex formation. In well known schemes employing organic ligands, the metal is surrounded with electron donor atoms of the uncharged ligands like crown ethers, malonamides, phosphine oxides, CMPO like or modified calixarenes [16–21], able to form a low polar, but still $n(+)$ charged complex. In this case, hydrated nitrate anions have to be transferred across the interface together with the target cation.

According to our considerations and the recent positive results in extraction properties of carbon substituted **1** derivatives gained by another group [22], cation transfer would be facilitated, provided that both chelating and hydrophobic anionic particles form inherent parts of the same molecule. The polyhapto-substituent/s, would allow for strong bonding of the target cation and displacement of water molecules in its primary coordination sphere. The cationic $n(+)$ charge of one M^{n+} metal ion would be compensated by the minus charge of n hydrophobic univalent anions on a short distance. Consequently, the resulting molecular assembly comprising of an inner polar cavity enveloped with an hydrophobic outer core (composed of cluster anions and organic hydrophobic groups) would tend to leave the water phase and enter the low-polar organic solvent. This principle is schematically depicted in Fig. 2.

The new compounds *closo*-[(8-X-$(CH_2–CH_2O)_2$-1,2-$C_2B_9H_{10})$(1′,2′-$C_2B_9H_{11}$)-3,3′-Co]$^-$ (**3**–**7**) prepared to test the above idea and described in this article, amalgamate in one molecule the strongly hydrophobic hydroborate anion with delocalised (1-) charge together with polyhapto-substituents bonded to boron atom $B_{(8)}$, allowing for selective bonding of the target cation. In these compounds, boron atom substitution brings an advantage in the direct blocking of the most reactive skeletal site $B_{(8)}$ of the molecule. Also some protection of the second one ($B_{(8')}$–H) bond by steric hindrance can be assumed. This causes an enhanced stability in strongly acidic HLW solutions.

The synthetic, electrochemical and extraction results described in this article bring evidence about viability and validity of the above concept.

2. Experimental

2.1. General

All reactions were carried out with use of standard vacuum or inert-atmosphere techniques as described by

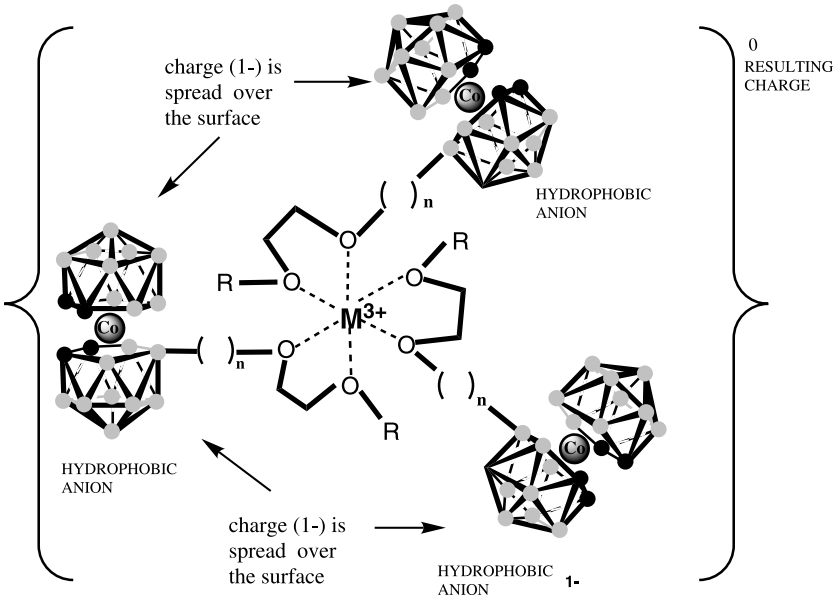

Fig. 2. Schematic drawing of the complex formation around M^{3+} cation with the ligating species of the general formula $[(8\text{-}X\text{-}(CH_2CH_2O)_2\text{-}1,2\text{-}C_2B_9H_{10}(1,2\text{-}C_2B_9H_{11})\text{-}3,3'\text{-}Co]^-$. The bonding via oxygen atoms in the spacer is just an example. Nevertheless, it can be considered as well for coordination *via* other donating atoms (O,P) in the selective terminal moiety.

Shriver [23], although some operations, such as column chromatography, were carried out in air. The starting dioxane of the anion **1**, *closo*-[(8-($\underline{CH_2CH_2–O}$–CH_2–CH_2O)-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)-3,3′-Co]^0 (**2**) was prepared from commercially available anion **1** (Katchem Ltd., Prague, Czech Rep.) according to the literature procedure [24]. Toluene (Lachema, Brno, Czech Rep.) was dried over Na metal, THF (Aldrich) with sodium diphenylketyl and freshly distilled before use. High surface sodium hydride made at I.I.C. was used with a BET surface area of about 1 $m^2\ g^{-1}$. The commercially available dibutylphosphite (Aldrich) was used for introduction of the dibutylphosphite terminal moieties. Other chemicals were reagent or analytical grade and were used as purchased. Column chromatography was carried out on silica gel (Aldrich, 200–400 mesh) and the purity of the individual chromatographic fractions was monitored by analytical TLC on Silufol (silica gel on aluminium foil; yellow–orange spots, eventually detected by diiodine vapors followed by 2% aqueous $AgNO_3$ spray) and HPLC.

2.2. Physical measurements

2.2.1. NMR and mass spectrometry

Proton (^1H) and boron (^{11}B) NMR spectroscopy were performed at 11.75 T on Varian Unity-500 instruments. The procedure for [^{11}B–^{11}B]-COSY [25,26] and ^1H–{$^{11}B_{(selective)}$} [27] NMR experiments were essentially as described in other papers from our laboratories [28]. NMR chemical shifts are given in ppm to high-frequency (low field) of} = 160.380 MHz (nominally $F_3B{\cdot}OEt_2$ in $CDCl_3$) for ^{11}B (quoted ±0.5 ppm.) and} = 500 MHz ($SiMe_4$) for ^1H (quoted ±0.05 ppm.)} being defined as in the literature [25,26]. Residual solvent ^1H resonances were used as internal secondary standards. Coupling constants $^1J(^{11}B–^1H)$ are taken from resolution-enhanced ^{11}B spectra with a digital resolution of 2 Hz and are given in Hz. Peaks in ^{31}P spectra are referenced to H_3PO_4 as the external standard.

Mass Spectrometry measurements were performed on a Bruker Esquire-LC Ion Trap instrument using Electrospray Ionization. Negative ions were detected. Samples dissolved in acetonitrile (concentrations 1 ng μl^{-1}) were introduced to the ion source by infusion of 3 µl min^{-1}, drying temperature was 300 °C, drying gas flow 5 l min^{-1}, nebulising gas pressure 10 psi.

2.2.2. Analytical HPLC

Chromatographic procedure: The Ion-Pair RP chromatographic method for separation of hydrophobic borate anions with DAD detection was used [29] based on results described earlier in the literature [30] by authors from this laboratory. Column: RP Separon C8 7 µm (silica with chemically bonded octyl groups) Tessek Ltd., Prague. Chromatographic conditions: Mobile phase: 3 mmol hexylamine acetate in 58% aqueous acetonitrile, Flow rate 1 ml min^{-1}, detection DAD, fixed wavelengths 280, 295, 312 and 325 nm, Sensitivity range: 0.2 A.U.F.S, samples of concentration approximately 1 mg ml^{-1}, injection volume 5 µl.

2.2.3. X-ray crystallography

The orange crystal of compound **3** of dimensions 0.3 × 0.25 × 0.2 mm was mounted on a glass fiber with

glue and measured on four-circle diffractometer κ CCD with CCD area detector at 150(2) K with (graphite monochromated) Mo Kα radiation. The crystallographic details are summarized in Table 1. The structure was solved by the direct method (SIR-92) and refined by a full-matrix least-squares procedure based on F^2 (SHELXL-97) [31]. The absorption was neglected. Hydrogen atoms were localized on a difference Fourier map and refined isotropically except those of the methyl moiety, which were recalculated into idealized positions and refined with a temperature factor restricted to $1.2[U_{eq}(C)]$. A water molecule is disordered into two positions, one oxygen with higher occupancy was refined anisotropically, the second isotropically, because of the vicinity of disordered atoms, the positions of the hydrogen atoms of the water molecule could not be determined. Scattering factors were those implemented in the SHELX programs.

2.2.4. Electrochemical measurements

The details of the experimental arrangement have been described in the previously published article [32].

2.2.5. Extraction tests

All extraction experiments were performed in glass test-tubes with polyethylene stoppers at laboratory temperature (23 ± 1 °C). The phase volume ratio was 1:1 (2 ml of each phase). The samples were shaken for 1 h (10 min was sufficient for attaining extraction equilibrium) on a horizontal shaker. After shaking, the test-tubes were centrifuged and 1 ml samples of each phase were taken for radioactivity measurement. All reagents and solvents used were of A.R. quality. The distribution of Eu was investigated using carrier-free ^{152,154}Eu (radiochemical purity). The radioactivity of samples was measured using single-channel analyzer with NaI (Tl) well detector.

2.3. General synthetic procedure for the preparation of 8-L-functionalized derivatives by closo-[(8-(CH_2CH_2–O–CH_2–CH_2O)-1,2-$C_2B_9H_{10}$)(1′,2′-$C_2B_9H_{11}$)-3,3′-Co]^0 (2) ring opening

The respective phenol or dibutylphosphite reagent (10 mmol) dissolved in toluene (30 ml) was added dropwise under stirring to the high surface solid NaH (12 mmol) overlayed with toluene (20 ml) and the resulting slurry was stirred at room temperature for 1 h. Then a slurry of the starting compound **2** (2 g, 4.9 mmol) in toluene-THF solvent mixture (30 and 10 ml) was added and the reaction mixture was gently refluxed for approximately 2 h. The reaction course was monitored by TLC and the heating was stopped when the spot of the starting zwitterionic species **2** disappeared on TLC ($R_F = 0.47$, CH_2Cl_2). After cooling down, ethanol (10 ml) was carefully added followed by water (20 ml).

The solvents were evaporated almost to dryness, water (30 ml) was added and the products were extracted into diethylether (three times 25 ml). Water (10 ml) was added to the combined ether extracts and the solvents were evaporated. The residue was dissolved in chloroform-acetonitrile solvent mixture (3:1) and the products were purified by flash chromatography on a silica gel column using the same mobile phase for elution. After evaporation of the respective fractions to dryness orange powders resulted. For the respective yields, TLC R_F values, HPLC k', NMR data and other properties see Tables 1–3. Crystals of the $Na^+\mathbf{3}^-$ salt were obtained by crystallization upon slow cooling down of its hot aqueous-ethanolic solution.

2.4. Hydrolysis of the 8-$(BuO)_2PO$-$(CH_2CH_2O)_2$-cobalt bis(dicarbollide) (6) to the respective monobutylester 7

The sodium salt of compound **6** functionalized with dibutylester of the phosphonic acid (2 g, 3.2 mmol) was dissolved in 2.5 M sodium hydroxide solution in 60%

aqueous ethanol (30 ml). The solution was gently refluxed for a period of 1 h. After cooling down, the ethanol was stripped off in vacuum. The resulting aqueous slurry was acidified with HCl (4 M, 100 ml) and the species was extracted with three portions of ether (20 ml). A small volume of water (25 ml) was added to the combined ether extracts and the organic solvent was evaporated. Calcium chloride in water (1.6 mmol) was added. Then ethanol was added in small portions to the resulting slurry under gentle reflux until the product dissolved. After cooling down, the product was filtered off and dried. A second crop was obtained after partial evaporation of ethanol. Orange powder, yield 74%.

2.5. Conversion of the compounds (*3*–*7*) to the form of tetrabutylammonium salts used in electrochemical measurements

The respective sodium or calcium salt (0.5 g) (compound **6**) was dissolved in 50% aqueous ethanol (15 ml) and an excess of Bu_4NBr in water (10 ml) was added causing precipitation of a fluffy or oily precipitate. This was separated by decantation, stirred four times with

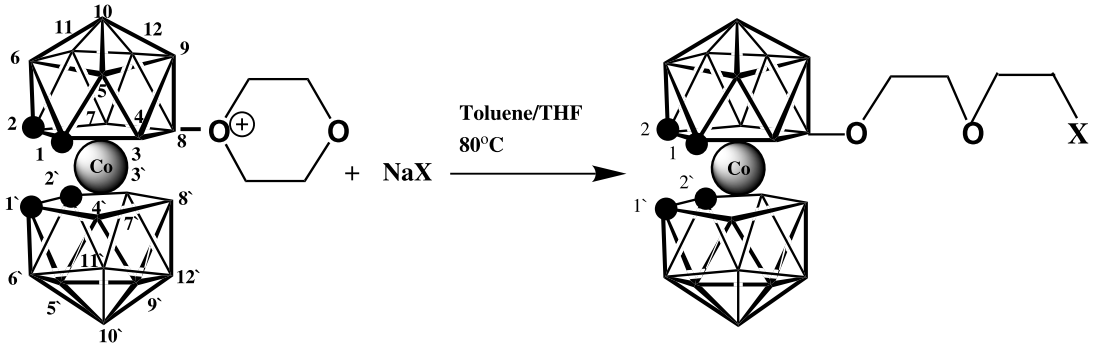
20% aqueous ethanol (15 ml), decanted and dried in vacuum. Most of the products resulted as a sticky dark orange mass.

3. Results and discussion

3.1. Synthesis and properties of substituted cobalt bis(dicarbollide)anions



A reliable reaction path was found, producing boron substituted compounds at position $B_{(8)}$ in high yields. Resulting species differ only in the character of the sequestering end groups. This allowed for deeper comparison of effects of the combination of the selective group covalently bonded to cobalt bis(dicarbollide) anion on the metal extraction properties across the whole series. The possibility to modify the properties of the end-group R and whole substituent/s including steric strain of the chain, apparently also able to participate in metal bonding, was studied.

The synthetic method in this study is based on a simple, one step reaction, i.e. dioxane-ring cleavage of the 8-dioxane derivative of anion **1** (bi-polar species **2**). This compound became available on a larger scale only recently (based on results made recently by the I.I.C. Group) [24] and proved to be a versatile synthon in the present study. The dioxane ring of this compound, containing an oxonium oxygen atom, can be easily opened by almost any base $\mathbf{X}^-$ of choice (phenolate, dialkyl- or diaryl- phosphite, etc) producing the respective functionalized anionic species. For reaction paths see Scheme 1.

Parts of the molecule **X** were selected from a broad range of possible candidates with the aims of reaching a wide diversity in the solubility and bonding properties of the resulting extraction agents. In the compound **3**, 2-MeO-phenoxide (Guaiacol) with an extended system of the (–O–Ph–O–) groups was introduced, 2-benzylphenoxide in compound **4** provided a more hydrophobic and mobile benzyl group. The branched *p*–*t*-octylphenoxide moiety in compound **5** was selected as a relatively rigid end-group with increased basicity of the phenoxy-oxygen and providing expected enhancement in the solubility in organic solvents. In compound **6**, $[(BuO)_2P{=}O]^-$ with known powerful sequestering properties represented another kind of end-group attached to anion **1**. The resulting product with terminal ester functionalities was later hydrolyzed to the $[(BuO)(HO)P{=}O]^-$ monoester end group in compound **7**, in order to incorporate another acidic center into the molecule. The subsequent alkaline hydrolysis of this ester did not proceed even under forced conditions and prolonged reflux. On the other hand, further partial hydrolysis apparently occurs upon contact with concentrated nitric acid as can be seen from stability tests described in the extraction part (see below). As can be seen from extraction tests, presence of $[(BuO)(HO)P{=}O]^-$ monoester functionality, as another acidic center in the molecule, proved to increase the transfer of the cations to the organic phase from highly acidic waste solutions substantially.

The reactions were smooth and quantitative in the first four cases, whereas in the synthesis of compound **6** two species in the ratio approximately 2:1 resulted. Only one species contained the desired C–P bond, whereas the minor product, not fully characterized, probably containing a $-C-O-P(O)(O-Bu)_2$ arrangement, was useless for extraction. With the exception of compound **7**, which was purified as its calcium salt, all other species were isolated as sodium salts. Samples in this form were submitted for extraction tests, and after conversion to the Bu_4N^+ salts were submitted for electrochemical measurements. The molecular structure of compound **3** was determined by X-ray diffraction, for details see text below. For physical properties and NMR data of the new compounds see Tables 1–3.

It should be pointed out that the solubility of Na^+ salts of all species in low polar solvents (toluene, xylene, cumene, etc.) was substantialy enhanced compared with

Scheme 1. General synthetic method leading to anionic species bearing polydentate ligands based on ring cleavage of compound **2**.

the cobaltacarborane parent species **1** and its chlorinated derivatives. This fact seems to be a crucial point in the possible application of compounds of this class as selective extractants.

3.1.1. NMR and X-ray diffraction results

In the ^{11}B NMR spectra of all anions **3**–**7** (Table 2), a significant downfield (to higher frequency) shift of the substituted boron –O–$B_{(8)}$ signal (singlet) could be observed in comparison to the unsubstituted parent species **1** (6.4 ppm). The ^{11}B NMR spectral pattern of all compounds **3**–**7** in the series is very similar. As in the recently reported spectrum of 8-OH substituted anion **1**, boron signals of the unsubstituted and substituted dicarbollide ligands are mutually shifted and could be distinguished from ^{11}B–^{11}B-COSY NMR experiments. Each of two dicarbollide ligands exhibits six peaks of relative intensities 1:1:2:2:2:1, for signal assignment see Table 2. An interesting feature found in the spectra of compounds **3**–**6** is that the resonance corresponding to $B_{(8')}$ atoms of the unsubstituted dicarbollide ligand in compounds **4**–**6** are significantly shifted upfield in comparison with signals of the recently reported mono-hydroxy derivative of anion **1** (8-OH-**1**) (6.9 ppm) [33] and the parent zwitterion **2** (6.4 ppm) [24]. The magnitude of these effects seems larger than could be expected considering simple solvatation or long-range electronic effects caused by substituents. Such a difference in $B_{(8')}$ chemical shifts can probably be ascribed either to diethyleneglycol chain strain due to bonding of the cation close to the cage or to possible involvement of the B–H→M$^+$ contact in the cation bonding, or combination of both effects. Surprisingly, the $B_{(8')}$ signals and all spectral patterns of compound **3**, in which solid state structure was found to contain a short B–H–Na contact (see below), and anion **7** with the strongest metal binding properties closely resemble that of 8-OH-**1**. Again, the chemical shifts of the proton $B_{(8')}$-H resonance in ^{1}H-{^{11}B(selective)} NMR spectra of compounds **3** and **7** are the closest to the values found in 8-OH-**1** anion (3.10 ppm) [33]. Respective signals of compounds **4**–**6** are shifted by approximataly 0.5 ppm.

The signals in ^{1}H NMR spectra of all compounds in the series could be assigned, despite the spectra complexity. The spectral patterns and intensities correspond to the presence of one particular selective group per cage. For peak assignment see Table 2. Compounds **6** and **7** exhibit each one peak in ^{31}P{^{1}H} spectra at 30.74 and 28.75 ppm, respectively.

Also, the mass spectrometry results are in clear agreement with the composition of all compounds under study. Cut off peaks corresponding to molecular mass of all particular compounds were found using an electrospray ionization technique (see Table 1).

The molecular structure of the Na$^+$ complex of anion **3** (see Fig. 3 and Tables 4 and 5) proved the position of the sodium atoms being in the plane formed by the oxygen atoms of guaiacol moiety (distance of Na1 from the least-square plane defined by O1, O2, O3 and O4 is 0.248(1) Å. The unsubstituted part of the carborane cage with the shortest contact H8′-Na1 2.26(3) Å, is situated on one side of this plane, one molecule of water is located on the other side. This distance belongs to the shortest Na...H–B contacts among those found in the Cambridge Structural Database [34] (minimum at 2.169 Å being found in sodium triethylhydroborate [35]). In (7,8-(1,13-dithia-4,7,10-trioxatridecane-1,13-diyl)-7,8-dicarba-nido-undecaborane)-sodium [36], the compound considered as the most suitable for comparison, two symmetrically related intermolecular contacts Na···H(4) equal to 2.31 Å can be found. However, this particular hydrogen shows very unusual bond angles, since the interval H(4)–B(4)–B has limits 87.7–146.7°, unfortunately this effect has not been discussed by the authors in [36]. In the structure presented in this article, on effect of similar magnitude does not occur, the bond angles for H8′ are within 112–128° with an average estimation equal to 1.5°. In our knowledge, this sodium complex represents the first known example where the B–H–Na$^+$ bond was formed by crystallization under aqueous conditions. Apparently tight metal bonding of the Na$^+$ cation inside the polar cavity formed by oxygen atoms and water repulsion due to steric effects of BH and CH_2 groups forming the hydrophobic outer shell may account for this kind of bonding. Other geometric parameters of the cobalt bis(dicarbollide) cluster of compound **3** fall within the usual range including cobalt coordination (see Table 2). Only the substituted boron atom B(8) is moved slightly further from metal atom.

3.2. Electrochemical results

The ability of the synthesized anionic ligands to form a complex with metal cations was tested by means of cyclic voltammetry at the interface between two immiscible electrolyte solutions [37]. In the presence of ligand L in the organic phase (o), the transfer of cation M from the aqueous phase (w) is facilitated by complexation at the interface [38]:

$$M^{z+}(w) + sL^-(o) \leftrightarrows ML_s^{(z-s)}(o) \quad (1)$$

which results in a negative potential shift of the ion transfer reaction. This potential shift is related to the stability constant K_{MLs} of the complex in the organic phase by:

$$K_{MLs} = (c_{Mz+(w)})^{-1}(c_{L(o)})^{1-s}e^{(zF/RT)\Delta E1/2} \quad (2)$$

where c is the concentration and $\Delta E_{1/2}$ is the difference between the half-wave potential of the simple (in the absence of ligand L) and the facilitated ion transfer.

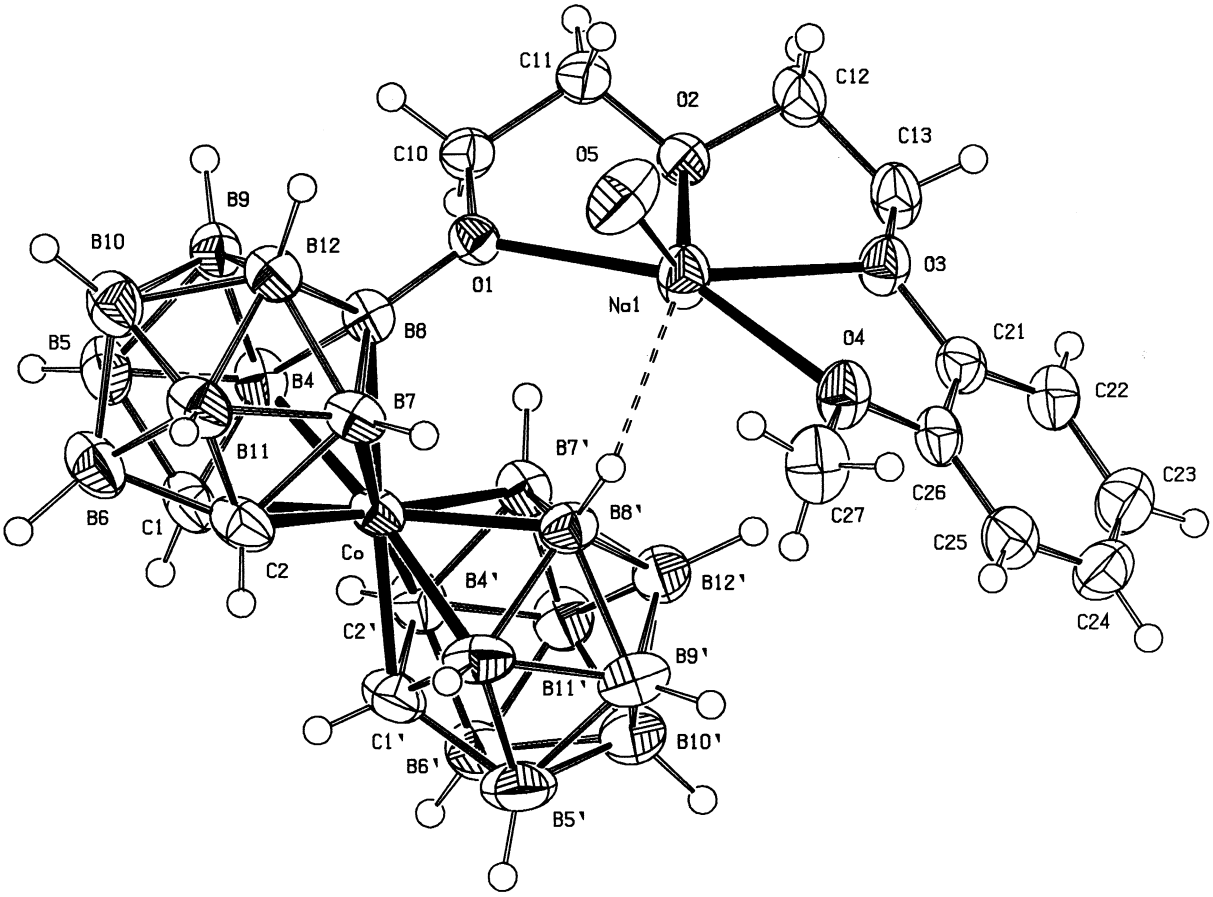


Fig. 3. Molecular structure with atom numbering scheme for **3**. Second position of water molecule (at 1.3 Å from O5) is omitted for clarity. Thermal ellipsoids are drawn at 50% probability level.

It has been shown [39] that if the transferred ion is present in excess with respect to the ligand, the peak potential difference of the cyclic voltammogram for the diffusion controlled charge transfer process is $0.059/z$, $0.087/z$ or $0.112/z$ for the stoichiometry of 1:1, 1:2 or 1:3 (cation:ligand), respectively.

Cyclic voltammograms of the facilitated transfer of Eu^{3+}, Cs^{+} and Na^{+} in the presence of ligand **3** in the organic phase are shown in Fig. 4. The peak potential difference for Cs^{+} and Na^{+} transfer is 0.06 V which corresponds to the stoichiometry of the complex of 1:1 (cation:ligand). The transfer of Cs^{+} is shifted to less positive potentials as compared with the transfer of Na^{+} and Eu^{3+}. This suggests that Cs^{+} would be extracted more easily from an equimolar solution in the aqueous phase, even when the stability constant of Cs^{+} is lower than that of Na^{+} and Eu^{3+} (Table 6). The peak potential difference of 0.04 V with Eu^{3+} is in agreement with the theoretical value $\Delta E_p = 0.112/3 = 0.037$ V, calculated for the stoichiometry of 1:3 (cation:ligand) of the complex. The same peak potential difference $\Delta E_p = 0.04$ V was also found for the transfer of La^{3+} and Ce^{3+} facilitated by the other ligands (Table 6), which indicates formation of a complex with the same stoichiometry. The peak potential difference $\Delta E_p = 0.045$–0.05 V of the facilitated Sr^{2+} transfer corresponds to the stoichiometry of the complexes of 1:2 (cation:ligand) (Table 6).

The half-wave potentials $E_{1/2}$ of the facilitated transfer of the studied ions by ligands **3**–**7** are shown in Fig. 5. Ligands 4 and 5 exhibit a similar behavior to ligand **3**. The apparent selectivity of these ligands for Cs^{+}, i.e. the lowest $E_{1/2}$ as compared with the other ions, points to a lower value of the formal potential of Cs^{+} transfer rather than to the value of the stability constant (Table 6). Ligand 7 exhibits the opposite behavior. In this case the lowest half-wave potential of the facilitated ion transfer is obtained for Eu^{3+}, La^{3+} and Ce^{3+}, which indicates that ligand **7** will be efficient in their extraction from aqueous solution.

Parameters of the facilitated ion transfer reaction of the studied ions derived from cyclic voltammograms are displayed in Table 6. Stability constants of the complexes of anionic ligands **3**–**7** with Cs^{+} and Na^{+} were calculated using the half-wave potential $E_{1/2}$ of the simple ion transfer, 0.56 V [40] and 0.788 V [41], respectively. The value of $E_{1/2} = 0.729$ V for Eu^{3+} was estimated from the cyclic voltammograms of the base

electrolytes with different concentration of $EuCl_3$ in the aqueous phase and 0.01 M tetrabutylammonium tetrakis(4-chlorophenyl)borate (TBATPBCl) in 1,2-dichloroethane. In all other measurements 0.01 M aqueous solution of MCl_z was used. The facilitated transfer of cations was measured in the presence of 0.5 mM of the ligand in 1,2-dichloroethane containing 0.01 M TBATPBCl or 0.01 M tetrabutylammonium dicarbollylcobaltate (TBADCC) as the base electrolyte. The potential E of the electrochemical cell was related to the formal potential difference for tetrabutylammonium ion $\Delta_o^w\phi^0_{TBA+} = -0.226$ V [42].

3.3. Extraction tests

It should be noted, Cs^+ extraction (not shown here) of all compounds was negligible, therefore Eu^{3+}/Cs^+ selectivity was quite high. Europium extraction results obtained with the above polydentate extractants are summarized in Table 7(a–d). All anionic species **3**–**7** were tested for Eu^{3+} extraction from acidic media. As can be seen from Table 7(a), with one exception, all compounds under study extract europium fairly well from media of slight acitidity up to 0.01 M HNO_3. However, with increasing acidity Eu distribution ratios strongly decrease, so that with the exception of extractant **7** no extraction of Eu can be observed from 1 M HNO_3 (Table 7(a)). Poor extraction properties of

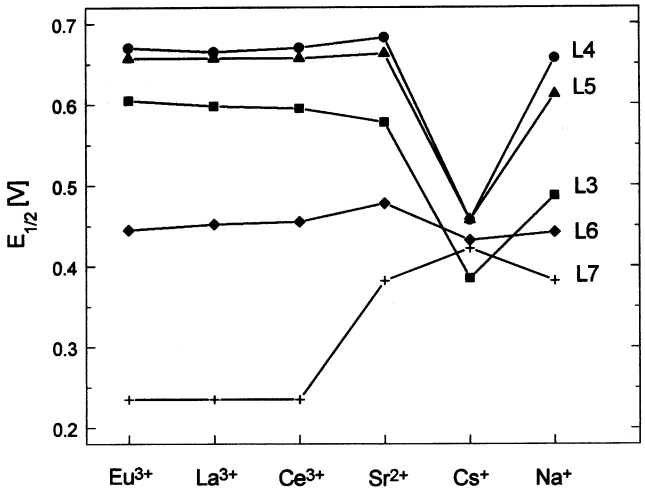

Fig. 5. Half-wave potentials of $E_{1/2}$ of the facilitated transfer of studied cations by anionic ligands **3**–**7**.

extractant **6** can be explained by complete esterification of the phosphate end group and steric hindrance of butyl groups. The same steric hindrance probably plays a role in the extraction mechanism of extractants **3** and **5**, however, the effect of protonization of oxygen atoms on the connecting link cannot be excluded. From this series, only compound **7** seems to be a potentially interesting effective extractant for treatment of highly acidic HLW. The dependence of extraction efficiency of extractant **7** on acidity is given in Table 7(b).

It can be seen that in the order of increasing acidities, the extraction of Eu starts to steeply increase then passes through maximum at approximately 0.1 M nitric acid and then steeply decreases in the media of high acidity. Nonetheless, the extraction from 1 M nitric acid is still sufficiently high for possible technological applications. The existence of a maximum can probably be explained by competition of protonized species for the extractant molecule. Interesting results were obtained with extractant **7** in the extraction—back-extraction cycle. The enormous increase of distribution ratio indicates the further hydrolysis of ester groups on the phosphate end group and increase of extraction efficiency (Table 7(c)).

Similar results were obtained during the tests of chemical stability (Table 7(d)) of extractant **7**. The continuous increase of distribution ratio of europium with time of contact again indicates the progress of a possible extractant hydrolysis. These two series of experiments seemed to indicate that hydrolysis of ester groups by 1 M nitric acid may be a convenient route to obtain the extractant with $(HO)_2(O)P$-end group. On the other hand, the ^{11}B and ^{1}H spectra of the sample dissolved in toluene and stirred for 1 month with 1 M HNO_3 proved that the unchanged butylester **7** was still present as the main component.

4. Conclusions

The first screening study is presented herein, showing a wide potential of the compound **2** dioxane ring cleavage reaction for the attachment of a variety of metal ligating groups. Reactions have proven to be smooth, reliable and of high yield for bonding oxygen donor atoms containing selective groups, as well as phosphorus comprising moieties. The first members of the novel class of the M^{3+} selective extractants were prepared, enabling transfer from acidic aqueous phase to aromatic solvents. The flexible podant chain apparently enables the selective groups to be appropriately oriented for the tight metal complexation and provides additional metal binding sites. The X-ray crystallography results obtained on the sodium complex of anion **3** indicate tight cation bonding inside the inner polar cavity enveloped by an outer hydrophobic sphere. The electrochemical study confirming 3: 1 stoichiometry of the complex, formed in the course of the M^{3+} cation transfer to the organic phase, brought basic evidence for the validity of the simple mechanistic model for metal transfer depicted in Fig. 2. Extraction results are in sound agreement with the above results and assumptions. They indicate that the cobalt bis(dicarbollide) derivatives combining polydentate ligands and hydrophobic anions in one molecule can serve as efficient selective extraction agents for M^{3+} cations. Indeed, results described in this study exemplify that such compounds, especially those with a phosphorus containing moiety, can serve for effective extraction of lanthanide M^{3+} cations from HLW into aromatic solvents without adding any synergic agent or other additive into the extraction system.

To our knowledge, compounds **6** and **7** represent the first combination of anion **1** with phosphorus contain-

Abstract

Hg(II) and Cd(II) complexes with 2-aminophenol (**Amph**) and 2-phenylenediamine (**Phda**) as ligands were prepared and characterized by elemental analysis, electrical conductivity, thermogravimetric analysis (DTA/TG), X-rays, FT-IR and FT-Raman spectra. The complexes formed can be formulated as $[M(L)_2 \cdot n H_2O] \cdot m H_2O$. The electrical conductivity of 0.001 M DMSO solutions revealed the non-electrolytic behavior of the **Amph** complexes while **Phda** complexes behave as a 1:2 electrolyte. DTA analysis reveals the presence of two types of water coordinating as aligned and as water of crystallization. ΔE_a of the stepwise decomposition was evaluated. X-ray powder diffraction studies on the ligands and their complexes are described. The fundamental frequencies of these complexes have been assigned on the basis of normal coordinate calculations, carried out using a generalized valence force field (GVFF). The proposed assignments are discussed in relation to the group frequencies in structurally related molecules and in terms of the computed potential-energy distributions among the symmetry coordinates. © 2002 Elsevier Science Ltd. Keywords: Cd(II) and Hg(II) complexes; Spectroscopic properties; Normal coordinate; Force constant; 2-Phenylenediamine; 2-Aminophenol

1. Introduction

The nature of metal–oxygen and metal–nitrogen bonds in metal chelate compounds has been a subject of considerable interest, and the studies of the vibrational spectra of metal chelates of 2-aminophenol and 2-phenylenediamine themselves are interesting from the viewpoint of molecular spectroscopy. So far, no normal coordinate treatment has been made on such a chelate ring system, where the M–O and M–N modes are of particular interest.

Kincaid and Nakamoto [1] first assigned both M–O and M–N stretching modes based on normal coordinate analysis of bis(glycino) complexes of Ni(II), Cu(II) and Co(II). However, their assignments were different from those of previous investigations. Loethr and Thomas [2] assigned the M–O and M–N stretching bands from an approximate normal coordinate analysis of bis(biuretato) and bis(oxamido) complexes. The study of Hg(II) and Cd(II) complexes of 2-aminophenol and 2-phenylenediamine is a subject of considerable interest due to their structural and spectroscopic properties in addition to their being potential models for a number of important biological and ecological systems [3,4]. The main purpose of this investigation is to provide a complete band assignment of 2-aminophenol and 2-phenylenediamine Cd(II) and Hg(II) complexes based on normal coordinate analysis for 1:1 complexes, taking into consideration the puckering of the six and five-membered rings. XRD combined with DTA/TG were additionally used to elucidate the structure of the complexes.

2. Experimental

2.1. Chemical

All chemicals used in the present study were reagent grade.

2.2. Preparation of the complexes

The complexes were prepared by mixing stoichiometric amounts of the ligand and metal ions (Cd(II), Hg(II)) in a 2:1 ratio in ethanolic solution. The mixture was refluxed for 2 h. The solid complexes formed after a few minutes when the temperature of the contents reached room temperature. $HgCl_2$ and $CdCl_2$ were used as the source of metal ions. The formed precipitates were washed and recrystallized from hot ethanol.

2.3. Instrumentation and analysis

Elemental analyses were carried out using an Heraeus C, H, N Rapid Analyzer. The conductance measurements of 0.001 M solutions of the complexes in DMSO were performed using a WTW model LF-42 conductivity bridge fitted with a LTA-100 conductivity cell. Thermal analysis of the complexes was carried out on a Perkin–Elmer DTA-7 differential thermal analyzer with a TAC 7/DX controller instrument using a platinum cell under nitrogen atmosphere at a heating rate of 10 °C min^{-1}. X-ray data were measured using Simens D 5000 XRD with scanning range $2\theta = 5–70°$. The infrared spectra were recorded with a Nicolet Magna 750 FT-IR spectrometer equipped with a room-temperature DTGS detector. The spectra of the solid (in the 4000–400 cm^{-1} spectral region) were recorded in the form of KBr pellets at 4 cm^{-1} spectral resolution accumulating 128 scans. The Raman spectra were measured with a Nicolet 950 FT-Raman spectrometer equipped with a liquid nitrogen cooled Ge detector, a 1064 nm Nd:YAG laser was used for excitation at 30–150 mW output power.

3. Results and discussion

Analytical data (Table 1) of the complexes show that Cd(II) complexes have the composition $[Cd(Amph)_2 \cdot 2H_2O] \cdot 2H_2O$ and $[Cd(Phda)_2 \cdot 2H_2O] \cdot 2H_2O \cdot 2Cl$. The Hg(II) complexes occur as $[Hg(Amph)_2] \cdot 2H_2O$ and $[Hg(Phda)_2] \cdot 2H_2O \cdot 2Cl$. The purity of the prepared complexes were confirmed by chemical analysis, melting point and TLC (silica gel GF 254 type 60, mesh size 50–250, eluted with H_2O–ethanol). The synthesized complexes were found to be grey or brown colored, non-hygroscopic powders.

3.1. Conductivity

The conductance of the complexes in DMSO (0.001 M) (Table 1) indicates that **Phda** complexes act as 2:1 electrolytes, consequently, two free Cl^- ions are present outside the coordination sphere of the Cd(II) and Hg(II) complexes [5]. The **Amph** complexes have non-electrolytic behavior.

3.2. Thermal gravimetric analysis (DTA/TG)

The application of TGA to evaluate solid-state reactions involving weight loss (or gain) has been studied by a number of workers [6–9]. The measurements were carried out in the temperature range 25–600 °C. The thermal gravimetric diagrams of the complexes (see Figs. 1–5) (Table 2) gave rise to the following observation:

1) Hg(II) complexes (**III** and **IV**) gave endothermic peaks in DTA, centered at 95 °C for complex **III** and 92 °C for **IV**, while at this temperature there is no weight loss in the TG diagrams. Consequently, these peaks could be assigned as phase transitions [9].
2) Cd(II) complexes (**I** and **II**) have endothermic peaks centered at 94 and 96 °C for complexes **I** and **II**, respectively. The Hg(II) complexes gave bands at 113 and 114 °C of the same nature for complexes **III** and **IV**, respectively. All the endothermic peaks were accompanied by weight loss in the TG diagram, which denote the liberation of water of crystallization; the % weight loss denotes liberation of two molecules of water [10,11].
3) Cd(II) complexes gave endothermic peaks centered at 151 and 171 °C for complexes **I** and **II** respectively, with % weight loss equivalent to losing two H_2O molecules, which may be assigned to water of coordination [10,11].
4) The decomposition of the ligand appeared as exothermic peaks for complexes **I** and **II** at 214 and 261 °C respectively; complex **III** gave an endothermic peak at 225 °C.
5) The endothermic peaks which appeared at 278 and 276 °C for complexes **III** and **IV**, gave no change in the TG diagrams and so could be assigned to phase transitions [7].
6) The activation energies of the thermal decomposition steps were calculated using the Piloyan method [12] (see Table 2), which can be summarized as follows:
   a) E_a of the liberation of water of crystallization has the following trend: **II** > **IV** > **I** > **III**.
   b) The liberation of water of coordination has the following sequence: **II** > **I**.

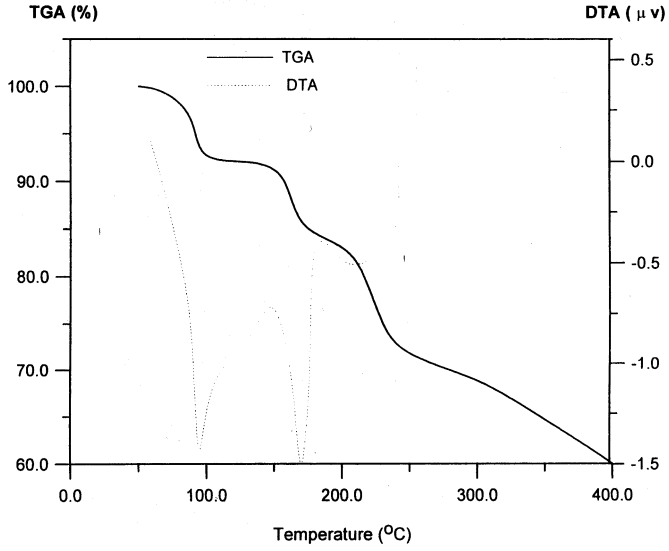

Fig. 2. Cd–phenylenediamin complex.

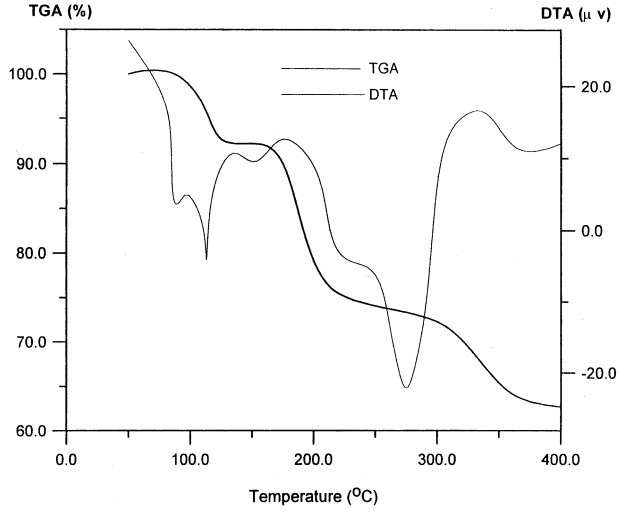

Fig. 4. Hg–phenylenediamin complex.

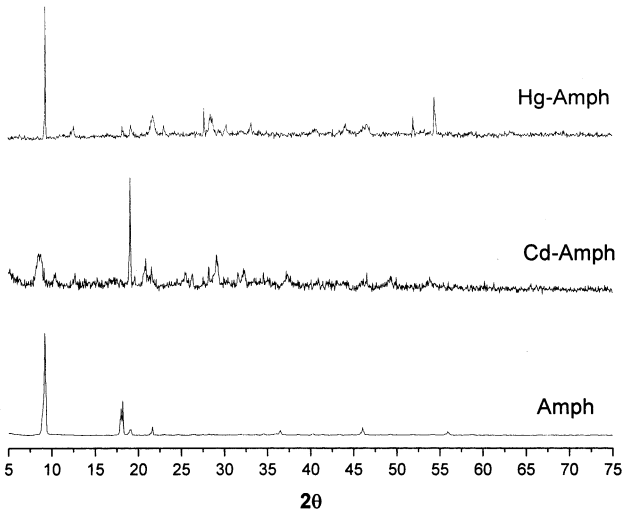
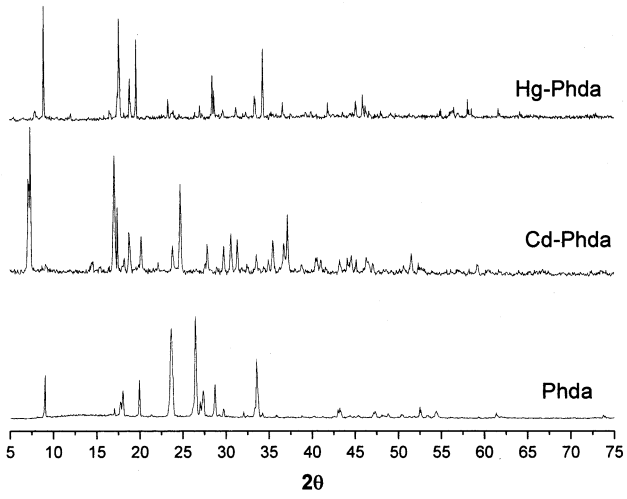


c) From the previous results, we can write the general thermal properties of the prepared complexes (**I**–**IV**): (1) water of crystallization for Cd(II) complexes has a greater stability than Hg(II) complexes. (2) The **Phda** complexes are generally more stable than **Amph** complexes. The stability of the **Phda** complexes may be due to the crystallinity structure of these complexes, which consequently require higher activation energies for decomposition.

3.3. X-ray for powder diffraction



X-ray patterns of the prepared solid **Phda** and **Amph** complexes were taken over the range of $2\theta = 5–75°$. The principal 'd' lines and their intensities are represented in Table 3 and shown in Fig. 5. Generally the prepared complexes have a high degree of crystallinity when compared with the parent ligands. Cd(II) complexes have crystallinity higher than Hg(II) complexes. The complexes of **Phda** have crystallinity higher than **Amph** complexes. High symmetry, large unit cells size and various degrees of crystallinity, are characteristics of all crystalline compounds [13]. The results obtained confirmed the results obtained previously by using thermal gravimetric analysis.

3.4. FT-IR, FT-Raman and normal coordinates

In order to study the metal–oxygen and the metal–nitrogen vibrations of 2-aminophenol (**Amph**) and 2-phenylenediamine (**Phda**), a normal coordinate treatment has been made on a chelate ring using a 1:1

X-ray powder diffraction of the Amph ligand and its complexes

$\alpha = \cos 72^\circ = 0.309017$, $\beta = \cos 144^\circ = -0.809107$.

complex model as shown in Fig. 6. Both models can be consider planar, **Amph** belongs to the C_s point group, where 39 fundamental vibrations are distributed as $29A'+10A''$, all i.r. and Raman active. **Phda** has C_2v symmetry, where 45 vibrations are grouped into four classes. Furthermore, the in-plane vibrations ($15A_1+14B_2$) are vibrationally separate from the out-of-plane vibrations ($8A_2+8B_1$). Inspection of the spectra for all the complexes reveals more i.r. than Raman features. This can probably be accounted for by a poor scattering ability of the complexes. The structure parameters were transferred from the X-ray data on the metals complexes

[14]. The bond length and bond angles are: C–C = 1.39 Å, C–N = 1.32 Å, C–H = 1.09 Å, C–O = 1.46 Å, N–H = 1.012 Å, N–M = 1.63 Å, O–M = 1.92 Å; CCC = 120°, CCH = 120°, CCN = 124°, CCO = 116°, CNM = 112.718°, COM = 109°, NMN = 90°, NMO = 90°.

The vibrational problem was set up in internal valance coordinate as given in Fig. 6. For the six and five-membered rings deformation and torsion local symmetry coordinates were constructed, which were defined in terms of the internal valance coordinates, following the IUPAC recommendation [15,16] and given in Table 4. Wilson's GF method [17] was applied to compute the normal frequencies. Before solving the secular equations the G and F matrices were transformed to the symmetry coordinates. For the in-plane vibrational frequencies of both planar complexes, the force constants used for the aromatic ring were transferred from the force field of nitrobenzene [18] substituting the values of γ and R from the force constant set of 6-amino-*m*-cresol [19] and *p*-dimethylaminobenzonitrite [20]. The force field for the internal coordinates around the metal atom was initially estimated from the force field of biuret and oxamide complexes [2].

The out-of-plane force constants of the aromatic ring were taken from the 23 parameter force field of fluorobenzene developed by Pearce and Steele [21], and those of the five-membered ring were transferred from the force constant of an oxamide complex [22]. An additional force constant was necessary to adjust the out-of-plane bending of the two rings relative to each other, the so-called butterfly motion of the molecule (π). It was noted that by introducing interaction constants $\infty\gamma$ and $\beta\gamma$ together with the values of the force constants η, ∞, $R\gamma$, $d\varepsilon$ and $s\eta$, the frequency fit could be improved. In Table 5 the final set of force constants used for **Amph** and **Phda** complexes are listed, where the numerical computation and refinement of the force constants were carried out using the PC version of the computer program MOLVIB [23].

Table 5
Set of force constants used in the calculation of **Amph** and **Phda** complexes

Diagonal force constant		Interaction force constants	
r_s^+	6.938	Rr	0.543

The following abbreviations have been used: ν_s, symmetric stretching; ν_{as}, asymmetric stretching; δ, bending; ω, out-of- plane bending; δ_r, rocking; δ_{sc}, scissoring; τ, torsion; π, torsion of the two rings.

[a] The potential energy distribution defined as $\chi_{ik} = 100$. $F_{ji}L_{ik}^2/\lambda_k$; those less than 10% have been neglected.

and ν_{43} in **Phda)** are also related to the benzene ring absorption. The absorption arising from the five-membered ring deformation modes ν_{13} and ν_{44} in **Phda** complexes show very variable intensity, these bands are assigned to ν_{23} and ν_{26} modes at lower wavelengths in the reduced C_s symmetry in **Amph** complexes.

The calculation reveals that the observed vibrational frequencies are generally a complex mixture of different vibrational modes, as shown in different band assignments. However, our calculation for the complexes of **Amph** shows that the (C–O) symmetric stretch, (C–C) and (C–N) are coupled, and would yield a (C–O) stretching mode around 1230 cm^{-1}. Indeed, two bands were observed at 1236 and 1366 cm^{-1} in the i.r. Studies by Fujita and Nakamoto [25] on oxalate complexes have shown the (C–O) symmetric stretch to be about 1230–1400 cm^{-1}, using several force field models in the calculation. The ring-N stretching vibrations are strongly mixed with other motions. The i.r. active vibrations at 1459 and 1334 cm^{-1} and Raman active at 1458 and 1326 cm^{-1} in **Phda**–Hg spectra have the largest contribution from ring-N stretching coordination.

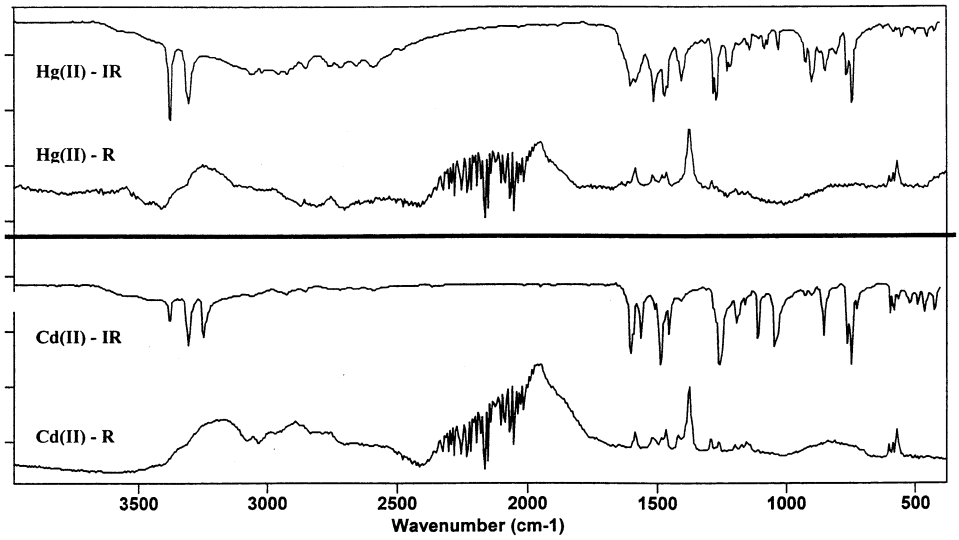

Fig. 8. FTIR and Raman spectra of the **Amph**–Cd(II) and Hg(II) complexes.

The bands observed at 447 and 411 cm^{-1} in the **Phda**–Cd complex and at 457 and 418 cm^{-1} in the spectra of the corresponding mercury complex are all predominantly due to (M–N) stretching. In a recent study of Hg(II) and Cd (II)-aminobenzophenon, a peak at ~ 366 cm^{-1} was tentatively assigned to (Cd–N) and (Hg–N) [26], which is ~ 81 cm^{-1} lower than our calculated value. However, that study did not mention Raman data. In addition Nakamoto [1] have examined the i.r. spectra of bis(glycino) complexes, and have assigned ν(M–N) at 457 cm^{-1} which is very close to our assignment of the same band. ν(M–O), observed at 458 and 448 cm^{-1} in the i.r. spectra of Cd and Hg–**Amph**, are about 124 cm^{-1} higher than the calculated value in the bis(glycino) complex. It should be mentioned that for bis(biuretato) and bis(oxamido) complexes these bands range from 270 to 485 cm^{-1} [2]. Since such a large range for ν(M–N) and ν(M–O) exists for similar complexes, it is not unreasonable to encounter (M–N) and (M–O) frequencies that differ by 81 and 124 cm^{-1} in related compounds.

Abstract

Nickel(II) dichromate and chromate complexes with 1,10-phenanthroline were isolated from basic (pH 8–9) solutions. $[Ni(phen)_3]Cr_2O_7\cdot 8H_2O$ (**1**), $NiCrO_4$ (**2**), $[Ni(phen)_3]Cr_2O_7\cdot 3H_2O$ (**3**) and $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ (**4**) were characterized with spectroscopic (UV–Vis, IR, FIR) methods and one (**4**), additionally, with X-ray data. In the complex (**4**) the chromate ion is monodentately coordinated to nickel ion. This complex crystallizes in the triclinic crystal system (space group $P\bar{1}$). The single crystal electronic spectrum of complex (**4**) at 4 K reveals a rare feature when the structured second d–d band (O_h symmetry) is unsplit in spite of lowering symmetry. The filtration process has revealed that this band is vibronically structured in the ν_s Ni–O–Cr quantum. A new broad low intensity band at approximately 14 000 cm^{-1} was assigned to the forbidden transition in the bridge. An attempt to explain precipitation of dichromates from alkaline solutions has been given. © 2002 Published by Elsevier Science Ltd.

Keywords: Nickel(II) chromate and dichromate complexes of phenanthroline; Monodentate coordination of CrO_4^{2-}; Crystal structures; IR and UV–Vis–NIR band analysis

1. Introduction

According to common opinion, the CrO_4^{2-}, $HCrO_4^-$ and $Cr_2O_7^{2-}$ anions are present in basic, slightly acidic and acidic solutions, respectively [1]. However, these oxo species exist in various equilibria depending predominantly on pH and Cr(VI) concentrations [2–7]. Thus, some dichromate anions are present in basic solutions of high Cr(VI) concentrations in amounts corresponding to the magnitude of proper equilibrium constants (for example, calculated abundance of $Cr_2O_7^{2-}$ (10^{-2} M) at pH 8 is 0.1%) [6].

Here we report data showing the effect of 'the environment' of chromium(VI) i.e. accompanying nickel(II) ions and the organic ligand—1,10-phenanthroline (phen) on the chemical composition of precipitated chromium(VI) species. We have isolated from pH 8–9 four complex salts containing the dichromate ($[Ni(phen)_3]Cr_2O_7\cdot 8H_2O$ (**1**), $[Ni(phen)_3]Cr_2O_7\cdot 3H_2O$ (**3**)) and chromate anions ($NiCrO_4$ (**2**), $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ (**4**)).

Generally, the chemistry and geometry of complexes containing Cr(VI) can be interesting as they play an important role in transportation of this cancerogenic metal ion through the cellular membrane and its further metabolization in the cytoplasm [8,9]. Thus, the potential complexation of the Cr(VI) ion may influence its genotoxicity.

2. Experimental

Reagent grade commercially available chemicals were used in all experiments. The system was studied at three different reagent ratios (Ni^{2+}:phen:CrO_4^{2-}): 1:1:1, 1:2:1

and 1:3:1 and with three different nickel(II) salts: $NiSO_4$, $NiCl_2$ and $Ni(NO_3)_2$. The general procedure was the same for all syntheses. The compounds (**1**–**4**) were formed during the reaction of methanolic solutions of phen previously mixed with a water solution of K_2CrO_4 and a water solution of the respective nickel salt. The complexes were precipitated from the reagent mixture in the following order: **1**, **2**, **3** and **4** (see Table 1).

2.1. Syntheses

2.1.1. Reagent ratio 1:1:1

A methanolic solution of 1,10-phenanthroline (5 cm^3, 0.75 M) was mixed by stirring with 15 cm^3 of K_2CrO_4 (0.25 M aqueous solution). The yellow precipitate, which was immediately formed, dissolved upon addition of phen solution. Then 15 cm^3 of 0.25 M $NiSO_4$ ($NiCl_2$, $Ni(NO_3)_2$) aqueous solution, was added. From the resulting orange–red solution, a yellow precipitate (compound **1**) was isolated at pH 8.62. The precipitate was filtered, washed several times with water and finally dried in a desiccator over P_2O_5. After separation of **1** the solution became turbid and a brown powder was obtained (compound **2**) at pH 8.82. The resulting red–orange solution was allowed to stand for 24 h and thin orange crystals were formed (compound **3**) at pH 8.86. The final olive green solution was left to stand overnight. The obtained crystals (compound **4**) were separated at pH 8.90, washed with water and dried in air.

Analytical results:

(**1**) Found: C, 44.70; H, 4.10; Cr, 10.67; Ni, 5.82; N, 8.65. Calc. for $C_{36}H_{40}Cr_2N_6NiO_{15}$: C, 45.07; H, 4.20; Cr, 10.84; Ni, 6.12; N, 8.76%. IR spectrum (cm^{-1}) (KBr): Cr–O: ν_{17}-936s; ν_{21}-367m; Ni–N: ν_{as}-302 and ν_s-250; Cr–O–Cr: ν_{as}-771w, ν_s-559; –C=N–: ν-1517m.

(**2**) Found: H, 4.33; Cr, 18.31; Ni, 20.70. Calc. for $CrNiO_4$: H, 4.28; Cr, 18.39; Ni, 20.76%. IR spectrum (cm^{-1}) (KBr): Cr–O: ν_1-874w; ν_3-912vs; ν_4-392ms; Ni–O: ν_s-425.

(**3**) Found: C, 46.96; H, 3.60; Cr, 12.19; Ni, 6.71; N, 9.11. Calc. for $C_{36}H_{30}Cr_2N_6NiO_{10}$: C, 49.74; H, 3.48; Cr, 11.96; Ni, 6.75; N, 9.67%. IR spectrum (cm^{-1}) (KBr): Cr–O: ν_{17}-936w; ν_{21}-367m; Ni–N: ν_{as}-300, ν_s-250; Cr–O–Cr: ν_{as}-770w, ν_s-558; –C=N–: ν-1516m.

(**4**) Found: C, 33.24; H, 3.92; Cr, 11.43; Ni, 13.17; N, 6.40. Calc. for $C_{12}H_{16}CrN_2NiO_8$: C, 33.76; H, 3.78; Cr, 12.18; Ni, 13.75; N, 6.56%. Table 1
General characteristics of the compounds isolated from the system [Ni^{2+}–phen–CrO_4^{2-}] in succession

Symbol	Formula	Color	pH
1	$[Ni(phen)_3]Cr_2O_7 \cdot 8H_2O$	yellow powder	8.62
2	$NiCrO_4$	brown powder	8.82
3	$[Ni(phen)_3]Cr_2O_7 \cdot 3H_2O$	orange crystals	8.86
4	$[Ni(phen)(OCrO_3)(H_2O)_3] \cdot H_2O$	olive crystals	8.90

Compounds **1**–**4** were also isolated with various yields in the same order for the 1:2:1 (Ni^{2+}:phen:CrO_4^{2-}) reagent ratio. However, for the 1:3:1 molar ratio, only **1**–**3** were precipitated.

2.2. Physical measurements

Elemental analyses were done using the Kupman (C, H, N) and ICP AES (Ni, Cr) methods.

2.2.1. X-ray data collection, structure solution and refinement for complex (*4*)

The single-crystal measurements were carried out on a four circle X-ray KM4 diffractometer (Kuma Diffraction Company). The data were collected using a CCD detector. Mo Kα graphite-monochromated radiation ($\lambda = 0.71073$ Å) and the omega scan with $\Delta\omega = 0.75^\circ$ for one image were used for data collection at room temperature (r.t.) (300 K). The 960 images for six different runs covered 89.2% of the Ewald sphere. 7755 reflections of $[Ni(phen)(OCrO_3)(H_2O)_3] \cdot H_2O$ were recorded which merged to give a total of 3875 reflections.

The structure of $[Ni(phen)(OCrO_3)(H_2O)_3] \cdot H_2O$ (**4**) was solved by direct methods using the SHELXS-97 program [10]. Refinement was carried out using SHELXL-97 [10]. The initial lattice parameters were calculated from 150 reflections obtained from 30 images for ten runs with different orientations in reciprocal space and the final lattice parameters were refined for all reflections with $I > 2\sigma(I)$. Anisotropic thermal displacement parameters were used for all non-hydrogen atoms. The positions of hydrogen atoms were determined from difference Fourier maps and they were well refined. Empirical absorption correction was applied for observed reflections and no extinction correction was introduced in the refinement. The crystal data and details of the data collection and refinement are shown in Table 2.

2.2.2. Spectroscopic study

FIR (500–50 cm^{-1}) and IR (4000–500 cm^{-1}) spectra were recorded on a FTIR Perkin–Elmer 2000 and Perkin–Elmer 1600 spectrophotometers, respectively. Electronic absorption spectra were obtained on a Cary 500 Scan UV–Vis–NIR Spectrophotometer (Varian).

[b] $R_w = [\Sigma w(|F_0| - |F_c|)^2/\Sigma w|F_0|^2]^{1/2}$ $w = (\sigma_c{}^2 + (0.02|F_0|)^2)^{-1}$.

The low-temperature (4 K) single crystal spectrum was measured using a Cryostat Optistat CF (Oxford) with an open-cycle helium system with identical conditions as a baseline.

The band analysis of the electronic spectra was performed using the variable digital filter method to obtain the approximate band position values [11–15]. To obtain the exact band positions, intensities and half-widths, the spectra have been deconvoluted into Gaussian components [15–18].

Originally, the variable digital filter method described by Biermann and Ziegler was used for analytical purposes [11] and later adopted for electronic spectra analysis [14]. The filter acts by a single convolution of the spectral data $T(k)$ with a filter function $a(n)$:

$$T(k) = \sum_{n=-N}^{N} a(n) f(k-n)$$

where

$$a(n) = \{[(2\alpha+1)/(2N+1)] - [2\alpha|n|/N(N+1)]\}$$

$T(k)$ is the filtered spectrum with k equally distanced measured points, $a(n)$ is the filter function, f is the unfiltered spectrum, N is the integer number greater than $|n|$, and α is a real number determining the degree of the resolution enhancement. By varying α and N one can achieve different degrees of noise reduction, increase of height and decrease of width of the component bands.

The process of the resolution of the experimental contour into component bands was performed by using a modification of the Non-Linear Least-Squares algorithm [16–18]. The number of bands and their approximate positions were taken from filter analysis described above.

3. Results and discussion

From the mixture of components: Ni(II) salt, K_2CrO_4 and phen at three various molar ratios and three anions of the Ni(II) salts in solutions at pH 8–9, four compounds were isolated in succession (Table 1). The most striking was the isolation of two dichromate salts with a $[Ni(phen)_3]^{2+}$ complex cation: a yellow powder and orange–red crystals, differing only in the various amounts of water (Table 1). The crystal structure of the orange crystals (**3**) was reported recently [19]. Here, we present the respective data for the olive crystals of $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ (**4**), precipitating as the last species.

3.1. Crystal structure analysis

The $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ crystals (**4**) have a triclinic symmetry with space group $P\bar{1}$ and two chemical units forming, at room temperature, the unit cell which is similar to that in $[Ni(phen)(S_2O_3)(H_2O)_3]\cdot H_2O$ [20]. However, the atomic coordinates of $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ were determined independently using the direct method. Selected interatomic distances and angles of $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ are shown in Table 3. Fig. 1 presents the projection of the atom arrangement in the unit cell of this crystal along the a axis. The molecular diagram for $[Ni(phen)(OCrO_3)(H_2O)_3]$ is illustrated in Fig. 2 (displacement ellipsoids are drawn at the 50% probability level). The complex is monomeric. The Ni(II) coordination environment can be considered as a distorted octahedron. The coordination positions are occupied by the two N atoms from 1,10-phenanthroline acting in the usual bidentate mode, three water molecules and one O atom

from the chromate anion. Two water molecules are situated in equatorial positions whereas one O atom from the water molecule and one O atom from the chromate group occupy the axial positions. The Ni–N bond lengths [2.0749(10) and 2.0801(11) Å] are longer in comparison with other similar complexes [20–22]. The Ni–O distances [2.0662(9) and 2.0553(10) Å] from the equatorial water molecules are shorter than those from the axial water molecule [2.1008(11) Å] and the chromate anion [2.1089(11) Å], and are normal in this type of complex [20,23,24]. Coordination does not seem to affect the geometry of the chromate moiety in this crystal. The mean value of the Cr–O distances agrees well with those reported previously for the uncoordinated unit of CrO_4^{2-} [15,24].

The complex crystallizes with a molecule of water. It takes part in four hydrogen bondings (HBs) with two O atoms from the chromate groups and two water ligands from independent complex molecules. Furthermore, four HBs are formed between two molecules of equatorial water and O atoms from the chromate anion. Amongst these eight HBs, the aqua ligand O(2) forms the shortest [1.820(14) Å] intramolecular HB with O(13) atom from the chromate ion. The strength of the other HB interactions varies from normal to weak. The

Symmetry transformations used to generate equivalent atoms: ^{i}, $x+1, y, z$; ^{ii}, $-x, -y+1, -z+1$; ^{iii}, $-x, -y, -z+1$; ^{iv}, $-x-1, -y, -z+1$.

hydrogen-bonding geometry in $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ is shown in Table 4. This three-dimensional network of the HBs involving the molecule of crystallization water, O atoms from the chromate moieties and the aqua ligands appears to be important for the stabilization of the crystal lattice. The small values of the anisotropic temperature factors of all atoms indicate that the structure of the $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ crystals is ordered. The refinement of the crystal structure confirmed that the $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ crystals are isostructural to $[Ni(phen)(S_2O_3)(H_2O)_3]\cdot H_2O$ [20].

3.2. UV–Vis studies

The results of the electronic spectral analysis are shown in Table 5 and in Fig. 3. As the region 20 000–50 000 cm^{-1} is well known both for chromates, dichromates [25–27] and phen [28,29] in this work we have concentrated on the low energy region 5000–20 000 cm^{-1} characteristic of the Ni(II) (d^8) d–d transitions. Moreover, $[Ni(phen)_3]^{2+}$ (**1** and **3**) complexes with the NiN_6 chromophore are also well known in the literature [30] so in this work detailed analysis of the chromate complex (**4**) has been performed.

In spite of the real symmetry (C_{2v}) of the NiN_2O_4 chromophore (**4**), it can be effectively analyzed in the tetragonal D_{4h} symmetry of the metal ion surroundings. During the deconvolution process of the 4 K single crystal $[Ni(phen)(OCrO_3)(H_2O)_3]\cdot H_2O$ spectrum (Fig. 3) it was found that the most reliable crystal field parameters were obtained with the following assumption: the first spin-allowed $^3T_{2g}$ state (O_h) splits into ^3E_g and $^3B_{2g}$, the spin-forbidden ^1E_g state splits into $^1A_{1g}$ and $^1B_{1g}$, whereas the second spin-allowed d–d transition ($^3T_{1g}$) remains unsplit (Fig. 3). Such a rather rare situation where $^3T_{1g}$ is unsplit has been described earlier in the literature [30]. If we assume the splitting of both lowest energy spin-allowed d–d bands, the calculated Racah B parameter gives the wrong result ($B > B^0$!). The

third d–d band at $\sim 27\,000$ cm^{-1} is covered under strong CT (O→Cr) bands and was not analyzed. The following crystal field parameters (in cm^{-1}) for the NiN_2O_4 chromophore have been obtained: Dq = 1063; Ds = 145; Dt = −218; B = 825.

The one extra band at approximately 14 000 cm^{-1} (Fig. 3) was assigned to the Ni–O–Cr bridge transition [15,32]. The low intensity of this band suggests that it must be multiple times forbidden, being e.g. an effect of the position of the oxygen between two metal ions and thus its 'frustration' [32].

The filtration process uncovered the vibrational fine structure of the second d–d band (Fig. 3 inset). The differences in the positions of its components (ca. 538 cm^{-1}) indicate that it can be the result of coupling between the electronic transition and the ν_s Ni–O–Cr vibration (ground state at 560 cm^{-1}). This further supports spectroscopically the presence of the bridge found from the crystal data. Both crystallographic and UV–Vis studies exhibit the symmetry of an elongated octahedral environment around the Ni(II) ion. However, the comparison of the Cr–O bond lengths (Table 3, Fig. 2) shows that the longest bond is not Cr(2)–O(14) i.e. with the oxygen atom not coordinated to Ni(II), but that forming the intramolecular hydrogen bond. Such a situation implicates a further decrease of

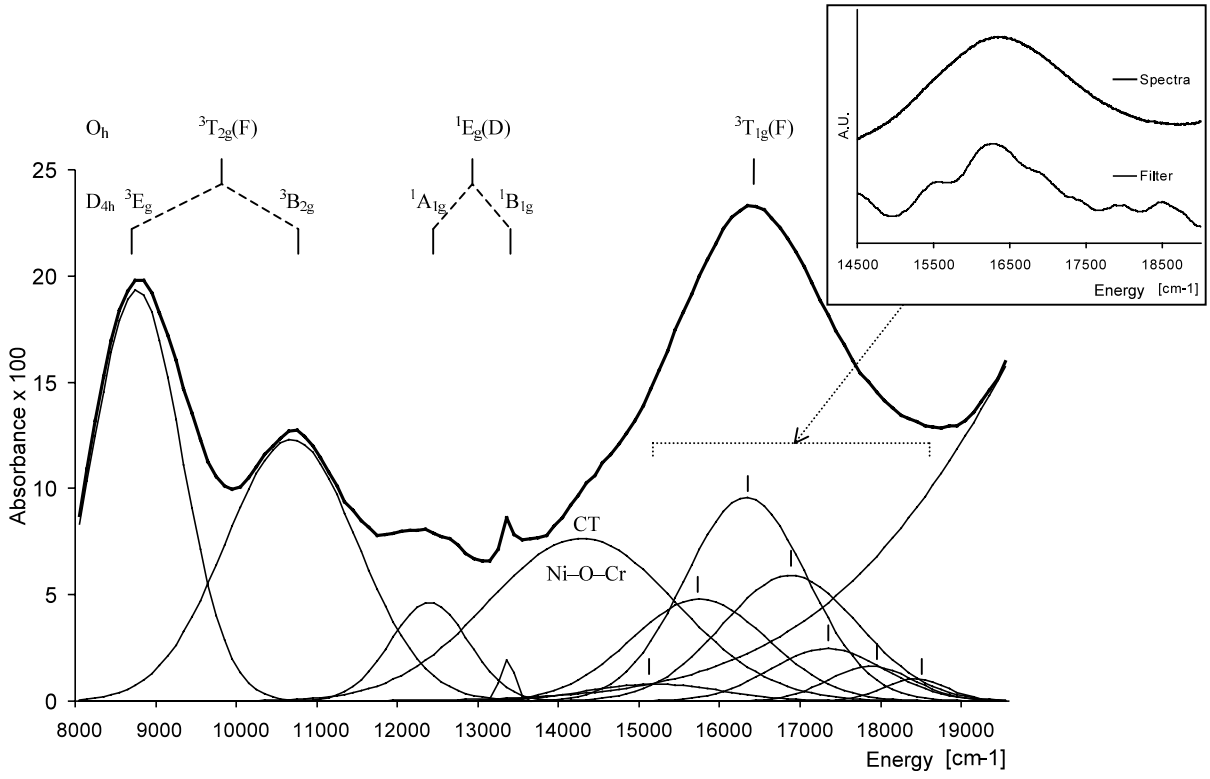

Fig. 3. The GAUSSIAN analysis of the 4 K single crystal electronic spectrum of $Ni(phen)(OCrO_3)(H_2O)_3]H_2O$ in the 8000–20 000 cm^{-1} region. Inset: the part of second d–d band ($^3A_{2g} \rightarrow {}^3T_{1g}$ transition) exhibiting vibrational fine structure as the result of filtration (filter parameters $\alpha = 200$, $N = 30$, step = 10 cm^{-1}).

the CrO_4^{2-} entity symmetry ($C_{3v} \rightarrow C_1$), which is not seen in the IR spectra. The hydrogen bonding interaction, being weaker than a coordination bond, is not able to 'disturb the C_{3v} symmetry' of the chromate to such a degree as to be seen in the IR spectroscopy. A more detailed study (better resolution of the spectra) could exhibit the competition between both types of bonding.

3.3. The precipitation of the dichromate salts from basic solutions

It is well known that Cr(VI) can exist in various oxoforms depending on acidity and chromium(VI) concentration [1–7]. Generally, at pH 8.5–9.5 the predominant species is CrO_4^{2-} and no $Cr_2O_7^{2-}$ entities should be present in a significant amount. In our experiment, among the various species existing in solution that of $[Ni(phen)_3]Cr_2O_7 \cdot 8H_2O$ must have the lowest solubility (**1**) as it is the first to precipitate. The dichromate anion is just withdrawn from the solution due to the lowest solubility of the $[Ni(phen)_3]Cr_2O_7 \cdot 8H_2O$ complex. However, underlying the importance of the solubilities of the species present in solution it would be interesting to analyze the possible influence of other factors e.g. metal ion, phen (and $Hphen^+$) on the chromate–dichromate equilibria. For example, in similar conditions the respective chromates (not dichromates) were isolated from the system [M–bpy–CrO_4] M = Ni, Co, Cu, Zn [15,31–33].

The chromium(VI) equilibria in the presence of complexes of other metal ions are evidently a rich area for further research.

4. Summary

Four Ni(II) compounds; two containing dichromate and two containing chromate species, have been precipitated in succession from basic solutions of the [Ni^{2+}–phen–CrO_4^{2-}] system. As the last of these, olive crystals of the formulae $[Ni(phen)(OCrO_3)(H_2O)_3] \cdot H_2O$ (**4**) with monodentate coordination, untypical (but not unexpected) for the chromates, have been isolated. The structure of these crystals is ordered and isostructural to $[Ni(phen)(S_2O_3)(H_2O)_3] \cdot H_2O$. The three-dimensional network of hydrogen bonds involving the $[Ni(phen)(OCrO_3)(H_2O)_3] \cdot H_2O$ molecule and aqua ligands seems to be essential for the stabilization of the crystal lattice. Monodentate coordination of the chromate group to the Ni(II) ion in these crystals was supported with vibrational and electronic spectroscopic data. The electronic spectral analysis of (**4**) exhibited a tetragonal deformation of the Ni(II) ion in the NiN_2O_4 chromophore.

The precipitation of the dichromate species from alkaline solutions can be an effect of their lowest solubility among the reagents present.

5. Supplementary material

Supplementary data are available from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition number 164162.

Received 20 November 2001; accepted 25 January 2002

Abstract

Four closely related polyamino tripodal ligands 1,3,5-tri(*n*-2′,5′-diaminohexane)-benzene (**L1**), 1,3,5-tri(*n*-2′,5′-diaminoheptane)-benzene (**L2**), 1,3,5-tri(*n*-2′,5′-diaminooctane)-benzene (**L3**) and 1,3,5-tri(*n*-2′,5′-diaminononane)-benzene (**L4**) were synthesized and characterized. Each tripodal ligand forms six protonated species in solution. The binding of these tripodal ligands to the nucleotide anions ATP, ADP and AMP are described in detail, with equilibrium constants given for each species formed. The strength of binding increases with the number of protons, corresponding to an increase in the number of hydrogen bonds and to an increase in the coulombic attractive forces. Moreover, the existence of a benzene spacer takes π-stacking interactions with the nucleobase residue of the nucleotides. At the same time, the coordination properties of the ternary complexes formed from the above tripods and Zn(II) and ATP were studied. The metal complexes of tripods recognize the nucleotides via multiple interactions that are similar to those occurring in the center of enzymes. © 2002 Elsevier Science Ltd. All rights reserved.

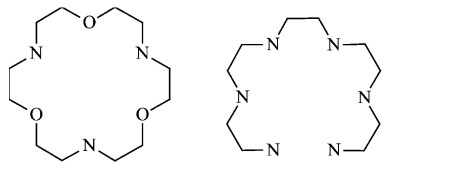
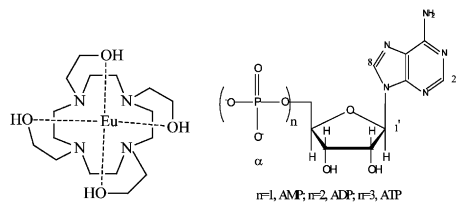
1. Introduction



Molecular catalysis represents a major feature of the functional properties of supramolecular systems [1]. In particular, the recent development of anion receptors [2], that is organic ligands which bind organic and inorganic anions, opens the way to the design of molecular catalysts capable of affecting reactions on a bound anionic substrate [3].

The nucleotide adenosine 5′-triphosphate (ATP) and its di- and monophosphate analogs (ADP and AMP, respectively) are of great importance in the life science. It is the principal biological energy store, and about one sixth of all enzyme systems need ATP or a related adenine cofactor [4]. With this fact in mind, it is not surprising that the properties of adenine nucleotides are receiving much attention. ATP is a stable polyvalent anion at neutral pH that is the substrate for a highly efficient group of enzymes termed ATPases. Of particular interest are the factors that contribute to the 10^{10}-fold difference between the uncatalyzed and the ATPase-catalyzed hydrolysis of ATP [5]. Many protonated polyaza ligands, especially polyaza macrocyclic ligands (Scheme 1, compound **1**), have been shown to bind strongly with ATP, ADP and AMP [3,6] and in some instances, are able to catalyze their hydrolysis. On the other hand, the linear pentaethylenehexamine can also produce a rate enhancement [7,8]. However, successful catalysis by polyammonium ligands relies heavily on the recognition and selectivity of the initially bound substrate and the release of the product formed following chemical transformation [7–9].



Since metal ions (for example, the Eu^{2+} complex **3** in Scheme 1) take part in the enzymatic hydrolysis of ATP, the metal-ion-promoted non-enzymatic hydrolysis has been extensively investigated [10–14]. In general, the assisted hydrolysis of polyphosphate and ATP by coordinating to a metal ion complex is affected by factors such as electron-withdrawing effects of the metal ion, strain in the chelated ring, proximity of the bound nucleophile [15], and so on. It is believed that a strong

binding strength of the catalyst with ATP is required but not necessary for ATP-hydrolysis, and the hydrolysis heavily depends on the nature of the additives, which may relate to structural factors as well as protonation at a given pH.

Although numerous studies have been performed to determine the supramolecular interactions between receptors and nucleotides, polyaza tripodal ligands, however, have been rarely investigated in this aspect. Tripodal ligands are capable of forming complexes with metal ions which exhibit unusual coordination features, high thermodynamic stability and kinetic inertness [16–19]. The tripodal ligands can form octahedral complexes by wrapping around the metal ion, leaving an open face with three arms positioned so that it can be capped by suitable reagents. Also, molecules or ionic fragments can enter the cavity and bind the metal ion and at the same time can be involved in hydrogen bonding to the 'semi-cryptand'. In this paper, we report a study of the complexes formed between polyaza tripodal ligands in their various protonated forms as well as their Zn(II) complexes with ATP, ADP and AMP. This investigation constitutes a good basis for ATP-hydrolysis and can lead to a better understanding of certain biological functions as well as to new catalysts of value in chemical synthesis.

2. Experimental

2.1. Materials

Most of the starting materials were obtained commercially and were purified prior to use. The sodium salt of ATP, ADP and AMP were purchased from Aldrich Chemical Co. The aqueous stock solutions of the nucleotides were freshly prepared daily and the exact concentrations were newly measured each time by titration with KOH. All other materials used in the experiments including the potassium hydrogen phthalate, HNO_3, KOH, and the metal ion solution of $Zn(NO_3)_2$ were prepared with redistilled water and stocked in jar bottle. The concentration of KOH used for titration was established with potassium hydrogen phthalate. The exact concentration of the stock $Zn(NO_3)_2$ solution was determined via its EDTA complex.

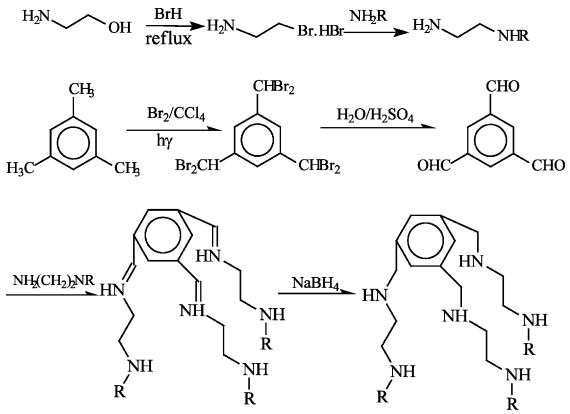
2.2. Equipments

C H N elemental analyses were made on a Perkin–Elmer 240C Analyzer (American). ^1H and ^{31}P NMR spectra were recorded on a Varian UNITY-plus 400 MHz Spectrometer. IR spectra were recorded by an Euinox 55 FT Spectrometer (Bruker). Titration was carried out with a Beckman pH Meter (model Φ71) equipped with a type 39481 combination glass electrode.

2.3. Potentiometric pH titration

Potentiometric determination was measured in a 50ml jacketed cell thermostatted at 25.0 ± 0.1 °C by a refrigerated circulating water bath. Anaerobic conditions were maintained using pre-purified N_2 as an inert atmosphere, and the ionic strength was maintained through the addition of KNO_3 to each solution to achieve $I = 0.1$ mol dm^{-3}. All the concentrations of tripod, nucleotides and metal ion are 1.0×10^{-3} mol dm^{-3}. The calibration of the glass electrode was the same as described in the literature [20]. The values of $k_\omega = 1.68 \times 10^{-14}$, $\gamma_H^+ = 0.851$ of water were used for calculations.

The protonation constants of the tripodal ligands were determined by adding KOH to the acid forms of the ligand (20.00±0.05 ml). The ligand with a concentration of 1.0×10^{-3} mol dm^{-3} was dissolved in an adequate amount of dilute HNO_3 and then was titrated with approximate 0.1 M KOH. The calculations were carried out through the curve-fitting computer program (TITFIT), which uses a Newton–Gauss–Marquardt non-linear least-squares program [21]. The final results are the averages of at least five independent titrations. For the tripodal ligand L, the pH range used in the calculation was 2.7–11, and for the three nucleotides, ATP, ADP and AMP, all pH ranges were 2.2–11.



The interactions of protonated polyammonium tripods with nucleotide anions were determined under the same conditions as used for the protonation constants. The ligand L and ATP, ADP or AMP were placed in the jacked cell and titrated using 0.1 mol dm^{-3} KOH. The stoichiometry of L:Nu (that is, ATP^{4-}, ADP^{3-}, AMP^{2-}) was 1:1 and both the concentration of L and Nu were 1.0×10^{-3} mol dm^{-3}. The pH range for calculation was 2.6–10.5. Since it has been reported [3,6] that protonated polyaza ligands can accelerate the rate of ATP hydrolysis in water solution, the titration was carried out at once after the mixing of the reactants and was finished within 15 min. The stability constants of the L–Nu systems were the result of at least six independent pairs of titrations.

The conditions for the determination of the stability constants of Zn(II)–L systems were the same as for the protonation constants, but now $Zn(NO_3)_2$ was added with the stoichiometry of Zn^{2+}:L = 1:1. At the same time, the stability constants of binary systems Zn(II)–Nu as well as the ternary systems Zn(II)–L–ATP were studied. The pH range was 2.7–10 for the two systems. The ratios of the reactants Zn(II):Nu and Zn(II):L:ATP were 1:1 and 1:1:1 (1.0×10^{-3} mol dm^{-3}), respectively. As Zn(II) promotes the dephosphorylation of nucleotides [11], both reactants were only mixed in the last minute before the titration, and this was completed within 15 min. In this way the hydrolysis of ATP was kept to a minimum. The stability constants were computed from five independent pairs of titrations for each system.

3. Results and discussions

3.1. Synthesis

2-Hydroxylethyleneamine was treated with concentrated HBr to give the product 2-bromoethyleneamine, which was reacted with the corresponding R-substituted amine RNH_2 to form N–R–en [22]. The two starting materials 1,3,5-tris-(dibromomethyl)benzene and 1,3,5-tricarboxaldehyde-benzene were synthesized according to reported processes [23]. The synthesis route of tripods is shown in Scheme 2.

Scheme 2. Route of synthesis of the new tripodal ligands.

3.1.1. Synthesis of 1,3,5-tri(n-2′,5′-diazahexane)-benzene (*L1*)

N-methyl-ethylenediamine (3.42 g, 46.2 mmol) was dissolved in ethyl alcohol (200 ml). 1,3,5-tricarboxaldehyde-Benzene (2.5 g, 15.4 mmol) dissolved in ethyl alcohol (40 ml) was added dropwise over 2 h with stirring at room temperature. After the addition was completed, the suspension was stirred for further 12 h at 35 °C and then filtered. $NaBH_4$ was added in small quantities and the mixture reacted for 6 h. The solvent was removed under reduced pressure, leaving a white residue, NH_4HCO_3 (4 g) in 10 ml water was then added to the white residue. The aqueous mixture was extracted with chloroform (4 × 100 ml). The organic fractions were combined, washed with distilled water (3 × 20 ml), and then dried over $MgSO_4$. The solution was filtered and the chloroform was removed on a rotary evaporator to give a yellow oil 2.06 g, yield 41.1%. ^{1}H NMR ($CDCl_3$): δ 7.18 (s, 3H, C_6H_3); δ 3.80 (s, 6H, CH_2-ph); δ 2.50–2.80 (t, 12H, NCH_2–CH_2N); δ 2.18 (s, 9H, CH_3–N). IR (KBr pellet): 1161(ν_{C-N}); 2945(ν_{CH_3}); 865, 456, 1595(Ar); 2845(ν_{CH_2}). Elemental analysis: Calc. for $C_{18}H_{36}N_6$: C, 59.06; H, 7.12; N, 21.35. Found: C, 58.93; H, 7.36; N, 21.35%.

3.1.2. Synthesis of 1,3,5-tri(n-2′,5′-diazaheptane)-benzene (*L2*)

N-ethyl-ethylenediamine (4.10 g, 46.2 mmol) and 1,3,5-tricarboxaldehyde-benzene (2.5 g, 15.4 mmol) were reacted to give **L2** as a oil of 2.21 g, yield 38.0%. The oil was dissolved in alcohol and then hydro bromide was added. The white–yellow precipitate formed was collected and dried on P_2O_5. ^{1}H NMR (D_2O): δ 7.18 (s, 3H, C_6H_3); δ 3.85 (s, 6H, CH_2-ph); δ 2.50–2.80 (t, 12H, NCH_2CH_2N); δ 2.00 (s, 6H, N–CH_2–C); δ 1.15 (t, 9H,

CH_3–C–N). IR (KBr pellet): 1044(ν_{C-N}); 717(δ_{C-C}); 865, 1452, 1595(Ar). Elemental analysis: Calc. for $C_{21}H_{43}N_6 \cdot 6HBr$: C, 55.35; H, 7.38; N, 9.68. Found: C, 55.64; H, 7.05; N: 9.66%.

3.1.3. Synthesis of 1,3,5-tri(n-2′,5′-diazaoctane)-benzene (*L3*)

N-*n*-propyl-ethylenediamine (4.6 g, 45.0 mmol) and 1,3,5-tricarboxaldehyde-benzene (2.5 g, 15.4 mmol) were reacted to give **L3** 3.37 g, yield 51.9%. ^{1}H NMR (D_2O): δ 7.15 (s, 3H, C_6H_3); δ 3.75 (s, 6H, CH_2-ph); δ 2.50–2.80 (t, 12H, NCH_2–CH_2N); δ 1.45 (t, 6H, N–CH_2–C–C); δ 0.95 (m, 15H, CH_3–C–C–). IR (KBr pellet): 1164(ν_{C-N}); 2957(ν_{CH_3}); 863, 1458, 1590(Ar); 2872 (ν_{CH_2}). Elemental analysis: Calc. for $C_{24}H_{49}N_6$: C, 50.56; H, 8.10; N, 10.72. Found: C, 50.84; H, 8.03; N, 10.57%.

3.1.4. Synthesis of 1,3,5-tri(n-2′,5′-diazanonane)-benzene (*L4*)

N-*n*-butyl-ethylenediamine (5.48 g, 47.3 mmol) and 1,3,5-tricarboxaldehyde-benzene (2.5 g, 15.4 mmol) were reacted to give **L4** 3.03 g, yield 42.5%. ^{1}H NMR (D_2O): δ 7.55–7.80 (d, 3H, C_6H_3); δ 4.45 (s, 6H, CH_2-ph); δ 3.38–3.85 (t, 12H, NCH_2CH_2N); δ 3.15 (t, 6H, NCH_2–C–C–C); δ 1.75 (m, 6H, N–C–CH_2–C–C); δ 1.40 (m, 6H, N–C–C–CH_2–C); δ 0.95 (t, 9H, CH_3–). IR (KBr pellet): 1114(ν_{C-N}); 2961(ν_{CH_3}); 862, 1462, 1590(Ar). Elemental analysis: Calc. for $C_{27}H_{55}N_6 \cdot 6HCl$: C, 51.57; H, 8.26; N, 10.59. Found: C, 51.46; H, 8.26; N, 10.44%.

3.2. Protonation of the ligands

The ligands synthesized in the present work consist of a hexaaza tripod with six secondary amino nitrogen atoms, so they are able to bear six protons at the most. The tripods differ from one another in the following respects: (a) the N-substituents and the length of the arms; (b) the size of the 'semi-cavity' formed by the arms of these tripods. The decimal logarithms of stepwise protonation constants of the ligands resulted from potentiometric pH titration are listed in Table 1. The titration curve and the species percentage distribution diagram of **L1** are shown in Fig. 1(a) and (b), respectively. The titration and distribution diagrams of the other three ligands are similar to those of **L1** shown in Fig. 1.

As seen from Fig. 1(a), there are no significant inflection points in the titration curves. In general, the inflection points are only seen when pK_a values are well separated; otherwise the buffering means that only small changes in slope are observed. This indicates that all the six amino nitrogen atoms are considered to be moderately strong bases.

Both basicity and steric effects may play important roles in the protonation process of the ligands. By comparison with the benzylic amino groups, the terminal ones have a smaller space hindrance for proton attraction as well as stronger basicity due to the electron-pushing effect of aliphatic substituents, which is contrary to the electron-withdrawing effect of π-benzene to the former via a methylene group. Thus, the first three protonation constants belong to the terminal amino groups while the others involve the benzylic amino groups. As shown in Table 1, the protonation constants of the first three amino groups of **L1**, **L2** and **L3** are higher than 9.50 while the last three amino groups behave as weaker bases than the former. It is an exception that the first two amino nitrogen atoms of **4** are more basic than the others.

A comparison of the data listed in Table 1 shows the order of **L1** > **L3** > **L2** > **L4** for the first, fourth and fifth protonation constants. Thus, the biggest protonation constant of **L1** indicates that steric effects do play a main role in the first protonation process, in spite of the weakest electrostatic effects of its N-substituent among the four ligands. However, all the smaller values of 5.19–6.01 for the sixth protonation constants respond to cumulative electrostatic repulsion effects.

In conclusion, these protonation features make **L1**–**L4** promising receptors for nucleotides anions. As seen from the species distribution diagram (Fig. 1(b)), the most significant tetraprotic species H_4L^{4+} exists in the wide pH range of 4–10 with its maximum concentration at pH ~ 7.5. Therefore, these polyprotic species at neutral pH containing a polyammonium chain are potential binding sites for the anionic phosphate moiety of nucleotides. Moreover, the benzene unit may give π-stacking interactions with the nucleobase residue.

Table 1
The stepwise protonation constants for the tripodal ligands

Equilibria	L1	L2	L3	L4
$[(LH)^+]/[L][H^+]$	10.98 ± 0.06	10.45 ± 0.02	10.70 ± 0.06	10.34 ± 0.08

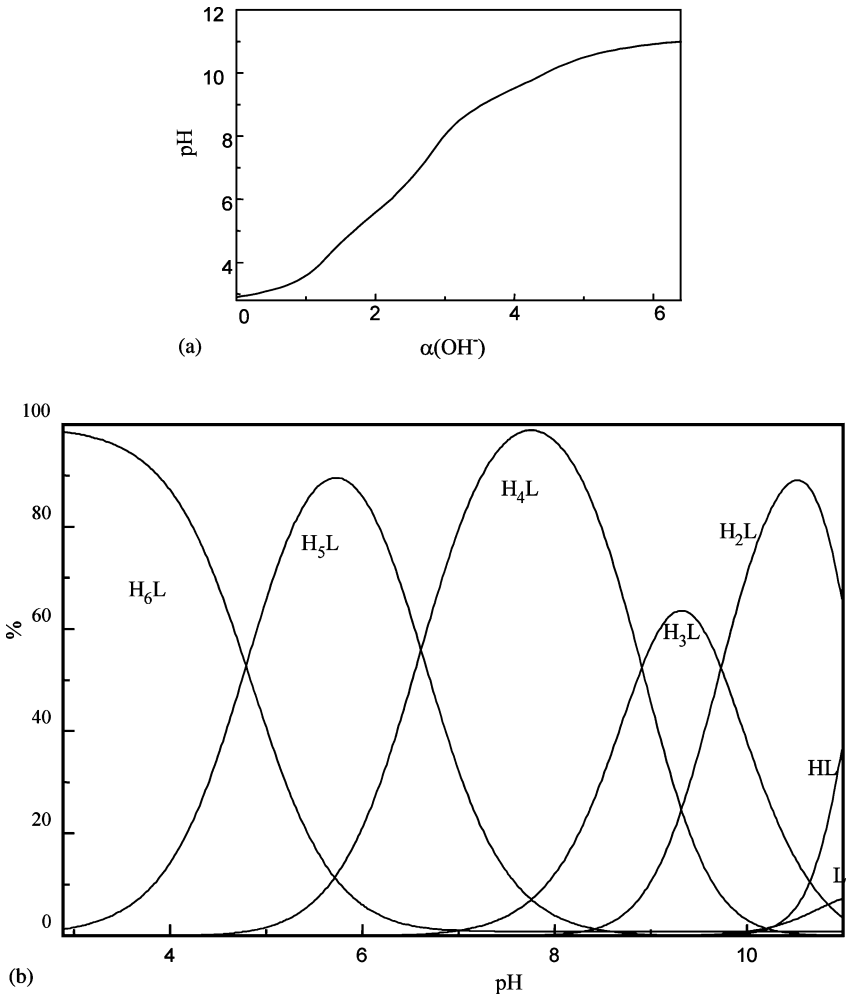

Fig. 1. (a) Titration curve of **L1**–H^+ system, 25.0±0.1 °C, $I = 0.1$ mol dm^{-3} KNO_3, [L] = 1×10^{-3} mol dm^{-3}. (b) Species percentage distribution diagrams of protonated **L1** as a function of pH, 25.0±0.1 °C, $I = 0.1$ mol dm^{-3} KNO_3, [L] = 1×10^{-3} mol dm^{-3}.

3.3. Binding strength between tripods and nucleotides

The protonation constants for nucleotides involved in this study are shown in Table 2. The corresponding values found for ATP, ADP and AMP are consistent with those reported in the literature [24].

Table 2
The stepwise protonation constants for Nu (Nu = AMP, ADP and ATP) and the stepwise stability constants of their Zn^{2+} complexes

Nu	H^+				Zn(II)	
	Literature [a]		Measured		ZnNu [a]	ZnNuH [a]
	HNu	H_2Nu	HNu	H_2Nu		
ATP	6.50	4.02	6.59	4.12	5.16	4.16
ADP	6.36	3.95	6.45	4.01	4.18	
AMP	6.21	3.80	6.27	3.95	2.38	

The protonation constants determined were almost the same as the reported values, and the stability constants were directly used as cited in literature [24].

[a] See reference [24], 25 °C, 0.10 mol dm^{-3} K^+.

Protonation of the receptors gives charged species, for example polyammonium, which can bind a single inorganic phosphate, such as orthophosphate, pyrophosphate and triphosphate as well as nucleotides, such as AMP, ADP and ATP in aqueous solution [3,6,15,25,26]. The interactions of protonated polyammonium ligands with the nucleotides anions have been determined by potentiometric pH titration and the biding strength are listed in Tables 3–5. The percentage distribution diagrams of **L1**–**L4**–ATP are shown in Fig. 2. The binding strengths mean the $-\log K$ value of equilibrium (1), which is obtained from equilibria (2), (3) and (4). The equilibria (2), (3) and (4) stand for the overall stability constants of species $[LATPH_{(m+n)}]^{m+n-4}$, the overall protonation constant of LH_m^{m+} and the overall protonation constant of H_nATP^{4-n}, respectively.

$$LH_m^{m+} + H_nATP^{4-n} = [LATPH_{(m+n)}]^{m+n-4} \quad (1)$$

$$(m+n)H^+ + L + ATP^{4-} = [LATPH_{(m+n)}]^{m+n-4} \quad (2)$$

$$mH^+ + L = LH_m^{m+} \quad (3)$$

$$nH^+ + ATP^{4-} = H_nATP^{n-4} \quad (4)$$

The data in Tables 3–5 show an increase in the binding strength with the number of protons on the hexaaza tripodal ligands increasing to a maximum of six, corresponding to the maximum number of hydrogen bonds between the host and guest. In the systems of L (**L1**–**L4**)–ATP and **L3**–ADP the number of protons reaches a maximum of seven. Thus, when the number of protonated amino nitrogen atoms increases upto six, it can be seen from Tables 3–5 that the stepwise equilibrium constants increase as the number of hydrogen bonds as well as the coulombic attraction between the host and guest increase. However, any further increase in the number of protons of complex H_6LATP (Table 3) or H_6(**L3**)–ADP (Table 4) causes a decrease in the binding constants. This is because under this condition, the additional proton must attach to the guest, decreasing its charge (and thus decreasing the coulombic attraction to the host) and the number of oxygen atoms in the guest that can be hydrogen bound to the host.

It is interesting to discuss the possible structure of the supramolecular binary species as illustrated in Scheme 3. The number of H-bonds of the adducts is shown as equal to or higher than the number of protons present in the complexes, since the H-bonds cannot only form the type NH···O, but also the types NH···N, OH···O and OH···N. As shown in Scheme 3, the non-ligating behavior of α-phosphate of ATP is tested by ^{31}P NMR spectra, which show significant upfield shifts of the chemical resonances of β- and γ-phosphate but only a slight shift of α-phosphate. For example, the ^{31}P signals of α-, β- and γ-phosphate of ATP in the presence of **L2** at pH 7.6 shift upfield by −0.01, 0.78 and 0.17 ppm, respectively. On the other hand, the ^1H NMR spectra reveal that in the **L2**–ATP system H-8, H-2, H-1′ of ATP as well as protons on benzene and the benzylic protons of L shift upfield when compared with free ATP and L at pH 7.6, which indicates that the existence of the benzene ring leads to π-stacking interactions with the nucleobase residue of nucleotides.

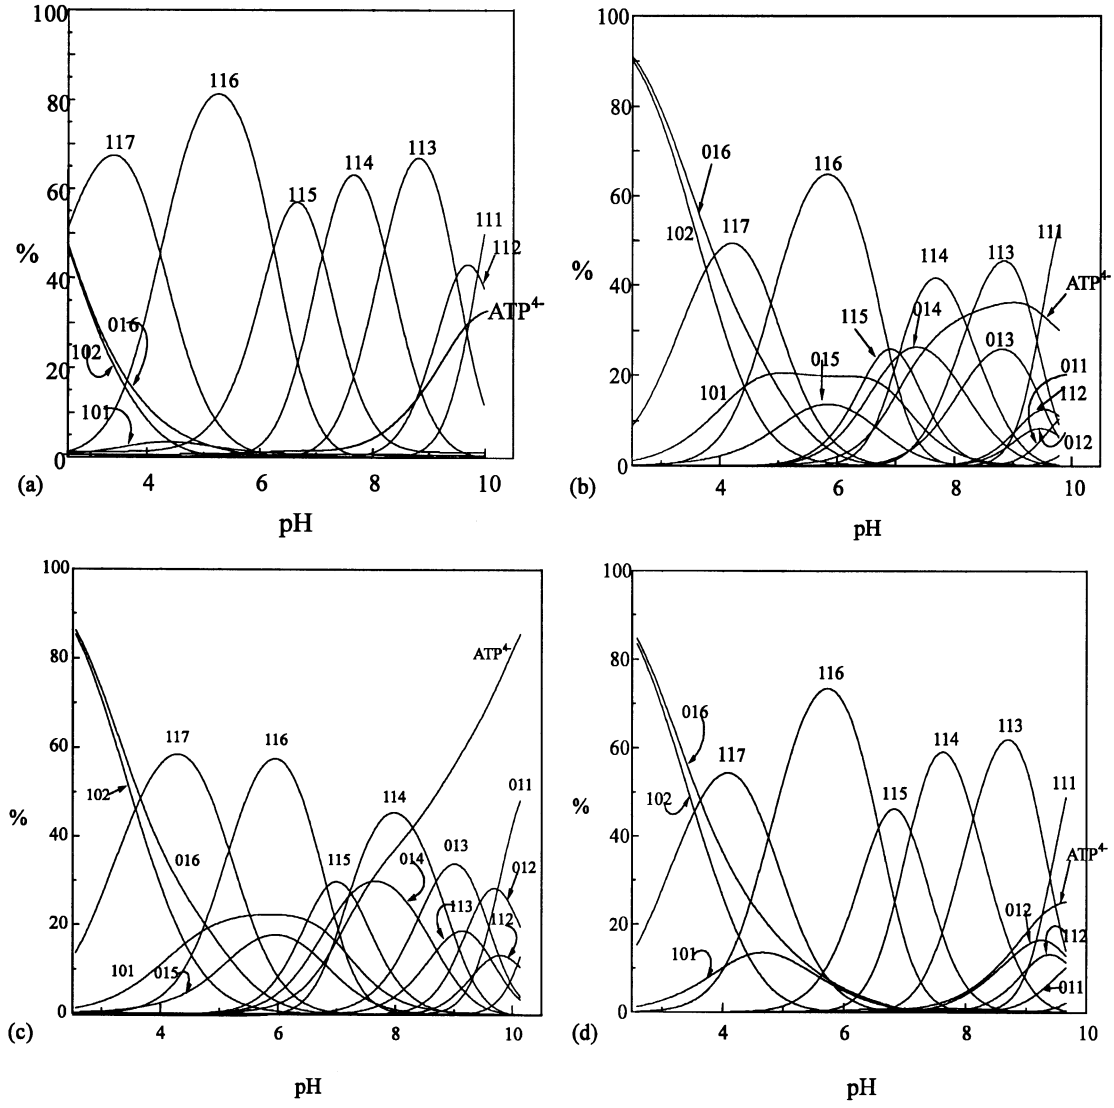
Both the concentration of Am (Am = AMP) and L are 1×10^{-3} mol dm^{-3}. The symbol 116 is representative for $AMPLH_6^{4+}$.

By examining the different values of binding constants, several main features can be readily noted. (1) The present results demonstrate the ability of polyammonium to strongly bind nucleotides, giving a variety of complex species. As seen from Fig. 2, the receptor-substrate adducts mainly form at weakly alkaline to



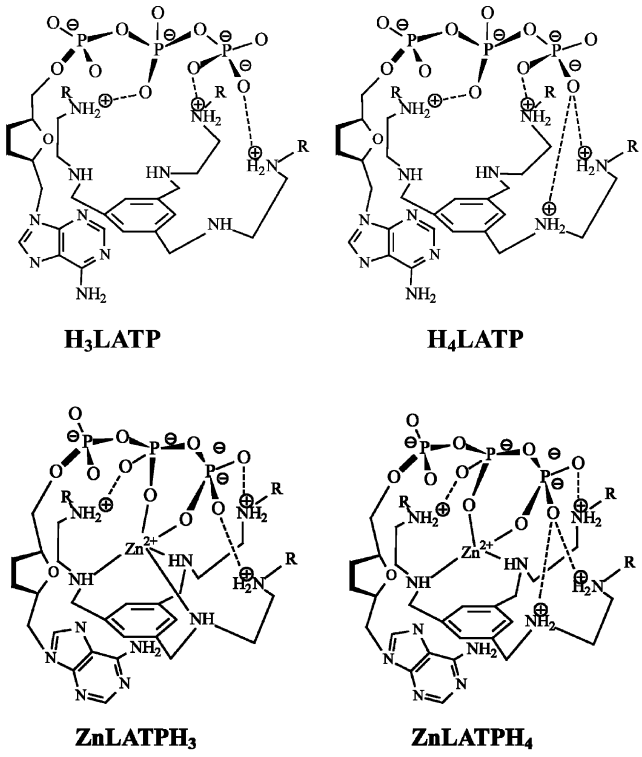


Fig. 2. Distribution diagrams for the species present in solution for the system ATP–L of (a) ATP–**L1** and of (b) ATP–**L2** and of (c) ATP–**L3** and of (d) ATP–**L4**. The secondary species are ATPLH, $ATPLH_2$, $ATPLH_3$, $ATPLH_4$, $ATPLH_5$, $ATPLH_6$ and $ATPLH_7$. The charge of complexes is omitted. The symbols for instance 117 are representative for species $ATPLH_7^{3+}$, (1×10^{-3} mol dm^{-3} L: 1×10^{-3} mol dm^{-3} ATP in water at 25 °C and $I = 0.1$ mol dm^{-3} KNO_3).

Scheme 3. Possible spuramolecular structure species H_3LATP, H_4LATP, $ZnLATPH_3$ and $ZnLATPH_4$.

slightly acidic pH values where the ligands are protonated as shown in Fig. 1(b). It is fairly reasonable to say that there is no interaction when the pH raises above 11. (2) Based on electrostatic predications, more stable complexes are expected to form between the most charged species. (3) For a given ligand, the adducts in the more highly protonated forms are more likely to involve the protonation of the anions, HNu (101 in Fig. 2) and H_2Nu (102 in Fig. 2) which exist at low pH values. With regard to the species H_7LATP^{3+}, at least one proton is located at a phosphate group of the nucleotide since the tripods can bear six protons at the most. On the other hand, the first protonation constant of ATP (6.59) is larger than the sixth protonation constants (5.30–5.89) or even some fifth protonation constants of L, leading to the existence of $HATP^{3-}$ and H_2ATP^{2-} (see Fig. 2, species 101 and 102). However, neutralization of the substrate would decrease the number of H-bonds as well as the electrostatic interactions and then the stability.

The magnitudes of the binding strength between the polyammonium tripodal ligands and the substrates ATP, ADP and AMP increase in the order ATP > ADP > AMP, as one would expect from corresponding decreases in the length of phosphate chain and as a consequence of the hydrogen bonding and coulombic forces. Thus, the recognition of nucleotides by polyammonium ligands via multiple interactions relies on the length of phosphate chain and the charge of substrates. According to the stability constants shown in Tables 3 and 4, the catalytic conversion of ATP → ADP in the presence of protonated polyammonium tripods is reasonable. The product of the reaction, ADP, is less strongly bound than ATP due to its shorter phosphate backbone and the lower negative charge, facilitating the regeneration of the next catalytic cycle.

3.4. Stability constants of metal complexes

The stability constants of Zn^{2+} metal complexes of **L1**–**L4** are given in Table 6. The species distribution diagram of Zn(II)–**L1** (Fig. 3) shows that the mononuclear Zn^{2+} complex ZnL begins to form when pH > 8. The other complexes, $ZnLH^{3+}$, $ZnLH_2^{4+}$, $ZnLH_3^{5+}$ and $ZnLH_4^{6+}$ form stepwisely as pH increase, and reach a maximum at pH around 9, 7.5, 6.5 and 5, respectively. The major species $ZnLH_4^{6+}$ containing four protons exists at pH 4–7 with maximum concentration at pH 5.0, but $ZnLH_4^{6+}$ has low concentration when pH < 5 where the ligand **L1** is mainly in its hexa- or penta-protic forms. Both the species $ZnLH^{3+}$ and $ZnLH_2^{2+}$ are predominant in the pH range 6–8 and their maximum amount are higher than 70%. It is worth noting that $ZnLH_2^{4+}$ gets to its maximum concentration (> 80%) at pH 7.5, the most ideal pH value for bioactivity.

Since the tripodal ligand acts as a three-dimensional receptor, various kinds of its metal complexes would probably coexist in solution. It is also difficult to discern which atoms take part in the coordination as well as the number of the donor atoms in a specific coordination, because the formation of complexes is also controlled by the pH of the solution. We have supposed the configurations for each binary species formed. Tripod L may coordinate with Zn^{2+} through all its six amino groups to form the species ZnL in a distorted octahedral fashion. When protonated, the hydrogen ion is believed to locate at the two amino nitrogen atoms of one arm through an H-bridge. Successively, the H-bridge may be broken down by the attack of the second proton with the formation of the species $ZnLH_2^{4+}$. The protonation pattern for $ZnLH_3^{5+}$ and $ZnLH_4^{6+}$ follow the same pattern. The metal complexes cannot hold five protons since if this occurs the Zn^{2+} will be replaced by H^+ completely. Although all these instances may exist in solution, it is notable that metal ion and tripod prefer to form mononuclear complexes when in a 1:1 ratio, which has been verified by the pH titration measurements.

3.5. Zn(II)–nucleotide interactions

Zn(II) ion has some tendency to bind the polyphosphate of nucleotides. On the other hand, the adenine residue offers metal ions N-1, occasionally N-3, and N-7 as binding sites. Consequently for adenosine this leaves a dichotomy in metal ion binding of N-1 versus N-7 [27].

Table 6
The stability constants of complexes formed by L in the presence of 1:1 Zn^{2-} (25 °C, $I = 0.1$ mol dm^{-3} KNO_3, $C_L = C_{Zn} = 1 \times 10^{-3}$ mol dm^{-3})

Equilibria	L1	L2	L3	L4
$Zn + L + 4H = ZnLH_4$	39.32 ± 0.06	40.03 ± 0.06	40.52 ± 0.02	41.10 ± 0.05
$Zn + L + 3H = ZnLH_3$	34.10 ± 0.07	32.39 ± 0.07	33.18 ± 0.05	35.34 ± 0.04
$Zn + L + 3H = ZnLH_2$	27.42 ± 0.08	25.07 ± 0.04	25.61 ± 0.06	27.23 ± 0.02
$Zn + L + H = ZnLH$	19.18 ± 0.10	17.82 ± 0.05	17.01 ± 0.09	18.40 ± 0.03
$Zn + L = ZnL$	9.85 ± 0.06	8.62 ± 0.03	8.61 ± 0.08	8.43 ± 0.06

The charge of the complexes and hydrogen ions are not given.

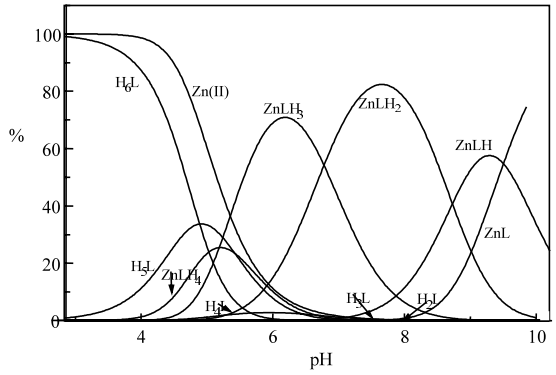

Fig. 3. Distribution diagrams for the species present in solution of Zn(II)–L system. The charge of complexes is omitted for clarification, (1×10^{-3} mol dm^{-3} Zn(II): 1×10^{-3} mol dm^{-3} L in water at 25 °C and $I = 0.1$ mol dm^{-3} KNO_3).

Recently, it has been believed that N-7 of purine chelates the zinc ion when the pH is around 7–9 [28] and N-1–Zn^{2+} binding interaction is reasonable at higher pH values [29]. Mao Xi-an et al. also reported that N1 is the dominant binding site of Zn^{2+} between pH 2 and 5, while takes favors binding with N-7 between pH 5 and 7 [30].

Another feature of metal-nucleotides interactions is the open-macrochelate isomeric equilibrium since N-7 is orientated towards the phosphate group in the dominating anti-conformation of ATP, but N-7 is a weak coordinate point in macrochelate formation. Indeed, the release of N-7 upon mixed ligand complex formation in solution has been demonstrated with different ligands [31]. The stability constants of Zn(II) complexes with nucleotides (AMP, ADP and ATP) are listed in Table 2, which are consistent with literature values [24].

3.6. Interactions of metal complexes and ATP

The binding constants of Zn(II) complexes of L with ATP are listed in Table 7. The ternary species distribution curves of Zn(II)–**L1**–ATP and Zn(II)–**L4**–ATP are shown in Figs. 4 and 5, respectively. The binding strength means the stability constants of equilibrium (5), which is obtained from equilibria (6), (7) and (4),

$$ZnLH_l^{l+2} + H_nATP^{n-4} = [ZnLATPH_{(l+n)}]^{l+n-2} \quad (5)$$

$$Zn^{2+} + (l+n)H^+ + L + ATP^{4-} = [ZnLATPH_{(l+n)}]^{l+n-2} \quad (6)$$

$$Zn^{2+} + lH^+ + L = ZnLH_l^{l+2} \quad (7)$$

Apparently, considerable interactions took place when the nucleotide was introduced to the 1:1 M:L systems. It is interesting to note that the presence of nucleotide stabilizes the ternary system so that species involving up to six protons ($ZnLATPH_6$) can stably form. However, it is reasonable that the additional protons of ZnH_4L to ZnH_5LATP and ZnH_6LATP, bind to the anions. The nucleotides can offer additional coordination sites to the metal ion and thus increase the stability of the ternary complexes.

The tripodal ligand can incorporate a metal ion with two amino groups in the case that the metal ion is also coordinated with the substrate, and thus in turn may form up to four hydrogen bonds between the oxygen atoms of the phosphate chain of ATP and the polyammonium groups of the tripod. Such binding, involving a coordination bond and hydrogen bonds as well as electrostatic interactions, can bind the nucleotide anion quite strongly. For the mononuclear complex $ZnLATPH_2$ (Fig. 4), which is due primarily to coordination bonding of Zn(II) to the tripodal ligand, the stability steadily increases with protonation up to $ZnLATPH_4$ with four hydrogen bonds. Further protonation cause a decrease in stability and the more stable species are found when the polyphosphate groups of the nucleotides are not protonated. The addition of protons beyond this point weakens the hydrogen bonding as well as lowers the charge and hence the coulombic forces.

The distribution diagrams Figs. 4 and 5 show five detected species containing nucleotide bound to coordinated M(II) and/or protonated amino groups. There are four ternary major species in the 1:1:1 systems, namely $ZnLATPH_6$, $ZnLATPH_4$, $ZnLATPH_3$ and $ZnLATPH_2$ (the charge is not given) as well as the species $ZnLATPH_5$ that is in a small amount in Zn(II)–**L1**–ATP and Zn(II)–**L4**–ATP systems. As shown in Fig. 4, the ternary species containing L1 form in a pH range 4–10. When pH < 4, the species H_6L^{6+} and H_2ATP^{2-}

All the concentrations of Zn(II), At (At = ATP) and L are 1×10^{-3} mol dm^{-3}. The symbol 1116 is representative for species $ZnLATPH_6^{4+}$.

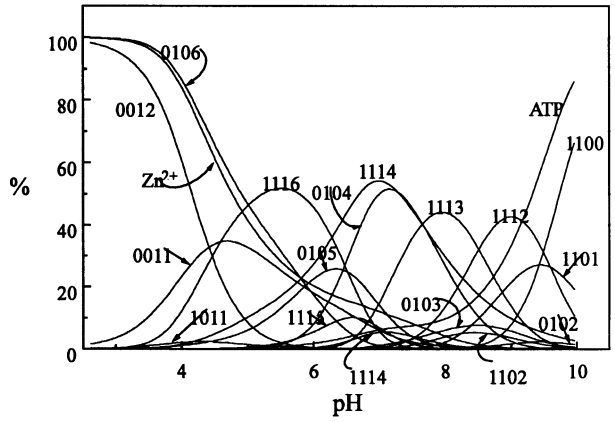

Fig. 4. Percentage distribution diagrams for species present in 1:1:1 Zn(II):**L1**:ATP system. The symbols (for example 1116) are representative for species $ZnLATPH_6^{4+}$, (1×10^{-3} mol dm^{-3} Zn^{2+}, 1×10^{-3} mol dm^{-3} L: 1×10^{-3} mol dm^{-3} ATP in water at 25 °C and $I = 0.1$ mol dm^{-3} KNO_3).

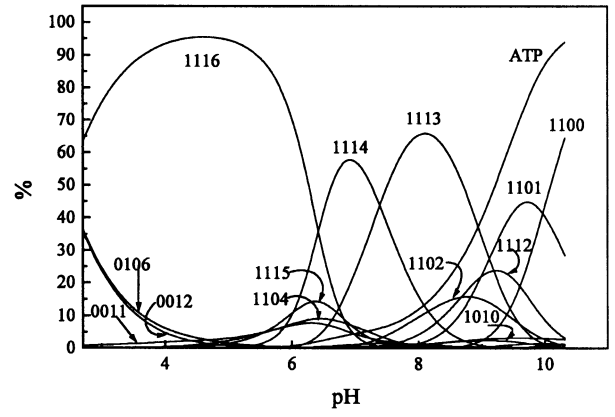

Fig. 5. Percentage distribution diagrams for species present 1:1:1 Zn(II):**L4**:ATP system. The symbols (for example 1116) are representative for species $ZnATPLH_6^{2+}$, (1×10^{-3} mol dm^{-3} Zn^{2+}, 1×10^{-3} mol dm^{-3} L4, 1×10^{-3} mol dm^{-3} ATP in water at 25 °C and $I = 0.1$ mol dm^{-3} KNO_3).

coexist and dominate. In Fig. 5, the species $ZnLATPH_6$ is the major compound from pH 3 to 7 with its maximum at pH about 4–6. In addition, the other ternary species form at a similar pH range in the two systems except for the higher percentage concentration of Zn(II)–**L4**–ATP complexes. Comparing Fig. 4 with Fig. 5, a reasonable conclusion can be drawn that the behavior of the two systems are similar in basic and slightly acidic solution while it is only different at pH below 6.

Due to the different affinity of Zn(II) to oxygen atoms or nitrogen atoms, there exists competitive reaction between the mixed ligands, tripod and nucleotide. The nucleotide acts as a subordinative receptor at higher pH values because of its lower basicity (6.59) compared with that of L. Thus, the polyaza tripodal ligands control the coordination there, which was attested with the results of NMR experiments. For example, at pH 7.6 in the Zn(II)–**L2**–ATP and Zn(II)–ATP systems phosphate signals of α, β and γ-sites of ATP are −0.13, 1.21 and 0.45 ppm for the former, or 0.35, 2.55 and 1.03 ppm for the latter. It is evident that the stronger coordination of L to Zn(II) makes the electron density of the metal ion flux to the amino groups and then decreases the ability for Zn(II) to attract phosphate groups of the substrate. On the other hand, ^1H signals of H-8, H-2 and H-1′ of ATP, as well as protons on benzene and benzylic protons in Zn(II)–L2–ATP are shifted by −0.30, −0.26, −0.32, −0.32 and −0.35 ppm, respectively, while Zn(II) causes the ^1H signals of H-8, H-2 and H-1′ to shift by −0.17, −0.14 and −0.13 ppm, respectively. Comparing ^1H signals of Zn(II)–**L2**–ATP with the corresponding values of **L2**–ATP, −0.45, −0.42, −0.50, −0.40, −0.45 ppm, the downfield shifts of ^1H signals indicate that the bridge of the Zn(II) ion decreases the stacking interactions between benzene and the nucleobase residue. The structures of ternary systems $ZnLATPH_3$ and $ZnLATPH_4$ are drawn in Scheme 3.

From Table 7 we can see that ATP coordinates with Zn(II) complexes of **L1**–**L4** with different binding strength for species with the same stoichiometry. So the nucleotide recognizes the receptors with different size via multiple interactions. For example, at physiological pH values, the coexisted species $ZnLATPH_3$ and $ZnLATPH_4$ have the order of **L1** ~ **L2** > **L3** ≫ **L4** and **L1** > **L2** ~ **L3** > **L4** for binding strength, respectively.

The addition of metal ion to L–Nu systems not only increases the stability of the ternary systems, but also makes competition for L and the substrate to coordinate with Zn(II). Therefore, the action of metal ion can be considered as a 'messenger' between the receptor and the substrate.

3.7. Conclusion

In this paper we primarily investigated the interaction of four polyaza tripodal ligands as well as their Zn(II) complexes with the nucleotides ATP, ADP and AMP. The protonated tripodal ligands can bind anions through hydrogen bonding, and because they are positively charged, through additional coulombic forces. This kind of interaction has been thoroughly explored by Lehn and coworkers [2,3,7,25] for the binding of nucleotides to protonated forms of macrocycle. On the other hand, the existence of aromatic benzene rings makes an additional contribution to the binding strength through π-stacking interactions with the adenosine and/or the ribose of nucleotides. The increased stability of ternary complexes is believed to be caused by substrates, which coordinate to a metal ion complex through such factors as electron-withdrawing effect of the metal ion, strain in the chelated ring and proximity of the bridged receptor/substrate. The results obtained in this study give a quantitative assessment of the different factors governing the receptor-substrate binding interactions. Furthermore, this study extends the coordination chemistry of ions to a class of anionic substrates, which play a fundamental role in the bioenergetics of living organisms.

Abstract

The reaction of bulky ligand precursor 2,2′-methylenebis(4-methyl-6-*tert*-butylphenol) (H_2mbp) or 2,2′-ethylidenebis(4,6-di-*tert*-butylphenol) (H_2ebp) with trisdiolatotungsten(VI) complex [W(eg)$_3$] **1** (eg = ethanediolate dianion) provides heteroleptic complexes [W(mbp)(eg)$_2$] **2** or [W(ebp)(eg)$_2$] **3**, respectively. Sterically less hindered 2,2′-dihydroxy-1,1′-dinaphtylmethane (H_2dinap) forms heteroleptic disubstituted complex [W(dinap)$_2$(eg)] **4**. The X-ray crystal structure determinations confirmed that the isolated compounds are made of monomeric tris(diolato)tungsten(VI) molecules in which the central tungsten atom is bonded to six oxygen atoms forming a distorted octahedral coordination sphere around the metal ion. Complexes **2** and **3** catalyse the ring opening metathesis reaction of norbornene when activated by Et_2AlCl. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

Chelating oxygen donor ligands, e.g. binaphthols and biphenols have confirmed to be useful accessories in organic syntheses with early transition metals [1]. The hard Lewis-base character of the phenoxide group makes these compounds ideal for attaching to the metal ions having high oxidation states (hard Lewis-acids). Sterically hindered auxiliary groups on the bis(phenolato) ligands allow the degree of shielding to be tuned without significantly altering the electronic properties of the ligands. Furthermore, the influence of the number of atoms between the phenoxide oxygen atoms in such ligands to the coordination geometry of metal can be also modified. 1,1′-coupled biphenolates and binaphtholates of W(VI), often with other ligands, have been used successfully as catalyst precursors in olefin metathesis reactions [2]. However, reports on tungsten complexes with bridged bis(phenolate)s are scarce. Heppert's group has reported preparation and spectral characterisation of tungsten(VI) complexes [W(=X)Cl$_2$(mmp)] and [W(=X)Cl$_2$(ebp)] [X=O, NPh-2,6-Me$_2$; H_2mmp = 2,2′-methylenebis(4,6-dimethylphenol); H_2ebp = 2,2′-ethylidenebis(4,6-di-*tert*-butylphenol)] [3]. Nakamura's group has studied complexes of sulfur-bridged bis(phenol), and has characterised several crystal structures, e.g. [W(η^2-EtC≡CEt)(tbp)Cl$_2$] (H_2tbp = 2,2′-thiobis(4,6-dimethylphenol) [4]. In the context of a broader program aimed at developing transition metal catalysts for olefin metathesis reaction, our laboratory has recently become interested in the chemical manipulation of tungsten aryloxide complexes [2b,5]. Our long-term goal is to prepare polymer-based tungsten(VI) phenoxides and use them as recoverable catalyst precursors. To gain a greater degree of understanding this chemistry, we have now prepared three new monomeric tungsten(VI) complexes with bis(phenolato) ligands and used them as catalyst precursors for ring opening metathesis polymerisation of norbornene.

2. Results and discussion

2.1. Synthesis and spectroscopy of the complexes

The addition of 1 equiv. of the ligand precursors 2,2′-methylenebis(4-methyl-6-*tert*-butylphenol) (H_2mbp) or H_2ebp to the refluxing toluene solution of [W(eg)$_3$] **1** (H_2eg = 1,2-ethanediol) leads to the formation of the heteroleptic, monomeric compounds **2** and **3**, respectively (Scheme 1). The red solid products can be purified by crystallisation or by column chromatography to obtain air stable complexes in high yields. They are soluble in chlorinated hydrocarbons, ethers and aromatic solvents but only slightly soluble in hexane. Bulky *tert*-butyl groups in *ortho*-positions of phenoxide moieties seems to prevent further substitution of eg ligands as the use of excess bis(phenol) do not result in complexes of type [W(biphenolate)$_2$(eg)]. However, 2 equiv. of sterically less hindered 2,2′-dihydroxy-1,1′-dinaphtylmethane (H_2dinap) reacts with 1 equiv. of **1** in toluene at reflux temperature to form heteroleptic complex [W(dinap)$_2$(eg)] (**4**) (Scheme 2). This intense red coloured compound is slightly soluble in toluene and chlorinated solvents and it is stable enough to be purified by column chromatography. Unfortunately, **4** was not soluble enough to be used in our catalyst tests (see below).

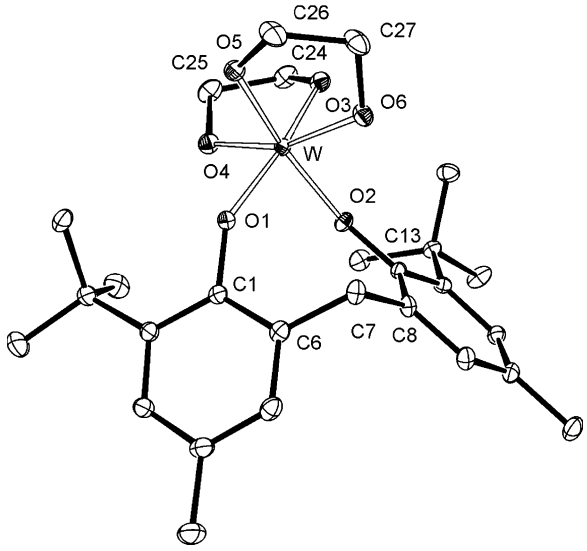
Earlier studies on transition metal complexes of 2,2′-methylenebisphenoxides have shown that the puckered eight-membered ring formed by chelation to metal centre undergoes slow flipping on the NMR timescale [6–8]. Therefore, the methylene protons in the chelate backbone are typically diastereotopic at ambient temperature.[8] The ^{1}H NMR spectra of complexes **2** and **3** show typical resonances for aromatic protons and alkyl substituents of ligands. In the aliphatic region of the spectra of these complexes are seen two multiplets for ethanediolate groups, which implies that there are two different environments for these methylene protons. The diastereotopic methylene protons in the chelate ring of **2** are separated by 2 ppm showing doublets at 3.3 and 5.4 ppm. Also the methine proton in the chelate ring of **3** shows doublets at 4.4 and 5.8, respectively.

^{1}H NMR spectrum of compound **4** is not very informative. Methylene protons in the bis(naphtolate) rings showed three multiplets at 4.8–5.9 ppm. A sharp singlet at 5.7 ppm was assigned as a signal for ethanediolato protons, as similar signal for that ligand in comparable W(eg)(OAr)$_4$ complex, [W(calix)(eg)] (calix=calix[4]arene), is found at 5.83 [9].

Scheme 2. Activation and regeneration of catalyst precursors.

2.2. Crystal structures

Compounds **2**–**4** form monomeric molecules in which six oxygen donors surround the central tungsten atoms (Figs. 1–3). The distorted octahedral WO_6 units are generally similar, but not identical in all these compounds, as seen from the bonding parameters presented



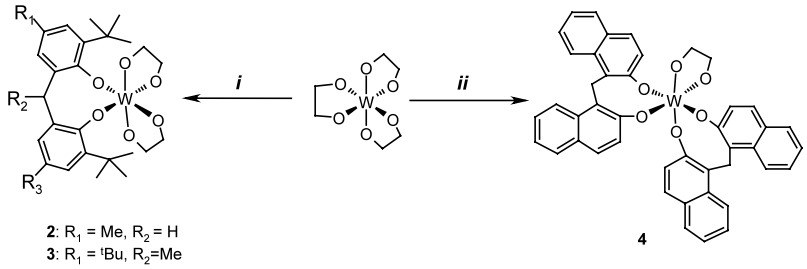


Fig. 1. Molecular structure of [W(mb)(eg)$_2$] (**2**). Hydrogen atoms have been omitted for clarity. Thermal ellipsoids have been drawn at 30% probability level.

Scheme 1. Preparation of complexes. (i) H_2biphe–PhMe, reflux; (ii) 2 H_2dinap–PhMe, reflux.

in Table 1. If we have [W(biphenolate)(eg)$_2$] type compound, where biphenolate is a bidentate phenolate dianion (or two monodentate phenolate anions), the shape and rigidity of biphenolate ligand modify the actual octahedral coordination sphere of the W(VI) ion. Comparing the structural parameters of **2** and **3** shows that these have fairly similar overall structure, so the substituents in the main body of the ligand modify the structure of the complexes only slightly. To see the influence of different ligand bodies on the complex structure, we should compare the structures formed by 2,2′-methylenebis(phenolato) ligand and binaphtholato ligand, thus also bonding parameters of [W(bino)(eg)$_2$]

[c] C(n) is a carbon atom bonded to a host oxygen atom.

have included in Table 1 [5b]. Consequently, we can see large changes in bonding parameters of these bis(phenolato) ligands to W(VI) ion. For ex. W–O(1) bond lengths, as well as O(1)–W–O(2) and C(1)–O(1)–W bond angles are quite different in **2** and [W(bino)(eg)$_2$]. Normally O(phenolato) is bonded more tightly (shorter bond distances) to W(VI) center than O(alcoholato). However, we can see now that a rigid ligand bonds less effectively to W(VI) center. This phenomenon is also seen in the bonding parameters of **4**, where two bis(naphtolato) ligands are attached to W(VI): one of these ligands is quite loosely bonded to W(VI) center. Finally, the bonding parameters of aliphatic diolato groups are quite similar in compounds studied now as in earlier reported tungsten(VI) diolato complexes with simple phenoxides or binaphtholates, e.g. [W(eg)$_2$(OPhR$_2$-2,6)$_2$] [5a] and [W(bino)(eg)$_2$] [5b].

2.3. Polymerisation studies

We have earlier studied ROMP processes employing complexes of type [W(diol)$_2$(OAr)$_2$] and found that the catalytic activities depends on the bulkiness of alkyl substituents at the phenoxide groups [2b]. In this study we used sterically hindered complexes **2** and **3** as precatalysts in ROMP of norbornene and dicyclopentadiene, using a Et$_2$AlCl cocatalyst. Both tungsten precatalysts showed moderate activity for polymerisation of norbornene at 0 °C as the yields of polymers after 15

min reaction were 38% for **2** and 42% for **3**, respectively. Though, they were inactive for the polymerisation of dicyclopentadiene. At 80 °C both precatalysts produced polynorbornene and polydicyclopentadiene in practically quantitative yields. However, the high yields of polydicyclopentadiene were not necessarily due to the increased activity of the catalysts in elevated temperature, but it is possibly simply due to the thermally induced cross-linking reaction [10]. The nature of the active species is unknown, but we can suppose the traditional model for precatalyst activation-dialkylation followed by α-H elimination to produce the reactive Schrock-type alkylidene [11]. Nevertheless, active catalysts can be transformed into compounds **2** or **3**, respectively, by adding excess H_2eg, thus these precatalysts can be recovered from reaction mixtures in nearly quantitative yields (Scheme 2).

3. Conclusion

Bulky methylene-bridged bis(phenol)s react with tris-diolatotungsten(VI) complex [W(eg)$_3$] (eg = ethanediolate dianion) providing heteroleptic complexes [W(biphenolate)(eg)$_2$], where bis(phenol) = 2,2′-CH_2(4-Me-6-^{t}BuPhOH)$_2$ or 2,2′-CHMe(4,6-^{t}Bu$_2$PhOH)$_2$. Sterically less hindered 2,2′-dihydroxy-1,1′-dinaphtylmethane forms disubstituted complex [W(biphenolate)$_2$(eg)]. In solid state these isolated compounds consist of monomeric tris(diolato)tungsten(VI) molecules in which the central tungsten atom is bonded to six oxygen atoms forming a distorted octahedral coordination sphere around the metal ion. Compounds of the type [W(biphenolate)(eg)$_2$] can be activated by Et_2AlCl to catalyse ring opening polymerisation metathesis of norbornene.

4. Experimental

Chemicals were from commercial origins and were used without subsequent purification. Toluene used in polymerisation studies was distilled over sodium under a nitrogen atmosphere. Monomer solutions in toluene were stored over 4 Å molecular sieves. 2,2′-dihydroxy-1,1′-dinaphthylmethane was prepared as described earlier [12]. NMR spectra were recorded on Bruker AM-200 spectrometer. Elemental analyses were obtained using a Perkin–Elmer CHNS-Analyzer 2400. Analytical samples were dried in vacuo at 40 °C for 2 h prior to elemental and spectral analyses.

4.1. Preparation of complexes

[*W*(*eg*)$_2$(*mbp*)] (**2**) 1.09 g of **1** (3.00 mmol) was heated with 1.02 g of H_2mbp (3.00 mmol) in 60 ml of toluene at reflux to form a red solution. The H_2eg that formed was removed by azeotropic distillation with toluene during 4 h. The solvent was evaporated and orange solid residue was column chromatographed (silica–CH_2Cl_2) to give complex **2** as orange–red solid, which was crystallised from 10 ml of acetonitrile to obtain intense red prisms with the formula **2**·CH_3CN in yield of 82% (1.68 g). Samples were dried in vacuo at 40 °C for 6 h before elemental and spectral analyses to remove any solvent of crystallisation. For **2**: δ_H ($CDCl_3$, standard $SiMe_4$): 7.07 (s, 1H, ArH), 6.97 (s, 2H, ArH), 6.92 (s, 1H, ArH), 5.72 (br, s, 2H, –OCH_2–), 5.53 (br, s, 2H, –OCH_2–), 5.38 (d, 1H, –CH_2–), 5.35 (br, s, 2H, –OCH_2–), 5.17 (br, s,2H, –OCH_2–), 3.28 (s, 1H, –CH_2–), 2.34 s, (s, 3H, *p*-CH_3), 2.28 (s, 3H, *p*-CH_3), 1.41 (s, 9H, C(CH_3)$_3$), 1.34 (s, 9H, C(CH_3)$_3$). Found: C, 50.2; H, 5.8. $C_{27}H_{38}O_6W$ requires C, 50.5; H, 6.0%.

[*W*(*ebp*)(*eg*)$_2$] (**3**) 1.09 g of **1** (3.00 mmol) was heated with 1.32 g of H_2ebp (3.00 mmol) in 60 ml of toluene at reflux to form a red solution and the H_2eg that formed was removed by azeotropic distillation with toluene during 4 h. The solvent was evaporated and an orange solid residue was crystallised from 40 ml of hexane to obtain complex **3** as orange-red microcrystals in yield of 90% (2.05 g). Crystals of **3** for X-ray structure analysis were grown from acetonitrile. For **3**: δ_H ($CDCl_3$, standard $SiMe_4$): 7.24 (1H, ArH), 7.17 (m, 3H, ArH), 5.8–5.1 (9 H, several multiplets, –OCH_2– and –CHCH_3), 1.65 (d, 3H, –CHCH_3), 1.32 (q, 36H, C(CH_3)$_3$). Found: C, 55.4; H, 6.9. $C_{34}H_{52}O_6W$ requires C, 55.1; H, 7.1%.

[*W*(*dinap*)$_2$(*eg*)] (**4**) 120 mg of **1** (0.33 mmol) was heated with 200 mg of H_2dinap (0.67 mmol) in 60 ml of toluene at reflux for 4 h to form a red solution. The solution was then concentrated to 15 ml and allowed to stand at r.t. overnight to obtain complex **4** as red powder in 69% yield (190 mg). Crystals of **4**·CH_2Cl_2 for X-ray structure analysis were grown from CH_2Cl_2 by slow evaporation. δ_H ($CDCl_3$, standard $SiMe_4$): 8.80–7.20 (several multiplets, 24H, ArH), 5.90–4,80 (several multiplets, 4H, –CH_2–), 5.73 (s, 4H, –OCH_2–). Found: C, 62.6; H, 4.0. $C_{44}H_{32}O_6W$ requires C, 62.9; H, 3.8%.

4.2. Polymerisation studies

Polymerisations were performed under a nitrogen atmosphere applying the protocol reported by Barnes et al. [2]. Our experiments were carried out employing a 1:4.5:50 tungsten precatalyst: activator:monomer ratio. The precatalyst (2×10^{-5} mol in 10 ml of toluene) was treated with 0.05 ml of Et_2AlCl solution (1.8 M in toluene, 9×10^{-5} mol). The red reaction mixture was stirred for 5 min and 1 ml of 1 M olefinic monomer (1.0 mmol) in toluene was added. After 15 min stirring the solution was treated with 10 ml of methanol to precipitate polymer as a white solid. Polymers were

swelled in toluene, re-precipitated by methanol and dried in vacuo at 40 °C for 8 h.

4.3. Single crystal X-ray diffraction

Crystal data for compounds **2**–**4**, along with other experimental details, are summarised in Table 2. The crystallographic data were collected for **2** and **3** at 173 K on a Nonius Kappa CCD area-detector diffractometer using graphite monochromatised Mo Kα radiation ($\lambda =$ 0.71073 Å). Lattice parameters were determined from ten images recorded with 1° φ scans and subsequently refined on all data. The data collection was performed using φ and ω scans with 1° steps using an exposure time of 5 s per frame for **2** and 2 s per frame for **3.** The crystal-to-detector distances were 30 and 40 mm for **2** and **3**, respectively. The data were processed using DENZO-SMN v0.93.0 [13]. MULABS [14] absorption correction was applied for the data of both compounds, but in final calculations the corrected data were used only for **3**, because corrected data for **2** give higher R-values than the uncorrected one.

Single-crystal data collection for **4** was performed at ambient temperature on a Rigaku AFC5S diffractometer using graphite monochromatised Mo Kα radiation ($\lambda = 0.71069$ Å). Data reduction and subsequent calculations were performed with TEXSAN for Windows [15]. The data were corrected for Lorenz and polarisation effects, for absorption (PSI-scans [16]) and for decay.

[a] Values in parentheses for reflections with $I > 2.0\sigma(I)$.

The structures were solved by direct methods using the SIR-92 program [17] and full-matrix least-squares refinements on F^2 were performed using the SHELXL-97 program [18]. For both all heavy atoms were refined anisotropically. The CH hydrogen atoms were included at the fixed distances with fixed displacement parameters from their host atoms. Compound **3** was refined as a racemic twin (Flack's parameter is 0.65(1). Figures were drawn with ORTEP-3 for *Windows* [19].

5. Supplementary data

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 174185–174187. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Neutral *cis*-dioxomolybdenum(VI) complexes with potentially pentadentate ONSNO donor Schiff bases of thiocarbodihydrazone of salicylaldehyde (H_3L^1), 5-bromo (H_3L^2), 5-nitro salicylaldehyde (H_3L^3) and 2-hydroxyacetophenone (H_3L^4) acting as tridentate ONS donor ligands have been synthesised. The complexes are found to be of the form $MoO_2LH(R–OH)$ ($R = CH_3$) where, LH = L^1H, L^2H, L^3H and L^4H. The complexes were characterised by elemental analyses, UV, IR, and ^1H NMR spectroscopy, magnetic susceptibility measurement, molar conductivities in solution and by cyclic voltammetry. Two of the complexes $[MoO_2(L^2H)(MeOH)]$ and $[MoO_2(L^4H)(MeOH)]$ were crystallographically characterised. The structures reveal that the molybdenum acceptor centre is present in a distorted octahedral NO_4S donor environment. The presence of a substituent either on the aromatic ring of the salicylaldehyde moiety or on the carbon atom of its carbonyl group is found to exhibit little effect on the corresponding metal ligand bond distances and angles. The sixth coordination site of the complexes harboring the weakly coordinated R–OH moiety is found to act as the binding site for various neutral monodentate Lewis bases. © 2002 Elsevier Science Ltd. 1. Introduction

Chemistry of the mixed hard–soft nitrogen–sulfur chelating ligands bound to Mo at higher oxidation state is a field of current interest. Such studies did assume greater importance after the revealation that several oxido-reductases like DMSO reductase, xanthine oxidase and other oxo-transferases contain Mo(IV), Mo(V) and Mo(VI) as their prosthetic groups coordinated to nitrogen–sulpur donor points of a macromolecular ligand system [1]. EXAFS study of xanthine oxidase has confirmed the simultaneous presence of nitrogen, sulfur and oxygen donors at its active site [2–4]. The capacity of sulfur donor centres in mixed hard–soft ligand systems to stabilise uncommon oxidation states, to generate unfamiliar coordination number in the resultant transition metal complexes and to take part in diverse type of redox reactions—both chemical and electrochemical, is recognised [5–13]. Our group has been quite active in this field for more than a decade and has reported the synthesis, characterisation, chemical and electrochemical activity of Mo(VI), Mo(V) and Mo(IV) complexes which were found to resemble the oxo-transfer molybdoenzymes [7,14–16]. Schiff bases of thiocarbodihydrazide are known to constitute an interesting ONS chelating ligand system with some other potential donor sites [17]. This work presents a comparative study of the $[Mo(VI)O_2]^{2+}$ complexes of a few multidentate thiocarbodihydrazide-based ONS chelating ligands differing from each other in the nature of the substituent placed at strategic positions with respect to the ONS donor set holding definite possibility of

modifying the over all electron environment around MoO^{2+} centre. Apart from various spectroscopic (UV–Vis, IR, ^{1}H NMR), electrochemical and chemical techniques, crystal and molecular structures of two complexes $[MoO_2(L^2H)(MeOH)]$ and $[MoO_2(L^4H)(MeOH)]$ have been determined by single crystal X-ray diffraction technique.

2. Results and discussion

2.1. Synthesis and characterisation of the ligand

The Schiff base ligands (H_3L^1, H_3L^2, H_3L^3 and H_3L^4) were prepared by condensing thiocarbohydrazide [18] with the appropriate 5-substituted salicylaldehydes in 1:1 molar proportions in refluxing ethanol: glacial acetic acid mixture. The ligands have been satisfactorily characterised by elemental analysis (Table 1), IR (Table 2), and ^{1}H NMR (Table 3) data.

2.2. Synthesis and characterisation of molybdenum(VI) complexes

Dioxomolybdenum(VI) complexes (**1**–**4**) of general formula $MoO_2LH(R–OH)$ were prepared [19] by refluxing $MoO_2(acac)_2$ with the appropriate ligand in 1:1 molar proportion in high yield (80–85%)[Scheme 1] using the appropriate alcohol as the reaction medium. All of them are dark orange–red crystalline solids, which are air and heat stable and diamagnetic as is expected for a species with d^0 Mo(VI) center [20]. They are insoluble in water. They have rather low solubility in common organic solvents but most are quite soluble in polar aprotic co-ordinating solvents like DMF and DMSO. Molar conductivity data in 10^{-3} M DMF solutions indicate that they are non-electrolytes. Cyclic voltammograms and electronic spectra of all the complexes were recorded in DMF (Tables 4 and 5). The solvent (R–OH) molecule at the sixth coordination site is rather weakly coordinated and can be easily replaced by different neutral monodentate Lewis bases like imidazole, substitutet imidazoles, pyridine, methyl pyr-

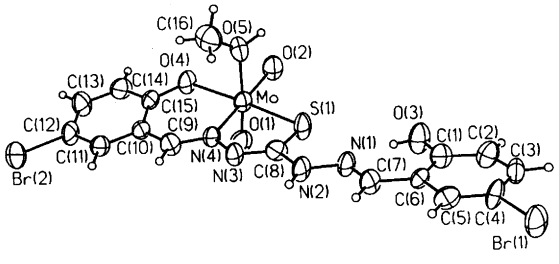
2.3. Structures of complexes

The perspective drawings of the complexes **2** and **4** are given in Figs. 1 and 2, respectively. Experimental details are given in Table 6. Selected bond lengths and angles are listed in Tables 7 and 8, respectively. The tridentate dinegative Schiff base ligand is bonded to the *cis*-$[Mo(VI)O_2]^{2+}$ core on a meridional plane [21,22] through S(1), O(4), and an imine nitrogen atom, which is trans to an oxo group. The sixth coordination site around Mo is occupied by a solvent (MeOH) molecule, thereby providing a distorted octahedral coordination environment around Mo in which the coordinated MeOH lie trans to another oxo group. In both the compounds **2** and **4**, the average O=Mo=O bond angle [106.0(2)°] and Mo–O bond length [1.664(7)–1.700(3) Å] which are very common for *cis*-dioxomolybdenum(VI) complexes [23–26]. The imine nitrogen and methanol oxygen atoms, which are trans to the terminal oxo-groups, are bound to Mo(VI) ions at distance of 2.281(8)–2.290(3) Å for nitrogen and 2.347(3)–2.278(8) Å for oxygen, respectively. The *cis* angles around Mo ranges from 75.5(2)° to 77.53(9)° for N(4)–Mo–S(1) to 105.9(4)°–106.0(2)° for O(1)–Mo–O(2), while the two trans L–Mo–L angles vary from 168.9(2)° to 171.6(3)°



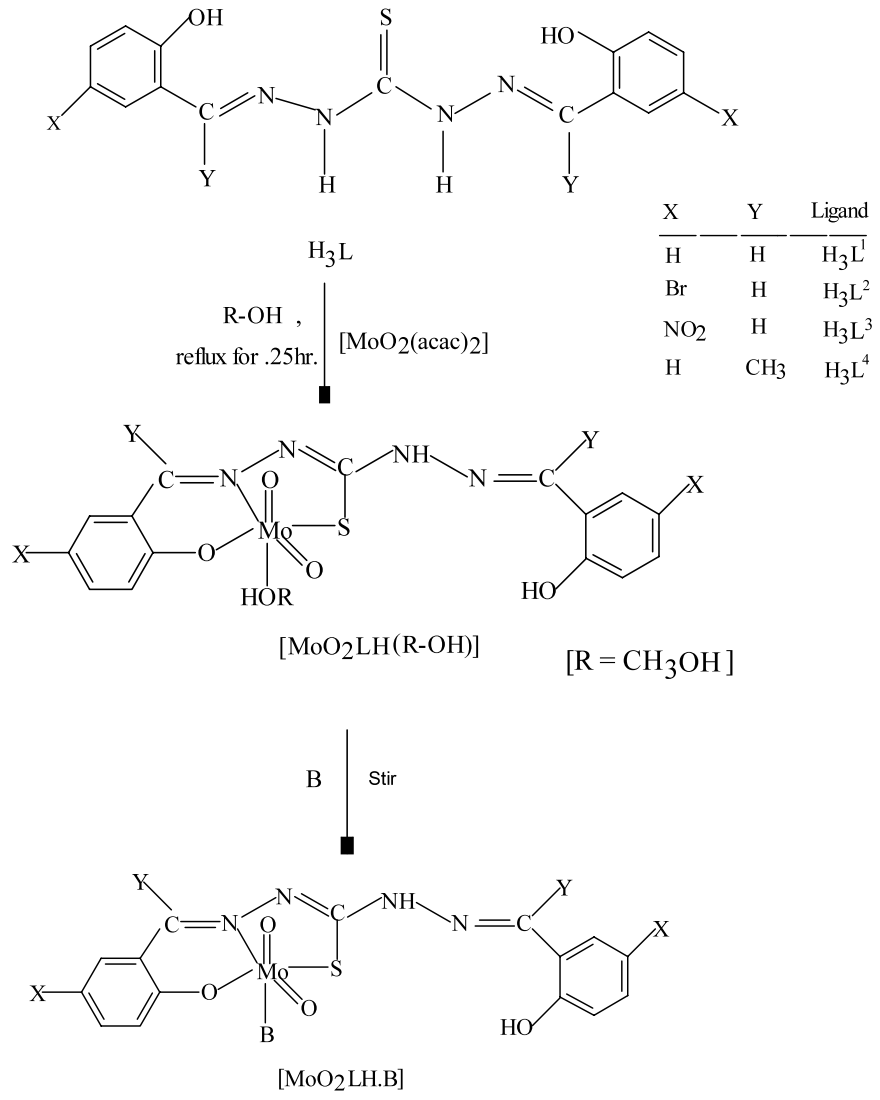


Fig. 1. ORTEP plot of complex **2** [$MoO_2L^2H(MeOH)$].

[B = imidazole, substituted imidazoles, pyridine and methyl pyridines etc.]

Scheme 1. Reaction diagram for the isolation of Mo(VI) complexes.

for O(1)–Mo–O(5) and 150.6(11)°–153.1(2)° for O(4)–Mo–S(1). The C(8)–N(3) bond distance of the two compounds vary from 1.281(5) to 1.297(12) Å is pretty close to the usual C=N length [19,27]. The Mo–S bond distances are found to vary from 2.4299(14) to 2.462(3) Å [22,28,29].

It is observed from the torsional and dihedral angles that, twists occur about three bonds, viz., N(4)–C(9), C(9)–C(10) and N(4)–N(3). Such twists have also been reported previously [21,22,25]. An interesting feature in comparison between two structure is that, in compound **2** the uncoordinated phenolic –OH remains on the same side as the Mo centre with respect to the C(10)–C(9)–N(4)–N(3)–C(8)–N(2)–N(1)–C(7)–C(6) skeleton. However, in compound **4** they are anti to each other, through a primary rotation of ~180° around C(8)–N(2) bond along with a little rotation around N(2)–N(1) and C(7)–N(1) bonds. This is probably to avoid van der waal's interaction between the C(9a) and C(7a) methyl moieties. Careful analysis of the bond lengths and bond angles leads to the following observation. Irrespective of the substitution in the 5-position of the benzene ring or the carbonyl carbon atom of the salicylaldehyde moiety of the ligand, the bonds expected to be affected by such substitution showed no significant differences in length in the MoO_2-complexes reported in this work. Such an observation, though contrary to expectation [30], may be accounted for by invoking the idea of extensive delocalisation of electron density throughout the complex molecule.

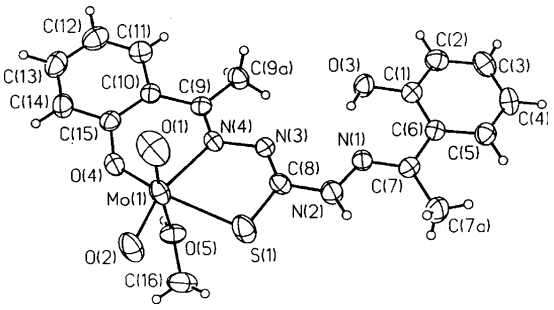

Fig. 2. ORTEP plot of complex **4** [$MoO_2L^4H(MeOH)$].

2.4. IR and ^1H NMR studies

All the four ligands exhibit two to three broad IR bands of medium intensity at 3650–3200 cm^{-1} region, the higher frequency one is due to the ν(O–H) mode while the lower ones are assigned to the ν(N–H) vibrations [31] (Table 2). Presence of these O–H and N–H hydrogens are also revealed in the X-ray crystal structure of the complexes **2** and **4**. Two or more strong ν(C=N) bands are observed in the 1650–1590 cm^{-1} region. Multiplicity of this band may be attributed to the presence of more than one different type of ν(C=N) moieties in the ligands and complexes which is clearly revealed in the crystal structure of the complexes **2** and **4**. Like most of the *cis*-dioxomolybdenum(VI) complexes, two IR bands are observed in the 940–910 cm^{-1} region, the higher frequency band originating from the antisymmetric while the lower one from the symmetric stretching mode of the $[MoO_2]^{2+}$ moiety [25,32,33]. A strong ν(C=S) band was observed around 1295–1280 cm^{-1} for the ligands, which disappeared upon complex formation. Two new bands at $\sim$595 cm^{-1} and in the 510–560 cm^{-1} region are observed in the IR spectra of the complexes. They are assigned to the ν(Mo–N) and ν(Mo–O), respectively, [25,31].

^1H NMR data for the complexes are summarized in Table 3. The non-equivalence of the two N–H moieties in each of the ligand is due to the involvement of the nitrogen atom of one of them in intramolecular hydrogen bonding. NMR spectra of the corresponding complexes (Table 3) exhibit only one N–H proton signal shifted downfield. The spectra of the complexes exhibit only one phenolic O–H proton signal corresponding to the uncoordinated half of the ligand. The broad nature of this O–H proton signal is indicative of intramolecular H-bonding. Coordination from the azomethine nitrogen is reflected in the downfield shift of the CH=N proton in the NMR spectra of the complexes **1**, **2** and **3**. In the complex **4**, the involvement of the azomethine nitrogen is indicated by the shift of the $-CH_3$ proton signal from

2.39 to 2.75 δ while the other $-CH_3$ proton signal remains unaltered at 2.39 δ corresponding to the uncoordinated part of the ligand.

2.5. Electrochemical properties

Cyclic voltammograms of all the ligands and complexes at a platinum electrode were recorded in dry degassed DMF containing 0.1 M TEAP as the supporting electrolyte over a potential range of 0.0 to −1.9 V. The numerical data are given in Table 4 and representative voltammograms are shown in Fig. 3. All the complexes exhibit two successive reductive responses in the given potential range. The first one is a metal centred $2e^-$ process [19] as was evidenced from a comparison with authentic $1e^-$ systems [6,15,34]. The second reduction wave for the complexes and the corresponding free ligands is found to occur almost at the same potential within the −1.3–−1.8 V region. Such close correspondence of the reduction potential of the ligand–complex pairs points to the ligand based character of this process. Both the reductions observed for all the compounds are irreversible. It is to be noted here that reduction of dioxomolybdenum(VI) complexes in aprotic solvents are generally irreversible [7].

2.6. Electronic spectra

Electronic spectra of the Mo(VI) complexes were recorded in DMF solution and the spectral data is presented in Table 5. The lowest energy absorption maximum is observed in the 510–400 nm range and may be assigned to $S(p\pi) \rightarrow Mo(d\pi)$ LMCT transition caused by the promotion of an electron from the filled HOMO of the ligand of primarily sulfur pπ character to the empty LUMO of molybdenum dπ character. Other LMCT bands are observed in the region 400–300 nm [6,15,19,21]. The bands appearing around 350 and 310 nm may be assigned to the nitrogen to molybdenum and oxygen to molybdenum charge transfer transitions [19]. The bands appearing below 300 nm are due to intra-ligand transitions.

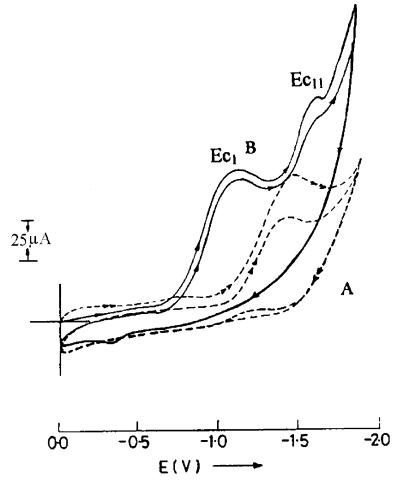

Fig. 3. Cyclic voltammograms for ligand A (H_3L^2) (---) and Mo(VI) complex B [$MoO_2L^2H(MeOH)$] (—) in DMF solution.

2.7. Study of reactivity of $[MoO_2LH(MeOH)]$

Binding of alcohols used as the reaction medium for the preparation of the complexes of the general formula [$MoO_2LH(ROH)$] led us to the idea that this sixth coordination site around Mo(VI) acceptor centre may be utilised for the site of binding of monodentate Lewis base substrates. The weakly coordinated nature of R–OH is apparent from TG-DTA data of the $MoO_2LH(ROH)$ species, which exhibited ready loss of R–OH around 110 °C. This is further substantiated by the facile replacement of R–OH by other neutral monodentate base. Refluxing and even prolonged stirring of a suspension of $MoO_2LH(ROH)$ in dry CH_2Cl_2 or EtOH with the relevant base B such as imidazole, 1-methyl imidazole, 4-methyl imidazole, pyridine, β- and γ-picoline, etc. resulted in formation of $MoO_2LH \cdot B$. So, it is established that the sixth coordination position of the distorted octahedral $MoO_2LH(ROH)$ moiety may be considered as the binding site for various monodentate oxygen (alcohols) and nitrogen (imidazoles and pyridines) donor ligands.

3. Experimental

3.1. Materials

[$MoO_2(acac)_2$] was prepared as described in the literature [35]. Reagent grade solvents were dried and distilled prior to use. All other chemicals were reagent grade, available commercially and used without further purification.

3.2. Physical measurements

Elemental analyses were performed on a Perkin–Elmer 240 C, H, N analyser. The NMR spectra were recorded on a Brüker 300 NMR spectrometer. IR spectra were recorded as KBr pellets on a Perkin–Elmer 783 spectrometer. Electronic spectra were recorded on a Shimadzu UV–Vis recording spectrophotometer Magnetic susceptibility was measured with a PAR model 155 vibrating sample magnetometer with Hg [$Co(SCN)_4$] as calibrant. Electrochemical data were collected with a BAS CV-27 electrochemical analyser and a BAS model X-Y recorder at 298 K, using a three electrode cell, fitted with a purge gas inlet and outlet, consisting of a platinum working electrode, platinum auxiliary electrode and Ag–AgCl reference electrode. Voltammo-

grams were recorded in DMF solutions of the metal complexes containing 0.1 M tetraethylammonium perchlorate as supporting electrolyte.

3.3. Schiff base ligand preparation

All the four ligands were prepared by a method outlined below. $(NH_2NH)_2CS$ (1.83 g, 17.3 mmol) was dissolved in refluxing solution of 21.6 ml glacial acetic acid and 88.4 ml ethanol. Salicyldehyde (4 ml, 34.5 mmol or appropriate mass of the substituted salicylaldehyde) of dissolved in 15 ml ethanol was added to it. The mixture was refluxed on water bath for 4 h. The pale yellow compound that separated on cooling was filtered out, washed with cold dehydrated ethanol and was dried over fused $CaCl_2$. Yield: 80–85%.

3.4. Synthesis of $[MoO_2LH(MeOH)]$ $[LH = L^1H, L^2H, L^3H, L^4H]$

Compounds **1**–**4** were prepared by a method similar to one reported previously [19] using appropriate ligands (Scheme 1). Schiff base ligand (5 mmol) was dissolved in 100 ml dry methanol under reflux. A filtered solution of $[MoO_2(acac)_2]$ in dry methanol was added to this refluxing solution and was stirred for 0.25 h. The dark orange–red crystalline solid so formed was filtered, washed with cold dry methanol and was dried in vacuum over fused $CaCl_2$. Yield 75–80%.

3.5. Crystallographic measurement

Crystal data sets for complexes **2** and **4** were collected on an Nonius CAD-4 four-circle diffractometer [36] (Table 6) employing graphite-monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation, using ω-scans. A decay correction was applied to the data during data reduction [37]. The structures were solved by direct methods [38] and refined to F_0^2 using all data [39,40]. All hydrogen atoms were seen in a difference Fourier map, except for one hydrogen of the methyl group in each structure. The non-methyl hydrogen atoms were refined freely, each with its own isotropic displacement parameter. The non-hydrogen atoms of the molybdenum complexes were all refined with anisotropic displacement parameters.

4. Supplementary data

Crystallographic data have been deposited with the CCDC, 12, Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-366033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) and are available on request, quoting the deposition number 162612 and 162613 for the complex **2** and complex **4**, respectively.

Steric effects on the stereochemistry of copper complexes of 2,6-bis(pyrazol-1-ylmethyl)pyridines

Caroline L. Foster, Colin A. Kilner, Mark Thornton-Pett, Malcolm A. Halcrow *

School of Chemistry, University of Leeds, Woodhouse Lane, Leeds LS2 9JT, UK

Received 4 December 2001; accepted 25 January 2002

Abstract

The stereochemical preferences of copper complexes of 2,6-bis-(3,5-dimethylpyrazol-1-ylmethyl)pyridine (L^1Me_2) and of 2,6-bis-(phenylpyrazol-1-ylmethyl)pyridine (L^1Ph) have been investigated. The single crystal X-ray structures of $[Cu(OH_2)(L^1Me_2)](BF_4)_2$ and $[CuCl(HOMe)(L^1Me_2)]BF_4$ show near-regular tetragonal geometries with one or two axial solvent and/or BF_4^- ligands. In contrast, $[Cu(OH_2)_2(L^1Ph)](BF_4)_2$ adopts an irregular geometry in the crystal mid-way between square-pyramidal and trigonal-bipyramidal. The single crystal X-ray structure of $[Cu(NCMe)(L^1Me_2)]BF_4$ exhibits a distorted tetrahedral geometries, while $[Cu(L^1Ph)]BF_4$ adopts a T-shaped stereochemistry. By a combination of UV–Vis, EPR and conductivity studies, the solution structures of $[CuCl_2(L)]$, $[CuCl(solv)(L)]BF_4$ and $[Cu(solv)_x(L)](BF_4)_2$ ($L = L^1Me_2$, L^1Ph; solv = H_2O, MeCN; $x = 1$, 2) have, in many cases, been shown to be the same as in the crystalline state. The cyclic voltammograms of $[Cu(OH_2)(L^1Me_2)](BF_4)_2$ and $[Cu(OH_2)_2(L^1Ph)](BF_4)_2$ in MeCN/0.1 M $NBu^n_4BF_4$ exhibit chemically reversible Cu(II/I) couples. © 2002 Elsevier Science Ltd. 1. Introduction

Much of the biomimetic Cu(II) chemistry that has been published over the past 15 years employs facially or meridionally coordinating *tris*-N-donor ligands as protecting groups [1–4]. These are intended to mimic the $[Cu(II)(his)_3L]^{n+}$ ($L = OH^-$, $n = 1$; $L = OH_2$, $n = 2$) centres found in many Type 2 copper [5,6], and all Type 3 and multi-copper [7], proteins. However, despite their utility in this regard, relatively few systematic studies of the stereochemical preferences of Cu(II) centres using this type of ligand have been carried out. This is an important question since, in contrast to many other biometals, the Cu(II) ion readily adopts a wide range of stereochemistries [8]. This can make its chemistry unpredictable and difficult to study, particularly in the absence of strongly coordinating anions.

This paper describes a crystallographic and spectroscopic investigation of the Cu(I) and Cu(II) chemistries of two ligands, L^1Me_2 and L^1Ph (Scheme 1), in the presence and absence of a coordinating anion. Our results complement data from Manoharan and Mukherjee, who reported several compounds of type $[CuX_2(L^1Me_2)]$ (X^- = halide, pseudohalide, NO_2^- or NO_3^-) while our own work was in progress [9–12], and offer a good example of how the Cu(I) and Cu(II) ions adapt their coordination environments in response to steric crowding from the L^1R protecting group. We are aware of only a few similar studies involving other *tris*-N donor ligands. The most relevant example is L^2R, which Karlin and Réglier have shown to cleanly form tetrahedral $[Cu(solv)(L^2R)]^+$ and tetragonal $[Cu(solv)_2(L^2R)]^{2+}$ (solv = MeCN, H_2O) complexes with weakly coordinating anions like triflate and perchlorate [13]. These stereochemistries resemble the structures exhibited by Type 2 and 3 copper biosites, which has contributed to the utility of L^2R ligands in biomimetic Cu chemistry [3,4]. The complexes of L^3–L^9 with Cu(II) salts of weakly coordinating anions have also been studied by Williams [14], Evans [15], and

Scheme 1. Ligands referred to in this study.

Bernauer [16]. However, L^3–L^5 and L^7R form helical dimeric complexes with Cu(I) that are not biomimetically relevant [17].

2. Results and discussion

The ligand L^1Me_2 was prepared by the literature method [18], while the new ligand L^1Ph was synthesised in good yield from 3{5}-phenylpyrazole [19] and 2,6-bis-(chloromethyl)pyridine [20], following the literature procedure for L^1 [21].

2.1. Copper(I) complexes of L^1R

Complexation of $[Cu(NCMe)_4]BF_4$ by 1 mole equiv. of L^1Me_2 in MeCN under N_2 gave an air-sensitive yellow solution. Layering of this solution with Et_2O afforded air-stable yellow crystals of $[Cu(NCMe)(L^1Me_2)]BF_4$ (**1**) in low yield, together with a larger amount of unreacted $[Cu(NCMe)_4]BF_4$ which was removed manually. Similar reactions in $MeNO_2$ or CH_2Cl_2 afforded a mixture of **1** and a new pale yellow solid, which we were unable to obtain in analytical purity from this mixture. The FAB mass spectrum of this latter species was identical to that of **1**, while its IR spectrum demonstrated the presence of BF_4^- and L^1Me_2 only. Hence, we tentatively formulate this second complex as solvent-free $[Cu(L^1Me_2)]BF_4$. In contrast to the above reactions, treatment of $[Cu(NCMe)_4]BF_4$ with an equimolar amount of L^1Ph in MeCN, followed by precipitation with Et_2O as before, cleanly afforded the pale yellow air-stable compound $[Cu(L^1Ph)]BF_4$ (**2**).

Single crystals of formula $[Cu(NCMe)(L^1Me_2)]BF_4$ (**1**) and $[Cu(L^1Ph)]BF_4$ (**2**) were grown by layering solutions of the complexes in MeCN and $MeNO_2$, respectively, with Et_2O under N_2. The structure of **1** shows an irregular, distorted tetrahedral geometry at Cu(1) (Fig. 1, Table 1), which is, however, similar to those previously described for $[Cu(PPh_3)(L^1Me_2)]ClO_4$ and $[\{Cu(L^1Me_2)\}_2(\mu\text{-dppe})](ClO_4)_2$ [22]. Of particular interest are the unequal angles N(10)–Cu(1)–N(24) and N(18)–Cu(1)–N(24), and the fact that all four Cu–N bond lengths are significantly different. There are no intramolecular steric contacts that would account for these irregularities. However, the packing diagram of **1** shows there is a close contact between C(26) and F(30′) (symmetry operation $x, -1+y, z$) of 3.352(2) Å, which would appear to prevent the MeCN ligand from occupying its idealised position in the coordination

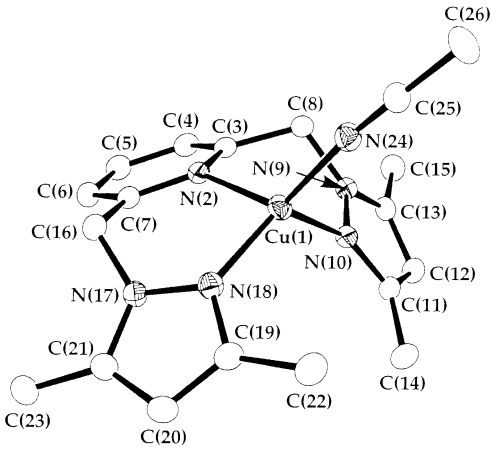

Fig. 1. View of the $[Cu(NCMe)(L^1Me_2)]^+$ complex cation in the structure of **1**, showing the atom numbering scheme employed. Thermal ellipsoids are drawn at the 35% probability level. For clarity, all C-bound H atoms have been omitted.

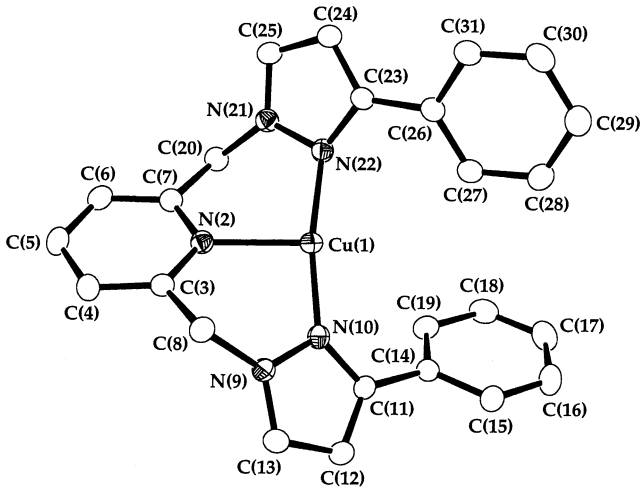

Fig. 2. View of the $[Cu(L^1Ph)]^+$ complex cation in the structure of **2**, showing the atom numbering scheme employed. Details as for Fig. 1.

Table 1

N(18)–Cu(1)–N(24)	121.04(6)		

sphere. Hence, these molecular distortions can probably be attributed to intermolecular steric contacts.

The complex cation in **2** has a regular T-shaped geometry (Fig. 2, Table 1). The bonds Cu(1)–N(10) and Cu(1)–N(22) are now crystallographically equal, while the angle N(10)–Cu(1)–N(22) has increased to 168.74(8)°, compared with the equivalent angle in **1** of 120.84(5)°. Despite this large variation in *trans*-N–Cu–N angle, the chelate bite angle of the L^1R ligand varies only slightly in the two structures, from an average of 92.14(7)° in **1** to 95.36(11)° in **2**. Rather, these differences reflect differing chelate ring conformations in the structures, which are chair-like in **1** and boat-like in **2**.

2.2. Syntheses and crystal structures of copper(II) complexes of L^1R

Complexation of hydrated $Cu(BF_4)_2$ by an equimolar amount of L^1Me_2 in $MeNO_2$, followed by diffusion of Et_2O into the resultant solution, yielded hygroscopic dark blue microcrystals. Upon prolonged drying in vacuo, these transformed to a blue powder that analysed consistently as $[Cu(OH_2)(L^1Me_2)](BF_4)_2\cdot H_2O$ (**3**·H_2O). Since the crystallographic analysis of this material (see below) showed only 1 mole equiv. of water, it is uncertain whether the second mole of water absorbed by the 'dried' solid is coordinated to the copper ion. A similar reaction employing L^1Ph gave a red–brown crystalline solid $[Cu(OH_2)_2(L^1Ph)](BF_4)_2$ (**4**). Green, sparingly soluble $[CuCl_2(L^1Me_2)]$ (**5**) [9] and $[CuCl_2(L^1Ph)]$ (**6**) were also prepared, by treatment of $CuCl_2$ with the appropriate ligand in MeCN. Reaction of these solids with 1 molar equiv. of $AgBF_4$ in MeCN yielded blue ($L = L^1Me_2$) or green ($L = L^1Ph$) solutions, which were evaporated to dryness. Recrystallisation of the crude materials from MeOH–Et_2O gave $[CuCl(HOMe)(L^1Me_2)]BF_4$ (**7**) and $[CuCl(OH_2)(L^1Ph)]BF_4$ (**8**) as microcrystalline solids.

Single crystals of formula $[Cu(OH_2)(L^1Me_2)](BF_4)_2$ (**3**) and $[CuCl(HOMe)(L^1Me_2)]BF_4$ (**7**) were grown by vapour diffusion from MeOH–Et_2O. Crystals of $[Cu(OH_2)_2(L^1Ph)](BF_4)_2$ (**4**) were similarly obtained from $MeNO_2$–Et_2O. The molecular structures of **3** and **7** are rather similar. Complex **3** contains a near-regular square-planar $[Cu(OH_2)(L^1Me_2)]^{2+}$ centre (Fig. 3, Table 2; structure A in Scheme 2) with a τ index [23] of 0.10, which is very close to the ideal value of 0 for a regular square-pyramid. There are weak axial interactions between Cu(1) and both BF_4^- anions to yield a [4+2] tetragonal Cu(II) ion [Cu(1)···F(26) = 2.531(2), Cu(1)···F(34) = 3.049(3) Å]. Both anions are also involved in hydrogen-bonding to the aqua ligand. One anion interacts with the aqua ligand on the same cation to which it forms an axial interaction. The other (disordered) anion forms hydrogen bonds to a neighbouring cation, yielding a 1-D polymeric lattice composed of alternating Cu···F and F···H–O interactions.

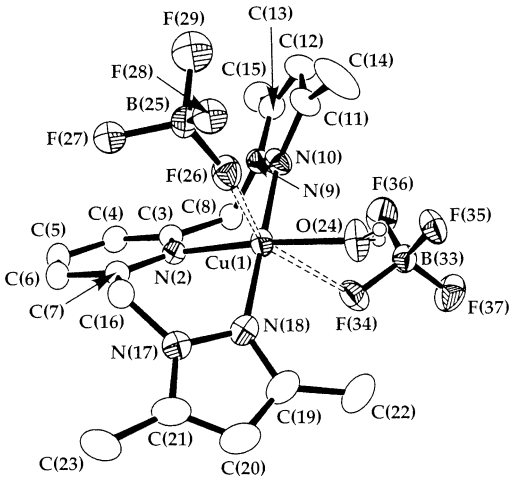

Fig. 3. View of the $[Cu(OH_2)(L^1Me_2)](BF_4)_2$ moiety in the structure of **3**, showing the atom numbering scheme employed. Details as for Fig. 1. For clarity, only one orientation of the disordered BF_4^- anion B(25)–F(29) is shown.

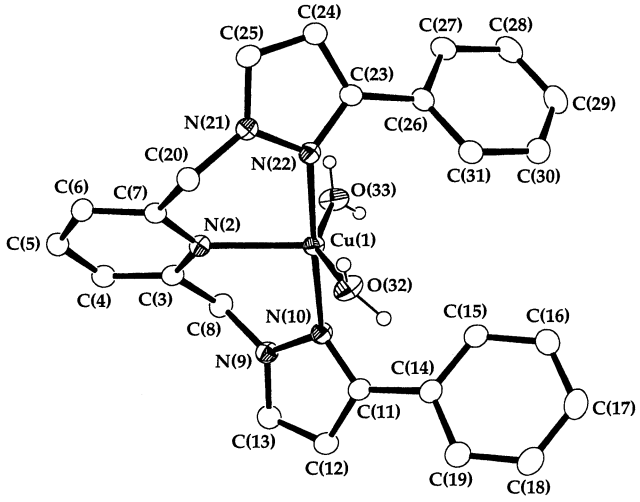

Fig. 4. View of the $[Cu(OH_2)_2(L^1Ph)]^{2+}$ complex dication in the structure of **4**, showing the atom numbering scheme employed. Details as for Fig. 1.

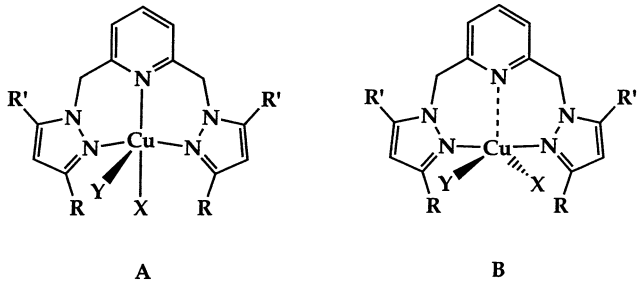
In **7**, the copper ion also adopts structure A (Scheme 2), with an apical MeOH ligand [Cu(1)–O(25) = 2.362(3) Å, $\tau = 0.11$] (Fig. 5, Table 2). The cations in the crystal are arranged into dimers, by hydrogen-bonding between the MeOH hydroxyl proton and a Cl^- ligand of a neighbouring cation related by $1-x, -y, 1-z$.

In contrast to the L^1Me_2 compounds, the copper ion in **4** has an irregular five-coordinate structure, which corresponds to structure B in Scheme 2 (Fig. 4, Table 2). This structure could be considered as trigonal-bipyramidal with the pyrazole N-donors axial [N(10)–Cu(1)–N(22) = 177.84(6)°], or as square-pyramidal with the pyridine N-donor apical [Cu(1)–N(2) = 2.1879(15) Å]. The τ index for this compound is in fact 0.46, almost exactly midway between the limiting values for a regular square-pyramid ($\tau = 0$) or trigonal-bipyramid ($\tau = 1$) [23]. The four protons on the water ligands in **4** are each hydrogen bonded to a different BF_4^- anion, forming a 1-D chain polymer motif in the crystal.

2.3. Conductivity, UV–Vis and EPR measurements

Solution UV–Vis and conductivity data for the Cu(II) compounds in this study, in both MeCN and $MeNO_2$ solutions, are listed in Table 3. Conductivity measurements for all of the Cu(II) complexes in this study were consistent with their solid state molecular structures. Hence, complexes **5** and **6** exhibit molar conductivities consistent with their being non-electrolytes in both these solvents, while **7** and **8** are clearly 1:1 electrolytes and **3** and **4** are 2:1 electrolytes [24]. This demonstrates that Cl^--dissociation does not take place upon dissolution of the chloride-containing complexes in MeCN or $MeNO_2$, which is consistent with an earlier study of **5** in dmf solution [9].



The visible spectra of **3**–**8** each exhibit a single d–d band (Table 3). The d–d spectra of **5**–**7** are essentially identical in MeCN and $MeNO_2$. This shows that they adopt the same molecular structures in these two solvents, and that dissociation of Cl^- or the L^1R ligand does not take place upon dissolution. However, the d–d maximum for **8** lies at a slightly lower wavelength in $MeNO_2$ than in MeCN. This suggests that, although the coordination geometry of **8** probably does not vary between the two solvents, solvent coordination is more important to the solution structure of **8** than **7**. Unsurprisingly, the d–d maxima of **3** and **4** are very solvent dependent. For **3**, **4** and **8**, the d–d maxima lie at longer wavelength in MeCN than in $MeNO_2$, which is consistent with the relative positions in the spectrochemical series of MeCN and H_2O [25] (the probable 'solv' ligand in $MeNO_2$, since $MeNO_2$ itself is an extremely poor ligand [26]).

As solids, the X-band EPR spectra of **4**–**6** and **8** are well-resolved into a clearly rhombic pattern, the g-values for each of these compounds being quite similar (Table 4). We, therefore, propose that **6** and **8** adopt structure B (Scheme 2) in the solid, as do **4** and **5** in the crystal [10]. The solid state EPR spectrum of **7** is distinct from the others and is clearly axial, with the $g_\parallel > g_\perp > g_e$ pattern and an $A_\parallel\{^{63,65}Cu\}$ value typical of a tetragonal $\{d_{x^2-y^2}\}^1$ or $\{d_{xy}\}^1$ Cu(II) species [27]. This is consistent with the crystal structure of this complex. The powder EPR spectrum of **3** is broad and unresolved.

The frozen solution EPR spectra of **6** and **8** in 10:1 MeCN:toluene and 10:1 $MeNO_2$:toluene are isotropic and uninformative. In contrast, **3**–**5** and **7** all exhibit axial or pseudo-axial frozen solution EPR spectra with $g_\parallel > g_\perp > g_e$, that are again consistent with $\{d_{x^2-y^2}\}^1$ or $\{d_{xy}\}^1$ Cu(II) species (Table 4) [27]. Hence, it seems clear that **3** and **7** both retain their crystallographic tetragonal geometry upon dissolution. However, there are some

differences between the EPR spectra of **4** and **5** in these two phases. Therefore, the detailed stereochemistries of **4**–**6** and **8** in solution are presently uncertain. Importantly, for all complexes where the comparison could be made, these spectra are essentially invariant between solvents, suggesting that changing the identity of solvent ligands to the $[CuCl_x(solv)_{2-x}(L^1R)]^{(2-x)+}$ $(x = 0–2)$ centres barely perturbs the coordination geometry at Cu.

2.4. Electrochemistry

A preliminary voltammetric study was carried out in MeCN/0.1 M $NBu^n_4PF_6$ at 293 K, to elucidate the potentials of the $[Cu(solv)_xL]^{2+}/[Cu(solv)_yL]^{+}$ (L = L^1Me_2, L^1Ph) couples. Cyclic voltammograms (CVs)

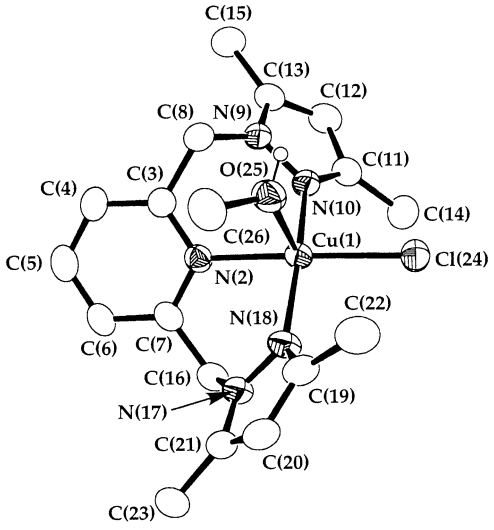

Fig. 5. View of the $[CuCl(HOMe)(L^1Me_2)]^{+}$ complex cation in the structure of **7**, showing the atom numbering scheme employed. Details as for Fig. 1.

of Cu(II) and Cu(I) complexes containing each ligand were run for comparison; in each case, the CVs obtained from the oxidised and reduced congeners of a given couple showed only small differences (Table 5).

For each Cu(II) complex **3** and **4**, a chemically reversible Cu(II/I) couple was obtained. However, plots of Ip versus $v^{1/2}$ (v = scan rate) for these processes did not give a straight line, showing that these couples are

not electrochemically reversible. This probably reflects the kinetics of solvent coordination or decoordination that take place following Cu-based redox at these centres. The **1/3** couple is approximately 0.6 V more positive than the Cu(II/I) reduction previously reported for **5** in dmf [9], consistent with the presence of more strongly donating Cl^- coligands in the latter compound. Interestingly, the **2/4** couple is approximately +0.15 V more positive than the **1/3** couple, showing that the identity of the L^1R 'R' substituents has a substantial effect on the redox chemistry of the coordinated Cu ion.

3. Concluding remarks

Within the $[Cu(solv)_x(L^1R)]^{2+}/[Cu(solv)_y(L^1R)]^+$ system there are substantial structural variations, which appear to depend upon the identity of both 'R' and the exogenous ligands 'solv'. For the Cu(I) complexes, the ability of a $[Cu(L^1R)]^+$ fragment to bind exogenous ligands is dependent on the identity of 'R'. This is

presumably a steric effect, since the greater basicity of 3,5-dimethylpyrazole compared with 3{5}-phenylpyrazole [28] suggests that the $[Cu(L^1Ph)]^+$ moiety should be *less* electron-rich [29], and so more likely to bind exogenous ligands, than $[Cu(L^1Me_2)]^+$. This being the case, it is uncertain whether the lower oxidation potential of **1** compared with **2** is driven by the more donating character of L^1Me_2 compared with L^1Ph [29], or by the higher co-ordination number at Cu in **1**.

Combining our results with earlier work (Table 4), it is clear that $[Cu(II)XY(L^1R)]^{n+}$ (X, Y = halide, pseudohalide or solvent, $n = 0$–2) complexes can adopt one of two limiting geometries; tetragonal, with Y apical (structure A in Scheme 2); or, tetragonal with the L^1R pyridyl group apical (structure B). The available data suggest that these structural types can be distinguished by EPR spectroscopy (Table 6). All structurally authenticated type A complexes exhibit axial $g_\parallel > g_\perp \approx 2.07$ powder EPR spectra, where these can be clearly resolved, while all known type B complexes show strongly rhombic powder EPR spectra, with $g_3 \leq 2.04$. Bulky L^1R 'R' substituents appear to favour structure B, since EPR data show that all of the L^1Ph-containing complexes in this work exhibit structure B in the solid. Most of the L^1Me_2 complexes follow the trend expected on steric grounds, in that $[CuXY(L^1Me_2)]$ (X = Y = Cl, Br) adopt structure B while those complexes containing smaller N- or O-donor X and Y ligands exhibit structure A. However, the anomalous observation that $[Cu(N_3)_2(L^1Me_2)]$ is a structure B complex [9,12] suggests that electronic, as well as steric, factors might play a role in the stereochemistry of Cu(II)–L^1R complexes.

4. Experimental

Unless stated otherwise, all manipulations were performed in air using commercial grade solvents. 2,6-Bis-(chloromethyl)pyridine [20], 3-phenylpyrazole [19], L^1Me_2 [18], $[Cu(NCCH_3)_4]BF_4$ [30] and $[CuCl_2(L^1Me_2)]$ (**5**) [9,10] were prepared by the literature procedures. $Cu(BF_4)_2{\cdot}6H_2O$ (Avocado), KH (Aldrich) and all solvents were used as supplied, except that diglyme was dried over sodium before use. Microanalytical, mass spectrometric, UV–Vis, EPR and conductivity data for the complexes are listed in Tables 3, 4 and 7.

4.1. Synthesis of 2,6-bis-({3-phenylpyrazol-1-yl}methyl)pyridine (L^1Ph)

A mixture of 3-phenylpyrazole (15.9 g, 0.11 mol) and NaH (4.0 g, 0.11 M) in dry THF (50 cm^3) was stirred at 60 °C under N_2 for 30 min. 2,6-Bis-(chloromethyl)pyridine (9.7 g, 0.055 mol) was then added, and the mixture stirred at 60 °C for 24 h. The solvent was removed under reduced pressure and the residue taken up in chloroform (3×50 cm^3). The combined organic fractions were washed with water and saturated aqueous NaCl, then dried over $MgSO_4$. The filtered solution was evaporated to dryness to leave an off-white solid which was recrystallised from thf–Et_2O. Yield 15.0 g, 70% (Found: C, 76.7; H, 5.3; N, 18.1; Calc. for $C_{25}H_{21}N_5$: C, 76.4; H, 5.4; N, 17.8%). M.p. 98–100 °C. EI mass spectrum: m/z 391 $[M]^+$, 248 $[M-pz^{Ph}]^+$, 157 $[CH_2pz^{Ph}]^+$, 144 $[Hpz^{Ph}]^+$, 77 $[C_5H_3N]^+$. NMR spectra ($\{CD_3\}_2SO$, 293 K): ^1H; δ 7.93 (d, 2.3 Hz, 2H, Pz H^5), 7.77 (m, 5H, Ph $H^{2/6}$+Py H^4), 7.38 (m, 6H, Ph $H^{3/5}$+Ph H^4), 6.98 (d, 7.8 Hz, 2H, Py $H^{3/5}$), 6.78 (d, 2.3 Hz,

2H, Pz H^4), 5.50 (s, 4H, CH_2). ^{13}C; δ 157.4 (Py $C^{2/6}$), 151.1 (Pz C^3), 138.0 (Py C^4+Pz C^5), 133.9 (Ph C^1), 129.7 (Ph $C^{2/6}$), 127.2 (Ph $C^{3/5}$), 125.0 (Ph C^4), 120.7 (Py $C^{3/5}$), 103.3 (Pz C^4), 57.6 (CH_2).

4.2. Synthesis of acetonitrile[2,6-bis-({3,5-dimethylpyrazol-1-yl}methyl)pyridine]copper(I) tetrafluoroborate (*1*)

A solution of L^1Me_2 (0.25 g, 8.4×10^{-4} mol) and $[Cu(NCMe)_4]BF_4$ (0.26 g, 8.4×10^{-4} mol) in MeCN (25 cm^3) was stirred under N_2 for 10 min at room temperature (r.t.). The yellow solution was concentrated to approximately 5 cm^3 and layered with Et_2O, affording a mixture of pale yellow needles and colourless blocks that were separated manually for analysis. The colourless crystals were identified as $[Cu(NCMe)_4]BF_4$ by comparison with a genuine sample. Yield of yellow crystals that were sufficiently large to separate by hand 0.064 g, 8%. IR spectrum (Nujol): 2310w, 2275w cm^{-1}.

4.3. Synthesis of [2,6-bis-({3-phenylpyrazol-1-yl}methyl)pyridine]copper(I) tetrafluoroborate (*2*)

A solution of L^1Ph (0.25 g, 6.4×10^{-4} mol) and $[Cu(NCMe)_4]BF_4$ (0.20 g, 6.4×10^{-4} mol) in $MeNO_2$ (25 cm^3) was stirred under N_2 for 10 min at r.t. The yellow solution was concentrated to approximately 5 cm^3 and layered with Et_2O, affording pale yellow needles. Yield 0.16 g, 47%.

4.4. Synthesis of [2,6-bis-({3,5-dimethylpyrazol-1-yl}methyl)pyridine]aquacopper(II) ditetrafluoroborate (*3*)

A solution of L^1Me_2 (0.25 g, 8.4×10^{-4} mol) and $Cu(BF_4)_2\cdot6H_2O$ (0.29 g, 8.4×10^{-4} mol) in $MeNO_2$ (25 cm^3) was stirred for 15 min at r.t. The resultant blue solution was concentrated to approximately 5 cm^3 and filtered. Vapour diffusion of Et_2O into this solution gave a sticky blue solid, which was dried over P_2O_5 and recrystallised from $MeNO_2$–Et_2O to give very hygroscopic blue blocks. Yield 0.29 g, 61%.

4.5. Synthesis of [2,6-bis-({3-phenylpyrazol-1-yl}methyl)pyridine]diaquacopper(II) ditetrafluoroborate (*4*)

A mixture of L^1Ph (0.25 g, 6.4×10^{-4} mol) and $Cu(BF_4)_2\cdot6H_2O$ (0.22 g, 6.4×10^{-4} mol) in $MeNO_2$ (25 cm^3) was stirred for 15 min at r.t., affording a green solution which was concentrated to approximately 5 cm^3 and filtered. Vapour diffusion of Et_2O into this solution yielded red–brown cubes. Yield 0.31 g, 73%.

4.6. Synthesis of dichloro[2,6-bis-({3-phenylpyrazol-1-yl}methyl)pyridine]copper(II) (*6*)

A suspension of L^1Ph (0.66 g, 1.7×10^{-3} mol) and $CuCl_2$ (0.22 g, 1.7×10^{-3} mol) in MeCN (30 cm^3) was stirred for 1 h at r.t., affording a green precipitate. This was filtered, washed with MeCN and Et_2O, and dried in vacuo. This product was analysed without further purification. Yield 0.58 g, 65%.

4.7. Synthesis of chloro[2,6-bis-({3,5-dimethylpyrazol-1-yl}methyl)pyridine](methanol)copper(II) tetrafluoroborate (*7*)

A solution of **5** (0.36 g, 8.4×10^{-4} mol) and $AgBF_4$ (0.16 g, 8.4×10^{-4} mol) in MeCN (25 cm^3) was stirred for 2 h at r.t. The blue solution was filtered, and evaporated to dryness. Recrystallisation of the residue from MeOH–Et_2O yielded dark blue microcrystals. Yield 0.17 g, 40%.

4.8. Synthesis of chloro[2,6-bis-({3-phenylpyrazol-1-yl}methyl)pyridine]aquacopper(II) tetrafluoroborate (*8*)

Method as for **7**, using **6** (0.44 g, 8.4×10^{-4} mol). The product formed green microcrystals from MeOH–Et_2O, which became brown upon drying. Yield 0.16 g, 52%.

4.9. Single crystal X-ray structure determinations

Single crystals of X-ray quality of [Cu(NCMe)-(L^1Me_2)]BF_4 (**1**) were grown by diffusion of ether into a solution of the complex in MeCN. Crystals of [Cu(L^1Ph)]BF_4 (**2**) and [Cu(OH_2)$_2$(L^1Ph)]$(BF_4)_2$ (**4**) were similarly grown from $MeNO_2$–Et_2O, and of [Cu(OH_2)(L^1Me_2)]BF_4 (**3**) and [CuCl(HOMe)(L^1Me_2)]-BF_4 (**7**) from MeOH–Et_2O. Experimental details from the structure determinations are given in Table 8. All structures were solved by direct methods (SHELXS-97 [31]) and refined by full-matrix least-squares on F^2 (SHELXL-97 [32]), with H atoms placed in calculated positions.

4.10. X-ray structure determinations of [Cu(NCMe)(L^1Me_2)]BF_4 (*1*) and [Cu(L^1Ph)]BF_4 (*2*)

No disorder was detected during the refinement of either of these structures, and no restraints were applied. All non-H atoms were refined anisotropically, and all H atoms were placed in calculated positions and refined using a riding model.

4.11. X-ray structure determination of [Cu(OH_2)(L^1Me_2)]$(BF_4)_2$ (*3*)

During refinement, one BF_4^- anion was found to be disordered by rotation about one B–F bond. The disordered F atoms were modelled over two equally occupied orientations. No restraints were applied. All non-H atoms with occupancy >0.5 were refined anisotropically. The H atoms for the aqua ligand were located in the difference map and allowed to refine freely; all other H atoms were placed in calculated positions and refined using a riding model.

4.12. X-ray structure determination of [Cu(OH_2)$_2$(L^1Ph)]$(BF_4)_2$ (*4*)

During refinement, one BF_4^- anion was found to be disordered over three orientations, with occupancy 0.50, 0.30 and 0.20. All B–F distances in the disordered anion were restrained to 1.38(2) Å, and non-bonded F···F distances within a given disorder orientation to 2.25(2) Å. All non-H atoms with occupancy ≥ 0.5 were refined anisotropically. The H atoms for the aqua ligands were located in the difference map and allowed to refine freely; all other H atoms were placed in calculated positions and refined using a riding model.

4.13. X-ray structure determination of [CuCl($HOCH_3$)(L^1Me_2)]BF_4 (*7*)

During refinement, the BF_4^- anion was found to be disordered over three equally occupied orientations. All B–F distances were restrained to 1.36(2) Å, and non-bonded F···F distances within a given disorder orientation to 2.22(2) Å. All wholly occupied non-H atoms were refined anisotropically. The hydroxyl H atom of the methanol ligand was located in the difference map and allowed to refine freely; all other H atoms were placed in calculated positions and refined using a riding model.

4.14. Other measurements

Infra-red spectra were obtained as Nujol mulls pressed between KBr windows, between 400 and 4000 cm^{-1} using a Nicolet Avatar 360 spectrophotometers. UV–Vis spectra were obtained with a Perkin–Elmer Lambda 900 spectrophotometer, operating between 1100 and 200 nm, in 1 cm quartz cells. All NMR spectra were run on a Bruker ARX250 spectrometer, operating at 250.1 MHz (^{1}H) and 62.9 MHz (^{13}C). Electron impact (EI) and positive ion fast atom bombardment (FAB) mass spectra were performed on a VG AutoSpec spectrometer, the FAB spectra employing a 3-NOBA matrix. CHN microanalyses were performed by the University of Leeds School of Chemistry microanalytical service. Melting points are uncorrected. X-band EPR spectra were obtained using a Bruker ER200D spectrometer.

Conductivity measurements were obtained with a Jenway 4310 analyser, at concentrations of approximately 5×10^{-3} mol dm^{-3}. All electrochemical measurements were carried out using an Autolab PGSTAT30 voltammetric analyser, in MeCN containing 0.1 M $NBu^n_4BF_4$ as supporting electrolyte. Cyclic voltammetric experiments involved the use of platinum working and counter electrodes and a silver wire reference electrode; all potentials quoted are referenced to an internal ferrocene/ferrocenium standard and were obtained at a scan rate of 100 mV s^{-1}.

5. Supplementary material

Full crystallographic data for the structure analyses in this study are available on request from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). The CCDC deposition numbers are 165783 (**1**), 165785 (**2**), 165786 (**3**), 165787 (**4**) and 165788 (**7**).

Received 8 January 2002; accepted 8 February 2002

Abstract

A new chiral *P*,*N*-donor iminophosphine ligand was used to synthesize a series of palladium(II) and platinum(II) complexes. Single crystal X-ray analysis showed that in all cases the *P*,*N* ligand forms a six-membered chelate ring, and the square-planar coordination of the metal atom is completed by two halide ions, two methyl groups, or one methyl group and one halide ion. In the latter instance, the methyl group is *cis* to the phosphorus atom. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Palladium complexes; Platinum complexes; Chiral iminophosphine ligand

1. Introduction

P,*N*-Donor bidentate ligands are among the most used hemilabile ligands in coordination and organometallic chemistry [1]. Their late transition metal complexes adopt several coordination modes (*P*-monodentate, *N*-monodentate, *P*,*N*-bridging, *P*,*N*-chelate) depending on the ligand bite and the hardness of the metal atoms. In general, the rigid and short-bite *P*,*N*-ligands coordinate to metal atoms in the bridging mode, whereas a non-rigid ligand easily forms a five- or six-member chelate ring. In various catalytic applications, the capability of ligands to adopt different coordination modes is mandatory [2–4].

P,*N*-Donor ligands are expected to exhibit hemilabile behavior when coordinated to a soft metal center such as palladium. The soft P atom coordinates very strongly to palladium whereas the hard N donor is weakly bound. This feature of pyridylphosphine palladium complexes has been employed to catalyze a series of important C–C bond-forming reactions, such as the oligomerization of olefins, the co-polymerization of CO–ethylene, and the telomerization of butadiene [5]. Recently, oligomerization of ethene in polar solvents at higher temperatures is achieved using palladium iminophosphine catalysts, and the oligomer selectivity can be controlled by the nature of the ligand substituents [6]. In the transfer hydrogenation of ketones, bidentate iminophosphine exhibits more efficient catalytic activity than the corresponding amino derivative [7a]. In contrast, the mutidentate *P*,*N*,*N*,*P*-aminophosphine ligand has higher catalytic activity than the corresponding iminophsphine ligand [7b]. A palladium complex bearing *N*-(2-diphenylphosphinobenzylidene)-2-phenylethylamine was found to be more catalytically active than others for the cross-coupling of various types of aryl halides with alkynyl-, alkenyl- and arylstannanes to give the corresponding coupling products in high yields [7c]. A chiral iminophosphine ligand prepared from enantiopure 1-mesitylethylamine and *o*-(diphenylphosphino)benzaldehyde proved to be effective for palladium-catalyzed allylic alkylation. For example, (R)-$MeO_2CCH(CHPhCH{=}CHPh)CO_2Me$ was obtained in 98% yield with 94% ee [7d].

Here we report the preparation of another chiral iminophosphine ligand and its use in synthesizing a

series of palladium(II) and platinum(II) complexes, whose structures were determined by X-ray analysis.

2. Experimental

Na_2PdCl_4, $PtCl_2$(cod) (cod = cyclo-1,5-octadiene), $PtMe_2$(cod) and $HgBr_2$ were obtained from Aldrich and used without further purification. [PdCl(Me)(cod)] [8] and 2-diphenylphosphine-benzaldehyde were synthesized by literature procedures [9].

2.1. Synthesis of the ligand: N-[{2-(diphenylphosphino)phenyl}methylene]-[6,6-dimethyl-{1S-(1α,2β,5α)-bicyclo[3.1.1]heptane}]-2-methaneamine, L

A mixture of 2-diphenylphosphine-benzaldehyde (5.1 g, 13 mmol) and (−)-*cis*-myrtanylamine (2.0 g, 13 mmol) in toluene (25 ml) was refluxed for 18 h on molecular sieves under N_2 atmosphere. After filtration and subsequent evaporation of the solvent under reduced pressure, the crude product was obtained. Recrystallization from CH_2Cl_2–hexane afforded L as a white powder in 85% yield. *Anal.* Found: C 81.72, H 7.61, N 3.28. Calc. for $C_{29}H_{32}NP$: C 81.85, H 7.58, N 3.29%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): −12.1 ppm.

2.2. Synthesis of palladium and platinum complexes

2.2.1. $PdCl_2(L)$, (**1**)

Ten milliliters MeCN was added to a Schenk tube containing Na_2PdCl_4 (0.1g, 0.34 mmol) and ligand L (0.144 g, 0.34 mmol). The reaction mixture was stirred for 2 h during which brown Na_2PdCl_4 disappeared and a yellow solution with a white NaCl precipitate was obtained. After filtration, the solution was evaporated to give **1** in nearly quantitative yield. After a few days, yellow block-like crystals of **1**·MeCN suitable for X-ray analysis was obtained by slow evaporation of a MeCN solution of **1**. *Anal.* Found: C 57.64, H 5.24, N 2.50. Calc. for $C_{29}H_{32}NCl_2PPd$: C 57.78, H 5.35, N 2.32. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): 32.0 ppm.

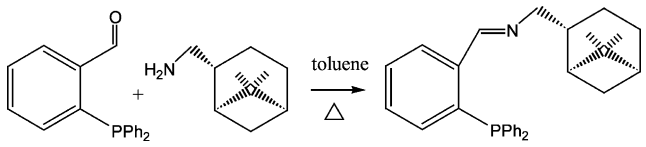
2.2.2. PdMeCl(L) (**2**)

PdMeCl(cod) (0.1 g, 0.42 mmol) and L (0.18 g, 0.42 mmol) were mixed in 10 ml MeCN and stirred for 20 min. After filtration, the filtrate was dried in vacuo to give **2** as a yellow solid. *Anal.* Found: C 61.96, H 6.00, N 2.34. Calc. for $C_{30}H_{35}NClPPd$: C 61.86, H 6.06, N 2.40%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): 38.2. Single crystals of **2**·MeCN were growth from slow evaporation of a solution of **2** in MeCN. Yellow prismatic crystals of **2**·1.5CH_2Cl_2 suitable for X-ray analysis were obtained from diffusion of isopropyl ether into a solution of **2** in CH_2Cl_2.

2.2.3. $PtCl_2(L)$ (**3**)

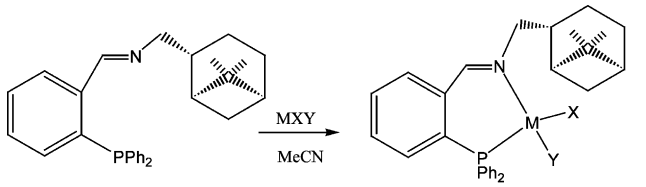
The procedure was similar to that for **1** using $PtCl_2$(cod) instead of Na_2PdCl_4. *Anal.* Found: C 49.96,H 4.56, N 2.16. Calc. for $C_{29}H_{32}NCl_2PPt$: C 50.37, H 4.66, N 2.03%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): 3.9 $^1J(^{195}Pt, ^{31}P) = 3735$ Hz.

2.2.4. $PtMe_2(L)$ (**4**)



The procedure was similar to that for **1** using $PtMe_2$(cod) instead of Na_2PdCl_4. *Anal.* Found: C 57.04, H 5.68, N 2.26, Calc. for $C_{31}H_{38}NPPt$: C 57.22, H 5.89, N 2.15%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): 24.5. $^1J(^{195}Pt, ^{31}P) = 1982$ Hz.

2.2.5. PtMeBr(L) (**5**)



To a solution of **4** (0.1 g, 0.15 mmol) in 5 ml MeCN, $HgBr_2$ (0.09 g, 0.15 mmol) was added. The solution was stirred for 24 h at room temperature (r.t.). The solvent was evaporated in vacuo and the residue was redissolved in 2 ml CH_2Cl_2. Diffusion of isopropyl ether to the solution gave yellow crystals of **5**·0.75CH_2Cl_2. *Anal.* Found: C 50.12, H 5.08, N 1.82. Calc. for $C_{30}H_{35}NBrPPt$: C 50.36, H 4.93, N 1.96%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293k, δ): 17.0. $^1J(^{195}Pt, ^{31}P) = 4657$ Hz.

2.3. X-ray crystallography

The intensity data for **1**·MeCN were collected at 293 K in the variable ω-scan mode on a Siemens R3m/V four-circle diffractometer using Mo Kα radiation (λ = 0.71073 Å, 50 kV, 30 mA; $2\theta_{max} = 55^\circ$). An empirical absorption correction was applied using ψ-scan data. For each of complexes **2**·MeCN, **2**·1.5CH_2Cl_2, **3**·MeCN, **4** and **5**·0.75CH_2Cl_2, a selected single crystal was mounted on a Bruker SMART 1000 CCD diffractometer operating at 50 kV and 30 mA using Mo Kα radiation ($\lambda = 0.71073$ Å). Data collection at 293 K and reduction were performed using the SMART and SAINT software [10], with frames of 0.3° oscillation in the θ range $1.5 < \theta < 28^\circ$. An empirical absorption correction was applied using the SADABS program [11]. The structures were solved by direct methods and all non-hydrogen atoms were subjected to anisotropic refinement by full-matrix least-squares on F^2 using the SHELXTL package [12]. Non-hydrogen atoms were subjected to anisotropic refinement. All hydrogen atoms were generated geometrically (C–H bond lengths fixed at 0.96 Å), assigned appropriate isotropic thermal parameters, and included in structure factor calculations in the final stage of F^2 refinement. Flack parameter [13] and the known chiralities of chiral ligands as starting synthetic materials ensured the correct assignment of the absolute configuration of all compounds.

3. Results and discussion

The new iminophosphine ligand L was synthesized from the corresponding amine and aldehyde as a white powder in 85% yield (Scheme 1). The ^{31}P NMR $\{^{1}$H$\}$ spectrum of L showed a singlet at −12.1 ppm. The reaction of L with palladium and platinum salts afforded the corresponding chelated product **1**–**5** (Scheme 2).

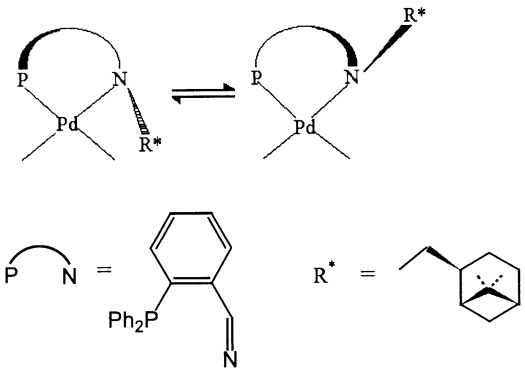

Fig. 1. Two possible configurations of a PdXY(L) complex.

The ^{31}P NMR $\{^{1}$H$\}$ spectrum of $PdCl_2$(L) (**1**) showed a singlet at 32.0 ppm. In **1** the ligand L adopts a κP, κN coordination mode in a square-planar coordination geometry for the palladium center. An ORTEP drawing of **1** is shown in Fig. 1. Selected bond lengths and angles are given in Tables 1 and 2. The least-squares plane through the atoms Pd(1), P(1), N(1), Cl(1) and Cl(2) shows a mean atomic deviation of 0.065 Å. The Pd–P, Pd–N, Pd–Cl(1), and Pd–Cl(2) bond distances are in the normal range [14]. The Pd–Cl bond length *trans* to the P atom (2.380(1) Å) is longer than that *trans* to the N atom (2.281(1) Å) owing to the stronger *trans* influence of a tertiary phosphine with respect to an imine. The bond angles at the Pd(1) atom exhibit only minor deviations from a right angle. The ligand forms a six-membered, puckered chelate ring with the metal so

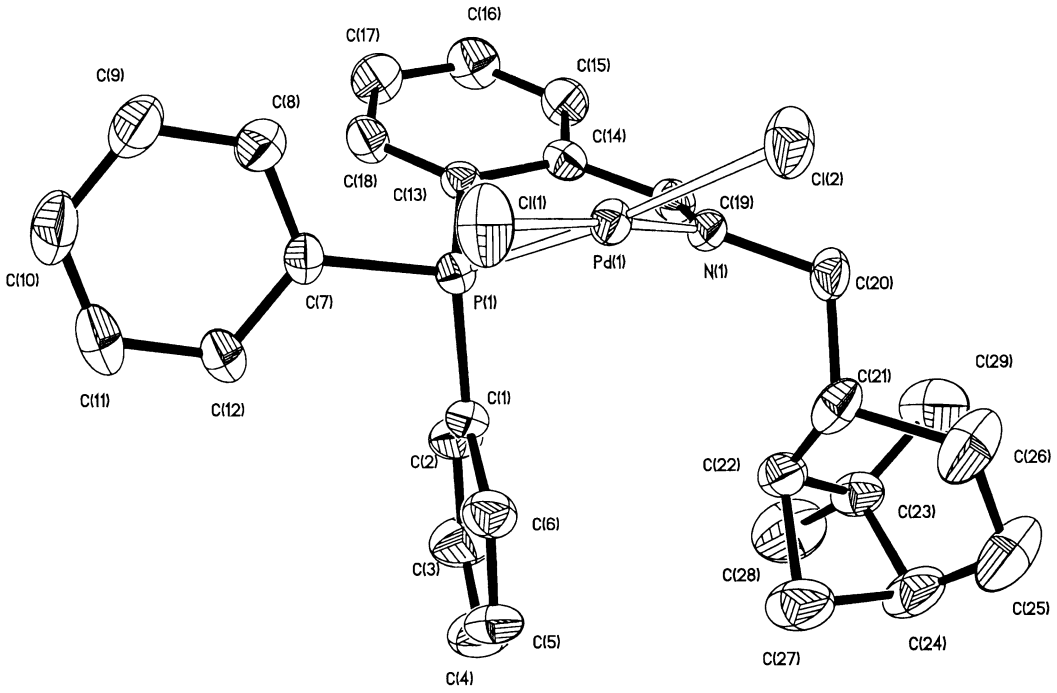

Fig. 2. Perspective drawing (35% thermal ellipsoids) of the molecular structure of $PdCl_2(L)$ (**1**).

that there are two possible isomers of each configuration (Fig. 2). The torsion angle Pd(1)–P(1)–C(13)–C(14) = 42.0(4)° can be conveniently used to indicate the location of the $=CHC_6H_4-$ unit with respect to the $PdCl_2(P,N)$ plane; the plus sign means that the $=CHC_6H_4-$ unit lies above the plane, as seen in a side view from the chloride ligands toward the Pd atom, and the minus sign means the unit lies below the plane.

The reaction of L with PdMeCl(cod) afforded complex **2**, which was crystallized in two solvated forms from different solvents: **2**·MeCN and **2**·1.5CH_2Cl_2. In **2**·MeCN, the asymmetric unit consists of two independent molecules of **2**, in which the $=CHC_6H_4-$ unit lies either below (Fig. 3) or above the PdMeCl(P,N) plane (Fig. 4). The corresponding Pd(1)–P(1)–C(13)–C(14) and Pd(2)–P(2)–C(43)–C(44) torsion angles are

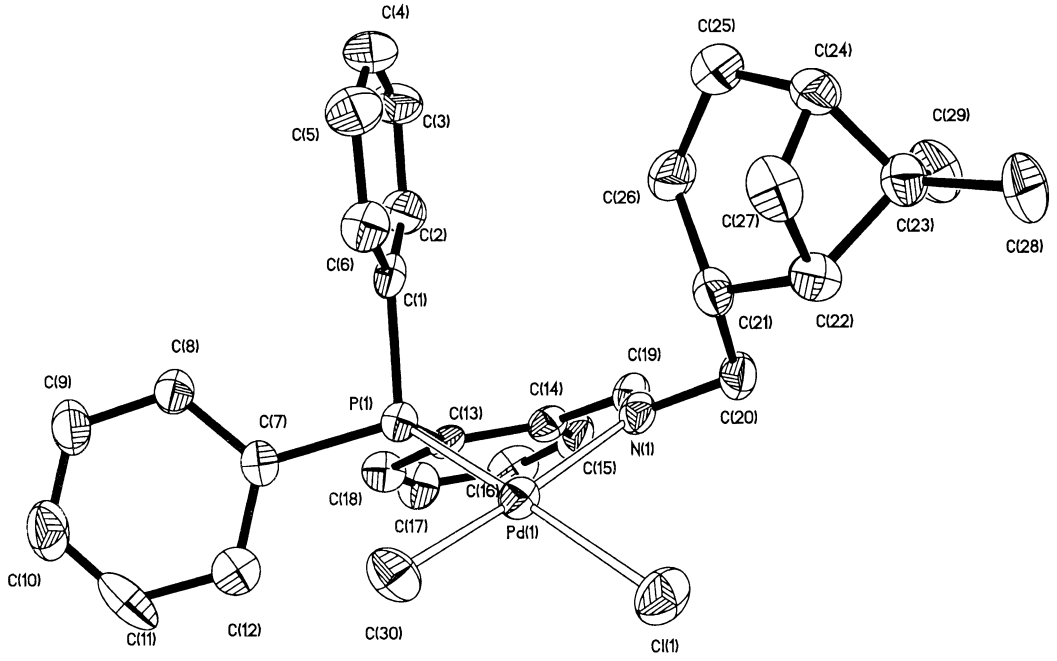

Fig. 3. Perspective drawing (35% thermal ellipsoids) of one of the two independent molecules of PdMeCl(L) (**2**) in **2**·MeCN.

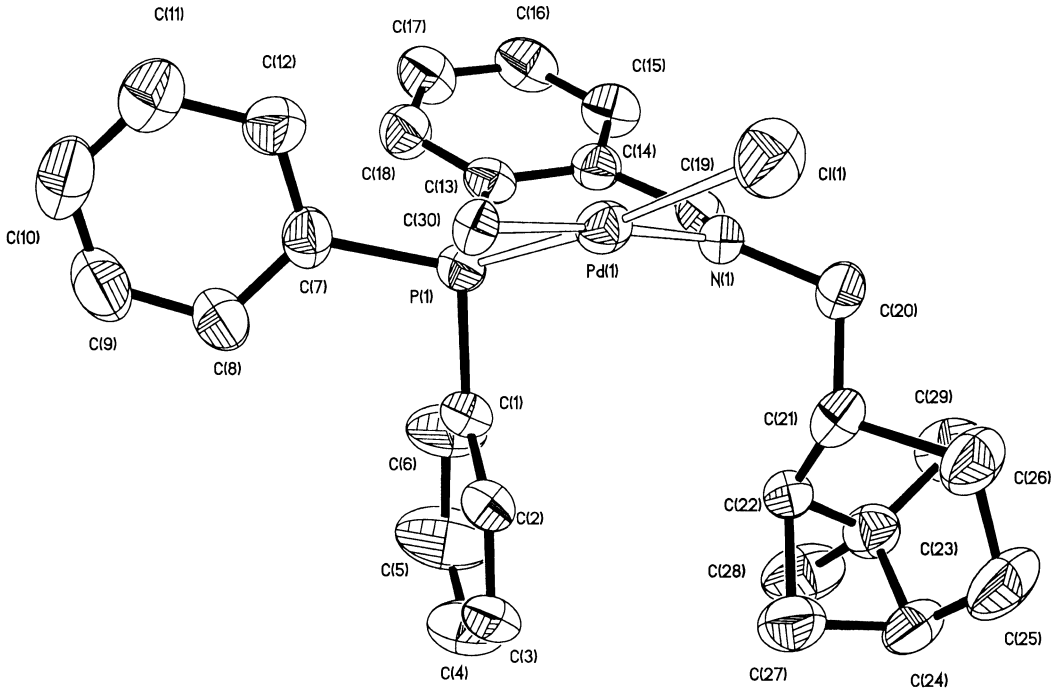

Fig. 4. Perspective drawing (35% thermal ellipsoids) of the second independent molecule of **2** in **2**·MeCN.

−45.4(4)° and 42.4(5)°, respectively. On the other hand, in **2**·1.5CH_2Cl_2 just one configuration exists, in which the =CHC_6H_4– unit lies above the PdMeCl(P,N) plane with torsion angle Pd(1)–P(1)–C(13)–C(14) = 40.4(5)°. The Pd–ligand bond distances and angles are similar in different configurations and different solvate crystals (Table 2). The methyl group is arranged *trans* to the N donor site, as found in other known PdMeCl(P,N) complexes. The least-squares plane through the donor atoms around the palladium atom shows a mean deviation of 0.053 Å for Pd(1), 0.093 Å for Pd(2) in **2**·MeCN and 0.074 Å for Pd(1) in **2**·1.5CH_2Cl_2.
